The model is used to predict the number density, the geometric mean diameter and the geometric standard deviation of the particles inside the generator. Figure 2 presents the spatial distribution of the geometric mean diameter. The main flow rate is 100 slpm and the injection is 60 slpm. The formation of particles is at two different positions, near the entrance and at the injection. At the entrance nucleation takes place near the cold wall, and a boundary layer, similar to a thermal one, is formed. The high injection rate penetrates the boundary layer and decreases the temperature of the gas inside the reactor. The injection also induces recirculation of cold gas near the wall. The low temperature in this zone prevents coalescence of the particles; therefore the mean diameter does not increase here. The high concentration of particles nucleated at the injection increase the coagulation rate. Since no new particles are formed, besides the two nucleation spots, the concentration of particles decreases along the reactor due to coagulation, thus slowly decreasing the coagulation rate.

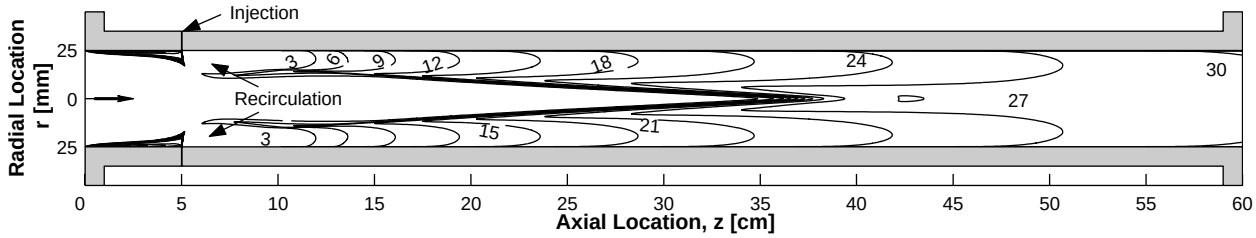

Figure 2: Spatial distribution of the geometric mean diameter (d_{pg} [nm]). Main flow rate 100 slpm and Injection rate 60 slpm

Injection

One of the main advantages of gas aerosol processes is that the characteristics of the product are relatively easy to control by adjusting key operating parameters. The easiest to change and control is the quenching flow rate. However, increasing the injection rate introduces turbulence in the reactor. At low injection rates, the flow rate should be laminar. Studying the effect of operating parameters, such as injection rate, will assist in the selection of optimum conditions for the synthesis of aluminum powder with the desired characteristics.

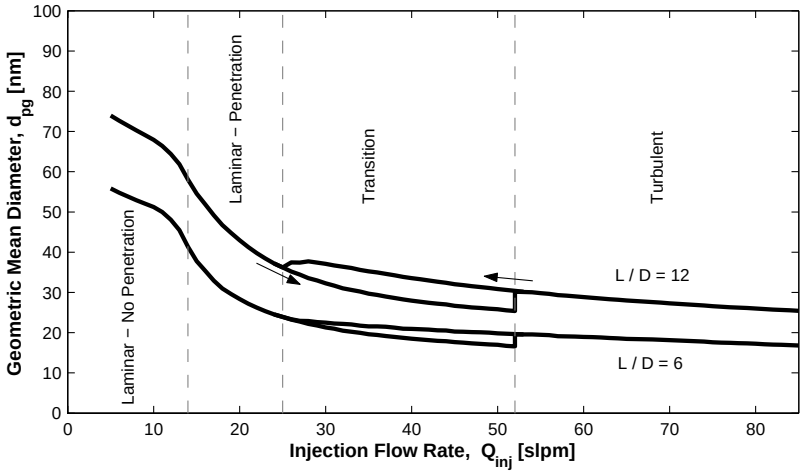

Figure 3: Mixing cup geometric mean diameter as a function of the flow rate of quenching gas. The figure shows the size of the particles at tow different positions in the reactor.

The effect of the injection flow rate on the particle characteristics was studied. The quenching gas flow rate was changed from 5 to 85 slpm, while the main flow rate was kept constant at 100 slpm. Figure 3 shows the effect of the injection rate on the geometric mean diameter. This figure presents mixing cup results at two different positions in the reactor. As the injection rate was increased four different flow regimes were found. At low flow rates, there is a laminar zone (<14 slpm) where the jet cannot penetrate the concentration boundary layer. Then there is a laminar zone (14 – 25 slpm) where the jet penetrates and a second nucleation zone occurs. This is followed by a transition zone (25 – 52 slpm) where either the turbulent or the laminar characteristics may prevail, and finally, there is a turbulent zone (>52 slpm).

Increasing the injection rate increases the number density, decreases the size and slightly increases the polydispersity of the particles. One of the important features of Figure 3 is that the particle geometric mean diameter is almost constant for high injection rates. This is important because it shows that at high injection rates the particle characteristics are less sensitive to changes in the injection than for low flow rates.

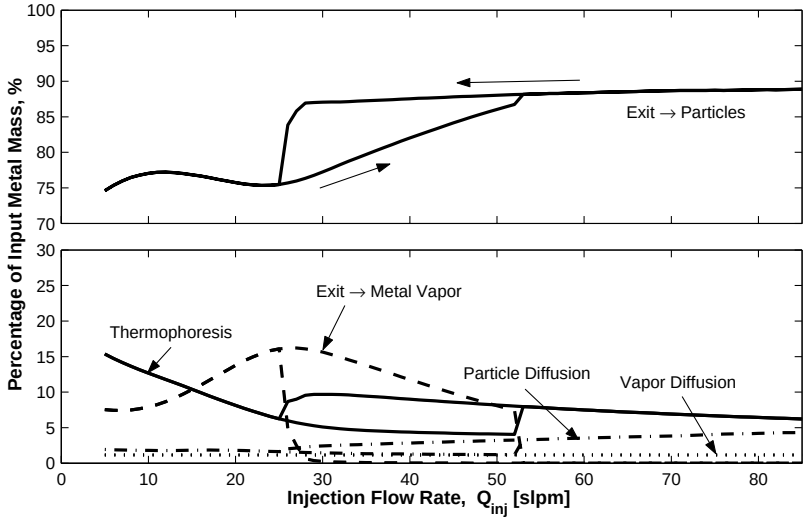

Figure 4: Mass balances and percentage of metal removed by different mechanisms as a function of the flow rate of quenching gas. The figure shows the results at the end of the reactor (L/D = 12).

It is also important to quantify the amount of material that has been condensed and that can be collected as product at the end of the reactor. Figure 4 shows the percentage of metal removed by different mechanisms and the percentage of metal at the exit of the reactor in either condensed or vapor phase. As the injection rate is increased, more material can be recuperated as particles at the end of the reactor since turbulence

increases. Thermophoresis is the main mechanism for deposition of particles on the wall of the reactor. For small injection rates it is responsible for depositing up to 16% of the metal.

Scale up

Two cases are presented here; the first case is scale up with dynamic similitude, where the geometry and the Reynolds number are held constant. Figure 5 shows the effect of increasing the scale factor on the particle size. An almost linear increase in the geometric mean diameter with increasing the reactor diameter can be observed from this figure. The increase in the particle size is accompanied with a decrease in the particle number concentration and slight increase in the geometric standard deviation. The main reason for these changes with increasing reactor size is the increase in the mean residence time, allowing particles to coagulate for longer periods of time.

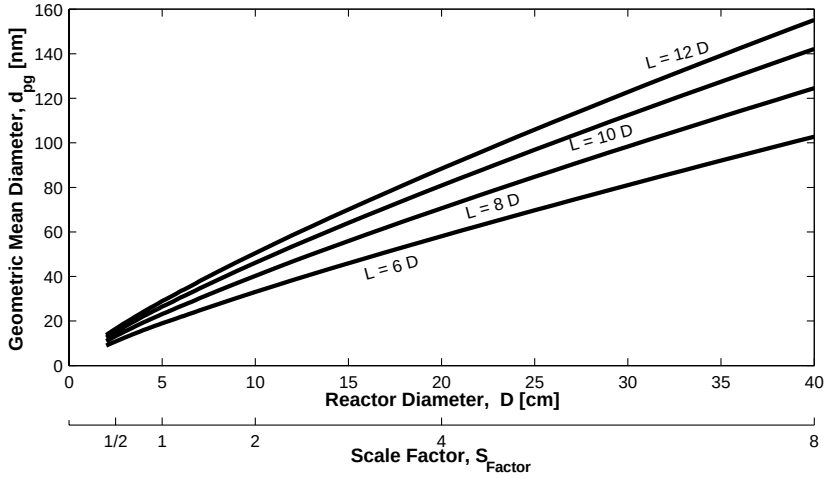

Figure 5: Mixing cup geometric mean diameter as a function of the scale factor for different length to diameter ratios. Scale up with dynamic similitude and 60 % injection.

The second case studied is scale up maintaining geometric similitude and constant mean residence time. When this type of scale up is performed, dynamic similitude no longer holds, and changes in the flow regime are likely to occur as the size of the reactor increases.

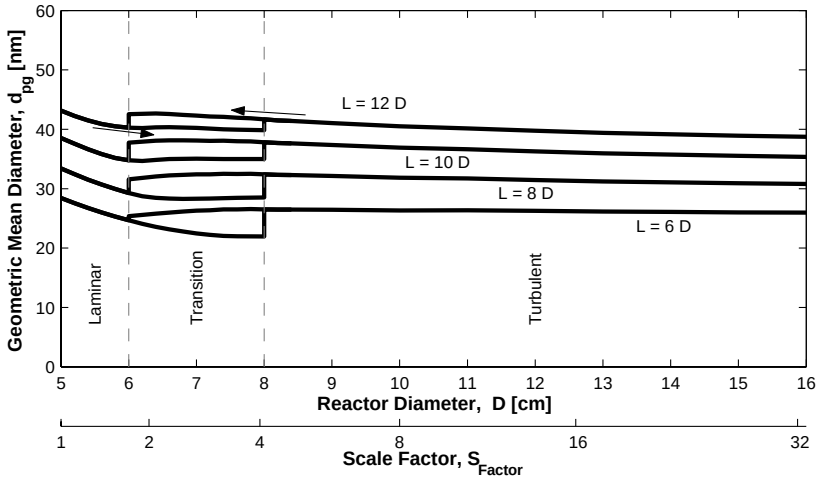

Figure 6: Mixing cup geometric mean diameter as a function of the scale factor for different length to diameter ratios. Scale up with constant mean residence time and 20 % injection.

Figure 6 shows the mixing cup geometric mean diameter for different length to diameter ratios. Although the mean residence time is constant, this figure shows that the particle characteristics are affected by the flow regime. For small length to diameter ratios the effect is significant while for longer reactor the effect

vanishes. By increasing the reactor diameter holding the mean residence time constant, the particle number concentration increases, while the geometric mean diameter and standard deviation decrease.

The question of what would be the best way to scale up this process has not been answered. In fact, there are many ways of increasing the product mass flow rate for the system. For example, pushing higher flow rates through the same reactor, or increasing the concentration of the metal vapor at the inlet, amongst others which can also be analyzed using the present model [2].

4. Conclusions

A two dimensional axi-symmetric model was used to study the phenomena taking place inside the particle generator. It was found that as the quenching rate is increased, the flow regime changes from laminar to turbulent, and four different regimes have been identified. Particles nucleate near the walls at the entrance of the reactor and at the injection; they then grow either by condensation and/or coagulation, being coagulation the dominant mechanism. The characteristics of the particles can be easily controlled by adjusting the quenching gas flow rate. Increasing this parameter increases the number of particles produced, and decreases the mean geometric diameter.

The study of process scale up examined two cases. The first was scale up at constant Reynolds number with geometric similitude, to have dynamic similitude between the small and large scale. Here, scale up increases the mean residence time and decreases the particle number concentration due to nucleation suppression. The particle geometric mean diameter increases almost linearly with the size of the reactor while the geometric standard deviation is almost constant. The second case maintained geometrical similitude and constant mean residence time. Here the flow field regime changes from laminar to turbulent in the scale up process. These changes in the flow regime affect the particle characteristics significantly for reactors of small length to diameter ratio (L/D = 6), but are almost insignificant for large length to diameter ratios (L/D = 12). Turbulent reactors showed small changes in the particle characteristics, plus a better percentage of mass recuperated at the end of the reactor.

Experimental Study on Propagation Characteristics of Microwave in GlidArc Discharge Plasma

LIN Lie, WU Bin, WU Cheng-kang, PAN Wen-xia
Institute of Mechanics, Chinese Academy of Sciences
Beijing 100080, China

Abstract

The GlidArc discharge plasma at atmospheric pressure is a type of non-thermal plasma, and has many applications in chemical industry and environment engineering. In this paper we study the propagation characteristics of the microwave in GlidArc discharge plasma. And then according to the power absorption coefficient we calculated the electron density in plasma.

1. Introduction

Research on the propagation of electromagnetic wave in plasmas has been sustained many years as a result of applications, such as broadcast communication, radio astronomy and plasma diagnostics with microwave [1-5]. The propagation properties of electromagnetic wave in plasma are related to many factors, such as the frequency of electromagnetic wave, electron density, electron temperature, collision frequency and size of the plasma slab.

The GlidArc discharge is a type of production technologies for non-equilibrium plasma at atmospheric pressure. The electron density is a very important parameter for his application. By the Research on the propagation of electromagnetic wave in plasmas, we can calculate the electron density in plasma. But the GlidArc discharge plasma is a type of pulse discharge plasma, so the measurement of electron density is more difficult. In this paper we measure the power absorption coefficient with a microwave transmission system and then calculated the electron density in plasma.

2. Measurement of the power absorption coefficient

In this paper, we assume:

(1) The electromagnetic wave is a plane wave and has single frequency.
(2) The plasma slab is a uniform medium.
(3) The incident wave travels vertically on the plasma slab.
(4) The effects of electromagnetic wave on plasma can be neglected for the low-power electromagnetic wave.

In this case, we can calculate the electron density with the propagation properties of electromagnetic wave (power absorption coefficient) in a plasma slab.

Fig. 1 shows the model for calculation of propagation characteristics of electromagnetic wave in plasma slab.

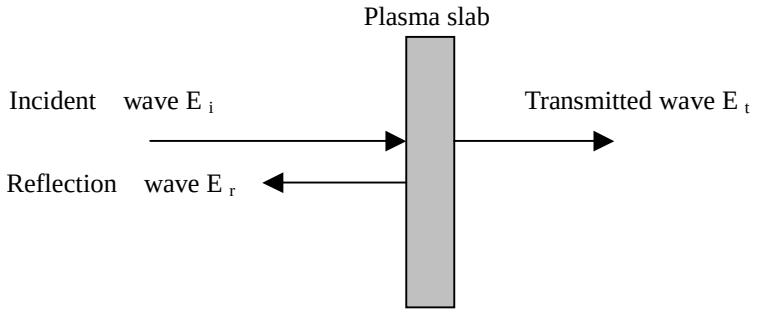

Fig.1. One dimension model for calculation.

In this condition, the refractive index μ and attenuation index χ are [5]

$$\mu = \{\frac{1}{2}(1-\frac{\omega_p{}^2}{\omega^2+\nu^2}) + \frac{1}{2}[(1-\frac{\omega_p{}^2}{\omega^2+\nu^2})^2 + (\frac{\omega^2}{\omega^2+\nu^2}\frac{\nu}{\omega})^2]^{\frac{1}{2}}\}^{\frac{1}{2}} \qquad (1)$$

$$\chi = \{-\frac{1}{2}(1-\frac{\omega_p{}^2}{\omega^2+\nu^2}) + \frac{1}{2}[(1-\frac{\omega_p{}^2}{\omega^2+\nu^2})^2 + (\frac{\omega_p{}^2}{\omega^2+\nu^2}\frac{\nu}{\omega})^2]^{\frac{1}{2}}\}^{\frac{1}{2}} \qquad (2)$$

Where ω is the circular frequency of the electromagnetic wave, ω_p is the plasma frequency, ν is the collision frequency.

The attenuation coefficient α is

$$\alpha = \chi\frac{c}{\omega} \qquad (3)$$

Where c is the velocity of light in vacuum.

The collision frequency is

$$\nu = \sqrt{\frac{8kT_e}{\pi m_e}}(N_i Q_{ei} + N_n Q_{en}) \qquad (4)$$

Where k is the Boltzmann constant, T_e is the electron temperature, m_e is the electron mass, N_i is the number density of the positive ions, Q_{ei} is the collision cross section of electron to ions, N_n is the neutral particle number density, Q_{en} is the collision cross section of electron to neutral particle.

According to the above equations, we can calculate the electron density when the attenuation coefficient is measured.

3. Experimental setup

In the following we will describe the experimental setup for the measurement of the power absorption coefficient. The setup includes: a GlidArc non-equilibrium plasma generator, a microwave measurement system and a data treatment system. Fig. 2 shows the sketch diagram of the experimental setup.

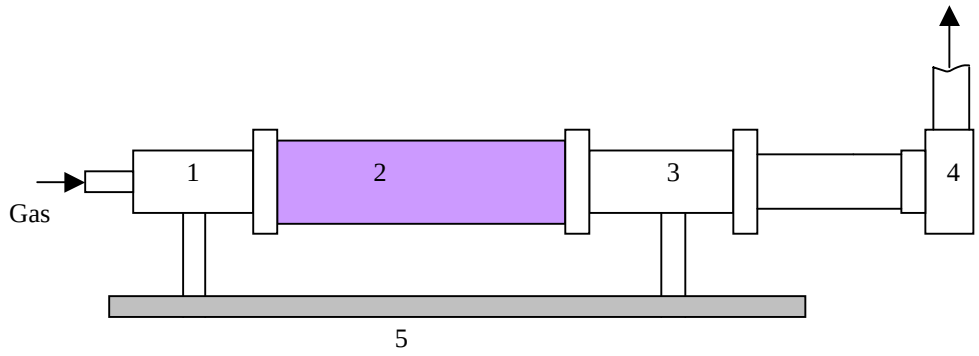

Fig. 2. Setup of the non-equilibrium plasma production
(1) GlidArc discharge plasma generator (2) Test section
(3) Cooling jacked (4) Exhaust blower (5) Seat of the equipment

The plasma generator is a rotating GlidArc discharge setup; the power of the plasma generator is 200-400Watts. The gas flow rate of the generator is 2.5-4.0m^3/h. The test section has a 30mm×60mm square uniform cross section. The test section is made of quartz glass. The transmitting antenna and receiving antenna are set the two lengthways sides of the test section.

Fig. 3 shows the block diagrams of the microwave measurement setup for the power absorption coefficient.

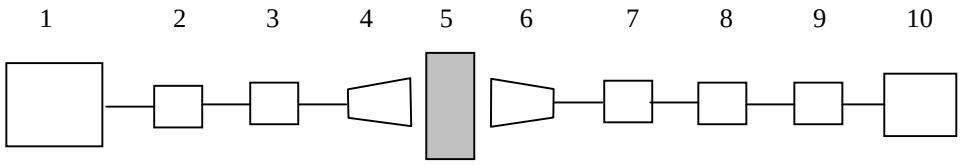

Fig.3. Experimental setup for measurement of power
absorption coefficient in GlidArc discharge plasma
（1）Signal source (2) Ferrite isolator (3) Coupler (4) Transmitting antenna
(5) Plasma region (6) Receiving antenna (7) Coupler (8) Crystal detector
(9) Amplifier (10) Digital oscilloscope

The signal source produces an electromagnetic wave with 9.6GHz frequency, and then the wave travels into the isolator, the coupler and transmitting antenna. The transmitted wave is received by the receiving antenna. The received electromagnetic wave can be detected by the crystal detector. The detected signals will be amplify by the amplifier, and treat with a digital oscilloscope. So we can obtain a curve with time about the measured signal of the transmitted electromagnetic wave. And then we can calculate the absorption coefficient and the electron density.

4.Results

Fig. 4 shows the curve of measured signal with time by the crystal detector in GlidArc discharge plasma.

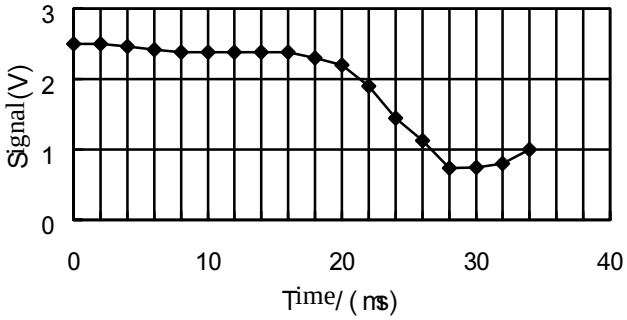

Fig. 4. Curve of measured signal by the crystal detector

According to the curve of the measured signal, we can calculate the power absorption coefficient and the electron density in GlidArc discharge plasma. The calculation results show that the peak electron density in the plasma is about $1\times10^{12}/cm^3$.

Investigations of CF and CF_2 in C_4F_8 Plasmas

Ina T. Martin, Ellen R. Fisher

Department of Chemistry, Colorado State University, Fort Collins, CO 80523

Abstract

C_4F_8 plasmas are used in both fluorocarbon film depositions and the etching of Si-based materials. To better understand the chemistry that occurs during these processes we have used our laser induced fluorescence (LIF) based imaging of radicals interacting with surfaces (IRIS) method to characterize the relative densities of CF and CF_2 in C_4F_8 plasmas and explore the surface interactions of CF_2 during plasma processing of Si.

1. Introduction

Fluorocarbon (FC) plasmas are widely used in the deposition of thin films and the etching of silicon based materials [1]. The predominant behavior of the plasma largely depends on the concentration and energetics of the different plasma species. Studying the behavior of a specific molecule in the plasma can yield information on its role in the chemistry that occurs at the plasma surface interface. CF_2 is a particularly interesting species in FC plasmas because its role differs under various plasma conditions and systems. Both CF_x (including CF_2) and C_xF_y radicals are cited as FC polymer deposition precursors [1,2]. Conversely, other work has shown cases where CF_2 is not a deposition precursor. For example, Kadota and coworkers have used LIF spectroscopy and quadrupole MS measurements to show that CF_2 was not a FC film deposition precursor in their C_4F_8 plasmas systems [3]. To date, we have explored the role of CF_2 molecules in both etching and depositing FC and HFC plasma systems: CF_4, C_2F_6, C_2F_6/H_2, and CHF_3 [4, 5, 6]. These results show that the CF_2 reactivity can be correlated to the overall plasma regime: etching or deposition. This work furthers these studies by exploring the role of CF_2 in C_4F_8 plasma processing of silicon. The processed Si was analyzed by XPS for additional insight into the overall plasma process.

The IRIS apparatus has been described in detail previously [7]. Briefly, it combines molecular beam and laser induced fluorescence (LIF) measurements to thoroughly characterize specific fluorescing species in a variety of plasmas. Ground state species are identified through the collection of excitation spectra, which are also used to measure their rotational temperatures (Θ_R). The relative gas phase density of these species can then be measured as a function of changing plasma parameters (input power, pressure etc.), and we are also capable of measuring the surface reactivity of gas-phase species during plasma processing of a substrate.

2. Experimental Details

In a typical IRIS experiment, the feed gas enters the rear of the reactor, 13.56 MHz rf power is applied and a plasma is produced. Expansion of the plasma into a differentially pumped vacuum chamber, and ultimately into a high-vacuum region, generates a nearly effusive molecular beam consisting of virtually all species present in the plasma, including the species of interest. An excimer-pumped (XeCl, 150 mJ, 70 Hz, 308 nm) tunable dye laser beam intersects the molecular beam downstream from the plasma source and excites the species of interest. Spatially resolved LIF signals are collected by an electronically gated, intensified charge coupled device (ICCD) located perpendicular to both the molecular beam and the laser beam, directly

above the interaction region (Figure 1a). For a reactivity experiment, a substrate is rotated directly into the path of the molecular beam and LIF signals are collected again (Figure 1b). Differences between the spatial distributions with the surface in and out of the path of the molecular beam (Figure 1c) are used to measure the ratio of incident radicals in the molecular beam with respect to those scattering from the surface (denoted as *S*).

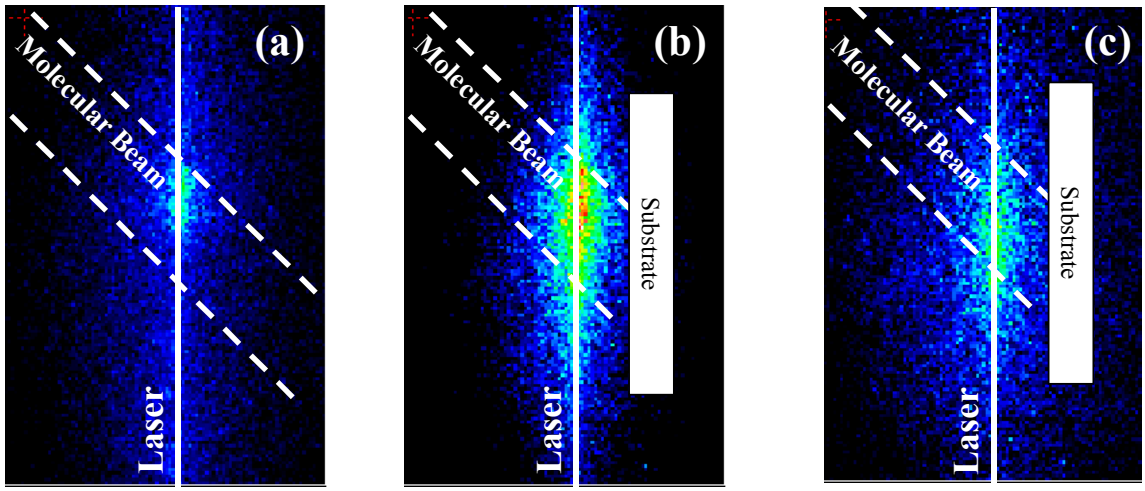

Figure 1. Spatially resolved 2D ICCD images of the LIF signal for the CF_2 (0,11,0) state (a) in the 50 W 100% C_4F_8 molecular beam (no substrate) and (b) with a 300 K Si substrate rotated into the path of the molecular beam. (c) Difference between the images shown in (a) and (b) which shows only the CF_2 molecules scattering from the surface.

In this work, tunable laser light in the 229-240 nm range was produced by frequency doubling the output of an excimer pumped dye laser (Coumarin 47, 0.6-1.3 mJ/pulse). Substrates were 25 x 40 mm p-type silicon (100) wafers with ~20 Å of native oxide; these were placed 2-5 mm from the laser beam. For CF_2 reactivity experiments, the laser was tuned to 234.323 nm, corresponding to the (0,11,0)-(0,0,0) vibronic band of the A^1B_1-X^1A_1 transition. For CF density measurements, the laser was tuned to 223.840 nm corresponding to the P_{11} bandhead of the $A^2\Sigma^+$–$X^2\Pi$ (1,0) transition. The molecular beam sources were plasmas created with 100% C_4F_8 (Matheson, 99.99%). The source pressure was maintained at ~ 40 mTorr and the applied rf power, *P*, ranged from 0 – 150 W. The effects of ions on *S* measurements were investigated by placing a grounded mesh in the path of the molecular beam. Previous work shows that the grounded mesh removes ~90% of the charged species from 50 W C_4F_8 plasmas [8].

XPS analyses were performed on a Physical Electronics PE5800 ESCA/AES system. Spectra were collected using a 2 mm monochromatic Al Kα X-ray source (1486.6 eV), hemispherical analyzer, and multichannel detector. A low energy (~1 eV) electron neutralizer was used for charge neutralization, and survey spectra were collected with a pass energy of 93.90 eV.

3. Results and Discussion

Figures 2a and b show excitation spectra collected from 228.000 – 240.000 nm in a 50 W C_4F_8 plasma and from 223.750 – 224.000 nm in a 100 W C_4F_8 plasma. Comparison to the literature confirms the presence of CF_2 and CF in 2a and 2b respectively [9, 10, 11].

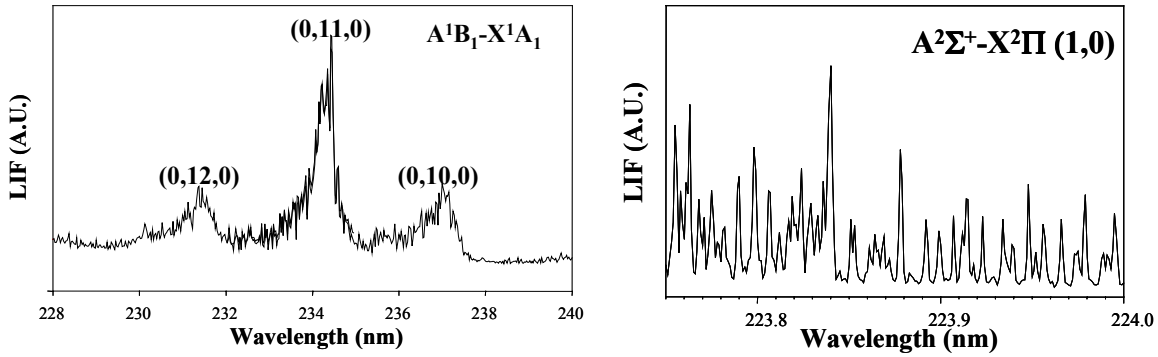

Figure 2. Experimental fluorescence excitation spectrum of (a) CF_2 and (b) CF in 100% C_4F_8 plasmas.

Figure 3 shows the relative densities of CF and CF_2 in C_3F_8 plasmas as a function of the applied plasma power (*P*). Increasing *P* results in an increase in the formation of both CF and CF_2 molecules, most likely a result of increased fragmentation of the monomer gas. Since the relative CF_2 density does not decrease, it appears that further fragmentation of CF_2 does not significantly contribute to CF formation in this *P* range.

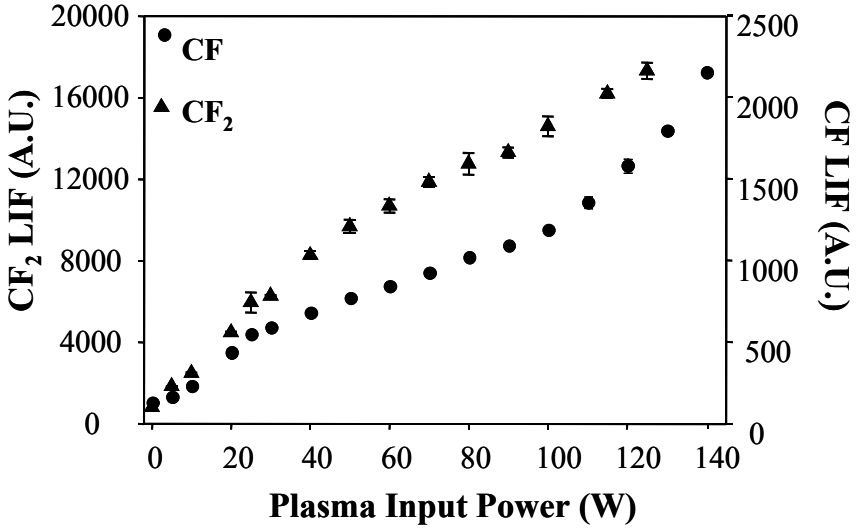

Figure 3. Relative LIF intensities of CF_2 and CF radicals in C_4F_8 plasmas as a function of applied rf power.

Table I lists *S* values measured for CF_2 from C_4F_8 plasmas during processing of a silicon substrate with and without a grounded mesh in the path of the molecular beam. Previous data taken for other plasma systems is included for discussion purposes.

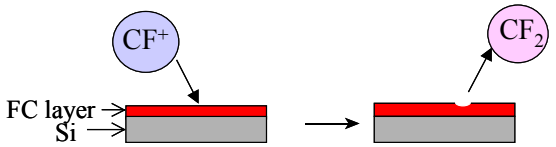
Table I. CF_2 scatter coefficients for FC processing of Si.

Plasma	25 W	35 W	50 W	200 W	Regime
C_2F_6 [6]	----	----	1.44 ± 0.03	----	Etching
50/50 C_2F_6/H_2 [6]	----	----	0.84 ± 0.02	----	Fast depositor
HFPO [6]	----	0.97± 0.03	----	1.29 ± 0.05	Slow depositor
C_4F_8	1.29 ± 0.03	----	1.67 ± 0.03[b]	----	**?**
C_4F_8 (ion free)	0.97 ± 0.05	----	1.08 ± 0.04[b]	----	**?**

[b] Values from reference [8]

Previous work in our group has shown that CF_2 reactivity can be generally used to gauge the overall behavior of a plasma system. $S < 1$ is characteristic of a fast depositing system, such as 50 W 50:50 C_2F_6/H_2 plasmas. $S \geq 1$ (35 and 200 W HFPO) is characteristic of a slowly depositing system, while $S >> 1$ is characteristic of an etching system (50 W C_2F_6). CF_2 S values measured for C_4F_8 plasmas suggest that it too is an etching system. XPS results do show that materials processed with C_4F_8 plasmas in the IRIS chamber have significantly lower F/C ratios than materials deposited under ion-limited conditions in 50 W C_4F_8 plasmas in similar reactors (F/C = 1.1 – 1.4) [12]. Indeed, the materials deposited in the IRIS chamber have F/C ratios ~0.2 which are even lower than that measured for 100 % C_2F_6 (F/C = 0.72) [6]. To further investigate this, ongoing work in our laboratory involves variable angle spectroscopic ellipsometry measurements of treated and untreated Si to determine if the overall regime is indeed etching.

Additional information can be garnered from the trends apparent in S values measured for the C_4F_8 system. For the unperturbed system, CF_2 is produced at the surface (i.e. $S > 1$) at all P studied, and S increases concomitantly with P. When a grounded mesh was placed in the path of the molecular beam, S decreases to ~1, and the power dependence is eliminated. This suggests that charged species significantly contribute to the surface production of CF_2, a trend that has been seen in several other FC systems [6]. Ions can contribute to CF_2 formation simply through ion bombardment of CF_2 from the surface. Increasing the applied rf power is known to increase the ion density in the plasma. This would result in increased ion bombardment of the surface, which could explain the increase of S with P. Previous work in our laboratory used plasma ion mass spectrometry (PI-MS) to identify nascent ions in C_4F_8 plasma molecular beams. Results showed that CF^+ is the predominant ion in this system, and, unlike other ions detected in the system, the relative concentration of CF^+ increased significantly with P [8]. This allows for the possibility of the following surface reaction:



For this to be possible, F would have to be present on the surface. Preliminary XPS data for Si processed in the IRIS chamber with a 50 W C_4F_8 plasma for 60 minutes showed that the surface composition was ~20% F, allowing for the above reaction. Even in a virtually "ion-free" system, the S values measured for CF_2 are ~1. This could be the result of several mechanisms, the simplest one being the adsorption/desorption of CF_2 from the surface. Another possible mechanism is the abstraction of surface F atoms by gas-phase CF molecules. To test this possibility, we will measure the surface reactivity of CF in these systems.

4. Conclusions

Whether or not CF_2 is a deposition precursor depends on the nature of the other species in the plasma systems. Discerning the role of a specific species in a plasma becomes more complicated as we move to larger chain molecules because the number of fragmentation products increases. This work has shown that CF_2 is not a deposition precursor in the unperturbed C_4F_8 system. S values measured for CF_2 in C_4F_8 plasmas suggest that this system falls into an etching regime. However since ions contribute significantly to the surface production of CF_2, further film deposition studies in the IRIS chamber will help us determine if this is still the case under "ion-free" conditions.

Relationship between the electron temperature and the spatial profile of the microwave power absorption in ECR plasma

N. Itagaki[1], K. Muta[1], N. Ishii[2] and Y. Kawai[1]

[2]*Tokyo Electron Co. Ltd., Osaka 532-0003, Japan*

Abstract
The electron temperature in an ECR plasma is clarified to depend on the spatial profiles of the microwave-power absorption by both the electromagnetic-waves measurement and the simulation of microwave power absorption. It is also found from the experimental and numerical results that the electron temperature in an ECR plasma can be controlled by varying the magnetic field configuration and/or the microwave frequency since the power absorption profile is influenced by the effective resonance zone width.

1. Introduction

Electron cyclotron resonance (ECR) discharges have attracted considerable attention due to their advantages which allow their use in several industrial processes such as submicron etching, thin-film deposition, etc [1,2]. A significant feature of ECR plasma sources is the high electron density which can be achieved at low gas pressures. Specifically, as devices and features decrease in size, an ECR plasma becomes indispensable for the etching process. Recently, great interest has been directed toward the electron-temperature control in order to realize the less-damage processing, because high electron temperature plasma sources have shown to cause serious problems such as substrate damage due to ion bombardment from plasma [3,4]. Moreover, in the case of plasma etching, charge build-up damage, low etching selectivity and local side etching are caused by the high degree of dissociation and charge accumulation on the substrate by high-energy electrons in the plasma [5,6]. Since the production of reactive species including plasma production or the decomposition of source gas molecules are triggered by the electron collisions, the electron temperature control is also essential to find out the best conditions necessary for qualified material processing. However, the electron temperature in an conventional ECR plasma produced by 2.45 GHz microwave is relatively high, and it is quite hard to control the electron temperature in a wide range.

Up to now, several attempts for producing an ECR plasma with variable electron temperature have been reported. In our previous experiment, the mean electron temperature was decreased by pulse modulation of the incident microwave power, and high-quality amorphous Si thin films were obtained at room temperature using such control [7]. Okugi et al. observed that applying the magnetic filter, which is the localized transverse magnetic field of sheet type geometry and has an ability to reflect preferentially the high energy electrons and pass through low energy ones, leads to reduction of the electron temperature [8,9]. Tanaka et al. controlled the electron temperature by inserting a mesh grid into plasma [10]. However, the electron-temperature control with keeping the high electron density, which is earnestly required from industry, has not been achieved with those methods.

Recently, the effects of the electromagnetic-wave frequency on the plasma parameters have been giving some attention and it has been reported that in the plasma produced by the microwaves of the frequency below 2.45 GHz the electron temperature and the density of high energetic electrons that contributes to ionization are low [11]. We also observed that a low-electron-temperature ECR plasma with high electron density was produced by using 915 MHz microwaves [12]. Furthermore, it was found from our experimental results that the electron temperature in a 915MHz ECR plasma can be controlled by adjusting the external conditions such as incident microwave power, gas pressure and magnetic field configuration. The numerical simulation of the microwave-power absorption suggested that the electron temperature in an ECR plasma changes with changing the spatial profile of the power absorption [13], however, the mechanism of low-electron-temperature plasma production by using the microwaves of lower frequency has not still

been clarified. In this report, we firstly tried to experimentally clarify the relationship between the electron temperature and the power-absorption profile by measuring the spatial profiles of the plasma parameters and wave patterns of the electromagnetic waves at the different values of the electron temperature. The results were also compared with 2.45 GHz ECR plasma in order to investigate the effect of the microwave frequency on the electron temperature. In addition, based on the experimental and numerical results, a new simple method of the electron-temperature control for an ECR plasma was proposed.

2. Experiment

A schematic diagram of the experimental apparatus is shown in Fig. 1(a). The cylindrical chamber was made of stainless steel with an inner diameter of 290 mm and a length of 1200 mm. The chamber wall was grounded. The microwave was introduced through a quartz window and a substrate holder was placed approximately 550 mm from the window. The chamber was evacuated using a rotary pump and a 2000 l/sec turbomolecular pump to a base pressure of less than 2×10^{-6} Torr. N_2 gas was introduced into the chamber at a total flow rate of 50 sccm and the operating pressure was selected to be 5×10^{-3} Torr. Six magnetic coils with a thickness of 100 mm and an inner diameter of 320 mm were placed adjacent to the chamber to control the magnetic field distribution. The resonant magnetic field for a frequency of 915 MHz and 2.45GHz were 0.0327 T and 0.0875 T, respectively, and the position was set at 120 mm or 300 mm from the window, which is shown in Fig. 1(b). Microwaves were converted from the rectangular TE_{10} mode to the circular TM_{01} or TE_{11} mode by a mode converter and were launched into the chamber through a waveguide uptaper [14]. The microwave power could be up to 5 kW. The plasma parameters were measured with a three-dimensional movable cylindrical Langmuir probe whose radius and length were 0.5 mm and 1 mm, respectively. The used loop antenna was made of a coaxial cable with heat-resistance (<1000 ℃) and the wave patterns were obtained by the interferometric method. A reference signal of electromagnetic waves from a directional coupler and signal of waves in a plasma are introduced into an balanced mixer, whose output shows the phase difference of these waves depending on the positions of a loop antenna. The amplitudes of wave patterns are given with arbitrary units because the loop antenna was not calibrated.

3. Results and Discussion

In order to clarify the actual relationship between the electron temperature and the power-absorption profile in an ECR plasma, the spatial wave patterns were firstly measured for different electron temperatures. Figures 2(a) and 2(b) show the spatial distributions of the amplitude of radial electric field at the electron temperature of 2 eV and 7 eV, respectively, where the magnetic field configuration was (A) and the electron density was about 2×10^{17} m^{-3}. The contour diagrams corresponding to the electric field strength were made using interferometer traces, and those waves were confirmed to be the R waves by calculating their dispersion relations. As seen in Fig. 2(a), the microwaves injected in TM_{01} mode, which has an electric field profile peaked near the waveguide wall, propagated not only in the vicinity of the chamber wall but also toward the centre of the chamber, consequently, the microwave diverged along the z-axis at the electron temperature of 2 eV. On the other hand, it was observed that the microwave gradually refracted toward the chamber wall along z-axis at the electron temperature of 7 eV, which is shown in Fig 2(b). These interferometer traces suggest that the spatial profile of the microwave power absorption at the electron temperature of 2 eV was different from that at the electron temperature of 7 eV, but do not show which way the power is really transported. Therefore, the spatial distribution of microwave electric fields and the power absorption corresponding to the interferometer traces were calculated to investigate the correlation between the electron temperature and the power-absorption profile, which was performed by using a simulation code 'TASK/WF' [15]. This is a code that uses the finite-element method to solve boundary value problems of the Maxwell equation for stationary oscillation of electromagnetic waves, and makes two-dimensional analysis of wave propagation in a partially filled plasma chamber possible. Figures 4 and 5 show the spatial

distributions of the amplitude of the radial electric field and the power absorption numerically obtained by assuming that the plasma profiles were similar to the experimental results shown in Fig. 3. The contour diagrams correspond to the strength of the electric field and the power absorption. As seen in Figs. 4(a) and 5(a), the microwave diverged along the z-axis when the electron temperature was low, and the ones refracted toward the chamber wall when the electron temperature was high, which was consistent with the experimental results. In the former case, the positions where the power absorption took place spread out in both of r and z directions, on the other hand, the power absorption profile peaked strongly near the window in the vicinity of the chamber wall in the latter case, which was seen in Figs. 4(b) and 5(b). It was clarified from these experimental and numerical results that the electron temperature in an ECR plasma depends on the spatial profiles of the power absorption, that is, the electron temperature is low when the power absorption takes place in a wide area and the electron temperature increases when the power absorption is concentrated.

As mentioned in Sec. 1, the electron temperature in a 2.45 GHz ECR plasma is higher than that in a 915 MHz ECR plasma, whose reason is considered as follows. Since the effective resonance zone width is in inverse proportion to $\sqrt{\omega}$, where ω is the microwave angular frequency, the width becomes narrower as the frequency becomes higher [16]. Therefore, the power absorption profiles at higher microwave frequency are expected to peak strongly and to be changed little with changing the external conditions. consequently, the electron temperature becomes high and cannot be controlled in a wide range in a 2.45 GHz ECR plasma. Figure 6 shows the measured spatial profiles of the electric-field amplitude and the contour plot at the microwave frequency of (a) 915 MHz and (b) 2.45 GHz, respectively. The resonance point was set at z = 300 mm and the gradient in the magnetic field strength was about 0.2 G/mm for each cases, whose configuration is similar to the magnetic field configuration (A) in Fig. 1(b). Here, the pressure of N_2 gas and the incident power were 5 mTorr and 0.5 kW, respectively. As seen in Fig. 6, the microwaves gradually damped along the z-axis in the case of 915 MHz, on the other hand, the waves abruptly damped in the 2.45 GHz ECR plasma, which suggests that the area where the power absorption takes place in a 915 MHz ECR plasma is much larger than that in a 2.45 GHz ECR plasma.

In addition, the electron temperature in the magnetic field configuration (B) was observed to be higher than that in the configuration (A) and could not be controlled efficiently. The reason is also considered in the same way. In case of the configurations (B), the gradient in the magnetic field strength near the resonant zone was steep, so that the effective resonance zone width was narrow compared with that of the configuration (A) [16]. Therefore, the power absorption profiles in these configurations are expected to peak strongly and to be changed little with changing the external conditions, consequently, the electron temperature becomes high and cannot be controlled in a wide range. In fact, it was observed that the microwaves gradually damped along the z-axis and propagated for several wavelengths up to the ECR point in the case of magnetic field (A), on the other hand, the microwaves abruptly damped in the case of magnetic field (B), which is shown in Fig. 7.

Thus, our experimental and numerical results suggest that the electrton temperature in an ECR plasma can be controlled by changing the microwave frequency and/or the gradient in the magnetic field strength near the resonant zone because the power absorption profile is controlled by changing the effective resonance zone width. Furthermore, N_2 gas was used to investigate the electron-temperature control in our experiments, however, many kinds of reactive gases such as CF_4, C_4F_8, Cl_2 and SF_6 are used in the plasma processing and the plasma parameters depend on the gas species. It is necessary to clarify the electron-temperature control not only in nitrogen plasma but also in the reactive plasmas, which will be future work.

4. Conclusions

In order to investigate the production mechanism of a low-electron-temperature ECR plasma, the relationship between the electron temperature and the power-absorption profile was studied. The spatial profiles of the electromagnetic wave patterns were firstly measured for different electron temperatures, which suggested that the electron temperature changes with changing the spatial profiles of the power absorption.

This dependence of the electron temperature on the power absorption profile was examined by numerical simulation, and it was confirmed that the spatial profile of the microwave absorption by plasma has an effect on the electron temperature in an ECR plasma, that is, the electron temperature is low when the power absorption takes place in a wide area and the electron temperature increases when the power absorption is concentrated. Furthermore, our experimental and numerical results suggest that the electron temperature in an ECR plasma is controlled by changing the gradient in the magnetic field strength near the resonant zone and/or the microwave frequency because the power absorption profile is changed with changing the effective resonance zone width.

Scaling up of a Magnetic Pole Enhanced Inductively Coupled Plasma Source (MaPE-ICP)

T. Meziani, P. Colpo, and F. Rossi

Joint Research Centre of the European Commission, Ispra, Italy

Abstract

The principles of a Magnetic Pole Enhanced Inductively Coupled Plasma are presented. Plasma characterization made on a 200 mm source show that the electrical coupling efficiency is increased by a factor 4 as compared to a conventional coil configuration. Scaling up of the reactor to the dimension of 800×800 mm poses several technological problems that have been solved and are presented. Results of plasma diagnostic are presented. Characterization of the large scale source show that a plasma density of 2 to 4.10^{11} cm^{-3} in *Ar* plasma at 2 MHz is obtained with a homogeneity of the ion current density better than 20 % over 800 mm. Application of the source to the etching of SiO_2 layers is presented. Etching rates of the order of 100 nm/mn are obtained over the whole area.

I Introduction

Inductively coupled plasma (ICP) sources are now recognized to be major processing tools for dry etching thanks to their very good performances in terms of etch rates and uniformity, and to their ability to work under low pressure conditions. Nevertheless, the size of the available ICP sources remains limited mainly because of the uniformity problems appearing above 200 mm diameter. The scale up to a large, uniform, high density plasma source poses a few technological problems that need to be addressed: uniform electromagnetic heating profile with a large antenna, careful scale up of the dielectric window to ensure both an efficient electromagnetic coupling and vacuum sealing, loss of coupling efficiency, correct impedance matching, and standing wave effects. Part of these major issues was not completely solved up to now even if several large area plasma sources have been reported in the literature [1-4]. The magnetic pole enhanced inductively coupled plasma source was developed in our lab in order to solve the aforementioned problems [5]. In this paper is presented the development of this source with a study of a 200 mm reactor in a first part, followed by the main results of the scale up study to a 1 m^2 reactor.

II Principle

The main improvement in our ICP source consisted in embedding the coil antenna in a magnetic core. This magnetic core is a low loss material having a high magnetic permeability. Due to its large magnetic permeability, the magnetic field tends to zero within the core. Thus, it concentrates the magnetic flux on the load (i.e. the plasma) and reduces the losses in the back path (figure 1). Furthermore, it provides higher process flexibility since the magnetic field may be concentrated in specific zones. As soon as the power density value and its distribution can be controlled, the plasma uniformity can also be expanded.

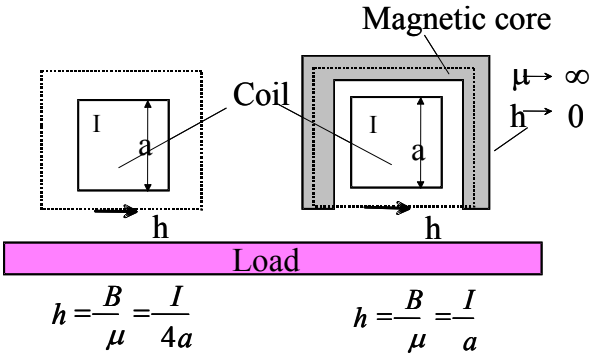

figure 1. Illustration of the magnetic core effect applying Ampere's theorem.

Scaling up an ICP source to a large, uniform, high-density plasma source requires a careful scale up of the two following components:

- the coil antenna that generates the electromagnetic energy
- the dielectric window to ensure the electromagnetic coupling and the vacuum sealing

To achieve a good uniformity over large areas, the usual spiral antenna is not efficient because of the inherent non-uniformity of the electromagnetic field profile that peaks at the semi-radius. Alternative antenna geometries showing much better uniformity are available (like the serpentine, the ladder-shaped antenna, etc.) but they suffer from a low coupling efficiency.
The loss in the electromagnetic coupling efficiency when scaling up the coil antenna can be partly compensated by the concentration of the magnetic flux. But, the increase in the antenna diameter is done together with an increase in the dielectric window diameter. The thickness of this element (that should withstand the pressure difference between the atmosphere and the vacuum chamber) has thus to be increased in order to maintain its the mechanical strength. Then, the mutual inductance decreases with the higher plasma to coil distance [6] and this results in a drastic decrease of the power transfer efficiency.
This problem can be solved by using the magnetic core, which is a rigid material, as a vacuum seal, or by integrating the inductive source (antenna + magnetic core) in a stainless steel cover flange leading to an easier scaling up of the system. The dielectric window doesn't have a mechanical function anymore and only acts as an insulating barrier between coil and plasma. Its thickness can then be reduced thus improving the magnetic coupling between coil and plasma.

III 200-mm diameter MaPE-ICP source

In a first part, we developed a 200-mm diameter source in order to assess the effect of the magnetic core addition and of the dielectric window thickness reduction on plasma density and uniformity at reduced scale.

III.1 Experimental setup

A schematic diagram of the 200 mm diameter MaPE-ICP reactor is shown in figure 2. The stainless steel plasma chamber has a square geometry with a 300 mm characteristic dimension and a 150 mm height.
The 2-turn water-cooled coil is powered by a 13.56 MHz RF generator via a 'Γ' layout matching network composed of two driven air capacitors (Advanced Energy RFX II generator 1.25 kW, matching network AZ90). The gas is injected through a single tube placed at the top of a chamber wall, in the center. The gas feed uniformity is of particular importance for achieving good plasma uniformity and care has been taken to optimize it in the large-scale reactor that will be described in the second part. The magnetic core used in this study is a 200-mm diameter disc, having a 45 mm thickness.

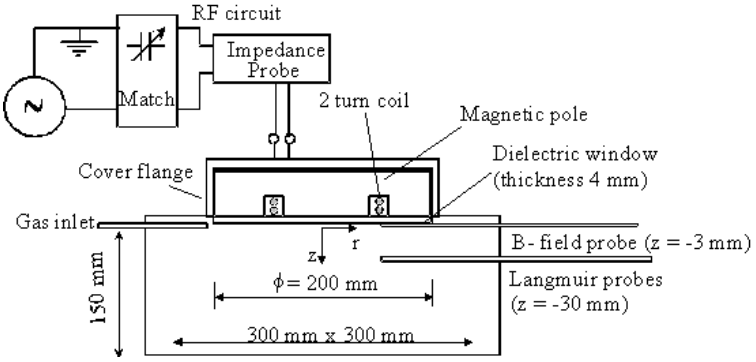

figure 2. Schematic diagram of the experimental setup of the 200-mm diameter MaPE-ICP reactor

To determine the effect of the magnetic core on plasma characteristics, a set of different inductor configurations has been tested:
C1: a two turn cylindrical coil (ϕ=120 mm) with a thick dielectric window (thickness = 25 mm)
C2: a two turn cylindrical coil (ϕ=120 mm) embedded in the magnetic core with a thick dielectric window
C3: a two turn cylindrical coil (ϕ= 120 mm) embedded in the magnetic core with a thin dielectric window (4 mm). This device is arranged within a cover flange for vacuum sealing. This configuration is the so-called MaPE-ICP configuration.
C4: a four-turn spiral coil made from 20-mm large copper strap has been used. This geometry is used in planar ICP processing and acted as a reference for comparative purposes (diameter = 200 mm).
The electrical parameters of the discharge were measured with a RF impedance probe (Advance Energy Z-scan). This device allows the measurements of the r.m.s. RF voltage applied to the coil, the r.m.s. coil current, the phase angle between voltage and current, and the impedance of the circuit load (coil and plasma).

The radial component B_r of the magnetic induction field has been measured with a magnetic induction probe [7]. All the measurements were carried out at approximately 3-mm from the dielectric window.
Plasma characteristics have been measured in a pure argon discharge by means of two different Langmuir probes. A planar probe has been used to measure the radial profile of the ion current density in the chamber whereas the electron temperature has been measured by a compensated cylindrical probe. Both probes were placed at a distance of 3 cm below the dielectric window. This distance ensures an absence of perturbation to the measurements since the magnetic induction field is low in such systems (< 10 G) and decreases exponentially with the axial distance from the window.

III.2 Results and discussion

At constant net power, the magnetic core induces a reduction of the coil current by a factor 2 whereas the coil voltage is only slightly modified. Thus, the ohmic losses in the matching network circuitry are reduced resulting in an increase in power transfer efficiency.

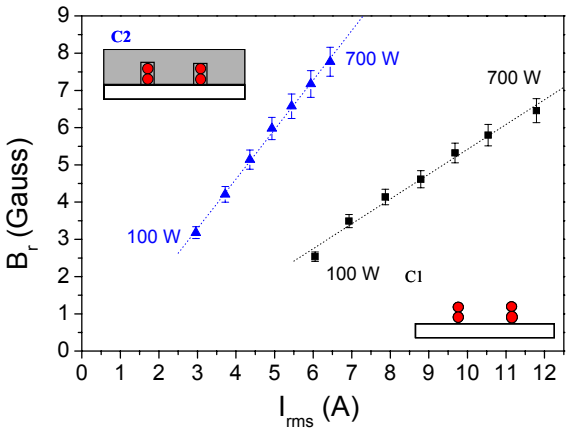

figure 3. Radial component of the magnetic field vs coil current with (▲) and without (■) magnetic core.

Ion current density measurements have been performed on C1 and C2 configurations to assess the magnetic core efficiency in a classical configuration (with a thick dielectric window). The results show that at constant RF power, the ion current density is increased by nearly 50 % with the use of a magnetic core, which corresponds to the 24 % increase observed on the radial component of the magnetic induction.
The ion current density measurements on the MaPE configuration (C3) as compared to the C1 configuration (with a thick window and without magnetic core) and C4 configuration (spiral coil) is represented in figure 4. In the final configuration (MaPE) the ion current density is increased drastically as compared to other configurations due to the combined effect of the magnetic core addition and the dielectric window thickness reduction. The

The time-varying radial magnetic field magnitude B_r has been measured with (▲) and without (■) magnetic pole to assess the flux concentration efficiency. Figure 3 shows that the magnetic field intensity is increased by the presence of the flux concentrator at constant RF power. But, the magnetic induction value should be compared at constant coil current and we observe then that a significant increase takes place thanks to the magnetic core. The gain achieved also indicates a net increase of the power absorbed by the plasma since it is directly proportional to the square of the magnetic field ($P_{abs} \approx n_e^{1/2} B_r^2$) [8]. This figure shows also that the magnetic induction B_r presents a linear dependence with the coil current, demonstrating that the magnetic core does not saturate when the power increases in the range of parameters studied. Saturation is unwanted since losses, and especially eddy current losses, increase when saturation is reached.

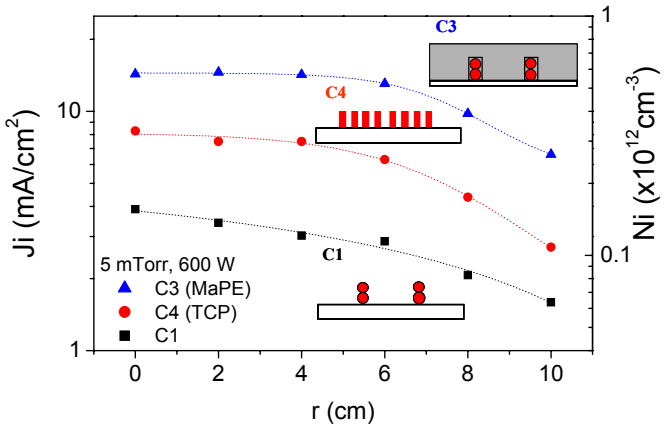

figure 4. Ion current density radial profiles for the MaPE configuration as compared to the spiral coil source (C4) and to the 2-turn helicoidal coil source (C1).

ion current density is increased as compared to the cylindrical coil antenna C1 by a factor of 3 and a factor 2 as compared to the spiral coil.
The plasma uniformity is also improved with a deviation from ion current density uniformity going from 16 % with the single 2-turn coil to approximately 5 % within the area of the coil radius in the MaPE configuration.

IV Scale-up to a Large Area MaPE-ICP source

Based on the previous study, a large area plasma semi industrial reactor was constructed using the same technology. The antenna geometry was modified though in order to provide for a uniform electromagnetic heating profile over such a large area. Following previous studies [9], experiments on the 200 mm diameter MaPE-ICP reactor and numerical simulations, a serpentine coil antenna appeared to be the best solution.

IV.1 Experimental setup

A schematic diagram of the experimental setup is presented in figure 5. The reactor is a squared chamber of 1000 × 1000 mm for 300 mm in height. The 13.56 MHz RF power is supplied by a 5.5 kW Advanced Energy APEX generator via a 'Γ' matching network (Advanced Energy AZX 90) composed of two driven vacuum capacitors.
The tested antennas were embedded within a magnetic core as shown in figure 5. The inductive source arrangement is included in the vacuum part of the chamber in order to use a thin dielectric window (5 mm). The gas is uniformly injected in the reactor through the magnetic core through small pipes equally distributed along the inductive source area.

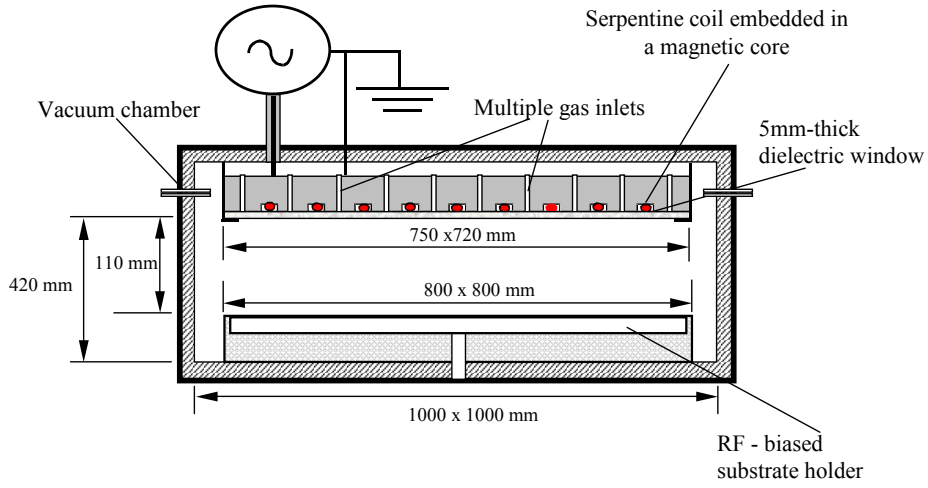

figure 5. Schematic representation of the experimental setup.

For the diagnostic of the plasma in this source, a multiple Langmuir probe system was used. This system is composed of 9 probes placed in line so that we can measure the electron density every 10 cm along the whole substrate-holder length on the *X* direction. The multiple probe system is then translated in the *Y* direction to get a bidimensional profile.

IV.2 Results and discussion

First tests have been made using two serpentine coils connected in series and arranged in order to form current loops keeping the same current direction in each magnetic core groove and an opposite direction between neighbouring grooves. The normalized ion density profile measured at 3 cm from the dielectric window across the coil (along the *X* direction, at *Y = 0*) is presented in figure 6. The first results showed that the profile is

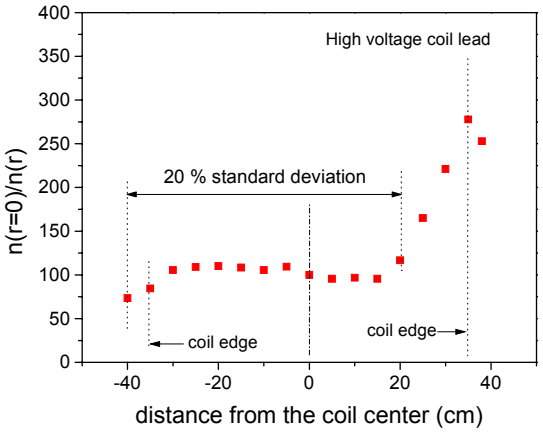

figure 6. Normalized ion density profile in a 5mtorr Ar discharge.

MHz than at 13.56 MHz. This is mainly due to the different electric behavior of the inductive source. Indeed, the magnetic core specifications show that its characteristics are much better at 2MHz with in particular a 5 times higher magnetic permeability and lower losses.

Following numerical simulations and experimental investigations, the antenna geometry was optimized and a special arrangement was used in order to improve the plasma uniformity.

The ion current density profile measured along the *X* axis (at *Y = 40* cm from the edge) shows a much higher uniformity (figure 8) than was previously obtained (figure 6). The uniformity as defined by the ratio (standard deviation/average) reaches 7 % over 60 cm and 14 % over the inductive source length. The

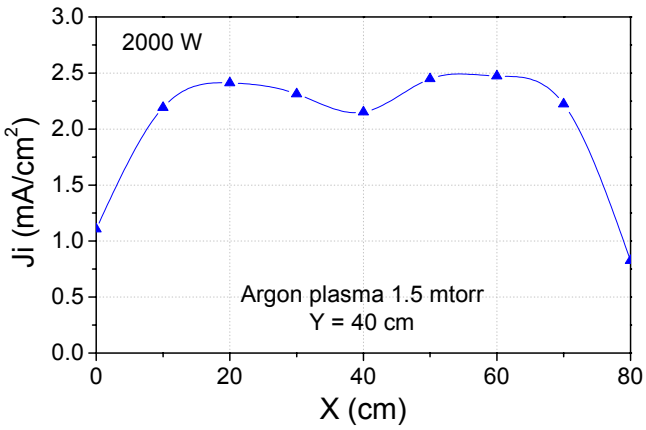

figure 8. Longitudinal profile of the ion current density measured in an Ar plasma at 1.5 mtorr and 2 kW.

relatively flat except at the edge close to the coil leads. Considering the coil length, this strong non-uniformity was likely to be due to standing wave effects resulting in non-uniform dissipation.

To get rid of these standing wave effects, we decided to decrease the coil length/wavelength ratio by using a 2MHz RF excitation frequency. The 13.56 MHz RF power supply was thus substituted by an Advanced Energy 2 MHz RF generator delivering 8 kW maximum power.

With a shorter antenna, the first noticeable difference between the two-excitation frequency operations was observed on the ion density values. As shown in figure 7, the ion current density is 4 to 5 times higher at 2

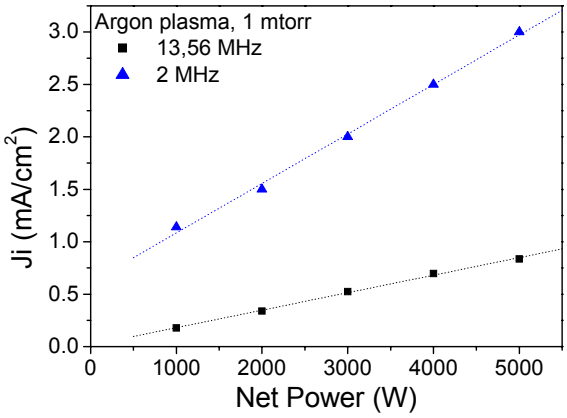

figure 7. Ion current density vs RF power in an Ar plasma excited at 13.56 MHz and 2MHz.

profile suffers from the vicinity of the walls that are only at 10 cm away from the substrate holder on each side.

The uniformity achieved over the whole area is relatively good with approximately 30 % over 80×80 cm^2 and less than 15 % over 60×60 cm^2.

The ion density is around 3.10^{11} cm^{-3} for 5 kW, which is quite high considering the source size and the relatively low pressure (1.5 mtorr).

The same kind of measurements was carried out in CHF_3, which has been used for the etching of SiO_2 layers. The results were similar with the ones obtained in *Ar* in terms of uniformity, while the ion density was 30 % lower.

SiO_2 etching tests were carried out in this reactor with CHF_3 and latter with CF_4 gas. The etching rate reaches about 100 nm/min at 3 kW input power applied to the inductive source and 1 kW RF bias power applied to the substrate holder. Preliminary SiO_2 etching results are presented in figure 9. The normalized profile shows that the overall uniformity is around 9 % on 60×60 cm^2. Further improvement is expected to be achieved by a correct tuning or process parameters such as substrate holder temperature uniformity and gas flow control.

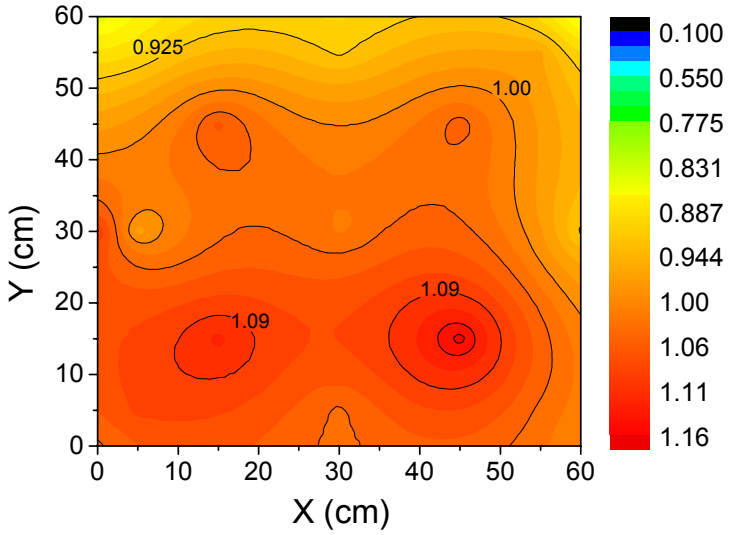

figure 9. Normalized SiO_2 etching rate profile in CF_4 atmosphere at 1.5 mtorr and 2 kW.

V Conclusion

The development of a novel reactor using an improved inductive source opened the way to the design of a large area ICP source. The key issues of impedance matching, standing wave effects, capacitive coupling, and plasma uniformity were addressed and solved. Plasma density is of the order of 10^{11} cm^{-3} at argon pressures as low as 1 mtorr and the uniformity was better than 15 % on 60×60 cm^2. Preliminary etching SiO_2 etching experiments showed very promising results in terms of etching rates and uniformity with less than 9 % on 60×60 cm^2.

Abstract
Diamond-nickel disperse composite materials (DCM) representing diamond powder consisting of particles with mean size of 5 μm, covered by nickel metal was obtained using dusty plasma technique. Amount of DCM obtained is quite enough for physical and technologic studies. The coating is shown to be a solid nickel layer of 10 nm in thickness with characteristic roughness of 3 nm.

1. Introduction

Disperse composite materials (DCM) consist of small particles having the size of $10^2 \div 10^4$ nm and covered with a coating. These materials can be used both in the processes of fabricating structural and special materials with unusual properties and in the production of highly efficient catalysts. This report presents some results of studying DCM produced in a dusty plasma trap by means of the technology which is similar to [1,2]. Disperse particles in such a trap are charged with electrical charges of $10^3 \div 10^4 e$ where e is the charge of electron. The Coulomb repulsion results in suppressing of the coagulation processes forming long-lived quasi-liquid state in our case.

2. The setup for DCM production

The experimental setup for dusty plasma trap creation includes the vacuum chamber with electrode system inside where the RF discharge plasma is available. The electrode system is powered by the RF generator at fundamental frequency of 5.28 MHz. The discharge power was up to 30 W. The argon gas was used at pressure of 0.1÷0.3 Pa and 1÷5 sccm flow rate. The disperser of the accelerative type was used to inject a cloud of powder particles into discharge chamber. The cloud levitated in the plasma trap and exposed it to the atom beam from magnetron sputtering system (fig.1).

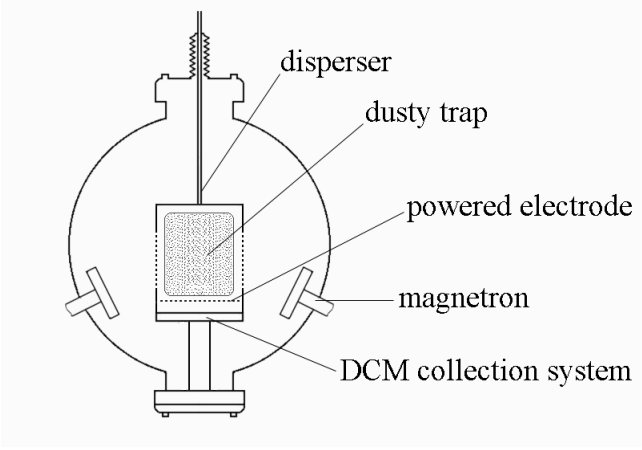

Fig. 1. Scheme of the reactor.

We used two ion-plasma sputtering magnetron systems with the cylindrical cathodes. The ring magnetic balanced system is inside the water cooled cathode frame. The magnetic system is pieced together from permanent Nd-Fe-B magnets with residual induction of 0.45÷0.55 T. The sputtering target is placed over the magnetic system. Nickel is a magnetic material, so the target is of special construction providing the effective sputtering of magnetic materials at the magnetron mode of operation where strong arc magnetic field (0.03 T) is present above the target surface. The latter is necessary for trapping of the electrons above

the intensive sputtering zone. The construction provides the nickel sputtering in a high-speed mode at the power density of 45÷50 W/cm^2 (intensive sputtering zone takes the ring-shape with the external diameter of 52 mm and with the square of 19 cm^2). The magnetron sputtering systems are located close to the RF-electrode and its magnetic fields influence significantly to the discharge properties and the dusty trap location.

3. Results and discussion

Analysing the fabricated product was accomplished with the use of a number of methods including electron-microscopic research, X-ray analysis, cathode-luminescent analysis, X-ray photo-electron spectroscopy, precision chemical analysis, and some others.

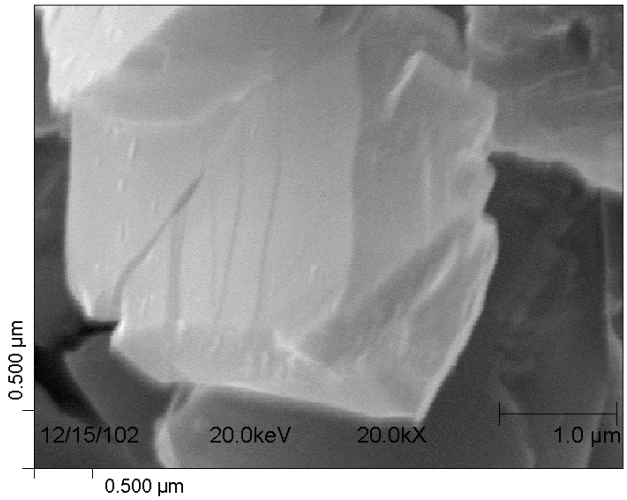

Fig. 2. SEM photo of the diamond particle covered by nickel metal

Electron-microscopic research of diamond particles coated with Ni was performed with using the high-resolution (~30 nm) scanning electron microscope. Electron-microscopic pictures show that the coated particles, unlike the particles of the initial diamond powder, are quite sharply defined (fig. 2). This indicates high electro-conductivity of the coating. Within the mentioned resolution the formed coating is quite smooth, follows the substrate relief, and does not contain fractured structures of "cauliflower" type.

Besides that, we obtain the micrographs of the specimens by means of the transmission electron microscope at accelerating voltage of 50 kV. The specimens were spotted on the copper mesh coated preliminarily by collodion and reinforced by carbon. The micrographs of the coated powder particle edge are given in Fig.3. The edges of the main part of the investigated particles seem to be quite uniform, similar to the edges of the initial diamond. The coating characteristic roughness size is about 3 nm. There are no signs which would be evidence of the nickel coating exfoliation from the diamond substrate.

Measurement of the mean nickel content

To analyze the nickel content C_{Ni} in the powder we used the method of specimen combustion in oxygen at the temperature of 1673 K. The initial powder burns completely in this process. The rest of DCM combustion seems to be consisting of the nickel oxide NiO. The mass of nickel in the rest to the initial mass of processed specimen is the quota of the metal in the composite material. Three samples from each specimen were combusted, the obtained data were averaged. Calculated from the averaged data, the concentration of the metal in one of investigated specimens is given in Table 1.

Measurement of the specific surface

The method of the argon adsorption at the liquid nitrogen temperature was used for measuring of the powder specific surface. The characterization of specific surface S from the adsorption measuring is reduced to the measuring of quantity of matter which is necessary to cover the surface by the monomolecular layer. This quantity was measured according to the method using the linear form of the adsorption isotherm equation. The specimen was degassed at the temperature of

150°C. The special argon (5%) – helium mixture was used as the working gas. The relative error in the specific surface measured is 5%. The results are given in Table 1.

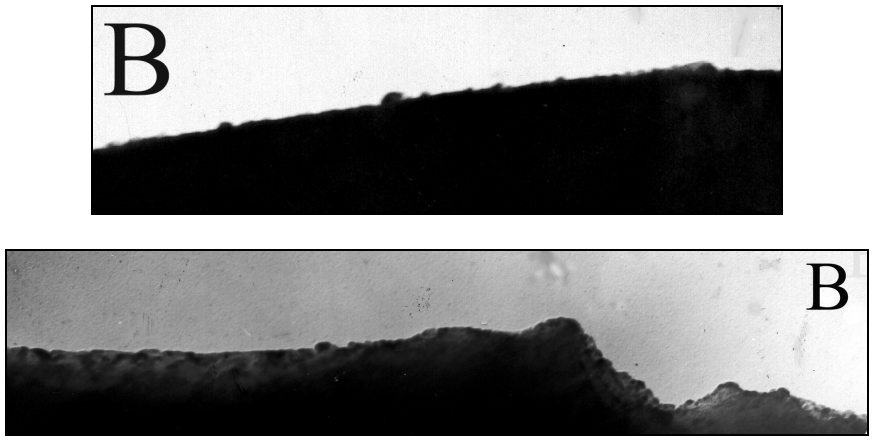

Fig. 3. The micrographs of the edges of the diamond particles covered by nickel metal. The vertical size of "B" is of 57 nm.

Table 1. The results of analysis.

specimen	C_{Ni}, mass.%	S, m^2/g	H_c, Oe	M_1, emu/g (H =10^4 Oe)	C_{fNi}, mass.%
The original diamond powder	0	0.76	0	0	0
Diamond covered by nickel	7.5	1.14	131	0.85	1.55

X-ray diffraction investigations

The X-ray diffractograms were obtained using monochromatic Cr K_α radiation. The original diamond diffractograms exhibit the alone peak due to the diamond (111) lattice reflection (Fig. 4).

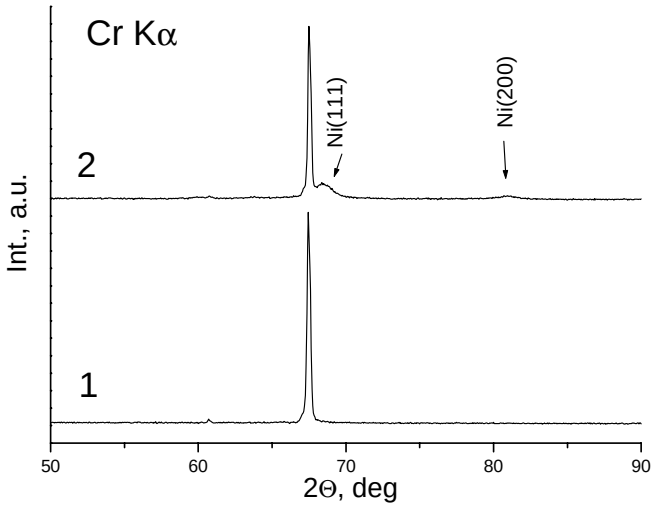

Fig. 4. The X-ray diffractograms of the original diamond powder (1) and of the processed specimen (2)

Nickel is seen in the diffractogram of the processed specimen as two peaks corresponding to the reflections of (111) and (200) face-centered cubic lattice. The lattice parameter value calculated using these peaks data is of 0.3529 nm and exceeds one of a bulk nickel (0.3524 nm [7]). The size estimation of the nickel coherent scattering domain corresponding to the coating thickness in the direction which is perpendicular to the plane (200) was carried out. The estimation formula was $D_{200} = \lambda/\beta\cos\Theta$, where λ is the X-ray length, β is the half-width of the Ni (200) diffraction peak. The lower peak was chosen because it is noticeably easer to size its half-width compared to the Ni (111) peak, which is overlapped by the diamond (111) peak. The D_{200} value seems to be of 12 nm according to the mean thickness value, obtained as result of the specific surface and the mean nickel content measurements.

Magnetic properties of the processed powder

We studied the magnetic properties of the specimens by means of vibration magnetometer EG&G PARC M4500. The specimens under investigation were placed into a thin diamagnetic ampoule whose own signal may be allowed in the course of analysis of observations. The magnetization curves of the processed specimens are the hysteresis loops with $H_c = 130$ Oe, where H_c is the coercive force (Fig.5).

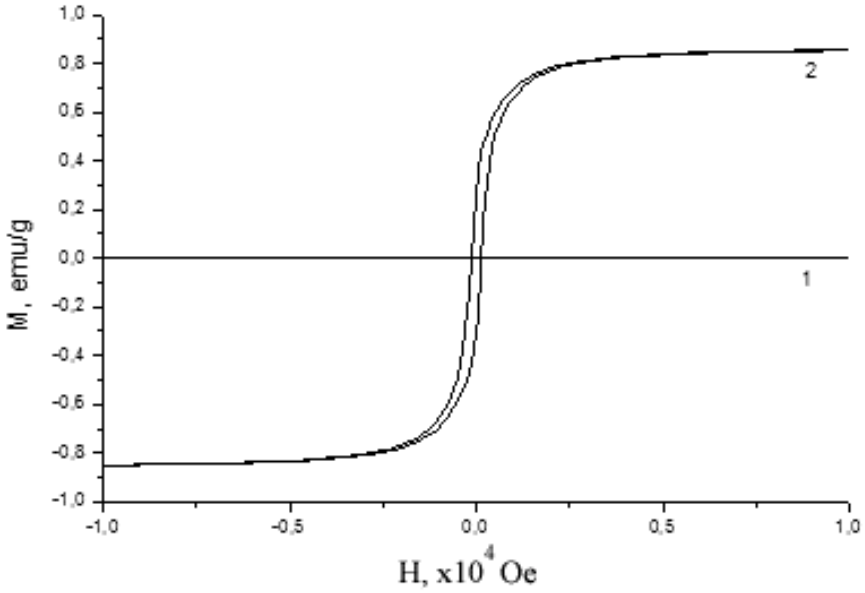

Fig. 5. The magnetization curves of the initial diamond (1) and of the processed specimen (2)
M is the specific magnetic moment, *H* is the magnetic strength.

One may see that the saturation state is not achieved even at $H = 10^4$ Oe. Therefore there are superparamagnetic nickel particles in the specimen. One may estimate the relative content of ferromagnetic nickel $C_{f\,Ni}$ in the specimen by formula $C_{f\,Ni} = M_1 / M_s^0$ where M_1 is the experimental value of M at $H = 10^4$ Oe, M_s^0 is the saturation specific magnetic moment for a bulk nickel ($M_s^0 = 55$ emu/g [8]). The $C_{f\,Ni}$ value is appreciably smaller than C_{Ni} value which was sized using the method of specimen combustion (Table 1). So nickel in the form of nickel oxide is thought to be present in the specimen besides the super-paramagnetic nickel particles. Nickel oxide is known to be antiferromagnet [9].

X-ray photoelectron spectroscopy

The X-ray photoelectron spectra were taken with the spectrometer PHI-5500 *(Physical Electronics Industries*) equipped by the precision analyzer of spherical type. The spot diameter where analysis is carried out was of 0.8 mm. The specimens were embedded into the indium substrates as permanent layer. The base gas pressure in the spectrometer chamber did not exceed $7 \cdot 10^{-8}$ Pa. The ion gun built in the spectrometer chamber makes it possible to clean the specimen surface from the adsorbed admixtures and to carry out the ion etching of the specimen to the hundreds of nanometers in depth.

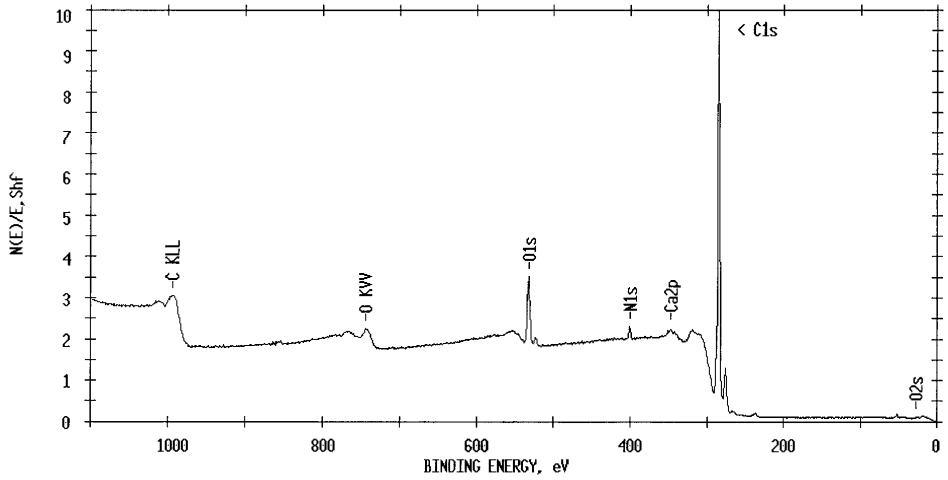

Fig. 6. The general X-ray photoelectron spectra of the initial diamond powder

The general X-ray photoelectron spectra of the diamond powder before and after the sputtering process realization are given in Figs. 6 and 7 correspondingly.

The carbon is seen to be the main element of the initial specimen surface. After the sputtering process performed, the nickel becomes the main one. Nickel is in the specimen surface layer in two forms: as the metal and as the nickel oxide over the metal surface. The Ni 2p (Fig.7) line is the complicate curve consisting of three peaks, the two of which appear due to nickel oxide (861.2 and 855.6 eV), and the rest (852.8 eV) – due to metal nickel. The correspondence of the peaks was taken from [10]. Cleaning of the smooth surface region of the specimen by Ar^+ ions leads to vanishing of nickel oxide peaks and to only metallic nickel practically remaining in the surface layer. It means that the coating is quite uniform and even if there are large aggregations on the particle surfaces, their relative part is not great.

So, according to X-ray photo-electron spectra the coating thickness was not less than 10 nm. The short-time etching of the specimen by an ion beam in the chamber of X-ray photo-electron spectrometer made it possible to practically completely remove the NiO film from the specimen surface. That indicates abnormally low oxidation of the produced composite material in spite of the fact that this material had been kept for quite a long period (about 10 days) in the air medium before it was placed in the chamber of the X-ray photo-electron spectrometer.

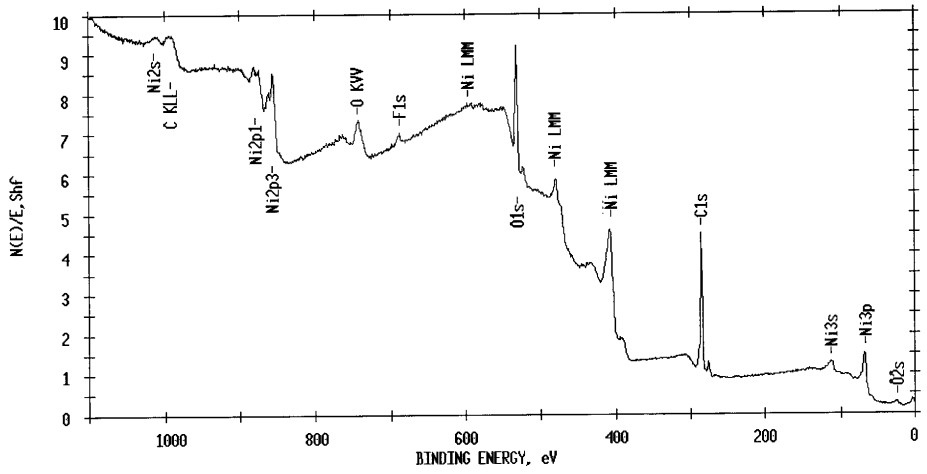

Fig. 7. The general X-ray photoelectron spectra of the processed powder

4. Conclusion

The performed investigation showed that the dusty plasma technology made it possible to obtain the diamond-nickel composition material in such amount which was enough for physical and technologic studies. The coating is a solid nickel layer of 10 nm in thickness with characteristic roughness of 3 nm.

Dendrite fragments and coatings with fractal structure are practically absent in the metal layer and the nickel film is strongly bound up with the diamond surface.

Treatment of Incineration Ash and Sludge using Thermal Plasma

Hak In Kim and Dong-Wha Park

Department of Chemical Engineering, Inha University, Incheon, 402-751, Korea

Abstract

The application of thermal plasma to waste treatment may be a possible method for treating various kinds of hazardous waste through volume reduction and detoxification. The vitrified slag's safety test was performed. The leaching tests of the solution in pH 2, 4, 6 were examined. At pH 4, the leaching limit was satisfactory. The concentration of non-organic material in sludge was not enough to vitrify. Properties of slag were affected by differences in cooling rates. A fast cooling rate showed good elution proof.

1. Introduction

Recently, the products of hazardous waste have increased with the increase of population, improvement of living quality, etc. Waste treatment involves disposal cost, environmental pollution and social problems. One waste treatment is landfill. However, this method causes many problems--for example, groundwater pollution from landfill leachate, shortage of landfill site, and soil contamination. Another type of waste treatment is incineration. However, fly ash contains many inorganic compounds of hardly decomposable heavy metals such as Pb, Cr, Zn. So even though they are buried, they could strike a lethal blow if the heavy metal is exposed and accumulates to excess [1]. Therefore, incinerated ash needs a proper treatment method that excludes the possibility of leaching heavy metal [2].

Sludge forms after wastewater treatment. Most sludge is buried underground or dumped into the sea. But direct disposal is prohibited by law. So after partial incineration the sludge is buried underground. However, incinerated ash needs proper treatment. With incinerated ash treatment, there is cementation or solidification of plastic, which results in economic problems and increased volume. Therefore, the vitrification process is more efficient; with this process, the temperature is higher than the melting point of the fly ash, which turns into slag. Thus, thermal plasma arc vitrification is one possible solution, since plasma arc systems can reach high temperatures regardless of the maximum temperature of fossil fuel. With the plasma arc system, it has been expected that the ashes can be converted to high-quality slag, thereby reducing the volume.

Treated slag can be used as construction materials such as interlocking blocks and roadbed material because the hazardous substances are fixed in the slag without leach [3]. This research studied volume reduction, detoxification (removal of hazardous elements) of fly ash, conversion to stable slag, and behavior of hazardous material by elution tests with ashes. Then, through testing the physical properties of the slag, we confirmed that it could be reused.

2. Experiment

2. 1 Experimental equipment and process

Figure 1 shows a schematic diagram of the experimental apparatus for plasma vitrification. The apparatus consisted of a plasma torch, a reaction chamber and an off-gas system. The non-transferred type of plasma jet was used, with a tungsten cathode and a copper anode. Both electrodes were water-cooled and the plasma torch was made to rotate 360°. The chamber was made with a double wall of water-cooled stainless steel and had a view port. The sludge and fly ash were put inside the chamber where they were melted. The fly ash, consisting of very fine particles, would be blown away by the plasma jet; therefore, it could not be placed on the crucible as it was. So we prepared pellets for samples. The samples were put on a water-cooled Cu holder to control the height between pellet and torch. The arc length was kept to thirty mm, and the output power of plasma was about six to nine kW. The exhaust gas was treated and led through a scrubber and duct. The sludge and fly ash were melted for ten to fifteen minutes, respectively, and then the slag was analyzed by a leaching test. Table 1 shows the experimental conditions. The leaching solution was analyzed by a ICP-MS and a conductivity meter. Vickers hardness of slag was measured with a micro hardness tester.

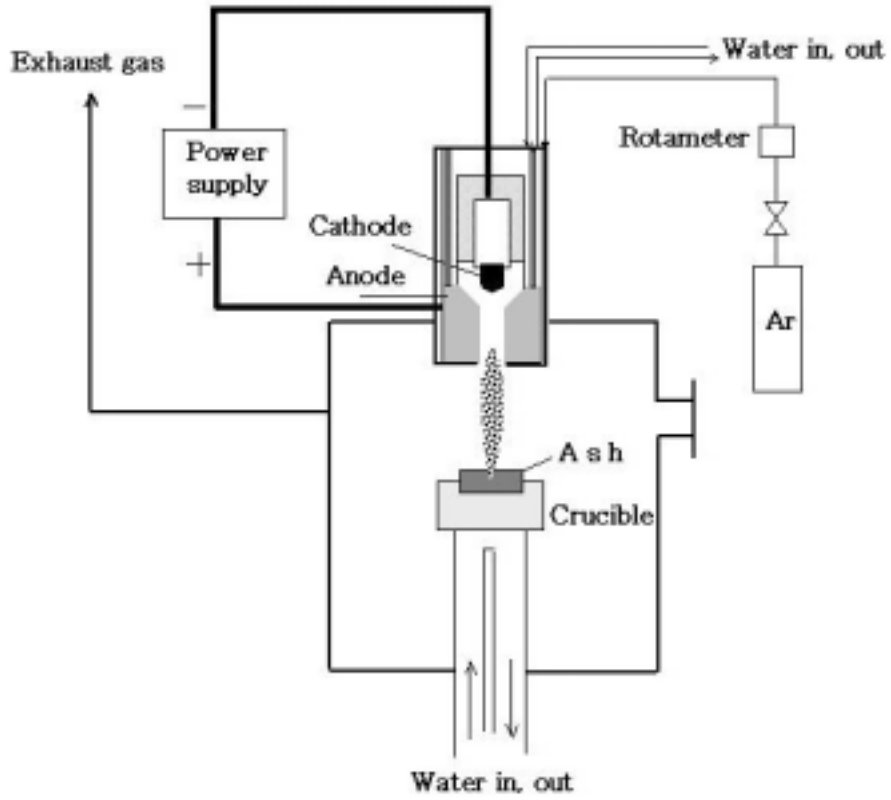

Fig. 1. Schematic diagram of set-up

Table. 1. Experimental condition

Plasma torch	Input power : 6 - 9 kW (40V)
Plasma gas flow rate (Ar)	15 l/min
Distance (from torch to waste)	30 mm
Ash weight	25 g
Operating time	10-15 min

2. 2 Leaching Test

2. 2. 1 Standard leaching test

The leaching test was used to estimate the elution of hazardous waste. A criterion of the leaching test is given in Table 2. The standard leaching test was carried out using acid solutions (pH 5.8-6.3) with a liquid-to-solid ratio of one hundred ml of solution for ten g of solids. The solution was stirred by the shaker with an amplitude of four to five cm at two hundred rpm for six hours in the atmospheric temperature, pressured and filtered on one μm filter paper to separate the solid and liquid phases.

Table 2. Criterion of leaching test [ppm]

Item	Cd	Pb	Zn	As	Se	Pb	Cr	Hg
Leaching limit	0.3	3	-	1.5	-	3	1.5	0.005

The leaching solution was analyzed concerning As, Cr, Cu, Cd, Hg, Se, Pb, Zn, following the Korea Standard Leaching Procedure [4]. Zn, Se is not a standard elution test material but is included for reference in this research because it is plentiful in the environment and toxicity is a concern.

2. 2. 2 Leaching test by different conditions

The pH condition and the slag diameter have the most influence on leaching of the heavy metal [5]. So we conducted a leaching test of plasma molten slag by changing the pH 2, 4, 6 of the solution and changing the slag diameter to pH 4. Other leaching terms are equal to that of the standard leaching test.

2. 3 Contrast of the cooling rate

After ash and sludge are melted, the property of molten slag is influenced by different cooling rates. So we conducted differences of cooling rates. The Vickers hardness of molten slag was measured. The leaching solution, slag, was analyzed by ICP-MS, KEM conductivity.

3. Result and discussion

3. 1 Fly ash and sludge

Fly ash contains amounts of heavy metal, so if buried in the ground it would be exposed to acid rain in the future. Therefore, it should be treated before being buried. Before and after vitrification, we conducted leaching tests of fly ash and sludge. The Korean Standard Leaching Procedure stipulates that the leachate for the test should be pH 5.8-6.3. In this experiment, we performed leaching tests in pH 6. Tables 3 and 4 show the results of the leaching test before and after vitrification. Zn, Se is not in the standard leaching test materials but it is included for reference in this research. After vitrification, more heavy metals flowed from the sludge. The concentration of non-organic material in sludge was not enough to vitrify. So we mixed sludge and fly ash to increase non-organic material in the sludge. In the mixture the fly ash-to-sludge ratio was 1 : 1 in wt %. In the mixture, each heavy metal had a value below the leaching limit after vitrification.

Table 3. Leaching test results of fly ash and sludge [ppm]

	Cd	Cu	Zn	As	Se	Pb	Cr	Hg
Leaching limit	0.3	3	-	1.5	-	3	1.5	0.005
Fly ash	142.8	3640.5	2869.3	0.334	1.330	11.19	1.170	ND
Mixed	62.39	843.6	1228.5	0.206	0.619	0.490	0.106	ND

Sludge	0.144	12.47	2.955	0.044	0.022	1.904	0.182	ND

3.2 Heavy metal leaching according to changing conditions

The pH has the most influence on leaching of heavy metal. So a leaching test of the molten slag by changing pH was performed. Other leaching conditions are equal to that of standard leaching procedure. Tables 5 and 6 show the results of leaching tests by changing pH. The slag was safe in pH 4 compared to the standard leaching limit. As the pH becomes more acid, more heavy metals leach out. Table 7 shows the results of the leaching test by changing the slag's diameter. If the slag is buried underground, it breaks easily, so the surface area increases. If the particle diameter decreases, more heavy metal leaches out. The slag's

diameter is classified to 1~5mm, 5~10mm and over 10mm. The leaching test was performed in pH 4. The result shows that more heavy metals leached out as the slag's diameter decreased.

Table 5. Leaching test of the fly ash slag by changing pH [ppm]

	Cd	Cu	Zn	As	Se	Pb	Cr	Hg
Leaching limit	0.3	3	-	1.5	-	3	1.5	0.005
pH 4	0.145	1.836	1.096	0.005	0.007	0.093	0.0004	ND
pH 2	0.213	20.449	3.337	0.060	0.010	0.083	0.0002	ND

Table 6. Leaching test of the mixed slag by changing pH [ppm]

	Cd	Cu	Zn	As	Se	Pb	Cr	Hg
Leaching limit	0.3	3	-	1.5	-	3	1.5	0.005

Table 7.The result of leaching test by changing the slag's diameter at pH 4 [ppm]

	Cd	Cu	Zn	As	Se	Pb	Cr	Hg
Leaching limit	0.3	3	-	1.5	-	3	1.5	0.005
X > 10 mm	0.128	1.512	1.043	0.006	0.007	0.04	0.001	ND
5 ~ 10 mm	0.25	1.692	1.779	0.006	0.012	0.118	0.0002	ND
X < 5 mm	0.335	3.163	2.647	0.012	0.014	0.176	0.0007	ND

3.3 Comparison of cooling rates

The property of molten slag is influenced by different cooling rates. If the cooling rate is fast, slag becomes amorphous, and the slag's hardness increases. An experiment with different cooling rates was performed. A leaching test was performed, and the slag's hardness was measured. The leaching solution was analyzed by ICP-MS. The electric conductivity for the leaching solution was measured using the KEM conductivity meter. Tables 8 and 9 show the results of the ICP-MS and the conductivity meter. The cooling rate was classified as fast, medium and slow. Fast is water-cooled; medium is air-cooled; slow is natural convection.

.

Table 8. The results of leaching tests by different cooling rates (sludge + bottom ash) [ppm]

	Cd	Cu	Zn	As	Se	Pb	Cr	Hg
Leaching limit	0.3	3	-	1.5	-	3	1.5	0.005
Slow	0.0042	0.7444	0.1619	0.0149	ND	0.0184	0.0263	ND
Medium	0.0046	0.4675	0.1311	0.0183	ND	0.0198	0.0074	ND
Fast	0.0006	0.1954	0.0211	0.0043	ND	0.0017	0.0058	ND

Table 9. Electric Conductivity of mixed slag by different cooling rates [μs/cm]

	Slow	Medium	Fast
Electric Conductivity	53	35.3	28

Vickers hardness of mixed slag and mixed slag after leaching tests by different cooling rates is shown in Table 10. All slags have a strong physical property like ceramics. The amount of heavy metal and Vickers hardness decreased if the cooling rate was fast. This fact indicated that the amorphous structure enhanced the problem of heavy metals flowing out. With a faster cooling rate, the physical hardness decreased but had more Vickers hardness than the ceramic. This slag was found to exhibit sufficient strength to be utilized as construction material such as interlocking blocks or road-bed material.

Table 10. Vickers Hardness of mixed slag by different cooling rates [Hv]

	Slow	Medium	Fast
Before leaching test	1983.4	1669.7	1243.7
After leaching test	1585.7	1600.4	1238

4. Conclusion

The fly ash and sludge were treated by a DC non-transferred type of thermal plasma. It was concluded that the heavy metal in slag leached a value below the standard level by plasma vitrification. The leaching test by changing conditions was conducted. An experiment with different cooling rates was also performed. The results are as follows:

1. The results of leaching tests showed that such heavy metals as Cu, Zn, Pb in fly ash leached over the standard. Fly ash must be detoxified by plasma vitrification before its final disposal.
2. By plasma vitrification of fly ash, the heavy metal in fly slag leached a value below the standard.
3. After vitrification, more heavy metals flowed from the sludge. The concentration of non-organic material in sludge was not enough to vitrify.
4. The sludge and fly ash for increasing non-organic material in sludge was mixed. In the mixed, each heavy metal had a value below the leaching limit after vitrification.
5. As the pH becomes more acidic, more heavy metals leach out. And as the particle diameter decreases, more heavy metals leach out.
6. The results of differing cooling rates show a lower leaching from rapidly cooled slag than from the slowly cooled slag. This is due to the structure of the slag.

Plasma Deposition of Nano-Structured and Nano-Layered Thin Films for Biomedical Applications

P. Colpo, G. Ceccone, F. Rossi

European Commission, Joint Research Centre, Italy

The present work concerns the deposition of multi-component nano-structured thin films to control the adhesive surface properties under conditions of contact with the bio-medium. Nano-structured thin films based on the system Ti-X-Y (X=Al,Si,V,Zr,Nb, and Ca; Y=C,O, and N) are deposited using ionised PVD (I-PVD) of composite targets.

Plasma diagnostics is performed by means of optical emission spectroscopy, and mass spectrometry including ion detection. The relative ionised fraction of metal atoms for different PVD parameters is measured. Influence process parameters (power, pressure…) on the structure and mechanical properties of the layers was studied and related to the diagnostics results.

The Study on Plasma Pyrolysis of Biomass and Plastic

Zeng-li Zhao[1], Hai-bin Li[1], Chuang-zhi Wu[1] , Yong Chen[1], You-san Fan[2]

[1]*Guangzhou Institute of Energy Conversion，CAS, Guangzhou ,China*
[2]*Tsinghua University, Beijing, China*

With the rapid urbanization and industrialization in China, the amount of municipal solid waste (MSW) produced is increasing at a rate of 8~10% each year. The calorific value and composition of MSW are also changing due to increasing waste plastic and paper. Now many landfill sites are full beyond capacity. Other traditional disposal technologies caused serious environmental pollution that deserves public concern. There are two principal combustible wastes in MSW: cellulose (paper, wood, etc) and polymer (plastic, textile and tire). These wastes constitute about 20~30% by weight and only a small amount can be recycled as material. Thermal process is one kind of effective technologies to reduce the volume and mass, while the energy can be recovered in an environmentally friendly and safe way.

There are many thermal treatment processes of converting these complex mixtures into valuable products, such as pyrolysis, gasification, etc. Because of their high calorific and volatile, currently there is considerable interest in the efficient use of combustible composition in MSW as a fuel source or a possible chemical feedstock. But it is very difficult for the complete and ecologically safe disposal of unsorted, unpurified mixed plastic waste. Thermal plasma technology can offer a new way to convert the mixtures [(1,2)]. Plasma pyrolysis process uses extremely high temperature to completely decompose waste material into very simple molecules and the byproduct is an energy-rich gas used for power generation or methanol synthesis.

A DC plasma pyrolysis device with a maximum power input of 50KVA was used in the experiments. The mixtures of biomass and plastic were feed continuously into the reactor using nitrogen as the operating gas and carrier gas. The feeding rate varied from 1.0kg/h to 3.6kg/h. Polyethylene（PE）and Polypropylene (PP) are chosen as the plastic materials in pyrolysis experiments for that they are the principal components contributing to the plastics in MSW. The results indicated that product gas is rich in hydrogen, carbon monoxide and acetylene. The influences of the feeding rate and steam partial pressure on the products distribution and gas composition were investigated. Appropriate synthesis gas for difference industry uses may be obtained by adjusting those key process parameters. It indicates that synergetic effects happen in the co-pyrolysis process. By using instruments analysis (TG, XRD, ICP and SEM/TEM), the characteristics of the pyrolysis char, the transfer mechanism of heavy metals and acid gases emission from the pyrolysis process were obtained.

CONTRIBUTION OF CU VAPOUR TO RADIATION TRANSFER IN SF_6 AND PTFE ARC PLASMAS

V. Aubrecht[1] and M. Bartlova[2]

[1] *Department of Power Electrical and Electronic Engineering, Brno University of Technology, Brno, Czech Republic*
[2] *Department of Physics, Brno University of Technology, Brno, Czech Republic*

Abstract
An approximate method of partial characteristics (MPC) was used to evaluate radiation properties of SF_6 and PTFE arc plasmas with various admixtures of Cu (1%, 5% and 10%, respectively). Radiation flux and net emission were calculated using MPC for various temperature distributions in the arc plasmas. Our calculations have proved that admixture of Cu vapour in a plasma contributes to the both radiation flux and the net emission increasing.

1. Introduction

An electric (switching) arc between separated contacts is an integral part of a switching process. For any kind of high power circuit breakers, the basic mechanism is the extinguishing of the switching arc at the natural current zero by gas convection. The switching arc is responsible for proper disconnecting of a circuit. In the mid and high voltage region, SF_6 self-blast circuit breakers are widely used. Radiation transfer is dominant energy exchange mechanism during the high current period of the switching operation. Detailed information about the local arc structure can only be given by mathematical models, which allow the calculation of the distribution of emission and absorption throughout the entire arc plasma volume. Recently, we have used an approximate method of partial characteristics (MPC) to evaluate the radiation properties of pure SF_6 and various mixtures of SF_6 with PTFE (material of ablation nozzle) [1, 2]. In this paper, the method of partial characteristics has been used to extend previous data for Cu vapour contribution with various Cu admixture ratios. Resulting data could be used for a modeling of the radiation transfer in the switching arc, including vaporization from Cu contacts.

2. Plasma composition.

Radiation in arc plasmas depends, besides others physical quantities, also on concentrations of all chemical species occurring in the plasma. In mixture of SF_6 and Cu plasma, we assume the following species: SF_6 molecules, S, F, Cu neutral atoms, S^+, S^{++}, S^{+++}, F^+, F^{++}, Cu^+ ions and electrons. In case of PTFE (C_2F_4) plasmas, there are also C, C^+, C^{++}, C^{+++} atoms and ions taken into consideration. In Figs. 1 and 2, we plot the particle densities for 99% SF_6 + 1% Cu and 90% PTFE + 10% Cu plasmas, respectively as a function of the plasma temperature. Concentrations of each species were calculated at RWTH Aachen, Institute for High Voltage Technology [3]. Molecules and highly ionized atoms were neglected since up to know we have not found simple appropriate mathematical model for description of molecule dissociation. We have only taken into account SF_6 molecules with their experimentally measured absorption cross sections [4].

2. Theory – Method of Partial Characteristics

The basic quantity in radiation transport of energy is intensity of radiation I ($\mathbf{n}$, X) which is the radiation power per solid angle per unit area perpendicular to the direction $\mathbf{n}$ at a point X. An exact calculation of the radiation intensity is based on the knowledge of the plasma composition and subsequently absorption coefficients. Prediction of the later is a very difficult task since one must usually deal with complex structure of atomic spectra [5, 6] which is a very time consuming for any kind of computation. One must deal both with continuous radiation made by photo-recombination and “bremsstrahlung” processes and discrete radiation which consists of hundreds of spectral lines. Spectral lines broadening and their complex shapes have to be carefully considered. Due to the very fine structure of the lines, very fine integrations step has to be chosen in all considered computations which leads to the enormous computation times.
The approximate method of partial characteristics consists of "pre-computing" the most time consuming calculations in the form of data tables which can be then easily used for the prediction of radiation quantities. Details of the method of partial characteristics have been described in our previous paper [1].

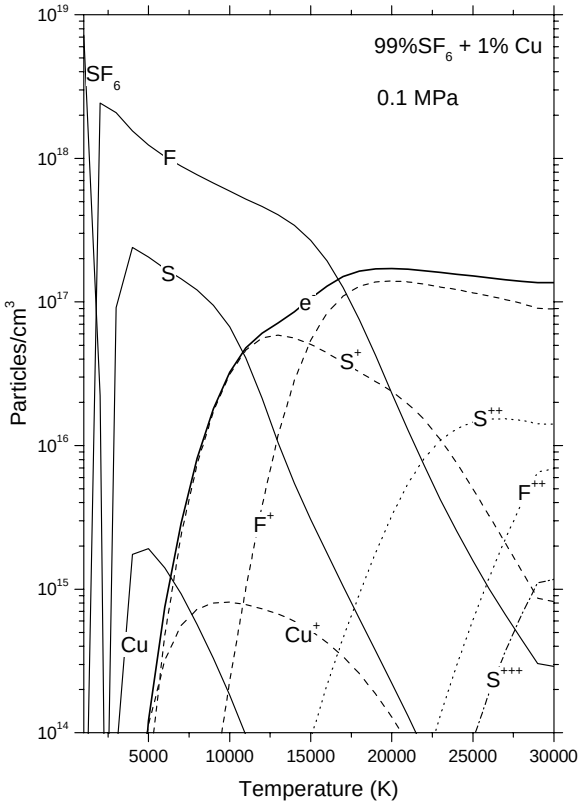

Fig. 1: Composition of 99% SF_6 + 1% Cu plasma as a function of temperature at a pressure of 0.1 MPa.

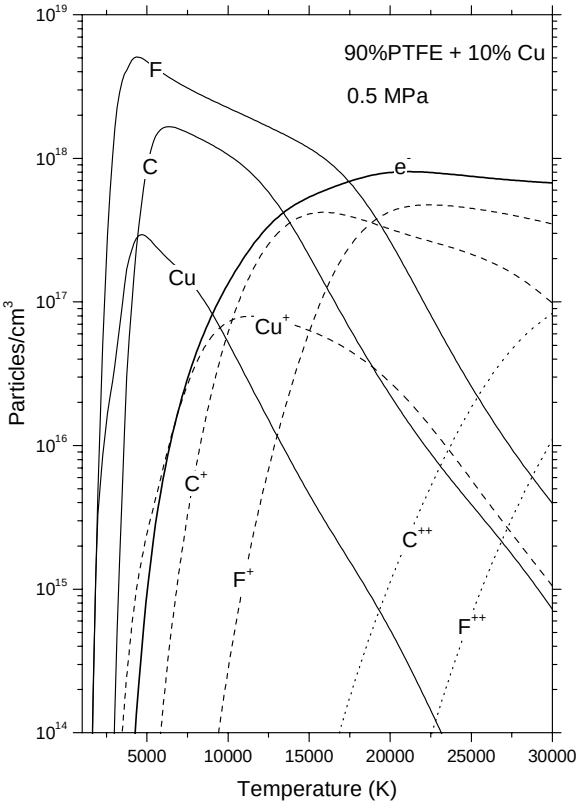

Fig. 2: Composition of 90% PTFE + 10% Cu plasma as a function of temperature at a pressure of 0.5 MPa.

Total radiation intensity at point X can be calculated by summation of all partial intensities between point X and plasma boundary R

$$I(X) = \int_X^R \Delta I\left(T_X, T_\xi, |X-\xi|\right) d\xi \tag{1}$$

Explanation of the meaning and symbols of partial intensities is in Fig. 3. Signs "+" and "-" denote radiation intensity in direction $R \rightarrow X$ and $X \leftarrow R$, respectively.

Net emission of radiation $\nabla I(X)$ along a line segment $\overline{XR}$ can be evaluated as

$$\nabla I(X) = \Delta I\left(T_R, T_X, \overline{XR}\right) - \int_X^R \Delta Sim\left(T_X, T_R, \overline{X\xi}\right) d\xi \tag{2}$$

where the functions ΔI and ΔSim are the partial characteristics defined in [1]. These two functions are pre-calculated in advance with parameters T_X, T_ξ, $\overline{XR} = |X-R|$ and they are used in the form of tables for prediction of radiation intensities, fluxes and their divergences (net emission). Equations (1) and (2) have to be integrated over all angles to obtain complete radiation emission or absorption from all directions.

With a simple one dimensional plasma of length $2R$ the formulas for radiative flux and its divergence in terms of the partial characteristics are given by:

$$\mathbf{F}^{1D}(X) = \int_{-R}^{X} \Delta I\left(T_\xi, T_X, \overline{X\xi}\right) dx - \int_X^R \Delta I\left(T_\xi, T_X, \overline{\xi X}\right) dx \tag{3}$$

and

$$\nabla \mathbf{F}^{1D}(X) = \Delta I\left(T_{-R}, T_X, \overline{-RX}\right) + \Delta I\left(T_R, T_X, \overline{XR}\right) - \int_{-R}^{R} \Delta Sim\left(T_X, T_\xi, \overline{X\xi}\right) d\xi \tag{4}$$

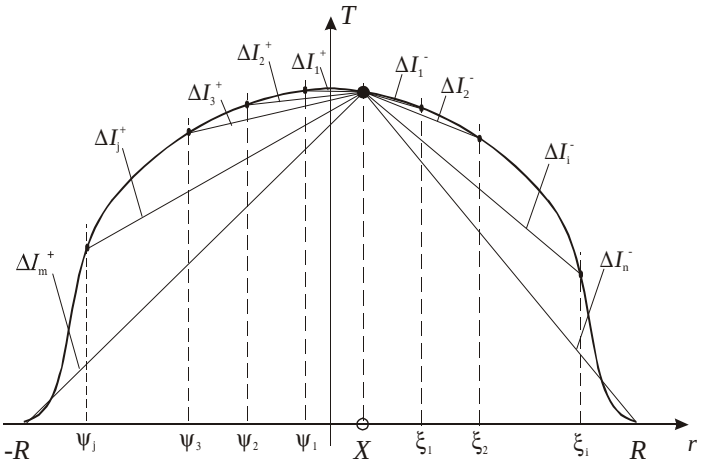

Fig. 3: Schematic drawing with symbols explaining principle of the method of partial characteristics.

The radiation quantities in three-dimensional plasma – the radiation flux $\mathbf{F}^{3D}$ and divergence of radiation flux $\nabla\mathbf{F}^{3D}$ - are predicted according formulas (5 - 8), where the intensity of radiation I and the net emission ∇I along a particular directions (angles) are evaluated using tables of pre-calculated partial characteristics ΔI and ΔSim.

In spherical coordinates, the individual components of vector $\mathbf{F}^{3D}(X)$ are given as follows:

$$F_x^{3D}(X) = \int_0^{\pi}\int_0^{2\pi} I(X,\theta,\phi)\sin^2\theta\cos\phi\, d\phi\, d\theta \tag{5}$$

$$F_y^{3D}(X) = \int_0^{\pi}\int_0^{2\pi} I(X,\theta,\phi)\sin^2\theta\sin\phi\, d\phi\, d\theta \tag{6}$$

$$F_z^{3D}(X) = \int_0^{\pi}\int_0^{2\pi} I(X,\theta,\phi)\sin\theta\cos\theta\, d\phi\, d\theta \tag{7}$$

and the divergence of radiative flux

$$\nabla\mathbf{F}^{3D}(X) = \int_0^{\pi}\int_0^{2\pi} \nabla I(X,\theta,\phi)\sin\theta\, d\phi\, d\theta \tag{8}$$

Meaning of symbols in the previous formulas is given in schematic diagram of the integration over angles in Fig. 4.

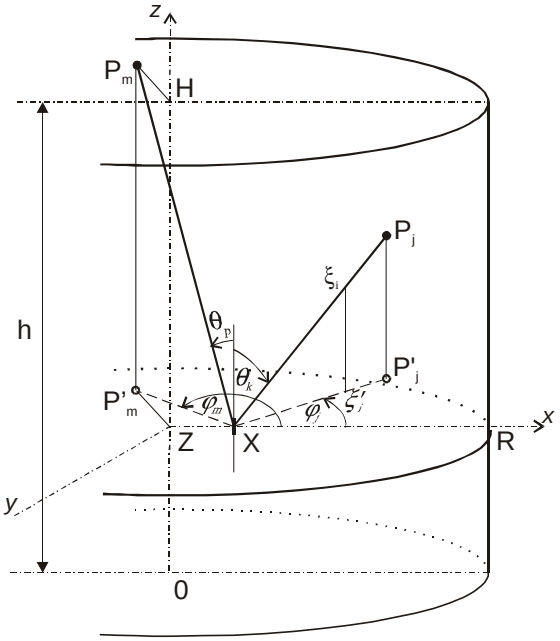

Fig. 4: Schematic diagram of the integration over angles.

3. Results

We have calculated tables of partial characteristics for mixtures of SF_6 and Cu and PTFE + Cu plasmas, respectively at temperatures between 2 000 K and 30 000 K and pressures of 0.1 and 0.5 MPa. Our tables cover admixture ratios of Cu of 1%, 5% and 10%, respectively. In the following figures we show some results of net emission (divergence of radiation flux) calculations, using the tables of partial characteristics.
In Figs. 5 and 6, we compare our results with ones published by Raynal et al. [7]. Fig. 5 represents a variation of function Sim (one of the partial characteristics) as a function of end-temperature for given temperature with the second end-temperature as a parameter. Agreement between our calculations and ones of [7] is quit well. Discrepancies are given fairly by various sources of atomic data and different approach to prediction of absorption coefficients. In Fig. 6, we plot calculated radial distribution of divergence of radiation flux (net emission) using MPC at the cross section of SF_6 + Cu plasma cylinder with height of 8 cm at a pressure of 0.1 MPa. Given radial temperature profile is the same as for [7].

Contribution of Cu vapour to the net emission in SF_6 and PTFE arc plasmas at a pressure of 0.5 MPa is illustrated in Figs. 7 and 8. Radial temperature distribution for these plots has been chosen according to experimental predictions [3]. The resulting divergences of radiation flux are related again to the plasma cylinder with height of 8 cm with radial distributions of net emission given at the central cross section of the cylinder. From the figures it can be seen that copper admixtures contributes mainly to the radiation emission in the hot central regions whereas the absorption in the cold regions is not much influenced. Furthermore, as can be seen from the Figs. 7 and 8, the influence of copper is significant for relative higher admixture ratios, more then a few percent.
In real applications copper concentrations varies both in radial and axial directions. In our calculations we assumed the constant Cu admixture ratio as well as the constant plasma pressure within the arc column. It is very rough approximation, but in spite of this we are convinced of a benefit of the method of partial characteristics which can be used at least for the first estimation of radiative heat transfer in the arc plasmas.

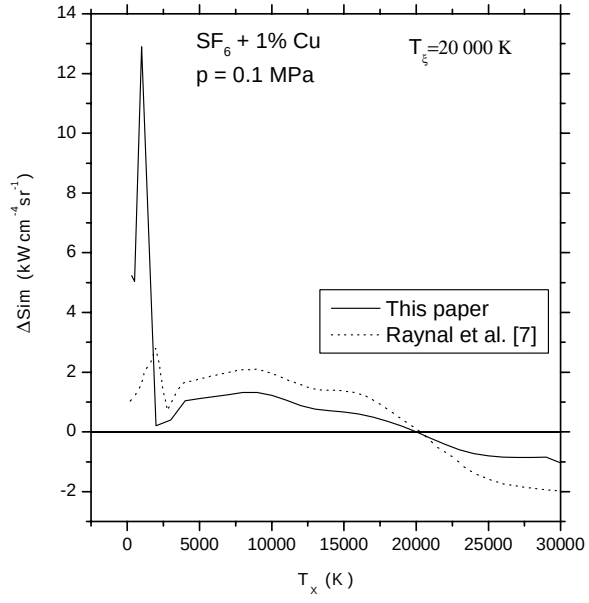

Fig. 5: Partial function ΔSim as a function of end-point temperature T_X for source temperatures T_ξ of 20 000 K in gaseous plasma of 99% SF_6 + 1% Cu at a pressure of 0.1 MPa.

Production and reduction of higher silanes in modulated silane plasmas

A. Suzuki

Energy Electronics Institute, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan

Abstract
Higher silane production and reduction processes in modulated silane plasmas are investigated by measuring time-dependent densities using photoionization mass spectroscopy. With a discharge is turned on, higher silanes increase and saturate with several seconds, and decrease with the rate of diffusion after a discharge-off. These results indicate that the higher silanes are not trapped around plasma/sheath boundary, different from silicon particles.

1. Introduction

Plasma enhanced chemical vapor deposition (PECVD) process by a radio frequency (13.56 MHz) silane (SiH_4) discharge is the most favorable method to prepare hydrogenated amorphous silicon (a-Si:H), which is important material for solar cells and thin film transistors [1, 2]. Higher silanes are hydrogenated silicon molecules such as disilane (Si_2H_6), trisilane (Si_3H_8) tetrasilane (Si_4H_{10}) and pentasilane (Si_5H_{12}), and produced by gas-phase reactions in the silane plasmas.

Among the silane plasmas, it is well known that modulated silane plasmas are effective to suppress silicon particles, which degrade photoelectric properties of a-Si:H films [3]. The silicon particles can be contamination in the silane plasma process as is seen in semiconductor process, therefore, should be reduced from the gas-phase in the silane discharge to improve quality of a-Si:H films. A couple of works reported that the silicon particles start to grow from small radicals, ions, atoms, and molecules through gas-phase reactions [4]. The higher silanes are also one of products by these gas-phase reactions. With increasing in the size of higher silanes, they are electronegative because of their larger electron affinity. Such negatively charged hydrogenated silicon clusters are trapped by the sheath potentials between the parallel electrodes. This concentration enhances growth of the clusters via condensation reactions with the positive ions generated by ionization of neutral radicals and molecules in the plasma [4]. Rates of the condensation reactions between positive and negative ions are several times higher than that of the other reactions between ions and neutral species, and between neutral species [5]. The modulated plasma reduces the silicon particles by terminating the condensation reactions. Intermission of the plasma by the modulation breaks the concentration of the negatively charged clusters by collapsing the sheath potential between the electrodes. It is reported that several microsecond terminations are enough to break the sheath potential and suppress the silicon particles [3].

Since the silicon particles grow from small chemical species through gas-phase reactions, higher silanes can be intermediate to the silicon particles. Suppression of the higher silanes might be effective to reduce the silicon particles in the process for a-Si:H more drastically. From this point of view, it is important to identify the time evolution of the higher silanes in the modulated plasmas and compare with that of the silicon particles. Few works reported the temporal change of chemical species in the modulated plasma including higher silanes. This information should be helpful not only to understand the kinetics of higher silanes but also to reduce the silicon particles in the modulated silane plasmas.

In addition, the higher silanes need to be reduced to improve the a-Si:H film properties because it is suggested that they are responsible to photodegradation of the photoelectric properties of a-Si:H [6]. Higher silanes may induce the deviated structure of a-Si:H because they are difficult to diffuse the surface during the a-Si:H film growth due to their heavier mass than those of monosilicon radicals such as sylil (SiH_3) radicals.

As above, it is worth investigating the time evolution of the higher silanes in the modulated silane plasmas to improve the properties of a-Si:H films. In this work, the time-dependent higher silane densities in the gas-phase of the modulated silane plasmas are measured by photoionization mass spectroscopy (PIMS). From saturation and decay time after discharge-on and –off, the production and reduction of the higher silanes in the modulated silane plasmas are discussed and compared with that of the silicon particles.

2. Experimental

Experimental setup is shown in Fig. 1. A power-modulated silane rf (13.56 MHz) glow discharge plasmas, which is controlled by a pulse/function generator, were generated between parallel-plate electrodes in a conventional PECVD chamber. The electrically neutral higher silanes in the gas-phase of the modulated silane plasmas were detected by PIMS using a reflection type time-of flight mass spectrometer (RETOF). Details are described elsewhere, briefly, the higher silanes from the gas-phase of the silane plasma are introduced in to the RETOF, and photoionized by an ArF excimer laser (193 nm, 6.4 eV, 10 mJ/pulse, 30 ns). Positively ionized higher silanes are mass separated in the RETOF. The ion signals from a high mass detector (HMD) are processed by a digital storage oscilloscope and a personal computer [7].

The discharge-on and –off time in one period of the modulation are 10 and 20-50 seconds, depending on the initial silane pressure of 4.0 – 13.0 Pa. A flow rate of a silane gas, an anode temperature, and a rf power density is 5 SCCM, 250 ˚C and 100 mW/cm^2, respectively.

To identify the time-dependent higher silane densities in one period of the modulation, the PIMS measurement must be synchronized with the modulation temporally. Here, the optical emission from the plasma is used to trigger the PIMS measurement against the modulation. There are many emissive species in silane plasmas such as Si* (288 nm), SiH* (413 nm), H* (656 nm), and H_2 (602 nm) [8]. The emission is the probe for rf power introduction into the electrodes because the rate of the emission is on the order of femtoseconds. The steep decrease in the emission detected by a photomultiplier (PMT) triggered a delay generator that gives a delay time to a laser beam from the ArF laser. By varying the delay time by the delay generator, the time dependent higher silane densities over one cycle of the modulated plasma can be obtained. Under the conditions above, the production and reduction of higher silanes over one period of the modulation were investigated.

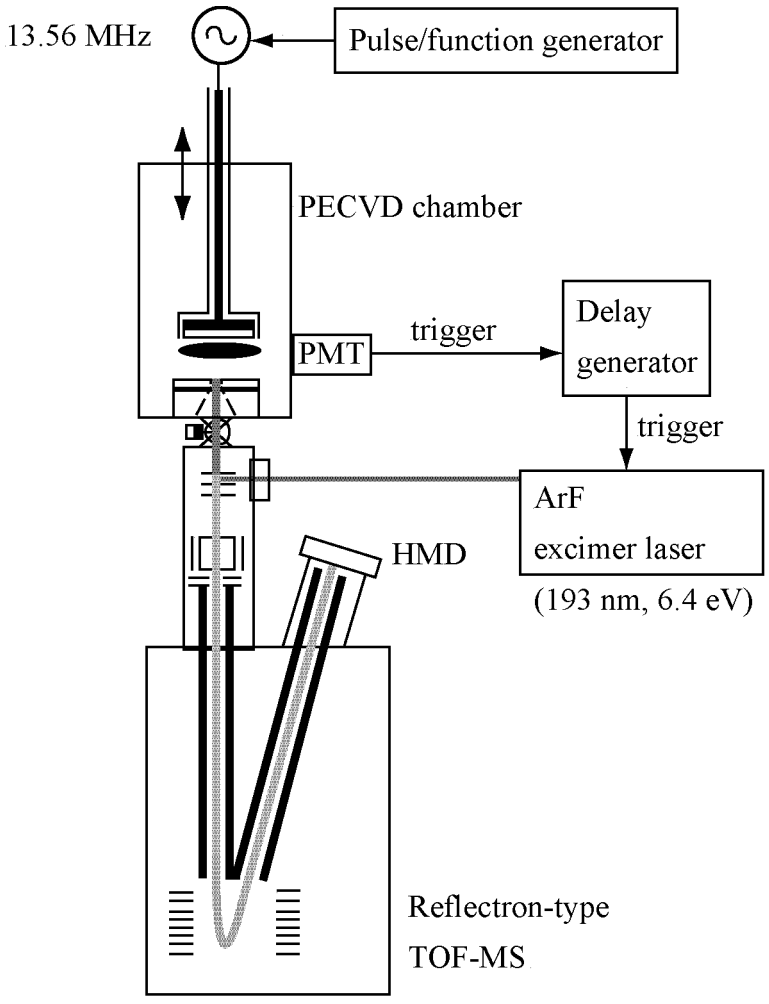

Fig. 1 Experimental setup used in this study.

3. Results and discussion

Figure 2 shows the time-dependent densities of higher silanes in one cycle of the modulation plotted against the time after a discharge starts at the total pressure of 13 Pa. The saturated higher silane densities at the discharge time of 10 s are corresponds to the densities observed in the continuous silane discharge at 13 Pa. It is suggested that the higher silanes in figure 2 are produced by the gas-phase reactions as follows [9];

$$SiH_4 + SiH_2 \rightarrow Si_2H_6$$
$$Si_2H_6 + SiH_2 \rightarrow Si_3H_8$$
$$Si_3H_8 + SiH_2 \rightarrow Si_4H_{10}$$

These reactions are the radical-molecule reactions, which rate is on the order of microsecond [10]. The higher silanes generated during the discharge-on period decay after the discharge is turned off until a next discharge starts. At 60 seconds after a discharge starts, which is 50 seconds after the discharge is turned off, the ion signals from all higher silanes by PIMS are below detection limit. Each higher silane increases with comparable rate; that is, the relative densities between disilane, trisilane, and tetrasilane are almost constant. No results are obtained that higher silanes are sequentially grown in this study, because the time-resolution of the present experimental condition is on the order of sub seconds, which is mainly limited by the fluctuation in the modulation of the plasma. Since the reaction time of higher silane generation is of the order on microseconds, it is impossible to investigate each generation reaction with sufficient temporal resolution.

Disilane production at 4 and 13 Pa is shown in fig. 3. The time evolution of disilane can be fitted by a following formula;

$$\text{Ion signal from the disilane} = C(1-\exp(-t/t_{SAT})) \quad (1)$$

Where t_{SAT} is the time for the saturation. The equation (1) is the solution to the mass diffusion by the simple Fick's model, which expresses one-dimensional mass diffusion [10]. This indicates that disilane production follows the one-dimensional mass diffusion. This result shows that the higher silanes are generated at the narrow area that is probably the sheath region, and not uniformly filled in the PECVD chamber before the saturation. The t_{SAT} is derived to be 4 - 8 s at 4 - 13 Pa, respectively, from the fitting by the equation (1).

Since the stable state disilane density at 13 Pa is higher than that at 4 Pa as shown in fig. 2 and 3, the higher silane production at 13 Pa should be higher than that at 4 Pa. However, it takes much time to saturate at 13

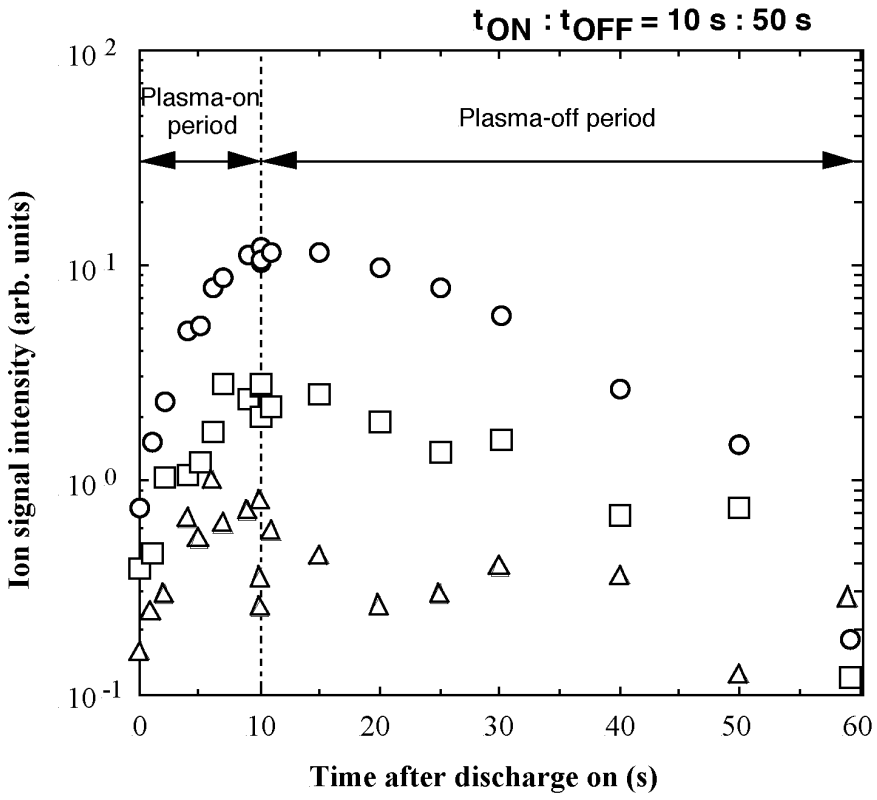

Fig. 2 Time evolution of disilane (○), trisilane (□), and tetrasilane (△) in one cycle of the modulation.

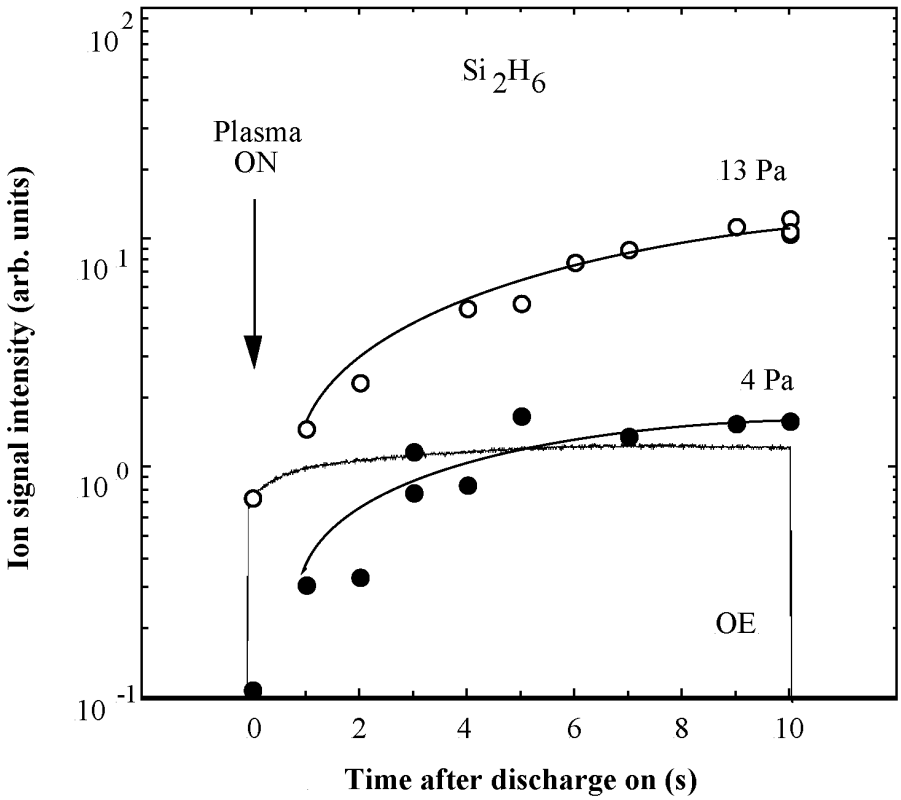

Fig. 3 Time evolution of disilane in the plasma-on period at pressure of 4 Pa (●), and 13 Pa (○). Fittings are by one-dimensional mass difussion (*see in the text*). Time evolution of optical emission (OE) at 4 Pa is also plotted.

Pa than at 4 Pa. This means that the present slow saturation of higher silane density is not attributed to the rate of the production reactions.

The optical emission from a PMT at 4 Pa is also plotted in fig. 3. Clearly, the t_{SAT} for disilane is more slowly than the saturation time of the optical emission. Although the optical emission is mainly from SiH*, its time evolution should be the same as those of other reactive species such as atoms, ions, and radicals. These reactive species can be the reactants for the higher silanes and the silicon particles, thereby, the time evolution of the disilane should follow that of the optical emission from the plasma.

One explanation for this discrepancy is difference in the measured area between optical emission spectroscopy (OES) and PIMS. A photomultiplier detects the emission at the close position to the emissive area that is near the cathode electrode. On the other hand, the ion signal from the PIMS is a trace of the averaged density because PIMS measures the sampled gas from the PECVD chamber.

From this point of view, it is supposed that the slow saturation of the higher silanes results from the slow diffusion to fill the PECVD chamber. If the diffusion of higher silane is the rate determination step for the time evolution, the t_{SAT} of the higher silanes can be of the order on several seconds even if the rate of higher silane production reactions is on the order of microseconds. This also explains the reason for that the saturation at 13 Pa is slower than that at 4 Pa because the rate of diffusion is proportional to the total pressure as is confirmed in the proceeding section.

After a discharge is turned off, disilane decreases with an exponential decay until a next discharge starts as shown in fig. 4. Diffusion lifetime (t_{DIF}) depends on pressure, and is obtained to be 7 – 20 s at 4.0 - 13 Pa, respectively, by exponential fitting. They are consistent with a residence time of a gas in the PECVD chamber in the present experimental conditions, implying that the higher silane reduction is attributed to a diffusion loss. This means that the higher silanes are uniformly filled in the PECVD chamber after the saturation. Since the decay rates of disilane, trisilane, and tetrasilane are mostly comparable, it is concluded that all higher silanes are reduced by a diffusion loss.

As expressed previously, it is reported that silicon particles can be drastically suppressed by the termination of silane plasma. Several microseconds intermission of a discharge can reduce silicon particles drastically [3].

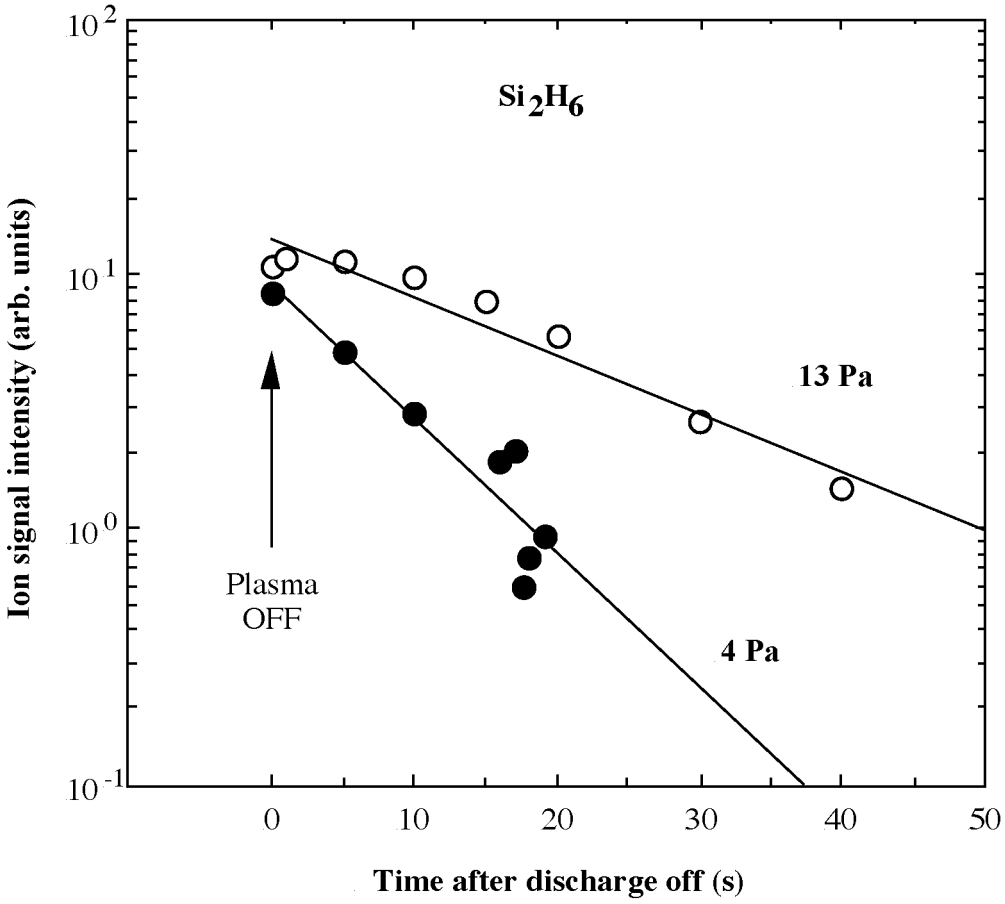

Fig. 4 Time evolution of disilane in the plasma-off period at pressures of 4 Pa (●) and 13 Pa (○). Lines are by exponentioal fitting.

Result in figure 4 indicates that the decay of higher silane is different from that of silicon particles. This difference can be explained by the difference of the measurement between PIMS and laser scattering (LS), which measure silicon particles. As well as OES, LS is optical measurement. Since LS only measures an area where a laser beam is passed, it is easy to concentrate the laser beam to the position which the silicon particles concentrate such as the plasma/sheath boundary. That is, LS and OES measurement is more spatially sensitive than PIMS. The sudden decrease of silicon particles in the modulated silane plasmas measured by LS indicates that the population of silicon particles is spatially concentrated. Since the higher silane is measured by PIMS in the present experiment, the spatially insensitive measurement can not detect the spatial distribution of the higher silanes even if they are concentrated. The higher silane densities should be also relatively high near the plasma/sheath boundary because the radical reactions which generates higher silanes occur near the cathode electrode. However, for the case of higher silanes, its t_{DIF} is comparable to the residence time of a gas, thereby, the higher silanes are filled uniformly in the PECVD chamber except the sheath region at the end of the discharge-on period. This is different from the silicon particles, which are trapped near the sheath/plasma boundary and difficult to escape from the sheath region under the discharge.
Diffusion coefficient (D) of the disilane is calculated from t_{DIF} using following formula based on the Fick's model [11].

$$D = L^2/2\, t_{DIF} \quad (2)$$

Where L is a characteristic length of the diffusion and assumed to be 32 cm, which is the maximum length of the axis of the PECVD chamber. From the results of t_{DIF} from fig. 4, D of disilane is estimated to be 25 – 60 cm^2/s at 4.0 - 13 Pa, respectively, in the present experiment conditions. The D is mostly identical to that of trisilane and tetrasilane because the decay rate is comparable to all higher silanes.
In general, lifetimes of high reactivity reactants such as radicals are short to be on the orders of millisecond [9]. Longer t_{DIF} indicates that the higher silane molecules measured by PIMS is non-reactive, and are not terminated by a reaction with a chamber wall or other reactants. Because of their non-reactivity, the role of

higher silanes for the a-Si:H deposition is small, however, contributes to the deposition through the source of higher silane radicals (Si_nH_x, $x<2n+2$), which probably one of the precursors to the a-Si:H films. For the silicon particle formation, the electrically neutral higher silanes are not only the direct intermediates but also the source of the positive higher silane ions which contributes to the condensation reactions at the plasma/sheath boundary where the negative cluster ions are trapped.
The pressure dependence of t_{SAT} is also explained by the slow diffusion of higher silanes. Since it takes time for higher silane to diffuse in the gas-phase in the PECVD chamber, the t_{SAT} is on the orders of several seconds even if the rate of the higher silane production reactions is on that of microseconds. Consequently, t_{SAT} is proportional to t_{DIF}, and to the total pressure in the PECVD chamber as well.
As above, there are many different characteristics between higher silanes and silicon particles. First of all, the spatial distribution of higher silanes and silicon particles is not identical. Higher silanes are almost spatially uniform in the PECVD chamber during the discharge, on the other hand, silicon particles concentrate around the plasma/sheath boundary. Second, higher silanes are not reduced by the modulated plasmas, different from silicon particles. To suppress higher silanes drastically, each production reaction should be suppressed. The longer lifetime of higher silanes might be advantage to exclude them from the gas-phase in the PECVD chamber.

4. Conclusions

The time-dependent densities of higher silanes in the modulated silane plasmas are investigated by PIMS for the first time. It is seen that the saturation of higher silanes in the PECVD chamber takes several seconds and does not follow that of the optical emission. The slow saturation of higher silanes is explained by the slow diffusion, as seen in the discharge-off period. Even if the generation reactions for higher silanes are fast, it takes time to saturate a chamber because the saturation is limited by the slow diffusion.
The reduction process of higher silanes after a discharge-off is dominated by the diffusion, not by the reaction with a wall, molecules, and a deposition. It is found that the modulation is not effective to suppress higher silanes, indicating that they are not concentrated at the sheath region, different from silicon particles. The slow decrease in higher silanes after the discharge-off is also not observed for the silicon particles, which rapidly decrease by the intermission of a discharge. D of higher silane was estimated to be comparable to a residence time of a gas from the decay lifetime in the discharge-off period.
As above, the behavior of higher silanes is different from that of the silicon particles in the PECVD chamber. Higher silane contributes to the a-Si:H deposition as a source of the higher silane radicals. To reduce the higher silane gases in the gas-phase of the plasma to improve the photoelectric properties of a-Si:H, their production reactions need to be controlled.

TPCVD of Si-[X-]C-N from Liquid Organometallic Precursors

E. Bouyer, M. Müller, G. Schiller

German Aerospace Center (DLR), Institute of Technical Thermodynamics, Stuttgart, Germany

Abstract
Coatings of Si-B-C-N from *1,1,3,3,5,5hexamethylcyclotrisilazaneborane* were deposited by means of thermal plasma chemical vapour deposition (TPCVD). The elemental composition of the deposited materials was dependent on the precursor and the plasma gas composition. Silicon carbide is the only crystalline phase formed during the process while silicon nitride was not formed even in a nitrogen containing plasma. The boron is integrated in an amorphous boron nitride compound.

1. Introduction

Several phases in the system Si-C-N are forming a group belonging to high performance ceramics with outstanding properties concerning thermomechanical strength. The addition of a fourth element X with X = B, Ti, Zr giving a quaternary phase Si-X-C-N will permit to even improve many of the properties. As an example addition of boron (Si-B-C-N) enhances the stability of the silicoboron carbonitrides in the range between 1400 and 2000°C. The origin of the enhanced thermal stability is not yet understood. It is assumed that boron plays a major role in stabilising the metastable amorphous phase and in suppressing the thermal degradation of the silicon carbonitride matrix [1]. The presence of a turbostratic non-stoichiometric B-C-N phase that inhibits diffusion processes and decreases the activity of free carbon was also mentioned [2]. These turbostratic layers probably consist of a mixed phase of boron nitride and carbon with various amounts of B, C and N. Multielement ceramic materials are difficult to synthesise by traditional high-temperature synthesis methods such as solid-state reactions, owing to the thermodynamic instability of their solid solutions, especially of those in the ternary and quaternary systems considered in this work. The Si-B-C-N system exhibits an increased thermal stability with respect to pure Si_3N_4 even in nitrogen-free atmospheres. The high onset temperature of crystallisation and/or the high thermal stability are properties required for the development of novel high temperature resistant ceramics with sufficient mechanical properties to withstand service temperatures exceeding 1500°C.
The goal of the study is the thermal plasma deposition of coatings in the system Si-X-C-N with X = B, Zr, Ti from X-bearing silazane precursors. Since so far the most intense part of the study was dedicated to the Si-B-C-N system our contribution will focus only on this material.

2. Experimental

2.1 Materials

The precursor used is a silazane borane (*1,1,3,3,5,5hexamethylcyclotrisilazaneborane*) obtained from the boration of 1,1,3,3,5,5hexamethylcyclotrisilazane by borane with tetrahydrofurane. The precursor is a monomer/oligomer with n = 1 to 3. The stoichiometric ratios of the organometallic precursor are the following: Si/N = 1 ; Si/C = 0.5 ; Si/B = 3. Thus the theoretical formula is $SiB_{0.33}C_2N$.
Plates of molybdenum 40 x 40 x 3 mm³ in size were used as substrates. The Mo plates were either non-cooled or maintained at a low temperature by means of a water cooling system.

2.2 Plasma Processing

The experimental set-up for the synthesis experiments was basically built of an rf plasma torch connected to a vacuum reactor. The liquid precursors were directly injected into the hot plasma core by means of a gas-assisted atomiser (Fig. 1) as previously described more detailed [3]. The process might be understood as a thermolysis process but with the reverse temperature characteristics. Figure 2 describes schematically the steps involved in the synthesis process by high temperature thermolysis of the oligomer Si-B-C-N precursor. Most of the fundamental plasma parameters were kept constant at previously optimised conditions: (i) reactor pressure 20 kPa, (ii) spray distance 200 mm, (iii) plasma central gas 15 slm argon, (iv) atomisation gas 8 slm argon, (v) precursor feed rate 1,3 ml/min, and (vi) rf power about 25 kW. One parameter was varied to study its influence on the synthesis: (vii) plasma sheath gas composition either 60 slm Ar + 3 slm H_2 or 50 slm Ar + 10 slm N_2.

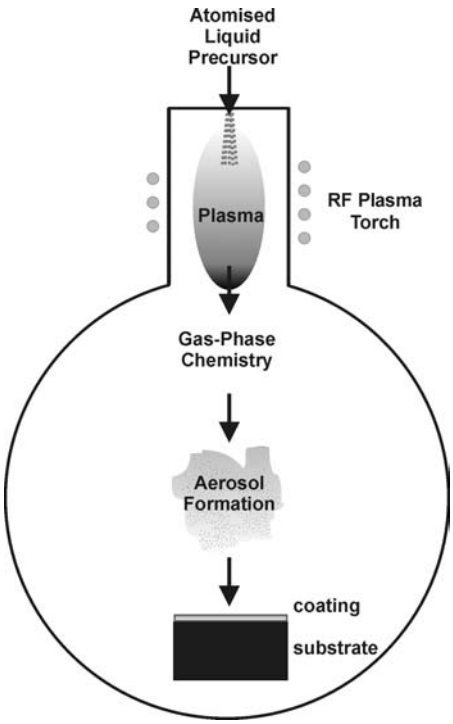

Fig. 1: RF plasma synthesis

2.3. Characterisation

Several techniques were used for the characterisation of the synthesised materials. First of all, the composition of the product is determined by elemental analysis in order to derive the stoichiometry of the material. The study of the crystalline phase was performed by means of X-ray diffraction. The structural evaluation of the product is also performed by using multinuclear solid-state nuclear magnetic resonance spectroscopy (NMR) and Fourier transform infrared spectroscopy (FT-IR). The morphology as well as the elemental distribution were investigated by means of transmission electron microscopy associated with an electron energy loss spectrometry imaging detector (TEM-EELS).

3. Results and Discussion

The coatings obtained so far revealed usually poor cohesion and adhesion properties. Therefore the material to be characterised was scratched from the substrates to be investigated as powders.

3.1 Elemental Content and Distribution

Table 1 shows the molar composition and the derived empirical formula of two samples synthesised under two different plasma conditions, basically differing in the plasma gas composition. While in the first case H_2 was added to the sheath gas, the second run plasma contained N_2.

Table 1 – Molar composition of the synthesised powder, ratio of the elements and empirical formula

Run	Si	B	C	N	O	H	Si/B	Si/C	Si/N	Empir. formula
Ar-H-plasma	34.7	10.8	39	9.9	5.6	<0.1	3.2	0.9	3.5	$SiB_{0.31}C_{1.1}N_{0.29}$
Ar-N-plasma	35.6	10.7	36.4	13.9	3.4	<0.1	3.3	1.0	2.6	$SiB_{0.30}C_{1.0}N_{0.39}$

From these results one can observe that the second sample synthesised under slightly nitrogenated conditions contains more nitrogen than the one synthesised in an Ar/H_2 plasma. It is worth noting that in both samples Si and C have almost a 1 to 1 ratio as well as B and N. In comparison to the liquid precursor's theoretical formula, i.e. $SiB_{0.33}C_2N$, the silicon and boron remain with the same amount while a loss of carbon and nitrogen is observed during the plasma treatment. It is probably due to a loss of the elements which possess the greater ability to recombine with hydrogen to form a gas phase like CH_x and NH_x. The loss of nitrogen was partly suppressed by the addition of elemental nitrogen to the plasma gas.

The elemental distribution can be illustrated with TEM-EELS maps that were established using the three window technique [2,4]. Figure 3 shows both the TEM image with the corresponding EELS maps obtained from material synthesised under Ar/H_2 (left) and Ar/N_2 (right) plasma conditions. The EELS elemental maps confirm that carbon as well as silicon are the two main components in the resulting synthesised products. In contrast to silicon and carbon, boron and nitrogen are less present corresponding to the stoichiometry of the precursors and the products. It is worth noting that the elemental distribution of the elements through the particles considered is relatively homogeneous. One has to be careful with the interpretation of the EELS results. Indeed, the intensity of the signal measured, namely the electron current transmitted through the sample to be investigated, strongly depends on the probe thickness. The thinner the sample the higher is the transmitted electron signal. A dark area on the map shows either a zone with a low element content or can also signify that the zone is too thick to permit the electrons to go through the sample. To overcome this possible misinterpretation, one has to compare the different EELS maps with the original bright-field TEM image. The intensity of a classic TEM image is principally a function of the sample thickness crossed by the electron beam and therefore does not depend, in first approximation, on the elements contained in the sample. Even with respect to this preconditions the higher nitrogen content of the sample obtained in an Ar-N-plasma can be observed. Furthermore in some regions rich zones of both B and N show the presence of BN either in the hexagonal form or as turbostratic structure.

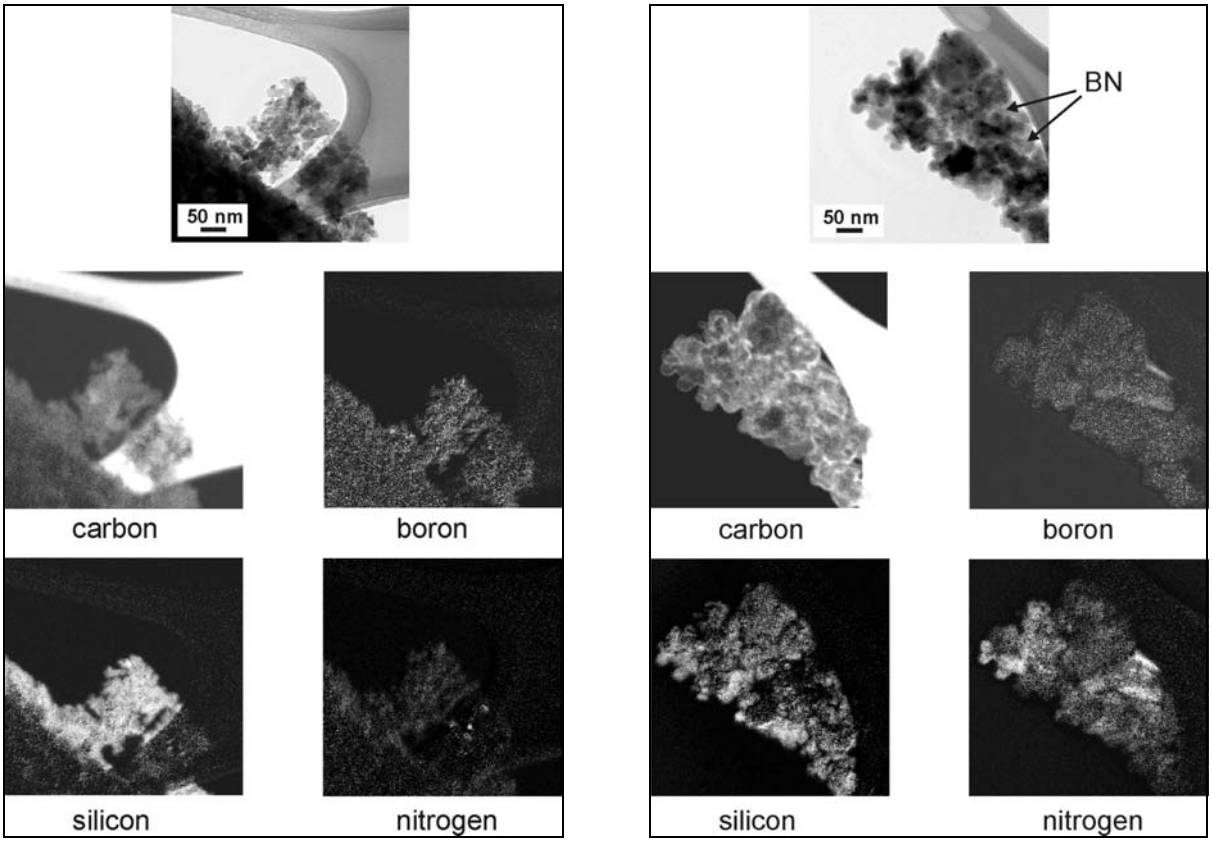

Fig. 3: TEM-EELS maps of Si-B-C-N synthesised in an Ar-H-plasma (left) resp. in an Ar-N-plasma (right).

3.2 Chemical Structure

Fourier transform infrared spectroscopy is used as analytical technique to investigate the chemical structure of the product. The absorption band in the mid infrared (2.5-25 μm) gives the richest information. Figure 4 shows the FTIR spectra which contain only two broad absorption peaks. The absorption peak at ~850 cm^{-1} corresponding to the Si-C bond fundamental stretching vibration is observed [5]. The weak absorption peak at about 1400 cm^{-1} is interpreted as the in-plane B-N stretching vibration of sp^2 bonded BN, which is a typical peak for hexagonal boron nitride (h-BN) [6]. The broadness of the peak shows the low crystallinity of the synthesised material. The spectrum on the right hand side of Fig. 4 corresponds to the material synthesised

using a slightly nitrogenated plasma. The intensity of the peaks is lower than the one of the spectrum of the material derived from the argon-hydrogen plasma.
A signal of Si-N bond could not be detected in any sample indicating no significant formation of silicon nitride. In addition, neither signals of Si-H nor of C-H bonds are detected as a consequence of a complete dehydrogenation of the precursor during thermolysis under plasma condition.

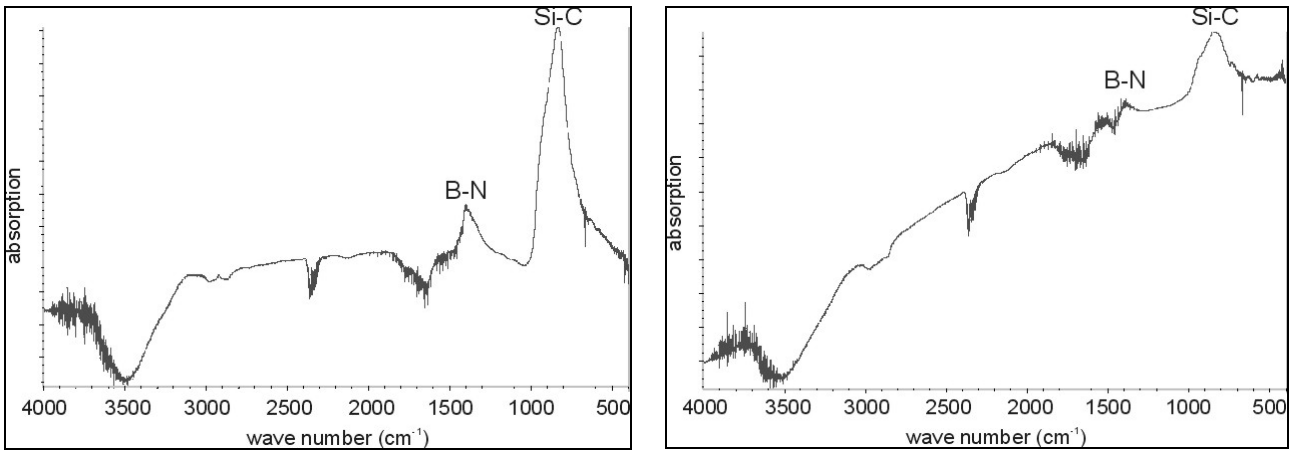

Fig. 4: FTIR spectra of Si-B-C-N synthesised in an Ar-H-plasma (left) resp. in an Ar-N-plasma (right).

To characterise the low range chemical structure of the as-synthesised materials, magic angle spinning nuclear magnetic resonance (MAS-NMR) was employed, both ^{29}Si and ^{11}B MAS NMR were used. Figure 5 shows the results of the sample obtained from an argon-hydrogen plasma. The signal at –15,7 ppm chemical shift (Fig. 5 left) is typical for a beginning or a poor crystallisation of β-SiC. The ^{11}B MAS NMR spectrum (Fig. 5 right) indicates the existence of boron in a B^3 but amorphous environment.
The results of the argon-nitrogen plasma were quite similar but even less precise: A peak at –17 ppm indicates the existence of Si in an SiC_4 environment (any SiC polytype), and the boron content is confirmed but no structural information can be assigned.

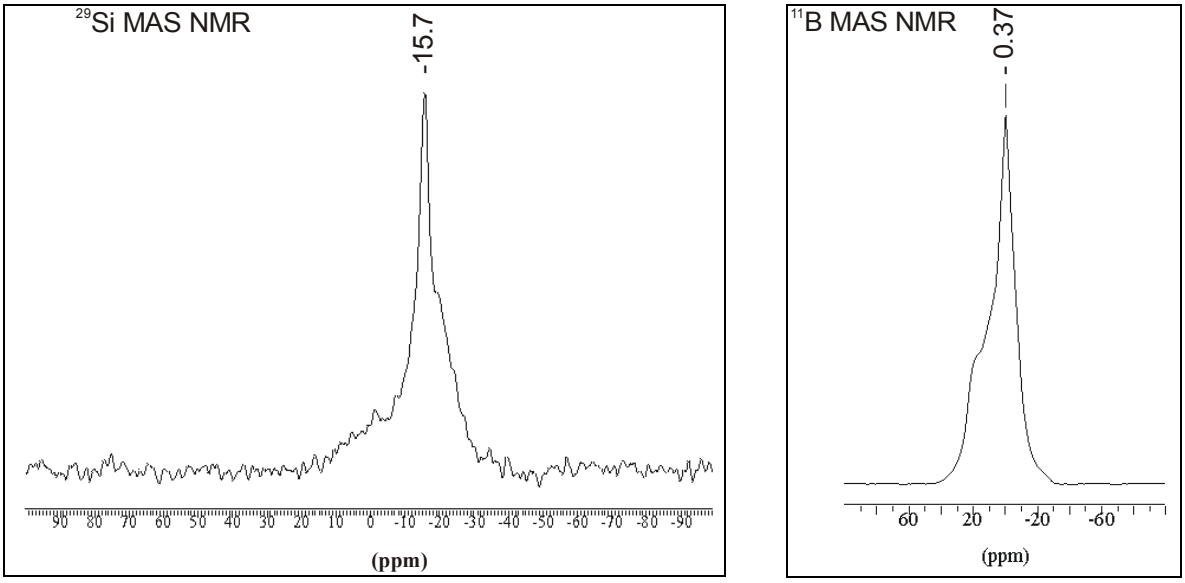

Fig. 5: MAS NMR spectra of Si-B-C-N synthesised in an Ar-H-plasma, ^{29}Si spectrum (left) ^{11}B spectrum (right).

3.3 Phase Content

The X-ray diffraction investigations made on the as-synthesised samples gave the following results: only relatively poor crystallised SiC material without presence of crystalline silicon nitride, boron nitride, boron silicide nor boron carbide has been detected, Fig. 6 (left). The absence of silicon nitride is probably due to the relatively low nitrogen content in the precursor as well as in the plasma even for the attempt made with 10 slm nitrogen in the plasma sheath gas. From the empirical formulas of the products it becomes obvious that a large amount of amorphous phases is present in the product. In some XRD patterns one can notice a broad peak/dome centred at 21° (two theta) which represents the appearance of amorphous phases (C or Si-B-C-N) in the sample.

The XRD pattern of the sample synthesised in a slightly nitrogenated plasma (Fig. 6 right) shows a lower intensity of the diffraction peaks compared to the sample synthesised under similar conditions except no addition of nitrogen but hydrogen to the plasma. This confirms the results of a former study namely that nitrogen impedes the crystallisation of SiC [3].

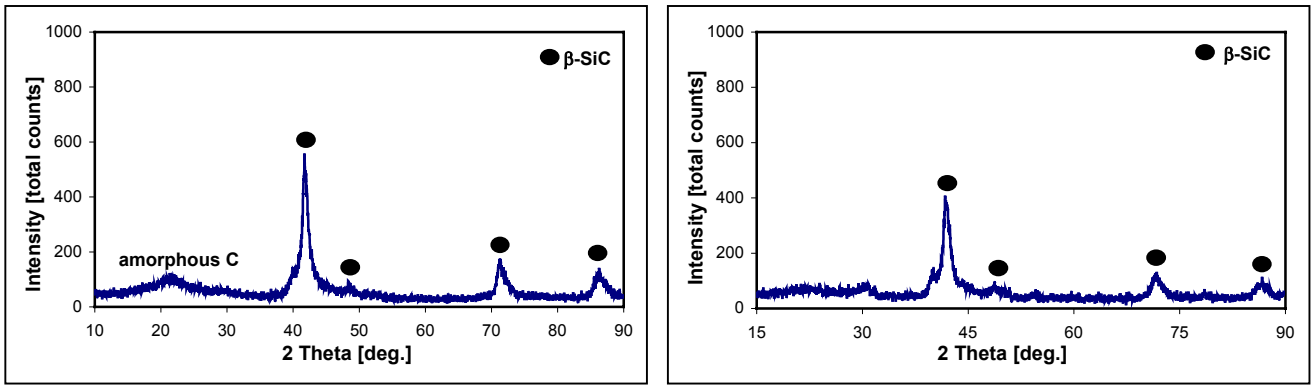

Fig. 6: XRD patterns of Si-B-C-N synthesised in an Ar-H-plasma (left) resp. in an Ar-N-plasma (right).

3.4 Discussion

With the small amount of nitrogen in the plasma gas chosen in our experiments the formation of Si_3N_4 is not observed. The precursors contain an excess of carbon, and according to the following equation the formation of silicon nitride is suppressed:

$$Si_3N_4 + 3C \xrightarrow{T>1440°C} 3SiC + 2N_2$$

In the experiments described above it is more likely that most of the silicon is caught by carbon to form SiC as a result of the higher affinity.

The thermal stability of nitride-based ceramics is strongly dependent on the nitrogen partial pressure. The decomposition reaction of the binary compound Si_3N_4 according to the equation

$$Si_3N_4(s) \leftrightarrow 3Si(l) + 2N_2(g)$$

has an equilibrium vapour pressure of 0.1 MPa at 1775 °C [7]. The volatility of silicon nitride ceramics limits their use to about 1,500°C. Therefore, according to Le Chatelier's principle, an increase of the nitrogen partial pressure permits the stabilisation of the silicon nitride phase at high temperature. This was observed previously with chlorocarbodisilane precursors: a small amount of nitrogen does not permit to synthesise silicon nitride while with a plasma containing 60 % nitrogen only silicon nitride was formed [8].

As recently published, boron stabilises the amorphous state in the Si-B-C-N ceramics. In other words boron hinders crystallisation and forms a turbostratic BN phase built at elevated temperature [9].

The observation of poor crystallisation of both silicon carbide and silicon nitride as a result of the addition of nitrogen to the process as reported previously for plasma conditions [3] was confirmed more generally in another study [10].

4. Conclusions

The experiments performed with this new precursor, i.e. *1,1,3,3,5,5 hexamethyl-cyclotrisilazaneborane*, have shown that the phases synthesised under plasma conditions are mainly constituted of poor crystallised SiC mixed with amorphous BN and probably amorphous carbon. Despite of the nitrogen content in the precursor and in the plasma presence of Si_3N_4 has not been detected neither crystalline nor amorphous, by means of the different characterisation methods employed. However, the results of the different investigation methods show a logical mutual correlation.

Since the microstructural and mechanical properties of the coatings as well as the phase composition are still far away from our project goal the understanding of the process and the process itself must be improved mainly in terms of (i) the formation and the homogeneity of the spray, (ii) the composition of the plasma, and (iii) the vaporisation, condensation, and deposition processes.

5. Acknowledgement

The project is supported by the Deutsche Forschungsgemeinschaft under contract number Schi 539/1-2. The precursors were prepared by the research group of Prof. Röwer at the Institute of Inorganic Chemistry of Freiberg University of Mining and Technology, Germany.

Abstract

The modifications induced on PET surface by an excimer laser radiation performed below the ablation threshold, and by a low pressure plasma were investigated, as well as their ability to improve Al-PET adhesion. The results indicated that, if very significant and similar improvements of the Al-PET adhesion were obtained after both laser and plasma treatments, the mechanisms responsible for the adhesion gain were different for the two types of pretreatments.

1. Introduction

Al/PET adhesion has been extensively studied and it is widely known that a strong adhesion is obtained at the interface due to the formation of C-O-Al bonds from C=O and ether groups of PET. Despite the natural affinity of PET to create bonds with Al atoms, the strength of the Al/PET interface can be further enhanced using surface pretreatment of PET. Improvement of Al/PET interface strength after plasma treatment was observed and attributed either to surface crosslinking or increase of the oxygen and /or nitrogen concentrations. Laser surface treatment can also enhance adhesion at the metal/polymer interface. This was observed for metal electroless deposition or evaporation [1,2]. Improvements of the adhesion at PET/Co alloys [3] or PI/Al [4] interfaces were reported for treatments performed below the PET ablation threshold whereas in similar conditions PBT/Al [5] adhesion was degraded. Despite this literature, the respective contribution of the observed surface changes under UV photons to the mechanism of the adhesion improvement (or degradation) is still to be investigated. In this work, the modifications of PET resulting from laser and plasma treatments were studied as well as the consequences of such treatments on the strength of the Al-PET interface.

2. Experiments

100 μm thick films of PET (Melinex) were used. The laser treatment was carried out using a pulsed excimer laser emitting at 193 nm (20 ns pulse duration) or, at 248 nm (pulse duration : 30 ns). A beam homogenizing system was used in order to perform a uniform treatment of the whole surface of the polymer and X-Y motorized tables were used to scan the polymer under the laser beam. Treatments were carried out at atmospheric pressure. A gas shielding device around the interaction zone permitted to perform the treatment under different gaseous atmospheres : air, helium (or He-O_2 mixtures). Laser treatments were always performed below the ablation threshold of PET, i.e. below 17 mJ/cm^2 at 193 nm and 22 mJ/cm^2 at λ = 248 nm. The pulse repetition rate was 10 Hz and the number of pulses varied from 1 to 2000.

Plasma treatment were realized in a glass reactor with a non-symmetrical configuration of electrodes. RF power (70 kHz) was capacitively coupled to a blade type electrode. The polymer films were enrolled on the grounded cylinder. Plasma power was 2.2 watts (plasma power density was 3.5 W/cm^3) and gas pressure was 100 Pa. Treatments were carried out in a He-O2 (5%) optimized gas mixture [8, 9]. Treatment time was ranging between 1 and 20 s.

Al film was then deposited by thermal evaporation in a vacuum chamber (P = 10^{-3} Pa).

The surface roughness of the PET film surfaces was investigated using AFM. The polymer surfaces were analyzed by XPS. Contact angle measurements were performed using the sessile drop technique using methylene iodine and double-distilled water. The strength of Al/PET interface was investigated using a 180° peel test technique using an EAA (Ethylene-Acrylic Acid) adhesive as detailed in [6]. The peeling occurred at the Al/PET interface and the peel force was recorded (N/cm).

3. Results

3.1 Chemical modifications

After laser treatment in air (or He-5% O_2 mixture), the evolution of the O_{1s}/C_{1s} ratio of treated PET versus the number of pulses was sensitive to the laser fluence i.e. : at low fluences, a global surface oxidation took place while at high fluences (> 10 mJ/cm^2), oxygen depletion was observed (Table 1). This fluence dependent behavior was a consequence of a competition between decarboxylation under UV photons (which is the predominant phenomenon detected under He gas) and oxidation of the UV activated surface in presence of a reactive atmosphere [7]. Plasma treatments always gave rise to an increase of the O_{1s}/C_{1s} ratio. The O_{1s}/C_{1s} ratio was 0.44 after 0.1s and 0.46 after 1s (plasma power : 2.2 watts). As a general feature, a higher level of surface oxidation was observed after plasma compared to laser (only laser treatments at low fluence and high number of shots allowed to reach an oxidation level similar to that reached after plasma treatment). The specific decarboxylation of PET under UV laser may be responsible for the rather moderate level of oxygen incorporation.

Table 1 : O/C after excimer laser (λ = 248 mn) and plasma treatments

Laser (pulses)	0	50	100	200	500
Air,5 mJ/cm^2	0.39	0.37	0.41	0.43	0.48
Air,10 mJ/cm^2	0.39	0.42	0.37	0.37	0.42
Air,20 mJ/cm^2	0.39	0.38	0.39	0.37	0.31
He,10 mJ/cm^2	0.39	0.31	0.29	-	0.26
He,20 mJ/cm^2	0.39	0.32	0.28	0.20	0.16

Plasma	0.1 s	1 s
2.2 W	0.45	0.46
[8] 3.3 W	0.53	0.54

After decomposition of the C_{1s} spectra, some differences were noticed concerning the nature of the chemical bondings detected on the surface after plasma or laser treatment. In the case of plasma treatment, surface oxidation was responsible for the increase of both O-C=O/C and C-O/C ratios and no other peak could be identified. In the case of laser treatment in air**,** besides the presence of the two oxygen components corresponding to C-O and O=C-O groups, a third peak was identified probably corresponding to C=O groups (287.3 eV). This peak was detected for all the laser treatments in air, in oxidizing (low fluence) and deoxidizing (high fluence) conditions but was not identified for laser treatments in helium. Therefore the formation of the C=O groups on PET is specific to the reaction of the UV activated layer with oxygen. It should not be ruled out that plasma treatment also led to the formation of new chemical bondings (carboxilic acid, alcohol, ...) . However, XPS analyses did not allow to identify them. Even for a similar O_{1s}/C_{1s} ratio of the laser and plasma treated PET, differences in the chemical bondings were thus reported as the result of XPS analyses.

3.2. Surface Wettability

The contact angle on untreated PET surface was 77° ($\pm$3°) with water and 26°($\pm$3°) with methylene iodide.For laser or plasma treatments (in air or He-O_2 (5%) mixture), the water wettability (measured just after the treatment) was enhanced (methylene iodine wettability remained almost unchanged). The lower the laser fluence was, the higher the surface wettability (Table 2). Increasing the plasma treatment time improved the water wettability that stayed stable after a 1s treatment. The evolution of wettability, when liquids with different pH values were used, also indicated that acidic sites were created on the surface after plasma and laser treatments.

Table 2 : Water contact angle wettability of PET after laser and plasma treatments (λ = 248 nm ; *: λ *=193 nm*).

Laser (pulses)	10	50	100	500	1000
Air,5 mJ/cm^2	77	78	77	52	41
Air,10 mJ/cm^2	77	72	64	53	55
Air,20 mJ/cm^2	72	63	61	61	60
**Air,5 mJ/cm^2*	77	66	65	56	38
**Air,10 mJ/cm^2*	76	63	60	55	52
**He,10 mJ/cm^2*	68	-	64	68	70

Plasma	0	0.1 s	1 s	5 s
2.2 W	77	68	36	36

The stability with time of the water wettability of treated PET after plasma and laser treatments were compared. For both treatments, the surface stability was good and the increase of the water contact angle with time stayed rather moderate. For plasma treatment, it has already been shown that PET treated with He-O_2 plasmas containing less than 5% O_2 had a very good stability (about 10 % variation of the water contact angle after 60 days) and that increasing the percentage of O_2 in the gas mixture degraded the stability [6]. For a He-O_2 (5%) gas mixture, the water contact angle increased from 28° just after treatment up to 35° after 60 days (20 % variation of the water contact angle). Even if a considerable variation the water wettability with time was observed, it stayed very low compared to the untreated PET. The stability with time of laser treated PET was slightly lower than that observed for plasma treated PET. Variations of 9 % to 30 % were obtained after 60 days (compared to the water wettability just after the treatment). Smaller variations were observed for treatments at high fluences compared to lower ones.

The wettability of the PET surface treated in oxidative conditions (5 mJ/cm^2, 1000 pulses) was changed after surface washing. After water rinsing, the hydrophilicity of the surface was lowered (water contact angle increased from 40° before rinsing to 48° after rinsing) but stayed higher than that of the untreated surface; after rinsing in acetone, the wettability was almost equal to that of the untreated surface (water contact angle : 70°). This shows that fragments, that could be removed after surface rinsing, were created on the laser treated surface.

3.3. Surface Topography

The changes of the surface roughness after the treatment under air, probed by AFM. For a low number of laser pulses (10 pulses), the surface was not significantly modified after treatment at low fluences. When increasing the fluence to 20 mJ/cm^2, very fine cone-like structures (often reported after treatment near the ablation threshold fluence) started to be visible. For a high number of pulses (> 50 pulses), the surface roughness increased with the number of pulses and micrometer size nodules appeared after the treatment. No quantitative data concerning the change of the roughness was obtained from the present results but rougher surfaces were obtained after treatments in air compared to helium. The surface topography of laser treated PET in oxidizing conditions before and after acetone rinsing was compared and the elimination of the degraded layer after washing was clearly evidenced. Washed treated surfaces showed grooves. Surfaces treated by plasma with a low treatment time (0.1s and 1s) were not significantly modified compared to the untreated surface.

3.4. Adhesion Properties

The efficiency of the laser and plasma treatments to improve Al-PET adhesion was demonstrated (Fig.1). Without treatment, the peel force was negligible and visual observation of the peeled surfaces showed that the failure took place at the Al-PET interface. It is generally assumed that, due to the strong affinity between Al and PET, the failure occurred in the skin layer (which represents a weak boundary layer on the PET film surface due to the manufacturing process of stretched films). After an optimized laser treatment, a considerable improvement in the Al-PET adhesion was obtained : the peel force reached 6N/cm and the failure occurred in the EAA adhesive. The Al/PET interface strength was dependent on the laser treatment conditions. The results

obviously emphasized the influence of the laser fluence : as a matter of fact, the peeling force was maximum after a treatment at 20 mJ/cm^2 and a failure occurred within the EAA adhesive even after a single laser pulse. On the contrary, after a low fluence treatment (5 mJ/cm^2), limited improvement of the Al-PET strength was obtained (failure at the metal-polymer interface). Degradation of the Al-PET interface strength always occurred when increasing the treatment time irrespective of the laser fluence. Same trends were observed for Cu/PET interface strength after laser treatment. A comparison of Cu/PET adhesion on treated PET with and without rinsing before copper deposition indicated that Cu-PET adhesion is much higher on rinsed PET. (Table 3).

Al-PET adhesion was also enhanced after a plasma treatment . In the investigated range of time (0.1 s to 5 s), no degradation of Al/PET adhesion due to over-treatment was noticed.

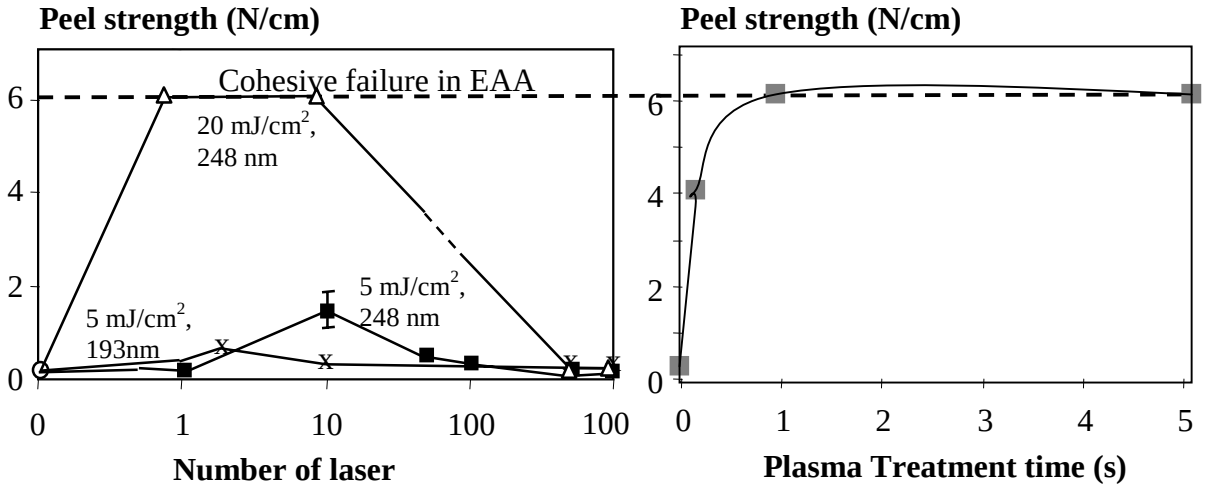

Figure 1 : Al-PET peel strength after laser (a) and plasma (b) treatments.

Number of laser pulses	0	100	1000
Cu-PET peel strength before rinsing (N/cm)	0.2	0.15	0.02
Cu-PET peel strength after rinsing (N/cm)	0.2	0.47	0.40

Table 3 : Role of the surface rinsing of PET on Cu-PET adhesion after laser treatment : Cu-PET peel strength for different number of pulses with and without PET rinsing before Cu deposition.
(Laser treatment : air, 5 mJ/cm^2)

4. Discussion

The efficiency of the laser and plasma treatments to improve the strength of the Al-PET interface has been undoubtedly demonstrated. Now the evolutions of the Al-PET strength, and the surface properties with the laser or plasma parameters will be discussed.

In the case of laser treatment, it was found that the number of pulses and the fluence had a major influence on Al-PET adhesion. For moderate number of pulses (1 to 100 pulses), the adhesion was enhanced and the role of the laser fluence was crucial : the higher the fluence was, the better the Al-PET adhesion. At 20 mJ/cm^2, the highest adhesion (failure in the EAA adhesive) was obtained ; at 5

mJ/cm^2, an improvement of the adherence compared to the untreated surface is also detected but to a much lower level. For a high number of pulses (> 100 pulses), surface degradation and poor Al-PET adhesion were always the major consequences of long laser treatments whatever were the conditions. This is attributed to an extended photolysis and/or photo-oxidation.

For plasma treatments, an increase of the Al-PET adhesion was always obtained. No sign of surface degradation was ever noticed.

Comparison of the effects of plasma and laser treatments on Al-PET adhesion showed that, for each treatment, the highest adhesion level was obtained for surfaces presenting very different surface properties. As a matter of fact, for a similar improvement of the water wettability after plasma or laser treatment, the Al-PET adhesion was completely the opposite : good adhesion resulted from plasma treatment but laser treatment did not significantly enhance the adhesion. In the case of plasma treatment, the improvement of Al-PET adhesion possibly depended on the enhancement of the surface wettability resulting from surface oxidation (as detected by XPS). On the opposite, for laser treatment, oxidation and high water wettability degraded the adhesion (Fig. 2).

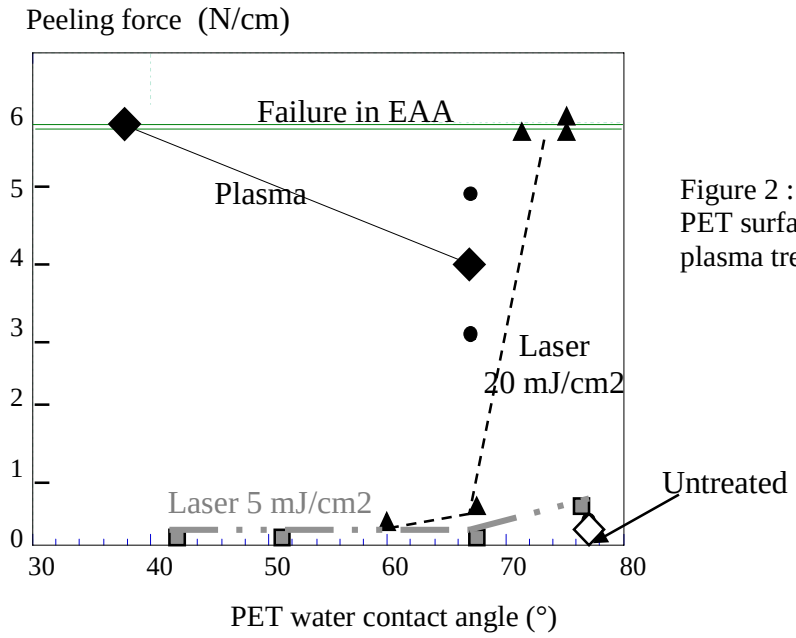

Figure 2 : Al-PET peel strength versus the PET surface water wettability after laser or plasma treatments.

The difference in the chemistry of treated surfaces, induced by laser or plasma treatment for an identical oxidation level could be responsible for differences in their adhesive properties. However the lack of adhesive properties after laser treatment was rather attributed to the surface degradation and to the formation of low molecular fragments due to photolytic or pyrolytic mechanisms under UV.

Consequently, for an "identical oxygen uptake", less damages were induced after plasma treatment. It can also be postulated that surface degradation under excessive oxidation was not reached in our treatment conditions due to the optimized gas mixture and plasma conditions. As a matter of fact, the He-O_2 plasma favoring surface crosslinking prevented the surface degradation [9, 10]. In addition, for plasma treated surfaces, the removal of a degraded layer (if any) in the gas flow rate during the treatment could be possible. Surface etching was detected by mass spectrometry and weight loss measurements [9].

For laser treatment, the highest enhancements of the adhesion were obtained for PET surfaces showing no (or very little) change of the surface wettability and identical Al-PET strengths were obtained after treatment under He and air (manual peeling).

For both fluences, the maximum Al-PET adherence obtained for a given fluence was always reached after a few pulses (between 1 and 10 pulses). The nature of the physical and/or chemical effects responsible for this enhancement remained unclear because for such short treatments, PET surface

modifications were hardly detected. Only AFM analyses indicated some visible modifications of the surface topography after a single laser pulse at high fluences. If changes of the surface topography may play a role in improving Al adhesion by providing anchoring points, a possible oxidation of the first atomic layers of the surface (not detected by XPS) and its participation to the adhesion improvement should not be ruled out. However, oxidation is not expected to be the major effect involved in the adhesion enhancement since at high fluences the carboxylic and ether groups (sites for Al atoms binding) removal rate was maximum and re-oxidation rate was not increased. Consequently, the excellent efficiency of a high fluence treatment with a very low number of pulses should possibly depend on the morphological modifications of PET under an intense flux of photons. Among possible changes, the removal (or modifications) of the initial skin layer (due to thermal and/or photolytic effect), changes of the surface cristallinity, increased surface mobility after chain scission could significantly participate to the adhesion improvement. At low fluences, the degree of surface morphological transformation would not be sufficient due to the low temperature increase and/or limited photolytic transformation. Surface adequate transformation would be fully achieved at higher fluences. Since surface amorphization after surface melting has been found to take place around 10 mJ/cm^2 (7 mJ/cm^2 at 193 nm and 17 mJ/cm^2 at 248 nm), it could be postulated that surface morphological transformations after surface melting obtained above that threshold were responsible for the high adherence.

5. Conclusion

Modifications induced on PET after an excimer laser irradiation or a low pressure plasma treatment performed below the polymer ablation threshold were characterized and the efficiency of such treatments on the Al-PET adhesion of thermally evaporated aluminum was investigated. The results clearly indicated that very significant improvement of the adhesion can be obtained after very short treatment times both with laser and plasma. However, the present observations support the idea that the mechanisms responsible for the adhesion gain were different for the two types of pretreatments. In the case of plasma treatment, surface oxidation and increased wettability associated with surface crosslinking were probably responsible for the reinforcement of the Al-PET strength In the case of laser treatment, surface oxidation had a deleterious effect on the adhesion. An accelerated degradation of the surface by UV photons irradiation is probably responsible for such a behavior. The improvement of the Al-PET adhesion after laser treatment was particularly evident at high fluences after a single or a few laser pulses. Consequently, the effects of a single high dose of photons to on the enhancement of the Al-PET adhesion, could probably be either initial skin layer removal or change of the surface morphology.

Plasma conversion of fluorocarbon waste materials to useful products

A.A. Ponelis and I.J. van der Walt

PELDEV, The Fluorochemical Technology Division of of NECSA, PO Box 582, Pretoria 0001, South Africa

1. Introduction

NECSA (South African Nuclear Energy Corporation), and its subdivision PELDEV have been involved since the early 1990's developing technology to manufacture tetrafluoroethylene (TFE or C_2F_4) and associated useful products from alternative fluorocarbon feedstock. The experimental results of the plasma conversion of typical fluorocarbon waste materials such as industrial off gas, liquid effluent, solid fluoropolymer and others are reported. It is shown that typically a yield of 40% TFE (w/w) is achieved.

2. Process description and operation

The process basis for the conversion is that the fluorocarbon material is subjected to very high temperatures (5000 to 10000 K). This results in radicals such as CF_2 and C_2F_2 being formed. These are then quenched and during the simultaneously occurring reactions, olefinic fluorocarbons form. Else, if the plasma product mixture is cooled slowly, the initial feed composition would essentially form, predicted by thermodynamics.

The plasma conversion system consists of the DC power supply, the plasma torch, decomposition zone, dry quenching zone and product collection. In some cases the torch can be turned into an upside down configuration with the tail flame flowing upwards into a spouted bed reactor, which is filled with carbon particles.

The plasma torch is the central part of the equipment and the 30 kW unit is shown in figure 1.

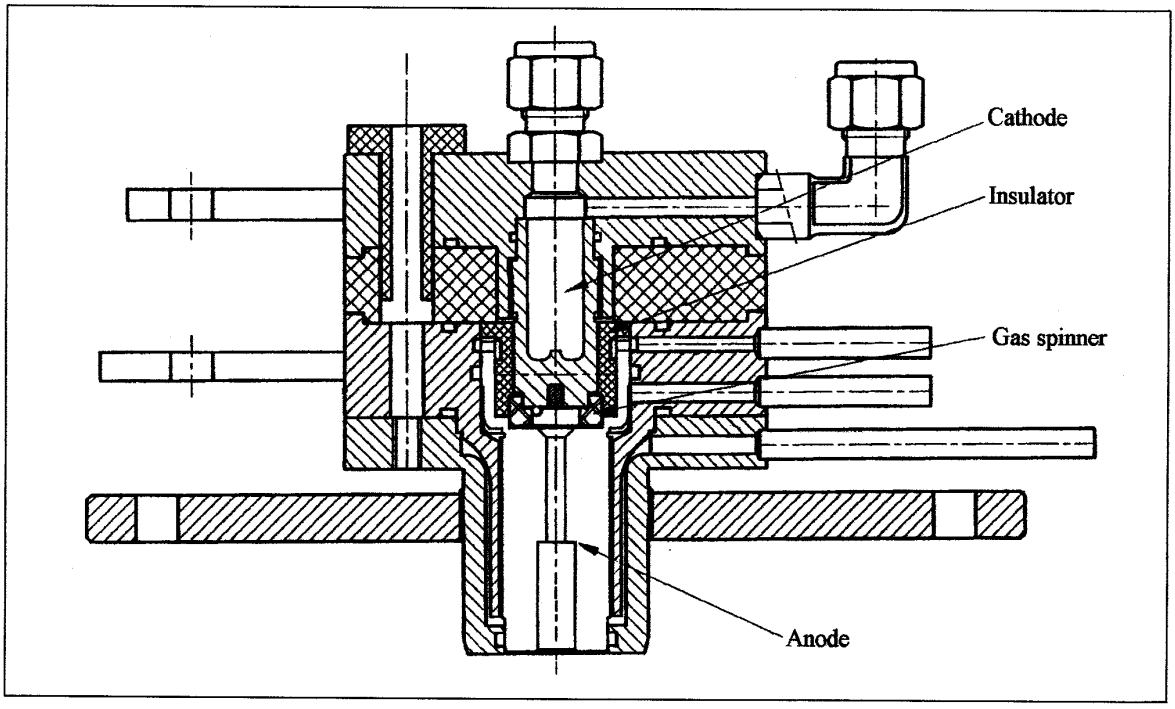

Figure 1: AEC designed plasma torch

The toch consists of a hollow copper cathode (for cooling water) with a graphite insert and a concentric copper anode. The arc chamber is inside the tubular anode. The arc length is kept as near as possible at a constant value by using a stepped anode as indicated. The upper inner diameter is 4mm diameter and the bottom section has an 8mm inner diameter. The lengths of the two sections are 24 and 24 mm for the 24/24 anode or 33mm and 15 mm for the 33/15 system. The linear direct current plasma arc is established between

the graphite insert in the cathode and the "step" in the anode. The DC power supply is current controlled and the resulting voltage of the arc is determined by its length. The cathode and anode are separated by an insulator made from polycarbonate. This piece fits inside on the top of the anode and a gas spinner made from pyrophyllite which fits into the bottom of the insulator. The plasma gas enters the torch through four small holes in the top of the anode, moves downward between the anode and the insulator and is fed into the plasma arc through four 2 mm holes in the gas spinner. The plasma is vortex stabilised. Both the anode and cathode are water cooled during operation.

The fluorocarbon feed material is fed (in the case of the 30 kW) just below the anode into the tailflame, but it can also be co-fed at the top with the plasma gas (Ar, CF_4, N_2, etc). In the case of the 150 kW or 450 kW plasma torches the feed position can be also between the first and second anodes. (Anode inner diameter and lengths: 16mm x 124mm + 30mm x 67mm = 191mm length for the 150 kW; for the 450 kW: 18mm x 375mm + 46mm x 160mm = 535mm). The decomposition zone is a graphite lined cylindrical section where the temperature is maintained at about 3500 K with sufficient residence time 10 to 20 ms, so that the fluorcarbon material can be dissociated into precursor radicals like CF_2, C_2F_2, C(g), F, etc.

Just downstream of the high temperature decomposition zone is the quenching zone where the radicals react chemically to form the required products. The quenching is achieved on a dry water cooled surface. The quench section is like an annular heat exchanger, consisting of an inner water cooled finger made of copper enclosed in a water cooled stainless steel cylinder. The diameter is about 20mm and length about 500 mm (80mm en 770mm for the 150 kW; 244mm and 850mm for the 450 kW). The gas flowing from the hot decomposition zone flows in the annulus between the copper finger and the stainless steel cylinder. The quenching of the gas mainly takes place in the first few centimetres of the quench exchanger. The rest of the surface serves as a heat exchanger to cool the gas to temperatures lower than 400 K. It is essential that the quenching rate exceeds 10^5 K/s to obtain the desired products.

The process schematic for the 30 kW torch is shown in figure 2. The layout for the 150 kW demonstration system and 450 kW semi-technical plant is similar to this, except that the semi-technical plant has a plasma gas handling system downstream of the vacuum pump, where the gas is compressed and fed into a four column distillation train to separate the TFE from the other product gases, mainly CF_4 and C_3F_8.

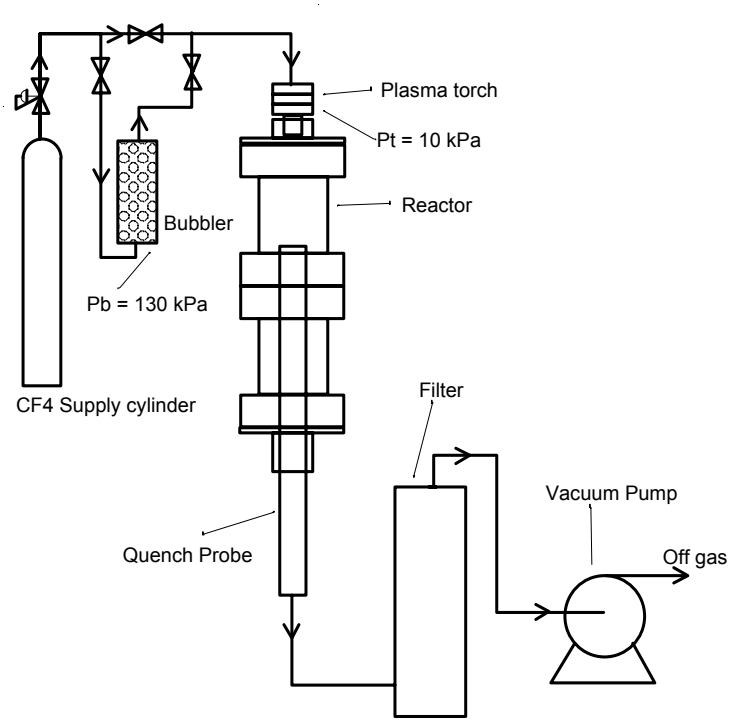

Figure 2: Process schematic of 30 kW experimental system

The arrangement in figure 2 shows how liquid fluorocarbons are first evaporated and fed as vapour into the torch, together with a carrier gas, which is typically CF_4. In the case of R23 (CHF_3), large amounts of HF is generated by the plasma and this is removed from the product gas with a condenser (150 kW) followed by a NaF trap. For the smaller 30 kW test rig a NaF trap is sufficient to remove the bulk of HF.

The startup and operational procedure is typically as follows. The entire process system, which is vacuum tight, is evacuated to about 1,0 kPa with the vacuum pump. Plasma gas is now fed into the torch (Ar, CF_4, N_2, etc). The spark is now initiated across the cathode anode gap. The values of the plasma gas mass flow rate and the power supply current are set to the required set points. The voltage of the torch is then obtained. For the 30 kW torch with an anode of 48mm the voltage is about 125V (CF_4). After the plasma arc has been established the fluorocarbon can be fed. In some cases the pure fluorocarbon gas is fed or the gas might be co-fed with CF_4 as carrier gas. Samples of the product gas are taken periodically and analysed with a GC (and in case of HF a Infra Red spectrum is also taken.) In the case of the 150 and 450 kW systems, there are inline GC analysis.

3. Experimental results and interpretation

The conversion of five types of fluorcarbon materials are reported here. The compositions are given in table 1 below. It can be seen that liquid (low boiling amines), industrial off gas, a pure vapour, solid carbon particles and a solid polymer (THV – tetrafluorethylene hexafluoropropylene vinylidene fluoride) were converted.

Table 1: Fluorocarbon feed material composition

Feed fc Material	**Composition**	**% (v/v)**	**C/F**	**Formula**
Liquid fc Effluent	$C_6F_{14}N$ $C_7F_{17}N$ $C_8F_{19}N$ $C_9F_{21}N$	15 24 17 44	0,42	$C_8F_{19}N$
Industrial Off Gas #2	CHF_2Cl CCl_2F_2 c-C_4F_8 C_3F_6 C_3F_5H C_2F_4H C_3F_7H	3 5 9 22 43 9 8	0,53	$C_{20}F_{38}H_5Cl$
R23 vapour	CHF_3	100	0,33	N/A
CF4 + C)s	CF_4 C	10% (w/w) 90%(w/w)	16	N/A [C particles:106-150Φm]
THV solid Spouted bed	-$(CF_2$-$CF_2)_x$-(CF-CF_3-$CF_2)_y$-(CF_2-$CH_2)_z$-	100	~0,50	N/A

Table 2 give the operational conditions, where some parameters were varied to indicate effects if some typical controlling parameters are varied. The parameters being varied, while keeping the other parameters constant, were: reactor pressure (8 to 50 kPa), plasma gas type (CF_4, N_2, Ar) fluorocarbon feed rate (3.62 and 8.63 kg/h).

Table 3 show the converted fluorocarbon's product gas composition and the calculated value of the yield of TFE from the fluorocarbon on a weight basis. The conversion of the fluorocarbon in all cases is 100% except for the case where the carbon particles are fed in vast excess.

The following observations can be made. **Pressure:** The lower the pressure, the higher the yield of TFE (ref's 1, 2, 3 & 6, 7 & 8, 9). The **liquid effluent** (low boiling amine), gives a 40%(w/w) of TFE on the larger plasma system at 20 kPa, rather than the 64% expected value. This is still an economic yield though. The **industrial off gas** gives a 87% yield of TFE at 10 kPa reactor pressure, with N_2 as plasma gas. The yields with CF4 is higher, but this is due to CF_4 also being converted. The typical freon off gas **R23** gives a 20%

yield of TFE. Solid carbon particles together with CF_4 of 106-150Φm are converted to TFE. Conversion of the solid polymer THV results in a yield of about 60% TFE.

In addition, it can be seen from table 2 that the Specific Energy Requirement (SER) to convert the fluorocarbons vary approximately between 3,0 and 7,0 kWh/kg, except for the THV which is only 1,8 kWh/kg. This is due to Argon being used as plasma gas which requires a low voltage to generate the plasma, in contrast to CF_4. From table 1 it can be seen that the voltage (30 kW) for Ar is 25V, for N_2 it is about 90V and for CF_4 it is about 125V.

The wide operational window of the DC plasma is shown for the 150 kW plasma conversion of liquid effluent at either 3,62 or 8,63 kg/h, Both these feed rates give a yield of about 40% (w/w) – References 4&5.

4. Practical aspects of the DC plasma process

The following aspects are of importance of the process and must be taken into account during design and operations.

* Clogging and deposit formation in the quench due to incorrect positioning of feed point
* Low molecular weight PTFE type materials deposition in downstream equipment
* Electrode erosion due to oxygen inleakage
* Arc instability due to acoustic resonance, feed gas flow variations
* Safety due to toxic gases generation (PFIB) and explosive gases (TFE)
* Plasma gas selection depends on the downstream capabilities, e.g. CF_4 separation
* The liquid fc effluent generates CF4, this excess must be converted with $C)_s$
* There is no nett effluent stream from the plasma, unwanted products are recycled (e.g. C_2F_6).

5. Conclusions

The DC plasma is a powerful process unit with wide potential to convert fluorocarbon materials whether it be solids, liquids or gases. The basic plasma torch can be used in a number of configurations to suit the physical requirements of the of the materials, i.e. a downward flow for gases, vapours and solid small particles flowing towards the quench or the torch facing upwards in a spouted bed to convert the solids in the bed.

Typical yields of TFE is 40% (w/w) for a variety of fluorocarbons. The conversions are in the order of 100%.

6. Acknowledgements

The authors wish to thank the South African Nuclear Energy Corporation for permission to publish the results and attending the ISPC 16. We are also indebted to Dyneon GmbH for their support and assistance during some of these investigations.

Chemical and physical properties of hydrophobic coatings obtained in a dielectric barrier discharge

S. Paulussen, O. Goossens, D. Vangeneugden

Materials Department, Flemish Institute for Technological Research (VITO), Mol, Belgium

Abstract
The presented work reports on the formation of hydrophobic plasmapolymer coatings in a dielectric barrier discharge at atmospheric pressure. Coatings characterized by a low surface energy were produced in N_2 and Ar plasma starting from a variety of both gaseous and liquid precursors, including pure organic compounds, fluorinated hydrocarbons and organically modified silicon compounds.

1. Introduction

Over the last decade, several applications of low pressure plasma assisted treatments for surface modification have reached the point of industrialization and are currently being used in production. However, for many applications the use of low pressure plasmas is too expensive, mainly due to the high equipment and exploitation cost and the inability to work in-line.
In recent years, a lot of effort has been put into the development of plasma treatments at intermediate and atmospheric pressure. In this new field of technology, dielectric barrier discharges (DBD) have proven successful in a number of applications including tailoring of the surface wettability properties, improving adhesion properties, cleaning and sterilization [1-4]. Currently, research focus is shifting towards the deposition of thin films.
The configuration used to obtain a DBD consists of two parallel electrodes of which at least one is covered with a dielectric material. When an AC-field in the range of 250 Hz - 250 kHz and 1 - 30 kV is applied to the electrodes a transient, spatially uniform glow can be observed [5]. The space between the electrodes may range between 1 and 10 mm. Reactive species or polymer precursors can be administered to the plasma in order to enhance surface activation or to achieve thin film deposition. The main advantage of this technique is that it allows environmental-friendly (solvent-free), in-line processing of heat-sensitive materials like plastic foil and textiles. The latter is due to the fact that the gas temperature of the plasma varies between room temperature and 100 °C, while the mean electron temperature can amount up to 10 eV (1 eV ≈ 11600 K).
This paper deals with the formation of hydrophobic plasmapolymer coatings in a dielectric barrier discharge at atmospheric pressure. Such coatings are of great industrial relevance as they can, among other things, optimize printing properties and introduce water and dirt repellent properties to surfaces of a wide range of materials. The chemical and physical properties of hydrophobic coatings obtained in N_2 and Ar plasma starting from a pure organic precursor, a fluorinated hydrocarbon and an organically modified silicon compound will be compared.

2. Experimental set-up

The experimental configuration of the dielectric barrier glow discharge (DBD) consists of two parallel electrodes (160x180 mm), both covered with an insulating Al_2O_3 plate of 2 mm thickness (figure 1). In order to perform tests in a controlled atmosphere, the electrode configuration is mounted in a closed chamber which is evacuated and subsequently filled with the carrier gas before deposition is started. To ensure stable plasma operation, the gap between the electrodes was limited to a few millimeters. Plasma discharges were generated by a 20 kV/200 mA AC power supply with variable frequency, in this case ranging between 1 and 10 kHz. In this set-up, the bottom electrode is connected to a high voltage AC power source while the top electrode is grounded.
Coatings were produced in N_2 and Ar plasma starting from both gaseous and liquid precursors. The flow rate of the carrier gas was controlled by mass flow controllers and set at 15 l/min. Liquid precursors were added to the inert carrier gas by means of an atomizer which generates a polydisperse submicron aerosol. Gaseous plasmapolymer precursors were simply mixed with the carrier gas at 1 l/min. The precursor molecules under investigation include butane (C_4H_{10}, Air Products), perfluorohexane (C_6F_{14}, 99 %, Aldrich) and

hexamethyldisiloxane (HMDSO) ($C_6H_{18}Si_2O$, 98+%, Aldrich). The deposition time was set at 10 minutes for deposition experiments with butane and at 2 minutes for the other precursors.

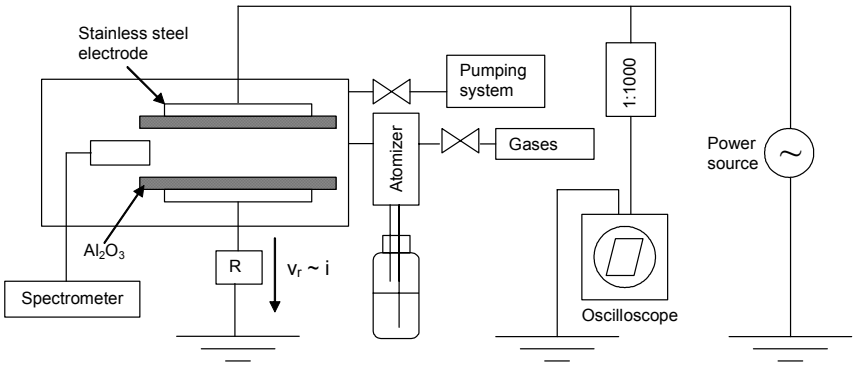

Figure 1: Configuration of the dielectric barrier discharge.

Double polished silicon substrates (12 x 12 mm) were used as substrates for plasmapolymer deposition and placed on the lower (high voltage) electrode. Contact angle measurements of the coatings were carried out using the sessile drop technique (OCA 15 Plus, Dataphysics Instruments GmbH, Germany). In addition, the samples were analyzed by FESEM (JSM-6340F, JEOL, USA), XPS (Fisons Instruments, USA) and FTIR-spectroscopy (Avatar 360 ESP, Nicolet, USA). The plasmapolymers used for NMR measurements (Varian Inova, USA) were recovered from deposits on polished glass substrates. Coatings obtained from perfluorohexane could not be removed from the glass surface.

3. Results and Discussion

Surface Energy Measurements

According to the Owens-Wendt (OW) method, the surface energy of a material (γ) equals the sum of a dispersive (γ^D) and a polar component (γ^p) [6]. The latter two can be determined from the measurement of the contact angles of the surface under investigation with two different liquids of which the dispersive and the polar components of the surface energy are known. The OW-method is commonly used in the studies of the surface energy of polymer films. In this work, surface energy calculations are based on the contact angles of water (CA_{H2O}) and diiodomethane (CA_{CH2I2}) with the coated surface. The values obtained are summarized in table 1.

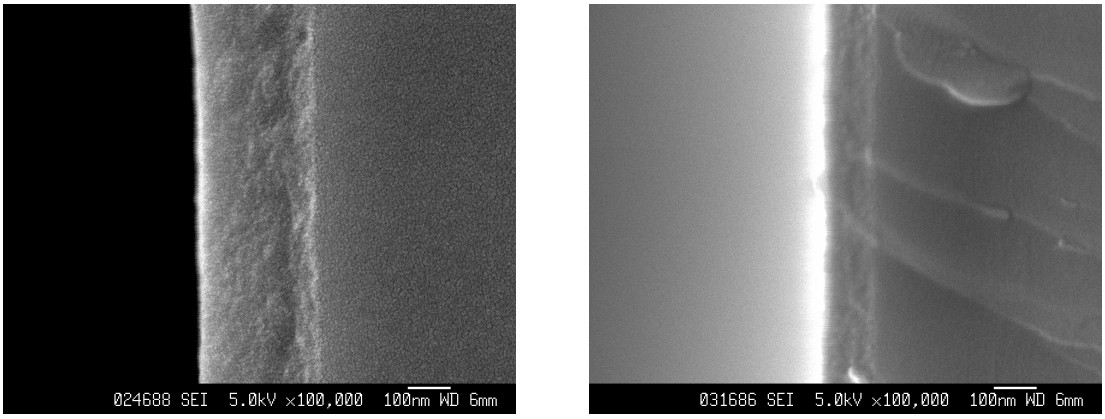
Table 1: Contact angle of the coated surfaces with water (CA_{H2O}) and diiodomethane (CA_{CH2I2}), surface energy (γ) and polar (γ^P) and dispersive component (γ^D) of surface energy for coatings obtained after plasmapolymerization of butane, perfluorohexane and HMDSO in Ar and N_2 plasma.

Precursor / Carrier Gas	CA_{H2O} [°]	CA_{CH2I2} [°]	γ [mJ/m^2]	γ^P [mJ/m^2]	γ^D [mJ/m^2]
Blanco substrate (Si)	60.7	49.7	46.5	15.7	30.8
Butane / Ar	85.8	45.3	37.9	2.5	35.4
Butane / N_2	83.5	47.8	37.3	3.5	33.8
Perfluorohexane / Ar	102.6	88.2	15.3	2.7	12.6
Perfluorohexane / N_2	94.9	76.9	21.4	3.6	17.8
HMDSO / Ar	99.8	71.8	22.6	1.5	21.1
HMDSO / N_2	105.6	67.7	24.2	0.3	23.9

The lowest surface energies and thus the most hydrophobic coatings are obtained with the fluorinated hydrocarbon precursor. Values as low as about 15 mJ/m^2 could be obtained after plasmapolymerization of perfluorohexane in argon, while plasmapolymerization in a nitrogen discharge resulted in a somewhat higher surface energy. The latter phenomenon was also observed for other precursors and can be attributed to the incorporation of polar N-based functional groups into the coating as expressed by a higher value for γ^P. In

addition, the interactions responsible for the dispersive share of the surface tension, like van der Waals forces, may be influenced by the presence of stable radicals in the coating.
Apart from the fluorinated hydrocarbon precursor, also plasmapolymerization of the hybrid organic-inorganic precursor HMDSO resulted in the formation of hydrophobic plasmapolymer coatings. Although the total surface energy of these coatings is slightly higher compared to the values obtained with the perfluorohexane-based coatings, γ^P is even lower and the contact angle of the coating obtained in N_2 plasma with water is the highest value achieved in this set of experiments.
The plasmapolymer coatings obtained from butane are characterized by significantly higher surface energies than those obtained from the other two precursors.

SEM-analysis
Figure 2 shows some FESEM pictures taken from cross-sections of coatings deposited on polished silicon. From these pictures, the thickness of the coatings and hence the deposition rates could be determined. The values obtained are summarized in table 2.



(a) (b)

Figure 2: FESEM pictures of plasmapolymer coatings obtained from HMDSO (a) and perfluorohexane (b) in N_2 plasma.

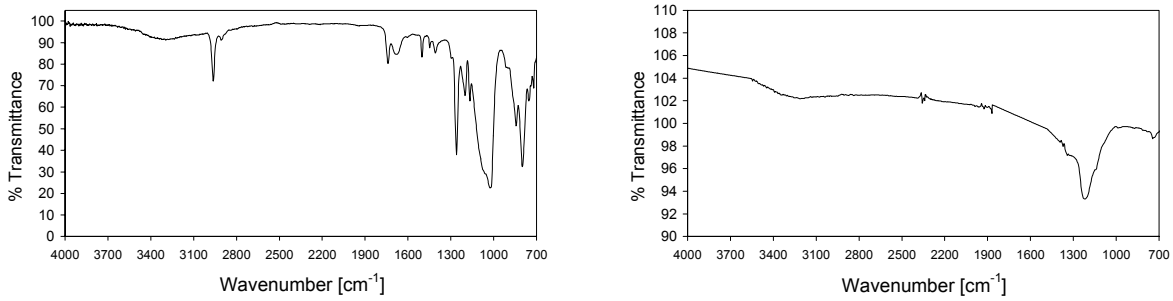
Table 2: Coating thickness and deposition rate of plasmapolymer coatings obtained from butane, perfluorohexane and HMDSO in Ar and N_2 plasma.

Precursor / Carrier Gas	Coating Thickness [nm]	Deposition Time [min]	Deposition rate [nm/min]
Butane / Ar	150	10	15
Butane / N_2	200	10	20
Perfluorohexane / Ar	80	2	40
Perfluorohexane / N_2	120	2	60
HMDSO / Ar	160	2	80
HMDSO / N_2	250	2	125

Coatings obtained in both argon an nitrogen discharges appear homogeneous and without pinholes or structural defects. Deposition rates were however between 25 and 35 % lower in argon discharges than in nitrogen discharges, probably due a different polymerization mechanism. The highest deposition rates were obtained with the atomized precursors perfluorohexane and HMDSO. Plasmapolymers of the latter precursor grew about twice as fast as those of perfluorohexane and 5 times as fast as the ones obtained from the gaseous precursor butane. This is due to the fact that the amount of precursor administered to the plasma was higher in the case of the liquid precursors.

FTIR

Although it is quite difficult to obtain adequate information about the hydrocarbon or silicon backbone of coatings using FTIR analysis, some information concerning the presence of functional groups in the coatings could be gathered this way. Figure 3a shows the FTIR spectrum of the plasmapolymer obtained from HMDSO in a N_2 discharge. Obviously, the functionalities present in de monomer are retained after plasmapolymerization ($Si-(CH_3)_n$ at 1260 and 840 cm^{-1}, $R_3Si-O-SiR_3$ at 1030 cm^{-1}, C-H stretching at 2960 and 1460 cm^{-1}). Additional signals include a broad peak around 3300 cm^{-1}, which can be attributed to O-H or N-H stretching, and two peaks at 1700 and 1750 cm^{-1}, which are typical for C-O stretching in ketones and aldehydes. These signals are not found in the spectrum of the coating obtained after polymerization of HMDSO in argon plasma and they probably result from the incorporation of nitrogen and oxygen in the coating, either from the carrier gas or from exposure to air after deposition. The latter assumption will be verified by XPS and NMR-measurements. The spectrum of the plasmapolymer coating obtained from perfluorohexane in a N_2 discharge (fig. 3b) contains a large peak around 1220 cm^{-1} and a small peak near 740 cm^{-1}. Both signals are attributed to the presence of C-F bonds. As could be expected from the chemical nature of the precursor, no hydrocarbon signals are observed. The weak signal near 3200 cm^{-1} is only found after plasmapolymerization in N_2 and can be rationalized in the same way as for figure 3a. The spectra obtained form the plasmapolymer coatings based on butane are not shown but merely contain hydrocarbon signals.



(a) (b)

Figure 3: FTIR spectra of plasmapolymer coatings obtained from HMDSO (a) and perfluorohexane (b) in N_2-discharges.

XPS

X-ray photoelectron analysis was carried out in order to determine the relative amounts of C, O, N, F and Si at the plasmapolymer surfaces (table 3).

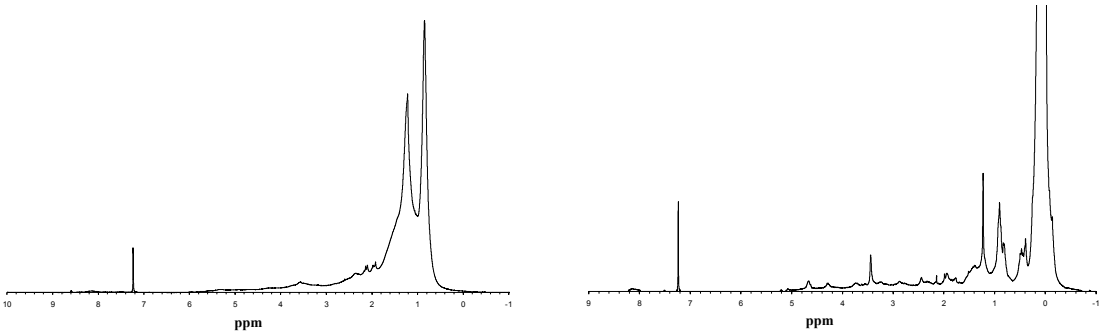
Table 3: XPS-data (surface mole fraction of elements excluding hydrogen in %) obtained from butane, perfluorohexane and HMDSO plasmapolymer coatings prepared in N_2 and Ar DBD glow discharges.

Precursor / Carrier Gas	C [%]	O [%]	N [%]	F [%]	Si [%]
Butane / Ar	82.5	16.9	-	-	0.6
Butane / N_2	77.7	17.3	4.6	-	0.4
Perfluorohexane / Ar	47.5	8.8	0.1	43.0	0.6
Perfluorohexane / N_2	42.3	7.9	7.0	42.3	0.5
HMDSO / Ar	51.9	22.2	-	-	25.9
HMDSO / N_2	50.3	24.0	2.0	-	23.7

While perfluorohexane and butane do not contain any oxygen, relatively large amounts of oxygen were found at the surface of their plasmapolymers. Moreover, when N_2 was used as the carrier gas, also some nitrogen could be detected, which may be incorporated in the coating during polymerization. However, after exposure of the plasmapolymer coatings to air, stable radicals of organic origin that remain present in the coating after deposition may react with oxygen and/or nitrogen and thus give rise to the formation of nitrogen or oxygen containing functional groups at or near the surface as well. Such functionalities were

found in some of the FTIR spectra and may be the cause of the higher surface energies found after plasmapolymerization in N_2.
Another striking fact in table 3 is the C/F-ratio of the plasmapolymers obtained from perfluorohexane. While the C/F-ratio of perfluorohexane equals 0.42, the C/F-ratio of its plasmapolymers is about 1. Apparently, some fluor is split of during plasmapolymerization and although some oxygen (and nitrogen) is incorporated in the coating, this indicates that a cross-linked carbon network is formed.
A similar effect is observed in the case of HMDSO. While the C/Si-ratio of HMDSO equals 3, the C/Si-ratio of its plasmapolymers is only about 2 which may indicate that cross-linking of silicon occurs.

NMR-measurements
Nuclear magnetic resonance (NMR), and in particular ^{13}C-NMR, has proven to be a powerful technique to perform detailed investigations of the hydrocarbon backbone of polymers [7]. It also seemed an interesting technique to gain some more insight in the chemical structure of the plasmapolymers obtained. In principle, one should be able to evaluate for instance the retention of the chemical structure of the monomers in the plasmapolymers and the degree of cross-linking. Therefore, ^{13}C-NMR measurements were performed on plasmapolymers of butane and HMDSO recovered from depositions on large glass plates. The plasmapolymers obtained from perfluorohexane could not be isolated from the substrate and hence no spectra of these compounds are available.
However, the recorded ^{13}C-NMR spectra only showed very weak signals that were strongly broadened and hence not very informative. This could be due to the presence of strong paramagnetic sites, such as remaining stable radicals.
In contrast to the ^{13}C-NMR measurements, ^{1}H-NMR analysis of the plasmapolymers resulted in more useful spectra (figure 4). Although the line broadening in these spectra is also considerably higher than usual for polymers, some qualitative information can be extracted.



(a) (b)

Figure 4: ^{1}H-NMR spectra of plasmapolymers obtained from butane (a) and HMDSO (b) in N_2 discharges.

The spectrum obtained from the plasmapolymers of butane (fig 4a) is dominated by the signals of $–CH_3$ (at 0.8 ppm) and $–CH_2$ (at 1.3 ppm).The latter peak has a shoulder at about 1.6 ppm, which can be attributed to the presence of CH-groups. The relatively low intensity of the CH_3-peak compared to the proportion of CH3-groups in butane and the presence of a CH-signal indicate that cross-linking of C-atoms has occured in the plasma.
The origin of the weak signals between 2 and 3.5 ppm is difficult to determine but they probably originate from the presence of hetero-atoms like O and N in the plasmapolymers.
The strong signal near 0 ppm in figure 4b is typical for CH_x-Si bonds. The signals at 0.8 and 1.2 ppm can be attributed to-CH_3 and -CH_2 groups bound to other carbon atoms, which indicates that new C-C bonds are formed in the plasma. Also in this case, the small peaks between 2 and 3.5 ppm probably result from the incorporation of O and N. More information on the plasmapolymers obtained from HMDSO will be available after ^{29}Si-NMR-measurements.

4. Conclusions

Hydrophobic films characterized by surface energies as low as 15 mJ/m^2 were obtained by plasmapolymerization of perfluorohexane in a dielectric barrier discharge at atmospheric pressure. While also HMDSO proved to be a suitable precursor for the deposition of hydrophobic coatings with surface

energies between 20 and 25 mJ/m^2, a pure hydrocarbon precursor like butane gave rise to significantly higher surface energies. In general, lower surface energies are achieved when argon is used as a carrier gas. This is due to the fact that in a DBD discharges with nitrogen as carrier gas, more oxygen and nitrogen-containing functionalities are incorporated at the surface of the coating, which in turn results in slightly higher surface energies. However, higher deposition rates are obtained in nitrogen discharges. In addition, XPS and NMR-measurements indicate that a cross-linked network of carbon (and silicon when HMDSO is used as a precursor) is formed through plasmapolymerization of hydrocarbons, fluorinated hydrocarbons and organically modified silicon compounds.

The device and algorithm for estimation of the chaos on mechanical activated plasma in blood of patients with gastric cancer

V.E. Orel, Yu.I. Mel'nik, A.V. Romanov, N.N. Dzyatkovskaya

Physics-Technical Laboratory, Institute of oncology, 33/43 Lomonosova Str., Kiev, 03022, Ukraine

Abstract

The mechanoemission (ME) of blood is developed as a result of mechanical activation of plasma in a sample which is layered onto chromatographic paper. This paper describes computer-controlled device, aimed for generation, detection and analysis of ME data in blood of investigated persons. The original algorithm for estimation of ME chaos in blood is developed. For gastric cancer patients an increase of ME chaos is observed in comparison with healthy individuals and patients with inflammatory of gastric mucosa.

Introduction

The idea that in living structures plasma physico-chemical mechanisms can occur was first expressed more than 30 years ago. Subsequently Sedlak published qualitative considerations of the plasma state in living systems leading him to suggest the existence of a fifth state of matter he termed “bioplasma”. Inushin and his group focused on applications of the bioplasma concept to clinical practice. Fröhlich alluded to possible plasma oscillations in cells in the context of Böse condensation within biological structures [1].

Yet none of the work cited above was devoted to detailed consideration of whether plasma physical mechanisms are compatible with biological structures. But we don’t know about non equilibrium effects in the plasma for cancer patients.

ME or triboemission – is the property of non-equilibrim discharges in nitrogen plasmas during mechanical stresses, deformation, or friction in biological objects. The mechanism of ME excitation is based on the processes of conversion of the mechanical energy of a substance into other forms: electronic excitation and ionization, chemical bond energy and the kinetic energy of atoms, etc. The dissipation of mechanical energy results in the emergence of polar electric charges, between which, in the presence of gas and liquid, there appear weakly luminescent aggregates of ionized particles in the form of Lichtenberg figures [2]. Accompanying this process are mechanochemical reactions of free radical oxidation, chemisorption and other events influencing ME. The relaxation of mechanical tension is also accompanied by pulse electromagnetic emission due to fluctuation in the electrical dipole moment [3–5].

This mechanism may be represented by the following equations

$$\sigma = \frac{\varepsilon_0 \varepsilon}{H}\left(\Delta\Phi - \frac{kT}{e}\ln n_i \pm HE \right), \tag{1}$$

$$\frac{\mathrm{d}\Phi}{\mathrm{d}t} = \sum_i W_i\, n_i, \tag{2}$$

where: σ – the surface density of the charge; ε_0 – an electric constant; ε – a relative dielectric penetrability; $\Delta\Phi$ – work function; k – Boltzman constant; T – thermodynamic temperature; e – electron charge; n_i – particle concentration; H – distance between electrization surfaces; E – electrostatic field strength. Equation (2) describes the process of microdischarge between dielectric barriers, where W_i – drift velocity of electrons, ions, photons, neutral atoms and molecules.

The present work use physical principles described above for the device and algorithm for estimation of the ME chaos in blood of patients with gastric cancer.

Materials and methods

Device description. The principal element of the analyser of ME is a tribogenerator unit (Fig. 1). An electret fluoroplastic probe is used as a roll measuring 30 mm in diameter. The rolling unit is installed on axis and is rotated with an electric motor. The sample in frame is moved to the electret probe using a pressing device. The measuring electrode for recording of electrical component of electromagnetic ME generated by electret probe and sample friction is located directly in the vicinity of the sample contact and rotating probe. Electrical signals enter the input of the aerial amplifier and after amplification in the frequency range of 1 Hz

to 100 kHz, they are transmitted to the input of the analogue-digital converter (ADC). A grounded cleaning brush wetted with 25 % ethanol solution removes electrostatic charge from the probe surface after each measuring cycle. The tribogenerator chamber is continuously flushed with nitrogen gas.

Tribogenerator unit with electric channel of ME detector: 1. chamber; 2. frame with the investigated sample; 3. device of the frame pressing to the electret probe; 4. device of the frame passing to the chamber; 5. electret probe; 6. the measuring electrode; 7. device of the working surface clearance; 8. operational amplifier; 9. electric motor.

Description of the algorithm. The phase space method was used for the analysis of ME chaos in blood [6]. Let I_0, I_1, …, I_N be the ME value being measured at discrete time moments t_0, t_1, …, t_N, $t_i = t_0 + i\tau$, $i = 1, 2, \ldots, N$. In order to build a continuous phase trajectory, values I_0, I_1, …, I_N were interpolated with a cubic spline $f(t)$, $t_0 \le t \le t_N$

The phase trajectory is defined as the multitude $\{(x, y) | \, x = f(t+\tau), \; y = f(t), \; t_0 \le t \le t_{N+1}\}$. Let $\Phi = \{(x, y) | \, x = \varphi(t), \, y = \psi(t), \, t \in [\theta_1, \theta_2]\}$ be the phase diagram of a certain process, functions φ and ψ being continuously differentiable on segment $[\theta_1, \theta_2]$. Let $x_{\min} = \min\limits_{t \in [\theta_1, \theta_2]} \varphi(t)$, $x_{\max} = \max\limits_{t \in [\theta_1, \theta_2]} \varphi(t)$, $y_{\min}(x) = \min\limits_{t \in \varphi^{-1}(x) \cap [\theta_1, \theta_2]} \psi(t)$, $y_{\max}(x) = \max\limits_{t \in \varphi^{-1}(x) \cap [\theta_1, \theta_2]} \psi(t)$. Let us define spread parameter $S(\Phi)$ of phase diagram Φ as

$$S(\Phi) = \int_{x_{\min}}^{x_{\max}} (y_{\max}(x) - y_{\min}(x)) dx. \tag{3}$$

The physico-mathematical interpretation of statistical parameter S is approximately the area of the figure outlined with the envelope of the phase trajectory.

To approximately calculate the integral on the right in the formula (3), let us use the quadrature rectangles formula:

$$S(\Phi) \approx S_\varepsilon(\Phi) = \sum_{i=0}^{n-1} (y_{\max}(x_i) - y_{\min}(x_i)) \cdot \varepsilon, \tag{4}$$

where $n = [(x_{\max} - x_{\min})/\varepsilon]$, $x_i = x_{\min} + i\varepsilon$, $i = 0, 1, \ldots, n$.

A special algorithm is developed for calculation of the blood ME phase trajectory spread parameter S [7]. The flowchart of the algorithm of estimation of the phase trajectory spread parameter is shown in Fig. 2.

Patient population. We studied ME in three groups of patients. Group 1 included patients with gastric cancer (22 persons), group 2 – patients with inflammation of gastric mucosa, chronic gastritis (20 persons) and group 3 – healthy subjects (21 persons). Cancer patients were evaluated at Stage II-IV with morphologic and histologic confirmation of diagnoses. All groups consisted of male aged 45–60.

Mechanoemission studies. 0.02 ml of blood (3 samples from every patient) was layered onto FN-2 chromatographic paper (Filtrak, Germany) which was placed in the slide frame. A sample of whole blood dried to 45 % relative humidity was triboelectrified using a rotating electret probe at 1400 ± 50 rpm with

enhanced mode of 1.2 N in the atmosphere of highly purified gaseous nitrogen under excessive pressure of 1 kPa at 37 ± 0.5 °C.

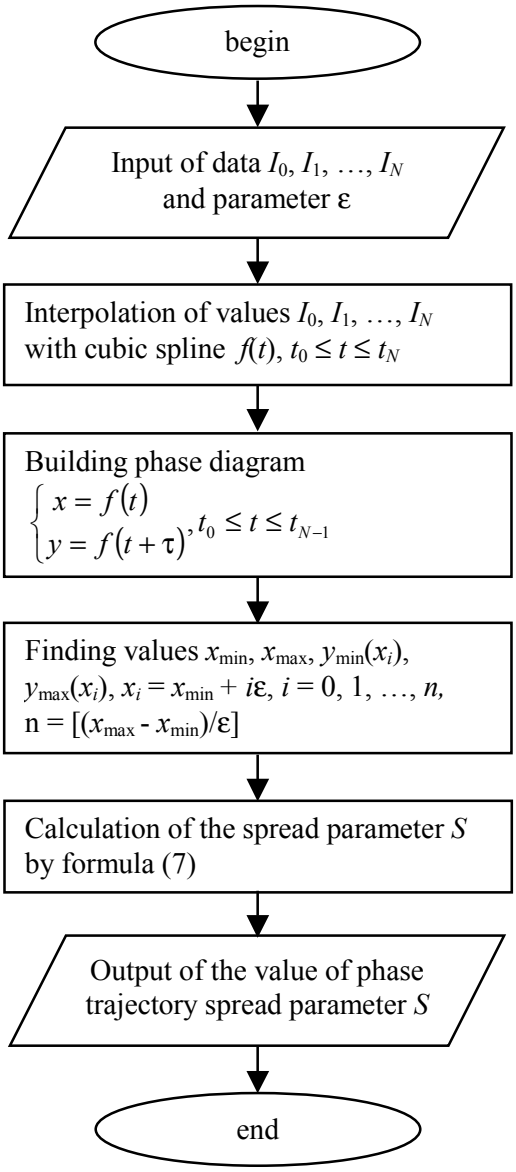

Fig. 2. The flowchart of algorithm for calculation of phase trajectory spread parameter.

Results and discussion

Fig. 3 shows a signal time series ME from blood of patients with gastric cancer, patients with inflammation disease, apparently healthy volunteer patients, and technological control (bidistilled deionized water). The time duration $[\theta_1, \theta_2]$ taken for experimental results is from 0 to 12.5 msec. Measurements were taken every 25 μsec. Fig. 3.2. shows phase diagrams of blood ME. We can see that cancer patients have greater spread parameter *S* than healthy individuals. At the same time, the mechanical activation of a chromatography paper with the bidistilled deionised water showed a different pattern of ME. The spread parameter *S* for technologic control was the least. Our findings allow to view oncogenesis as an expression of impairments of determined chaos of homeostasis.

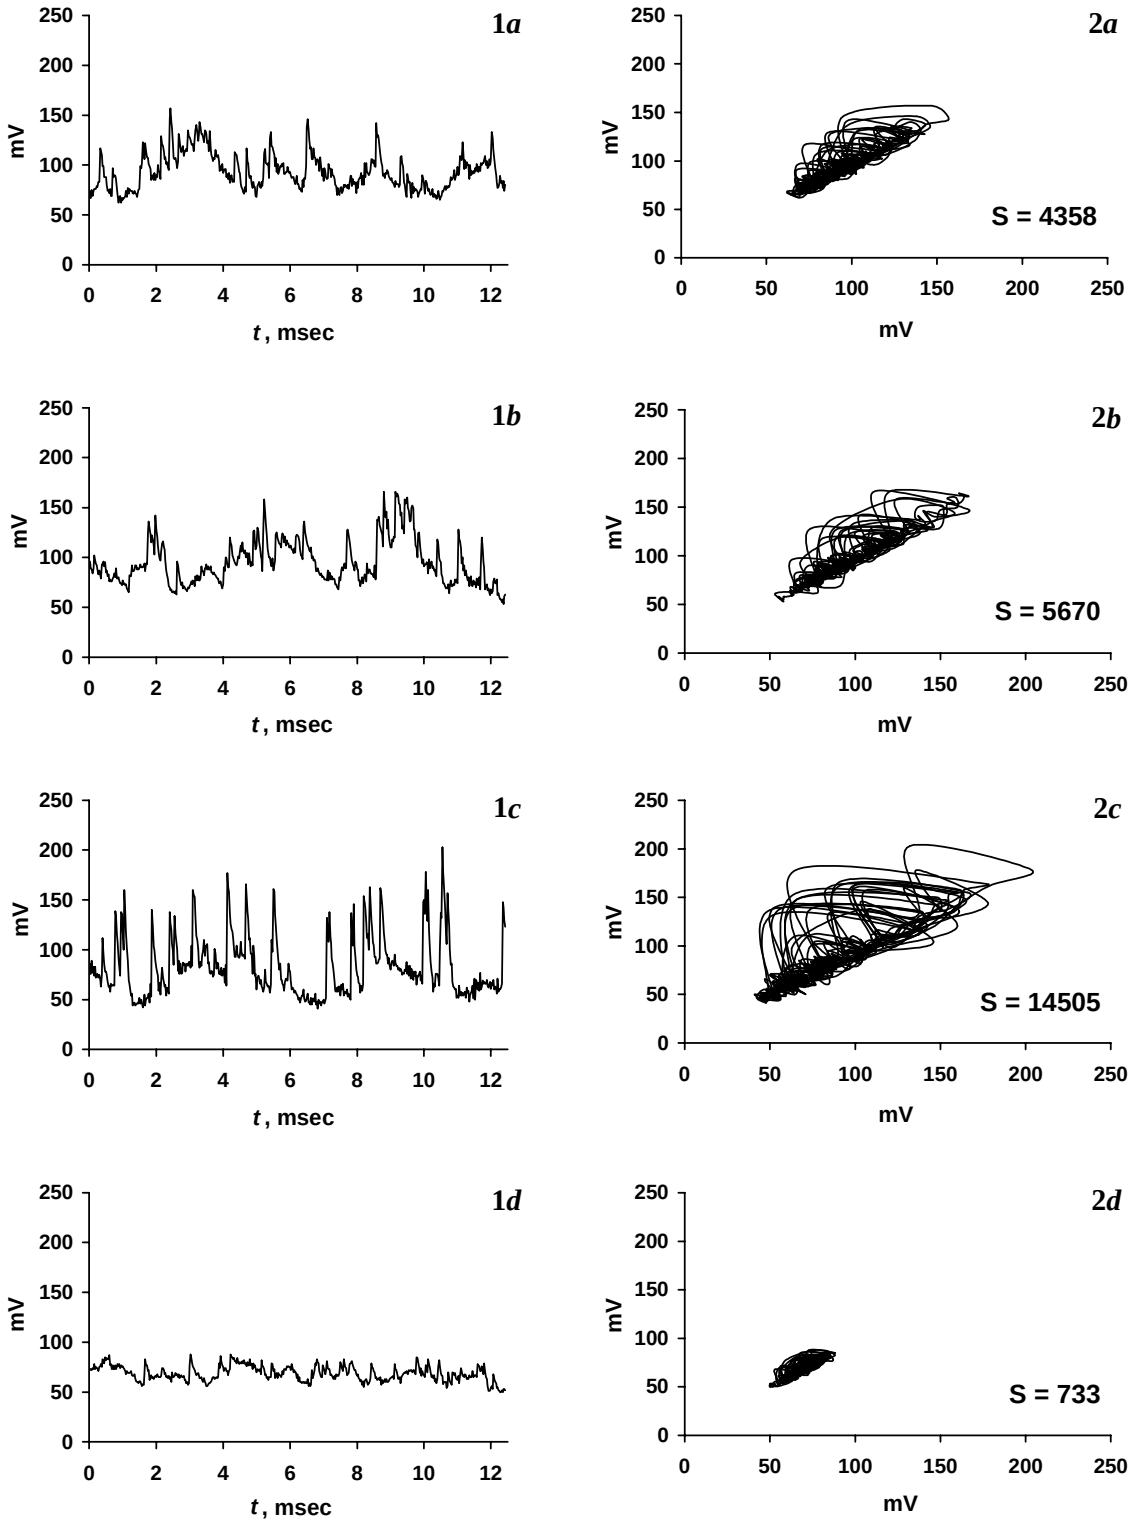

Fig. 3. Time evolution (1) and phase diagram (2) of ME. Blood of patients: *a* – healthy individuals; *b* – inflammatory conditions of gastric mucosa; *c* – gastric cancer. Technologic control: *d* – bidistilled deionized water.

Thus, during a malignant tumor process blood ME dynamics is characterized by higher chaotics. In normal subjects and in inflammations the ME kinetics has an intermediate stable unbalanced nature. One might suggest that manifestation of ME chaos effects the processes of host self-organization for activating determined fluctuations as defensive reactions in inflammatory processes [8] and initiation of self-disorganization in accidental imbalanced fluctuations in oncogenesis [9].

What is the interrelation between the physical and biomedical process? The chaotic structure of blood flow is typical for cancer [10]. Gastric cancer is usually accompanied by disseminated intravascular coagulation. In our early papers we found the effect anticoagulant influence additionally influencing on the autocorrelation function of ME in blood [11]. We suggest that the coagulation has an influence on chaotic topological properties of structural elements of blood and stipulate ME chaos. These results allows to consider oncogenesis as a kind of impairment of a homeostatic deterministic chaos at the molecular level [12].
It seems likely that nature uses such self-disorganization principles not only in blood, but also in other biological systems. The concept of deterministic chaos is biohierarchical for host in contemporary ideas about role of chaos for potential applications in oncology [13–15].

Conclusion

A formalized description utilizing the algorithm for estimation ME chaos in blood parameters can be used in future for estimation and prognosis of treatment efficiency of patients with gastric cancer.

Decomposition Behaviors of Gaseous Cyanides in Non-thermal Plasma and Plasma-Catalyst Hybrid Reactor

S. G. Ryu, M. K. Park, H. W. Lee, and H. B. Park

Agency for Defense Development, Yuseong P.O. Box 35-1, Yuseong, Daejeon, 305-600, Korea

Abstract

The decomposition behaviors of gaseous cyanides in non-thermal plasma and plasma-catalyst hybrid reactor have been investigated with the variation of discharge power, influent concentration of cyanide, humidity of air carrier and packed materials in the reactor. Destruction of cyanides by plasma only process was very difficult compared to that of trichloroethylene. But the destruction efficiencies of cyanides were dramatically improved through packing Pt/alumina bead in the plasma discharge region.

1. Introduction

Because of the strong toxicities of cyanides (ex. hydrogen cyanide and cyanogen chloride), methods for destruction of them are of considerable interest in both industrial and military environments. Currently used systems for military air purification are carbon-based. But the service lives of the carbon-based air purification systems are limited especially for gaseous cyanides, and shortened by degradation of carbon under some environmental conditions such as high humidity and high temperature. Recently catalytic oxidation of gaseous cyanides was studied some extents [1, 2] for the purpose of offering some advantages over the carbon-based systems. Some limited results were reported [3] about the destruction of hydrogen cyanide in a non-thermal plasma reactor. But the detailed results of gaseous cyanides destruction in non-thermal plasma/catalyst hybrid systems are not reported yet.

In this research, the decomposition behaviors of gaseous cyanides (mainly methyl cyanide, CH_3CN) in non-thermal plasma and plasma-catalyst hybrid reactor are investigated with the variation of discharge power, influent concentration of cyanide, humidity of air carrier and packed materials in the reactor. And the reaction kinetic of cyanides in non-thermal plasma condition and the synergic effect of plasma-catalyst in cyanides decomposition are discussed with some experimental evidences.

2. Experimental

A laboratory scale packed-bed-plasma-reactor(PBPR) is adopted for the experiments of gaseous cyanides decomposition in non-thermal plasma conditions. The schematic diagram of the experimental system is illustrated in Fig.1.

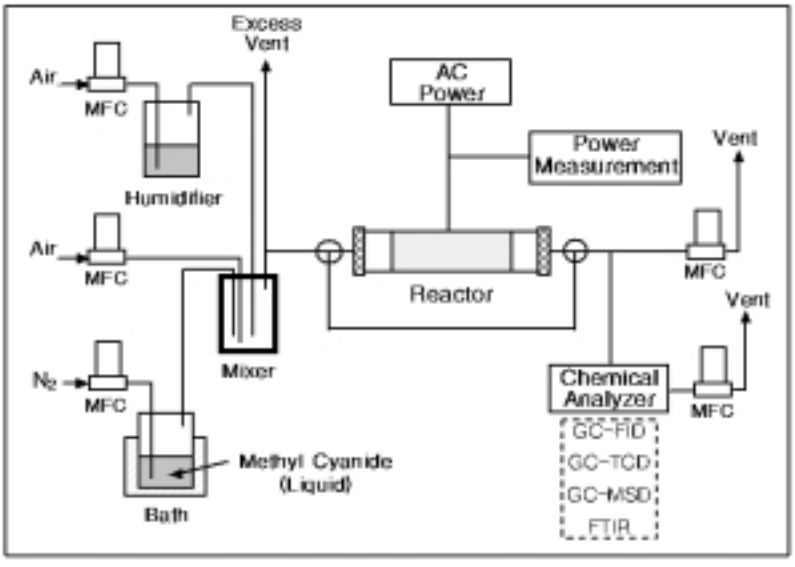

Fig.1. Schematic diagram of the non-thermal plasma apparatus for cyanides decomposition

The system is consisted of a continuous flow gas generation apparatus, a laboratory scale PBPR, a high voltage alternative current power supply, discharge power measuring system, and gas sampling and detection system. The PBPR is made of a quartz tube with the inner diameter of 26 mm and wall thickness of 2 mm. The inside electrode, made of a stainless steel rod with a diameter 1 mm, is aligned horizontally along the centerline of the reactor. The outside of the quartz tube is wrapped by copper foil, which is served as the outside electrode. The reactor is packed with spherical $BaTiO_3$ (diameter, 3-4mm) for smoothing the plasma discharge, and is packed with γ–Al_2O_3 or 0.25 wt% Pt/γ- Al_2O_3 for investigation of the catalytic effect in the non-thermal plasma reaction. The packing volume is 53 cm^3 in the reactor with 10cm length of discharge and 106 cm^3 in the reactor with a 20cm length of discharge. The bed porosity is about 0.4 for all packing. All experiments are performed at atmospheric pressure and relative humidity 8% or 75% condition at 25^{o}C of air carrier. The discharge power in the reactor is measured by a digital oscilloscope (Tektronix TDS 460) and voltage dividers. Gas flows of the system are controlled by mass flow controllers (MFC, Brooks 5850E). The analysis of cyanides concentration in the feed and the effluent of the reactor is performed with a on-line GC(HP 5890 FID), and other byproducts such as O_3 and N_xO_y are monitored with a FTIR or a GC-MSD.

3. Results

In Fig.2, decomposition efficiency of methyl cyanide (acetonitrile) in a $BaTiO_3$ packed bed plasma reactor is illustrated as a function of discharge power with the variation of influent methyl cyanide concentration from 500 to 3000ppm at 2 L/min of dry air carrier.

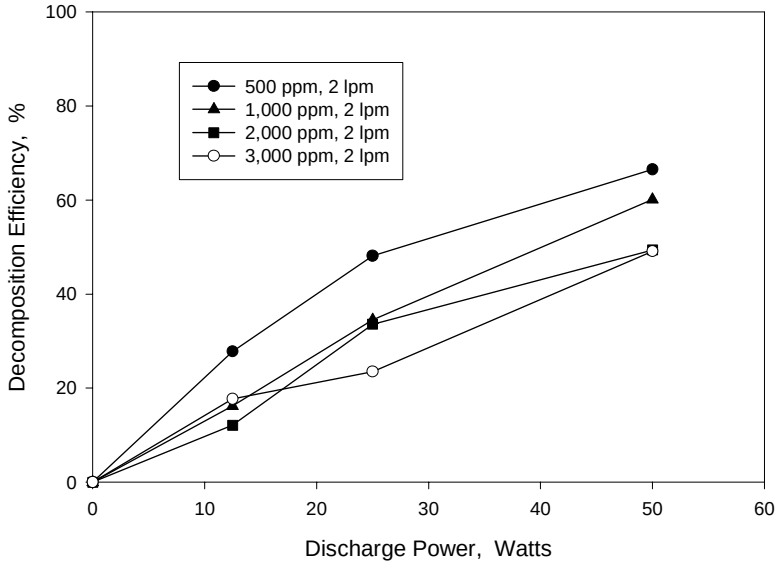

Fig.2. Decomposition efficiency of methyl cyanide as a function of discharge power
Humidity of supplied air flow: RH 8% at 25^{o}C, Length of discharge: 20cm

Because the gas adsorption capacity of $BaTiO_3$ bead could be neglected, the results in Fig.2 represent the only effect of non-thermal plasma discharge. The figure shows that the decomposition efficiency of methyl cyanide is increased when the discharge power is moved to higher energy as expected. And the decomposition efficiencies are slightly higher when influent concentration is lower than the cases of high influent concentration at a given discharge power. Some discrepancies or uncertainties of the data in Fig.2 are seemingly caused by fluctuation of discharge in the reactor. The decomposition efficiencies are slightly above 60% and 40% at 50 watts of discharge power when the influent concentrations are 500ppm and 3000ppm respectively. The differences of decomposition efficiencies of methyl cyanide with the variation of influent concentrations are not significant. Namely, the difference of decomposition efficiencies is only 20% between 500ppm and 3000ppm at the discharge power of 50 watts, but the difference of concentrations between them is six times.

The detected noxious products at the effluent of $BaTiO_3$ packed PBPR are hydrogen cyanide (HCN), O_3,

N_2O, NO_2 and remaining (not decomposed) methyl cyanide. Ozone is detected at the conditions of lower discharge power, N_2O and NO_2 are produced at the conditions of higher discharge power, but the quantitative analyses of them are not attempted. The concentration of produced hydrogen cyanide and remaining methyl cyanide at the effluent of $BaTiO_3$ packed PBPR versus discharge power are shown in Fig.3.

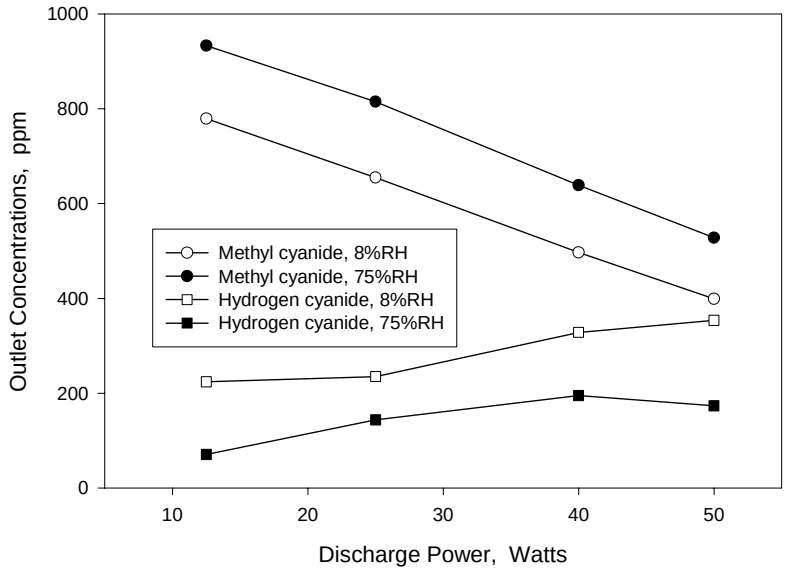

Fig.3. Outlet concentrations of remaining CH_3CN and produced HCN as a function of discharge power
Reactor: $BaTiO_3$ packed PBPR, Length of discharge: 20cm, Inlet concentration of CH_3CN: 1000ppm
Humidity of supplied airflow: RH 8 and 75% each at 25^oC,

The effects of airflow humidity (RH 8 and 75%) on the product distribution and the efficiency of methyl cyanide decomposition are also presented in Fig.3. The results show that the humidity in the airflow affects negatively to the decomposition of methyl cyanide in $BaTiO_3$ packed PBPR; at the higher relative humidity condition, the higher outlet concentration of remaining methyl cyanide is detected. The produced HCN concentration is over 200ppm and below 400ppm at the condition of RH 8% of air carrier, and the concentration of HCN is increasing with the discharge power. But the produced HCN concentration is below 180ppm through the entire range of discharge power at the humidified condition of RH 75%.

The concentration of produced HCN and remaining methyl cyanide at the effluent of Al_2O_3 packed and Pt/Al_2O_3 packed PBPR versus discharge power are shown in Fig.4 and Fig.5 each. In Fig. 4, the concentrations of produced HCN and remaining methyl cyanide at the effluent of Al_2O_3 packed PBPR are reduced to some extent compared to the results of $BaTiO_3$ packed PBPR (Fig.3), but the humidity effect to the decomposition of methyl cyanide is still existed. And the increasing trend of HCN concentration with the increasing of discharge power that is shown at the $BaTiO_3$ packed PBPR is existed only at low discharge powers. On the other hand, the HCN concentration is slightly diminished at the discharge power of 30 and 40 watts than the concentration at the discharge power of 20 watts. Especially, the concentration of remaining methyl cyanide is below 80ppm and the concentration of HCN is only 15ppm at the condition of discharge power 40 watts and RH 8%.

In the case of Pt/Al_2O_3 packed PBPR as shown in Fig.5, the concentration of produced HCN and remaining methyl cyanide are quite low compared to that of $BaTiO_3$ or Al_2O_3 packed PBPR even at the low discharge powers 10 and 20 watts. The outlet concentrations of remaining methyl cyanide are under 50ppm at above 30 watts of the discharge power. Especially, HCN concentration is zero (not detectable with GC-FID at the effluent of the reactor when the discharge power is over 30 watts).

The humidity effect on methyl cyanide decomposition exists evidently below 30 watts in the case of Pt/Al_2O_3 packed PBPR also. But the gap between dried and humidified air carrier is diminished evidently above 30 watts as shown in Fig.5.

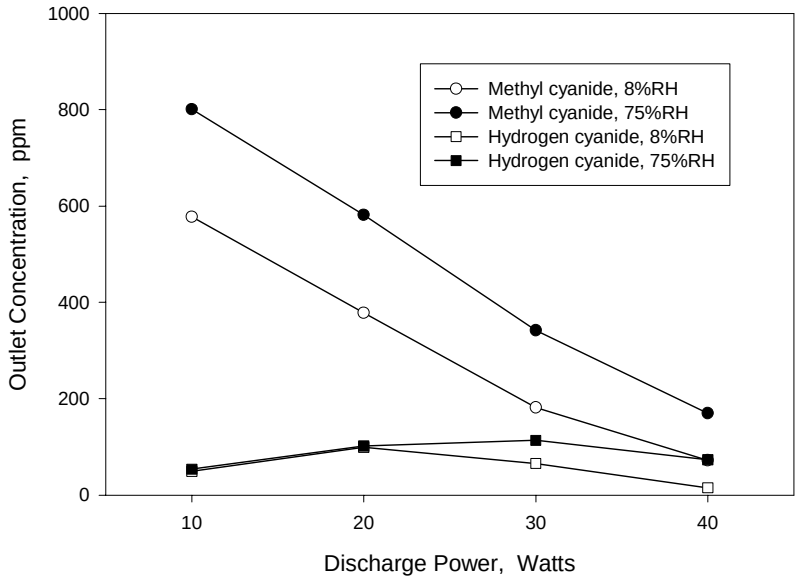

Fig.4. Outlet concentrations of remaining CH_3CN and produced HCN as a function of discharge power
Reactor: Al_2O_3 packed PBPR, Length of discharge: 10cm, Inlet concentration of CH_3CN: 1000ppm
Humidity of supplied airflow: RH 8 and 75% each at 25°C,

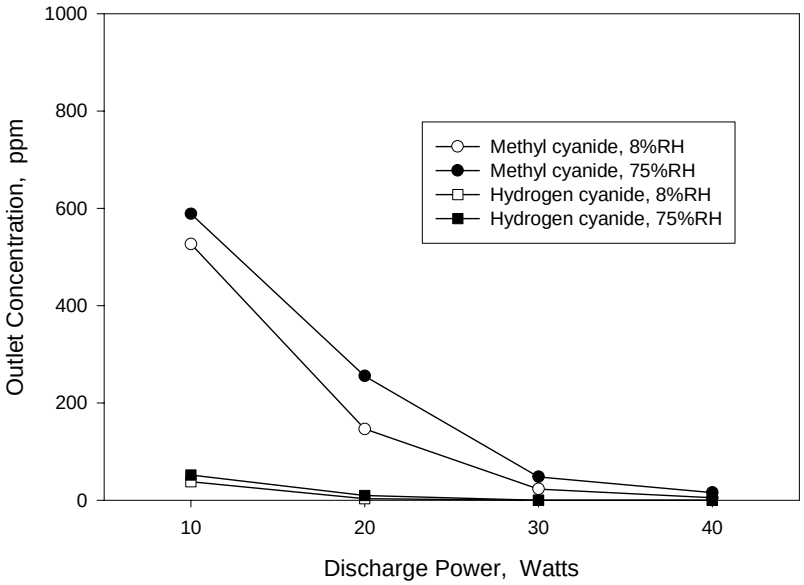

Fig.5. Outlet concentrations of remaining CH_3CN and produced HCN as a function of discharge power
Reactor: Pt/Al_2O_3 packed PBPR, Length of discharge: 10cm, Inlet concentration of CH_3CN: 1000ppm
Humidity of supplied airflow: RH 8 and 75% each at 25°C,

4. Discussions

From the result of Fig.2, it is known that the differences of decomposition efficiencies of methyl cyanide with the variation of influent concentrations are not significant. So, it reflects that the energy efficiency namely, the total numbers of decomposed molecules at a given supplied energy (discharge power) increase with increasing the influent concentration.

To show the difference of decomposition behaviors of cyanides and general VOC materal (here we select trichloroethylene, TCE), the degrees of removal ($[X]/[X]_o$, [X] : outlet concentration of cyanides or trichloroethylene, $[X]_o$: inlet concentration of them) versus specific energy density (SED) are presented in Fig.6.

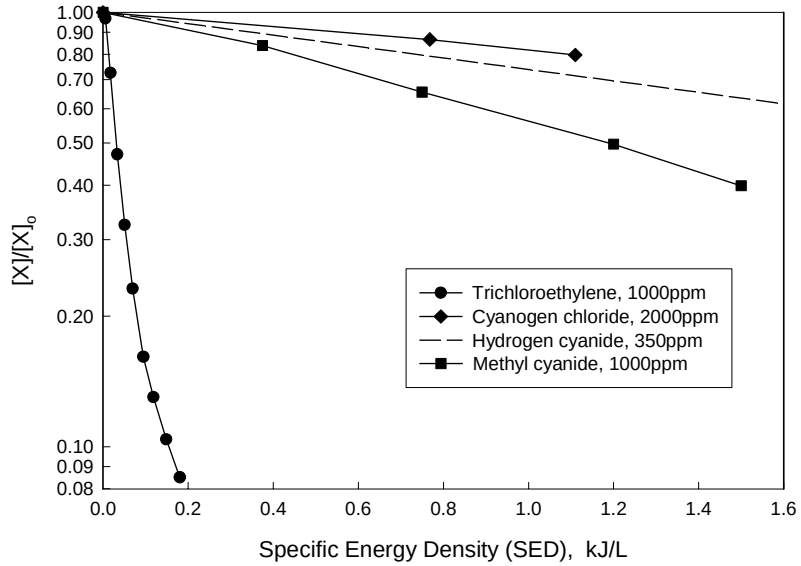

Fig.6. Degrees of removal for cyanides and trichloroethylene in non-thermal plasma reactor
Humidity of supplied airflow: RH 8 % at 25°C

The data for trichloroethylene and cyanogen chloride in Fig.6 are from the previous results of this laboratory [4, 5]. And, the data for hydrogen cyanide are extrapolated from the results of Fraser et. al. [3]. It is confirmed from the data of Fig.6 that trichloroethylene is one of the easily decomposed VOC compound [6] in non-thermal plasma reactor, but cyanides are considerably hard to decompose in non-thermal plasma condition. The question is still remained what makes the big difference in degrees of removal between trichloroethylene and cyanides. Krasnoperov et. al. [7] suggested that the decomposition of molecules on non-thermal plasma condition in air is closely related to the ionization energy of molecular oxygen (12.06 eV). If Krasnoperov's suggestion is effective, the decomposition of a molecule that the ionization energy is lower than that of oxygen molecule will be easy in a non-thermal plasma condition, but the ionization energy of a molecule is higher than that of molecular oxygen the opposite phenomenon will be appeared. The ionization energies of cyanides (cyanogens chloride: 12.49, hydrogen cyanide: 13.8, and methyl cyanide: 12.2eV respectively) are higher than that of molecular oxygen. But the ionization energy of trichloroethylene is 9.45eV that is lower than that of oxygen molecule. So the data of Fig.6 could be explained somewhat with the relation of ionization energy of molecular oxygen. But more data will be needed for the detailed discussion about the reaction kinetic of cyanides in non-thermal plasma condition.

From the results of Fig.3 to Fig.5, it is found that packing materials in the discharge region affect significantly on the decomposition of cyanides. Degree of removal for methyl cyanide versus SED is illustrated in Fig.7 for detailed comparison. In the case of $BaTiO_3$ packed, the destruction of methyl cyanide has linear relation to the supplied energy density, so the reaction order is pseudo-first. It reflects that the decomposition of methyl cyanide in $BaTiO_3$ packed PBPR is the only function of supplied energy density.

Enhancement of the decomposition in alumina and Pt/alumina packed reactor is more significant at the higher energy densities. The relation between degree of removal and supplied energy density is not leaner, therefore it means the order of reaction is changed and is not first anymore. Similar result was observed in the case of the decomposition of cyanogen chloride in PBPR [5] also. The alumina and Pt/alumina packed in the reactor have high specific surface area of around 250 m^2/g.

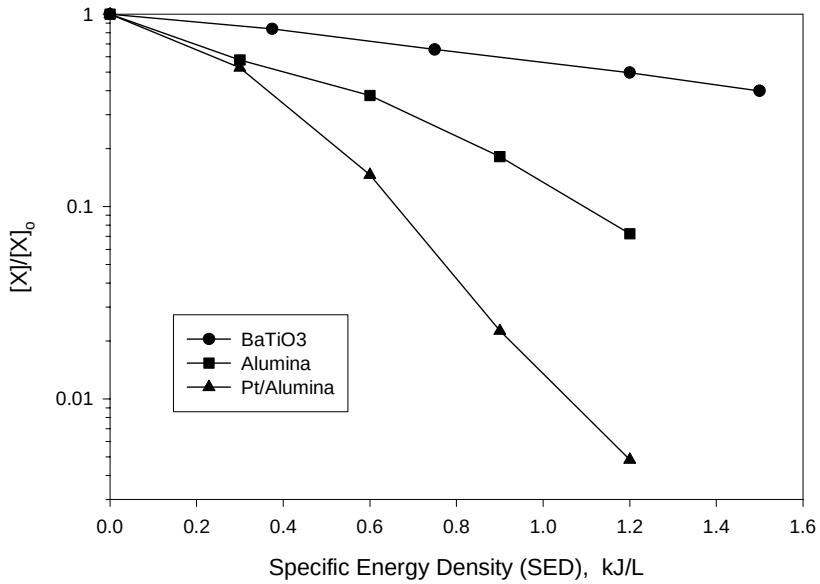

Fig.7. Effects of packing materials on the decomposition of methyl cyanide
Humidity of supplied airflow: RH 8 % at 25^{o}C, Inlet concentration of CH_3CN: 1000ppm

So we could assume that adsorption or (and) thermal catalytic effect in addition to the plasma effect is involved in the destruction of methyl cyanide (and cyanogens chloride) on the alumina or Pt/alumina packed PBPR. From the lower effluent consideration of HCN in Fig.4 and Fig.5, it could be assumed also that the HCN produced by plasma discharge is further decomposed by thermal catalytic effect on alumina or Pt/alumina.

5. Conclusions

The decomposition of methyl cyanide in a non-thermal plasma and plasma-catalyst hybrid reactor is conducted with the variation of discharge power, humidity of air carrier, and packed materials. HCN is produced by the decomposition of methyl cyanide, and the humidity of air carrier affects negatively to the decomposition of methyl cyanide. In comparison with the decomposition of trichloroethylene, cyanides are considerably hard to decompose in non-thermal plasma condition. The reason is explained somewhat in connection with the ionization energy of molecular oxygen. And, thermal catalytic effect in addition to plasma effect appears when alumina and Pt/alumina is packed in the PBPR.

Abstract

The software for data acquisition and processing in spatial resolved optical emission spectroscopy is developed. The experimental set up is controlled by LabView and compatible instrument interfaces . The algorithm of joint data processing is based on principal components method and allows to increase the stability of results of the radial transform and the instrument distortion elimination in the presence of noises. The method is applied to diagnostics of the arc discharge in mercury vapors with addition of thallium.

Introduction

For determination of inhomogeneous plasma local parameters, such as ground state and excited atom and electron densities, atomic and electronic temperatures, the great array of experimental data is to be collected, which contains spatial, spectral and temporary distribution of a source surface radiance. Some image spectrometers can be used for this purpose [1], but they, as a rule, have the software unauthorized for the user. The set up and software for local plasma spectroscopy based on LabView and compatible instrument interfaces is described here. It is built of separated modules and can be easily adapted for any set of the spectral equipment and any modern operational environment. In the given case the concrete variant of an installation includes scanning diffraction spectrometer and spatial scanning block, it allows to choose the certain moments of time for radiation measurement, if a source characteristics are periodically varying. The received experimental data array is processed by rational joint algorithm, which allows to decrease the processing time as well as the noise influence to results.

Experimental set up and software

The set up for local plasma spectroscopy is based on large aperture diffraction spectrometer with dispersion 0.05nm/mm in the range 300-800 nm. Spectral scanning is carried out by step motor, one step corresponds to $\delta\lambda$=0.015nm. Special spatial scanning device with step motor and mirror system allows to receive the source surface radiance distribution in direction perpendicular to system optical axis. The step of spatial scanning is δx= 0.0076 mm in the range ±3cm. Light intensity is measured by photomultiplier, amplifier with time resolution less than 10^{-3} c and analog- digital converter (ADC). As an instrument interfaces in automated experiment the CAMAC crate is used. It contains two modules for stepper motors control, modules for scanning begin - end control and two analog- digital converters: one for light intensity measurement and the other for discharge voltage measurement. It allows to carry out the intensity measurements in chosen phases of current period.

The software of the experiment is based on LabVIEW system and connected with CAMAC by special program driver. In our case it runs under the control of the IBM-compatible computer with OS Windows-98 but it is known that virtual instruments, developed by LabVIEW may be easily adapted to other modern operational environment (e.g. Macintosh, Linux [2]). The software for data acquisition in local plasma spectroscopy consists from separate modules mounted as virtual instruments (VI) The software includes:

a) VI for spectral device calibration on wave lengths by a source with a known spectrum ("Spectrum calibration").

b) VI for the photodetector sensitivity calibration by the registration of a certificated temperature lamp spectrum. ("Sensitivity calibration").

c) VI for spectrum scanning in the given spectral range with the given step ("Spectrum scanning"). It is used on the preliminary stage of experiment for choosing spectral lines for further analysis and then for measurement of the spectral device spread function. The example of the module control panel one can see in Fig. 1.

d) VI for spatial gating at a given wave length ("Spatial scanning"). It is used for measurement of surface radiance values. First of all the spatial point, corresponding to the maximum of radiance is found. This point is accepted as the center of discharge (x=0). The measurement of radiance are carried out for the center and other points x_k (k=1, 2...m-1), corresponding to m equidistant positions of the spatial gating system.

e) VI for automated spatial and spectral scanning in the given spectral and spatial intervals and the definite phase of current period. ("Spectrum -spatial scanning").
f) Module of data loading for subsequent analysis ("Spectrum load/Analysis"). This module allows to load any data, received by other modules and to derive various information from a spectrum (e.g. maximum positions and values, line widths) by LabVIEW tools for graphic processing (scaling and cursor positioning). If the photodetector sensitivity calibration have been done this module transforms photodetector readings $F(\lambda, x)$ to spectral surface radiance values $b(\lambda,x)$. It allows also to join some arrays, corresponding to different spectral ranges and different time moments (but spatial points must be the same), in common array for joint processing , calculate the covariance matrix of this array, find its eigenvalues and eigenvectors (there is the standard LabVIEW module for this purpose "EigenValues & Vectors.vi"), and calculate the projections of each spectral point to all eigenvectors. It is the essential part of the joint processing algorithm, which will be described in detail in the next section.
This module is also used for calculation of estimator S^2 of experimental random error by using data corresponding the same spectral, spatial and phase points received in several recurring experiments. In this estimator not only instrumental noises but also light source possible instability are taken into account.
g) Module of the remote access server. It is used for remote control of experiment (mainly in student laboratory training).

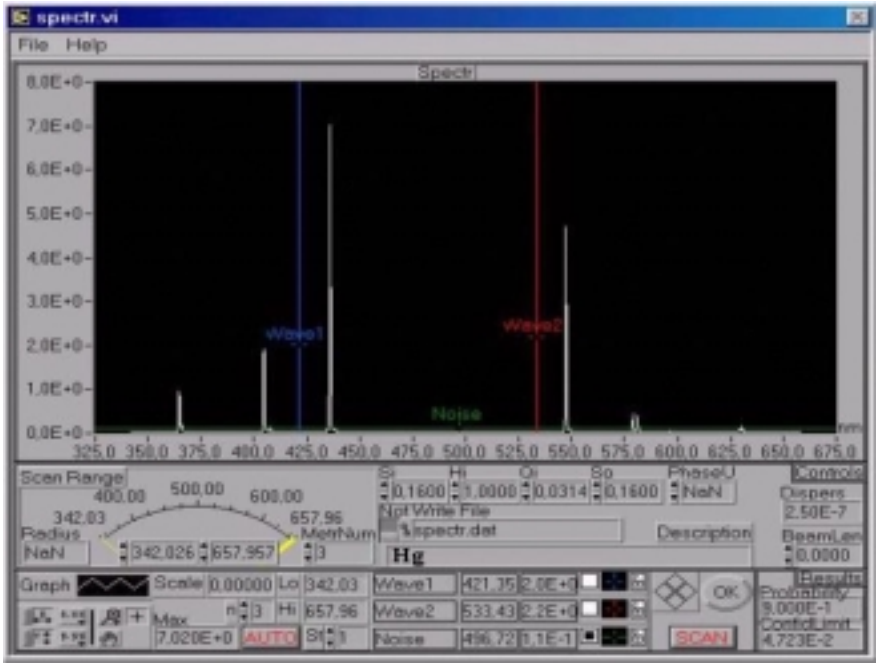

Fig.1 Control panel of VI "Spectrum scanning".

3. The data processing algorithm

For investigation of one section of cilindrically symmetric plasma the two-dimensional array of reading $F(\lambda_i,x_j)$ corresponding to spectral surface radiance spectral $b(\lambda_i,x_j)$ have to be measured along a series of chords, perpendicular to plasma axis (x_j- the displacement of chord from plasma centerline, λ_i - wavelength of spectral point inside the profile). From the array $b(\lambda_i,x_j)$ the array of spectral emissivities $\varepsilon(\lambda_i,r_j)$ has to be reconstructed and spectral line profiles $\varepsilon_j(\lambda_i,)$ for distance r_j from the section center have to be found. These profiles may be used for the determination of plasma parameters in this spatial point. The reconstruction of emissivity $\varepsilon(r)$ from measured intensity $b(x)$ is known as Abel's inversion

$$\varepsilon_\lambda(r) = -\frac{1}{\pi}\int_r^L \frac{db_\lambda(x)}{dx}\frac{dx}{\sqrt{(x^2-r^2)}}. \qquad (1)$$

Here L is the discharge tube radius.
It is so called improperly posed problem and the solution is impossible without using of *a priory* information about function $\varepsilon(r)$. The quantity of this information is to be in accordance with the level of

experimental noise. The rational algorithm of Abel's inversion, when a big data array is collected, was proposed in the paper [3]. But it was not taken into account there that measured line profiles $F(\lambda_i,x_j)$ may be distorted by the spectrometer spread function.

$$F_{out}(\lambda) = \int F_{int}(\lambda') \cdot g(\lambda - \lambda') d\lambda' . \quad (2)$$

$g(\lambda)$ is the spectrometer spread function , F_{out} is the observed line profile, F_{int} is the true line shape, it is proportional to $b(\lambda)$. The elimination of instrument distortion is possible, for example, by use of the convolution theorem:

$$\Phi\{F_{out}(\lambda)\} = \sqrt{2\pi}\Phi\{F_{int}(\lambda)\} \cdot \Phi\{g(\lambda)\} , \quad (3)$$

where Φ is Fourier transform operator. If $g(\lambda)$ is known we simply have to divide Fourier transform of F_{out} by Fourier transform of g and restore F_{int} by the inverse Fourier transform of the result. But it is also an improperly stated problem, its solving is very sensitive to experimental data noises. The algorithm proposed here significantly increases the result stability in the presence of experimental data noises, when it is necessary to solve at once both improperly stated problems. The algorithm is based on collective processing of large data arrays of readings $F(\lambda_i,x_k)$, measured along a series of chords, perpendicular to plasma axis. (If we are interested only in line shapes but not in the intensities we may use the array $F(\lambda_i,x_k)$ instead of $b(\lambda_i,x_j)$. We only have to be sure that the photodetector system is linear. If it is necessary, the coefficient of proportionality of readings to intensities may be introduced at the final step of calculation because all the following data transformations are linear.)

For the first step of algorithm one has to calculate the covariance matrix A of the array of profiles $F(\lambda_i,x_k)=F_{ik}$, corresponding to one or , perhaps , several spectral lines and time points.

$$A_{k,j} = \frac{1}{n}\sum_{i=1}^{n}(F_{i,k} - \overline{F}_k)(F_{i,j} - \overline{F}_j) , \quad (4)$$

where n is a number of spectral points, $\overline{F_k} = \frac{1}{n}\sum_{i=1}^{n} F_{i,k}$ is the average spatial vector .

Then the array F_{ik} may be described by a model:

$$F_{i,k} = \overline{F}_k + \sum_{p=1}^{q} M_{i,p} U_{p,k} \quad (5)$$

where U_p are eigenvectors of the covariance matrix A. and $M_{i,p}$ are the projections of i-th spectral point to eigenvector U_p

$$M_{i,p} = \sum_{k=1}^{m}(F_{i,k} - \overline{F}_k) U_{p,k} \quad (6)$$

As a consequence of mutual dependence of elements of F the number q of significant eigenvectors of A is less than m. The eigenvector is significant if corresponding eigenvalue is no less than S^2. Before further processing one has to prove that model (5) with m(q+1)+qn coefficients is adequate. For this purpose the Fisher criterion has to be used [4].

Let us note that vectors $\overline{F}$ and $\mathbf{U}_p$ depend only on spatial coordinates and projections $M_{i,p}$ depend only on spectral points. The operations of radial transform (let us denote the corresponding operator $\boldsymbol{R}$) and elimination of instrument distortion (let us denote the corresponding operator $\boldsymbol{C}$) are linear and applied to different variables. So instead of the instrument distortion elimination from each profile $F_k(\lambda)$, and then Abel inversion for each wave length λ_i for the next steps of algorithm one can eliminate the instrument distortions from projection $M_{i,p}$, then fulfill the radial transform for $\overline{F}$ and $\mathbf{U}_p$ and restore the required profiles $\varepsilon(\lambda_i,r_j)$ in various plasma points r as:

$$\varepsilon(\lambda, r) = \boldsymbol{R}\{\overline{F}\} + \sum_{p=1}^{q} L_p(\lambda)\, \boldsymbol{R}\{U_p\}, \quad (7)$$

where $L_{ip} = \boldsymbol{C}\{M_{i,p}\}$ are the results of instrument distortion elimination from parts of projections $M_{i,p}$, corresponding to the each spectral line.

4. The example of application of experimental technique and data processing algorithm

The application of described experimental technique and data processing algorithm is illustrated in the case of diagnostics of high pressure arc discharge in mercury vapors with the addition of thallium iodide. The observed array F contains 558 rows and 10 columns. The rows from i=0 to i=198 correspond to thallium line 553 nm ($9^2P_{3/2} \rightarrow 7^2S_{1/2}$) and first phase of current period, i=199 - 397 correspond to the same line and second current phase, i=398 - 477 correspond to mercury line 577 nm ($6^3D_2 \rightarrow 6P_1$) in first phase of current period, i=478 - 557 correspond to the same line and second current phase. Each column corresponds to one spatial position (m=10).

The comparison of eigenvalues of A with estimator S^2 shows that in our case only q=2 eigenvectors are significant and model (4) with this two eigenvectors is adequate. In Fig.2 one can see the average vector $\overline{F}$ and eigenvectors of covariance matrix U_1 , U_2 before and after radial transform. (relative units corresponds to units in which the ADC readings were expressed).

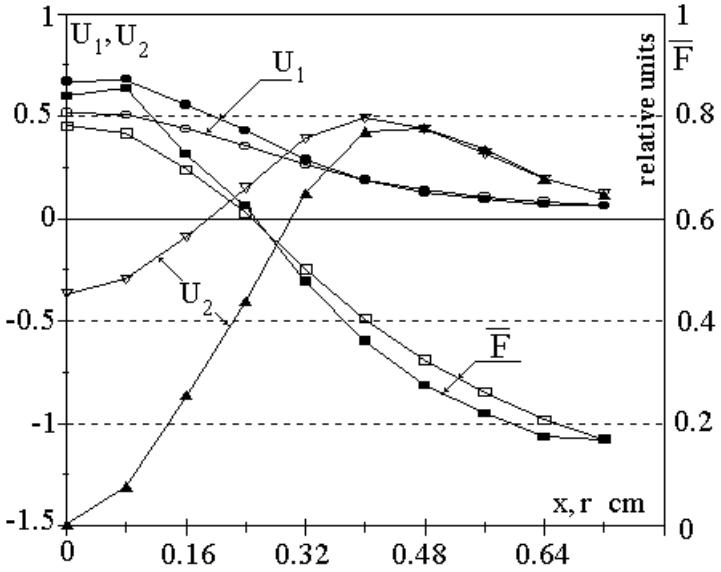

Fig.2 Average vector $\overline{F}$ and eigenvectors of covariance matrix U_1 , U_2 before (light markers) and after (black markers) radial transform

The spread function was received in experiment with the cadmium spectral lamp. The line widths in this lamp are less than 0.001nm. The computer program for elimination of instrument distortion was described in [5]. It was shown that the algorithm is very sensible to experimental noises, even to limited accuracy of computer calculation. The stability of the results may be reached by multiplying Fourier transform of restored distribution by special function, which is equal to 1 inside specified part Q of full spectral range Ω ($\Omega = 2\pi/\delta\lambda$, $\delta\lambda$ is the step of spectral scanning) and exponentially decreases to the range ends.

Q depends on noise level and ratio of output and spread function widths. Very small Q leads to additional distortion of the restored function.

In each case the appropriate value Q may be selected by simulating experiment. In Fig.3 the results L_{ip} of instrument distortion elimination from parts of projections $M_{i,p}$, corresponding to the each spectral line, are presented.

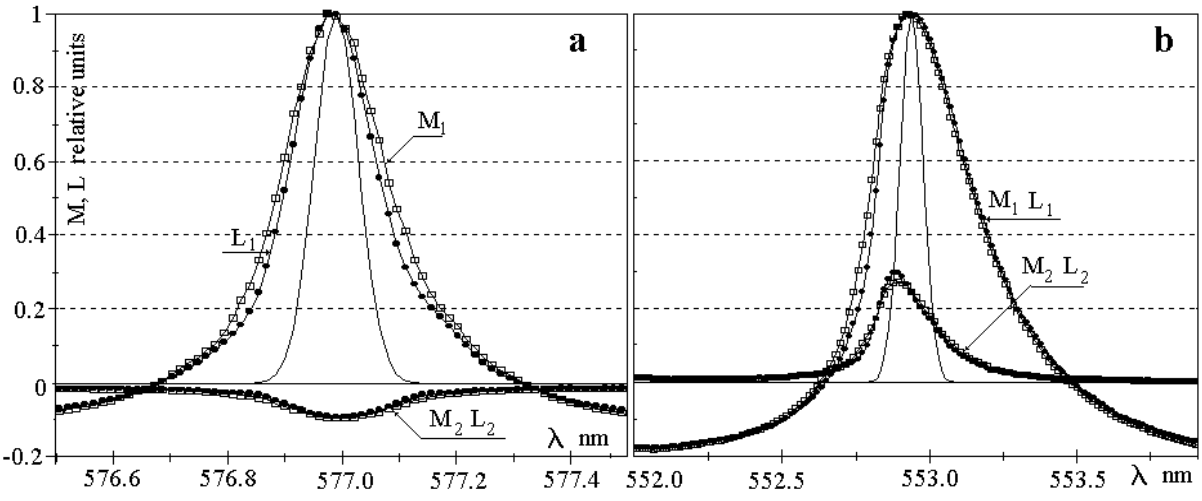

Fig.3. The projections to eigenvectors for mercury (a) and thallium (b) spectral lines before (light markers) and after (black markers) elimination of instrument distortions. Thin line without markers is the spread function.

For the wider thallium line the instrument distortion is small and L_{ip} practically coincides with $M_{i,p}$. The restored line profiles for one current phase are presented in fig 4.

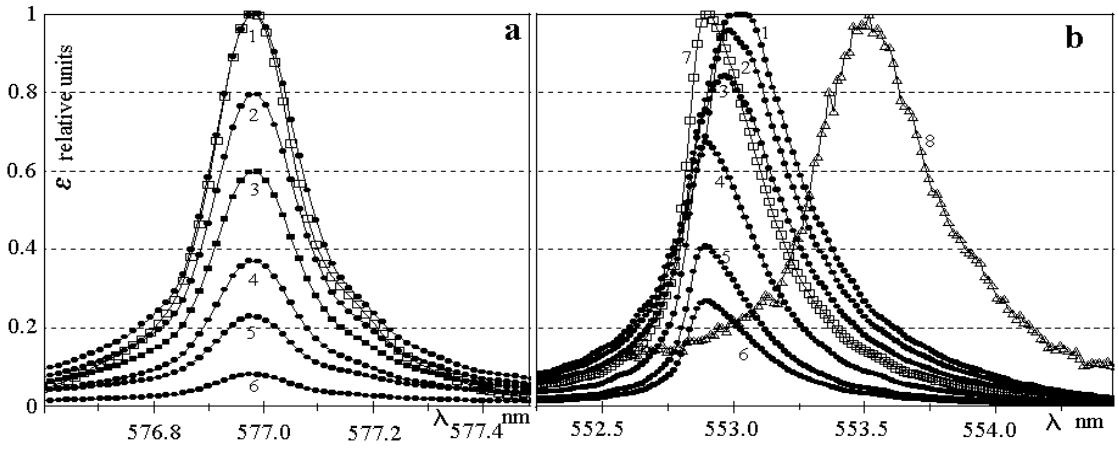

Fig 4. Restored line profiles of mercury (a) and thallium (b) spectral lines for different spatial points 1-r=0, 2-r=0.16cm, 3- r=0.32cm, 4- r=0.48cm, 5-r=0.64cm, 6-r=0.72 cm. Light markers (curve 7 in "b") denote the profile for r=0.72 cm, these curves are standadized to 1 in maximum to demonstrate visually the line shift in comparison with the case r=0. Curve 8 in "b" -the result for r=0 of "individual" processing of experimental array of thallium line profiles: elimination of instrument distortion from each of 10 profiles and radial transform from each of 199 spectral points by using the same programs as for joint processing. (for clearness the maximum of this curve is shifted from true position).

The mercury line 577 nm broadening is resonance [6]. So there are no shifts in profiles corresponding to different spatial points and different time moments. Line width is almost constant for different spatial points. It is in accordance with our previous work, where by the analysis of plasma interference data it was shown that in such sources mercury atoms density is almost constant over the most part of the arc section and changes sharply only near the source wall [7]. By this line width we can estimate mercury atoms density in the first current phase as $N_{Hg}=(6.8\pm0.2)\cdot10^{18}cm^{-3}$.

The thallium line 553 nm is broadened mainly by Stark-effect, it leads to appreciable shifts of profiles in different spatial points and different current phases. The broadening by Van-der-Waals interaction with Hg atoms , estimated with above-mentioned N_{Hg} value, is less then 10% from full line width. It is within of accuracy of the known Stark- broadening constant [8], therefore we attributed the experimental line width and shift to Stark- broadening and estimated electron density in the arc center in the first current phase as $N_e(r=0)=(1.0\pm0.1)\cdot10^{16}cm^{-3}$ and $N_e(r=0.72cm)=(7.5\pm0.5)\cdot10^{15}cm^{-3}$ (The radius of the source L=1cm).

Abstract

The experimental installation and software for studying the ordered dusty plasma structures in the direct current glow discharge were developed, which provide the simultaneous control of the electrical and spectroscopic parameters of plasma and dusty cloud images registration. The area of ordered structure existence has been found. The dependence of interparticle distance on the gas pressure and current and the influence of particles on spectral line intensities and spatial distribution have been investigated.

1. Introduction

The ordered dust structures in the plasma, formed by the interaction charged macro particles with each other, components of plasma and an environment, represent significant interest for fundamental physics and its applications. Problems of their synthesis, controlled modification and destruction are far from decision. The effects of "crystallisation", melting of "crystals" and "evaporation" are accepted to connect with Coulomb parameter [1].

$$\Gamma_p = \frac{Z^2 e^2}{akT_g} \exp(-a/r_D) \qquad (1)$$

Here e is the electron charge, Ze is the particle charge, a is the interparticle distance, k is the Boltzmann constant, $T_g$is the particle temperature, r_D is the Debye length.

The condition of "crystallisation" Γ_p>170 and more precise condition Γ_p>54/(a/ r_D) $^{1.38}$ were received by theoretical calculation and simulating experiments [2,3]. However, one cannot use these conditions for prognostication of plasma crystal forming, because even if the plasma parameters, determining r_D, are known, Z may be estimated from particle size ant electron temperature [4] and T_g is accepted to be equal to plasma atom temperature, the interparticle distance cannot be predicted before experiment. So one can say that in spite of a lot of papers devoted to dusty plasma the relations between plasma parameters, dust particle substance and properties of ordered dusty structure have not been investigated in detail. Therefore the experimental research of dusty ordered structure characteristics remains the problem of today.

2. The experimental set up and software

The scheme of experimental set up is presented in Fig.1

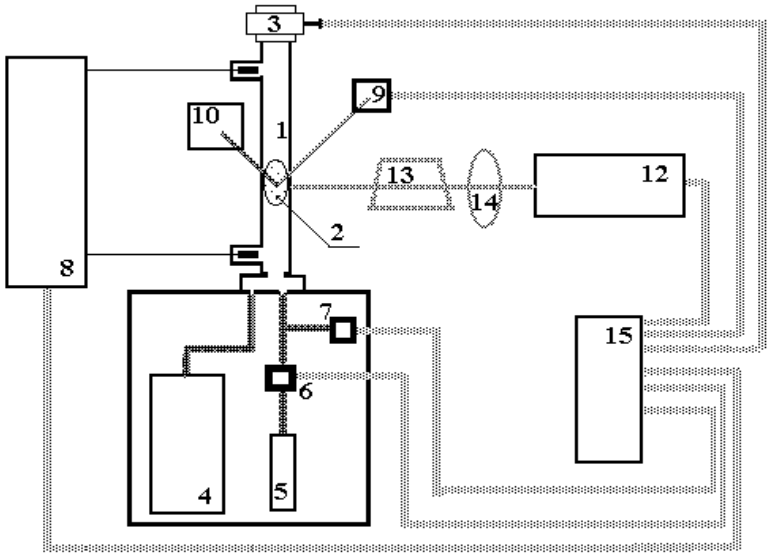

Fig. 1 Experimental set up for researches of dusty structure in the glow discharge

Here (1) denotes the discharge tube with dusty cloud (2), (3) is the system for injection of particles, (4)is the vacuum pump , (5) is the gas cylinder with the system of gas injection control (6) and pressure control (7). (8) is the system of power supply and discharge electrical parameters control. (9) is CD camera for dusty cloud image registration when the structure is illuminated by "laser knife" or other light source (10) (we use also flash lamp and mercury high pressure lamp with addition of thallium iodide). (12) is the spectral system based on diffraction spectrometer with resolution of 0.015nm in the range 300-800 nm. The photo-electric registration of spectrum is possible in two variants: single channel - with photomultiplier and multichannel - with CCD matrix. The lens (14) draws the discharge image to the spectrometer input slit, the direction of the slit is parallel to the direction of discharge tube axis, the Dovet prism (13) is used for turning of the tube image perpendicularly to slit direction when the spatial distribution of spectral line intensities along the tube diameter are investigated.

All experimental devices are controlled by personal computer (15) with instrument interfaces based on LabPC board, CAMAC equipment and LabView graphical enviroment, which provides the simultaneous control of optical and electrical parameters of the plasma, synchronized with the moment of particles injection. (In Fig.1 black lines are electrical channels, thin grey lines are optical channels and thick grey lines are information channels). In Fig.2 the panel of the virtual instruments for control of discharge electrical parameters is presented. One can see a leap of voltage and current at the moment of particle injection.

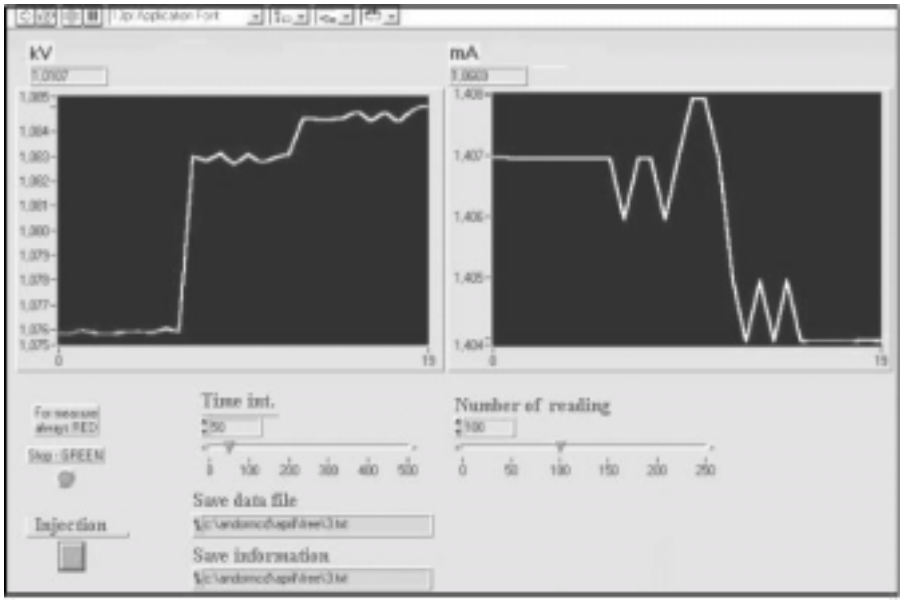

Fig. 2. The virtual instruments for control of discharge electrical parameters.

CCD matrix allowed to register simultaneously the spectral interval of 20 nm before and just after injection of particles. The same interval was registered also in several seconds after injection when all plasma parameters have been stabilized. In Fig.3 virtual instruments for control of the spatial distribution of the spectral line radiance is presented.

For registration of structure images digital photo and video cameras were used. Some observed dusty structures are shown in Fig. 4.

The software for the analysis of the 2D and 3D structure images in plasma has been developed. The program builds the histogram of distances between particles (i.e. experimental analogue of the binary correlation function) if the image of structure is a black-and-white graphic file. The program allows to delete some noise of the image, and in a case of a very "bad" picture (for example, the glass spheres are poorly appreciable on the background of plasma radiation), when the computer processing is impossible, one can "mark" particle images manually.

The program window for menu item "2D image processing" is shown in Fig.5. The number of peaks of binary correlation function is the criterion of structure classification as "crystal", "liquid" or "gas"

The program also allows to restore 3D distribution of particles, if not less than three projections are received.(But this function of software is tested now only in simulating experiment).

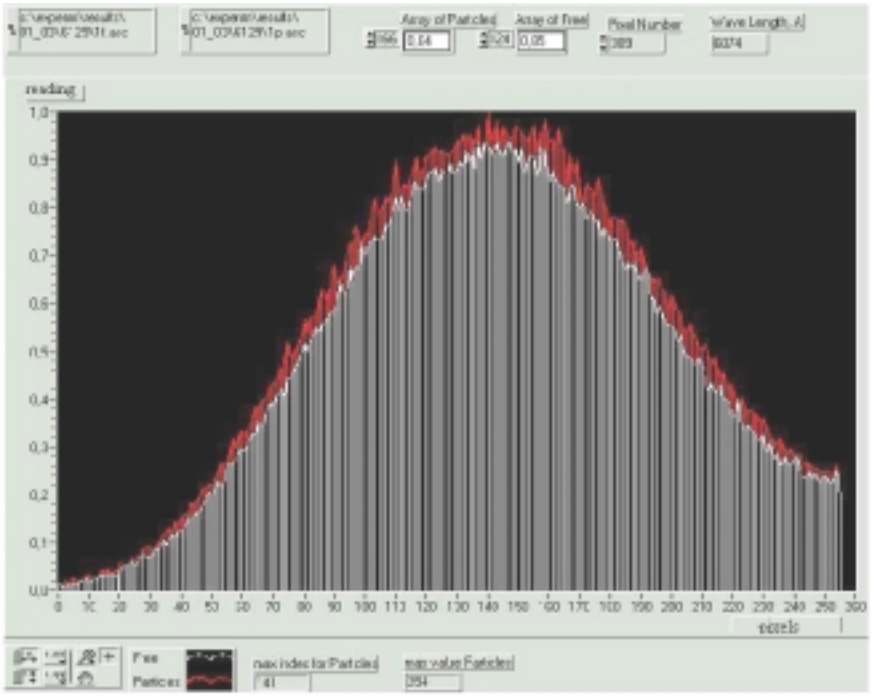

Fig 2. Spatial distribution of neon spectral line (674 nm) before (white) and after (red) particle injection

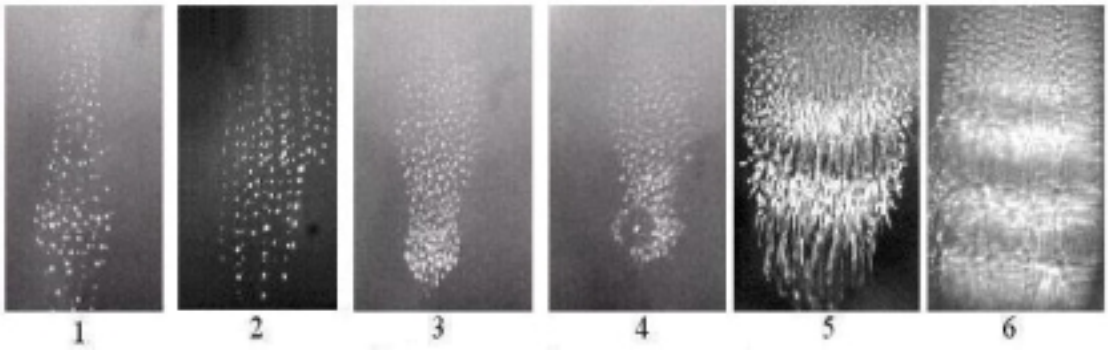

Fig. 4. The examples of observed dusty cloud images in striated glow discharge: 1-5 Al_20_3 in neon (1-P=0.4 Torr, I=0.3mA; 2-P=0.5 Torr, I=0.4 mA; 3- P=0.7 Torr , I=0.5 mA; 4- the unique picture , the condition is the same as in the case 3; 5- dusty-acoustic waves, P=0.7 Torr, I=2.3 mA). 6- dusty-acoustic waves in the cloud of Zn particles in neon, P=1.3 Torr, I=1.5 mA.

3. Experimental conditions and results

The direct current striated glow discharge, was initiated in Ne, Ar, N_2. Discharge tube was established vertically, had an internal diameter 2.6 cm and space gap between electrodes 45 sm. Dust macro particles with diameter from 5 up to 60 microns were injected from the top end of the discharge tube.

Different substances were used: metal (Zn), semiconductor (VN), dielectric (Al_2O_3 and glass micro spheres)

The aforementioned experimental set up has allowed us to establish the areas of existence of various dusty ordered structures. For example, in neon for Al_2O_3 particles with the size up to 5 microns the structure was observed in a range of currents (I) 0.4-3 mA and pressures (P) 0.26-1.4 Torr.(Fig.6).

In nitrogen the range of currents for structure existence is wider than in neon (0.1-8 mA), and the range of pressure is narrower (0.2-0.5 Torr). The same range of conditions for structure existence in neon, as for Al_2O_3 , was defined for VN particles , zinc and for glass spheres. It has been revealed, that the vacuum conditions and the gas purity are very important for ordered dusty structures properties. Therefore careful gas

and particles cleaning is necessary, as well as continuous control of pressure in discharge volume and spectral control of gas clearness during the experiment.

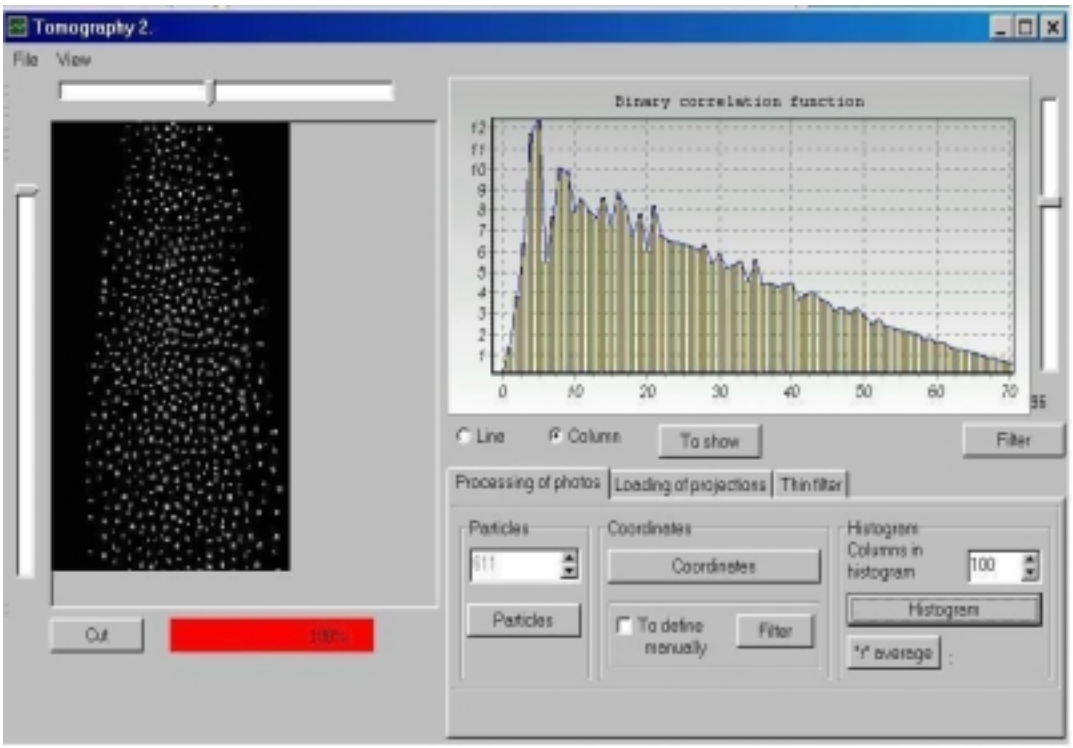

Fig.5. Main window of 2D dusty cloud image processing

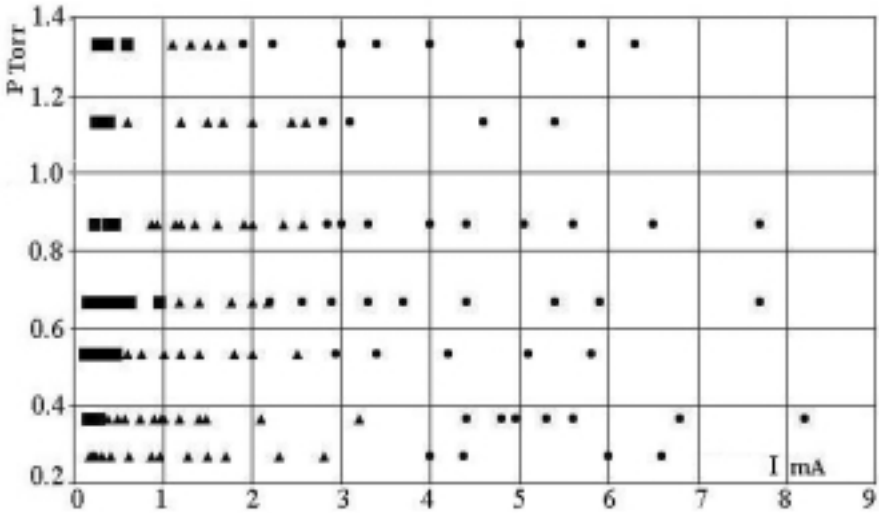

Fig. 6. The area of dusty structure of Al_2O_3 particles in neon: rectangles-"crystal", triangles -"liquid", circles-"gas".

It have been shown that mean distance between particles increases as a rule with the discharge current. The dependence of mean interparticle distance (R) on discharge current (I) was investigated in detail for Al_2O_3 particles in neon. It was shown that for definite pressure this dependence may be approximated by linear function

$$R=bI+c, \qquad (3)$$

where b noticeably depends on pressure.(Fig.7)

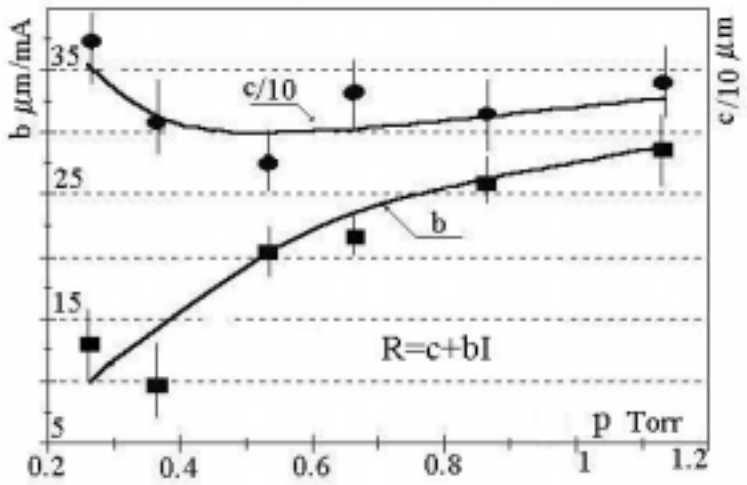

Fig. 7 The dependence of interparticle distance on current (I) and pressure (p) for Al_2O_3 in neon

We have investigated also the dependence of plasma spectroscopic characteristics on dust particle presence. Whereas the changes of discharge electrical parameters after particle injection are less the 1%, the changes of spectral line intensities are above the noise level [5]. The dependence of line intensity change after the injection of Al_2O_3 particles on the discharge current in neon discharge with pressure 0.4 Torr is presented in Fig. 8. Here $\Delta F = F_p - F$, where F_p is the photodetector reading for given spectral line in the presence of particles and F is the reading for the same line without particles in the discharge. Values $\Delta F/F$ are averaged over 10 spectral lines corresponding to transitions $2p^53p$-$2p^53s$ in neon atom. The change of the intensity of lines may be explained by influence of dust particles on the electron energy distribution function. The spatial distribution of spectral line intensity also depends on the presence of particles. The statistic processing of array of spatial radiance distributions has showed that the spatial distribution width becomes wider by 3% after the injection of particles. These results shows that in spite of a very low particle density (about 10^4 cm^{-3}, when electron density in our condition is about 10^8 cm^{-3}, and atom density is about 10^{16} cm^{-3}) not only dusty structure properties depends on plasma conditions but plasma characteristics also depends on dust presence.

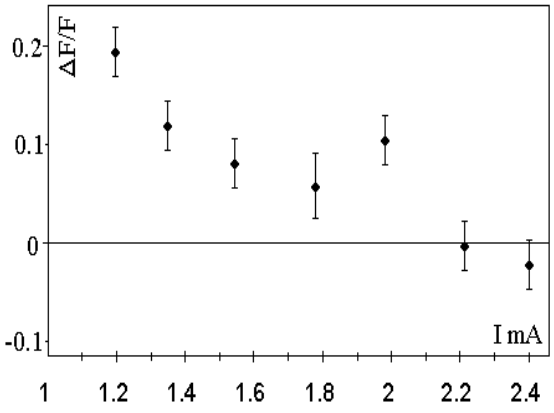

Fig. 8 The dependence of relative intensity change on the discharge current

So the complex investigations of such objects have to be continued.

Abstract
The subject of the investigations was the process of deposition of thin organo-silicon films on polycarbonates in the pulsed dielectric barrier discharge. Thin films were deposited from gas mixture of helium, oxygen and tetraethoxysilane at the atmospheric pressure. The deposition rate decreased with increase of O_2 concentration was observed Two separately sets of the deposition rate was obtaining for two different ranges of discharge gap, 0.2-0.5 and 0.75-1.5 mm.

1. Introduction

Polycarbonates (PC) are found in number of products from essential medical devices (3%), electronics equipments (22%), cars (9%), building and construction applications (32%) as well as consumer goods. PC is extensively used in optical data storage applications, safety equipment and lightweight, transparent roofing in building and construction. The global market for PC was 1,800,000 tons in 2000 and growth with an average growth rate of approximate 10% with new applications developed [1]. PC is a high quality, engineering plastic with a unique combination of properties including strength, lightness, durability, high transparency, and heat resistance. However, PC must be coated with a protective, thin film against scratching and action of solvents, oxygen, humidity or solar radiation.

An interesting technique to improve of the surface properties seems to be the plasma enhanced/assisted chemical vapor deposition (PECVD/PACVD). The thin film is formed directly in the electric discharge volume (PECVD) or out of it (PACVD). The process of depositing protective film from the gas phase is initiated by electric discharge. The reactive species, like excited molecules, radicals and ions, are formed as the result of collisions of high-energetic electrons with gas molecules of precursors. These reactive species take part in the formation of the thin film on the surface. Various gases were used, as the precursors, like tetraethoxysilane, hexamethoxydisilazane or tetramethylosilane for deposition of organo-silicon film and methane or acetylene for deposition of diamond-like film.

The processes of thin film deposition usually run in glow discharges at low pressure (1-1000 Pa) [2-4], but the low-pressure apparatus and it operation is expensive. On the other hand, it was found, that the thin films might be deposited on solid surfaces using filament barrier discharges at the atmospheric pressure. However, the film was usually not uniform [5,6]. In order to increase the homogeneity of the barrier discharge, we have developed a new process run under conditions of pulsed dielectric barrier electric discharges (PDBD).

In this study were investigated:

1) influence of the position of PC in reactor on the deposition rate;
2) influence of the width of discharge gap on the deposition rate;
3) influence of the oxygen concentration on the deposition rate.

2. Experimental

The process of thin films deposition was carried out in the apparatus consisted of plasma reactor, gas supply system, and electric supply system. These elements are described in our former work [7,8]. The PC plates were placed on both, high-voltage and grounded electrodes. The PC plates were characterized by the relative electric permittivity 2.3 (measured by a Precision LCR Meter HP 4284A). The PC plates formed double dielectric barrier. The discharge gap, where discharge was developed and plasma was generated, was between the PC plates. In the discharge zone chemical reactions were initiated.

The thin films were deposited from mixture of helium, oxygen and vapor of tetraethoxysilane (TEOS). The experimental parameters are shown in **Table I**.

Table I. Experimental parameters

Total gas flow rate [l (s.t.p.)/h]	100
Pressure [atm]	1
He concentration [% by vol.]	50-95
O_2 concentration [% by vol.]	5-50
Vapor of TEOS concentration [ppm]	220-320
Discharge gap [mm]	0.2-1.5
Thickness of PC plates [mm]	0.5-0.75
Frequency of pulse repetition [Hz]	400

The mass of deposited film was determined gravimetrically using Sartorius BP 221S balance. On the basis of on these measurement the deposition rate was evaluated.
Morphology and topography of thin film were investigated using atomic force microscopy (AFM – Nanoscope 1030) and scanning electron microscopy (SEM – LEO1530).
The chemical composition was studied using Fourier transform infrared spectroscopy and X-ray energy disperse detector attached to LEO1530.
The electric parameters (voltage pulse, current pulse and frequency of pulse repetition) were recorded using Tektronix TDS 3054 oscilloscope.

3. Results and Discussion

FTIR spectra exhibited Si-OH, Si-$(CH_3)_x$, Si-O-Si, Si-O-C and EDX spectra exhibited Si, C, O elements as component of thin films [7,8].
The AFM and SEM microimages, as presented in our former work [7,8], showed, that thin film coated uniformly PC. The surfaces of deposited films were similar to the surfaces of original PC plates. The surfaces of films was very smooth and any holes were observed on the surfaces after thin film deposition.
PDBD, which was used in our study, was a special form of dielectric barrier discharge. PDBD was characterized by very short time of voltage pulses (50ns) and current pulses (20 ns) [7,8].
The masses of deposited film referred to unit of covered PC area ($\Delta\mathbf{m}$) versus time of plasma treatment ($\boldsymbol{\tau}$) are shown in **Fig. 1-4**. It was linear dependence, but the regression lines did not cross the origin. It demonstrated that the deposition process was not started in the same time as plasma treatment started. This behavior was different than the thin film deposition on inorganic material, because plastics are lesser resistant on plasma action than metals or silicon wafers. Probably before the process of deposition some other processes, like etching or activation, take place in the first period of plasma treatment of polymer material. This problem was discussed in other work [9-11].
The linear dependencies were described by equation:

$$\Delta\mathbf{m} = \boldsymbol{r} \bullet \boldsymbol{\tau} + \boldsymbol{b} \qquad (1)$$

The value of ***r*** parameter in this equation correspond to the deposition rate, which is shown in **Table II** and **Table III** for various discharge gap and oxygen concentration respectively. The results in these tables showed, that PC position on the electrodes have an influence on the deposition rate. There was found, that the deposition rate on PC placed on high-voltage electrode was usually higher, than the deposition rate on PC placed on grounded electrode.

Table II. The deposition rate of thin film on PC placed on grounded and high-voltage electrodes for various discharge gaps (thickness of PC – 0.75 mm, TEOS concentration – 330-320 ppm, O_2 concentration – 5%)

Discharge gap [mm]	Deposition rate of thin film on PC placed on grounded electrode [μg cm^{-2} min^{-1}]	Deposition rate of thin film on PC placed on high-voltage electrode [μg cm^{-2} min^{-1}]
0.2	4.6±0.1	4.1±0.3
0.5	6.1±1.1	6.8±0.8
0.75	2.5±0.4	3.4±0.2
1.0	6.0±0.4	7.3±0.4
1.5	10.1±0.5	10.4±0.4

Table III. The deposition rate of thin film on PC placed on grounded and high-voltage electrodes for various O_2 concentration (thickness of PC – 0.75 mm, discharge gap – 0.2 mm, TEOS concentration – 330-320 ppm)

Discharge gap [mm]	Deposition rate of thin film on PC placed on grounded electrode [μg cm^{-2} min^{-1}]	Deposition rate of thin film on PC placed on high-voltage electrode [μg cm^{-2} min^{-1}]
5	5.6±0.4	7.8±0.5
25	2.3±0.3	2.6±0.1
50	0.6±0.1	0.7±0.1

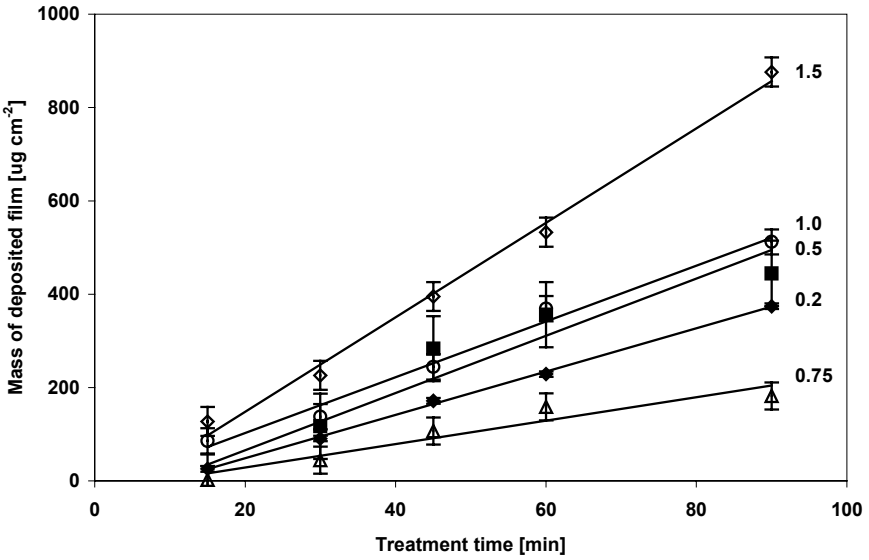

Fig. 1. Variation of the mass of deposited film on PC placed on the grounded electrode versus time of plasma treatment for discharge gap in range of 0.2-1.5 mm (thickness of PC – 0.75 mm, TEOS concentration – 220-320 ppm, O_2 concentration – 5%)

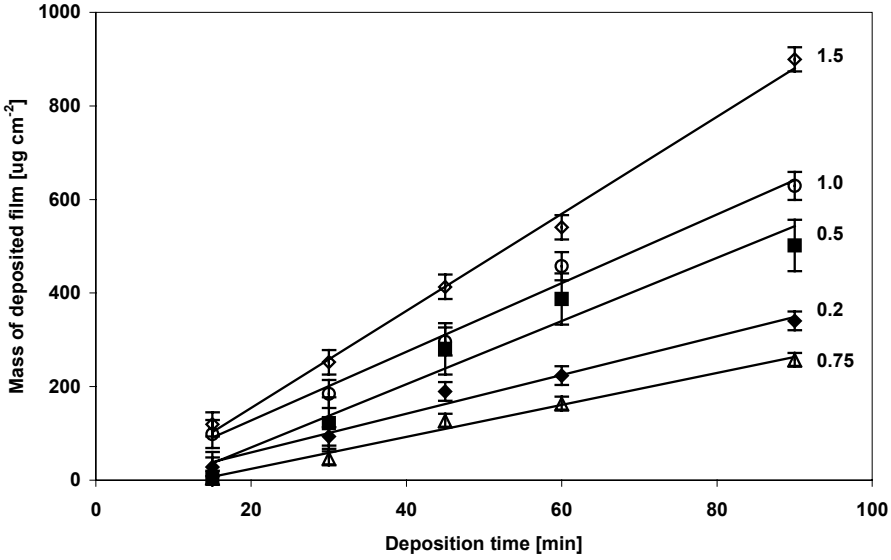

Fig. 2. Variation of the mass of deposited film on PC placed on the high-voltage electrode versus time of plasma treatment for discharge gap in range from of 0.2-1.5 mm (thickness of PC – 0.75 mm, TEOS concentration – 220-320 ppm, O_2 concentration – 5%)

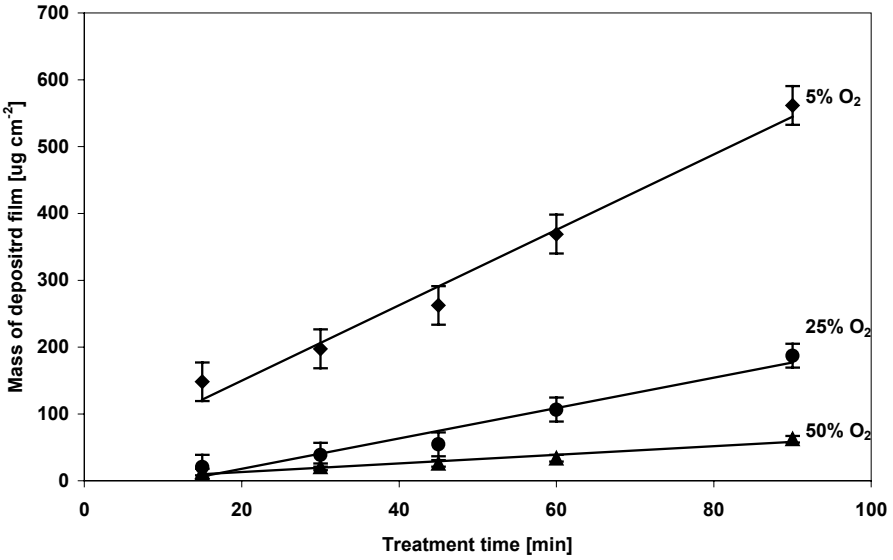

Fig. 3. Variation of the mass of deposited film on PC placed on the grounded electrode versus time of plasma treatment for O_2 concentration in range of 5-50% (thickness of PC – 0.75 mm, TEOS concentration – 230-250 ppm, discharge gap – 0.2 mm)

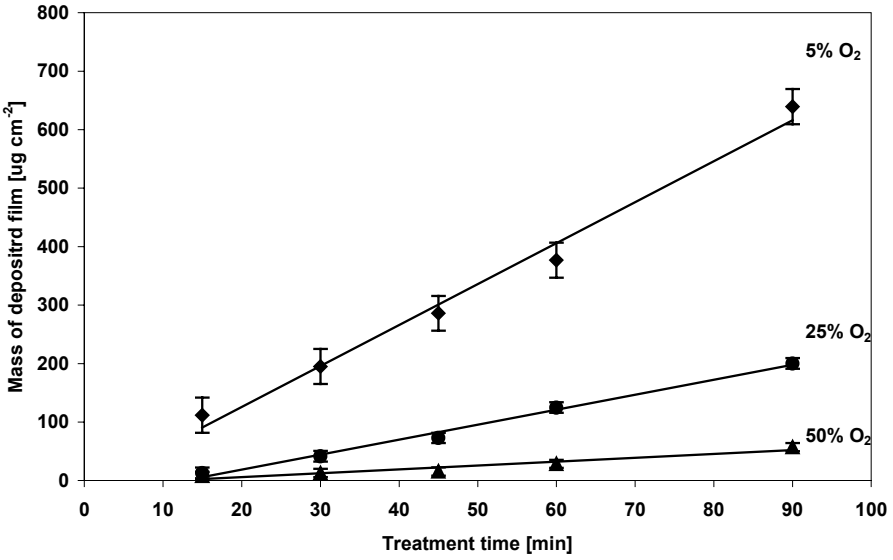

Fig. 4. Variation of the mass of deposited film on PC placed on the high-voltage electrode versus time of plasma treatment for O_2 concentration in range of 5-50 (thickness of PC – 0.75 mm, TEOS concentration – 230-250 ppm, discharge gap – 0.2 mm)

The deposition rates versus discharge gap are shown in **Fig. 5**. It was found, that two separately sets of the deposition rate was obtaining for two different ranges of discharge gap. The first set was form for the discharge gap in range of 0.2-0.5 mm and the second set was form for the discharge gap in range of 0.75-1.5 mm. This behavior was the same for PC placed on high-voltage electrode and PC placed on grounded electrode. The deposition rate increased from 4.6 to 6.1 μg cm^{-2} min^{-1} (grounded electrode) with increasing of discharge gap from 0.2 to 0.5 mm. Next the deposition rate decreased to 2.5 μg cm^{-2} min^{-1} (grounded electrode) when the discharge gap increased to 0.75 mm and the deposition rate again increased to 10.1 μg cm^{-2} min^{-1} (grounded electrode) with increasing of discharge gap to 1.5 mm (**Table II**). It was obvious, that the characteristics were similar for both sets of the deposition rate points and they regressions were almost parallel (**Fig. 5**).

This behavior could be possible to explain by change of character of PDBD. It was possible, that homogeneity of PDBD decreased while discharge gap changed from 0.2-0.5 to 0.75-1.5 mm. This problem has not been fully researches yet and it will be studied, but similar result was obtained in former work [8] while were compared the deposition rate obtained for different configuration of reactor. When the deposition process was carried out in reactor with single dielectric barrier (PC of 0.75 mm of thickness, discharge gap 0.75 mm) placed on grounded electrode the deposition rate was 40.8 nm min^{-1} and was much higher that the deposition rate (3.4 nm min^{-1}) obtained for reactor with double dielectric barriers (two PC, each of 0.75 mm of thickness placed on high-voltage and grounded electrodes, discharge gap 0.75 mm) [8].

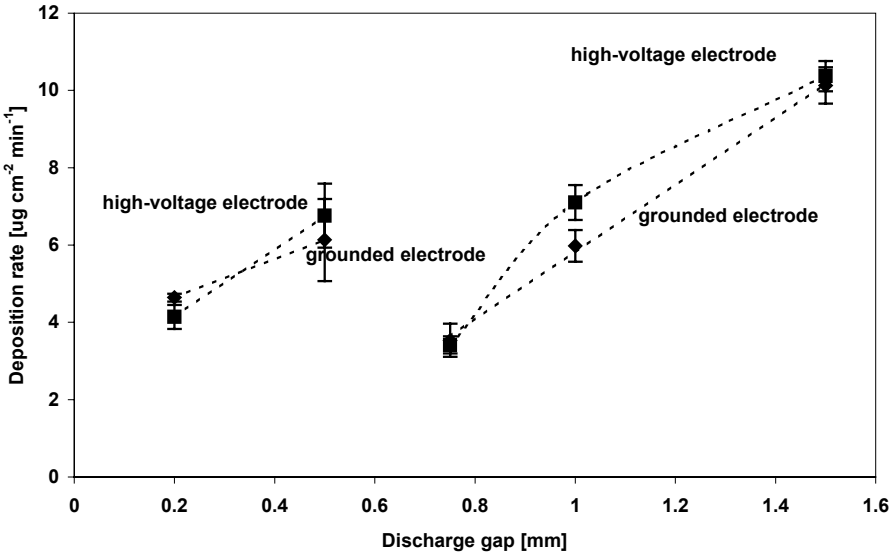

Fig. 5. The effect of the discharge gap on the deposition rate (thickness of PC plates – 0.75 mm, TEOS concentration – 220-320 ppm, O_2 concentration – 5%)

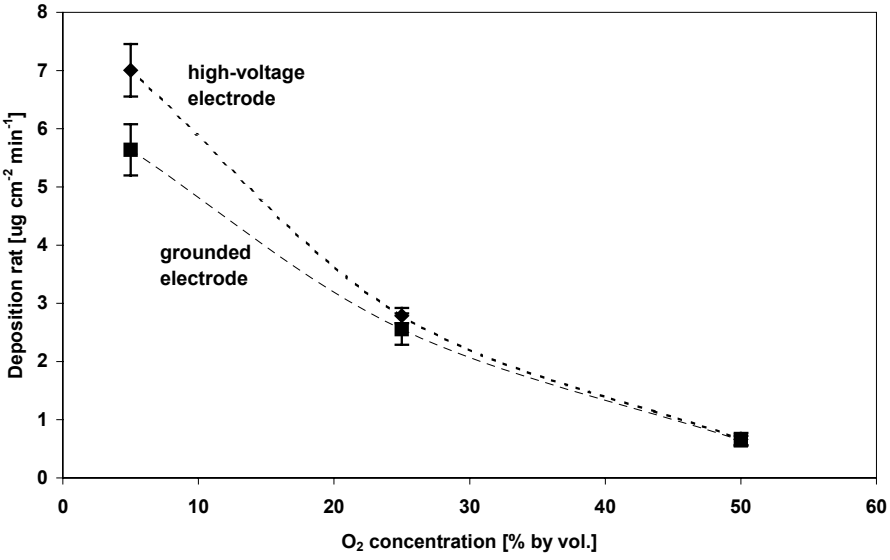

Fig. 6. The effect of the O_2 concentration on the deposition rate (thickness of PC plates – 0.75 mm, discharge gap – 0.2 mm, TEOS concentration – 230-250 ppm)

The deposition rates versus oxygen concentration were shown in **Fig. 6**. Oxygen and TEOS participated in the reaction of thin film forming [12], but the results demonstrated that high concentration of oxygen have negative effect on the deposition rate. The influence of O_2 concentration on the deposition rate was simple, the deposition rate decreased with increase the oxygen concentration in plasma-generating gas. This was in agreement with the results obtained under different conditions [7,13-15] and could be explained by increase

of the etching rate with increase of O_2 concentration in plasma-generating gas. For this reason, the gas composition, especially O_2 concentration, must be choose with care.

4. Conclusions

Pulsed dielectric barrier discharge (PDBD) is useful technique for thin organo-silicon film deposition on polycarbonate (PC) at the atmospheric pressure. The obtained results showed that:

1. The process of thin film deposition did not started immediately with plasma treatment of polymer material. Probably, before that process some, in the first period of plasma treatment, other processes, like etching or activation, take place.
2. The deposition rate of thin film on PC placed on high-voltage electrode, was faster than the deposition rate on PC placed on grounded electrode.
3. The deposition rate decreased with increase of the oxygen concentration in plasma-generating gas.
4. Two separately sets of the deposition rate was obtaining for two different ranges of discharge gap, 0.2-0.5 and 0.75-1.5 mm and the regressions of the two sets were almost parallel:
   - 4.1. The deposition rate increased from 4.6 to 6.1 $\mu g\ cm^{-2}\ min^{-1}$ (grounded electrode) with increasing the discharge gap from 0.2 to 0.5 mm.
   - 4.2. The deposition rate decreased from 6.1 to 2.5 $\mu g\ cm^{-2}\ min^{-1}$ (grounded electrode) with increasing the discharge gap from 0.5 to 0.75 mm.
   - 4.3. The deposition rate increased from 2.5 to 10.1 $\mu g\ cm^{-2}\ min^{-1}$ (grounded electrode) with increasing the discharge gap from 0.75 to 1.5 mm.

Abstract
In this paper we report the results of the surface modifications of PES films induced by treatments in argon rf discharge, modifications which could improve the properties of adhesion. Our results of XPS analysis and contact angle measurements stood out the introduction of oxygen functionality in the PES surface by argon rf treatment. An increasing of the surface roughness with treatment time increasing, was found.

1. Introduction

Polyethersulphone (PES) has many properties that make it suitable for many applications as resists for microelectronics, heat-resistant materials in aerospace applications, polymeric membranes, matrices for composites, etc., More precisely polyethersulphone (PES) has many issues that are suitable for electronics, but not a very good adhesion with Si [1]. Hence, surface treatment of PES is expected to achieve good adhesion. Modification by exposure to cold plasmas (which only affect the uppermost layers) has been found to be one of the most reliable methods of improving adhesion.
In this paper we report the results of the surface modifications of PES films induced by treatments in argon rf discharge, modifications which could improve the properties of adhesion. The polymer surface modifications were investigated using X-ray photoelectron spectroscopy, contact angle methods and AFM measurements.

2. Experimental

Low pressure plasma surface modification experiments were carried out in an asymmetrical industrial OPT (Oxford Plasma Technology) Plasmalab 100 capacitively coupled system with the grounded electrode (including the chamber walls) area much larger than the driven electrode [2]. A matching network was used to match the impedance in order to maximise the energy transfer from the power supply to the plasma. The pressure was achieved automatically by measurement of the pressure via a capacitance manometer (CM) gauge and a pumping throttle valve.
The PES samples Good fellow 200 μ foils, were washed with methanol and dried with hot air before the treatment.
Argon of 99.095 % was used without further purification. No effort was made to dry the gas, because of the amount of residual water adsorbed on the surfaces of the reactor vessel, which could not be readily removed. The reactor was flooded with argon to a pressure of 1 Torr, for 5 min. prior to plasma treatment.
Typical treatment parameters were: Ar gas pressure between 100 mTorr and 400 mTorr, rf power 100 W, gas flow rate 10 sccm, treatment times between 1 min and 30 min. XPS and contact angle measurements were employed to characterise PES surface modifications.
XPS was performed in a VG ESCALAB 200D spectrometer with non-monochromatized MgKα radiation. The binding energy is determined by setting the aromatic carbon at 284.7 eV and shifting the complete spectrum accordingly. This is necessary due to charging of the non-conducting polymer samples. Survey spectra and high resolution spectra were taken with 50 eV and with 20 eV pass energy, respectively, in the constant analyser energy mode. The XPS peaks were analysed by means of a computer program incorporated in the VG Eclipes data system. Elements concentration was evaluated from peak area after Shirley background subtraction using the theoretical cross sections [3]. The XPS investigations were realised at two photoelectron take-off angles, about 0° and 70°, measured with respect to the sample normal. If the mean free path (λ) for the C 1s electrons is taken approximately 14 Å, the sampling depths ($3\lambda\cos\theta$, where θ is the take-off angle) for 0° and 70° are found to be 42 and 14.3 Å, respectively.
In terms of the Lifshitz-van der Waals-acid/base (LW-AB) model, Young's equation for the work of adhesion of a liquid to a solid surface W_a can be written [4]:

$$W_a = \gamma_l(1+\cos\theta) = 2\left[\left(\gamma_s^{LW}\gamma_l^{LW}\right)^{1/2} + \left(\gamma_s^{+}\gamma_l^{-}\right)^{1/2} + \left(\gamma_s^{-}\gamma_l^{+}\right)^{1/2}\right]$$

where γ^+ and γ^- note the contribution due to the electron acceptor (Lewis acid) and donor (Lewis base) part respectively, for solid (s) or liquid (l). The Lifshitz-van der Waals contribution to the solid surface energy γ_s^{LW} is obtained using a non-self-associating liquid with no acidic or basic character (i.e. a "neutral liquid") with the relation:

$$\gamma_s^{LW} = \left(\frac{\gamma_{probe}}{4}\right)\cdot\left(1+\cos\theta_{probe}\right)$$

where θ_{probe} and γ_{probe} are the contact angle and surface tension respectively for neutral liquid.

The AFM images were obtained using a Topometrix scanning probe microscope. Contact mode topographic images were recorded with a scan rate of 0.5 Hz.

3. Results and discussions

The XPS analysis for the untreated PES – sum formula $(C_{12}H_{12}O_3S)_n$ - showed three main peaks: O1s, C1s and S2p. In particular, the O1s peak can be resolved into a component at lower binding energy (531.31 eV) assigned to the oxygen present in SO_2 groups and a component at 532.89 eV assigned to the other type of oxygen binding (O-C). The ratio of the two components is slightly different from that expected (1.67:1 instead of 2:1). The C/S ratio (12.05:1) is in very good agreement with the theoretical composition of PES (12:1).

Untreated PES has an acidic component of the surface energy, $\gamma_l^+ = 10.2$ mN/m, much greater that the basic one $\gamma_l^- = 0.3$ mN/m and also a great dispersive or Lifshitz-van der Waals component $\gamma_l^{LW} = 43.1$ mN/m.

XPS analysis

In the literature one of the most striking feature for the PES treated in Ar-plasma is the reduction of the oxygen content, mainly by the reduction of the sulphonic ($-SO_2-$) to sulphide (-S-) groups [5]. Such reduction is very important especially at very low pressure ($<10^{-3}$ Torr). Treatment of PES with keV Ar atoms also stood out a strongly decreasing in oxygen content [6]. In both mentioned studies, the XPS surface analyses of the treated samples were performed without contamination from the atmospheric contact.

Both exposure to the laboratory atmosphere and some oxygen-containing plasma species are thought to be responsible for oxygen functionalisation in our experiments.

Results about XPS analysis made one day after the treatment are presented in this section. Both types of treatment, at 100 mTorr and at 400 mTorr, show the diminishing of C%, increasing of O% and slightly diminishing of S% (Figs. 1 and 2). The most important changes in the total atomic percentages of carbon, oxygen and sulphur are realized in the first 10 minutes of treatment. A saturation trend is stood out for longer exposure times for both treatment pressures.

Generally, the total oxygen content is similar in the outermost and in the deep surface layers, which shows that the thickness of the oxide surface layer is greater that the XPS analysis depth.

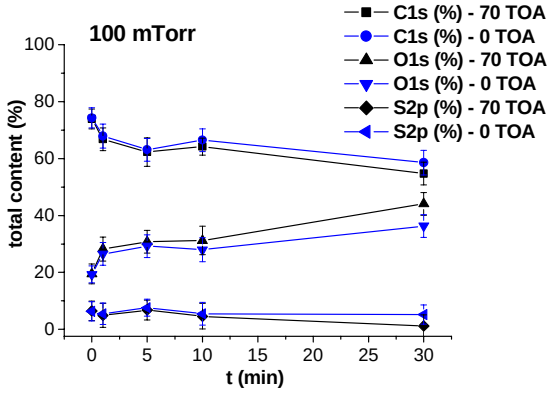

Fig. 1

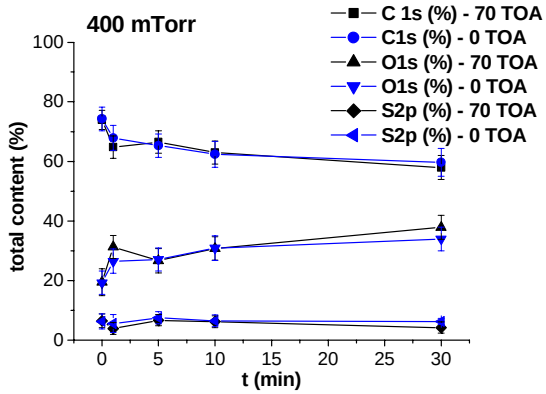

Fig. 2

For all investigated plasma conditions the C1s trend vs. time is guided by the ArC (284.7 eV) peak decreasing. At 100 mTorr, on the polymer surface (TOA = 70º) the C-S (285.0 eV) peak is increasing with the treatment time, and the C-O peak (286.3 eV) is slightly decreasing. In the polymer depth (TOA = 0º), both C-S and C-O peaks are decreasing (Figs 3 and 5). At 400 mTorr and 70º TOA the contribution of C-S and C-O peaks trend to be equal for longer exposure times. The XPS analysis at 0º TOA show that the C-O peak is more important than C-S (Fig.5).

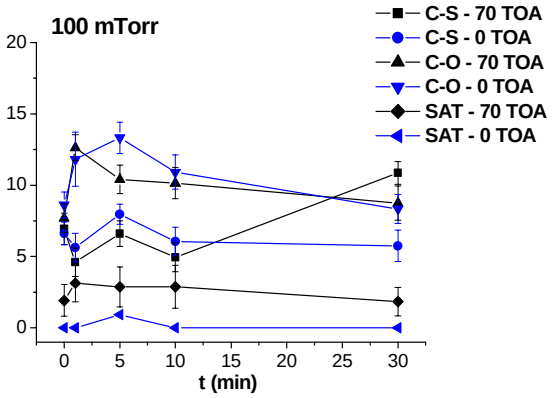

Fig. 3

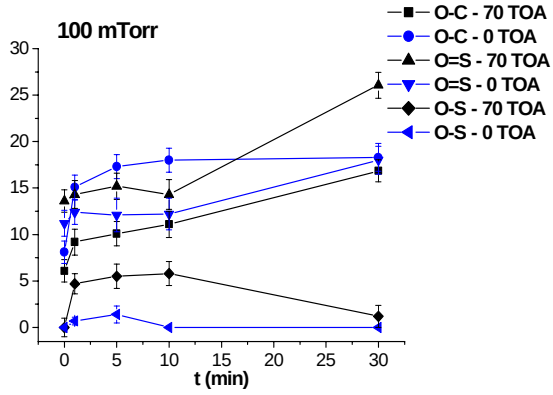

Fig. 4

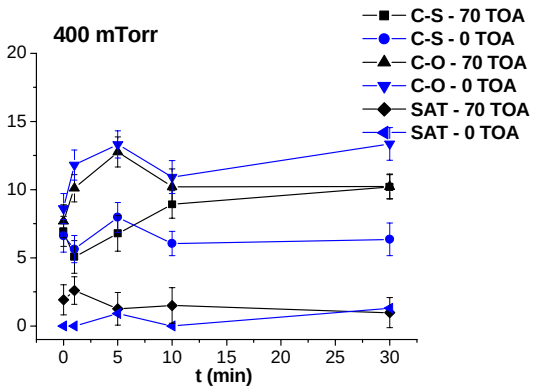

Fig. 5

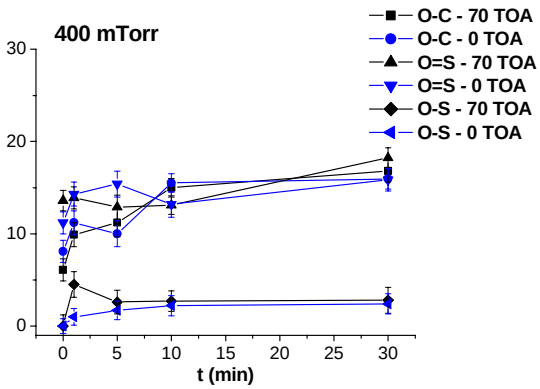

Fig. 6

The total O1s peak is increasing for all investigated plasma conditions (Fig. 1 and 2). At 100 mTorr, we found an increasing of the O=S and O-C peaks for longer exposure time. On the surface (TOA = 70º) the O=S is the most important peak, whilst in polymer depth (TOA = 0º) the contribution of the O-C is bigger (Fig.4). Increasing the treatment time, at 400 mTorr, the O=S peak is almost constant and O-C peak is slightly increasing (Fig. 6).

Surface energy data

The surface free energy components were determined by sessile drop technique. The reported values are the average over at least ten measurements performed in different areas of the sample surface, the typical dispersity of the values being ±2°. The values for the surface energy components of the liquids used in this study, in mN/m, are given in Table 1.

	γ_l^{LW}	γ_l^+	γ_l^-	γ_l
water	21.7	25.5	25.5	72.8
formamide	32.0	3.0	22.4	57.4
α-bromonaphthalene	44.8	0		44.8

Table 1

Surface energy data collected one day after the treatment will be presented in order to compare with XPS data.

Treatments in Ar discharges do not appreciable modify γ_s^{LW} component, a medium value of 44.5 mN/m being obtained for treated PES.

Acid/base component $\gamma_s^{ab} = \gamma_s^+ + \gamma_s^-$ versus treatment time and type is presented in Fig. 7. There is a very good concordance between the change the O_{total} component (Figs. 1 and 2) with treatment time and γ_s^{ab}, for both investigated pressures. The direct correlation between oxygen component and γ_s^{ab} means that the few outermost layers, which directly influence the γ_s^{ab} value, have the same oxygen component as the depth layers. These results confirm the depth dependence of oxygen functionality, obvious from XPS data.

Acid γ_s^+ and base γ_s^- components increase for both pressures and treatment types (as comparing with values for untreated PES), but more important is the increase in γ_s^+ (Fig. 8). Only one minute of treatment is necessary to increase γ_s^+ from 10.2 mN/m to 30-38 mN/m and γ_s^- from 0.3 mN/m to 5-6 mN/m. For longer exposure times either γ_s^+ and γ_s^- do not appreciable change or they decrease slightly.

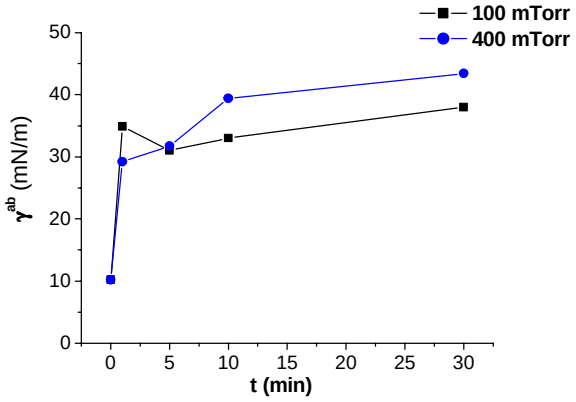

Fig. 7

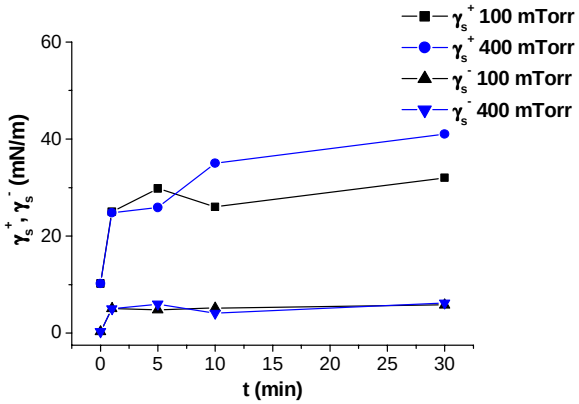

Fig.8

Ageing effects

Surface energy measurements, for all treated PES samples were collected immediately and after 1 day, 3 days, 5 days and 7 days from the treatment. The γ_s^{LW} component remains almost unchanged during the investigated ageing period.

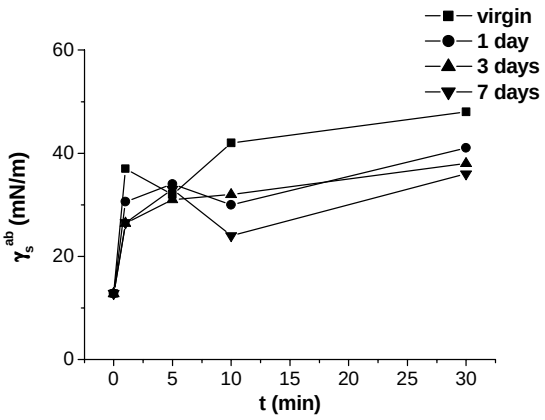

Fig.9

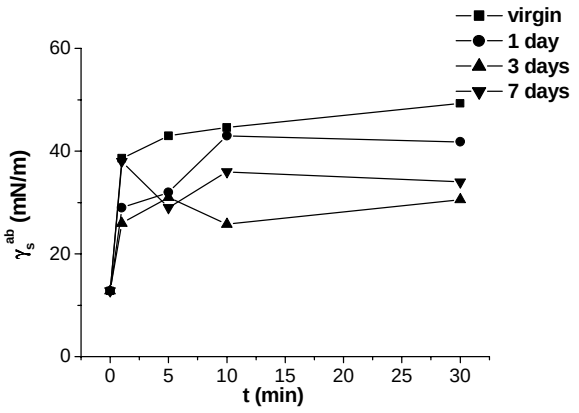

Fig. 10

The change in γ_s^{ab} with the ageing time, for PES samples treated at 100 mTorr and 400 mTorr are illustrated in Figs. 9 and 10 respectively. Besides the expected behaviour, namely a more or less decreasing of γ_s^{ab} with the ageing time, an unexpected feature is also evident, especially for PES samples treated at 400 mTorr. After an initial decrease, γ_s^{ab} increases at various ageing times, this increase being appreciable for some samples. The transient increase in γ_s^{ab} could be also present for the other Ar-treated PES samples, but for longer ageing times.

Behaviour such as this has also been observed for other polymers PET treated with low energy oxygen ions [7]. Generally γ_s^+ decreases and γ_s^- increases with the ageing time, as comparing with values measured immediately after the treatment. More information about the contribution of each process in the ageing effects were obtained from XPS data. The obvious similarity of the development with the ageing time of γ_S^{ab} and O_{total} (%) for these samples (Fig. 11) sustain the fact that migration of the small fragments from the surface is the main process involved in the surface reorganisation.

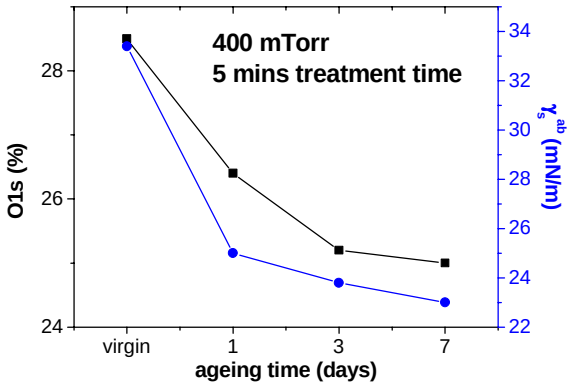

Fig. 11

AFM results

Increasing the treatment time, we found an increasing of the surface roughness, especially for 100 mTorr (Figs. 12, 13, 14.)

a) c)

Fig. 14. AFM images for PES at 400 mtorr and 10 min(a) and 30 min (b) treatment time

Conclusions

We found in the literature that at very low pressure (<10^{-3} Torr) one of the most important feature for the PES treated in Ar-plasma is the reduction of the oxygen content, mainly by the reduction of the sulphonic (-SO_2-) to sulphide (-S-) groups [5]. Treatment of PES with keV Ar atoms also stood out a dramatically decreasing in oxygen content [6]. In both mentioned studies, the XPS surface analyses of the treated samples were performed without contamination from the atmospheric contact.

Our results of XPS analysis stood out the introduction of oxygen functionalities in the PES surface by argon rf treatment. The oxygen component is higher, higher the pressure.

More oxygen functionalities are introduced in PES film treated at the same treatment time, at 400 mTorr, for all investigated treatment times.

The oxidation rate is increasing more quikly in the first minute of the treatment for both work pressures. For the treatments at 100 mTorr, the oxidation rate is increasing especially due to the O=S=O group increasing. At 400 mTorr both oxygen peaks, O=S=O and O-C, are increasing in the same manner.

The total C content is decreasing for all investigated plasma conditions, especially due to the ArC peak decreasing.

Surface energy data collected one day after the treatment were compared with the XPS results.

Treatments in Ar discharges do not appreciable modify γ_s^{LW} component, a medium value of 44.5 mN/m being obtained for treated PES. Direct correlation between oxygen component and γ_S^{ab} is obvious for both investigated pressures. he direct correlation between oxygen component and γ_s^{ab} means that the few outermost layers, which directly influence the γ_s^{ab} value, have the same oxygen component as the depth layers. These results confirm the depth dependence of oxygen functionality, obvious from XPS data.

Both acid and base components are increased whatever the pressure and treatment type, but the increase in γ_S^+ is more important. The more or less decreasing of γ_S^{ab} with the ageing time is evidentiated for most of treated PES samples; for some of them a transient increase in γ_S^{ab}, at different ageing time, is observed.

Acknowledgements

The experiments were performed in Surface Science Laboratory, Aston University, Birmingham, UK. The authors would like to thank Mr. A. Abbot and all members of the laboratory for their collaboration during experiments.

Deposition of thick diamond-like nanostructured coatings by Plasma Enhanced CVD

S. Thollon, M. Plissonier, N. Scheer, C. Cayron, A. Ruchier [1]

[1] *CEA Grenoble, Département des Technologies des Energies Nouvelles, 17 rue des Martyrs, 38054 GRENOBLE cedex, France*

Abstract
Thick multilayer coatings consisting of a stack of Diamond Like Carbon nanolayers alternated with Hydrogenated Silicon doped carbon nanolayers were developped by a Low Frequency PECVD computer-controlled technology (50-100 kHz), which can be easily scaled up from the laboratory to the industrial scale. Comparing to traditionnally high compressive stressed DLC coatings, this specific architecture consisting of dense and amorphous stacked nanolayers with a total thickness up to 10 µm leads to lower internal stresses, better adhesion and very good mechanical and tribological properties in dry and humid conditions, enabling promising industrial applications in various fields.

1. Introduction

Hydrogenated or non-Hydrogenated Diamond-like carbon (DLC) films have been the subject of intensive technological research since they exhibit many attractive properties : high hardness and wear resistance, low friction coefficient (<0.15 in air), chemical interness, IR optical transparency, high thermal and low electrical conductivities [1-4]. Owing to these properties, DLC films are suitable for a wide range of applications such as protective coatings for mechanical, optical, biomedical or electronic applications. However, DLC coatings exhibit drawbacks. Some applications may be limited by the high internal compressive stress (usually several GPa) [5-7] mainly induced by the ionic bombardment during deposition process and by the significant increase of the friction coefficient as the environmental humidity increases.
Consequently, alternative coatings for widening technical application fields have been developed. It was commonly assumed that alloying element such as Si improves tribological properties (friction and wear) under humid atmosphere and reduces internal stresses, enhancing better coating adhesion strength [8,9]. Still with the aim to enhance adhesion and reduce the level of compressive stress in these films, there has been recently interest in the development of amorphous diamond-like nanocomposites coatings (DLN), consisting of atomic-scale composite random networks of carbon (a-C:H) and silicon (a-Si:O) with mininal bonding between them [10, 11] and in the deposition of thick multilayer coatings being an alternation of wear resistant DLC layers and stress relieving DLN films [12]. Such Diamond-like carbon based structures have been synthesized through RF or DC Plasma Enhanded CVD combined with a heated filament [10**,** 12] and PVD (ion-beam assisted deposition) [13].
These developments have shown very promising applicability of such materials where abrasive wear mechanisms become predominants. For such specific industrial applications, thick coatings (up to 12 µm) combining high hardness and low friction coefficient in dry and humid conditions have been developed. In this paper, first results concerning the deposition and characterization of the as-deposited multilayer coatings consisting of a stack of Diamond Like Carbon nanolayers alternated with Hydrogenated Silicon doped carbon nanolayers obtained by Low Frequency Plasma Enhanced CVD technique in a pilot scale reactor are reported.

2. Experimental details

The experimental apparatus used is schematically reported in figure 1. The deposition process was carried out in a stainless steel reactor with a capacitively coupled electrode configuration and a 5 cm inter electrode gap. The lower electrode serving as substrate holder is powered via a 100kHz LF transmitter. The pressure was monitored using a capacitance manometer (MKS Baratron) and the deposition chamber was pumped down with a rotary pump and a roots with volume flow rates of 80

and 1200 $m^3.h^{-1}$, respectively. A base pressure of 0,1 Pa is reached with the reactor set-up used. Cyclohexane in hydrogen and tetra methylsilane in argon were respectively used for C:H and SiC:H deposition. Both monomers were evaporated at 30°C under reduced pressure, supplied through mass flow controllers into the upper electrode and diffused downward from nozzles onto the lower electrode. A thin bond layer of SiC:H was deposited between the thick multilayer coatings and the substrate in order to promote adhesion. The multilayer deposition was performed with Diamond Like carbon nanolayers alternated with hydrogenated silicon carbide nanolayers and a final Diamond like carbon coating approximately 1 µm thick. Thickness and periodicity of nanolayers were modified in order to keep a total thickness constant at about 12µm. During processing, reactor's devices were automatically controlled with a computer.

Diamond-like nanostructured coatings were deposited on <110> oriented silicon to perform the microstructural characterization and on steel substrate (HS 6.5.4.2) in order to investigate mechanical and tribological behaviour. Cross sections of the multilayer structure were examined by Transmission Electron Microscopy (TEM) on a Jeol 2000FX microscope (200 kV). The elementary depth profiles in the multilayered structure were investigated by means of Dynamic Secondary Ion Mass Spectrometry (DSIMS) using a radio frequency quadrapole detector and a liquid metal source Ga^+. The samples were depth profiled under ultra high vacuum with positive ions for Silicon, Carbon, Hydrogen elements. The erosion speed was fixed quite low in order to achieve an excellent depth resolution.

Wear and friction properties were evaluated using a conventional ball-on-disk apparatus with control of the relative humidity. The unlubrificated sliding experiments were performed at room temperature, applying a normal load of 5 N on a 1.58mm alumina bearing ball and a sliding speed of 0.17 $m.s^{-1}$. The wear volume of the wear track was then evaluated from profilometry measurements.

A Nanoindenter CSEM apparatus with a Vickers diamond tip was used to measure hardness (H) and Elastic modulus (E) values. The continuous stiffness option was used, the maximun depth was fixed at 200 nm, the loading and unloading rates at 10 mN/min. The H and E values were calculated from the indentation load-displacement data [14].

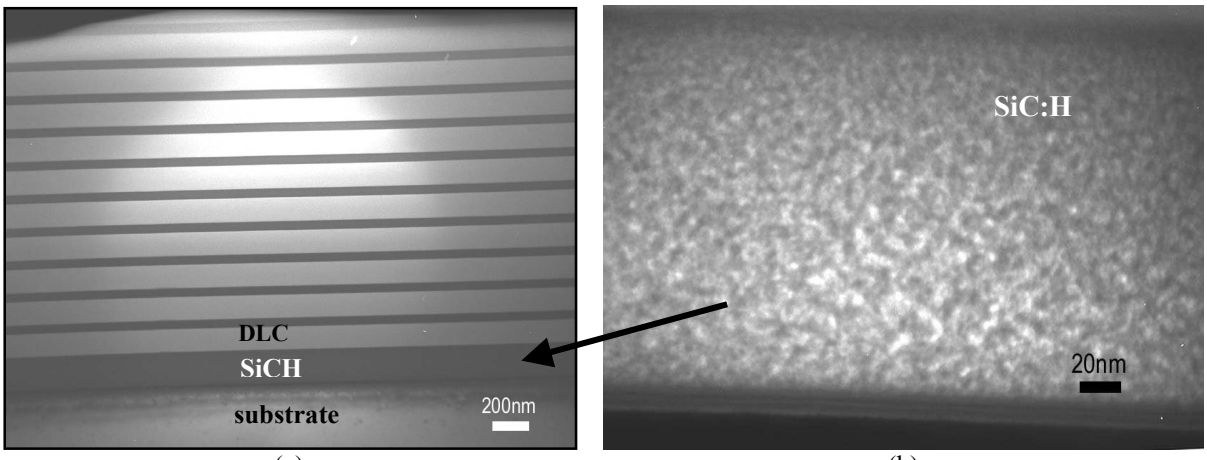
3. Results

	SiC:H Base layer	**Multilayer Structure** (number of layers, elementary thicknesses)	DLC top layer
Sample A	225 nm	**240 layers** (120 periods): $e_{SiC:H}$= 45nm, e_{DLC}=110nm	1 µm
Sample B	195 nm	**980 layers** (490 periods): $e_{SiC:H}$= 5nm, e_{DLC}=15nm	1 µm

Table 1 : Experimental details on the multilayer coating architecture.

In table 1 are reported details on the diamond-like nanostructured coating architecture.
Cross sectional Transmission Electron Microscopy images of two PECVD diamond-like nanostructured coatings, samples A and B (see table 1) clearly revealed the multilayer microstructure of the films (figures 2 and 3) : *i.e.* the stack of Diamond Like Carbon (DLC) nanolayers alternated with Hydrogenated Silicon doped carbon (SiC:H) nanolayers, with a glassy underlying layer of SiC:H. Selected Area Diffraction patterns showed the amorphous nature of the stacked DLC and SiC:H nanolayers. Nanolayers elementary thicknesses were estimated within 5 to 50 nm and 10 to 150 nm for SiC:H and DLC respectively, depending on the process conditions.



(a) (b)

Figure 2 : Cross-sectional TEM images of sample A near the substrate interface (a) global view of the first SiC:H and DLC nanolayers, (b) SiC:H base layer.

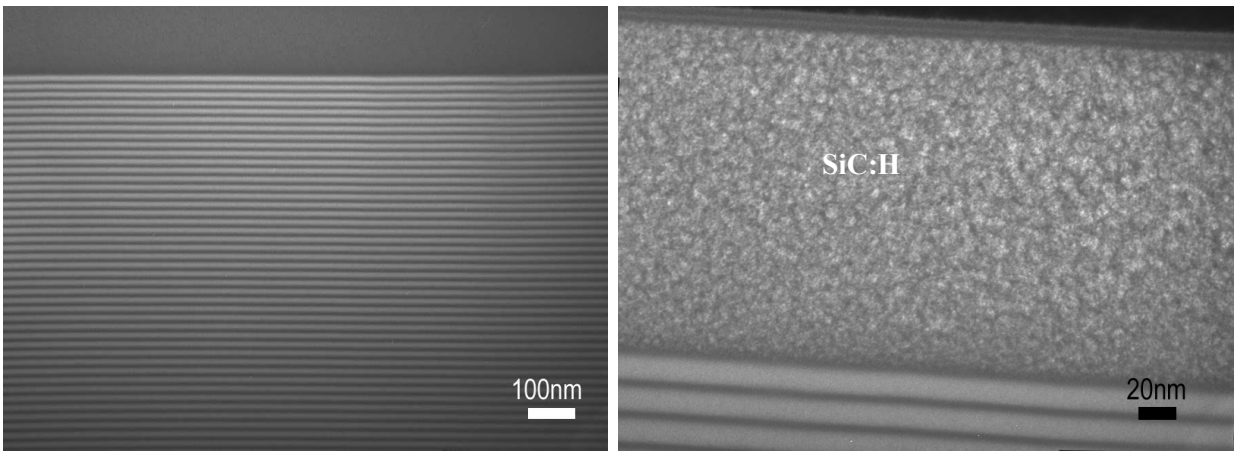


Figure 3 : Cross-sectional TEM images of sample B near the substrate interface (a) global view of the first SiCH and DLC nanolayers, (b) SiCH base layer.

The microstructural integrity of this structure was demonstrated since no defects were observed within nanolayers and at interfaces. Furthermore, the nanolayers appeared to be very dense, homogeneous and well bonded to the substrate and to each other. The observed microstructure and the sharpness of the interfaces clearly tends to point out that this process is readily controlled by surface reaction

kinetics, *i.e.* the rate limiting step is strongly dependent on the amout of reactant gases available. This point is very significant since, by proper manipulation of the process parameters, it is possible to control the reaction and deposition rate to a great degree, insuring very good step-coverage characteristics even on complex shaped pieces.

The repeatability of the investigated LF-PECVD process within time was confirmed by SIMS investigations. On figure 4 is presented the SIMS depth profiles of sample B in positive ions ($^{1}H^{+}$, $^{12}C^{+}$, $^{16}O^{+}$, $^{28}SiC+$) from the top layer surface up to the hundredth layer of the multilayer structure obtained with a slow erosion speed. This profile presents a depth resolution not even shaded off after the 80th layer. This analysis confirms the TEM observations that the stacking of the nanolayers is reliable and perfectly repeatable in time.

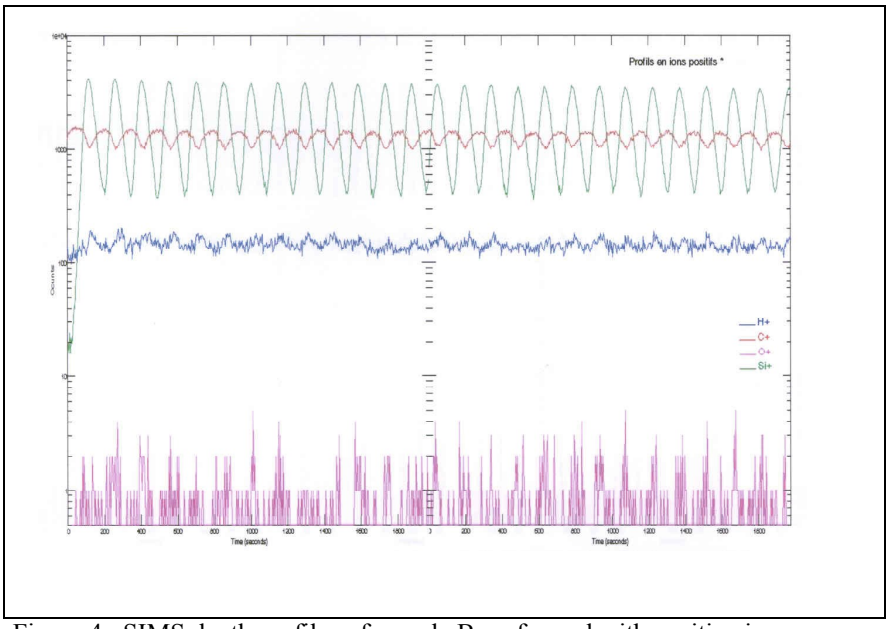

Figure 4 : SIMS depth profiles of sample B performed with positive ions

The results of the different mechanical tests performed on the diamond-like nanostructured coatings (samples A and B) are summarized in the following table, where μ is the friction coefficient and V_w the wear volume.

	Tribological test		Nanoindentation test	
Atmosphere	**Dry**	**Wet**	**H (MPa)**	**E (GPa)**
DLC : reference	μ=0.063 V_w= 4.10^{-8} mm^3.N^{-1}.m^{-1}	μ=0.122 V_w= 2.10^{-5} mm^3.N^{-1}.m^{-1}	21000	190
Sample A	μ=0.053 V_w= 2.10^{-6} mm^3.N^{-1}.m^{-1}	μ=0.094 V_w= 7.10^{-7} mm^3.N^{-1}.m^{-1}	20000	180
Sample B	μ=0.038 V_w= 8.10^{-6} mm^3.N^{-1}.m^{-1}	μ=0.088 V_w= 5.10^{-7} mm^3.N^{-1}.m^{-1}	18000	140

Table 2 : mechanical and tribological properties of the as-deposited multilayer coatings

As shown in figure 5, even with the incorporation of silicon into the stacking network within the SiC:H nanolayers, the multilayer structure exhibit a linear friction behaviour, consistent with that of DLC coatings deposited in a RF-PECVD coating system [15]. An improvement of the tribological properties under humidity was clearly achieved with the silicon doping in the nanolayered structure (table 2) : the friction coefficient of the multilayer structure has been shown to remain below 0.1 even at relative humidity levels of 99%. In the case of the DLC film, the friction coefficient increased significantly under water, up to 0.122. In the case of tribological tests performed under high humidity rate, large fluctuations of the friction coefficient values were recorded. These variations may be due to

the debris trapped and recycled in and out of the transfer layer formed during sliding contact. This mechanism has been already pointed out with silicon containing coatings [16].
The wear volumes obtained by profilometry measurements of the cross-sectional areas of the wear tracks are listed in table 2. The hardness values of the as-deposited multilayer coatings were found to range from 18000 to 20000 MPa and elastic moduli values from 140 to 180 GPa from Nanoindentation test. The general trend is that wear volume decreases as hardness value increases ; similar behaviour was noticed by Kester *et al.* in sliding wear behaviour tests of diamond-like nanocomposites coatings worn by WC balls [10]. Thus, the hardness of the as-deposited LF-PECVD multilayer structure is lower than the standard hardness of DLC but the mechanical properties of these stackings combine good microhardness with elasticity and low friction under dry and wet atmopheres. The lower hardness level could be explained by the "dilution"effect of diamond-like properties in the carbon network with the presence of the Silicon element.

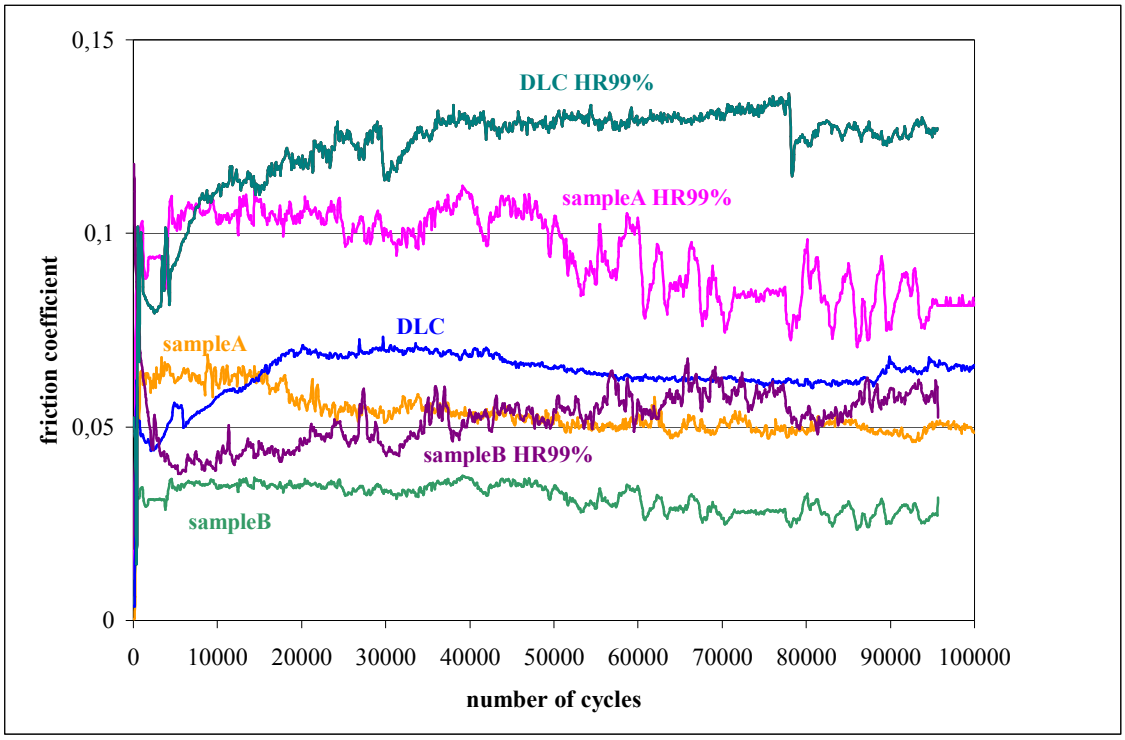

Figure 5 : evolution of the friction coefficient of the as-deposited materials (see table 2) as a function of cycles number : under dry atmosphere and with humidity rate (HR) of 99%.

3. Conclusion

Thick multilayer film consisting of several hundreds of Diamond-Like carbon nanolayers alternated with hydrogenated silicon carbide nanolayers were deposited in a LF-PECVD computer controlled reactor. Thickness and periodicity of nanolayers have been sucessfully controlled by proper manipulation of the process parameters and, thus, we demonstrated that this process is reliable and repeatable. Furthermore; this study performed in a Low Frequency pilot-scale reactor can be scaled up relatively easily from the laboratory to the industrial scale, enabling promising industrial applications.
It has been shown that silicon incorporation is favourable to the tribological properties in humid atmosphere : in fact, the friction coefficient of the multilayer structure remains below 0.1 even at relative humidity levels of 99%.
Further work with these nanostructured coating is in progress, especially with respect to the mechanical and tribological behaviour.

Particle-in-cell/Monte Carlo simulation of cc rf $Ar/CF_4/N_2$ discharges

V. Georgieva, A. Bogaerts and R. Gijbels

Department of Chemistry, University of Antwerp (UIA), B-2610 Antwerp, Belgium

Abstract
A one-dimensional particle-in-cell/Monte Carlo model is developed to study capacitively coupled radio-frequency discharges in a gas mixture of Ar, CF_4, and N_2. The calculation is performed for a 0.8/0.1/0.1 ratio of $Ar/CF_4/N_2$ mixture at a pressure of 30 mTorr in a dual frequency (2+27 MHz) reactor. Results show that the structure of the discharge is electronegative and CF_3^- ions are the main negative carriers. The IEDF is wide and bimodal. The EEPF has a bi-Maxwellian profile with a high energy tail.

1. Introduction

Radio-frequency (rf) plasma etching is well recognized for its anisotropy, which is a critical process parameter in integrated circuit (IC) manufacture. Conventional capacitively coupled (cc) reactors powered by 13.56 MHz rf sources meet many plasma processing requirements. However, the scaling evolution of semiconductor devices needs more and more accurate transfer patterns with minimum damages on the substrate, which can be achieved by precise control of both the ion bombardment energy and the ion flux. Single frequency systems face difficulties providing an independent control of ion energy. For that reason dual-frequency systems have been introduced and studied [1-3]. The dual rf excitation scheme allows the plasma density to be determined by one high-frequency (HF) source, while the substrate self-bias voltage can be controlled by the secondary low-frequency (LF) source. In addition, the LF-HF scheme provides a significantly wider ion bombardment energy range in comparison with a single HF configuration.

Plasma chemical issues are as much important in further optimization of etching processes as plasma processing units. Feedgas mixes are usually complex because of the conflicting requirements on the etch rate, selectivity to mask, and anisotropy. Carbon tetrafluoride CF_4 is a basic component in gas mixtures for plasma etching of silicon and silicon dioxide, and therefore is the most well-studied etch system [4-6]. While the investigation of pure CF_4 discharges gives the pattern for describing plasma etching, the study of discharges in a mixture of Ar and CF_4, which is a representative feedstock gas, provides insight into the process. In our previous paper we presented a one-dimensional particle-in-cell/Monte Carlo (PIC/MC) model and clarified the plasma structure and parameters in electropositive Ar, in electronegative CF_4, and in Ar/CF_4 discharges at different ratios [7]. A rapid decrease in electron density is observed with the addition of even a small amount of CF_4 to Ar, i.e. the dominant negative carriers are the negative ions, which profoundly influence the sheath dynamics. In the present paper the model is extended to examine the discharge structure in a mixture of Ar, CF_4 and N_2, which is a feedstock gas for etching in a cc dual-frequency rf reactor.

A PIC simulation treats the charged particles in a kinetic way. It is attractive because the fields and the energy distributions are obtained self-consistently from first principles. The collisions between the charged particles are added by combining the PIC model with a MC procedure. In case of modeling of electronegative discharges the major disadvantage of this method is that it requires a long computational time to reach convergence. The negative charges are confined in the bulk plasma and the only loss mechanism, i.e., ion-ion recombination, has a relatively low reaction frequency. Kawamura *et al*. point out many physical and numerical methods of speeding up the PIC calculations [8]. Some of the methods, such as longer ion time steps, different weights for electrons and ions and improved initial density profiles, are applied in this simulation. In Sec. 2 the input parameters, the outline of the model, and the collisions included in the simulation are given. In Sec. 3 the results of the simulation, such as the electric field, charged particle densities, and energy distributions, are presented and discussed. Finally, in Sec. 4 a summary is given.

2. Description of the model

A schematic diagram of the cc rf reactor considered in this study is shown in Fig.1. The plasma is sustained between two parallel plates, each 20 cm in diameter and separated from the other by 2 cm. One of the electrodes is driven by a dual frequency (2+27 MHz) power supply. The amplitude of the applied voltage is 700V. The other electrode is grounded. The simulation is carried out at a pressure of 30 mTorr. It should, however, be mentioned that the model presented here can be applied to other operating conditions. The

computation is based on a one-dimensional coordinate space and three-dimensional velocity space PIC/MC algorithm. The motion of the charged particles is simulated by the PIC method using the standard explicit 'leap frog' finite difference scheme. A detailed description of the PIC technique can be found in Birdsall and Langdon [9]. Electrons are absorbed and ions are neutralized on the electrodes. Secondary electron emission is included here because the rf discharge is assumed to be in the γ-regime at the conditions under study [10]. The initial densities of the charged species in the model are based on experimental and simulation data [4-7]. The initial velocities are calculated from the Maxwellian distribution at an average electron temperature of 2 eV and an average ion temperature of 0.043 eV (500K).

The charged species, which are followed in the model, are: electrons, Ar^+, CF_3^+, N_2^+, F^-, and CF_3^- ions.

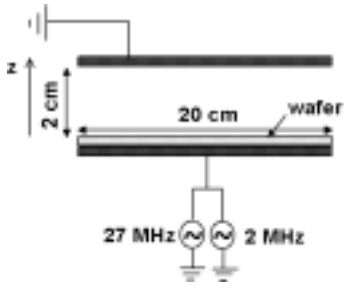

FIG. 1. Schematic diagram of the reactor

Simulation results in a pure cc rf CF_4 discharge show that the dominant positive ions are CF_3^+, with a density exceeding those of CF_2^+, CF^+, C^+ and F^+ by more than 2 to 3 orders of magnitude, and $N_{CF_3^+} \cong N_{F^-} + N_{CF_3^-} + N_e$, where N denotes the number densities in the bulk plasma [6]. For that reason CF_3^+ is the only type of positive ions of CF_4 followed in the model.

The interactions between the particles are treated by a Monte Carlo method, which is basically a probabilistic approach. To calculate collision probabilities, it is necessary to have the corresponding collision cross section data, which are not always available. Hence, the present model uses several techniques to define the collision probabilities even when the collision cross sections are unknown. The electron - neutral collision probability is determined by the null collision method based on cross section data [11]. In the present model, however, the expression for determining the electron scattering angle differs from the one proposed in Ref. 11, as it is explained in Ref. 12. The Ar^+ - Ar, Ar^+ - N_2, N_2^+ - N_2 and N_2^+ - Ar collision probabilities are calculated in the same way. The other ion – neutral elastic and reactive collisions, included in the model, are calculated by an ion-molecule collision model for endothermic reactions [6]. The probability for positive-negative ion recombination is determined from a recombination rate constant [13]. The outlines of all techniques are given in our previous paper [7]. In this paper the electron – positive ion (CF_3^+ and N_2^+) recombination is newly included and details for the method are given later in this section.

The electron-neutral collisions considered in this simulation, along with the corresponding threshold energies and references are presented in Table I.

The Ar^+ - Ar and N_2^+ - N_2 elastic isotropic and backward scattering (to simulate charge transfer) cross sections are taken from Phelps [18]. The cross section data for non-resonant charge transfer between Ar^+ and N_2 and between N_2^+ and Ar are adopted from Spalburg and Gislason [19]. The collision probabilities for these reactions are calculated by the null-collision method [11].

[a] N_2^* (Y) = N_2 (υ = 0-8, A $^3\Sigma$, B $^3\Pi$, W $^3\Delta$, B′ $^3\Sigma$, a′ $^1\Sigma$, a $^1\Pi$, w $^1\Delta$, C $^3\Pi$, E $^3\Sigma$, a″ $^1\Sigma$, and "sum of singlets", including dissociation)

[b] N_2^+ (Y) = N_2^+ (X $^2\Sigma$ and A $^2\Pi$)

The CF_3^+ - CF_4, F^- - CF_4 and CF_3^- - CF_4 elastic and reactive collisions are simulated using the ion-molecule collision model for endothermic reactions developed by Nanbu and Denpoh [6]. All ion - CF_4 reactions considered in the model and the corresponding thermodynamic threshold energies, are given in Ref. 7. The Ar^+ - CF_4, CF_3^+ - Ar, F^- - Ar, and CF_3^- - Ar elastic collisions are treated by means of the same technique [7].
The positive-negative ion and electron – ion recombination and the corresponding rate constants, along with the references are presented in Table II.

TABLE II. Positive-negative ion and electron – positive ion recombination reactions considered in the model and the corresponding recombination rate coefficients.

Reaction	Rate constant (m^3/s)	Ref.	Reaction	Rate constant (m^3/s)	Ref.
$F^- + Ar^+ \rightarrow F + Ar$	1×10^{-13}	20			
$F^- + CF_3^+ \rightarrow F + CF_3$	1×10^{-13}	20	$e + CF_3^+ \rightarrow CF_3$	$3.95\times10^{-15}/\sqrt{T_e}T_i$	21
$CF_3^- + Ar^+ \rightarrow CF_3 + Ar$	1×10^{-13}	20			
$CF_3^- + CF_3^+ \rightarrow CF_3 + CF_3$	1×10^{-13}	20	$e + N_2^+ \rightarrow 2N(^4S)$	$7.72\times10^{-14}/\sqrt{T_e}$	22

The ion-ion and electron-ion recombination cross sections and hence the probabilities are determined from a given expression for the corresponding rate constant, as proposed by Nanbu and Denpoh [13, 21]. We have already explained the collision model for ion – ion recombination [7]. The dependence of the electron - ion rate constants on the electron temperature T_e and ion temperature T_i makes the model more complicated. The electron – ion recombination is treated using the null-collision technique [21]. Let us express the electron – ion rate constants as $k_{e\text{-}i} = a / (T_e)^{1/2}$, where a is equal to 3.95 x 10^{-15} / T_i and 7.72 x 10^{-14} for electron – CF_3^+ and electron – N_2^+ recombination, respectively. The electron temperature is calculated from $T_e = m_e v_e^2 / 3e$, where m_e and v_e are the mass and velocity of the electron, respectively, and e is the electron charge. The probability that an electron with velocity v_e recombines with a positive ion in time step Δt is given by [21]

$$P_{r_{e-i}} = W_i \frac{N_i}{V_c} \frac{a}{\sqrt{m_e/3e}} \frac{\Delta t}{v_e}, \quad (1)$$

where W_i and N_i are the ion weight (representing the real ions in one simulated super-particle) and the number of the simulated ions, respectively, in a cell with a volume V_c. Since eq. (1) has a singularity at v_e = 0, a cutoff parameter $(v_e)_{\min}$ is introduced to obtain the maximum recombination probability [21]. The cutoff parameter is chosen to be 1/5 of the mean electron velocity in each cell so that the probability that a randomly sampled electron has a velocity less than $(v_e)_{\min}$ is only 1.1 % in equilibrium [21]. If the number of the simulated electrons in a cell is N_e, the maximum number of the simulated electrons N_{re} that can recombine is calculated from

$$(N_{re})_{\max} = W_i \frac{N_e N_i}{V_c} \frac{a}{\sqrt{m_e/3e}} \frac{\Delta t}{(v_e)_{\min}}. \quad (2)$$

The colliding electrons $(N_{re})_{\max}$ are chosen randomly. Then call a random number R and check each electron with velocity v_e if it recombines with an ion, i.e., if R is less than $(v_e)_{\min}/ v_e$. If $R \geq (v_e)_{\min}/ v_e$ the recombination is null.
It should be kept in mind that in case of different weights for ions W_i and electrons W_e, as in the present simulation, the maximum number of simulated ions that can recombine $(N_{ri})_{\max}$ is not equal to $(N_{re})_{\max}$ and is given by $(N_{ri})_{\max} = (N_{re})_{\max} W_e/W_i$.
For the electron – CF_3^+ recombination model the ion temperature is determined as the mean energy in each cell, i.e. $T_i = m_i \langle v_i^2 \rangle / 3e$, where m_i and v_i are the mass and velocity of the ion, respectively [21].
In the simulation the recombination time step is taken to be 10^5 times longer than the electron time step; the probability for recombination is, indeed, low because of the much lower ion densities in comparison with the neutral gas density.

3. Results and discussion

The calculation is performed for an $Ar/CF_4/N_2$ mixture at a ratio of 0.8/0.1/0.1. In Figs. 2 - 4 the rf powered electrode is at position 0 and the grounded electrode is at position 2cm. The gas temperature is set to 300 K. The choice of the grid spacing and the time steps is defined by the accuracy criteria for PIC/MC codes with explicit mover [8]. Typical results of this model are electron and ion densities, fluxes and energy distributions, collision rates and electric field and potential distributions.

Fig. 2 presents the simulation results of the electric field distribution (a) and (b), and the electron density distribution (c) in 2 LF cycles. A close look at the electric field in the bulk plasma [Fig. 2(b)] shows the appearance of double-layer structures and field reversal near the bulk – sheath interface, i.e. the discharge structure is electronegative (cf. with the results for a pure CF_4 discharge, presented in Ref. 7). The electron density has maxima at the bulk – sheath interface [Fig. 2(c)]. Moreover, the main negative carriers are CF_3^- ions and their density in the bulk exceeds the electron density by 1 order of magnitude [cf. Figs. 2(c) and 3(c)]. The average electron energy in the bulk plasma is calculated to be around 7 eV, which is comparatively high due to the substantial electric field in the center (on the order of 5000 V/m). The electron density and consequently the sheath width oscillate with the applied double frequency.

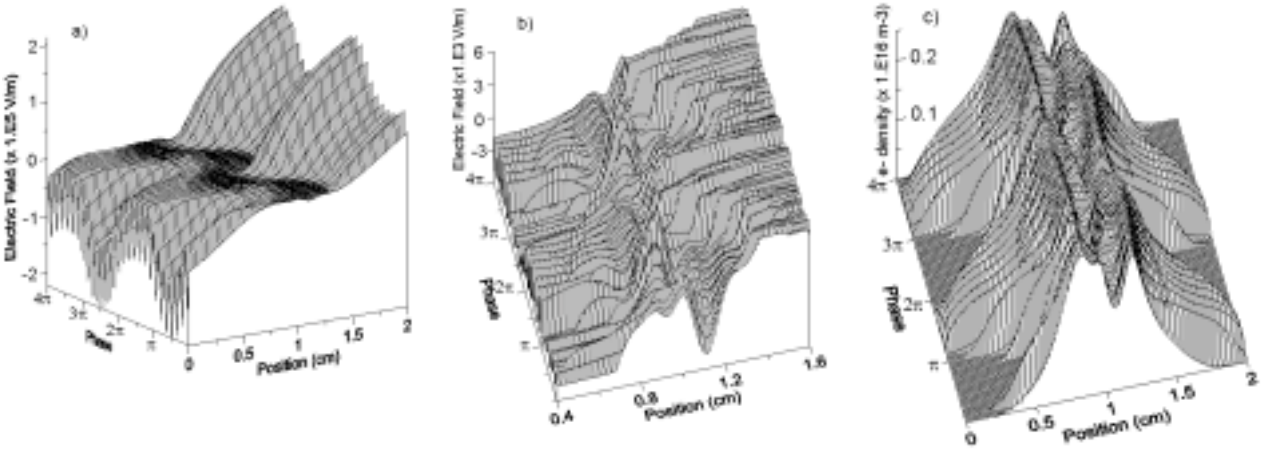

FIG. 2. Electric field in the simulated (a) and in the bulk region (b), and electron density (c) in 2 LF cycles.

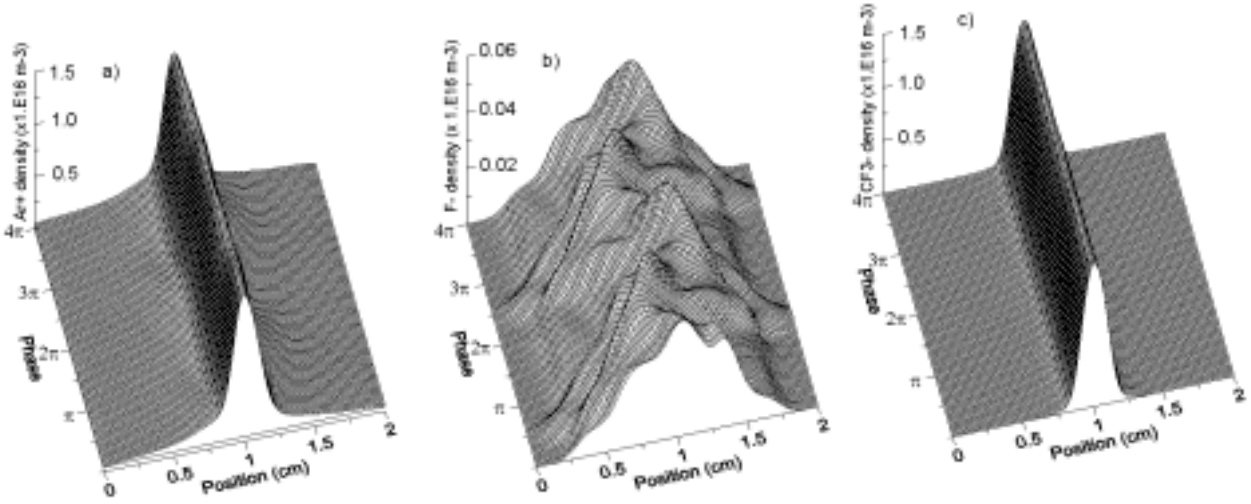

FIG. 3. Ar^+ (a), F^- (b), and CF_3^- (c) ion densities in 2 LF cycles.

The Ar^+ (a), F^- (b) and CF_3^- (c) ion densities in 2 LF cycles are shown in Fig. 3. The density distributions of the other positive ions CF_3^+ and N_2^+ are not given because their profiles are similar to that of Ar^+ ions. The major positive ion is Ar^+ and its density in the bulk center has a value of 1.5×10^{16} m^{-3}, whereas CF_3^+ and N_2^+ densities have values of only 1.2×10^{15} m^{-3} and 6.0×10^{14} m^{-3}, respectively (not shown). Contrary to other investigations of cc single HF pure CF_4 and Ar/ CF_4 discharges, CF_3^- ions are the dominant negatively

charged species and the density of the F^- ions is rather small [4-7]. In the presence of LF (2MHz) and the strong electric field the light F^- ions are not confined in the bulk plasma as in one-frequency discharges. They have enough time to move towards the electrodes. The much heavier CF_3^- ions cannot respond to the LF and they remain in the bulk plasma [cf. Fig. 3 (b) and (c)]. The F^- density profile is greatly modulated by the LF and F^- ions are detected at the powered electrode at phase $\pi/2$ of the LF cycle. From the electric field distribution one could expect that F^- ions are able to reach the powered electrode at phase $3\pi/2$, when the electric field is almost 0, like the electrons [Fig. 2]. However, at that time F^- ions are detected at the grounded electrode [Fig. 3(b)]. A possible explanation is that F^- ions are inert in comparison with the electrons and 2 MHz is not low enough for F^- to respond instantaneously to the electric field. Our simulation results for a dual frequency (1+27 MHz), which are not presented here, show that F^- ions reach the electrodes at phase shifted with $\pi/2$ (cf. with π in the present simulation) in comparison with the phase when the electric field is almost 0. In addition, the higher electron density [cf. Figs. 2(c) and 3(b)] and the movement of electrons with 2 frequencies make the detailed analysis very complicated.

The Ar^+ (a), CF_3^+ and N_2^+ (b) ion energy distribution functions (IEDF) at the powered electrode, averaged for 2 LF cycles is presented in Fig. 4. The IEDF is broad and bimodal as it is expected in the presence of the LF [23, 24]. In LF regime the ion transit time τ_{ion} is less than the rf period $\tau_{rf} = 2\pi/\omega_{rf}$, i.e., the ions cross the sheath in a small fraction of the rf cycle and they reach the electrode with an energy equal to the instantaneous sheath potential drop. The two outstanding peaks in the profile correspond to the minimum and maximum sheath potential drop. In this simulation τ_{ion}/τ_{lf}, where τ_{lf} is the LF period (f = 2MHz), is calculated to be 0.6, 0.8 and 0.5 for Ar^+, CF_3^+, and N_2^+ ions, respectively. Analytical calculations and experiments show that the IEDF width $\Delta E = E_2 - E_1$, where E_1 and E_2 are the energies at which the peaks are observed, depends on the ion mass ($\sim m_i^{-1/2}$) [23]. The simulation verifies that as m_i is increased, ΔE is reduced [cf. the IEDF width for the 3 positive ions in Fig. 4 (a) and (b), considering that $m_{N2+} < m_{Ar+} < m_{CF3+}$].

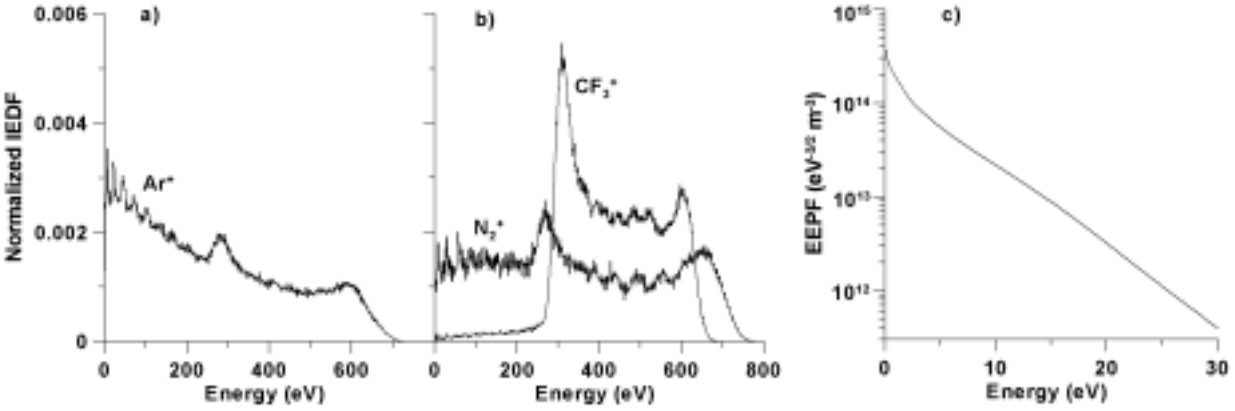

FIG. 4. Ar^+ (a), CF_3^+ and N_2^+ (b) IEDF at the powered electrode, and the EEPF at the bulk center (c), averaged for 2 LF cycles.

The number of secondary peaks in the Ar^+ and N_2^+ IEDF are due to the frequent resonant and non-resonant charge transfer between Ar^+ or N_2^+ and Ar or N_2 [24]. The charge transfer CF_3^+ - CF_3 is not considered in the model since the density of the CF_3 radicals is much lower in comparison with the CF_4 density, with a value in the order of 10^{17} m^{-3} [5]. Elastic collisions lead to the tail of lower energies in the IEDF of the 3 ions [24]. The IEDF profile dependence on the applied frequency and ion mass will be described in detail in another article.

Fig. 4 (c) shows the electron energy probability function (EEPF) $f_e(\varepsilon)$ (= $F_e(\varepsilon)\varepsilon^{-1/2}$, where $F_e(\varepsilon)$ is the electron energy distribution function and ε is the electron energy) at the center of the discharge and averaged for 2 LF cycles. The profile is a bi-Maxwellian distribution. The high energy tail is due to the comparatively strong electric field in the bulk, which is a characteristic feature of electronegative discharges.

4. Summary

A one-dimensional PIC/MC model has been developed to describe the structure of a cc rf discharge in a gas mixture of Ar, CF_4 and N_2. The model follows electrons, Ar^+, CF_3^+, F^-, CF_3^-, and N_2^+ ions. The collisions

treated by the Monte Carlo method include electron – neutral (Ar, CF_4, and N_2) collisions, various kinds of collisions of Ar^+, CF_3^+, F^-, CF_3^- or N_2^+ with neutrals, positive - negative ion recombination, and electron – ion recombination.

The simulation is performed for 0.8/0.1/0.1 ratios of $Ar/CF_4/N_2$ mixture in a dual frequency (2+27 MHz) reactor at a pressure of 30 mTorr. This model yields results for the electron and various ion densities, their fluxes and energy distributions, the collision rates and the electric field and potential distributions.

The results show that the structure of the discharge is electronegative, i.e. double layer structure and electron density maxima at the bulk – sheath interface are observed. Contrary to other investigations of pure CF_4 or mixes of CF_4 discharges in single frequency reactors, in the present simulation CF_3^- ions are the dominant negatively charged species and the density of the F^- ions is rather small. In the presence of LF (2MHz) and the strong electric field F^- ions are not confined in the bulk plasma as in single HF discharges and they have enough time to move towards the electrodes. The much heavier CF_3^- ions cannot respond to the LF and they remain in the bulk plasma. The electron density and the sheath width oscillate with the applied double frequency.

The IEDF is broad with two outstanding peaks, which correspond to the minimum and maximum sheath potential drop. The EEPF has a bi-Maxwellian profile with a high energy tail.

Developing a Particle Detection System in a Capacitively Coupled GEC Cell

S. Hong[1], J.-C. Schauer, J. Berndt, J. Winter

Institute for Experimental Physics II, Applied Plasma Physics, Faculty for Physics and Astronomy, Ruhr-University Bochum, Universitätsstr. 150, 44780 Bochum, Germany

Abstract

The behavior of the harmonics at different conditions including Ar/CH_4 dusty plasma is studied. It is found that the presence of the 7th harmonic is strongly correlated with the plasma sheath thickness. This may be due to a series resonance. A simple explanation for the increase of the 2nd and 3rd harmonics during the dust particle formation is given.

1. Introduction

The dust particle formation in reactive plasmas is now well known. Since the growth of the particles in reactive plasmas, especially so called "killer particles", causes major defects of the semiconductor productions in industry, detecting, monitoring, and controlling methods for the particle formations are highly desired. Known particle diagnostic methods are 1) laser light scattering for presence and density [1], 2) Mie-ellipsometry for particle density, size, size distribution, and shape of particles [2], 3) *in situ/ex situ* infrared absorption, Raman spectroscopy, mass spectrometry for chemical compositions [3], 4) mass spectrometry, photodetachment for particle charge and electronegativity [4], 5) phosphoresence, black body radiation for particle temperature and velocity distribution [5, 6] 6) SEM/TEM, X-ray diffraction, photoluminescence for morphology and structure of the particles [1, 7], and 7) optical spectroscopy, electrical probe measurements, mass spectrometry, and microwave diagnostics for the influence of particles on the plasmas [7, 8, 9].

In this paper, we have investigated the influence of particles on the plasmas by means of electrical voltage/current probe measurements in a capacitively coupled plasma. It is well known that the presence of dust particles in a rf excited plasma has a dramatic effect on the plasma impedance [8, 9]. Consequently, the Fourier analyzed voltage/current harmonic signals of both electrodes are strongly influenced by the formation of particles. A possibility to use the change of the plasma impedance monitored by a spectrum analyzer as a particle detecting system is suggested by Boufendi et al [8]. Recently the use of the 7th harmonic voltage signal as a particle size indicator was suggested by Hong et al [7]. However, care must be taken, since voltage/current measurements show the global change from the whole reactor. Also, particle density and spatial distribution of the particles can not be measured or determined directly. Despite of those disadvantages, it is shown that a strong correlation exists between two completely independent "global" and "local" measurement methods, e.g. between Fourier analyzed signal of the powered electrode and Mie-ellipsometric measurements [10]. These results support the basic idea of using the harmonic signals as a particle detector and size indicator. As a first step, we have investigated the change of plasma impedance, i.e., the behavior of the harmonics at different conditions.

2. Experimental Setup

Figure 1 shows a simple sketch of the experimental setup. A standard GEC cell is pumped by a rotary vane vacuum pump (Pfeiffer DUO 10 C) resulting in a pressure of about 10^{-4} mbar. Flow rates of the gases are controlled by MKS Mass-Flow controller. Gases are introduced through the showerhead of the upper electrode. A 13.56 MHz rf generator (Dressler Cesar 133) is capacitively coupled to one of the electrodes through an impedance matching network. To be sure that external circuit elements do not affect the measurements, we have carefully tested the measurements using three different types of matching networks. The other electrode is grounded. The electrodes are 10.2 cm in diameter and are separated by 3.1 cm. Homemade voltage/current probes are attached to the end of each electrode. The voltage/current signals are then measured *in situ* by a digital oscilloscope (Tektronix TDS 784A). For the Fourier analyzed signal measurements, the digital oscilloscope is removed and one of the voltage measurement nodes of the probes is connected to a spectrum analyzer (Rohde & Schwarz FSEM 30) directly and the harmonic signals are measured.

3. Parasitics of the GEC Cell

In general, care must be taken during the interpretation of measured voltage/current signals, since higher harmonics can be caused by resonances with external circuit components used in the matching network or probe itself. Such resonances caused by the admittance of driven Langmuir probe systems have already been reported

[1]e-mail address: hong@plas.ep2.rub.de

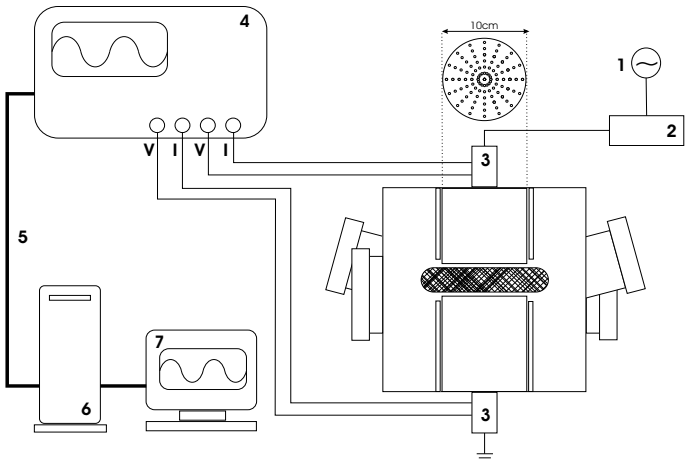

Figure 1: Experimental Setup. (1) 13.56 MHz rf power generator, (2) Matching Network, (3) Voltage/Current probe, (4) Oscilloscope, (5) GPIB cable, (6) PC, (7) Monitor

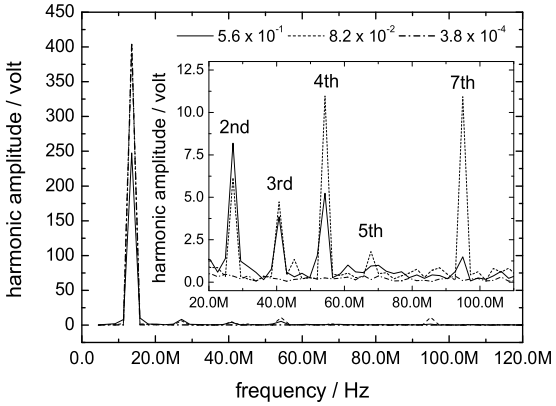
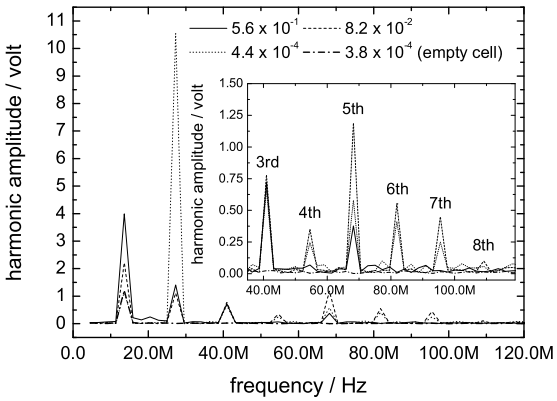
[11]. In order to clarify that the external circuit connected to the upstream of the voltage/current probes does not influence the measurements, we have tested the harmonics of the voltage signal using 6 different combinations of three different types of matching networks and two different types of voltage probes. The "empty cell" measurements (no gas flow, 20 Watt input power only) show the fundamental frequency of 13.56 MHz only. Despite the different configurations of the matching networks, even when we have replaced the matching network by a blocking capacitor, we have confirmed the same characteristic behavior of the harmonic signals up to the 8th harmonic measured by two different types of voltage probes in an Ar plasma. Furthermore, we have simulated plasma impedance using a "well-matched" 2nd matching network placed at the position of the reaction chamber, while the setting of the primary matching network for the Ar plasma is maintained. The term "well-matched" means that the 2nd matching network is adjusted for the primary one in order to get maximum power transfer. In this case, however, we have different harmonic signals, i.e. the fundamental, the 2nd, and a very small amplitude of the 3rd harmonic. These results reveal that the higher harmonic signals are mainly generated by the impedance from the downstream of the voltage/current probe. The sources of the resonance might be nonlinear behavior of the sheath and/or parasitic impedance of the electrodes resonating with plasma sheath capacity. Since parasitic impedance of the electrodes is an important factor which can make systematic errors for both measurements and interpretations of the harmonic measurements, the effects should be carefully considered [12, 13]. Direct measurements of the impedance of the electrodes in the range of 1-200 MHz by a network analyzer (HP4195A) show that main resonance frequencies for the parasitic impedances of both electrodes are 28.5 MHz (lower) and 37 MHz (upper) respectively. These resonance frequencies are consistent with the results performed using 5 different GEC cells, reported by Hargis et al [12]. Together with the "empty cell" measurements and the harmonic measurements using the "well-matched" 2nd matching network, these results indicate that the higher harmonics might be generated by the nonlinear behavior of the sheath. These will be discussed in the next section in detail.

4. Presence of Harmonics

Figure 2(a) and 2(b) show the Fourier analyzed harmonic signals present in an Ar plasma at different pressures. The input power is coupled to the upper electrode at a constant level of 20 Watts. The voltage signals are measured by the voltage probe placed at both upper and lower electrodes and the measured waveforms are Fourier analyzed by fast Fourier transformation. At a high pressure of 5.6×10^{-1} mbar, the fundamental, the 2nd, the 3rd, the 4th and a small amplitude of the 7th harmonic are present at the upper electrode (solid). As the pressure decreases, other higher harmonics are present. At a pressure of 8.2×10^{-2} mbar, the 5th harmonic signal is present. At this pressure the 4th and the 7th harmonic signals have higher amplitudes than other harmonic signals. At a pressure lower than 3.8×10^{-4} mbar, the Ar plasma can not be maintained with 20 Watts input power. At this pressure the "empty cell" measurement is performed. It is clear that only the fundamental frequency is present (dash-dot). In the case of the grounded lower electrode, the fundamental, the 2nd, the 3rd, and the 5th harmonics are present at a high pressure of 5.6×10^{-1} mbar. At a pressure of 8.2×10^{-2} mbar, the harmonics up to the 8th are present. As the pressure decreases further, the 2nd harmonic signal is the most dominant harmonic (dot in the figure 2(b)) at a pressure of 4.4×10^{-4} mbar.



(a) at the powered upper electrode



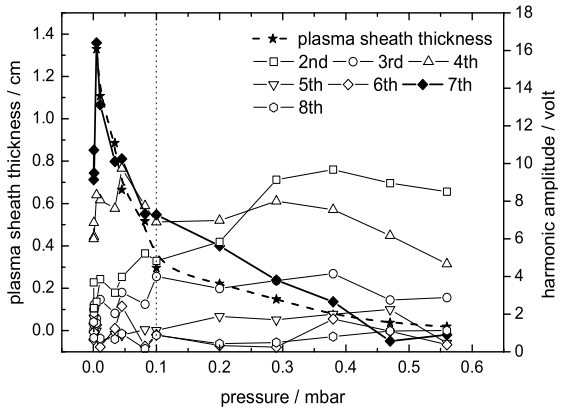
(b) at the grounded lower electrode

Figure 2: Fourier analyzed harmonic signals from the fundamental up to the 8th frequency measured as a function of pressure (solid: 5.6×10^{-1} mbar, dash: 8.2×10^{-2} mbar, dot: 4.4×10^{-4} mbar, dash-dot: 3.8×10^{-4} mbar: empty cell).

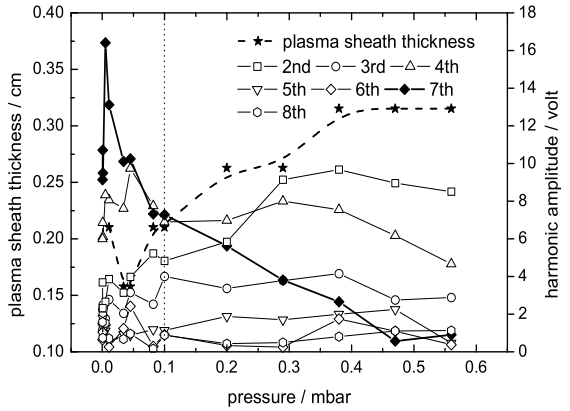
Figure 3 shows the harmonic amplitudes from the 2nd up to the 8th harmonic signals and both plasma sheath thicknesses at both electrodes as a function of pressure. At a pressure higher than 1×10^{-1} mbar, the amplitudes of the harmonics are slightly changed at the powered upper electrode, and they are independent of the plasma sheath thickness of the upper electrode except for the 7th harmonic (figure 3(a)). Instead, it seems that they depend on the plasma sheath thickness of the lower electrode as shown in figure 3(b). At a pressure lower than 1×10^{-1} mbar, the plasma sheath thickness at the upper electrode increases rapidly, the 7th harmonic behaves the same as the plasma sheath thickness (figure 3(a)). The strong correlation between the 7th harmonic and the plasma sheath thickness indicates that the resonance might be a series resonance. A series resonance occurs when a cold plasma behaves inductively and resonates with two sheath simultaneously at a frequency below the electron plasma frequency, $\epsilon = 1 - (\omega_{ep}^2/\omega_R^2) < 0$. It depends on the plasma and sheath thickness and the plasma density. Figure 3(c) and Figure 3(d) show that the harmonics measured at the grounded lower electrode behave the same as the plasma sheath thickness of the upper electrode except for the 3rd harmonic at a high pressure. At a pressure lower than 1×10^{-1} mbar, the 3rd harmonic shows the same behavior. Ku et al. have reported [14] that, 1) the plasma-sheath resonates at a lower pressure than 1 Pa (1×10^{-2} mbar), 2) the resonance regime at a higher pressure than 1 Pa has been identified as the sheath capacity of the driven electrode resonating with the inductance of the external rf circuitry. However, it should be pointed out that the plasma sheath resonance can be tuned by altering excitation voltage [14]. The excitation voltage V_{pp} is over 700 V, which is much higher than in their experiments (V_{pp}=400 V), the harmonics present in the plasma - in our case - cannot be interpreted simply as a resonance with external rf circuits.

5. Response of the Plasma to the Formation of Dust Particles

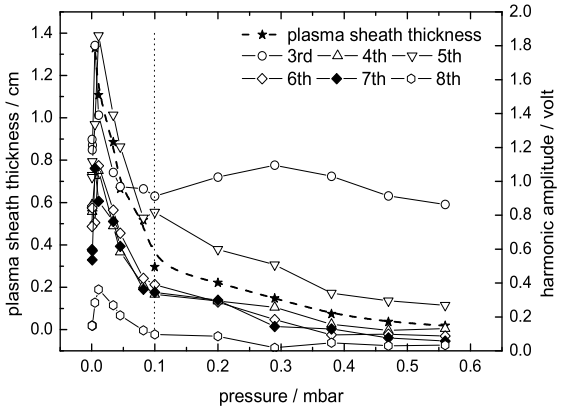
As long as the plasma is dust free, the harmonics remain almost constant. As soon as dust particles are present in the plasma, all measured harmonics show certain characteristic features indicating the particle formation and their growth as a function of time: the evolution of the signals measured in an Ar/CH_4 plasma is divided into 4 time periods as labelled in figure 4(a). To initiate the particle formation in the Ar/CH_4 plasma, it is necessary - in our experiment - to apply transiently high power (ignition power > 60W, 15∼30 sec; maintenance power 20 W) to the plasma [7]. The first time period of the evolution (label 1 in figure 4(a)) consists of two physical situations: 1) the initiation of the particle formation. The critical concentration of proto-particles is generated as long as high input power is applied, and the particle formation is initiated. 2) the coagulation process takes place [8]. As the coagulation takes place, the particle size grows up while the particle number density in the plasma decreases rapidly. The emission light intensity starts to increase indicating that the $\alpha \rightarrow \gamma'$ transition takes place. The plasma resistance increases and the plasma sheath thickness decreases resulting the decrease of resonance amplitudes. Especially the 7th harmonic amplitude decreases rapidly. The 8th harmonic signal is completely disappeared. However, the 2nd and the 3rd harmonics increase slightly. These results reveal that



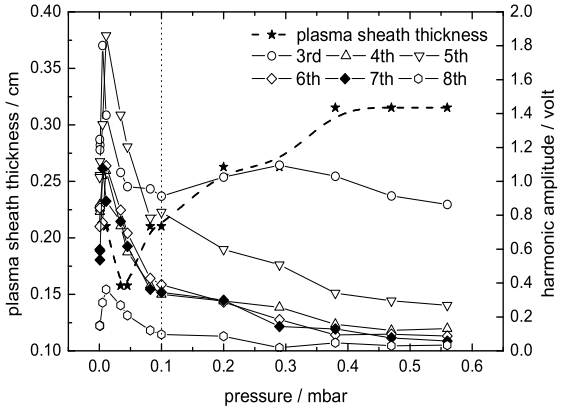
(a) harmonics at the powered upper electrode with the plasma sheath thickness at the upper electrode



(b) harmonics at the powered upper electrode with the plasma sheath thickness at the lower electrode

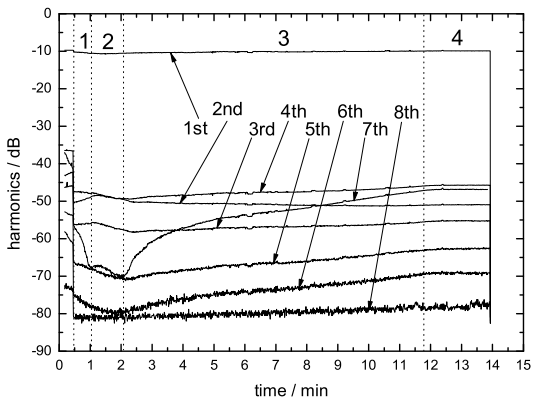


(c) harmonics at the grounded lower electrode with the plasma sheath thickness at the upper electrode

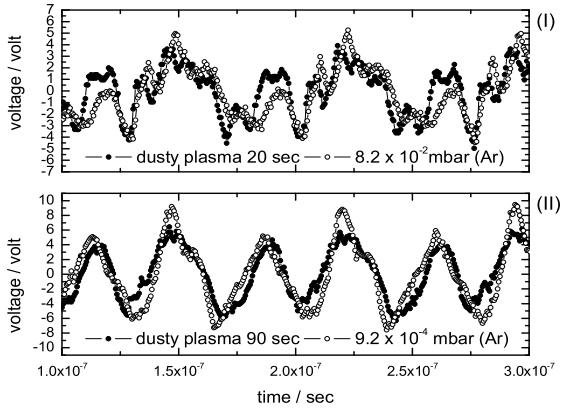


(d) harmonics at the grounded lower electrode with the plasma sheath thickness at the lower electrode

Figure 3: Amplitude of Fourier analyzed harmonics from the 3rd up to the 8th harmonic frequency and plasma sheath thicknesses as a function of pressure [closed star: plasma sheath thickness, open square: the 2nd (27.12 MHz), open circle: the 3rd (40.68 MHz), open triangle: the 4th (54.24 MHz), open inverted triangle: the 5th (67.8 MHz), open diamond: the 6th (81.36 MHz), closed diamond: the 7th (94.92 MHz), open hexagon: the 8th (108.48 MHz)]



(a) harmonics at the powered upper electrode



(b) waveform at the grounded lower electrode (closed circle: dusty plasma - 20 second (I), 90 second (II) operation time in an Ar/CH_4 plasma, open circle: 8.2×10^{-2} mbar (I), 9.2×10^{-4} mbar (II) in an Ar plasma)

Figure 4: Amplitude of Fourier analyzed harmonic signals at the powered upper electrode and waveforms at the grounded lower electrode in two different situations of the particle formation comparing with situations in an Ar plasma

the plasma characteristic at the upper electrode region might be shifted towards that of the high pressure region in figure 3, because the plasma sheath thickness decreases as a function of time. Therefore the 2nd and the 3rd harmonics might be increased slightly. If the plasma at the lower electrode region behaves the same way as that of the upper electrode region, i.e. the plasma sheath thickness decreases as a function of time, the 2nd harmonic should be the dominant frequency as shown in figure 2(b) and the plasma characteristics shold be shifted towards that of the lower pressure region. During this phase, as expected, the 2nd harmonic is found as the dominant frequency at the lower electrode. Figure 4(b) shows waveforms at the lower electrode at two different situations for the particle formation compared with situations in an Ar plasma: closed circles show the waveform measured at 20 seconds (I) and 90 seconds (II) after the particle formation is initiated in an Ar/CH_4 plasma. The open circles represent the waveform measured at pressures of 8.2×10^{-2} mbar (I) and 9.2×10^{-4} mbar (II) in an Ar plasma. Shortly after the particle formation is initiated, the two waveforms in both plasmas are similar as shown in figure 4(b)-(I). Since the pressures are at the same range, there are only small effects of the dust particles. As the dust particles grow up, measured waveforms show completely different patterns. The 2nd harmonic is the dominant one as shown in figure 4(b)-(II). A similar situation is observed in the Ar plasma at a low pressure of 9.2×10^{-2} mbar (see figure 2(b)). This similarity can be explained in following way. A strong correlation between mass spectra (i.e. partial pressure) and the 7th harmonics has been found [7, 15]. Because the dust particles behave as a sink for the small particles, they absorb the particles in the plasma resulting a high growth rate of about 100nm/min. As a result, the partial pressure starts to decrease the same as the 7th harmonic does. Then, the plasma at the lower electrode region might react as if the pressure is decreased: the plasma sheath thickness decreases. The 3rd harmonic shows similar behavior.

The decrease of the harmonic signals in the 2nd time period (label 2 in figure 4(a)) indicates - in our case - the development of the void. The presence of the void is strongly correlated with the particle size in the plasma, since the neutral drag force acting on the particles plays an important role. When the void starts to develop the 7th harmonic shows a small shoulder. The particle diameters before and after the void development are about 150±15 nm and about 318±30 nm, respectively. This means that particles that have a size greater than approximately 150-200 nm in diameter will be pushed away from the center region by the neutral drag force.

After the void is developed, the dust particles are continuously grown up at the outside of the electrodes where the electric field is relatively weak (label 3, the 3rd time period in the figure 4(a)). The emission light intensity decreases as the electron temperature decreases. The plasma becomes slowly capacitive again, the amplitudes of the harmonics begin to return to their initial values. At the last stage of the 3rd time period, the particle diameter is about 673±65 nm. In the 4th time period when the particles that have a size lager than 800 nm $\sim$

1 μm are lost due to the gravitational force, harmonic signals show a steady state.

6. Summary and Discussion

We have investigated behaviors of the harmonic signals at different conditions as a first step of developing a particle detection system in a capacitively coupled plasma. As a result we have found that the presence of the 7th harmonic is strongly correlated with the plasma sheath thickness, it might be due to a series resonance. We have described the correlation between particle formation, the plasma sheath and the behavior of the harmonics. The change of plasma impedance and sheath thickness may cause the small increase of the 2nd and 3rd harmonics during the particle formation in the 2nd time period in figure 4(a). Further investigation is under way to analyze these phenomena.

Acetylene carbon black production in plasma process

Tomasz Zieliński, Teresa Opalińska, Jacek Kijeński

Industrial Chemistry Research Institute, Rydygiera 8, 01-793 Warsaw, Poland

Abstract
Carbon black is an important raw material for plastics and rubber industries all over the world. The efficient, economical, and environmental friendly process for acetylene carbon black manufacturing was the goal of our investigations. The new method and the apparatus for preparation of high quality carbon black from acetylene and plasma mediums, argon and helium, using gliding discharge was proposed.

1. Introduction

The increase of using and application of plastics and rubber products in various branches of industry all over the world, creates the needs of finding new and safe methods of making carbon black. The competition on rubber market forces the carbon black industry to improve, modernize and develop. That is why there is ceaseless necessity of the elaboration the high efficient, economical and environment friendly process and finding new technologies of carbon black production of the best quality and purity. Besides rubber industry, carbon black is used in plastics industry (as a filler) and in production of paints, lacquers and inks.
Carbon black is generic name, which describes wide group of industrial carbon products with systematic nanostructures of elementary carbon [1,2]. The conventional processes for carbon black making under industrial conditions are based on an incomplete combustion of high-boiling aromatic oils or natural gas (furnace and channel processes). These processes are hardly operable and fails to meet the environmental requirements, because of the emission to the atmosphere of CO, CO_2, NO_x volatile hydrocarbons, carbon black and aromatic hydrocarbons seated on carbon black particles [3]. There is also known number of methods of carbon black making from acetylene, but with using mostly equilibrium plasma. Up till now, some investigations have been performed where a new process and apparatus were developed for hydrocarbon processing into carbon black by gliding discharge under non-equilibrium plasma conditions.
The present paper shows the results of our investigations relating to some physical and chemical properties and surface development of carbon black received in non-equilibrium plasma from acetylene, as feedstock, and argon and helium, as plasma mediums.

2. Experimental

In our study, acetylene, as a source gas, was used under argon or helium, as plasma mediums, using gliding discharge process to produce carbon black.

2.1. Apparatus

The gliding discharge was fed by a special three-phase 50 Hz high voltage power system. The plasma reactor consisted of three stainless steel main bar electrodes of special shape and one ignition electrode. The main bar electrodes were situated symmetrically around the ignition electrode at an angle of 120º. The reactor was connected to the water cooler and cyclone where all the post-reaction dust was precipitated from gas. Carbon black was accumulated in a tank situated under the cyclone. Next to the cyclone, the filtering system was located for final remove of the dust from gas. The cleaned gas was taken to the gas burettes for analysis using g. c. method. The chromatograph was supplied by the flame ionization detector (FID). B/5% Fluorocol™ Packed Column was put into use with length of 4m and diameter of 3mm. The helium was used, as a carrier gas, in the chromatograph, with flow rate of 25ml/min. the temperature of the detector was contained between 30°C and 50°C with heatup rate of 4°C/min. The equipment allowed to realize the process continuously. The schema of the apparatus is shown in Fig. 1.

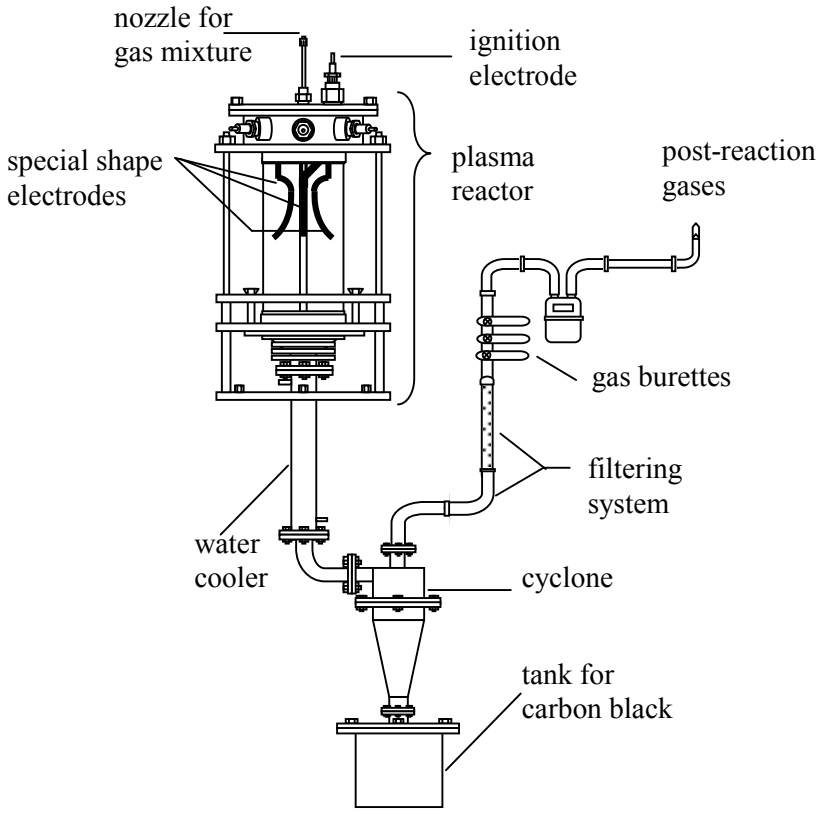

Fig. 1. The schema of acetylene carbon black making apparatus in gliding discharge.

2.2. Procedure

Gas stream of suitable composition and flow rate was injected into the reactor by a nozzle, which was situated above the electrodes. The plasma reactor and installation parameters were optimized to form the most effective field of reactions in gliding discharge. This field of reactions was situated in the whole plasma flame area, which included the maximum volume of gas mixture during the discharge in the reactor. The optimal setting of the main electrodes, besides the maximum field of reactions, allowed to get the conversion of gas reactants to 77%. Scanning electron microscopy (SEM) was used to characterize shape and size of carbon black particles formed in plasma process from various reactants. The carbon black structure properties, like interplanar distance (d_i), diameter of areas of the aromatic layers (L_a), the average thickness of layers packets (L_c), were established with using X-ray diffraction (XRD) method. The flow rate of gas mixture was changeable form 0.5 to 1.25 m^3/h and the source gas content was also changeable from 2 to 10 vol.% in the gas mixture. The compositions of the studied gas mixtures are listed in Table 1.

Table 1. The gas mixtures composition in carbon black making process.

Gas composition [plasma medium and gas reactant in gas mixture]	**Content of reactant in gas mixture** [vol.%]
Ar – C_2H_2	5
He – C_2H_2	10

3. Results and discussion

The efficiency of the process and energy consumption depend on kind of carrier gas in the mixture content of the hydrocarbon in the gas mixture. The process efficiency in acetylene carbon black production in different plasma mediums is shown in Table 2. For example, conversion of C_2H_2 and conversion of C_2H_2 to carbon black in Ar-plasma are similar and they grow up with increasing of the source gas content in the mixture, the same like process leaded in He-plasma (Fig. 2, Fig. 3). Fig. 2 shows the process conditions of Ar-C_2H_2 gas mixture composition with changeable source gas content from 2vol.% to 5vol.% of C_2H_2 in the mixture with

1.0 m^3/h flow rate of the gas mixture. Fig. 3 shows the process conditions of He-C_2H_2 gas mixture composition with changeable source gas content from 2vol.% to 10vol.% of C_2H_2 in the mixture with 1.0 m^3/h flow rate of the gas mixture.

Table 2. Process efficiency in acetylene carbon black production.

Gas composition [source gas and plasma medium mixture]	**Process efficiency**	
	[% of conversion of source gas]	[% of conversion of source gas to carbon black]
Ar – C_2H_2	37-48	35-48
He – C_2H_2	42-60	41-60

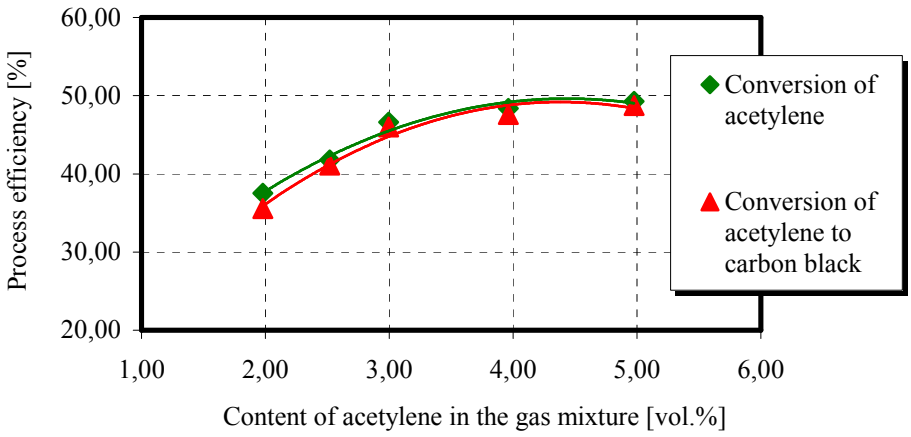

Fig. 2. Process efficiency of carbon black making process depended on content of acetylene in Ar-plasma

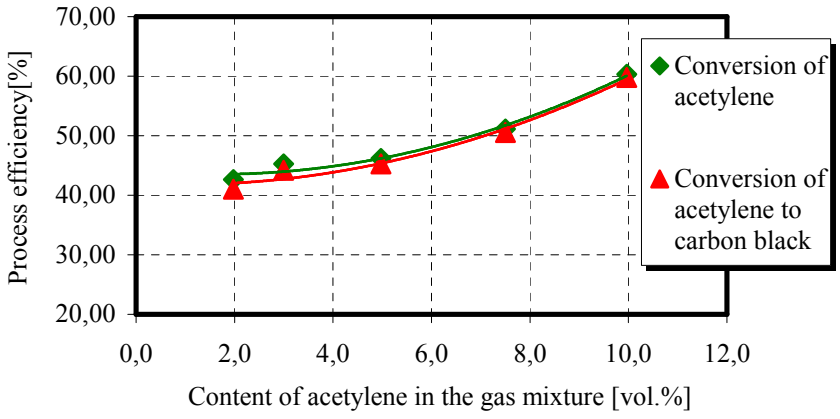

Fig. 3. Process efficiency of carbon black making process depended on content of acetylene in He-plasma

The first group of carbon blacks was obtained from acetylene and in argon as plasma medium. The results of the investigations indicated that changes of the amount of acetylene in reacting gas and its flow rate do not remarkably influence the properties of carbon black surface and its physical-chemical properties. At the different contents of gas reactants in gas mixture carbon black was synthesized of the same structure of the surface. The application of argon as plasma medium led to the formation of carbon black of more interesting properties. The optimal content of reactant in gas mixture was 5vol.% of C_2H_2 in argon plasma and with 1.0 m^3/h of gas mixture flow rate under the atmospheric pressure. SEM pictures indicated that the shapes of particles of obtained carbon black were similar independing on reaction conditions. They look like fuzzy flakes

connected together very closely. The morphology of carbon black made from acetylene in argon plasma is shown on Fig. 4.

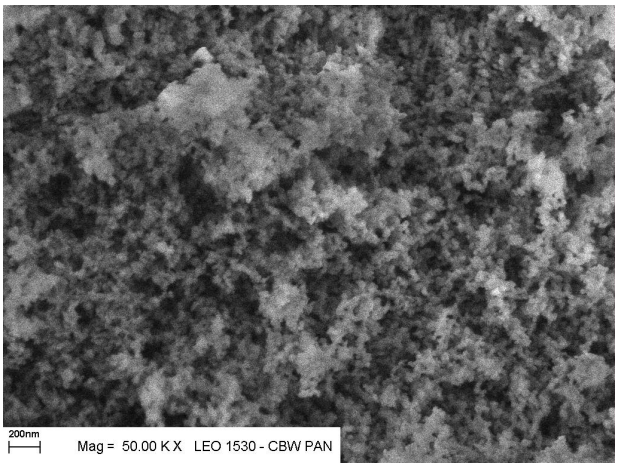

Fig. 4. The surface morphology of carbon black made from acetylene in argon plasma

The SEM picture of carbon black, prepared from C_2H_2 both in Ar plasma, showed that the particles possessed large area. Fuzzy flakes indicated on very good surface development, what was strictly connected with the high adsorption capacities. The X-ray diffraction results have shown that interplanar distance (d_i) measured for carbon black obtained from gas mixture with 5vol.% of C_2H_2 in Ar-plasma was large (Fig. 5). The large distance between layers can be considered as large as graphite layers interplanar distance (c.a. 3.4Å). The diameter of agglomerates of the aromatic layers (L_a), (Table 2) was also large and the layers did not have a bearing point. The aromatic layers could easily deflect and were mobile. The average thickness of layers packets (L_c) (Table 2) resulted in good properties and behavior of large agglomerates. The physico-chemical properties, mostly the interplanar distance closed to graphite (close to 3.4Å of d_i) and the results of BET adsorption – the specific surface area over 80 m^2/g, the iodine adsorption capacity (IA) – over 80 mg/g and dibutyl phthalate adsorption capacity (DBP) – over 100cm^3/100g, in comparison with the commercial furnance carbon black, confirmed the significant development of the surface. The produced carbon blacks exhibited high absorbability, which could facilitate the drive of molecules of various substances into their internal structure and the subsequent deposition. This was reflected by the results of adsorption like BET, adsorption of iodine (IA) and adsorption of DBP (Table 3).

Table 3. The results of XRD and adsorption measurements of carbon black made in gliding discharge

Gas mixture composition	**d_i** [Å]	**L_a** [Å]	**L_c** [Å]	**BET** [m^2/g]	**IA** [mg/g]	**DBP** [cm^3/100g]
Ar – C_2H_2	3.8	7.8	32	156	95	125
He – C_2H_2	3.7	10	38	164	127	128

The carbon black prepared from acetylene in He, as plasma medium, exhibited similar properties to the carbon black obtained from acetylene in Ar-plasma. SEM picture of C_2H_2 carbon black from He-plasma have shown the similar surface structure as in the case of C_2H_2 derived carbon black from Ar-plasma. The shape and size of particles were very borne resemblance and look like fuzzy flakes too. Nevertheless, the structure of C_2H_{42} carbon black generated in helium plasma was more agglomerated and less fluffy than C_2H_2 carbon black obtained in Ar-plasma. The particles had similar sizes like these of C_2H_2 carbon black from Ar-plasma. The morphology of carbon black surface from acetylene in He-plasma is shown on Fig. 6.

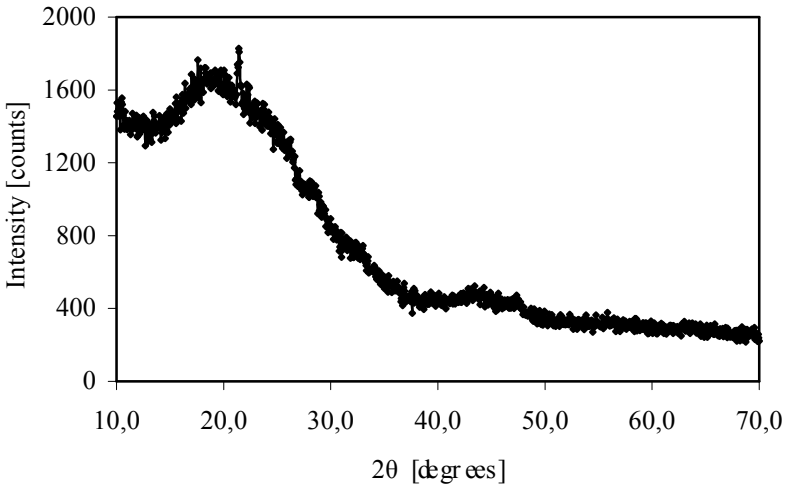

Fig. 5. The XRD pattern of carbon black surface (5vol.% of C_2H_2 in Ar)

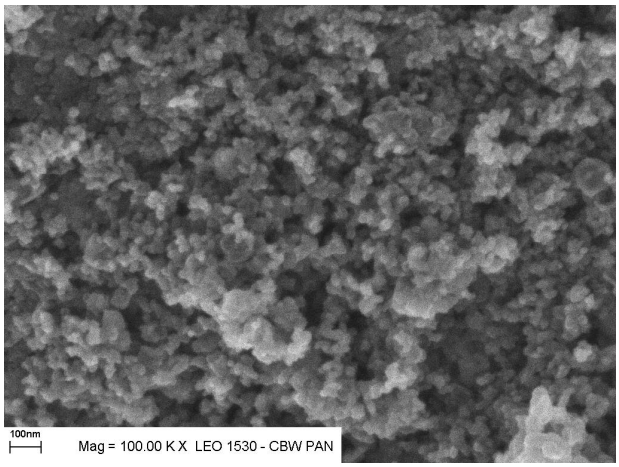

Fig. 6. The surface morphology of acetylene carbon black made in helium plasma

The structure of C_2H_2 carbon black formed in helium plasma was also similar to the one of C_2H_2 carbon black in argon plasma, however, it was more densely packed and little less fluffy. The particles had smaller diameter and were little more minute, but they were more compact.
The interplanar distance (d_i=3.7Å) established for carbon black obtained from 10vol.% of C_2H_2 in He-plasma was little lower (Fig. 7) than the interplanar distance measured for carbon black produced from gas mixture with 5vol.% of C_2H_2 in Ar-plasma (Fig. 5) (Table 3). The diameter of agglomerates of the aromatic layers (Table 3) of C_2H_2 carbon black prepared from gas mixture in He-plasma equaled to 10Å and was significantly higher than the diameter of agglomerates of C_2H_2 carbon black obtained from gas mixture in Ar-plasma, which equaled to 7.8Å. The average thickness of layers packets was higher for C_2H_2-He carbon black (38Å) than for C_2H_2-Ar carbon black (32Å). The high values of XRD parameters (L_a and L_c), calculated for Ar-C_2H_2 carbon black (Fig. 5) and for C_2H_2-He carbon black (Fig. 7.), showed their influence on upgrading the carbon black physicochemical properties. The large dimension of the agglomerates of the aromatic layers and the large average thickness of layer packets together with small interplanar distance (more densely packed particles, more stable and regular strusture) resulted in good commercial properties of carbon black surface.

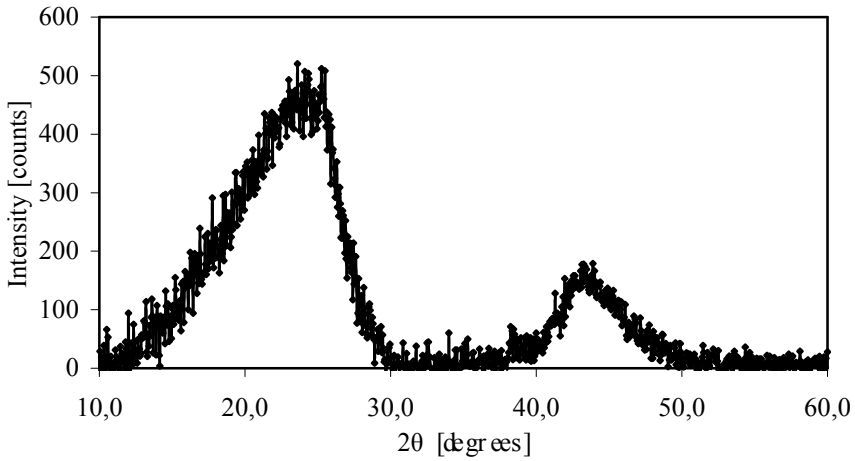

Fig. 5. The XRD pattern of carbon black surface (10vol.% of C_2H_2 in He)

The carbon black obtained in helium as plasma medium possessed the largest specific surface area and adsorption capacity (Table 3), independing on the content of gas reactant used for synthesis. From XRD results one could ascertain that C_2H_2-He carbon black had the best surface properties (facility of drive into and deposition of introduced alien molecules) of all studied carbon blacks.

4. Conclusions

The task of the study was to investigate the surface development of carbon black made in gliding discharge plasma treatment of acetylene in argon or helium. The results of the studies indicated the high increase of the carbon black surface area, especially measured by BET adsorption of nitrogen. The application of gliding discharge for the preparation of carbon black from acetylene allowed to produce material of stable and regular structures. The high adsorption capacity of the prepared carbon black in respect to nitrogen (BET), iodine and dibutyl phthalate indicated a good absorbability, allowing molecules of various substances easily drive into and settle on carbon black surface. This makes possible to use these kinds of carbon black as fillers in rubbers or plastics. There existed the relationship between the values of XRD parameters, like average interplanar distance, diameter of agglomerates of the aromatic layers, the average thickness of layers packets and studied physicochemical properties. E.g. the increase of interplanar distance was reflected in a rise in adsorption capacity. The process efficiency depends on and grows with the increase of source gas content in the mixture, but it has no influence on properties of produced carbon black. Therefore the C_2H_2 in Ar-plasma derived carbon black seemed to be more useful than the one produced from C_2H_2 in He-plasma, because of the economy of the process and the much lower commercial price of argon, than helium, as plasma medium.

SPECTROSCOPIC CHARACTERIZATION OF PLASMA DURING PULSED LASER ABLATION OF GRAPHITE FOR THE SYNTHESIS OF CARBON NANOSTRUCTURES

V.S. Burakov, N.V. Tarasenko, A.F. Bokhonov and M.I.Nedel'ko

Institute of Molecular and Atomic Physics National Academy of Sciences of Belarus, 70 Scaryna Ave., 220072 Minsk, Belarus

During recent years laser ablation of carbon containing targets has been an attractive subject of studies because of promising technological applications, in particular, carbon clusters and nanotubes fabrication [1,2]. For optimization of these applications the detailed understanding the basic physical and chemical processes governing the ablation plume composition and reliable methods for controlling of the relative amounts of plume species are required. The physical properties of plasma plume, such as species concentrations and temperature, directly affect the properties of the material being formed. Different laser-induced effects through mechanisms of laser-surface and laser-plasma interactions may be useful for the management of ablation plume characteristics. In this context, the double-pulse laser ablation technique leading to better coupling of laser pulse energy to the target and ablated matter is of great interest.

This paper presents diagnostic data obtained for the laser ablated plume of a graphite composite samples during the synthesis of carbon nanostructures.

The Nd-YAG (1064 nm, 10 ns, $5 \cdot 10^8$ W/cm^2) laser radiation in combination with the second harmonic (532 nm, $5 \cdot 10^7$ W/cm^2) radiation of another Nd-YAG laser at different temporal delays between pulses were employed for ablation. The laser beams were focused on the surface of the graphite sample (with 1% nickel catalyst) placed in the chamber under helium environments.

Spectroscopic characterization of the ablated plume was performed by the time resolved emission spectroscopy and laser-induced fluorescence methods. The details of these diagnostic techniques were described in [3].

The plasma emission spectra (300-700nm) were recorded and compared for different ablation regimes (single pulse and double pulse in coincidence and in sequence at various delays between pulses and laser fluences). The major species including CI, CII, and C_2, C_3 radicals within the plume have been identified. The spectra were dominated by the C_2 Swan bands ($d^3\Pi_g$ - $a^3\Pi_u$). The emission in the wavelength range 390 - 410 nm was identified as the C_3 (Comet Head System: $A^1\Pi_u$ - -$X^1\Sigma_u^+$). The C_2 high-pressure bands in the spectra were also recorded including the (6 - 7) band at 543.4 nm and (6 - 8) band at 589.9 nm. From emission spectrum of C_2 molecules the vibrational temperatures at various experimental conditions were determined. The vibrational temperatures were found to be much higher than the carbon sublimation temperature (≈4100K for 100 Torr helium atmosphere).

The experiments demonstrated increased plasma emission, higher degree of particle atomization and a higher proportion of ions in dual-pulse ablation regime compared to the plasma produced by one laser. The optimal pulse separations were found both for atomic and ionic lines. The coupling of the second laser beam into the laser-ablated plume caused both significant ionic excitation as well as changes of molecular plume dynamics.

The C_3 band intensity in plasma produced by the sequence of two laser pulses was larger in comparison to the single pulse mode. In contrast to the ionic lines the enhancement of molecular emission was observed in a rather small interval of pulse separations (0-5 μs for C_3 molecules). The dependence of C_2 band intensities on the time delay between laser pulses was similar to that for C_3 molecules, but the enhancements were smaller. When two pulses were fired simultaneously the effect was more than just additive both for the C_3 and C_2 band intensities.

So, the double-pulse laser ablation enables the plasma to be further affected in a controlled way. By proper selection of the pulse separations and wavelengths in the sequence of two laser pulses the parameters of the near-surface plasma can be adjusted to optimize the synthesis of carbon nanostructures.

Abstract
In this paper a complete modeling methodology is applied to the simulation of the dry-etching process of SiO_2 substrates in fluoride-carbon plasmas. The model, implemented in a profile solver based on the level-set method for evolving surfaces, considers the concurrent ion enhanced chemical etching of the adsorbed film and the deposition of an inhibitor compound (polymer) film. The simulation results are compared with experimental etched profiles in different conditions in order to demonstrate the approach reliability.

1. Introduction

The control of the plasma-etched profile geometry in term of the profile Aspect Ratio (AR) and topography is a stringent requirement for the front-end and back-end manufacturing process for microelectronics devices [1]. The complexity of the surfaces phenomena occurring during the erosion process makes strongly inefficient an empirical process development procedure, since a simple extrapolation of the needed machine parameters from known process recipes leads frequently to erroneous predictions of the etching results. In the case of fluoride-carbon plasma etching the situation is even more critical since dry-etch proceeds by means of concurrent Ion-enhanced Chemical Etching (IeChE) of the exposed surface and the deposition of an inhibitor compound [2,3]. Consequently, the need for reliable simulation codes, supporting the process development, is urgent.
Recent theoretical works have been dedicated to investigate different aspects related to the modeling of the plasma etching process, addressing e.g.: the plasma status [4] the surface erosion mechanism [5], the profile evolution [6]. However a comprehensive approach to the plasma etching problematic in view of the application to the process development is still in evolution. Aim of this work is presenting a complete formulation and the implementation of a computational tool for the dry-etching simulation, which should able to support the experimental work on this field.

2. The etching modeling

We implemented our model for the dry-etching process using the level-set scheme for the simulation of an evolving front proposed by Sethian and co-workers [7]. In the level-set method the evolution of the moving front is ruled by a master equation for a function having the moving surface as zero level. Assuming that the initial position of the interface can be represented by the curve Φ in R^d, we can define a function $\phi(r, t=0)$ from R^d to R having the following property $\Phi(t=0) \equiv \{r \in R^d: \phi(r, t=0) = 0\}$. The evolution equation for ϕ is

$$\phi_t + F\,|\nabla\phi| = 0 \qquad (1)$$

where F is the speed of the front in its normal direction (i.e. the etch rate or the deposition rate). The profile curve at a given time $\Phi(t=t^*)$ can be interpolated as the zero level of the evolving function $\phi(t^*)$ since $\Phi(t=t^*) \equiv \{r \in R^d: \phi(r, t=t^*) = 0\}$.
Dry etch in medium/high density fluoride-carbon plasmas is believed to be the result of a concurrent etching (of the SiO_2 substrate) and deposition (of a fluorocarbon film) phenomena. In our model we consider a single active specie (namely the reagent), a single inhibitor specie (namely the polymer) and a single ion specie. Three surface coverages (i.e. the fraction of surface covered by given specie) are considered in the model Θ_e, Θ_P and $\Theta_{e/P}$ relative to the dielectric-reagent, polymer and polymer-reagent. The coverages satisfy to the following sites balance equations:

$$\frac{d\Theta_e}{dt} = J_e S_e (1 - \Theta_e - \Theta_P) - k_{ei}^e J_i Y_{ei}^e \Theta_e - k_{ev} J_{ev} \Theta_e \cong 0 \qquad (2)$$

$$\frac{d\Theta_P}{dt} = J_P S_P - J_i Y_{ei}^P \Theta_P \Theta_{e/P} \cong 0 \qquad (3)$$

$$\frac{d\Theta_{e/P}}{dt} = J_e S_{e/P}(1-\Theta_{e/P}) - J_i Y_{ei}^P \Theta_{e/P} \cong 0 \qquad (4)$$

We assume a simple sticking model for the dielectric-reagent, polymer and polymer-reagent adsorption and the relative sticking coefficient are S_e, S_P and $S_{e/P}$ respectively. These latter are the probabilities to obtain a reactive event form an impinging (surface encounter) event. We note that the reagent can cover the nude dielectric surface or the polymer coverage. Therefore, while polymer coverage growth-rate is proportional to the relative flux J_P; both dielectric-reagent and polymer reagent growth-rate is proportional to the global neutral fluxes J_e. Ion enhanced chemical etching is assumed to occur for the three species (negative terms in Eqs (2-4) proportional to the ion flux J_i) whilst evaporation is considered only for the dielectric-reagent (term in Eq. 2 proportional to the evaporation flux J_{ev}). Note that J_{ev} is proportional to J_e, and in the following we $J_{ev} = 2.71^{-3}\ exp(-0.168/kT)\ J_e$. The other parameters are the k factor relative to the stochiometry of the reactions and the chemical sputter yields Y_{ei} (normalised to the local ion fluxes).

The etched surface speed in eq. (1) depends on the materials (reagent or polymer) covering the surface element taken into account, and it can be positive (etch case) or negative (deposition case). Let us consider first the polymer case. Assuming a polymer erosion by chemical sputtering we have that polymer etch rate is

$$ER_P = \rho_P^{-1} Y_{ei}^P J_i \Theta_{e/P} \qquad (5)$$

where ρ_P is the polymer density. The polymer deposition rate is

$$DR_P = \rho_P^{-1} S_P J_P \qquad (6)$$

If $DR_P > ER_P$ (i.e. if $\Theta_P>1$) the inhibitor polymer film will soon cover the whole surface elements. Therefore we can neglect Eq.2 and the normal profile speed will be

$$F = \rho_P^{-1}(Y_{ei}^P J_i \Theta_{e/P} - S_P J_P)\,. \qquad (7)$$

Where ρ_P is the polymer density. Else if $DR_P \le ER_P$ the film etches can occur. We can derive the coverage Θ_e from the equations (2-4) and the etch rate is

$$F = \rho_{SiO2}^{-1}\left[J_i Y_{ie}^e \Theta_e + J_i Y_s (1-\Theta_e) + J_{ev}\Theta_e\right] \qquad (8)$$

here ρ_{SiO_2} is the dielectric density. In this case we consider also the possibility of physical sputtering of the SiO_2 substrate and Y_s are the sputtering yield.

Yields, fluxes and, consequently, coverages in Eqs. (2-8) depends self-consistently on the profile evolution and they should be explicitly determined at each profile point *P* when the instantaneous global geometry of the front itself is given. Neutral and polymer fluxes J_e and J_P are isotropic; therefore the component of the flux normal to the surface element located at a given front point *P* is

$$J_{iso} = J_0 / 4\pi \int_\Omega \cos[\alpha(\hat{n}(P),\hat{\omega})]d\hat{\omega} \qquad (9)$$

where J_{iso} is J_e *or* J_P, while J_0 is J_{e0} or J_{P0}, i.e. the incoming fluxes on the wafer (flat) surface. $\alpha(\hat{n}(P),\hat{\omega})$ is the angle between the normal at the profile point *P* and the direction ω of the incoming molecular specie, while the integral is performed over the whole visibility solid angle Ω. Ion flux is directional and its value is the summation over the ionic distribution exiting from the sheath potential zone. If the sheath is collisionless, we can reasonably assume that the ion distribution is a shifted maxwellian [7] and for the ion flux we obtain

$$J_i = (J_{i0}/2\pi)\iint_\Omega \cos[\alpha(\hat{n}(P),\hat{\omega})]G(\theta)d\hat{\omega} \qquad (10)$$

where

$$J_{i0} = n_{i0}\left(2kT_+ / M\pi\right)^{1/2} \qquad (11)$$

is the ionic flux over a flat surface, $3kT_+/2$ is the average kinetic energy of the ions when they reach the sheath edge, while the $G(\theta)$ function depends only on the angle θ which the ions form with the electric field

$$G(\theta) = \exp(R)\exp(-R\sec^2\theta)(1 + R\sec^2\theta) \qquad (12)$$

with $R=eV_s/kT_+$. In the following we assume that T_+ is equal to the electron temperature T_e.

Using analogous considerations and assuming an univeral dependecnce of the yeild efficiency on the ion energy [5]: $Y(E) \propto E^{1/2}-E_{th}^{1/2}$; we can derive the local yield functions:

$$Y(P) = \widetilde{Y} / 2\pi \int_{\Omega} Y(\alpha[\hat{n}(P), \hat{\omega}]) G_Y(\theta) d\hat{\omega}; \qquad \widetilde{Y} = A / \eta \left(kT_+ / \pi\right)^{1/2}, \qquad (13)$$

here η is the rate between of the ion density at the substrate n_s and ion density in the plasma region

$$\eta = n_s / n_{i0} = 0.5\exp(R)erfc(\sqrt{R}). \qquad (14)$$

The expression of $G_Y(\theta)$ depends on the sheath potential value. In particular, if $eV_s \geq E_{th}$

$$G_Y(\theta) = \exp(R)\left[\exp\left(-R\sec^2\theta\right)\left[1 + R\sec^2\theta - \sqrt{RR_{th}}\sec\theta\right] - \sqrt{\frac{\pi}{2}}\sqrt{RR_{th}}erfc\left(R\sec\theta\right)\right] \qquad (15)$$

with $R_{th} = E_{th} / kT$. Once the actual profile geometry is given, we can calculate the front speed at each profile point, using the fluxes and yields expressions (Eqs. 9-18) in the equations of the deposition/etch model (Eqs. 2-8).

We note that the etching features related self-consistently with the profile geometry during the etching evolution could be analysed only using the profile solver. Simulation results relative to dry-etching processes ($t_{tot}=80s$ and $\Delta t=2s$) at different values of reagent and polymer fluxes ($J_{i0}=5.6\times10^{16}$ at/cm^2s) are shown in the fig. 1. We consider a 300nm thick ideal resist film ($F=0$ in the resist region) and different window sizes: 300nm, 200 nm, 400 nm (only the final profile is shown for these last two cases). The profile shape is the result of the interplay between geometrical constrains and the relative weight of the active/passive adsorbed species. Of course the increase of the active component improves the vertical speed of the etch; however it also causes a further shrinking of the profile bottom (see Figs 1 a,b,c) which does not allows to change substantially the verticality of the wall. In turn the decrease of the polymer component (fig. 1 b,c) , while it does not affects so much the vertical speed, results in a less tailored profile. The entity of the RIE-lag effect is more pronounced for low polymer fluxes when the visibility constrain reduces mainly the role of the active component. Finally the effect of the window size on the overall profile shape is typical of the single processes.

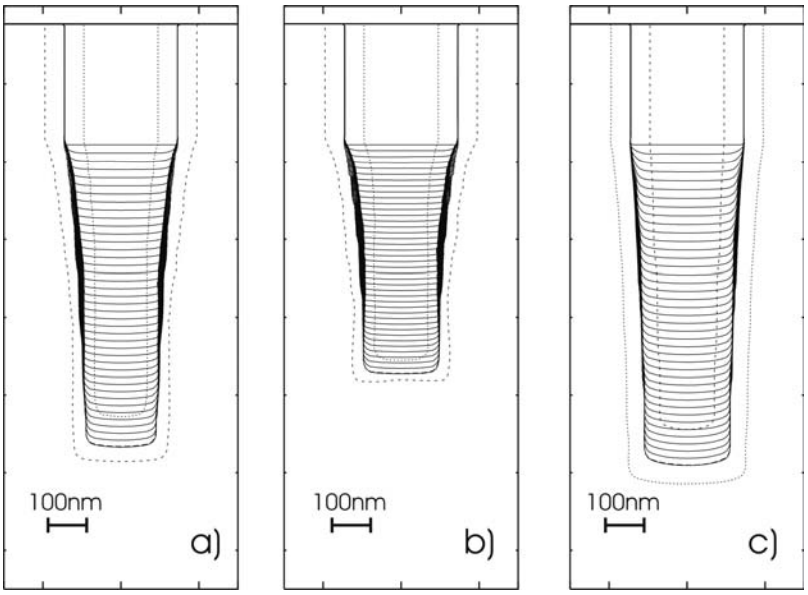

Fig. 1 Simulated profile evolution as consequnce of different dry-etching processes in a trench geometry. The initial profiles are a 300nm (solid lines), 200nm (points), 400nm (dashed lines) wide vertical windows opended in a 300 thick nm ideal resist mask. The flux values are a) $J_{i0}=5.6\times10^{16}$, $J_{e0}=3\times10^{17}$ and $J_{P0}=1\times10^{17}\,at/cm^2s$; b) $J_{i0}=5.6\times10^{16}$, $J_{e0}=1\times10^{17}$, $J_{P0}=1\times10^{17}\,at/cm^2s$ c) $J_{i0}=5.6\times10^{16}$, $J_{e0}=3\times10^{17}$ $J_{P0}=3\times10^{16}\,at/cm^2s$. The total etching time is $t_{tot}=80s$. In the 300nm cases profiles simulated after time interval of $\Delta t=2s$ are also shown.

4. Experimental conditions and model parameters estimate

The application of the model to the simulation of experimental dry-etching processes requires the estimate of model parameter in relation to the equipment parameters, which can be tuned by the process engineers (electrode powers, gas fluxes, etc.). In the experiments, the equipment used is a dual frequency Diode Reactor Etcher (see ref. [9] for details on the equipment characteristics). The plasma formation is controlled by the top electrode at the frequency of *27 MHz*, whilst the ion acceleration by the bottom electrode at *2 MHz*. The equipment parameters that we can handle are: the electrode watt top (*Wt* in watt), the electrode watt bottom (*Wb*), the gas fluxes (Q_X in standard cubic centimeter *sccm, 1sccm = 2.689 · 10^19 molecules/min* at standard condition, i.e. at *Pressure=1Atm* and *T =273.15°K*), the chamber pressure (*P* in *mT*). In the process, analysed with the simulation code in the following section, we choose this set of machine parameters: *Wt=1000W*, *Wb=2000W*, *P=30 mT*. The used chemistry is based on C_4F_8 and more precisely we have used this following gases mixing $Ar/C_4F_8/N_2/O_2$ with fluxes $Q_{Ar}=120sccm$, $Q_{C4F8}=10sccm$, $Q_{O2}=3sccm$, $Q_{N2}=70sccm$, therefore the correspondent total flux (Q) is $Q=203\ sccm$.

In order to test the reliability of the simulation code we considered different geometries for the etching, therefore a ~80nm thick anti-reflecting film and ~320nm thick resist film (formed by different moistures of organic polymers) were deposited on the SiO_2 substrate and different windows was opened in the film, considering: 1D flat zone (18μm wide), 2D trenches (340 nm wide) and 3D hole (radius 100nm). The etching time was $t_{tot} = 40s$. In fig. 6 we show an analysis of the etched profile in the case of the 2D trench, performed by means of Scanning Electron Microscopy (SEM). The resist film, the anti-reflective film and the substrate zones are well visible in the image, as well as the residual polymer film deposited mainly on the walls in the substrate zone.

In the derivation of the model parameters (see Ref [10] for details] we should distinguish the chemical-physical (fixed) parameters from the parameter related to the plasma characteristics, which can be modified, is means of the equipment setting. In the first set we can include the quantities related to the interactions between ions, etchant, polymer and material, i.e. IeChE and sputtering yield efficiencies, sticking coefficients, stoichiometry factors, threshold energies, material properties. We extracted these parameters from literature data (see Refs.[5,8]) and their are reported in Table 1. The second set table2 includes fluxes and sheath potential (in particular $R_s=eV_s/kT_e$, J_{i0}, J_{n0}, J_{p0} or equivalently R_s, n_{i0}, n_{n0}, n_{p0}) which can be relied to W_t,W_b,P,Q_X.

5. Comparison between experiments and simulation results

In order to demonstrate the simulation reliability we should achieve a reasonable agreement between the morphology of simulated profiles and the real profile for different geometric constrains. In fact, as we verified by means of simulations performed in a wide range of condition, the profile topography is a fingerprint of the assumed plasma related parameters.

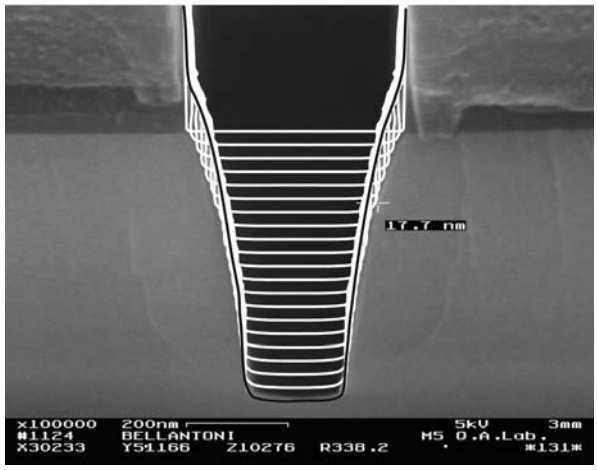

Fig. 2 Comparison between eroded profile and simulated profile evolution in the 2D trench geometry. The density values are $n_{i0} = 2.3\times10^{11}$, $n_{e0}=1.6\times10^{13}$, $n_{p0} = 6.4\times10^{12}$ cm^{-3}. Simulation parameters are reported in Tables I and II. The final simulated profile is evidenced by the black line.

In fig 2 we show a SEM image of the etched profile obtained by means of the process described in the previous section in the case of large stripes. The eroded depth in a flat zone is $z_{1D} \cong 490$nm (i.e. an etch rate of $F_{1D} \cong 12.25$ nm/sec), where the depth measurement was performed away from the edge zone. Of course the measured etch rate in a flat zone can be predicted only for a further restricted range of parameters, with respect of the range reported in Table II. However, using the same parameter set, we should be able to recover the profile evolution and morphology in the 2D and 3D geometries (trench and hole).

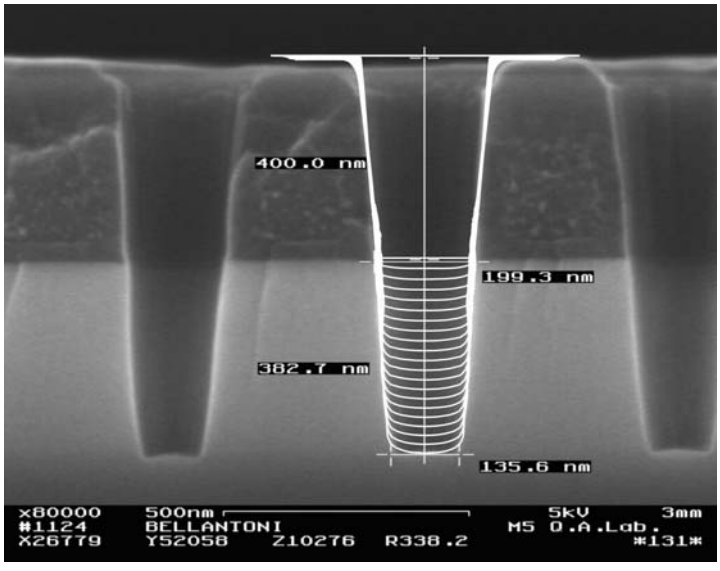

Fig.3 Comparison between eroded profile end the simulated profile evolution in the 3D hole geometry The density values are $n_{i0} = 2.3\times10^{11}$, $n_{e0}=1.6\times10^{13}$, $n_{p0} = 6.4\times10^{12}$ cm^{-3}. Simulation parameters are reported in Tables I and II.

In fig. 3 the simulation of the etched profile evolution in the trench case is compared with the SEM analysis of the process. In this case also the evolution in the resist zone (resist + antireflective film) is simulated using the same model used in the case of the SiO_2 substrate. The different resist behaviour is recovered considering low IeChE yield ($A^e_{ei}(Resist) / A^e_{ei}(SiO_2) = 10^{-3}$) and sticking coefficients ($S_e(Resist)=0.1$,

$S_P(Resist)=0.01$) so that the physical sputtering mainly causes the resist erosion ($A^e_{sp}(Resist)/A^e_{sp}(SiO_2)=1.5$). Moreover, we assume that $S_P=0.6$ in the antireflective organic film (see the darker zone over the SiO_2 substrate). We note that a reliable simulation of the erosion evolution in the resist zone is necessary since, in general, it could affect considerably the visibility angle seen by the profile points in the substrate. The following parameter are used $n_{i0} = 2.3\times10^{11}$, $n_{e0}=1.6\times10^{13}$, $n_{p0} = 6.4\times10^{12}$ cm^{-3} (which give the flat etch rate value F_{1D}=12.25 nm/s). Note in the optimisation of the model parameters we used valued in the range reported in the Table II, moreover practically only n_{p0} was changed considerably (within one order of magnitude wide range) in order to obtain a good estimate of the polymer deposited thickness on the walls.
A noteworthy agreement between simulation and experimental analysis of the profile can be observed. Simulation reproduces correctly the small *inverse RIE-lag* evidenced by the erosion process in the 2D trench (520 nm eroded depth with respect of 490nm eroded depth of the flat zone). Moreover, both the profile shape than the amount of polymer deposited on the wall evidenced by the SEM analysis are recovered by the simulation within the grid resolution (10 nm).
Finally, in fig.9 we show the comparison between simulations results and SEM analysis of the etching process in the 3D-hole geometry (a section passing on the hole axes is reported). In this case the geometric constrain causes the *RIE-lag*. All the flux components are strongly reduced and the small polymer deposition on the wall cannot be experimentally evidenced. The comparison demonstrates further the reliability of the numerical simulations: a good agreement between the simulated and eroded profile can be observed in term of depth and shape.

6. Discussion

The methodology presented in this work deals with all the steps needed in order to build up a simulation code which should lead to useful prediction on profiles resulting after a plasma-etching process. These steps are: the implementation of a robust profile solver, the formulation of a surface etching model including all the relevant microscopic phenomena, the derivation of the relationships between local parameter to plasma parameters and between plasma parameters and machine parameters and, finally, the application on real processes by means a comparison between simulations and eroded profile microscopes. Our aim is implementing a code which is able to predict the resulting profile shape in various geometry constrain. Achieving this target should provide to the process engineers a useful tool in the scaling-down of the microelectronic device technology. The method looks like promising: Indeed the code is robust and highly versatile; moreover is able to capture the features commonly observed in the development of dry-etching processes varying the machine parameters and the gas moisture. The capabilities of the simulator has been demonstrated comparing simulated profile evolution and the SEM analysis of the profile resulting in plasma-etching processes specifically designed in different geometries in order to test the code. After a suitable paramerization the simulations quantitatively estimate the profiles depth and shape in really different geometrical constrains where inverse-RIE, lag, RIE-lag and profile tailoring occur changing the opened window.

RF electrode sheath formation near non-flat substrates

K.E. Orlov, A.S. Smirnov, T.V. Chernoiziumskaya, D.A. Malik

Plasma Physics Department, St.-Petersburg State Polytechnical University, Politechnicheskaya 29, St.-Petersburg, 195251, Russia

Abstract

In this work we present experimental results concerning electrode sheath and ion flux formation near non-flat electrode with dimension of a cavity comparable to the electrode sheath length. It is shown that the secondary electron emission can play a crucial role in plasma molding over electrode surface. It is also observed that plasma has a tendency to "self-leakage" in electrode cavities. In this case, separate discharges sustained by enhanced secondary electrons ionization are formed in cavities.

1. Introduction

The interaction of plasma with a surface containing topographical features is critical for coating of curved objects, etching of surfaces of complex form and plasma immersion ion implantation. The flux, energy, and angular distributions of ions incident on the target are of primary importance. These quantities depend critically on the shape of the meniscus plasma–sheath boundary formed over the surface topography. Electrode sheath formation near surface topography is governed by ratio between electrode sheath length (L) and characteristic dimension of surface structure (d). In limiting cases L>>d (thick sheath) and L<<d (thin sheath) two dimensional perturbation of a sheath structure is minimal and the sheath can be considered as a locally flat one [1]. In this work we present experimental results concerning sheath structure formation in an intermediate case of cavity dimension comparable with electrode sheath length.

2. Experimental setup

Experiments were carried out using a setup schematically drafted on Fig.1. 13.56 MHz driven discharge was burned between two parallel plane electrodes. The upper electrode 22 cm in diameter was connected through a blocking capacitor to RF generator, the lower electrode was connected to the grounded discharge chamber walls. The chamber was equipped by standard electrical diagnostics, thus, the applied voltage amplitude, self-bias, RF current and loaded power were controlled during experiments. The discharge was operating in Ar with background pressure 4?30 mTorr. Due to low operating pressures and the difference in electrodes area, the discharge was operating in asymmetrical regime and the voltage drop in the grounded electrode sheath was typically 10 times lower than on powered electrode. An energy distribution of ions impinging the grounded electrode surface was controlled by means of a multi-grid energy analyzer [2-3]. The analyzer was placed in differentially pumped high vacuum chamber and connected with discharge region by 1 mm diameter orifice. Ion energy distribution functions (IEDF) were obtained by differentiation of the retarding characteristics. The overall energy resolution in obtained ion spectra was about 3 eV.

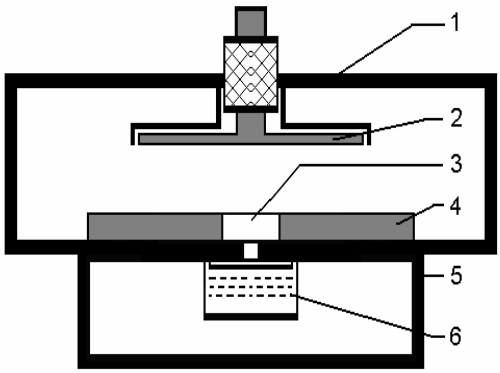

Fig. 1 Schematic draw of the experimental system. 1 – discharge chamber, 2 – powered electrode with ground shield, 3 – cavity on the grounded electrode, 4 – grounded electrode, 5 – high vacuum chamber, 6 - multi-grid energy analyzer

Experiments were carried out in two regimes; flat and holed electrode surface. In the first set of experiments, IEDF was measured for usual capacitive discharge configuration with flat, parallel electrodes. In the second series, the grounded electrode was equipped by a flat cover plate with a cylindrical cavity (15 mm. diameter, 10 mm. height). The axis of the cavity was alignment with 1 mm inlet orifice of the energy analyzer. In this series the IEDF was measured for ions flowing to the down faceplate of the cavity.

3. Experimental results

Experimentally observed ions spectra are presented in Fig.2,3. For the flat electrode regime, the IEDF always has a clearly pronounced peak at high energy part with a semi-exponential tail towards low energy part. The maximal ions energy rises with increasing loaded power. Such ions spectra are typical for low-pressure RF discharges and were previously observed by many authors [3,4].

The main features of the ions flux formation in the cavity are represented in Fig.3. As the discharge loaded power increases the IEDF experiences two realignments of the shape. In the low power regime (Fig.3a), the IEDF stepwise switches from single peaked shape to two-peaked one. The low energy peak is observed around energies 8-9 eV. With increasing of loaded power the height of low energy peak increases while the energy remains approximately constant. The high energy peak is also observed and its energy increases with increasing loaded power. With further increasing of loaded power (Fig3.b) the IEDF switches back from two-peaked shape to single peaked one.

4. Discussion

To analyze obtained data let us consider general features of electrode sheaths formation in a RF driven discharges. The condition $?_i << ? << ?_e$ ($?_i$, $?_e$ are ions and electrons plasma frequencies respectively, $?$ is driven frequency) is typically satisfied for RF discharge operation regimes. In this case, ions form a steady-state density profile and positive charged sheaths are formed near electrode surfaces. The boundary between the quasi-neutral plasma and space charge sheath oscillates between maximum distance from electrode L (typically called "sheath length") and electrode surface. Consequently, voltage in the sheath changes from a maximum value U_{max} to zero. Ion movement toward electrode surface is governed by an averaged over many RF periods electric field in the sheath. Ions energy distribution near electrode surface critically depends on ratio between ions mean free path ($?_i$) respect to charge-exchange collisions and electrode sheath length (L).

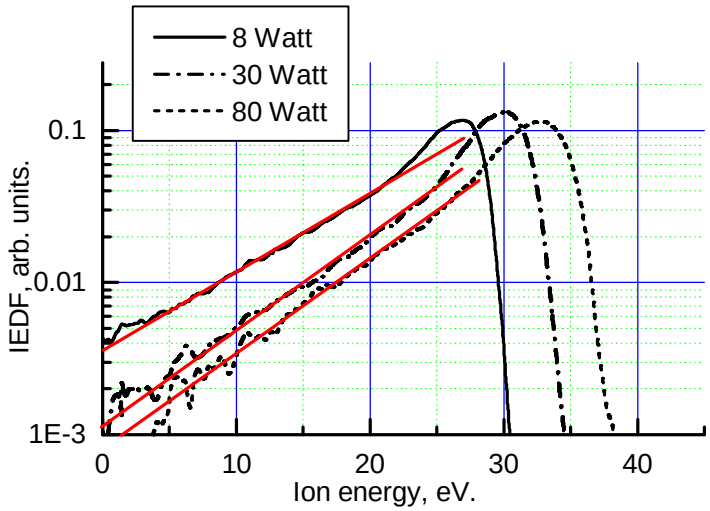

Fig. 4 Exponential fitting of IEDF slope, obtained for the flat electrode case. Ar, p=5mTorr.

In a collisionless regime ($?_i >> L$), ions are continuously accelerated during their traveling to the electrode surface and IEDF has a strong maximum around energies corresponded to an averaged potential drop in the sheath <U>. The IEDF tail towards lower energies is formed due to a non-zero collision probability for ions traveling in the sheath. For a linear regime, then a probability to experience only one collision in the sheath is much higher than probability of two collisions, the IEDF slope can be roughly fitted by exponential dependence which is proportional to $\exp(-?_i/L)$. By this way, the sheath thickness can be extracted directly from experimentally measured IEDF (Fig.4). For presented experimental conditions, $?_i/L$ can be estimated in the range of 4?5. Combining above data with the charge-exchange cross-section value for Ar ions [5] we can estimate the sheath length as L~4?5 mm.

In the regime with holed electrode, the sheath formed far away from the cavity should be identical to sheath formed in regimes with the perfectly flat electrode. Consequently, the cavity diameter is in the same order of magnitude as doubled unperturbed sheath length (d~2L). The sheath structure is essentially two-dimensional as it is illustrated on Fig.5. The plasma-sheath boundary oscillates by the same way as in unperturbed regions and periodically touches the internal surface of the cavity. However, a stationary quasi-neutral plasma can not be sustained inside the cavity until 2L>d.

The observed features of IEDF (Fig.3) can be explained be secondary electron emission from electrode surface and extension of the secondary electron trajectories in the cavity. Electrons are emitted from electrode surface mainly due to ion bombardment. These electrons are accelerated by a momentary value of voltage drop in the sheath (since $? << ?_e$) toward plasma body. A sufficient fraction of secondary electrons is accelerated up to energies equal to a maximal potential drop in the sheath (U_{max}) [6]. As U_{max} becomes larger than ionization potential secondary electrons could produce a sufficient ionization. However, in the low pressure case considered here, an electrons mean free path respect to ionization collisions ($?^i_e$) exceeds the sheath length ($?^i_e >> L$). Consequently, in the flat region, ionization by secondary electrons in the sheath is negligible. The situation in the cavity is sufficiently different. The potential structure in the cavity is radial-symmetric, so that, the secondary electrons emitted from side walls of the cavity are trapped in a potential well. The bouncing between the potential walls leads to an increasing of the electrons path in the cavity region. The total electron path in the cavity is now $?_{eff} \sim nd$ (n is a number electron flight across the cavity) and can be comparable with ionization length ($?_{eff} \sim ?^i_e$). The similar mechanism of electron trapping and extension of the secondary electron trajectories in the cavity is observed in so called "hollow cathode" discharges and leads to increasing of ionization rate in DC sheath [7,8].

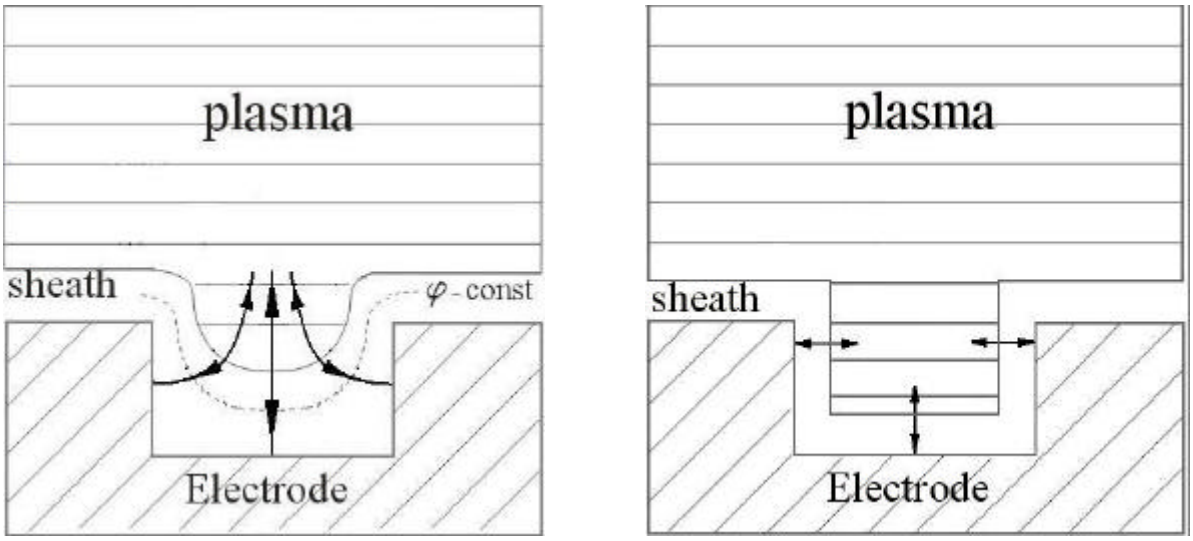

Fig. 6 Illustration of a sheath structure near cylindrical cavity for different ratio of cavity diameter (d) and sheath length (L). Left picture corresponds to the case 2L>d, right – 2L<d. Lines with arrows schematically show plasma-space charge boundary oscillations during RF period.

Now the observed IEDF features can be explained by the following way. First transition in the IEDF shape (Fig.3a) appears when the voltage drop in the cavity becomes enough to accelerate electrons emitted from cavity wall up to an ionization potential. Consequently, low energy fraction of IEDF is formed by ions produced inside the cavity while the high-energy fraction consists of ions travelling from a plasma edge lying in outside the cavity. The high energy group of ions is accelerated up to total averaged sheath potential <U>, while low energy group is formed in a region where averaged potential is about 8?9 volts. As it was discussed above, secondary electrons are accelerated by a momentum value of the sheath voltage. The ratio between averaged and maximum momentum potential value can by roughly taken as ? . Above consideration now can be confirmed by comparing Ar ionization potential (*?i=15.8* eV) and doubled ions energy in the low energy peak.

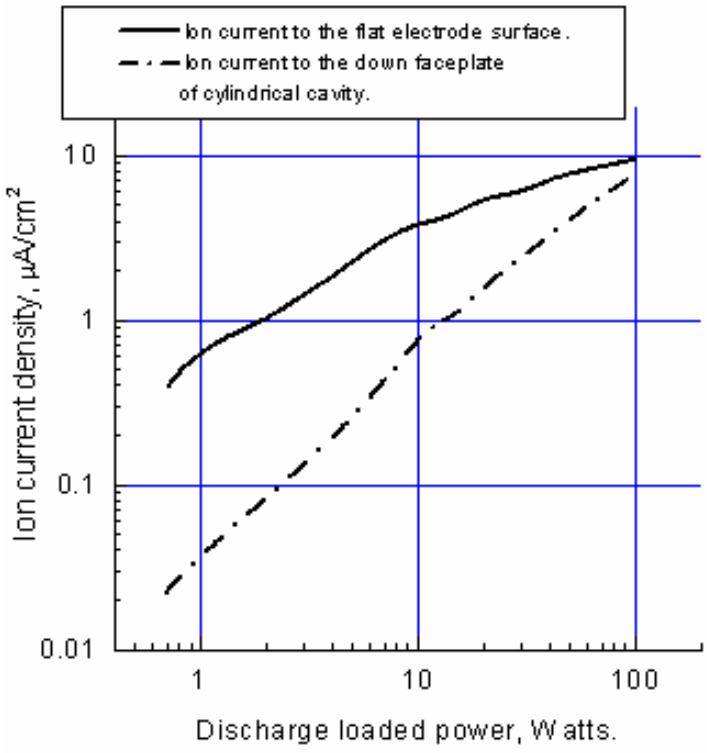

Fig. 5 Ion current density to the flat electrode and down faceplate of the cavity. Ar, p=5mTorr.

With increasing the power loaded in the discharge, the sheath potential, ions energy, ions flux and secondary electrons emission rate increase. Simultaneously, the ionization ratio and ions density in the cavity grow up. The sheath length is related to ion density and voltage amplitude by rough estimate $L\sim(U_{max}/en_i)^{1/2}$ [9]. While potentials of electrode surface and plasma body are fixed, the voltage drop in the unperturbed sheath should be similar to one in the cavity region. The increasing of ions density in the cavity now leads to local decreasing of the sheath length. The second evolution of IEDF shape (Fig.3b) appears when the ionization inside the cavity becomes high enough to locally decrease the sheath length to satisfy a condition 2L<d. At this stage, the cavity

is filled up by stationary quasi-neutral plasma and a thin electrode sheath is faced parallel to the cavity surface as it is schematically illustrated on Fig.5. The ions born inside the cavity are accelerated by a total potential drop in the sheath and low energy fraction of IEDF disappears.
An existence of a sufficient ionization in the cavity by secondary electrons is also confirmed by absolute measurements of ion currents flowing to the down faceplate of the cavity. On Fig.6 ion current densities are compared for flat electrode and electrode with cavity. It is easily seen that ion current from cavity grows faster than ion current to flat electrode. Consequently, we can conclude that in a high power regime, separated secondary electron sustained plasma is formed inside the cavity.

Concluding remarks

The presented investigation can be drafty resumed by following conclusions:

Secondary electron emission plays a significant role in plasma molding over non-flat electrode surface.

In the case of symmetrical cavities on electrode surface secondary electrons are trapped by potential well inside the cavity, this leads to extension of secondary electron trajectories and high ionization by secondary electrons in the cavity.

Additional ionization in the cavity leads to local decreasing of the space-charge sheath length and provoke plasma leakage inside the cavity.

An isotropic ion bombardment of the cavity surface can be obtained only in the regime of thin sheath (d>2L), however, due to additional ionization in the cavity, ion flux intensity in the cavity may be higher than in flat electrode region.

Abstract

The main features of carbon films low temperature (250^0C) radio frequency plasma enhanced chemical vapor deposition (RF PECVD) process, structure and properties of diamond like carbon films were studied. Obtained films properties were found to depend on substrate material, film thickness, RF power and DC bias. Regime of ion bombardment of growing film surface was found to be the key factor controlling carbon (including diamond like) films deposition.

Introduction

In the present time, carbon and particularly diamond-like carbon (DLC) films are widely studied materials because of its attractive visible and infrared optical, electrical, chemical and tribological properties. The films have been fabricated by a variety of methods including single low-energy beams of carbon ions, dual ion beams of carbon and argon, ion plating, sputtering from graphite target, vacuum-arc discharges, laser ablation and different modifications of plasma-enhanced chemical vapor deposition. The details of the films deposition techniques and specific references can be found in [1].

PECVD possessing has such advantages as possibility of uniform coating of large area, simplicity of impurities incorporation, absence of uncontrolled heating of the substrate, flexibility and controllability of the process, possibility of charged particles flows control by applying of magnetic field or (and) DC electrical fields and low cost. It makes PECVD an attractive technique for thin carbon films fabrication under low temperature processes required to obtain technological compatibility in complicated technological lines. For example - coating of substrates with low melting temperature, semiconductor device structures fabricated at low temperatures (e.g. those on base of hydrogenated amorphous silicon layers), metal details “afraid” of thermal annealing and other similar tasks.

Since then a first successful DLC films deposition was achieved [2], all the researchers noted importance of a continuous ions bombardment of the growing film for DLC preparation by different deposition technique including RF PECVD [3, 4, 5]. The goal of this work is to develop the technology of the DLC films growth on low temperature substrates in capacitively coupled discharge reactor and to understand the influence of ion bombardment on film growth rate and film properties.

Experiment

The films were prepared by RF (40 Ì Hz) PECVD in the flat capacitive diode system. Both RF power and positive DC bias were applied to the upper 220 mm diameter electrode. The substrates were mounted on the lower electrode (230?230 mm^2) which was grounded. Ion flux characteristics were investigated by a flat four-grid retarding field energy analyzer mounted close to the substrate. Pure methane was used as carbon film precursors source.

Glass covered by titanium and/or molybdenum, crystalline silicon and Ti, Mo, Ni, Ta and stainless steel foils were used as substrates. The deposition was performed within a variety of parameter sets. Variation parameters were: final film thickness (d=0.3-2?m), positive DC bias applied to the powered electrode (U=50–300V) and RF power (W=100–700W). The values of these parameters for used deposition regimes are summarized in Table 1.

Methane flow rate and substrate temperature were kept constant during the films deposition: 16 sccm and 250^0 C correspondingly. Low operating pressure (10^{-2} Torr) was chosen in order to minimize scattering of ions accelerated by DC bias of the powered electrode towards the substrate.

The values of ions energy and ion flux onto the substrate were estimated from retarding characteristics of the energy analyzer. The energy analyzer construction and key points of the measurement procedure have been described earlier [6, 7]. The input aperture of the energy analyzer was 2 mm in diameter. All parts of

the analyzer, except the stainless steel casing, were made of nickel. The grids had a 140?140 ?m^2 mesh size and 80 % transmission. The energy scanning time was approximately 5 s.

Raman scattering spectroscopy of the samples was used for chemical and structural characterization of the films.

Results and discussion

Retarding curves measured at different RF power and applied DC bias values are presented in Fig. 1. Because of fundamental difficulties to adequate detect high ion energies by retarding field analyzer, ion flux parameters were extrapolated for some deposition regimes with high loaded power and high positive bias. Scaling laws describing a dependence of ion flux parameters from RF power and DC bias were found earlier in [8]. Such scaling generally states that an increasing of RF power leads to increasing of ions flux value with negligible changes in ion energies, increasing of positive DC bias strongly increases ions energy and slightly affect ions flux value. These scaling are generally valid until RF power loaded in the discharge is larger that DC power. For some regimes with extremely high DC bias the above condition may not be satisfied, consequently, the corresponded ion flux characteristics should be considered only as a rough estimate. The summarized data concerned ion bombardment characteristics are presented in Table 1.

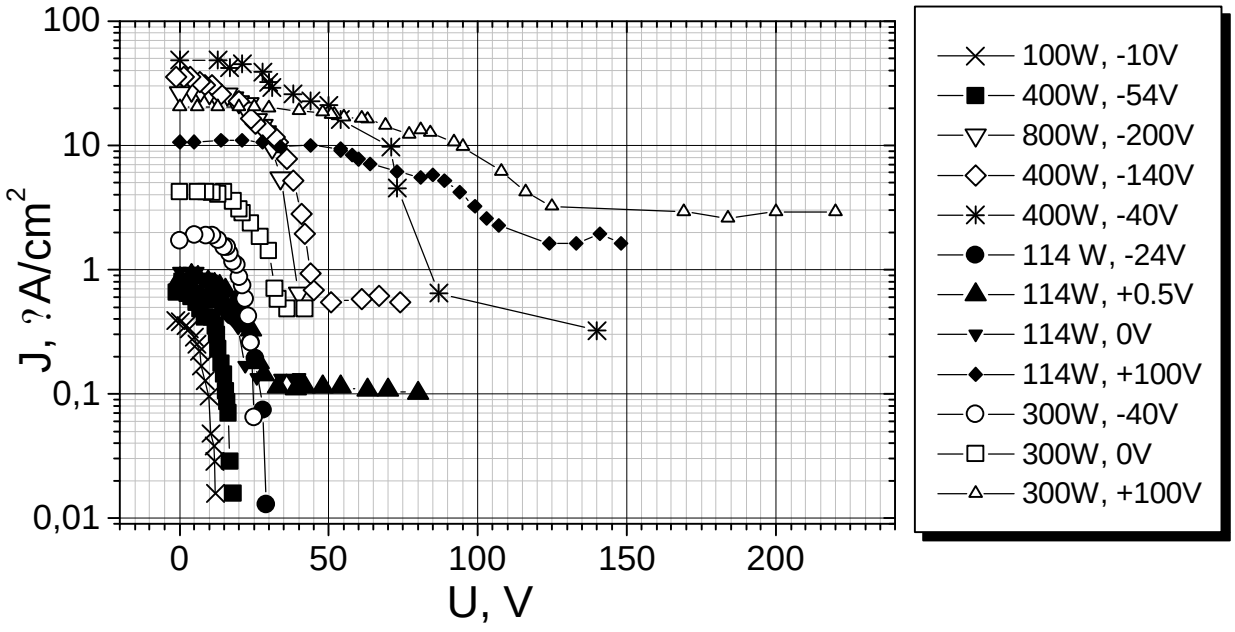

Fig. 1: Retarding characteristics obtained with the energy analyzer for different deposition regimes

From the Table 1 one can see that the films deposition rate increases with RF power and DC bias. More obvious it is demonstrated in the diagram presented in Fig. 2. This observation confirms that ion

bombardment is stupendous in the deposition process in spite of the low ion concentration in gas phase compared with neutral particles once.

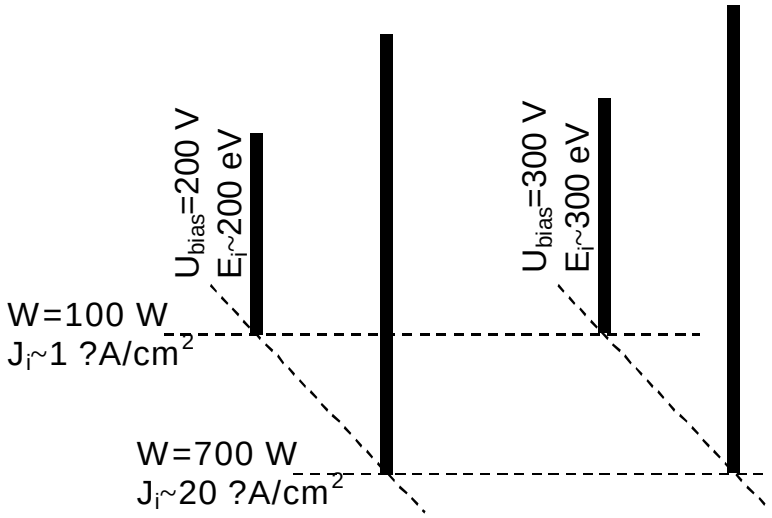

Fig. 2: Diagram of the films deposition rate values
vs. RF power and DC bias (ions energy and flux).

All the films deposited were transparent and demonstrated room temperature conductivity less than 10^{-14} $Ohm^{-1}cm^{-1}$. It was found that all the films deposited at RF power less than 100 W and/or DC bias less than +50 V were soft. All the films deposited under heavy ion bombardment (RF power more than 100 W and applied DC bias more than +100 V) were hard and demonstrated good adhesion to crystalline silicon and foil substrates. The film adhesion to the metal covered glass substrate was very poor. Adhesion of the films deposited on silicon and metal substrate was satisfactory.

Raman spectra of the films studied are presented in Fig.3.

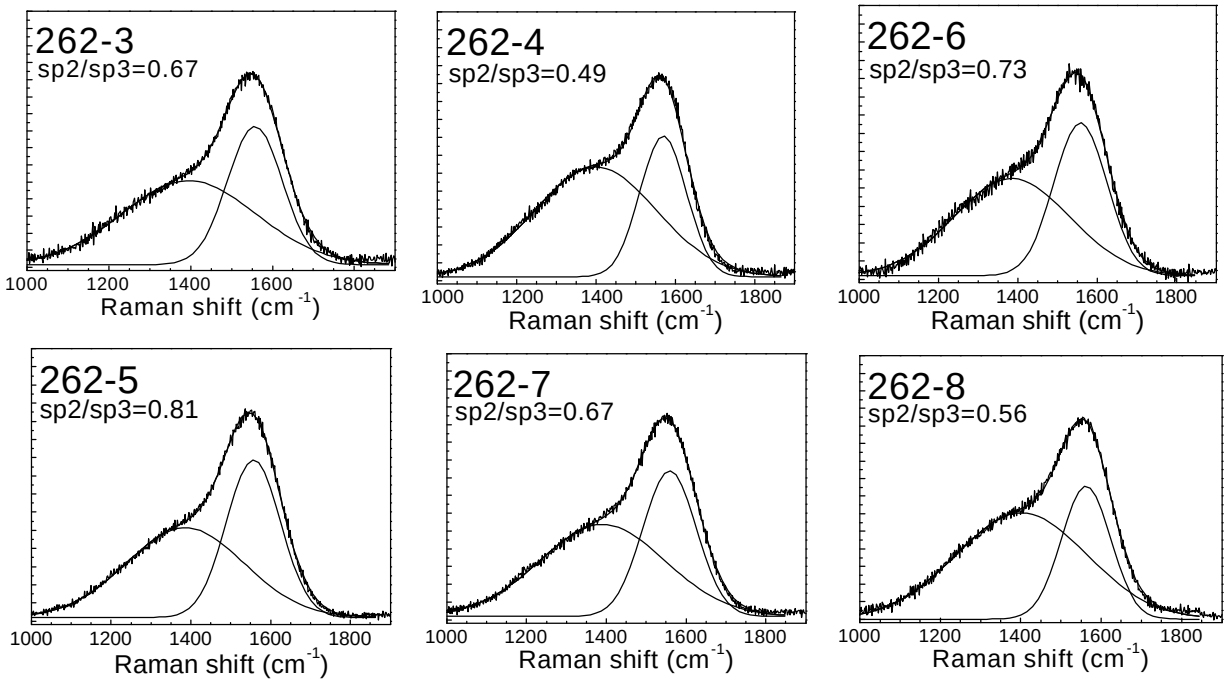

Fig.3: Raman spectra of the films studied.

Deconvolution of the spectra by Gaussians at about 1580 cm^{-1} (G - peak) and 1350 cm^{-1} (D – peak) in correspondence with [9, 10] showed that all the films deposited consisted of two phases: sp^3- and sp^2-hybridized carbon. We supposed that sp^3-hybridized carbon is diamond-like carbon and sp^2-hybridized carbon is polymer-like carbon rather than graphite-like carbon. Optical transparency and very low conductivity of the films corroborate this.

The ratios of sp^2 to sp^3 peak area are presented in Fig.3. Determined from these ratios sp^3-hybridized carbon fraction, which supposed to be proportional to the peak area, are presented in Table 1. From the table one can see that both: increase of ion flux, which increases with discharge power, and increase of ion energy, which increases with bias voltage, results in increase of sp^3-hybridized carbon fraction. Maximal sp^3 fraction content 67% was found in the film deposited under the heaviest ion bombardment (W=700W, U_{ab}=300V).

Typical 0.63 ?m wave length laser beam interference patterns plotted in reflection mode during the films deposition is presented in Fig.4. This trace demonstrates a change of the film growth at the point 2, which usually corresponds to the film thickness about 0.5 ?m. At this point light amplitude sharply falls due to the strong light absorption or scattering. Really, the thicker films were found to be hard but the films surface roughness was evident by sight. Optical microscope image of thick film (sample 262-8) is shown in Fig. 5b in comparison with surface of the thinner film presented in Fig. 5a.

Approximately linear dependence of sp^3-hybridized carbon fraction on film thickness was found. It is presented in Fig. 6. This feature of the film growth and dependence of sp^3-hybridized carbon fraction on film thickness can be explained by formation of negative floating potential on highly resistive carbon film and ion bombardment enhancement due to charging of film surface. Another possible reason is increasing of the film surface temperature due to the ion bombardment and suppressing of the heat transmission through thick film.

Fig. 5: Optical microscope image of the films of 0.3 (a) and 2 ?m (b) thickness.
Images diameter is 1 mm.

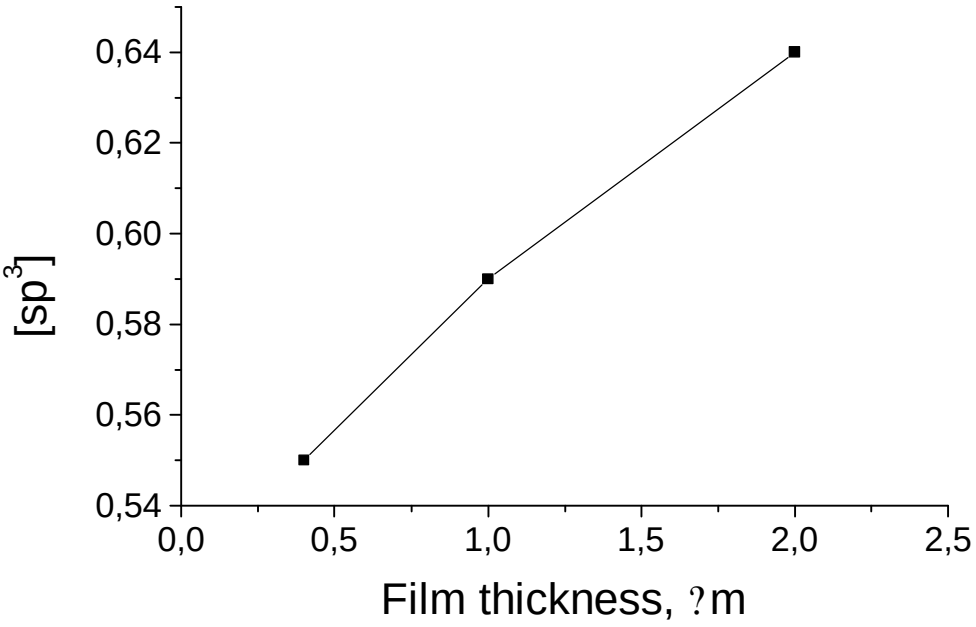

Fig. 6: Dependence of sp^3-hybridized carbon fraction on film thickness.

Summary and conclusions

1. The samples of hard carbon films with good adhesion to substrate were deposited at controllably varied regime of ion bombardment of the growing film surface.
2. Growth rate and sp^3-hybridized carbon fraction increase with the flux and energy of the ions impinging on the substrate.
3. Film smoothness and sp^3-hybridized carbon fraction changes with the increasing of the film thickness. This effect can be connected with film surface heating or charging.

4. Substrate material, film thickness and ion bombardment of growing film surface (controlled by RF power and DC bias) were found to be the key parameters providing hard carbon films deposition.

Abstract

The simple method is proposed to calculate the vibrational level rate constants of endothermic reactions with the vibrationally excited reactants. The method is based on using of some empirical and semi-empirical models for calculation of level rate constants and information about the energy fraction ξ_v – total energy part going into vibrations of the molecule-product of reverse exothermic reaction. The comparative analysis of three known models for level rate constants of chemical reactions is carried out with use of this method.

1. Introduction

The intensive development of the non-equilibrium plasma chemistry and laser chemistry excites the great interest to investigation of kinetics for chemical reactions, which are proceeded in the non-equilibrium conditions for vibrations of molecules – reactants. For study such reactions it is necessary to know the values of its level rate constants that are the reaction rate constants for molecules–reactants on the individual vibrational levels. The some analytical models exist for these rate constants. There are the information theoretical approach (ITA) [1–3], intuition empirical α–model [4,5], and CVCV–model [6]. The level rate constants $k(m,T)$ for diatomic molecules – reactants are calculated in the framework of these models with use of simple formulas as a function of vibration energy for level "*m*" of molecule – reactant and one or two parameters. These parameters determine the efficiency for vibrational energy to get over of the activation barrier of endothermic reaction. The values of these parameters are, for many cases, not known and must be determined.

One of simple method for determining of these parameters is the use of information about the reverse exothermic reaction – it is exactly about the energy fraction ξ_v – total energy part which goes into vibrations of the molecule-product of reverse exothermic reaction, that is the molecule – reactant of direct endothermic reaction. Now, many experimental and computational data are existed for values ξ_v of different exothermic reactions [7].

The purpose of present work is to obtain the relatively simple equations and its solutions as well as the universal figures-diagrams, which can be easy used to determine the level rate constants $k(m,T)$ of the direct endothermic exchange reactions of molecules-reactant AB(*m*) on the vibration level *m*:

$$\mathrm{AB}(m) + \mathrm{C} \rightarrow \mathrm{AC} + \mathrm{B} \qquad (1)$$

2. The basic equation and used model rate constants

To solve the task we will use the principle of detailed balance for the level rate constant $k(m,T)$ of a direct (from the level *m* of AB molecule) and $k(\rightarrow m,T)$ of a reverse (to the level *m* of AB) reaction (1):

$$K(T)P(m,T)k(m,T) = k(\rightarrow m,T) \qquad (2)$$

Here $K(T)$ is the equilibrium rate constant for direct and reverse reaction; $P(m,T) = \exp(-E_m/kT)/Q_{vib}$ is the equilibrium (at the gas temperature *T*) normalized vibrational distribution of AB(*m*) molecules; Q_{vib} is the vibrational partition function; E_m is the energy of vibration level *m*. Taking into account (2) we have for fraction ξ_v:

$$\xi_v = \frac{1}{E_a}\frac{\sum_m E_m k(\to m,T)}{\sum_m k(\to m,T)} = \frac{1}{E_a}\frac{\sum_m E_m e^{-E_m/kT} k(m,T)}{\sum_m e^{-E_m/kT} k(m,T)}, \qquad (3)$$

where T is gas temperature, E_a is the total energy realized in the reverse exothermic reaction (1). It will be assumed here that this reverse reaction has not the activation energy barrier. Therefore E_a is the activation energy for direct endothermic reaction. The summing in (3) is carried up to level "m" with energy $E_m \le E_a$. Three different models will be used to describe the level rate constant $k(m,T)$ in eq. (3).

We have for information theoretical approach (ITA) model [2]:

$$k(m,T) = A(T)\frac{1}{1-\lambda}\left\{\left[12+\frac{6}{1-\lambda}+\frac{2}{(1-\lambda)^2}\right]-\left(6+\frac{2}{1-\lambda}\right)\Delta_m+\Delta_m{}^2\right\}\exp\{(1-\lambda)\Delta_m\}$$

for $\Delta_m \le 0$, (4a)

$$k(m,T) = A(T)\left\{12\left(\frac{1}{1-\lambda}-\frac{1}{|\lambda|}\right)+6\left(\frac{1}{(1-\lambda)^2}+\frac{1}{\lambda^2}\right)-\frac{2}{|\lambda|^3}+\frac{2}{(1-\lambda)^3}\right\}-$$

$$-A(T)\frac{1}{|\lambda|}\left\{12+\frac{6}{|\lambda|}+\frac{2}{\lambda^2}+\left[6+\frac{2}{|\lambda|}\right]\Delta_m+\Delta_m{}^2\right\}\exp(-\Delta_m|\lambda|)$$

for $\Delta_m > 0$ (4b)

$$\Delta_m = (E_m - E_a)/kT, \qquad (5)$$

where $A(T)$ is the normalization multiplier; $\lambda(T)$ is the searched parameter of "vibrational surprise"[8]. It determines the difference of the real rate constants from the "prior" rate coefficients $k^0(m,T)$, which are depended only on density of states and full (internal and translational) energy of colliding particles. The values $k^0(m,T)$ are determined by formulas (4) with $\lambda(T)$=0.

Well known α- and CVCV- models [4-6] have been modified in the present work to obtain more correct description of rate constants $k(m,T)$ and $k(\to m,T)$ on upper levels *m,* such that $E_m > E_a$. The one parametric dependence has been also used for description of rate constants in the CVCV- model.

For modified α -model the following formulas have been used:

$$k(m,T) = k_0(T)\exp\left[-\frac{E_a - \alpha E_m}{kT}\right] \quad \text{if } \alpha E_m \le E_a \text{ (for } \alpha \le 1\text{) or if } E_m \le E_a \text{ (for } \alpha > 1\text{)} \quad (6a)$$

$$k(m,T) = k_0(T) \quad \text{if } \alpha E_m > E_a \text{ (for } \alpha \le 1\text{)} \quad (6b)$$

$$k(m,T) = k_0(T)\exp\left[-\frac{E_a}{kT}(1-\alpha)\right] \quad \text{if } E_m > E_a \text{ (for } \alpha > 1\text{)} \quad (6c)$$

For modified and already one parametric CVCV−model the following level rate coefficients have been used:

$$k(m,T)=\begin{cases} k_0'(T)\exp\left(-\dfrac{E_a-E_m}{kT}+\dfrac{E_m}{U}\right) & \text{for } E_m \le E_a \quad \text{(a)} \\ k_0'(T)\exp\left(\dfrac{E_a}{U}\right) & \text{for } E_m > E_a \quad \text{(b)} \end{cases} \tag{7}$$

Notice, that dependence of level rate constants (7) on vibrational energy E_m of molecules-reactants for modified CVCV-model is identical with CVDEV model, suggested in [9].

For case $E_a/kT >>1$ all investigated models give the similar dependencies $k(m,T)$ on E_m for low vibrational levels (where $E_m << E_a$). It takes place, if the parameters $\lambda(T)$, α and U are connected by relationship

$$\lambda(T) \approx 1-\alpha \approx -T/U\,. \tag{8}$$

The correlation (8) can be easy obtained if to compare the models formulas for $|\Delta_m| >>1$. It is necessary to emphasize that the λ parameter in ITA–model can be both positive and negative. It is confirmed by numerical calculations and experiments. Therefore, it is logically (in according with (8)) considered that the parameter α in α –model can be both less and more than 1 and parameter U in CVCV–model can be positive or negative. It can be in our modified formulas (6), (7).

3. The finding of parameters for level rate constants

Let's find the parameters λ, α and U. If to insert (4)–(7) in (3) we have the equation for λ, α or U as a function of ξ_v and dimensionless input parameters $a = kT/E_a$, $b_m = kT/E_m$. The results are also depended on view of function E_m (that is on vibrational model: harmonic or anharmonic model of molecular vibrations). However, the simplification of analysis can be obtained if to use for function E_m the model of harmonic oscillator $E_m = mE_1 \equiv mE_{10}$, where E_{10} is the energy of vibrational quanta of molecule-reactant AB in reaction (1).

More clear view of the nonlinear equation for α, U and λ, which are depended on ξ_v and $a \equiv kT/E_a$, $b_1 \equiv kT/E_{10}$ for each of model, can be obtained with additional condition

$$E_{10} \ll E_a\,, \quad \text{that is } a << b_1\,,\ m_a >> 1 \tag{9}$$

In this case, the integration can be carried out in eq.(3). As a result, the following nonlinear equation have been obtained to determine α and U parameters:

$$\xi_v \approx \frac{1}{x_a}\cdot\frac{1+(x_a-1)\exp(x_a)}{\exp(x_a)-1} \tag{10}$$

Here $$x_a = (\alpha-1)E_a/kT \quad \text{for modified } \alpha\text{–model} \tag{11a}$$

$$x_a = E_a/U \quad \text{for modified CVCV–model} \tag{11b}$$

For ITA–model with condition (9), the obtained equation is more complicated and has the following view:

$$\xi_v = -\frac{1}{x_a}\cdot\frac{A+\dfrac{2B}{x_a}+\dfrac{6}{x_a^{\,2}}+x_a\left(A-B+1-\dfrac{A-2B+3}{x_a}+\dfrac{6-2B}{x_a^{\,2}}-\dfrac{6}{x_a^{\,3}}\right)\exp(x_a)}{A+\dfrac{B}{x_a}+\dfrac{2}{x_a^{\,2}}-\left(A-B+1-\dfrac{2-B}{x_a}+\dfrac{2}{x_a^{\,2}}\right)\exp(x_a)} \tag{12}$$

Here
$$x_a = -\frac{\lambda}{a} \equiv -\frac{E_a}{kT}\lambda \tag{13}$$

$$A = 1 + Ca + Da^2\,; \quad B = 2 + Ca\,;\; C = 6 + \frac{2}{1-\lambda}\,; \quad D = \frac{2}{1-\lambda}\left[6 + \frac{3}{1-\lambda} + \frac{1}{(1-\lambda)^2}\right] \tag{14}$$

The approximate solution of eq. (10) for modified α– and CVCV–models is

$$x_a \approx -\frac{1}{\xi_v} + 0.928 \qquad \text{for} \quad \xi_v < 0.289 \tag{15a}$$

$$x_a \approx 12\left(\xi_v - \frac{1}{2}\right) \qquad \text{for} \quad 0.289 < \xi_v < 0.711 \tag{15b}$$

$$x_a \approx \frac{1}{1-\xi_v} - 0.928 \qquad \text{for} \quad \xi_v > 0.711 \tag{15c}$$

Here the parameter x_a is connected with α and U by relationships (11).

We also obtain the approximate solution of eq.(12) for ITA-model:

$$x_a \approx -\frac{1}{\xi_v} + x_1 \qquad \text{for} \quad \xi_v < \xi_1\,, \tag{16a}$$

$$x_a \approx \frac{\xi_v - \xi_v^o}{(R - \xi_v^0)\xi_v^0} \qquad \text{for} \quad \xi_1 \le \xi_v \le 1 - \xi_1\,, \tag{16b}$$

$$x_a \approx \frac{1}{1-\xi_v^0} + x_2 \qquad \text{for} \quad \xi_v > 1 - \xi_1\,, \tag{16c}$$

$$\xi_1 = \sqrt{(R - \xi_v^0)\xi_v^0}\,, \quad x_1 = \frac{2\xi_1 - \xi_v^0}{\xi_1^2}\,, \quad x_2 = \frac{1 - 2\xi_1 - \xi_v^0}{\xi_1^2}\,, \quad R = \frac{2.4 + 4A - 3B}{3 + 6A - 4B} \tag{17}$$

Here the parameter x_a is connected with λ by formula (13); ξ_v^0 is the value ξ_v for $\lambda = 0$, that is the total energy part which goes into vibrations of the molecule AB in the reverse exothermic reaction (1) with assumption that the level rate coefficients $k(\to m, T)$ for such reaction are the "prior" rate coefficients. The value ξ_v^0 is calculated from (3) with use of (2), (4a), (5), (9) and is following:

$$\xi_v^0 = 0.25\left(1 + 16a + 120a^2\right)\Big/\left(1 + 12a + 60a^2\right) \tag{18}$$

The solutions (15b), (16b) are corrected in the range of ξ_v which gives $x_a << 1$. However, the numerical calculations show that this range can be extended without marked loss of precision. It is made in (15b), (16b). At this, the range boundaries are chosen so that the values x_a and derivatives $dx_a / d\xi_v$ (which are calculated from (15b), (16b)) must be equal to the values x_a, $dx_a / d\xi_v$ calculated from (15a), (16a) and (15c), (16c). The accuracy of these formulas increases with growth of $|x_a|$ for respectively $x_a \ll -1$ and $x_a \gg 1$. Thus, the searched parameters α, U and λ for α–, CVCV– and ITA–models can be easy estimated form (10), (12), (15), (16) if the activation energy E_a and part of energy ξ_v are known for direct and reverse reaction (1) and the condition (9) are fulfilled. The more exact calculation of α, λ and U parameters can be carried out if to solve the eq.(3) by the numerical method. Such solution has been obtained for both harmonic and anharmonic (Morse oscillator) vibrational models. It is found that the anharmonicity has weak influence on the values α, λ and U.

Some results of numerical solution of the equation (3) are given on Figs. 1,2. Here the dependence of the dimensionless parameter x_a on the energy part ξ_v is presented for different values of the dimensionless parameters $a = kT/E_a$, $b_1 = kT/E_{10}$. These figures can be as diagrams for the fast determination of λ, α, U.

The analytical dependencies $x_a(\xi_v)$ (formulas (15)) are also given on Fig.1 for α-model and CVCV-model. The approximate analytical solutions (16) for ITA-model are presented on Fig.2.

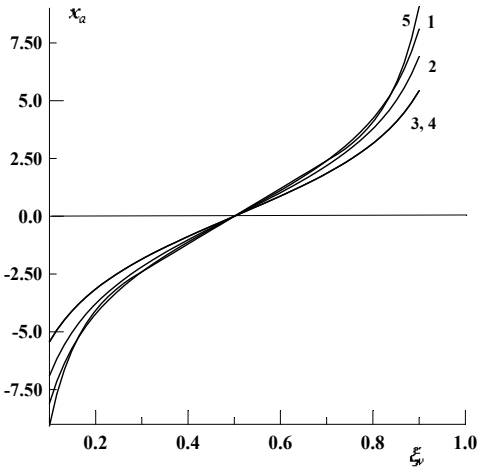

Fig. 1. Dependence of the dimensionless parameter x_a on the energy part ξ_v for α- and CVCV-models. Different lines are for different parameters E_{10}/T and m: 1 – E_{10}/T = 0.5, m = 20; 2 – E_{10}/T = 1.0, m=10, 3 – E_{10}/T = 25, m = 5; 4 – E_{10}/T = 0.5, m = 5. 5 is the results of approximate solutions

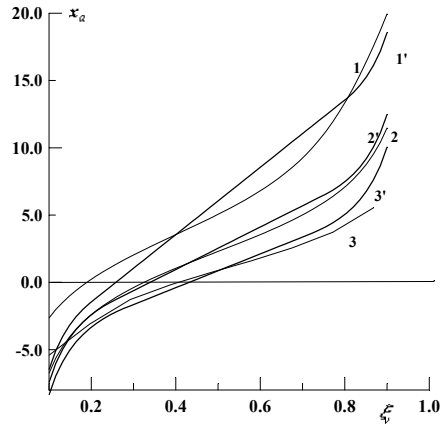

Fig. 2. Dependence of the dimensionless parameter x_a on the energy part ξ_v for ITA-model. Different lines are for different parameters E_{10}/T and m: 1, 1′ – E_{10}/T=25.0, m=5; 2, 2′ – E_{10}/T =0.5, m=20; 3, 3′ – E_{10}/T =0.5, m=5. 1,2,3 are the results of numerical calculations; 1′, 2′, 3′ are the results of approximate solutions.

The dependencies λ, α and U on the gas temperature T calculated from numerical solution of eq.(3) are given on Figs.3, 4 for some specific reactions. The dependencies of relative level rate constants $k(m,T)/k(0,T)$ and $k(m,T)/k(1,T)$ on vibrational level m are presented on Fig.5, 6 for reactions O + $N_2(m) \rightarrow$ NO + N at T = 10000 K and HCl(m)+I→Cl+HI at 850 K. Calculation is carried out for anharmonic Morse oscillator and ITA–, α– and CVCV–models with obtained from eq. (3) parameters λ, α and U. It is seen that all models gives the similar results for low levels.

2, (2') HCl(m)+Cl→H+Cl_2 , ξ_v = 0.39 (ξ_v = 0.44)

3, (3') N_2(m)+O→N+NO, ξ_v =0.25 (ξ_v = 0.31)

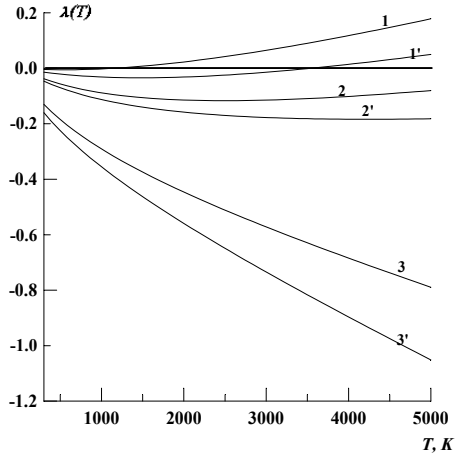

Fig. 4 The dependence of parameter λ on the gas temperature T in ITA-model with taking into account experimental errors of measurement of ξ_v.

1, (1') N_2(m)+O→N+NO, ξ_v =0.25 (ξ_v = 0.31)

2, (2') HCl(m)+Cl→H+Cl_2 , ξ_v = 0.39 (ξ_v = 0.44)

3, (3') HCl(m)+I→Cl+HI , ξ_v = 0.67 (ξ_v = 0.75)

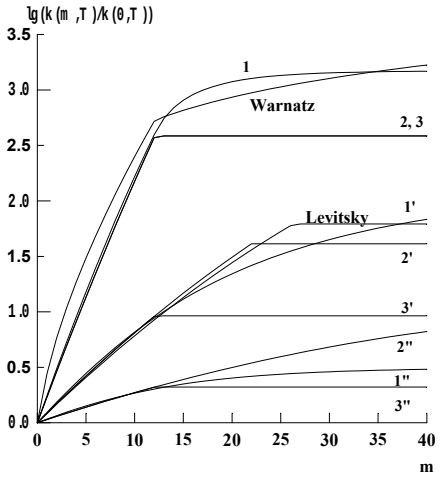

Fig. 5. The dependence of relative rate constant *k(m,T)/k(0,T)* on number of vibrational level *m* for reaction $N_2(m)+O \rightarrow NO+N$ at $T = 10000$ K. Lines shows results which were obtained by Warnatz [10] and Levitsky [11], and by investigated models with various values of ξ_v: 1, 1′, 1″ – ITA-model; 2, 2′ ,2″ – α-model; 3,3′,3″ – CVCV-model; 1, 2, 3 – $\xi_v = 0.7$; 1′, 2′, 3′ – $\xi_v = 0.36$; 1″, 2″, 3″ – $\xi_v = 0.25$.

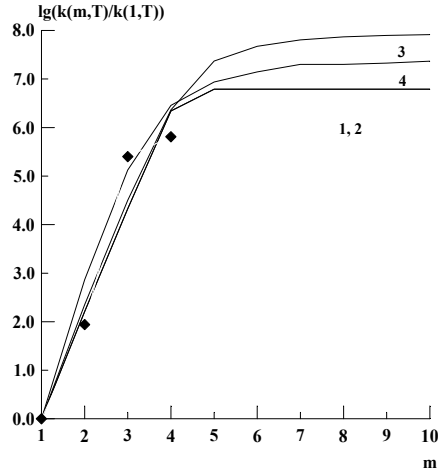

Fig. 6.The dependence of relative rate constant *k(m,T)/k(1,T)* on number of vibrational level *m* for reaction $I+HCl(m) \rightarrow Cl+HI$ at $T = 850$ K. Lines shows following models: 1 – α-model; 2 – CVCV-model; 3 – ITA-model; 4 – results of trajectory calculations [2]; points are values obtained by way recalculation of experimental data of reverse reaction $Cl+HI \rightarrow I+HCl(m)$ [7].

3. Conclusion

Thus, the simple and reliable method for calculation of the relative level rate constants $k(m,T)$ of endothermic exchange reaction (1) is given in the present work. The method uses three simple intuitive empiric models for description of these rate constants (ITA–, α– and CVCV–models) and only one parameter: energy part ξ_v, which goes into vibration in the reverse exothermic reaction. The modification of literature α– and CVCV–models is made to correct description of the level rate constant for cases $\alpha > 1$ and $0 < U < T$ on the levels with energy $E_m > E_a$. It is found that the proposed method for calculation of $k(m,T)$ can good describe both experiment and difficult trajectory computational calculations.

Abstract
Cold plasma jet was produced by electrical glow discharge in a gas jet under reduced pressure and at a low frequency. The precursor gases used were 1-butene and a mixture of oxygen (O_2) and vapor of tetraethyl-orthosilicate (TEOS). Although the surface plasma treatment with 1-butene resulted in water repellence, permeability to water vapor remained unaltered. A mixture of TEOS and O_2 allowed us to investigate the ability of the glow discharge to coat the internal surface of slits made in wood.

1. Introduction

Solid wood is a natural polymer composite in which lignin plays the role of the continuum matrix phase and the cellulose acts as the reinforcement fibers. Hemicelluloses are the coupling agents between the matrix (lignin) and fibers (elementary cellulose fibrils), and the extractives are the additives [1].
The use of cold plasmas is common in treatments of polymer surfaces for multiple applications; it stands to reason, therefore, that wooden surfaces should also be treatable.
Two of the characteristics of solid wood are hydrophilicity and hygroscopicity. Moist wood, which is vulnerable to attack by fungi and termites, loses its dimensional stability. Solid wood can be subjected to a wide variety of treatments to make it suitable for specific technical applications. The most widely used treatments for solid wood are impregnation [2] and coating with paints and varnishes [3]. Film-forming finishes slow both the absorption of water vapor and drying out of the wood. This retardation of drying, in cyclic high and low relative humidities, causes the moisture content of the wood to increase over time. Thus, the moisture content of the wood can approach the range wherein decaying fungi may become active. Plasma coating can overcome this drawback, rendering the outermost surface highly hydrophobic without altering either the natural appearance or the water vapor permeability of wood.
Solid wood permeability can be altered along the grain with cold radiofrequency plasma [7]. Several gases (CH_4, C_2F_2, vapor of hexamethyldisiloxane, O_2, vapor of acrylic acid) have been used to control the hydrophobicity of solid wood surfaces and to improve paint adhesion [8]. Vapor of hexamethyldisiloxane – plasma has also been used to produce water repellent characteristics [9]. Plasma treatment can be used to improve the weathering resistance of wooden surfaces [10,11]. Cold plasmas capacitively arranged and operated at low frequencies, such as 60 Hz, though efficient to alter wooden surfaces chemically, cannot be used to treat orifices smaller than 3 mm wide [4,11].
The apparent contact angle is a useful and cheap technique to identify the penetration of liquids into rough wooden surfaces [5]. The apparent contact angle depends on both the roughness and the chemical nature of the surface [6]. This technique is also used in the present study to characterize plasma-treated wooden surfaces.
A new technique for finishing wood - called plasma jet - was tested in this study. This technique appears promising in view of the low vacuum level and low 60 Hz power supply required, the lack of pollutants, and the use of industrial chemicals.

2. Materials and methods

Defect-free pine (*Pinus caribaea hondurensis*) was sawn into blocks with a 2.0x2.0x1.0 cm nominal size in the radial, tangential and longitudinal directions, respectively. Flat-grained boards with a nominal dimension of 0.5x2.0x2.0 cm were sawn and sanded with 220-grit sandpaper. The blocks and boards were oven-dried at 100^{o}C for 24 h, plasma treated, and then used for water absorption measurements in a controlled environment. After being plasma treated, the boards were used for contact angle measurements along the grain.
The 1-butene, argon (Ar) and O_2 gases were supplied by Air Liquid do Brasil and the tetraethyl orthosilicate (TEOS) came from DATIQUIM Produtos Químicos Ltda (Brasil). The rest of the chemicals were supplied by Aldrich Chemical Company Inc.

Scanning electron microscopy (SEM) micrographs and Si mappings were made using a Zeiss 980 microscope equipped with an EDS Analytical Link QX 2000 analyser.
Static advancing water contact angle measurements were taken at room temperature by the sessile drop method, using optical microscopy (MM Optics, Inc. Brazil) and digitizing the image obtained with a CCD (LG Honeywell) camera. The photographs were enlarged on a computer screen, providing a clear picture of the contact between the droplet (2 μl) and the substrate surface. About 9 contact angle measurements were measured at different points of one wood sample for each reported average value of the angle in the parallel and perpendicular directions of the wood's surface grains. The standard deviation of the contact angle was less than 2 degrees for glass substrates and less than 8 degrees for wood substrates.
The 1-butene deposition rate was measured on 1 mm thick B270 optical glass substrate. The film growth rates were calculated after measuring the film thickness on glass substrate using a Tyle Step Hudson stylus profilometer. The glasses were immersed for 1 h in a sulfuric acid/hydrogen peroxide 70/30 volume solution, after which they were washed with pure water and dried with dry nitrogen. After they were cleaned and rendered hydrophilic, these glasses were used as substrate for the plasma treatments.
For deposition of the plasma jet, an ion beam was built (fig 1) and operated attached to a homemade plasma chamber window that has been described elsewhere [4]. The plasma jet consists of a cylindrical aluminum tube (2.0 cm inner diameter) into which the gas or the mixture of gases is admitted at one end, while three metallic grids with different electric potentials are mounted at the other end to generate and accelerate the plasma through the substrate. The first grid operates at 260 VAC, 60 Hz, the second one at minus 5 kVDC, and the third at 15 kVAC, 60 Hz. Permanent ring magnets are fixed around the external aluminum cylinder. Thus, the magnetic field (1,200 Gauss) is applied parallel to the cylinder's axis. Electrons repelled from the cathodes are attracted to the anode but the magnetic field constrains the electrons to follow helical trajectories, increasing their path length and enhancing the ionization efficiency.

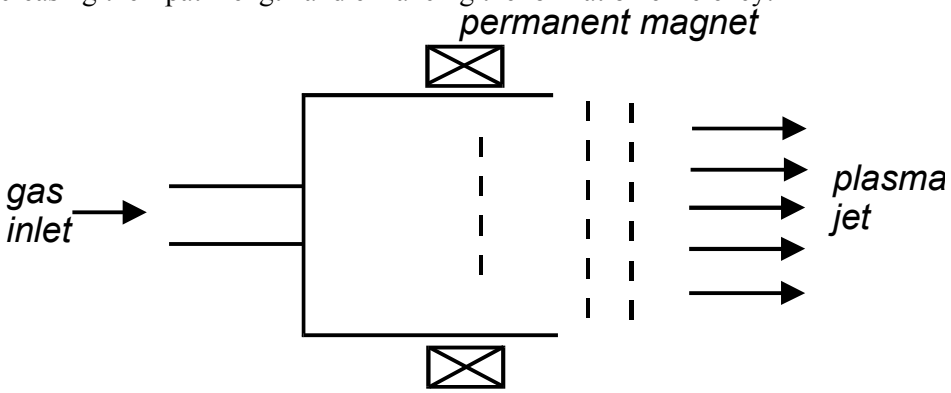

Figure 1- Diagram of the plasma jet.

Before deposition of the plasma-polymerized film, the reactor chamber was evacuated to a base pressure of 9.33 Pa and flushed three times with argon. A glow discharge with Ar at 30 mTorr and 50 sccm was then applied for 5 min to clean the surfaces, after which the reactor was again evacuated to the base pressure. The next step was the admission of the reactive gas, with the control valve adjusted to set the pressure and the flow in the chamber at pre--established levels before the glow discharge was switched on. A four factor (pressure, gas flow, substrate distance from the third grid, and deposition time), two level experiment design was followed. Two levels of pressure and gas flow were tested for 1-butene plasma jet experiments, 30 or 10 mTorr and 50 or 25 sccm, respectively. The substrate distance was 2.0 or 1.0 cm apart from the third grid, and the deposition time was 10 or 1 min.
TEOS was vaporized into the interior of the reactor using an appropriate apparatus with heating. The partial pressure of the TEOS vapor was 25 mTorr, and that of the O_2 was 75 mTorr. TEOS/O_2 mixture plasma jet deposition time was 20 min and the total flow was 50 sccm.

3. Results

Table 1 shows the values of the film growth rate, which was evaluated using optical glass substrates at a distance of 2.0 and 5.0 cm from the third metallic grid of the ion beam. It can be noted that the deposition rate was greater for the substrate closest to the third grid. The substrate's distance from the grid is an important factor owing to the low level of vacuum in the chamber, since the mean free path of the ions is very short. Thus, if the distance is great, the ions collide with the gas species along the way rather than with

the substrate's surface. The film growth rate reported in table 1 does not depend on the deposition time, which ranged from 1 to 15 minutes in this experiment. Moreover, the film deposition rate does not depend on substrate thickness, contrary to the capacitive coupled plasma operated at low frequencies. Thus, the plasma jet technique is highly efficient for thickly coating solid wood surfaces.

Table 1- Film growth rate of 1-butene plasma jet deposition. The thickness of the film was measured at two glass substrate distances from the third metallic grid of the ion beam.

	Substrate distance from the third grid	
	2 cm	5 cm
film growth rate (nm/min)	33.0	25.0

A TEOS/O_2 mixture was used as reactive gas in the plasma jet in order to deposit SiO_x films on the solid wood surface. The deposited film was characterized by Si EDX mapping. Figures 2 and 3 show SEM micrographs of solid wood surfaces exposed to the TEOS/O_2 plasma jet. Figure 2A illustrates the morphology of the SiO_x deposited film, showing that the deposit is as rough as the woody substrate. However, the coating concealed the ultrastructure of the solid wood surface. Figure 2B shows the Si mapping, revealing white dots spread over the entire surface, which confirms the complete coating of the wooden surface.

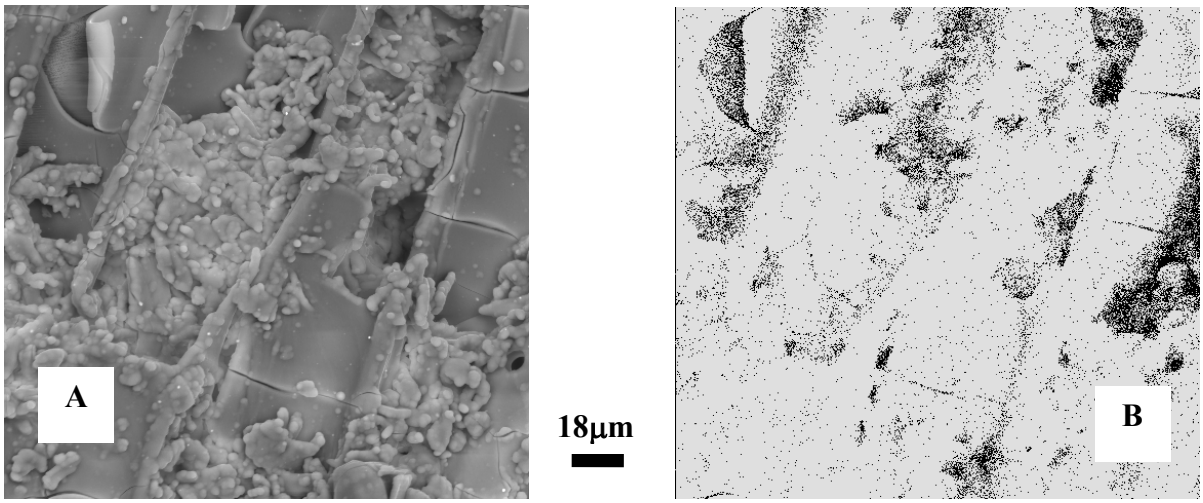

Figure 2- Solid wood surface along the grain coated with SiO_x by plasma jet. A) SEM using secondary electrons, and B) Si mapping of the same region. Magnification: 500X.

Figures 3A and 3B show, respectively, SEM micrographs and Si mapping of the surface of the 1.0-mm wide, 3.0-mm deep slit cut into the solid wood. These micrographs reveal that the plasma jet coated orifices which capacitively-coupled plasma was barely able to coat.

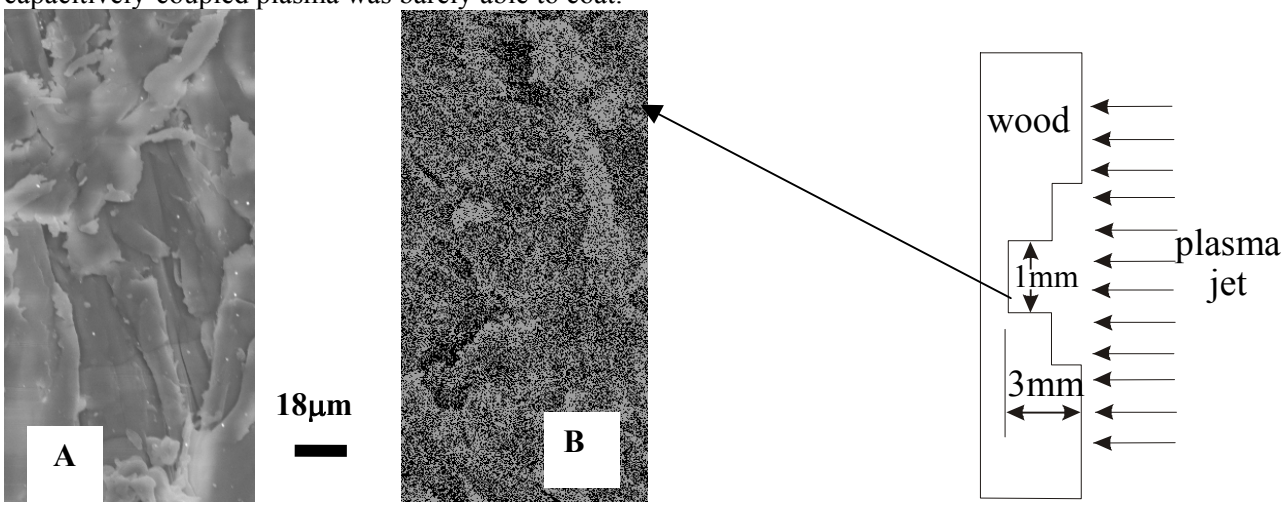

Figure 3- Surface of the slit cut into the solid wood and exposed to TEOS/O_2 plasma jet. A) SEM, and B) Si mapping of the same region.

Table2 shows the contact angle of a water droplet on a plasma jet-treated flat grained wooden surface with 1-butene gas for a 2^4 factorial design experiment. It was interesting to find that the contact angle was different and depended on the direction of the measurement. The contact angle values were found to be higher in the direction perpendicular to the grains and lower in the direction parallel to the grains. The distinct contact angle values in both cases were attributed to uneven roughness or porosity and chemical heterogeneity of the surface. It is a well known fact [6] that the roughness or porosity of the substrate alters the apparent contact angle (Wenzel's law). If the true contact angle is large and the surface is porous or sufficiently rough, the apparent angle shows higher values than the true angle. The plasma jet treatment changed the hydrophilic character of the solid wood surface to a hydrophobic one, with contact angles of up to 144 and 137 degrees in the directions perpendicular and parallel to the grain, respectively.

Table 2- 2^4 factorial design for the plasma jet experiment.

experiment	Pressure -=10 mTorr +=30 mTorr	Gas flow -=25 sccm +=50 sccm	Substrate distance -=1 cm +=2 cm	Deposition time -=1 min +=10 min	Contact angle (degrees) //	Contact angle (degrees) ⊥
1	+	+	+	+	108.9	128.1
2	-	+	+	+	123.7	132.7
3	+	-	+	+	130.0	135.3
4	-	-	+	+	130.6	134.9
5	+	+	-	+	136.7	142.1
6	-	+	-	+	113.7	124.6
7	+	-	-	+	129.7	125.5
8	-	-	-	+	117.8	124.1
9	+	+	+	-	130.5	138.0
10	-	+	+	-	135.2	144.5
11	+	-	+	-	137.4	136.5
12	-	-	+	-	117.3	132.8
13	+	+	-	-	129.5	140.7

15	+	-	-	-	132.0	126.8
16	-	-	-	-	117.4	122.5

An analysis of table 2 revealed the effects that remained over the statistical noise. These effects, for a contact angle parallel to the grain, were the pressure of the chamber and the crossed effects of second order- pressure/distance, gas flow/deposition time – and the crossed effect of the third order – pressure/distance/deposition time. Increasing the pressure from 10 to 30 mTorr caused a 6 degree increment of the contact angle. The angle parallel to the grain contact angle did not depend on gas flow or on the substrate's distance from the third grid of the ion beam. As the deposition time increased from 1 to 10 min, the angle parallel to the grain contact angle decreased by 4.5 degrees.

For the angle perpendicular to the grain contact angle, the effects that remained over the statistical noise were different from the effects responsible for alterations in the angles parallel to the grain. The second order cross effects of gas flow/substrate distance and gas flow/ deposition time were the ones that most strongly influenced the angle perpendicular to the grain contact angles.

The same change in the operating parameters of the plasma jet caused different statistical increments between contact angles perpendicular and parallel to the grain. This important difference indicated that the roughness of the wooden surface after treatment was the main reason for uneven contact angles. In fact, the deposition rate was too low to alter the more widely spaced irregularities in the direction perpendicular to the grain because of the wood's cellular structure. Along the grain, inside exposed semi-cylindrical wood fibers, the plasma jet was able to alter the roughness (fig 4).

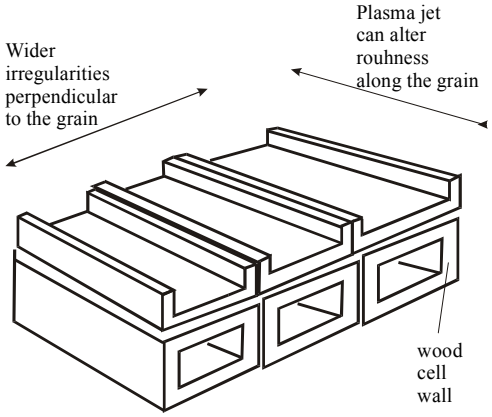

Figure 4- Schematic of wood surface showing semicylinder fibers exposed to the plasma.

Since the plasma jet penetrates solid wood orifices more efficiently than does the capacitively-coupled plasma, new experiments with 1-butene as precursor were conducted to evaluate water vapor exclusion. Wooden blocks and boards were used as substrates, with both the cross section and the flat-grained surface exposed to the plasma jet. Each wood surface was exposed to the plasma twice owing to the plasma jet's small (2 cm) diameter. Only the two largest surfaces of the wooden samples were directed coated by the plasma jet; the other four faces were treated indirectly.

The untreated and treated samples were cyclically exposed to a humid and dry environment and their weight monitored at regular intervals. Figure 5 shows graphs of the water vapor absorption of the 1-butene treated and the untreated solid wood. Although the plasma jet treatment provided efficient protection from liquid water, it proved ineffective against humid air.

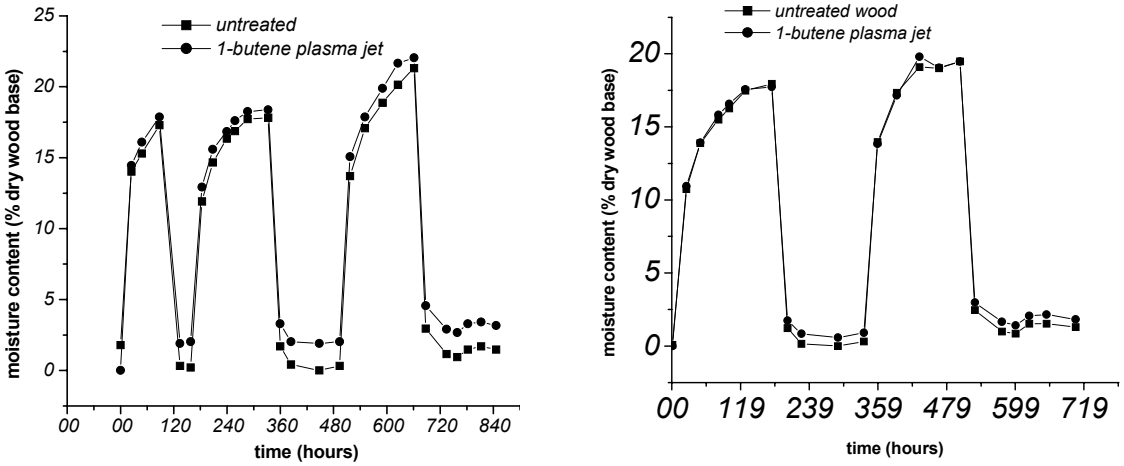

Figure 5- Change in moisture content of Caribbean pine finished with 1-butene plasma jet coat and exposed to alternating cycles of 95 and 22 percent relative humidity at room temperature, compared with untreated wood. Left: boards with nominal dimensions of 0.5 (R) x2.0 (T) x2.0 (L) cm. Right: blocks with nominal dimensions of 2.0 (R) x2.0 (T) x0.5 (L) cm

Although the plasma jet easily penetrates 1-mm size slits and fibers exposed lengthwise, deposition inside the cell lumen of the cross section wood plane (diameter smaller than 40 μm and length longer than 1 mm) is very difficult. When the jet's incidence was not aligned with the longitudinal cell axis, internal coating of the cell wall was very difficult to achieve. Moreover, wood powder and debris adhered to the surface after the wood was sanded and machined, serving as a shield that prevented the capillaries from being coated.

4. Conclusions

A thin solid film deposited by 1-butene-cold plasma jet successfully coated solid pine wood. Plasma jet treatment is more effective for coating wooden surfaces than capacitive coupled plasma treatment. The plasma jet is a promising technique owing to its low cost and its ability to coat orifices up to 1 mm wide and 3 mm deep. Moreover, the technique can be successfully used to coat solid wood with SiO_x films.

The wooden surface became highly hydrophobic after the plasma treatment. The plasma-deposited film was unsuccessful in preventing water vapor absorption and desorption because the technique proved inadequate to coat wood capillaries. By allowing the wood to breathe, plasma jet coating does not trap moisture that might otherwise lead to decay.
The contact angle showed different values depending on the direction of the measurement, being highest and lowest, respectively, in the direction perpendicular and parallel to the grain. The contact angle value was affected by the chemistry and roughness of the surface, which were both altered by the plasma jet treatment.

Temperature measurements in absorbing inhomogeneous plasmas by relative intensity of spectral lines

E. Ershov-Pavlov[1], K. Catsalap[1], K. Stepanov[2]

[1]*Institute of Molecular and Atomic Physics, National Academy of Sciences, Minsk, Belarus*
[2]*Heat and Mass Transfer Institute, National Academy of Sciences, Minsk, Belarus*

Recently temperature measurements have been considered by relative intensity of spectral lines in emission spectra of inhomogeneous plasmas [1]. The plasmas have been supposed to be optically thin, close to thermal equilibrium and to have temperature distributions along the observation direction y, which could be approached by the formula: $T(y)=T_0[1+(y/y_0)^{\alpha}]^{-1}$, where y_0 is an effective dimension of the volume, α determines a rate of the plasma inhomogeneity ($\alpha=\infty$ for homogeneous plasmas). It has been in particular shown, that maximum temperature T_0 can be measured using an intensity I ratio of two (or more for Boltzmann plot) spectral lines of the same atom:

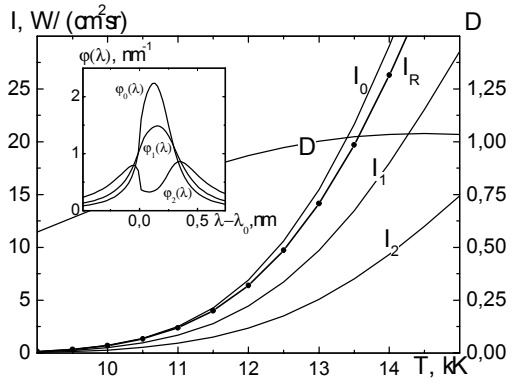
$$kT_0 \approx (E_a-E_b)[\ln(C_a/C_b)-\ln(I_a/I_b)-\alpha^{-1}\ln(E_a/E_b)]^{-1}, \quad (1)$$

where E is energy of the upper level of the transition under consideration and C is a common parameters combination for every (a, b) line. The equation differs from the conventional Boltzmann relation by the member $\alpha^{-1}\ln(E_a/E_b)]^{-1}$ depending on the plasma inhomogeneity and on the lines used. Also, emission intensity of the plasma volume is here instead of plasma emissivity, which normally must be taken for inhomogeneous plasmas.

Eq. (1) cannot be directly used for the measurements in absorbing plasmas, as far as emission intensity for optically thin plasmas must be taken in it. One can overcome the problem using an additional information. It has been shown [2], that emission intensity I_0 of an optically thin plasma volume identical to the absorbing one under consideration (having the same properties and temperature distribution) can be found from the following relation:

$$\frac{I_0}{I_1} \approx \frac{1}{2}\left(1+\frac{I_1}{I_2}\right), \quad (2)$$

where I_1 and I_2 are emission intensity of the absorbing plasma measured directly and after it re-passes the same volume in the observation direction. The value I_2 can be measured, e.g., with a mirror placed at the volume backside, as a difference between intensity measured with the mirror (I^*) and without it (I_1), i.e. $I_2=I^*-I_1$ (the intensity loses are not taken into account). The relation works at moderate optical density ($D\leq 1$, $I_1/I_2\leq 1.5$). For strongly absorbing plasmas ($D\leq 5$) a parametrical approximation of eq. (2) was found [2].



Spectral line Ar I 696.5 nm intensity and profiles in the emission of the argon plasma volume at 5 bars, y_0=5 cm, α=2 and temperature T_0=9-15 kK. The line profiles for T_0=13 kK are shown.

A numerical simulation of different plasma volume emission has been performed to study the possibility and errors of determination of I_0 and T_0 using eqs (2) and (1) at absorbing plasma diagnostics. Calculations of I_0, I_1 and I_2 have been performed with a numerical code reported elsewhere [3]. Argon plasma and atomic lines has been used for the modelling. Plasma volumes with different temperature distributions and optical thickness have been simulated by changing α, T_0 and y_0 at the program entrance. Also, atmospheric and higher plasma pressure has been taken to widen the volume absorption interval. One of the simulation results is shown in the figure. Here, with I_R the results are shown of our I_0 "measurements" using simulated values of I_1 and I_2 and eq. (2).

Complex (dusty) plasmas: trends in applications and diagnostics

H.Kersten[1], R.Wiese[1], G.Thieme[1], H.Deutsch[1], E.Stoffels[2], W.W.Stoffels[2], G.M.W.Kroesen[2]

[2]*Department of Physics, TU Eindhoven, P.O.Box 513, NL-5600MB Eindhoven*

The research effort in the area of complex (dusty) plasmas initially aimed at avoiding particle formation and controlling the contamination level in industrial reactors. Nowadays, dusty plasmas have grown into a vast field and new applications of plasma-processed dust particles are emerging. There is demand for particles with special properties, and for particle-seeded composite materials. Low-pressure plasmas offer a unique possibility of confinement, control and fine tailoring of particle properties.

An approach for coating of externally injected particles will be demonstrated, where an argon rf-plasma was employed to charge and confine particles, while a metal coating has been performed by means of a separate dc-magnetron sputter source. Also, we perform the synthesis of small carbon particles as well as the deposition of thin amorphous carbon (a-C:H) films onto SiO_2 grains (~1μm) in an acetylene process plasma. Already after a very short process duration, the laser light scattering increases remarkably due to the simultaneous formation of dust in the course of a-C:H deposition. After examination of the collected particles by electron microscopy (SEM) the carbon dust particles show almost the same size.

The interaction between plasma and injected micro-disperse powder particles can be used as a diagnostic tool for the study of plasma surface processes, too. Examples for determining the electric fields in front of electrodes, substrates or beam sources by dust particles are given as well as for obtaining information on the energy fluxes in the plasma. As examples, the additional electrostatic forces are supplied by inserting floating substrates which are placed perpendicular to the rf-electrode, by an external ion beam source, or by a dc-magnetron.

Etching of SiO_2 rods by a DC plasma torch

Abstract

Etching of SiO_2 rods has been obtained with a DC torch with argon as process gas; the high temperature of the plasma jet causes vaporisation of the area exposed. Apparatus and torch operative parameters have been set up to obtain a depth etch rate of 0.6 mm/min corresponding to 0.826 g/min. An enthalpy probe has been employed to monitor plasma condition before thermal plasma etching (TPE) process and from experimental values of etch rate a surface temperature of T_{sur}=2057 K has been derived. Etching has been obtained with uniformity over the entire area exposed with peak to peak differences below 1%.

1. Introduction

Thermal plasmas appeared in the sixties, either produced by arc plasmas by the interaction between an electric arc (DC) [1] or inductively coupled plasma discharges (ICP) [2] and a gas which ionises and becomes a plasma near the condition of local thermodynamic equilibrium (LTE).

Since then, a number of industrial applications were developed. Among these some examples can be given as: welding, cutting, spraying in ambient air and under soft vacuum, surface treatment with plasma transferred arcs, heating of air in blast furnaces or cupolas, purification of metals, ICP analysis, extractive metallurgy and steel dust recovery, optical fibers production [3].

SiO_2 rods, usually preforms, from which optical fibers are drawn, need surface treatments due to OH radical contamination, external pollution or surface imperfections. OH ions contamination is generally due to optical fibers conventional manufacture method which utilises hydrogen or methane burners as thermal source. These burners produce water causing OH ions contamination on silica rod surface. The external polluted layer reaches depths of about 0.3-1 mm and can be removed by chemical (HF) or plasma etching. Faster etch rate than conventional anisotropic plasma-chemical etching used in micro-electronics industry [4-11] (typical etch rate of about 0.5-1 μm/min) is needed, due to the tick layer to remove.

Mechanical removal (grinding) is not suitable because it can cause mechanical stress and can lead to SiO_2 rods structural failure, e. g., formation of cracks propagating through the rod.

Chemical etching is obtained by HF attack: the rod is plunged in a H_2O-HF solution allowing an isotropic corrosion but with poor etch rate. In this paper thermal plasma etching (TPE) is employed exposing the rod surface to a substantial portion of the electrically conducting plasma region (the plasma core) extending from a DC plasma torch with argon as process gas. Significantly, the surface material is substantially removed by vaporisation, due to the extremely high plasma temperature of the plasma torch.

Though the temperatures in the tail of the plasma jet are lower than at the plasma core, the temperatures are generally still several hundreds degrees centigrade. These tail temperatures typically are sufficiently high to cause vaporisation of most refractory dielectrics.

Even if a portion of the refractory dielectric body surface changes from a solid phase to a vapor phase, the remainder substantially maintains its pre-etch shape.

2. TPE experimental set-up

The experimental set-up employed for TPE is showed in figures 1 and 2.

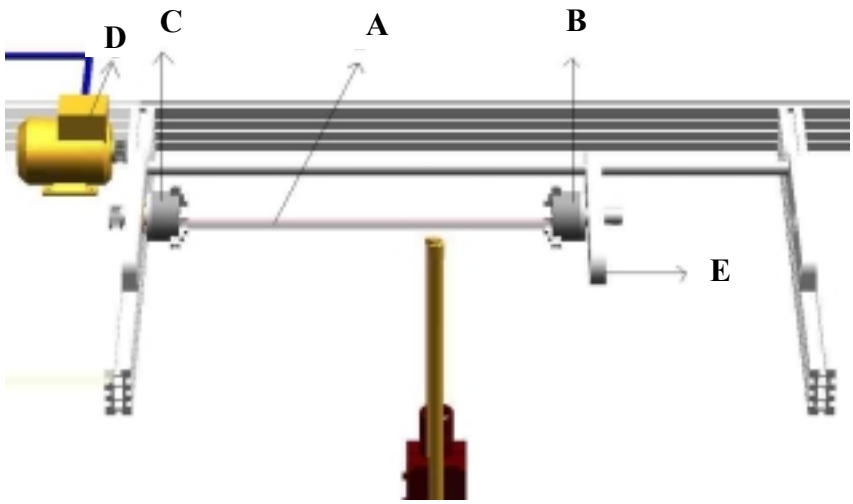

Figure 1: TPE experimental set-up: rod assembly.

SiO_2 rod ends (A) have been placed between two mandrels; the first (C) is connected to an engine (D) through a transmission system, whereas the second (B) can be moved on a guide (E). The engine allows a rotating speed ranging between 27 and 1200 r.p.m.

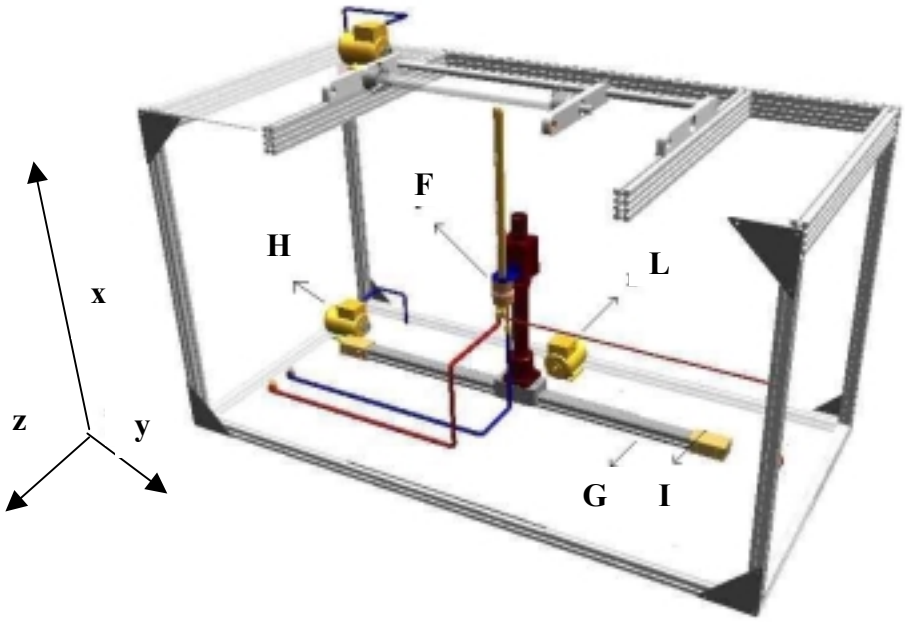

Figure 2: TPE experimental set-up: torch assembly.

The DC torch (F) is mounted on a 2D-displacement system. The engine (H) supplies a speed between 0.034 cm/s and 3 cm/s, whereas the engine (L) allows the torch to be moved along z-axis.
Rotating the cylindrical silica rod uniformly, with proper movement of the plasma torch along the rod, allows material to be removed from substantially the entire surface such that the rod retains its cross-sectional shape. The plasma jet, as it moves across the rotating rod, contacts and etches the rod. The etch rate is a function of plasma transverse speed and, among other factors, to the extent the transverse speed influences the silica rod surface temperature.

Apparatus parameters
Apparatus and torch operative parameters employed are summarized below.

- torch to rod distance: 1-4 mm
- rod revolving speed: 30-900 r.p.m.
- torch transverse speed: 0.04-1 cm/s
- torch to rod orientation: axial

Torch operative parameters

The reactor used (F) is a non-transferred plasma torch, connected to a power supply of 16 kW maximum power.
Operative conditions employed for plasma etching are the following:

- Process gas: argon
- Gas flow rate: 20 slm
- Power supplied: 5.4 kW
- Thermal efficiency: 27%

The choice of argon as process gas has been dictated by the potential less electrode erosion that reduces the risk of metal contamination on the silica rod surface as a consequence of the low thermal local heat flux on the electrodes compared with other molecular gases such as N_2 or H_2.
Gas flow rate has been taken as low as 20 slm to avoid instantaneous cracks due to the excessive kinetic impact and for increasing the mean temperature, making vaporisation easier.

Discussion and results

An enthalpy probe [12-18] has been used to monitor plasma condition in order to obtain plasma temperature, velocity and air entrainment maps [19] before TPE process. In figure 3 the air entrainment distribution in the plasma jet is shown, whereas in figures 4 and 5 radial and axial temperature and velocity profiles at the nozzle exit are presented for a 5 mm torch nozzle operating at 200 A with 20 slm of argon.

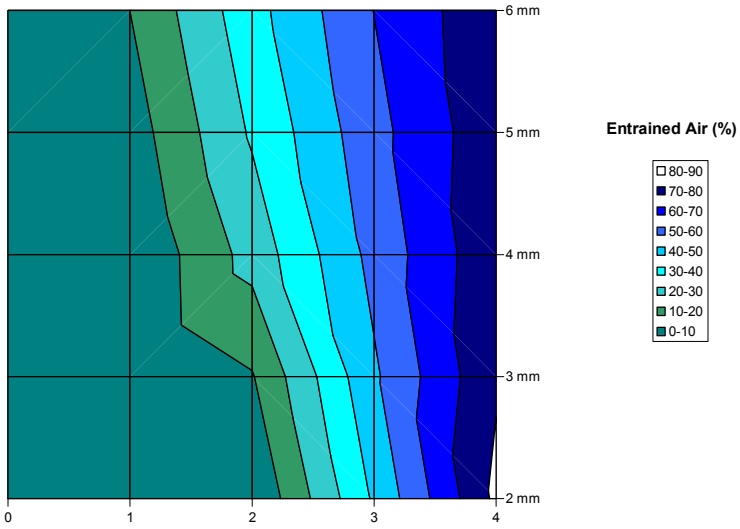

Figure 3: Air entrainment map of an argon plasma jet at 200 A, 20 slm.

In figure 3 the core region is clearly recognized inside the zero percentage contour. This zone is characterized by high temperature 3000-4000 K (figure 4) and high velocity 400-500 m/s (figure 5) whereas in the outer region the presence of air tends to chill and slow the argon region.

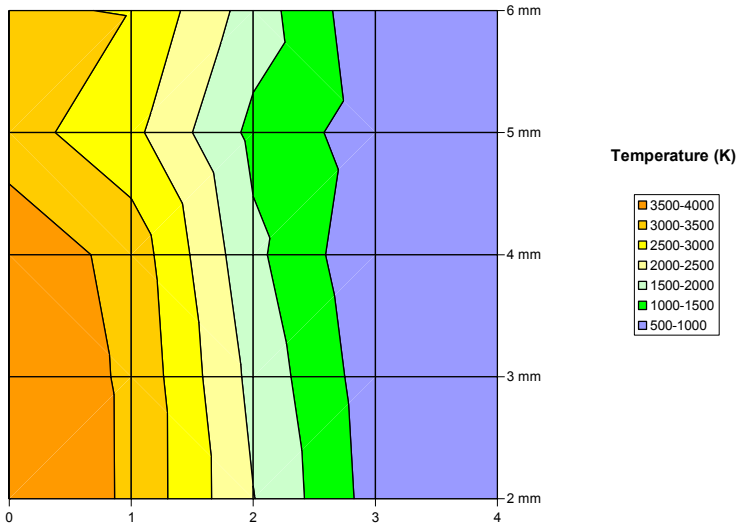

Figure 4: Temperature map of an argon plasma jet at 200 A, 20 slm.

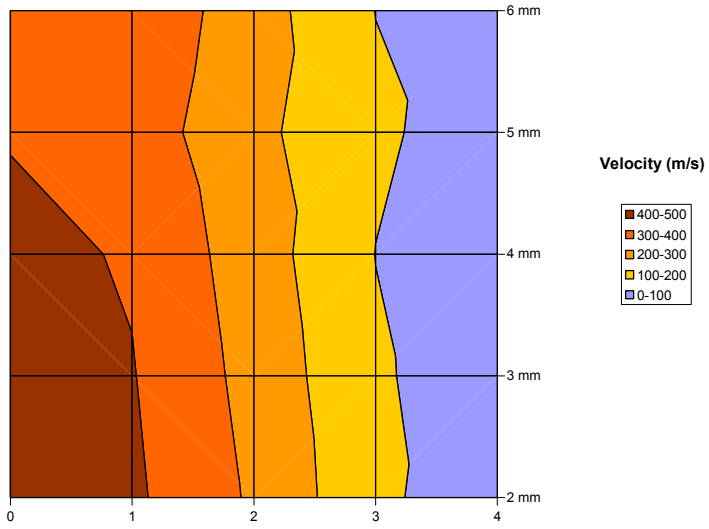

Figure 5: Velocity map of an argon plasma jet at 200 A, 20 slm.

Torch to rod distance, rod rotating speed, torch transverse speed have been optimized on a number of silica sample rods in order to reduce surface etch non uniformities and cracks formation. Such tests lead to the definition of the following apparatus working parameters:

- Torch to rod distance: 2 mm
- Rod rotating speed: 42.96 r.p.m.
- Torch transverse speed: 0.056 cm/s

With the previous parameters three silica rods (length 1 m, diameter 10 mm) have been treated at a distance of 2 mm from the anode exit. Table 1 reports the volume removed from each rod, the time interval of treatment, the total mass removed (SiO_2 density = 2.2 gr/cm^3) and the mass loss rate (M_c).

	rod 1	rod 2	rod 3
Total volume removed [mm^3]	9660	7725	19295
Total time of treatment [min]	28.9	36	52
Total mass loss [g]	26	20.85	52.1
M_c [g/h]	53.9	34.75	60.11

Table 1: TPE experimental data.

A mean vaporisation value of M_c = 49.58 g/h ± 7.47 g/h has been obtained with the described set of operative condition. The lower rod 2 vaporisation rate compared to rod 1 and rod 3 has been ascribed to initial non uniform diameter of rod 2 causing different longitudinal torch to rod distances. The result is a lower mean vaporisation rate.
Assuming that the main cause, in stationary conditions, for the rod erosion is due to material evaporation, ignoring redeposition of materials as whiskers, the mass loss can be calculated through the number of atoms leaving the cathode per unit time and surface area (vapour density flux). According to the kinetic theory of gases the vapour pressure $p_{ev}(T_c)$ can be described as a process in which the particles leaving the surface transfer their momentum per unit surface area and time to the surroundings. The maximum vapour density flux J_n^{max} will be given by:

$$J_n^{max} = \frac{p_{ev}(T_c)}{\bar{p}} \qquad (1)$$

where

$$\bar{p} = m_c \sqrt{\overline{v^2}} = \sqrt{3 m_c k_B T_c} \qquad (2)$$

$m_c = 1.0049 \cdot 10^{-25} kg$ being the silica atomic mass and T_c the surface temperature. Thus the mass loss rate M_c^{max} is given by:

$$M_c^{max} = J_n^{max} \pi r_s^2 m_c \qquad (3)$$

where r_s is the jet radius, taken as 2.5 mm (see figure 4).
From equations (1-3) and the experimental mass loss rate M_c, a surface temperature T_c=2057 K during the TPE process has been calculated (see figure 6).

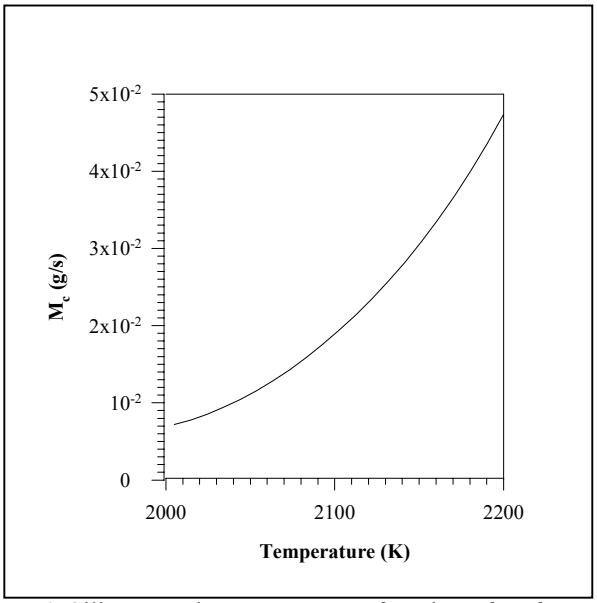

Figure 6: Silica mass loss rate M_c as a function of surface temperature.

TPE rate has been compared with chemical etching rate carried out on two silica rods.
The reaction exploits HF (40% solution for RPE analysis in watery solution at 20° C temperature) as etch agent to give:

$$SiO_2+4HF\rightarrow SiF_4+2H_2O$$

Silica rods have been plunged in a cylindrical box containing 4 l of HF and connected to a peristaltic pump.
Time of treatment has been based on calibration measurements previously obtained with periodic check of rod diameter.
Before rod inspection and at the end of silica etching treatment, rods have been washed with distilled water in order to stop the acid corrosion.
The two silica rods have been step treated lengthwise in order to estimate chemical etching rate for increasing level of removing.
The four segments, illustrated in figure 7, correspond to different levels of silica removed depth, that is to say 0.1, 0.2 ,0.4 and 0.8 mm.

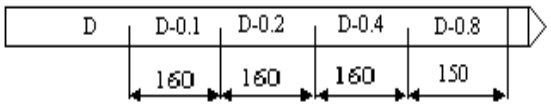

Figure 7: Treatment outline of chemical etching.

A mean chemical etch rate of 0.1 ± 0.01 mm/ h has been measured.
Despite the high uniformity achievable through chemical etching, the presence of surface defects tend to amplify their dimensions due to the isotropic features of chemical action. On the other hand TPE is an anisotropic process being directed essentially as the plasma jet. The coupled displacement of the torch and the rod rotation can give rise to grove formation. However the described choice of parameters have been found to minimise the difference between the maximum and minimum rod diameter $\frac{d_{\max} - d_{\min}}{d_{rod}}$. This value has been evaluated to be less than 1 %.

3. Conclusion.
TPE through the use of a DC plasma torch has been employed to remove surface impurities from silica rods. The process allows etching rate up to about 50 g/h (36 mm/h) to be obtained.
This etching rate is very high compared to both chemical and RF or MW plasma etching at low pressure. Though uniformity is the key issue to be pursued, a correct choice of plasma and relative displacement parameters allows acceptable surface non uniformities (below 1%) together with limited surface thermal stress.

Effect of reactive gas partial pressure on plasma chemistry during magnetron sputtering

S. Mráz, J. M. Schneider

Materials Chemistry, RWTH-Aachen, Aachen, Germany

The plasma composition of sputtered aluminium in an oxygen background has been investigated by mass energy analysis. As the oxygen partial pressure is increased during reactive magnetron sputtering a sharp decrease in deposition rate is commonly observed. This can be explained by the formation of a compound layer at the target surface. Here we report initial plasma chemistry data of an aluminium – argon – oxygen system. Changes in plasma chemistry are measured versus the oxygen partial pressure while the total pressure was kept constant. A strong dependence of the plasma chemistry with respect to the oxygen partial pressure was found. Besides the identification of the expected aluminium, argon and oxygen based ionic species and their dependence on the oxygen partial pressure, we present initial data supporting the formation of aluminium based clusters.

Experimental validation of a model predicting the evaporation of zinc in an argon transferred arc

L. Aguilera, R.J. Munz, and D. Berk

Plasma Technology Research Center (CRTP), Dept. of Chemical Engineering, McGill University

Abstract

Experimental work was carried out on a transferred arc evaporator to validate and calibrate a simple numerical model which predicts metal evaporation rates as a function of crucible temperature, arc current, arc length and plasma gas flow rate. The model gave good qualitative predictions of the effects of all parameters but arc length. The model underpredicted the evaporation rates because of the assumption that the evaporation rate was heat transfer controlled at the boiling point of the metal. The low thermal gradients in the metal result in considerable evaporation at lower temperatures. It is recommended that the model be modified to take this into account

1. Introduction

A transferred arc system, in which an arc is struck from a thoriated tungsten cathode to a metal bath anode, is a convenient way of producing a superheated stream of metal vapour which may be quenched externally to produce ultrafine metal powders or reacted further to produce ultrafine ceramic powders. The scaleup and optimization of the overall system requires knowledge of the operational characteristics and efficiency of the plasma metal evaporator. A simple model has been developed [1,2] which predicts the temperature and velocity fields in the plasma arc and the molten metal bath and also the evaporation rate of metal as a function of arc current, gas flow rate and composition, and arc length. In the present work, experimental data are presented for the validation and calibration of this model using an argon plasma to evaporate zinc. Zinc was chosen because its relatively low melting and boiling points allow more precise experimental measurements to be made.

2. Experimental Set-up

The experimental equipment (Figure 1) consisted of a transferred arc torch set in a cylindrical, water-cooled stainless steel vessel (I.D. = 25 cm; h= 43 cm) a side outlet (I.D.=3.5 cm). The cathode assembly consisted of a water-cooled conical thoriated tungsten tip surrounded by a water-cooled copper nozzle which acted as auxiliary anode. The anode (Figure 2) was a graphite crucible (O.D.= 13.0, h=3.1 cm) with a truncated cone internal cavity (depth=2.1 cm, I.D= 10 cm at the top and I.D.= 5.0 cm). The cathode assembly could be moved vertically to adjust the torch-crucible distance. The crucible was mounted on a hollow graphite cylinder (16.2 cm in length with O.D.=1.3 cm and I.D.= 0.95 cm) inserted in a graphite base. The purpose of the cylinder was to provide an electrically conductive path while minimizing heat losses from the crucible.

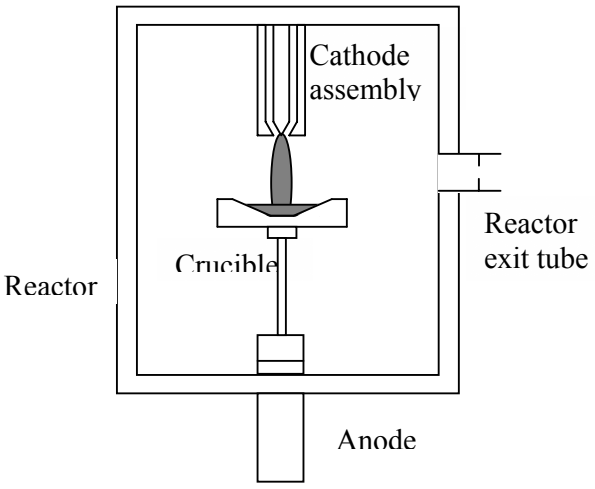

Figure 2:Equipment

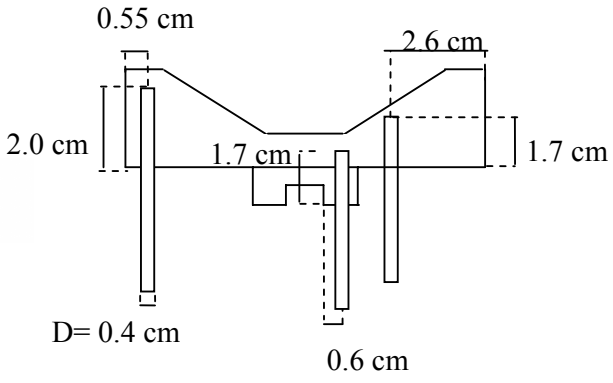

Figure 1: Details of Crucible

Eight DC rectifiers connected in series supplied power to the transferred arc torch with a maximum current of 275 A and an open circuit voltage of 600 V. The outputs of the rectifiers were connected to a high frequency generator used for igniting the arc.

The current and voltage of the arc were monitored using an analog ammeter and voltmeter located in the control console. The current was measured across a shunt (500 A, 50 mV) placed in series with the anode. The voltage was measured between the cathode output of the high frequency generator and the anode of the reactor. The variation of temperature at three different points in the crucible was measured using ungrounded type K thermocouples (see Figure 2). The values of temperature, current and voltage were recorded with the a data acquisition system starting 60 s after arc ignition. The pressure inside the chamber was monitored using a pressure gauge

3. Experimental Procedures

The metal used was zinc with a purity of 99.97 % supplied by Noranda Inc (Quebec, Canada). Before each experiment, a sample of zinc weighing about 400 g was loaded into the crucible and the reactor was purged with argon to remove any residual oxygen. The cathode assembly was positioned to within a few millimeters of the zinc and the arc ignited. The arc was then adjusted to the appropriate length, current and gas flow rate and operated for the required time. After the experiment, the reactor was cooled under argon purge, and the metal remaining in the crucible was weighed.

4. Results and Discussion

a. Temporal variation of crucible temperature and calculation of evaporation rate

The model being tested is a steady state model but the experiments are necessarily batch. Figure 3 shows the temperature variation at the centre of the crucible for several experiments performed under the same conditions with different operating times. The results show a rapid increase in temperature over approximately the first 720 seconds after arc ignition. During that time the zinc melts and is heated to a pseudo steady state temperature. Following that time the temperature of the crucible increases slowly by 0.12°C/s. Long runs were inappropriate because the temperature increases were higher due to appreciable changes in the level of metal in the crucible and arc length. After arc extinction, the metal and crucible cooled, exhibiting a freezing plateau about 19 degrees below the freezing point of zinc. This temperature difference allowed the true wall temperature at the zinc-crucible interface to be estimated for the simulations.

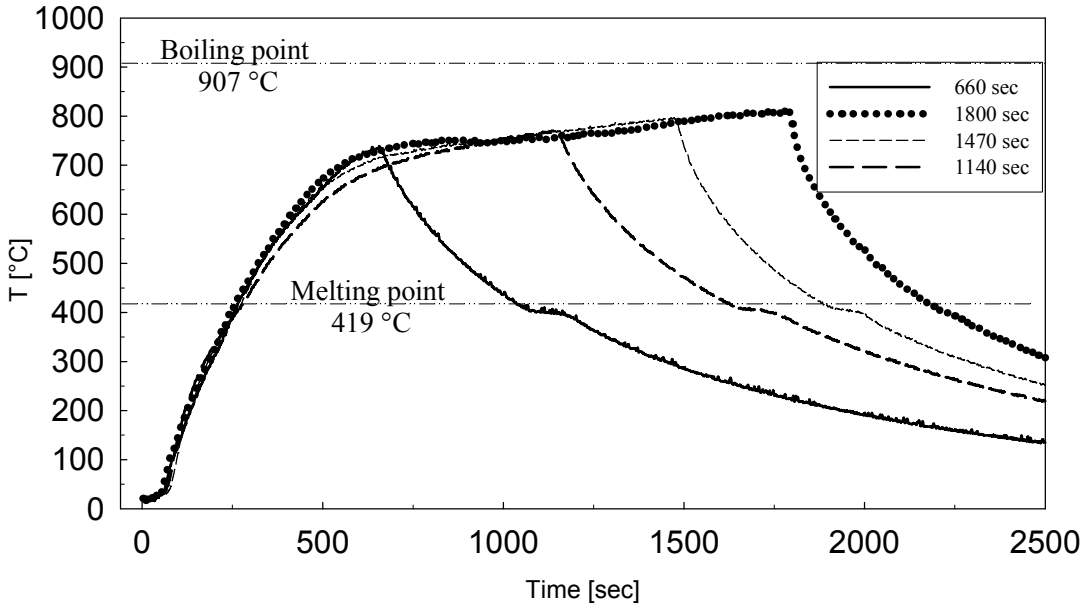

Figure 3. Temperature variation at the center of the crucible under the same conditions of operation: plasma gas: argon, I=104 A, arc length = 3 cm, gas flow rate = 11.5 lpm at 21°C and 1 atm.

The slight differences between crucible temperatures in runs performed at identical operating conditions are attributed to variations in the thermal contact resistance in the crucible-anode assembly and were unavoidable. In the subsequent discussion, the evaporation rate during an experiment was based only on the time from 720 s to arc extinction, and the metal evaporated during the heat up period was subtracted from the weight lost during the entire experiment.

b. Spatial variation of temperature in crucible.

Figure 4 shows the temperature variation at three different points in the crucible during a typical experiment as well as the arc current and voltage. Thermocouple 1, which is located far from the metal is lower than thermocouple 2 by a maximum of 50^{o}C during the pseudo steady state while thermocouples 2 and 3 showed a difference of no more than 10^{o}C during the pseudo steady state.

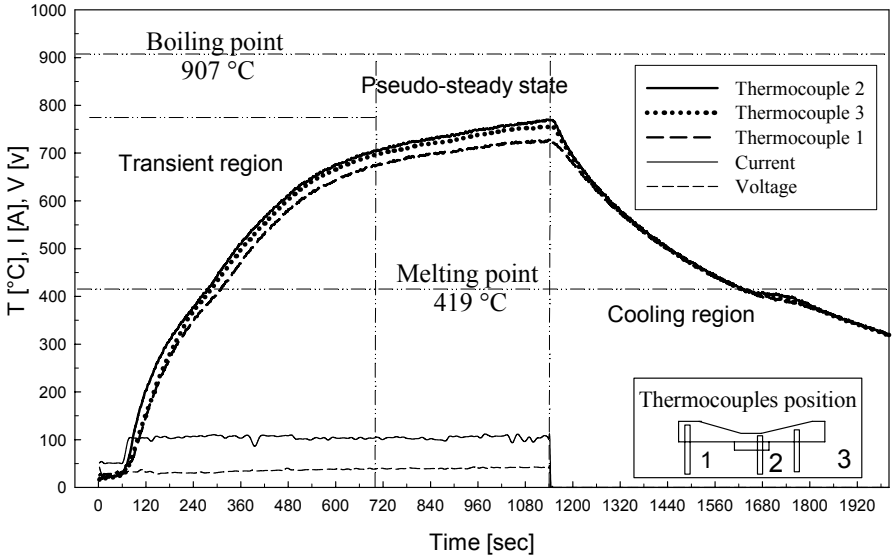

Figure 4. Temperature variation of the crucible, operation conditions: I=104 A, arc length = 3 cm, gas flow rate = 11.5 lpm at 21°C and 1 atm.

c. Evaporation rate at base conditions as a function of crucible wall temperature

Figure 5 shows the experimental and predicted values of the evaporation rate as function of the mean wall crucible temperature at a single set of operating conditions. Although the maximum variation in mean temperature is only 45^{o}C, the experimental and predicted evaporation rates are quite sensitive to the crucible wall temperature. The model predicts a positive linear increase of evaporation rate with temperature. If it is accepted that the experimental evaporation rates are also linear with temperature, the experimental rates are an average of 2.3 times higher. A major assumption of the model is that the evaporation of metal is heat transfer controlled and limited to the area immediately below the arc where the metal reaches its boiling point. The experimentally observed higher evaporation rates may be attributed primarily to the evaporation of metal by a mass transfer mechanism from areas of the surface which are below the boiling point.

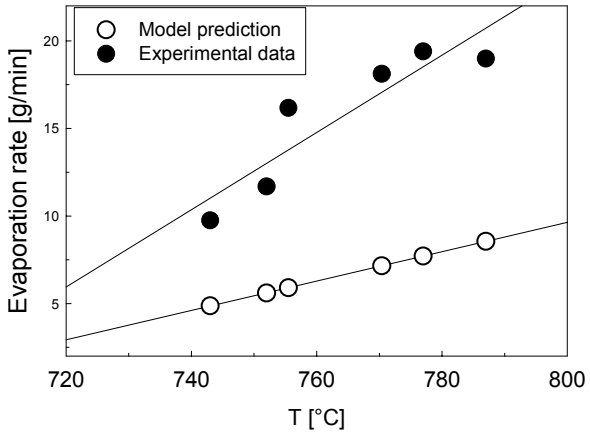

Figure 5. Experimental and predicted values of evaporation rate as function of the crucible wall temperature: Operation conditions: plasma gas: argon, I=104 A, arc length= 3.0 cm, gas flow rate=11.5 lpm at 21°C and 1 atm

d. Effect of the current on the evaporation rate

The effect of the current on the evaporation rate was studied by melting the zinc and heating it at the standard conditions shown in Figure 5 for 720 s, followed by an adjustment of current to the test value for the remainder of the experiment. The experimental and model results showed that an increment in the current led to higher evaporation rates (figure 6 and 7). Figure 6 shows the raw values with the unavoidable changes in crucible temperature. Figure 7 is a plot of the results at a constant temperature of 780^{o}C. In this plot, the effect of current is seen to be linear for both the experimental results and the predictions. Again, the model underpredicted the evaporation rates.

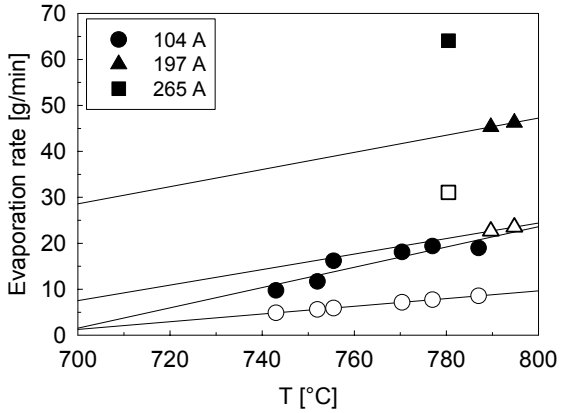

Figure 6. Experimental and predicted values of evaporation rate as function of the crucible wall temperature. Current effect, plasma gas: argon, arc length= 3.0 cm, gas flow rate=11.5 lpm at 21°C and 1 atm, Dark symbols are experimental, open symbols are predictions.

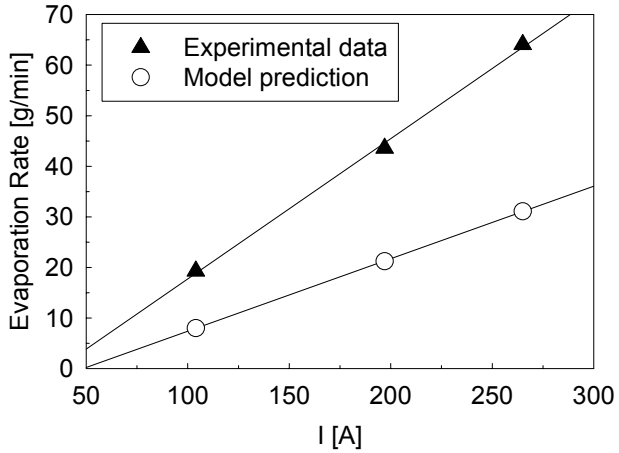

Figure 7. Experimental and predicted values of evaporation rate as function of the current at a crucible wall temperature of 780^{o}C; operation conditions: plasma gas: argon, arc length= 3.0 cm, gas flow rate=11.5 lpm at 21°C and 1 atm.

e. Effect of the gas flow rate on the evaporation rate

To examine the effect of plasma gas flow rate, the system was again operated at the base conditions for 720 s after which the plasma gas flow rate was increased from 11.5 to 30 lpm. Experimentally, increasing the plasma gas flow rate decreased the crucible temperature as is shown in Figure 8. The experimental evaporation rate increased with increasing gas flow rate. The model predicted that increasing the gas flow rate would slightly increase the evaporation rate of metal. The model does not predict the crucible temperature since this is a boundary condition. The effect of gas flow rate on the evaporation rate at the arc root is very complex. The model assumes a heat transfer limited process for evaporation at the boiling point of the metal. Increasing the gas flow rate increases convective heat transfer to the surface by increasing the gas velocity but also modifies the arc power through voltage. The arc voltage was predicted to increase from 16.8 to 20.8 V or by 24% as the gas flow rate increased from 11.5 to 13 slpm. The measured voltage increased from 19.8 to 23.6 which is very similar. Experimentally, increasing the plasma gas flow rate modifies the arc and also increases mass transfer at the surface leading to higher than predicted evaporation rates. For this reason, the experimental results are more sensitive to plasma gas flow rate than the modeling results.

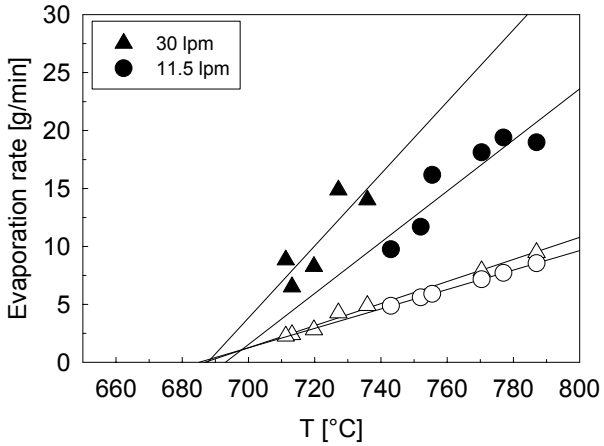

Figure 8. Experimental and predicted values of evaporation rate as function of crucible wall temperature, Plasma gas flow rate effect, plasma gas: argon, I=104 A, Arc length=3.0 cm. Dark symbols are experimental, open symbols are predictions.

f. Effect of the arc length on the evaporation rate

To examine the effect of arc length on evaporation rate, the arc length was increased from 3 cm to 5,2 cm after 720 s. The results are summarized in Figure 9. As was always the case, the experimental evaporation rates were higher than those predicted by the model. The effect of arc length on the experimental results is less clear. The model predicts an increase of evaporation rate with shorter arcs. However there appears to be a crossover in the experimental results with higher evaporation rates observed for longer arcs at higher crucible temperatures. The arc voltage was predicted to increase from 16.8 to 19.4 V as the arc length increased from 3.0 to 5.2 cm, an increase in power of 16%. The reason for the predicted higher evaporation rates for shorter arcs is due to the higher rates of convective heat transfer due to higher jet velocities. Experimentally, the arc voltage increased from 19.8 to 32 V as the arc length was increased. This 62% increase in power may explain the higher evaporation rates observed for these arcs. The reasons for the poorer prediction of the model voltage in this case are still unclear.

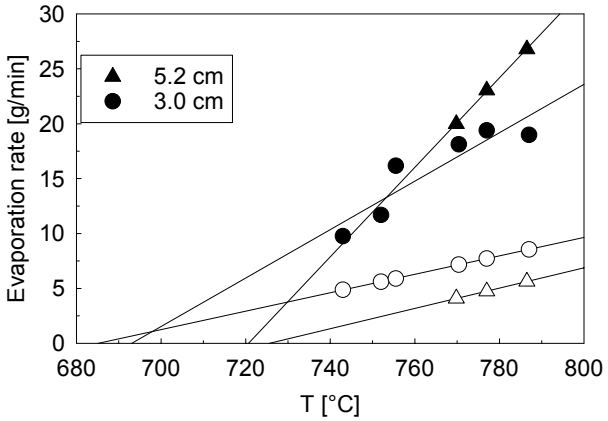

Figure 9. Experimental and predicted values of evaporation rate as function crucible wall temperature, Arc length effect, plasma gas: argon, I=104 A, gas flow rate=11.5 lpm at 21°C and 1 atm. Dark symbols are experimental, open symbols are predictions.

5. Conclusions

Experimental work was carried out on a transferred arc evaporator to validate and calibrate a simple numerical model which predicts metal evaporation rates as a function of crucible temperature, arc current, arc length and plasma gas flow rate. Argon gas and zinc metal were used as the test system. The model gave good qualitative predictions the effects of all operating parameters except the effect of arc length. The model consistently underpredicted the evaporation rates by a factor of about two and this is attributed to the assumption that the evaporation rate of liquid metals in this system is a heat transfer controlled process at the boiling point of the metal. The low viscosity and high thermal conductivity of the metal result in considerable evaporation of metal outside the region immediately below the arc. It is recommended that the model be modified to take this into account.

Abstract
Films of polyvinylidene fluoride (PVDF) have been treated in a microwave nitrogen plasma, for different conditions, in order to establish the treatment parameters which constitute a good compromise between an optimum functionalization and a minimum degradation. Surface properties of PVDF have been modified in a controlled manner, allowing its metallization, necessary in a wide range of applications.

1. Introduction

In order to be used in acoustic sensors, a polymeric material have to fulfill two essential conditions, that is to present a piezoelectric character and to be covered with an homogeneous metal layer, with a good adherence to the polymer surface.

It is well known that fluoropolymers are characterized by a small surface energy, which does not allow an adequate adhesion with a metal layer. That is why, activation of polymer surfaces prior to metallization is absolutely necessary. Before metallization of fluoropolymer, the respective surface must be modified to become hydrophilic, in order to be well-wet by an electrolessplating solution [1]. Gas plasma treatment under various glow discharge conditions was extensively used for this type of surface modification of fluoropolymers [2]. Polar groups introduced by plasma treatment on the film surface favor the reaction of copper (for eg.) to form a copper-nitrogen-carbon complex in the interface region [3]. It was proved that Cu binds preferentially to oxygen and nitrogen functional groups. It is thus expected that, by treating the polymer surface with nitrogen or oxygen plasmas, the reactivity of the polymer with the copper may increase [4].

The introduction in abundance of functional groups or polymer chains is not always a good surface modification for the electrical insulators. That is why, the choice of the remote plasma as a pretreatment method for obtaining a Cu/fluoropolymer composite is often used [1].

In this study, polyvinylidene fluoride (PVDF) films have been treated in a nitrogen microwave plasma, for different treatment conditions, in order to appropriate modify its surface properties, without significantly changing the bulk ones (in this way, the piezoelectric character being not influenced by the treatment). After applying the plasma treatment, the PVDF surfaces have been covered with a copper layer, by means of an electrolessplating procedure.

2. Materials and methods

Films of polyvinylidene fluoride (PVDF) (0.25 mm in thickness), obtained from Goodfellow, England, have been used in this study. This is a semi-crystalline, semi-opaque and white fluorinated polymer. Its density is 1.76 g/cm^3 and its upper working temperature ranges between 135 and 150 ºC.

In order to prepare a polymer surface with a good adhesion to the metal (condition which has to be fulfilled for being used in acoustic sensors), pretreatment of the PVDF film prior to metallization is necessary. In this purpose, PVDF films have been treated in a microwave nitrogen plasma (the gas flow: D=10 sccm), for different conditions, in order to establish the treatment parameters which constitute a good compromise between an optimum functionalization and a minimum degradation. Treatment power

varied between 20 and 80 W, the distance between the sample and the surfatron was comprised between 2.5 and 30 cm, and the exposure time between 30 and 300 s.

Modification of the surface and bulk properties of PVDF has been followed by contact angle and weight loss measurements, XPS, UV spectroscopy, wide angle X-ray diffraction. Subsequent surface metallization was realized by an electrolessplating procedure.

3. Results and discussion

3.1. Contact angle and weight loss measurements

Whatever the applied treatment power and the exposure time, an important increase in the hydrophilicity of the PVDF surfaces was obtained. This behaviour is evidenced by the significant decrease of the advancing and receding water contact angles in respect with the untreated sample (Figure 1) and it was also evidenced by other authors [5].

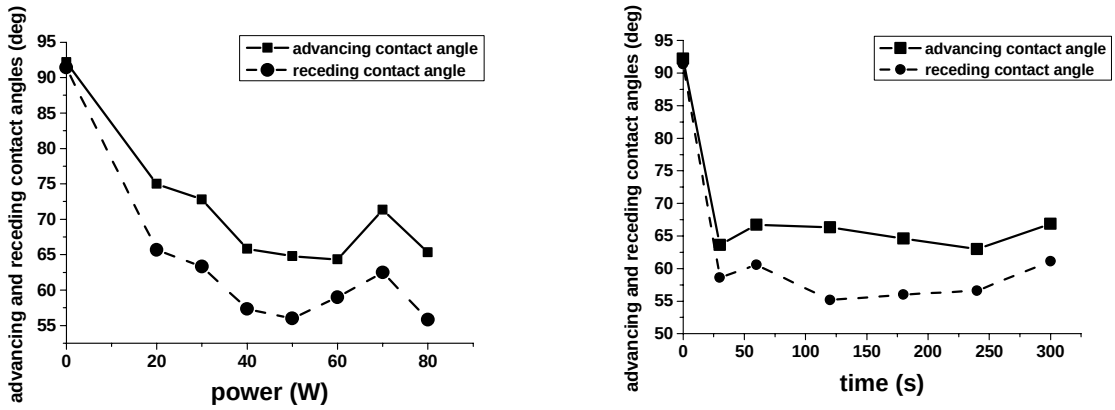

Figure 1. Water advancing and receding contact angles vs the discharge power and the treatment time for PVDF, N_2 plasma treated.

After plasma exposure, water contact angle hysteresis increases when compared with the pristine PVDF (Figure 2), indicating the obtainment of a significant roughness for the treated surface [6, 7]. The important hysteresis of the water contact angle in the case of PTFE ammonia plasma treated was explained by Badey et al. [8] by the fact that, in contact with water, nitrogen and oxygen containing groups reorient to minimize the interfacial energy, a very low receding water contact angle being measured. An increase in the micro-roughness could be a sign for the obtainment of a better adherence of the respective surface with a metal layer [9].

It is well known [6] that N_2 or NH_3 plasma treatments give rise to N–containing functionalities, such as: amine ($–NH_2$), imine (–CH=NH), cyano (–C=N) on polymer surfaces, as well as oxygen–containing groups, such as amide ($–CONH_2$), due to post-discharge atmospheric oxidation. This fact is also evidenced in our case, the increase of the acid-base component of the free surface energy with the discharge power and the treatment time being obvious (Figure 3. a, b).

As the polymer surface functionalization under plasma exposure is a very rapid phenomenon which, generally, occurs during a period inferior to 1 min [10], the acid-base component of the free surface energy significantly increases during the first 30 s, after this period, its value remaining almost constant for the entire period of plasma exposure (Figure 3.b).

For a given power, treatment time and gaseous flow, the acid-base component decreases with the distance sample-surfatron (Figure 3.c). This behaviour evidences that, in the case of a polymer sample treated far enough from the direct plasma, the influence of the charged particles (electrons, ions) is

cancelled [8] and radicals alone should be predominantly as active species for the surface modification [11].

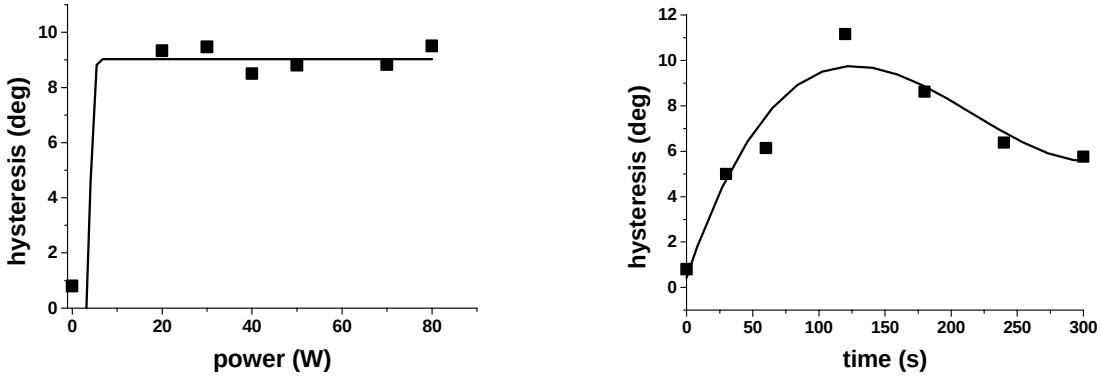

Figure 2. Water contact angle hysteresis vs the discharge power and the treatment time for PVDF, N_2 plasma treated.

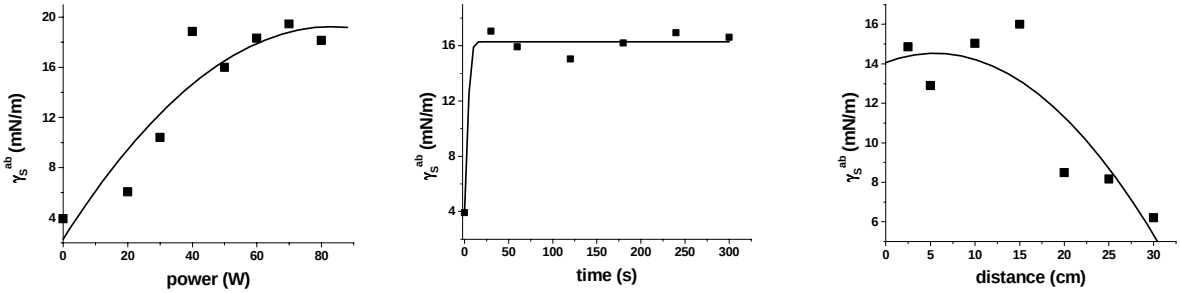
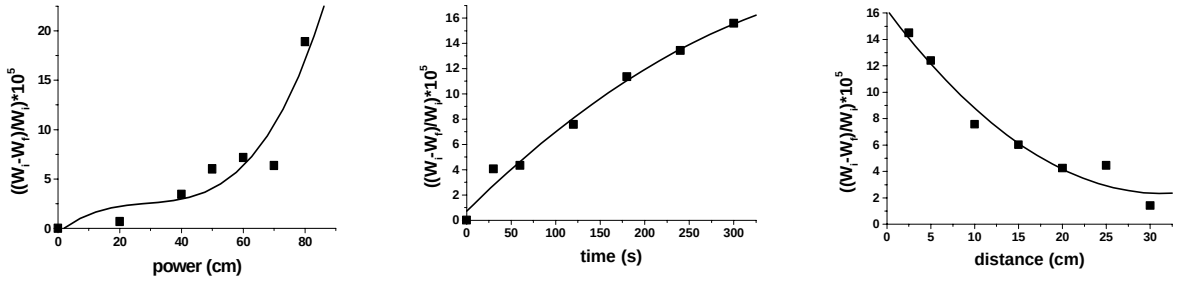


a **b** **c**

Figure 3. Acid-base component of the free surface energy for PVDF, N_2 plasma treated, vs: (a) the discharge power, (b) the treatment time, (c) the distance between the polymer sample and the surfatron.

Taking into account also the weight losses results (Figure 4), it could be concluded that the optimum treatment conditions which constitute a good compromise between an optimum functionalization and a minimum degradation for PVDF, N_2 plasma treated, are: P = 50 W, t = 1 min, d = 10 cm.



a **b** **c**

Figure 4. Weight losses for PVDF, N_2 plasma treated, vs: (a) the discharge power, (b) the treatment time, (c) the distance between the polymer sample and the surfatron.

3.2. XPS results

In order to obtain information on the type of functional groups introduced on PVDF surface under plasma treatment, XPS analysis has been realized. As it was expected, N-containing groups were detected on the polymer surface after the applied treatment (Table 1).

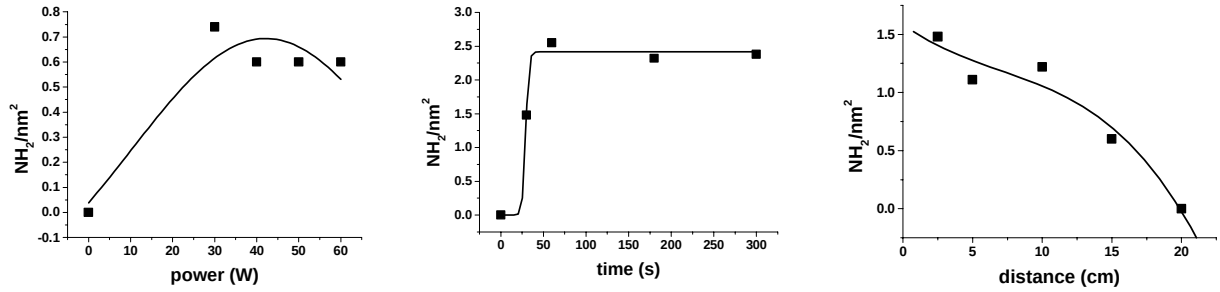
Table 1. Results of XPS analysis for untreated and N_2 plasma treated PVDF surface.

Sample	Spectrum	Position of the pics (eV)	Attributed groups
untreated PVDF	C1s	280.4 284.8	carbide carbon
	F1s	685	
	O1s	531.1	carbonates
PVDF / N_2	C1s	280.1 284.7	carbide carbon
	F1s	685.1	
	O1s	531 532.6	metal oxides nitrates
	N1s	397.9	nitride

As it was also pointed out by other authors [12], atomic composition on PVDF surfaces evidence a surface defluorination under plasma exposure (a decrease in fluorine atom concentration from 41.5 % for the untreated PVDF to 28 % for the N_2 plasma treated surface). In the meantime, an increase in oxygen atom concentration (from 3.2 % to 9 %) is obvious after the applied treatment.

3.3. Titration of the surface amino groups

Titration of the surface amino groups, followed by UV spectroscopy [13], was in a good agreement with surface energetic results, the variation of the amino groups concentration with the treatment parameters following almost the same behaviour as the polar component of the free surface energy (Figure 5 a, b, c).



a **b** **c**

Figure 5. Concentration of the amino groups on PVDF surface, N_2 plasma treated, vs: (a) the discharge power, (b) the treatment time, (c) the distance between the polymer sample and the surfatron.

3.4. Wide angle X ray diffraction

No significant change in the diffraction pattern for N_2 plasma treated PVDF has been observed, whatever the discharge power, the treatment time and the distance between the polymer sample and the core of the discharge (Figure 6). In the meantime, the crystallinity degree for PVDF does not change significantly under plasma treatment (Table 2).

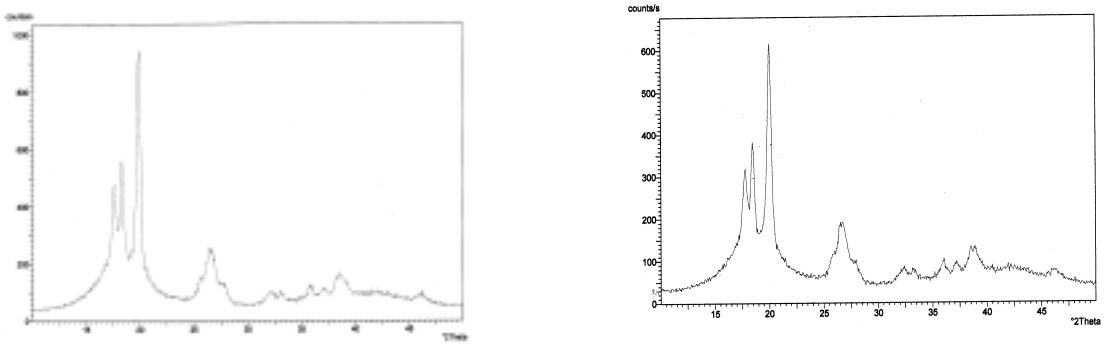


Figure 6. X-ray diffraction patterns for: (a) untreated PVDF and (b) N_2 plasma treated PVDF (50 W, 1 min, 10 cm).

Table 2. Crystallinity degree evaluated from X-ray spectra for untreated and plasma exposed PVDF, in different treatment conditions.

Treatment conditions	X_C
Untreated	0.870
50 W, 30s, 10 cm	0.870
50 W, 2 min, 10 cm	0.880
50 W, 5 min, 10 cm	0.876
70 W, 2 min, 15 cm	0.880
50 W, 2 min, 2.5 cm	0.876

The fact that bulk properties of PVDF seem to not change under plasma exposure could be a good sign for the maintenance of the piezoelectric character of polymer samples treated in these conditions.

3.5. Preliminary results on PVDF metallization

Samples of PVDF, plasma pretreated, were metallized by chemical way, using a two step procedure [14], consisting in the substrate activation using a mixed solution of $PdCl_2$ and $SnCl_2.2H_2O$ (realized at two different temperatures, 25 and, respectively, 40°C), followed by acceleration in HCl 1M, and, finally, the metallization in a solution based on $CuSO_4$ [4]. All the pretreated samples were covered with an homogeneous layer of copper, with an improved adhesion at the PVDF surface, in respect with the pristine sample (Table 3).

Table 3. Results obtained by the normalized scotch test for PVDF surface, untreated and N_2 plasma exposed (P = 50 W, t = 1 min, d = 10 cm).

Sample	Adherence (%)	
	t = 25 °C	t = 40 °C
untreated PVDF	0	0
PVDF / N_2	72	93

4. Conclusions

Choosing appropriate treatment conditions, surface properties of PVDF can be modified in a controlled manner, allowing its metallization, necessary in a wide range of applications. The fact that no significant changes appear in bulk properties of the polymer could be a good sign in the possibility of maintaining the piezoelectric character of some plasma exposed polymers, condition necessary in order to be used in acoustic sensor.

The plasma synthesis of ultrahydrophobic surface : the study of its 'hydrophilic behavior' !

J. Fresnais[1], L. Benyahia[1], J.P. Chapel[2], F. Poncin-Epaillard[1]

The synthesis of low density polyethylene (LDPE) ultrahydrophobic surfaces with controlled roughness is described in a two steps O_2 and CF_4 plasmas treatment. Water contact angle as high as 171°, contact angle hysteresis less than 2 °, and sliding angle as 2 ° are obtained on those surfaces. Beside dynamic dewetting experiments show a particular behavior. While it is wet by water, the surface seems to loose its ultrahydrophobic properties.

While natural ultrahydrophobic materials are observed for a long time [1], synthetic ultrahydrophobic surfaces are of great interest for few years[2-6]. The definition of an ultrahydrophobic surface is now clear[2] : this surface must present very high contact angles with water (more than 150°), small contact angle hysteresis (less than 10°) and small sliding angle (less than 10°). The sliding angle is the angle needed from which the droplet is removed from the surface. A smooth hydrophobic surface[7] does not show those properties. With rough hydrophobic surface, ultrahydrophobic behavior appears. However the applications of such surfaces[8] are still limited because of their non transparency and their fragility.

We present, here, the synthesis in a two steps microwave plasmas treatment (O_2 then CF_4 plasmas) of low density polyethylene ultrahydrophobic surface with controlled roughness.

First an O_2 plasma treatment is used to increase LDPE roughness by etching the amorphous phase. O_2 plasma parameters are optimized by mass spectrometry. Figure 1 shows partial pressure of oxygen atoms in O_2 plasma versus the power delivered by the microwave generator. Too high O concentration in the plasma will induce the etching of both amorphous and crystalline phases. In order to only degrade the amorphous phase and to limit the ablation of the crystalline phase, we choose an intermediary situation : 15 sccm (standard cm^3 per minute) rate and a power of 50 W (see figure 1). In this case roughness will increase as the amorphous phase is etched.

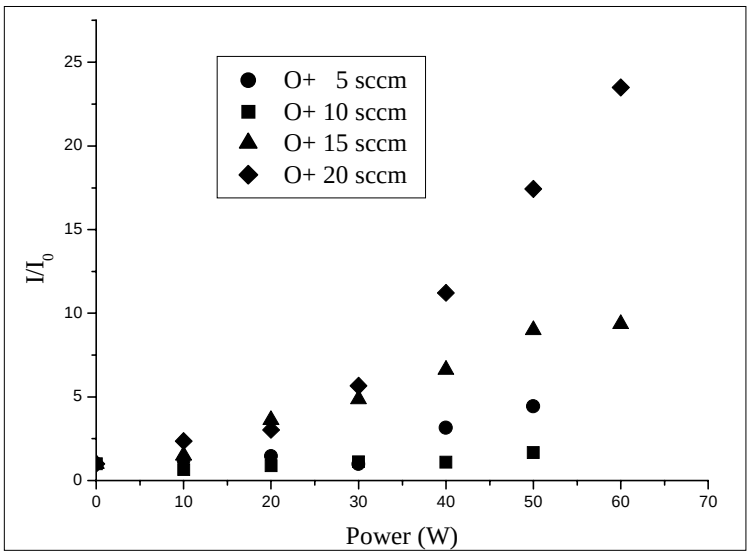

Figure 1 : normalized partial pressure of oxygen atoms in O_2 plasma versus the microwave discharge power (rates from 5 sccm to 20 sccm)

These conditions (50 W and 15 sccm) of plasma treatment are applied to LDPE surfaces. A 3 minutes O_2 plasma treatment allows the maximum increase of contact angle hysteresis (figure 2). As the chemical nature of the surface should be homogeneous, the increase of contact angle hysteresis is due to the increase of roughness. This roughness will be characterized later in this article. So that plasma treatment at 50 W corresponds to the optimized treatment in terms of roughness.

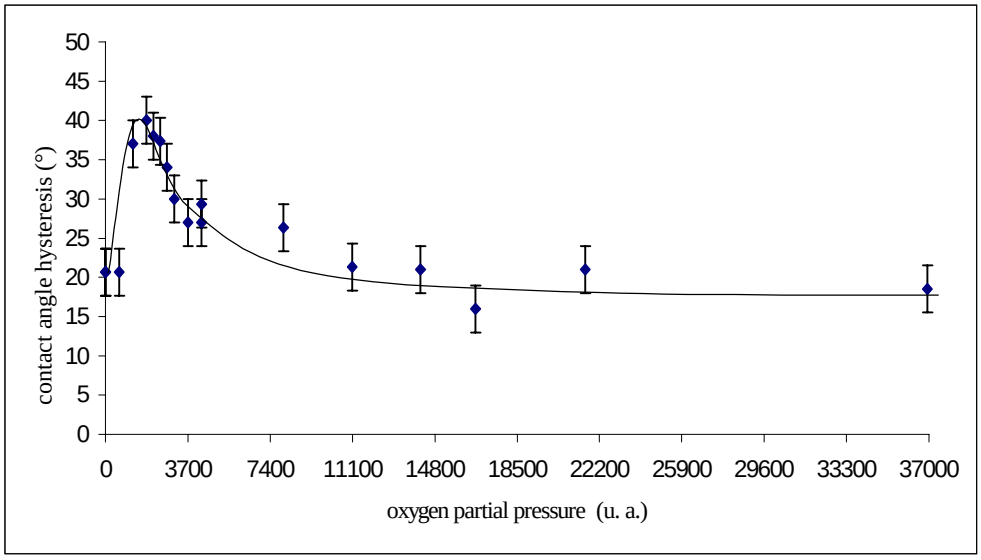

Figure 2 : contact angle hysteresis of O_2 plasma treated films versus the partial pressure of O atoms (time multiplied by the partial pressure of O per second determined by mass spectrometry) (P=50 W ; D=15 sccm ; d=15 cm)

The plasma etching is confirmed by weight loss measurements (figure 3). Those results show that an O_2 plasma treatment can divide the film weight by a factor 2 after one hour treatment with a rate of 43 $\mu g.cm^{-2}.mn^{-1}$.

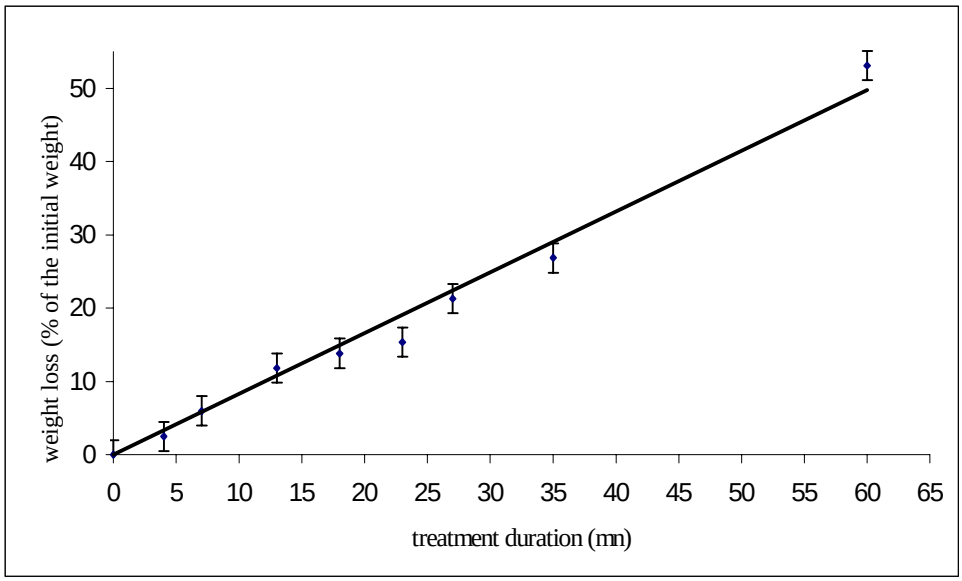

Figure 3: weight loss (the difference between treated and untreated films weight divided by the untreated film weight) versus the treatment duration (P=50 W ; D=15 sccm ; d=15 cm)

Then, the following CF_4 plasma treatment increases both hydrophobic behavior and roughness of the surface. The figure 4 shows the dependence of water contact angle versus plasma parameters. Several sets of durations and discharge powers lead to an ultrahydrophobic surface. For example, with contact angle of 171°, contact angle hysteresis of less than 2° and sliding angle of 2° is obtained at P=40 W for 15 minutes of

duration. The water droplet looks like a pearl (in this case : figure 5). Longer treatments give also ultrahydrophobic surfaces, however with too long durations the modified films become opaque.

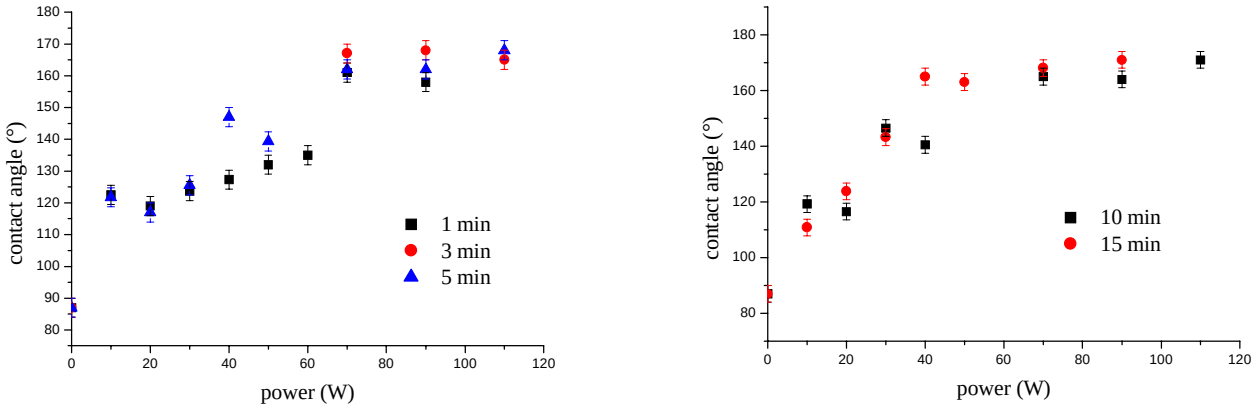

Figure 4 : optimization of the CF_4 plasma treatment : contact angle measurement for different powers and treatment durations (d=5 cm)

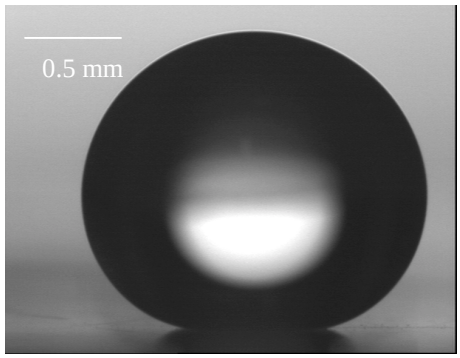

Figure 5 : water droplet on an ultrahydrophobic LDPE surface (θ= 171 °)

The contact angle hysteresis of these ultrahydrophobic surfaces falls to less than 3° (figure 6).

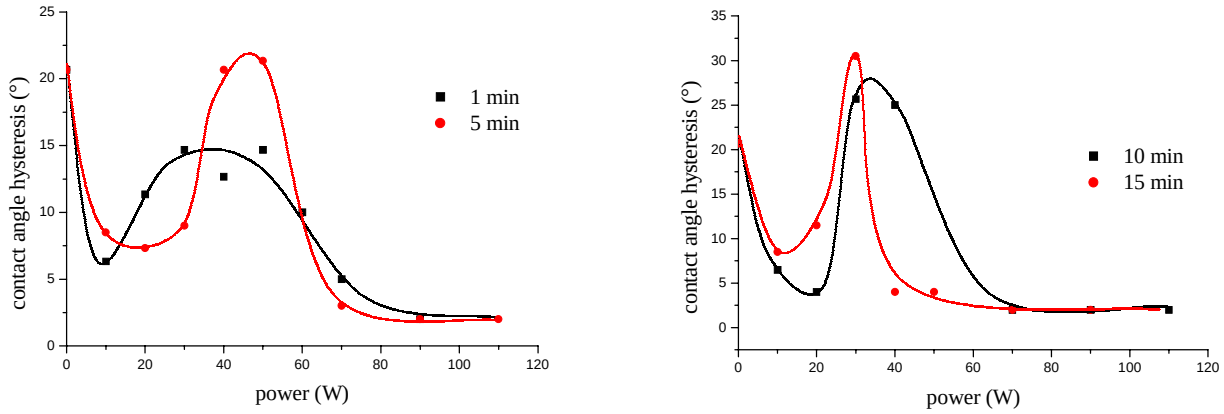

Figure 6: contact angle hysteresis versus power of treatment for different treatment durations (d=5 cm)

The ultrahydrophobic surface topography is analyzed by Atomic Force Microscopy. Rms roughness (eq 1) of ultrahydrophobic surfaces increases when the power and the treatment duration increase (table 1). Because their roughnesses are lower than 200 nm, some ultrahydrophobic surfaces are transparent.

$$R_{ms}=\sqrt{\sum(z_i-z_{ave})^2/N}\ , \qquad (1)$$

Z_{ave} is the average of the z values within the given area, z_i is the z value for a given point, and N is the number of points within the given area.

Table 1 : Rms roughness and contact angle for ultrahydrophobic surfaces treated with O_2 plasma (3 minutes at 50 W) and then with CF_4 plasma

sample	Rms roughness (nm) 10*10µm / 1*1µm	Contact angle (°)
Untreated LDPE	5.3 / 2.2	87
15 minutes at 40 W	34.9 / 26.4	169
10 minutes at 90 W	94 / 14	171
15 minutes at 90 W	248 / 135	171

X-ray photoelectron spectroscopy characterizes the surface fonctionnalization. Whatever the plasma parameters are, the fluorine amount (figure 7) is constant and closed to 60%.

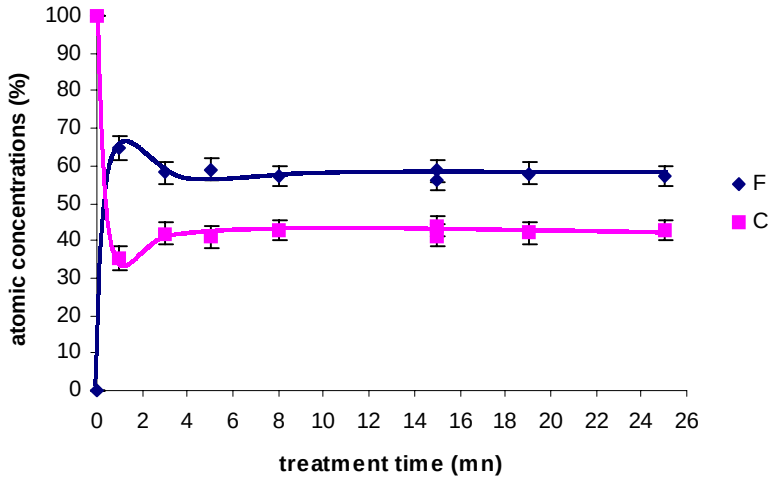

Figure 7 : fluorine and carbon proportions versus treatment duration for different LDPE plasma treated samples (P= 40 W; d= 5 cm)

The C_{1s} spectra of an ultrahydrophobic surface (figure 8) shows the C-C bond peak at 285 eV[9]. 5 other peaks corresponding to $*CH_2$-CF_2, CHF, CF, CF_2 , CF_3 respectively are found on this C_{1s} spectra. This result may confirm the fact that the LDPE surface is only fonctionalized and that no deposition process is taken place.

Then dynamic dewetting properties of ultrahydrophobic films are studied. Depositing a water droplet on a such surface gives information about the surface repellency, but what will be its behavior when a water film is deposited on it ?

A water film with controlled thickness is deposited on an ultrahydrophobic film. When the dewetting is initialized by creating a dry patch in the middle of the surface, the dry patch diameter increases until the complete dewetting of water from the surface. The speed of the water front is about 5 to 10 cm/s. A rim[10] is created and goes from the center of the film to the border.

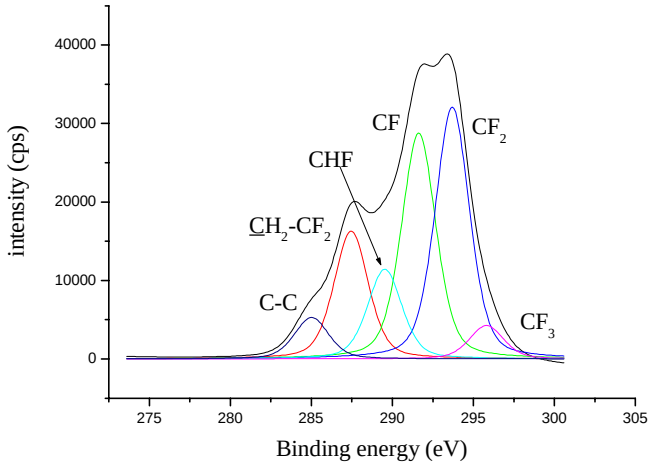

Figure 8 : C_{1s} spectra of LDPE ultrahydrophobic surface (P= 90 W, d= 5 cm, D= 15 sccm, t= 15 min)

If ultrahydrophobic film is wetted by water vapor then dried under vacuum, the surface behavior changes. The water film deposited in the same conditions will dewett the surface more slowly.

To describe more precisely this phenomenon, other experiments are run. The ultrahydrophobic film is placed in contact of water surface and the force needed to break the water / LDPE interface is measured with an ARES type rheometer (Rheometrix Scientific). If the film shift is disrupted just after dewetting begins, the untreated LDPE film (figure 9a) dewett very rapidly while an ultrahydrophobic surface dewets slowly in the same conditions (see figure 9b).

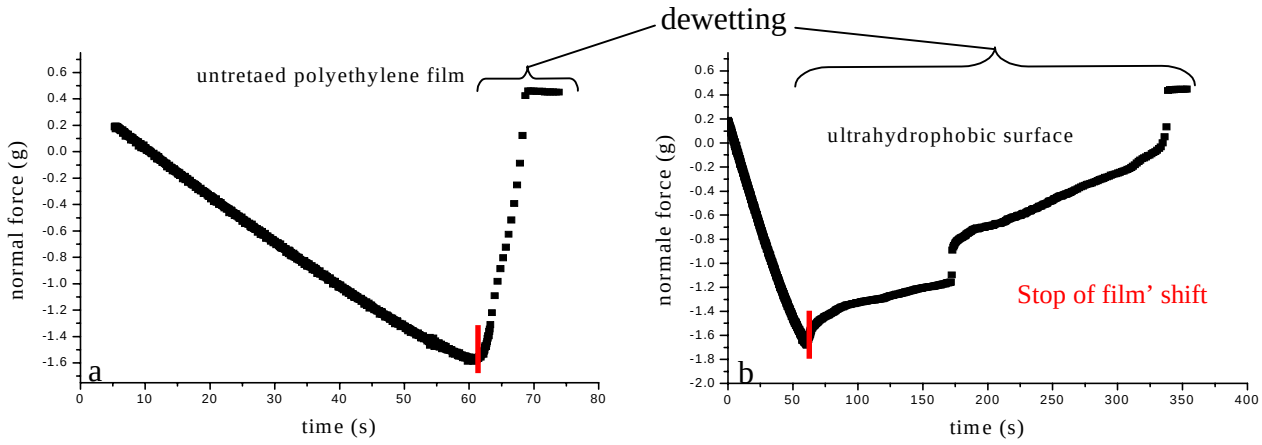

Figure 9 : normal force versus time : (a) untreated PE film; (b) Ultrahydrophobic film (rms roughness : 35 nm; P= 50 W, d= 5 cm, D= 15 sccm, t= 15 min)

The two different methods of the dewetting observation show both that ultrahydrophobic surfaces loose their properties when several times dipped in water (fig 10) or in contact with water vapor. If only a droplet is deposited, this phenomenon is absent. Moreover, the behavior is not dependent of the roughness. Same results are obtained with larger roughnesses. These experiments confirm the fact that the more the surface is wetted, the more the normal force needed to dewett the film surface is high.

Another experiment confirms the total wetting of the holes in the roughness of the ultrahydrophobic surfaces (figure 11) showing water contact angles varies from 171° to 142° after 10 minutes of immersion.

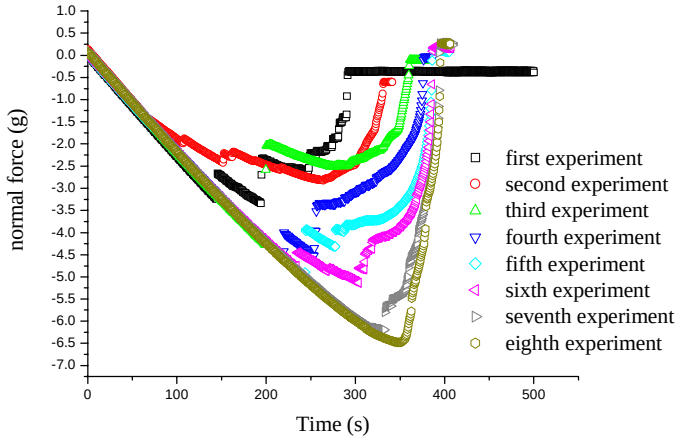

Figure 10 : normal force versus time : multiple experiments with the same experimental conditions (P= 90 W, d= 5 cm, D= 15 sccm, t= 15 min)

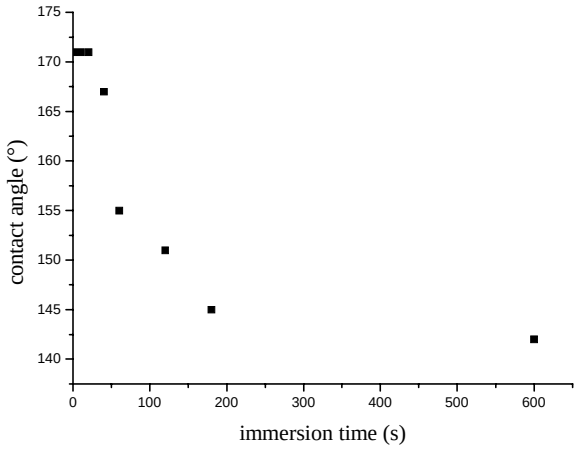

Figure 11 : contact angle versus immersion time

To conclude, we synthesize LDPE ultrahydrophobic surfaces with controlled roughness. We also show that those ultrahydrophobic surfaces have different behavior when they are totally wetted. This behavior differs strongly in the case of partial wetting (water droplet deposition). Ultrahydrophobic roughed surfaces loose their properties and contact angle decreases strongly.

Abstract

This paper presents the self-consistent coupling of a two-dimensional charged particle transport model, for a parallel plate radio frequency discharge in pure hydrogen, with a homogeneous kinetic model including $H_2(X^1\Sigma_g^+,v=0..14)$ molecules and H(n=1-5) atoms. It is shown that the inclusion of vibrational kinetics increases both the H_3^+ ion density and the electrical coupled power by 40% .

1. Introduction

Parallel plate capacitively coupled radio frequency (RF) discharges are of great interest in plasma assisted material processing applications, as in the plasma enhanced chemical vapour deposition (PECVD) of silicon and diamond thin films using hydrogen based mixtures. The correct optimisation and scale-up of such reactors, requires the development of complete transport plasma models including the gas phase description of charged particle transport and multicomponent diffusion of neutral species, to be coupled to a kinetic description of reactor surface.

The present work is part of an effort to model and optimise an existing PECVD reactor for quality μ-Si:H deposition, using SiH_4-H_2 mixtures under high dilution conditions for silane. The RF reactor is similar to the GEC reference cell, with 6.2 cm radius and 3 cm inter-electrode distance [1], operating at pressures between 0.1 – 1 Torr, frequencies in the 13.56 - 80 MHz range and RF voltages 50 – 250 V. The translational gas temperature is assumed to be 323 K.

We have started by studying a 13.56 MHz capacitively coupled RF discharge in pure hydrogen, using a two-dimensional (2D) time dependent fluid model that describes the production, transport and destruction of electrons, H^+, H_2^+ ,H_3^+ and H^- ions in the reactor under study [2]. In a previous work [3], it was shown that this model predicts the correct trends of the plasma density and self-bias voltage variations with changes in the driving frequency or the RF voltage. However, model predictions were found to be systematically underestimated with respect to measurements, which was attributed to both experimental uncertainties and the simple hydrogen kinetics considered.

A realistic hydrogen chemistry must include the kinetics of vibrationally excited molecules and electronically excited atomic species. In particular, the hydrogen vibrational excited species can have an important role in RF discharges, as a significant part of the electrical coupled power is lost in low energy vibrational excitations. Moreover, these species are also important channels of atomic hydrogen and charged particle production. In order to clarify the role of these species, we have self-consistently coupled the previously developed charged particle transport model to a homogeneous kinetic model for hydrogen, including $H_2(X^1\Sigma_g^+,v=0..14)$ molecules and H(n=1-5) atoms.This paper analyses the effect of the improved hydrogen kinetic model in reactor operation.

2. Model

A rigorous description of low temperature non-equilibrium plasmas, must couple the electron transport to the gas phase chemistry, because the electron rate coeficients strongly depend on the gas chemical composition. The correct modelling of this problem involves the calculation of the non-equilibrium electron energy distribution function (EEDF) and the vibrational distribution function (VDF) of hydrogen molecules.

2.1 Hydrogen Kinetics

The very complete hydrogen kinetics adopted here was based in the work of several authors [4-14]. It describes the dynamics of vibrationally excited molecules in ground state $H_2(X^1\Sigma_g^+, v=0..14)$, hydrogen atoms in different electronic states H(n=1-5), positive ions H_3^+, H_2^+, H^+, and negative ion H^-. The kinetic processes considered are datailed in table 1.

Table 1

	Process	Reference
Vibrational species		
e - V	$e + H_2(v) \leftrightarrow e + H_2(v\pm i)$, i=1..3	[4,5]
E - V	$e + H_2(v) \rightarrow e + H_2(B^1\Sigma_u^+, C^1\Pi_u) \rightarrow e + H_2(v')$	[4,5]
V - V	$H_2(v) + H_2(w) \leftrightarrow H_2(v\text{-}1) + H_2(w+1)$	[5]
V - T	$H_2(v) + H_2 \leftrightarrow H_2(v\pm 1) + H_2$	[5]
V - T	$H_2(v) + H \leftrightarrow H_2(v\pm i) + H$, i=1..5	[5,6]
Dissociation	$e + H_2(v) \rightarrow e + H_2(a^3\Sigma_g^+, b^3\Sigma_u^+, c^3\Pi_u, e^3\Sigma_u^+) \rightarrow e + 2H(1s)$	[4,5]
	$e + H_2(v) \rightarrow e + H(1s) + H(n=2,3)$	[4]
Ionisation	$e + H_2(v) \rightarrow e + e + H_2^+$	[4,15]
	$\rightarrow e + e + H^+ + H$	
Diss. Attachment	$e + H_2(v) \rightarrow e + H_2^- \rightarrow H + H^-$	[8]
Wall	$H_2(v>0) \rightarrow H_2(v=0)$	[7]
Dissociation by Vib. Pumping	$H_2(v=14) + H_2 \leftrightarrow 2H(1s) + H_2$	[9]
	$H_2(v=14) + H \leftrightarrow 3H(1s)$	
Atomic species		
Exc/De-exc.	$e + H(n) \leftrightarrow e + H(m)$, n,m=1..5	[13]
Ionisation	$e + H(n) \rightarrow e + H^+$	[13]
Rad. De-exc.	$H(n) \rightarrow H(m) + h\nu$	[13]
Deactivation	$H(2s) + H_2 \rightarrow H(2p) + H_2$	[11]
	$H(2p) + H_2 \rightarrow H(2s) + H_2$	[13]
Ass. Ionisation	$H(2s) + H_2 \rightarrow H_3^+ + H$	[11]
	$H(2s) + H_2 \rightarrow 3H(1s)$	[13]
Wall	$H(1s) \rightarrow \frac{1}{2}H_2(v=0)$	[12]
	$H(n>1) \rightarrow H(1s)$	[13]
Aditional Processes		
Electron – ion recombination	$e + H_3^+ \rightarrow 3\ H$	[10]
	$e + H_2^+ \rightarrow H(1s) + H(n)$, n>1	[10]
	$e + H^+ \rightarrow H(n) + h\nu$	[10]
	$2e + H_3^+ \rightarrow H_2 + H + e$	[9]
	$2e + H_2^+ \rightarrow 2H(1s) + e$	[9]
	$2e + H^+ \rightarrow H(n) + e$	[9]
	$e + H_3^+ + wall \rightarrow H_2 + H$	
	$e + H_2^+ + wall \rightarrow H_2$	
	$e + H^+ + wall \rightarrow H$	
Ion – ion neutralization	$H^- + H_3^+ \rightarrow 2\ H_2$	[9]
	$H^- + H_2^+ \rightarrow H_2 + H(n>2)$	[14]
	$H^- + H^+ \rightarrow H(n=3) + H$	[9]
Ass. detachment	$H + H^- \rightarrow H_2 + e$	[9]
Ion conversion	$H_2^+ + H_2 \rightarrow H_3^+ + H$	[9]
	$H_2^+ + H \rightarrow H^+ + H_2$	[9]
	$H^+ + 2H_2 \rightarrow H_3^+ + H_2$	[9]
	$H^+ + H_2(v>3) \rightarrow H_2^+ + H$	[9]

2.2 Charged particle model

A 2D time-dependent fluid model was developed to describe the transport of electrons, H^-, H^+, H_2^+ and H_3^+ ions in the reactor under study [2], by solving the corresponding continuity, momentum transfer and mean energy equations (the latter for electrons only), coupled with Poisson's equation.
Electron transport parameters are calculated adopting the local electron mean energy approximation [2], which assumes that the space-time dependence of the EEDF and its related transport parameters proceeds via the electron mean energy. The latter has space-time profile given from the solution to the fluid code, being related to the EEDF by solving the electron Boltzmann equation (EBE) (in a homogeneous and stationary, two-term approximation) using the electron cross-sections compiled in reference [4,5,13]. The ion mobilities are those of reference [15].
The system of equations is discretized in a grid of 16x32 points using finite differences, and is solved subject to appropriated boundary conditions. Typically, 1000 time steps are used within each RF period, and a few hundred RF cycles are needed to reach the convergence criterion: relative changes of particle densities, mean electron energy, plasma potential and self-bias voltage, between two consecutive periods, less than 0.05%.

2.3 Kinetic model

The kinetic model solves the set of coupled rate balance equations for the different neutral species considered here. To limit calculation times (due to the considerable number of species and kinetic processes involved), we have adopted zero dimensional versions of the continuity equation for each species, by averaging them in space as follows

$$\frac{\partial \overline{n}_i}{\partial t} = \left(\frac{\partial \overline{n}_i}{\partial t}\right)_{coll} - \left(\frac{\partial \overline{n}_i}{\partial t}\right)_{wall} . \qquad (1)$$

In equation (1), $\left(\frac{\partial \overline{n}_i}{\partial t}\right)_{coll}$ is the average net gain rate of species i in the volume, $\left(\frac{\partial \overline{n}_i}{\partial t}\right)_{wall}$ is the net loss rate of species i at the wall, and $\overline{n}_i$ represents the averaged density defined as

$$\overline{n}_i = \iint n_i r dr dz \Big/ \iint r dr dz . \qquad (2)$$

The integration in equation (2) distinguishes between two regions in the plasma: a spatially homogeneous one, corresponding to the plasma bulk; and a boundary layer with size equal to the plasma sheath thickness, where the densities of neutral species are assumed to vary linearly. This assumption is accurate enough as to allow an analysis of the neutral chemistry influence, in reactor operation. The resulting set of non-linear equations was couply solved using a semi-implicitly Gauss-Seidel relaxation technique. The procedure converges after several thousand iterations, for relative variations of 10^{-12} in the densities of any neutral species.

The coupling between the above models is made by calculating the average (in space and time) electron collision frequencies as obtained from the charged particle model, and by using them as input data to the kinetic model. The kinetic model is solved every 5 RF periods, until steady-state convergence is achieved. The densities of neutral species, obtained after each run of the kinetic model, is used to update the electron transport parameters and rate coeficients by solving the homogeneous and stationary EBE (under the two-term approximation), before running the plasma transport model. Note that this kind of self-consistent coupling between plasma transport and chemical kinetics was sucessfully used in other works [16].

3. Results

The problem was firstly solved by negleting the presence of both atomic hydrogen excited species and negative ions, for an applied RF voltage of 100V, pressure of 300 mTorr and excitation frequency of

13.56MHz. Figure 1 represents the calculated axial profiles (at discharge axis) of the time averaged H_3^+ density, obtained in this work and using our previous model with a simplified hydrogen kinetics [2,3]. From this figure we conclude that the adoption of more complete hydrogen kinetics increases the H_3^+ ion density by 40 %, which can be atributed to the enhancement of the global ionisation coeficient when vibrationally excited species are considered. Figure 2 shows the calculated VDF of hydrogen molecules.

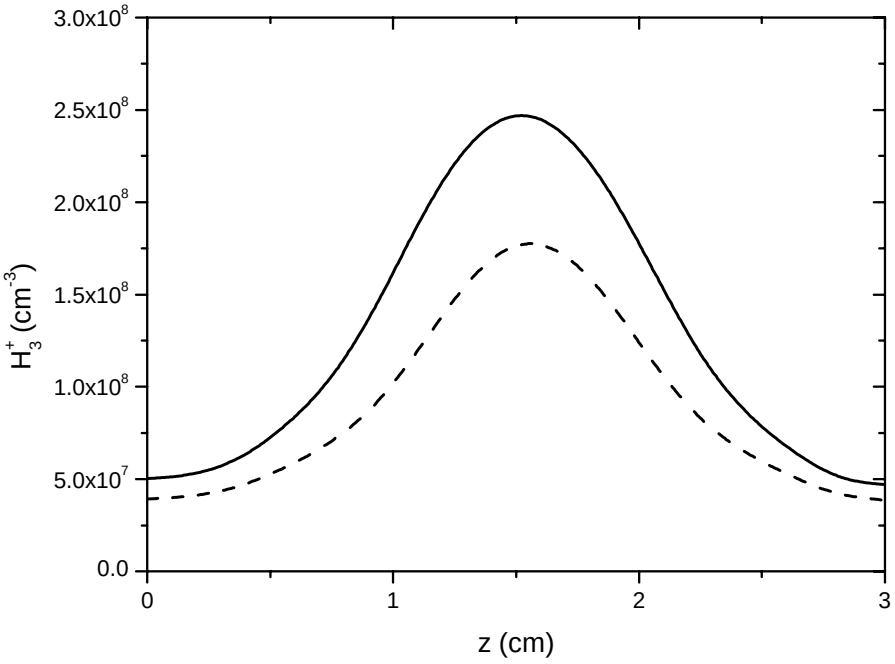

Figure 1 Axial profile of H_3^+ ion density.
Present (——) and previous (-----) model estimates.

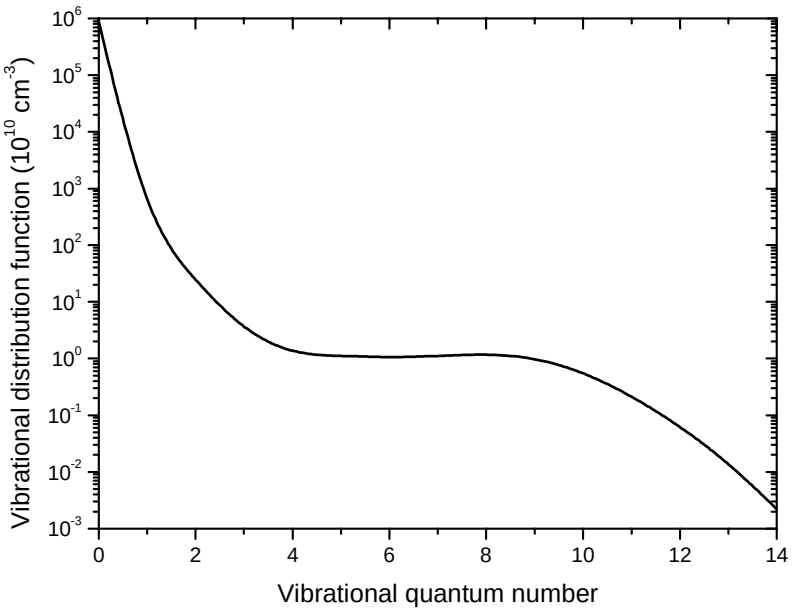

Figure 2 Vibrational distribution function of hydrogen molecules.

Simulations show that the electrical power coupled to the discharge also increases by 40 % when vibrational kinetics is considered, because more energy is lost in the vibrational excitation, ionisation and dissociation of hydrogen. Note that the self-bias voltage is only slightly affected by the improved kinetics.
Introduction of negative ions in the kinetics results in a significant slow down of model convergence. The H^- ion concentrates at discharge centre, where the plasma potential is higher, and its density is comparable to that of H_2^+ and H^+, while the main plasma parameters are only marginally affected.
When atomic excited species are considered the associative ionisation mechanism (see table 1) becomes the most important production channel of electrons and H_3^+ ions, contributing to a significant increase of their densities. Unfortunately, the introduction of this mechanism deteriorates the convergence of the global model, as the absence of a spatial profile for the atomic species leads to an overestimation of the ionisation rate near reactor boundaries. Studies are in progress to correctly solve this problem, in particular by taking into account more realistic de-excitation probabilities for atomic species.

4. Conclusion

We have self-consistently coupled the vibrational kinetics of hydrogen to a charged particle transport model in capacitively coupled RF discharges. The inclusion of low energy vibrational excitations allows to correct previously model predictions, which were underestimated when compared to experimental measurements. We have shown that associative ionisation involving atomic excited hydrogen species is a fundamental mechanism to consider.

Abstract

Our goal is to qualify the recombination coefficients gamma of the atomic oxygen on the target, to measure the correlation between gamma and the gap of the semiconductor and finally to determine the activation energy of recombination for the n and p semiconductor surface. These results point out the correlation between the activation energy of recombination and the electronic gap of the semiconductor targets which demonstrate that catalytic phenomena and excited states of oxygen atoms depend of specific properties of the semiconductor oxide surface.

1. Introduction

Under the condition of a hot shock wave or a plasma discharge, oxygen and nitrogen molecule will be dissociate into oxygen and nitrogen atoms. This atom will diffuse in the boundary layer of surface of a material and they may be recombined to form molecules. The formed molecules can transfer part or all of their heat of formation to the surface. The number of the recombined atoms and the energy transferred depend on the nature of the surface and the process is referred to be a catalytic atom recombination. The recombination reaction can be quantified by the recombination coefficient (γ) and the accommodation coefficient (β) representing respectively the mass and the heat transfer to the surface. When the recombination species are oxygen atoms, the process leads to the formation of an oxide layer on the surface, resulting in a modification of the nature of the surface and its properties[2-9].

The aim of this work is to underline the influence of the electronic properties of the material on its catalytic activity by measurements performed on n and p-type semiconductors having different band gap energies, in a pulsed plasma reactor, using an actinometrical method. In result of these experiment we can observe a correlation between the activation energy of recombination and the electronic gap of the semiconductor targets. The interest of these phenomena is great toward the conception of catalytic materials and the qualification of materials submitted to high thermal constraints[1]. Furthermore for SiO2/SiC, the surface oxidation is followed by ESCA, SEM and dynamic SIMS analyses.

2. Experimental Set-Up

2.1 Experimental Device

The experimental set-up includes a plasma tubular reactor, the controlling and acquisition device. Tests are performed at 110 Pa pressure, with 400 sccm flow for the air gas flow, and 25 sccm flow for the Argon (about 5% of the total gas flow). The plasma is created by a 13.56 MHz generator. The time discharge “on” is of 2s for each measurement and the time discharge “off” is of 5s. The emission spectroscopy signal was transmitted via a fibre optics, analysed by a monochromator and detected by an Optical Multichannel Analyser (O.M.A.).

2.2 The Actinometric Method Applied to Recombination Coefficient Measurement

The recombination coefficients are calculated using the actinometry spectroscopic method[10]. Actinometry involves using of optical emission intensity ratios to provide an estimation of ground state species concentrations. The intensity emitted from the species is divided by the emission intensity from actinometer (Argon) which is added to the plasma in small quantity, without any modification of discharge properties in comparison with other one . In our case the O atom concentration has been monitored with optical emission from O (844.6 nm) and Ar (811.5 nm). The ratio I_O/I_{Ar} obtained by actinometry is related to the concentrations ratio by the following relation[11]:

$$I_O / I_{Ar} = k\,(O) / (Ar)$$

and it can be used as a tracer for atomic oxygen concentration. The validity of the actinometry method has been previously verified by titration of the atomic oxygen with nitric oxide.

The movement of oxygen atoms in the boundary layer near the sample is controlled by diffusion and described by the general diffusion equation. The recombination coefficient (γ) can be deduced from this equation and can be calculated from the atomic oxygen concentration profile along the reactor:

$$\gamma = \frac{-4D\nabla(I_O/I_A)_x}{c(-\nabla(I_O/I_A)_x L + (I_O/I_A)_o)}$$

D: binary diffusion coefficient ($m^2.s^{-1}$)
c: atomic velocity ($m.s^{-1}$)
L: width of the boundary layer (m)
$\nabla(I_O/I_{Ar})_x$: axial concentration gradient
$(I_O/I_{Ar})_o$: steady state concentration

3. Results and interpretation

3.1. Determination of the Recombination coefficient (γ) and the activation energy (Ea) from the recombination on oxide semiconductors and ceramics materials.

The targets consist in discs of pure oxides semiconductors. The recombination coefficient of atomic oxygen on each sample have been measured in a temperature range of 300 K- 923 K. The energy gap of the materials has been measured by optical reflection measurements[13] (Table 1).

For all the samples, it can be noted an increasing of the recombination coefficient with its surface temperature.

From the Maxwell-Boltzmann statistic, we can link the recombination coefficient to the surface temperature (T) by the following relation (1):

$$\gamma = \frac{T_o}{T}\exp\left(-\frac{E_a}{RT}\right) \quad (1)$$

Where $T_o = \frac{Cah^2}{2\pi m_o k}$

Ea= activation energy of the surface reaction ($J.mol^{-1}$)
Ca= number of active sites ($atoms.m^{-2}$)
m_O= mass of an oxygen atom (kg)

The activation energy of the process and the number of the active sites can be deduced by plotting Ln(γT) versus 1/T (Table 1 and figure 1).

Figure 1 Evolution of the recombination coefficient with the surface temperature. Determination of the activation energies

The results for p type semiconductors show an increase of the activation energy with the energy gap increase. The lowest is the energy gap of the oxide, the highest is the recombination coefficient. The electronic properties of the material influences strongly the heterogeneous recombination of the oxygen atoms. In the case of n type semiconductors the activation energy can be correlated to the number of active sites[16] (Table 1).

In a previous work it was showed that the behaviour of p type or n type oxide semiconductors is due to the absorbed oxygen on the material[15-17].

Moreover for some samples we can observe that it appears a break in the slope that means a modification of the recombination mechanism (figure 1). For a SiC sample, the reaction process is clearly different and we can distinguish two scales of temperature. First of all, at low temperature (300 K - 900 K) the activation energy of the reaction can be estimated at (7±1) $kJ.mol^{-1}$. At 900 K, it appears a break in the slope which means a modification of the recombination mechanism. From 900 K to 1123 K the activation energy is now equal to (74±11) $kJ.mol^{-1}$. The strong difference between the activation energies shows clearly a change in the reactional process when the temperature increases. Indeed, at low temperature, the reactional mechanism is compared to an Eley-Rideal mechanism whereas at high temperature, the recombination reaction is controlled by a Langmuir-Hinshelwood mechanism. As we show in Table 1 this mechanism is available for other samples as WO_3, $BaTiO_3$ and $CaTiO_3$.

3.2 Surface Characterization : Chemical evolution of the material

The plasma-surface interaction, and particularly the specific surface recombination reaction of atomic oxygen, depends strongly on the chemical state of the surface material. In fact, the reactive flow interaction should be different if the material is already oxidised or not. Moreover, this surface "passivation" can occur in the very first milliseconds of the discharge.

3.2.a. Oxidation of the surface

The chemical structure of SiC surfaces has been followed by XPS analyses. Figure 3 relates the quantitative evolution of the O, C and Si species on the material surface when the sample is exposed to the plasma and heated. Figure 2 compares the silicon carbon bond and the silicon oxygen bond peaks for an untreated sample and for a sample exposed to the plasma at 300 K and at 1073 K.

$T_{surface}$=1073 K

Figure 3 XPS analysis. Evolution of the silicon carbon bond and the silicon oxygen bond peaks for treated and untreated SiC at different temperatures.

The whole results shows the progressive evolution of the SiC structure towards an oxidized silicon structure as SiO_2. Carbon atoms are substituted by oxygen atoms and the recombination reaction does not occur on the SiC surface but on the SiO_2 layer formed since the first exposure times to the oxygen plasma. This layer presents semiconductive properties; the SiC material is also covered by a -n type semiconductor of SiO_2. The recombination mechanisms are still controlled by the electronic conduction of the semiconductor. The low reactivity of the material in respect with atomic oxygen is in agreement with the previous study carried out on semiconductors[17,18].

3. 2.b. Diffusion of oxygen in the bulk material

In order to control the diffusion of oxygen into the bulk material, Secondary Ions Mass Spectrometry (SIMS) analyses have been performed on an untreated SiC, SiC exposed 60 s to oxygen plasma at 300 K and SiC exposed 60 s to oxygen plasma at 1000 K.

Concerning the untreated sample, the oxygen content decreases rapidly under 100 nm depth and is stabilized. One can note a few oxidation of the surface in that case. As expected, when the material is exposed to the oxygen plasma at 300 and 1000 K, the decrease of the oxygen content in the bulk material is slower than previously. Some oxygen atoms have diffused into the SiC matrix. On figure 4, one can compare the oxygen content in the material for different treatments to the oxygen plasma.

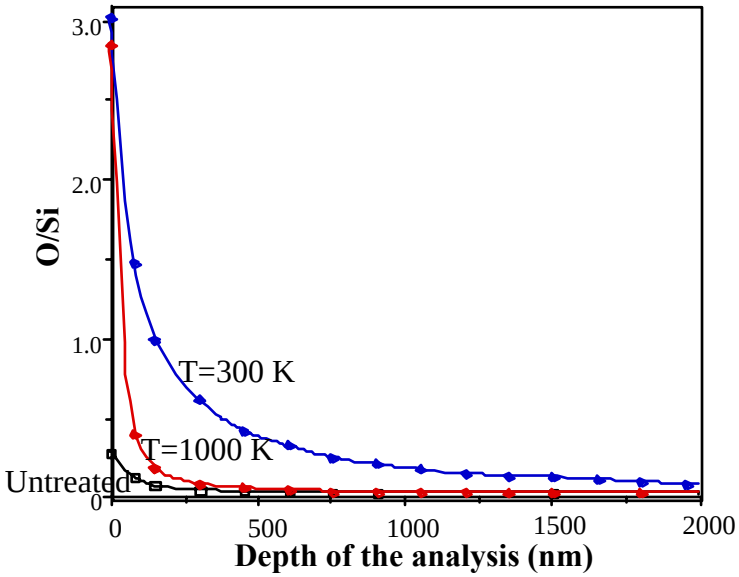

Figure 4: Evolution of oxygen content in the material bulk for untreated SiC, Air plasma/SiC interaction at 300 K and Air plasma/SiC interaction at 1000 K.

First of all, the concentration of oxygen is really important near the surface of the material when it is exposed to the oxygen plasma. However, when the material is heated at 300 K, the oxygen content is higher than for a surface treatment at 1000 K. So, the diffusion of oxygen is less important at high temperature. This result seems to eliminate the hypothesis of a predominant diffusion mechanism in this temperature range (T>900 K). So, the change in the reactional mechanism is not due to the diffusion of oxygen. The hypotheses of a change in the recombination mechanism (Eley-Rideal/Langmuir-Hinshelwood) or more complex mechanisms of oxidation/ablation are more probable.

Moreover Scanning Electronic Microscopy (SEM) have been performed on treated and untreated SiC surfaces. Comparing to the surface oxidation pointed out by ESCA analyses, SEM analyses show a macroscopic change of the surface structure after exposition to the plasma gas. These structure modifications can also be due to the surface oxidation[19].

Conclusion

The determination of gamma coefficient on metallic oxide semiconductors, leads to the determination of the role of the electronic properties of material. The p-type semiconductors are more efficient to recombine the oxygen atoms than the n-type semiconductors. The electronic conduction of

the material seems to have a great importance in the recombination efficiency. There is a correlation for p type semiconductors between the activation energy and the gap energy. The lowest is the gap energy of the oxide, the highest is the recombination coefficient. Moreover for the n type semiconductors the activation energy can be correlated to the number of active sites. The evolution of the activation energy of silicon carbide in a large field of temperature has demonstrated a real change in the reactional mechanism around 900 K. The recombination reaction occurs according to an Eley-Rideal mechanism at low temperature and to a Langmuir-Hinshelwood mechanism at high temperature. Moreover, the surface analyses by ESCA show clearly an important evolution of the SiC surface when it is exposed to the oxygen plasma. The SiC structure is oxidised to a SiO_2 structure and then the recombination reaction occurs on the SiO_2 layer formed since the first exposure times. The SIMS analyses show the diffusion of oxygen into the bulk material when silicon carbide is under oxygen plasma conditions, but this diffusion mechanism is not so dramatic even for high surface temperatures. So, the change in the recombination mechanism does not depends at all on the diffusion reaction. In complement of this work, a modelling of the recombination of oxygen atoms and transfer of the energy to a metallic or ceramic material by using the Chemkin® code was made[20]. The results shows a good agreement for at least silica.

Alternative Routes of Thermal Plasma Synthesis of Composite Oxide Nanopowders

Jerzy W. Jurewicz, Glen Lemoine, Alexandre Fortier

CRTP – Plasma Technology Research Centre
Chemical Engineering Department, Faculté de génie
Université de Sherbrooke

The extensive use of solid oxide fuel cells (SOFC) as an electrical energy source requires among others the use of very efficient electrodes especially the fuel electrode (anode). The anode is characterized by such parameters as the low overvoltage, the thermal expansion coefficient comparable to the electrolyte material, the chemical resistance to reduction by a combustible as well as to some sulfur presence in the fuel, controlled porosity etc. The choice of materials for such electrode is very limited and some composite oxides have been identified as possible candidates.

The induction plasma system has been used for the synthesis of nanosized composite oxides. The process is based on the high temperature oxidation of either solid or liquid (water soluble) precursors followed by rapid quenching of products by the water spray. The powdered feed was composed either of metallic powders or of chlorides. The liquid (water based) feed was in the form of saturated solution of chlorides. The metallic feed of identical elemental composition (Ni-Cr ratio) was fed in three different form: pure mixture of metals, mechanically agglomerated powders or the intermetallics synthesised prior to the combustion. The obtained very fine (d_p< 100 nm) products were subjected to extensive physico-chemical analysis including that by SEM, EDX and XRD methods. The particle size analysis was done by Zeta potential analyser. The results of the influence of the processing parameters including the plasma power, powder feedrate, processing pressure and oxygen partial pressure in a plasma gas as well as particle size of the raw materials on the final products particle size distribution and their chemical composition will be presented.

Solution Plasma Spraying of NiO/YSZ Cermet Anode for SOFC Preparation. Influence of Plasma Processing Parameters on the Porosity of Deposits.

Glen Lemoine, Hugues Ménard and Jerzy W. Jurewicz

CRTP, GRAPES,
Université de Sherbrooke, Qué. J1K 2R1

The objective of the present study is to determine the influence of plasma processing parameters on the porosity of NiO/YSZ deposits obtained by solution plasma spraying (SolPS). The SolPS technology is based on injection of atomized concentrated solution of chlorides into the RF thermal plasma discharge where droplets are thermally treated resulting in solvent evaporation, evaporite consolidation, melting of the formed solid followed by its deposition on a preheated target. Oxygen rich argon plasma was used in this work as the processing atmosphere. The thin (30 – 60 μm) layers of NiO/YSZ anodes so obtained were analysed by X-ray diffraction (XRD), scanning electron microscopy (SEM) and image analyses. The porosity of the deposits as a function of the plasma power, the deposition angle and the rotation speed of the target, was also studied.

Powder densification and spheroidization using induction plasma technology

X. Fan, J. Guo, N. Dignard, and C. Normand

Tekna Plasma Systems Inc., 2935 Boul. Industriel, Sherbrooke, Quebec, Canada, J1L 1X7

Abstract

Spheroidization of powder particles is one of the successful commercial applications of induction plasma technology. A review is presented of case studies in which powder densification and spheroidization using induction plasma technology has played a key role in substantial improvement of powder quality and fluidity. Results are given for both metallic and ceramic powders at the pilot and industrial scale production.

1. Introduction

The last decades has seen a vivid technology transfer from laboratory to industrial scale application of induction plasma processing [1, 2]. While a number of the subjects of induction plasma process, such as plasma-particulate interaction, heat and mass transfer, plasma reactor mixing pattern mode, and particulate nucleation and growth mechanism etc. have been widely studied in laboratory, the successful industrial application of induction plasma process depends largely on many fundamental engineering support. For example, the industrial plasma torch design, which allows high power level (50 to 600 kW) and long duration (24 hours) of plasma process. Another example is the powder feeders that convey large quantity of solid precursor (1 to 100 kg/h) with reliable and precise delivery performance.

Tekna Plasma Systems, inc., one company bridging the gap between academic laboratory and industry, has developed many induction plasma processes in various industrial applications. Powder particles spheroidization/densification is one of the successful example in commercial application of induction plasma process. The requirement of powders spheroidization comes from very different industrial fields, e.g., from powder metallurgy to the electronic packaging. Generally speaking, the pressing need for an industrial process turns to the spherical powders, is to seek at least one of the following benefits, the spheroidization process would bring in:

Figure 1: A 200 kW industrial unit of powder spheroidization, manufactured in Tekna Plasma Systems. This system produces spheroidized cemented powders at the productivity of 30 kg/h.

- Improve the powders flow-ability ;
- Increase the powders packing density ;
- Eliminate powder internal cavities and fractures ;
- Change the surface morphology of the particles ;
- Other unique motive, such as optical reflection, chemical purity etc.

For instance, in the field of thermal spraying, the quality of coatings (density, microstructure etc.) can be dramatically improved by using spherical and dense powder particles as the starting material for spray.

The specific advantages of induction plasmas have been well defined in earlier researches[3,4]. Owing to its large volume, axial materials feeding, and long residence time of precursor, induction plasma process is an ideal process for the spheroidization of powders. In recent years, Tekna has provided clients a number of integrated units of powder spheroidization at the industrial scale. The particular features of these industrial systems of induction plasma process are their easy operation, automatic control, real-time data acquisition, and the facilitating collection of the treated powders on the basis of continuous operation mode. One typical system is shown in Figure 1.

A great variety of ceramics, metals and metal alloys have been successfully spheroidized/densified using Tekna's integrated systems. The following table lists some typical materials spheroidized in commercial scale by Tekna integrated systems.

Table 1: Typical powder materials spheroidized in industrial scale by Tekna integrated system.

Powder category		Powder name
Ceramics	Oxide	SiO_2, ZrO_2, YSZ, Al_2TiO_5, glass
	Non-oxide	WC, WC-Co, CaF_2, TiN
Pure metals		Re, Ta , Mo, W
Alloys		Cr/Fe/C, Re/Mo, Re/W,

2. Spheroidization Process Case Studies

CEMENTED ALLOY POWDERS

Cast Tungsten Carbide is powder materials of WC-W_2C alloy. This material is harder than most steels, has greater mechanical strength, transfers heat quickly, and resists wear and abrasion better than other metals. The service life of many kinds of machinery can be greatly prolonged by the surface coating of wear-prone materials with cemented alloy. It has wide applications in construction, coal mining, cement production, rock crushing and agricultural industries, The powder metallurgical products of this material are used primarily and extensively for making drilling tips tunneling, mining and quarrying purposes, i.e. for most geological activities.

Table 2: Mechanical properties of cemented alloy before and after spheroidization

	Angular	Spheroidized
Tap density (g/cm^3)	7.5	10
Micro-hardness (kg/mm^2)	2000	4000

Besides the powder metallurgical method, the laser cladding, PTA (Plasma transferred arc) overlaying, plasma spraying etc. are widely used as the vehicle of hard-surfacing of cemented alloy[5]. The latest practice revealed that using spheroidized cemented alloy powders significantly increase the quality of cemented coating layers, overcoming the notorious "corner effect", in associated with the usage of angular shape of WC powder particles in a hard Ni-Cr or Co matrix. While there is no apparent improvement in powder flow rate, a significant change in powders tap density is obtained after Tekna's spheroidization processing. The materials hardness of the cemented alloy components could be

doubled. This is no-doubt relevant to the dense, flaw-free microstructure obtained in Tekna's spheroidization processing. The common existence of fissures, pores etc. in angular cemented powders, inherited from the WC powders manufacture processing, could be eliminated.

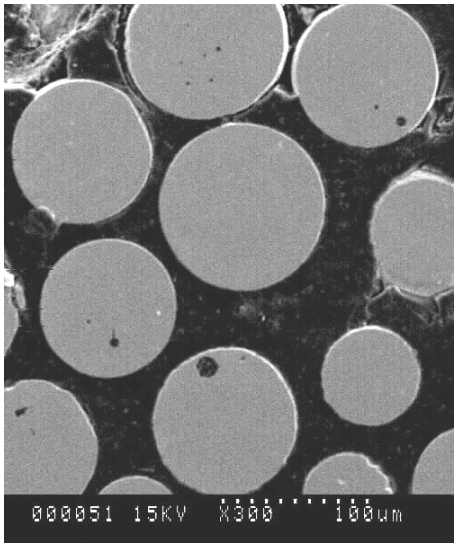

Figure 2: The dense, flaw-free microstructure of the spheroidized WC powders.

REFRACTORY METALS

In modern high-tech filed, some refractory metals play key role.

Tantalum: Tantalum is used to make electrolytic capacitors and vacuum furnace parts, which account for about 60% of its use. The metal is also widely used to fabricate chemical process equipment, nuclear reactors, aircraft, and missile parts. A tantalum carbide graphite composite material is said to be one of the hardest materials ever made. Tantalum also found wide use in making surgical appliances. The growth in demand Ta material has been due largely to the use of tantalum capacitors in small portable electronic components such as laptop computers, video cameras, games consoles and, most importantly, mobile phones.

Rhenium: Rhenium is extremely attractive for high temperature structural and energy system applications, such as space and missile propulsion systems. Used either as a pure structural material or as a liner in conjunction with graphite or carbon-carbon structural materials in high temperature rocket engine and hot gas valves. Rhenium is the only material to date that exhibits near-zero erosion in the high temperature (2000 – 4000 °C) high-pressure rocket throat and nozzle and is virtually inert to thermal shock . Using as a coating on carbon materials, rhenium does not form carbide, yet it has an excellent bond strength between the two materials. Rhenium has repeatedly outperformed all other coating candidates on solid rocket hot section components in tests.

The apparent motive to spheroidized these powder materials is to increase their packaging density and to impart the fluidity to the flaky powders, so that the further engineering manufacture with these materials becomes easier or feasible. Figure 3 shows the Re powders before and after the induction plasma spheroidization processing. The spheroidization efficiency is 100 %, despite the high melting point of rhenium (3180 °C). It is worth mentioning here, that there is no electrode contamination problem in induction plasma processing, on the other hand, the processing with Ar-H_2 plasma may further purify the precursor materials. This is a strong attraction for those clients seeking high purity, to turn to the induction plasma spheroidization processing.

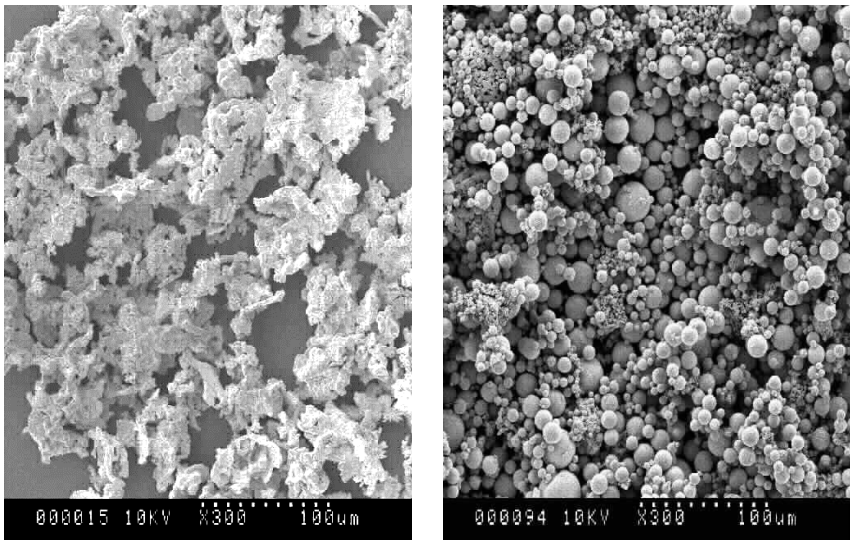

Figure 3: The flaky, sticky Re powder (left) become dense and spherical (right) after the induction plasma spheroidization processing.

OXIDES CERAMICS

As the mainstay of the oxide ceramics material market, Al_2O_3 and ZrO_2 powders, are widely used as the structural material. Lately, the demand of spheroidized oxide ceramic powders are increasing. Though, some powders of them are spray-formed and originally assume the spherical shape, further densification or phase transformation via plasma processing is requested for some special applications.

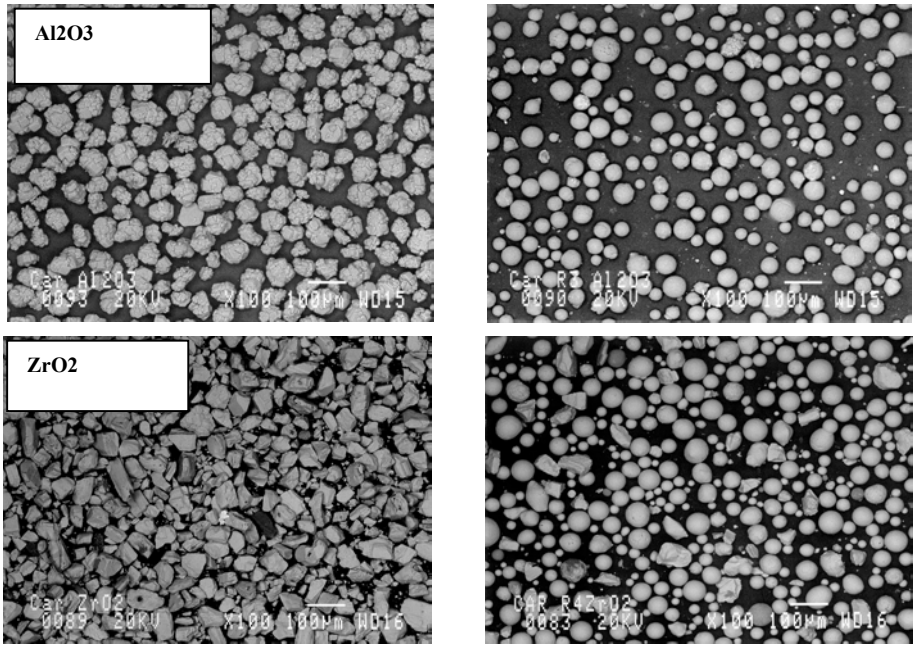

Figure 4: Oxide ceramic powders before and after the induction plasma spheroidization processing.

The challenge for induction plasma spheroidization processing to spheroidize/densify these materials are (1) the poor thermal conductivity, and (2) the relatively high melting point of the material. Although, the spheroidization of these powders in laboratory scale has produced many interesting results, see Fig. 4. The further scale-up to a commercial production (20 kg/hr) is hindered by the fact that the power intensity of induction plasma is relatively "thin" , despite its large volume and the longer residence time of precursors.

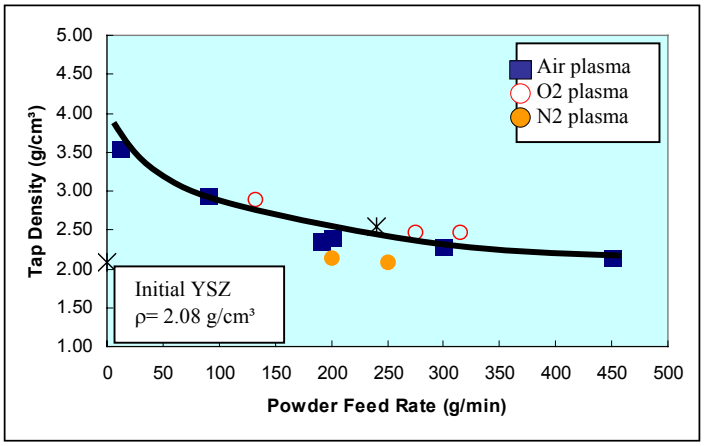

Figure 5: The relationship between tap density and the precursor (YSZ) feed rate in different induction plasma spheroidization/densification processing.

QUARTZ POWDERS AND OTHERS

"Semiconductor packaging material" is one of the key-technologies for the electronic industry. The material encapsulates integrated circuit and other discrete components (resister, capacitor etc.) to disconnect electrically, and reinforce mechanically as well as chemically. It use a resin polymer composite filled with silica (SiO_2) filler-powder. The material necessitates a high thermal conductivity, a low thermal expansion and good mold-ability. Spherical SiO_2 filler-powder is highly desired in this field, as the good fluidity of the filler and the high packing density impart more reliable insulation function to the packaging process, which is more critical issue when the electronic devices become smaller and smaller.

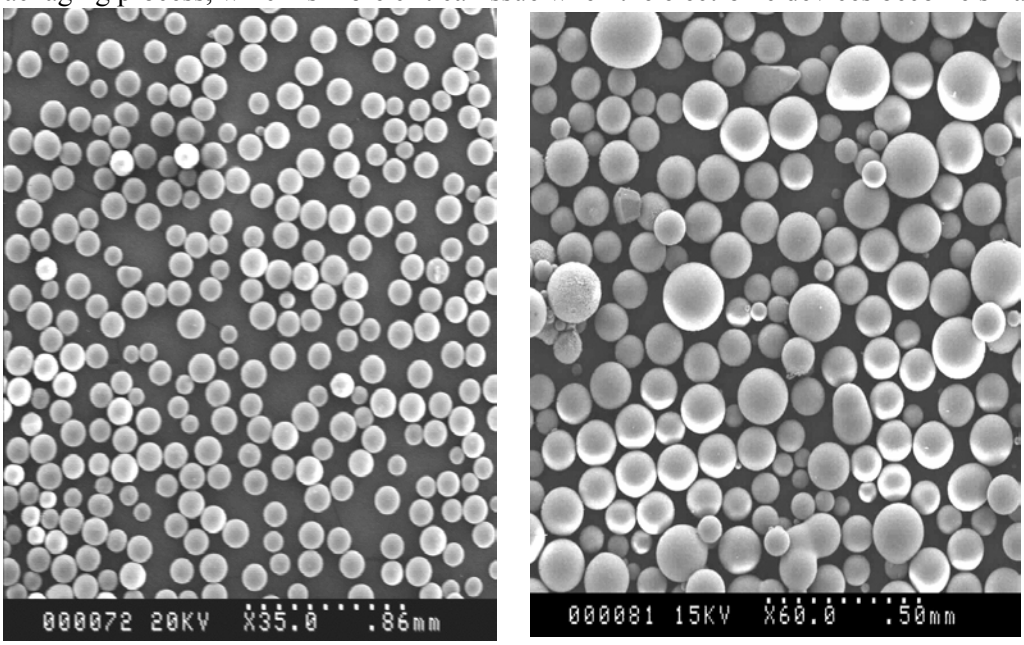

Figure 6: (left) SiO_2 powder spheroidized by air plasma, output 10 kg/h. (right) silicate glass beans, output 15~20 kg/h.

The spheroidization demand also come from the traffic sign board manufactures. Spherical glass beans are superior to the convenient glass powders in the uniformity and intensity of the reflexion, that widely used in the reflective paints. Owing to its low glass transition temperature, spherical glass beans could be obtained via induction plasma process in very high throughput, provide that there are high efficient precursor feeding and product collection capacity.

3. Process cost analysis

With the fact that induction plasma processing could spheroidize almost any kind of powder material, the only determinant factors for its successful application in commercial scale are the operation cost and the price/quality ratio, especially where there is another competing industrial processing, such as combustion processing; *d.c*. plasma processing etc.

An industrial systems of induction plasma process should have the throughput as high as possible. Theoretically and technically, this capacity is limited by (1) the maximum power level (energy density) the induction plasma torch can achieve; and (2) the maximum precursor feed rate determined by the "loading effect"[6]. These issues remain the subjects in the research and development work of induction plasma science. Tekna is to present 500 kW industrial unit in the near future and turn to the solid-state inverter as the radio frequency power source, in order to increase the electric coupling efficiency, and so the energy density of the induction plasma.

In aspect of industrial engineering, Tekna has designed many unique mechanisms to decrease the operation cost. For example, the cooling water and the heat energy are recycled. The plasma gases(argon, hydrogen etc.) are also recycled during operation to lower down the operating cost of the process.

Another important cost reduction advantage of the integrated systems manufactured by Tekna Plasma Systems is the ability to treat the powders in a 24 hours continuous operation mode. The continuous production of powder will greatly reduce the overall cost of the powder by allowing depreciation of the investment costs on a more important number of hours and powder production.

4. Summary

The late decade has seen the induction plasma technology reached a level of maturity. Induction plasma processing has been successfully applied in many materials' commercial scale production. Tekna Plasma Systems, inc. promotes and pioneers this laboratory-industry technology transfer. In our commercial practice and expertise, we have recognized many opportunities to apply induction plasma processing to spheroidize the powder material, in responding the challenging and demanding of different industrial fields.

Abstract

In this paper, we describe and show the main results performed by an etching simulator based on a Monte Carlo method. It allows to calculate the temporal evolution of a Si substrate under a SF_6/O_2 plasma chemistry. One collisioneless sheath model is connected to the surface model to introduce accuracy incident energetic and angular ion distribution function. Surface parameters such as fluorine and oxygen sticking coefficients were estimated by comparing simulation results with experiments. Our study mainly concerns the defects encountered during one etching process: undercut, bowing and roughness. For their understanding, it appears that the ion bombardment plays an important role in particularly for the bowing and trenching formation, whereas chemical reactions are the key to explain the undercut intensity and roughness growth.

I Introduction

The realisation of new power components needs a strong control of the different manufacturing steps. In particular, the emergence of the microelectro mechanical systems (MEMS) requires the development of rigorous, reliable and reproducible technological processes. In this context, the research to improve the techniques of dry plasma etching is an essential stake. The studies are focused on profiles properties, as well topographic as kinetic ones.

Our work deals with the understanding of silicon etching mechanisms in an ICP Alcatel reactor with a SF_6/O_2 plasma chemistry. The objective is the realisation of very deep trenches with high aspect ratio (AR). For these properties, the mean etching rate and anisotropy are the essential parameters. The process is cryogenic (a drop in the chuck temperature around – 100°C), allowing to reduce the chemical etching mechanisms by the growth of an oxide layer on the trench sidewalls. To complement our experimental study [1], we have developed a silicon etching simulator, which takes into account the main plasma-surface mechanisms involved in this type of process.

In our ICP reactor, we obtain thin and deep trenches (AR>50) with a high mean etching rate (> 5µm/mn) and good anisotropy. Nevertheless, as it is shown in Figure 1, the profile is still deformed by two main lateral defects: an undercut, just under the mask, and the bowing phenomenon whose consequences are very dramatic during the post etching steps (a void appears during trench refilling).To reduce these defects and improve the process, it is necessary to understand their growth mechanisms. This research implies a detailed study of plasma-surface interaction mechanisms.

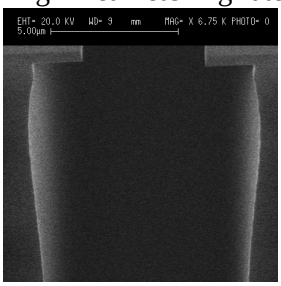

Fig 1 : High part of an experimental trench. This area is marked by the growth of undercut and bowing.

In this article, we present and discuss numerical results performed by the 2-D silicon etching model. Based on Monte Carlo techniques, this simulator has been already described in a previous paper [2]. After a brief recalling of its main characteristics in the following part, we will show profiles obtained according to specified parameters.

II The Monte Carlo simulator

II.1 Initial structure

The first step is the definition of the material submitted to the etching plasma. It is composed by a silicon substrate and a mask for which we specify physical and geometrical parameters (thickness, width and side slope). The method consists in a two dimensional cellular discretization. Each cell has the same size which really defines a number of sites inside. With this approach, we can follow at any moment a specific photography of physical state of the silicon etched surface through the mask.

II.2 The chemical precursors

The main reactive species in the gas phase plasma are fluorine and oxygen radicals. Provided by SF_6 dissociation, the fluorine atoms react with silicon sites to form Si-F bonds. The final step of surface fluorination is the creation of SiF_4 species which are spontaneously volatile, producing the isotropic chemical etching. These reactions of adsorption are defined according to a fluorine-silicon reactivity parameter which is introduced into the simulator by an adsorption probability (P_{aF}). We have studied its effect on the profile isotropy degree. Figure 2 shows experimental results realised in these following conditions: a pure SF_6 plasma, no bias to limit the ionic bombardment effects and a pressure of 22 mTorr. Two temperatures were tested: + 30 °C (Fig. 2.a) and – 110 °C (Fig. 2.b). The trenches are characterised by the same etching rate of about 1.4 µm/min, with an isotropic profile. In a first approximation, these results allowed to consider a constant adsorption parameter with temperature. To define P_{aF}, a series of simulations were calculating. Some results are shown in Fig. 2.c and Fig. 2.d. The profiles were obtained by considering a pure fluorine flux and different values of P_{aF}: 0.9 and 0.1. One notes that undercut is all the more developed that P_{aF} is small. The many random reflections of fluorine atoms inside the trench before being adsorbed explain this trend. These reflection processes lead to the increase of the flux of the reactive chemical species in the totally shadowed areas, like that located just under the mask. A comparison between experiments and simulation results allowed to estimate P_{aF} at 0.1 [2].

A work concerning the reactivity between oxygen atoms and silicon (parameter P_{aO}) is given in Fig 2. e, f, g and h. The experiments were realised in the same conditions mentioned previously, with an oxygen addition of about 10%. For a chuck temperature of + 30 °C, no significant differences are noted with precedent results: topography is still isotropic and the etching rate is the same. In contrary, a drop of substrate temperature modifies seriously the surface kinetics: the profile becomes more anisotropic and the etching rate increases. At –110 °C, the passivation processes are also activated. In simulation, we show results for two values of P_{aO}: 0.1 and 0.9. For a low P_{aO}, the profile

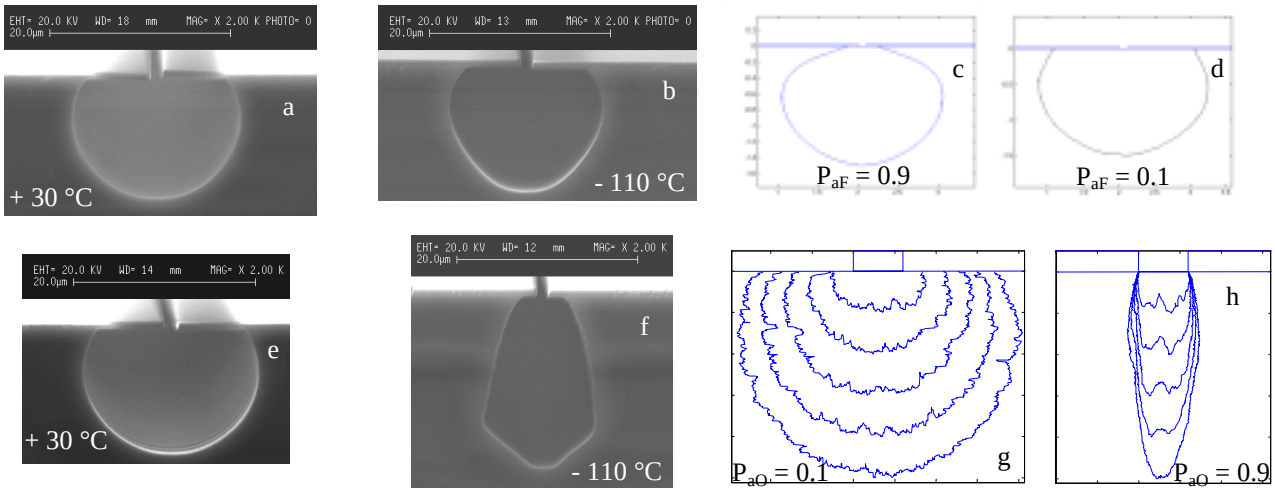

Figure 2 : Study of surface parameters by comparison between experiments and simulation results. a and b : etching with a pure SF_6 chemistry for two temperatures. c and d : simulation results for high and low P_{aF}. e and f: etching with a SF_6/O_2 plasma mixture at + 20 and – 110°C. g and h: corresponding simulations obtained with two levels of P_{aO}.

is still isotropic, with a strong roughness due to micromasking effects. When this parameter increases, the trench becomes anisotropic and the roughness is lower on the sidewalls. The simulator predicts also a rise of the etching rate. So, to model a cryogenic etching process using a based-oxygen chemistry, it is necessary to introduce an high value of the oxygen-silicon adsorption probability.

II. 3 Plasma ions

Ion distribution function are determined by a transport model in the sheath [3] which is connected to the surface model. Based on Monte Carlo technique, it takes into account sheath characteristics that are controlled by pressure, bias tension voltage and injected power in the reactor. Two reactions are considered: elastic and charge exchange collisions.

When one ion strikes the surface, a preferential sputtering yield is determined in accordance with ion energy [4], local angular incidence and the nature of impacted sites. A sputtering process is automatically followed by a redeposition study of the etched species. The level of this mechanism is defined by an homogeneous surface parameter which allows to consider etchings with low or high redeposition. Even if the experiments show a strong selectivity between the mask etching and the silicon substrate, the simulator can introduce processes of mask erosion caused by the ionic bombardment in the case of an used soft-mask. For high ion energy, specular reflexions from the trench sidewalls are considered.

II. 4 Surface displacement

In the model, etching is symbolized by a cellular transition between a full state to an empty state. Etched surface displacement is also realised by site disappearance, produced by spontaneous chemical etching or preferential sputtering. For a given depth, an average etching rate is calculated by comparing the total number of introduced species with the real experimental fluxes.

III Results and discussion

We have studied final trench topographies by varying independently relevant parameters: effect of an oxygen addition, mask geometry and angular dependence of the sputtering yield.

III. 1 Role of the SF_6/O_2 rate

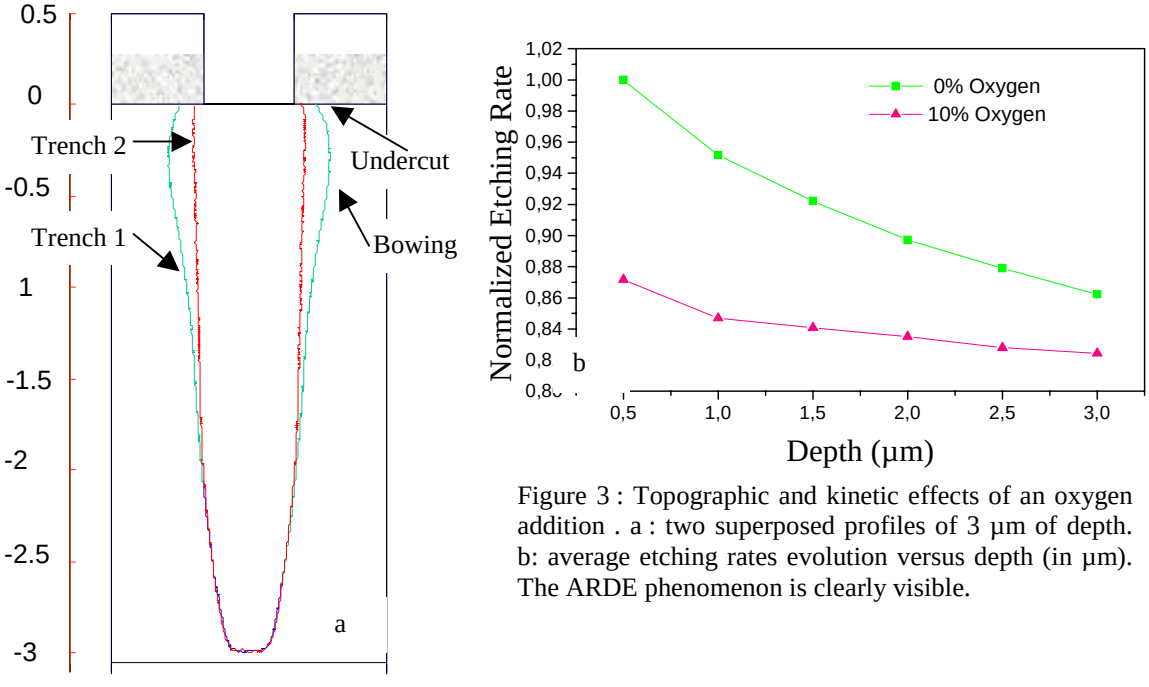

Figure 3 : Topographic and kinetic effects of an oxygen addition . a : two superposed profiles of 3 µm of depth. b: average etching rates evolution versus depth (in µm). The ARDE phenomenon is clearly visible.

Figure 3.a presents two simulated profiles of 3 µm of depth obtained with these initial conditions: a pressure of 22 mTorr, a bias of –30 V, an ion flux of 0.1 %. The mask has the following geometry: a thickness and aperture of 0.5 µm, vertical slopes. The trench 1 was realised without oxygen flux, whereas trench 2 was calculated with 10 % of oxygen in the total neutral flux.

The trench 1 is characterised by a good general anisotropy, with, in the upper part, a large undercut and bowing. These defects are completely removed in the trench 2, for which oxygen produces a passivation layer on the sidewalls. Figure 3.b shows the corresponding etching rates variation versus depth, so with time processing. The data are normalised with the higher one. The ARDE (Aspect Ratio Dependent Etching) phenomenon is obviously visible. This progressive vertical etching rate reduction is due to the transport mechanisms of the introduced species in the trench. The shadowing effect becomes all the more important that the etched depth increases. The surface kinetic lowers and so the etching rate falls. We can observe that this trend is a quiet different for the two simulations, with a more marked decrease for the trench 1. We have shown [5] that this kinetic comportment is caused by a more significant fluorine flux at the trench 2 bottom when the silicon sites are saturated with oxygen on the upper sidewalls.

III. 2 Mask geometry

It is well known by experimental results that mask aperture and thickness can have great consequences for the final trench properties. However, the role of the mask slopes orientation is not usually investigated, this geometrical parameter being not easily modifiable. On this point, the simulation can give complementary and new information. In Figure 4.a, we present two superposed profiles obtained with the same conditions as Trench 1 but with two different masks: one with vertical sides (Trench 3) and one other with inclined sides (Trench 4). Compared with Trench 3, Trench 4 is more deformed, with a greater undercut and bowing. Moreover, one can remark a second lateral overetch in the middle of the structure.

To understand these modifications, we have calculated the neutral angular distribution function after their mask crossing. The results are shown in Figure 4.b. Two differences are observed in relation with the mask sides inclination: when the sides are sloped, the total neutral flux is more important and spreader. In consequences, the surface kinetics are motivated, increasing the etching processes. Undercut and bowing are also more developed. Thanks to the cellular discretization, we have studied the nature of the surface corresponding to the area where the second lateral overetch occurs. It appears that this zone is less fluorinated, the ion bombardment being very important. This elevated sputtering process is due to impacts of the reflected ions which come from the inclined sides

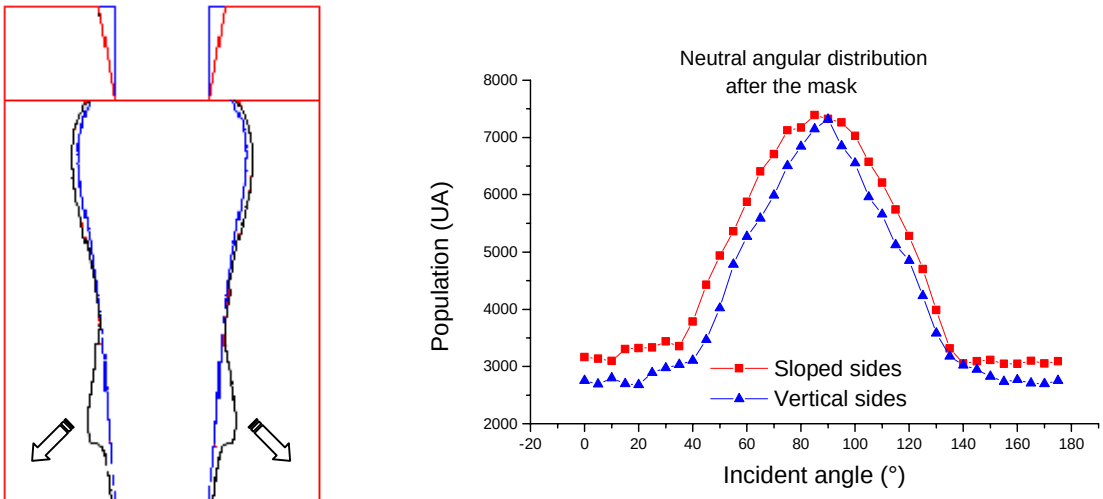

Figure 4 : role of the mask sides. Their inclination plays a great role on the incident flux received on the sidewalls. Undercut and bowing are strong dependent on this geometrical parameter.

of the mask. If we consider this defect as a part of the bowing, this study allows to define one cause of it.

III. 3 Angular dependence of the sputtering yield

Figure 5 shows the sputtering yield evolution calculated by using TRIM [6] for a pure silicon wafer versus ion incident angle and for three different input energies. The shapes are strongly different and we observe one peak structure around 60° for higher energy. For this work, we have assumed an uniform angular distribution for any input energies and we have studied the impact on feature profiles of various angular dependence laws. An example is given in Figure 5 (law-2).

Figure 6 presents two simulation results with the following input parameters: an aspect ratio of 20 for an ion to neutral flux ratio of 0.3. No oxygen was added. In figure 6-a, angular dependence of sputtering yield is not introduced, while in figure 6-b a constant value between 0 and 60° was imposed, followed by a linear decrease of sputtering yield until 90°. For very low incident ion energy, this shape is usually met on silicon substrate. One can observe for (b) a strong trench contracting, with a very narrowed bottom. The sidewalls are also more inclined. This typical feature profile has been obtained in our ICP reactor by using a grid system placed above the wafer to reduce all incident charged species.

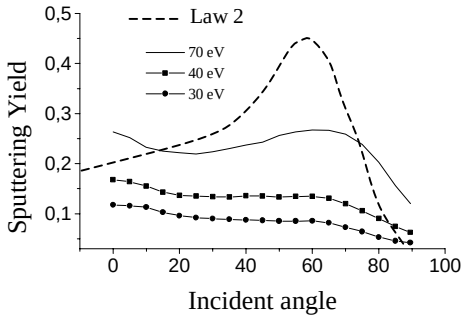

Figure 5 : Sputtering Yield evolution versus incident angle for three ion energies.

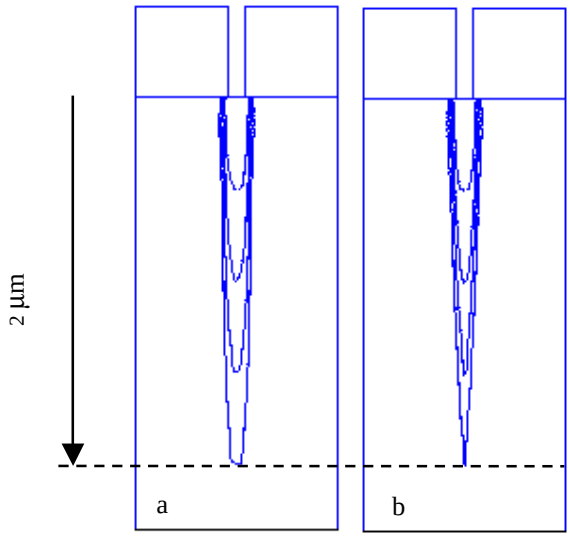

Figure 6 : Two simulations obtained by the etching simulator for two different laws of sputtering yields versus incident angle. The mask has vertical sides with 0.1 µm of opening and 0.5 µm of thickness.

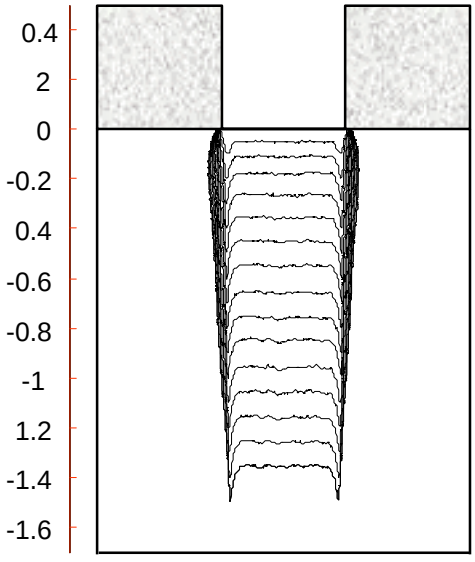

Figure 7 : Formation of microtrenches at the trench bottom.

In the Figure 7, we have used the Law 2 to calculate the sputtering yields. The corresponding trench was calculated without oxygen, a pressure of 22 mTorr and a high ion flux of 5 % in the total

incident flux. We observe the growth of two microtrenches at the trench bottom. This defect has been already expected by other authors [7] and their investigations have shown a strongly dependence of microtrenches evolution with plasma parameters. Moreover, simulation results obtained by Vyvoda et *al* [8] present a prominent role of ion scattering behaviour for microtrenches appearance. In this context, our results appear as a new mean of study and understanding of this defect which induces damage for the post etching steps.

IV Conclusion and perspectives

We have described and illustrated our silicon etching simulator. This work, which is developed in strong collaboration with experiments, introduces coherent kinetic parameters and reactional scheme. The results permit to show the implications of certain parameters such as nature of incident fluxes, mask geometry and angular dependence of the sputtering yield.

Improvements of the model to simulate the etching profiles with a good accuracy are in hand. In the next step, we will develop a kinetic model allowing to quantify the fluxes of different reactive species of SF_6/O_2 plasma. A such model will be coupled to the present etching surface model. With this approach, we can thus describe self consistently the etching process directly with the reactor parameters.

Moreover, a special study concerning the surface kinetic to understand the growth of the passivation layer has started [9].

Plasma based ionic implantation of titanium and titanium alloy : Ti6Al4V.

V.Fouquet, L.Pichon, M.Drouet, A.Straboni
Laboratoire de Métallurgie Physique, université de Poitiers, Chasseneuil France

Abstract

Plasma co-implantations of N_2 and H_2 in titanium and Ti6Al4V were shown to introduce high doses of nitrogen below the surface leading to the growth of δ-TiN nitride layer. Moreover the high density of defects created by the high energy ion fluxes in the subsurface region enhance its diffusivity ; then the δ-TiN layer didn't act as a diffusion barrier any more and a long range diffusion mechanism can occur at moderate temperature.

1. Introduction

Titanium and titanium alloys, especially Ti6Al4V, are attractive materials with low density, very good resistance to corrosion and high strength. Nevertheless, their resistance to frictional wear is poor. Surface nitridation has been proposed to improve surface properties. However the conventional thermo-chemical processes require high temperatures [1], which may induce structural modifications and thus degradation of the mechanical properties. Plasma Based Ion Implantation (PBII) is a novel process [2] that enables the lowering of temperature by increasing the nitrogen incorporation efficiency. Compared to conventional in-line implantation, the advantage of PBII is that the process is non-directional and that all surface are simultaneously treated. Samples are immersed in a plasma and a pulsed high voltage is applied. Large fluxes of ions are available and high doses are incorporated in the near surface of the sample. Together with the ions impinging the surface, a substantial amount of thermal energy is transferred.

2. Experiment

2.1 Samples

Commercial Ti6Al4V and Ti plates were cut into circular shapes with dimensions of 16 mm in diameter. Work pieces were mechanically ground with abrasive papers and polished with diamond spray (1μm) then degreased ultrasonically in acetone and in ethanol and finally dried with nitrogen. The nitrogen and hydrogen plasma co-implantations were carried out using our PBII equipment.[3-4] The cold and homogeneous down-stream plasma is generated in the entire silica tubular chamber using r.f excitation. A three-zone furnace around the tube allows to control the temperature and the voltage is pulsed in order to reduce the thermal energy deposited. The operating pressure in the chamber was fixed at 1 Pa, and the flow rates of the N_2-H_2 (90%-10%) gas mixture was fixed at 25 sccm. The nitriding temperatures were taken between 200°C and 800°C and implantation were performed for 120 minutes to 360 minutes. Applied voltage varied between 10 kV and 35 kV. Pulse duration, repetition rate were fixed at 10 μs and 200 Hz respectively.
Phase identification was conducted by X-Ray diffraction (XRD) and carried out on a Siemens diffractometer D5005 with monochromatic CuKα radiation in a glancing geometry (5°) with a scan step of 0.02°. Surface analysis by X-Ray photoelectron spectroscopy (XPS) was conducted in the Leybold AG LHS12 spectrometer with a MgKα (1253.6 eV) X-Ray source of the LPCM de Nantes. Detailed spectra of the O1s, Ti2p, N1s and C1s lines were recorded in 0.1 eV steps for all samples. Quantification and chemical-state determination were conducted by using a Shirley-type background. The Nuclear Reaction Analysis (NRA) measurements were carried out with the Van de Graaff accelerator of the Université de Paris VI et VII, by using an incident deuteron energy of 3 MeV. Vickers micro-hardness tests were made using SHIMAZU HMV 2000 micro-hardness tester with 0.10N 0.25N 1N 2N and 3N loads for micro hardness measurements on surface and 0.25N load for

micro hardness measurements on cross section.

2.2 X-Ray measurements

The figure 1 shows the effect of temperature on the diffraction patterns for 25 kV implanted Ti6Al4V samples for 240 minutes. At 200°C, the presence of surface nitride compound is revealed by the disappearance of the β-Ti phase. According to the N-Ti phase diagram this phase is destabilized by nitrogen incorporation. A phase identification shows the presence of δ-TiN for temperatures over 200°C and ϵ-Ti_2N for temperatures over 500°C. The δ-TiN peaks are growing as the treatment temperature increases. The main nitride phase are respectively δ-TiN up to 500°C and ϵ-Ti_2N at 800°C, whereas α-Ti grains disappear in the probed depth with the nitriding temperature. A slight shift with increasing temperature of the α-Ti(100) peak to the high 2θ values and α-Ti(002)peak to the low 2θ values can be noticed. It indicates a lower a cell parameter and a bigger c cell parameter. Moreover the δ-TiN peaks have slightly shifted towards the low 2θ values, indicating a larger cell parameter.
The figure 2 illustrates the effect of nitriding time for 25 kV implanted samples at 500C. The δ-TiN peaks appears as soon as 120 minutes of treatment and grows with the treatment time. After 360 minutes of implantation the peaks relative to ϵ-Ti_2N are evidenced. Whatever the treatment time, a line shifts of the α-Ti peaks is observed compared to the α-Ti initial. Moreover a shift of δ-TiN peaks to the high 2θ values evidences that the probed inter reticular distance increases with treatment duration.
The figure 3 illustrates the effect of the applied high voltage for treatment at 500°C and for 240 minutes. At 10 kV δ-TiN phase is not clearly observed whereas it appears at 25 kV and its intensity keeps constant with increasing applied voltage. Nevertheless the presence of surface nitride compound is revealed by the disappearance of the β-Ti phase. The ϵ-Ti_2N phase is only evidenced for treatment performed at 35 kV.

2.3 XPS measurments

In order to counteract charge effect, impurity carbon (C-C and C-H bounds) was set at 284.7 eV binding energy (BE). Results of chemical-state determination are presented in table 1. The Ti2p envelope of a nitrogen plasma implanted sample is composed of 3 synthetic components (T_1 T_2 T_3). The measured binding energies of the $Ti2p_{3/2}$ for the various identified or assigned chemical states were compiled and are listed in Table 1 together with data from our experiments. As shown, the position of $Ti2p_{3/2}$ for nearly stoichiometric TiN_x (x=1) falls in the range of 454.8-455.5 eV (T_1)and the T_3 peak found between 458.0 and 458.2 eV is unambiguously identified as Ti in a TiO_2 environment. The T_2 peak appearing in the 456.4-457.0 eV range is assigned to TiN_xO_y or TiN_xO_{1-x} type oxynitrides together with the super-stoichiometric TiN_{1+x} nitride.

Table 1 : Chemical state and binding energies of our samples and literature values of $Ti2p_{3/2}$ line positions

Line	Name	State	Position	State	Position	Reference
Ti2p	T_1	Ti in $TiN_{x=1}$	454.8-455.5	Ti^0	453.8 ± 0.2	[5]
	T_2	Ti in TiN_{1+x}orTiN_xO_y	456.4-457.0	TiN	454.5-455.3	[5-8]in[5]
	T_3	Ti in TiO_2	458.0-458.2		454.7 ± 0.1	[5]
N1s	N_1	N in TiN_{1+x} or TiN_xO_y	395.7-396.0	TiN_xO_{1-x}	455.4	[22]in[5]
	N_2	N in $TiN_{x=1}$	396.7-397.0		456.4	[14]in[5]
	N_3	N in contaminant	398.2-398.8	TiN_xO_y	456.9-457.3	[22]in[5]
O1s	O_1	O in TiO_2	529.6-529.8		456.7	[9]in[5]
	O_2	O in TiO_xN_y	531.2-531.5	TiN_{1+x}	456.9	[7]in[5]
	O_3	O in contaminant	532.6-532.9	TiO	454.9	[6]in[5]
C1s	C_1	C in TiC_x	281.7-282.9		455.2	[22]in[5]
	C_2	C in contaminant	284.7	Ti_2O_3	457.0	[22]in[5]
	C_3	C in contaminant	286.1-286.4	TiO_2	458.9	[22]in[5]
	C_4	C in contaminant	288.3-288.6		458.9	[5]

The N1s envelope of our samples is composed of 3 synthetic components (N_1 N_2 N_3). Considering the literature [5], the N_2 component is representative of N in stoichiometric TiN. The origin of the N_1 component found between 395.7 and 396.0 eV can be correlated with the Ti2p component for TiN_xO_y compounds or to a super-stoichiometric nitride. The peak N_3 is related to the N-O bound of the surface contaminants.

Oxygen and carbon are common bulk surface contaminants. The O1s envelope is composed of 3 synthetic components (O_1 O_2 O_3). A major part of oxygen belongs to adsorbed water and C-O type adsorbed impurity corresponds to the peak O_3. The two peaks O_1 and O_2 are related to oxygen chemically bound to Ti. The C1s enveloppe is composed of 4 synthetic components (C_1 C_2 C_3 C_4). All the peak are related to surface contaminant. Quantification was recalculated, according to equation (1), by removing the contaminants contributions ; the results are presented in table 2.

Table 2 :Recalculated elements concentration

$[Xi] = \frac{Xi}{\sum Ti}$ (1)	25kV		10kV		35kV		2h		6h		200C		800C	
	Ti	alloy	Ti	alloy	Ti	alloy	Ti	alloy	Ti	alloy	Ti	alloy	Ti	alloy
$[T_1]$	0.23	0.27	0.27	0.29	0.24	0.24	0.28	0.30	0.23	0.26	0.23	0.24	0.41	0.39
$[T_2]$	0.28	0.27	0.27	0.26	0.26	0.25	0.29	0.28	0.25	0.25	0.33	0.33	0.21	0.22
$[T_3]$	0.49	0.47	0.46	0.45	0.50	0.51	0.43	0.41	0.52	0.49	0.44	0.43	0.38	0.39
$[N_1]$	0.39	0.38	0.39	0.43	0.39	0.44	0.39	0.39	0.40	0.40	0.60	0.75	0.19	0.21
$[N_2]$	0.62	0.50	0.69	0.73	0.66	0.72	0.60	0.67	0.56	0.56	0.42	0.38	0.63	0.66
$[O_1]$	1.38	1.31	0.98	1.07	1.39	1.57	1.07	1.13	1.23	1.48	1.02	1.10	0.84	0.81
$[O_2]$	0.56	0.62	0.36	0.35	0.61	0.85	0.39	0.55	0.54	0.71	0.39	0.48	0.38	0.35

Relationships between the different contribution are obtained by plotting the obtained concentrations versus the different $Ti2p_{3/2}$ contributions. Results indicate that $[O_1]$ and $[O_2]$ grow as $[T_3]$ and $[T_2]$ increases. $[N_1]$ grows as $[T_2]$ increases. On the other hand $[N_2]$ increases as $[T_1]$. These results are in agreement with peak attribution. The oxyde contribution $[T_3]$ increases as increasing treatment time and applied voltage but decreases with increasing temperature contrary to δ-TiN contribution $[T_1]$ which behave in the opposite way. $[T_2]$ decreases with increasing treatment time and temperature but doesn't seem to have a linear behavior according to the applied voltage.

2.4 NRA measurements

Few samples were characterized by NRA. Nitrogen and oxygen concentrations are presented in table 3. Calculated implanted dose were obtained using equation (2)

$$IonicDose = \frac{f * t * \tau * I}{(1+\gamma) * S * e} \quad (2)$$

with f the repetition rate (Hz), t the implantation time (s), τ the pulse duration (s), I the sample current (A), S the electrode surface (cm^2), γ the secondary electron emission coefficient. In order to obtain atomic dose the ionic dose is multiply by a factor 2 by considering that that nitrogen ions are 100% N_2^+ type. Nitrogen fixed rate (ρ) is deduced from the ratio of the concentration obtained by NRA over the calculated implanted dose. The δ-TiN layer thickness equivalent to the detected N concentration was calculated using the cell parameter obtained by XRD (a= 0.423nm). The same kinds of calculus was realized by considering that nitrogen is fully present within ϵ-Ti_2N phase (a= 0.492nm, c= 0.303nm JCPDS). Projected ranges were calculated using SRIM.

table 3 NRA results

Sample	240min 500°C 10kV	240min 500°C 25kV	240min 500°C 35kV	240min 500°C 25kV	360min 500°C 25kV	240min 500°C 25kV	240min 500°C 25kV
$N_{calculated}$: calculated implanted N (10^{15}at.cm^2)	225	1050	1800	1050	1800	1800	1800
Projected Range(Rp)(nm) (SRIM)	10.7	22.9	31.6	22.9	22.9	31.6	31.6
ΔRp (nm) (SRIM)	$\pm$8.9	$\pm$16.6	$\pm$21.5	$\pm$16.6	$\pm$16.6	$\pm$21.5	$\pm$21.5
N_{byNRA} : N concentration(10^{15}at.cm^2)	101	180	245	180	218	245	359
ρ Nitrogen fixed rate ($N_{byNRA}/N_{calculated}$)	0.45	0.17	0.14	0.17	0.12	0.14	0.20
Equivalent δ-TiN thickness (nm)	19	34	47	34	41	47	68
Equivalent ϵ-Ti_2N thickness (nm)	37	66	90	66	80	90	130
oxygen concentration (10^{15}at.cm^2)	145	162	145	162	175	145	110

Effective nitrogen concentration is more than twice lower than calculated dose and slightly increases with increasing applied voltage and increasing treatment duration. The effective oxygen concentration is not negligible but seems to be independent from treatment parameter. As no oxide phases has been detected, the major part of the oxygen is thought to be dispersed within the nitride or the titanium grains. In the case of 10kV applied voltage the amount of oxygen is upper than the amount of implanted nitrogen. Effective nitrogen concentration seems to be higher in the case of titanium samples, but whatever the treatment performed the equivalent thicknesses obtained are lower than one micrometer and remain in the range of Rp $\pm$ δRp.

2.5 Vickers micro hardness measurements

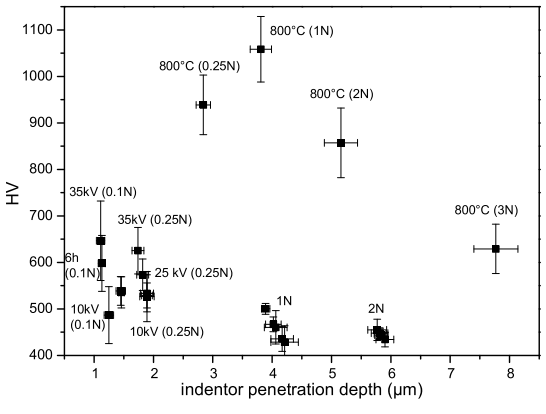

Fig 4 surface micro-hardness of samples treated by PBII

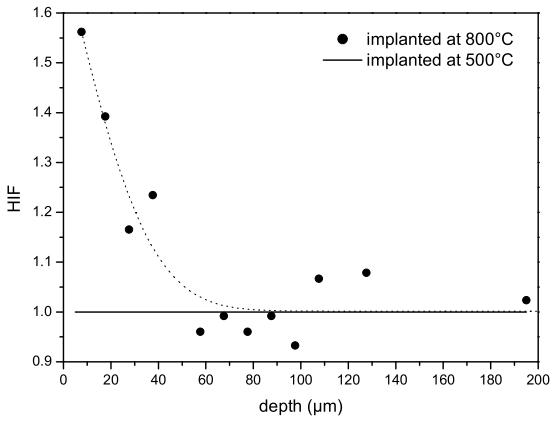

Fig 5 micro-hardness profiles of samples treated by PBII

The hardness of implanted samples were measured at various loads (Fig.4). With the exception of treatment performed at 800°C the values obtained are similar whatever the treatment. Although the data are scattered, it can be seen that the hardness improvement is more pronounced at low loads ; with increasing load it approaches the hardness of the unimplanted samples. Micro-hardness profiles

were realized with 0.25N load on the cross section of the samples treated at 800°C and 500°C for 240 minutes and an applied voltage of 25kV. The figure 5 presents the hardness improvement factor (HIF) calculated as the hardness ratio of an implanted sample to the hardness of the bulk. Flat profile is obtain for the sample treated at 500C. Concerning the 800°C the inward modification of the hardness is effective up to a depth of about 50 ± 10 μm. The curve can be fitted by a erfc function. The diffusion coefficient obtained is 2.7 10^{-10} $\pm$ 1 10^{-10} $cm^2.s{-}1$. According to literature nitrogen diffusion coefficients obtained by conventional plasma nitriding are in the range of 10^{11} $cm^2.s{-}1$ [6].

3. Results ans discussion

The plasma implantation nitriding reaction has been shown to lead to the formation of a surface δ-TiN layer with α-Ti grains underneath. The ϵ-Ti_2N phase is only detected on sample treated for a long time or at a high temperature. Micro hardness profiles performed on cross section may be related with nitrogen diffusion. The flat profile obtained on sample treated at moderate temperature ($\leq$500°C) evidence the slow diffusion process in bulk titanium at this temperature.
For low temperature ($\leq$500°C) stoichiometric nitride layers are obtain by PBII process whereas their formation is not possible using conventional process such as thermo chemical treatments or plasma reactor. Nitride layers formation is then related to the nitrogen implantation in the titanium subsurface. Ions impinging on the surface transfers a substantial amount of energy to the material and leads to the formation of the nitride by activating the chemical reaction. Consequently the thickness of the detected δ-TiN layer is of the order of the projected range. Moreover the fixed nitrogen rate is much lower than 1. In fact, only nitrogen necessary to the nitride formation on the implanted depth is remaining. Surplus nitrogen exo-diffuses or is eliminated by sputtering. At low or moderate temperature the deep nitrogen diffusion process, governed by the presence of impurity [7], remains very slow.
For long treatment time, enough nitrogen may however diffuse to the titanium bulk. It leads to the formation of ϵ-Ti_2N compound under the δ-TiN layer. However, in spite of an increase of treatment time, the δ-TiN layer almost doesn't grow and remains of the order of the projected range. A saturation-like phenomenon is then occurring, as shown by the decrease of the fixed nitrogen rate (ρ)with the implanted dose.
The nitride layer grows with ions energy. This is mainly linked with the longer projected range. Moreover defects created and energy transferred by impinging ions leads to a local activation of the deep nitrogen diffusion process. The detected ϵ-Ti_2N compound on sample treated with high applied voltage (35 kV) may be induced by this last phenomenon. Moreover the surface sputtering yield depends on applied voltage. SRIM calculations show the decrease of the sputtering yield with the applied voltage within the studied range. However nitrogen fixed rate is found to decrease with the applied voltage. Indeed the nitrogen implanted dose is higher and higher compared to the nitrogen quantity necessary to form a δ-TiN layer which thickness remaining of the order of the projected range. The saturation phenomenon is one again evidenced.
At higher temperature (800°C) PBII treatment coupled implantation effects and an efficient deep diffusion process. Mode of diffusion through the δ-TiN layer changes to a lacunar mechanism [7] leading to : a thicker nitride layer, the formation of ϵ-Ti_2N phase and of a few tens of micrometers long zone with nitrogen in solid solution in α-Ti bulk. The presence of ϵ-Ti_2N compound is also favored by the long period of the sample cooling : time consuming diffusion processes of nitrogen coming from δ-TiN layer to the α-Ti bulk can then occur, leading to a flatness of the nitrogen profile. Compared with a conventional plasma treatment, the apparent diffusion coefficient is higher. Indeed, in case of conventional treatment, the presence of a thick nitrogen-rich compounds layer induces a limitation of the inward nitrogen diffusion. The diffusion coefficient in the nitride being significantly lower than in the titanium. Plasma implantation allows the direct incorporation of high concentration of nitrogen in the subsurface. The first step of conventional nitriding plasma treatment, consisting in transforming nitrogen adsorbed on surface to nitrogen in solid solution in δ-TiN, is then skipping over. Moreover the surface nitride becomes super-stoichiometric and acts as an unstable nitrogen storage, which supplies and activates the nitrogen diffusion through the δ-TiN layer. Finally the high

defect density created by nitrogen implantation contributes to an increase of the nitrogen diffusion coefficient through the δ-TiN layer.
The internal compressive stress of the δ-TiN layer induce a cell distorsion of the α-Ti phase. The lower a and the bigger c cell parameters may imply that nitridation of the grains depends on their orientation. It is effective on the grains with (100) plans parallel to the surface : N diffuse in between the basal plane leading to an higher c cell parameter and, by consequence, to a lower a cell parameter. On the other hand nitridation of grains with their plans (001) parallel to the surface is less efficient and these grains sustain the compressive stress due to the δ-TiN growth.
In order to find an optimal treatment, the nitride oxidation should remain low. High applied voltage and long treatment induce a slight increase of the surface temperature. As in this moderate temperature range the oxidation is thermodynamically favored reaction, it is found to increased as shown by XPS. However at temperature high enough to promote the nitride formation, oxydation is reduce to the benefit of nitride formation as it can be concluded for the XPS results on the samples treated at 800°C.

4. Conclusion

Plasma implantations of N_2 were performed in titanium and Ti6Al4V samples. High doses of nitrogen were implanted in a depth of the order of the projected range leading to the formation of a δ-TiN layer. At moderate temperature a saturation-like phenomenon occurs. At high temperature the high defect density created by nitrogen implantation and the high nitrogen concentration in the subsurface contribute to an increase of the nitrogen diffusion coefficient.

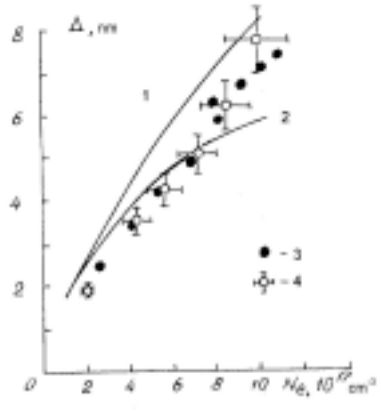
Local plasma diagnostics using H_β-profile features

L. Krat'ko, K. Catsalap, E. Ershov-Pavlov

Institute of Molecular and Atomic Physics, National Academy of Sciences, Minsk, Belarus

Balmer lines are widely used at low-temperature plasma diagnostics. Especially H_β line is very popular at electronic density measurements by the line half-width. It is because the line profile can be easy recorded, and good theoretical approximations exist to account for the profile and its principal parameters. However, in emission spectra of plasmas at high electron density the line is very large, and it is rather difficult to select it at the plasma background continuum, which intensity also strongly increases. In these conditions, measurements of the line halfwidth are not practical, and one usually uses the profile approximations by existing models. For inhomogeneous plasmas, the line profiles in the plasma emissivity spectra have to be measured demanding solution of the inversion problem. Measurements of the H_β-profile features in the plasma emission spectra can be a good alternative. This paper is devoted to the problem.

First, H_β-profile characteristics in plasma emissivity spectra have been studied depending on electron density N_e for the region of N_e high (up to 10^{18} cm^{-3}) values poor studied before. A special arc in hydrogen and argon has been used to produce the plasma at pressure up to 30 bars [1]. The arc column is a highly stable plasma volume of axial symmetry, and common Abel inversion procedure has been used to find plasma emissivity. The following H_β-profile characteristics have been studied versus N_e: a distance between its maxima Δ (nm) (peak separation), a dip in the profile centre $D=(\bar{I}_{\max} - I_{\min})/\bar{I}_{\max}$ ($\bar{I}_{\max}=(I^B_{\max}+I^R_{\max})/2$, $I^B_{\max}$ and $I^R_{\max}$ are the profile blue and red maxima, respectively), as well as the profile asymmetry $\delta I=(I^B_{\max} - I^R_{\max})/I^B_{\max}$. Some of the study results are shown in the figure in comparison with the calculation [2, 3] and experiment [4] data. It is seen from the figure, that our results agree with the measurement data [5] in an optical discharge. At $N_e<10^{17}$ cm^{-3} our data are closer to [3] and increase faster at high electron density. General view, the experimental $\Delta(N_e)$ dependence corresponds to that calculated in [2], but measured Δ values are lower.The measured data confirm that a ratio of the peak separation Δ to the H_β halfwidth depends little on N_e up to 10^{18} cm^{-3}. But we have obtained a bit lower ratio values (~0.3). The profile asymmetry δI measured here agrees with other experiment data till $N_e<7\cdot10^{17}$ cm^{-3}. At higher density our δI values increase with N_e stronger. We have also observed different dip D behavior in emission spectra of Ar and H_2 plasmas having reduced masses of the perturbing particles $\mu\approx1$ and $\mu=0.5$, respectively.



Peak separation Δ (nm) in H_β-profile vs N_e calculated [2] (1), [3] (2), and measured [4] (3). Points 4 - our data.

Generally, we have found Δ value to be the most promising for the plasma diagnostics at high electron density, where H_β is very broad. First, because of this value is much more measurable in this conditions in comparison with other profile characteristics. So, one can easily measure Δ, and determine N_e, e.g., using Δ ratio to the line halfwidth. Secondly, due to a weak dependence on N_e of the ratio, one can suppose it will be applicable also at diagnostics by emission spectra of inhomogeneous plasmas. We have made a numerical simulation of the H_β emission by inhomogeneous plasmas having different temperature distributions. A numerical code for the radiation transfer has been presented earlier together with the temperature distribution approach [5]. The results show the H_β peak separation in the directly measured plasma emission spectra can be used for the plasma diagnostics.

Abstract

N_2/H_2 and NH_3/H_2 RF plasmas are used to activate the polystyrene (PS) surface. The capacitively coupled RF plasmas applied for the surface modifications have been characterised by commercial plasma diagnostic methods including ion flux probe, RF power sensor, and mass spectrometer. In particular the ion species and the ion energy have been measured as well as the ion dose impinging onto the polymer surface. The surface modifications are characterized with surface sensitive X-ray Photoelectron Spectroscopy (XPS).

Introduction

Polystyrene (PS) is a popular substrate for disposable ware in medical diagnostic, primarily due to its optical transparency, durability, low cost, and good mouldability.[1] Non-modified polystyrene may cause non-specific adsorption. Therefore it is customary to modify it with hydrophilic polymers.[2] Many polymers such as poly(ethylene glycol) and dextran have been studied for their usefulness in producing pharmacologically active complexes with proteins or drugs. PS surfaces have been successfully modified by high-energy irradiation: γ and UV radiation,[3, 4] plasma treatment[1, 5] and glow discharge plasma.[6]

Plasma surface treatments are potentially very useful for the covalent incorporation into polymer surfaces of extraneous reactive groups suitable for participation in further, conventional chemical reactions at the surface.[7] It is possible to change continuously the chemical composition and properties such as wettability, metal adhesion, dryability, lubricity and biocompatibility of materials surfaces.[8] The plasma modification can be carried out in the presence of specific gases, such as O_2, Ar, He, NH_3, N_2, and H_2. This results in the generation of active species, which can activate and modify the material depending on the nature of the gaseous medium.

The aim of this work is to prepare chemically reactive yet specific PS surfaces for subsequent high-density bio-immobilization such as protein molecules. These modified surfaces are potentially efficient substrates of medical diagnostic tools for use in a proprietary ADS fluorescence reader.[9] The surface modification strategy is shown in Figure 1. In this paper we present the plasma activation and correlated to XPS surface characterization with XPS. Subsequent functionalizations with proteins such as Streptavidin and Neutravidin, and the application study by optical fluorescence measurements will be reported later.

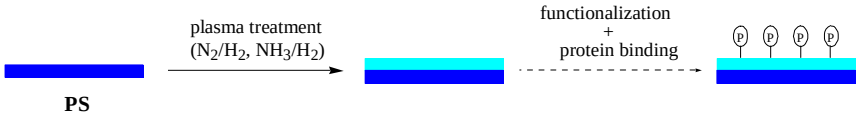

Fig.1 Functionalization (schematic) of a polystyrene chip

Experimental

Polystyrene chips were obtained by injection molding of Polystyrol (BASF). Plasma treatment of PS chips was carried out in a capacitively coupled rf reactor operating at 13.6 MHz. The reactor consisted of two cylindrical electrodes of 13 cm diameter and 4.3 cm apart in a cubic vacuum vessel. The upper electrode and the reactor walls were grounded. The PS chip was placed on the grounded electrode and the system was evacuated to 10^{-6} mbar. The needed gas mixture was introduced into the chamber at a flow rate of 60 sccm and the plasma was operated at a gas pressure of 0.4 mbar at a power of 60 W. The sample exposure time was 3 minutes. The PS chip was directly transferred after exposure for XPS analysis.

For plasma diagnostics only commercial equipment has been used in order to demonstrate that basic plasma diagnostics is now commercially available and to show its necessity for an advanced understanding of the surface modification by plasmas and the industrialisation of the processes. A Scientific System ion flux probe (IFT) has been applied to measure the ion flux on the grounded electrode. A Balzers PPM 422 mass spectrometer system has been used to measure the ion composition and the energy of the impinging ions. Both measuring systems have been incorporated into the grounded electrode. This experimental arrangement permits to measure the characteristics of the ion bombardment at the same place as the treated substrate. Therefore correlations and comparison between plasma parameters and the results from surface analysis can be made.

XPS analysis was performed using an imaging Kratos Axis Ultra X-ray photoelectron spectrometer equipped with a conventional hemispherical analyser. The X-ray source employed was a monochromatized Al Kα (1486.6 eV) source operated at 150 W. Data acquisition was performed under UHV (10^{-9} mbar) conditions. Analysis area was 0.21 mm^2 (300 μm × 700 μm) using a take-off angle of 70° relative to the surface normal. The pass energies were 80 eV and 20 eV for wide scan and high-resolution elemental scans, respectively. The operating software, Vision2, corrects for the transmission function. Charge compensation was performed with a self-compensating device (Kratos patent) using field emitted low energy electrons (0.1 eV) to adjust the main C-C component to 285 eV.[10] The data reduction (atomic concentration, shifting, curve fitting, etc) was performed with CasaXPS Version 2.1.9 software.

Results and Discussion

The electrical asymmetry of the plasma reactor leads to maximum ion energies in the order of 15-20 eV. Under these conditions the ion energy does change only weakly with RF power and other process parameters. Therefore the maximum energy of the bombarding ions for all the cases studied here was below 20 eV (data not shown). However, the energy spectrum depends on the properties of the considered ion. In the case of ions undergoing charge exchange reaction a broad energy spectrum was measured whereas for ions without these reactions the ion energy was peak around the maximum energy.

Table 1 shows the influence of gas mixtures on ion flux and ion doses for various N_2/H_2 and NH_3/H_2 plasmas.

Table 1. Parameters for plasma activations[a]

Prim. Gas / Sec. Gas (% / %)	Ion Flux (mA/cm^2)	Ion dose ($Ions/cm^2$)
100 NH_3 / --	26	2.9E+19
92 NH_3 / 8 H_2	26	3.0E+19
95 N_2 / 5 H_2	87	9.8E+19
90 N_2 / 10 H_2	95	1.1E+20
70 N_2 / 30 H_2	101	1.1E+20

[a] Activation conditions: 60 W, 0.4 mbar, exposure of 3 minutes.

Figure 2 shows the effect of hydrogen dilution on ion compositions when nitrogen is used as a primary gas. In the dilution range from 0-25 % N_2^+, N_2H^+, and H_x^+ are the dominating ions. For higher hydrogen dilutions the measured ion composition is not significantly affected.

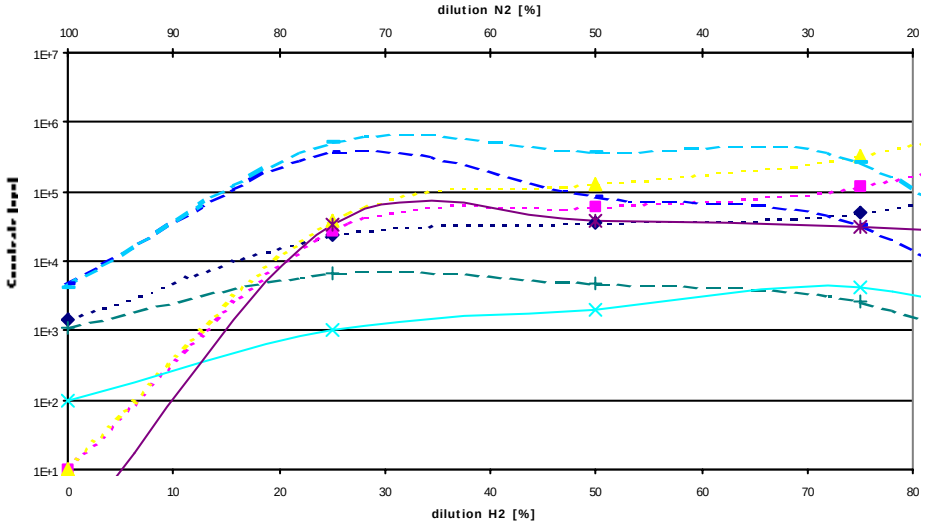

Figure 2. Effect of H_2 admixture on the ion compositions for N_2/H_2 plasmas.
H^+, H_2^+, H_3^+; N^+, N_2^+, N_2H^+; NH_3^+, NH_4^+.

The effect of hydrogen dilution on ion compositions was also studied for ammonium used as a primary gas. The result is shown in Figure 3. One observes that the admixture of hydrogen doesn't affect the ion composition: NH_x^+ ions are always by far the most abounded ion in these plasmas.

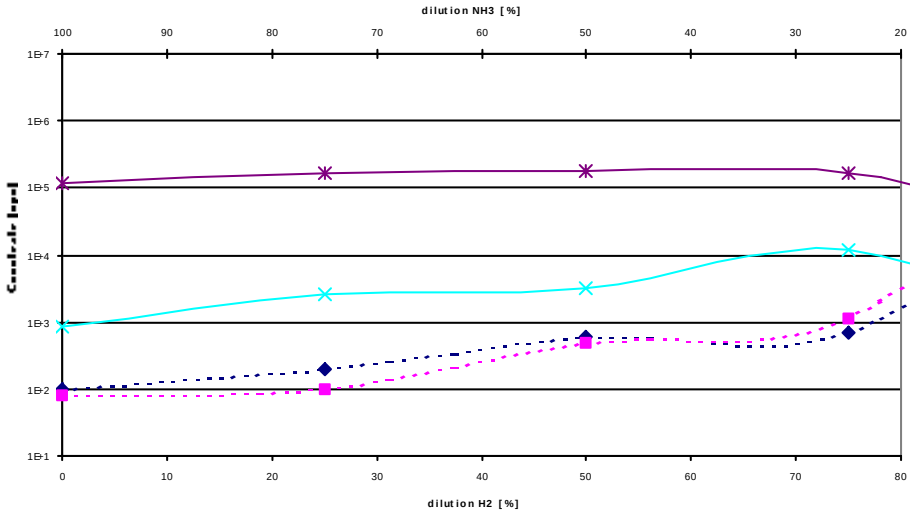

Figure 3. Effect of H_2 admixture on the ion compositions for NH_3 plasma.
H^+, H_2^+; NH_3^+, NH_4^+.

PS samples are treated with N_2/H_2 (95/5, 90/10, and 70/30 respectively), NH_3/H_2 (92/8) and pure NH_3 plasmas. The efficiency of the plasma activation on PS is checked by nitrogen concentration from XPS analysis. These results are summarized in Table 2. Inspection reveals that hydrogen dilution into a nitrogen plasma has no direct effect on the modification efficiency. According to the results concerning the plasma composition as a function of the hydrogen dilution in N_2 plasma (Figure 2), N_2H^+ ions are the most abundant ion. In the case of hydrogen diluted ammonia plasma NH_x^+ ions are dominating. XPS analysis showed that in these three considered N_2/H_2 plasma cases, similar surface modification efficiencies are observed. Under the present plasma conditions, NH_3 or NH_3/H_2 plasmas are more efficient than N_2/H_2 plasma in providing a nitrogen-amino surface. C1s narrow scan spectrum of PS treated with a NH_3 plasma is shown in Figure 4. Spectra for other samples listed in Table 2 give similar results. Aromatic and aliphatic carbons from PS are observed between 284.7-285.3 eV. As expected, C-N is observed at 286±0.1 eV. The detected oxygen results from the exposure of PS surface to the air when the plasma chamber is opened after the plasma treatment.

Table 2. Nitrogen concentrations of plasma activated PS[a]

Prim. Gas / Sec. Gas (% / %)	at % N
95 N_2 / 5 H_2	11
90 N_2 / 10 H_2	14
70 N_2 / 30 H_2	11
100 NH_3 / --	19
92 NH_3 / 8 H_2	19

[a] Activation conditions: 60 W, 0.4 mbar, exposure of 3 minutes.
error: ± 3 at %

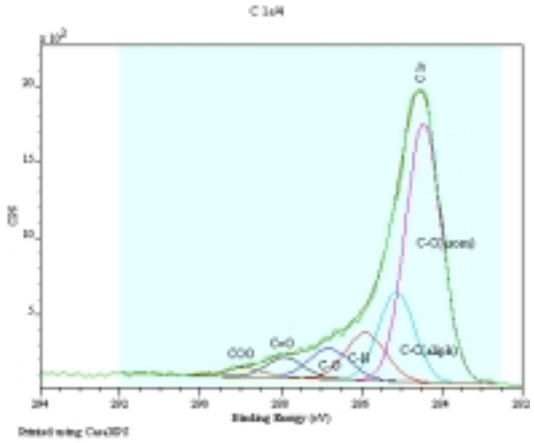

Figure 4. XPS narrow scan spectrum of PS treated with plasma by using pure NH_3.
(Take-off angle 70 degree from surface normal)

Although the ion doses of N_2/H_2 plasmas are higher than for the NH_3/H_2 plasma (Table 1), their efficiency to produce nitrogen-containing functional groups at the surface is lower, i.e. that the NH_3 plasma treatment is more effective. Comparing Figure 2 with Table 2 for N_2/H_2 plasmas one notices that the influence of the variation of H_2 is small: although the admixture of H_2 influences strongly the plasma composition in the range from 5-30 %; the nitrogen concentration found at the PS surface remains constant within experimental precision as shown in Table 2. A monolayer of PS contains approximately 10^{15} molecules/cm^2. Compared to the doses values given in Table 2 this means that 10^4-10^5 ions/molecule are needed for nitrogen activation on the PS surface.[11]

Conclusions

The ion energy of the bombarding species is found to be 15-20 eV and the necessary ion density for PS surface activation is 10^4-10^5 ions/molecule per cm^2. H_2 admixture to N_2 or to NH_3 has only small influences on ion composition and nitrogen concentrations at the surface. However a NH_3 plasma is almost two times more efficient than a N_2/H_2 plasma to create active nitrogen-containing sites.

Abstract
Models of stationary direct-current and surface-wave discharges in atmospheric-pressure air and its mixtures with hydrocarbons are developed that account for deviation of plasma state from the local thermodynamic equilibrium. Results of discharge simulation are presented for a wide range of external conditions. Calculated plasma parameters agree with available experimental data.

1. Introduction

Simulation of discharges in molecular gases at pressures of the order of one atmosphere is usually based on the approximation of local thermodynamic equilibrium (LTE). This approach is justified if the gas temperature in the discharge core is high enough (typically higher than 4000 K), which is the case in DC discharges in atmospheric-pressure air if the electric current is higher than approximately 0.1 A. Recently, considerable attention has been paid in the literature to experimental investigation of atmospheric-pressure DC discharges in the current range 0.01-0.1 A (e.g., [1-6]), in which non-equilibrium effects become important. In this work, a model of a low-current DC and surface-wave discharges in air and its mixtures with hydrocarbon fuels is developed on the basis of a solution of kinetic equations for the densities of plasma species. (Note that discharges in fuel-air mixtures are considered as a perspective tool for production of hydrogen.) Calculation results are presented for the case of a wall-stabilized discharge in a cylindrical tube.

2. The model

Among various non-equilibrium effects that come into play at decrease of the gas temperature inside the discharge core, the most essential is the deviation of the electron number density n_e from its LTE value, caused by the change of dominating ionization mechanism. While at high gas temperatures the major source of electrons is ionization in collisions between heavy particles (in air, the associative ionization in collisions of N and O atoms), at low gas temperatures the direct ionization of molecules by electron impact dominates. The rate constant of the latter process is governed by the value of the electron temperature T_e, depending both on T and on the reduced electric field E/n (here E is the electric field and n is the gas number density).
The distribution of the gas temperature along the radial coordinate r is governed by the Elenbaas-Heller equation

$$\frac{1}{r}\frac{d}{dr}\left(\chi r \frac{dT}{dr}\right) + \sigma E^2 = 0, \qquad (1)$$

where χ and σ are the thermal and electrical conductivity coefficients. Since the plasma temperature does not exceed 6000 K under the conditions considered, radiation effects are minor and can be neglected. The boundary conditions for equation (1) are as follows:

$$\frac{dT}{dr} = 0 \text{ at } r = 0, \quad T = T_W \text{ at } r = R. \qquad (2)$$

Here T_W is the wall temperature, R is the tube radius.
Knowledge of the thermal and electrical conductivity coefficients χ and σ is required for a solution of equation (1). The thermal conductivity coefficient is not affected strongly by non-LTE effects, therefore the LTE χ values are used in the present calculations. An effect of deviations from LTE on the electrical conductivity coefficient σ is much more substantial, because the value of σ is proportional to the electron number density n_e. In a wide range of discharge conditions the radial distribution of n_e may be calculated,

with high enough accuracy, using the local approximation (neglecting diffusion term). The local balance equation for electrons with account of both ionization channels mentioned above is

$$K_i n_e n + \beta_{ei}(n_{e0}^2 - n_e^2) = 0 \,, \tag{3}$$

where K_i and β_{ei} are the rate constants of direct ionization and electron-ion recombination, n_{e0} is the LTE value of n_e. The rate constant K_i, depending on E/n, T, and on the mixture composition, is obtained by solution of the Boltzmann equation for the electron energy distribution function.
The system of equations for DC discharge includes also the Ohm's law

$$I = 2\pi E \int_0^R \sigma(r) r dr \,, \tag{4}$$

where I is the electric current.
Calculation of discharges sustained by travelling electromagnetic waves is based on a simplified approach in the framework of which the wave equation (for axially and radially uniform plasma with given parameters) and discharge equations (at a given value of the maintenance electric field) are treated separately with a subsequent matching of results. In this approach the plasma parameters in any plane z are determined by the local value of the power loss per unit length, $L(z)$. The latter is related with the flux of electromagnetic power $P(z)$ by the equation of electromagnetic energy balance, $L(z) = - dP/dz$. The distribution of the power flux along z axis is described by the equation

$$\frac{dP}{dz} = -2\alpha P(z) \,, \tag{5}$$

where α is the attenuation coefficient. The value of α is obtained by solution of the system of equations describing propagation of the electromagnetic wave along a plasma filament. For weakly non-uniform plasma, this system may be solved in the local uniformity approximation (e.g., [7]). That is, the value of α is related to a given position z through the plasma parameters in z plane and, hence, through the local value of $L(z)$. The distribution $P(z)$ is governed by equation (5) with the initial condition of a given power flux, $P = P_0$ at $z = 0$ (at the beginning of the discharge). The value of P decreases with z, due to absorption of the electromagnetic energy by the discharge plasma, and vanishes at some point $z = l$ (at the discharge end). The discharge model, that includes equations (1)-(3), is the same as for DC discharges. Conditions are considered when skin effect is small, and the electric field inside the plasma filament is nearly independent on the radial position. The value of E in equation (1) is related with the power losses per unit length L as

$$L = 2\pi E^2 \int_0^R \sigma(r) r dr \,. \tag{6}$$

The discharge model allows one to calculate radial distributions of plasma parameters in the cross section z as functions of the local value $L(z)$. At known radial distribution of n_e, the attenuation coefficient α can be expressed as a function of L.

3. Results of simulation

Modelling has been performed of DC discharges in cooled tubes (at T_w = 300 K) with radii R = 1-10 mm, for the current range 0.005-1 A. Figure 1 shows axial values of the gas temperature T versus the discharge current in atmospheric-pressure air. The gas temperature at low currents is nearly independent of the tube radius. In figure 2 the relation is shown between the axial values of n_e and of the gas temperature (the latter being dependent on the current, as shown in figure 1). The equilibrium, at the gas temperature, values of n_e are also shown. Deviations from equilibrium manifest themselves at low enough gas temperatures at the axis. The larger is the tube radius, the smaller is the value of $T(0)$ corresponding to the boundary between the LTE and non-LTE discharge regimes.

The model described above has been developed for discharges in tubes. In experiments [1-6], DC discharges have been studied in atmospheric-pressure air with free boundaries (without walls): low-current arc discharges between parallel electrodes, with liquid [1,6], plasma [3] or metal [5] cathodes, and gliding arcs [2,4]. The heat losses were due to convection under conditions of these experiments. Therefore, a direct comparison of the simulation results with the experimental data is not possible. Still, some common features exist between discharges stabilised by walls and those stabilised by convection. In both cases the discharge volume includes two regions: a central conducting zone (a core) and an outer region. In both cases the heat transfer from the discharge core to the outer region is due to thermal conduction, and the central part of the discharge may be described by means of the above model. Thus, with a proper choice of the radius of conducting zone, the model is applicable to discharges stabilised by convection. The measured and calculated values of the electric field versus the current are given in figure 3. Simulation results obtained using the equilibrium values of the electrical conductivity are also shown. It is seen that the measured values of E agree with the results of non-LTE calculations.

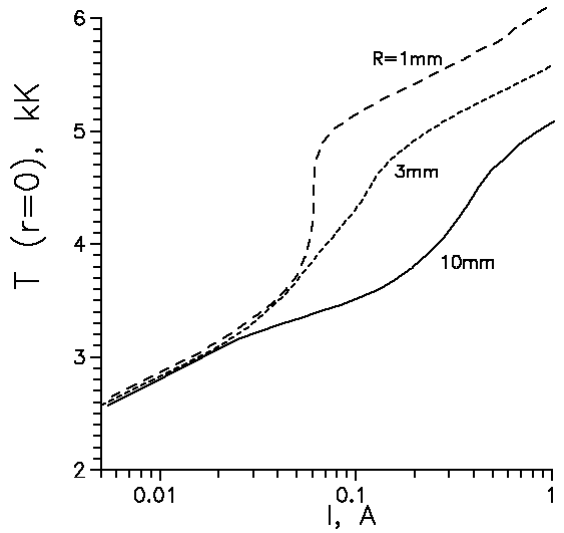

Figure 1. The gas temperature at the axis versus the current in DC discharges in air.

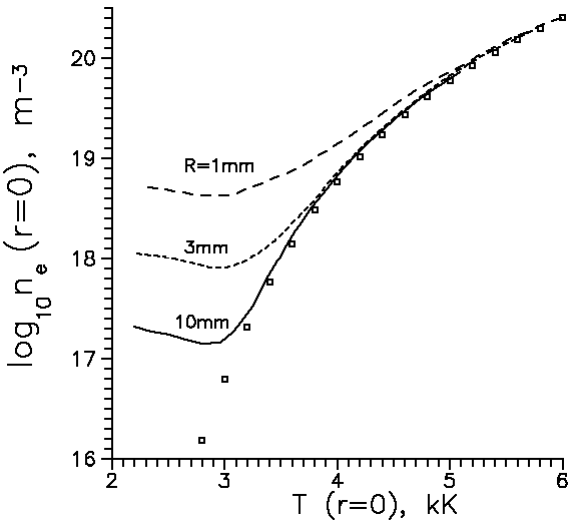

Figure 2. The electron number density at the axis versus the gas temperature at the axis of DC discharges in air. Points: equilibrium n_e values.

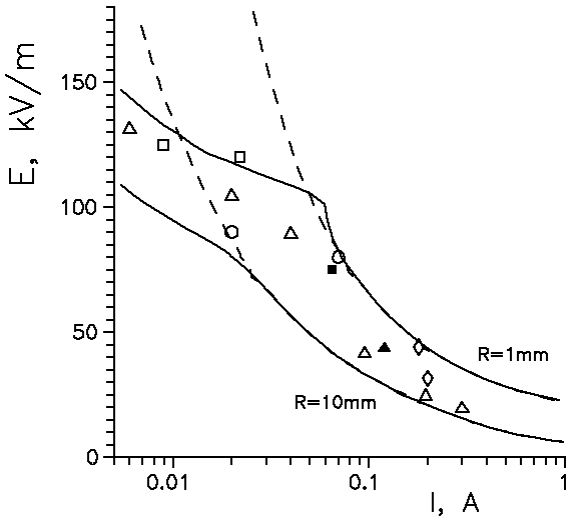

Figure 3. The electric field versus the current in DC discharges in air.
Experimental data: ○ [1], ◊ [2], □ [3], Δ [4], ▲ [5], ■ [6];
simulations: solid lines – non-LTE, dashed lines – LTE.

In figure 4 the electric field is given versus the current in discharges in atmospheric-pressure mixture of octane with air C_8H_{18}:O_2:N_2=1:4:15 (the mixture composition close to optimal for production of hydrogen), for two values of the tube radius R. Results obtained using both non-LTE (solid lines) and LTE (dashed lines) σ values are shown. It is seen that non-LTE effects become substantial at currents lower than 0.1 A. In comparison with air (figure 3), in fuel-air mixtures the transition between LTE and non-LTE regimes is sharper.

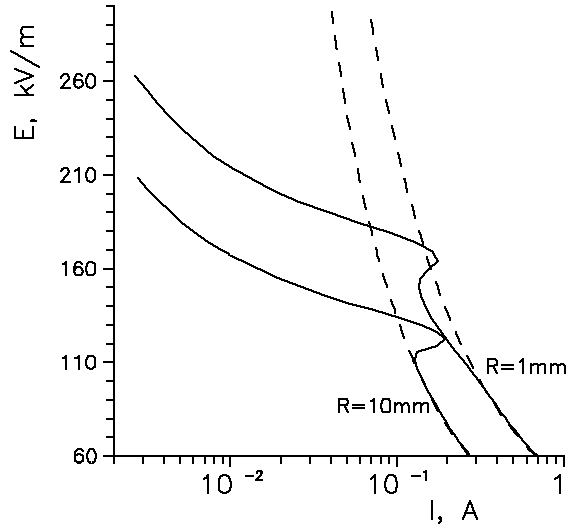

Figure 4. The electric field in arc discharge in the mixture C_8H_{18}:O_2:N_2=1:4:15 versus the current

Distributions of the axial value of the gas temperature $T_{ax} = T$ (r=0) along the surface-wave discharge in air in a tube with radius 10 mm are given in figure 5. The axial coordinate $x = l - z$ is counted from the discharge end, that is, the wave propagates from the right to the left. (Note that the increase of the total absorbed power P_0 results only in elongation of the discharge and does not influence the distributions of plasma parameters

along the discharge axis, as functions of x.) The temperature has a minimum at the discharge end and increases monotonously with x. The values of T_{ax} grow with increase of the wave frequency.

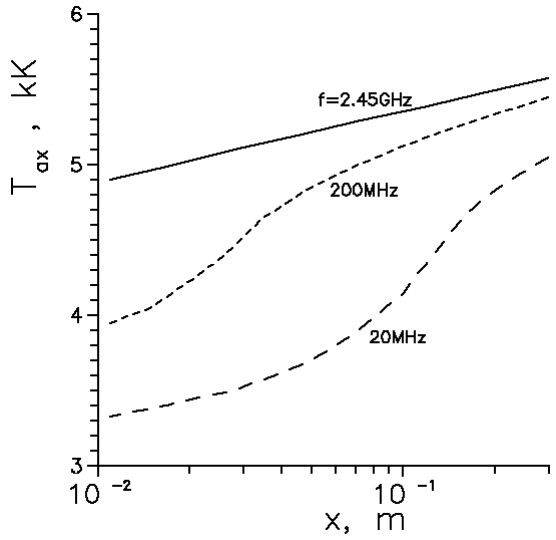

Figure 5. The distribution of the gas temperature at the axis along the surface-wave discharge in air at the tube radius R = 10 mm.

In figure 6 the values are given of the surface-wave discharge length l versus the total power P_0 absorbed by the discharge in a tube with radius R = 10 mm, in atmospheric-pressure air, nitrogen and mixture C_8H_{18}:O_2:N_2=1:4:15. In the same figure experimental data [8] are shown. It is seen that, at given P_0, the discharge length in fuel-air mixture is about three times smaller than in air.

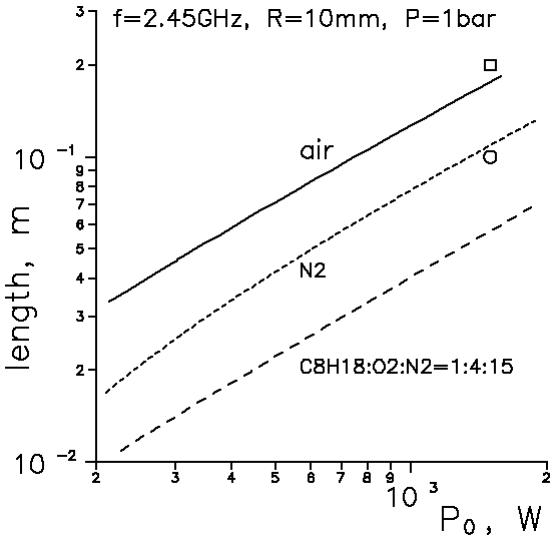

Figure 6. The surface-wave discharge length versus the power.
Points – experimental data [8] for air (square) and N_2 (circle)

Distributions of the axial value of the gas temperature along the discharge are given in figure 7, for the same conditions as in figure 6. The temperature has a minimum at the discharge end and increases monotonously with *x*. The temperature in fuel-air mixture is about 1000 K higher than in air. Calculated decrease of temperature in nitrogen-oxygen mixture (air) in comparison with pure nitrogen agrees with measurements [9].

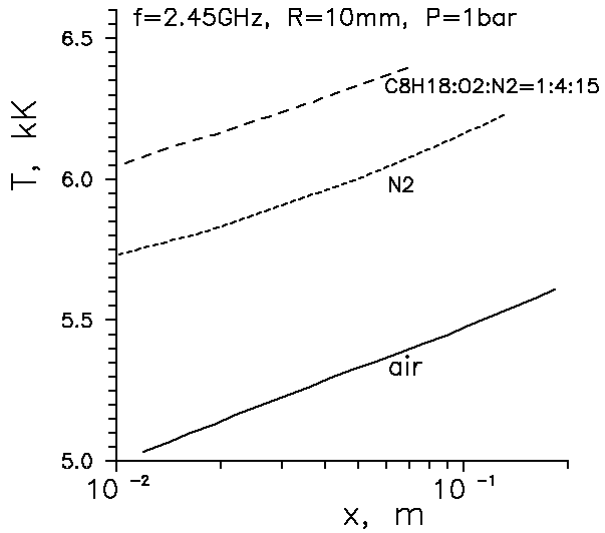

Figure 7. The gas temperature at the axis of surface-wave discharge versus *x*.

4. Conclusion

Departures of the electron density from the LTE take place at gas temperatures in the discharge core lower than 3000-4000 K. In DC discharges in atmospheric-pressure air and its mixtures with hydrocarbons such low temperatures correspond to currents lower than about 0.1 A. In surface-wave discharges the non-LTE effects may be substantial at wave frequencies lower than several tens of MHz. In microwave frequency range the discharge parameters may be calculated in the framework of LTE approximation.

Abstract

A set of experimental electron-impact total ionization cross sections (TICSs, ICSs) of CCl_4, CCl_3F, CCl_2F_2 and $CClF_3$ chlorofluoromethanes obtained with a linear double focusing time-of-flight mass spectrometer, have been compared with the *ab initio* and (semi)empirical based ICS available methods: binary-encounter-Bethe method (BEB), the Deutsch-Märk formalism (DM) and the modified additivity rule (MAR).

1. Introduction

The knowledge of the electron-impact ionization cross sections (ICS) of chlorofluoromethanes in the energy range 0-100 eV is crucial for the modelling and optimization of industrial plasmas [1]. Chlorofluoromethane molecules are widely employed to create reactive etching species in semiconductor processing plamas and in other plasmas.

In the studied energy range of electron energies most of the precursor excited electronic states and dissociative ionization channels are accessible, and the cross section curves reach their maxima. The production of highly reactive fragments and ions create efficient systems able to produce chemical attack on low reactive surfaces.

Electron impact dissociative ionization of halogen containing molecules is of importance in many applications, inasmuch as such interactions are fundamentals in low-temperature non-equilibrium production plasmas [2]. Release of halogen atoms and/or halogenated ions and radicals from these molecules make them useful in plasma vapour deposition, high quality thin films, etching of semiconductor structures, etc. Precise knowledge of ICS and other related parameters are required in the modelling of these plasma processes. The efforts to develop efficient and easily applicable theories to calculate ICS of molecules have grown considerably during the last years. However theoretical progresses are more evident in the low energy region of the electron-molecule interaction, where rotational and/or vibrational excitation are produced.

This work presents computational ICS carried out by a variety of methods and the results are compared with our experimental measurements on chlorofluoromethanes: $CClF_3$, CCl_2F_2, CCl_3F and CCl_4.

2. Experimental

Experimental ICS measurements were carried out in a time-of-flight mass spectrometer. A pulsed supersonic molecular beam of the selected chlorofluoromethane collides at a right angle with a pulsed electron beam (0.5 eV full width at half maximum, at 10 μA electron intensity and energy up to 100 eV) in the ionization region. 300 ns after the collisions are over, a negative voltage pulse is applied to the extraction grid, creating and electric field that drives the ions onto the 86.5 cm long flight tube, perpendicular to both molecular and electron beams, where a set of *x-y* plates focuses the ions onto a three-stage microchannel plate (MCP).

Reference and/or target gases were stored in a stainless steel cylinder at a pressure of about 3 bar (1% accuracy). The supersonic expansion beam was skimmed and further crossed with a well-characterized energy electron beam. Ions resulting from the collisions were converted to absolute scale by comparison with the ICS of close-in-mass reference gases (Ar or He). The absolute partial ICS for the CF^+ ion, chosen as an illustration of the method is given by:

$$\sigma_{CF^+}(E) = \frac{I_{CF^+} . n_{Ar}}{I_{Ar^+} . n_{CCl_xF_{4-x}}} . \sigma_{Ar^+}(E) \qquad (1)$$

where I_{CF^+} and I_{Ar^+} are the detector currents for CF^+ and Ar^+ ions, and n_{Ar}, $n_{CCl_xF_{4-x}}$ the gas density of the reference and precursor gas.
Total ionization cross sections (counting) were determined by adding up the partial ICS of all ions observed [3].

3. Total ionization cross sections

Electron-impact ICS have been computed by the binary-encounter-Bethe method (BEB) [4], the Deutsch-Märk (DM) formalism [5] and the modified additivity rule (MAR) [6]. Strictly speaking these methods are the most accepted in ICS determinations. However theoretical and experimental ICS agreement depends on the atom or molecule, and measurements on different molecule families are useful to clarify these disagreements.

BEB method

This method requires molecular orbital energies (B), and average kinetic energy (U) knowledge, and the ICS as a function of the kinetic energy of the incident electron (T) is computed as

$$\sigma_{MO}(T) = \frac{S}{t + \frac{(u+1)}{n}}\left[\frac{\ln t}{2}\left(1-\frac{1}{t^2}\right)+1-\frac{1}{t}-\frac{\ln t}{t+1}\right] \qquad (2)$$

with t=T/B; u=U/B and $S=4\pi a_o^2 N(R/B)^2$; a_o is the Bohr radius, R the Rydberg energy, N the occupation number, and n is an empirical parameter to be applied for molecules that contain atomic like orbitals with quantum number n≥3.

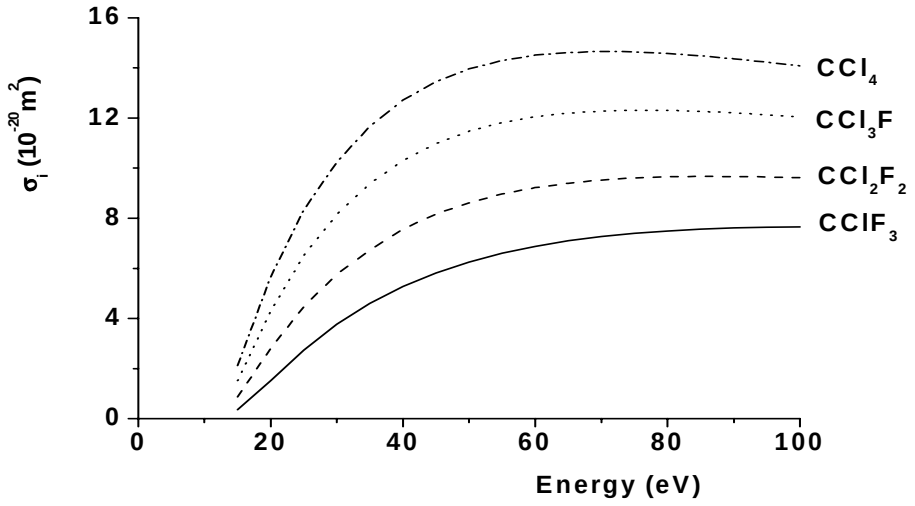

Figure 1. Total ICS computed by the BEB method for CCl_xF_{4-x} molecules

DM formalism

The Deutsch-Märk formalism is an extension to molecular species of earlier models for the electron-impact ionization of ground state atoms. This method computes ICS as:

$$\sigma_{MO}(T) = \sum_j g_j \pi r_j^2 \xi_j f(u) \qquad (3)$$

where g_j are weighting factors which value is atomic orbital dependent, r_j the mean atomic radius of each atomic orbital and ξ_j the atomic orbital contribution determined by a population analysis (for example by the Mulliken method). The function f(u) describes the energy dependence of the ionisation cross section and is related with both electron kinetic energy and ionization energy, its explicit form has different values for s-, p-d-, and f-electrons.

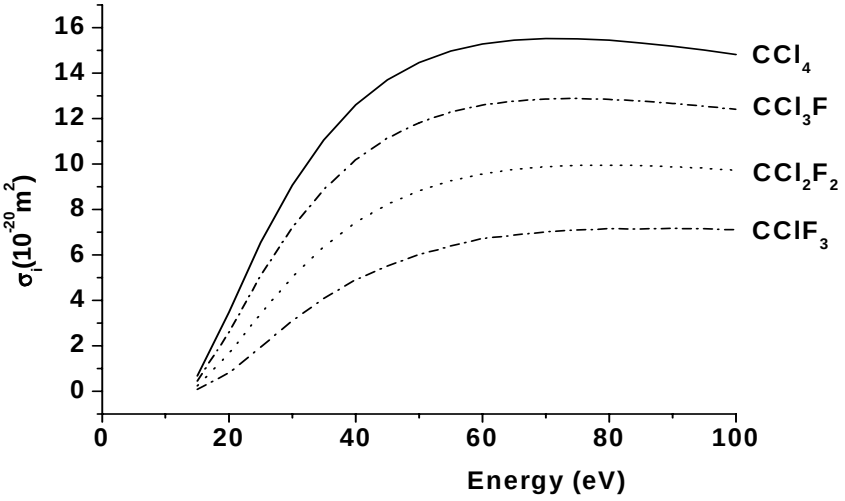

Figure 2. Total ICS computed by the DM method for CCl_xF_{4-x} molecules

MAR approach

The molecular additivity rule is a semiempirical method. Total ICS is given by the sum of weighted ionization cross sections of the different atoms of the molecule:

$$\sigma(CCl_xF_y) = f_C\sigma_C^+ + xf_{Cl}\sigma_{Cl}^+ + yf_F\sigma_F^+ \quad (4)$$

where f_C, f_{Cl} and f_F are parameters related to the number of atoms, the atomic radii and the number of electrons.

Molecule	$\mathbf{f_C}$	$\mathbf{f_F}$	$\mathbf{f_{Cl}}$
CCl_4	0.12	-	3.89
CCl_3F	0.16	0.26	5.17
CCl_2F_2	0.16	1.32	1.77
$CClF_3$	0.16	4.43	0.42

Table 1. MAR coefficients for ICS determination of chlorofluoromethanes

Experimental results

Figure 3 shows experimental results of total ICS for CCl_2F_2, $CClF_3$ and CCl_4 molecules.

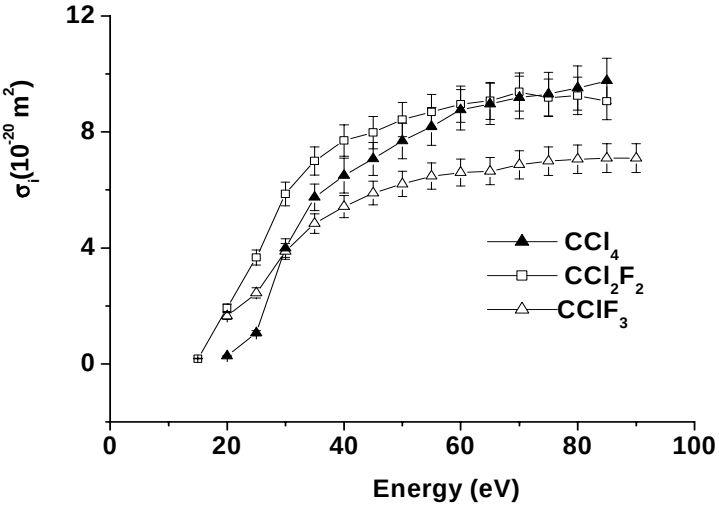

Figure 3. Experimental total ICS for CCl_2F_2 and $CClF_3$ molecules

A discussion on the theoretical and experimental ICS agreement, along this chlorofluoromethane family, will be presented.

Influence of DC voltage field on ion and O_3 formation in a high frequency surface discharge

M.V.Kozlov[1], M.V.Sokolova[2], A.G.Temnikov[2], V.V.Timatkov[2], I.P.Vereshchagin[2]

Possibility of intensification of plasma chemical processes that go on in a high frequency surface discharge is analyzed. The HF discharge is generated on a surface of a ceramic plate with metallic stripes on its surface and a metallic layer on its other side. Such element is used generally as an ozone generator. The frequencies of the applied voltage are in the range 500-6000 Hz.

When a DC high voltage is applied to a metallic plate placed 5 – 15 mm above the ceramic plate surface (the DC electric field being in the range 3 – 12 kV/cm) a DC current appears connected with ion movement in the gas gap between the surface discharge layer and the metallic surface.

As the DC current is defined by the intensity of the ion formation in the HF surface discharge, it depends on the surface discharge conditions such as the frequency and amplitude of the applied HF voltage and on the field intensity of the DC voltage. In addition to this fact an influence of the type of the ceramic material of the dielectric barrier on the ion and ozone formation intensity has been registered.

Theoretical equations for current characteristics and ion concentration are derived. Calculations based on these equations show good coincidence with experimental current values. An analyze of the results for a wide range of the frequency and amplitude of the applied HF voltage shows that there is a significant increase of ozone formation with an increase of the DC voltage. The investigations have shown also that for high values of the frequency and amplitude of the HF applied field the concentration of ions near the surface of the barrier increases with an increase of the DC field and this fact is explained by an increase of the thickness of the ionized gas layer near the barrier.

At the same time it has been found that this increase can be only for a certain range of surface discharge conditions. More of it such range depends on the material of the dielectric barrier.

PEG/PMAA patterned structures performed by plasma treatments; stabilisation and etching

Abstract
In this work we report the processing of micropatterned templates based on the non fouling Polyethylene glycol (PEG) and the functional surfaces of polymethacrylic acid (PMAA). Two Ar plasma treatments were optimised to: a) stabilise the inherently soluble spin casted PEG and b) to expose the underlying PMAA through a masked etching treatment. Both spectroscopic and surface morphology techniques have been used to characterise these devices.

1. Introduction

Patterned polymer surfaces present ideal properties for performing biomedical assays at molecular and cellular level. On one side, a polymer with high affinity towards the target biomolecule can be prepared while the negative part is formed by depositing a non-fouling film. With this configuration a biomolecule can be constrained to certain regions of a surface (f.i. in order to detect it [1]) or a group of cells can be forced to follow a desired distribution (f.i. for cell physiology and cellular engineering [2]).
Polyethylene glycol (PEG) is a reputed non-fouling polymer. However, it forms unstable films that dissolve in water [3] so that a stabilization treatment is required for the processing of a device. Stable PEG films can be performed in different ways. PEG silanes can be grafted to a glass or silicon surface after an intense acid treatment [4,5]. Gold surfaces can be also coated by using an oligo(ethylene glycol) associated to a thiol group which leads to self assembled monolayes of great fundamental interest.
However, these chemical techniques present a main drawback since they are not universal (not every substrate can be used). Thus, physical methods applied to spin casted PEO films can give an added value if they prove their non-fouling reliability. In this frame, photo and ionizing irradiation inducing random cross linking can be expected to have a favourable effect towards stabilization [6].
On the other hand, Polymethacrylic acid (PMAA) contains carboxylic groups which can be activated to functionalise its surface. PMAA combines the stability of polymethylmethacrilate with the biofunctional properties of polyacrylic acid. These polymers frequently used in the biomedical field, ensure a high quality response of this polymer in biomolecular assays.

2. Materials and Methods

The polymers PMAA (in practice methacrylic acid-methylmathacrylate copolymer, Mw 500000, Fluka) and PEG (Mw 6000, Fluka) were dissolved in methanol and trichloroethylene respectively. The solutions were used to form films onto Si (100) substrates for analytic purposes and finally PEG/PMAA/Si structures were also grown for device processing. The device preparation scheme is presented in figure 1.Firstly, a plasma treatment in a distributed electron cyclotron resonance (DECR) reactor is applied to the PEG surface in order to stabilize it. A microwave power of 1400 W (2.45 GHz) was supplied to the Ar plasma (10 sccm, 1 mTorr) for 30 s. Ar ion energy was further increased by applying a –50 V RF bias (13.54 MHz) to the substrate holder. After covering with a mask, a second plasma treatment is applied in order to etch the non fouling polymer reaching the PMAA surface and rendering its carboxylic groups active. In this case MW power was 1000 W and the RF bias reduced to –25 V increasing the treatment time to 120 s.
Plasma diagnostic techniques (Langmuir probe and mass spectrometry) were used to monitor relevant plasma parameters such as ion densities and temperatures. The film characterisation was performed by using Fourier transformed infrared spectroscopy (FTIR, Bruker Vector 22, 4 cm^{-1} res.), X-ray photoelectron spectroscopy (XPS, Ultra photoelectron spectrometer, KRATOS UK, monochromatic Al Kα 150 W, high resolution pass energy 20 eV, operating pressure, 2.10^{-9} mTorr), atomic force microscopy (AFM, NT-MDT Solver-Smena head, silicon cantilevers k= 5 N/m and first harmonic frequency of 158 KHz), scanning electron microscopy (SEM, LEO) and contact angle measurements (CA, DGD Fast/60, GBX technologies).

Finally the device processing parameters were obtained with the help of a quartz crystal monitor (QCM, LH Inficon deposition monitor).

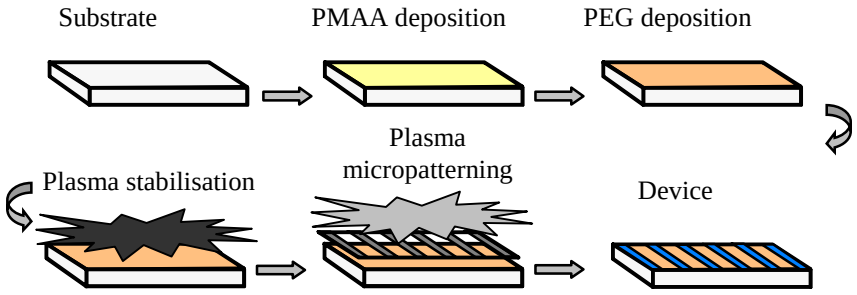

Figure 1. Scheme of the procedure followed for the processing of the PEG/PMAA biomedical micropatterns by using a double step plasma treatment.

3. Results and Discussion

The stabilisation treatment of the spin casted PEG was monitored by studying the changes induced by the plasma treatment on the molecular configuration of the polymer. Figure 2 depicts the FTIR spectrum of the PEG film after modification in the DECR reactor in comparison with an as spin casted film. The bands detected in both samples are in accordance with those reported for high quality PEG crystals [7]. Two main differences between the etched and the as deposited samples are worth to note. First, the notable decrease in the film absorption (the thickness of both PEG films was identical before the plasma treatment), which indicates that the plasma treated PEG experiences an intense etching process. Remarkably, this decrease is not homogeneously distributed being more acute in the case of bands oriented in parallel to the polymer backbone (indicated with ▲ in figure 2). This preferential decrease can be clearly evidenced by comparing the changes in relative intensities between the following pairs of perpendicular-parallel bands: 1358-1342 cm^{-1}, 1278-1240 cm^{-1}, 947-958 cm^{-1}. These features indicate a drastic modification of the molecular structure. The originally linear polymer chains are broken by the Ar ions and reorganise giving a branched-crosslinked structure.

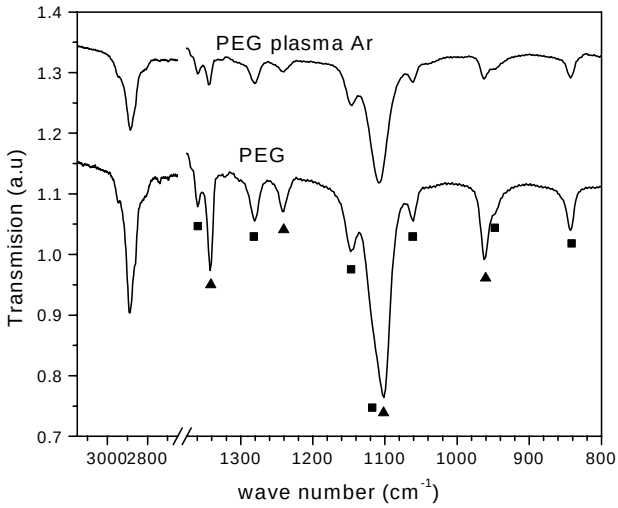

Figure 2. FTIR spectra corresponding to as deposited (bottom) and plasma treated (top) PEG films. (▲, ■) Modes parallel and perpendicular to the polymer backbone, respectively.

As derived from the evidences of the intense etching process, the plasma treatment was selected as to be energetic enough to produce crosslinking, but short enough as to avoid excessive sputtering. In order to optimise the treatment, plasma diagnostic techniques allowed us to derive that, the mean energy of the Ar+ ions followed a linear behaviour with respect to plasma power, reaching a value of 18 eV for 1400 W. The extra energy and directionality supplied by the bias RF voltage was found to increase the PEG film stability at any plasma power tested. However, films stabilised at plasma powers lower than 1400 W could not be satisfactorily processed requiring too long plasma exposure which made etching processes dominant.
A first evaluation of PEG film stability was performed by water CA. A clear change in the wettability dynamics was observed between the as deposited and the plasma modified film. Water droplets on the as spin casted films presented an initial CA of $14^{o}6$. In the following seconds the droplet retracted and stabilising at $24^{o}3$ after 5 s. This tendency, attributed to a modification of the water surface tension as a result of the polymer solubility, was not observed in the plasma treated samples. A stable CA of $20^{o}4$ was measured in this case, evidencing a certain decrease in the PEG film hydrophilicity.

The surface of the functional PMAA were characterised by XPS in order to evaluate the content of the carboxyl functional group. Figure 3 presents the XPS spectrum corresponding to the as spin casted films. The raw spectrum (dots) could be deconvoluted on the basis of four components which stand for the four main C 1s interactions in the polymer [8]. From lower to higher binding energies the peaks were assigned to: C-C, CH-COOH, CO-COOH and -COOH. In such films the carboxyl content (peak 4) was estimated to be at around 15 % of the C surface composition.
The plasma treatment was observed to modify the polymer carboxyl content. In order to minimise the loss of carboxyl groups when performing the device, the plasma power was reduced to 1000 W for the etching of the overlaying stabilised PEG film. In this conditions the carboxyl content remained over the 10% of the C surface composition.
CA measurements also confirmed that the plasma treatment induces a modification of the PMAA surface composition. Water CA's were observed to reduce from $62^{o}4$ to $58^{o}2$ after the plasma etching treatment. The total formamide wettability of as deposited and plasma etched PMAA surfaces confirmed that surface tension of this polymer presents in both cases a preferential acid polar component. However, the reduction of the water CA after the Ar plasma treatment indicates a slight increase of the base polar component.

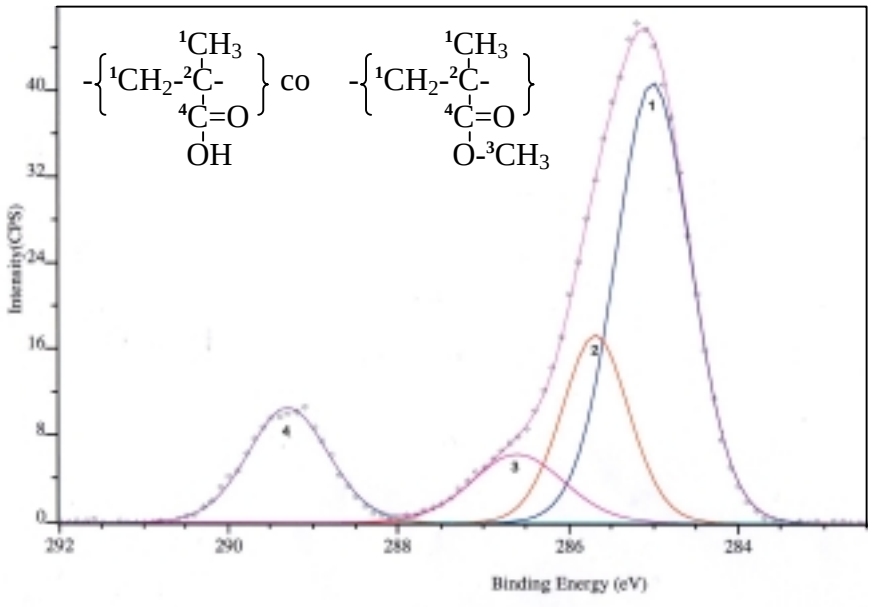

Figure 3. XPS C1s spectrum of PMAA as casted from 2% methanol solution. The peak is de-convoluted in four components.

This behaviour of the CA on PMAA surfaces is in agreement with the loss of carboxylic groups detected by XPS. In any case, the difference in water CA's between the stabilised PEG and exposed PMAA ($20^{o}4$ against $58^{o}2$) evidences the relevant contrast in the wettability properties.

A QCM was used in order to help in the determination of the device processing parameters. The curve presented in figure 4 stands for a two step plasma process inducing two major mass reduction slopes. The first step produced a very intense mass decay as a result of the high energy input (MW plasma and RF bias). The lower slope of the mass decay in the second step confirms the milder plasma conditions during the final etching of the PEG film to expose the PMAA film. In the early stages of the second step the curve clearly shows a non constant derivative. As long as the time passes the derivative becomes almost constant and not so steep as a result of the etching of a denser material. Polymers present non uniform etching yields that induce non constant derivatives while dense homogeneous materials (i.e. gold underlying contact) present an almost linear mass decay. Devices performed on Si confirmed that limiting the second plasma treatment time to 120 s (i.e. non constant derivative region) the etching process was stopped at the PEG/PMAA interface. The samples were subsequently observed by AFM to confirm these features.

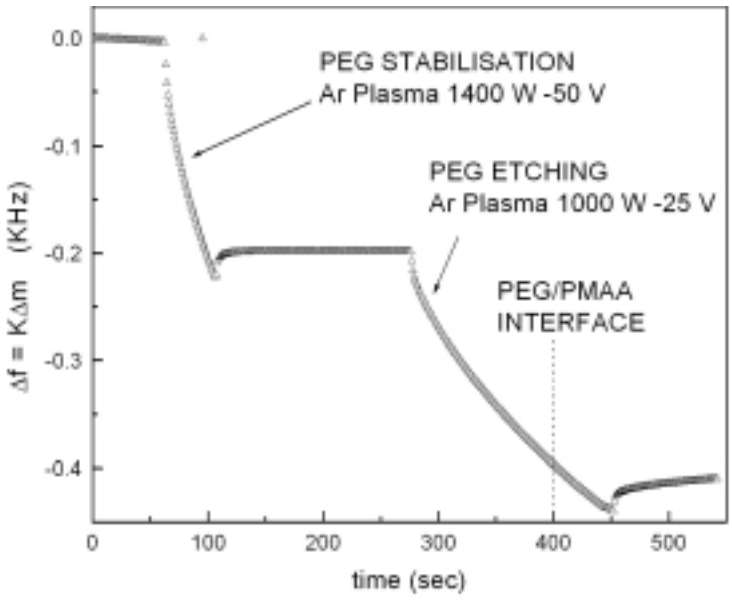

Figure 4. Quartz crystal monitor profile of a PEG/PMAA device.

SEM and AFM images were used to show the morphological changes induced by the plasma treatments on the PEG/PMAA device. The SEM image presented in figure 5a shows a general overview of the device with 500 μm homogeneous stabilised PEG regions separated by 50 μm wide PMAA stripes. Higher magnification images were obtained by AFM. The as deposited PEG is characterized by a polycrystalline organization [9] with grains with the typical size of hundreds of micrometers. Inside these micro-grains there are long parallel chains of flake-like elements with well defined shape and typical lateral size of 300 nm.
The AFM image presented in figure 5b evidences that the Ar plasma induces a redistribution of these long chains, mainly as a result of the intense sputtering process co-induced during stabilisation. The crystalline structure is modified and a new morphological organization occurs. The modified film is characterized by deep wrinkle–like structures. The lateral size of the hills and the grooves is 5 μm and the typical peak-to-valley height is 150 nm. Figure 5c shows a detail of the PMAA stripe with the neighbouring PEG. It can be outlined that the particular morphology of the stabilised PEG is transferred to the PMAA surface after the plasma etching treatment. In this case the typical peak-to-valley height is reduced to 40 nm. The transfer of the PEG treated morphology to the PMAA surface is due to the high directional character of the Ar ions in the plasma discharge induced by the RF bias applied to the sample. The thickness profile presented in figure 5.d clearly illustrate these features.

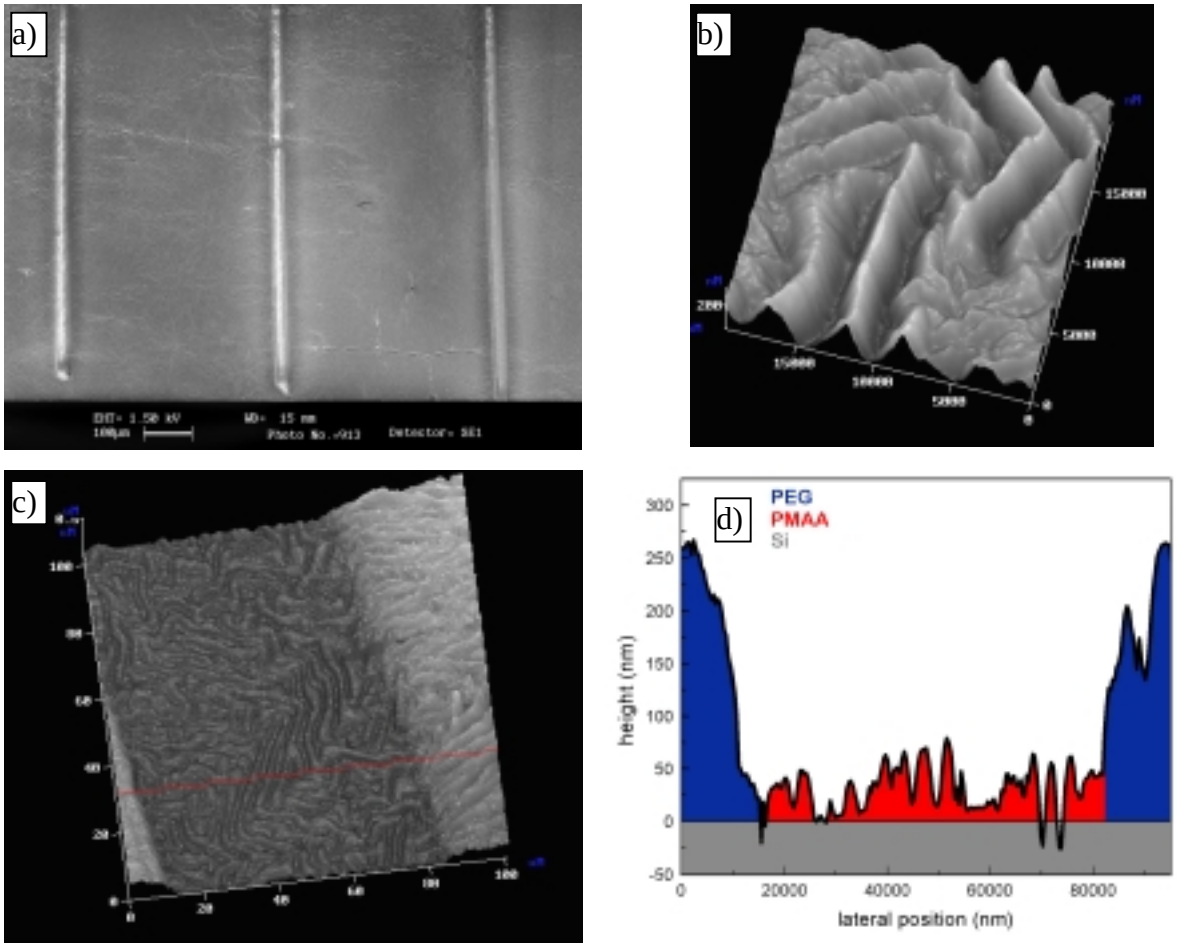

Figure 5. (a) SEM image of the device surface with three 50 μm PMAA stripes spaced out by 500 μm PEG regions. (b) 20x20 μm AFM image of the PEG surface. (c) 100x100 μm AFM image of one etched stripe of the device. The darker region corresponds to PMAA exposed after plasma etching while the clearer one corresponds to stabilised PEG protected by the nickel mask. (d) Cross section from the horizontal line in (c). The etched film thickness is approximately 200 nm setting the height zero at the PMAA/Silicon interface.

4.Conclusions

A procedure for the processing of micropatterned PEG/PMAA structures has been described. Before device processing, the plasma treated films of both PEG and PMAA were analysed independently by surface characterisation techniques. FTIR measurements showed the presence of crosslinking on PEG films as deduced from the changes in the relative absorption of bands assigned to parallel and perpendicular modes. XPS was used to follow the behaviour of the PMAA carboxylic group along with different plasma treatments. Furthermore, PEG water CA's were observed to increase after the plasma treatment as a result of the reduction of the dissolving interactions. In the case of the PMAA surface, the XPS results were correlated with CA measurements, which allowed to explain the changes induced in the polymer surfaces after the plasma treatment in terms of evolution of the surface tension components. A topographic evaluation of the film was performed by atomic force microscopy. Near contact images revealed that the surface roughness of the films was increased during the treatment but remained in any case below 150 nm for both polymers after the final plasma treatments selected for device processing.

The first assays in biomolecular media are in progress in order to prove the functionality of the PEG/PMAA micropatterns. From the biomolecular point of view, protein attachment tests will be performed in order to illustrate whether the Carboxylic groups in PMAA retain their functionality and the stabilised PEG behaves efficiently as a non fouling film. From the cellular point of view, these structures are of significant interest because of the competitive chemical and topographical mechanisms towards cell attachment [10].

Structure and current characteristics of surface discharge for different kinds of barrier materials

M.V.Sokolova, A.G.Temnikov, V.V.Timatkov

Dept. Of Electro Physics and High Voltage Technique, Moscow Power Engineering Institute Technical University), Moscow, Russia

Recent publications show that surface discharge can be effectively used for modification of the surface of dielectric materials, especially of polymers. The intensity of the treatment depends on the discharge structure and on the kind of the high voltage applied. Our previous studies [1] have shown that the electrical and structure characteristics of the discharge in its turn depend on the applied impulse voltage amplitude and its duration and on the ceramic material used as the dielectric barrier. As a result the intensity of the ozone formation can change as well if the surface discharge element is used for ozone production.

The above investigation has been extended on a more wide range of the dielectric barrier materials including not only ceramics, but polymer material as well.

To analyze the influence of the polymer material several polymers have been used such as Plexiglas, Polytetraftorethylene, Polyvynylchloride, Polyethylene that have very near values of surface and volume resistance and ε values. The electrode system consists of a metallic stripe (1 mm wide and 50 μm thick) on the surface of a dielectric barrier (its thickness being in the range 1-2 mm) with a wide metallic layer on the other side of the dielectric plate. To analyze the discharge structure voltage pulses of nanosecond duration (350 ns) and different polarity and dust technique have been used. The dust figures permit to see the charge distribution on the barrier surface after the discharge.

In all cases of positive discharge a distinct discrete structure is seen but for negative polarity much depends on the amplitude of the applied voltage and polymer material. Current pulses of the discharge are analyzed and show a certain dependence on the material as well.

Molecular dynamics simulations of radical-surface interactions: Growth of amorphous carbon films

D. Humbird[1] and D. B. Graves[1]

[1] *Department of Chemical Engineering, University of California, Berkeley, USA*

Radical-surface interactions are often crucial in plasma and beam technologies. While molecular dynamics (MD) simulations have proved useful for modeling ion impacts on surfaces, they have been less successful in simulating the reactions of radicals on surfaces, mainly because these occur on larger time scales than are tractable with MD.

Using the REBO interatomic potentials for carbon and hydrogen developed by Brenner and coworkers [1], we have considered the growth of amorphous hydrogenated carbon films from beams of H· and CH_3· radicals. The experimental beam studies of von Keudell and coworkers suggested that the rate-limiting step in film growth is abstraction of a surface H by an incident H· to create a dangling bond where an incoming CH_3· can attach [2,3]. Initial simulations confirmed this to be case. By treating the abstraction process with a pseudo-steady-state approximation, we greatly accelerated our simulations of carbon film growth, e.g. the one shown in Fig. 1, which was deposited with 1eV CH_3·. We feel the high kinetic energy helped to bring the reaction probability to observable levels without changing the mechanisms significantly.

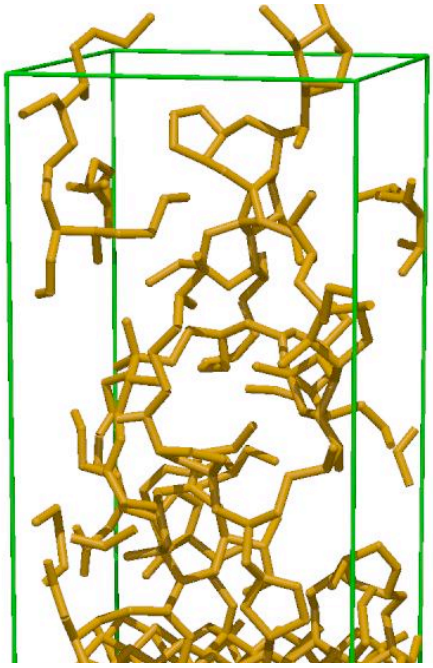

Fig 1. Complex structure of hydrogenated carbon film grown on diamond (100) surface. Hydrogens are not shown.

The film growth mechanisms from the simulations are in good qualitative agreement with the beam experiments: H· abstracts H to create a dangling bond and CH_3· saturates it. At first, growth occurs in chains originating from the surface. As the film grows larger, the chains branch into complex tree structures. As the structure becomes more complex, dangling bonds appear near each other and cross-links and rings are formed. The formation of these new C—C bonds in the film reduces the H/C ratio. The density of our film is the same as in the experiments (1 g/cm^3), but the H/C ratio is higher—about 1.7, compared to 1 in the experiment.

Abstract

A cryogenic process is used to etch high aspect ratio silicon structures. An inductively coupled plasma of SF_6/O_2 is created and expands through the diffusion chamber to a biased silicon wafer. This configuration was used to study silicon drilling by plasma for via production from one side to the other side of the wafer. Etching rates as high as 7 µm.min^{-1} were reached with 12 µm diameter vias using this process. A parametric study of the process performances is presented.

1. Introduction

Deep silicon dry etching processes are used for the elaboration of integrated components in power microelectronics and for MEMS and MOEMS fabrication (see for example references [1,2]). For example, deep trench isolation is necessary to separate active components on chips and requires etching of high aspect ratio silicon structures. In this paper, we present the etching of high aspect ratio via structures. As integrated circuits require a high level of integration, electrical connexions can be reported to the backside of the wafer increasing the integration level. Connexions are made by means of resistive vias, which cross the wafer from one side to the other side (400 µm thick wafers). Via etching is performed using an ICP plasma reactor and the so-called cryogenic process for deep silicon etching.

Deep silicon dry etching can actually be achieved by different processes. The Bosch process, which is intensively studied and used for industrial production and especially for MEMS fabrication [1,2], operates at ambient temperature [3]. It consists of alternative steps of etching (SF_6 plasma) and deposition (C_4F_8 polymerizing plasma). In this process, a passivating layer is obtained on the sidewalls during the deposition step. The passivating layer deposited on the trench bottom is sputtered during the etching step by incident ions accelerated in the plasma sheath. Even if it is currently used, some particular characteristics due to the Bosch process itself (scalloping, deposition on the reactor walls, long dead times necessary for gas changes…) can appear as a drawback for some component elaboration. When such drawbacks have to be avoided, the so-called cryogenic etching process can be a good alternative, if it is perfectly controlled.

The cryogenic etching process requires a low chuck temperature of about –100 °C to form a passivating layer on the sidewalls while silicon is etched on the trench bottom. The plasma is composed of a SF_6/O_2 mixture. Cryogenic etching was first studied by Tachi et al. in 1988 [4] and by other teams (see for example reference [5]). Trench slopes can be adjusted by changing the wafer temperature [6], which could be of interest for designing special MEMS. A high etch rate (ER > 5 µm.min^{-1} for a 5 µm aperture trench) and very large selectivity Si:SiO_2 (~1000) were obtained using this process [7,8]. However, the passivating layer seems to be much more fragile than in the Bosch process [9].

In this paper, we will present our last results on silicon via drilling. Some experiments have been carried out to decrease local bowing effect and improve the passivation layer efficiency present on sidewalls. Since Aspect Ratio Dependent Etching is an important phenomenon in this kind of structure, vias were first etched on one side and etched on the other side. Endpoint detection was carried out when vias join at about the middle of the wafer. Drilling is faster by using this technique. At lower temperature, crystal orientation dependent etching can appear [10,11]. This phenomenon can be responsible for negative slope observed when temperature is lower than in the working point. We will discuss this aspect as well.

2. Experimental setup

Via drilling is performed in an Alcatel 601 etcher. A schematic of the machine is given in reference [8]. A mixture of SF_6 and O_2 gas is introduced in the reactor. The plasma is created inductively with an antenna excited at 13.56 MHz, placed around an Al_2O_3 tube. The maximum incident power is 3000 W. Plasma confinement is supposed to be enhanced by a magnetic field produced by a coil surrounding the tube. The plasma expands towards the diffusion chamber where an electron density as high as 10^{10} cm^{-3} is obtained for a total pressure of about 3.10^{-2} mbar. The silicon wafer to be etched is located in the lower part of the diffusion chamber. We use (100) wafers with 35 Ω.cm resistivity. The wafer is independently self biased using an RF capacitive coupling. The ion energy on the wafer can be varied from 10-15 eV (plasma potential) to several hundreds eV. The wafer is mechanically clamped on a cryogenic chuck cooled by liquid N_2. A good thermal conductivity is ensured by 10 mbar of helium gas flowing at the backside of the substrate. The wafer temperature (~ -110°C) is maintained by ohmic heating of resistances placed at different positions of the chuck. After etching, the wafer is cleaved with a clivage machine equipped with a binocular system to cut along a line of vias and in the middle to study the profile on the cross section. Via patterns (aperture, depth, slope, and defects) are measured by Scanning Electron Microscopy (SEM) with a Leica Cambridge Ltd. S360 microscope.

3. Optimization of cryogenic process for via drilling

The cryogenic process has been previously used to etch trenches with a high aspect ratio (depth up to 100 µm) [7, 8]. As mentioned in the introduction, the aim of this work is to drill 400 µm thick silicon wafers and to form 20 µm diameter vias. To optimize the process, etching is carried out in two steps on each side of the wafer. To efficiently etch a silicon thickness of 200 µm without defect, a previous process we used for trench patterns is actually modified. Indeed, a constant ratio O_2/SF_6 can induce defects on via sidewalls in the end of the process, because oxygen is not sufficient to maintain the passivation layer during the whole process. In order to prevent those defects, passivation mechanisms must be activated and increased during the process. Hence, oxygen concentration must be increased while the total area of the via sidewalls increases. With a linear increase of oxygen content in the plasma, via profile can be preserved as shown in Figure **1**.

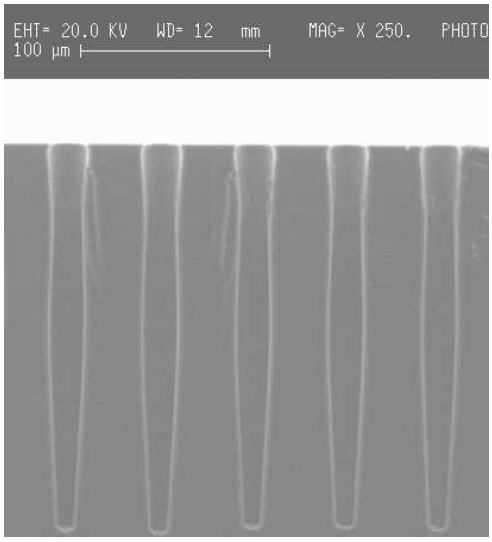

Figure 1 : SEM picture of 12 µm diameter etched vias. (Depth : 210 µm ; final diameter < 19 µm)

Via drilling has been studied for various via diameters: from 9 to 30 µm, some process parameters (SF_6/O_2 ratio and bias voltage) are optimised in each case to obtain a depth between 130 to 200 µm depending on the via aperture.

Industrial specifications concern not only the etching depth but also the final via diameter, which must remain below 20 µm (with an initial diameter of 12 µm). To achieve this specification, it is necessary to

reduce etching defects such as bowing and undercut. The next section is dedicated to the reduction of bowing [12].

4. Reduction of bowing

In via etching, bowing appears during the first minutes of the process. As mentioned in a previous study [12], the bowing origin can be due to ions, which can sputter the passivation layer present on the sidewalls. In that case, oxygen content in the plasma seems not sufficient to form an efficient passivating layer. To limit the bowing effect, etching rate is reduced during the first minute of the process using a lower SF_6 flux and an O_2 flux varying linearly. After this step called "soft etching", the process is continued with the standard process parameters. Results on bowing are presented in **Figure 2**. The bowing evaluation in standard conditions is indicated on this figure. As appearing on the figure, an increase of O_2/SF_6 ratio reduces bowing effect. But for a O_2/SF_6 ratio higher than 13.5 %, black silicon appears, which indicates an over-passivating regime.

27 µm diameter vias dedicated to this particular study were etched to facilitate the cleavage before analysis. Nevertheless, this technique to reduce bowing effect has been successfully applied to 12 µm vias, leading to a significant reduction of bowing and undercut.

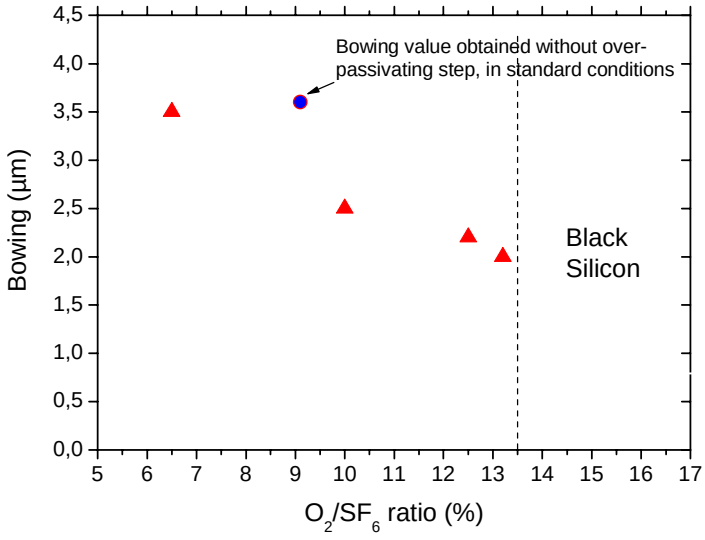

Figure 2 : Bowing evolution versus O2/SF6 ratio during the first step of etching

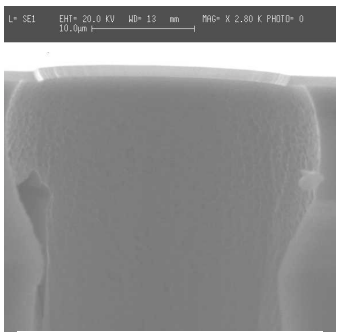
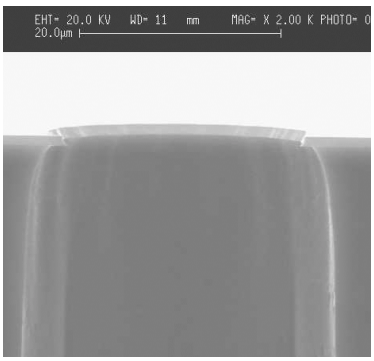
(a)



Bowing: 3,6 µm

(b)



Bowing: 2 µm

Figure 3 : Top of etching vias : (a) standard point process,
(b) insertion of a passivation step at the beginning of the process

In optimal conditions, bowing can be reduced by a factor of about 50% without affecting the etching rate as this passivation is only done during a very short time (1 minute). Scanning electron microscopy images of the top of the via are presented in **Figure 3**.

5. End point detection

As illustrated in Figure 4, vias of each side join in less than one hour corresponding to an average etching rate as high as 7 µm.min^{-1}. The etching of the upper part of the wafer was first performed. During the 10 first minutes, the etch rate is greater than 10 µm.min^{-1}. The profile is quite vertical on the first 100 µm. Then, the profile slope becomes positive. Up to 230 µm depth silicon was etched during this first step. The backside etching was performed in the same conditions.

(a) (b)

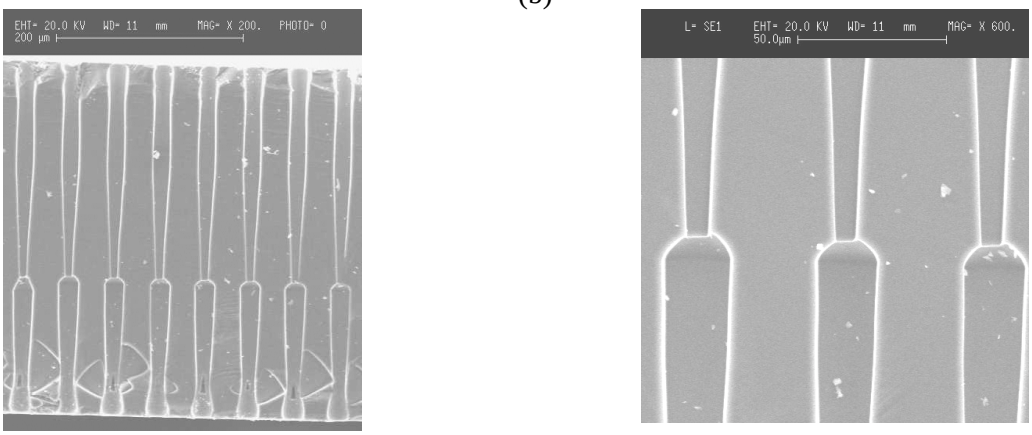


Figure 4 : SEM pictures of vias drilled in both sides of a wafer. The upper part was first etched (30 minutes process). The wafer is then returned to etch the backside. (b) is a zoom of (a)

As appearing in Figure 4, via profiles are different for each side of the wafer, whereas the same process is used for both sides. The profile slope of the backside vias is negative. This different profile shape could be due to the fact that temperature was not exactly the same for both sides during the proces. When the temperature is too low, profile slope is usually negative [10]. When the wafer is returned in order to etch the backside, we have to take into account the fact that vias which we observe were not etched exactly at the same position as the ones appearing on top side, excepted if the vias are exactly in the middle of the wafer (see Figure 5). In the case of figure 4, we were not able to cleave the wafer exactly at the center of the wafer to observe via profiles. Since the vias which were etched were not exactly at the same position on the chuck, there might be a difference in temperature. The cryogenic process is very sensitive to temperature variations. One degree difference is sufficient to modify the profile shape. We plan to use an electrostatic chuck equipped with a cooling system achieving a very high uniformity in temperature on the wafer.

But another mechanism can explain this profile difference. Due to the presence of the etched vias on the first side, temperature regulation can be perturbed.

The process duration of the front side must be reduced to make vias join in the middle of the wafer. End point detection is obtained by the helium leakage occurring at via junction. Plasma is maintained few minutes after the junction to make sure that all vias are joined.

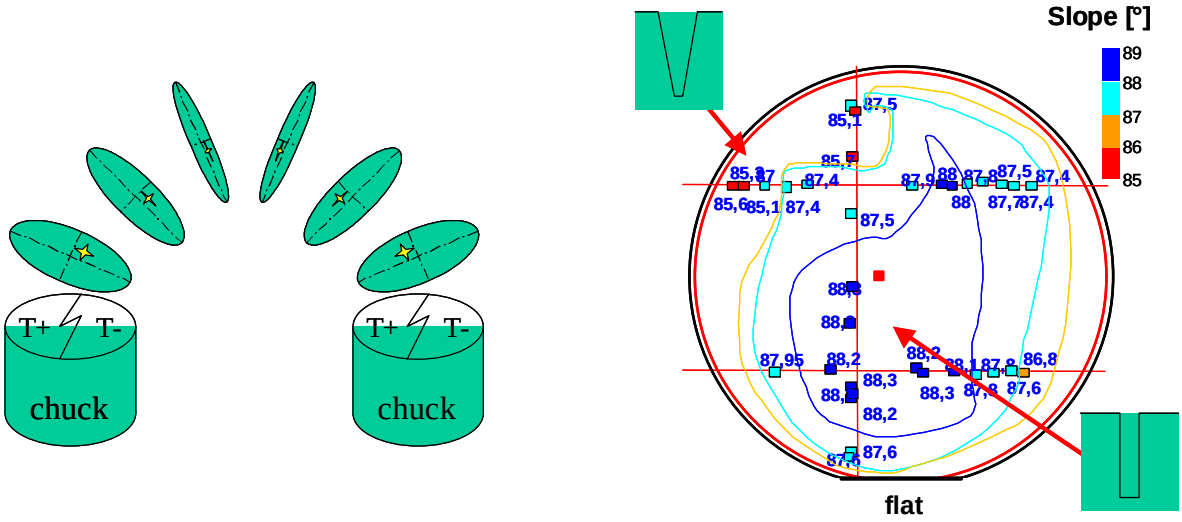

Figure 5 : (left) Schematic diagram, which shows that analyzed vias from both sides are not etched at the same position on the chuck. Wafer temperature is not highly uniform on the wafer surface and can induce some difference in the profile slope.

(right) : wafer mapping showing the trench slope value obtained on a wafer, which is directly connected to temperature non uniformity.

6. Crystal orientation dependent etching

As mentioned in some other papers, crystal orientation dependent etching can appear at very low temperature [10, 11, 13]. We have also observed this mechanism. Etching rate is enhanced in the <111> crystal direction. This effect can be responsible for the negative slopes, which are observed when the wafer temperature is lowered. As shown in figure 6-a, in this case of very low temperature, the etching rate is composed of two components: one high vertical component (V_G) and another one (V_C) in the <111> direction. The total etch rate leads to a negative slope as appearing in figure 6-a and -b.

(a) (b)

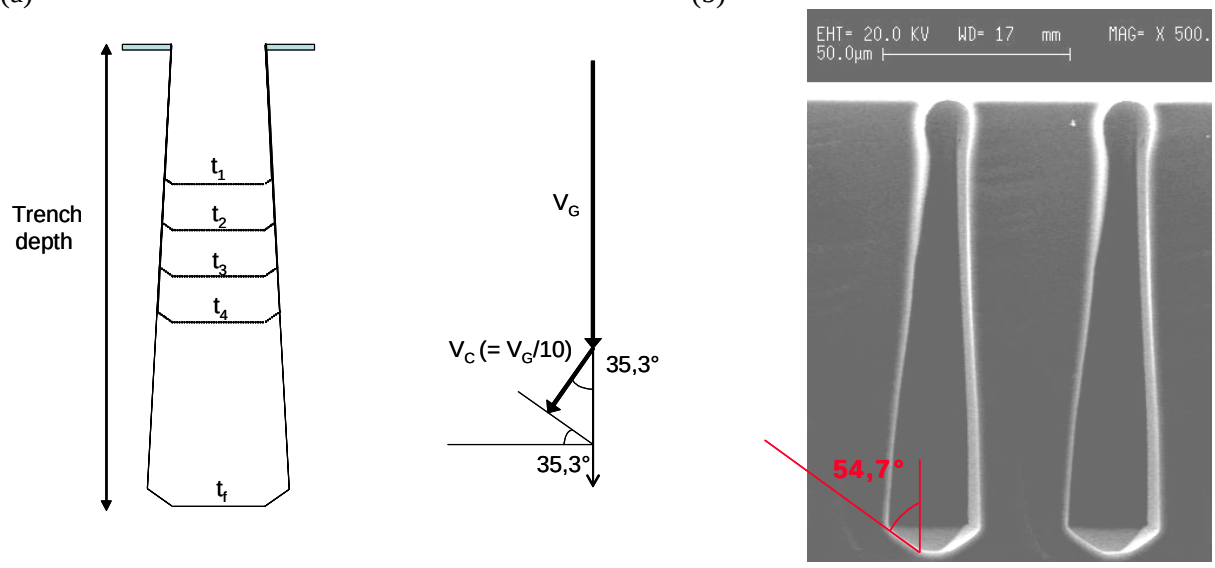

Figure 6 : Crystal orientation dependent etching :

(a) Schematic diagram of the crystal orientation dependent etching. As shown on the profile, the crystallographic component of the etch rate induces a negative slope. On this example of principle, the crystallographic component VC is one order of magnitude smaller than the averaged etching rate vertical component VG

(b) Experimental result obtained for vias. The crystal orientation etching appears clearly at the bottom of the structure

7. Conclusion and perspectives

Via structures were etched using the cryogenic process. Average etch rates as high as 7 µm.min^{-1} were obtained for 12 µm diameter and about 200 µm deep vias. Etching is performed in two steps to drill faster the wafer. Bowing effect can be reduced significantly by introducing a fast overpassivating step at the beginning of the process. Endpoint detection is obtained with the He leakage. The backside etching might require a modified process compared to the front side treatment. Crystal orientation dependent etching was observed for lower temperatures. This mechanism can be responsible for the negative slope, which is obtained in this case of very low temperature. Via profiles of the middle of the wafer were characterized in this study. The uniformity of profile shape on the wafer will be improved by using a new electrostatic cryogenic chuck supplying a high uniformity of temperature ($\Delta T<0.5$ °C).

7. Acknowledgments

This work is supported by STMicroelectronics (Tours, France) and by the French ministry of economy, finance and industry. The authors would like to thank R&D service of Alcatel Vacuum Technology - MMS (Annecy, France) for its strong technical support.

Abstract
The deposition of copper phthalocyanine (CuPc) thin films for gas sensing applications by using a plasma-based method i.e. glow discharge-induced sublimation (GDS) is studied. Deposition rate of the CuPc molecules was measured by a quartz thickness sensor. The properties of the deposited films were studied by FT-IR spectroscopy, RBS, ERDA, SEM and AFM. Preliminary measurements of the gas-sensing properties of the films were performed by measuring the electrical conductivity in N_2+NO_2 10 ppm gas mixture.

1. Introduction
The unique properties of metal phthalocyanines (MPcs), such as thermal stability, chemical inertness and biocompatibility make these organic semiconductors very interesting for several applications, including chemical sensing, photoconducting agents, photovoltaic cell elements, non-linear optics and electrocatalysis [1]. As far as the gas sensing applications are concerned, it is well known that the electrical conductivity of thin MPc films changes owing to the adsorption of oxidizing or reducing gases such as NO, NO_2 and CO.
The classical deposition methods of thin organic films such as spin coating, dip coating and the sol-gel method cannot be easily applied to the production of MPc coatings owing to the low solubility of these compounds in organic solvents, inaccurate thickness homogeneity control and solvent retention. These drawbacks are avoided by using high vacuum evaporation which has become the most widely used technique for the deposition of MPc films over the last decades. In particular, plasma-activated evaporation has been reported to be very effective in improving the mechanical properties and chemical resistance of copper phthalocyanine (CuPc) films without compromising their gas-sensing features [2].
Recently a plasma-based technique has been developed for the deposition of thin organic coatings [3,4]. This method is based on the use of a weakly ionized glow discharge produced in a standard radio frequency magnetron sputtering equipment. Low energy (E<1 keV) noble gas (He, Ar, ..) ions impinge on the solid organic precursors (e.g. pyromellitic dianhydride, PMDA, and 4,4'-oxydianiline, ODA, for the PMDA-ODA polyimide deposition [3] or 3-hydroxyflavone [4]), leading to the sublimation of the organic molecules and to their condensation onto the substrate. In the case of polyimide coating deposition, the as-deposited films mainly consist of a mixture of polyamic acid and nonreacted monomers, as revealed by Fourier transform infrared spectroscopy (FT-IR). The polymerization of the deposited coatings is completed only after a thermal treatment (typically 250°C, 1 hour, in air or argon). As compared to the well known chemical synthesis methods the main advantage of this physical technique is the absence of any solvent.

In this work is tested the deposition of CuPc films by means of this novel technique, named Glow Discharge induced Sublimation (GDS). The sublimation of the CuPc molecules is studied by measuring the deposition rate using a quartz crystal microbalance. In order to compare the properties of the GDS films with standard samples, CuPc films are also deposited by vacuum evaporation (VE). The chemical structure of the deposited films is studied by FT-IR analysis. Rutherford Backscattering Spectrometry (RBS) and Elastic Recoil Detection Analysis (ERDA) are used to determine the film composition. Scanning Electron Microscopy (SEM) and Atomic Force Microscopy (AFM) are performed in order to investigate the film morphology.
Preliminary measurements of the gas response of the VE and GDS deposited films have been also performed by exposure to a N_2+NO_2 10 ppm mixture.

2. Experimental

The experimental setup used for the deposition of CuPc films consisted of a vacuum chamber evacuated by a turbomolecular pump to a base pressure of 10^{-4} Pa. The device used to sustain the glow discharge was a 1-inch cylindrical magnetron sputtering source connected to a radio frequency power generator (600 W, 13.56 MHz) through a matching box. The CuPc powder (99.5% purity, Acros Organics) was put on the surface of an aluminum target, placed on the sputtering source. The amount of powder used in every deposition was 750 mg. The glow discharge feed gas was argon (99.9999%). The pressure inside the chamber was measured through a capacitance gauge. Typical values of rf power, target DC self-bias and working pressure were in the ranges 10 to 20 W, -20 to –300 V and 5.00±0.05 Pa, respectively.
CuPc coatings were deposited on two types of substrates: 350-μm thick silicon wafer (Atomergic Chemetals Inc.) for FT-IR, RBS/ERDA and SEM analyses and quartz glass (Heraeus Quarzglas GmbH & Co) for the electrical measurement. The substrates were mounted on a rotating sample holder placed 6 cm above the source. The thickness of the organic layer and the deposition rate were measured in real time by a quartz crystal microbalance.
The experimental setup used for the evaporation of CuPc coatings has been described elsewhere [5]. The substrates were placed on a sample holder placed 7.5 cm above the crucible. The deposition rate was measured by a quartz microbalance.
FT-IR spectra of the samples were recorded using a Jasco FT-IR 660 Plus spectrometer with a resolution of 4 cm^{-1}. During the measurements, the sample cell and the interferometer were evacuated so as to remove from the spectra the absorption peaks coming from the atmospheric gases, therefore obtaining a cleaner signal.
The measurement of the film composition was performed by Ion Beam Analysis (IBA) using a Van de Graaf accelerator at the Laboratori Nazionali di Legnaro. Copper, nitrogen and carbon concentration was determined by Rutherford Back-scattering Spectrometry (RBS) using a 2.2 MeV $^4He^+$ beam, at normal incidence and at the scattering angle of 160°. Hydrogen concentration was measured by Elastic Recoil Detection Analysis (ERDA) using a 2.2 MeV $^4He^+$ beam at a recoil angle of 30° and at grazing incidence of 15°.
The surface morphology of the samples was investigated by using a Scanning Electron Microscope (SEM, Philips XL-30) and an atomic force microscope (AFM, Danish Micro Engineering model C-21, mounting a DualScopeTM Probe Scanner 95-50).
The electrical measurements were performed with an electrometer (Keithley Instruments, model 237). Twenty gold parallel rectangular electrodes (0.57 mm far apart) were evaporated on the quartz glass and then the CuPc film was deposited on the sample. The CuPc sample was put inside the measurement chamber and a background pressure of 1 atm of flowing N_2 was fixed. A ceramic heater was used to increase the sample temperature up to 150°C and then the electrodes were biased at 10 V and the current was measured. In order to avoid humidity contribution to the measured values, the conductivity in N_2 atmosphere vs 1/T was measured after the starting heating during the temperature decrease. For the test of the gas sensitive behaviour the sample was kept at 150°C and the flowing N_2 was replaced by N_2+NO_2 10 ppm mixture and the conductivity changes were recorded. All the measurements were performed without light irradiation (dark measurements).

3. Results and discussion

In Figure 1 is reported the deposition rate and the total thickness of films deposited by GDS as a function of deposition time: as can be seen, the deposition rate is relatively unstable during the first 150 seconds, being quickly increasing at the beginning and then abruptly decreasing, while it becomes nearly constant during the

last part of the deposition. However the mean value of the deposition rate is very high as compared to the evaporation one (up to ten times) and it gives rise to films which are some microns thick in few minutes.

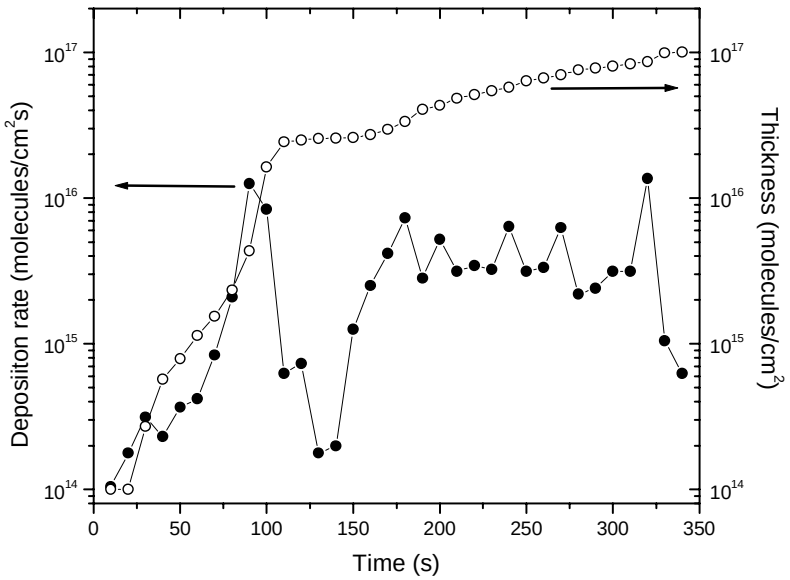

Figure 1. Deposition rate (•) and thickness (o) of CuPc films deposited by GDS as a function of time

FT-IR spectra of a vacuum evaporated film (VE) and of a GDS film in the range 3800 to 500 cm^{-1} are compared in Figure 2: the spectra appear very similar and all the main peaks of CuPc molecule can be identified in the GDS film, showing that a significant incorporation of integer CuPc molecules in the deposited film takes place.

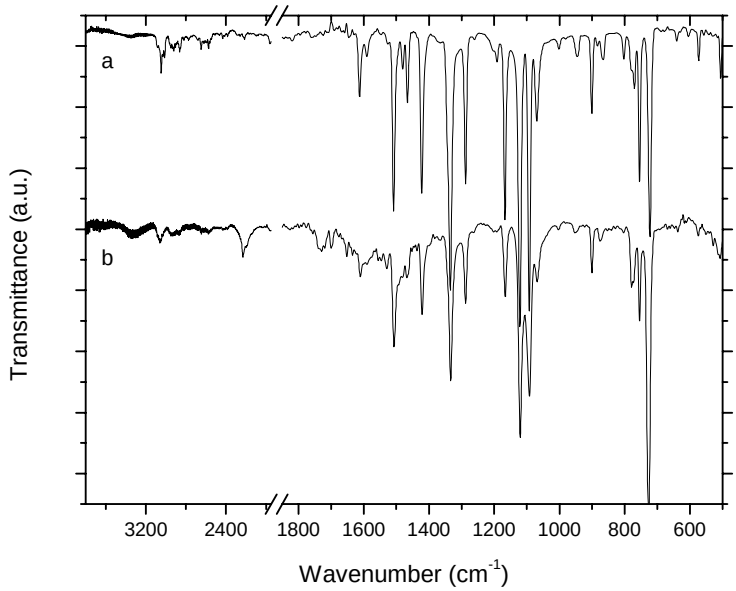

Figure 2. FT-IR spectra of evaporated film (a, upper curve) and GDS film (b, lower curve)

However some differences between the reported spectra can be found: a peak centred at 2230 cm^{-1}, which is ascribed to the C≡N stretching, a small band at 3350 cm^{-1}, due to the N-H stretching, and a broad, small band between 1700 and 1250 cm^{-1}. All these features suggest a non negligible incorporation of CuPc molecular

fragments during the GDS deposition, as due to the ion bombardment of the target CuPc powder. The molecular damage is thought to involve mainly the N atom bonds in the central region of the CuPc molecule as also shown by the low ratio between the intensity of the peaks at 900 and 573 cm^{-1} (metal-ligand Cu-N vibration [2]) and the peak at 724 cm^{-1} (C-H out-of-plane vibration) in the GDS film as compared to the VE one.

FT-IR analysis has been also used to study the film structure since it is well known that the MPcs crystal form is detectable by infrared spectroscopy [6,7]. In particular have been considered the position of the peak between 730 and 720 cm^{-1} and the intensity ratio between the peak at 780 cm^{-1} and the peak at 770 cm^{-1}. Figure 3 shows the infrared spectra of the starting CuPc powder, VE film and GDS film in the range from 820 to 680 cm^{-1}. In the spectrum of the CuPc powder, which is mainly β-phase as shown by several authors [6,8], the first peak is centered at 729 cm^{-1} and the peak at 780 cm^{-1} is more intense than the peak at 770 cm^{-1}. On the contrary, the spectrum of the VE film shows a peak centered at 722 cm^{-1} and the peak at 780 cm^{-1} is less intense than the peak at 770 cm^{-1}: these features characterize the α-phase as it could be expected for CuPc films evaporated on substrates kept at room temperature [8]. The spectrum of GDS film is different from both the previous samples: the first peak is centered at 727 cm^{-1} and the peak at 780 cm^{-1} is only slightly intense than the peak at 770 cm^{-1}. These features can be explained by assuming that the structure of the GDS film consists of a mixture of α- and β-phase.

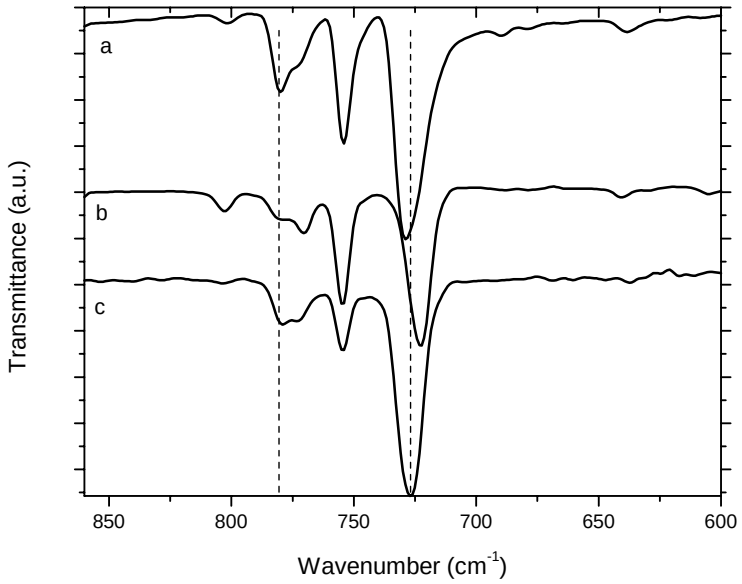

Figure 3. FT-IR spectra of CuPc powder (a, upper curve), VE film (b, middle curve) and GDS film (c, lower curve)

Table 1 shows the atomic ratios between the main elements of the GDS film (Cu, N and H) and carbon as determined by RBS/ERDA analyses. Taking into account that the experimental error on the hydrogen determination is relatively high, the average molecular formula of GDS film well corresponds to the expected CuPc molecular formula. This result confirms that the GDS film mainly consists of integer CuPc molecules as already shown by FT-IR analysis.

Table 1. Atomic ratios between the elements of the GDS film as determined by RBS/ERDA

Cu/C	N/C	H/C	Molecular formula
0.031 ± 0.002	0.25 ± 0.02	0.50 ± 0.07	$C_{32}H_{16}N_8Cu$

SEM micrographs of the deposited films (Fig. 4) together with the AFM analysis point out their very different morphology: the VE film is relatively flat (the mean roughness is about 40 nm) and small grains (0.5-1 μm wide) appear on a smoother background. On the contrary a rough structure with big grains (up to 5

μm wide) characterizes the GDS film, whose roughness is too high to be measured by AFM. The morphology of the GDS film suggests a more porous structure than the VE one, which can be particularly suitable for gas sensing applications, since the interaction surface between gas and sensor and the gas diffusion into the film are enhanced.

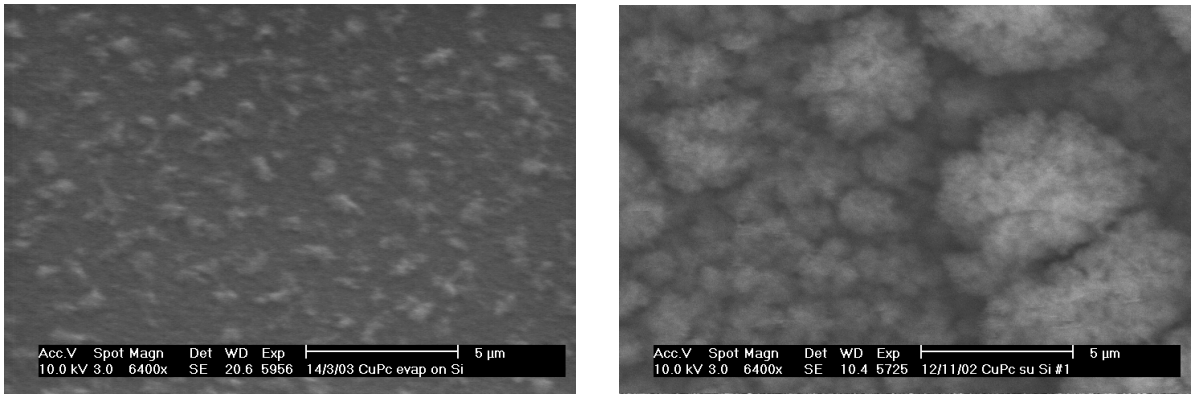

Figure 4. SEM micrographs of VE film (left) and GDS film (right)

The results of the electrical conductivity measurements of GDS film are reported in Figure 5: the temperature ranged from 313 to 423 K. The linear trend of LnI points out the semiconductor nature of the deposited film: the activation energy is calculated to be 0.23 eV.

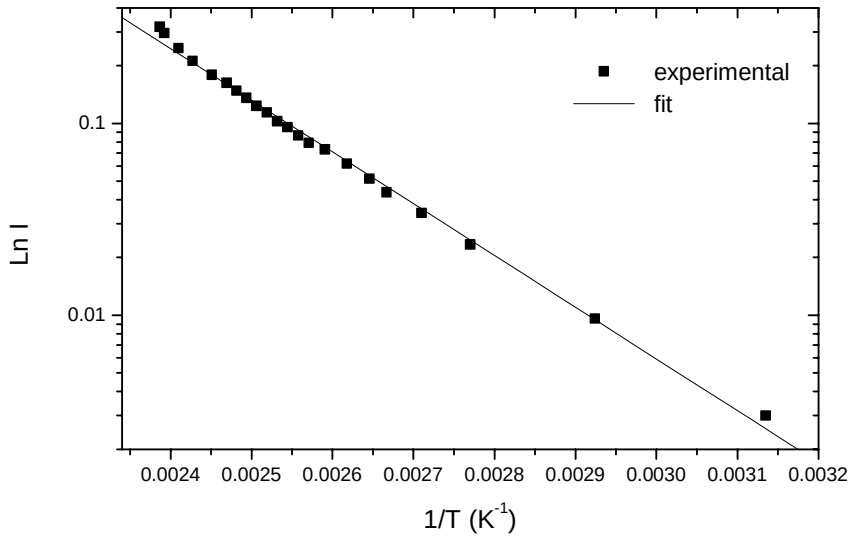

Figure 5. LnI vs 1/T for the GDS film

Preliminary measurements of the gas sensing properties of the VE and GDS films in N_2+NO_2 10 ppm mixture are compared in Figure 6: the gas mixture was admitted at the beginning of the measurement and it was removed after 20 minutes. Some interesting features can be observed: before the gas admittance the conductivity of the GDS film is slightly higher than the VE one, showing that the electrical properties of CuPc are preserved during the GDS deposition process. Moreover both films are very sensitive to NO_2: when the gas is removed the current has increased three orders of magnitude for the VE film and two orders for the GDS one. The conductivity increase is steeper for the VE film than for the GDS one, suggesting a higher sensitivity of the former film. However both films are characterized by high response and recovery times. On the other hand, the most important feature for the final gas sensing application concerns the reversibility of the electrical behaviour of the tested films: 160 minutes after the gas removal the conductivity of the VE film is nine times the starting value and an asintotic trend can be also assumed, pointing out the electrical

irreversibility which characterizes the evaporated CuPc films [9]. On the contrary the conductivity of the GDS film decreases down to 1.4 times the starting value, indicating that the gas/film interaction gives rise to reversible effects. This different behaviour is thought to be mainly due to the different structure of the films: the GDS film is more porous and the gas adsorption and release are promoted, while for VE the higher compactness appears to inhibit the gas release. However since these measurements are only preliminary, further work shall be done to confirm this difference.

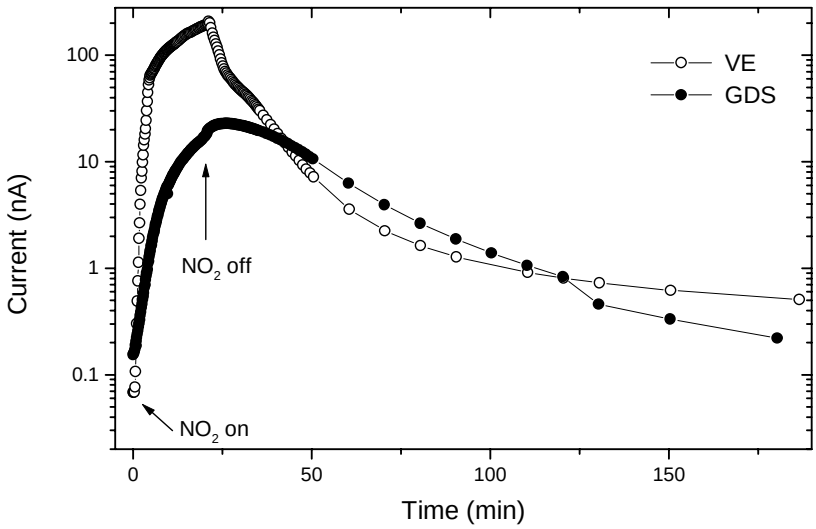

Figure 6. Electrical response of VE film (o) and GDS film (•) to NO_2 10 ppm exposure

4. Conclusions

The deposition of gas sensitive coatings by using plasma-based method has been shown. Glow Discharge induced Sublimation (GDS) has been used to grow thin coatings of copper phthalocyanine (CuPc).

The deposited films mainly consist of integer CuPc molecules as shown by FT-IR and RBS/ERDA analyses. However the incorporation of a non negligible amount of molecular fragments in the GDS film is found.

The film structure is different from the powder and from the evaporated film one and consists of a mixture of α- and β-phase. The porous and rough morphology of GDS films as compared to the VE ones makes these coatings particularly interesting for gas sensing applications.

The gas sensitivity of the deposited films has been shown by preliminary measurements of the electrical response to a N_2+NO_2 10 ppm mixture: both VE and GDS films are particularly sensitive to NO_2, but long response and recovery times are found. As far as the reversibility of the gas response the GDS films show a reversible behaviour maybe due to their less dense structure as compared to the VE films which, on the contrary, are characterized by irreversibility.

Comparative study of energy deposition estimation in Dielectric Barrier Discharge reactor

O. Martinie, J. M. Cormier and A. Khacef

GREMI, Université d'Orléans, 14 rue d'Issoudun, B.P. 6744, 45067 Orléans Cedex 2, France

Abstract

The aim of this paper is to present NO reduction experimental results obtained in non-thermal plasma (dielectric barrier discharge). Because of very fast transient discharges, energy deposition measurements are quite difficult in such reactors. This determination is a key factor to estimate the process efficiency. Various energy measurement techniques are presented. We operated with a N_2/NO mixture and we particularly interest to the chemical reduction of NO by the N radical. Finally we determined the yield for this process by measuring the NO destruction rate as a function of the power deposited into the reactor.

1. Introduction

Plasma processing and particularly non-thermal plasmas are subjected to a new interest for pollution control. The research in this field gained considerable interest and a number of researchers are working on it. Number of various devices had been developed in laboratories and proposed for. The already well known industrial applications processes are:

- Radio frequencies and microwaves discharges,
- Electrons-beam reactor,
- Corona discharge,
- Dielectric barrier discharge (DBD),
- Gliding discharge.

The energy cost involved on treating a given volume of polluted gas in normal conditions and the pollutant rate conversion are the main parameters in view of industrial applications are.

DBD is a well known transient discharge applied to pollutant control [1-6]. A dielectric layer covers one or two of the electrodes in the discharge gap. At a sufficiently high voltage, the discharge starts in the gas volume between the electrodes. Afterwards, it spreads out until it reaches the electrodes but at the dielectric it builds up a space charge that cancels the electric field. At that moment the discharge stops. The dielectric barrier discharge is supplied by a high voltage generator and the energy is transferred to the discharge with energy losses. One of the main problems is to know the real energy deposed in the plasma mixture. The aim of the paper is to measure this energy by various methods.

2. Experimental arrangement

The DBD reactor consists of a cylindrical pyrex tube. The 1.5 mm diameter electrode is arranged on the axis. A 10 μm thick external electrode is rolled up on the tube. The efficient inner volume of the reactor is about 6.8 cm^3.

The inlet gas consists of a 1000 ppm NO in N_2 as balance at atmospheric pressure. The gas flow rate is fixed at about 8.1 $cm^3.s^{-1}$.

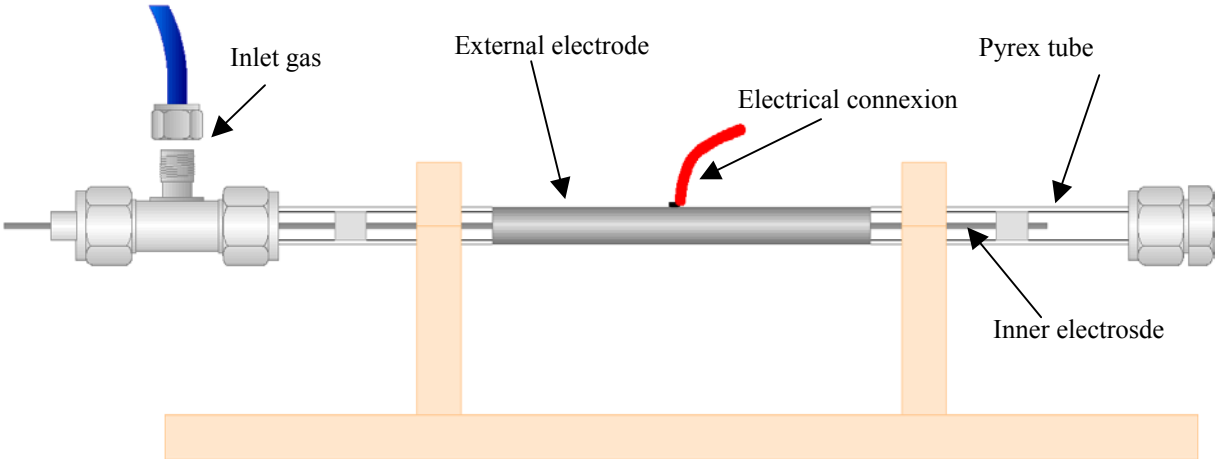

Figure 1: The DBD reactor.

The DBD reactor can be described using a series capacitance circuits as shown in figure 2. Details of capacitances effects are given in details by Z. Falkenstein and J. J. Coogan in reference [7]. The first capacitance C_g is corresponding to the gas capacitance and the second C_d is corresponding to the dielectric capacitance. These well-known capacitances are given by:

$$C_g = \frac{2\pi\varepsilon_0 l}{\ln\left(\frac{d}{r_0}\right)} \qquad \text{and} \qquad C_d = \frac{2\pi\varepsilon_0\varepsilon_r l}{\ln\left(\frac{d+x}{d}\right)}$$

Values are respectively: C_g = 3.7 pF and C_d = 91 pF.

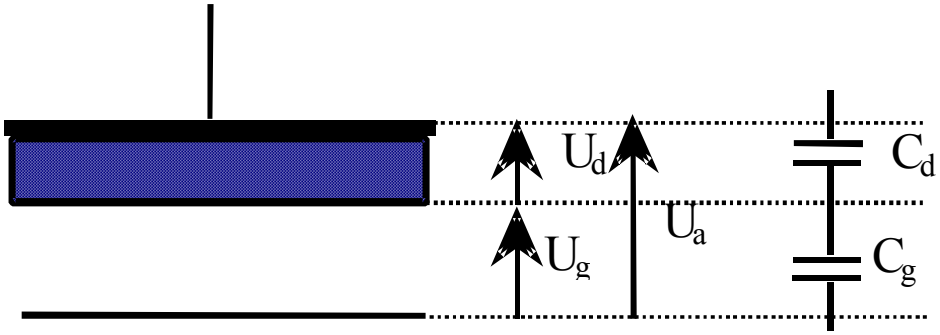

Figure 2: Equivalent circuit of a dielectric barrier discharge.
The generator voltage is: $U_a = U_g + U_d$

The power supply is a 50 Hz sinusoidal generator which deliver a 10 kV RMS voltage. No limitation of current is needed because of the dielectric effect. The corresponding voltage and current are showed in figures 3 and 4.

During the breakdown phase a number of discharges are generating in gap. In order to determine the corresponding number of elementary discharges a specific electronic counter has been designed. The elementary discharges number for positive voltage is written n_+ and the number in negative ones is written n_-. Experimental and model ($\exp(-t/\tau)$) of a typical current peak for an elementary discharge is plotted on figure 4. Time constant of positive peaks are written τ_+ and negative ones τ_-.n_+

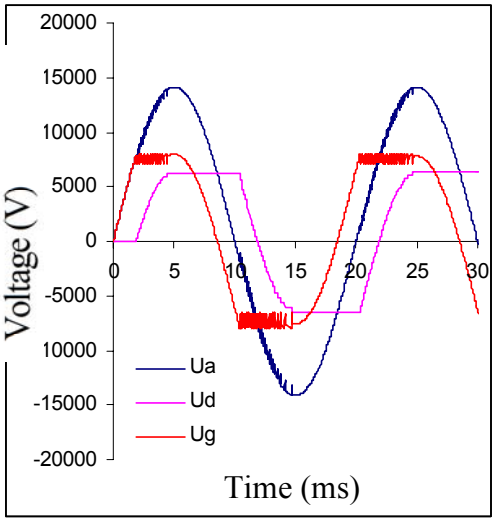

Figure 3: Voltage waveforms

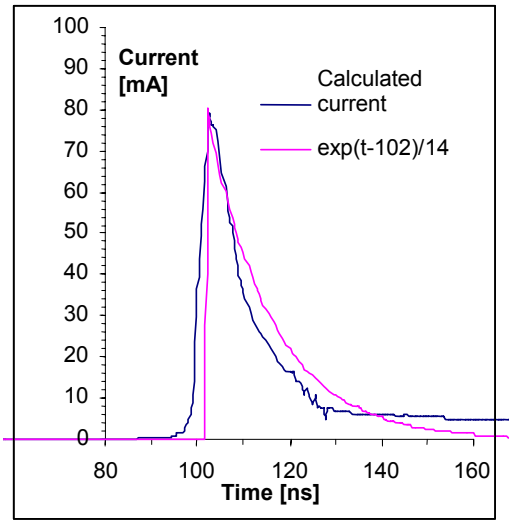

Figure 4: Current waveforms

3. Energy Measurements using voltage and current recording

A special probe is used for current variation measurements, both voltage and current can be recorded using an oscilloscope.

Energy exchange for an elementary discharge is written:

$$W_c = \int_\tau U_g i_{pic} dt$$

We have to notice that the corresponding voltage is the gap voltage which is generally quite different of the generator voltage

As it is shown above the discharges current variations are exponentials and have to be extracted from a more complex signal with a 50 Hz component. Extraction of the useful signal is performed using a high frequency pass filter. We make the assumption that the gas voltage has approximately the breakdown value. In this case the mean power can be written as:

$< P >= U_{bd} \times 0.63 \times (n_+ i_+ \tau_+ + n\_i\_\tau\_) f$ where U_{bd} and f are the breakdown and frequency voltage respectively.

The experimental results for N_2-NO mixture and air respectively are shown in the table 1.

	U_{bd} [kV]	i_+ [mA]	n_+	τ_+ [ns]	i_- [mA]	n_-	τ_- [ns]
N_2/NO	9.2	800	32	40	430	20	120
Air	8.6	900	78	18	450	39	45

Table 1: Experimental parameters for NO-N_2 and air plasma.

From the above formula we obtain <P> = 0.57 W for the N_2/NO mixture and <P>=0.53 W in the case of discharge in air.

4. The "Manley method"

This method wad proposed by Manley [8] in 1943. This is a simple way to determine the energy of the discharge in the case of a sinusoidal powering system. Parameters involved are the breakdown voltage U_{bd} and the two capacities C_g and C_d. Results are deduced by analysis of voltage versus charge plot (Lissajous figure). An auxiliary condenser (C_m = 2 nF) is series connected with the reactor in order to determined the electric charge Q. Typical Lissajous figures are shown below.

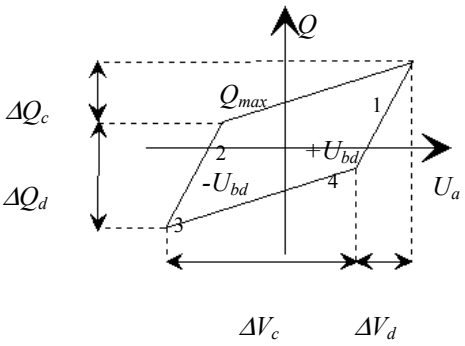

Figure 5: Theoretical Lissajous figure

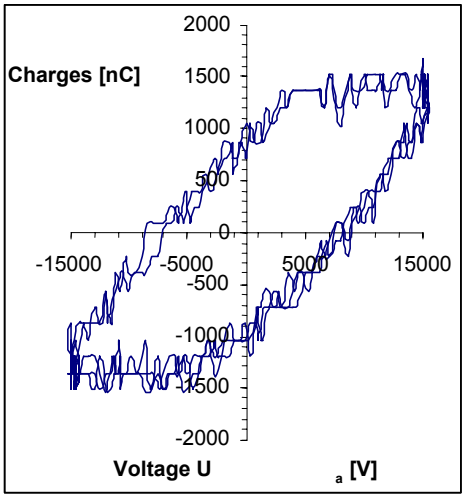

Figure 6: Experimental Lissajous figure

The power of the discharge can be calculated from the following relation :

$$P = 4U_{bd}C_d\left(U_{a,max} - \left(C_d + C_g\right)/C_d U_{bd}\right)f$$

For $U_{a,max}$ = 14.1 kV, C_g = 3.7 pF and C_d = 91 pF, we found that the calculated power is in the range 0.773 W and 0.743 W.

5. Energy deposition obtained from chemical reaction N + NO → N_2 + O

Plasma process efficiency is often characterized by the G-Value defined as the number of molecules removed by 100 eV of input energy.

$$G_{100eV} = \frac{100\,k_{ion/diss}}{v_e E/n}$$

The quantity $k_{ion/diss}\, n_e n$ is the number of reactions in a unit volume per unit time where n_e is the electron density. The quantity $n_e E v_e$ represents the amounts of energy expended by the electrons in a unit volume per unit time.

Because of variations in electric field an average value of the G factor must be used:

$$\left\langle G_{100eV}\right\rangle = \frac{1}{\tau}\int_0^{\tau} G_{100eV}(t)\,dt$$

where τ is the time duration of the discharge.

The $<G_{100eV}>$ factor had been calculated as a function of the reduced field, using a code described in reference [9] for pure N_2 and air. Results are presented below.

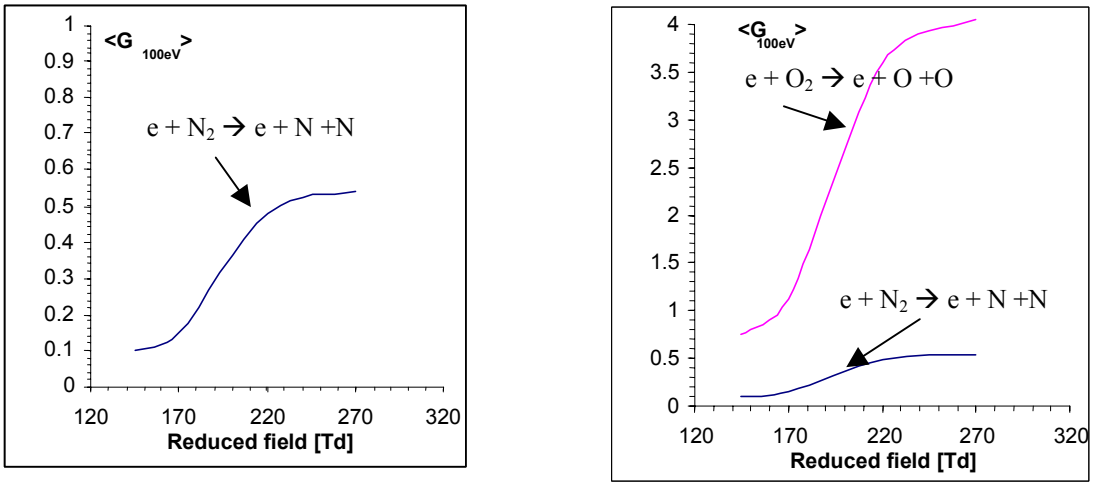

Figure 7: G_{100eV} as a function of the reduced field in nitrogen (a) and air (b).

From the destruction rate for a well chosen species it is possible to determine an electron production rate. Using the streamer simulation and breakdown voltage the input energy can be calculated.

We operated with a N_2/NO mixture and we particularly consider the chemical reduction of NO by the N radical [3]:

$NO + N \rightarrow N_2 + O$

This 2-body reaction predominates on the 3-body reactions:

$N + N + M \rightarrow N_2 + M$

and

$NO + O + M \rightarrow NO_2 + M$

N radicals are produced by electronic impact on N_2 molecule. The number of dissociations can be obtained from the $<G_{100eV}>$ factor.

For plasma processing of N_2-NO (1000 ppm) mixture, we measured at the output of the reactor 843 ppm NO and 75 ppm NO_2. This means that 75 ppm NO are oxidised in NO_2, and 82 ppm NO reduced in N_2. In that case, the residence time in the reactor is τ_s = 0.6 s, the reacting volume V = 4.85 cm^3 and the flow rate Q = V/τ_s = 8.1 $cm^3.s^{-1}$. Then, it is possible to calculate the number of nitrogen dissociations (8.13 10^{15} in that case). Using the G value for a reduced field of 170 Td, we determined the corresponding power of 0.62W.

Conclusion

The average value of the energy deposition into the gas in DBD reactor was determined by three methods: current-voltage characteristics, Manley's method and chemical transformation. The three techniques give a similar magnitude order (0.6 W) but accuracy (15%) is not sufficient to extend the results for large gas flow treatment devices. It should be necessary to performed accurate losses measurements in order to obtain a detailed balance of Joule effect heating and dielectric losses. Such a work is in progress to study.

Possibilities of VOC Treatment in Cylindrical Foaming Reactor

J. Pawlat[1], K. Hensel[2], C. Yamabe[1] and A. Mizuno[2]

[1]*Department of Electrical and Electronic Engineering, Saga University, Saga, Japan*
[2] *Department of Ecological Engineering, Toyohashi University of Technology, Toyohashi, Japan*

Abstract
The possibility of the treatment of VOC in the cylindrical foaming reactor is presented. About 55 mg/l of H_2O_2 and 20 ppm of O_3 were formed within the foam as an effect of the electrical discharges in oxygen. The experiments evaluating the absorption range of acetaldehyde within foam formed with pure water and additionally with the solution of surfactant in pure water were performed. The influence of the electrical discharge on the absorption and on the decomposition of acetaldehyde was observed.

1. Introduction of the foaming system

The problems of accretive devastation of natural environment and the increasing emissions of pollutants gain recently much attention of the authorities and local communities. It is necessary to develop new, environmentally safe techniques of production of goods, and also of recycling and utilization of wastes.

In this paper a foaming system is proposed. Despite of the small amount of required liquid, foaming column could be applied not only for polluted gas treatment but also for specific type of water and wastewater purification. The electrical discharge might be applied directly in foam, partly consisted of pollutant. Foaming column became the generator of various oxidants and the reaction vessel in the same time. The losses of oxidants in the providing system could be reduced.

Foam belongs to the special colloids group [1,2]. It can be generated in various ways in dependence of the required structure. On the base of those qualities foams are categorized as homogenous, (standing) and pneumatic (dynamic) foams [3], which both ensure the significant expansion of the contact surface between gaseous and liquid phases.

The most of foams are produced using the surface active compounds. However, foams created without any surfactants were very desirable from the environmental point of view. The experiments using this kind of foam, generated from gas and pure water only were performed as well as with the addition of the surface active substance to improve the absorption, to lower the gas flow limits and to avoid the pressure losses.

Pneumatic foam in presented experiments was formed without the addition of any foaming agents using only the gas kinetic energy, keeping the strict conditions of the medium flow and using the diffusers. Co-current flow, when gas and liquid flow through the same diffuser's hole, allowed for the appropriate inside-area usage [4]. The linear velocity of substrate gas for whole apparatus cross-section for dynamic foam should range 0.1-4.0 m/s, the gas velocity in the diffuser hole - 10-20 m/s, and 5-20% perforation of whole shelf area of the diffuser is advised.

2. Acetaldehyde as a substrate for technology and as an undesired pollutant in environment.

The treatment methods of ethanal

Acetaldehyde was first produced commercially in the United States in 1916. Nowadays, it is manufactured by the oxidation of ethylene with a palladium catalyst and by the catalytic hydration of acetylene.

Acetaldehyde is used in various branches of the industry as a chemical intermediate and basic substance for the production of acetic acid, pyridine and pyridine bases, peracetic acid, butylene glycol, esters, flavor and fragrance acetals, paraldehyde, metaldehyde, phenolic and urea resins, antioxidants, polymers, and various halogenated derivatives. It is also a common compound in manufacturing of aniline dyes, synthetic rubber, silver mirrors, fuel compositions, disinfectants, drugs, perfumes, explosives, pesticides, and room air deodorizers. Acetaldehyde is used as a fungicide, substrate of food flavorings, preservatives, lacquers and varnishes, photographic chemicals as well [5, 6].

Properties of acetaldehyde are presented in Table 1 and its molecular structure is depicted in Fig.1A.

Tab.1. Properties of acetaldehyde.

Name/Formula:	Acetaldehyde, Ethanal, acetic aldehyde, ethyl aldehyde, CH_3CHO, NCI-C56326
Physical Properties	Volatile, flammable, clear, colorless liquid, miscible in water, alcohol, ether, benzene, gasoline, solvent naphtha, toluene, xylene, turpentine, acetone, and other common organic solvents
Odor	Pungent, suffocating (in low concentration- fruity) odor, detectable at 0.0068 to 1000 ppm
Molar Weight	44.05
Specific Gravity	0.78 - 0.79
Vapour Density	1.52 (air = 1.0)
Vapour Pressure	740 mmHg at 20 °C
Melting Point	of -123.5°C
Boiling Point	20.2 to 20.8°C
Flash Point	-38 °C
Autoignition Temperature	185 °C
Stability	A highly reactive compound that undergoes numerous condensation, addition, and polymerization reactions (autopolymerization with metals (iron) or acids (concentrated sulfuric acid)). It oxidizes readily to form corrosive acetic acid.
Toxicity Data	LD_{50} oral (rat) 661 mg/kg
Major Hazards	Highly flammable liquid, its vapor is explosive in the concentration range 4 to 66% in air. Irritating to the eyes and respiratory system.

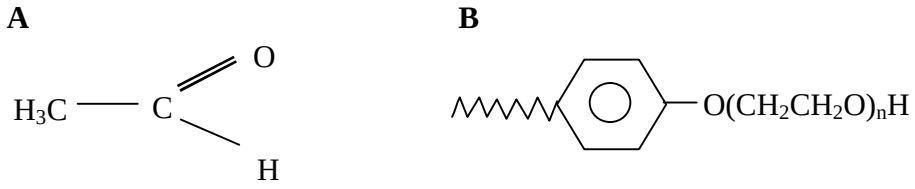

Fig.1. The structure of acetaldehyde (A) and Tritron X-100, n=9,10 (B).

Acetaldehyde is considered as a mutagen and possible human carcinogen [5-7]. Exposure to acetaldehyde by inhalation is irritating to the respiratory tract and mucous membranes; this substance is a narcotic and the chronic exposure can produce symptoms similar to alcoholism. Ingestion of acetaldehyde may cause severe irritation of the digestive tract. Ethanal causes irritation upon skin contact and eye burns.

Above premises gave an additional propulsion for research centers to study on the removal of acetaldehyde from exhaust gases and wastewaters.

Acetaldehyde decomposes above 400°C to form mainly methane and carbon monoxide, however thermal methods with large volumes seemed to be quite costly.

Various attempts of immobilization and treatment of acetaldehyde have been done. The amorphous silica [8], activated carbon with about 13% adsorption efficiency [9] and the polymer filters [10] were used to limit the concentration of acetaldehyde in the outlet fluid. Interesting solution based on biodegradation of ethanal in packed column with immobilized activated sludge gel was presented by Ibrahim et al. [11].

Other direction was the photodecomposition using surfactants and organic solvents, which amplified the overall decay rate [12]. The photon dissociation of acetaldehyde was described by [13, 14] with indicating

formaldehyde, metylhydroperoxide, CO as the products generated mainly via free radical channel. Those results were partly confirmed by the report based on acetaldehyde reactions with hydroxyl radicals [15].

In this paper a new method of absorption of acetaldehyde within foam is introduced. Additionally, the oxidants were formed in foam as an effect of electrical discharge [16] and the results of combination of electrical discharge and absorption in foaming apparatus were analyzed. The ideal treatment process of acetaldehyde using generated oxidants could be described by the equations (1-4) :

$$3CH_3CHO + O_3 \rightarrow 3CH_3COOH \quad (1)$$
$$3CH_3COOH + 4O_3 \rightarrow 6CO_2 + 6H_2O \quad (2)$$
$$2CH_3CHO + H_2O_2 \rightarrow 2CH_3COOH + H_2 \quad (3)$$
$$CH_3COOH + 4H_2O_2 \rightarrow 2CO_2 + 6H_2O \quad (4)$$

3. Experimental apparatus

The experimental set-up consisted of the foaming sub-system (gas and liquid providing), the electrical discharge sub-system and the chemical analysis sub-system.

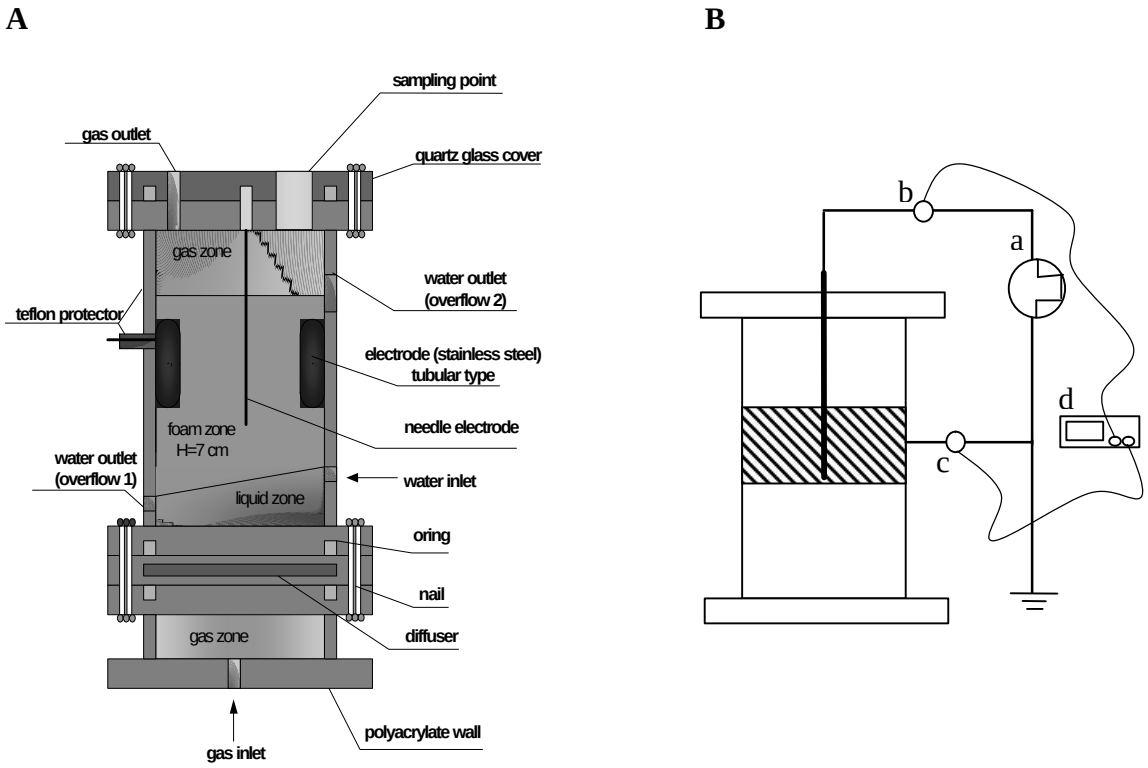

Fig. 2. Cylindrical foaming column (A) and the electrical circuit (B),
(a- pulse power source, b- high voltage probe, c-current probe, d-oscilloscope).

Main reactor, depicted in Fig. 2A was a cylindrical column (D_{in}=50 mm, L=200 mm). The ceramic diffuser type IA-500 was placed inside the apparatus. Stainless steel electrodes were located in the homogenous foam zone, above the diffuser. The inner electrode (d_{out}= 1.5 mm) was placed inside the outer electrode (d_{in}=40 mm, l= 30 mm).

The column was connected to the liquid and gas providing system. In the performed investigations pure water or pure water with addition of common surfactant (1 ml/500 ml H_2O) and Tritron X-100 (1ml/300ml H_2O)

was used as a substrate liquid. Substrate gases were air, oxygen and acetaldehyde with nitrogen as a carrying gas.

The electrical circuit is presented in Fig.2B. The pulse power source was operated at 250 Hz. The discharge voltage and current were measured using the high voltage probe (Tektronix, model P6015A) and the current probe (Tektronix, model P6021) with an oscilloscope (Tektronix, model TDS 644A), respectively.
The discharge pictures were taken using the digital camera Olympus Camedia X-2.

The hydrogen peroxide concentration was determined using Hydrogen Peroxide Test Kit (HACH, Model HYP-1). Thiosulfate titration of the sample (liquid after discharge application, mixed with specially formulated starch-iodide reagent used in hydrogen peroxide tests and with ammonium molybdate reagent) was performed in a low pH (pH=3.5) condition.

The ozone concentration in the outlet gas was measured using the GASTEC and KITAGAWA ozone gas probes. Outlet gas was collected in the gasbags and sampled.

The acetaldehyde concentration was measured using GASTEC and KITAGAWA acetaldehyde gas probes and gas chromatography (SHIMADZU GC-14B).

3. Results and discussion

Dynamic foam was formed in the reactor. Average diameter of the single bubble in foam ranged from 1 mm to 5 mm. The diameters of the bubbles tended to be bigger in the case of the lack of the surfactant, with increasing the distance from the diffuser and with increasing the substrate gas flow as well. Dosing of the additional amount of water caused the bubble diameter to decrease. Foam with surfactant was stable. Natural decay of foam formed with Tritron X-100 took more than 5 minutes whereas decay of dynamic foam without surface active compound took place immediately after the gas flow was shut down.

Several types of non- uniform discharges were obtained within dynamic foam. The typical electrical characteristics of the discharge and its photo taken from the top- side of the reactor in oxygen and pure water are shown in Fig.3.

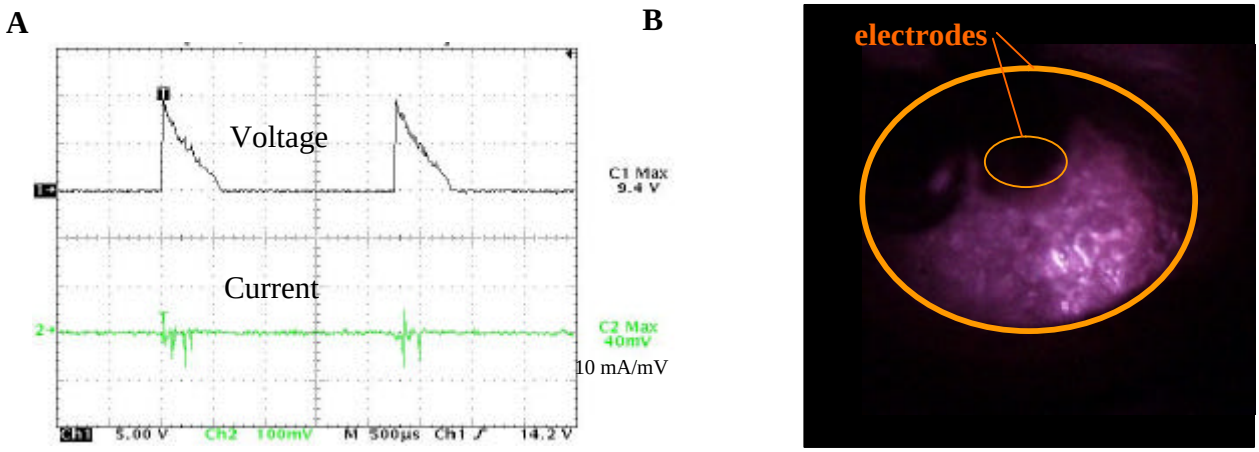

Fig. 3. Typical applied voltage and current waveforms of the electrical discharge in foam (A), and the photograph of the discharge (B). Oxygen flow rate 5 l/min, total power (including losses) 40 W.

The measurements were performed to confirm the presence of hydrogen peroxide and gaseous ozone generated by the electrical discharge. The concentrations of hydrogen peroxide in cylindrical column in the case of air without and with the addition of the common surfactant are depicted in Fig. 4. The small amount of gaseous ozone was also detected.

Generally, with the higher applied voltage, the concentration of oxidants increased as expected. For the relatively low gas flow rate for the formation of foam in the column, only low concentration of hydrogen peroxide was achieved. In the case of addition of surfactant the oxidants concentration decreased within the

same flow limits as without the addition of surface active compound. In the case of long term experiment added surfactant was gradually decomposed by formed oxidants and foam stability decreased.

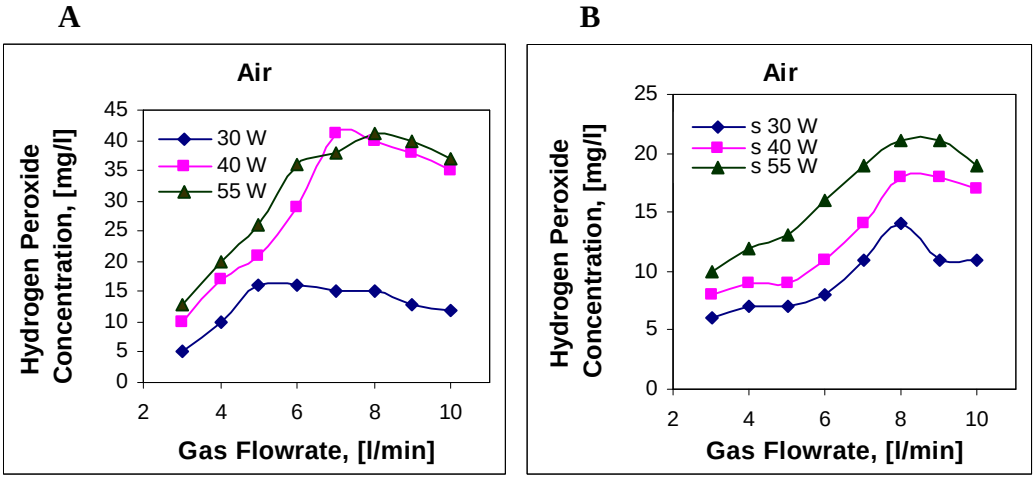

Fig.4. The hydrogen peroxide concentration in dependence on the gas flow without (A) and with the common surfactant (B), (power losses included).

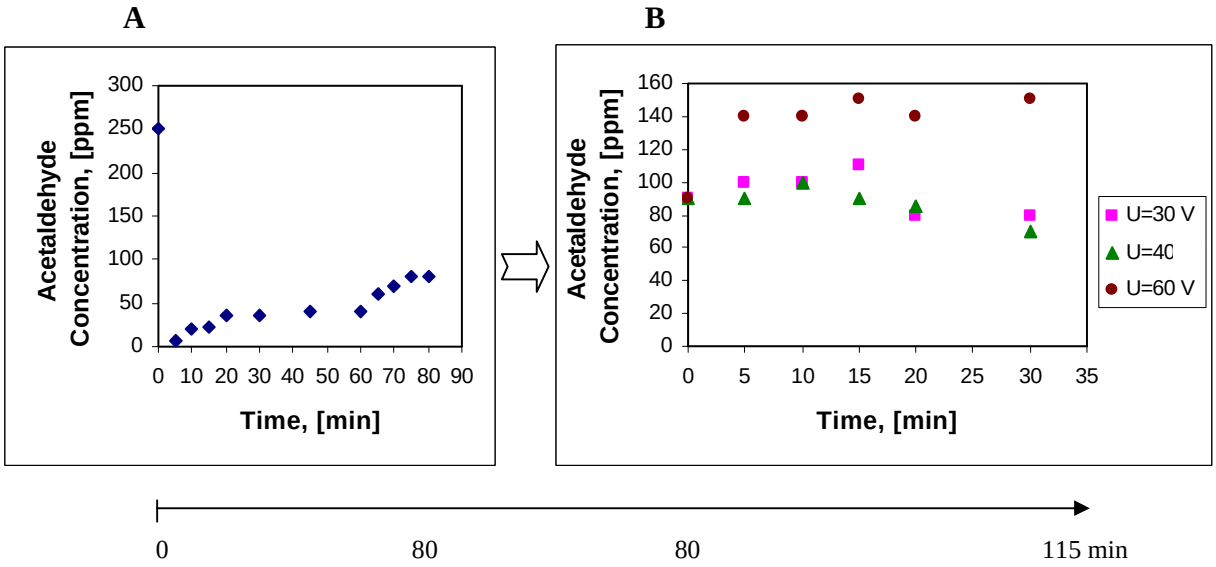

Fig.5. The absorption of acetaldehyde within foam with addition of Tritron X-100 versus time (A) and change in acetaldehyde concentration after application of electrical discharge to the saturated solution (B), (power losses included).

The process of absorption of acetaldehyde within foam without and with addition of Tritron 100 X was studied. The example of the one absorption cycle with 5 ml of the solution of surfactant in pure water is presented in Fig.5. In that case air-acetaldehyde in nitrogen gas flow rate was 1,2 l/min and initial concentration of ethanal was 250 ppm. After the 80 minutes of saturation time, the electrical discharge was applied. The proceeding of electrical discharge caused the releasing of acetaldehyde absorbed before and decomposition of the surfactant then gradually concentration of CH_3CHO decreased. The absorption process in presence of

Tritron was much more efficient than in the case of pure water only because of hydrophobic nature of acetaldehyde molecule.

4. Conclusions

An apparatus based on the discharge in the foam was designed.

Foam was obtained without the dosing of the surface-active substances, keeping the strict conditions of the gas flow rate and with the addition of common surfactant and Tritron X-100.

The high amount of hydrogen peroxide and low amount of gaseous ozone were formed within foam. The combination of various kinds of oxidants makes foam belong to the Advanced Oxidation Processes.

The acetaldehyde could be absorbed within the foam. The superposition effect of combining the absorption process with the electrical discharge was not fully confirmed. The absorption was improved when the surfactant was dosed to the substrate liquid.

The foaming system allows obtaining various species in one compact apparatus, potentially even directly in the polluted medium and it connects in one body the advantages of oxidants' generator and the reaction vessel.

On the use of a magnetic blow out glidarc reactor for the syngas production by steam reforming

J.M. Cormier[1], I. Rusu[2] and A. Khacef[1]

Abstract

This work is dedicated to the experimental study of methane steam reforming using a magnetic blow out discharge at atmospheric pressure. Results obtained from a new three-phase reactor using a rotating effect produced by a magnetic field on the ionised gases, are presented. Experiments clearly demonstrated the ability of magnetic blowing discharges to increase the conversion efficiency of chemical reactions at low temperature.

A simple model is deduced from the chemical and physical analysis. According to this model we have calculated the gas fraction that passes through the discharge and discussed the efficiency.

On the other hand, we notice the possibility of using this kind of device to feed fuel cells with hydrogen. Therefore, due to its compactness and small dimensions the glidarc reactor may have potential automotive applications.

1. Introduction

There are several methods to produce syngas but most of it (40%) is obtained by steam reforming (SR) [1]. The conventional catalytic technology presents several shortcomings as: large size of the equipment, high investments and exploitation costs, limitations on rapid response, catalyst sensitivity to poisons, and extreme operating conditions that limit the lifetime of reactors [2, 3].

Plasma is known to be a very high energy density media and gives an attractive alternative for the production of hydrogen and synthesis gas. In this approach, the plasma replaces catalysts and accelerates chemical reactions due to both temperature and active species effect. Plasma reactors represent an incisive approach by their simplicity, compactness and low price.

Gliding arc reactors are the subjects of multiple possible applications to a variety of chemical processes. The gliding discharges allow high specific throughputs in the reaction zone, which generally largely exceed other chemical methods, including electrochemical and thermal ones. However, previous studies on the methane steam reforming indicated that these types of reactors must be improved in order to obtain better conversions [2-5].

The aim of this paper is to present a new three-phase reactor which has been proposed with good results, the conversion increasing up to 50% [6]. The reactor uses a rotating effect, produced by a magnetic field, on the ionised gases.

2. Experimental

1.1. Magnetic blowing arc reactor

The new reactor design is shown in Figure 1. The plasma reactor consists of three anodes that are arranged around of a single cathode. The cathode is a 6 mm diameter tungsten rod. The anodes are fixed at the output of the inlet tube, which is made in ceramic. A magnet is surrounding the inlet tube. Discharges are ignited at the outlet of this tube and then pushed by the flow. The discharge column is a plasma string with a visible diameter less that one millimetre that slides in the gas flow and the magnetic field. At the same time the

voltage increases and the length of the discharge grows up. Due to the magnetic field a rotating effect of the plasma strings is produced.

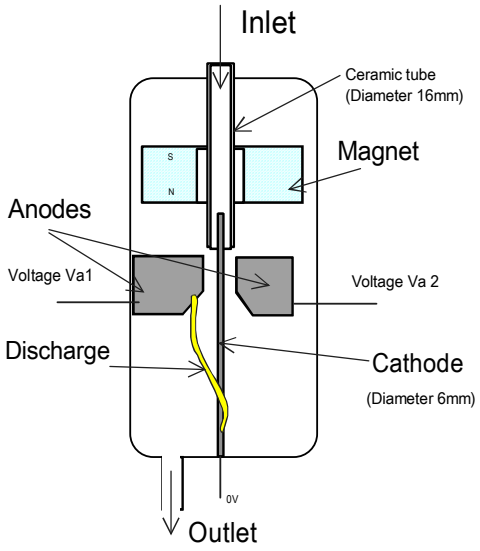

Figure 1: Photo and scheme of the new reactor

The discharge behaviour in a magnetic field is quite different than the usual gliding discharges. The first effect is the increase of the mixing properties of the reactor [6]. The plasma string performs a helix movement and looks like a wrapped wire around the cathode. As a result the plasma can sweep a large part of the inlet gas. The second effect is the maintaining of the non-equilibrium behaviour of the discharge. For usual gliding discharges, the transition to the arc must be avoided using external current limitation (resistors, reactors, etc). In the case of magnetic blow out, the force acting on the lengthening discharge column is proportional to the product between the current and the magnetic-field strength. This force produces a very rapid lengthening of the discharge column (Figure 2). The de-ionisation occurs much faster, leading to the mixing of the discharge gases with the cold gas through which the core is forced to pass in its rapid motion. Due to the magnetic field, a self-limitation of the current intensity is produced.

The electrical supply is a three channels one, which is used to power up the three cascading discharges. One channel consists of two transformers with rectifiers that allow two running phases: the ignition at high voltage and low current intensity and a complementary energy supply with higher current [7]. Due to the magnetic field there is no need of additional resistance for current limitation.

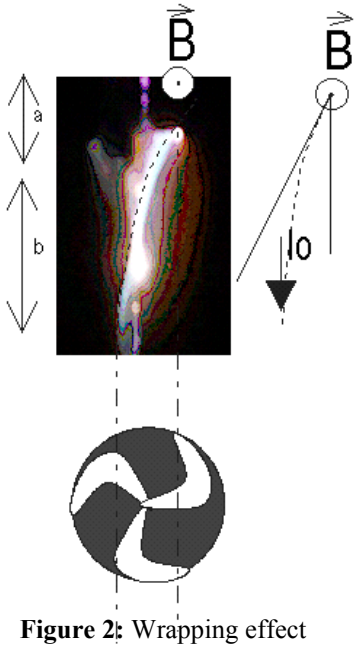

Figure 2: Wrapping effect

Figure 3 shows the variation of voltage current and power for one of the three discharges as a function of time. In order to clarify the diagram from Figure 3 we have to mention that the voltage is plotted as a negative signal. As can be seen on this figure, the discharge behaviour is not definitely periodic due to the instabilities in the growing discharge. The electrical power is obtained by averaging results over a large number of periods.

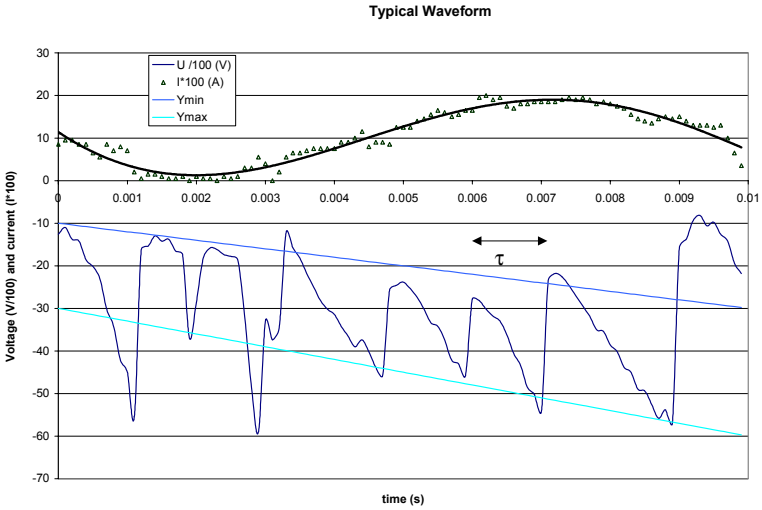

Figure 3: Voltage and current waveforms

1.2. Chemical tests

All experiments were conducted at atmospheric pressure. The water and methane are mixed before injection in a heating line. The inlet temperature was fixed at about 150°C for all the experiments. The exhaust gas from the reactor was passed through a condenser and then through a desiccant column. The major gaseous components were analysed on-line and quantified using gas chromatography (TCD detector - HP5890 for H_2, FID detector - Varian 3400CX for CO, CO_2, CH_4 and C_2).

2. The magnetic wrapping effect and sweeping effect.

Let us consider the orthogonal component of the magnetic field B (figure 2). The plasma wire is lengthening in the flow and the wrapping effect is produced around the cathode.

The first zone corresponds to the magnetic disturbed region (a) and the second is the lengthening region (b). From a very simple point of view the reactor efficiency is directly related to the plasma volume in comparison of the gas volume.

Below the opposite photo, the covered discharge area is pictured in white. And from experimental determinations we can consider that only 35-45 % of the gas is swap by the discharge

3. Temperature of the plasma string

One of the most important features of gliding discharge is the so called "*back-breakdown phenomenon*". The plasma string is stretched in the flow and its length is increasing till the back-breakdown time. At this time, the electrical charges take a short cut resulting from the spark breakdown between two parts of the plasma column. Then the new shortened plasma string is stretched in the flow till a new back-breakdown.

The saw-tooth variation of voltage is corresponding to the extension of the plasma string which is followed by the fast back-breakdown, the corresponding duration is written τ. The voltage drop along the positive column is approximately proportional to the discharge length. Then the minimum of voltage is corresponding to a minimum of length and the maximum voltage to a maximum of length.

Then from a previous paper [8], it is possible to express the discharge power as a function of the discharge parameters. We consider a classical discharge string surrounded by an excited region which is few

millimetres wide. We make the assumption that the electrical charges drift in the core of a cylindrical discharge of radius r_o. This surface is supposed to represent the boundary between the high temperature conduction core and the excited region.

The ambient temperature is T_a and the temperature at $r=r_o$ is $T_b \# T_m$. The mean power exchange for a plasma column with an average length <L> during the extension duration τ is given by:

$$EI = 4\sqrt{\pi}\ \frac{\lambda}{\sqrt{D}}\ T_m\left(1-\frac{T_a}{T_m}\right)\ \frac{r_o}{\sqrt{\tau}}$$

E: Electric field strength
I: Electric current
D: diffusion coefficient in the temperature range [T_a, T_m].
λ: Thermal conductivity at the temperature T_m
r_o: discharge core radius
T_m: axial gas temperature

From the above relation the temperature can be evaluated using the experimental values of EI, r_o, and τ. The values of $\lambda/\sqrt{D}$ are taken from the literature and are fitted as a function of the temperature.
Then we find that the T_m temperature range is 2000-4000 K.

Taking account these results and the sweeping efficiency it can be assumed that, approximately 50% of the gas, can be treated. This value indicated a significant improvement of the results in comparison with the previous ones.

4. Experimental results

Concentrations of the outlet products are shown in figure (4) as a function of the power. The CO_2 and C_2 concentrations are not significant (less than 1%).

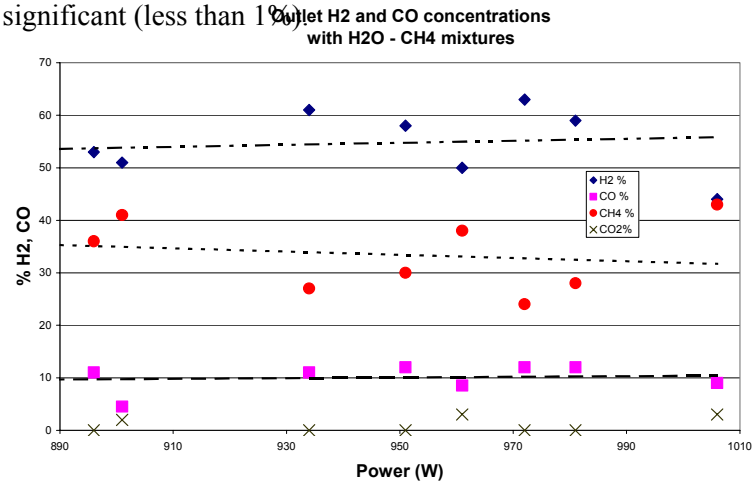

Figure 4: Outlet H_2 and CO concentrations with H_2O-CH_4 mixtures

5. Discussion

5.1. Thermodynamic model

We have tried to model the chemical processes occurring in the glidarc reactor starting from conclusions drawn in our previous studies [4]. Firstly, we considered that the reactions occur mainly in the discharge string. As is shown above 35-45% of the inlet gases penetrates the discharge [6]. Therefore, in our model we have considered that the inlet gas stream is divided in two parts: the main part that remains at 400 K and a smaller percent that is heated up in the discharge. We also have considered that both streams arrive at thermodynamic equilibrium. According to the above measurements, the temperature on the outer surface of the discharge string ranges between 2000 and 4000 K. The fact that the mean temperature in the reactor is increasing during the experiments from one end to another with only 100 K [8], is leading to the conclusion that the glidarc zone has to be treated as an almost adiabatic zone. In this kind of model, the gas penetrating the discharge is almost instantly heated up to more than 2000 K. Afterwards, its temperature follows the

temperature profile of the arc and when it leaves the string, sharply cools down to ambient temperature almost without heat exchange.

5.2. Comparison between model and experiment

An example of thermodynamic calculation results for the composition of gases quenched out from the arc discharge is shown in Figure 5. The calculations suggest that the temperature is usually not higher than 2700K, but in some cases the possibility of having higher temperatures (up to 3000K) on the outer surface of the arc could explain the presence of acetylene in some of the samples collected from the reactor outlet.

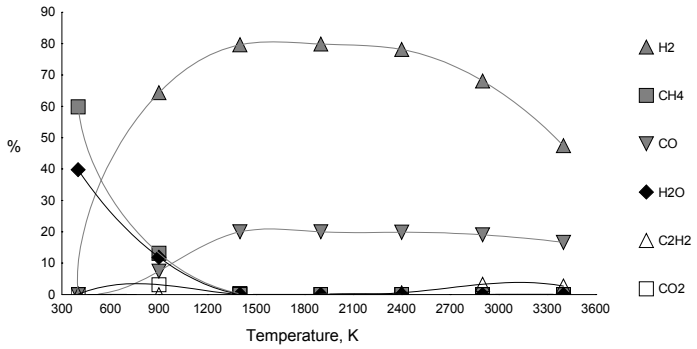

Figure 5: Concentration of different reaction products at the outlet of the discharge string calculated by means of the Chemical Workbench code for the molar ratio $CH_4/H_2O = 1.5$.

If we consider a large heat exchange between the discharge and the gas stream, the outlet temperature from the reactor has to rise up to about 800 K. However, this is not true, because neither the chemical analysis (i.e. the lack of CO_2) nor the temperature measurements indicate this behaviour. Therefore, the model implies mass transfer but no heat transfer between the arc and the rest of the gas stream.

According to this model we have calculated the gas fraction that passes through the arc as a function of chemical analyses. On our calculation, we also have taken into account the volume modification due to the chemical reactions occurring in the glidarc. As expected, the values are in the range 50-45% explaining the methane conversions.

Conclusions

The new magnetic blow out glidarc reactor has reached its main aim – the increase of the methane rate conversion. The back- breakdown model leads to the temperature range operating conditions. A simplified model then can be used. On the other hand the system is well suited for plasma catalytic reactions. Further tests must to be performed, in order to determine the best feeding parameters of the reactor and the effect of plasma catalysis and/or classic catalysis on hydrogen production.

Surface Changes of Atmospheric Glow Discharge Treated PTFE Films

Aubrecht L., Koller J.

Department of Physics, Faculty of Electrical Engineering, Czech Technical University, Technická 2, 166 27 Prague 6, Czech Republic

Both atmospheric and low-pressure electrical discharges are used for enhancing properties of polymer substrates. The deposition and modification of thin films is mostly performed by high frequency or microwave discharges under vacuum conditions in the range between 0.001 and 1 mbar. Due to the requirement of a vacuum system, these processes are very expensive, particularly for large substrates. Therefore, the plasma-enhanced deposition and modification of various films at atmospheric pressure is a promising approach to perform the modification of large-sized low-cost products such as polymer foils, metal bands, textiles or papers.

The state of the art of this new technology is discussed. The influence of various process parameters on the discharge properties is shown. The various surface modification plasma technologies are also discussed.

This paper deals with phenomena observed during the study of plasma deposition and modification of polymer surfaces – effects of corona discharge treatment on PTFE surfaces and the influence of treatments on the physical properties of these surfaces.

Positive ion and neutral radical measurements in $Ar/C_4F_8/O_2$ capacitive discharges

Nicolas Bulcourt[1], Jean-Paul Booth[1], Jacques Jolly[1], Eric A. Hudson[2], Jorge Luque[2]

[1] *Laboratoire de Physique et Technologie des Plasmas (LPTP), Ecole Polytechnique, France.*
[2] *Lam Research Corp., Fremont, USA*

Introduction

Capacitive discharges in gas mixtures such as $Ar/C_4F_8/O_2$ are widely used in the microelectronic industry for integrated circuit fabrication. This plasma chemistry allows selective etching of SiO_2 over Si, while depositing polymer films to control the feature profiles and dimensions. Nevertheless, small changes in the gas composition can cause drastic changes in the etch behavior, giving a narrow process window. It is therefore necessary to obtain a better understanding of the processes governing the fluxes of reactive ionic and neutral species to the etched substrate.

1. Ions in a single frequency discharge

Experimental Setup

The $Ar/O_2/C_4F_8$ capacitive discharge is generated in a confined parallel plate reactor at a pressure of 50 mTorr. The diameter of the electrodes is 12 cm and the gap distance is 3 cm. A grid connected to ground confines the plasma. Consequently the area ratio, defined as area of the ground electrode (and grid) to the powered electrode is equal to 2. A Hiden quadrupole mass spectrometer (QMS) is implanted under the ground electrode. The species are collected through a hole with a diameter of 100 microns in the center of the ground electrode. A differential pumping system maintains a pressure inside the mass spectrometer lower than 10^{-6} Torr. The figure 1 shows a schematic diagram of the experimental apparatus.

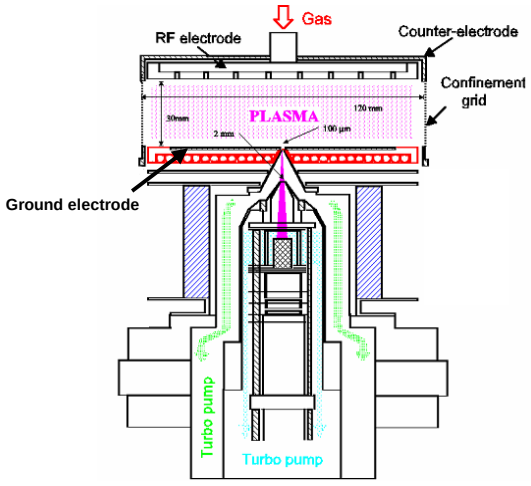

Figure 1: *Experimental Setup for the mass spectrometry.*

Results

We determined the composition and energy distribution functions of the positive ions (figure 2 and figure 3) for different conditions of discharge. We especially investigated the effect of the RF power (20 and 50 Watts), the addition of oxygen gas to the mixture and the excitation frequency (13.56 to 40.68 MHz).

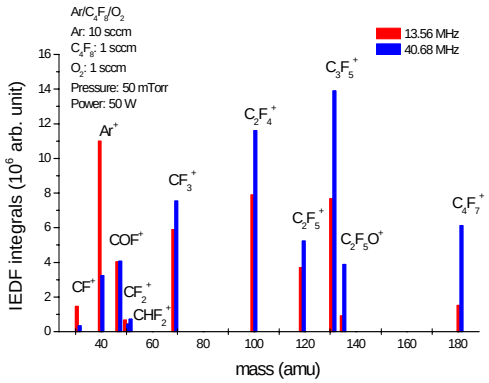

Figure 2: *Effect of the frequency on the positive ionic composition.*

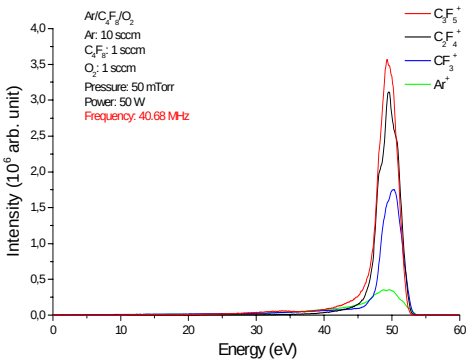

Figure 3: *Ion energy distribution functions for some positive ions.*

The major positive ions observed were Ar^+, COF^+, CF_3^+, $C_2F_4^+$, $C_2F_5^+$, $C_3F_5^+$ and $C_4F_7^+$. This mass distribution is in broad agreement with the measurements of Jiao et al. [1] of the dissociative ionization cross-sections of C_4F_8. Increasing the oxygen flow-rate favors the ions CF_3^+ and COF^+ and decreases the flux of the heavier fluorocarbon ions.

Figure 4 shows an example of the ion energy distribution functions observed at the grounded electrode. At the lowest excitation frequency the ions have a high average energy due the high plasma potential in this nearly symmetrical system, and the saddle structure can be seen, caused by the large RF modulation of the plasma potential [2,3,4]. As the excitation frequency is increased, the average ion energy decreases, as does the width of the saddle: at 40.68 MHz the ions are nearly mono-energetic.

Figure 5 shows the IEDF's of certain ions that show low energy structure. As expected, the Ar^+ ion is strongly affected by the rapid symmetric charge exchange occurring with neutral Ar, present in large concentration [5, 6 and 7]. More surprising is the low-energy structure observed for CF_2^+, CF_3^+ and CF^+. We attribute this again to symmetric charge exchange, this time with the appropriate neutral free radicals, present in significant concentration. This technique can therefore also give information about the presence of neutral free radicals in the plasma.

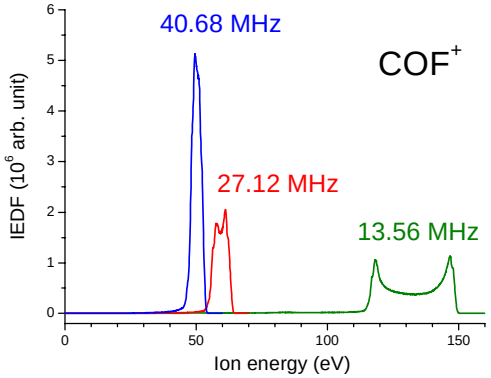

Figure 4: *IEDF of the ion COF^+ as a function of excitation frequency: 50 mTorr, 50 W RF power.*

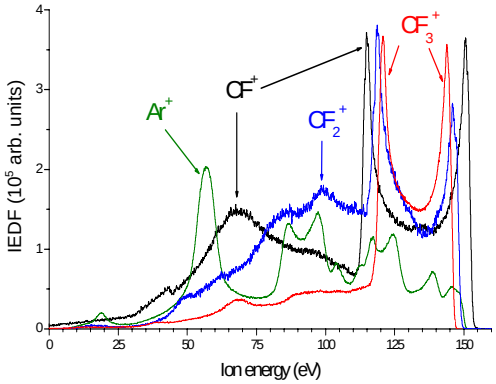

Figure 5: *IEDF's showing low energy structure. 13.56 MHz, 50 W, 50 mTorr.*

Mass spectrometry allows measurement of the mass distribution of the discharge and the energy distribution functions of the different species that are present in the plasma. We were able to study the major positive ions that are present in this discharge and to demonstrate the importance of complex mechanisms such as charge exchange.

2. CF_2 study in a Dual frequency capacitive discharge

Experimental Setup

The CF_2 radicals were created in an $Ar/C_4F_8/O_2$ dual frequency (27 MHz + 2 MHz) capacitive discharge. The discharge was generated in a commercial dielectric etch system (Lam Research) that was modified to permit optical measurements (figure 6). We measured the UV absorption spectra of CF_2 A-X band using the broad band UV spectroscopy technique [8] using a commercial broad band Xenon lamp and a commercial 0.75 m spectrograph with multi-channel photodiode array detector (PDA).

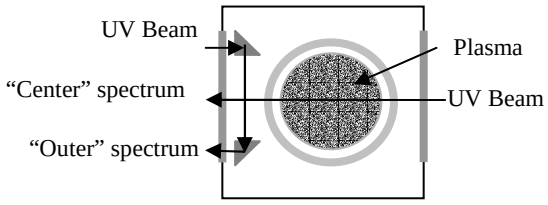

Figure 6: *Experimental Setup for the measurements of the UV absorption spectra.*

The plasma is radially confined by quartz rings. The CF_2 radical is relatively unreactive and therefore is present in significant number density outside the confined plasma volume. Consequently, to measure the CF_2 density in the plasma we need to measure two spectra. The "center" spectrum (measured across the chamber (figure 6)), and an "outer spectrum" measured in the chamber but outside the confinement quartz rings (figure 6) using quartz prisms to direct the beam. From these two spectra we were able to determine the CF_2 density in the plasma. Figure 2 shows examples of the UV absorption spectra obtained.

These results show that the CF_2 spectra in the plasma and outside the confinement rings have a very different shape. The "center" spectrum is more intense and hotter (the vibrational hot bands are more visible) than the "outer spectrum". Moreover we can see that the radical CF is present inside the confinement rings but not outside the rings. This is due to its shorter lifetime compared to CF_2 (the surface reaction coefficient of CF is higher,).

A more detailed analysis of the "center" spectrum indicates that CF_2 is not only hot but has vibrational energy distributions that deviate from a Boltzmann distribution (figure 8).

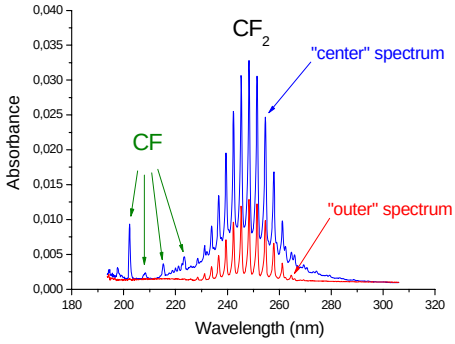

Figure 7: *UV absorption spectra of the radical CF_2.*

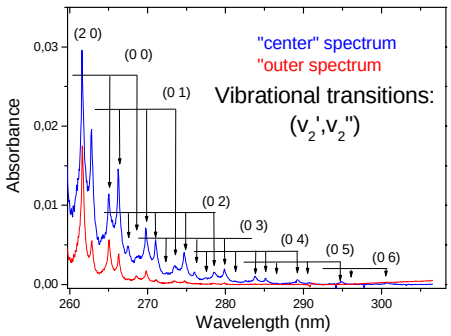

Figure 8: *Assignment of the vibrational hot bands for the CF_2 spectra.*

This suggests that the CF_2 molecules are initially produced in highly-excited vibrational states and are only partially relaxed by collisions. The presence of these highly-vibrationally-excited molecules can explain the apparent continuum absorption that we can see in figure 7. However, even for the "hot" spectra it should be possible to deduce the CF_2 density from the *integrated* band intensity, independent of the vibrational level distribution.

Determination of the CF_2 density

A fitting routine was written to determine the density and the temperature of CF_2 from the UV absorption spectrum. We simulated the different spectra using a program that takes into account the spectroscopic constants, the wavelengths and the Franck-Condon factors (FCF's) of the different transitions we considered. The spectroscopic constants and the wavelengths were taken from the literature [9, 10]. When the constants were not known they were estimated by linear extrapolation.

The formula used to fit the different spectra is:

$$Y = Baseline + \sum_{\nu'\nu''} P_{\nu''} * FCF_{\nu'\nu''} * \lambda_{\nu'\nu''} * S_{\nu'\nu''}(Trot) \quad (1)\ [11]$$

where:

$P_{\nu''}$ is proportional to the relative number density of the different vibrational levels in the ground state.

$FCF_{\nu'\nu''}$ is the Franck-Condon factor of the transition $A(0,\nu',0) \leftarrow X(0,\nu'',0)$.

$\lambda_{\nu'\nu''}$ is the wavelength in nanometers of the transition.

$S_{\nu'\nu''}(Trot)$ is the rotational envelope for each vibronic transition, calculated from the rotational temperature and the spectroscopic constants. Each integrated band intensity is normalized to unity.

Results

Figure 9 shows the agreement between the simulated and experimental spectra. The Franck-Condon factors were deduced using the following formula:

$$Y = Baseline + \sum_{\nu'\nu''} P_{\nu'\nu''} * S_{\nu'\nu''}(Trot) \quad (2)$$

where $P_{\nu'\nu''}$ is equals to $P_{\nu''} * FCF_{\nu'\nu''} * \lambda_{\nu'\nu''}$.

Consequently, the ratios of the different parameters $P_{\nu'\nu''}$ for the same ground state level and the relation $\sum_{\nu'} FCF_{\nu'\nu''} = 1$ allows the FCF's to be deduced, as shown in Table 1:

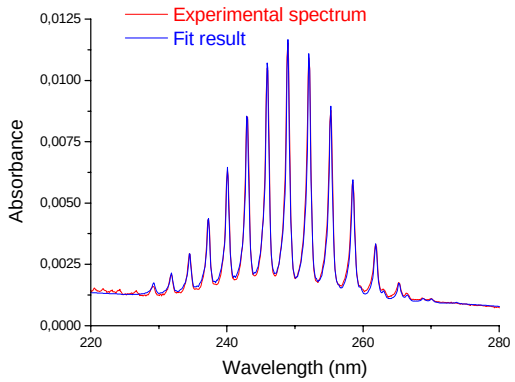

Figure 9: *Result of the fit of a CF_2 spectrum.*

Table 1: *Experimental Franck-Condon Factors*

The FCF's are normalized to unity for the same ground state level.

Fitting of the spectra allows the line-integrated CF_2 number density to be determined as a function of process parameters including pressure, total gas flow, residence time etc. Figure 10 is an example of results for this study.

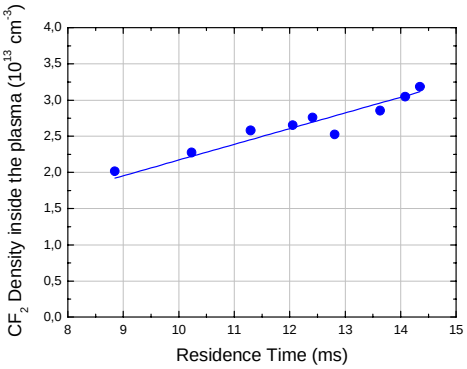

Figure 10: *CF_2 density versus the residence time.*

Ultraviolet absorption spectroscopy is a simple technique for measuring the density and the temperature of the radical CF_2. The measurements of the "outer" and "center" spectra have different band shapes that can be explained in terms of the different cooling, production and destruction mechanisms.

3. Conclusion

The chemistry of the Ar/O2/C4F8 capacitive discharges brings into play complex mechanisms where the positive ions and the neutral species play an important part. Indeed, this kind of discharge contains a large range of species. The major positive ions are Ar^+, COF^+, CF_3^+, $C_2F_4^+$, $C_2F_5^+$, $C_3F_5^+$ and $C_4F_7^+$ with quite different energy distribution functions due to charge exchange processes. Concerning the study of CF_2 , we deduced from the experimental results a set of Franck-Condon factors that permitted us to simulate with a good agreement the UV absorption spectra and to determine the absolute density and the rotational temperature of this radical which plays an important part for etching SiO_2 during processes applied in microelectronics industry.

Abstract

An atmospheric pressure plasma abatement system of PFC in a capacitive-coupled plasma (CCP) reactor is proposed. CF_4 abatement attained 96 % decomposition efficiency of CF_4(flow rate, 20 sccm) at 2.4 kW of discharge power in the H_2/O_2/He plasma. We also proposed an atmospheric pressure plasma abatement system of PFC using 27.12 MHz inductive-coupled plasma (ICP) reactor. In case of ICP plasma, CF_4 abatement attained almost 100 % decomposition efficiency for 100 sccm at 2.5 kW of discharge power in the H_2O/Ar plasma. We found only CO_2 and HF as the reaction products in the composition of exhaust gas.

1. Introduction

In the semiconductor fabrication industry, fluorocarbons (FC) such as CF_4, C_2F_6, and CHF_3 are used as the etching gases. They have been identified as global warming gases. For example, CF_4 has a long lifetime of more than 50000 years and the global warming potential (GWP) of CF_4 is 65000 times higher than CO_2. From the point of view of the protection of the environment as required in the Kyoto protocol, scientists had been requested to remove perfluorocompounds (PFCs) from the exhaust gases. The large combustion system had been used to achieve the abatement of PFCs. But such a combustion system is unable to decompose all of the fluorinated compounds and needs great running cost. Therefore, a compact and effective abatement system was required, such as a point-of-use (POU) reactor in the exhaust gas line. Recently, a plasma abatement system that was inserted between a primary process turbo pump and a secondary dry pump was introduced as the POU abatement system for exhaust gas [1]. However, the inner surface of the secondary dry pump must be protected from the erosion of HF or F atoms, which were exhausted from the abatement system. When the abatement system needs repairing or cleaning inside, the main etching chamber that is kept in very clean condition must also stop and one must spend longer than 2days for interruption and rebuilding, because the etching chamber needs hard baking out for out - gassing of the chamber walls exposed in atmosphere. If we could destroy the PFC just after the dry pump at atmospheric pressure, this problem should be solved. We need not open the etching chamber for repairs and we need not clean the inside of the atmospheric abatement system. So we propose new atmospheric pressure plasma abatement systems. The first system uses 13.56MHz capacitive-coupled plasma (CCP) as low temperature plasma system and the second one uses 27.12 MHz inductive-coupled plasma (ICP) reactor as high temperature plasma system.

2. Experimental

Figure 1 shows the schematic diagram of capacitive-coupled (CCP) abatement system (reactor No. 1). The inner electrode is a stainless steel tube cooled by water. The outer tube is an alumina tube that is covered by a stainless mesh outer electrode, to which is applied 13.56 MHz RF high voltage. The outer tube was cooled by blown air. We used He as a carrier gas and O_2 and H_2 as abatement gases in CCP system.

Figures 2 and 3 show the schematic diagram of ICP abatement system (reactors No. 2 and 3). We used a

cylindrical quartz reactor (reactor diameter: 30mm ϕ for No.2 and 28mm ϕ for No.3). The outer side of the reactor cylinder was cooled by a silicone oil flow. A three-turn water-cooled coil is wound on the reactor and 27.12 MHz RF high voltage is applied; then ICP discharge is generated in the reactor. Ar is a carrier gas to sustain the ICP discharge at atmospheric pressure. For the apparatus in Figure 3 (reactor No. 3), the configuration is not different from reactor No.2 except for a smaller coil diameter than in reactor No.2. In ICP system, we used H_2O vapor as abatement gas supplied from Ar-water bubbling system and mixed with main flow. CHF_3 and CF_4 were used as fluorocarbon sample gases mixed with Ar carrier. The discharge conditions of CCP and ICP (reactors No. 2 and No. 3) are shown in Table 1.

The chemical products in the exhaust gas were analyzed by means of GC-MS (Shimazu, QP-5050) and FTIR (Nihon Bunko, Ltd; FT2000).

3. Results and Discussion

3.1 CHF_3 decomposition using CCP

First, we used the CCP system for CHF_3 abatement. We found CHF_3, CF_4, H_2O, CO_2 and SiF_4 in the FTIR

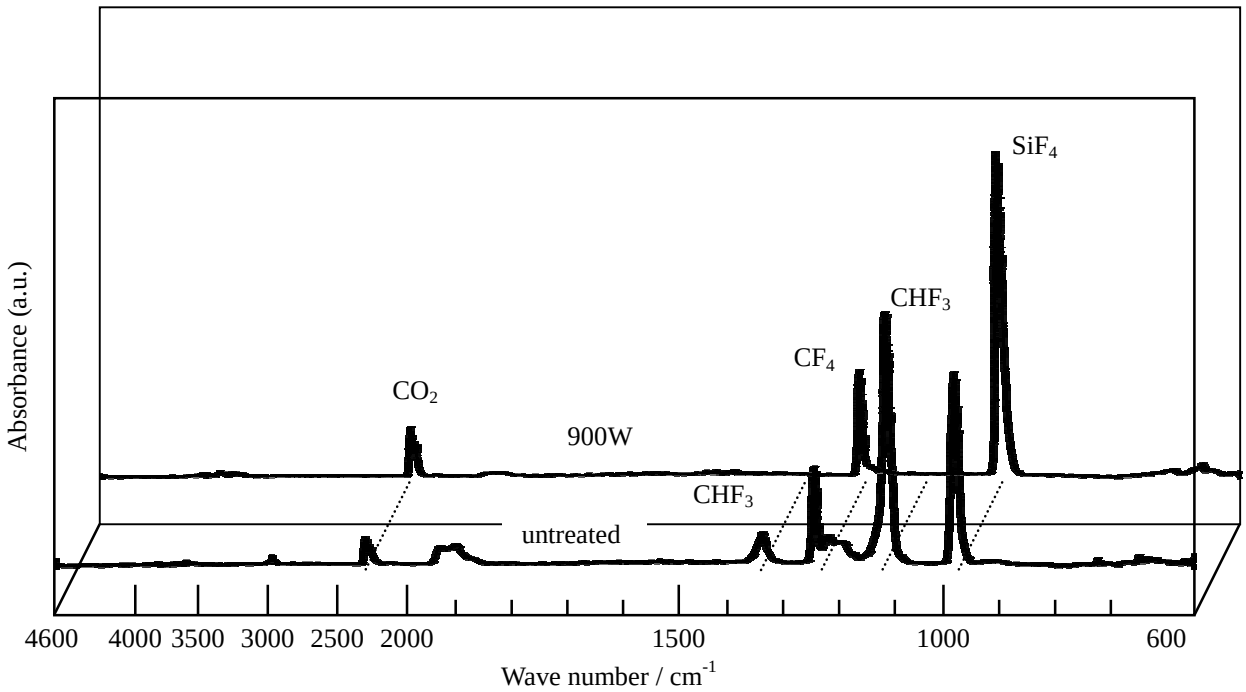

Fig. 4 The FTIR spectrum of CHF_3 decomposed by H_2/O_2/He system

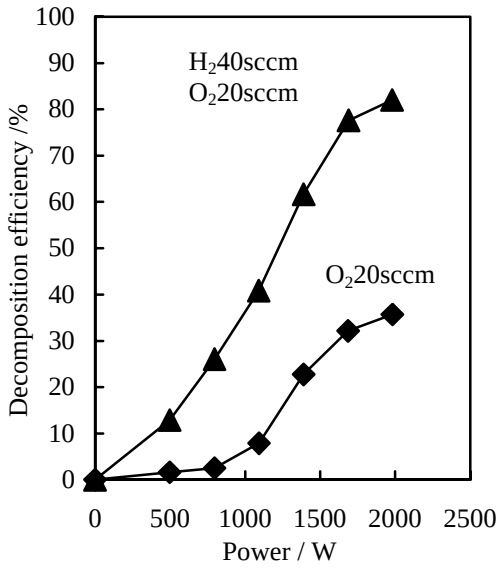

Fig. 5 Decomposition efficiency vs. discharge power

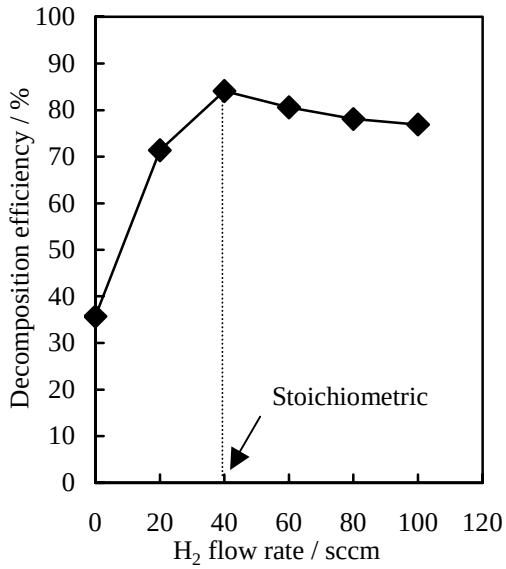

Fig. 6 The efficiency vs. H_2 flow rates in conditions of CF_4: 20sccm, O_2: 20sccm, He: 2slm

spectrum of CHF_3 decomposed by H_2/O_2/He system, as shown in Figure 4. The system line was partly made of Pyrex glass. The HF gas generated in plasma zone reacted with SiO_2 and produced SiF_4. The amount of CHF_3 decreased rapidly with increasing of the RF power and then disappeared at 700 W [2-3]. On the other hand, CF_4 that was one of the products increased with increasing of the CHF_3 decomposition, because CF_4 is one of the most stable FC molecules. CHF_3 produces CF_4 that has higher GWP than CHF_3 in the reactor. It is frequently reported that CF_4 is a kind of final product obtained by decomposing of other HFCs [1] not only for CHF_3. It seems that if CF_4 is decomposed completely, the abatement system will be effective enough in other FC decompositions. This means CF_4 is the next important target of FC abatement.

3.2 CF_4 decomposition using CCP

We tried to abate CF_4 by H_2/O_2/He using CCP system. Figure 5 shows decomposition efficiency vs. discharge power. In the figure, the parameters are abatement gas mixing conditions. When we put H_2/O_2 as (H_2: 40 sccm and O_2: 20 sccm) abatement gas in the reactor, the decomposition efficiency of CF_4 attained about 80% in 2kW, but if we put only O_2 (with out H_2) in the mixture, only 35% of CF_4 is dissociated at the same power. We suppose that produced F atoms immediately reacted with H_2 to produce stable molecules such as HF in H_2/O_2 system. But, due to the lack of H_2, F atoms reacted with CF_x radicals to produce CF_4 in the reactor. In the latter condition, when we increased O_2 concentration higher than 20sccm, we could not have higher efficiency than in Figure 5, because the reaction rate of F and H_2 is some orders higher than with F and O_2.

Figure 6 shows the efficiency vs. H_2 flow rates in conditions of CF_4: 20sccm, O_2: 20sccm, He: 2slm. We attained maximum efficiency at 40sccm of H_2. This means the stoichiometric concentration of H_2, O_2 and CF_4 gives a maximum for the CF_4 abatement, as in the total reaction scheme (1):

$$CF_4 + 2H_2 + O_2 = CO_2 + 4HF \qquad (1)$$

The efficiency decreased with increasing of the concentration of H_2 for higher stoichiometric flow rates. When we put more hydrogen than stoichiometric, hydrogen consumes the power to produce hydrogen atoms. On the other hand, the hydrogen atoms can not take part in abstraction reactions of fluorine atoms from CF_4. Therefore the efficiency decreases in the concentration region higher than stoichiometric.

Figure 7 shows the effect of carrier gas flow rate or residence time vs. efficiency in the reactor in the stoichiometric condition of H_2, O_2 and CF_4. In the Figure, there is almost no change of the efficiency for the He flow rate changing from 2slm to 10slm. In the plasma, the starting reaction is He excitation by electron impact. Then, He in excited state reacts with all molecules as sample gases to produce many kinds of radicals. All reaction rates containing fluorine abstraction reaction must be very fast compared with the

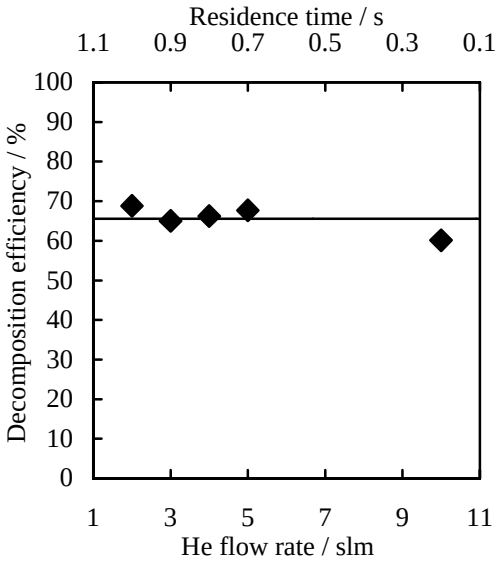

Fig. 7 The effect of carrier gas flow rate or residence time vs. efficiency in the reactor with the stoichiometric condition of H_2, O_2 and CF_4

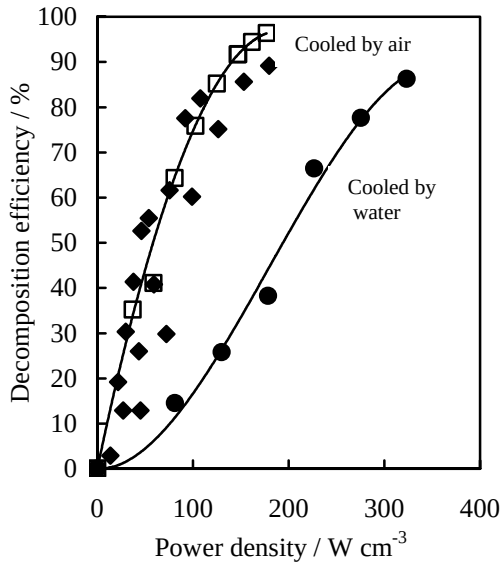

Fig. 8 Decomposition efficiency of CF4 vs. discharge power density in H2O/He CCP system

residence time in the reactor.

Figure 8 shows the decomposition efficiency vs. discharge power density; parameter is cooling situation of outer electrode of the reactor tube. As shown in Figure 8, the results were separated into two groups. One was using an outer electrode cooled by blown air and the other was using the outer electrode cooled by water. When we used blown air-cooled outer electrode, the maximum dissociation efficiency attained 99.6% with 20sccm of CF4, but in the case of using water-cooled outer electrode, the efficiency decreased to 85%. The decomposition efficiency is dependent on the temperature in the reaction zone as shown in the Figure 8. Because the temperature in the discharge zone will be changed by cooling conditions of outer electrode. It seemed that the plasma decomposition mechanism might include part of the thermal dissociation even in CCP. But in the CCP system, the temperature of reaction zone was somewhat higher than 1200 K measured by thermal crayon method. So it wasn't high enough to abate CF_4 completely because the thermal dissociation of CF4 will begin at about 1500 K resulting from the higher bond energy of C-F.

In the CCP discharge, primary electrons to start the glow discharge will be exhausted from the reactor wall then accelerated by the field and will ionise the molecules to maintain the discharge. The main part of the source power is not consumed to heat gases but to accelerate electrons. We conclude that, if we wish to dissociate more than 20 sccm of CF4, we need higher than 3kW of the power in the CCP. So CCP system cannot accomplish the perfect dissociation of concentrations higher than 20 sccm of CF4 at reasonable source power.

3.3 CF_4 decomposition using ICP

In the ICP system, it is easier to obtain high temperature than in the CCP system. In the ICP, after the discharge starts, the electron will be produced from molecules or atoms by thermal ionisation in high temperature condition (higher than a few thousand K). Thus, electron energy is consumed only for heating the gas molecules. So we used the ICP system for FC abatement to obtain higher power density and higher temperature in the reactor. We tried to abate the CF_4 in H_2O/Ar system as shown in

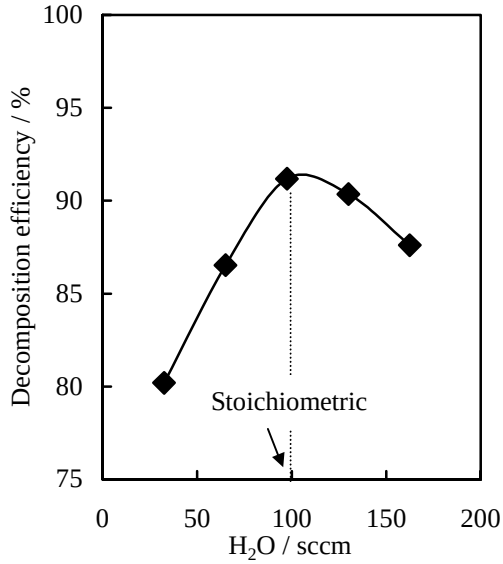

Fig. 9 The decomposition efficiency as a function of flow rate of H_2O vapour

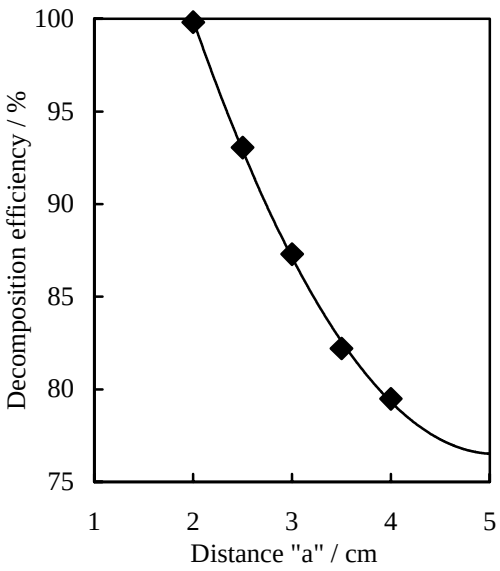

Fig. 11 The decomposition efficiency vs. the position of an inlet tube with fixed coil

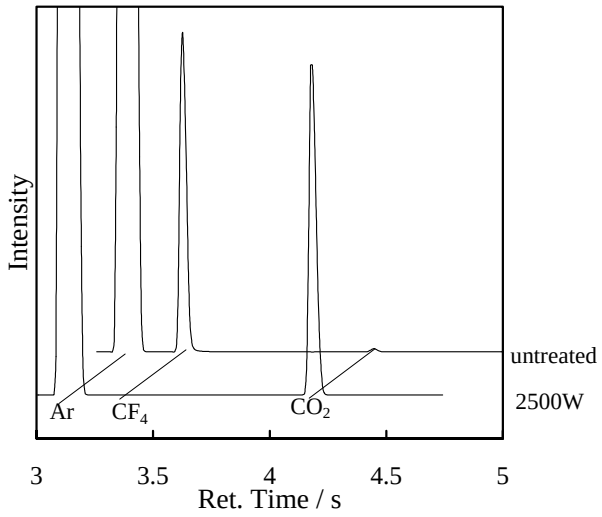

Fig. 12 GC-MS spectra of untreated gas containing CF_4 100sccm and treated gas

Figure 2 (reactor No.2). Figure 9 shows the decomposition efficiency as a function of flow rate of H_2O vapour. The maximum efficiency is always attained at stoichiometric concentration of H_2O with CF_4 added as in the CCP system. We fixed the concentrations of CF_4 and H_2O at stoichiometric ratios. Figure 10 shows the decomposition efficiency vs. Ar flow rates obtained in the reactor No.2. The maximum decomposition efficiency of 50 sccm CF_4 was 100 %, attained at 2.4kW discharge. By using ICP, we attained much higher decomposition efficiency than in CCP system even at about the same discharge power.

Figure 11 shows the decomposition efficiency vs. the position of an inlet tube with fixed coil. The distance (a) means the distance to inlet top measured from the centre of the coil. The centre of a hot plasma bowl is almost in the coil centre. The efficiency is strongly dependent on the distance (a). When we introduce the sample flow in the plasma centre or near the coil centre (1-2cm), we have maximum efficiency, but at longer than 2.5 cm, the efficiency is going to decrease. The space of the reactor was cooled through the wall by the silicone flow. When the inlet is far from the plasma bowl, a part of the sample flow will pass through the cooled crevice between the wall and the edge of the hot plasma bowl. The decreasing of the efficiency in

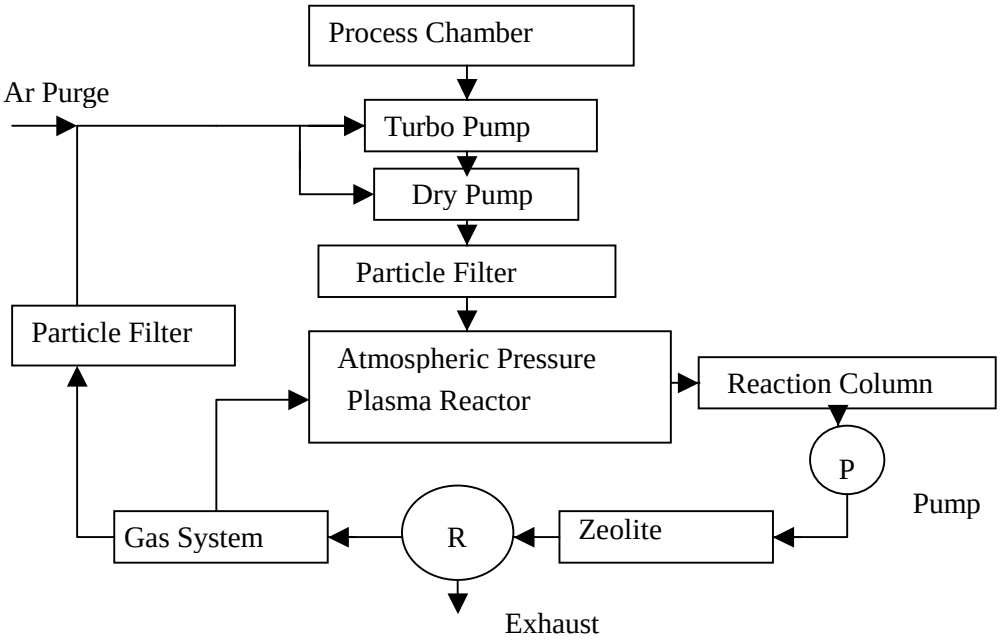

Fig. 13 Schematic of carrier gas recycling system for the atmospheric CF_4 abatement

Figure 11 can be explained by the presence of a of low temperature region at the side of the crevice flow. Because CF_4 molecules will not dissociate enough in the low temperature zone, the sample flow must be placed as close as possible to the centre. We found only CO_2, H_2O and HF as the products by using GC-MS and IR measurements of the exhaust gas. HF and other fluorine components were trapped with a solid alkaline absorber. The maximum dissociation ability for CF_4 flow rate was 50sccm at Ar flow rate of 3.25slm in reactor No.2.

Trying to realize the dissociation of a certain amount of CF_4 (100 sccm) and to find optimum conditions by H_2O/Ar ICP, we used smaller diameter of the induction coil to have higher plasma density in the reactor. The coil diameter of reactor No.3 is 45mm ϕ instead of 58.5 mm ϕ in reactor No.2. By using the small size coil, the field strength in the reactor will become stronger than that of large one.

Figure 12 shows GC-MS spectra of untreated gas containing CF_4 100sccm and treated gas. In the treated gas, CF_4 peak is lost and CO_2 peak is increasing. The system that can dissociate 100sccm of CF_4 is able to correspond to the total exhaust amount of a few normal-sized etching apparatuses.

We will finally propose the **NO EMISSION SYSTEM** using Ar carrier gas recycling circuit and solid absorber such as soda-lime for HF and CO_2 absorption, as shown in Figure 13.

Abstract

A cryogenic SF_6/O_2 plasma process is used to etch silicon trenches with a high aspect ratio (depth/width>10). Test experiments have been carried out to characterize the passivating layer, which forms on the structure sidewalls. These tests revealed that the layer doesn't need sulfur to be rebuilt. In certain process conditions (high O_2 flow), black silicon phenomena appears in trench bottom. A statistical study of its apparition will be also presented.

1. Introduction

Power microelectronics and microsystems industries intensively utilize silicon deep etching processes to elaborate high aspect ratio structures. At least two different kinds of dry etching process are used to realize such structures.

First, the so-called Bosch process [1] is probably the most used in industry. It operates at ambient temperature and consists of a succession of etching and deposition steps. Etching is performed with SF_6 plasma and deposition with C_4F_8 plasma. The etching step is isotropic. The passivation layer, which is deposited on the bottom of the structure during the C_4F_8 plasma, is then sputtered by energetic incident ions produced during the etching step. Sidewalls remain protected by the passivating layer since ions don't sputter this part of the structure. After many steps of etching and deposition, a high aspect ratio structure forms. This process can be very well controlled and can be applied to many different types of structure. Although it is often used, the Bosch process presents many drawbacks. First, a scalloping effect appears on sidewalls. This issue can be important especially when structures have to be filled with specific materials. During this filling step, some unwanted voids can be obtained due to the scalloping effect. Moreover, the reactor has to be frequently cleaned since deposition on reactor walls can induce some process parameter shifts.

An other process can be used for anisotropic etching of silicon: the cryogenic process. Cryogenic process consists of cooling the wafer during etching. A mixture of SF_6 and O_2 gas is introduced into the reactor. A passivation layer is formed on sidewalls while silicon is continuously etched at the bottom of the structure. This passivation layer forms only at very low temperature and in presence of oxygen. This phenomenon was first observed by Tachi et al.[2] in the end of the 80's. The etching rate can be as high as 4 $\mu m.min^{-1}$ for a 80 µm deep, 4 µm wide Si trenches [3]. In this process, the reactor remains quite clean and doesn't need any step of cleaning. Moreover, structure sidewalls are particularly smooth and no scalloping effect appears, which is quite convenient for filling steps. In spite of these significant advantages, the cryogenic process is not yet very much used because it is a very sensitive process. For example, a shift of one degree at the surface of the wafer is sufficient to modify the profile shape.

The passivation layer, which forms at low temperature, is not yet very well characterized. It seems to be composed of $SiO_xF_yS_z$. Some previous XPS analyses have shown that the passivation layer is removed when the wafer is warmed up to the ambient temperature [4]. This passivating layer is not mainly composed of SiO_2. Some characterization tests were realized to rebuild this passivation layer when it is destroyed [4]. We present in this paper new results, which indicate that the passivation layer doesn't need the presence of sulphur to efficiently protect sidewalls from etching.

In some process conditions (high O_2 content and low temperature), black silicon forms in the bottom of structures. This black silicon is considered as a significant defect since it can definitely stop etching. The black silicon origin is not very well defined. It seems to come from roughness, which dramatically amplifies in such processes [5,6]. We performed a parametrical study of the black silicon apparition versus O_2 content, bias and temperature. A statistical study will be presented as well.

2. Materials and methods

2.1 ICP reactor

Etching experiments are carried out in an ICP (Inductively Coupled Plasma) reactor (601E Alcatel) (Figure 1). On the top of plasma source, up to 1000 sccm SF_6 flow and 200 sccm O_2 flow can be injected. Up to 3000W power can be applied to the plasma source. Si wafer is mechanically clamped on the wafer holder. Chuck is cooled by liquid nitrogen and heated by a set of resistors to control the temperature between +40°C to – 150°C. Thermal contact is assured by helium at pressure of 10 mbar. The wafer is self-biased by applying independently an RF voltage (capacitive coupling). A constant magnetic field is applied to the plasma source part to confine the plasma. Permanent magnets are placed around the diffusion chamber.

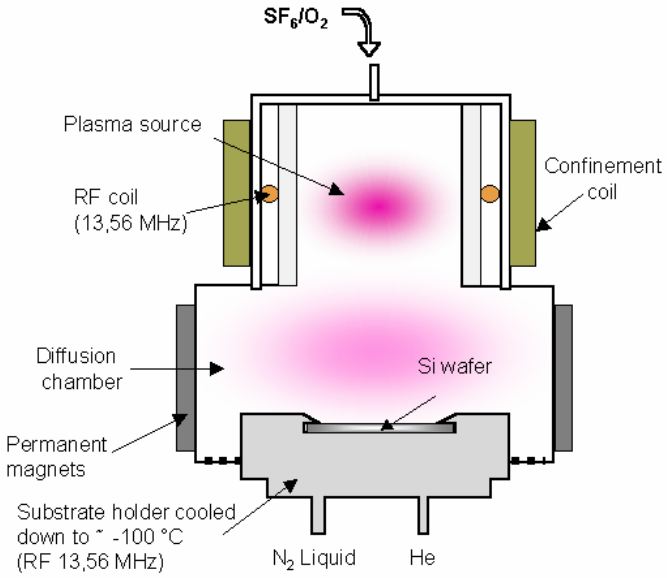

Figure 1 : Schematic diagram of the ICP reactor

Profiles are characterized using a Scanning Electron Microscope after cleavage. We worked with (100) silicon wafers (P doped). For passivation test experiments, we used trench patterned wafers with a 1 µm thick SiO_2 mask, which offers a very high selectivity (>300:1) [3].

2.2 Statistical method for black-silicon analysis

Top views of black silicon are observed by SEM and recorded. Images are then treated using imaging software. An example, which does not correspond to a real SEM image, is given in figure 2. We made a test picture (figure 2.a) to validate the image analysis method.

The first treatment consists of applying a threshold to detect areas in relief (figure 2.b). The different areas are then numbered and their surface is measured (figure 2.c). A table is made gathering all the detected areas. An histogram can be drawn giving the number of objects versus area ranges.

	BinCtr(X)	Count(Y)	BinEnd	Sum(Y)
1	500	17	1000	17
2	1500	12	2000	29
3	2500	2	3000	31
4	3500	0	4000	31
5	4500	0	5000	31
6	5500	0	6000	31
7	6500	0	7000	31
8	7500	0	8000	31
9	8500	0	9000	31
10	9500	1	10000	32

Figure 2 : Image analysis method for the black silicon statistical study

3. Passivation layer

As described in a previous paper, the passivating layer is not mainly composed of SiO_2 [4]. This was shown by XPS analysis. The passivating layer is actually removed when the wafer is warmed to ambient temperature. We have made some new test experiments to better understand what the passivation layer is composed of. As mentioned in reference [4], the passivation layer can be rebuilt when it is destroyed. It requires the insertion of a so-called "over-passivating" step. We reported that a plasma with oxygen only (without SF_6) was not able to reform an efficient passivating layer. The passivation layer was successfully rebuilt by linearly increasing the SF_6 flow during 1 min so that O_2/SF_6 ratio varied from 86 % down to 6.5 % at constant O_2 flow. This result showed that SF_6 was necessary to properly rebuild the passivation layer when destroyed.

In figure 3, we present some new experiments, which indicate with more accuracy the necessary SF_6 content for a good passivation layer reconstruction. In figure 3.a, we remind the reference profile, which corresponds to a 10 minute process in standard etching conditions. The profile slope is slightly negative. With this particular process, usual defects are significantly reduced (very low bowing, weak undercut). It is important to notice that this process was very reproducible. Hence, it is used as a reference for this set of test experiments.

As explained in [4], after this 10 min etching step, the wafer is warmed up to remove the passivation layer. The wafer is then cooled again down to -110°C. The experiments corresponding to 3.b, 3.c, and 3.d figures were dedicated to the passivation layer reconstruction. On each profile, the reference profile was added in dotted line for comparison. One can notice that this reference process is very reproducible since the obtained profiles fit perfectly with other profiles. The 3.b profile was obtained after a 30 second step of "over-passivating" regime. In this regime, SF_6 flow is reduced and O_2 is maintained at the standard etching condition value. In figure 3.b, an O_2/SF_6 ratio as high as 1.3 was settled. After the over-passivating step, a 3 min standard etching process is applied to check if the passivation layer was well rebuilt. The profile is partially destroyed during the 3 min additional etching step. Damages appear on top of the trench, which indicate that the passivating layer was not completely rebuilt.

In the next experiment (figure 3.c), the same experimental procedure was performed except that the over-passivating step was modified : O_2/SF_6 ratio was reduced to 0.65 instead of 1.3. In this case, we see on figure 3.c that the 3 min additional etching step didn't induce any defect. We can conclude that this over-passivating process successfully rebuilt an efficient passivation layer. Other experiments showed that the upper O_2/SF_6 ratio limit must be lower than 0.85 to make the passivation layer grow in our experimental conditions. The lower O_2/SF_6 ratio limit is not yet defined. We just know that a ratio of 0.065 is too low to properly rebuild the passivation layer [4].

Finally, an experiment was carried out to check if sulphur is a necessary element in the passivation layer. The over-passivating step was modified in order to check this point. SF_6 was replaced by SiF_4 gas during the over-passivating step to rebuild the passivating layer. As shown on figure 3.d, SiF_4 was injected

with O_2 (O_2/SiF_4 = 0.65) during 30 seconds before the 3 min etching in standard conditions. The profile shows that the passivating layer was successfully rebuilt with SiF_4. This result indicates that sulphur is not a necessary element in the passivation mechanisms involved in the cryogenic process.

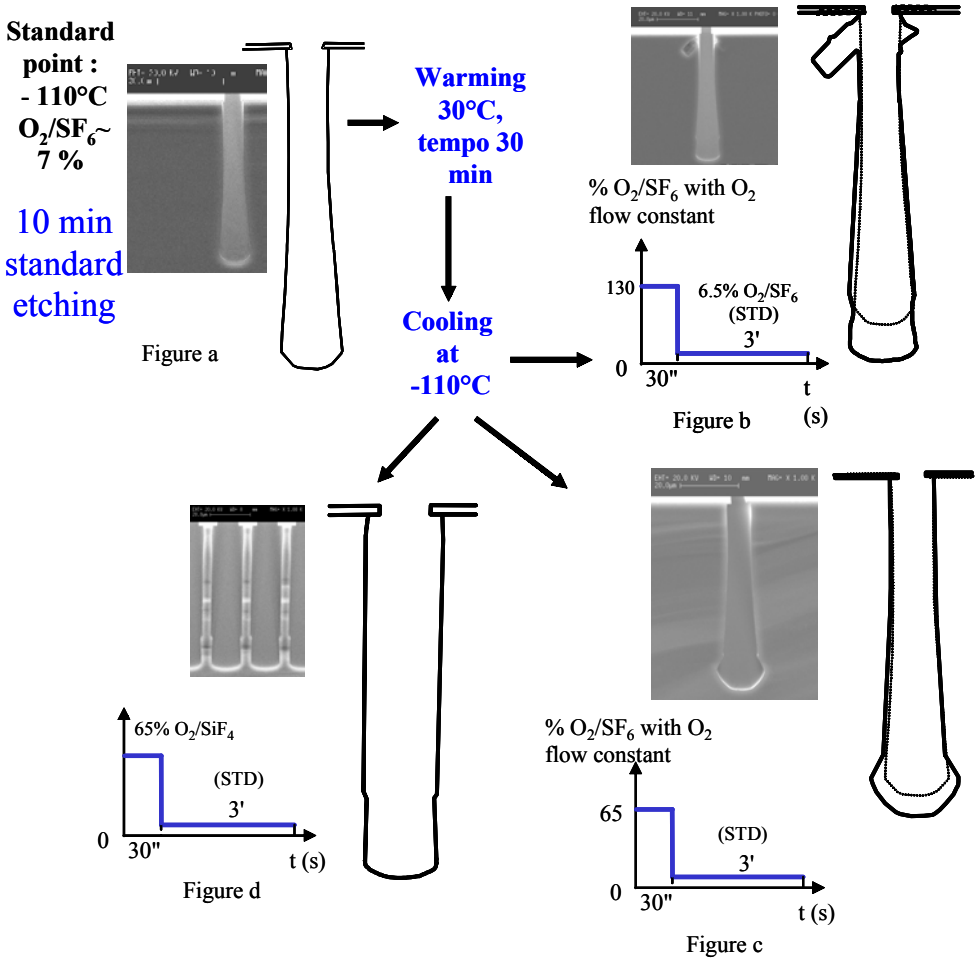

Figure 3 : Test experiments to rebuild the passivation layer after destruction

a)- Reference profile, 10 min etching in standard conditions

b)- After passivation layer destruction (warming step) and cooling back down to -110, insertion of a 30 sec long over-passivation step with O2/SF6 = 1.3, followed by a 3 min etching in std conditions.

c)- Reduction of the O_2/SF_6 ratio to 0.65 during the over-passivating step

d)- SF6 is replaced by SiF4 during the over-passivating step

3. Black silicon

Black silicon can appear in the bottom of trenches. It consists of a sort of "grass" in the micrometric scale, which appears black when enlightened. This phenomenon can be significant and can stop the etching process. Black silicon can be produced on wafers without mask. Experiments were carried out to investigate black silicon apparition mechanisms. 4 cm² silicon samples without mask were used for this experiment. They were cooled by the same system as the one used for regular wafers.

Black silicon appears only when O_2 flux is sufficient and at very low temperature. In figure 4, profile (a) and a top view (b) SEM images of black silicon are shown. On the top view, the black parts are in depth and white parts are in relief. This particular black silicon was obtained after a 40 min long process in over-passivating regime. Black silicon dimensions can reach several tens of micrometers (figure 4.a). Quite circular patterns are naturally generated. Their diameter is of the order of 1 µm in these process conditions.

A study of black silicon apparition was performed versus bias applied to the wafer in order to investigate the role of ion energy on its apparition. Other parameters (wafer temperature, pressure, source power, and process duration) were kept constant. We just varied the wafer bias, and the O_2/SF_6 ratio. On the graph of figure 5, squares are drawn when black silicon appeared and circles were used to indicate that no

black silicon was obtained. Between squares and circles, a boundary can be defined between the two regions of presence and absence of black silicon. It is clear that black silicon only appears whenever oxygen content is sufficient. A bias increase can be used to avoid black silicon apparition since the boundary shifts to the higher O_2/SF_6 values for higher bias. Some additional experimental points have to be added to draw the boundary of the two regions with accuracy.

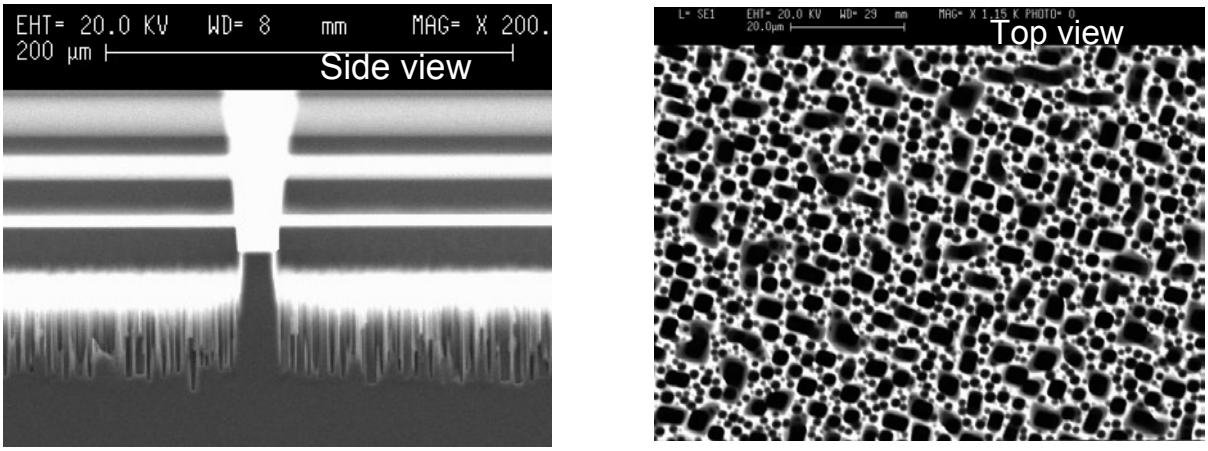

Figure 4 : Side view (left) and top view (right) of black silicon obtained after 40 min process in over-passivating regime

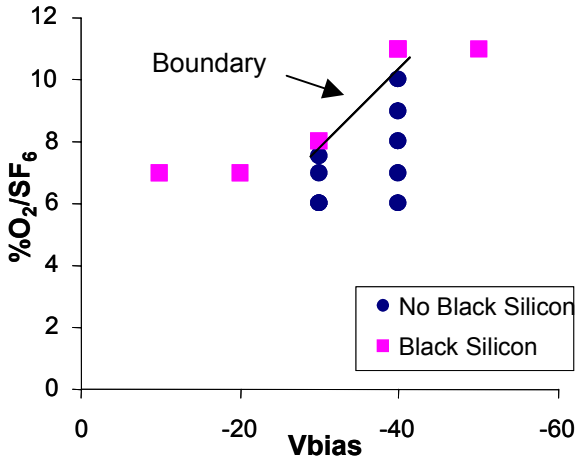

Figure 5 : Black silicon apparition versus Vbias and O2 content (SF6 flow was kept constant)

A statistical study on patterns created in the black silicon region is under progress in our laboratory. The method was described in paragraph 2.2. An example of such a statistics is given in figure 6 where a SEM picture (left) and the corresponding histogram (right) are presented. A characteristic dimension of 0.25 µm is obtained in the experimental conditions (T :-110 °C, O_2/SF_6 = 0.07, Pressure : ~3 Pa, Bias = -20 V). When temperature is increased up to –105°C, we observed that characteristic pattern dimensions increased (figure 6). Characteristic height of the black silicon can also be determined. We observed that this value increases with bias. Typically, in the same conditions, a typical height of 5 µm was obtained for a -20 V bias whereas it reaches up to 40 µm with a -50 V bias.

Black silicon formation seems to be linked to the surface roughness [5,6]. In the cryogenic process, this roughness amplifies dramatically due to passivation and shadowing effects [5]. Some additional experiments are planned to better understand the kinetic formation of black silicon.

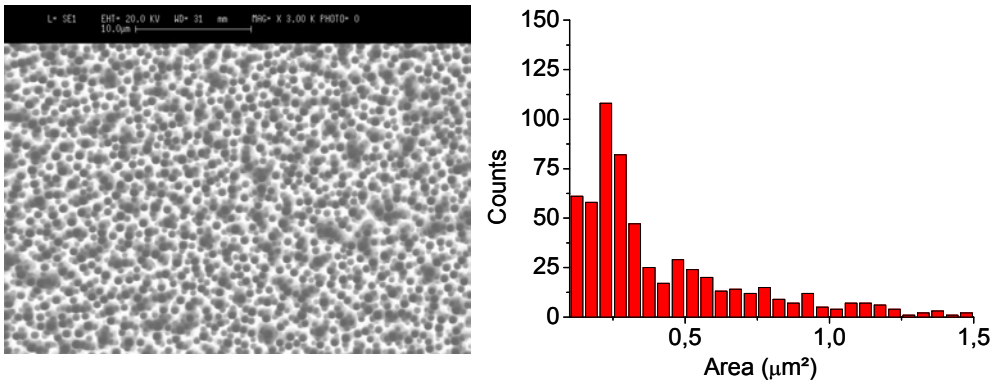

Figure 6 : SEM image (left) and its histogram (right) giving the number of detected holes vs. their area

4. Conclusion

Passivation layer and black silicon formation were investigated in order to better understand the mechanisms involved in the cryogenic process. Moreover, these experiments can help for defining special processes for which the passivation layer has to be rebuilt. They can also give hints to avoid black silicon apparition.

After destruction, the passivation layer can be rebuilt. It requires not only the presence of oxygen, but also the presence of SF_6 in a right concentration (typically of the order of 0.6 for the O_2/SF_6 ratio in our experimental conditions). Another experiment showed that sulphur is not necessary to rebuild an efficient passivating layer.

Concerning black silicon, we have seen that it forms when temperature is sufficiently low and O_2 content high enough. A characteristic dimension can be determined by statistical analysis. This characteristic dimension increases with temperature. The average height increases with bias voltage. At constant O_2 content, black silicon can be avoided by increasing bias.

Other experiments are planned to refine this first study. The lower O_2/SF_6 ratio limit to rebuild the passivating layer has to be determined. We will investigate the necessary process duration, which should be smaller than 30 seconds, to reform this layer. Black silicon apparition will be modelized using the Langevin diffusion equation [5,6]. Other experiments will also be carried out to complete the charts. In situ ellipsometry experiments will be performed to study the passivation layer growth.

5. Acknowledgments

This work is supported by STMicroelectronics (Tours, France) and by the French ministry of economy, finance and industry. The authors would like to thank Julien Steelandt (ESPEO-Orleans) for his help during the passivation characterization experiments.

Abstract

The aim of this paper is to present experimental results using a non-thermal plasma arc in order to reduce nitrogen monoxide (NO). We operated with a N_2/NO mixture and we particularly interest to the chemical reduction of NO by the N radical ($N + NO \rightarrow N_2 + O$). The yield for this process was determined by measuring the NO destruction rate as a function of the power deposited into the reactor.

1. Introduction

Plasma processing and particularly non-thermal plasmas (discharges) are subjected to a new interest for pollution control. The research in this field gained considerable interest and number of researchers is working about it. The reduction of the nitrogen oxides (NO, NO_2, N_20_5, N_2O) from industrial systems and exhausts is one of the critical and urgent topics in environmental and pollution control researches. Among the systems proposed for the NOx reduction are those based on atmospheric non-thermal plasma (NTP) discharges.

A new generation of technologies based of non-thermal plasma (NTP) has been developed since 1960. NTP can be produced by large variety of processes: electron beam or electric discharge methods. The plasma is non-thermal in the sense that the electron temperature is different from that of gas which remains at room temperature. The great part of the input electrical energy goes into electron production rather into gas heating. In these methods, energetic electrons (up to 5 eV for electric discharges and up to a few MeV for electron beam processes) are produced. Then, these electrons create free radicals, secondary electrons and ions which react with the pollutants. Therefore, non-equilibrium plasmas can be used for a selective destruction of dilute concentration of pollutant molecules, typically from 1 to 10 000 ppm.

In order to choose the best operating conditions for the NOx removal it is necessary to compare different non-thermal plasma sources. The two principal characteristics of a plasma process are the destruction rate and the energy cost. Plasma process efficiency is often characterized by the G-Value defined as the number of pollutant molecules removed by 100 eV of input energy.

$$G_{eV} = \frac{\text{Number of pollutant molecules destroyed}}{\text{Deposite energy [eV]}} * 100$$

Many types of sources have been studied as dielectric barrier discharges (DBD), corona discharge or surface discharge (1-5). These methods proved their efficiency to destroy a great variety of pollutants.

Results obtained from a transient arc-glow discharge called "NTP Arc" are presented in this paper. Dilute amounts of NO in N_2 were chosen as mixture test. NO was described to be destroyed by

the N radical [3]. To avoid NO reformation by reaction between nitrogen and oxygen which complicated the removal mechanisms identification, we used N_2 rather than air.

2. Electron and Chemical Kinetic

In non-equilibrium plasma discharge, the main part on the input energy is used for producing high-energy primary electrons. If the pollutant molecules are very dilute, these electrons principally collide with the gas background molecules. Then these electrons produce secondary electrons, free radicals and ions which react with the pollutant molecules. In N_2 background electrons have two ways for reacting.

- Electron impact dissociation produces the fundamental atomic nitrogen N(4S) and excited nitrogen $N(^1D)$

$$e + N_2 \rightarrow e + N(^4S) + N(^4S)$$

$$e + N_2 \rightarrow e + N(^4S) + N(^1D)$$

- Electron impact ionization produces the N_2^+ and N^+ ions and secondary electrons.

$$e + N_2 \rightarrow N_2^+ + 2e$$

$$e + N \rightarrow N^+ + 2e$$

The reaction rates for above reactions are strongly dependent of the electron mean energy. The electron energy function is difficult to obtain due to the complexity of non-elastic energy transfer mechanisms. Furthermore, all the equations required to calculate this function are time dependent.

For few energetic electrons (< 8 eV) only a few part of the initial input electrical energy is used for dissociation or ionization because the main part of this energy is used for exciting N_2 vibrationnal states.

All the following reaction rates are taken from the NIST database [6]. In the following, T is the local plasma temperature (in Kelvin), and k is the reaction rate (in cm^3/molecule.s). The main mechanism for NO removal is the reaction with the N radical by the reaction:

$$N + NO \rightarrow N_2 + O$$

$$k = 7.12\ 10^{-11} \exp(-787/T)$$

One must consider the NO oxidation by the O radical following the three body reaction (X is a third body, principally N_2 in our case)

$$NO + O + X \rightarrow NO_2 + X$$

$$k = 9.1\ 10^{-28}\ T^{-1.6}$$

The NO_2 molecules product by this reaction are reduced by O radical

$$O + NO_2 \rightarrow NO + O_2$$

$$k = 6.5\ 10^{-12} \exp(120/T)$$

NO can be reformed too by the reaction

$$N + O_2 \rightarrow NO + O$$

$$k = 1.5\ 10^{-11} \exp(-3573/T)$$

3. Experimental set-up

For the results presented in this work, we operated with an atmospheric-pressure flow-through configuration. The gas flow was controlled using two mass-flow controllers. The first one was connected to a pure N_2 bottle whereas the second one was connected to a mixture bottle containing

3600 ppm of NO diluted in N_2. This allows us to control the NO concentration in the gas. We fixed it to about 100 ppm with a flow rate of 10 Nl/min.

The reactor is shown on figure 1. Two parallel Pyrex plates and two divergent copper electrodes form it. The arc ignites where the electrodes are the nearest, then it glides upwards where it remains caught. When the arc extinguishes, a new one starts immediately. The gas flow must not be too important otherwise the arc cannot remain caught at the electrode top.

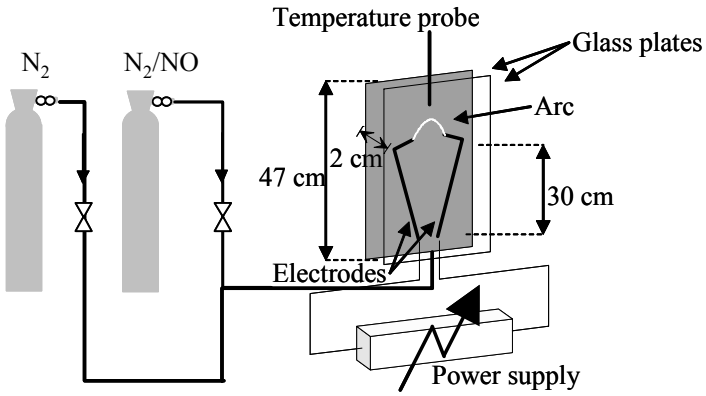

Figure 1: Experimental setup

The power supply was a leakage transformer able to deliver a 50 Hz sinusoidal current of typically 100 mA intensity. The voltage delivered by this system adjusts itself between 1 kV and 10 kV according to the gas nature and the input voltage transformer. The power into the discharge could adjusted by varying the input voltage. The arc current I and voltage U variations were directly registered using a numeric oscilloscope [Tektronix TDS 460 A] equipped with voltage and current probes. The average power (over a period of time) consumed by the arc was calculated by meaning the product "U_xI". Figures 2 and 3 show an example of the time-behaviors of the voltage and the current.

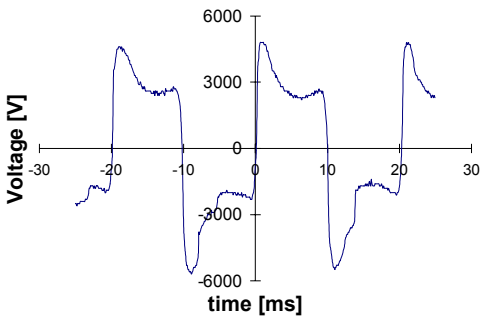

Figure 2: Voltage curve. N_2/NO (100 ppm), Primary power 390 W, Flow rate 10 Nl/min.

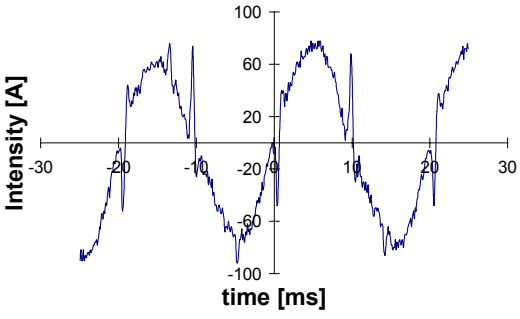

Figure 3: Current curve. N_2/NO (100 ppm), Primary power 390 W, Flow rate 10 Nl/min.

The chemical analyzes were performed in line using a Fourier Transform Infrared (FTIR) spectrometer (Nicolet MAGNA IR 550 Series II). The FTIR was used for by-product identification. For monitoring the NO evolution we used a combustion analyzer (Quintox) which works by chemiluminescent. This device was also used for output gas temperature measurement (T_{output}) at 10 cm above the discharge.

We used a fast CCD camera (Sony) for arc radius and length measurement. It allowed us to take two consecutive pictures in 100 ms with a variable exposure time.

4. Plasma Characteristics

First the plasma aspect is rather that of a flame. But this results from the retinal persistence. Indeed if we took a short time exposure (10 µs) picture of the arc we can see distinctly two zones appearing (figure 4). The first zone corresponds to a very bright thin wire of plasma. Its apparent diameter is about 0.1 mm and its mean length increase linearly with the flow rate as shown on figure 5. We can consider that the electrical current is confined in this area, supposed to be quasi cylindrical. This kind of representation is often used in arc modeling [7-8]. Inside it, the gas temperature T_{gas} was measured by spectroscopic method using the UV $OH(A^2\Sigma, v=0) \rightarrow OH(X^2\Pi, v'=0)$ band spectrum [9]. We found values between 1600 and 2000 K. The plasma wire is cooled by convection.

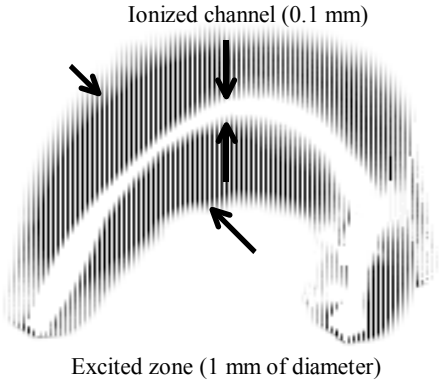

Figure 4: Short time exposure picture of the arc (10 µs).

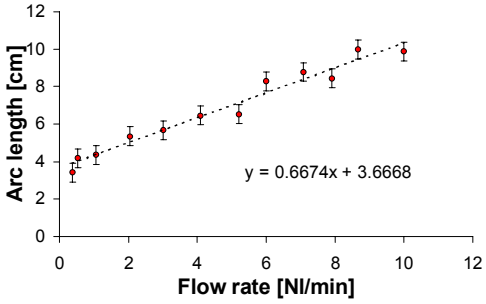

Figure 5: Arc length as a function of the flow rate

Due to the action of the anodic and cathodic arc spots, Cu atoms are extracted from electrodes. Assuming that the energy levels of Cu atoms are populated by electronic collisions following a Maxwell distribution, we can determine the electron temperature. A typically value of 12 000 K was obtained. This quantity is almost independent of the radial position.

When the number of electrons in the discharge increase beyond 10^{18} electrons per cm^3, the plasma becomes very ionized. In this case the electrons cannot reach a high energy value because the main part of the electrical power obtained from the electric field is lost by collision with ions. This kinetic energy transfer mechanism is very efficient due to the Colombian interaction. Then, the ions transfer a fraction of their energy to gas molecules by elastic collisions. The energy is well distributed between all the plasma species ($T_{gas} \approx T_{ions} \approx T_{electrons}$). Such a discharge is called electric arc or thermal arc. But in our case the electrical generator limits the current value and consequently the electron and ion densities are not very high. In that case the electrons collide principally with the gas molecules, and in this case the Colombian interaction stays negligible. The elastic collision are not able to heat the gas molecules (the electron mass is 10^4 lower than N atoms mass). That is why our plasma is non-thermal.

The second zone presents like a weakly luminous halo. Its diameter is about 1 mm. We suppose that the chemical reactions occur principally in this area. The ionized canal produces primary electrons and excited species that diffuse outside it and react with the pollutant molecules.

5. Experimental results

Using FTIR spectroscopy we observed that the only by-products formed in the discharge are NO_2. None of the other nitrogen oxides, like N_2O or N_2O_5, has been detected. Figure 6 show the concentrations of NO (residual) and NO_2, and the output reactor gas temperature (T_{Output}) as a function of the electrical energy density deposition.

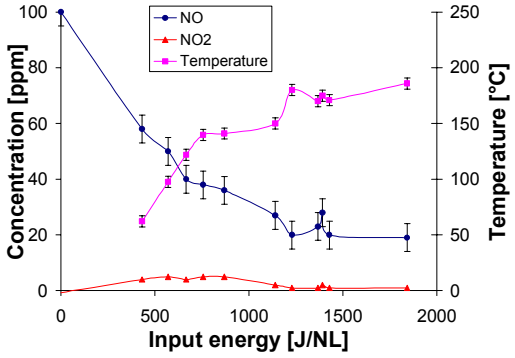

Figure 6: Output NOx concentration - 100 ppm NO in N_2 - Flow rate 10 Normal liter/min.

The destruction process efficiency increases with the input energy until the value reaches 880 J/Nl. In this area the only reaction that occurs is $N + NO \rightarrow N_2 + O$. Thus, the number of NO molecules destroyed is equal to the number of N atoms produced. In that case, the energy cost for NO removal (G_{eV} value) varied between 0.034 and 0.020.

Above 1000 J/NL the NO concentration is constant. We suppose that the main reason of such a behavior is the NO production according the reaction $N + O_2 \rightarrow NO + O$. This reaction becomes more and more significant due to gas heating. These NO produced are called "thermal NO". The additional electrical energy deposit into the reactor is simply lost.

For both previous cases the NO_2 production is not higher than 5 ppm. All the destroyed NO molecules are chemical reduced to N_2 and O_2.

The yield obtained for this non thermal plasma arc is ten times smaller than this obtained by Penetrante et al [3] using DBD or corona discharge. In these experiments, the input gas was heated and the energy cost for this operation was not taken into account.

Conclusion

In this work we have shown the efficiency of non-thermal plasma arc used for dilute NO removal in N_2. We could determinate the chemical efficiency of this process by measuring the number of pollutant molecules destroyed per 100 eV of input energy. We have observed that it is not useful to inject more than 1000 joules per liter of gas. Furthermore the only undesirable by-product formed is NO_2 and its production is not higher than 5 ppm.

Results obtained from discharge in air are not similar because of oxidation processes. So, there is no direct application of this process but such experiments can help us to understand plasma physical processes. The subject of electrical discharges for environmental purpose is still in its infancy, the above results shows the interest to keep up and develop research in this field

Deposition of diamond-like carbon film on three-dimensional objects using glow plasma CVD method

S. Takada, Y. Ohgoe, T. Saito and K. Hirakuri

Department of Electronic & Computer Engineering, Tokyo Denki University, Ishizaka, Hatoyama, Saitama, 350-0394, Japan

Deposition of a functional thin film, surface modification and fine pattern etching are available by the plasma chemical vapor deposition (CVD) method at low temperature. Since it is popular to form and control uniform plasma on the flat surface of the objects, flat parallel electrodes are generally used to plasma CVD process. However, there are big restrictions of the application of this system because it is difficult to generate the uniform plasma on the objects with 3-dimensional structure. N. Mutsukura et al reported the relationship between the structure of objects and the property of deposited carbon films; i.e. position dependence between bulk-plasma and ion-sheath region.[1)] The properties of carbon films deposited in each region were quite different. In the bulk-plasma region, the film was transparent in visible wavelength and mechanically soft. In contrast, the film formed in the ion-sheath region was chromatic and extremely hard. The kinetic energy of the ion bombardment at the substrate surface can be estimated from the mechanical hardness of the deposited carbon film. The reason is that the hardness is strongly depended on the cathode dc self-bias voltage in the rf plasma CVD. And the authors also indicated that hard carbon film deposition to insulator objects, such as glass plate, at the across the sheath-plasma boundary are available by metal step on the cathode electrode. It enables to develop an obvious sheath formation around the metal step. Therefore, ion bombardment always occurs during deposition at spatial position.

In order to realize uniform deposition of the diamond-like carbon (DLC) film to the 3-diminsional insulator objects, the electrode adjusted to the objects (improved electrode) was utilized. Improved electrode was set on the cathode electrode and generates the uniform plasma to the surface of the object. Then the availability of improved electrode was discussed by evaluating uniformity of DLC film properties. Since the characteristics of DLC film is remarkably depended on the plasma condition, it is effective to analyze the process by evaluation of the film characteristics. If deposition of uniform DLC film to the 3-dimensional objects using plasma CVD method is attained, an application are expected to the other thin film deposition techniques.

In this experiment, two kind of 3-dimensional structures, the hemispheric surface and the cylindrical inner wall surface, were used as the object of DLC film deposition. Hemispheric object was made of polyurethane, and cylindrical one consisted of polycarbonate. Improved electrodes were set on the cathode electrode with the dc self-bias voltage, and objects were fully covered by them from backside. In order to estimate the uniformity of DLC film properties, small pieces of silicon substrates were located on each point of the objects on the improved electrodes. Deposition uniformity was measured on thickness and hardness, and properties of DLC film was investigated from infrared spectroscopy and Raman spectroscopy.

In case of hemispheric object without improved electrode, film thickness and hardness was dispersed within 60.4nm ~ 511.7 nm and 8.3GPa ~ 14.8GPa, respectively.

On the other hand, in our proposal process, thickness and hardness were quite uniformized. Film thickness was within 492.6nm ~ 618.7nm, and film hardness was within 12.0GPa ~ 13.4GPa. Furthermore, similar result was indicated by the properties of DLC film. Standard DLC film has two typical Raman peaks, around 1390cm^{-1} from D-band and 1530cm^{-1} from G-band. Raman spectra of deposited films without improved electrode were broad and had no carbon peak because substrates were in the bulk-plasma region and the object was attacked by ion bombardment with low energy. In contrast, each Raman spectrum of DLC films deposited by the improved electrodes was similar and had two typical peaks of DLC film. These experimental results are based on the ion-sheath formation around the object's surface by improved electrodes. Finally, the use of improved electrodes was enabled to deposit uniform DLC film on 3-dimensional objects.

Abstract

In order to remove niobium (Nb) from Zirconium-Niobium alloy, some experiments which uses thermal fluorine plasma has been carried out. When processing around the melting point of this alloy, Zr is extracted in the evaporated fine particles and Nb enriches in the bulk alloy. This phenomenon can be explained well by using Gibbs free energy of fluorinate reactions. For the better separation the higher temperature of the sample is kept and the more effective mass transfer of Nb in the melting alloy is required.

1. Introduction

The plasma technology, which is used widely for producing many valuable materials[1], can be also an effective technology in nuclear engineering fields. In downstream and backend of fuel cycle, several researchers have suggested various applications[2,3], for example, the direct melting method of spent fuel assembly, the treatment of spent fuel separation, vitrification of HLW, the volume reduction of LLW and the stabilization of radio nuclides and the decommissioning of reactors.

Objective of this study is to remove niobium (Nb) from Zirconium-Niobium alloy, which has been used for pressure tubes of the Japanese advanced thermal nuclear reactor "Fugen". This alloy has small cross section of thermal neutron absorption and is very convenience for reactor material. Although Nb in this alloy is stable isotope "Nb-93" before neutron irradiation, but it converts to radioactive "Nb-94" after absorbing thermal neutrons. "Nb-94" has a very long half-life and emits high-energy gamma ray. This is the reason why we have to separate this alloy, remove "Nb-94" and recycle zirconium.

Some research works concerning with metal separation by using reactive plasma have been done already. Mimura[4] reported the refining of zirconium by using hydrogen plasma and Takeuchi et.al.[5] reported the separation of Fe and Ni from Fe-Co-Ni alloy by using chlorine/oxygen mixture plasma.

In this paper, we report some results of experiments to separate Zr and Nb from Zr-Nb alloy by using reactive fluorine thermal plasma and we make mechanism of separation and optimum conditions clear. And we also discuss about possibility of removing "Nb-94".

2. Experimental

Figure 1 shows the experimental set up. Experiments were carried out in a water-cooled plasma chamber where an thermal plasma generator and a sample holder are set inside. A DC plasma jet and an DC arc were used as a thermal plasma generator. Processing gas is argon/CF_4 (carbon tetrafluoride) mixture or argon/F_2 mixture which were prepared properly and fed at the constant flow rate. Experimental conditions are arc current 100-250A and operation pressure 760Torr. The waste gas which is toxic is introduced into a scrubber and processed befor releasing into the atmosphere. A sample holder is a water-cooled hearth or a graphite cruisible with the coil for high frequency (420kHz) induction heating. Figure 2 shows the typical configuration of experiments, which uses plasma jet and inductiuon heating.

Samples of fine particles generated by the plasma processing were collected by sampling tube and membrane filter and by scraping from the chamber wall. The samples were analyzed by using WDS (Wave Dispersive Spectrometer) of X-ray fluorescence, whose data were calculated by fundamental parameter method for highl accurate quantitative analysis.

Sample surface temperature was measured by an pyrometer. This pyrometer is connected to personal computer for data transfer and processing. Although it is impossible to measure accurate temperature according to the plasma emission during plasma processing, the surface temperature was estimated by recording transition data before and after plasma irradiation sampled every 0.06sec and taking this sampling time into account.

Sample metal, Nb-Zr alloy, which has not been installed and radioactivated in the nuclear plant was used in this experiments. This sample was cut to small size (about 6g) for experiments. Components of this metal sample are listed in Table.1.

Table 1. Components of Nb-Zr alloy used in this experiments.

Elemnts	Zr	Nb	O	Fe	C	Ta	Co

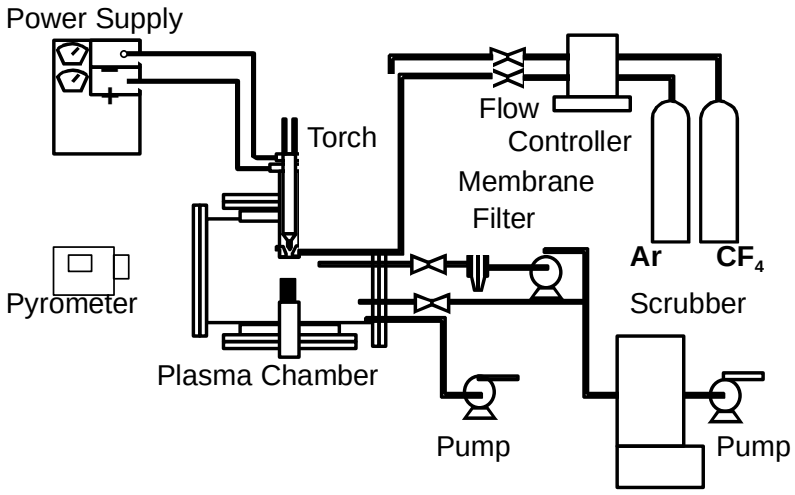

Fig.1 Schematics of experimental setup.

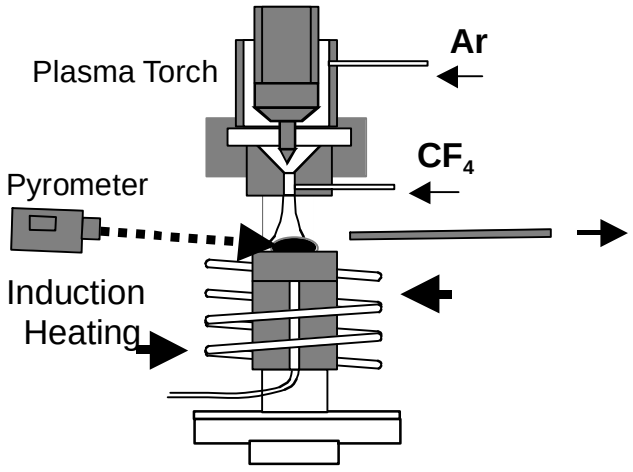

Fig,2 Detailed configuration of heating, gas feeding and sampling systems.

3. Results and Discussions

3.1 Definition of separation factor.

In order to express separation effect, we use the separation factor defined by the following equation.

$$\alpha = \frac{C_{Nb}/C_{Zr}}{C_{Nb0}/C_{Zr0}}$$

Here C_{Nb} and C_{Zr} mean the concentration (weight fraction) of each components after plasma processing and C_{Nb0} and C_{Zr0} mean those before plasma processing. Therefore, α=1 and α=0 mean no separation and perfect separation of zirconium, respectively.

3.2 Plasma jet experiments and themodynamics.

At first we show the results in the plasma jet experiment. In these experiments only argon gas was used for discharge gas and CF_4 gas was introduced into its tail plasma. It is convenient for the tungsten cathode when using such eroded gas as fluorine, the erosion of cathode can not be avoided in the case of arc discharge. In order to compensate low heat flux caused by using plasma jet installation, the induction heating was used for these experiments. In this situation, we have two important parameters to control the separation effect. One is the sample temperature and another is CF_4 concentration in plasma gas.

In the fluorination reaction of alloy, it is guessed that products are NbF_5 and ZrF_4 according to following reactions.

$$Zr + 4F(g) \rightarrow ZrF_4 \qquad Nb + 5F(g) \rightarrow NbF_5$$

Their boiling point at atmospheric pressure is 229 ^{0}C and 580 ^{0}C, respectively. Although according to this information it can be expected that Nb fluoride evaporates prior to Zr fluoride, experiments bring the opposite result. However, it is clear from the temperature dependence of Gibbs energy of fluorination reaction for Zr and Nb, as shown in Fig.3. The fluorination reaction of Zr is dominated over 1000K, which is the high temperature range expected in the plasma processing

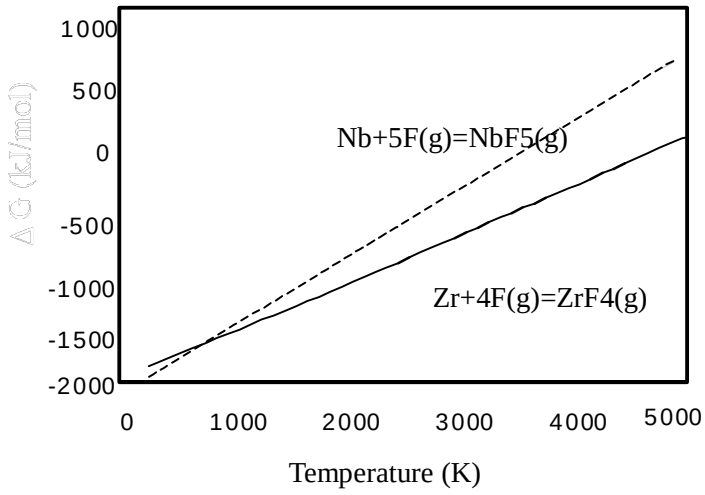

Fig.3 Temperature dependence of Gibbs energy of fluorination reactions.

3.3 Separation factor and evaporation factor.

Figure 4 shows the dependence of the sample temperature and the CF_4 concentration on the separation factor, simultaneously. Also Fig.5 shows the dependence of those parameters on the evaporation rate (weight reduction rate). All of key marks imply the various discharge and heating conditions. In these data the processing continues during several minutes and data are the time averaged ones, unless a special notice is stated. In Fig.4 it is clear that the higher temperature gives the better separation of zirconium and the complete separation (α=0) can be obtained over 2000 ^{0}C. Also it seems that the separation factor depends slightly on the CF_4 concentration. On the other hand there appears no effect of temperature in the evaporation rate and it depends on the CF_4 concentration as shown in Fig.5. From other experiments, we obtain some information that the reactive fluorine atom concentration increases with the CF_4 concentration, although it is not linear according to the temperature lowering by dissociation reaction. We can not explain its slight dependence on the separation factor, although it is nature that the evaporation rate depends on fluorine concentration.

Here, we consider about two additional reasons why the temperature and the CF_4 concentration depend on the separation factor. One is that the melting point is around 1800 ^{0}C and another is the existence of carbon atoms deriving from CF_4 in the reaction system. Carbon atoms react with Zr and Nb to form metal carbides, whose melting point is so high. In fact, we observed the carbide formation on the sample surface. When carbide formation is going on, the surface changes to black color and it prevents from evaporation. The reason why separation becomes bad around 1800 ^{0}C seems similar to that, although it is not carbide formation. The common point in these two facts can be fluidity of sample alloy. When the sample temperature is enough to melt the sample alloy, it has enough convection and gives the proper mass transfer inside the bulk. Also when the carbide forms on the sample surface, it disturbs convection and the proper mass transfer.

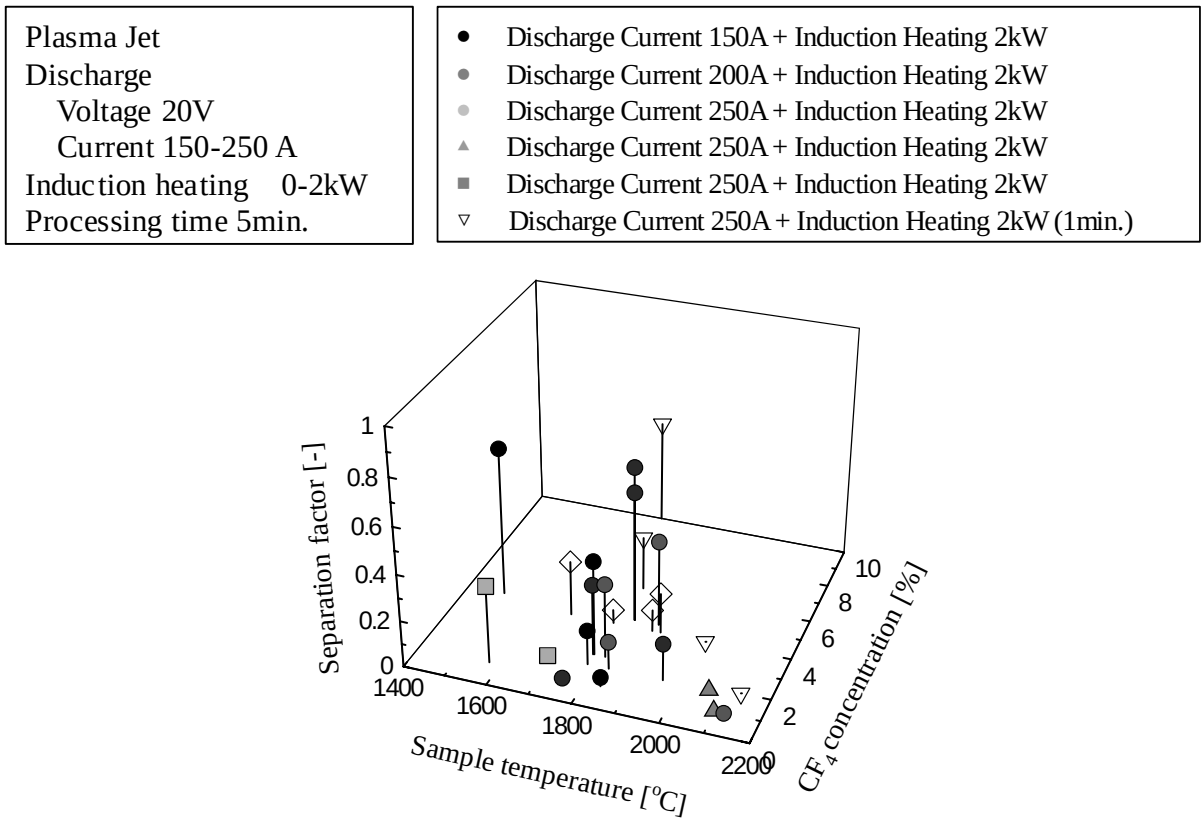

Fig. 4 Dependences of sample temperature and CF_4 concentration on separation factor.

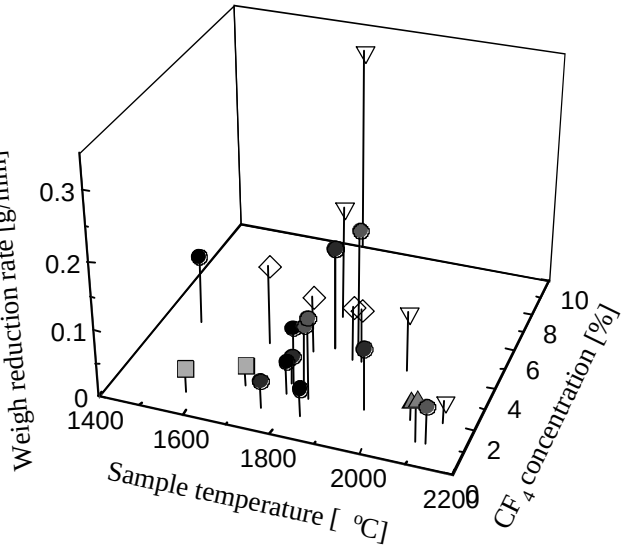

Fig. 5 Dependences of sample temperature and CF_4 concentration on weight reduction rate.

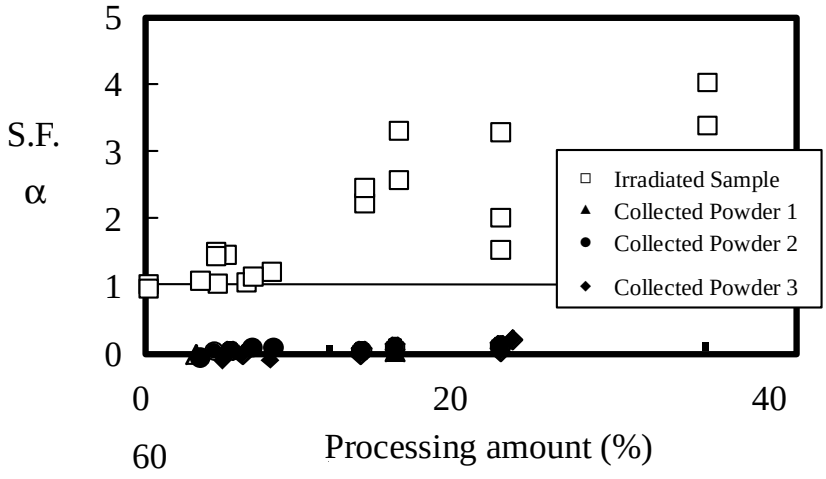

Fig.6 Dependence of processing amount on separation factor. As products shown by black keys evaporating, Nb enriches in the bulk alloy shown by white key implies Nb enrichment.

3.4 Separation experiments by arc discharge.

The plasma processing by arc discharge drawn between tungsten cathode and metal sample anode has advantage to obtain higher temperature than the plasma jet processing, although arc discharge has disadvantage of cathode erosion by reaction with plasma gas. Especially, fluorination reaction with tungsten anode takes place easily to erode it rapidly. In order to verify the conclusion obtained by the plasma jet processing, however, we dare to try some high temperature experiments by using arc discharge at the sacrifice of cathode erosion. Figure 6 shows the results. Here, the product Zr contains no Nb and also Nb enriches gradually in the bulk alloy as the Zr extraction proceeds. From these results it can be verified that the high temperature processing leads to good separation. Practically, we suggest that the transferred arc system is the best one for this purpose and it should be chosen.

From the above-mentioned results we conclude that Zr can be extracted from Nb-Zr alloy, effectively. Although extraction of a large amount of Zr instead of Nb is not economy, it can be favorable at the viewpoint of safety aspect. The most important issue is safety, when adopting this method to the separation process of radioactive “Nb-94”. Especially, this process generates the fine particle by fluorination reaction and it will be required to estimate the release of radioactive aerosol into the environment. However, the radioactive nuclide “Nb-94” enriches in the bulk alloy fortunately and it will minimize the release of radioactive aerosol. Of course, an amount of radioactive elements entrained by zirconium should be estimated for safety assessment.

4. Conclusion

In order to remove niobium from Zirconium-Niobium alloy, we carried out some experiments which uses thermal fluorine plasma and obtained the following conclusions.

(1). When processing around the melting point of Nb-Zr alloy, Zr is extracted in the evaporated fine particles and Nb enriches in the bulk alloy.

(2). This separation phenomenon can be explained well by using Gibbs free energy of fluorinate reactions.

(3). For the better separation the higher temperature of the sample is kept and the more effective mass transfer in the melting alloy is required.

(4). For the separation process a transferred arc system should be used to avoid the cathode erosion and to heat sample effectivelly.

(5). This process can be effective to separate the radioactive Nb-94, also.

Boron carbide synthesis by plasma spray process

P.Ctibor[1], V. Brozek[1], R. Hofman[2]

[1]*Institute of Plasma Physics, Academy of Sciences of the Czech Republic, Praha, Czech Republic*
[2]*Institute of Chemical Technology, Praha, Czech Republic*

Abstract
Boron carbide was synthesized from precursors in a classical plasma spray process. Layers deposited as coatings on metallic substrates were studied to resolve the degree of boron carbide formation in the layer and its character. The chemical composition and structural characteristics of free-flight particles were studied as well to establish support for a determination which stage of the plasma spray process is critical for reactions leading to boron carbide formation.

1. Introduction

1. 1 Boron carbide in research and technology

Boron carbide with its hardness between 39 and 45 GPa is the third hardest industrially produced material with only diamond (H = 75 - 100 GPa) and cubic boron nitride (H = 50 - 76 GPa) being harder. Until today boron carbide was used as free abrasive in applications for which the hardness of silicon carbide (H = 38 - 41 GPa) is not satisfactory and the price of natural or synthetic diamond is unacceptably high. Machining of silicate glass is an example of such a process. High effective absorption profile for neutrons, excellent chemical stability of boron carbide in oxidizing, reducing, acidic, or alkaline environment and high thermal decomposition point (2990 K) are properties favorable for using this material in nuclear energy-related applications.

1. 2 Water stabilized plasma and its features

At the Institute of Plasma Physics, a plasma generator WSP® with water-stabilized plasma has been developed, in which the temperature range is entirely suitable for most endothermic chemical reactions and makes it possible to melt not only the incoming precursors but also the products of the thermally and plasma-activated synthesis.
Comparing the gases commonly used for gas-stabilized plasma (GSP) generation (Ar, N_2…) with water-stabilized plasma, it is evident that the sonic velocity and enthalpy of water-stabilized plasma are higher, while the electrical conductivity at higher temperatures is similar to gases. Consequently, the enthalpy flow rate, or, in other words, the power dissipated in the arc column per unit length is higher for the water plasma. Water stabilized plasma gun takes the advantage of combining stabilizing system and cooling system in one.
To summarize the effect of material properties of water-stabilized plasma, we can conclude that WSP provides the possibility to achieve very high power outputs and higher flow velocities and temperatures of generated plasma. One of the probable reasons behind the limited use of WSP is the widely accepted beliefs that the oxidation power of WSP spraying is intolerably high and that the quality of the coatings made by WSP is generally insufficient. Therefore, for a long time there has been a general belief that WSP must be used for oxide ceramics spraying only.
It is important to note, that for each atom of oxygen in the plasma jet there are two atoms of hydrogen. Therefore oxidizing power of oxygen from the water plasma is balanced by reducing power of hydrogen and overall chemical influence of the stabilizing water in the flame is rather neutral. However, oxides were found in the non-oxide coatings. They are of similar origin as for GSP – i.e., oxidation due to the entrainment of surrounding atmosphere (air) into a highly turbulent plasma jet and from the carrier gas used for the powder feeding.
Comparing GSP and WSP, the main advantages of the WSP® deposition system are: i) lower operational costs; ii) higher production rates with a possible use of less expensive feedstocks (higher throughput); iii) higher attainable temperature allowing spraying of materials with higher melting

points. The operational costs are reduced because water is used instead of expensive stabilizing gases and also because the cooling and stabilizing systems are combined, thus simplifying maintenance. In addition to that, larger and wider cuts of feedstock powders can be used which are less expensive.
Also the temperatures in the plasma jet are significantly higher: maximum temperature is around 30 000 K, compared to about 15 000 K maximum for GSP. Even when the velocity of plasma jet is from 5 000 to 7 000 ms^{-1} at the nozzle [1], compared to 1 000 to 1 500 ms^{-1} for GSP, the impact velocities of deposited particles however are about the same or slightly lower than for GSP spraying. This is caused by a lower acceleration of injected particles due to the lower density of plasma.
Higher plasma temperature and higher available thermal energy can be used to spray materials with high melting points (e.g. MgO or W) [2, 3], and for a whole spectrum of less-common processes, such as solid feedstock based synthesis by plasma spraying.

1. 3 Synthesis by plasma spraying utilizing WSP system

Feedstock powder is introduced into the water plasma jet outside of the gun using one or several injectors. The goal of all thermal spray processes is to deliver a powder particle to the substrate in such a state that after impacting the substrate, the particle will flatten as one piece. To achieve that the particle (droplet) must be either slightly above liquidus, between the liquidus and solidus curves or, at worst, in a plastic state just below the solidus line. During melting of a high-melting point component of multi-component powder a low-melting point component could be released from the droplet in gaseous state.
Even from the short description of the WSP system, the main processing parameters for spraying can be derived:
- spraying distance (or stand-off distance) SD, which is the distance between the gun's nozzle and a substrate (same as for GSP);
- feeding distance FD, which is the position of an injector downstream from the nozzle;
The actual state of a droplet on impact is given mainly by SD. FD, on the other hand, decides on melting/evaporation state of an injected particle. The right melting for a given chemistry results from a proper combination of the power, feedstock's size and feed rate (dwell time at a high temperature). Taking into account the enormous amount of available heat in WSP, larger powder sizes are needed to avoid evaporation or bouncing-off of the injected particles from the plasma jet. This condition is important even in the case of solid precursors for synthesis plasma spraying. Similarly, the melting point of a given feedstock generally suggest the FD value – a low melting point materials cannot be fed into high temperature regions of the plasma jet.
Boron carbide synthesis from both solid and liquid precursors in water-stabilized plasma and also injection and formation of coating and free standing parts of B_4C powder were subject of previous research carried out by the authors [4]. Utilization of high-velocity plasma systems for synthesis by plasma spraying of precursors fed-in as solid feedstock is less common process and it represents serious challenge for the above-described water-stabilized system. Direct deposition of boron carbide from non-carbide solid precursors on metallic substrates is the main topic of the present paper.

2. Experimental

2. 1 Precursor and critical aspects of its use

Boric acid creates only 5-percentual solution in the water at room temperature. It was shown in the previous set of experiments [5], where water solution of the precursor was used, that it was very difficult to ensure parameters of plasma system suitable for stable plasma flow and for precursor melting at once. At majority of suitable plasma system settings with current between 300 A and 500 A, the water evaporation was enormous. Fine particles of solid precursor, and also the entire precursor dissolved in water solution, were evaporated. Only coarse-grained fraction was captured as a product, but it contained large amount of impurities, first of all from the water and industrial purity boric acid.
The authors' attention in the next series of experiments turned to preparation of BUS precursor (Boric acid - Urea - Sucrose) in the form of powder sprayable by classical plasma spray procedure. The nature of the precursor makes it difficult to obtain powder with proper size distribution and with good flow properties. BUS precursor is not inert to water at all because sucrose content. Problems with its

moistening and in contrary softening under ambient conditions – powder is not hard enough to be successfully fed – were serious. Despite such problems pure precursor (size 90-180 μm) was used as a feedstock.
Better yield – powder amount captured after passing through the plasma – was achived when the precursor was mixed with a mild amount of inert ceramic powder. The fact was utilized, that alumina is a material commonly used in thermal spray, especially by WSP. Moreover, alumina is described [6] as a material enhancing mechanical properties of B_4C, if the alumina content in the mixture is around 10 vol. percent. This amount was not high enough to create powder with acceptable flow behavior, therefore the authors decided to increase the alumina content to 40 – 50 vol. percent.

2. 2 Plasma spray procedure

The feedstock was composed from BUS precursor (size 75-224 μm) and alumina (size 50-63 μm) and plasma sprayed. Previous tests ensured that alumina helped to feed the properly mixed powder into the plasma flow whereas size distribution of BUS was not critically important.

Table 1
Experiment 1 - Spray round with precursor BUS only
Experiment 2 - Spray round with precursor BUS with Al_2O_3

Parameter	Unit	Experiment 1	Experiment 2
FD	mm	20	20
SD	mm	280	280
Torch power	kW	114	114
Theoretical temperature at the feeding point	K	18 000	18 000
Feeding medium	-	Compressed air	Compressed air
Throughput	kg/hour	6	12 at all, BUS cca 6

Purity of the feedstock was measured by XRF analysis. The sum of major impurities (Si, Ca, Fe) does not exceed 0.5 percent. XRF is not able to detect boron; therefore boron analysis was carried out by the Atomic Absorption Spectroscopy method after burning up the substance in the air (boron transfer to B_2O_3) and its dissolution (Varian Spectr AA 880).

2. 3 Samples of free-flight particles (FFP) and deposits

Free-flight particles were obtained as feedstock particles conventionally fed into the plasma, but caught into a vessel placed in the distance high enough from the plasma gun. In such a way, the particle state is “frozen” and the influence of the substrate on solidification is eliminated. In the studied case the distance was 900 mm. FD was set as 22 mm, for other parameters see Tab. 1.
Plasma deposited samples were prepared by the process described in the paragraph 1.3, where at SD = 280 mm, a substrate from carbon steel (dimensions 120x40x8mm) was placed.

3. Results and discussion

3. 1 Free-flight particles (FFPs)

The feedstock was amorphous in all cases. FFPs contain everywhere large carbon content (identified by XRD in the product) in crystalline form, see Fig. 1. This fact is interesting – extremely short dwell time in the plasma leads at the majority of substances to amorphization of the originally crystalline feedstock, but rarely to the opposite process. Shape of FFPs signalizes reaching of the melting point of all feedstock components in the plasma flow. Originally irregular and porous precursor particles (Fig. 2, left) were spheroidized in the plasma (Fig. 2, right).
The size of single FFPs implies remelting and densification of originally larger precursor particles. Standard deviation of mean size (equivalent diameter) measured by image analysis is two times lower for the FFPs compare to the feedstock. This fact signalizes that only certain size fraction of particles could be caught as FFPs. The smaller ones were evaporated or bounced-off at the feeding into the

plasma. Too large particles dwell only in colder parts of the plasma flow and remain unmelted, out of the main particle stream caught.
X-ray diffraction shows that monocomponent FFPs are amorphous; several extracts from FFPs exhibit presence of graphite in addition to the amorphous phase. The FFPs crystallize upon annealing in protective atmosphere at 1600°C for 1 hour. Indication of boron carbide presence in FFPs was indirect: comparison of infrared spectra of crystalline B_4C (or $B_{12}C_3$) of the annealed precursor with IR spectra as-caught FFPs. In both the spectra, antisymmetrical vibrations of B-C bonds at 650 cm^{-1} and 1150 cm^{-1} as well as symmetrical vibrations between 850 and 750 cm^{-1}, typical for crystalline B_4C, were detected. Other vibrations detected at 1627 cm^{-1} and 1385 cm^{-1} by IR measurement were not the subject of deeper investigation.

3. 2 Deposits

For the observation by scanning electron microscope, single particles were deposited on steel substrates. Such a particle, or better, particle conglomerate, is shown on Fig. 3, left.
Fig. 3, right picture, demonstrates that particle conglomerate passed through the plasma and embedded on the substrate consists of elements with lower atomic number Z compared to surrounding surface. Energy-dispersive microanalysis shows that the elements found in the particles have lower Z than what is possible to detect by used apparatus. This serves as an indirect proof of boric compound. Therefore, those particles were stripped from the substrate and studied by IR, XRD and AAS. The same results as in the case of FFPs were obtained – i.e. XRD shows amorphous structure and IR confirms the B_4C pattern. AAS analysis found lower boron content in the product, which documents higher content of free carbon, embedded in the precursor particles to create CO/CO_2 protective atmosphere around individual particle at spray process. It is reported [7] that free carbon in B_4C decreases the melting point at the B_4C-C interface to the eutectic point and thereby enhances the material transport. Optimization of the carbon content in the precursor to fulfill the above-mentioned roles is rather complex task, in this moment not well solved. Free carbon removal from the carbide product doesn't represent insoluble chemical problem.
When spraying the mixture BUS-Al_2O_3, first of all, interlayer of pure Al_2O_3 0.4 mm thick was sprayed to enhance removal of the deposits from the substrate, which was helpful for certain measurements. Figure 4, left, shows substrates covered by plasma deposits. The deposit of the mixture BUS-Al_2O_3 is partly removed to show individual layers. Right picture shows the detail of the deposit surface. Here it is visible that the structure is "columnar" with individual globular particles bonded together dominantly perpendicularly to the substrate. As a result of imperfect contact between the "columns", the structure is extremely porous. This is valid also for the alumina component, whereas spray conditions were in the frames of common alumina spraying. Alumina normally builds layers with lamellar structure and good cohesion. Here (Fig. 4) the resulting structure is related more to those of plasma deposits of B_4C, which were sprayed from B_4C powder as the subject of former projects [8, 9]. Absence of typical splats Al_2O_3 is interesting, spheroidal particles of boron carbide are the consequence of higher melting point. Infrared spectroscopy again indicated presence of B-C bonds in the product. X-ray diffraction recorded in the deposits the α phase of Al_2O_3, AlB_{10} phase and amorphous fraction in all cases. Presence of AlB_{10} documents boronizing ability of the used precursor. This ability is thereby present also at an extremely short reaction time represented by heating in thermal plasma. Absence of δ phase of Al_2O_3, normally present in alumina plasma-sprayed layers, could indicate inhibitive action of the boride phase.

4. Conclusions

Described experiments document that at the conditions of thermal plasma, creation of amorphous product, having reactions typical for boron carbide, is possible. Precursors were invented and synthesized to contain over-stoichiometric carbon content whose aim was to create protective atmosphere for boron carbide production in the plasma and subsequent deposition. This protection is crucial because water-stabilized plasma system has very narrow redox-zone of the plasma. Other measures to limit losses of bonded boron should be tested in future research (system gas-tight sealing, shrowding). The first stage of the plasma spray process – i.e., before solidification of the particles – was resolved as a critical period, which decides the boron carbide formation and the product nature at all.

Abstract

We examined the silica coating methods on the surface of TiO_2 powder by means of atmospheric pressure glow discharge using TEOS adsorbing and plasma oxidation. XPS analysis and TEM photography were performed to determine whether the powders were covered by silica. The attained silica protection layer could prevent the oxidation of squalene oil with TiO_2 in the UV irradiation.

1. Introduction

Some kinds of pigments that are used for cosmetics give rise to a skin irritation problem when they contact the skin directly. In this study, we used TiO_2, a UV-reflective white pigment powder that is frequently used for cosmetics. TiO_2 is a kind of photosensitive catalyst. So the photosensitised powder may oxidize oil in the sweat as a squalene. Such oxidized oil can easily attack a human skin surface. An oxidized squalene molecule produces many kinds of per-oxy-organic compounds that arouse allergies or sometimes a cancer. Our previous studies reported the possibility of powder handling with atmospheric pressure glow discharge [1-4]. We thus tried to develop the SiO_2 coating methods on the TiO_2 powder pigments by means of atmospheric pressure glow discharge using TEOS adsorbing and plasma oxidation to prevent the oxidation of squalene oil in the UV irradiation.

2. Experiment

The diameter of TiO_2 (anatase 80%, rutile 20%; $15 m^2/g$ in adsorption area; Toho Titanium Corporation) particles is a few hundred nm. In this study, we employed the Adsorb and Dry method using He-O_2 system [5]. We used squalene oil (2,6,10,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaene; Maruha Co,Ltd) to examine the surface activity of TiO_2 powder. First, the TiO_2 powder was pre-treated with TEOS (tetraethoxysilane) - ethanol mixture aero - sol to adsorb TEOS on the surface of particles. After the ethanol dried (about 2 days) in air ambience, the powder was treated in He-O_2 plasma to produce SiO_2 as an inorganic super - fine layer on the TiO_2 surface. The amount of deposited SiO_2 can be controlled by the concentration of TEOS in the solvent ethanol during the adsorbing process. Figure 1 shows a schematic of the discharge reactor. It consists of a quartz glass tube and a stainless steel centre electrode, which is

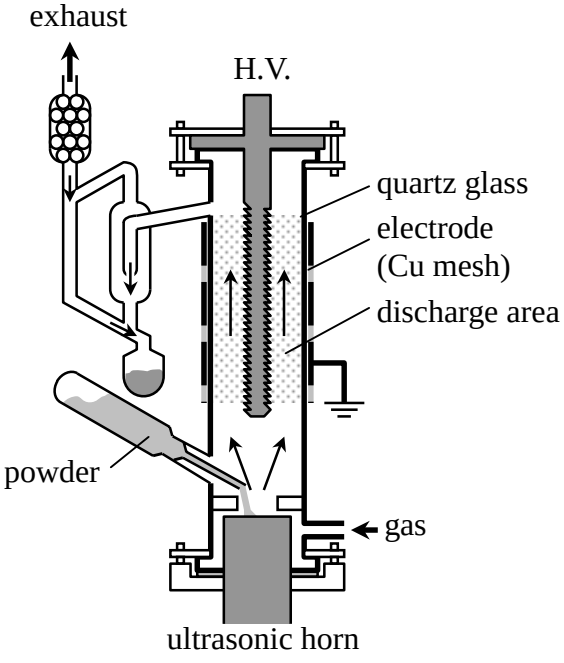

Fig.1 Schematic of discharge apparatus

Discharge Conditions	
Powder / g	10
Discharge Time / min	5
He Flow Rate / cm^3min^{-1}	10000
O_2 Flow Rate / cm^3min^{-1}	100
Discharge Power / W	2500
Discharge Frequency / MHz	13.56

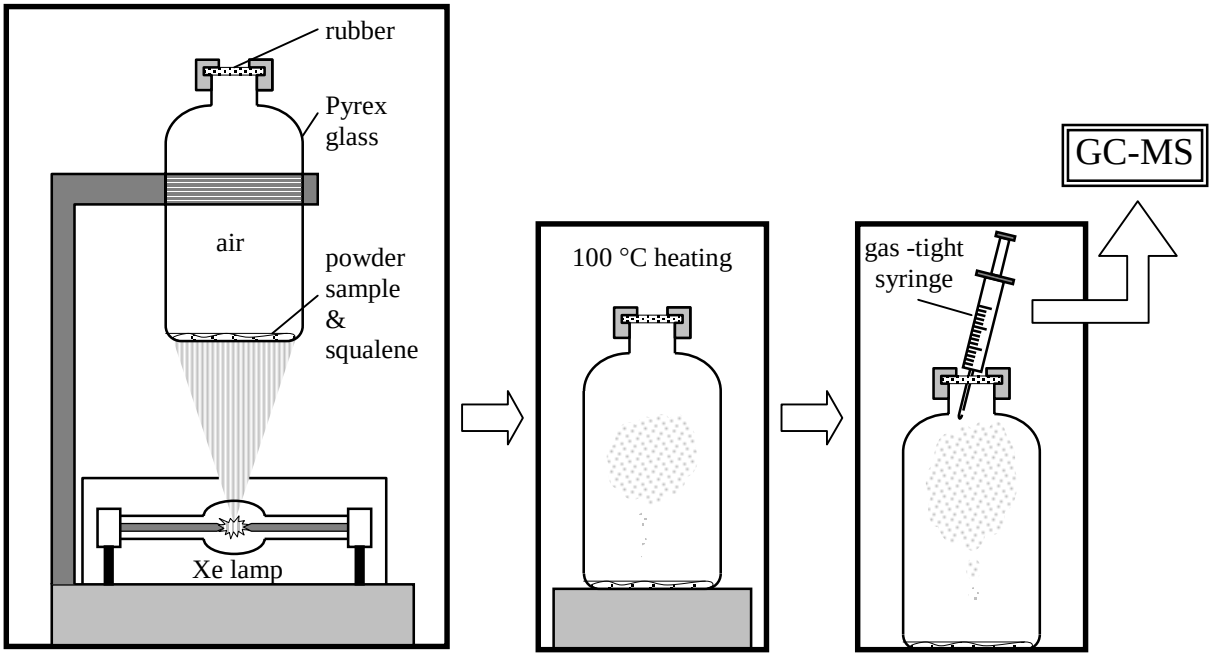

Fig.2 Schematic of the apparatus to measure the gas reaction products from UV-irradiated mixtures of powder and oil.

connected with a matching network and a radio frequency generator (13.56MHz); a Cu mesh outer electrode is connected with the earth. The apparatus was also equipped with an ultrasonic homogeniser to flocculate the aggregated powder into the single particles. RF power applied to the reactor was 2500W . Reaction gases were He and O_2. Gas flow rates were 10 l and 100 ml per minute, respectively. In the reaction device, fine particles were introduced on an ultrasonic horn and were flicked strongly. Then they were carried in the gas and went through the plasma area and were carried into the separation trap, and finally they were collected into the collecting bottle. Treating rate is about 100gr/50min for the powder.

The surface of treated TiO_2 that was coated with SiO_2 was analysed by XPS. Besides, we irradiated UV squalene oil with treated TiO_2 in a Pyrex glass bottle, which contained air. Then the composition of the gas that arose from UV-irradiated squalene oil by heating of the bottle was measured by GCMS (Shimazu QP5050).

3. Results and Discussion

3.1 XPS specta

In Figure 3, we measured Si2p spectra on TiO_2 (a) and that had adsorbed TEOS on TiO_2 (b), and that had

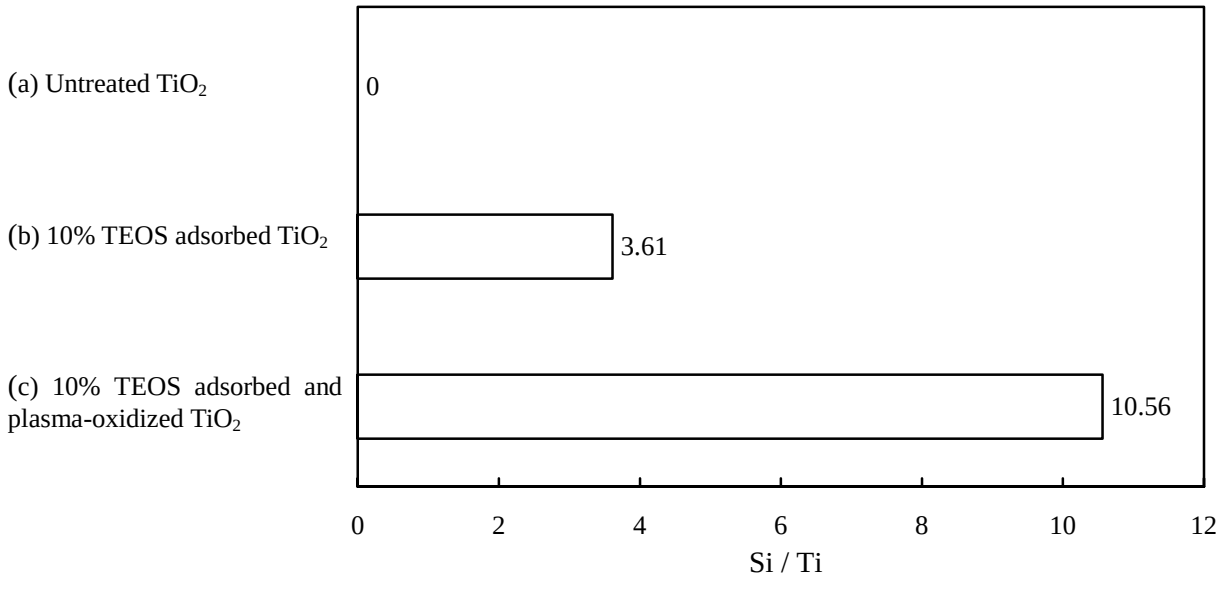

Fig.3 Atomic concentration ratios of Si /Ti on the treated TiO_2 powder surfaces.

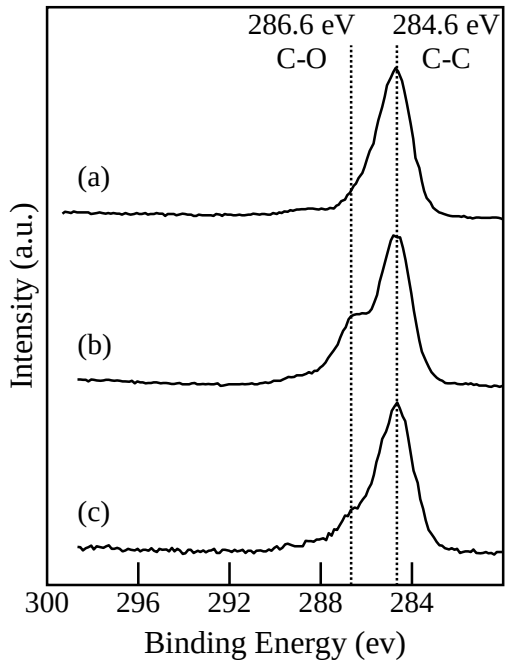

Fig. 4 C_{1s} spectra of XPS.
(a) untreated TiO2,
(b) 10wt%TEOS adsorbed TiO_2,
(c) 10wt%TEOS adsorbed TiO_2, and plasma oxidation.

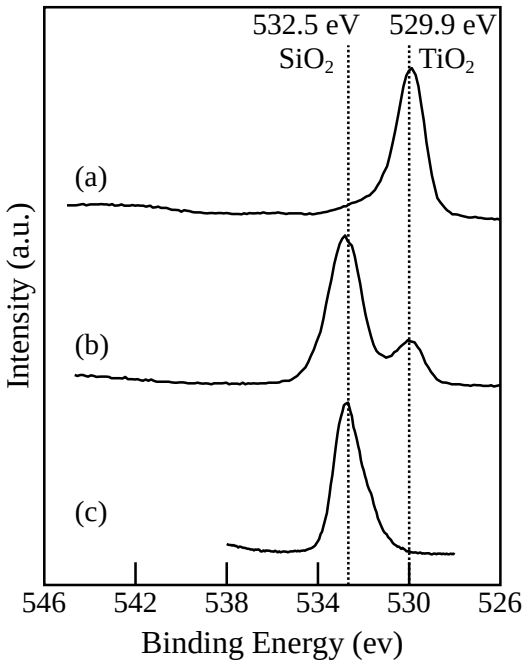

Fig.5 O_{1s} spectra of XPS.
Marks (a), (b), and (c) are the same as the marks in Fig. 4.

adsorbed TEOS and then was oxidized in the He-O_2 plasma (c). After the plasma oxidation(c), atomic concentration is increased because naked TiO_2 surfaces are lost and inorganic SiO_2 thin layer arose on the surface.

Figures 4 and 5 show C1s spectra and O1s of TiO_2 by XPS of untreated TiO_2 (a), 10% TEOS adsorbed TiO_2 (b), 10% TEOS adsorbed and plasma oxidized TiO_2 (c) respectively. In Figure 4, peak (a) shows

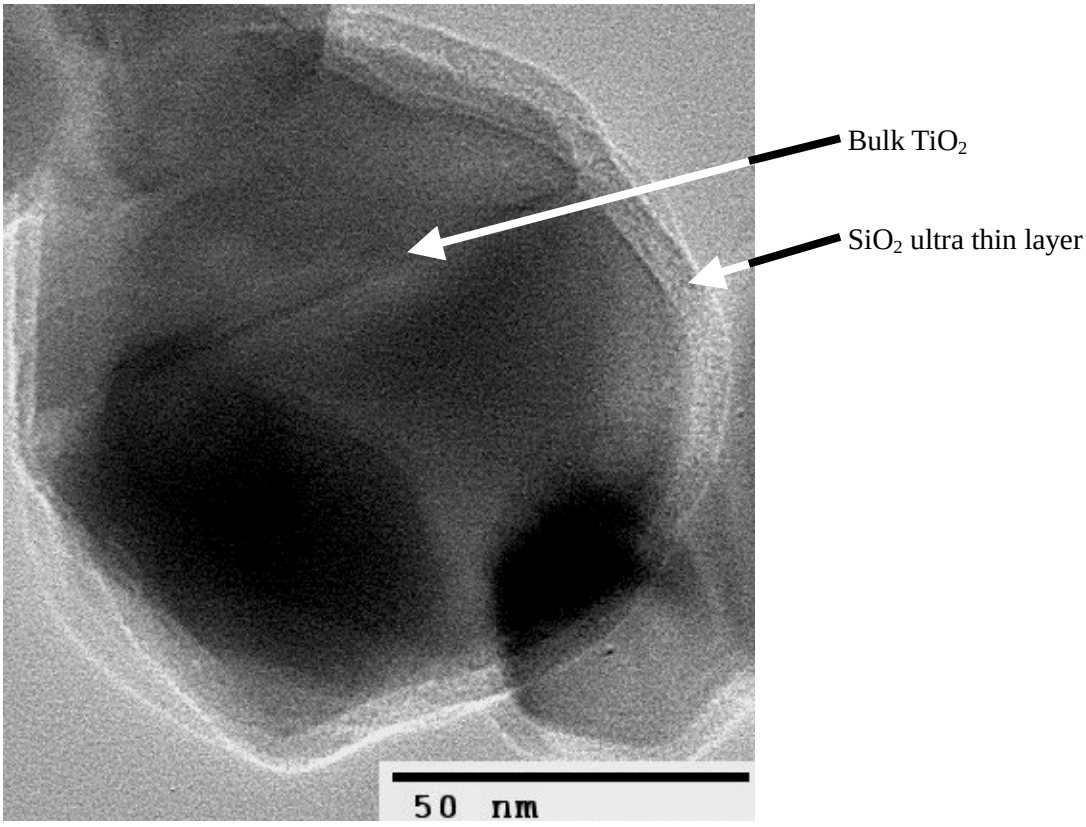

Photo 1 TEM photography of TiO_2 treated by SiO_2 in plasma oxidation.

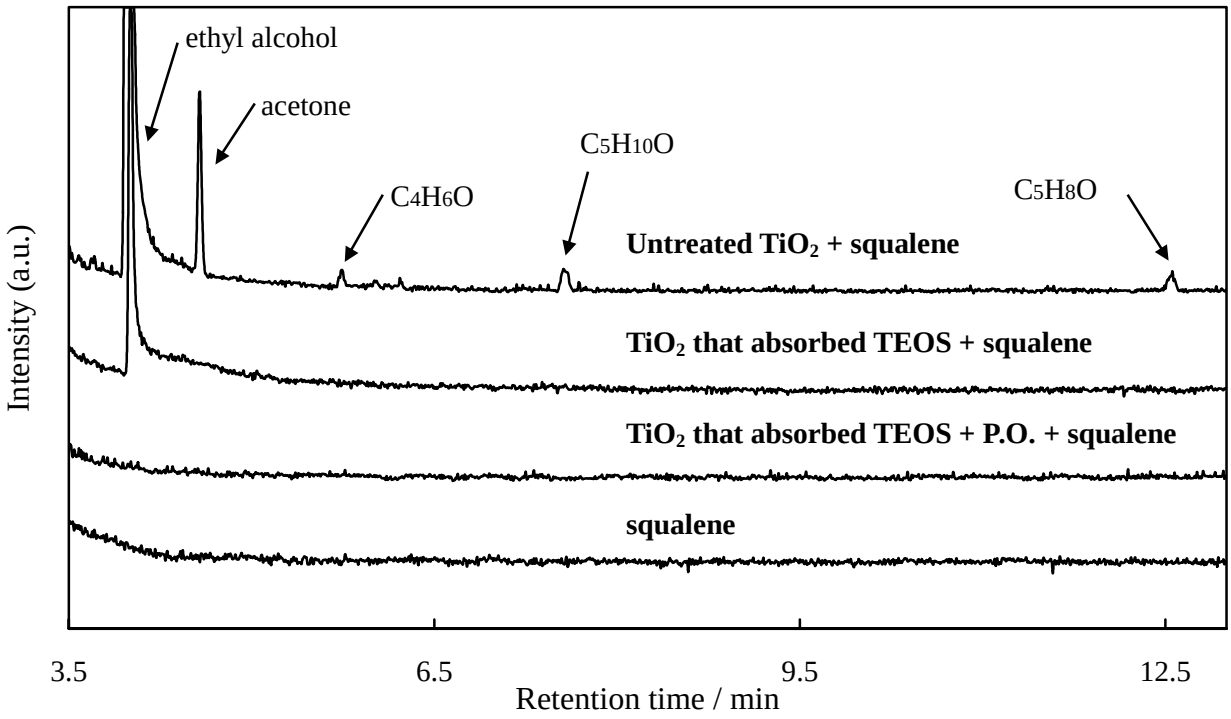

Fig. 6 GCMS spectra of vapor that arose from UV - irradiated mixture of the squalene oil and treated powders.

untreated TiO_2 powder that contains small amounts of carbon impurity that came from as-received TiO_2. After TEOS was adsorbed on the powder surfaces, another peak arose on the shoulder of the main peak; this should be assigned to the carboxyl groups in adsorbed TEOS molecule. In peak (c), carbon contamination peak is decreased by plasma oxidation and coating of SiO_2.

In Figure 5, sharp peaks of O_{1s} were obtained in the spectra of (a), (b) and (c). In the spectrum of (a) only one peak (529.9eV) assigned to TiO_2 existed. On the other hand, in the spectrum of (b) the peak (532.5eV) assigned to SiO_2 newly appeared, while the peak assigned to TiO_2 decreased. Therefore, it was found that the surface of (b) was coated with SiO_2 but the coating was not complete. In other words, the surface of TiO_2 is still partly covered by half - dissociated TEOS molecules. That is supported by the result of Figure 4. In the spectrum of (c) the peak assigned to TiO_2 almost disappeared and the shape of the peak looked like that of pure SiO_2. So, we could confirm that the surface of (c) was coated completely with inorganic SiO_2 layer without any organic contamination.

3.2 TEM photograph of powder

In the TEM photographs of treated particles, we can see an ultra thin layer covering the TiO_2 bulk powder surfaces. The thickness is about 5nm. It seems that the homogeneous inorganic layer interrupts the penetration of large - sized molecules such as squalene. The layer should be an amorphous SiO_2 because inside of the layer we can see no crystal lattice. Hence, as for the particles which adsorbed TEOS and were dried in air without plasma oxidation, their surfaces were covered by a thick porous layer.

3.3 GCMS spectrum of a vapour from UV - irradiated squalene oil mixed with the powders

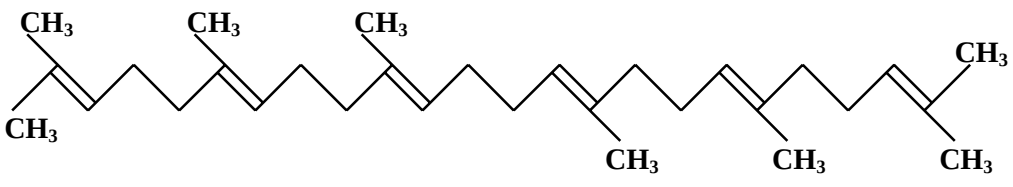

Fig. 7 Molecular structure of squalene ($C_{30}H_{50}$).

Figure 6 shows the GCMS spectrum of UV - irradiated squalene with TiO_2 and without TiO_2 in the atmosphere. The marks of (a), (b), and (c) are the same as the marks above. The spectrum of UV-irradiated squalene with (a) has peaks of ethyl alcohol and acetone and so on. These compounds are being generated in the squalene. The spectrum of UV-irradiated squalene with (b) has only one peak of ethyl alcohol; the small peak of acetone and those of other materials disappeared. The peak of ethyl alcohol decreased drastically but the quantity of the detected ethyl alcohol is still harmful to human skin. The spectrum of UV-irradiated squalene of sample (c) has no signal, so it was found that (c) could form a SiO_2 protection film that will prevent the oxidation of squalene oil even in the UV irradiation.

The squalene molecule has 8 methyl groups in the sides of the structure. The naked TiO_2 surface has strong oxidation reactivity. Thus, untreated TiO_2 will react with squalene and cut the main chain of the molecule, producing many kinds of organic oxide products such as $C_5H_{10}O$ shown in Figure 6. On the other hand, sample (b) has only a few low molecular number oxides such as acetone or ethanol. Probably, the surface of the sample (b) has been partly covered with SiO_2 caused by hydrated TEOS molecules that reacted with adsorbed water on the TiO_2, as shown in reaction (1).

$$Si(CH_3CH_2O)_4 + 2H_2O = SiO_2 + 4C_2H_5OH \qquad (1)$$

We confirm that ethanol found in spectrum(c) in Figure 6 should not be attributed to the solvent ethanol used for C_2D_5OH and GC-MS analysis. So, the surface of the sample (b) should have many small pits whose sizes are smaller than nm. A large molecule such as squalene cannot fully penetrate inside of the SiO_2 layer through the pits. Only the small size parts of ends of the main chain such as methyl groups can creep into the inside layer, and can react with TiO_2 surfaces to produce low molecular number oxides. But the sample (c) is completely covered by a tight quartz layer. No hydrocarbon molecules can penetrate the hard layer. This is the reason why we have no signals in the line of sample (c) in GCMS spectra.

4. Conclusion

We attained the ultra - thin silica layer by means of atmospheric pressure glow plasma using TEOS adsorbing and plasma oxidation method. The attained silica protection layer interrupted perfectly the oxidation of squalene oil mixed with treated TiO_2 powder under the UV irradiation. The ‘Adsorbing and Plasma Oxidation Process’ can be applied not only for TiO_2 but also for many kinds of powders that should have complete protection from the penetration of gases or molecules. The powder treatment system shown in Figure 1 has many advantages compared with the low pressure glow plasma powder treatment system, for example, very simple apparatus and easy cleaning of inside of the reactor without breaking any complicated vacuum seals. Moreover, because only radical reactions will only take place in the reactor without any ion-damaging effect in such high pressure–non thermal plasma reactors, one can treat very soft materials such as biomedical powders or organic pigments [4][5].

Abstract
Highly selective plasma-assisted amino-functionalization of polystyrene (PS) and polyetheretherketone (PEEK) was developed with regard to a controllable density of nitrogen-containing functional groups in general and of amino groups, specifically. The results were tested for polymer utilization as biomaterials, either direct in cell culture or after immobilization of collagen I (COLL I). Cell culture experiments were performed to check the plasma treatment and immobilization strategy.

1. Introduction

Low pressure gas-discharge plasmas are widely used for polymer surface functionalization on industrial scale. For biomaterial applications, functionalization density and selectivity are of particular importance, since functional groups are needed to control the conformation of biomolecules during adhesion and coupling reactions for immobilization [1], [2]. The idea is, that amino groups itself or in combination with a biofunctionality are very well suited for these purposes. In this context, nitrogen-containing plasmas are widely used to equip biomaterials surfaces with amino groups [3], although the plasma technology is not perfect regarding a controlled and selective generation of amino groups on polymer surfaces.
Here, we describe results of experiments of microwave (MW) - excited plasmas in continuous wave (cw) and pulsed mode (pp) in NH_3 in respect of PS and PEEK surface functionalization to check the above mentioned ideas in detail. Initially, a well-defined functionalization was acquired in a clean, ultra high vacuum (UHV) - compatible plasma environment. The results were tested for utilization, either direct in cell culture or indirect by transfer of the processes to a biologization of PEEK surfaces. In the latter case, collagen I (COLL I) was immobilized via different spacer molecules and osteoblast cells were cultivated to check the plasma treatment and immobilization strategy.

2. Experimental

Plasma experiments on PS were performed in 15 sccm ammonia (0,1 mbar) at 600 W in the afterglow (distance 9 cm) in a UHV-compatible reactor. The base pressure of the reactor is better than 10^{-6} mbar. It is part of a cluster tool, which comprises reactors, analysis and storage chambers (for details see ref. [4]). This cluster tool allowed to perform experiments under very well-defined conditions and including quasi *in situ* X-ray photoelectron spectroscopy (XPS) surface analysis of plasma-functionalized samples via a transfer in UHV from the reactor to the analysis chamber.
PEEK (25 µm thick foils for minimized fluorescence) was treated in an ammonia plasma in 40 sccm ammonia (0,2 mbar) at 550 W in the afterglow (distance 5 cm) in a commercially available reactor (V55GM, Plasma Finish, Germany), i.e. under conditions typical for application.
Amino groups were quantified via the fluorine surface density (XPS) after a derivation reaction with trifluoromethylbenzaldehyde (TFBA) within two hours after leaving the vacuum system (for details see [4]).
The reactors are installed in clean room areas for direct transfer of samples to the biological work space, subsequent processing steps, and sample transfer to cooperating cell-biological research groups.
The immobilization of COLL I was performed either with glutardialdehyde (GDA, 2 % in H_2O) for 2 h or a polyethylene glycol (PEG) spacer containing diacid (HOOC-PEG_{10}-COOH in PBS) by the carbodiimide (EDC) method over night.
Nasopharyngeal epithelial cells (KB) were cultivated on PS for 24 h, whereas MG-63 osteoblast cells were seeded on differently modified PEEK surfaces for 1 h. In both cases, temperature and CO_2 concentration were kept constant at 37 °C and 5 % CO_2, respectively. For staining of the actin-cytoskeleton of MG-63 cells, the samples were rinsed with PBS and fixed with 4 % paraformaldehyde and permeabilised with 0,1 %

[1] Present address: Bundesanstalt für Materialprüfung und -forschung, Berlin, Germany

TritonX-100 (in PBS) for 10 min at room temperature. After washing with PBS, cells were incubated for 30 min with BODIPY®FL phallacidin (diluted 1:40 with PBS) at room temperature and washed with PBS. The samples were embedded and analysed with a 63× oil immersion objective by confocal laser scanning microscopy (LSM 410, Carl Zeiss, Jena, Germany, excitation 488 nm, emission bandpass 510-525 nm).

3. Results and discussions

Highly selective functionalization of polymer surfaces represents the principal prerequisite for a successful subsequent improvement of surface biocompatibility, because it is the origin of the exploitation by materials of the proteins and cells of the body, independent of the subsequent manner of interaction. Amino groups carry a positive charge in aqueous solution at physiological pH values and possess a good chemical reactivity. On these accounts, amino groups are especially well-suited for the improvement of biocompatibility of usual polymers, which do not possess functional groups.

Consequently, plasma-enhanced selective generation of amino groups is an essential research topic. Until now, plasma processes in nitrogen and ammonia equip surfaces with multiple nitrogen- and oxygen-containing functional groups. Here, we will present some experiments aimed at an improved functionalization.

For oxygen-containing plasmas, it is well known, that optimum plasma functionalization is only possible for short treatment duration not exceeding a few seconds. Longer treatments cause undesired surface decompositions accompanied by deterioration of the desired functionalization [5].

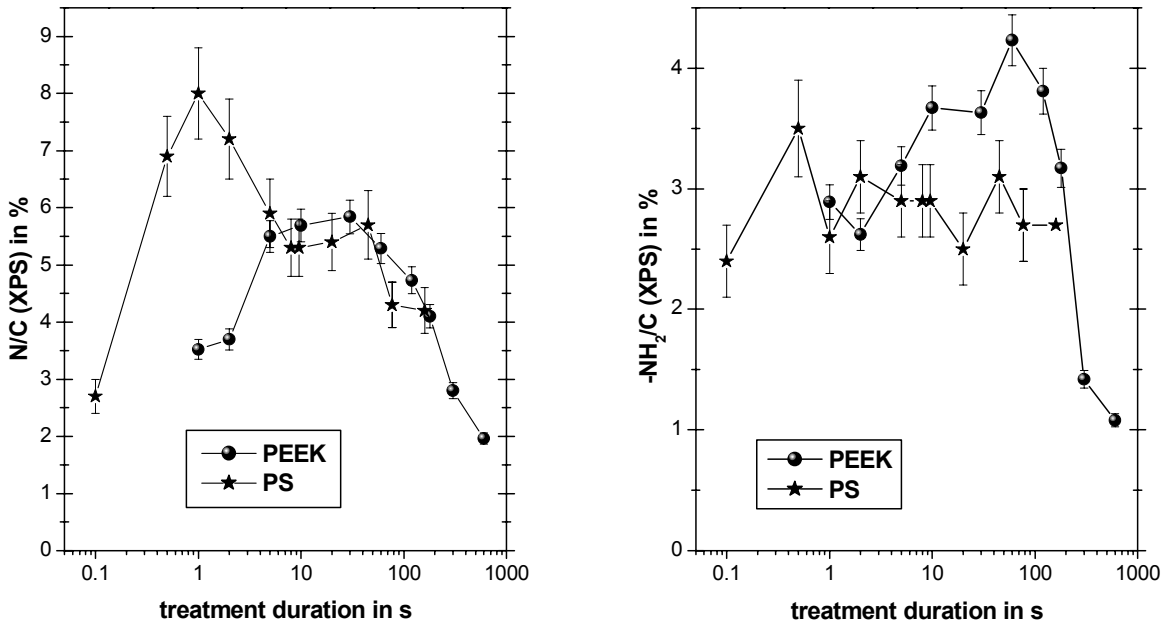

Fig. 1: Nitrogen (left) and amino group (right) density in dependence of treatment duration in a cw ammonia plasma for PEEK and PS.

Indeed, this effect was also seen in our case for ammonia plasma treatment both for PS and PEEK and similarly in UHV- and HV- environment. A cw MW plasma in ammonia lasting for 100 ms generated a PS surface with a N/C ratio and -NH_2/C ratio smaller than after a treatment duration of 300 ms and more. Interestingly, these short treatment times yielded the maximum selectivity of -NH_2/N (100 %) [6]. A similar situation was found for PEEK at elongated treatment duration. A maximum of N/C and –NH_2/C at still short treatment duration of 1-60 s is clearly visible for both polymers. This way, the polymer surfaces can be equipped with N/C of 5-8 % densities by considering the treatment time dependence. Optimized amino group densities reach more than 3 % -NH_2/C, i.e. 50 % of the implemented nitrogen (50 % -NH_2/N). Note, that plasma treatment in an environment with normal purity yielded similar levels of –NH_2 concentrations like in the ultra-clean reactor.

As expected, these changes in surface chemistry affect the water contact angle, shown in Fig.2.

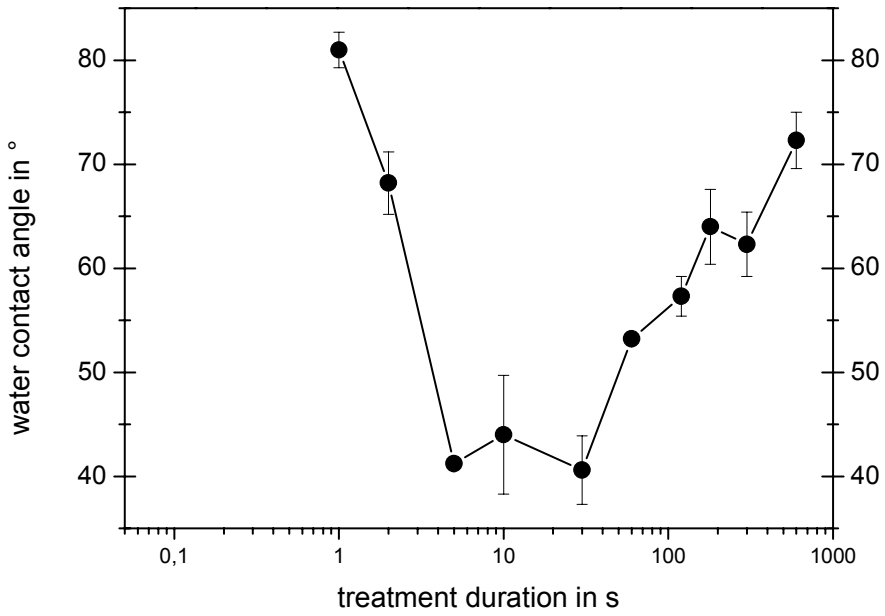

Fig. 2: Water contact angle of PEEK in dependence of the treatment duration in cw MW ammonia plasma.

This figure demonstrates the enormous dynamic of plasma-induced surface alterations. Obviously, wettability is related to the nitrogen content of the surface.

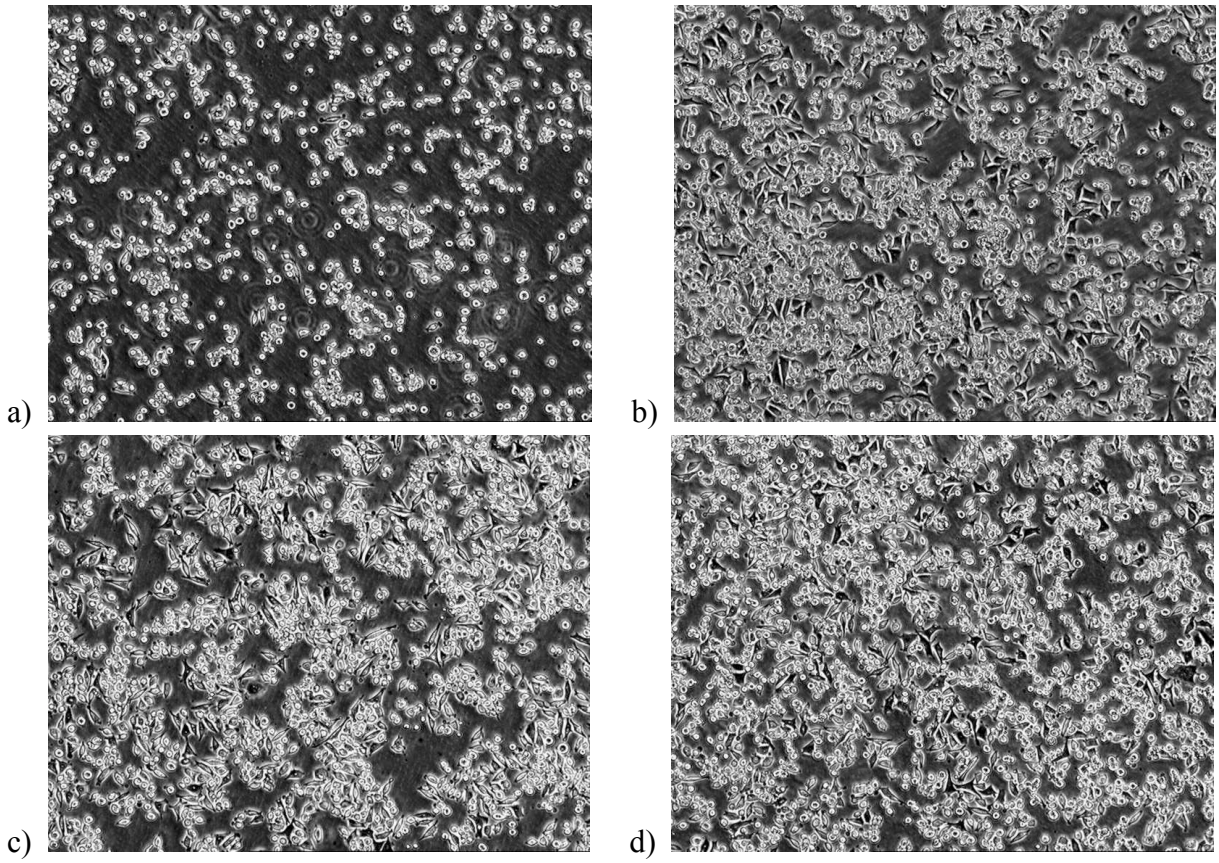

Fig. 3: Nasopharyngeal epithelial cells grown on different plasma treated PS substrates for 24 h: a) untreated PS, b) tissue culture treated PS (TCPS), c) 80 s cw MW NH_3 plasma treated, d) 10 s pp MW NH_3 plasma treated.

PS dishes treated in these short cw NH_3 plasmas are superior cell culture substrates, compared to PS and TCPS [3] (Fig. 3c). Additionally, the diversification of functionalization could be used to tune cell culture results. Extremely high densities of nitrogen were obtained after pp MW NH_3 plasma with a treatment duration of 10 s and more [7]. In this case, an exceptionally high cell density could be achieved (Fig. 3d). Here, cell behaviour must be understood as a result of self-organized attachment of biomolecules on chemically functionalized polymer surfaces.

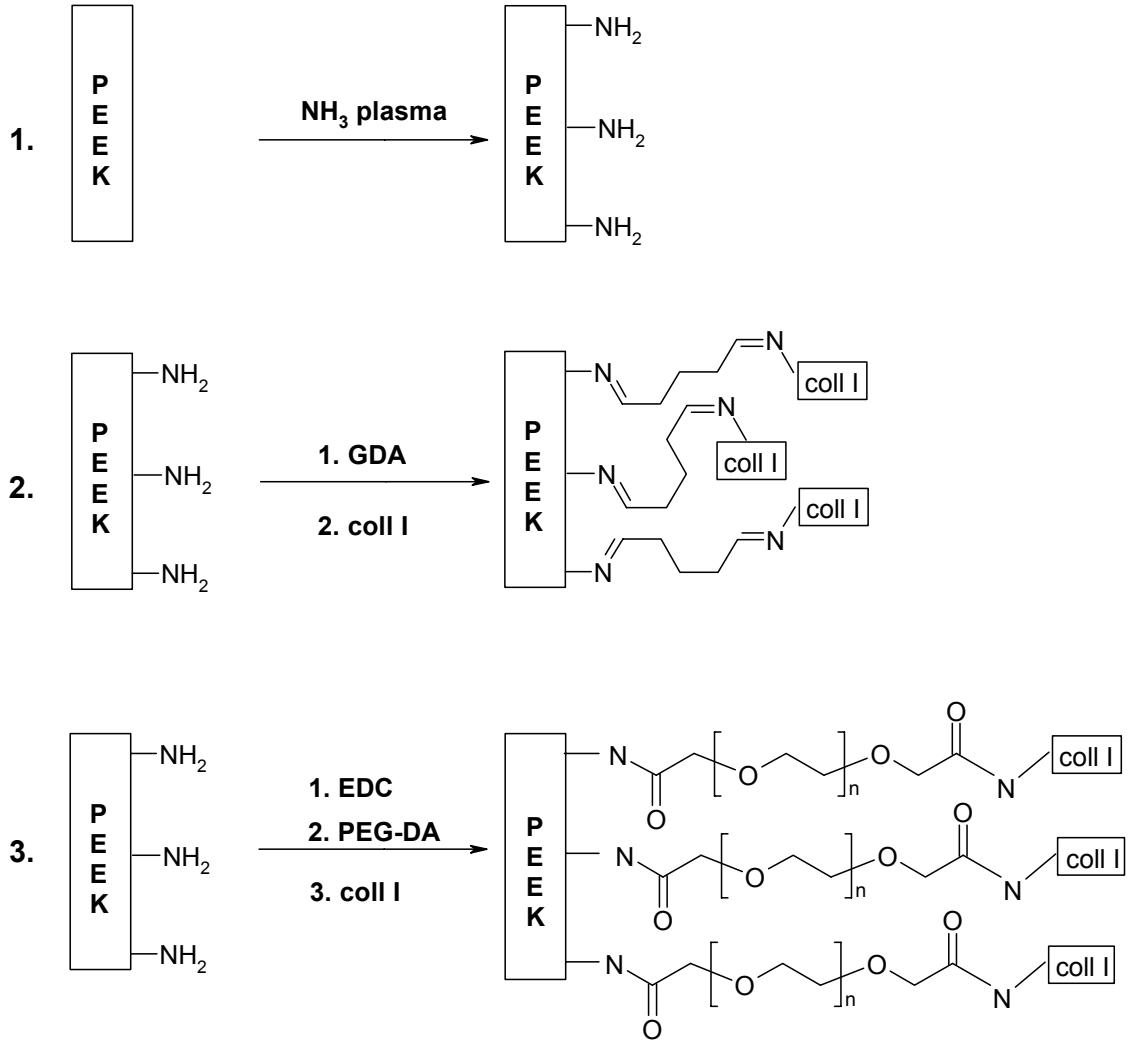

Fig. 4: Scheme of plasma induced PEEK surface activation in ammonia plasma (1) and collagen I (COLL I) immobilization via glutardialdehyde GDA (2) or carbodiimide (EDC) with a polyethylene glycol (PEG) spacer molecule PEG-diacid (PEG-DA) (3), respectively.

Instead of self-organization, immobilization of selected biomolecules can be performed by a directed covalent chemical coupling strategy. This necessitates:
- assembly of different well-defined layers, which bridge the inert polymer surface to the signal-guided cell environment and
- establishment of defined and durable connections between the single layers, i.e. covalent bonding and
- adequate characterization of every single layer or reaction step to ensure the reproducible success.

This strategy was tested for COLL I coating of PEEK. The fundamental step again is surface functionalization (scheme 1 in Fig. 4). The cw ammonia plasma lasted for 5 s in order to realize a very high amino group density ($–NH_2/C$) of about 3,5 % and a high wettability, i.e. contact angle of 40-50 ° (see Fig. 2). A short distance covalent link of COLL I to these surfaces could cause conformational hindrances reducing its bioactivity (scheme 2 in Fig. 4). More extended spacer molecules should facilitate an improved sterical constitution. Additionally, PEG should maintain functionality by optimized chain length and prevent

unspecific adsorption of proteins (scheme 3 in Fig. 4). These ideas were tested by means of GDA versus PEG/EDC bifunctional linker molecules (Fig. 5).

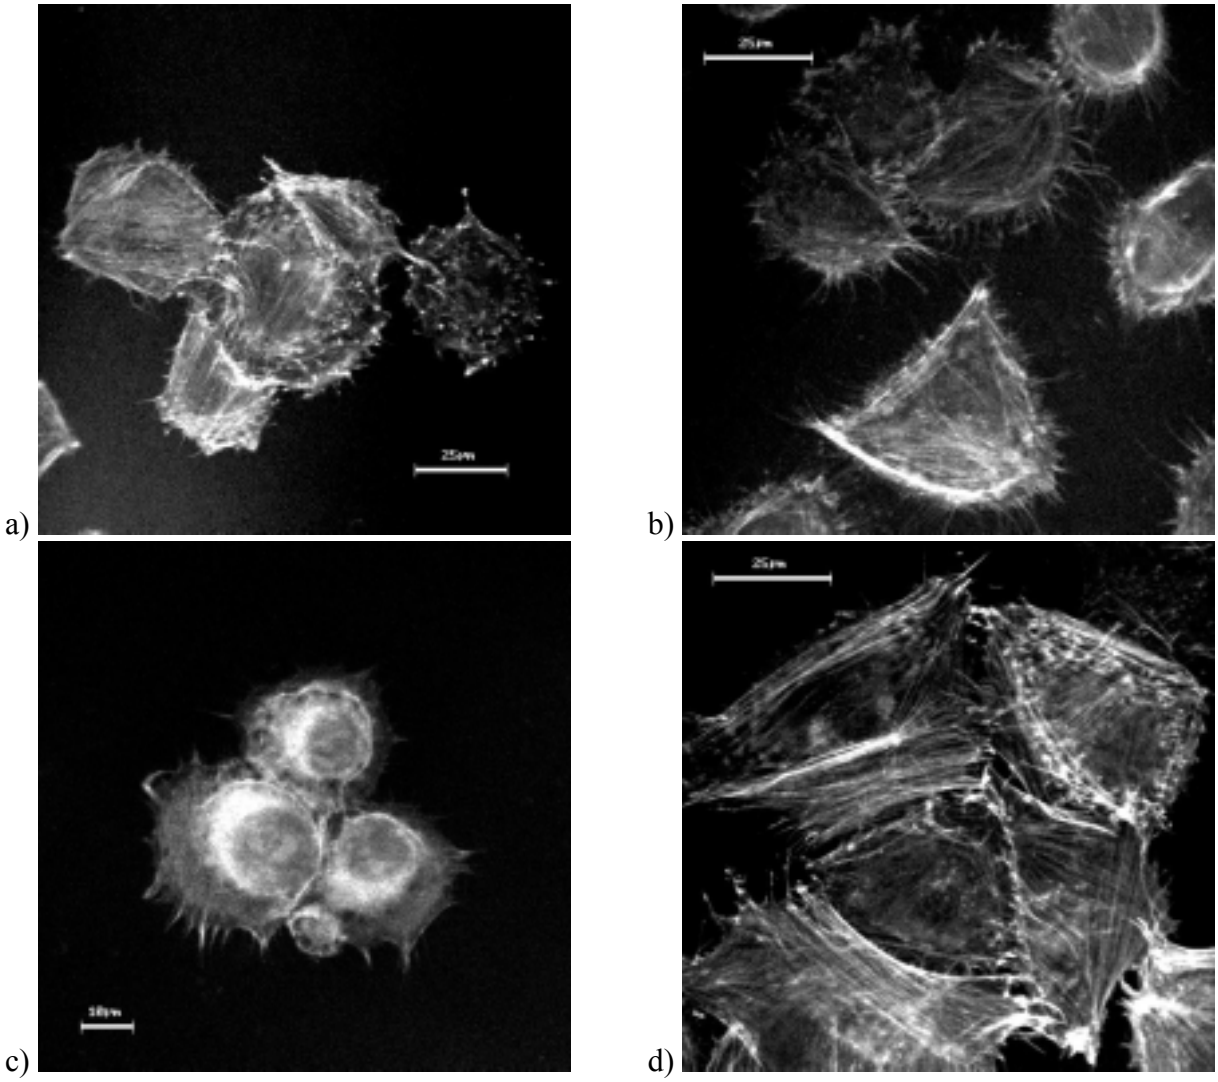

Fig. 5: MG-63 osteoblastic cells grown on differently treated PEEK surfaces, Fluorescence staining of F-actin (component of the cytoskeleton): a) untreated, b) 5 s NH_3 plasma, c) COLL I coupled via GDA after 5 s NH_3 plasma, d) COLL I coupled via EDC after 5 s NH_3 plasma. For the abbreviations see Fig 4.

MG-63 osteoblastic cells were seeded for 1 h in order to investigate the formation of the cytoskeleton. MG-63 cells on non-treated PEEK were still round, but contained a distinct cytoskeleton visible even through the strong fluorescence of PEEK (Fig. 5a). This behaviour was different from "normal" *in vitro* behaviour, namely COLL I adsorbed on cover glass (not shown). There, slightly spread and polygonal cells were obtained with a strongly developed actin-cytoskeleton. If the cells were cultivated on ammonia-plasma treated PEEK, they appeared much more spread in comparison to non-treated PEEK (Fig 5b). Cells on PEEK with covalently bound COLL I showed a different appearance when cultivated either on COLL I bound with glutardialdehyde (GDA, Fig 5c) or with carbodiimide (EDC) and polyethylene glycol (PEG, Fig 5d) spacer molecule. The cells on PEEK with COLL I bound with the PEG spacer (Fig 5d) were more spread than on PEEK with COLL I bound via GDA (Fig. 5c). In comparison to ammonia plasma treated PEEK(Fig 5b), the cells on COLL I coupled with PEG spacer (Fig. 5d) showed a more uniform appearance starting to form a meshwork of F-actin fibres.

These results correspond to the time dependence of MG-63 osteoblast adhesion (Fig. 6). Once more, clear differences between untreated and ammonia plasma treated PEEK could be demonstrated. Additionally, cell adhesion on COLL I immobilized by a GDA spacer is inferior to an immobilization via PEG spacer. Note, that only minor differences could be measured between ammonia plasma treated surfaces and surfaces with immobilized COLL I via PEG spacer. This indeed correlates with the results given in Fig. 5.

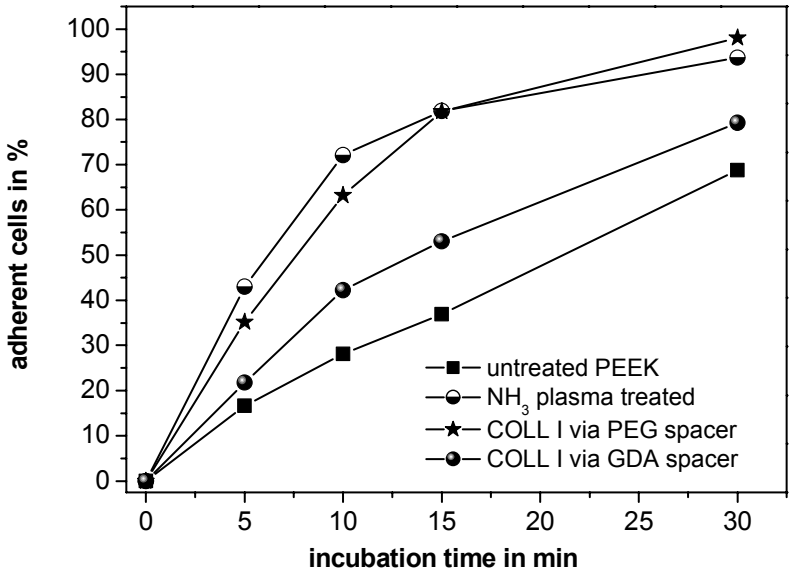

Fig. 6: Time-dependent adhesion of MG-63 osteoblastic cells on differently treated PEEK surfaces. Note, that the coupling of COLL I was carried out on NH_3 plasma treated surfaces.

Summary

Functionalization of PS and PEEK surfaces was performed in MW-excited ammonia plasmas. Short treatment durations enabled reproducible amino group and nitrogen densities of more than 3 % -NH_2/C and 35 % N/C, respectively. Hence, the wettability of the surfaces was increased reaching a medium hydrophilic character. These surfaces were either directly applied for cell culture or after using a directed immobilization strategy based on plasma chemically generated amino groups. Both approaches demonstrated significantly improved cell behaviour compared to untreated polymers. The successful covalent immobilization of COLL I depended on the applied spacer molecule and chemistry. A very promising result was obtained if a PEG-based spacer was utilized. The cell density after cultivation on solely plasma functionalised polymers was exceedingly high and of similar quality as for PEG/EDC based immobilization of COLL I. The result indicates, that further considerations and investigations are necessary to refine the design strategy of biomaterials surfaces.

Abstract

Microwave oxygen plasma is irradiated on glass melt which contains mixed metal chlorides. The chlorine in glass melt is removed and large amount of oxygen dissolved into melt by using oxygen plasma. An advanced experiment is done to investigate the dissolution behaviour of oxygen into glass in detail. As a result, it is found that oxygen dissolved in surface of glass melt and the solubility of oxygen into glass melt increase with increasing applied power.

1. Introduction

In the field of nuclear industry, it is one of main problem to solidify high-level radioactivity waste into safety form, and dispose it. Especially, the waste from the pyrochemical reprocessing of future is discharged as metal chloride. Then, the problem of safety appears, when these chloride wastes vitrified into glass as same as now going on. As one solution of this problem, we have suggested and developed the methods to oxidize chloride into oxide directly by using oxygen plasma.

In this method, we use the plasma torch by heating microwave. This plasma torch can generate the plasma of 100% oxygen easily at atmospheric pressure. We reported that many kind of metal chlorides could be oxidized by its strong oxidation power.[1] Then, for using a heat from plasma, we suggest the application to direct vitrification of chloride waste by using this oxygen plasma. And we study its feasibility. Some experiments are carried out to investigate the effect appeared on glass when the glass melt was irradiated by plasma, especially, the influence of amounts of chlorine in glass. In this paper, we will report some experimental results, including the result from experiment that for study the effect of plasma to dissolving phenomena of oxygen.

2. Investigation of chlorine removal in glass melts

2.1 Experimental

Figure1 shows a diagram of experimental setup. This setup consists of an electric furnace part for glass melting and a plasma torch part for oxygen plasma generation. Furnace has a shutter board made from heat insulating material. In a process to melt glass, torch part is isolated from furnace by shutter board to prevent to escape the heat from furnace and to overheat the torch.

In this study, microwave plasma torch is used to generate pure oxygen plasma at atmospheric pressure. Figure 2 shows the diagrams of plasma torch. Torch is made from stainless steel and is a coaxial cavity resonator. Microwave power is introduced to plasma torch through wave guides. Plasma gas is introduced into torch cavity and then flow downwards to discharge around nozzle by impedance matching. The discharge starts with spark at nozzle part, then the bell shaped plasma generate to flow towards down stream. The net power that consumed by plasma is defined as difference of supplied power and reflects power measured by power monitor placed on wave-guide.

Glass sample is the mixture of 100g borosilicate glass and 5.0g metal chlorides. Composition of glass is 56.1wt% SiO2, 17.1wt% B_2O_3, 6.0 wt% Al_2O_3, 3.6 wt% CaO, 3.6 wt% ZnO, 3.6 wt% Li_2O, and 10.0 wt% Na_2O. Glass transition temperature and soften point are 500 and 618 ^oC, respectively. Here, bead formed glass is used to avoid gas babble mixing into melt and to make homogenous melt easily.[2] Sr chloride and Ni chloride are used as metal chloride to be mixed with glass. Used chlorides are divalence and hexahydrete each other mixed 5.0g as hydrate.

At first, mixture sample was put into alumina crucible to be heated in furnace. To make homogeneous glass melt without gas babble, sample was heated slowly to 1000 ^oC with taking one and a quarter hours, and kept at same temperature during 1 hour for Sr mixed sample and 2 hours for Ni mixed one. Then oxygen plasma is irradiated to a homogeneous glass melt that prepared by above procedure. Applied power is 1.9kW or 1.5kW and gas flow rate is 19.0L/min. or 13.1L/min, respectively. An spacing for irradiation between plasma torch and the surface of glass melt was 65mm. Irradiation time was changed up to 60min. However,

in the case of 60min. irradiation, the irradiation period was divided into 2 time irradiations to avoid overheating the plasma torch.

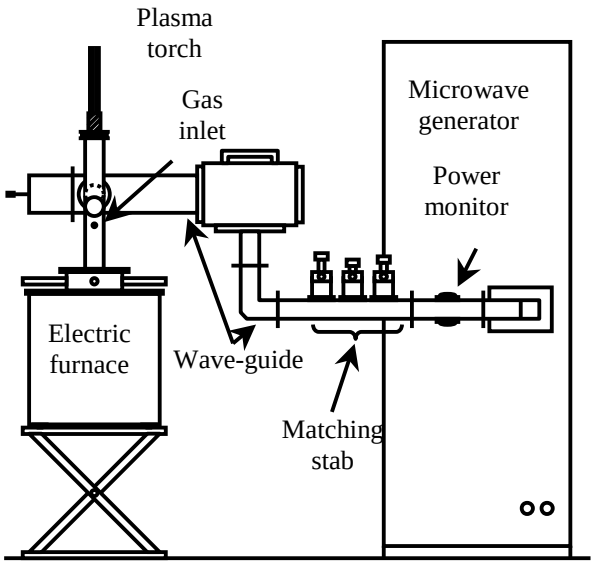

Fig.1 Schematic diagram of experimental setup

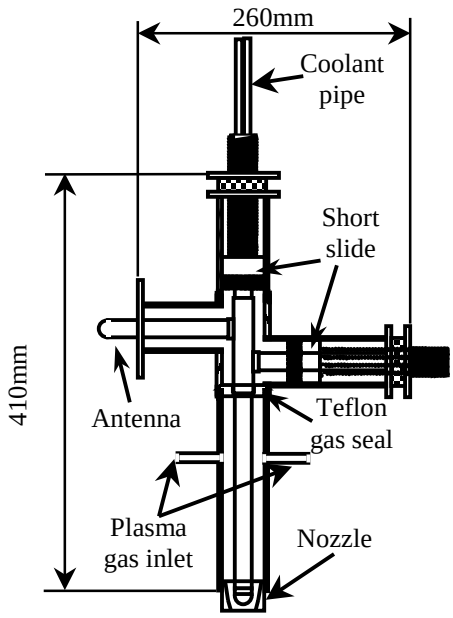

Fig.2 Schematic diagram of microwave plasma torch

2.2 Results and discussion

Solidified glass sample after cool down coloured by metal dissolution into glass melt. The colour of glass which contains Sr was transparent. And Ni one was purple. No change of colour was observed during plasma irradiation. We observed sometimes a mall amount of precipitation on surface of glass product after irradiation. In the glasses containing Sr, the layer of precipitation was observed on all samples whether plasma irradiate or not. On the other hand, in the glasses contained Ni, the layer was observed on samples irradiated by plasma, except samples irradiated on 1.5kW for 60min and no irradiation samples. A composition of precipitation was analyzed on wavelength-dispersed XRF. It was found from result of analysis that this precipitation consists of mainly Sodium, Chlorine (Na: Cl=52:45) and small amount of Si.

The composition of glass product was analyzed by WDXRF, to investigate the change of amount of chlorine contained in glass. Data were converted into the ratio to whole weight of glass product. The ratio of chlorine is shown in Fig.3. In this figure, ratio measured before experiment is also shown.

The figure indicates that the ratio of chlorine in glass decreases by plasma irradiation. Focusing on its detail; same tendency appears in the case of applying same power. The ratio of chlorine decreases simply with increasing irradiation time, when plasma irradiated on 1.9kW. While, in the case of irradiated on 1.5kW, the ratio decreases until 15 min. and increases slowly. This increasing tendency causes to decrease other components. There is clearly difference between the change of ratio during plasma irradiation and during heating. When plasma irradiating, there appears no difference between tendency of glass which contain Sr and one which contains Ni. However, the change of ratio during heating was affected on metal, which was mixed into melt. Judging from the above, it is found that we can remove chlorine from glass by using plasma treatment.

The change of sample weight during plasma irradiation is shown in Fig.4. The weight of sample which contains Sr increases with increasing plasma irradiating time. The rate of change in weight is calculated to investigate in detail. This rate is shown in Fig.5. Since a mixed chloride is hexahydrate, the weight of sample decreased due to thermal decomposition of hydrate during heating. Because water releasing occurs up to 200^{o}C and the glass melting takes place above 900^{o}C. Therefore, the interaction between water and melt can be ignored consequently. The weight of water which is contained as hydrate is subtracted in calculation of rate during heating. In the case of irradiating on 1.9kW to melt which contains Sr, the rate is calculated in

two parts. one part is increasing part until 15min. and the other is decreasing part after 15min.The rate of change in weight during plasma irradiation decreases in comparison to the rate on heating in the glass which contains Ni, the weight of sample dose not increase. However, the rate of change in weight increases against the rate on heating.

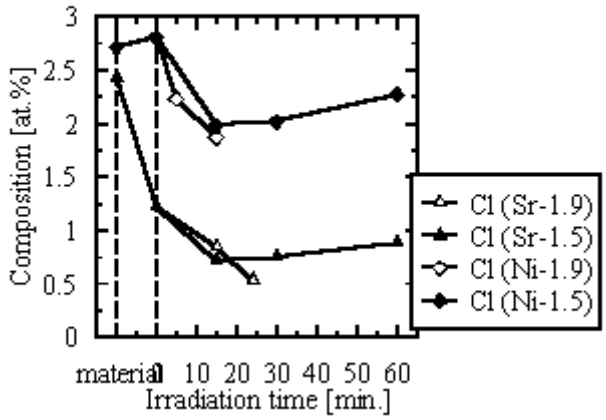

Fig.3 The effect of plasma irradiation on Cl composition in glass

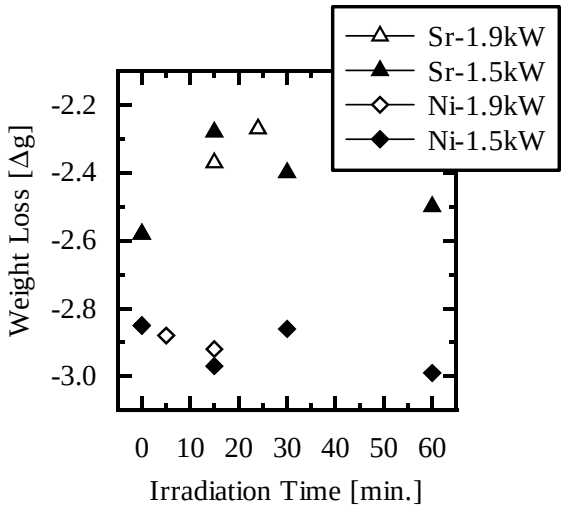

Fig.4 The effect of plasma irradiation time on glass weight loss

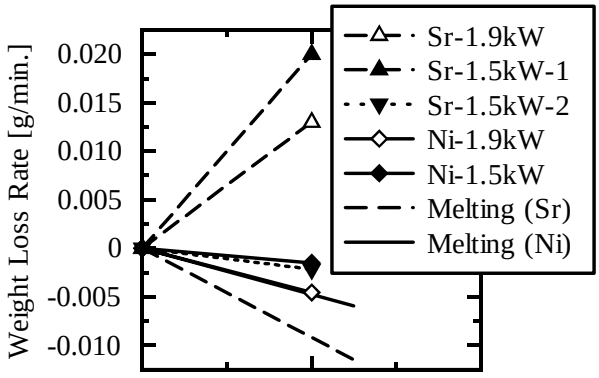

Fig.5 Competition of weight loss rate

It is well known that the components that have high vapour pressure such as alkali metal volatilizes easily from glass melt. The volatilization is affected on a composition of glass melt and on a temperature of melt. It is reported that borosilicate glass which contains B_2O_3, and phosphate glass which contains P_2O_5 have large change in weight on volatilization. The volatile rate per unit area is constant until 10 hour[3][4][5] and the weight of melting glass decreases. Therefore, it seems reasonable to conclude that the positive change of weight, which is seen in this experiments is cause to the dissolution of plasma gas into melts by irradiating plasma. It is found that plasma irradiation can dissolve more gases into glass melt in comparison to using normal gases.

It is supposed that the dissolution of large amount of gas into inorganic melt affects to so many properties of melt. For example, it is known that the activity of glass melt is affected on the non-bridging oxygen. In

addition, argon gas is babbled into ferric melt to remove gases in field of making steel. Then it may be truth that the remove of chlorine from melt is related to dissolution of oxygen. More investigation is needed to discuss this relationship.

3. Investigation of dissolution of oxygen into melts

3.1 Experimental

It is found that the amount of dissolved oxygen increases by irradiating plasma to glass melts. Experiment to investigate the behaviour of dissolving in detail is done. Setup, which is used in this experiment, is shown on Fig.6. Sample glass is melted in silica tube. The change of gas composition is measured. A coaxial-type dielectric barrier discharge is used. Pt electrodes place on centre of tube and on outer wall of tube. Phosphate glass, which have low melting point, is used as sample glass, because of temperature limit of seal material. The composition of glass is 3.4Wt% B_2O_3, 18.2 Wt% Na_2O, 15.9 Wt% ZnO and 62.5 Wt% P_2O_5. The glass transition temperature is 315 ^oC. The glass sample was put on SiO_2 tube to heating with pumping out for preparing the glass melt. Glass was heating up to 900C to avoid gas mixing into melt. Kr was added 500 Torr to tube, and then the melt kept at 700^oC for 5 hours. After addition of 300 Torr of O_2 , melt kept at same temperature for more 1 hour. Then glass melt is irradiated plasma. The ratio of O_2/Kr is measured continuously on gas chromatography after irradiating plasma for constant times. Plasma turned off during sampling gases. It is assumed that the ratio of O_2/Kr is reflected the behaviour of O_2 directly, with ignoring the behaviour of Kr. Because atomic size of Kr is enough too large than that of O_2 in dissolution phenomena.

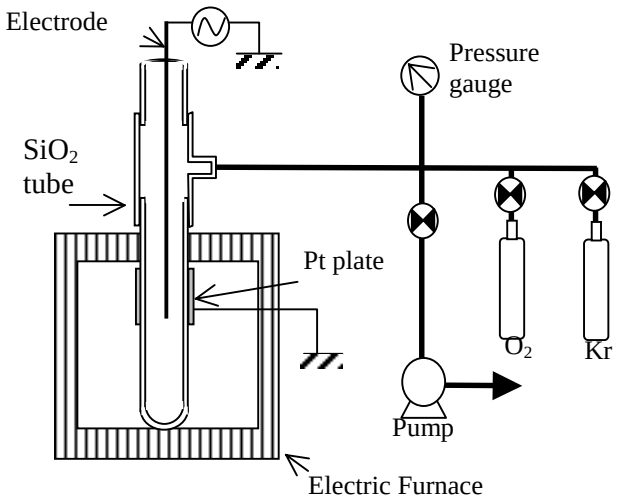

Fig.6 Schematic diagram of experimental setup

3.2 Results and discussion

The result of experiment on various applied power is shown on Fig.7. Amount of glass is 0.3g. O_2/Kr ratio increased until 1 hour in experiment. The cause of this increasing is mixing of O_2 and Kr in gas phase. Therefore, the difference O_2/Kr ratio from maximum value of O_2/Kr ratio is shown in this figure.

The tendency changes at the point of 4 hour. Until 4 hour, the oxygen ratio increases with linear relationship. The degree of change increases with increasing applied power. On the other hand, over 4 hours, fluctuation and the discontinuous points appears in the series of data. However, tendency that O_2/Kr ratio increases with increasing applied power appears.

Next, plasma irradiated to sample with various volume. Applied power is fixed on 40W.This result is shown in Fig.8. In this figure, the gradient changes at the point of 4 hours. Until 4 hour, the change of O2/Kr ratio is not affected on the volume of sample. In addition, also over 4 hour, the behaviour of O2/Kr ratio on 0.3g corresponds to the behaviour on 1.0g. In the series of 3.0g, it is seen that the dissolution occurs continuously over 4 hours, too. However, there is the discontinuous point between 3 and 4 hour. In this experiment, the same sample is measured continuously. Therefore, a possibility that this discontinuous point

comes from any mistake on operation cannot deny. It is shown from discussed above that the amount of dissolved oxygen is not affected on glass weight. Therefore, the dissolution of oxygen is occurring on near the surface.

Plasma can supply active gas species such as some ions or atomic gas. It is mainly difference between neutral gas and plasma, and merit of using plasma for treatment of material. The oxygen which is supplied to glass melt from plasma contained a large amount of atomic oxygen in this experiment.

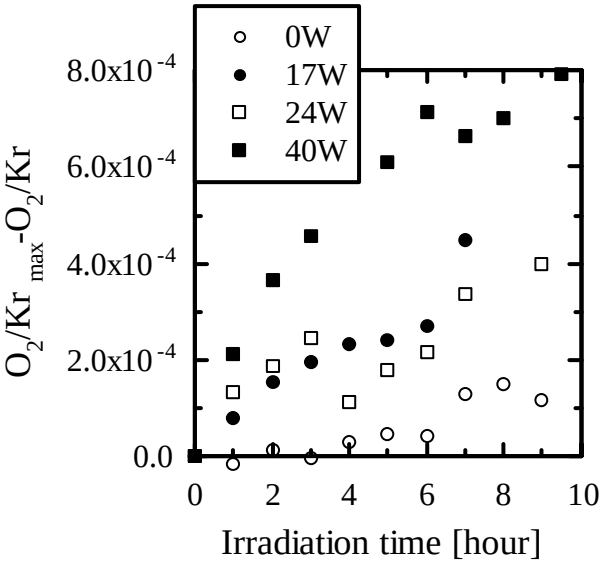

Fig.7 The oxygen behavior by plasma irradiation in various powers

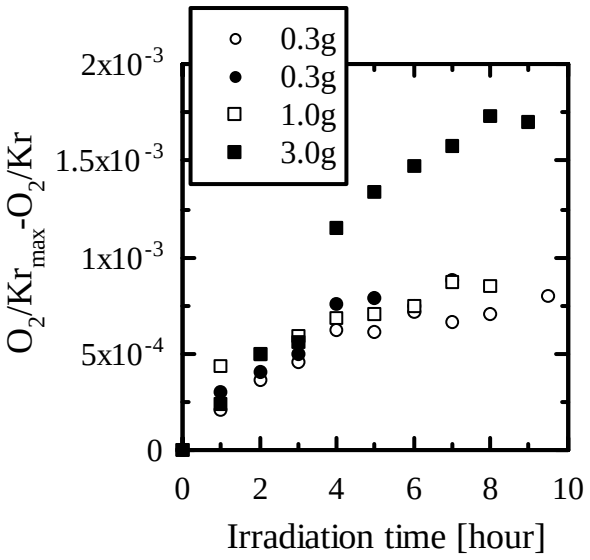

Fig.8 The oxygen behavior by plasma irradiation in various volume of glass.

It is known that a solubility of gases to liquid is depended on the size of solute, the polarity between solute and solvent and the viscosity of solvent. The size effect in the case of dissolving inert gases into inorganic melt is reported by Lax[7]. The solubility decreases with increasing the size of solute gases. As stated above, the solubility on surface of melts increases, since the atomic oxygen that has half size of molecular oxygen supplied from plasma. It is known that the volume of dissolved gases into glass melt obey the Henry's low. When amount of dissolving gases increase, the behaviour cannot obey the Henry's low exactly. However, it is reasonable to suppose that the volume of dissolved gases proportionate the amount of gases existing on surface. The change in applied power causes to change the amount of atomic oxygen supplying to surface of melt. This is a reason to increase dissolved oxygen with increasing applied power. In the data of 17W and 25W, the difference between both series is not clear. Further research is needed to understand this problem. Oxygen dissolution into whole glass melts con be promoted effectively by such as convective mass trasnsfer.

4. Conclusion

Firstly, we carried out some experiments that microwave oxygen plasma was irradiated on glass melt which contains mixed metal chlorides and obtained the following results

- Oxygen plasma irradiation enhances to remove chlorine from glass melt
- Oxygen plasma affects on behavior of oxygen gas dissolution in comparison with the case that used neutral oxygen.
- Plasma irradiation promotes gas dissolution.

Secondly , we carried out experiment to investigate the dissolving behavior of oxygen into glass melt and obtained the results, which are shown below.

- The amount of dissolved oxygen increases as the applied power increases.
- Plasma irradiation promotes oxygen dissolution on melt surface.

From above results, following conclusions are lead. It is found that oxygen plasma irradiation enhances oxygen dissolution and it plays a role to remove chlorine from glass melt. It is concluded that plasma can be strong tool to give new state for melt in field of material processing .

Investigations of the Dissociation of NH_3 in Pulsed and Quasistationary Microwave-generated Plasmas

J. Krueger, T. Kubach, M. Walker, U. Schumacher

Institute of Plasma Research, University of Stuttgart, Faffenwaldring31, D-70569 Stuttgart, Germany

Abstract

The process of the dissociation of ammonia in pulsed and quasistationary microwave-generated plasmas is investigated by means of optical emission spectroscopy and Langmuir probe measurements. The results of the determined spatially and temporally resolved plasma properties as electron density, electron temperature, optical emission and rotational temperature of N_2 are discussed and correlated with the reaction rate constants of the dissociation of NH_3.

1. Introduction

Pulsed microwave-generated plasmas are of increasing importance for low temperature plasma applications. Detailed knowledge of the spatial and temporal dependence of the plasma parameters and of the species distributions is indispensable for the understanding of the plasma technological process and for optimising the surface property of the treated substrates as well. The investigations are performed applying the microwave generated plasma source Plasmodul®[1], a modular plasma reactor with a diameter of 35 cm, provided from two sides with microwaves at 2.45 GHz with a maximum power of 2x2 kW, for discharges in ammonia NH3. The plasma is analysed by a Langmuir probe system and, moreover, by emission spectroscopy in the spectral range from 300 to 900 nm. With a spectral resolution of 40 pm of the emission spectra it is possible to determine the rotational temperature from the shape of the vibrational bands of N_2 and N_2^+. In the observed spectra the temperature values are between 600 and 900 K, showing a strong dependence on the distance to the plasma source as well as on the applied parameters of the plasma pulses. In the plasma of ammonia the emission lines of 9 different molecules and atoms such as NH_3, NH_2, NH, NH^+, N_2, N_2^+, N, H_2 and H are identified. In the temporal evolution of the plasma these different species show a different behaviour: In the beginning of the discharge all lines show a clear increase of their intensities and further on a decrease to a value of 50-90% of the initial intensity, according to the observed atoms or molecules. While most of the lines reach a quasistationary value after about 50 µs, the emission of NH starts a strong increase and reaches its quasistationary final value after 700-800 µs. Also, compared to most of the observed lines, NH shows a different decay time after switching off the microwaves. Assuming that the intensity of the emitted lines corresponds to the density of the respective species, a well directed tuning of the pulse parameters is a way to adjust the composition of the species in the plasma in order to optimise the deposition process of Si_3N_4 layers in pulsed silane-ammonia plasmas. The temporal and spatial behaviour of the emissions will be discussed by means of reaction rate constants of the dissociation of NH_3.

These investigations are part of a German BMBF project (13N8048) to examine the influence of pulsed plasmas on surfaces.

2. Experimental Setup

The experiments are performed in the Plasmodul®, based on the principle of the Duo Plasmaline, which is schematically shown in Fig. 1. The device consists of an array of four Duo Plasmalines, each of them has a copper rod centred in a quartz tube, being fed from each end by microwaves at 2,45 GHz from two magnetrons with a maximum power of 2000 W each. The vacuum chamber can be pumped down by rotary and turbo molecular pumps to a pressure of less than about 0.1 Pa. The chamber wall has large windows for diagnostic

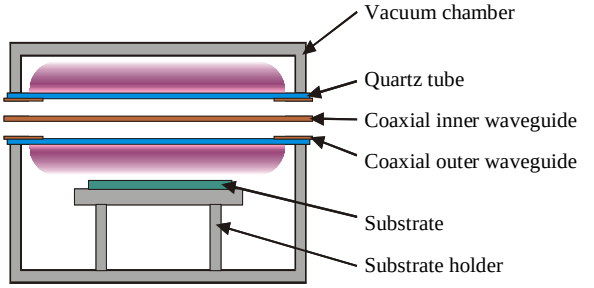

Fig. 1 Experimental setup, schematic description of the Duo Plasmaline®.

access for the Langmuir probe as well as for the optical spectroscopy. The Langmuir probe system is a Smart Probe manufactured by Scientific Systems, Dublin, Ireland, and the spectroscopic measurements are performed with the 750 mm Acton spectrometer and the MicroMAX ICCD camera.

3. Probe measurements

Results for the radial distribution of the electron density perpendicular to the plasma source for different microwave powers are given in Fig. 2. The measurements were performed at a total pressure of 20 Pa in the temporal afterglow of an ammonia plasma, 50 µs after the pulse power was switched off with a temporal resolution of 1 µs. The discharge was pulsed with a frequency of 1 kHz and a pulse to pause ratio of 1:1, The electron density distribution shows a clear maximum at a distance of about 15 mm from the quartz tube. The position of this maximum strongly depends on the total ammonia pressure, i.e. with decreasing pressure the density increases and the discharge expands. With variation of the deposited microwave power this expansion cannot be observed, the shape of the radial distribution is preserved but only the density increases linearly with the applied microwave power.

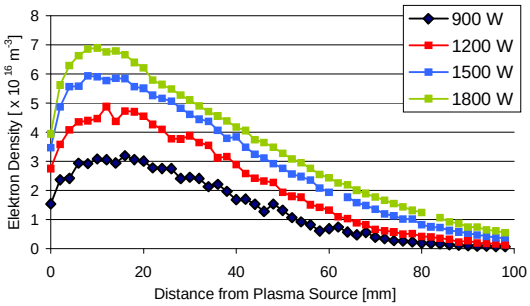

Fig.2: Radial distribution of the electron density for different applied pressures.

4. Spectroscopic Diagnostics

Fig. 3 shows an overview spectrum of an ammonia plasma at a gas pressure of 20 Pa, pulsed with 1 kHz at an aspect ratio of 1:1 and an injected average microwave power of 500 W (1 kW peak power) in the spectral range from 330 nm to 410 nm with a resolution of 40 pm. In this range the spectrum is dominated by the emission of N_2 and N_2^+ but also NH and the atomic hydrogen Balmer lines H_ε and H_δ, fragments at the dissociation of ammonia, are clearly visible. In the spectra of ammonia plasmas spectral lines of nine

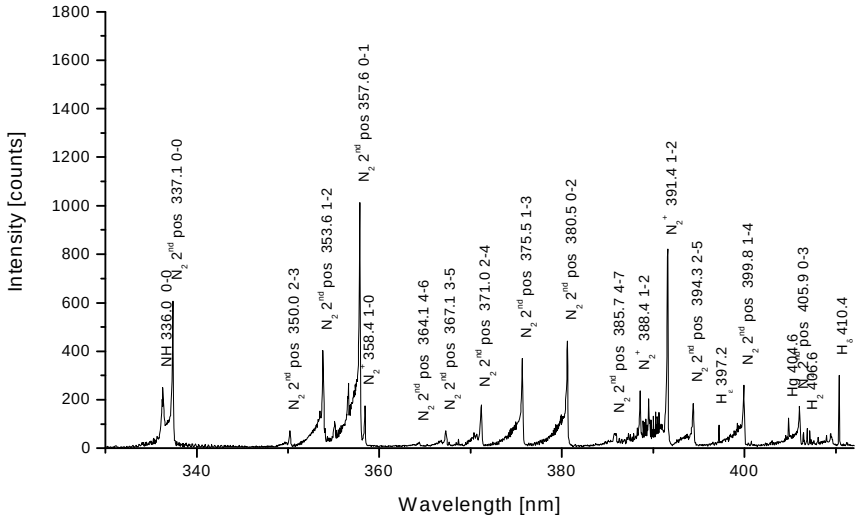

Fig. 3: Overview spectrum of an ammonia plasma at 20 Pa, pulsed at 1 kHz temporally averaged.

different species of atoms and molecules such as N_2, N_2^+, H_2, N, H, NH, NH^+, NH_2 and NH_3 could be identified. To point out the difference between a pulsed and a quasistationary plasma the spectra of two bands in NH and N_2 are compared with decreasing gas pressure in Fig. 4. On the left side the spectrum in a pulsed plasma (1 kHz, 1:1) is seen and on the right side the same spectrum in a quasistationary plasma at the same applied microwave peak power, averaged in time is shown. Both band heads show a uniform increase with decreasing pressure. This decrease is notably stronger in the emission of NH, an intermediate product at

the dissociation of ammonia, leading to the assumption that the dissociation process is slower at lower pressure due to less chemical reactive impacts.

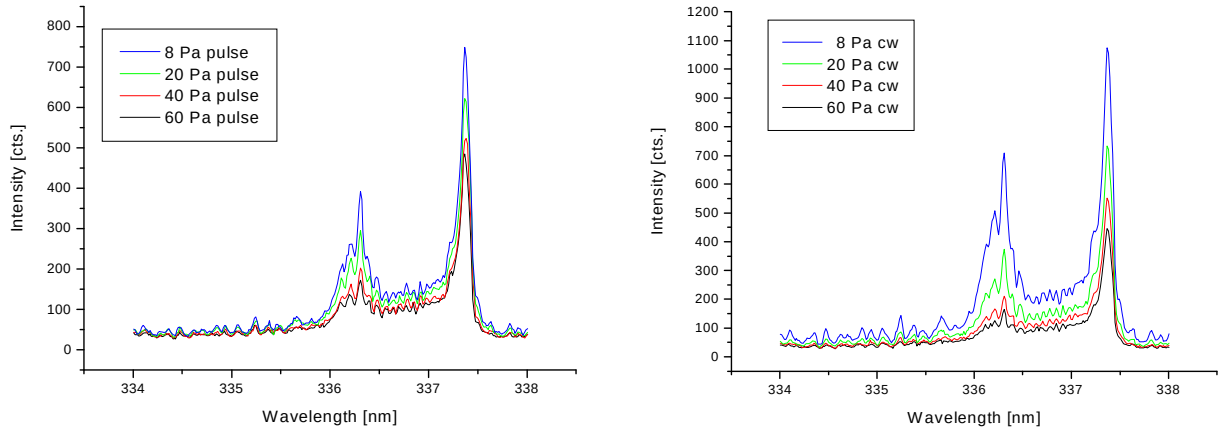

Fig. 4: Comparison of the emission of NH and N_2, left side in a pulsed plasma, right side in a quasistationary plasma of NH_3. In the continuous plasma the emission of NH increases stronger compared to the emission of N_2, and also compared to the pulsed plasma.

Comparing a quasistationary and a pulsed plasma directly, Fig. 5 shows the difference of the two spectra in the range from 330 nm to 460 nm. The spectra were obtained at a total gas pressure of 8 Pa and an average absorbed microwave power of 400 W. In pulsed mode the emission was registered averaged over 2000 complete pulse cycles and thus the exposure time was equal in both cases (1 second). To work out the

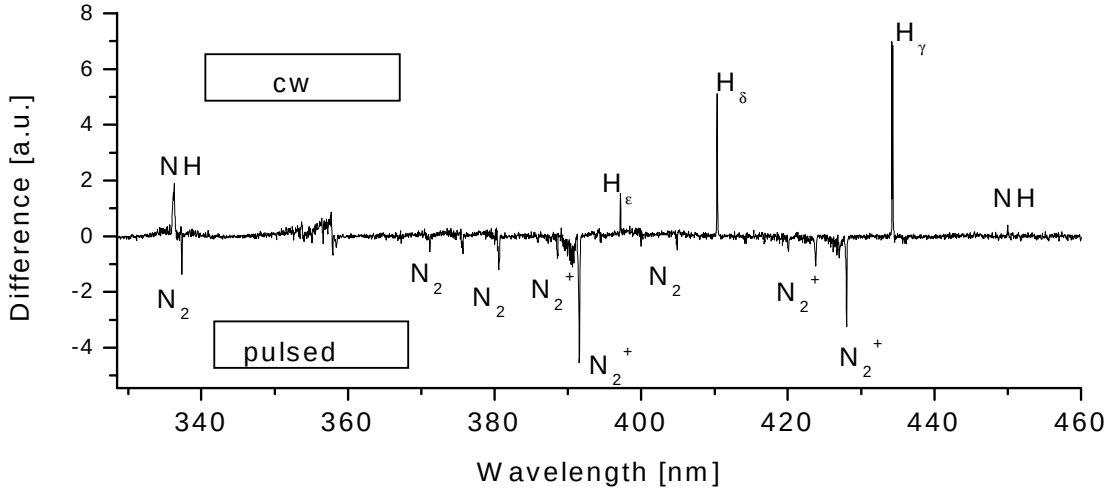

Fig. 5: Difference between a pulsed and a quasistationary plasma with constant average microwave power, normalised to H_2-emission.

difference, both spectra were normalised to the emission strength of molecular hydrogen. Thus positive values show a stronger emission in the stationary plasma and negative values show a stronger emission in the pulsed case. It is evident that the emissions of NH and atomic hydrogen are stronger in the continuous mode while in the pulsed plasma the bands of molecular nitrogen, especially N_2^+ appear stronger.

4.1 Rotational temperature

In the spectra of ammonia the molecular bands of N_2 and N_2^+ are well resolved such that the rotational temperature of nitrogen could be determined from the rotational band structure. Based on an algorithm of K. Behringer [2] for simulations of the rotational bands in the first negative system of N_2 and the second positive system of N_2^+, a computer code was developed to match the simulated rotational bands to the measured spectra by variation of simulation parameters, in particular the rotational temperature, and minimisation of the mean square errors given in the difference between measured and simulated spectra. The program is automated in order to analyse a large amount of data, i.e. several spectra from a sequence of temporal succeeding measurements.

The parameters for the simulation were the offset of the measurement, the intensity of the band, an offset for the wavelength (for a possible misadjustment of the spectrometer), the spectral resolution for the linewidth of the single transitions and finally the rotational temperature. Fig. 6 shows a comparison of a measured and a simulated spectrum of the $1 \rightarrow 4$ transition in the second positive system of N_2. The fit in the upper example results in a rotational temperature of 811 ± 25 K.

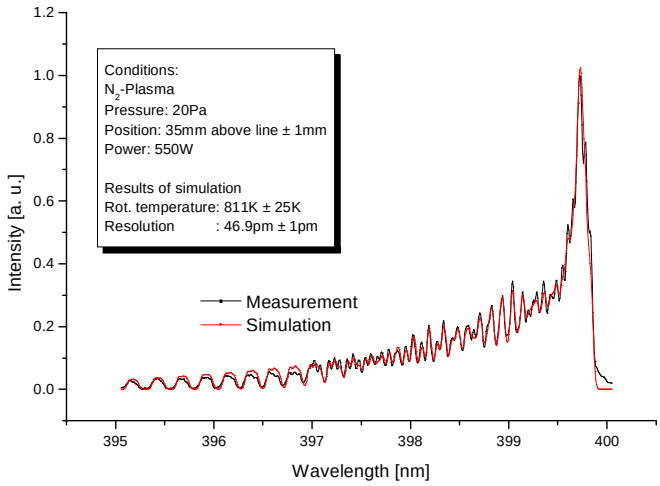

Fig. 6: Measured and simulated spectrum of the 1à 4 transition in the 2nd pos. system of N_2.

The dependence of the rotational temperature from the pulse frequency shows an interesting correlation (Fig. 7): with increasing frequency the rotational temperature initially decreases exponentially until a minimum is reached at about 7 kHz. With higher frequencies the temperature raises again. The only variable parameter was the pulse frequency besides the constant conditions like microwave power and pulse-pause proportion. For each measuring point an own spectrum was registered and the rotational temperature was respectively determined, thereby the emission intensity was integrated over the whole pulse leading to an average temperature.

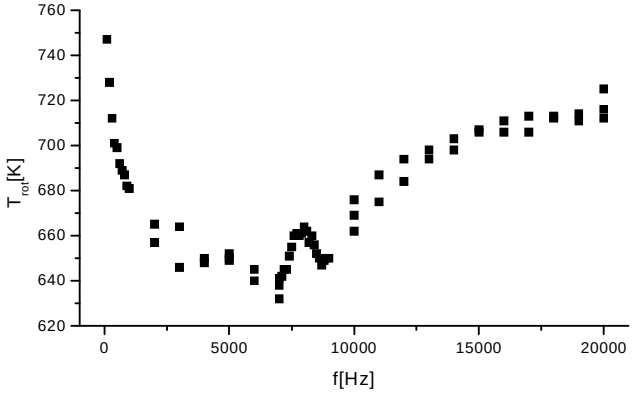

Fig. 7: The dependence of the N_2 rotational temperature from the pulse frequency shows a clear minimum at 7 kHz.

The minimum in the rotational temperature is due to the fact that the rise time of the temperature during the pulse phase is different to the decay time in the (temporal) afterglow. The rise time mostly depends on the applied microwave power, while the cooling of the gas depends on the geometry of the reactor and the gasflow and thus from the removal of the heated gas. With the given geometry and plasma parameters and the interaction of heating and cooling of the gas, a minimum of the rotational temperature appears at a pulse frequency of 7 kHz. This effect can be used to prevent thermally sensitive substrates from damages.

The small but clear peak appearing at the frequency of 8 kHz, could be identified as a resonance of a standing sonic wave in the reactor.

4.2 Time-dependent Investigations

By means of the gated ICCD camera and the spectrometer the temporal behaviour of the emission during the pulses could be registered with a temporal resolution of 300 ns. The emission of some selected species at

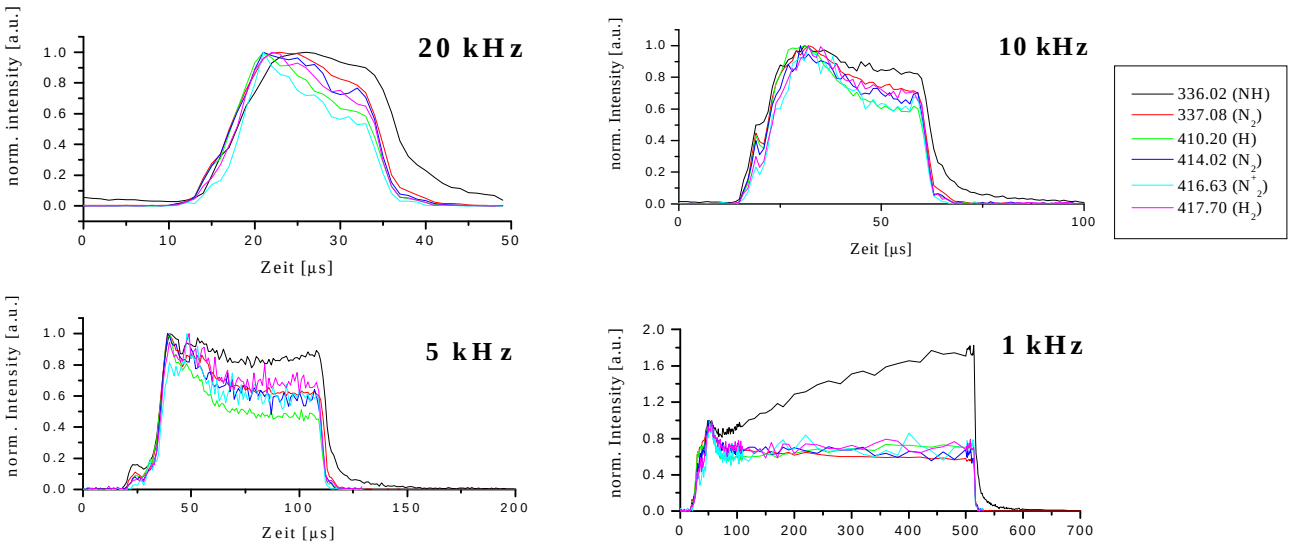

Fig.8: Temporal behaviour of some selected lines in the spectrum of ammonia.

different pulse frequencies is shown in Fig. 8. All lines indicate a distinctive overshoot in the emission at the beginning of the pulses. This region is featured by excitation and dissociation with fast electrons during the ignition of the plasma. After this overshoot the emission decreases down to a value of about 50 % to 90 % of this maximum value, according to the kind of molecule or atom. Most of the line emissions reach a quasistationary value in about 100 µs after the overshoot. An impressive exception in this behaviour is given by the NH molecule at 336.0 nm: though this emission shows the same characteristic at the beginning of the pulse, it starts raising strongly after 50 µs and finally reaches its quasistationary value after 700-800 µs. In the next section possible reaction channels in the dissociation of ammonia are discussed. Here a hint is given for the late appearance of NH in the plasma. Also the continuous plasma showed a stronger emission of NH compared to the pulsed mode. By a suitable choice of the pulse parameters the mean concentration of NH in the plasma could be influenced directly.

Further on, the emission of NH distinguishes by an explicitly longer decay time at the end of the pulses. Observing even shorter pulses, also a different behaviour in the overshoot can be seen (Fig.9). Here the pulse frequency was kept constant at 1 kHz and the temporal behaviour of the emissions of NH and N_2 is compared at different pulse lengths. With increasing pulse length also the overshoot of N_2 increases,

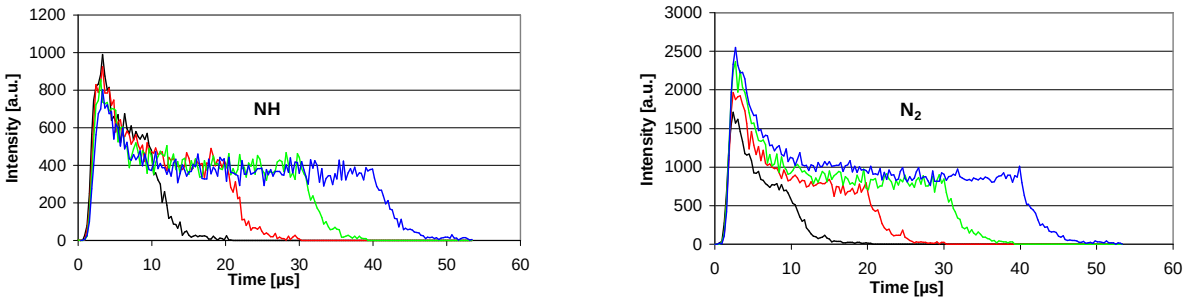

Fig. 9: The emissions of NH (336.0 nm) and N_2 (337.1 nm) at constant pulse frequency (1 kHz) and variable pulse duration between 10 µs and 40 µs.

indicating that with a short pulse duration the dissociation of ammonia is less advanced, i.e. that the stable end products of the dissociation are not yet formed completely. In the emission of NH, an intermediate step of the dissociation of NH_3, this effect is rather slightly reverse.

5. Discussion of the reaction channels during the dissociation of ammonia

The dissociation of ammonia is accompanied by an outstanding phenomenon: The acceleration of the dissociation by reactions with radical dissociation products. There is a large number of possible reactions at the dissociation of ammonia, some of the most important reaction rate constants are compiled from different sources [3,4,5]
In the first step the dissociation is dominated by collisions of molecules with electrons and leads to neutral or excited products via excitation of unstable electronic states. Reaction products by electron collisions are produced such as

$NH_3 + e$	$\rightarrow$	$NH_2 + H + e$	
	$\rightarrow$	$NH + H_2$ (2H) +e	10%-30% of all processes
	$\rightarrow$	NH_2- + H	in stationary plasmas
	$\rightarrow$	$NH_2 + H^-$	
		etc.	

This type of reactions is responsible that in the beginning of a plasma pulse all investigated species are existent and emitting. This points to the overshoot in the time resolved spectra which occurs in all species similarly. This overshoot was also predicted theoretically for the behaviour of the electron temperature in pulsed plasmas [6]. After some time in the pulse these reactions amount only to 10% - 30% of all processes [7].
Mainly chemical reactions are now contributing to the dissociation process like reactions of ammonia with excited nitrogen atoms or imidogen:

$NH_3 + NH$	$\rightarrow$	$2NH_2$	$k_0 = 1.32 \cdot 10^{-10}$ cm3/s
$NH_3 + N^*$	$\rightarrow$	$NH + NH_2$	$k_0 = 1.1 \cdot 10^{-10}$ cm3/s
		etc.	

These secondary reactions provide a different distribution of concentrations until a stationary state is reached.
NH_2 and NH are unstable intermediate products and are reacting rapidly:

NH_2	+ H	$\rightarrow$	H_2 +NH	$k_0 = 6.6 \cdot 10^{-11}$ cm^3/s
NH_2	+ N	$\rightarrow$	N_2 + 2 H	$k_0 = 1.2 \cdot 10^{-10}$ cm^3/s
NH	+ N	$\rightarrow$	H + N_2	$k_0 = 5.0 \cdot 10^{-11}$ cm^3/s
NH	+ H	$\rightarrow$	N + H_2	$k_0 = 4.4 \cdot 10^{-11}$ cm^3/s
NH	+ NH	$\rightarrow$	N_2 + 2H	$k_0 = 8.5 \cdot 10^{-11}$ cm^3/s
			etc.	

Molecular nitrogen N_2 and hydrogen H_2 are the stable end products of the dissociation of ammonia.

6. Summary

The measurements in ammonia plasmas increased our knowledge of the correlations and dependencies of plasma parameters in pulsed plasmas in ammonia. A suitable set of plasma parameters can now be chosen in order to adjust the concentration of radical molecules like NH or to control the gas temperature to prevent thermal sensitive substrates from damage. These results can now be applied to the treatment of substrates like the deposition of silicon nitride layers in ammonia-silane plasmas.

Abstract
A planar coil inductive rf pulsed discharge in N_2-He mixtures has been investigated by optical spectroscopy. The kinetic analysis of vibrational excitation of $N_2(C)$ state reveals a high vibrational excitation of ground state nitrogen. The atomic nitrogen has been monitored by TALIF. The decay of N-atoms in post discharge at different pressure, and duty cycle has been investigated.

1. Introduction

A planar coil inductive *rf* pulsed discharge generated in N_2-He mixtures has been investigated by optical spectroscopy. The planar coil faced to a quartz window has been used to produce a plasma inside a cylindrical stainless steel chamber. We have investigated two different ignition of the inductive regimes. One (type-A) is operated by a pre-short pulsed capacitive discharge produced inside the chamber with an internal electrode faced to the inductive one [1]. The planar coil is screened using a Faraday shield between the coil and the quartz window. The electrostatic shield of the type described in [2] completely cancels any capacitive coupling. Since a purely inductive discharge is not self-ignited, a secondary capacitive discharge is produced by a plate electrode by another pulsed low power rf supply. The second one (type-B) operated without Faraday shield is spontaneously ignited by the capacitive coupling formed by the planar coil and the grounded plasma chamber. The main 500 watt inductive discharge can be driven under pulsed or continuous *rf* regime. In our previous study [1] carried out by Langmuir probes in He-N_2 ICP discharge type-A with large planar coil (12 cm diameter) and Faraday shield evidenced a pure inductive pulsed regime characterized by electron density close to 10^{12} cm^{-3} and electron mean energy of about 1-2 eV at 0.2 Torr. The decay of N_e in post discharge was in a millisecond time scale. T_e of about 0.5-1 eV, depending on the experimental conditions (pressure and mixture composition), was maintained in the post-discharge at 1 ms. This slow electron relaxation was considered as due to molecular collisions with long lived species. This issue is of great relevance because of the present widespread use of planar ICP reactors as alternative way to dense plasma commonly realized by microwave discharges, and calls for further diagnostic investigations.

Here an analysis of vibrational excitation of $N_2(C^3\Pi u)$ state at different duty cycles, mixture compositions and pressures has been carried out by time and space resolved emission spectroscopy, running ICP discharge under regime type-A as in [1], and regime type-B with a coil of 6 cm diameter. The measurements have been done at the end of the discharge pulse after transition from capacitive to inductive regime for different duty cycles. Since a relevance of long lived species processes is expected, laser diagnostics have been set in order to measure atoms, vibrationally excited molecules and metastable. In the present contribution we describe only preliminary results on N-Atoms TALIF detection.

2. Experimental and Results

The experimental apparatus supports Langmuir probes, LIF and CARS diagnostics. The sketch of the experiment in ICP type-B is shown in Fig. 1. In the figure it is also sketched the laser configuration. It allows production of VIS -UV photons with narrow line width through the Second and Third Harmonic generation of the dye. The laser set-up can be switched from LIF configuration to a CARS one for collinear or box-CARS narrow band measurements. A planar coil faced to a quartz window ignites a plasma inside a cylindrical stainless steel chamber with axial and radial glow inhomogeneity.

a) Time resolved Langmuir probe

In tab 1 we have reported the values of the electron temperature and the electron density measured at the end of the discharge pulse [1] in ICP type-A discharge. The measurements have been done at 0.2 Torr with the Langmuir probe tip set on the axis of the discharge at two distances form the discharge window (p_1= 1 cm

and p_2= 2.5 cm) for three nitrogen contents (m_1=5% N_2 , m_2=25% N_2 m_3=100% N_2) and for three duty cycles $d=T_{ON}/(T_{ON}+T_{OFF})$ (d_1=1/15, d_2= 5/15, and d_3=15/15 for T_{OFF}= 15 ms). Total flow rate is 40 sccm.

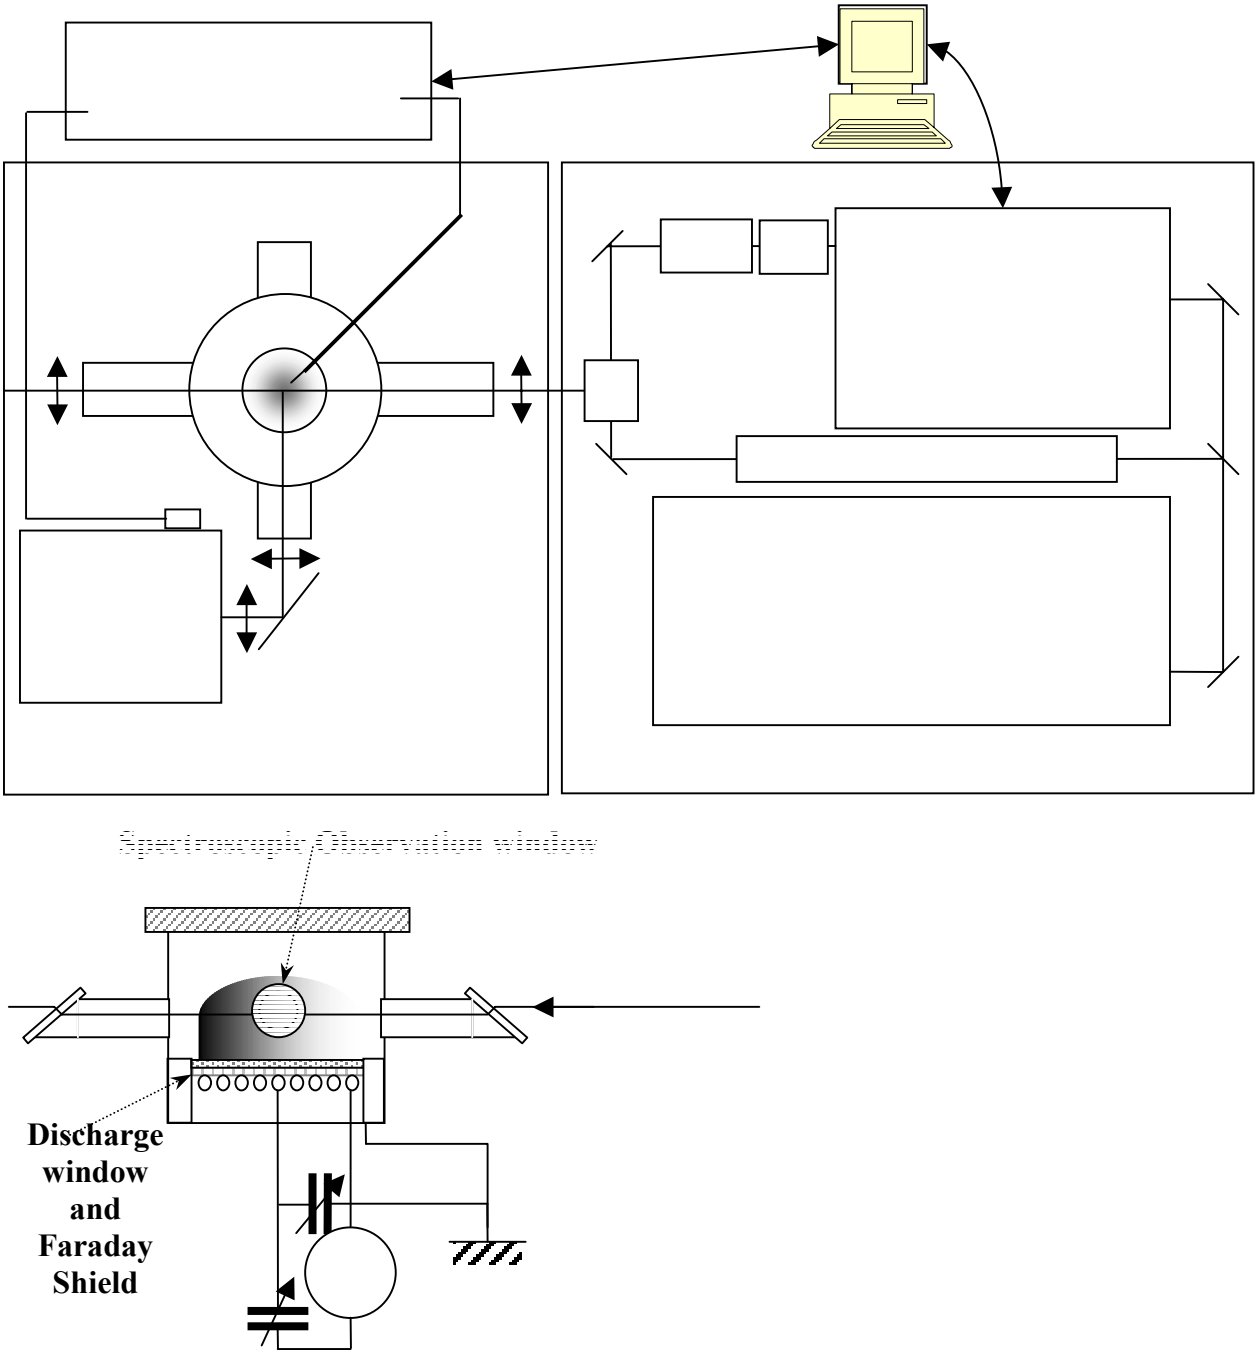

Fig. 1 Experimental setup. Top and side view of the reactor of ICP type B discharge with laser facilities (Quanta System)

Table 1 Electron parameters in ICP type- A, at P= 0.2 Torr for various axial positions (p_1= 1 cm and p_2=2.5 cm), duty cycles d=$T_{ON}/(T_{ON}+T_{OFF})$ (d_1=1/16, d_2= 5/20, and d_3=15/30 for T_{OFF}= 15 ms), mixture compositions (m_1=5% N_2 , m_2=25% N_2 m_3=100% N_2).

Experimental conditions	p_1 d_2 m_1	p_2 d_2 m_1	p_1 d_2 m_2	p_1 d_3 m_2	p_2 d_2 m_2	p_2 d_3 m_2	p_1 d_2 m_3	p_2 d_2 m_3
Te (eV)	2.9	1.4	2.45	2.55	1.11	1.29	2.10	0.95
Ne ($10^{11}cm^{-3}$)	3.5	6.1	2.5	2.0	0.42	0.43	1.0	0.26

b) Time resolved emission spectroscopy

The spectroscopic measurements have been done at p_2 distance in the ICP type-A and at p_3= 0.7 cm in the ICP type-B. The $N_2(C,v)$ vibrational distributions inferred from Δv =-2 sequence of nitrogen Second Positive spectra are shown in fig. 2.

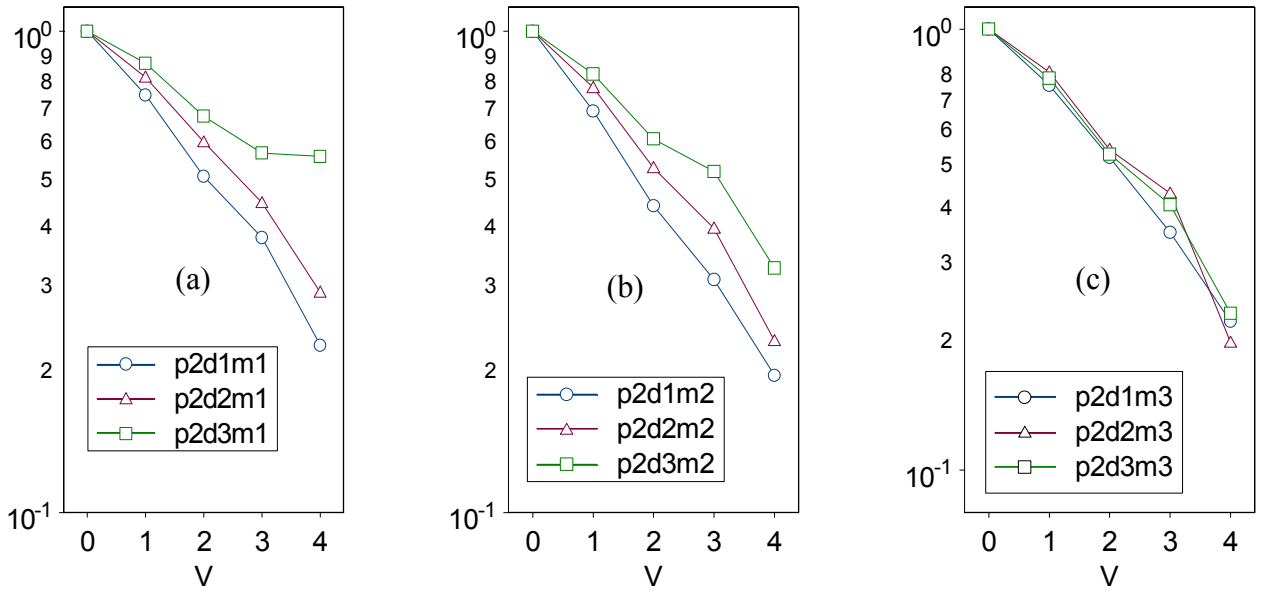

Fig. 2 $N_2(C,v)$ vibrational distributions in ICP type-A measured at p_2=2.5 cm, P= 0.2 Torr for various mixtures(m_x), duty cycle (d_x) (see table 1).

c) TALIF measurements

TALIF measurements of $N(^4S)$ have been carried out using the two-photon excitation pathway

$$N(\,2p^3\,{}^4S^0 + 2h\nu_L \rightarrow 3p\,{}^4S^0_{J=3/2} \rightarrow 3s\,{}^4P + h\nu_E) \qquad (1)$$

In this pathway the laser excitation occurs with two photons at λ_L =206.718 nm while fluorescence is detected at λ_E = 746.83 nm. The excitation wavelength is obtained by Third Harmonic Generation (THG) of the dye output by means of a BBO crystal. In this laser set-up the line width of the R610 dye fundamental is quite narrow (0.04 cm^{-1}). This allows a quite high LIF signal with typical TH energy of about 300 μJ. The N-TALIF signals measured at 5 mm from the discharge window in P=2.0 Torr pure nitrogen for various times in post-discharge and for different duty cycle (T_{ON}+T_{OFF} = 30 ms) are shown in figures 3 and 4. The decays are significantly non-exponential and look similar at 0.5 and 1.0 Torr.

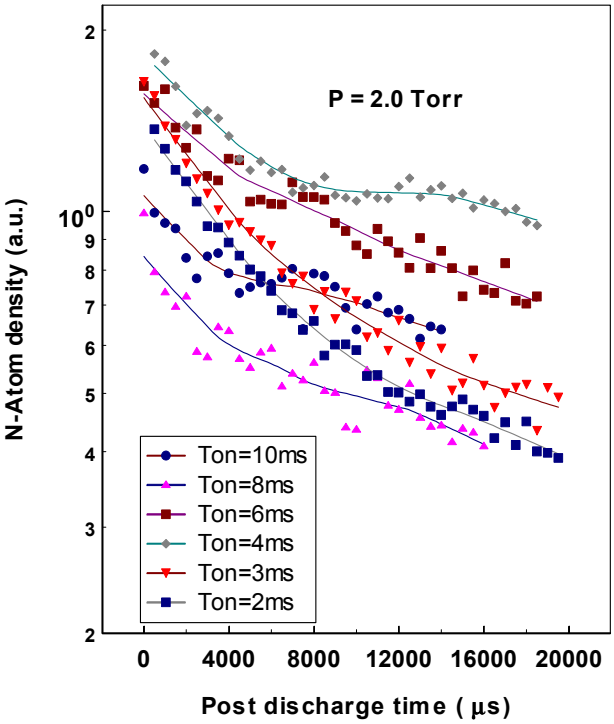

Fig. 3 N-atom TALIF signal decay in post discharges at various T_{ON} (*2D lowess plot*)

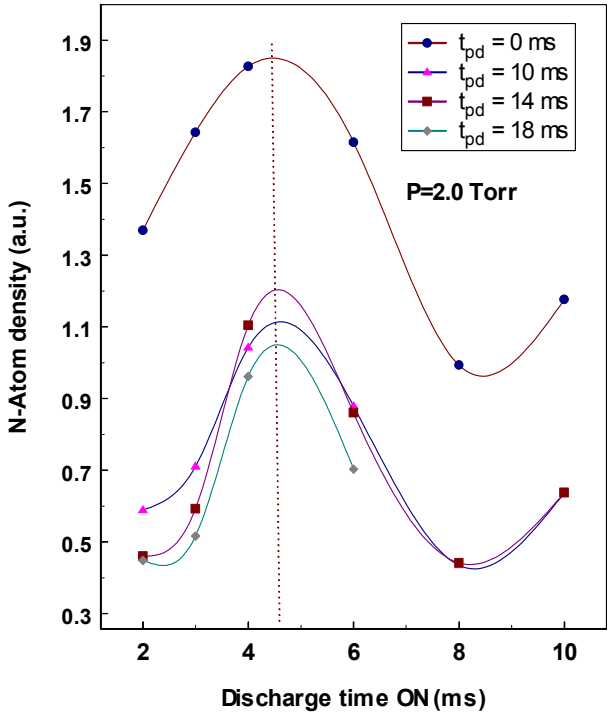

Fig. 4 N-atom TALIF signal vs. T_{ON} at various post discharge times (*2D lowess plot)*

3. Analysis of the discharge

The analysis of the electron data evidences that, at any mixture and position, the increase of the discharge T_{ON} leads to an increase of the electron temperature in discharge and post-discharge. The electron temperature and the density decreases as moving far from the discharge windows, while increases as the nitrogen content mixture is decreased.

Having in mind this view, we have applied the kinetic analysis of $N_2(C,v)$ formation described in [3,4] using the electron data measured in the present conditions and synthetic $N_2(X,v)$ and $N_2(A,v)$ distributions. The simulation of the distribution $<p_2d_2m_2>$ are shown in Fig. 3. The best fit is achieved with a Boltzmann like (X,v) distribution at 7000-8000 K and $N_2(A)/N_2(X)=3.7x10^{-4}$ together with a low vibrational excitation of $N_2(A)$ metastable. $N_2(A,v)$ distribution has been approximated by a Boltzmann one at about 2000K. The main point of (C,v) distribution analysis is that the best fit is achieved only when electron impact excitation from $N_2(X,v)$ and $N_2(A,v)$ manifolds have almost similar rates, then the structures depend on $N_2(X, v)$ and $N_2(A, v)$ shapes. The contribution by pooling A+A process is about one order lower and affects only the high vibrational levels. Fits by individual processes like (in the legend: NVCEX <e+X>, NVCEA <e+A>, NVCP <A+A> calculated with Piper rate coefficients (see in [3]), NVCPGAP <A+A> calculated with energy gap state–to-state rate coefficients [3, 4], NVC is the complete distribution) were not adequate. The relevant fact is that $N_2(X,v)$ vibrational excitation must be high, but fits using Treanor-Gordietz distribution with various lengths of plateau are not adequate.

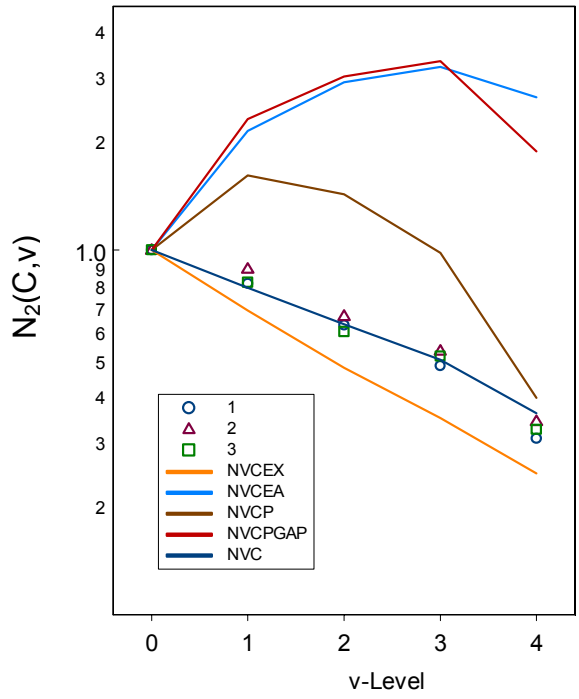

Fig. 5 Measured and calculated $N_2(C,v)$ vibrational distribution. ICP type A: (1) $<p_2d_2m_2>$ at 0.2 Torr; ICP type B: (2) at 4 Torr and (3) at 0.2 Torr. Calculations (continuous line) of single processes and complete distribution (see text). Best fitting rates: ReX≈(4xReA)≈ (10xRAA)

For ICP discharges, a high vibrational pumping of $N_2(X,v)$ low vibrational level would be expected because of the high electron density and the Maxwell character of the EEDF, but the absence of the plateau typical of the vibrational pumping is not established, likely because of the low pressure as well as because of a significant nitrogen atom quenching effect that could be also responsible of the deactivation of the whole vibrational manifold of the A state.

It should be noted that the distribution $<p_2d_2m_2>$ measured in ICP type-A is practically coincident with that measured in the reactor ICP type-B under similar conditions (0.2 Torr, and 25% N_2) even though measured at a shorter distance from the discharge windows (p_3=0.7 cm). So the previous analysis is still valid under this discharge configuration. The present experiments, hence, do not evidence significant differences due to the presence of a Faraday shield once the inductive regime is established. The (C,v) distribution at 4 Torr measured at a distance of about 0.5 cm close to discharge window, shown in Fig. 3), indicates a significant vibrational (even higher) excitation of C and X states. It should also be noted that the glow is contracted towards the discharge window on increasing the pressure.

For what concerns the N-atoms the decay of TALIF signal in post-discharge is non exponential. Under some cases it reveals quasi double-exponential character. The slow part of the decay seems to depend on the time of discharge ON as can be seen in figure 4 where the TALIF signal is reported as a function of T_{ON}. The N–atoms production apparently presents a maximum in the discharge for T_{ON} of about 4 ms.

4. Concluding Remarks

The excitation of $N_2(C,v)$ molecules of the present ICP discharge differs from that we observed in a capacitively coupled discharge, where it was dominated by electron impact excitation from a Treanor-Gordietz $N_2(X,v)$ like distribution, typically characterized by a 3000-4000K first level temperature and a plateau extending up to 15-16 levels. Here, the shape of $N_2(C,v)$ distributions measured at 5 and 15 ms (end of discharge time) is very similar to that measured in the afterglow of capacitively coupled pulsed *rf*

discharge [3] or in plasma jet [4] in millisecond time scale. The peculiarity of electron properties in ICP excitation appears also on the vibrational excitation of the $N_2^+(B,v)$ state. The distributions measured in He-(2-10%) N_2 at 0.2 Torr in the reactor ICP type-A through the analysis of the $\Delta v=-2$ sequence of First Negative spectra have been shown in Fig. 4 of ref. [5]. The vibrational distributions (v=0-6 levels) evidence structures and 0-1 population inversion. Instead in typical parallel plate capacitive coupled discharges the distributions measured in similar mixtures [6] declined regularly covering more than one order of magnitude. The excitation was mainly due to $He(2^3S)$ Penning ionisation and/or to electron impact (see ref. [6]). In the present ICP experiments we expect a predominant electron impact excitation.

Actually we have examined only the TALIF signal behaviour with the discharge parameters. The effective measurement of N-atom density by TALIF does require a calibration procedure. It is in due course according to [7,8]. However considering our previous detection experiments, the high TALIF signal indicate that the N density could be significant, thus in agreement with the deactivation of $N_2(X,v)$ tails. Further work in progress concerns preliminary investigations of the vibrational excitation of ground state by CARS.

Calculations for a global model of the plasma of a pulsed microwave discharge in nitrogen at atmospheric pressure

J. Stańco, H. Nowakowska, Z. Zakrzewski

Institute of Fluid-Flow Machinery, Polish Academy of Sciences, Gdańsk, Poland

Abstract
A global numerical model of the plasma of a pulsed microwave discharge in nitrogen has been developed. The aim was to determine the temporal variation of the densities of various species present in the discharge. The object modeled is the plasma of a microwave torch operating at atmospheric pressure. The ultimate goal is to adopt the methods developed for these calculations for studying properties of discharges in polluted air.

1. Introduction

Non-thermal discharges offer a promising way of pollutant abatement in air or flue gases. The primary role of a gas discharge in the process of pollutant elimination is to provide free electrons which, colliding with the gas molecules, give rise to production of chemically active species that can favor decomposition of pollutants. Adjusting the discharge to that purpose is an important issue. Especially worth studying seem to be pulsed discharges. A pulsed microwave discharge with a properly chosen pulse power, length and repetition rate may prove more energetically efficient in pollutant abatement than a continuous wave discharge. Also the thermal loading of the plasma reactor materials can be reduced.
This paper is concerned with modeling the plasma of a microwave discharge in polluted air or flue gas. For preliminary evaluations of the modeling procedures a discharge in N_2 is considered. The object modeled is the atmospheric pressure plasma of microwave torches, known and investigated for the last decades (e.g. [1], [2], [3]). More recently a device of simple design, capable of sustaining multiple torches, has been disclosed [4]. Such a torch system is well suited for large-volume treatment of pollutants.

2. The model

We consider a 2.45 GHz microwave plasma generated in a torch as described above, operating in nitrogen at a low flow rate of the gas. The discharge is fed with microwave power pulses at a kilohertz repetition rate, superimposed on a continuous power background.
A global, that is a spatially averaged model is formulated. Although such a model can not provide spatial distributions of the plasma parameters, it is useful for establishing their scaling with the operating parameters of the discharge. For a discussion of the model see [5]. The following assumptions are adopted:

- densities and temperatures of all species are averaged over the plasma volume;
- the electric field is regarded as uniform within the plasma volume and the effective field approximation is applicable;
- the non-equilibrium plasma of the microwave torch is characterized by two temperatures: the heavy particle temperature T and the electron temperature T_e. The vibrational temperature T_v is assumed to be equal to T;
- radiation is neglected.

The set of equations describing the global model consists of particle balance equations and energy balance equations. The latter provide species densities n_i, while the particle balance decides on the value of the electron temperature T_e.

2.1. Electron kinetics

For preliminary calculations we limited the number of species and primary reactions considered in the balance equations for the model to those which really matter. We adopted for the global model the following set of reactions between the plasma species of the discharge in nitrogen:

- electronic excitation

$$N_2 + e \rightarrow N_2^* + e \qquad (k_1) \qquad (1)$$

- quenching of electronically excited molecule states by N atoms

$$N_2^* + N \rightarrow N_2 + N \qquad (k_2) \qquad (2)$$

- ionization by electron impact

$$N_2 + e \rightarrow N_2^+ + e + e \qquad (k_3) \qquad (3)$$

- dissociation

$$N_2 + e \rightarrow N + N + e \qquad (k_4) \qquad (4)$$

- neutral recombination

$$N + N + N_2 \rightarrow N_2 + N_2 \qquad (k_5) \qquad (5)$$

- dissociative recombination

$$N_2^+ + e \rightarrow N + N \qquad (k_6) \qquad (6)$$

The following species are taken into account: nitrogen molecules in the electronic ground state, their concentration assumed to be almost equal to the overall concentration of N_2 molecules (n); electronically excited nitrogen molecules N_2* (n_x); nitrogen atoms N (n_a); electrons e (n_e); molecular nitrogen ions N_2^+ (owing to the plasma quasi-neutrality their concentration is equal to n_e).

The rate coefficients for the processes involving collisions with electrons depend on the form of the electron energy distribution function f_e for the discharge plasma. They are determined by solving the Boltzmann equation for the electrons and calculating the rates as cross section averages over f_e. For that purpose the ELENDIF code [6] is used. The rate coefficients k_5 and k_6 are taken from [7] and [8], respectively.

2.2. Particle balance equations

The particle balance equations according to reactions (1)-(6) read

$$dn_x/dt = k_1\, n\, n_e - k_2\, n_x\, n_a \qquad (7)$$

$$dn_a/dt = 2k_4\, n\, n_e + 2k_6\, n_e\, n_e - 2k_5\, n\, n_a\, n_a \qquad (8)$$

$$dn_e/dt = k_3\, n\, n_e - k_6\, n_e\, n_e \qquad (9)$$

In the first approximation we neglect the flow. This is justifiable for calculations covering time intervals no longer than 100-200 μs, as the characteristic time of particle residence in the torch under consideration is of the order of 10 ms.

2.3. Energy balance equations

The electron energy balance equation is written as

$$\frac{3}{2} k_B n_e \frac{dT_e}{dt} = P_v - n_e \nu_{iz} \varepsilon_L \qquad (10)$$

where k_B is the Boltzmann constant, $\nu_{iz}\, \varepsilon_L$ is the plasma energy loss per electron-ion pair created due to all electron-neutral collision processes and

$$P_v = \sigma E^2 \qquad (11)$$

is the density of the microwave power absorbed by the plasma. Here E is the effective electric field intensity and σ is the plasma conductivity

$$\sigma = (e^2 n_e \nu/m_e)/(\omega^2 + \nu^2) \qquad (12)$$

where m_e is the electron mass, ν is the electron collision frequency for momentum transfer and ω is the microwave field circular frequency.

The energy balance equation for the heavy particles has the form

$$\left[\frac{7}{2} kn + \frac{5}{2} kn_a\right] \frac{dT}{dt} = \frac{3}{2} \delta_e \nu n_e k (T_e - T) - \frac{2\lambda}{3R^2} T \qquad (13)$$

where δ_e is the fraction of energy lost by an electron in a collision with a heavy particle, and λ is the thermal conductivity. The value of λ is taken from[8], and ν is calculated by ELENDIF, as is $\nu_{iz}\, \varepsilon_L$ in equation (10). For preliminary calculations the heavy particle temperature was assumed constant, as the characteristic time for temperature changes due to heat conduction is on the order of several milliseconds.

Equations (7)-(10) and (13) for 4 unknowns n_x, n_a, n_e and T_e form the set to be solved for given microwave power density values P_{v1} (background) and P_{v2} (pulse), the repetition rate and duty cycle of the pulse waveform and the heavy particle temperature T.

3. Calculation method

To solve the set of ordinary differential equations describing the global model one must determine first the initial values of the unknowns for given discharge conditions corresponding to the cw microwave background. This is done by putting

$$dn_i/dt = 0 \qquad dT_e/dt = 0 \qquad dT/dt = 0 \tag{14}$$

in the respective equations, where $i = x, a, e$, and solving the resultant set of nonlinear algebraic equations. Actually, in the presented model some equations may be solved independently of the others, which simplifies the solving procedure.

The reduced electric field intensity E/n and electron concentration n_e are calculated by simultaneously solving the steady-state balance equation for ionization and dissociative recombination and the energy balance equation for the heavy particles. Calculations are performed by iteration, with the Boltzmann equation for the electrons solved in each step in order to update the values of the electron temperature, rate coefficients, collision frequencies and electron energy losses.

Next, particle balance equations for the stationary initial state are solved, providing the initial values for populations of the electronically excited nitrogen molecules N_2^* (n_x) and nitrogen atoms N (n_a). The rate coefficients are again determined based on the solution to the Boltzmann equation for the electrons.

For solving the set of stiff differential equations (7)-(10) the Gear's method is used. The instantaneous value of E/n is determined in each step of integration by iteration, based on a transformed formula (11) $P_v = \sigma (E/n)^2 n^2$. This is done on assumption that the efficiency of power transfer from the microwave field to the plasma is constant and independent of the input power density level. Any rise of P_v must result in an instantaneous rise of E/n, as the electron concentration can not change instantaneously. The rise of E/n causes an increase of the ionization rate. That results in an increase of the electron concentration and plasma conductivity, and a decrease of E/n. In the numerical code each change of E/n triggers solving the Boltzmann equation for the electrons and updating the rate coefficients.

4. Calculation results

The example of calculation results presented in this paper concerns the following initial data: continuous wave background with a power density $P_{v0} = 1300$ Wcm^{-3}, gas flow rate of 2 l/min, gas temperature $T = 2200$ K, rectangular pulses 15 μs long, with a peak power $P_{v1} = 3250$ Wcm^{-3}, repeated at a rate of 15.4 kHz.

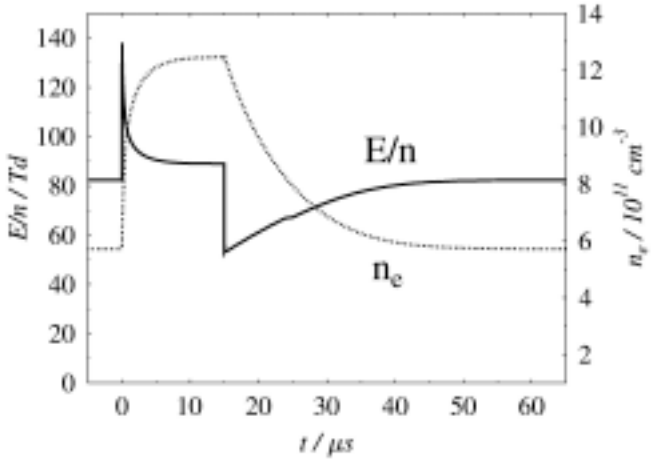

Fig. 1. Variation of the reduced electric field intensity E/n and electron concentration n_e for the first pulse; $t_{pulse} = 15$ μs, $t_{period} = 65$ μs, peak power density $P_{v1} = 3250$ Wcm^{-3}.

Figure 1 shows the variation of the reduced electric field intensity E/n and electron concentration n_e for the first period of the pulse waveform at the very beginning of pulsed operation. The stepwise rise of the power density input to the plasma causes a rapid rise of the electric field, as the electron concentration can not change instantaneously. The resulting rise of the ionization rate causes the electron concentration increase, which in turn allows E/n to decrease gradually.

Figure 2 shows changes of the electron temperature T_e and electron concentration n_e for the same period. Temporal changes of populations for all plasma species considered in the model are shown in Figure 3. The number density of N atoms remains almost unaffected by the pulse, while those of electrons (and, on the strength of plasma quasi-neutrality, of N_2^+ ions) as well as electronically excited nitrogen molecules N_2* increase rapidly during the pulse, to decrease behind it to the initial level in about 50 μs. It is interesting to note the difference in the rise and fall times of the electron concentration, reflecting the different plasma behaviors in the ionizing and recombining regimes.

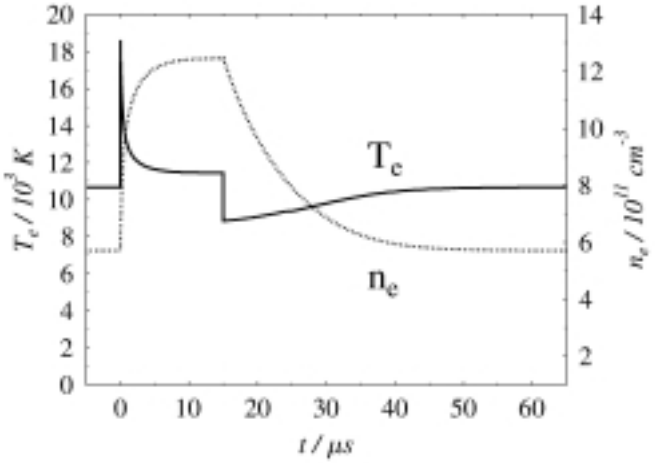

Fig. 2. Variation of the electron temperature T_e and concentration n_e for the first pulse; conditions as for Fig. 1.

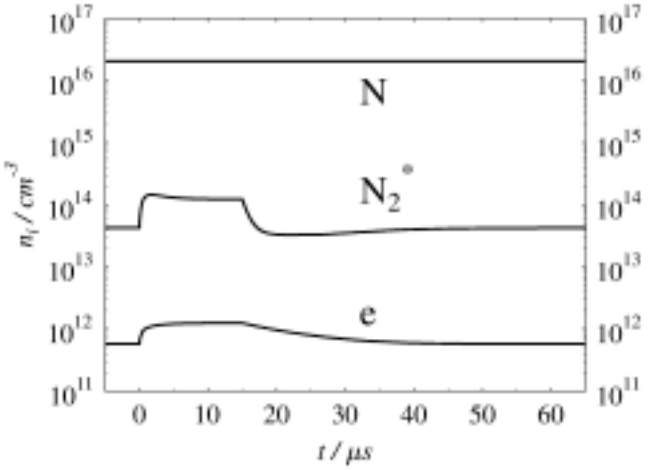

Fig. 3. Variation of the plasma species concentrations during the first cycle of pulsed operation; conditions as for Fig. 1.

5. Conclusions

It should be emphasized that the results presented are correct only within the limits imposed by the adopted model. For more precise calculations a more consistent model is needed. Unfortunately, the nature of the microwave plasma torch makes formulation of a sound global model difficult. Nonetheless, the model described in this paper provides relatively easily insight into temporal variations of plasma parameters in the microwave torch.

A high-frequency plasma discharge effect on polymeric films irradiated by heavy ions

Lyubov I. Kravets[1], Serguei N. Dmitriev[1], Vladimir V. Sleptsov[2], Vyacheslav V. Potryasai[2]

[1] *Joint Institute for Nuclear Research, Flerov Laboratory of Nuclear Reactions, 141980 Dubna, Russia; Tel., Fax: (7-09621) 65955, E-mail: kravets@lnr.jinr.ru*

An effect of plasma RF-discharge on the chemical etching rate of heavy energy ion tracks in poly(ethylene) terephthalate (PET) and polypropylene (PP) films has been studied. Investigated was also an influence of the plasma treatment conditions on the structure and the properties of the track membranes produced in the course of etching. Polymeric films of a thickness of 10 μm exposed to 1 MeV/nucleon xenon ions and 3 MeV/nucleon krypton ions accelerated at the cyclotron (FLNR, JINR) were used at the experiments. The plasma treatment was performed by the method described in [1] at a plasma-chemical device (MSTAU) providing RF-discharge of 13.56 MHz frequency. Only one side of the films was exposed to plasma. Nitrogen and a mixture of nitrogen and cyclohexane in the ratio of 3:1 were used as plasma-forming gas. Discharge parameters (gas pressure, discharge power) and duration of plasma effect were varied. Chemical etching is performed in a conductometrical cell by method [2]. A water solution of 3 mol/l sodium hydroxide was used as an etchant for the samples of PET films and a water solution of chromic anhydride with concentration of 1000 g/l for the samples of PP films.

It has been shown that the character of the changes in etching the ion tracks in a polymer and a polymeric matrix at plasma effect is specified, mainly, by the nature of the polymer. So, the effect of the non-polymerizing gas plasma on the PET films exposed to heavy ion causes a decrease in the etching of both the tracks and the source polymeric matrix. The rate of these processes depends upon the discharge parameters, i.e. increasing the discharge parameters leads to decreasing the etch rate. The changes in the track etching and the polymeric matrix caused by coupling the polymer surface layer lead to appearing an asymmetry in the PET track membrane structure. As electron microscopic investigations have shown, the pore diameter on the side exposed the plasma treatment is less than the pore diameter on the opposite side not treated by plasma. The effect of the non-polymerizing gas plasma on the PP films exposed to heavy ion causes as against an increasing in the etching of tracks, i.e. lead to their sensitization. This effect can be explained by a thermal effect of the plasma discharge on the tracks in PP. The rate of these processes also depends upon the discharge parameters – increasing the discharge parameters leads to more essential increasing the etch rate. The character of etching the polymer in this case does not change. This means that the effect of plasma of under investigation gas does not result in appearing an asymmetry in the shape of the pores formed at the chemical etching of PP track membranes.

It has been found that the polymerizing gas plasma effect on the PET films exposed to heavy ions also causes decreasing the track etching effect. This result from the formation of a thin polymeric chemically stable diamond-like carbon (DLC) film on the surface exposed to plasma. The chemical etching of the PET films exposed to ions with the deposited DLC layer leads to formation of composite semipenetrable membranes. Changing the time of etching in organic compound plasma and the composition of the plasma-forming gas allows one to vary a thickness of the deposited polymeric layer and the selective properties of the formed composite membranes.

Linearly Extended Plasma Source Based on Bifocal Microwave Concentration

M. Kaiser*, M. Graf, R. Emmerich, H. Urban, E. Räuchle

Fraunhofer Institute For Chemical Technology, Pfinztal, Germany

Plasma chemistry is used in a wide field of application, especially for PECVD-deposition, activation and etching. Many plasma sources are constructed with high electrical field and therefore the highest plasma density close to the antenna, with a divergent (usually 1/r) decay outwards. Such a set-up is accompanied by some disadvantages. The recombination process of the plasma is accelerated through plasma wall interactions with highest plasma activity at the antenna or the place of power input. There highest deposition rates, plasma activity, light emission and heating occurs. Usually this phenomena is a parasitic effect, that is only desired, when the substrate itself is the interface to the plasma generating power source. To separate the power input from the plasma zone, usually the ECR-effect, typically used in the sputter technology, or any kind of high frequency resonator is used. The disadvantage of these systems is the requirement of low pressure or the punctiform plasma generation.

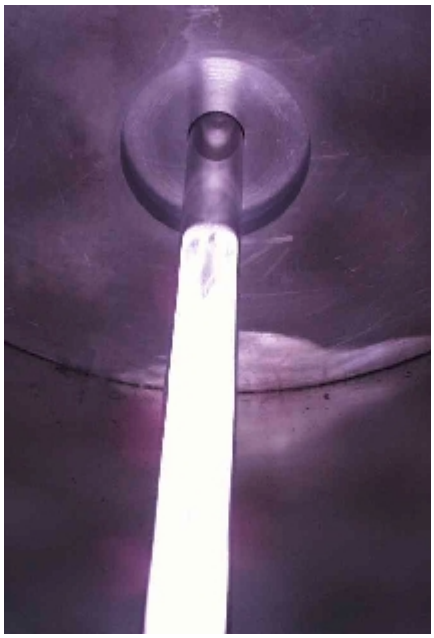
A new solution for this problem will be introduced in this contribution. The key point is the microwave concentration, used to generate the plasma and performed by a linearly extended bifocal plasma device. With this device a linear extended plasma up to atmospheric pressure has been tested successfully.

The prototype of the device was built up from a cylindrical barrel with elliptical cross-section. The dimensions of the ellipse was 30cm and 50cm for the respective semi–axes. The linear extension was 1m.

This bifocal shape has two focus lines where a linearly extended microwave antenna is placed in one focus line and the sector of plasma generation is placed in the second focus line. The divergent emitted microwave radiation is reflected by the metallic walls of the barrel and concentrated in the second focus line apart from the antenna.

In the sector of plasma treatment a quartz tube of 3 cm diameter was used for simple pressure and gas flow control. With the assumption of geometrical optics for the reflection and concentration of microwaves, the shape and set-up was simulated with a numerical simulation program (flex pde). Changes and limits of the microwave concentration in dependence on geometry and simulated power consuming load (plasma) was investigated.

The following picture shows an argon plasma at atmospheric pressure:



Laminar plasma jets: generation, characterization and applications for material surface processing

W.X.Pan, G.Li, X.Meng, W.Ma, C.K.Wu

Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, China

Non-transferred DC plasma jets under turbulent flow condition at atmospheric pressure have been widely used and much discussed. The laminar flow plasma jet, although seldom studied and used, has stable flow, low noise and favorable temperature and velocity distributions for materials processing usage [1, 2]. The reasons that handicapped its development could be the insufficient understanding which emphasized its shortcoming of low thermal efficiency [3], relatively complicated torch structure [1, 3], narrow range of generating parameters, and delicate state that can be easily disturbed by additional operating parameters such as powder feeding in plasma spraying.

In the present work, DC laminar plasma jets of pure argon were generated at atmospheric pressure with a generator having an inter-electrode insert between the cathode and the anode. The fluctuation of arc voltage, light intensity and stagnation pressure of the jet flow were measured simultaneously to examine the flow stability and response of its characteristics to the change of generating parameters. Thermal efficiency, jet power and jet length were measured, and the mean gas temperature at the anode exit was calculated. Combined with the experimental results, similarity theory [4] was adopted to establish formulas for examining the arc voltage character, thermal efficiency and jet length of the laminar plasma. The application of laminar plasma jets for materials surface processing, such as ceramics coating spray and remelt strengthening of metals surface, were attempted.

The arc column seems to be stable and almost fully developed in the torch channel. Thermal conductivity feature of the plasma working gas could play an important role in affecting thermal efficiency character of the laminar-plasma generator having relatively long arc channel. The mean flow temperature at the torch nozzle exit could be over 14000 K at arc current of 200 A. The stable high-energy intensity and relatively low flow velocity make the laminar plasma jet suitable for remelt hardening of metal surface. When used for spraying, the long laminar jet flow can't be easily disturbed by the powder feeding gas injection, and the long stable jet could improve the heating effect on powder particles.

METHANE-OXYGEN MIXTURE COMBUSTION INITIATED BY HIGH-CURRENT GLIDING SURFACE DISCHARGE

I.A.Kossyi, V.P.Silakov and N.M.Tarasova

General Physics Institute of Russian Academy of Sciences,
19991, Vavilov Street 38, Moscow, Russia

Results of experimental investigation of combustion of $CH_4 + O_2$ mixtures ignited by high-current pulse gliding surface discharge are presented.

It has been demonstrated [1-3] that the process of combustion initiated by gliding surface discharge exhibit certain characteristic features such that the propagation of combustion.

Application of high-current initiator changes significantly the process of ignition of the gaseous volume remote from the initiator (as compared with standard low-power two-electrode spark ignition or ignition with a heated metal filament). The standard dynamics of combustion described by thermal or detonation waves propagated from a point of local heating (or a breakdown) of gas medium is replaced – in initiating by a high-current gliding discharge – by a complicated sequence of phenomena. Such a sequence consists in exciting a glow wave that lifts off the initiator and halts in the sufficient vicinity of the initiator with the subsequent homogeneous combustion in the whole volume of the reactor. In this case the glow wave can not be identified neither with a combustion wave, nor with a detonation wave.

It has been found that the burning time of $CH_4 + O_2$ mixture significantly depend on the energy released in the slipping surface discharge decreasing with its increasing.

New experimental results concerning to the nonidentified wave preceding the combustion have been received. Analysis of these results is presented. According it a new form of long-lived plasmoid in a chemical active gaseous medium is predicted. The role of such a plasmoids in combustion ignition is discussed. New optical spectroscopic diagnostics intended to the gas temperature determination are described. Dependence of gas temperature on the energy release in the gliding surface discharge and on the content of flammable gaseous mixture has been received.

Abstract

Chemical transformations occurring in distilled water and aqueous phenol solutions during treatment with an oxygen plasma jet were experimentally studied. The phenol conversion by plasma treatment of its aqueous solutions was found to be mainly due to reactions involving free radicals.

1.Introduction

In the last decade, a great interest of researchers was focused on studying processes resulting in complete oxidation to carbon dioxide and water of organic compounds initially dissolved in water. Despite fundamental differences in their conduction, these processes are based on chemical reactions of oxidation of organic molecules by highly reactive OH radicals [1]. The OH radical is a highly reactive species whose reaction rate with organic components in aqueous solutions is of the order of 10^6-10^9 mol 1^{-1} s^{-1} [2]. In the aqueous medium OH radicals can be generated in various chemical and physicochemical processes such as Fenton reactions, photolysis of ozone or hydrogen peroxide, and the actions of ultrasound or pulsed electric discharge.

On ultrasonication of aqueous solutions, as well as during a pulsed electric breakdown in a liquid, the primary generation of reactive species (atoms and radicals) takes place in the gas phase as a result of thermal dissociation of water molecules in the volume of gas bubbles at the expense of ultrasonic or electric field energy, respectively.

Reactive species in gas phase can be generated outside the bulk of water in thermal-plasma generators in which the dissociation of starting molecules is induced by passing a gas through an arc, radiofrequency, or microwave electric discharge. The treatment of an aqueous solution of organic compounds with a highly dissociated gas stream under certain conditions must lead to oxidation of these compounds in reactions involving atoms and radicals.

The fundamental difference of such a process from the aforementioned ultrasonic or pulsed electric discharge-induced processes is that an aqueous solution can be treated not only with water dissociation products but with virtually any reactive species (e.g., atomic oxygen), thus allowing oxidation reactions to be induced in a liquid by various reactive particles.

It is clear that the mass transfer intensity in gas phase will be the rate-determining step of oxidation of components in solution since atoms and radicals are unstable particles within the temperature range of existence of water in the liquid state and that recombination of atoms and radicals upon their gas-phase transfer in a temperature gradient Held is inevitable at a low intensity of mass transfer processes.

In this work, the processes of oxidation of organic compounds in aqueous solution are furnished by an outflow of a stationary high-velocity (about 10^3 m/s) jet of a dissociated gas into the bulk of a liquid. Under these conditions, the gas-liquid system has an intense turbulence resulting in a rapid degradation of the jet into small-sized gaseous inclusions. This ensures high rates of mass transfer processes [3] and, hence, the possibility of transport of dissociated entities to the gas-liquid interface and their subsequent participation in chemical reactions with the liquid-phase components.

Despite a wealth of studies concerned with chemical reactions in a thermal plasma, attempts at using stationary flows of thermal plasma to conduct oxidation reactions of organic compounds in aqueous solutions under conditions of plasma efflux into the bulk of a liquid have not been reported.

2.Theoretical

Thermal Dissociation of Molecules in Gas Phase. For accomplishing oxidation reactions of organic compounds, the most interesting are oxygen and water vapor dissociation products. As follows from calculations of equilibrium dissociation constants for oxygen and water molecules, a noticeable dissociation of the initial molecules at a pressure of the order of atmospheric begins at a temperature above 2000 K, and, at a temperature above 4500 K, the atoms (O from O_2 or O and H from H_2O) become dominating components (Fig. 1).

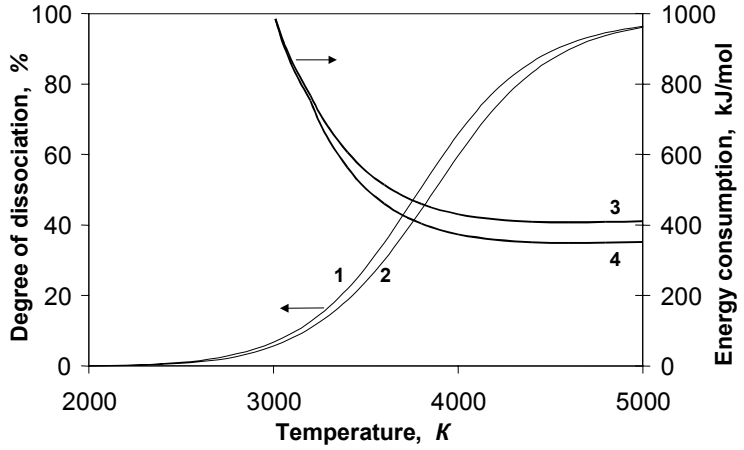

Fig.1. Temperature dependence of the degree of dissociation and the energy consumption for generation of atoms and radicals from H_2O (/, *3)* and O_2 (2, *4)* molecules (a pressure of O.I MPa).

For the equilibrium dissociation of oxygen and water molecules in the gas phase, the minimum energy consumption for generating O atoms (from molecular oxygen as a process gas) and the set of species O + H + OH (from water vapor) corresponds to a temperature in the vicinity of 4500 K (Fig. 1), about 70% of the energy being consumed directly to the breaking of chemical bonds, thus suggesting a quite high energy efficiency of generation of atoms by thermal dissociation.

Thus, these calculations show that the generation of "reactive species" by equilibrium thermal dissociation of molecular oxygen and water vapor is characterized by close values of both yield and energy consumption.

Plasma Jet Outflow into Liquid. Although the mechanics of gas-liquid systems formed upon gas efflux into a liquid are rather extensively studied (e.g., see the review [3]), the problems of interaction mechanics in such systems are far from being resolved. This is due to difficulties in describing and experimental studying such systems since they are generally nonequilibrium, unstable, and nonstationary systems. In the case of plasma efflux, the problem is additionally complicated by strong initial nonisothermicity. Experimental studies on the structure of the gas-liquid system formed upon high-velocity (subsonic) discharge of a plasma jet into a water bath [4] showed that the character of plasma jet discharge in general corresponds to phenomena in weakly nonisothermic systems.

For horizontal outflow, two regimes of gas efflux into a liquid are observed depending on the dynamic action of a plasma jet on the liquid (according to the classification [5]): the transient and the jet regimes. The intensity of the dynamic action of a gas jet can be evaluated with the modified Froude number Fr_0 ($Fr_0 = \rho_0 w_0^2 / \rho_l d g$, where ρ_0 and w_0 are density and the velocity of gas outflow, respectively; ρ_l is the density of the liquid; d is the diameter of a gas flow nozzle; and g is the acceleration of gravity).

The jet regime is realized at high values of the Froude number ($Fr_0 > 500$), a short region of stable jet flow of the gas existing near the nozzle so that the gas flow breaks to form a system of small bubbles at the end of this region. This regime is characterized by the most intense breaking of the gas flow and by the highest rates of mass transfer processes in the system gas-liquid.

As shown experimentally, the penetration depth of a plasma jet into a liquid is significantly smaller than that of an isothermal gas jet, which is explained by an additional decrease in the dynamic head along the plasma jet length as a result of cooling.

The results of investigation of heat transfer in the system plasma jet-liquid in the case of horizontal outflow show that virtually complete heat transfer from the plasma to liquid phase is provided at a nozzle immersion $Hid > 15$ and an Fr_0 value greater than 20, the central role upon thermal interaction of plasma jet with the liquid being played by the jet breaking rather than bubbling region.

3. Experimental

An experimental apparatus (Fig. 2) comprised a direct-current arc plasma torch of 5 kW power, a barrel reactor having a system for thermostat ting (cooling) a treated solution, and a droplet entrainment trap. The cooling system provided the maintenance of a constant temperature in the reactor during outflow of a high-temperature gas jet. Two reactor modes, the one with the lateral and the other with the bottom feed of the. plasma jet were used, the volume of treated liquid in these modes being 3 or 0.71, respectively.

Plasma gases were oxygen-argon mixtures (an oxygen concentration of 10-35 vol. %) which were heated in the torch up to a mass-average temperature of 3300-3700 K. In some experiments, nitrogen-argon mixtures were used. The total flow rate of a plasma gas was 0.5-0.6 m^3/h.

The mass-average temperature was determined by calorimetric measurements and thermodynamic calculations of equilibrium compositions.

The plasma jet discharged into a solution through the lateral hole in the reactor body had a velocity of 300-400 m/s. The pressure in the reactor was close to atmospheric.

Subjected to treatment were phenol (C_6H_5OH) solutions and distilled water. The concentrations of phenol and its oxidation products were determined by the conventional procedures, photometrically with 4-aminoantipyrine and by gas-liquid chromatography [6]. The concentration of hydrogen peroxide was measured by titration with a $KMnO_4$ solution.

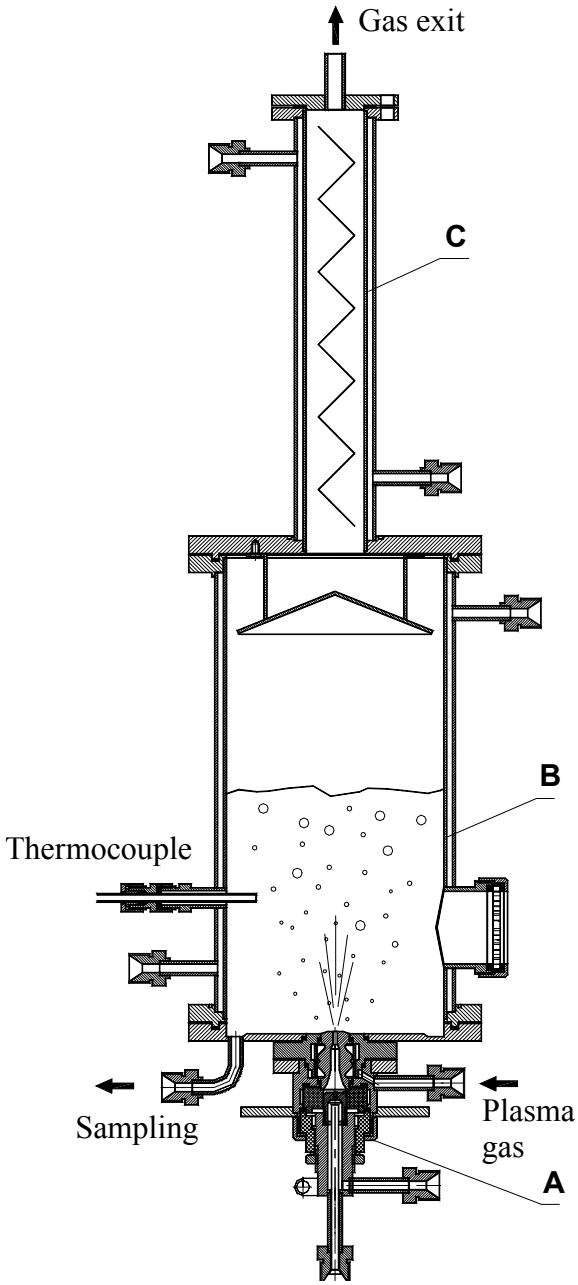

Fig. 2. Schematic of experimental apparatus: (A) plasma torch, (B) reactor, and (C) droplet entrainment trap.

4. Results and discussion

The experiments on the thermal-plasma jet treatment of aqueous phenol solutions were preceded by the set of experiments on the treatment of distilled water in the bottom feed plasma-jet reactor. The conditions of the experiments are given in the Table 1.

As seen from the data presented in Fig. 3, the formation of hydrogen peroxide takes place when the plasma jet is discharged into the bulk of distilled water.

Hydrogen peroxide formation in water is characteristic of such a water treatment process as sonolysis [7] or pulsed electric discharge treatment [8].

According to the current concepts, dissociation of water molecules

$$H2O \rightarrow H + OH \quad (1)$$

and dissolved oxygen O_2

$$O2 \rightarrow O + O \quad (2)$$

in produced vapor bubbles takes place under these conditions.

The resulting atoms and radicals react to yield H_2O_2 molecules:

$$O + H2O \rightarrow OH + OH, \quad (3)$$

$$OH + OH \rightarrow H_2O_2 \quad (4)$$

$$H + O2 \rightarrow HO2 \quad (5)$$

$$Ho2 + HO2 \rightarrow H_2O_2 + 0_2 \quad (6)$$

A similar mechanism can be used to describe chemical reactions in the gas-liquid system formed by plasma jet outflow into the bulk of water.

From the experimental results, it follows that the amount of H_2O_2 produced in water by plasma jet treatment is much greater in the case of an oxygen-containing rather than argon-nitrogen plasma (Fig. 3). This difference suggests that the major role in chemical reactions is played by oxygen atoms generated in the plasma torch and the role of water vapor dissociation products ejected by the plasma jet is relatively small. The dissociation of process oxygen in the plasma torch occurs by passing the gas through an electric discharge in which the arc zone temperature is higher than 10^4 K, whereas the dissociation of water vapor takes place upon degradation of the plasma jet in the liquid; i.e., under conditions of rapid cooling of the gas.

Table 1. The conditions of experiments.

No.	Plasma gas composition, volume fraction			Enthalpy of plasma, MJ/m^3	Temperature of water, C
	N_2	0_2	Ar		
1	0.19	0.00	0.81	4.80	45
2	0.48	0.00	0.52	8.42	50
3	0.00	0.19	0.81	6.66	45
4	0.00	0.19	0.81	4.57	70
5	0.00	0.19	0.81	6.01	45
6	0.30	0.04	0.66	6.34	45

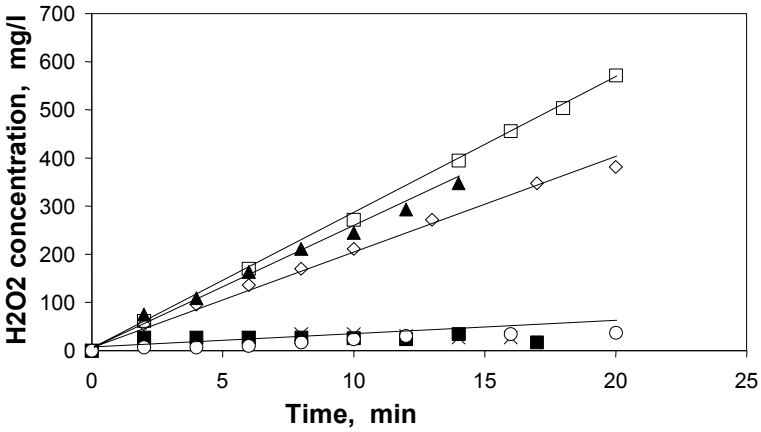

Fig. 3. Change in time for H_2O_2 concentration in distilled water upon thermal-plasma jet treatment: (1) x , (2) ■ , (3) ▲ , (4) ◇, (5) □ , and (6) O. Curve numbers correspond to numbering the experiments in the table.

The dissociation energy of water molecules by reaction (1) is 105 kcal/mol [9]; therefore, the reaction rate does not provide a noticeable yield of atoms and radicals within a short time of plasma jet degradation.

The oxidation of phenol was studied with the oxygen-argon plasma jet. The concentration of oxygen in the initial mixture was 35 vol. % and the equilibrium mass-average gas temperature at the plasma torch outlet was 3600 K. The experiments were carried out in the lateral feed plasma-jet reactor, the initial phenol concentration in water was 15 or 145 mg/1, and the temperature of solution during the treatment was 55°C. It was found that the plasma jet treatment decreases the phenol concentration in solution (Fig. 4). The phenol conversion rate depends on the pH of the starting solution. The maximum conversion rates were attained in experiments at a low pH (5.45). The conversion of phenol is accompanied by the formation of hydrogen peroxide (Fig. 5) whose concentration monotonically increases with time in an almost identical manner at any pH value.

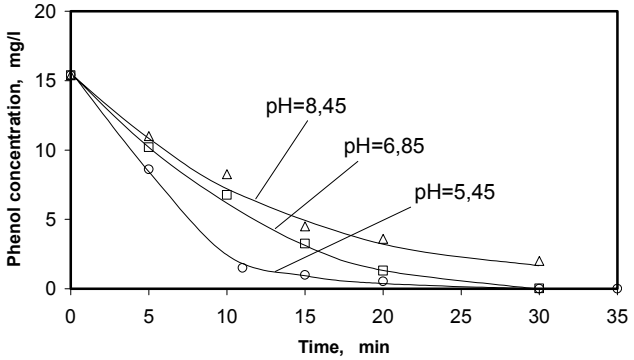

Fig. 4. Change in time for phenol concentration in water solution at different initial pH values.

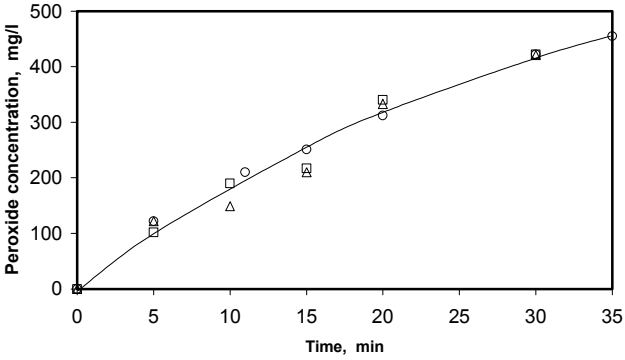

Fig. 5. Change in time for H_2O_2 concentration in water solution at initial pH of 5.45, 6.85, and 8.45.

The oxidation of phenol upon plasma treatment of its aqueous solution seems to be due to reactions involving free radicals, as in the case of ultrasonic treatment [10,11].

The identification of phenol oxidation products showed that, after the 115-min plasma jet treatment of a solution having an initial phenol concentration of 145 mg/1, the final solution contained phenol (7.5 mg/1), pyrocatechol (8.1 mg/1), pyrogallol (10 mg/1), formaldehyde (0.26 mg/1), and acids (67 mg/1).

This set of products indicates that phenol conversion by plasma jet treatment may occur via two routes (reactions (7) and (8)) which should not be considered elementary steps. By the first route, successive oxidation of phenol yielding polyhydric phenols (pyrocatechol, pyrogallol, hydroquinone) takes place:

$C_6H_3OH + 20H — C_6H_4(OH)_2 + H_2O$, (7)

$C_6H_3OH + 30H — C_6H_4(OH)_3 + H_20$. (8)

The polyhydric phenols are further oxidized to quinonoid compounds, which, in turn, are oxidized to cleave the quinone ring yielding unsaturated acids and, ultimately, carbon dioxide and water.

On the other hand, the conversion of initial phenol can proceed directly by cleaving its molecules to yield formaldehyde which, under certain conditions, forms phenol-formaldehyde resins via condensation with phenol. This reaction route is qualitatively confirmed by appearance of a transient brown color of solution during the treatment, although this color further disappears.

It may be assumed that the presence of H_2O_2 in solution plays a minor role in phenol oxidation reactions, as in the case of ultrasonic treatment.

4. Conclusion

The experiments have shown that the treatment of aqueous solutions by oxygenated thermal plasma jet can induce chemical reactions initiated by free radicals. The major role in generating these radicals seems to be played by oxygen atoms that are present in thermal plasma, whereas the effect of dissociation of water molecules ejected by plasma jet is insignificant.

The plasma jet treatment of aqueous phenol solutions results in chemical reactions with participation of phenol, its chemical transformations being qualitatively consistent with the mechanism involving OH radicals.

The obtained results open up new possibilities for using a thermal plasma jet as a means of accomplishing gas-liquid oxidation reactions of organic compounds in aqueous solutions.

Abstract
Hydrogenated carbon films have been deposited on Si substrates in a RF plasma-enhanced chemical vapor deposition (PECVD) system, using CH_4-CO_2 mixtures as gas precursor. A multi-technique approach has been used for a thorough characterization of the deposited films. Aim of this work has been the optimization of the deposition process for obtaining dense and hard films, by studying the effects of parameters such as the gas composition, the cathode self-bias (V_{RF}) and the sample negative biasing level.

Keywords: PECVD, carbon films, CH_4-CO_2 plasma, characterization.

---

1. Introduction

Increasing interest in the deposition and characterization of amorphous hydrogenated carbon (a-C:H) films stems from their outstanding attractive properties that offer a wide range of commercial applications. Various plasma-assisted deposition techniques and carbon bearing source materials have been investigated and can be used for the synthesis of a-C:H films. In particular, radio frequency (RF) plasma-enhanced chemical vapor deposition (PECVD) systems are the most common type employed, over a broad range of deposition voltages, gas pressures, gas composition and substrate temperatures [1,2,3].

Nevertheless deposition of coatings by PECVD is one of the most complex of all plasma surface treatment techniques. In-depth understanding is still limited and the development of new deposition processes is mostly empirical. A large number of process parameters have to be controlled such as power, total pressure, flow rates of the different gases, substrate temperature, electrode spacing and ion bombardment of the growing film. Their effects are interdependent and it is generally accepted the existence of a strict relationship between film properties and process conditions [1,3,4]. The deposition temperature and the degree of ion bombardment during growth, in particular, mostly determine several material features. Moreover ion bombardment during deposition at low temperatures can yield film properties similar to those of films deposited at higher temperatures without ion bombardment [5]. Dense and hard materials can be deposited at high values of impact ion energy. Bombardment can be controlled by varying the RF power, the pressure and the substrate bias voltage [1,4].

The main purpose of the present work has been the optimization of the deposition process to obtain dense and hard carbon films at room temperature in a RF-PACVD reactor, using a mixture of methane and carbon dioxide. We examined process parameters such as the gas precursor composition, the cathode self-bias (V_{RF}) and the sample negative biasing level. In order to study their effects on the material chemical structure, composition and mechanical behavior, a systematic characterization of the films was performed. Specifically, the chemical composition and structure were investigated by means of X-ray photoelectron spectroscopy (XPS) and Fourier-transform infrared spectroscopy (FT-IR). Positron annihilation spectroscopy (PAS) was used for the detection of nano-scale open volume defects. Finally, mechanical tests using indentation and profilometric techniques were made to evaluate the hardness and the internal residual stress.

The first results indicate an evolution of the film structure from a mainly polymer-like one to that of a more rigid amorphous carbon phase when increasing the impact ion energy on the film surface during the deposition.

2. Experimental procedure

Hydrogenated carbon films were deposited on (100) Si wafers, previously organically degreased in ultrasonic bath and then etched in dilute HF. The deposition was carry out in a capacitively coupled RF-PECVD system (13.56 MHz) using a mixture of CH_4-CO_2 as gas precursor. The samples were mounted on a moveable electrode which acts as anode. The distance between cathode and anode was set at 6.8 cm. The base pressure (p) in the reactor was in the 10^{-8} Torr range while the deposition was operated at pressure values varying from 0.09 to 0.2 Torr. A total gas flow of 70 sccm was always used in the deposition process. A series of samples was prepared ranging the content of carbon dioxide in the feed gas from 0 to 50 at.%, while a constant concentration of carbon dioxide (50%) was used in all the other experiments. In addition, the substrates were polarized by applying a DC negative bias voltage (V_{BIAS}), which was changed in a range depending on the V_{RF} and on the film adhesion.

The application of high values of bias voltages to the anode resulted in poor adhesion of the films on the substrate. In order to enhance adhesion and allow the study of ion bombarding effect on the film quality, a pre-treatment of the Si wafer had then to be performed before deposition. This point will be discussed in the next section where the details of the treatment will be given.

Spectroscopic techniques were used to evaluate the chemical composition and the structural features of the films. X-ray photoelectron spectroscopy (XPS) spectra were recorded with a Scienta ESCA 200 instrument equipped with a hemispherical analyser and a monochromatic Al Kα (1486.6eV) X-ray source. The core lines were acquired at a pass energy of 150 eV, which leads to an energy resolution of about 0.4 eV. After a Shirley-type background subtraction, the spectra were fitted using a non-linear least squares fitting program adopting a Gaussian-Lorentzian peak shape. Detailed scans were acquired for the C1s and O1s regions.

The FT-IR spectra were collected by a Bio-Rad FTS 185 spectrometer equipped with a DTGS detector and a KBr beamsplitter. The spectra were then fitted using Gaussian line-shape and a linear baseline subtraction. For semi-quantitative analysis purposes, the areas under the bands were normalized to the film thickness. The normalization was necessary to relate the different signal intensity variations to real differences in the concentration of a given group.

The film thickness was measured with a Kla Tencor P15 profilometer. The deposition rate of the films was then calculated from the film thickness and the deposition time. The films were also characterized from the mechanical point of view using nanoindentation and profilometric techniques to evaluate their hardness, Young's modulus and internal stress. Determination of the stress in particular was based on measuring radii of curvature of the wafers [6], after and before deposition, by means of the profilometer.

Finally, for the detection of the film nano-scale open volume defects, positron annihilation spectroscopy (PAS) analysis was performed. The positron trapping by defects was detected by the Doppler broadening technique. The shape of the positron annihilation line, sensitive to the momentum distribution of electrons, was characterized by the so-called S parameter. The last is the ratio of the counts in a central region of the annihilation line and the total counts in the line. The data were normalized to the bulk value S of silicon. The mean positron penetration depth was calculated on the basis of the positron implantation energy and the film density. For the latter we used a mean value of 2.1 g/cm^3, as obtained from gravimetric measurements.

3. Results and discussion

This work has been a systematic investigation on the chemical and structural evolution, with regard to the process conditions, of carbon films deposited via RF-PACVD technique at room temperature. We tried to optimize the plasma parameters, such as the gas precursor composition, the cathode self-bias (V_{RF}) and the sample negative bias level (V_{BIAS}), in order to produce carbon thin films as much as possible approaching a diamond-like structure. This means that we explored different experimental conditions to obtain films with good mechanical properties (e.g. high hardness) and a structure evolving towards a three-dimensional interlinked array of carbon atoms, which may be achieved by enhancing sp^3 carbon hybridization. In this paper we'll present the first results of the work.

As a first step a series of samples was deposited on a grounded substrate (V_{RF} = –300V ; p= 0.2Torr) at different CO_2 concentrations ranging from 0 to 50 at. %. The composition of the gas precursor affects the deposition rate of the films, so strongly that 50% of CO_2 is the maximum fraction allowing the formation of a carbon film, as can be seen from Table 1. This parameter has an influence also on the mechanical properties of the material. Relatively harder films can be deposited at the highest CO_2 content. Even though the values obtained are typical of polymeric carbon films, the doubled hardness values and the increase in the

Young's modulus lead us to choose a mixture with 50% of CO_2 as gas precursor for any further deposition experiment.

Table 1. Deposition rate, nano hardness H, Young's modulus E of films deposited at different concentration of CO_2 in the feed gas mixture and at two sample bias values.

% CO_2	Sample Bias [V]	Deposition rate [nm/h]	Nano Hardness, H [GPa]	Young's modulus, E [GPa]
10	0	786.54	0.747	7.043
50	0	90.86	1.482	11.185
50	-60	74.46	2.257	22.993
66	0	0	-	-

The influence of the self-bias V_{RF} was then examined. The RF power applied to the cathode was such to have V_{RF} changed in the range –200V to –500V. The deposited films were probed with positron annihilation spectroscopy (PAS) to obtain information about nano-scale open volume defects. The PAS measurements (S parameter versus depth) on the carbon films obtained with different V_{RF} values are reported in Fig. 1. Let's recall that S increases if more open volume defects are present in the material. Apart the initial surface values, the S parameter is here almost constant throughout the films, which indicates that the coatings are homogeneous in their bulk. At the film-silicon interface, S increases to reach the bulk value of silicon at a depth that depends on the film thickness. In spite of the similarity in shape, the S parameter profiles give a relatively lower mean value of S for V_{RF}=-300V than for all the other conditions, showing that films grown at –300V of V_{RF} contain less open-volume defects.

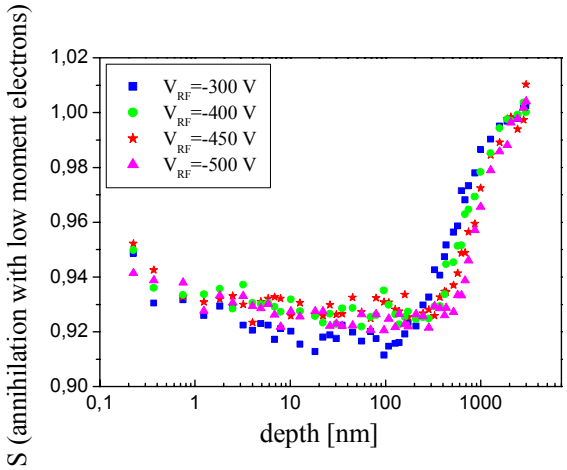

Fig.1 S parameter versus positron mean implantation depth in carbon films deposited at various V_{RF}. (p=0,2Torr; [CO2] = 50%, V_{BIAS} = 0V).

Such a result indicates that samples deposited at low V_{RF} are denser. This might correlate with a peculiar structure of the films, characterized by a higher sp^3 sites content. Such hypothesis is borne out by the outcomes of the FT-IR analyses described in what follows.

IR spectroscopy has been often used for characterizing C-H bonds in hard carbon films, for its capability to give information on the vibration modes of the interconnected sp^3 carbon sites (provided the latter were hydrogenated) and on a semi-quantitative determination of the hydrogen content of the films [8,9,10,11].

In the spectra acquired on the films deposited for different RF powers (not shown here), prominent absorption bands occur at approximately 2875, 2890, 2930, 2960 and 3020 cm^{-1} which can be assigned to the sp^3-CH_3 (symm.), sp^3-CH, sp^3-CH_2 (asymm.), sp^3-CH_3 (asymm.) and sp^2-CH_2 stretching modes, respectively [9]. Another absorption band emerges at approximately 1613 cm^{-1} (sp^2 C=C stretching). These spectra are typical of polymer-like carbon films [9] with large bonded-hydrogen content that, in the present case, decreases at higher RF powers (data not shown here). In Fig.2 we plotted the area ratio sp^3/sp^2 between the hydrogenated sp^3 C and the sp^2 C versus the V_{RF} voltage. This parameter is calculated as the ratio of the sum

of the areas of the Gaussian components fitting the sp^3-CH_x bands (x= 1-3) to the area of the sp^2 C=C band. The rise in the sp^3/sp^2 ratio, which we observe when decreasing the RF power, is consistent with the PAS analysis results. This means that deposition at the lowest V_{RF} (-300V) yields films with the lowest defect-content in correlation with the highest bounded hydrogen amount and an increase of the sp^3 character of the polymeric component of the film structure. For this reason, such plasma condition was kept as a starting point for a further optimization of the process parameters aiming to the increase of the film density.

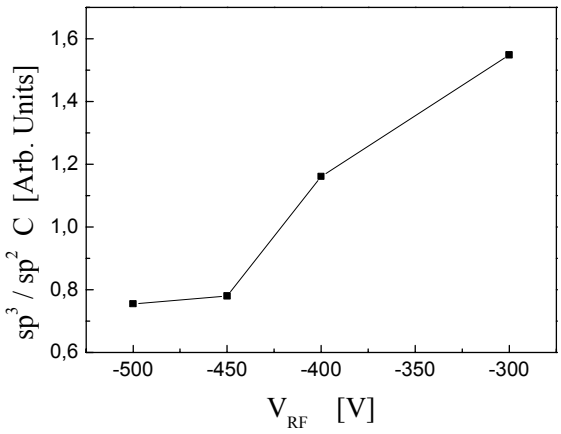

Fig. 2. Dependence of the C sp^3/sp^2 ratio on the V_{RF}. (Values obtained from the fitting of the normalized C-H_x stretching range of the FT-IR spectra.)

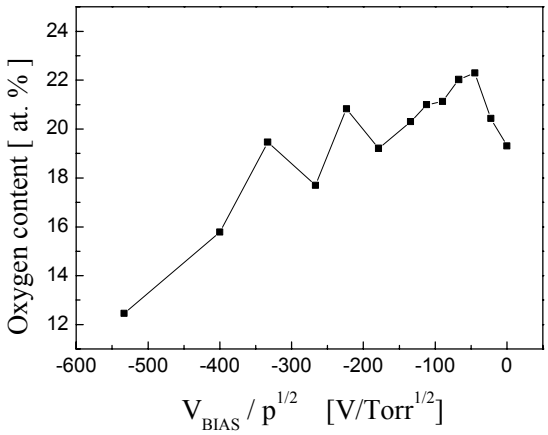

Fig. 3. Trend of the oxygen content in the carbon films with the $V_{BIAS} / p^{1/2}$ parameter, as measured by XPS.

Regarding the densification of films by ion-assistance during the film growth, experimental evidence in literature is abundant [1,2,7,12]. In order to promote the formation of dense films, some activation of surface diffusion of the atoms which impinge and stick to the substrate must be provided. Energetic particle bombardment, prior and during the initial stages of film formation, may enhance the surface mobility of ad-atoms by the introduction of thermal energy directly into the surface region, thus decreasing interfacial voids. Besides, the bombardment of the growing film surface with energetic ions is believed to be a key step in layer formation and film densification [12]. Within a collision cascade, impinging and penetrating ions displace atoms, mainly bonded hydrogen, in the film: these can desorb producing surface dandling bonds or can be recoil-implanted below the surface. The process results in an activation of the growing surface and in an inward packing of the atoms, which favours the deposition of a densely packed structure.

In the present work, ion assistance of the film growth was carried out in the deposition of a series of samples at V_{RF} =-300V, by biasing negatively the substrates. The average impact energy of ions bombarding the growing film depends on both the negative bias applied to the substrate (V_{BIAS}) and on the inelastic collisions between ions and the neutrals in the sheath surroundings the substrate, in other words on the pressure. Bubenzer et al. [13] found the relation

$$E \propto \frac{V_{BIAS}}{p^{1/2}}.$$

From now on, the data obtained from the analyses of films deposited at different impact ion energy will be presented in terms of $V_{BIAS}/ p^{1/2}$. Such a choice stems from the necessity of joining together and correlating data regarding films grown at different energetic conditions by tuning either the pressure or the negative bias.

In order to fulfil the ion-assistance effect study, a pre-treatment of the substrate surface was necessary, as already mentioned in section 2. Due to the ion bombardment, carbon films suffer from extremely high intrinsic compressive stress, which limits the thickness of adhesive films [3]. The basic problem is that the stress and the diamond-like character of the carbon films are strongly linked. This means that any attempt towards a densification of the film will result also in an increase of the stress level. We encountered such kind of problem during the deposition of the films on polarized substrates (measured stress values not shown

here). When applying to the sample a bias voltage higher than –60V, spontaneous adhesion failure occurred if the substrates were not previously treated.

In order to enlarge the bias value range to be applied and allow the study of the ion bombardment effect, various strategies were used to enhance the adhesion even at higher bias voltages. The substrates were first sputter-cleaned for 30' using an Ar DC glow discharge (p=0.3Torr, V_{RF}=-360V). Then followed a treatment of 10' in a RF glow discharge (p=0.2Torr, V_{RF}=-300V, V_{BIAS}=-80V) from a mixture of Ar (5sccm) and CH_4 (35sccm). The former step was used for completely removing any residual contaminants and oxide from the wafer, the latter to cause ion beam mixing between film and substrate in order to ensure a mixed interface [14, 15]. For high sample bias conditions a further step was finally introduced to improve the ion mixing, which consisted in the use of high ion energy (V_{BIAS}=-200V) for the very first stage of the deposition (5'). This allowed to reach bias values up to –160V without undergoing adhesion failure of the films.

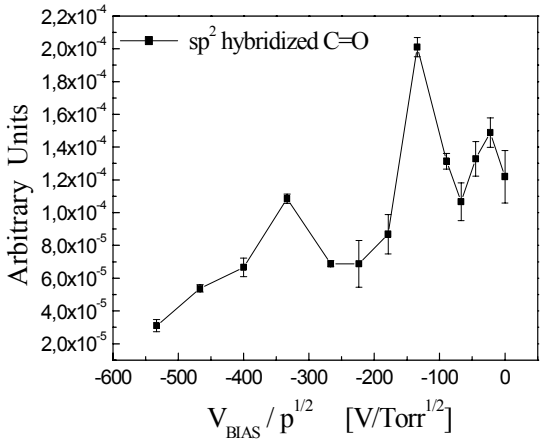

Fig. 4. Dependence of the sp^2 hybridized C=O band area on the V_{BIAS} / $p^{1/2}$ parameter. (Values obtained from the fitting of the normalized FT-IR spectra.)

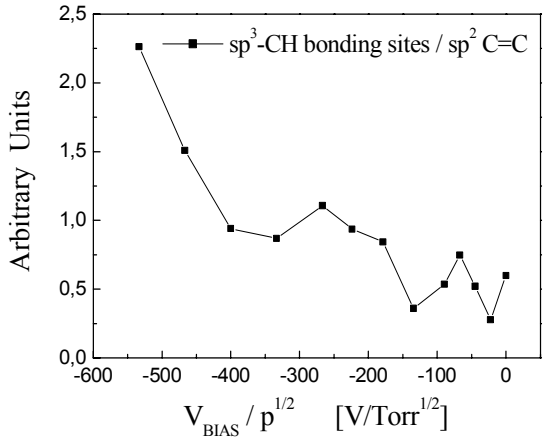

Fig. 5. Dependence of the sp^3-CH /sp^2-C=C ratio on the V_{BIAS} / $p^{1/2}$ parameter. (Values obtained from the fitting of the normalized FT-IR spectra.)

As far as the correlation between film chemical and structural properties and impact ion energy is concerned, XPS and FT-IR analyses provided us with some information. As we can see from the data reported in Fig. 3, the chemical composition of the films, in particular the oxygen content, was found to be dependent on the level of ion bombarding during the deposition. The intensity of the O1s peak in the XPS spectra was observed to significantly decrease with increasing impact ion energy on the surface of the growing film. This result was confirmed by the IR absorption analysis, which revealed a reduction in the oxygen bonding sites amount when raising the ion bombardment energy. In Fig. 4 we can see the evolution of the sp^2-C=O stretching band area (peak occurring at 1710 cm^{-1}) as a function of the ratio $V_{BIAS}/p^{1/2}$, as evaluated from the curve fitting.

The IR spectra of the samples deposited with different impact ion energy still contain the broad band due to CH_x bonding and that due to C=C. As in the case of films grown without bias, the sp^3-CH_3, sp^3-CH_2 and sp^3-CH bands were identified. In order to clarify the effect of the bias on the film structure, the sp^3-CH and the C=C peaks in particular were followed. In Fig. 5 the area ratio between these two peaks is presented. The plotted results indicate a clear trend of the number of sp^3 hybridized C-H sites to get higher, at the expense of the sp^2 C=C ones, with increasing impact ion energy. What is interesting is that we didn't observe a similar trend in the total amount of hydrogenated carbon sites, which would otherwise indicate an increase in the bounded-hydrogen content. On the contrary, the total bounded hydrogen content (as it can be estimated from the area under the whole CH_x band) was found to remain constant when varying V_{BIAS} (data not shown here). This means that the increase in the sp^3-CH/sp^2-C=C ratio shown in Fig. 5 for the films prepared at higher energetic conditions could be attributed to a real evolution of the film structure.

Regardless of the sp^3-CH_3 end groups, which cannot contribute to the structure rigidity, it's worth noting that a trend like the one shown in Fig.5 is more pronounced for the sp^3-CH groups (where the C atom is linked to other three C atoms) rather than for the sp^3-CH_2 ones. The evolution of the sp^3-CH/ sp^3-CH_2 area

ratio in fact is found to increase with the average impact ion energy (plot not shown here). This therefore implies that high ion bombardment energies during the film growth are useful to enhance the formation of a three-dimensional interlinked structure.

The first mechanical tests performed by nano indentation technique on films deposited on polarized substrates gave a confirmation of our hypothesis. Applying a –60V bias to the substrate in fact produced an increase in the Young's modulus and in the hardness, with respect to the values obtained from the unbiased samples (data displayed in Table 1). The change in the bonding configuration, as inferred from the FT-IR spectra, so results in a denser material which may indicate an evolution of the film structure from a mainly polymer-like one towards that of a more rigid amorphous carbon phase.

4. Conclusions

Hydrogenated carbon films were deposited at room temperature by RF PACVD using a mixture of CH_4-CO_2 as gas precursor. Different plasma conditions were explored and the effect of the physical parameters of the glow discharge on the chemical, structural and mechanical features of the coatings were investigated.

It was found that the composition of the gas precursor affects the deposition rate and the mechanical properties of the material. In particular the higher the CO_2 content the harder the film obtained. PAS and FT-IR analyses indicate that samples deposited at low V_{RF} have a denser structure, with less open volumes. Finally, depositions carried out at low energetic conditions result in essentially polymeric films, as revealed by the FT-IR spectra. On the contrary ion bombardment during the film growth enhances the formation of a more rigid and dense structure, composed by carbon sites involved in three-dimensional sp^3-C-C bonding.

We believe this route to be promising for the production of diamond like carbon films, for both the mixture chosen as gas precursor and the energetic activation of the deposition process.

Acknowledgments

The authors are thankful to "Fondo Progetti – Provincia Autonoma di Trento" who financed the project. Many thanks also to CNR- Istituto di Biofisica (Laboratorio Biomolecole e Membrane Biologiche, Trento) for making available the FT-IR spectrometer and to G. Favaro from CSM Instruments (Neuchatel, Switzerland) for the nanoindentation measurements.

A DC Diaphragm Discharge in Water Solution

Z. Stara, F. Krcma, Z. Raskova

Faculty of Chemistry, Brno University of Technology, Purkynova 118, 612 00 Brno, Czech Republic

Abstract

In this contribution, the DC diaphragm discharge in water solutions is described. The batch reactor was used in experiments. The discharge configuration was „electrode-less". The dependence of the light intensity of hydroxyl radicals on the discharge conditions (applied voltage, initial conductivity of the liquid, salt in water solution) was studied by optical emission spectroscopy. The influence of these conditions on the generation of hydrogen peroxide by the discharge was also investigated.

1. Introduction

The discharges generated in liquids have been subject of intense research during a few last yaers [1-4]. The processes taking place in such discharges are applied in fields of water treatment, destruction of various organic pollutants dissolved in water and in specific reactions in liquid phase. The common discharge configurations are point-to plane [1, 2] and coaxial [3], several experiments were done in diaphragm (electrode-less) configuration [4]. During almost all of these experiments, a pulsed high voltage in range from about 10 to 20 kV was used to create the discharge. The present contribution focuses on the diaphragm discharge created using the non-pulsed DC high voltage, which could be lower than in case of the pulsed high voltage (only about 2 kV) [5]. Various active species are produced by such discharge (hydroxyl radicals, hydrogen ans oxygen radicals, hydrogen peroxide etc.) [2].

2. Experimental

A simplfied scheme of the discharge reactor is shown in Fig. 1. It consists of two parts – a negative part with a cathode and positive part with an anode. The stainless steel electrodes were planary and the distance between them was 4 cm. The parts of the reactor were divided by the PTFE diaphragm (0,25 mm) with a pinhole in the centre. To generate high voltage and to create the discharge, a non-pulsed DC high voltage source was used. The range of voltage was from 1,4 kV to 2,8 kV. Due to considerable heating of the reactor by the discharge and to prevent the destruction of the hydrogen peroxide, two cooling boxes with ice were installed in both parts of the reactor. This system kept the temperature under 15˚C. To ensure the homogeneous conditions in the whole volume of the liquid, a mixing system was used. The demineralised water containing NaCl and Na_2HPO_4 salts were used to obtain the defined initial conductivity [5].

The optical emission spectroscopy was used for investigating the emission intensity of hydroxyl radicals.

Hydrogen peroxide was determined spectrophotometrically using the specific reaction with titanyl ions in presence of the sulphuric acid (the titanium reagent) [6]. The created peroxotitanyl complex gave a yellow color with the maximum absorbance at 407 nm. The absorbance intensity was depended on the amount of the hydrogen peroxide according to the equation [7]:

$$y = 0{,}4596 \cdot x, \tag{2.1}$$

were y means absorbance intensity and x is the concentration of the hydrogen peroxide.

The samples were taken from both parts of the reactor (negative and positive) and the sampling time was estimated on 5 minutes.

The metallic traces (Fe, Cr) involved from the electrodes during the discharge were determined by the ICP method [5].

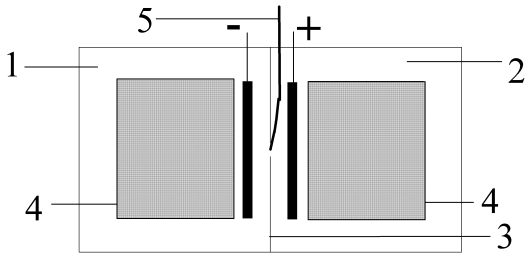

Fig. 1: Scheme of the reactor: 1 – negative part, 2 – positive part, 3 – dielectrical diaphragm with a pinhole, 4 – cooling boxes, 5 – optical fiber.

3. Results and discussion

During the experiments the emission spectra of the diaphragm discharge were observed. Especially hydroxyl radical and some elements contained in used salts (Na) were determined in the spectra. The relative OH integral intensity from the range 306.5 – 318 nm, a quantitative parameter of the diaphragm discharge, was counted from each measurement and plotted as a function of the discharge conditions. The spectroscopic observations were done in both salts (NaCl and Na_2HPO_4), the high voltage varied from 1,4 to 2,8 kV and two different initial conductivities (400 and 550 $\mu S \cdot cm^{-1}$) were used. The same feature in evolution of the light intensity in both salts was its decreasing magnitude in time (Fig. 2). In case of NaCl, the decrease was slower than in the hydrogenphosphate. Comparing the relative OH intensity as a function of the initial conductivity, the difference in NaCl salt was more evident than in Na_2HPO_4, where the evolution in time was similar. In NaCl, the decrease in intensity was much higher at the higher initial conductivity (550 $\mu S \cdot cm^{-1}$).

The dependence of the relative OH intensity on the magnitude of the applied high voltage is shown in Fig. 3. The emitted light increases with increasing voltage for both types of salts. The evolution of this dependence is more or less linear and it is similar to the dependence of H_2O_2 concentration on the applied voltage (Fig. 10). In the case of NaCl and higher initial conductivity, the increase in relative OH intensity was lower than in Na_2HPO_4 salt at the same initial conductivity. There was no obvious difference between the two initial conductivities in Na_2HPO_4 solution. The increase in relative OH intensity in the case of NaCl at a lower conductivity (400 $\mu S \cdot cm^{-1}$) was much higher than at another conditions.

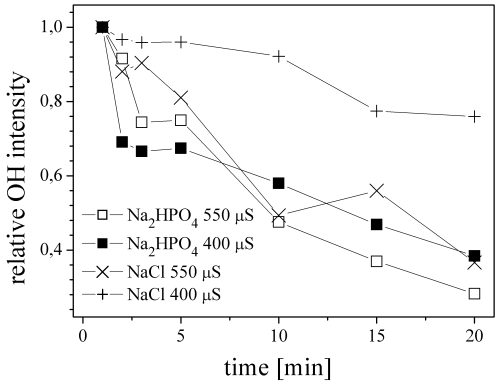

Fig. 2: The time evolution of the relative OH intensity (for various salts and initial conductivity).

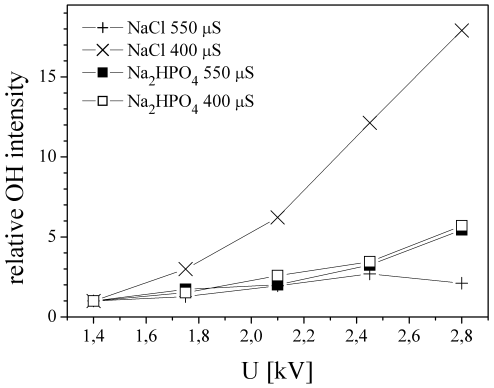

Fig. 3: The relative OH intensity as a function of the applied voltage.

The production of the hydrogen peroxide generated by the discharge was not the same in both parts of the reactor (Fig. 4). The produced amount of hydrogen peroxide was much higher in the negative polarity than in the positive part of the discharge reactor. Due to this phenomenon, next measurements were focused on the negative part of the discharge reactor. The evolution of H_2O_2 concentration in time was during the experiment (60 minutes) approximately linear (Fig. 4). In the case of longer measurement (over 60 minutes), the production of hydrogen peroxide reached the point of saturation (Fig. 5). The concentration of H_2O_2 could be described as a function of time by the following equation:

$$c_{H2O2,\,t} = k_{H2O2} \,.\, t, \tag{3.1}$$

where $c_{H2O2,\,t}$ means concentration of hydrogen peroxide, k_{H2O2} is the rate constant of the H_2O_2 production and t is time of the discharge.

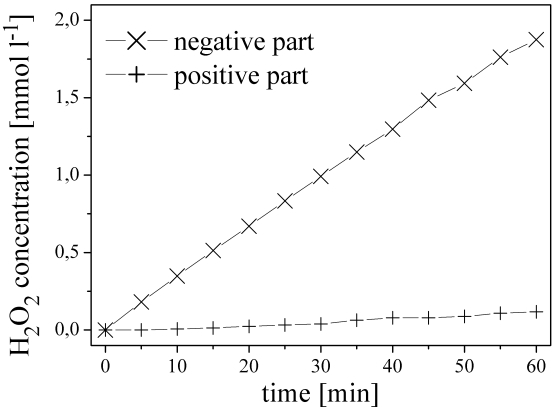

Fig. 4: Hydrogen peroxide generation in time (2,4 mM Na_2HPO_4, 2,1 kV, 500 μS·cm^{-1}).

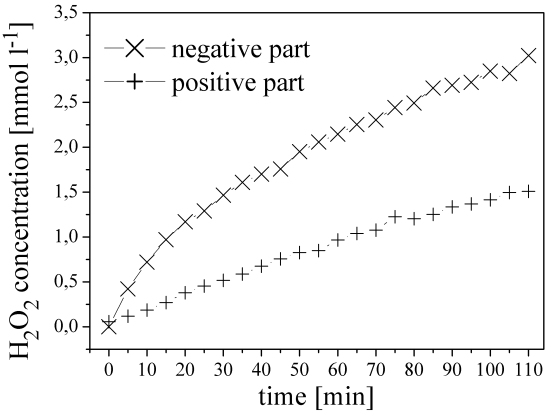

Fig. 5: Hydrogen peroxide generation in time (5 mM NaCl, 2,8 kV, 500 μS·cm^{-1}).

The rate constant of the generation of hydrogen peroxide was different for various discharge conditions. Table 1 shows the comparison of the rate constants in case of NaCl and Na_2HPO_4 salt at different initial conductivity. The dependence of the rate constant on the applied voltage, in the NaCl solution, is given in Table 2. The highest rate constant was achieved in the case of NaCl salt at the initial conductivity 600 μS·cm^{-1} and applied voltage 2,8 kV.

Table 1: The rate constants of H_2O_2 production in NaCl and Na_2HPO_4 solutions at different initial conductivity (2,8 kV, 2,1 kV respectively).

	Rate constant (·10^{-7} mol·l^{-1}·s^{-1})								
Initial conductivity (μS·cm^{-1})	100	200	300	400	500	600	700	800	900
NaCl	1,43	5,35	5,68	6,20	5,13	6,70	4,63	2,75	
Na_2HPO_4			3,10		5,67		6,20		6,43

Table 2: The rate constants of H_2O_2 production in NaCl solutions at different applied voltage (300 μS·cm^{-1}).

	Rate constant (·10^{-7} mol·l^{-1}·s^{-1})			
High voltage (kV)	1,75	2,10	2,45	2,80
NaCl	1,32	3,55	4,35	6,00

The estimated concentration of H_2O_2 in the positive part of the reactor was slightly increased by diffusion from the other part of the reactor and by metallic traces (Fe, Cr). They were involved from the stainless electrodes by the electrolysis. This phenomenon was confirmed by the ICP method. The involved amount of metals depended on the initial conductivity of the solution as given in Fig. 6.

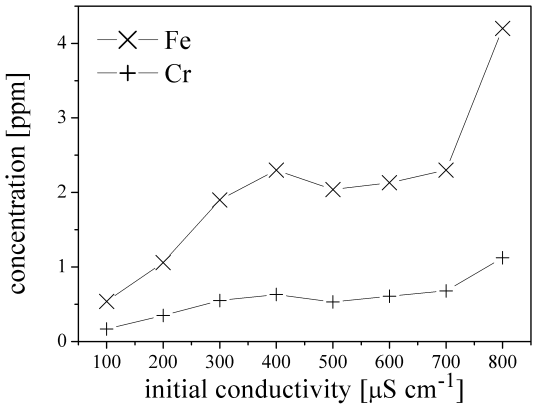

Fig. 6: Concentration of Fe and Cr traces as a function of the initial solution conductivity.

The conductivity of the solution was not constant during the discharge. It significantly increased in time and in each part of the reactor it had a different growth (Fig. 7). The increasing conductivity was caused by the involved metallic traces (Fe and Cr ions).

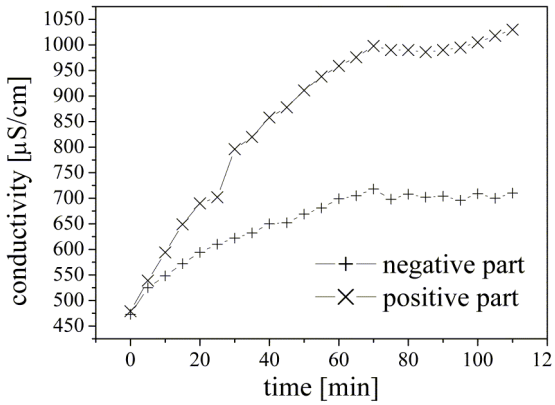

Fig. 7: Time evolution of solution conductivity (5 mM NaCl, 2,8 kV, 500 $\mu S \cdot cm^{-1}$).

The hydrogen peroxide dependence on the initial conductivity was more complicated. The experiments were done in both salts (NaCl and Na_2HPO_4) with initial conductivity in the range 100 – 900 $\mu S \cdot cm^{-1}$. In the case of Na_2HPO_4, the production of H_2O_2 increased with increasing initial conductivity (Fig. 8). In the case of NaCl, the dependence was also increasing but at the initial conductivity of 400 $\mu S \cdot cm^{-1}$ it achieved its maximum and then the dependence became descended. This is shown in Fig. 9. The small amount of hydrogen peroxide produced by the discharge in the solution with very small conductivity (until 300 $\mu S \cdot cm^{-1}$) was caused by a very unstable discharge under these conditions. The discharge at the initial conductivity of 100 $\mu S \cdot cm^{-1}$ burnt very irregularly so the generation of hydroxyl radicals and consequently hydrogen peroxide was discontinuous.

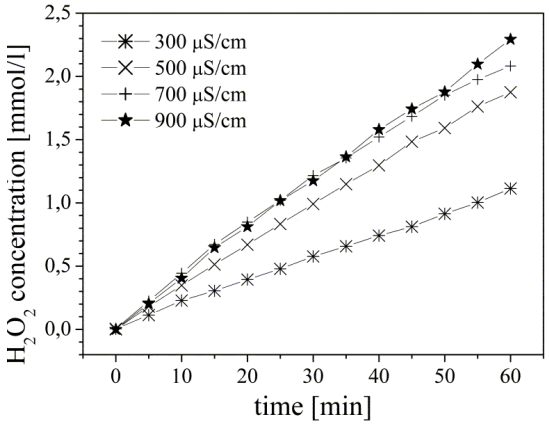

Fig. 8: Hydrogen peroxide generation in time as a function of the initial conductivity (Na_2HPO_4, 2,1 kV).

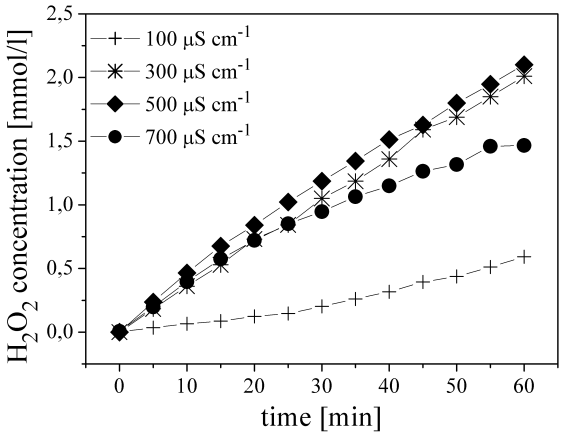

Fig. 9: Hydrogen peroxide generation in time as a function of the initial conductivity (NaCl, 2,8 kV).

The production of H_2O_2 was influenced by the used electrolyte. But this influence also depended on the initial conductivity. In the case of lower initial conductivity (about 300 µS·cm^{-1}), the hydrogen peroxide generation was higher in the NaCl solution. At about 500 µS·cm^{-1}, the H_2O_2 production was similar in both salts and at the higher initial conductivity (700 µS·cm^{-1}), higher production overweighed in Na_2HPO_4 solution. The reduced amount of H_2O_2 at the higher initial conductivity is caused by the chloride anions, which destructed hydrogen peroxide in several reactions.

The hydrogen peroxide generation also depended on the applied high voltage. The lowest limit at the configuration used was about 1,4 kV and the generation increased with the increase in the applied voltage as shown in Fig. 10.

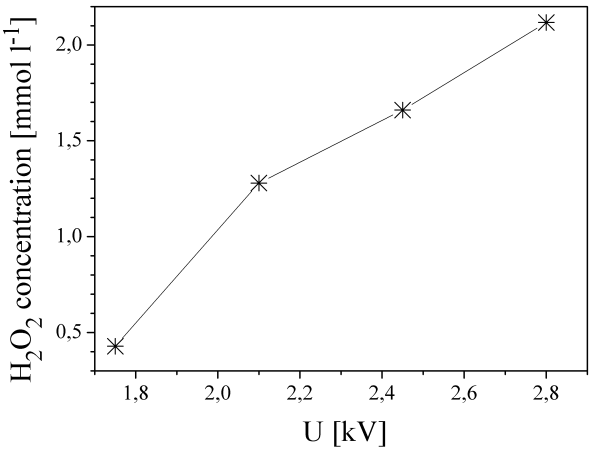

Fig. 10: Hydrogen peroxide concentration after 60 minutes of the discharge treatment as a function of the applied voltage (3 mM NaCl, 300 µS·cm^{-1}).

4. Conclusion

The results of optical and chemical observations of the DC diaphragm discharge in water solutions are presented in this contribution. The dependence of the emission spectra of hydroxyl radicals on the initial discharge conditions for two salts was studied. The relative OH integral intensity in the range 306.5 – 318 nm was calculated. The light intensity of OH radicals increases with increasing voltage in both types

of used salts. But the light intensity decreased with increasing initial conductivity. This phenomenon was more remarkable in NaCl solution. The relative OH integral intensity rapidly decreases in time for both types of the solution. In the case of NaCl, the decrease was the lowest at lower initial conductivity.

The hydrogen peroxide generation as a function of the initial discharge conditions (applied voltage – its magnitude and polarity, initial solution conductivity and used salt) was studied. The rate constants of the H_2O_2 production were calculated. The production of H_2O_2 is higher in the negative part of the discharge reactor in the both salts (NaCl and Na_2HPO_4). It increases with the increasing applied high voltage. The dependencies of H_2O_2 concentration and OH intensity on the applied voltage had an analogous development. In the case of Na_2HPO_4, the hydrogen peroxide concentration grows with increasing initial conductivity. In the case of NaCl, this dependence is growing at the lower initial conductivity, it reaches a maximum at about 400 $\mu S \cdot cm^{-1}$ and the next generation of H_2O_2 is decreasing with increasing conductivity. The production of hydrogen peroxide is higher in NaCl solution than in Na_2HPO_4 at lower initial conductivity. At the initial conductivity above 500 $\mu S \cdot cm^{-1}$, the situation is opposite.

The estimation of H_2O_2 concentration was influenced by metallic traces (Fe, Cr) involved by the electrolysis during the discharge. The amount of involved metals was proportional to the initial conductivity. This phenomenon is one of the reasons of increasing conductivity of the solution during the discharge.

Flow Field and Heat Transfer Characteristics of a Laminar Plasma Jet

Xian Meng, Wenxia Pan, Chengkang Wu

Institute of Mechanics, Chinese Academy of Sciences, Beijing, 100080, China `

Abstract

Spectrometric method was applied to measure the temperature distribution of a DC argon laminar plasma jet. A stick-shaped transient probe of 1 mm outer diameter was designed to measure the heat flux distribution. A water-cooled pitot tube was used to measure the impact pressure and the flow velocity was calculated according to the measured pressure and temperature. The dependence of heat transfer coefficient from jet flow to the transient probe on flow temperature and velocity was derived.

1. Introduction

Non-transferred DC laminar plasma jet has the stable flow, low entrainment of the surrounding atmosphere, and thus low temperature and velocity gradient along its axis. Pure argon laminar jet can be 550 mm in length with little change in diameter under suitable generating conditions [1], and the jet length changes appreciably with good repeatability with the change of arc current and gas flow rate. These characters could be favorable for systematic experimental characterization of the jet flow field, compared with turbulent jets of serious fluctuating parameters and complex boundary condition at the interface with the surroundings [2-4]. It could also be advantageous for the comparison study between experiment and numerical simulation work.

Experimental characterization and simple simulation of the free laminar plasma jet and a jet impinging on a copper plate were carried out recently [1, 5, 6]. Due to the lack of experimental data of the laminar jet temperature and velocity, the simulation and analytic work of the laminar plasma jet were usually based on assumed values. Therefore, it is necessary to characterize the flow field of laminar plasma jet systematically for its better understanding and application.

In this study, the jet temperature, maximum heat flux to probe surface and impact pressure were measured by using spectrometric method, small transient heat flux probe of the stick type and a pitot-tube separately, with the argon laminar plasma jet issuing into air atmosphere. The relationship between heat transfer coefficient and gas flow velocity or gas temperature were derived through the measurement data.

2. Experiment

The laminar plasma generator is the same as used in former work [1, 5]. Plasma jet was generated with pure argon as the working gas at a feeding rate of 1.57×10^{-4}kg/s to 2.47×10^{-4}kg/s at arc currents of 110-180 A. The plasma jet was injected into the atmosphere after leaving the torch nozzle.

Relative-intensity method [7] was used to measure the jet temperature. The spectrometric system consisted of a lens with focal length of 120mm, an optical fiber of 0.4mm in diameter, and an Optical Spectra Analyzer (OSA) through which the light signals of spectral lines could be detected. The image of the plasma jet was formed on one side of the optical fiber through the lens, and was transferred to the slit of the OSA by the fiber. The light intensities along the radial direction of the jet were detected point by point at a step of 0.5mm. The spectral lines of argon atom, 750.4nm and 751.5nm were used, and the jet temperature could be obtained according to the LTE assumption and the Abel inversion [8].

Impact pressures along the jet axis were measured by using a water-cooled pitot tube with the spherical tip facing the jet to reduce disturbance to the flow. The probe is 13mm in diameter with a Φ0.8mm hole in its center, the small hole was connected to an U-tube manometer. The measured pressure is the impact gage pressure. Then, the flow velocity at the measuring point can be calculated by using the Bernoulli's equation at the stagnation point $P=1/2\rho v^2$, where P, ρ, v are the impact pressure, gas density and jet flow velocity respectively, while ρ is a function of gas temperature.

A stick-type, 1mm-diameter transient heat-flux probe was used to measure the heat flux to the probe surface. Fig. 1 shows the schematic diagram of the sweeping probe method. A 0.8mm -diameter and 0.8mm-length copper slug was fixed at one end inside a 1mm-diameter glass tube, ensuring just the front surface exposed as the heat flux response surface. The rear surface of the copper slug was attached with a pair of

Nickel/Chromium -Nickel/Aluminium thermocouple. Two thermocouple wires of 0.1 mm diameter are insulated from each other with Teflon and then connected to a data collecting system. The heat flux probe was fixed in the center of a cone-typed water-cooled support, and the 1mm-diameter probe stretched 20mm out of the support to ensure minimum disturbance to the laminar jet flow. The temperature-response curve could be obtained by sweeping the probe across the laminar jet perpendicularly at a speed from 130mm/s to 260mm/s to prevent the probe from melting. The heat flux distribution can be obtained by differentiating the temperature with respect to time according to the response curve [6, 9]. The maximum heat flux corresponds to the heat flux at the jet center.

The heat transfer coefficient h_i from the jet flow to probe surface can be obtained by using the heat transfer equation $q = h_i(i_e - i_w)$ [10], where q is the heat flux to the probe surface, i_e is the stagnation enthalpy of the gas outside the boundary layer, and i_w is the enthalpy at the wall surface. Besides the temperature change, effect of jet flow velocity on heat transfer was also considered.

The mean temperature of the jet flow at the torch exit was estimated by measuring the jet power. The setup is the same as the former work [1], which ensures a complete cooling of the jet flow to the room temperature with little disturbance of the jet condition. The enthalpy change of the cooling water caused by the temperature rising is considered to be equal to the jet power, and then the specific enthalpy of the argon jet is the ratio of the jet power to the gas flow rate. Thus, the mean temperature of the jet flow at the torch exit can be obtained by referring to [11].

3. Results and discussion

Fig. 2 shows that the maximum heat flux of the laminar plasma jet changes as a function of the sweeping speed from 130mm/s to 260mm/s at different axial distance of 0.5mm to 80mm from torch nozzle to probe surface. It is evident that the maximum heat flux increases as the sweeping speed decreases. This phenomenon is consistent with the results in Ref. [12, 13], which could infer that the frozen boundary layer existed during the heat transfer process, because the heat from the jet flow had more time to reach the probe surface as the sweeping speed decreases. It is also found that the effect of sweeping speed on the detected maximum heat flux appreciably increased as the probe was close to the torch nozzle. This means that increasing the probe sweeping speed will increase the measured heat flux error from its real value, especially when flow temperature and velocity increased. However, in the following experiments, the sweeping speed was chosen as 260mm/s to prevent the probe from melting, because the main measurement region is close to the torch nozzle, though it is better to choose low sweeping speed for accurate measurement.

Fig. 3 shows the axial distributions of maximum heat flux and flow temperature of the laminar plasma jet at the arc current of 170A and gas flow rate of 1.57×10^{-4}kg/s, measured by the heat flux probe and the spectra analyzer separately. The temperature along the jet axis changes smoothly with the temperature gradient of about 55K/mm within the distance of 10mm from the torch nozzle, and about 50K/mm from the distance about 10mm to 80mm. This measured value of the axial temperature gradient has the similar trend as the numerical simulation work [5], and it is much lower than that of a turbulent plasma jet flow [14] which is generally over 200K/mm at the position near the torch nozzle. Though the maximum heat flux changes smoothly along the distance from 20mm to 80mm, it varies significantly within the distance of 20mm, especially within the distance of 5mm from the torch nozzle. This significant variation of the maximum heat flux is difficult to be explained clearly now, because of the possible complex affecting factors, such as the surrounding atmosphere mixing with the jet flow, the catalytic effect on the probe, etc. In order to get exact results, much careful work should be carried out to eliminate the effect of disturbance factors.

Fig. 4 shows the dependence of jet flow temperature on the gas flow rate. The arc current was fixed at 170A and the gas flow rates changed from 1.57×10^{-4}kg/s to 2.47×10^{-4}kg/s. The center temperature is the jet axial temperature 0.5mm away from the nozzle exit; and the mean temperatures at the nozzle exit were obtained by measuring the jet power. The results show that the jet center temperature and mean temperature at the nozzle exit are almost constant with the change of gas flow rate. That is, the change of gas flow rate could change the power (total enthalpy) of the plasma jet, but the gas temperature at the torch nozzle will keep unchanged, when the arc current is kept at a constant within the range of this experiment.

Fig. 5 shows the variations of the maximum heat flux and gas temperature on arc current at gas flow rate of 1.57×10^{-4}kg/s. The measuring point for the probe and spectra analyzer is all 0.5mm from the torch nozzle. Temperatures and maximum heat fluxes increase almost linearly with the increasing arc current. The points

at the bottom of the graph stand for the mean temperatures at the exit of the torch nozzle estimated by measuring the jet power. It has the same trend as the measured center temperature by using spectrometric method.

The distributions of impact pressure and calculated jet velocity along the jet axis are shown in Fig. 6. The working conditions are the same as for Fig. 3. Since the diameter of the pressure probe is somewhat large, it could influence the gas flow field when put very close to the torch nozzle. Thus, the impact pressures within the distance of 5mm from the torch nozzle were not used for the calculating of the corresponding flow velocity. In this range, the pressure value was corrected as the dash line by extrapolating the measured data at 10mm and 5 mm from the torch nozzle. As a result, the velocity distribution along the jet flow axis is obtained through the corrected pressure and the temperature data by using Bernoulli's Equation. The flow velocity along the jet axis decreases, as the distance from torch nozzle increases. The axial variation trend of the velocity is similar to the simulation result [15], with large gradient at close distances. The maximum velocity of the jet flow at the torch nozzle exit is about 840m/s under the generating condition with the arc current of 170A and gas flow rate of 1.57×10^{-4}kg/s. The estimated velocities of the laminar plasma jet flow are almost the same order as a turbulent jet, which is much higher than the generally considered values for the laminar plasma jet. Reynolds number of the jet flow is calculated to be about 340, which is reasonable for laminar jet flow [16].

The results in figures 3 and 6 also indicate that the laminar plasma jet keeps high temperature and kinetic energy along the axis for a large distance. These characteristics of the laminar plasma jet could result in high reliability and controllability for materials surface processing [5].

According to the experiment results shown in Fig. 4, the jet center temperature at the nozzle exit is almost independent of the gas flow rate when arc current is a constant, but the corresponding velocity increased as the increasing gas flow rate. On the other hand, i_w could be neglected in the heat transfer equation, for its small value compared to the gas enthalpy outside the boundary layer. Then the relationship between the heat transfer coefficient and the flow velocity is obtained as show in Fig.7, at a constant arc current of 170 A and gas flow rates from 1.57×10^{-4}kg/s to 2.45×10^{-4}kg/s, because the exit center temperature of the jet flow is about a constant of 16500K, and the change of heat flux can be considered only caused by the velocity change, under this condition. The heat transfer coefficient increases simply as the increasing of flow velocity when the flow temperature kept constant.

Fig. 7 also shows the relationship between the heat transfer coefficient and gas temperature. The relationship was obtained by measuring the center temperature and the heat flux at the same point of the laminar plasma jet at constant gas flow rate of 1.57×10^{-4}kg/s and changed arc current from 110A to 180A. The effect of gas velocity on heat transfer coefficient was also implied in this curve, the flow velocity generally increases too as the increase of flow temperature at a certain gas flow rate. The variation trend of heat transfer coefficient here is a result of the simutaneous changing of the flow velocity and temperature.

4. Conclusion

The sweeping speed can affect appreciably the measuring results of maximum heat flux from laminar plasma flow to the probe surface, which could infer that frozen or non-equilibrium boundary layer existed during the heat transfer process; The mean temperature and jet center temperature at the torch exit are independent of the gas flow rate, while the temperature increase as the increase of the arc current, within the working range; And the heat transfer coefficient was derived through the experimental data of gas temperature, heat flux and flow velocity, both the gas temperature and jet flow velocity could affect the heat transfer coefficient.

Hydrogen atom formation in the magnetically enhanced RF discharge in Ar-CH_4 mixtures

S.V. Avtaeva, D.K. Otorbaev

Kyrgyz-Russian Slavic University, Bishkek, Kyrgyzstan

Abstract
Effect of argon on production of atomic hydrogen in the magnetically enhanced RF discharge in argon-methane mixtures is studied by optical actinometry method. It is shown that in the experimental condition formation of hydrogen atoms is realised by Penning dissociation of methane molecules by collisions with metastable argon atoms: $Ar + e \to Ar^* + e;\ \ Ar^* + CH_4 \to CH_3 + H + Ar$.

1. Introduction

At present time low-temperature plasma in mixtures of hydrocarbon containing gases with noble gases and hydrogen is an object of greeting interest. This is cased with applications of the plasma for plasma deposition of amorphous hydrogenated carbon films. In the plasma deposition methods, the structure and properties of deposited carbon films can be varied widely by changing deposition parameters. It has been found that the atomic hydrogen radicals play a key role in the formation of properties of the layers in all kinds of carbon deposition schemes. Their presence is very essential for the stabilization of the carbon bonds and for the selective etching of the dangling bonds during the deposition processes [1, 2]. This paper is devoted to study effect of argon on production of atomic hydrogen in the magnetically enhanced RF discharge in argon-methane mixtures.

2. Experiment

A magnetically enhanced asymmetric capacitive coupling RF reactor was used in the experiments [3]. The reactor chamber consists of the stainless steel cylindrical vessel with a diameter of 30 cm and a height of *25* cm and has the ports to allow optical and contact diagnostics. The chamber walls were grounded. RF power (frequency is 13.56 MHz) from the RF generator has been applied to the stainless steel plane square electrode (*10×10 cm)* arranged in a middle of the chamber. The power supply was connected to the electrode through the special matching device (L-type matching circuit). Two magnetic coils induced in the chamber a homogeneous magnetic field in respect to the vertical symmetry axis.
The basic vacuum was produced and maintained by two pumps connected to the discharge chamber via a magnetic valve. The system can be evacuated to a base pressure of 10^{-3} *Pa*. Reactive gas was injected into the plasma region through a hole at the bottom of the chamber after passing a mass flow controller. The mixtures of methane and argon have been used as working gases. The partial methane pressure in the discharge chamber was maintained equal to *0.1 Pa*. The volume content of methane in the gas mixtures was varied from *1* to *10%*, while a gas pressure was adjusted in the range of *1÷10 Pa.* A magnetic field can be adjusted in the range of 25 - *200 G* and a discharge power was *80 W*.
The gas temperature measurements in the plasma have been carried out by a thermocouple, which could be moved along the radial direction of the chamber, perpendicularly to the powered electrode. For the determination of electron density and the electron temperature a double Langmuir probe has been employed. The probe was made from tantalum wire with the diameter of *0.1 mm*, and has free tip length of *8 mm*. The probe was immersed in the plasma region at the distance of *1 cm* from powered electrode. The optical system, based on the high resolution monochromator and the photomultiplier has been used to measure the spectral line intensities. An Intel 8088 microprocessor has been used to digital recording of the measured data.

3. Results and discussion

In the low pressure glow discharge plasma in the gas mixtures of hydrocarbons with the noble gases it is possible, in principle, to measure the absolute density of atomic hydrogen by optical actinometry method. For measuring atomic hydrogen density by this method it has been proposed to use a spectral line of hydrogen HI 656.2 nm (H_α of Balmer's series) and a spectral line of argon ArI 696.5 nm [4, 5]. However, in

the conditions of glow discharges plasma in the gas mixture of hydrocarbon-argon not only the direct electron excitation from the ground state, but also the process of stepwise excitation of the radiative states of argon Ar($4p^3P_1$) and hydrogen H(3S,3P,3D) through the metastable states Ar($^3P_{0,2}$) and H($2^2S_{1/2}$) respectively, becomes important. Therefore it is essential to make a detailed analysis of the excitation kinetics of the radiative states Ar($4p^3P_1$) and H(3S,3P,3D) for the particular experimental situation. The following excitation and de-excitation reactions for radiative A^* and metastable A_m atomic states should in principle be discussed [3]:

$$A + e \xrightarrow{k_1} A^* + e, \quad (1) \qquad A + e \xrightarrow{k_2} A_m + e, \quad (2)$$

$$A_m + e \xrightarrow{k_3} A^* + e, \quad (3) \qquad A_m + e \xrightarrow{k_4} A + e, \quad (4)$$

$$A_m + M \xrightarrow{k_5} A + M, \quad (5) \qquad A^* + M \xrightarrow{k_6} A_k + M, \quad (6)$$

$$A^* \xrightarrow{k_7} A_k + h\nu, \quad (7) \qquad A_m + wall \xrightarrow{k_8} A \quad (8)$$

Where e means the electrons and M the heavy particles (atoms and molecules) (Ar, CH_4, H_2, etc..) in the ground and in the excited states, A_k is the atoms in the excited state k.

Combining (1) -(8) the stationary density of the ground state A can be derived:

$$[A] = [A^*] \cdot \frac{k_7 + [M]k_6}{[e]k_1 + [e]^2 k_2 k_3/([e](k_3+k_4) + [M]k_5 + k_8)} \qquad (9)$$

Finally the absolute population density of atomic hydrogen in the ground electronic state $[H]$ can be derived from known absolute density of argon atoms $[Ar]$, relative population densities of hydrogen $[H^*]$ and argon $[Ar^*]$ in the excited states, and the rate coefficients of elementary collisional and radiative processes:

$$\frac{[H]}{[Ar]} = \frac{[H^*]}{[Ar^*]} \cdot \frac{\{k_1+[e]k_2k_3/([e](k_3+k_4)+[M]k_5+k_8)\}_{Ar}\{k_7+[M]k_6\}_H}{\{k_1+[e]k_2k_3/([e](k_3+k_4)+[M]k_5+k_8)\}_H\{k_7+[M]k_6\}_{Ar}} \qquad (10)$$

In the equation (10) for density ratio $[H]/[Ar]$ it is assumed that the excitation of the radiative states of Ar($4p^3P_1$) and H(3S,3P,3D), were realized directly from the corresponding ground states of Ar and H, as well as stepwise via metastable levels of Ar($^3P_{0,2}$) and H($2^2S_{1/2}$), respectively. The de-excitation of Ar($4p^3P_1$) and H(3S,3P,3D) levels were assumed to be a result of the radiative decay and their depletion by collisions with the heavy particles (atoms and molecules in the ground states).

Quantitative analysis of importance of the various kinetic processes of formation of stationary population densities of the radiative Ar($4p^3P_1$) and H(3S,3P,3D) states in the case of magnetically-enhanced RF discharge under our experimental conditions allow us to get the following conclusions :

1. Let the excited state of Ar($4p^3P_1$) are depleted by the Ar atoms in the ground state. Then under conditions of our experiments the quenching time τ for the excited state of Ar($4p^3P_1$) is ~ 10^{-4} - 10^{-5} s that is much larger in comparison with the radiative decay time ($\tau_{rad} \sim 1.5 \cdot 10^{-7}$ s) [6]. Therefore, it is possible to exclude the equation (6) from our consideration. There is a valid reason to apply the same approach to $3^2S_{1/2}$, $3^2P_{3/2}$, $3^2P_{1/2}$, $3^2D_{5/2}$, $3^2D_{3/2}$ states of H, which are responsible for the emission of the Balmer's H_α line.

2. Quenching of the metastable states of argon Ar($^3P_{0,2}$) and atomic hydrogen H($2^2S_{1/2}$) are taken place predominantly under collisions with the methane molecules CH_4. Flux of the direct excitation remarkable exceeds flux of the stepwise excitation of the radiative states of Ar($4p^3P_1$) and H(3S,3P,3D), if the metastable states of Ar($^3P_{0,2}$) and H($2^2S_{1/2}$) are effectively depleted by collisions with the methane molecules. Under condition of small methane concentration in the initial gas mixture of CH_4-Ar the picture presented above is not valid any more since the stepwise excitation mechanism via the corresponding metastable states will play more significant role. Especially it should be taken into account by the examination of the population mechanism of Ar($4p^3P_1$) state.

In particular experimental conditions, in according with the evaluations, excitation of the radiative state of $Ar(4p^3P_1)$ was realized stepwise via the metastable level of $Ar(4s^3P_{0,2})$ and excitation of the radiative state of H(3S, 3P, 3D) was realized directly from the ground state of hydrogen atoms. The de-excitation of both radiative states is the result of radiative decay. In this case relationship of densities of hydrogen atoms [H] and argon atoms [Ar] is related to relationship of of H_α(λ=656.2 nm) and Ar (λ=696.5 nm) spectral line intensities with the expression

$$\frac{[H]}{[Ar]} = \frac{I_H (A_{ki}/\lambda_{ki})_H}{I_{Ar} (A_{ki}/\lambda_{ki})_{Ar}} \left(\frac{1}{k_{1H}}\right) \times \left(\frac{k_2 k_3 [e]}{(k_3 + k_4)[e] + k_5[CH_4] + k_8}\right)_{Ar} \frac{\tau_{Ar}}{\tau_H} \quad , (11)$$

where k_{1H} is excitation rate constant of H(3S, 3P, 3D) level, $k_2k_3[e]$ is proportional to excitation velocity of $Ar(4p^3P_1)$ level, k_4, k_5, k_8 are collisional quenching coefficients for the metastable state $Ar(4s^3P_{0,2})$, A_{ki} is the absolute transition probability at the wave length λ_{ki}, τ is the lifetime of the radiative state.
The more simple expression may be taken for the relationship of the rate constants k_{2Ar} and k_{1H}:

$$\frac{k_{2Ar}}{k_{1H}} = \frac{\sigma_{2Ar}(\varepsilon) f(\varepsilon)_{|\varepsilon=\varepsilon t+1}}{\sigma_{1H}(\varepsilon) f(\varepsilon)_{|\varepsilon=\varepsilon t+1}} \quad , \qquad (12)$$

where $\sigma(\varepsilon)$ is the electron impact cross-section for the corresponding reactions of excitation, $f(\varepsilon)$ is the electron energy distribution function (EEDF), ε is the energy of free electrons, εt is the threshold energy of the excitation. So evaluation of hydrogen atom density from the relationship of the spectral line intensities calls for knowing electron densities, which were measured independently with the double probe.
The rate constants k_1 and k_2 have been calculated using excitation cross sections of the reactions (1) and (2), respectively. The excitation cross section for the transition H(1S →3S,3P,3D) has been taken from work [7], for the transition H(1S $\rightarrow 2^2S_{1/2}$) from work [8]. In case of argon the excitation cross section σ_1 and σ_2 were taken from work [9].
The transition probabilities and the radiative lifetimes (constants k_7) were taken from [6,10].
Intensities of spectral lines ArI (696.5nm) and H_α(656.2nm) as functions of gas pressure and magnetic field are shown in figure 1 (a, b). Intensities of both spectral lines increase with increasing magnetic field, that is caused by increase in excitation velocity of radiative states due to magnetic confinement of electrons. The decreasing intensities of both spectral lines ArI (696.5nm) and H_α(656.2nm) with increasing gas pressure is probably because of the reduced magnetic confinement with pressure (the Hall parameter for the electrons becomes smaller). The effect of collisional de-excitation of the radiative and metastable states in particular experimental conditions should be small.
The dependencies of electron density on argon pressure measured in RF discharge plasma in pure argon are

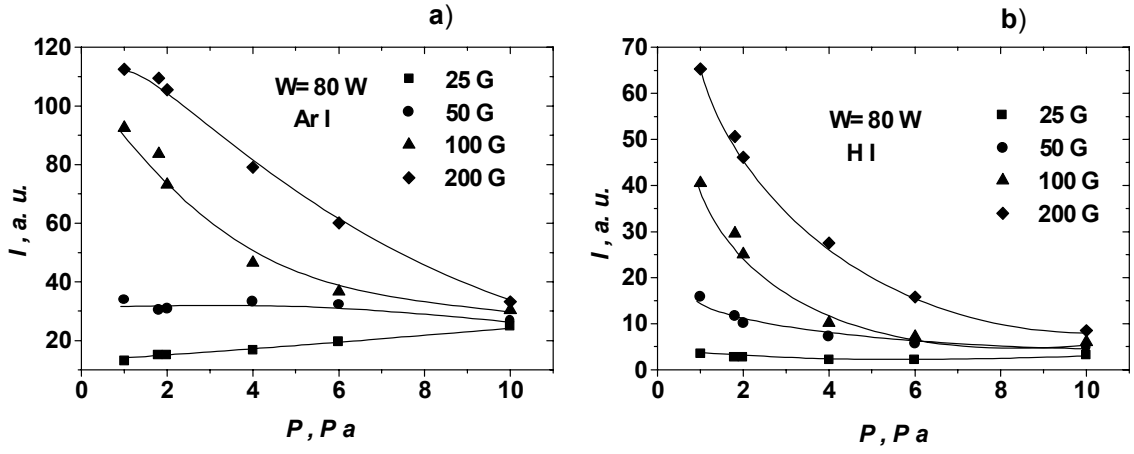

Figure 1. Intensities of emission lines of ArI (696.5nm) –(a) and H_α(656.2nm)-(b) with increasing argon pressure in CH_4/Ar RF discharge.

shown in figure 2(a). In magnetically enhanced discharges magnetic field has a high effect on velocities of charged particles generation and loss processes. Due to magnetic confinement the electron losses on the chamber walls decrease but frequency of electron collision with atoms increases, caused to increase in ionization frequency and, consequently, in electron density. For magnetized electrons Holl's factor decreases with increasing gas pressure, that caused to increase in electron losses on walls, therefore electron density decreases with increasing gas pressure. Electron temperature was in the range of 6÷8 eV in particular experimental conditions.

The dependencies of the charged particle density on argon pressure and magnetic field well correlate with similar dependencies of intensity of argon spectral line ArI (696.5 nm). Addition of small methane content to argon not changes the behavior of electron density dependencies on gas pressure. One can see it in figure 1 (a).

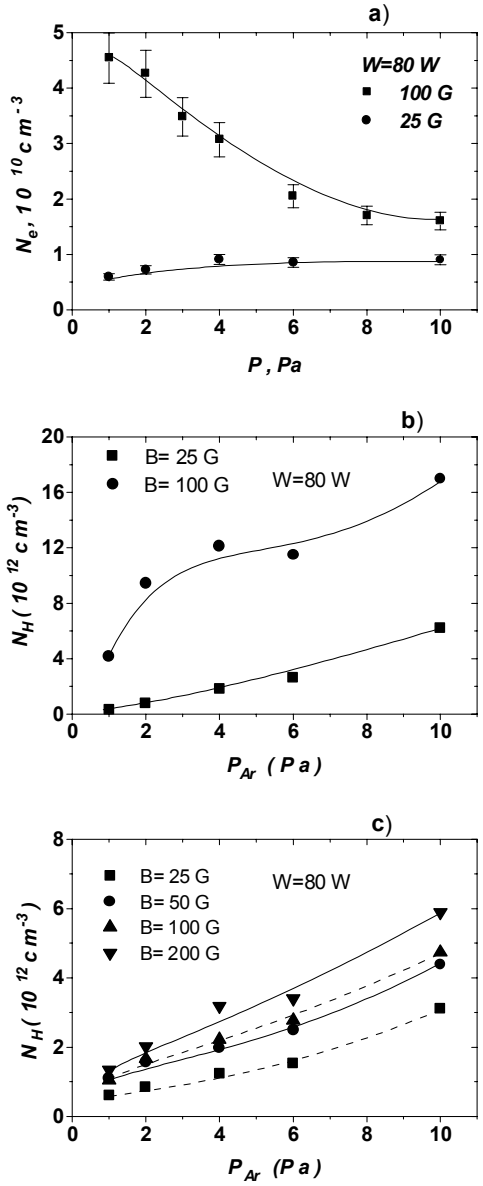

Figure 2. Electron density (a) and absolute density of hydrogen atoms (b, c) as a function of gas pressure; b) the stepwise excitation of the radiative state of $Ar(4p^3P_1)$ via the metastable level of $Ar(4s^3P_{0,2})$; c) the direct excitation of the radiative state of $Ar(4p^3P_1)$ from the ground state.

The atomic hydrogen densities in the RF discharge in argon-methane mixtures as a function of gas pressure, calculated without and with account of stepwise excitation of the radiative state of argon $Ar(4p^3P_1)$ via the metastable level of $Ar(^3P_{0,2})$ are shown in figure 2(b, c). It was assumed EEDF is maxwellian with electron temperature ~6 eV. The account of stepwise excitation of the radiative state of argon $Ar(4p^3P_1)$ via the metastable level of $Ar(^3P_{0,2})$ caused to variation of calculated density of hydrogen atoms approximately from 1 to 5 time.

As it can be seen in figure 2, the atomic hydrogen density increases with increasing argon pressure and magnetic field. At the same time methane density remains constant and electron density decreases (100 G) or increases weekly (25 G) with argon pressure.

Let us to analyze mechanisms of formation of atomic hydrogen in magnetized plasma of the RF discharge in argon-methane mixtures. The formation of the hydrogen atoms in the RF discharge in argon-methane mixtures under separation of electron temperature from gas temperature can proceed by electron impact methane dissociation:

$$CH_4 + e \rightarrow CH_3 + H + e \qquad (13)$$

$$CH_4 + e \rightarrow CH_3^+ + H + 2e \qquad (14)$$

$$CH_4 + e \rightarrow CH + H_2 + H + e \qquad (15)$$

and by following electron impact dissociation of methane radicals. Velocity constants of the processes (3)- (5) depend on form of EEDF and in a case of the maxwellian EEDF this constants are functions of electron temperature. The velocity constant values of reactions (3)-(5) were used from work [11], where capacitive RF discharge (f=2MGz) in methane at pressure ~40 Pa and power 15 W was investigated. There are following values of velocity constants $45 \cdot 10^{-15} m^3 s^{-1}$, $32 \cdot 10^{-15} m^3 s^{-1}$ and $3.7 \cdot 10^{-15} m^3 s^{-1}$ for reactions (3), (4) and (5), accordingly. However, under predominant

formation of hydrogen atoms in reactions (3)- (5) the dependence of hydrogen atom density on gas pressure should to agree with analogic dependence of charged particle density. As it can be seen in figure 1, 2(b), 3 opposite dependencies are observed at magnetic field values >25 G.

The methane thermal decomposition is small at the characteristic gas temperature (more than 1000K) in the magnetically enhanced RF discharge [3]. Methane radicals interaction causes to formation of more heavy hydrocarbons and their radicals and also no promotes to increase in hydrogen atom density.

The dissociative ionization of methane molecules in the process of charge exchange on argon ions [12] causes to formation of hydrogen atoms also. However, the velocity constant of resonance charge exchange ($\sim 1 \cdot 10^{-15} m^3 s^{-1}$ (T=1000K) [12]) is substantially less than the velocity constant of electron impact methane dissociation (3), (4). So phenomenon of charge exchange of methane molecules on argon ions can not compete with processes (3) and (4) as long as approximate equilibrium of electrons and ions density exists.

In review [13] is remarked, that in the glow discharges in argon methane- mixtures at pressure ~10 Pa, when density of metastable argon atoms reaches a value about $10^{11} cm^{-3}$, quench of metastable argon atoms in the Penning dissociation of methane molecules produces basic contribution into methane dissociation

$$Ar^* + CH_4 \rightarrow CH_3 + H + Ar \qquad \left(3 \times 10^{-16}\ м^3 c^{-1}\right). \qquad (16)$$

The metastable argon atoms Ar* are formed by electron impact excitation

$$Ar + e \rightarrow Ar^* + e; \qquad (\sigma_{max} = 4.8 \times 10^{-21}\ м^2) \qquad (17)$$

and its density N_{Ar^*} is proportional to product of $N_{Ar} N_e$. At that formed by Penning dissociation hydrogen atom density is ~ $N_{Ar^*} N_{CH_4} \sim N_{Ar} N_e N_{CH_4}$. While gas pressure increases from 1Pa to 10 Pa argon density N_{Ar} increases into 10 times, at that electron density decreases about in 2.5 times (Fig. 2(c)). In so far as methane pressure was maintained constant, hydrogen atom density must increase in about 4 times with increasing gas pressure from 1 Pa to 10 Pa as long as hydrogen atoms are predominantly formed by Penning dissociation (16). As one can see in figure 2, experimentally observed increase in hydrogen atom density with increasing argon pressure is close to the evaluated value.

4. Conclusion

Formation of hydrogen atoms in the magnetically enhanced RF discharge in argon-methane mixtures (1÷10% CH_4+Ar) in pressure range of 1-10 Pa can not be responsible for electron impact methane dissociation and following methane radicals dissociation also by electron impact. Increase in hydrogen atom density with increasing argon pressure as long as charged particle density decreases (figure 2) is possible when hydrogen atoms are formed in processes of the Penning dissociation of methane molecules by collisions with metastable argon atoms: $Ar + e \rightarrow Ar^* + e;$ $Ar^* + CH_4 \rightarrow CH_3 + H + Ar$.

Introduction

In the framework of thermonuclear fusion research**,** increasing interest is focussed on high power high frequency millimeter-wave generators like gyrotrons. Measurements of gyrotron power and energy allow an accurate energy balance in ECRH (Electron Cyclotron Resonance Heating) to be carried out during plasma heating. The ongoing improvements in generator power and pulse duration ask for uninterrupted development of matched calorimetric loads in terms of design and technological solutions.

The expected increase of the power, until 2 MW, and time, until 10 s (or continuous wave), calls for new technological solutions in manufacturing bolometric loads, particularly in making use of absorbing layer ceramics better resistant to thermal shocks. In this particular case, the use of high thermal shock resistance ceramic coating is requested as well as a good absorption capability at 140 GHz.

The present work is devoted to studying and selecting an absorbing ceramic coating to be deposited on the inner surface of the load. The aim is to characterize the material with respect to absorbing capability at a frequency of 140 GHz and thermal shock and fatigue resistance caused by long-term exposure to high power mm-wave radiation. Bolometric loads are planned to resist to 1-2 MW power continuously.

To this purpose APS (Air Plasma Spray) ceramic deposits have been studied to search for a convenient substitute to the actual Alumina-Titania coating (Al_2O_3-$13TiO_2$) [1].

A number of physical parameters such as thermal conductivity, thermal expansion coefficient (TEC), coating porosity and melting point were also considered to select among the candidate materials.

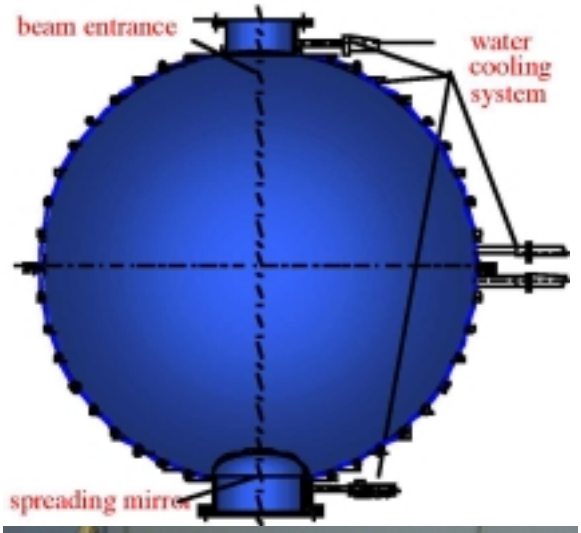

Fig. 1: Matched load. Cross sectional view.

Fig. 2: Matched load. View lower hemisphere.

The bolometric spherical load

The load consists basically of a hollow copper sphere having the inner wall covered with a plasma-sprayed lossy ceramic, a spreading mirror in front of the beam entrance and an external cooling circuit (Fig.1). Its high absorbition capability allows fast calorimetric measurement of the millimeter-wave power also at long pulse duration.The low total reflectivity, measured in the order of 5%, is obtained with multiple reflections on the inner walls, characterized by an average reflectivity of 40%, and with a proper design of the mirror (visible in fig.2), whose surface profile was computed assuming an input beam with gaussian distribution of power and correct phase front curvature radius [2]. Four loads like that described are installed on the ECRH (Electron Cyclotron Resonance Heating) plant of the FTU (Frascati Tokamak Upgrade) in Frascati at present. They are used at a frequency of 140 GHz, power of 0.5 MW and pulse duration of 0.5 s.
The same load is being tested at higher power and longer pulse (0.7 MW and 1 s) on the ASDEX Upgrade ECRH plant in Garching (Germany).

Thermal diffusivity measurements

The thermal diffusivity of the coating was investigated using bolometric loads like the one described by measuring the absorber temperature during and after the pulse**,** both on the inner wall of the sphere, during a real full-power pulse (Fig.3) and on samples of different coatings, placed on the edge of the main beam.
In the first case the measurements were performed with an infrared detector directed into the load from the entrance, imaging a small spot (<1cm diameter) near the mirror. The temperature of the coating in real working conditions was measured; the pulse shape was fitted with the waveform resulting from a thermal model of the coating over the copper substrate, in slab geometry.
The code solves the partial differential equation for heat transport with given deposition profile in the coating layer: the spatial and temporal evolution of the coating temperature depends mostly on its diffusivity. A good agreement with experimental data was obtained for a 0.5 s. shot, provided the substrate diffusivity is taken around 2.73 10^{-7} m^2 s^{-1}, less than half the values found in literature [3,4].This is explained as either due to a greater porosity obtained in the plasma spray process or a weakened contact between the small drops constituting the plasma sprayed ceramics or with the copper layer, due to repeated thermal cycling.

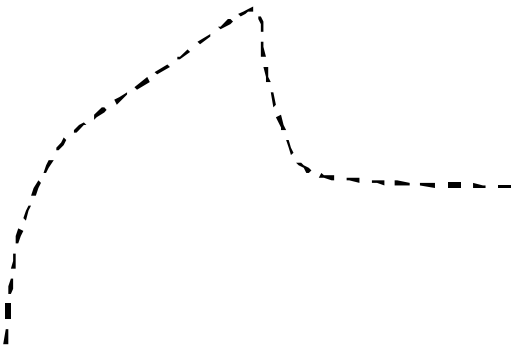

Fig. 3: IR temperatures of the coating during shots.

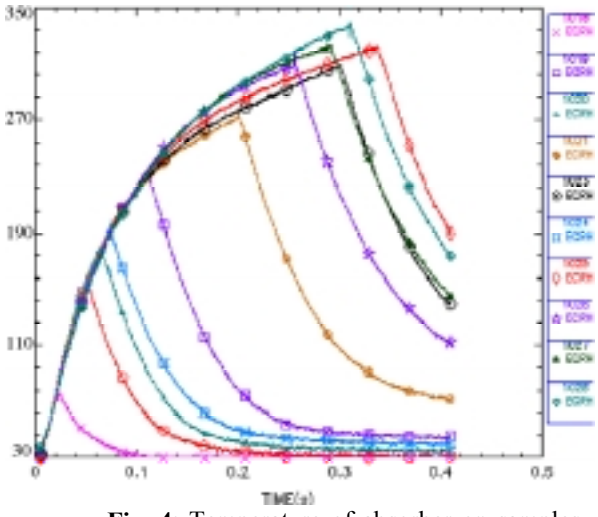

Fig. 4: Temperature of absorber on samples.

The effect of higher power densities on samples placed near the edge of the beam has been investigated. At higher temperatures than observed in the sphere, a new effect appears: above a certain threshold the temperature of the coating increases faster, pulse after pulse, as one can see from fig 4, where pulses of the same power, but different length, were overlapped. The slope of the curves can be clearly seen to vary after 100ms, showing a larger power absorption. Analysis of the temperature recovery time constant also shows that cooling becomes slower when the anomalously high absorption appears, indicating a permanent change in the thermal diffusivity that leads to the runaway process. The thermal conductivity of the samples can be inferred, knowing the incident power density on the measured area of the substrate, even if the presence of steep gradients in the power density (and as a consequence in the local temperature) at the beam edge makes the analysis with the slab code less accurate.

Measurements of electromagnetic properties

The electromagnetic properties of any candidate material (table 1) must be measured to allow the proper choice of thickness for achieving the required absorption level with a sufficiently thin deposit.

The complex dielectric constant of the sample material deposited on a thick metal substrate can be inferred from free-space reflection measurements.

The material reflectivity was estimated by the ratio of power reflected from the metallic side of the target and the one reflected from the deposit side. The target support allows reproducible positioning. The measured on-axis power was used in computing the ratio, which is correct as long as the substrate is flat.

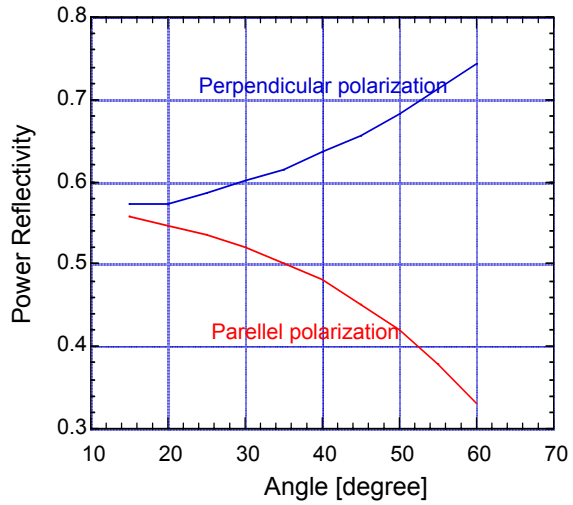

Fig. 5: Reflectivity at fixed frequency

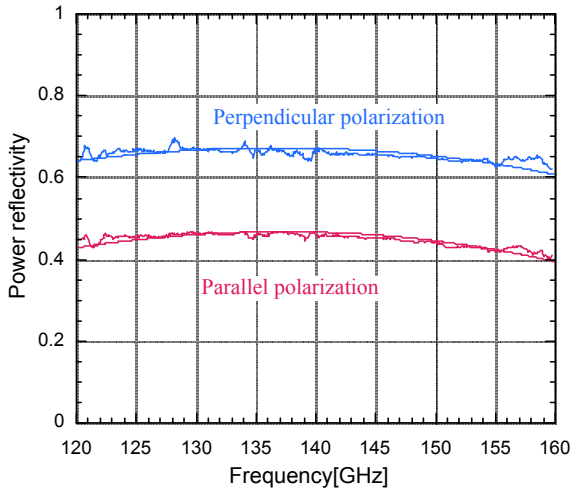

Fig. 6: Reflectivity at fixed angle

The reflectivity was measured at first for all samples at fixed angle of incidence (15°) and fixed frequency (140 Ghz) only for the polarization perpendicular to the plane of incidence. Then, only for suitable samples, varying the angle of incidence between *15* and *60 deg*, for both polarizations, parallel and perpendicular to the plane of incidence, and for the largest range of frequency easily achievable *(120–160 GHz)* with the vector network analyzer we used. Only the amplitude information was used in the analysis, though (fig. 5).

The dielectric constant was found with a least-squares fit between experimental data and the predictions of a model. The model assumes that the incident wave is plane, the metal substrate is a perfect conductor, the sample deposit is an infinite homogeneous slab and the dielectric-metal interface is abrupt and perfectly smooth. The model used for wave propagation inside the dielectric is general for arbitrary lossy, homogeneous, isotropic, linear materials.
When the deposit thickness is precisely known, the reflection measurements allow the estimate of the dielectric constant**.** Fig. 6 shows the comparison between experimental data and model predictions in a sample case, as a function of frequency at fixed angle.

The choice of coating
The choice of the candidate coating for an optimum use, according to the operative conditions of bolometric loads (1MW-CW power capability), mainly regards some physical features such as: good absorption capability to microwave in the range 120-160 GHz, high thermal conductivity, high melting temperature and thermal shock resistance. Among the considered deposits, alumina based coatings have been rejected, even in presence of low reflectivity to microwaves. As a matter of fact, in depth analysis with various techniques - ESEM (Environmental Scanning Electron Microscopy), micro-analysis with X-ray EDS, Differential Scanning Calorimeter (DSC), X-ray diffraction analysis (XRD) - showed that repeated exposure to high energy flux causes the degradation of the absorber. The main constituents of such coating, γ-Al_2O_3 is subject to a phase transition for temperatures above 950 °C turning into α-Al_2O_3 (Corundum). The associated density change thus may cause the coating deterioration and detachment from the substrate [5]. Other investigated deposits such as: NiCoCrAlY alloy, ZnO, ZrO_2-Y_2O_3, ZrO_2-10Y_2O_3-18TiO_2, TiO_2 have not been considered because of the high reflectivity (>90%) at low power measurements at 140 GHz (table 1).

Two ceramic coatings (Cr_2O_3 e la ZrO_2-$8Y_2O_3$) revealed good structural and electromagnetic characteristics to be elected as valid substitute of Al_2O_3-$13TiO_2$. Table 2 shows the relatively high thermal diffusivity and melting temperature of Cr_2O_3 as well as the high melting point for ZrO_2-$8Y_2O_3$. This latter is known to have its chief application as Thermal Barrier Coating (TBC) in gas turbines for its good TEC (Thermal Expansion Coefficient) and low thermal conductivity. For this reason thick deposits of about 1.5 mm against state of the art 0.5 mm have been recently procured with a porosity up to 20 % [6].
The present application requires the thermal conductivity to be as high as possible in order to rapidly transfer heat to the cooling system. As a reference the actual ZrO_2-$8Y_2O_3$ specimens have been obtained using standard spraying parameters as those employed for TBC applications. Moreover the resistance at thermal shock is better of Cr_2O_3 because his TEC is near that of copper.
The coatings we examined for this preliminary survey tests in order to identify suitable ceramic materials, have been obtained with APS technique using a Sultzer Metco F4 plasma gun.

Table 2: Comparison between physical features of some coating with respect to the copper. (The Science and Engineering of Thermal Spray Coatings – L. Pawlowski) . The last column contains information about the powders really employed (*).

	(m^2/s)	(W/m*°C)	(Mpa)	(1/°K)	°C	%	μm
	x10 $^{-6}$			x10 $^{-6}$			
Al2O3-13TiO2	1 (300 °K)	2	30	8.0	2050	4÷9	-53+15
Cr2O3	1.3 (900 °K)		20	7.5	2330	2÷5	-45+22
ZrO2-8Y2O3	0.2	0.6		10.9	2400	10÷14	-90 +15
Bond Coat (NiAl)	4 (900 °K)	10		14.9		<1	-106 +45
Copper		390		17.0	1083		

Conclusions
Two coating materials have been selected among a number of ceramic and non-ceramic deposits**.** They have absorption capabilities to microwave radiation in the range of 120-160 GHz as good as those of Al_2O_3-$13TiO_2$, but with better characteristics in terms of TEC (ZrO_2-$8Y_2O_3$ as discussed above), melting temperature and thermal diffusivity (Cr_2O_3).
The coating deposits obtained using APS technique are prone to further improvements in terms of thermal conductivity using VPS (Vacuum Plasma Spray). This technique should reduce open porosities thus providing better adhesion and density which are the key issues to rise the maximum thermal flux to the deposit for fixed surface temperature.
Another perspective is to employ a bond coat between the top coat and the copper support, with an intermediate TEC (see table 2 for NiAl), thus allowing thermal shock resistance to be further improved.

ATMOSPHERIC PRESSURE PLASMA LIQUID DEPOSITION – A NEW ROUTE TO HIGH PERFORMANCE COATINGS

Stuart Leadley, Liam O'Neill, Andy Goodwin

Dow Corning (Ireland) Ltd., Owenacurra Business Park, Midleton, Co.Cork, Republic of Ireland.

Plasma enhanced coating processes are well known as a route to well adhered, conformal, high performance coatings. These processes deliver industrial coatings without the need for solvent, surfactant and drying ovens. However, application has often been restricted to high value opportunities as plasma processes typical operate at reduced pressure, with high capital cost and batch wise operation.

By combining Atmospheric Pressure Glow Discharge (APGD) technology with a unique precursor delivery system Dow Corning Plasma has developed a new coatings approach – Atmospheric Pressure Plasma Liquid Deposition. Operating at atmospheric pressure and ambient temperature this process allows the use of a wide range of liquid precursors delivering high coating rates onto flexible substrates. Patented APGD equipment enables the treatment of wide area substrates in true reel-to-reel conditions. Substrates can be both insulating and conducting. The apparatus and process will be described, with a summary of unique coating chemistry that is achieved.

Deposition of protective hydrophobic thin films in surface discharge at atmospheric pressure

Abstract
In the present paper an atmospheric pressure deposition technique has been introduced enabling to protect the paper or pulp board surface with thin films with desired surface properties, permeability and wear resistance. The protective hydrophobic films were deposited by means of surface barrier discharge using different mixtures of organosilicon monomers with nitrogen. The water permeability of thin film substrate system decreased more then 5000 times. The surface free energy decreased from 53 mJ/m^2 (uncoated paper) to 9-20 mJ/m^2 due to protection with plasma deposited thin polymer organosilicon film.

1. Introduction

Even in our electronic age the paper remains the most common information carrier. In 19th century, the technology of the paper fabrication changed in order to decrease the manufacturing costs. However, this fact caused succesive decrease in quality, mainly in resistance against the air pollution, humidity and UV radiation [1]. One way to suppress the above mentioned degradation processes and improve the paper strength may be the deposition of thin protective transparent coating on the paper surface. The film can protect the paper not only against the aggressive environmental conditions but also against natural disasters as floods etc.
Plasma enhanced chemical vapor deposition (PECVD) techniques enable to prepare coatings with well-defined wetting and sticking behavior. The disadvantage of the low-pressure PECVD techniques is that they demand expensive vacuum pumping systems [2]. Moreover, there are difficulties to arrange the deposition system for large area depositions. Recently plasma deposition at atmospheric pressure becomes a promising technology due to its economical and ecological advantages [3].

The objective of the present work is to develop technique for deposition of thin films with desired surface properties, permeability and wear resistance on paper by means of atmospheric pressure surface barrier discharge. The decrease in surface energy and permeability may enable protection of wettable materials against deterioration due to soaking of liquids. Thanks to good mechanical properties of the deposited films the covered paper is reinforced. Moreover, the films deposited from organosilicons have high absorption down to 200 nm that is why this coating protects paper against the UV radiation.

2. Experimental

The deposition of thin films was carried out by barrier surface discharge at atmospheric pressure with the operation frequency of 5 kHz. The surface discharge was created on the surface of the insulating glass plate, which was from one side fully covered with metal electrode. On the other side of the glass plate the metal electrode consisted of 9 connected rotating rods with 9 mm of spacing. The rods were 6 cm long. The whole arrangement was placed in deposition chamber. The paper strips

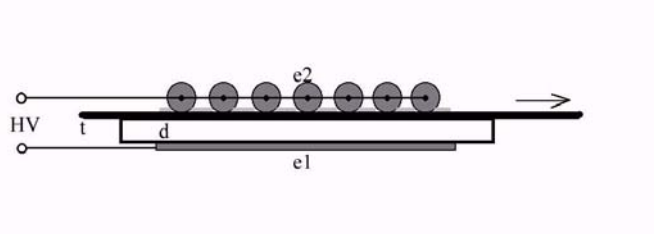

Fig. 1 Configuration of the deposition reactor. The bottom metal electrode is marked as e1, the upper rotating electrodes are marked as e2, d is the insulating glass plate, t is the paper strip and the arrow indicates its movement.

were drawn with controlled speed through the chamber between the metal electrodes and the glass insulator plate. The discharge appeared along the insulator and the substrate surface in the decreasing initial electric field from the side of the thin metal electrodes. The surface power density was kept at 0.4 W/cm^2 in all cases. Configuration of the reactor is shown in Fig. 1.

The films were deposited from different mixtures of organosilicon monomers (hexamethyldisilazane - $C_6H_{19}Si_2N$ - HMDSZ, hexamethyldisiloxane - $C_6H_{18}Si_2O$ - HMDSO) with nitrogen. The nitrogen was bubbled through liquid HMDSZN or HMDSO monomers. The flow rate of nitrogen Q_{N2} was kept at 6 l/min. The organosilicon to nitrogen flow rate ratio Q_{org}/Q_{N2} was varied between 0.01 and 0.2 in order to optimize the coating properties.

Filter paper was used as a substrate because of its similar properties to pulp. The film total surface energy was investigated by means of the sessile drop technique using the Surface Energy Evaluation System (SEE System) developed by our research team [4]. The contact angles were measured directly from the images of the solid-liquid meniscus of a liquid drop set on a solid, taken with CCD camera. The liquids used for the testing and their surface parameters are listed in Table I.

The surface free energy of the deposited films was calculated according Lifshitz-Van der Waals/acid-base approach proposed by van Oss, Good and Chaudury [5]. This method enables to determine the electron-acceptor and electron-donor parameters of the surface tension.

The total surface tension is a sum of its apolar and polar components

$$\gamma = \gamma^{LW} + \gamma^{AB}, \tag{1}$$

where LW indicates the total apolar (dispersive) Lifshitz-Van der Walls interaction and AB refers to the acid-base or electron-acceptor/ electron-donor interaction according to Lewis.

The surface energy can be calculated according to Young-Dupré equation expressed by terms as acid component γ^+ (acceptor effect) and basic component γ^- (donor effect)

$$(1+\cos\theta_i)\gamma_i = 2\left(\sqrt{\gamma_i^{LW}\gamma_j^{LW}} + \sqrt{\gamma_i^+\gamma_j^-} + \sqrt{\gamma_i^-\gamma_j^+}\right), \tag{2}$$

where i refers to liquid and j refers to solid material. The values can be determined from contact angle measurement with three liquids of which two must have polar component. The polar component is given by

$$\gamma^{AB} = 2\sqrt{\gamma^+\gamma^-}\ . \tag{3}$$

Testing liquid	γ [mJ·m^{-2}]	γ^{AB} [mJ·m^{-2}]	γ^+ [mJ·m^{-2}]	γ^- [mJ·m^{-2}]	γ^{LW} [mJ·m^{-2}]
Water	72,8	51,0	25,50	25,5	21,8
Glycerol	64,0	30,0	3,92	57,4	34,0
Ethylene glycol	48,0	19,0	3,00	30,1	29,0
Diiodomethane	50,8	0	0	0	50,8

Table. 1 Surface tension parameters of the testing liquids used for the contact angle measurement.

The wetting properties were studied by means of industrial permeability tests. The permeability was measured as time necessary for penetration of 5 ml of testing liquid through the sample to special wettable paper ERT FF3. This measurement is consistent with the norm ISO 9073-8:1995.

The composition of the film was studied by means of Fourier Transform Infrared Spectroscopy (FTIR). The refractive n and absorption k indices were determined by means of the optical transmission measurement (OT) obtained by spectrophotometer LAMBDA4. The mechanical properties were studied by means of the depth sensing indentation technique using a Fischerscope H100 tester. In the case of the mechanical tests polycarbonate plates were used as the substrate. The morphology of the paper surface before and after deposition was observed using a Philips SEM 505 scanning electron microscope.

The discharge was studied by means of the optical emission spectroscopy. The spectra emitted by the discharge were recorded by the Jobin – Yvon TRIAX 550 monochromator, equipped with CCD detector cooled by liquid nitrogen.

3. Results and discussion

In the first part of the presented study, the discharge properties are investigated by optical emission spectroscopy. The free surface energy of the coated papers and wettability are studied in second part. Optical parameters are investigated in next subsection, morphology and mechanical properties of the systems are presented in last part.

3.1. Optical emission spectroscopy

Emission spectra of the discharge in nitrogen were recorded in the range 300 – 800 nm. A typical spectrum of the discharge created in mixture of nitrogen and HMDSZ vapours is shown in Fig. 2. The spectra recorded for HMDSO/N_2 mixture are very similar to the spectra of HMDSZ/N_2 mixture.
The spectrum is plotted in the range 300 - 500 nm, because above 500 nm only the second spectral order was registered.

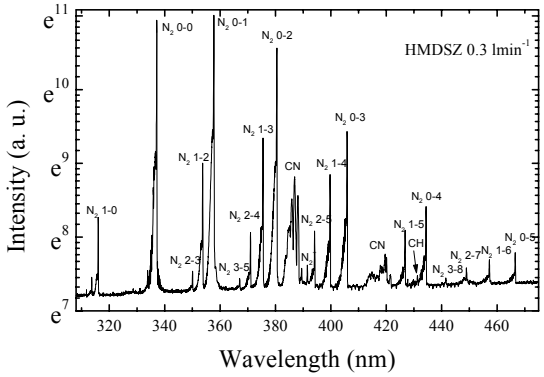

Fig. 2 Emission spectrum of the surface discharge in nitrogen with admixture of HMDSZ

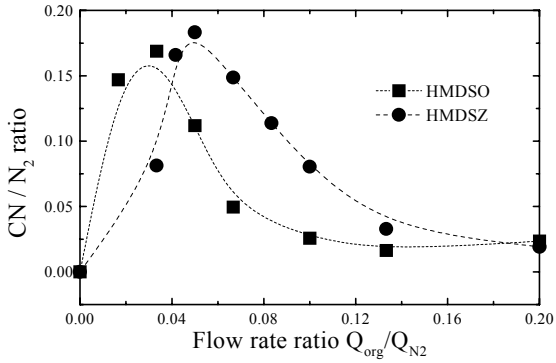

Fig. 3 Ratio of integrated intensities of CN and N_2 bands for different flow HMDSO to N_2 and HMDSZ to N_2 flow rate ratio.

The spectra consist of the molecular bands of second positive system of nitrogen ($C\ ^3\Pi_u \rightarrow B\ ^3\Pi_g$). When organosilicon monomer was mixed into nitrogen, intensive bands of CN violet system ($^2\Pi \rightarrow\ ^2\Sigma$) at 388 nm and 422 nm were observed. The weak band at 431 nm belongs probably to CH system ($^2\Delta \rightarrow\ ^2\Pi$).
Intensity of N_2 and CN system depends on the organosilicon to nitrogen flow rate ratio Q_{org}/Q_{N2}. Therefore integrated intensity of the CN band at 388 nm and integrated intensity of N_2 system was calculated. The ratio of integrated intensities of CN and N_2 bands as a function of organosilicon to nitrogen flow rate ratio Q_{org}/Q_{N2} is shown in the Fig. 3. The CN/N_2 ratio at the beginning increases with increasing flow rate of organosilicon, than it decreases. The maximum decomposition of monomer is at Q_{org}/Q_{N2} = 0.03 for HMDSO, however in the case of HMDSZ the maximum is shifted to Q_{org}/Q_{N2} = 0.05.
The vibrational temperature was calculated from the bands of second positive system of nitrogen N_2 0-2, N_2 1-3 and N_2 2-4. The value of the vibrational temperature varied only slightly with flow rate of organosilicon admixed to pure nitrogen, and its value was at about 1800 K in all cases.

3.2.Surface energy and wettability

Highly hydrophobic thin polymer-like layers were deposited on the filter paper surface in order to protect it against the water penetration. Because of well known hydrophobation effect of silicon [6], organosilicon monomers mixed with nitrogen were used to create protective layers. The deposition time was 90 s. We

tested the wetting properties of the prepared coatings by permeability tests. All tested coatings were well resistant and thick enough to protect the whole paper surface against the penetration of water. As the water of testing volume 5 ml dropped on the coated filter paper did not soak even after 10 hours, the permeability test was stopped after achieving this time.

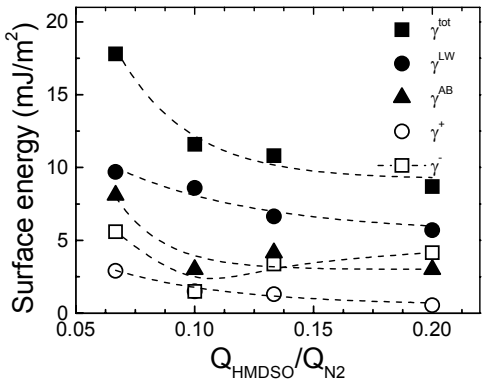

Fig. 4 Dependence of the coating total surface energy γ^{tot} and its apolar γ^{LW}, polar γ^{AB}, acid γ^+ and base γ^- components on the HMDSO to N_2 flow rate ratio.

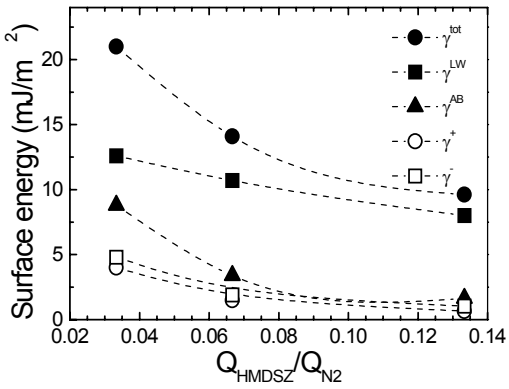

Fig. 5 Dependence of the coating total surface energy γ^{tot} and its apolar γ^{LW}, polar γ^{AB}, acid γ^+ and base γ^- components on the HMDSZ to N_2 flow rate ratio.

Figs 4 and 5 show free surface energy and its polar and apolar parts as a function of monomer (HMDSZ or HMDSO) to N_2 flow rate ratios. Similar behavior was observed for both types of films i.e. the total free surface energy exponentially decreases with increasing monomer to N_2 flow rate ratio. While the apolar part of surface energy changes only slightly, the polar part of free surface energy exhibits more significant changes. The acidic and basic components of polar part of free surface energy are plotted too. However, these values are only informative, due to high experimental error in this case.

3.3 Chemical composition

The chemical composition was investigated by means of FTIR spectroscopy. The characteristic spectra of the film deposited from HMDSO and HMDSZ are shown in Figs 6 and 7. Most dominant are absorption peaks at

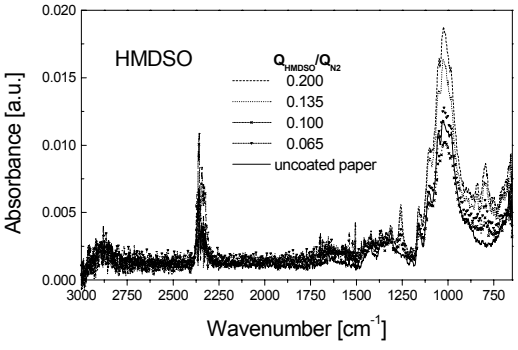

Fig. 6 FTIR spectrum for coatings prepared from HMDSO/N_2 mixtures.

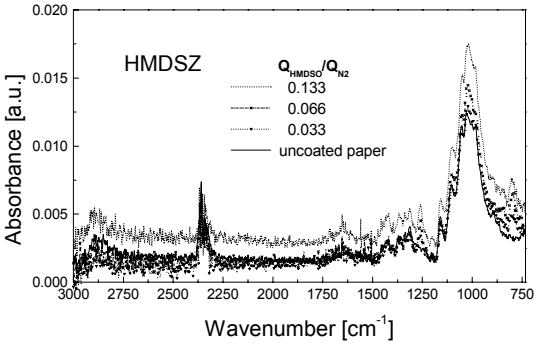

Fig. 7 FTIR spectrum for coatings prepared from HMDSZ/N_2 mixtures.

760-860cm^{-1} corresponding to Si-C stretching bonds. The increase at 1000 - 1130 cm^{-1} can be correlated with Si-O-Si or Si-O-C stretching bonds. The CH_3 bonds represent small absorption peaks at 1255 -1280 cm^{-1}

3. 4. Structure, morphology and mechanical properties

An important result is, that the plasma deposition of the hydrophobic films did not affect the appearance of the paper surface, i.e. we did not observe any yellowing of the substrate material. Moreover the morphology of the filter paper did not change during the plasma deposition (see SEM micrographs illustrating the surface morphology of the paper before and after plasma deposition on the Fig. 9). The coatings exhibited good abrasion resistance and the microhardness of the films deposited from organosilicon/nitrogen mixtures (measured on films deposited on polycarbonate plate) was about 0.1 -0.2 GPa. This value is comparable with the microhardness of wide range of polymer materials.

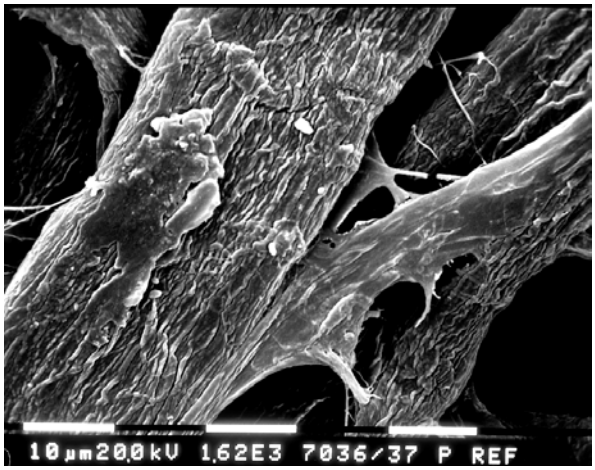

Fig. 8 SEM micrograph of the uncoated paper surface

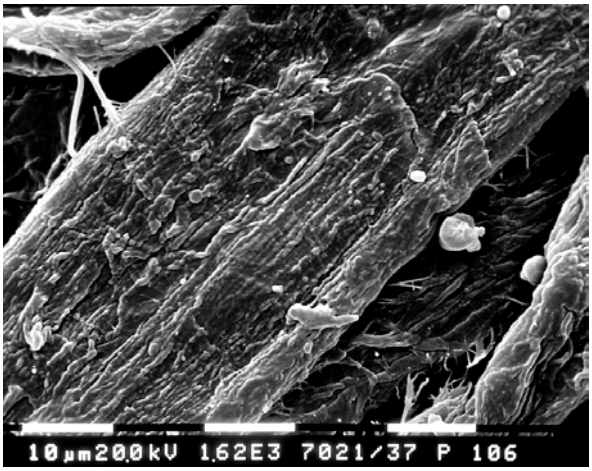

Fig. 9 SEM micrograph of paper surface coated by hydrophobic protective film

4. Conclusion

A new deposition technique based on atmospheric pressure barrier surface discharge was developed in order to protect the paper surface against air pollutant, humidity and UV radiation. Highly hydrophobic plasma polymer coatings were deposited on the filter paper substrate from mixtures of organosilicon monomers with nitrogen. The free surface energy decreased from 53 mJ/m^2 for the uncoated paper to about 9 -17 mJ/m^2 (HMDSZ/N_2, 11-22 mJ/m^2 and (HMDSO/N_2). A substantial decrease of the water permeability was achieved in all cases. The water permeability decreased in the case of the organosilicone/nitrogen mixtures at least 5000 times already after one minute of deposition. This deposition technique may enable for example the utilisation of the pulp board made of waste paper as ecological containers.

Abstract
The present study deals with the deposition of acrylic acid thin films by RF PACVD. This kind of surface modification is suitable for biomedical application to control proteins adsorption and to surface immobilization of bioactive molecules. Plasma diagnostics, surface analysis and physical-chemical characterisation have been performed in order to relate the deposition processes to the film properties. The protein attachment kinetics, as well as the cells growth are presented and discussed.

1. Introduction

Low-pressure plasma processes have been widely recognised as technology of choice for the functionalisation of the material surfaces to control the biological response of the host (human body) to improve the biocompatibility. One of the advantages that plasma techniques offer is the possibility to modify very first layers of the surface, keeping the bulk material properties unchanged [1, 2]. Plasma treatments and plasma deposition of films are easily controllable by choosing suitable precursors and appropriate plasma conditions. Moreover, in case of polymers, the selectivity (or density) and the mobility of the functional groups on the surface can be varied to some extent by changing the degree of crosslinking. Thus, biomedical materials can be engineered with different surface properties in order to improve and control their compatibility with the biological fluids. Among the wide spectrum of possible treatments, plasma polymerisation of acrylic acid (PPAA) has proven to provide highly functionalised surfaces, with a high retention of the monomer structure and high density of –COOH groups. This kind of surface modification is suitable either to promote and control cellular growth [3] and for immobilisation of bioactive molecules [4]. Therefore one of the key issue in this deposition process is the stability of the films in liquid environments. In the present article, we report results on the PPAA films by rf-plasma assisted chemical vapour deposition (PACVD). The plasma parameters were investigated by means of plasma diagnostics, while surface analysis and physico-chemical characterisation of the coatings have been performed in order to explore possible relation between the deposition processes and the film properties.

2. Materials and method

The source used for the deposition is a Capacitively Coupled Plasma source described in detail elsewhere [5]. The plasma chamber consists in a cylindrical stainless steel vessel (Φ = 210 mm, h = 350 mm) in which the part to be processed is placed and the process gases introduced at reduced pressure (10^{-3} to 1 torr). The plasma discharge between the two internal SS parallel plate electrodes is sustained by a RF unit operating at 13.56 MHz. Samples are placed on the powered electrode, while the upper one is grounded. The electrodes are located at the half height of the plasma chamber and the distance between them is of 5 cm. The liquid precursor (Acrylic Acid of > 99% purity from Aldrich Chemical Co) is vaporised from a heated vessel connected to the reactor. The monomer is injected through the upper electrode at a constant flow rate (ϕ) of 5 sccm, and it The working pressure is fixed at 50 mTorr, whilst the RF power range explored is between 5 and 60 Watts. Finally, the deposition time is fixed to 15min.

Plasma phase diagnostics are performed both with mass spectrometry (MS) and with optical emission spectroscopy. Mass Spectral analyses are realised with a Hiden HAL PSM spectrometer interfaced to the deposition chamber. The sampling aperture (30 μm) is at the geometric centre, in the middle of the electrodes. The signals are collected in Residual Gas Analysis (RGA) and in Secondary Ion Mass Spectrometry (SIMS) mode. Optical Emission Spectroscopy (OES) is performed with a Chromex 500IS/SM spectrometer having a 50 cm focal length for a theoretical resolution of 0.08 nm. The associate detector is an air-cooled CCD camera (DV401-UV CCD2477 Andor Technology). A 600 μm diameter fused silica optical fibre is used to transmit the signal to the spectrometer. The optical detection is made through a quartz window. A semi-quantitative evaluation of the species present in the different conditions is obtained by using the actinometric approach [6, 7]. Argon is used as actinometer in concentration of 5% of the total flux.

The chemical characterisation of the deposited films is performed by X-ray Photoemission Spectroscopy (XPS) and Fourier Transformed Infrared Spectroscopy (FTIR). The XPS analyses are performed with a Nanoscan 50 (Cameca, France) instrument with non-monochromatic MgK_α radiation (12 KV, 20 mA) X-ray source. Spectra are acquired at a take-off angle of 45°, with an energy resolution of 1 and 0.5 (CAE mode), and 0.1 eV of step width. On each sample, a survey scan (0-1100eV) is recorded together with high-resolution scans for the C1s and O1s regions. Sample charging was between 3 and 6 eV and has been corrected for by setting hydrocarbon to 285 eV. All fittings were performed using a commercial software package (XI-SDP, XPS Int., USA). Curve fitting of C1s peaks was carried out using the same initial conditions and inter-peak constrain, with a G/L mix of 0.7-1, and a total intensity of β-shifted carbon constrained to be equal to that of the carboxylic acid component [8].
The FTIR Spectra of the coatings are acquired in transmission mode using a Perkin Elmer 1600 spectrometer with 8 cm^{-1} of resolution.
The protein adhesion experiments were studied with the QCM-D technique (from Q-Sense AB, Göteborg, Sweden) is used in order to study the protein adsorption kinetics. The detection principle of this technique is described by Rodhal et al. [9]. Briefly the Quartz Crystal Microbalance sensor is an AT-cut piezoelectric-crystal usually coated with thin metal film electrodes deposited on its faces. The crystal is induced to oscillate in the thickness share mode at its fundamental (or an overtone) resonant frequency by applying a RF voltage across the electrodes. A mass added to the electrodes induces a decrease in the resonant frequency; the relationship between Δm and the relative Δf is given by the Sauerbrey's equation [10]:

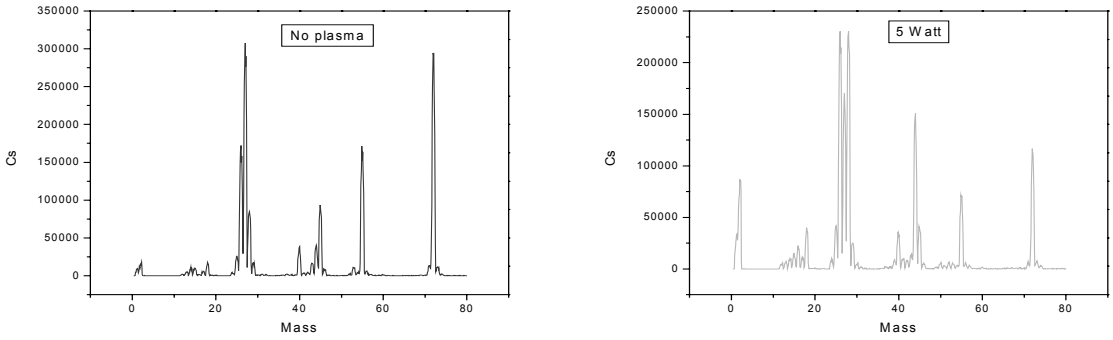
$$\Delta f = -\Delta m/nC \qquad (1)$$

where C is the mass sensitive constant and n is the overtone number. Usually a mass load introduces dissipative losses in the oscillating systems; in such cases also the dissipation factor (D) has to be considered. When the voltage is switched off, the voltage over the crystal decays as an exponentially damped sinusoidal. By recording the decay voltage and by numerically fitting the relative curve, both the resonant frequency and the dissipation factor of the crystal are obtained simultaneously in real time. Therefore the frequency and the dissipation shifts caused by the adsorption of the proteins to the crystal surface can be measured as a function of the time. The frequency and the dissipation shifts caused by the adsorption of the proteins to the crystal surface are measured as a function of the time. Human Serum Albumin in water (1 μg/ml) was used in order to test the first biological response to PPAA obtained in different conditions and with different surface properties. The measurements were performed at 37 °C.
Scanning probe experiments were performed with a commercial Atomic Force Microscope, AFM, (SMENA head, Solver electronics, NT-MDT Zelenograd, Moscow, Russia). All measurements were done directly on QCM crystals after experiments in the Q-Sense, positioning the scanning probe in the crystal active zone using the optical microscope integrated with the AFM. Measurements were done in Milli-Q water using standard Si_3N_4 cantilever (NT-MDT) in resonating mode (ν_{res} = 65 KHz) in order to prevent possible surface damages..
CRL-1999 cells, human endothelial fibroblast from smooth muscle of aorta, were cultured in Ham's F12K medium with 2mM L-glutamine, 1.5 g/L sodium bicarbonate (Gibco Life Technologies Italia S.r.l) supplemented with 10% of Fetal Bovine Serum (Gibco Life Technologies Italia S.r.l), 10 mg/ml insulin, 10 mg/ml transferin, 10 ng/ml sodium selenite and 20 mg/ml endothelial cell growth supplement (Sigma-Aldrich S.r.l.). CRL-1999 cells were counted in a hemocytometer and resuspended in medium (Sigma-Aldrich S.r.l.). $30x10^5$ cells per chamber were then plated onto the coated 4-chambers slide and $60x10^5$ cells per well onto coated 6-well plates and incubated at 37°C, 5% CO_2 and 100% of humidity. The cells growth was controlled with an inverted optical microscope after 2h, 24h, 48h, 96h and 1 week of incubation.

3. Results and discussion

The plasma phase is first characterised with MS and OES. Characteristic Electron Impact (EI) mass spectrum peaks of neutrals for an acrylic acid plasma are observed at m/z 72 $M^{\cdot+}$, 26 ($C_2H_2^{\cdot+}$), 27 ($C_2H_3^{\cdot+}$), 28 ($CO^{\cdot+}$), 44 ($CO_2^{\cdot+}$), 45 (CO_2H^+), 55 (CH_2CHCO^+) (Fig.1). The MS peaks can be divided in 2 categories based on their origin, following the fragmentation scheme proposed by Candan et al. [11]. In fact the 72 and 55 peaks are due to the mass spectrometer ionisation of the "intact" acrylic acid; whilst the 26, 28 and 44 peaks are predominantly formed during the production of precursor fragments in the plasma phase, which are subsequently ionised in the mass spectrometer. In particular the peaks at m/z=17 (OH) and 28 (CO) are

followed because they are strictly linked to the monomer functionality fragmentation (-COOH) in the discharge.



(a) (b)

Figure 1: Typical Mass Spectrum of Acrylic Acid (a) without and (b) with plasma.

Even in the Optical emission Spectroscopy (OES) the OH and the CO emission systems are analysed in order to link these results to those of the MS and to the monomer functionality retention. Either Mass spectral analyses or OES measurements show that in the plasma region, the precursor fragmentation (CO and OH products) increases with the RF power injected in the plasma. Both the OH and the CO fragments have an initial fast increase and then they suddenly reach a plateau at 50 Watt of RF Power. It could mean that only at low RF Power the fragmentation degree is minimum and the COOH retention on the coatings could be high.

Furthermore the discrimination of dissociative ionisation products can be inferred from the examination of radical species of the plasma by using the Appearance Potential MS (APMS) in RGA mode [12].

Briefly, the selective ionisation of a radical (X) can be obtained from APMS measurements through the energy difference (typically grater than 2 eV) between the ionisation threshold of the radical ($E_i^{X\rightarrow X^+}$) and the dissociative ionisation threshold of the parent molecule XY ($E_a^{XY\rightarrow X^+}$). For electron energies $E_i^{X\rightarrow X^+}<E<E_a^{XY\rightarrow X^+}$, the signal measured is only due to the direct ionisation of the radical, and thus the radicals density can be estimated together with their dissociation paths. Our APMS experiments have been carried out by following the most significant MS ion peaks, i.e. m/z=72, 55, 44, 28, 26, whilst the electron energy scale has been calibrated by following the process: $Ar + e \rightarrow Ar^+ + 2e$ at 14.75 eV(EI) [13].

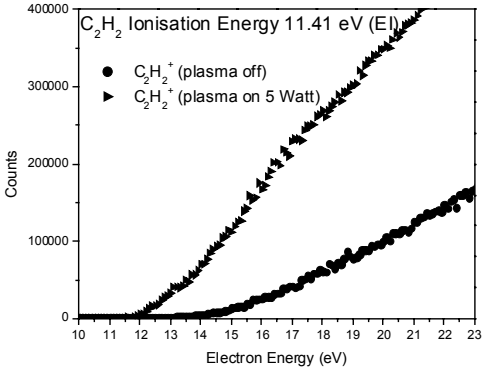
Figure 2a) shows the APMS data obtained for m/z=26, corresponding to the $C_2H_2^+$ ions. It can be seen that additional ions are produced for electron energies of 11.5 <E< 15 eV when the plasma is turned on. The plasma off curve corresponds to the fragmentation of the acrylic acid starting monomer in the MS, whilst when the plasma is turned on, additional ions are produced by the direct EI reaction: $C_2H_2 + e \rightarrow C_2H_2^+ + 2e$. The ionisation energy of the $C_2H_2^+$ is 11.41 eV (EI) [13]. The same behaviour is observed when analysing peaks at m/z=28 ($C_2H_4^+$ and CO^+ ions)

In Figure 2b) APMS data for m/z= 72 (AA^+) are illustrated; a strong decrease of signal, due to the depletion of acrylic acid is observed when the plasma is turned on. Similar results are obtained for the peak at m/z=55 ($C_3H_2O^+$).

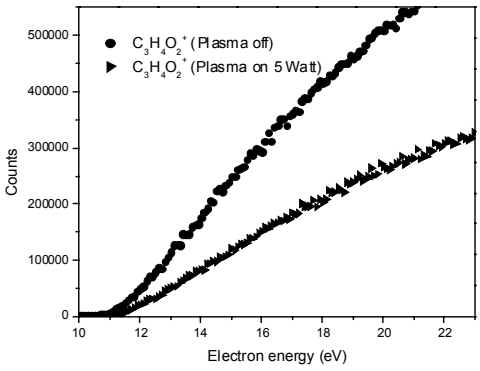
A different situation is observed for the peak at m/z= 44 (CO_2^+) (Figure 2c). In plasma on condition, the contribution of CO_2^+ fragments originating from EI in the plasma phase (13.78 eV) increases, like in the case of the m/z=26 and 28 ions. However in the plasma off condition, additional radical contributions are observed due to other fragmentation processes that could occur in the mass spectrometer. This can come from contamination products or acrylic acid dimers or trimers that the mass spectrometer can detect (for instance the formation of $C_2H_4O^+$ ions: EI= 10.14 eV [13]). However further investigations are on going to clarify this point.

The APMS results are in agreement with the considerations derived from the analysis of the neutral spectra (Figure 1) confirming the different origin of fragments and the acrylic acid fragmentation path published [11]. By following the positive ions spectra coming from the fragmentation and the ionisation of acrylic acid at different power in SIMS mode, it can be pointed out the presence of fragments above m/z 72. The ion at m/z145 corresponds to $2(M+H)^+$, and peaks in the cluster around corresponding to the addition or loss of H, the m/z 127 corresponds to $145\text{-}H_2O$. The oligomerisation in the plasma phase could be evaluated by

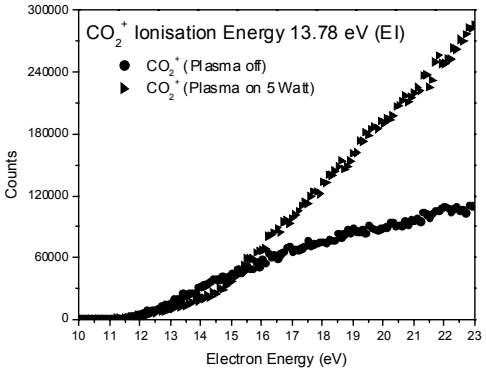
dividing these peaks to that of acrylic acid monomer. The Figure 3 shows that the RF power has a strong influence in the retention of the oligomers in the plasma phase. It can be observed a transient region between 5-10 and 20 Watt; at very low power there is a strong contribution from oligomers created in the plasma region taking part in the polymerisation process by falling down and being incorporated in the plasma coating structure. This could be a reason of the low stability of the film growth at very low power, as has been discussed elsewhere [5].



(a)



b)



(c)

Figure 2: Measured beam signal for different radicals with Plasma Off and Plasma On (at 5 Watt of RF power) respectively: (a) $C_2H_2^+$, (b) $C_3H_4O_2^+$ and (c) CO_2^+

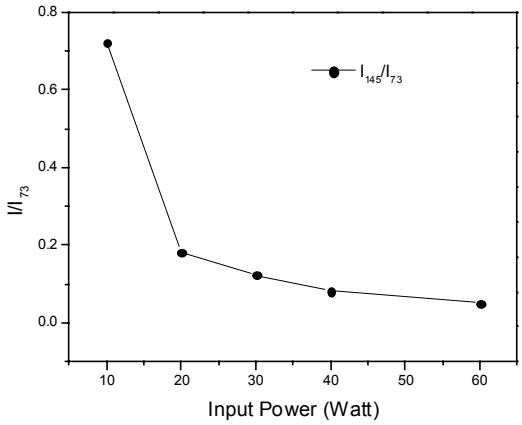


Figure 3: Intensity ratio measured at m/z 145 and m/z 73 in the positive-ion plasma mode mass spectra of acrylic acid vs power

In order to study the RF power influence on the PPAA deposited films structures, different films have been deposited at different powers 30, 40, 60 Watts respectively. From a typical XPS survey spectrum obtained for a PDAA film, only carbon and oxygen are detected. The C1s core level spectrum obtained for each sample has been peak-fitted based on chemical basis [11], starting with the hydrocarbon signal at 285 eV. Other four components are identified: C-CO_2H/R (+0.5 eV); C-O (+1.9 eV); C=O (+2.9 eV); CO_2H/R (+4.35

eV) (the values in brackets correspond to the shifts relative to the hydrocarbon positions). The C1s core level spectra analysis shows that the percentage of the peak due to COOH/R carbon in the spectra decrease as the power increases [14]. Cross-linked results are found between surface analysis (XPS) and plasma diagnostics (MS/OES): the COOH concentration in the films decreases with the CO molecules increase in the plasma phase. The next step consists in the assessment of the plasma parameters influence on the proteins and cells response. Figure 4 shows different responses to different coatings in the QCM experiments. It is clear that films with the highest retention of the carboxylic groups (deposited at low RF-power) have the highest amount of BSA adsorbed. Analysis of the morphology of the films after the protein adsorption with the AFM, reveals a different organization of the protein films onto different surfaces. The films deposited at 30 watts (Figure (5a)) permit the adsorption of the proteins in different multi-layers, showing the highest affinity versus the biomolecules adhesion; by increasing the RF power, the proteins adhere in minor extension (Figure 5(b)). For the films obtained at very high power we can observe from figure 5(c) that only few proteins are attached to the surface.

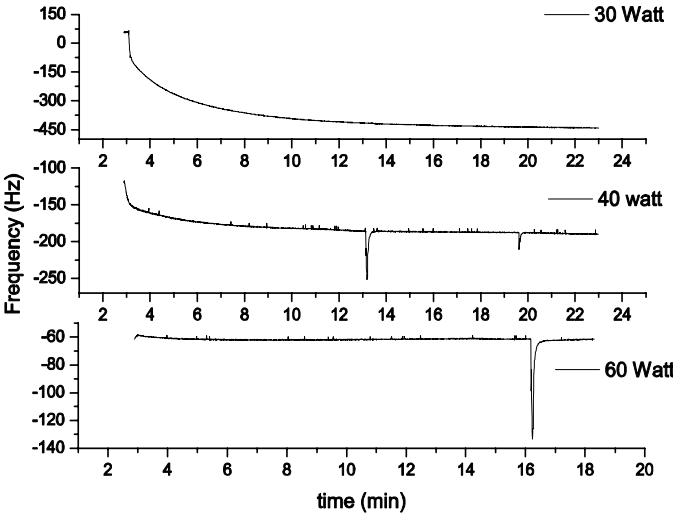

Figure 4 QCM-D results on PPAA films deposited at 30, 40 and 60 Watts

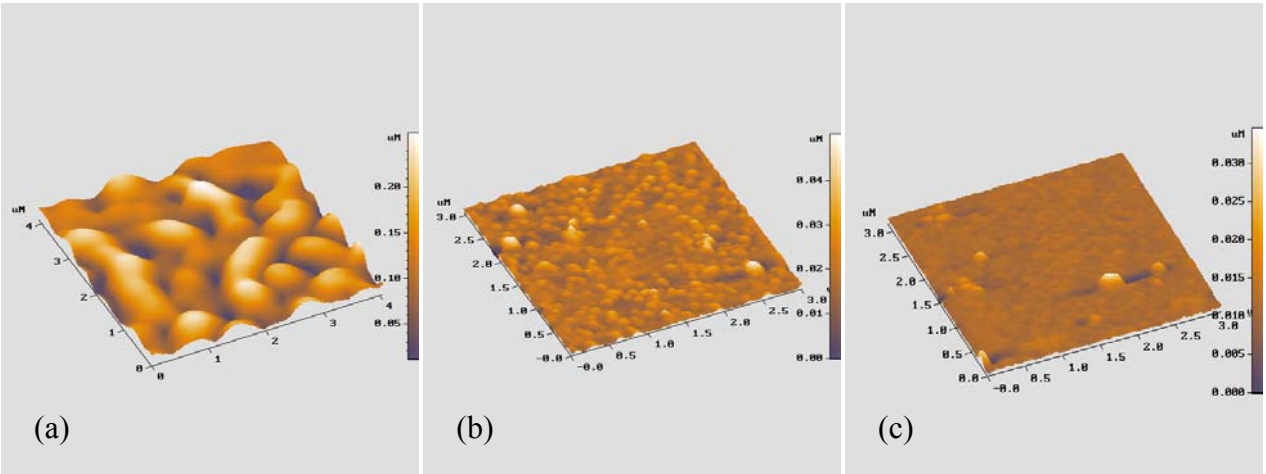

Figure 5: AFM images of BSA on PPAA films deposited at (a) 30 Watts (b) 40 Watts (c) 60 Watts.

Optical microscopy studies of fibroblast cells growth show that cells adhered well to the coated support, showing the typical morphology of fibroblast growth in monolayer, reaching the confluence after 96h of culture. In particular as shown in figure 6, for the coating deposited at low RF power conditions, the cells

reach the cellular confluence symptomatic of good cells adhesion. On the other hand a remarkable decrease of the cell adhesion is observed on the films deposited at high RF power (figure 6 (b)).

4. Conclusion

The combination of the plasma phase diagnostics and the PPAA films surface analysis is a powerful tool for drawing important conclusion concerning the plasma polymerisation processes.
It can be observed a clear distinction between conditions of low and high power. The process can be rationalised by using the Yasuda concept about an "energy- deficient region" at low power and a "monomer-deficient region" at high power [15]. By increasing the RF power the acrylic acid content in the plasma phase is depleted, and the COOH functionality retention on the deposited films decreases. On the other hand, in low power region there is a strong contribution of the oligomers formed in the plasma phase to the plasma deposition, this could be linked to the highest retention of the acrylic acid structure, but also the cause of a bad stability of the obtained films. By tailoring the deposition conditions it is possible to prepare films with different surface properties leading to diverse biological responses.

Abstract
Removal of formaldehyde by streamer corona discharge was studied. Efficiency of the removal and by-products formation in the non-thermal plasma of the discharge depending on the initial concentration, gas flow rate, carrier gas and discharge polarity was evaluated. The combined effect of plasma and catalytic pellets of various materials placed in the discharge reactor was investigated via by-products formation. Adsorption abilities of catalyst pellets combined with discharge affected the chemical process and formed by-products. An improvement compared with using plasma or catalyst only was observed for TiO_2, γ-Al_2O_3 and 13X pellets at higher input energies and long operating times.

1. Introduction

Formaldehyde is one of the most common volatile organic compounds (VOC), used mainly for the production of urea-formaldehyde resins, phenol-formaldehyde resins, plastics and intermediates. It is also used in building materials such as plywood, chipboard and panelling, released by gas cookers, found in tobacco smoke and emissions from gasoline powered motor vehicles. Numerous adverse health problems have been ascribed to formaldehyde exposure, such as eye, nose and throat irritation, to more controversial claims including asthma, cancer, chronic respiratory diseases and neuropsychological problems [1].

A number of studies have been directed to formaldehyde removal, most of them related to its removal by adsorbents, e.g. activated carbon, ceramic porous materials and composite oxidized catalyst [2, 3]. Recently a promising method of non-thermal plasma is used to control VOCs. The plasma is highly effective producing active radicals, enhancing molecular dissociation and promoting oxidation. In addition, its combination with the catalyst was found to effect the formation of active radicals, control their distribution and therefore process of treatment [4, 5].

The authors performed the research to investigate the possibilities of formaldehyde reduction from dry air and nitrogen using DC streamer corona discharge. Evaluation of removal efficiency in different conditions was made. In addition, a combination of discharge plasma with catalyst was investigated too. Pellets of various catalytic materials were placed in the discharge reactor and their effect on the decomposition and by-products formation was studied.

2. Experimental Apparatus

The used experimental reactor is depicted in the fig. 1. Discharge reactor of multi-point-to-mesh geometry was used and set inside Pyrex glass tube 35 mm diameter. The distance between electrodes was set to 16 mm. The tube was closed with silicon stoppers at the both ends. A layer of 8mm thickness composed of catalytic pellets (average diameter 2-3 mm) was placed on the mesh electrode. The investigated materials were TiO_2, Pt/Al_2O_3, γ-Al_2O_3, zeolites 13X and LZ-Y54. The formaldehyde vapours were produced by bubbling 36% liquid solution of formaldehyde by dry air or nitrogen. The total gas flow rate 0.25, 0.5 or 1.0 l/min was controlled by mass flow meters. DC high voltage power supply was used to generate streamer corona discharge. Evaluation of efficiency of the removal

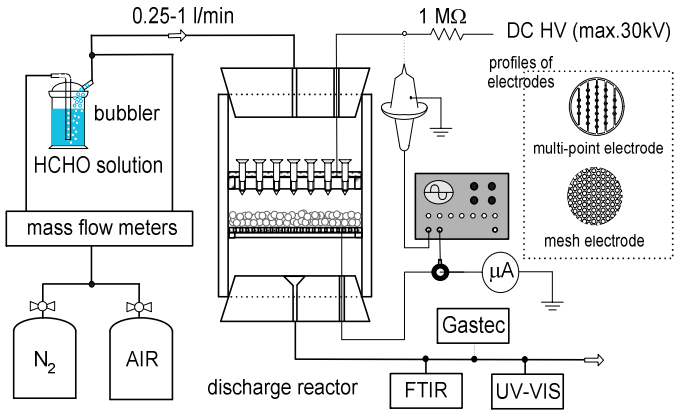

Figure 1: *Experimental setup.*

process the term of specific input energy (SIE), defined as discharge energy dissipated per unit volume of the gas, was used. The analysis of gas composition was performed using infrared spectrometry (Bio-Rad FTS-3000), ultraviolet spectrometry (Shimadzu UV-1200) and gas analyzing tubes (Gastec).

3. Experimental Results

Formaldehyde is an organic compound, which can be comfortably detected by infrared absorption spectrometry. Typical aldehydic absorption characteristics are stretching vibration of carbonyl group C=O in the region 1740-1720 cm^{-1} and aldehydic C-H stretching vibration in the 2830-2695 cm^{-1} region (fig. 2). The formaldehyde solution used for the experiment contained methanol as a stabilizer. The infrared spectrometry is effective for the quantitative and qualitative analysis of products of formaldehyde decomposition, and therefore was utilized in the experiment.

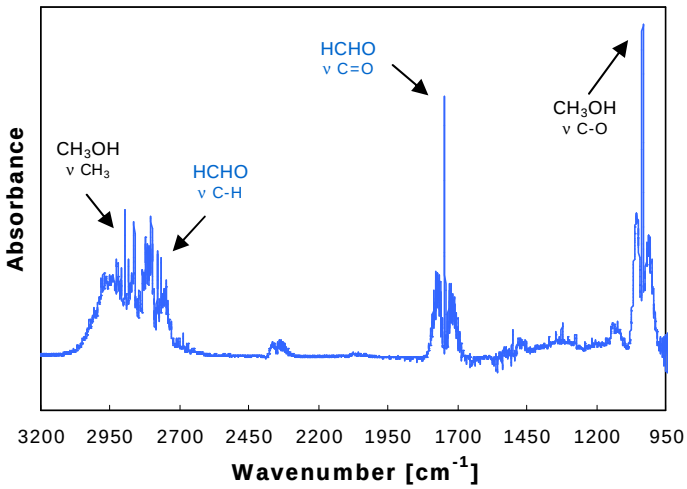

Figure 2: *IR spectrum of used formaldehyde vapours.*

3.1 Chemical Processes and By-Products

Formaldehyde decomposition results mostly into formation of carbon oxide CO and formic acid HCOOH. The formation of CO occurs most probably by photolytic reactions ($HCHO + h\nu \rightarrow HO_2 + CO$ or $HCHO + h\nu \rightarrow CO + H_2$) by light produced by streamer discharge. In dry air, where oxygen is present, CO can also be formed by reaction ($HCHO + h\nu \rightarrow H + HCO$), followed by ($HCO + O_2 \rightarrow CO + HO_2$). Oxygen in the gas mixtures also supports formaldehyde oxidation to formic acid by oxygen radicals, produced through dissociation of molecular ozone by the discharge ($HCHO + O \rightarrow HCO + OH \rightarrow HCOOH$). The reaction with ozone ($HCHO + O_3 \rightarrow HCOOH + O_2$) appeared not to be much effective. Oxidation of formaldehyde mixed with the gas containing high concentration of ozone (up to 1000 ppm) was negligible. Carbon oxide formed is expected to be further oxidized in carbon dioxide, either by ozone but rather OH radicals ($CO + OH \rightarrow CO_2 + H$, $CO + O_3 \rightarrow CO_2 + O_2$). Due to the existing oxidation process the removal is slightly better in dry air mixtures. The process of formaldehyde removal leads also to formation of many other minor products (e.g. CH_3O, CH_3OCO and CH_4).

3.2 Removal by Plasma

Removal efficiency of formaldehyde depended on its *initial concentration*. For smaller initial concentrations, higher removal efficiency was achieved. An increase of initial concentration of formaldehyde resulted in the increased formation of CO and HCOOH. Increasing SIE resulted in decrease of relative production of HCOOH and increase of relative production of CO. As follows from the carbon balance, part of CO is also produced from methanol contained in the formaldehyde solution. Increasing the *gas flow rate* from 0.25 to 1.0 l/min at the constant SIE caused more formaldehyde was removed with relatively smaller production of HCOOH and CO. As follows also from carbon balance, it can be explained by smaller decomposition of methanol at higher gas flow and better utilization of energy for HCHO removal. The effect of *discharge polarity* was examined too. Achieving the same production of oxygen radicals/ozone in both polarities (although at different SIE) resulted in approximately the same amount of formaldehyde removed.

Finally the removal efficiency of formaldehyde depends also on the *carrier gas*. At the same SIE, the removal is better in dry air mixtures, rather than nitrogen. It is because of existing oxidation processes driven by oxygen radicals. The reaction of formaldehyde with oxygen radicals can either lead to formation of HCOOH or production of CO. Generally, the production of CO is higher in dry air, while formation of formic acid was found negligible in nitrogen mixtures. Removal of formaldehyde in nitrogen mixtures is less effective, however, compared with dry air it produces less CO_2, NO_2 and N_2O.

3.3 Removal by Plasma and Catalyst

The presence of catalyst pellets in the discharge volume has been investigated for effect on removal of formaldehyde and formed by-products. A layer of catalyst pellets with the thickness of 8 mm was placed

onto mesh electrode. Catalysts were expected to affect the formaldehyde decomposition, either due to their activation by discharge (TiO_2), and utilizing their oxidative properties (Pt/Al_2O_3) both resulting in improvement of oxidative removal of small amounts of VOCs and/or to their adsorption abilities (especially zeolites).

Effects of Catalyst

The effect of catalytic material without discharge was examined from differential spectra of gas composition at inlet and outlet of reactor. The presence of the catalytic material in the discharge reactor caused concentration of formaldehyde at the outlet of the reactor decreased, due to adsorption to the surface of pellets or oxidation properties. Thus prior to the every experiment a certain time was needed (several hours) until concentration of formaldehyde at the reactor outlet saturated. The outlet concentration either almost reached the level of input concentration (e.g. TiO_2) or saturated at the value down bellow the inlet concentration, e.g. Pt/Al_2O_3 or zeolites (fig.3). Comparing the absorption spectra of the input and output gas composition, generally observed effect was specific removal of formaldehyde and methanol, without formation of by-products. Formation of CO, CO_2 and HCOOH was not observed. It can be explained by adsorption properties of the used pellets.

The effect of adsorption without by-products formation was the most evident in the cases of γ-Al_2O_3 and LZ-Y54. Using 13X, also the effective removal of water vapours was observed. Adsorption effect of TiO_2 pellets after was minimal among the used catalyst. The best result for formaldehyde removal was obtained using Pt/Al_2O_3 catalyst, which can be explained by both adsorption and effective oxidative removal of formaldehyde by catalyst. Different to all other catalysts, the removal here was accompanied by formation of CO_2 (2360 cm^{-1}) and CH_3OCO (1755 cm^{-1}).

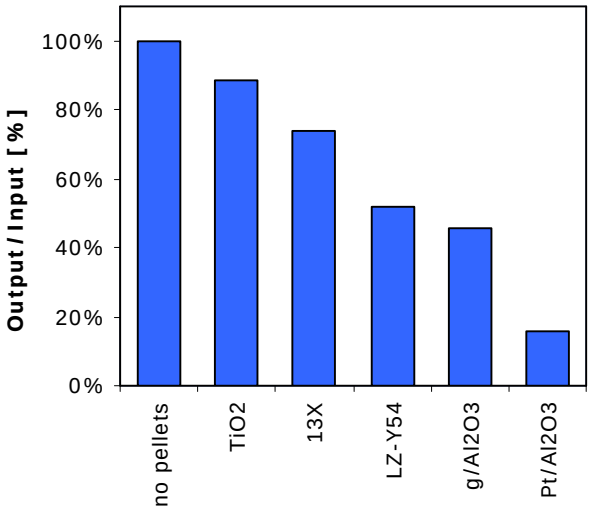

Figure 3: *Formaldehyde removal by pellets without discharge (230 ppm in air; after 12-14 hours).*

Effects of Discharge and Catalyst

The layer of catalyst pellets between electrodes resulted in smaller onset and operating voltage for a given current. The streamers generated by discharge with pellets had faster rise time and their distribution appeared to be more uniform. The discharge was more stable with minimum of random spark breakdowns (fig. 4).

Formaldehyde treatment using discharge with catalyst pellets and its development in time and depended on SIE in the case of TiO_2 pellets is reported here as an example (fig. 5). Concentration of formaldehyde was 200 ppm. An application of the discharge resulted in sudden increase of formaldehyde concentration (exceeding the initial value). Within 240 minutes during which SIE of the discharge was kept almost

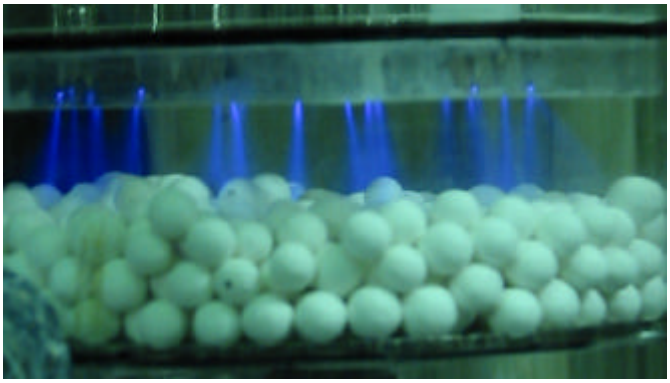

Figure 4: *Streamer corona discharge with TiO_2 catalyst placed on the grounded electrode.*

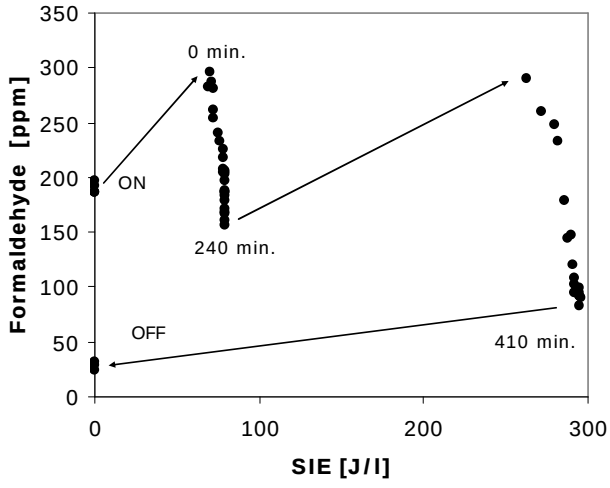

Figure 5: *Formaldehyde decomposition using TiO_2 pellets in the discharge volume (200 ppm in air).*

constant (approx. 75 J/l) the concentration decreased bellow the input concentration. Increasing SIE further (265-294 J/l) and waiting for additional 170 minutes, the amount of formaldehyde removed increased to 60% (294 J/l) slowly saturating in time. After switching the discharge off, the concentration of formaldehyde decreased a little further and then gradually started to recover toward the initial value.

The increase of the concentration of formaldehyde during the discharge with catalytic pellets can result from *desorption* of formaldehyde molecules adsorbed before the discharge. It is suggested that desorption from the surface occurs during the contact of the streamers with the surface of pellets, which increase the local temperature. In a similar way a possibility of discharge formation between catalyst pellets must be considered as another source of formaldehyde increase. Assuming TiO_2 catalyst, the concentration of formaldehyde may also increase due to its formation from adsorbed molecules of methanol $CH_3OH \rightarrow CH_3O(ad) \rightarrow HCHO(g) + H(ad)$ at higher temperatures [6], eventually formic acid $HCOOH(ad) \rightarrow HCHO(g) + ½O2$ and $2HCOOH(ad) \rightarrow HCHO(g) + CO_2 + H_2O$ [7]. The effect of desorption is the most evident after the discharge application or during sudden increase of the discharge power. In such moment desorption effect prevails the removal caused by discharge for a limited period giving a negative result of the treatment. The negative result is however recovered during long operation times and using higher SIE and is also dependent on the used catalyst material.

Comparing the results of formaldehyde removal using *different catalysts*, the relative improvement of removal efficiency was observed especially at higher SIE (> 200 J/l). The effect of treatment time was important as the concentration of formaldehyde decreased slowly and at the constant SIE more than three hours were needed for data saturation. Tendency similar to that of TiO_2 was observed in the cases of 13X, LZ-Y54 and γ-Al_2O_3. Small SIE (less than 100 J/l) gave negative result of formaldehyde removal. However increasing SIE to 300 J/l the treatment efficiency was improved, while achieved efficiency was better than using either catalyst or plasma alone (e.g. TiO_2, 13X, γ-Al_2O_3). The case of Pt/Al_2O_3 appeared to be a little different compared with the other catalyst. Although similar to other catalyst, the discharge caused concentration of formaldehyde at the reactor output increased, however further increase of SIE had negative impact on the removal efficiency. Using discharge and catalyst affects also the type and amount of by-products formed both without and with discharge (fig. 6).

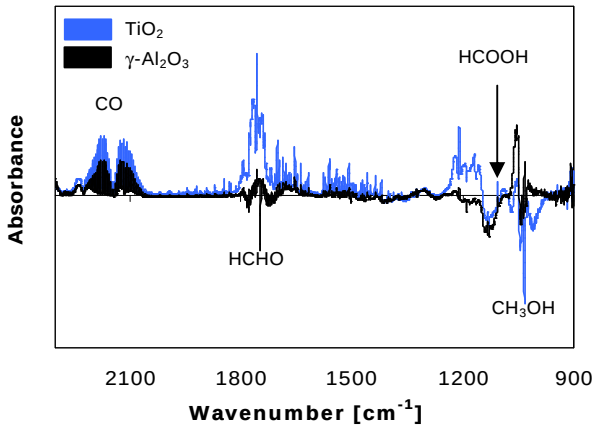

Figure 6: *Part of differential spectra for discharge with TiO_2 and g-Al_2O_3 catalyst (250 ppm HCHO, 250 J/l).*

Conclusions

The possibility of formaldehyde removal by streamer corona from the dry air and nitrogen was investigated. For a given SIE, removal efficiency increased when initial concentration of formaldehyde and decreased with the gas flow rate. Removal was more effective in dry air mixtures, due to the existing oxidation process. A combination of plasma and catalyst was investigated and improvement was observed when TiO_2, γ-Al_2O_3 and 13X pellets were used at higher SIE. Presence of catalyst affected also formation of by-products

Problems of Gas Discharge Processing of Medical Instruments

A.G.Shishkin[1] and G.G.Shishkin[2]

[1] *Department of Computational Mathematics & Cybernetics, Moscow State University, Moscow, Russia*
[2] *Moscow Aviation Institute, Moscow, Russia*

Abstract
The use of gas discharge plasma for sterilization of different types of articles is considered. The main processes of plasma sterilization and requirements to gas discharges are discussed. The role of each process is estimated. The results obtained in plasma sterilization for the last several years are analyzed. The advantages and problems of plasma sterilization technique are shown.

1. Introduction and background of plasma sterilization
Various methods have been used for the sterilization of different types of articles including disposable and reusable medical equipment, materials and foods [1]. But all of them suffer from different great shortcomings. For example, sterilization by steam or by dry heat is not useful to sterilize materials that are adversely affected by such heat or steam. Ethylene oxide gas has also been used but suffers from residues on the articles to be sterilized, which may have adverse effects, particularly on patients and demands long-time period of detoxication. Radiation sterilization has been limited to large industrial applications because of the large investment to build gamma irradiation facilities, the stringent technical controls for safe operation and change of bulk properties of some nonmetallic materials.
Gas discharge plasma sterilization has been considered for several years [2] as an alternative to heat sterilization and as a method close to an ideal sterilization. The ideal sterilization system can be summarized as follows: quick turnaround time, low temperature, versatility, low toxicity. The ideal sterilization should at least have instrument turnaround time less than one hour as modern hospital steam sterilizers have; an operating temperature should be between 45-55$^{\circ}C$ as in ethylene oxide sterilizers; the technology of ideal sterilization should be adaptable for a wide range of applications and give a good safety with respect to both operators and patients as well as to the environment in general. From a fundamental point of view glow discharge plasmas approach the features desired for an ideal sterilization systems and realize the above demands [1, 3].
In present paper we discuss the main problems of the plasma sterilization and give estimations of the main underlying processes.

2. Physical and chemical sterilization agents
Viruses and bacterial spores are the most resistant microorganisms to various sterilization methods [4]. Bacterial spores are complex structural entities (Fig.1).

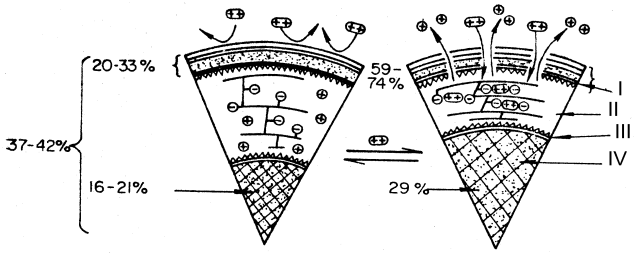

Fig.1 The surface structure of endospores. Here I is a coat, II is a cortex, III is a cytoplasmic membrane, IV is a core. The left part of the figure is a thermal stable anabiotic spore form, the right one is a thermal sensitive spore form. "+" denotes mono- and polyvalent ions, "-" denotes peptidoglycan ions, % denotes regional water content.
Bacterial endospores, that are spores formed within cells, are peculiar species of anabiotic cells. The structure of endospores includes multilayer albumen coats, outer and inner membranes, cortex and core (Fig.1). From the cytological point of view spores differ from vegetative cells primarily by its surface

structures that lie outside the cytoplasmic membrane and differ from each other drastically by chemical content:

- ?? by cortex that includes layer of mucopolymers lying between inner and outer membranes;
- ?? by covers that are the layers of protein nature covering the outer membrane;
- ?? by exosporium that is a structure lying outside the covers and having a form of wide coat (often with many layers) where the spore lies.

The cortex consists largely of peptidoglycan, and a dense inner layer (cortical membrane) develops into the cell wall of the emergent cell the cortex is degraded during germination. The inner and outer forespore membranes become the cytoplasmic membranes of the germinating spore or persist in the spore integuments, respectively. The spore coats consist mainly of protein. The RNA, DNA and most of the calcium, potassium, manganese and phosphorus are present in the spore and are located in the protoplast (spore core) [4].

The main factor that determines the ametabolic (anabiosis) state of spore protoplast is its relative dehydration. The obtained data show that dehydration of spore is of regional nature. The water content in the protoplast of intact spores is only about 16-21% (Fig.1) whereas in cytoplasm of vegetative cells it exceeds 80%. Spores have a perfect mechanism of stabilization of structures and cell macromolecules, of their defenses from the influence of both external and internal media.

Bacillus subtilis spores are very often used as a test objects. The thickness of the cell wall is 30-40 nm, the cell wall is a spongy structure with pore diameters (1-6) nm. The coat is adjoined to cytoplasmic membrane very tightly by fibralate bridges. Inner osmotic pressure of *B. subtilis* is 25-30 atmosphere. Optimal conditions of spore germination are: 7 days in peace, then heating at 60 C in 5 minutes. The sterilization conditions: vegetative cells perish in 5-10 minutes; 90% spores perish in 28 s for T=100 C and in 0.5 s for T=160 C [5].To sterilize the spores the chemical, physical and plasma physical processes are used.

Chemical agents - biocides

The comparatively high resistance of spores to many biocides is related to the presence of the spore coats and cortex [4]. Ethylene oxide (ETO) is effected by alkylation of amino groups in the proteinaceous structure of any microorganism. ETO sterilization requires the attachment of the entire ETO molecule, a polyatomic structure containing seven atoms to the protein. This is accompanied by the requirement of hydrogen atom rearrangement on the protein to enable the attachment of ETO. Because of the space factors governing the attachment of such a bulky molecule, the process needs to be carried out at high pressure and be extended over a long period of time [1]. There are two ways of chemical sterilization: gas (ETO) sterilization and with the help of aldehydes (glutaraldehyde and formaldehyde).

Physical agents

Effects of physical processes are connected with inactivation of bacterial spores by high temperatures, high doses of ionizing, ultraviolet or electromagnetic radiations, gas discharge plasma, vacuum and often by combinations of mentioned physical factors.

Temperature.

Thermal sterilization can be realized by moist and dry heat. Moist heat resistance depends upon several factors, in particular, on sporulation, heating and recovery conditions. The exact mechanism of heat resistance remains unclear, but the main reasons are associated with partial dehydration of coat and general molecular stabilization of core components (stabilization results from molecular rearrangements in the core).

The heat sensitive site and resistance to dry heat depends mainly on the location of water in the spore and on its association with other molecules [4].

Ionizing radiation. Ionizing radiation (IR) is highly lethal to most organisms. IR induces single strand and dirible strand breaks in microbial DNA that can be repaired and likely to inhibit DNA synthesis or cause some error in protein synthesis, leading to cell death [4]. Ionizations occur principally in water, resulting in the formation of short-lived, but highly reactive hydroxyl radicals and protons. Damage to DNA is brought about by OH radicals which are responsible for inducing strand breakage.

Ultraviolet radiation. Ultraviolet radiation (UV) is a less effective process than ionizing radiation since UV radiation does not possess energy to eject an electron to produce ion. UV spores resistance is associated with the ability and UV sensitivity with failure, to remove the spore photoproduct TDHT (5 thyminyl - 5,6 dihydrothymine). TDHT is identical to a product that accumulates in DNA exposed dry to UV radiation.

Vacuum. Vacuum influence on different micro-organisms have been investigated to understand panspermia problems connected with technical and ethical evolution of seeding nearby the solar systems [6]. There are

several mechanisms of vacuum destruction of microorganisms such as dehydration, diffusion osmotic pressure, biochemical effects, cell destruction connected with large inner pressure in vacuum condition etc.

Gas discharge plasma effects. The efficiency of plasma chemical processes is due to small sizes of the active plasma entities (usually monoatomic or diatomic) and therefore exhibit an enhanced ability to attach themselves to a proteinaceons structure and abstract hydrogen atom from it. Another specific types of interaction is rupturing ring structures, particularly those including nitrogen, or carbon-carbon bond cleavage.

Thus analysis of physical and chemical processes in existing sterilization methods shows that the main mechanisms leading to microorganisms perishing are the following ones:

- ?? dehydration of various elements of microorganism structure (thermal sterilization);
- ?? chemical reactions of sterilizing agent with chemical elements of microorganisms (gas sterilization);
- ?? energy damage and excitation of atom and molecule structures of microorganisms resulting in sporicidal compound formations (ultraviolet and radiation sterilization);
- ?? mechanical damage of microorganism structures (vacuum, particle bombardment etc.).

All these processes are relevant to the gas discharge plasma generated for the certain degree of rarefaction.

3. Discharges suitable for sterilization

All sporicidal processes in plasma can be divided into two large groups: physical and plasma-chemical ones. It should be noted that in any case these two groups cause the interaction of particles with the surfaces of medical instruments. This is especially important for metal, dielectric (polymer) instruments and some other products that can change their physical properties under the influence of plasma processes such as sputtering and vaporization of surface material, adsorption of surface atoms etc.

The intensity of these processes strongly depends on particle energy distribution. In Fig.2 the dependences of ions and neutral particles energy distribution are shown for different plasma-vacuum processes. Curve 1 corresponds to theoretical material vaporization. Thermal heating is due to the surface heating by particle fluxes from the plasma to the surfaces of instruments. Curves 2 show the energy distribution of vaporized particles near the electrodes, one of which can be the processed instrument. It should be noted that in principle the instrument can be not only sputtered because of plasma action but also can be covered by thin film formed by sputtering of other elements of gas discharge (sterilizing) chamber. The particle distribution function for different shift potentials between the discharge and electrodes that create the plasma is illustrated by curves 3 and 4.

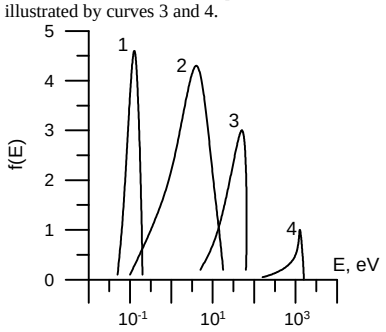

Fig.2 Ion and neutral particles distribution function in arbitrary units for different plasma-vacuum processes.

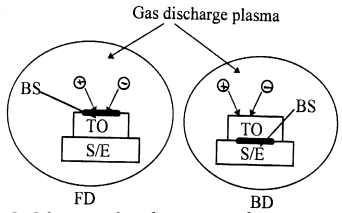

Fig.3: Schematic plot of two types of experiments to study the effect of particle bombardment. Here BS denotes *B.subtilis*, TO - test-object, S/E - substrate or electrode. FD: *B.subtilis* are bombarded by particles. BD: bombardment is absent.

In most cases the plasma ion bombardment of surfaces prevails over other processes during material sputtering. The impulse transfer in elastic collisions resulting in direct knocking-out of atoms from equilibrium states is the main way of interaction between bombarding ions and material atoms.

The ion sputtering of material starts when the ion energy E_i exceeds the threshold value E_{thr}. The energy E_{thr} depends weakly on the masses of colliding particles and lies in the range 10-30 eV [7]. For plasma

sterilization of medical instruments the ion energy must be less than E_{thr}. In that case ions do not sputter the material. During the intensive ion bombardment the surface layers of monocrystals first are transformed into polycrystal layers and then into amorphous ones. In most cases it is inadmissible for medical instruments.
The average distance the intruded ion covers before being stopped depends on ion energy and atom number both the intruded ion and bombarded material. For example, the average depth of Ar^+ intrusion into aluminum equals to ~1.5 nm/keV (this value is significantly greater for dielectrics). 70-90% of ion energy is dissipated into the material in the heat form, less than 5% is expended on the sputtering and the rest part of the energy is expended on the radiation damage of material, ion intrusion and secondary electron emission and electromagnetic radiation in a wide frequency range [7].
Thus to approach the features desired for an ideal sterilization systems it is necessary to create a plasma with definite values of parameters such as:

1. The energy of falling-down on the electrodes particles must be as low as possible to exclude the sputtering and damage of dielectric and metallic products;
2. The operating gas of the discharge must allow to create sporicidal agents;
3. To prevent the intensive heating of sterilized products the particle fluxes to their surfaces must be small that is the plasma current density must be insignificant;
4. Discharge plasma must provide the complex physical and chemical actions on microorganisms for greater efficiency and reliability of sterilization. Among these actions are thermovacuum actions, radiation treatment of products by electromagnetic fields and some other effects [8].

Among the large number of gas discharges studied to the moment the discharges in alternative fields especially high-frequency (HF) and microwave (MW) ones meet the above requirements. In alternative fields discharges the electrodes can be absent and this is an advantage for the sterilization. Such discharges can be divided in low frequency (LF) and impulse ones with a long duration of a pulse, HF (radio frequency) and MW discharges. Low-frequency fields ($f < 10^5$ Hz) do not result in any additional effects that differ drastically from the direct electric field discharges. The typical frequency for HF discharges is ~10^5-10^8 Hz, for MW ones – 10^9-10^{11} Hz.

4. Plasma sterilization action

To determine the role of particle bombardment we used LF and HF capacitive and inductive air gas discharges. The test-objects with *B.subtilis* were located inside plasma in two different manners: they were (FD) and were not (BD) subject to particle bombardment action (Fig.3). The results are in Table 1.

Table 1. Influence of particle bombardment on *B.subtilis* survival (*N*). N_0 is initial number of organisms.

τ_{st}, min	Test-object (TO)	Substrate material	*N*
f=27 MHz, *p*=1 Torr, P_{RF} =65-70 W, $N_0 = 10^4$			
1	*Al* foil BD	Teflon	10^2 - 10^3
1	*Al* foil FD	Teflon	0
20	glass BD	Teflon	10^0
20	glass FD	Teflon	0
20	rubber BD	Teflon	10^2
20	rubber FD	Teflon	0

Plasma chemical processes

Operating gas selected for plasma sterilization determines not only the antimicrobial species but also toxicity-related factors such as chemical residues and products from the process. It is very desirable to have active species with high sporicidal activity such as OH, H_2O, O and H in plasma and to select precursors gases with nontoxic compounds such as O_2, H_2O and H_2. In order to evaluate their relative sporicidal activity, oxygen, hydrogen, nitrous oxide, nitrogen dioxide and others in various combinations as precursor gases were used for microwave and RF discharges (Fig.4) [9]. The mechanism for the generation of the highly reactive mixture in a hydrogen peroxide plasma can be simplified as illustrated below [3]:

$$H_2O_2 \text{ - H-O-O-H} \xrightarrow[1 < 10eV]{e} HO^{\cdot} + {}^{\cdot}OH; \qquad HO^{\cdot} + \text{H-O-O-H} \rightarrow HOH + {}^{\cdot}\text{O-O-H}$$

$$\text{H-O-O-H} \xrightarrow{e,\ h\nu} \text{H-O-O-H}^{\cdot}; \qquad \text{H-O-O-H}^{\cdot} \rightarrow \text{H-O-O-H + optical radiation including UV radiation.}$$

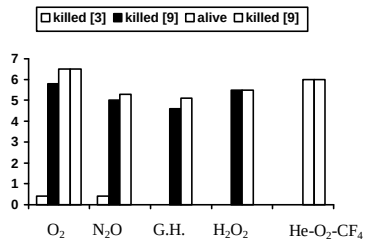

Fig.4: Sporicidal activity of various plasmas against *B. Subtilis*. Here *N* is the number of microorganisms, *G.H.* stands for glutaraldehyde.

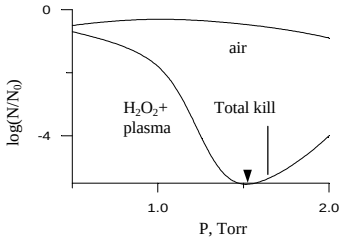

Fig.5: Effects of gas pressure on sporicidal activity of plasma. N and N_0 are the surviving and initial numbers of microorganisms.

The efficacy of these processes depends on hydrogen peroxide concentration, gas pressure and RF power [3] (Fig.4,5) and is connected with the fact that active plasma species are small in comparison with ethylene oxide. The space restriction for these species is at least one thousand time lower than that for ETO alkylation and so they penetrate into bacteria through pores (diameter 1-6 nm for *B.Subtilis*) in outer covers and attach themselves to a proteinaceous structure and abstract hydrogen atoms from it. Another specific type of interaction is rupturing ring structures with nitrogen or carbon-carbon bond cleavage. These processes produce only gaseous effluents (for example H_2O and O_2). There are many oxygen atoms in hydrogen peroxide and air plasmas, so negative oxygen ions are produced very effectively. In the patent [9] examples of sporicidal activity of different gases (O_2, N_2, *He*) and gas mixtures such as O_2-CF_4, (O_2-*He*)-CF_4, (O_2-CF_4)-*He*, air are given for sterilization temperature about 60°C. The most sporicidal activities are inherent in O_2 and oxidizing gas mixture (Fig.4). A predominance of oxygen in the above mixture is preferred but not mandatory [9]. The inert gas fraction can be varied in the range 10 to 95%; the higher the fraction the lower the processing temperature for a given pressure and power density, but sterilization exposure time increases the higher the inert gas fraction in the mixture.

Thermovacuum effects

Analysis of microorganism stability in vacuum for various temperatures is the most informative one for understanding high vacuum action on microorganisms. Investigations show that microorganisms destruction does not change for residual pressure $10^{?1}$-$10^{?9}$ Torr. The total temperature range for these pressures can be divided on three ranges: from cryogenic till room ones, 20-70°C and higher than 70°C.

Table 2. Thermal-vacuum processing of test objects for p~1 Torr, $N_0=10^5$ *B.subtilis*. Figures in table denote the total (sterilized) number of test-objects.

Type of test-object	$?_{st}$, min	Sterilization temperature, °C		
		110	130-135	120-125
metal	15		7(7)	7(7)
glass	15		6(6)	1(1)
metal	60	6(6)	3(3)	6(6)
glass	60	4(4)		4(4)

Table 3. Survival of *B.subtilis* on different materials. Here f=40 MHz, P_{RF}=100 W, p=0.1-1 Torr, $N_0=10^5$, TO is test-object.

Material of TO	$?_{st}$, min	N
rubber	(1-5)/10	$10^4/10^3$
glass	(1-5)/10	10^3-$10^4/10^2$
Al foil	(1-5)/10	0/0
rubber	10	10^3-10^4
glass	10	10^2
Al foil	10	0

For high temperatures (T>70°C) irreversible injures of bacteria membranes and outer covers are predominant ones. These injuries are provoked by cell water vaporization, complex biochemical processes connected with protein denaturation etc. Results of our investigation for pressure 0.1-1 Torr in 110-135°C range are given in Table 2 where 7(7), 6(6) are control (sterilized) number of test-objects. Heating of test-objects have been carried out by inductive RF coil without gas discharge. *B. Subtilis* spores can be killed by

thermal-vacuum effects for temperature below 120 C. These results agree with Silverman's and Beecher's findings for survival of cocci after exposure to ultra high vacuum and different temperatures [10].

Ultraviolet radiation and elecromagnetic field

Bacterial spores are inactivated by high doses of ultraviolet (UV) radiation. UV light is only slowly lethal to spores and thus is not considered to be a sterilization. As for the electromagnetic field action our estimations and experiments show that it can change inner processes in cells.

Influence of medical instruments material

Medical instruments are substrates for microorganisms. Our microbiological testing of an efficacy of sterilization on test-objects from different materials including rubber, stainless steel, aluminum, glass etc. showed that spores were injured more effectively on metal test-objects than on dielectric ones (Table 3).

Physical contact between a microorganism and solid state determines charge distributions and influence on ion transport of cell [11]. Contact parameters cell-metal and cell-dielectric are considerably different. Possible reasons of bacteria injury on metal and dielectric are connected with charge transition between bacteria and different solid states and with thermal conditions of the material.

5. Discussion. Plasma sterilizers

Our analysis of experimental data show that there are no special difficulties for the sterilization of medical products having direct contact with a plasma. Under the influence of all considered above processes microorganisms perish in several seconds or minutes at worst. The particle bombardment, thermovacuum conditions and the dynamics of change of parameters that determine these conditions play the main role. The problems of microorganisms killing in hollows, channels and hidden surfaces of medical instruments made from metal, ceramic, glass, plastic and other solid materials are quite difficult. In such cases the sterilization is due to plasma-chemical, thermal and vacuum processes. As a confirmation of that is an only industrial plasma sterilizer STERRAD by Johnson & Johnson Medical Ltd.

STERRAD-100 is a sterilizer for the processing of thermo-sensitive medical products that uses low temperature gas discharge hydrogen peroxide plasma [12]. Plasma generated is by its nature a plasma-chemical reactor that creates sporicidal factors described above. Sterilization time is about 75 min. It is necessary to use special adapters for long narrow products. Closed from one end channels are hardly processed due to weak penetration properties of H_2O_2 and its fractions since there is no gas movement. Beside some materials adsorb H_2O_2 resulting in decrease of its concentration and in negative consequences.

Thus in our opinion the main problems to be solved are the following ones:

1. To eliminate the use of special operating gases such as H_2O_2 since it leads to the complication of plasma system constructions and their service. The best solution is a use of air.
2. To find the optimal combination of plasma-chemical and plasma-physical processes.
3. To study the influence of dynamics of parameters change on the sterilization efficiency.
4. To sterilize the narrow channels especially closed from one end, hollows, hidden surfaces etc.
5. To sterilize the cotton, woven, other organic materials and some polymer and synthetic products.

Abstract

The flowing afterglow and stationary afterglow experiments were used to study recombination of D_3^+ and D_5^+ ions with electrons in afterglow in He-Ar-D_2 mixtures. Two experiments were used to cover large extend of pressures of He buffer gas (2-10 Torr) and large extend of partial number densities of D_2 (10^{10}-10^{16} cm^{-3}). It was observed that the rate of the decay of D_3^+ and D_5^+ containing afterglow plasma is dependent on partial pressure of D_2 and on temperature.

Introduction

The ions H_3^+ and D_3^+ have been the subject of a number of studies because of their important roles in the astrophysical and laboratory research. Recent discovery of interstellar H_3^+ in molecular clouds has opened a problem of observed high column density, which critically depends on the rate of recombination of H_3^+ with electrons. The kinetics of the formation of H_3^+ and D_3^+ ions and their reactions with neutrals are well understood. However, despite enormous efforts the results of studies determining the rate of recombination of H_3^+ and D_3^+ ions with electrons are very controversial [1]. In the late nineties, it was generally accepted that recombination coefficient for H_3^+ ions $\alpha \sim 2\times10^{-7}$ cm^3 s^{-1}. This finding was in agreement with results of many beam studies and several afterglow experiments. Studies of D_3^+ recombination reported smaller rate coefficient values, generally by a factor about 1-4. Among the recent measurements on D_3^+ recombination, we wish to mention explicitly flowing afterglow (FALP) studies of the recombination of D_3^+. Smith and Španěl obtained in FALP studies $\alpha \sim 2\times10^{-8}$ cm^3 s^{-1} [2]. In 1995, Gougousi *et al.* [3] obtained in the FALP study $\alpha \sim (0.7\text{-}1.3)\times10^{-7}$ cm^3 s^{-1} dependent on deuterium partial pressure. Laubé *et al.* [4] obtained in FALP-MS a value of $\alpha \sim 0.7\times10^{-7}$ cm^3 s^{-1}. All experimental recombination rate coefficients obtained at thermal energies for both H_3^+ and D_3^+ are significantly larger than the values predicted by theory [5,6]. In our recent study of recombination of D_3^+ ions with electrons we have observed strong dependence of recombination rate coefficient of recombination of D_3^+ ions on partial pressure of D_2 [7]. In present study we further increased partial pressures of D_2 and buffer gas pressure to enhance formation of D_5^+ and to measure recombination in afterglow plasma containing mixture of D_3^+ and D_5^+.

Experiment

The Flowing Afterglow with Langmuir Probe (FALP) is based on simple principle: the buffer gas flowing along the flow tube is carrying decaying plasma created upstream in the plasma source. In the different positions along the tube there is plasma in different degree of decay. The cardinal condition is to adjust parameters in the flow tube in such a way that the process under study is the dominant process during the afterglow. In present experiment it is the recombination of D_3^+ and the formation and destruction of D_5^+. High pressure and low temperature is required to form D_5^+. These conditions are fulfilled in our High Pressure Flowing Afterglow – HPFA. In the present UHV version of HPFA the differential pumping of mass spectrometer chamber is used to increase the operational pressure of the buffer gas. The HPFA has been described in detail previously [8,9], so only short description will be given. The schematic diagram in Figure 1 outlines the essential parts of the used HPFA. The axially movable Langmuir probe (tungsten wire 14 μm in diameter and 7 mm long) is used to determine the electron number densities along the flow tube. A region of the saturated electron current of probe characteristics is used to calculate electron number densities. **Formation of $D_3^+/D_5^+/e^-$ plasma**: The pure He is flowing through the microwave discharge and He^+, He^m and electrons are formed. Downstream from the discharge region (position corresponding to ~ 1 ms of the decay time) Ar is added to the flow and the plasma is converted to the Ar^+ dominated plasma.

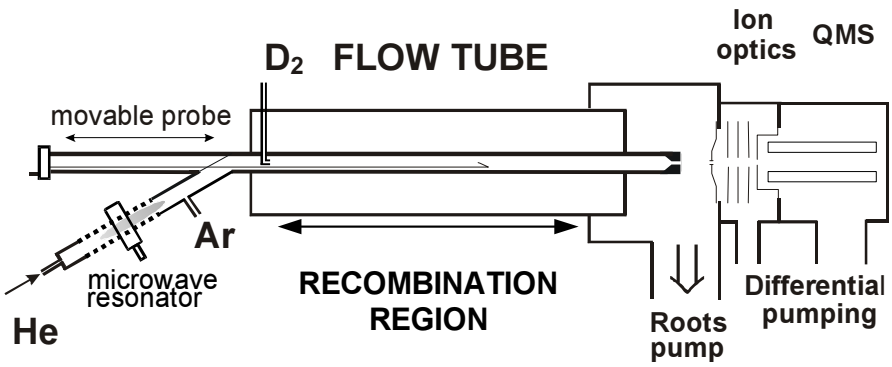

Figure 1: The schema of High Pressure Flowing Afterglow. QMS indicates the downstream mass spectrometer with a detector.

Further downstream (~ 2 ms of the decay) deuterium is added to the already relaxed Ar^+/electron plasma and D_3^+/D_5^+/electron plasma is formed in a sequence of ion-molecule reactions. The kinetics of these processes is well understood and the rate coefficients are known. The rate coefficients of the reactions important in the formation of D_3^+ and D_5^+ ions are given in Table 1 [10]. Briefly, deuterium reacts with Ar^+ ions to form ArD^+ (major channel) and some D_2^+. Both ions react further with D_2 and D_3^+ ions are formed. In the present experiment the high pressure and lower temperature of the buffer gas is essential to enhance formation of D_5^+. We are not discussing eventual vibrational excitation of recombining ions, because of high probability of deexcitation in multiple collisions with He and D_2 We assume that few cm downstream from deuterium entry port the plasma is fully thermalised and the temperature of the ions and of the electrons is equal to the temperature of the buffer gas, this assumption is confirmed by the probe measurements of the electron temperature in the decaying plasma. Relaxation of kinetic and rotational temperature of H_3^+ ions in similar conditions is discussed in accompanying paper [11].

TABLE 1: Rate coefficients of the reactions are participating in the formation of D_3^+ and D_5^+ ions. The reaction rate coefficients are given for 300 K. The typical reaction times were calculated for decay at 9 Torr of He and for $[D_2] = 4\times10^{14}$ cm^{-3} and $[Ar] = 3\times10^{13}$ cm^{-3}. (*) Rate coefficients were deduced from equivalent reactions with hydrogen.

Reaction	Rate coefficient [cm^3 s^{-1}] or [cm^6 s^{-1}]	Reaction time [ms]
$He^+ + 2He \rightarrow He_2^+ + He$	1×10^{-31}	1.1×10^{-1}
$He^m + Ar \rightarrow Ar^+ + He + e$	7×10^{-11}	4.8×10^{-1}
$He_2^+ + Ar \rightarrow Ar^+ + 2He$	2×10^{-10}	1.7×10^{-1}
$Ar^+ + D_2 \rightarrow ArD^+ + D$ $\rightarrow D_2^+ + Ar$	7.5×10^{-10} ArD^+ is dominated	3.3×10^{-3}
$D_2^+ + Ar \rightarrow ArD^+ + D$	1.5×10^{-9}	2.2×10^{-2}
$D_2^+ + D_2 \rightarrow D_3^+ + D$	1.6×10^{-9}	1.6×10^{-3}
$ArD^+ + D_2 \rightarrow D_3^+ + Ar$	4.6×10^{-10}	5.4×10^{-3}
$D_3^+ + D_2 + He \rightarrow D_5^+ + He$	$<1 \times 10^{-29}$ *	8.4×10^{-1}
$D^+ + He + He \rightarrow DHe^+ + He$	0.9×10^{-31} *	1.2×10^{-1}

The axially movable Langmuir probe enables the measurement of the electron number density n_e along the flow tube. In the Figure 2 examples of probe characteristics measured along the flow tube in the D_3^+/D_5^+/electron plasma are plotted. Because of the semilogarithmic plot the absolute values of the probe current are used in the plot (the branches corresponding to electron and ion current are plotted both with

positive sign). The values of n_e(t) are obtained from the slope of the plot of I_e^2 versus probe potential, U. The examples of such plots are given in Figure 3.

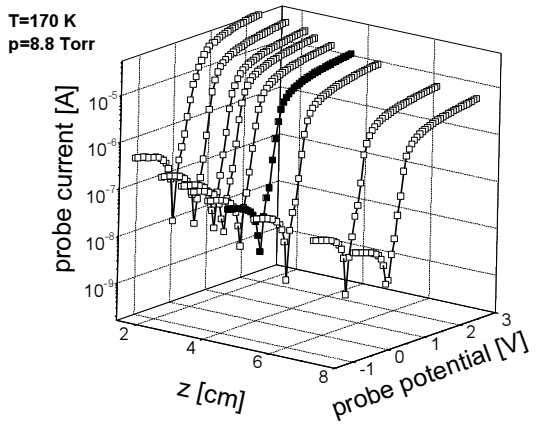

Figure 2: The evolution of the probe characteristics along the flow tube. Decay time is correlated with position along the flow tube, $z = \upsilon_p \cdot t$. The probe potential U_p is measured against the potential of the metal body of the flow tube.
P_{He} = 8.8 Torr, Ar flow 1.1 sccm (corresponding to 1.4 mTorr), $[D_2] = 2.4\times10^{14}$ cm^{-3}, T = 170 K.

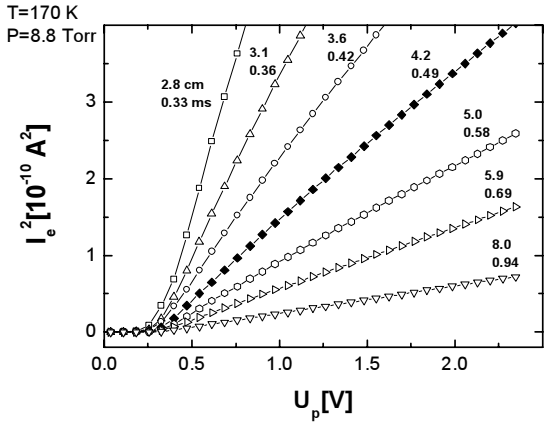

Figure 3: The examples of plots of I_e^2 versus probe potential. The data were measured at different positions (decay times) along the flow tube. The slopes of linear portions of the plots provide the electron number densities. The data from Figure 2 are used in the plot. The numbers indicate position in the flow tube (z) and corresponding decay time in cm and ms, respectively.

Data analysis

If D_3^+ ions are the dominant ions in decaying plasma and the diffusion can be neglected then the determination of the rate coefficient (α_3) is straightforward. The balance equation for electrons is:

$$\upsilon_p \frac{dn_e(z)}{dz} = \frac{dn_e(t)}{dt} = -\alpha_3[D_3^+]n_e = -\alpha_3 n_e^2 \tag{1}$$

Where z, υ_p and t are a position in the flow tube, plasma velocity and decay time, respectively. These parameters are coupled by equation: $z = \upsilon_p \cdot t$. $[D_3^+]$ indicates number density of D_3^+, and α_3 is the recombination rate coefficient. Last equality is given by quasineutrality of the plasma, $n_e = [D_3^+]$. The solution of the balance equation is:

$$\frac{1}{n_e(t)} = \frac{1}{n_e(0)} + \alpha_3 t \tag{2}$$

Thus a plot of $1/n_e$ against t should be linear if the recombination rate coefficient is constant along the flow tube.

In HPFA at a relatively low temperature and at high pressures of He and D_2 a formation of cluster ions D_5^+ in three-body association reaction and their destruction by a collision induced dissociation (CID) in collisions with He atoms [12,13] can play essential role. On such case we have to consider reaction scheme:

$$D_3^+ + D_2 + He \underset{k_{-3}}{\overset{k_3}{\leftrightarrow}} D_5^+ + He \tag{3}$$

Where k_3 is the rate coefficient of the three-body association (the forward process) and k_{-3} is the binary rate coefficient of the CID (the reverse process). In the same time both ions recombine with electrons:

$$D_3^+ + e \xrightarrow{\alpha_3} products \tag{4}$$

$$D_5^+ + e \xrightarrow{\alpha_5} products \tag{5}$$

Where α_3 and α_5 are respective recombination rate coefficients. We are not considering diffusion losses at this moment. In actual data analysis we are taking diffusion into account. When considering processes (3), (4) and (5), the balance equation for electrons is:

$$\frac{dn_e(t)}{dt} = -\alpha_3[D_3^+]n_e - \alpha_5[D_5^+]n_e = -\left(\alpha_3 + R\alpha_5\right)\frac{n_e^2}{1+R} = -\alpha_{eff}n_e^2 \tag{6}$$

Where $R = [D_5^+]/[D_3^+]$, $n_e = [D_3^+] + [D_5^+]$. We introduced here effective recombination rate coefficient α_{eff} by equation:

$$\alpha_{eff} = \left(\alpha_3 + R\alpha_5\right)\frac{1}{1+R} \tag{7}$$

If the ratio R is constant during the decay of the plasma (along the flow tube) then α_{eff} is constant and we can observe decay typical for plasma governed by recombination. Such situation occurs e.g. if the ions are during the decay of the plasma in the equilibrium described by the scheme (3). For ions in equilibrium we can write:

$$R = [D_5^+]/[D_3^+] = k_3[D_2]/k_{-3} = K_C[D_2] \tag{8}$$

Where K_C is the equilibrium constant, given by an entropy and an enthalpy change (van't Hoff equation) [14,15]. Using K_C and $[D_2]$ the equation (7) can be written in the form:

$$\alpha_{eff} = \left(\alpha_3 + \alpha_5 K_C[D_2]\right)\frac{1}{1+K_C[D_2]} \tag{9}$$

This equation describes the influence of a deuterium partial pressure on the overall (apparent) rate of the recombination in $D_3^+/D_5^+/e^-$ plasma. From equation (9) follows: for a very small $[D_2]$ $\alpha_{eff} = \alpha_3$, for a medium $[D_2]$ value $\alpha_{eff} = \alpha_3 + \alpha_5 K_c [D_2]$ and for very high deuterium pressure $\alpha_{eff} = \alpha_5$. This conclusion is obvious; for very small $[D_2]$ formation of D_5^+ is negligible and the recombination of D_3^+ is dominant, for a medium $[D_2]$ both ions recombine and for very high deuterium pressure formation of D_5^+ is very fast and its recombination is the dominant loss process. If α_{eff} is constant then the solution of the equation (6) is given by formula (2).

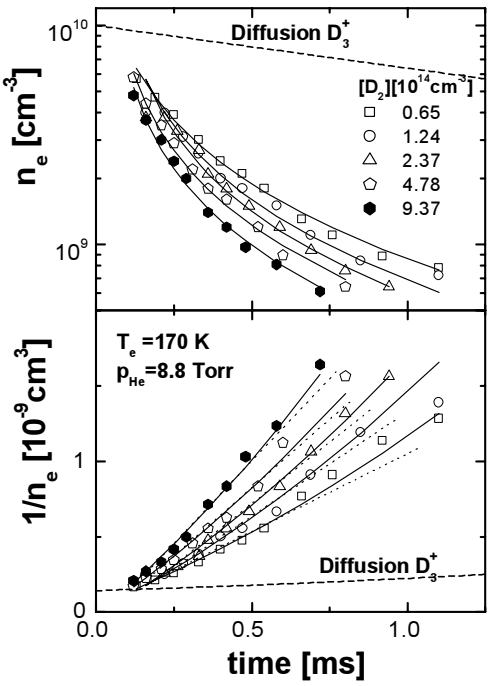

Figure 4: The decay of the plasma containing a mixture of D_3^+ and D_5^+ ions at 170 K and P_{He} = 8.8 Torr.
Upper panel: The decay of the electron number density measured at several number densities of deuterium.
Lower panel: The corresponding plots of $1/n_e$ versus decay time.

Results and Discussion

We have measured decay of the plasma in He/Ar/D_2 mixture at several temperatures ranging from 170 K up to 260 K. The deuterium number density was changed from $[D_2] = 2\times10^{13}$ cm^{-3} up to $[D_2] = 10^{16}$ cm^{-3}. This

large variation makes it possible to cover plasmas dominated: by the recombination of D_3^+ ions, by the recombination in the mixture of D_3^+ and D_5^+ ions and also by the recombination of D_5^+ ions only. In Figure 4 there is example of several decay curves measured in one set of measurements at 170 K, 8.8 Torr, Ar flow 1.1 sccm (corresponding to 1.4 mTorr). In the lower panel there are reciprocal plots. The dashed line indicates decay dominated by the diffusion; the dotted lines indicate the fit by the simple formula (2) considering only the recombination losses. From the data plotted in Figure 4 it is obvious that the decay of plasma at 170 K is dependent on a deuterium number density.

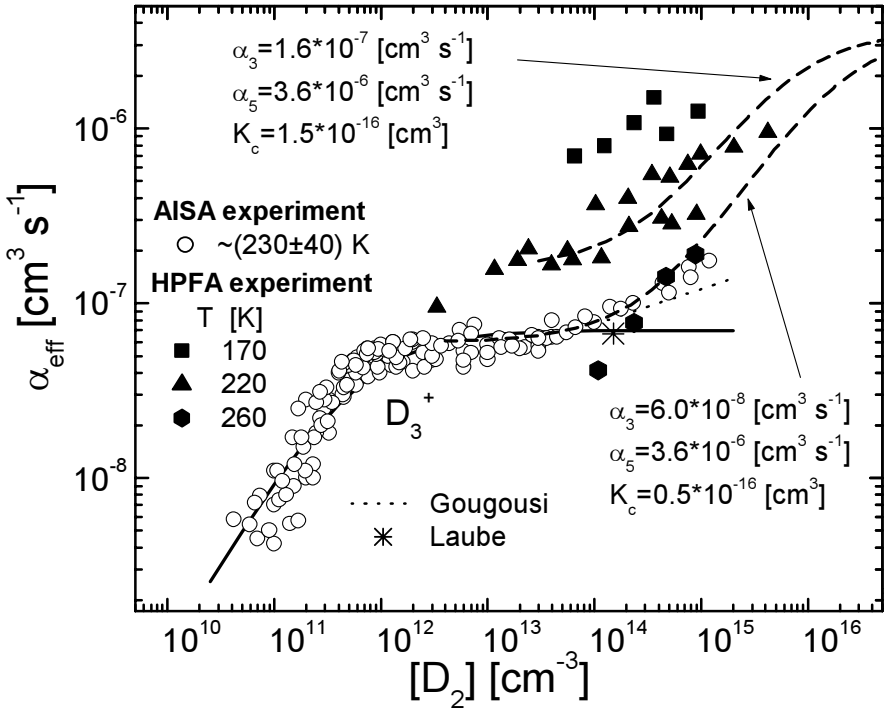

Figure 5: The effective recombination rate coefficients α_{eff} measured over very broad range of deuterium number densities on AISA (open symbols) and on HPFA (closed symbols).

We will not discuss here data obtained on AISA at very small deuterium number densities, $[D_2] < 10^{12}$ cm^{-3} where is D_5^+ not formed in time scale of experiment and cannot play role [7] in variation of α_{eff} with $[D_2]$. Lets consider at this moment data obtained on HPFA at 260 K and data from AISA obtained at 230 K as data corresponding to one temperature. Increase of α_{eff} at $[D_2] > 5\times10^{13}$ cm^{-3} observed in both experiments can be explained by formation of D_5^+ ions. We assume that α_3 is given by value of α_{eff} at $[D_2] \sim 10^{13}$ cm^{-3} , which gives $\alpha_3(260\text{ K}) = 7\times10^{-8}$ cm^3 s^{-1}, and we also assume that H_5^+ and D_5^+ have similar recombination rate coefficients and $\alpha_5(D_5^+, 260\text{ K}) \sim \alpha_5(H_5^+, 260\text{ K}) = 3.6\times10^{-6}$ cm^3 s^{-1} [16]. Using these values we can fit the data with function (9) to obtain K_C, see dashed line in Figure 5. It is evident that observed increase of α_{eff} can be explained by formation and consequent recombination of D_5^+.

By assuming that $\alpha_5(D_5^+)$ is not changing substantially with temperature we have used value $\alpha_5(D_5^+) = 3.6\times10^{-6}$ cm^3 s^{-1} to fit the data obtained at 195 K (not plotted in Figure 5) and 220 K and we obtained $K_C(195) = (1.5\pm0.7)\times10^{-16}$cm^3 and $K_C(220) = (1.1\pm0.4)\times10^{-16}$cm^3, respectively. The obtained K_C are in excellent agreement with thermodynamic data obtained by Hiraoka and Mori [17] in their high-pressure mass spectrometer. We have studied also pressure and temperature dependence of recombination in $H_3^+/H_5^+/e^-$ plasma [18,19] and we obtained similar results.

The aim of the present work was to study influence of formation of D_5^+ in $D_3^+/D_5^+/e^-$ plasma and to define regions of partial pressures and temperatures where formation of D_5^+ cannot be neglected in deionisation of deuterium containing plasma. The study confirms that pressure dependence of α_{eff} at $[D_2] < 5\times10^{13}$ cm^{-3} observed in AISA experiment is not due to formation of D_5^+.

Low-pressure arc discharge plasma sources

P.M. Schanin, N.N. Koval, S.V. Grigoriev

Institute of High Current Electronics, RAS, Tomsk, Russia

The low voltage and low pressure at which the high - current arc discharge is initiated and steadily burns allow one to consider this discharge promising for the production of gas plasmas of high density in large volumes. The high plasma density with reasonable homogeneity at low pressures makes it possible to realize the different technological processes of surface modification with high energetic efficiency: ion nitriding, plasma - assisted deposition and ion implantation [1, 2, 3, 4].

Two types of stationary arc discharge sources with a hollow cathode are presented. In the first type of source a non self-sustained arc is initiated by the electrons emitted by a hot W-filament inserted into hollow cathode. The cylindrical hollow cathode of diameter 100 mm and length 150 mm is immersed in the axial magnetic field created by a magnetic coil. The electrons emitted by the filament in the magnetic field efficiently ionize the working gas that is leaked in the hollow cathode and produces gas plasma. The non magnetized ions accelerated in the cathode potential fall knock secondary electrons and enhance ionization processes in discharge gap between the hollow cathode and working chamber which serve as a hollow anode in this discharge system. A low pressure arc discharge with a low burning voltage is thus established. The discharge current can be controlled over a range without a cathode spot by varying the filament current and the gas flow rate in hollow cathode. Discharge currents of 30 A to160 A have been obtained with the filament current varied in the range from 90 to 130A and discharge voltage of 50 V and flow rate of 96 sccm and magnetic field of 0.02 T. The plasma with density of $n_e = 1\times10^{11}$ cm^{-3} and temperature Te = 5 eV was generated in the vacuum chamber volume of 0.3 m^3 at an Ar-gas pressure of 3×10^{-1} Pa and a discharge current of 50 A.

The plasma source with a cold hollow cathode was developed to produce plasmas of chemically active gas such as O_2, CH_4, and the like. The design and the power supply circuit of discharge system are similar to these considered above, but the initiation of an arc is performed by a trigger system based on a dielectric flashover, placed inside the hollow cathode. The cathode spot develops on the internal surface of the hollow cathode and produces primary plasma. In traversed electric and axial magnetic fields, the cathode spot executes a rotational motion over the internal surface of cathode at a maximum of magnetic field. The electrons emitted by the cathode spot and accelerated in the cathode potential fall ionize the gas in the hollow cathode and in the discharge gap. In these conditions, the ions, atoms, and droplets of the cathode material deposit on opposite, relative to the spot, side of the hollow cathode and this increases the cathode lifetime. Experiments have shown that there is practically no cathode material in the plasma of the working chamber and the erosion rate of this cathode is about ten times smaller then that of a conventional arc.

In similar discharge condition the first type plasma source produces oxygen plasma with density $n_e = 5\times10^{10}$ cm^{-3} and temperature Te = 2.5 eV.

Abstract
Nano powder of aluminum nitride (AlN) is one of the necessary materials in order to develop solid insulating materials with high thermal conductivity. This paper describes calculation results of chemical equilibrium composition and the results of experiments in synthesizing AlN nano powder using transferred type arc plasma. In order to increase the AlN content in synthesized powder, ammonia was recommended as a reacting/quenching gas, to be blown into aluminum gas in a temperature region of between 2100 and 2300 K.

1. Introduction

Downsizing of electrical equipment has meant that such equipment have required high thermal conductivity. In order to develop solid insulating materials with high thermal conductivity, it is necessary to add large quantities of ceramic powder with high thermal conductivity to organic insulating materials. Mixing small powder with large powder is considered a good way to achieve a high ceramic powder content. Aluminum nitride (AlN) is a ceramic with high thermal conductivity. Commercially available AlN powder is sized at a few microns, therefore AlN nano powder is required. However the low production capacity of nano powder makes it extremely expensive. There are many methods of producing nano powder, however methods that utilize arc plasma are a good choice in terms of raising the production rate, because they allow plasma power to be upgraded with ease. There are many reports on synthesis of AlN nano powder using the arc plasma [1-8]. The production rate will increase if the raw materials are injected into the high power arc plasma continuously. Transferred type arc plasma has a long high temperature zone and the advantage of making it easy to upgrade plasma power, and therefore the potential to reduce production costs [9]. A report exists on the subject of AlN nano powder production by injecting aluminum powders into the transferred type arc plasma [3]. The report however does not discuss the AlN content and diameter of the synthesized powder in sufficient detail. This paper describes the synthesis of AlN nano powder from aluminum (Al) powder using transferred type arc plasma. Calculations of chemical equilibrium composition and experiments in the synthesis of AlN nano powder were carried out. Nitrogen (N_2) – ammonia (NH_3) mixed gas was used as the reacting/quenching gas, and the AlN content and average diameter of the synthesized powder were investigated.

2. Equilibrium modeling of the synthesis

Chemical equilibrium composition was calculated to predict the optimal conditions for AlN synthesis. The calculation was carried out using the "HSC Chemistry (Outokumpu)" program based on the minimization of Gibbs free energy of the system. Calculation conditions (molar rate, pressure) were similar to the experimental conditions described later in chapter 3.

2.1 Conversion of Al into AlN

Figure 1 shows the calculation result for an Al/NH_3 system. Al gas was converted into AlN solid at around 2300K. Figure 2 shows the conversion temperatures for Al/NH_3 and Al/N_2 systems. In the Al/NH_3 system, conversion of Al gas into AlN solid started at approx. 2300K and finished at approx. 1900K. On the other hand, in the Al/N_2 system, conversion started at approx. 2400K and finished at approx. 2000K.

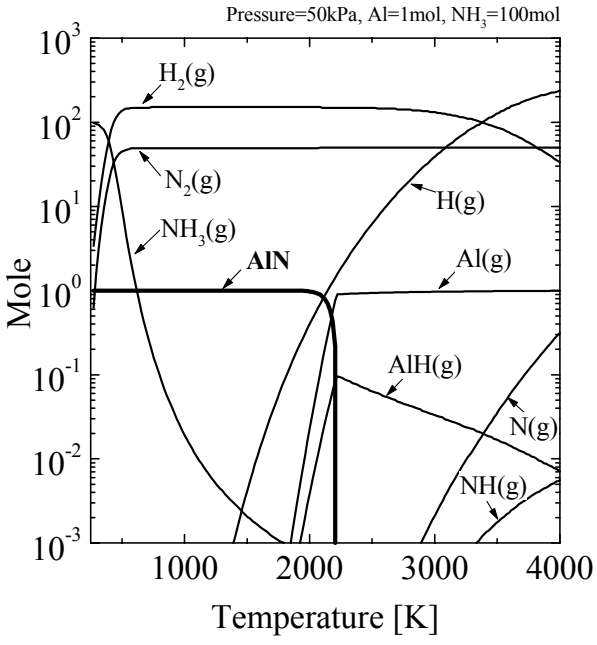

Figure 1. Equilibrium composition of Al/NH_3 system.

2.2 Condensation of non-reacted Al

In order to predict the conditions under which non-reacted Al gas would condense and convert to Al solid, equilibrium composition was calculated assuming that AlN solid was not synthesized. The condensation temperature that the Al solid started to appear was calculated when the non-reacted rate of Al gas of 1mol was varied 0.1-100%. Figure 3 shows the condensation temperature of Al gas. As the non-reacted rate of Al gas decreased, the condensation temperature of Al fell, due to a decline in the partial pressure of Al gas in the system. The condensation temperature of Al/N_2 system was higher than that of the Al/NH_3 system by approx. 100K. The condensation temperature was 2000-2100K when the non-reacted rate of Al gas was 100%.

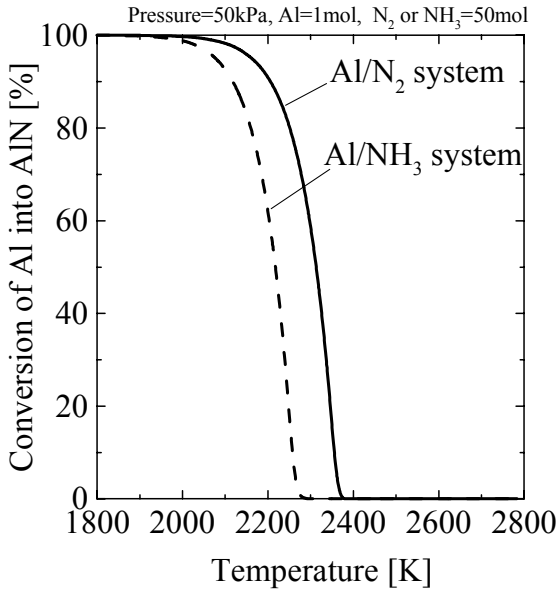

Figure 2. Characteristics of AlN synthesis for different systems.

2.3 Optimal conditions for AlN synthesis

In order to increase AlN content in the synthesized powder, it was recommended that a reacting gas be blown into the Al gas in a temperature region between the conversion temperature and the condensation temperature mentioned above. The optimal temperature region was between 2100 and 2300 K.

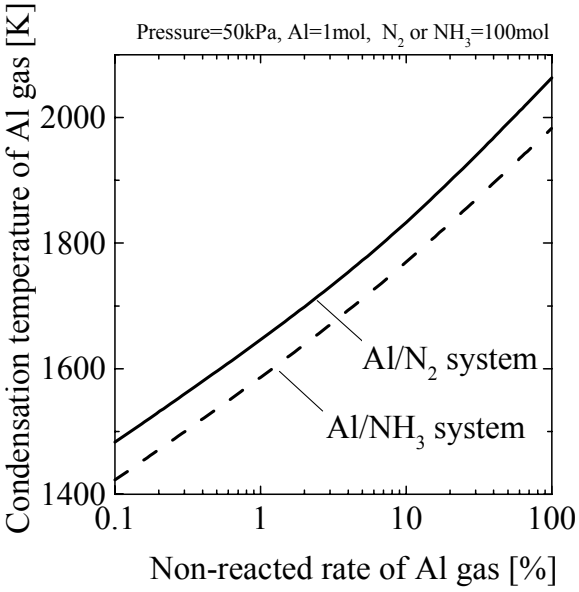

Figure 3. Condensation temperature of Al gas.

3. Experimental setup and conditions

Figure 4 shows the experimental setup. A transferred type arc plasma was generated between a tungsten cathode of plasma torch and a graphite anode in a chamber. The distance between the two electrodes was 75mm. The cathode consisted of a tube-shaped electrode, and the anode a rod-shaped electrode, and the two electrodes were water-cooled. Al powders were injected into the arc plasma through the cathode using a plasma gas (N_2). Diameter of the Al powder was 20-25μm with a feed rate of 0.5g/min and a feed time of 1-2 minutes, and DC arc current was 140A. A suction pipe was positioned downstream from the anode. The distance between the anode and the tip of the suction pipe was 75mm. A reacting/quenching gas was blown into the suction pipe. N_2-NH_3 mixed gas was used as the reacting/quenching gas. The Al powder melted and evaporated in the arc plasma, then the Al gas reacted with and was quenched by the reacting/quenching gas. The synthesized powder was collected on the wall of the suction pipe. The flow rates of plasma gas and reacting/quenching gas were 20 liters/min and 10-50 liters/min respectively. The off-gas was exhausted through the suction pipe and a filter using a vacuum pump. The pressure in the chamber was 30-50kPa. The temperature of the space near the powder-collection area in the suction pipe was measured by an R-type thermocouple with a cap of alumina at the tip. In order to determine the flight velocity of the Al powder in

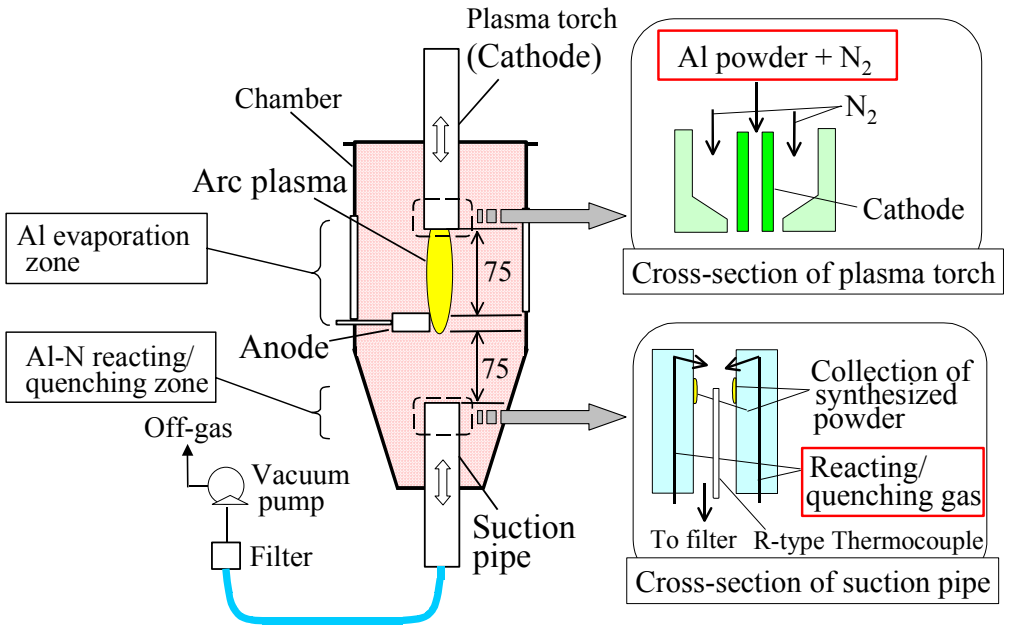

Figure 4. Experimental setup.

arc plasma, the emission of Al atomic line (396.1nm) owing to evaporation of Al powder was recorded using a high-speed ICCD camera with a band-pass filter (central wavelength: 394nm, half-width wavelength: 13nm). The interval time and exposure time of the observation were 100μs and 3μs respectively. The AlN content in the synthesized powder was analyzed by X-ray diffraction (XRD). The diameter of the powder was analyzed by the BET method and TEM observation.

4. Experiment results

4.1 Evaporation of Al powder in arc plasma

The flight velocity of the Al powder in arc plasma was determined from the movement of the emission from the powder using the same method as ref [9]. The flight velocity was 10-20m/s. Calculations of the melting and evaporation behavior of Al powder injected into arc plasma were performed using the heat transfer coefficient based on the Ranz-Marshall equation. The calculation method is described in detail in ref [10]. As a result, an Al powder (25μm) evaporated completely in approx. 2ms even when the powder passed through the plasma outskirts (5000K). Therefore the required plasma length was 40mm. Since the plasma length was set at 75mm, the Al powder injected into arc plasma would evaporate completely.

4.2 Effect of NH_3 content of the reacting/quenching gas

Figure 5 shows an XRD profile of the synthesized powder. Both AlN and Al peaks were observed. AlN content in the synthesized powder was determined by comparing the observed intensities of two lines, i.e. AlN(100) and Al(200). These lines were selected because the intensities were strong and not subject to interference by another lines. The ratio of intensities of AlN(100)/Al(200) was calibrated using the data of pre-mixed AlN/Al powder. Figure 6 shows the AlN content in the synthesized powder at a reacting/quenching gas flow rate of 20 liters/min. As NH_3 content of the reacting/quenching gas increased from 0% to 100%, the AlN content in the synthesized powder increased from approx. 20%wt to approx. 90%wt. Temperature of the space near the powder-collection area was 1500-1600K, irrespective of the NH_3 content of the reacting/quenching gas. Since the temperature was near the condensation temperature of Al gas mentioned in section 2.2, the non-reacted Al gas could be expected to condense and convert to Al solid. Therefore the results exhibited in figure 6 were considered to be due to the increase in the NH_3 content of the reacting/quenching gas causing the generation of a reacting N-source due to the ease of NH_3 decomposition.

Figure 7 shows the average diameter of the synthesized powder. The average diameter was 30-40nm irrespective of the NH_3 content of the reacting/quenching gas. TEM observation of the synthesized powder

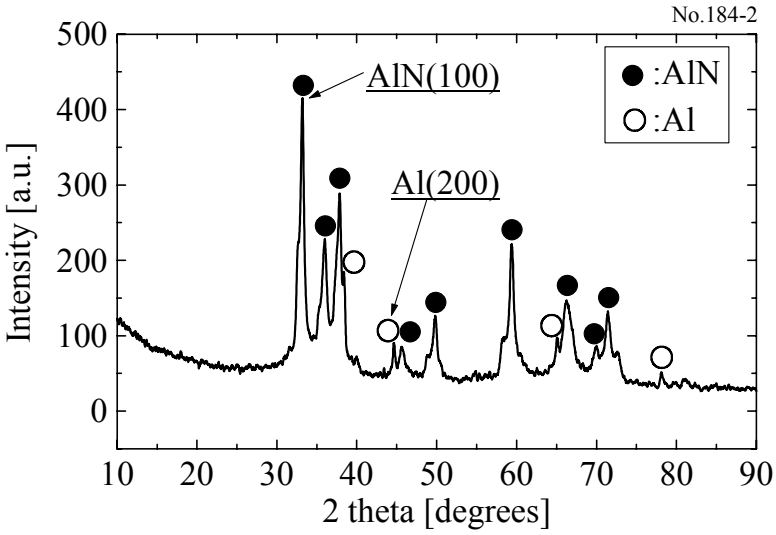

Figure 5. X-ray diffraction profile of synthesized powder.

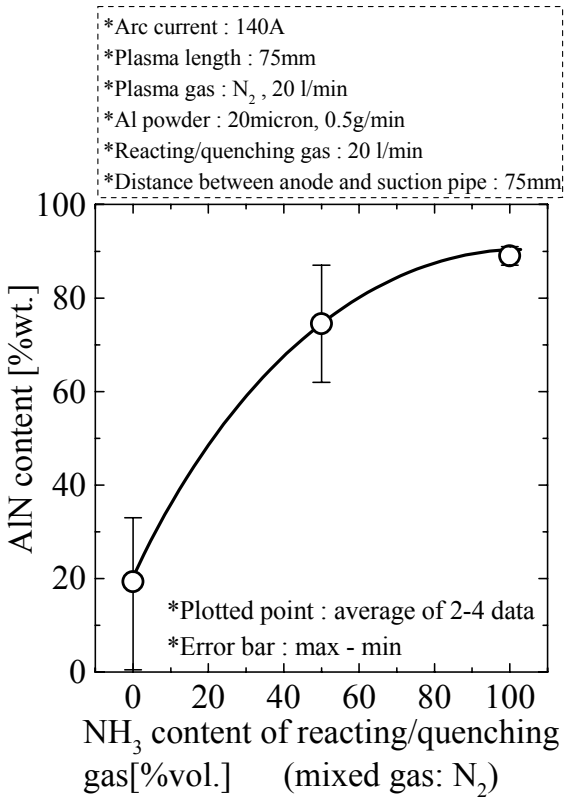

Figure 6. Dependence of AlN content in synthesized Powder upon NH_3 content of reacting/quenching gas.

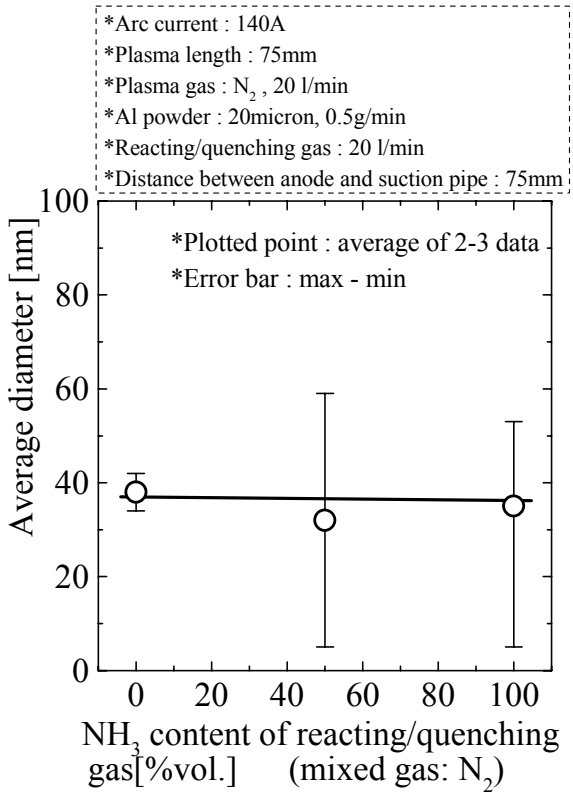

Figure 7. Dependence of average diameter of synthesized powder upon NH_3 content of reacting/quenching gas.

was carried out. Many spherical particles of 20-50nm and a few cubic/hexagonal particles of approx. 50nm were observed when the reacting/quenching gas was N_2. On the other hand, a few spherical particles of approx. 10nm and many cubic/hexagonal particles of 30-70nm were observed when the reacting/quenching gas was NH_3. The spherical particles were non-reacted Al, and the cubic/hexagonal particles AlN [1, 4]. The results of TEM observation coincided with the tendency observed in the results for AlN content in the synthesized powder as shown in figure 6.

4.3 Effect of flow rate of the reacting/quenching gas

The circular and triangular plots in figure 8 show AlN content in the synthesized powder and temperature of the space near the powder-collection area respectively when the reacting/quenching gas used was NH_3. As the flow rate of the reacting/quenching gas increased from 10 to 50 liters/min, the AlN content increased from approx. 70%wt to approx. 90%wt and decreased to approx. 70%wt, while the temperature decreased from approx. 1700K to approx. 1400K. These results suggest that with the increasing flow rate of NH_3 gas the reacting N-source and the AlN content would increase and the condensation of non-reacted Al gas would increase owing to the decline in temperature.

The average diameter of the synthesized powder was measured by the BET method supposing that density of the synthesized powder would be that of AlN because the AlN content in the synthesized powder was relatively high as shown in figure 8. Figure 9 shows the average diameter of the synthesized powder. As the flow rate of the reacting/quenching gas increased from 10 to 50 liters/min, the average diameter decreased from approx. 90nm to approx. 20nm. A reason for this decrease in diameter was considered to be that the temperature of the powder-synthesized space decreased [11, 12] and the AlN density and time spent in the space decreased [11]. TEM observation of the synthesized powder clarified the presence of a few spherical particles of approx. 10nm and many cubic/hexagonal particles when the flow rate of the NH_3 gas was 10 and 20 liters/min. The size of the cubic/hexagonal particles was 100nm and 30-70nm when the flow rate of the NH_3 gas was 10 and 20 liters/min respectively.

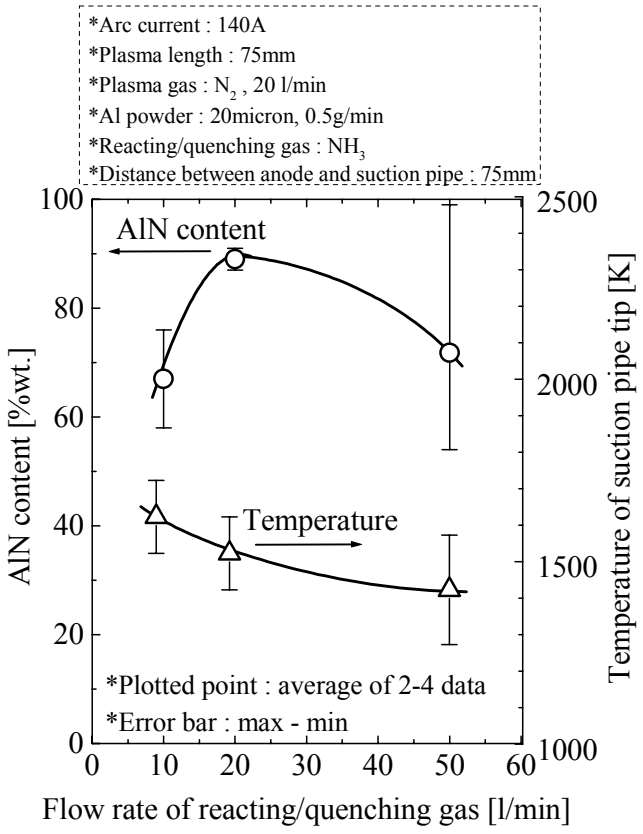

Figure 8. Dependence of AlN content in synthesized powder and temperature of the space near the powder-collection area upon flow rate of reacting/quenching gas.

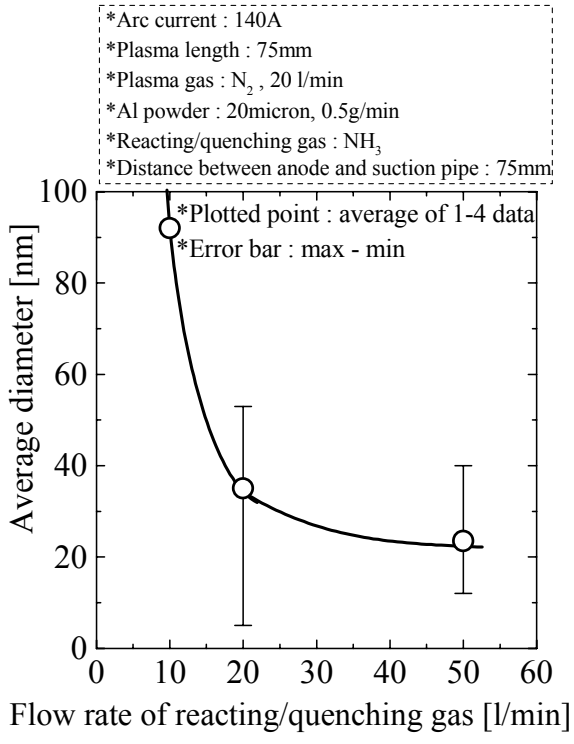

Figure 9. Dependence of average diameter of synthesized powder upon flow rate of reacting/quenching gas.

5. Conclusions

Calculations of chemical equilibrium composition and experiments in the synthesis of AlN nano powder by a transferred type arc plasma were carried out. The calculations clarified that the reacting/quenching gas was recommended to be blown into Al gas in a temperature region of between 2100 and 2300 K, in order to increase AlN content in the synthesized powder. Parameters in the experiment were the NH_3 content and the flow rate of reacting/quenching N_2-NH_3 mixed gas blown into Al gas. As the NH_3 content of the reacting/quenching gas increased from 0% to 100%, the AlN content in the synthesized powder increased from approx. 20%wt to approx. 90%wt, however the average diameter of the synthesized powder did not change greatly (30-40nm). As the flow rate of the reacting/quenching gas increased from 10 to 50 liters/min, the AlN content increased from approx. 70%wt to approx. 90%wt and decreased to approx. 70%wt, while the average diameter decreased from approx. 90nm to approx. 20nm.

Abstract

The recombination of $H_3^+(v=0)$ ions with electrons was studied in stationary afterglow apparatus equipped with infrared Cavity Ring-down absorption spectrometer. From the decay of $H_3^+(v=0)$ density during the afterglow in He/Ar/H_2 mixture the recombination rate coefficient was measured. The recombination rate coefficient obtained at hydrogen density $[H_2] = 1\times10^{14}$ cm^{-3} is $\alpha = 1.2\times10^{-7}$ cm^3 s^{-1}. The kinetic and rotational temperature of recombining $H_3^+(v=0)$ ions was determined from absorption spectrum.

Introduction

H_3^+ ions play very often the dominant role in laboratory and astrophysical hydrogen containing plasmas. $H_3^+(v=0)$ ions were many times detected in interstellar molecular clouds and in atmospheres of large planets (Jupiter, Saturn, Uranus, and Neptune). The knowledge of the reaction kinetics of $H_3^+(v=0)$ ions with molecules and with electrons is required to understand formation, evolution and destruction of those environments. Kinetic of ion – molecule reactions of $H_3^+(v=0)$ ions was subject of numerous studies and is well understood. There are also many experimental and theoretical studies dealing with recombination of H_3^+ ions. The corresponding rate was measured by means of different beam and swarm techniques, however the discrepancy between the most recent data is still very large. Despite the fact that in interstellar medium $H_3^+(v=0)$ ions are present, only very exceptionally internal state of recombining ions was directly determined in experimental studies.

In our very recent stationary afterglow studies of H_3^+ recombination we observed dependence of the recombination rate coefficient on partial pressure of hydrogen molecules [1,2,3]. The density of the ions was measured using a Langmuir probe thus the internal excitation of recombining ions was not directly determined. In the present study infrared Cavity Ring-down absorption spectrometer is used to measure number density of $H_3^+(v=0)$ ions, their kinetic and rotational temperature during the afterglow. From these data recombination rate coefficient for $H_3^+(v=0)$ at 320 K was obtained.

Apparatus

A new cavity ring-down spectrometer was built in our laboratory recently (see description inref. [4]). This absorption technique allows us to detect $H_3^+(v=0)$ ions in a given rotational state. The spectrometer is equipped with an infrared tuneable diode laser in a continuous mode. The high sensitivity of the method is due to the enhancement of the effective optical path-length when laser light is reflected back and forth between the mirrors of an optical cavity. The cavity is inside the discharge chamber and plasma is created between the mirrors of the cavity. A presence of absorbing medium, $H_3^+(v=0)$ ions in our case, is influencing the decay rate of the energy stored in the cavity. The absorption signal is obtained from the characteristic time of the light intensity decay. The characteristic decay time of empty cavity is ~43 μs. The experimental set-up is described in Figure 1. Pulsed microwave plasma is created in the central part of the optical cavity. The discharge operates in a mixture of He and Ar with small amount of H_2. Because the decay of the plasma is very fast it is essential to have very fast operating switch to stop microwave generator (2.45 GHz).

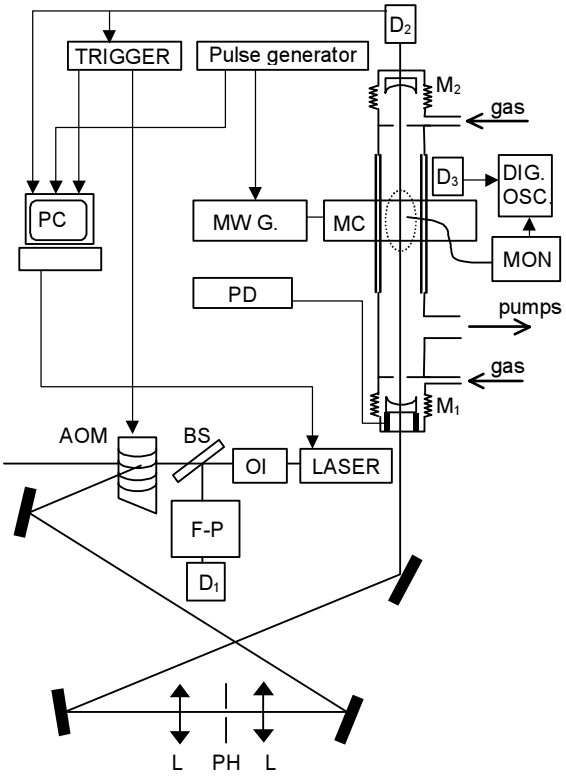

Figure 1: The experimental setup:
OI - optical isolator,
BS - beam-splitter,
F-P - Fabry-Perot interferometer,
AOM - acousto-optical modulator,
D_1 - InGaAs photodiode,
D_2 - avalanche photodiode,
L - lenses, PH - pinhole,
$M_{1,2}$ - dielectric mirrors,
D_3 - high-frequency diode,
MON - monochromator equipped with photomultiplier tube,
MW G. - microwave generator,
PD - piezo-element driver,
MC - microwave cavity.

We have measured microwave signal inside the microwave cavity and in addition also emission of light generated by plasma (see Figure 2). The light emission can be considered as information about electron temperature. From the plots in Figure 2 it is clear that microwaves are cut down within <20 μs and similar it is with light emission.

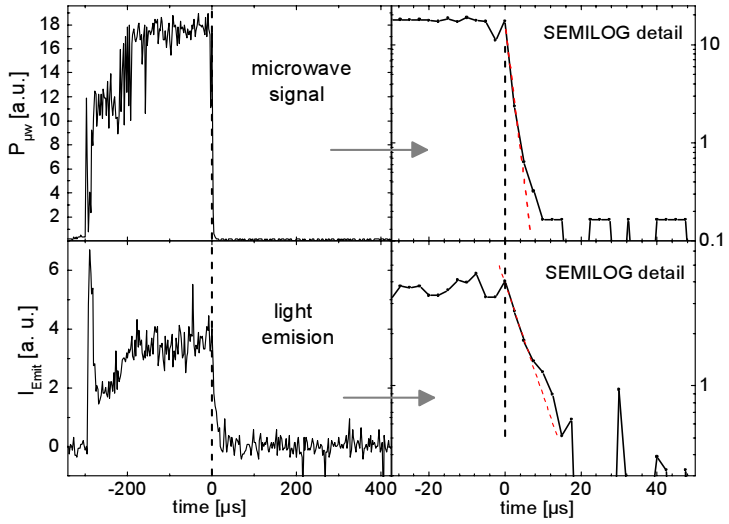

Figure 2: The fall off in the microwave signal and light emission after the discharge switch off. The emission line was not identified. Note that after 20 μs s microwave signal and light intensity can be considered to be zero.

At this moment we are not interested in processes taking place during the microwave discharge. To obtain information about recombination of $H_3^+(v=0)$ ions it is enough to monitor decay of the afterglow plasma in the moment when $H_3^+(v=0)$ ions are dominant ions and when electron temperature is close to buffer gas temperature. We calculated from the kinetic model [1] that in the used mixture of gases the majority of ions and metastables formed during the discharge are converted to $H_3^+(v=0)$ ions within less than 50 μs. In this sense we can skip first 50 μs of the afterglow – early afterglow and use only decay after 50 μs

to determine recombination rate coefficient. The spectrometer was calibrated with water vapor. In Figure 3 there is scan used for calibration

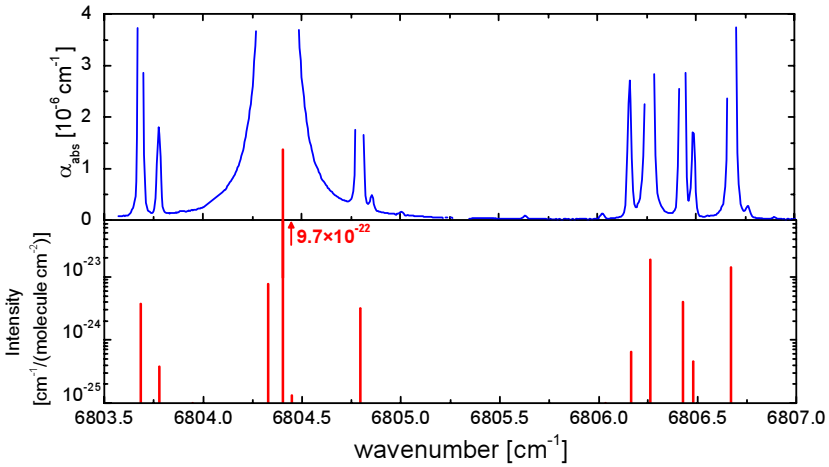

Figure 3: The scan in water vapours, which is used to calibrate the spectrometer. Upper panel: The signal obtained from water vapours. Lower panel: Intensities of the absorption lines from HITRAN 96 database.

Results and discussion

When wavelength were calibrated we introduced mixture of He, Ar and H_2 and we measured absorption spectrum in range 6807 to 6808 cm^{-1}. The composition of the mixture was calculated from kinetic model to obtain maximum absorption. The spectrum was measured in continuous and pulsed discharge. Example of the obtained spectra is plotted in Figure 4.

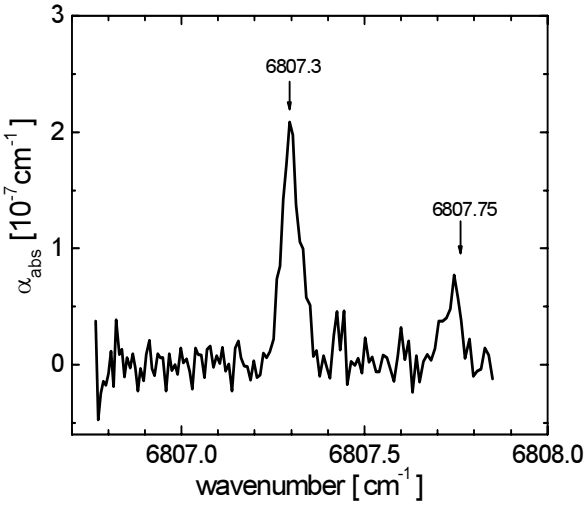

Figure 4: The absorption spectrum of H_3^+(v=0) for ν_2 = 3←0. The line 6807.3 cm^{-1} was used for further evaluation. Conditions in the experiment: the overall pressure p_{He} = 7 Torr, [Ar] = 6×10^{-14} cm^{-1}, and [H_2] = 1.5×10^{-14} cm^{-1}.

The absorption signal corresponding to number density of H_3^+(ν=0) ions was detected on the 6807.3 cm^{-1} (ν_2=3←0) transition. The resonance of the cavity is achieved by sweeping the length of resonator through the resonance position. Once the light intensity becomes high enough the laser beam is switched off and the decay of the light intensity (leaking through one of the mirrors) is detected. Assuming linear absorption the decay is exponential with decay time $\tau(\nu)$, given by:

$$\frac{1}{\tau(\nu)} = \frac{1}{\tau_0} + \frac{d}{L} c\alpha(\nu) \quad . \tag{1}$$

ν is the frequency of the laser light, τ_0 is the decay time in the absence of absorption, d and $\alpha(\nu)$ are the length and absorption coefficient of the absorbing medium, respectively. L is the length of the cavity.

In the Figure 5 the measured time evolution of $H_3^+(v=0)$ density is plotted. The simple evaluation procedure with assumption that the ion density is constant during the ring-down was used to obtain the data were obtained using.

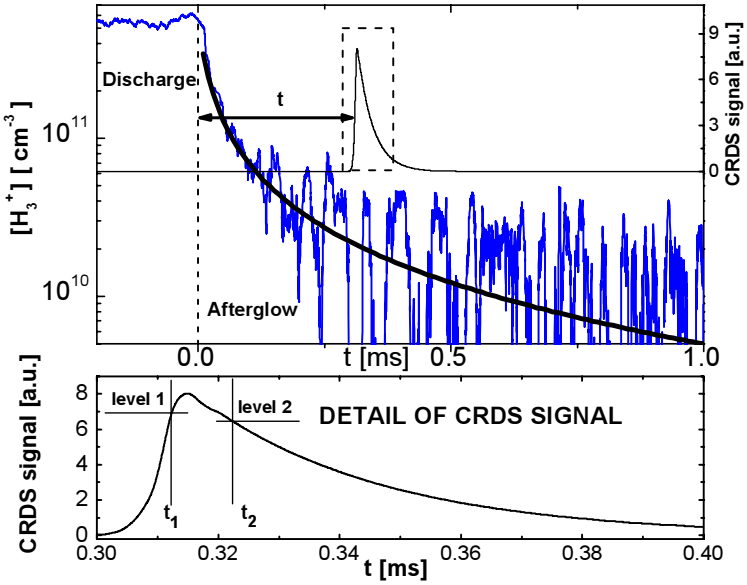

Figure 5: Upper panel: Schematic data showing time dependence of $[H_3^+]$ during the discharge and the afterglow period. Simulated CRDS signal obtained with time delay of t is also shown. Lower panel: detailed view of the CRDS signal. The laser is switched off at the moment t_1, when the signal reaches "level 1". Data acquisition starts at t_2, when the signal drops below "level 2".

As can be seen from the plot, the ion density drops very rapidly in the early stages of the afterglow, this can influence ring-downs started during this fats decay. The ring-down signal cannot be any more described with a single exponential decay and variation of ion density during ring down has to be considered. We decided to use an iterative correction method to improve the density evaluation. The example of obtained decay of $H_3^+(v=0)$ ion density during the afterglow is plotted in Figure 6. The decay curves were fitted by function in which both recombination and diffusion were considered. The obtained recombination rate coefficient is given by the decay in early stages of the afterglow, first ~250 μs. As was already mentioned first 50 μs are influenced by transition from active discharge to afterglow and by formation of $H_3^+(v=0)$. The data from this interval are not considered in evaluation of recombination rate coefficient. The ion number density decrease by one order in magnitude during interval 50-250 μs and this decay is sufficient to obtain reliable recombination rate coefficient.

Absorption spectra during active discharge and during afterglow were also measured. From the shape of spectra rotational temperature of $H_3^+(v=0)$ ions was calculated. From the Doppler broadening the kinetic temperature of $H_3^+(v=0)$ ions was also calculated. Because the decay of $H_3^+(v=0)$ density is very fast signal to noise ratio drops down during early stages of afterglow. That is why kinetic temperature was measured only during the active discharge and during early afterglow period.

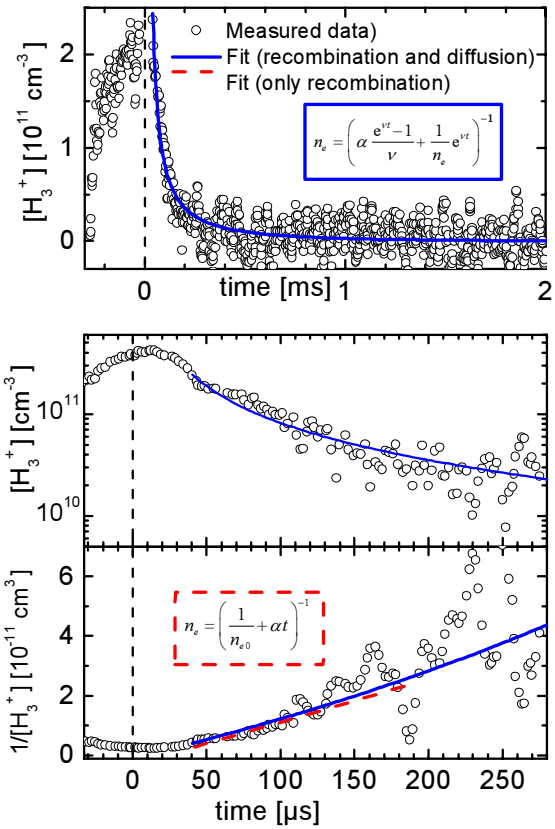

Figure 6: Time dependence of the $H_3^+(v=0)$ density during the afterglow. Upper panel: A decay of $H_3^+(v=0)$ during afterglow. Data are obtained by iteration method. Central panel: The detail of the decay of recombination dominated plasma in log scale. Lower panel: The detail of data in central panel in reciprocal scale. The slope of the linear part of plot is given by rate coefficient of recombination.

In Figure 7 is plotted evolution of kinetic temperature obtained from Doppler broadening. Note that in the active discharge kinetic temperature is ~350 K and within 50 μs after shutdown of microwaves it drops down to ~320 K. The actual temperature of the discharge tube was also ~320 K. We can conclude, that kinetic temperature of the recombining $H_3^+(v=0)$ ions is equilibrated with buffer gas temperature. Similar result was obtained for rotation temperature of recombining $H_3^+(v=0)$ ions. In used experimental conditions pressure broadening can be neglected in comparison with Doppler broadening.

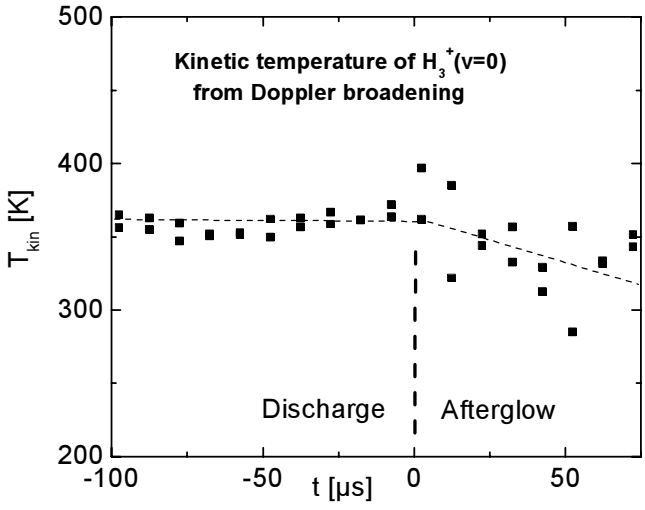

Figure 7: Kinetic temperature of $H_3^+(v=0)$ as obtained from Doppler broadening of the spectral line.

As an average result of many different data sets the rate-coefficient for recombination of $H_3^+(v=0)$ ions with electrons was derived to be $(1.2 \pm 0.7) \times 10^{-7}$ cm^3 s^{-1}, this value belongs to hydrogen density of about 4×10^{14} cm^{-3} and to temperature 320 K. We stress here once again that kinetic temperature and rotational temperature of recombining ions was measured in present experiment. The obtained recombination rate coefficients are plotted in Figure 8 together with our earlier results. In the figure are included data obtained in three different experiments: AISA – Advanced Integrated Stationary Afterglow [1,2,3]; HPFA – High Pressure Flowing Afterglow with Langmuir probe [5,6]; and present SA - CRDS – Stationary afterglow with infrared cw-diode cavity ring-down spectrometer (see also refs. [4]). Because of dependence of recombination rate coefficient on hydrogen number density symbol α_{eff} is used to stress the fact that observed recombination is a three-body process. Data obtained on HPFA at high pressures and lower temperature shows influence of formation of H_5^+ ions and their recombination to the overall loss process in hydrogen plasma [5,7]. This recombination channel is not playing role at lower pressure in AISA and at higher temperature in SA – CRDS. Note that independent on differences in temperature and buffer gas pressures the recombination rate coefficients obtained in different experiments for similar hydrogen number densities are in very good agreement.

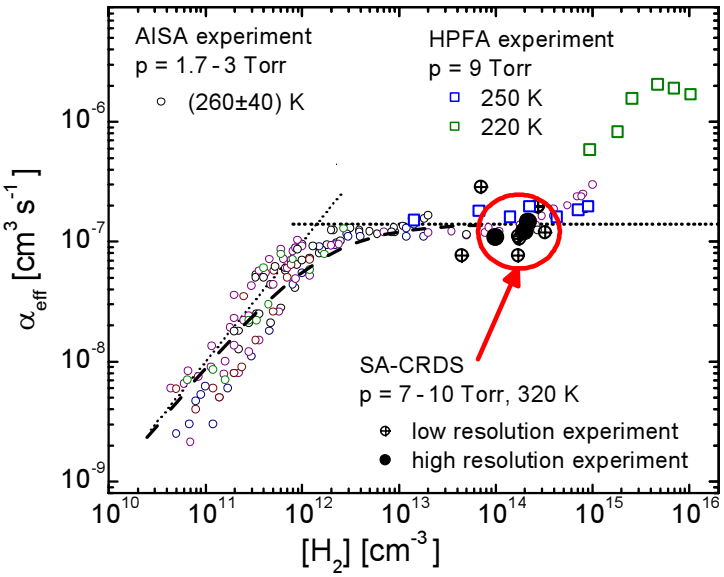

Figure 8: Dependence of observed α_{eff} on hydrogen number density. The FALP and AISA data are also included.

Abstract
In this paper a laser-plasma source of soft x-rays and extreme ultraviolet (EUV) is presented. The source is based on a recently developed double-stream gas puff target, irradiated with a Nd:YAG laser. The characterization and optimization of the source measurements have been made using the grating spectrographs and the absolutely calibrated silicon photodiodes.

1. Introduction

A laser plasma can be produced in result of interaction of a high power laser pulse with a gas puff target, created by pulsed injection of gas through the nozzle of the electromagnetic valve. The use of the gas puff target eliminates production of target debris associated with solid targets [1]. The gas puff laser plasma can be an efficient source of soft x-rays and extreme ultraviolet in the wavelength range from about 1nm to 20 nm. The radiation characteristics of the source have been improved by using a new double-stream gas puff target approach, developed at the Institute of Optoelectronics, Warsaw, Poland [2]. In this approach the gas puff target is formed by injection of high-Z gas (xenon, krypton, argon) from the circular nozzle into a hollow stream of low Z gas (hydrogen or helium) from the outer nozzle in a form of a ring. The target design assures high density of gas in the interaction area, what leads to efficient absorption of the laser energy and high production of x-rays and EUV. Strong x-ray and EUV production from the double-stream gas puff target irradiated with nanosecond laser pulses from Nd:glass and Nd:YAG, approaching production from solid targets irradiated in the same conditions, has been demonstrated [3, 4].

In this paper a compact laser plasma soft x-ray and EUV source based on a double-stream gas puff target is presented. The target is irradiated using a Nd: YAG laser producing pulses with time duration of 4 ns and energy about 0.5 J. The spectral characteristics of x-ray and EUV emissions have been studied with the use of the transmission grating spectrograph (TGS) and the grazing incidence spectrograph (GIS). Additionally, the absolutely calibrated photodiodes (AXUV-100 Si/Zr and AXUV HS1, IRD Inc.) were used to measure the EUV yield at 13.5 nm. The source has been developed under the European MEDEA + programme (project T 405).

2. Experimental arrangement

2.1. Laser plasma x-ray and EUV source

The laser plasma x-ray and EUV source consists of a vacuum chamber equipped with the gas puff target system and a Nd:YAG laser to irradiate the target. The gas puff target system is made of two electromagnetic valves combined in a common body and a double-nozzle setup. The nozzle setup is schematically shown in Fig. 1. Both valves are separately driven by the current pulse from the power supply. The power supply is synchronized with the laser pulse. The diameter of the inner nozzle was 0.4 mm and the diameters of the outer nozzle 0.8 mm and 1.5 mm, respectively. The outer stream from low-Z gas confines the high-Z gas stream along the nozzle axis and prevents from its decompression. By changing the time delay Δt between the laser pulse and the opening of the valve one can change the parameters of the target. An example view of the shadowgram of the target is presented in Fig. 2. The valve system allows to produce the gas puff targets with the repetition rate up to 100 Hz, but only a single laser shot operation was used in this study.

The schematic diagram of the laboratory model of the laser plasma x-ray and EUV source with diagnostics is shown in Fig. 3. The experimental setup consists of a vacuum chamber with the electromagnetic valve system, an aspherical lens to focus the laser beam, a compact Nd: YAG laser system, which generates 4ns pulses with repetition rate up to 10 Hz and energy up to 550 mJ, and an oil-free vacuum pump (Varian) enabled to evacuate the chamber up to pressure of about $2 \cdot 10^{-2}$ mbar. The laser beam is

focused onto the gas puff target perpendicularly to the gas flow. The laser focus was about 100 μm in diameter giving the radiation power density of about 10^{12} W/ cm^2.

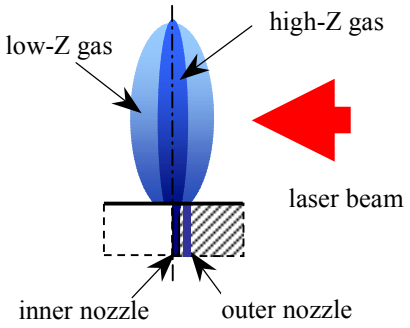

Fig. 2. Schematic of the double nozzle setup.

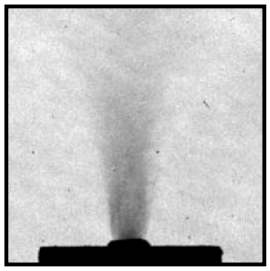

Fig. 1. View of the shadowgram (Δt_{Ar} = 600 μs, Δt_{He}= 600 μs).

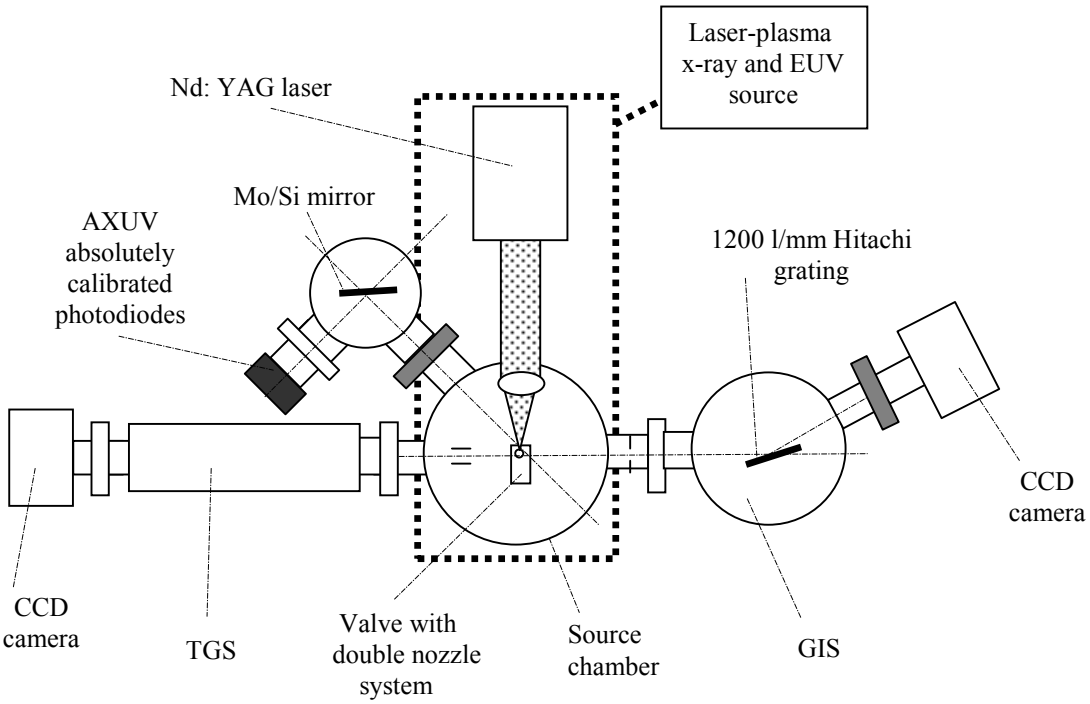

Fig. 3. Schematic of the source with diagnostic.

2.2. Transmission grating spectrograph (TGS)

Spectral studies of the x-ray and EUV emissions from the source for different spatial position of the laser beam focus to the gas puff target using the transmission grating spectrograph were carried out. The spectrograph was equipped with the free-standing grating of 1000 lines/mm inside the 50 μm in diameter pinhole (Heidenhain GmbH) and enabled use a slit and was coupled to back-thinned array CCD camera, 1340 x 400 pixels, 20 μm square shape each (Roper Scientific, SX-400). The chip of the camera was placed at the distance of 70 cm from the grating, giving the magnification of about 10 and could cover the spectral range up to 20 nm. Although the spectral resolution of the used transmission grating was smaller as compared with the reflection grating, however location the grating in a pinhole with known diameter makes it possible to estimate absolute energy of the source at specific wavelength.

2.3. Grazing-incidence spectrograph (GIS)

For spectral measurements of the source in the soft x-ray and EUV region a spectrograph with a gold reflection grating Hitachi 1200 lines/mm was used. The spectrograph may be used to measure x-ray wavelength between the 5 nm and 15 nm region. The spectrograph was equipped with a back illuminated

CCD camera (Roper). Experimentally the spectral resolution of the spectrograph about 0.2 Å on basis the oxygen spectra was estimated.

2.4. Photodiode detectors

The photodiode detectors were set beyond a selective multilayer Mo/Si mirror (IOF, Jena). The selective Mo/Si multilayer mirror was located inside the separate chamber between the source and the spectrograph. The mirror has a shape of a 1 cm^2 square and was optimized at 13.5 nm in the EUV region for an incidence radiation angle of 45°. Two absolutely calibrated photodiodes AXUV-100Si/Zr (pass band 11 nm – 17 nm) with a filter made from 200 μm thick Zr onto a 100 μm Si plate, sensitive especially at 13.5 nm and AXUV-HS1 photodiode with a filter made from a 0.2 μm thick Si_3N_4 membrane onto a 1 μm thick Mo layer were used to register energy signals of EUV pulses. Detector HS1 was placed at the distance of 485 mm from the plasma and photodiode with Zr filter at 610 mm distance.

The signals from the AXUV-100Si/Zr were registered with the use of the monitoring system. The signals from fast HS1 detector exceeding the time resolution of 0.25 ns were detected by the 500 MHz digital oscilloscope, thus time shape of the EUV signal could be stored.

3. Results of experiments

3.1. Transmission grating spectrograph measurements

Four distances Δh between the laser focus and the nozzle output were chosen: 0.8; 1; 1.5 and 2 mm for which investigations were carried out. For this distances various locations of the laser beam in relation to the axis of the nozzle were set. Depending on the laser focus position different spectral distributions were observed. The change of the focus position perpendicularly to the axis beam strongly affected on the emission measurements, while the change towards the axis beam weakly depends on the results. Because the grating was placed inside the pinhole, perpendicular distribution to spectral distributions in the spectra are spatial sizes of the source at specific wavelength. An example of the Soft x-ray and EUV spectra corresponding to the laser focus position, where the focus was set 2 mm beyond the target and 1.5 mm above the nozzle output is shown in Fig. 4. The x-ray and EUV emissions from the spectra can be distinguish. In the soft x-ray region a dominant spectral feature is laid near 6 nm, in the EUV region near 10.7 nm. From the spectra the x-ray yield 4.1 mJ/sr at the wavelength 6 nm ± 1 nm and EUV yield 4.3 mJ/sr at the wavelength 13.5 nm ± 1 nm was evaluated.

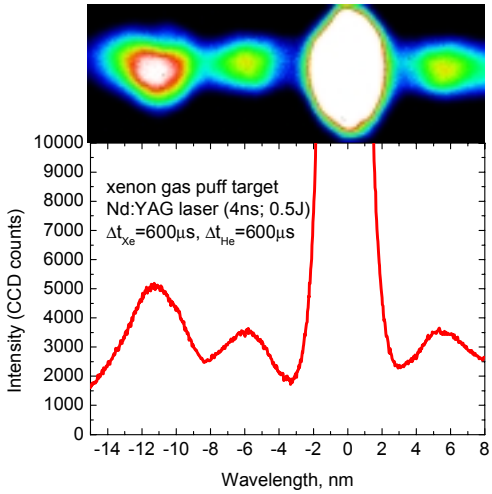

Fig. 4. Spectral image and distribution of the Xe/He source for no slit case (Δ t_{Xe}= 600 μs Δ t_{He}= 600 μs).

3.2. Grazing-incidence spectrograph measurements

Although the source covers x-ray and EUV emission ranges the most interesting for us spectral region was laid near 13.5 nm. This region is strongly important for EUV metrology and lithography application, because advanced optics in this range was developed. Thus was put emphasis on diagnostic at 13.5 nm. A dependence of the emission of the source at 13.5 nm from the time delay between the laser pulse and the triggering pulses of the valves was investigated. Measurements for the time delay in the range from 500 μs to 900 μs with the step 100 μs were carried out. For each time delay settings mentioned above time delay for

helium or hydrogen valve in the range from 200 µs to 800 µs, 100 µs step were set. In Fig. 5 the typical spectra and calculated from images spectral distributions for Δt_{Xe}=800µs, $\Delta t_{He,H}$=350µs in the Xe/He and Xe/H cases are shown. For fixed time parameters four measurements for statistics in single laser shot regime were done. The maximum emission at 10.7 nm (4d - 4f) from created in those condition laser plasma was observed. The strongest emission at interesting us 13.5 nm was registered for Δt_{Xe}= 800 µs and $\Delta t_{He,H}$ in the range 300 µs to 400 µs. These results are presented in Fig. 6. This range of the time delay for auxiliary gas was investigated with the step 25 µs what is presented in Fig. 7. From this picture is clearly seen that for fixed other parameters the optimum conditions are Δt_{Xe}= 800 µs, $\Delta t_{He,H}$= 350 µs, where the EUV yield was the highest, moreover emission ratio of the radiation at 13.5 nm to radiation at 10.7 nm was as 1:2. Generally for various time delays higher emissions at 13.5 nm were registered for hydrogen as a auxiliary gas as compared with helium. Proper results are presented in Fig. 8.

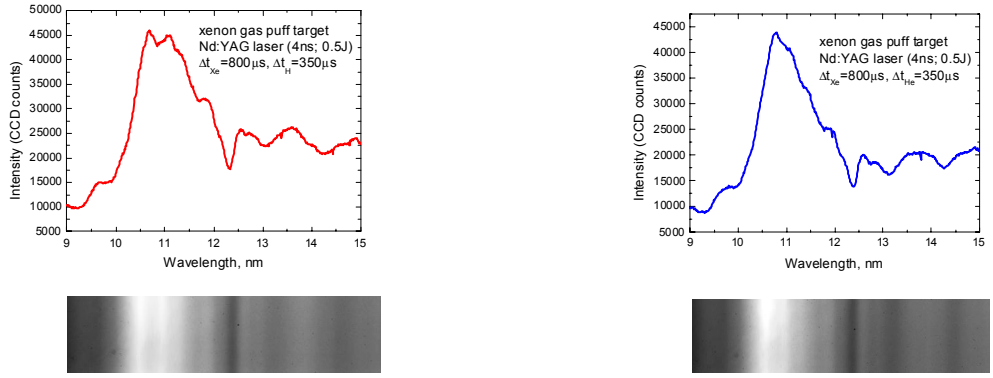

Fig. 5. Spectral images and spectral distributions obtained from GIS for Δt_{Xe}=800µs, $\Delta t_{He,H}$=350µs. (a) Xe/H, (b) Xe/He

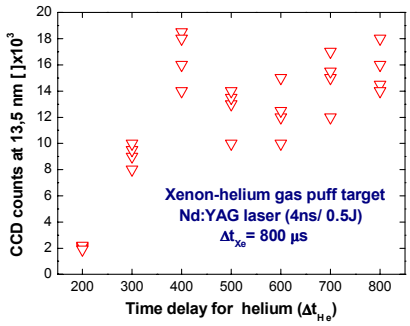

Fig. 6. CCD counts at 13.5 nm. Δt_{Xe}=800µs, Δt_{He}=200-800µs

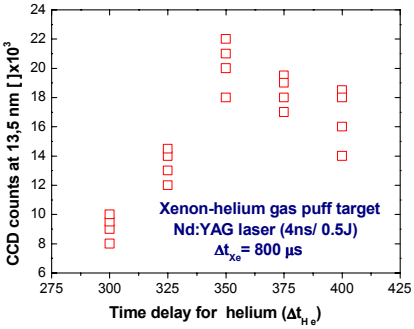

Fig. 7. CCD counts at 13.5 nm. Δt_{Xe}=800µs, Δt_{He}=200-800µs

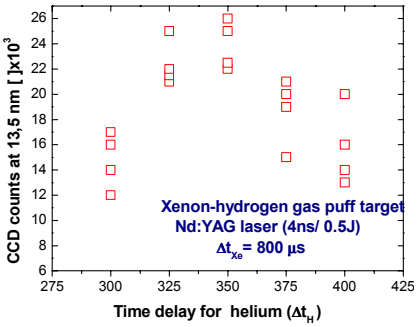

Fig. 8. CCD counts at 13.5 nm. Δt_{Xe}=800µs, Δt_{H}=200-800µs

3.3. Silicon photodiodes measurements

The detectors beyond the selective multilayer Mo/Si mirror were installed. The signals from the absolutely calibrated AXUV-100Si/Zr photodiode for various locations of the laser beam in relation to the axis of the nozzle were measured. A proper geometry is shown in Fig. 9

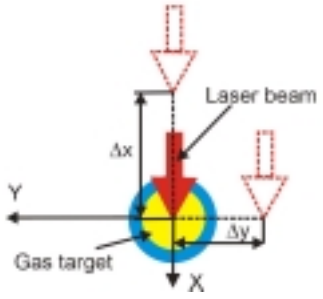

Fig. 9. Settings geometry for fixed distance between the laser focus and the nozzle output.

In Fig. 10 the results from the AXUV-100Si/Zr detector are presented. From these pictures is seen that the position of the laser focus above the nozzle output and along the axis of the beam as well are not critical.

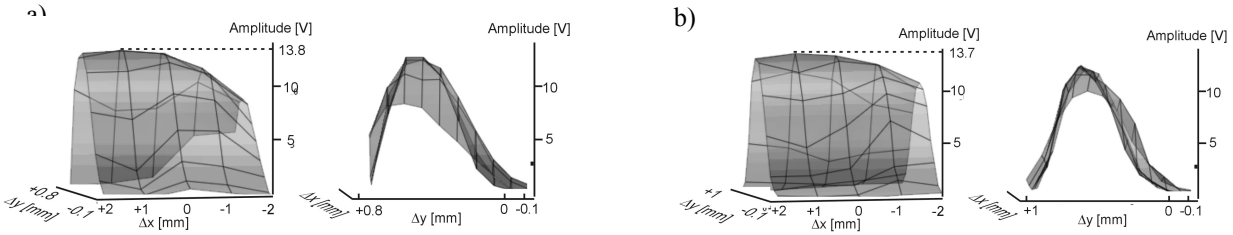

Fig. 10. Dependence of EUV production at 13.5 nm on the position of the laser focus to the nozzle output from AXUV-100 Si/ Zr. (a) 1.5mm, (b) 2 mm distances between the laser focus and the nozzle output of the valve.

The use AXUV-HS1 photodiode with a time resolution of 0.25 ns made it possible to measure time shape of the EUV pulse out of the selective mirror. The typical signal from HS1 diode is presented in Fig.11.

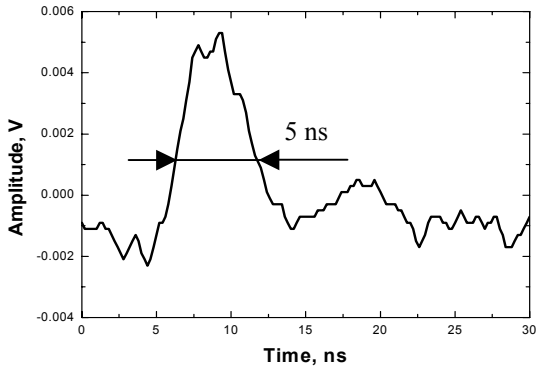

Fig. 11. Typical pulse shape from AXUV-HS1 detector.

The highest emission of the source for $\Delta x = 0$ and $\Delta y = 0.5$ mm settings was observed, however size of the plasma in this case was bigger compared with focusing the laser beam on the axis of the valve nozzle ($\Delta x = 0$, $\Delta y = 0$). Although the emission in those condition was the biggest the plasma size was big too. Considering the EUV source application for metrology one ought to optimize position of the laser focus in order to obtain high emission at 13.5 nm behaving the spatial sizes of the plasma as small as possible.

4. Conclusions

Recently carried out research of the laser plasma EUV source were presented. In the source a commercial Nd: YAG laser (4 ns, 0.5 J, 10 Hz) and developed at the Institute of Optoelectronics double nozzle valve system to create double stream gas puff target were used. The measurements of the source emission near 13.5 nm were made. Thus an emission of about 4.3 mJ/sr from TGS, 1.45 mJ/sr for AXUV-HS1 diode and 2 mJ/sr for AXUV-100Si/Zr at the wavelength 13.5 nm was estimated. Next step should be the measurements with the repetition rate regime of the work source with the use a differential gas pumping, each chamber separately method.

Abstract
Initial insight into the plasma chemistry taking place during deposition of textured ZnO is obtained from mass spectrometry. A new method for fast dry ZnO etching using a remote argon - hydrogen plasma is demonstrated, including competitive film modification. Atomic hydrogen is considered to be the reactive species, the excess of molecular hydrogen in the gas phase does not contribute to the etching.

1. Introduction

Zinc oxide (ZnO) is a transparent conducting oxide (TCO) of considerable technological interest for amongst others application in thin film solar cells. Recently, a new method has been presented for low temperature deposition of surface textured ZnO utilizing an expanding thermal argon plasma created by a cascaded arc [1]. It has been shown that high quality material is obtained, showing excellent performance in thin film a-Si:H solar cells [1,2,3]. Initial plasma chemistry aspects obtained from mass spectrometry are presented. Considering the recently recognized role of hydrogen in ZnO film modification [4,5,6], a new method for fast dry etching is demonstrated using a remote argon - hydrogen plasma implying the absence of significant ion bombardment. Contrary to numerous wet etching chemistries for ZnO [7,8,9], just a few attempts on dry ZnO etching have been reported [10,11,12] all involving ion-assisted halogen- or carbon-based chemistries.

2. Experimental

Undoped substoichiometric ZnO films are deposited on Corning 1737F glass substrates (100x50 mm^2) by the expanding thermal plasma (ETP) chemical vapor deposition process as described in detail elsewhere [1]. Oxygen and diethylzinc (DEZ) are used as the (co)precursors for deposition. In order to gain initial insight into the chemistry taking place, a Balzers QMS 200 Prisma mass spectrometer operating at an ionization energy of 70 eV is mounted in the reactor pump line. This way, only stable reaction products can be detected. All recorded m/Z signals are normalized to argon to compensate for fluctuations of pressure and temperature, and corrected for the background contribution of this specific m/Z value.
Etching experiments are performed in a similar ETP set up. A subatmospheric thermal argon plasma (typically 0.3 - $0.4 \cdot 10^5$ Pa) is generated in a dc arc discharge and expands supersonically into the low pressure (100 Pa) reactor chamber. At 5 cm from the arc outlet, the hydrogen is injected in the plasma by means of a ring. No power is coupled in downstream leading to a low electron temperature (0.2 - 0.3 eV) in the expanding beam [13,14]. Electron-induced molecular dissociation is unlikely to occur, the chemistry is dominantly controlled by (Ar^+, e^-) emanating from the arc [15],

$$Ar^+ + H_2 \rightarrow ArH^+ + H \qquad 1.2\ 10^{-9}\ cm^3/s \qquad (1a)$$
$$ArH^+ + e^- \rightarrow Ar + H^* \qquad 10^{-7}\ cm^3/s \qquad (1b)$$

The mixture of reactive particles flows at subsonic velocities to the substrate placed at 60 cm from the nozzle where, without any significant ion bombardment [16], etching takes place. *In-situ* real time spectroscopic ellipsometry is applied to evaluate the etching process in terms of structural and compositional modification. Ellipsometric Ψ and Δ data were acquired at an angle of incidence of 68° over the spectral range of 245 – 1000 nm with a resolution of 1.6 nm using a Woollam M-2000F rotating compensator ellipsometer.

3. Results and Discussion

Spontaneous decomposition of DEZ, $Zn(C_2H_5)_2$, in absence of either oxygen or plasma exposure is very low. A strong signal at m/Z values related to the monomer is visible, there appear to be no reaction products other then belonging to the monomer cracking pattern visible in the spectrum. Decomposition of DEZ can occur either thermally, directly stimulated by the plasma, or through reaction with oxygen due to its pyrophoric

nature. Under plasma exposure DEZ is completely decomposed, even in the absence of oxygen. In all conditions no Zn related fragments are detected, indicating the relatively low density of $Zn(C_2H_5)_2$, $Zn(C_2H_3)_2$, ZnH_2, $Zn(OC_2H_5)_2$, $Zn(OCH_3)_2$, $Zn(OH)_2$ and ZnO in the gas phase. Main products detected in the plasma induced decomposition are C_2H_6, C_2H_4, C_2H_2, and H_2, see Figure 1, in the plasma induced oxidative decomposition CO, CO_2, H_2O and H_2. The presence of these product suggests a rich plasma induced hydrocarbon chemistry.

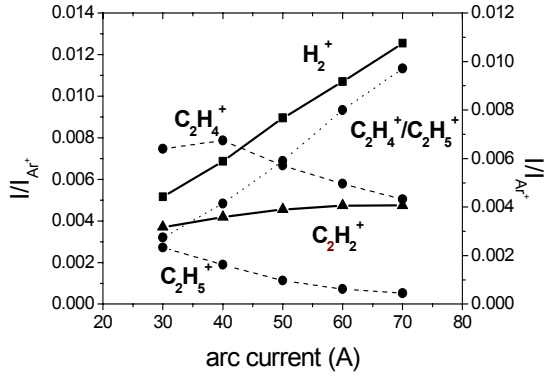

Figure 1: Different reaction product related fragments detected with mass spectrometry in the plasma induced decomposition of DEZ. Notice that the fragment $C_2H_4^+$ can be attributed to both C_2H_4 and C_2H_6. To distinguish its contribution to these species, the ratio $C_2H_4^+/C_2H_5^+$ has been plotted as the fragment $C_2H_5^+$ is solely attributed to C_2H_6.

The initial decomposition of DEZ is stimulated by (Ar^+, e^-) emanating from the cascaded arc favorably breaking the Zn-C bond (Figure 2), although in presence of oxygen (Ar^+, e^-) will be partly consumed to produce atomic oxygen, which also directly might attribute to the decomposition of DEZ.

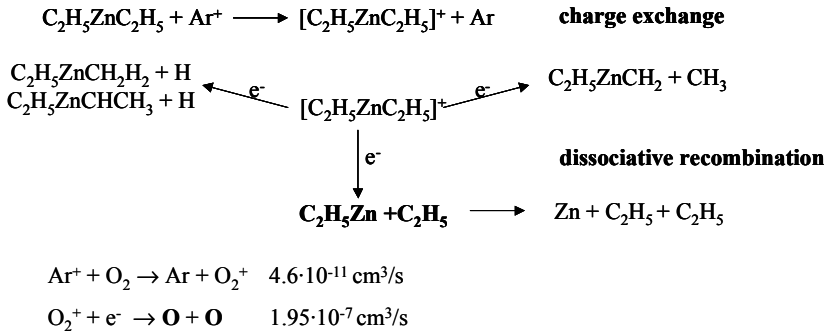

Figure 2: (Ar^+, e^-) dominated plasma induced decomposition pathways of DEZ and oxygen.

Dry etching of textured ZnO is demonstrated using a remote argon - hydrogen plasma. In absence of plasma exposure, i.e. in an argon / hydrogen gas mixture, as well as under plasma exposure without any hydrogen dosing, no etching is observed at all. From 2 sccs hydrogen, saturation occurs, indicative for a limitation of the reactive etching species present, see Figure 3. This is confirmed by the lowering of the effective etch rate at a lower amount of (Ar^+, e^-) emanating from the arc at a lower arc current or total argon flow, indicating atomic hydrogen is the reactive species whereas the excess of molecular hydrogen in the gas phase does not contribute to the etching.

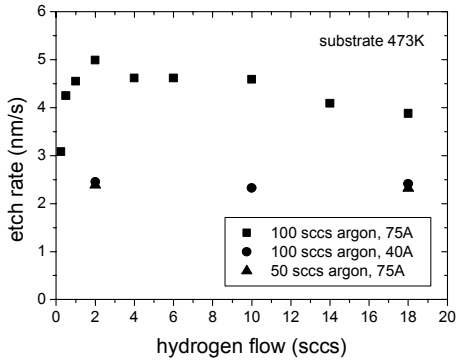

Figure 3: ZnO etch rate versus hydrogen flow for different amounts of (Ar^+, e^-) emanating from the arc.

With a variation of substrate temperature in the range 323 – 573K, visualised in Figure 4, an *overall* apparent activation energy of 0.23 ± 0.01 eV (22.3 ± 1.0 kJ $mole^{-1}$) is determined, which is indicative for a limitation of formation and removal of reaction products from the substrate surface (surface kinetics control). It's likely the etching occurs due to removal of O bij H, followed by vaporisation of free Zn [12]. Removal of the latter might be the limiting step due its rather low vapor pressure (10^{-3} mbar at 573K) [17].

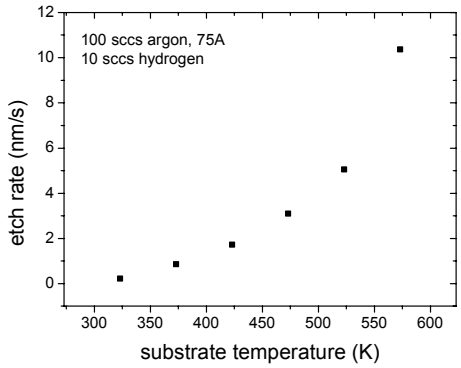

Figure 4: ZnO etch rate versus substrate surface temperature.

Evaluation of the etching process in terms of structural and compositional modification is obtained from *in-situ* real time spectroscopic ellipsometry. A simple but appropriate optical model for the visible wavelength range is the Cauchy model, an approximated polynomial form of the Sellmeier relation commonly used for ZnO [18]. The optical constants of the silicon substrate with native oxide are determined separately for each different temperature. The model is used to determine film thickness and roughness, the optical constants of the surface layer being described as a mixture of ZnO and void (ambient) using the Bruggeman Effective Medium Approximation (BEMA). The presence of any voids in the bulk layer is neglected, and the optical properties are considered to be homogeneous in depth initially. The optical constants of the film are calculated subsequently 'point by point', that is, without assuming any dispersion model.

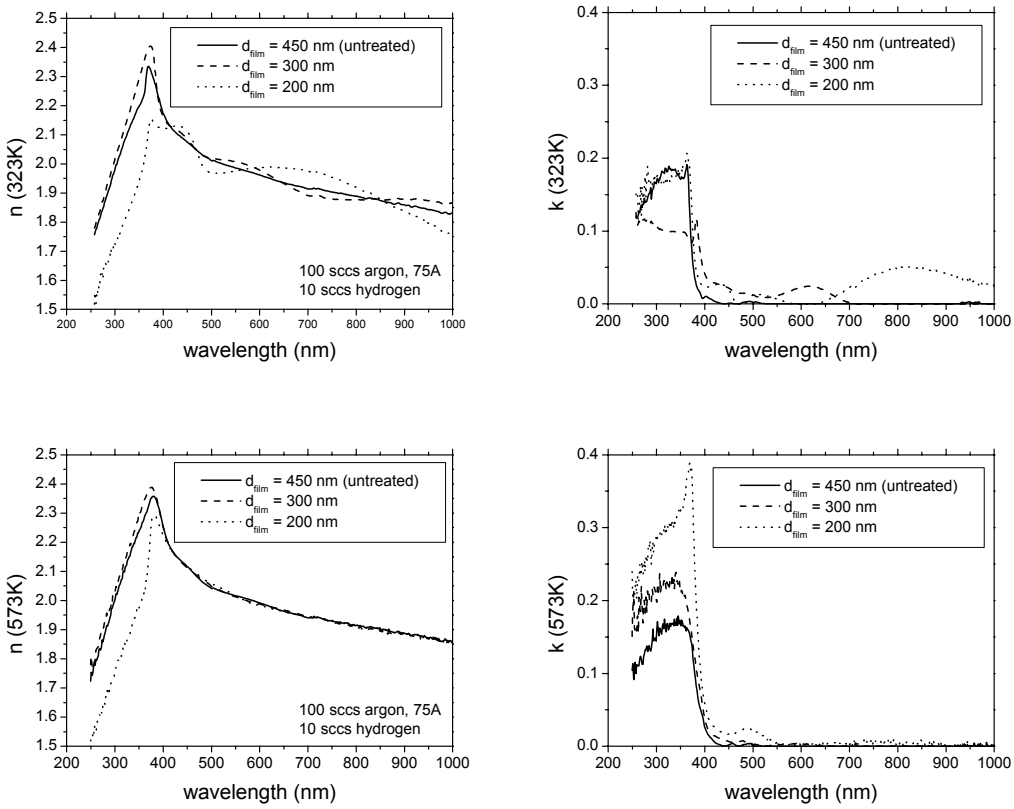

Figure 5: Ellipsometric film composition (optical constants n and k) for untreated and hydrogen treated ZnO films at different substrate surface temperature.

At a high substrate temperature, etching appears to be homogeneous, moderate surface roughening e.g. increasing top layer thickness and void fraction is observed, indicating a merely confined hydrogen film penetration. On the contrary, with lowering the substrate temperature it is assumed the formation and / or reaction product removal is becoming slow compared to hydrogen film penetration, resulting in both significant roughening and a changing film composition as deduced from the optical constants, see Figure 5. Hardly any change in film composition in comparison to the untreated material is observed at a high substrate temperature. Film etching and modification therefore become competitive processes, possibly in combination with a faster removal of the modified material.

4. Conclusions

Initial insight into the plasma chemistry taking place during deposition of textured ZnO is obtained from mass spectrometry. Main products detected in the plasma induced decomposition of $Zn(C_2H_5)_2$ are C_2H_6, C_2H_4, C_2H_2 and H_2, in the plasma induced oxidative decomposition CO, CO_2, H_2O and H_2. A new method for fast dry etching of textured ZnO using a remote argon - hydrogen plasma is demonstrated, including competitive film modification in terms of surface roughness and composition. Etch rates up to over 10 nm/s have been obtained. Atomic hydrogen is considered to be the reactive species, the excess of molecular hydrogen in the gas phase does not contribute to the etching. A more detailed study with respect to film properties is in progress.

Abstract
We present a model describing the main trends of the principal processes occurring in nitrogen DC glow discharge plasma with two parallel graphite electrodes. The computational model describes the axial structure as composed by the bulk plasma in the positive column of the gas discharge tube. Due to the surface processes occurring at both electrodes, the gas phase species C, CN are generated in the discharge. These particles together with N atoms are deposited on discharge tube surface. The sputtering efficiency for production of CN molecules from cathode due to ion bombardment and the probability of wall losses of CN are determined from comparison with the experiment.

1. Introduction

The study of CN molecules has attracted much interested in the last decades due to the prominent role played in astrophysical processes. Much research effort has recently been also directed to the use of plasma-enhanced chemical vapour deposition (PECVD) to produce thin-films which consist of components C and N.
Here we present a model describing the main trends of the principal processes occurring in the positive column of a nitrogen DC glow discharge with graphite electrodes. This device is a source of gas phase C and N atoms and CN molecules and can be used for deposition of C and N and thin film production.

2. Kinetic model for bulk plasma processes

Only the positive column is described. The cathode sheath extends through a small region l_{cathode} (l_{cathode} (cm) ~ 0.45/p, with p the gas pressure in Torr). Electron current and electron density are small in this region, the plasma is not quasineutral and the main current is formed of positive ions to cathode. These ions have a big average kinetic energy, bombard graphite cathode cause the sputtering of C atoms and CN molecules. The calculation of C atom and CN molecule densities in the discharge is carried out in our model. The negative glow region is not investigated in the present work. In the positive column, electron transport parameters are obtained by solving the homogeneous Boltzmann equation, as derived from the classical two-term expansion in spherical harmonics; quasi-neutrality is assumed and ambipolar diffusion control the behavior of electrons and ions in the bulk plasma.
The kinetics in nitrogen considered in this model is the same as used in previous model [1]. Spectroscopic measurements done on this kind of discharge [2], have indicated that the most important carbonated species are CN(X) and CN(B). That is why, additionally to C, CN the calculations of CN(B) and CN^+ densities are also included in model. To simplify, we assume that all C atoms are in the fundamental state and the chemical reactions take place both in volume and at the surfaces. The CN(B) kinetics are the same as used in [3]. The most important reactions pertaining to the kinetics of carbonated species are listed in [4].

3. Surface model

The wall tube losses for all species can be described in the framework of one dimension by the formula [5]

$$K_w\,(\text{s}^{-1}) \approx [R^2/(5.8D) + 2R/(\gamma_i < c >)]^{-1} \qquad (1)$$

Here, D is the diffusion coefficient, $< c >$ is the particle mean velocity near the wall and γ_i is the probability of wall deactivation for the *ith* species. For ions γ_{ion}=1; this gives losses by ambipolar diffusion.

We introduce in our kinetic model the production of C atom and CN molecules at the graphite electrodes. At the cathode, it occurs the well-known process of sputtering of C atom due to bombardment of the cathode by energetic positive ions, which are accelerated in the cathode fall region:

$$N_2^+ \text{ (or } N_4^+) + \text{C(surface)} \rightarrow \text{C(gas)} \qquad (2)$$

However, experiments show that the source of C and CN can be also at anode. That is why we have assumed that the surface process for production of C atoms is the process of collision with graphite surface of metastable molecules $N_2(a')$:

$$N_2^* + C(surface) \rightarrow C(gas) \quad (3)$$

Here N_2^* is $N_2(a')$. The energy of these metastables is enough to break the chemical bond C-C on graphite surface

We have also assumed that similar processes can produce gas phase CN molecules:

$$N_2^+ \text{ (or } N_4^+) + CN(surface) \rightarrow CN(gas) \quad (4)$$

$$N_2^* + CN(surface) \rightarrow CN(gas) \quad (5)$$

The surface molecules CN(surface) on graphite electrodes can be produced due to chemical adsorption of gas phase N atoms. We have introduced the processes (4), (5) in our kinetic model because the calculation of [CN] with taking into consideration only volume processes gives the very small CN density which is not in agreement with experiment.

4. Calculation of carbonated species

If we accept these mechanisms for surface production of C atoms and CN molecules, the fluxes $G_{cathode}$ and G_{anode} of gas phase C or CN from cathode and anode, respectively, are equal:

$$G_{cathode} = B\,[N_2(a')]_{cathode} + F\,J, \quad (6)$$

and

$$G_{anode} = B\,[N_2(a')]_{anode} \quad (7)$$

Here J is the current density (in A cm^{-2}) and the metastable densities $[N_2(a')]$ (in cm^{-3}) are the densities nearby the cathode or anode. The dimension of coefficients B is cm s^{-1} and it is, in fact, a value of the type $b\langle c \rangle$, where $\langle c \rangle$ is thermal average velocity of N_2 molecules near the surface and $b < 0.25$. The dimension of F is 1/e (e=1.6 10^{-19} is electron charge in Coulomb). The parameter F is differ from 1/e by some coefficient *d*. The coefficients *b* and *d* have been estimated in the present work using experimental data for relative intensities of CN(B->X) and N_2^+(B->X) bands near the cathode and in the positive column, respectively. The mechanism for generation of these bands is the same (see below, process (12) and [1]) and connects the relative intensities I(CN(B->X))/I(N_2^+(B->X)) with relative densities [CN(X)]/[N_2^+]. The concentration of N_2^+ have been calculated from our kinetic model (see Table 1) and [CN(X)] was obtained considering the flux $G_{cathode}$ as well as both coefficients *b* and *d*. If we neglect the volume production of C atoms and CN molecules, the approximate analytical solution is searched for the transport of C and CN from cathode and anode inside of the discharge tube. Taking into account axial diffusion with the diffusion coefficient D (in $cm^2\ s^{-1}$) and gas flow velocity **v** (from cathode to anode) we have the following equation:

$$dG(A)/dz = -L_C[A]; \qquad L_C = k_w. \quad (8)$$

Here, A=C or CN; k_w is the probability (in s^{-1}) for wall losses of C or CN (see Eq. (1)); G is the flux of "A" along the gas discharge tube:

$$G = \{v - (D/[A])\, d[A]/dz\}\,[A] \quad (9)$$

Here, z is distance from the point of gas inlet (cathode) into discharge. The transport equation for the "A" particle has the analytical solution

$$[A] = B_1 \exp\{z/L_1\} + B_2 \exp\{z/L_2\}, \quad (10)$$

where $L_1 = 2D/[v + \sqrt{(v^2 + 4\,k_w\,D)}]$ and $L_2 = 2D/[v - \sqrt{(v^2 + 4\,k_w\,D)}]$ are a kind of "relaxation lengths" for "A" particles. The values B_1 and B_2 depend on anode and cathode fluxes due to surface production of "A" particles which are the flux boundary values of G..

Note that the comparison of relative value of the [CN(X)] along the discharge tube with the experimental measurements gives the possibility to estimate k_w and, as a result, the probability γ_{CN}.

The calculation of electronically exited species CN(B) is interesting because the violet CN(B) bands are recorded experimentally. Those radicals are assumed to be created and deactivated according to the following reactions

$$CN(X) + N_2(A) \rightarrow CN(B) + N_2(X, v=0) \quad (11)$$

$$CN(X) + N_2(X, v \geq 12) \rightarrow CN(B) + N_2(X, v-12) \quad (12)$$

$$C + N + N_2 \rightarrow CN(B) + N_2 \quad (13)$$

$$CN(B)+N_2 \rightarrow CN(X)+N_2 \quad (14)$$
$$CN(B) \rightarrow CN(X) + h\nu \quad (15)$$

The diffusion coefficients were calculated using a known expression and we present results for probability for losses of C and CN to the wall: $\gamma_C = \gamma_{CN} = 0.05$. The value of γ_{CN} have been obtained by fitting of theoretical value of relative intensities $I(CN(B->X))_{z=1\ cm}/ I(CN(B->X))_{z=7\ cm}$ to the experimental ones.

As carbonated species diffuse to the wall, a thin film is building up. Its properties depend on the ratio [N]/[C].

5. Partial results

The calculations were done for conditions similar to the experiment [2] for conditions: p=0.451 Torr, I=2.5 mA,. The tube diameter is 2.17 cm and the tube length is 25 cm.

As the gas velocity is small (at p=0.451 Torr, v=0.7 cm/s), the magnitude of the gas and vibrational temperatures, as well electronic temperature and densities remain constant along the positive column, as shown in Table 1.

Table 1 - Relevant discharge output at two different pressures at the positive column

	p=0.451 Torr		P=1 Torr	
	2.5 mA	10 mA	2.5 mA	10 mA
$N_2(A)$	6.95×10^{11}	1.10×10^{12}	9.72×10^{11}	1.61×10^{12}
$N_2(a')$	4.07×10^{11}	1.70×10^{12}	2.66×10^{11}	1.23×10^{12}
N	1.15×10^{14}	3.84×10^{14}	1.14×10^{14}	3.65×10^{14}
N_e	3.46×10^{8}	1.21×10^{9}	3.35×10^{8}	1.42×10^{9}
N_2^+	2.34×10^{8}	9.89×10^{8}	9.95×10^{8}	5.11×10^{8}
N_4^+	5.38×10^{7}	2.19×10^{8}	2.35×10^{8}	9.07×10^{8}
T_g (K)	308	335	317	363
T_{vib} (K)	3230	4270	3120	3980
E/N(10^{-16} V cm^2)	14.3	13.2	11.4	10.5
T_e (eV)	2.41	2.45	1.98	2.06

Figs.1,2 show the concentrations of C atoms along the discharge tube for p=0.451 Torr and 1 Torr. The same values of parameters γ_C, b and d were used to obtain [CN] (see below) as well for the C concentration.

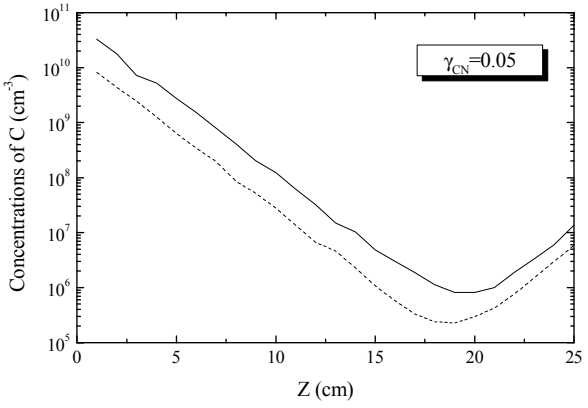

Fig. 1 - Concentrations of C along the discharge tube at p=0.451 Torr. Solid curve I=10 mA; dashed curve I=3 mA.

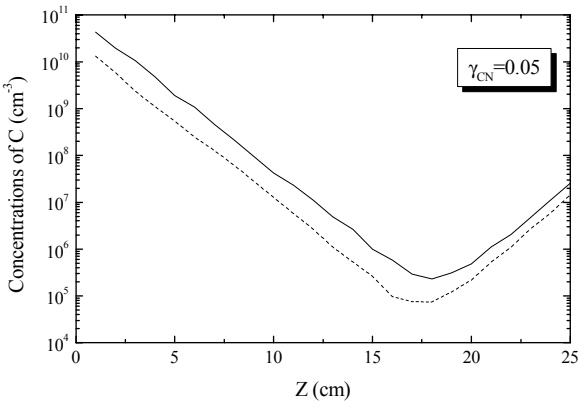

Fig. 2 - Concentrations of C along the discharge tube at p=1 Torr. Curves as in Fig.1.

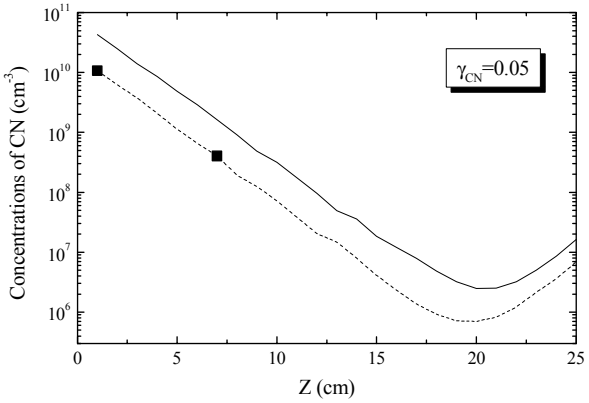

Fig. 3 - Concentrations of CN vs. position for p=0.451 Torr. Solid curves, I=10 mA and dashed curves, I=3 mA. ▫ - Values extracted from experimental data [6].

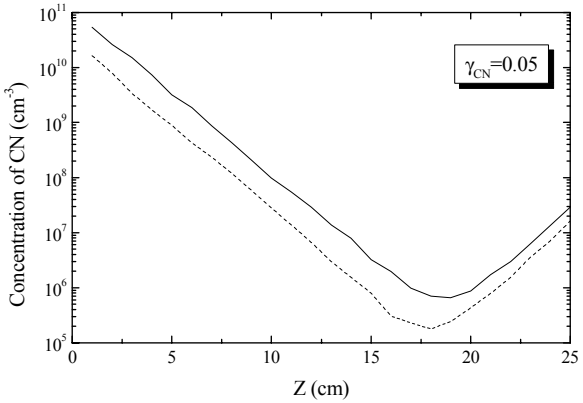

Fig. 4 - Concentrations of CN vs. position for p=1 Torr. Curves as in Fig.3.

As can be seen through Figs.3-4, the CN species concentration decreases from cathode to anode and increases with current. The agreement with experiment at p=0.451 Torr is good for the following values of parameters: $\gamma_{CN} = 0.05$; d=6.7 10^{-3}; b=6 10^{-6}. Figs.5-6 show the relative intensities of CN(B→X) band. The best agreement with experiment is attained when using the above given values for γ_{CN}, d and b.
To conclude, we believe that the electrode graphite surface source for gas phase production of CN molecules is more effective than the volume production. However, to obtain more accurate calculations and to compare with experiment, it is necessary to include in the present model the negative glow region of the discharge, which has in our operating conditions a relative big length in the discharge tube. In this region, additional interesting experimental results have been obtained. This topic will be investigated in the near future.

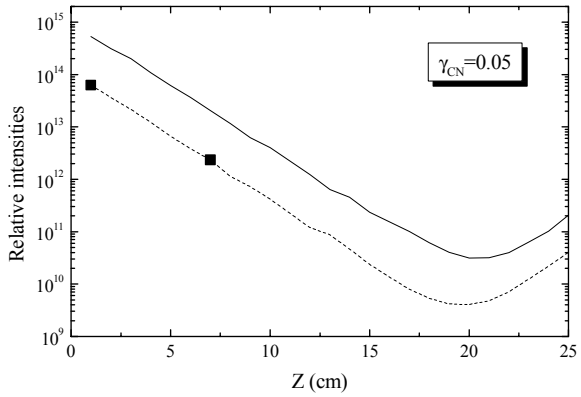

Fig.5 - Relative intensities of CN(B→X) at p=0.451 Torr. Curves as in Fig. 1. ▫ - Experimental data [6].

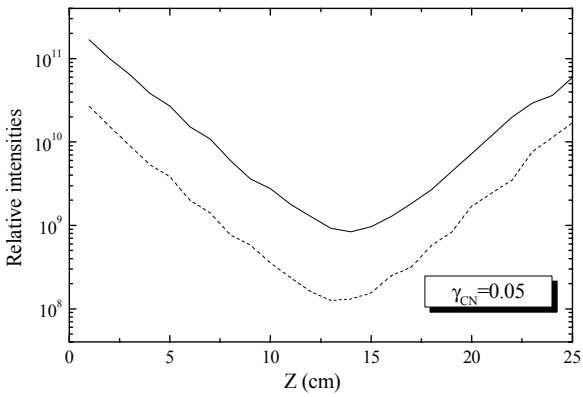

Fig. 6 - Same representation as in Fig. 5, but at p=1 Torr.

Acknowledgments

Atmospheric pressure CVD processes are promising for the development of cost effective technologies for wide area coating. Two distinctly different plasma sources have been studied for continuous CVD: (i) CYRRANUS®, a non-thermal volume source with microwave activation, developed at (3) and, (ii) LARGE, a thermal line plasma source based on an extended DC arc, developed at (2). Both plasma sources have been used to deposit oxide and non-oxide layers on temperature sensitive substrates. Comparative source evaluation was based on obtained layer properties. Different methods including optical emission and *in-situ* FTIR spectroscopy have been used for process/source characterisation. Temperature distributions have been measured within the plasma downstream region using spectroscopic and conventional tools. Depending on plasma gases applied a range of atomic and molecular intermediates, TEOS precursor fragments, and reaction products have been identified. Several gaseous key species have been found indicating e.g. the degree of precursor conversion and/or its tendency for powder formation. The plasma chemical reactions involved result in a complete conversion of the element-organic precursor into an inorganic layer without any organic residues. Extensive fluid dynamic calculations have been applied targeting on both the optimisation of reactor design and the kinetics of the rate determining step. Comparing the calculated layer profile with the experimental obtained ones the conclusion has been drawn that the deposition process is transport controlled.
It was demonstrated, both the CYRANNUS, and the LARGE plasma source, are well suited for plasma enhanced CVD at atmospheric pressure.

Humidity sensitivity of hydroxyapatite films by r.f. plasma sputtering method

K. Shimizu[1], T. Ishikawa[2], K.Ozeki[3], K.K. Hirakuri[2] and H. Aoki[4]

Hydroxyapatite (HAp:$Ca_{10}(PO_4)_6(OH)_2$), a crystallographical analogue to calcified tissues of vertebrates, has been well developed as an implant material because of its outstanding biocompatibility. Recent studies are spreading its application to such fields as liquid chromatographic column for the separation of proteins and nucleic acids, a catalyst for dehydration or dehydrogenation of some alcohols, powder carries for removing heavy metal ions, and chemical sensors for various gases [1]. The characteristics of HAp are strongly depended on their stoichiometry, crystallinity and particle size [2]. The stoichiometry of ratio between calcium and phosphorus of a HAp is 1.67.

A common ceramic sensor with humidity sensitivity was used adsorption of the moisture. However, it has big problem to use for humidity sensor because the moisture is adsorped on the surface and it reacts to make hydroxyl group. Furthermore, the resistivity was increased with time of use. However, HAp has be expected that this degradation can be prevented, because it has the hydroxyl group during the crystal. Although the humidity sensor using the HAp of sintered compact have already been put in practical use, the thin film of HAp is developed for trial.

In this study, we have been investigated the humidity-sensitive characteristics of the HAp thin film deposited by the sputtering method and the validity as a humidity sensor material. The aim of this study is to apply a HAp to sensing material, and develop a new type of humidity sensor.

Using r.f. plasma sputtering method, Ar was utilized for the deposition of the HAp films on a silica glass substrate. Target of disc shape consist of the HAp powder, which is made of Ube Material Industries, LTD. Discharge power of plasma was kept at 100W. Frequency of th r.f. generator was 13.56 MHz. Gas pressure and gas flow rate were 5 Pa and 10 sccm, respectively. HAp was deposited with thickness of 0.2 μm at room temperature.

Furthermore, hydrothermal process was carried out to enhance crystallization of the deposited films. Hydrothermal process is a water solution reaction which raises a crystallinity of the films at high temperature and high-pressure conditions. The films were treated in the reaction chamber at 200 ℃ and 1.5 MPa. The time of reaction is 24 hours.

The humidity-sensitive characteristics of the samples was measured before and after the hydrothermal process. The characteristic is the relationship between electrical resistivity and relative humidity (30～90%).

Structure morphology of the deposited films was observed by scanning electron microscopy (SEM). The crystalline phase and the Ca/P ratio of the deposited films were estimated by X-ray diffraction (XRD) and energy dispersive spectroscopy (EDS). The analysis of adsorption of hydroxyl group in before and after measurement of humidity-sensitive characteristics was measured by FT-infrared (IR) spectroscopy.

As the result of the analysis, it seems that the composition deviance of the films before the hydrothermal process has been caused by the heat of the plasma.

However, the composition deviance has been improved by the hydrothermal process. The excellent humidity-sensitive characteristics of the HAp films after the process is confirmed as compared with those of other ceramic humidity sensors.

Characterization of oxygen plasma with a catalytic probe

U. Cvelbar[1], M. Mozetič[1], I. Poberaj[2]

[1] *Plasma laboratory, Institute of Surface Engineering and Optoelectronics, Ljubljana, Slovenia*
[2] *Department of Physics, University of Ljubljana, Ljubljana, Slovenia*

Reactive oxygen plasmas are used in several advanced technologies including the unisotropic plasma etching, plasma drilling, plasma oxidation, plasma cleaning, plasma ashing and plasma surface activation [1-6]. Different technologies require application of plasma with different parameters. For unisotropic etching and drilling, a plasma with a high degree of ionization is needed, while for some other technologies, an oxygen plasma with a low density of charged particles performs better. For very delicate treatments of samples, for instance during plasma ashing and selective plasma etching, a state of a gas with a negligible concentration of charged particles should be used. In such cases, it is much better to treat samples in post - discharges rather than in plasmas themselves. In systems used for delicate plasma treatments, the most important parameter is the density of neutral oxygen atoms.
The density of neutral oxygen atoms can be measured by different means including a variety of optical emission and absorption spectroscopy methods, NO titration, and catalytic probes. Recently, it was shown that catalytic probes have some advantages over the other methods[10,11]. The main advantage is a low cost and the ability for real time measurement of the O density.
A catalytic probe was used to measure the O density in a plasma reactor. An integral part of the reactor was a movable recombinator that allowed for adjusting the O density without changing other plasma parameters. The O density was measured at different pressure between 10 and 100 Pa and different recombinator position. The result is plotted in Figure 1.

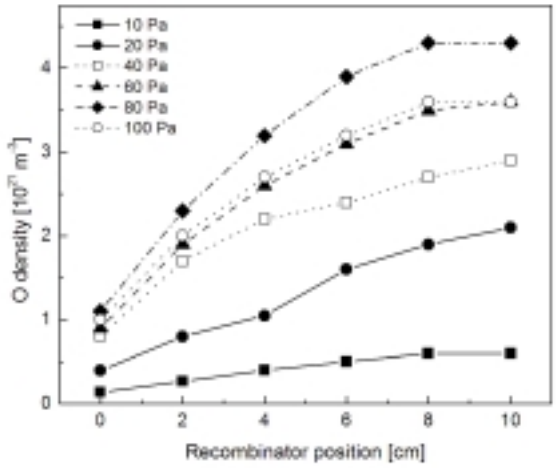

Fig. 1. Density of neutral oxygen atoms versus the distance between the probe and recombinator tip.

Abstract:
The glidarc degradation of various dyes (Orange I, Indigo Carmine, Eriochrome black T) has been studied, using non thermal plasma. All dyes solutions underwent a decolourization. The kinetics of reaction have been studied and were found to be zero or first order with respect to the dyes. A hight decolourization degree was however accompanied by an important reduction of chemical oxygen demand (COD), a correlation between decolourization and degradation has been established.

Introduction
Dyes makes our world beautiful, but it brings us pollution; colored water is unattractive and generates more and more complaints.
Environmental pollution by organic dye sets a sever ecological problem, which is increased by the fact that most of them are difficult to degrade by traditional techniques. In this process, hydroxyl radicals (OH°) are generated when a discharge is applied in the presence of air and water. The reactives species generated are able to degrade the organic pollutants like dyes, because the treatment consists of oxidative destruction [1,2,3,4].
Azo dyes constitue the largest class of dyes in industry, in the present work, we examine the degradation of Orange I and Eriochrome black T. The destruction of the azo bond –N=N– of this dyes, in the chromophore of azo dyes led to decolourization of dyes solutions. The Indigo Carmine is an indigoid dye, acid blue 74 (AB74), it's a carbonyl dye[5].

Material and methodes:
The tested azo dyes: Orange I, Carmine indigo, Eriochrome black T (EBT) were purchased from Aldrich. Purified water was obtained from a Millipore equipment. COD of samples from various treatment times was mesured by the potassium dichromate standard methods
The gliding arc system was described previously [6]. An electric is created between two metallic electrodes raised a convenient voltage difference (10 kV). The arc is blown away by a gas flow air the axis of the system and glides towards the end of the electrode before it breaks and a new arc forms. A plasma is generated by the arc in a volume located at the tips of the electrodes . Aqueous solutions are exposed to the plasma flux. The degradation was followed for different treatment times.

Results and discussion:
The color of solutions was studied from the comparaison of UV-VIS spectra. Each dye solution was scanned and its maximum absorbency visible wavelength determined.
The color of water polluted with organic colorants reduces when the cleavage of the –C=C- bonds, the –N=N- bonds and the aromatic rings occurs. The absorption of light by the associated molecules shifts from the visible to the UV or IR region of the electromagnetic spectrum, it is means that the dye is degraded into smaller products [7]. The UV-VIS spectra obtained for all the dyes shown a reduction in the absorbance at the maximum wavelenght. We can see on the spectra UV-VIS the decrease of the absorbance for the Orange I (475 nm), Indigo Carmine (288 and 612 nm) and Eriochrome Black T (525 nm) respectively (fig 1,2,3).

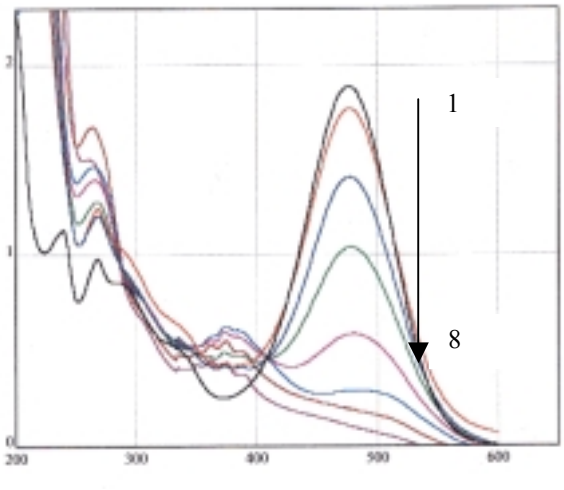

Fig 1: Variation of the spectral absorbance with time of OrangeI
1 : 0 min ; 2 : 1,5 min ; 3 : 2min ; 4 : 2,5min ;
5 : 3min ; 6 : 3,5min ; 7 : 8min ; 8 : 13min.

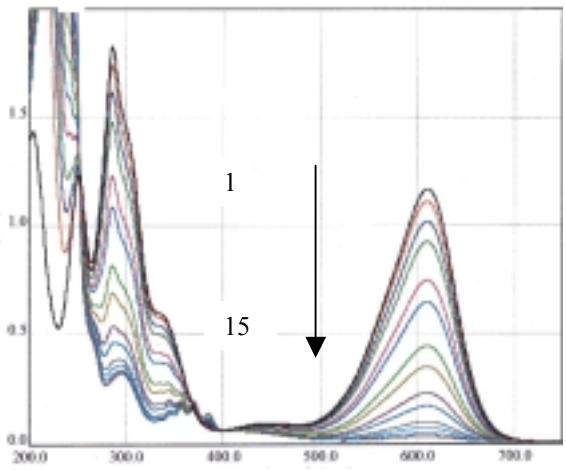

Fig 2: Variation of the spectral absorbance with time of Carmine Indïgo
1 : 0min ; 2 : 1min ; 3 : 2min ; 4 : 3min ;
5 : 4min ; 6 : 5min ; 7 : 6min ; 8 : 7min ; 9
8min ; 10 :9min ; 11 :10min; 12 : 11min ;
13 : 12min; 14 : 15min .

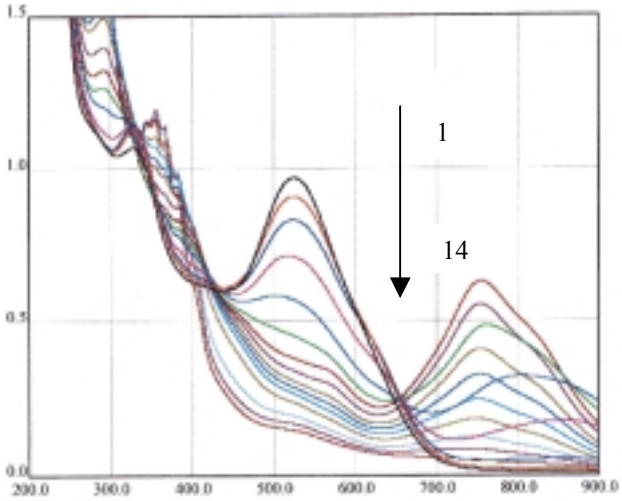

Figure 3 : Variation of the spectral absorbance with time of Eriochrome black T
1 : 0min ; 2 : ,1,5min ; 3 : 1,75min ; 4 : 2min ; 5 : 42,5min ; 6 : 3,25min ; 7 : 4min ; 8 : 5,5min ;
9 : 9min ; 10 :15min ; 11 :20min; 12 : 30min ; 13 : 40min ; 14 : 50min ; 60: min .

The decrease of absorbance means the decolourization of dyes solutions [8]. The table 1 shows the kinetics constants of decolourization and degradation of the three dyes.

Table 1: the kinetic constants of decolourization and degradation

Dyes	Orange I	Indigo Carmine	Eriochrome Black T
Kinetic constants of decolourization (min^{-1})	0,886	0,311	0,1
Kinetic constants of degradation (min^{-1})	0,0173	0,0237	0,0296

The decreased of apparent colour was accompanied by an reduction of COD (fig 4,5,6). The removal of the color and COD were 94,6% and 41,7% for the Orange I, at 30 min of treatment, while it was 97,9% and 8,8% for the Indigo Carmine for 15 min of treatment, we noticed that the decolourization is

easier than COD removal. The removal of color and COD of Eriochrome black T solution was equal to 64,2% and 51,4% respectively after 50 min .

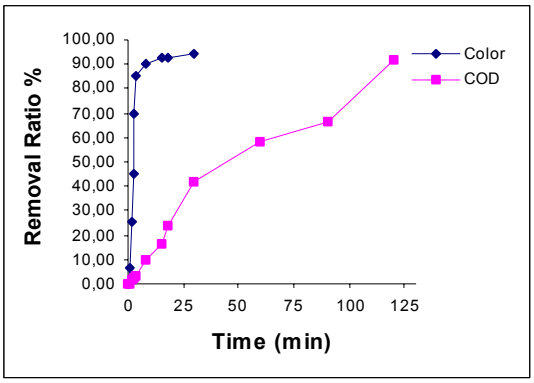

Fig 4: The decolorization and COD removal of Orange I

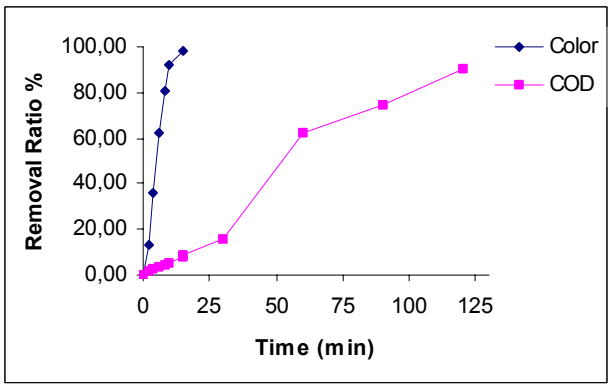

Fig 5: The decolorization and COD removal of Carmine Indigo

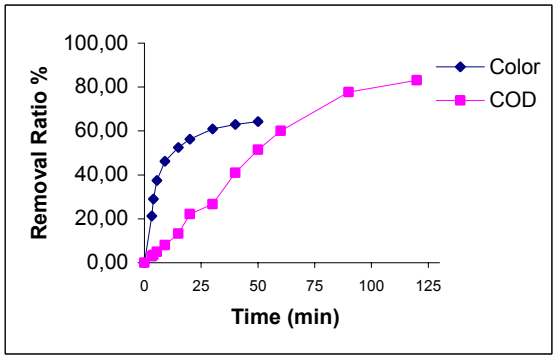

Fig 6: The decolorization and COD removal of Eriochrome black T

The degradation of dyes has been followed using the COD. The disappearance of the COD expresses the detoxification level of water and mineralization of organic compounds according to the equations of the dye total oxidation (1, 2, 3) .

Orange I

$$C_{16}H_{11}N_2O_4S^- + \frac{42}{2} \rightarrow 16CO_2 + 2NO_3^- + SO_4^{2-} + 3H^+ + 4H_2O \qquad (1)$$

EBT

$$C_{20}H_{12}N_3O_7S^- + \frac{50}{2} \rightarrow 20CO_2 + 3NO_3^- + SO_4^{2-} + 4H^+ + 4H_2O \qquad (2)$$

Carmine

$$C_{16}H_8N_2O_8S_2^{2-} + \frac{79}{4} \rightarrow 16CO_2 + 2NO_3^- + 2SO_4^{2-} + 5H^+ + \frac{3}{2}H_2O \qquad (3)$$

The COD values decreased as the treatment time increased as we can see on figures (7,8,9). The COD removal of Orange I, Indigo Carmine, and Eriochrome Black T are 92%, 90,6%, 83%, respectively after 120 min of treatment.

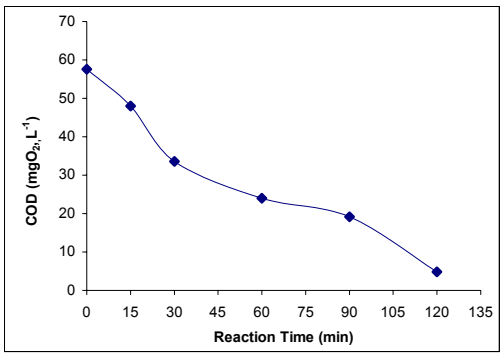

Fig 7: Variation of COD of Orange I dye

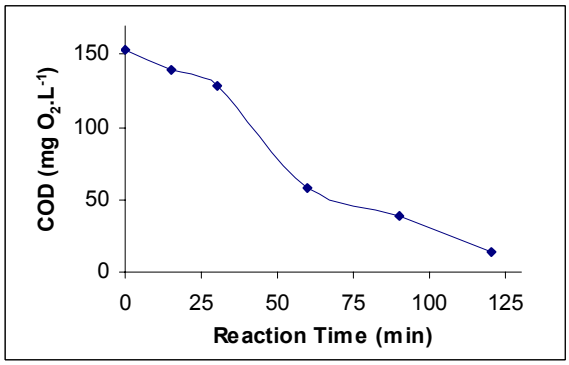

Fig 8: Variation of COD of Carmine Indigo dye

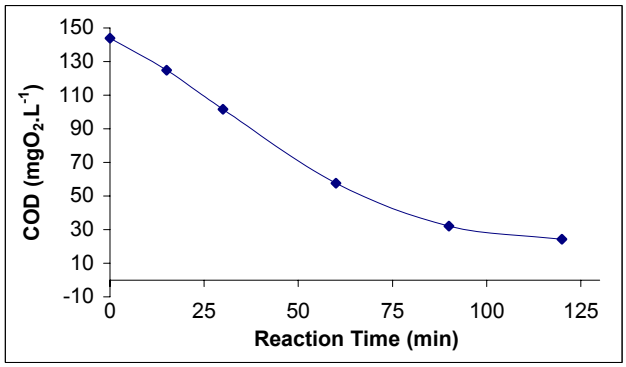

Fig 9: Variation of COD of Eriochrome black T dye

Formation and disappearance of Eriochrome Black T intermediate were evaluated by monitoring the evolution of absorbance at 764 nm during the treatment, as we can see on fig 10.

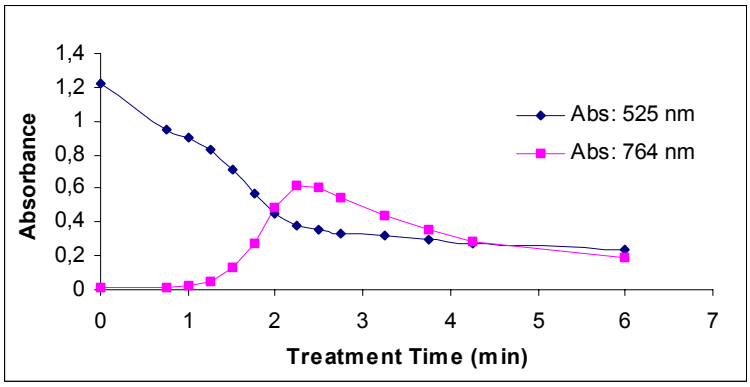

Figure 10: Formation and disappearance of intermediate at 764 nm

Conclusion:

The gliding arc treatment proved to be powerful in destroying the three dyes. The following conclusions can be drawn:

- Complete color removal needed 15, 30 and 50 min for Indigo Carmine, Orange I and Eriochrome black T respectively.
- Complete COD removal can be obtained after 120 min of treatment.
- Relationship between decolorization and degradability of dyeing solutions, the complete decolourization is achieved for about 15, 30, 50 min. At the same time, the COD conversion was 8,8 %, 41,7 % and 51,4 % respectively.
- Relationship between the rates removal of color/COD and kinetic constants of decoloration/degradation.

Abstract.
Liquid wastes of several manufactures in west Algeria, are poured in the country's longest "Oued Cheliff" river bed, polluting its mountain born water. It is reused by neighbouring agricultural farmers for cultures and crops irrigation. The actual report shows that the water is strongly contaminated by heavy metals and non-biodegradable organic compounds due to the high toxicity level of the liquid wastes. We propose, here, a method of their degradation by plasma of humid air.

1. Introduction.

The Oued cheliff river is the longest river in Algeria tributary to the Mediterranean sea. Several industries (tannery, cutlery) use enormous amount of water for their running and pour it afterwards in the river, filled with excess of toxic dyes, organic and mineral compounds, causing water pollution which in turn affect cultures, harm fish reproduction in ponds alongside the river and cause health problems, etc. The aim of this work is to evaluate the Oued Cheliff contamination level caused by industries. Some physico-chemical parameters such as: the chemical oxygen demand (COD), the amount of nitrites, chlorides as well as the metallic traces of elements were measured for various water samples. They were exposed afterwards to the plasma particles flux where the treatment parameters are set constant throughout the investigation. The application of the plasma to these water samples is carried out in order to investigate the effect of the interaction of the simultaneously present highly neutral reactive species OH° (as an oxidant agent) and NO° (as an acidic agent) obtained in the plasma with the solution [1]. We expose here the sampling procedure, the measurements of the toxic level and the results of the plasma treatments.

2. Experimental set-up and methods.

Sampling procedure has been realised in various sites localised in adjacent industrial sectors to the river which pour into the Mediterranean sea during different periods of the year. Various samples collection sites were chosen such that:

- site X(0) is situated at the exit of the factory and corresponds to the raw industrial effluent
- site X(1) corresponds to the first contact of industrial effluent with the river, or the impact of the industrial wastes with the river
- site X(2) is chosen upstream before the site effluent impact X(1)
- site X(3) is situated downstream the point X(1). This will furnish precious information on the origin of the pollution along the river.

Waste samples taken at the waste contact with the river X(1)) are analysed first of all in order to evaluate the mineral compounds. Various specific analytical techniques are used:

- inductively coupled plasma-atomic emission spectrometry (ICP-AES) for the determination of Zn, Cr, Cu, and Fe concentrations [2];
- BOD-meter BSB-Controller 1020T type, pH-meter Multiline P4 type, UV-Vis ANTELLI Spectrometer for the nitrites
- volumetric methods with AFNOR norms to evaluate Cl^{-}, COD and PIS (particles in suspension) [3].

The experimental procedure is described in detail elsewhere and shown in figure. 1.

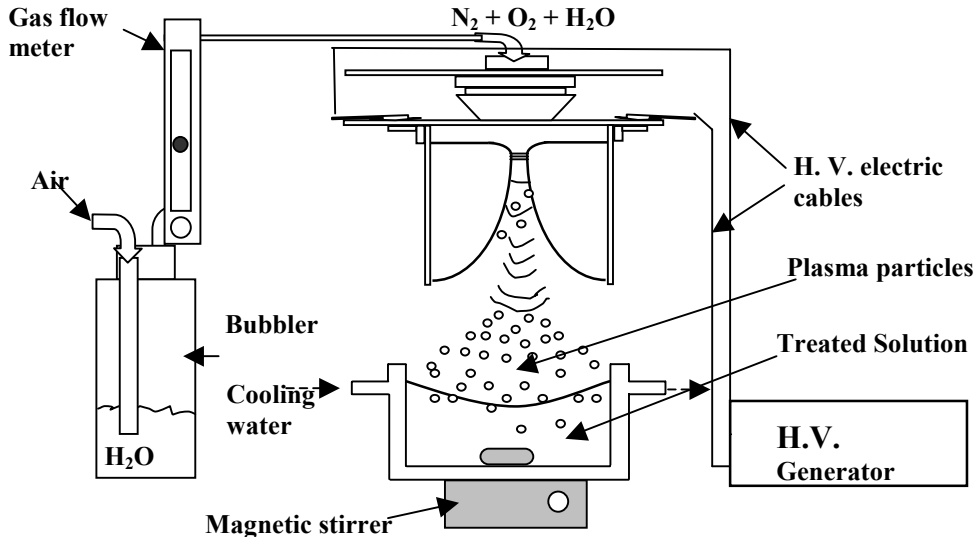

Figure 1 : Experimental set-up of the glidarc.

Pressurised humid air gets though a gliding electric arc obtained between two diverging electrodes where a high voltage is applied [4]. The electronic collisions between energetic electrons and humid air compounds provoke chemical interactions which lead to the formation of highly reactive neutral radicals OH° and NO°. The simultaneous presence is already confirmed in previous emission spectroscopy investigation [4]. The oxidant radical OH° abundance over the acidic NO° confers to the humid air plasma a major oxidant role
The manufactures wastes are exposed afterwards to the humid air plasma with a constant air flow rate, at a fixed distance and different exposure time: 5, 10, 15, 30, 60 and 90 minutes. COD measurements are taken before and after plasma treatments in order to evaluate the rate of degradation of the waste samples.

3. Results and discussion

3. 1 Analytical results.

The tannery uses, in its fabrication processes, products of organic (leather, dye) and mineral (oxidants of $K_2Cr_2O_7$ type) nature. On the other hand, cutlery products are made of metals but industrial oil, some mineral acids for cleaning and inhibitive products of corrosion are also encountered. This information clearly shows organic and mineral pollutions generated by their products.
The existence of maroon alga level within the Oued Cheliff river, on the tannery side near site X(1), is confirmed by a higher concentration of particles in suspension of the order of 2930 mg/L which goes far beyond the fixed norm 30 mg/L of approximately 100 times [5]. Besides, we remark that the concentration of nitrites (0.75 mg/L) is seven times higher than the standard norm (0.1 mg/L), where it is only twice more in the stream. The value of chrome (≈18 mg/L at X(0) point), is too much higher than the current norm (0.5 mg/L). The site of collection is also contaminated by iron.
Concerning the cutlery manufacture results, the values of registered nitrites in this part of the Oued Cheliff are eight times superior to the standards norm, where it is only twice more in the stream. Values of metals concentrations: chrome, copper, zinc and iron revealed in the sample are, in all cases, far beyond the required norms. In fact, the analysis has given 9.5 mg/L of chrome at the point of the impact of effluent with the river X(1), which may be due to the dilution in the Oued Cheliff river. Sampling points are also contaminated by iron and zinc, which are used in the cutlery. The registered COD value of 1600 mg d'O_2/L which goes beyond all admissible values, is in fact 39 times more than the norm in the point of effluent. The high values of COD during all sampling campaigns show high level pollution.
Around the cutlery manufacture pouring sites, the high values COD measured during all campaigns, show a quiet important organic pollution. Thus we have noticed the presence of inhibitive organic corrosion. A summary of the results of wastes analysis concerning both cutlery and tannery manufactures at sites X(1) and X(2) are shown in the table 1.

Table 1: Results of physico-chemical analysis and humid air plasma treatment of tannery and cutlery wastes samples.

	Tannery		Cutlery		Standard (mg/L)
Elements (mg/L)	X(1)	X(2)	X(1)	X(2)	
NO_2^-	0.75	0.75	1.24	0.32	0.1
Cl^-	6000	5700	3036	600	200
Cr	17.85	14.02	9.52	4.05	0.5
Fe	12.63	10.01	3.43	11.18	5
Zn	0.37	0.29	3.01	15.14	5
Cu	0.08	0.03	19.56	10.44	3
PIS	2930	2910	5445	900	30
BOD_5	233	250	850	270	40
COD	4000	2000	16000	1344	120
Treatment by plasma COD (mg of O_2/L)					
After 90 minutes	Before	After	Before	After	Standard (mg/L)
	2000	150	1344	80	120
	93 %		94 %		

3. 2 Plasma treatment

We record that the pollution in the Oued Cheliff river presents mineral and more important organic pollution characteristics. This pollution which will eventually cause too many problems, must be taken rapidly into account in order to preserve the river and its ecosystem. We take advantage of the oxidant phenomenon of the glidarc reactor which can be used to degrade non-biodegradable organic products as potential pollutants. Previous work was undertaken to treat aqueous solutions and organic products by plasma of humid air of gliding arc type [6]. In the aim of investigating the oxidation properties of OH° radicals produced by plasma, we have studied their degrading power on the tannery and cutlery industrial wastes poured in the river. We mention that the effluents collected at point X(0) are those treated by the gliding arc plasma of humid air.

The analysis of the tannery and cutlery industrial wastes which follow the plasma treatment, have revealed that the COD measured values increase with the treatment time. In fact, we expected a decrease in the values since the plasma is endowed of a high oxidant power and consequently degradation should follow. The results obtained are illustrated in figures 2 and 3.

A possible explanation to the COD behaviour could be attributed to the presence of nitriding entities NO° generated by the plasma. They transform to nitrites in aqueous media which may probably hinder oxidation to proceed and become then, due their reduction properties, cumbersome in the COD measurement [7]. So, the presence of radical species of type NO° slows down the degradation of the industrial wastes by the plasma of humid air. The reduction properties of nitrites have been minimised if not achieved by the addition of quantities of sodium azide (NaN_3) or sulfamic acid (H_3NO_3S) [7].

After the elimination of nitrites, the effluent samples are treated, with the same conditions as previous established, at different exposure times. The tannery and cutlery treated liquid effluents show that the COD values decrease considerably with the treatment time (figure 2 and 3).

The results of degradation show that the plasma treatment in the presence of sodium azide produced, after 90 minutes, a COD decrease from 2000 mg/L to 150 mg/L, which corresponds to a rate of elimination of 93% of the COD initial value. The corresponding results are presented in the table 2 and illustrated on figure 2.

Table 2: COD values of tannery waste samples treated by humid air plasma.

Time (min)	COD (mg d'O_2/L)			
	Tannery		Cutlery	
	700L/h	900 L/h	700 L/h	900 L/h
0	2000	2000	1344	1344
5	1732	1560	1050	1020
10	1376	1252	860	757
15	981	916	630	500
20	983	873	400	249.6
30	586	543	280	158.4
60	331.6	285	230	134.4
90	195.5	150	190	80

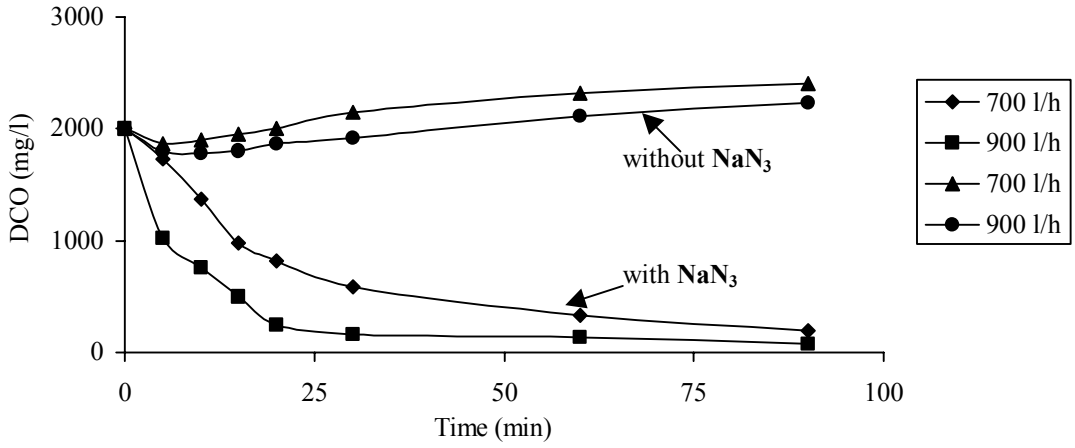

Figure 2. Tannery effluents behaviour with plasma treatment time with or without NaN_3

The COD measured after 90 minutes of treatment of the cutlery effluent samples is 80 mg/L against 1344 mg/L initially, a decrease which corresponds to a rate of elimination of 94%. The results obtained are gathered in the table 2 and presented on figure 3.

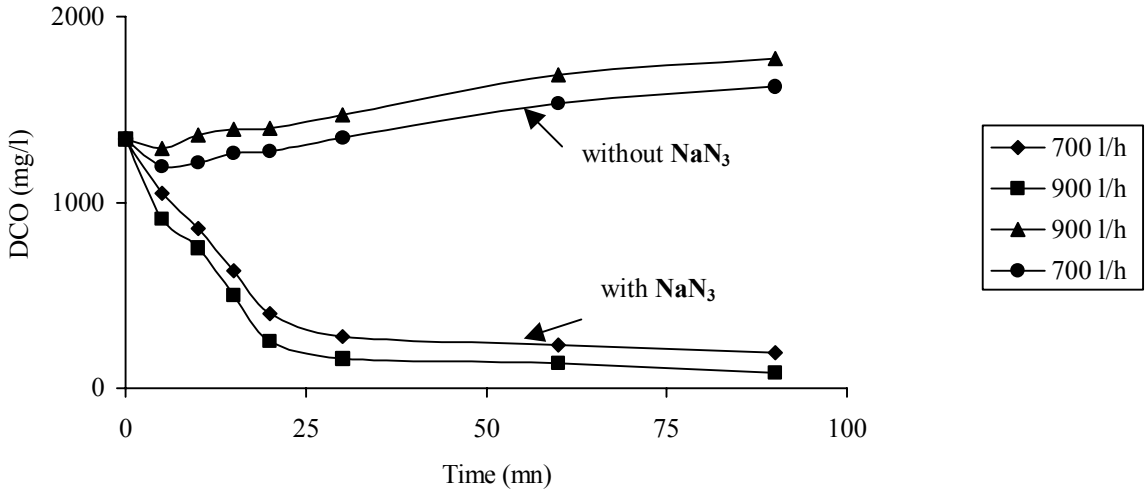

Figure 3. Cutlery effluents behaviour with plasma treatment time with or without NaN_3

The knowledge of the ratio COD/BOD_5 enables to appreciate the quality of the mineral pollution (BOD_5 ≈80% COD) [1]. After that, proportions of $COD/BOD_5>12$ for the tannery and $COD/BOD_5>11$ for cutlery were obtained. They indicate that the contamination was due to heavy effluents rich in organic materials content owing to COD values, as well as heavy metals presence preventing the evolution of the BOD_5. This indicates that the detected pollution was mainly due to uncontrolled wastes pouring of neighbouring manufactures located alongside the river. Previous remarks suggest that metallurgy manufactures such as cutleries and tanneries using leather for skin treatment, are the main sources of all kinds of pollution.
The treatment of the industrial wastes by the gliding arc plasma in humid air, evaluated by the measurement of the COD, proved to be efficient for both the cutlery and tannery cases only in the presence of sodium azide.
We have noticed as well a high resistance to the plasma treatment from the tannery effluents. This resistance is mainly due to the existence of organic charges in this type of effluents compared to the cutlery ones. That is translated by a final COD value 93.5 % which is nearly similar for both the tannery and the unity of cutlery.

4. Conclusion

The investigation carried out at different sites of the polluting industrial manufactures pouring their effluents in the Oued Cheliff coastal river, revealed two main sources of mineral and organic pollution of the water. All the concentrations values obtained for this mineral and organic pollution, or both for some sites, are alarming and far beyond the minimum standards.
The sampling sites alongside the river expose a real image of marine environment. The results show clearly that the plasma treatment changes the effluent character as well as of its general chemical composition. This is evidently in favour of an attack by high reactive oxidant species generated by the plasma of humid air .
The use of plasma enables us to degrade both manufacture wastes for a period of 90 minutes treatment by an attack of OH°, NO°, O_3 , H_2O_2 species, at a speed of which depends the chemical nature of the effluent [8]. All treatment resulted in a pollution abatement of 93.5 % of the COD independently on the nature of the effluent composition which confirms the reliability of the technique for such a domain. The plasma efficiency is also proved for the treatment of effluents containing toxic dyes such Yellow Supranol 4 GL and Scarlet Red Nylosan F3GL [7] where the degradation results in a decrease of dyes in the effluents. The different steps of oxidation could be determined by the use of CPG/MS, HPLC or more powerful techniques in order to make in evidence the chemical reaction mechanisms undergone for a better exploitation in the future.

Dust particles in the dc glow discharge plasma: self-organization and peculiarities of behavior

V.E. Fortov, A.G. Khrapak, V.I. Molotkov, O.F. Petrov, M.Y. Poustylnik, V.M.Torchinsky

Institute for High Energy Densities, Russian Academy of Sciences, Moscow, 125412 Russia

Abstract

The review of the investigations of strongly coupled dusty plasma in the dc glow discharge striations is presented. The formation of plasma crystals, liquids and plasma liquid crystals is considered. Results of the experiments on different external influences on dusty plasma structures are discussed. It is demonstrated that external influences can be used to measure the grain charge and field of forces acting on a dust grain levitating in the plasma.

1. Introduction

The work is devoted to investigations of dusty-plasma formations in the dc glow discharge striations. Striations in the neon gas discharge have been studied in [1,2].

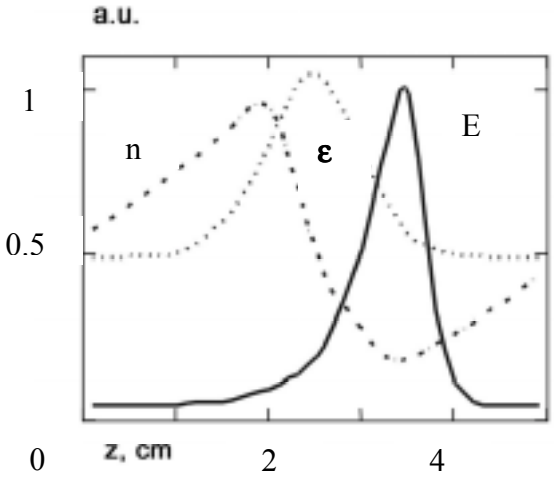

Fig.1. Relative distributions of plasma density n, mean electron energy ε and electric field E in the neon glow discharge

Fig.1 presents relative distributions of the electric field, plasma density and mean electron energy in a striation of the glow discharge in neon. It is seen that there is a region where the electric field increases in the direction of the cathode. If the discharge is vertically oriented and the lower electrode is a cathode stable levitation of dust grains in the striation is possible. Plasma parameters in striations may reach the following values: electric field up to 10 –15 v/cm, plasma density 10^7 – 10^8 cm^{-3}. These values just correspond to conditions of the strongly coupled dusty plasma [3].

The plasma nonuniformity in striations, a presence of the longitudinal electric field gradients lead to an appearance in the dusty plasma structures some peculiarities such as convective motions of dust grains, dust-acoustic instability and others.

In section 2 we present the experimental set-up for the dc glow discharge dusty plasma studies. In section 3 different kinds of dusty plasma structures formed in the neon glow discharge striations are given.

Section 4 is devoted to wave phenomena of the dust component including self-excited waves and waves excited by the gas dynamic impact. In section 5 we present methods to measure a charge of dust grains and a field of forces acting to the dust particle levitating in the plasma.

2. Experimental set-up

The experimental set-up for studies of the dusty plasma in the dc glow discharge is shown in Fig.2. It is a vertically positioned glass tube in which the glow discharge with cold electrodes is created.

The upper electrode is the anode and the lower one is the cathode. The tube is filled with neon or with a mixture of neon with hydrogen up to the pressure 0.1-2 Torr.

The discharge current varies from 0.1 to 4 mA. The standing striations exist in these regimes. The plasma parameters are as given in Section 1.

The dust particles were held above the discharge area in a container with the grid bottom. When shaking the container the dust grains fell down through the grid and levitate in striations forming the ordered structures.

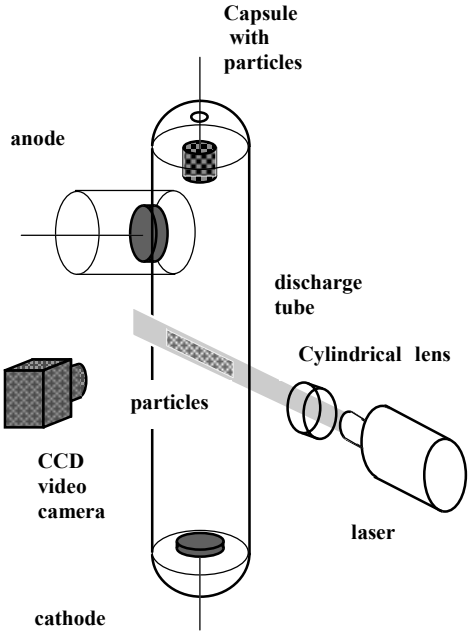

Fig.2. Experimental set-up

The dust grains are visualized with a diode laser sheet. The sheet thickness is 150 μm and the width is 1.5 cm. The laser sheet may be positioned both vertically and horizontally that allowed us to obtain the vertical section of the structure as well as the horizontal one. The light scattered by dust grains was imaged by a video camera.

To register fast processes the video camera Phantom 5 with a frame frequency up to 1000 frames per second was used. The video frames were later digitized for computer processing.

The glow discharge with cold electrodes is characterized by discharge oscillations connected with the cathode spot movements. This leads to fluctuations of dusty plasma structures. To damp out these fluctuations the additional insert with a constriction was placed in the lower part of the discharge tube above the cathode [4].

3. Plasma crystals and liquids

3.1 Structures of spherical grains

The formation of structures in the dc glow discharge striations proceeds in the following way: after the container shaking dust particles fell down and are captured in a trap created by the longitudinal and radial electric forces of a striation. The charged dust grains form the ordered structure preserved for as long as the discharge exists at constant parameters.

We used spherical particles of different materials: borosilicate glass (ρ= 2.3 g/cm^3) in the form of thin-walled, hollow spheres of diameter 50 – 60 μm with wall thickness 1 – 5 μm, Al_2O_3 particles (ρ= 4 g/cm^3) with diameter 3 –5 μm, melaminformaldehyde spheres (ρ= 1.5 g/cm^3) with diameters 1.87, 4.82, 10.24, 13.57 μm. The mass of the particles lies in the range from 10^{-12} to 10^{-7} g.

Fig.3. Horizontal section of plasma crystal

The particles formed in striations ordered structures with a different degree of ordering.

Fig.3 shows a video image of the plasma crystal. The structure was obtained in the discharge in a mixture of neon with hydrogen when the ratio of the length of the visible part of the striation to its total length decreases and the electric field acting on grains increases. The interparticle distance of the plasma crystal presented is about 700 μkm. In the case when the discharge current increases the plasma crystal is being melted firstly in the peripheral region and then in the center. This is connected with an increase of the plasma density, a decrease of the screening length of the dust grains, a weakening of an interaction between dust particles and an increase of the dust particles kinetic temperature.

In our experiments we observed levitation of separate particles as well as chains of several particles arranged along the axis of the discharge [5]. The formation of structures with a coexistence of different regions has been revealed. It is possible to study complicated formations with the regions of strong ordering (plasma crystal) and the regions with convective and oscillatory motion of grains (dusty plasma liquid) [5]. The complicated structures are associated with the peculiar distribution of forces acting on the dust particles: the ion drag force, the electrical force and distribution of plasma parameters along the striation.

3.2. Plasma liquid crystal

Besides spherical grains we used extended cylindrical grains.

To provide the levitation of nylon (ρ= 1,1 g/cm^3) microcylinders of diameter 10 μm and length 600 μm a neon-hydrogen mixture was used. These dust grains formed the structures consisting of 3-4 horizontal layers. Lighter particles (diameter 7.5 and 10 μm, length 300 μm) levitated in neon striations and formed much more axially prolonged structures. The structures formed of microcylinders indicated a pronounced short-range order [6]. All the particles lied in the horizontal plane and all aligned in the certain direction.

The preferential direction of the particle orientation seems to originate from the slight constructional asymmetry of the discharge tube. To verify this supposition an asymmetrical distortion was introduced into the discharge. A dielectric plate with a hole placed several centimetres above the cathode induced it.

The plate overlapped the discharge section so that the formation of the column started through the hole with the diameter of 1 cm. The visually observed distortion of the standing striation indicated the presence of the axially asymmetric part of the electric field. The turning of the plate resulted in the change of the orientation of particles.

The charge on the dust particles estimated from the levitation conditions is assumed to be about $8 \cdot 10^5$ electrons.

The structures formed of the highly charged elongated cylindrical grains exhibit the properties similar to those of nematic liquid-crystal structures, namely, that the positions of the centers of gravity of the grains show the short range ordering; the grains are oriented strictly in parallel with a certain common axis. The experiments with microcylinders of diameter 10 μm and length 300 and 600 μm with a thin layer of a conducting polymer revealed that these particles behaved in the same way and formed structures of the same shape as dielectric micro-rods of the same size.

4. Wave phenomena

Wave phenomena in the dust component are at present of great interest for researchers. The presence of the dust component in a plasma leads to the appearance of new modes in the wave spectrum in comparison to the plasma without dust grains. It has been demonstrated [7] that the dc glow discharge dusty plasma is a very useful instrument to study self-excited waves of the dust component density. It has been revealed that under certain conditions the self-excited dust-acoustic waves could appear in the dc glow discharge striations.

It was shown [7] that the instability is caused by the joint effect of the ion drift and fluctuations of the dust grain charge.

To excite instabilities of the dust component we proposed a gas-dynamic impact. The experimental set up was similar to that shown in Fig.2. But the lower electrode was made as the hollow cylindrical cathode.

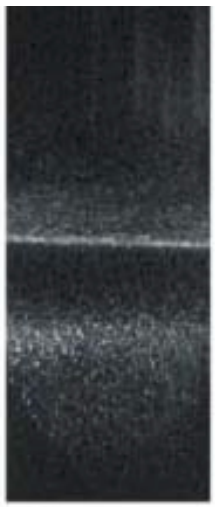

Fig.4. Video image of the disturbance

The electrodes were separated by 26 cm. In some experiments a grid was inserted into the tube 7 cm above the upper cut of the cathode. The grid was kept under the floating potential.

For the excitation of the waves a plunger was set below the cathode. The plunger was a hollow thin-walled nickel cylinder of 26 mm diameter and height with the bottom made of a polymeric pellicle.

It was freely installed at the bottom of the tube and moved with the help of a permanent magnet manually approached to the plunger from outside the tube. The plunger could be moved upward and downward with a speed of 30-40 cm/s and 4-5 cm space, creating a gas flow with a duration of 0.1 s which displaced the dust grains with respect to the striation. Current of 0.1-1 mA could be driven through this system at neon pressure of 0.3 Torr. Melamineformaldehyde dust grains 1.03 μm diameter were used to form dusty plasma structures in striations.

In the case of experiments without the grid it was possible to generate waves of dust density component. The properties of these waves are similar to the properties of the self-exited waves obtained in [7].

In the case of experiments with the grid quite a new type of instability was obtained. This occurred at the current value of 0.1 mA. The dusty plasma structure was very close to the grid (at a distance of 4 mm). After moving the plunger downward the structure was again for some time streaming downward, then it stopped and began moving towards its initial equilibrium position and when it returned to the stable position a disturbance propagating through it appeared (Fig.4).

Fig.5 presents the shape of the compression factor ξ, which is the ratio of the distribution of brightness in the initial structure, at different moments of time. The disturbance consists of two humps (A,C) separated by a

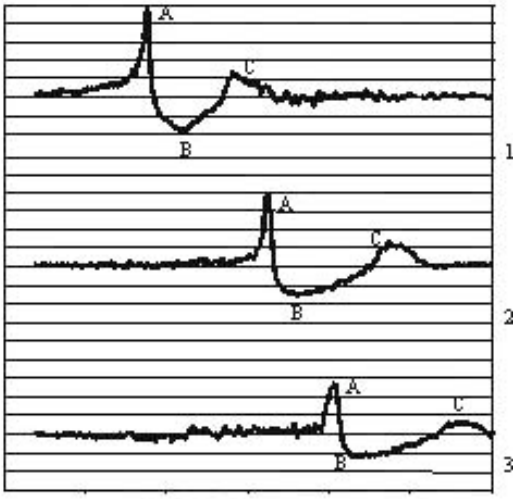

Fig.5. Compression factor in the wave at different moments of time. Time interval between curves 1and 2 – 120 ms, between 2 and 3 –60 ms.

dip(B). It is seen that the amplitudes for zones A and C reach to the values of 2.1 and 1.2 and 0.65 for the rarefaction.

All three structures move approximately with the same speed of 2-2.5 cm/s. These velocities of the wave lie in the range of the dust acoustic velocity C_{da} estimated from the plasma parameters, dust density and the grain charge. According to this C_{da}=1.8-5.2 cm/s.

The gas pressure in our experiments is rather high and the character time of the wave damping, estimated on pressure, mass of the dust grain and thermal velocity of neon atoms is about 15 ms. But the observed time of the wave propagation is 500 ms. It means that the wave must have an energy source other than the initial impulse. The dust acoustic instability could serve as a mechanism by means of which the energy is supplied to the wave.

5. Diagnostics of the dc glow discharge plasma

5.1. Measurement of the grain charge

Measurements of the charge were conducted in the following way. The light beam from an Ar^+ laser was focused onto a single particle in the structure. The beam power was up to 200 mW, the waist thickness was about 60 μm and the corresponding power density of the order of 10^3 W/cm^2. Under the effect of the light pressure the particle moves 1.5 – 3 mm out of the structure, then comes out of the beam and returns back to the structure. When returning back to the structure a dust particle is the subject mainly to the radial electric force and the neutral drag force. The radial electric field is found from the ambipolar diffusion condition. Since the deflection of the particle is small compared to the tube radius R = 18 mm the linear approximation of the radial electric field can be used:

As follows from the observation, the particle performs the aperiodical motion. Starting its way back with the zero radial velocity the particle is first accelerated by the electric force and then, while its velocity increases and the electric field decreases towards the tube center, neutral drag starts to prevail and the particle is slowed down. Thus there must be a maximum of velocity on the returning trajectory of the particle. In the point of this maximum the radial electric force must be balanced by the neutral drag:

$$E_r q = \frac{16\pi}{3} p a^2 \frac{v}{v_{th}} \qquad (1)$$

where E_r is the radial electric field, q is the charge, a is the grain radius, ν is the particle velocity, v_{th} is the thermal velocity of gas atoms. This equation gives the possibility to determine the charge. Estimated accuracy of the εq product measurements is 40%.

5.2. Application of thermophoresis for diagnostics of dust particle's confinement

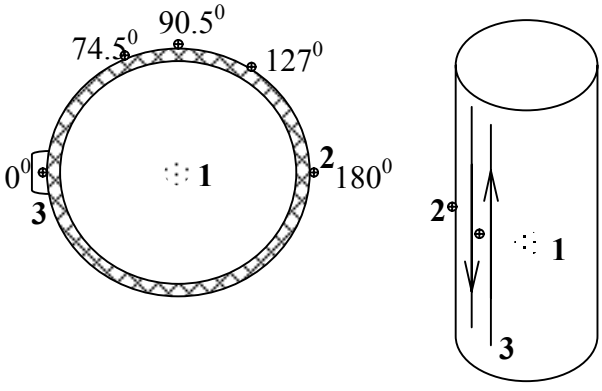

Fig.6. Scheme of the experiment on the thermophoretic influence on the dusty plasma structures. 1 – dust particles, 2 – thermocouples, 3 – heater.

Thermophoretic force is the force acting on a body in a rarefied medium, in which the temperature gradient exists.

To create the temperature gradient a heater was maintained on a discharge tube. The heated was made as a double-wound wire in order to exclude the influence of the magnetic field. The distance between single wires was 7 mm. The heater was (Fig.1) installed parallel to the discharge axis. Its length was 16 cm, whereas the tube diameter was 3 cm. So, the temperature distribution produced by the heater could be treated as two-dimensional.

Temperatures were measured in a certain section of the tube close to the area of levitation of the dust grains. Chromel-alumel thermocouples were employed for temperature measurements. Their sensitivity is of the order of 65 μV/K. Thermocouples were placed in 5 points of the tube semicircle as shown in Fig.1. The other semicircle is left free to allow the observation of the dust grains. The measured temperature profile is symmetrically depicted onto the free semicircle and in this way the temperature profile on the whole circumference is determined.

To reconstruct the temperature distribution inside the tube we have to solve the following equation

$$\Delta T = 0$$

$$\frac{T_w(\phi) - T(R,\phi)}{d} \lambda_{glass} = \lambda_{gas} \frac{dT}{d\rho}\Big|_{R,\phi} \tag{2}$$

where ρ, ϕ are polar coordinates, T(R, ϕ) is the temperature distribution inside the tube, $T_w(\phi)$ is the interpolation of the measured temperatures over the tube circumference, R is the tube radius, d is the tube wall thickness, λ_{glass} and λ_{gas} are heat conductivities of glass and gas in the tube respectively. Equation (2) is considered linear since the dependence of the gas heat conductivity on the temperature is negligible due to small temperature variations. The boundary condition accounts for the continuity of the heat flux on the internal surface of the tube.

The experiment proceeds as follows. First a chain of dust particles is formed on the axis of the discharge tube and initial positions of the dust grains are recorded. Then the heater is turned on. It takes about 15 minutes for the temperature to reach steady-state distribution. Dust particles acquire new equilibrium positions. Their positions are again recorded and indications of the thermocouples are taken. Then the heater power is increased and the procedure is repeated.

Measured temperatures are interpolated along the circumference and equation (1) is solved. In this way the distribution of temperatures for each equilibrium position of dust grains is obtained. In an equilibrium position the thermophoretic force acting on a dust particle is balanced with a confining force of the discharge. The thermophoretic force is expressed as follows:

$$F_{th} = \frac{8}{45} \sqrt{\pi}\, p a^2 l \frac{\nabla T}{T}, \tag{3}$$

where p is the neutral gas pressure, l is the mean free path of neon atoms, a is the dust grain radius. F_{th} can be easily calculated if the temperature distribution and the particle position is known. Calculating thermophoresis for a set of equilibrium positions of the dust grains we acquire the distribution of the confining force.

Conclusion

In this work we have presented the results of the investigations of the behavior of the dust grains in the dc glow discharge striations. It has been shown that dust particles can form structures with short-range as well as long-range order. The experiments were performed with spherical and elongated cylindrical grains. In the case of microcylinders structures with strong orientational order were obtained. These structures were called plasma liquid crystals. It has been demonstrated that the gas-dynamic impact is a useful tool for excitation of high-amplitude waves of dust density. A method for measuring the charge on the dust grains levitating in plasma was suggested. Influence of thermophoresis on the dust grains was used to measure the field of confining forces.

Temporal development of a charge state resolved Zr plasma stream in a N_2 environment.

J. Rosén[1], A. Anders[2], J. M. Schneider[3]

[1] *Department of Physics, Linköping University, Linköping SE-58183, Sweden*

The temporal development of the plasma composition in a pulsed cathodic arc has been investigated. Charge state resolved data has been evaluated for a Zr cathode used at various nitrogen pressures. The plasma composition was measured by time-of-flight charge-to-mass spectrometry and showed a strong time as well as pressure dependence. Large nitrogen concentrations were detected in the beginning of the arc pulse. These results may be explained by the formation and erosion of a compound layer at the cathode surface, and a varying interaction between the expanding plasma and the surrounding gas. The time dependence of the metal charge states was most pronounced at lower pressures, with as much as 40 % and 20 % of Zr^{3+} and Zr^{4+} respectively. As the pressure increased the concentrations of Zr^{1+} and Zr^{2+} increased at the expense of the former concentrations, which may be due to an increased probability of charge exchange collisions. These findings are of importance for reactive plasma processing, through an increased understanding of the film composition and via the ion energy the film microstructure.

Measurement of N(^{2}D) density in nitrogen afterglow

Abstract

Post-discharges were created from direct current (dc) discharges operating at pressures varying from 3.0 to 9.0 Torr, current between 20 and 50 mA and flux from 300 to 950 sccm. Densities of N(^{4}S) and N(^{2}D) were measured along the post-discharge respectively by emissions of the first and second positive systems of N_2. These measurements reveal that N(^{2}D) may reach densities of about 5 % [N(^{4}S)].

1. Introduction

Nitrogen afterglow has been studied along the last years due to technological applications of these post-discharges in nitriding [i], sterilization [ii] and study of atmospheric chemistry [iii]. Another importance of afterglow studies is the understand of the complex non-equilibrium kinetics of this medium that involves transport of vibrationally excited molecules, molecular and atomic metastable states. One important active specie is the nitrogen atom, so the comprehension of its transport along the flux is very important. Nitrogen atom in their first excited state N(^{2}D) is a very important radical in atmospheric chemistry and in materials processing, because it has 2.38 eV of energy above the ground state N(^{4}S), radiate lifetime of 26 hours and is a key specie in the transport of N(^{4}S) atoms along the post-discharge afterglow through reactions with $N_2(A\ ^3\Sigma^+_u)$. In this work we propose a novel method to determine the N(^{2}D) density along the pink and Lewis-Rayleigh afterglow. The densities of N(^{4}S) and N(^{2}D) were measured along the post-discharge respectively by emissions of the first and second positive systems of N_2. These measurements reveal that N(^{2}D) may reach densities of about 5 % [N(^{4}S)].

2. Experimental set-up and methods

The experimental apparatus consisted of a 14-mm i.d. Pyrex tube, 1m long with a post-discharge length of 600 mm. A direct current (dc) discharge is operated at pressures varying from 3.0 to 9.0 Torr, current between 20 and 50 mA and flux from 300 to 950 sccm. Two electric probes, 10 cm apart, were inserted into the positive column in order to measure the electric field. The pressure was measured in the central region of the post-discharge tube by means of a capacitive transducer Baratron. A mechanical pump maintains the flow of the gas. The nitrogen employed in the experiments was of ultra-high purity 99.999%. The gas flow was controlled by a flowmeter connected to the discharge tube. The light emitted by the discharge and post-discharge was sent, by an optical fiber, into the entrance slit of a 1 m monochromator (THR 1000) equipped with a grating of 1800 lines mm^{-1} and blazed in the region 450 – 850 nm. The light collimated at the exit slit was converted to electric current by a R928 Hamamatsu photomultiplier tube. This current was sent to a data acquisition electronics Spectralink and the signal processed by a Spectramax software. The whole optical system was calibrated in intensity with aid of a tungsten lamp and in frequency with a pure argon discharge.

3. Inverse predissociation kinetics in the afterglow

Büttenbender and Herzberg [iv] observed predissociations in the $N_2(C\ ^3\Pi_u)$ state at v = 2, 3 and 4. Carroll and Mulliken [v] attributed these predissociations to an $N_2(^5\Pi_u)$ state. Carroll and Mulliken also identified another predissociation channel through the $N_2(C'\ ^3\Pi_u)$ state. Tanaka et. al. [vi], working in a nitrogen cooled afterglow, observed abnormal strong emission line intensity from the v'=4 level in the Second Positive System (transition $N_2(C\ ^3\Pi_u) \rightarrow N_2(B\ ^3\Pi_g)$) and proposed inverse homogeneous predissociation involving $N(^4S)$ and $N(^2D)$, forming the $N_2(C\ ^3\Pi_u$, v = 4) state, to explain this strong emission. They suggested that the cooled discharge tube wall produced conditions favorable for preventing decay of the metastable atoms thus enabling the observation of the Second

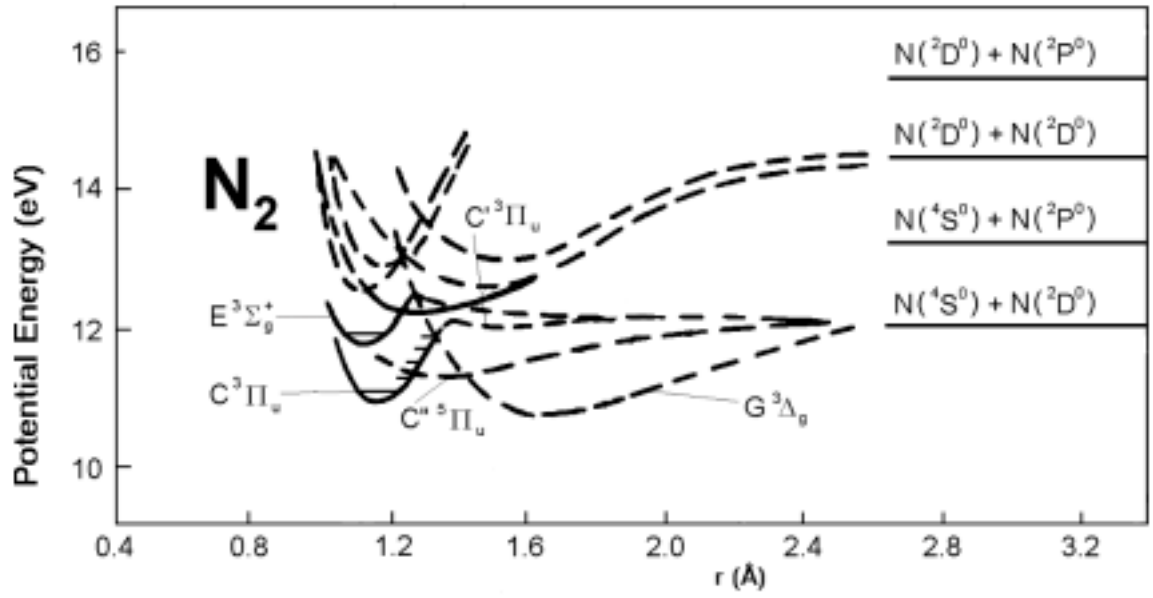

Figure 1 : Potential energy curves of N_2

Positive System. As can be seen in Fig. 1, inverse homogenous predissociation involving $N(^4S)$ and $N(^2D)$ may induce the formation of N_2 ($C'\ ^3\Pi_u$, $C''\ ^5\Pi_u$, $G\ ^3\Delta$) states.

The potential energy curve of the N_2 ($C''\ ^5\Pi_u$) state crosses the potential energy curve of the N_2 ($C\ ^3\Pi_u$) state near v =2 while the potential energy curves of N_2 ($C'\ ^3\Pi_u$, $G\ ^3\Delta$) states intersects the potential energy curve of the N_2 ($C\ ^3\Pi_u$) state at v =4.

In the conditions found in nitrogen afterglow, *i.e.* temperatures lower than those found in the discharge, inverse predissociation reaction may induce overpopulation on the N_2 ($C\ ^3\Pi_u$, v=4) state by:

$$N_2(A\ ^3\Sigma^+_u) + N(^4S) \rightarrow N_2 + N(^2D) \quad (1)$$

$$N(^2D) + N(^4S) + N_2 \rightarrow N_2\ (C'\ ^3\Pi_u) + N_2 \rightarrow N_2\ (C\ ^3\Pi_u, v=4) + N_2 \quad (2)$$

$$N(^2D) + N(^4S) + N_2 \rightarrow N_2\ (C''\ ^5\Pi_u) + N_2 \rightarrow N_2\ (C\ ^3\Pi_u, v=2) + N_2 \quad (3)$$

This overpopulation leads to an increase in the intensity of the Second Positive System of nitrogen, transition $N_2(C\ ^3\Pi_u$, v=4 $\rightarrow$ B $^3\Pi_g$, v=6). However, pooling reactions due to $N_2(A\ ^3\Sigma^+_u)$ state may populate N_2 (C' $^3\Pi_u$, C'' $^5\Pi_u$) states :

$$N_2(A\ ^3\Sigma^+_u) + N_2(A\ ^3\Sigma^+_u) \rightarrow N_2(X\ ^1\Sigma^+_u) + N_2\ (C'\ ^3\Pi_u) \qquad (4)$$

$$N_2(A\ ^3\Sigma^+_u) + N_2(A\ ^3\Sigma^+_u) \rightarrow N_2(X\ ^1\Sigma^+_u) + N_2\ (C''\ ^5\Pi_u) \qquad (5)$$

In the Lewis-Rayleigh post-discharge, the density of the $N_2(A\ ^3\Sigma^+_u)$ state is about ten times lower than in the pink afterglow [vii]. Simple estimation of rate of formation of the $N_2(C\ ^3\Pi_u$, v=4) state by N_2 (C' $^3\Pi_u$) and N_2 (C'' $^5\Pi_u$), taking into account rate coefficients for reactions (4) and (5) [viii,ix], give values that are negligible if compared with formation by reactions (2) and (3). This is not the case in the pink afterglow were pooling reactions are more efficient in the formation of the $N_2(C\ ^3\Pi_u$, v=4) state.

In this work we studied the variation of the vibrational distribution (VDF) of the Second Positive System of nitrogen as a function of post-discharge parameters.

4. Results

The vibrational distribution of N_2 (B $^3\Pi_g$,v) and N_2 (C $^3\Pi_u$, v) states have been determined in the early, pink and late afterglow from the First and Second Positive systems:

$$I_{B,C} = K(\lambda_i)\, hc/\lambda_i\, A_i\, [B/C, v] \qquad (6)$$

where $K(\lambda_i)$ is the system spectral optical response at λ_i , A_i is the Einstein transition probability of spontaneous emission and [B/C, v] is the N_2 (B $^3\Pi_g$ *v*) or N_2 (C $^3\Pi_u$, *v*) density. The normalized VDF can be obtained from:

$$r_{C,v'} = N_2(C\ ^3\Pi_u, v) / \Sigma\, N_2(C\ ^3\Pi_u, 0 \le v \le 4) \qquad (7)$$

Typical normalized VDF of the N_2 (C $^3\Pi_u$, v) state can be seen in Figure 2. The normalized VDF in the late afterglow is overpopulated for v = 4. Vibrational levels *v* =2,3 are less populated in the late afterglow than in the early and pink afterglow. This figure illustrate the population inversion for v = 4 due to homogeneous inverse predissociation. The same procedure was applied to the N_2 (B $^3\Pi_g$,*v*) levels in order to obtain its VDF.

From normalized VDF for the N_2 (B $^3\Pi_g$,*v*) state, we determined the N(^{4}S) density along the post-discharge following the method described in [x]. This method is based on abacus constructed from the normalized VDF's of the N_2(B $^3\Pi_g$) state. It revealed an increase in the population of the N_2(B $^3\Pi_g$, v =11) level, which is due to inverse predissociation of two recombining N(^{4}S) atoms, through the N_2 (A' $^5\Sigma_g$) intermediate state.

The same procedure was applied in this work for the VDF of the N_2 (C $^3\Pi_u$, v) state. Briefly, in the late afterglow, the most important mechanism responsible for populating the level N_2 (C $^3\Pi_u$, *v* = 4) is homogenous inverse predissociation.

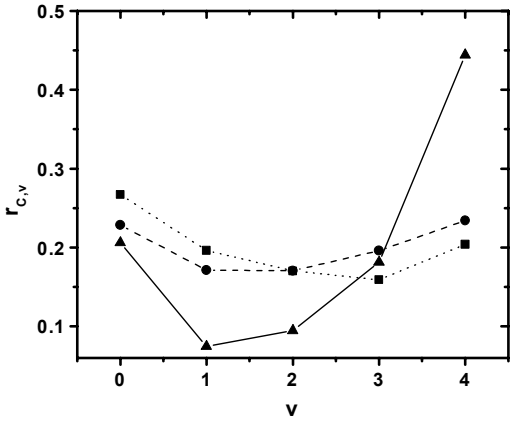

Figure 2 : Normalized vibrational distribution of N_2 (C, v') for v' = 0-4 in a dc post-discharge, 5 Torr, 300 sccm, 30 mA. early (square); pink (circle); Lewis-Rayleigh afterglow (triangle).

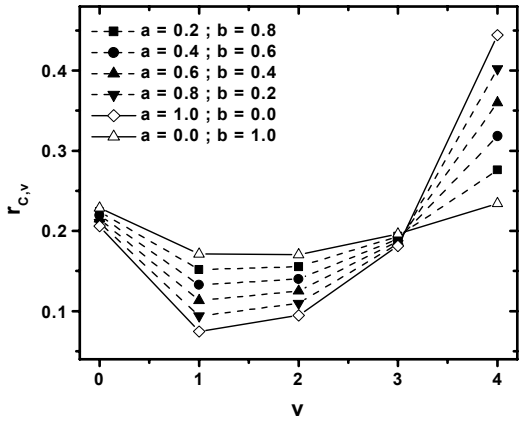

Figure 3: Normalized vibrational distribution of N_2 (C, v') for v' = 0-4 calculated (dash lines) by adding the $r_{C, v'}$ [$N(^4S)$ + $N(^2D)$] (a) and $r_{C, v'}$ [pooling](b) contributions.

In early and pink afterglow the pooling involving $N_2(A\ ^3\Sigma^+_u)$ states is the predominant mechanism in populating level N_2 ($C\ ^3\Pi_u$, v = 4). Along the post-discharge, both mechanisms are presented in the formation of the N_2 ($C\ ^3\Pi_u$, v = 4) state. As we are interested in the part of the emission coming from inverse predissociation, normalized VDF's were constructed, see Figure 3, where a combination of the two process were taken into account. In Figure 3, are presented the $r_{C,v'}$ = $a\ r_{C,v'}$ ($N(^2D)$ + $N(^4S)$) + $b\ r_{C,v'}$ (pink) in the v' = 0 - 4 range for a = 0, 0.2, 0.4, 0.4, 0.6, 0.8 and 1.0. Given a specific experimental condition, the value of a is determined and the density of the $N(^2D)$ state is obtained from :

$$\frac{a\ I_{N2\ (C\ 3\Pi u,\ v=4)}}{b\ I_{N2\ (B\ 3\Pi g,\ v=11\ )}} \quad \alpha \quad \frac{hc/\lambda_i\ A_i\ [N(^2D)]\ \ [N(^4S)]\ [N_2\ ]\ k_2}{hc/\lambda_j\ A_j\ [N(^4S)]\ \ [N(^4S)]\ [N_2\ ]\ k_1} \qquad (8)$$

where b is the fraction of the First Positive emission that comes from ground state $N(^4S)$ atoms recombination, k_1 is the rate coefficient for $N(^4S)$ atoms recombination. Due to the lack of knowledge of rate coefficient for reaction (2), we supposed in this work to be equal to, k_1 = 2.4 x 10^{-33} $cm^6\ s^{-1}$ [xi]. The density of the $N(^2D)$ was determined along the afterglow as a function of [$N(^4S)$].

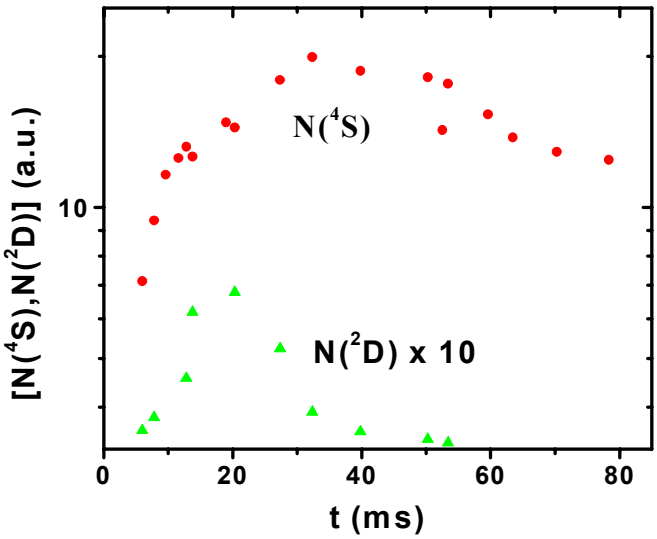

Figure 4: N(^{4}S) and N(^{2}D) atoms as a function of time. Pressure of 5.0 Torr, Id = 30 mA and flux of 300 sccm.

As can be seen in the figure 4, the N(^{4}S) atoms density is maximum at t ~ 32 ms while the N(^{2}D) density is maximum at t ~ 20 ms. Another important result is that the maximum density of N(^{2}D) state measured is ~ 5% of the N(^{4}S) density.

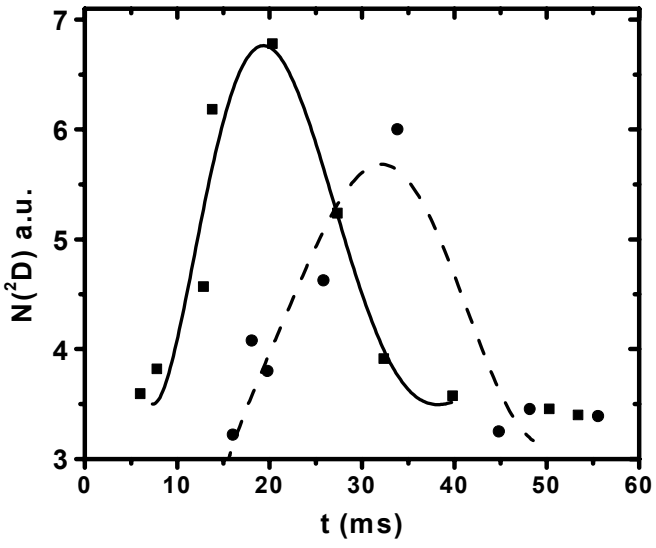

Figure 5: [N(^{2}D)] as a function of time. Pressure of 5.0 Torr, Id = 30 mA (square) and 20 mA (dashed) for a flux of 300 sccm.

Figure 5 shows the variation of N(^{2}D) density as a function of time when the discharge current is varied between 20 mA and 30 mA. The time for maximum of [N(^{2}D)] changes from 20 ms to 32

ms. This displacement is due to changes in the density of $N_2(A\ ^3\Sigma^+_u)$ and $N(^4S)$ specie, that are precursors for $N(^2D)$ formation when discharge current is changed.

5. Conclusion

The study of homogenous inverse predissociation of $N(^4S)$ and $N(^2D)$ atoms was accomplished in order to measure the $N(^4S)$ and $N(^2D)$ densities along the post-discharge. The density of $N(^4S)$ was initially determined using an abacus constructed from the VDF of the N_2 ($B\ ^3\Pi_g$,v) state. From the measured VDF of the N_2 ($C\ ^3\Pi_u$, v) state, a second abacus was done in order to obtain the fraction of emission of the Second Positive System due to inverse predissociation. From the ratio of First and Second Positive Systems, due to inverse predissociation reaction, the density of $N(^2D)$ could be obtained along the afterglow. For discharge pressure of 5.0 Torr, current of 30 mA and flux of 300 sccm, the density of $N(^2D)$ atom was found to be 5%[$N(^4S)$] at t ~ 20 ms.

ABSTRACT

A numerical model was implemented to describe the behaviour of many N_2 molecular states and also the N(^{4}S), N(^{2}D) and N(^{2}P) atomic ones in the N_2 short-lived afterglow. We have assumed the reactions N(^{4}S) + N_2(A $^3\Sigma^+_g$) $\rightarrow$ N(^{2}D, ^{2}P) + N_2(X $^1\Sigma_g^+$) to account for the N(^{2}D, ^{2}P) generation in the post-discharge. The atomic species densities, as a function of residence time, present the same behaviour observed experimentally for the excited molecular states since they are strongly coupled to N_2(A $^3\Sigma^+_g$) by the quenching mechanisms.

INTRODUCTION

The short-lived afterglow has been recently studied both theoretically and experimentally **[1-3]**. In our last work **[3]**, we developed a numerical model to describe the short-lived afterglow (SLA). The model described qualitatively well the behavior of many experimentally studied species, as the N_2(A $^3\Sigma^+_g$) and n_e (electron density) **[2]**, the N_2^+, N_3^+ and N_4^+ ground state-ions **[4]**, the N_2($B^3\Pi_g$), N_2($C^3\Pi_u$) and N_2^+($B^2\Sigma^+_u$) radiative states **[5]** and the N(^{4}S) fundamental state atom **[6]**. Nowadays, it is a common idea the fact that the short-lived afterglow results from the relaxation of the N_2(X $^1\Sigma_g^+$) vibrational distribution function (VDF) in the post-discharge, which tends to populate the intermediate **[3]** and high **[1]** vibrational levels of the N_2 electronic fundamental state. These energetic species are capable to initiate all

the reactive pathways responsible for the phenomenon. Loureiro *et al.* **[1]** attribute to the formation of the molecular metastables $N_2(A\ ^3\Sigma^+_g)$ and $N_2(a'^1\Sigma^-_u)$ the following mechanisms:

$$N_2(X\ ^1\Sigma^+_g, v>24) + N(^4S) \rightarrow N_2(A\ ^3\Sigma^+_g) + N(^4S) \quad \text{and} \quad \textbf{(01)}$$

$$N_2(X\ ^1\Sigma^+_g, v>37) + N(^4S) \rightarrow N_2(a'^1\Sigma^-_u) + N(^4S) \quad . \quad \textbf{(02)}$$

Levaton *et al.* **[3]** suggest other pathways:

$$N_2(X\ ^1\Sigma^+_g, v>15) + N_2(X\ ^1\Sigma^+_g, v>15) \rightarrow N_2(a'^1\Sigma^-_u) + N_2(X\ ^1\Sigma_g^+, v)\ , \quad \textbf{(03)}$$

$$N_2(a'^1\Sigma^-_u) + N_2(X\ ^1\Sigma_g^+) \rightarrow N_2(B^3\Pi_g) + N_2(X\ ^1\Sigma_g^+) \quad \text{and} \quad \textbf{(04)}$$

$$N_2(B^3\Pi_g) + N_2(X\ ^1\Sigma_g^+) \rightarrow N_2(A\ ^3\Sigma^+_g) + N_2(X\ ^1\Sigma_g^+) \quad . \quad \textbf{(05)}$$

This local creation of molecular metastables, in a region with a large density of $N(^4S)$ atoms **[6]**, seems to be a helpful environment to the $N(^2P)$ generation via reaction:

$$N(^4S) + N_2(A\ ^3\Sigma^+_g) \rightarrow N(^2P) + N_2(X\ ^1\Sigma_g^+)\ . \quad \textbf{(06)}$$

The rate constant of this reaction was measured by Piper **[7]** as being $4x10^{-11}$ cm^3s^{-1}. Moreover, he also observed the presence of the $N(^2D)$ state in an environment rich in $N_2(A\ ^3\Sigma^+_g)$ and $N(^4S)$ species **[8]**. Its density was of the same order of magnitude of the $N(^2P)$ one. Recent experiments **[9]** indicate the existence of $N(^2D)$ atoms in the N_2 flowing post-discharge when the SLA is observed. The $N(^2D)/ N(^4S)$ ratio is estimated to be on the order of 1 – 5 %.

The purpose of the present work is to introduce the relevant kinetics concerning the excited atomic states $N(^2D)$ and $N(^2P)$ in the model and to study the behaviour of them in the SLA. The local generation of the $N(^2D)$ is discussed on the basis of the introduction or not of reaction:

$$N(^4S) + N_2(A\ ^3\Sigma^+_g) \rightarrow N(^2D) + N_2(X\ ^1\Sigma_g^+)\ , \quad \textbf{(07)}$$

whose rate constant is considered the same as that one of reaction (06).

NUMERICAL MODEL PRESENTATION

The model main features are exhaustively depicted in ref.**[3]**. A new set of reactions was included to describe the atomic metastables kinetics and to complete the former set of reactions. Altogether, the diffusion constant of the $N_2(A\ ^3\Sigma^+_g)$ metastable was changed. The V-V and V-T rate coefficients were calculated following the formalism presented in ref.**[10]**.

DISCUSSION

The SLA has been recently analysed **[1,3]**, but no attention has been devoted to the metastable atomic states. As discussed in the introduction, both of works predict the formation of $N_2(A\ ^3\Sigma^+_g)$ species in the afterglow region. In fact, Sadegui *et al*.**[2]** have experimentally demonstrated that $N_2(A\ ^3\Sigma^+_g)$ density increases from 4 x 10^9 cm^{-3}, at the SLA minimum, to 5.5 x 10^{10} cm^{-3}, at SLA maximum. Such a high metastable density, along with the high $N(^4S)$ density (10^{14} – 10^{15} cm^{-3} **[6]**), develop a strong source term for the $N(^2P)$ state via reaction (06). In this way, we have included this mechanism and the other relevant mechanisms (reactions R1, R4, R6-R14) in the main block of reactions of the model **[3]**.

In figure 1 are presented the atomic and the $N_2(A\ ^3\Sigma^+_g)$ and $N_2^+(X\ ^2\Sigma^+_g)$ molecular densities as a function of time. We have considered the initial vibrational temperature as 6000 K and the same initial concentrations assumed in ref.**[3]**, which implies in initial concentrations of 7.5 x 10^{12} cm^{-3} for $N(^2D)$ and 3 x 10^{12} cm^{-3} for $N(^2P)$. We are considering the ratio $N(^2D)/N(^4S)$ as 1% in the discharge and the ratio $N(^2D)/N(^2P)$ being 2.5:1, as determined by Piper in the Ar-N_2 post-discharge **[8]**. Also, in addition to the metastable $N_2(A\ ^3\Sigma^+_g)$ generation mechanisms assumed before, we have included reaction (R1) (see table I), as proposed by Loureiro **[1]**. The constant of this reaction was obtained from the fit of numerical data to our experimental results. As shown, the $N(^2P)$ density follows the $N_2(A^3\Sigma^+_g)$ one, presenting the same behaviour of the molecular species in the SLA. The $N(^2D)$ density also presents an increase in the afterglow that is caused by the quenching of $N(^2P)$ (see reaction R13 in table 1). In this simulation, the product of reaction (R12) was $N(^4S)$, but it should be equally considered as $N(^2D)$. To our knowledge, there is not clear information about the branching ratio of reaction (R12) or about its rate constant (see table I), whose value is widely spread. We have studied the contribution of reaction (R12) in the $N(^2D)$ density when the product of this reaction is $N(^2D)$. A drastic change is observed in the density profiles (see figure 2) only for the rate constant proposed by Lin and Kaufmann **[11]**. In this case, the $N(^2D)$ density becomes greater than the $N(^2P)$ one, being in qualitative agreement with experimental results. As

discussed above, Piper found a N(^{2}D) density 2.5 times greater than the N(^{2}P) one in the post-discharge, even though he worked with an Ar-N_2 discharge

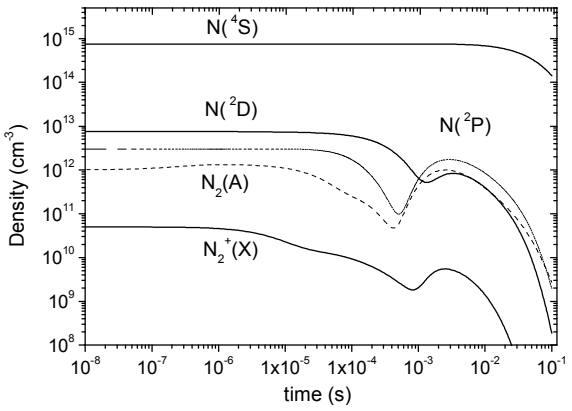

Figure 1 – Post-discharge temporal profiles for the $N_2(A\ ^3\Sigma^+_g)$, $N_2^+(X^2\Sigma^+_g)$, N(^{4}S), N(^{2}D) and N(^{2}P) densities with the product of reaction (R12) being N(^{4}S) and the rate constant 6x10^{-14} cm^{3}s^{-1}.

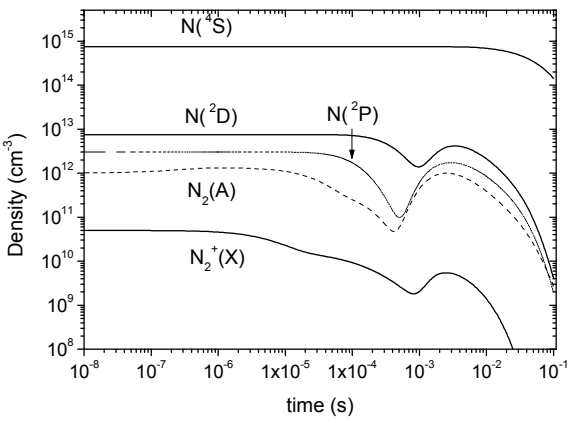

Figure 2 – Post-discharge temporal profiles for the $N_2(A\ ^3\Sigma^+_g)$, $N_2^+(X^2\Sigma^+_g)$, N(^{4}S), N(^{2}D) and N(^{2}P) densities with the product of reaction (R12) being N(^{2}D) and the rate constant 6x10^{-14} cm^{3}s^{-1}.

A similar result was obtained by Foner and Hudson **[12]** working in a pure N_2 discharge. They found N(^{2}D)/N(^{4}S) = 7 x 10^{-3} and N(^{2}P)/N(^{4}S) = 2.5 x 10^{-3}. However, the calculated N(^{2}D)/N(^{4}S) ratio at t = 10 - 50 ms, which varies from 3 x 10^{-3} to 3 x 10^{-4}, is too low. Kiohara *et al.* **[9]** worked in a N_2 post-discharge, in the presence of the SLA, and have found a N(^{2}D)/N(^{4}S) ratio on the order of 10^{-2} for the same range of residence time. Moreover, if the rate constant for reaction (R12) is that one proposed by Lee *et al.* **[13]**, or by Slovetskii and Smirnoff **[in 14]** or, if N(^{4}S) is generated in the N(^{2}P) quenching, the N(^{2}P) density overcomes the N(^{2}D) one (see figure 1) and even the qualitative behaviour with the experimental observations is not achieved. Thus, the numerical results point to the lack of mechanisms to account for N(^{2}D) generation in the post-discharge. Given that the energies of N(^{2}D) and N(^{2}P) are close, 2.38 eV and 3.58 eV, we propose the inclusion of reaction (R3) (see table I), with a rate constant of the same order of that one estimated

for reaction (R2). Figure 3 presents the densities temporal profiles, with the addition of reaction (R3). When reactions (R3) and (R4) are included in the model, it is observed that the $N(^2D)$ density is greater than the $N(^2P)$ one, for times longer than 1 ms (compare with the profile presented in figure 1), no matter what is the product of reaction (R12) or its rate constant. Although the qualitative behaviour of $N(^2D)/N(^2P)$ ratio is observed, reaction (R3) is not capable to promote the ratio $N(^2D)/N(^4S)$ to values on the order of those ones observed experimentally.

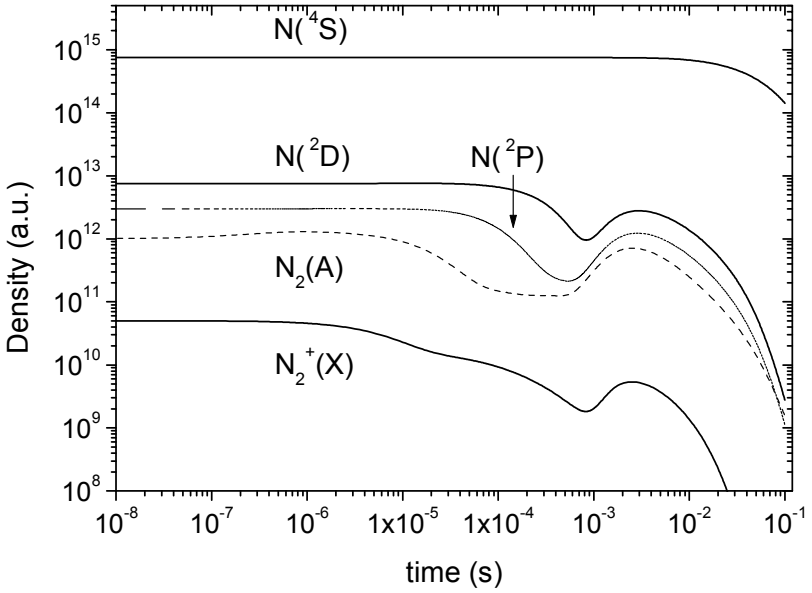

Figure 3 – Post-discharge temporal profiles as in figure 1 with the inclusion of reaction (R3).

CONCLUSION

A numerical model developed to study the N_2 short-lived afterglow was upgraded to include the atomic metastables $N(^2D)$ and $N(^2P)$. The densities of these metastables have shown the same temporal behaviour of the already studied molecular species in the SLA. A not usual mechanism (reaction R3) is required to reproduce qualitatively the $N(^2D)/N(^2P)$ ratio behaviour observed in N_2 flowing post-discharge experiments. The $N(^2D)/N(^4S)$ ratio obtained by the model is, at least, one order of magnitude lower than that one observed experimentally in a N_2 post-discharge with the presence of the SLA. Other possible $N(^2D,^2P)$ formation pathways have to be analysed to cover this issue.

Handling of fine, cohesive particles in a circulating riser reactor

B. Borer[1], Ph. Rudolf von Rohr[1]

[1] *Institute of Process Engineering, ETH Zurich, Zurich, Switzerland*

In this study three different approaches have been evaluated to improve the handling of fine, cohesive particles in a circulating riser reactor. Mixing the fine particles with large glass beads was the most suitable way to process the cohesive powder. The influence of the large particle ratio on separation efficiency of the cyclone was negligible. The deposited barrier coating showed several defects, caused by dust particles.

1. Introduction

Most solid materials used in industrial or chemical processes are processed as particles with sizes below 1 mm. Advantages are the easy handling and the high specific surface area allowing high-rate reactions with liquids and gases.

With advanced products, there is a demand for specified particle materials with controlled properties. Particle properties are strongly influenced by the surface. The deposition of thin films is a convenient way to adjust particle properties over a wide range. The broad spectrum of applications includes corrosion protection, diffusion reduction, wettability and catalytic properties.

Plasma enhanced chemical vapor deposition (PECVD) techniques are widely used for deposition of thin films at low temperature and dry environment. The circulating fluidized bed (CFB) plasma reactor provides uniform and efficient coating of particles at high deposition rates. Both, diffusion barrier and catalytic layer were successfully deposited on particles with mean diameter of 100 – 200 μm [1, 2].

However, in industry there is an increasing demand to treat even smaller particles. In the future, particle sizes of 1 μm and smaller should be possible to be processed. But the small particle size causes several problems, because cohesive forces between particles, like Van-der-Waals- or electrostatic forces become dominant compared to gravitational forces. Consequently small particles stick together and form stable agglomerates.

The cohesive behavior of the particles caused plugging and instable fluid dynamic conditions in the CFB system. Due to strong fluctuations of the solid ratio in the reactor it was not possible to ignite the plasma, and therefore the deposition process could not be performed. By introducing the circulating riser reactor design, the process conditions could be dramatically improved. However, on the cyclone wall an extensive particle layer was formed, because of the strong cohesive inter-particle forces (see Fig.3a). As a result the separation efficiency of the cyclone was decreased, and half of the valuable product was lost on the cyclone wall.

The objective of this study was to avoid a layer formation in the cyclone. Device-dependent, as well as a product-specific approaches have been investigated. Here the results of these investigations are presented.

2. Experimental

The main parts of the circulating riser reactor are a riser tube (ID 40 mm, length 900 mm) with integrated microwave plasma source, a cyclone and a re-feed section, as shown in Fig. 1. The particles are stored in the re-feed section, consisting of a PE-tube and a siphon. Introducing a small argon gas flow at the bottom of the siphon fluidizes the particle bed. By fluidizing the particle bed, the particles are fed into the riser tube, and subsequently are transported upward by the process gas flow (2570 sccm), which is distributed by a porous plate at the bottom of the riser tube. As process gas a mixture of argon, oxygen and precursor (Hexamethyldisiloxane, HMDSO) is used. In the riser tube a plasma source (μ-SLAN, *JE Plasma Consult GmbH*) is integrated, where the microwave power (2.46 GHz) is coupled into a quartz glass tube to ignite and sustain a low temperature plasma. In the plasma zone the coating process is performed at a reduced pressure of about 3 mbar. Downstream the plasma reactor the gas solid flow is separated by a cyclone, and the particles are collected in the re-feed section. The cyclone diameter is 100 mm and the height 260 mm.

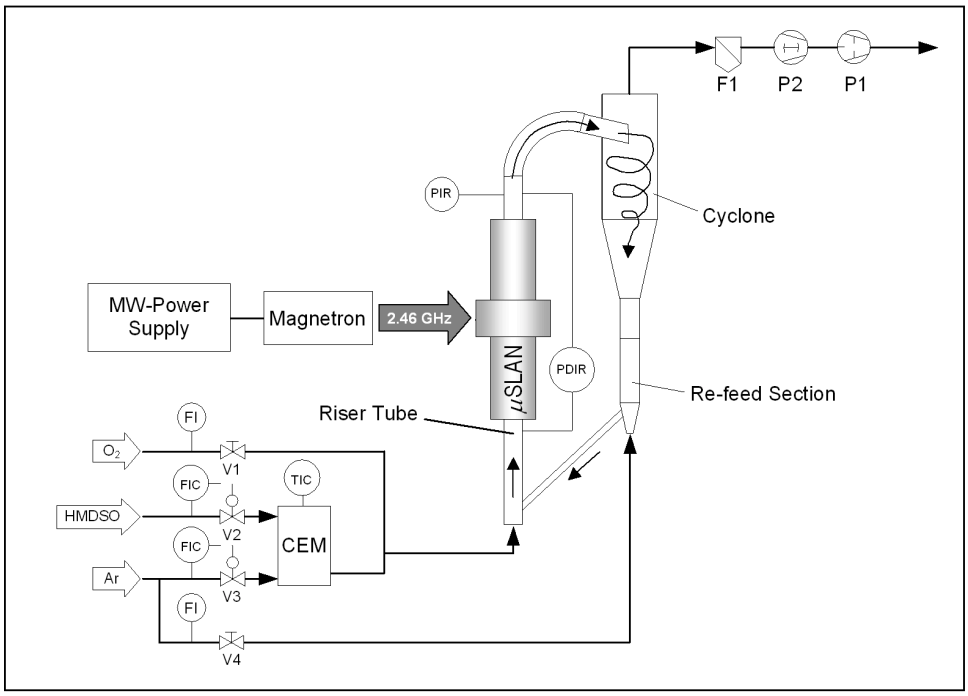

Figure 1: Scheme of the experimental setup, including the riser tube, the cyclone and the re-feed section

The gas inlet is inclined by an angle of 20° to improve the separation efficiency. The diameter of the outlet tube (vortex finder) is 35 mm, and its length 110 mm.

During a typical deposition procedure of 3.5 hours the particle batch is circulated several hundred times. This high number of circulations provides a narrow residence time distribution, thus a uniform coating thickness of the whole batch. However, the cyclone separation efficiency must be very high.

The liquid precursor (Hexamethyldisiloxane) is evaporated and subsequently mixed with the argon gas in the Controlled Evaporator Mixer (CEM, *Bronkhorst High-Tech B.V.*) device. The flow rates and the mixing temperature are controlled. The oxygen gas flow is regulated by a rotameter (V100*, Vögtlin Instruments AG*) and mixed with the argon / HMDSO gas flow downstream the CEM. The argon gas flow for fluidizing the particle bed in the re-feed section is also regulated by a rotameter (V100, *Vögtlin Instruments AG*).

The vacuum pump system (*LEYBOLD VAKUUM GmbH*) consists of a two-stage rotary vane backing pump (P1) and a Roots vacuum pump (P2). Between the cyclone and the vacuum pump system an inlet dust filter (ITM800, *BOC Edwards AG*) is installed to collect fine particles in order to protect the pumps.

The pressure is measured right above the plasma reactor by a Pirani cold cathode pressure sensor (*Balzers*). Between the reactor in- and outlet the differential pressure is measured by a low pressure differential sensor (*Honeywell*).

Non-spherical particles (ρ = 4.1 g/cm^3) were used as fine, cohesive material. The mean diameter was 15.97 µm. Further size distribution parameters were: d_{10} = 2.62 µm, d_{90} = 26.19 µm.

3. Results and discussion

3.1. Device dependent approaches

The first device-dependent approach was to decrease the electrostatic forces between the particles by reducing the electrostatic charges on the particles, because of strongly increased layer formation after igniting the plasma. Due to the higher mobility of the electrons, particles are charged negatively in the plasma at the given conditions [3, 4]. After entering the cyclone the particles repelled one another to the grounded cyclone wall, where they lost the charges and formed a stable layer.

In the outlet of the plasma reactor a honeycomb structure was installed to discharge the particles, in order to reduce the layer formation. However, shortly after starting the deposition process, the honeycomb structure was coated itself with a SiO_x layer, in spite of the attrition effect of the particles. The particles were not discharged anymore, because the SiO_x layer electrically insulated the honeycomb.

Another device-dependent approach was a mechanical cleaning system of the cyclone wall. For that purpose an elastomer liner (0.5 mm thickness) was attached to the cyclone wall. By pumping gas between the wall and the liner, the elastomer liner was inflated and the dense, stable particle layer was detached from the elastomer. Subsequently the gas was exhausted, and the elastomer liner was sucked tightly on the cyclone wall (Figure 2 & 3). This cleaning process was typically repeated every 60 seconds. Since the elastomer liner was inflated only for 0.5 seconds the flow conditions in the cyclone were not interfered remarkably, which was an important requirement for a mechanical cleaning system.

Although the cleaning system was an effective way to prevent the particle layer formation on the cyclone wall, it caused a new problem. Due to the electrical insulation of the cyclone wall by the elastomer liner, the behavior of the charged particles was dramatically changed. Again the predominantly negative charged particles repelled one another to a grounded surface. Since the gas outlet tube of the cyclone was the only grounded surface, particles formed a layer up to a thickness of 2 cm on that tube. Therefore this system was not suitable either.

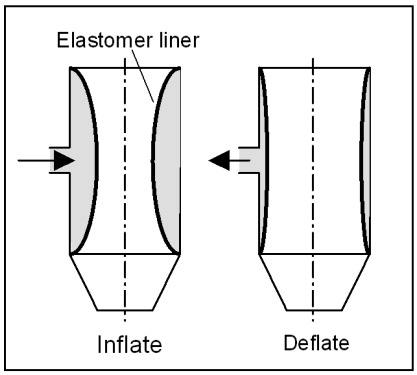

Figure 2: cleaning system principle

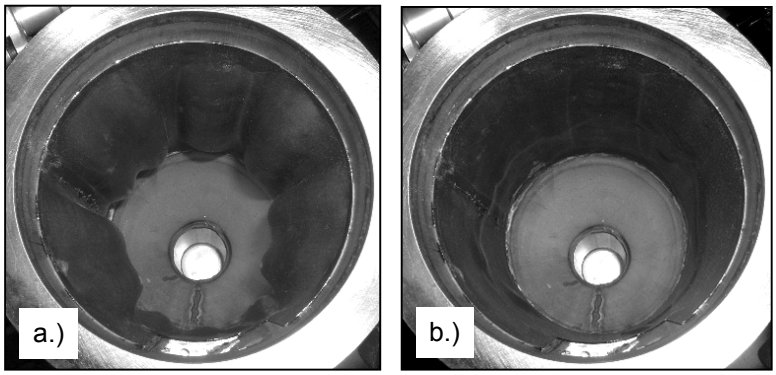

Figure 3: elastomer liner on the cyclone wall (top view): a.) inflated and b.) deflated

3.2. Product specific approach

Another approach to solve the problem of particle layer formation in the cyclone was to change the properties of the product. Mixing larger particles with the fine, cohesive powder significantly improves the handling [5]. This approach offered two advantages. First, the fluidization of the mixture was facilitated, and therefore the dosing in the re-feed section was improved. Second, the larger particles cleaned the cyclone wall, colliding with fine particles forming a layer.

However, the following drawbacks have to be considered. After the deposition process, an extra separation step is necessary to remove the large particles from the product batch. Second, by adding cleaning particles, the surface area, which has to be coated, is increased. Hence the deposition process is prolonged. Considering typical mixture parameters (diameter of fine particles: 16 µm, diameter of cleaning particles: 100 µm, mass ratio 1:1), the deposition time is increased by 25 %.

The objective of the following experiment was to investigate the influence of the "large" cleaning particles in the mixture on particle layer formation in the cyclone and the separation efficiency of the cyclone during a deposition procedure. Glass beads (d_{50} = 100 µm), used as cleaning particles, were mixed with the fine particles (d_{50} = 16 µm). Mixtures of mass ratios of 1, 2 and 4 were investigated. The mass ratio is given by the mass of large particles divided by the mass of fine particles. For each experiment 600 g of mixture were treated. The process gas flow consisted of 2250 sccm Argon, 300 sccm Oxygen, and 20 sccm HMDSO, respectively. Further process parameters are listed in Table 1.

Table 1: Process Parameters and Results

Mass ratio m_{large} / m_{fine}	**1 : 1**	**2 : 1**	**4 : 1**
Fine particles d_{50} = 16 µm	300 g	200 g	120 g
Large particles d_{50} = 100 µm	300 g	400 g	480 g
Deposition time	102.5 minutes	82.0 minutes	65.5 minutes
Specific deposition time	20.5 s/g	24.6 s/g	32.7 s/g
Reactor pressure	2.75 mbar	3.01 mbar	2.81 mbar
Solid volume concentration	0.46 %	0.46 %	0.61 %
Total loss of fine fraction d < 50 µm	31 %	30 %	39 %
Total loss of large fraction d > 50 µm	2 %	1 %	2 %
Particle layer in the cyclone	13.1 g	11.9 g	6.1 g

The deposition time was determined in order to achieve a SiO_2-layer thickness of 100 nm on the particle batch. In terms of comparison of the different deposition times, it is reasonable to consider the specific deposition time, which is the ratio of deposition time and mass of fine particles. Obviously, the specific deposition time is increased by additional amount of cleaning particles.

After each experiment the cleaning particles were separated from the fine particles using a sieve (mesh size 50 µm). Each fraction was weighted and compared with the initial amount. Thus the size dependent loss by the cyclone could be determined (Table 1). The loss of the fine particles was high in each experiment, but the experiment with 4:1 particle mixture revealed the highest loss. An explanation of this behavior is the solid volume concentration in the riser tube. It is proportional to the circulation rate of the particles. Assuming that at every circulation the same amount of fine particles is not separated by the cyclone, the circulating rate is proportional to the loss rate. The comparison of the results of particle loss and solid volume concentration confirms this statement. Thus the loss rate is independent of the mass ratio of large particles.

The particle layer on the cyclone wall was investigated by weighting. The particle layer consisted only of fine particles. Compared with previous experiments without cleaning particles a significant reduction of the particle layer has been reported, as shown in Figure 3. Considering the mixtures with 1:1 and 2:1 cleaning particle ratio the reduction was 95 %. The 4:1-mixture reduced the layer formation by 98 %.

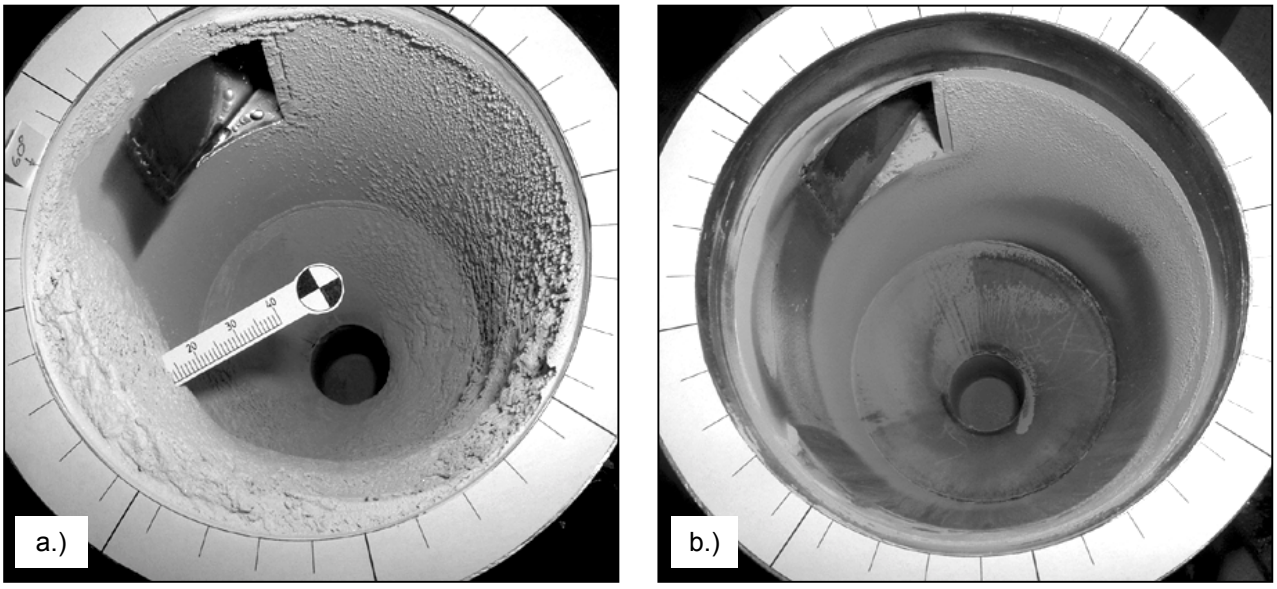

Figure 3: Particle layer on cyclone wall (top view) after circulation: a.) Without cleaning particles the layer thickness was up to 15 mm; b.) With cleaning particles only a light dust layer was deposited.

3.3 Coating structure

In this preliminary test 750 g particle mixture with a large particle mass ratio of 2:1 were coated with a 200 nm SiO_x-layer. The deposition time was 3.5 hours. The process gas flow consisted of 2250 sccm Argon, 300 sccm Oxygen and 20 sccm HMDSO, respectively. The reactor pressure was 3.17 mbar and the solid volume concentration 0.46 %.

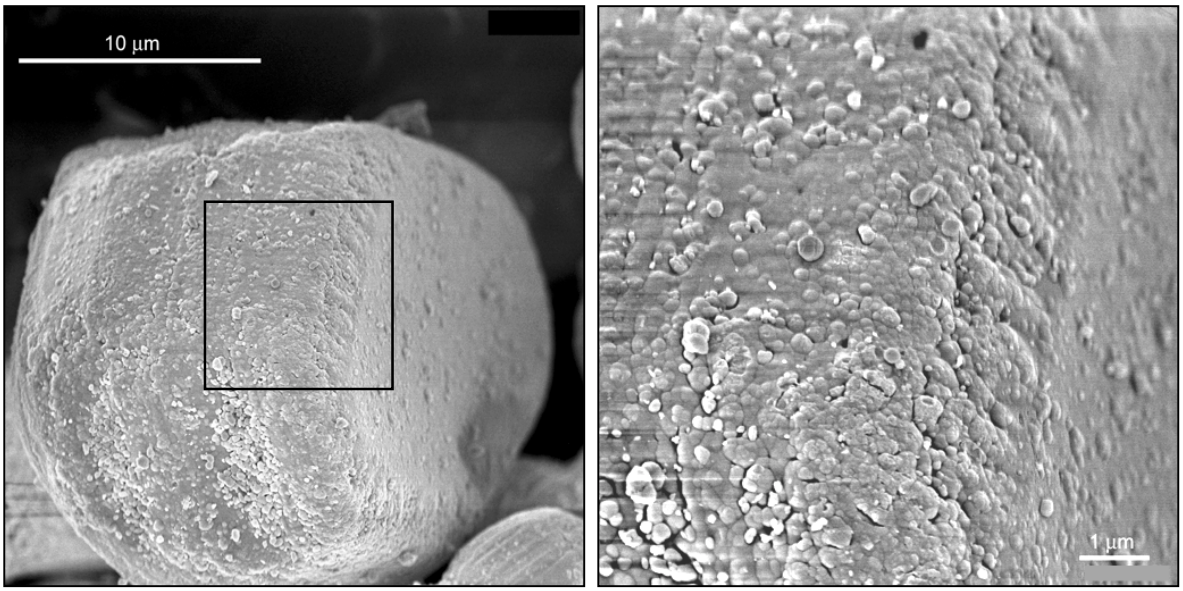

Figure 4: SEM micrographs of a coated particle; left: overview, right: enlarged section

The coating structure was qualitatively investigated by SEM micrographs (Fig.4). The SiO_x layer structure can be divided into three different categories. The first category is a smooth and dense layer. The second is a cauliflower like layer, consisting of fine, agglomerated SiO_x primary particles, which also form a dense film. Finally the third represents relatively large SiO_x particles (up to 350 nm), which loosely stick to the SiO_x layer. The first two structure categories are expected to provide good diffusion barrier properties, because they form a dense layer. But due to the large SiO_x particles sticking to the surface some pores were not coated, which could decrease the diffusion barrier properties. Future measurements of the diffusion barrier property of such coating will reveal quantitative results.

4. Conclusions

The handling of fine, cohesive particles in a circulating riser reactor is improved by mixing the batch with large 100 µm glass beads. The fluidization of the particles is facilitated and the formation of a particle layer in the cyclone is reduced. The ratio of large particles does not influence the separation efficiency of the cyclone in the investigated range. Increasing the ratio of large particles reduces the layer formation in the cyclone, but increases the specific deposition time.

The structure of the diffusion barrier coating shows several defects caused by large SiO_x dust particles. Quantitative measurements will be performed next to determine the influence of these defects on the barrier properties.

Abstract
Laser interferometry using the cavity of a gas laser as a reference arm (Ashby and Jephcott's interferometer [1, 2, 3]) is often employed to determine the time evolution of the electron density in unsteady plasmas. As the refractivity of free electrons varies as the square of the wavelength of the interferometer, we use a CO_2 laser (wavelength: 10.6 μm) and the recording of temporal fringes appearing at a frequency of a few kHz is carried out with a photoacoustic effect.

1. The Ashby and Jephcott interferometer

In contrast to classical interferometers (Michelson, Mach-Zehnder...), the Ashby and Jephcott interferometer is a true laser interferometer [1, 2, 3] that uses the cavity of a gas laser as the reference arm of the interferometer. However, it is limited to the study of transitory interference fringes obtained by recording the instantaneous laser intensity as a function of time.

The Ashby and Jephcott interferometer, currently employed in plasma diagnostics is based on an observation from King et Steward in 1963 [1]. These authors had noticed that the intensity of a He-Ne laser could be modulated by injecting back a low percentage of the laser beam into the laser cavity. This modulation is a function of the phase or of the optical path of the laser beam back injected in the laser cavity [4].

Let us consider the mounting presented in figure 1. Mirrors M_1 and M_2 are the mirrors of the laser cavity, a distance L apart. The mirror M_2 is semitransparent. The mirror M_3 is put outside of the laser cavity, and can be moved of a distance d. The semitransparent mirror placed between the mirrors M_2 and M_3 allows to record the laser intensity as a function of time with a photovoltaic sensor.

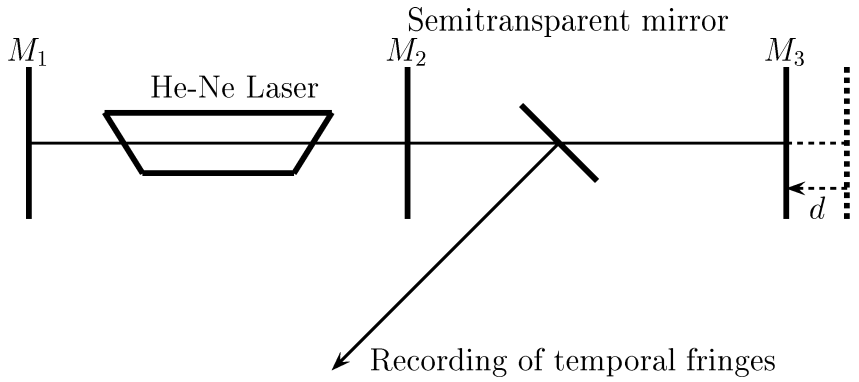

Figure 1: Principle of the Ashby and Jephcott interferometer

In the following, we suppose that the refraction index of ambient air is close to unity.

Resonance is obtained for the beam moving between M_2 and M_3 when the time necessary for a double path is equal to a whole number of time periods:

$$\frac{2D}{c} = \frac{q}{\nu}$$

where q is the order of the considered mode, c the velocity of the light and ν the wave frequency.

In the case when the mirror M_3 is moved a length d, the propagation time is:

$$\frac{2}{c}(D+d) = \frac{2}{c}D + \frac{2}{c}d.$$

The excitation frequency ν of the laser in constant, and to obtain resonance after a displacement d, it is necessary to check the relation:

$$\frac{2}{c}D + \frac{2}{c}d = \frac{q'}{\nu}.$$

The smallest detectable length d_{min} corresponds to an evolution from a mode to an adjacent mode, so

$$q' = q + 1.$$

For the shortest detectable length, we obtain:

$$\frac{2}{c}D + \frac{2}{c}d_{min} = \frac{q+1}{\nu} \implies \frac{2}{c}d_{min} = \frac{1}{\nu}$$

or, by introducing the laser wavelength λ ($\lambda = c/\nu$):

$$d_{min} = \frac{\lambda}{2}. \tag{1}$$

Experimentally, the effect described higher produces an evolution of the laser intensity that may be interpreted as a "temporal fringe".

Let us now consider that the mirror M_3 is moved at a constant speed v, and let us call f the frequency of the temporal fringes. If δt is the time between two adjacent fringes, we have $v = d_{min}/\delta t$. Since $f = 1/\delta t$, the frequency f of the temporal fringes as a function of the laser wavelength is:

$$f = \frac{2v}{\lambda}. \tag{2}$$

In plasma physics experiments, the variation of the optical path of the beam back injected in the laser cavity is given by an unsteady plasma produced in a cell (figure 2) ; the variation of the plasma refraction index as a function of time produces a variation of the optical path and consequently, apparition of time fringes which interpretation allows to measure the electron density as a function of time.

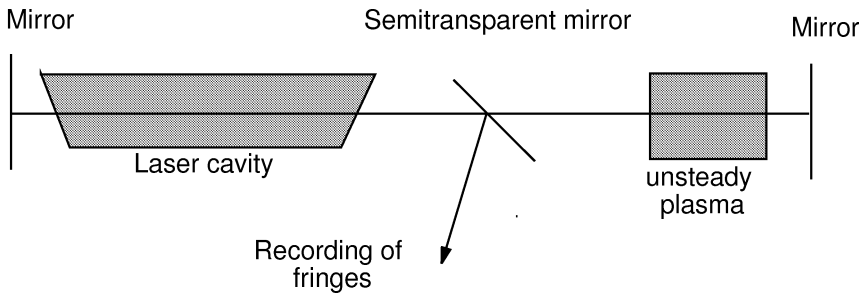

Figure 2: The Ashby and Jephcott interferometer to study the time evolution of electron density in unsteady plasmas.

It is important to underline that it is necessary to have a signal giving a rough idea of the time evolution of the electron density, because the interferometric method is not sensitive to the way of evolution (increase or decrease) of the electron density; very often, the integrated radiation of the plasma is used to fix this indetermination.

2. Plasma refractivity

The refractivity $(n-1)$ of plasmas, where n is the real part of the refraction index is given by the sum of the refractivities of particules of the plasma: neutral particules (atoms or molecules) in their fundamental state and in their excited states, ions and electrons.

The contribution of excited states in the refractivity of the plasma is negligible in front of other contributions [5]. The optical refractivities of neutral particles and of ions in their fundamental state are given by a Cauchy formula as a function of the wavelength λ. The refractivity $(n-1)_e$ of free electrons is given by

$$(n-1)_e = -C\lambda^2 N_e \tag{3}$$

where C is a constant and N_e the electron density number. Equation (3) explains the choice of laser radiations in infrared instead of in the visible part of the electromagnetic spectrum, because of the quadratic variation of the refractivity wavelength λ. This remark was employed by Ashby et Jephcott [1] with the use of the line at $3,39\ \mu$m of a He-Ne laser to probe the plasma, and the red line at $0,63\ \mu$m to detect the laser intensity variations, knowing that these two laser lines have the same upper level.

3. Elaboration of an infrared laser interferometer

In order to increase the sensitivity of the laser interferometer in the determination of electron density in unsteady arc plasmas, (see equation (3)), we employ a CO_2 laser at the wavelength $10,6\ \mu$m. The laser intensity variations are recorded with a photoacoustic effect which time response is better than the time response of common infrared sensors. The experimental results given in this communication demonstrate that an infrared interferometer is easily feasible.

The experimental set up is presented in figure 3. We use a SYNRAD Trade Mark CO_2 laser with a maximum power of 10 W.

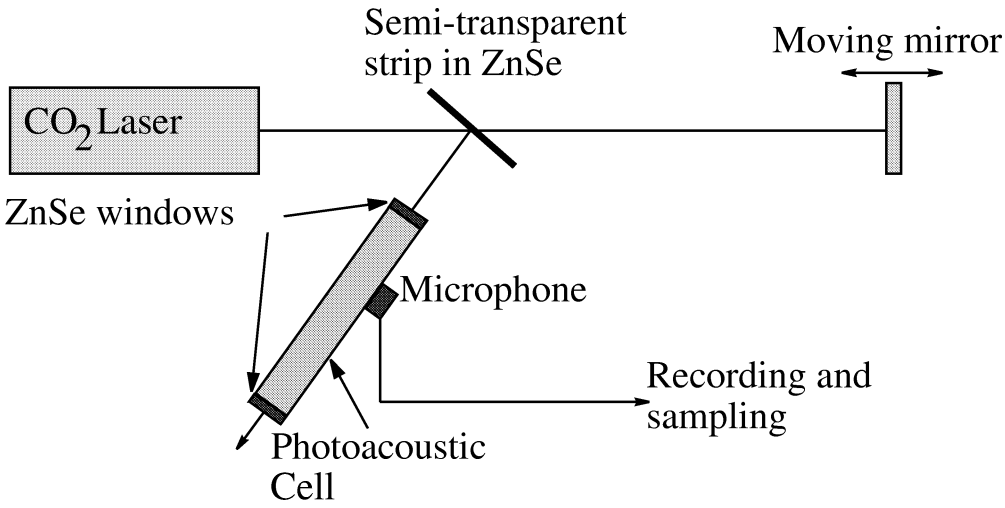

Figure 3: Experimental set up

The infrared beam is back injected in the laser cavity with a mirror fixed on a device allowing to move it along the axis of the laser beam. The motion of the mirror is sinusoïdal, with a period T and an amplitude x_0 experimentally determined with a relative precision lower than 5% with an optical sensor (KEYRENCE Trade Mark, model LB-72). The speed of the mirror is given by

$$v(t) = \frac{2\pi}{T} x_0 \sin 2\pi t/T,$$

and by applying (2), we obtain the expression of the frequency $f(t)$ of the temporal fringes as a function of

time. We have:

$$f(t) = f_0 |\sin 2\pi t/T| \tag{4}$$

with

$$f_0 = \frac{4\pi}{\lambda T} x_0,$$

the absolute value being introduced in expression (4) because the interferometric method in not sensitive to the sign of the speed v.

A semi-transparent mirror in ZnSe (see figure 3) sends a fraction of the laser intensity in a cylindrical photoacoustic cavity (diameter: 30 mm and length: 30 cm) filled with CO_2 gas at atmospheric pressure. Other absorbing systems were tested: carbon black, CH_4 ..., but the best results were obtained with CO_2 gas.

The absorption of the laser beam which intensity varies with time by the gas contained in the photoacoustic cell produces a cylindrical acoustical wave [6] with a frequency given by expression (4). The sound is recorded with a microphone and sampled at 44100 Hz with a desk computer.

With T=1 s and x_0=0, 15 mm, figure 4 presents the speed of the mirror M_3 as a function of time, and the expected acoustical frequency. One notices that the period of the signal giving the frequency f against time is half the period of the speed, because interferometry is not sensitive on an the sign of the evolution of the optical path.

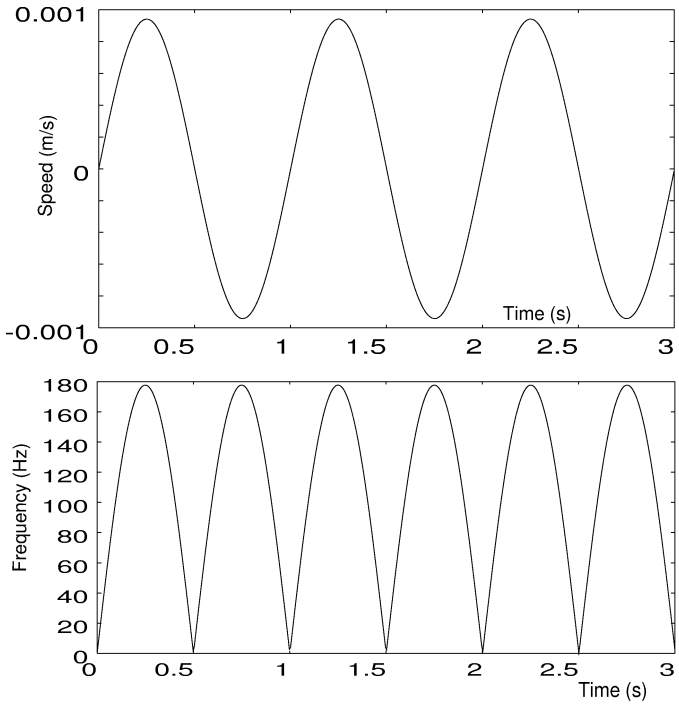

Figure 4: Plots giving the speed of the mirror M_3 against time (top) and the frequency f obtained with equation (4) (bottom).

Data processing essentially consists in the determination of the fundamental frequency as a function of time. This operation is easily realized with a speech analysis software where one deals with acoustical frequencies close to the frequencies obtained in the acoustical cell with the parameters T and x_0 chosen above.

Figure 5 gives a typical experimental result. In agreement with equation (4), one notices that the signal amplitude increases twice every period of the mirror M_3 motion.

The plot given in the bottom of figure 5 is the fundamental frequency against time. It is in agreement with theory (equation (4)), and a maximum f_0 at 166 Hz $\pm$ 10 Hz close to the theoretical predictions:

$$f_0 = \frac{4\pi}{\lambda T} x_0 = 4\pi\, 0,15\, 10^{-3}/(10,6\, 10^{-6}) = 178\,\text{Hz at 5 \%}.$$

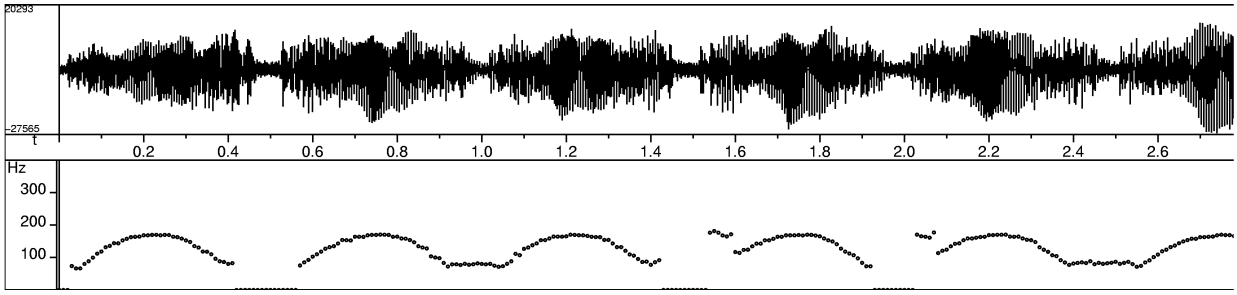

Figure 5: Example of sound signal obtained (top), and plot of the fundamental frequency as a function of time (bottom) obtained after data processing.

4. Conclusion

In this communication, we have presented an innovative infrared laser interferometer with a photoacoustic detection of temporal fringes. This interferometer has been call "F.I.R.L.I.P.A.D." (**F**ar **I**nfra**R**ed **L**aser **I**nterferometer with **P**hoto**A**coustic **D**etection).

Before to apply it in plasma diagnostics, it is necessary to consider the optimization of the photoacoustic detection chain (design of the cell, choice of an medium for absorption, ...).

Chamber Size Effect on ICP discharges and Comparison with Global Model

Jie Ma[1], Yikang Pu[2]

[1]*Department of Electrical Engineering, Tsinghua University, Beijing, 100084, China*
[2]*Department of Engineering Physics, Tsinghua University, Beijing, 100084, China*

Plasma discharge chamber size is considered to be a very important factor in determining parameters such as electron temperature(Te) and electron density(Ne) in the Global Model, in which an effective area A_{eff} is introduced to evaluate this effect on plasma. In this work, the influence of different diameter sizes of the chamber on ICP discharge characteristics is investigated experimentally. A Langmuir probe and emission spectroscopy are used to measure electron temperature, electron density, plasma potential, and electron energy distribution function in different gases (and their mixture) discharges. Results will be compared with that predicted by the Global Model.

Particle formation in capacitively coupled hydrocarbon plasmas

J. Berndt, E. Kovacevic, I. Stefanovic, J. Winter

Institute of Experimental Physics II, Ruhr-University Bochum, Germany

Abstract

This paper deals with the formation of hydrocarbon dust particles in capacitively coupled discharges in argon/acetylene mixtures. First experiments performed in acetylene/nitrogen discharges are also presented, showing the existence of carbon nitride particles polymerized in the plasma. The formation of dust particles in the plasma is studied by means of in-situ-Fourier transform infrared spectroscopy (FTIR). The response of the plasma to the formation of the particles has been analyzed by plasma-ion-mass spectroscopy.

1. Introduction

Since Langmuir and his co-workers have discovered the existence of dust particles in glow discharges [1], the formation of particulates in plasmas is a well-known phenomenon. The formation of dust can be observed in several plasma processes such as etching, sputtering or thin film deposition. In semiconductor manufacturing dust particles were recognized as "killer particulates" responsible for the malfunction of integrated circuits. [2]. On the other hand a controlled growth of particles is desired for applications in catalysis and pharmacy and for the fabrication of nano-crystalline materials. In the latter case nanoparticles are incorporated into the growing film for a controlled modification of film properties [3].

This contribution deals with the formation of carbon containing dust particles in capacitively coupled hydrocarbon discharges. Although reports on powder formation in hydrocarbon plasmas together with proposed models of nucleation [4,5] have already been made in the seventies the process of particle formation in such plasmas is still not fully understood. To gain more accurate insight in the chemical nature of dust particles and the growth mechanism of powder formation for various discharge conditions and gas mixtures we used a reactor, especially suitable for multipass in-situ FTIR spectroscopy. In contrast to ex-situ FTIR-spectroscopy the corresponding in-situ observation allows to monitor the properties of the particles directly during their formation. The measurements presented in this paper are performed in discharges containing mixtures of acetylene and argon and acetylene and nitrogen respectively. Acetylene as monomer was chosen because of its important role in powder formation in hydrocarbon plasmas [4,6,7,8]. It was shown that in saturated and unsaturated hydrocarbons plasma polymerization follows after acetylene compound was formed. Also, acetylene undergoes polymerization process instantaneously, especially at low flow rate. First experiments performed with nitrogen as a carrier gas have been stimulated by the growing interest in carbon nitride materials especially in the field of thin film deposition.

Independent of the actual choice of the carrier gas it is a well known fact that the presence of particles is strongly influencing the properties of discharges [9]. This response of the plasma to the formation of particles has been analyzed in the present paper by measuring the fluxes of ions escaping from the discharge.

2. Experimental set up

The investigations were performed in a radio-frequency (RF) capacitively-coupled parallel plate reactor working at 13.56 MHz (Fig.1). The power is coupled symmetrically to both electrodes, which have a diameter of 30 cm and are separated by 8 cm. The gas flow rates are controlled and monitored by MKS mass-flow controllers. The typical flow rates are 8 sccm argon and 0.5 sccm acetylene resulting in a pressure of about 0.1 mbar. The applied RF power was 10-20 W measured before the match-box.

For diagnostic purposes we have used in this experiment a FTIR-spectrometer. The infrared (IR) absorption spectroscopy was performed in situ using a commercial Bruker FTIR (Fourier Transformed Infrared) apparatus Equinox 55. The IR beam from the spectrometer was directed through KBr windows in the plasma chamber and was focused with an off-axis gold mirror onto a liquid-nitrogen-cooled mercury-cadmium-telluride detector (MCT). By means of a multi-pass technique we were able to change the optical path length in the plasma from 0.6 meters (2 passes through plasma reactor) to 7.2 meters (24 passes) accordingly increasing the sensitivity of our system. Absorption spectra in the range 500-6500 cm^{-1} were recorded with a spectral resolution 0.5 to 3 cm^{-1}. The spectral resolution of 3 cm^{-1} was used to increase the recording speed. A plasma monitor (PPM 422, Balzers) was mounted at a side port of the reaction chamber in order to measure ion fluxes escaping from the plasma bulk. A bellows assembly allowed us to vary the distance between the sampling orifice (100 microns diameter) of the plasma monitor and the edge of the electrodes. For the measurements presented here the orifice was placed 5 cm outside the electrodes (outside the bulk of the plasma) on the mid-plane between the electrodes.

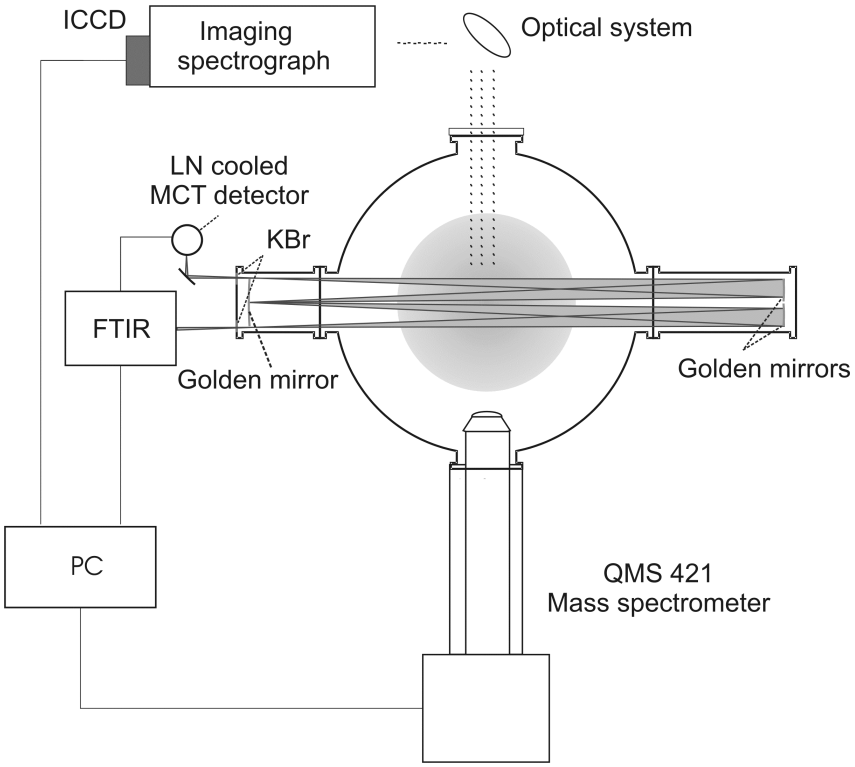

Fig. 1: Experimental set up

3. Experimental results

In this section we will present two different kinds of experimental results. In the first subsection we will focus on the in-situ-FTIR-spectroscopy, which delivers information about the temporal development of the dust formation and about the chemical nature of the dust particles formed in the discharge. In the second subsection we will discuss the response of the plasma to the formation of these particles. Here we focussed mainly on the measurement of the ion fluxes escaping from the discharge.

3.1 In-situ investigation of particle formation by means of FTIR spectroscopy

Fig. 2a shows the absorption spectrum of dust particles measured in an argon/acetylene mixture. The most striking feature of this spectrum is the strong increase of the absorbance towards higher wavenumbers. This effect is caused by Rayleigh or Mie scattering respectively and is a direct indication for the presence of dust particles in the reaction chamber. Beside this effect the spectrum exhibits several absorption peaks, which are not present in the spectrum of pure acetylene. The complicated signature of this spectrum becomes more obvious after a baseline correction. Although a unique identification of the whole spectrum is difficult to perform, some characteristic peaks can be attributed to specific, most abundant, compounds (Fig.2b).
As the formation of nanoparticles is a dynamical process the shape of the recorded FTIR spectra is strongly time dependent. An overview over the temporal development of the dust formation is given in fig.3 a and b. This figures shows the absorbance at different wavenumbers as a function of time. Depending on the

wavelength the absorbance exhibits either a damped (fig. 3a) or an undamped (fig 3b) oscillating behavior. The undamped periodic behavior can be explained in the frame of a simple model. Negatively charged particles are confined in the plasma potential as long as the different forces acting on the single particle are balanced. Since theses forces – as the electric the force, the ion drag force, the neutral drag force, the force caused by thermophoresis and the gravitational force scale with different powers of the particle radius the confinement of the particles strongly depends on their size. As soon as the particles reach a critical size they are dragged out of the plasma bulk and a new growth cycle starts. The damped oscillations observed for the absorbances at 1700 $cm^{-1}$and 3300 cm^{-1} are probably an effect induced by impurities as oxygen or water. The peak at 1700 cm^{-1} can be attributed to carbonyl C=O stretching vibrations, which results from the oxidation of carbon caused either by water or oxygen.The absorption band around 3300 cm^{-1}, which is also decreasing in time, is most likely an indication for the presence of trapped water/ OH stretching vibrations [10,11]. The temporal decrease of these peaks can be explained, if we assume, that the concentration of residual water or oxygen molecules is also decreasing in time which is indeed confirmed by mass spectrometric measurements [9]. A possible mechanism, which could enhance the removal of water is: Oxygen containing contaminations are released from the surface of electrodes and walls during their exposure to the plasma. Once these impurities arrive at the bulk plasma they can chemically react with the dust particles. In this way the dust grains itself serve as a kind of a "getter" for water molecules that are released from the chamber walls. Consequently the concentration of oxygen/water is decreasing from cycle to cycle.

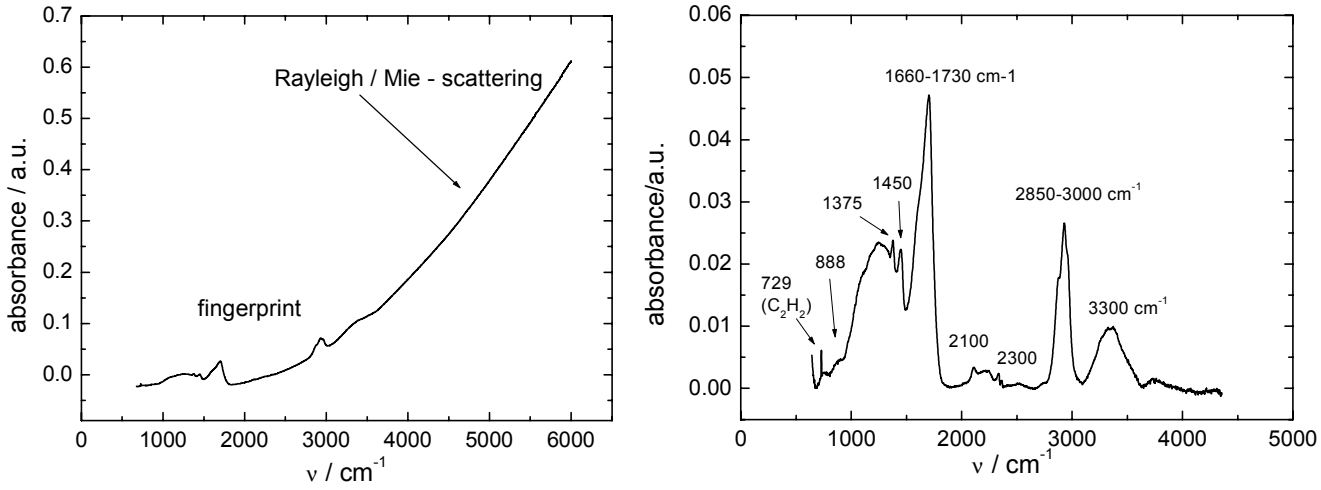

Fig. 2 a,b: Figure a shows a FTIR-spectrum measured in an argon/acetylene mixture 35 minutes after the discharge was switched on. Figure b shows the same spectrum after a baseline correction, which allows the identification of the most important absorption structures: 1375±5 cm^{-1}:CH_3 symmetric bending; 1450±20 cm^{-1}: CH_3 asymmetric bending ; 2850 – 3000 cm^{-1}: -CH_3 symmetric stretching at 2870 cm-1, antisymmetric at 2960 cm^{-1} and antisymmetric -CH_2 stretching at 2926 cm^{-1}. 1604 cm^{-1} (appearing as a shoulder within the broad peak between 1660 and 1730 cm^{-1}): aromatic C=C stretching vibrations. (The presence of aromatic compounds is confirmed by weaker peaks around 888 cm^{-1} which originate from C-H deformation vibrations of aromatic hydrocarbons [11, 12].) The strong peak between 1660 and 1730 cm^{-1} comes from carbonyl C=O stretching vibrations [9, 10, 11, 12].

Due to this effect the shape of the FTIR spectrum is changing from period to period. In the first cycle the dominating peak is that at 1700 cm^{-1}. In the next cycles the height of this peak is continuously decreasing until it is much smaller than the height of the peak at 2900 cm^{-1}. The fingerprint of the spectrum is thus changing although the absorbance at higher wavenumbers, which results from Rayleigh/Mie-scattering, is the same. This clearly demonstrates the advantages of the in-situ broadband FTIR-diagnostic. Simple scattering or absorption techniques using monochromatic laser light are not suitable for the detection of changes in the chemical composition of the particles.

A comparison between nanoparticles polymerized in an argon/acetylene discharge and particles polymerized in a mixture of nitrogen and acetylene is shown in figure 4. The infrared spectrum of the particles from the

nitrogen/acetylene discharge exhibits a strong broad absorption peak centered at about 1625 cm^{-1}. According to Gonzalez et al.[13] this peak could be attributed to N–sp^2 C vibrations which would indicate the presence of nitrogen atoms within the dust particles. The presence of C≡N bonds is indicated by the peak centered at about 2200 cm^{-1}. Although a unique identification of the whole spectrum is a difficult and somewhat tentative task a comparison of our spectra with spectra from amorphous CN_x-films shows great similarities [14,15,16]. This supports the assumption that nitrogen atoms are incorporated into the particles. Further investigations of these carbon nitride nanoparticles will include Micro-Raman and TEM measurements.

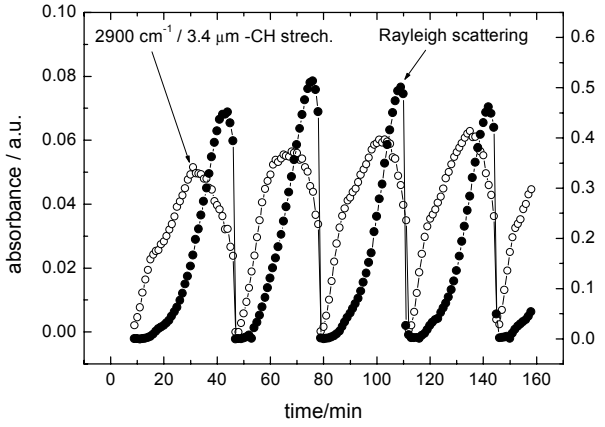

Fig.3a: Absorbance at 5000 cm^{-1} and 2900 cm^{-1} as a function of time.

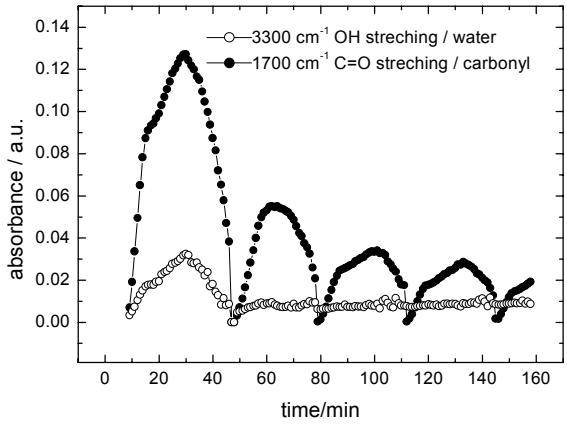

Fig.3b: Absorbance at 1700 cm^{-1} and 3300 cm^{-1} as a function of time.

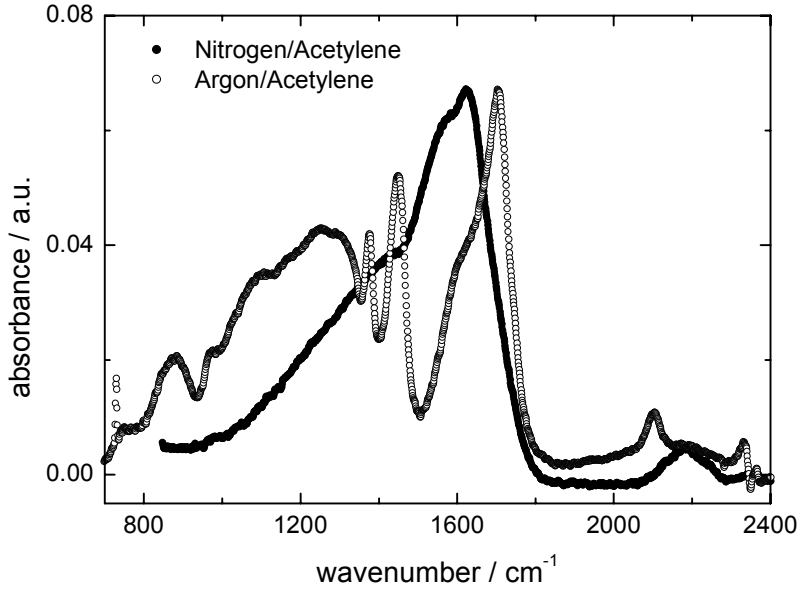

Fig. 4 Comparison between FTIR spectra polymerized in argon/acetylene and argon/nitrogen discharges.

3.2 The response of the plasma to the formation of particles

Independent of the actual choice of the carrier gas or the chemical composition of the dust particles the presence of such particles is strongly influencing discharge properties such as electron temperature, electron density, plasma composition or plasma impedance. In this paper we will mainly focus on the question how do the dust particles influence the fluxes of ions escaping from the bulk plasma. For this purpose a plasma monitor (Balzers PPM 422) was mounted at a side port of the reaction chamber. For the measurements presented here the orifice of the plasma monitor was placed 5 cm outside the electrodes (i.e. outside the plasma bulk) on the mid-plane between the electrodes. The time resolution for these measurements was 25 seconds.

Energy scans of argon ions for four different times are shown in figure 5. These times correspond to the positions also marked in figure 7 (number 1 for 33 minutes , 2 for 42 minutes, 3 for 43 minutes, and 4 for 48 minutes after the discharge ignition). The results show that the signal height as well as the position of the maximum of the distribution function is changing in time.

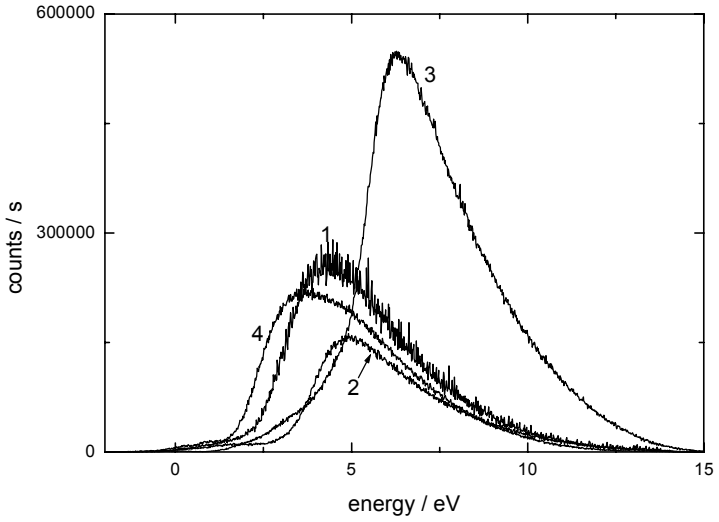

Fig. 5 : Ion energy distribution functions. The different curves correspond to different times.

The total flux of argon ions in arbitrary units, obtained by summing the count rates over the whole energy range, is shown in figure 6. The ion fluxes escaping from the bulk plasma exhibits a periodical behavior that corresponds to the periodical behavior of the dust formation observed in the FTIR measurements. The corresponding mean energy is depicted in figure 7.

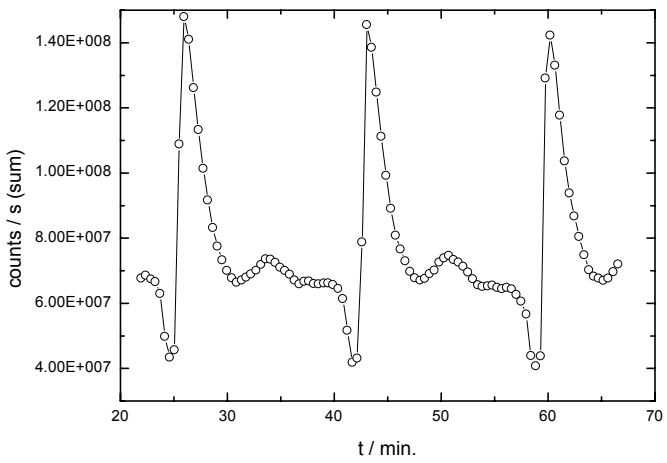

Fig. 6: Total argon ion fluxes escaping from the plasma bulk as a function of time (in arbitrary units).

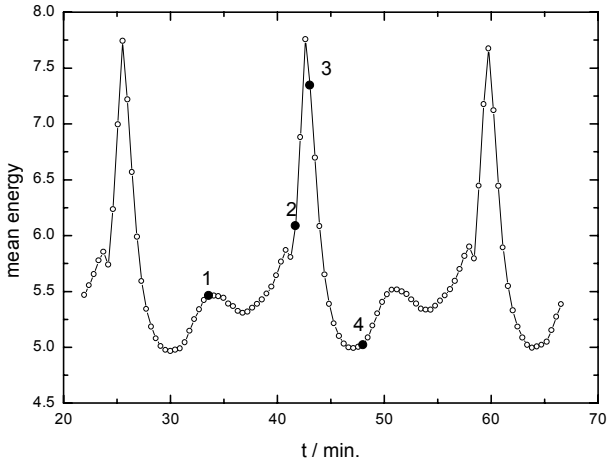

Fig 7: Mean energy of argon ions escaping from the plasma bulk as a function of time.

Both pictures exhibit complicated structures which are far from being fully understood. FTIR-measurements performed simultaneously with the plasma monitor measurements show that the period length observed in the infrared signal is the same as that observed for the signal of the ion fluxes. This fact at least proves that the complicated temporal behavior of the ion fluxes is strongly correlated to the formation of dust particles. To what extend the structures visible in figures 6 and 7 correspond to some stages in the particle formation (e.g. nucleation, agglomeration etc.) is not yet fully clear [9].

4. Conclusion and outlook

In-situ FTIR-spectroscopy in combination with a multipass arrangement was proved to be a powerful tool for the diagnostic of plasma-synthesized nanoparticles. The temporal development of the dust formation as well as the chemical composition of the dust particles can be analyzed. The latter feature is especially useful for the generation of particles in different gas mixtures. First experiments performed in acetylene/nitrogen discharges showed the existence of carbon nitride particles formed spontaneously in the plasma. Further analysis using Micro-Raman-Spectroscopy and Transmission-Electron-Microscopy has to be done to get a better insight in chemical structure and morphology of these particles.

The response of the plasma to the formation of the particles has been analyzed by measuring the energy distribution function of argon ions escaping from the plasma bulk. The measurements show a strong correlation between the ion energy distribution function and the formation of dust particles. To what extend the ion fluxes are correlated to different stages of the particle growth has to be clarified in further studies.

The Plasma Destruction of Odorous Molecules: Organosulphur Compounds

Imtiaz K. Ahmad*, Anna E. Wallis and J. Christopher Whitehead

Department of Chemistry, University of Manchester, Oxford Road, Manchester, M13 9PL, UK

Abstract

The plasma destruction of methyl mercaptan and dimethyl sulphide has been studied in nitrogen or air gas streams by a non-thermal, atmospheric pressure discharge using a packed bed of $BaTiO_3$ beads. Destructions in excess of 85% can be achieved for pollutant concentrations of 30 -100 ppm with energy costs in the order of 75 – 200 kW h / kg. The end-products of the processing are H_2S, HCN, NH_3 in a N_2 stream and SO_2, CH_2O, CO and CO_2 in air. The implications for odour control are discussed

1. Introduction

Non-thermal, atmospheric pressure plasma technology has considerable advantages to offer in the field of odour control over the existing technologies of catalytic oxidation and of chemisorption on substances such as activated charcoal. Olfactory detection thresholds for methyl mercaptan and dimethyl sulphide are approximately 0.002 ppm and 0.001 ppm respectively, much more odorous than other sulphides such as CS_2 (0.121 ppm), SO_2 (0.47 ppm) and H_2S (0.005 ppm) [1]. It is well known that plasma destruction becomes significantly more efficient as the concentration of the pollutant decreases making plasma destruction a potentially effective remediation technique for odours.

We have studied the destruction of methyl mercaptan (CH_3SH) and dimethyl sulphide ($(CH_3)_2S$) diluted in gas streams of both nitrogen and air using an AC, packed-bed plasma reactor loaded with $BaTiO_3$ beads. The principal products obtained from the plasma processing are identified using FTIR spectroscopy and chemical mechanisms are proposed for the destruction processes. The only previous plasma studies of the destruction of these compounds of which we are aware all relate to experiments at reduced pressures using RF plasmas. Nicholas *et al*.[2] studied the decomposition of both dimethyl sulphide and methyl mercaptan using a pulsed RF source in the pressure range 0.1 – 2 Torr. Tsai et al. [1] have examined the decomposition of methyl mercaptan in a non-thermal RF plasma at 30 Torr. Czernichowski [3] has review the field of plasma destruction of mercaptans concentrating on the technique of gliding arcs. To our knowledge, this paper is the first reported study of the plasma destruction of dimethyl sulphide and methyl mercaptan at atmospheric pressure using a non-thermal plasma.

2. Experimental

The experimental arrangement was essentially that employed previously [4,5]. The plasma source was a dielectric pellet-bed reactor consisting of a glass tube of 24 mm internal diameter with two electrodes ~25 mm apart through which the gas passes. The space between the electrodes was packed with 3.5 mm diameter barium titanate beads. The diameter of the beads was chosen to allow for as large a number of beads as possible (~ 315), thereby maximising the number of contact points for the formation of discharges whilst not restricting the porosity of the reactor significantly. This balances the requirements of gas flow and having as uniform a discharge as possible. An AC voltage ($V_{pk\text{-}pk} \approx 15$ kV) at a frequency between 10.25 and 13.25 kHz was applied between the electrodes. Using a digital storage oscilloscope (Tektronix TDS 3012), we recorded the current and voltage waveforms for the discharge by using a calibrated high voltage probe and measuring the current across a 1 kΩ resistor in the return earth path from the reactor. The average power of the discharge is then obtained by integrating the product of voltage and current as a function of time.

A flow (0.1 - 1 litre min^{-1}) of pure air or nitrogen at room temperature controlled by flow controllers (MKS Mass Flo) was either blended with a small flow of gaseous methyl mercaptan or bubbled through liquid dimethyl sulphide at room temperature giving a concentration of ~ 30 – 140 ppm of methyl mercaptan or ~ 25 – 50 ppm of $(CH_3)_2S$ entering the plasma reactor. The gas mixture was maintained at a pressure of ~ 1 bar. For a gas flow of 1 litre min^{-1}, the residence time in the reactor is 0.25 s. Methyl mercaptan (Aldrich, 99.5+ % purity) and dimethyl sulphide (Fluka, ≥ 99% purity) were used as supplied. No attempt was made to further purify or dry the gases. The end-products of the plasma processing were monitored on-line by infrared spectroscopy using a long-path gas cell (4.8 m, Venus Series) and a Fourier Transform Infrared (FTIR) spectrometer (Shimadzu 8300) with a resolution of 1 cm^{-1}. Stainless steel, nylon and PTFE tubing, valves and fittings of 1/4" external diameter were used to handle the gases as appropriate. No attempt was made to bake or otherwise condition the surfaces of the system.

3. Results

Figure 1 shows a comparison of the FTIR spectrum obtained for dimethyl sulphide without plasma processing and with plasma processing in nitrogen and air. The degree of destruction for dimethyl sulphide (at initial concentrations of ~ 30 ppm) in pure nitrogen was measured as ~ 35% and the major end-products as detected by FTIR spectroscopy were found to be HCN and NH_3. No sulphur-containing end-products could be detected using infrared spectroscopy where our minimum detection limits for the likely end-product H_2S represents a concentration of ~ 1000 ppm. Using a qualitative analysis method (Draeger tube sampling), we can confirm the presence of H_2S in the processed gas stream and it is most likely that all the sulphur is converted into H_2S although alternative detection methods must be employed to confirm and quantify this. Correspondingly higher degrees of dissociation (up to 72%) were obtained when 30 ppm of dimethyl sulphide was passed through the plasma reactor in a gas stream of air. In this case, the major end-products of the destruction of dimethyl sulphide as detected by FTIR were CO, CH_2O, SO_2 and a trace amount of CO_2. The carbon balance indicates that 50% of the destroyed carbon becomes CO, 45% CH_2O and

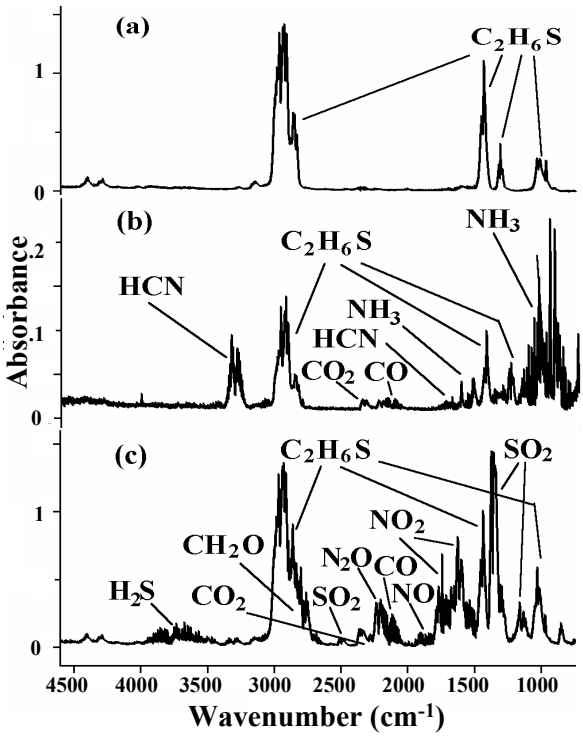

Figure 1 Plasma processing of dimethyl sulphide. (a) plasma off; (b) in nitrogen; (c) in air.

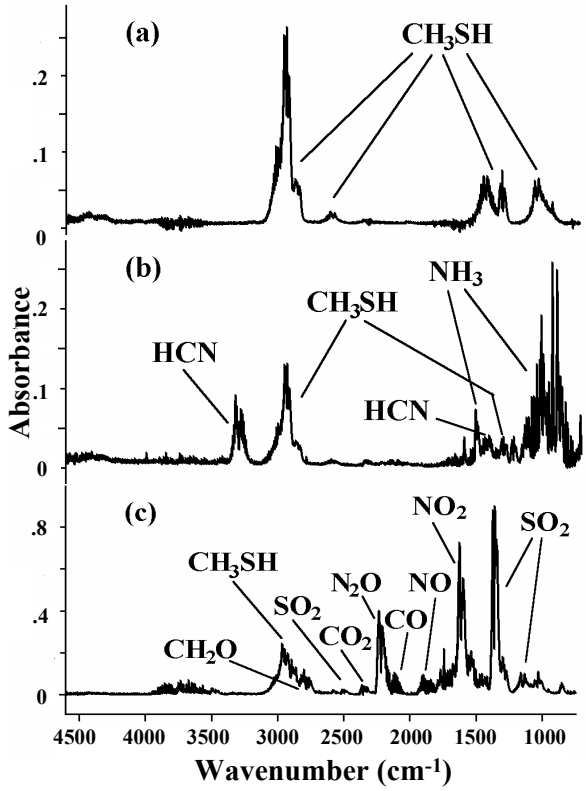

Figure 2 Plasma processing of methyl mercaptan. (a) plasma off; (b) in nitrogen; (c) in air.

balance becomes H_2S but this needs to be confirmed. Significant amounts (~ 200 ppm) of nitrogen oxides (NO, N_2O and NO_2) were also produced under these conditions, mainly N_2O and NO_2.

Figure 2 shows the corresponding spectra for the plasma processing of methyl mercaptan in both air and nitrogen. The degree of destruction for methyl mercaptan in pure nitrogen was measured as ~ 15% for an initial concentration of ~ 390 ppm and as ~ 20% at a concentration of 550 ppm in air. As with dimethyl sulphide, the major products of the plasma processing in a stream of pure nitrogen were HCN and NH_3. Qualitative sampling again indicates the production of H_2S. In the presence of air, the major detected, carbon-containing, end-product are CO (55%), CH_2O (35%) and a small amount of CO_2 (10%). The production of SO_2 accounts for ~ 30% of the sulphur removed. Again, there is significant formation of the oxides of nitrogen for processing in an air stream with ~ 170 ppm of NO, NO_2 and N_2O being formed with 50% being in the form of NO_2.

In addition to the compounds detected by FTIR as end-products of the plasma processing, we were able to eliminate the formation of any of the following compounds within our detection limits: ozone, hydrogen peroxide, acetaldehyde, any C_2 or higher hydrocarbons, OCS and CS_2.

The degree of destruction for dimethyl sulphide in air as a function of the concentration of dimethyl sulphide is shown in Figure 3. It can be seen that the destruction rises rapidly as the concentration decreases implying that essentially complete destruction will be achieved at the sub-ppm levels where odour levels are a concern. Limited studies were performed for the destruction of ~ 100 ppm of dimethyl sulphide in nitrogen where the flow rate was reduced from 1 litre min^{-1} to 0.1 litre min^{-1} causing the percentage destruction to increase from 6% to 86% as a result of the ten-fold increase in plasma residence time.

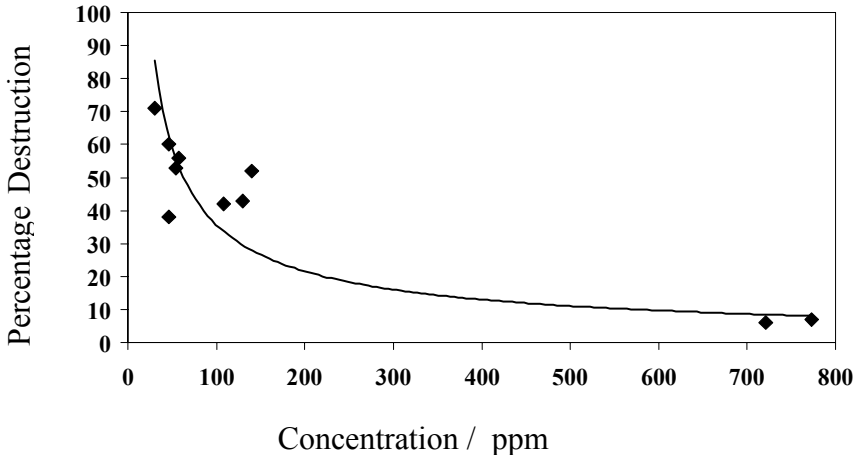

Figure 3 The percentage destruction of dimethyl sulphide in air as a function of concentration for an atmospheric pressure, non-thermal plasma discharge at a flow rate of 1 litre min^{-1}. The solid curve is to aid the eye.

The average electrical power deposited into the plasma is ~ 0.98 W, giving a reduced energy of 59 J / litre for a flow of 1 litre min^{-1}. These figures can be translated into the minimum energy required to destroy a single molecule which becomes 175 eV and 455 eV for dimethyl sulphide in air and nitrogen, respectively, and 140 and 255 eV for methyl mercaptan in air and nitrogen, respectively. For the destruction of dimethyl sulphide in nitrogen at a flow rate of 0.1 litre min^{-1}, this reduces to 175 eV per molecule destroyed.

4. Discussion

Products

We can compare the products that we find with the results from previous studies. The study of Nicholas *et al.* [2] concentrated on a spectroscopic investigation of the intermediates involved in the decomposition together with mass spectrometric and GLC analysis of the stable end-products. For methyl mercaptan, they found CS, SH and S_2 were formed as transient species and that the end-products were CS_2, CH_4, various C_2 hydrocarbons and some possible sulphur-containing hydrocarbons. The results for dimethyl sulphur showed CS and S_2 as transient species but no SH and a similar range of end-products. Tsai et al. [1] studied the destruction of methyl mercaptan in an Ar gas stream with and without the addition of molecular oxygen. In the absence of oxygen, the products that they observed included CS_2, H_2S, $(CH_3)_2S$, $(CH_3)_2S_2$, CH_4, C_2H_4 and C_2H_2. For an oxygen rich CH_3SH / O_2/ Ar mixture, the major products were found to be SO_2, CO_2, CO and H_2O which is in close agreement with our findings except that we also detect formaldehyde, CH_2O. However, in none of our systems do we detect CS_2 as an end-product even though we have a sensitivity of 3 ppm for its detection.

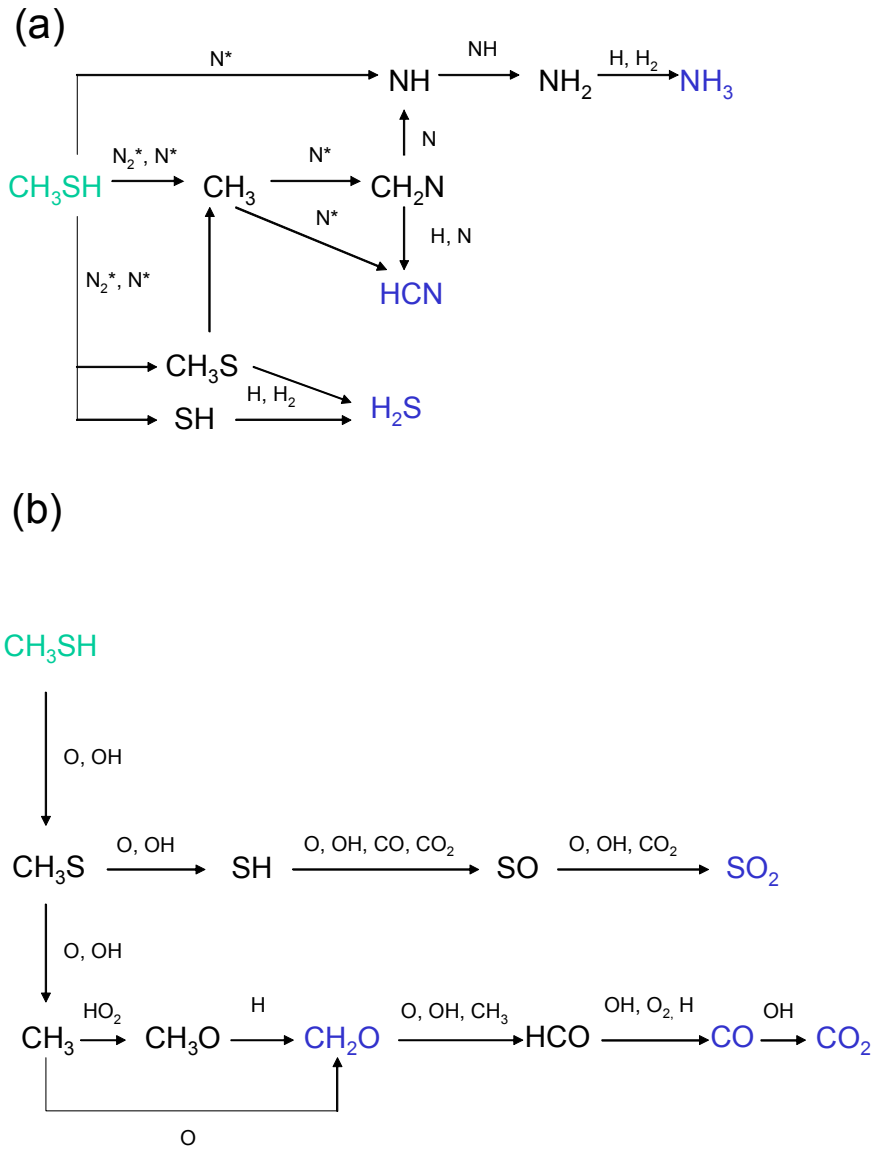

Figure 4 Schematic mechanisms for the plasma destruction of methyl mercaptan in (a) nitrogen and (b) air.

It is difficult to extrapolate from chemical mechanisms appropriate at low pressure to those at atmospheric pressure where three-body recombination processes become more important and the concentration of peroxy radicals, RO_2, becomes significant. Figure 4 shows our suggestion for the mechanism by which methyl mercaptan is destroyed in an atmospheric pressure, non-thermal plasma. This mechanism is based on our experience with modelling the plasma destruction of methane [6] and dichloromethane [5].

For both dimethyl sulphide and methyl mercaptan, the main products in pure nitrogen are HCN and NH_3 whilst in the presence of oxygen these products are not formed and CH_2O, CO and CO_2 are the oxidation end-products. In pure nitrogen the important species created in the discharge are electronically-excited nitrogen atoms, $N(^2D)$, and metastable triplet molecular nitrogen, N_2 ($A^3\Sigma_u^+$). Reaction of $N(^2D)$ with CH_3SH can give CH_3S and NH. Collision-induced dissociation of CH_3SH by $N_2(A^3\Sigma_u^+)$ is likely to break the weaker bonds to give CH_3 and SH and to a lesser extent CH_3S and H. These two processes require energies of 3.17 and 3.73 eV, respectively, considerably less than the 6.23 eV possessed by the metastable $N_2(A^3\Sigma_u^+)$. CH_3S and SH are then the precursors of H_2S, our presumed sulphur-containing end product, and CH_3 and NH provide the route (Figure 4a) to ammonia and HCN as we observed for methane and dichloromethane.

In the presence of oxygen, we observe a change in the mechanism and there is no further production of HCN and NH_3. This arises because the excited state nitrogen atoms now react with molecular oxygen to form NO which is further oxidised to NO_2

$$N^*(^2D) + O_2 \rightarrow NO + O \qquad (6)$$

The metastable *A* state of nitrogen also reacts much more rapidly with molecular oxygen than with methyl mercaptan because of the much larger concentration of O_2. The chemistry involving the nitrogen species formed in the discharge is the source of the NOx that is produced in the air discharges and is largely decoupled from the oxidative chemistry responsible for the destruction of the methyl mercaptan.

The major reactive species in the air discharges that is responsible for the destruction of CH_3S is atomic oxygen. This initially reacts with the mercaptan by abstraction of a hydrogen atom generating CH_3S which is the source of the sulphur-containing end products and OH radicals which being more reactive than O atoms rapidly take over the oxidation process and are regenerated. Oxidation of CH_3S to methyl radicals, CH_3, allows the well established pathways that yield CO_2 and CO *via* CH_2O to proceed (Figure 4b). Complete oxidation to CO_2 is not achieved under our conditions. It is possible that some of the SH formed in the oxidation of CH_3S may also yield H_2S which we speculate may be present as a sulphur-containing end-product. However, this requires additional experimental validation.

We are less certain about the chemistry involved in the decomposition of dimethyl sulphide because of a paucity of electron impact and reaction kinetic data for the sulphur containing species involved. The production of NH_3 and HCN in pure nitrogen suggests a mechanism that involves methyl and NH radicals as in Figure 4a. Methyl radicals can be formed by collisional energy transfer from metastable nitrogen, $N_2(A^3\Sigma_u^+)$, formed in the discharge through a range of dissociation channels

$$N_2(A^3\Sigma_u^+) + C_2H_6S \rightarrow C_2H_6S^* + N_2(X^1\Sigma_g^+)$$

$$C_2H_6S^* \rightarrow CH_3 + CH_3S$$

$$\rightarrow 2CH_3 + S$$

$$\rightarrow CH_3 + CS + H + H_2$$

NH radical chemistry can be initiated by abstraction of a hydrogen atom from dimethyl sulphide by $N^*(^2D)$ in an analogous manner to the reactions outlined in Figure 4a. As with methyl mercaptan, in the presence of air, NOx will be formed by the reaction of $N(^2D)$ with O_2. The reactions of O atoms, and subsequently OH radicals, with dimethyl sulphide will produce simple hydrocarbon and sulphur-containing radicals. Hynes *et al.* [7] have shown that the reaction of OH with dimethyl sulphide gives CH_3S and CH_2O under atmospheric conditions. The hydrocarbon radicals will then be oxidised to give CO, CO_2 and CH_2O in the usual manner.

The sulphur-containing end-products will be determined largely by the subsequent reactions of the free sulphur and sulphur-containing radicals formed in the initial decomposition steps. In the pure nitrogen gas flow, we conjecture that the likely end-product is H_2S which will be formed by reaction of the sulphur species with the hydrogen as in Figure 4a. With the oxygen component of the air discharge, the sulphur radicals will be oxidised to SO_2 *via* SO in reactions with O, O_2 and OH.

Energy Costs

We can compare the energy costs of the destruction of methyl mercaptan and dimethyl sulphide in our non-thermal, atmospheric pressure plasma with the work of others. Tsai *et al.* [1] find values between 30 and 90 kW h / kg for the destruction of dimethyl sulphide in a RF plasma and Czernichowski [3] quotes values between 10 and 1000 kW h /kg for the gliding arc plasma destruction of H_2S under differing conditions stating that similar energies were required for methyl mercaptan / air mixtures. In our experiments, we find comparable values of 80 – 140 kW h / kg for methyl mercaptan and 75 – 195 kW h / kg for dimethyl sulphide depending on the carrier gas and the experimental conditions.

5. Conclusions

We have demonstrated that non-thermal, atmospheric pressure plasma can be used to destroy methyl mercaptan and dimethyl sulphide in an energy efficient manner. The products are H_2S, HCN and NH_3 in an inert nitrogen gas stream and SO_2, CH_2O, CO and CO_2 in an air stream. Both of these destruction routes offer the potential for recovery of the sulphur by scrubbing of the processed gas stream. In terms of odour control, we have shown that the destruction efficiencies for these compounds at the sub ppm level where odour becomes noticeable will be complete with conversion into SO_2 or H_2S which are less odourous.

Abstract
A large-scale, slot-antenna excited surface wave plasma source operating in N_2-Ar mixtures is investigated. Surface waves propagating radially and axially along the interface between the plasma and a dielectric plate are the energy source for the plasma. The overdense plasma, close to the wave energy source, sustained by a pure TM_{33} surface mode, is analyzed. Maxwell's equations and the rate balance equations for the most important excited species – vibrationally and electronically excited states, ions and nitrogen atoms N(^{4}S) - are consistently solved and the species spatial distributions are calculated and analyzed, in correlation with the total electric field spatial variation.

1. Introduction

Microwave plasma sources based on surface wave propagation without applied magnetic field are of interest for forthcoming large-scale plasma processing technologies. Recent microwave discharge experiments [1] revealed that a slot antenna is a simple and useful launcher of microwaves to obtain large volume stable plasma.

In the present work, a slot antenna excited large area surface wave plasma source operating in N_2-Ar mixtures is investigated. Surface waves propagating radially and azimuthally along the interface between the plasma and a dielectric plate located at the top wall of a large diameter cylindrical metal camera are the energy source of the plasma (see Fig. 1). The waves form a resonant eigenmode satisfying the boundary conditions and the plasma takes discrete density values which ensure that the resonant eigenmodes exactly appear at the excitation frequency (2.45 GHz). A discrete pure TM_{33} surface mode excitation is considered. The energy of the propagating surface waves close to the interface sustains an overdense plasma. As the distance from the interface increases the wave electric field exponentially decreases and vanishes at some critical distance z_{cr}. Consequently, due to the diffusion an afterglow (electric field free) plasma appears at $z > z_{cr}$.

A theoretical model for the source discharge is developed. The plasma density at which a given mode appears and the electric field 3D (r-φ-z) pattern are calculated from the Maxwell´s equations and the wave dispersion equation in complex algebra. The electrodynamical part of the analysis is coupled to the particle kinetics through the value of the electron density at which a given mode appears. The rate coefficients for electron impact processes are obtained by solving the electron Boltzmann equation. By taking into account the principal collisional and radiative processes which determine the populations in the $N_2(A^3\Sigma_u^+, B^3\Pi_g, C^3\Pi_u, a'^1\Sigma_u^-, a^1\Pi_g, w'\Delta u)$, $N_2(X^1\Sigma_g^+, v)$, and Ar($3p^5 4s$), Ar($3p^5 4p$) excited levels of molecules and atoms and the concentration of positive ($N_2^+, N_4^+, Ar^+, Ar_2^+$) ions and ground state N(^{4}S) atoms, the rate balance equations are solved and the 3D (r-φ-z) distribution of the species is obtained.

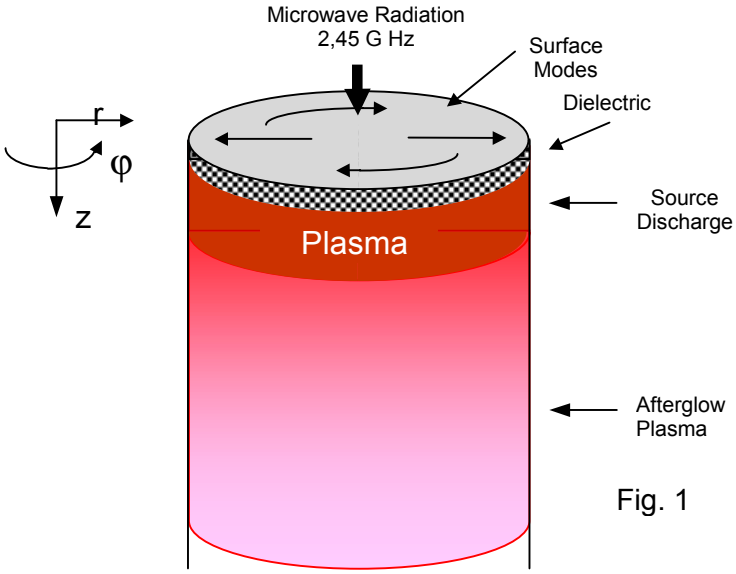

Fig. 1

2. Theoretical model.

The system under analysis is a vertical wave-guide of arbitrary cross-section (radius R) short-circuited at the top by a metal wall (Fig. 1). A dielectric plate of thickness d and permittivitty ε_d completely fills the upper region of the wave-guide. The discharge plasma (where the surface wave propagates) underneath is supposed to be homogeneous with electron density N_e. Such a structure can support transverse magnetic TM and transverse electric TE modes. Here, "pure" TM surface modes, i.e, evanescent waves along z, are considered. Weakly damped free oscillations of the type $\propto\exp(-i\omega t)$ with a complex frequency $\omega=\omega' - i\omega''$ are considered. At fixed geometry and plasma parameters, such oscillations can exist only for some discrete values of the complex frequency corresponding to the various eigenmodes.

Assuming that the surface wave propagates on the r-φ plane and is evanescent along z, the dispersion equation is obtained, as usual, from the continuity of the transverse electric and magnetic field components at the plasma dielectric interface

$$(\gamma_d/\varepsilon_d)\tanh(\gamma_d d) = \gamma_{pl}/\varepsilon_{pl}$$

Here, $\gamma_d = -\left[k^2 - \varepsilon_d \omega^2/c^2\right]^{1/2}$ and $\gamma_{pl} = -\left[k^2 - \varepsilon_{pl}\omega^2/c^2\right]^{1/2}$ are the axial propagation constants in the corresponding medium, i.e., dielectric and plasma. The relative plasma permittivity is $\varepsilon_{pl} = 1 - \dfrac{\omega_{pl}^2}{\omega(\omega + i\nu_{en})}$, where $\omega_{pl} = e(N_e/\varepsilon_o m_e)^{1/2}$ is the electron plasma frequency (m_e and e being the electron mass and charge, respectively). The transverse wave number k_τ depends only on the camera geometry and the mode; for a TM_{mn} mode, $k_\tau = U_{mn}/R$, where U_{mn} is the n-th root of the m-th Bessel function J_{mn}, i.e., $J_{mn}(U_{mn}) = 0$.

The discharge part of the model is coupled to the discharge electrodynamics through the electron density (in the discharge zone) at which the TM_{33} mode appears. The electron energy distribution function (EEDF) is determined by solving the homogeneous electron Boltzamnn equation in the local approximation [2]. The wave frequency is supposed to be much larger than the characteristic frequency of electron energy relaxation, so that the isotropic part of the distribution function may be regarded as time-independent. Momentum transfer collisions of electrons with heavy particles [N_2, N(^{4}S), Ar], electron impact excitation of electronic levels of molecules (N_2) and atoms [N(^{4}S), Ar], ionisation, step-wise processes, inelastic and superelastic collisions of electrons with vibrationally excited N_2 molecules, and electron-electron and electron-ion collisions are taken into consideration in the collision integral. The inelastic and superelastic processes taken into account and the sources used for the corresponding cross-sections are the same as in [2,3]. The electron transport parameters and the rate coefficients calculated from the EEDF are functions of the reduced electric field E/N (N is the total density of the neutrals) and of the vibrational distribution function (VDF) of the electronic ground state $N_2(X^1\Sigma_g^+, v)$, since vibrationally excited N_2 molecules constitute an appreciable fraction of the total molecular population.

Due to the significant populations in the vibrationally excited levels of the electronic ground state, the Boltzmann equation and its moment equations are coupled to the system of non-linear rate balance equations for these populations through both inelastic and superelastic collisions. The rate balance equations describing the kinetics of $N_2(X^1\Sigma_g^+, v)$ molecules take into account the processes of excitation and de-excitation of vibrational levels by electron impact (e–V processes), vibration–vibration (V–V) and vibration–translation (V–T) energy exchange processes, de-activation of $N_2(X^1\Sigma_g^+, v)$ molecules on the wall and the dissociation and re-association mechanisms of N_2. The V–T reactions concern N_2–N_2, N_2–N and N_2–Ar collisions. Due to the lack of data, the same rates are assumed for the exchanges associated with N_2–Ar and N_2– N_2 collisions [2,3]. The equations and mechanisms accounted for are described in detail in previous articles [2,3] to which the reader should refer for further information.

In addition to the above electron and vibrational kinetic processes, the model includes a large number of physical-chemical reactions which determine the populations of the electronically excited molecular states $N_2(A^3\Sigma_u^+, B^3\Pi_g, C^3\Pi_u, a'^1\Sigma_u^-, a^1\Pi_g, w'\Delta u)$ and atomic states $Ar(^1P_1, ^3P_0, ^3P_1, ^3P_2)$ as well as the concentration of positive ($N_2^+, N_4^+, Ar^+, Ar_2^+$) ions. The radial profile of excited metastable particles is assumed to be a zeroth-order Bessel function. The axial diffusion losses are taken into account in an approximative way, i.e. by introducing an effective axial diffusion coefficient. In the present model, four

types of positive ions ($N_2^+, N_4^+, Ar^+, Ar_2^+$) have been considered. The nitrogen N_2^+ ions are created by electron impact ionisation of N_2 molecules, step-wise ionisation, associative ionisation and charge transfer reactions between Ar^+ and nitrogen molecules [2,3]. N_4^+ ions are created by associative ionisation involving $N_2(A^3\Sigma_u^+)$ and $N_2(a'^1\Sigma_u^-)$ metastable molecules. Argon ions are created by direct and step-wise electron impact, charge transfer and pooling reactions [2]. The main process for the removal of charged particles is bulk dissociative recombination (N_2^+, N_4^+).

Numerous volume and wall processes involving atoms influence strongly the discharge operation. In the present model, the kinetics of nitrogen atoms in the ground $N(^4S)$ and metastable $N(^2D,^2P)$ states is taken into account by considering a number of source and loss channels. Electron impact dissociation ($e + N_2(X^1\Sigma_g^+, v = 0) \rightarrow e + N(^4S) + N(^4S)$ and dissociative recombination $e + N_2^+ \rightarrow e + N(^4S) + N(^4S)$ are important source channels for the present conditions. For the determination of the electric field maintaining the discharge ($E_t = \sqrt{E_z^2 + E_r^2 + E_\varphi^2}$) the continuity equations for the electrons and the positive ions [$N_2^+, N_4^+, Ar^+, Ar_2^+$] together with the quasineutrality condition [$n_e = N_2^+ + N_4^+ + Ar^+ + Ar_2^+$] are solved consistently. In fact, the balance between the total, volume averaged, rate of ionization {including direct, associative ionization [involving collisions between the metastable $N_2(A^3\Sigma_u^+)$ and $N_2(a'^1\Sigma_u^-)$ species], pooling ionization [involving $Ar(^1P_1, ^3P_0, ^3P_1, ^3P_2)$ species] and step-wise ionization processes [from $N_2(A^3\Sigma_u^+, a'^1\Sigma_u^-, B^3\Pi_g)$ states]} and the total rate of electronic losses due to diffusion and electron-ion bulk recombination is used to obtain the absolute values of the electric field components. In order to account for axial and radial diffusion losses of electrons an effective diffusion length is introduced. The equations are solved altogether in a self-consistent manner.

3. Results and Discussion

The 2D distribution of the total electric field ($E_t = \sqrt{E_z^2 + E_r^2 + E_\varphi^2}$) at z = 0.1 cm for the N_2 –Ar discharge (N_2(50%) –Ar(50%); p = 2 Torr) is depicted in Fig. 2. As seen, a well pronounced TM_{33} mode structure is observed. The intensity of the total electric field reaches about 5000 V/m at the maximum of the standing wave pattern. In the axial direction the electric field decays exponentially (Fig. 3) and vanishes at a distance z = 1 cm from the interface. For microwave radiation of 2.45 GHz a TM_{33} mode is satisfied when $N_e = 9\times10^{11}$ cm^{-3}. The attenuation coefficient is 2 cm^{-1}. A deep minimum of the electric field intensity in the discharge center is formed. The corresponding variation of the population density of the radiative state $N_2(C^3\Pi_u)$ closely follows the electric field distribution. Due to the fast radiative decay to $N_2(B^3\Pi_g)$, diffusion is negligible and sharp maxima corresponding to the electric field intensity maxima appear in the 2D $N_2(C^3\Pi_u)$ population density distribution. N_2^+ ions are the main positive charged particles for the conditions considered. Their principal source channel appears to be charge transfer ($Ar^+ + N_2 \rightarrow N_2^+ + Ar$) between argon ions and nitrogen molecules. The contribution of this channel at low electric field intensity is more than 90 %. As a result, the N_2^+ ion density has a maximum when the electric field intensity is minimum. The 2D distribution of ground state $N(^4S)$ atoms shows some peculiarity as demonstrated in Fig. 6. The ground state atom distribution clearly does not follow the electric field intensity distributions as the comparison shows. As seen from Fig. 6, additional maxima to those corresponding to the electric field intensity also appear. These maxima are found to be a result of dissociative recombination processes $e + N_2^+ \rightarrow N(^4S) + N(^4S)$. The correlation between the 2D distributions of the total electric field intensity, N_2^+ ion distribution and ground $N(^4S)$ state atom distribution shows that electron impact dissociation and dissociative recombination are the main source channels for ground state $N(^4S)$ atoms for the present conditions.

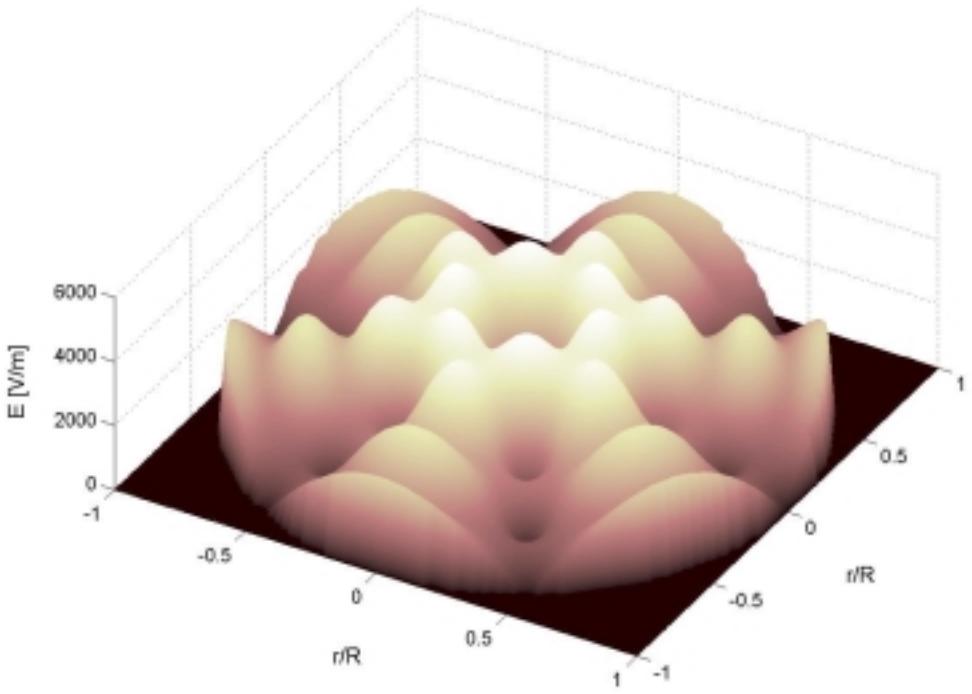

Fig. 2: (r – φ) Distribution of the total electric field intensity

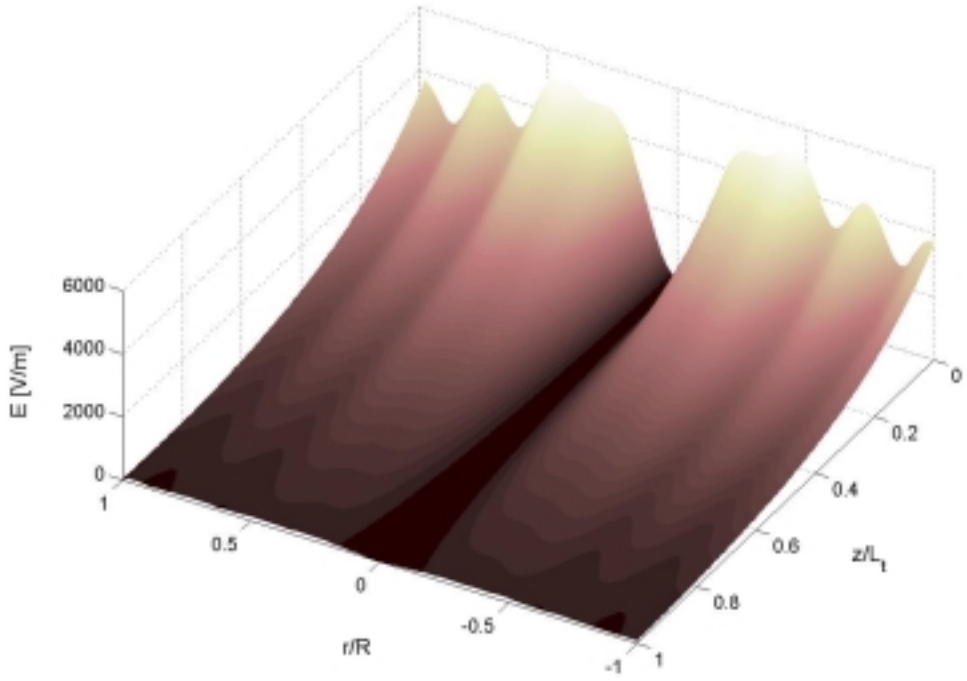

Fig. 3: (r – z) distribution of the total electric field intensity

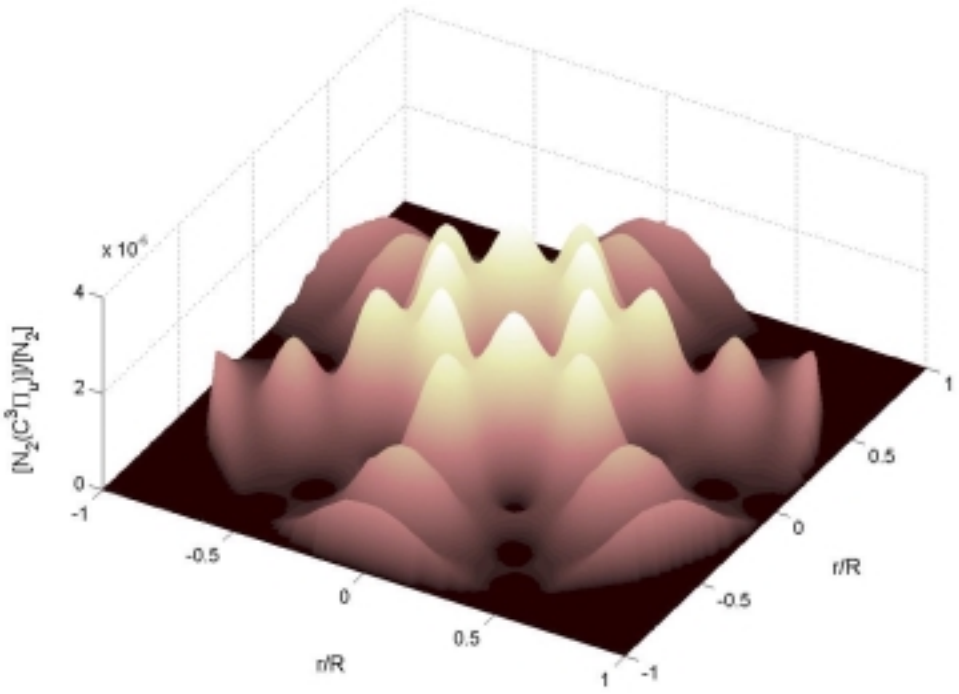

Fig. 4: (r – φ) distribution of the $N_2(C^3\Pi_u)$ state population density

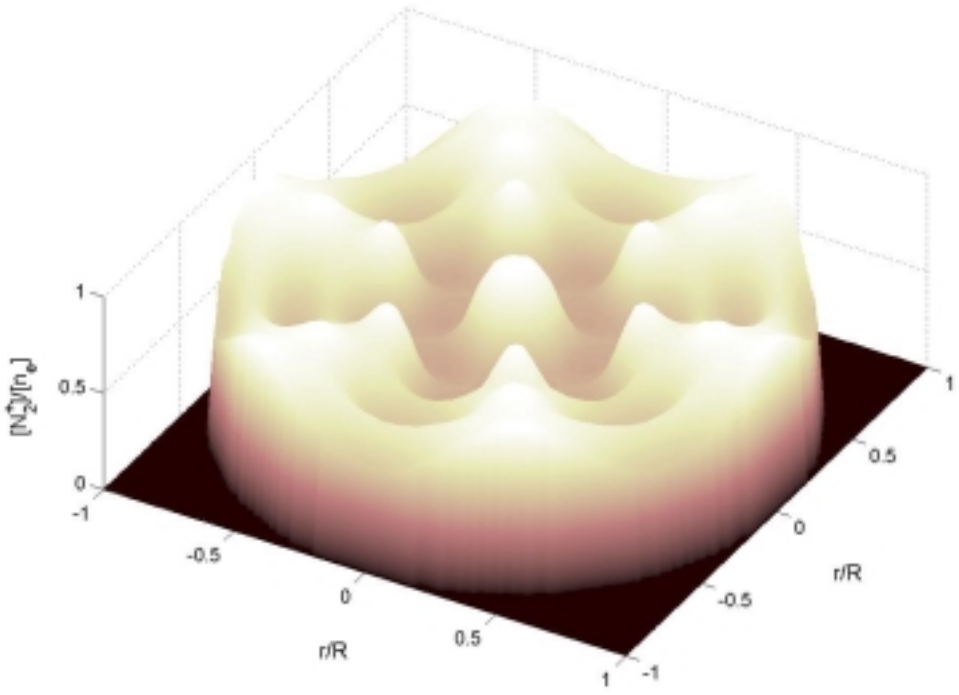

Fig. 5: (r – φ) density distribution of N_2^+

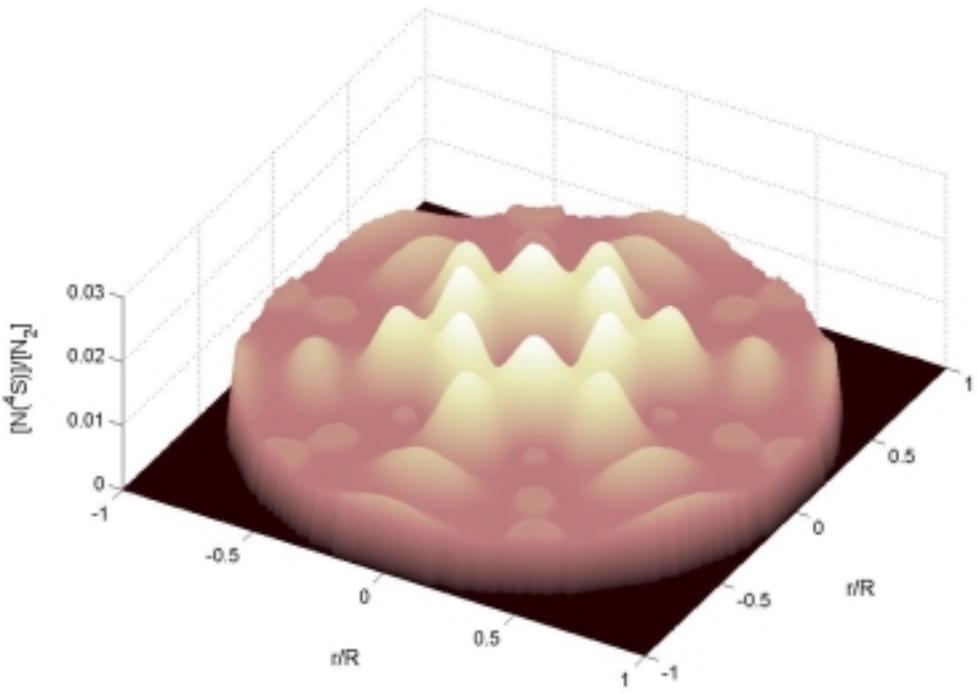

Fig. 6: (r – φ) $N(^4S)$ population density distribution

3. Conclusions

The electric field intensity distribution is strongly correlated to the density distribution of the $N_2(C^3\Pi_u)$ radiative state. Due to the contribution of charge transfer processes between argon ions and N_2 molecules, N_2^+ are the dominant positive ions for the conditions considered. The dissociative recombination processses determine the appearance of additional maxima in the 2D ground state $N(^4S)$ atom distribution with respect to those of the electric field.

Abstract
Since the discovery of the dust acoustic wave, there has been a great interest in investigating numerous collective processes in dusty plasmas. Positively and negatively charged dust grains can co-exist both in the space and in the laboratory plasmas. As it was shown [1] the presence of a positive dust component in a multi-component dusty plasma gives rise to such novel features of the nonlinear structures as the monotonic double-layers, which otherwise are absent. In this work the finite amplitude localized electrostatic solutions in multi-component unmagnetized dusty plasma [1] was applied to the laboratory plasma reported by Oohara et al. [2]. Fullerene-ion plasma of the same mass (C_{60}) was produced in the process of a hollow electron-beam impact ionisation. Authors [2] observed two low-frequency electrostatic waves. The constituents of fullurene-ion plasma are warm electrons and negatively C_{60}^- and positively C_{60}^+ charged cold dust grains, which are simultaneously present. We introduce small quantity of positive ions so as to ion temperature did not exceed 10% of the electron temperature. Applying the conditions of the existence of double layer [1] to that experimental situation it was obtained that a double layer might be possible to be launched. The constituents of fullurene-ion plasma are warm electrons and negatively C_{60}^- and positively C_{60}^+ charged cold dust grains, which are simultaneously present. We introduce small quantity of positive ions so as to ion temperature did not exceed 10% of the electron temperature. Applying the conditions of the existence of double layer [1] to that experimental situation it was obtained that a double layer might be possible to be launched.

1. Introduction

Since the discovery of the dust acoustic wave (DAW) [3], there been a great interest in investigating numerous collective processes in dusty plasmas. In their paper, Rao, Shukla, and Yu [3], discovered the dust-acoustic wave (DAW), and introduced a theory for dust-acoustic solitons in three-component dusty plasma with negatively charged dust grains. Recently, it has been suggested that positively and negatively charged dust grains can co-exist in space [4]-[6] and laboratory [7] plasmas. Therefore, it is desirable to investigate the linear and nonlinear properties of dust-acoustic waves in four-component plasma that consists electrons, ions and positively and negatively charged dust grains.

Here we present the governing equations for the DAW when both the negative and positive dust components are simultaneously present (see [8]). We discuss the properties of the DAW in the presence of positive and negative dust components, and define parameters that are relevant for the analysis of the nonlinear DAW. Stationary solutions of the governing non-linear equations for arbitrary large amplitudes are discussed. Here, we derive the energy integral with a modified Sagdeev potential. The latter is analysed both analytically and numerically to obtain the parameter regimes where DA double-layers are possible. It turns out that the presence of a positive dust component in a multi-component dusty plasma gives rise to such novel features of the non-linear structures as the compressional DA potential distribution and the monotonic double-layers, which otherwise are absent. Finally, a possible application of our investigation in laboratory plasmas is given.

2. Governing equations

We consider unmagnetized dusty plasma consisting of the electrons, the ions, negatively and positively charged massive dust particles, with similar masses.

The quasi-neutrality at equilibrium is written

$$N_{e0} + Z_n N_{n0} = N_{i0} + Z_p N_{p0}\,, \tag{1}$$

where, N_{e0} and N_{i0} are the average electron and average ion number densities, Z_n and Z_p are the negative and positive dust particle charge, N_{n0} and N_{p0} are the average dust particles number density, respectively.

The dust particles are assumed to be point charges and their sizes are much smaller than the effective Debye length. For low phase velocity (compared to the electron and ion thermal velocities) dust-acoustic

waves, both the electrons and ions can be considered inertialess fluid and their number densities can be given by the Boltzmann distribution, respectively,

$$N_e = N_{e0} e^{e\Phi/T_e} \quad \text{and} \quad N_i = N_{i0} e^{-e\Phi/T_i}, \tag{2}$$

where, Φ is the electrostatic potential and e is the magnitude of the electron charge.

The dynamics of charged dust grains are governed by the equations of the continuity and the momentum, which are, respectively,

$$\frac{\partial N_p}{\partial t} + \frac{\partial \left(N_p V_p \right)}{\partial x} = 0 \quad \text{and} \quad \frac{\partial N_n}{\partial t} + \frac{\partial \left(N_n V_n \right)}{\partial x} = 0 \tag{3}$$

and

$$\frac{\partial V_p}{\partial t} + V_p \frac{\partial V_p}{\partial x} = -\frac{Z_p e}{M_p} \frac{\partial \Phi}{\partial x} \quad \text{and} \quad \frac{\partial V_n}{\partial t} + V_n \frac{\partial V_n}{\partial x} = +\frac{Z_n e}{M_n} \frac{\partial \Phi}{\partial x} \tag{4}$$

for positively and negatively charged dust grain. Here V_p, V_n, M_p, M_n are the fluid velocities and mass of the positively and negatively charged dust grains, respectively. We are assuming cold dust particles, so no pressure term is present. The system of equations is closed with the Poisson's equation

$$\frac{\partial^2 \Phi}{\partial x^2} = 4\pi e \left(N_e - N_i + Z_n N_n - Z_p N_p \right). \tag{5}$$

3. Finite amplitude non-linear dust acoustic waves

We can get a plane wave solution for the set of linearized equations of (1) to (5) for small amplitude disturbances with angular frequency ω and wave number k, with the dispersion relation:

$$\frac{\omega}{k} = \frac{C_{da}}{\sqrt{1 + \lambda_{Dd}^2 k^2}}, \quad \text{where} \quad C_{da}^2 = \frac{T_0}{M_0} \quad \text{and} \quad \lambda_{Da} = \frac{C_{da}}{\omega_{pd}}. \tag{6}$$

We have introduced the symbols ω_{pd}, N_0, T_0 and M_0 as

$$\omega_{pd}^2 = \frac{4\pi e^2 N_0}{M_0}, \quad N_0 = N_{e0} + N_{i0}, \; \frac{N_0}{T_0} = \frac{N_{e0}}{T_e} + \frac{N_{i0}}{T_i}, \quad \frac{N_0}{M_0} = \frac{Z_n^2 N_{n0}}{M_n} + \frac{Z_p^2 N_{p0}}{M_p}. \tag{7}$$

Here, C_{da} is the dust-acoustic velocity, λ_{Dd} the effective Debye length, ω_{pd} the dust plasma frequency, N_0, M_0, and T_0 are the effective number density, the mass and the temperature, respectively.

With the purpose of understanding the parametric space, which limits the existence of double-layers, we are normalizing all the parameters. The natural quantities for the normalization are T_0, N_0 and M_0, the effective temperature (in unit of energy), the plasma particle number density and the mass, respectively. From these we get the normalizing quantities for the time, $t \rightarrow t\omega_{pd}$, the space, $x \rightarrow x/\lambda_{Da}$, and the mass, $M_j \rightarrow M_j/M_0$. The normalized velocities are expressed as the Mach number, $M = V_0/C_{da}$.

We define, then

$$\phi = \frac{e\Phi}{T_0} \quad \text{and} \quad u(\phi) = \frac{U(\Phi)}{4\pi N_0 T_0}, \tag{8}$$

where $U(\Phi)$ is the potential energy density, and which will appear in the later context,

$$n_{e0} = \frac{N_{e0}}{N_0}, \quad n_{i0} = \frac{N_{i0}}{N_0}, \quad a_e = \frac{T_0}{T_e}, \quad a_i = \frac{T_0}{T_i} \tag{9}$$

for the electron and ion number densities and the temperatures,

$$n_n = \frac{Z_n N_{n0}}{N_0}, \quad n_p = \frac{Z_p N_{p0}}{N_0}, \quad a_n = \frac{Z_n T_0}{M_n V_0^2}, \quad a_p = \frac{Z_p T_0}{M_p V_0^2} \tag{10}$$

for the dust particle number density.

From equation (1), (7) and (8) – (10) for the non-linear dust acoustic wave parameters we have

$$n_{e0} + n_n = n_{i0} + n_p \tag{11}$$

$$n_{e0} + n_{i0} = 1 \tag{12}$$

$$n_{e0} a_e + n_{i0} a_i = 1 \tag{13}$$

$$n_n a_n + n_p a_p = \frac{1}{M^2} \tag{14}$$

These last four equations are very important because they show the relation between the four component dusty plasma parameters. We will use them for our calculations to define the regions of existence of the double layer.

For weakly non-linear perturbations we can use a higher order perturbation method and get a soliton solution or a double layer. Taking up to the second order perturbation and using the reductive perturbation technique we get Korteweg - De Vries (KdV) equation with soliton solutions. For the third order perturbation we get the modified KdV equation with a double layer solution (see [8]).

Our main thrust for this work is to find the parametric limits for the existence of double layers using equations (7) and (8) of reference [8], which we reproduce here

$$\frac{1}{2}\left(\frac{\partial\phi}{\partial\zeta}\right)^2 + u(\phi) = 0\,, \tag{15}$$

where the modified Sagdeev potential [?] for our purposes is

$$u(\phi) = -\left\{\frac{n_{e0}}{a_e}\left(e^{a_e\phi}-1\right)+\frac{n_{i0}}{a_i}\left(e^{-a_i\phi}-1\right)+\frac{n_n}{a_n}\left(\sqrt{1+2a_n\phi}-1\right)+\frac{n_p}{a_p}\left(\sqrt{1-2a_p\phi}-1\right)\right\}, \tag{16}$$

with the conditions for the existence of double layers:

$$\begin{aligned} &(i) \quad u(\phi) = u'(\phi) = 0 \text{ at } \phi = 0, \\ &(ii) \quad u(\phi) = u'(\phi) = 0 \text{ at } \phi = \phi_1 \neq 0, \\ &(iii) \quad u(\phi) < 0 \text{ for } 0 < |\phi| < |\phi_1|. \end{aligned} \tag{17}$$

Now the conditions in the item (*ii*) provide two relations:

$$n_{e0}a_e + n_{i0}a_i - n_n a_n - n_p a_p = 0 \quad \text{and} \tag{18}$$

$$n_{e0}a_e^2 - n_{i0}a_i^2 + 3n_n a_n^2 - 3n_p a_p^2 = 0\,, \tag{19}$$

which are conditions under which double-layers exist.

4. Numerical results

We proceed to obtain the parametric regions where conditions (17) are satisfied. Starting with 9 parameters defined in (9) – (10) with the inclusion of 4 equations (11) – (11), we have a 5-parameter region. We introduce parameters α and β in substitution of a_i and a_n, $\alpha = a_e/a_i = T_i/T_e$ and $\beta = a_p/a_n = Z_pM_n/Z_nM_p$. So, we have to deal which a function $f(n_{e0}, n_p, M, \alpha, \beta)$ which satisfies relations given in (17).

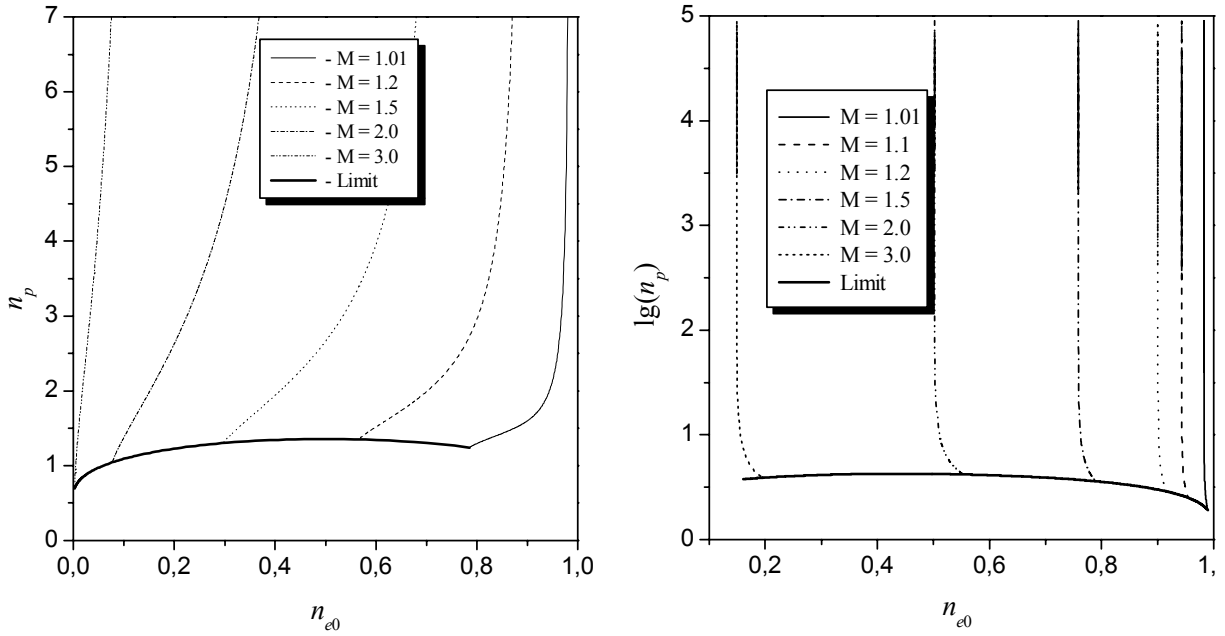

Figure 1. Relations between the parameters n_p and n_e for different values of Mach number M and parameter α = 0.09: a) β = 0.10; b) β=1.0.

Furthermore we reduce the 5 parameters to a even smaller number by taking a reasonable physical values for α, β and M, resulting in a two parametric space: $g(n_{e0}, n_p)$. In Figure 1a, we show the curves where the double layer solutions are found. We have chosen $\alpha = 0.09$ and $\beta = 0.10$. For each given value of M, from 1.01 to 3.0, a curve is drawn on $n_{e0} \times n_p$ space where DL exists.

The same treatment was applied for the particular case of laboratory plasma reported by Oohara et al [2], where a fullerene-ion plasma of the same mass (C_{60}) was produced in the process of a hollow electron-beam impact ionisation. Authors observed two low-frequency electrostatic waves. For calculations we used main characteristics of the dusty plasma, i.e. $n_e / n_p \sim 10^{-6}$, $n_e = 1.0$, $n_p = n_n \sim 10^{6}$ and $M_p = M_n$. Moreover, we introduce, on their experimental conditions, a small quantity of ions to fulfill conditions of the four component dusty plasma. Thus we have parameter $\alpha = 0.09$ and $\beta = 1.0$ that is different from the case discussed above.

In the Figure1b the result of the double layer conditions for different M values is shown. As we can see, the authors [2] have possibility to obtain a double layer in laboratory plasma. It is interesting to observe the different comportment of the curves for small values of the n_p. In contrast to the case of low β, for the DL exist it is necessary increasing both n_e and n_p for some constant M. Furthermore, the limit of the double layer existence decrease with increasing β.

5. Summary

The linear and non-linear properties of dust-acoustic waves (DAW) were studied. We used the model of multi-component dusty plasma with inertialess electrons and ions as well as positively and negatively charged inertial dust grains. We found that in four component dusty plasma there are remarkable changes in the non-linear properties of the DAW. The presence of positively charged dust grains produces double-layers in those parameter regimes. The theory was applied to the laboratory plasma reported by Oohara et al. We predict that a double-layer might be possible to be launched in their experiment if a trace ions component is added. The results of the investigation can be useful for designing laboratory experiments dealing with the demonstration of DAW in multi-component dusty plasma with the positive and negative dust grains. Our parametric studies and double-layers should be useful in identifying coherent non-linear structures in the Earth's mesosphere. Furthermore, non-stationary double-layers could be potential accelerators for dust particulates in space plasmas..

Abstract.
In this work, carbon films were deposited on activated carbon fibers (ACF), by using RF discharges of hydrocarbon-nitrogen mixtures. Raman and XPS spectroscopy were used to evaluate the modifications on the fiber surface after plasma treatment. The molecular sieve properties of raw and plasma treated ACF were studied by CO_2 and CH_4 adsorption measurements. Depending on hydrocarbon and plasma power used, the ideal selectivity of CO_2/CH_4 for adsorption, improved significantly after plasma treatment.

1. Introduction.

Carbon molecular sieves (CMS) are widely used in separation and purification processes. They are porous materials having the ability to discriminate between molecules of different size and shape [1,2]. Their unique pore structure is achieved either by controlled activation using oxidizing media [3] or by carbon deposition on an inherent pore structure in order to obtain homogenous pores with dimensions in the range of molecular size [4-6]. Both of these methods are associated with difficulties concerning the control of gasification in the first case and of deposition in the second [7].
An attractive alternative for CMS production is the deposition of a carbon thin film, possessing molecular sieve properties, on a suitable substrate [8,9]. Plasma polymerization processes, using various gas monomers, are quite suitable for the deposition of thin films [10,11]. Such thin films, deposited on porous supports have been tested as separation membranes [12,13], but they often cannot withstand the separation process environment [14].
ACF have the unique characteristic of possessing micropores directly connected to the surface of the fiber, thus permitting fast adsorption kinetics [15]. This feature of ACF, in addition to their relatively homogeneous pore size distribution, renders the material suitable precursor for carbon molecular sieve (CMS) production.
In this work, CMS production was attempted by depositing a carbonaceous film, on ACF surface. The molecular sieve properties of the raw and plasma treated fibers were evaluated by carbon dioxide and methane adsorption experiments. Raman and XPS spectroscopy was used in order to evaluate the film chemical structure, which probably affects the gas adsorption rates of CO_2 and CH_4, thereby improving the ideal selectivity of CO_2/CH_4 separation. SEM was used to examine the film thickness and surface.

2. Experimental.

The deposition apparatus used in this study consisted of a quartz reactor, an RF generator with an impedance matching network and a mechanical pump. The reactor was a quartz cylinder 1 m long, 65 mm diameter placed coaxially through a working coil. The coil was made of 9 turns of ¼ in diameter copper tube. RF power was supplied from a 1 KW, 13.56 MHz generator. The system was also equipped with a water circulation unit, necessary for cooling the various RF plasma components.
About 35-40 mg of activated carbon fibers (FR-10, Kuraray Chemical Co.) were introduced in the reactor in the middle of the coil and sealed therein by vacuum flanges. After system evacuation, a gas mixture, of 20% hydrocarbon and 80% nitrogen was introduced in the reactor, and plasma was ignited. Hydrocarbons used were ethane, ethylene, propane and propylene. The sample was always treated for 15 min at an 80 or 120W plasma power. Since no additional heating was employed, the temperature of the activated carbon fibers (ACF) rose only by inductive heating and energy transfer from the plasma.
Raman spectroscopy was employed to characterize the type of carbon-carbon bonds before and after plasma treatment. The 514 nm line spectra of an Ar^+ laser was used for excitation. XPS analysis was also employed to characterize the functional groups on the ACF surface before and after plasma treatment. The ionizing radiation, MgKa, was provided by a non-monochromatic X-ray source with characteristic energy 1253.6 eV.

The range of kinetic energies of the analyzer was calibrated according to the ASTM-E 902-88 standard method. Scanning electron microscopy (SEM) was also used for surface examination of the initial and the plasma treated ACF. The molecular sieving properties of samples were evaluated by measuring the adsorption of CO_2 and CH_4, volumetrically under ambient conditions.

3. Results and discussion.

3.1 Raman spectra.

The Raman spectrum of the untreated carbon fibers, shown in Figure 1(a), consists of two peaks at 1580 and 1350 cm^{-1}, and is similar to those of disordered carbons [16]. The plasma treated fibers, however, gave excessive luminescence, Figure 1(b), which is probably related to high levels of impurities, such as hydrogen [17].

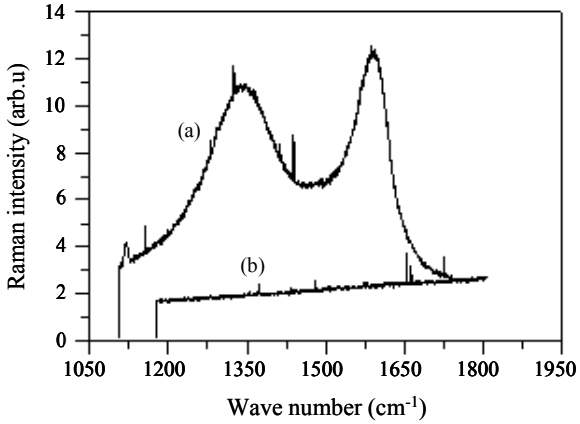

Figure 1. Raman spectrum of commercial activated carbon fibers (FR-10)
(a) before plasma treatment (b) after plasma treatment

3.2 XPS analysis.

The surface chemistry of activated carbon fibers before and after plasma treatment was characterized by XPS analysis. The main C1s peak of the raw carbon fibers was deconvoluted to three components at around 284.6, 286 and 288eV, Figure 2, which probably correspond to C–C (sp^2 or sp^3), C–OH or bridged –C=O–H–O=C–, and COOH or COOR [18-20]. A fourth peak, at the highest binding energy, is attributed to the filter used as substrate for the XPS analysis. The C1s XPS spectra of samples after plasma treatment are similar. However, C-N bonds show quite similar binding energies at 286-288eV [19]; hence, the assignment of peaks at 286 and 288eV to C-O bonds, based on C1s spectra alone, is ambiguous. For this reason, N1s spectra of raw and plasma treated samples were also obtained. Raw fibers before plasma treatment showed no N1s spectra, therefore, the peaks observed from 286 to 288eV in the C1s spectra, Figure 2, can be assigned to C-O groups as discussed above. Nitrogen is detected in plasma treated samples, analysed by XPS, Figures 3-6. The main N1s peak of plasma treated samples was deconvoluted to different components at binding energies shown in Table 1. The N1s spectra of ACF treated by alkene-nitrogen discharges are similar, Figures 3 and 5. N1s peaks at around 399eV are attributed to pyridine or amino groups [21,22], while N1s peaks at around 400eV could be attributed to pyrole or primary amine [21,23,24]. The N1s peaks at high binding energies (eg. 402eV) are probably attributed to oxidized nitrogen forms (NO), possibly embodied on the fibers surface after its exposure to atmosphere [21,25]. However, oxygen incorporation in plasma polymers is also possible during plasma treatment, even when oxygen is not introduced in the reactor intentionally. At higher plasma power (120W), with C_2H_4-N_2, the deconvoluted N1s peaks are shifted to higher binding energies, than those at 80W, probably because of intense hydrocarbon fragmentation. The peak appearing at 401.9 could probably be attributed to a free protonated amine [24], while the peak at 404.3 to pyridine-N-oxide type nitrogen [16]. With a C_3H_8-N_2 plasma at low (80W) power, peaks also shift to higher values, compared to C_3H_6-N_2, probably due to variations in the polymerization mechanism. Thus, in addition to the peak at around 400eV, a peak at 401.3eV was detected. The latter can probably be attributed to quaternary nitrogen [26].

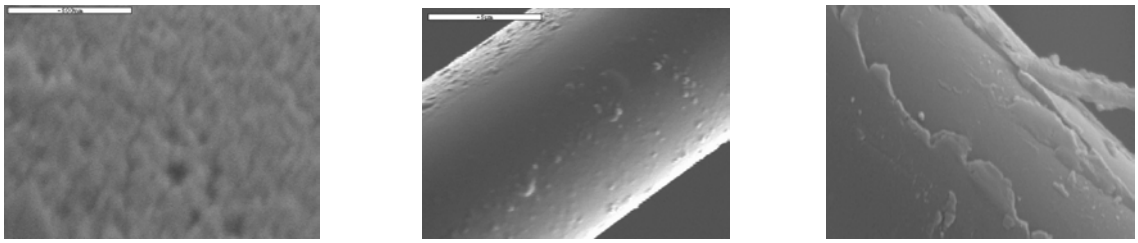
3.3 SEM examination.

Figure 6, shows the surface of the activated carbon fibers, as observed by SEM. In Figure 6(a) the pore structure of ACF surface can be identified, while Figure 6(b) demonstrates that the fiber surface is rough and contains defects. Figure 6(c) shows the film deposited on the activated carbon surface after propylene-nitrogen plasma treatment. The film thickness along the fiber varies between 150 and 300 nm.

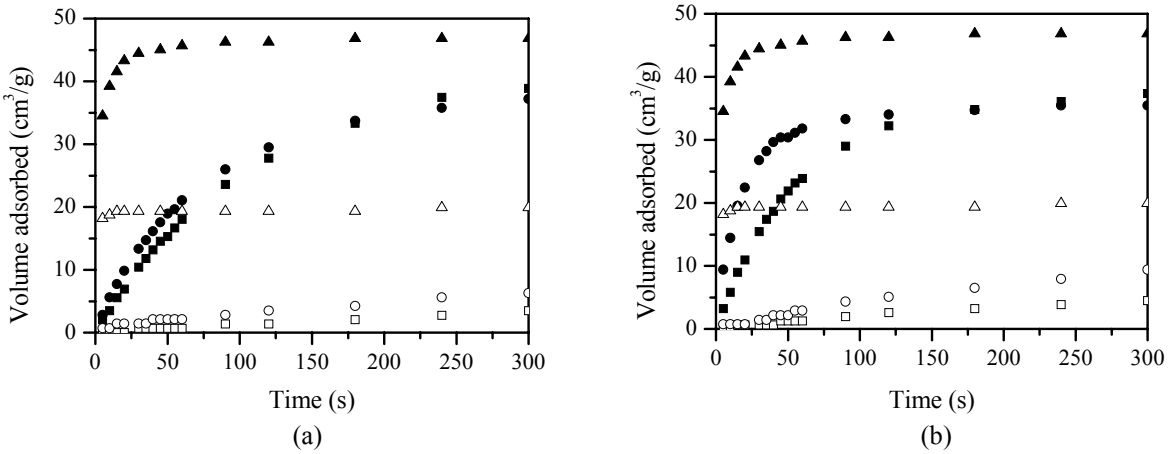


(a) (b) (c)

Figure 7. SEM characterisation of ACF
(a,b) before plasma treatment, (c) after propylene-nitrogen plasma treatment.

3.4 Molecular sieving properties.

The molecular sieving properties of the raw and plasma treated activated carbon fibers were evaluated by CO_2 and CH_4 adsorption measurements, Figures 8-9. In all cases, adsorption capacity decreased for both gases (CO_2 and CH_4), after plasma treatment, because the film formed on the ACF surface causes restriction to gas diffusion and adsorption. However, the adsorption rate decline is greater for CH_4 than for CO_2, as anticipated from the different size and shape of the two molecules. The planar CO_2 molecule diffuses faster through the film, compared to the bigger in size and spherical CH_4 molecule. In addition, CO_2 adsorption could be enhanced due to an acid-base interaction between the CO_2 molecules and the basic pyridine or amino groups [27].



(a) (b)

Figure 8. CO_2 and CH_4 uptake curves of commercial activated carbon fibers treated by hydrocarbon-nitrogen plasma at 80W (closed symbols: CO_2 open symbols: CH_4).
(a) (▲△ FR-10, ■□ C_2H_4/N_2, ●○ C_2H_6/N_2) (b) (▲△ FR-10, ■□ C_3H_6/N_2, ●○ C_3H_8/N_2)

Adsorbed volumes of CO_2 and CH_4, especially in the first two minutes, also differ, depending on hydrocarbon used for plasma deposition. Such differences could be attributed to film chemistry and/or to film structure (thickness, tightness). Thus, films deposited on ACF by C_2H_4 and C_3H_6 plasma at 80W, contain the same nitrogen functional groups, as shown by XPS analysis. However, adsorbed volumes of CO_2 and CH_4 in the first two minutes of the adsorption process differ. Considering that film structure is related to film thickness [14], it is reasonable to correlate the variation in CO_2 and CH_4 adsorbed volume with the film thickness obtained in each case. Since, the deposition time is kept constant in all experiments, differences in film thickness, at constant plasma power, could result from different deposition rates for each gas. This is possible because the rate of deposition depends on the energy input per gram of hydrocarbon used, which in turn depends on the molecular weight of the hydrocarbon and plasma power employed. One should note that the minimum wattage necessary for plasma polymerization differs significantly among the hydrocarbons [28]. Therefore, for the same energy supplied to the hydrocarbons tested (C_2H_4, C_2H_6, C_3H_6 and C_3H_8) at a specific plasma power (80W), the energy input per gram is higher for C_2H_4 than for C_2H_6, C_3H_6 or C_3H_8 at the same flow rate. The same reasoning seems to apply also on CO_2 and CH_4 adsorbed volumes of ACF treated in C_2H_4, C_2H_6 and C_3H_6 plasma at 120W, Figure 9. Compared to results at 80W, adsorbed volumes of

CO_2 and CH_4, during the first two minutes of adsorption, increase at 120W for C_2H_4, C_2H_6, C_3H_6 sources. This implies that the deposition rate obtained at the higher plasma power (120W) resulted in a film structure which permitted easier gas transport, compared to the one obtained at 80W. However, polymers deposited at elevated plasma energies should possess a tighter network structure than those obtained at low energy input [29]. Since, gas transport depends on film thickness and structure tightness [30], it is reasonable to assume that films deposited on ACF at 120W are thinner than those obtained at 80W. This could imply that ablation takes place simultaneously with film deposition [31]. Film ablation is expected to be stronger at 120W, resulting in a lower overall deposition rate, compared to that at 80W plasma power. In contrast to C_2H_4, C_2H_6 and C_3H_6 treated ACF, adsorption of CO_2 and CH_4 decreases with plasma power for a C_3H_8-N_2 discharge. This probably indicates that for C_3H_8 polymerization, deposition prevails at 120W in the competitive plasma deposition-ablation process.

Ideal selectivities (expressed as the ratio of the amount of CO_2 adsorbed to that of CH_4) were calculated for all samples at various times of adsorption, Table 2. The best results were obtained for the C_2H_4-N_2 plasma treated activated carbon fibers at 80W. The CO_2/CH_4 ideal selectivity, measured at 60s of adsorption, improves from 2.4, for the raw ACF, to 26 for C_2H_4-N_2 plasma treated fibers. As noted earlier, C_2H_4-N_2 plasma probably gives the thickest film on ACF. The selectivity decrease, observed at longer adsorption times, e.g. ≥120s, is in agreement with the kinetic separation rules [32]. Similar behavior is also observed at plasma power of 120W, with the exception of C_3H_8 source. The low adsorption measured on ACF treated by C_3H_8-N_2 plasma, discussed previously and attributed to thicker film deposition, is accompanied by improved CO_2/CH_4 selectivity, Table 2. Further characterization of the physical and chemical structure of the plasma deposited films should provide better understanding of possible surface group interactions with the adsorbing gases and of selectivity modification.

Table2. Ideal selectivity (CO_2/CH_4) of raw and plasma treated ACF (FR-10) at 60 and 120s of adsorption.

Gas feed	Ideal selectivity (CO_2/CH_4)-60s		Ideal selectivity (CO_2/CH_4)-120s	
	80W	120W	80W	120W
C_2H_4/N_2	26	19.5	20	10
C_3H_6/N_2	18.5	15.6	12.5	9.2
C_2H_6/N_2	10	4.5	8.4	4.2
C_3H_8/N_2	11	17.5	6.7	11
Raw ACF	2.4		2.4	

4. Conclusions.

Carbon films were deposited on ACF by C_2H_4/N_2, C_2H_6/N_2, C_3H_6/N_2 and C_3H_8/N_2 RF discharges. XPS analysis revealed that nitrogen reacted and remained on ACF surface during plasma treatment. Films of similar chemical structure were obtained by C_2H_4/N_2 and C_3H_6/N_2 discharges, while films formed by C_2H_6-N_2 and C_3H_8-N_2 gave different N1s peak binding energies. All plasma trated ACF gave improved molecular sieve properties, as indicated by a 5 to 10 fold increase in CO_2/CH_4 ideal selectivity for adsorption. The enhanced adsorption rate of CO_2 against CH_4 can be attributed to the deposited film structure and/or to possible acid-base interactions between CO_2 and basic nitrogen groups. Selectivity variations with hydrocarbon and plasma power employed are probably caused by differences in the thickness of the deposited films.

5. Acknowledgments.

We thank the European Coal and Steel Community for financial support of this work. We also thank the Physics Division, School of Engineering of Aristotle University of Thessaloniki for Raman measurements, and the Institute of Chemical Engineering and High Temperature Processes of Patra for XPS measurements.

Abstract
A microwave N_2-H_2 discharge driven by traveling surface waves is investigated as a source of ground state $N(^4S)$ and H(1s) atoms. The dissociation kinetics is discussed in the framework of experimental results and the a theoretical model based on a self-consistent treatment of the main discharge balances, wave electrodynamics and plasma-wall interactions.

1. Introduction

The kinetics of microwave discharges driven by a propagating wave is a complex subject due to the highly non-linear collisional reaction processes occurring simultaneously that strongly affect the non-equilibrium discharge kinetics. For this reason, it is essential to combine theoretical and experimental investigations in order to reveal the main kinetics mechanisms, in particular those of dissociation kinetics. Moreover, the whole discharge physics is strongly influenced by the degree of molecular dissociation. Keeping in mind applications, the investigation of discharges operating in N_2-H_2 mixtures presents an interest because nitrogen atoms $N(^4S)$ are the most important precursors in a number of surface treatment processes, while hydrogen atoms H(1s) are efficient etching species [1].

In this work we present experimental and theoretical results from the investigation of molecular dissociation in a traveling surface wave sustained discharge operating in N_2-H_2 mixtures. Experimental investigations have been carried in a plasma source operating at 2.45 GHz at low-pressure conditions (p = 0.5 – 2 Torr). By means of optical emission spectroscopy and probe diagnostic techniques the population densities of ground state atoms [$N(^4S)$ and H(1s)] have been detected. Since the relation between the intensity of the emission lines and the density of the corresponding species is not straightforward, the experimental results have been analyzed in the framework of a theoretical model based on a self-consistent treatment of particles kinetics, gas dynamics, wave electrodynamics and plasma-wall interactions. The dependence of the discharge properties, in particular of molecular dissociation, on the mixture composition is discussed.

2. Experimental conditions and procedures

The experiments have been performed in a microwave discharge sustained by an azimuthally symmetric surface wave of frequency $\omega/2\pi$ = 2.45 GHz excited by a waveguide-surfatron device. The plasma column, which extends outside the launcher, is created in an N_2-H_2 gas mixture at pressure p = (0.5 – 2 Torr) in a quartz glass tube with inner radius R = 0.75 cm (see Fig. 1). The gas components (N_2, H_2, Ar) are introduced in the discharge tube by means of mass flow controllers with a flow rate in the range Q = 2 – 100 sccm. The power delivered to the launcher is between 200 and 770 W. Photons emitted by the plasma are collected by a collimator and transferred via an optical fiber into the entrance slit of a SPEX 1250 M spectrometer (2400 g/mm grating) equipped with a Hamamatsu R928 photomultiplier. The current generated by the photomultiplier is sent to a data acquisition electronic device Data Scan2, and processed by Spectramax software. The whole optical system is calibrated with a tungsten lamp.

For electron temperature measurements, a probe diagnostic technique has been applied. The gas temperature has been determined, as usual for nitrogen, by measuring the rotational distribution of the 2nd positive system of N_2 in the 375.5 – 379 nm wavelength range assuming that the rotational and the translational modes are in equilibrium.

The intensity ratios $I(744)/I(750)$ and $I(746)/I(750)$ of the two nitrogen atomic lines λ = 744.23 nm and λ = 746.83 nm (transition $3p^4S^o \rightarrow 3s^4P$) to the λ = 750.39 nm argon line (transition $2p_1 \rightarrow 1s_2$) have been detected as a measure of the dissociation degree $[N(^4S)]/[N_2]$ of nitrogen molecules in the mixture. For this reason, a small amount of inert Ar gas has been added to the mixture.

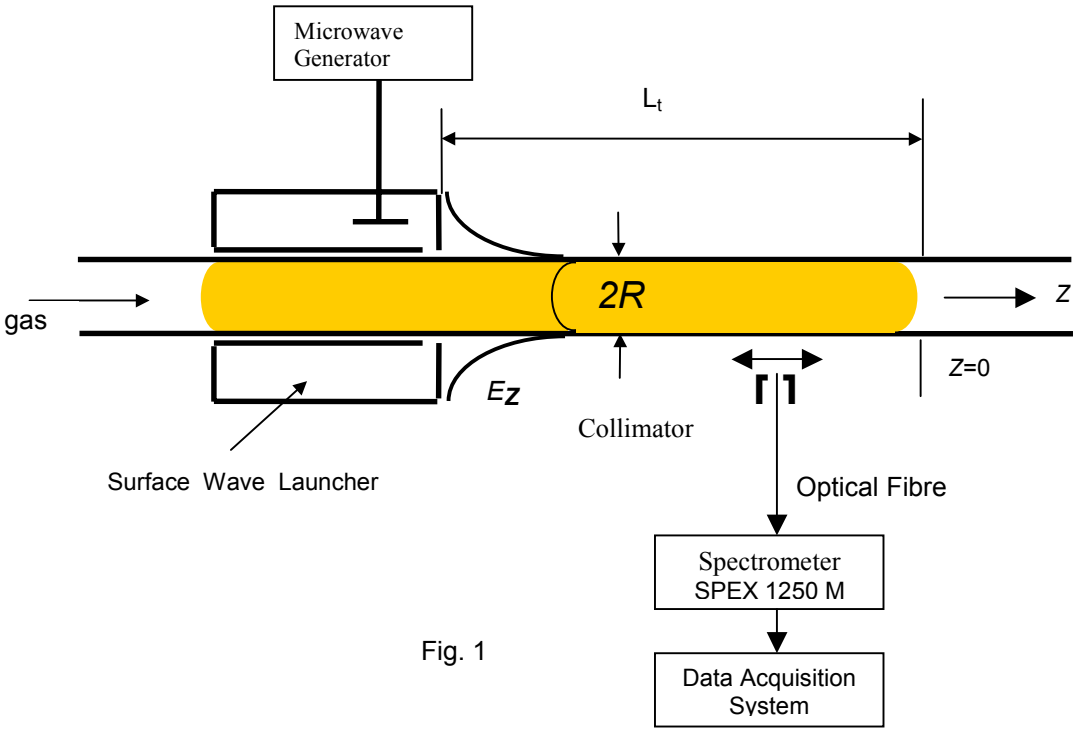

Fig. 1

Taking, for example, the λ = 744.23 nm atomic line, the relative concentration of ground state N(^{4}S) atoms can be calculated using the relation:

$$\frac{[N(^4S)]}{[N_2]} = \frac{R_{750}}{R_{744}} \frac{h\nu_{750}}{h\nu_{744}} \frac{A_{750}}{A_{744}} \frac{k_{Ar}}{k_N} \frac{\left\{\sum A_{ij}^N + K_M^N[M]\right\}}{\left\{\sum A_{ij}^{Ar} + K_M^{Ar}[M]\right\}} \frac{[Ar]}{[N_2]} \frac{I(744)}{I(750)} \qquad \text{M} = (N_2, H_2, Ar)$$

Here, $\sum A_{ij}^N$, $\sum A_{ij}^{Ar}$ are the sum of the transition probabilities for all radiative de-excitation processes from the considered excited levels (A_{744} = 1.06 × 10^7 s^{-1} and A_{750} = 4.72 × 10^7 s^{-1}), K_M^N, K_M^{Ar} are the quenching coefficients for the N(3p^{4}S^o) and Ar(2p$_1$) states by the M species and R_{744}, R_{744} are the spectral response of the system at 744 and 750 nm, respectively. The total nitrogen [N_2], hydrogen [H_2], and argon [Ar] concentrations, and the ratio [Ar]/ [N_2] can be calculated using the measured gas temperatures (applying the ideal gas law $p = NkT_g$ under nearly isobaric conditions) and the flow rates of the gas components.

3. **Theoretical model**

A nitrogen-hydrogen discharge sustained by the field of a HF, azimuthally symmetric (TM mode), traveling surface wave is under investigation. In the present work, molecular dissociation is studied on the basis of a self-consistent model including coupled equations for the plasma bulk describing the kinetics of free electrons, the vibrational kinetics of electronic ground state molecules $[N_2(X^1\Sigma_g^+, v), H_2(X^1\Sigma_g^+, v)]$, the kinetics of excited electronic states of molecules $[H_2(a^3\Sigma_g^+, c^3\Pi_u, e^3\Sigma_u^+, d^3\Pi_u^-, B^1\Sigma_u^+, c^1\Pi_u)]$, $[N_2(A^3\Sigma_u^+, a'^1\Sigma_u^-, B^3\Pi_g, C^3\Pi_u, a^1\Pi_g, w^1\Delta_u)]$ and atoms [H(1s), N(^{4}S)], the chemical kinetics of ions $[N_2^+, N_4^+, H^+, H^-]$ and the gas thermal balance. The equations for wave dispersion and wave power balance are further incorporated in the system of equations. The elementary processes taken into account to describe the electron and the heavy particles kinetics are described in previous articles [2,3] and the reader should refer to these works for details. The populations of $N_2(X^1\Sigma_g^+, v)$ and $H_2(X^1\Sigma_g^+, v)$ vibrational levels are derived from a coupled system of master equations taking into account vibrational excitation and de-excitation by electron collisions, vibration-vibration exchange between molecules, vibration-translation

single-quantum energy exchanges between molecules and molecules and atoms, (V-T) multiquantum energy exchanges between molecules and atoms, energy exchange in collisions with the wall and chemical reactions involving vibrationally excited H_2 molecules. For hydrogen, there exists an efficient vibrational excitation mechanism through electron impact excitation of the $H_2(B^1\Sigma_u^+)$ and $H_2(C^1\Pi_u)$ electronic states followed by fast decay to excited vibrational levels of the ground state $H_2(X^1\Sigma_g^+, v)$. Interaction with the discharge tube wall which strongly influences the population of some species in low-pressure discharges is taken into account by using radially averaged rates of wall losses [1] depending on the diffusion to the wall and the probability for wall deactivation γ [2,3]. For the calculation of the diffusion coefficients, the same expressions and approximations as in [2] are used. The loss of N and H atoms in low-pressure discharges is mainly due to wall reactions. The values of γ_N and γ_H substantially change in gas mixtures and have been determined on the basis of a kinetic model of surface processes involving N and H atoms which enables the calculation of γ_N and γ_H in N_2-N-H_2-H mixtures [3]. The radially averaged gas temperature has been calculated from the gas thermal balance equation together with the vibrational and chemical kinetics equations. The most important gas heating sources are V-T relaxation of N_2 and H_2 molecules and dissociation of N_2 and H_2 with production of "hot" N and H atoms. Thermal conduction to the tube wall is the main cooling mechanism. A parabolic gas temperature profile has been assumed for the calculation of the radially averaged gas temperature. The wall temperature T_W is also an important parameter because its value influences not only the gas temperature but also the probabilities for atomic wall reassociation, and, thereby, the surface kinetics of both types of atoms. The value T_W has been calculated approximately. It was assumed that T_W changes linearly along the tube and takes the value 295 K at the discharge end.

The theoretical treatment of wave-to-plasma power coupling is based as in [4] on a simultaneous solution of the wave power balance equation and the electron power balance equation, as obtained from the Boltzmann equation. The latter expresses the balance between the power gained by the electrons from the wave field and the electron collisional power losses in the plasma. Under steady-state conditions, the spatial rate of power change is due to the power absorbed by the electrons per unit discharge length. The sole input parameters of the model are the externally controlled parameters in the real experiment: operating frequency, ω; total absorbed power, P; discharge tube radius, R; pressure, p; and gas flow rate Q. As a result of the self-consistent treatment, the model determines the axial discharge structure (i.e. the axial variation of the discharge and wave quantities), and the population densities of the species of interest as a function of the mixture composition.

3. Results and discussions

The predicted and experimental discharge lengths are compared in Fig. 2 and Fig.3 as a function of the H_2 percentage. It is seen that the predicted and experimental discharge lengths are in good agreement. The observrd discrepancies can be attributed to the difference between the power delivered to the launcher (which is measured in the experiment) and the power absorbed in the discharge (which is an input parameter of the model). Another reason of discrepancy is the sensitivity of the calculated discharge length to electron ionization rate coefficients used. The large uncertainties of these coefficients should be pointed out.

When hydrogen is introduced into the mixture, the discharge length decreases because the discharge impedance changes. The reasons of this decrease are the following.

First, the role of N_2 associative ionization processes

$$N_2(A^3\Sigma_u^+) + N_2(a'^1\Sigma_u^-) \rightarrow N_4^+ + e$$

$$N_2(a'^1\Sigma_u^-) + N_2(a'^1\Sigma_u^-) \rightarrow N_4^+ + e$$

decreases since the populations of $N_2(A^3\Sigma_u^+)$ and $_2(a'^1\Sigma_u^-)$ metastables decreases due to deactivation in collisions with H_2 and H.

Second, the ionization potential of hydrogen molecules is higher than for nitrogen and more power is needed to maintain an electron-ion pair. Thus, the discharge length decreases when the H_2 percentage increases at constant power delivered to the discharge.

The axial distribution of the amount of power transferred into gas heating for 10% hydrogen percentage in the mixture is illustrated in Fig. 4. The gas temperature decreases non-linearly towards the plasma column end, scaling the non-uniform wave power dissipation.

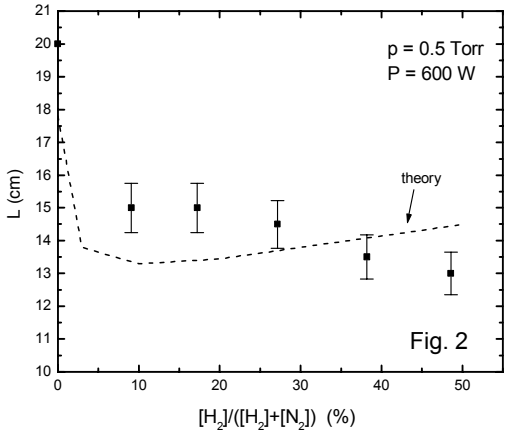

Fig. 2

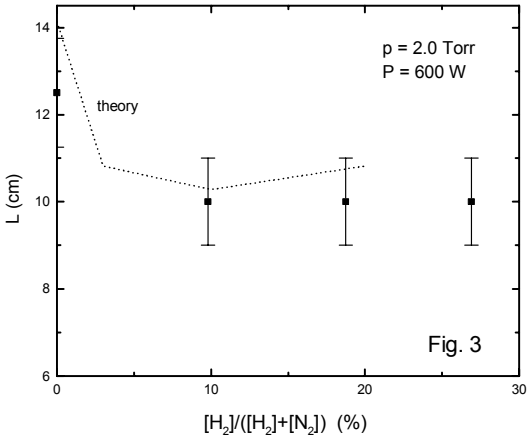

Fig. 3

The experimental gas temperatures were determined by measuring the rotational distribution of the second positive system of nitrogen $N_2(C^3\Pi_u, v') \rightarrow N_2(B^3\Pi_g, v'')$ in the 375.5- 379 nm wavelength range (i.e. 0-2 vibrational transition). Under nearly isobaric conditions as in the present experiment, the decrease in T_g results in a change of the neutral density along the discharge.

The experimental and the theoretical variation of the relative number $[N(^4S)]/[N_2]$ of ground state nitrogen atoms versus the H_2 percentage in the discharge is shown in Fig. 5. As can be seen, increasing the amount of H_2 in the discharge up to 50% causes an increase in the degree of molecular dissociation (up to about 10%) for the conditions considered. A good agreement between experimental and theoretical results should be pointed out. Besides electron impact dissociation, the important source channels of ground state atoms for the present conditions are the surface electron-ion recombination reactions

$$N_2^+ + e + \text{surface} \rightarrow N(^4S) + N(^4S)\ \text{(gas phase)}$$

$$HN_2^+ + e + \text{surface} \rightarrow NH + N(^4S)\ \text{(gas phase)}$$

The ions N_2^+ and HN_2^+ and the electrons reach the tube surface due to ambipolar diffusion. The ion HN_2^+ becomes the main positive ion with a small admixture of H_2 due to the fast ion-molecular reactions with parent ions N_2^+, H_2^+:

$$N_2^+ + H_2 \rightarrow HN_2^+ + H$$

$$H_2^+ + N_2 \rightarrow HN_2^+ + N$$

The intensity ratio of the Hα (λ = 656.2 nm) hydrogen atomic line to the λ = 750.39 nm argon line multiplied by the ratio of the fractional concentrations of Ar and H_2 in the discharge $[Ar]/[H_2]$ has been taken as a measure of the degree of hydrogen dissociation. As seen from Fig. 6 no changes have been experimentally observed when the H_2 percentage varies in the range 10-50%, i.e. the degree of molecular dissociation keeps approximatively constant for the present conditions. This behavior appears to be a net result of the competitive interplay of two important source channels of ground state hydrogen atoms, namely:

(1) electron impact dissociation;
(2) dissociation of H_2 upon quenching of nitrogen metastables [2]

$$N_2(A^3\Sigma_u^+) + H_2 \rightarrow N_2(X^1\Sigma_g^+) + H + H$$

$$N_2(a'^1\Sigma_u^-) + H_2 \rightarrow N_2(X^1\Sigma_g^+) + H + H$$

Figure 7 shows a comparison between the calculated and the measured axial profiles of the relative number density of hydrogen ground state atoms.

4. Conclusions

The experimental investigations and the modeling of kinetic processes in N_2-H_2 surface wave discharge discusses in this paper enable one to understand the main processes of production of $N(^4S)$ and H(1s) atoms in this type of discharges. It was found that surface electron-ion recombination involving HN_2^+ ions is an important source of $N(^4S)$ gas phase atoms.

Abstract
Results are presented from Monte Carlo calculations of the electric charge of dust grains in a plasma produced during the slowing down of the radioactive decay products of californium nuclei in neon. The dust grain charging is explained as being due to the drift of electrons and ions in an external electric field. It is shown that the charges of the grains depend on their coordinates. The time-averaged dust grain charges are used to carry out computer modeling of the formation of dynamic vortex structures observed in experiments.

1. Introduction

The objective of this paper is to produce dynamic ordered dust structures in a nuclear-track plasma created by nuclear-reaction products in inert gases and to carry out computer modeling of the processes that lead to their formation.

We apply the Monte Carlo (MC) method to calculate the time dependence of the charge of dust grains in a nuclear-track plasma that decays under the action of an external electric field into the flows of electrons and ions drifting toward the oppositely charged electrodes. We show that, since the grain charge is alternately affected by electron and ion flows, it fluctuates strongly about a value smaller than that typical of a quasineutral plasma. The mean values of the grain charge agree with those measured experimentally.

We theoretically explain the formation of the experimentally observed dynamic vortex dust structures in a nuclear-track plasma in neon in the presence of an external electric field and experimentally test our theoretical model for describing such a plasma. Numerical investigations carried out using the method of molecular dynamics make it possible to explain the characteristic features of the formation of vortex dust structures. The numerical results presented here agree qualitatively with the experimental data. Evidence is obtained of the potential character of the electrostatic forces experienced by the dust grains.

2. Calculation of the dust grain charge

Investigations of the behavior of dust grains in a plasma created by nuclear-reaction products provide new information on the self-organizing abilities of the dust in the plasma. The nuclear-track plasma differs considerably in properties from other plasmas, the primary difference being that it is strongly inhomogeneous in space and highly unsteady in time. In a nuclear-track plasma, a dust grain is affected by the flows of drifting electrons and ions that are cylindrically symmetric in structure (the symmetry axis being parallel to the propagation direction of an ionizing particle). Because of diffusion, the electron and ion flows spread out in the radial direction; simultaneously, because of a difference in the electron and ion diffusion coefficients, the radii of the electron and ion cylindrical flows increase to a far greater extent. As a rule, the dust grains acquire a negative electric charge, because the electrons are much more mobile than the ions. The ion flows efficiently discharge the grains. The external electric fields of both the dielectric walls of an experimental device and its electrodes can substantially redirect the drift flows of plasma particles.

The experimental device in which we observed the formation of levitated dust structures consists of an ionization chamber with horizontally oriented parallel electrodes. The chamber was filled with neon at a certain pressure. Dust grains were injected through a hole in the upper electrode into the interelectrode space, in which the external electric field was created. The role of the radioactive source was played by a 7-mm-diameter plane layer of ^{252}Cf at the lower electrode. The numerical results presented below were obtained for the experiments condition under which we observed liquidlike dust structures (see table 1 and Fig. 1).

Table 1. Conditions of our experiments on the formation of dynamic dust structures

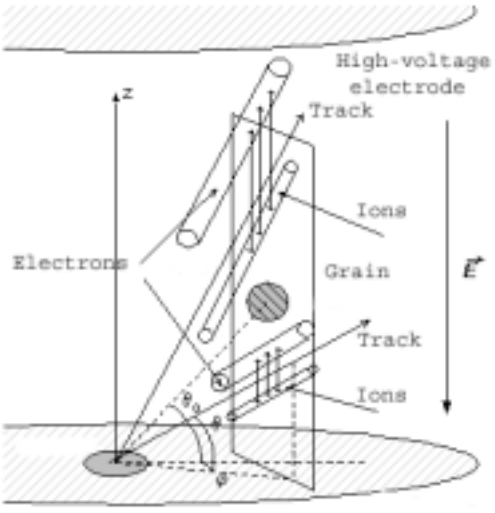

Fig. 2. Schematic of electron and ion motions in the vicinity of a dust grain in an electric field and geometry for MC simulations.

The physical model of dust grain charging consists in the following. The ionizing particles emitted from the source are stopped in the gas over a time of several nanoseconds. In turn, the primary electrons ionize neon atoms and thus produce a plasma cloud, which is called the track of an ionizing particle. The length of the track is much larger than the diameter of its cross section. As time elapses, the diameter of the track increases and, correspondingly, the electron and ion densities within the track decrease. The electric field generated in the track hinders charge separation [1] and delays this process in the presence of an external electric field. However, since the electron density gradient is large, the electron diffusion eventually reduces the electric field inside the track, so that the charges begin to be separated by the external field. Hence, the process of the formation of a track plasma and the charging of dust grains proceeds in the following two stages. The first, extremely short (~100 ns [1]), stage of the track evolution is far from being studied completely. In the second, much longer (several microseconds), stage (electron drift in the interelectrode space), the dust grain charge changes after the track plasma decays into two flows, namely, the flows of electrons and ions drifting toward the oppositely charged electrodes and toward the charged dielectric walls of the device.

Let us discuss the main physical assumptions underlying the mathematical description of the dynamic processes in a nuclear-track plasma. We start by considering the second stage of the formation of dust structures and charging of the dust grains, because the processes occurring in this stage have been studied in great detail. Since the electric field strength in our experiments was such that the measured current reached the saturation stage, we neglect the recombination of charged particles. When a dust grain is affected by an electron flow from the track toward the positively charged electrode (anode), it collects some of the electrons and thus acquires a negative charge. When an ion flux meets this grain, it decreases the grain's negative charge and may even charge the

grain positively (Fig. 2). A statistical treatment of these charging processes in time constitutes the essence of the mathematical model for calculating the grain charge. The main constants for these processes were chosen from the published data so as to satisfy the conditions of our particular experiments on the formation of ordered dust structures in neon. The energy losses were normalized to the energy cost of the production of one electron–ion pair (for neon, this cost is 35 eV). As usual, we assumed that the energy cost does not change as the energy of the ionizing particles decreases. The mathematical expression for this current is governed to a large extent by the ratio of the grain diameter to the mean free paths of the plasma particles. Thus, a grain diameter of 1μm is four times smaller than the electron mean free path, but six times larger than the ion mean free path. That is why we used two different approaches to calculating the electron and ion currents to the grain surface. The electron current, which is determined by the absorption cross section for plasma electrons, was calculated from the formula [2]

$$I_{-} = 2\sqrt{2\pi} \cdot n_{-} \cdot v_T \cdot a^2 \cdot \exp(-\frac{e\varphi}{T_{-}}), \qquad (1)$$

where a is the grain radius, n_- is the electron density, T_e is electron temperature, v_T is the electron thermal velocity, and φ is the potential acquired by the grain during the charging process. The charge acquired by a negatively charged grain in ion flows is determined by the currents of positive and negative ions to its surface. These currents are described by the following analytic formulas, which were obtained in the diffusion approximation:

$$I_{\pm} = \mp \frac{4\pi D_{\pm} N_{\pm} qe^2}{T_{\pm}\left[\exp(\mp qe^2 / r_0 T_{\pm}) - 1\right]} \qquad (2)$$

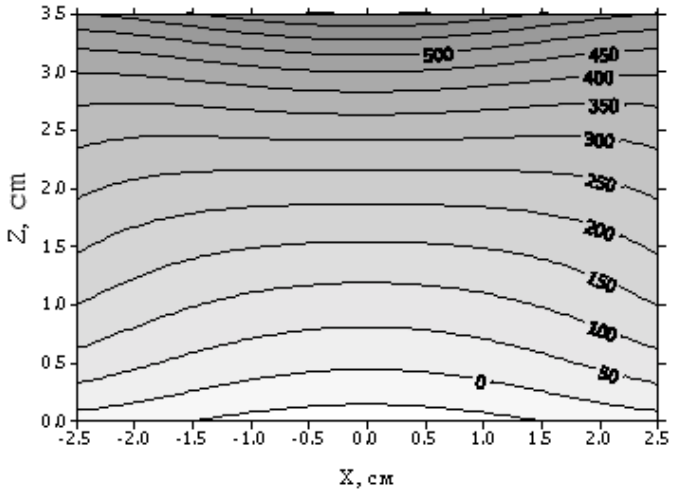

Fig.3. Dependence of the dust grain charge (in units of e) on the spatial coordinates under the conditions given in the table for a grain diameter of 2.1μm. The x-axis lies in the plane of the source, which is located at the point (0, 0).

The charge of the grain affected simultaneously by the electron and ion flows is determined by the total current of the electrons and ions. If the electron mean free path is much larger than the grain diameter, the electron current is calculated from formula (1); otherwise, it is calculated from the first of formulas (2). For electron mean free paths comparable with the grain diameter, the electron current is calculated by matching formula (1) with the first of formulas (2). The ion current to the grain surface is calculated from the second of formulas (2). As a result, the dynamics of the grain charge is described by the equation

$$\frac{dq}{dt} = I_{-} - I_{+} \qquad (3)$$

In a nuclear-track plasma with a low degree of ionization and a low electron temperature, the dust grains acquire small charges. Calculation results of time-average dust grain charge distribution are presented in fig.3.

3. Computer modeling of the dynamics of the formation of liquidlike dust structures

Since this is the first paper in which an attempt is made to model the formation of vortex structures from dust grains in a nuclear-track plasma, our theoretical approach does not pretend to completely describe the dust behavior under the experimental conditions in question. Our main objective here is to develop a reasonable model for describing the most characteristic features of the grain behavior in a plasma and to reveal the main physical mechanisms for the formation of a potential trap that ensures the levitation of the dust grains. That is why it is expedient to carry out numerical modeling for the experimental conditions under which vortex structures were stable. In this context, it is most reasonable to model the structures like that shown in Fig. 1, which were observed to form in a nuclear-track neon plasma at pressures from $2.5 \cdot 10^4$ to $7.5 \cdot 10^4$ Pa.

In order to investigate the levitation of dust grains and their mutual interactions, it is necessary not only to establish the mechanism for their charging but also to reveal the nature of the forces acting upon them. At present, several different mechanisms are being discussed in the literature that affect both the balance between the gravity and electrostatic forces experienced by the levitated dust grains and the interactions between them (see [3, 4] for details). Here, we investigate the complex dynamic problem under consideration by a simplified approach that makes it possible to trace the formation of dynamic vortex structures and their evolution using a reasonable amount of computer time. First, because of the comparatively small charges of dust grains and comparatively large mean distances between them, we neglect their mutual interactions. Second, because of the low intensity of the radioactive source and low degree of ionization of the nuclear-track plasma created by it, we ignore the drag forces exerted on dust grains by drift ion flows, which are directed primarily downward, i.e., toward the grounded electrode (with the radioactive source) and the dielectric wall of the device. In future studies, we are going to consider how the drag forces influence the formation of dynamic vortex structures. In the model developed here, we take into account the interaction of grains with the electrostatic fields of both the electrodes of the device and its walls, the weight of the grains, and the effect of their friction with the buffer gas. The levitation of dust grains results from the balance between the gravity force associated with the mass of the grain and the electrostatic forces of the device, in which case the electrostatic fields are governed equally by the internal plasma processes and by the processes of recombination and adsorption of the charges on the walls. In our experiments, the electrostatic trap was created by the electrostatic fields of both a negative surface charge on the walls of the device and a positive charge of the electrode with a hole. The effect of the steady state positive space charge induced in the plasma near the radioactive source is insignificant because the electron mobility is much higher than the ion mobility. This effect will be taken into account in ongoing studies. Numerical modeling of the vortex structures of charged dust grains in the electrostatic trap of the device requires the use of convenient analytic expressions for the electrostatic potential that should correctly reflect its physical nature. The numerical results presented in this paper were obtained from the expressions derived in [3].

Dynamic vortex dust structures in a nuclear-track plasma were simulated using the standard method of molecular dynamics. This method usually assumes calculations for a finite number N of particles in a cell of size L. In order for the computations to take a reasonable amount of time on available computers, we restricted our simulations to $N = 200$–1000. Accordingly, in order for an MC cell to capture the characteristic dust structure, the linear cell size was chosen to be equal to $L = 100 r_D \approx 3$ cm, which approximately corresponds to our experimental conditions. Note that such a small cell size, as well as a smaller number of dust grains in comparison with that in the experiments, substantially relaxed the requirements on computational resources and made it possible to reduce the run time of the code to about ten hours. We modeled levitated dust grains in an electrostatic trap with the potential derived in [3]. The characteristic potential at the chamber wall was varied in the range from 0.5 to 3 V. The z-axis was directed downward, i.e., along the direction of the gravity force. The initial spatial distribution of dust grains and their initial velocities were specified with the help of computer-generated random numbers, distributed uniformly within the interval from zero to unity.

4. Discussion of the calculated results

Here, we present the results of numerical simulations carried out by the standard method of molecular dynamics

for a cylindrical volume in space. Figure 4a shows parts of the grain trajectories inside a planar vertical axial layer of small radial thickness. The trajectories were calculated at three successive times. The arrows indicate the direction of the grain motion. The physical cause of the onset of dynamic vortex structures is the dependence of the charges of both dust grains and the device walls on the distance from the source. In fact, let us consider a grain located near the upper electrode, in which case the grain's negative charge is small because its distance from the source is large. Under the action of the gravity force, which exceeds the electrostatic force of attraction toward the upper electrode, the grain starts falling downward, i.e., toward the lower electrode. In such motion, the grain charge, first, decreases and, then, begins to increase. A downward moving grain experiences increasingly strong radial fields of the dielectric walls, whose charge, in turn, increases near the radioactive source. The radial forces bend the grain trajectory and cause the grain to move toward the device axis and toward the radioactive source at the axis. On the other hand, as the charge of the grain increases, it is affected by the increasingly strong upward-directed electrostatic force of the positively charged upper electrode. Because of inertia, the grain passes the equilibrium position and its charge continues to increase until the electrostatic force becomes larger than the gravity force. The grain begins to move upward, keeping its radial velocity component unchanged, until the gravity force becomes larger than the electrostatic force. Then, this cycle of the grain's motion repeats itself. As a consequence, most of the grain trajectories are very similar in shape to the infinity symbol. In the axial region of the device, the grains move predominantly upward, while, in the peripheral region near the walls, the grains fall downward. As a result, a dynamic vortex structure forms that consists of dust grains rotating in the same direction as the vortex structures observed in our experiments.

We stress the following important feature of the results obtained here. In our study, the main attention is focused on energy transfer from the radioactive source, which creates the plasma, to the disperse grains. The energy-transfer mechanism is associated with the variation in the charge of a moving dust grain. The charge of the grain is a function of its spatial coordinates and also depends on the energy parameters of the inhomogeneous plasma closely around it. Hence, the above system of levitated dust grains is an open system, which exchanges energy with its surrounding. Following [4], we assume that the electrostatic forces acting upon the grains are potential in character. As a result, these forces (which are defined as minus the spatial gradient of the potential energy) are described by two types of terms. The terms of the first type are formally similar in structure to those describing the Coulomb forces of particles with coordinate-dependent charges. The terms of the second type (non-Coulomb correction) account for the dependence of the charges on the spatial coordinates and are represented in terms of the gradients of the grain charges and the gradient of the surface charge on the dielectric walls of the device. Note that the effect of the surface charge is equivalent to that of an effective macroparticle. Non-Coulomb forces are directed opposite to the gradient of the absolute value of the grain charge and displace a dust cloud toward the region where the grain charges and, accordingly, the Coulomb repulsion energy in the device are both minimum.

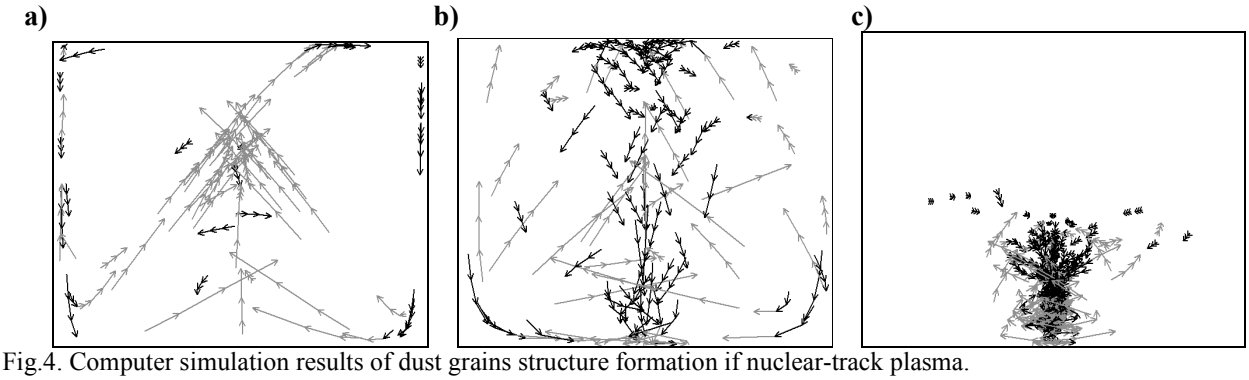

Fig.4. Computer simulation results of dust grains structure formation if nuclear-track plasma.

In the alternative approach [5], the electrostatic forces acting upon the dust grains in a plasma are assumed to be Coulomb forces $|F| \sim q(r_1)q(r_2)/| r_1 - r_2 |$ with coordinate-dependent grain charges. However, as was noted in [5], these forces cannot be represented in terms of the gradient of a certain effective potential. Consequently, the

terms describing these forces do not contain the charge gradient, as is the case with the terms of the second type. The results obtained from the alternative approach [5] for the same parameters and the same model device as in Fig. 4a are illustrated in Fig. 4b, which again shows parts of the grain trajectories inside a thin planar vertical axial layer, calculated at three successive times. We can see the formation of a vortex structure in which the grains rotate in two opposite directions, which, however, contradicts our experimental observations. Hence, a comparison of the results of numerical modeling with experimental data clearly indicates the potential character of the forces acting upon the grains in a nuclear-track dusty plasma.

The effect of the frictional forces exerted by the buffer gas on the dust grains is illustrated in Figs. 4c, which shows parts of the grain trajectories inside a vertical axial layer of small radial thickness in the model device, calculated at three successive times. The frictional forces were calculated from Stokes' law. The computations were carried out using the above two approaches. We can see that, under the action of the frictional forces, the linear dimensions of the dynamic vortex structures of dust grains become several times smaller than in the initial stage and the structures themselves evolve to a nearly steady stable state analogous to that simulated by the MC method in [5]. The calculated time evolution of the vortex structures agrees qualitatively with the experimental observations illustrated in Fig. 1. The supplemented video clip shows the simulated 3D motion of the dusty particles in the chamber of our experimental device. Red particles are moving upwards, while yellow particles are moving down. With the time evolution the size of the vertexes becomes smaller due to the friction energy losses. Detailed analysis of this motion is discussed above and the schemes of the trajectory in the thin axis layers are presented on Fig.4a and 4c.

Abstract

The erosion of soot in a non-thermal, atmospheric pressure plasma has been modelled using a simplified, two layer, kinetic scheme for the surface reactions coupled with a gas-phase reaction mechanism that is appropriate to diesel exhaust gas. Experimental measurements of the rate for carbon erosion and the evolution of CO and CO_2 have been used to validate the model which has been extended to investigate the role of NOx, OH radicals and ozone in the plasma oxidation of the soot.

1. Introduction

Future legislative limits mean that it is necessary to substantially reduce the levels of pollutants such as oxides of nitrogen (NOx) and particulates in the exhausts from diesel engines. One approach is to use a non-thermal plasma or a hybrid plasma-catalyst system which has the potential for the removal of both NOx and particulates.

The work at Accentus on plasma aftertreatment has been reported previously [1,2] and it has been shown that it is possible to remove up to 99.9% of particulate matter of diameter around 60 nm. In support of this, a programme of chemical kinetic modelling of diesel exhaust aftertreatment has been undertaken. This has the objectives of aiding the understanding of the underlying principles behind the remediation processes, the improvement of these processes, and the prediction of aftertreatment performance under conditions not investigated by experiment. This paper describes the study of the heterogeneous oxidation of carbonaceous soot representative of particulate matter in diesel exhaust.

2. Experimental

The plasma reactor used for the experimental calibration tests was a single Dielectric Barrier Discharge (DBD) reactor. This consists of two concentric cylindrical electrodes; the inner electrode being the dielectric barrier in the form of a metal electrode in intimate contact with a surrounding alumina dielectric tube. The design is however flexible so that single or double dielectric barrier configurations can be evaluated. The reactor has the option of being packed with a filter material such as ceramic pellets *e.g.* 3-4mm diameter alumina spheres, fibres or monolithic type structures. The DBD reactor was powered by a 1-5 kHz AC power supply with typical applied voltages ranging from 3-15 kV resulting in plasma energy densities controlled up to ~100 J/L.

Gaseous analysis was performed using a Signal MaxSys 900 series emissions rack measuring NO_x, NO, CO_2, CO, O_2 and total hydrocarbon (THC). Hydrocarbon was measured using Flame Ionisation Detection (FID), NO / NOx using chemiluminescent analysis (CLA), CO & CO_2 using an Infra Red analyser and O_2 via a paramagnetic analyser. An FTIR (Bowmen Work*ir* / 2m gas cell pathlength; resolution $1cm^{-1}$) was used to crosscheck the THC and NOx emissions from the FID and CLA.

Experiments were performed using a pre-loaded, packed bed reactor in which the ceramic pellets were coated with carbon black (Degussa) to give a loading of about 500 mg of carbon. Soot oxidation runs were carried out at 200 °C and 300 °C with an atmospheric pressure gas stream for a fixed plasma energy density. The evolution of CO and CO_2 was recorded for varying deposited energy densities and the effect of added NOx upon the CO and CO_2 levels was also investigated.

3. Modelling

The modelling of the surface reaction chemistry is based on the mechanism detailed in Table 1. This was developed in a step-wise and systematic manner to explain the experimental results. The model represents the soot as two distinct layers. The chemistry and erosion takes place in an outer surface layer (C_s). The second layer is an inner or bulk layer which contains most of the mass of the soot (C_b). Site vacancies in the outer layer (X_s) are immediately replaced by carbon from the inner bulk layer (Reaction 5). Soot that is deposited from the gas phase as elemental carbon is absorbed into the sub-surface bulk layer (Reaction 6). The oxidation or erosion rate of the soot is given by the change in mass of the bulk layer as a function of time. The model reproduces the surface to volume ratio of the experimental reactor. This simplified two layer model derives from the work of Wicke *et al.*[3] and Mitchell *et al.*[4] It is assumed that the first step is the rapid adsorption of atomic and molecular oxygen onto the carbon surface followed by reaction to form surface adsorbed CO (Reactions 1 and 2) which can either react in a Langmuir-Hinshelwood type of mechanism to give CO_2 (Reaction 4) or desorb into the gas phase (Reaction 3). This last process is relatively slow. The rate constants are derived from the work of Wright [5], Laurendeau [6], Mitchell *et al.* [4], Backreedy *et al.*[7] and Bews *et al.*[8] The surface density of the outer layer, C_s, is taken to be 15 $m^2\ g^{-1}$. In practice, this value may be considerably larger depending on the carbonaceous material being studied [9] and its porosity which may also change during oxidation. We use the model to investigate the effect of surface density upon erosion rate.

	Reaction	A	E_a / cal $mole^{-1}$
1	$C_s + O \rightarrow CO_s$	5.00×10^7	1000.0
2	$C_s + C_s + O_2 \rightarrow CO_s + CO_s$	1.15×10^{15}	15000.0
3	$CO_s \rightarrow CO + X_s$	1.00×10^2	0.0
4	$CO_s + CO_s \rightarrow CO_2 + C_s + X_s$	4.00×10^{13}	0.0
5	$C_b + X_s \rightarrow C_s$	1.00×10^{40}	0.0
6	$C \rightarrow C_b$	1.00×10^5	0.0
7	$C_s + OH \rightarrow CO_s + H$	5.00×10^7	1000.0
8	$C_s + NO_2 \rightarrow CO_s + NO$	7.30×10^{16}	7000.0
9	$C_s + O_3 \rightarrow CO_s + O_2$	1.25×10^7	1000.0

Table 1 The surface reaction mechanism for the plasma oxidation of carbon soot. The subscript –s represents surface bound species and the subscript – b, the bulk sub-layer. Rate constants are in the form $k = A \exp(- E_a / RT)$, where A is in the units of cm^3, mol, s, as appropriate to the reaction order.

In the final stages of the modelling, gas-phase chemistry was also included in the model to simulate the presence of diesel exhaust gas mixtures. Typically, this included 10% O_2, 400 ppm propene, 500 ppm NO, 50 ppm NO_2, balance N_2. This enabled us to investigate the competition between homogeneous and heterogeneous reactions for important species such as NOx, OH radicals and atomic oxygen. The gas-phase hydrocarbon mechanism which has been extensively validated by experimental plasma measurements is outlined in Figure 1 and is detailed elsewhere [10].

The chemistry involved in the plasma processing is modelled using a FORTRAN program, PELLSOOT, which is based on the chemical kinetics package, SURFACE CHEMKIN-II [11]. Following the method of Gentile and Kushner [12,13], we assume that there is uniform processing of the gas as it passes through the reactor. During each half-cycle, the microdischarge current pulses create active species which then go on to initiate or continue the chemistry. In our model, a fresh supply of the active species is injected into the reaction mixture at each pulse and the chemistry is allowed to continue until the next pulse. The modelling continues until the experimental residence time (determined by the gas flow rate and the reactor volume) when the processing ceases and the final concentrations are output. We calculate the densities of the species produced in the discharge using the program ELENDIF [14] which indicates that atomic oxygen is the only

significant reagent produced at the plasma energy densities used in this work. Other reactive radicals such as OH may be produced by secondary gas-phase reactions.

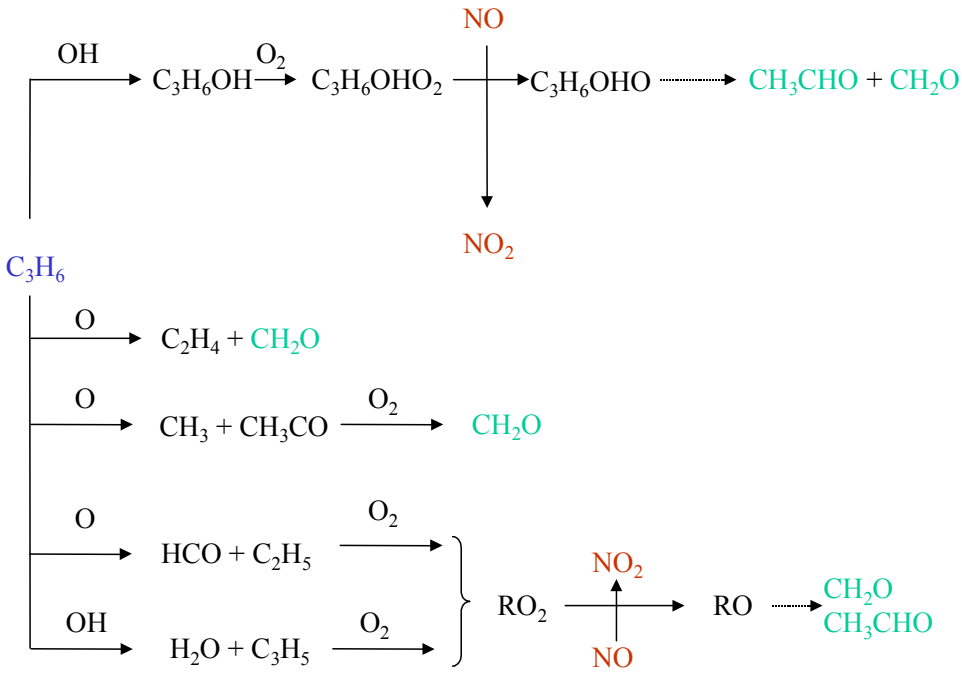

Figure 1 A schematic representation of the gas-phase reaction mechanism for propene oxidation in the presence of NOx

4. Results and Discussion

Figure 2 shows the measured evolution of CO and CO_2 resulting from the plasma oxidation of a packed bed of carbon black at 200 °C using a gas flow of 10% O_2, 90% N_2. It can be seen that the gases are evolved almost immediately upon switching on the plasma, reach a steady-state concentration and then decrease when all the soot has been removed by oxidation. The ratio of CO_2 to CO remains constant at about 2.5. Wicke et al. [3] found a value of between 1.6 and 2 for the same ratio when studying the oxidation of paraffin soot by atomic oxygen at room temperature. The oxygen atoms were produced by microwave dissociation of molecular oxygen at a pressure of 1 Torr in their experiment.

Figure 3 shows the results of the modelling of the soot erosion and the consequent evolution of CO and CO_2 using reactions 1 – 6 in Table 1. The time scale is limited by computational restrictions but it can be seen that it successfully models the form of the experimental measurements shown in Figure 2 and accurately reproduces the concentrations of the evolved CO and CO_2 and their measured ratio. Figure 4 shows the comparison of the modelling with the experimental measurements of the evolution of CO and CO_2 studied as a function of the energy deposited into the plasma (in J / litre). This deposited energy effectively controls the amount of atomic oxygen produced in the discharge. Again the agreement is good, although the curvature observed experimentally for the CO_2 evolution is not reproduced in the modelling. The modelling shows that the soot erosion rate is linear with the concentration of atomic oxygen supplied by the plasma discharge and that it is non-linear in temperature. The calculated erosion rates range between $1 - 20 \times 10^{-5}$ g s^{-1} at 200 °C. Another parameter that determines the calculated erosion rate is the surface density of the soot in the surface layer that is being eroded. A change in the surface density from 10 to 50×10^{-8} mol cm^{-2} increases the erosion rate by a factor of about 3.

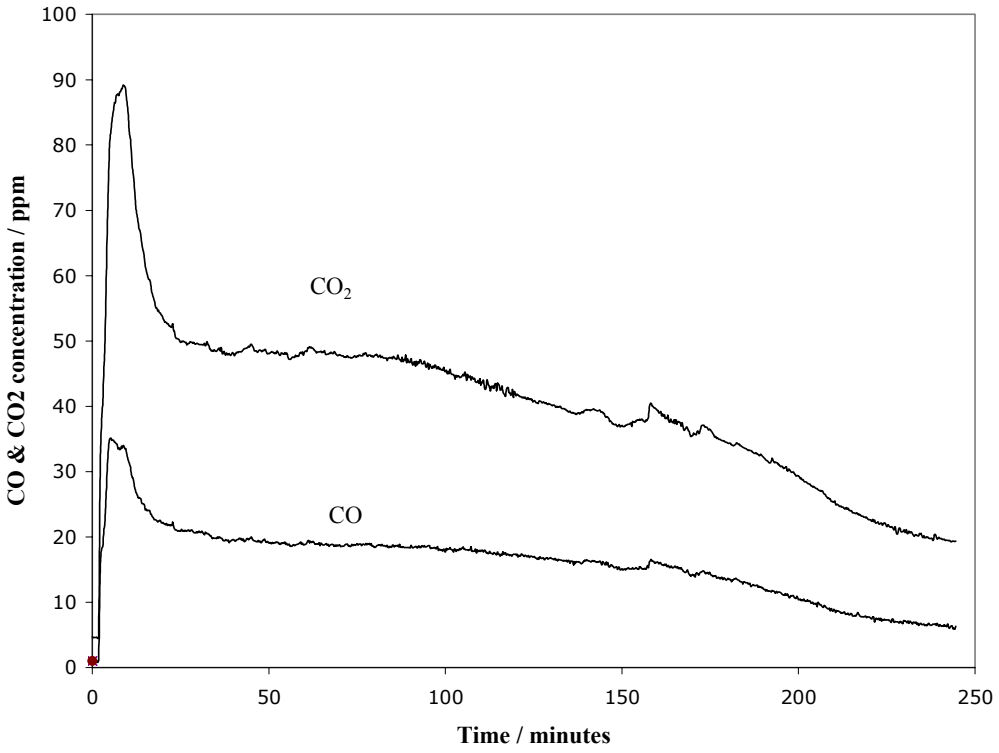

Figure 2 The time evolution of gaseous CO and CO_2 resulting from plasma oxidation of a packed bed of soot at 200 °C..

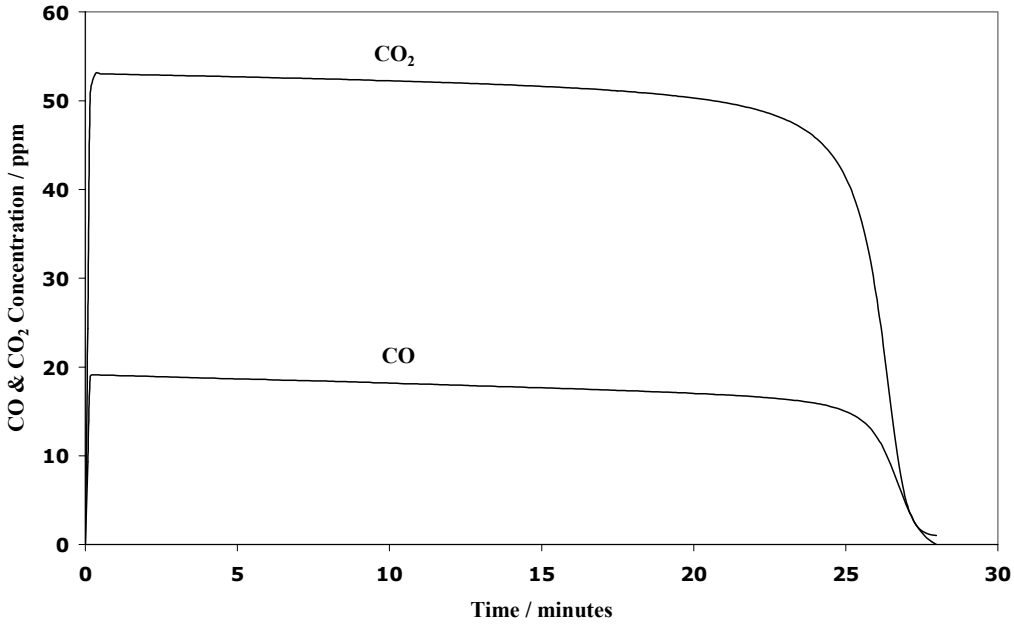

Figure 3. The modelling of the evolution of CO and CO_2 for the plasma oxidation of soot at 200 °C in 10% O_2, 90% N_2.

When the gas-phase chemistry appropriate to diesel exhaust gas is included in the plasma discharge in addition to the surface chemistry, reactions of additional species need to be considered. These include the oxides of nitrogen (NOx), ozone (O_3) and the hydroxyl radical (OH). In the absence of the simulated diesel exhaust gas with its hydrocarbon component, we find that the addition of NO (the major component of NOx in the diesel exhaust) to the reactor inhibits the formation of CO and CO_2 and decreases the oxidation rate. A similar observation has been made by Wicke and Grady [15] who attribute the reduction to the absorption of NO onto the soot surface blocking potential sites for the oxidation by the adsorption of atomic oxygen.

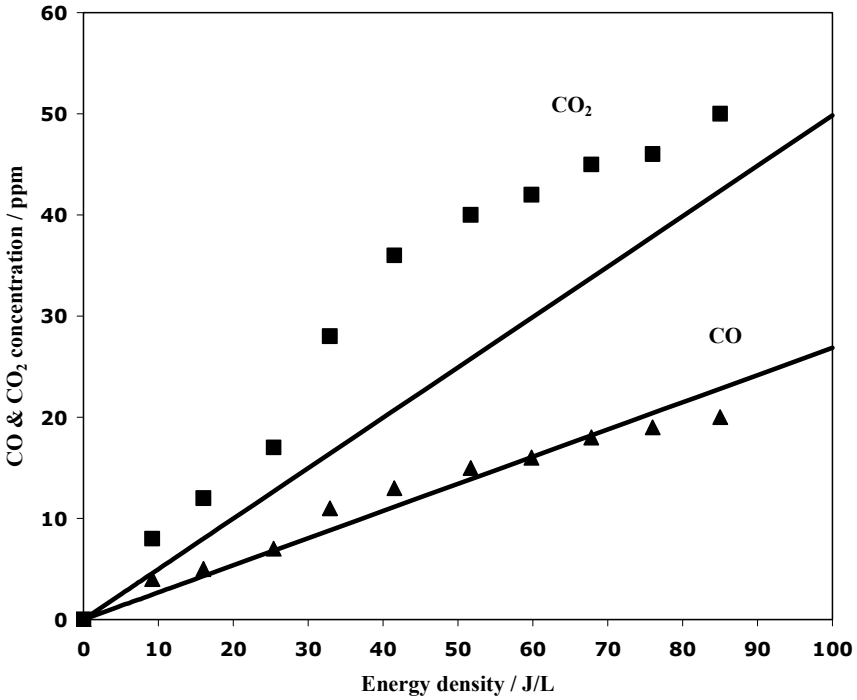

Figure 4. The variation of gas evolution as a function of the plasma deposited energy. The experimental measurements are represented by points (■ CO_2; ▲ CO) and the modelling results are the solid curves.

However, when propene is added to the system rapid gas-phase reactions convert the NO to NO_2. These reactions mainly involve HO_2 and peroxy radicals, RO_2, and are indicated in Figure 1

$$NO + HO_2, RO_2 \rightarrow NO_2 + OH, RO.$$

This conversion is the first stage of plasma remediation of NOx and the use of catalytic converters downstream of the plasma to reduce the generated NO_2 into N_2 and O_2 is the subject of much current research. However, it is known that NO_2 participates in the oxidation of soot via reaction 8 in Table 1 resulting in a heterogeneous conversion of the plasma generated NO_2 back to NO. Dorai and Kushner [16,17] have shown that the extent of this back conversion depends on the amount of soot present. We find that in the presence of 400 ppm of propene, the soot oxidation rate increases markedly for the addition of 50 ppm of NO and then becomes constant for NO concentrations above about 100 ppm.

It is known that OH radicals are more reactive than O atoms towards the oxidation of graphite at 298 K [18]. It might be expected then that in the presence of the hydrocarbon component of the simulated diesel exhaust where OH radicals are produced and play an important part in the gas-phase mechanism, there would be considerable enhancement in the soot oxidation rate via reaction 7. However, the model shows only a very modest increase in the oxidation rate of less than 10% when reaction 7 is included. This can be rationalised

when it is realised that OH radicals are very reactive in the gas-phase and participate in a chain reaction in which the hydrocarbon is oxidised. This means that the steady state concentration of OH radicals is very small and there are very few available to oxidise the soot.

In gas flows that do not contain hydrocarbon or NOx, it is possible to generate ozone when oxygen atoms are in excess. This will reduce the oxidation rate unless the mechanism correctly accounts for the oxidation of carbon by ozone (Reaction 9). It was found that a rate that is about 25% that for oxidation by atomic oxygen (Reaction 1) is required. When the simulated gas stream containing hydrocarbon and NOx representing diesel exhaust is used, it is possible that ozone is an important transient intermediate in the gas-phase chemistry. However, no net ozone is produced in the gas phase and surface oxidation *via* Reaction 9 does not take place.

5. Conclusions

We present a simplified model for the oxidation of soot by the products of a plasma discharge that considers two distinct surface layers or regions. We find that this is able to account for the measured rate of carbon erosion and the evolution of CO and CO_2 in plasma discharges of O_2 / N_2 gas streams. The model has been used to examine the effect of soot erosion when the gas stream is chosen to be representative of diesel exhaust gas using a simplified gas-phase mechanism that has been previously validated under a range of experimental conditions. In this way, the role of NOx, OH radicals and ozone has been investigated. The versatility and simplicity of the model will allow it to be used to examine a range of experimental conditions in a time-efficient manner. It is our aim to continue to support this modelling activity with a range of experiments that can be used to further validate and extend the model.

Analysis of plasma-generated radicals on polymer surfaces

B. Finke, A. Meyer-Plath[1], K. Schröder, A. Ohl

Institut für Niedertemperatur-Plasmaphysik, Greifswald, Germany

Abstract
Plasma functionalisation in gas phases like ammonia allows to equip polymer surfaces with amino functional groups. An important question of this functionalisation consists in the limited knowledge about heterogeneous interface reactions, especially radical formation and subsequent reaction processes. Useful analytical methods comparable to those available for gas phase reactions are scarce. Here we report on investigations of plasma generated C-radicals by NO-labelling, showing similar effects for different plasmas.

1. Introduction

For novel applications of plasma functionalised polymer surfaces, progress in quality of surface functionalisation is desirable with respect to selectivity and efficiency. Polymer surface radicals created during the plasma process by bond scission play a prominent role for heterogeneous surface reactions and give rise to post – process oxidation.
Several papers deal with the investigation of radical formation in plasma treated polymers. Kuzuya et al. [1] studied plasma induced surface radicals of polyethylene (PE) by ESR. Another group [2] used diphenyl-picrylhydrazyl (DPPH) as radical scavenger for the same purpose. This liquid phase reaction has some disadvantages such as altering the surface only by the DPPH solution. Holländer et al. [3] investigated the formation and subsequent reaction of VUV- and hydrogen plasma generated radicals on surfaces of polyethylene (PE), polypropylene (PP) and polystyrene (PS) by using the scavenger nitrogen monoxide NO. The gaseous NO belongs to the few natural and reactive compounds with a lone electron and is therefore particularly suitable for a radical verification. Plasma generated primary, secondary and tertiary carbon radicals react with NO in a different way (see fig. 1). The produced nitrogen and/or oxygen containing functional groups can be differentiated by X-ray photoelectron spectroscopy (XPS) using the N1s region by analysis of their chemical shift. Radical concentrations are linearly correlated to the added nitrogen by reaction with NO. The present work studies surface radicals on polystyrene generated by cw and pulsed microwave-excited plasmas in Ar and NH_3.

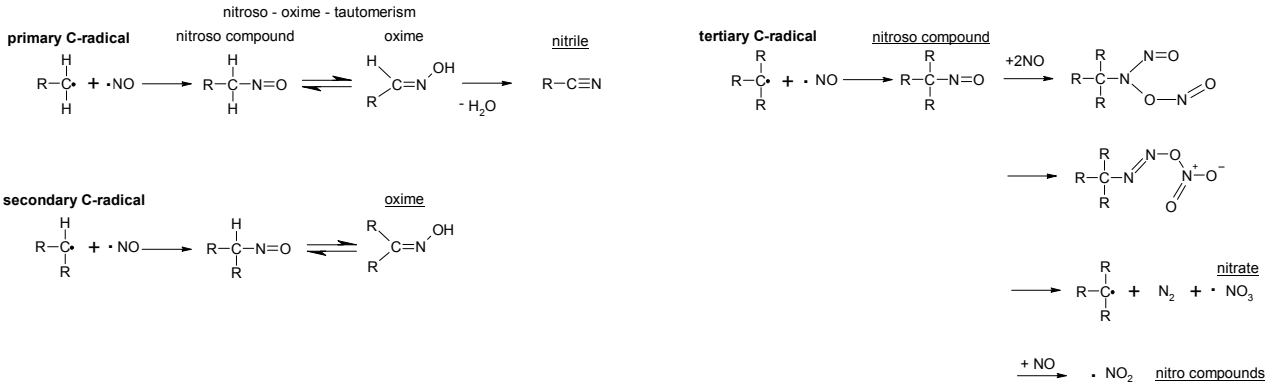

Fig. 1: Reaction of different C-radicals with NO after [3]

2. Experimental

2.1 Processing

Surface functionalisation processes are extremely sensitive to process contaminations. For this reason extraordinary diligence was set to a clean process environment. The experiments were performed in a UHV cluster tool which combines clean plasma reactors with *quasi in situ* XPS analysis and gas phase derivatisation [4]. After switching off the plasma, the samples were transported via the UHV-transfer system

[1]present address: *Bundesanstalt für Materialprüfung und –forschung, Berlin, Germany*

to the XPS and the derivatisation chamber, respectively. The separately pumped UHV-transfer system ($p = 10^{-8}$ mbar) ensures contamination free sample exchange between the three subsystems. In order to avoid wall contamination, the UHV-plasma reactor (base pressure: circa 10^{-7} mbar) was kept all the time free of oxygen-containing gases. Oxygen impurities are known to reduce the nitrogen functionalisation efficiency [5]. Several additional techniques have been applied to reduce the residual contamination level of oxygen and for our purposes also nitrogen, as much as possible. Nonetheless, a small but noticable nitrogen contamination was verified on Ar-plasma treated PS surfaces without NO-derivatisation (see fig. 3). The MW plasmas were generated in surface-wave-sustained (SWS) mode forming a radially-spread plasma glow of 22 cm in diameter in close contact to the MW-coupling window. Their thickness varied with pressure, being about 2 cm at the standard pressure of 0,1 mbar (NH_3-plasma) and 1 mbar (Ar-plasma) respectively. The polymer samples were treated in the afterglow 9 cm below the active plasma zone.
Experiments were carried out in continuous wave (cw) and in pulsed (pp) plasma mode. In the pp mode, the *effective* treatment duration, i.e. the product of duty cycle and *total* treatment duration was kept constant at 9.6 s (1 ms pulse / 100 ms pause). The gas flow rate was 15 sccm NH_3 and 20 sccm Ar, respectively. A detailed study of the excitation mode is given in [6].

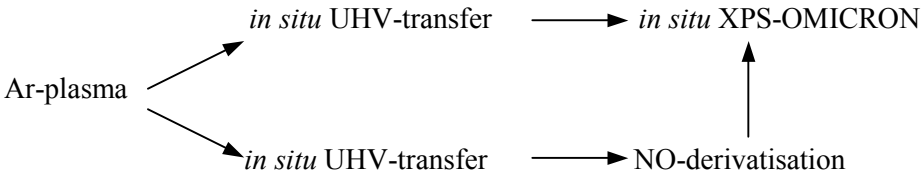
2.2 Surface Diagnostics

A special measuring procedure was employed to analyse radicals after having reacted with NO both *in situ* and *ex situ* by means of X-Ray Photoelectron Spectroscopy (XPS). The results of the quasi *in situ* XPS (EA125 U5, OMICRON, Taunusstein, Germany, unmonochromatic Mg-K_α-line) surface analysis were combined with high resolution measurements of the *ex situ* XPS (Axis Ultra, KRATOS, Manchester, GB). The ascertained *in situ* XPS values were calibrated by the *ex situ* values of the high quality machine. In fig. 2 and 4, examples are given for the achieved quality of a peak fit performed in this manner. Quantification of the amino groups was achieved *ex situ* via fluorine surface density after derivation reaction with trifluoro-methylbenzaldehyde (TFBA) [7,8]. The radical verification was carried out with NO at 400 mbar and ambient temperature in a stainless steel derivatisation chamber for 1 h. 5 minutes were needed for the sample transport from the reactor to the derivatisation chamber.

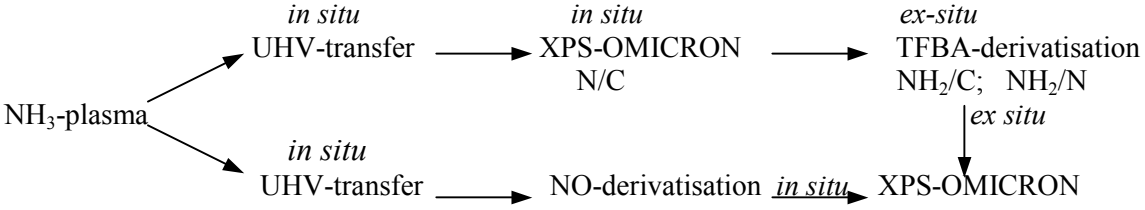
2.3 Experimental procedure

First investigations were realised with a pure Ar-plasma. Meta stable Ar-species are known to efficiently create surface radicals on polymers. For the pure Ar-plasma, no nitrogen contribution from the plasma process should be considered in a clean plasma reactor. But as mentioned above, it´s not as simple as that (see 2.1). The slight nitrogen incorporation could be clearly identified by XPS. However, the attained knowledge on the quenching NO reaction allowed to extend the radical quantification method to surfaces that were subjected to nitrogen–containing plasmas.
The **procedures** are characterised by the following schemes:

A) Ar-plasma



B) NH_3-Plasma a means of amino functionalisation and radical proof



ex situ XPS-KRATOS (high resolution)

According to the schemes, the plasma experiments with and without NO based radical verification were carried out parallel. That means every "normal" Ar- or NH_3-plasma treatment was accomplished by a second, identical experiment, which includes the NO-derivatisation procedure. Polystyrene (PS) was investigated (FalconTM tissue culture dishes, Becton-Dickinson, NJ,USA) and used without further chemical cleaning.

3. Results and discussion

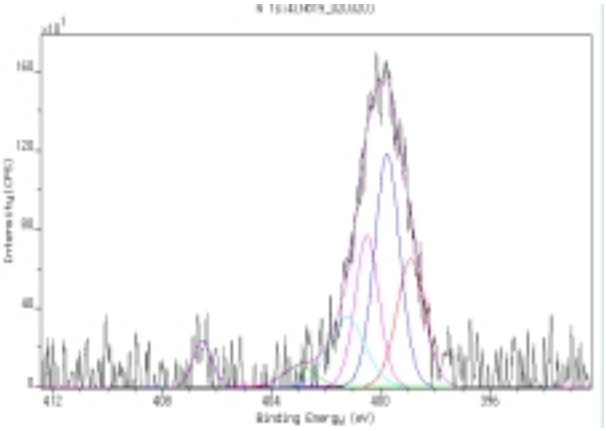
3.1 Analysis of plasma generated surface radicals

Radical creation efficiencies were very similar for cw Ar- and NH_3-plasmas. Quenching reactions with NO were used to explain the formation of different nitrogen-containing functional groups and their derivation from primary, secondary and tertiary carbon radicals. The reaction products for instance amines, oximes, nitroso and nitro compounds, nitrites and nitrates appear at significantly different chemical shifts in the XPS N1s region and were determined by peak fitting, following a formal procedure similar to that suggested by [3]. Conclusions on the concentration of radicals were possible, in our case as difference of the N/C concentrations after the plasma process without and with NO-derivatisation.

3.1.1 Ar-plasma

Comparison between the peak fitting of the XPS-KRATOS and the XPS-OMICRON *in situ* measurements for one and the same sample with NO-derivatisation are exemplified in fig. 2 and fig. 4. Certain differences between *in situ* and *ex situ* XPS spectra become generally apparent. Especially the $–NO_2$ and $–NO_3$ peaks disappear *ex situ* by exposure to air. This cannot be explained until now.

Fig. 2: *ex situ* XPS Kratos measurement of the N1s peak **with** NO-derivatisation (PS; 35s cw Ar-plasma).
The peak fit procedure applied below were derived from such highly-resolved scans. While the peak position was exactly allotted, the peak width was not considered.



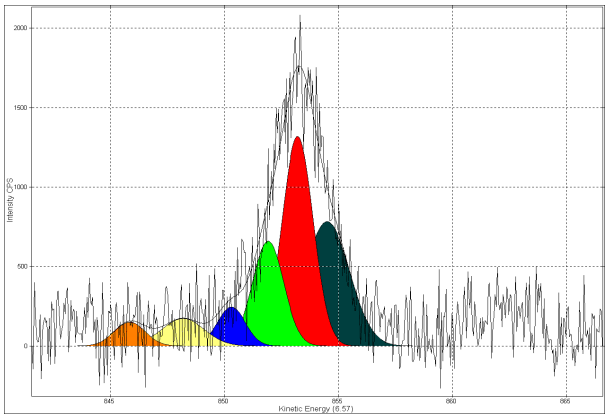


Fig. 3: *in situ* XPS measurement of the N1s peak **without** NO-derivatisation (PS; 35s cw Ar-plasma).
The reactor wall contamination leads to the N1s peak.

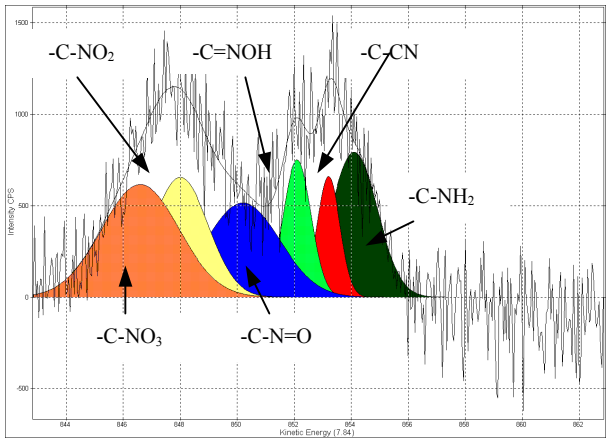

Fig. 4: *in situ* XPS measurement of the N1s peak **with** NO-derivatisation (PS; 35s cw Ar-plasma).

Interestingly a PS-surface after cw Ar-plasma treatment without *in situ* NO-derivatisation (fig. 3) shows N1s peaks for nitrogen in different binding states - a sign for residual reactor contamination. After NO-derivati-

sation a second broad peak appears at binding energies of 403 – 408 eV which can be assigned to the reaction products of tertiary C-radicals with NO.
The formal peak fit shows the following results:
For primary and secondary radicals reaction products are amines –C-NH_2, nitriles –C-CN and oximes –C=N-OH >>> N1s peak in the XPS spectrum between 397 eV and 402 eV
For tertiary radicals reaction products are nitroso –C-N=O and nitro compounds –C-NO_2 as well as nitrates –C-NO_3 >>> a second N1s peak between 403 eV and 408 eV

A more detailed picture arises by quantification of the possible nitrogen functionalities (fig. 5) and drawing comparison of the presented bands.

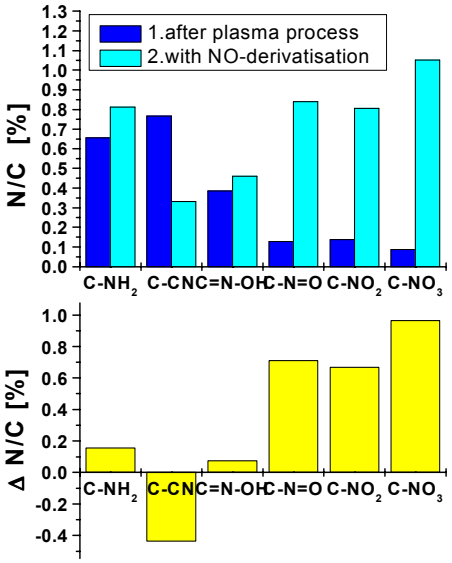

Fig. 5: Detection of surface radicals (PS, 35s cw Ar-plasma, *in situ* N1s-XPS)

Comparison of NO-derivated and not derivated polystyrene:
The available species like amines, nitriles, oximes, nitroso and nitro compounds, nitrites and nitrates were generated in an Ar-plasma in a dimension up to circa 1 % N/C each.
Clearly the differences of the fitted peak areas ΔN/C show the predominant formation of approximately 2.3 % tertiary radicals/C. In parallel to that conclusion a comparative calculation of the whole nitrogen content N/C after NO-derivatisation minus N/C after plasma treatment of XPS measurements results in good agreement 2.2 % radicals/C.
Obviously, the existence of primary and secondary C-radicals is questionable, because the markers are only small for these functional groups and even negative in the case of the nitriles –C-CN.

3.1.2 NH_3-plasma
The procedure of radical verification for the cw Ar-plasma could be successfully transferred to cw and pulsed NH_3-plasma. Fig. 6 and 7 show the peak fit of the N1s bands of polystyrene treated with 40 s cw NH_3-plasma first after the plasma process and second with NO-derivatisation. Analogous results for a pulsed NH_3-plasma are given in fig. 8 and 9. The measured, not NO derivatisated N1s XPS peaks (fig. 6 and 8) at approximately 399 eV characterise the accomplished plasma process, in this case the amino functionalisation. Note that tertiary radicals are really not marked here. However C-radicals are present as shown after NO-derivatisation. The NH_3-plasma process therefore appears to be a clean process. After NO-derivatisation additional to the known first peak a second N1s peak appears at circa 405 eV in the XPS spectrum (fig. 7 and 9). Radical creation processes seem to be very similar to the Ar-plasma, but there exists also appreciable differences in quantity (see fig. 10).

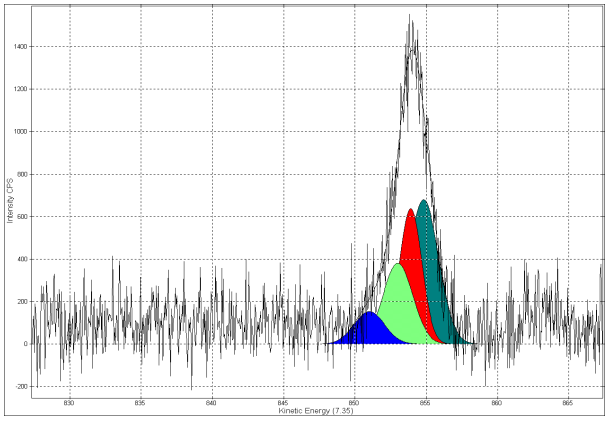

Fig. 6: *in situ* XPS measurement of the N1s peak **without** NO derivatisation (PS; 40 s cw NH_3-plasma).

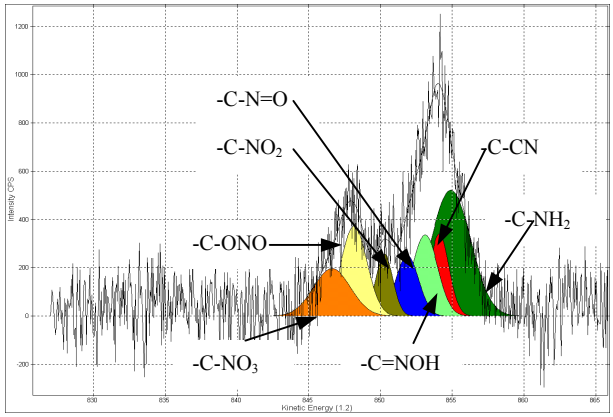

Fig. 7: *in situ* XPS measurement of the N1s peak **with** NO derivatisation (PS; 40s cw NH_3-plasma)

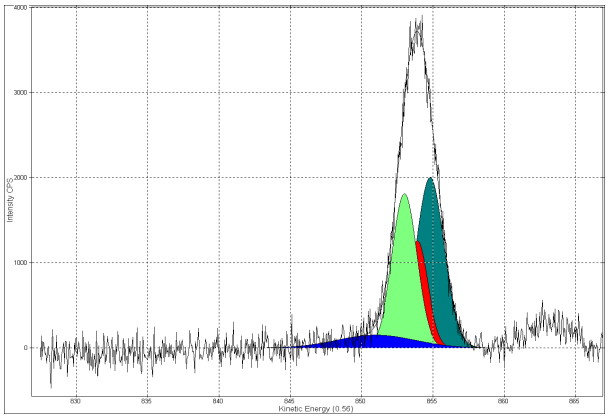

Fig. 8: *in situ* XPS measurement of the N1s peak **without** NO derivatisation (PS; 10s eff. pulsed NH_3-plasma)

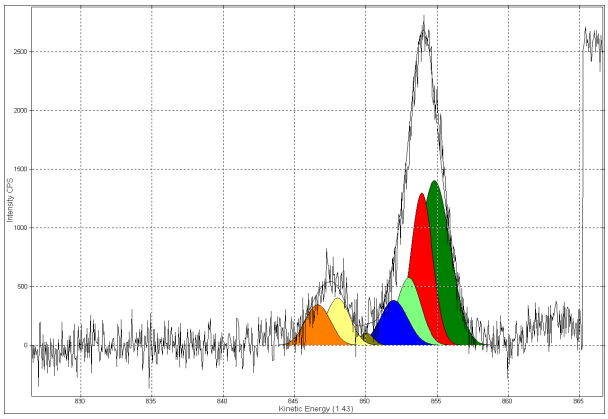

Fig. 9: *in situ* XPS measurement of the N1s peak **with** NO derivatisation (PS; 10s eff. pulsed NH_3-plasma)

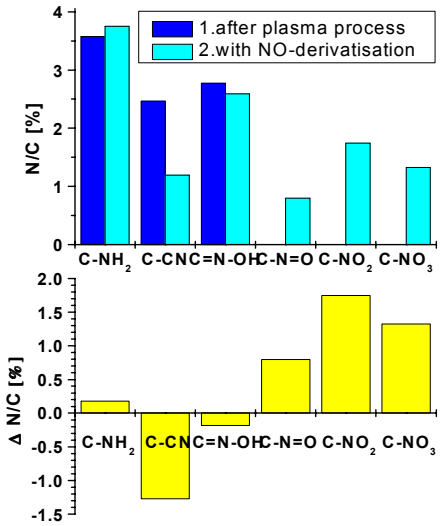

Fig. 10: Detection of surface radicals (PS; 40 s cw pulsed NH_3-plasma, *in situ* N1s XPS

Comparison of NO-derivated and not derivated polystyrene, activated with a cw NH_3-plasma are given in fig. 10. Nitrogen containing functional groups were generated in an cw-NH_3-plasma in a dimension up to circa 4 % N/C. The difference of the fitted peak areas ΔN/C shows the predominant formation of approximately 3.8 % tertiary radicals/C.
Obviously, here as in the case of the Ar-plasma the existence of primary and secondary C-radicals is questionable.
First results were obtained with a pulsed NH_3-plasma exhibiting nitrogen containing functional groups in a dimension up to 11-12 % N/C. The nitrogen entry is considerable higher in a pulsed than in the cw NH_3-plasma mode. But it is also known that the NH_2-efficiency and -selectivity is lower than in the cw-plasma mode [6]. Further investigations are necessary in this case.

Nevertheless, the amino functionalisation may be not affected by the NO derivatisation. That is surprisingly, because NO could react with NH_2-groups. From the experiment it is known that 50 % of the surface nitrogen are NH_2-groups.That can be also observed in an Ar-plasma.

3.2 Post Plasma Processes

An accompaniment of the amino functionalisation processes are the post-plasma processes with oxygen. This may be ascribe also the effect of tertiary radicals.

It can be expected, that the storage stability of functionalised polymer surfaces can profit from a derivatisation with the scavenger NO. First results show, that the ageing of derivatised polymers is less pronounced. Post plasma processes appear to be less expressed after NO-derivatisation.

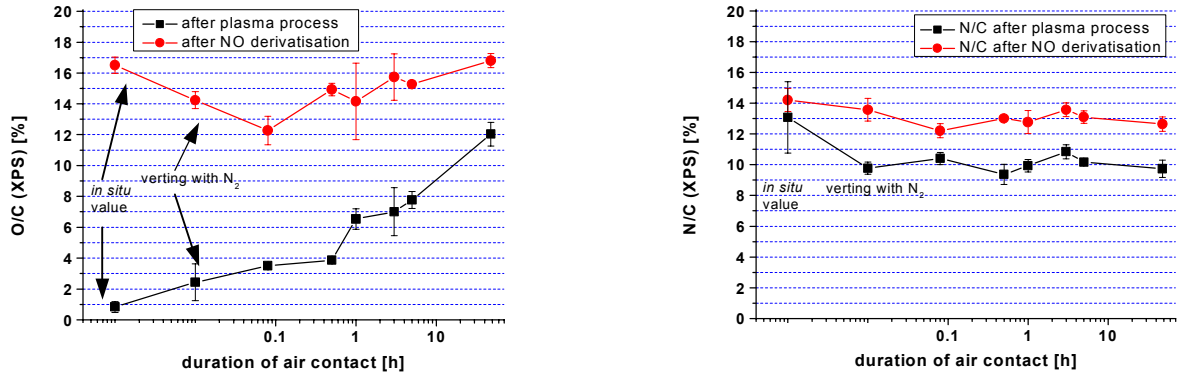

Fig. 12: Storage stabilisation of polystyrene after derivatisation with the radical scavenger NO.

4. Summary

Quenching reactions with NO were applied to investigate the formation of different nitrogen and / or oxygen containing functional groups and their derivation from primary, secondary and tertiary carbon radicals. Radical creation processes seem to be very similar in an Ar- and NH_3-plasma in the cw mode. It could be demonstrated that under the represented conditions tertiary radicals are expected to be predominatly formed. The amino group could react with NO, that doesn´t seem to be the case.

Abstract

For a better understanding of the reaction kinetics in complex media like diesel and gasoline engine exhaust, pulsed dielectric barrier discharge (DBD) in high repetition rate regime and low energy per pulse deposition were investigated into gas mixtures with composition more and more complex: from N_2-C_3H_6 mixture to N_2-NO-O_2-C_3H_6-H_2O-CO-CO_2 mixture simulating diesel engine exhaust.
Analysis of gas composition at the outlet of the plasma reactor revealed a variety of by-products depending on the inlet gas. Acetaldehyde (CH_3CHO), formaldehyde (CH_2O), methanol (CH_3OH), formic acid (CH_2O_2), methyl nitrate (CH_3ONO_2), formic acid (CH_2O_2), nitromethane (CH_3NO_2), and nitrous acid (HONO) are the main by-products observed.
Results show that NOx removal improves with increasing specific energy deposition. For exemple, in the case of simulated diesel exhaust, 60% of NOx have been removed at 26 J/l with a W-value less than 30 eV.

1. Introduction

Air pollution is becoming a serious problem as a result of combustion waste from stationary and automotive engines. As a potent technology, the non-thermal plasma (NTP) process has been studied extensively to remove air pollutants such as NOx, SOx, and volatile organic compounds (VOC) in the exhaust gas stream under atmospheric pressure.

NTP that has a low gas temperature and a high electron temperature can be produced by a variety of electrical discharge methods (pulsed corona discharge, barrier discharge, and dc discharge) [1-3] or electron beam irradiation [4-5]. Pulsed corona and dielectric barrier discharge (DBD) techniques are two of the more commonly used methods for producing electrical discharge plasmas. Regarding their intrinsic properties DBDs appear very well adapted to treat large gas quantities with relatively low energy cost. In these plasmas, the electrons do not react directly with the NOx molecules. The kinetic energy of the electrons is deposited mainly into the background gas molecules like N_2, O_2, and H_2O. The most useful deposition of energy is associated with the production of N, O, and OH radicals through electron-impact dissociation. These radicals are the active species of the plasma that eventually lead to the chemical conversion of NOx. Due to the presence of H_2O and O_2, plasma processing of NOx is dominantly oxidative resulting primarily in NO_2 and some extent in HNO_2, HNO_3. Also, hydrocarbons in exhausts have been found to play an important role in the NOx removal processes.

This paper will present the results of an extensive series of experiments aimed towards understanding the effect of gas composition on the NOx conversion chemistry in plasma. Pulsed dielectric barrier discharges in high repetition rate regime (up to 200 Hz) and low energy per pulse deposition (35 mJ/pulse) were investigated into gas mixtures with composition more and more complex (from N_2-C_3H_6 mixture to N_2-NO-O_2-C_3H_6-H_2O-CO-CO_2 mixture simulating diesel engine exhaust).

2. Experimental set-up

The experimental system consists of a continuous flow gas generation system, laboratory-scale dielectric barrier discharge (DBD) reactor, and a gas detection system (Figure 1). The system was described in detail previously [6] and is briefly described for clarity.

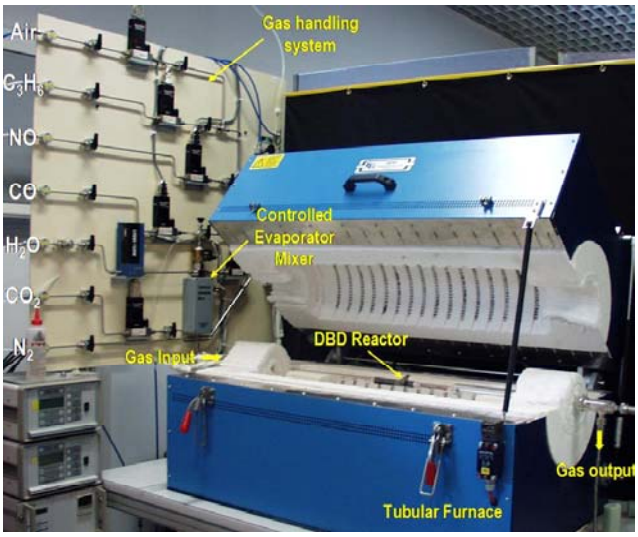

Figure 1: Schematic diagram of the experimental set-up.

Synthetic gas containing mixtures of O_2, N_2, NO, C_3H_6, CO, CO_2, and H_2O were prepared in a gas handling system. The gas composition was controlled with calibrated high-precision mass flow controllers. Water vapor with controlled concentrations was added to the gas mixture using a controlled evaporator mixer CEM®. It consists of a liquid flow control, a carrier gas control and a mixing chamber for liquid and carrier gas with heat exchanger for total evaporation. This device can provide a high reproducibility and a very stable water vapor flow. After mixing in the manifold, the gas then passes through a temperature-controlled line which preheats the gas and prevents condensation.

The DBD reactor (wire to cylinder type) was made of a quartz tube with 12 mm inner diameter and 1 cm wall thickness. The inner electrode was made of a 0.9 mm diameter tungsten wire and the other was a brass mesh. The length of the outer electrode can be adjusted and then determines the active volume of the DBD reactor. The results presented in this paper were obtained with a plasma volume of about 16 cm^3.

The DBD reactor is powered by a homemade high-voltage power supply. This pulse generator is capable of delivering high voltage pulses (up to 150 kV open circuit voltage) into 80 ns (FWHM) pulses and short rise times (40 ns) at variables repetition rates (up to the kHz). The fast voltage rise time allows achieving significant overshoot of breakdown voltages (several kV/ns) and allowing working at larger reduced field values (E/n) than in AC-conventional DBDs.

The electrical energy deposition in the plasma reactor was measured with a capacitive circuit. The input energy density, Joules per liter (J/l), is the ratio of the power deposited into the gas to the gas flow rate at standard conditions (25°C and 1 atm). Experimental conditions are listed in table 1

Discharge pulse energy	35 mJ/pulse
Discharge voltage	20 kV
Repetition rate	Up to 200 Hz
Gas flow rate	4 and 16 l/min

Table 1: Experimental conditions

The major gaseous components as NO, NO_2, CO, CO_2, and C_3H_6 were analyzed online and quantified using Fourier transform infrared absorption spectrometer (FTIR) equipped with a heated 10m-multiple pass absorption cell. An electrochemical NOx analyzer was also used for monitoring continuously NO, NO_2, NOx as well as CO levels in the gas stream.

3. Experimental results

The first set of experiments examined plasma processing of C_3H_6 (500 ppm) in N_2, and NO (500 ppm)-C_3H_6 (500 ppm) in N_2. Figure 2 shows the typical Fourier Transform Infrared (FTIR) spectra illustrated the plasma processing effect on these mixtures at room temperature and for an energy deposition of 27 J/l.

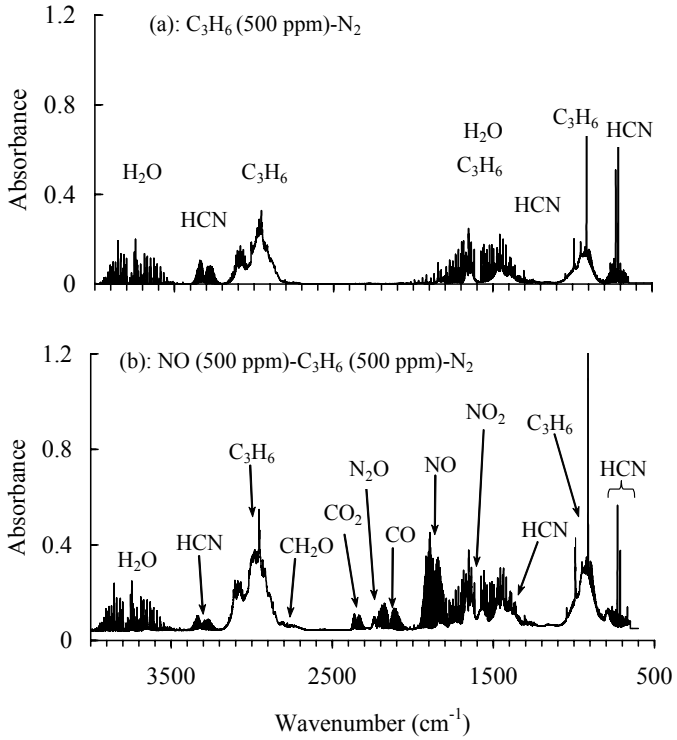

Figure 2: Typical FTIR spectra produced by plasma processing (27 J/l) of (a) C_3H_6 (500 ppm)-N_2 and (b) NO (500 ppm)-C_3H_6 (500 ppm)-N_2.

In the case of C_3H_6-N_2 mixture 50% of propene was converted at energy density of 53 J/l. This conversion leads to the production of hydrogen cyanide (HCN). When 500 ppm of NO was added to N_2-C_3H_6 mixture (case b), oxidation processes take place and NO_2, CO, CO_2 formaldehyde (HCHO) and nitrous oxide (N_2O) were observed.

Figure 3 shows the concentrations of C_3H_6, CO, NO, and NO_2 as a function of energy deposition. The NO to NO_2 oxidation is very weak (< 2%) and NO could be chemically reduced into nitrogen (N_2). The consumption of propene increases with increasing input energy. In that case, at energy deposition of about 53 J/l the measured reduction of C_3H_6 concentration is about 18%. This partial oxidation of propene lead to the production of a small amount of CO (30 ppm), CH_2O (15 ppm) and CO_2 (8 ppm).

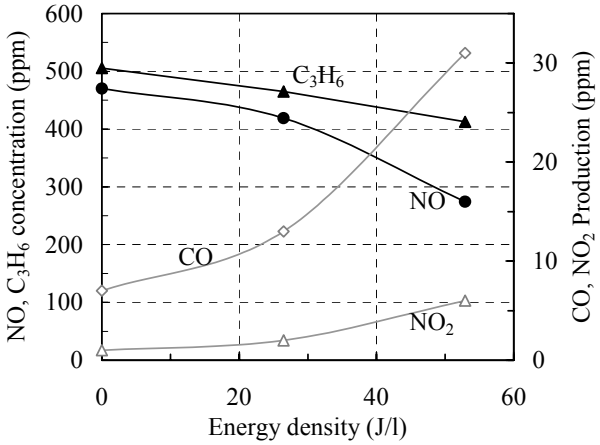

Figure 3: NO, NO_2, CO, and C_3H_6 output concentrations as a function of energy deposition. Inlet gas contains 500 ppm NO, 500 ppm C_3H_6, and balance N_2.

In the second set of experiments we study the following mixtures: O_2 (10%)-C_3H_6 (500 ppm)-N_2 and O_2 (10%)-C_3H_6 (500 ppm)-NO (500 ppm)-N_2. Figure 4 shows typical FTIR spectrum of plasma processing (27 J/l) effect on mixture without NO.

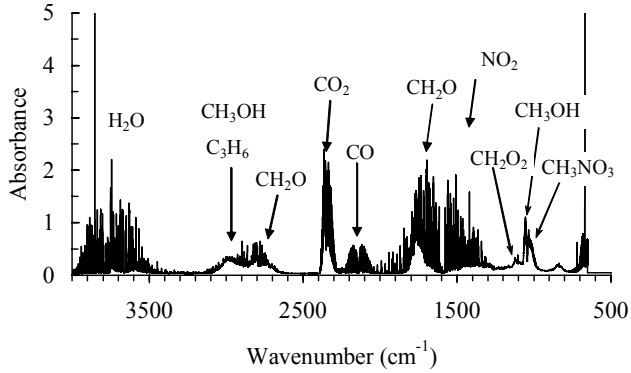

Figure 4: Typical FTIR spectrum produced by plasma processing (27 J/l) of O_2 (10%)-C_3H_6 (500 ppm)-N_2.

When NO was added to this mixture the spectra show a similar behavior and exhibit a high intensity signal in the absorption band of NO_2. Briefly, when the O_2 concentration is higher than 5% the plasma gas phase chemistry is initiated mainly by the production of oxygen radicals via electron induced dissociation of O_2. The dissociation of O_2 promotes the gas-phase oxidation of NO to NO_2. It is well known that when hydrocarbon is added to the gas mixture, NO to NO_2 oxidation is enhanced by large extent as the amount of hydrocarbon increase. The hydrocarbon act as a getter of O and OH radicals, with the resulting products reacting with O_2 to yield peroxy radicals (HO_2) which efficiently convert NO to NO_2.

As expected under these oxygen rich conditions, in addition of the main products of the plasma (NO_2, CO, and CO_2), the plasma partially oxidizes the hydrocarbons. Formaldehyde (CH_2O), methanol (CH_3OH), methyl nitrate (CH_3ONO_2), formic acid (CH_2O_2), and nitrous acid (HONO) are formed. This data are consistent with previously published results [14, 30].

Figure 5 shows CO, CO_2, and NO_2 concentration as well as C_3H_6 conversion rate as a function of energy deposition. At the maximum energy deposition used in that study (53 J/l), the NO to NO_2 conversion was ≈ 90%. The consumption of propene increases with increasing input energy. The reduction of C_3H_6 concentration is about 62%. Formaldehyde is one of the major by-products of the partial oxidation of propene in these plasmas. Carbon products could be quantified as follow: 36.2% CH_2O, 19% CO, 11.3% CO_2 and 33% "others". "Others" represents the by-products like formic acid and methyl nitrate which were not quantified in that study. When CO and CO_2 were added to the O_2-C_3H_6-NO-N_2 mixture no significant changing in the spectrum was observed.

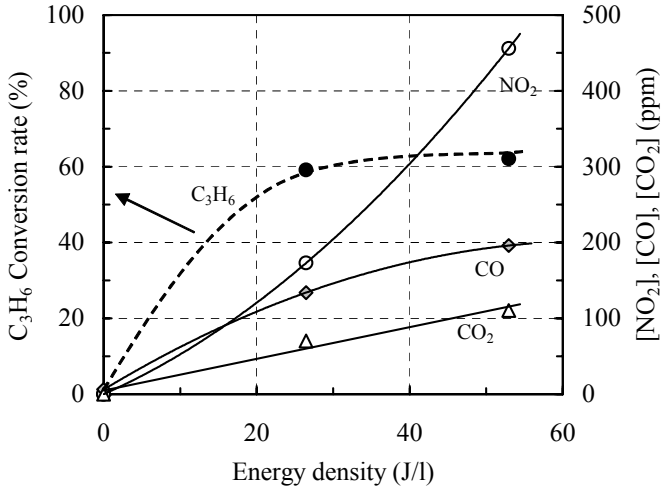

Figure 5: NO_2, CO, CO_2 output concentrations and C_3H_6 conversion rate as a function of energy deposition. Inlet gas contains 10% O_2, 500 ppm NO, 500 ppm C_3H_6, and balance N_2.

In the following section, experiments using gas mixture simulated diesel engine exhaust were conducted at two gas temperatures (150°C and 300°C). The treatment was performed at flow rate of 16 l/min with the same electrical conditions than presented before. The composition of the simulated diesel engine exhaust was: 12% O_2, 10% H_2O, 500 ppm CO, 10% CO_2, 300 ppm NO, 300 ppm C_3H_6, and N_2 as balance. In these humid mixtures, OH radicals produced from water vapor by the plasma plays a major role in the NOx removal chemical reactions. Output NO and NO_2 concentrations and NOx removal rate as a function of energy deposition is shown in figure 6. With increasing energy deposition, the NO concentration decreases while that of NO_2 initially increases (maximum at ≈8 J/l) and then decreases. This phenomenon could be explained by reactions between NO_2 and OH radicals leading to the formation of R-NOx compounds (R=hydrocarbon radicals).

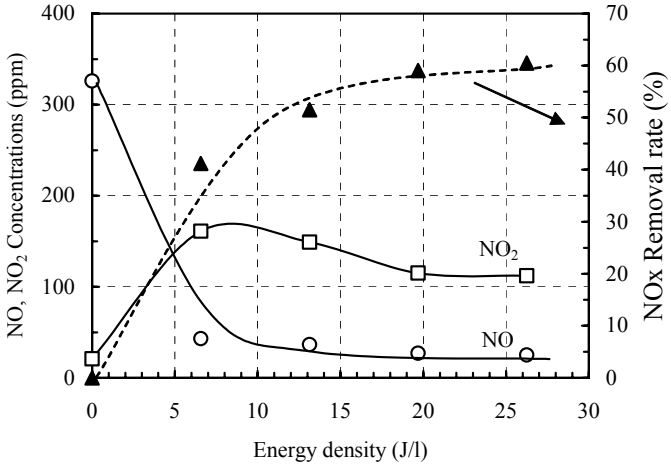

Figure 6: NO, NO_2 concentrations and NOx destruction rate as a function of input energy density in plasma processing of simulated diesel engine exhaust at 150°C.

The NOx (sum of individual concentrations of NO and NO_2) removal efficiency significantly increases with increasing input energy density. Approximately 60% of NOx were removed by the DBD discharge at energy density of about 26 J/l. The products of hydrocarbons processing are those reported commonly in the homogeneous gas phase processing of diesel exhaust containing propene [7, 9]. These by-products are acetaldehyde (CH_3CHO), propylene oxide (C_3H_6O), formic acid (CH_2O_2), methyl nitrate (CH_3ONO_2), and nitromethane (CH_3NO_2). Acetaldehyde and nitromethane were detected by Gas Chromatography coupled with Mass Spectrometer. To our knowledge CH_3NO_2 have not been observed in any other reported experiments. However that specie was predicted as a major by-product from propene induced NO to NO_2 conversion by Shin et al [10].

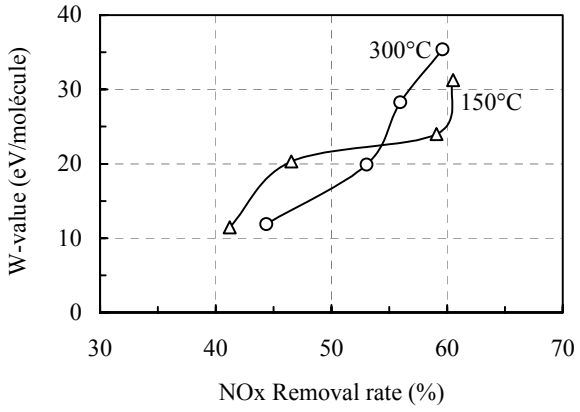

Figure 7: Energy cost as function of NOx removal rate in plasma processing of simulated diesel engine exhaust at 150°C and 300°C.

Energy cost has been used for the evaluation of system performance in gas cleaning using a discharge

plasma system. The efficiency of these processes can be quantified by W-values [11]. W-values (eV/molecule) are the amount of energy required to remove one molecule of the compound. The lower values correspond to more efficient processes. The W-values as a function of NOx-removal rates in simulated diesel engine exhaust at 150°C and 300°C are shown in figure 7. This figure illustrates how the important parameters - the NOx removal efficiency and energy cost per removed molecule - are strongly correlated. At high temperature (300°C), W-value increase rapidly with NOx-removal. Below energy density of about 15 J/l, it appears that the plasma processing of diesel is much more efficient at high temperature. About 45% of NOx are removed with W-value around 12 eV. At higher energy density (26 J/l) and lower gas temperature (150°C), NOx removal efficiency of about 60% was obtained with an energy cost less than 30 eV/molecule. Assuming an engine with a load of 100 kW and an exhaust gas flow rate of 100 l/s, this plasma treatment will correspond to a consumption of about 2.6% of the engine energy output.

Summary

Pulsed dielectric barrier discharge plasma processing of gas mixtures with composition more and more complex (from N_2-C_3H_6 mixture to N_2-NO-O_2-C_3H_6-H_2O-CO-CO_2 mixture simulating diesel engine exhaust) was performed at relatively low energy deposition. The nature of the by-products produced and the effect of gas composition on the NOx conversion chemistry in plasma were studied as a function of energy density deposition and gas temperature. For example, NOx removal efficiency of about 60% was obtained with an energy cost less than 30 eV/molecule in the case of simulated diesel engine exhaust.

Under oxygen rich conditions, in addition of the main products of the plasma (NO_2, CO, and CO_2), acetaldehyde (CH_3CHO), formaldehyde (CH_2O), formic acid (CH_2O_2), methyl nitrate (CH_3ONO_2), nitromethane (CH_3NO_2), methanol (CH_3OH), and nitrous acid (HONO) could be are formed.

Abstract
From previous studies on electrothermal launchers, GIAT Industries (France) has developed a micro-torch system for ignition using plasmas. A transient electric arc is generated between two electrodes connected to a capacitor bank in a polymer cell in order to produce an ablation of the polymer surface, leading to a highly chemically reactive plasma jet at the exit of the torch nozzle. The spectroscopic investigation is performed using atomic emission spectroscopy : excitation temperature has been obtained with a Boltzmann plot and electron density has been measured with the Stark width of H_α Balmer line coming from the ablated polymer: the electron density level is high ($> 10^{18}$ cm^{-3}). By considering an elementary thermodynamical plasma model, it was possible to determine a value of the pressure of the emitting area at the micro-torch nozzle; its value is about 160 MPa.

The plasma jet produces a strong pressure perturbation. It has been experimentally showed that this pressure perturbation is a detonation in agreement with the theoretical model of Sedov-Taylor. The overpressure values obtained from spectroscopic data are in agreement with the overpressure given by the Sedov-Taylor model.

1. The micro-torch igniter

The micro-torch system presented in figure 1 was designed by GIAT Industries [1] with a scaling made according to similar systems operating with higher energy values. The basis concept of this one shot plasma device is to generate an electric arc between two electrodes in a polymer cell in order to produce an ablation of the polymer surface, leading to a highly chemically reactive plasma jet at the exit of the torch nozzle.

The micro-torch has an axisymmetric geometry with an axial brass cathode and a steel body used as an anode. The torch nozzle has a diameter of 4 mm and the polymer cell a 2 mm hole. The polymer to be ablated (POM: PolyOxyMetyl-acetal) is a cylinder having the same axis as the micro-torch system. In addition, a copper wire (diameter: 0.15 mm) is used to initiate the electrical discharge.

The electrical power supply is a low energy energy capacitor bank (1.5 kJ) operating at the maximum voltage of 500 V. The typical duration of the transient plasma jet is about 1 ms, driven by the typical times of the electrical capacitor bank.

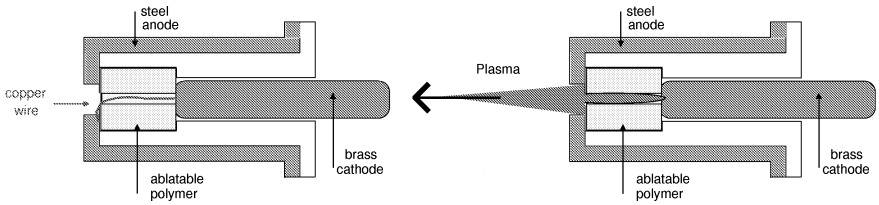

Figure 1: Schematic drawing of a micro-torch system (cut along the axis). Left figure: before the capacitor bank discharge and right figure: during the capacitor bank discharge with the plasma jet at the exit of the torch nozzle.

2. Emission spectroscopy investigation

Spectroscopic data acquisitions are performed with a Chromex monochromator of the Ébert-Fastié type having a focal length of 0.5 m and a 1200 grooves/mm grating operating in the first order. Photodetection is provided with a Princeton Applied Physics OMA equipped with a CCD matrix array having 256 rows of 1024 pixels. In the first spectroscopic order, the detector covers a spectral range of 45 nm.

In order to study the time evolution of a spectral area in the visible range, the CCD array is controlled using a kinetic mode. In this mode, only a number n of rows are illuminated during an exposure time t_e. At the end of the exposure time, these n rows are shifted in the CCD array such that it is also employed as a fast storage memory. The shift of each row is accomplished during a time t_s depending on the kind of CCD controller. In our case, the shortest time shift available is t_s=6 μs. The number of lines illuminated is n=2, and the exposure time t_e=15 μs; these values have been chosen using a trade off between time resolution and signal level. To summarize, data acquisition allows a spectral area to be sampled every $t_e + n \times t_s$=27 μs. Since the typical time of discharge is about 600 μs, the sampling rate is sufficient to obtain a time resolution of the spectral emission of the discharge.

The transient plasma jet created by the discharge is observed side-on at the exit of the torch nozzle. An image of the plasma jet is formed using a lens (focal length of 75 mm) on the tip of a 200 μm diameter optical fiber connected to the monochromator entrance. The fact that the light collected by the optical fiber corresponds to an averaged value of the plasma emissivity across the torch nozzle diameter must be highlighted.

Data acquisition is triggered using a fast time response ($\approx 6\,\mu$s) photodiode (Texas Instruments TSL 252), illuminated by the transient plasma jet.

In all experimental spectra, emission lines of neutral copper are always predominant, and may be used to obtain a temperature value. Figure 2 gives a typical spectral region with Cu_I lines and its evolution over time. At the beginning of the discharge, the Cu_I atomic lines at 515.5 nm and 521.8 nm present a typical self-absorption shape and, consequently, their overall intensity cannot be used directly to obtain a temperature value. However, this self-absorption give useful information concerning the geometry of the emitting source: it can be considered as a hot emitting area surrounded by a cold copper gas mainly coming from the exploded wire. Over time, the line shapes lose their self-absorption shape, meaning that the emitting area is either colder or more homogeneous, or else that the density of the copper ejected from the capillary tube decreases. In this case, the line intensities can be used to build a Boltzmann's plot[2]. The neutral copper lines observed in our spectra are:

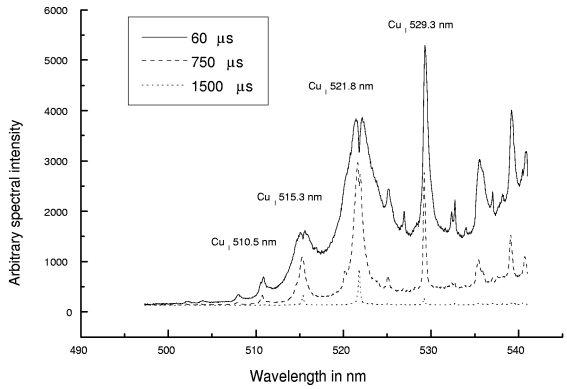

Figure 2: Time evolution of emission spectra for POM material

510.5 nm, 515.5 nm, 521.8 nm and 529.3 nm with transition probabilities [3, 4, 5] known with a rather large associated error. When POM is ablated, Boltzmann's plot gives a temperature of around 10000 K, decreasing over time to 9000 K. It is obvious that the torch emission is not steady. First of all, the copper wire explodes and is ejected from the torch. The plasma is generated. The emission reaches a maximum very rapidly. Thereafter, the spectral emission drops slowly to approach a relatively long light emission at approximately 10 % of the maximum value. The peak current and the maximum spectral emission appear at the same time.

Since the Stark effect is well characterized for atomic hydrogen and the transitions fall within a convenient region of the optical spectrum, the Balmer series is frequently used for line shape analysis. Usually, the H_β (486.1 nm) line has a rather characteristic and broad profile, and is far less sensitive than the H_α. In our plasma, the H_β line profile is complicated by many lines in this spectral region and it is impossible to obtain a tem-

perature estimation. Thus, our analysis focuses on the more prominent H_α (656.3 nm) which Stark broadening gives a direct measurement of the electronic density.

In the spectral the spectral range from 630 nm to 680 nm presents two kinds of emission: lines from the neutral atomic iron resulting from the vaporization of the anode steel and the Balmer α line of hydrogen (H_α). As for the copper, we can obtain the arc plasma temperature from the slope of Blotzmann's plot using iron lines emission [6].

The electronic temperatures were inferred from Boltzmann plots of the iron emission lines observed on the blue wing of the H_α line. The electron densities were inferred from Stark broadened H_α emission lines. In the range from N_e $=10^{13}$ to 10^{20} e/cm^3 the different theories (Kepple-Griem [7], Sholin-Dmura-Lisitsa or Ispolatov-Oks [8]) are very close.

For each data acquisition, temperature and electron density are measured. The figure 3 presents the evolution of the electronic density as a function of the temperature. In the case of a singly ionized plasma in local thermodynamic equilibrium, the electronic density N_e is given by:

$$N_e^2 = CT^{3/2} \exp\left(-b/T\right)$$

where C is a constant.

Fitting experimental results with an analogous mathematical model ($N_e^2 = CT^a \exp\left(-b/T\right)$) gives $a = 1.518 \pm$ 0.055; consequently, Saha's law is valid, and finally, the plasma produced is in local thermodynamic equilibrium. As Saha's law is verified, the density of neutral species (N_0) can be found. For this, a straightforward thermodynamical model of plasma must be used. By considering a 10000 K argon plasma in local thermodynamical equilibrium with electronic density of about $5\,10^{18}\,\text{cm}^{-3}$, the density of neutral species is about N_0 $=3\,10^{21}\,\text{cm}^{-3}$. Using Dalton's law we obtained an over pressure in plasma jet of about 160 MPa. This pressure is considerable, and it will be compared in the following section to the over pressure obtained using a blast wave model.

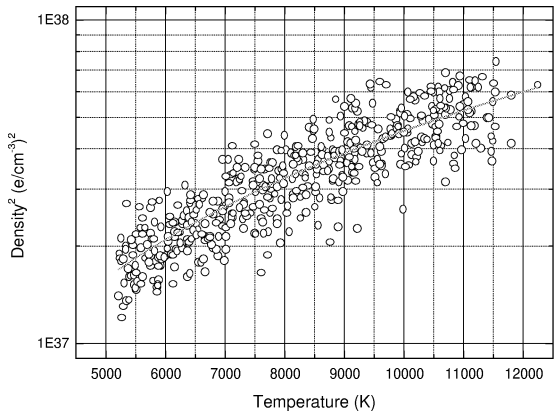

Figure 3: Square of the electronic density as a function of the temperature $N_e^2 = f(T)$

3. Investigation of the overpressure generated by the micro-torch

It was decided to investigate the strong overpressure perturbation generated by the micro-torch system by applying the modified Sedov-Taylor model [9, 10] in an ideal gas.

In the case of the spherical blast wave described by the Sedov-Taylor model, an energy E is deposited instantaneously in an ideal gas of specific mass ρ. The initial energy E is localized in a point taken for reference, and produces a spherical blast wave of radius R from the center which time evolution is [11, 12]:

$$R(t) = \beta \left(\frac{E}{\rho}\right)^{1/5} t^{2/5} + v_s t, \tag{1}$$

where β is a constant and v_s is the sound velocity at ambient pressure.

The experimental investigation of the overpressure perturbation is made by using three pressure sensors disposed on the same plan along a line. The ranges between sensors and between first sensor and the nozzle of the torch are known. The radius of the blast wave front, which is assumed to be the distance from the bore exit to the shock measured along the axis, was measured (sensor position) of time. The over pressure value and the blast wave flight time were directly given by the pressure sensor.

According to the Sedov-Taylor model, the blast wave is supposed follow two mains equations. The first one gives the flight time of the blast wave front (equation (1)), and the second gives the pressure variation on the blast wave radius as function of time [9]:

$$p_2 = C^{te} t^{-6/5}. \tag{2}$$

Experimental data are compared with theoretical blast wave equations (1), (2). The experimental evolution of the blast wave front as a function of time is in good agreement with theoretical predictions (see figure 4). In addition, the comparison of the experimental over pressure is also in good agreement with the Sedov-Taylor model (see figure 5).

Since the Sedov-Taylor blast wave model is showed to be valid, we can easily determine the over pressure as a function of the radial distance by combining equations (1) and (2). Figure 6 shows that the pressure level at the micro-torch nozzle ($\approx$ 175 MPa at the distance r=1 mm) and the pressure found by using Dalton's law (see above) are in good agreement.

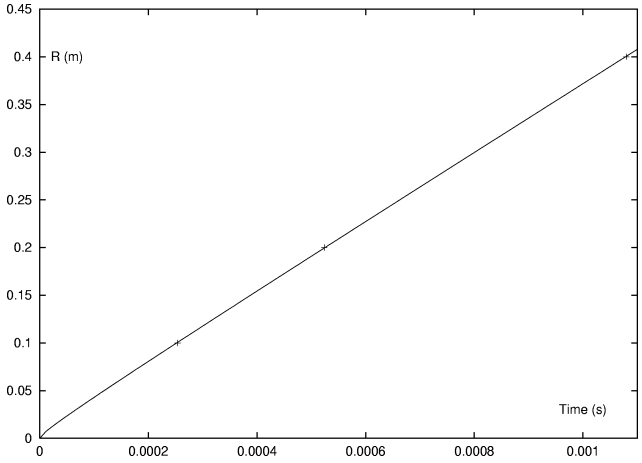

Figure 4: Experimental data for the time dependence of the blast wave front radius R. The solid line is a fit of equation (1).

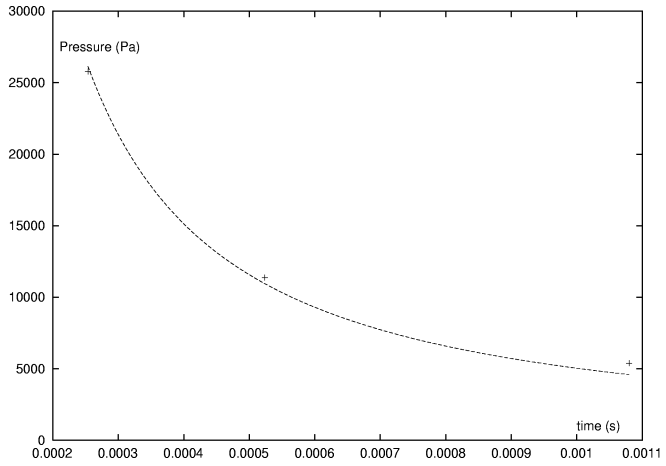

Figure 5: Experimental data giving the over pressure as a function of time on the blast wave front(2).

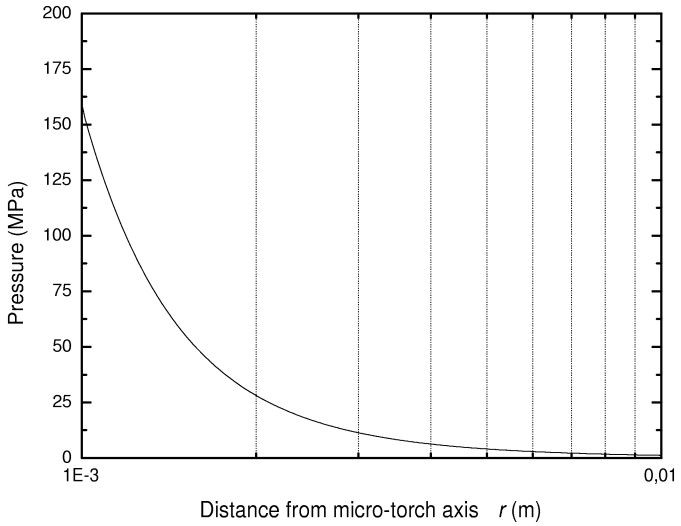

Figure 6: Evolution of the pressure as a function of the radial distance from the micro-torch nozzle (1) (2).

4. Conclusion

In this experimental study, the time evolution of the emission spectra in a micro-torch plasma jet is obtained. All spectra are dominated by the presence of the strong emission lines of the neutral metallic elements mainly coming from the electrodes materials (iron and copper). The presence of diatomic molecular bands such as C_2 Swan bands is not clearly established, mainly because the presence of the strong neutral copper lines that decrease the dynamic range of the optical detector.

The temperature determination from Boltzmann plots is only available at the end of the discharge, because of very strong self-absorption of atomic copper lines at the beginning of the discharge. This self-absorption decreases with time. The reasons of self-absorption are many and should be deeply studied. The hydrogen H_α emission line is easily observed and is employed to measure the electronic density.

Electronic density values are relatively high ($> 10^{18}\,\mathrm{cm}^{-3}$) leading to a plasma in local thermodynamic equilibrium, and allowing to determine the pressure inside of the plasma jet with Dalton's law. This pressure is approximately 160 MPa. In addition, the study of the over pressure generated by the transient arc discharge

shows that it is successfully described with a blast wave model.The notion of blast wave from each discharge (from 1 kJ to 20 kJ) scale as expected for a strong shock resulting from instantaneous energy deposition at a point. In accordance with this model, the pressure of the blast wave front and its velocity are determined. The pressure value obtained by spectroscopy and the pressure value estimated using the modified Sedov-Taylor model are in good agreement.

Abstract
In a previous paper [1], we have presented a new method to carry out the rotational temperature from the UV OH band at 306.357 nm (transition $A^2\Sigma, \nu = 0 \rightarrow X^2\Pi, \nu' = 0$) frequently observed in hot gases containing oxygen and hydrogen (flames, arc plasmas). The method is mainly based on a calibration of the height of 3 unresolved groups of lines obtained by performing a numerical simulation of OH spectrum for different temperatures and for different widths of gaussian apparatus functions. In this paper, we underline that the apparatus function needed to carry out the temperature with the method described in the reference [1] is not only the pure optical apparatus function of the optical spectroscopic device commonly measured by employing a laser line, but must include the broadening effects of the rotational lines. At least, we propose a numerical method to determine a global apparatus function needed to apply the temperature determination method presented in the paper by de Izarra [1].

1. Introduction

In a previous paper [1], we have presented new method to carry out the rotational temperature of OH radicals, by considering the sensitivity against the temperature of the amplitude of two unresolved groups of lines for the UV OH band at 306.357 nm (transition $A^2\Sigma, \nu = 0 \rightarrow X^2\Pi, \nu' = 0$) frequently observed in hot gases containing oxygen and hydrogen (flames, arc plasmas).

Using reference data [2], a Dirac synthetic spectrum has first been computed for a given temperature T. Then, to produce a synthetic spectrum, the Dirac spectrum has been convoluted [3] with a normalized gaussian apparatus function

$$G(\lambda) = \frac{2}{\Delta\sqrt{\pi}} \exp\left(-\frac{(\lambda - \lambda_0)^2}{(\Delta/2)^2}\right)$$

where Δ represents the full width at 1/e of the maximum located at the wavelength λ_0. A set of about 2000 synthetic spectra has been computed for the temperature varying from 600 K to 9000 K with 200 K stepped and for Δ varying from 0.02 nm to 0.98 nm with 0.02 nm stepped.

Figure 1 gives a plot of synthetic spectra for an apparatus function with Δ=0.1 nm and for a rotational temperature varying from 1000 K to 8000 K with 1000 K stepped. All the synthetic spectra have been normalized against the intensity of the group of unresolved rotational lines G_{ref} (see figure 1) at ≈309 nm which appears to be the relative strongest group of unresolved lines when the rotational temperature is lower than 4000 K. The ratios G_0/G_{ref} and G_1/G_{ref} for different values of temperature T and apparatus function width Δ are given in the reference [1].

The determination of a temperature from an experimental spectrum needs to precisely know the apparatus function width Δ corresponding to the numerical simulation. If we consider the simulation process used to compute synthetic spectra (figure 2), it is obvious that the apparatus function width Δ corresponds to a global apparatus function, and both includes the broadening effects of the rotational lines and the apparatus function of the optical and spectroscopical devices. Consequently, the experimental determination of the parameter Δ with a laser line is a mistake and does not correspond to the global apparatus function employed in the numerical simulation. For that reason, it is necessary to propose a method to carry out the parameter Δ from experimental spectra.

2. Study of the UV OH Spectra

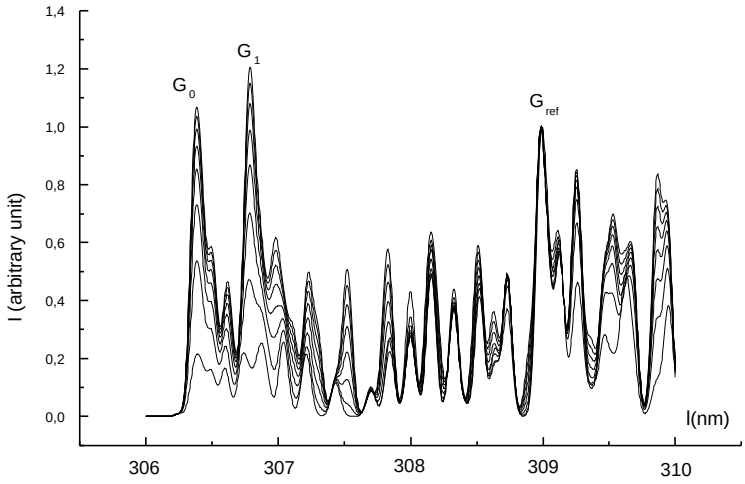

Figure 1: Plot of the UV OH spectrum for the rotational temperature varying from 1000 K to 8000 K, 1000 K stepped ($\Delta = 0.1\,nm$).

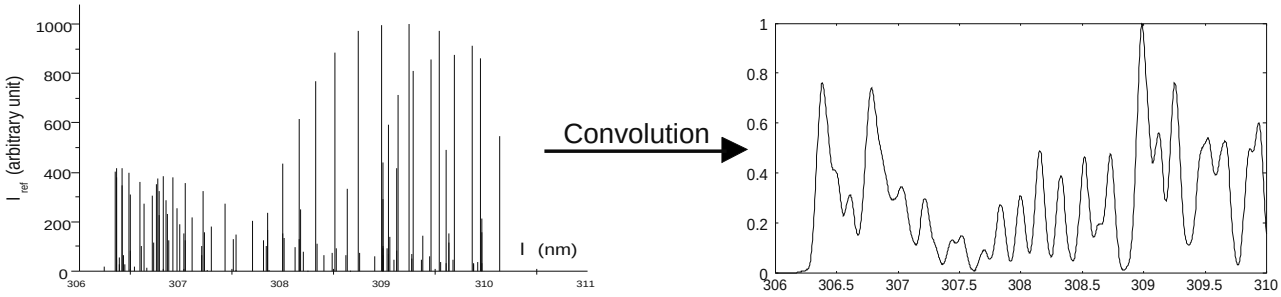

Figure 2: Simulation process used to produce a synthetic spectrum with a convolution of an impulse Dirac spectrum and a global apparatus function Δ.

2.1. Evolution of the spectrum with the temperature

Figure 1 gives a plot of UV OH synthetic spectra for an constant apparatus function (Δ=0.1 nm) and for various rotational temperature. The OH band in this wavelength range shows a red degradation with four main band heads R_1, R_2, Q_1 and Q_2 at respectively 306.537 nm, 306.776 nm, 307.844 nm and 308.986 nm. When the temperature is lower than 4000 K, the group of unresolved rotational lines Q_2 at ≈309 nm appears to be the relative strongest group of unresolved lines [1] and this band can be easily isolated in order to give useful informations. That's why all the synthetic spectra have been normalized against the intensity of this band that for clearness we'll name later on the G_{ref} line.

As shown in Figure 1, the width of lines seems to be independent of temperature value. Indeed, in the temperature range 1000-6000 K, broadening of the spectral lines results mainly from the convolution of the emission spectrum with the apparatus function, which is supposed to be gaussian [4]. To support this assertion, Figure 3 is a plot of half width at 0,7 in height of the G_{ref} line for various apparatus function as a function of the temperature. It is the half width to the low wavelength which is considered because the shape of this line is not symmetric.

The value of the half width for a given apparatus function is not thoroughtly constant. It increases lightly about less than 10% for apparatus functions between 0.02 to 0.5 nm with an increase of 8000 K of the temperature. This difference is reduced when, at one and the same time, the apparatus function is lower than 0.4 nm

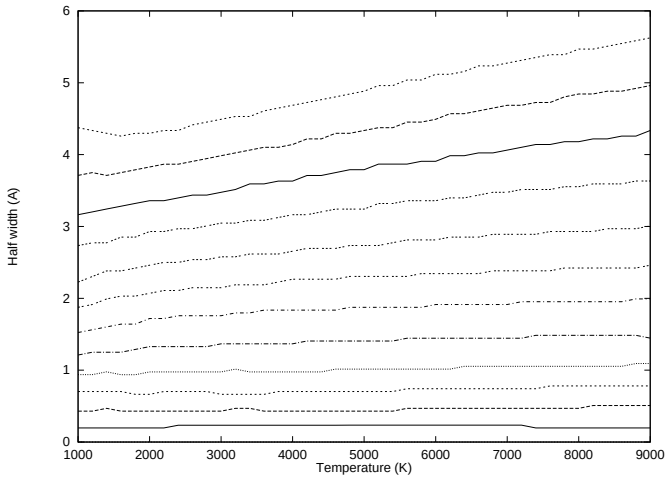

Figure 3: Plot of half width at 0.7 of the Q_2 band at 309 nm for the global apparatus function varying from 0.06-0.72 nm, in 0.06 nm steps, as a function of the temperature.

and the temperature is lower than 6000 K, but it should be taken into account in the error calculation.

2.2. Evolution of the spectrum with the apparatus function

The Figure 4 below shows the shape of the UV OH spectrum for a given temperature as a function of the apparatus function. More this latter increases, more the groups of unresolved lines are broadened. From about 0.5 nm, the width of the G_{ref} line is relatively important but spectra of this shape resulting from a poor resolution are rarely used because they are not interesting for spectroscopy analysis.

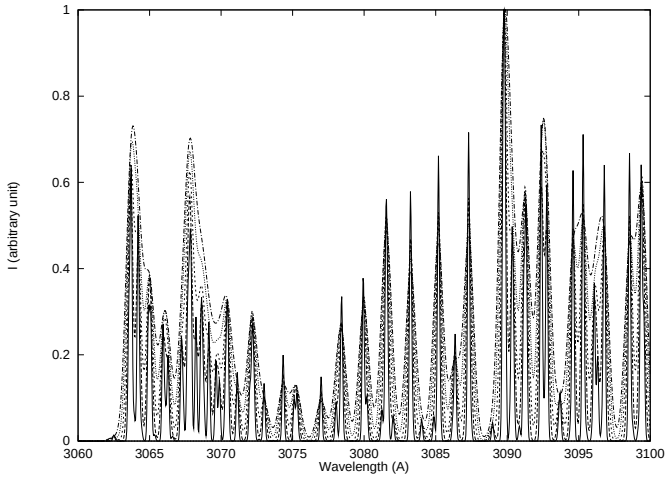

Figure 4: Plot of the UV OH spectrum for the global apparatus function varying from 0.1-0.5 nm, in 0.1 nm steps (T=3000 K).

3. Apparatus function method determination

3.1. Principle

The method presented in this paper allows the determination of the global apparatus function from a UV OH spectrum. In a first step, the equation of the global apparatus function against the half width of the G_{ref} line

must be find for a given height. The value of half width at 1/e can't be used because it is too low in the band. Its evolution as a function of the apparatus function is not linear in the 0.02-0.98 nm range because of the convolution, when its broadening is too important, the value of the half width is not purely corresponding to the G_{ref} line. This evolution stays linear from about 0.7 of the maximum of the line. From this, the choice of the height is free, and three different heights (0.7, 0.8 and 0.9) will be considered. The fact to have three different heights, hence three equations, will allow to be more accurate by making the average of the three found values of the global apparatus function.

Using the data from the synthetic spectra provided by the computer simulation of de Izarra, a computer program has been realized in QuickBasic. The principle is to calculate from a spectrum the difference between the wavelength where the intensity of the G_{ref} line is maximum (=1 a.u.), and the wavelengths where the intensity is 0.7, 0.8 and 0.9 a.u. in this same line. This operation is repeated for global apparatus functions going to 0.02 nm to 0.98 nm, in 0.02 nm steps for a defined temperature and, finally, for rotational temperatures varying from 1000-9000 K, in 200 K steps. For each height, we have 40 curves (for each temperature) of the apparatus function as a function of the half width. The equation of the average curve is the wanted equation and the 1000 K and 9000 K curves give the error boxes of the average curve introduced by the weak increase of the half width with the temperature which has been shown previously.

3.2. Equations

The obtained curves for heights of 0.7, 0.8 and 0.9, are presented in Figures 5 to 7 and the corresponding three order polynomial equations in the Table 1. For each figure, the average curve is in the middle, the 1000 K curve above and the 9000 K curve below.

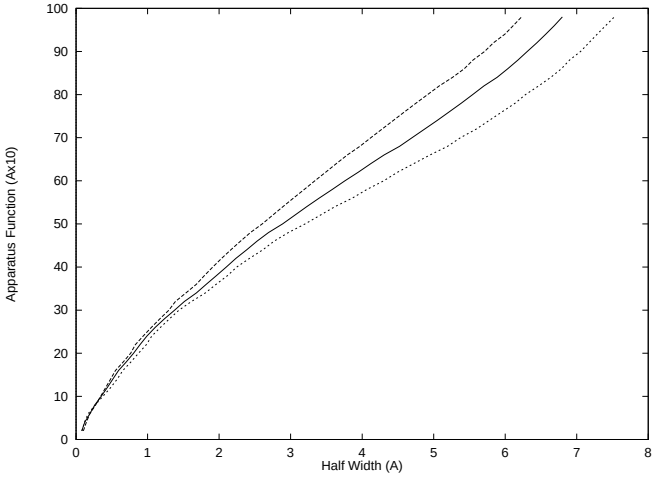

Figure 5: Plot of the global apparatus function as a function of the half width at heights of 0.7.

4. Check of the method

A Balmer lamp gives an emission spectrum of OH at low pressure. In that case, the Doppler broadening are very low and can be neglected. Thus, the measure of the global apparatus function corresponds to the optical apparatus function which is the principal broadening effect of this spectrum. Then, a comparison between the optical apparutus functions measured with a mercury lamp and a Balmer lamp enables to check the method.

The measures of apparatus fonctions are made on a spectroscopic acquisition chain. The monochromator is of Baush & Lomb type with a focal lenght of 2 m and it has a 1200 grooves/mm grating working in the first order. Photodetection is made with intensified controller model 1455 of Princeton Instrument with a single line of 770 intensified pixels of a matrix CCD possessing a internal Peltier cooler, and it is linked to a detector controller model 1461. A 100 mm silicium lens is used to focalise the light into the entrance slit of the monochromator. The width of the slit is fixed to 50 μm.

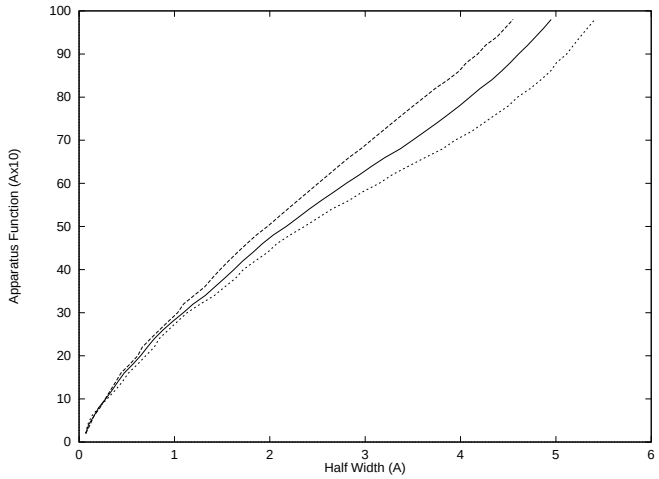

Figure 6: Plot of the global apparatus function as a function of the half width at the height of 0.8.

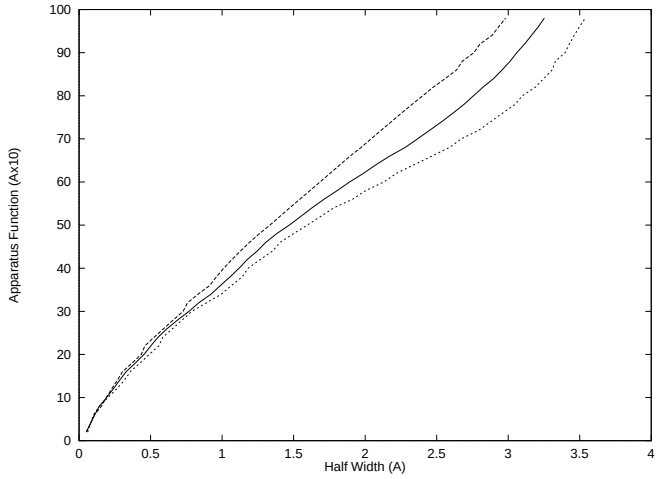

Figure 7: Plot of the global apparatus function as a function of the half width at the height of 0.9.

Table 1: Equations of the global apparatus function (Δ) as a function of the half width W (nm) for three different heights.

Height (a.u.)	**Equations**
	Δ(1000 K)=0.028W^3-0.341W^2+2.582W+0.154
0.7	Δ=**0.029**W^3**-0.352**W^2**+2.458W+0.179**
	Δ(9000 K)=0.0285W^3-0.361W^2+2.385W+0.157
	Δ(1000 K)=0.058W^3-0.519W^2+3.281W+0.129
0.8	Δ=**0.0698**W^3**-0.604**W^2**+3.225W+0.125**
	Δ(9000 K)=0.0704W^3-0.639W^2+3.178W+0.0941
	Δ(1000 K)=0.179W^3-1.042W^2+4.74W+0.114
0.9	Δ=**0.252**W^3**-1.397**W^2**+4.827W+0.0749**
	Δ(9000 K)=0.264W^3-1.548W^2+4.866W+0.011

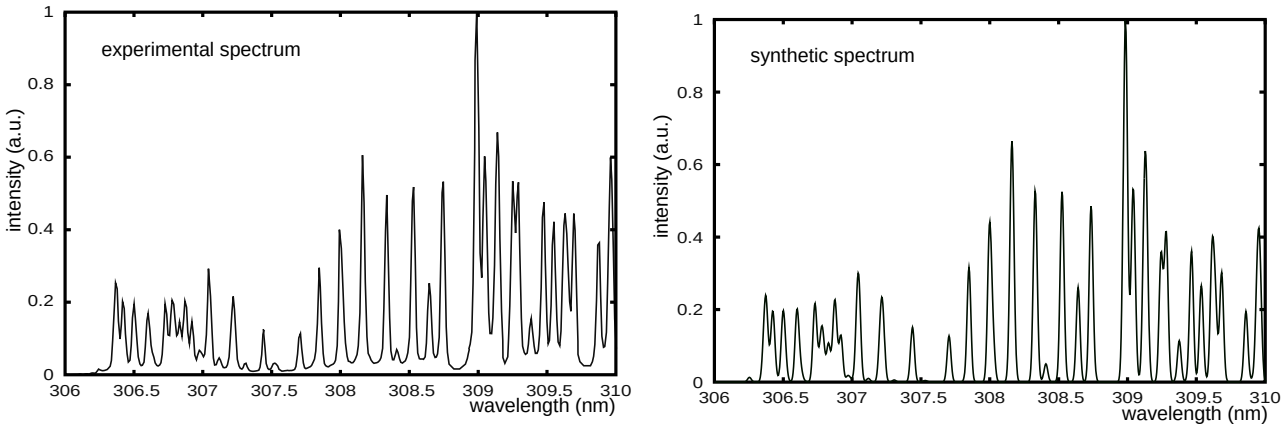

Figure 8: Plots of the UV OH spectra experimental and synthetic for a rotational temperature about 1200 K and for $\Delta = 0.04\,nm$.

In a first step, the apparatus function is measured with a mercury lamp which has two characteristic lines at 435.833 nm and 546.073 nm. These ones are fitted by gaussian functions and the widths at 1/e of these functions give an optical apparatus function about (0.042$\pm$0.003) nm on an average. In a second step, we used a Balmer lamp (Figure 8). The apparatus function is determined from the emission UV OH spectrum provided by this lamp and from the equations founded previously. Its value is about (0.039$\pm$0.003) nm. The comparison between the two values allows to validate the direct determination method of a global apparatus function in UV OH spectrum.

Figure 8 presents a comparison between an experimental spectrum obtained with our balmer lamp and a synthetic spectrum computed with $T = 1200K$ and $\Delta = 0.04nm$. This temperature value has been found by checking the superposition of the normalized experimental spectrum with the different synthetic spectra. The ratios G_0/G_{ref} and G_1/G_{ref} have been used to support the determination of the rotational temperature. It is clear that there is a good agreement between the experimental and the synthetic spectra.

5. Conclusion

This paper has presented a original method to determine the apparatus function of a spectroscopic device from the UV OH spectrum. The found results are equivalent to the experimental methods. A possible application of this work is to use the equations for simulation way with for final aim the elaboration of an 'OH molecular pyrometer', actually studied in our research group.

Institute of Thermomechanics AS CR, Dolejskova 5, 182 00 Praha 8, Czech Republic
Institute of Electrotechnical Engineering AS CR, Dolejskova 5, 182 00 Praha 8, Czech Republic

Abstract
The paper presents evidence of controlling role of plasma column self-organization in the entrainment of external medium (air) into the transitional thermal plasma plume. The analysis is based on the fact that the transport of thermal energy through the plume transiting to turbulence reflects unambiguously the dynamic phenomena controlling the process evolution. The discussion of the nature of the interrelations among the plume entrainment and heat transport processes suggests how and when the entrainment is performed.

Introduction and Motivation
In many advanced technologies thermal energy needed for their realization is supplied from transitional thermal plasma plumes. However the effective utilization of plasmas under such conditions is often limited owing scanty understanding of phenomena which should control them.

The main objective of our investigations is to grasp and describe these phenomena. However the dynamics of a complex system of non-linear dynamic processes which controls the plasma plume transition forms a dynamics of its own which can be understood only from a holistic description of the whole history of process evolution.

Our experimental evidence [1][2][3] indicated, that such holistic description is unambiguously and sensitively reflected by the history of thermal energy transport taking place in the plume core. It is described by a thermodynamic portrait of the transition process [2] which enables us to disclose what is the underlying nature of the system evolution that leads to strong interdependence of events and to resulting process complexity – what governs the transition in essence. This clue event is the plasma column self-organization [4]. And the gained knowledge base suggests also, how the self-organized energy separation controls directly the transport of heat through the plume which it transiting to turbulence [5].

However, not only the energy transfer but also the mass transport phenomena – the entrainment of external media into the plasma column primarily – represent the direct consequences of underlying column dynamics. The interrelations of these complex processes are controlled at the same time by the evolution of morphology of an ensemble of organized structures produced by all of self-organizing dynamic systems [6]. The morphology of these pattern systems, identified by specific identification procedure of a CCD camera pictures [7] controls obviously both the energy separation as well as the entrainment of external media into the plasma column and determines in such a manner the interrelations between the heat and mass transport through the plume.

In the following text an insight into the mechanism of interplay of these events is presented. However, the nonlinear interactions of the individual phenomena of the dynamic system studied preclude that these detailed observations can be "condensed" into a sole picture of the process. Under such conditions our insight can explain why there is variability or what typical pattern can emerge only – not what the particular outcome of a particular system will be.

Experiments and discussion of their results
The task of experiments was to obtain the data describing the behavior of distinct events taking part in the plume transition and on the basis of their confrontations to gain the responses which can be used in characterizing the complex plume transition phenomena.

The data characterizing the plume dynamics are presented in the form of thermodynamic portraits of the plume transition process [5]. They are represented by the relationships between the core cusp stagnation point heat flux on the plume geometric axis at the distance of 15 mm from the arc heater exit plane and by the plume power data in the arc heater outlet plane. These portraits enable us to disclose not only what is the underlying nature of the system evolution but also what governs the transition in essence. As stated above, this clue event is the plasma column self-organization. A self-organizing process characterizes itself by a specific type of its sensitivity to process initial conditions. Such a process exhibits in the course of reproduced experiments (under slight, randomly established initial conditions) in the process phase diagram

(in the thermodynamic portrait of the transition) different traces which during the process evolution intersect gradually in several process controlling states – in the process milestones [4]. The self-organization also induces and controls the energy separation in the column which markedly changes the energy generation process and the arc chamber thermal balance. As this takes place the arc power loss is clearly driven to attain a constant value at higher flow rates while the corresponding arc power tends to be fully used for plume power enhancement only [5]. And differences in the courses of transition processes in "flapping" and resonance "stabilized" plumes are produced by different evolution of energy separation in the plasma column.

The description of the experimental equipment and the methodics used in the heat flux measurements may be found elsewhere, e.g. in [1]. We will give only facts needed for understanding the text. The experiments have been performed in the plumes in which during an experiment the front sensitive surface of the heat flux probe was exposed in a gradual manner to the flow conditions from the laminar to the turbulent ones. As this takes place, the arc heater was working at constant arc current of 150 A and the argon flow rates varied from 10 to 150 slm. The plasma plume issuing from the arc chambers – which were 24 and 44 mm long – through an exit ring anode orifice of 8 mm diameter. The operation of the total heat flux measuring probe is based on on-line analysis of the unsteady conduction in a copper cylinder of 6 mm dia. mounted flush with the front surface of the probe. Temperature signals from the sensor are processed in an analog circuit in which the inverse heat conduction problem is solved and the heat flux history on the probe face is obtained. The body of informations gained show, that both of the known types of the thermal plasma transition processes [2][3] are represented among the data obtained. The "flapping" transitional plume issued from the arc chamber length of 24 mm; the plumes "stabilized" by the acoustical resonance in the arc chamber cavity issued from the arc chamber of 44 mm length. The turbulent flow – but not the fully developed one – has been attained in the plumes issued both from the arc chamber of 24 and 44 mm at the flow rate of 150 slm.

The needed air entrainment data were obtained by the use of a simple, home made sampling probe feeding the gas sample to the flue gas analyzer Testo 325/1 in which the proportion of O_2 in the sample was determined. The water cooled body of the probe – schematic on Fig. 1 – having the same outer diameter as the body of the calorimeter used is provided by draining hole of 1,5 mm diameter. Next the sample enters the water jacketed part of the sampling tube through which is directly drawn to the gas analyzer. The analysis is based on electrochemical principle; the sensor used can supply the required data of the proportion of O_2 in the sample with the accuracy of ± 0.2 % Vol at the resolution of 0.1 % Vol in 120 s.

The experimental arrangement and the evaluation procedures used during the investigations of the dynamic patterns appearing in the self-organizing plasma plume in the course of its laminar-turbulent transition is described in detail in [7]; we present only inevitable information here. In the course of experiments a fast shutter CCD camera was used. The camera was equipped with a rotating mirror situated between the CCD chip and objective lens. The regime of multiple camera exposures was used to record a sequence of 8 shots with exposure times 1 μs and interval between the exposures 10 μs. The evaluation procedure was based on the correlation analysis of vectors the components of which are defined either as intensities of the same pixels in the succeeding pictures or the intensities recorded by the pixels in the neighborhood of each point of the plasma plume image. The results show, that the images of plasma plumes include regions characterized by various correlations between the succeeding images of the plasma plume. It is possible to identify both the regions where the correlations is very high (the value of the correlations coefficient is close to +1) and the regions related probably to turbulent structures characterized by the negative correlations coefficients close to –1.

The results of experiment obtained in the course of the plume heat transport and air entrainment investigations are presented in Figs 2 – 4. A series of thermodynamic portraits of the heat transport through the plume reflect the evolution of the plume dynamics in the course of self-organized transition processes. The self-organization drives in the course of different experiments the corresponding branches of the process through several fixed process controlling thermodynamic states. The plumes issued from the arc chambers of 44 and 24 mm lengths exhibit two readily distinguishable courses of events (Fig. 2). In the evolution of the "flapping" plume one process phase is "missing" in comparison with the case of resonance "stabilized" plume. The reason is in different arc heater working conditions in which the full energy separation in the plasma column starts [8]. Under such condition the arc chamber power loss attains a value which does not change further while the corresponding arc power increase is then fully used to plume power enhancement. In both cases such state starts under the conditions of maximum measured heat flux – at the plume net

powers of 2.0 and 3.3 kW (at 30 and 60 slm mass flow rates) issuing from the chambers 24 and 44 mm. It suggests, that the plume power enhancement manifests itself in scattering of self-organized structures which results in the decrease of measured plume heat flux. However, the strong decrease of the plume heat flux taking place in these, pre-turbulent phases of the transition process results not only from the fact that the heat flux probe face is struck by small amount of scattered fragments of the self-organized structures but also from the effect of increased entrainment of external environment into the plume through these fragments – Fig. 3a, 3b and 4c, 4d, probably.

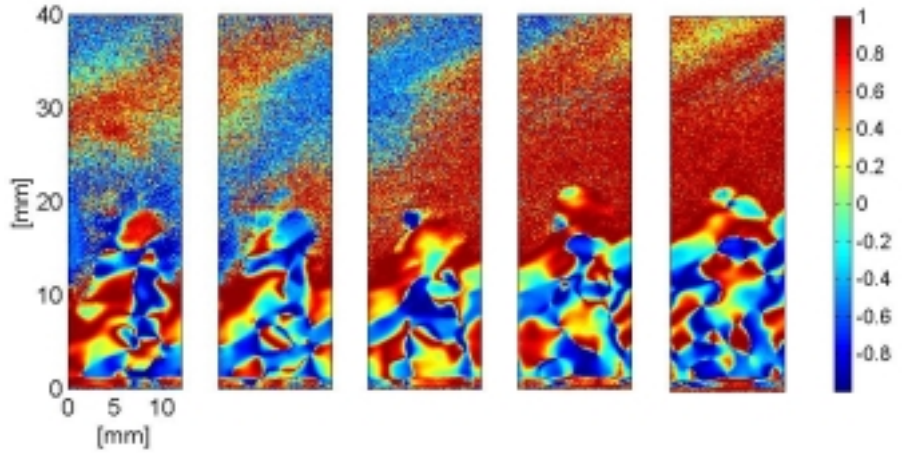

Fig. 4d) Analysis of the sequence shown in Fig. 4c) using temporal correlations

Fig. 4 Motion of self-organized structures in a argon plasma column arc chamber length 44 mm, arc current 150 A

On the other hand, as the self-organized structures develop – at low flow rate values – at 20 slm in the flapping and at 50 slm in the resonance "stabilized plume – the "large" segments – Fig. 4b – shield the hot column interior and striking the heat flux sensor face increase appreciably the heat flux transported through the resonance stabilized plume. It is not the case of "flapping" plume, however as there does not exist a possibility to control the energy separation consecutively as it is in foregoing case [8].

Summaring the piece of knowledge presented it is clear that the behavior of the plasma plumes in the course of their transition to turbulence can no longer be understood in terms of the behavior of the individual events – or the other way round, the distinct phenomena e.g. the entrainment can be understood only from the properties of the dynamic behavior of the entire system. However, such an assertion concern only a set of particular states – of the process "milestones" – which are almost not sensitive to process initial conditions and which exhibit remarkable reproducibility both of dynamic as well as of thermal behavior of the transitional plasma column. This fact is on the one hand employed e.g. just in detailed investigations of the external environment entrainment into the plasma column; on the other hand it represents the main obstacle in searching for a suitable turbulence model used for entrainment computing.

Abstract
RF plasma polymerization of acrylic acid enables the formation of polyacrylic-like layers containing carboxylic groups on different substrates. The stable layers with high functionalities are deposited. Furthermore the processes can be up-scaled.

KEY WORDS: plasma deposition, pulse plasma, acrylic acid.

1. INTRODUCTION

For industrial application it is required that plasma results obtained successfully with small scale reactors and for particular substrates can be transferred to larger systems and different materials.
Recently we succeeded in creating stable polyacrylic-like ultrathin and thin coatings containing carboxylic-groups on polypropylene [1] with the help of RF continuous plasma. In the present work we investigated the possibility to obtain similar thin layers by means of pulse plasma and tried to understand the rule of the equivalent power in these processes. As second purpose it was attempted to generate the same coatings also on polycarbonate, polyethylene and polystyrene. At last it was tried to find a semi-empirical law to transfer the results to other reactors, in our case from a small round reactor to a bigger reactor "DIN A3" [2]. For all plasma-derived layers, stability tests were carried out. Characterization of the plasma-modified substrates was performed by using fluorescence spectroscopy in combination with derivatization techniques and FTIR (Fourier Transformation Infrared Spectroscopy). The thickness of the polymer films was analyzed by AFM (Atomic Force Microscopy).

2. EXPERIMENTAL

2.1. Materials

The polypropylene film (PP) without additives, used in these studies, was supplied by Alkor Folien GmbH Germany and had a thickness of 50 µm. polystyrene and polycarbonate (144C, Makrolon 2405), in the form of object slides were used without further purification. Low molecular weight polyethylene film, 25 µm thick, was washed with acetone before using. Acrylic acid (AAc) was obtained from Fluka with >99 % purity and was used as received. The silicon wafers, needed for determination of the layer thickness via AFM, were preventively washed with ethanol and partially masked with a temperature stable adhesive tape during the plasma deposition.
thioninacetate (THA, Sigma), ethanol (EtOH, Chromatographie Handel Müller) and chloride acid (HCl, Fluka), needed for the fluorescence labeling, were also used without further purification.

2.2. Plasma deposition apparatus

The plasma experiments in pulse mode and in continuous mode with different substrates (polyethylene, polycarbonate, polystyrene, Si wafer, titanium, nickel free steel), were performed by means of a round symmetrical parallel plate (200 mm diameter) reactor. The discharge was confined between the electrodes by a glass vessel. The gas flow and monomer vapors was introduced through the "hot" electrode towards the substrates. The lower electrode was grounded and served as substrate holder. The shown experiments in the round reactor, were carried out with continuous and pulse RF discharge (duty time 1 ms, dead time 2 ms up to 9 ms) at different input powers. Plasma coatings were carried out by means of continuous and pulse plasma with discharge times up to 30 min.
For the pulse plasma experiments, the average Power $P_{equivalent}$ delivered to the system was calculated using the following expression:

$$P_{equivalent} = P_{CW} \frac{t_{on}}{t_{on} + t_{off}}$$

where $\frac{t_{on}}{t_{on} + t_{off}}$ is defined as duty cycle.

In a first step, the surfaces of the PP samples were cleaned/activated with hydrogen plasma (H_2 flow 4 sccm, pressure 0.05 mbar, time 5 s) and afterwards, a mixture of hydrogen/acrylic acid (AAc flow ca. 1 sccm, total pressure 0.1 mbar) plasma was introduced. Plasma duration time and dead time T_{off} were varied.
In order to reproduce the same plasma experiments obtained in [1], a larger "DIN A3" parallel plate reactor (290x390 mm^2) [2] was adapted. The activation/carrier gas as well the monomer were introduced by means of a gas shower through the hot electrode in the plasma chamber, providing a homogeneous flow and diffusion.
As in the round reactor, also in the "DIN A3" reactor, the surfaces of polypropylene samples were cleaned/activated by means of hydrogen plasma (H_2 flow 10 sccm, pressure 0.05 mbar, time 5 s) and subsequently treated with a hydrogen/acrylic acid (AAc flow ca. 2.5 sccm, total pressure 0.1 mbar) plasma. The activation/treatment discharge power was varied.
Both reactors enable power input with a minimum of losses, even in pulse mode.

2.3. Characterization Techniques

2.3.1. Fluorescence spectroscopy
Fluorescence intensities were measured with a spectrometer (Spectrapro 275, Acton Research Corporation) after fluorescence derivatization of the carboxylic groups with thionin acetate (THA) and ethanol as described in [3, 4]. The concentration of chemically bounded fluorescence groups was determined using a calibration curve. The excitation wavelength of THA was 594 nm, the emission was measured at 618 nm.

2.3.2. Infrared spectroscopy
HATR (horizontal attenuated total reflection) spectroscopy was performed with a Perkin Elmer FTIR Spectrometer (Spektrum 1000). A 45° ZnSe crystal was used; spectra were scanned 32 times between 4000 and 650 cm^{-1} with a resolution of 1 cm^{-1}. Prior to each set of analysis, the ZnSe crystal was cleaned with ethanol and dried with nitrogen. During the measurements the HATR mirrors compartment was purged with nitrogen to reduce water adsorption; the samples were pressed with a graduated pressure clamp to improve a reproducible contact to the ZnSe crystal.

2.3.3. Thickness measurements by AFM
Thickness measurements are necessary to estimate carboxylic groups concentration in plasma deposited layers. These were carried out by means of a Park Scientific Autoprobe CP microscope. The analyzed silicon wafers were partly covered with a temperature stable adhesive tape during the plasma deposition. To analyze the thickness of the plasma polymers, the adhesive tape was removed with caution. The sample surface was aligned in the AFM such that the boundary between the plasma polymer coated and uncoated wafer was beneath the AFM tip.

2.3.4. Stability tests
The treated samples were tested with different polar and non-polar solvents: they were immersed in bi-distilled water, ethanol, 10% twen solution, isopropanol, and mono-ethyl-diethyl-ether and stirred for 30 min at room temperature. Moreover a long time stability was executed by immersion of a thionin acetat derivatized sample in ethanol for 10 days. No change in carboxylic group concentration and in layer morphology were detected applying these tests.

3. RESULTS AND DISCUSSION
Deposition of acrylic-like layers containing carboxylic groups, by means of lab-scale plasma reactors is often difficult to reproduce in industrial scale, since it depends on various plasma parameters. In this section it will be shown how input power mode, substrate materials, form and volume of reactors influence these processes and how it is possible to transfer them to larger reactors.

3.2.1. Dependence on equivalent input power and dead times in pulse plasma
With the objective to investigate the effectiveness of pulse plasma compared to continuous wave, and studying the dependence on input power and pulse ratio, a new set of experiments in the round reactor were carried out. The plasma parameters as in the previous paper [1] were used: the treatment time was 30 min.
Input power $P_{equivalent}$ and on/off pulse ratios between 1/2 ms and 1/9 ms were varied. For continuous wave plasma the input power was also changed between 16 W and 34 W.
In Figure 1 the fluorescence measurements of carboxylic group concentrations for different input power and pulse ratio are reported. For lower continuous power inputs (plasma power input deficiency region) [5], the plasma is no longer

stable and consequently, the formation of powder in the chamber was observed. A poor adhesion of deposited layers is correlated with this effect.

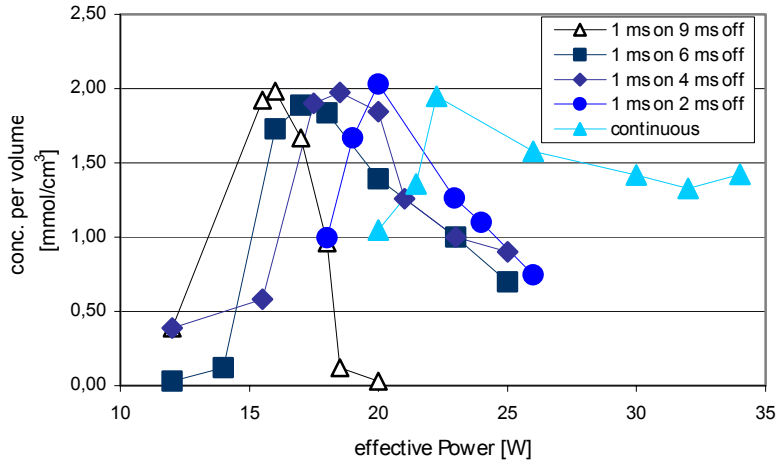

Figure 1: Dependence of COOH concentration on dead times and effective power.

Clearly, it appears that for a fixed pulse ratio varying the equivalent power, a maximum in carboxylic groups is achieved. These maxima depend on dead times: for shorter dead times a higher energy is required. In continuous mode further increased energy is necessary.
Moreover, the maximum concentration values are, within experimental uncertainty, comparable, independent of power on/off ratios and of plasma mode.
To explain these surprising and outstanding results, we have to consider two wave forms with dead times 4 ms and 9 ms as depicted in Figure 2.

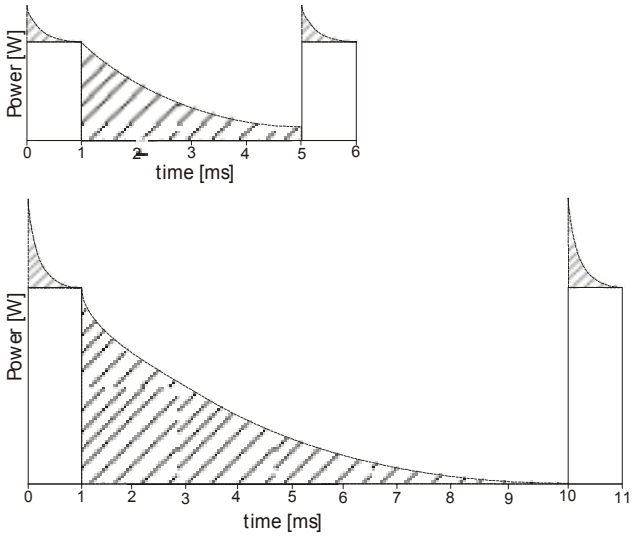

Figure 2: comparison between ideal and experimental pulse sequence at 1/4 ms and 1/9 ms ratios.

So, in order to reproduce the same experiments with different pulse ratios in an ideal case (see whole curves in Figure 2) the equivalent power $P_{equivalent}$ has to remain constant, it results that:

$$P_{equivalent1/9} = \frac{1}{10} P_{Max1/9} = P_{equivalent1/4} = \frac{1}{5} P_{Max1/4}$$

$$P_{Max1/9} = 2P_{Max1/4}$$

Hence it might be assumed that at 1/9 ms a double input power is needed to obtain comparable conditions as at 1/4 ms (after glow).
In the real case however, the pulses have a form as depicted in Figure 2 with dashed curves.
When the generator is switching on, a spike occurs and this is clearly higher for higher maximal powers. When the generator is switching off, the plasma discharge remains for a certain time on. Considering the areas below the dashed curves, it appears evident that with longer dead times a larger input energy is introduced. Consequently, to achieve equal results at longer dead times, a lower equivalent power $P_{equivalent}$ is required.
Furthermore it could be supposed that in continuous mode a lower energy to activate/ support plasma polymerization to avoid the fragmentation of carboxylic groups is necessary. But, during the on-period, in pulse mode, the electron density responsible for the existence of H^+ and for the building free radicals is higher than in continuous mode [6]. Therefore a greater input power in continuous wave is required . These suppositions are confirmed by the results presented in Figure 1.

3.2.2. Transfer to different substrates

Functionalization by means of carboxylic groups is not restricted to polypropylene but it can be extended to other substrates. In our experiments we also used successfully polycarbonate, polyethylene, polystyrene, as well as Si wafer, titanium or nickel free steel.
For the achievement of these treatments, it is important to match the necessary activation energy in order to create free radicals for every substrate.
All the samples were stirred in bi-distilled water for 30 minutes and then dried. Infrared spectra, registered before and after washing, show no changes. In all spectra a new peak at 1715 cm^{-1} appears and it demonstrates that carboxylic groups on the surfaces are present and chemically bounded. Furthermore, three peaks emerge: a broad band with center at about 3000 cm^{-1} is typical for -OH bridges stretching oscillations; another band likewise broad band appears between 2700 and 2500 cm^{-1}, characteristic for carbon acid dimers is the result of combination oscillations of C-O stretchings and O-H deformations. At last, a broad band between 1315 and 1280 cm^{-1} but not always good discernable, to attribute to C-O stretching oscillations is also expected.
All samples, apart from polystyrene, were also analyzed by means of fluorescence coupling [4,5] and the carboxylic groups were detected.
For Si wafer, titanium, and steel we presume that an oxide layer already present on the surface of materials can contribute to the formation of O-H Bridges.

Up-scaling to different reactors

With the aim of transferring the successful experiments of the round reactor to the “DIN A3” one, or in general to another reactor with different forms or volumes, it is important to consider some plasma parameters as well as electrical connections, monomer inlet and pump system. The generator was connected via a matchbox and a V/I Probe in the middle of the “hot” electrode ensuring an homogeneous power input and minimizing the reflected power. The lower electrode was grounded centrally maintaining the system as best as possible symmetrical. The monomer, in our case acrylic acid, was introduced in the round reactor, directly in the middle of the powered electrode, confining a polymerization process only between the electrodes. Therefore, the samples (75 mm in diameter) situated in the middle of the lower electrode were met perpendicular from all the possible plasma created species.
For this reason the “DIN A3” reactor was chosen: a shower system ensured that plasma particles encountered the rectangular samples (240 x 340 mm^2) in a similar way as in the round reactor.
In both reactors the rest gases were exhausted through three tubes by means of a vacuum pump, providing also uniform monomer/activation gas flows in the plasma chamber. Also the distance between electrodes is a consistent parameter to obtain stable plasma polymer with high carboxylic-groups concentration. This variable was also investigated; it was found when maintaining all other plasma parameters fixed, a maximum in COOH concentration at 80 mm distance was reached. This value was hold constant in both plasma systems.
A parameter which depends directly on the flow rate is the residence time τ of a gas molecule, that is the mean time it remains in the process chamber before being pumped away. If the volume of the chamber is V and S is the pump rate then:

$\tau = V/S = pV/pS = pV/Qp_o$

where Q is the flow rate of the molecular gas, p is the pressure in the reactor and p_o is the atmosphere pressure.
If we suppose to have a hydrogen flow of 4 sccm in the round reactor with the pressure p = 0.054 mbar and a plasma volume V = 2513 cm^3 = 2.513 l, the residence time results τ_{round} = 2 s. In the "DIN A3" reactor the plasma chamber has a volume of V = 9726 cm^3 = 9.726 l about 4 times bigger than the round one. This implies that in order to maintain the residence time τ constant also in the " DIN A3" reactor, it is necessary to increase the hydrogen flow rate of a factor 4 at the same pressure.
Similar considerations can also be made for the monomer, acrylic acid: for the experiments carried out in the round reactor the acrylic acid flow was about 1sccm at a pressure of p = 0.032 and consequently a flow of ca. 4 sccm in the "DIN A3" was required. Unfortunately acrylic acid has a relative low vapor pressure at room temperature (3,8 hPa at 20 °C) . The two possible solutions to maintain the pressure constant were either to heat up the monomer or to throttle the vacuum system. The second alternative was chosen because a higher monomer temperature could cause a polymerization of acrylic acid in the system before it reached the plasma chamber. The monomer flow was set to about 2.5 sccm and the hydrogen to 10 sccm (in an ideal case the flow should be Q_{AAc} = 4 sccm and Q_{H2} = 16 sccm).
In figure 1was shown that the polymerization process, in pulse or in continuous mode, is only possible within some input power regions, in which the carboxylic group concentration reaches a maximum. We focused our attention on the process in continuous mode at 22 W with a maximum of COOH-groups concentration being reached. At this input power reactor an optimal matching is achieved in the round and we attempt to reproduce the same results also with the "DIN A3" reactor.
Hence, in order to applicate the same input energy, it is important to correlate the discharge power to the glow discharge volume or to the glow discharge surface (because, in our case, the distance between electrodes is kept constant).
For the round reactor, the input power density $D_{round} = W_{round} / A_{round}$ = 22 / 314.12 = 0.07 W/cm^2, where A_{round} is approximated to the area of the electrode. Since the density value has to remain constant in both systems and the area "DIN A3" electrode is A_{A3} = 1131 cm^2, the input power should be around 80 W. In table 1 the results of plasma polymerization experiments are reported in the round and the "DIN A3" reactor with three different deposition times at 22 W and 80 W, respectively.

	Plasma treatment time [min]	Film thickness after washing [nm]	-COOH group concentration [10^{-9} mol/cm^2] (fluorescence)	-COOH group concentration [10^{-4} mol/cm3]
Untreated PP	-	-	0	0
AAc plasma coated PP in a round reactor	10	176 ± 7	26 ± 3	14 ± 2
	20	285 ± 9	37 ± 4	13 ± 2
	30	394 ± 8	53 ± 5	13 ± 2
AAc plasma coated PP in a DIN A3 reactor	10	177 ± 19	30 ± 3	17 ± 2
	20	265 ± 25	46 ± 5	17 ± 2
	30	379 ± 7	60 ± 6	16 ± 2

Table1: ESCA, fluorescence and thickness measurements results of samples treated in the round and "DIN A3" reactor with different deposition times

It appears that in both reactors homogeneous comparable layers can be produced: considering fluorescence measurements, the carboxylic group concentration of the volume growths with the deposition time, that means the density of the functionalities remains constant in the bulk.

4. CONCLUSIONS

We can conclude that for the formation of acrylic-like layers with a very high concentration of carboxylic groups, according to our findings, a pulsed plasma is not necessarily required to modify PP substrates.
These layers are stable and can also be deposited on different substrates.
As described RF plasma polymerization with acrylic acid can successfully be performed in different reactors regarding certain plasma parameters.

An Efficient Model For Inductively Coupled Multi-component Plasmas

G. Wenig[1], P. Scheubert[1], P. Awakowicz[1]

[1] *Institute for Physics of Electrotechnology, Munich University of Technology, Munich, Germany*

Abstract
An efficient model for inductively coupled plasma sources is presented. It unifies physical accuracy with computational efficiency. The plasma is divided into bulk and sheaths with separate models for each region. For sheath regions a compact model is used. It takes the particle fluxes as input parameters and gives back the plasma variables at the cut edge between bulk and sheath. For the plasma bulk a drift-diffusion-model is applied. Model results are in excellent agreement with full hydrodynamical calculations.

1. Introduction

Most technological applications of low pressure low temperature gas discharges rely on plasma chemical processes. Prominent examples are given by semiconductor manufacturing or surface coating technology, e. g. These plasmas often contain more than one neutral and ionic species. Inductively coupled plasma sources (ICPs) offer high electron densities and low ion energies at the same time. Therefore, they are well-suited for many, especially sensitive, applications. In order to optimize such processes, a detailed knowledge about the discharge characteristics such as spatial profiles of particle densities or particle fluxes towards the walls is desired. Furthermore, the dependence of the discharge properties on external parameters like neutral gas pressure or input power is of great interest. This information can be obtained by an intimate interplay between diagnostics on the one and modelling and simulation on the other hand. With respect to simulation, two partially opposed major goals are physical accuracy and computational efficiency. In this paper, a model for inductively coupled plasma sources with more than one positive ionic species is presented which satisfies these two demands.

2. An Efficient Two Fluid Plasma Model

Fluid models are commonly applied to describe inductively coupled plasma sources. They consider the plasma as a mixture of two fluids (electrons and ions), which are described by a set of conservation equations. Fluid models can be divided into hydrodynamic models and drift-diffusion-models. The hydrodynamic models use a full momentum balance, whereas the drift-diffusion-models simplify the momentum balance by neglecting the influence of the particle's inertia. Hydrodynamic models can describe the transport properties of all species in a plasma, including the plasma boundary sheaths, e.g. [1]. This however requires a large computational effort, which can be reduced by applying a drift-diffusion-model. Models of this class, however, cannot describe the transport properties of ions in the sheath correctly, as ion transport is dominated by inertia there. In order to gain computational efficiency without sacrificing physical accuracy, in this work a drift-diffusion-model for the plasma bulk was combined with a compact model for the sheaths.
This compact model takes the fluxes of all species as input parameters [2]. It gives back the values of the plasma parameters at the cut edge between sheath and bulk. These values are used as boundary conditions by the bulk module, which in turn delivers updated values for the fluxes. In this way the calculation of a self-consistent solution for the whole discharge is possible.

2.1. Plasma Bulk Model

In the plasma bulk, conservation of mass is considered for all species,

$$\frac{\partial n_k}{\partial t} + \nabla \cdot \vec{j}_k = G_k(T_e), \qquad (1)$$

where $k = e$ for the electrons and $k = i$ for the ions. Here, n_k is the particle number density and j_k the corresponding particle current density. Particle generation of species k is described by the generation rate $G_k(T_e)$, which depends on the electron temperature T_e. The current densities are given by the drift-diffusion-approximation,

$$\vec{j}_k = \frac{q_k n_k}{m_k n_k}\vec{E}_{amb} - \frac{1}{m_k n_k}\nabla n_k k_B T_k . \qquad (2)$$

Here, k_B denotes Boltzmann's constant, q_k the charge and m_k the mass of species k. The collision frequencies n_k describe elastic collisions with neutral atoms. The ambipolar electric field is $\vec{E}_{amb}$.
Additionally, conservation of energy is considered for the electrons:

$$\frac{\partial n_e e}{\partial t} + \nabla \cdot \vec{\Gamma}_e = q_e \vec{E}_{amb} \cdot \vec{j}_e - P_c + P_h . \qquad (3)$$

Here, $e = \frac{3}{2} k_B T_e$ is the mean electron energy. Energy losses by collisions with neutral particles are described by P_c. The heating of the plasma is accounted for by P_h. The electron energy current density $\vec{\Gamma}_e$ consists of a convective and a thermal conductivity contribution:

$$\vec{\Gamma}_e = \frac{5}{2} k_B T_e \vec{j}_e - \frac{5}{2}\frac{n_e k_B T_e}{m_e n_e}\nabla k_B T_e . \qquad (4)$$

The ambipolar electric field $\vec{E}_{amb}$ is derived from an electrostatic potential Φ, which in turn can be calculated from Poisson's equation,

$$\Delta\Phi = -\frac{1}{e_0}(q_e n_e + \sum q_i n_i) , \qquad (5)$$

where the sum runs over all ionic species.

2.2 Plasma Boundary Sheath Model

In the plasma boundary sheath, ion transport is governed by inertia. Therefore, the compact model presented below is based on the full hydrodynamic equations for ions. Due to their small mass, the electrons can be described by the drift-diffusion-approximation in the sheath region as well.

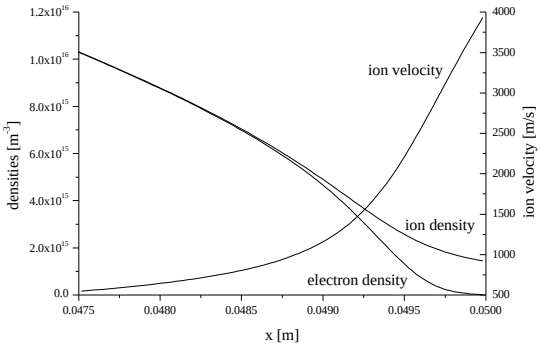

Figure 1: Profiles of particle densities and ion velocity in front of a conducting wall

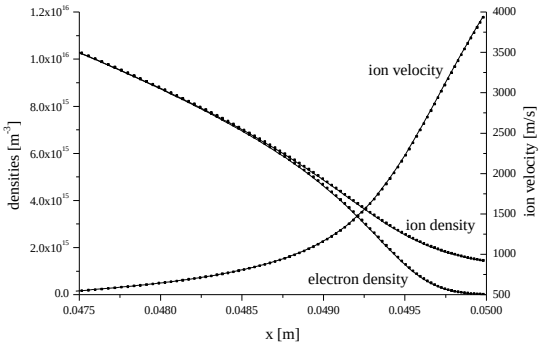

Figure 2: Comparison between full (symbols) and reduced (lines) sheath simulation

The case of a plasma with one single positive ionic species may serve as a starting point for the derivation of the compact modell. Fig.1 shows the sheath region of an argon plasma at $p = 10$ Pa and $T_e = 19300$ K as obtained by a hydrodynamic simulation of the discharge. The discharge length is 10cm and only the last 2.5mm in front of a conducting wall at $x = 0.05$ m are shown. The lines indicate density and velocity profiles as obtained from a hydrodynamic simulation of the whole discharge. In a first step, the goal is a hydrodynamic simulation of the sheath region only, without solving the equations for the bulk. It is assumed that the particle fluxes from the bulk into the sheath are known. They serve as input parameters for the sheath model. The missing three boundary conditions at the cut edge are derived as follows: As the plasma bulk must be quasi-neutral, the electron and ion densities approach each other away from the wall. Therefore, the density gradients can be equated with each other at x= 0.0475m,

$$\frac{\partial n_e}{\partial x} = \frac{\partial n_i}{\partial x} . \qquad (6)$$

Furthermore, the ion velocity profile flattens out towards the bulk, i.e. the curvature vanishes,

$$\frac{\partial^2 v_i}{\partial x^2} = 0. \tag{7}$$

This is due to the disparity between the relevant length-scales, namely the Debye-length for the sheath and the ion mean free path or the reactor dimension for the bulk. This scale is typically at least one order of magnitude larger than the Debye-length. Finally, one has to define the cut-edge between bulk and sheath. The use of the Bohm criterion is not adequate here, as it does not judge the relative importance of ion inertia. Therefore, we track beginning space charge separation and define the cut edge by the relation

$$\frac{n_i}{n_e} = 1 + a, \tag{8}$$

where a is a positive real parameter. Reasonable values are given by $a = 10^{-3}...10^{-2}$. The results of the hydrodynamic simulation of the sheath only are shown by the lines in fig. 2. By comparison with the full solution (symbols in fig. 2) one concludes that the above approximate boundary conditions introduce small errors only. From here, one derives the sheath compact model consisting of a small algebraic system of equations. This will be sketched below, a complete derivation can be found in [3]. From the necessary five algebraic equations, two are delivered by equating the prescribed values of the particle fluxes with their model expressions. Two more equations are obtained by further exploring the above boundary conditions with the help of the stationary fluid equations: In the stationary case the fluid equations express the ion density and velocity gradient as functions of the plasma variables. These functions can be inserted into the boundary conditions, yielding two more algebraic equations between the unknowns at the cut edge. The last equation is given by the definition of the cut edge which remains unaltered.

For the case of multiple positively charged ionic species, the model is generalized as follows: As before, the model uses the electron particle flux and the fluxes of all ionic species as input parameters and equates them with the corresponding model expressions. In eq. (6) the single ion density is replaced by the total ion particle density, leading to

$$\frac{\partial n_e}{\partial x} = \sum \frac{\partial n_i}{\partial x}, \tag{9}$$

where the sum again runs over all ionic species. The same replacement transforms eq. (8) into

$$\sum n_i \Big/ n_e = 1 + a, \tag{10}$$

with the meaning of the parameter a unaltered. Furthermore the model assumes that the velocity curvature of all ionic species vanishes at the cut edge. For S ionic species we thus have $2S+3$ unknowns and just as many algebraic equations. The solution of the algebraic equations delivers the cut edge parameters in a computationally very efficient manner.

As an example, the sheath region of an argon-helium-plasma with $p = 20\,\text{Pa}$ and $T_e = 22500\,\text{K}$ is shown in fig. 3.

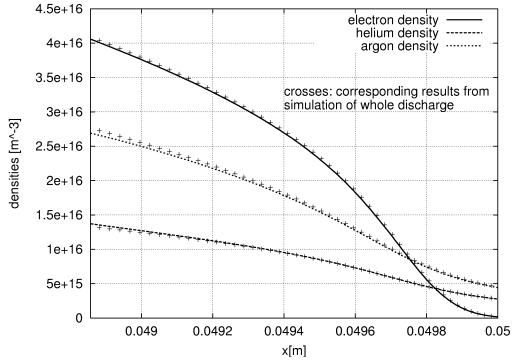

Figure 3: Comparison between full (symbols) and reduced (lines) sheath simulation for the argon-helium-plasma

The symbols indicate the particle density profiles as obtained from a hydrodynamic simulation of the whole discharge. The full lines show the results of the simulation of the sheath region only. As for the case of one ionic species, the results of the reduced model are in excellent agreement with the full solution. The largest discrepancy is visible for the argon ion density. Tab. 1 compares the values of the plasma variables at the cut edge as obtained by full hydrodynamic simulation and the sheath compact model.

Table 1: Comparison of values of the plasma variables at cut edge from simulation of the whole discharge and the sheath model.

	Whole discharge	Sheath model	Error [%]
Electric field [V/m]	940	960	2.10
Electron density [m^{-3}]	$4.10 \cdot 10^{16}$	$4.06 \cdot 10^{16}$	1.00
Helium ion density [m^{-3}]	$1.35 \cdot 10^{16}$	$1.37 \cdot 10^{16}$	1.46
Argon ion density [m^{-3}]	$2.80 \cdot 10^{16}$	$2.69 \cdot 10^{16}$	3.93
Time consumed	~ hours	~ seconds	

The last column in tab. 1 lists the absolute values of the relative error between the hydrodynamic solution of the whole discharge and the values computed by the sheath compact model. The largest deviation occurs for the argon ion densitiy and amounts to roughly 4 %. Compared to the enormous increase in computational efficiency an error as small as this is easily acceptable.

2.3. Electrodynamic Model

Inductively coupled plasmas are heated by externally applied rf fields. In order to calculate these fields self-consistently along with the plasma parameters, an electrodynamic model [4] derived from Maxwell's equations is used. If all quantities vary harmonically in time with an angular frequency w, the induced rf electric field $\vec{E}$ is described by the partial differential equation

$$\Delta\vec{E} + k^2\vec{E} = iwm_0\vec{j} \text{ with } k^2 = e_r\frac{w^2}{c_0^2} - iwm_0 s \ . \tag{11}$$

Here, c_0 denotes the vacuum speed of light, m_0 the permeability of free space and e_r the relative dielectric constants of the reactor materials. The current density in the coils is given by $\vec{j}$. Finally, s describes the electrical conductivity of the different regions. For the conducting reactor walls infinite conductivity is assumed. The conductivity of the plasma is described by the cold plasma approximation [5]

$$s = n_e\frac{n_e e^2}{m_e(n_e^2 + w^2)} - iw\frac{n_e e^2}{m_e(n_e^2 + w^2)}. \tag{12}$$

The power density deposited in the plasma is then given by

$$P_h = \frac{1}{2}\Re\{s\}|\vec{E}|^2 \ . \tag{13}$$

3. Results

Results are presented for cylindrical reactor vessel with a radius of 75mm and a height of 100mm. The reactor is operated at an rf frequency of 27.12 MHz. The following figures show electron density profiles along a radial cutline at half the reactor height.

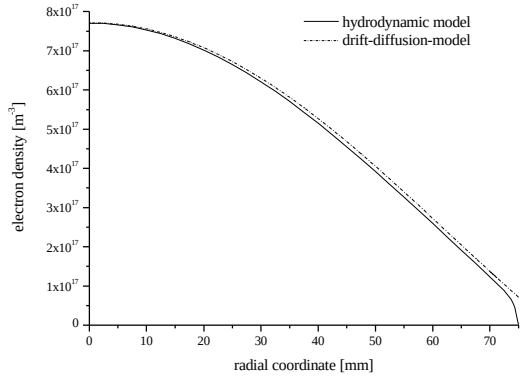

Figure 4: Radial profile of electron density as obtained by hydrodynamic (full line) and drift-diffusion-modell(dashed line) for a coil current of 16.0 A.

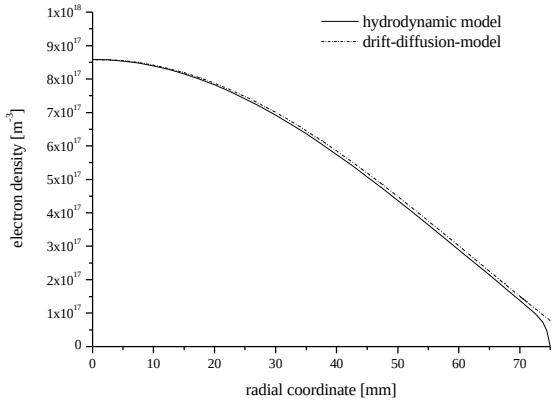

Figure 5: Radial profile of electron density as obtained by hydrodynamic (full line) and drift-diffusion-modell(dashed line) for a coil current of 16.7A

Fig. 4 and 5 show radial profiles of the electron density for a helium plasma at 20 Pa. The coil currents are 16.0A and 16.7A, respectively. The axis of symmetry corresponds to $r = 0$ mm, the reactor wall is situated at $r = 75$ mm. In both figures the solid line represents the results of a full hydrodynamic calculation. The dashed line was obtained by a drift-diffusion calculation in combination with the boundary sheath model sketched above. The value $a = 10^{-3}$ was used. Both model predictions are in excellent agreement. The conceptual difference between both models becomes visible in front of the reactor wall. The hydrodynamic model resolves the steep gradient of the electron density in the boundary sheath. This requires a very fine computational grid in front of the walls and increases the computational demand. In the drift-diffusion-model, however, the boundary sheath is treated by the compact model. This especially means that the small spatial extension of the sheath is neglected. The boundary of the computational domain is now actually defined implicitly by eq. (8) and differs from the reactor dimension by the geometrical extension of the sheath. In the simulation, however, this difference is neglected and the boundary of the computational domain is re-defined by the reactor wall. This leads to the small differences between both models. These differences can be controlled by varying the cut edge parameter a .

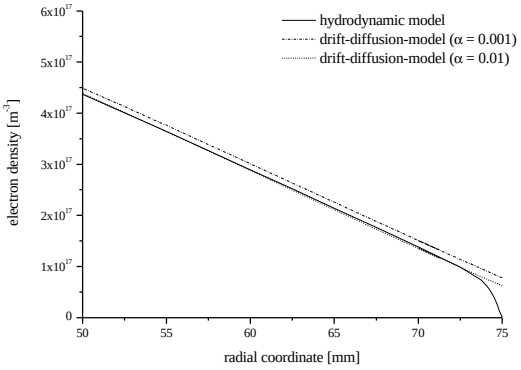

Figure 6: Variation of electron density profile with cut edge parameter a .

Fig. 6 shows two electron density profiles obtained from the drift-diffusion-model for $a = 10^{-3}$ and $a = 10^{-2}$, respectively. The curve for $a = 10^{-2}$ can hardly be distinguished from the hydrodynamical results, whereas the curve for $a = 10^{-2}$ shows the deviations discussed above. This improvement in agreement is due to the fact that a larger value of a corresponds to a definition of the cut edge closer to the reactor wall.

4. Conclusion

A new approach to modelling inductively coupled plasmas has been presented. Here, the plasma bulk is described by a drift-diffusion-model. The plasma boundary sheaths are represented by an efficient compact model which can handle various positive ionic species. This compact model consists of a small system of algebraic equations from which the plasma variables at the cut edge can be calculated in dependence of the particle fluxes into the sheath. This compact model has been proven to yield results in good agreement with much more expensive hydrodynamic calculations.

Comparison between two different torches to inject a suspension to produce thin perovskite coatings

C. Monterrubio-Badillo, H. Ageorges, T. Chartier, J. F. Coudert and P. Fauchais

Laboratoire SPCTS-UMR-CNRS 6638, Université de Limoges, Faculté des Sciences et Techniques, 123 avenue Albert Thomas, 87060 LIMOGES CEDEX, FRANCE.

Abstract

When plasma spraying $LaMnO_3$ perovskite very often decomposition occurs. Thus the purpose of this work is to study the phases present in coatings obtained by injecting a suspension of sumicrometric $LaMnO_3$ perovskites powders (d_{50} = 1 μm) in a direct current d.c. plasma jet produced with two different plasma torches (laboratory torch and PT F4 torch) working with different plasma forming gases : Ar (45,8 slm) and Ar/He (44/10, 43/20 and 30/20 slm). The process consists in mechanically injecting a well dispersed stable suspension of submicrometric perovskite particles in a dc plasma jet. In the process, large suspension droplets (~300 μm) are sheared into tiny ones (a few μm) by the plasma jet flow. Then the solvent is evaporated and the particles melt resulting in perovskite droplets of about 1 μm impacting on the substrate. These coatings will be used as cathodes for the SOFCs (Solid Oxide Fuel Cells). Best results are obtained by injecting a stable suspension in an Ar plasma forming gas when increasing its mass flow rate (with both types of torch). This is due to the higher momentum transfer towards particles and the lower heat transfer to reduce their decomposition.

1. Introduction

Semiconducting oxides (perovskites) based on $LaMnO_3$ doped with SrO and CaO, are most often used as cathode material for the solid oxide fuel cells (SOFCs), [1] due to their high electrical conductivity and their compatibility with the solid electrolyte, generally yttria doped-zirconia [2]. Solid oxide fuel cells are promising candidates for future systems because of their high energy conversion efficiencies and low environmental hazards. Many investigations have been carried out with regard to the choice of materials and processing techniques. However, there are few processes that can be used to fabricate high performance cells quickly and inexpensively. Plasma spraying is a promising candidate for such a process [3]. Until now, only thick coatings (> 100 μm) of perovskite have been elaborated using d.c. plasmas, by injecting, with a carrier gas, micrometric particles in the plasma flow [4]. But it is not possible to inject too small particles (<5 μm) without drastically perturbing the plasma jet by the high carrier gas flow rate necessary to give particles a sufficiently high momentum. In addition, the coatings with nanometric to submicrometric grain sizes exhibit unique properties due to their different physical and chemical properties (electric, dielectric and photoelectric properties) in comparison with coatings having coarse grain sizes [5], thus they are attractive for various high performance applications (such as fuel cell).

The plasma spray process to obtain perovskite thin films is more attractive because of its fast deposition rate and easy masking for deposition of patterned structures, compared with other films formation processes such as electrochemical vapor deposition, chemical vapor deposition, and sputtering. Therefore, the plasma spray process is being considered as a means to reduce manufacturing costs. Coatings of perovskite oxide, may change in chemical composition compared to that of the initial powder and exhibit chemical heterogeneity due to the material volatility in the plasma jet [6]. These problems must be avoided in order to obtain a high electrical conductivity of the cathodes and match the thermal expansion coefficients, as required for SOFCs. The aim of this work is the production of thin coatings (10 to 20 μm) of perovskite with a minimal decomposition by injecting a suspension with submicrometric particles (d_{50} < 1 μm) dispersed in a solvent (ethanol). The principal objective of this study is to compare the difference between two plasma torch types (laboratory torch and industrial torch) with their injection systems of the perovskite suspension. In particular, the following items are investigated :

- The effect of the two different plasma torches on the composition of perovskite coatings.
- The effect of the composition of plasma gases on the composition and morphology of collected particles in flight.

2. Experimental

2.1 Starting materials

La_2O_3 (d_{50} = 24 µm) and MnO_2 (d_{50} = 3.32 µm) powders supplied by CERAC with a high-purity grade (99.99 %) were weighed in stoichimetric proportions and finely ground and thoroughly mixed by attrition milling during 4 hours. The mixture was sintered at 1100 ^{o}C for 6 hours in air. The sintered material was subsequently broken up and finely ground again by attrition milling. The particles obtained after milling have a size distribution in the range 0.1 to 2 µm, with a d_{50}= 0.8 µm, Figure 1a, and a prismatic shape, Figure 1b. The suspension was prepared by adding perovskite powders into an ethanol solution with a dispersant [7]. The solvent allows the solubility of the organic dispersant and the well dispersed particles result in a homogeneous stable suspension.

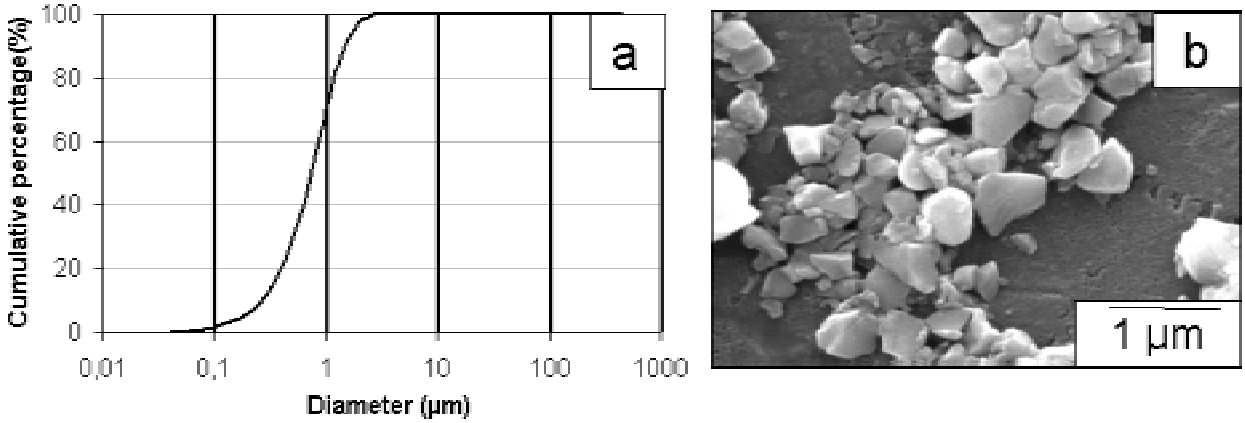

Figure 1. a) Particle size distribution of a perovskite powder elaborated by sintering and b) morpgology of the milled perovskite powder.

Physical properties of the milled perovskite powder are shown in Table 1 and the characteristics of the suspension in Table 2.

Table 1 Physical properties of $LaMnO_3$ perovskite powder

Powder	D_{50} (µm)	D_{90} (µm)	S (m^2/g)
$LaMnO_3$	0.8	1.5	4.2

Table 2 Characteristics of the perovskite suspension

Suspension	wt % of powder	wt % dispersant	Viscosity (mPa.s)
$LaMnO_3$	20	0.4	12

2.2 Plasma Spraying Set-ups

Figure 2 presents a scheme of the experimental system in the configuration used for collecting the splats and films in air. Atmospheric Plasma Spraying (APS) is achieved with conventional d.c. plasma guns with a 6 mm internal diameter anode-nozzle to produce thin films [8]. This process consists in a mechanical injection of a liquid suspension in the plasma jet produced by two different plasma torches. One torch, made in the laboratory, has a copper anode with a rather long nozzle where the suspension is injected internally while the other one is an industrial PTF4 torch where the suspension is injected externally.

The mechanical injection creates calibrated droplets with controlled velocity and flow rate. The torch working parameters have been adjusted according to the liquid injection by using different plasma gas mixtures and arc currents. It is worth to note that, for the same input parameters, both torches with the same anode nozzle i.d. have different voltages, those of the PTF4 torch being systematically higher (by 4 to 10 V according the plasma gases).

The $LaMnO_3$ perovskite suspension is injected in plasma jets obtained with different plasma forming gases in both torches: Ar (45.8 slm) and Ar/He with three different mixtures of gases (44/10, 43/20 and 30/20 slm) corresponding to different enthalpies and mass flow rates (see Figure 3 and Table 3, respectively). The arc current used to create the plasma jet is fixed at 300 A in order to limit the jet enthalpy, because of the extreme sensitivity of the perovskite powder to high temperatures, promoting its decomposition. Other

parameters were kept constant: stand off distance 40 mm, injection pressure 0.4 MPa, torch cooling water flow rate 16.5 slm at a pressure of 0.16 MPa.

The investigation of the behavior of the particles in the plasma jet requires their collection in flight at different distances from the torch-nozzle exit (Figure 2). This is achieved by passing once, at a controlled velocity, through the plasma jet a glass plate disposed at the extremity of a pendulum. The collected particles or splats are used to determine their molten state or morphology. However, in order to achieve a sufficiently thick coating for X-ray diffraction (XRD), the substrate (a 316 stainless steel plate) needs to be passed 30 times through the plasma (keeping the torch fixed).

2.3 Characterization and Analysis

The microstructure and morphology of particles, splats and coatings were examined by scanning electron microscopy SEM, (Phillips XL 30). All the images obtained were made with secondary electrons (SE). The energy Dispersive Spectroscopy EDS, (LINK ISIS 300) was used to analyze the distribution of chemical elements in samples. The X-Ray diffraction (XRD, Cu Kα) was used to determine the phases present in powders and coatings, the spectra being recorded on a Siemens diffractometer. To determine the particle size distribution a Cilas Laser granulometer was used.

3. Results

3.1 Splats Collection, Morphology and Composition

Figure 4a and 4c show the morphology of collected splats and particles with Ar (45 slm) as plasma gas (arc current of 300A), with the laboratory and PTF4 torches, respectively. The particles correspond to molten ones which have cooled down, impacted on the plate in a plastic state and stuck to it but have not deformed. It can be seen that, with the laboratory torch, a high percentage of non molten or partially molten particles is found, however with the PTF4 torch all particles are well melted due to the higher enthalpy (see figure 3). But, when helium is added to the plasma gas, all particles are well melted in both torches at all plasma conditions. However, differences in morphologies and particle diameters are observed. Figures 4b and 4d show splats and particles collected with an Ar/He (44/10 slm) plasma gas with both torches, splats collected

result from well molten particles. Figure 4b, shows fingered splats with a diameter in the range of 5 to 10 µm whereas splats obtained with the PTF4 torch are disk shaped and their diameter is in the range of 1 to 5 µm. With the others Ar/He plasma forming gases, the particles collected are also well melted.
Figure 4e, shows an EDS analysis of the collected splats with Ar as the plasma forming gas and a PTF4 torch (Figure 4c); manganese, lanthanum and oxygen elements are present in all splats. This confirms that the perovskite phase is present in melted particles. Ca, Si and Mg are elements of the glass plate used to collect splats and Au detection is due to the metalization. The Figure 4f shows a fractured surface of perovskite coating collected at 40 mm of nozzle exit, obtained with the PTF4 torch working with Ar (45 slm). It can be observed, the tiny spherical particles incorporated in the coating, which could correspond to the small particles collected with the splats (see Figure 4a, b, c and d).

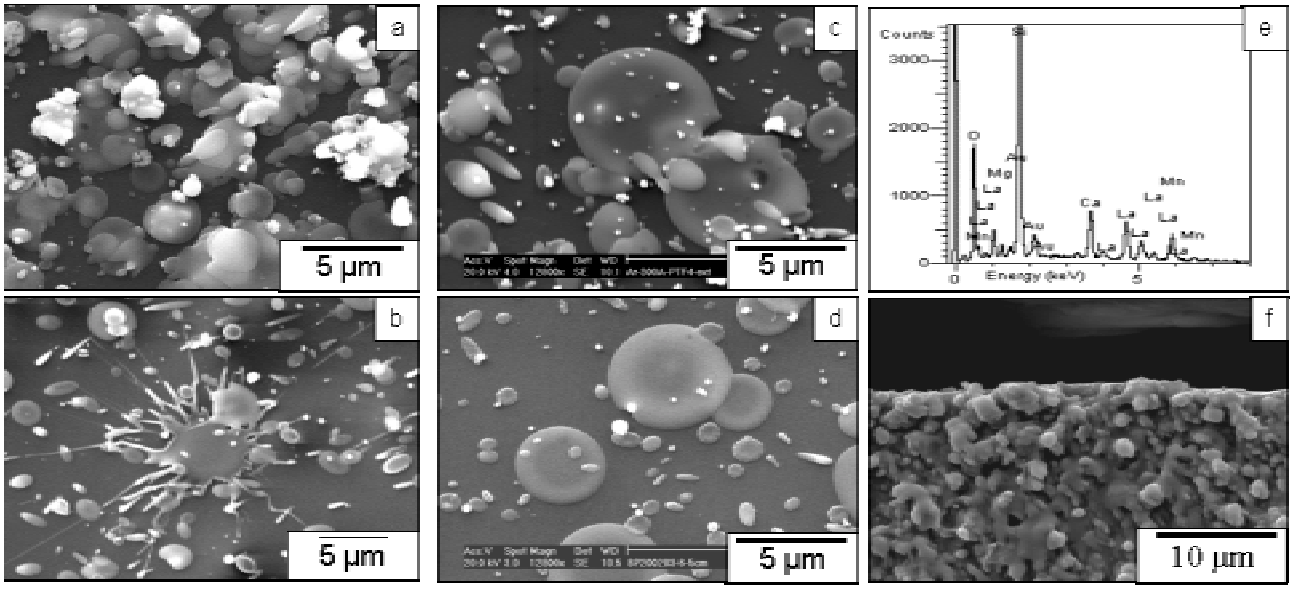

Figure 4. Splats collected on glass plates at 40 mm of the nozzle exit, with the laboratory torch: a) with Ar (45.8 slm), b) with Ar/He (44/10 slm) and with PTF4 torch: c) with Ar (45.8 slm), d) with Ar/He (44/10 slm); e) EDS analysis of the splats collected in figure 4c; f) fractured surface of a perovskite coating, sprayed with the PTF4 torch at 40 mm with Ar (45 slm).

3.2 Obtained Phases in Coatings with both types of torches

Figure 5a, shows the cross section of a perovskite coating (obtained with Ar as plasma forming gas and a PTF4 torch) on an yttria stabilized zirconia (YSZ) plasma sprayed coating, starting from an YSZ suspension, which is used as electrolyte. The perovskite thickness is 20 µm aproximately. The film exhibits sufficient porosity to be used as cathode for the fuel cells. Figure 5b shows a magnification of the interface of $LaMnO_3$ and YSZ films where a good adherence of the two films can be observed.
To study the phases present in the perovskite deposits, stainless steel substrates without zirconia have been used to avoid the superposition of YSZ peaks with those of perovskite. Figures 6a and 6b show the phases obtained in coatings when a perovskite suspension is sprayed with laboratory and PTF4 torches respectively. $LaMnO_3$ and La_2O_3 are present in coatings and with the PTF4 torch a higher percentage of decomposition of perovskite is observed whatever may be the plasma forming gas used (probably due to the higher enthalpy compared to that of the laboratory torch). In cases of the figure 6b, substrate peaks appears because the thickness of the substrate is lower than in case 2, 3 and 4.

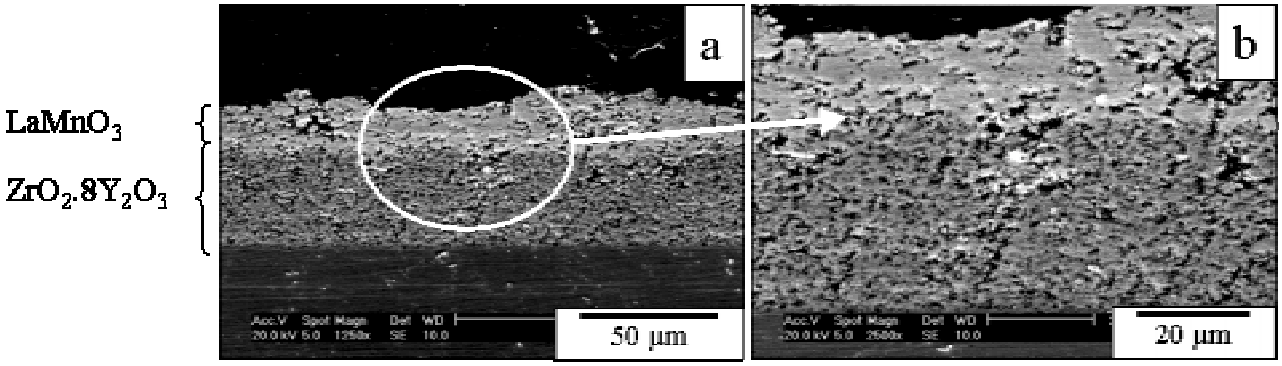

Figure 5. a) Cross section of a $LaMnO_3$ film on a YSZ electrolyte film plasma sprayed and b) magnification of the interface $LaMnO_3$ and YSZ films.

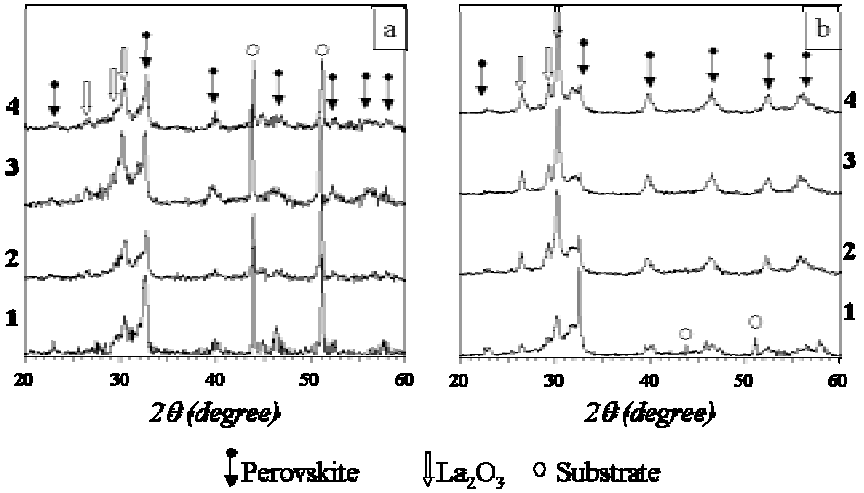

Figure 6. XRD of perovskite coatings obtained with a) the laboratory torch and b) the PTF4 torch. Conditions: 1) Ar (45.8 slm), 2) Ar/He (44/10 slm), 3) Ar/He (43/20 slm) and 4) Ar/He (30/20 slm).

The phases present in deposits are composed of $LaMnO_3$ with a La_2O_3 phase, MnO_2 is not present due to its high degree of volatilisation, its melting temperature being only 1840°C. A mechanism of the particles treatment in the plasma jet was proposed by Wittman et al [8] in which the first step in the occurring phenomena is the destruction, in about 1 µs, of the initial suspension drop (~ 300 µm) into numerous smaller droplets (~ 1 µm) upon penetration into the plasma, secondly the vaporization, in times of the µs order, of the solvent of those smaller droplets followed by the melting of the resulting agglomerates of submicrometric particles during their flight in the plasma jet. In the case of perovskite, evaporation of manganese occurs during the last step.

To synthesize the results obtained by X-ray diffraction, a quantitative analysis of the phases present in the coatings was carried out. Figure 7 shows the decomposition percentage of the perovskite phase in the plasma jet according to the conditions described in Table 3 with both types of torches.

The percentages of decomposition obtained with the laboratory torch are smaller than those obtained with the PTF4 torch for all different plasma forming gases. The results are in good conjunction with the enthalpy of the plasma jets (see figure 3), except for the first condition that corresponds to a pure argon plasma gas.

The variations of the spray parameters have shown that the perovskite decomposes, which is especially the case when H_2 is added to the plasma gas [9]. A careful adjustement of the plasma gas parameters is necessary to inject a suspension into the hot core of the plasma in order to have a minimum decomposition of the perovskite and achieve a sufficient particles melting in the plasma jet. It has been shown that the particles decomposition depends strongly on the spray parameters such as the type of the plasma torch, gas composition and gas enthalpy.

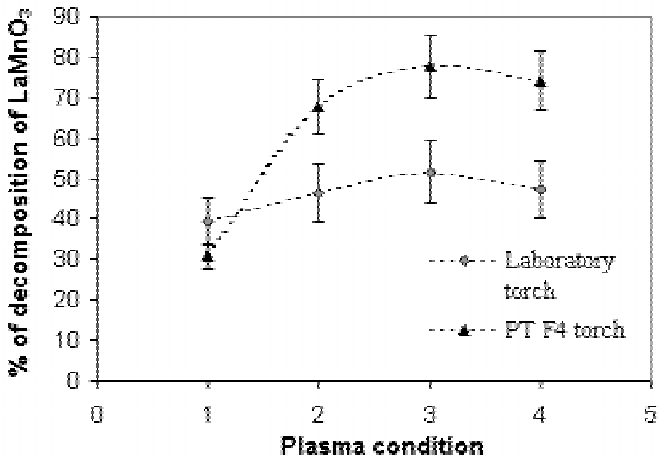

Figure 7. Comparison of the decomposition percentage of perovskite particles in the plasma jets, produced by laboratory and PTF4 torches.

Conclusions

A $LaMnO_3$ perovskite suspension was injected mechanically in a d.c. plasma jet with two types of torches (laboratory and PTF4 torches) to produce thin films (~20 μm). The plasma forming gases have been varied in order to obtain a perovskite thin coating without decomposition. Nevertheless, perovskite decomposition has been found in coatings. So, in the future, a perovskite rich in manganese and also a higher mass flow rate of gases will be consider, in order to obtain a coating with a good homogeneity in chemical composition after the thermal spray process.

Self-consistent kinetic approach to stratified regimes of plane and spherical glow discharges

A.V. Fedoseev, G.I. Sukhinin

Institute of Thermophysics, Novosibirsk, Russia

In the paper, a self-consistent model of stratified low-pressure argon glow discharge in plane and spherical geometries is presented. The model includes:

1. The non-local Boltzmann equation in two-term approximation for isotropic part of electron energy distribution function (EEDF) written in total energy–space coordinate representation

$$\frac{1}{r^n}\frac{\partial}{\partial r}\left[\frac{r^n U}{3H(U)}\frac{\partial}{\partial r}f_0(\varepsilon,r)\right]=\frac{\partial}{\partial\varepsilon}\left[2\frac{m}{M}U^2N_gQ^d(U)f_0(\varepsilon,r)\right]+\sum_k UN_gQ_k^{in}(U)f_0(\varepsilon,r)-\sum_k(U+U_k^{in})N_gQ_k^{in}(U+U_k)f_0(\varepsilon+U_k^{in},r), \quad (1)$$

where n=0 for plane geometry and n=2 for spherical one.

2. The non-stationary continuity equation in drift approximation for ions

$$\frac{\partial n_i}{\partial t}+\frac{1}{r^n}\frac{\partial}{\partial r}(r^n n_i\mu_i E)=n_e\nu_I, \quad (2)$$

$\nu_I(r)$ is the direct ionization frequency, μ_i is ion mobility coefficient.

3. Poisson equation for self-consistent electric field

$$\mathrm{div}\vec{E}=4\pi e_0(n_i-n_e) \quad (3)$$

The iterative numerical procedure for the solution of the striation problem is used. At the first step, to obtain the first approximation of distribution function f_0^0(r,U), the parabolic equation (1) is solved in some proposed electric field $E^0(r)$. From the f_0^0(r,U), the electron density distribution $n_e^0(r)$ and the ionization frequency $\nu_I^0(r)$ are obtained. With the help of Eqs.(2-3), new approximation of electric field E(r) is found and the procedure is repeated until successive iterations of electric field are converged. Usually ten iterations are enough for the procedure of convergence, and the final electric field distribution E(r) does not depend on the initial approximation of $E_0(r)$. However the voltage drop is kept constant.

It was found that the iterative process converges only for the case of moving striations. In plane discharge, the solution for ion density and electric field are looked for in the form $n_i=\overline{n}_i(\mathrm{v}_i t+r)$, $E=\overline{E}(\mathrm{v}_i t+r)$, with the striation velocity $\mathrm{v}_i=-\alpha\mu_i E_0$, $0\geq\alpha\leq 1$. For spherical case these relations are more complex. In Figs. 1-2, example of self-consistent field distribution and striation length is presented.

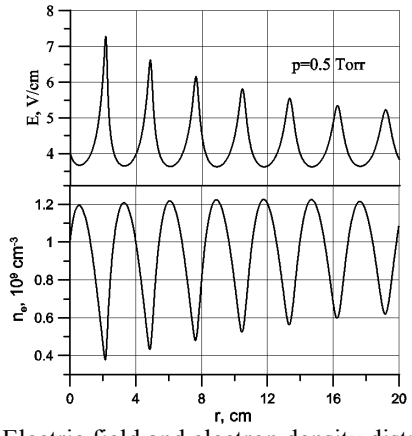

Fig.1. Electric field and electron density distributions in plane striated argon glow discharge.

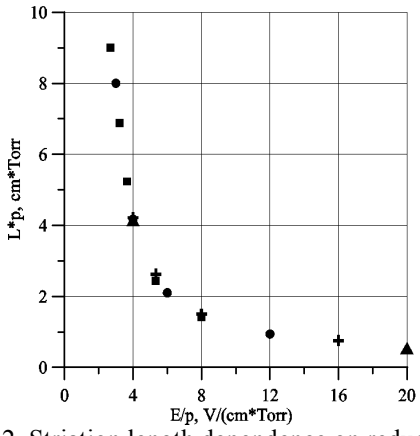

Fig.2. Striation length dependence on reduced electric field in plane glow discharge.

It is found that for argon pressures p>1.5 Torr striation are damped due to energy losses in elastic collisions. For spherical case, the averaged electric field radial distribution varies inversely proportional to the distance from anode, r, and is modulated with striations. The radius of n-th striation obeys the law $r_n\approx r_1\beta^n$.

Comparison of stainless steel coatings alumina reinforced by plasma spraying different size mechanofused particles

R. Cuenca Alvarez, H. Ageorges, A. Grimaud and P. Fauchais

Laboratoire SPCTS-UMR 6638, Université de Limoges, Faculté des Sciences et Techniques
123 avenue Albert Thomas, 87060 LIMOGES CEDEX, FRANCE

Abstract
Two different size distributions of stainless steel particles, with mean particle sizes of 126 µm (big: B) and 65 µm (small: S), coated by an alumina shell obtained by the Mechanofusion process (MF) were plasma sprayed in air (APS) to produce coatings with a ductile matrix reinforced by alumina particles uniformly distributed. The morphology of the splats collected onto non preheated and 300°C preheated substrates, the microstructures and micro hardnesses of coatings were analyzed.
Two types of splats are observed depending on the substrate temperature and the molten state of particles at impact. On cold substrates, the splats are extensively fingered. On preheated substrate at 300°C, with fully melted particles the alumina and stainless steel (SS) splats, almost disk shaped, are layered while with particles in a plastic state alumina pieces are randomly distributed around a SS splat. The occurrence of un-melted particles is important with the big ones. Thus the coatings obtained with small composite particles and sprayed on substrate preheated at 300°C exhibit a uniform distribution of alumina and a higher hardness (370 $\pm$ 43 HV5) than that of SS starting from the same particles size distribution (270 $\pm$ 22 HV5). With big composite particles due to the presence of unmelted particles coating hardness is slightly below that of pure SS starting from small particles.

1. Introduction
The mechanical properties of plasma sprayed metallic coatings depend strongly on the feedstock powder characteristics such as the particle shape, size and purity [1]. However these properties can be improved when composite raw powders are used to achieve composite coatings by the combining hardness of ceramics and the ductility of metals or alloys, provided that the ceramic phases are uniformly distributed within the coatings.
A variety of methods exist for the composite powders production for example agglomeration, chemical cladding, organic bonding and mechanical alloying [3-5]. However, the interest of using a mechanical route, such as the Mechanofusion (MF) process, is sustained by the lower cost of the technique and the fact that no additives are necessary [6-9]. The final characteristics of the mechanofused powder depend on the phenomena that take place during the MF processing, such as compression, attrition, frictional shearing and rolling. When two different particles, in terms of chemical composition and size distribution, are MF processed, the finest particles (guest particles) agglomerate on the coarser ones surface (host particles) with no need for binders [6]. Then, the resulting mechanofused composite particles can be used to achieve the composite coatings.
The aim of this paper is to evaluate the influence of two different stainless steel (316L) particle size distributions coated with an alumina shell of about the same thickness on the resulting splat morphologies and coating hardness.

2. Experimental Procedure
2.1. Composite particles preparation
The composite particles are prepared using an in-laboratory designed mechanofusion set-up, described elsewhere [8], with an internal diameter of 100 mm and a height of 30 mm. Four sets of powdered mixtures are analyzed to display the influence of the loading conditions on the oxide shell formation. Two host particle size distributions with mean particle size of 65 (S = small particles) and 126 µm (B = big particles) are considered. They result from the gas atomization of austenitic stainless steel (Fe +19wt.% Cr + 11wt.% Ni). The guest particles are from an alumina powder (CR6 from Baikowski Chimie, France) with a mean particle size of 1.0

μm. The powder loading conditions are summarized in Table 1. After mechanofusion processing, the resulting bigger particles are mesh sieved between 100 - 200 μm.

Table 1: Set of conditions of powdered mixtures.

Set name	Host particles		Guest particles
	316 Stainless Steel Particle Size Distribution [μm]		Mass Ratio of Al_2O_3 Powder/Stainless steel Powder [wt %]
B10	Big particles	-140 + 100	6.25
B20			11.77
S10	Small particles	-90 + 45	6.25
S20			11.77

2.2. Plasma spraying set-up

The mechanofused particles are sprayed using a d.c. plasma gun working in air (APS) with the spraying parameters listed in Table 2. The thoriated tungsten cathode is 10 mm in diameter with a conical tip (40° cone angle). The gun anode/nozzle is made of OFHP copper and has a conical shape (40° cone angle) followed by a cylindrical duct 7 mm in internal diameter and 28 mm in length. The particles are injected perpendicularly to the plasma jet axis through a 1.8 mm i.d. injector located 3 mm upstream of the gun nozzle exit.

Cast iron disk shaped substrates (25 mm in diameter and 15 mm in height) are used for splat collection and for the coating tests. The splats are collected onto non preheated and 300°C preheated substrates. All the substrates used for the splat collection are polished with SiC paper, then with diamond abrasives to achieve a final mean roughness of 0.02 - 0.05 μm (Ra). The substrates for coatings are grit blasted with a suction type machine using a corundum powder (400 μm mean particle size) at 0.4 MPa. The resulting mean roughness is Ra = 6.7 $\pm$ 0.6 μm.

Table 2. Plasma spraying parameters.

	Big Particles	Small Particles
Arc current, [A]	500	500
Voltage, [V]	57	57
Gun thermal efficiency, [%]	56	56
Argon flow rate, [slm]	45	53
Hydrogen flow rate, [slm]	15	7
Spray distance, [mm]	90	100

Note: the carrier gas flow rate was adjusted to achieve a mean particle trajectory making an angle of 3.5° with the torch axis.

2.3. Sample characterization

Changes of the composite particles induced by the mechanofusion process are followed by X-ray diffraction (XRD, Cu-Ka radiation, model D-5000, Siemens), scanning electron microscopy (SEM, model XL30, Phillips), energy dispersive spectroscopy (EDS, Oxford, Link ISIS) and laser granulometry (Malvern, Mastersizer Hidro2000). The raw and mechanofused powder samples for SEM are embedded in a Mecaprex resin, ground and polished following the standard procedures. The cross sections of coated substrates are ground and polished as the powder samples. Surfaces for SEM examination are metallized with gold.

3. Results and Discussion

3.1. Composite particles

The morphology and cross sections of stainless steel-Al_2O_3 mechanofused-composite particles are illustrated in fig. 1. After the MF processing, for the two types of stainless steel particle size distributions, the fine alumina particles are uniformly distributed at the surface of stainless steel particles as shown in fig. 1a. The thickness of the alumina layer depends of the Al_2O_3 ratio to stainless steel mass ratio as given in Table 1 (alumina

corresponds to the gray color as detected by EDS analysis). the views of the cross sections of the mechanofused particles (Figs. 1b and 1c) show that the alumina shell mean thickness attains about 4.8 $\pm$ 0.4 µm for B20 and S20 powders set whereas for the B10 and S10 powders it is in the range of 3.35 $\pm$ 0.25 µm.

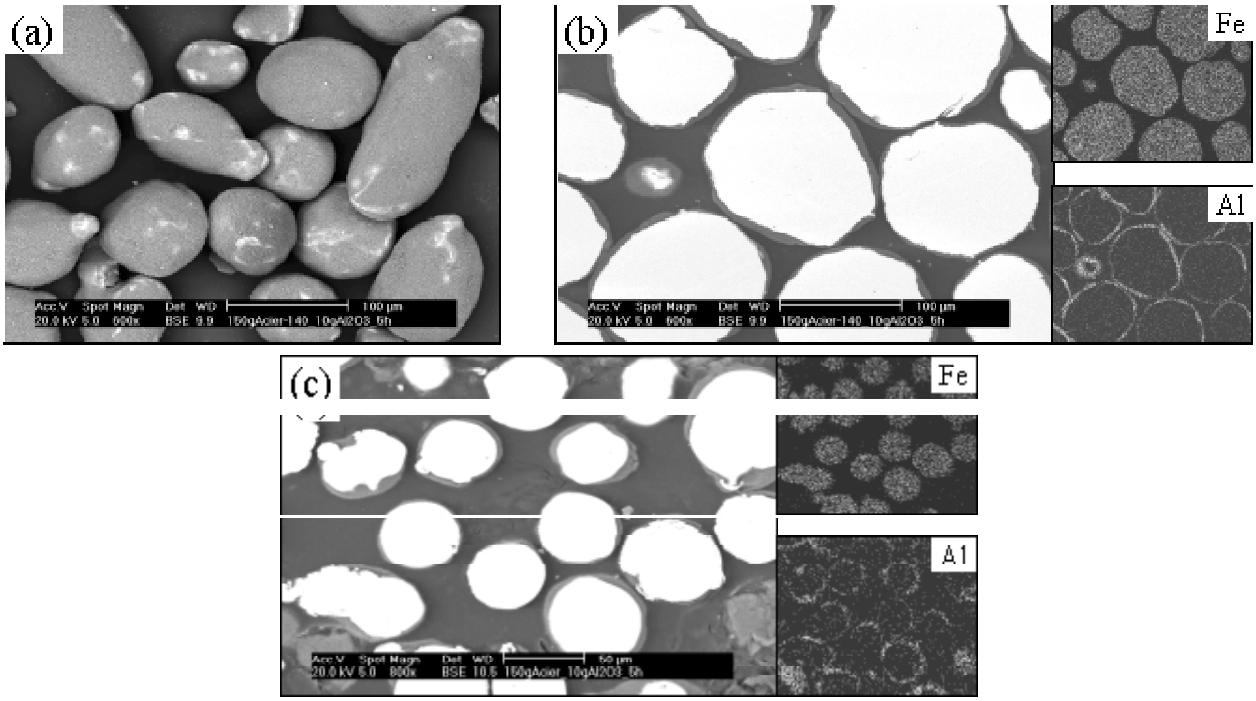

Figure 1. (a) An example of the typical morphologies of composite particles (B20) obtained by the mechanofusion process. Cross sections showing the elements distribution in white color as detected by EDS mapping analysis for the (b) big (B10) and (c) small particles (S10).

3.2. Splats collection

The splat morphologies of small and big composite particles are almost the same for a given temperature of the substrate surface. As it has been previously observed [9], on "non-preheated" substrates, the splats are extensively fingered (figs. 2a and 2b) whereas those collected onto 300°C preheated substrates (figs. 2c and 2d) become more circular. Each splat is composed of alumina and stainless steel too but depending of the particle size, when particles are fully molten before their impact, alumina is either distributed on or under the stainless steel splats, or scattered in small pieces and randomly dispersed over the stainless steel splat (fig. 2e) when the melting is poor. Moreover when collecting the composite particles in flight within the plasma jet, the fully melted ones exhibit a spherical shape with a cap made of alumina while the poorly melted ones have alumina pieces distributed all around the steel core. For the first two cases, calculations [10] have shown that the center of gravity of melted small composite particles with a cap is decentred by less than 2 µm, while with coarse particles it is by less than 0.1 µm. Thus small particles with caps can be considered as heterogeneous ones. In the plasma jet core where the gas velocity is much higher than that of particles the molten alumina shell is entrained at the front edge of the particles. In the plasma plume, when the gas velocity becomes lower than that of particles, due to their heterogeneity particles rock and the alumina shell is now at the particle tail behind the stainless steel. On the contrary, coarse particles behave as perfect spheres and due to their inertia, outside the plasma core, they keep the alumina cap in front of them.

For the third case of splats (fig. 2e), the alumina dispersion is due to the fact that the stainless steel particles are in a plastic state while the alumina shell still retains a semi-solid state in the plasma jet and brokes into pieces due to the large difference of expansion coefficients between both materials ($17x10^{-6}K^{-1}$ for stainless steel and $8x10^{-6}K^{-1}$ for alumina).

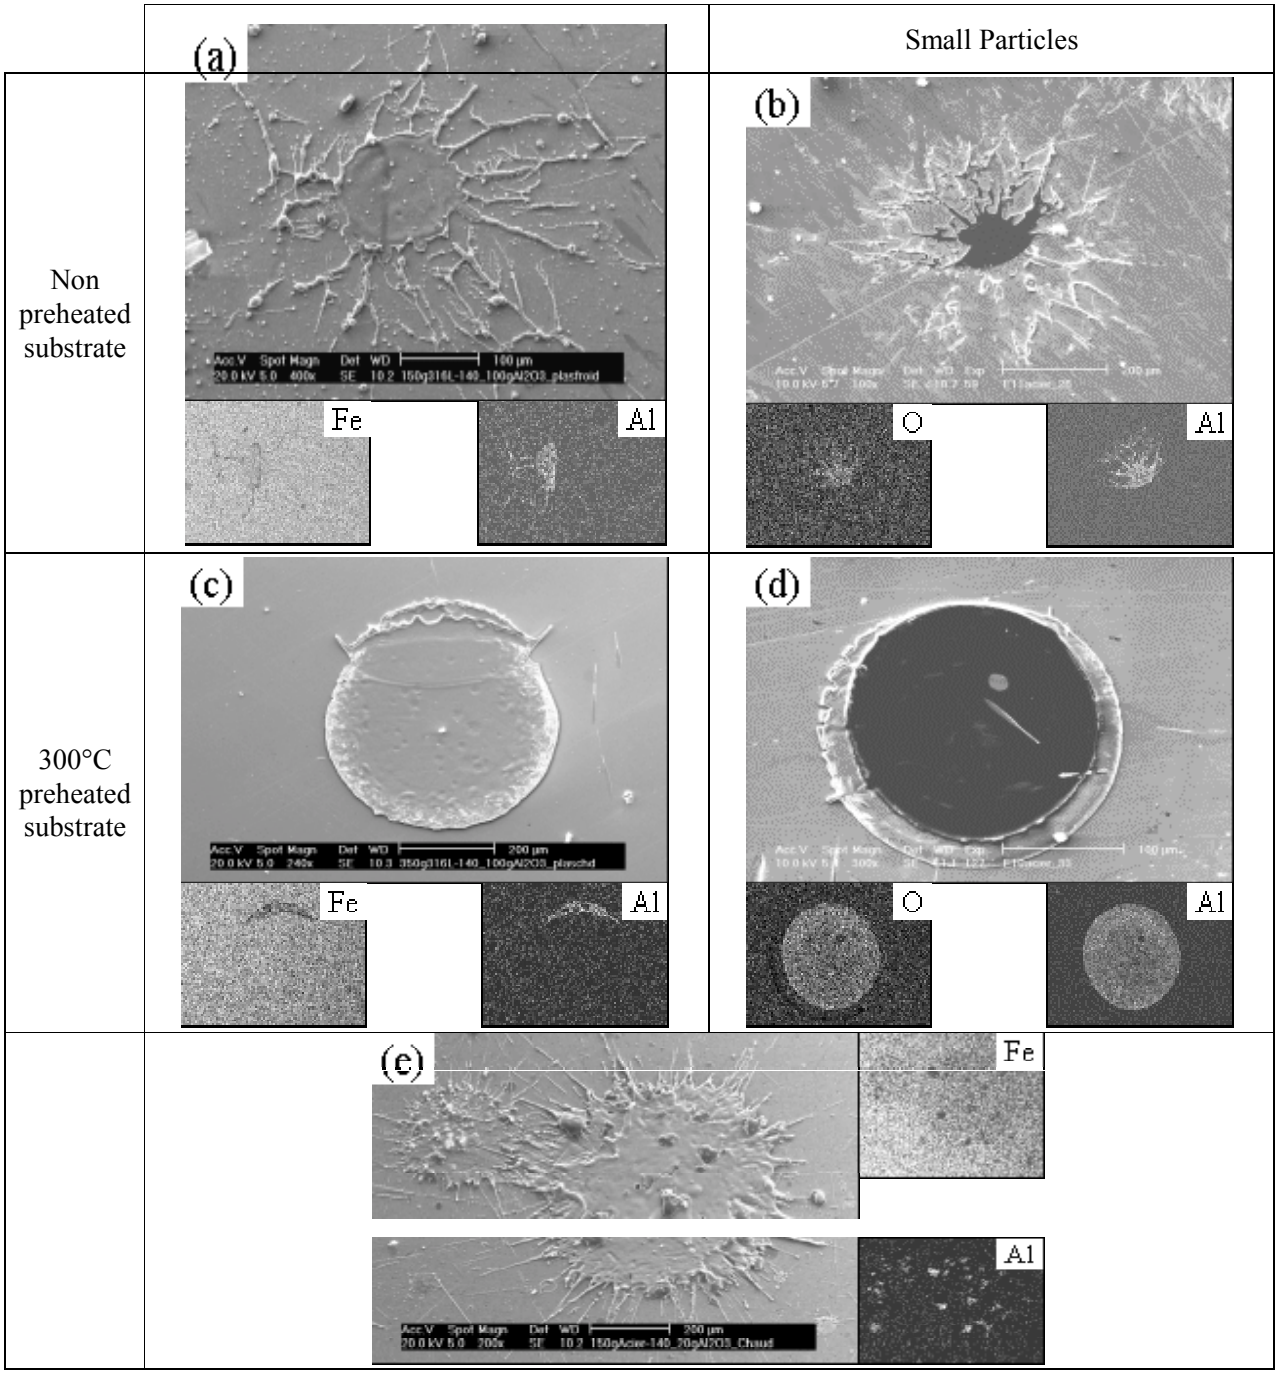

Figure 2: Views of splat morphologies showing in white color the alumina distribution as detected by EDS analysis. Big composite particles collected onto a (a) cold and (c) 300°C preheated substrates. Small composite particles collected onto a (b) cold and (d) 300°C preheated substrates. (e) Splat morphology corresponding to particles which still retains a semi-solid state in the plasma jet with the alumina shell broken into pieces.

3.3. Coatings formation

Typical coating microstructures from the mechanofused big and small particles exhibit a dense lamellar structure with a dark phase randomly distributed within the stainless steel matrix corresponding to the alumina phase detected by EDS analysis. In the Fig. 3a, the coatings resulting from powders with a small particle size distribution exhibit, a uniform distribution of alumina, with a rather dense and fine microstructure. However, in the coatings made with the big particle size distribution, it can be observed a coarse stainless steel particle surrounded by an alumina layer. It is thus clear that big particles do not completely melt during their flight within the plasma jet. To check the influence of particle melting, plasma spraying of coarse particles was performed with a high carrier gas flow rate (8 slm) to limit their residence time in the hot gases and thus their melting. Fig. 4 shows a view of a non melted composite particle collected in flight and which is composed of a stainless steel core covered by pieces of alumina as detected by EDS analysis.

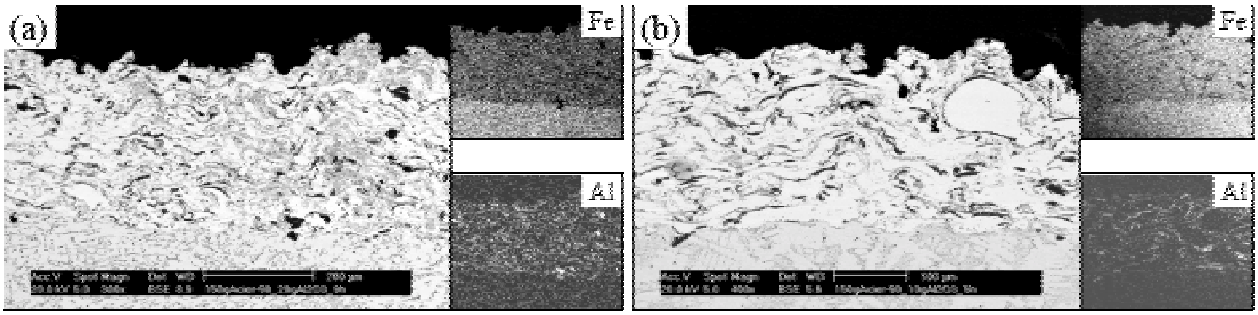

Figure 3. SEM micrographs of typical microstructures of the resulting plasma sprayed coatings from (a) smaller and (b) bigger stainless steel-Al_2O_3 mechanofused powders and their corresponding EDS mapping analysis for Iron (Fe) and Aluminium (Al) in white color .

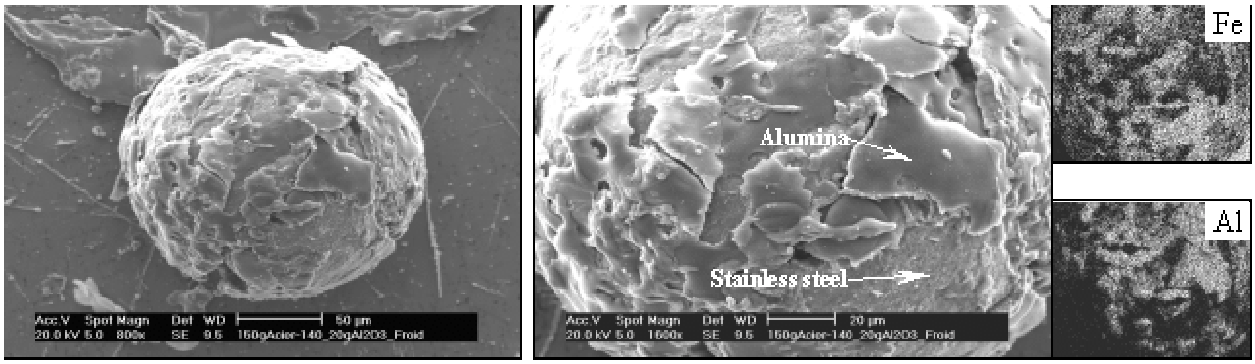

Figure 4. SEM micrographs of a non melted composite particle collected at the impact with a mirror polished substrate.

The hardness of coatings sprayed with small composite particles attains 370 ±43 HV5 and is higher than that reported for pure stainless steel deposits made with particles with a mean particle size of 60 µm (270 ±22 HV5) [6]. Due to the uniformly distributed alumina within the coating, its hardness is increased by the dispersion strengthening of the hard phase. However with coarse composite particles, the hardness attained is lower than that obtained with small composite particles and is almost the same as that of pure stainless steel deposits. This is due to the poorly melted particles at impact resulting in non uniformly scattered alumina pieces and rather poor contact between lamellae.

4. Conclusions

Mechanofusion process is an effective means to control the plasma spray deposit microstructure especially when covering small stainless steel particles (mean particle size of 65 µm) with an alumina shell of few µm in thickness.

The high energy input of the mechanofusion process is directed towards the creation of an alumina shell via the agglomeration of alumina particles with a very fine size (1 μm) on stainless steel particles (either –140 μm + 100 μm or –90 μm +45 μm). It is likely that the mechanofusion process activates the agglomeration of the fine alumina particles on the stainless steel ones, provided the difference in particle size distributions is large.
When spraying composite particles with a particle size distribution between 45 and 90 μm, alumina splats, uniformly distributed, are found embedded in a dense steel matrix enhancing its mechanical properties such as hardness as compared with coatings obtained from pure stainless steel particles with about the same size. With big composite particles (mean particle size = 126 μm) which melting is poor, the coating hardness is lower than that of pure stainless steel of small sizes (~60 μm). Work is in progress to improve big particles melting.

Abstract
The effect of indirect ionization on the discharge properties in a Hall thruster is examined in this paper. We use a two-dimensional hybrid model where ionization from excited states as well as direct electron impact ionization is taken into account. The contribution of stepwise is obtained using an un-coupled collisionnal radiative model. We also show comparisons between measurements and calculations of the density distribution of xenon excited states in the thruster.

1. Introduction

Stationary Plasma Thrusters – SPTs (or Hall thrusters) are efficient electric thrusters for satellite stationkeeping. In SPTs, a discharge is created between two coaxial dielectric cylinders by ionizing a flux of neutral atoms (xenon). Neutral atoms (mass flow rate of 5 mg/s) are injected at one end of the channel, while electrons are emitted from a hollow cathode located outside the channel. The typical length of the channel is 2.5 cm, with internal and external radii of 3.5 cm and 5 cm respectively. Due to the low pressure in the channel (few mTorr), a radial magnetic field is necessary to confine electrons to efficiently ionize the gas. The magnitude of the applied magnetic field is such that the motion of ions is not affected by the magnetic field. A potential drop around 300 V is applied between the anode located in the bottom of the channel and the external cathode. The electric field is distributed in the zone of low electron conductivity and high magnetic field. Ions generated in the channel see most of the applied voltage and are accelerated to energies close to 300 eV, providing the thrust. Many satellites have been launched in the last 3 decades, essentially in the former Soviet Union, with Hall thrusters on board. The space vehicle SMART-1 will be launched around the moon by Ariane V soon with one PPS1350 on board used as orbit transfer for the first time [1].
Although Hall thrusters have been studied since the beginning of the 60's by Russian scientists, the physics of the engine is far from been completely understood. A research group has been created in France in 1996 associating laboratories from CNRS, CNES, SNECMA and ONERA to study the physics of the engine with experimental and modeling research activities [2], [3]. A testing facility is based in Orléans (France) with a SPT equipped with a set of electric and optical diagnostics [2], [4]. Extensive results have been obtained for the spatial and temporal distributions of the optical emission of the plasma within the thruster channel [4]. In parallel to experiments, a two-dimensional axisymmetric model of the discharge in the channel and the near outside regions has been developed. This code combines fluid equations for the electron transport and particle description for both ion and neutral species. In the paper described in Ref. [3], the ionization from the ground state of xenon is only considered. We have taken into account the ionization from excited xenon states to examine the influence of the stepwise ionization on the discharge properties. The contribution of these excited states is obtained from an un-coupled collisionnal radiative model [4], [5] which is able to give the distribution of the metastable and excited levels densities.
The discharge and collisionnal radiative models are briefly described in section 2. Stepwise ionization effect and comparisons between calculated and measured xenon excited states densities are presented section 3.

2. Description of the models

We first give a brief description of the transient hybrid two-dimensional model of the discharge. The collisionnal radiative (CR) model is discussed in the second part of this section.

2.1. Discharge model

† email : garrigues@cpat.ups-tlse.fr, tel : +33.5.61.55.62.43, fax : +33.5.61.55.63.32

A hybrid, axisymmetric two-dimensional model of the thruster has been used. The magnetic field, which is a input of the simulation code, is calculated with an external software. The transport of heavy particles, xenon atoms and ions is described with a particle model where the trajectories of macro-particles representing large number of ions or neutrals are followed. The particle model has been largely described in the paper of Hagelaar *et al.* [3].
The electric field is deduced from the electron momentum equation, assuming quasineutrality (the plasma density is deduced from ion transport). Electron collisions with neutral atoms are not sufficient to explain the transport of electrons across the large radial magnetic field and the observed plasma conductivity in the exhaust region. Anomalous conduction across the magnetic field lines has been attributed to electron-wall collisions or to field electric field fluctuations. Ref. [3] gives a description of the treatment of anomalous conductivity in the model.
In Ref. [3], only ionization from the ground state of xenon atoms was taken into account. In the present paper we study the possible contribution of stepwise ionization and its influence on the model results. We have simplified the problem by extracting information about the total ionization from an un-coupled collisionnal-radiative (CR) model (see below). In practice, we decompose the ionization in two contributions, a first one due to the direct ionization from the fundamental level ($1s_0$ – Paschen notation) and a second one corresponding to the indirect ionization of excited levels. We assume a local equilibrium such that for a given triplet (n_e, T_e, n_a), where n_e is the electron density (equal to ion density – quasineutral plasma), T_e is the electron temperature and n_a the neutral atom density, we estimate the total contribution to the ionization using the CR model results. The CR results have been tabulated so that knowing (n_e, T_e, n_a) at a given location and at a given time in the thruster (from the hybrid 2D model) we can deduce the density of xenon excited states (especially the $2p_5$, $2p_6$, and $3p_6$ levels which will be compared with experimental measurements) and the contribution of stepwise ionization at the same location and time. We have also modified the electron energy equation with a supplementary term of energy loss for the electrons due to the effect of indirect ionization. The idea is to consider a fictive excited state level Xe* with a mean threshold of excitation of few eV. Results show that varying the threshold of excitation between 2 and 4 eV does not influence the results presented in section 3.

2.2. The collisionnal radiative (CR) model
This numerical model solves a set of kinetic equations relative to the excited states of xenon atoms. We consider that the various excited states are produced and quenched by inelastic and superelastic electron-atom collisions; deexcitation due to radiative transitions or collisions with walls are also taken into account. The system of master equations governing the time evolution of the excited species is the following :

$$\frac{dN_i}{dt}=\sum_j C^e_{ji}.N_j.n_e-N_i\left[\sum_j C^e_{ij}.n_e+\sum_{j<i}(1-\Lambda_{ij}).A_{ij}+C^e_{ion,i}.n_e\right]+\sum_{j>i}(1-\Lambda_{ji}).A_{ji}.N_j\pm\sum_{k,l}K^{hp}_{kl}.N_k.N_l-\gamma_i.N_i/\tau_i \qquad (1)$$

where n_e is the electron density and N_i the density of level i. $C^e_{ji}=\int v.f(u).\sigma_{ji}(u)du$ is the electron impact excitation coefficient for the transition $j\rightarrow i$ and $C^e_{ion,i}$ the ionisation coefficient of the level i. $f(u)$ is the electron energy distribution function (EEDF) normalized to 1. σ_{ji} is the electron impact cross section for the transition $j\rightarrow i$. A_{ij} is the Einstein coefficient for the transition $i\rightarrow j$. We can also take into account the self-absorption by introducing a calculated factor ($1-\Lambda_{ij}$) [6]. K^{hp}_{kl} is the rate coefficient of collisions between heavy particles k and l. γ_i is the destruction probability of metastables at the walls, which is taken to be 99%. τ_i is the equivalent lifetime for diffusion and destruction of metastable levels at these walls.
The cross sections for the following processes have been introduced in the model [4], [5] :

- electronic excitation from the fundamental level [7]
- electronic excitation from excited states [7], [8]
- simple and double ionisation [9] [10]
- Penning ionisation

The data from radiative transitions (transition probabilities, oscillator strengths) are from Refs [11], [12]. A detailed description of the model is given in Refs [4], [5].

A parametric study of the contributions to ionisation versus the neutral xenon density (10^{12} – 10^{14} cm^{-3}), the electron density (10^{9} – 5×10^{12} cm^{-3}) and the electron temperature (1 – 50 eV) has been achieved. The main results are the following :

- xenon ionization is mainly obtained through electron collision with ground state xenon atoms as well as 1s (metastable and radiative), 3d, 3-6s and 4-5p levels of neutral xenon
- the contribution of the fundamental level depends strongly on the electron density : it decreases when n_e increases due to stepwise ionisation, especially from the metastable level
- the electron temperature has a smaller influence
- neutral density is also important when electron density is high because of self-absorption of emission lines particularly of resonance lines

Looking at the creation and destruction rates of the different levels, we come to the conclusion that it is possible to reduce the entire xenon scheme to only a few levels, which are the following : ground state, 1s, 2p, 3d, 3-6s, and 4-5p.

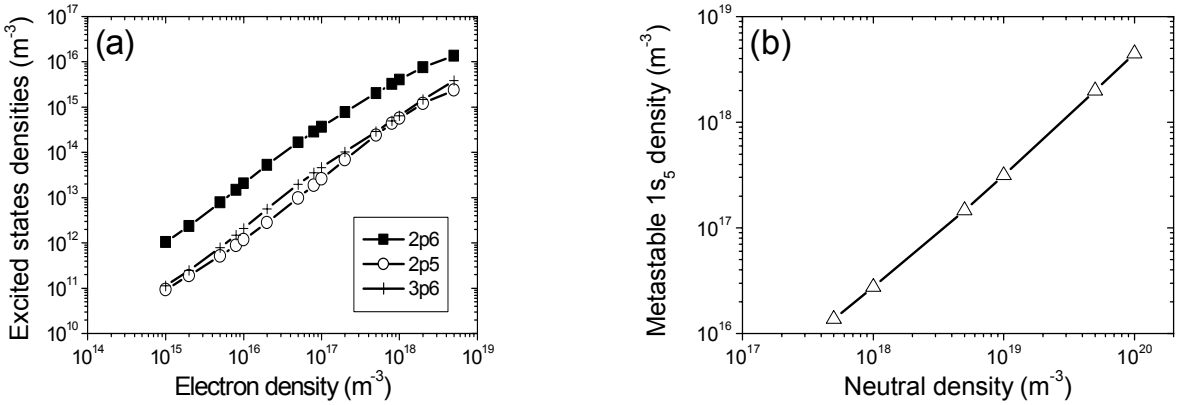

Figure 1 : (a) excited states densities as a function of the electron density in log-log scale for a given neutral density of 10^{19} m^{-3} and an electron temperature of 10 eV; (b) metastable density as a function of the neutral density (log-log scale) for an electron density of 5×10^{17} m^{-3} and an electron temperature of 10 eV.

The influence of the electron and neutral densities, and electron temperature on the densities of $1s_5$, $2p_5$, $2p_6$, and $3p_6$ levels have also been examined. Summarizing,

- the densities of the 2p and 3p levels depend linearly in log-log scale of the electron density as wee can see Fig. 1a. The effect of the electron temperature is not dominant, the population of the excited states is quasi constant for a temperature greater than 10 eV.
- the contribution of the neutral fundamental state on the $1s_5$ population is clearly shown Fig. 1b. Varying the electron temperature between 10 and 50 eV multiply only by a factor 2 the metastable density. For electron density superior to 5×10^{17} m^{-3}, the $1s_5$ level density decreases due to the formation of the 6p level.

3. Results and discussion

We examine the influence of the stepwise ionization in the sub-section 3.1. and we compare calculations with experimental results in sub-section 3.2. The inner and outer ceramics of the SPT are respectively positioned at r=3.45 cm and r=5 cm. The channel length is 2.5 cm. The calculation domain is a box of 8 cm x 8 cm with the inside channel and the near outside region. The coil current is 4.5 A, the xenon mass flow rate is 5 mg/s and the potential fall 300 V in nominal conditions. The neutral backpressure inside the facility is 2.5 mPa. We average the simulation results over a time duration of 3 ms.

3.1. Influence of the stepwise ionization on the discharge properties

In a Stationary Plasma Thruster, most of the ionization occurs in the high magnetic field region close to the exhaust plane. The plasma density is maximum (on the order of 10^{18} m^{-3}) a few mm before the exhaust plane (Fig. 2a). Xenon is injected at the end of the channel and the xenon atom density is maximum (typically 10^{20} m^{-3}) in the anode region. The xenon density (Fig. 2b) is strongly depleted (below 10^{18} m^{-3}) in the exhaust region where the electron temperature (Fig. 2c) is large and most of the ionization occurs.

The contribution of direct ionization to the total ionization is shown on Fig. 2d. The contribution of direct ionization to the source term (number of electron-ion pairs generated per unit volume per unit time) will be

refereed to as S_{direct}. When S_{direct} reaches 1, the indirect contribution is negligible ; when S_{direct} tends to 0, ions are essentially created by stepwise ionization. We must keep in mind that our model is quasineutral, i.e. the electron density is everywhere equal to the ion density. Comparing Figs. 2a and 2d, we conclude that the contribution of the indirect ionization from the excited and metastable levels is essentially influenced by the electron density and not by the electron temperature (in the range of value considered in the SPT) in agreement with the output data calculated by the CR model (see sub-section 2.2). We clearly see a region where the direct ionization source term S_{direct} is low (typically 30-40 %). This zone covers a large area concentrated between the anode and the maximum of ionization. In the outside zone, where the electron density (and so the ion density) is minimum, the contribution of stepwise ionization is negligible.

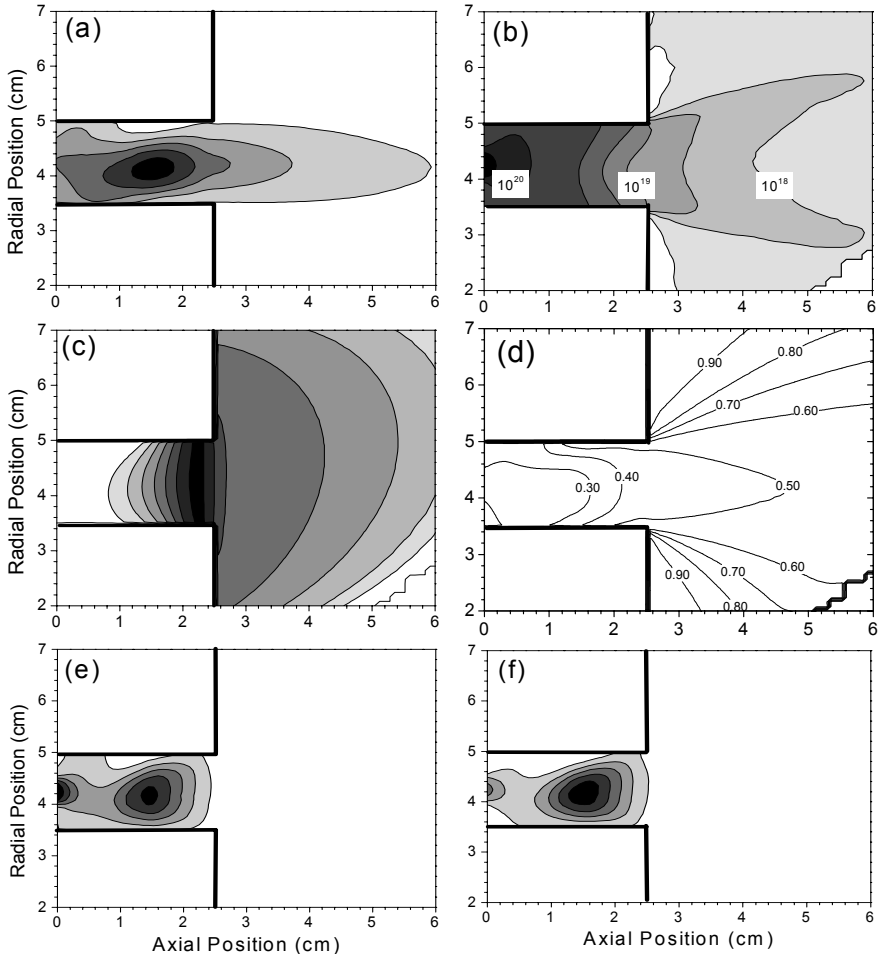

Figure 2 : (a) plasma density distribution in the thruster (each interval of gray scale corresponds to 2×10^{17} m^{-3}) ; (b) neutral atom density distribution in log-scale covering 3 decades; (c) electron mean energy in the thruster from 5 to 20 eV (each interval corresponds to 2 eV) ; (d) contribution S_{direct} of the direct ionization source term ; (e) contours of constant ion source term with stepwise ionization (each interval of gray scale corresponds to 10^{23} m^{-3} s^{-1}) ; (f) contours of constant ion source term without stepwise ionization (same scale than fig. 2e). The channel is located on the left-hand side of the plots the exhaust is at axial position 2.5 cm and the anode is at x=0.

We have reported Fig. 2e the ion source term including stepwise ionization. The maximum is located around the center of the channel and reaches 6×10^{23} m^{-3} s^{-1}. We observe a region of non-negligible ion source term upstream the peak, according to fig. 2a. The density of the metastable level $1s_5$ reaches 2×10^{18} m^{-3} in the anode zone. This is because the atom density is much larger in the anode region than in the exhaust region. The peaks of density of $2p_5$, $2p_6$, and $3p_6$ levels are respectively 2.2×10^{15} m^{-3} for both $2p_5$ and $3p_6$ states and 1.5×10^{16} m^{-3} for $2p_6$ state, that is only a few percent of the total ion density (with a maximum of 1.2×10^{18} m^{-3} – see fig. 2a). The excited states $2p_5$, $2p_6$ and $3p_6$ are produced in the same zone as the maximum of ionization source term. Finally, the total ion source term excluding the stepwise ionization is presented fig. 2f. The maximum is located in the same zone as in fig. 2e, but we note that the ion source is less spread out than when indirect ionization is taken into account, especially in the anode region.

It is interesting to note that if we calculate the total ion current leaving the domain with and without stepwise ionization, we obtain 3.4 A in both cases. The main reason is that the electron mean energy is large enough under nominal operating conditions of the thruster (300 V) to ionize ground state xenon atoms.
We also looked at the effect of the stepwise ionization for lower applied voltage. In the range of 100-200 V, due to the lower electron mean energy, the ionization of the neutral mass flow rate from the fundamental state becomes difficult and the discharge is not initiated. Experimental voltage-current characteristic gives discharge current on the order of 4 A at low voltage [2]. Taking into account the indirect ionization does not change the calculations results because the electron density is too low to populate the xenon excited states and to ionize them. We can therefore conclude that the omission of stepwise ionization in previous models is not responsible from the observed discrepancy between calculations and experiments at low voltage, and that other phenomena must be invoked (see, e.g. [13]) to explain the fact that the models cannot describe the low voltage part of the current-voltage characteristics.

3.2. Comparisons with experimental results

We present figure 3a the densities of the $2p_5$, $2p_6$ and $3p_6$ levels calculated with the two-dimensional discharge model and integrated over the radial direction. We have reported figure 3b the emission intensity obtained on the PIVOINE facility in Orléans using a system of optical fibers distributed on the outer ceramic [2], [4].

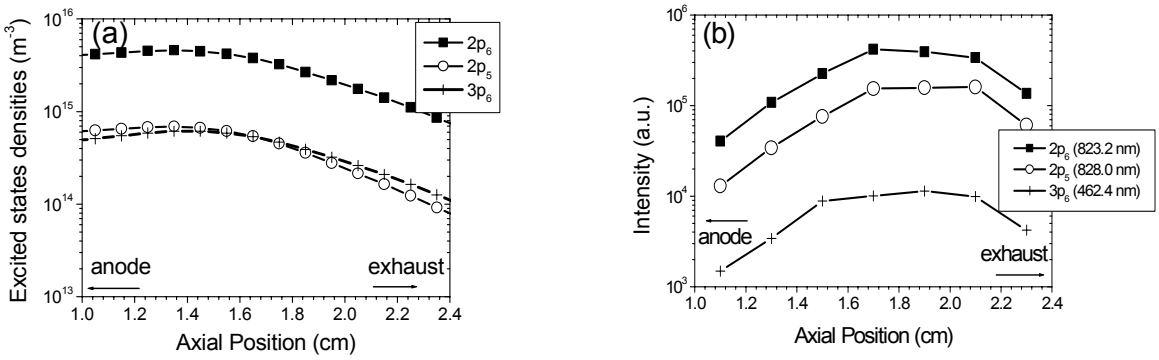

Figure 3 : (a) axial profiles in log-scale of the densities of the $2p_5$, $2p_6$ and $3p_6$ levels obtained with the two-dimensional code ; (b) emission intensity of the 828.0 nm, 823.2 nm and 462.4 nm lines obtained experimentally [4].

Under SPT conditions, the local emission spectroscopy is simply related to the excited states densities [4]. Calculations show a maximum of excited states densities typically 1 cm downstream the exhaust, while the emission is observed in a region nearby (between 5 and 8 mm) the exit. If the density of the $2p_6$ level is large in the channel of the engine, as observed experimentally, comparisons between experiments and calculations of the densities of $2p_5$ and $3p_6$ states present discrepancies. Simulations give the same value for the densities of $2p_5$ and $3p_6$ levels, whereas the intensity variations of the transitions at 828.0 nm and at 462.4 nm differ from more than one order of magnitude. Calculated densities are in agreement with input data extracted from the CR model (see Fig. 1). In the model presented here, we use a simplified method where the excited states density is deduced from an un-coupled CR model assuming local equilibrium. The observed discrepancies may be due to the fact that the transport of excited species is neglected in this simplified model.

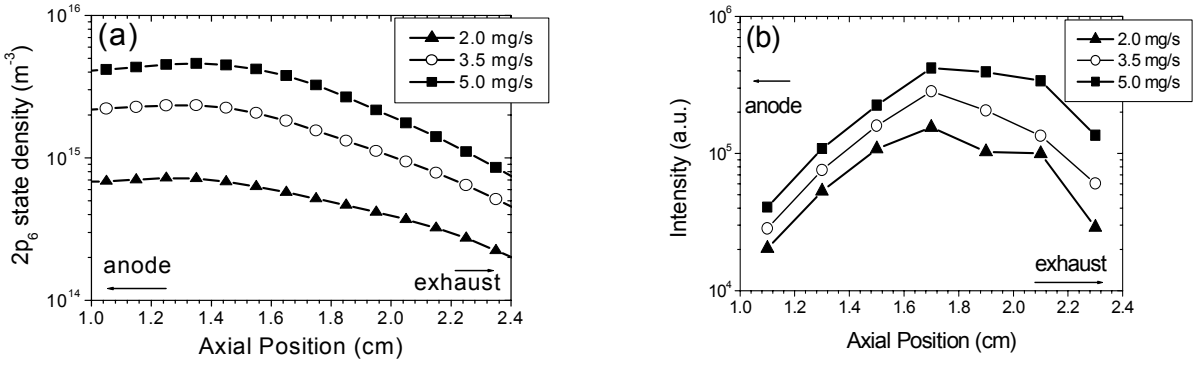

Figure 4 : (a) axial profiles of the $2p_6$ density obtained with the two-dimensional code ; (b) emission intensity at 823.2 nm obtained experimentally for three different mass flow rates of xenon [4].

We end this section with a study of the influence of the mass flow rate in the 2-5 mg/s range, on the density of the $2p_6$ state (see Fig. 4). The applied voltage is 300 V. The modeling and experimental results confirm that the intensity of the $2p_6$ level depends on the xenon mass flow as expected. However, the influence of the Xe debit is much more pronounced in the calculations. The location of the excitation region is not strongly affected by the xenon flow rate if we compare the axial position of the maximums of density and emission.

4. Conclusions

This paper presents a study of the influence of stepwise ionization from xenon excited states on the discharge properties and shows comparisons between calculated densities of $2p_5$, $2p_6$ and $3p_6$ levels with spectroscopy emission in a Hall thruster. Input data for the two-dimensional model of the plasma are extracted from a un-coupled CR model where the species densities had been tabulated as a function of the triplet (n_e, T_e, n_a). Results show that stepwise ionization can reach 60-70 % in the region located between the anode side and the center of the channel. Nevertheless, the total ion current leaving the thruster is the same with and without taking into account the stepwise ionization. This result shows that, for a large enough electron energy, the mechanism of direct ionization from the ground state is sufficient to ionize the neutral flux injected. For low applied voltages, indirect ionization is negligible because the excited states are not populated due to the low electron density. The current-voltage characteristic is not strongly affected by stepwise ionization and we can conclude that stepwise ionization is not responsible for the discrepancy between models and experiments in the low voltage part of the I-V characteristics. The discharge properties are more sensitive to the abnormal electron transport as we have observed in Ref. [3].

Both models and experiments lead to $2p_6$ densities significantly larger than the $2p_5$ and $3p_6$ densities but the $3p_6$ level is significantly less populated than the $2p_5$ in the experiments, which is not the case in the model predictions. The location of the calculated maximums of excited species densities in the channel is deeper than in the measurements. The thruster model presented in this paper uses the results of an external CR model assuming local equilibrium. Some of the discrepancies between model and experiments may be due to the fact that the transport of excited states is not taken into account in this simplified approach (i.e. the excited species densities only depend on the local values of the electron density, temperature, and neutral atom density).

Abstract
We present in this paper self-consistent simulations of the discharge properties in Hall thrusters with a two-dimensional hybrid model. Understanding the parameters controlling the beam divergence and wall sputtering to optimize the lifetime of the thruster is an important issue. The influence of the magnetic field distribution on the properties, performance and lifetime of the thruster are discussed.

1. Introduction

Stationary Plasma Thrusters – SPTs (or Hall thrusters) provide economic advantage for satellite stationkeeping compared with conventional chemical thrusters (arcjets or resisto-jets). Orbit control missions require a high specific impulse and a low thrust. Due to the high specific impulse, Hall thrusters offer the advantage of reducing the mass of propellant on board on commercial telecommunication satellites (typically 500 kgs for a satellite of 3.5 tons) and so the launch cost. Manufacturers use the gain in propellant mass to increase the payload on new spacecrafts. At the present time, 25 satellites are equipped with Hall thrusters for satellite station keeping [1]. New missions such as deep space applications are now in consideration using 50 kW SPT [2]. Electric thrusters such as Hall thrusters use xenon as propellant. A discharge is created in a cylindrical channel – about 3 cm long and 2 cm wide – by ionization of the xenon flux (density on the order of 10^{19} m^{-3}) by electrons coming from a cathode located outside the engine. Xenon ions, accelerated by the plasma field, provide the thrust. The originality of SPTs is due to the fact the ions are extracted from the thruster without accelerating grids. The accelerating field in the plasma is induced by a drop in the electron conductivity associated with the presence of a transverse magnetic field generated by external coils. Ions are ejected from the channel with velocities on the order of 20 km/s in the exhaust region for a 300 V applied voltage.
The thrusters operating conditions and performance are very sensitive to the magnetic field topology. An efficient engine requires a high level of ionization and ion acceleration must be performed with minimum wall erosion. In modern SPTs, the magnetic circuit consists of two systems of magnetic coils and poles – external and internal. This magnetic system creates a quasi-radial magnetic induction in the exhaust region [3]. Magnetic screens surrounding the accelerating channel allow adjustment of the magnetic gradient in the exhaust region and reduction of the B field magnitude in the anode region [4]. The configuration of the magnetic field lines is convergent and approximately symmetric with respect to the mid surface between the channel walls. The potential drop along the B field lines is small and the equipotential contours tend to line up with the B field lines. The electric field therefore focuses the ion beam in the axial direction [5]. In this paper, we examine the effect of the magnetic field configuration on the thruster regime using a two-dimensional model of the discharge and a freeware code to calculate the magnetic field topology. These models are briefly described in section 2. The influence of the magnetic field on the ion beam properties, on the wall erosion and on the discharge current oscillations is presented section 3 and we conclude in section 4.

2. Description of the models

We begin with a short description of the transient hybrid two-dimensional model of the discharge. We then present the calculation of the magnetic field.

2.1. Discharge modeling

The hybrid model of the discharge is axisymmetric and two-dimensional. This model includes the channel and the exhaust regions, a few centimeters away from the exhaust plane. The model assumes quasineutrality of the plasma. The electric field is deduced from the current continuity equation. Electrons are considered as a fluid while a particle model is used to describe the transport of neutral atoms and ions. The ionization rate

[†] email : garrigues@cpat.ups-tlse.fr, tel : +33.5.61.55.62.43, fax : +33.5.61.55.63.32

is obtained from the electron energy equation assuming a maxwellian electron distribution function. As in many magnetized plasma, the question of electron transport across the magnetic field lines is not clear and "anomalous electron transport" must be invoked to explain the observed electron current. The anomalous transport in the thruster channel has been attributed to electron-wall collisions by many authors, while Bohm diffusion seems to play an important role in the region outside the channel. The model uses empirical parameters (which are adjusted to match the experimental results) to describe this anomalous transport [6]. The model provides the space and time variations of the electric potential, neutral and ion densities, ion velocity distribution function, and the performance of the engine. A complete description of the model and the numerical technique can be found in the paper of Hagelaar *et al.* [6].
In the present paper, the calculation of the erosion rate of the channel walls due to ion bombardment has been included. The erosion rate (eroded thickness per unit time) is :

$$R=\frac{\Gamma_i m_w}{\rho_w}\langle Y(E)C(\theta)\rangle\,, \qquad (1)$$

where Γ_i is the total incident ion flux, m_w is the mean mass of the wall particles, ρ_w is the mass density of the wall material, and the triangular brackets indicate averaging over the incident ions (ion flux). The sputtering yield Y represents the number of eroded particles per incident ion. The correction factor C accounts for the effect of the angle of incidence θ (defined with respect to the radial direction). Empirical formula for the sputtering yield Y and experimental measurements for the correction factor C are deduced from Refs. [7], [8].
The model has been recently improved to describe complex and realistic magnetic field configurations including structures with a zero magnetic field. The calculation domain is divided in four zones limited by the magnetic fields lines passing through the point of zero magnetic field. In each zone, the electron equations are solved separately. The solutions for the zones containing the anode and the cathode are implicitly coupled, so that a total voltage drop can be applied in the current conservation equation. The other zones are connected explicitly. In the zones where the field lines entirely close themselves on the outer or inner walls, the total current in the current conservation equation is taken to be zero.

2.2. Magnetic field modeling

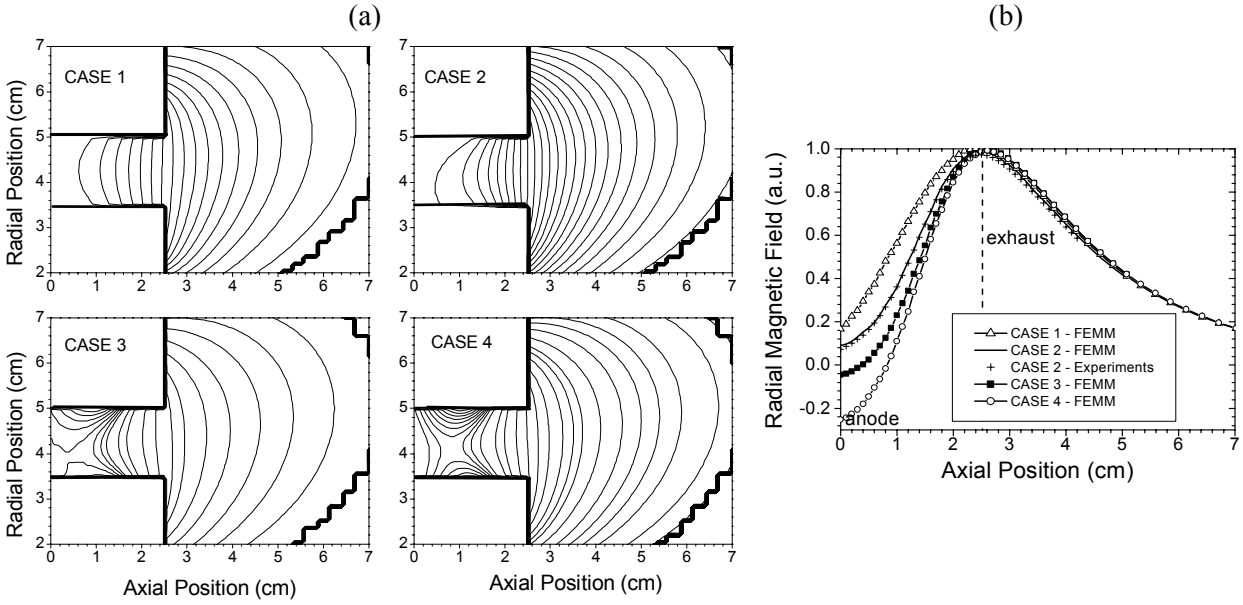

Figure 1 : (a) SPT100 magnetic field lines calculated with FEMM for 4 different configurations of the magnetic circuit. The channel is located on the left-hand side of the plots between the radial positions 3.45 and 5 cm ; the exhaust is at an axial position of 2.5 cm ; (b) axial variations of the calculated radial magnetic field strength at the thruster channel median for different configurations. Measurements for the SPT100-ML are also plotted for CASE 2 [11].

We use the FEMM (Finite Elements Method Magnetic) freeware code [9] to calculate the magnetic field distribution for a given arrangement of the magnetic circuit. This user-friendly software solves Maxwell's

equation for the magnetic vector potential in a cylindrically symmetric geometry with the finite element method. The details of the magnetic circuit and material properties and the current through the coils are inputs of the magnetic field code. We neglect the possible effect of the plasma current on the total magnetic induction. Different geometry of the magnetic circuit have been designed to generate different magnetic field topology with different axial gradients of the radial magnetic field. We extrapolate the calculated B field on the triangle mesh used by FEMM on the two-dimensional grid of the discharge code.
The magnetic field lines are plotted fig. 1a for four different topologies and for a SPT100 (100 mm of external diameter). The inner and outer ceramics of the SPT are respectively positioned at r=3.45 cm and r=5 cm. The channel length is 2.5 cm. Note that the magnetic field in the region outside the channel and the magnetic field lens are practically the same in all configurations. We clearly see the presence of a region of zero magnetic field in the anode region for CASES 3 and 4. A supplementary coil, positioned behind the anode, with a negative coil current was used to create a zone of low magnetic field inside the channel [10].
CASE 2 corresponds to the standard configuration of the magnetic field of the SPT100-ML studied in the PIVOINE facility [11]. The calculated and measured magnetic fields (see Fig. 1b) for this configuration are in good agreement (the coil current in the model has been adjusted to obtain a good match of the maximum field near the exhaust plane).
Variations around this configuration have been obtained by modifying the magnetic circuit. CASE 1 exhibits a larger magnetic field magnitude in the channel and a smaller gradient than CASE 2. The radial magnetic field goes through zero in the anode region and changes sign in a zone of a few millimeters in CASE 3 and 1 cm in CASE 4. The width of the region of large magnetic field is also smaller for CASES 3 and 4 ; this is correlated with the existence of a zero magnetic field region (the region of large magnetic field is pushed toward the exhaust when the point of zero magnetic field is shifted away from the anode).

3. Results and discussion

We first discuss the influence of the magnetic field topology on the thruster properties and performance (3.1). The thruster wall erosion is estimated for different magnetic field configurations (3.2). Finally, the effect of the magnetic field on the oscillations of the discharge current is presented in sub-section 3.3.

3.1. Ion beam properties

The typical conditions are the following : the applied voltage is 300 V and the xenon mass flow rate is 5 mg/s. The gradient of electron temperature is set to zero on the anode while the temperature is fixed to a few eV on the cathode line. As we said in section 2., the difficulty concerns the abnormal electron conductivity in the direction perpendicular to the magnetic field and we use empirical parameters to quantify this effect. The influence of the parameters characterizing anomalous conductivity on the thruster properties has been described in the papers of Hagelaar *et al.* [3]. Comparisons between simulations and experimental results concerning the performance and the amplitude of the current oscillations [12] have allowed us to adjust ours empirical parameters to give the best fit between experiment and simulations in the SPT100 engine. We used the same values for these parameters in the present paper and for the 4 configurations of CASES 1 to 4. This seems reasonable since the magnetic field magnitude is almost the same in the region outside the channel where Bohm diffusion is important. Moreover, in the channel region near the exhaust plane, where the electron-wall collisions play an important role, the intensity of the magnetic induction is very similar in the 4 cases.
We have plotted in figure 2 the time-averaged spatial distributions of the ionization source term (gray scale) and the electric potential (contour lines) for CASES 1 to 4. The zone of high intensity of the magnetic field and low electron conductivity controls the spatial profile of the electric potential. Changing the width of the high magnetic field region influences the electric field distribution. The potential drop inside the channel is concentrated within a few millimeters in CASE 2 and 1 centimeter in CASE 1. The low field region on the anode side extends to 2 centimeters in the case with a zero magnetic field (CASE 3 and 4). An important part of the potential drop occurs in the region outside the channel in all cases, but the exact ratio of the potential drop inside and outside the channel is different for each case and, as expected, depends on the magnetic field distribution. The potential drop outside the channel represents 44 % and 59 % of the applied voltage in CASES 1 and 4 respectively.
The electron energy is deposited deeper in the channel for larger widths of the region of large magnetic field as it can be deduced from the ionization source term distributions plotted in Fig. 2. A zero magnetic field topology leads to a more complex structure of the ionization rate. In the region around the location of the

point of zero magnetic field the electron mobility is larger and the ionization rate decreases (see e.g., CASE 4). In the regions where the magnetic field lines are closed on the channel walls the electron mean energy and ionization source term drop. In all cases, we see a second ionization peak in front of the anode injector. The results in that region are sensitive to the boundary condition that is used for the energy equation (zero energy gradient or fixed energy). A zero energy gradient is imposed in this paper, but a fixed low electron energy would lead to a much smaller ionization rate in that region. Unfortunately, this boundary condition is rather arbitrary (although zero energy gradient seems reasonable), and there are no clear experimental data on the electron energy in this zone. Morozov and Savelyev estimate the magnitude of ionization to a relatively small value (~10 % of the maximum rate) [5]. However, we find that the influence of the boundary condition for the electron energy on the anode is not crucial for the SPT performance. The performance is characterized by typically 3 parameters. We define the thrust T as the force in reaction to the acceleration of ions, the specific impulse I_{sp} as the impulse per unit weight (directly proportionnal to ion beam mean axial velocity if the gas in fully ionized) and the total efficiency η as the kinetic power over the electrical injected power.

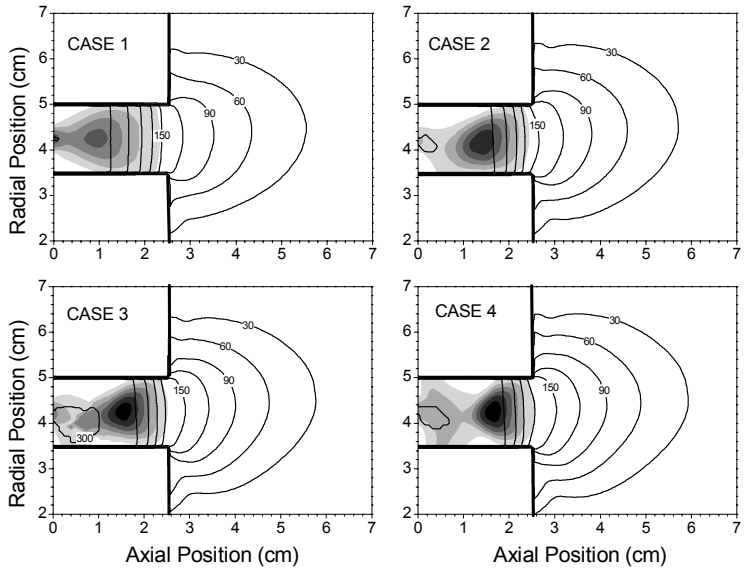

Figure 2 : Time-averaged spatial profiles of the electric potential (contours) and the ionization source term (gray scale). The contours are equally spaced with intervals of 30 V. The gray scale is linear, the intervals correspond to 10^{23} m^{-3} s^{-1}.

An efficient Hall thruster requires efficient ionization of the neutral flow and efficient axial acceleration of the ions (i.e. through a potential as close as possible to the total applied potential). The model results show that the total efficiency η (~50 %), the thrust T (80 mN) and the specific impulse I_{sp} - 1600 s - are almost the same for the different cases. To explain this high level of performance, we can look at the propellant utilization η_u (i.e. the part of xenon flux ionized) and beam energy η_E efficiency (associated to the mean energy of the ion beam compared to the potential drop). The ion production zone is clearly separated from the acceleration region (look at the position of the maximum of ion production compared to the potential fall), and ions are therefore efficiently extracted from the channel thruster, with η_E on the order of 80 %. The neutral flow is efficiently ionized since we obtain typically an efficient propellant utilization efficiency η_u of 90 %. We must note that in the calculations presented here, we assumed that neutrals created by ions recombination on the walls are thermalized and emitted with a temperature of 500 K. In the case of magnetic configurations with a zero B-field, the ion current striking the channel walls can reach values as high as 1 A (only 0.4 A in CASE 2). This is a consequence of fact that ions produced in the regions where the magnetic field lines are closed on the walls are lost to the walls.

3.2. Wall sputtering and lifetime

Figure 3 exhibits the calculated inner wall erosion rate as a function of axial position. Although the ion flux to the walls is larger deeper in the channel, the ion energy flow is much larger in the exhaust region because ion acceleration takes place in the last cm before the exhaust plane. The length of the eroded zone and the intensity of the erosion strongly depend of the configuration of the B field. A zone of 1 cm is eroded in CASE 1, only 3 mm in CASE 4. After 1000 hours of thruster operation, the maximum of material eroded in the exit plane reaches 0.5 mm for CASE 1 and only 0.08 mm for CASE 4.

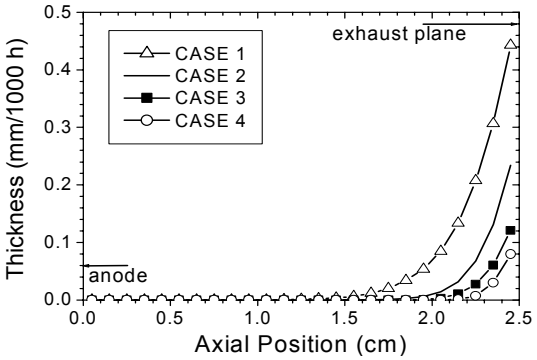

Figure 3 : Calculated erosion rate of the inner channel wall.

The length of erosion is directly connected to the positions of the source term combined with the electric potential fall. In CASE 1, the ion production and acceleration regions cover a large area of the channel, in contrast to CASE 4. A smaller electric potential drop inside the channel leads to a serious decrease in the erosion rate because of the smaller energy of the ions impacting the walls. The mean energy of ions striking the ceramics is 110 eV in CASE 1 and 80 eV in CASE 4 in the exhaust plane. Since the sputtering yield is very sensitive to the ion energy in this energy range, relatively small changes in ion energy may have dramatic consequences for the wall erosion. These results provide a quantitative confirmation of the intuitive fact that the thruster lifetime increases when a larger part of the potential drop is outside the channel. A magnetic field structure with a zero B field topology allows a reduction of the width of the large magnetic field region inside the channel and leads to good performance with improved lifetime (as observed experimentally on the PPS® 1350 [13]).

3.3. Discharge current oscillations

We present on figure 4, the discharge current as function of time for both CASES 1 and 4. The model results show a smaller amplitude of the low frequency oscillations in CASE 4 compared with CASE 1. This is associated with a smaller width of the region of large radial magnetic field in our model calculations. This feature has also been observed in the ATON Hall thruster [14] where the magnetic field also goes through zero in the channel. Note that current oscillations in the range of 100-200 kHz is also observed especially in CASE 4 where the low frequency oscillations is less pronounced. This oscillation has already been described in Ref. [6].

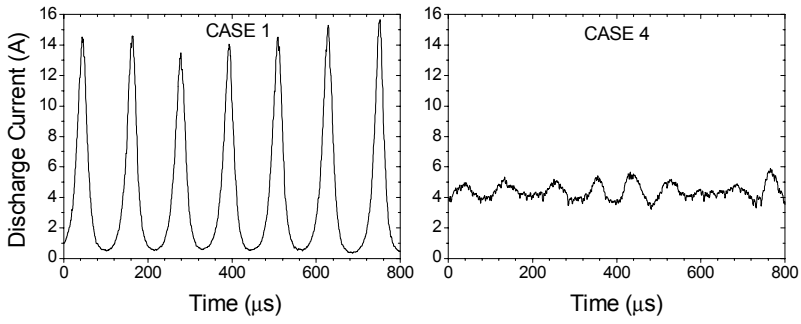

Figure 4 : Discharge current as a function of time for CASES 1 and 4.

4. Conclusions

This paper is dedicated to the study of some aspects of the sensitivity of the SPT properties to the B field configuration using a two dimensional hybrid model. Different magnetic topologies with different widths of the region of large magnetic field near exhaust have been studied, keeping constant the maximum magnetic field intensity and magnetic lens. The results show that the ratio of potential drop inside and outside the channel is controlled by the magnetic field distribution and it has consequences for the thruster wall erosion and lifetime, and on the beam divergence. This is an important aspect of SPTs which is not thoroughly discussed in the literature and we think that more systematic experiments are needed to clarify this point. Systematic measurements of the part of potential inside and outside the channel (e.g. through Laser Induced Fluorescence experiments) would be very useful to confirm the effects predicted by the model. This would also help to validate the simulation results which depend on some adjustable parameters.

The transient behaviour of the thruster, briefly discussed in this paper, also shows that the amplitude of the low frequency current oscillations decreases when the B field configuration exhibits a zero field in the anode region. This stability is associated with a smaller width of the region of large radial magnetic field in the calculations. This feature has also been observed in the ATON Hall thruster [14] where the magnetic field topology presents a zero-B field configuration.

Abstract
The formation and morphology of micrometric splats of stabilized zirconia collected on glass and stainless steel substrates have been studied. Splats result from direct current (d.c.) plasma spraying of a suspension of nanoparticles of stabilized zirconia. A system based on a pendulum allows in-flight particles collection at different distances from the injection point. In our process, as in classical plasma spraying, the material of the substrate as well as its temperature play a very important role in the shape of splats The particles and splats size distribution is measured by means of image analysis and an estimation of the average flattening ratio is made from measurements of splats thickness.

1. Introduction

In conventional d.c. plasma spraying, particles with a size between 10 and 100µm are injected into the plasma jet by using a carrier gas in order to obtain coatings with a thickness of at least 50µm formed by layering lamellae (splats) resulting from the spreading of molten particles. These splats have typically a diameter close to 100µm for a thickness of 1µm [1].
The injection of ceramic suspensions containing submicronic particles (a few tens to a few hundreds of nanometers) in a d.c. plasma jet is a new process which allows to achieve thin coatings (thickness between 1 and 100µm) with a fine microstructure. It results from the fact that the molten droplets of ceramic are in the range 0.1 to a few µm in diameter instead of a few tens of µm for classical spraying. The resulting splats are thus one to two orders of magnitude smaller than in classical plasma spraying. Previous studies of this process allowed to evaluate the influence of the different spray parameters such as standoff distance, current intensity, plasma gas composition, nozzle internal diameter, suspension solvent and suspension load on the state of collected splats. These preliminary works allowed to determine different sets of working conditions [2]. They have shown that the big suspension drops (~300 µm) injected with a momentum high enough to penetrate within the plasma jet are sheared (in times ~ 1µs) by the plasma jet in tiny droplets in the µm size range. The suspension solvent is then evaporated (in the µs time range) and the resulting ceramic agglomerates are melted and accelerated towards the substrate.
There is a great interest in obtaining thin dense stabilized zirconia coatings, in order to deposit electrolytes in SOFCs for instance. The injection of an yttria-stabilized zirconia suspension in a d.c. plasma jet is an interesting way to achieve thin nanostructured stabilized zirconia coatings with a deposition rate almost as high as that of a conventional spray process.
The formation and morphology of micrometric or submicrometric splats of stabilized zirconia have been studied on glass and stainless steel substrates with smooth surfaces (Ra<0.1 µm).

2. Experimental procedure

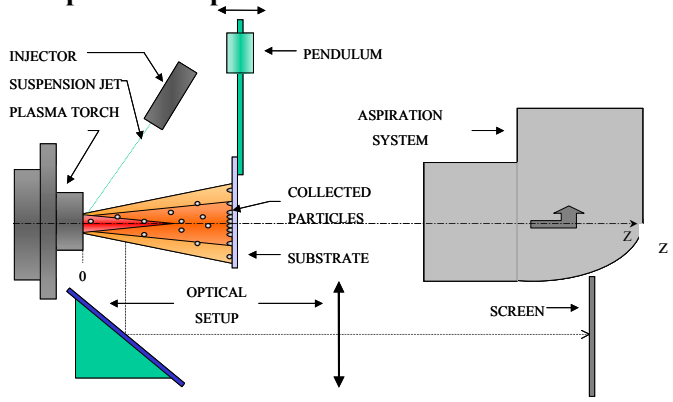

Fig 1 : Experimental set-up

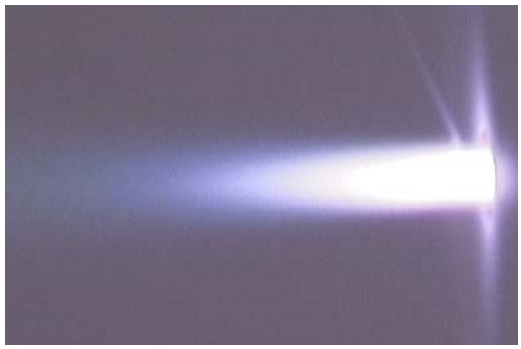

Fig 2 : Liquid injection in the plasma jet

The experimental set-up consists in a d.c. plasma torch (PTF4 type), an injection system for the suspension, a furnace for substrate preheating and a pendulum to collect in-flight particles (Fig.1).
The d.c. plasma torch is operated at 400 or 500A with an Ar/H_2 (45/15 slm) mixture as plasma forming gas and a 6 mm internal diameter nozzle. During all experiments, the characteristics of the plasma torch (arc current intensity and voltage, torch thermal efficiency and gas specific enthalpy) are measured and recorded with a specifically developed computer code.

The injection system is composed of a tank, in which the suspension is stored, and an injector consisting in a stainless steel tube with, at its extremity, a calibrated injection hole which is manufactured by electro-erosion. Suspension is mechanically injected by controlling, with compressed air, the pressure of the liquid in the tank, the pressure of injection being monitored with a gauge. The injector axis is aimed at the nozzle exit, in such a way that the suspension flow penetrates the plasma at counter-flow and targets the nozzle axis (Fig.2).

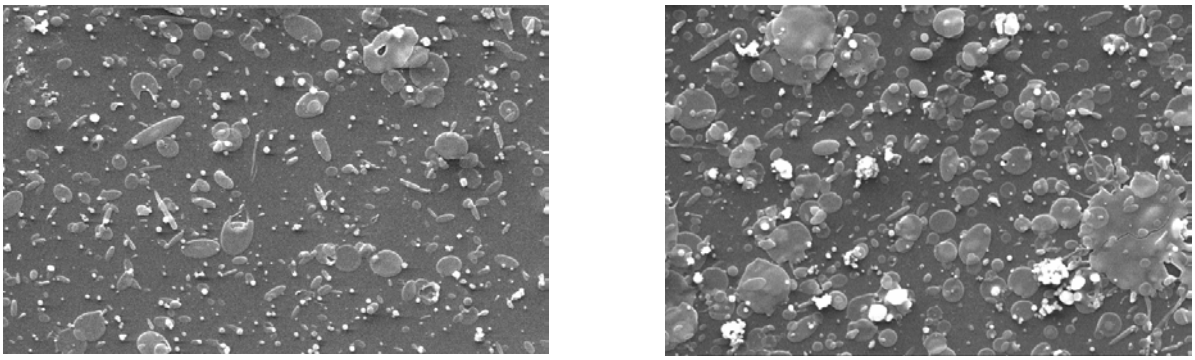
The ceramic powder used is zirconia doped with 13 wt% yttria (Tosoh TZ-8Y). It has a specific surface area of 13 m^2/g and a mean crystallite size of 25 nm. The solvent used is ethanol. The suspension must have a low viscosity and a good stability to be compatible with the process. A suitable dispersant, which adsorbed on the particles surface, allows an effective dispersion of the powder in the solvent. The dispersant used is a phosphate ester. It acts by a combination of electrostatic and steric repulsions.
After weighing the dispersant, solvent is added and the mixture is stirred until the liquid becomes clear. The zirconia powder is then added and the use of an ultrasonic probe to break the powder agglomerates is the last step to obtain the desired suspension. The mean agglomerated particle size in the suspension is 500 nm and the majority of particles has a size ranging between 100 nm and 2 µm. The rheological studies show that suspensions containing 2 wt% of dispersant display the minimum viscosity of 3.5 mPa.s.
The suspension has a loading of 7 wt% and is injected with the previously described injector. To study the in-flight phenomena acting within the plasma on the initial suspension drops (estimated with the help of a C.C.D camera to be about 300 µm in diameter), particles are collected at different distances downstream of the injection point which correspond to different residence times of particles in the plasma jet.
The pendulum can be positioned relatively to the nozzle exit along the z-axis (Fig.1). Its velocity depends principally on its mass, length and the angle from which it is thrown. Thus, by controlling its velocity and position, a substrate collects different quantities of particles after their treatment in the plasma at different distances downstream of the injection point. The collecting time corresponds to a few milliseconds. The resulting samples are analyzed with a Scanning Electron Microscope (SEM), an Atomic Force Microscope (AFM) and an Interferometric Microscope (IM) in order to observe the collected particle or splat morphologies.

The furnace used for substrate preheating is composed of 2 copper blocks, each of them being electrically heated up to a maximum power level of 250 W. The plate is maintained in this heating device before being thrown at the extremity of the pendulum for the particles collection . The space between the two copper blocks is adjustable. The whole device is insulated by glass wool. A K type thermocouple allows to control the temperature of the copper blocks, which is recorded together with the characteristics of the plasma torch. Knowing the oven temperature, the rise in substrate temperature is determined numerically instead of experimentally because of practical difficulties (moving system, low thickness from a few tenths to a few mm of the heated plate).

3. Results related to the influence of the substrate parameters

3. 1 Glass substrates

The first experiments were made with glass substrates (Ra =0.02 µm). The oven temperature was fixed at 500°C and then substrates were heated during different times corresponding to different temperatures. The flying plate collected particles during about 3 ms. Different collecting distances were tested. The results presented below correspond to the distance where collected particles are fully molten and spread the best.
At 500 A, no change in splats morphology can be observed whatever the glass temperature could be between 20 °C and 480°C. A new experiment (Fig.3) was made at 400A and only a slight effect is observed:

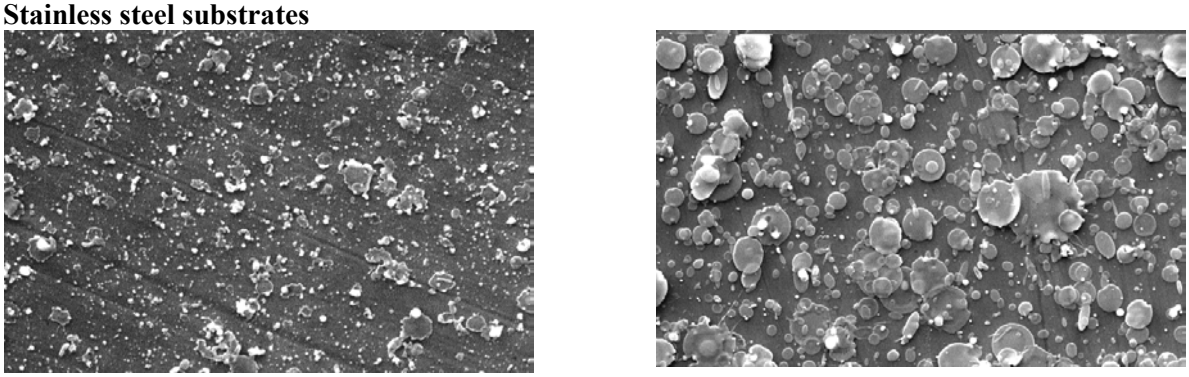


Glass substrate at T=20°C Glass substrate heated at T=400°C

Fig 3: zirconia particles collected on glass substrates I=400A (× 10000). ⟷ 5μm

More particles are collected when the substrate is heated at 400°C and they spread better. With the substrate preheated at 400°C, results comparable to those observed on cold substrates with an arc current intensity of 500 A are obtained with a lower current intensity of 400A. No clear explanation has been found for this behaviour.

3.2 Stainless steel substrates



Stainless steel substrate at T=20°C Stainless steel substrate heated at 400°C

Fig 4 : zirconia particles collected on polished stainless steel substrates I=500A (× 10000). ⟷ 5 μm

There is a clear effect of the influence of the substrate temperature on splat morphologies and splats number when the substrate used is made of stainless steel (Fig.4). No preheating leads to few collected splats which are irregularly shaped. A preheating temperature of 400°C for stainless steel substrates leads to disk shaped splats, with a much better spreading. It can be been explained by a better wetting [3], but it is very likely due to the desorption of condensates and aggregates at the substrate surface when the critical temperature called transition temperature is reached [4,5].

4. Results from particles analysis

4.1 Image analysis of collected particles

When the splats collection is made far from the injection point, only spheroidized particles are obtained on the plate. Those are the particles injected which have cooled down, due to their low thermal inertia, and are mostly in a plastic state after having been fully melted in the plasma jet and which impact velocity is now too low for their spreading. Image analysis can be made from the S.E.M photos of different samples collected on the plates (Fig.5,6). Particles with sizes from below 100 nm to 2 μm are observed with a mean size of 200 nm. 65% of particles have a size below 200 nm but they only represent 5% of the collected weight. Particles with a size over 500 nm are only 5% in number but they represent 60% in weight.

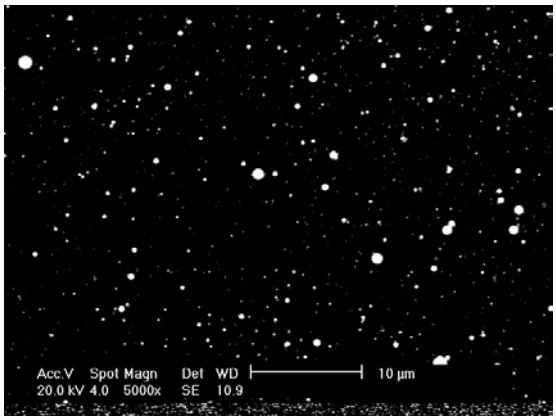


Fig 5 :collection of particles far from the injection point for image analysis. ⟷ 10 µm

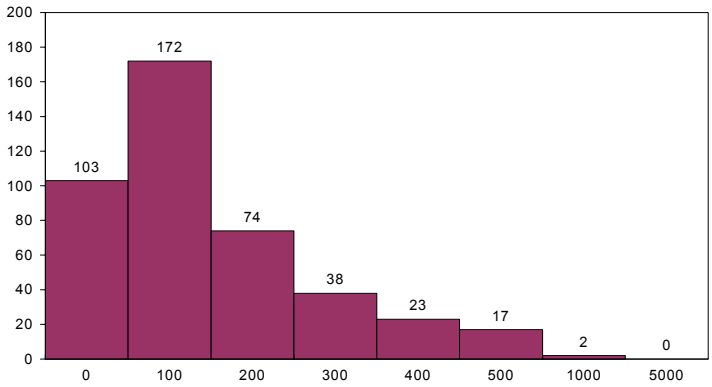

Fig 6: number of collected particles evolution with their size

4.2 Estimation of splat thicknesses

From splats collection, on glass substrates at good spraying distances (where quite dense coatings can be achieved), the observation is made with an interferometric microscope (IM) and an atomic force microscope (AFM) in order to obtain the 3 dimensional (3D) representation of splats and to measure their diameters and thicknesses.

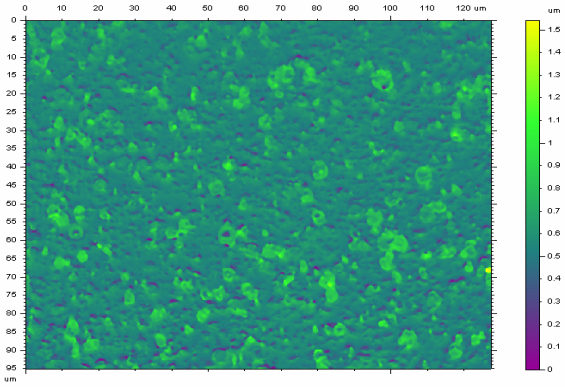

Fig 7 : map of a 127.7*95.3 µm zone obtained with the interferometric microscope

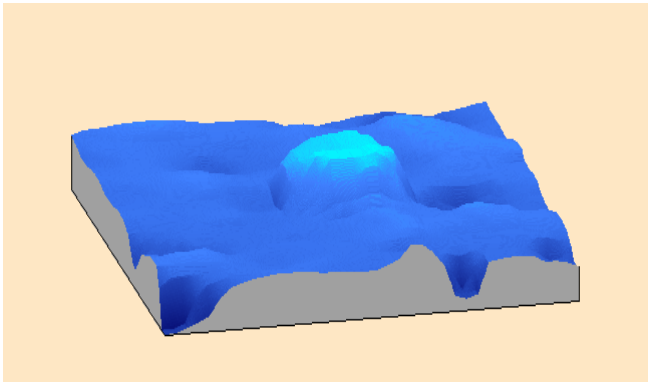

Fig 8 : 3D imaging of an yttria stabilized zirconia splat (D=2µm, h=300nm) thanks to the interferometric microscope

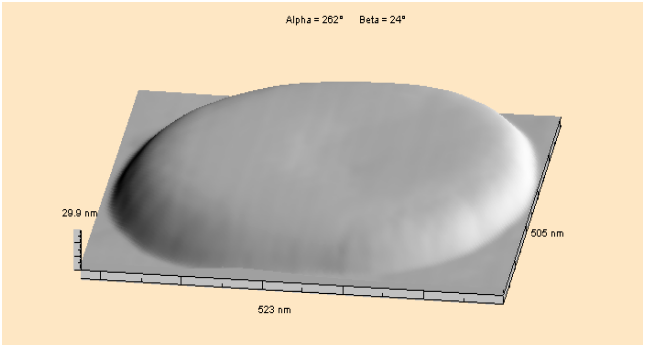

Fig 9 : 3D imaging of a YSZ splat with AFM (D=0.5 µm, h=30 nm)

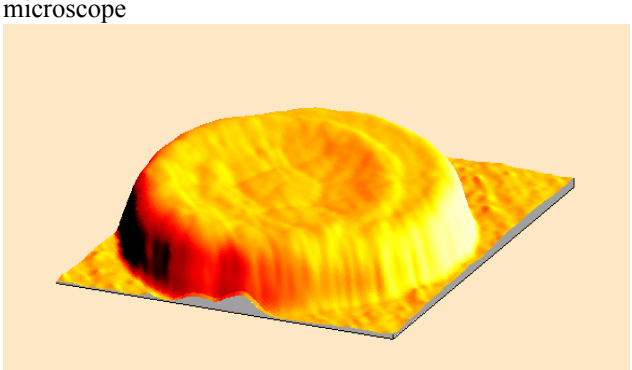

Fig 10 : 3D imaging of a YSZ splat with AFM (D=0.8 µm, h=60 nm)

With the interferometric microscope only the biggest splats (diameter over 1µm) can be observed accurately (Fig.7,8), while the atomic force microscope allows to see smaller splats with more details (Fig.9).
Most of the splats observed have a more or less regular cylindrical shape (Fig.10). The profiles from splats (Fig.11) were taken at the middle of the most regular splats and then their mean diameter D and thickness h were measured.

When considering splats as perfect cylinders, initial diameter of the impacting spherical particle can be calculated from the formula:

$d = \sqrt[3]{1.5 * D^2 * h}$ (1) and the flattening ratio $\xi = \frac{D}{d}$ (2) can be deduced.

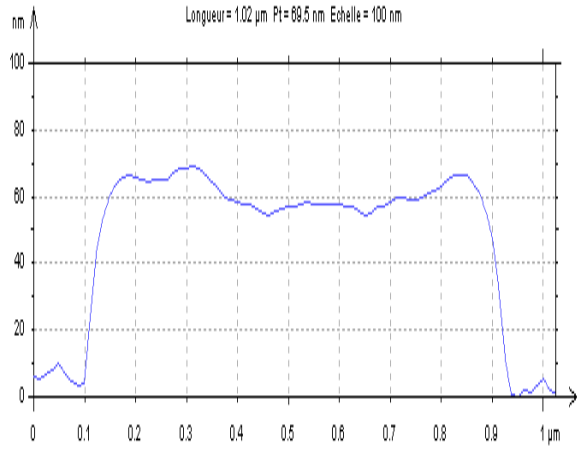

Fig 11 : Example of a profile taken from the splat represented in Fig. 10.

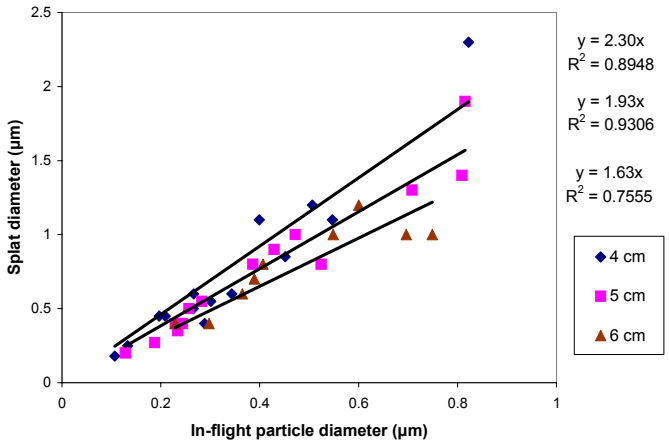

Fig 12 : Estimation of the flattening ratio for different distances downstream of the injection point

With the interferometric microscope the splat diameters considered are in the range 1.8-4.6 µm with their thicknesses varying from 0.17 µm to 0.35 µm while with the atomic force microscope the splat diameters are in the range 0.2-1.9 µm with their thicknesses between 25 nm and 280 nm. The corresponding flattening ratio is between 1.3 and 2.8. As it could be expected, the mean value of ξ decreases when the collection distance from the injection point increases (Fig.12). At 4cm a mean value of 2.30 is obtained for ξ while it is only 1.93 at 5cm and 1.63 at 6cm.

The values of ξ obtained with our process are less than those obtained for bigger particles used in classical spraying [6]. Such values can be explained by lower Reynolds and Weber numbers of particles. The Madjeski's formula $\frac{3\xi^2}{We} + \frac{1}{\mathrm{Re}}\left(\frac{\xi}{1.2941}\right)^5 = 1$ can be used to try to determine the impacting particles speed. A mean value of ξ=2 results in equation $\frac{12}{We} + \frac{8.8}{\mathrm{Re}} = 1$. Neglecting the surface energy term at impact (high We) leads to Re=8.8. Besides, a resolution of the whole equation leads for a 1µm diameter particle at a temperature of 3200 K (assuming that ρ=5700 kg.m^{-3}, µ=0.034 Pa.s, σ=0.5 N.m^{-1}) to an impact velocity v_p of 68 m/s (Re=11.4, We=52.7) while for a 500 nm particle v_p=122 m/s (Re=10.2, We= 84.8). A value of Re~10 is then obtained for our particles. But during flattening We diminishes very fast and so surface tension forces will play a key role on the particle flattening especially at its end. This oversimplified calculation gives indication about particle velocities which are lower than in classical spraying which can be due to the plasma quenching by the solvent evaporation and also the Knudsen effect for these small particles. Moreover, according to particles sizes their thermal inertia is low and as soon as the spray distance increases after an optimal distance, as shown by collected splats and particles, their cooling is very important and ξ decreases. With a mean value of ξ=2 the thicknesses predicted by formulas (1) and (2): $h = \frac{d_p}{1.5\xi^2}$ are h=80 nm for d_p= 500 nm and h=30 nm for d_p= 200 nm which is in good agreement with experimental results.

The images from AFM show that splats have a microstructure similar to that of splats obtained in classical spraying (Fig.13), with microcolumns growing perpendicularly to the substrate with column sizes between 20 and 100 nm for a 1µm diameter splat. However the size distribution of the columns is not as regular as in classical spraying showing that the cooling is not uniform all over the splat surface. In classical spraying the column mean size is between 100 to 400 nm depending on the splat cooling rates.

Besides, x-ray diffraction analysis made on coatings show that our 13wt% yttria-stabilized zirconia crystallizes under the cubic form.

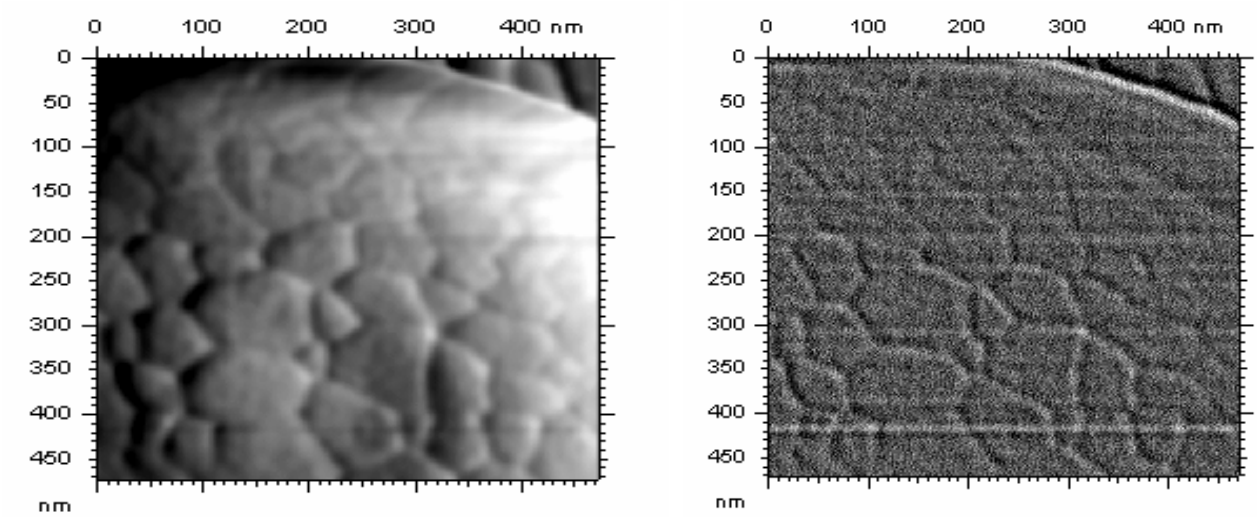

Fig 13 : view of the top of a splat (diameter of 1μm) showing a columnar structure

Conclusion

Nanometric particles have been d.c. plasma sprayed by injecting them as a suspension in ethanol. The formation and morphology of the resulting micrometric splats of stabilized zirconia on smooth surfaces (Ra<0.1 μm) have been studied for glass and stainless steel substrates. The substrate material as well as its temperature play a very important role in the shape of splats in our process as in classical plasma spraying. At low temperatures (T~300K), splats are close to disk shaped on a glass substrate and fingered and exploded with many holes on a stainless steel substrate. At a higher temperature of 670 K, only disk shaped splats are observed on both types of substrates. They are well spread and there is no flagrant difference between glass and stainless steel substrates for splats formation. The image analysis on glass substrates has been made, showing that the majority of molten impinging particles have a size below 1μm but particles over 500 nm in diameter represent more than 50% of the deposited weight. Interferometric microscopy and atomic force microscopy allowed to measure the diameter and thickness for splats corresponding to these molten particles. The flattening ratio was found to be around 2, depending on the spraying distance, corresponding to a mean thickness of 80 nm for an impacting particle size of 500 nm. Splats crystallize in a cubic structure and it was observed that for splats of diameter close to 1μm crystallization occurs under the form of microcolumns growing perpendicularly to the substrate.

Abstract
This paper is devoted to the production of thin coatings (5<e<100 µm) finely structured. This is achieved by direct current (d.c.) plasma spraying of ceramic suspensions containing submicronic Yttria Stabilised Zirconia (YSZ) and Al_2O_3 particles. The suspensions are either separately or simultaneously injected into a d.c. plasma jet. The spray parameters, influencing the structure of collected splats have been previously studied and this paper is devoted to the coating growth and the achievement of a multi layered coating.

1. Introduction

Many thermal spray techniques are available to work out nanostructured coatings such as Thermal Plasma Chemical Vapor Deposition (TPCVD) [1], pneumatic Suspension Plasma Spraying (SPS) [2], High Velocity Oxy-Fuel guns [3] with agglomerated nanoparticles, Thermal Plasma Spray Pyrolysis (TPSP) [4], Thermal Plasma Flash Evaporation [5] or Hypersonic Plasma particle Deposition (HPPD) [6]. But none of them permits to achieve coatings rapidly, easily and economically.
The objective of the present study is the production of thin coatings with a wide thickness range (5 µm to 100 µm) and a fine structure, meeting the following requirements: a high deposition rate and a cost price as close as possible to those of plasma spraying and of course an easy implementation on existing installations. This is achieved with a new process designed at the SPCTS laboratory [7] [8], where ceramic suspensions containing submicronic particles (a few tens nm) of Yttria Stabilised Zirconia (YSZ) and Al_2O_3, are mechanically injected either separately or simultaneously in a d.c. plasma jet. First, the influence of spray parameters on the structure of splats collected on glass plates is studied in order to determine the best adapted working conditions. Second, the coating growth and the influence of different parameters such as the substrate surface conditions, plasma generation conditions and spray pattern are studied.

2. Experimental method

The SPCTS laboratory experimental set-up consists in a PTF4 (Sulzer Metco) plasma torch, a mechanical injection system for the suspension, a pendulum to collect in-flight particles and a substrate holder to realise coatings by the overlapping of beads at the same location (Fig.1).
The d.c. plasma torch is operated between 300A and 500A with Ar/H2 (45/15 slm) or Ar/H2/He (24/9/30 slm) mixtures as plasma forming gases. The nozzle internal diameter used is 6 mm. During all experiments, the characteristics of the plasma torch (arc current intensity, voltage, thermal efficiency and plasma specific enthalpy) are measured and recorded with a specifically developed computer code.

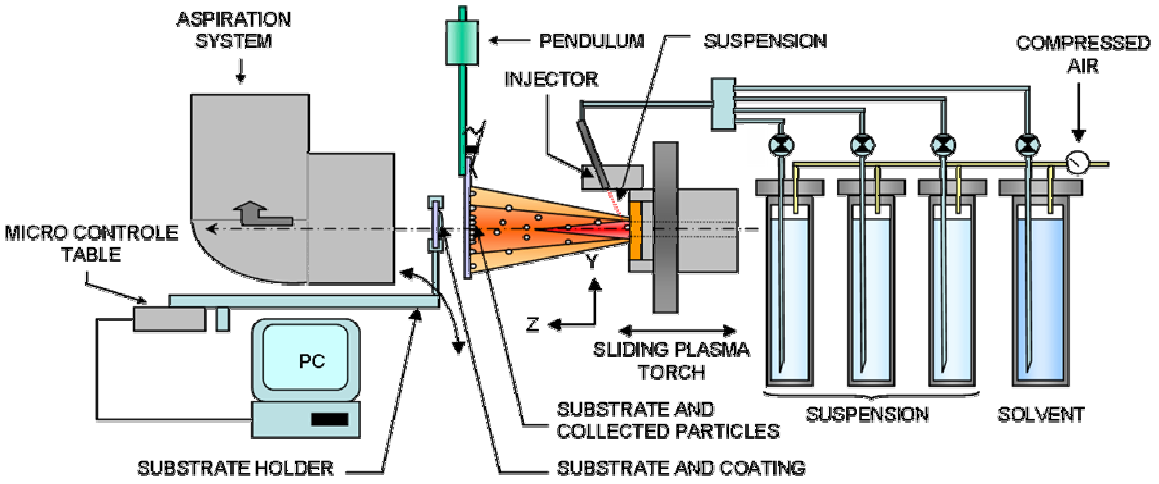

Figure 1: Laboratory experimental set-up.

The injection system is composed of tanks (Fig.1) in which the suspensions and the solvent are stored and an injector consisting in a stainless steel tube with a laser-machined nozzle in order to obtain a calibrated injection hole. The suspension is injected thanks to the pressure of the liquid in the tank, controlled with compressed air, and monitored with a gauge. The injector is positioned directly onto an especially designed ring fixed on the torch nozzle, in such a way that the suspension particles penetrate the plasma at counter-flow and targets the centre of the plasma flow at the nozzle exit.
The zirconia powder used is doped with 13 wt% yttria (Tosoh™ TZ-8Y). It has a specific surface area of 13 m2.g-1 and the mean crystallite size is 25 nm. The alumina powder (Baïkowski™ CR125) has a specific area of 105 m2.g-1. In both cases the solvent used is ethanol. The suspension must have a low viscosity and a good stability to be compatible with the process. A density of 1 vol % has been chosen for the both ceramic suspensions. A suitable dispersant which adsorbs on the particles surface allows an effective dispersion of the powder in the solvent. The dispersant used is a phosphate ester. It acts by a combination of electrostatic and steric repulsions. The stability of the suspensions is longer than one month.
The pendulum is used to study the influence of the operating parameters on the morphology of individual splats. It can be positioned relatively to the system {plasma torch + liquid injector} along the z-axis (see Fig.1), with a precision of 1 mm. Its velocity depends principally on its mass, length and the angle from which it is thrown. Thus, by controlling its velocity and position, the glass plate collects different quantities of particles after their treatment in the plasma at different distances downstream of the injection point. For a single pass, the collecting time corresponds to approximately 3 milliseconds. The resulting samples are analyzed with a Scattering Electron Microscope (SEM) in order to observe the collected particle morphologies in SE (Secondary Electron) and BSE (Back Scattering Electron) modes.
A substrate holder is used to realise coatings by overlapping beads at the same location. It is composed of a sliding arm, which is moved by a computer controlled Micro-Contrôle® table (200 passages, time between two successive passages (1.25 s) and velocity (0.7 $m.s^{-1}$)). For a single pass, the collecting time corresponds to approximately 30 milliseconds. In the same way as for the pendulum it can be positioned relatively to the distance z. In this case, the substrates used are made of stainless steel 316L. The resulting coatings are vacuum impregnated and polished before their cross sections are observed by SEM. This study is done to understand the spray parameters influence on coating elaboration in order to optimize them before an industrial test.

3. Influence of the operating parameters on the morphology of individual splats

The first parameter studied with the pendulum was the influence of the particle collection distance at a current intensity of 500A with an Ar/H2 (45/15 slm) mixture and for a 6 mm nozzle internal diameter (Table 1). In this paper only two collection distances are discussed, the optimal one (d1) for which the best results are observed, and the coating one (d2) such as, d1< d2. In fact the coatings were not manufactured at the optimal distance d1, because the collection time of the substrate holder for one passage is ten times longer than that of the pendulum and a coating requires hundreds of passages. As the substrate is not cooled, the thermal strains are too important and, at the optimal collection distance d1, the coating can't relax the strains, and part of it peels off.

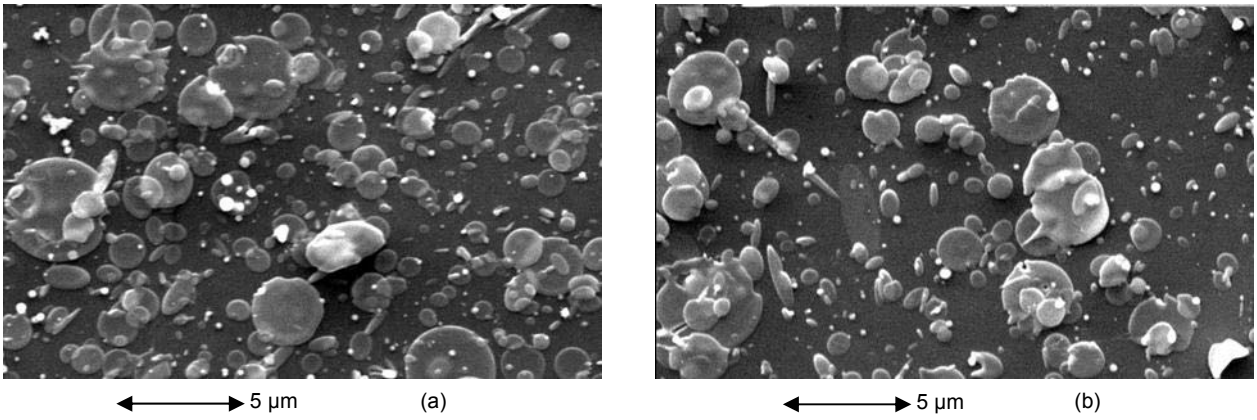

Figure 2: For a 6 mm internal diameter nozzle, an Ar-H_2 (45-15 slm) plasma gas, an arc current of 500 A, and with a suspension containing 1 vol% of YSZ, splats and spherical particles collected, at different distances, a) d1 close to nozzle exit, b) d2>d1.

The results obtained with YSZ particles are shown in Fig.2. For the distance d1 several layers of piled splats and few tiny spheroidized particles, already partially solidified are observed, but as the distance of collection increases, fewer particles are collected with more spherical tiny ones due to the jet expansion and the molten particles fast cooling due to their low thermal inertia.
The Al_2O_3 results are shown in Fig.3. The trend is obviously the same, except the fact that the alumina is more difficult to melt. Consequently at the d2 collection distance (d2=d1+10 mm), the particles are much less spread onto the substrate.

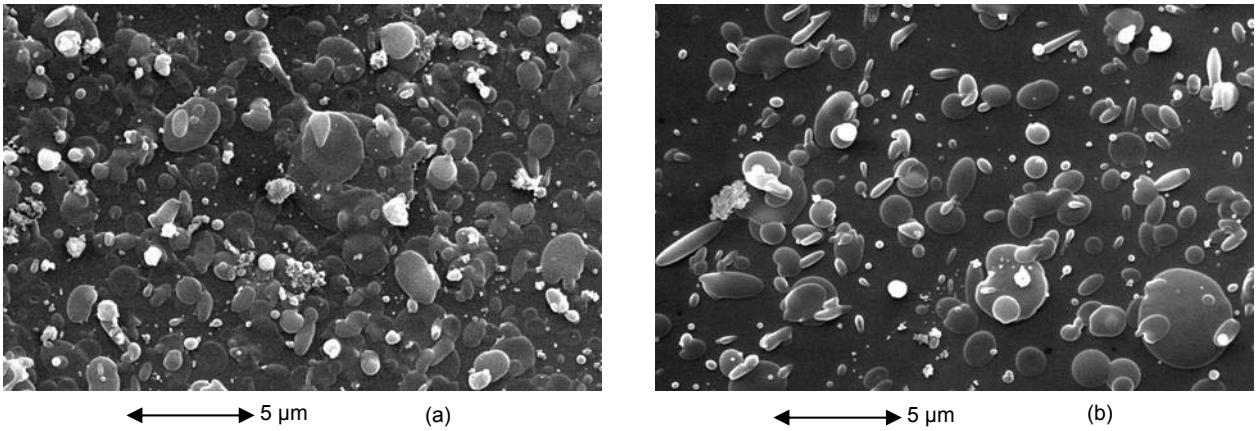

Figure 3: For a 6 mm internal diameter nozzle, an Ar-H_2 (45-15 slm) plasma gas, an arc current of 500 A, and a suspension containing 1 vol% of Al_2O_3, splats and spherical particles collected, at different distances, a) d1 close to nozzle exit, b) d2>d1.

The second parameter studied was the influence of the plasma gas composition at the d1 particle collection distance and a current intensity of 500A. The new plasma gas studied is a ternary mixture composed of Ar (24 slm), H_2 (9 slm) and He (30 slm) which represent 3/5 of an Ar/H2 (45/15) mixture mass flow rate (Table 1). The results obtained with YSZ particles (Fig.4.a) didn't show significant differences with those obtained with a binary gas mixture (see Fig.2.b). The collected particles are numerous, well molten and spread.

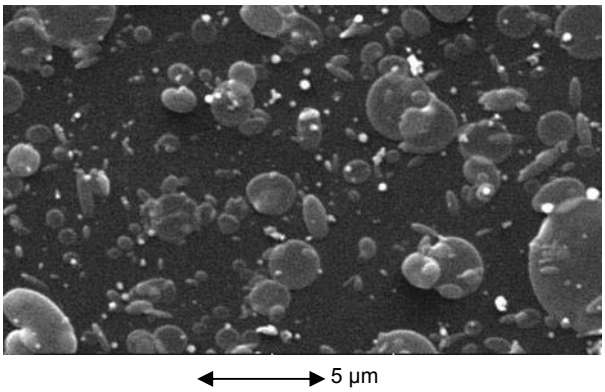

Figure 4: Splats and spherical particles collected for a 6 mm internal diameter nozzle, a d2 collection distance, an Ar/H_2/He (24/9/30 slm) plasma gas, an arc current of 500 A, and a suspension containing 1 vol% of YSZ.

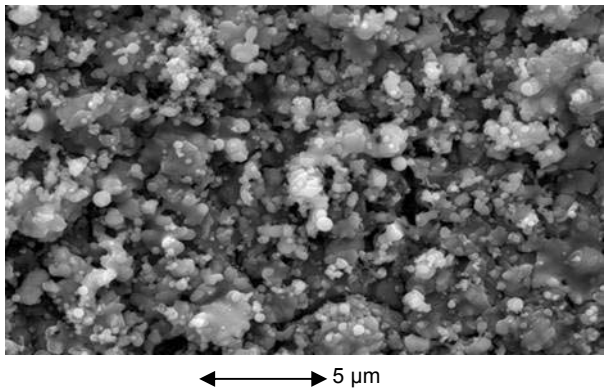

Figure 6: Coating corresponding to 2 overlapping beads at the same location, for a 6 mm internal diameter nozzle, a d2 collection distance, an Ar/H_2 (45/15 slm) plasma gas, an arc current of 500 A, and a suspension containing 1 vol% of YSZ.

Plasma gas composition	Current intensity (A)	Arc voltage (V)	Specific Enthalpy (MJ/kg)
Ar/H_2 (45/15 slm)	500	60.5	13.96
Ar/H_2/He (24/9/30 slm)	500	58.2	23.7

Table 1: Experimental plasma characteristics for a 6 mm nozzle internal diameter for two plasma gas mixtures.

Lastly, the particle collection of a YSZ and Al_2O_3 mixed suspension was studied, at a current intensity of 500A with an Ar/H2 (45/15 slm) mixture and a 6 mm nozzle internal diameter (Fig.5). As it can be seen, the molten particles of YSZ and Al2O3 are not miscible and layer very well.

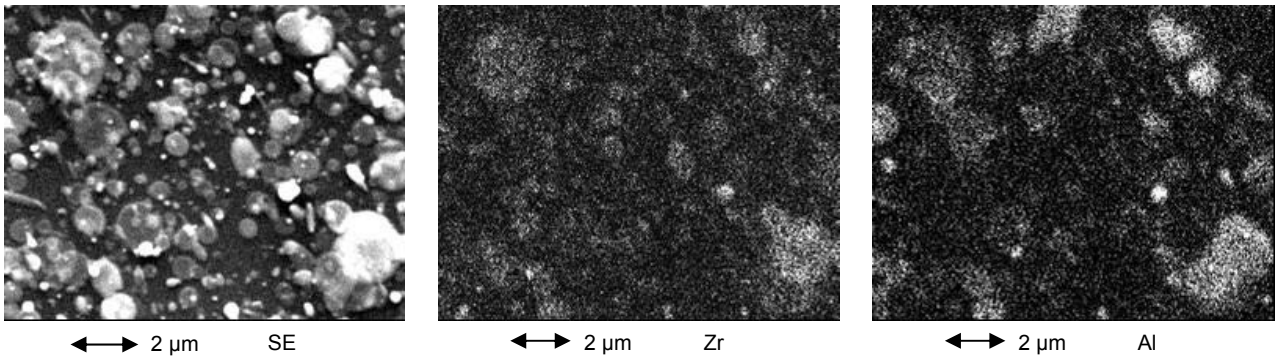

Figure 5: Particles collected at d1 particle collection, for a 6 mm internal diameter nozzle, an Ar-H_2 (45-15 slm) plasma gas, an arc current of 500 A, and a suspension containing a mix (50 vol%/50 vol%) of YSZ and Al_2O_3 (1 vol%).

4. Influence of the operating parameters on coatings

The set-up used to achieve beads layering is far to be optimal because spraying is performed relatively close to the torch nozzle exit (stand-off distance 2 or 3 times shorter than in classical spraying). Thus, even when using the stand-off distance d2, and especially when spraying refractory materials such as zirconia or yttria, it results in a very fast heating of successive passes and substrate, with important temperature gradients (up to 2000 K/mm). Besides, such high temperature gradients generate stresses within coatings, especially at the coating substrate interface, stresses which are relaxed by cracking. This cracking relaxation is more catastrophic in our conditions due to the smooth substrates. In classical plasma spraying, as soon as the zirconia coating temperature increases micronic particles travelling in the periphery of the plasma jet stick to the pass surface and create defects. This is what is observed in Fig.6, representing two successive passages of the torch on a not preheated substrate. In all cases and whatever are the experimental conditions chosen (gas mixtures, suspension composition, collection distances), the same trend is observed. A first layer composed of well spread and layered splats with a few tiny rounded particles at the top covered by a second layer at the top of which spheroidized tiny particles are numerous. This is due to the substrate travelling in front of the plasma flow (Fig.7). During the first pass, only the molten particles travelling in the plasma jet flow centre adhere onto the not preheated substrate, only a few of the finest particles partially solidified, from the periphery of the plasma jet sticking to it, because of the low substrate temperature. During the second pass, the first layer is hot enough for the spheroidized particles to stick on it (Fig.6). The overlapping of molten and unmolten particles is partially responsible of porosity. Consequently the surface temperature is a crucial parameter for the realization of dense coatings. When before the two successive passages of the plasma torch the substrate is preheated, by ten successive passages of the torch without suspension injection, spheroidized particle stick on even during the first pass and more tiny particles (< 1 µm) cover the layered splats. The contact of the first layer with the substrate is worst and it is leads to a detachment of the coating (Fig.8.a).

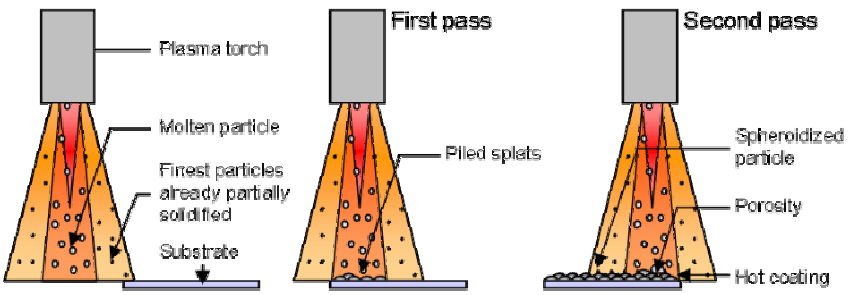

Figure 7: Mechanism proposed for the coating growth.

Some parameters were studied in order to understand the mechanism of the coating growth and confirm the results obtained for individual splats, such as the preheating of the substrate and the plasma gas composition. Experiments were performed at a current intensity of 500A, with a 6 mm nozzle internal diameter at the d2

collection distance and an YSZ suspension (Fig.8 and Fig.9). The coatings on stainless steel 316L substrates were elaborated by 200 successive passages of the substrate holder.

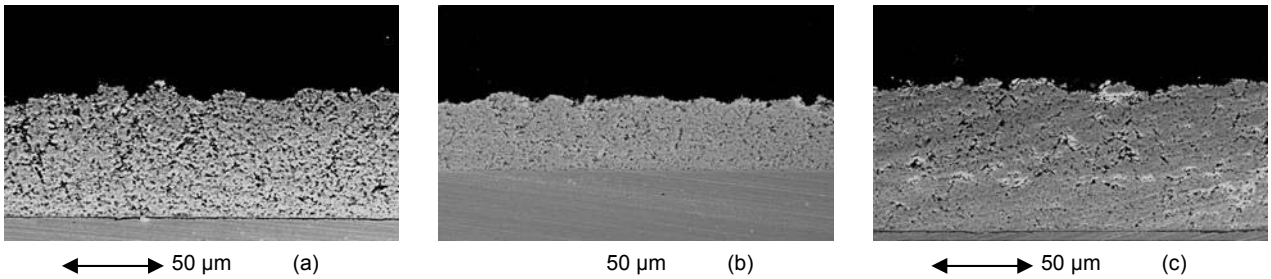

Figure 8: YSZ coatings for a 6 mm internal diameter nozzle, an arc current of 500 A, a) with an Ar-H_2 (45-15 slm) plasma gas with a 10 successive passages preheating, b) with an Ar-H_2 (45-15 slm) plasma gas and without preheating, c) with an Ar-H_2-He (24-9-30 slm) plasma gas and without preheating.

For a binary plasma gas composition and without preheating (Fig.8.b and Fig.9.b), relatively dense YSZ coatings can be achieved, with a thickness of 40 µm. Nevertheless when the substrate surface is preheated (Fig.8.a and Fig.9.a), the porosity and the thickness of the coating are more important, and some adhesion defects can be observed at the interface. It seems that porosities correspond to locations where more tiny spherical particles can be observed (see Fig.9.a).

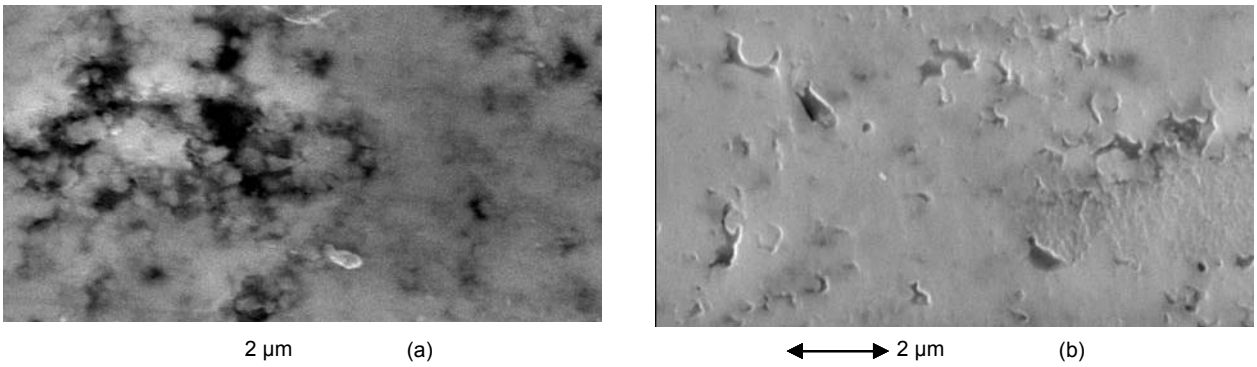

Figure 9: YSZ coating for a 6 mm internal diameter nozzle, an arc current of 500 A, a) with an Ar-H_2 (45-15 slm) plasma gas and without preheating, b) with an Ar-H_2 (45-15 slm) plasma gas with preheating by 10 successive passages of the torch with no particles.

The use of the ternary plasma gas composition with no preheating also leads to a relatively dense coating. Moreover the thickness is twice that achieved with the binary plasma gas mixture. This can be explained both by less air engulfment within the plasma jet for a ternary plasma gas composition, reducing its cooling and its higher enthalpy promoting particles melting. This results in higher coating deposition efficiency.
In the same conditions which permit the production of relatively dense YSZ coating, that is to say with a binary plasma gas composition, a current intensity of 500A and a collection distance of d2, the Al_2O_3 coatings achieved is very porous as shown in Fig.10 which exhibits one of the part of the coating that keeps the entire structure all over its height. The other parts of the coating correspond only to the base of the structure that still stick to the substrate.

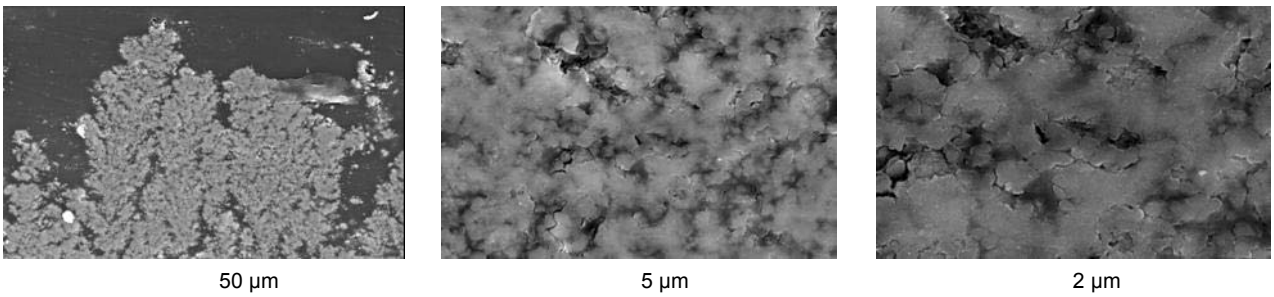

Figure 10: Al_2O_3 coating for a 6 mm internal diameter nozzle, an arc current of 500 A, with an Ar-H_2 (45-15 slm) plasma gas and a collection distance of d2. Pictures taken with different enlargements.

In the case of an alumina-YSZ mixed injection (Fig.11), the same spraying distance d2 could not be used for the coating production, the stresses at the coating-substrate interface being not accommodated. As a consequence the coating was sprayed at a farther distance d3. As for the alumina coating, the observed structure is porous but conserved all along the entire coating (despite that this longer stand-off distance should have enhanced the weakening phenomena of the coating due to the particle cooling, especially the alumina ones). At this distance the YSZ particles are still molten whereas the alumina ones are already in a plastic state. YSZ cements the alumina particles in a porous structure. This result seems interesting for the production of porous structures.

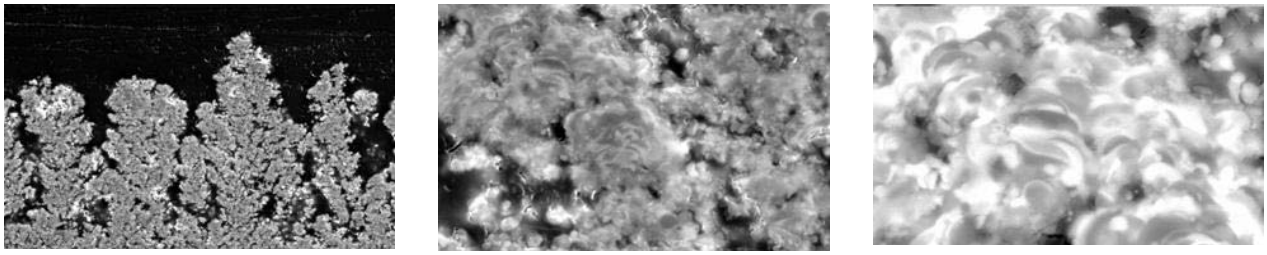

Figure 11: YSZ-Al_2O_3 mixed coating for a 6 mm internal diameter nozzle, an arc current of 500 A, with a Ar-H_2 (45-15 slm) plasma gas and a collection distance of d3. Pictures taken with different enlargements.

5. Conclusions

The injection of ceramic suspensions in a d.c. plasma jet is promissing for the realisation of dense or porous thin coatings. The process is quickly adaptable at low costs to all industrial d.c. plasma spray equipments. Yet the first results proved that it can be used to elaborate thin layers (with a thickness from 5 to 100 µm), with a high deposition rate (15 µm.m^2/h). These layers are made by layering splats having a size one to two orders of magnitude smaller than that obtained in classical d.c. plasma spraying. The next step of this study, is to control the surface temperature and reduce the fine almost solidified particles sticking between successive layers.

Design of a DBD wire-cylinder reactor for NO_x emission control – Experimental and simulation approach

A. Vincent, M. Moscosa-Santillan, J. Amouroux

Laboratoire de Génie des Procédés Plasma et Traitement de Surface, Université Pierre et Marie Curie, Paris, France

Abstract

A DBD wire-cylinder reactor was designed for NO_x removal from a exhaust gas mixture. The NO conversion has been investigated as a function of main parameters like HV electrode material, catalytic layer on the dielectric surface, initial NO concentration and gap reactor. Isotopic labelling analysis revealed that atomic oxygen produced is the main responsible of the mixture reactivity. Hence, a CSTR-in-series model with multiple injections of atomic oxygen has been proposed in order to explain relationship between reactor parameters and results. Optimisation of model parameters has permitted to fit experimental and simulation with an maximum absolute error of 5 %.

1. Introduction

The removal, based on electrical discharge in non-thermal plasma reactor, of nitrogen oxides from exhaust gases has been the object of several previous works[1,2,3]. The restrictive regulations in order to reduce pollution from motor vehicles exhaust gases permit the development of new processes for NO_x reduction. Some of these are : dielectric barrier discharge (DBD), corona discharge and in a recent study, a photo-trigged reactor has been used with this propose. In a previous work, a first study on DBD systems has been accomplished[4], this study concerned the electrical characterisation of a DBD wire-cylinder reactor as well as the influence of operating parameters and by-products analysis (essentially aldehydes and R-NO_x). For this study, the reactor was used to remove the NO contained in an O_2(10%), CO_2((10%), H_2O(5.4%), C_3H_6(1000 ppm), NO(max. 1000 ppm) and N_2(balance) gas mixture. Characterization and quantification of by-products was realized by Gas Chromatography coupled with Mass Spectrometry (GC-MS). Isotopic oxygen introduced in the inlet flow helped to elucidate the reaction mechanisms conducting to the formation of by-products. Analysis revealed that atomic oxygen produced by electronic impact over O_2, CO and CO_2 molecules is the main responsible of the mixture reactivity. So, a complete mechanism of involved reactions was proposed from O^{18} isotope experiments. Moreover, for each experiment, the electrical characterization of the discharge was carried out using a numerical oscilloscope. This way, measurement of voltage, current intensity, electrical power and electrical charge of the plasma pulses were determined. A correlation was proposed between discharge electrical power and atomic oxygen formed.

In this framework, the aim of this article is to develop a mathematical model in order to understand the relationship between operation parameters (inlet flow rate, inlet composition, electrical energy density, electrical gap) and reactor results (NO_x conversion, stability time, reactor performance). In the first part the experimental set-up is described. Then, reactor characteristics and behaviour are presented in two parts : hydrodynamics of reactor and reaction pathway retained. This basis permits to chose a mathematical model consisting in a cascade of continuous stirred tank reactor (CSTR) with multiple injections of atomic oxygen. Since atomic oxygen injection is intermittent, the mathematical model is intrinsically dynamic. Optimisation of model parameters has permitted to fit experimental and simulation with a maximum absolute error of 5 %. So, the simplified model showed a good agreement with the experimental results. Finally, the robustness of mathematical model was tested introducing some parameter variations (gas flow inlet and electrical gap) and confronting each time model and experimental results.

2. Experimental set-up

The reactor is a cylindrical dielectric tube, a alumino-silicate tube of 15mm and 21mm of internal and external diameters respectively. The high voltage electrode is a 6 or 8 mm diameter copper screw (gap=2.5 or 1.5mm) and the grounded electrode is a sheet of copper. Energy is supplied by a “Calvatron SG2” high voltage 44kHz AC supply. So, applied voltage is comprised between 9 and 15kV peak to peak. Figures 1 and

2 represent the experimental set-up. Instrumentation of the reactor comprises four inlet electronic flowmeters, a GC-MS device (Gas Chromatography–Mass Spectrometry) for outlet gas mixture analysis, a Quintox infrared gas analysers for measuring NO, NO_2, CO, CO_2, O_2, SO_2 concentrations and finally a numerical oscilloscope in order to characterise electrical discharge.

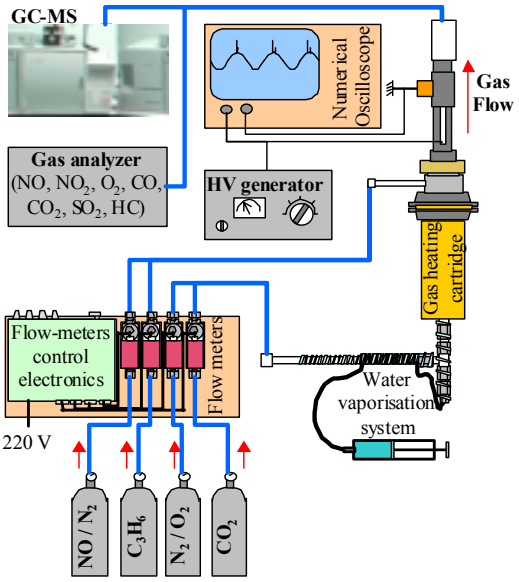

Fig. 1 Experimental set-up of the wire-cylinder reactor, gas feeding system and analysis apparatus.

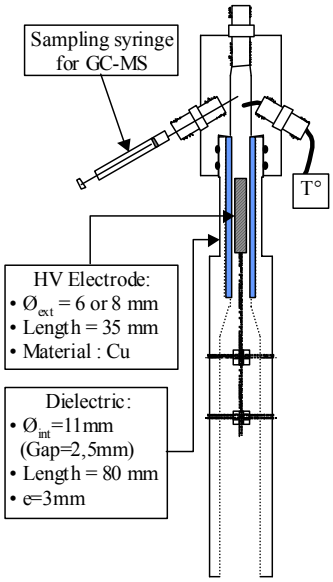

Fig. 2 Detailed schema of the wire-cylinder reactor.

The reactor is fed with a gas mixture at atmospheric pressure. Each gas (except water steam) is introduced in the reactor using electronic mass flow-meter. Inlet gas mixture containing O_2(10%), CO_2(10%) and N_2(balance) are introduced in a heating cartridge while NO (250 to 1000 ppmv) and C3H6(1000 or 2000 ppmv) are introduced after this stage. A motorized syringe pusher introduces H_2O (5,4%) in a heated 1/8" diameter and 2 meters long stainless steel tube. Vaporized water is then mixed with pre-heated gas mixture. The total gas flow is about 12.9 NL.min-1. Gas mixture temperature is measured by a thermocouple at 3cm after the discharge zone.

3. Simulation an modelling of reactor

Hydrodynamics of reactor is presented in order to justify application of a stirred pattern model. Then, we suggest the use of a simple reaction pathway to describe the transformation of main chemical components. Since mathematical model describes complex relationship (electrical, magnetic, chemical and diffusional characteristics), model constants are not only kinetic and they represent the degree of freedom of the model. So, their optimisation permits to fit model and experimental results. The basis of model design are explained at once, an analogy is made between electrical characteristics and model parameters in order to transform actual operating conditions in simple model inlets. Finally, results of simulation and comparison to experimental results are presented as a function of NO concentration, inlet flow rate and electrical gap.

3.1 Hydrodynamic behaviour of DBD reactor

The cylindrical geometry of the reactor and flow pattern suggest the use of a plug flow reactor (PFR) model. However, taking into account dimensions of the HV electrode and by extrapolation of hydrodynamic results obtained in a squared section reactor for a cylindrical configuration[5]. It can be proposed the hydrodynamic behaviour showed in figure 3. Spontaneous stirring observed is explained by the presence of electrical wind caused by discharge, which is responsible of great mobility of reaction species. The electrical wind produce an important retro-mixing in the reactor.

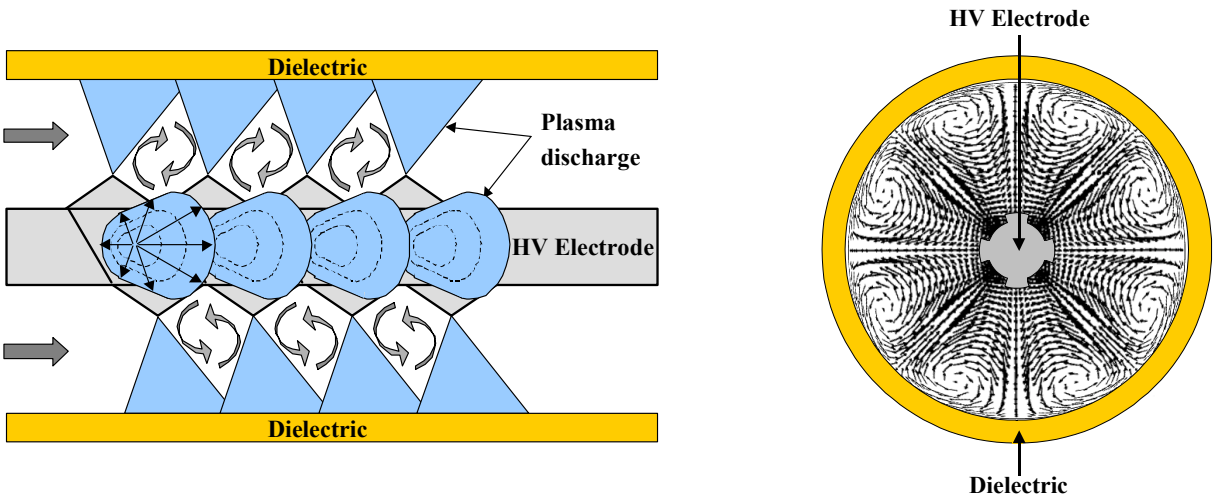

Fig. 3 Longitudinal **[a]** and radial **[b]** reactor sections presenting recycling zones and a stirred behaviour of the wire-cylinder reactor.

Hydrodynamic phenomena of convection and shearing endured by the gas mixture when it crosses longitudinally the reactor, justify the model choice for the reactor description as a cascade of continuous stirred tank reactor (n-CSTR). Figure 4 schematises correspondence between the wire-cylinder reactor and the system of serial CSTR cascade considered in simulation.

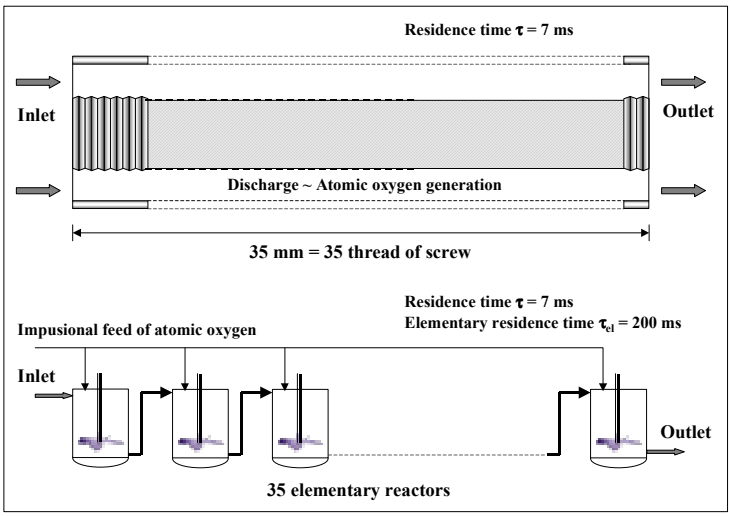

Fig. 4 Equivalence between DBD reactor and the serial CSTR system

3.2 Reaction pathway and design considerations

In order to simulate effects of electrical discharge on the reactor operation, some hypotheses were used based on experimental observations. First, it was considered that the atomic oxygen created by discharge is the main responsible of the mixture reactivity. Second, the electron impulsion flow creates an impulsion flow of atomic oxygen. Finally, a simplified reaction pathway, consisting in three reactions and shown below, was used to provide a global comprehension of the reactor behaviour.

$NO + O \rightarrow NO_2$	$r_1 = k_1 P_{NO} P_O$	Oxidation
$2O \rightarrow O_2$	$r_2 = k_2 P_O^2$	Destruction
$NO_2 + O \rightarrow NO + O_2$	$r_3 = k_3 P_{NO2} P_O$	Reduction

As it was explained before k_i are not kinetic constants but model constants taking into account different phenomena. So, these parameters must to be calculated and optimised. From these hypotheses, the electrical discharge represents a direct variation of the concentration of atomic oxygen in each elementary reactor. To characterize electrical discharge, the electric impulse duration is determined analysing electrical signal in a numeric oscilloscope and the impulse period is calculated directly from the frequency. Due to the short duration of the electric impulse (10 ns) with regard to the period (22 ms), we can consider the impulse as instantaneous. In consequence, the impulse can be translated like an instantaneous injection of atomic oxygen to each elementary reactor. Subsequently, the oxygen injection extent is calculated directly from the energy density.

Once reactor model is proposed, the reactions that govern system behaviour must be settled down. For a multi-component feed for a perfectly mixed tank, the mass balance for component *j* would be as shown in equation 1.

$$\frac{d(C_{jo}^{k}V^{k})}{dt} = F_{i}^{k}C_{ji}^{k} - F_{o}^{k}C_{jo}^{k} + r_{j}^{k}V^{k} \qquad (1)$$

where F^k is volume flow (inlet or outlet) of *j* component, $C_{ji}^{\ k}$ is the concentration of *j* species in the inlet stream of k^{th} reactor, $C_{jo}^{\ k}$ is the concentration of *j* species in the outlet stream of k^{th} reactor, V^k is the elementary reactor volume and r_j^k is the reaction of rate of the generation of component *j*.

Inlet conditions in k^{th} reactor are obtained directly from outlet conditions from previous reactor. Nevertheless, in the case of atomic oxygen, the inlet term is a time function expressed as,

$$C_{Oi}^{k} = C_{Oo}^{k-1} + C_{Oimp}^{k}(t) \qquad (2)$$

where $C_{Oimp}^{\ k}(t)$ term traduces atomic oxygen injection. So, this term is a discrete function expressed by equation 3 and $C_{Oo}^{\ k-1}$ is atomic oxygen flow from $k\text{-}1^{th}$ reactor

$$C_{Oo}^{k}(t)\begin{cases} = \Delta C_{Oinj}^{k} & t = mT_{inj} \\ = 0 & t \neq mT_{inj} \end{cases} \qquad (3)$$

For a system with *n* components, there are *n* component balances. The total mass balance and component balances are not independent. Generally, the mass balance and *n-1* component balances are used. However, in our case, the total mass balance equation is not used in reason of low concentration of reaction species (max. 1000 ppm). So, it was applied a mass balance for each component only for the minority species. The result is a system of n-ordinary differential equations.

The well-known 4th order Runge-Kutta method was used to determine the evolution of concentrations as a function of time along the reactor. Table 1 summarizes experimental parameters used in simulation. With the aim of adjust experimental data and modelling results, optimisation of parameters was carried out using model constants.

Table 1. Experimental DBD reactor conditions used in modelling and simulation

Inlet flow	20 $L.min^{-1}$	Gap	1.5 mm
Gas speed	5.4 $m.s^{-1}$	Reactor length	35 mm
Residence time	6.5 ms	Electrical period	22 µs
NO concentration	250 – 1000 ppm_V	O concentration	Pulsed injection
O_2 concentration	10 $\%_V$	N_2 concentration	Balance

3.3 Simulation results

Each reactor simulation implies solution of the 35X3 system of ordinary differential equations as a function of time. That means a discrete integration in the reactor length and a continuous integration in the time. Moreover, initial conditions (t=0) are fixed as: reactor concentrations for all components are equal to inlet concentration. So, a time of integration large enough must be applied in order to find the pseudo-steady state

mode in outlet (fig. 5), typical values of final time for integration are 8 seconds. The final cyclic pseudo-steady state point in figure 5 represents only one experimental data.

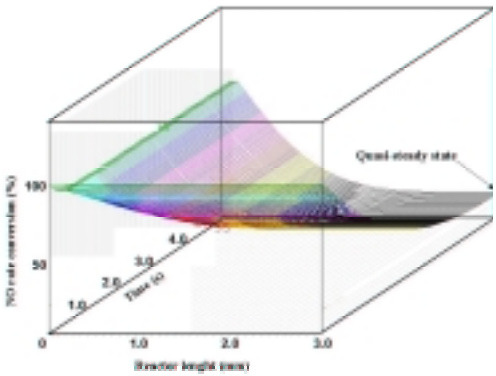

Fig. 5 NO conversion vs. reactor length and time for $C_{NOinitial}$=250ppmv and 40 J.L-1.

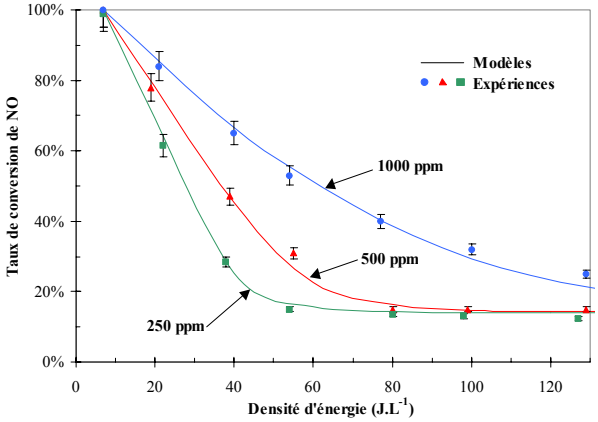

Fig. 6 NO conversion vs. electrical energy density for different NO initial concentrations.

Hence, parameter optimisation on k_i values has been made in order to adjust experimental results of NO conversion as a function of electrical energy density. This has been made for an initial NO concentration of 250ppmv. The k_i values describe some internal process but they are supposed to be independent of NO concentration or inlet flow. Then, robustness of k_i values were tested for different NO concentration (250 to 1000ppmv) and for different inlet flows (6.5 and 12.9 NL.min-1). Simulation and experimental data are compared in the case of three concentrations (fig. 6) and two inlet flows (fig. 7). In the case of electrical gap a simple theoretical correction in the correlation between oxygen impulse intensity and electrical energy density is needed. Actually, this correlation is a straight line and the electrical gap is directly proportional to the slope. The results of this last simulation are shown in figure 8. In general, a good agreement between simulation and experimental is verified, so the CSTR cascade model describes in a pertinent way the DBD wire-cylinder reactor.

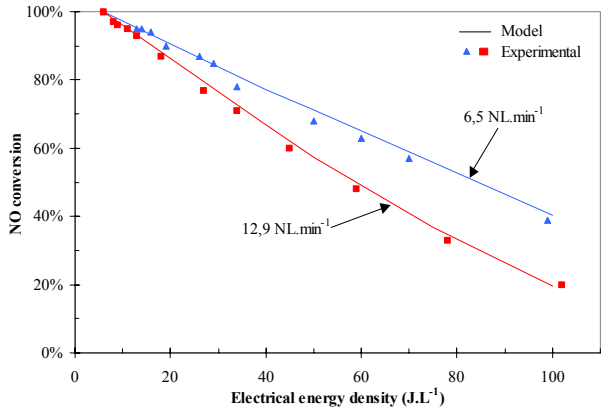

Fig. 7 NO conversion vs. electrical energy density for different inlet flow.

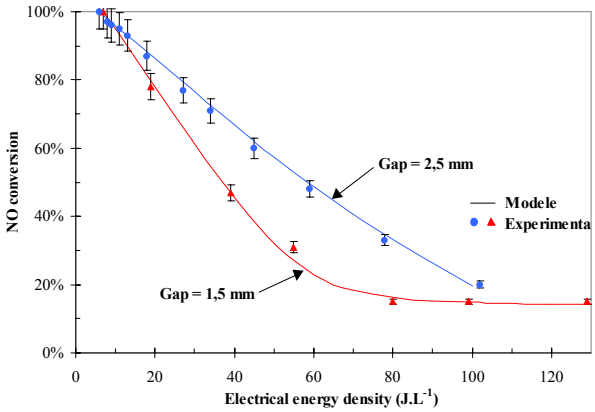

Fig. 8 NO conversion vs. electrical energy density for different electrical gap.

4. Conclusion

In this work, the behaviour of a wire-cylinder DBD reactor was simulated. The validation of mathematical model permits to understand the role of reactor characteristics and operative electrical parameters on the formation of the atomic oxygen. This one been the main responsible of chemical mixture reactivity.

Impulse characteristic of electrical discharge and effects the electrical wind on the reactor streamline suggested a dynamic macroscopic model based on a cascade of 35 elementary stirred reactors. A discrete atomic oxygen flow is introduced in every elementary reactor to represent the formation of active species by the electrical discharge.

The model has been tested on a kinetic pathway representing the processes of formation and destruction and of the atomic oxygen and the oxidation of the NO molecule. The knowledge of reaction pathway, acquired

by O^{18} isotopic analysis, permitted us to propose a simplified model of three reactions. The physico-chemical characteristics of reactions in non-thermal plasma (transport phenomena, excitation levels, thermal gradients…) have been taken implicitly into account in the model by the use of apparent model constants (k_i). However, the role of water was not introduced and that forbidden the approach of mass balances to nitrous and nitric acids.

In order to simulate the DBD wire-cylinder reactor, Mathematical model considers physical (elementary reactor volume, inlet stream composition, inlet flow…) and electrical characteristics (injected atomic oxygen flow in every elementary reactor according to the electrical density of energy, the electrical gap, the electrical duty…). Model results are in good agreement with experimental ones. Actually, maximum absolute error can be estimated to 5% and for almost 95% of experimental data, model error is lower than experimental standard deviation. Some interesting results can be obtained from these simulations, like delay to the establishment of a pseudo-steady state (10 ms), length of the reactor performance (maximum NO_x conversion) and evolution of concentration of main species (NO, NO_2 and O°). This model permits has understanding of complex phenomena present in tea reactor and open interesting ways in design and extrapolation of DBD reactors applied to pollution solutions.

Selective deposition of fluorocarbon films on Al versus SiO_2 surfaces in high density plasmas

A. Tserepi, P. Bayiati, E. Gogolides, K. Misiakos

Institute of Microelectronics-NCSR "Demokritos", POB 60228, 153 10 Aghia Paraskevi, Attiki, Greece

Abstract

Plasma-deposited fluorocarbon coatings have found a variety of applications, as they modify the surface properties of the materials on which they are deposited. The present work focuses on the selective deposition of fluorocarbon (FC) films on metal surfaces, and more specifically on aluminum, versus SiO_2 surfaces, in order to obtain surfaces of distinctly different wettability. The process selectivity was optimized through proper selection of the deposition conditions, mainly gas mixture composition and deposition time, and was quantified by means of contact angle measurements on Al and SiO_2 surfaces.

1. Introduction

Plasma-induced formation and deposition of polymer films on surfaces is an important issue in etching plasmas; for example, it allows selective etching of a SiO_2 layer over a Si or Si_3N_4 underlayer, while it provides side wall passivation necessary for anisotropic high-aspect ratio Si etching. In fact, the majority of the current research effort relative to fluorocarbon etching plasmas invests in understanding plasma-surface interactions in order to improve etching performance mainly for selective SiO_2 over Si etching or for high aspect-ratio Si etching [1-3]. In both of the aforementioned processes, deposition of FC layers of appropriate thickness and chemical composition is of vital importance to the etch selectivity. In particular, a general trend is observed, that is the thickness of the FC film present on a surface is inversely proportional to the etch rate of the substrate material [2-5]. This has been demonstrated and used for explaining the SiO_2-to-Si and SiO_2-to-Si_3N_4 selective etching. However, analogous studies concerning selective deposition on other materials such as metals and consequent modification of their surface properties are rare in the literature.

The present work focuses on the selective deposition of fluorocarbon (FC) films on metal surfaces, specifically on aluminum, over SiO_2 surfaces, in order to obtain surfaces of distinctly different wettability. Since polymer layers on surfaces are easily formed in fluorocarbon discharges with high concentrations of radical CF_x species, fluorocarbon gases such as C_4F_8 and mixtures of CHF_3/CH_4 were used in our experiments, in high density plasmas known for their overwhelming polymerization ability. For the selection of conditions appropriate for selective deposition of FC films on Al over SiO_2, plasma parameters such as plasma power, bias voltage, electrode temperature, gas pressure and composition were varied, while etch rates of SiO_2 were measured in-situ by laser interferometry. We find that conditions which provide highly selective etching of SiO_2 over resist materials are also appropriate for selective deposition of FC films on Al surfaces. The modified wettability of SiO_2 and Al surfaces exposed to FC plasmas is characterized by contact angle measurements, which are used to demonstrate the selectivity of the deposition process. If, finally, the obtained wettability of the plasma-modified metal surface can be electrostatically switched from a hydrophobic to a hydrophilic state, such FC films preferentially deposited on metal (Al) surfaces can be employed for fluid transport in microfluidic devices (with Al pads patterned along a channel built on a SiO_2 substrate) [6].

2. Experimental

The high-density plasma reactor used in this work is an Alcatel (MET, Micromachining Etch Tool) Inductively Coupled Plasma etcher, consisted of a load-lock and an ultra-high vacuum (10^{-6} mbar) main chamber. A one-loop ring-shaped antenna is supplied by a 0-2000 W rf (13.56 MHz) source, and it generates the plasma through a 150-mm in diameter cylindrical alumina dome. The plasma diffuses from the

generation area in the process chamber, where samples are introduced for processing, loaded on an anodized aluminum holder (100 mm in diameter) mechanically clamped on a chuck. The chuck is located at a distance of 20 cm downstream from the ICP source and allows the sample to be biased and cooled during processing. The sample can be biased independently from the plasma source with a 300 W maximum rf (13.56 MHz) source. Biasing the processing electrode enables to control the ion energy independently from the production of the plasma. A helium pressure of 12 mbar is applied on the backside of the sample holder to provide good thermal conduction between the sample and the chuck. The temperature of the chuck is controlled by circulation of liquid nitrogen and simultaneous heat supply through six heaters, in order to achieve temperature regulation at a desired set point. Good thermal contact between the sample holder and the sample is achieved by means of a thermal paste. The electrode temperature is fixed at values between 0 and –50 ºC in this study.

For this study, the fluorocarbon gases C_4F_8 and mixtures of CHF_3/CH_4 are used, while the substrates to be processed are SiO_2, Al, and AZ 5214 commercial photo-resist. During plasma processing with the above gases, deposition occurs on the reactor walls. Therefore, before each experiment, the processing chamber is thoroughly cleaned using a O_2 or O_2/SF_6 plasma to remove fluorocarbon films from surfaces previously exposed to polymerizing plasmas. After the cleaning, the reactor is reconditioned under the process conditions for 2 min. Plasma parameters, such as the gas pressure and composition, the electrode temperature, the process time, the rf plasma power and bias voltage, are varied. In some experiments, a pretreatment of the sample surfaces prior to deposition is also carried out using Ar and O_2 and its effect on the wetting properties of the surfaces before and after deposition is investigated. The etching or deposition rates on SiO_2, Al, and resist surfaces are measured in real-time by means of in-situ laser (650 nm) interferometry.

The wettability of the treated samples is characterized by contact angle measurements using a GBX Digidrop system. The system allows automatic loading of single droplets on the surfaces under investigation and measurements of *static* contact angles are performed through observation of the droplet (and its reflection) at nearly right angles with respect to the sample surface. For static contact angle measurements in this work, 4μl droplets of de-ionized water are placed on the treated surface. The same system allows also measurement of the contact angle in the *dynamic* mode, where a droplet of increasing or decreasing volume is loaded on the surface, during which process the advancing and receding contact angles as well as the contact angle hysterisis are measured. If a voltage difference is applied between the droplet (through the droplet-depositing syringe) and the substrate, the modification of the contact angles in the presence of an electric field (electrowetting) can be observed.

3. Results and Discussion

3.1. Etching and deposition in C_4F_8 plasmas

3.1.1 Effect of electrode temperature

Numerous investigations of the SiO_2 etching mechanism in high density etching tools have shown that the SiO_2 etching rate can be quite different depending on the bias voltage developed during the etching process [4, 5]. In specific, as the bias voltage increases, the fluorocarbon film deposition regime is followed by the fluorocarbon suppression regime and finally by the oxide sputtering regime, since deposition and etching have different dependencies on the energy of the ions bombarding the surface. In our work, we used the electrode temperature as the tuning parameter which could induce the transition from etching to deposition, as the temperature determines the rate of desorption of products from surfaces, and thus determines the balance between etching and deposition, when the other plasma parameters are fixed. We conducted experiments in C_4F_8 plasmas, at substrate temperatures from 0 down to -50^{o}C. These experiments demonstrated that, on all of the tested surfaces, etching is followed by deposition that occurs at a rate inversely proportional to temperature. The interferometric signals shown in Fig. 1 correspond to a constantly changing top layer thickness on a resist film, as a function of the electrode temperature. In detail, the sinusoidal signals corresponding at T=15 and –20 ºC indicate etching of the resist film up to an end-point, whereas the sinusoidal signal corresponding at T=-50ºC indicates a fluorocarbon film being continuously deposited on the resist surface. Etching and deposition rates determined from such interferograms are shown

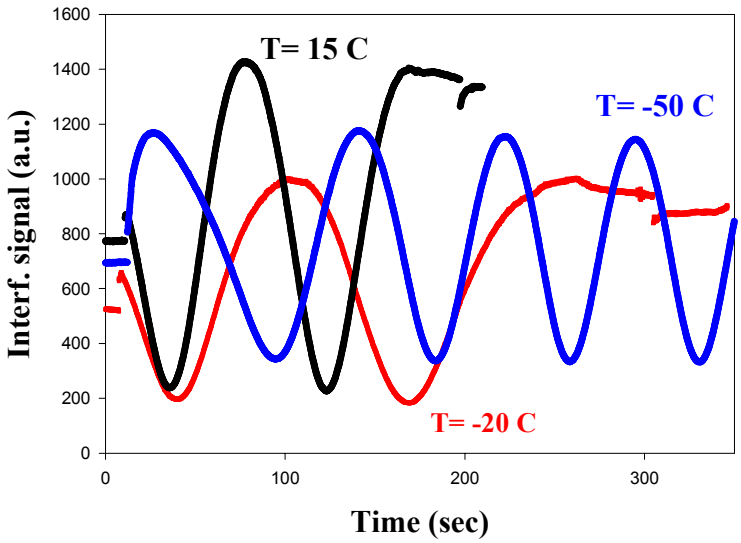

Fig. 1. Interferometric signals from a resist surface (AZ5214) exposed to a C_4F_8 high density plasma, at different electrode temperatures. Two of the signals (T=15 ºC and –20 ºC) indicate etching, while the signal at T=-50ºC indicates deposition of FC film.

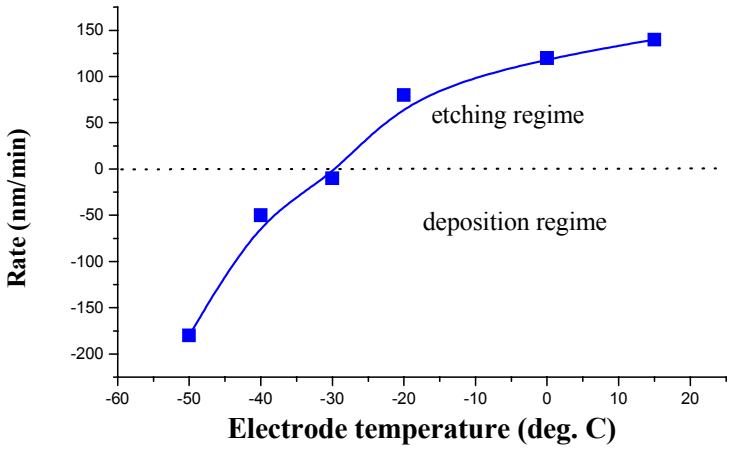

Fig. 2. Etching and deposition rates of a resist (AZ5214) surface exposed to a C_4F_8 high density plasma as a function of the electrode temperature.

in Fig. 2 for a resist material as a function of electrode temperature, indicating the transition from etching to deposition as the temperature decreases.

Similar experiments performed on a SiO_2 film indicated that etching of SiO_2 takes place at lower temperatures (e.g. at -40 °C) compared to that of a resist layer. This is attributed to the fact that a SiO_2 surface consumes more CF_x radicals than a resist surface, thus there are fewer species available for deposition on a SiO_2 surface. Therefore, etching dominates deposition in the case of a SiO_2 surface at temperatures at which deposition takes place on a resist surface. For aluminum surfaces, deposition rates of FC films can be estimated from similar interferograms, and are shown on Table I together with deposition rates on a resist surface. Deposition rates are found to increase as temperature decreases, as shown previously in Fig. 1, and are higher on aluminum than on resist surfaces (see Table I). The latter indicates that conditions that provide selective etching of SiO_2 to resist are also appropriate for FC deposition preferentially on aluminum compared to SiO_2. For example, exposure of surfaces to a C_4F_8 plasma at -40 °C leads to etching of a SiO_2 surface (E.R.= 230 nm/min), deposition on a resist surface (deposition rate= 50

nm/min), and even higher deposition on an Al surface (D.R. =130 nm/min). Therefore, this temperature is appropriate for selective deposition on Al versus SiO_2 surfaces. Furthermore, the selectivity of SiO_2/resist etching can be used as a guide to the selection of appropriate conditions for selective deposition on Al to SiO_2 surfaces. However, contact angle measurements on Al and SiO_2 surfaces exposed to such conditions (-40 C, 1500W, 10 mTorr, -250 V_{bias}) for 1 min or more showed a small difference (smaller than 10°) in the surface hydrophobicity. Therefore, a wider space of plasma conditions was searched for better results.

Table I. Deposition rates of FC films on Al and photo-resist surfaces in C_4F_8 plasmas

Deposition rate (nm/min)		Temperature (ºC)
Al metal	AZ 5214 resist	
90	10	-30
130	50	-40
200	180	-50

To achieve highly selective Al/SiO_2 deposition, various plasma conditions were investigated. The C_4F_8 pressure was varied in the range 1-5 mTorr, the rf power was varied from 1000 to 1800 Watt, the bias voltage from –100 Volts to -150 Volts, and the electrode temperature range from -20 ^oC to 15 ^oC. For the conditions investigated, the selectivity increased with the power, while it decreased with the temperature and the pressure. An experiment which was conducted under the best conditions (1 mTorr, 1800 W, -100V, -20 ^oC) gave a SiO_2/resist selectivity of 2.4. Aluminum and SiO_2 surfaces exposed to such plasma conditions during 1 min exhibited a drastic change of the wetting properties; the contact angle on a treated SiO_2 surface increased to 78º, while that of Al surface increased to 85º. Thus, Al exceeded SiO_2 in hydrophobicity, however at a low degree, presumably due to the fact that deposition of even a thin FC film on the SiO_2 surface is sufficient to cause significant modification of the wetting properties of the SiO_2 surface. The measured difference in contact angle between Al and SiO_2 modified in C_4F_8 plasmas was not big enough to allow exploitation of this difference for fluid control in microfluidic devices based on the electrowetting effect.

3.1.2 Effect of surface pretreatment in non-polymerizing plasmas

In an effort to enhance the selectivity in the Al/SiO_2 deposition, a second set of experiments was designed to elucidate the role of the surface condition prior to the FC deposition. The Al and SiO_2 surfaces were pretreated in O_2 and Ar plasmas for a short time (15 s). The effect of pretreatment on the final contact angles is shown in Fig. 3. For pretreatment with a high bias voltage applied to the electrode, the Al surface

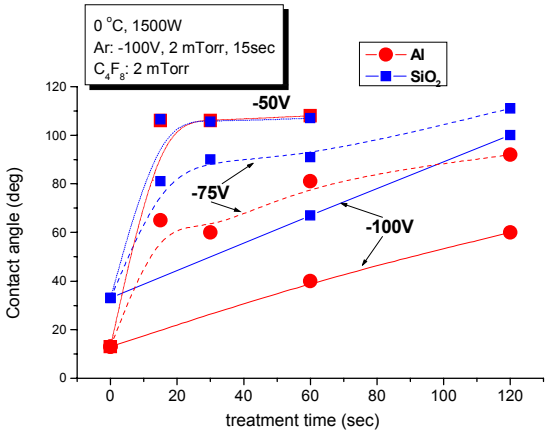

Fig.3a. Water contact angle as a function of treatment time in C_4F_8 after a pretreatment in Ar (15 s, bias voltage –100 V) for various values of the treatment bias voltage.

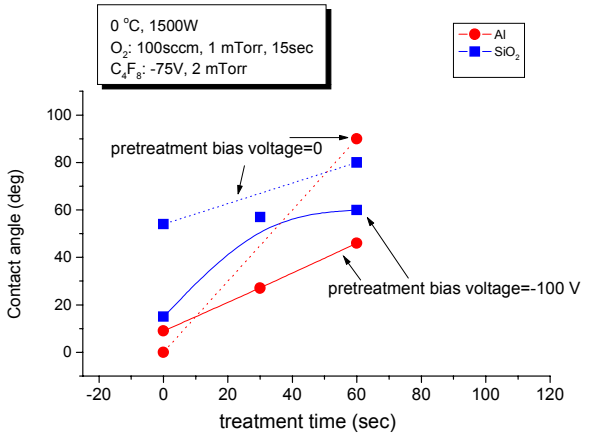

Fig.3b. Water contact angle as a function of treatment time in C_4F_8 after a pretreatment in O_2 (15 s) for different values of the pretreatment bias voltage

remains always more hydrophilic than the SiO_2 surface for treatment times as long as 60 s, in contrast to the previously presented results in the absence of surface pretreatment. Only in the case that the pretreatment is carried out at zero bias voltage, the Al surface becomes more hydrophobic (10º difference in contact angle) after a 60 s treatment in C_4F_8 plasmas (Fig. 3b).

The observed behavior can be explained by the fact that application of a high bias voltage in the pretreatment contributes to the reduction of the oxidized layer on Al. As a result, a clean Al surface characterized by a high sputtering yield is obtained, and thus during subsequent exposure in polymerizing plasmas, sputtering dominates deposition on this surface. Consequently, a surface less hydrophobic than that without the pretreatment is obtained. On the contrary, for the pretreatment without bias, the Al surface retains its surface oxide, a fact that allows after C_4F_8 treatment (60 s) a final surface more hydrophobic than a SiO_2 surface exposed to the same treatment. Certainly, the surface wetting properties should be evaluated for different treatment times, in order to achieve enhanced selectivity.

3.2. CHF_3/CH_4 etching and deposition experiments

In these series of experiments, we used mixtures of CHF_3/CH_4 in various proportions of the two gases. All the measurements of etch rates and selectivity were carried out at a total pressure of 3 mTorr, plasma rf power 1500 W, bias voltage –150 V and at low temperatures (0 and –20 °C). As shown in Figure 4, the selectivity increases as the mixture becomes richer in CH_4, and it reaches a value of about 5 and 7 at 0 °C and –20 °C, respectively. When the content of CH_4 in the gas mixture is higher than 21%, selective deposition of a fluorocarbon film is observed on the resist (AZ5214), whereas the silicon oxide is still etched. We argue that around this CH_4 percentage FC films would be deposited preferentially on Al to SiO_2 surfaces.

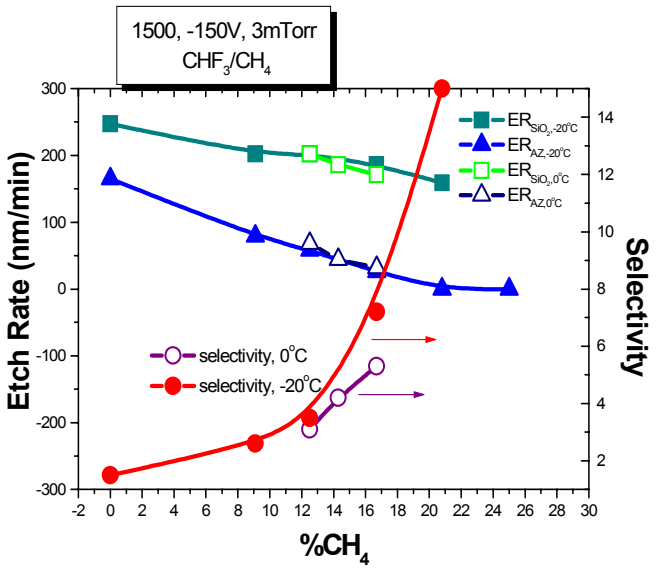

Fig. 4. SiO_2 and resist etch rates and the selectivity as a function of the CH_4 percentage in a CHF_3/CH_4 high density plasma.

Surfaces of silicon dioxide and aluminum were exposed to a plasma containing 79% CHF_3 and 21%CH_4, under the conditions that gave the best selectivity (Pressure=3 mTorr, P=1500 W, V_{bias}=-150 V, T=-20 °C). The plasma exposure time was varied between a few seconds to a few minutes. Subsequently, we determined the water contact angle to verify the hydrophobic character of the treated surfaces. As shown in Figure 5, both substrates exhibit surface modification and indeed a hydrophobic behavior even after a few seconds exposure to CHF_3/CH_4 plasmas. In fact, surfaces become hydrophobic within 15 sec of plasma exposure. However, there is a difference in contact angle between the two surfaces, with a highest value of about 10 degrees for 30-45 sec of plasma exposure time. As shown in the figure, after 1 min of plasma exposure both surfaces exhibit the same contact angle. This result is surprising since, under the conditions used in these experiments, etching occurs on SiO_2 surfaces. However, studies in the literature [2, 3, 5] have

shown that a (thin) fluorocarbon film is deposited even on etched SiO_2 surfaces, through which etching proceeds, in high density plasmas (this is often called "the fluorocarbon suppression regime"). If the deposited layer grows thicker than a certain value, the modified SiO_2 surface properties become indistinguishable from those of the modified Al surface. Therefore, in order to achieve good selectivity for deposition between SiO_2 and Al surfaces, we should restrict the plasma exposure time for the surfaces to 30-45 sec.

Figure 6 shows how the contact angle changes with the content of CH_4 in the gas mixture, for 45 sec of deposition time (Pressure=3 mTorr, P=1500 W, V_{bias}=-150 V, T=0 ^oC). For a 27% CH_4 in the mixture, the difference in contact angles of Al and SiO_2 is as high as 30 degrees. This difference seems satisfactory for allowing fluid control through electrowetting, exploitable in microfluidic devices.

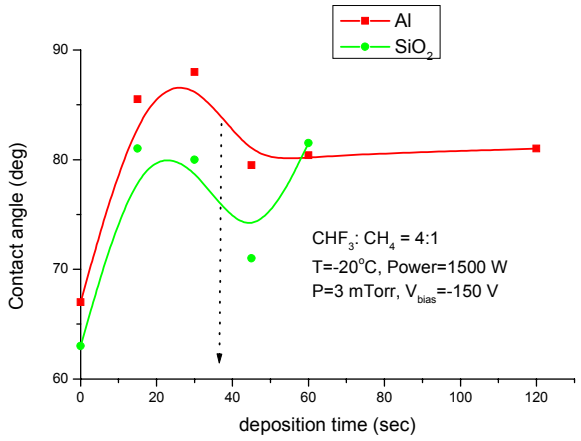

Fig.5. Evolution of the SiO_2 and Al surface properties with treatment time in a CHF_3/CH_4 (4:1) plasma.

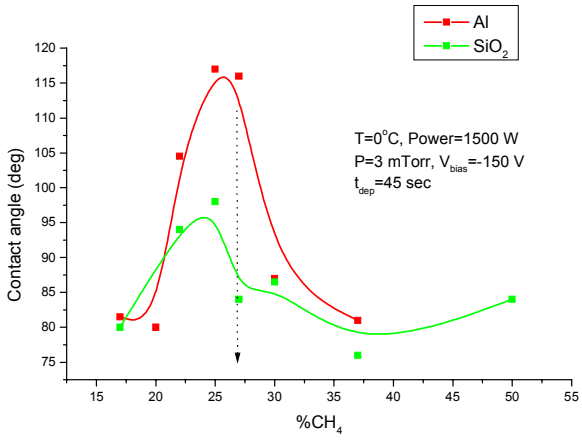

Fig. 6. Dependence of the Al and SiO_2 contact angle of water on the CH_4 percentage in the CHF_3/CH_4 plasma.

4. Conclusions

Differential hydrophobicity of Al and SiO_2 surfaces was achieved through preferential deposition of FC film on these surfaces, by means of C_4F_8 and CHF_3/CH_4 high density plasmas. Conditions ensuring high SiO_2/resist selectivity were found to be appropriate for selective deposition of FC films on Al versus SiO_2. However, a (thin) fluorocarbon film is also deposited on SiO_2 surfaces even at conditions where SiO_2 is etched, thus limiting the selectivity. Therefore, the treatment time must be short enough (30-40 s) such that the SiO_2 surface stays less hydrophobic than an Al surface. The best results are obtained so far in CHF_3/CH_4. The condition of the surface prior to deposition is found to be essential to the outcome of the treatment.

Future work includes measurements of the FC film thickness on SiO_2 and Al surfaces as a function of the treatment time as well as of the gas composition. In addition, the chemical composition of the deposited films will be studied in order to gain more understanding and possibly to further improve the differentiation between Al and SiO_2 surfaces with respect to their wetting properties.

Nozzle shape and plasma jet generated by a cutting plasma torch

A. Rodríguez-Yunta, C. Pardo, J. González-Aguilar and M.A.G. Calderón

Department of Applied. Physics. University of Cantabria. Santander. Spain

Plasma arc cutting is a process of metal cutting by a plasma jet, that it is widely used because of its high productivity and ability to cut practically all metals. In order for the plasma jet to provide a fast and high quality cut, a narrow supersonic plasma jet must be generated, with a high energy density to be able of a fast melting of the work-piece material. Also the force exerted on work-piece by the plasma jet must be high enough to remove the molten material quickly to avoid dross formation. This is made possible by a special nozzle, through wich the plasma is blown out of the torch. The nozzle creates a narrow highly concentrated plasma flow and also provides the high velocity of the plasma jet. By the other side the nozzle is one of the most vulnerable parts of the torch due to its exposure to extremely high heat fluxes.

In this work we use a theoretical model to study the effect of the nozzle shape on the plasma jet properties. The model is based on a set of one fluid conservative equations for mass density, momentum and energy taking into account compressible effects of the working gas under the usual simplifications of local thermodynamic equilibrium (LTE) and axial symmetry, but with the three momentum components. This kind of models had shown to be in good agreement with experimental data [1,2]. So, the model allows us to study the details of the flow and to make predictions on arc voltage, heat transfer to the workpiece, force and pressure exerted by the plasma jet on the material at the cutting zone.

This numerical model is applied to a conventional air plasma cutting torch with different nozzle orifice shapes. The obtained results show different torch performances for the same minimum diameter, current and total gas mass flow. A comparison of the plasma jet properties, as energy and momentum flows, wideness and double arcing risk, is given for several nozzle shapes.

Analysis of Optical Emission Spectroscopy from arcs for plasma vitrification of hazardous wastes

A. Rodríguez-Yunta, C. Pardo, R. García Sánchez and M.A.G. Calderón

Department of Applied. Physics. University of Cantabria. Santander. Spain

Plasma vitrification has been demonstrated as a safe, eficient, cost-efective technology for the treatment of wastes, including hazardous wastes. In this process, a problem is the volatilisation of some elements, as heavy metals or radioactive isotopes, which escape from the final vitrified product, generating secondary ashes that need to be treated again. There is currently significant interest in the development of a real-time monitoring technology for radioactive or trace metals pollution in the stack exhaust of high temperature processes such as those used for waste remediation, power production, and manufacturing.

A promising approach for achieving a practical on-line monitoring, is the atomic emission spectroscopy of the atmospheric pressure plasma generated in the furnace. The optical radiation emited by the plasma from which the metals are identified and quantified, can improve the understanding of the plasma parameters. Measurements are needed of electron temperature, electron density, neutral gas temperature, spatial profiles of these parameters, and their relationship to trace metals atomic emission strengths. Questions of the degree of thermal equilibrium in the plasma need to be answered, as well as plasma conductivity, and the effect of gas composition and particle loading. Spectroscopic measurements of the optical plasma radiation can provide much of the information that is needed.

In this work emission spectra in the range 350-1100 nm were recorded during the vitrification of waste with a system of twin plasma torches operated at an average power of 30 kW. The obtained spectra are rich in atomic lines and diatomic molecular bands superimposed on a blackbody continuum. The detailed properties of the spectra show a strong dependence with the operating conditions and with the feeding of waste and vitrifying agents.

The species concentrations in the plasma were obtained by comparison of the experimental spectra with synthetic ones generated by computer. A complete model based on Saha–Boltzmann and molecular dissociation equilibrium relationships, is used to calculate the plasma properties, as the emission and self-absorption of light. After a normalization of the experimental and theoretical results we are able to obtain data on Temperatures and element concentrations from a set of selected line-to-line and line-to-continua ratios

Using this results, spectroscopy diagnosis could be very useful to have a control on-line of the process. The spectroscopic observation of the intense light emitted by the plasma column can be used to estimate on line the chemical element ratios in the reactor atmosphere. Furthermore, the spectroscopy measurements also provide estimations for the plasma and melted material temperatures. These data can be used to control and study the vaporisation of selected hazardous elements.

Excitation Mechanism of High-Frequency Instability in Anode Layer of Plasmatron

A. Smakhtin, V. Rybakov

Department of Space Electrical Engines and Power Plants, Moscow Aviation Institute (State Technical University), Moscow, Russia

A plasma source for solving different plasma chemistry problems that has enjoyed the widest application is a plasmatron. The reason is that the plasmatron, using the arc discharge in a number of working gases and vapours, has high efficiency and ling-term reliability.

However, variety of instabilities of the plasmatron operating mode set limit on its technical parameters. Each type of these instabilities, distinguished by the inherent frequency and intensity of electromagnetic oscillations, has its own the excitation mechanism.

The excitation mechanism of electromagnetic high-frequency instability considered in this paper is due to the formation of the solid negative electrical charge inside the anode layer of the plasma arc. The kindred instability is exhibited by an experimental approach in different technical systems using the plasma arc. For example, under appropriate conditions this type of instability is in the magnetic plasma dynamic (MPD) thruster. This process is called as the limiting operating conditions of the MPD thruster.

As known there is a double electrical layer near the arc anode where electro-neutralization of the plasma is broken. The thickness of this layer is equal to near the Debye's length. This fact allows to consider the anode layer of the plasma arc as an ordinary vacuum-diode. In this case a quasi-neutral plasma column is defined as the cathode. Hereafter we shall use the term "anode current" to mean "discharge current" as it is conventional to call in literature about the vacuum-diode.

The calculating method of the electronic emission from the plasma column volume takes into account both the temperature radial distribution of the plasma column and the Maxwell's electronic speed distribution in each point of plasma volume. The emission current, issuing from each point of plasma cathode, involves electrons with a collision mean free path is longer than a distance from this point to the anode. In other words, the emission or cathode current involves electrons from Maxwell's "tail" only.

The calculation shows that the electronic emission current from the plasma column increases with increasing of the anode current. The pace of emission increasing is more rapid than the same parameter of the anode current. The emission current becomes more the anode current starting with some value. This operating mode of the vacuum-diode is called as a virtual cathode. When the emission current is higher than the current corresponding to Child-Langmuir law the solid negative charge emerges in the anode layer. In this case there is a potential well between the plasma column and the anode of the plasma arc. As it is in the vacuum-diode this electrical potential distribution is not stable and this mode of plasma arc operation is accompanied by electromagnetic high frequency instability of plasma arc.

The analysis of this excitation problems shows that the situation when the emission current is greater than the anode current reveals itself more effective with decreasing of the plasma column density. This fact has been confirmed experimentally by different scientific teams.

Characterisation of a Double Inductively Coupled Plasma Reactor

P. Messerer[1], B. Boenigk[1], P. Awakowicz[1],

[1] *Institute for Physics of Electrotechnology, Munich University of Technology, Munich, Germany*

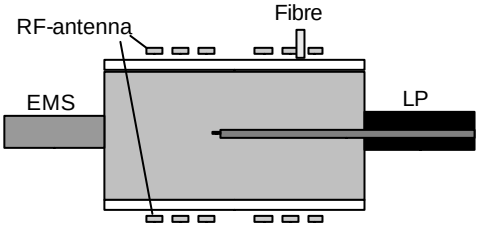
Abstract
Due to the need in medical technology for dry sterilisation processes with non toxic agents, a low pressure radio frequency driven plasma reactor was developed. In order to implement a radially and axially homogenous sterilisation plasma, the concept of the inductively coupled plasma (ICP) was transfered into a double ICP (DICP) with two rf antennas, one on top the other on bottom. In order to characterize the DICP plasma under various conditions and to correlate plasma parameters to sterilisation efficiency, investigations with a Langmuir probe system, optical emission spectroscopy (OES) and a energy mass spectrometer (EMS) were completed with a coupled hydrodynamic-electrodynamic simulations of this plasma.

1. Introduction

In contrast to the needs of the semiconductor industry for a two dimensional homogeneous plasma process, plasma sterilisation has to deal with three dimensional medical items like implants, syringes or surgical instruments. Sterilisation is defined as a reduction of spores by a factor of 10^6. Since it is known that a combination of uv light and reactive radicals are necessary for fast sterilisation processes, a double inductive coupled plasma reactor has been developed which combines a reasonable homogenous plasma in voluminous vessels with high uv intensity caused by a high electron density. Additional to sterilisation, the functionality of medical items has not to be influenced, especially the ability to treat the objects without harming the materials while fulfilling the high demands of medicine to inactivate germs and spores by a factor of one million. In some occasions a modification of the material is desirable. As an example artificial joints are made of ultra high weight polyethylene (UHMWPE). This material is exposed to wear of friction. Therefore a hardening of the surface would improve the quality. Experiments with gel analysis show that between 2% and 6% of the material show cross linking which hardens the surface, whereas after sterilising with electron beams a cross linking of about 50% can be observed. This would make the whole material brittle. Another important material is polylactide. This material is used for dissolvable screws, nails etc. in fracture treatment and must not be altered to guarantee a constant rate of dissolution. First tests have shown that polylactide screws could be sterilised without any modification of the properties.
As a second step it was interesting to find the reactions, which are responsible for sterilisation process. Therefore the plasma parameters had to be evaluated and correlated to the results of many sterilisation experiments under various conditions. The Langmuir probe was used to measure the radial profiles of electron density and mean electron energy. The energy mass spectrometer was applied to investigate the flux of the heavy particles towards the wall. The optical emission spectroscopy (OES), as a non intrusive measurement system, was used to find the gas temperature and the amount of uv radiation inside the plasma chamber.

2. Set-up of the reactor

The DICP is a improvement of the known concept of the ICP. The chamber has a diameter of 40 cm and a height of 20cm. The power is generated by a 13,54 MHz rf-generator with an adjustable power between 0 W and 5 kW. The rf coil at the bottom of the chamber complements the rf coil on top. In this way a more even distribution of the power input can be reached. A sketch of the set-up can be seen in fig. 1. The typical pressure range is from 5 Pa to 20 Pa for sterilisation experiments. The diagnostic consists of a Langmuir probe at the side wall, a fibre optic to focus the emissions to a 1/2m spectrometer



EMS: Energy-mass-spectrometer (ions + neutrals)
LP : Langmuir probe (electron density, mean electron energy and potentials)
Fibre: Optical wave guide + spectrometer+intens. CCD (gas temperature,UV-light)

Figure 1. Set-up of the DICP

connected to an intensified camera and an energy mass spectrometer almost opposite to the Langmuir probe with an optical resolution of 0.04 nm.
The EMS is operated in neutral and ion detection mode in order to collect the number density of the neutrals and the ion fluxes at the wall. Of special interest are the ions since they gain energy in the plasma sheath and the reactive radicals because of their high reactivity. While the ions are easily detectable, the measurement of the radicals poses some difficulties. Here, the method of ionisation threshold mass spectrometry (ITMS) [3] was used.
The OES was used to measure the spectra in the uv range from 180 nm to 400 nm. It is known from literature that the range below 250 nm is most effective [4] for sterilisation purposes. In addition, the shape of some rotational bands of nitrogen were recorded, allowing to evaluate the rotational temperature of the heavy particles which may be identified with the gas temperature under special circumstances.
With the Langmuir probe it is possible to retrieve spatial distributions of the following plasma parameters: the mean electron energy, the electron, the floating and the plasma potential.

3. Langmuir probe

Plasma modelling reveals that the density along the z-axis is by far more homogeneous with both coils. To strengthen this result, radially resolved measurements have been performed. The spatial distribution of the electron density at three rf power values can be seen in figure 2. A constant value of the electron density

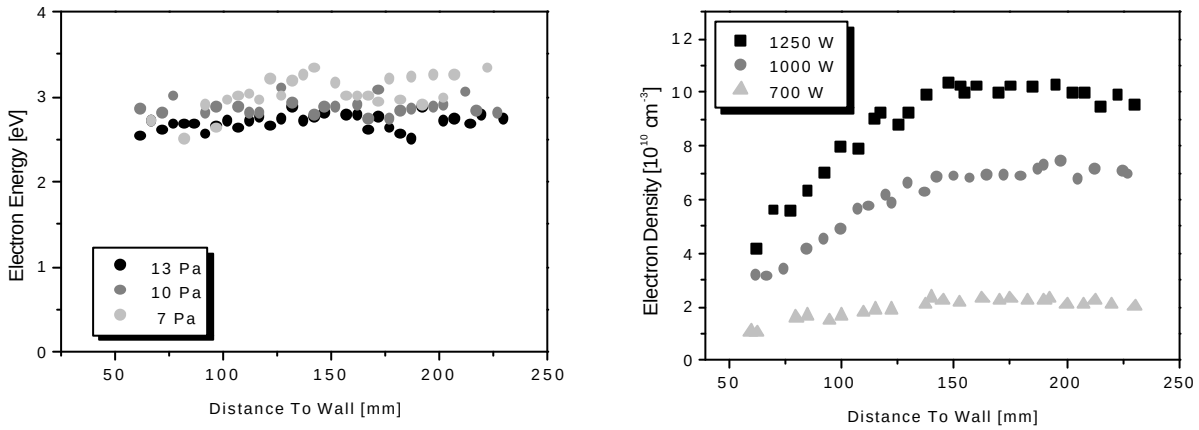


Figure 2: Mean electron energy (left) and electron density (right)

reaches up to a radius of 10 cm, which is half of the radius of the chamber. Sterilisation experiments show a much wider area, almost up to the chamber wall, of constant sterilisation efficiency. This is due to the strong dependency of the UV radiation on the electron energy, given in fig. 2. The mean electron energy remains, in contrast to the electron density, constant almost up to the chamber wall.

4. Optical emission spectrometry

One of the most important factors in the treatment of medical materials is the temperature of the heavy particles. Most of the materials, like polylactide and UHMWPE, will change their properties when the temperature exceeds even low limits of about 70 °C. In order to adjust the rf power input the gas temperature was measured. By adding a small amount of nitrogen and by evaluating the v'=0 – v''=2 rotational band of the second positive system of nitrogen, the shape of the band was compared to calculated profiles, which are very sensitive to the gas temperature [2]. Because of redistribution of the exited levels of the molecular nitrogen, this

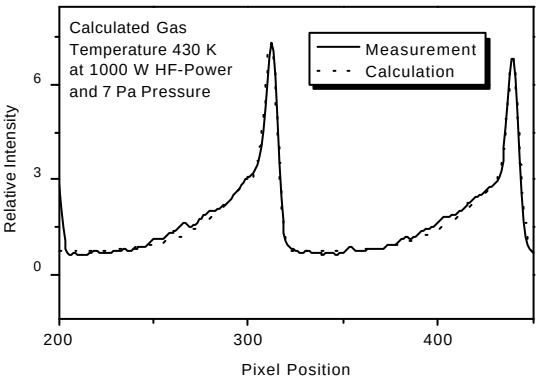

Figure 3: Estimation of the gas temperature

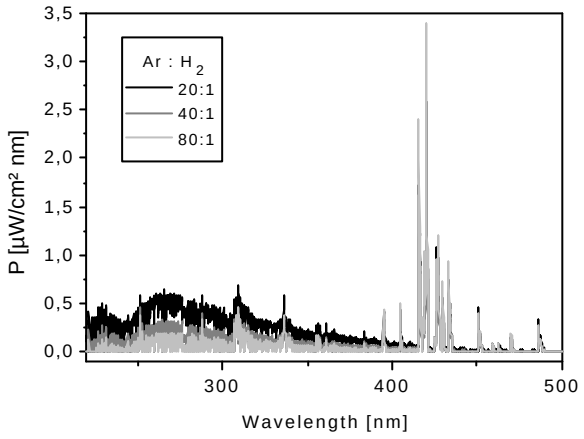

Figure 4: UV radiation in a hydrogen argon plasma

method will only give an upper limit of the gas temperature in mixtures of nitrogen and argon. The temperatures found for the used sterilisation plasmas were below the limit of 430K (fig. 3).
Due to heavy particle collisions of Ar and N_2, the profile of the N_2 rotational band is altered and the temperature derived from this procedure is overestimated. Therefore the real gas temperature seems to be even lower.

The uv radiation is responsible for the fast sterilisation of the materials. Results from such measurements show some amount of uv light in the range below 250 nm, which proved to be the main part of the sterilisation process (fig. 4). The DNA of most bacteria, like B. subtilis, can be broken by high energy radiation. The threshold of the wavelength is at 250 nm, below which sterilisation is good. An exception is A. niger with its black outer layer which protects the DNA from the uv light. This spore can be inactivated with light quanta with even higher energy.

5. Energy mass spectrometry

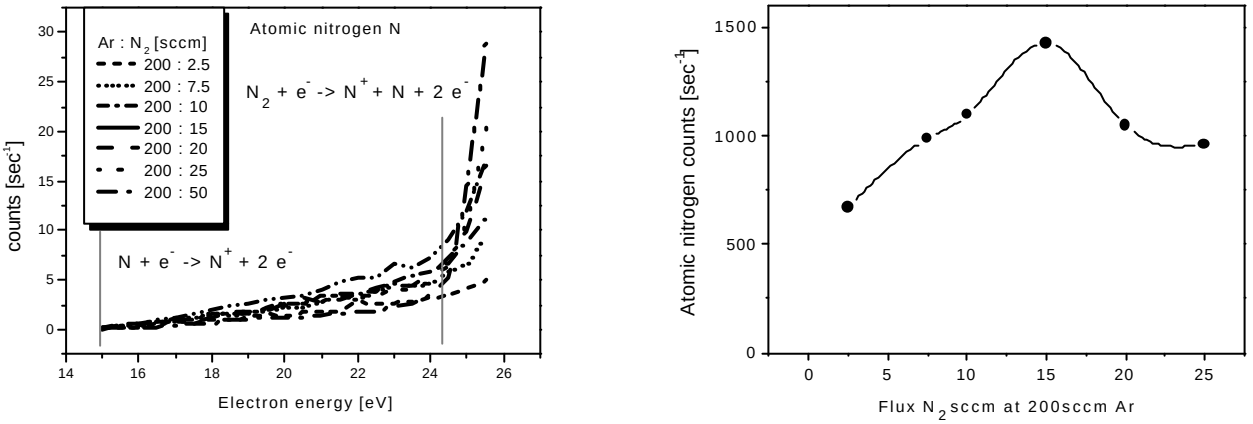

Figure 5: Atomic nitrogen at different concentrations of nitrogen in argon

The EQP 500 (Hiden Technologies) was used for ionisation threshold mass spectrometry (ITMS). The EQP 500 can detect neutral particles. To do that these particles have to be ionised. This is done with two filaments right after the orifice of the instrument. An electron beam with an adjustable energy is directed towards the incoming particles. Due to the interactions with these electrons, the heavy particles are ionised. By varying the energy of the electron beam inside the EQP, used to ionise the radicals inside the instrument, it is possible to detect radicals. It is necessary to adjust the ionising electron beam current inside the EMS in order to gain a detectable signal and to minimise the dissociation of the

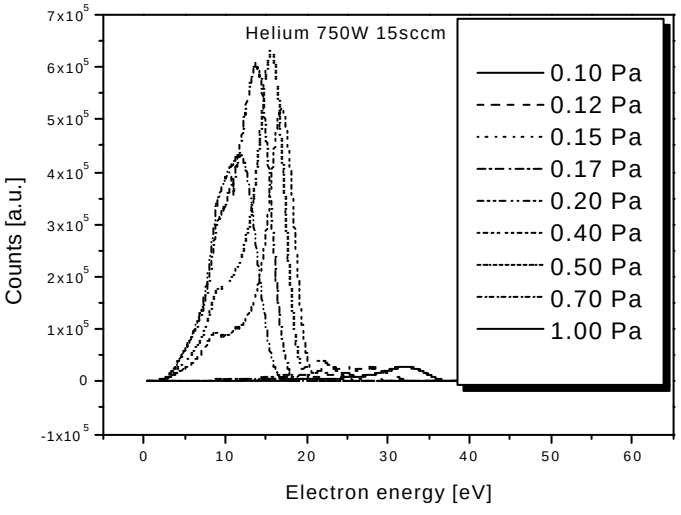

Figure 6: Ion energy of helium at various pressures

radicals (fig. 5). Nitrogen radicals interacting with electrons of an energy less than 14.5 eV are not ionised while electrons with an energy above 24.3 eV can dissociate molecular nitrogen. Nitrogen dissociated inside the EQP 500 would erroneously be counted as radicals. The measurements with different mixtures of nitrogen and argon revealed that the maximum of the flux of radicals to the wall coincides well with a maximum of sterilisation efficiency. This does not state that the radicals are responsible for the sterilisation of the objects but it is a hint that the parameters for a good sterilisation are the same as the parameters which are advantageous for the production of atomic nitrogen in an argon nitrogen plasma.

With respect to sterilisation, another important species are the ions, because they transport kinetic energy of to the substrate. Therefore a first assumption about the sterilisation process was, that the ions take major part by bombarding the objects. The typical energy of ions reaching the wall is 8 to 10 eV, depending partially on the pressure and the gas mixture. Experiments with very low pressure in a helium plasma could produce ions with energies up to 50 eV (see fig. 6). No further experiments were conducted in this direction because the sterilisation is most effective at pressures one magnitude above, at 10 Pa. But a controlled surface modification may be possible with adjusted ion energies.

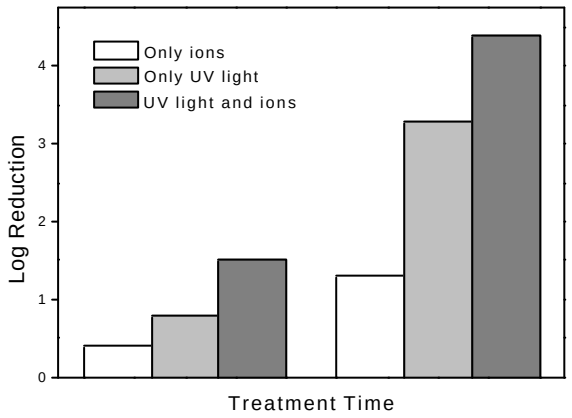

Figure 7: Logarithm of the Reduction of spores (b. subtilis) at different times split up into the parts of UV light and ions.

In order to investigate the influence of the various mechanisms separately an ion beam experiment was set up. The beam was directed onto B. subtilis endospores located on a steel plate. The same experiment was then conducted with uv light from the DICP added, and finally with both, uv light and the ion beam in operation. The results can be seen in fig 7 with treatment times of 5 minutes and 30 minutes at a fixed ion flux density of 10^{14} s^{-1} cm^{-2}. This flux density is around two orders of magnitude below the ion flux density in the DICP. Despite the fact that uv light is the main effect in plasma sterilization, the ions are needed to reach the high reduction rate which is necessary in medical, pharmaceutical and in food applications.

6. Simulation

The measurements can only be done on some locations inside the chamber. For a two dimensional characterisation of the DICP, an in-house hydrodynamic-electrodynamic model was used. The ion transport properties are described by a full hydrodynamic model including the sheath regions. Due to their small mass, the drift diffusion approximation was applied for the electrons. The rf energy input is described by an electrodynamic model derived from Maxwell´s equations [1].

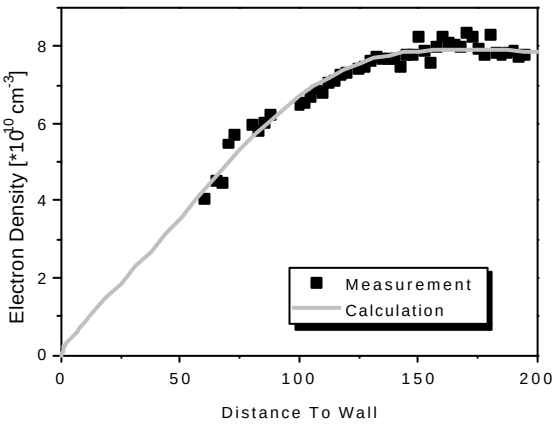

Figure 8: Simulation of mean electron density

From Langmuir probe measurements the radial peak electron density was taken and a coil current was chosen to match the density in measurement and simulation. The neutral gas temperature derived by the OES was taken as input parameter. The calculated electron density could then be compared to the results of the Langmuir probe measurements. Fig 8 shows one measurement in comparison to a simulation. Measured and calculated data are in good agreement.

Further is it possible to calculate the ion density and ion velocity profiles, as well as the induced power density distribution in the chamber. Especially the spatial distribution of the power input into the chamber is of importance when the reactor has to be scaled up. Simulation in interplay with diagnostics can synergetically simplify the construction of newly shaped chambers. The shape and dimensions of the reactor chamber or the antennas can be customised to produce the desired discharge characteristics.

7. Conclusion

While the profile of the electron density cannot be used to describe the profile of the sterilisation rate it is an important part of the characterisation of the plasma. The measurements in combination with a hydrodynamic and electrodynamic simulation of the plasma inside the chamber produced a consistent picture of the parameters everywhere in the reactor chamber. Alternate processes for different applications, like surface modification, can now be developed faster with the knowledge of the state of the plasma in all three dimensions. The future construction of customised plasma reactors is greatly simplified by the simulation of the plasma parameters. Together with the knowledge of the sterilisation process reactors of desired properties can be constructed more efficiently.

8. Acknowledgement

The authors wish to thank the Frauenhofer Institute for Process Engineering and Packaging IVV in Freising for the microbiological preparation and evaluation of the test samples and the Bundesministerium für Bildung und Forschung for funding under contract numbers 13N7681, 13N7607.

Structure and properties of the intermetallic Ti-Al type surface layers produced on titanium alloy.

T. Wierzchoń[1], M.Ossowski[1], E. Łunarska[2]

[1] *Warsaw University of Technology,Faculty of Materials Science and Engineering,02-507 Warsaw, . Wołoska 141, POLAND*

Alloys composed of intermetallic phases of the Ti-Al system belong to the group of new materials that show unique physical, chemical and mechanical properties. Unfortunately, their susceptibility to brittle fracture, poor plasticity and the occurrence of fatigue cracking observed within a wide temperature range greatly restrict their practical applications of these alloys. Therefore, attempts are being made at developing methods for producing surface layers of these materials on titanium alloys, which are characterized by a high strength, good corrosion resistance, and a low density but unfortunately a low resistance to friction.
A prospective line is the production of composite layers of the Al_2O_3 + $TiAl_3$ + TiAl + Ti_3Al type by combining (in a way justified from the point of view of the cost involved) various surface engineering methods, such as vacuum evaporation technique of aluminium and the glow discharge assisted treatments.
The paper specifies the conditions under which composite surface layers of the Ti-Al intermetallic phases with a top Al_2O_3 layer are produced on the two-phase Ti6Al2Cr2Mo titanium alloy by using a multiplex process enhanced by the glow discharge phenomenon. The results of examination of the structure, chemical and phase composition and properties, such as corrosion and friction wear resistance of these layers are presented. The composite layers of the Al_2O_3 + $TiAl_3$ + TiAl + Ti_3Al types have a surface hardness of the order of 1600HV0.05 and a good resistance to corrosion and frictional wear.
This multiplex technique, developed in the present study, permits producing surface composite layers of the diffusion character with a precisely specified structure and chemical and phase composition, tailored to suit the increasing use of titanium alloys in industry.

Plasma Parameters During High Power Pulsed Magnetron Sputtering

Abstract

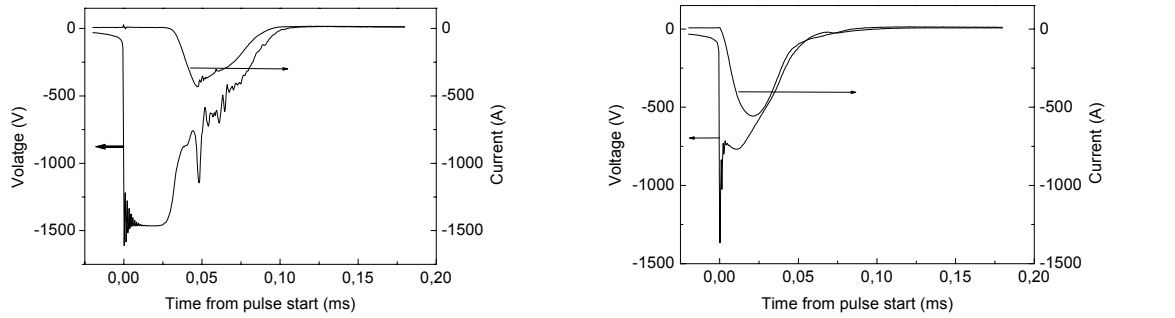
We report on Langmuir probe measurements of high power pulsed magnetron discharge. Space and time-dependent plasma parameters are obtained as functions of the process parameters. It is shown that the electron density of a pulsed magnetron plasma, in the substrate vicinity, is three orders of magnitude (10^{18}-10^{19} m^{-3}) higher than that of a d.c. magnetron discharge. The electron temperature evolution was measured by a triple probe, and found to be in the 0.2-3.1 eV range.

1. Introduction

In a conventional d.c. magnetron sputtering the power density is limited by the thermal load on the target. In unipolar pulsing, the power supply operates at zero power level and then pulses to a high level for a short period each cycle. Plasma density in conventional d.c. magnetron sputtering is known to be no more than 10^{15}-10^{16} m^{-3} at ~ 5-10 cm [1] from a metal target, with an ionisation fraction of 1-10% [2]. For the high power unipolar pulsed magnetron sputtering used in this work, density was measured to be three orders of magnitude higher than in a d.c. discharge [3] and with an ionisation fraction of 30-70 % [4]. The magnetron in this case was pulsed with a unipolar pulse wave of 50-100 μs pulse length and 11 J pulse energy. Furthermore, it was shown that the electron energy probability function (EEPF) exhibits a bi-Maxwellian distribution with a cold electron group having an electron temperature T_c=1.1 eV and a hot electron group with T_h=1.9 eV [5]. Langmuir probe measurement is a common technique to investigate plasma parameters such as electron temperature, plasma and floating potential, plasma density, and electron energy density function (EEDF). It allows for understanding the plasma dynamics as well as indicating how to control plasma species, in highly ionised plasmas, for specific film growth purposes. The aim of this work is to investigate the spatial and temporal evolution of both the plasma density and the electron temperature and compare these with measurements for a d.c. plasma.

2. Experimental setup

The measurements were made for a balanced magnetron discharge that has a tantalum (Ta) target with a diameter of 150 mm. The target functions as the cathode and is located inside a stainless steel sputtering chamber of radius R = 24 cm and height L = 75 cm. The cathode is driven by a pulsed power supply that delivers up to 3 MW peak power (2500 V and 1200A) at a repetition frequency of 50 Hz. The pulse length is in the range of 50 – 100 μs (Fig. 1). In this work, measurements were made with an average power of 550 W corresponding to pulse energy of 11 J. As a discharge gas, argon of purity 99.9997% and pressure of 0.5, 5, and 20 mTorr was. Target current, target voltage, and Langmuir probe current and voltage were monitored by a Tektronix TDS 520 C (500 MHz, 1 Gs/s) oscilloscope. The target voltage was measured using a Tektronix P6015 high voltage probe (1000 × attenuation) and the target current by a Tektronix CT-04 high current transformer (20 KA peak current and bandwidth 20 MHZ) and a TCP202 current probe (15A ac/d.c. and bandwidth 50 MHz).



(a) (b)

Figure 1 Target current and voltage versus time from initiating the pulse for (a) 0.5 mTorr and (b) 20 mTorr argon discharge

Plasma parameters were measured using a cylindrical Langmuir probe consisting of a tungsten wire of length l_{pr}= 5.0±0.5 mm and diameter 0.10±0.01 mm. The probe holder is an alumina tube with an outer radius r_{prh}=0.5 mm and a length l_{prh}= 19 mm. The probe is made in such a way that $r_{prh} << l_{pr}$ and r_{pr}, r_{prh}, $\lambda_{De} << \lambda_e \sim$ 10 mm [6]. Here λ_{De} ~14 – 100 μm is the Debye length and λ_e ~ 10 mm is the electron mean free path. The probe was placed perpendicular to the discharge axis, and thus to the electric and magnetic field lines. The Langmuir probe current is determined by measuring the voltage over a resistor (R=10 Ω). The measured voltage together with the probe bias voltage are displayed on an oscilloscope, and collected in a computer. The computer stores the data for later analysis, and controls the power supply that gives the probe bias voltage.

For the Langmuir probe measurements to be valid, the error caused by the magnetic field strength must be minimized [6]. The probe was positioned 4 – 28 cm from the target along the centre line. Time resolved probe measurements were taken for 1000 μs at 2 μs intervals from the start of the pulse for each bias voltage, starting from –15 V and ending at +10 V with a stepping voltage of 0.1 V. For each time value the I–V data was recorded and analysed. First the measured I–V curve was smoothed by convoluting it with a Blackman window [8], then the first and second derivative of the I –V curve was calculated and the EEDF $g_e(\varepsilon)$ was found. The EEDF is given by the Druyvesteyn formula as [9]:

$$g_e(V) = \frac{2m}{e^2 A_{pr}} \left(\frac{2eV}{m}\right)^{\frac{1}{2}} \frac{d^2 I_e}{dV^2} \tag{1}$$

The electron energy ε is given in equivalent voltage (V) units. The plasma potential V_{pl} is the voltage where the second derivative of the electron current I_e is zero, and the floating potential V_{fl} is where the probe draws equal ion and electron currents. The electron density n_e is determined as:

$$n_e = \int_0^\infty g_e(\varepsilon) d\varepsilon \tag{2}$$

To determine the electron temperature, we applied the triple probe [7]. Fig. 2 shows a scheme of the measurement setup; three separate Langmuir probes of identical to the one used for density measurements placed 2 mm apart. An important requirement of the triple probe technique is that all of the Langmuir probes are immersed in plasma sample volumes of identical character. Otherwise a different I-V characteristic exists at each probe and a complete set of measured quantities for a single I-V characteristic is not obtained. P_2 is left floating while a constant voltage is applied to P_1 and P_3.

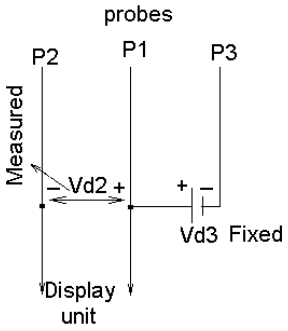


Figure 2 Direct display system utilizing the triple probe

V_{d2} is related to V_{d3} and T_e by the following relation [7]:

$$\frac{1-\exp(-eVd_2/KT_e)}{1-\exp(eVd_3/KT_e)}=\frac{1}{2} \tag{3}$$

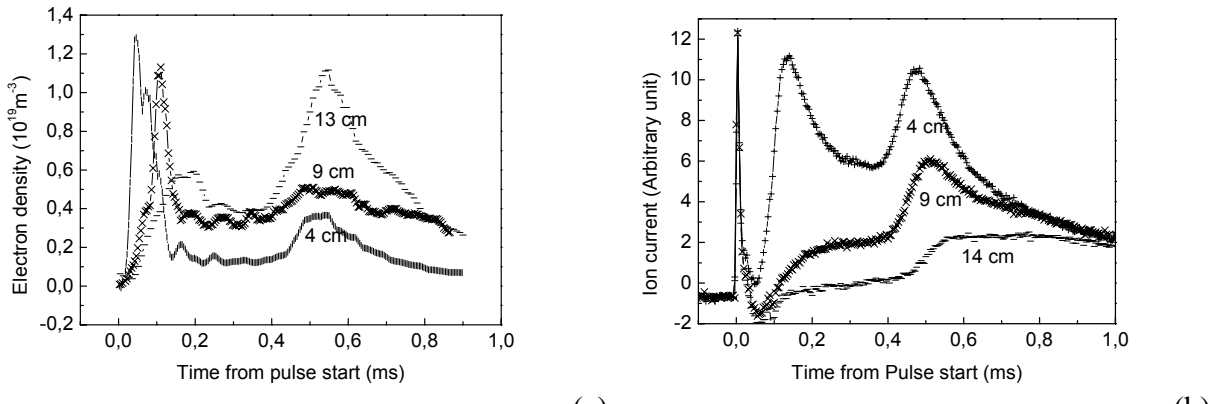
To ensure the collection of the saturation current V_{d3} has to be large enough ($eV_{d3} \cong 3kT_e$) but not too large so as to minimize the probe shadowing. We choose this to be 9 V. Equation (3) simplifies to give the electron temperature as [10]:

$$T_e \cong eV_{d2}/\ln 2 \tag{4}$$

To measure the ion current, a negatively biased (-50 V) flat probe, a metal disk of 2 cm in diameter equipped with a guard ring was used.

3. Experimental results and discussion

Electron density was measured at different distances from the Ta target using the Langmuir probe, along the middle axis. Fig. 3(a) shows the electron density as a function of time from initiation of the pulse, for various distances from the Ta target. The density curves with two density peaks. At 4 cm from the sputtering target the first density peak is measured to be $1.2\text{x}10^{19}$ m^{-3} some 42 μs after the pulse start. At 9 cm, the peak value is $1.1\text{x}10^{19}$ m^{-3} after 102 μs and at 13 cm a density peak of $0.6\text{x}10^{19}$ m^{-3} is reached after 166 μs. The same behaviour is seen for the ion current, i.e. the further from the metal target the measurement is done the later the current peak appears indicating a flow of electrons and ions away from the target.



(a) (b)

Figure 3. (a) Electron density at different distances away from a Ta sputtering target measured using a Langmuir probe (b) Ion current for the same system measured by a flat probe in Ar discharge at 20 mTorr and average power 550W.

In Fig. 3(a) a second density peak appears at approximately 0.56 ms after initiation of the pulse. It appears roughly independently of the distance from the sputtering target, in this range. Also, the second electron density peak is higher than the first one the further away from the sputtering target the measurement is done. We relate the formation of more than one peak to ion acoustic solitary waves that propagate through the plasma. We assume that dense plasma is created next to the target during the pulse. This high density of ions and electrons leads to a compressive wave train that propagates into a less dense plasma similar to what was reported by Ikezi *et al*. [11]. The character of the electron and ion density pulse is believed to follow the predictions of the Korteweg-de Vries equation, with respect to the shape and velocity of the solitary waves, although the magnetization of electrons may have to be considered [12]. In Fig. 3(b) the corresponding ion current peak is shown to appear earlier the closer to the sputtering target the measurement is done. An ion current peak is also measured right at the beginning of the pulse. Ehiasarian *et al*. [13] showed that the majority of the charged particles at this point are ions of the working gas, Ar^+. The corresponding electron density measurements are very unstable during these first 10 μs of the pulse and further analysis of the signal here is left for future work.

Electron temperature was measured at different positions underneath the Ta target using the triple probe technique. Fig. 4(a) shows the temporal and along the axis electron temperature evolutions for 20 mTorr Ar pressure and a pulse energy of 11 J. It shows that, while the pulse is on, the electron temperature reaches it's maximum of about 2.8 eV. This decreases sharply as the pulse is switched off and reaches a value of 0.2 eV after just 80 μs from the pulse start. The electron temperature then increases again to about 0.5 eV and then decreases more slowly to 0.1-0.2 eV and stabilises at this value.

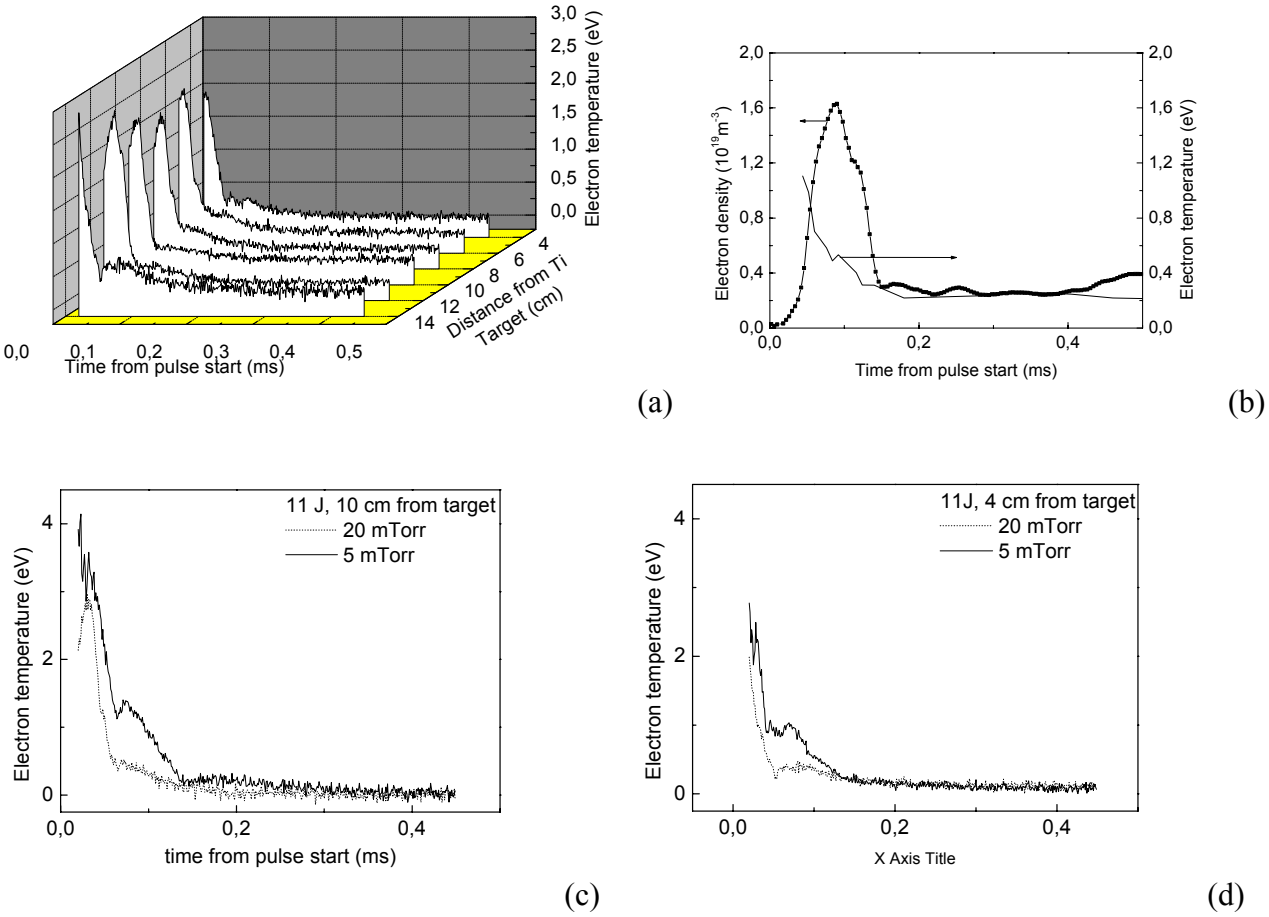


Figure 4. Electron temperature versus time from initiation of the pulse. (a) temporal and along the axis evolution for 20 mTorr Ar pressure and 11 J pulse energy. (b) Temperature decreases as density increases (c) For 5 and 20 mTorr, 10 cm from the target and (d) 4 cm from target.

Fig. 4(b) shows the electron temperature and electron density as functions of time from initiation of the pulse. We note that the electron temperature decreases as the plasma density increases. Fig. 4(c) shows the electron temperature versus time. We see that increasing the magnetron power results in a decrease in the electron temperature. One can also see the effect of the delayed high-energy tale, corresponding to a second electron temperature increase at about 0.8 ms from the pulse start. It is shown to peak at 1.8 eV for the 5 mTorr plasma and is almost non-existing for the higher pressure one, indicating that the 20 mTorr plasma not only has a higher electron density but is also the colder of the two plasmas. This is confirmed in Fig. 4(d) where the measurements were made at 4 cm bellow the target. Fig. 4(d) shows also that the electron temperature at this distance is lower than that measured 10 cm from the target.

Conclusion

Using higher power pulsed magnetron sputtering, we demonstrated that very high plasma density, up to 1.3 10^{19} m^{-3} is achieved 10 cm from a Ta target, which is three orders of magnitude higher than that of a d.c. plasma. The discharge was shown to be cold with average electron temperature well beneath 0.5 eV. A second density peak was shown 0.56 ms after pulse initiation

Model of the Plasma Movement and Walls Erosion in the Hollow Accelerator Channel

R. Chuyan, N. Avdeenko, S. Khartov, J. Zikeeva

Department of Space Electrical Engines and Power Plants, Moscow Aviation Institute (State Technical University), Moscow, Russia

One of the most popular plasma accelerator is the stationary plasma accelerator with lingering annular channel, external magnetic field and circular (Hollow) electron current. These accelerators are used in the different technological plants for the surface finish, in the several physical plants etc. In this report we try to create the complex mathematical models for investigation of plasma and its components in the accelerators channel.

One of the head problem of this accelerator is problem channel walls erosion. Part of the fast ions by this acceleration scheme inevitable fall to the channel walls and knock some atoms of walls material out. The channel walls erosion is head process, which limited the accelerators lifetime.

The complex of model consist of some connected blocks and based on statistic experimental data, reflecting the process of ions creation in the magnetic field.

1. Block of ions creating process simulation in the acceleration channel in the area of increasing magnetic field.
2. Block of ions' motion simulation in the acceleration channel up to channel boundaries and also out of them if they come out into the external space.
3. Block of ions' interaction with channel's walls (neutral atoms knocking out from walls' material).
4. Block of channel boundaries from changing simulation and re-calculation of the interaction.
5. Block of neutral particles(knocked out from the walls) motion simulation and their interaction with channel walls.

In the report the results of modeling are leaded.

Ions distribution function in the acceleration channel and in the external space and lifetime performances should be obtained as a result of simulation.

Developed method with some corrections and additions can be used for other types of accelerators.

Model of ions creation in the acceleration channel based on the local probe measurement. In the model there is the possibility to correct the initial distribution using results of experiment dealing with stationary plasma thruster (SPT-100) wearing under long-time lifetime tests. But at the that time this method is universal and can be used with some corrections for another of accelerator's models.

By calculation only single-charged ions sputtering action has been taken into account. Such assumption is correct as far as the share of double- and more charged ions in the discharge of the modern accelerators models is not more then 10%.

The structure and main blocks of mathematical model for particles motion in the accelerator's channel and out of it are developed.

The developed model and the software, created on its base, permit to calculate ion creations process, charged and neutral particles motion inside the channel and out of it, their interaction witch channel's walls, to built vector diagram of "dust" exhausting, to calculate channel wall profile change as a dependence on time and to determine thruster's life time.

Large-scale surface wave discharges in N_2-O_2

V. Guerra, E. Tatarova and C. M. Ferreira

Centro de Física dos Plasmas, Instituto Superior Técnico, 1049-001 Lisboa, Portugal

Abstract
In this work we present a theoretical investigation of a large-scale, slot antenna excited surface wave plasma source operating at $\omega/2\pi = 2.45$ GHz ($p = 2$ Torr) in $N_2 - O_2$ mixtures. The spatial distribution of the species of interest and the total electric field spatial variation are calculated and analysed for the discharge zone of the plasma source. The importance of $N_2(X,v)$ and of the electronically excited metastable states $N_2(A)$ and $N(^2D)$ is pointed out.

1. Introduction

Gas discharges operating in nitrogen-oxygen mixtures are used in many plasma-based technologies as, for example, cold sterilization of medical devices or removal of nitrogen oxides (NO_x) from flue and exhaust gases. Furthermore the kinetic processes occurring in low-temperature plasma of atmospheric gases N_2, O_2 and their mixtures are presently the subject of many investigation due to their importance in atmospheric and ionospheric physics. In this respect plasma sources based on microwave propagation are of interest for a new generation of large-scale plasma based technologies.
In this work we report a theoretical investigation on a large area slot antenna excited plasma source operating at 2.45 GHz and $p = 2$ Torr in N_2-O_2 gas mixtures. The plasma is created by surface waves propagating radially and azimuthally along the interface between the plasma and a quartz dielectric plate located at the top wall of a large diameter cylindrical metal camera. The electric field intensity exponentially decreases from the interface thus the plasma source can be separated in two parts. The first one is the active discharge zone close to the interface and the second one is the remote, electric field-free, plasma. The theoretical analysis is made for the active zone. The discharge is sustained by the discrete pure TM_{33} surface mode, which is the proper mode of the system considered. The Maxwell equations and dispersion equation are solved in order to obtain the 2D electric field pattern in a fixed $r - \varphi$ plane in the discharge zone. The electron Boltzmann equation is solved in the local approximation, coupled with a set of rate balance equations describing the production and loss of the most important neutral and charged heavy particles, such as vibrationally excited ground-state N_2 and O_2 molecules, N_2 and O_2 electronically excited states, N and O atoms, NO and O_3 molecules, and the different positive ions present in the discharge. The calculations provide the spatially averaged concentrations of the different species in the discharge zone and the 3D distributions of the electric field and electronic excitation rate coefficients.

2. Theoretical model

In the present model, the real camera geometry is simplified to a vertical wave-guide of an arbitrary cross-section (radius R) short-circuited at its top wall by a metal wall (Fig. 1) [1,2]. A dielectric plate of thickness d and permitivitty ε_d fills the upper region of the wave-guide entirely. The discharge plasma (where surface waves sustain and propagate) below is supposed to be homogeneous with electron density N_e. Weakly damped free oscillations of the kind $\propto \exp(-i\omega t)$ with a complex frequency $\omega = \omega' - i\omega''$ are considered. At fixed geometry and plasma parameters such oscillations can exist only for some discrete values of the complex frequency corresponding to the various eigenmodes. The waves form a resonant eigenmode satisfying the boundary conditions and the plasma "sticks" to some discrete density values.
Such a structure can support pure transverse magnetic (TM) and transverse electric (TE) modes, respectively. Pure TM modes are considered in the present model. In each medium, i.e. plasma and dielectric, the electric filed (ρ, φ, z) components are follows:

$$E_r(\mathbf{r},t) = \frac{1}{k_\tau} J_m'(k_\tau \rho)(\cos m\varphi)\frac{d\xi(z)}{dz}\exp(-i\omega t)$$

$$E_\varphi(\mathbf{r},t) = \frac{1}{\rho k_\tau^2} J_m(k_\tau \rho)(-m\sin m\varphi)\frac{d\xi(z)}{dz}\exp(-i\omega t)$$

$$E_z(\mathbf{r},t) = J_m(k_\tau \rho)(\cos m\varphi)\xi(z)\exp(-i\omega t) \quad (1)$$

Here, the transverse wave number k_τ depends only on the camera geometry and mode indices, and for a TM_{mn} mode it is $k = U_{mn}/R$, where U_{mn} is the n-th root of the m-th Bessel function J_{mn}, i.e., $J_{mn}(U_{mn}) = 0$. In order to fulfil also the boundary conditions at the plasma dielectric interface the transverse field distributions and thus the transverse wave numbers in both media must coincide. Therefore they have the same value in the plasma and dielectric and this value depends only on the cross-section geometry, mode type and mode indices. The function *ξ(z)* describing the axial field distribution is:

$$\xi(z) = E_{01}\exp(\gamma z) + E_{02}\exp(-\gamma z)$$

Here $\gamma_d = -\left[k^2 - \varepsilon_d \omega^2/c^2\right]^{1/2}$ and $\gamma_{pl} = -\left[k^2 - \varepsilon_{pl}\omega^2/c^2\right]^{1/2}$ are the axial propagation constants in the respective medium, i.e., dielectric and plasma. The relative plasma permittivity is

$$\varepsilon_{pl} = 1 - \frac{\omega_{pl}^2}{\omega(\omega + i\nu_{en})},$$

where $\omega_{pl} = e(N_e/\varepsilon_o m_e)^{1/2}$ is the electron plasma frequency (m_e and e being the electron mass and charge respectively). At $z = +\infty$ the wave must decay exponentially along z in the plasma, so that E_{02} must be zero. Assuming that surface wave propagates on the r-φ plane and is evanescent along z- direction, the dispersion equation is obtained, as usual, from the continuity of the transverse electric and magnetic field components on the plasma dielectric interface

$$(\gamma_d/\varepsilon_d)\tanh(\gamma_d d) = \gamma_{pl}/\varepsilon_{pl}.$$

The discharge part of the model is coupled to the discharge electrodynamics through the electron density (in the discharge zone where SWs propagates) at which TM_{33} mode appears. The absolute value of the electric field E_{01} (from now on denoted simply as E_0) can be obtained by solving the electron and heavy-particle kinetics for the spatially averaged populations of the most important neutral and charged species in the discharge region. The kinetic scheme considered is described in detail in [3,4], but a brief outline is given below. The electron energy distribution function is determined by solving the homogeneous Boltzamnn equation in the usual two-term expansion in spherical harmonics, taking into account elastic collisions, excitation and de-excitation of the rotational levels, inelastic and superelastic collisions of electrons with $N_2(X, v)$ and $O_2(X, v')$ molecules, inelastic collisions for excitation of electronic states and ionization of N_2 and O_2. The Boltzmann equation is coupled to a system of rate balance equations describing the kinetics of the vibrationally excited molecules $N_2(X, 0 \le v \le 45)$ and $O_2(X, 0 \le v \le 15)$, which include the processes of excitation and de-excitation of vibrational levels by electron impact (e – V processes), the vibration-vibration (V – V) and vibration-translation (V – T) energy exchange processes ($N_2 - N_2$, $N_2 - O_2$, $O_2 - O_2$, $N_2 - N$, $N_2 - O$, $O_2 - O$), the vibrational deactivation of $N_2(X, v)$ molecules at the wall and dissociation and re-association mechanisms of N_2. The vibrational distribution function of $N_2(X, v)$ molecules is still coupled to the kinetics of electronically states of N_2, and to those of NO, N and O species. The averaged concentrations of the heavy-particles are obtained by solving the corresponding system of master equations for their populations. Besides the manifold of vibration levels $N_2(X\ ^1\Sigma_g^+, v)$ and $O_2(X\ ^3\Sigma_g^-, v')$, the species to be considered are the most populated electronic states of N_2 ($A\ ^3\Sigma_u^+$, $B\ ^3\Pi_g$, $C\ ^3\Pi_u$, $a'\ ^1\Sigma_u^-$, $a\ ^1\Pi_g$, $w\ ^1\Delta_u$, $a''\ ^1\Sigma_g^+$) and O_2 ($a\ ^1\Delta_g$, $b\ ^1\Sigma_g^+$), the atoms N(^4S, ^2D, ^2P) and O(^3P), the molecular species NO($X\ ^2\Pi_r$) and O_3, and the ions N_2^+, N_4^+, O_2^+, O^+, NO^+ and O^-. The kinetics of the metastable atomic species N(^2D, ^2P) was not considered in [3,4], and was added in this work. For the case of pure nitrogen the kinetics of the atomic metastable states is described in [5]. For the mixture it is worth to mention the reactions of formation and destruction of NO, $N(^2D) + O_2 \rightarrow NO + O$ and $N(^2D) + NO \rightarrow N_2 + O$. As it will be seen below, this later reaction can give a significant contribution to the destruction of NO. The maintenance reduced electric field is determined using the requirement that under steady-state conditions the total rate for ionization must compensate exactly for the total rate of electron loss.

The system of equations just described allows the determination of the spatially averaged concentrations of the different heavy-particles, as well as the absolute value of the electric field E_0. Using this value in the set of equations (1) we have then the 3-D values for the electric field in the discharge zone. For the pressures of interest in this work, the homogeneous Boltzmann equation can subsequently be solved in each point in space for the local electric field given by (1), providing the 3-D distribution of the electron excitation, dissociation and ionization rate coefficients.

3. Results and discussion

The computed resonance frequencies (R = 11 cm, d = 1 cm, ε_d = 3.78) of experimentally observed TM_{33} mode as a function of the electron density and electron-neutral collision frequencies are shown in Fig.2. The resonance and the plasma frequencies are normalized to the mode cut-off frequency in the dielectric region, i.e., $\omega_0 = ck/\sqrt{\varepsilon_d}$ .The calculated dispersion curves of TM_{33} mode, for two significantly different values of electron-neutral collision frequency, $\nu_{en} = 10^8$ (solid lines) and $\nu_{en} = 10^{10}$ s^{-1} (dashed lines), are presented. As seen, the resonance frequencies are lower for higher collision frequencies and the effect of collisions is more pronounced at lower electron densities.

According to the dispersion equation, and keeping in mind a real situation when the microwave radiation frequency is 2.45 GHz, the TM_{33} mode is satisfied when the electron density N_e is 9.0×10^{11} cm^{-3} and the attenuation coefficient α is 2.00 cm^{-1}. The corresponding radial and azimuthal variations of the electric field components (at a fixed axial position z=const) are depicted on Fig. 3 and 4 respectively. The intensity of the electric field components is normalized to the value of the field E_0 at the plasma-dielectric interface.

Figure 5 shows the 2-D relative concentration of the $N_2(C\ ^3\Pi_u)$ state, for the conditions of figures 3 and 4, in a mixture of 95% N_2 – 5% O_2. The calculated value of E_0 is E_0 = 130 V/cm. The spatial distribution of the population of this strongly radiative state can be obtained directly from the Boltzmann equation, by assuming that it is mainly created by direct electron impact, $e + N_2(X) \rightarrow e + N_2(C)$, and destroyed by its radiative decay to the $N_2(B\ ^3\Pi_g)$ state, $N_2(C) \rightarrow N_2(B) + h\nu$. If this is the case, the concentration $[N_2(C)]$ in each position **r** is simply proportional to $n_e(\mathbf{r})C_X^A(\mathbf{r})$, where $C_X^A(\mathbf{r})$ denotes the rate coefficient for excitation of $N_2(C)$ from $N_2(X)$ calculated from the Boltzmann equation. In this figure the structure of the TM_{33} mode is clearly identified. However, at the present stage this figure must be considered only as indicative, since our calculations indicate that the remaining mechanisms of excitation of $N_2(C)$, namely the pooling through reaction $N_2(A) + N_2(A) \rightarrow N_2(X) + N_2(C)$ and the stepwise excitation $e + N_2(A) \rightarrow e + N_2(C)$, are also contributing significantly to populate the $N_2(C)$ state.

Finally, figure 6 shows the spatially averaged calculated concentration of NO molecules as a function of the relative concentration of O_2 in the mixture. As it is seen from this figure, for the conditions of this investigation the fractional population of NO can be close to 1%. As largely discussed in [3,4], NO molecules are created by reaction

$$N_2(X, v) + O \rightarrow NO + N \qquad (2)$$

and destroyed by the reverse reaction

$$NO + N \rightarrow N_2(X, v) + O\ . \qquad (3)$$

However, our present results indicate also a strong coupling between the kinetics of $N(^2D)$ metastables and NO molecules. As a matter of fact, NO is further created and destroyed very effectively in collisions that form and destroy $N(^2D)$ atoms as well, respectively via

$$N_2(A) + O \rightarrow NO + N(^2D) \qquad (4)$$

and

$$NO + N(^2D) \rightarrow N_2(X) + O. \qquad (5)$$

Processes (4) and (5) are very similar to (2) and (3), and seem to suggest that, together with nitrogen vibrations, atomic and molecular metastable states can play an important role in the overall discharge kinetics.

Initial growth of Cu-nanoparticles in plasmas studied by Mie-ellipsometry

G.Gebauer, T.Galka, J.Winter

Institute for Experimental Physics II, Faculty for Physics and Astronomy
Ruhr-University Bochum, D-44780 Bochum
gg@plas.ep2.ruhr-uni-bochum.de

Plasma generated nanoparticles play an important role in modern materials technology, in catalyses and, for instance, in astrophysics. The development of measuring systems for the study of the transition from macromolecules to coagulated nanoparticles makes it possible to gain insight in to the growth process of nanoparticles and consequently allows their process control.
Nanoparticles of metals are vital for high catalytic activity. Copper particles, for example, are known to enhance the catalytic activity and selectivity of ZnO in hydration and dehydration reactions e.g. methanol synthesis and play an important role in solid-oxide fuel cells [1].
The particle size, the size-distribution and the dielectric properties of the nanoparticles are measured by Mie-ellipsometry [2][3][4]. Careful analyses of the ellipsometric angles Psi and Delta allows to push the sensitivity down to a few 10 nm particles size. We have analyzed the initial phase of Cu-nanoparticles growth in Ar capacitively coupled RF-plasmas. Reactive Cu-atoms required for the growth of particles are eluted from the upper Cu-electrode by DC-sputtering. The lower electrode is divided into several circular segments, which are insulated electrical from each other. The particle enclosure and the growth process is controlled by applying different potentials on these segments.

Lifted flame stabilisation by a nanosecond pulsed DBD discharge

R. Delorme[1], P. Vervisch[1]

[1] *UMR 6614 CORIA CNRS, Saint Etienne du Rouvray, France*

Abstract

In this study, we have realized a burner using a CH_4-air premixing which allows to easily obtain a lifted flame at some centimetres from the exit of the injector. Two electrodes, on which we apply pulsed voltage (rising-time of 10ns, 15 to 25 kV), are placed perpendicularly to the direction of the flame in order to form a streamers sheet near the exit of the injector. When the discharges occur, we observe the catching of the flame base by the streamers sheet whereas this base flame was before a few centimetres above this streamers sheet.

1. Introduction

One of the most problems of the industrial burners or engines concerns the stabilisation of the lean flames which are lifted far from the exit of the gas injectors and thereby, they become very sensible with external or internal perturbations in the flow. Non-equilibrium gas discharge which leads to radicals production can be a solution for flame stabilisation. In different types of electrical discharges, pulsed discharges are the most attractive since the major part of the energy released in the discharge concerns gas internal degrees of freedom.
The choice of Dielectric Barrier Discharge (also named silent discharge) has been made for several reasons :

- in DBD, the electrodes aren't directly in contact with the gas in which this discharge occurs. The lifetime of these electrodes depends on neither the nature nor the flow of the gas. The contamination of the gas with evaporated electrode material is impossible [1]
- a wire-to-wire discharge allows us to generate a plane of streamers perpendicularly to the direction of the flame and so a height's referential for the flame base
- the DBD is a non-equilibrium high-pressure gas discharge which generates energetic electron with 1-20 eV, low excited atomic and molecular species, free radicals and excimer with several eV energy [2]
- the dielectric avoids the spark breakdown between the two electrodes
- the DBD can work at atmospheric pressure, at low pressure or at high pressure.

In the case of a wire-to-wire DBD, the distribution of the streamers is quasi-uniform all along the space between the two wires whereas in the case of a classical discharge between two wires, there are privileged points where the discharges occur due to the inhomogeneity of the material constituting the electrodes.
We often use high-voltage nanosecond pulse generator in the studies realized at our laboratory. In fact, the rise time of the high voltage pulse is a fundamental parameter for the energy of the created electrons. In such discharge, a propagation front (a streamer) crosses the gap from the high-voltage electrode to the low-voltage electrode with high velocity. In the head of this streamer, the electric field has high intensity and this leads to gas ionization, dissociation and excitation [3]. This electric field in the head of the streamer depends on the rising time of the high-voltage pulse : the narrowest the pulse is, the highest the electronic energy is [4].

2. Experimental set-up

The burner is realized in a ceramic tube presenting an internal diameter of 4,7 mm ± 0,05 mm, this tube is sealed into a vertical support made of cordierite. The gas injection allows to choose a premixed or non-premixed flow. In these experiments, the gas injection is always a non-premixed flow of Methane controlled by a Brooks flow-meter model GT-1355 with an Inox 316 model R-6-15-B float ball. This flow-meter has a range of measure comprised between 0 to 2020 l/h of Methane with a precision of 5% full range. With this burner, we can easily obtain a lifted flame at some centimetres from the injector exit.
The discharge system is constituted by two thin wires (diameter 0,1 mm) inserted into two parallel ceramic tubes (external diameter 2 mm) with a gap of 21 mm axis to axis. This gap corresponds to the diameter of the

base of the flame with the maximum used flowing velocity of 14 $m.s^{-1}$. These two tubes take place into a support in order to have a strictly parallel plane of streamers. The width of the discharge sheet is about 40 mm. This discharge system is mounted on a vertical displacement which have a range of 55 mm. This possibility of height variation is useful for the placement of the discharge sheet at any position in the flame or upstream of the flame. The Fig.1. presents this discharge system.

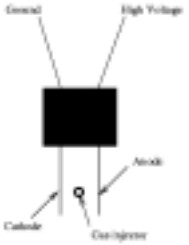

Fig.1. : Scheme of the discharge system

The nanosecond pulsed discharge, between these two electrodes across the dielectric, is generated by an home-made Marx generator, for which the electrical scheme is presented in the Fig.2., linked with a continuous power supply.

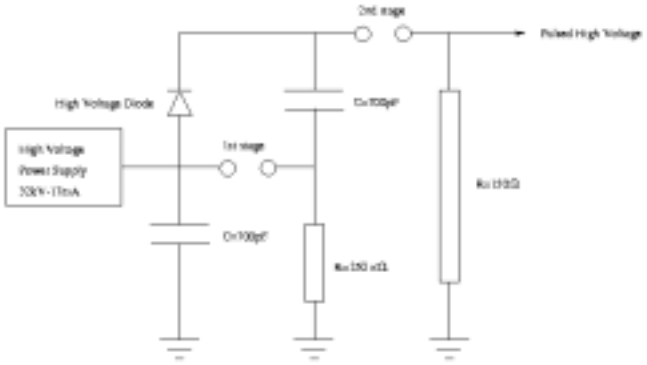

Fig.2. : Electrical scheme of the Marx generator

The principle of this Marx generator is simple, the two capacitors are charged in parallel by the 0-32 kV, 0-17 mA power supply. When the capacitors are sufficiently charged, the dielectric gas (Nitrogen in our case) in the first stage becomes ionized and so conducting. As the potential across the second stage gap is twice the charging voltage, the dielectric gas in the second stage allows the breakdown and an high-voltage pulse is created with the typical characteristics showed in Fig.3.. This signal is obtained by the mean of 500 pulses at a 200 Hz running. This generator can have a maximum repetition rate up to 300 Hz.

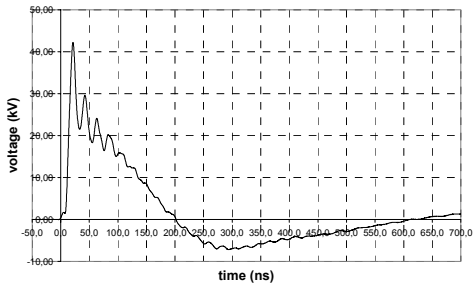

Fig.3. : Typical characteristic of the high-voltage pulse obtained with the Marx generator in the Methane flame

The digital oscilloscope Tektronix TDS-7104 (1 GHz, 4 channels, 10 Gsamples/s, 500 kpoints on 4 channels) allows to have minimal time resolution of 400 ps/point when all the channels are used. The voltage is measured with a capacitive probe Effitech with a time resolution below 1 ns. The measure of the current is realized with a pulse current transformer Stangenes 0.5-1.0 (rise time of 10 ns) between the cathode and the

ground. These two probes are linked to the oscilloscope. The set-up of this experiment is showed in the Fig.4..

Capacitive probe Effitech, **6**. Pulse current transformer Stangenes, **7**. Digital oscilloscope Tektronix TDS-7104, **8**. Flow-meter Brooks GT-1355, **9**. Methane Inlet

3. Results and discussion

The home-made burner allows to have various flowing velocities from laminar flame to high velocity lifted flame up to at least 35 $m.s^{-1}$ (Reynolds number of 10000) without extinguishing. But in the case of stabilisation, a limit appears due to the maximal discharge gap usable with our Marx generator. This gap measures 21 mm and the maximum flowing velocity corresponding to the base flame diameter is equal to 14 $m.s^{-1}$. In the Table.1., the different flowing velocities used are presented with their associated Reynolds number.

Table.1. : Flowing velocities face to the Reynolds number associated

Flowing Velocity ($m.s^{-1}$)	Reynolds Number
9,7±0,7	2976±244
10,8±0,8	3307±271
11,9±0,8	3638±298
12,9±0,9	3968±395
14,0±1,0	4299±352

The minimum number of Reynolds in this table is greater than the limit of the turbulent comportment who is 2320 in cylindrical tubes. The flame is so a turbulent flame far from the transitional speed.
In the first experiments, the flame was lifted a few centimetres above the plane delimitated by the two electrodes before the discharges apply. When the discharges occur, we observe the catching of the flame base by the streamers sheet. This catching can be seen in the Fig.5., on the left side the flame without discharge and on the right side with discharge for the same flowing velocity.

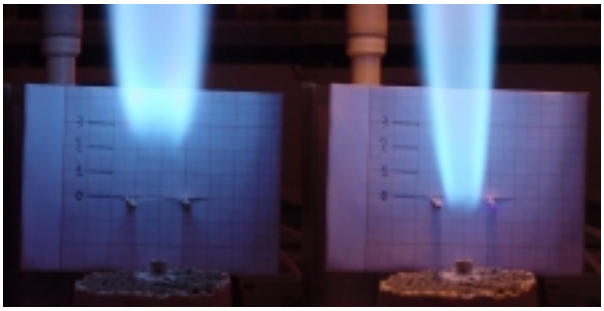

Fig.5. : Catching of the methane flame by the streamer sheet

With this catching, the flow of the injected gases in comparison with the case without streamers can be increased.
With this arrangement, the cathode current and so the injected energy in the discharge can be measured. Their characteristic are showed in Fig.6.. The signals are obtained by the mean on 500 pulses at a frequency of 200 Hz.

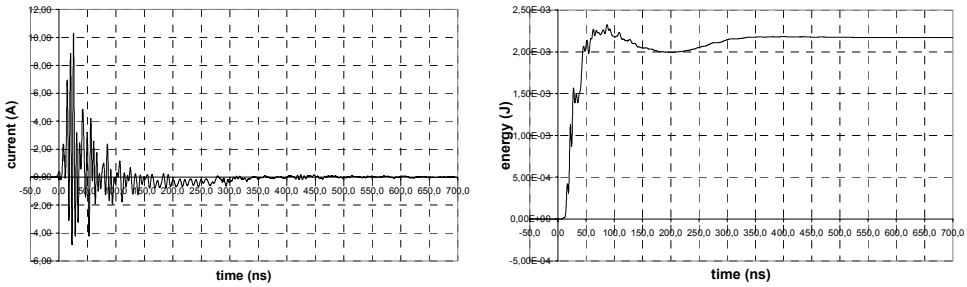

Fig.6. : Typical characteristic of the cathode current and the injected energy obtained with the Marx generator in the Methane flame

The characteristics of this discharge are 42 kV max., 26 A max., 23 mJ max..
With

$$Q = \int_0^{t\max} I dt \,, \qquad (1)$$

the calculated number of charges injected in the discharge is typically 0,02 µC.
The discharge characteristics change drastically according to the streamer sheet position in comparison with the flame position. The variation of the injected energy in the streamers according to the position in the flame can be seen in the Fig.7.. The signals are obtained by the mean on 500 pulses at a frequency of 200 Hz.

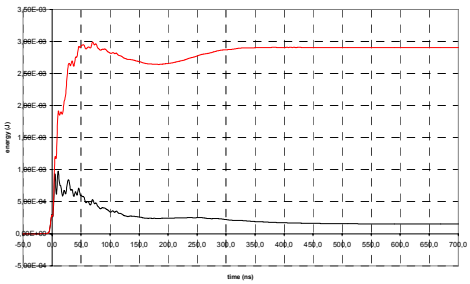

Fig.7. : Typical characteristics of the injected energy according to the position of the streamer sheet in the Methane flame: upper curve in the flame, lower curve below the flame

The choice of the criteria of the flame stabilisation by the streamers sheet can be easily solved by the direct measurement of the injected energy in the streamers (the digital oscilloscope allows this measure). This minimal energy has been chosen equal to 2-3 mJ (in the case of 40 kV discharges), this value corresponds to a good catching of the base flame.
With this criteria, the experiment consists on the flow measurement in the case of streamer discharge for some streamer repetition frequency and for some initial flows of methane. The different repetition frequencies usable with the Marx system are in the range from 1 Hz to 250 Hz, the different methane flowing velocities are in the range from 9,7 $m.s^{-1}$ (the minimal flowing velocity to lift the flame) to 14 $m.s^{-1}$ (the maximal flowing velocity corresponding to the base flame diameter equal to the electrodes gap). The Fig.8. presents the results of this experiment.

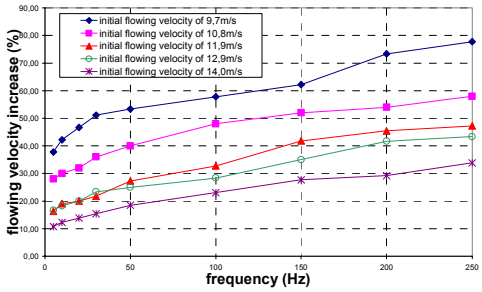

Fig.8. : Characteristics of the flowing velocity increase according to the streamer repetition frequency

The different curves present the flowing velocity increase for 5 cases of initial flowing velocities (the values are in the Table.1.) according to the streamer repetition frequency. In fact, for a same lift height, the flowing velocity can be increased by the specified percentage showed in the Fig.8. in keeping with the corresponding streamer repetition frequency. The flowing velocity increase has a quasi-linearly evolution according to the streamer frequency repetition. With this type of discharges at 250 Hz, the injected power in the streamers is equal to 0,75 W.
The difference between the minimum and the maximum increase of the flowing velocity is showed in the Fig.9..

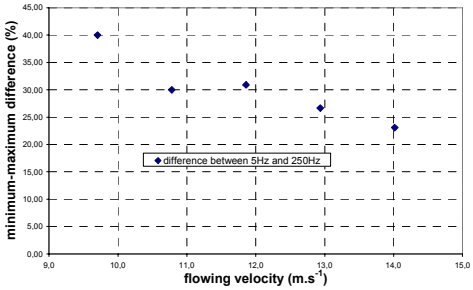

Fig.9. : Characteristic of the minimum-maximum efficiency difference according to the initial flowing velocity

This figure presents, for each initial flowing velocity of the Table.1., the difference between the flowing velocity increase at low frequency (5 Hz) and the flowing velocity increase at high frequency (250 Hz). This difference decreases with the increase of the initial flowing velocity. The repetition streamer frequency seems to be the most important factor to the stabilisation of lifted flame, especially in the case of high flow velocities. From these characteristics, an extrapolated mean value of the flowing velocity increase according to the frequency can be calculated, this value is equal to (0,13 ± 0,03)%/Hz.
Furthermore, a change in the brightness of this diffusion flame appears as soon as the discharges begin, the flame front between the combustion gas and the air forms a cone who presents an lower angle than in the case without discharges. The flame velocity seems so to be higher when the discharges occur, this flame velocity would be measured in the future[5].

4. Conclusion

In this study, we have seen that the stabilisation by nanosecond streamer discharges in double DBD running is possible. The effect of these discharges on the flowing velocity allows to have up to 80% of increase at constant distance between the exit of the injector and the base of the flame. The discharges power contribution in the total power of a such flame of methane is quasi-negligible (less than 1 W) in comparison with the burner power (10 $kW.m^{-3}$). The major objective for the improvement of this lifted flame stabilisation system rests on the possibility of high frequency discharges (more than 1 kHz) in the case of high flowing velocities. The use of such discharges system in industrial burner seems to be a good opportunity if the rise in frequency is feasible.

A pulsed UV source with a nanosecond streamer discharge in DBD running in a Ar-H_2 mixture

R. Delorme[1], P. Vervisch[1]

[1] *UMR 6614 CORIA CNRS, Saint Etienne du Rouvray, France*

Abstract

In this study, we have realized a pulsed DBD radiating source running in a Ar-H_2 mixture which can be suitable in particular in the wavelength region where usual Xenon and Mercury lamp are less efficient. The derived spectrum is a quasi-constant continuum from 188 nm to 350 nm with nevertheless a peak near 205 nm (uncorrected of the detection system spectral response). This radiation is associated with the dissociative transition of H_2 ($a^3\Sigma_g^+ \rightarrow b^3\Sigma_u^+$).

1. Introduction

Most of the commercial lamps, like Xenon or Mercury lamps, have discontinuous spectra with some typical radiations usable for a spectrometer calibration for example. As the emission of these lamps is continuous regarding the time, the utilization of this lamps is very easy and they have proved their qualities for emission measurements. But, in the case of absorption measurement in UV, a pulsed source prevents the contribution of the self emission of the studied medium especially if this one is strongly emissive. Furthermore, a feature less wavelength spectrum is more appropriate for absorption measurements in molecular bands especially in the UV range.

The use of a pulsed Dielectric Barrier Discharge (also named silent discharge) in a cylindrical configuration is of interest for several reasons :

- in cylindrical double DBD, the electrodes aren't directly in contact with the gas in which the discharge occurs. So the electrodes lifetime is increased. The contamination of the gas by evaporated electrode material is avoid [1]
- the construction of the discharge system is easy and is cheaper in comparison with other sources such excimer lasers
- the cylindrical configuration with a wire-to-wire discharge allows us to generate a plane of streamers in the axis of the cylinder
- the DBD is a non-equilibrium high-pressure gas discharge which generates energetic electron with 1-20 eV, low excited atomic and molecular species, free radicals and excimers with several eV energy [2]. These excimers can convert electron kinetic energy into UV radiation [3]
- non-toxic materials or gases are used in our configuration in comparison with some UV sources found in the literature [4], [5]. There is no risk for the environment and for the users
- the DBD can work at atmospheric pressure whereas the excimer lamps are usually sealed at low-pressure with all the disadvantages linked like the fragility of these lamps.

In the case of a wire-to-wire cylindrical DBD, the distribution of the streamers is quasi-uniform all along the space between the two wires whereas in the case of a corona discharge between two wires, there are privileged points where the discharges occur due to the inhomogeneity of the material constituting the electrodes.

We have realized, some years ago, a DBD source running with a power supply delivering 7 kV at 20 kHz [6]. In this source, the discharge is initiated between two fine metallic straight lines of 400 mm length painted on a quartz tube of 5 mm of diameter and 1 mm of thickness. This source was running in Ar to produce the third continuum of Ar_2* excimer. The brightness of this source was too low to perform absorption measurement in an emissive medium. To overcome this difficulty, another power supply has been developed to generate nanosecond high voltage pulses. Indeed, nanosecond high voltage discharges are more suitable since higher electric field can be applied. The large electric field energizes large number of electrons to high energy level. Those numerous energetic electrons lose very little energy in collision with gas atoms

and molecules because the electron mass is very small in comparison to typical molecular mass. So the major part of their energy contributes to generate a large amount of excited states in the medium [7] [8].

2. Experimental set-up

The discharge cell is shown in Fig.1. It consists of a 260 mm length ceramic tube. The outer diameter is 11,9 mm for 1,95 mm thick. The length of discharge is l=130 mm. The tube has two opposite by diameter grooves in which are placed two fine wires (diameter 0,1 mm). The thickness of these wires is important because the electric field generated depends on the electrode curvature radius. The lowest the radius is, the highest the electric field is. The gap between the two electrodes is about 11 mm ± 0,5 mm. The windows are in MgF_2 due to their high transmittivity for λ>128nm [6].
The gases flows are adjustable for each gas, the typical range of Argon flow is from 0 to 20 l/min and that of Hydrogen is from 0 to 15 l/min. In fact, the Argon's flow is higher than the Hydrogen's, the best efficiency for a intense radiation is with 4 l/min of Argon and some tenth of litre of Hydrogen. The pressure at the outlet gas tube is ambient pressure.

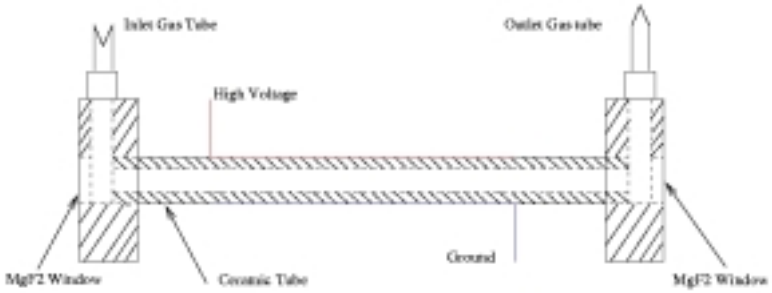

Fig.1. : Scheme of the discharge cell

The nanosecond pulsed discharge, between these two electrodes across the dielectric, is generated by an home-made Marx generator, for which the electrical scheme is presented in the Fig.2., linked with a continuous power supply.

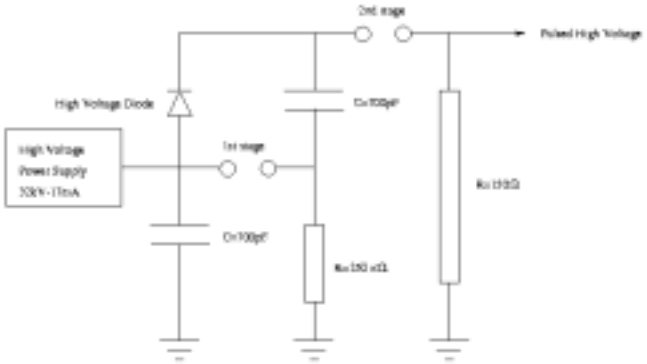

Fig.2. : Electrical scheme of the Marx generator

The principle of this Marx generator is simple, the two capacitors are charged in parallel by the 0-32 kV, 0-17 mA power supply. When the capacitors are sufficiently charged, the dielectric gas (Nitrogen in our case) in the first stage becomes ionised and so conducting. As the potential across the second stage gap is twice the charging voltage, the dielectric gas in the second stage allows the breakdown and an high-voltage pulse is created with the typical characteristics showed in Fig.3.. This pulse has a typical rise-time below 10 ns (in this pulse, the rise-time is 8,9 ns), the FWHM of this signal is quite 40 ns knowing that the signal showed in Fig.3. is obtained by the mean on 64 pulses. This generator can have a maximum repetition rate up to 300 Hz.

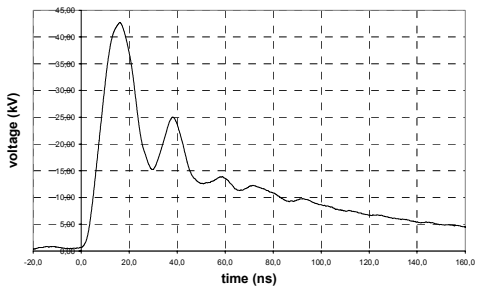

Fig.3. : Typical characteristic of the high-voltage pulse obtained with the Marx generator in Hydrogen and Argon

The discharge cell is imaged on the entrance slit of a Jobin-Yvon THR-1000 spectrometer (focal length 1000 mm, aperture f/7.5 , grating with 4320 grooves/mm) on which is mounted a fast photomultiplier Philips XP-2020Q linked with a digital oscilloscope Tektronix TDS-7104 (1 GHz, 4 channels, 10 Gsamples/s, 500 kpoints on 4 channels) which allows us to have minimal time resolution of 400 ps/point when all the channels are used. The voltage is measured with a capacitive probe Effitech with a time resolution below 1ns. The current measure is realized with a pulse current transformer Stangenes 0.5-1.0 (rise time of 10 ns) between the cathode and the ground. These two probes are linked to the oscilloscope. The mixture of the Argon and the Hydrogen is realized upstream the discharge cell. The control of the grating's displacement is realized by a Spectralink (displacement precision 0,001 nm in wavelength). The experimental set-up is showed in the Fig.4..

3. Results and discussion

With this arrangement, the cathode current and so the injected energy in the discharge can be measured. Their characteristic are showed in Fig.5.. The signals are obtained by the mean on 64 pulses.

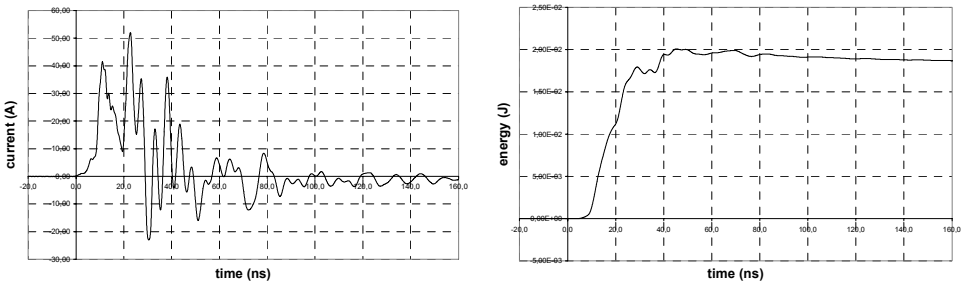

Fig.5. : Typical characteristic of the cathode current and the injected energy obtained with the Marx generator in Hydrogen and Argon

The characteristics of this discharge are 42 kV max., 50 A max., 20 mJ max..

With

$$Q = \int_0^{t_{max}} I dt \,, \tag{1}$$

the calculated number of charges injected in the discharge is typically 0,5 µC.

The O_2 Schumann-Runge bands of ambient air strongly absorb VUV radiation. So, the wavelength range studied in this experiment starts from 185 nm and stops at 350 nm due to the grating used. The Schumann-Runge bands can be clearly seen in the spectrum up to 195 nm due to their absorption.
The generation of a continuous spectrum in wavelength with this source has been obtain after some tries with other gases added to the Argon. The Hydrogen is the only gas which permits us to success in our research.
The technique for the realization of a spectrum in this range with a pulsed source is quite different than in the case of continuous source. In continuous source, generally, a continuous photomultiplier is used and the signal is send to a drawing table or a recorder. The grating's monochromator is displaced all along the wavelength range in one time with a constant velocity and the spectrum is easily obtained. But in our case, the fact that this source is a pulsed source doesn't allow us to use this technique. The digital oscilloscope has a function of curve recorder called Fast Frame. With a program, it is possible to extract the features of this curve like the maximum, the minimum, the area between two cursors, etc... Fig.6. shows a typical characteristic of the impulsional photomultiplier signal response in the case of a detected radiation, the interesting part due to the radiation is gated within the vertical cursors. On this figure, the signal noise is due to electromagnetic perturbations induced by the proximity of the Marx generator which is bad isolated. Here the signal level detected by the photomultiplier is far from the detection limit since typical voltage value is about 10 V.

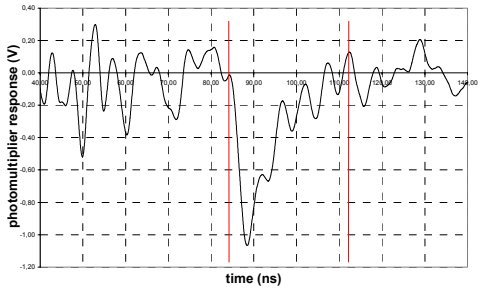

Fig.6. : Typical characteristic of the photomultiplier signal response

Fig.7. presents the spectral behaviour of this source filled by an Argon and Hydrogen mixture. Present results were performed with a 0,01 nm spectral resolution.

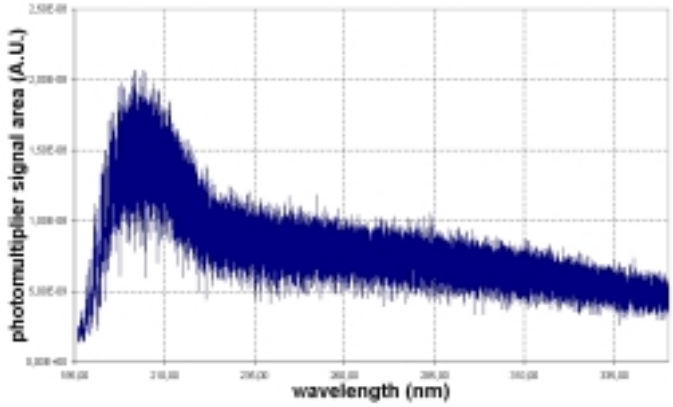

Fig.7. : Spectrum of the pulsed UV source in DBD running in Argon and Hydrogen

The noisy aspect of this spectral behaviour is due to the generation principle of the radiations. Between each pulse generated by the Marx generator, the level signal fluctuates. This fluctuation is one of the parameters which would be resolved in the optimisation of the source. The derived spectrum has a quasi-continuous

aspect regarding the wavelength behaviour from 185 nm to 350 nm with nevertheless a peak near 205 nm. With our system, a delay appears between the rise's beginning of the high voltage pulse and the detection of the radiation, this delay is equal to 95 ns. It is necessary to cut out from this delay, the photomultiplier's delay of optical-electrical conversion equal to 28 ns and the delay of signal transmission from the photomultiplier to the digital oscilloscope (7 meters of cable : 42 ns). The final temporal shift between the rise's beginning of the high-voltage pulse and the detection of the radiation is equal to 25 ns. The duration of this detection signal depends on the rate of Hydrogen in Argon, in the case of the mixture who presents the maximum effect, this duration is equal to 15 ns. This type of spectrum has been also realized with Fast Ionization Wave at a pressure of 10 Torr by Pancheshnyi [9].

This spectrum is issue from the dissociative transition of H_2 ($a^3\Sigma_g^+ \rightarrow b^3\Sigma_u^+$) which presents a continuum from 160 nm to 500 nm [10], [11]. Fig.8. presents this transition.

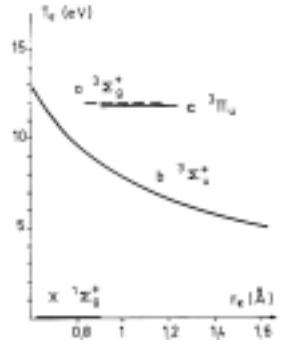

Fig.8. : Electronic states of Hydrogen (— metastable ---- radiative) [11]

In pulsed DBD, some electrons have sufficient energy to overlap the energetic range of the Argon metastable excitation cross section as showed in Fig.9..

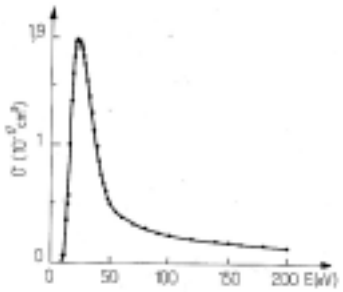

Fig.9. : Argon metastable excitation effective section [11], [12], [13]

In our configuration, the $a^3\Sigma_g^+$ level is over populated by excitation transfer with metastable level of Argon as showed in equation (2).

$$Ar\ (^3P_2, {}^3P_0) + H_2 \xrightarrow{k_{2Q}} Ar + H_2^* \qquad (2)$$

4. Conclusion

This study shows the interest of this nanosecond pulsed UV source to generate a quasi-continuum spectrum from 185 nm to 350 nm due to the dissociative transition of H_2 ($a^3\Sigma_g^+ \rightarrow b^3\Sigma_u^+$). The use of a pulsed Dielectric Barrier Discharge in a cylindrical geometry allows to have several possibilities of tests like the kind of gas injected, the flow of these gases, the electrical characteristics of the discharge... The only limitation is the detection of radiations below 180 nm which imposes to realized an arrangement under vacuum in order to avoid the Schumann-Runge bands. Several tests are in progress to enhance the source efficiency and stability, in particular, by delaying the mixture with a buffer gas to limit the collisional quenching of the concerned excited states.

Abstract: The non-intrusive optical emission spectroscopy (OES) and degenerate four-wave mixing (DFWM) spectroscopy, in the backward phase-conjugate (PC) geometry, have been used in local studies of low-temperature plasma generated in a free-burning arc. The semi-empirical model of the PC-DFWM that relates DFWM signal intensity and plasma parameters has been worked out and successfully applied to plasma diagnostics and line profile measurements.

1. Introduction

The concept of local thermodynamic equilibrium (LTE) plays the crucial role in research of atmospheric-pressure thermal plasmas. That is because the knowledge of one parameter, i.e. electron temperature, allows for determination of all other plasma parameters what is particularly simple in case of one component plasma. However, in order to take advantage of the LTE, first the state of plasma must be verified experimentally. This, in turn, requires two independent parameters to be measured with reasonable spatial and, in the case of pulsed plasmas, temporal resolution.

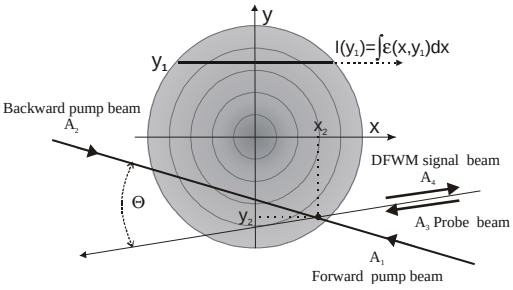

Figure 1. Principles of the OES and the PC-DFWM spectroscopy.

Investigations of the atmospheric arc plasma are mostly based on the OE spectroscopy. A simple experimental set-up and non-intrusive measurement are its major advantage. On the other hand, only intensity integrated along a line of sight can be directly measured and local values of emission coefficient can be obtained exclusively for layers either homogeneous or with cylindrical symmetry by Abel inversion. The legitimacy of application of the OE spectroscopy is questionable in studies of the vicinity of electrodes where plasma symmetry strongly depends on the position of the cathode spot on the electrode surface as is the case for free burning arcs. Moreover, this region of the discharge is highly influenced by the flow rate of gas and deviations from the LTE state have been already reported by many authors [6, 7]. All of these observations were carried out using the OE spectroscopy. In the light of the foregoing discussion alternative and complementary methods are necessary for comprehension of plasma processes.

The application of high spatial and temporal resolution laser-based methods such as laser induced fluorescence, laser collision induced fluorescence or saturation spectroscopy to investigate dense plasmas is impossible because of the relatively high elastic and inelastic collision rates and high photon emission of the plasma. The signal to be detected would be destroyed either by velocity changing collisions or the non-radiative decay of the excited atoms or would disappear in the background of the strong plasma radiation. Application of Thomson scattering method, well established in the field of Tokamak plasmas, however leads to strong plasma disturbance and can result in misinterpretation of the results as it has been recently showed by Murphy [1].

We developed the PC-DFWM method in application to low-temperature plasma with electron collisions to be the dominant processes responsible for depopulation and line broadening. We report on investigations of an argon plasma generated in a free-burning arc using PC-DFWM method at the wavelength corresponding to the 4*s*[3/2]^{o}-4*p*'[1/2] ArI transition (696.543 nm). DFWM spectroscopy with high spatial resolution was used to measure the Stark shift of the line and, independently, to obtain the plasma temperature. The latter was determined using the relationship between DFWM signal intensity and plasma parameters assuming LTE. The results of plasma diagnostics obtained by PC-DFWM methods are compared with those obtained using the OES as described by Pellerin *et al.* [6] and Pokrzywka *et al.* [8].

2. Degenerate four-wave mixing in application to plasma studies

Degenerate four-wave mixing (DFWM) is a nonlinear optical process involving three laser beams of frequency w, which interact through the nonlinearity of a medium to generate a fourth, signal beam, at the same frequency.

We deal with DFWM in the backward phase-conjugate (PC) geometry where the probe beam of amplitude A_3 crosses the two counter-propagating (forward and backward of amplitudes A_1 and A_2, respectively) pump laser beams at an angle q (see Fig. 1). Such configuration satisfies the phase-matching relations for all angles q and makes the spatial resolution of the method to be limited only by dimension of the laser beams. The signal beam, phase-conjugated to one of the incident laser beams, is highly collimated and so can be readily distinguished from the plasma radiation. Moreover, the Doppler broadening effect is significantly reduced because only atoms resonantly interacting with all laser beams contribute to the signal.

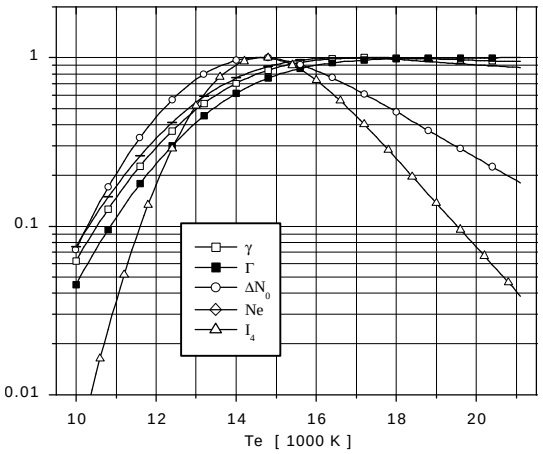

Figure 2. Temperature dependence of atomic and plasma parameters as well as DFWM signal intensity calculated for atmos. pressure argon plasma in LTE. The relative values are shown.

The details concerning the model of PC-DFWM as applied to thermal plasma are given in thesis by Bratasz [2]. Briefly, it assumes the PC-DFWM configuration for an open two-level system of resonance frequency w_0, in an optically thin medium. It considers three laser beams of arbitrary intensity and of linear and parallel polarizations interacting as in Fig.1. The standard formalism of the time dependent density matrix was used to calculate the total polarization of the system irradiated by laser beams. The atom is described by the dipole moment m of the considered transition while an influence of the plasma is described by coherence, g, and population, G, decay rates.

Under above assumptions and for laser beams of equal intensities a semi-empirical expression for the PC-DFWM signal intensity, I_4, has been derived and it reads:

$$I_4(d) \propto (m\,\Delta N_0)^2 \,\frac{\Gamma}{g}\left(\frac{1}{1+d^2}\right)^p \left(\frac{I}{I_{sat}}\right)^p \qquad (1)$$

The p-index equals 3 at low laser intensity limit in accordance with other works, for instance of Abrams *et al*. [3]. On the other hand, at intermediate (close to the saturation intensity) and high laser intensities, the p strongly depends on the pulse shape. And it can vary between 0 and -1. In Eq.(1) we denote laser intensity $I = e_0 c h^2 A^2/2m^2$, the saturation intensity $I_{sat} = e_0 c h^2 g\Gamma/2m^2$ and the dimensionless laser detuning $d = (w_0 - w)/g$. The g and G decay rates in the case of a medium dominated by electron collisions are expressed as

$$g = \frac{N_e}{2}\left(k_1(T) + k_2(T) + k_{el}(T)\right), \qquad \Gamma = \frac{N_e}{2}\,\frac{k_1(T)\,k_2(T)}{k_1(T) + k_2(T)}. \qquad (2)$$

The temperature dependent rate coefficients, $k_n(T)$ and $k_{el}(T)$, stand for the electron velocity averaged cross sections for depopulation of level n and inelastic electron collisions, respectively. Finally DN_0 stands for the equilibrium population difference in the absence of laser beams while N_e denotes electron density. The depopulation rate coefficients, $k_n(T)$ for the involved ArI levels have been calculated by Pokrzywka [4]. DN_0 and N_e as a function of electron temperature T were calculated under conditions of atmospheric-pressure argon plasma in the LTE and their relative values are presented in Figure 2 together with coherence, g, and population, G, decay rates. The p-index was experimentally determined based on the saturation curve (signal intensity versus laser intensity for d=0) to be 0 at intermediate laser intensities over about one order of magnitude of the saturation parameter (I/I_{sat}). The temperature dependence of the PC-DFWM signal intensity, I_4, was then calculated using Eqs.(1) and (2) and is shown in Figure (2). It is characterized by a local maximum at plasma temperature around 14700 K.

There are some reasons to use high instead of low laser intensities for determination of plasma temperature: 1) the PC-DFWM signal is stronger therefore the sensitivity of the method is higher, 2) the signal is almost independent on the laser intensity what results in smaller uncertainties due to possible laser intensity fluctuations, and 3) due to the large power broadening (larger than expected Stark shift of the

investigated line) the PC-DFWM signals measured at a given laser frequency and at different plasma regions can be directly compared without corrections for the Stark shift of the spectral line.

3. Experimental arrangement

The experimental setup is presented in Figure 3. Details concerning the experimental arrangement can be found in the paper by Dzierzega *et al*. [5]. Briefly, the arc discharge was generated between a conical thoriated-tungsten cathode tip and an anode in the form of a disc. The arc was operated in argon at atmospheric pressure and powered by current of 100 A and the flow of argon was maintained at 4l/min.

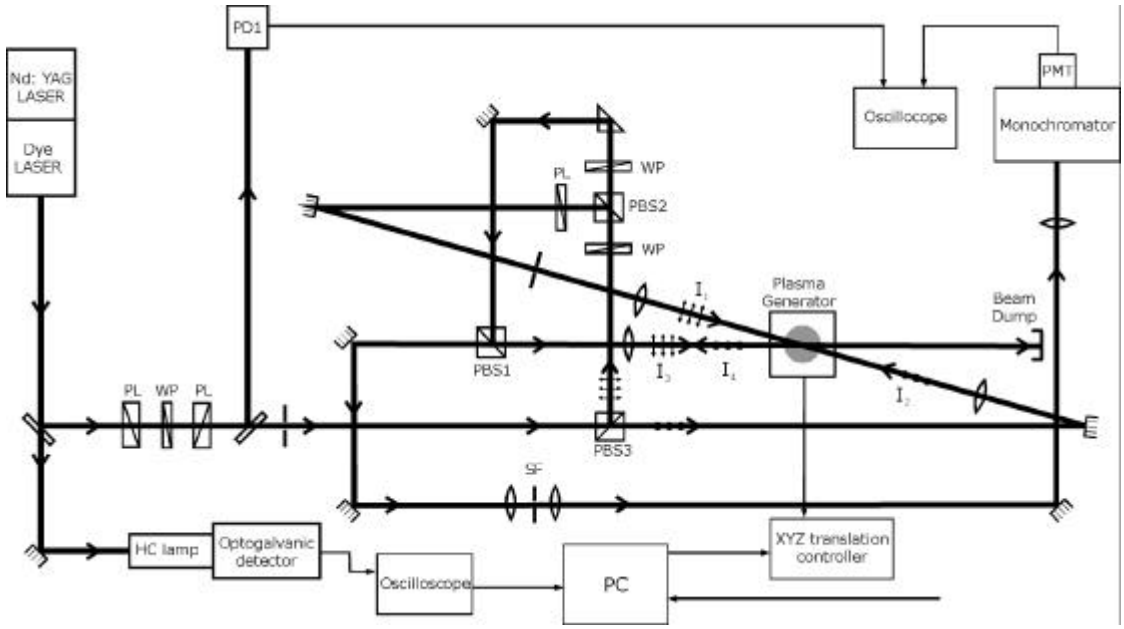

Figure 3. Experimental setup.
PD – photodiodes, WP – waveplates, PL – polarizers, PBS – polarizing beam splitter cubes, PMT – photomultiplier tube.

A tunable dye laser was pumped by the second harmonic of a Nd:YAG laser with 10 Hz repetition rate. The dye laser provided 8 ns pulses of about 10 mJ energy with a spectral bandwidth less than 0.03 cm^{-1}. The output beam of the dye laser was split into three laser beams of equal intensities with the backward pump beam polarized perpendicularly to the other two beams. The 500 mm focal length lenses were used to focus the laser beams at the plasma symmetry axis with a waist diameter of less than 0.2 mm. Two counter-propagating pump beams crossed with the probe beam at an angle of 300 mrad. The generated PC-DFWM signal I_4, propagated backwards along a probe beam path. It was then transmitted through a polarizing beam splitter cube and so separated from the probe beam reflections. The prism monochromator discriminated the signal from the background of plasma light. The signal detection was performed with a fast photomultiplier placed behind the exit slit of the monochromator and directly connected to a digital oscilloscope. The dye laser wavelength was calibrated with an argon hollow-cathode lamp (HC) using an optogalvanic detection system. Signals were averaged over 25 to 100 laser shots and then integrated over a time period of 30 ns.

4. Results

4.1. Spatial distribution of the PC-DFWM signal at high laser intensities

The measurements were performed with laser power density set as to satisfy condition of $p = 0$ in entire plasma volume being investigated. Figure 4 shows the relative PC-DFWM signal intensity versus the distance from the cathode tip, i.e. along the arc axis. This axial distribution reveals maximum at about 2.5 mm from the cathode which we consider as the maximum signal for argon plasma in the LTE (see Fig.2). Assuming LTE all along plasma axis the plasma temperature was then determined it ranges from about 12000 K et the anode side up to 19500 K in the vicinity of the cathode (see Figure 4).

Similar measurements of the PC-DFWM signal intensity distributions were performed in direction perpendicular to the arc axis at different distances from the cathode tip (see Figure 5). These profiles reveal off-axis maxima when measured close to the cathode. However, these maxima are lower than predicted by the theoretical model assuming LTE what we attribute to deviation of our plasma from the LTE in these regions, as it was already observed by many authors, for instance by Haidar [6] and Pellerin *et al.* [7]. At the

edge of the plasma column (about 2mm apart from the axis) the PC-DFWM signal intensity drops by a factor of 10 with respect to the maximum value. This, in turn, corresponds to plasma temperature about 11500 K as can be inferred from Figure 2.

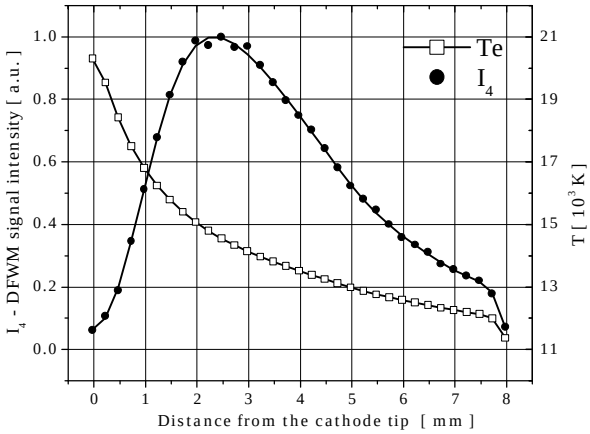

Figure 4. The axial distribution of the PC-DFWM signal intensity (I_4), and electron temperature (T) as determined from the above signal distribution and LTE plasma model.

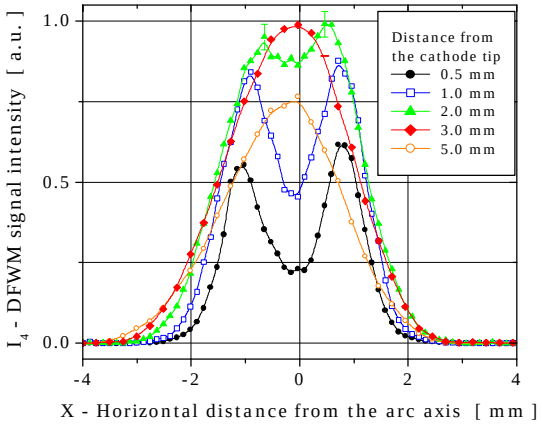

Figure 5. The axial distributions of the PC-DFWM signal intensity measured at different distances from the cathode tip. Arc discharge operated at 100 A and Ar flow maintained at 4l/min.

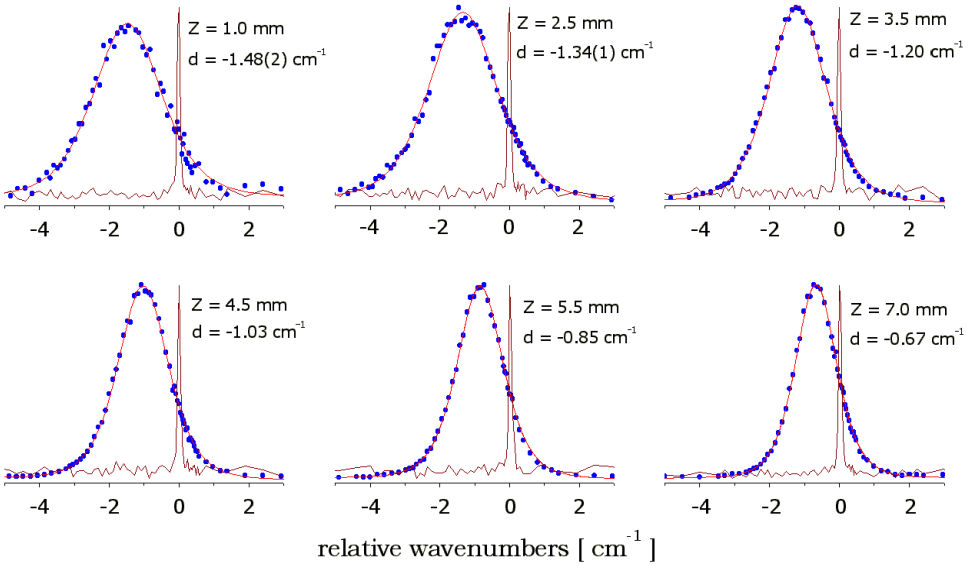

Figure 6. The spectral profiles of the PC-DFWM signals measured at different distances from the cathode tip and at low intensities of laser beams.

4.2. Stark profile measurements at low laser intensities

The other method commonly used in thermal plasma diagnostics is by measuring the Stark profile parameters of spectral lines which are independent on the plasma model assumed. These measurements are almost exclusively based on the OES and so the same problems with data analysis are encountered as already discussed.

We propose the PC-DFWM spectroscopy as the new method in studies of Stark profiles. The PC-DFWM spectrum was simultaneously measured with the HC spectrum at low laser intensity and then it was fitted with the Lorentzian profile to the third power according to Eq.(1). The line shift, d, was determined with uncertainty of 0.01 cm^{-1} as the difference between the fitted resonance frequency and frequency of the maximum of the HC spectrum. Unlike the Stark shifts, the measured line widths were influenced by laser (even at low laser intensities), and their determination needs first a few measurements at different laser intensities and next the real Stark width can be determined as the extrapolation to the zero laser intensity. Figure 6 shows the PC-DFWM spectra measured at different distances from the cathode and on the arc axis. The experimental data points are shown together with the fitted profiles (red curves) and the HC signal intensity.

Figure 7a shows the Stark shifts determined at different plasma regions as a function of electron density while Figure 7b presents the same but normalized (to N_e=10^{23}m^{-3}) Stark shifts, d_n, versus plasma temperature. All data below 12000 K correspond to the region of plasma edge (from at least 1.5 mm from the plasma axis). The significant change of d_n below 12000 K only indicates underestimation of electron densities for these Stark shifts and so the departure of our plasma from the LTE state.

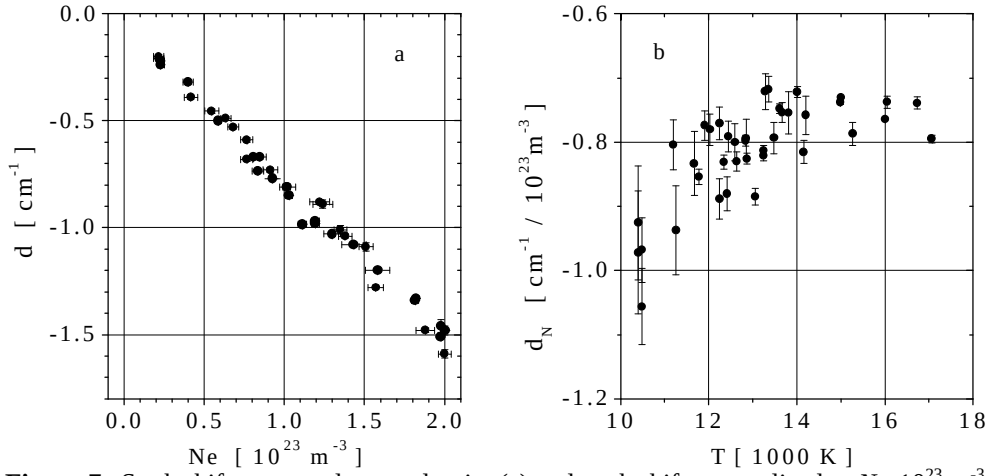

Figure 7. Stark shifts versus electron density (a) and stark shifts normalized to N_e=10^{23} m^{-3} versus electron temperature (b).

4.3. Comparison with optical emission spectroscopy results

The same plasma was studied using OES. Plasma column was observed side-on and at different distances from the cathode tip. Argon line profiles and continuous emission were measured at various chordal positions to perform Abel inversion. Plasma diagnostic was performed by various methods applied to ArI, ArII and ArIII lines assuming LTE state [6, 8]. For example, the total intensity of a spectral line is a function of one parameter: namely the temperature, and always reaches maximum value at so called norm temperature. This fact is a principle of the Larentz-Fowler-Milne method of temperature determination, and was already used for plasma diagnostic by the PC-DFWM method.

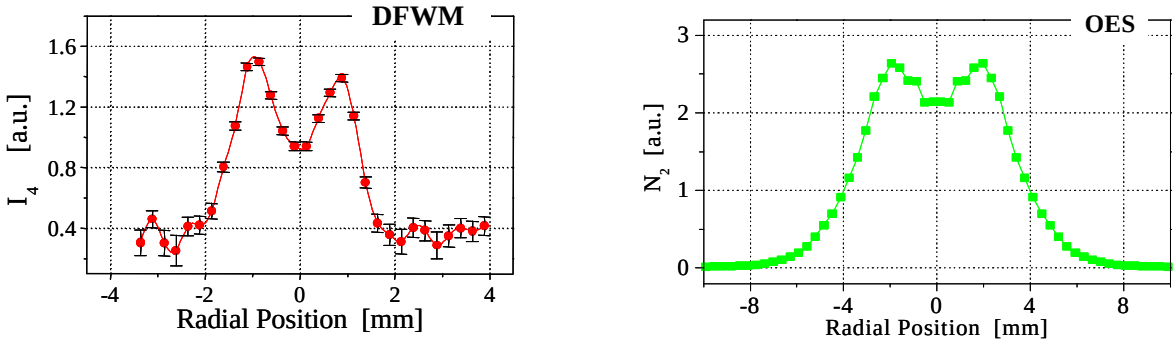

Figure 8a. Radial distributions of DN_0 and N_2 obtained using DFWM and OES methods
Arc discharge operated at 90 A and Ar flow maintained at 4l/min; z=0.75mm from the cathode tip.

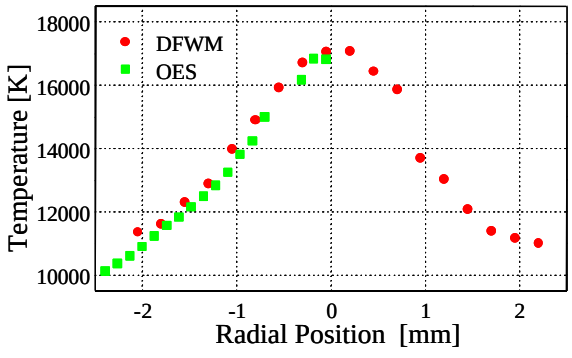

Figure 8b. Radial plasma electron temperature distributions obtained using DFWM and OES methods
Arc discharge operated at 90 A and Ar flow maintained at 4l/min; z=0.75mm from the cathode tip.

Comparison of radial distributions of PC-DFWM signal intensity I_4 and N_2 obtained by OES method measured at distance z=0.75mm from the cathode tip in an arc discharge operating in pure argon (4l/min) at 90A is shown in Figure 8a. The corresponding plasma electron temperature distributions are shown in Figure 8b. It must be noted that the good symmetry observed by OES is due to the Abel process that impose a forced symmetrisation of the data. Nevertheless, the final temperature obtained with these two methods agree very well (on the error bars), even if the DFWM method underlines a real asymmetry of the plasma column.

Moreover, we observed that intensity of the off-axis maximum for neutral argon lines, varies with the distance from the cathode tip, and remains constant for distances greater than approximately 2.5mm. Very similar observations are done with the DFWM spectroscopy [See Figure 5]. From our extended analysis, one can conclude that the arc plasma near the cathode tip shows radial dependence of the physical equilibrium state. Particularly, the Olsen-Richter (O.-R.) graph based on ArI and ArII lines [6, 8], shows that, in the hot core, close to the arc axis, the plasma is in the LTE state, and in the outer zones, the plasma state deviate from the LTE state at p=1atm.

For plasma column layers (slices) closer to the cathode tip, deviation from the LTE state begins at smaller distance from the axis and for higher temperature, even if the electron density is greater than $1.5\times10^{23}m^{-3}$. This deviation from the LTE state decreases with the axial distance from the cathode tip and practically vanishes for z>3mm. It can be caused by an overpopulation of the ArI ground state, that may be quite high. The dominating impact on the ArI ground state overpopulation is the inward transport of the ground state atoms into the plasma column due to the fast flow of the plasma near the tip. Our theoretical estimations of the ArI ground state overpopulation give results consistent with experiment [8].

5. Conclusions

We have reported on the application of the degenerate four-wave mixing (DFWM) method to Stark width and shift measurements of the 696.543 nm ArI line in LTE arc plasma. The DFWM spectroscopy has been used not only for line profile measurements but also for plasma diagnostics.

The DFWM signal is originate from a very limited region of the medium (only due to the dimensions of the laser beams) and so makes the DFWM method to be the method of high spatial resolution. This feature is especially important when one compares the DFWM to an optical emission spectroscopy (OES). The latter one commonly used in plasma investigations directly gives only some global, spatially integrated parameters and their local values are calculated under assumption of the axial symmetry of the plasma column and applying the abel inversion procedure.

At high laser intensities, the relationship between the PC-DFWM signal intensity and plasma temperature has been experimentally determined and then used in plasma investigations. The results of plasma diagnostics by DFWM have been compared to those by commonly used OES method. Particularly, our studies of free-burning argon arc plasma show spatial dependence of plasma state both using the PC-DFWM and OES. In the main core we can conclude that our plasma is in the LTE state and deviates at outer zones and that deviation starts to be significant at smaller distances from the axis in the cathode region.

In the range of low laser intensities the measured line profile is approximated by the Lorentzian profile to the third power with the line width depending on laser intensity and with negligible Doppler broadening. The results of this work imply the DFWM method to be reliable in Stark profiles studies, and especially in the determination of the Stark shift. The method can be particularly recommended in the case of elements with large Doppler broadening and for plasmas with the lack of symmetry. The DFWM method with its high spatial and temporal sensitivity can serve as an excellent tool for further plasma investigations.

Plasma conversion of waste, which is not useable for gasification

D. Bendix[1], D. Hebecker[2]

Abstract

Plasma waste conversion has established applications in special fields or single situations of waste conversion. A new application field for plasma technology could be the conversion of waste material, which is not suitable for gasification or hinders the efficiency of incineration plants. According to this investigation, a plasma plant was in operation for six months parallel to the rotary kiln of an incineration plant. It has been shown that there is no aspect, which would exclude this technology from industrial applications in general.

1. Introduction

Modern incineration plants are designed to process nearly all kinds of municipal and industrial waste. They are able to feed-in about 15% of the primary energy, energy included in the waste material, as electrical energy. The reasons for these low conversion rates are mainly economical. An increase of the conversion rate would lead to a super proportional increase of investment costs because of the mixture of hot offgas after the incineration process. An increase of the efficiency would be possible, if almost only waste material that includes no materials that forms species which lead to high temperature corrosion would be incinerated. Better conditions for a higher conversion rate offer technologies, which produce in their first step a highly energetic offgas by dosage of the oxygen supplier understoichimetric. The high energy gas can be used in motors, turbines or combined processes. Such technologies are economically feasible, when they are specialized to limited sorts of waste materials. The conversion of waste materials, which are segregated after such a waste separation, could be a new application field for plasma technology.

2. Plasma technology for waste conversion

During the last 20 years, plasma technology has been applied to a limited area in the field of waste conversion. Since 1984 the plasma plant of the Swedish company ScanDust has recycled about 600.000t of filter dust from stainless steel production and about 300.000t of metals has been recovered. World wide, about 30 plants for plasma waste conversion have been put online since 1992. The application fields of these plants are niche-application (like filter dust and slag conversion, the disposal of medical waste), single application (conversion of a byproduct of a chemical plant) or temporary tasks (disposal of halogenated hydrocarbons, disposal of military waste). In these applications plasma technology has shown that it has reached an evolutionary level, which would allow a wider range of industrial use. Otherwise, they have shown some difficulties in the operation of plasma waste conversion systems. There are some publications, which show using emission analyses, that plasma waste converters have the potential to produce dioxins and furans in higher concentrations than conventional techniques [01, 02]. An unexpectedly high concentration of dioxins and furans were also analyzed in the offgas of a small plasma reactor for waste conversion (on a laboratory scale) at the Martin – Luther – University. The radically change of the reactor atmosphere, the specific energy input and the mixing conditions of the model substance and reaction partners made only negligible changes in the concentration of dioxins and furans in the offgas. During the continuing search for other explanations for these unexpected concentrations, the specifics of this plasma-chemical waste conversion technology – the energy input by plasma jets – became the focus of the investigation. There are many publications that describe the movements of the anodic arc attachment in DC – plasma torches as the cause of unwanted phenomena in plasma spraying. The movement of the anodic arc attachment can be documented by voltage / current traces, by high - frequency changes of noise and light intensity of the plasma jet and by the erosion traces on the anode [03, 04]. The movement of the anodic arc attachment leads to a high – frequency change of the specific enthalpy and velocity of the plasma jet. Although the average

energy input would lead to the desired condition, which seems to be favorable for the process, the conditions in parts of the reactor close to the minima or maxima of the energy input could be favorable to the formation of unwanted species. Increasing the frequency and decreasing the amplitude will help to decrease the influence of the oscillations. This was achieved by a change of the power supply and some changes in the geometry of the plasma torch [05]. The schematic of the "back flow plasma torch" and the power supply can be seen in Figure 1. This combination generates a plasma jet with a lower amplitude and a higher frequency of the enthalpy fluctuations in comparison to a conventional plasma torch.

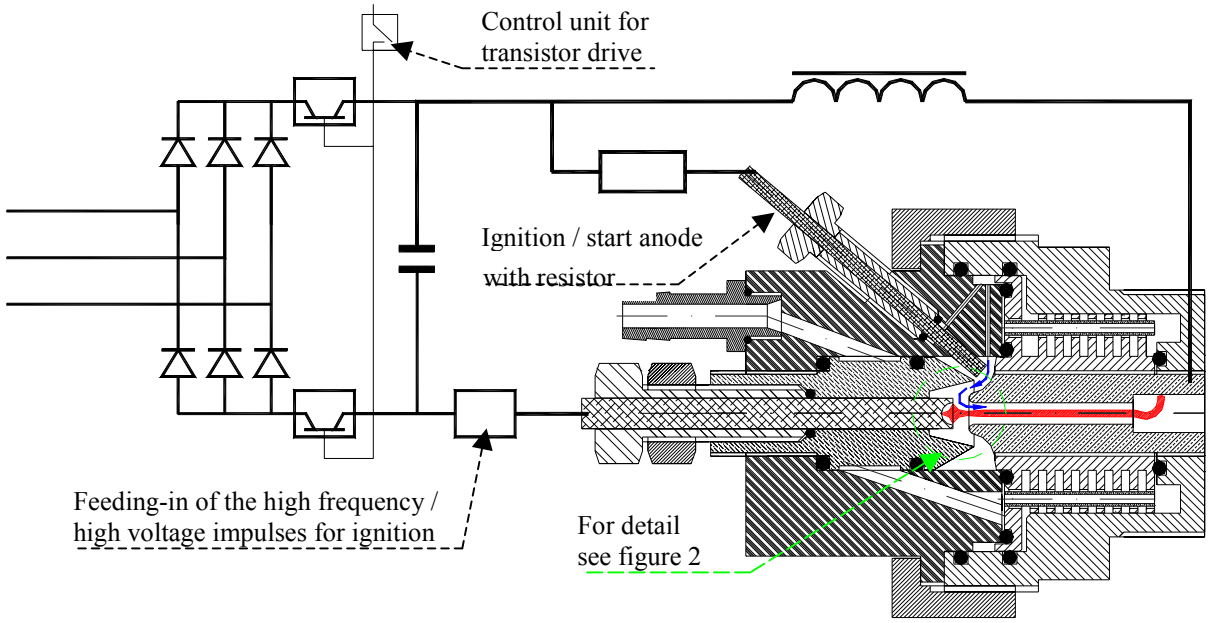

Figure 1 schematic of the "back flow plasma torch" and the power supply

Conventional power supplies for DC – plasma torches are built on the basis of thyristors. Since the possibility for closed loop control of the desired values with this technology is dependent on the commercial power frequency, the minimum damping period is in the range of 10ms. By using diodes and transistors for the power rectification, a minimum control time in the range of 0,1ms can be reached. The frequency of the fluctuations as a result of the movement of the anodic arc attachment is in the range of 1kHz. The power supply can now change the power input for the arc about 10 times during one large movement of the arc. The purpose of changes in the geometry of the plasma torch was to stabilize the arc as long as possible in the centerline of the anode and to decrease the erosion rate of the cathode material with the combination of reasonable cathode material (standard tungsten rods) and oxygen containing plasma gases.

Figure 2 shows the result of the evolution process of the design of the cathodic region. The swirling plasma gas (tangentially input) has a strong turnaround by decreasing the diameter of the passage. According to the conservation of the torsional momentum, the rotational speed of the plasma gas increases. An additionally strong axial symmetric swirl will be generated. In result of this axial symmetric swirl (shaped like a torus), there should be a velocity component inside the arc in the opposite direction of the global flow. That's why the torch was named "back flow plasma torch". A local limited axial symmetric area with a strong cooling of the arc will be formed in consequence of the flow regime. Furthermore a decrease of the arc diameter in this region can be observed (marked as $d_{arc\text{-}min}$). One effect of this is the aerodynamic focusing of the arc on the symmetry axis. Another effect is the generation of a secondary swirl close to the cathodic arc attachment. If the tungsten rod is new (flat top) this secondary swirl creates conditions for an increase of the erosion rate. As a result of this erosion a pit is formed. If the pit is deep enough, the gas volume in the secondary swirl is fixed, the mass transfer from the gas volume in the secondary swirl to the ambient gas will rapidly decrease. The concentration of tungsten vapor or volatile tungsten oxides will reach

equilibrium and the erosion of the cathodic material will be drastically decreased. Only during the arc ignition will tungsten be eroded until equilibrium is reached for the fixed gas in the secondary swirl.

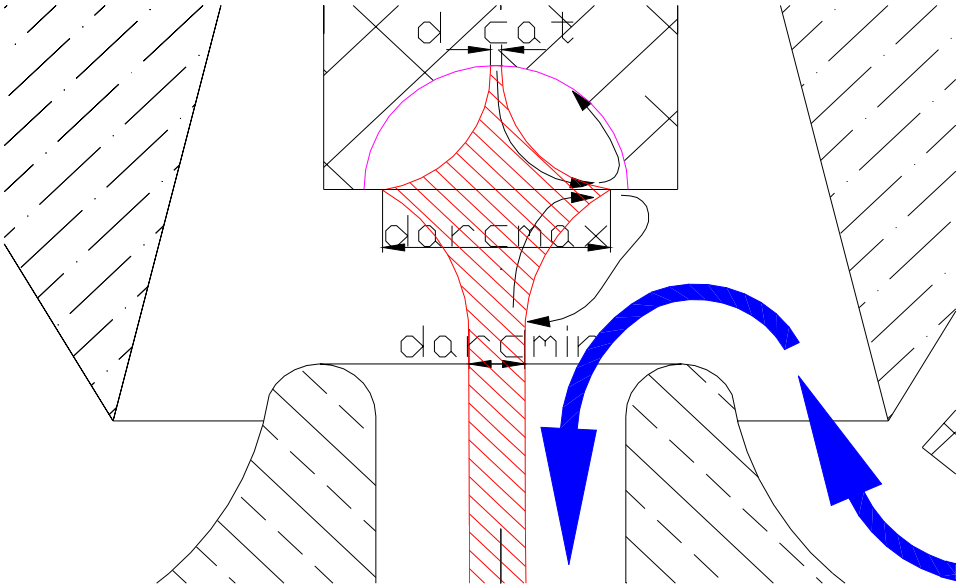

Figure 2 schematic of the cathodic region of the "back flow plasma torch"

The torch was tested with several plasma gases (mixtures: 10-100% N_2, 0-50% CO_2, 0-30%O_2, 0-15% water steam) with variation of the plasma gas volume flux and the DC-current. Figure 3 shows the power output (included in the plasma jet, P_{output}) and the power input (current x voltage, P_{input}) as functions of the plasma gas volume flux (1-5m³/h) and the current (30-100A) with nitrogen as plasma gas.

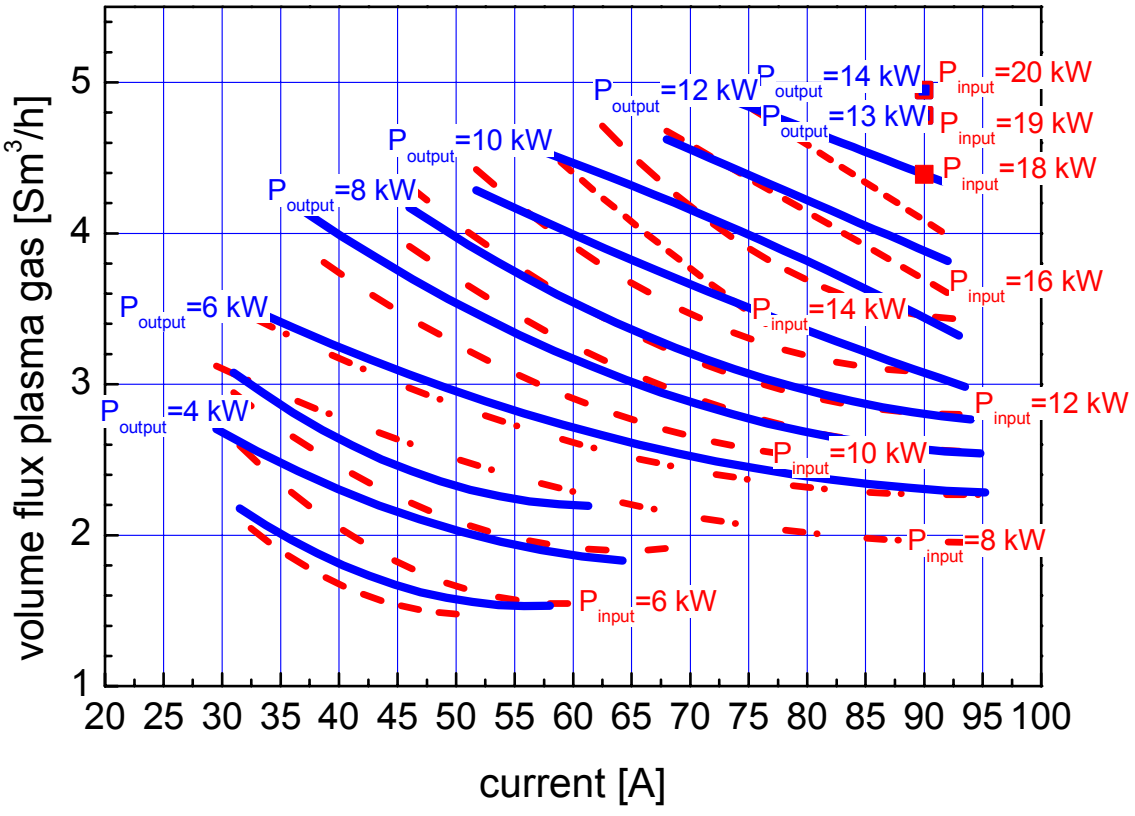

Figure 3 power output and power input
as functions of the plasma gas volume flux and current with nitrogen as plasma gas

A plasma plant with three back flow plasma torches parallel to the rotary kiln of an incineration plant was in operation for six months. The schematic of the plasma plant can be seen at Figure 4.

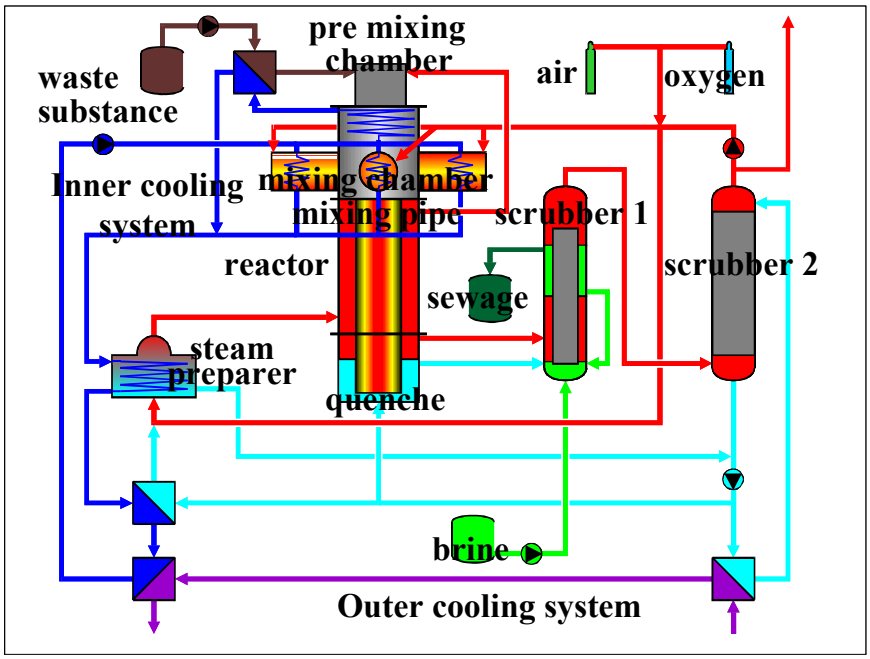

Figure 4 schema of the plasma plant

The waste substances (used organic solvents like propanol and trichloroethylene) are sprayed preheated into the pre mixing chamber. There they comes in contact with the reaction partners (and forms so the reaction system). In the mixing chamber the reaction system encounters the three plasma jets. After passing through a gas cooled SiC – reactor the reaction system is cooled down in the quench. After cleaning and further cooling in two scrubbers, most of the gas will be emitted, another part of the offgas is used as plasma gas and the third part of the offgas is conditioned with oxygen or air and steam to cool the reactor and to form with the model substance the reaction system in the premixing chamber. The mass flux of the waste substance was up to 35 kg/h, and the energy input was in the range of 4 to 15 kW per plasma torch. The plasma plant has shown that it is possible to convert highly chlorinated waste materials (like trichloroethylene) into harmless substances in compliance with all German emission limits. After 50 hours of operation the complete plant was disassembled. Investigation of the wear phenomena has shown that the interval for changing the anodes (this is easy to do in 2 to 3hours of work) should be 50 hours. The wear state of all other parts would allow continued operation. Figure 5 shows cathode and the cross section of an anode after 50 hours of operation time.

Figure 5 cathode new and after 50 hours of operation and the cross section of a anode after 50 hours of operation

3. Inclusion of the plasma technology in the energetic use of waste material

The use of this plasma plant parallel to the rotary kiln of an incineration plant for six months has shown that plasma waste conversion technology has reached a level of evolution, which would allow inclusion of plasma technology in the energetic use of waste materials. Municipal solid waste and industrial waste (in the following named as waste) are of interest for the energetic use. Landfilling is still the predominant way of disposal. In Germany, about 40% of the waste is used energetic or substantial (paramount in biologic - mechanical systems). Good conditions for a high efficiency energetic use offer technologies, which produce a high energetic offgas by dosage of the oxygen supplier understoichimetric in the first step and which use the high energetic gas in the second step in motors, turbines or combined processes. In Germany, there are three gasification technologies in commercial use for the conversion of ungraded municipal waste, which all have financial problems that hinder expansion. Such technologies have better favorable economical, if they are specialized on limited sorts of waste materials. The conversion of waste materials, which are segregated after such a waste separation, could be a new application field for plasma technology.

Operational data of gasification plants in comparison to conventional incineration plants would be convincing to show, that the integration of plasma technology has the potential to increase the efficiency of the energetic use of waste material. The comparison of incineration plants and gasification technology is still not serious, because the existing incineration plants are the result of a 100 years of extensive commercial experience – gasification plants are still the object of research and development. That's why it is more important to use data from real incineration plants, although there are still some unanswered questions left as well. The published data of the modern incineration plant Velsen (Germany, commissioned in 1998, [07]) and the experiences of the 6-month operation time of the plasma plant should be used for the discussion of the sense of plasma technology integration to improve the efficiency of the energetic use of waste. In 2001 206,319t of waste (m_{waste}) with an average heating value of 9,287kJ/kg (Hu_{waste}) were incinerated in the incineration plant Velsen. Besides this, energetic inputs were electrical energy ($P_{el.WI}$=29,527MWh), natural gas (14,637MWh for the catalysts) and fuel oil (392,975l to run up and rack out). A special valuation of the different kinds of energy can be spared, because the only useful energy was electrical energy (2001: $P_{el.netto}$=91,828MWh) and the fraction of fossil fuel (P_{fossil}) is small in comparison to the amount of energy input. The efficiency can be defined as:

$$\eta_{el.\,netto} = \frac{(\dot{m}_{waste} \bullet Hu_{waste} + P_{fossil} + P_{el.\,WI} - \dot{Q}_{offgas} - \dot{Q}_{reactor})\eta_{SP} - P_{el.\,WI}}{\dot{m}_{waste} \bullet Hu_{waste} + P_{fossil}} = 16.7\% \qquad (01)$$

Although the thermal losses of the offgas ($Q_{offgas} \approx 0{,}11 Q_{input}$) and reactor ($Q_{reactor} \approx 0{,}12 Q_{input}$) are average values compared to other thermal plants, the efficiency ($\eta_{el.netto}$) is rather low in comparison to power plants. The reason for this is the low efficiency of the steam process (η_{SP}), which is the result of the low live steam parameters (p=4MPa, T=673K). These low live steam parameters are chosen to diminish high temperature corrosion. The high temperature corrosion would be the result of the heat exchanger material reacting with some species (HF, HCl and other), which is inevitable if ungraded waste was incinerated. If waste materials (χ_{sep}), which include ineligible concentrations of precursors for the formation of species, which restrict the live steam parameters, could be disposed off in a separate way (plasma technology), the efficiency of the steam process in the incineration plant could be increased. The equation for the calculation of the efficiency of the energetic use of waste would have the following structure:

$$\eta_{el.\,netto} = \frac{(\dot{m}_{waste} \bullet Hu_{waste} + P_{fossil} + P_{el.\,WI} - \dot{Q}_{offgas} - \dot{Q}_{reactor})(1-\chi_{sep})\eta_{SP} - (P_{el.\,WI}(1-\chi_{sep}) + \chi_{sep}\,\dot{m}_{waste}\,\varsigma)}{\dot{m}_{waste} \bullet Hu_{waste} + P_{fossil}(1-\chi_{sep})} \qquad (02)$$

The experiments with the plasma plant have shown, that with a specific energy input (ς) of about 1kWh/kg a satisfactorily conversion rate can be reached. Figure 5 was calculated by using this data.

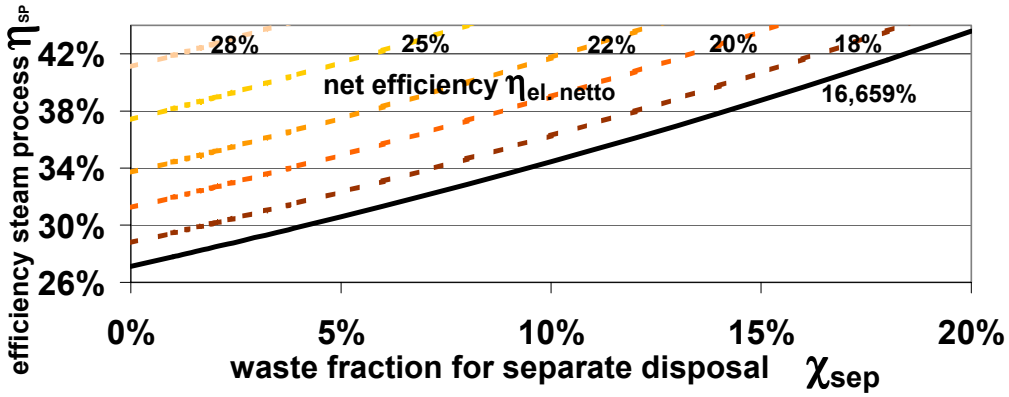

Figure 5 increase of the efficiency by inclusion of a separate disposal

The waste material is not homogenous. With the implementation of the separate gathering of material that can be recycled, the quantity of the waste was decreased and the composition had changed. In some countries the waste delivered to landfills or incineration plants is analyzed year by year to find out the efficiency of the separate gathering [08]. Published data of this "waste analyses" shows that in the atomic composition of the waste there are only about 3% elements, which restrict the live steam parameters. It is clear, that it is not possible to separate only these elements. Now investigations of the developer of incineration plants and waste separation / gathering systems have to show the coherence between the fraction that must be converted separately and scope for increasing the efficiency of the steam process in the incineration plant.

According to the present state of investigation, an increase of the efficiency by the energetic use of waste materials is anticipated by the inclusion of plasma technology in the waste conversion. The project was granted by "Deutsche Bundesstiftung Umwelt" Az:07061/02.

Multiphase processes at recovery of metals from halogenides by pulsed electron beam.

Kondratev N.A., Pushkarev A.I., Remnev G.E., Pushkarev M.A.

Research Institute of High Voltages, Tomsk, Russia.

Abstract

The results of experimental study of plasmachemical processes which are flowing past at injection of a high-current pulsed electron beam in a mixture of the gases $SiCl_4 + Ar + H_2$ and $SiCl_4 + O_2 + H_2$ are introduced. It is shown that in chain reaction initiated by high – current pulsed electron beam optimum conditions of formation nanosize powders are realized.

1. Introduction.

The analysis of plasmochemical processes which take place in gases at injection of pulsed high-current electron beam (HCEB) has shown, that the requirements which realized at stimulation of gases, are favorable to organize of chain and catalytic processes [1-3]. Thus the energy of HCEB constitutes small part of a total energy expended on carrying out of reaction. The unique properties of plasma generated at affecting of pulsed electron beam (a high scale of no equilibrium, homogeneous stimulation of large bulks of gas at high pressures, high speed of stimulation), allow realizing new physical principles of initiation of chemical reactions. To them the dissociation of oscillating - activated molecules, chain plasmochemical processes, plasma - catalytic reactions etc is referred. In plasmochemical processes of decomposition of industrial gases (CS_2, SO_2, CO_2, NO_2) and oxidation of hydrocarbons the power inputs of electron beam did not exceed 30% of dissociation energy of source molecules [1-3]. At recovery of tungsten from tungsten hexafluoride under HCEB affecting the power inputs of a electron beam did not exceed 5% of a dissociation energy WF_6 [4].

2. Experimental setup.

In report the results of analysis of dissociating processes of silicon tetrachloride gas-phase under affecting by pulsed HCEB are introduced. Parameters of electron beam - maximal electrons energy 500 keV, beam current in a maximum 6 kA, pulse duration at half-maximum 60 ns, pulsed frequency 2 Hz, current density on an input of a reactor no more than 0.4 kA/cm^2. The plasmochemical reactor is realize as a tube with an inside diameter 90 mm and length 300 mm, total volume 3 liters. Injection of electron beam in a reactor from butt end through a aluminium metal foil with thickness 130 microns. For definition of mix proportion of source gas mixture and products of reaction we have used a mass spectrometer MX-7304 and chromatograph GCHF18.3. An energy deposition of electron beam in gas and amount of energy allocated in reaction was measured on a pressure jump in a reactor [5,6]. Reactor beforehand pumped off up to pressures about 10^{-2} Torr and warmed up to 60°C, then filled up with studied gas.

3. Experimental study of $SiCl_4$ dissociation.

Variations of gas composition in a reactor with increasing of beam current pulses number are presented on fig.1 (mixture 30 Torr $SiCl_4$ + 120 Torr H_2 + 300 Torr Ar). The composition of mixture is determined by a mass spectrometer. With increasing of shots number the loss of silicon tetrachloride and creation of hydrogen chloride is recorded. In bulk of reactor the sad-colored powder was produced, which after letting-to-air in a reactor obtained white color. X-ray structure analysis of a powder has shown, that it is amorphous SiO_2.At beaming a mixture 30 Torr $SiCl_4$ + 120 Torr H_2 + 300 Torr Ar the energy HCEB which absorbed in gas, compounded 100 J for a one shot and was equaled of energy absorbed in a reactor, which filled argon or nitrogen at pressure more than 600 Torr. Let's estimate power inputs of an electron beam on dissociation of silicon tetrachloride. At a loss $SiCl_4$ on 40% for 30 shots (see fig.1) at 1 shot dissociates no less than $4.6 \cdot 10^{19}$ molecules of silicon tetrachloride (gravity $SiCl_4$ at 20°C and 200 Torr is equals to $2.15 \cdot 10^{-3}$ g/cm^3 [7]). As shown in proceeding [8], only about 20 % of electrons energy with energy more than 30 eV is spent for dissociative ionization. Is admissible, that the electrons interact only

with silicon tetrachloride, then the power inputs HCEB on dissociation of a one molecule $SiCl_4$ will make no more than 1.9 eV (upper bound).

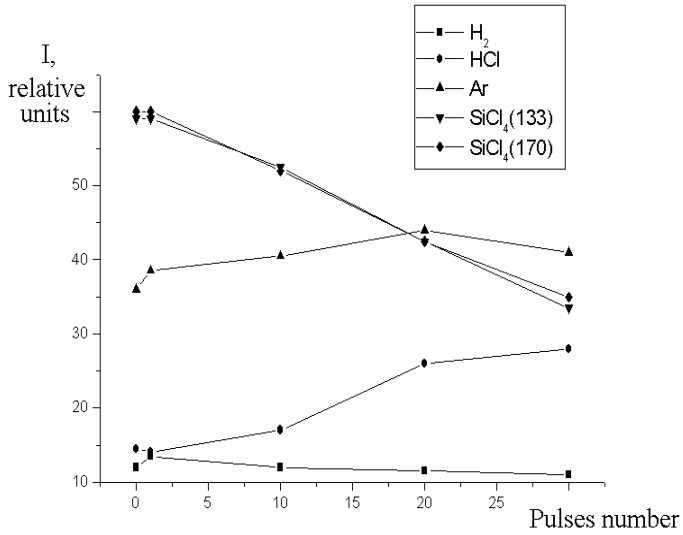

Fig.1 - Dependence of components content of a mixture in plasmachemical reactor as function of exposure.

The reason of anomalously low power inputs, it is essential smaller then dissociation energies of silicon tetrachloride (6.6 eV) at affecting a electron beam, is passing chain reactions in plasmachemical process. In jobs [9,10] for an explanation of low power inputs on dissociation CS_2, also is significant smaller than dissociation energies of carbon disulphide, the ion - radical mechanism is proposed, which one is initiated by process of dissociative adhesion of secondary electrons of beam to molecules O_2 and CS_2. CS radicals, generated at it, and atomic oxygen, reacting with source carbon disulphide, produce accordingly atomic oxygen and radicals CS, constructing a chain reaction.

In our case, at the expense of dissociation of silicon tetrachloride by electronic shock:

$$SiCl_4 + e \rightarrow Si + 4Cl \qquad (1)$$

and dissociative adhesion of low-energy electrons:

$$SiCl_4 + e \rightarrow SiCl^-_4 \rightarrow Si + 4Cl \qquad (2)$$

The atomic chlorine is formed, which initiates reactions in a mixture with molecular hydrogen. The major reactions are (similar to low-temperature homogeneous reacting of chlorine with hydrogen [9,11]):

$$Cl + H_2 = HCl + H + 0.05\ eV \qquad (3)$$

$$Cl + Cl + M = Cl_2 + M + 2.5\ eV \qquad (4)$$

$$H + Cl_2 = HCl + Cl + 2\ eV \qquad (5)$$

$$H + HCl = H_2 + Cl - 0.05\ eV \qquad (6)$$

The displacement of chlorine in $SiCl_4$ on hydrogen with formation trichlorosilane takes place at temperature 400°C at the presence of catalysts (aluminum or zinc) [7]. At injection HCEB in a mixture of silicon tetrachloride with hydrogen the temperature of gas increased not higher than 50°C, therefore loss $SiCl_4$ in reacting $SiCl_4 + H_2 = SiHCl_3 + HCl$ or $SiCl_4 + H \rightarrow SiHCl_3 + HCl$ or $SiCl_4 + H_2 \rightarrow SiH_2Cl_2 + HCl$ and so in our requirements is improbable. Chlorsilane was not detected in reaction products just after injection of HCEB. Other products of reaction, which one could enter to reacting with $SiCl_4$ in our

requirements and to reduce to its loss, are not formed. Therefore ion - radical mechanism of a chain reaction at injection HEB in gas-phased $SiCl_4$ will not be realized.

At analysis of making mechanisms of a chain reaction in our experiments are necessary to take into account the ion - cluster mechanism proposed in operation [12] for explanations of low energy expenditures on dissociation of methane on hydrogen and carbon at affecting pulsed - periodic microwave pseudo-corona discharge. Indirect endorsement of clusters formation in bulk of reactor is forming centers of the ruby laser ray dispersion at passing through bulk of a reactor (formation of a "track" of a laser beam in bulk of reactor) after injection of an electron beam. In a source working mixture "track" of a laser beam was not observed. Investigation of acoustical waves damping, which formed in a reactor at injection of a electron beam, has shown, that the absorption coefficient at a dissipation of a electron beam in vapor-phase silicon tetrachloride 12-19 times more, than calculation value under the formula which is taking into account damping of harmonic motions in a self-contained cylindrical reactor [6]. In a fig. 2 the dependence of an acoustical oscillating energy absorption coefficient in a reactor from pressure for different gases is presented.

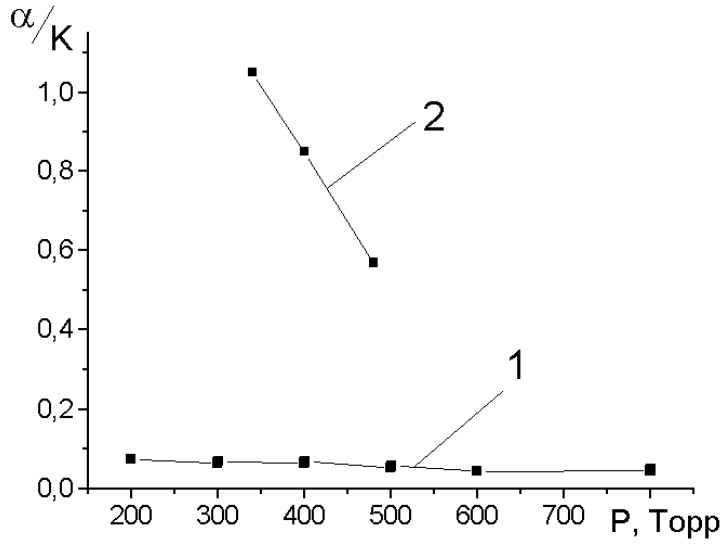

Fig .2 - Dependence of a normalized absorption coefficient of sound in reactor as a function of pressure. 1- Ar, O_2, N_2; 2 - $SiCl_4$.

For comparison of absorption coefficients in different gases the magnitude of coefficient was normalized on coefficient taking into account thermal properties of gases [6]. The dots in figure 2 will correspond to experimental data, curve 1 - to calculation under the formula which is taking into account absorption at reflex from butt ends of a reactor and side walls at propagation along a reactor [6]. For nitrogen, argon and oxygen the discrepancy of calculation and experimental values does not exceed 30%. The curve 2 will correspond to experimental values of an absorption coefficient at generation of acoustical waves in vapor-phase silicon tetrachloride. The considerable increasing of an absorption coefficient thus can be conditioned by formation of clusters in a reactor at injection of an electron beam.

The specific enthalpy of tearing off silicon atom from a metallic cluster equal 4.1 eV, is less than a dissociation energy of a one molecule $SiCl_4$. Therefore energy, selected at formation of a cluster from metallic silicon, is not enough for disintegrating $SiCl_4$ molecules that condense on this cluster. Combined exothermal reactions energy (3-5) and energy of formation of a metallic silicon cluster is most likely for dissociation of silicon tetrachloride molecules.

The carried out studies of dissociation of vapor-phase tetrachloride of silicon and the measuring of power inputs have shown, that at injection of a high-current pulsed electron beam the chain reaction will be realized. The joint action of the ion - cluster mechanism of a chain reaction and dissociation of oscillating - activated molecules with participation of disintegrating product in a exothermal reaction is most likely, because other mechanisms of making of chain process in our case can not explain balance of energy between power inputs on direct recovery of silicon and indispensable power inputs taking into account of number of the dissociated molecules $SiCl_4$ and dissociation energy of tetrachloride of silicon

4. Experimental study of SiO_2 nanoparticle.

It is shown in our experiments that in chain reaction initiated by high – current pulsed electron beam in a mixture of the gases $SiCl_4 + O_2 + H_2$ optimum conditions of formation nanosize powders are realized. In figure 3 the photograph of SiO_2 nanosize powders for mixture of the gases 140 Torr O_2 + 210 Torr H_2 and 1.5 ml $SiCl_4$ after one shot of high – current pulsed electron beam is shown. The photograph on transmission electron microscopy is obtain. The bar chart of this SiO_2 nanoparticle in fig.4 is shown.

5. Summary

The analysis of known mechanisms of chain reactions (radical mechanism, ion - molecular mechanism, catalytic mechanism and ion - cluster mechanism) demonstrates, that at time of halogenides recovery the considerable contribution is brought by energy of additional exothermal reactions and energy selected at coagulation of silicon atoms. It is illustrated, that in a chain reaction, initiated by a high-current pulsed electron beam, the optimum condition for forming nanosize particles will be realized.

Abstract
The type of the applied shielding gas has a strong influence on quality of the welding process. In particular, increase of the percentage of carbon dioxide in argon, results in increase of the transition current while changing from the globular to spray mode of metal transfer. In order to explain this phenomenon, the arc shape was investigated at different mixtures of argon and carbon dioxide in the shielding gas. As a result, we conclude that there is a limit of the percentage of relative concentration CO_2/Ar beyond which the shape of the arc is significantly modified.

1. Introduction

MIG ("Metal Inert Gas")/MAG ("Metal Active Gas") are the welding processes that utilize arc plasma between a consumable solid metal electrode and a weld pool. The upper wire-electrode, liquid metal transferring inside arc and weld pool are protected against air by inert gas flux in the case of the MIG welding, or active gas in the case of the MAG welding. These welding methods are used in all sectors of activity to assemble all grades of metal (ferric and non-ferric) in all positions. The schematic description of the welding torch is presented in Figure 1.

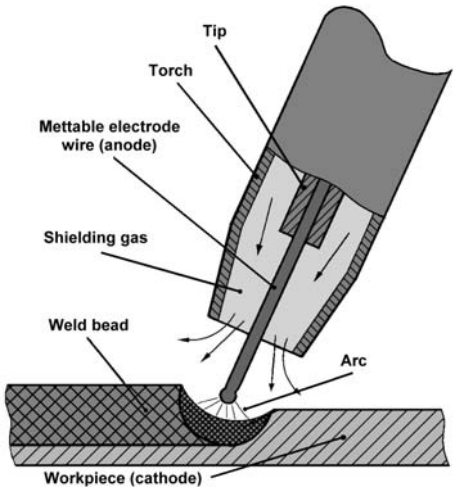

Figure 1: The welding torch

The most frequently used gases or gas mixtures are argon or/and helium in the MIG welding and carbon dioxide as well as various mixtures of these gases with CO_2, H_2, O_2, N_2 in the MAG welding. The MIG-MAG welding is usually performed with reverse-polarity direct current, where the melting electrode serves as an anode, what assures better arc stability.

The wire melting and the metal transfer in the arc can take place in three fundamental ways [1, 2]: short-circuit transfer ("short-arc"), transfer by large drop ("globular transfer") and axial spray transfer ("spray-arc"). The mode of the transfer depends on shielding gas type, dimensions and compositions of the wire electrode, electrode extension, arc voltage and current, and wire speeds. These three modes are characterised by different

arc stability, weld penetration, sputter of the melted metal, gas consumption and quantity of fume. Each of these modes has different applications, operating conditions and welding quality:

- In the ”short-arc” transfer, metal is deposited by series of short circuit resulting from regular contact between the electrode and weld pool. This type of transfer proceeds for low current intensity and relatively low arc voltage. After arc ignition, the tip of wire is being melt due to he resistance heating, and leads to the droplet formation. For these conditions, the electrode melting rate is not sufficient for the droplet detachment, and so melted metal is transferred from the wire to the workpiece during the contact period. Due to the relatively small heat transfer, short-circuit gas metal arc welding is used to weld thin metal plates in all positions.

- As the welding current is increased and the arc voltage is greater than in short-circuit mode, the melting rate rises and becomes fast enough to allow formation of large droplets. Then the pendant droplet size exceeds the electrode diameter and one observes metal transfer by large droplets (”globular transfer”). The electromagnetic force, gravity and other forces lead to drop detachment without contact between electrodes at a frequency of only few hertz. In general, globular transfer mode is difficult to use in practice because it is unstable and accompanied by considerably weld sputter.

- A gradual increase of the current intensity and arc voltage accelerates the melting rate of the wire electrode and subsequent transition to the axial spray transfer mode (”spray-arc”) is observed. The droplets have a diameter smaller than the wire’s diameter and a tapering tip forms at the end of the electrode. When the arc current exceeds a given limit (transition current), the frequency of the droplet detachment increases sharply to the value over 100Hz. This mode insures maximum arc stability and minimum spatter.

2. Shielding gas effect

The type of shielding gas has a major importance in the welding process. Good detachments of the formed droplets, and their correct transfer to the cathode, have a significant stake for the quality of welding. This phenomenon depends on the properties and composition of the plasma around the electrode. In particular, the gradient of voltage at a given current, and thus the power injected from plasma, strongly depend on gas used. The metal transfer mode is also affected by the chemical activity of shielding gas. Argon is the basic gas for MIG welding, but admixtures of oxidising elements increase the possibility of the cathodic emission and improve the stability of arc.

The behaviour of the pendant attached droplet is determined by the current distribution inside, it means by the magnitude and sign of the induced behaviour electromagnetic force: the Lorentz force can act either as a force of detachment (if current lines diverge) or on the other hand, as a force attaching the droplet to the wire electrode (if current lines converge) [3, 4]. In the latter case, a repelled metal transfer was observed during welding process using CO_2 as shielding gas [5]. Detailed calculations made by Haidar [6] indicate that depending on welding conditions, the axial component of the electromagnetic force can perform this double function, and its radial component is the dominant detaching force and is responsible for the transition from the globular to the spray transfer mode.

Rhee & Kannatey-Asibu [7] studied modifications of the droplet diameter and droplet transfer frequency for various compositions of the shielding gas. Changing CO_2/Ar ratio in the shielding gas, they measured the transition current from globular to spray transfer mode. In general the higher quantity of CO_2, the higher transfert current is observed, as far as the mode of spray transfer becomes unrealisable. There are different explanations of the observed phenomenon, in particular:

- As a result of the increased O_2 concentration and so larger oxidation of the electrode surface than under the pure argon, the amount of alloying elements vapours increases what decreases the rate of the droplets formation and disturb their detachment by giving rise to vapour-recoil force [8].

- An influence of the repulsive electromagnetic force is reinforced by the addition of molecular gases such as O_2, H_2 or CO_2 and would increase with concentration and dissociation energy of considered molecular

additives [8]. Rhee & Kannatey-Asibu observed the metal transfer to be similar for helium and carbon dioxide. The arc column is not attached to the entire droplet, probably as a result of relatively high ionisation energy of helium and additional energy required for dissociation in the case of carbon dioxide.

- Kim & Eagard [5] postulated the cathode jet to be responsible for the repelling force (proportional to the square of the current in the case of Tungsten Inert Gas (TIG) welding) and observed repelled metal transfer mode with helium and carbon dioxide shielding gases.

On the other hand, in the case of CO_2, the surface tension coefficient of the molten metal changes under influence of the chemically active gas (both oxygen and carbon decrease the surface tension coefficient for steel). Thus, in principle, it should be easier to obtain spray transfer, but the experiments show that it takes place only for small addition of CO_2. Moreover, the transition current increases considerably along with CO_2 concentration.

The shielding gas effect on welding process is a phenomenon that has been not completely understood. In this work, the arc shape was observed during the MIG-MAG welding for various relative concentrations of argon and carbon dioxide in the shielding gas mixtures.

[T - Manual moving table; WEEQ - Step-by-step moving table]
[F - Interference filter; P - Metallic plate; W - Glass window]

3. Experimental procedures

The scheme of the experimental system is presented in Figure 2. Its main part is the welding set SAFMIG 480 TRS PLUS [9] equipped with the SAFMIG 480 TR 16 kit [10]. The welding was performed at reverse-polarity (wire-anode, workpiece-cathode) direct current. The wire-anode used in our experiments was a mild steel consumable electrode (AWS A5.17) with a diameter of 1.2 mm.

Two moving tables were used. The first, a micrometric table driven by step motor, ensured the displacement of the mild steel metal plate in the welding direction with horizontal velocity 4 mm/sec. The second, a manually driven table, was used for moving in the direction perpendicular to the previous one. The welding torch was fixed on the third table that can be displaced manually in vertical direction, in order to adjust the arc length by modifying the distance between electrodes.

The gas was provided by two cylinders of the industrial gas. All types of gas mixtures can be considered, but for this study, we used a mixture based on argon and carbon dioxide. Two mass flow-meters allow measurement and control of gas flow.
The measurements of voltage between the electrodes and arc current were carried out by a differential voltage probe St500-3 (FRANAISE D'INSTRUMENTATION) and current probe (Hall effect transducer) LEM LT 500-S. These electrical characteristics were stored using numerical oscilloscope LECROY LT584L.

The observation of the arc and the recordings of the pictures' sequences, were performed with fast camera FASTCOM MVS-135 [11], equipped with photodiodes matrix (512×512 pixels) manufactured in CMOS technology. The registration frequency and exposure time depend on the size of recorded images: to increase the speed of the camera, one must decrease active surface of the photodiode matrix, but within the limit fixed by arc dimensions. A narrow bandwidth interferential filter centred at 466 nm in front of the camera's objective was used to limit the spectral bandwith [Figure 2].

4. Experimental conditions

The power supply set was used in the constant current mode. The configuration of the power supply SAFMIG was identical for all measurements and corresponded to the spray transfer mode for pure argon shielding gas. The wire feed rate was fixed to 9 m/min. The distance between the contact-tube and the metal plate amounted to 20mm. The thickness of the workpiece was 8 mm for all measurements. The chemical composition of the wire material and metal plate is given in Table 1. For the described experiments, shielding gases used were pure argon and various mixtures of argon and carbon dioxide (in the range 0.8 to 15.4% CO_2) with total flow rate about 20l/min.

	C	Si	Mn	Cr	Ni	Mo	P	S	Cu
Metal plate	0.14-0.22	0.05-0.15	0.40-0.65	0.05	0.30	-	0.04	0.30	0.30
Wire	0.09	0.35	1.07	0.02	0.06	0.04	0.01	0.01	0.16

Table 1: Chemical composition of the metal plate and welding wire.

In each welding processes the average welding current intensity (for stable welding process without arc initiation characteristic) was about 318 A. On the other hand, the average value of the voltage changed depending on composition of gas mixture: for pure argon, it was of 36V; for the mixture with 0.8% CO_2: 32.7V and increased until to 40.4V for the mixture with 15.4% CO_2 [Figure 3].

The camera was operated at the frequency of 157.2 pictures/sec (6.4ms between two pictures), according to an active size of the photodiode matrix of 120×120pixels. All observations were carried out with blue interference filter to limit light intensity.

5. Results

The observations carried out show that the type of gas has a significant influence on a plasma column shape [Cf. Figure 4].

In the case of pure argon at an average current of 318 A the arc column has a form similar to that observed in the case of the spray-arc mode of metal transfer [12]. The arc shape is almost not modified in a presence of a small admixture of CO_2 in the mixture of shielding gas [Figure 4]. Then the arc is very stable, what ensures great effectiveness and good quality of welding. The end of the wire was tapered and completely surrounded by the arc, in accordance with description of this mode of molten metal transfer presented in other articles [1, 5, 13, 14]. According to the results observed by Rhee [7] the break-up stream length becomes shorter and the size of the droplets increase with CO_2 concentrations.

On the other hand, the arc voltage decreases abruptly when only 0.8% CO_2 is added [Figure 3]. The difference between the arc voltage for pure argon shielding gas and for small CO_2 concentration (less than 3%) amounts to 3 V what suggests a drop of plasma resistance. Higher CO_2 concentration in argon shielding gas results in gradual increase of the arc voltage and, subsequently welding resistance in the arc and arc energy.

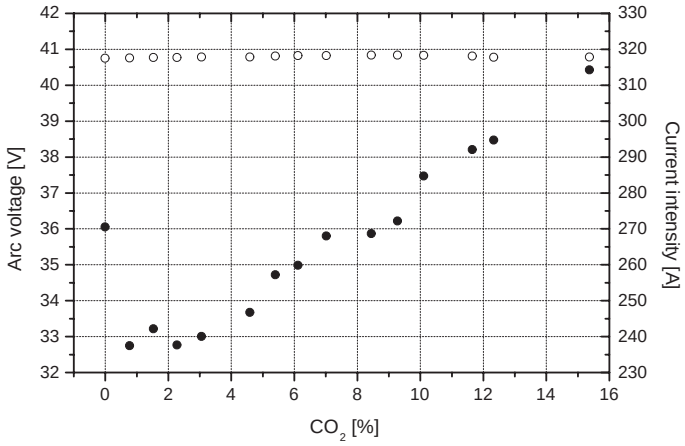

Figure 3: Arc current and voltage as a function of CO_2 concentration in gas mixture.
[● - Arc voltage; ○ - Current intensity]

When the amount of CO_2 in the shielding gas exceeds 9%, one can clearly observe detachment of droplets. The arc loses stability, produces sputter and intensive fume formation. The arc shape is significantly modified (longer and more diffusive) when the percentage of CO_2 exceeds 12%. The molten metal transfer completely changed: large droplets are formed at the end of the electrode as a result of the transition to the globular transfer mode.

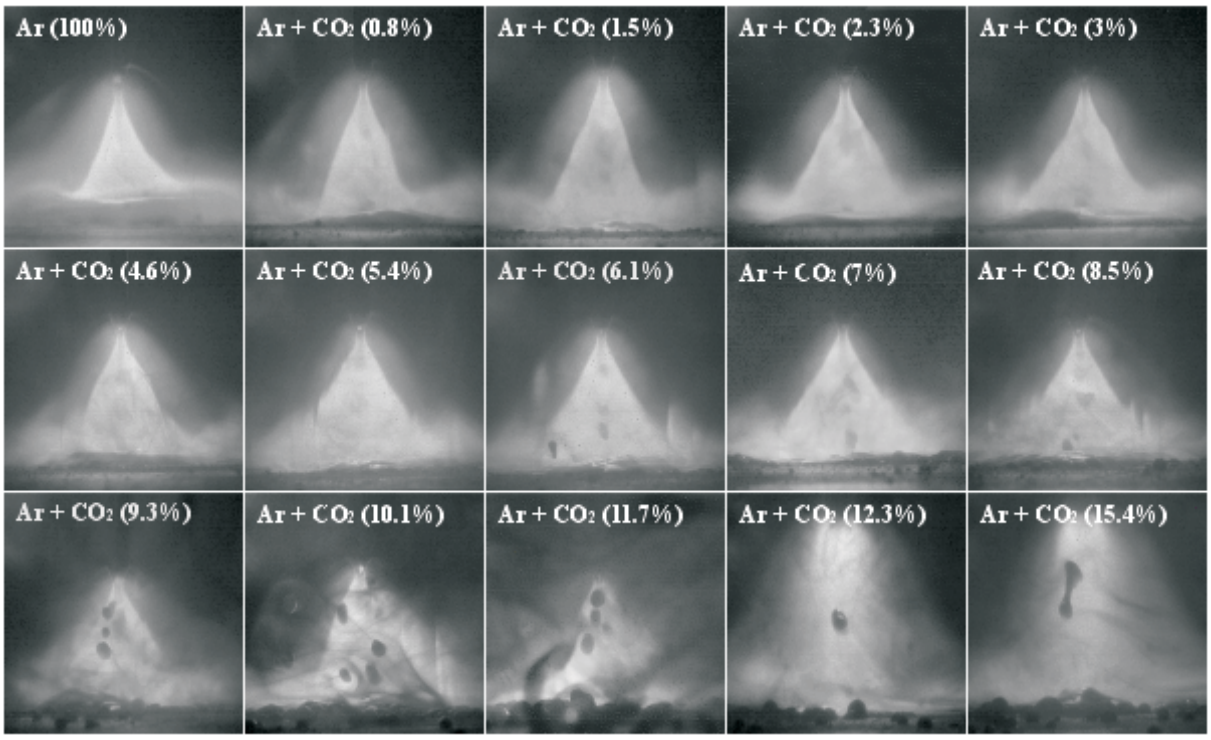

Figure 4: Arc shape for different gas mixture

4. Conclusion

We have proposed one method for welding arc visualization using a fast camera and narrow bandwidth interference filter to limit the light intensity. All measurements were carried out at the same welding current intensity (318 A) and experimental arrangements. The observations of the arc shape during MIG-MAG welding process

have been investigated for 15 different gas mixtures: pure argon, Ar+0.8% CO_2, Ar+1.5% CO_2, Ar+2.3% CO_2, Ar+3% CO_2, Ar+4.6% CO_2, Ar+5.4% CO_2, Ar+6.1% CO_2, Ar+7% CO_2, Ar+8.5% CO_2, Ar+9.3% CO_2, Ar+10.1% CO_2, Ar+11.6% CO_2, Ar+12.3% CO_2, Ar+15.4% CO_2).
The experimental results show that, under our assumed conditions:

- The shape of welding arc strongly depends on CO_2 concentration in the Ar shielding gas: for small relative concentrations, the arc column shape corresponds to the one observed in the case of the spray-arc transfer mode, but the metal transfer is highly modified when the percentage of CO_2 exceeds 12%.
- CO_2 as an admixture to Ar shielding gas changes current-voltage characteristics of the welding arc: small additions of this gas changes the arc shape only in minor way but lead to a significant decrease of arc voltage;
  The further increase of CO_2 concentration causes gradual increase of arc voltage, what might result from the increase of arc resistance, energy and its length as well (visible for larger carbon dioxide quantity in figure 4).

Wear resistance of Al_2O_3 and Cr_2O_3 coatings deposited by water-stabilized plasma spraying

J. Nohava[1], P. Chráska[1]

[1] *Materials Engineering Department, Institute of Plasma Physics AS CR, Prague, Czech Republic*

Abstract

Plasma sprayed ceramic coatings are known for their excellent wear resistance [1]. In our recent work, the influence of water-stabilized plasma torch (WSP®) on the wear properties of gray alumina and cromia coatings was studied. Two methods for determination of wear resistance WSP® sprayed coatings were combined: wet slurry abrasion test and scratch test. Fractographic analysis of the damaged samples was used to determine the main wear mechanisms and to justify superior wear resistance of cromia coating.

1. Experimental setup

WSP® plasma torch was used for spraying of gray alumina (Al_2O_3+3% TiO_2 wt.), cromia (Cr_2O_3) and metal coatings. High temperature in the WSP® plasma torch (approx. 25 000K) allowed to use large grain size powders leading to high deposition rates. The coatings were deposited on rectangular mild steel substrates of 2.5 to 4 mm thickness. The substrates were grit-blasted prior to the deposition. The list of sprayed samples is given in Tab. 1.

Tab. 1 – List of samples.

Sample label	Coating	Powder grain size [μm]	Density of the coating [g/cm^3]
AL	Al_2O_3	-63 +40	3.7
CR	Cr_2O_3	-90 +45	5.2
NI	Ni	-140 +100	8.4
NC	Ni+20% Cr wt.	-140 +100	7.4
ST	AISI 316L	-140 +100	6.9

Two methods for determination of wear resistance of plasma sprayed coatings were combined: wet slurry abrasion test according to ASTM G75-95 and scratch test. The wet slurry abrasion test was performed on a specially designed apparatus, schematically depicted on Fig. 1. The abrasion resistance is determined by using the measured mass loss of a standard-shaped block, driven in a reciprocating motion by a rotating crank, riding in the bottom of a tray containing the slurry. A direct load of 22.4N is applied to the block. The interior of the tray has a flat-bottomed or truncated "V" shape formed by the filler, that confines the slurry particles to the path taken by the wear block. At one end of each stroke, the block is lifted off the lap by a cam action for sufficient time to allow fresh slurry material to flow under the block. The block holder is made of plastic, as are the trays, so that electrolysis inherent in some slurries is minimized. The distance run by the block within one rotation is 400mm.

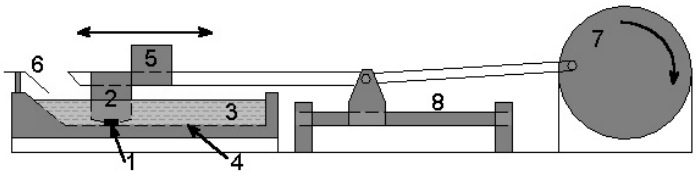

Figure 1 – Wear test machine layout: (1) sample, (2) sample holder, (3) slurry, (4) neoprene lap, (5) dead weight, (6) block lifting cam, (7) rotating wheel, (8) direct drive.

Four rectangular samples in dimensions of (12x25)mm are tested simultaneously in four parallel trays. The wear test consists of four consecutive 2h-runs (distance of 2304m). After each run the samples are rinsed in water, cleaned in ultrasonic bath in ethanol, dried and weighted so that weight loss can be calculated. The cumulative weight loss is divided by coating's density and cumulative volume loss is obtained. Damage of the coating is expressed in the wear rate ***w***, which is defined as the loss of material volume per unit distance [2]. The average wear rate was determined as a coefficient of linear regression

fitted to cumulative volume loss vs. distance experimental data. Wear resistance of a coating can then be quantified as a reciprocal value of the wear rate ***w***.

Scratch test was performed on a CSEM® Revetest scratch tester. In a scratch test, Rockwell C-type indenter is sliding on the coating under continuously increasing load, causing damage to the coating and removal of the coating material. The scratch test was carried out on the as-sprayed coating in plane perpendicular to spraying direction. The length of the scratch was 10mm and the normal load was smoothly and continuously increased from 0 to a maximum value of 100N during each scratch test. Scratching speed was set to 10mm/min and the indenter tip was wiped with ethanol before each scratch test.
Damaged surfaces of AL and CR samples subjected to both wet slurry abrasion and scratch tests were examined in scanning electron microscope (SEM) JEOL JSM 840A and JEOL JSM 5510LV in secondary and backscattered electrons modes. Analysis of damaged surfaces of the wear test samples after every run enabled to study the structure of the coating in depth and trace the changes in morphology during the abrasion tests.

2. Results

Wet slurry abrasion test results

The results of wet slurry abrasion test are plotted in Fig. 2. The most wear resistant coating was the cromia coating with the average wear rate of $0.55\times10^{-2}mm^3/m$. The average wear rate of gray alumina was $1.24\times10^{-2}mm^3/m$, i.e. more than two times higher than that of cromia coating.
The average rate of metal coatings (AISI 316L, NiCr20 and Ni) are higher than wear rates of both gray alumina and cromia coatings. However, the AISI 316L steel coating has wear rate comparable to that of gray alumina coating ($\boldsymbol{w}=1.32\times10^{-2}mm^3/m$). Nickel coating exhibited the highest wear rate, with average value of $2.87\times10^{-2}mm^3/m$.

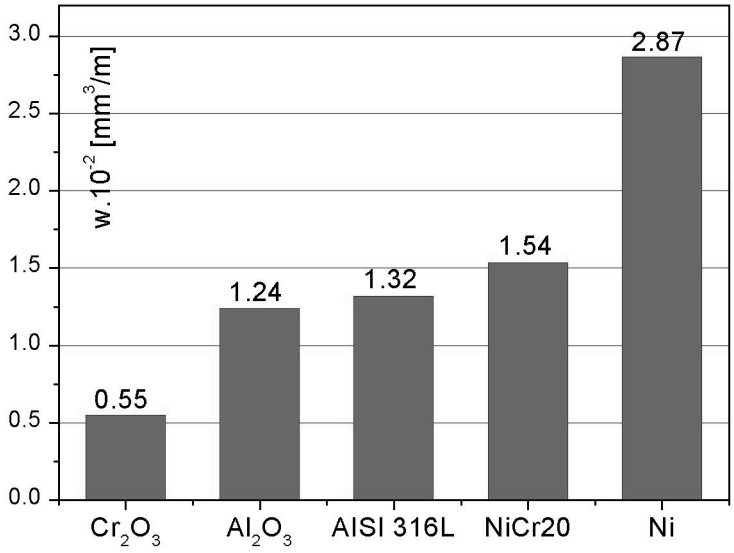

Figure 2 – Wear rates for different types of WSP® sprayed coatings.

Surface morphology of the coatings sprayed by WSP®

The typical morphology of the as-sprayed gray alumina and cromia coatings is shown on Figs. 3a, b. Both gray alumina and cromia coatings exhibited typical splat morphology. Thickness of the splats was in the range of 2 to 10μm.

Several differences in morphology between gray alumina and cromia coatings were found:

- the cromia coating contained less spherical particles than gray alumina coating,
- in some cases crystallization of melted cromia particles on the substrate surface lead to formation of fine, randomly oriented microstructure (see Fig. 3b).

Two types of microstructure inside of the splats were found:

- columnar, predominant in Al_2O_3 splats, reported also by other authors [3, 4] – see Fig. 3c,
- fine with randomly-oriented grains (predominant in Cr_2O_3 splats – see Fig. 3d),
  - the dimensions of the fine grains were in the range of 1 to 5μm.

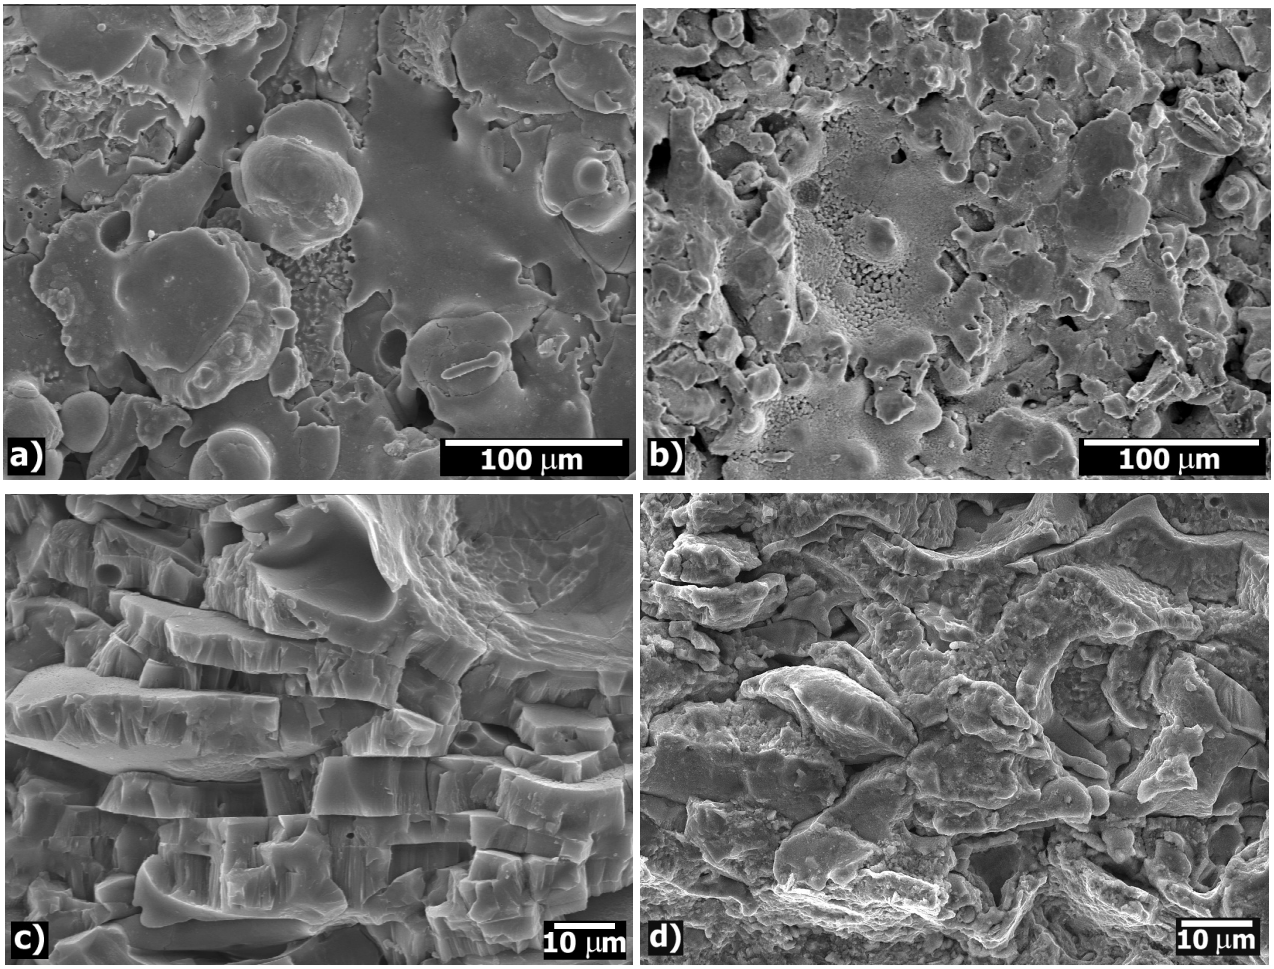

Figure 3 – The surface of Al_2O_3 coating **(a)** and Cr_2O_3 coating **(b)** sprayed by WSP® before the wear tests. Microstructure inside of **(c)** Al_2O_3 and **(d)** Cr_2O_3 splats.

Fractographic analysis of samples subjected to wear and scratch tests
