Abstract

Mach probe measurement was carried out in order to evaluate ion Mach numbers and velocities of plasma flows for a supersonic direct-current arc plasma jet generator in a low pressure environment. The plasma flow velocity increased by adding hydrogen compared with the cases with only nitrogen. Accordingly, the high plasma flow enthalpy with mixtures of nitrogen and hydrogen is considered to enhance nitriding effect in addition to efficient chemical reaction of NH radicals.

1. Introduction

The direct-current arc plasma jet generator is a promising plasma device suitable for economically assisting material processing in which a high throughput of material is desired. In low pressure plasma spraying, an arc jet generator with a supersonic expansion nozzle is useful for spraycoating hard and large-area films adhering strongly to substrates. In surface treatment such as nitriding, a supersonic plasma jet in a low pressure environment also has benefits of efficient plasma treatment by using irradiation of highly excited and/or chemically active particles in the thermodynamical nonequilibrium plasma in addition to large-area and uniform treatment[1],[2].

In our previous study, ammonia and mixtures of nitrogen and hydrogen were used for nitriding processing[1],[2]. Since these gases were chemically active, the processing efficiency was enhanced. However, plasma properties of ammonia and mixtures of nitrogen and hydrogen are unknown because of complicated chemical reactions among many fragmented particle species. Particularly, plasma characteristics near substrates are hardly clear because the existence of substrates influences the plasma features. Therefore, spectroscopic and electrostatic probe measurements were made to examine plasma characteristics near substrate plates[3]-[8]. Heat fluxes into substrates were also measured[9]-[11]. The relationships between the plasma and heat flux characteristics and the substrate nitriding characteristics were discussed.

In the present study, Mach probe measurement is carried out in order to evaluate ion Mach numbers and velocities of plasma flows for a supersonic direct-current arc plasma jet generator in a low pressure environment. The influence of plasma flow velocity on the nitriding characteristics is discussed.

2. Experimental Apparatus

Figure 1 shows the cross-sectional views of the supersonic direct-current arc plasma jet generator used for this study. A constrictor of a convergent-divergent nozzle throat has a diameter of 6 mm and a length of 7 mm. A divergent nozzle has an exit diameter of 34 mm and is inclined at an angle of 52 deg. The ratio of the cross-sectional area of the nozzle exit to that of the constrictor is 32.1. A cylindrical cathode made of 2% thoriated tungsten has a diameter of 10 mm. The gap between the electrodes is set to 2 mm. Ammonia and mixtures of nitrogen and hydrogen are used as the working gas. In the mixture of N_2+nH_2, the H_2 mole fraction n is varied from 0 to 3, in which mole fractions of 0 and 3 correspond to pure nitrogen and simulated ammonia, respectively. The working gas is injected tangentially from the upstream end of the discharge chamber. The arcjet generator is operated with input powers of 3-12 kW at discharge currents of 70-150 A. The arcjet generator, as shown in Fig.2(a), is located in a vacuum tank 0.8 m in diameter and 1.5 m long, which is evacuated using a mechanical booster 1600 l/s connected in series with a rotary pump 160 l/s.

Mach probe measurement is carried out in order to evaluate ion Mach numbers and velocities of plasma flows. The probe, as shown in Fig.2(b), mainly consists of two wires 0.5 mm in diameter, and their end surfaces are parallel and perpendicular to flow. The ion Mach number can be estimated from the ratio of the two ion saturation currents, and then the flow velocity is predicted from the ion Mach number, and electron and ion temperatures obtained by means of Langmuir probe and spectroscopic measurements[12],[13],[6]-[11]. Particularly, the ion temperatures are assumed to equal rotational temperatures of NH or N_2 obtained by emission spectroscopic measurement.

3. Results and Discussion

In all experiments, the discharge current and the mass flow rate are fixed to 150 A and 0.21 g/s, respectively. The input power and the tank pressure are 6.3 kW and 34 Pa for N_2, 9.45 kW and 82 Pa for N_2+H_2, 10.8 kW and 150 Pa for N_2+2H_2, and 11.85 kW and 205 Pa for N_2+3H_2, respectively.

Figure 3 shows the axial variations of ion saturation current for the two wires parallel and perpendicular to plasma flows on the central axis. The ion saturation current gradually decreases downstream. At a constant axial position, the current for N_2 is the largest of all gas species, and an increase in H_2 mole fraction increases the current. This is expected because for N_2 the degree of ionization is relatively high with the small particle number flux at the lowest tank pressure and because for mixtures of N_2 and H_2 more intensive thermal pinch occurs with increasing H_2 mole fraction, resulting in enhanced ionization.

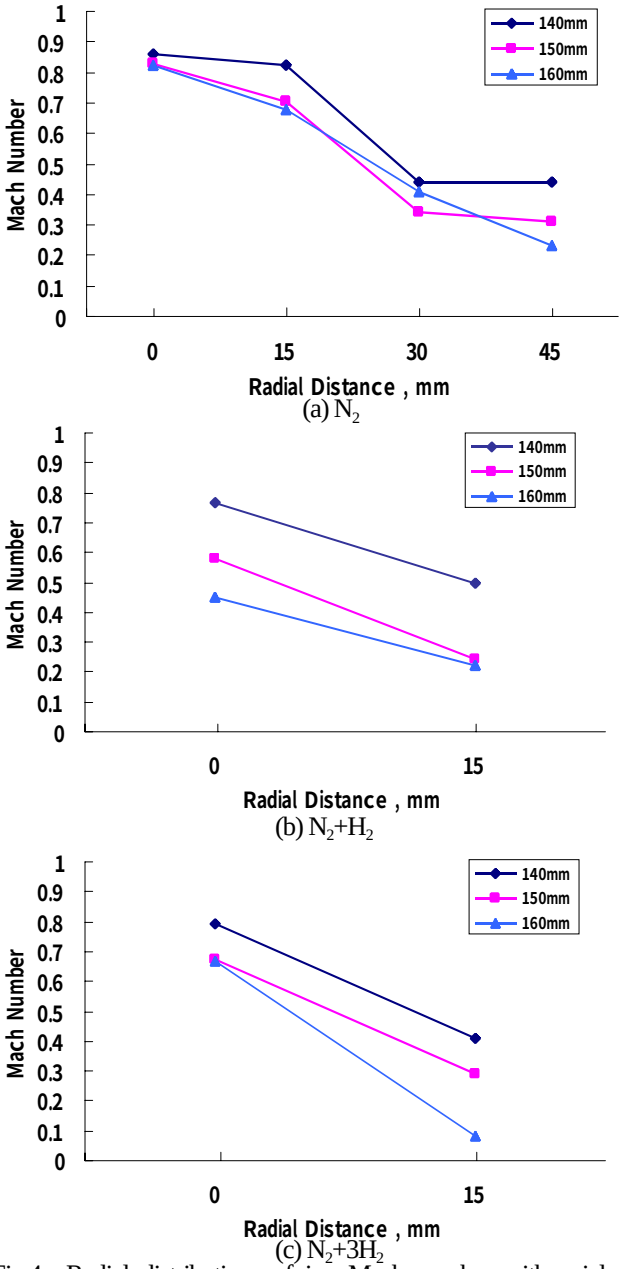

Fig.4 Radial distributions of ion Mach number with axial positions of 140, 150 and 160 mm from nozzle exit for N_2, N_2+H_2 and N_2+3H_2.

Figure 4 shows the radial distributions of ion Mach number with axial positions of 140, 150 and 160 mm from the nozzle exit for N_2, N_2+H_2 and N_2+3H_2. For N_2+H_2 and N_2+3H_2, the ion Mach number at large radial positions of 30 and 45 mm could not be evaluated because of too small ion saturation currents; that is, because plasma is concentrated on the central axis due to thermal pinch effect. The ion Mach number for N_2 gradually decreases radially-outward, and at a constant radial position the Mach number at 140 mm is the highest. For the mixture gases, the Mach number rapidly decreases radially-outward compared with that for N_2, and at a constant radial position the Mach number decreases downstream.

Figure 5 shows the axial variations of ion Mach number on the central axis with varying gas species. Although the ion Mach number decreases downstream regardless of gas species, the rate of decrease for N_2 is very small, and for mixtures of N_2+H_2 and N_2+2H_2 the rate is relatively large. For N_2+3H_2, the Mach number rapidly decreases at axial positions from 140 to 150 mm, and then the characteristic is almost flat enough

downstream. At a constant axial position, the Mach number for N_2 is the highest of all gas species because of intensive expansion with the lowest tank pressure. For the mixture gases, the Mach number for N_2+$3H_2$ is the highest because of intensive acceleration by enhanced thermal pinch even with the highest tank pressure.

Figure 6 shows the radial distributions of flow velocity with axial positions of 140, 150 and 160 mm from the nozzle exit for N_2, N_2+H_2 and N_2+$3H_2$. The

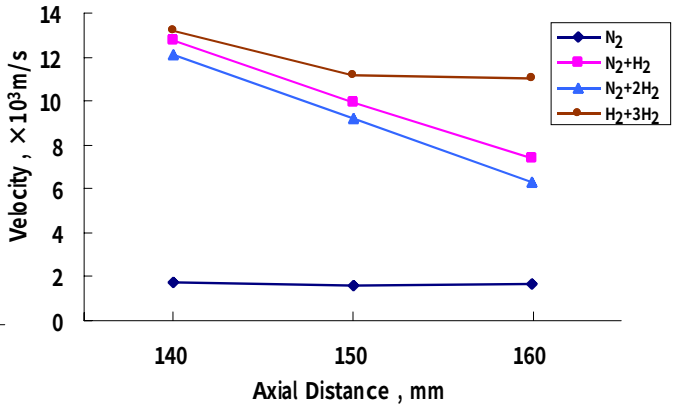

Fig.7 Axial variations of flow velocity on central axis with varying gas species.

flow velocity characteristics agree with the ion Mach number characteristics mentioned above.

Figure 7 shows the axial variations of flow velocity on the central axis with varying gas species. Although the ion Mach number for N_2 is the highest of all gas species, the flow velocity is the lowest. This is because the particle mass of N_2 is smaller than the average particle mass for mixtures of N_2 and H_2. The flow velocity for N_2 ranges from 1.63 to 1.75 km/s and for the mixture gases from 6.28 to 13.21 km/s. Accordingly, the high plasma flow enthalpy with mixtures of N_2 and H_2 is considered to enhance nitriding effect in addition to efficient chemical reaction of NH radicals[1],[2].

4. Conclusions

Mach probe measurement was carried out in order to evaluate ion Mach numbers and velocities of plasma flows for a supersonic direct-current arc plasma jet generator in a low pressure environment. Mixtures of N_2 and H_2 were used as the working gas. In the mixture of N_2+nH_2, the H_2 mole fraction n was varied from 0 to 3, in which mole fractions of 0 and 3 corresponded to pure nitrogen and simulated ammonia, respectively. Although the ion Mach number decreased downstream regardless of gas species, the rate of decrease for N_2 was very small, and for N_2+H_2 and N_2+$2H_2$ the rate was relatively large. For N_2+$3H_2$, the Mach number rapidly decreased near the nozzle exit, and then the characteristic was almost flat enough downstream. At a constant axial position, the Mach number for N_2 was the highest of all gas species because of intensive expansion with the lowest tank pressure. For the mixture gases, the Mach number for N_2+$3H_2$ was the highest because of intensive acceleration by enhanced thermal pinch even with the highest tank pressure. Also, the ion Mach number for N_2 gradually decreased radially-outward although for the mixture gases it rapidly decreased. As a result, the flow velocity for N_2 ranged from 1.63 to 1.75 km/s and for the

mixture gases from 6.28 to 13.21 km/s. The flow velocity for N_2 was the lowest of all gas species. Accordingly, the high plasma flow enthalpy with mixtures of N_2 and H_2 is considered to enhance nitriding effect in addition to efficient chemical reaction of NH radicals.

A novel approach to cathode / anode modelling for high-current AC arcs

G.Sævarsdottir[1], M. T. Jonsson[1], J.A. Bakken[2]

Abstract
Boundary conditions at cathode and anode are crucial when electric arcs are simulated. In the case of high current industrial AC arcs with currents ~100 kA, phase voltages ~100 V and total furnace power ~10 – 60 MW, the surfaces that the arc attaches to, receive enormous amounts of energy from the arc. Therefore a novel approach has been made to the cathode and anode simulation. Radiation from the arc is taken into account. An energy balance for the space charge sheath, isolated from the arc, is omitted whereas an overall energy balance for the arc-cathode-anode system is fulfilled. The result is a *diffuse* arc attachment.

1 Introduction

The arc simulation models require knowledge about conditions at the cathode and anode. However, it is preferable that assumptions are kept to a minimum. As arc behaviour is very sensitive to the boundary conditions at cathode and anode, considerable work has been put into the development of cathode sub-models for high-current AC arcs. In fact three different models have been developed. The first model, here called *the classic model* was based on the assumption that the cathode spot is self-sustained with energy, and that the cathode fall voltage is constant all over the cathode spot, which in turn requires the cathode spot to deliver excess energy to the arc. The second model called *the variable u_C model* allows the cathode fall voltage to vary over the cathode spot, but assumes that an energy balance is fulfilled in each element of the cathode. The weakness of this model is that when energy transfer by radiation from the arc to the cathode is taken into account, the integrated current density from the model is much higher than the total arc current. Therefore measures must be taken to reduce the total integrated current. The third model which is presented in this paper, *the diffuse spot cathode / anode model*, is different from the first two in that it does not require the energy balance in the ionization sheath to be fulfilled as there is an abundance of energy from the electric arc that enters this layer in the form of radiation or energetic plasma electrons.
In this paper only the diffuse spot model will be presented. The cathode fall voltage is assumed constant over the cathode surface and determined by the requirement that the total current from the electrode should be equal to the imposed arc current. The anode is treated in the same way as the cathode. This model is the most promising of the three in the case of a high-current industrial arc which corresponds to the limit of an arc dominated cathode spot.

2 General cathode spot theory

2.1 The plasma sheath

If there initially is a wide body of LTE plasma and suddenly a part of it is surrounded by an isolating wall, the wall will initially be bombarded and charged up by fast moving plasma electrons. The negatively charged wall will then repel approaching plasma electrons and attract ions, thus forming a *space charge sheath* that shields the plasma gas from the effect of the negatively charged wall. Approaching plasma electrons will not notice the wall before they enter the space charge sheath, but as they penetrate the ion layer the shielding effect is reduced and they are slowed down by the electric field. For an isolating wall the potential drop in the sheath must be exactly high enough to ensure zero total current. When a net current is applied upon a plasma contained between two walls, it is natural to assume that the potential fall is adjusted such that the there is a net charge exchange between the plasma and the wall consistent with the applied current. The thickness of this space charge sheath is approximately $25\lambda_D$ which is close to 1 μm and orders of magnitude smaller than the thermal boundary layer, which in the case of an industrial arc is close to 500 μm.

2.2 General expressions

The AC Cathode/Anode Sub-Model (CASM) to be described is based on the following assumptions: The cathode current density j is composed of three components: Thermionically emitted electrons j_e, ions from

the plasma that reaches the cathode surface j_i, and finally plasma electrons that pass through the potential barrier and reach the surface j_{epl}. The models are to a certain extent based on ideas appearing in Neumann's theory [1] and Benilov's model [2] for low-current DC arc cathodes.

When a body is sufficiently hot, a fraction of its electrons have kinetic energy high enough for them to overcome the energy barrier called the work function ϕ which traps them in the body. The thermionic emission current density is given by Richardson-Dushman's equation :

$$j_e(T_C) = 1.2 \cdot 10^6 T_C^{\,2} f \exp\left(\frac{e(\varphi + \Delta\varphi)}{k_B T_C}\right) \tag{1}$$

where T_C denotes the cathode surface temperature, e is the electronic charge, ϕ the thermionic work function, k_B is Boltzmann's constant and $\Delta\phi$ is the Shottky correction. The factor f in the Richardson-Dushman equation is a scaling factor accounting for the fact that a thermionically emitted current with the theoretic value of $f = 1$ has never been observed. According to Pfender et al.'s [3] estimate, $f = 0.5$, which is used in this work. The hot plasma gas contributes with electrons that diffuse over the cathode fall potential u_C and enter the cathode. *The counter-diffusing plasma electron current* is given by:

$$j_{epl} = \frac{1}{4} e n_{e0} c_e e^{-eu_c / k_B T_c}$$

$$c_e = \sqrt{\frac{8 k_B T_e}{m_e \pi}} \tag{3}$$

where n_{e0} is the electron density at the edge of the space charge sheath, and c_e is the mean electron velocity in each direction. Benilov *et al* [2] reported a solution for the plasma sheath equation that leads to the following expression for the current density of *plasma ions* towards the surface:

$$j_i = n_{i\infty} \frac{0.8}{2 + \alpha} \sqrt{\frac{k_B (T_C + T_e)}{M_i}}$$

$$\alpha = \sqrt{\frac{k_B T_h}{m_i D_{ia\infty} k_r n_{i\infty}^2}} \tag{4}$$

where $D_{ia\infty}$ is the ion-atom diffusion coefficient, k_r is the ion-electron recombination rate coefficient and T_h the heavy particle temperature, all evaluated at the edge of the ionization layer. In conventional cathode models it is assumed that the energy balance for the ionization of atoms by emitted electrons is fulfilled in the ionization layer all over the cathode spot, then the radially dependent cathode fall voltage $u_C(r)$ can be determined:

$$j_e\left(u_C + 2\frac{k_B T_C}{e} - 3.2\frac{k_B T_e}{e}\right) = j_i\left(U_i + 2\frac{k_B T_i}{e} + 3.2\frac{k_B T_e}{e} - 2\frac{k_B T_C}{e}\right)$$

$$+ j_{epl}\left(u_C + 2\frac{k_B T_e}{e} - 3.2\frac{k_B T_e}{e}\right) \tag{5}$$

Here j_e and j_i represent the electron and ion current densities in the near cathode layer and U_i is the ionization potential. The thermionically emitted electrons are accelerated over the space charge sheath potential fall u_C,. The thermionic electrons are emitted with their two-dimensional enthalpy in equilibrium with the cathode body, but need to be heated up to the plasma temperature to be in thermodynamic equilibrium. The energy supplied by the thermionic electrons is used to ionize atoms, and bring the electrons excited from the atoms to equilibrium with the arc plasma. The counter-diffusing electrons must overcome the space charge potential, and carry a two-dimensional enthalpy to the cathode.

An extension to AC is accomplished by imposing a periodically varying arc current. The non-steady two-dimensional axi-symmetric Fourier equation is solved for the electrode body using the heat flux in Equation 6 as a boundary condition, to obtain a periodically varying cathode surface temperature $T_c(r,t)$. The computational domain is assumed large compared to the cathode spot radius (0.1 m) in the radial direction and to the thermal penetration depth of 50 Hz temperature oscillations (1 mm) in the axial direction. As a boundary condition we need an expression for the cathodic heat flux:

$$\dot{q}_c = j_i(u_c + 2\frac{k_B T_i}{e} - 2\frac{k_B T_C}{e} + U_i - \phi) - j_e\left(2\frac{k_B T_C}{e} + \phi\right) + j_{epl}\left(\frac{k_B T_e}{e} + \phi\right) + \dot{s}_{rad} \quad (6)$$

Radiation from the arc as well as energy contributed by the particle impact on the surface during the anodic half-period is considered, and calculated values from the MFD model are used. However, ohmic heating in the electrode is disregarded as it is judged as insignificant as compared to the heat input from the arc and the particle impact in the cathode spot. The electromagnetic equations are not solved for the electrode body, and the current density within the electrode is not known. In the present results sublimation of the electrode body has not been taken into account, but the introduction of a *maximum temperature* ensures that the sublimation temperature is not surpassed.

3 The Diffuse Spot Cathode/Anode Sub-Model

The diffuse spot cathode/anode sub-model (CASM) is based on the observation that in a relatively short high-current industrial arc, the energy supply from the arc is so overwhelming that it is not possible to divide the cathode and the arc into two separate energy domains that do not exchange energy. It cannot be required that thermionically emitted electrons accelerated through the cathode fall supply all energy required to sustain the arc spot as the radiation from the arc and the abundance of much more energetic plasma electrons is sufficient to ionize neutral atoms and equilibrate colder electrons. This means that instead of *two separate energy balances*, Equation 5 on the one side, and the *MFD* transport equations for the arc on the other, an energy balance for the whole system must be solved *within the MFD model.* In the *CASM* only the energy balance for the electrode itself, using boundary conditions in Equation 6 will be considered. The heat flux into the cathode/ anode body must be tapped from the arc by a boundary condition for the arc model. In this new model cathode and anode are considered to be formally identical, and the total current balance

$$I(t) = 2\pi \int_0^{r_{\max}} j_e(r,t) r dr + 2\pi \int_0^{r_{\max}} j_{isat}(r,t) r dr - 2\pi \int_0^{r_{\max}} j_{epl}(r,t) r dr \quad (7)$$

is fulfilled at any time for both electrodes. This means that the cathode as well as the anode thermionically emit electrons consistently with their temperatures, and that they are both bombarded with plasma electrons and ions dependent on the temperature of the plasma next to the electrode. The difference between cathode and anode is only that the net current is negative in the cathodic half-period and positive in the anodic half-period. The cathode/anode fall voltage, here termed u_C for consistency, is determined by solving Equation 7 for the given current at each timestep. This means that the potential fall is adjusted such that the there is a net charge exchange between the plasma and the wall consistent with the applied current. Radiation fluxes and plasma temperatures are obtained from arc simulations. For this model to be optimal it will be necessary to couple the MFD arc model and the cathode /anode sub-model and solve both models simultaneously. This has not been possible within the time frame of this work, but an iterative procedure is used. In the simulations it is assumed that the cathode/anode body is a good current conductor as compared to plasma. It is also assumed in this model that u_C is constant over the surface.

The abundance of energy provided by the electric arc is such that the energy balance in Equation 5 is not fulfilled, separated from the arc. But as the heat flux by particle impact in Equation 6 includes heat transport due to ambipolar diffusion and heat flux due to current, the boundary condition for heat transport in plasma must be set up correspondingly in the *MFD* arc model. The source term is included in the cells next to the cathode/anode surfaces. This source term then has the form:

$$\dot{q}_{bound} = -j_i\left(2\frac{k_B T_i}{e} - 2\frac{k_B T_C}{e} + U_i\right) - j_e 2\frac{k_B T_C}{e} - j_{epl} 2\frac{k_B T_e}{e} + j u_C \quad (8)$$

Notice that the thermionic work function ϕ terms have been removed as ϕ is exclusively a material property, which determines the energy of an electron within the material as compared to a free electron. The electric arc is not directly affected by the work function except by the work function's effect on the current density of emitted electrons. Also note that the term $j_i u_C$ has disappeared and been replaced with $j u_C$. This is because the power generated by the total current over the cathode fall voltage, $p_{uC} = j u_C$ has to be taken into account. The same equations apply at the anode.

P [MW]	5.4	6.5

3.1 Simulation results

When the energy balance is omitted and the potential drop u_C is assumed constant, u_C decreases, and thereby the plasma electron current density j_{epl} increases exponentially. This leads to a much lower total current density in the cathode (anode) spot dependent on the plasma temperature. If the plasma temperature is high enough, that results in a negative current density in a part of the arc spot. The resulting total current is composed of three components, two of which have a much higher total value than their difference. Figures 1 display the time variation in the total current and the integral current components as well as the cathode and anodic fall voltages for maximum cathode temperatures 4000 K. It is seen that the three current components are each larger, and in the anodic half-period much larger, than the resulting total current. Another result is that the potential fall required to hamper the flow of plasma electrons in the anodic half-period is only about 0.3 V lower than the cathode fall voltage in the case of the 'hot' electrode. In the cathodic half-period the voltage reaches a maximum at 3.0 V and in the anodic half-period the maximum voltage is 2.7 V. All this only demonstrates the necessity of coupling together the MFD arc model and the cathode / anode model to get more reliable values for the plasma temperature at the surface. It should be kept in mind that between the two half periods the overall arc voltage has changed sign, so that the anode fall voltage is indeed *subtracted* from the arc voltage – we have a *negative* anode fall. Let us now consider the current distribution at the surface. The plasma temperature at the electrode varies with the distance from spot center. The potential fall is, however, constant over the surface, so inevitably, the current density distribution is strongly varying. Figure 2 shows the time-varying cathode current density as a function of radius with a maximum cathode temperature of 4000 K. It is seen that the current density is negative in the center of the arc spot both in the anodic and cathodic half-periods.

Figures 3 and 4 show the radial distributions of the current density components at peak current with a maximum cathode surface temperature of 4000 K and 3640 K, respectively. The cathode radial temperature distribution is shown as well. The most obvious difference between the two sets of current densities is that all densities are lower for the colder cathode. Lower cathode surface temperatures naturally lead to lower thermionic emission of electrons j_e, and therefore a higher cathode fall voltage is needed to hamper the flow of plasma electrons towards the cathode surface. The cathode fall voltage is thereby increased from 2.9 V up to 5.8 V. The plasma electron current density j_{epl} is insignificant for the colder cathode, and therefore the resulting current density is a rather smooth curve with its highest value at the cathode spot center. The hotter cathode emits thermionically a larger amount of electrons. Therefore it must receive more plasma electrons to keep the balance, and the voltage is half of that of the colder electrode. As a result, the total current density is negative at the center of the cathode spot, while it is positive over the main part of the cathode. Such a current density profile is rather unphysical and would probably not occur if the electromagnetic equations were solved for the electrode body, and the energy balance for the entire arc/cathode system were properly fulfilled. These results are summed up in Table 1

3.2 Effect on industrial arc simulations

MFD simulations have been performed on the high-current AC arcs expected to exist in the craters of a 30 MVA three-phase submerged-arc furnace for production of *silicon metal*. The crater gas was assumed to consist of SiO and CO in molecular ratio 1:1 with or without Al and Ca contaminants. The computational domain again corresponds to the assumed shape and size of the crater cavity of the industrial furnace. The arc length was varied from 5 to 20 cm. It was soon found that arc lengths of 5 – 10 cm gave the best fit to industrial data. The available transformer secondary voltage is not high enough to sustain e.g. a 20 cm long arc. As an example, Figures 5 and 6 show the simulated current and voltage waveforms for a 5 cm long arc in pure SiO-CO gas. The results shown here are for three-phase calculations using both the traditional boundary conditions (Old BCs) with a constant parabolic cathode current density with a mean value of $j_c = 1.4 \cdot 10^7 A/m^2$ and the new BCs obtained by the cathode / anode sub - model (CASM).

Neglecting parallel charge conduction, the calculated RMS currents for a 5 cm long arc varies from 64.5kA for the arc using the older type of boundary conditions, up to 84 kA for the boundary conditions based on the cathode / anode sub-model (CASM). A normal RMS electrode current for the furnace in question is around 80 kA, and the measured voltage between electrode holder and furnace bottom 100 V. That corresponds to approximately 80 V over the arc, when phase reactance has been accounted for. In an industrial furnace under normal operation it is generally believed that a considerable part of the electrode current bypasses the arc and goes through the charge material surrounding the electrode. That will lead to a larger electrode current at the same voltage than shown here for the pure arc. The recent CASM boundary conditions that considerably reduce the arc resistance actually allow a longer arc. Simulations of a 10 cm long arc using the recent boundary condition give a RMS current of 56 kA and a RMS voltage of 110V. If a charge current is taken into account, realistic electrode currents and voltages are obtained.

4 Discussion and conclusions

The diffuse spot model deviates in important aspects from cathode models that have been reported in the literature. Most existing models have been made for low-current DC arcs, where the cathode spot must be energetically self-sustained, and no energy is extracted from the arc itself. This novel model represents the other limit: The cathode/anode spot is dominated by energy impact from the arc, and must be included in the energy balance for the arc. Although the CASM has not yet been fully integrated into the MFD arc model, the tentative iterative results indicate a much lower cathode current density than previously assumed and a much smaller cathode fall voltage, which indeed has the same sign in the anodic half-period. This means that in the voltage considerations for the total arc-cathode-anode system, the voltages for the cathode and anode almost cancel out! A *negative* anode fall voltage has previously been suggested by Pfender, but the standard assumption is that cathode and anode fall voltages add up. The relatively low current density gives rise to a *diffuse* cathode spot, wider than the part of the arc attached to it. Such diffuse cathode spots have been observed and discussed on many occasions.

This diffuse arc spot also leads to a smaller resistance in the arc itself. Changing the arc boundary conditions in this direction in fact allows us to lengthen the arc from 5 to 10 cm and maintain a reasonable phase resistance *neglecting the charge conduction*. Taking charge conduction into account, assuming that for example half of the current passes through the charge, the arc resistance may be increased and the arc itself lengthened accordingly, but still the order of magnitude is the same. The arc length is not much more than 15 cm.

Decomposition of HCl and Chlororganics in RF Plasma

G. Paskalov

Department of Physics, University of California, Los Angeles, USA

Abstract
Plasma decomposition of HCl, C_6H_5Cl, and $C_6H_2Cl_4$ were studied. A RF plasma reactor was constructed to study the fundamental reaction kinetics and thermodynamics for decomposition of HCl and chlororganics at atmospheric pressure. The experiments were performed in a mixture of HCl and Chlororganics with Ar and H_2O at different ratios. It was shown that dissociation of HCl is efficient only at plasma temperatures higher than 5000K.

1. Introduction

Industries manufacturing chlorohydrocarbons such as tetrachloroethylene (PCE), 1, 2 dichloroetan (EDC), trichloroethylene (TCE), vinyl chloride (VCM), diphenyl methane (DME), fluorochemicals and fluoropolymers typically produce anhydrous hydrogen chloride as a by-product. When manufacturing fluorochemicals, generally via halogen exchange reaction, the resulting reaction product mixture is distilled allowing for the recovery of anhydrous HCl.

The thermal decomposition of HCl was studied in [1, 3]. The experiments were performed in a mixture containing 1.4 to 3800 ppm HCl diluted in Ar in a temperature range 2500K to 4600 K. A rate coefficient for the reaction HCl + Ar = H + Cl + Ar , was determined. The elementary reaction of HCl with H and Cl were studied in the temperature range 240 K to 1000 K by a different group. High temperature data are not available. HCl pyrolysis was performed in two shock tubes as described in [1]. The measurements were made using ARAS and IR Diode Laser Spectroscopy.

Hydrogen Chloride is very aggressive and thermally stable gas. Its dissociation energy is 4.48 eV. This is not very high compared to the dissociation energy for the Hydrogen - 14.48 eV. The dissociation process starts only at the temperatures higher than 2000 K. The needed constants for the evaluation of HCl conversion can be obtained from the following classical reaction:

$$H_2 + Cl_2 = 2HCl + 44\ kCal.$$

The reaction rate constant K_r is expressed as

$$K_r = p^2 [HCl] / (p [H_2] \times p [Cl_2])$$

Thus, $K_r = 9554/T - 0.533 \times lgT - 2.42$ or $K_r = 4x (1 - \alpha)^2 / \alpha^2$, where α is the dissociation degree of the HCl. The following table shows the dependence of α from temperature, T.

T, ^oC	20	400	700	1200	1700	2200
α	$3x10^{-17}$	$4.4x10^{-8}$	$0.9x10^{-5}$	$5.2x10^{-4}$	$3.8x10^{-3}$	$1.2x10^{-2}$

To understand the problems with HCl dissociation one has to analyze the process of HCl synthesis. The synthesis of the HCl is a simple chain reaction. The reaction is initiated by the quantum lights in the visual spectrum. This was confirmed by Nernst in the 19th century and the photo synthesis of HCl can be described by the following reaction:

$$Cl_2 + h\nu = Cl + Cl^* ;\ Cl^* + H_2 = HCL + H^* ;\ H^* + Cl_2 = HCl + Cl^*$$

The number of chain reactions that can reach 10^5, i.e. one quantum of light can create 10^5 molecules of HCl. This reaction speed can be increased by using the water vapor, coal, quartz and titanium. Thus, the dissociation of the HCl can be achieved if the following conditions occur:

1. adjust the dissociation temperature, so that $\alpha = 1$
2. stop the recombination process

2. Thermo-dynamic evaluation of the HCl dissociation

The thermodynamic evaluation of the dissociation reaction of HCl is performed in the temperature range from 2000K to 6000K. This lowest limit of temperature was chosen based on the value of α equals 0.0122. This temperature characterizes the beginning of the dissociation of HCl. Thermodynamic calculations were made based on the minimization system of all of the thermodynamic functions of HCl. We evaluated the reaction product, such as Cl_2, Cl, H, and H2. Fig. 1 presents the changes in the number of moles of HCl, H_2, H, Cl dependent on the temperature. The changes in Cl_2 are not shown, because they are so small at temperatures higher than 2000K ($< 10^{-2}$). The data, which is shown on fig.1, needs to be matched to the degree of conversion, α, vs. temperature (fig.2).

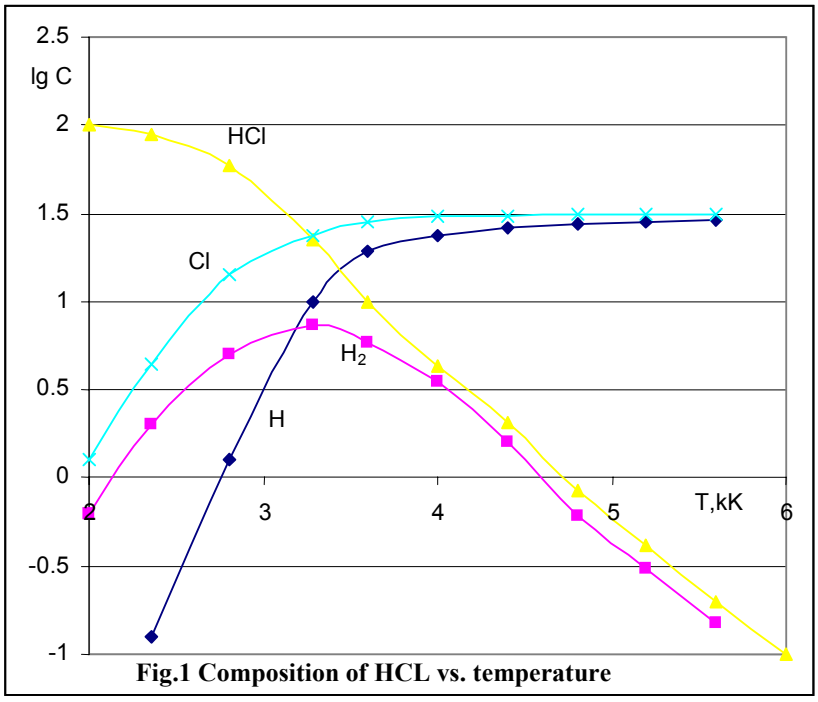

Fig.1 Composition of HCL vs. temperature

Analysis of the data from fig.1 and fig.2 shows that the effective dissociation of HCl should be at temperatures higher than 5500K. At the above temperature Δ approaches 100%. At temperatures higher than 5500K the plasma gas consists only of the Hydrogen and Chlorine atoms. However, thermodynamic evaluation is not enough to evaluate the speed of recombination and the conversion process itself.

3. **Kinetics of the dissociation of HCl**

Calculations of the thermal dissociation of HCl are made between temperatures of 4000 – 7000K based on the coefficient of the reaction

$$K = A\, T^n\, E / kT, \quad \text{where}$$

E – is the dissociation energy; T – temperature, A,n – parameters.

This calculation was made based on the model, which described in the following reaction [3]

$$HCl + Ar == H + Cl + Ar$$

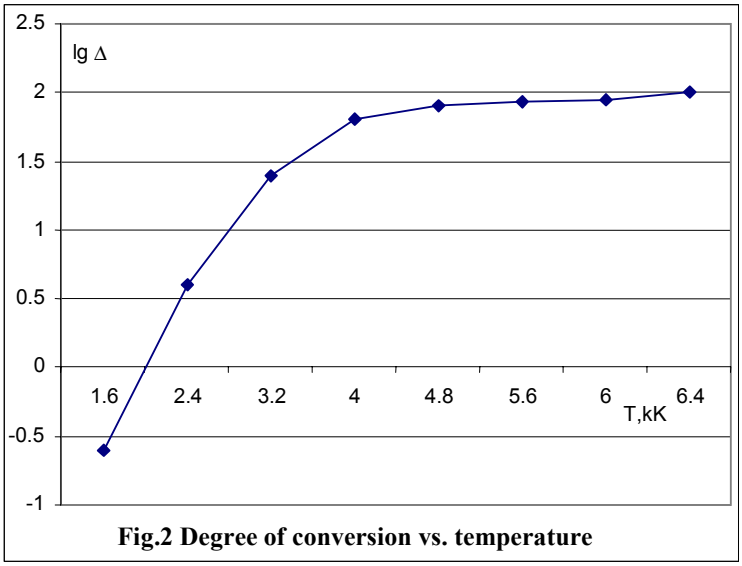

Fig.2 Degree of conversion vs. temperature

The calculation results are shown on fig 3 for two values of n: 0 and 0.5.

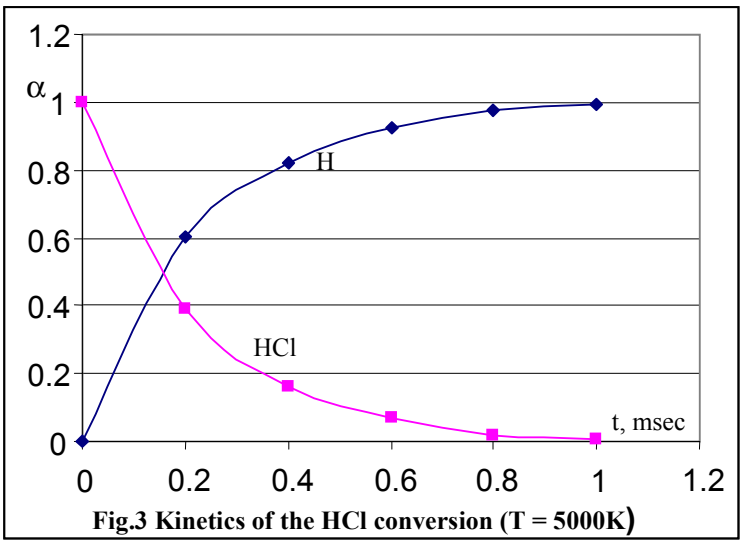

Fig.3 Kinetics of the HCl conversion (T = 5000K)

Comparison of the thermodynamic and kinetic calculations shows that dissociation temperature, which was calculated above, is higher then real. At this temperature the full dissociation is achieved at 7×10^{-3} sec for n = 0. For n = 0.5 the dissociation time is near 0.5×10^{-3} sec. The analysis shows that the treatment time can be achieved in the 0.01 – 0.2 meters long discharge chamber at an average plasma velocity of 30 m/sec.

4. Experimental Set-Up

The experimental diagram is shown on fig.4.

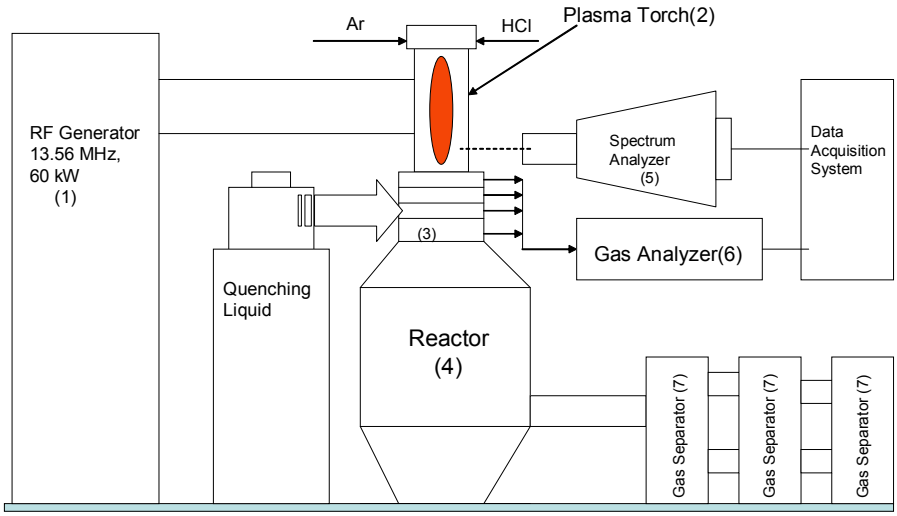

Fig.4 Experimental Set-Up

The Plasma Unit consists of a 60 kW RF generator(1) at 13.56 MHz working frequency, a hybrid plasma torch (2), a quenching device (3), a reactor (4), a spectrometer (5), a gas analyzer (6), and gas separators (7). The average gas temperature was 6000K at 10 kW discharge power. The plasma temperature didn't change within the range of a plasma gas rate between 0.25 l/sec and 10 l/sec. The plasma spectrum was obtained using an industrial spectrometer within a 220nm – 900 nm range with a linear dispersion of 4 Angstroms per mm. The gas was analyzed by a RGA -300. Samples were taken just after the quenching device.

Hydrogen Chloride was introduced to the plasma torch as a feed mixture using Argon as the plasma forming gas. Recombination of the Chlorine and Hydrogen ions into molecular H_2 and Cl_2 was achieved by cooling the product stream in the quenching device at different quenching rates (10^3 K/sec - 10^7 K/sec).
A high yield of Cl_2 and H_2 (typically 90 – 95% by weight) was obtained by plasma conversion of HCl as well as by cooling the gas product stream. Gaseous H_2 and Cl_2 do not react at normal temperatures in the absence of the light. However, at the temperatures above 300^0C, or in the presence of sunlight or artificial light (~ 470 nm wavelength), they combine explosively. The explosive limits of this mixture of pure gases are approximately an 8 % vol. of H_2 and a 12% vol. of Cl_2. This limit depends on temperature, pressure and concentration, additives, etc. Converted hydrogen and chlorine are separated after the quenching device by standard method (membranes).

5. Results and Discussion

The experimental data shows that the processes of HCl dissociation can be realized using RF plasma discharge and a small amount of Argon. The full dissociation of HCl to Hydrogen and Chlorine can be achieved with the following conditions: a plasma gas consisting of a mixture of Ar and HCl at a ratio of 1:1; a plasma gas rate = 1 liter per second; discharge power = 10 kW. These results are confirmed by gas analysis of the product before and after the quenching device. The plasma spectrum consists only of Argon, Chlorine and Hydrogen exited lines (Bulmer series). The intensity of Ar lines decreases with the increase of HCl ratio. At the same time the intensity of Hydrogen and Chlorine lines increases. The most sensitive "indicator" of the efficiency of the dissociation process are the Hydrogen lines (Bulmer series), especially, the H_α line (α =

6562.81 Angstrom). In this spectrum we observed the Chlorine lines, such as ClI (6531.43A), ClI(6434.80A), ClI(4363.3A), ClI4369.52A and ClI(94389.76A). The plasma spectrum between H_γ and H_δ (λ = 4101.74A) consists only of Argon lines. Also, we observed some very weak lines that are matched to impurities from the reactor's wall. The control of dissociation of HCl can be organized based on the analysis of the intensity of H_α, group of Cl lines in the range between 4370A and 4490A, as well as the Argon spectrum lines between H_δ and H_γ.

The analysis of the gas mixture in the reactor shows that they contain Argon, Chlorine and Hydrogen in molecular form. Fig. 5 shows the dependence of the HCl contents, C, in the plasma product mixture vs. RF plasma power.

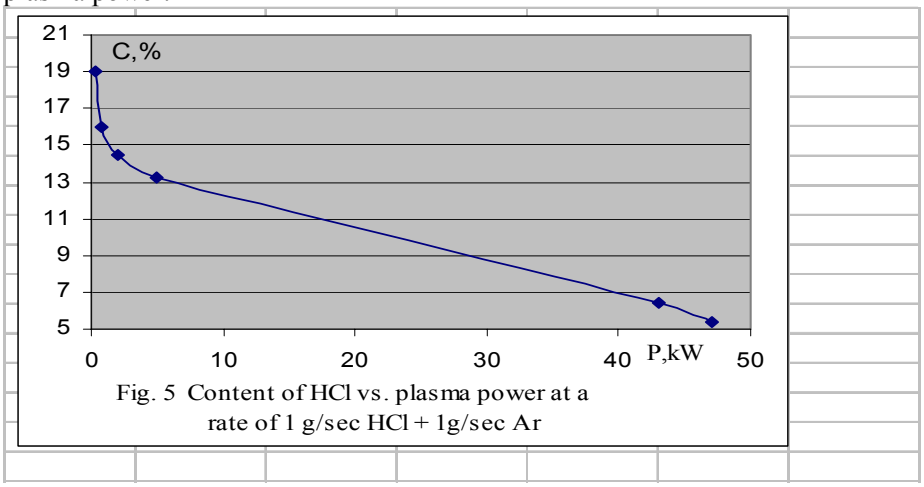

Fig. 5 Content of HCl vs. plasma power at a rate of 1 g/sec HCl + 1g/sec Ar

The dissociation of the C_6H_5Cl and $C_6H_2Cl_4$ was performed in the capacitive plasma discharge in the presence of water vapor. Fig. 6 shows the dependence of the destruction temperature vs. the specific plasma power.

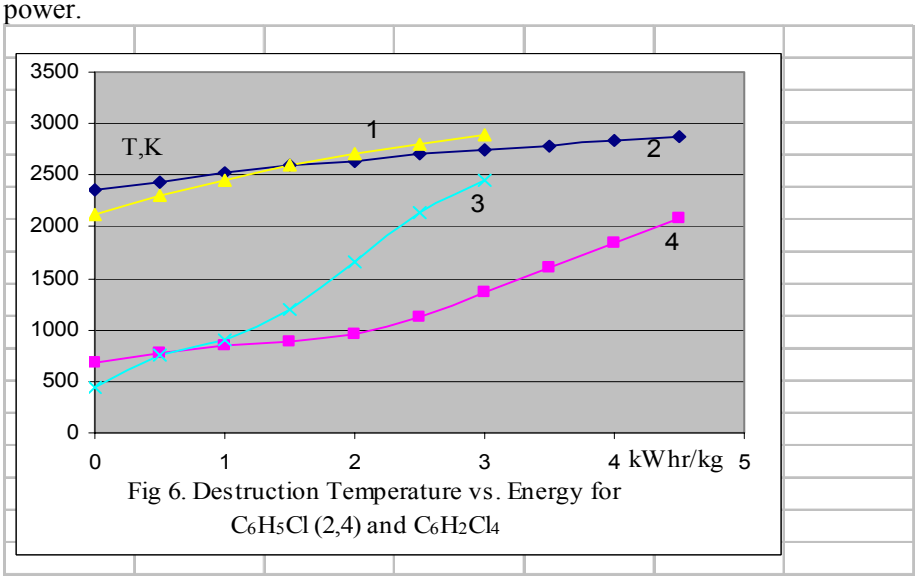

Fig 6. Destruction Temperature vs. Energy for C_6H_5Cl (2,4) and $C_6H_2Cl_4$

The advantage of capacitive plasma discharge over an inductive discharge is the higher stability of the operation at a lower discharge power due to a lower minimum sustained power [2]. Also, the electron temperature is considerably higher than the temperature of heavy particles that leads to an increase in the rate of dissociation (fig 7).

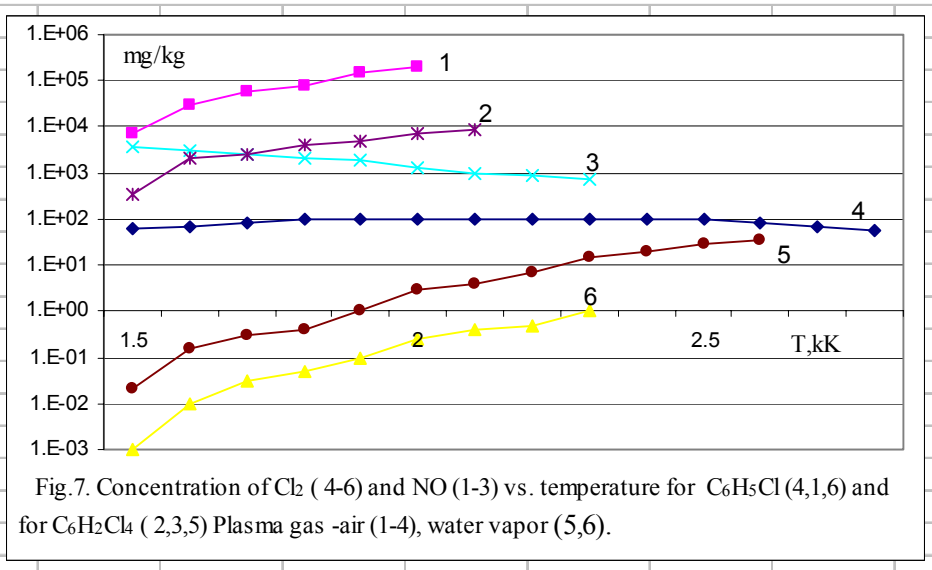

Fig.7. Concentration of Cl_2 (4-6) and NO (1-3) vs. temperature for C_6H_5Cl (4,1,6) and for $C_6H_2Cl_4$ (2,3,5) Plasma gas -air (1-4), water vapor (5,6).

Using the water vapor as plasma gas allows one to increase the discharge power while helping to decrease the by-products, like NO etc.

6. Conclusion:

1. The dissociation of HCl within the RF plasma discharge with the temperatures above 6000K has a thermodynamic character that is described above. Based on reactor design (the distance between discharge and quenching device was about 10 cm) the processing time was around $3x10^{-3}$ sec. According to our theoretical calculations for processing time $3x10^{-3}$ sec at T = 6000K, we can achieve 95% conversion (parameter n =0). This is close to our experimental results. The difference arises because the temperature profile is not uniform.
2. An important factor is the Argon. Argon was chosen for two reasons:
   -The ignition and stabilization of the RF discharge at atmospheric pressure is not difficult - Argon is an inert gas and can be recycled.
   It is known that fast argon ions Ar^+ can create a stable complex of $\{ArH\}^+$ and Cl during the collisions of Ar^+ and HCl [3-4]. The dissociation energy of the above complexes is around 2 eV. The existence of the above complexes was confirmed at low pressure and with fast ions in the discharge. The following reactions take place:

   $$Ar + e \text{ ---- } Ar^+ + 2e;$$
   $$Ar^+ + HCl \text{ -----} \{ArH\}^+ + Cl$$

   With RF plasma at high pressure in equilibrium the level of fast Ar^+ is relatively low. Thus, the probability of getting $\{ArH\}^+$ is also is very low. The same dissociation mechanism can be observed in the mixtures with other noble gases.

CLUSTERING PROPERTIES OF RARE GAS ATOMS ON AROMATIC MOLECULES

Abstract

The behaviour of rare gas atoms bound to aromatic molecules has been investigated by means of experimental and computational techniques. Experimental results are reported for aniline-neon and –argon systems, while theoretical results showing the importance of using realistic interaction potentials to rationalize the stereo dynamics of this type of systems is discussed for the model benzene-argon clusters.

Introduction

The behaviour of rare gas atoms bound to aromatic molecules was investigated experimentally by measuring the 0-0 band of the $S_1 \leftarrow S_0$ electronic transition of several van der Waals complexes formed in a molecular beam using high resolution electronic spectroscopy [1]. The analysis of the rotationally resolved spectra allowed us to determine the rotational constants and, therefore, to estimate the effective value of the various components of the moment of inertia for these systems. From these data it was also possible to determine, in special cases, the equilibrium value of the rare gas atom coordinates and the amplitude of the zero point motion.
Experimental results can be compared with theory by working out an interaction potential and performing a molecular dynamics (MD) simulation. To carry out meaningful MD simulations it is essential to use realistic representations of the potential energy surface. The difficulties arising in the description of the interaction of heterogeneous clusters and the sensitivity of the potential energy minima and transition states to the value of the parameters of the adopted functional form stress out the importance of providing an accurate description of the force field of the system [2]. In particular, for strongly anisotropic systems, like the benzene-rare gas ones, the atom-atom pairwise additive functional form has serious difficulties in describing geometries other than the most stable one. Nevertheless, these additional less stable geometries are very important since at certain temperatures they are accessible and make the system isomerize by transforming between different isomers via unstable geometries. Despite the fact that, as shown in several contexts, pairwise additive potentials give a poor description of inter- and intra-molecular forces, many MD studies of clusters of aromatic molecules and rare gas atoms have been performed using these potentials. There are basically two main reasons for this. First, pairwise additive potentials are easy to evaluate, allowing thus, faster computations. Second, it is difficult to obtain realistic estimates of the potential energy surface for complexes dominated by long range interactions using *ab initio* techniques.
In this paper we present experimental results for the aniline-neon and aniline-argon systems and we discuss the use of alternative formulations of the interaction by considering the prototype benzene-Ar system.

Experimental

Experimental studies on van der Waals complexes have been carried out at the Molecular Beam facility of LENS in Florence [1]. The apparatus for high resolution electronic spectroscopy consists of a 50 microns diameter nozzle that allows the flow of a high pressure gas mixture (sample and carrier gas; the total pressure is typically 600 KPa) into a vacuum chamber (pumped by a 6000 l s^{-1} diffusion pump). In the expansion process the collisions cool the sample gas down to a few Kelvin degrees. The expanded gas is then spatially filtered by a skimmer and enters in a second high vacuum chamber (10^{-4} Pa during the experiment) pumped by a 2000 l s^{-1} diffusion pump. The resulting molecular beam consists of very cold molecules travelling in the direction of the expansion in a collision free environment. Therefore, weakly bound intermolecular van der Waals complexes formed during the expansion can live long enough to be studied. By crossing the

molecular beam with a laser beam in a 90° configuration and by detecting with large aperture optics the total fluorescence emission from the excited molecules, we have set up a Doppler free molecular beam laser spectrometer working in the visible-ultraviolet region of the spectrum. The laser source is a single mode, frequency stabilized, ring dye laser (a modified Coherent 699-21, 1 MHz bandwidth, up to 2W mission round 590 nm) pumped by a large frame argon ion laser (up to 9W at 514.5nm). The dye emission is frequency doubled in a BBO crystal placed in an external optical resonator. In this way a laser beam of 40mW having a wavelength around 295 nm is generated. The instrumental frequency resolution of the spectrometer is about 15 MHz in a Gaussian profile, dominated by the residual Doppler broadening.

Results

The laser induced fluorescence spectra of the van der Waals complex of aniline with rare gas atoms obtained with a full rotational resolution (see Figure 1) have been analysed using custom software.

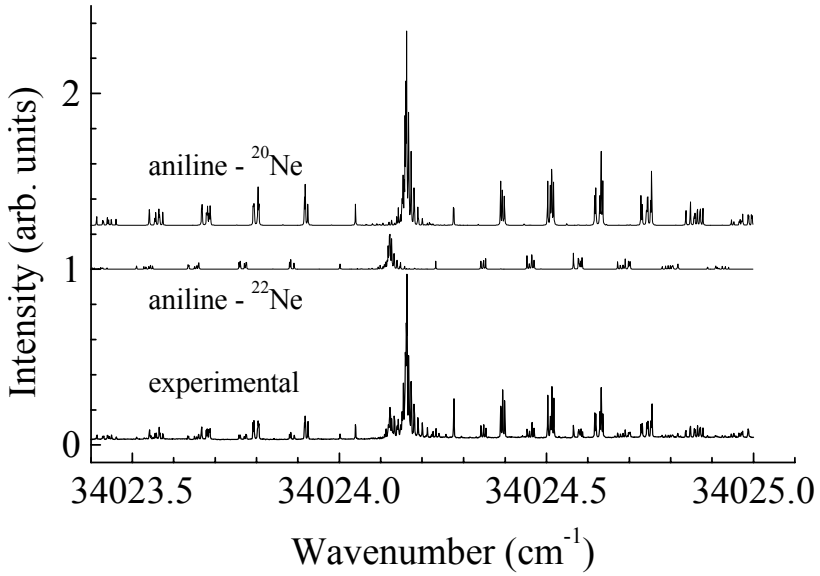

Figure 1: A comparison of the measured (lower curve) high resolution LIF spectrum of the 0_0^0 $S_1 \leftarrow S_0$ vibronic transition of the aniline-neon complex with its simulations (upper curves) calculated using the parameters of Table 1.

The pattern of the rovibronic spectrum has been simulated using the Hamiltonian of a rigid rotor by a trial and error procedure. This allowed us to assign a large set of transitions and to adjust the value of the ground and upper state rotational constants by a least square fit. The rotational constants offer a direct measure of the vibrationally averaged value of the various components of the inertia tensor. The related coordinate values are *effective* coordinates. The information contained in the rotational constants is in fact of the type $\langle X^2 \rangle$ whilst the structure is related to $\langle X \rangle$, with X being a generic coordinate of the complex. However the two quantities are related to the following equation

$$\langle X^2 \rangle = \langle X \rangle^2 + \langle \delta X \rangle^2$$

where $\langle \delta X \rangle$ is the mean vibrational displacement. Relevant data for the investigated systems are given in Table 1 where the ground and the excited state rotational constants of the aniline-neon and aniline-argon complexes are given.

Table 1: Ground and upper state rotational constants[a] of the aniline–neon and aniline–argon van der Waals complexes.

	A”	B”	C”	A’	B’	C’
Aniline–^{22}Ne	0.06100(2)	0.05537(1)	0.04182(2)	0.06043(2)	0.05478(3)	0.04251(9)
Aniline–^{20}Ne	0.06184(2)	0.05750(1)	0.04359(1)	0.06138(3)	0.05672(3)	0.04432(9)
Aniline-Ar	0.060029(8)	0.038265(2)	0.031023(2)	0.059306(9)	0.039083(2)	0.031989(2)

[a] Units: cm^{-1}; the standard deviation of the fit is reported in parentheses in units of the last significant digit.

In the case of the van der Waals complexes formed by aromatic molecules and rare gas atoms, the binding energy is so small (typically below 500 cm^{-1}) to consider the internal coordinates of the aromatic molecule unchanged after the formation of the complex. Therefore, the inertia tensor of the complex can be easily written using the rotational constants of the isolated aromatic molecule.

$$\begin{Bmatrix} k/A_0 + \mu(Y^2 + Z^2) & -\mu X\,Y & -\mu X\,Z \\ -\mu X\,Y & k/B_0 + \mu(Z^2 + X^2) & -\mu Y\,Z \\ -\mu X\,Z & -\mu Y\,Z & k/C_0 + \mu(X^2 + Y^2) \end{Bmatrix} \quad (1)$$

In equation (1) μ is the reduced mass of the complex, *X*, *Y* and *Z* are the Cartesian coordinates of the rare gas atom in the original reference frame of the aromatic molecule, and *k* is the proportionality constant $h / (8\pi^2 c)$ (in units of cm^{-1} amu $Å^2$) [3]. The effective values of *X*, *Y* and *Z* can be analytically derived by diagonalization of the inertia tensor, using the so-called Kraitchmann equations[4]. The reference frame has been placed on the aniline center of mass with the *XZ* plane coinciding with the symmetry plane of aniline (C_s symmetry) and the aromatic ring placed on the *XY* plane. The values of the vibrationally averaged coordinates obtained from the analysis of the inertia tensor are reported in Table 2.

Table 2**:** Ground (") and upper (') state effective coordinates[a] of the rare gas atom with respect to the center of mass of aniline (see the text for further information on the axis orientation).

	X"	Y"	Z"	X'	Y'	Z'
Aniline–^{22}Ne	0.2088(18)	0.2582(23)	3.40(3)	0.2203(10)	0.1660(8)	3.38(2)
Aniline–^{20}Ne	0.1807(15)	0.1279(11)	3.41(3)	0.1986(9)	0.1188(6)	3.38(2)
Aniline-Ar	0.2852(1)	0.2797(1)	3.504(1)	0.3434(2)	0.3541(3)	3.514(2)

[a] Units: Å; the standard deviation is reported in parentheses in units of the last significant digit.

The most significant information is provided by the effective value of the *Y* coordinate that represents the mean vibrational displacement of the rare gas atom out of the aniline plane of symmetry (C_s configuration). The value determined for the effective coordinate *Z* is also of relevance since it mainly reflects the average distance of the rare gas atom from the aromatic ring ($\langle Z \rangle >> \langle \delta Z \rangle$). The effective coordinate *X*, instead is less informative. In fact, it is impossible to disentangle the equilibrium and the vibrational terms which are both expected to be non zero and not differ by orders of magnitude.

Dynamical Calculations

As already mentioned, dynamical calculations were carried out for the model benzene-Ar(n) system. For this system some dynamical studies were performed in the past using pairwise additive potentials[5-7]. In our study, the potential proposed by Wales et al.[8] (obtained by summing the relevant Lennard-Jones (12-6) diatomic contributions (PES1)) was used. Preliminary results of our dynamical calculations for benzene-Ar(2) are given in references[9].
Recently, a realistic analytical potential energy surface (PES2) for benzene-rare gas systems, explicitly dealing with the dependence of the potential energy from the collision angles has been proposed[10]. This functional form, $V(R,\theta,\phi)$, is expressed as the product of a Morse-Swithing-van der Waals radial term times the spherical harmonics (expressed in terms of Legendre and associated Legendre polynomials[11]) describing the angular dependence of the interaction

$$V(R,\theta,\phi) = V_0^0(R) + V_2^0(R)P_2(\cos\theta) + V_4^0(R)P_4(\cos\theta) + \\ + V_6^0(R)P_6(\cos\theta) + V_6^6(R)P_6^6(\cos\theta)\cos(6\phi) \quad (2)$$

where the first radial term, $V_0^0(R)$, represents the isotropic component on the interaction and the remainder terms describe the overall anisotropy.
The parameters of the functional are optimised to the reproduction of crossed molecular beam data. The $V_0^0(R), V_2^0(R)$ and $V_4^0(R)$ radial terms have been parameterized switching a Morse function at short and intermediate distances and with a van der Waals dispersion attraction at long range. $V_6^0(R)$ and $V_6^6(R)$ have been parametrized switching an exponential function at short range with a simpler long range dispersion attraction.
In Figure 2 we show the coordinate system used to describe the benzene-rare gas complex adopted in this work.

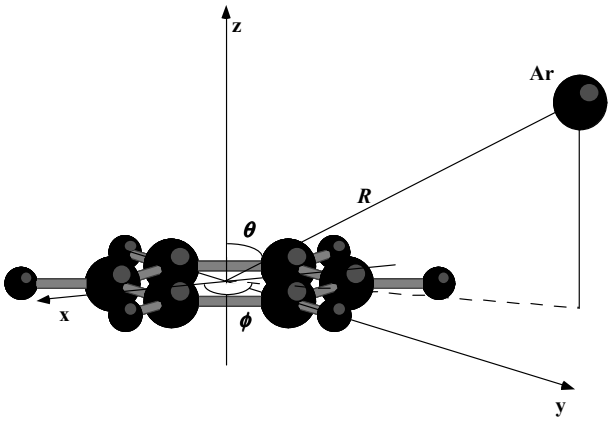

Figure 2. Coordinate system for the benzene-rare gas complex.

The value of the parameters of PES1 are given in Table 3 while those of PES2 are given in reference [10].

Table 3: Lennard- Jones parameters of PES1.

Atom pair	σ/ Å	ε / kcal mol^{-1}
Ar-C	3.42	0.11494
Ar-H	3.21	0.09435

A comparison of the properties of the two PESs is given in Figure 3 where the potential energy is plotted as a function of the angle θ for a given value of R and ϕ. The figure clearly shows that PES1 and PES2 have quite different properties near the in-plane configuration. (θ=90 degrees). Indeed, the energy barrier appearing when the system approaches to planar structures is much more pronounced for PES1 than for PES2.

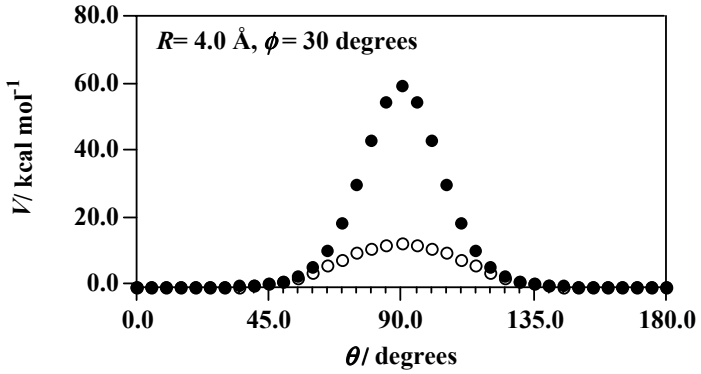

Figure 3. Potential energy *vs* angle θ. Solid circles (PES1), open circles (PES2).

It is interesting also to note that, as can be observed in Figure 4, the two PESs show non negligible differences also for geometries away from in-plane configurations ($\theta \neq 90$ degrees).

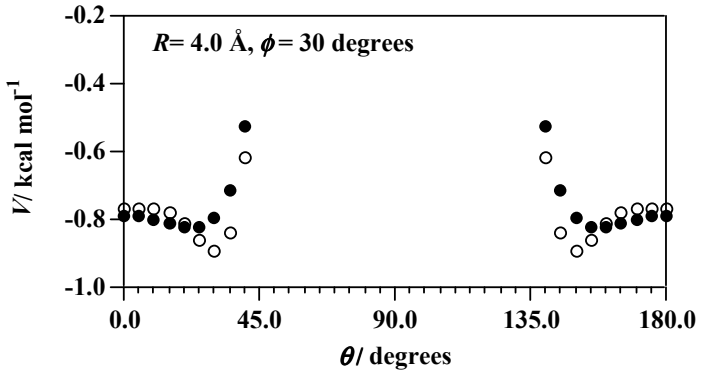

Figure 4. Potential energy *vs* angle θ. Solid circles(PES1), open circles (PES2).

As it can be seen in Figure 5, significant differences between PES1 and PES2 have been also found for the dependence of the potential energy on the ϕ angle. As a matter of fact the two curves show an opposite phase (i.e. a minimum for PES1 corresponds to a maximum for PES2 and *vice versa*). The behaviour of PES2 agrees with accurate *ab initio* calculations[12] predicting a minimum of energy when the Ar atom approaches C_6H_6 at the middle of the C-C bonds.

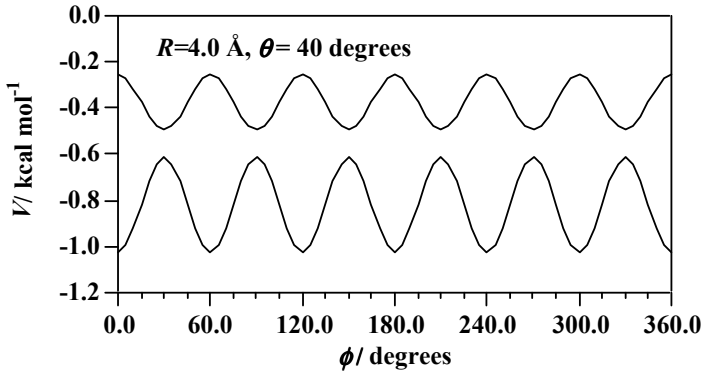

Figure 5. Potential energy *vs* angle ϕ. Dotted line (PES1), continuous line (PES2).

To carry out a dynamical test of the PES2 functional form, calculations were carried out using the DL-POLY suite of programs[13]. The temperature of the benzene-Ar system was set at 15 K and 25 K by taking the benzene molecule frozen at its equilibrium configuration. To introduce PES2 in DL-POLY an extended customization work was necessary. To this end, the interaction between the Ar atom and the centre of mass of the benzene molecule (once the molecule is correctly placed in the *XY* plane) is treated as an interaction bond by adding a dummy atom at the centre of mass of C_6H_6. The rotation of the system, needed to calculate the potential energy and the corresponding derivatives, was treated using the quaternion matrix representation. The forces were calculated by working out an analytical expression for the first derivatives of the potential.

This preliminary study shows that PES2 is appropriate for use in dynamical calculations. Dynamical simulations in the microcanonical ensemble during 100 ns allow to test the conservation of the total energy.

However, evidence was also obtained for the need of further improving the formulation of the potential functional. To this end work is being carried out on the development of a pseudo additive pair potential based on bond order coordinates[14,15].

Conclusions

The study of clustering properties of rare gas atoms and aromatic molecules is both an important experimental application and a challenging theoretical problem.

In this paper the experimental work carried out using the Molecular Beam apparatus at LENS has shown that it is possible to obtain from the experiment valuable information on the structure of the adducts.

From the theoretical point of view, the work pointed out some critical features of the interaction and the need for working out more accurate functional representations of the potential energy surface.

Abstract
The paper reports experiments on the glow-to-arc transition in deuterium in the pressure region 1-12 mbar. Rectangular high voltage pulses have been applied to electrodes of various materials at gap distances of 5-10 mm and in the presence of magnetic fields of 0-0.4 T in various configurations. The transition to the arc manifests itself by formation of cathode spots. The transition was analysed by high speed imaging with time resolution of 100 ns. It has been found that the formation of arc cathode spots is preceded by an enhancement of the particle density near the cathode. This can be reached by the formation of anodic plasmas (anode spots) prior to the occurrence of the cathode spots or by gas desorption from the cathode surface. If the latter is reduced by heating the cathode, the pulse voltage necessary for the transition is considerably increased. Also, conditioning effects can be explained by the role of adsorption. Admixture of 1 % oxygen to the gas strongly reduced the transition voltage for some materials. The consequence of these findings is that for the transition the electric field at the cathode is more important than the surface temperature.

1. Introduction

The transition of a glow discharge into an arc is an important issue of gas discharge physics. This phenomenon takes place at breakdown and after transient extinction of burning arcs. In spite of its widespread occurrence it is poorly understood. Since arcs with cold electrodes need cathode spots to exist, the transition means the generation of such spots where surface material is molten, evaporated and transformed into a surface plasma. So a general opinion is that contraction of the glow discharge plasma must enhance the energy transport to the surface until local melting takes place [1]. The present paper examines this question experimentally.

2. Experimental setup

The electrodes consisted of half-spheres of 10 mm diameter made of graphite, or of hairpins of tungsten or molybdenum made of wires of 1 mm diameter. They were placed in glass tubes connected to a clean vacuum system with base pressure 10^{-8} mbar. Spectrally pure gases could be introduced, especially deuterium, hydrogen and oxygen. The hairpin electrodes could be heated up to 2000 K by passing a current from a battery. Magnetic fields parallel or perpendicularly to the electrode axis could be produced by using coils or permanent magnets with an induction of 0.1–0.4 T. Figure 1 shows a section of the glass tube placed inside the coils. The upper electrode is the graphite anode, the lower electrode is the heated tungsten cathode. Rectangular high voltage pulses of 0.5-15 kV were applied to the electrodes via a series resistor of 110 Ohm. This resulted in a glow discharge, followed by the transition into an arc at sufficiently high voltage. The discharges were registered (i) by the high speed camera IMACON 468 having seven frame channels that use the same optical axis [1], (ii) by the sensitive color camera SENSICAM, and (iii) by a four channel digital oscilloscope having a bandwidth of 1 GHz.

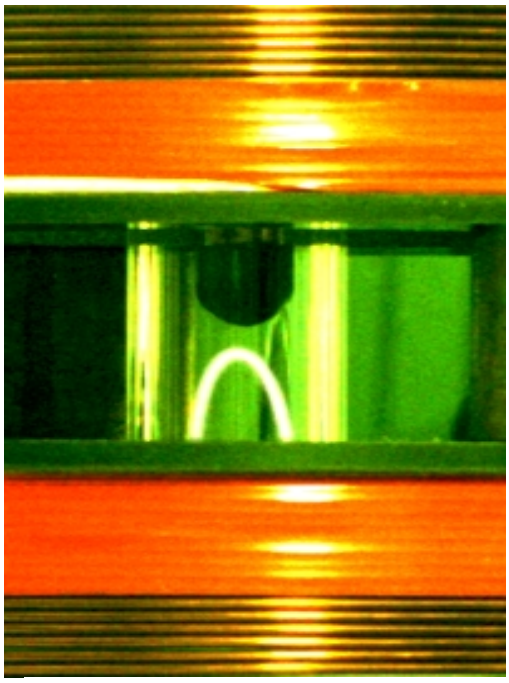

Figure 1: Discharge tube with electrodes, placed inside magnetic field coils. Upper electrode: graphite, 10 mm diameter. Lower electrode: hot tungsten hairpin.

3. Results

Figure 2 shows a discharge between graphite electrodes in 1 mbar deuterium with magnetic field parallel to the electrode axis. The magnetic field confines the glow discharge to a column with a diameter of the electrode size. The arc is characterized by a cathode spot and a luminous column. Figure 3 gives a time resolved sequence of the phenomenon. Here the glow-to-arc transition lasts 200-400 ns. Without magnetic field this transition is preceded by the formation of anode spots as demonstrated in figure 4. In frame 2 the glow discharge constricts itself at the anode, leading to anode spots after about 200 ns, frames 3-7. Another 200 ns later a cathode spot appears, frame 4. It produces surface plasma that expands against the ambient gas, frames 4-7. Thus, if there exits no magnetic field that confines the plasma, additional plasma must be generated at the anode to support the formation of cathode spots.

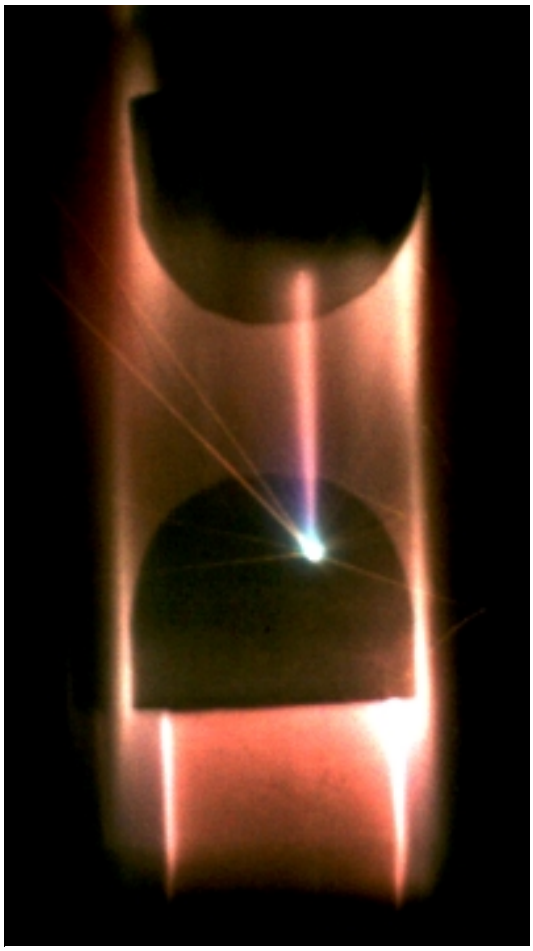

Figure 2: Glow-to-arc transition in deuterium between graphite electrodes. Electrode distance 7 mm, magnetic field (0.12 T) parallel to the electric field, pressure 1 mbar.

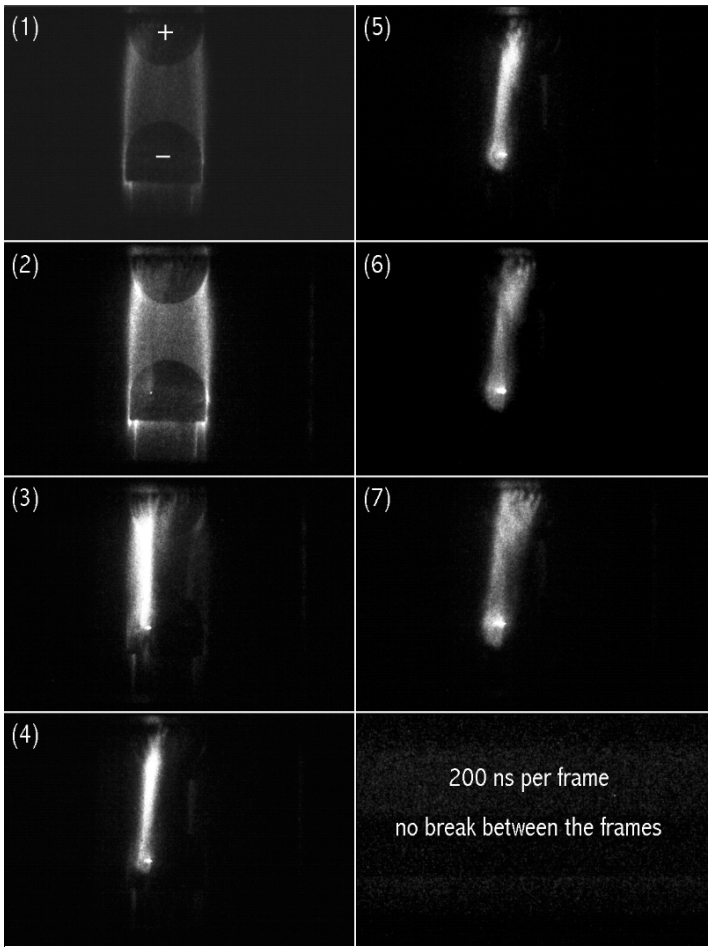

Figure 3: High speed photograph of a glow-to-arc transition at conditions equal to figure 1. Frame sequence down the columns, exposure time 200 ns, no break between the frames.

In a second experiment, the probability of unipolar spot formation (i.e. arcing by the contact of a floating electrode with a hot plasma) has been studied with a hot hydrogen plasma. The device has been described in ref. [2]. Here the plasma parameters were measured by Langmuir probes. As shown in figure 5, the probability rises strongly with the electron density.

Indirectly, another phenomenon could be identified that is important for the ignition of cathode spots, viz. the desorption of gases at the cathode. It manifests itself by conditioning effects and the influence of the cathode temperature. Figure 6 shows the arcing probability to decrease strongly as a function of the number of applied pulses for graphite electrodes. Figure 7 shows the pulse voltage necessary for 50% arcing probability as a function of the temperature of a molybdenum cathode. At about 1000 K there occurs a steep increase of the curve, reaching saturation at about 1400 K. Figure 8 demonstrates a combination of heating and conditioning effects. The arcing probability decreases by heating and by the repetition of the discharges.

After each curve the cathode was allowed to cool down, and the following curve started again with high arcing probability. Finally, admixture of oxygen reduced the arcing voltage as listed in Table 1.

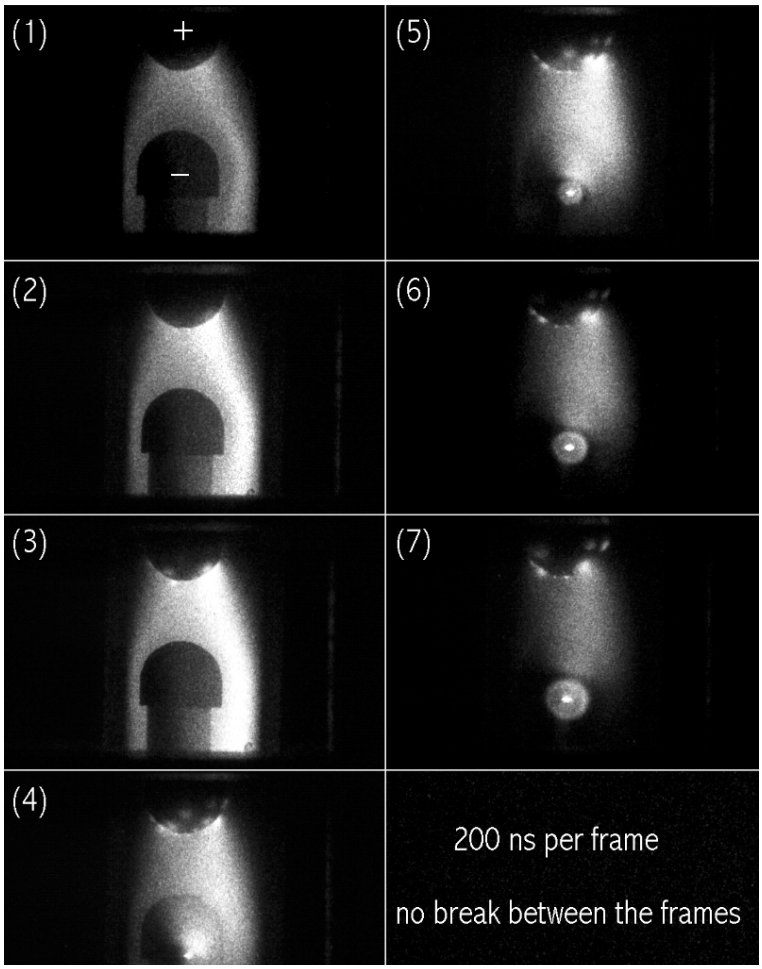

Figure 4: Analogous to figure 3, but without magnetic field.

Table 1**:** Voltage for 50% arcing probability after conditioning

Material	1 mbar D_2	1 mbar D_2 +1% O_2
Graphite at room temperature	2.3 kV	2.2 kV
Mo at room temperature	7.5 kV	5.9 kV
W at room temperature	13.5 kV	5.2 kV
Mo, W at 1400K	>15 kV	-

4. Discussion

The experiments show that cathode spot formation must be preceded by an increase of the particle density near the cathode. This can be achieved by the action of anode spots or by desorption of gases from the cathode surface. The latter explains the decrease of the arcing probability during conditioning (figures 6, 8) or the increase of the necessary pulse voltage as a function of cathode temperature (figure 7). As indicated in Table 1, adsorption of oxygen plays an important role. Such adsorbates have a high binding energy, so temperatures around 1000 K are necessary for desorption, in agreement with figure 7.

The steep curve in figure 5 demonstrates that the electron density is a very critical parameter. The effect must be due to the electric field in the space charge sheath rather than by the surface temperature. Otherwise the arcing probability would grow with the temperature. However, as figure 7 demonstrates, the breakdown

voltage increases strongly with the cathode temperature. From figure 8 it can be concluded that conditioning is more effective at high temperatures.

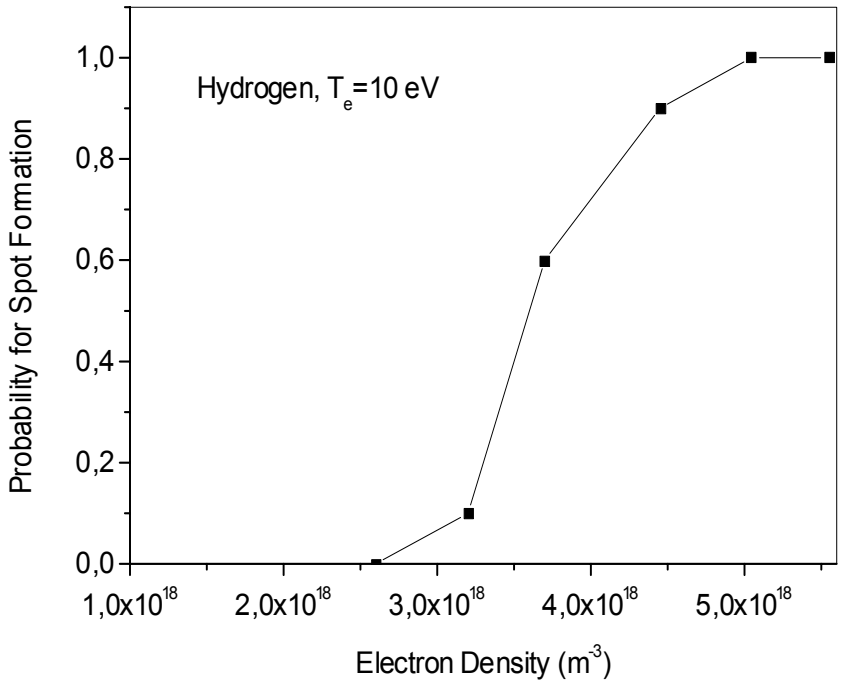

Figure 5: Probability of unipolar arcing in hot hydrogen plasma as a function of the electron density.

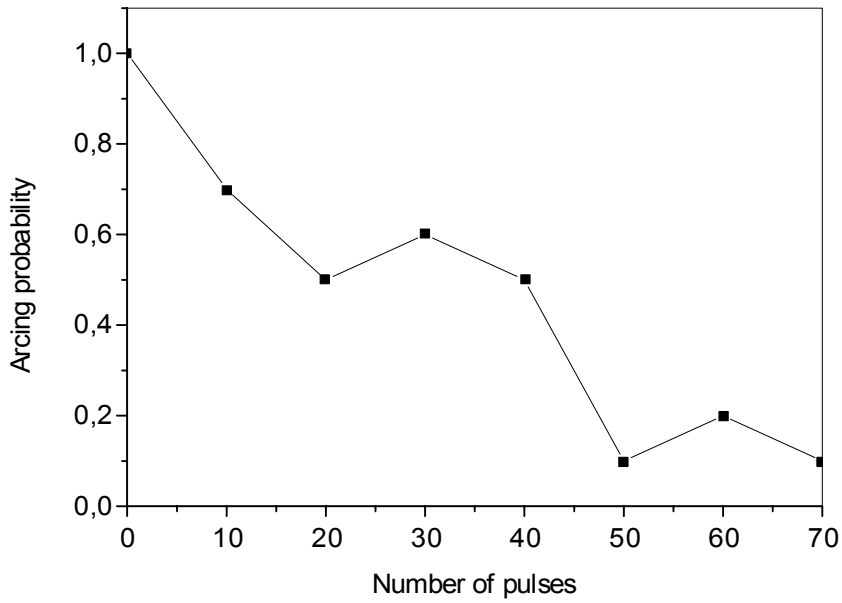

Figure 6: Arcing probability for graphite electrodes in deuterium (1 mbar) as a function of the number of applied pulses with an amplitude of 1.6 kV.

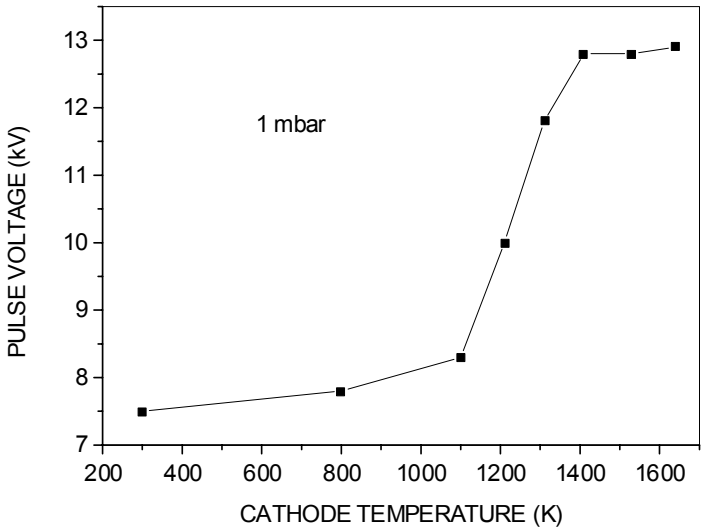

Figure 7: Pulse voltage necessary for 50% arcing probability as a function of the temperature of the molybdenum cathode.

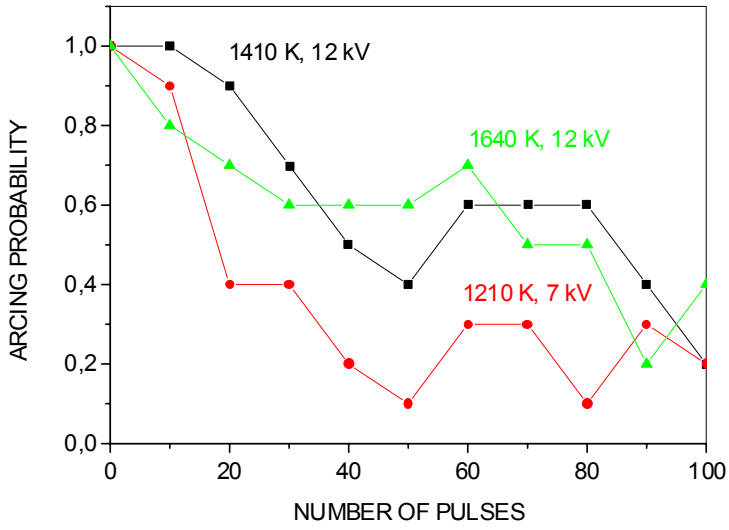

Figure 8: Decrease of the arcing probability as a function of the number of applied pulses at various temperature of a hot molybdenum cathode.

In a simplified form, the space charge field F at the cathode reads

$$F \approx \frac{kT_e}{e\lambda_{D,e}}\left(\frac{eV_c}{ZkT_e}\right)^{1/4}$$

where T_e and $\lambda_{D,e}$ are temperature and Debye length of the plasma electrons, respectively, Z is the ion charge, and V_c is the cathode fall voltage. With plausible values of plasma temperature and density, this formula yields fields $<10^7$ V/m, more than two orders of magnitude smaller than required by the Fowler-Nordheim equation for noticeable field electron emission. However, this does not mean that such emission is not possible. A similar

discrepancy is known from experiments with vacuum breakdowns. Here electron emission can be measured at similarly small fields (e.g. ref. [3]). Still another analogy is the vacuum-microelectronics where arrays of field emitters are produced by well defined solid-state techniques. For such systems Obraztsov et al. [4] found high emission at microfields that are by 1-2 orders of magnitude smaller than expected from the Fowler-Nordheim-equation. According to these authors the surface barrier is more complicated than assumed in the theory, so the tunneling probability is markedly increased.

5. Conclusions

At reduced pressures the glow-to-arc transition is controlled by the particle density at the cathode rather than by the local surface temperature. This points at the role of cold field electron emission for the initiation of cathode spots. Estimated values of the electric surface field indicate that this emission cannot be described by the classical Fowler-Nordheim-equation, a situation which is similar to phenomena of prebreakdown electron emission in vacuum.

A simple experimental method is proposed to investigate the radiation emitted from the boundary layer, which is formed near the insulator wall. This method consists of a fast-pulsed exploding aluminum wire set on the Low-Density PolyEthylene (LDPE) flat wall. Two phases have been observed in the intensity shape of the aluminum and the carbon atoms lines showing an enhancement during the collisionless interaction regime. The photoablation of LDPE wall was occurred during the plateau as observed in the temporal behavior of the intensity of the carbon atom line, which agree with the observed peak value in the UV radiation emission.

Deposition of High Density Aligned Carbon Nanotubes by Pulsed Plasma

Abstract

The growth of uniform films of well-aligned carbon nanotubes using pulsed plasma enhanced chemical vapor deposition is here reported. So, it is demonstrated that nanotubes can be grown on a certain critical catalyst film thickness and that their alignment is primarily induced by pulsed plasma excitation time. It is, in fact, found that switching the plasma source for 0.1s effectively turns the alignment mechanism on, leading to a sharp transition between the pulsed plasma-grown straight nanotubes and continuous plasma-grown curly nanotubes.

I. Introduction

Carbon nanotubes (CNTs), synthesized by different methods - arc discharge [1,2], laser vaporization [3], pyrolysis [4], plasma-enhanced chemical vapor deposition (CVD) [5,6] - have been extensively investigated for its unique physical and chemical properties [7-12] and for applications in nanoscale devices [13-15]. The main issues in this field are the synthesis in large quantities, reproducibility, controllability of diameters and lengths, selective growth and its further applications in nanoscale devices such as field emission displays, electrodes for secondary batteries, fuel cells, memory devices and so on [13-16]. In order to apply nanotubes to field emission displays, in situ growth of vertically aligned nanotubes in a large area of substrates is always desirable, since it does not require complex sample-preparation processes. For this purpose, vertically aligned nanotubes have been grown on glass [5] and on porous media [17], although the growth mechanism is still far from being clearly understood. Recently Zhou and coworkers [18] used a microwave methane/hydrogen plasma and clearly showed that the plasma enabled a vertically oriented growth of MWNTs. This encouraging results suggest that low temperature plasmas, particularly those with independent control of the substrate bias, can be useful in the growth of nanotubes with vertical alignment. In this paper, the growth of vertically aligned CNTs using a pulsed radiofrequency plasma enhanced chemical vapour deposition (PECVD) glow discharge system on a Ni catalyst layer is reported and a detailed parametric study of the various factors influencing the growth of CNTs is performed. Specifically, we investigated the effects of the timing of plasma excitation and catalyst layer thickness on the nanotube growth. The nanotubes are characterized using field emission scanning electron microscopy (SEM), atomic force microscopy.

II. Experimental Details

CNTs films were grown on (100) silicon substrates by pulsed plasma enhanced chemical vapor deposition of CH_4 plasma. Thin films (3 and 5 nm) of Ni catalyst were deposited onto Si_3N_4/Si substrates using thermal evaporation. With the plasma discharge in the off position prior to initiating the deposition, the substrates were heated to 650°C and held at this temperature for 15 minutes to induce the clusters formation of the catalyst layer before the activation of the CNTs plasma deposition.

Substrates were positioned onto the heated cathode, capable of reaching a maximum temperature of 850°C, connected to the radiofrequency (RF) power supply. For pulsed-PECVD runs, a peak RF power of 100W was applied during on-time excitation. In our experiment we used an on-time excitation of 0.1s with the duty cycle, defined as a fraction of the total time during which the power was applied, fixed at 50%.

The CNTs depositions were carried out with deposition pressure and temperature fixed at 53 Pa and 570°C, respectively. The total precursor (CH_4) gas flow rate was kept constant at 40 sccm. The film deposition was performed with a rf bias voltage fixed at –150V.

Atomic Force Microscopy (AFM) measurements were performed to evaluate the surface morphology of the films on a Digital Instrument (Model D5000) using the contact mode technique. The scanning electron microscopy investigation was performed on a field emission scanning electron microscope LEO 1530 operated at 5 kV.

III. Results and Discussion

Figure 1 shows AFM images of Ni films of varying thickness (3-5nm) after annealing at 650°C. It was seen that the annealed Ni forms small islands and that the island size depends on the thickness of the initial Ni films; in particular the higher the initial Ni layer thickness the larger the island diameter [19]. The XPS spectra of Ni 2p and O 1s core levels indicate the presence of oxygen physisorbed on Ni due to sample exposure to atmosphere after thermal evaporation [20].

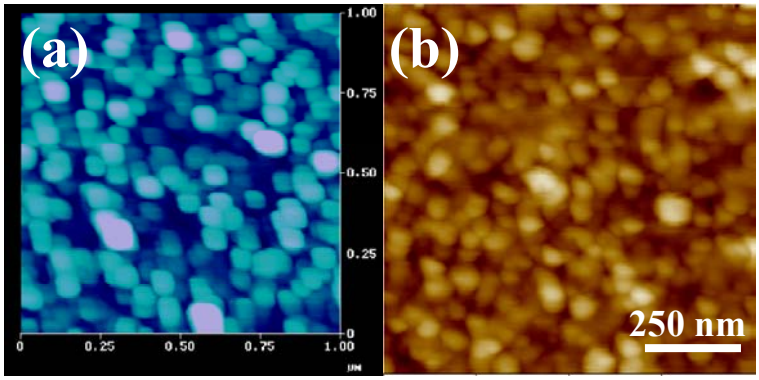

Figure 1: AFM images of Ni films with varying thickness, (a) 5 nm and (b) 3 nm, after annealing at 650°C.

Figure 2 shows high-resolution field emission SEM images of CNTs grown by plasma continuous mode on annealed Ni layers of different initial thickness. From the white spots in this figure it is clear how all nanotubes tips are terminated by the metal particles at the top. This strongly suggests, according to previous reports [21,22], that the metal particles play a crucial role as catalyst for the growth of the carbon nanotubes. With a catalyst layer thickness of 5 nm (Figure 2a) the density of nanotubes is low and amorphous carbonaceous particles are observed with nanotubes. As the catalyst layer thickness decreases to 3 nm the density of nanotubes increases with an average diameter of ≈30nm (Figure 2b). In both cases (Figs. 2a) and 2b) the nanotubes were seen to grow in a random and curly fashion.

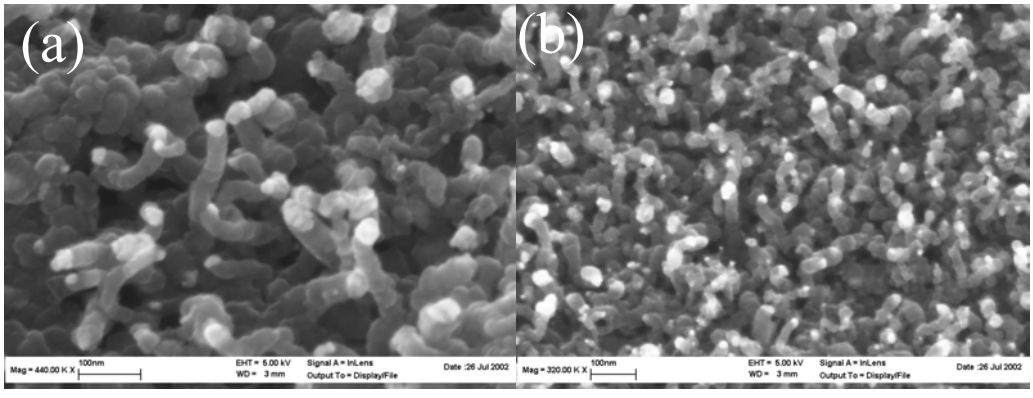

Figure 2: High resolution SEM photograph of CNTs grown by continuous plasma mode on (a) 5 nm and (b) 3 nm Ni catalyst layer thickness.

The micrographs of CNTs deposited with pulsed plasma are plotted in figure 3. Figure 3b) shows that well aligned CNTs can be grown on a Ni thickness of 3 nm. Figure 3b) also shows that the density of the tubes

increases with respect to that reported for the same sample deposited in continuous mode. As the catalyst layer thickness increases to 5 nm, the SEM image shows (Figure 3a) that the tubes appear always aligned but with a lower density.

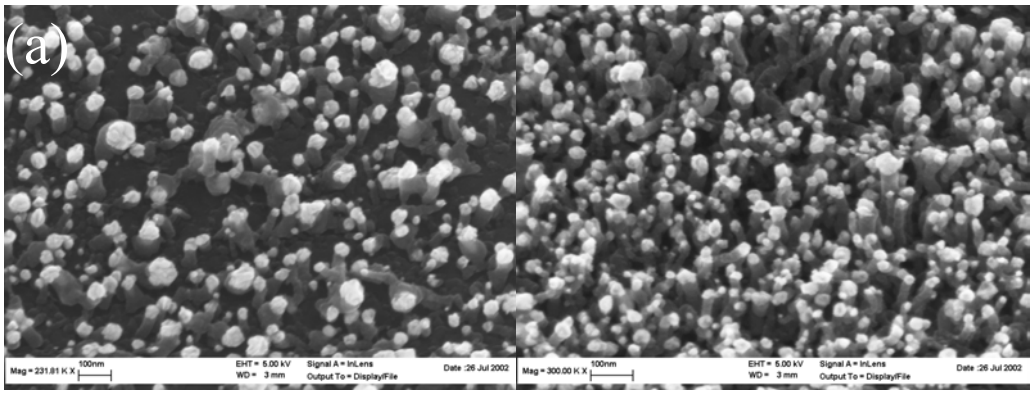

Figure 3: High resolution SEM photograph of CNTs grown with 0.1s on-time plasma excitation on (a) 5 nm and (b) 3 nm Ni catalyst layer thickness.

From the results reported here, two different carbon structures can be identified, depending on the plasma excitation mode: i) randomly oriented CNTs, which are formed by continuous plasma and ii) well aligned CNTs obtained with pulsed plasma.

The effects of the catalyst layer thickness seem to indicate a growth mechanism of CNTs similar to that reported in references [23-25]; in particular that the carbonaceous gas decomposes on the surface of the catalyst particle, the carbon diffuses across the particle and then, the carbon precipitates outwardly. As carbon atoms are further supplied, a carbon-metal eutectic alloy can be formed, decreasing the melting temperature of the alloy. The formation of carbon-Ni eutectic enhances the diffusion of carbon in the metal alloy, initiating carbon aggregations which act as a nucleation seed for nanotube growth. The carbon diffusion is limited by the domain size within the metal particles and thus the diameter of nanotubes should be smaller than the domain size. As the nanotube grows further, part of the metal domain is pushed upward, forming a metal cap. When the nanotube growth is initiated on the larger droplets, the force required to detach and raise them from the substrate is higher than that required for smaller Ni particles. This mechanical pulling of the larger Ni particle could be the origin of the observed round shape of graphite embedded in an amorphous carbon matrix [26].

Since all the carbon nanotubes are graphitic, and therefore conductive, two morphologically identical tubes will be subjected to the same electrostatic force without regard of the catalyst particle. Nevertheless, the images in Figs. 2 and 3 indicate that the magnitude of the electrostatic force on the CNTs is not the only determining factor in the nanotubes alignment. While the formation of a CNT can be explained by the formation of Ni droplets, uniform orientation is probably related to the different energy and flux of ion bombardment. In the case of deposition by continuous mode with analogous pure methane plasmas, it has been reported that the most abundant species are neutral species like CH_4, CH_3, C_2H_2, C_2H_4 and atomic hydrogen [27,28]. These neutrals species move in random directions, whereas the electric-field lines govern

the direction of travel for the ions. We noted that in our case, the Debey shielding distance is of the order of 100 μm. This distance is significantly larger than the CNT height and therefore, CNTs are located in the dark space of the glow discharge. If the etchant species are absent, then, in addition to the vertical growth process, carbon begins to precipitate also at the wall of the growing CNT. As a result, co-deposited amorphous carbonaceous particles are not removed selectively. Thus, in this case the excess of methane leads to a higher carbon deposition rate. On the contrary, in the case of deposition by pulsed plasma, the scenario for nanotube formation is quite different. In particular, according to Vandentop et al. [29], by pulsing the cathode to large negative voltages during the deposition, in addition to the primary ions CH_3^+ and CH_4^+ which are species produced by electron impact ionization of methane, secondary ions are present in relatively high ratios when the cathode is grounded (i. e. off-time excitation). These secondary ions, such as CH_5^+ and $C_2H_5^+$ are produced through ion molecule reaction. Furthermore, since the self-bias potential is proportional to the mass of the ions [$V=(kT_e/2e)\ln(m_i/2.3\ m_e)$] where k is Boltzmann's constant, T_e is the electron temperature, e is the charge of the electron, and m_i and m_e are the mass of ions and electrons respectively, the production of heavier ions by means of pulsed plasma is helpful in establishing a stronger local field at the surface, compared with other types of much lighter-mass ions produced by a continuous plasma. The electrostatic force would then induce these one-dimensional tubular structures to align in the field direction.

IV. Conclusions

To summarize, we have demonstrated that aligned carbon nanotubes can be obtained using pulsed plasma enhanced chemical vapor deposition with pure methane precursor. The nanotubes obtained by pulsed plasma grow always perpendicular to the local substrate surface regardless of the Ni catalyst layer thickness. Moreover, the use of this technique does not require the presence of etchant species in the plasma to reduce the formation of amorphous carbon during the deposition of the carbon nanotubes as reported for continuous plasma processes [19,30,31]. The electrical pulsed self-bias imposed on the substrate surface appears to be the primary mechanism responsible for the conformal alignment. In particular, by turning off the plasma source with an excitation time of 0.1s, which effectively turns on the alignment mechanism, a transition can be introduced between a pulsed plasma-grown straight nanotube and a continuous plasma-grown curly nanotubes.

Spectroscopic Diagnostics of Atmospheric Argon Radio Frequency Inductively Coupled Plasma

G. Gao[1], J. Mostaghimi[1], and L. Pershin[1]

[1] *Department of Mechanical & Industrial Engineering, University of Toronto, Toronto, Canada*

Abstract

An experimental study was conducted to determine the property fields of radio frequency inductively coupled plasma using optical emission spectroscopy. Various spectroscopic methods were checked for the measurement of non-equilibrium plasma fields. The Boltzmann plot method was proved to be still valid to obtain the plasma temperature. The electron density was estimated by the continuum emission method. Emission asymmetry of plasma close to the coil zone was also investigated and solved.

1. Introduction

Ever since Babat's discovery in 1942 [1], radio-frequency (RF) inductively coupled plasma (ICP) has found many applications in a number of different disciplines. It is used in analytical chemistry as a source of atomic excitation; in spray coating of metals and ceramics; and in nucleation and growth of submicron powders; etc. The distinguishable advantages of the ICP over other types of plasmas are that the plasma can be operated both in reduced and above atmospheric pressure, and because of the lack of electrodes, the discharge is contaminant free, and thus, its chemical composition can be precisely controlled. Furthermore, since the size of the plasma depends on the applied frequency and power of the induction current, it comes in a broad range of powders and sizes.

ICP is formed within a quartz tube by applying a radio frequency current across a load coil wound around the tube (Fig.1). Q_1 represents the carrier gas flow, Q_2 represents the plasma gas flow and Q_3 is the sheath gas flow. Depending on the application, the operating pressure may vary between 50 Torr to above atmospheric pressure; induction frequency from 0.2 to 100 MHz; plate power from 0.5 to more than 500 kW; and torch diameter from 13 to 200 mm. The choice of the plasma gas(es) depends on the type of application and any gas and/or mixture of gases can be excited by the RF fields.

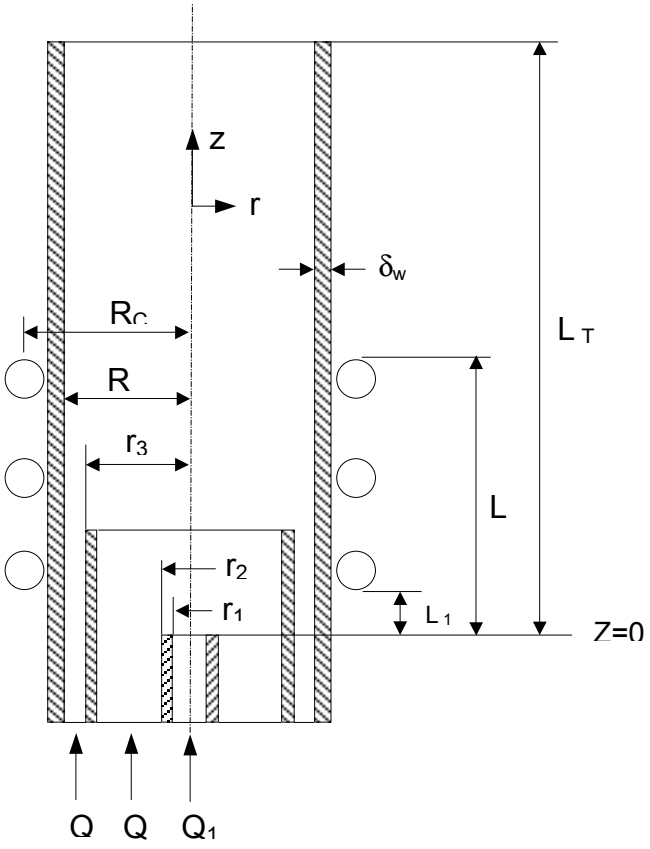

Figure 1 Schematic of a typical rf-ICP torch

The success of the applications of RF ICP depends to a large extent on our ability to control the conditions in the discharge. To have a complete understanding of the plasma processing and validate the mathematical model, the measurement of the crucial features of plasma is required. As is well known, the plasma temperatures, electron number densities, atom and ion emission intensities, number densities of analyte and argon species, and spectral line widths are generally considered to be the fundamental parameters of plasma.

We built a 40 MHz RF ICP in our lab running at atmospheric pressure with argon gas. For this high frequency, the size of the plasma torch can be quite small. The diameter of torch is 18 mm. However, in the small plasma area, the high temperature of heavy particles such as atoms and ions can reach 6000 K, while the electron temperature can be up to 8000 K. Due to the extremely high temperature and small size of the plasma torch, it is almost impossible to apply any intrusive measurement. The atomic emission spectroscopy (OES) method has been extensively used for plasma property measurements in the past

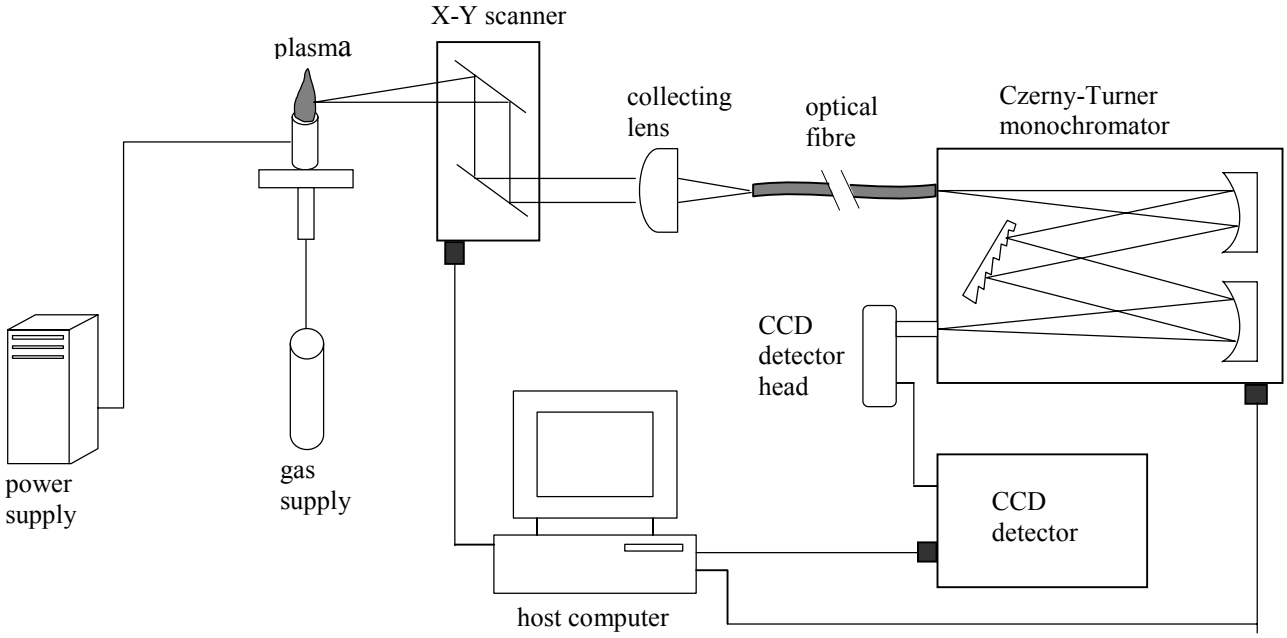

Figure 2 Setup of plasma emission spectroscopic diagnostics

decades. Although the measurements of plasma properties may rely on the equilibrium assumption in most cases and optically thin plasmas, emission spectroscopy remains one of the most powerful techniques for plasma diagnostics. It is still the most popular non-invasive diagnostic technique for temperature measurements, especially in axially symmetric plasmas. We established a fully computer controlled AES measurement system and measured the emission of argon RF ICP. The plasma temperature and electron number density were then obtained using different methods.

2. Experiment Facility

The equipment used for this study in our laboratory includes a radio frequency plasma generator, an OES measurement system, and a data acquisition system. The experimental setup for spectroscopic measurements of plasma fields is schematically shown in Figure 2. The 40MHz RF plasma torch was operated at the input power of 0.1 ~ 1 kW and under atmospheric pressure. The working gas was pure argon. The optical spectroscopic system includes a monochromator fitted with a CCD detector, a mirror scanner, and optical focusing lenses. The spectroscopic measurements were performed using a Jobin-Yvon monochromator. It has 0.025nm Resolution with 1200 g/mm grating. A 2-D electro-optical scan head and a digital scanning controller (DSC) from General Scanning Inc. were used for the sampling of optical emissions from any desired location in the plasma and can precisely scan a portion of the plasma radially and axially. A host computer controlled device operation and data acquisition. A calibrated quartz tungsten halogen (QTH) lamp from Thermo Oriel was used for absolute calibration of spectral intensities.

3. Spectroscopic methods

Most spectroscopic methods require the plasma is in equilibrium state in certain level such as local thermal equilibrium (LTE), local Saha equilibrium (LSE), etc. However, the plasma in our study is in strong non-equilibrium state. Therefore it is essential to find methods still valid under this condition. The spectroscopic methods we used require that the plasma is at least in the state of partial local Saha equilibrium (PLSE), in which electrons in higher exicted states are in equilibrium with free electrons and their distribution is given by Saha-Boltzmann relation characterized by a temperature equal to the electron temperature. And the electron is allowed to differ from the temperature of heavy particles. For temperature measurement, we checked several methods

Provided populations of excited states obey Boltzmann distribution, the emission coefficient ε_{pq} of an atomic line corresponding to a transition from a level p to a level q can be written in the form

$$\ln\left(\frac{\varepsilon_{pq}\,\lambda_{pq}}{g_{pq}\,A_{pq}}\right)=-\frac{E_p}{kT}+\ln K(T) \qquad (1)$$

where λ_{pq}, A_{pq}, E_p, and g_p are the wavelength of the spectral line, Einstein transition probability, statistical weight and excitation energy of the upper level respectively, and $K(T)$ includes parameters independent of the transition. Plotting $\ln(\lambda\varepsilon/Ag)$ versus E_p using emission coefficients of measured atomic lines forms the Boltzmann plot. The excitation temperature T_{exc} is then obtained from a slope of the straight line fitted to the points in the Boltzmann plot.

As a variation of this technique, two line intensities with sufficiently different excitation energies can be used to determine the temperature directly from

$$T=\frac{E_2-E_1}{k\ln\left(\frac{\varepsilon_1\lambda_1 A_2 g_2}{\varepsilon_2\lambda_2 A_1 g_1}\right)} \qquad (2)$$

where λ, A, E, and g are the wavelength of the spectral line, Einstein transition probability, statistical weight and excitation energy of the upper level of two spectral lines respectively.

4. Results

For one spatial position, we let the AES system do one test and obtain the spectrum at certain wavelength. Line and continuum emission intensities and spectral line width were recorded for this scanning point. By moving the mirrors of the electro-optical scanner, we can collect the spectra of all the positions within the plasma area.

Due to the ability of rapid diagnostics of our system, we can collect the 2D spatial emission distribution profiles in minutes. Figure 3 shows the lateral line emission profile at 696.54 nm of argon plasma. Usually we only need to measure half of the plasma region in order to get the local emission coefficient as long as the axisymmetry assumption is valid. In our experiment, we scanned the whole plasma area. The interesting

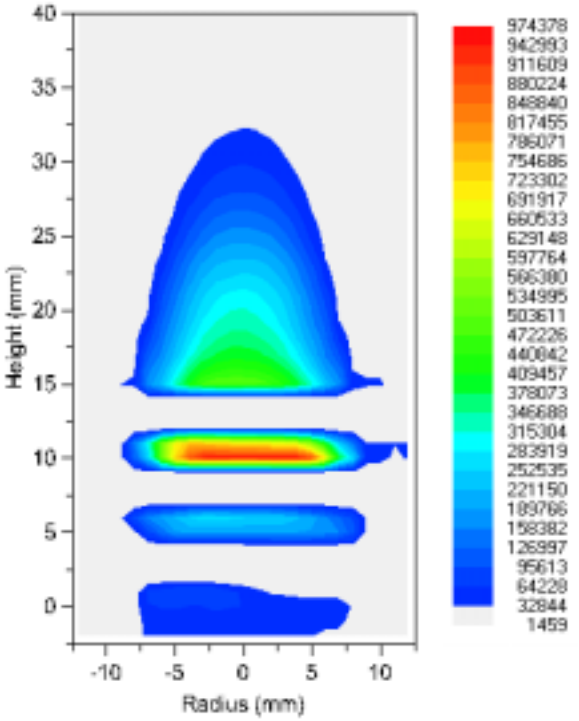

Figure 3 Lateral line emission profile at 696.54 nm

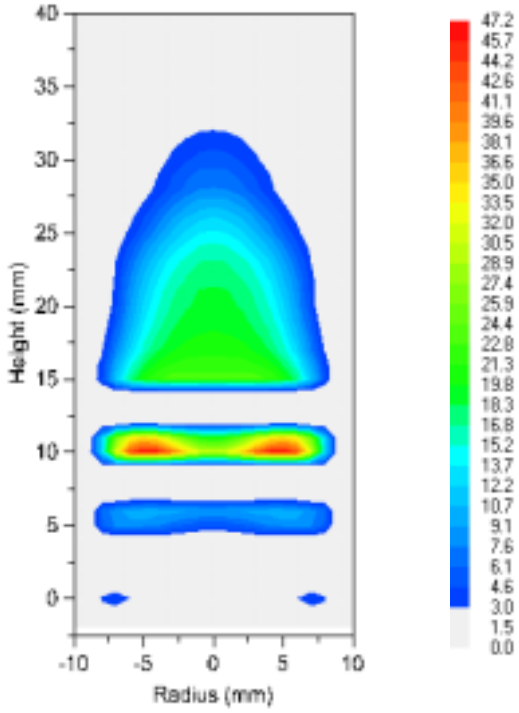

Figure 4 Local line emission coefficient at 696.54 nm

thing we found is that there was obviously non-axisymmetry existing within the load coil zone, while outside of the coil zone the emission distribution appeared to be symmetric. Abel inversion is popularly used to obtain the local emission coefficients but it is only valid for axisymmetric emission distributions. Figure 4 shows the local emission coefficient profile at 696.54 nm obtained by applying Abel inversion.

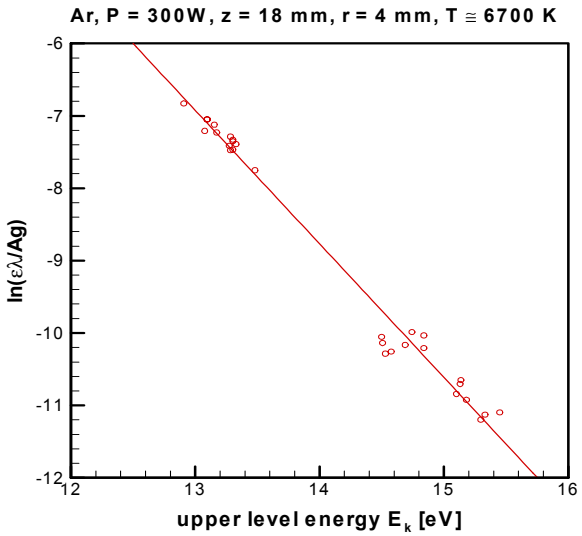

Figure 5 Boltzmann plot

Without knowing the electron number density at first, the Boltzmann plot is a method for getting the plasma temperature. However, the Saha-Boltzmann relation is not always valid in the Ar ICP. So we need to check the Boltzmann plot for both different position and different temperature range. To cover the most part of atomic argon state distribution, we selected about 30 spectral lines with wavelengths between 415 and 912 nm. All atomic properties were taken from [2]. A typical Boltzmann plot is shown in Figure 5. As we can see, the resulting Boltzmann plot is of quite high quality with the slope of the linear relationship through the data producing an unambiguous plasma temperature. The Boltzmann plots obtained from different regions of the plasma demonstrate a good capability to measuring temperatures over a wide range between 2500 K and 10000 K. Two Ar-I emission lines at wavelengths λ_1 = 696.54 nm and λ_2 = 518.77 nm were chosen for rapid diagnostic use of the line-intensity ratio method for plasma temperature measurement. This selection was based on the stronger intensities of these lines compared to others as well as the sufficiently different excitation energy levels of these transitions as indicated in Figure 5.

Figure 6 shows the measured plasma temperature by two wavelengths at 696.54 nm and 518.77 nm. According to the comparison between the measured temperature and the prediction of the Two-temperature

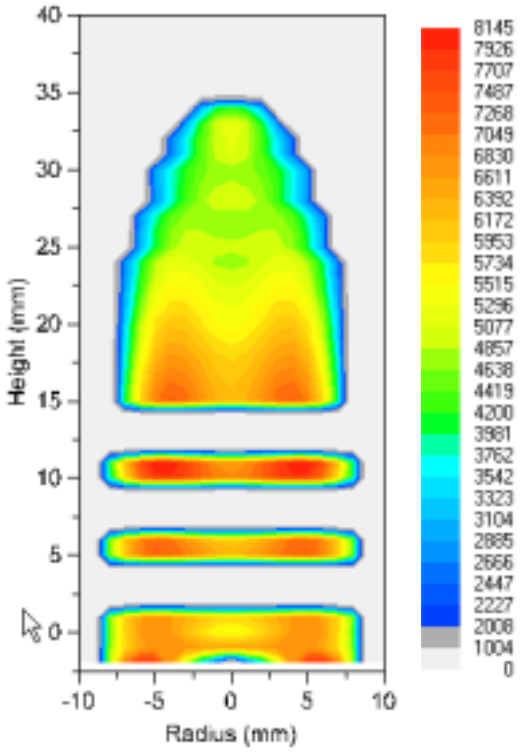

Figure 6 Measured temperature by line-intensity ratio method with wavelengths at 696.54 nm and 518.77 nm

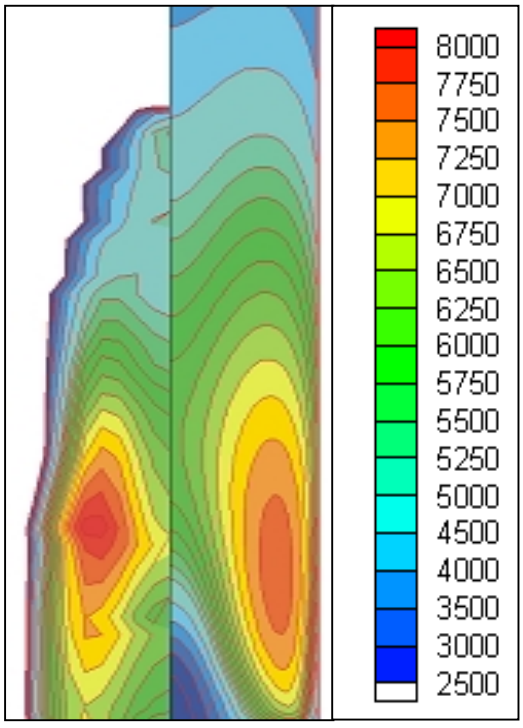

Figure 7 Comparison between measurement and prediction from the mathematical model

model, as shown in Figure 7, good agreement between measurement and calculation exists within the plasma torch. The difference at the downstream area may be caused by the assumed "infinite long tube" boundary condition used in the model. Plus, at the outlet of the tube, pure argon gas is mixed with cold air, mostly the nitrogen, which cools the plasma flow much faster than that estimated in the model.

Besides the Boltzmann plot method, the other methods of temperature measurement, however, were proven to be not suitable for the non-equilibrium plasma in our study.

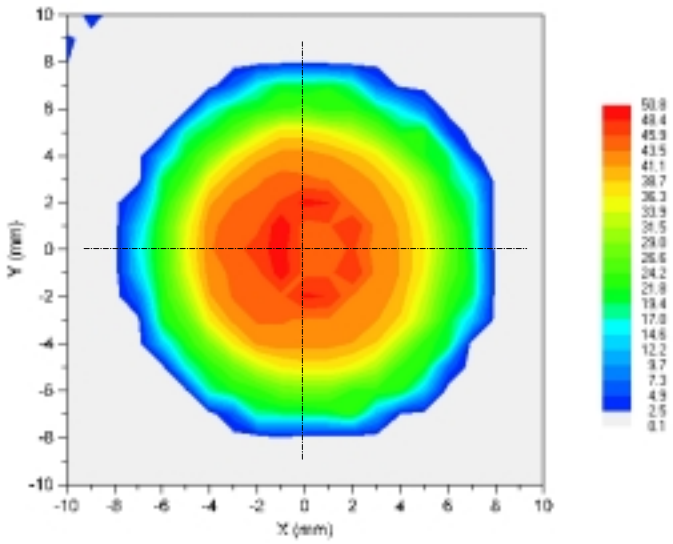

Figure 8 Top view of plasma line emission at 696.54 nm

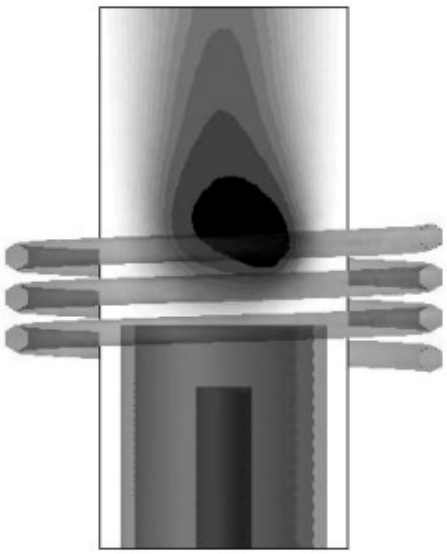

Figure 9 Schematics of induction coil configuration

To investigate the non-axisymmetry emission of plasma, we measured the emission from the top of the plasma torch. As shown in Figure 8, the line emission at 696.54 nm clearly shows the non-axisymmetry. Although it is the integral of the local emission along the axis direction, the measured emission still represents the asymmetry of the plasma temperature field. We figured that the asymmetry distribution is due to spiral configuration of the induction coil. As shown in Figure 9, the each turn of coil doesn't remain in the same flat surface. This results in the non-axisymmetric electric field and consequently the plasma fields.

Since the Abel inversion is not valid any more for non-axisymmetric emission distribution, we need to find other effective way to obtain the local emission under this situation. Fortunately, the asymmetry happens mostly in the regions within or close to the coil zone. Above the coil zone, we still can apply Abel inversion.

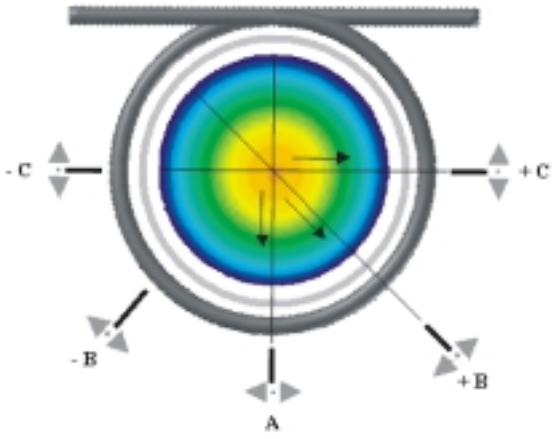

Figure 10 Definition of directions of the side-on measurement

We applied emission tomography method to calculate the non-axisymmetric local emission coefficient based on the lateral emission profiles measured at different directions around the plasma torch. As shown in Figure 10, we measured several lateral emission profiles at A, ±B, and ±C directions. Some of them show nearly symmetry, while others don't. Firstly, we assume an axisymmetric local emission coefficient as initial guess. Then we use each measured lateral emission to correct the original profile. When the procedure finally comes to convergence, we will obtain the 2D local emission $\varepsilon(r,\theta)$, which fits all the lateral emission profiles.

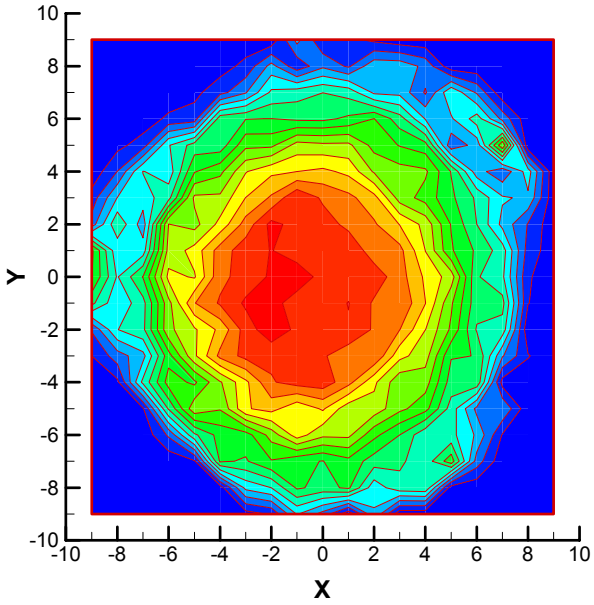

Figure 11 2D local emission coefficient profile obtained by applying the emission tomography method

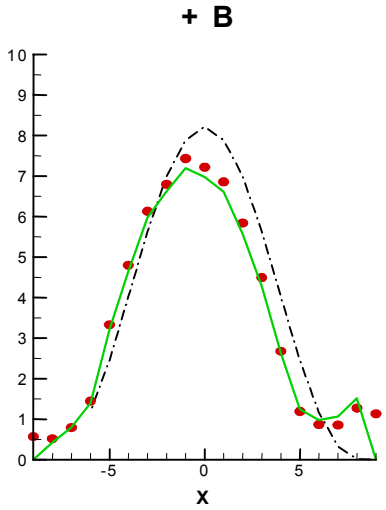

Figure 12 Comparison of lateral emission among symmetric initial guess (black dash-dot line), measurement (red points), and calculated profile based on the 2D local emission in Figure 12 (green solid line).

Figure 11 shows the calculated the local emission profile at height z=16 mm (just above the coil zone) by applying emission tomography method. From this distribution, we can calculate the lateral emission at each projection direction. As shown in Figure 12, the calculation at "+B" direction is in great agreement with measurement.

5. Conclusions

A fully computer-controlled optical emission spectroscopic (OES) measurement system for plasma studies was established. The emission coefficients of line and continuum radiation and spectral line width were measured for each spatial position within the plasma area. Based on the emission profiles, different methods were applied to calculate the plasma temperatures and electron number density. The Boltzmann plot was checked for different positions and different temperature ranges. The results show that the Saha relation exists in the plasma studied. Therefore the line-intensity ratio method provides reliable temperature without knowing the electron density. The non-axisymmetric emission of plasma was investigated. And the emission tomogrphy method was proven to be a effective way to obtain the 2D local emission profile.

Abstract
We have developed a new 'two-mesh' low-pressure plasma reactor for the surface treatment of polymeric materials, in which the electron temperature (and therefore ion energy) and ion flux can be controlled independently in the range 0.2 to 5.6 eV, and 0.2 and 5.4 x 10^{18} m^2 s^{-1} respectively. XPS analysis of treated PS samples show that the surface O/C ratio rises from 20% to 29%, with increasing ion dose from 1 to 5 x 10^{20} m^{-2} at an ion energy of 21 eV. However, our preliminary results indicate that the O/C ratios are insensitive to changes in the ion energy between 1.5 and 21 eV.

1. Introduction

There is currently much interest in developing low-pressure plasma discharges with greater control over the plasma parameters, for instance, the electron energy distribution function (eedf), so that the ion energy and flux at a material substrate or work-piece can be tailored, to provide selectability in the surface process.

One method to alter the eedf is to separate the plasma into two parts: a main plasma, which is sustained through electrical excitation and a diffuse process plasma which is maintained by transport of particles from the main discharge. This has been done using a single fine electrically biased separating mesh [1 - 5], allowing T_e to be changed from about 0.2 to 5 eV, however it is difficult to independently control the ion flux Γ. For instance, with increased negative mesh bias, both T_e and Γ fall substantially in much of the usual mesh bias range, say –20 to +30 V. Some independent control over T_e and Γ has been achieved with the single mesh technique [6], however, it is necessary to vary either the discharge power and pressure simultaneously or the substrate location. Recently, the technique has been extended to the use of two meshes instead of one [7], in which both meshes are biased separately, giving greater control over both T_e and Γ downstream. The important feature employed in all these techniques is that the secondary plasma has no plasma sustaining electric field across it and the emerging electrons can cool through collisions with the gas. Here, we develop the two-mesh discharge and treat polystyrene surfaces in it over arrange of independently controllably plasma parameters.

2. The experimental set-up

The two-mesh separated discharges configuration is shown in figure 1. It consists of an RF plasma source separated from the downstream process chamber plasma by an assembly containing the two electrically biased fine meshes. A turbo-molecular pump unit was used to pump the system to a base pressure of 10^{-3} Pa. The system is described in more detail in [7]. An electrostatic double probe [8] have been used to determine the plasma parameters (T_e, Γ) at a distance of 15 mm downstream of the mesh in the process chamber, for different bias potentials on mesh 1 (5-30 V) and mesh 2 (-20 to +30 V). In this study, the pressure was fixed at 2.6 Pa, and an RF plasma power of 20 W was used. Contour maps of T_e and Γ are shown in figure 2. For the surface treatment work, the polystyrene samples (1 cm diameter coated glass cover slips) were processed 15 mm from the second mesh in a specially constructed sample holder. The holder was equipped with a special draw, which was opened after the plasma discharge was allowed to settle down for approximately 10 minutes prior to treatment. The open face of the polystyrene samples were orientated upwards, perpendicular to the meshes, so as to reduce the vacuum ultra violet radiation (VUV) bombardment from the source plasma, i.e. to block the line-of-sight with the RF plasma source.

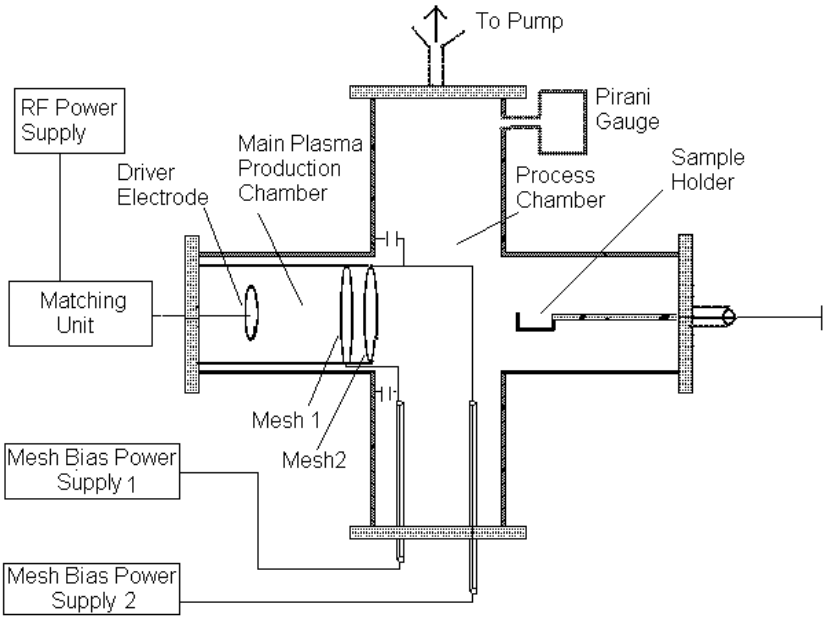

Figure 1: A schematic diagram of the two-mesh-separated plasma discharge, and the sample holder.

3. Results and Discussion

The double probe results (figure 2) show that through grid biasing, the electron temperature in this discharge can be varied from 0.2 to 5.6 eV. Given that there is no RF field in the discharge, and assuming idealised argon plasma, this corresponds to bombarding ion energies in the range 1 to 29 eV. This calculated from 5.2 x T_e (in eV) for argon plasma [10]. The probe results also show to an electrically isolated surface, the ion bombarding fluxes can be controlled between 0.2 and 5.4 x 10^{18} m^2 s^{-1}. Importantly, through grid control, (the line $V_{mesh\ 1}$ = +20 V), the electron temperature varies by an order of magnitude while ion flux varies by only a factor of two.

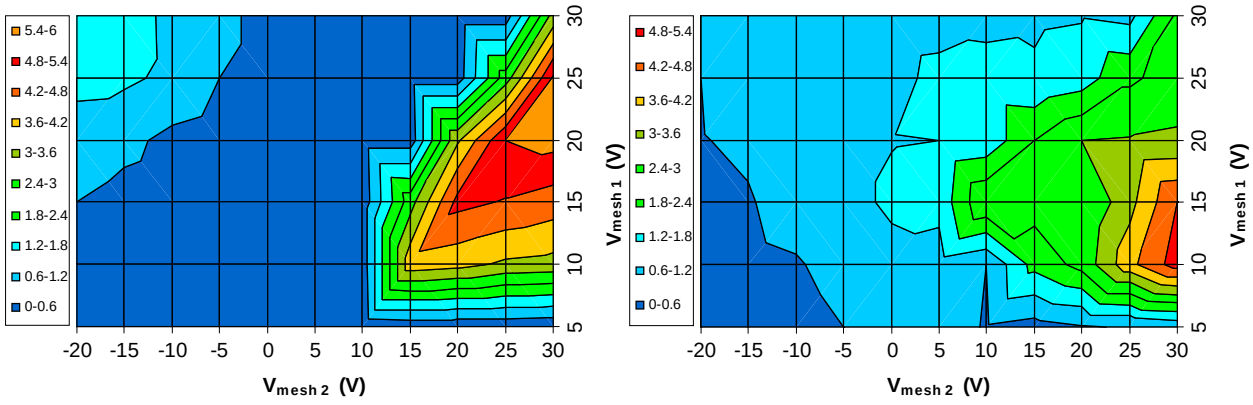

Figure 2: Contour plots of a) electron temperature T_e (eV), b) the ion flux Γ (x 10^{18} particles $m^{-2}s^{-1}$) at a position 15 mm from the mesh in the process chamber, for a variation in mesh biases, $V_{mesh\ 1}$ and $V_{mesh\ 2}$. The pressure is 2.6 Pa and the main plasma power is 20 W.

Figure 3 shows the oxygen to carbon ratios (O/C) measured in the top surface by XPS after the samples were exposed to atmospheric oxygen, (i.e. post-treatment) against the total ion dose to the

surface (flux x treatment time). The treatment time was 120 seconds in each case. Through biasing the meshes we have varied the ion bombarding flux for two different electron temperatures, 0.26 and 4 eV respectively, corresponding to approximately 1.5 and 21 eV ion bombarding energies. In the high-energy case, the O/C ratios clearly increase with dose as expected [11], however it is difficult to judge the trend for the low ion energy case due to the lack of data points taken in these preliminary experiments. The results do show however, similar treatment levels for the high and low ion energy cases, and we may tentatively suggest that the O/C ratios are independent of ion energy in this energy range.

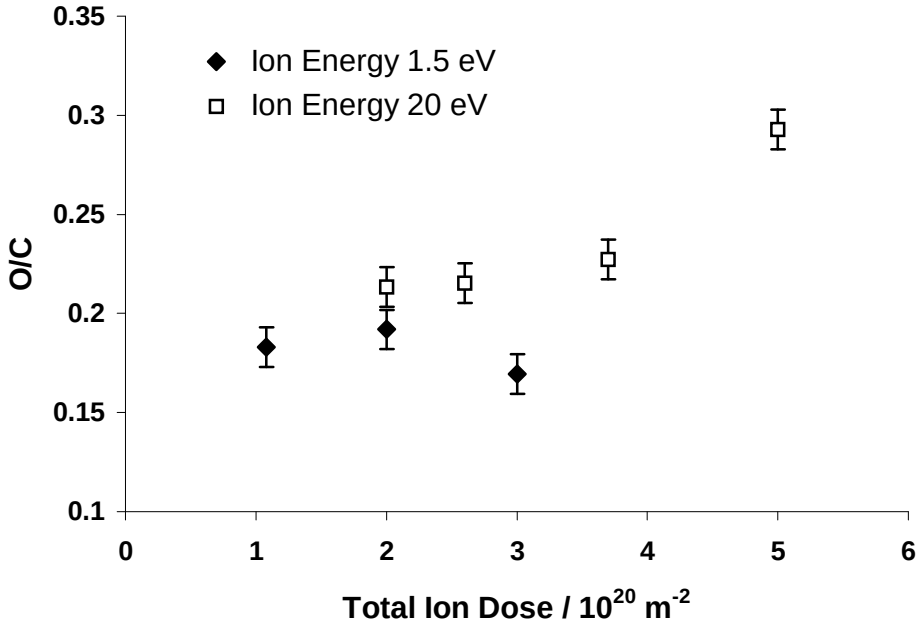

Figure 3. The O/C ratios measured by XPS, against total ion dose (flux x treatment time) for two different ion energies, 1.5 and 21 eV.

4. Conclusions

We have developed a two-mesh separated plasma discharge in which the electron temperature and ion flux can be well controlled through the variation of the DC bias on both meshes. Using the discharge we have treated polystyrene surfaces for a range of plasma conditions and measured the O/C ratios in the top surface, post exposure to air using XPS.

For ion energies of about 21 eV, we find the O/C ratios increase with ion dose (flux x time), rising from about 20 % at 1 x 10^{20} m^{-2} up to about 29 % at 5 x 10^{20} m^{-2}. At low ion energy (1.5 eV), the results are inconclusive, however the treatment level is similar to that at higher energy. These preliminary results suggest that the O/C ratios are independent of ion energy in this energy range, however clearly more work is needed to confirm this.

With refinement of the discharge, this technique for plasma control may prove particularly useful in advanced studies of the plasma treatment of polymeric materials, both from a practical but also scientific point of view. It may also have applications in plasma polymerisation of chemically functional materials, through control of the electron energies, which determine the dissociation and ionisation of the monomer gases molecules. In future studies, the possible effect of the VUV radiation in the surface treatment should be evaluated, although here we have taken steps to reduce its flux to the polymer surface.

Abstract

In this work, filter paper was coated with plasma depositions of hexamethyldissilazane (HMDS), and double layers of HMDS and n-hexane. All coating films formed adhered well to the substrate, and resulted in water repellent paper surfaces with apparent water contact angles above 100 degrees and water adsorption around 15 g/m^2. The porosity of paper was not altered showing that all depositions were conformal. The paper was tested successfully as a selective membrane for water and hydrocarbons of different chain length.

Introduction

The hydrophilic character of cellulose is a desirable property for some paper applications such as utilities, but is a problem for applications like liquid recipients, printing, or other applications where dimensional stability is important. It is known that in 50% relative humidity environments, cellulose adsorbs about 5% of water [1]. Due to its fibre network structure, paper is a porous material, and can be covered by polymer films in order to make it impermeable to water. In some applications however, it is desirable that the system be permeable to air but water repellent. Therefore, making cellulose fibres hydrophobic can be interesting in applications such as printing with non-water based inks. Currently, water repellence is accomplished using solvents and organic reagents, mostly wax emulsions, quaternary ammonium salts and hydrophobic resin finishes, which requires discarding and can cause environmental problems [2].

Cold plasma processing is already a well known and widely used technique for etching and surface modification in electronics industry. Plasmas create extremely reactive species like ions, free radicals and metastable species, which allow reactions to occur at much lower temperatures than in conventional methods, or even reactions that would not occur at all, unless the reagents are under plasma conditions. Low quantities of reagents are used and discarded in plasma processing since treatment times are very short (a few minutes for deposition and even seconds in activation processes), and low pressures are used. Furthermore, low energies are used in most processes making them economically attractive.

Plasma polymerisation of hydrocarbon monomers like ciclohexane [3] has been demonstrated to make cellulose surfaces hydrophobic. However, the treated paper in this case looses its porous structure due to the film's bridging over the fibres. Plasma polymerisation of carbon tetrafluoride[4] and fluorine alkyl silanes [5,6] have also been studied leading to high contact angles as a result of intense surface fluorination. However, the use of CFCs and other compounds containing fluorine, is not an environmentally friendly process owing to the hazardous effects on, for example, the atmosphere's ozone layer. Organic silicon compounds are commonly used for plasma depositions in microelectronics, optics and surface protection industries [7,8]. One of their great advantages is the ease of manipulation, since they are liquids of low toxicity [7,9,10]. Plasma deposition of Hexamethyldisilazane (HMDS) presents interesting characteristics owing to: 1) the presence of Si-N-Si bonds, creating the possibility of forming silicone type structures, 2) the presence of silicon in the molecule and its strong affinity to oxygen atom of various substrates such as cellulose [11,12], alumina[13] etc. 3) the presence of CH_3 groups which can modify the surface properties of the coated material making it hydrophobic, 4) its high resistance to strong inorganic acids and bases[14], 5) the possibility of using it as an adhesion promoter for the deposition of n-hexane to obtain a hydrophobic surface at low cost[11]. All these characteristics make HMDS deposition interesting to obtain material surface with taylored properties.

The objective of this work was to study the hydrophobic protection of paper that can be obtained by plasma deposition of HMDS, and by the deposition of a double layer HMDS and n-hexane, with an intermixing layer in between. n-hexane was chosen as a second reagent since it is easily polymerised in plasma conditions, requiring low energy and low reagent flux [15]. Deposition of n-hexane with HMDS was attempted to lower costs, with a first layer of HMDS functioning as an adhesion promoter. An HMDS-n-

hexane interface layer is expected to have two polymers bonded either chemically (by Si-C bonds) or by Van der Waals interactions. A two layer deposition was chosen since previous experiments[16] demonstrated deposition difficulties when two reagents were used simultaneously. Filter paper was chosen as the cellulose substrate since it is the most hydrophilic type of paper. The modified paper was then tested as a membrane for water and hydrocarbon compounds.

Materials and Methods

Silicon wafers (<100>, p type, 10-20 Ωcm, 3"diameter) were used as substrates for profile meter and FTIR analysis of the films. High purity filter paper with less than 0,007% ash content from Binzer & Munktell was used as cellulose substrate, in 5cmX5cm samples. This type of paper was used because it does not contain non cellulosic components. Therefore, the contact angles values reported here do not depend on surface chemical heterogeneity. The reagents used were HMDS (Hoescht, industrial use) and n-Hexane (chromatographic grade).

The equipment used for plasma depositions was a parallel plate capacitively coupled reactor powered by a 40 kHz source. The reactor had two 20 cm diameter stainless steel electrodes, 3cm apart, one of them grounded and used as substrate holder. Base pressures of 20 mTorr could be reached within a few minutes with a rotary pump. Monomers were injected by pressure gradient at room temperature, with the working pressure controlled by changing the aperture of the pumping valve, and consequently the pumping speed. Figure 1 shows a schematics of the reactor used. Two types of depositions were made: 1) HMDS alone (called HMDS in the remaining of the text); 2) double layers of HMDS and n-hexane (called hexane in the remaining of the text). For double layered films, HMDS was first deposited for two minutes, after which the second monomer (n-hexane) was injected simultaneously for 30 seconds (the intermixing period). The HMDS reservoir valve was then closed, and the second monomer deposition for 6 minutes.

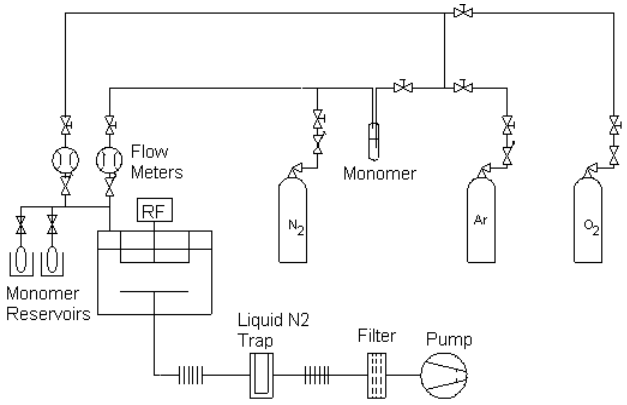

Figure 1: Schematics of the Plasma Reactor Used

A profile meter (model Dektak 3030) was used to measure the step height when part of a silicon wafer was covered during deposition, giving the film's thickness. The deposition rates of HMDS and Hexane were respectively 2200 A/min and 200Amin.

The morphological modifications on the paper surface were verified by scanning electron microscopy (Cambridge Instruments, Stereoscan 240). The porosity of the paper was evaluated by mercury porosimetry using a Micromeritics 92-10.

Apparent water contact angles were measured using a Rame-Hart goniometer after plasma treatment, and after tests of ultraviolet light and chemical resistance. The accuracy of the measurement was ± 2° and the dispersion of the data (five to six measurements were made for each sample in different positions) was around ± 7°. Water adsorption was tested using the Cobb method, which consists of placing a column of water on the treated paper for 20 minutes and measuring the water adsorbed by mass difference.

The deposited hydrophobic layers are intended mainly to protect documents and other applications of paper used in indoor conditions. Therefore, resistance to ultra-violet light was tested exposing the treated samples to filtered UV light, according to the international standard ISO 105-B02. This is a test of colour fastness of textiles to artificial light (Xenon arc fading lamp test), which is representative of the effects of indoor ultraviolet light, to which documents are typically subjected, in contrast to the much harsher outdoor

conditions. The samples were exposed for 8, 50 and 100 hours using a Hanau's Xenotest model 150 (1500W of lamp power, with lamp-sample distance of 65mm).

In order to test the treated paper as a separation membrane for water and hexane, ciclohexane, heptane, dodecane, benzene, silicon oil poly(dimethylsiloxane), Dow Corning 200 ® Fluid, 350 cs), carbon tetrachloride, acetophenon or phenol (all PA reagents) the following procedure was used: 2 ml of these different organic liquids were mixed to 1 ml of 1.5 wt% $CuSO_4$ aqueous blue solution. The 3 ml mixture was manually agitated and filtered by the treated paper. $CuSO_4$ aqueous solution was used instead of water for better visualisation of the liquids. Care was taken so that the organic liquid and water would not evaporate during the experiment by placing a cellophane film above the funnel in which the paper was located.

Results and Discussion

Infrared spectra of films deposited on silicon wafers showed Si-CH_3 (850-840 cm^{-1}), N-H (1180-1175 cm^{-1}), Si-CH_2-Si (1090-1020 cm^{-1}) and Si-N-Si (900-830 cm^{-1}) bonds for HMDS films[6], and C-Hn bonds only for n-hexane depositions. Measuring contact angles formed by drops of water of an unmodified filter paper is literally impossible as water penetrates rapidly the paper owing to its porous structure which makes it absorbent. We observed that the deposition of hexadimethylsilasane (HMDS) and double layers of HMDS and n-hexane, made the paper repellent to water and that stable drop forms were obtained to measure contact angles. Apparent contact angles around 120^o were measured. Water adsorption of around 15 g/m^2, a very good result for filter paper (untreated paper adsorbs normally around 300g/m^2), showed that for both deposition conditions the paper samples became water repellent.

The adhesion of the films to the substrate was tested by dipping the treated samples in the same acid and basic solutions for 5 seconds and measuring the apparent contact angles. It was still possible to measure an apparent contact angle as stable drop forms were still obtained. All apparent angles were unchanged (well above 90°) showing good adhesion of all films to the paper substrate, as expected.

Table 1 also shows the apparent water contact angles and water adsorption a) after the treated samples had been immersed in a strong basic solution for 15 minutes b) after immersion in strong acid solution (H_2SO_4) for 15 minutes and c) after UV exposure for different time duration. It can be seen that both the water apparent contact angles and water adsorption were not affected by strong basic or acidic immersion nor by EV exposure. The water adsorption decreased for HMDS samples, probably due to crosslinking induced by UV light.

Table 1: Water adsorption and contact angle

	Contact Angle	Water adsorption (g/m^2)
As coated		
HMDS	124	15
n-hexane	120	12
After immersion in a strong basic solution		
HMDS	118	20
n-hexane	112	25
After immersion in strong acidic solution		
HMDS	112	15
n-hexane	112	15
After UV exposure		
HMDS	120	10
n-hexane	115	15

The decrease in water adsorption of the HMDS film exposed to UV light was an interesting result, and was investigated in more detail by depositing the same film on silicon wafer and examining the FTIR spectrum before and after the sample was exposed to unfiltered ultra-violet light. The film was exposed to UVA light (a 22W lamp, with a wavelength of 350 nm, distant 5cm from the sample) for 20 hours and to UVC light (same parameters, but with a wavelength of 250 nm) for 5 hours. Table 2 shows the relative intensities of FTIR spectra obtained by exposure of HMDS films to UVA (Table 2a) and UVB (Table 2b)

light. Similar results were obtained for both tests: Si-CH_2-Si bonds increased if compared to Si-N-Si bonds, indicating that UV light is favouring crosslinks through carbon radical reactions. For UVA light a maximum in Si-CH_2-Si intensity was observed after 3 hours. However, the Si-CH_2-Si band showed traces of Si-O-Si bonds (both species have peaks in the same spectrum region) in both experiments, indicating that oxidation reactions occurred simultaneously. It should be noted that solar radiation consists mainly of UVA, some UVB and no UVC radiation. The fact that UVC, the most energetic of the three types of radiation, causes mainly crosslinkings after up to 3 hours of exposure, indicates that besides being resistant to indoor UV radiation, HMDS films could be used as a protection layer for paper in outdoor applications as well.

Table 2a: Relative intensities of FTIR spectrum of HMDS film exposed to UVA light. I(x/y) represents the relative peak heights between x and y species.

Relative Intensities of FTIR spectrum				Time
I(Si-CH_3/Si-N-Si)	I(N-H/Si-N-Si)	I(Si-O-Si/Si-N-Si)	I(Si-CH_2.Si/Si-N-Si)	(min)

0,80	0,25	Traces	0,6	600
0,47	0,14	Traces	0,35	1200

Table 2b: Relative intensities of FTIR spectrum of HMDS film exposed to UVC light. I(x/y) represents the relative peak heights between x and y species.

Relative Intensities of FTIR spectrum				Time
I(Si-CH_3/Si-N-Si)	I(N-H/Si-N-Si)	I(Si-O-Si/Si-N-Si)	I(Si-CH_2.Si/Si-N-Si)	(min)
0,81	0,27	-	0,44	0
0,86	0,27	-	0,76	15
0,88	0,23	trace	0,93	75
0,96	0,23	trace	1,16	275

Figure 2 shows the cumulative porosity of paper as a function of pore diameter for both treated and untreated paper. It can be seen that the pore distribution of the sheet of paper was not altered by the PECVD of HMDS and n-Hexane. Also the overall porosity of the untreated paper and treated paper were 68 and 71 % respectively which is the same within experimental error. Therefore, the chemical deposition did not modify the porous structure of paper.

Figure 2:Porosity of the paper before and after treatment

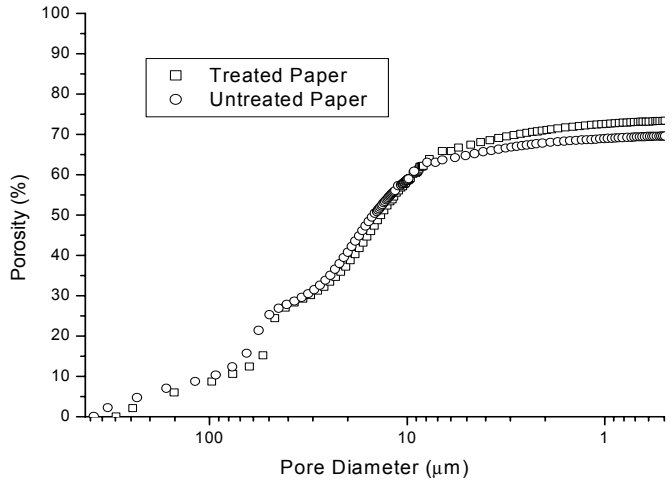

Table 3 shows a summary of separation experiments conducted. It can be seen from Table 3 that all the non polar liquids were filtered by the paper whereas the polar compounds (acetophenon, phenol and carbon tetrachloride) were not. It can also be seen that for all the non polar liquids only around 1 ml out of 2 ml was filtered indicating that some organic liquid stayed trapped in the paper or in the solution above the filter. This can be explained as follows: all the non polar liquids tested have a lower density than water. Therefore, when poured in the funnel they form a ring above a cone of water. Owing to its affinity with the double layer, the non polar liquid starts to percolate through the paper with which it is in contact. Once there is no more contact between the non polar liquid and the paper, the solution stops percolating. This was confirmed by the fact that once the liquid to be filtered was removed from the filter only a wet ring could be observed, the remaining of the paper being totally dry. The data reported in Table 3 also indicate that the time to filter is a function of viscosity; the time to filter the total quantity that percolated through the paper, Q_o, is increasing when the chain length of the organic compound is increasing and is much greater for poly(dimethyl siloxane). The results shown in Table 3 seem to indicate that the coated paper can be used as a phase separator between water and non polar organic compounds, if a mixing mechanism to enhance paper/non polar compounds contact is used.

Table 3: Separation Experiments

Organic liquid	Q_o: Quantity of liquid that passed through the paper (ml)	Time to filter the Q_o (minutes)	Time to start filtering (seconds)
n-Hexane	1.2	5	Immediate
Ciclohexane	1.0	5	Immediate
Heptane	1.2	5	Immediate
Dodecane	1.2	8	30
Benzene	1.2	8	30
Poly(dimethyl siloxane)	1.0	30	300
Acetophenon	0 after 30 minutes	-	-
Phenol	0 after 30 minutes	-	-
Carbon Tetrachloride	0 after 30 minutes	-	-

Conclusions

We have demonstrated that plasma deposition of hexamethyldissilazane (HMDS) is an efficient method for making paper surfaces hydrophobic, while still maintaining its porous structure. This deposition is resistant to strong bases and acids, as well as to indoor ultraviolet light. The deposition of a double layer of HMDS followed by n-hexane is an alternative to lower costs, resulting in a protection layer with the same characteristics as of HMDS alone. The HMDS layer functions in this case as an adhesion promoter of n-hexane to the cellulose substrate. The resistance of HMDS films to ultra-violet light through crosslinkings could make this process suitable for paper applications in more aggressive atmospheric conditions like outdoor panels. A filter paper modified by plasma enhanced chemical vapor deposition of a double layer of HMDS/Hexane was tested successfully as a membrane for water and hydrocarbon compounds.

Abstract
Nanocrystalline diamond films have been prepared by microwave plasma chemical vapour deposition from methane/nitrogen mixtures and the influence of the gas phase composition on the properties of the deposited films was investigated. The increase of the methane concentration up to 17 % resulted in a gradual change of morphology and topography, from a layer composed of ball-shaped clusters of nanocrystals to a uniform film of amorphous matrix with embedded nanocrystallites.

1. Introduction

Diamond possesses various unique properties such as extreme hardness, low friction coefficient, chemical inertness, high electrical resistance, excellent thermal conductivity and good biocompatibility [1]. Upon doping it becomes a large band-gap semiconductor with an extremely high breakdown voltage and a high carrier mobility. It is transparent over a wide wavelength range and can withstand high electromagnetic radiation power fluxes from X-ray or laser sources. These outstanding properties make diamond of potential interest for a wide spectrum of applications including wear resistive and transparent protective coatings for optical components, heat spreaders, novel semiconductor devices, etc. However, the diamond coatings prepared by chemical vapor deposition techniques (CVD) are in most cases rough and nonuniform over large areas. The high surface roughness is a major problem for wear resistant applications of diamond films [2], for example in optical coatings, since it causes attenuation and scattering of the transmitted light. It also hinders the application of polycrystalline diamond films as coatings for bioimplants.
The deposition of diamond-related films, e.g. diamond-like carbon (DLC), tetrahedral amorphous carbon (ta-C) or nanocrystalline diamond (NCD) can overcome the roughness problem [3]. These films are much smoother and at the same time extremely hard, not reaching, however, the hardness of diamond. The first two types of films (DLC and ta-C) are prepared by ion-assisted methods leading to high compressive stresses [4]. The stress in the films directly affects their adhesion to the substrate and causes delamination. Moreover, the wear resistance is not high enough for biomedical applications. NCD films can be deposited by CVD techniques, i.e. without ion impact on the growing films. In such a way the stress problem can be solved to a great extent [5].
In general, there are two main approaches for deposition of NCD films:
(i) „the polycrystalline diamond route“ based on standard low pressure techniques for diamond deposition (especially MWCVD) [6-8]. In order to interrupt the crystal growth and to enhance the rate of secondary nucleation (leading finally to nanocrystallites) one or more of the process parameters should deviate from the standard values for polycrystalline diamond growth: lowered working pressure; higher methane concentrations; partial or complete substitution of H_2 by N_2 or Ar; application of bias voltage during the entire process.
(ii) „the DLC and ta-C route“ based on ion assisted techniques such as sputtering [9] or rf plasma-enhanced CVD [10]. By using high pressures, increased concentrations of Ar in the plasma as well as addition of H_2 and providing sp^3-rich underlayers, it is possible to achieve diamond nanocrystals in an amorphous matrix.
From the existing literature it is evident that the NCD films possess the high hardness, the high wear resistance and the good biocompatibility of diamond combined with low roughness, low compressive stress and good adhesion which make them very perspective for a number of applications.
We report on the deposition of NCD films by MWCVD from CH_4/N_2 gas mixtures with methane concentrations up to 17%. The influence of the gas phase composition on the properties of the deposited NCD films was investigated and they were compared to that of polycrystalline diamond films.

2. Experimental

The MWCVD set-up (*Plasma Technology*) used in the present study consists of a stainless steel reactor with water-cooled walls. The reactor is connected to turbomolecular and rotary pumps which provide a base pressure of about 10^{-4} Pa. Monocrystalline silicon wafers (3 inch) were used as substrates placed on a movable graphite holder inside the chamber which was inductively heated by a copper coil within the holder. In order to achieve continuous films by MWCVD, the substrate surface was pretreated with a suspension of diamond powder in n-pentane in an ultrasonic bath. The working gases (CH_4 and N_2) were introduced in the upper part of the chamber (above the substrate holder) and their flows were regulated by MFCs. The signal from the microwave plasma generator (*Astex Inc.*, 1.5 kW, 2.45 GHz) was introduced by an antenna with variable length into the chamber through a quartz window at the top of the reactor. A scheme of the deposition set-up is shown in Fig. 1.

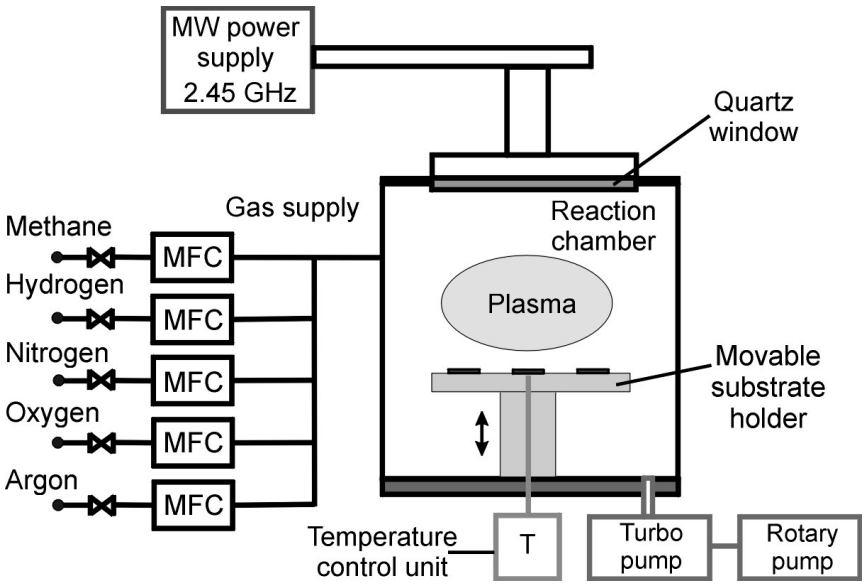

Fig. 1. Schematic drawing of the MWCVD set-up

Three series of samples were prepared by MWCVD: nanocrystalline diamond films from CH_4/N_2 precursor mixtures with 9% and 17% methane and polycrystalline diamond films from CH_4/H_2 with 1% methane, which were used as references. The substrate temperature (1043 K), the substrate position in the chamber, the input microwave power (800 W) and the working pressure (2600 Pa) were maintained constant during the deposition process.

The morphology and thickness of the deposited films were investigated by scanning electron microscopy (SEM). Atomic force microscopy (AFM) was used to derive information about the topography of the diamond coatings. The structure of the films was studied by X-ray diffraction (XRD) using the 0.514 nm CuK_α line, Raman spectroscopy with an Ar^+ laser at 514 nm, and Fourier transform infrared (FTIR) spectroscopy.

3. Results and discussion

The SEM pictures show the influence of the gas phase composition on the morphology of the layers – from large well-formed crystalline facets for polycrystalline diamond films through rounded nodules of sub-micron size, which entirely cover the substrate surface for the films deposited with 9% methane, to smooth and uniform NCD layers prepared with 17% methane (Fig. 2). The gas phase composition affects the growth mechanism and subsequently the structure of the films. Due to the absence of large amounts of hydrogen in the gas mixture, carbon dimers, C_2, appear to be the major nucleation and growth species instead of methyl radicals, CH_3^*, in the case of standard polycrystalline diamond deposition [11]. Higher methane concentrations lead to higher C_2 fractions which result in higher nucleation and growth rates (from 0.11 μm/h to 0.57 μm/h) and changes in the morphology (from sub-micron ball-shaped clusters of nanocrystals grown from the initial nuclei at the film-substrate interface (Fig. 2a) to uniform and smooth films (Fig. 2b)).

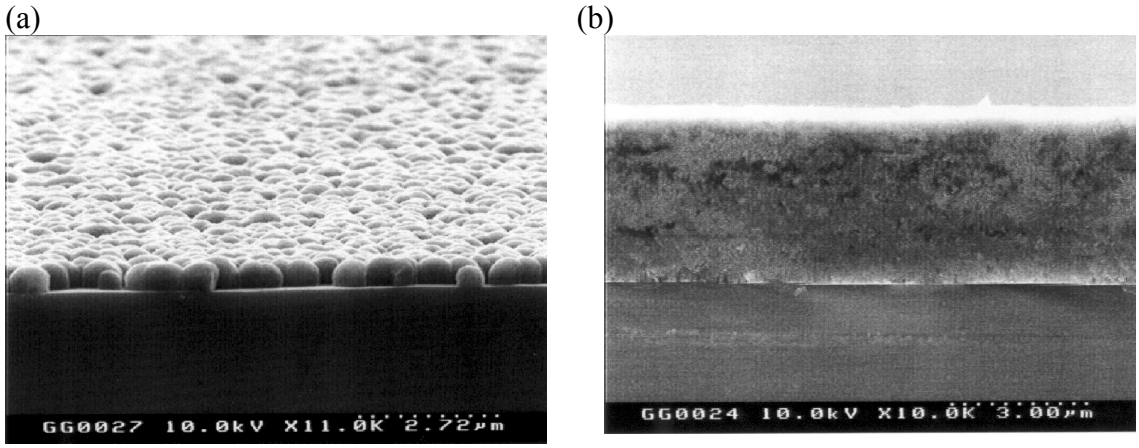

Fig. 2. Cross-section SEM micrographs of NCD films prepared by MWCVD from CH_4/N_2 mixtures: (a) 9% CH_4; (b) 17% CH_4

The surface roughness and topography of the NCD films are also dependent on the gas phase composition, as revealed by AFM investigations (Fig. 3). The topography changes with the CH_4 content from ball-shaped clusters of nanocrystals to smooth films with nanometer sized diamond inclusions. The rms roughness of the films and the grain heights decreases from 34 nm to 12 nm and from 380 nm to 43 nm, respectively, when increasing the methane concentration up to 17%. The obtained roughness is in the range of typical values for NCD films deposited by MWCVD [7,12].

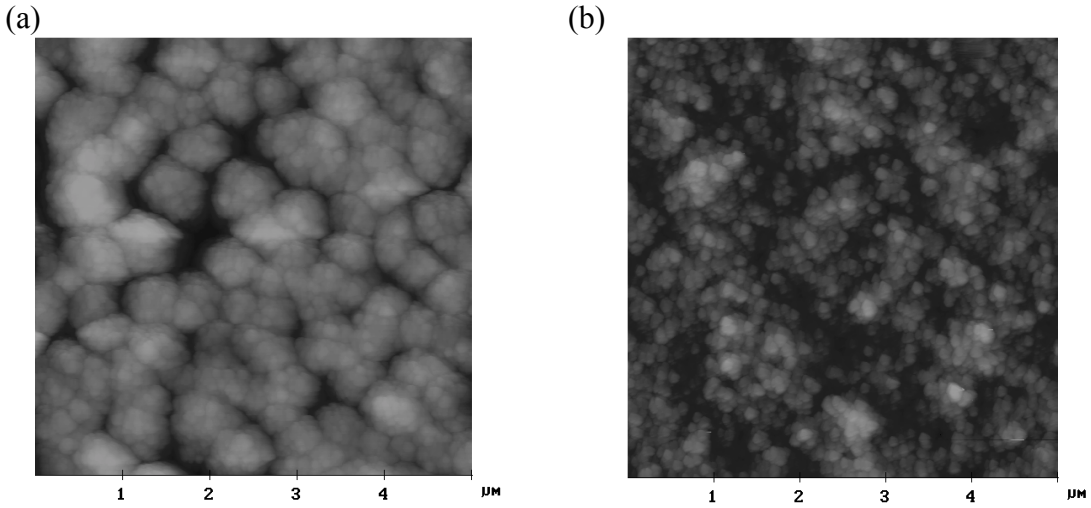

Fig. 3. AFM images of NCD films prepared by MWCVD from CH_4/N_2 mixtures: (a) 9% CH_4 (Z-scale 180 nm); (b) 17% CH_4 (Z-scale 50 nm)

The FTIR spectra of the NCD films showed significant absorption bands in the region 2800-3000 cm^{-1} attributed to superimposed CH_x asymmetric and symmetric stretching vibrations (Fig. 4). The hydrogen originate from the methane molecules since no H_2 was added to the gas mixtures. In general, sp^3-carbon atoms bonded to 1, 2 or 3 hydrogen atoms give rise to stretching modes in the region below 3000 cm^{-1}, while the sp^2-CH_x bonds are located above 3000 cm^{-1} [13]. In our case the C-H band is mainly below 3000 cm^{-1} suggesting that the hydrogen is predominantly bonded to sp^3-carbon, e.g. at the grain boundaries of the diamond nanocrystallites. The intensity of the infrared C-H band is greater for the films prepared with higher methane concentrations, suggesting a higher hydrogenation of the layers as a result of the increased hydrogen content in the gas phase.

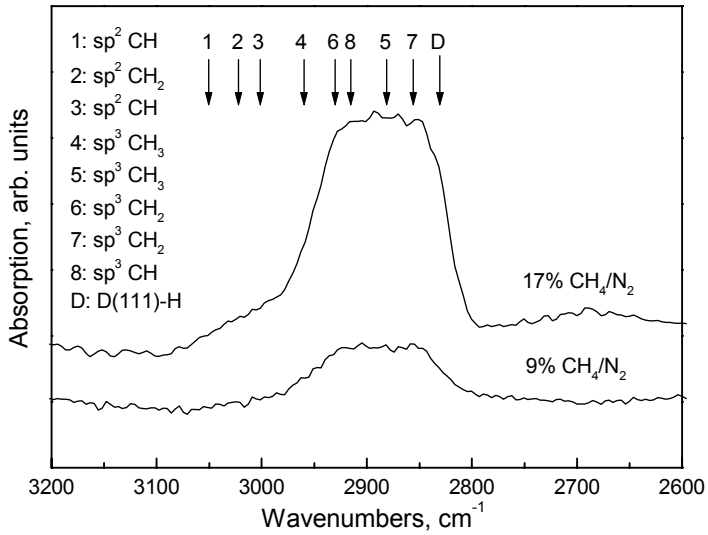

Fig. 4. FTIR spectra of NCD films prepared by MWCVD from CH_4/N_2 mixtures in the region of C-H stretching vibrations

The Raman spectra of the NCD films were fitted using four Gaussian peaks with variable parameters for peak width, position and area (Fig. 4); the results of the deconvolution are summarized in Table I. The attempt to deconvolute the raw spectra with three Gaussians did not give a sufficiently good fit, especially for the films prepared with 17% methane. The first band around 1160 cm^{-1} can be assigned to the presence of a nanocrystalline diamond phase, as well as the band around 1470 cm^{-1} [5,8,12,14]. Although the origin of these bands is controversially discussed in literature [15], a number of investigations of nanocrystalline diamond powder and films attributed these bands to the nanocrystallinity of the diamond, i.e. to the crystallite size. The other two broad bands, at about 1345 and 1560 cm^{-1} are attributed to the *D* and *G* bands of sp^2-bonded carbon, respectively. The diamond peak at 1336 cm^{-1} observed in the Raman spectrum of the polycrystalline films cannot be seen in the spectra of NCD films indicating, in agreement with the SEM observations that the films no longer consist of large, micron-size crystals. Rather, the Raman spectra suggest a mixture of diamond nanocrystallites and a sp^2-bonded graphitic phase.

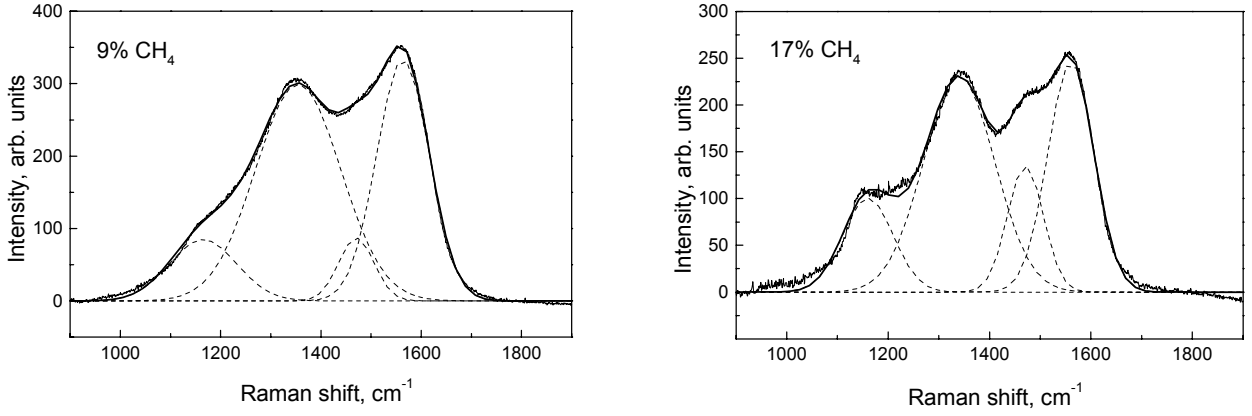

Fig. 4. Raman spectra of NCD films prepared by MWCVD from CH_4/N_2 mixtures with different methane concentrations

The I_D/I_G ratio remains the same while the intensity of the bands assigned to NCD $(I_{NCD}+I_{NCD*})/(I_D+I_G)$ increases with the increase of the methane concentration which, as already discussed, leads to smaller diamond crystallite sizes. Other trends observed from the deconvolution data are the decrease of the width and the downward shift of all bands with the increase of the CH_4 content in the gas mixture. However, in

order to draw further conclusions for the influence of the gas phase composition, the characteristics of the Raman spectra have to be correlated with some macroscopic properties of the films, like hydrogenation, density, hardness, optical gap, etc.

Table I. Analysis of Raman spectra deconvolution

	9% CH_4				17% CH_4			
	NCD	*D*	*NCD**	*G*	*NCD*	*D*	*NCD**	*G*
Peak position, cm^{-1}	1165	1345	1471	1564	1161	1340	1470	1560
FWHM, cm^{-1}	133	170	71	104	99	141	70	91
Peak intensity	14 170	63 786	7 726	43 877	12 592	40 536	12 024	28 085
I_D/I_G	1.45				1.44			
$I_{NCD}+I_{NCD*}/I_D+I_G$	0.20				0.36			

4. Conclusions

Nanocrystalline diamond films were prepared by MWCVD from CH_4/N_2 mixtures in which the methane concentration was increased up to 17 %. The complete substitution of hydrogen by nitrogen in the gas phase and the higher methane contents resulted in an increase of the deposition rate and changes in the film structure, morphology and topography. Gas mixtures with 9% CH_4 yield layers composed of ball-shaped clusters of nanocrystals, while at 17% a uniform film of diamond nanocrystallites embedded in an amorphous matrix was obtained. The coatings prepared with 17% methane were smooth with a rms roughness of 12 nm. The Raman spectra showed that a higher methane concentration leads to smaller grain sizes and higher fractions of the sp^2-bonded graphitic matrix in the films. Hydrogen, originating from the methane molecules, was present in the films, predominantly bonded to sp^3-carbon atoms.

Continuous Emission of O- Anion Radical from C12A7

Yoshifumi Torimoto *1, Masateru Nishioka *2, Quanxin Li *2 And Masayoshi Sadakata*2

*1 Production Technology Institute of Kao Coprporation,1334 Minato, Wakayama ,640 8405, Japan

*2 Dept. of Chemical System Engineering, School of Engineering, The Univ. of Tokyo, 7-3-1, Bunkyo-ku,Tokyo, 113-8656

Negative ions have become to gain a considerable attention recently, because they have great potential for applications ranging from material syntheses and modifications such as charge-free ion plantation to artificial formation of neuron- network[1-2]. The O- negative ion is one of the most active and useful radical for applications. The method conventionally used to generate O- is the attachment of a free low-energy electron to a molecule reaction, which can occur in a plasma process. We have proposed a simple method by using a solid electrolyte as an O- emitter. This approach is expected to obtain a high purity and sustainable ionic radical beam due to good ion conductivity. Although the sustainable and pure O- emission can be implemented by a Y_2O_3-stablized ZrO_2 (YSZ) electrolyte, we can not achieve a high-intensity of O- flux. In this letter, we present a strong and pure O- emission from the crystal 12CaO・Al2O3（C12A 7）, which is about three orders of magnitude higher than the O- current density from YSZ surface. A μA/cm2-level of O- emission from C12A7 has been achieved at the surface temperature of 800℃ and the extraction field over 1000V/cm. The mass signals of negative ion from C12A7 can be analyzed by time of flight (TOF) mass spectrometer. The dominant peak of TOF mass spectrum is the mass number 16 shown in Fig.1, which corresponds to the O- anion radical. We revealed that the emission features from C12A7 and YSZ electrolytes are significantly different because the strong O- emission from C12A7is likely to originate from a direct migration of O- through the C12A7 cage by the filed enhanced thermal diffusion. The comparison of absolute current density of O- between C12A7 and YSZ at 800℃ is shown in Fig.2.

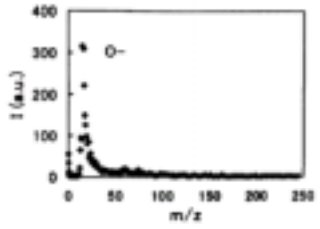

FIG. 1. Typical TOF spectrum measured at 750 °C. The strong peak corresponds to the O⁻ emitted from the C12A7 surface.

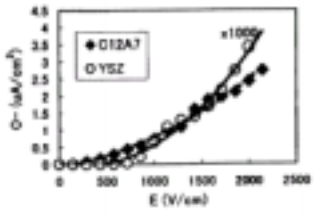

FIG. 2. Comparison of absolute current densities of O⁻ between C12A7 and YSZ at 800 °C. The emission current density from the C12A7 surface is about three orders of magnitude higher than that from the YSZ surface.

Preparation and Properties of SiNx-based Nitride Films by Liquid Injection Plasma CVD

S. Shimada and K. Tsukurimichi

Graduate School of Engineering, Hokkaido University, Sapporo 060-8628 Japan

Abstract

SiNx-based nitride films including monolithic SiNx films and composite and compositionally graded SiNx-TiN films were prepared on a Si wafer at 700 ^{o}C by a plasma chemical vapor deposition technique designed to inject ethanol solution of alkoxides (hexa-methyl-disiloxane and titanium tetra-ethoxide at a feed rate of 0.05 – 0.3 ml min^{-1} into a thermal Ar/H_2/N_2 plasma.

1. Introduction

Titanium nitride (TiN) has low resistivity (several tens μΩ cm), good hardness and chemical stability, and high melting point (> 3000 ^{o}C). TiN films are used as coatings on cutting tools, because they are harder than alumina and thermally stable to 3000 ^{o}C [1-3]. A disadvantage of TiN is its tendency to oxidize rapidly above ～500 ^{o}C to form TiO_2 that causes a drastic degradation of its wear resistance. Silicon nitride (Si_3N_4) exhibits high thermal conductivity and high oxidation resistance. Composite Si_3N_4-TiN films are thus useful because of their improved oxidation resistance at elevated temperatures and expected to exhibit higher hardness compared with the monolithic nitride.

The preparation of monolithic Si_3N_4 films by plasma-enhanced CVD (PECVD) has been reported by several authors [4,5], whereas there have been a very few reports on the preparation of composite SiNx-TiN films [6]. In previous papers, one of the authors (S.S.) has established the preparation of TiN and AlN films by injecting the solutions of titanium tetra-ethoxide ($Ti(OC_2H_5)_4$, TTEO) and aluminum tri-butoxide solution, respectively, into a thermal Ar/H_2/N_2 plasma, by a novel liquid injection PECVD (LI-PECVD) [7] and extended this work to the preparation of composite $(Ti_{1-x}Al_x)N$ films from the mixed solutions [8]. He has also made the compositionally graded (CGed) TiN-AlN films from the respective alkoxide solutions; the Ti and Al or Si complementarily change in depths in the films 1 - 2 μm thick [9]. Since it was found possible to prepare monolithic SiNx films from HMDS solution by LI-PECVD method, this method provides an alternative promising technique to make SiNx-based composite films using HMDS solution as the starting source. The present report describes the preparation of monolithic SiNx and SiNx-based films including composite and CGed SiNx-TiN films from HMDS and the mixed solutions of HMDS and TTEO by LI-PECVD. These films are characterized from viewpoints of impurity content, phase evolution, microstructure, micro-hardness, and electrical resistivity.

2. Experimental Procedures

The HMDS was used as the starting material for the preparation of monolithic Si_3N_4 films and dissolved in dried ethanol at a molar ratio of 1:1.7. The solution was fed into Ar/N_2/H_2 gas plasma using a

HPLC pump (GULLIVER PU-980, JASCO corporation) at a rate of 0.05 – 0.3 ml min^{-1}. Tri-ethanol amine (TEA) was used to stabilize TTEO solution. Ethanol solution of TTEO containing TEA was mixed with that of HMDS. The mixed solution with various mole ratios of TTEO and HMDS was fed at a total rate of 0.1 ml min^{-1} for 15 min into the plasma to make the composite TiN/Si_3N_4 films. The substrate used for film preparation was a 100 Si wafer, which had been treated with 46% HF solution for 10 min, followed by ultrasonic cleaning in acetone, ethanol, and deionized water. The substrate temperature was at 700 ^oC.

Each alkoxide solution of HMDS and TTEO was dissolved in dried ethanol at a molar ratio of 1:1 to 1:3. The CGed SiNx-TiN films were prepared; SiNx and TiN deposited on the surface and substrate, respectively, with complementary change of Si and Ti in the film (designated SiNx//TiN). For the CGed films to be prepared, the feeding rate of the two alkoxide solutions was complementarily changed with time, maintaining the total feeding rate at 0.1 ml min^{-1} using two HPLC pumps. The detailed procedures were reported elsewhere [9]. The substrate used in this experiment was also the (100) face of Si wafer.

Phases formed on the film were identified by thin film X-ray diffractometry (XRD) with CuKα radiation. The chemical states of Si, Ti, N, O, and C were determined by X-ray photoelectron spectroscopy (XPS). The relative atomic ratios of the elements (N, O, C) to Si were calculated from their XPS peak areas. The surface and cross section of the film was observed by scanning electron microscopy (SEM). The electrical resistivity of the composite films was measured by a four-probe method at room temperature and the relative Vickers micro-hardness was determined at a load of 1 fg.

3. Results and discussion

Figure 1 shows Si_{2p} spectra of the silicon nitride films on a Si wafer obtained at 700 ^oC from the HMDS solution at feed rates of 0.05 – 0.3 ml min^{-1}. It is obvious that the films made at a feed rate of 0.3 ml min^{-1} possess a main peak at a binding energy of 100.2 eV, which is due to SiC. The decreasing feed rate from 0.3 to 0.05 ml min^{-1} shifts the peak to the Si-N bond at 101.7 e V. Since the XRD patterns of these films gave no diffraction peaks, the films with the Si-N bond are designated as amorphous SiNx. The influence of the feed rate on the relative atomic ratios of N, O, and bonded/free C to Si in SiNx films was examined. At a feed rate of 0.3 ml min^{-1}, the films contained the N less than 0.7, although much bonded C was included in addition to free C and O. A feed rate of 0.2 ml min^{-1} did not remove the carbon and oxygen impurities. Lowering the feed rate to 0.1 ml min^{-1} increased the N content to about 1.0 with decreasing the bonded C and O. At 0.05 ml min^{-1}, the films possessed the N/Si = 1.35 near the composition of Si_3N_4 (N/Si = 1.33) with the lower free/bonded C and O contents.

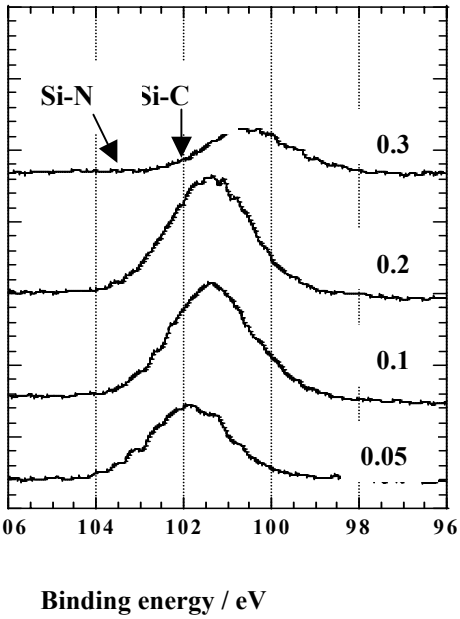

Figure 1 Si2p XPS spectra of SiNx films at feed rates of 0.05 – 0.3 ml min^{-1}

The surfaces of the SiNx films obtained at feed rates of 0.3 – 0.05 ml min^{-1} were observed by SEM. The films obtained at 0.05 ml min^{-1} is about 0.5 μm thick and show the formation of fine packed particles of 0.1 μm in size, with 0.4 μm-sized particles on the top. The films obtained at 0.1 ml min^{-1} exhibited relatively densely packed layer consisting of about 1 μm-sized particles, with larger particles of 2 – 7 μm in size sparsely on the top. Cross-sectional observation of the films showed several thin layers to be piled up to about 1 μm thick. The optimum feed rate for producing SiNx films was found to be 0.05 ml min^{-1} at which the films possess the composition near Si_3N_4 with the less free and bonded C and O impurities and exhibit the microstructure consisting of regularly 0.1 μm sized particles in bulk.

Composite SiNx-TiN films were prepared on a Si wafer at 700 ^oC by feeding the mixed solutions of HMDS and TTEO containing stabilizing TEA at a rate of 0.1 ml min^{-1}. Figure 2 shows the XRD patterns of composite SiNx-TiN films with various mole ratios of Ti to Si in the mixed solution. No peaks related to Si_3N_4 are seen at all the mole ratios, which is not contradictory to the XRD results of amorphous monolithic SiNx films. Very small broad peaks of TiN appear at a mole ratio of Ti:Si = 3:7, and increase with increasing the ratio. At 100 % Ti, sharp peaks of TiN are observed, similarly to those reported in a previous paper [7].

The relative atomic percentages of the Si, Ti, N, O, and total C (bonded and free C) elements determined from the respective XPS peak areas are

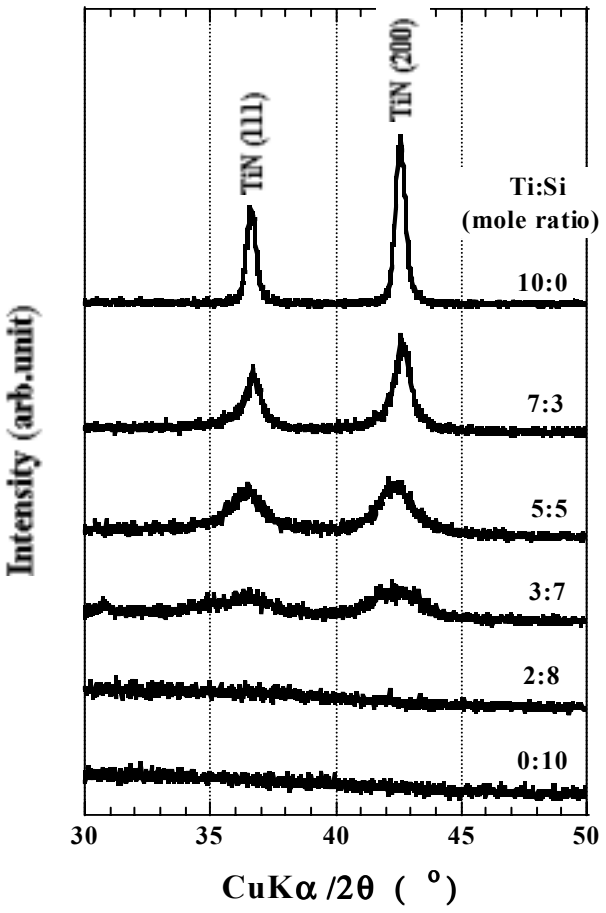

Figure 2 XRD patterns of composite SiNx-TiN films.

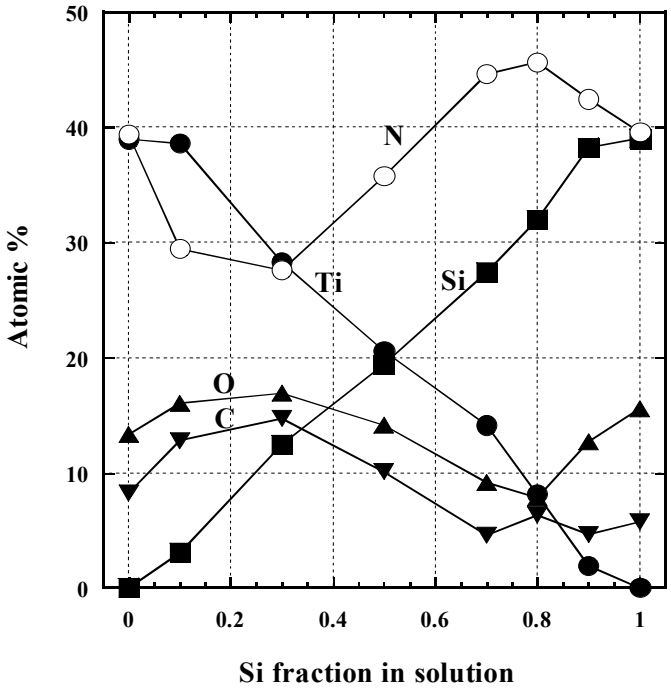

Figure 3 Change of atomic % of Si, Ti, N, O, and C in composite SiNx-TiN films

shown in Fig. 3 . The N content is relatively small (30 – 35 at. %) at a Si fraction of 0.1 – 0.5, while that is 40 – 45 at. % at Si fractions above 0.5. The total content of Ti and Si is around 40 at. %, each Ti and Si changing linearly and complementarily with the solution composition. This indicates that the respective Ti and Si component is effectively deposited from the solution without their selective etching or removal in the plasma. Approximately 10 – 15 at. % oxygen and carbon impurities are incorporated in the film at Si fractions of 0 – 0.5, whereas these impurities decrease to < 10 at.% at Si fractions above 0.5. The increase and decrease of the N content correspond to the reverse decrease and increase of the O and C impurities, suggesting that the O and C impurities replace the N atoms in the TiN or SiNx structure; the C impurity exists partly as free carbon. It is concluded that the SiNx-TiN composite films were successfully prepared on a Si wafer at 700 ^{o}C by injecting the mixed ethanol solutions of HMDS and TTEO containing TEA into a thermal $Ar/H_2/N_2$ plasma.

The surface and cross-section of the composite SiNx-TiN films were observed by SEM (Fig. 4). Monolithic SiNx film obtained at a feed rate of 0.1 ml min^{-1} was already explained above. Compact monolithic TiN film is formed, with angular particles of 200 nm in size (Fig. 4(a)), which slightly increased to the sizes of 300 to 400 nm at a Si fraction of 0.1. At Si fractions higher than 0.3 ((b) – (e)), particles are consolidated to be 1 to 2 μm in size, consisting of uniformly 200 – 300 nm sized particles, under which a layer with uniformly packed particles of 200 – 300 nm

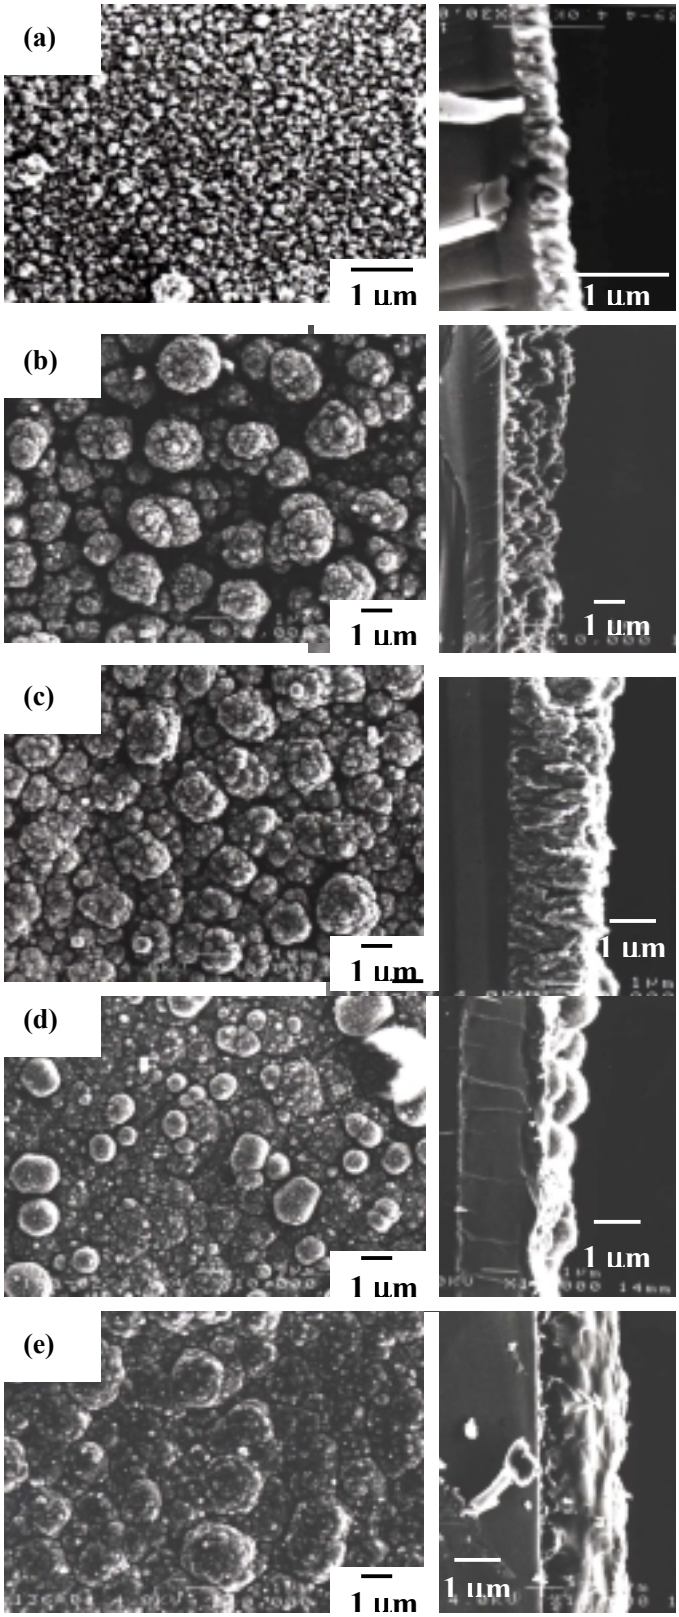

Figure 4 SEM of surface and cross-section of composite SiNx-TiN films. The atomic ratio of Ti:Si (a) 10:0, (b) 7:3, (c) 5:5, (d) 3:7.

size is seen. Consolidated particles slightly decrease to 1 μm size at 0.7 Si fraction, but increase again at 0.8 fraction. Films obtained at 0.9 Si fraction showed a microstructure similar to that prepared at 1.0 Si. From cross-sectional observation, the film is 0.4 μm thick for the TiN and thickens slightly with increasing Si fraction, up to about 1.5 μm thick at a Si fraction of 0.3 – 0.8. Further increase of Si fraction to 0.9 and 1.0 maintains a thickness of 1 – 1.5 μm. It is observed that columnar structures are formed normal to the substrate at Si fractions lower than 0.5, consisting of 200 – 300 nm grains, which are perpendicularly connected ((a) to (c)). At the higher fractions, flattened spherical particles of 1 μm size are observed on the top of the surface, under which dense layer is formed ((d) to (e)).

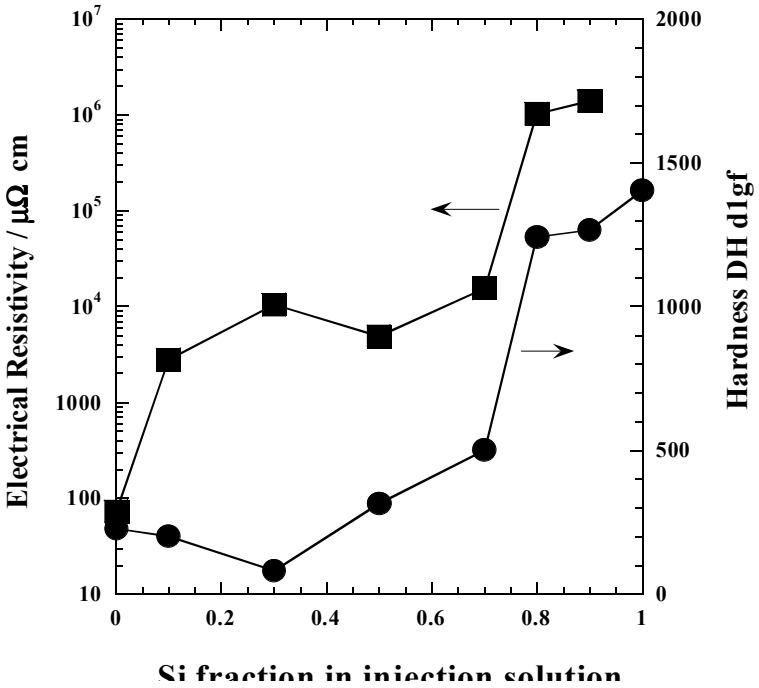

Figure 5 Relationship between electrical resistivity /microhardness and Si fraction in composite SiNx-TiN films.

The electrical resistivity and micro-hardness of the SiNx-TiN films, measured as a function of the Si content of the solution, are shown in Fig. 5. Since the surface of the films is rather rough, it was difficult to determine their absolute values, but the measured values are compared with each other. The resistivity of the films is low (80 μΩ cm) for the TiN film and suddenly increases to 2 x 10^3 μΩ at 0.1 Si fraction. The resistivity slightly increases to 10^4 μΩ cm at 0.3 –0.7 Si. It is believed that paths for electric current are maintained in the films up to this Si content. It is noted that the films at 0.7 Si fraction show still lower electrical resistivity (about 10^4 μΩ cm), compared with the value prepared by the magnetron sputtering (10^7 μΩ cm) and that obtained by the arc ion plating (10^8 μΩ cm). SiNx-rich films with 0.8 and 0.9 Si fractions showed resistivities of an order of magnitude of 10^6 μΩ cm; the value of SiNx films was too high to measure. The relative micro-hardness of the SiNx-TiN films were measured to levels off at the relative value of 250 at Si fractions of 0 - 0.3 and increases greatly with increasing Si content. The pure SiNx film shows a value of 1400.

It was found that the compositionally graded SiN_x//TiN films can be formed by liquid injection plasma CVD method using the alkoxide solutions. Changes of the concentrations of N, Si, Ti, O, and C with depth in the are shown in Fig. 6. The first 10 minutes of etching removed the concentrated impurities O and C from the SiN_x surface. After removal of the impurities, the N content increases to 46 at. %, becoming constant with depth. Concomitantly, the Si content rises to 38 at. %, then gradually decreases from 30 at. % over two-thirds of the film depth towards the substrate. The Si content then drops steeply to 3 at. %, in contrast to the Ti which concomitantly increases to 35 at. % near the substrate. The O and C impurities occur at less than 6 at. % over most of the film depth, but increase slightly near the substrate.

Surface and cross-sectional bservations of SiN_x//TiN films are shown in Fig. 7. Spherical particle 3 μm in size are formed on the outermost surface of the SiN_x//TiN film, beneath which ≦1 μm particles are seen. The cross-section shows the film to be 3 μm thick and dense, containing particles piled up from the substrate and growing larger toward the surface.

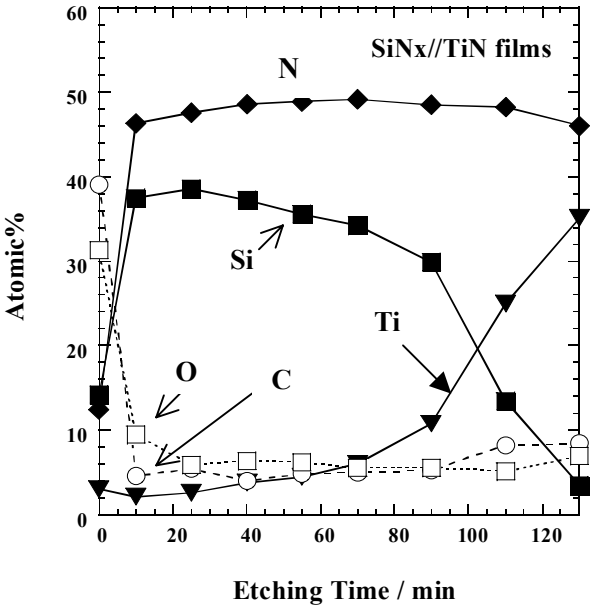

Figure 6 Changes in the depth direction of atomic % of N, Ti, Si, O, and C in the SiNx//TiN films

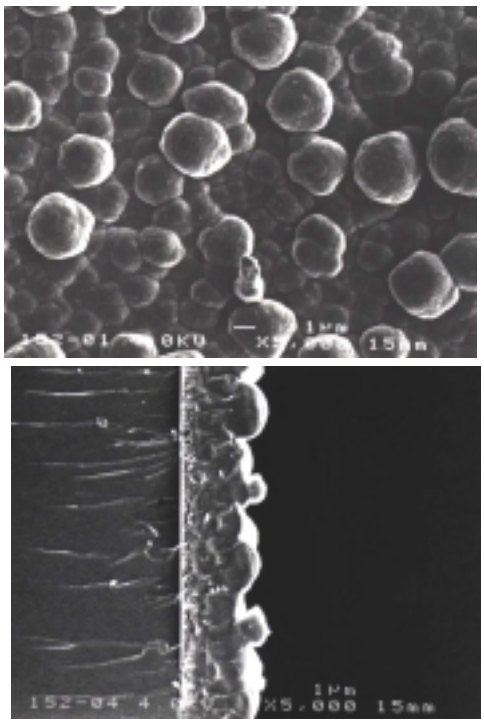

Figure 7 SEM photographs of surface and cross-section of SiNx//TiN films.

ABSTRACT.
Plasmochemical SiO_2 film was carried out by decomposition of the tetraethoxycilane vapor by the electrical discharge with the frequency of about 18 kHz. The excessive products of decomposition were pumped out with maintenance of the tetraethoxycilane vapor and argon pressure of about 0.2 Torr. The study of element structure has shown that the film represents Si_xO_y with $x \approx 1$ and $y \approx 2$ and contains an impurity of organic inclusions. This method is applied for preparing of the covering with uniform thickness on glass microspheres used as targets in laser fusion experiments on the installation "Iskra-5".

1. INTRODUCTION.

For a number of applications it are required transparent hollow microspheres with a wide set of diameters and wall thickness, and also with added various elements as impurity in wall. Manufacturing such microspheres from a glass with a diameter up to 1-1.5 mm now is possible with wall thickness up to 1-3 microns. It is rather inconvenient to receive spheres with the greater thickness of wall. The input in glass of tracer elements also requires the large technological work on a blend preparation, suitable for process of formation of hollow microspheres.
Earlier for the decision of these tasks we have tried to use usual thin-walled glass microspheres as substrates, on which the homogeneous covering of required thickness with composition and structure close to glass is deposited. Most suitable there was a film of silicon dioxide. For deposition of covering we used a plasmochemical method, by which it is possible to make a homogeneous on thickness covering on sphere [1-3]. Besides we hoped, that this method will allow entering into the basic matrix of a film an impurity of wide set of elements.
As basic substance we used tetraethoxycilane (TEC), which at decomposition in plasma provides fragments of SiO_2 forming the basic matrix [4]. This method does not give also strong heating of substrate. That is important at deposition of covering on ready sphere. This substance has an optimum vapor pressure for our installation at room temperature. Films were formed by decomposition of TEC vapor in a mix with argon 0.5: 0.5 (sample 1) or with argon and oxygen 0.5: 0.25: 0.25 (sample 2) in the glow discharge of alternating current with frequency ~ 18 kHz. The flowing mode was carried out both by continuous submission of initial substance and pumping out argon and volatile products of decomposition.

2. PROCESS OF SILICON DIOXIDE LAYER FORMATION.

Film deposition was carried out on flat and spherical substrates of glass, polished crystal NaCl, titanium, aluminum, cupper and gold. The thickness of layer achieved 25 microns. As a gas atmosphere the TEC vapor with argon or mix argon and oxygen were used.
The experiments have shown [3] that the thickness of formed SiO_2 film is practically linear function from time and from the TEC expense. The deposition velocity depends on a material of substrate. The least velocity was observed on the NaCl substrate, greatest velocity - on metal substrate. In Fig. 1a and 1b the dependences of film thickness from the deposition time and from the TEC expense are given for a case, when the glass spheres with diameter of ~ 300 microns were used as substrate. The deposition velocity did not depend practically on a partial pressure of Ar and O_2.

2. COMPOSITION OF FILMS.

2.1. Element composition.

The research of element composition was made by the following methods:

- qualitative analysis by mass-spectrometer with evaporation of a sample by laser pulse;
- quantitative analysis of elements with nuclear number Z>7 on the X-ray microanalyzer with excitation of a sample by an electronic beam;
- quantitative analysis of the contents of carbon and hydrogen by a method of reactionary gas chromatography (decomposition of a sample at presence of the oxidant catalyst) and by burning a sample in a current of oxygen at the presence of the catalyst with subsequent gravimetric measurement of formed products of burning (CO_2 and H_2O) after them settling to an absorber.

The analysis has shown, that the covering consists mainly of silicon, oxygen, carbon and hydrogen with gross - formulas

$$SiO_{1.85}C_{2.12}H_{3.54}$$

at excitation of plasma in the mix of TEC vapor and argon and

$$SiO_{1.97}C_{1.83}H_{3.53}$$

at excitation of plasma in the mix of TEC vapor, argon and oxygen (Ar:O_2= 1:1).

2.2. Molecular composition.

The molecular composition was investigated by registration and processing of IR-spectra of transmission, and also Raman spectra. In Fig. 2 the IR- spectra of films, prepared in mixes of TEC vapor + argon and TEC vapor + argon + oxygen, and in Fig. 3 Raman spectra of films are given. Here the appropriate spectra of initial substance (liquid tetraethoxycilane) and fused quartz are given [5].

The analysis of IR-spectra of plasmochemical films (Fig. 2) has shown, that they have two characteristic for amorphous SiO_2 stripes of absorption - wide intensive stripe with a maximum of ~ 1070 cm^{-1} and less intensive stripe with a maximum of 790 cm^{-1} [6,7]. Besides there are stripes connected with valence (wide stripe of 3600-3200 cm^{-1} and narrow stripe of 3570 cm^{-1}) and distortion (1690-1710 cm^{-1}, 960 cm^{-1}) vibrations of connections O—H [6,8]. There are also stripes of absorption caused by valence (2970-2880 cm^{-1}) and distortion (1445-1370 cm^{-1}) vibrations of the connection C—H in alkane [9]. In spectra of absorption the presence of connections C-Si-C (650-690 cm^{-1}) is visible. It is possible also existence of connections Si-H and defective centers of a type E′H. It worsens of strength property and loosens structure.

In Raman spectrum the stripes, characteristic for fused quartz, and lines caused by the connection C—H are visible.

Thus, the spectra show, that the structure of silicon oxygen films received by TEC decomposition in the decaying low-frequency electrical discharge by mixes of TEC vapor and argon (0.5: 0.5), and also TEC vapor, argon and oxygen (0.5: 0.25: 0.25), corresponds to stochiometric SiO_x at x ~ 1.8. Both films contain significant amount of an organic impurity as groups CH, CH_2 and CH_3, and also of hydroxyl groups.

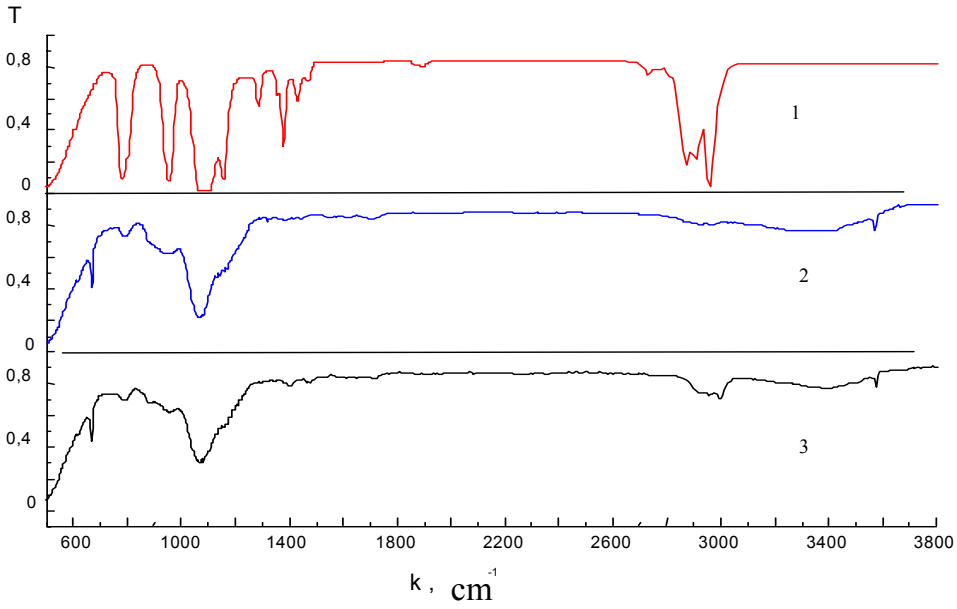

Fig. 2. IR-spectra of absorption of liquid TEC and plasmochemical silicon dioxide films.
1 - TEC; 2 - film prepared by mix of TEC vapor, argon and oxygen (0.5: 0.25: 0.25); 3 - film prepared by mix of TEC vapor and argon (0.5: 0.5).

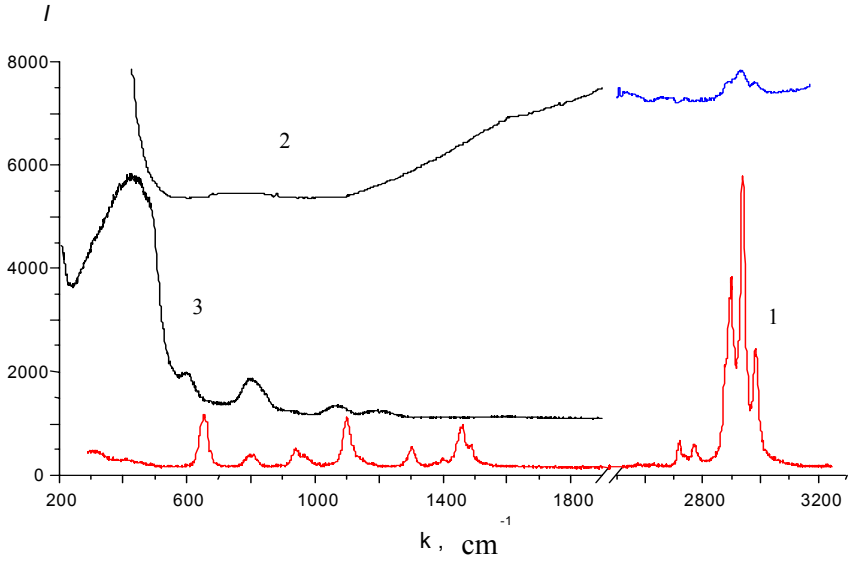

Fig. 3. Raman spectra of liquid TEC (1), plasmochemical silicon dioxide films (2) and fused quartz (3).

3. PHYSICAL PROPERTIES OF COVERING.

3.1. Density.

Density of a covering was determined by division of the substrate weight increase after deposition in comparison with the weight before deposition on volume of covering. Volume was determined as the sum of products of the elementary areas on covering thickness in middle of these areas. The thickness was determined on microinterferometer. The summation was carried out on all surface of a substrate. The values of density are equal

2.34 ± 0.03 g/cm^3

for discharge in mix of TEC vapor and argon and

2.17 ± 0.05 g/cm^3

for discharge in mix of TEC vapor, argon and oxygen ($Ar:O_2$= 1:1).

3.2. Factor of refraction.

The measurement of factor of refraction was carried out on microinterferometer by measurement of a difference of optical ways for beams, past through a layer of known thickness (2) and outside this layer (1). The scheme of measurements is submitted in Fig. 4. The measured value of refraction factor of films is

$$n = 1.46 \pm 0.02$$

independently of ratio of auxiliary gases in discharge (Ar and O_2).

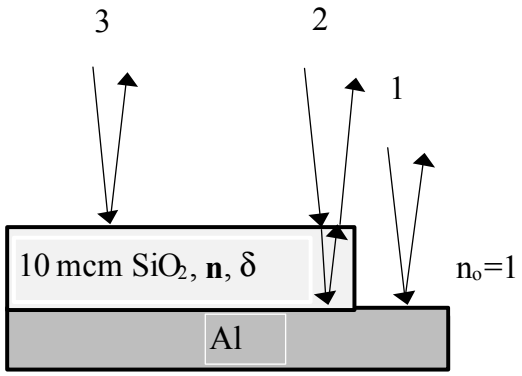

Fig. 4. The scheme for determination of refraction factor of SiO_2 deposition by interferometer method.

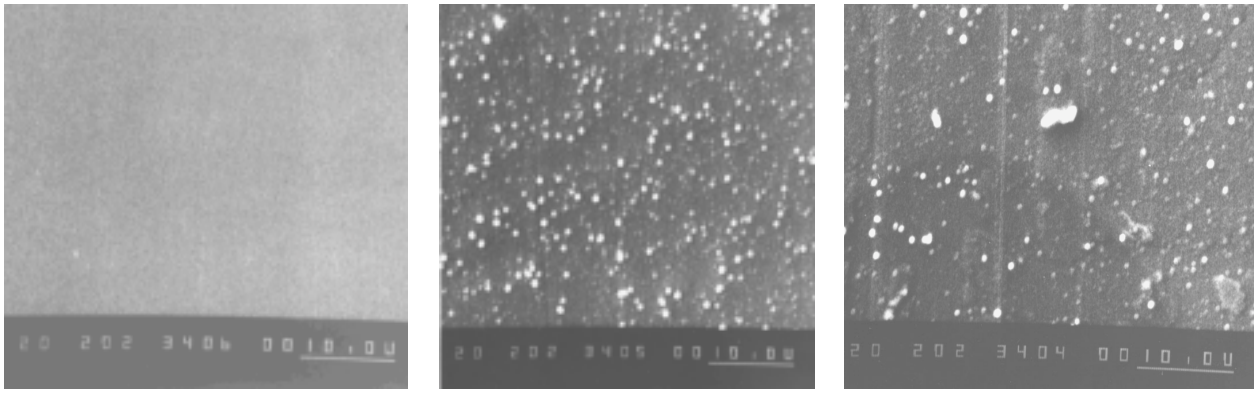
3.3. Structure and surface properties.

The X-structural analysis has not found out in films a crystal structure.

The image of a surface was received with the help of carbonic replica of surface on electronic microscope and on the microanalyzer in reflected electrons. Films received in pure argon (auxiliary gas) have a very smooth surface; at use of a mix argon-oxygen on a film surface the ledges or infringements of structure are observed. At work electronic microscope in a mode electron diffraction any diffraction picture was not observed, that also speaks about amorphous film condition. The images of a surface are given in Fig. 5.



a) b) c)

Fig. 5. Photomicrography of plasmochemical film surfaces with increase x 2000, length of marker - 10 microns; a) – film deposited in TEC and argon, b) – film deposited in TEC and argon with oxygen in the ratio 2:1, c) – film deposited in TEC and argon with oxygen in the ratio 1:1.

4. USE OF PLASMOCHEMICAL METHOD OF SiO_2 FILM PRECIPITATION FOR DEPOSITION HOMOGENEOUS ON THICKNESS OF A LAYER ON GLASS MICROSPHERES.

We apply the given method for jointing of wall thickness of glass microsphere filled by gaseous mix. The manufacturing of glass microspheres with thickness more than 5 - 10 microns at a diameter of > 300 microns is a difficult task. We took the glass microspheres filled with a gas mix and having small wall thickness as a substrate and deposited homogeneous on thickness SiO_2 covering. Optical interferogram of such sphere is given in Fig. 6 [2,10]. Good concentricity of interference rings speaks about high uniformity of thickness.

Fig. 6. Optical interferogram of glass shell received by displacement interferometer. On surface of glass microsphere the layer of plasmochemical silicon dioxide is put. Common thickness of wall together with a covering is 11 microns.

5. INPLANTATION OF IODINE.

We have begun experiments on deposition of plasmochemical covering of silicon dioxide with an impurity of iodine. Iodine was entered in the plasmochemical chamber as vapor. The partial pressure corresponded to pressure of saturated iodine vapor at room temperature. The film is received, in which the iodine presence is stably registered. In Fig. 7 is given mass-spectra of one of aria of a plasmochemical SiO_2 covering with an iodine impurity.

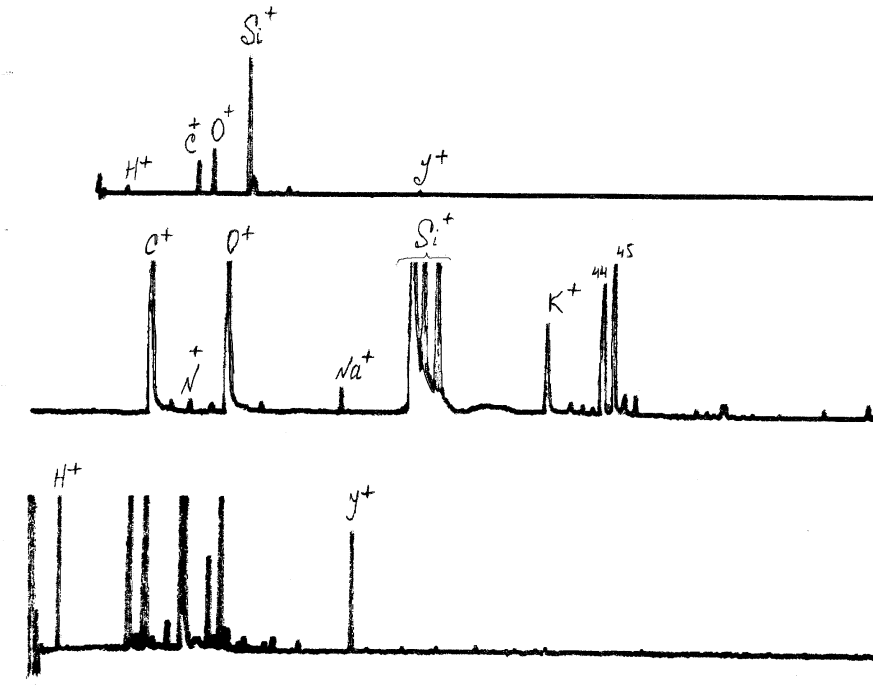


Fig. 7. Mass-spectra of one of area of a plasmochemical SiO_2 covering with an iodine impurity.

6. CONCLUSION.

Thus, the received covering represents a homogeneous amorphous silicon dioxide with good stochiometry containing significant amount of organic impurity. Density and refractive index are 2.34-2.17 g/cm^3 and 1.46 depending on composition of gas formed plasma - argon or mix argon with oxygen. Probably, there is a possibility of halogen introduction, in particular of iodine, in a plasmochemical SiO_2 film.

Abstract
In this study, polyamide fiber was treated with low temperature oxygen plasma. Morphological changes of the resulting samples were characterized by scanning electron microscopy (SEM) and tapping mode atomic force microscopy (TM-AFM). Chemical modifications by plasma treatment were studied by x-ray photoelectron spectroscopy (XPS) and time-of-flight secondary ion mass spectrometry (Tof-SIMS).

1. Introduction
Recently, there has been great interest in physico-chemical surface treatments for modifying polymer surfaces [1-5]. The low temperature plasma (LTP) technique is widely used to modify polymer and textile materials. It is regarded as an environmentally friendly process since no larger volumes of waste chemical are involved [6-8]. By controlling the working parameters of plasma, such as the nature of the plasma gas, the discharge power, the pressure, and the exposure time, a great variety of surface effects can be generated. In this study, the effects of plasma treatment on polyamides were studied by using different characterization techniques.

2. Experimental
2.1 Low temperature plasma treatment
A glow discharge generator (SPP-001, Showa Company of Japan) was employed for the plasma treatment of the samples with oxygen gas. The applied discharge power and gas flow rate were 50-200 W and 50 cm^3min^{-1} respectively. The exposure time was varied from 5 to 30 minutes.

2.2 Morphological study
The morphology of the samples was investigated by scanning electron microscope, SEM (Lecia Stereoscan 440), for untreated and laser treated samples. All of the samples were gold coated prior to SEM examination. Tapping mode atomic force microscopy TM-AFM study was performed with a NanoScope III (Digital Instruments) under ambient conditions (24 ± 2 °C, 45 ± 5% relative humidity). The images were recorded with typical scan speed of ½-1 line/s.

2.3 Surface chemical study
The surface chemical composition of laser treated nylon 6 samples was analyzed by X-ray photoelectron spectroscopy, XPS (Physical Electronic PHI 5600) with an Al $K\alpha$ source under conditions of 14 kV and 25 mA. Time-of-flight secondary ion mass spectrometry, Tof-SIMS experiments were performed using a Physical Electronics PHI 7200 ToF-SIMS. The examined area was 200 μm x 200 μm for each sample.

3. Results and Discussion
3.1 SEM study
Figure 1 shows the nylon 6 filaments subjected to oxygen plasma treatments with different treatment parameters. It can be observed that the filaments treated with a low discharge power and for a short duration of time are smoother than the untreated filament (see Figure 1b, c and e). The *surface cleaning* results can be attributed to plasma species that bombard the sample surface and remove some uneven places [9]. *Surface etching* occurs when the filament is subjected to a higher discharge power and longer treatment time. Granules and ripple-like

structures of sub-micrometer size are found on the treated surface perpendicular to the fiber axis (see Figure 1d, f, h and i). It should be mentioned that a further increase in the treatment time to 30-minute might cause *surface melting* of the material (see Figure 1g, h) [3]. The previously developed ripple structures merge together, leaving some micro cracks on the sample's surface.

3.2 TM-AFM study

Comparisons of the AFM images of untreated and oxygen plasma treated surfaces are shown in Figure 2 (5 μm x 5 μm size, top view). The images on the right hand side are phase images corresponding to the height images show on the left hand side. Oxygen plasma treatment produces a "fibrous" structure, leaving no trace of the original surface morphology. It is observed that the extent of plasma etching increases by increasing the discharge power. The plasma induced surface roughness is found to be on the sub-micron scale, leading to enhancements of the surface area.

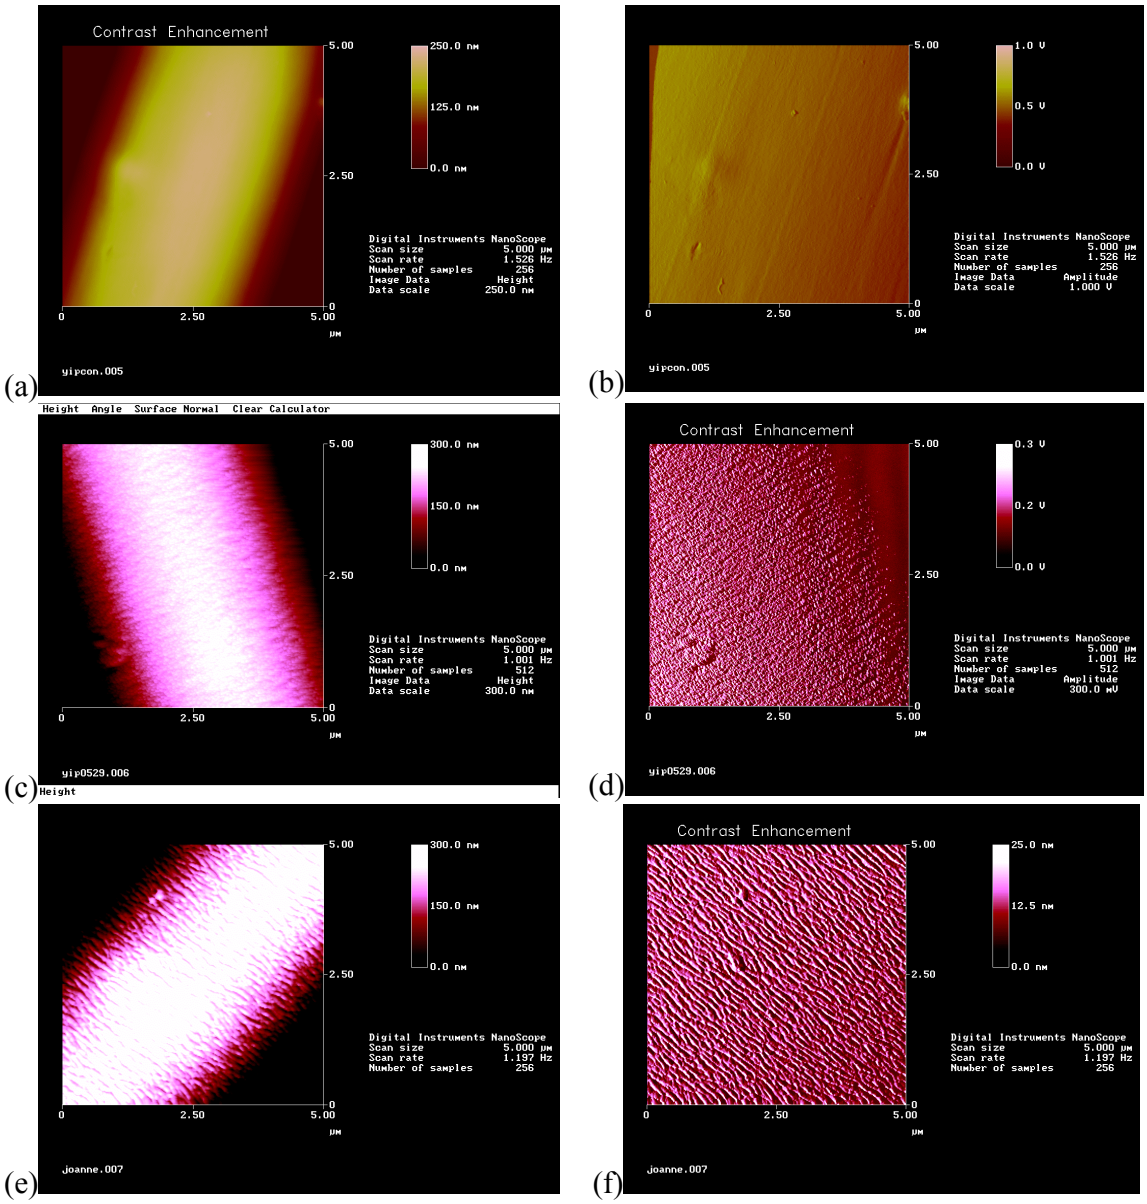

Figure 2 Surface morphology of polyamide fiber at the micrometer scale (5 μm x 5 μm)

(c) 100 W, 10-min Oxygen plasma treated (d) A phase image corresponding to part c.
(e) 200W, 10-min oxygen plasma treated (f) A phase image corresponding to part e.

3.3 XPS study

The O_{1s}/C_{1s} and N_{1s}/C_{1s} atomic ratios for untreated and 100-W oxygen plasma treated samples are shown in Table 1. The results show that after plasma treatment O_{1s}/C_{1s} and N_{1s}/C_{1s} ratios increase with increasing treatment time. It is suggested that oxidation has occurred and oxygen atoms are incorporated onto the surface of nylon.

Table 1 Elemental composition analysis of nylon 6 treated with O_2 plasma determined by XPS measurements

RELATIVE INTENSITIES OF CHEMICAL COMPOSITION	OXYGEN PLASMA TREATMENT DISCHARGE POWER: 100 W			
	Untreated	5 minutes	10 minutes	30 minutes
O_{1s}/C_{1s}	0.208	0.400	0.534	0.548
N_{1s}/C_{1s}	0.134	0.138	0.161	0.171

Figure 3 summarizes carbon 1s signals of the XPS spectra for both untreated and oxygen-plasma treated (100 W; 10-minute) nylon 6. It can be observed that the relative peak areas of sub-components change significantly after the treatment (see Table 2). The most obvious is the C_{1s} curve that rises from its minimum at about 289 eV after the treatment. This new peak at 289 eV can be assigned to a C5 (-**C**OOH) peak. The results also reveal that both peaks of C2 (-**C**H_2-C=O-) and C4 (-NH-**C**=O-) components have decreased. It is suggested that oxygen plasma treatment induced carboxylic acid groups in the polymer, either in hydrocarbon or carbonyl groups, which finally increases hydrophilicity of the polymer.

3.4 ToF-SIMS study

The characteristic positive and negative ions as well as their normalized intensities for both untreated and oxygen plasma (100W, 10-minute) treated nylon 6 are summarized in Table 3 and 4, respectively. It is observed that the intensities of most hydrocarbon secondary ions decrease and those of all hydroxyl or carboxyl-containing ions increase after the treatment. For example, the positive ions *m/z* = 31, 45, 133 and 149 correspond to CH_3O^+, $C_2H_5O^+$, $C_5H_9O_4^+$ and $C_6H_{13}O_4^+$ increase significantly after oxygen plasma treatment. It should be noticed that not all oxygen-containing peaks increase after the treatment: let us consider the positive ions at *m/z* = 114 ($C_6H_{12}NO^+$) and 227 ($C_{12}H_{23}NO^+$); negative ions at *m/z* = 31 (CH_3O^-) as well as 45 ($C_2H_5O^-$), these ions contain carbonyl groups have decreased obviously after the plasma treatment. The results reveal that oxygen plasma can induce many hydroxyl (-OH) and carboxylic acid (-COOH) functional groups. These groups replace mainly hydrocarbon or carbonyl groups in nylon and finally change the normalized intensities of the particular peaks.

Furthermore, the positive ions correspond to CH_4N^+ and $C_3H_6N^+$ (contain nitrogen atom) have increased after the treatment. The results can be attributed to ions bombardment by the plasma treatment. The treatment breaks the long polymer chain (C-N bond) and therefore increases the number of amine end-groups. Decrease in *m/z* =114 and 227 positive ions of treated sample (from 5.03 x 10^{-3} to 0.567 x 10^{-3}) are in good agreement with the above suggestion.

Table 3 Characteristic positive ions and the normalized intensity for untreated and oxygen-plasma treated (100 W; 10 minutes) nylon 6. The intensity of the peaks is normalized with respect to the total intensity of the selected spectra.

m/z	Positive ions	Normalized intensity (10^{-3})	
		Untreated	O_2 plasma-treated
15	CH_3^+	9.57	5.50

3.5 Adhesion property

Table 5 shows the mean ultraviolet protection factor (UPF) of *uncoated* and *aluminium coated* polyamide fabrics with various duration of plasma treatment. It can be observed that aluminium coating does not cause significant improvement in blocking UV radiation. However, the UPFs increase dramatically after the plasma treatment. A 10-min plasma treated fabric give excellent protection of UV light. The results can be attributed to the increased surface area and functional groups induced by plasma treatment.

Table 5 The Ultraviolet protection factor (UPF) of uncoated and aluminium coated polyamide fabrics with various duration of plasma treatment

Treatment	Untreated, Uncoated	Untreated, Coated	1-min plasma treated, Coated	3-min plasma treated, Coated	5-min plasma treated, Coated	10-min plasma treated, Coated
Ultraviolet Protection Factor (UPF)	16.3	18.2	28.7	38.5	59.6	66.4

4. Conclusion

Low temperature plasma treatment has become an important process for modifying polymer surfaces. The capability of plasmas to alter physical and chemical surface properties without affecting the bulk properties (especially mechanical properties) of the base material is advantageous in the design, development and manufacturing polymeric fibers. In this study, the effects of plasma treatment on polyamides were studied by using different characterization techniques.

Topographical results illustrated that changes in the surface morphology of the oxygen plasma treated polyamide correlate well with the discharge power and treatment time. The effects can be categorized into three groups: surface cleaning resulting in smoother surface, surface etching with formation of ripple-like structures in sub-micrometer size, and surface melting with material downgraded. Chemical studies showed that the surface oxygen content of polyamide increases after oxygen plasma treatment. The treatment induces many hydroxyl (-OH) and carboxylic acid (-COOH) functional groups. These groups mainly replace the hydrocarbon or carbonyl groups in polyamide. It was found that there is a strong interfacial interaction in the plasma treated polymer-coated particles. The adhesive properties and surface metallization of the modified material were significantly improved due to the increased surface area and functional groups.

SHORT RESIDENCE TIME HIGH-DENSITY INDUCTIVE PLASMA ETCHER FOR SiO_2 AND LOW-K

H. HATTORI, Y. HIRANO, A.KELLY, A. KURODA, V. MENAGARISHVILI, Y.TAKAHASHI, and G. VINOGRADOV

FOI Corporation, 6-38-28 Kamiasao, Asaoku, Kawasaki 215-002, JAPAN

Abstract

A novel compact narrow-gap flat ICP source (GROOVY™) for advanced high-density plasma etch of SiO_2 and Low-k materials on 300-mm wafers has been developed and successfully tested for a variety of materials and patterns. The groovy configuration overcomes the main problem of uniformity control in the plasma sources with flat inductive applicators.

1. Introduction

Plasma etching equipment utilizes the most advanced technologies known in semiconductor industry. However, there is presently only one type of 300-mm plasma processing chambers for highly selective SiO2 etch, especially for high aspect ratio contact holes (HARC): parallel-plate capacitive discharges. Inductively coupled plasma sources, usually referred to as ICP, realized in flat compact configurations do not provide necessary level of radial process uniformity, because of the basic toroidal structure of inductively excited plasmas. An increase of the discharge gap does improve the uniformity but decreases selectivity to photoresist at the same time. This trade-off between the narrow-gap parallel-plate capacitive and wide-gap inductive discharges was not overcome yet in favor of both plasma uniformity and process selectivity relied upon the short gas residence time in the discharge zone.

FOI Corporation has developed and manufactured new inductively coupled plasma sources with essentially flat narrow-gap geometry for advanced oxide etch and processing of a wide range of organic and inorganic Low-k materials. We present here process results obtained with our 300-mm etchers in order to show principal advantages and exclusive controllability of the new manufacturing equipment over traditional capacitive etchers. Such results are yet unachievable for other inductive etchers.

2. Experimental

300-mm GROOVY™ plasma source incorporates three geometrically separate and independently adjustable ring-shape inductive plasma sources designed as annular grooves in a flat roof made of monocrystalline i-type silicon or ceramics depending on the etching application. **Fig. 1** shows a cross-section view of the groovy roof with three inductive coils and an electrostatic chuck in a process chamber. Every coil has its own RF power supply. The coils and RF matching system are specially designed in order to avoid power interference between annular discharges in the grooves thus achieving full controllability over the radial sputtering profiles. Coils are not sensitive to each other for a wide range of RF power and operate as independent ICP sources in the integrated flat plasma source.

The silicon or ceramic roof incorporating inductive coils is temperature stabilized by a top metal plate attached to the roof and connected to a chiller/heater. High temperature condition favorable for carbon-rich plasmas and effective in HARC silicon oxide etch are thus established. Silicon as a roof materials is essentially good in terms of purity and low level of generated particles. The side wall of the process chamber (inner ring) is temperature stabilized for the same purpose.

Every groove in the roof, or every plasma ring in other words, has its own gas supply system for independent adjustment of chemicals in every ring discharge, and hence, the radial etch profile.

Consequently, GROOVY™ has two powerful and substantially independent means for profile/uniformity adjustment: rate of physical sputtering and density of chemically active components. Thus, the new plasma source allows independent distributions of physical and chemical plasma parameters without compromising damage issues caused by attempts to compensate one non-uniform parameter by another. Maximum inductive RF power in the roof is up to about 6 kW at the standard 13.56 MHz RF frequency.

Uniform process operation range for oxide and low-k etch is within about 5-60 mTorr gas pressure. Moreover, the integrated plasma source is also capable of oxygen discharges up to 2 Torr gas pressure, which is useful for free-radical dry chamber cleaning and in-situ ash.

The roof assembly is mounted with about 40-mm separation gap over the RF biased temperature stabilized electrostatic chuck. The bias RF power is up to about 5 kW. The process chamber of about 50-cm inner diameter has a temperature stabilized hot wall (inner ring) in order to supress polymer deposition and increase mean time between maintenance. Wafer transfer platform is capable of 200- or 300-mm wafers.

Commercial Langmuir probe system was used for spatial estimation of plasma parameters at the mid-plane of the discharge gap. The results were used only for inductive plasma uniformity evaluation, since the probe does not work well under the high RF bias power condition in a narrrow discharge gap.

Etching processes are well characterized on a number of bare and patterned production wafers with different materials: photoresists (KrF, ArF), silicon oxide (TEOS), organic and inorganic low-k materials like SiLK, SiOC, polyimidazole derived, fluorinated polymers, and silicon.

3. Results and discussion.

a) Low-power discharge ignition;

One of the most valuable features of the GROOVY™ is its ability for extremely low power ignition because of quasi-immerse nature of the induction coils. It is well known that large commercial etchers have essentially high power ignition of about hundred watts. Moreover, the ignition in very low-pressure etchers is usually performed at substantially higher gas pressure (50-100 mTorr) than the process level of a few millitorrs.

Fig. 2 shows the dependence of minimum ignition power with a groovy roof made of ceramics on the gas pressure for pure oxygen gas, which is known for rather difficult discharge ignition. A 100 W RF power is enough for discharge ignition at 10-mTorr gas pressure in case of the roof made of silicon, which is relatively higher than for ceramics but still very low absolutely. Therefore, it is not necessary to switch pressure levels between the ignition and process regimes as in many commercial etchers. Low-power ignition prevents production wafers from specific plasma damages typical for capacitive etchers.

b) Uniform plasma density;

Fig. 3 shows electron density distribution in the mid-plane of 40-mm discharge gap as measured with a movable Langmuir probe. There is no RF bias in this case: only inductive discharge was excited in the groovy roof. Plasma density is constant within the level of experimental errors over 300-mm wafer surface. There are no bumps or valleys at the grooves or between them.

Excellent sputter uniformity;

Oxide etchers operate under the highest RF bias power among all etchers. Therefore, the uniformity of sputter rate distribution over the wafer surface is vitally important for advanced processing. Fig. 4 shows three-dimensional sputter patterns for the separate ring discharges in the grooves (Coil 1, Coil 2, or Coil 3). Every individual sputter pattern demonstrates very good azimuthal uniformity and substantial axial symmetry. The ring discharges excited altogether, make flat uniform sputter rate distribution over the whole wafer. Typical example of normal three-coil discharge sputter distribution is shown in **Fig. 5**. The sputter rate non-uniformity of the GROOVY™ is below about 5% over the widest range of process conditions. It is certainly an excellent level of sputter uniformity taking into consideration that chemical factors in a real oxide etch process improve uniformity. There is no problem with the edge non-uniformity typical for a number of capacitive and ICP etchers

Independent controllability of radial plasma/sputter profiles is an essential feature of GROOVY™. Indeed, the process window of usual etchers is essentially limited with only a few external discharge parameters being controlled: power, pressure, flow rate, gas mixture. No one of these parameters is usually adjustable over the wafer radius. There is a narrow parameter range producing a flat etch profile: step up or step down changes the etch ratio center/edge. GROOVY™ overcomes this principal limitation by independent adjustment of the edge/center etch profile thus essentially expanding the process window.

c) Etch uniformity on bare wafers;

Etch rate distributions on bare wafers (no pattern) for different materials are quite uniform. Oxide

etch non-uniformity at about 5 mTorr pressure is within ±1.4% ([MAX-MIN]/[2xAVE]). Typical etch non-uniformity for organic (SiLK) or inorganic low-k materials at the discharge pressure of about 30 mTorr are within about ±2%. Even at 60 mTorr, the uniformity level is better than ±5%. It shows the widest process window of GROOVY™. Radial plasma density and process rate profile control relies upon independent RF power and gas flow control in the grooves. The developed plasma source practically excludes any self-redistribution of the RF power from one coil to another. **Fig. 6** shows typical dependence of the RF current in one coil fed with a constant RF power on the variable RF power in the adjacent coil. All three coils and corresponding inductive ring discharges operate as virtually independent plasma sources. It guarantees exceptionally wide process window in comparison with parallel-plate capacitive discharges, where radial profiles cannot be optimized for a range of different process conditions without substantial modification of hardware, for example, by gap control. Usual ICP etchers (wide-gap) of any configuration do not enter into advanced oxide etch processing at all, because of long gas residence time.

d) High aspect ratio contact etch;

In order to characterize an advanced oxide etcher, HARC holes are usually etched. An example of such processed pattern is shown in **Fig. 7** and **8**. Fig. 7 shows 80 nm hole pattern with aspect ratio 20. Oxide to photoresist etch selectivity of about 119 (bulk) and about 7.1 (facet) is easily achievable as Fig. 8 shows for partial deep oxide etch.

GROOVY™ plasma source demonstrates excellent performance in a wide range of process conditions including a very low-pressure condition of about 5 mTorr. Process conditions can be varied from "clean" etch mode to polymer deposition mode, which is preferable for highly selective etch in respect to the polymer resist.

e) Etching of Low-k materials;

GROOVY™ outperforms capacitive etchers in etching of Low-k materials. Indeed, its basic physical difference from capacitive discharges is the possibility to work under no-bias condition in principle unachievable for capacitive discharges due to their very nature. Therefore, GROOVY™ can smoothly operate in the widest range of RF bias conditions: from extremely high, typical for oxide etchers, down to extremely low, typical for pure inductive discharges. This unique combination of so many different, and incompatible in usually capacitive etchers, properties in one process chamber sets a new industrial standard for a Low-k etcher. This unique combinations of process parameters allows excellent multi step multi processing of newly developed structures with organic/inorganic low-k insulators and SiO2, SiC, or SiOC hard masks, spacers, and stoppers in one chamber. Obviously, such processing brings about essential improvement in overall quality, throughput, and reduces cost of ownership for end users.

Fig. 9 shows organic Low-k pattern (SiLK) with SiO2/SiC or SiOC hard masks processed in GROOVY™. It is seen, that there is no micro trenching in the low-k layer in a half-etched pattern, while the taper angle in the completed sample is 89 degree.

f) Comparison

Comparing capacitively coupled, conventional inductive, and GROOVY plasma sources, one inevitably concludes that GROOVY integrates the best features of capacitive and ICP sources. Indeed, it is a narrow-gap low gas residence time similar to a capacitive oxide etcher plasma source. At the same time, it is a wide pressure and power range ICP source. Moreover, it is an integrated plasma source with adjustable radial distributions of both RF power and gas flow rate. It is well seen that GROOVY plasma source represents a converging landmark of capacitive and inductive plasma technologies for advanced etching. The best features of narrow-gap capacitive and wide-gap inductive plasma sources have been implemented in one planar geometry.

4. Conclusion

A new integrated narrow-gap flat ICP plasma source has been developed and successfully implemented in advanced 300-mm etching technology. It is shown, that the new etcher has substantially wider process window in comparison with commonly used narrow-gap capacitive discharges. The new etcher demonstrates excellent process results for deep silicon oxide and low-k etch.

Abstract
The plasma technology for the production of carbon nanoparticles has been one of the major research areas developed by a consortium composed of Ecole des Mines de Paris, CNRS and ERACHEM for about ten years. The plasma technology has shown a very high versatility and it has been demonstrated that the very same technology can be used for the production of a wide range of carbon nanostructures ranging from Carbon Black over Fullerenes to carbon nanotubes with a high product selectivity.

1. Introduction
The total world production of carbon black is about 6 million tons per year, most of this production being applied in the rubber, plastics, inks, batteries industries [1],[2]. Although the partial combustion processes are able to produce at very low price carbon blacks, satisfying the present demand, it remains that the operating conditions are limited by thermodynamic reactions. Depending on the feedstock and on the quality of the product, the furnace process achieves poor carbon yields raging between 30 to 50 % and is characterised by a high level of atmospheric emissions. While the legislation in different countries will become more and more stringent, it will be an increase necessity, for CB industry, to take into account these environmental aspects [3],[4]. The carbon black industry also faces problems with the availability of adequate raw materials as highly aromatic hydrocarbons are required for the production of most carbon blacks.
Discovered in 1985, by Smalley, Curl and Kroto, the Fullerenes, a family of pure carbon cage molecules [5], moved from "laboratory curiosities" to stakes materials for a wide number of applications such as chemistry, biology, electronics, electrochemistry, materials, optics, energy science,…The availability of these new nanostructures in reasonable quantities, typically the order of several kilograms, is a compelling necessity for the development of future applications. Present production methods can only provide very limited quantities of the order of a few grams per hour !!!.. Currently known processes for fullerene synthesis use either of the following methods: Arc [6], laser [5], solar [7] or combustion method [8]. The first three processes, all of them based on the ablation of a solid carbon at reduced pressure have many things in common. The combustion method takes a slightly special position among the other three as the carbon precursor is derived from a hydrocarbon source. All these methods have in common a very low fullerene production capacity. This is in the end the critical parameter when it comes to the production of large quantities of fullerenes. In addition, attempts to upscale these processes have so far been of only limited success. The fullerene contents in the individual soot samples lie typically between 5 and 10 %-wt., whereby isolated fullerene yields of up to 40 % are reported for the arc process [9].
Finally, the carbon nanotubes (CNT), discovered by Iijima in 1991, [10] offer also exciting possibilities in the material, chemical and physical sciences and again, the production methods can be classified into two main categories : those using very high temperature (arc, laser, solar concentrated) and those using the catalytic decomposition of hydrocarbons [11] . For the methods belonging to the first group, the above limitations listed for the fullerenes are also valid.
Fundamentally new approaches can be developed using thermal plasma. Indeed, plasma technologies are particularly adapted to the production of nanoparticles. Being highly flexible they allow the use of a wide range of carbon feedstock (solid, liquid, gaseous, alone or associated with a catalyst element), the access to

very high temperatures and enthalpies densities unreachable with conventional combustion processes. Finally, the use of any plasma gas allows the control of the atmosphere (inert or reactive).

2. Plasma technology and diagnostics

Since 1993, a new 3-pase AC plasma technology for producing new carbon black grades and hydrogen has been under development [12], [13], [14]. The principle of the new process consists in replacing the incomplete combustion by directly splitting the hydrocarbon into carbon black and hydrogen thanks to an external electric energy supply.. The overall process illustrated in Figure 1 is composed of : a plasma power supply : 3-phase, 600 Hz, 0-400 A, 263 kVA maximum power. It supplies electricity to 3 graphite electrodes located at the top of the reactor, a high temperature chamber which upper part is equipped with a graphite nozzle where the hydrocarbon (HC) is introduced, a tail filter with PTFE bags where carbon and gas are separated and collected, gas and water networks develop to provide cooling fluid to the external kiln of the reactor which is double walled and water cooled.

This technology, initially designed for the treatment of hydrocarbons, was adapted in order to treat solid carbon powders [15]. The overall process is illustrated in Figure 2. In this case, solid powder is transported together with the plasma gas to the arc zone. The main difference with the classical arc process for fullerene and nanotube synthesis is that the input carbon rate is not limited to the electrodes erosion but can be controlled totally independently. In addition, a system was specially designed for the sampling of the species inside the reactor, their quenching and their transport up to a filter. This system is mainly composed of a water cooled suction pipe, a set of modular cooling pipes and a filter / gas recycle system.

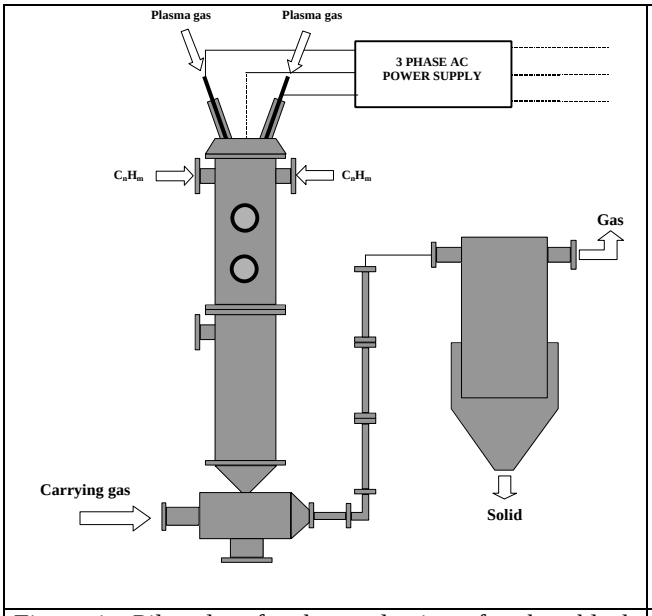

Figure 1 : Pilot plant for the production of carbon black (configuration 1)

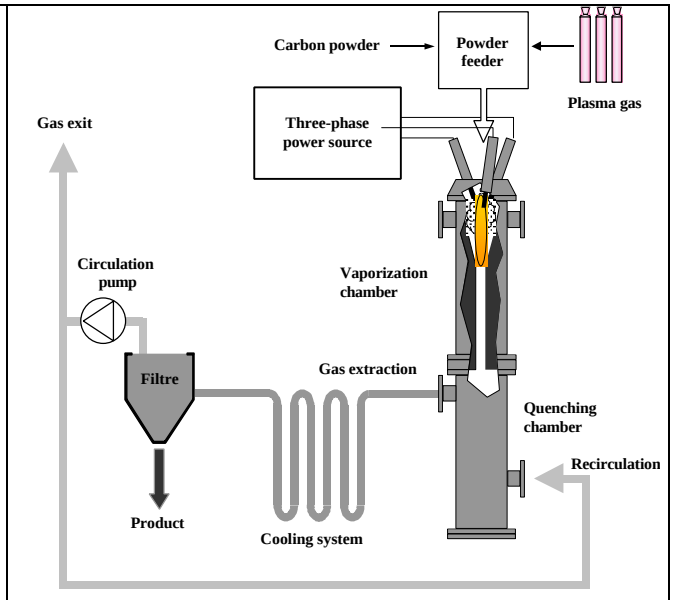

Figure 2 : Pilot plant for the production of fullerenes and nanotubes (configuration 2)

Flow and wall temperatures were measured along the reactor. In the high temperature zones, the measurements were carried out by optical emission spectroscopy (OMS) and optical pyrometry, whereas R-type and K-type thermocouples were placed in the low temperature regions. OMS was used for the plasma diagnosis. A quartz window located in the upper part of the reactor allowed the observation of the arc zone. By using an optical system composed of a lens, an optical fibre and a 3 dimensional measurement bench, the light emitted by the plasma is directed to the entrance of a monochromator (600 mm focal distance, with a 1200 lines/mm grating) with a 1024x256 photodiodes matrix detector. This device allows a quasi-instantaneous analysis in a spectral range in the order of 30 nm with a spectral resolution of 0,029 nm per photodiode. At the same time, the axial exploration of the plasma was also possible with the optical system. The pyrometic measurements were carried out by a bichromatic infrared pyrometer sighted on a graphite tube immersed in the plasma flow. A FT-IR spectrometer was also used for the on-line analysis of the off-gas composition. The sampling system was connected to the reactor exit.

3. Operating conditions

All the experiments were carried out at atmospheric pressure. For the production of carbon black, the experimental set-up was installed in configuration 1, while configuration 2 was used for the synthesis of fullerenes and carbon nanotubes.

	Parameter		**Operating conditions**	
Carbon Black	Precursor	Flow rate	CH_4, C_2H_4, PFO[1], C_8H_8, Colza oil	0.5-3 $kg.h^{-1}$
	Injection		Axial or radial	
	Plasma gas	Flow rate	N_2, Ar, He, Ar/H_2 , CO	50-220 $Nl.mn^{-1}$
	Electrical power		25-200 kW	
Fullerenes	Precursor	Flow rate	Acetylene Black, Carbon black, graphite powder	0.1-1 $kg.h^{-1}$
	Injection		Axial or radial	
	Aspiration zone		Upper[2] or Lower[3]	
	Plasma gas	Flow rate	Ar, He	50-150 $Nl.mn^{-1}$
	Electrical power		40-60 kW	
N**anotubes**	Carbon precursor	Flow rate	Acetylene Black, Carbon black, graphite powder, C_2H_4	0.1-0.3 $kg.h^{-1}$
	Metal catalyst	$\%_{mass}$	Ni, Co, Y, mixtures	1-15 %
	Injection		Axial or radial	
	Aspiration zone		Upper or Lower	
	Plasma gas	Flow rate	N_2, Ar, He	50-150 $Nl.mn^{-1}$
	Electrical power		50-100 kW	

Table 1 : Operating conditions for the production of the different nanostructures

4. Characterization of the carbon nanostructures

Carbon black samples were analysed by TEM and SEM together with the two major carbon black parameters: Nitrogen specific surface area BET and DBP-absorption and the crystallographic parameters. In addition, the carbon black samples were evaluated by standardised procedures in the following domains : polymer composites, rheological behaviour, tensile properties, hardness. A detailed description of the characterisation procedures can be found in [19].

For each Fullerenes sample, Soxhlet Toluene extraction was performed and the extract was analysed by UV-Vis spectrophotometry. The extract concentration in fullerenes C_{60} and C_{70} was evaluated from the two characteristic absorption peaks at 330 10^{-9} m and 470 10^{-9} m [16], [17], [18]. In addition, specific analysis were carried out on a limited number of samples in order to confirm the results : mass spectroscopy analysis, High Pressure Liquid Chromatography (HPLC) and TEM. A detailed description of the characterisation procedures can be found in [20].

For each Nanotubes sample SEM and TEM analyses were systematically performed. In addition, specific analyses by HRTEM, XPS, X-ray diffraction and Auger spectroscopy were carried out on a limited number of samples.

5. Results

The plasma technology allows the production of materials which can be classified as carbon blacks. The results have shown that the technology allows the adjustment of the two main morphological properties: specific surface area and DBP absorption (Table 2). In addition, the rubber compounded data confirm that these carbon blacks behave like all other blacks and obey to similar rules.

[1] Pyrolysis Fuel Oil

[2] 30 cm downstream the electrodes bottom. This position corresponds to a high temperature zone (T>2500°C) and a high quenching velocity

[3] 1 m downstream the electrodes bottom. This position corresponds to a low temperature zone (T < 1100°C) and a low quenching velocity

Feedstock	CH_4	C_2H_4	C_8H_8	PFO	Colza oil
Spec. Surf. Area (m^2/g)	50-90	30-80	50-90	70-90	50-80
DBP Absorption (ml/100 g)	90-210	100-250	150-190	150-220	100-250

Table 2 : Main morphological characteristics of the plasma carbon blacks

As expected, the materials produced by this process have shown no porosity as no oxygen is present in the reaction zone. Carbon blacks have also been investigated by TEM. These analyses have shown a smoother particle shape in the case of the lower energy input and an apparently higher graphitic nature at higher energy input. For some very high energy input, HRTEM pictures show hollow structures similar to electrical conductive grades.

Concerning fullerene synthesis, best yields of 5 % extractible fullerenes have been obtained with flow rates of 150 $g.h^{-1}$ what corresponds to a production capacity of 7.5 $g.h^{-1}$. The main results including the yield dependence on the most sensitive process parameters have been presented in [21]. The nature of the plasma gas and the distances between the three electrodes appear to be the most critical ones. Yields have been found to be about one order of magnitude higher when using helium as plasma gas rather than argon or nitrogen, a fact generally known for the arc or laser process. The nature of the carbon precursor, showed no drastic influence on the process performance. Almost all carbon types showed similar results apart from one carbon black grade showing significantly lower fullerene yields.

At the time being, more than 300 “nanotubes samples” have been produced. Their analysis is not yet achieved and this task will still take several years. However, as expected, it has been demonstrated that a very wide diversity of carbon nanotubes : MWNT[4] and SWNT[5], could be synthesised. In a lot of samples as shown on Figure 3 tubular structures were observed. These structures are generally found as deposit on the electrodes and on the graphite walls. High yields are obtained when Nickel is used as catalyst alone or associated with another catalyst. Their typical length is ranging from 1 ? m up to several tens ? m and their diameter is ranging between 10 to 100 nm. Some of this tubes appear being open (left) while others are terminated by catalyst particle (right).

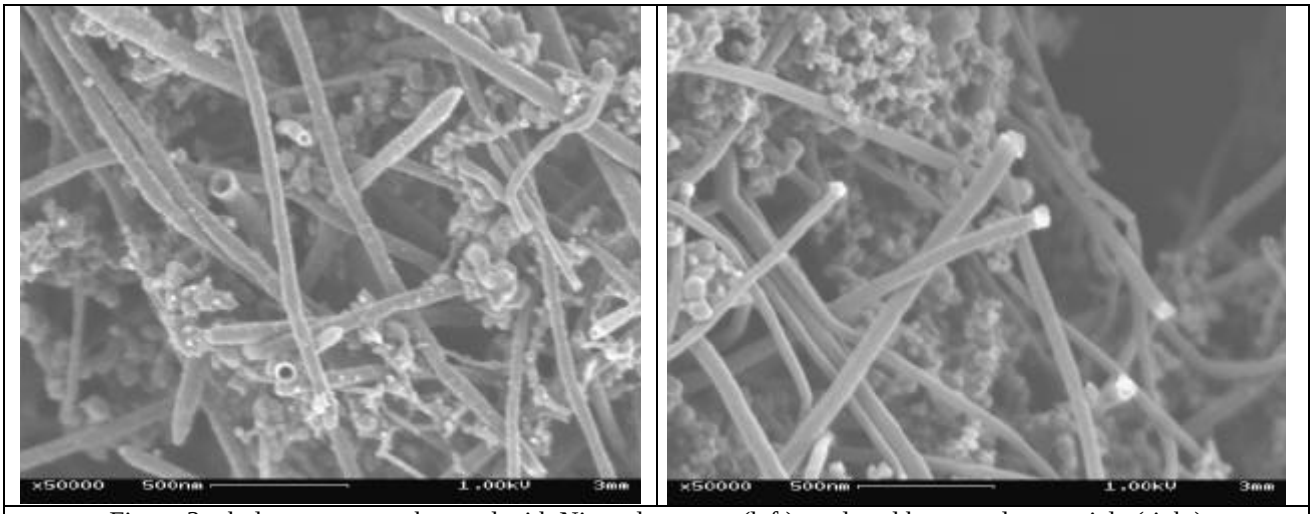

Figure 3 tubular structures observed with Ni catalyst open (left) or closed by a catalyst particle (right)

TEM observation show that these structures are composed of multi wall « bamboo like » structures, each element being composed of approximately 20 graphite sheets (Figure 4). The most commonly growth model proposed by [11] and [22] is represented in the Figure 5. The dissolved carbon diffused into the bottom of the Ni needle. After the graphitic layers is formed, the Ni particle is probably pushed out the Ni needle may be the stress accumulated in the graphtic sheath ; the segregation of carbon from the inside of the sheath brings a compressive stress on the Ni needle. The stress would be released by pushing out the Ni needle. This process is similar to that proposed by Oberlin et al. [23] for carbon fibers prepared by thermal

[4] Multi Wall NanoTube
[5] Single Wall NanoTube

decomposition of hydrocarbons. However, the lengthening of tubes proceeds intermittently for the bamboo-shaped tubes while it is continuous for pyrolytic fibers.

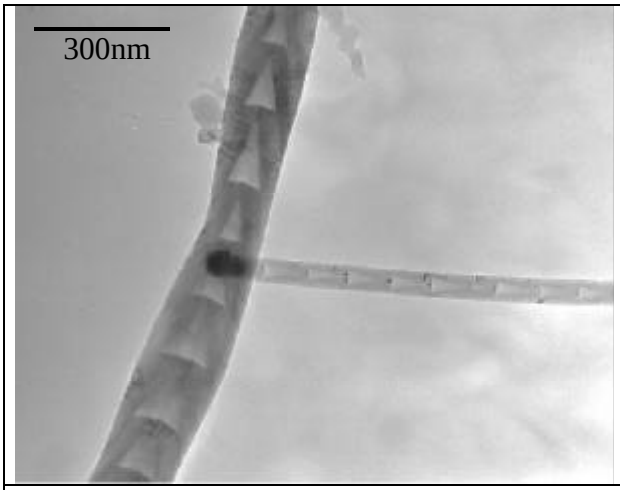

Figure 4 : TEM Observation of a « bamboo like » growth starting from a catalyst particle

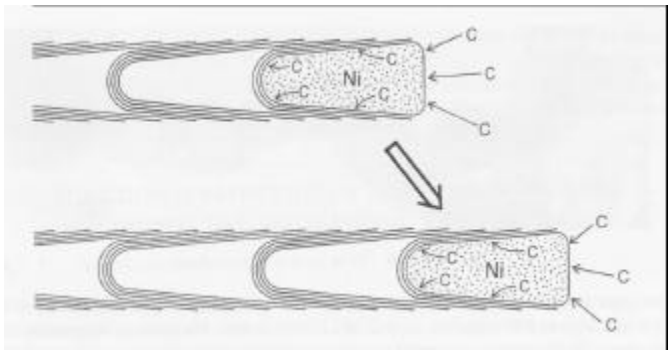

Figure 5 : Growth Model of « bamboo like » structures

As mentioned above, SWNT and other more "exotic" structures such like "carbon necklaces" have also been found in different samples but their complete characterisation is not yet completed. As example, Figure 6 and Figure 7 represent respectively SEM and HRTEM observations of a typical sample obtained by plasma under an helium atmosphere.

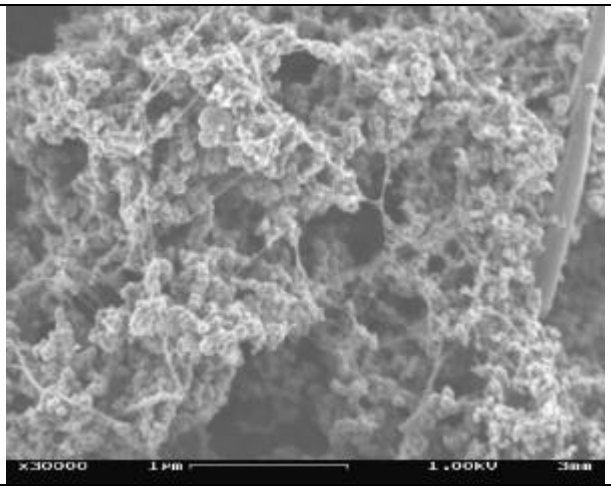

Figure 6 : SEM observation of a SWNT "web" together with amorphous carbon obtained by plasma

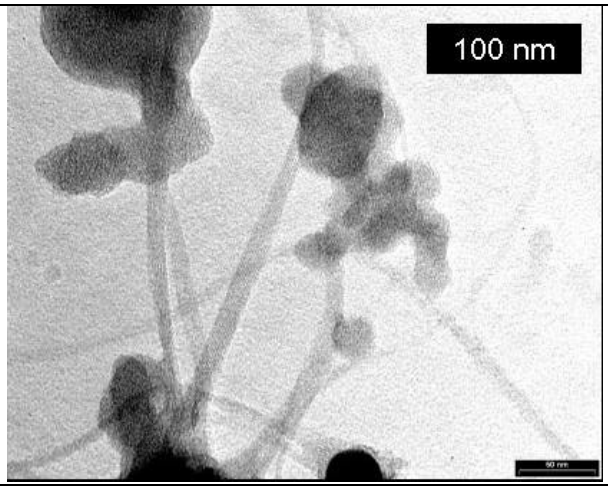

Figure 7 : HRTEM Observation of bundles of SWNT obtained by plasma

Conclusion

The plasma process opens a totally new area for the production of carbon nanostructures. In the conventional carbon black market, it will bring new carbon blacks thanks to thermodynamic conditions unreachable by conventional means. The plasma process will allow the use of new raw materials: waste oils, vegetable oils,…since it appears that any hydrocarbon can be used if enough energy is given. It will allow a more rational use of the raw material (100 % carbon yield), the production of carbon black free from CO_2 emission on the site and the production of hydrogen as by-product.

In the emerging domains, the plasma process will allow the production of novel materials of nano-size structure, which are without any doubt amongst the most promising resources for future industrial applications and systems. Moreover, nanomaterials based on carbon as fullerenes, nanotubes, nanofibers are classified as one of the major R&D goals in the scientific politics in material sciences and engineering,

giving rise to a whole new branch in nanotechnologies and nanosciences and the unrestricted availability of these materials at a reasonable price is a real challenge and opportunity for the plasma community.

Surface Fluorination of Nitrile Butadiene Elastomers

A. Tressaud, E. Durand, C. Labrugère, H. Benalla

Institute of Condensed Matter Chemistry of Bordeaux (ICMCB-CNRS), 87 Avenue du Dr. A. Schweitzer, 33608 Pessac Cedex, France.

Abstract - This work is devoted to surface treatment of thin NBR nitrile gloves using either plasma-enhanced fluorination in rf plasmas of fluorinated gases (CF_4, CHF_3) or direct fluorination (10% F_2-gas diluted in N_2). The mechanisms of fluorination of these co-elastomers are proposed on the basis of the assignment of the different components of the XPS spectra. When the treatments are carried out at room temperature a gradual fluorination occurs : monofluorinated CF groups are the species most found at the surface and perfluoro groups CF_n are present in lower amount. An addition reaction takes thus place at the $-(CH=CH)-$ double bonds of the polybutadiene entities, leading to $-(CHF–CHF)-$ units with large amounts of unfluorinated domains.
When the reaction is thermally activated at 90°C, an important increase of the fluorinated surface is noted from the elemental surface analysis, with a mean F/C ratio higher than 1.5. C1s spectra exhibit a maximum shifted of + 6.8 eV with respect to the starting material which can be assigned to CF_2 groups with first C neighbours bound to one F atom, for instance CF_2–CHF groups. Additional contributions at higher BE correspond to CF_2 groups with CF_2 first neighbours, as in PTFE, and to CF_3 groups . Similar trend is found in F1s XPS spectra.The relationships between fluorination experimental parameters and surface reactions will be discussed.

1. Introduction

Because of the outstanding characteristics of F_2 molecule, i.e. extreme reactivity and oxidizing power, F^- ion exhibits utmost electronegativity and hardness, in particular towards hydroxyl groups. Therefore fluorine and fluorinated gases constitute exceptional tools for modifying the surface properties of materials. In particular the fluorination of polymers has received wide spread attention and several review papers on this subject have appeared [1-3]. The surface modification of these materials can be achieved either during or after the manufacture process. Several advantages can be indeed outlined, when compared to more conventional methods : [i)] low temperature reaction (even at room temperature), [ii)]chemical modification limited to surface only without modifying the bulk properties, [iii)] possible non-equilibrium reactions. Depending on the type of starting materials and employed techniques, the improved properties may concern wettability, adhesion, chemical stability, permeation, electrical conductivity, biocompatibility, grafting, mechanical behaviour, etc.

The present work deals with the effect of fluorination on the surface of co-elastomers, which have been scarcely studied [4]. It is devoted to the surface treatment of thin nitrile gloves [made of carboxylated nitrile butadiene rubber latex (NBR)] using either plasma-enhanced fluorination (PEF) in rf cold plasmas using fluorinated gases (CF_4, CHF_3) or direct fluorination by 10% F_2-gas diluted in N_2. The mechanisms of fluorination of these co-elastomers will be proposed on the basis of the assignment of the different components of the XPS spectra.

2. Experimental procedure

Fluorination procedure

The experiments in rf plasma conditions were carried out in a S.E. 80 Barrel Plasma Technology System. CF_4 gas was excited by a rf source at 13.56 MHz. The chamber was thermostatically controlled and maintained either at room temperature or at about 90°C during the process. Taking into account previous plasma-enhanced fluorination (PEF) experiments on various types of carbon materials [5, 6], the optimized conditions could be established with the following parameters : CF_4 gas flow rate: Q = 8 ml min^{-1} ; total pressure: p = 300 mTorr ; rf power: P = 80 W. After the fluorination treatment, the samples were generally handled and kept in a glove box under an Ar atmosphere.

Elastomer samples

The thin nitrile gloves submitted to fluorination have a thickness of 100 µm. They were made by dipping a porcelain former previously coated with calcium nitrate into a latex compound, leaching in warm water, drying and curing the form at elevated temperature, and then stripping the gloves. The compound comprises carboxylated nitrile butadiene rubber latex (XNBR) having about 40 % dry rubber content and zinc oxide (1-2%).

XPS Characterization

XPS analysis were performed with a VG 220 i-XL ESCALAB. The radiation was a Mg non-monochromatized source (1253.6 eV) at 200 W. Surveys and high resolution spectra were recorded, then fitted with a Eclipse processing program provided by Vacuum Generators. Each C1s component was considered as having similar full width at half maximum (FWHM), i.e. 1.3eV. This procedure appeared to be the most reliable one, as previously proposed in investigations on fluorinated carbon materials [6]. A good agreement between the experimental curve and the full calculated envelope was obtained, explaining in addition subtle distinctions between the proportion of fluorinated components.

3. Results and discussion

On the XPS survey spectrum of the surface of NBR rubber, it can be noticed, besides the components of the polybutadiene and polyacrylonitrile backbone of the material (C, O, N), the presence of other elements which have been introduced during the different steps of the elaboration process of the glove : Ca, Na, S, Si, K, Zn, Cl. Oxygen which is present in large amount in pristine gloves occurs as carboxyl, carbonyl, hydroxyl groups or as pollution element. Because of the low contents of most of these components, we will only deal in the following with those elements which are able to provide an insight into the fluorination mechanisms, i.e. C and F.

Room temperature fluorination treatments

PEF treatments using CF_4 rf plasma at room temperature for treatment durations up to 120 min do not bring important modifications of C 1s spectra, as shown in Fig. 1a.

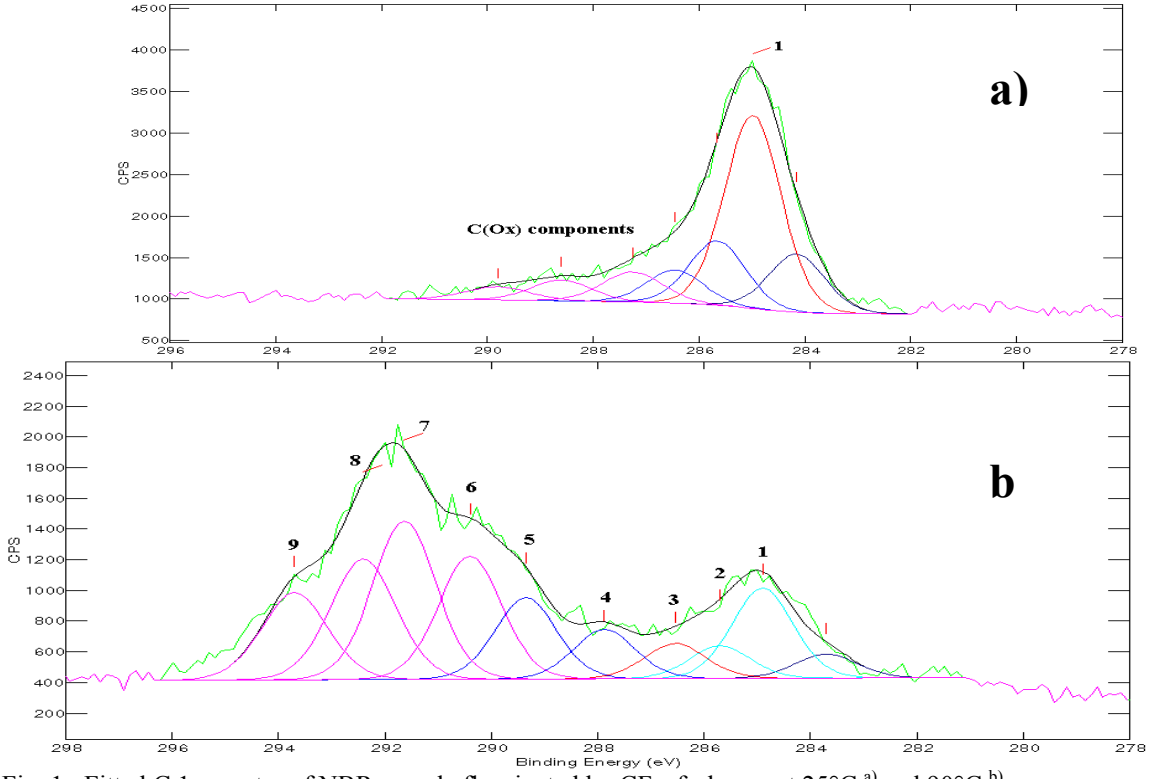

Fig. 1- Fitted C 1s spectra of NBR sample fluorinated by CF_4 rf-plasma at 25°C [a] and 90°C [b].

The main peak is located at 284.6 eV, as for the starting material, and corresponds therefore to CH or CH_2 bonds that are present in both starting PBD and PAN. A component can be noticed on the lower BE side of the C 1s envelope, which can be fitted at about -1eV relative to this peak. This contribution could arise from the presence in the samples of different types of hydrocarbon surface pollution and non-fluorinated domains with different levels of charging effect. The high energy shoulder which is found between 287 and 289 eV is mostly due to carboxyl and carbonyl groups whose BE fall in the 287-288.5 eV range. Small amounts only of CF bonds are formed and are attributable to CHF-CHF groups. On the other hand, 5 to 10% of F are found at the surface depending on the studied sample. Among the three contributions of the F 1s spectrum (Fig. 1b), the weakest one at 687.3 eV (10 %) corresponds indeed to the formation of C-F bonds while the two major components can be attributed to those of « inorganic » fluorides, in which fluorine is bound to inorganic elements that are present in the gloves: CaF_2 for the one at 684.3 eV, ZnF_2 or complex fluorides to the one at 685.3eV.

Thermally activated fluorination treatments

The effect of thermal activation is illustrated in Fig. 1b and 2b which show C 1s and F 1s spectra of the surface of NBR gloves treated in a CF_4 rf plasma at 90°C. In the survey spectrum, the F 1s peaks have considerably increased, with a mean F/C atomic ratio reaching 1.6. In this case, the C 1s spectra exhibit 2 clear maxima : one at a BE similar to that of the starting material, and another one with a shift of + 6.8 eV. If we take the same procedure as previously used, this second maximum can be assigned to CF_2 groups with first C neighbours bound to one F atom, for instance CF_2 – CHF groups.

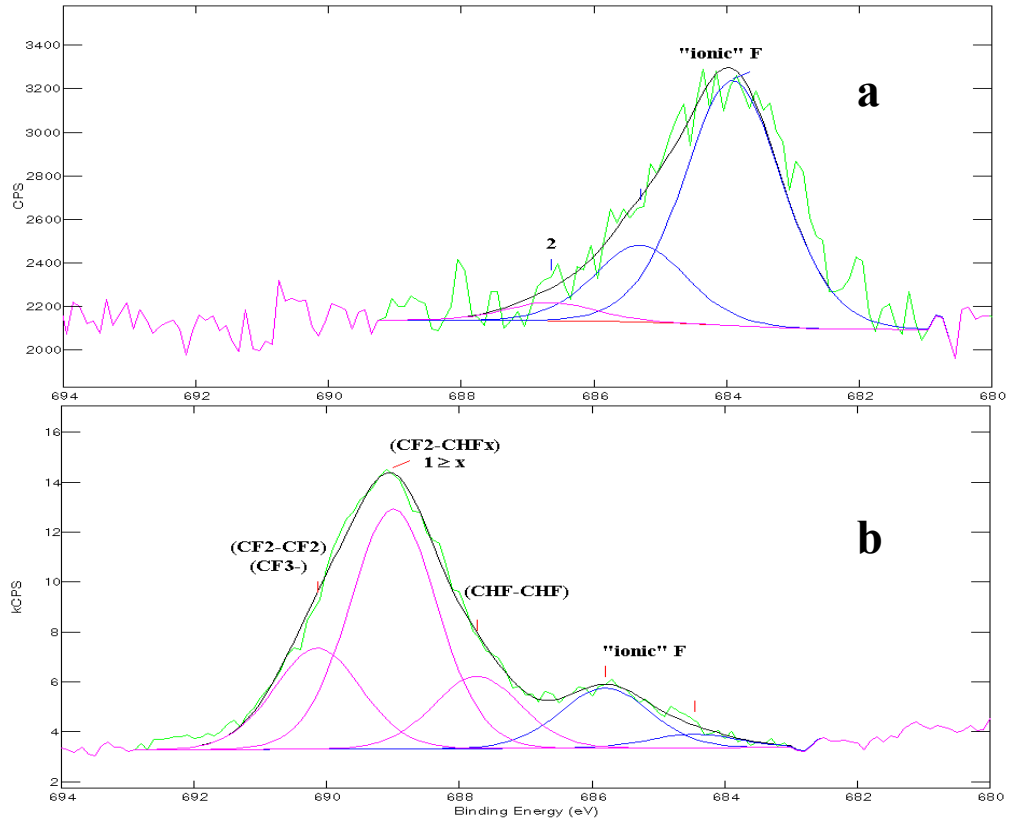

Fig. 2- Fitted high-resolution F 1s XPS spectra of NBR sample fluorinated by CF_4 rf-plasma at 25°C [a)] and 90°C [b)], and by F_2-gas at 25°C [c)].

Another feature of the spectrum which is consistent with an increase of surface fluorination is the presence of two more contributions at higher BE. The one with a shift at + 8.0 eV corresponds to CF_2 groups with CF_2 (or CF_3) first neighbours, or to CF_3 groups with non-fluorinated neighbours. The contribution with a shift of 9.1 eV can be assigned to terminal CF_3 groups with fluorinated neighbours. It can be noted that most of BE are shifted of 0.8 eV relative to the room-temperature experiments due to higher fluorination levels and increase of the insulating character of the sample. The same trend is

found in the F 1s spectrum, as shown in Fig. 2b. Although the amount of « inorganic » fluorides is more or less similar (12%), the maximum value of the envelope corresponding to the F-C components is shifted of about 1 eV towards higher BE. As previously stated, the value of the maximum at 688.7 eV should correspond to $CF_2 - CH_2$, or $CH\underline{F} - CF_2$ units. At lower BE, the CHF – CHF component at 687.3 eV is weaker (15%). In addition, a further component occurs from the fitting procedure at 689.8 eV, which can be assigned to perfluorinated CF_n groups, in particular PTFE-like $CF_2 - CF_2$ units and terminal CF_3 groups.It can be noted that similar results are obtained for shorter fluorination times, 30 min for example.

Comparison with direct F_2-gas fluorination

The direct F_2-gas fluorination process was performed at room temperature in a "fluorine line" using handling procedures previously described. The samples were set in a Ni boat which had been passivated. F_2 gas 10% diluted in N_2 (Air Products) was used at room pressure. The reaction duration did not exceed 120 min. At the end of the experiment, F_2-gas was eliminated from the container and substituted by N_2.

Fig. 3 shows the C 1s XPS spectra for 5, 30, and 120 min treatments. The high resolution C 1s spectra exhibit an envelope spread over 10 eV. For 30 min fluorination durations or higher, the maximum of the envelope is located at 288.1 eV, with a shift of 3.5 eV relative to the 284.6 eV reference. This value being similar to those of CHF-CHF groups in poly(vinylene fluoride), we can assume that the main effect of fluorination is to open the double bond of PBD with a subsequent addition of a F atom on both C atoms. A second important contribution is located at a chemical shift of + 5.5 eV, which could be attributed to of $-(CF_2 - CH_2)-$ units coming from the substitution of F for H, or alternatively C-F bond with highly fluorinated neighbors, such as CF_2 groups or terminal CF_3 groups. Further contributions can be assigned to CF_2-CHF and CF_2-CF_2 groups, respectively. The assignments of the different components are given in Table 1.

The F 1s peak, shown in Fig. 2c, is displaced of about 4 eV toward higher BE, when compared with that of room-temperature PEF experiments. The FWHM is also much larger, reaching 3 eV, which points out the presence of several contributions. The « inorganic » part of the spectrum (CaF_2, ZnF_2) with components at BE ~ 685 eV is very weak and corresponds to less than 10%. The maximum of the peak, at 687.6 eV, can be ascribed to a F-C bond with first carbon neighbours presenting also C-F bonds, i.e. (CHF-CHF) groups, which is in good agreement with the C 1s spectrum. The contribution at lower BE, that is 686.5 eV, should correspond to F-C bonds with non-fluorinated C neighbours, i.e. ($CHF-CH_2$) groups. On the other side, the contribution at higher BE, that is 688.8 eV, can be assigned to C-F bonds with CF_2 groups as first neighbours or alternatively to CF_2 groups with CH_2 or CHF units as first neighbours (unfortunately the only literature data on F 1s BE of (CF_2 – CHF) groups (BE = 690.1 eV) [7] is known to be too high [6].

4- Conclusions

The above results clearly show that in the fluorination of NBR rubbers several mechanisms can be observed depending on the experimental conditions. When CF_4 rf-plasma treatments are carried out at room temperature a gradual fluorination occurs: monofluorinated CF groups are the species most found at the surface and perfluoro groups CF_n are present in lower amount, most fluorine species reacting with inorganic cations such as Ca^{2+}. Thermal activation yields an increase of the amount of surface perfluoro groups that finally leads to a coating mostly formed of perfluorinated $-(CF_2)-$ groups and terminal $-CF_3$ groups. This trend is found in both C 1s and F 1s spectra. On the other hand, direct F_2-gas fluorination is more active, even at room temperature: the addition reaction takes place at the $-(CH = CH)-$ double bonds of the PBD, leading to $-(CHF - CHF)-$ units, whereas perfluoro groups CF_n are present in a lower amount.

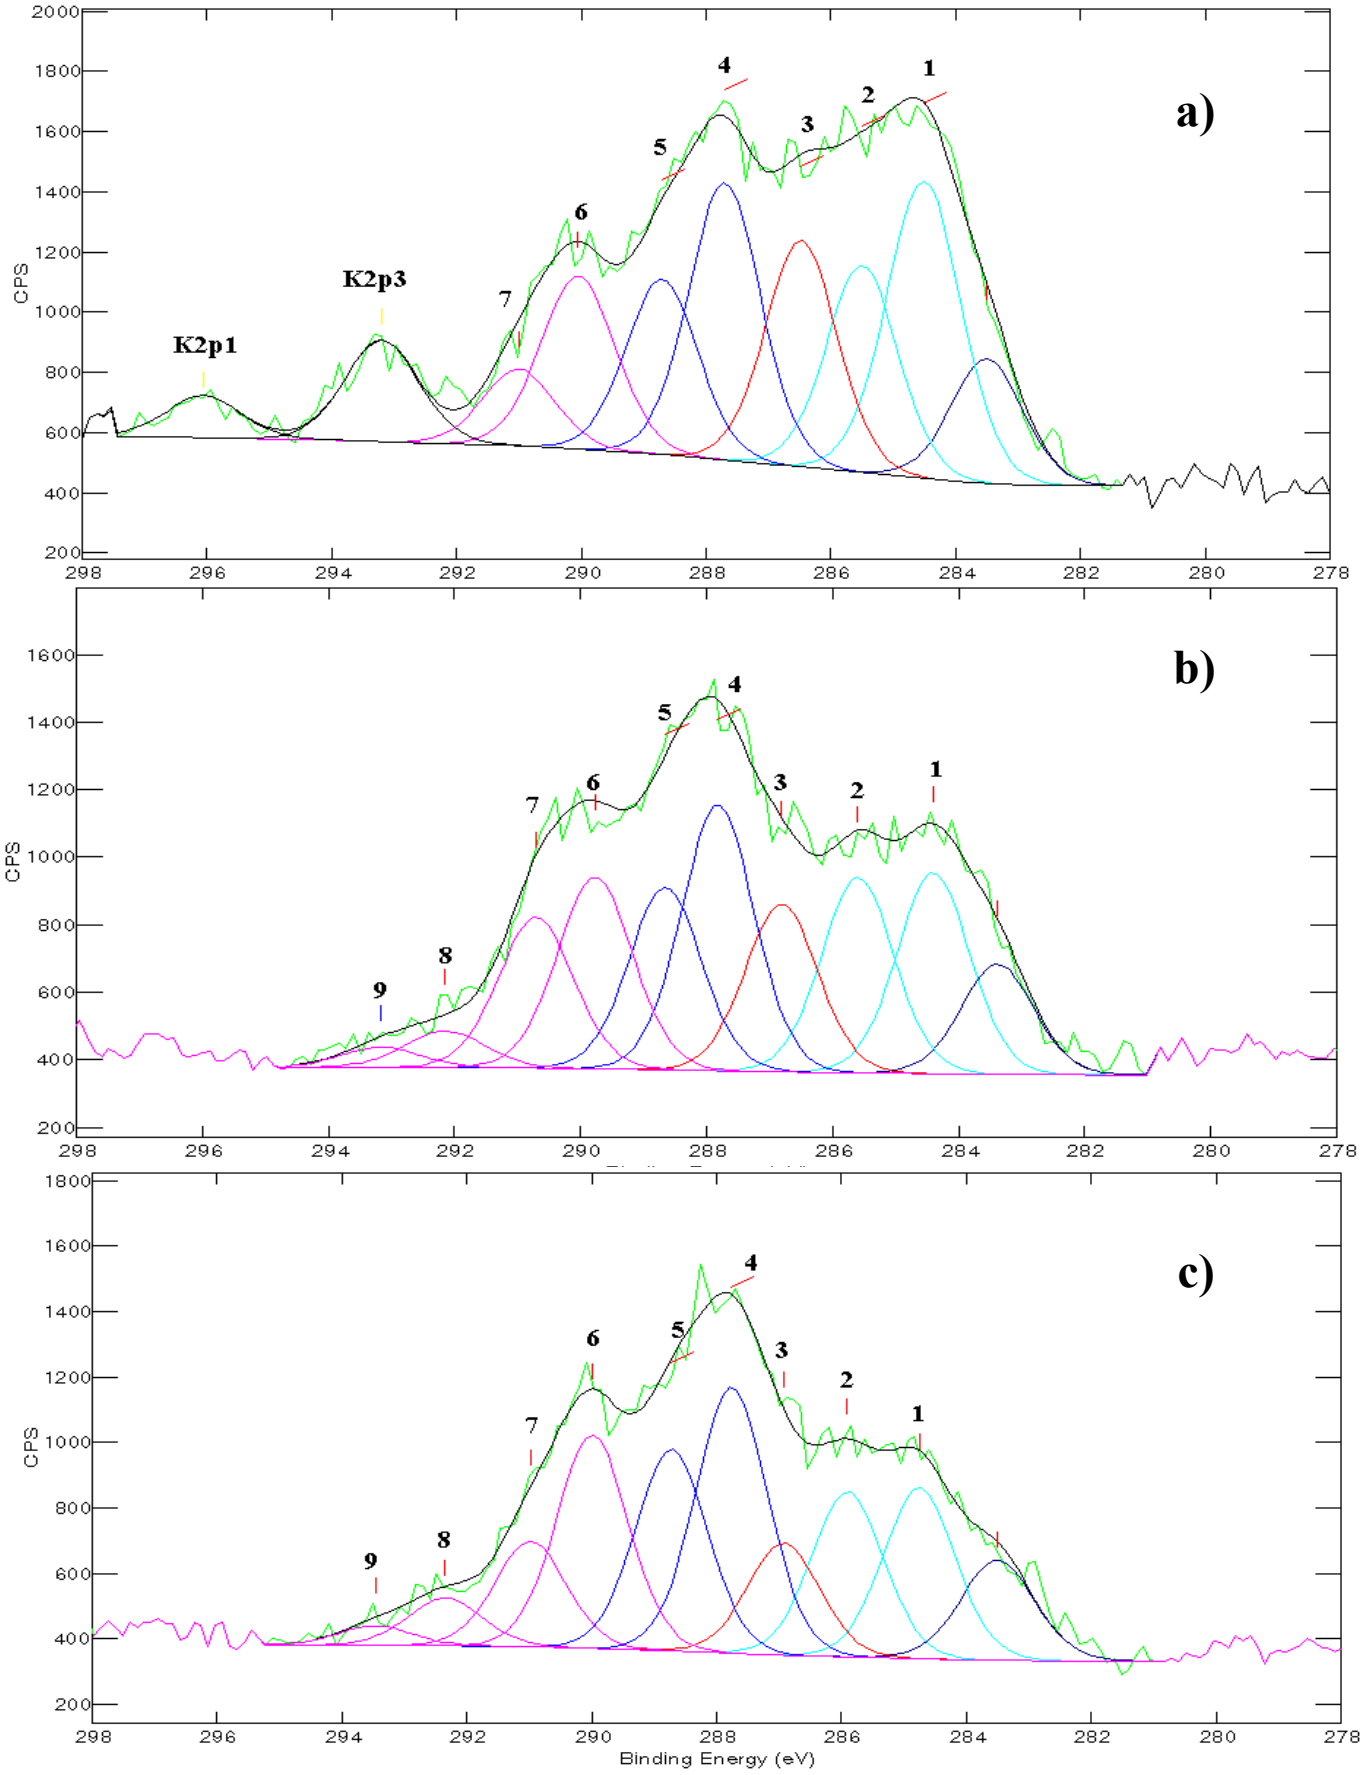

Fig. 3- Fitted high-resolution C 1s XPS spectra of NBR sample fluorinated by F_2 - gas at 25°C during 5 min [a)], 30 min [b)], 120 min [c)].

Table 1 - Assignments of the different components of the XPS spectra

N°	Chemical Bond	Shift (eV)
1	CH_n	-
2	$\underline{C}H_2$-CHF	0.7 - 1.1
3	$\underline{C}H_2$-CF_2	2.0
4	$\underline{C}$HF-CH_2 CHF-CHF	3.0 - 3.5
5	$\underline{C}$HF-CF_2	4.5
6	CF_x-$\underline{C}$F-$CF_{x'}$ (x, x'=2, 3) $\underline{C}F_2$-CH_2	5.3 - 5.5
7	$\underline{C}F_2$-CHF	6.2 - 6.8
8	CF_2-CF_2	7.8
9	$\underline{C}F_3$-CF_x	9.1

Different performance of Ar, O_2 and CO_2 RF Plasmas in the Adhesion of Thermoplastic Rubber Towards Polyurethane Adhesive

A.B. Ortiz-Magán, M.M. Pastor-Blas, J.M. Martín-Martínez

Adhesion and Adhesives Laboratory, Department of Inorganic Chemistry, University of Alicante, 03080 Alicante, Spain.

Abstract

RF plasma treatment has been used to improve the adhesion of synthetic vulcanized rubbers to polyurethane adhesives as an environmentally friendly alternative to the currently used chemical surface treatments. In this study, a non vulcanized (thermoplastic) styrene-butadiene-rubber -S0- was treated with argon, oxygen and carbon dioxide plasmas and the surface modifications were analyzed. Surface analysis of the failed surfaces after peel tests showed that the loci of failure was dependent on the gas plasma.

1. Introduction

Synthetic styrene butadiene (SBS) rubbers are thermoplastic elastomers which consist of block segments of a hard an rigid thermoplastic block polymer (styrene) and a soft and flexible elastic polymer (butadiene). The main advantage of thermoplastic rubbers over the thermoset elastomers is that upon heating above melting temperature of the hard phase, they melt and therefore they may be processed by conventional thermoplastic forming techniques. For this reason in a variety of applications, the thermoplastic elastomers have replaced the conventional thermoset elastomers. Typical uses for the SBS rubbers include automotive components, shoe soles and heels, sporting goods, medical barrier films and protective coatings, and they find application as components in sealants, caulking and adhesives. However, due to the non-polar nature of these rubbers, poor adhesion is produced with polyurethane adhesives. Consequently a surface treatment is required to chemically modify the rubber surface and produce suitable joints [1-3].

The most widely used surface treatment for SBS rubbers is halogenation with organic chlorine donors (trichloroisocyanuric acid or chloramine) which improves the wettability of these rubbers and enhances their adhesion properties [4]. However, this treatment involves the use of organic solvents, the chlorinating solutions have a limited stability and evolution of chlorine is a potential threat. Thus, an environmentally friendly treatment -RF plasma- has been proposed as an alternative to halogenation for thermoplastic SBS rubbers. Recent studies [5-7] have shown the effectiveness of RF plasma treatment in the treatment of rubbers. The energetic environment of the plasma creates surface free radicals as well as produces cleaning, ablation, crosslinking and chemical modifications on the rubber surface. However, these effects are greatly dependent on the gas used to generate the plasma. In this study the RF plasma treatment of an non vulcanized thermoplastic styrene butadiene rubber has been investigated. The effectiveness of different gas atmospheres (argon, oxygen and carbon dioxide) has been considered and the surface modifications and adhesion properties of the surface modified S0 rubber have been studied.

2. Experimental.

A block copolymer synthetic thermoplastic styrene-butadiene-styrene rubber (S0) has been used in this study. A simplified structure is given in Figure 1. The S0 rubber, which was provided by REPSOL QUÍMICA (Santander, Spain), does not contain oils, plasticizers or fillers but a small amount of antioxidant. The rubber samples were obtained by injecting the polymer into a heated mold at 150ºC, and test samples of 30 mm width, 150 mm length and 6 mm thick were obtained. The styrene block content of the S0 rubber is 30%, its tensile strength is 17 MPa and the Shore A hardness is 72º.

The S0 rubber was treated under low pressure RF plasma using argon, carbon dioxide and oxygen atmospheres for 1 to 15 minutes. The surface modifications produced on the S0 rubber were assessed by contact angle measurements, ATR-IR spectroscopy, XPS and SEM. Adhesion was evaluated from T-peel strength measurements of joints produced between two similarly treated S0 rubber samples bonded with a polyurethane (PU) adhesive in solution. The adhesive solution (18 wt% PU pellets in MEK + 5 wt% isocyanate) was applied to the rubber surface immediately after the treatment was carried out. Failed surfaces

after peel tests were characterized using ATR-IR spectroscopy to accurately assess the locus of failure of the joints.

3. Results and Discussion

As received S0 rubber shows (Figure 2) a high contact angle value (water, 25ºC), indicating a poor wettability due to its non polar nature. ATR-IR spectrum of the as received S0 rubber (Figure 3a) shows typical absorption of styrene (3010-3080, 1480, 915, 760, 696 cm^{-1}) and butadiene (2920, 2850, 1448, 1380, 968). Plasma treatment for 1 minute produced a noticeable increase in wettability of S0 rubber (Figure 2) with the three gases considered (oxygen, argon and carbon dioxide), being this increase more important when argon plasma was used. Besides, an extended plasma treatment (up to 15 minutes) produced a further decrease in contact angle on the Ar-plasma treated S0 rubber. Surface energy was evaluated using the Owens and Wendt approximation [8] (Figure 4). A noticeable increase of the polar component (γ^p) (Figure 4c) and a decrease of the dispersive component (γ^d) (Figure 4b) of the total surface energy (γ) (Figure 4a) was produced when the S0 rubber was treated with Ar plasma. This behavior can be explained on the basis of different surfaces modifications. ATR-IR spectra of plasma treated S0 rubber (Figure 3) show a decrease of hydrocarbon absorption (2920, 2850, 1448 cm^{-1}) and a decrease of C=C absorption (3080-3010, 915 cm^{-1}) when the S0 rubber was treated in Ar plasma. This corresponds to the decrease of the dispersive component of the surface energy (Figure 4b). However the treatment in O_2 or CO_2 plasmas produced the increase of the hydrocarbon absorption (2920, 2850, 1448 cm^{-1}) which is in agreement with the increase of the dispersive component of the surface energy (Figure 4b).

XPS allowed to restrict the depth of analysis from approximately 5 μm (ATR-IR) to the outermost 5 nm. As received S0 rubber is mainly composed (Table 1) of carbon and some oxygen and silicon (likely from a mold release agent, *i.e.* a silicone). Besides, some degree of oxidation of the surface rubber might be favored when the plasma treated rubber is exposed to the air. The plasma treatment for 3.5 min produced an increase of oxygen on the surface of the S0 rubber. This increase was more important when the S0 rubber was treated in Ar-plasma compared to CO_2 and O_2 plasmas, which is in agreement with the more pronounced increase in the polar component of the surface energy (γ^p) on the Ar-plasma treated S0 rubber (Figure 4c). Curve fits of the C 1s and O 2p photopeaks (Tables 2 and 3) show the creation of C-O, C=O and R-O-C=O moieties on the plasma treated S0 rubber, which contribute to increase the polar component of the surface energy (γ^p). Besides, C=O and Si-O moieties are removed from the S0 rubber surface (Table 3) when treated in plasma, this removal being more important with CO_2 and Ar plasmas. These findings suggest that CO_2 and O_2 plasmas produce ablation of the rubber surface and partially remove hydrocarbon and silicon moieties from the S0 rubber surface. On the other hand, Ar plasma does not produce such degree of ablation, consequently, hydrocarbon and silicon moieties are not such effectively removed and a more important degree of oxidation was achieved.

Ablation of the S0 rubber surface was monitored by SEM (Figure 5). Topography of the S0 rubber was modified by the plasma treatment. Thus, removal of surface layers (ablation) was produced mainly with CO_2 and O_2 plasmas. The increase in the length of plasma treatment produces a smoothing of the rubber surface (Figure 6) due to further ablation produced by an extended plasma treatment. This explains the decrease in the dispersive component of the surface energy (γ^d) when S0 rubber is treated wih Ar and CO_2 plasmas for 15 min (Figure 4b). Thus, the increase of the length of CO_2 and O_2 plasma treatments produce ablation of a previously oxidized rubber surface. On the other hand, Ar plasma oxidizes S0 rubber surface but is not sufficiently aggressive to remove this oxidized rubber surface. In consequence, oxidized polar moieties remain on the Ar-plasma treated S0 rubber surface producing an increase in the polar component of the surface energy (γ^p) (Figure 4c).

The different surface modifications produced by the several gas plasma treatments were expected to affect differently the adhesion properties of the S0 rubber. Adhesion was evaluated from T-peel test measurements in joints produced between two identically treated rubber strip test pieces bonded by a polyurethane (PU) adhesive. The non polar nature of the as received S0 rubber as well as the presence of a mold release agent (*i.e.* a silicone) on the rubber surface are responsible for the lack of adhesion of the joints produced with the

as received S0 rubber. The plasma treatment of the S0 rubber produced a noticeable increase of adhesion with all the plasmas irrespective of the length of treatment (Figure 7). Thus the T-peel strength values do not reflect the different chemical and morphological surface modifications produced by the different plasma treatments. This suggest that additional factors might affect the adhesion performance of treated S0 rubber. For this reason, the loci of failure of the joints were analyzed by ATR-IR spectroscopy on the failed surfaces after the T-peel test. ATR-IR spectra of the PU adhesive and the as received S0 rubber are included in Figure 8 and the absorption peaks are shown in Table 1 for comparison with those of the failed surfaces (Figures 9-11)

The ATR-IR spectra of the failed surfaces of the joint produced with the as received S0 rubber (Figure 9) show absorption from the rubber on the surface that visually corresponded to the rubber after the peel test (R-surface) and absorption from both the PU adhesive (3390, 2942, 2863, 1730, 1200-1100 cm^{-1}) and the S0 rubber (2920, 2850, 1480, 968, 915 cm^{-1}) on the failed surface that visually corresponded to the adhesive (A-surface). This suggest that a mixed failure mode (mainly adhesional) is produced. A cohesive failure mode was observed (Figure 10) in joints produced with S0 rubber treated in CO_2 plasma for a short time (1 min). Thus, a short treatment time is sufficient to produce an adequate adhesion of the S0 rubber. The increase in the length of plasma treatment did not affect the adhesion properties but modified the loci of failure of the joints. Thus, the treament of the S0 rubber in CO_2 or O_2 plasmas for 3.5 min produced a mixed failure mode (mainly adhesional) (Figures 11 and 12). This is consistent with the ablation of the outermost rubber surface by both the O_2 and the CO_2 plasmas prior to bonding. However, the Ar plasma treatment of S0 rubber for 3.5 min produced a mixed failure mode mainly cohesive in a thin rubber layer: there is rubber and PU absorption on the A-surface and absorption from the rubber on the R-surface (Figure 13). The mechanical properties of this thin crosslinked rubber layer, where the failure of the joint is located, are determining the peel value.

4. Conclusions

The Ar, CO_2 and O_2 plasma treatments produced an increase in adhesion of the S0 rubber toward a PU adhesive due to chemical and morphological modifications on the S0 rubber surface. Ar plasma created polar moieties on the rubber surface and a consequent increase of the polar component of the surface energy. Thus wettability was increased. On the other hand, CO_2 and O_2 plasma treatments produced ablation of the previously oxidized crosslinked outermost S0 rubber surface.

Short plasma treatment times are enough to produce adequate T-peel strength values and a cohesive failure was obtained with CO_2 plasma treatment for 1 minute. The increase in the length of treatment or the use of another gas plasma atmosphere did not affect adhesion properties but modified the loci of failure of the joints. Thus, with Ar plasma no ablation was produced so the failure of the joints was located within a crosslinked oxidized rubber surface. CO_2 and O_2 plasma treatments removed the previously oxidized thin rubber layer in such a way that no transference of hydrocarbon moieties from the rubber to the A surface was produced during peel test and a mixed failure mode (mainly adhesional) was produced.

Abstract
It is conventionally assumed that the plasma potential is the same everywhere in the plasma bulk. However, the non-zero plasma resistivity means that this is not true for the RF plasma potential in large area reactors. The spatial variation in plasma potential due to asymmetric electrode areas is described in terms of a telegraph equation, and the predictions of the model are compared with measurements using electrical probes mounted in the ground electrode of two large area RF plasma reactors.

1. Introduction

In small area capacitive reactors, the RF and DC components of the plasma potential can be assumed to be uniform over all the plasma bulk. In large area reactors, however, the RF plasma potential can vary over a long range across the reactor due to the finite plasma conductivity. A perturbation in RF plasma potential, due to electrode edge asymmetry or the boundary of a dielectric substrate, propagates along the resistive plasma between capacitive sheaths. This study consists of theoretical and experimental sections. In the first part, we develop a model based on a telegraph equation to show how the plasma potential is affected in large area reactors. Perturbations in potentials and currents due to the edge effects of the electrodes will be demonstrated by means of a simple analytical model assuming sinusoidal plasma potential and Langmuir-Hertz sheaths. In the second part we present measurements of the DC current and potential using an array of Langmuir probes in the ground electrode of two large area reactors, one cylindrical and the other rectangular. These measurements are used to test some predictions of the telegraph model.

2. The telegraph equation applied to large area reactors

At the edge of the RF plasma reactor represented in Fig. 1, the electrode areas are asymmetric because of the sidewall. In order to preserve RF current continuity, the RF sheath voltage at the larger area electrode will locally be less than the RF sheath voltage at the smaller electrode, the sum of the potentials being equal to the applied RF voltage. In the middle of the reactor, however, the electrode areas are symmetric and both RF sheath voltages would be expected to equal half of the RF voltage V_{RF}. The different sheath potentials in these two zones can be reconciled by allowing the RF plasma potential to vary across the reactor with a characteristic damping length Λ due to the non-zero plasma resistivity [1]. The redistribution of the sidewall RF current is represented by a lateral RF current in the simplified 1D equivalent circuit model in Fig. 1.

In the presence of a perturbation $\underline{V}(x,t)$ due to the sidewall, the ground sheath RF potential is

$$\underline{\tilde{U}}(x,t) = \frac{V_{RF}}{2} \cdot e^{i\omega t} + \underline{V}(x,t).$$

A lateral current $\underline{I}(x,t)$ flows through R and L, the plasma resistance and inductance per unit length, where

$\frac{\partial \underline{V}}{\partial x} = -R\underline{I} - L\frac{\partial \underline{I}}{\partial t}$, and

$\frac{\partial \underline{I}}{\partial x} = -C\frac{\partial \underline{V}}{\partial t}$, where C is the combined sheath parallel capacitance per unit length. We therefore obtain

$\frac{\partial^2 \underline{V}}{\partial x^2} = LC\frac{\partial^2 \underline{V}}{\partial t^2} + RC\frac{\partial \underline{V}}{\partial t}$ which is the telegraph equation.

The damping term dominates if $R/\omega L = \nu_m/\omega >> 1$ (high pressure, low excitation frequency).

In 1D Cartesian coordinates, with $\underline{V}(x,t) = \underline{V}(x)e^{i\omega t}$, the particular solution is

$$\underline{V}(x,t) = \underline{B}\exp\left(\frac{\pm x}{\underline{\Lambda}}\right)e^{i\omega t} = \underline{B}e^{\pm x/\Lambda}e^{i(\omega t \pm x/\Lambda)} \text{ where } \underline{\Lambda} = \frac{\Lambda}{(1+j)} \text{ and } \Lambda = \sqrt{\frac{2}{\omega RC}} = \omega_{pe}\sqrt{\frac{ag}{\omega\nu_m}}$$

with a the sheath width, g the plasma bulk height, ν_m the electron-neutral collision frequency, and ω_{pe} the electron plasma frequency. The voltage perturbation is a strongly-damped wave; the value of Λ increases with electron density, sheath thickness and bulk plasma height, and decreases with higher excitation frequency and collision frequency (higher pressure). If inductance is included, the damping length increases and the wavelength decreases. The boundary condition at the sidewall is

$$\left.\frac{\partial \tilde{U}}{\partial x}\right|_{x=L} = -I_{sidewall} R = -\underline{\tilde{U}}(L) j\omega C_W R \quad \text{where } C_W \text{ is the sheath capacitance at the sidewall.}$$

Note that this simple model assumes the plasma to be a uniform slab. The RF plasma potential is the same as the ground sheath RF voltage in this simple model where the impedance of the bulk plasma is neglected compared to the sheath impedance. The combination of a reduced and augmented sheath potential at the asymmetric edge results in a net increased power deposition at the edge. Comparison between this solution and solution of Maxwell's equations for the voltage distribution in a lossy dielectric shows that the telegraph model is a good approximation.

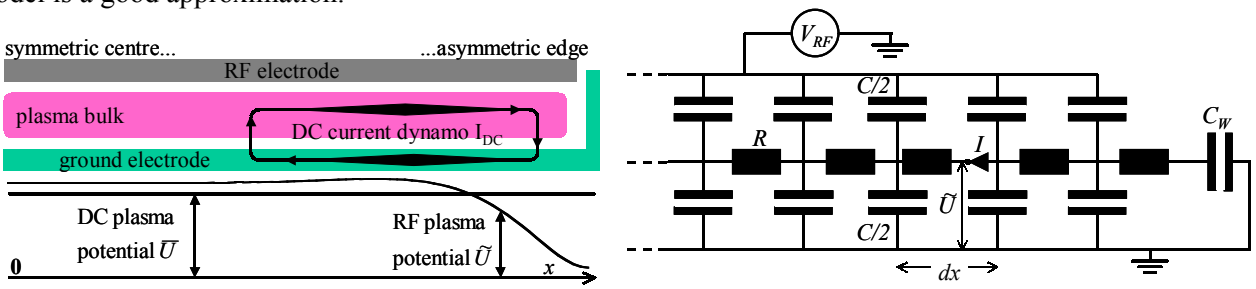

Figure 1. Left: schematic cross-section of an asymmetric reactor, from the centre to the right hand sidewall, showing profiles of the RF and DC components of the plasma potential, and the 'dynamo' of DC current between the ground electrode and the plasma. Right: the equivalent circuit used for the telegraph description. The sidewall sheath capacitance is represented by C_W.

3. Consequences of non-uniform RF plasma potential

Since the DC plasma potential is uniform across the plasma, and a conducting electrode is an equipotential surface (in absence of a dielectric substrate), a consequence of the non-uniform RF plasma potential is that local ambipolarity cannot be satisfied over all the electrode surface. This is because the RF and DC sheath voltages, $\tilde{U}$ and $\bar{U}$ respectively, cannot everywhere simultaneously satisfy the self-rectification condition [2] for zero DC current flow, which is $\bar{U} = \frac{T_e}{2}\ln\left(\frac{M_i}{2.3m_e}\right) + T_e \ln\left[I_o\left(\frac{\tilde{U}}{T_e}\right)\right]$ (a sinusoidal plasma potential, and therefore sinusoidal sheath voltages, have been assumed for the sake of convenience in this simplified model). Any spatial variation in the plasma RF potential will necessarily lead to time-averaged current flow across the sheaths. However, the reactor is capacitively coupled which prevents any DC current in the external circuit. Therefore, any DC current which flows across the sheaths must circulate through the plasma and return via the conducting surface of the electrode, so that the integral of the DC current over the electrode area is zero. The DC plasma potential adjusts to satisfy this condition at the ground electrode, and the self-bias of the RF electrode adjusts to satisfy this condition at the RF electrode. Consequently, the reactor asymmetry drives DC current 'dynamos' within the reactor as shown in Fig. 1. These DC sheath currents can be measured with grounded probes in the ground electrode surface, as shown in the following sections. These probes measure the local DC current density $j(\underline{x})$ to the ground electrode. The DC floating potential of the surface probes can also be used to give an indirect indication of the spatial variation of the plasma RF potential amplitude: in the previous equation, where the plasma potential is not equal to the value necessary for local ambipolarity, a floating probe in the electrode surface will have the time-averaged voltage:

$$\bar{V}_f(\underline{x}) = \bar{U} - T_e \ln\left[I_o\left(\frac{\tilde{U}(\underline{x})}{T_e}\right)\right] - \frac{T_e}{2}\ln\left(\frac{M_i}{2.3m_e}\right) \neq 0 \text{ because the grounded surface is not floating.}$$

$$\text{In the limit } \tilde{U}(\underline{x}) >> T_e : \bar{V}_f(\underline{x}) \approx \bar{U} - \tilde{U}(\underline{x}) + \frac{T_e}{2}\ln\left(2\pi\frac{\tilde{U}(\underline{x})}{T_e}\right) - \frac{T_e}{2}\ln\left(\frac{M_i}{2.3m_e}\right), \text{ therefore } \Delta\bar{V}_f(\underline{x}) \approx -\Delta\tilde{U}(\underline{x}).$$

i.e. the negative of the ground electrode probe floating potential $\overline{V}_f(\underline{x})$ is approximately equal to the variation in plasma potential amplitude $\widetilde{U}(\underline{x})$ across the reactor. To summarise: the experimental measurements in this work are made with probes mounted in the ground electrode. The current to a grounded probe represents the DC current density flowing to ground; and the negative of the probe floating potential represents approximately the deviation of the RF plasma potential amplitude from the value necessary for local ambipolarity.

4. Experimental results and comparison with a telegraph model in a cylindrical reactor

Figure 2 shows the measured radial profiles, across the one metre diameter of a cylindrical reactor, of the optical emission intensity, the DC current density, and the probe floating potential (the probes were mounted in the surface of the ground electrode). In this reactor, the grounded sidewall (1 cm high) is smaller than the sidewall of the RF electrode (2 cm high), therefore the grounded electrode has the smallest area, opposite to the case shown in Fig. 1. These radial profiles were cylindrically symmetric, as shown in the figure, provided that the sidewall height was precisely the same around the reactor circumference.

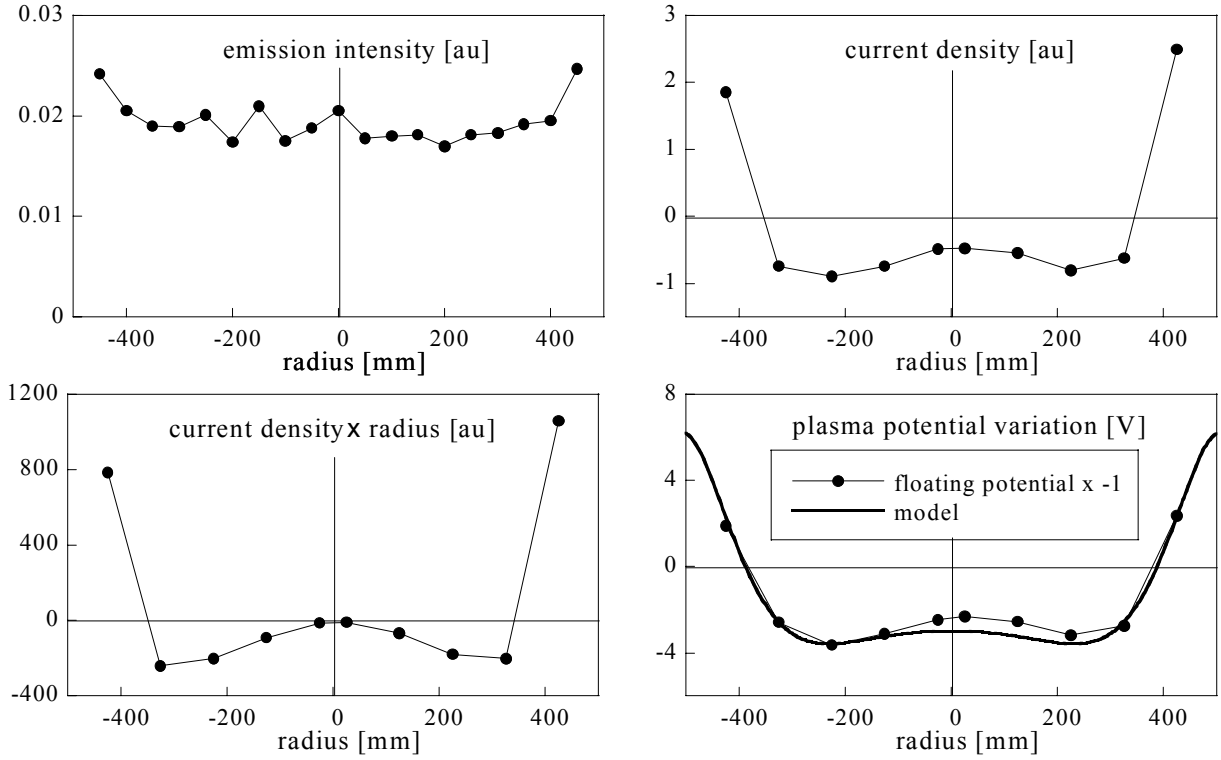

Figure 2: Measured profiles of emission intensity, DC current density, DC current, and floating potential profiles for probes mounted along a 1 m diameter of the cylindrical reactor. The DC current balance is approximately satisfied; and a comparison of the deduced RF plasma potential amplitude profile with a numerical solution of the telegraph equation (Λ=0.06 m) is also shown. Electrode gap 3 cm, grounded sidewall 1 cm high, RF sidewall 2 cm. Plasma parameters: argon/hydrogen flow ratio 2:1, 13.56 MHz, pressure 100 mTorr, 200 W RF power.

The damping length Λ is estimated to be a few cm [1] for the plasma parameters given in the caption to Fig. 2. At 13.56 MHz, any standing wave non-uniformity is negligible since the RF wavelength is much larger than the machine. The edge plasma non-uniformity can be seen on the emission intensity profile. The plasma power is higher towards the reactor edge, in agreement with the telegraph model. The radial profiles of the DC current density and floating potential are both bipolar, with the zero crossing point at the same radius as expected. This radius is the null point about which the DC dynamo rotates from larger to smaller radii. DC current from probe to plasma is defined as positive throughout this work. The surface integral $2\pi\int_0^R j(r)\,dr$ of the current density $j(r)$ shows that the net DC current to the ground electrode is indeed zero (within experimental error due to the limited number of probes defining the DC current profile) as expected for the capacitively-coupled reactor. The DC current density near the wall is majority electron current, being

balanced by a majority ion current within the radius of zero current; this corresponds to the current flow in Fig. 1 for the smaller (upper) electrode.

The negative profile of the probe DC floating potential is compared with a numerical solution of the telegraph equation for the RF plasma potential amplitude in cylindrical geometry. Given the approximations made and the assumption of uniform plasma resistivity and sheath capacitance in the telegraph model, there is reasonable agreement for a value of Λ = 0.06 m. Note that the deduced envelope of the RF plasma potential amplitude increases towards the wall, which corresponds to Fig. 1 for the smaller (upper) electrode.

When the sidewall height asymmetry was reversed (grounded sidewall larger than the RF electrode sidewall), the DC current and floating potential profiles were inversed, as expected. If the sidewall height differed by a few mm around the perimeter, the cylindrical symmetry was broken and the profiles became skewed with a marked slope across the diameter, demonstrating that the sidewall geometry can have a strong influence on the plasma uniformity, even across the entire 1 m diameter. However, when the RF and grounded sidewalls were accurately equalised (equal effective sidewall areas for the ground and RF electrodes), then the measured values of probe current density and floating potential were strongly reduced along the whole diameter, indicating that there was no systematic variation in RF plasma potential, and the plasma emission intensity was uniform. Any remaining edge non-uniformity is due to fringing fields which are localized close to the junction between the sidewalls.

As a supplementary demonstration of the experimental method, it is interesting to consider measurements performed at a higher RF frequency where standing wave effects become important, and even dominate edge effects. Figure 3 shows the same profile measurements as for Fig. 2, but at 67.8 MHz. In contrast to a telegraph model at low frequency, the plasma profile is dominated by a central peak. The RF voltage amplitude has the Bessel function radial distribution $J_o\left(k_{eff}\, r\right)$, where k_{eff} is the effective wavenumber due to the plasma permittivity [1]. This voltage profile is a solution of Maxwell's equations in parallel plate cylindrical geometry, and is independent of plasma resistivity effects. Nevertheless, any phenomenon which causes the RF plasma potential to be non-uniform (in the presence of a uniform DC plasma potential) will cause DC currents to circulate for the same reasons as given in the previous section. Figure 3 shows that the current density profile, as measured by the grounded probes, integrates approximately to zero. Furthermore, the negative floating potential profile approximates to a Bessel profile, shifted by a DC value corresponding to the DC plasma potential. This shows the probe method used in a different context independently of the telegraph effect.

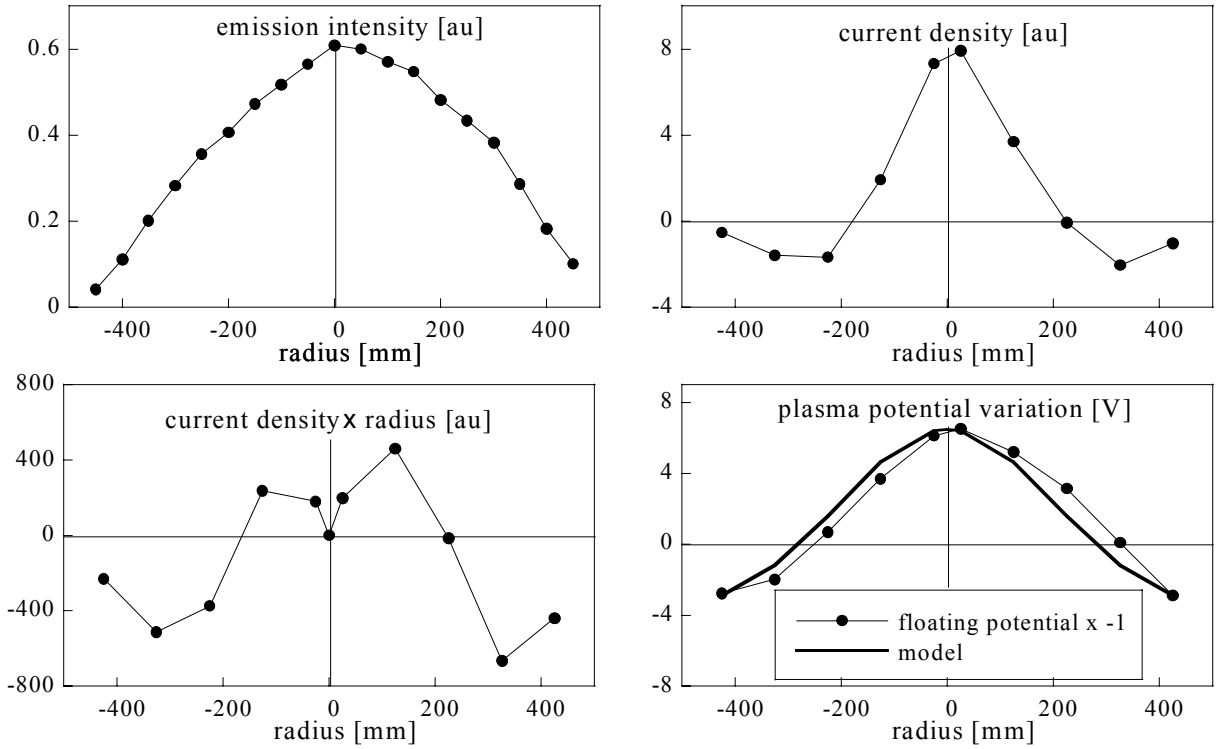

Figure 3: The same cylindrical reactor as for Fig. 2, but at 67.8 MHz, Ar 250 mTorr, 300 W. The RF plasma potential amplitude profile, deduced from the probe floating potential profile, is compared with a Bessel function solution for the standing wave. The standing wave effect is seen to dominate the edge asymmetry effect at this high frequency.

5. Experimental results and comparison with a telegraph model in a rectangular reactor

The rectangular reactor has electrode dimensions 47 cm by 57 cm, with a grounded sidewall of height 2.5 cm. The grounded electrode now has the largest area, corresponding to Fig. 1, which is the opposite case to the cylindrical reactor in the previous section. An array of surface probes is mounted in the ground electrode along a line from the reactor axis towards the sidewall (see Fig. 5 for the probe positions) with another probe in the sidewall itself. In Fig. 4(a) we see that the sign of the current density is inversed (with majority DC electron current contribution this time on the interior of the grounded electrode surface) with respect to Fig. 2 because the electrode area asymmetry is reversed. In contrast to the data presented up to now with no substrate, Fig. 4(c) shows the DC current density measurement in presence of a centrally-positioned glass substrate 37 cm x 47 cm, leaving a 5 cm gap between the substrate edge and the sidewall. The insulating substrate now constrains the DC current dynamo to circulate in the 5 cm gap between the sidewall and the substrate. The DC plasma potential and the RF electrode self-bias voltage adjust to maintain global ambipolarity. The integral of the DC current $\int_0^L j(x)\,dx$ is still roughly zero although accurate values are difficult to obtain because the current density in the vicinity of the sidewall is not measured with sufficient spatial resolution.

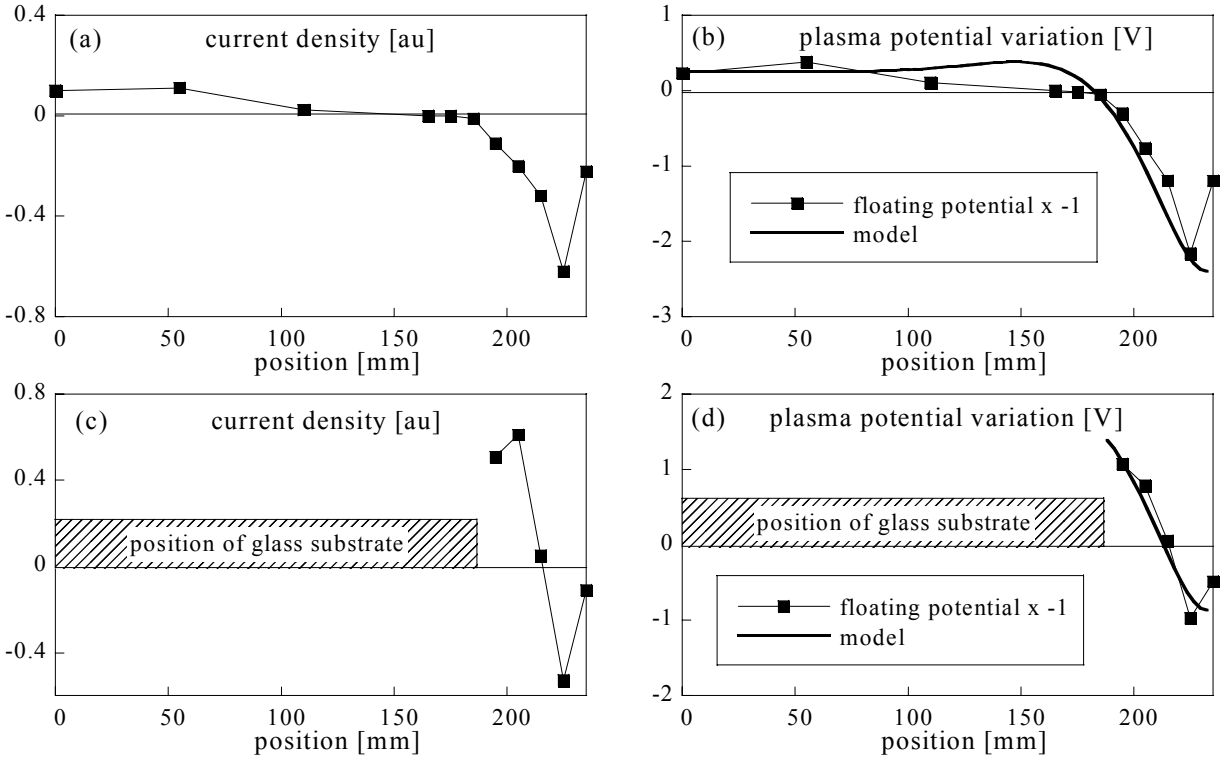

Figure 4: Measured DC current density and DC floating potential profiles for probes mounted along the 0.235 m halfwidth of a rectangular reactor. Top: no substrate. Bottom: with a glass substrate to 5 cm from the sidewall. The DC current balance is approximately satisfied in both cases; and comparisons of the deduced RF plasma potential amplitude profile with a telegraph solution (Λ=0.02 m) are also shown. Hydrogen plasma parameters: 40.7 MHz, 0.6 mbar, 60 W.

The envelope of the RF plasma potential, inferred from the negative of the DC floating potential profile, decreases towards the wall, also opposite to the behaviour for the previous results in Fig. 2 for the same reason of reversed electrode area asymmetry. This fall-off in amplitude is to reduce the RF current contribution from the grounded sidewall. The negative profile of the probe DC floating potential is compared with the analytic expression for the RF plasma potential amplitude in Cartesian geometry. There is reasonable agreement between the measurement and the telegraph 1D profile using a damping length distance Λ = 0.02 m, provided that the sidewall current is 2-3 x smaller than the extrapolated value, as observed experimentally. It seems reasonable that this is due to imperfect contact of the plasma with the sidewall. It is interesting to note that the condition for local ambipolarity above a thin insulating substrate can cause its surface potential to be maintained at a negative value – this would be impossible if the plasma potential were unique. The consequent negative charging of a hot glass substrate has been measured in many

different conditions [3], and is supporting evidence for the telegraph effect. The DC sheath potential then varies over a dielectric substrate resulting in a non-uniform ion bombardment energy.
The experimental parameters were purposely chosen to obtain a damping length much smaller than the reactor width, because otherwise a one-dimensional treatment is not justified. Fig. 5 shows 2D solutions of the telegraph equation in the reactor geometry for Λ = 0.03 m and 0.1 m. For Λ = 0.1 m, the voltage perturbation extends over a large distance, and the enhanced area asymmetry due to the corner sidewalls influences the DC current dynamo flow far from the corners, to the extent that all the probes measure a positive DC current density (unipolar profile), as observed, and the negative DC current density is concentrated in the corners. For Λ = 0.03 m and less, the range of influence of the corners is restricted, and, for most of the reactor perimeter, the perturbation can be described by the 1D model as used in Fig. 4.

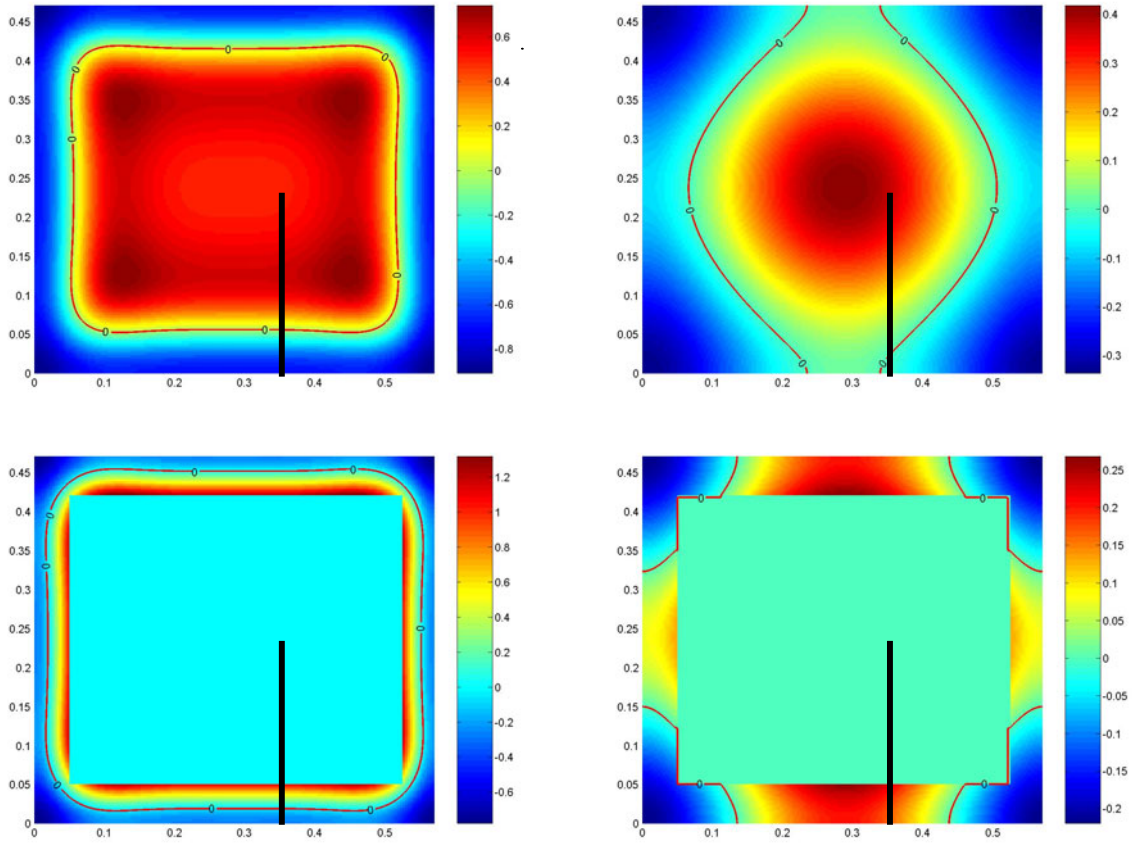

Figure 5: 2D colour contour plots of the RF current density solutions of the telegraph equation for damping lengths Λ = 0.03 m (left) and 0.1 m (right). Above: no substrate; below: with glass substrate. The location of the probe array is shown by the bar. The contour of zero DC current is indicated. For Λ = 0.03 m, the 1D description along the halfwidth at the probe positions is a good approximation. For Λ = 0.1 m, the current density everywhere is strongly influenced by the corner sidewalls.

6. Conclusions

Model and measurements with surface probes show that non-symmetric electrode areas cause a spatial variation in the RF plasma potential which can be described by a telegraph equation. This leads to non-uniform RF sheath voltages and RF power density. The non-uniform RF plasma potential in presence of the uniform DC plasma potential results in non-ambipolar currents circulating through the plasma and along conducting surfaces. If the electrode sidewall areas are accurately equalized, then the RF plasma potential amplitude and the power density are uniformalised.

Abstract
The electrochemical properties of oxide thin films produced by non thermal plasma of glidarc type on austenitic 304L and 316L stainless steel surfaces are investigated and compared to plasma treated pure iron samples by means of analytical techniques. The combined electrochemical, gravimetric and galvanic results of the stainless steels and iron samples lead to conclude that the iron (III) oxide formed enhances the material resistance in aggressive media and could have important future applications.

1. Introduction

The exposition of austenitic 304L and 316L stainless steel alloys to a humid air plasma of the gliding arc type provokes modification of the surface by forming a thin oxide film [1]. The identification of the iron hydroxide $Fe(OH)_3$ on the treated surface using electrochemical methods is confirmed by its characteristic reduction peak at –1.18 V/SCE in a NaOH solution (pH = 11.7). X-ray investigation of these samples shows the simultaneous presence of austenitic (γ-Fe) and ferric (α-Fe) phases where the former phase is predominant [2]. The exposure of the austenitic samples to the humid air plasma induces phase modifications. The observed decrease in the reduction peak intensities of the ferric (α-Fe) phase may suggest the contribution of the (α-Fe) phase in the hydroxide formation. The anticorrosive properties of the hydroxide were investigated using Tafel measurements performed in nitric acid solutions (10^{-2} $M.L^{-1}$) which show that the corrosion potential of 304L and 316L austenitic stainless steel surfaces increases and reaches a saturation step after a 30 minute treatment time.
Since identical iron (III) oxide thin films are grown on pure iron substrates when exposed to a humid air glidarc plasma for different exposure times, their properties are investigated by looking at different analytical techniques to those imposed to the austenitic samples. Plasma-treated iron surfaces are immersed in 3.5% NaCl solutions in order to simulate their behaviour in corrosive and aggressive marine environments such as inland industrial chemical processes, boats and off-shore petroleum equipment. Gravimetric measurements show that the mass loss linearly varies with the immersion time. The corrosion rates are deduced from the relevant slopes. The increase in the plasma treatment time of the iron electrode leads to lower slope values and consequently to lower corrosion rates.

2. Experimental procedures

2.1 Experimental set-up

The gliding arc reactor is described elsewhere [3]. A high voltage is applied across two diverging electrodes. Water saturated air flows between the electrodes gap. An electrical arc sets up at the shortest electrodes gap and spreads away towards the electrodes tips. It provokes electronic collisions with the air compounds and various chemical reactions including one or more air compounds occur, which generates highly reactive neutral species $OH^{\bullet}$ and $NO^{\bullet}$. These species are determined by their optical signals analyzed by emission spectroscopy in the 230–650 nm range and correspond to the $OH^{\bullet}\left(A^2\Sigma^+ - X^2\Pi, \Delta v = 0\right)$ and $NO^{\bullet}\left(A^2\Sigma^+ - X^2\Pi, \Delta v = -1\right)$ systems [4]. The electrical arc length increases towards the wider non equilibrium zone and breaks down before the cycle resumes.
Density measurements of the radicals show constant values along the whole non thermal plasma zone but the $OH^{\bullet}$ value is much higher than $NO^{\bullet}$, which confers oxidising properties to the plasma. Samples are exposed to the reactive radicals at a fixed distance d = 4.5 cm from the neck of the electrodes at a constant air flow rate Q = 16.25 $L.min^{-1}$.

2.2 Samples preparation

Pure iron and austenitic (304L and 316L) stainless steel discs (1.5 cm in diameter and 0.5 cm thick) are polished using various grinding papers (400, 800, 1200) and finished by a Mecaprex self-adhesive polishing disc using 3µm diamond paste. They are cleaned with acetone and nitrogen dried before being exposed at the electrodes limit to the non thermal zone of the glidarc.

The rectangular pure iron electrodes of total surface 2 cm^2 are mechanically polished, rapidly cleaned in 8% hydrogen chloride solution, degreased in trichloroethylene. The copper electrode receives the same polishing and cleaning procedure as the iron electrode but the copper/iron surface ratio is maintained at 3:1 throughout the investigation.

2.3 Analytical techniques

Stainless steel samples are investigated using electrochemical analysis (linear sweep voltammetry and Tafel plots) in a suitable solvent, while rectangular iron electrodes are studied in 3.5% sodium chloride solution.

- **Linear sweep voltammetry and Tafel**

The electrochemical investigation is carried out using a Potentiostat/Galvanostat Model 273 coupled to an IBM PC. The electrochemical cell is fitted with a platinum auxiliary and a SCE reference electrodes. The electrolyte is a 25 $mmol.L^{-1}$ NaOH solution ($pH = 11.7$). It is purged before each run for nearly 1h with nitrogen. The potential sweep is fixed to 1 $mV.s^{-1}$ for all runs. The characteristic current intensity (µA) is plotted straightaway vs. potential (mV).

The Tafel curves were recorded from –300 mV to +300 mV/SCE at a rate of 1 $mV.min^{-1}$ with (10^{-2} $M.L^{-1}$) nitric acid solutions as the electrolyte. The current intensity versus the potential variations define the corrosion potential E_{corr} of the sample. The intersection of the linear sections of the Tafel curves determines the corrosion potential E_{corr} and the corrosion current I_{corr} .

- **Immersion tests**

The influence of the rectangular iron electrodes treatment by the humid air plasma is investigated by looking at the electrodes mass loss and the galvanic current resulting. The iron electrodes are immersed in a cell filled with an aerated, non stirred 3.5% sodium chloride solution maintained at a constant temperature (30°C). They are kept inside the solution for increasing immersion periods (up to 6 hours) and different exposure times to the plasma. Liquid losses by evaporation are minimized by using a condenser. Gravimetric measurements were performed with an analytical weighing apparatus (A&D ER-180A) after every hour of immersion time. Corrosion rates are obtained from the curves of mass loss per unit area of the iron sample versus the immersion time for different plasma treatment times. The galvanic current is also monitored every hour using a digital, high internal resistance microammeter (PHYWE 0713200). It establishes on forming a galvanic cell, when the iron electrode is electrically coupled with a cleaned copper electrode disposed in the same electrolyte solution. The copper/iron surface ratio is maintained at 3:1. The purpose of using such a large ratio is to create a large anodic current density which in turn enhances the corrosion rate.

3. Results and discussions

3.1 Linear sweep voltammetry

The linear sweep voltammograms obtained during the scanning range [-1.0 to -1.4 V/SCE] show a reduction potential peak at –1.26 V/SCE in NaOH solution for the iron samples (Fig. 1). Plasma treated stainless steels samples show similar reduction peaks, which may suggest that presumably identical iron (III) hydroxide $Fe(OH)_3$ forms on the treated surfaces when dipped in NaOH solution. The slight difference between the reduction potential of the couple $Fe(OH)_3/Fe(II)$ (E = -1.168 V/SCE) [5] which is pH dependant is presumably due to the electrode overpotential. The intensity of the reduction peaks obtained increases with the plasma treatment times. As the current intensity depends only on the quantity of transformed matter and concerns only the same sample (constant geometry), we can put forward that the thickness of the oxide produced is a linear function of the treatment time.

On the other hand, RX diffraction shows a remarkable decrease in the ferric (α-Fe) phase lines intensity for short exposure times (≈ 30 min) for the 316L alloy, while long exposure times (≈ 8 hours) are needed to observe similar effects for the 304L alloy.

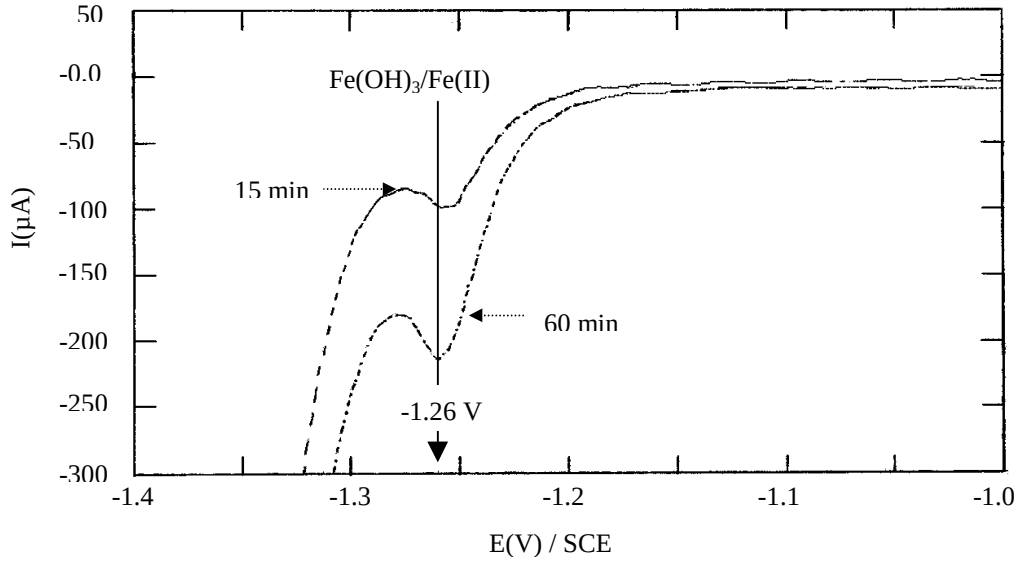

Fig. 1 : Voltammograms of plasma treated iron samples, in a NaOH solution of pH = 11.7, for exposure times 15 min and 60 min.

3.2. Tafel method

Non treated austenitic stainless steel samples show different corrosion potentials E_{corr} (-161.5 mV/SCE for the 304L and -186.6 mV/SCE for the 316L) in nitric acid solutions (10^{-2} $M.L^{-1}$). The high value of E_{corr} observed for 304L is probably due to the composition variation in chromium content: (≈18%) present in the 304L while (≈17%) in the 316L, or in nickel content: (≈ 9%) in the 304L while (≈ 12.5%) in the 316L or complete absence of molybdenum in 304L and 2% in 316L. Tafel measurements performed on plasma treated stainless steels show that the corrosion potential is influenced by the plasma interaction with the surface. The values of the corrosion potential E_{corr} of the treated austenitic stainless steel samples 304L and 316L increase with the increasing exposure time to the plasma. A sharp increase of the corrosion potential values is observed till 30 minutes followed by a rather plateau-like behavior close to a saturating value of –36 mV/SCE and –88 mV/SCE for the 304L and 316L alloys respectively. The values of the 304L stay higher than those of the 316L. Some values of the corrosion potentials are given in Table 1.

TABLE 1. Some corrosion potential values at critical exposure times.

E (mV/SCE)	$E_{t=0}$	$E_{t=30min}$	$E_{t=1h}$	$E_{t=2h}$	$(E_{t=2h}- E_{t=0})/ E_{t=0}$
304L	-161.5	-35.8	-34.1	-36.0	78 %
316L	-186.6	-102.8	-95.4	-87.8	53 %

The plasma treatment efficiency which could be expressed in terms of percent increase in corrosion potential is estimated at 78 % for 304L and 53 % for 316L whereas the corrosion current decrease is nearly 80% for the 304L and only 45 % for the 316L.

3.3. Gravimetric measurements

The iron corrosion rate is deduced from the linear mass loss *vs* immersion time curve. The untreated iron samples suffered the largest corrosion rate (17.84 $mg.cm^{-2}.hr^{-1}$) in 3.5% NaCl solutions while it diminishes with plasma exposure time. The corrosion rate of iron decreases as the exposure time to the plasma increases. The corrosion rate depends on whether the iron electrode is coupled or not to some more noble metal electrode, such as copper, in order to enhance corrosion effects. The mass loss decreases with the exposure time and depends also on whether only one face of the rectangular sample is treated or both. This is expressed by the percentage 50% and 100% surface area treated. Fig. 2 shows the mass loss of the iron electrode coupled to a copper electrode with one or both sides treated for 2 hours.

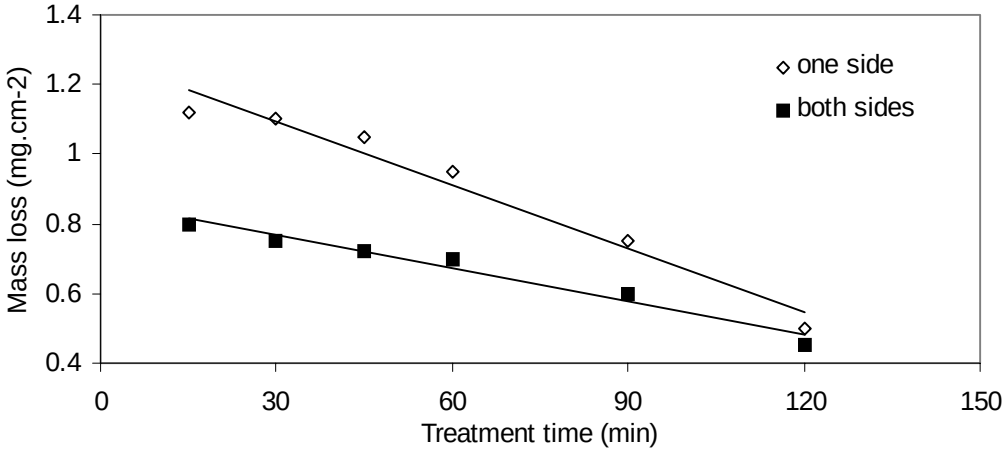

Fig. 2. Coupled iron mass loss versus immersion time : one side (50%), both sides (100%), treatment time 2 hours.

When both sides are treated, they are both oxidized to a higher potential and contribute less to the mass loss. This attains 5 and 4.5 $mg.cm^{-2}.h^{-1}$ for 2 hours treatment time for one and both sides respectively. The interaction of humid air plasma with the substrate surface results in a modification of the latter properties as the resulting hydroxide layer formed contributes to protection and then less corrosion is observed. When exposed to the humid air plasma, the iron samples start loosing less mass than untreated sample and the corrosion rate is deduced from the linear slope of Fig. 2. All the values of the corrosion rates for different plasma treatment times are shown in Fig. 3.

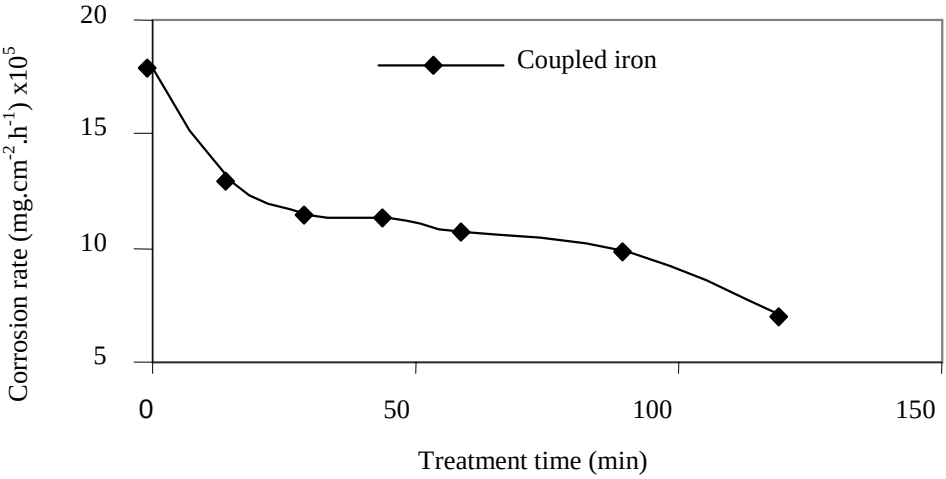

Fig. 3. Iron corrosion rate variation versus treatment time .

The rate decreases rather rapidly for the first 30 minutes and slightly less for the 60 minutes afterwards. It decreases even more for two hours treatment time, which may suggest that the all metal surface is oxidized and covered by an oxide film.

3.4. Galvanic current measurements

The galvanic current density between the iron sample and the copper electrode was measured in the 3.5% NaCl cell during the immersion tests. A slight decrease in the current is seen during the first thirty minutes exposure to the plasma as shown in Fig. 4.

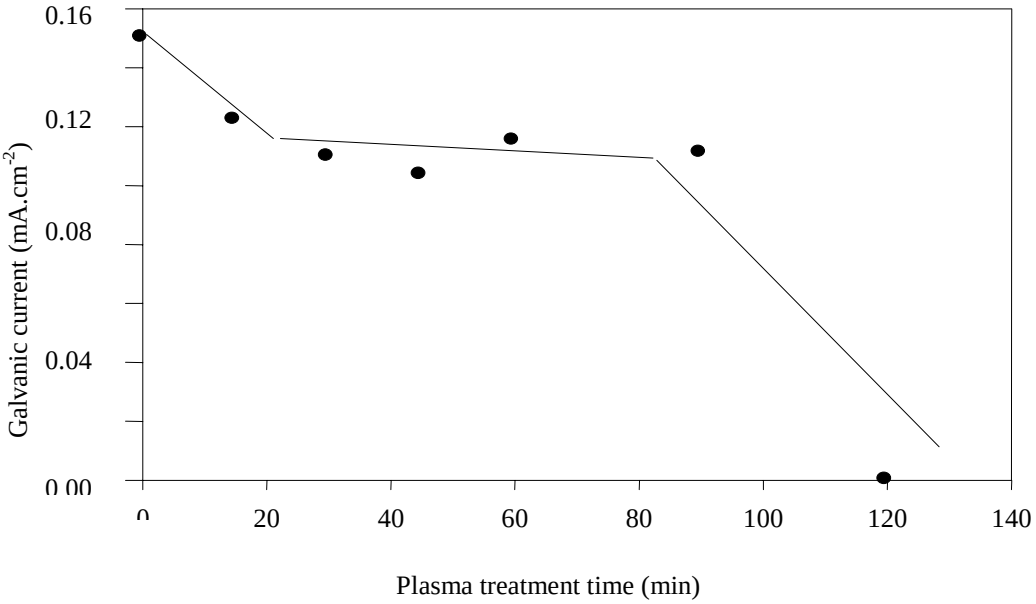

Fig. 4 : Galvanic current variation with the plasma treatment time of iron electrode.

The galvanic current decreases from 150 µA.cm^{-2} for the untreated specimen, to around 120 µA.cm^{-2} for the specimen treated for 60 minutes, and finally a sharp drop (to a few µA.cm^{-2}) around 120 min treatment time is observed. A constant current plateau-like behaviour follows during an hour of treatment time. It decreases sharply to an approximately zero value which means that the electronic drain from the treated iron electrode virtually ceases and can be attributed to the formation of a strengthened oxide film on the metal surface which firmly adheres to the substrate. The galvanic current is 100 times higher than the corrosion current I_{corr} (less than 1 µA.cm^{-2} for untreated samples) observed in the austenitic stainless steels specimens. These results can be explained by the fact that the processes involved during the interaction plasma-iron surface result in an effective protective and passivating layer of ferric oxide for long exposure times. Gravimetric and galvanic current measurements performed in the cell show a net decrease in the corrosion rate of the plasma-treated iron electrode.
The results show that the longer the iron surface is exposed to the gliding arc plasma in humid air, the lesser the mass is lost in the saline solution and the weaker is the galvanic current when iron is coupled to copper forming a galvanic cell.

4. Conclusion

The humid air plasma treatment produces surface modifications of easily corroded iron and highly corrosion resistant austenitic stainless steels 304L and 316L. The combined electrochemical methods with gravimetric and galvanic measurements show an increase in anticorrosive properties of the treated surfaces, which could be assigned to the formation of iron oxide thin film formed on the surface. The occurrence of iron (III) hydroxide is related with the basic nature of the electrolyte. As long as the iron hydroxide layer firmly adheres to the treated surface, it becomes a reliable protective layer, which could in the future widen its application field in more aggressive environments.

Plasma Processes for 2-D Photonic Crystal of C-S-Au Film

Yukinori Hirano, Chikao Yamasaki, Md. Abul Kashem, Masaki Matsushita and Shinzo Morita

Department of Electronics, Graduate School of Engineering, Nagoya University

Abstract

Photonic crystal introduced by E. Yablonovitch, S. John etc. in 1987 is expected to be a new and important optical element. For 2-D photonic crystal, C-S-Au (carbon-sulfur-gold) film formed by co-operation process of plasma CVD and sputtering was used as large refractive index (max 3.7) material which can be etched by oxygen plasma RIE (reactive ion etching). After the process of 2-D photonic crystal of C-S-Au film by an electron beam lithography, the 2-D photonic crystal surface was flattened by filling spin coated polymer, such as PMMA and then an organic EL was formed on the crystal surface to use as a light source for a photonic IC (integrated circuit).

1. Introduction

Photonic crystal was introduced by E. Yablonovitch and S. John etc. in 1987 [1,2]. The crystal has a periodic refractive index distribution in 1-D, 2-D, 3-D structure. By using the 2-D or 3-D photonic crystal, curved optical waveguide is expected to be fabricated in small size, where the optical waveguide can be formed by introducing defects linearly in the 2-D or 3-D photonic crystal. Additionally, 2-D photonic crystal acts as traps and emitters of photons depending on the size at the wavelength level if point defect is introduced near the waveguide in the 2-D photonic crystal [3].

For the photonic crystal, large refractive index material must be used. In this work, C-S-Au (carbon-sulfur-gold) film was developed, which is optically transparent in visible wavelength range and has process compatibility for oxygen plasma etching.

The C-S-Au film was fabricated by co-operative process of plasma CVD and sputtering with using CH_4, SF_6 and Ar mixture gas and Au plate discharge electrode.The optimized film was formed, which has refractive index of 3.5 and transmittance of 51 % at a wavelength of around 500 nm.

Using the C-S-Au film, 2-D photonic crystal was designed and fabricated by an electron beam lithography with using two-layer resist system of negative resist and evaporated Al film which works as an oxygen plasma etching stopper.

2. Experimental

C-S film and C-S-Au film were formed by plasma CVD reactor (ULVAC CPD-1108), which has a parallel plate electrode of 20 cm diameter and 1.5 cm gap distance. In order to eliminate impurity from the discharge electrode, the upper electrode was made of graphite plate and connected to RF power source. The reactive gas was introduced from the upper discharge electrode through numerous small holes. Substrates of Si wafer were set on the lower discharge electrode grounded and electrically connected to the reactor vessel of stainless steel.

The RF discharge frequency was 13.56 MHz. The deposition condition was kept to be constant at a pressure of 0.1 Torr, a discharge power of 100 W, and a discharge duration of 30 min. The flow rates of CH_4

and Ar were kept to be constant to 10 SCCM and SF_6 flow rate was varied from 2 to 25 SCCM. To form the C-S-Au film, an Au plate with area of 50×50 mm^2 was set on the upper electrode. The C-S-Au film was characterized by measuring the thickness and the refractive index using an ellipsometer, atomic compositions using ESCA measurements and transmittance using spectro-photometer.

2-D photonic crystal was fabricated as following. After Al film was evaporated on the C-S-Au film, which works as etching stopper, negative resist (SHIPLEY SAL601) was spin coated on the Al film by 4000 rpm and cured at 105 °C for 1 min. Then electron beam patterning apparatus (JEOL JBX-6000SG) was used for patterning of 200 nmϕ poles at three apex of triangle with 500 nm sides as a single cell shown in Fig. 1 at an acceleration voltage of 50 kV and a current of 100 pA. After development of delineated pattern on the resist, Al film was etched through the resist pattern by mixing liquid of HNO_3 5%, HF 3% and H_2O 92%, and the C-S-Au film with around 1 μm thickness was etched through the Al patterns by oxygen plasma with using RIE (SAMCO RIE-1C) at 13.56 MHz. The etching rate of this film was measured at oxygen flow rate of 10 SCCM and a pressure of 0.09 Torr as a function of discharge power.

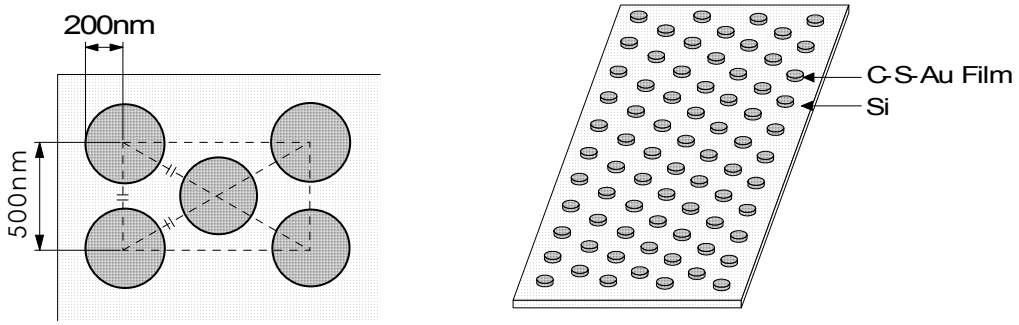

Fig. 1. The design of a photonic crystal

3. Results and Discussions

The C-S-Au film was formed in the co-operation process of plasma CVD and sputtering. The mechanism of Au mixing in the film was referred to the sputtering of Au plate on the discharge electrode, because the discharge electrode was self-biased to the negative potential during the plasma CVD[4].

As shown in Table 1, the sulfur content in the C-S and C-S-Au film was increased with increasing SF_6 flow rate. But Au content show the opposite tendency compared to the sulfur. Au atom density showed the maximum at 2 SCCM of SF_6 in this experiment and the value was 2.12 atomic%. The Au content was very small compared to other works reported [4-7]. They performed the deposition at one order lower pressure compared to our case. This may be a main reason why they obtained higher Au content in the film because Au sputtering will be enhanced at lower pressure. It is concluded that Au mixing in the film was realized under suppressed sputtering condition.

Table 1. Atomic composition and refractive index of the films (C-S & C-S-Au)

(CH_4: 10 SCCM, Ar: 10 SCCM, Pressure 0.1 Torr, Duration 30 min.)

Flow of SF_6 [SCCM]	C-S film				C-S-Au film			
	Atomic Composition [%]			Refractive Index	Atomic Composition [%]			Refractive Index
	C	S	Au		C	S	Au	
2	98.88	1.12	0	1.72	96.02	1.86	2.12	1.94
5	93.10	6.90	0	1.75	96.07	3.22	0.71	2.20
10	93.20	6.80	0	1.95	93.45	5.84	0.71	2.40
15	90.60	9.40	0	1.98	88.37	11.62	0.01	2.70
20	85.20	14.80	0	2.17	85.90	14.01	0.11	2.80
25	79.30	20.70	0	2.41	81.09	18.79	0.12	3.66

The refractive indexes for the C-S and C-S-Au films were measured by an ellipsometer at 628 nm. The refractive index of C-S film was increased simply from 1.7 to 2.4 with increasing the SF_6 flow rate from 2 to 25 SCCM. For the C-S-Au films, the refractive index was increased also simply from 2.0 to 3.7 for the same gas flow rate change of SF_6. For the photonic crystal, the large refractive index extends the photonic band gap wavelength range. To increase the refractive index, the increase of atomic content of Au and S in the film is effective according to the dielectric theory. However, the optical transmittance was decreased with increasing the atomic content of Au and S atom as shown in Fig.3. Whereas, Au and S atom content must be optimized on the optical transmittance and the refractive index. The optimization of C-Au-S film was realized by controlling the deposition condition, where the refractive index of 3.5 and the optical transmittance of 51% at 500nm were attained.

The etching rate of C-S-Au film and negative resist were measured in the RIE reactor as shown in Fig. 2. The etching rate was increased for the discharge power from 10 to 40 W. In this experiment, the etching rate of C-S-Au film at a discharge power of 25W was 263 nm/min and the negative resist showed the etching rate of 213 nm/min at the same plasma etching condition. So the etching time C-S-Au film was 4 min for the film thickness of about 1μm, and the negative resist was etched off at 70 sec for the resist thickness of about 250 nm. Therefore negative resist was etched completely before the C-S-Au film was processed, whereas we adopted the etching stopper of evaporated Al between C-S-Au film and negative resist.

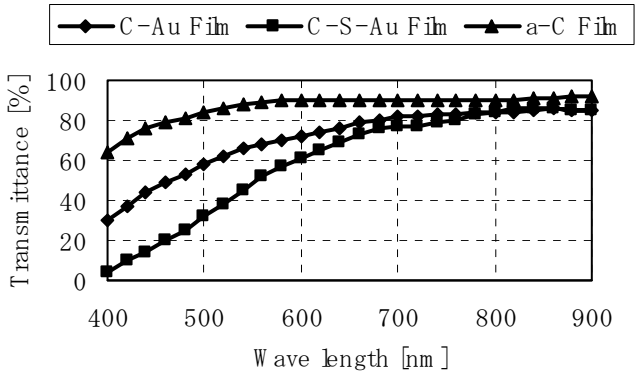

Fig. 2. Optical transmittance of C-Au, C-S-Au and a-C film as a function of wavelength.

(Pressure 0.09 Torr, Oxygen flow rate 10 SCCM)

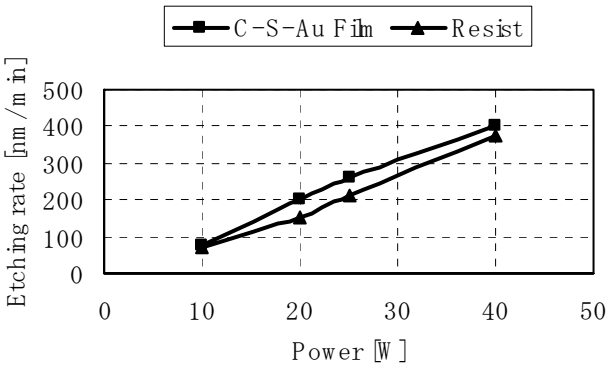

Fig. 3. Etching rate of C-S-Au film and resist

2-D photonic crystal fabricated by an electron beam lithography and oxgen plasma RIE are shown in Fig. 4 and 5. As shown in Fig. 4 after Al etching, 200 nmϕ poles at three apex of triangle with 500 nm sides as a single cell is observed. And Fig. 5 shows the photograph of the C-S-Au film after oxygen plasma etching, where the columns are arranged periodically. The etching duration was 5 min.

The photonic crystal structure of C-S-Au film was successfully processd even if chemically inert Au atom was included. In this process, carbon, sulfur and gold atom were expected to be etched forming volatile materials like as CO_2, SO_2 and $Au(CO)_x$ in oxygen plasma.

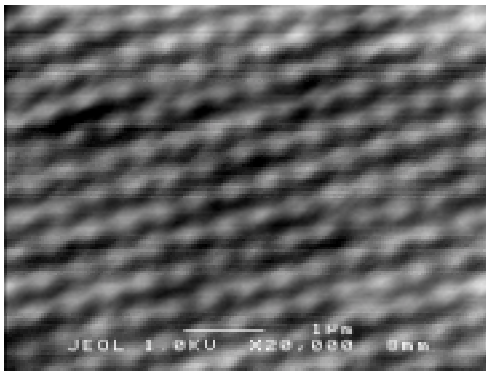

Fig. 4. The SEM photograph after Al etching

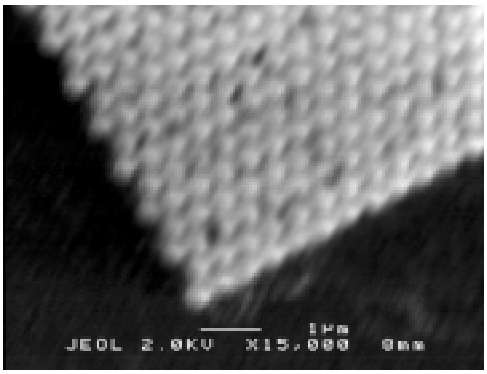

Fig. 5. The SEM photograph of the C-S-Au film etched by oxygen plasma

4. A light source for a photonic IC

To form organic EL on 2-D photonic crystal, the 2-D photonic crystal surface must be flattened by filling lower refractive index material. So PMMA is spin coated on the 2-D photonic crystal. After that transparent conducting layer will be formed on the crystal. Basic concept is shown in Fig. 6. Additionally how to take out the light from the sample is shown in Fig. 7.

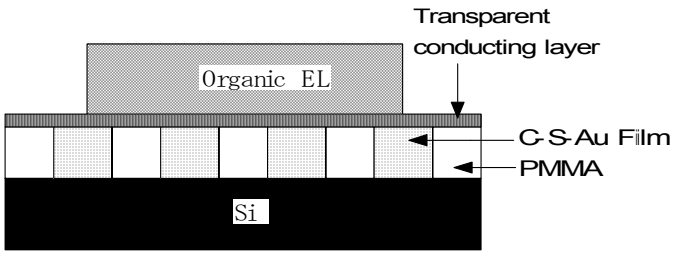

Fig. 6. Basic concept of connection

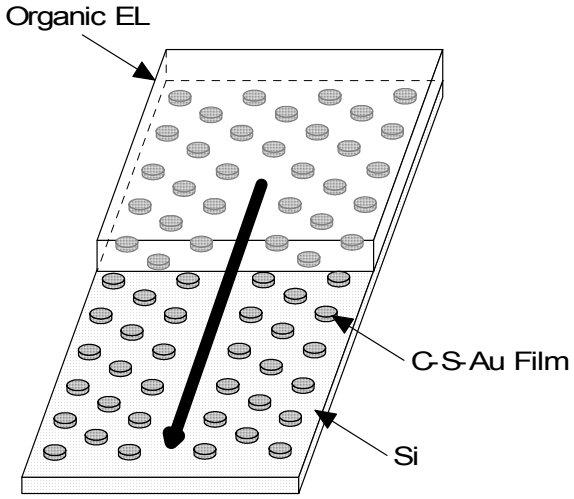

Fig. 7. Propagation of light from Organic EL

5. Conclusion

The C-S-Au film was synthesized by co-operation process of plasma CVD and sputtering with using methane, SF_6 and Ar mixture gas and gold plate on the discharge electrode. The refractive index was measured for the C-S and C-S-Au film. The refractive index increased as the sulfur content increased. By adding small amount of Au atom in a film, a refractive index was observed to increase largely. We found that the C-S-Au film was etched by oxygen plasma RIE. The etching rate was 263 nm/min. The 2-D photonic crystal of C-S-Au film and air space was successfully fabricated by using two layer resist system for oxygen plasma RIE. Finally the method of connection between the photonic crystal and organic EL was proposed.

Abstract
Silver-coated antimicrobial fabrics are often used for skin wound dressings (burn or chronic), after-surgery masks, and pressure-controlled garments. Other specific silver fabric applications, especially against biological hazards, include active antimicrobial sterile fabrics or dressing for prevention of infections. A knitted fabric consisting of a Nylon 6-Spandex (74:26) was plasma treated prior to the silver coating deposition carried out by magnetron sputtering. Silver sputtered fabric, after acid treatment, showed very high antimicrobial activity.

1. Introduction

Cold plasma technology offers a versatile, environmentally friendly and energy cost effective method for treatment and/or development of fabrics with applications in medical, hygiene, and protection markets. Such applications for protective clothing include fabrics exhibiting antimicrobial, electroconductivity or electrostatic dissipation properties, as presented in Figure 1. Silver-coated antimicrobial fabrics (or laminates) are often used for skin wound dressings (burn or chronic), after-surgery masks, and pressure-controlled garments. Other specific silver fabric applications, especially to counteract biological hazards, may include active antibacterial or antimicrobial sterile fabrics or dressing for prevention of microbial infections.

	Personal protection	***Transport and architecture***
Electrostatic risks or discharges	Anti-static garments for military, medical, electronic, police, fire workers and civils	Light weight composites (for substitution)
Microwave radiation	Uniforms for soldiers against microwave detection	Web, laminated or membrane structure for camouflage
Interactive device	Smart clothing incorporating alarm or sensor for soldiers and civils	
CB Threats	Anti-microbial or anti-bacterial suits	Fabrics for shelters, tents

Figure 1. Applications of silver coated fabrics in protective clothing.

Deposition of antimicrobial metals (like silver) on textile fabrics often requires complicated multi-step chemical process to provide useful antimicrobial properties to the fabric and sufficient durability. Furthermore, such chemical process may result in chemical pollution and variability of the quality of the silver coating, leading to reproducibility and quality control problems; therefore, new deposition technologies for antimicrobial silver fabrics need to be developped. Alternative technologies include physical vapor deposition, such as magnetron plasma sputtering which provide good adhesion and uniformity of the coating while allowing precise control of the nanostructural properties.

2. Deposition method

In this work, a knitted fabric consisting of a Nylon 6-Spandex (74:26) fabric was plasma treated prior to the silver coating deposition. A mixture of Argon and Nitrogen gas was used for plasma removal of silicone contaminants (used as lubricants in the knitting process) and plasma surface activation. Thus, plasma treatment resulted in a cleaner and more reactive fabric surface prior to deposition. The silver deposition was carried out with a magnetron sputtering system, as presented in Figure 2.

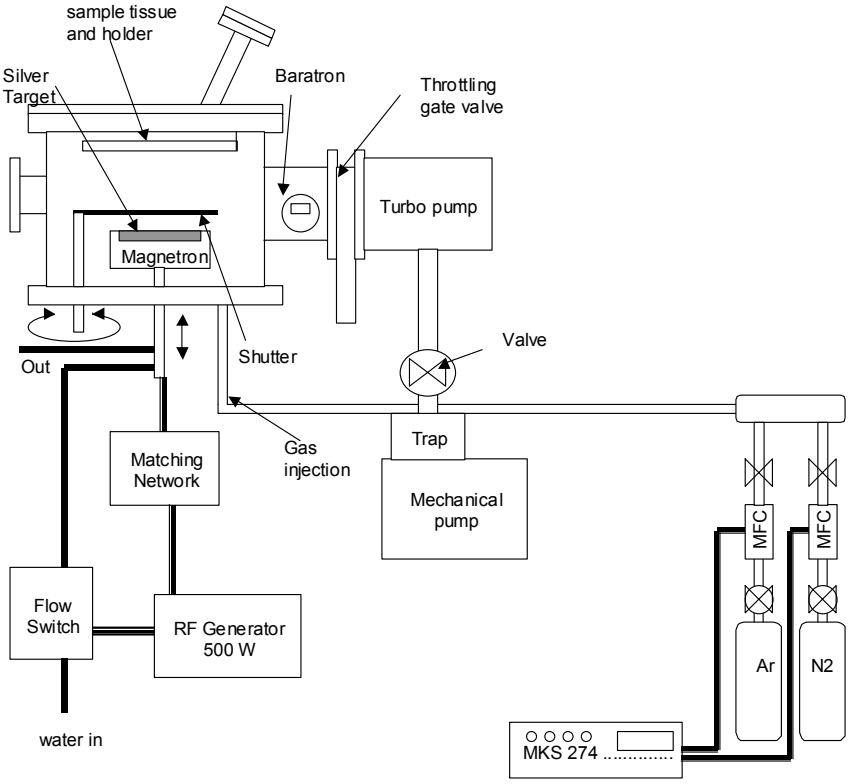

Figure 2. Magnetron sputtering system for silver deposition.

Following the silver deposition (by magnetron plasma sputtering), the knitted fabric was dipped in nitric acid solution using various acid concentrations and incubation time to improve further the antimicrobial properties of the coating.

3. Results

SEM photomicrographs of the virgin and silver treated fabrics are shown in Figure 3, where the virgin fabric is used as a control. While the virgin fabric appears to have a fiber surface relatively clean and smooth, the silver treated fabric depict a rough but uniform surface with visible silver particulates that form the coating.

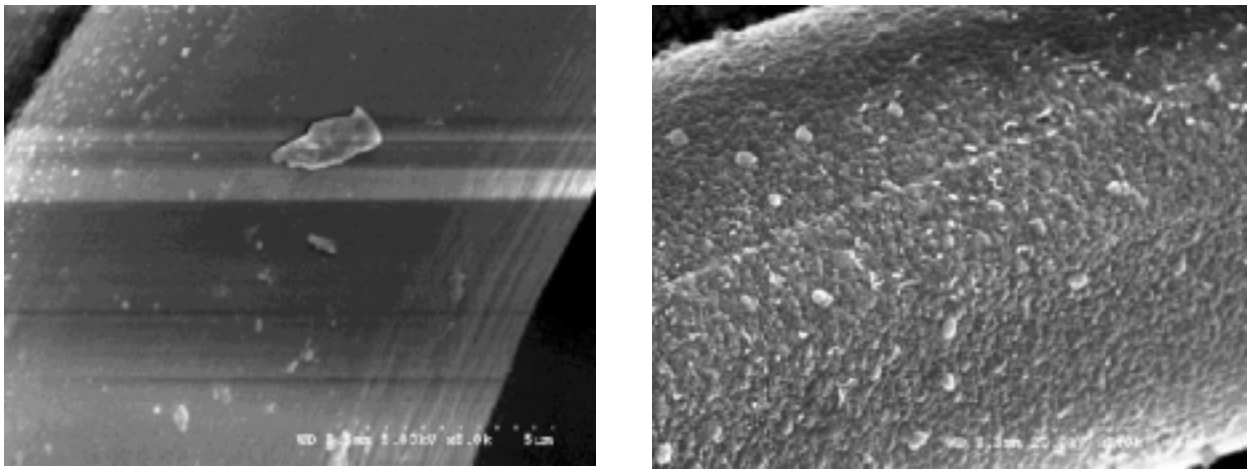

Figure 3. SEM photomicrographs at 8000 X magnification of the virgin (left) and acid-treated and sputtered silver fabric (right).

Antimicrobial testing (AATCC Test Method 147-1998) using gram positive and gram negative bacterias, S. Aureus and K. Pneumoniae respectively, revealed that the antimicrobial activity of the sputtered silver fabric was moderate. Results indicate that bacteria inhibition was observed only for bacteria in direct contact to – beneath- the fabric and no clear zone of inhibition beyond its edge was detected. However, a simple nitric acid treatment significantly improved the area of inhibition around the silver coated fabric's edge (inhibition zone, in mm). The initial experiments demonstrate that the acid-treated and sputtered silver fabric depicts a significantly higher inhibition zone, e. g. 2.0 to 6.0 mm and more, than the commercially available chemically-deposited silver fabric which possess a typical inhibition zone of 1.0 to 2.5 mm.

Other antimicrobial, metal-coated materials can be developped, using plasma-based techniques, such as woven fabrics, multilayer composites, laminates, non wovens and membranes.

Abstract
Double side surface modifications of PET film by roll-to-roll RF plasma system are described. The changes of chemical structure and composition of PET film treated by low-pressure CF_4 plasma was characterized by X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM) and water contact angle (CA). XPS and CA results revealed that the increasing of relative intensity of CF_2 and CF-CF_n species in the C (1s) spectrum could enhance the hydrophilic characteristic of the polymer surface. Nevertheless, the surface property would be hydrophobic when CF_3 species is detected from XPS C (1s) spectrum, even the relative intensities of CF_2 species increased to 23.45 %. Additionally, longer treating time and higher RF power (12 minutes, 600W), the surface wettability of both side of PET film appeared the division into two opposite extremes. One side is super-hydrophilic, 7.56^o, and another side is hydrophobic, 108.63^o. Furthermore, we will discuss the modified PET surface dynamics upon dipping into the potassium hydroxide water solution.

Introduction
Low temperature plasmas are ionized gases generated at pressures between 10^{-3} and 1 torr.
Plasma treatments have been widely used for the surface modifications of various materials; such as promoted the adhesion between the polymer and the metal or changed the wettability of materials. [1-5] Furthermore, modified the polymer surface can improve its permeability, biomedical compatibility or bacterial resistant without varying its bulk properties. [6-9] In this paper, we studied the effect of polyethylene terephthalate (PET) film exposed to RF CF_4 plasma. The changes of chemical structure and composition of PET film surface were characterized by X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM) and water contact angle (CA). Moreover, we also studied the dynamics behavior of the plasma treated surface. The surface dynamics of PET denote concentration-dependent characteristic (e.g. upon dipping into the different concentrations of sodium hydroxide solution).

Experimental
The materials used in this study are the commercial polyethylene terephthalate (PET) film. (188μm, DuPont Teijin Films) Plasma treatments were carried out in a roll-to-roll system (from AST Products) with two internal electrodes, and fitted with a gas inlet, pressure gauge, vacuum system, and matching network for capacity coupling of a 13.56 MHz radio frequency (RF) source. The pumping system consists a combination of a roots pump and a one-stage rotary vane pump. We used CF_4 as operating gas. The operating pressure and power were fixed at 0.35torr and 300-600W respectively. The treating time were varied from 0.5min to 12min. The chemical natures of the plasma treated PET films were characterized by X-ray photoelectron spectroscopy (XPS). XPS analyses were carried out on VG MicroLab MKIII spectrometer at a base pressure lower than 10^{-9} torr with non-monochromatized Mg Kα (1253.6 eV) radiation.

The changes of surface roughness for before and after plasma-treated PET film were measured on atomic force microscope (AFM). An atomic force microscope "Auto Probe CP " designed by Park Scientific

Instrument was used in the contact mode for the surface roughness investigation. The measurement of water contact angles used the sessile drop method with an automatic apparatus and deionized water. For each sample, the contact angle here is the mean of five measurement points, which located uniformly on the films. The deionized (DI) water and KOH solutions are used to recognize the effect of hydroxyl ion concentration on the plasma-treated films. Each sample was dipped into the solution within 1.5 min at room temperature and then rinsed with deionized water for another 1.5 min.

Results and Discussion

The water contact angle of modified PET films at various RF power are shown in Figure 1, while a working pressure of 0.35 torr and the treatment time of 2 min. From figure 1 we can find that contact angle of both side of PET film decrease with the increasing of RF power. But the "front side" (surface-facing cathode) almost keep constant contact angle when the RF power is above 400 W. Further, the "back side" contact angle still decreased almost linearly with the RF power.

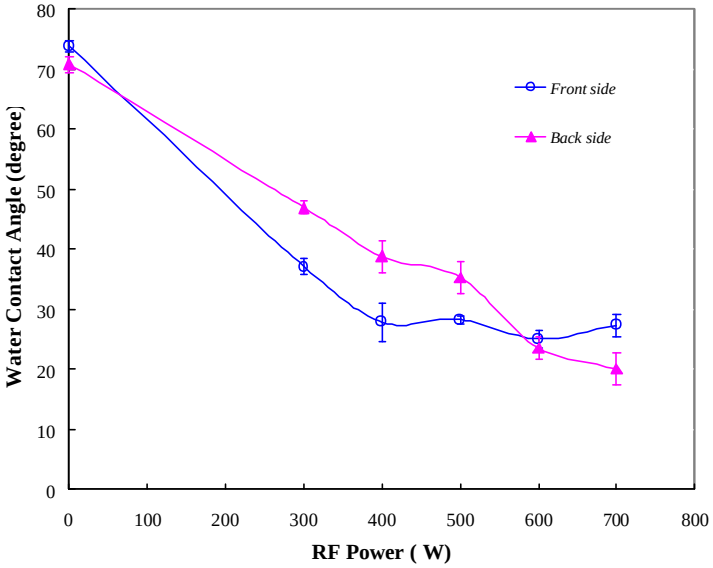

Figure 1. The water contact angle as a function of RF power (Plasma treated time: 2 min.; Working pressure: 0.35 Torr)

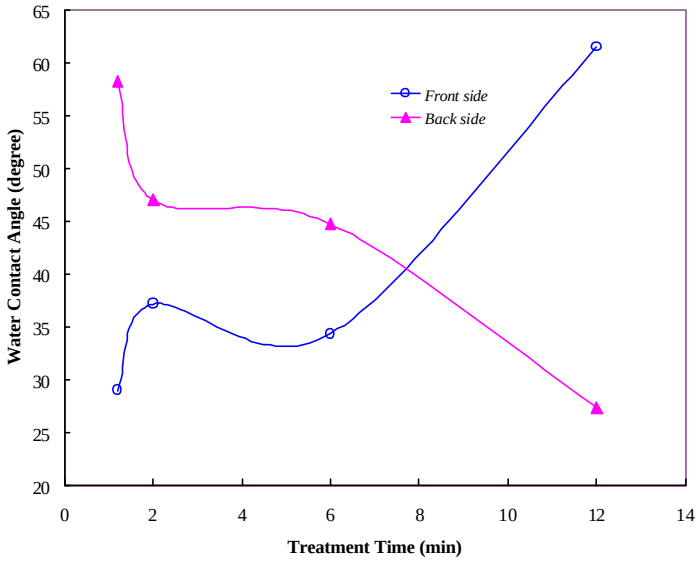

Figure 2. The water contact angle as a function of plasma treatment time. (RF power, 300 W; Working pressure: 0.35 Torr)

The contact angle as a function of treating time at RF power 600 W is given in figure 2. We can find that 1.2 min treatment time the difference of CA between "front side" and "back side" is above 30 ° and "front side" is more hydrophilic than "back side" and then both side CA will closed to 40 °. Above 6 min, the "back side " CA still keeps decreasing but the "front side" increasing with time. After 12 min treatment, "back side" decreased to 27.5° and front side increased drastically to 61.45 °. Furthermore, we can also find that "front side" contact angle nearly keep constant with increasing plasma treated time. And then it increases above 6 min treatment.

The C (1s) spectrum of untreated PET [Figure 3(a)] can be fitted to carbon environments corresponding to the carbon atoms in phenyl ring at 284.6 eV, the methylene carbon atoms singly bond to oxygen at 286.1 eV, the ester carbon bond at 288.6 eV, and the π-π* shake up peak at 290.6 eV. [10-11] The C (1s) spectra of plasma treatment on both sides of the PET surface are shown in Figure 3(b)(c). CF_4 plasma treated PET resulted in an enormous amount of fluorine incorporation at the surface. There is a dramatic change in the C (1s) XPS envelope, which can be attributed to formation of fluorinate carbon functionalities: $\underline{C}$-CF_n at 286.6 eV, $\underline{C}F$ at 287.8 eV, CF-CF_n at 289.3 eV, $\underline{C}F_2$ at 291.2 eV and $\underline{C}F_3$ at 293.6 eV. [10,12] Table 1 shows the relative peak areas of curve-fitted spectra for C (1s).

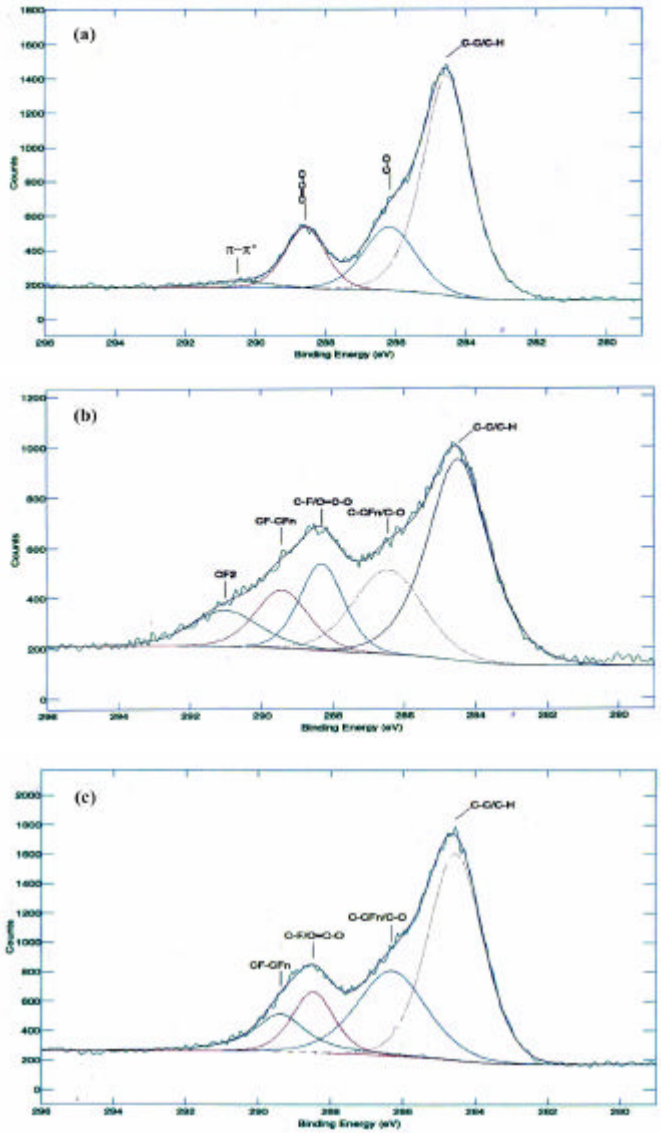

Figure 3. C (1s) XPS spectra of PET surface, (a) Untreated PET, and 600 W RF power plasma treated PET at treatment time 2 min onto the (b) Front side and (c) Back side.

Table 1: XPS data and Contact Angle data for the CF_4 plasma treatment PET

Treatment (rf power, Treatment time)		Untreated PET	300W, 2 min	300W, 2 min	600W, 2 min	600W, 2 min	600W, 12 min	600W, 12 min
			Front side	Back side	Front side	Back side	Front side	Back side
Water Contact Angle (degree)		73.8 ± 1.28	37.10 ± 1.04	46.96 ± 1.29	25.02 ± 1.83	23.54 ± 1.52	108.63 ±2.47	7.567 ±1.44
	F/C	0.00	0.00	0.00	0.58	0.11	1.44	1.05
% C (1s)	C-C/C-H	64.40	63.69	62.11	45.87	51.02	23.69	18.76
	C-O/C-CF_n	19.30	23.57	26.09	20.64	26.53	20.37	19.47
	O=C-O/CF	14.20	12.74	11.80	13.76	11.73	11.84	22.8
	CF -CF_n	-	-	-	11.00	10.72	10.9	15.2
	CF_2	-	-	-	8.72	-	23.45	23.75
	CF_3	-	-	-	-	-	9.71	-

According to the figure 3 and table 1, when PET is exposed to CF_4 plasma with lower RF power (e. g. 300W), the C (1s) spectrum does not change significantly. However, as the RF power increase, the relative peak areas of the curve-fitted C (1s) lines change and additional peak is observed at 600W. In a low-pressure plasma, electrons are accelerated by the oscillating field collide with CF_4 molecules, and cause bond cleavage and ionization. The predominant reactive components of CF_4 plasma are reported to be F atoms and relatively low concentrations of CF_n (n = 1,2,3) radicals. [6,13-14] With a low CF_n/F ratio, CF_4 does not polymerize in plasma, it can produces fluorination through a direct grafting of F atoms onto polymer surface. [15-18] Therefore, the fluorine atoms in the CF_4 plasma undergo hydrogen abstraction and substitution reaction at the PET surface yield CF, CF-CF_n, CF_2, and CF_3functionalties. The presence of CF_3 moieties signifies chain ends. [16] In comparing Figure1, 2 and Table 1, a clear distinction is observed in the shape of the corresponding to CF_2 and CF-CF_n which increasing the CF_2 and CF-CF_n can relatively enhance the hydrophilic characteristic of the polymer surface. Nevertheless, the surface property is hydrophobic when CF_3 species is detected from XPS C (1s) spectrum, even the relative intensities of CF_2 species increase to 23.45 %. On the other hand, as RF power increases to 600 W and treating time increase to 12 min., the wettability of both sides PET surface appeared the division into two opposing extremes. Water contact angle the faced cathode side of PET film is 108.63^o and opposite side is 7.56^o for example.

To understand the change of surface physical nature of PET after plasma treatment, AFM analysis was performed with both the treated and untreated PET. The results of comparative AFM surface roughness measurements for treated and untreated PET film are shown in Table 2. By increasing operating power and treating time will cause the surface smoothly. On the other hand, the roughness on front side is always smoother than the opposite side after plasma treatment.

The significant XPS data of CF_4 plasma treated PET after dipping into different KOH solution are summarized in Table 3. It is seen that the F/C ratio decreases with increasing OH^- concentration for both sides of PET surfaces. In addition to, the front side after dipping into the OH^- concentration of 0.1 M, it was found that the intensity of CF_3 and CF_2 in the C (1s) spectrum decreases from 9.71% to 0% and from 23.45% to 5.1 % respectively. However, CF_2 in the C (1s) spectrum decreases from 23.75 % to 0 % on the backside.

In a plasma-modified surface, the chain scission reaction can produce low molecular weigh compounds (e.g. oligomers). [19] By comparing table1 and 3, it was fount that the intensity of C-C/C-H peak in the C (1s) spectrum is increasing from 23.69% to 61.2% on front side and from 18.76% to 62.56 % on back side by dipping into the solution contains hydroxyl ion.

	CF_2	23.45	23.75	11.4	5.54	11.9	-	5.1	-
	CF_3	9.71	-	2.93	-	2.54	-	-	-

* Plasma treatment conditions: working pressure= 0.35 torr, RF power = 600 W, Web speed = 0.5 ft/min.

Conclusions

The interested result of CF_4 plasma treated PET in a roll-to-roll plasma system, water contact angle of one side is super-hydrophilic (7.56°) and another side is hydrophobic (108.63°), shows the wettability of both PET surfaces appeared two divisions of opposite extremes. The XPS analysis results are showing different functional group on both side PET surfaces. The CF_3 species in C (1s) spectrum can rather enhance the surface hydrophobic, no matter even the relative intensity of CF_2 increased to 23.45 %.

Furthermore, the surface dynamics of PET denote concentration-dependent characteristic that is dipping the sample into different $[OH^-]$ solutions exhibit the F/C ratio decreases upon the concentration of hydroxyl ion increase.

Abstract
In this work we present a theoretical study of the time-relaxation of the electron energy distribution function (EEDF) in the nitrogen afterglow. An equilibrium between the vibrational distribution function (VDF) of ground-state molecules $N_2(X,v)$ and low energy electrons is quickly established and the EEDF reaches a quasi-stationary state. Collisions of highly excited $N_2(X,v>35)$ molecules with N atoms are in the origin of a maximum in the electron density occurring downstream from the discharge. Slow electrons remain in the post-discharge for very long times and can be involved in electron stepwise excitation processes.

1. Introduction

Different plasma-chemical applications, such as N atoms production for metallic nitriding and polymer surface treatments, require the control of the plasma parameters in the nitrogen flowing afterglow. The knowledge of the basic processes occurring in these medium is therefore of primary importance. One essential aspect is the knowledge of the temporal evolution of the electron energy distribution function (EEDF), since it provides information relative to the electron energy and density relaxations and gives the characterization of the electron energy loss and gain mechanisms.

One interesting phenomenon exhibited by the post-discharge in nitrogen is the no-monotonic variation of the electron density n_e. More precisely, it has been shown that the electron density has an initial stage of decay, but then an increase occurs during a relatively long period, after which the plasma finally dies out [1,2]. The same behavior is presented as well by some heavy-particles in the post-discharge, like the $N_2(A\ ^3\Sigma_u^+)$ and $N_2(B\ ^3\Pi_g)$ electronically excited states [2] and $N_2^+(B\ ^2\Sigma_u^+)$ ions [3].

In this work we present a theoretical investigation of the time-dependence of the EEDF in the nitrogen afterglow of a $\omega/2\pi$=433 MHz flowing discharge at p=3.3 Torr, in a tube with inner radius R=1.9 cm. For these conditions the electron density in the beginning of the afterglow is estimated to be $n_e(0)=3\times10^{10}$ cm^{-3}, which corresponds approximately to the critical value for surface-wave propagation. Our analyses includes a self-consistent description of the discharge which allows to determine the EEDF and the concentrations of the different heavy species at the end of the discharge. The EEDF thus obtained is then used as the initial distribution at the beginning of the afterglow, where we solve the time-dependent Boltzmann equation – including a term describing the continuous reduction of the space-charge field [4] and a term for creation of new electrons in associative/Penning reactions – coupled to a system of rate balance equations for the heavy particles.

2. Theoretical model

The theoretical model used to investigate the evolution of the EEDF in the afterglow is largely based on the one presented in [4]. The study starts with a self-consistent description of the discharge, since it is the discharge that establishes the initial conditions for the afterglow. The discharge model accounting for the electron and heavy-particle kinetics in N_2 was described in detail in [5,6]. Briefly, the homogeneous electron Boltzmann equation is solved together with a system of rate balance equations for the population of the most important neutral and ionic species in the discharge, $N_2(X\ ^1\Sigma_g^+, v)$, $N_2(A\ ^3\Sigma_u^+, B\ ^3\Pi_g, C\ ^3\Pi_u, a'\ ^1\Sigma_u^-, a\ ^1\Pi_g, w\ ^1\Delta_u, a''\ ^1\Sigma_g^+)$, $N(^4S, ^2D, ^2P)$, N_2^+ and N_4^+. The electric field sustaining the discharge is obtained from the requirement that under steady-state conditions the total ionization rate must compensate exactly for the electron losses by electron-ion recombination and ambipolar diffusion to the wall. Ionization takes place by electron impact both from the ground-state and electronically excited N_2 molecules, as well as via the Penning/associative reactions [5]

$$\begin{aligned} N_2(A) + N_2(a') &\rightarrow N_2 + N_2^+ + e \\ &\rightarrow N_4^+ + e \end{aligned} \qquad (1)$$

and

$$N_2(a') + N_2(a') \rightarrow N_2 + N_2^+ + e$$
$$\rightarrow N_4^+ + e\,. \qquad (2)$$

The input parameters for the discharge model are the field frequency $\omega/2\pi$, tube radius R, gas pressure p and the electron density at the end of the discharge $n_e(0)$.

Once the EEDF at the end of the discharge is obtained, its time-evolution in the afterglow is obtained by the solution of the time-dependent Boltzmann equation, as described in [4]. The EEDF is normalized in the afteglow to the electron density, *i.e.* $\int F(u,t)\, u^{1/2}\, du = n_e(t)$, where $F(u,t)$ denotes de EEDF and u the electron energy. The electron Boltzmann equation is solved assuming zero electric field in the afterglow, and taking into account inelastic collisions for the excitation of electronic and vibrational states of N_2, superelastic collisions with the vibrational levels $N_2(X,v)$, elastic collisions, excitation of the rotational levels, electron-electron collisions, as well as the terms for loss of electrons by electron-ion recombination and by diffusion to the wall, using an effective diffusion coefficient to describe the transition from the ambipolar to free diffusion regimes [4]. The Boltzmann equation further includes the terms for creation of electrons by reactions (1) and (2) [7], in order to describe the increase in n_e after the initial stage of decay, as observed in [1,2].

Inspection of equations (1) and (2) reveal the need to know the time-dependent concentrations $[N_2(A)](t)$ and $[N_2(a')](t)$ in the afterglow. To this purpose, we described the relaxation of the heavy-particles that have been previously considered in the discharge, using the discharge calculated populations as initial conditions for the afterglow, by solving the corresponding rate balance equations. The detailed analysis of the heavy-particle kinetics is beyond the scope of the present work and can be found in [8]. Nevertheless, it is worth to note that the metastable states $N_2(A\ ^3\Sigma_u^+)$ and $N_2(a'\ ^1\Sigma_u^-)$ are created in the afterglow in collisions of N_2 vibrationally excited molecules in very high v-levels with N atoms, through the reactions

$$N_2(X, v \geq 39) + N(^4S) \rightarrow N_2(A) + N(^2D) \qquad (3)$$

and

$$N_2(X, v \geq 38) + N(^4S) \rightarrow N_2(a') + N(^4S)\,. \qquad (4)$$

The high vibrational levels of the VDF, which do not present a significant concentration under discharge conditions, can be effectively populated in the afterglow as a consequence of the so-called V-V pumping up mechanism [9]. After a certain time, these high v-levels become thus available to participate in reactions in the post-discharge. Therefore, there is a local production of the states $N_2(A\ ^3\Sigma_u^+)$ and $N_2(a'\ ^1\Sigma_u^-)$ in the afterglow, which will be subsequently involved in the production of new electrons via reactions (1) and (2). We note that reactions (3) and (4) correspond to a vibration-electronic (V-E) energy transfer, a mechanism that has been recently identified to occur in CO [10].

The calculated time-dependent populations of $N_2(A\ ^3\Sigma_u^+)$ and $N_2(a'\ ^1\Sigma_u^-)$ metastables are then introduced into the time-dependent Boltzmann equation, which is finally solved to obtain the EEDF and all its integrals. According to the calculations from [8], the populations of the vibrational levels $N_2(X,v \leq 10)$ has been kept constant during the resolution of the Boltzmann equation, which for the present conditions is certainly a good approximation for times lower than $\sim 10^{-2}$ s.

3. Results and discussion

All the calculations have been carried out for the conditions described above ($\omega/2\pi$=433 MHz, p=3.3 Torr, R=1.9 cm and $n_e(0)=3\times10^{10}$ cm^{-3}), to which correspond an effective electric field $E_e/N = 4.6\times10^{-16}$ V.cm^2 and a characteristic vibrational temperature of ground-state molecules $T_V \approx 6200$ K.

Figure 1 shows the EEDF $f(u,t)$ during the afterglow, with t in seconds. f is normalized to unity, so that $F(u,t) = f(u,t)n_e(t)$. It can be seen that the EEDF is largely modified in the first instants of the afterglow ($t < 10^{-6}$ s), as a result of inelastic collisions. On the other hand, for longer times the EEDF reaches a quasi-stationary state, which is due to an equilibrium achieved between the EEDF and the VDF, where the superelastic collisions of electrons with vibrationally excited molecules compensate for the inelastic vibrational losses.

Figure 2 shows the EEDF in the first instants of the afterglow, $t=10^{-9}$, 10^{-8} and 10^{-7} s. The rapid depletion of the high-energy tail is a consequence of inelastic collisions of electrons with ground-state molecules. We recall that the first electronically excited state is the metastable $N_2(A\ ^3\Sigma_u^+)$, with an energy threshold of about 6.2 eV. One interesting feature exhibited on figure 2 is the formation of a dip around u = 4 eV for afterglow times in the range $10^{-8} - 10^{-7}$ s. This is a consequence of the particular shape of the electron cross sections for excitation of the vibrational levels $N_2(X,v)$, which present a strong maximum at $u \approx 2$ eV and vanish for $u \geq 4$

eV. The mechanisms leading to the formation of this dip can be understood by inspection of figure 3, where we plot the frequency $\nu(u)$ of gain (ν positive) or loss (ν negative) of electrons with a certain energy u. It can be seen that the behavior of electrons with energies $u \leq 4$ eV is essentially determined by the inelastic and superelastic electron-vibration (e-V) collisions. Therefore, there is a loss of electrons in the energy range $2 \leq u \leq 4$ eV (where the vibration cross section is important) and a gain in the $0 \leq u \leq 2$ eV one. However, electrons with energies $4 \leq u \leq 6$ eV do not lose significantly their energy, since all the inelastic cross sections are zero in this region, which explains the formation of the dip at 4 eV. The formation of a similar dip was observed experimentally in [11].

The dip on the EEDF at 4 eV does not get deeper and deeper with time simply because the frequency $\nu(u)$ is not constant in time. As the electrons lose and gain energy in inelastic and superelastic e-V collisions the EEDF and the VDF attain an equilibrium, so that $\nu(u)$ becomes vanishing small for $0 \leq u \leq 4$ eV. When this happens, the electron temperature T_e of the $0 \leq u \leq 4$ eV electrons simply corresponds to the vibration temperature T_V. The effect is illustrated on figure 4, where $\nu(u)$ is depicted for three instants in the afterglow. As it is readily seen, the equilibrium between the EEDF and the VDF is established at times of the order of $t \sim 10^{-7}$ s.

In order to check the correctness of the present calculations, figure 5 shows the comparison of the calculated EEDF and the measured one for $t = 6.5\times10^{-3}$ s. The measured EEDF was taken from [7,12]. The excellent agreement between the calculated and measured EEDFs confirms the attainment of an EEDF/VDF equilibrium and gives an indication of the correctness of our calculations under discharge conditions, in particular of the calculated VDF. As mention before, the slope of the EEDF for $0 \leq u \leq 4$ eV essentially reflects the value of T_V, which remains constant from the discharge [8].

Figure 6 shows the electron density calculated from the time-dependent Boltzmann equation, by including (full curves) and neglecting (dashed curves) the creation of new electrons in reactions (1) and (2), together with the interferometry measurements from [2] (open circles) and the probe measurements from [7] (black squares). The agreement between the calculations and both measurements is quite good when the production of secondary electrons is considered. In particular, the no-monotonic behavior for n_e, previously observed in [1,2] is obtained as a result of the formation of the metastables $N_2(A\ ^3\Sigma_u^+)$ and $N_2(a'\ ^1\Sigma_u^-)$ through reactions (3) and (4), followed by ionization via (1) and (2).

In the previous figure we have shown that electrons remain in the afterglow for very long times. Therefore, it is important to quantify the possible importance of electron processes in the afterglow. Figure 7 shows the calculated electron kinetic temperature as a function of the afterglow time, with the same notation as in figure 6. It can be confirmed that in spite of the very fast equilibrium between low energy electrons and the VDF, which settles for $t \sim 10^{-7}$ s, a quasi-stationary EEDF in the full range of energy only establishes itself at $t \sim 10^{-6}$ s (see also figure 1). When this happens we have $T_e \approx T_V \approx$ *constant*.

From figures 1, 6 and 7 we can infer that, although the processes of direct electron impact on ground-state molecules are not effective in the afterglow, electron stepwise processes with low energy threshold may take place. This idea is indeed confirmed by figure 8, where we depict the rate coefficients for electron stepwise excitation of states $N_2(B\ ^3\Pi_g)$ and $N_2(C\ ^3\Pi_u)$ from $N_2(A\ ^3\Sigma_u^+)$. Since both coefficients remain significant at least up to times $t \sim 10^{-2}$ s, these processes can play a non-negligible role in nitrogen post-discharges.

4. Conclusions

In this work we have presented a theoretical study of the temporal evolution of the EEDF in the nitrogen afterglow. The electron Boltzmann equation has been solved taking account the creation of new electrons in the Penning/associative reactions (1) and (2). The concentrations $[N_2(A)](t)$ and $[N_2(a')](t)$ were obtained using a detailed kinetic model describing the relaxation of the heavy-particles.

It has been shown that an equilibrium between the vibrational distribution function (VDF) of ground-state molecules $N_2(X, v)$ and low energy electrons is rapidly established, in times of the order of 10^{-7} s, since in this time interval the energy of the electrons is determined by the balance between the heating and cooling due to de-excitation and excitation electron-vibration (e-V) processes. In these early instants of the afterglow the EEDF presents a dip around 4 eV, as it was experimentally observed in [11]. The EEDF reaches a quasi-stationary state for $t \geq 10^{-6}$ s, although the electron density still continues to decrease beyond this instant.

The very high vibrational levels of the VDF, as high as $v \sim 35$, can be effectively populated in the afterglow as a consequence of the V-V pumping up mechanism. Therefore, these high vibrational levels become

available to participate in reactions in the post-discharge, such reactions (3) and (4) that form $N_2(A)$ and $N_2(a')$ metastables.

The mechanism described by reactions (1)–(4) explains the existence of a maximum in the electron density occurring downstream from the discharge at times of the order of 10^{-2} s, detected experimentally in [2] for the same conditions as in this study. The metastable states locally produced in reactions (3) and (4) subsequently ionize the gas via (1) and (2), which in turn leads to the observed increase in n_e.

As a consequence of the long characteristic times for ambipolar diffusion and for creation of new electrons, slow electrons remain for very long times in the post-discharge, as long as 10^{-3}–10^{-2} s, and can be involved in electron stepwise processes with energy thresholds typically smaller than ~2–3 eV.

Spectroscopic Measurement of Electron Temperature and Density in Argon Plasmas Based on Collisional-Radiative Model

Katsuhiro Kano and Hiroshi Akatsuka

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Tokyo, Japan

Abstract

The paper describes a spectroscopic method for determining electron temperature T_e and density n_e in argon plasmas on the basis of Collisional-Radiative model. We measure T_e and n_e in a positive column of an argon DC arc discharge by the method developed. The results of T_e agree roughly with those by the probe. However, the limitation of our method for obtaining n_e is found. We also measure T_e and n_e of an expanding arc-jet, for which the results agree roughly with those by the probe.

1. Introduction

There exist several methods for obtaining electron temperature T_e and density n_e in plasmas from line spectra. Conventional methods, however, have the disadvantage that they are applicable only if atoms or ions are in particular equilibrium states, such as corona model or LTE. In the present study, we propose a method for determining T_e and n_e simultaneously based on Collisional-Radiative model (CR model). This method allows us to determine T_e and n_e from line spectra intensity where no specific equilibrium is assumed.

The principle of the method developed in the present study is to solve steady-state rate equations on the assumption that T_e and n_e are unknown quantities. Compared with the existing methods, the essential advantage of our method lies in its applicability not only to ionizing plasmas but also to recombining plasmas. This is because our method resolves T_e and n_e from equilibria of electronic transitions of excited levels by using a CR model directly, and accordingly it does not depend on whether the source of electronic transition is ground levels (ionizing plasmas) or ions (recombining plasmas). Historically, a number of atomic models for the measurement of plasma parameters have been proposed; there are, however, quite a few methods that actual measurement by the models has not been performed. For above reasons, it is worth developing a method for determining T_e and n_e in argon plasmas based on CR model, and examining its validity through measurement by the method.

The objective of the present article is to review our spectroscopic methods for determining T_e and n_e in two kinds of argon plasmas based on a CR model of argon. Another objective is checking its applicability by performing measurements. In this paper we review two simplified atomic models of the argon plasmas. One is a DC arc discharge plasma with its discharge pressure several Torr, used for fundamental research for isotope separation, as an example of an ionizing plasma [1]. The other is an arc-heated magnetically trapped expanding plasma jet, where an arc discharge plasma generated under atmospheric pressure is expanding into a lower pressure [2]. We check the suitability of the models and applicability of the method, by comparing T_e and n_e obtained by the spectroscopic method with those obtained by the probe measurement [3].

2. Spectroscopic Measurement of a DC Arc Discharge Argon Plasma in a Thin Capillary

2.1. Principle for a DC arc discharge argon plasma

An argon plasma treated in this section is a positive column of DC discharge, a typical ionizing plasma. Probe measurement showed that T_e and n_e ranged from 0.8 – 2.0 eV, and from 1.0×10^{14} – 1.0×10^{15} cm^{-3}, respectively, and the discharge pressure ranged from 4.0 to 31.6 Torr [4].

When the range of the electron temperature to be measured is relatively low, the electrons in the high-energy tail of electron energy distribution function (EEDF) play an important role in the electron-impact excitations and de-excitation [5]. In the present discharge plasma, we already found $V - I$ negative characteristics of the discharge, and hence, the discharge is considered to be an arc discharge [1]. This fact is considered to be equivalent to sufficient relaxation of electron gas. Therefore, we presume Maxwellian EEDF when calculating rate coefficients for electron-impact collisional transitions. The outline of the CR model is as follows: In this CR model, an Ar atom has 65 effective levels. Atom-atom inelastic collisions, diffusion losses of the metastables along with the electron-atom inelastic collisions, and radiative processes are taken into account. The model is available to study how the populations of the excited levels are effected

by the various set of parameters, such as electron temperature T_e, the gas temperature T_a, electron density n_e, the density of the ground state N_1, the plasma radius R, and optical escape factors [6]. In this section, the radius of the plasma is set to be 1.8 mm, and the gas temperature is derived from the empirical formulation [7]. The density of the ground state atom is approximated by the law of ideal gases.

The principle of our method for determining T_e and n_e based on the CR model is to solve steady-state rate equations describing electronic transitions on the assumption that T_e and n_e are unknown quantities. The rate equations comprising all the transitions become complicated. However, we can simplify them, since electronic transitions in atoms or ions of ionizing plasmas can be well described by specific transitions [8]. From now on, the levels of Ar atom is referred to by the level number defined in [6].

For input parameters $0.8 \le T_e$ [eV] ≤ 2.0, $10^{14} \le n_e$ [cm^{-3}] $\le 10^{15}$ and $5 \le P$ [Torr] ≤ 31.6, we have made a simplified model describing electronic transitions of the level from $i = 2$ (4s[3/2]$_2$) to $i = 30$ (7p') in such a way that the atomic model contains at least 80 % of all the electronic transition of the level defined in the CR model. As a result, we have found that T_e and n_e can be determined from the balance of electronic transition of the level $i = 20$ and $i = 7$, respectively. To determine T_e, the governing equations are as follows;

$$F_{25,20}N_{25} + F_{27,20}N_{27} = (C_{20,25} + C_{20,27})N_{20} \quad \text{for } 0.8 \le T_e \text{ [eV]} < 1.2, \tag{1}$$

$$C_{18,20}N_{18} = C_{20,23}N_{20} \quad \text{for } 1.2 \le T_e \text{ [eV]} < 2.0, \tag{2}$$

where N_i is the number density of the level i, C_{ji} and F_{ij} is the rate coefficient of electron impact excitation from the level j to i and its reversal de-excitation from the level i to j, respectively. It is found that the specific transitions in Eqs. (1)-(2) approximate the real electronic transition of the level $i = 20$. A solution to Eqs. (1) or (2) allows one to determine T_e. In both equations, unknown quantity is T_e only, if we have known population densities N_{18}, N_{20}, N_{25} and N_{27} by spectroscopic measurement prior to solving those equations.

Electron density is determined from the equilibrium of electronic transitions of the level $i = 7$. Equilibria of the electronic transition used for obtaining n_e require a radiative transition which is not negligible compared to electron-impact transitions. The equations to obtain n_e are expressed by the following simultaneous equations, which are population balance equations of the levels 7, 2, 3 and 5, respectively;

$$(C_{2,7}N_2 + C_{3,7}N_3 + C_{5,7}N_5 + F_{18,7}N_{18})n_e = (A_{7,2} + A_{7,3})N_7 + (C_{7,13} + C_{7,16} + C_{7,18} + C_{7,25})n_eN_7, \tag{3}$$

$$C_{1,2}N_1 + F_{3,2}N_3 = (C_{2,3} + C_{2,6} + C_{2,7} + C_{2,16})N_2, \tag{4}$$

$$C_{1,3}N_1 + F_{7,3}N_7 + C_{2,3}N_2 = (C_{3,6} + C_{3,7} + C_{3,16} + F_{3,2})N_3, \tag{5}$$

$$C_{1,5}N_1 = (C_{5,7} + C_{5,8} + C_{5,14} + F_{5,2} + F_{5,3} + F_{5,4})N_5, \tag{6}$$

where $A_{i,j}$ is the rate of radiation transition from the level i to j. In Eqs. (3)-(6), the unknown quantities are n_e, N_2, N_3 and N_5. The three latter number densities cannot be measured by the visible spectroscopic observation. To solve these equations, we need to know the densities N_7 and N_{18} by the spectroscopic examination in addition to N_1 and T_e. The details of the rate coefficients are given in [6]. More detailed discussion on the determination of Eqs. (1)-(6) is given in [1, 3]. We have found that the present model of atomic processes can predict T_e and n_e with accuracy of ± 39 % and ± 90 %, respectively [1, 3].

2.2 Experimental

Figure 1 shows the schematic view of our experimental arrangement [1]. The probe measurement was performed on the axial point at 1 cm out of the anode, as shown in Fig. 1. When performing spectroscopy, the probe was taken out from the discharge tube so that it did not disturb the plasma. In this study, spectroscopic measurement was also performed at the same point as the probe measurement. Because the spatial resolution of the optical system was 6 mm, the optical system measured emission from the entire plasma volume at the axial position.

An optical fiber was employed to guide the emission from the plasma to a visible monochromator system, whose wavelength resolution was 0.2 nm. The output from the monochromator was detected by a photo-multiplier tube, and signals from the photo-multiplier tube was recorded by a computer. The wavelength dependence of the sensitivity of the detection system is calibrated with a standard halogen lamp and a white standard reflectance plate as a diffuse reflector [9].

To obtain population densities N_7, N_{18}, N_{20}, N_{25} and N_{27} of Ar I, five wavelengths of 763.5 nm (4p[3/2]$_2$ → 4s[3/2]°$_2$), 436.4 nm (5p[1/2]$_1$ → 4s[3/2]°$_2$), 739.3 nm (6s[3/2]°$_1$ → 4p[3/2]$_2$), 360.7 nm (6p[1/2]$_0$ → 4s[3/2]°$_1$), and 699.2 nm (5d[1/2]°$_0$ → 4p'[1/2]$_1$) were chosen for their measurement,

respectively. In this study, radiative transitions are assumed to be perfectly optically thin except for the transitions to the ground level in the CR model. Vlček and Pelikán [10] have performed the CR calculation of atmospheric and sub-atmospheric pressure arc plasmas under this assumption, and they have presented that both population densities by the CR calculation and those obtained in their experiment agree well. The measured line intensities between excited states, however, might be affected by the opacity. We estimated optical escape factors with the aid of the CR calculation for the range of $0.8 < T_e$ [eV] < 2.0, $1.0 \times 10^{14} < n_e$ [cm^{-3}] $< 1.0 \times 10^{15}$ and $4.0 < P$ [Torr] < 31.6 [11]. The result is that the optical escape factor for the emission of 763.5 nm is larger than 0.97, and those for the rest of emissions are larger than 0.99. Consequently, it shows the appropriateness of our assumption that the spontaneous emissions between excited states are optically thin. However, we could not measure population densities N_{18} and N_{25} of our plasma due to absorption by cooling water that surrounded the discharge tube. For this reason, we estimated N_{18} by extrapolation and N_{25} by interpolation by excitation temperature determined from population densities N_{20} and N_{27}, respectively [12].

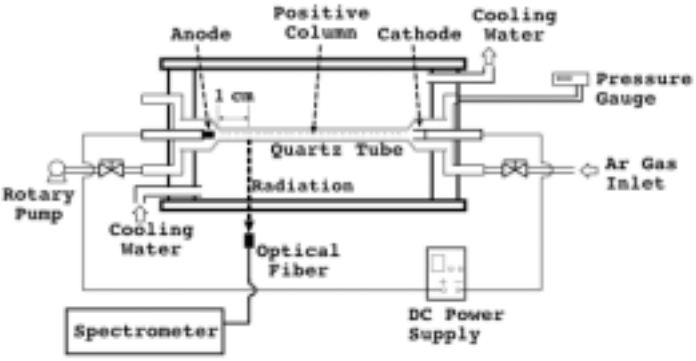

Figure 1. Schematic view of the experimental arrangement. The region where spectroscopic measurement was performed is also shown. Gas pressure of argon is measured with a pressure gauge connected to the cathode region.

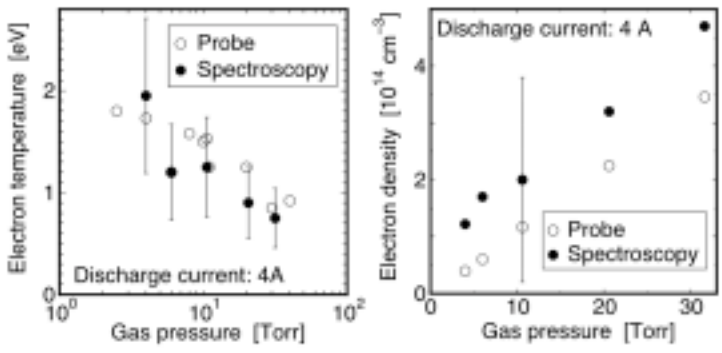
2.3 Results and discussion

Figure 2(a) shows dependence of T_e on the gas pressure when the discharge current is 4 A. Closed plots and opened plots denote T_e obtained by the spectroscopic method developed in the present study and that with the probe, respectively. Error bars indicate ± 39 % deviation points from the plots. The uncertainty of spectroscopic measurement arising from photon counting error is negligible compared with the error originating from the simplification of the atomic process. For this reason, error bars owing to experimental uncertainty are not shown in Fig. 2(a).

The result of T_e obtained by the spectroscopy also indicates the usual linear decrease in the temperature as a function of the logarithm of the gas pressure throughout the current range 2 – 8 A. This characteristic agrees with those obtained by the probe measurement. Strictly speaking, T_e obtained by the spectroscopy should be lower than that with the probe, since the former result corresponds to volumetrically averaged T_e and the latter to the local value on the axis of the discharge tube. In Fig. 2(a), there are some plots that do not obey this principle. Our spectroscopic method based on the CR-model, however, can predict T_e within the ranges of the error bars. We have found from the experiment that our spectroscopic method has feasibility for determining T_e in the range from 0.8 to 2.0 eV. The range of the feasibility of our spectroscopic method for determining T_e is small (± 0.6 eV) and is not much larger than the measurement uncertainty. Although we have not surveyed whether it could be applied in other range of T_e, the method for obtaining T_e could be also useful in other systems.



(a) (b)

Figure 2. Electron temperature (a) and density (b) obtained by the spectroscopic measurement based on the proposed model of atomic processes (closed circles) and that by probe (open circles) as a function of discharge pressure [Torr]: discharge current is 4 A. Gas pressure is measured with a pressure gauge at the cathode shown in Fig. 1.

Figure 2(b) shows the results of n_e obtained by the spectroscopic method and those measured with the probe as a function of gas pressure when the discharge current is 4 A. Closed plots and opened plots denote n_e obtained by the spectroscopic method and with the probe, respectively. Error bars indicate 90 % deviation points from the plots. Generally, electron density measured with the probe [4] increases linearly with the gas pressure. On the other hand, this feature does not hold for n_e determined by the spectroscopy

when n_e is higher than 2×10^{14} cm^{-3}, especially for other discharge current shown in Fig. 2(b).

Electron density determined by the spectroscopy should be also lower than that with the probe since the former result corresponds to volumetrically averaged n_e and the latter to the local one on the axis of the discharge tube. However, the result for n_e by spectroscopy does not posses the characteristic. This discrepancy is ascribable to the fact that the radiative transition of the level $i = 7$ does not have a large fraction enough to obtain n_e with high precision. Another reason of the discrepancy is that n_e is affected by the accuracy of determining T_e since n_e is calculated after T_e is determined.

We might be able to determine n_e more precisely from the balance of the electronic transition of the level $i = 3$ or 5 in this study, since lower levels contain a larger fraction of radiative transition. However, since spontaneous emission from the level $i = 3$ or 5 is in the range of ultraviolet, we could not measure them by our apparatus. Therefore, we had tried to measure n_e by using the balance of population of the level $i = 7$, and consequently, found the limitation of our spectroscopic method for the plasma whose electron density was higher than 2.0×10^{14} cm^{-3}. If n_e is lower than 10^{14} cm^{-3}, the fraction of the radiative transition of the level $i = 7$ is larger than 10 %, and this leads to a more precise measurement of n_e. Therefore, the method for determining n_e should be applied to Ar plasma whose electron density is lower than 1.0×10^{14} cm^{-3} [1, 3].

3. Spectroscopic Measurement of a Recombining Argon Plasma, an Expanding Argon Plasma Jet

3.1 Principle for an expanding argon plasma jet atomic model

We examined the argon arc jet plasma as the next objective to be observed, by the probe measurement prior to the spectroscopic observation, and found that T_e ranges from 0.3 eV to 0.9 eV and n_e from 10^{12} cm^{-3} to 10^{14} cm^{-3}, with the background pressure about $P_c = 22.6$ Pa. Next, we performed CR calculations on the assumption that the gas temperature $T_a = 1000$ K [2], $R = 3$ cm and the ion density $n_i = n_e$. The density of the ground state, N_1, is estimated from the law of ideal gases. The EEDF of the plasma should be Maxwellian, at least when it is generated by arc discharge. In the downstream expansion region, it is considered to be no electric field to maintain the discharge. Therefore, we can consider the EEDF of the recombining argon plasma should be Maxwellian.

The principle of our method for determining T_e and n_e based on the CR model is, again in this section, to solve the steady-state rate equations describing electronic transition on the assumption that T_e and n_e are unknown quantities. We found that T_e and n_e are determined from balance of the level $i = 18$ (5p) and the level $i = 7$ (4p$[3/2]_{1,2}$, $[5/2]_{2,3}$) respectively, within the ranges considered. The approximated balance equation of the transitions of the level $i = 18$ is given by

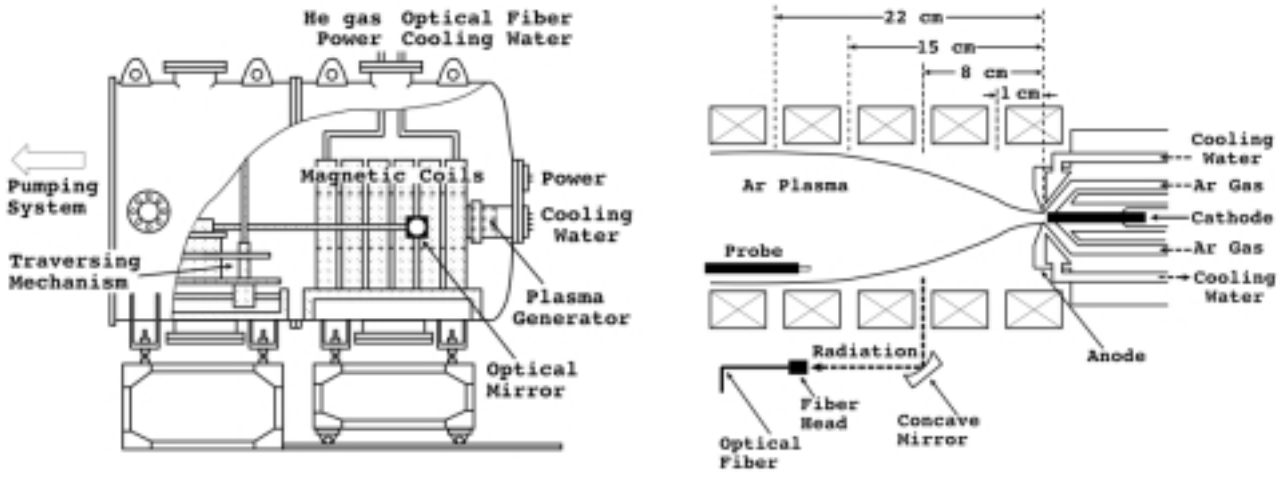
$$C_{7,18}N_7 + F_{20,18}N_{20} + F_{25,18}N_{25} = (F_{18,7} + C_{18,20} + C_{18,25})N_{18}. \quad (7)$$

It is found that the specific transitions in Eq. (7) approximate more than 80 % of the actual electronic transitions of the level. The population densities N_7, N_{18}, N_{20} and N_{25} in Eq. (7) can be obtained by the spectroscopic measurement in the visible range of light. In Eq. (7), the unknown quantity is solely T_e, if we know population densities N_7, N_{18}, N_{20} and N_{25} by the spectroscopic measurement.

On the other hand, the electron density is determined as solutions to the following simultaneous equations, namely, four population balance equations of the levels 7, 2, 3 and 13, and three LTE-like relationships of the sufficiently highly-excited level pairs (16, 18), (20, 23) and (23, 29) [8]:

$$\begin{aligned}
&A_{16,7}N_{16} + n_e(F_{13,7}N_{13} + F_{16,7}N_{16} + F_{18,7}N_{18} + F_{25,7}N_{25} + C_{2,7}N_2 + C_{3,7}N_3) \\
&\qquad = \{(A_{7,2} + A_{7,3}) + n_e(F_{7,2} + C_{7,13} + C_{7,16} + C_{7,18} + C_{7,25})\}N_7, && (8)\\
&n_eC_{1,2}N_1 + A_{7,2}N_7 + n_eF_{3,2}N_3 = n_e(C_{2,3} + C_{2,7})N_2, && (9)\\
&n_eC_{2,3}N_2 + (n_eF_{7,3} + A_{7,3})N_7 = \{n_e(F_{3,2} + C_{3,5} + C_{3,7}) + A_{3,1}\}N_3, && (10)\\
&A_{23,13}N_{23} + A_{29,13}N_{29} + n_e(C_{7,13}N_7 + F_{16,13}N_{16} + F_{18,13}N_{18} + F_{23,13}N_{23}) \\
&\qquad = \{A_{13,7} + n_e(F_{13,7} + C_{13,16} + C_{13,18} + C_{13,23})\}N_{13}, && (11)\\
&C_{16,18}N_{16} = F_{18,16}N_{18}, && (12)\\
&C_{20,23}N_{20} = F_{23,20}N_{23}, && (13)\\
&C_{23,29}N_{23} = F_{29,23}N_{29}, && (14)
\end{aligned}$$

Unknowns of Eqs. (8)-(14) are n_e, N_2, N_3, N_{13}, N_{16}, N_{23} and N_{29}. In the level 7, since there exists a large fraction of radiative transition, the electron density can be determined with good precision, which quite



(a) (b)

Figure 3. Cross-sectional view of (a) a plasma jet apparatus, and (b) electrodes, magnetic coils, and argon plasma.

differs from the previous section. It is confirmed that the specific transitions in Eq. (8) approximate more than 80 % of the actual electronic transitions of the level $i = 7$. To solve these equations, we need to know the densities N_7, N_{18}, N_{20} and N_{25} by the spectroscopic examination in addition to T_e. The details of the rate coefficients are given in [6]. More detailed discussion on the determination of Eqs. (8)-(14) is given in [2,3].

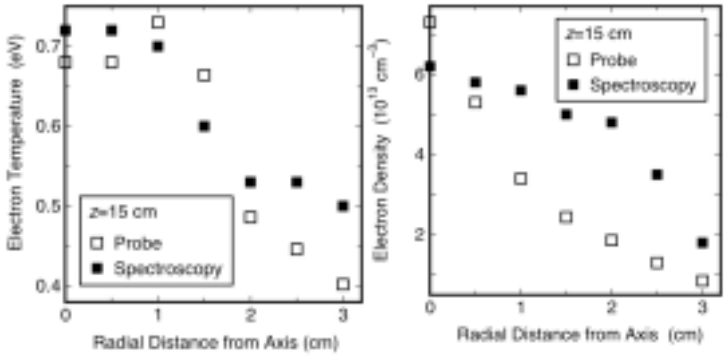
3.2 Experimental

Figure 3(a) shows the schematic view of the plasma jet apparatus [2]. The apparatus consists of a plasma generator, magnetic coils, traversing mechanism for an optical fiber terminal assembly. These components are placed in a rarefied gas chamber of 1.2 m in diameter and 2 m in length. The chamber is evacuated with a 12-inch mechanical booster pump, and the ultimate pressure in it becomes as low as 0.74 Pa. Figure 3(b) shows the cross-sectional view of the electrodes for generating the plasma and the expanding plasma from the nozzle, which is opened on the anode. In the wind tunnel, there exist six coils of 80 mm in inner diameter for confining the plasma. The strength of the magnetic field is 0.15 T. The discharge conditions are the following: arc voltage V_{arc} = 18 V, discharge current I_{arc} = 120 A, pressure in the wind tunnel P_c = 22.6 Pa, gas flow rate is 650 SCCM.

To obtain population densities N_7, N_{18}, N_{20} and N_{25}, four wavelengths, 763.5 nm ($4p[3/2]_2 \rightarrow 4s[3/2]^\circ_2$), 430.0 nm ($5p[5/2]_2 \rightarrow 4s[3/2]^\circ_2$), 693.8 nm ($4d[1/2]_0 \rightarrow 4p[1/2]_1$) and 360.7 nm ($6p[1/2]_0 \rightarrow 4s[3/2]^\circ_1$) were chosen, respectively. We could not, however, measure population density N_{25} of our plasma since the intensity of 360.7 nm emission was very weak. For this reason, we estimated N_{25} by interpolation by excitation temperature determined from densities N_{20} and N_{27}, respectively [12]. We measured N_{27} from the line intensity of 545.2 nm ($7s[3/2]^\circ_2 \rightarrow 4p[1/2]_1$).

3.3 Results and discussion

Figure 4(a) shows the radial distributions of T_e measured by the present spectroscopic method at the longitudinal position 15 cm. Abel inversion has been carried out to deduce spatial distribution of population densities, N_7, N_{18}, N_{20} and N_{27} from the averaged value along the line of sight. It is found that T_e becomes lower as axial distance r and longitudinal distance z increase. This characteristic is similar to the results by the probe measurement. The discrepancy between the result by the spectroscopic measurement and that by the probe measurement is smaller than ± 0.1 eV. Since the range of T_e considered in the



(a) (b)

Figure 4. Radial profiles of (a) electron temperature T_e and electron density n_e measured by the present spectroscopic method (filled squares) and by the probe method (open squares) wherethe longitudinal distance from the nozzle z is 15 cm.

present study is 0.3 eV through 0.9 eV, we should expand the availability of the range to apply the spectroscopic method to other plasmas. However, it is also found that we can determine T_e with good accuracy by the spectroscopic measurement based on the CR model, and that the present atomic model is an appropriate for obtaining T_e.

Figure 4(b) shows the radial distribution of n_e measured by the present spectroscopic method where z is 15 cm. Electron densities obtained by the CR model is about twice as higher as those by the probe method when $r > 1$ cm at $z = 8$ and 15 cm. The spectroscopic method for determining n_e cannot avoid the dependence on the result for T_e. The electron density obtained by the present spectroscopic method, however, agrees roughly with that by the probe. The spectroscopic method, therefore, is also feasible for knowing n_e of the wide range from 10^{12} cm^{-3} to 10^{14} cm^{-3} [2, 3].

4. Concluding Remarks

In the present study, we proposed a spectroscopic method for determining T_e and n_e from radiation intensities based on CR model. First, we measured these parameters of an ionizing plasma and compared them with the result obtained with a Langmuir probe. The experimental results show that the method developed has feasibility for determining T_e in the range from 0.8 eV to 2.0 eV. As for the measurement of n_e in the plasma, the limitation of the method was also found, since radiative transition became negligible compared to electron-impact ones due to its high electron density [1]. Second, we measured these parameters of a recombining argon plasma and compared them with the result obtained with a Langmuir probe. The experimental results show that the method developed has feasibility for determining T_e in the range from 0.3 eV to 0.9 eV, and n_e in the wide range from 10^{12} cm^{-3} to 10^{14} cm^{-3} [2].

We can apply the present method to many different kinds of argon discharge plasmas in principle. If we know approximate range of T_e and n_e of the argon plasmas by probe analysis, we can extract dominant processes to determine excited states populations by the CR model. After that, we can obtain simultaneous equations to describe population balances of the states, where T_e and n_e are unknowns. In order to solve the equations, number densities of excited states become necessary, and consequently, we should measure the number density by the spectroscopic examination. Sometimes, the simultaneous equations contain the number densities of excites states which cannot be measured spectroscopically. Then, all we have to do is to increase the number of the simultaneous equations that contain the densities of the unobservable levels, till the number of simultaneous equations becomes the same with that of the unknowns.

Fortunately, the EEDF of the argon plasmas examined in the present review is almost Maxwellian, and consequently, the rate coefficients are easily calculated as functions of the electron temperature. If the EEDF depends on the discharge conditions, it seems difficult to apply the present spectroscopic method. However, when the EEDF can be approximated by some function with a few unknown parameters, such as by Druyvesteynian or bi-Maxwellian, we can obtain the unknown parameters, since at this time again, the rate coefficients become functions of the unknown parameters instead of the electron temperature [3].

Acknowledgments

We thank Professor J. Vlček of University of West Bohemia for his excellent argon CR model code.

Deposition of a-Si:H films of high stability by cluster-suppressed plasma CVD

Yukio Watanabe, Kazunori Koga, Atsushi Harikai, Takanori Ogata, and Masaharu Shiratani

Department of Electronics, Kyushu University, Fukuoka, Japan

Abstract

Reduction of cluster amount in silane discharges is a key to a considerable decrease of micro-structure parameter R_α of a-Si:H films deposited with the discharges. The cluster amount is found to be reduced more than one order of magnitude using 60 MHz discharges instead of 28 MHz ones or using an H_2 dilution of H_2/SiH_4 ratio of 5. Cluster-suppressed plasma CVD using 60 MHz discharges realizes deposition of a-Si:H films of $R_\alpha \approx 0$ at a rate of 0.55 nm/s.

1. Introduction

A-Si solar cells have three issues to be solved: 1) a low stabilized efficiency of 9%, 2) light-induced degradation of efficiency, and 3) a low deposition rate of 0.2 nm/s for the best quality films, although they will play a considerable role as one of clean, sustainable electricity sources in this century [1]. Clusters smaller than a few nm in size formed in silane discharges employed for a-Si:H film deposition are one of causes of light-induced degradation of the films [2-4]. Previously, we have systematically studied growth kinetics of clusters by using two in situ cluster detection methods which are named double-pulse-discharge (DPD) [5, 6] and photon-counting laser light scattering (PCLLS) methods [7-13]. Based on the results, we have developed a cluster-suppressed plasma CVD method and by using the method together with the PCLLS method, we have shown that reduction of cluster amount in silane discharges is a key to a considerable decrease of micro-structure parameter R_α of a-Si:H films, leading to a high stabilized fill factor of a n^+Si/a-Si:H/Ni Schottky solar cell [14, 15].

These results motivate us to study effects of discharge frequency and H_2 dilution on amount of clusters incorporated into depositing films, since VHF discharges and H_2 dilution are often employed to deposit device quality films at a high deposition rate. In this paper, we will report these new experimental results together with some previous important ones. After a description of the reactor and experimental methods in the next section, we will present the effects of discharge frequency and H_2 dilution on cluster amount in section 3.1 and 3.2, and then we will describe dependence of microstructure parameter on deposition rate in section 3.3.

2. Experimental

Experiments were carried out using two capacitively-coupled high frequency discharge reactors A and B: the reactor A is of the cluster-suppressed plasma CVD type and employed for examining dependence of microstructure parameter on deposition rate; the reactor B is of conventional type and employed for studying effects of discharge frequency and H_2 dilution on the amount of clusters incorporated into depositing films.

The reactor A was developed by applying cluster suppression methods in which the growth of clusters were suppressed by using gas viscous force, thermophoretic force, as well as by reducing gas stagnation regions [14, 15]. Figure 1 shows the reactor A. For this reactor, a powered stainless steel mesh electrode of 120 mm in diameter and a grounded plane electrode of 120 mm in diameter, were placed 20 mm apart in a stainless steel vessel of 315 mm in diameter and 250 mm in height. Gas of SiH_4 was supplied towards the center axis of

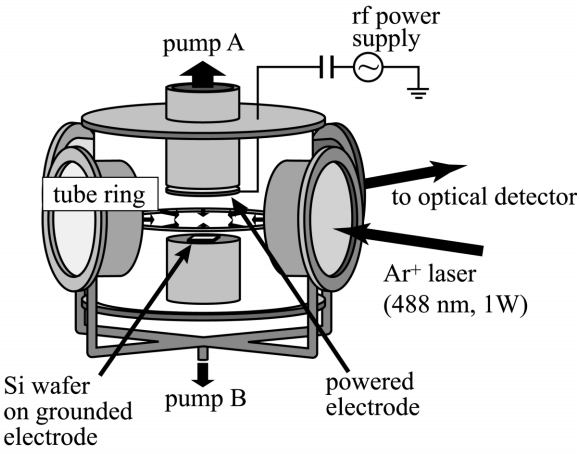

Fig. 1. Reactor A.

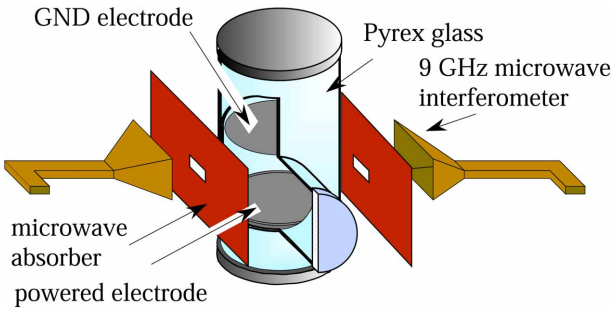

Fig. 2. Reactor B.

the discharge column from a tube ring of 240 mm in diameter, having 44 nozzles of 1mm in diameter directed to the center of the ring, which was placed at 10 mm above the grounded electrode as shown in Fig. 1. The flow rate and pressure were 5-30 sccm and 9.3 Pa, respectively. The discharge frequency and power were 28-60 MHz and 2-15 W (0.018-0.13 W/cm^2) respectively. Gas was pumped out through the powered electrode by a mechanical booster pump (pump A) and through four ports on the side wall by a rotary pump (pump B). Gas flow through the powered electrode contributes to reduce cluster growth in the radical generation region around the plasma/sheath boundary. When the grounded electrode is heated up to about 250˚C, gas temperature gradient drive clusters above a few nm in size to the powered electrode of room temperature. The pump B was employed to reduce accumulation of clusters due to their reflection at the wall and stagnation of gas flow.

The reactor B was described in detail elsewhere [12, 13]. Figure 2 shows the reactor B. For this reactor, two stainless steel plane electrodes of 85 mm in diametaer were placed at a separarion of 50 mm in a Pyrex glass vessel of 94.5 mm in inner diameter, and they were at room temperature. Pure SiH_4 gas was fed into the reactor at a flow rate of 5 sccm and a pressure of 13.3 Pa. The discharge frequency used was 13.56, 40 or 60 MHz, and the power was 10W (0.18 W/cm^2) for 13.56 and 40 MHz or 20W (0.35 W/cm^2) for 60 MHz, respectively.

Langmuir probe and 9 GHz microwave interferometer were employed for measuring densities of plasma ions and electrons [11]. The DPD and the PCLLS methods were employed to detect clusters in silane discharges [5-7]. For the DPD method, the size and density of clusters are determined by using both the density decay of clusters due to their diffusion and that of plasma electrons due to their attachment to clusters after turning off the discharge. For the PCLLS method, the size and density of clusters are determined by using time evolution of intensity of laser light scattering (LLS) from clusters due to their coagulation and diffusion after turning off the discharge. In order to obtain information on radical generation rate, emission intensities from Si and SiH, were measured with an optical detection system composed of apertures, lens and a monochromator.

For deposition experiments, two kinds of Si wafers were placed on the grounded electrode in the reactor A. One is Si (111) wafer with a high resistivity (1000-5000 Ωcm) for the measurement of microstructure parameter R_α of a-Si:H film, which is defined as the ratio of absorption intensity at 2100 cm^{-1} (Si-H_2 stretching mode) to that at 2000 cm^{-1} (Si-H stretching mode) which are measured by Fourier-transform infrared (FTIR) spectroscopy. In order to obtain a high sensitivity for R_α, the FTIR measurements were carried out in a vacuum with averaging more than 64 spectra, and also baseline determination and wave-form separation of the

FTIR results were made carefully. The other is n^+Si (100) wafer for the measurement of fill factor (FF) of a n^+Si/a-Si:H/Ni Schottky solar cell, which is defined as the ratio of the maximum power of the cell to the product of the short-circuit current and the open-circuit voltage. The FF was measured by irradiating an AM 1.5 solar spectrum light of 100 mW/cm^2. For the FTIR and FF measurements, the a-Si:H films of 1 μm in thickness were deposited at a substrate temperature of 250˚C.

3. Results and Discussion

3.1 Effects of discharge frequency on cluster amount

To study effects of discharge frequency f on growth of clusters, time evolution of their size and density was measured for f= 13.56, 40 and 60 MHz. The results together with time evolution of electron density n_e are shown in Fig. 3. The maximum n_e value increases from 1.7x10^9 cm^{-3} for 13.56 MHz to 1.3x10^{10} cm^{-3} for 60 MHz. The n_e value falls to a quasi-steady state value of about 1.5x10^9 cm^{-3} for 40 and 60 MHz, whereas ion densities for all f values (not shown here) and n_e for 13.56 MHz are nearly constant. Kinetic energy of electrons in a low energy bulk regime of an electron energy distribution, corresponding to the electron temperature T_e, becomes lower for the higher f and, hence, electron attachment to cluster becomes notable for the higher f, because the attachment cross section increase considerably with decreasing the electron energy. Therefore, the n_e value begin to decrease when clusters become detectable at around 2-3 ms after the discharge initiation for 40 and 60 MHz. Optical emission intensities of Si 288 nm and SiH 414 nm become high for a higher discharge frequency (not shown here), indicating a higher radical genaration rate or a higher depostion

Now, we focus our attention to cluster growth. For three cases, small clusters have an almost constant size of 0.5 nm and their density is about 1x10^{11} cm^{-3} in steady state of T_{on}> 100 ms. Large clusters are nucleated at T_{on}≈5 ms for 40 and 60 MHz, and ≈10 ms for 13.56 MHz. For three f's, they grow at an almost

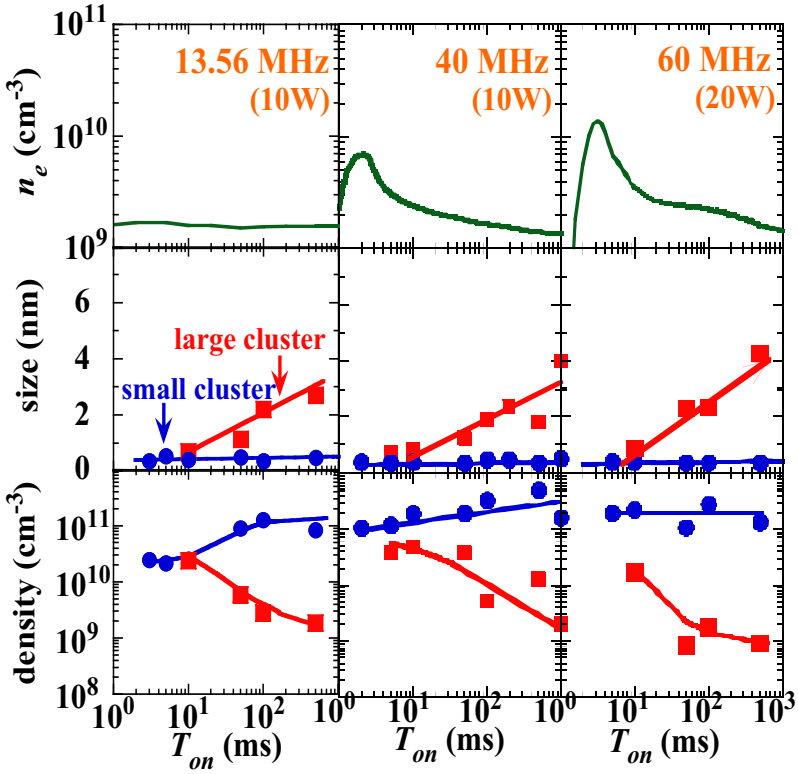

Fig. 3. Time evolution of electron density n_e, as well as size and density of clusters as parameter of f. Experimental conditions: SiH_4 (100%), 5 sccm, 13.3 Pa.

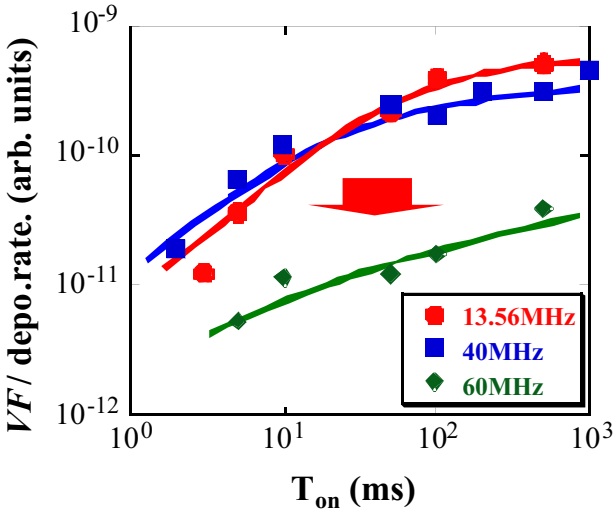

Fig. 4. Time evolution of volume fraction of clusters normalized by deposition rate. Experimental conditions: SiH_4 (100%), 5 sccm, 13.3 Pa.

same growth rate of about 4 nm/s. Their steady state density is about $1x10^9$ cm^{-3}.

Effects of f on the amount of clusters, incorporated into depositing a-Si:H films, were studied by evaluating a ratio of volume fraction of all clusters to a deposition rate, since most clusters generated in the discharge space are neutral and hence their amount is proportional to that of clusters incorporated into the films, if a sticking probability of clusters to the films is insenstive to the dischrage frequency and cluster size. The results are shown in Fig. 4. While the ratios for 13.56 and 40 MHz are almost the same, the ratio for 60 MHz is 1/10 of those for 13.56 and 40 MHz respectively. The result suggests that the incorporation of clusters is drastically suppressed for 60 MHz.

3.2 Effects of H_2 dilution on cluster amount

Effects of H_2 dilution on cluster amount was studied by the DPD method, since the dilution is often employed to deposit device quality films at a high deposition rate. The results are shown in Fig. 5. While n_e is almost the same value for the three P_{SiH4} values, large clusters cannot be detected for P_{SiH4}=20 and 50%. Moreover, the density of small clusters for P_{SiH4}=20% is 1/10 of those for P_{SiH4}=50 and 100%, whereas their size of 0.5 nm is insensitive to P_{SiH4}.

Effects of H_2 dilution on the amount of clusters, incorporated into depositing a-Si:H films, were studied by evaluating a ratio of volume fraction of all clusters to a deposition rate. The results are shown in Fig. 6. The

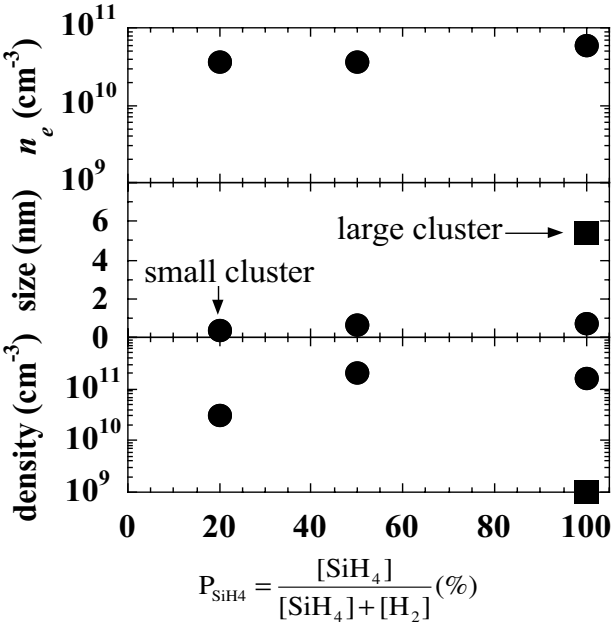

Fig. 5. Dependence of n_e, and size and density of clusters on P_{SiH4}.

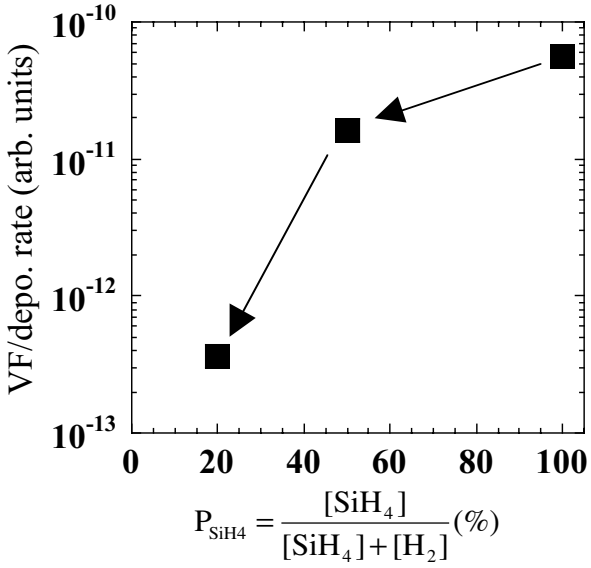

Fig. 6. Dependence of volume fraction of clusters normalized by deposition rate on P_{SiH4}.

ratios decreases drastically with decreasing P_{SiH4} value. The result suggests that the incorporation of clusters is drastically suppressed by employing an appropriate H_2 dilution.

3.3 Dependence of microstructure parameter on deposition rate

Gas flow near the powered electrode was found to have a great influence on R_α by using the powered electrodes 1 and 2: the electrode 1 was designed without considering the gas flow, while the electrode 2 was carefully designed for reducing gas stagnation regions near the powered electrode. Figure 7 shows dependence R_α on deposition rate. Solid circles and squares indicate results for the powered electrode 1. The value of R_α=0.084 at a high deposition rate of 0.74 nm/s for 60 MHz still remains low compared to R_α=0.115 at a rate of 0.38 nm/s for 28 MHz. Open squares in Fig. 7 show results for the electrode 2. The R_α values are notably low compared to those for the electrode 1. Especially, a-Si:H films of $R_\alpha \approx 0$ is deposited at 0.55 nm/s for the electrode 2. These results show that the VHF discharge and reduction of gas stagnation region are effective in reducing R_α.

Finally, we examine dependence of light-induced decrease of fill factor FF of a n^+Si/a-Si:H/Ni Schottky cell on SiH_2 concentration in a-Si:H films. Figure 8 shows our results (solid squares) together with the results of AIST (open cicles)[3]. Reduction ΔFF due to light irradiation tends to decrease with decreasing the SiH_2 concentration in a-Si:H films. Since the R_α value is proportional to the SiH_2 concentration and R_α=0.1 corresponds to a SiH_2 concentration of 1 atomic %, the results indicate that suppression of cluster amount brings about reduction of light-induced decrease in a-Si:H solar cell efficiency, which is proportional to FF.

4. Conclusions

The cluster amount is found to be reduced more than one order of magnitude using 60 MHz discharges or using H_2 dilution of H_2/SiH_4 ratio of 5. We have shown that the combination of the cluster-suppression

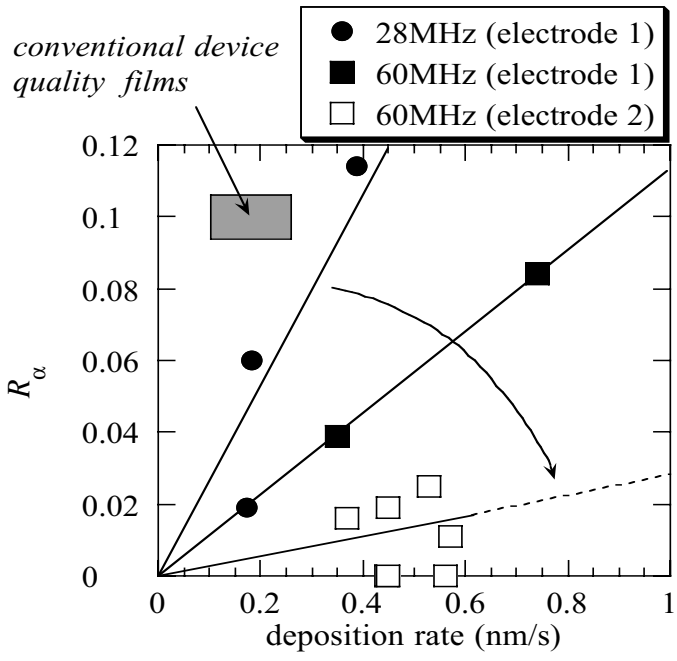

Fig. 7. Dependence of microstructure parameter on deposition rate.

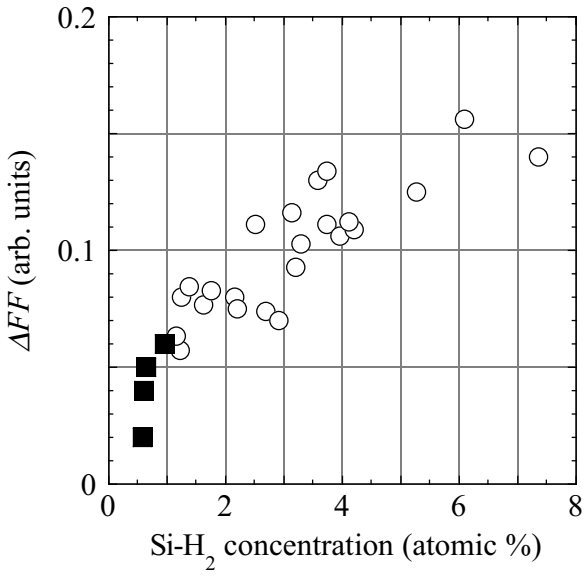

Fig. 8. Dependence of light-induced decrease of fill factor on SiH_2 concentration in a-Si:H films.

method and the VHF discharge is effective in depositing a-Si:H films of $R_{\alpha} \approx 0$ at 0.55 nm/s . The key for reducing the light-induced degradation is suppression of cluster amount in silane high frequency discharges for a-Si:H film deposition.

SURFACE MODIFICATION OF 8620 STEEL BY PULSE PLASMA TECHNIQUE AFTER PRIOR CARBURISATON PROCESS

Y.Yaralı, M.Durman, H.Akbulut

Sakarya University Engineering Faculty Department of Metallurji and Materials Eng.

The Pulse-plasma technology allows to produce surface strengthening of parts of machines and tools, and deposition of high performance coating from oxides and carbides. The technology and equipment are developed for modifying surface of tools and other pieces. The pulse-plasma technology and equipment for the high-energy of coating from metal oxides and hard alloys have been developed. The offered pulse-plasma technology provides a low consumption of alloying elements and electric power in combination with high productivity and the technology. These make it possible to treat only working (cutting) surfaces, which solves the problem of increasing wear resistance without any change in structural state of the entire workpiece.

In our study, the wear behaviour of detonation pulse plasma treated AISI 8620 steel was evaluated. The conventional carburizing steel was subjected to prior surface hardening by using two different carburisation routes. After a carburisation for 2 hours at 900 °C the first group of samples was quenched by air. The second group of the carburized steel was quenched into an oil bath which heated to 250 °C. The surfaces of these two group of samples were modified by nitrogen and argon gases by using plasma pulse technique appling two different battery capacities of 800 and 1000 C, μF. and, three different sample-plasma gun nozzle distances of 60, 80 and 100 H,mm. The surface modified steels were subjected to a ball-on-disc wear test and the wear rates and the friction coefficient values were determined.

Abstract

Tuneable infrared diode laser absorption spectroscopy has been used to detect the methyl radical and nine stable molecules, CH_4, CH_3OH, C_2H_2, C_2H_4, C_2H_6, NH_3, HCN, CH_2O and C_2N_2, in H_2-Ar-N_2 microwave plasmas containing up to 7 % of methane or methanol. It was found that HCN and NH_3 are the main final products of plasma chemical conversion. The fragmentation rates of methane and methanol and the respective conversion rates to HCN and NH_3, CH_4, C_2H_2, C_2H_4 and C_2H_6 have been determined for different H_2 to N_2 ratios. A model of the chemical reactions in the H_2-N_2-Ar-CH_4 plasma has been developed.

1. Introduction

Plasmas containing hydrocarbon precursors are used in a variety of plasma enhanced chemical vapour deposition (PECVD) systems to deposit thin films with advantageous mechanical, electrical or optical properties. By varying the plasma parameters coatings with a wide range of chemical and physical properties can be produced to open up new fields of application. This is a challenging subject for plasma technology. The key to an improved understanding of plasma chemistry and kinetics in such chemical active discharges is the analysis of the fragmentation of the precursor and the monitoring of transient or stable plasma reaction products, in particular the measurement of their ground state concentrations. This can be done by specific diagnostic methods using absorption spectroscopy. The decomposition of hydrocarbons in non-equilibrium plasmas containing reactive species has been the subject of a variety of experimental and theoretical studies. Some recent examples with nitrogen admixture shall be given here; a more comprehensive discussion related to oxygen admixtures can be found in [1-4].

Tuneable infrared diode laser absorption spectroscopy (TDLAS) in the mid infrared spectral region between 3 and 20 µm is a non-invasive technique for measuring number densities of stable molecules and radicals. TDLAS can also be used to determine neutral gas temperatures [1] and to investigate dissociation processes [2-4]. Due to their small laser line width (about 10^{-4} cm^{-1}) the lead-salt diode lasers used in the mid infrared region are well suited for high resolution spectroscopy purposes, e.g. of low molecular weight free radicals and molecular ions [5,6].

The TDLAS method allows also time resolved measurements with repetition rates exceeding 1 kHz. The time dependence of the conversion of methane to the methyl radical and three stable C-2 hydrocarbons was studied e.g. in surface wave plasmas [3]. Recently new compact and transportable TDLAS systems for plasma and gas phase process diagnostics and control have been developed. These use up to four diode lasers operating simultaneously and independently with a time resolution as short as ten microseconds [7,8].

2. Experimental

A detailed description of the experimental arrangement of the absorption cell and the discharge system can be found elsewhere [2]. A multi-pass optical arrangement was added to the planar microwave plasma source to improve the dynamic range by about one order of magnitude. The discharge configuration in planar microwave discharges has the advantage of being well-suited for end-on spectroscopic observations because a considerable homogeneity can be achieved over relatively long plasma path lengths (figure 1). The dimensions of the vessel used here were 150 × 21 × 15 cm^3. As described in ref. 2 the measurements were performed at a microwave frequency of 2.45 GHz and a power of 1.5 kW in an unpulsed plasma regime, corresponding to a power flux in the TDLAS observation plane of about 10 W cm^{-2}. Investigations were done under flowing and static discharge conditions. The gas flows were measured on mass flow controllers and then the gases mixed before entering the reactor. They were pumped out via a port in the reactor wall. The gas mixture supplying the reactor consisted of *x* sccm H_2+ 60 sccm Ar + *y* sccm N_2 + *z* sccm CH_4 or

CH_3OH. The total flow rate and pressure were kept constant at 555 sccm and 1.5 mbar respectively. For both methane and methanol containing gas mixtures four different flow rates (*z*) were selected: 5, 15, 25 and 40 sccm corresponding to 0.9, 2.7, 4.5 and 7.2 % of the total flow rate, respectively. When nitrogen was added the proportion of hydrogen was reduced correspondingly to maintain a constant flow rate.

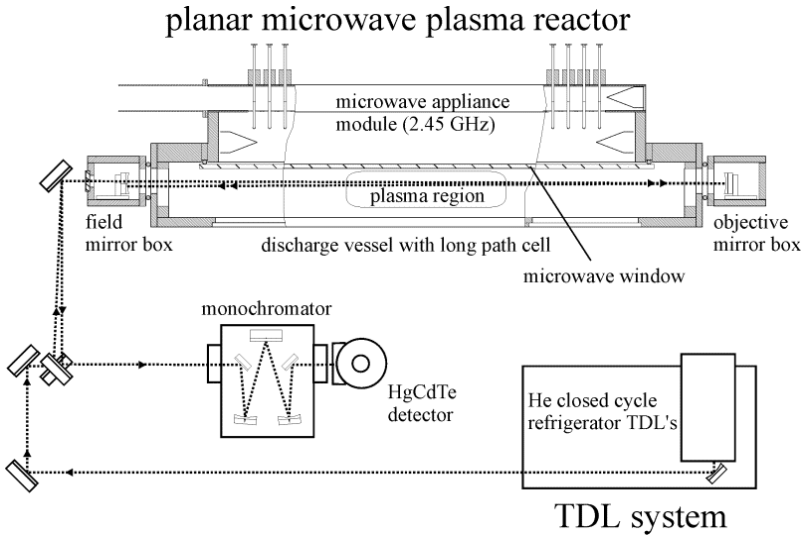

Figure 1: Experimental arrangement of the planar microwave plasma reactor (side view) with White cell multiple pass optical arrangement and tuneable diode laser infrared source. The laser beam path is indicated by dotted lines.

A representative TDL absorption spectrum of a H_2-Ar-N_2-CH_3OH microwave plasma with lines due to methanol and the methyl radical is shown in figure 2. The identification of lines and the measurement of their absolute positions were carried out using well documented reference gas spectra and an etalon of known free spectral range for interpolation. Absolute species concentrations are determined by non-linear least square fitting the measured lines and integrating the area under the transition. This data acquisition was carried out by a special software package described in detail in [7,8].

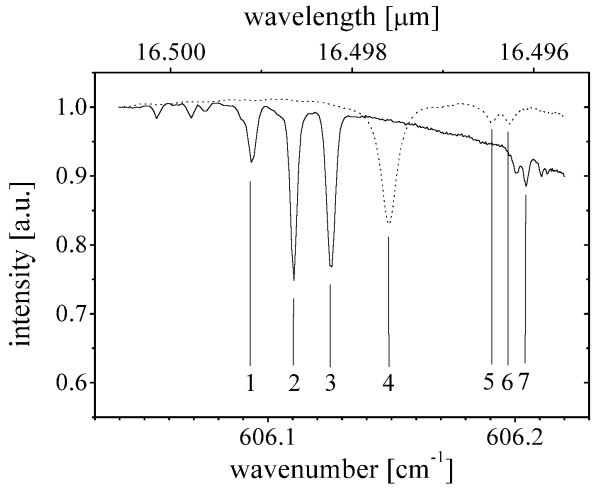

Figure 2: TDL absorption spectra of some methyl and methanol lines in a H_2-Ar-N_2-CH_3OH discharge (1,3,7 – CH_3; 2 – CH_3OH; 4,5,6 – N_2O). The dotted lines due to N_2O are from a reference gas cell placed in the beam path.

3. Results

General features

TDLAS has been used to detect the methyl radical and nine stable molecules, CH_4, C_2H_2, C_2H_4, C_2H_6, CH_3OH, CH_2O, NH_3, HCN and C_2N_2 in H_2-Ar-N_2 microwave plasmas containing up to 7.2% of methane or methanol. The concentrations of these species measured at nitrogen flows of up to 455 sccm are shown in figure 3 and 4 for flowing gas discharge conditions. The initial flow used in these figures for methane and methanol (40 sccm) was selected to represent typical flows used in practical CVD reactors.

The wide range of concentrations measured for the different species provides a convenient means for detailed discussions below. The degree of dissociation of the hydrocarbon precursor molecules varied between 20 and 97 %. It was determined from their concentrations measured before starting and in the discharge. The highest concentrations are for the precursor molecules and the major products HCN and NH_3 presented in figure 3, followed by the stable and unstable hydrocarbon products (C_2H_2, C_2H_4, C_2H_6 and CH_3, figure 4). Both HCN and NH_3 concentrations rise under flowing conditions rapidly as the proportion of nitrogen reaches 25 % and then they are approximately constant. In the case of methanol admixture methane is the dominant hydrocarbon product. Besides, C_2H_6 and C_2H_2 are produced with concentrations of 10^{13}-10^{14} molecules cm^{-3}. The CH_3 radical concentration was found to be in the range of 10^{13}-10^{14} molecules cm^{-3} too. Under all circumstances, C_2H_4 showed lower concentrations than the other hydrocarbons. For methanol in the gas flow H_2CO was observed as the prior dissociation product.

In contrast to the other species for the admixture of methane C_2N_2 rises steadily with the amount of nitrogen admixture in the plasma up to the maximum proportion of nitrogen. C_2N_2 was the species with the lowest concentration of all those studied.

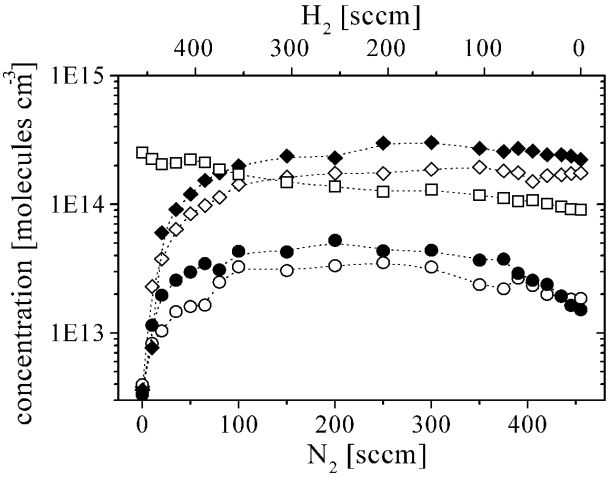

Figure 3: Molecular concentrations of final products under flowing discharge conditions over the nitrogen flow rate for methane (closed symbols) and methanol (open symbols) admixture. (Λ,M - HCN, ●,○ - NH_3, □ - CH_4).

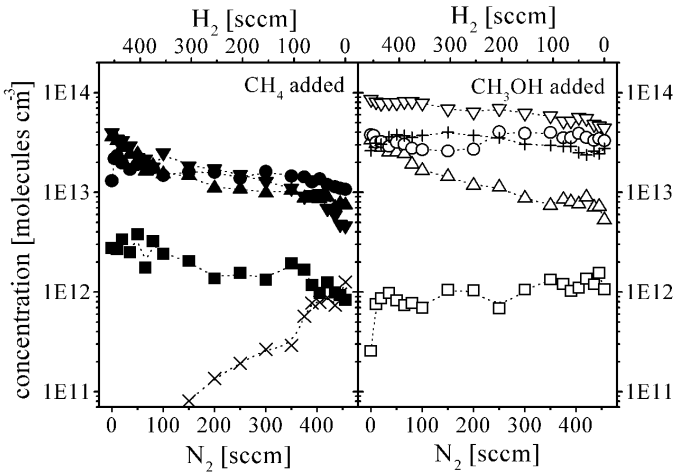

Figure 4: Molecular concentrations of hydrocarbons produced under flowing discharge conditions for methane (closed symbols) and methanol (open symbols) admixture over the nitrogen flow. (▲,△ - C_2H_2, ■,□ - C_2H_4, ▼,▽ - C_2H_6, ●,○ - CH_3, × - C_2N_2, + - CH_2O).

Fragmentation and Conversion Rates

To gain further insight into plasma chemical conversion the experimental data concerning methane and methanol dissociation was used to estimate absolute fragmentation rates of methane and methanol and conversion rates to the measured main products CH_4, HCN and NH_3. These rates are normalised on the discharge power.

The fragmentation rate R_F of the hydrocarbon precursor molecules methane and methanol is introduced by analogy to [3] as

$$R_F = \Phi_P \; 1/60 \;\; D/100 \;\; N_o/P$$

where R_F has the units of molecules J^{-1}, Φ_P is the precursor flow (sccm), D is the degree of dissociation of the precursor molecules given in percent, N_o is the number of molecules per cm^{-3} at norm conditions (2.69×10^{19} molecules) and P is the power (W).

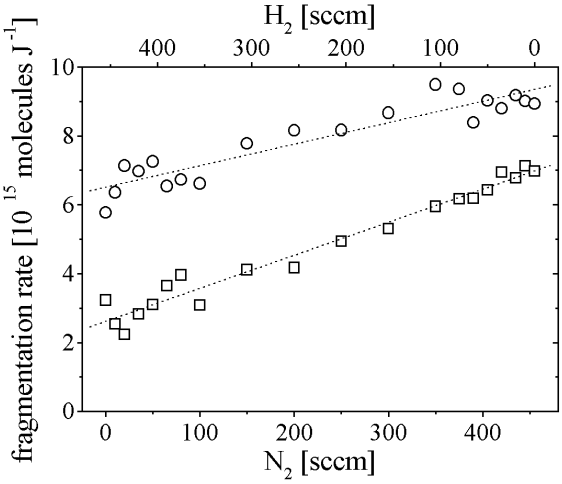

Figure 5: The rate of fragmentation of methane (□) and methanol (○) under flowing discharge conditions for various H_2 / N_2-ratios (CH_3OH, CH_4: 40 sccm).

Figure 5 shows the respective rate of fragmentation of methane and methanol for increasing nitrogen flows containing 7.2 % of the precursor gas and for flowing conditions. In nitrogen-free plasmas the rate of fragmentation of methanol ($R_F(CH_3OH) \approx 6 \times 10^{15}$ molecules J^{-1}) is twice as high as for methane ($R_F(CH_4) \approx 3 \times 10^{15}$ molecules J^{-1}). Adding nitrogen to the plasma, while keeping the total gas flow and the discharge pressure constant, i.e., varying the ratio of H_2 to N_2, both rates of fragmentation increase nearly linearly up to about 7×10^{15} molecules J^{-1} for methane and about 9×10^{15} molecules J^{-1} for methanol. Similar

results have been obtained for other admixtures of hydrocarbon precursors. In general smaller admixtures of hydrocarbons resulted in lower fragmentation rates. The values of the fragmentation rates of methane at high nitrogen flow rates presented here are near to those found in a H_2-CH_4 surface wave discharge at a comparable high total gas flow rate [3].

The conversion rate R_C to plasma product molecules is expressed analogously as

$$R_C = n_{molecule} \ \Phi_{total}/60 \ 10^3/p \ 1/P$$

where R_C has the units of molecules J^{-1}, $n_{molecule}$ is the measured molecular concentration in molecules cm^{-3}, Φ_{total} is the total gas flow in sccm, p is the pressure in mbar and P is the power (W).

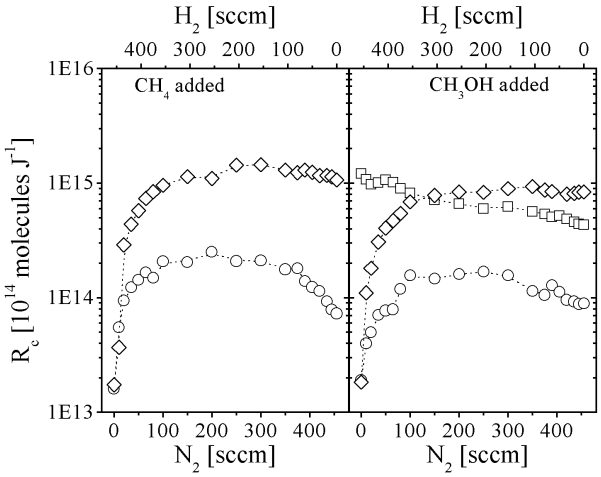

Figure 6: The rates of conversion to HCN (M), to NH_3 (–) and to CH_4 (∀) under flowing discharge conditions for various H_2 / N_2-ratios (CH_3OH, CH_4: 40 sccm).

Figure 6 shows the rates of conversion to HCN and NH_3 in H_2-Ar-N_2 microwave plasmas containing methane as well as the corresponding conversion rates, including that to CH_4, for plasmas containing methanol. The rates of conversion to particular reaction products are based on the measurements of their absolute concentrations. They range between 10^{14} to 10^{15} molecules J^{-1}. The conversion rate to HCN is about one order of magnitude higher than that of NH_3. H_2-Ar-N_2 microwave plasmas with methane as precursor tend to show slightly higher conversion rates compared to the methanol case. Both rates of conversion rise steeply to a maximum at the ratio of H_2 to N_2 of 1:1. Thus, CH_4 was detected in methanol containing plasmas, its conversion rate decreases from 12 – 4 x 10^{14} molecules J^{-1} with increasing nitrogen flow rate.

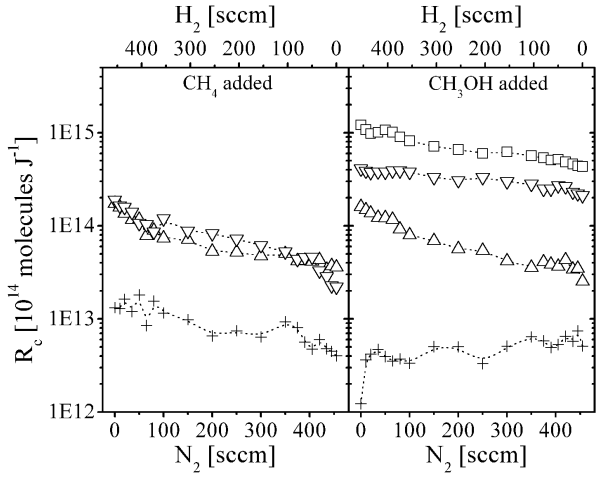

Figure 7: The rates of conversion to CH_4 (∀), to C_2H_2 (8), to C_2H_4 ( ) and to C_2H_6 (X) under flowing discharge conditions for various H_2 / N_2-ratios (CH_3OH, CH_4: 40 sccm).

Conversion rates to hydrocarbon products are presented in figure 7. While the values for C_2H_2 and C_2H_4 are similar for methane and methanol as precursor, the conversion rate to C_2H_6 is in the methanol admixture case by a factor of about 4 higher. A major difference in comparison with ref. 3 is that in the present work for high flow rates and methane as precursor hydrocarbon similar conversion rates to C_2H_2, C_2H_4 and C_2H_6 were found. These values are by a factor of about five smaller. This is mainly caused by the additional conversion to HCN and NH_3 under the presence of nitrogen in the actual gas mixtures.

Plasma Chemistry Model

The experiments were accompanied by model calculations of the kinetic processes in a plasma under static discharge conditions. The model established for a typical mixture composition of 73 / 9 / 11 / 7 % of H_2 / N_2 / Ar / CH_4 includes 22 species with 30 electron impact dissociation processes and 78 chemical reactions. Various rate coefficients for electron impact dissociation needed were determined by solving separately the time-dependent electron Boltzmann equation for given values of the reduced electric field, microwave frequency, mixture composition and recommended cross section data until approaching the periodic state. The data for neutral chemical reaction rate coefficients were taken from literature.

In principle the 22 species included in the model can be gathered into five different groups. First, there are the precursor molecules and their electron impact dissociation products. These eventually form NH_3, HCN and CH_4 or C_2H_6 by thermal reactions in the discharge volume. Species containing the CN group are mainly formed by the interaction of hydrocarbons with nitrogen or with species of the NH_3-group. In contrast, the production of NH_3 or hydrocarbons was found to be relatively independent of the hydrocarbon chemistry.

A comparison of calculated and measured species concentrations is shown in figure 8. A satisfactory agreement within the order of magnitude of the errors of the measurements was found for the species, which have been monitored by TDLAS. Moreover, concentrations of further species, in particular of important transient species, e.g. CH_2, C_2H_5, NH and NH_2, can be estimated from the result of the model calculations.

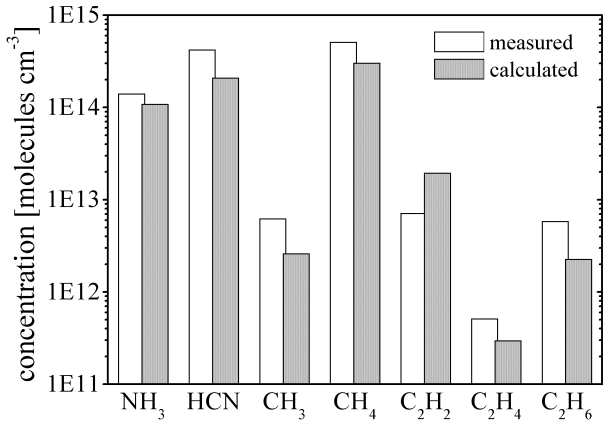

Figure 8: Comparison of measured and calculated species in a H_2-N_2-Ar-CH_4-plasma.

Atmospheric Pressure Afterglow Plasma In Argon

Navin Muthuswamy[1], Bijan Pashaie[2], and Shirshak Dhali[1]

[1]*Department of Electrical Engineering, Southern Illinois University, Carbondale, IL 62901*
[2]*Department of Engineering Physics, Southeast Missouri State University, Cape Girardeau, MO63701*

Abstract

An RF driven atmospheric pressure plasma source is discussed. The plasma produces an afterglow, which can be used for plasma chemical reactions under ambient conditions. The light intensity measurement shows that the discharge is continuous in time unlike low frequency discharges, which are intermittent in nature. The gas temperatures are near ambient and the afterglow temperatures do not exceed 180 ^{o}F.

1. Introduction

At atmospheric pressures, there are two popular methods for producing non-thermal plasmas; (1) a corona discharge and (2) a barrier-type ac discharge. Although corona discharges have found

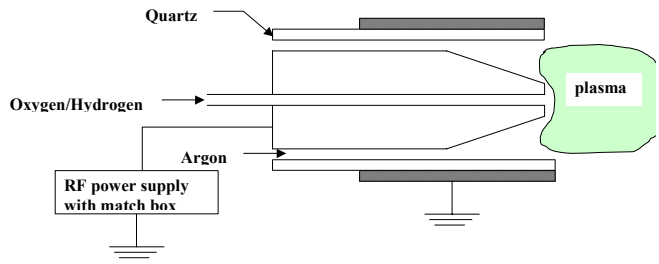

Fig. 1: Schematic of the atmospheric pressure discharge,

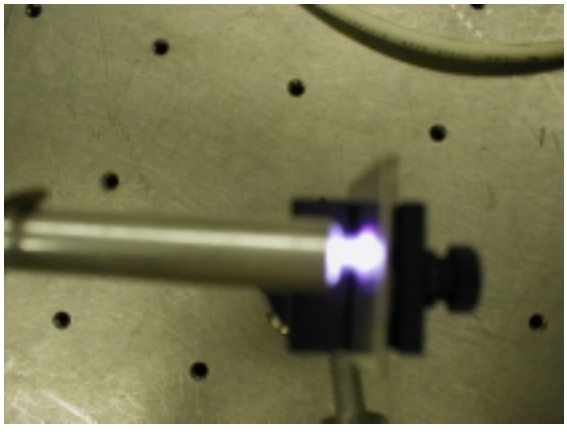
numerous applications, they are not particularly suitable for large surface or volume gas phase plasma processing [1]. The dielectric-barrier discharge, also known as a silent discharge or a partial discharge, is widely used in industry for ozone synthesis. These discharges are best characterized by streamers, which are a result of space charge dominated transport at high electric fields [2]. A



Fugure2: The picture of an atmospheric afterglow in a radio frequency Argon discharge.

disadvantage of existing plasma sources is that the specific energy (energy per unit volume of the processing gas) is low. This is a major shortcoming for adaptability to manufacturing processes. We have taken a different approach for the generation of plasma under ambient conditions. The discharge

has been used to treat metal surfaces prior to coating. Peel test, and XPS results show that Ar/H_2 and Ar/O_2 plasma are effective in cleaning the metal surface and produce superior coatings.

In plasma chemical devices, the aim is to produce desired radicals to carry out a particular reaction. The main thrust for atmospheric pressure plasma for our application is the production of H and O radicals and Ar ions. For efficient cleaning the production of radicals rather than gas heating is important. The ambient afterglow discharge is a cold discharge with most of its energy being utilized for the production of excited species. In $Ar/He/H_2/H_2O$ plasma the following electron impact processes will be present

$$Ar + e \rightarrow Ar^+ + 2e \text{ and } Ar^* + e$$

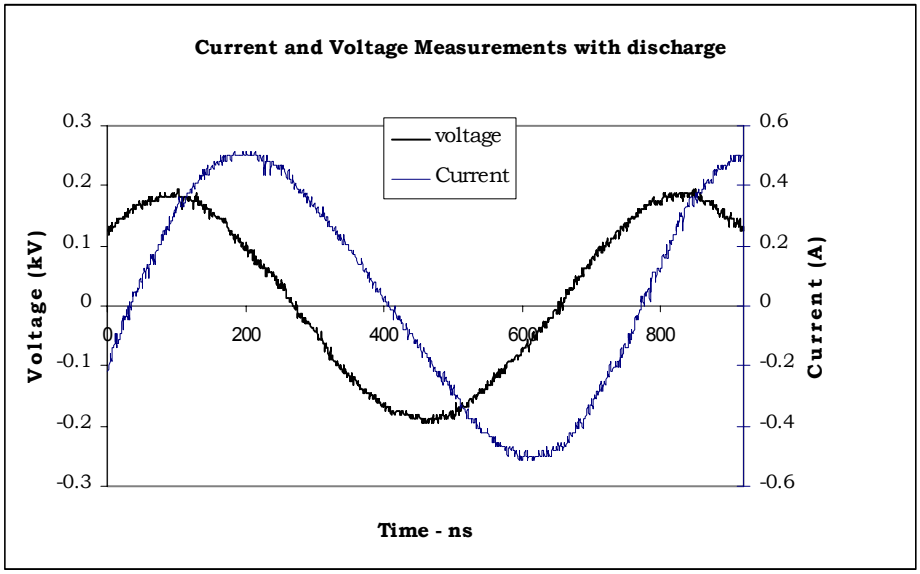


Fig 3. RF current and voltage waveforms at 13.56 MHz.

$$H_2 + e \rightarrow 2H + e$$

$$He + e \rightarrow He^+ + 2e \text{ and } He^* + e$$

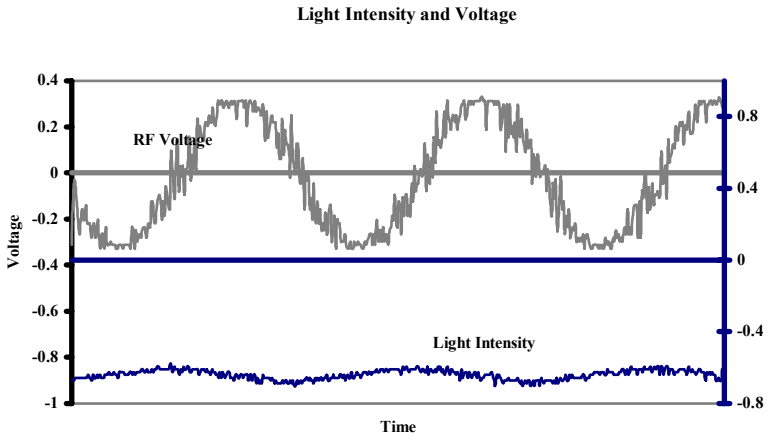

Figure 4: The integrated light output (relative) along with RF voltage as a function of time.

2. Results and Discussions

Shown in Fig. 1 and Fig.2 are the schematic and the picture of the plasma source. In the

configuration shown, the discharge is "struck" in the noble gas (Argon) and the reactive gas is added to the afterglow. The centered electrode is bored to allow the reactive gases to flow into the afterglow. This is critical for the stability of the discharge: Gases like H_2 and O_2 are attaching and change the physical characteristics of the discharge. Due to increase in breakdown voltage, even for concentration of reactive gases in few percentages, it is difficult to strike a discharge using radio frequency (RF). RF is the most suitable power source because it can be tuned to the load easily compared to low frequencies: Low frequency discharges have very high capacitive current, which is difficult to correct. Similar discharges at radio frequency are being investigated [3]. The discharges

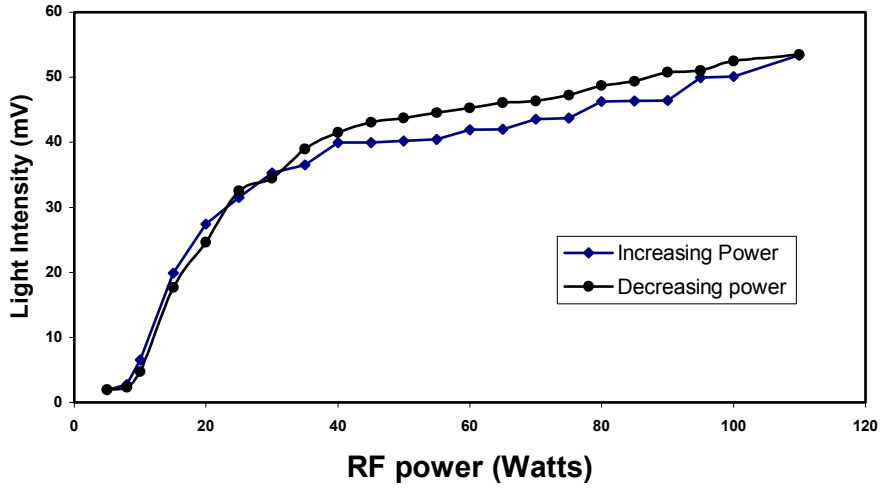

Figure 5: The light intensity as a function of RF power input.

by Park et al. produce a narrow plasma jet and are stabilized by very high flow of helium at 600 Torr. Our approach does not depend on high gas flow, but uses a dielectric to stabilize the discharge.

Figure 3 shows the RF current through the discharge and the voltage across the discharge. The RF current was measured with IPC CM-10-M (0.1 V/A into 50 Ω) current monitor. The current waveform is sinusoidal indicating a temporally uniform discharge. Figure 4 shows the total light intensity along with the voltage waveform. Again, the light is uniform in time therefore the discharge at 13.56 MHZ is temporally uniform. At low frequencies the dielectric barrier discharge is

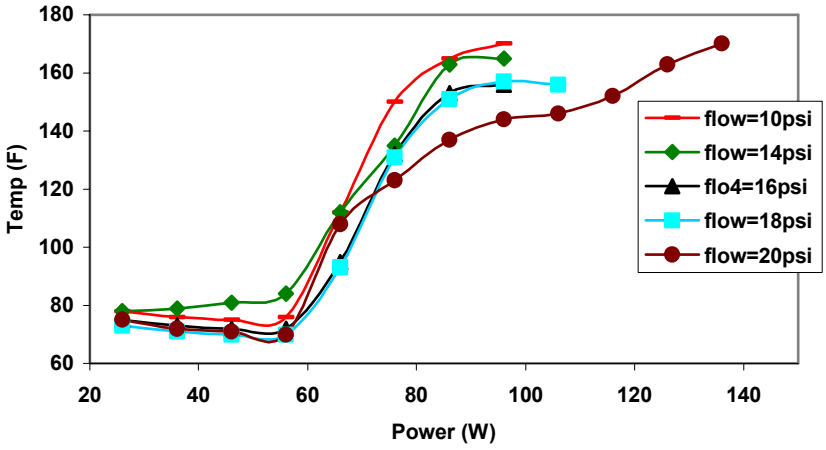

Figure 6: The afterglow temperature on axis at the exit of the discharge.

intermittent unlike Fig. 4 [4].

The afterglow was investigated by optical spectroscopy In an Ar/H_2 discharge the H_α and the H_β lines increase with increasing discharge power. In Ar/O_2 plasma, the dissociated oxygen line shoed a strong emission line. Figure 5 and 6 show the total light output and the gas temperature at the exit as a function of RF power. The temperature profile of the afterglow was obtained and the maximum

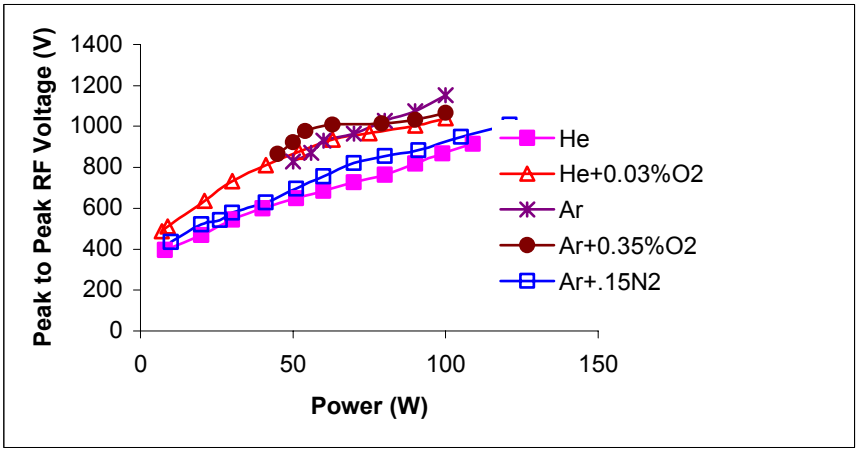

Figure 7: Voltage versus power for different gas composition.

value found on axis was about 60^0 C. With increasing RF power, the light intensity stars to saturate whereas, the gas temperature increases rapidly. It is clear that energy partitioning at higher powers favor gas heating as opposed to other nonelastic processes.

The discharge power, P, in a dielectric-barrier type discharge is given by [4][5]

$$P = 4fV_c'[c_d V_p - (c_g + c_d)V_c] = 4fV_c' c_d [V_p - \frac{(c_g + c_d)}{c_d} V_c] \qquad (1)$$

where f is the power frequency, c_g and c_d are the gap and dielectric capacitance respectively, v_p, v_c', and v_c are the peak to peak applied voltage, the critical gap voltage required to sustain a discharge, and the critical voltage at which the gap breaks down, respectively. The RF discharge discussed in this paper, the c_g=4.1 pF and c_d=7.7 pf. The voltages v_c and v_c' are nearly equal, however we have observed that v_c' tends to be lower than v_c [4]. This equation shows that the power input to a dielectric type discharge has a linear dependence on voltage. At low frequencies, dielectric-barrier discharges show this characteristics for all gases [4] [5]. Shown in Fig. 7 is the measured relationship between the discharge power and voltage for the RF discharge. For pure monatomic gases, the linear relationship predicted by the equation 1 is observed. The slope of the pure He and Ar depends on the critical field required for breakdown. However with trace amount of molecular gases the voltage starts to saturate with power. Due to the continuous nature of discharge, the vibratioanlly excited molecules, especially nitrogen, lower the critical voltage required for maintenance of discharge. This discharge is more pronounced at higher powers.

3. Conclusions

An ambient afterglow plasma source driven by RF power source has been demonstrated. The discharge at RF is continuous and behaves like a dielectric-barrier discharge. However at higher powers, the vibrationally stored energy in trace amounts of molecular gases start to influence the discharge.

Abstract

The results of using ambient plasma for cleaning and treating metal surfaces are presented. Metal surfaces are cleaned with atmospheric pressure argon/hydrogen or argon/oxygen plasma. The cleaned surface was characterized by XPS and was found to consist of exposed metal with very low carbon content. Profilometry and optical imaging results show that plasma are very effective in removing oil and paint coatings from the surface of metals. New sol-gel coatings on metal surfaces were investigated for their corrosion properties.

1. Introduction

There are various types of corrosion that can occur on the surface of steel: direct oxidation, atmospheric corrosion, electrochemical corrosion, stress corrosion, and galvanic corrosion. To prevent rusting or corrosion, ferrous metals must either be isolated from the environment or coated in such a way that the corrosion reactions are neutralized. Good protection is associated with good adhesion, and this requires a clean surface.

The basic principle of treatment processes for steel is chemical reaction of the metal surface to produce a compound, which is more resistant to corrosion than the metal itself. Very thorough cleaning of the steel surface necessarily precedes the coating processes. The conventional methods of cleaning consist of blast cleaning, flame cleaning, acid pickling, solvent wipe, and vapor degreasing [1]. The conventional methods produce substantial toxic waste, which are difficult to dispose. As noted in the Waste Management Research Center (WMRC TN98-043) fact-sheet, industries have begun to look for alternatives to chlorinated and organic solvents [2]. For specific types of contaminants, alternatives such as aqueous cleaners, semi-aqueous cleaners, and liquid carbon dioxide have found limited use [2]. Chlorinated solvents, despite their adverse environmental effects, are still used in critical cleaning of metal parts. Various less or non-hazardous metal parts cleaning processes for the preparation/masking of parts and metal surfaces for electroplating are currently under development. However, these processes tend to be either costly or less effective compared to the chlorinated solvent processes. Hence the search for a cost effective and efficient cleaning process continues.

Plasmas can produce a clean and activated surface, which can produce chemical conversion coating with sol-gels. Chemical reactions under plasma state are very specific and can be controlled. It can be easily manipulated to produce a reducing or oxidizing atmosphere by the proper choice of additives (H_2, O_2, H_2O, and H_2O_2). Therefore plasma is very effective in cleaning and pre-treating surfaces prior to coating and electroplating.

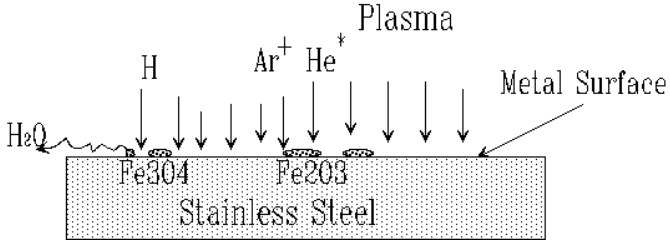

Fig. 1. Interaction of the plasma with the metal surface.

At atmospheric pressures, there are two popular methods for producing non-thermal plasmas; (1) a corona discharge and (2) a barrier-type ac discharge. Although corona discharges have found numerous applications, they are not particularly suitable for large surface or volume gas phase plasma processing [3][4]. The dielectric-barrier discharge, also known as a silent discharge or a partial discharge, is widely used in industry for ozone synthesis. These discharges can best be characterized as streamers, which are a result of space charge dominated transport in high electric fields [5].

In plasma chemical devices, the aim is to produce desired radicals to carry out a particular reaction. The main thrust for atmospheric pressure plasma for our application is the production of H and O

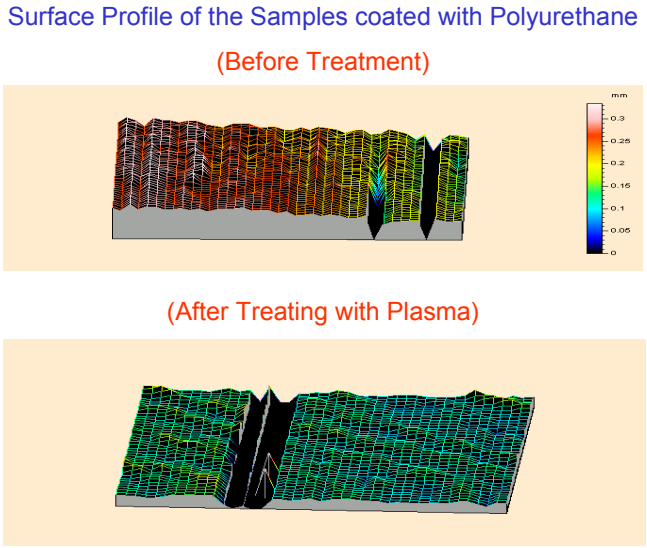

Figure 2: Results of Argon/Oxygen plasma treatment on a polyurethane coating on steel for 30 sec.

radicals and Ar ions. For efficient cleaning the production of radicals rather than gas heating is important. The ambient afterglow discharge is a cold discharge with most of its energy being utilized for the production of excited species. In $Ar/He/H_2/H_2O$ plasma the following electron impact processes will be present

$$Ar + e \rightarrow Ar^+ + 2e \text{ and } Ar^* + e$$
$$H_2 + e \rightarrow 2H + e$$
$$He + e \rightarrow He^+ + 2e \text{ and } He^* + e$$
$$H_2O + e \rightarrow H + OH$$

Modification of solid surface arising from interaction with non-thermal plasma can be broadly classified as surface cleaning and alteration, chemical alteration, etching, film deposition and texturing [6]. Non-thermal plasmas are used to remove trace contaminants and to produce rearrangement of atomic or molecular configuration, usually in preparation for further processing of the surface. The chemical composition of surface and near surface regions can also be altered by interactions with plasmas.

The interaction of the plasma with the metal surface is depicted in Fig. 1. The H atoms reduce the iron oxide along with physical sputtering by the heavy Ar^+ ions. It is expected that M-OH type of bonds will be introduced which will improve the binding properties of coating. However, the ion bombardment is not as intense as in a low-pressure discharge due to short mean free paths at high pressures. In addition to the neutral radicals, the plasma is also a rich source of UV and visible radiation. However the additional important species are the Argon metastables. These species are

long lived and have energies in 8-10 eV (electron volts). These species are capable of inducing surface reactions and break up bonds.

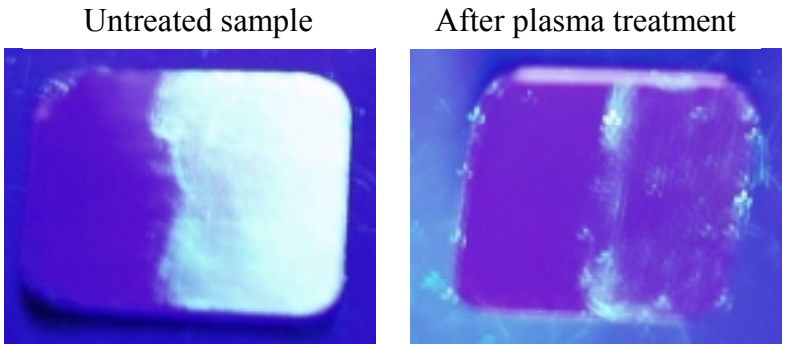

Figure 3: The bright area on the samples shows machine oil with a UV fluorescent dye. After plasma treatment of the same sample in Argon/Oxygen plasma for 30 seconds most of the oil has been removed.

A plasma treated surface can remove scaling and irregularities by hydrogen etch. This will be helpful in better adhesion of the further coating materials as well prevent corrosion of the metal surface itself by making the surface more homogeneous. Such a surface is likely to be resistant to corrosion due to removal of chemically active steps and other microdistortions [7].

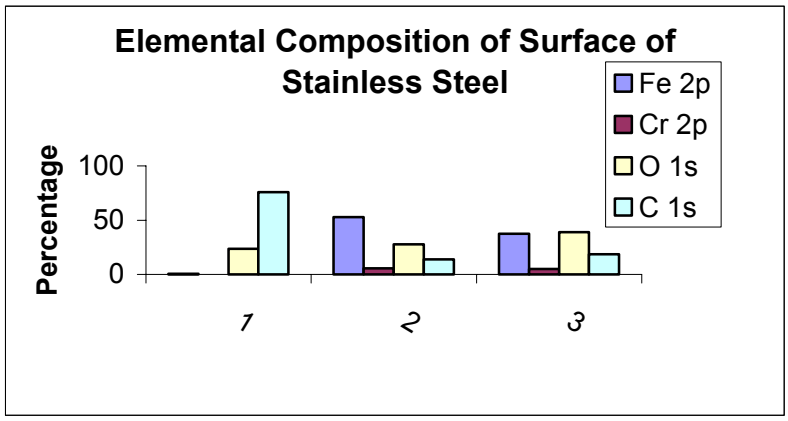

Figure 4: XPS analysis of stainless steel surface. The blank sample of steel has a coating of adhesive on it. (1) The surface composition of the blank. (2) The surface after 30 seconds of Ar/H_2 plasma treatment. (3) The surface composition after 30 seconds of He/H_2 plasma.

2. Results and Discussions

A survey of currently used methods for the removal of coatings suggests that plasma processing can be competitive due to pollution prevention. Preliminary results of plasma treatment of polyurethane on steel are shown in Fig. 2: Polyurethane is a hard durable coating and difficult to remove. The removal in Fig. 2 suggests that oxygen plasma can be very effective for removal of coatings. Traditional methods for the removal of coatings, from aircraft structures and components involve the use of chemical formulations containing strong solvating chemicals such as methylene chloride and methyl alcohol activated with strong organic acid or base materials. Scraping and/or sanding were required between applications of the strippers to remove the blistered and loosened coating. This

process involved the release of Ozone Depleting Chemicals, Volatile Organic Compounds, Hazardous and Toxic vapors, Hazardous Air Pollutants as well as the production of large volumes of contaminated wastewater from the rinsing process that is required [8].

Results from simple qualitative experiment demonstrate the effectiveness of plasma in removing contaminants. Shown in Figure 3 is a sample, which is partially coated with oil and subsequently treated with plasma. An oil soluble fluorescent dye was added to the oil to photograph the oil film.

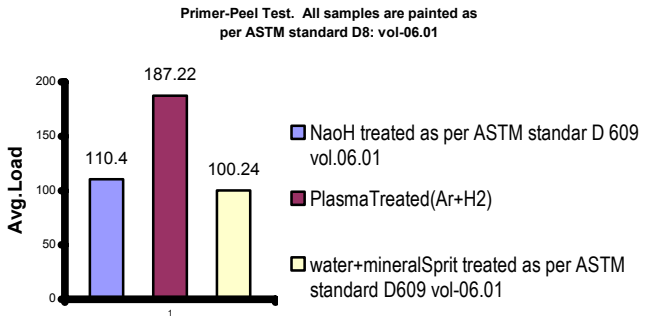

Figure 5: Peel strength for a zinc-based primer on steel.

The sample treated with Argon-Oxygen plasma for 30 seconds shows the nearly complete removal of oil from the surface of the metal. Machine oil is a silicone based organic that is high temperature resistant and stable under most chemical attack. However, an oxygen plasma removes the oil film by plasma chemical reaction through the O^* radicals to produce volatile compounds.

XPS analysis of a stainless steel surface (the surface had a layer of adhesive from a protective backing) treated with and without plasma is shown in Figure 4. The plasma used was hydrogen/argon. The untreated surface shows primarily carbon and oxygen from ester type adhesive compound. The plasma treatment removes majority of the carbon and exposes the iron and chromium. From the energy shift of the $O^1(s)$, it can be concluded that the O is bonded as OH groups to the metal on the surface. Macroscopic analysis such as contact angle adhesion of coatings and microscopic analysis such as XPS and infrared spectroscopy were used to characterize the surface and understand the cleaning mechanism.

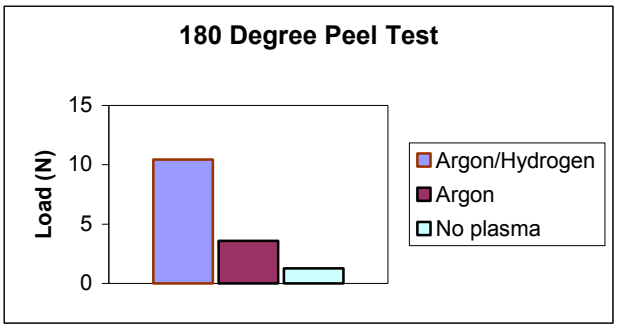

Figure 6: Peel test results of polyurethane coating on stainless steel samples. The treatment with Ar/H_2 plasma for 30 seconds shows the best peel strength.

The results presented are significant for this project as it validates the technical feasibility of the

proposed method. Figure 5 shows the results of peel strength of zinc oxide primer on steel. The Ar/H_2 plasma treatment for 30 s produces coatings, which are over 50% stronger, compared to two ASTM standards [9]. Results of polyurethane coating are even more dramatic for surfaces that are plasma cleaned compared to untreated samples. As shown in Figure 6, there is significant improvement in peel strength with plasma cleaning prior to polyurethane coating on stainless steel. The results are shown for samples, which were untreated and treated under various conditions. Treatment with Ar/H_2 plasma is most effective in cleaning compared to Ar plasma alone. The H_2 in the plasma produces the highly reactive H atoms that attack organic compounds from adhesives, grease and oil and produce volatile products.

3. Conclusions

This technique is a non-polluting alternative to surface treatments that currently use chemicals/solvents. In addition the plasma has been shown to improve the binding properties by uniformly hydroxylating the surface. The results from this research will allow the integration of plasma processes into manufacturing of metal parts.

Addition of oxygen to liquid fuel oils by means of non-equilibrium plasmas

Pedro Patiño

Escuela de Química, Facultad de Ciencias, Universidad Central de Venezuela,
P.O. Box 47102, Caracas 1041A, Venezuela

Abstract
The oxidation of 6 model liquid hydrocarbons, mixtures of them, and 3 commercial diesel fuels, by means of low pressure high-voltage oxygen plasmas was studied. O_2 pressure was 0.2 mbar, applied power was 35 W and reaction times ranged from 1 minute to 23 hours. Olefins were the most reactive with ground-state atomic oxygen, $O(^3P)$. Addition of 4.7 to 7.8% wt of oxygen was achieved for the diesels, depending on the particular composition.

Introduction
The use of oxygenate compounds as additives in fuel formulations improves the combustion process in engines because they diminish particulate emissions (PE), non-burnt hydrocarbons and carbon monoxide[1]. Recently, various types of oxygen containing compounds have been tested in engines to determine the effects of oxygenates on exhaust emissions[2-4]. Among 7, tripropylene glycol mono-methyl ether and dibutylmaleate have been the most promising for diesel engine testing[5-6]. PE has been 26.1% below that of the base fuel for 7% wt. of oxygen.
Oxidation of fuel oils has also been performed classically by means of methodologies based on $KMnO_4$ and $K_2Cr_2O_7$ with catalysts and pH adjustment[7-9]. More recently, O_2 low pressure plasmas have been employed to increase the cetane number of a light diesel fuel by 66%[10].
The interaction of plasmas with gases and solids has been studied extensively, leading to numerous syntheses techniques[11] and methods for surface modifications[12]. Under certain conditions, electrical discharges through molecular oxygen produce predominantly ground state atomic oxygen, $O(^3P)$. This species in turn reacts with liquid organic compounds[13-19].
This paper is devoted to the oxidation of commercial diesels by means of low pressure high-voltage oxygen plasmas. In order to fully understand the contribution of the different fractions forming part of every diesel, the oxidation of n-heptane, 1-octene, toluene, *cis*-decahydronaphthalene, mixtures of them, 4-phenyl-1-butene and 1,2,3,4-tetrahydronaphthalene have been investigated separately.

Experimental
The reactions were carried out by allowing the oxygen plasma to reach the low vapour pressure liquid substrate. The plasma was produced by means of a high voltage discharge. A diagram of the experimental assembly is shown elsewhere[17]. The reactor was a glass vessel of ca. 300 ml, supplied with two electrodes made of aluminium and Teflon. O_2 was introduced through one of the electrodes, which was hollow. Applied power was 35 W for all experiments. The liquid (2 ml) was placed in the reactor, cooled by means of a methanol-liquid nitrogen bath, and magnetically stirred. The system was connected to a vacuum line; one trap was used to collect any volatile product. The O_2 flow was measured with a 247 B-MKS flow meter and the pressure was monitored with a Leybold-Heraeus TM111 thermotron. The products of the reactions were identified and quantified by using the following: a Varian 3800 GC/Saturn 2000 MS system; a Perkin Elmer FTIR 1700X spectrometer; a JEOL ECLIPSE 270 MHz NMR spectrometer.

Results
Model compounds
1-Octene
The oxidation of 1-octene was studied as a function of the oxygen pressure in the reactor, at a constant temperature of –90°C. The shape of the curve is very similar to that obtained for the optical emission signal of the $3p\ ^3P \rightarrow 3s\ ^3S$ (λ=844.6 and 844.7 nm) transition[10], that can be

correlated to the population of O I (2p ^{3}P), the ground state of atomic oxygen. The results confirm that O(^{3}P) is the most relevant oxidant species in the plasma. In fact, the production of oxygen atoms by electron impact with O_2 is scarce at the side of low pressure. When the latter is increased more atoms are produced but, at a certain pressure, the frequency of collisions between electrons and oxygen molecules becomes great enough to reverse the tendency. The electrons are not sufficiently accelerated by the electric field and hence most of them do not acquire enough energy to produce the dissociation of O_2. The pressure for maximum production of O(^{3}P) is somewhere between the two extremes.

Total conversion was maximum at about 0.2 mbar. At –90°C, the vapour pressure (*vp*) of 1-octene is 0.0022 mbar, thus the pO_2/vp ratio was 90.9, i.e., in agreement with earlier works[17,18]. Products were 1,2-epoxioctane (39.0% of the mixture) and octanal (21.0%) for 60 minutes of reaction; 2-octanol, 2-octanone, octanoic acid and compounds with two oxygenate groups were byproducts. No evidence of singlet O_2 ($a^1\Delta_g$) was detected in the optical emission spectrum under the conditions of the discharge. The corresponding hydroperoxide, product of the reaction of singlet oxygen with olefins, was not observed in the reaction mixtures.

Toluene

By fixing pO_2 at 0.2 mbar, oxidation of toluene was studied versus its temperature, for 60 minutes. Conversion reached a maximum of 16.0% at –95°C, *vp* of toluene being 0.0011 mbar, i.e., $pO_2/vp = 182$. *o*-Cresol represented 12.6% of the mixture while *p*-cresol and *m*-cresol were 2.3% and 1.1% respectively. By increasing the temperature more toluene molecules evaporate. Therefore these molecules, much bigger than O_2, compete advantageously with it for the electrons and the amount of O(^{3}P) in the plasma decreases. Due to this, the conversion of toluene decreases too. If the temperature is too high, then collisions between electrons and toluene dominate the plasma and fragmentation plus condensation products, arising from oxygen-free organic radicals, are the main products. From the point of maximum conversion to lower temperatures, the reactivity decreases. Close to the freezing point of the hydrocarbon, the interaction becomes one between oxygen atoms and a solid. It is well known that the reactivity in this case is negligible[17].

n-Heptane

The study of n-heptane had been performed earlier at lower power[17]. In order to explore the conditions for the mixture of hydrocarbons, its oxidation was repeated at –88°C, 0.2 mbar of oxygen ($pO_2/vp = 33$) and 60 minutes. Total conversion was 26.0%, products distribution being 3-heptanol > 2-heptanol > 4-heptanol > 3-heptanone > 2-heptanone > 4-heptanone. None of the ketones was among the products in the mixture at 15 minutes of reaction, thus confirming that these compounds are produced by successive oxidation of the alcohols[17].

cis-Decahydronaphthalene

cis-Decaline was studied at similar conditions used for the previous compounds, except for its temperature which was –40°C ($pO_2/vp = 20$). Total conversion was 10.1%, the most important products being *cis*-10-decahydronaphtol (36.9%), *trans*-10-decahydronaphtol (3.2%), 1-decahydronaphtol (4.8%), *cis*-1-decalone (5.8%), *trans*-1-decalone (3.4%), 2-decahydronaphtol (12.6%), *cis*-2-decalone (6.0%), *trans*-2-decalone (4.7%), 1,10-deca-hydrodinaphtol (2.2%) and 5,10-decahydrodinaphtol (4.1%).

4-Phenyl-1-butene

This is an interesting model for it contains olefinic, aromatic and paraffinic fractions. The working conditions different from those for previous compounds were temperature, –63.0°C ($pO_2/vp = 46$), and time of reaction: 1, 2, 3, 4, 5, 30, 60 and 120 minutes, respectively. The objective was to determine how the different fractions reacted with O(^{3}P). At 1 minute, all signals in the ^{13}C NMR spectrum were assigned to 4-phenyl-1,2-epoxibutane. Four more signals appeared at 2 minutes, assigned to 4-phenylbutanal. By increasing the time of reaction these signals became stronger, and four new signals were observed after 30 minutes. They were due to 4-phenyl-2-butanone. Two more, weaker than the latter, assigned to 4-phenyl-2-butanol, were

observed after 60 min. There was no evidence of reaction on the benzene ring, nor on the 2 paraffinic $–CH_2–$. This result confirms that olefins are more reactive with $O(^3P)$ than alkanes and aromatics[10]. Total conversion was 45% at 60 minutes, main products being the epoxide (48.0 %), the aldehyde (38.3 %), 4-phenyl-2-butanone (9.4 %), and 4-phenyl-2-butanol (2.3 %).

1,2,3,4-Tetrahydrohaphthalene

Tetraline possesses 4 different carbons that can be attacked by $O(^3P)$, two in the aromatic ring and two in the naphthenic fraction. It was oxidized at –28°C, i.e, $pO_2/vp = 22$. Total conversion rate was 19.0% at 60 minutes of reaction. The main products were 1-hydroxi-1,2,3,4-tetradydronaphthalene (*A*), 2-hydroxi-1,2,3,4-tetradydronaphthalene (*B*), 7-hydroxi-1,2,3,4-tetradydronaphthalene (*C*), and 8-hydroxi-1,2,3,4-tetradydronaphthalene (*D*), the proportion *C:B:A:D* being 1:1:1.23:2.29. This means that the aromatic fraction was ca. 1.47 times more reactive than the naphthenic fraction, in agreement with the ratio toluene/*cis*-decaline ≅ 1.58.

Fuel oils

Some properties of the three diesel fuels are given in Table 1, together with those of LCGO, a light gas oil product of a coking process, previously studied[17]. They are commercial fuels with particular specifications. In order that the $p(O_2)/vp$ ratio of each fuel was >20, each sample was cooled down to a temperature close to its freezing point, thus guaranteing that the amount of hydrocarbon molecules in the gas phase was low enough to avoid homogeneous gas-phase reactions. The working temperatures are given in the first raw of Table 1. All samples were treated at an oxygen pressure of 0.2 mbar for 23 hours.

The main feature in the IR spectra of the three diesels, after treatment with the oxygen plasma, was the appearance of the bands at 1100, 1750 and 3400 cm^{-1}, due to the –C–O, –C=O and –O–H stretchings respectively. This was the first evidence of the addition of oxygen to the fuels.

The three diesels had in common ^{13}C NMR signals in the regions (ppm): 9-48 (aliphatic) and 121-148 (aromatic). Olefinic signals, around 3.8-5.2 ppm in the ^1H NMR spectra, showed an integrated area of less than 1% of the aromatic ones. After 23 hours of reaction, new signals appeared in the ^{13}C NMR spectra, at 50-75 ppm and 90-122 ppm, corresponding to carbons α to OH groups, and CH α and β to OH. Week signals due to carbonyl groups were observed around 200 ppm. Signals at 118 ppm, due to phenols, were not observed.

Table 1. Properties of fuel oils and percentage of oxygen added with the plasma

Property	10% Aromatics (TPCA) -32 °C	Ultra low sulfur (ULS) -38 °C	Low sulfur (LS) -35 °C	LCGO[10]. -40 °C
API gravity	34.24	39.77	36.21	33.80

Oxygen content (% wt.)	7.8	4.7	7.0	16.8
Treatment time (hours)	23	23	23	3

*Prior and (after treatment). Oxygen was not detected for any original sample and nitrogen was the balance element. [§]After treatment.

Mixtures

Four mixtures were studied representing LCGO[10] and the three diesel fuels respectively. n-Heptane, *cis*-decahydronaphthalene, 1-octene and toluene were mixed to simulate them. LCGO was the most widely studied. The compositions of the simulated mixture and the original gas

oil, prior and after treatment, are given in Table 2. The amount of the olefinic fraction in the synthetic sample was higher (4.5%) than in the original one (3.1%). That is the reason why the former needed a shorter time to be oxidized. Samples treated for 10 minutes only showed some signals of products arising from the olefin, i.e., 1,2-epoxioctane and octanal, in the ^{13}C NMR spectrum. At 60 minutes, the conversions of the four components were: 1-octene (100%), n-heptane (49.7%), toluene (40.6%) and *cis*-decahydronaphthalene (12.8%).

Table 2. Properties of original and simulated LCGO prior and after treatment

Property	Original	Original treated –40 °C, 120 min	Simulated	Simulated treated, -90 °C, 60 min
Alkanes (vol %)	62.1	73.9	61.4	73.9
Aromatics (vol %)	34.8	26.1	34.1	26.1
Olefins (vol %)	3.1	0.0	4.5	0.0
Carbonyl index (%)*	0.0	6.0	0.0	2.4
Alcohols and epoxide Index (%)*	0.0	4.4	0.0	6.5

*Calculated from NMR spectra

Table 3 shows the results for the treatment of the three simulated diesel fuels, namely Ten Per Cent Aromatics (TPCA), Ultra Low Sulphur (ULS) and Low Sulphur (LS). The calculated $p(O_2)/vp$ ratio of each mixture was higher than 20 at –90 °C. TPCA fuel was the synthetic sample that gave the highest conversion with the oxygen plasma, in agreement with its highest original percentage of paraffins. The higher contents of oxygen in the treated simulated samples compared to those of the original ones could be related to the fact that no poly-aromatic compounds were employed in the mixtures. These species are less reactive than mono-aromatics becasuse of the lower number of C-H bonds per carbon atoms in the former.

Table 3. Total conversions of simulated fuel oils treated with the oxygen plasma (0.2 mbar) for 23 hours. Temperature: -90 °C

Parameter	**TPCA**	**ULS**	**LS**
Paraffins (%)	60.1	74.7	77.3
Naphthenes (%)	32.5	2.0	13.2
Aromatics (%)	7.4	23.3	9.5
Total conversion (%)	35.0	28.3	33.5
Oxygen (% wt.)	12.1	9.4	11.0

Discussion

Among the different kind of hydrocarbons studied, olefins have shown to be the most reactive with $O(^3P)$. This is due to the electrophilic character of $O(^3P)$, the most accepted mechanism for the reaction with olefins involving the formation of a diradical triplet transition state[20-22].

The mechanism for the reaction of $O(^3P)$ with alkanes is the abstraction of an H atom to produce an alkyl and an OH radicals, followed by their recombination to produce the alcohol[17].

The results for toluene are similar to those for other aromatic compounds[18], and they all agree with the proposed mechanism for reaction of $O(^3P)$ with olefins. The situation has been quite different when oxidation of toluene has been studied in a radio frequency homogeneous plasma, i.e., by introducing mixtures of oxygen and gaseous toluene in the reactor[24]. In this case, the product is a mixture of benzaldehyde, benzyl alcohol, phenol, *o-, m-,* and *p*-cresol, and bibenzyl.

The most important result of this study has been the successful addition of oxygen to LCGO and the three diesel fuels. They are difficult to oxidize by classical means with inorganic agents.

According to expectations, LCGO showed the highest reactivity, due to its highest percentage of olefins. The amount of this kind of hydrocarbons was meaningless in the three diesel fuels. The lowest oxygen percentage of the treated ULS fuel can be associated with the higher percentage of aromatics in its composition. This fraction has shown to be less reactive than paraffins. The

different reactivity of the three fuels could be understood after deeply analyzing their ^{13}C NMR spectra. This technique was used to calculate the proportions of the different kinds of carbon atoms in each fuel. This parameter should be more suitable than the whole amount of hydrocarbons to be correlated with the conversion of each fuel. The 5-60 ppm region of the ^{13}C NMR spectra of non-treated TPCA, LS and ULS fuels, presented in Figure 1, corresponds to the aliphatic carbons. The regions of aromatic carbons (110-150 ppm) of LS and ULS show similar signals while that of TPCA is much simpler, indicating the presence of a higher percentage of mono-aromatic structures in this fuel. This observation favours the latter, in the reaction with $O(^3P)$, respect this kind of hydrocarbons. The spectra show sharp signals at 14.2, 22.8, 29-30 and 32.0 ppm, due to linear alkanes. It has been shown that the integration of their areas permits to determine the relative percentage of this kind of structures in the respective fuel[25]. Results are given in Table 4. They show a higher amount of aliphatic carbons (95.75%) and lower amount of aromatics in TPCA fuel. This is in good agreement with the fact that this fuel added the highest amount of oxygen. Although LS and ULS fuels contain similar amounts of aliphatic and aromatic carbons, the ^{13}C NMR spectrum of the former shows well defined signals at 11, 19, 27, 37 and 40 ppm, assigned to branched-paraffins. These sharp signals are not observed in the spectrum of ULS fuel. The complexity and higher dispersion of the many weaker bands observed in the latter are indicative of hydrocarbons with poly-ringed naphthenic structures. These two observations, particularly the first, could explain the higher conversion of LS fuel compared to ULS fuel. It has been demonstrated that the different C–H of alkanes react with $O(^3P)$ in the order tertiary > secondary >> primary. This is due to the average bond strengths, 92, 95 and 100 kCal/mol respectively. As an illustration, n-heptane and 4-methylheptane have both 5 carbons potentially reactive with $O(^3P)$ at short to moderate times, that is not taking into account the methyl groups which react at times as long as 120 minutes[10,17]. Their treatment with the plasma, at 0.2 mbar of oxygen for 30 minutes, produced total conversions of 14.1 and 39.9% respectively, i.e., the conversion per reactive carbon was 2.8% for n-heptane and 8.0% for 4-methylheptane. This is obviously due to a 25.8% extra reaction on the tertiary C–H respect to the methylenes.

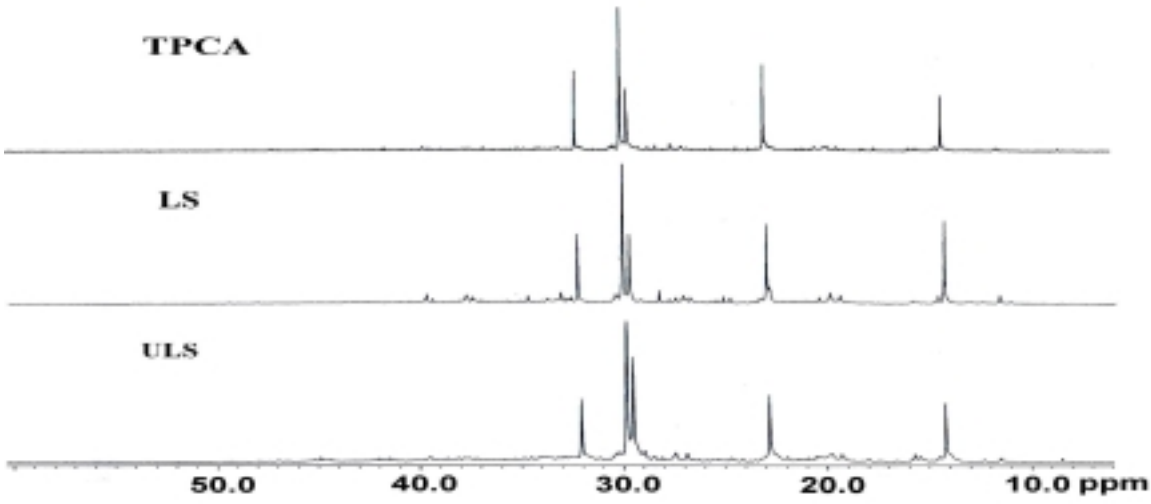

Figure 1. 75.4 MHz ^{12}C NMR spectra of the TPCA, LS and ULS fuel oils. Only the aliphatic region is shown.

Table 4. NMR percentages of different types of carbon in the diesel fuels.

Fuel	Aliphatic C (%)	Aromatic C (%)	n-Paraffinic C (%)
TPCA	95.75	4.25	34.38
LS	84.82	15.18	24.25
ULS	84.86	14.54	28.64

Conclusions

Once again, low pressure oxygen plasmas have proved to be an efficient tool to oxidize liquid hydrocarbons in one-step process. Addition of oxygen to commercial diesel fuels by this technique is comparable to mix them with commercial oxygenate compounds. This should traduce in improving automotive engine performance and reducing exhaust emissions.
Olefins are more reactive with $O(^3P)$ than the other kinds of hydrocarbons.

Plasma diagnostic of a pulsed MSIP-process by energy-resolved mass spectroscopy

E. Lugscheider, N. Papenfuß-Janzen
Materials Science Institute, RWTH Aachen University, Aachen, Germany

Abstract
Reactive Magnetron Sputter Ion Plating (MSIP) is a conventional process for the coating of tools. Nowadays, the coating of machine parts against wear and corrosion is an application of this process, as well. To produce homogeneous coatings and to achieve a higher efficiency, especially for the coating with insulating materials, the pulsed MSIP was developed. In this article, plasma diagnostic measurements of a pulsed MSIP process of TiAlN is presented using energy resolved mass spectroscopy showing the advantages of this process.

1. Introduction

Ceramic coatings show a good protection against wear and corrosion. Thus, they are commonly used to increase the life cycle of tools and machine parts. A coating process that is suitable for this application is magnetron sputter ion plating (MSIP). In this process, a target is mounted on a magnetron cathode where material is sputtered by impacting process gas ions, e.g. argon, produced by a low pressure glow discharge plasma. A thin ceramic compound forms at the metallic target, the substrate and the reactor walls during reactive MSIP. In this process mode, an reactive gas, e.g. oxygen or nitrogen, is supplied to the reactor in addition to the process gas. Due to the insulating behavior of a number of ceramics, e.g. Al_2O_3, a dc-voltage power supply to the cathodes is not suited for those materials. Instead of this, radio frequency (rf) plasmas are used to overcome this effect. The rf-MSIP process shows its potential in producing very homogeneous coatings, but it has only a low coating efficiency.
Within the last few years, the pulsed plasma technology has become an increasing importance. This technology shows the advantages of both process variations, the dc-MSIP and the rf-MSIP. Pulsed plasma MSIP is suitable for insulating coatings [1, 2] as well as for high quality, homogeneous coatings. Different types of pulsed plasma MSIP processes have been developed: sinusoidal and dc-voltage, single cathode and dual cathode mode, unipolar, bipolar, symmetric and asymmetric charged.
In this article, energy resolved mass spectroscopy measurements are presented. The reactive MSIP process of the well known coating material (Ti, Al)N was chosen for this purpose[3]. The mass spectrum in the sims mode (secondary ion mass spectroscopy) is shown and the titanium ion energy distribution for dc-MSIP is compared to the pulsed MSIP for different cathode power. The reason for the good performance of the pulsed process will be pointed out. At the end of the article, concluding remarks and an outlook to further research will be given.

2. Mass Spectroscopy

For the presented work a HIDEN EQP 300 mass spectrometer (Figure 1) was used. An excellent description of this diagnostic tool was given by Budtz-Jørgensen [4] and is sketched below. It was applied to a glow discharge sputtering unit to understand the argon-hydrogen plasma as well as the argon-nitrogen plasma in a plasma nitriding process. First measurements of the MSIP process to produce TiN coatings and TiWN were presented by Mišina et al. [5].
The HIDEN EQP 300 consists of five main sections. The functions of those sections should briefly be explained. The extraction section consists of the extractor and the lens 1. In this part the ions and neutrals that pass the orifice have to be directed towards the detector. The ionization source is only needed when measurements in the RGA mode are conducted. Then neutral particles are ionized by a dual-filament electron impact ionization source. The deceleration section consists of the axis, the lens 2 and the quadrupole lens. This section is needed to decelerate the ions to an energy of about 40 eV. Only at this low kinetic energy ions can pass the 45° bend to the analyzer. The energy filter is a 45° sector field energy analyzer, where ions are deflected by an electric field depending on their kinetic energy when the particles enter the section field. The last part of the HIDEN EQP 300 is the mass filter. This filter is a quadrupole mass spectrometer consisting of four metal rods with a superposed dc and rf voltage. Only particles with a special

mass-to-charge ratio can pass this filter and can be detected, while the other m/q ratios are removed by the rf-field and the dc-field, respectively.

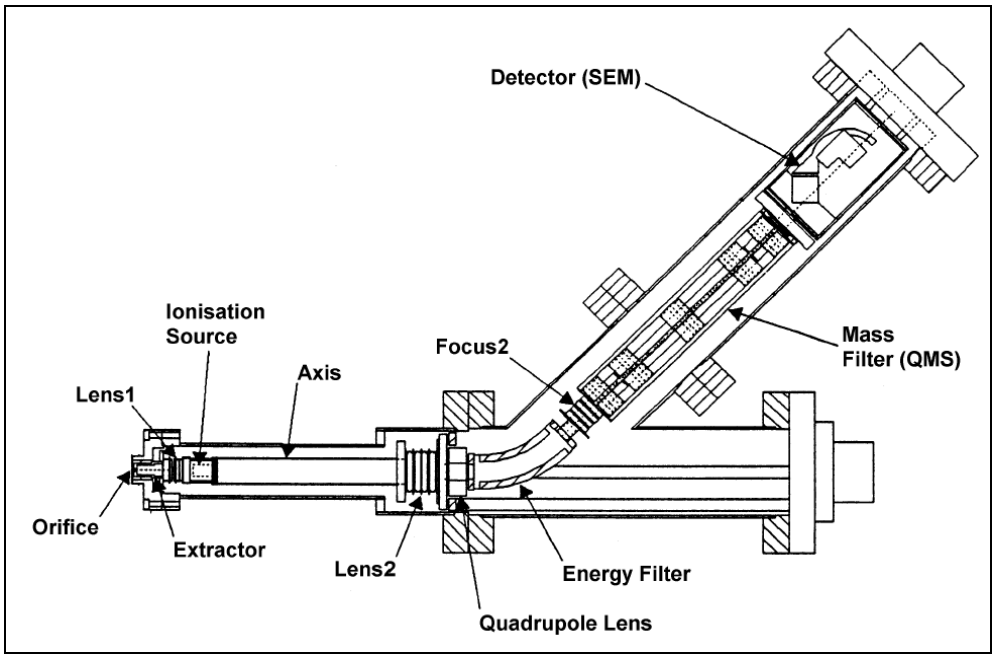

Figure 1: Assembly of the HIDEN EQP [4]

3. Experimental Details

The measurements were carried out with a HIDEN EQP 300 energy resolved mass spectrometer at the Materials Science Institute at the Aachen University on an industrial MSIP coating unit of the type CemeCon CC 800®/9 with four cathodes CST 288. The mass spectrometer was positioned parallel to the cathode with a distance of about 600 mm for the presented experiments. The observed coating material was (Ti, Al)N, produced by magnetron sputtering of two-component-Ti-Al-targets with nitrogen as a reactive gas. Argon and krypton were used as process gases.

The pulsed plasma experiments were conducted by using two sinusoidal pulsed power supplies of the type PE II by Advanced Energy Industries. These supplies operate in a dual cathode mode as shown in Figure 2. Two cathodes get a sinusoidal negative voltage, while the corresponding cathodes are discharged. The output frequency is 40 kHz. First results concerning the use of this technology on (Cr, Al) N coatings were presented, recently [6, 7].

The mass spectroscopy measurements were conducted in the sims mode. Therefore, only ions were detected and no further ionization of neutral particles was forced by high energy electrons.

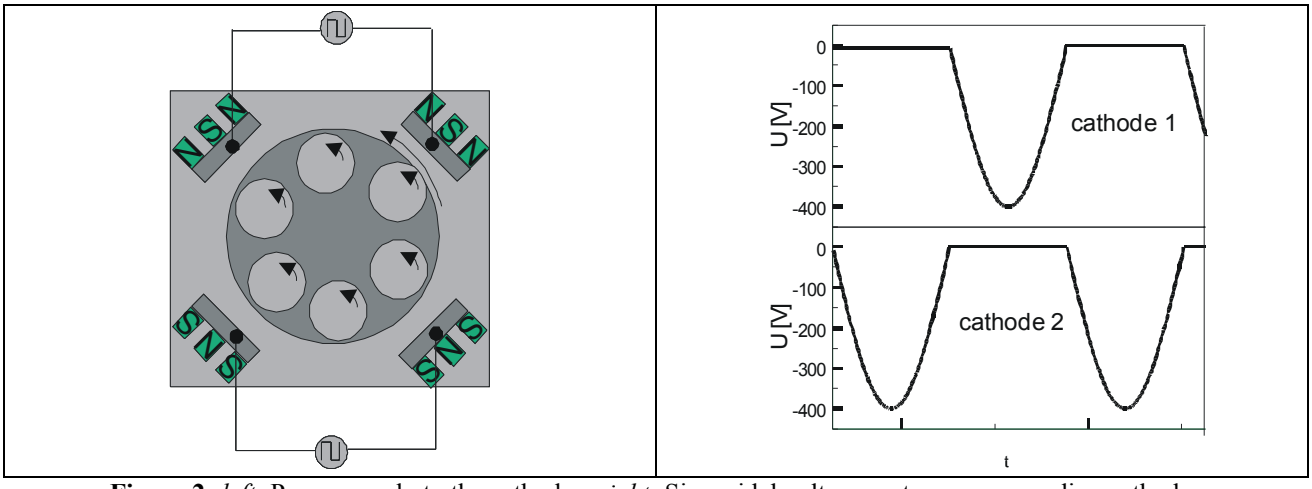

Figure 2: *left:* Power supply to the cathodes; *right:* Sinusoidal voltage on two corresponding cathodes

4. Results

First, a mass spectrum was taken in the dc-process as well as in the pulsed process with fixed gas flows and a power per cathode of 4 kW (Figure 3). It can be seen, that the spectra only differ slightly. Mainly, ionized gas atoms and molecules are detected (N^+, N_2^+, Ar^+, Kr^+). The ionization of the metal components Ti and Al is lower than the one of gases. It can be observed, that more titanium ions are detected than aluminum ions, which corresponds to the fact, that the sputter rate of titanium is much higher than the one of aluminum in the reactive mode. In this experiment, the ionization does not depend on the type of the power supply.

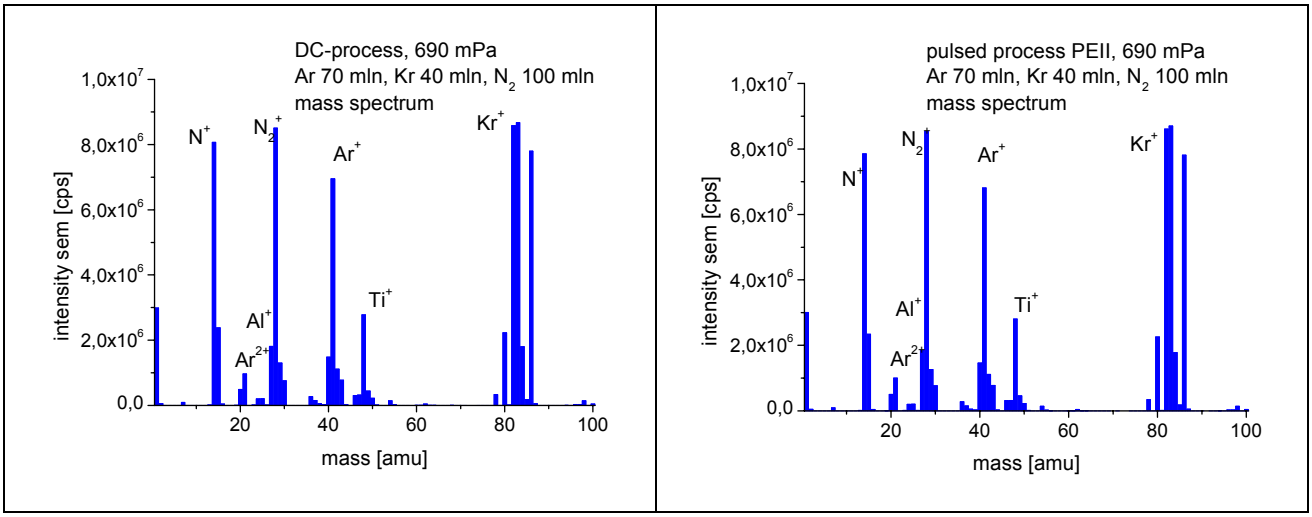

Figure 3: Mass spectra of a (Ti, Al)N coating process; *left:* dc-process; *right:* pulsed process

The energy distribution of Ti^+ 48 ions for different cathode powers is presented in Figure 4. In the dc-process, the maximum of the distribution is at about 5 eV. It can be seen, that there is a strong influence on the power per cathode on the intensity at the maximum. The increase of the detection intensity from 1 kW to 3 kW is more than one order of magnitude. However, the width of the distribution is only small (0-13 eV).
The ion energy distribution of the pulsed process shows a different behavior. The maximum of the distribution is at about 10 eV with only a slight increase of the intensity due to increasing cathode power. At 1 kW/per cathode a second maximum is observed at about 25 eV. With an increasing cathode power this maximum is flattened, but a broader distribution can be seen up to ion energies of 45 eV.

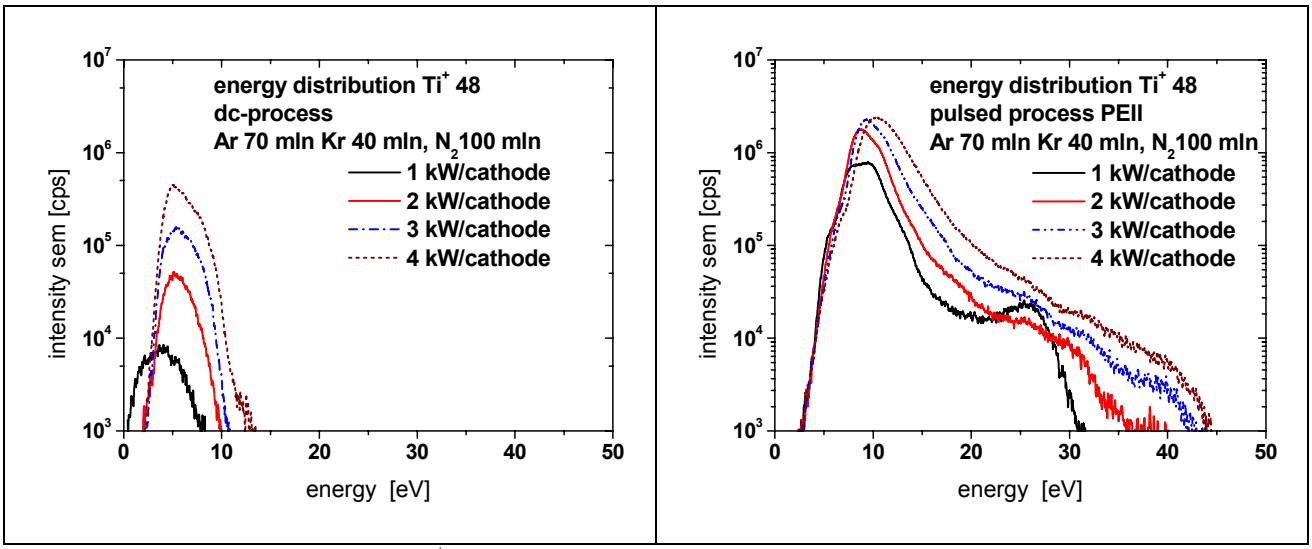

Figure 4: Energy distribution if Ti^+ 48 depending on the cathode power; *left:* dc-process; *right:* pulsed process

A characteristic value for the ion energy consumption is the integral of the distribution. The dependency of this integral on the cathode power is shown in Figure 5. Even with the lowest cathode power (1 kW/cathode) ions in the pulsed process have a higher energy than in the dc-process. Furthermore, a different behavior of the energy depending on the cathode power can be observed. While the pulse process exhibits an almost linear behavior, the energy increases superproportional with an increasing cathode power in the dc-process.

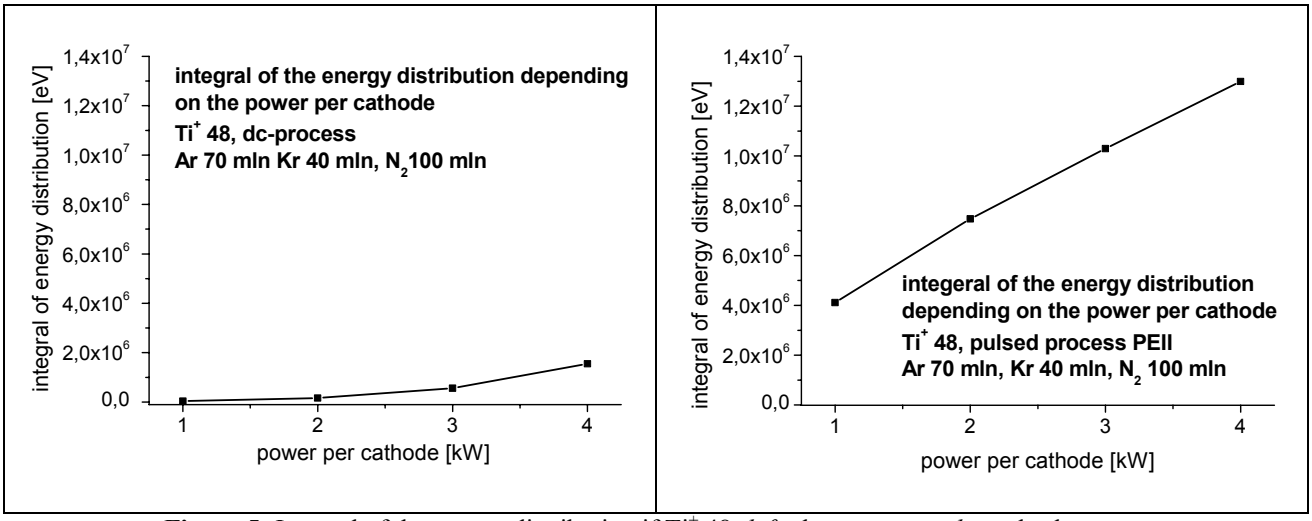

Figure 5: Integral of the energy distribution if Ti^+ 48; *left:* dc-process; *right:* pulsed process

5. Discussion

The results presented above underline the great potential of the pulsed MSIP process. It was shown, that the same cathode power in the pulsed process leads to a higher energy of ions. Thus, it can be explained why coatings from pulsed processes exhibit a more homogeneous structure.

In dc-processes the energy of the impacting ions and atoms is usually not sufficient to force the coating atoms to find the absolute minimum of the energy potential. Thus, the atoms stay in local potential wells forming a columnar crystalline structure. However, with the higher impact energy in the pulsed process the particles have a higher kinetic energy when they are caught at the substrate. The particles have a higher statistical probability to leave the local potential well to find the global minimum and form a homogeneous, crystalline structure. This is an effect that is observed in dc-processes. Coatings show a better quality when a higher cathode power was used for this process. However, coating processes with high cathode power are connected with a great amount of thermal energy input into the facility. This requires an increasing heat transfer out of the coating unit and it leads to a significant thermal load on the substrates.

Therefore, hard coatings can be applied at a low temperature with the pulsed process, because the energy is sufficiently high even with low cathode power. Due to the low power, the temperature load on the substrate is small compared to the load in the dc-process with an equivalent ion energy. This makes the pulsed process interesting for the coating of temperature sensitive substrates, e.g. machine parts or plastics.

6. Conclusion

In this article, a plasma diagnostic comparison between dc-MSIP and pulsed MSIP was presented. It was shown, that the composition of the plasma does not dependent on the process mode, whereas the energy is strongly connected with the process. It was observed, that the particles in the pulsed process have a much higher energy than in the dc-process. This may be one reason for the significant better quality of pulsed coatings with equivalent cathode power. Therefore, the use of the pulsed MSIP for low temperature processes with good coating performances is possible.

In future work, the behavior of other coating materials has to be observed. Especially, the energy of aluminum ions is of high interest, because the aluminum fraction in the coating is much smaller than the titanium fraction. To develop coatings with a greater aluminum fraction the knowledge of the dependencies between the ion energy and the process parameters is crucial.

In addition to this, the influence of the coating parameters pressure, gas flow composition, bias voltage has to be investigated. For the use in process control and process simulation, a spatial resolution of the plasma is

necessary. The energy resolved mass spectroscopy then would be able to measure required boundary conditions to conduct plasma simulation and thus to improve the knowledge about the process.

Tar (heavy hydrocarbon or PAH) removal from biomass derived fuel gas is one of the biggest obstacles in its utilization for power generation. We have investigated pulsed corona as a method for tar removal. Experimental results have indicated the energy density requirement to be about 400 J/L for naphthalene removal (model tar compound) from synthetic fuel gas (CO, CO_2, H_2, CH_4, N_2) at temperatures of 200 ^oC [1]. For the process to be competitive and economical, the energy consumption needs to be reduced. This requires an understanding of the chemical processes involved. In previous studies, we have investigated the primary processes at temperatures of 200 ^oC [2]. The present study aims to identify the main reactions involved by means of a sensitivity analysis

1. Introduction

Pulsed corona induced non-thermal plasma processes for pollution control applications have been investigated for over a decade [3]. One significant advantage of such a process is its ability to perform the necessary function at less stringent conditions. Typical example is that of PAH (PolyAromatic Hydrocarbon), dioxin etc. removal, which can be facilitated at atmospheric conditions. Research is directed towards both fundamental understanding [4] as well as developing dedicated equipment for the purpose [5]. In any case, to implement a new technology or method, it has to be competitive in terms of economics over the existing methods, or it should be the only method available to achieve a certain task. Perhaps one of the most widely investigated processes by using non-thermal plasma techniques would be combined NO_x and SO_x removal. In addition, this would be the most likely process to bridge the gap between research and industrial application [5,6]. Out of the several milestones regarding research in this area, one of the crucial turning points was the understanding of process chemistry involved [7]. Although several investigations have been made into understanding the fundamentals of gas discharges, several open questions remain. For example, one still needs to investigate the relation between power source properties and the streamer behavior. Several directions or indications are available which are used as design criteria (or thumb rules) [5], but lack of concrete understanding still hinders the transfer of knowledge from one system to another. Hence, each system has to be considered as a stand-alone system from an information point of view. As was stated before, understanding of process chemistry (in the area of NO_x, SO_x control) proved to be decisive in manipulating the process to one's needs. Fundamental reactions were outlined [7]; therefore, one could study the influence of addition of additives, catalysts, changing process conditions (temperature, gas composition)[8] and thereby reduce the energy consumption. In principle, any non-thermal plasma chemical process can be considered to take place in 4 discrete steps at various time scales

(a) Electron energy distribution (ps ~ ns)
(b) Physical processes leading to generation of radicals (ns ~ μs)
(c) Free radical chemistry (μs ~ ms)
(d) Ground state chemistry (ms ~ s)

The first three steps can be considered as a source for the last step. Since all the radicals and excited species that are generated by means of collisions between energetic electrons (> 5eV) and molecules and that survive the quenching process will act as reaction initiators for the purpose to be achieved. The design related to power source properties and electrode geometries is aimed at increasing the radical density. However, high local radical densities would lead to more quenching. The question related to "what is too much" varies from process to process and most often, it is to be obtained experimentally. A detailed streamer model is necessary to obtain the initial radical density, a question which remains unsolved in the area of non-

thermal plasmas. The present work related to kinetic modeling for tar/poly aromatic hydrocarbon removal from biomass gasification is aimed at developing a comprehensive yet brief set of reaction scheme, largely governing the process. Gasification of biomass produces a low calorific value gas typically 4 ~5 MJ/Nm^3, gas compositions as mentioned in table 1.

Table 1: Producer gas quality from two types of atmospheric, air blown gasifier [10]

Material		Downdraft	CFB[1]
Fuel Moisture	wt %	5~20	13~20
Particles	g/Nm^3	0.1~8	8~100
Tars	g/Nm^3	0.01~6	2~30
H_2	Vol %	15~21	15~22
CO	Vol %	10~22	13~15
CO_2	Vol %	11~13	13~15
CH_4	Vol %	1~5	2~4
C_nH_m	Vol %	0.2~2	0.1~1.2
N_2	Vol %	Rest	Rest

Non-thermal plasma processing or pulsed corona processing (in this case) of the above gas can occur via several routes leading to various chemical processes. On a more global level, the energy requirements for removal of representative compounds have been established experimentally. Results indicate energy requirements to be about 400~500 J/L for naphthalene removal to 900~1000J/L for phenol removal. Experiments have also been conducted for removal of these compounds in various gas mixtures to establish the chemical pathways. However, a detailed kinetic scheme is necessary to establish the secondary processes.

2. Method of Investigation:

The aim of the calculation is to

1) Have a chemical kinetic reaction scheme developed that can adequately describe the process.
2) To identify termination & competitive reactions

The short description below explains the method adopted for the purpose.
In general, to reach conditions in an actual process, one needs to have a “perfect” streamer model to describe the distribution of the species produced in both the axial and radial directions. However, this is far from reality. Hence, to achieve this a fitting parameter is used which physically means the amount of radicals necessary for the desired conversion of tar as observed experimentally. Radical production in reality is pulsed, that is, radical generation takes place during a period much shorter than the period between two pulses. In effect, it can also be said that radical concentration decays to zero between two pulses (Fig.1)
Another option that is followed is to have a continuous model instead of a discrete model as is described in the above case [11]. Here radical production is incorporated in the rate constant of the process. Therefore, both phases in the reactor, viz. the plasma phase as well as the bulk gas phase are well mixed; hence, the model can be termed as a pseudo-homogenous model.
The reactor used for the experiments is a tubular flow reactor or a differential reactor and it forms a part of a closed loop system [1,2]. Hence, the overall configuration represents a well-mixed system (Fig.2).
We assume,

1) Radicals produced are well mixed with the reactants.
2) Radicals once produced are uniformly distributed within the whole volume, i.e. a zero-dimensional model.
3) Chemistry of the process is solely described by radical behavior; ion chemistry is not taken into account.

For description of the chemical reactions, 106 reactions[#] and 15 species are taken into account viz. O, OH, H, CO, N, CH_3, O_2, H_2O_2, HO_2, HCO, CH_4, CH_2O, naphthalene, toluene, and phenol.

The general reaction scheme and the format of the mass conservation equation is:

[1] Circulating Fluidised bed gasifier
[#] can be provided if needed.

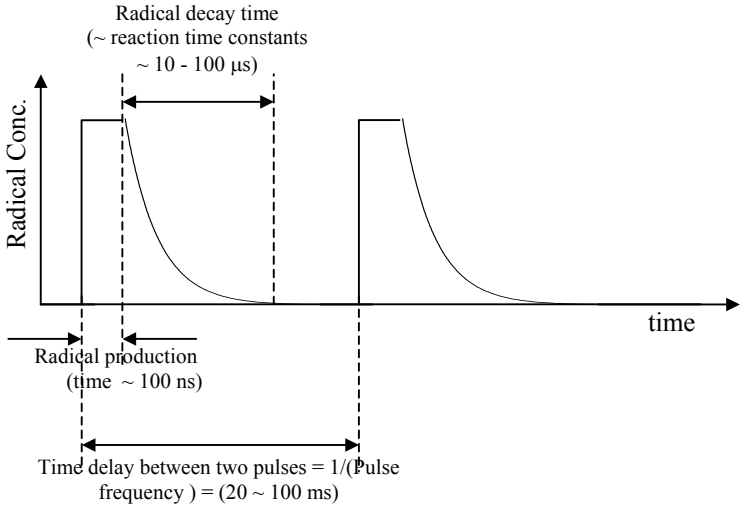

Fig.1. Time dependence vs. radical concentration profile

$$M \rightarrow R \qquad \text{…….(1)}$$

$$R + X \rightarrow \text{products} \qquad \text{…….(2)}$$

$$\frac{\partial R_i}{\partial t} = G_R \cdot E_p \cdot f. - \sum k \cdot [R_i] \cdot [X_i] \qquad \text{…….. (3)}$$

where, G_R = Radical production per Joule per m^3 ($mol.J^{-1}m^{-3}$)

$= K_R * [M]$

where, K_R = dissociation constant (J^{-1})

M = bulk species concentration (mol/m^3)

E_p = Energy per pulse (J/pulse)

f = Pulses per second (pulse/second)

k = reaction rate constant (s^{-1})

X, R = species concentration (mol/m^3)

Hence $G_O = K_{CO2} * [CO_2]$

$G_{OH} = K_{H2O} * [H_2O]$

$G_H = K_{H2} * [H_2] + K_{H2O} * [H_2O]$

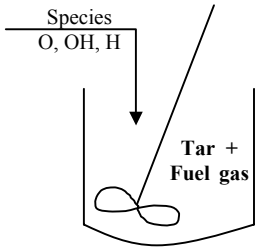

Fig.2 Well-mixed Reactor

Equation (3) presents a mass balance of radicals, with the first term on the right hand side indicating the production term and the second term indicating the formation or consumption of radicals by reactions. K_R is used as the fit parameter, and the value is adopted to achieve a good fit between the calculated and the experimental value. In principle, this value has to be obtained from an adequate streamer model, which as described before is not included into the present case. The G value or the radical yield can be evaluated from the above since

$$G\ (\text{molecules}/100\text{eV}) = G_R * V * 1.6\text{e-}17 \qquad \text{…… (4)}$$

where V = Volume of reactor (m^3)

and the conversion factor, 1eV = 1.6 e-19 J

The experiments are performed for near about 99.99 % conversion, and the equivalent time is about for the calculation purpose.

For eg: Naphthalene removal occurs at energy density of about 400 ~ 600 J/L, this is used to determine the calculation time.

$$\Delta T = \frac{E_D * V}{E_p * f} \qquad \text{……..(5)}$$

where ΔT = time for calculation (time for 99 % conversion)

E_D = Energy Density (J/L)

The calculations yield naphthalene removal as a function of time, which is reconverted to the adequate units by eq.5 and plotted to compare with the experimental results. However, because of the simplicity associated with the above calculations, the interpretations of the results are only valid within the experimental conditions. Since, for e.g. if the gas temperature changes, although change in the gas density have been incorporated, the resulting effect on the gas discharge phenomena is not taken into account. This may affect the value of the fit parameter or the apparent dissociation rate constant. Similarly, all factors related to the influence of the pulse power source cannot be investigated, because of lack of incorporation of a streamer model. However all parameters, which are influenced by the kinetics of the process or rather the chemistry can be investigated.

3 Experimental conditions:

The experimental set-up has been explained in detail elsewhere [1,2]. However, important details are summarized in table 2.

Table 2: Experimental conditions

Experimental operation: Batch wise			
Temperature = 200 ~ 210 °C			*Pulse power properties*
Pressure = 1 bar			70 ~ 80 kV
Biogas composition		*Tar Components*	20 ns rise time, 100 ns pulse width
CO	20 %	Naphthalene	50 ~ 80 MW peak power
CO_2	12 %	Toluene	1 ~1.2 J/pulse
H_2	17 %	Phenol	50 pulses per second
CH_4	1 %		80 % efficiency (from mains to corona)
N_2	Rest		

4 Results:

(a) Estimation of G-value

The first step is to reach the "right" value of the fit parameters. For this case naphthalene removal from fuel gas is taken as a reference and then further on, compared with the experimental results for the removal of other compounds It is assumed that for such a gas composition the primary step is the dissociation of CO_2 to produce O species. This is based on the previous experimental observations [2]. Based on a trial and error procedure, a reasonably good fit (Fig.3) with the experimental results was obtained for the values of

K_{CO2} = 2.5e-7 ➔ G_O = 4.654e17 mol/m^3/J

K_{H2} = 1.5e-9 ➔ G_H = 3.956e15 mol/m^3/J

Therefore, the radical yield can be estimated to be (reactor volume of 0.189 Nm^3)

G_O (G-value) = 1.41 mol /100 eV

G_H (G-value) = 0.012 mol/100 eV.

Fig.3 indicates a comparison between the calculated results using the above fit parameter with the experimental results.

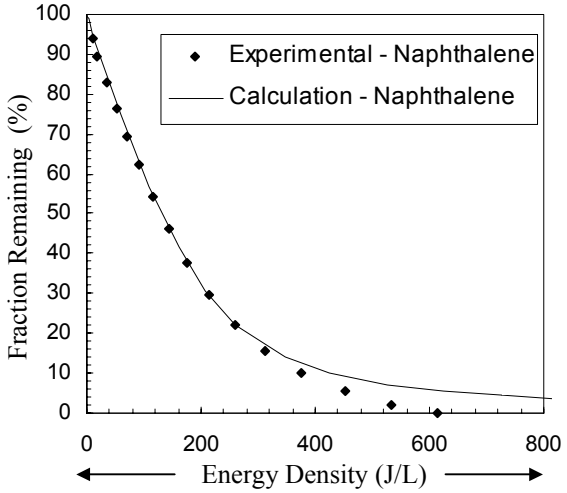

Fig.3 Comparison of experimental and calculated results

(b) Verification of parameters:

The estimated value of the parameter can be verified by comparing it with the experimental results for removal of toluene as well as for phenol. The experiments are performed under the same conditions as that for naphthalene. Fig.4 (a & b) shows comparison for the calculated as well as experimentally obtained results for the case of toluene and phenol.

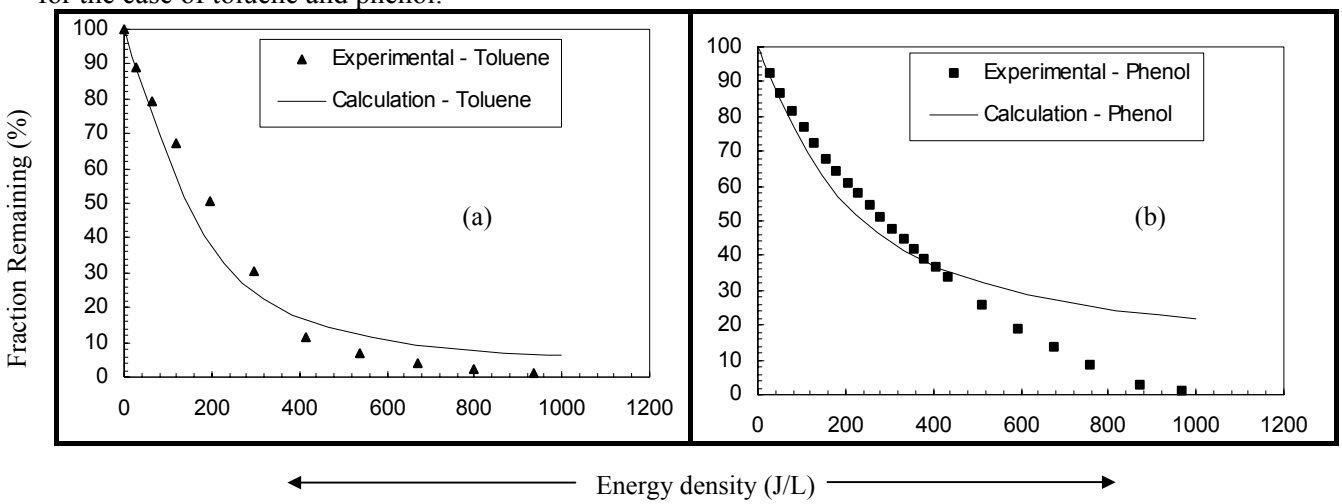

Fig.4. Verification of fit parameters (a- Toluene, b-Phenol)

The calculations show good agreement for the case of toluene and for the case of naphthalene. Deviations are seen for the last remaining fraction in the case of phenol. This may be due to one of the following factors or a combination of both

a) Phenol removal due to thermal dissociation can also be a factor (since in the calculation only removal due to reactions initiated by corona plasma is taken into account.)
b) Chemical reactions to describe phenol removal may not be complete, which suggests that the products formed after the breakdown play an important role.

Nevertheless, good fit is obtained with the values of the fit parameter for the case of naphthalene removal. Since further experiments for determining, the mechanisms are done only with naphthalene as the model compound as well as for the purpose of sensitivity analysis.

5 Sensitivity Analysis

The aim here is to isolate the main reactions that are more likely to effect the process from the "pool". This was performed as indicated in eq.6.

Every reaction rate constant was changed by about 50% of its value, and correspondingly its effect on naphthalene removal was observed. Evidently, those reactions, which showed an effect on the removal in terms of the energy density, are more likely to influence the process.

As can be expected, the calculations are sensitive to the value of the fit parameter, and thereby the gas composition, if changed by an order of magnitude. In addition, in the case of the rate constants, small changes to the values, to the extent of 5% do not influence the calculations.

The sensitivity analysis indicated the following reactions to be more critical than the others:

$$
\begin{array}{lcllcl}
O & + & \text{Naphthalene} & \rightarrow & \text{Products} & \\
H & + & \text{Naphthalene} & \rightarrow & \text{Products} & \\
OH & + & \text{Naphthalene} & \rightarrow & \text{Products} & \\
O & + & CO + M & \rightarrow & CO_2 + M & \\
O & + & H_2 & \rightarrow & OH + H & \\
O & + & CH_4 & \rightarrow & CH_3 + OH & \\
O & + & CH_3 & \rightarrow & CH_2O + H & \\
O & + & CH_2O & \rightarrow & HCO + OH & \\
HCO & + & M & \rightarrow & H + CO + M & \\
O & + & H_2 + M & \rightarrow & H_2O + M &
\end{array}
$$

$$\frac{\partial X}{\partial t} = \sum k \cdot [R] \cdot [X]$$

$$t = \frac{E_D * V}{E_p * f}$$

$$\partial t = \partial E_D * \left(\frac{V}{E_p * f} \right) \qquad \ldots\ldots\ldots (6)$$

$$\left(\frac{E_p * f}{V} \right) \frac{\partial X}{\partial E_D} = \sum k.[R].[X]$$

$$\frac{\partial}{\partial k_i} \left\{ \left(\frac{E_p * f}{V} \right) \frac{\partial X}{\partial E_D} = \sum k.[R].[X] \right\}$$

Based on the above analysis, it is now possible to start outlining the chemical scheme at the experimental conditions, and subsequently investigate the effects of additives and varying conditions.

5. Conclusion:

A chemical reactions database has been set up which can describe the process of tar removal from fuel gas. The adopted method produces result that agrees with the experimental observation within the conditions of investigation. Deviations do exist from the experimental results. In addition, a chemical scheme can be outlined based on the sensitivity analysis performed.

Abstract
The erosion of a cathode in a plasma torch is related to its surface condition, particularly with respect to its composition. An experimental and theoretical approach was developed in order to study the work function changes of copper (material mostly used for electrodes in plasma torches) induced by ion implantation. The Cu substrates were implanted with low energy P and Cs ions; the surfaces before and after implantation were analysed in terms of crystalline structure, composition, surface topography and work function changes.

1. Introduction

Plasma generator or plasma torch is an essential tool for various industrial processes, such as: production of new materials, refining of metals, applications for environmental issues (treatment of hospital and toxic industrial wastes) and others. Recently the use of plasma torches has been expanded into the field of treatment of soil contaminated with oil and the production of silicon for solar cells. The understanding of the electrode erosion of plasma torches used for those processes is essential in expanding even further the present applications.

The electron emission for electrodes in plasma torches is believed to be controlled by the Thermo-Field (TF) mechanism. This mechanism of electron emission uses the concepts developed originally by Fowler-Nordheim [1] with the thermionic concepts expressed by the Richardson equation modified by the Schottky effect [2]. The general equation describing the TF emission was first described by Murphy and Good [3]; many modifications to this original work have been suggested ever since. In general, the electron emission current density depends on the surface temperature, on the electric field above the surface and on the work function of the surface. Higher temperature and electric field, but lower work function, result in higher electron current densities, or in other words, in higher and easier emission of electrons. A lower current density and/or lower residence time of the arc on one spot of the cathode surface, which also depends on the work function, will decrease the erosion of the cathode [4-6].

An extensive experimental study on electrode erosion in a concentric cylinder geometry with magnetically driven electric arcs, simulating a plasma torch, was conducted in the past by one of the present authors; the study focused on the behaviour of the cathodes, since those electrodes are the ones presenting the more severe erosion in normal industrial applications. The addition from ppm to a few percent of polyatomic gases (N_2, O_2, CO, Cl_2, CH_4, H_2S) to inert gases (Ar or He) caused large variations in the arc velocities, arc voltage, in the arc movement and cathode erosion when compared with experiments using pure inert gases. It was determined that the contamination of the cathode surface, caused by the decomposition of the polyatomic gases by the electric arc and plasma jet, and the consequent attraction of the positive ions towards the cathode, was the cause for the observed changes. The change of the work function of the cathode material, due to the change in the surface composition, was determined for selected experiments using Kelvin Probe technique. More details can be seen in Refs. [6-9].

Since the contamination of the cathode surface was not controlled in those experiments, a more systematic study of the changes occurring on the cathode surface when it is contaminated with different elements needed to be conducted. An experimental and theoretical approach was developed here in order to study the changes of the work function of copper (copper is mostly used as electrode material for plasma torch) when small and controlled amounts of contaminants were placed on the surface by ion implantation [10,11]. The aim of the work is to understand the main phenomena controlling the emission of electrons from a metallic surface for future use of that material as cathodes in plasma torches. It is presented here some of our experimental and theoretical results obtained in the ongoing effort for understanding those phenomena.

2. Methodology

The methodology for the study of work function change of copper caused by ion implantation process is formed of two parts: theoretical and experimental.

The theoretical approach adopted in this work consisted of simulating the implanted surfaces using SRIM (Stopping and Range of Ions in Matter), version 2003.10, [12] and TB-LMTO-ASA (CPA) (Tight Binding – Linear Muffin Tin Orbital – Atomic Sphere Approximation (Coherent Potential Approximation)) [13] programmes. The SRIM programmes provide, among other parameters, the ion range distribution and sputtering yield (defined as the mean number of sputtered target atoms per incident ion) of surface components, which were used to estimate the concentration of implanted ions on the surface.

The TB-LMTO-ASA (CPA) programmes simulate the electronic structure of the surface, which was used to estimate the work function change of copper due to the presence of implanted ions on the surface. In this method, the crystal is considered to be totally filled out with spheres centred at individual nuclei (Atomic Sphere Approximation – ASA). The radius of each sphere is determined so that the sum of the volumes of all the spheres equals the volume occupied by all the atoms in the material. In the case of a material with just one atom type, the Wigner-Seitz radius of the solid is used as the sphere radius. At each sphere, a potential which is spherically symmetrical inside the sphere and constant outside (such potential is called Muffin-Tin - MT), is set. The radial solution of the Schrödinger equation for the system, which can be written as a linear combination of energy independent basis functions (Linear Orbitals – LO), inside the sphere (spherically symmetric potential) depends on the form of the solution outside the sphere (constant potential) through the boundary conditions of continuity of the base functions and their first derivations. The Tight Binding - TB basis, commonly used for the problem of imperfections in the metallic surfaces is obtained in such a way that the interactions between the neighbouring sites have the smallest possible range. The procedure used in the TB-LMTO-ASA (CPA), the method adopted here, can be summarised in two main steps:

1. The electronic density is calculated through the surface Green function method adapted for the TB-LMTO-ASA. In the case of the presence of random alloys or impurities without symmetry in the metallic surfaces, the average electronic density is calculated using Coherent Potential Approximation (CPA);

2. In the Density Functional Theory – DFT calculations, which assumes the existence of a functional of energy with a minimum value for the correct electronic density, the electronic density obtained in the previous step is used, thus providing variables necessary for the description of the properties of the solids (in our case, the work function).

The experimental approach consists in bombarding a target surface (made of copper) with certain ions, in a controlled manner and study the variation that the implantation of those ions cause on the surface of the target. In order to accomplish that, a mechanical mask was specially designed and manufactured; during the ion implantation process this mask is positioned above the substrate. The main objective for using a mechanical mask on the top of the sample undergoing an ion implantation process is to create, on the sample surface, a determined pattern of implanted and non-implanted regions; this allows the determination of changes induced by the process without the need for the reference sample (i.e., the non-implanted areas on the same sample serve as the reference). The mask had rectangular-shaped holes (rectangular area of $50x100\mu m^2$ with spacing of 10μm between them) through which the ions were able to pass and thus, the same pattern of implanted regions was created on the sample surface. The mechanical mask is made of silicon and silicon oxide; more details of the method for producing the masks can be seen elsewhere [10].

Two types of copper substrates were used in the study: polycrystalline copper sheets and thin film of deposited copper on silicon wafers. The sample preparation procedures for both substrates are presented below. The samples were produced in pairs so that one sample can be analysed exclusively by Kelvin Probe Force Microscopy (surface topography and work function measurements) and other techniques of interest.

The polycrystalline copper substrates were obtained by cutting an electrolytical copper rod into disks (1cm in diameter, 1mm of thickness); the disks were alternatively rinsed in ethanol and polished with diamond pastes, each time diminishing the diamond grain size (reaching 1μm grain size). The surface topography of the obtained substrates was examined using AFM (*Nanoscope IIIa*, *Digital Instruments*); the maximum topography difference, determined in those measurements, was of the order of 250nm. One pair of polished copper substrates were implanted with phosphorus ions with acceleration voltage of 39keV and with a dose of $3.4x10^{16}ions/cm^2$.

The copper thin film substrates were obtained by depositing copper on silicon wafer using the electron beam technique. The mean value for the deposition rate was 3Å/s and the thickness of the deposited

film was approximately 2000Å (determined by *Alpha-Step*). The crystalline structure of the film was obtained with XrD technique and it was determined to be similar to the polycrystalline copper substrate. The surface topography, determined with AFM, exhibited maximum topographic difference of the order of 100nm. One pair of copper film substrates were implanted with caesium ions with the acceleration voltage of 50keV and with a dose of $3.0x10^{15}$ions/cm^2.

The surfaces before and after implantation were analysed in terms of composition (Auger Electron Spectroscopy - AES), work function changes (Kelvin Probe Atomic Force Microscopy - KPFM), surface topography (Atomic Force Microscopy – AFM) and several other parameters (using different techniques such as Rutherford Backscattering Spectroscopy - RBS, X-ray Diffraction – XrD and others).

3. Results

In this section, the results obtained in the work, both experimental and theoretical, are presented.

The calculated range distribution of implanted ions for both ion types (i.e., P with acceleration voltage of 39keV and Cs with acceleration voltage of 50keV) were obtained with SRIM programmes (100,000 ions were used in the simulations) and are shown in Figure 1. The ion density at a certain depth can be obtained by multiplying the respective value on the right-hand axis with the implanted ion dose (i.e., $3.4x10^{16}$ions/cm^2 for P and $3.0x10^{15}$ions/cm^2 for Cs); the density of polycrystalline copper is approximately $8.45x10^{22}$at/cm^3.

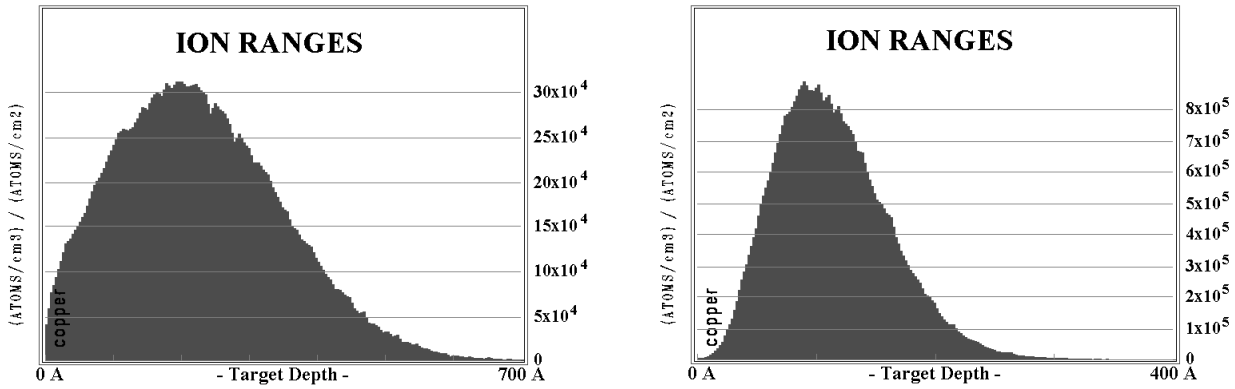

Figure 1a. Cu implanted with P (39keV) Figure 1b. Cu implanted with Cs (50keV)

Figure 1. Simulation of the Ion Range Distribution

Sputtering yield for copper was estimated for the case of phosphorus and caesium implantation using SRIM programmes and the values were 6.7at/ion and 12.7at/ion, respectfully. Therefore, a dose of $3.4x10^{16}$ions/cm^2 of P with acceleration voltage of 39keV should remove $2.28x10^{17}$ of copper atoms, which corresponds to approximately 270Å (i.e., there should be a step of 270Å between the implanted and non-implanted regions) and a dose of $3.0x10^{15}$ions/cm^2 of Cs with acceleration voltage of 50keV should remove $3.84x10^{16}$ of copper atoms, which corresponds to approximately 45Å. From Figure 1a., the surface concentration of phosphorus (estimated using the phosphorus concentration at 270Å) should be 10.9%. From Figure 1b., the surface concentration of caesium (estimated using the caesium concentration at 45Å) should be 1.3%.

A measure of surface composition was obtained in the present experiments from the peak-to-peak height of the P(LMM), Cs(MNN) and Cu(LMM) Auger lines plotted in the derivative mode. The P(LMM) Auger transition corresponds to a 120eV electron, the Cs(MNN) corresponds to a 563eV electron and the Cu(LMM) corresponds to a 920eV electron. The surface concentration of contaminants (C, N, O, S, Cl) was determined by comparing their respective representative Auger transition peak with the Cu(LMM). The analysis of the Auger spectra of implanted and non-implanted regions (for implantation processes of both ion specie, i.e., P and Cs) showed that the variation of the surface concentration of contaminants was within experimental error and that the implanted ions were detected only in the implanted regions. In the results presented in this article, the contaminant concentration was ignored and the percentage of implanted ion on the surface was calculated as if only copper atoms and implanted ions were present on the surface.

All Auger spectra reported here were obtained using primary beam energy of 3keV. In Figure 2a. the Auger spectrum for Cu implanted with P is shown. The form of the P(LMM) peak (at 120eV) is different

from the one in AES manual and therefore, its height could not be determined precisely. Consequently, the obtained phosphorus concentration of 2% on the surface should be taken with certain caution. In Figure 2b. the Auger spectrum for Cu implanted with Cs is shown. The obtained caesium concentration was 6%. Contrary to the case of phosphorus, the form of the Cs(MNN) peak was according to the AES manual.

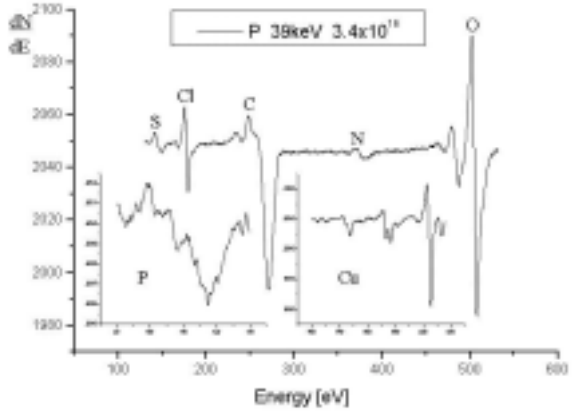

Figure 2a. Cu implanted with P (39keV)

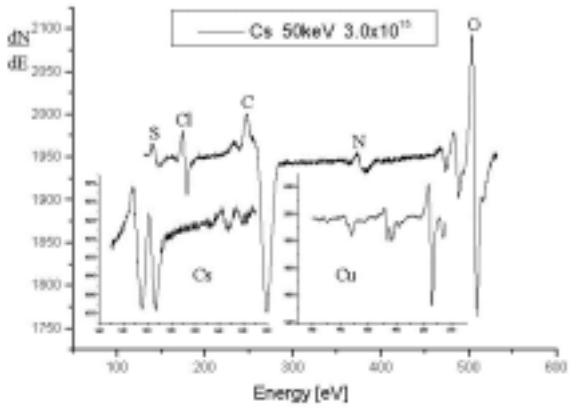

Figure 2b. Cu implanted with Cs (50keV)

Figure 2. Auger spectra of the implanted samples

RBS analyses were conducted in this work in order to determine how many ions were actually present in the sample after the ion implantation process (i.e., what is the "effective" ion implantation dose). The polycrystalline copper sheets (implanted with phosphorus) could not be analysed with this technique, since the copper signal "masks" the presence of all the elements with Z lower than 29. For the copper film samples, the detected dose of implanted caesium ions was approximately $1.3x10^{15}$ions/cm^2, which is less than half of the original dose ($3.0x10^{15}$ions/cm^2).

The KPFM measurements, which provide the work function change (determined by comparison of the surface potential of implanted and non-implanted regions) were performed on 5 different areas (100x100μm^2 for the P/Cu and 70x70μm^2 for Cs/Cu) within each sample. Typical results of copper sheets implanted with phosphorus and copper thin films implanted with caesium are shown in Figure 3.

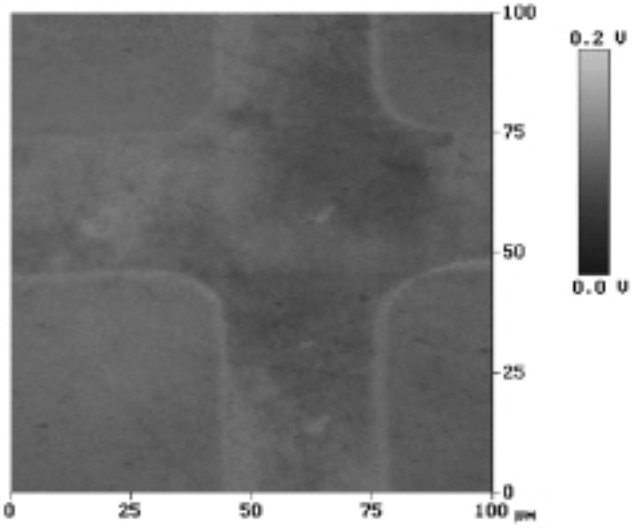

Figure 3a. Cu implanted with P

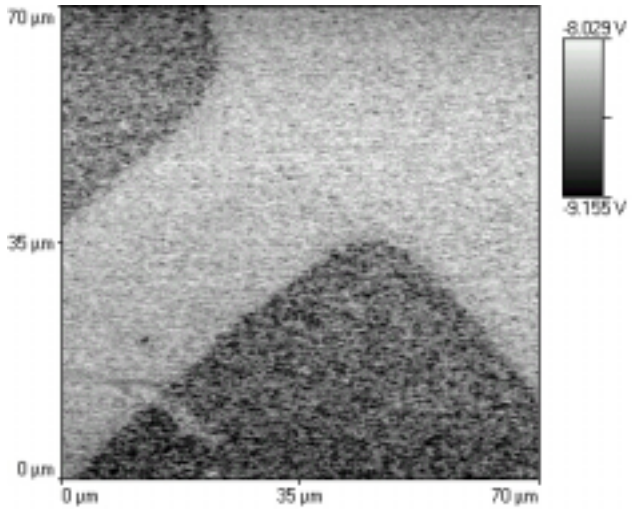

Figure 3b. Cu implanted with Cs

Figure 3. Typical results for KPFM measurements of the implanted copper substrates

As it can be seen, the implanted (rectangular) regions were brighter in the case of P/Cu and darker in the case of Cs/Cu than the non-implanted regions, indicating that the implantation of phosphorus increased the work function and the implantation of caesium decreased the work function in comparison with the

(pure) copper surface. In the case of phosphorus, the work function increased by approximately 50±30mV and in the case of caesium the work function decreased by approximately 400±100mV (the mean value of 10 different measurements within one area (100x100μm^2 for P/Cu and 70x70μm^2 for Cs/Cu case) was obtained (area mean value); this process was repeated for all the measurements performed on one sample (5 measurements) and the final value for one sample (sample mean value) was calculated as the mean value of all the areas). The error associated with the results are the maximum deviation of area mean values from the sample mean value.

The topography analyses (the equipment for KPFM simultaneously measures the change in the surface potential as well as the surface topography) of the samples revealed that the level of the implanted regions were lower compared with the level of the non-implanted regions; in the case of P/Cu, the step (between implanted and non-implanted region) was approximately 280±80Å and in the case of Cs/Cu, the step was approximately 70±30Å. Also, the analysis of the surface structure indicated that there was an increase in surface roughness of implanted regions (comparing with the non-implanted ones).

The surface obtained experimentally by implantation of Cs ions into copper film substrate was simulated, using TB-LMTO-ASA (CPA) programmes, by one monolayer of surface alloy (containing 6% of Cs and 94% of Cu) placed on top of Cu(111) crystalline facet. Preliminary theoretical results showed the decrease of approximately 240mV comparing to the work function value of pure copper, which is in relatively good agreement with obtained experimental value (400±100mV). This value decreased even further if the increase of the surface roughness, which occurs in the implanted regions due to the process of sputtering, was taken into account in simulations. The theoretical study of Cs/Cu system is being continued and the results will be published elsewhere [16]. The TB-LMTO-ASA (CPA) programmes are specially designed for purely metallic systems and, therefore, the P/Cu system could not be simulated with them.

4. Discussion

The fact that the surface concentration of contaminants was within experimental error (indicating that there was no change in the surface concentration of contaminants due to the ion implantation process) and that the implanted ions were detected only in the implanted regions (confirming that the mechanical mask produced here was indeed thick enough to stop all the ions and thus protect the substrate surface underneath) prove that the described methodology is appropriate for the studies conducted in this work. One can conclude that if there are some changes in the work function between the implanted and non-implanted regions this can be attributed to the presence of implanted ions on the sample surface and/or change in the surface roughness induced by ion bombardment.

The experimental results (obtained by AES) for the surface concentration of implanted ions (2% of P and 6% of Cs) were different than the values estimated with SRIM programmes (10.9% of P and 1.4% of Cs). The calculation based on the Kinchin-Pease formalism, used in SRIM simulations for a fast estimative of the damage induced by ion implantation, may not be appropriate for the samples investigated in this work. The sputtering, which occurs during the ion implantation process, changes the ion range distribution by broadening the peak and, upon prolonged implantation processes, by depletion of the implanted ion specie in the near surface region. Another mechanism which can significantly change the surface concentration of implanted ion is migration. At thermodynamic equilibrium, the surface composition of an alloy corresponds to the lowest possible surface free (Gibbs) energy. However, in a radiation environment, other processes start to influence the surface composition, such as: preferential sputtering, displacement mixing, radiation-enhanced diffusion, etc. [14,15]. Also, it should be considered the formation of compounds (changes in the phosphorus peak form indicates that a compound was formed during the ion implantation process) for a precise surface composition analysis. The experimental results indicate that the processes mentioned above indeed play a significant role in determining the surface concentration of elements in implanted copper. Further experiments and theoretical studies are being conducted in order to gain better understanding of the processes which control the surface composition of P/Cu and Cs/Cu systems.

The sputtering yield is very sensitive to the surface binding energy (in the simulation presented in this work, the value for copper of 3.52eV was used). For real surfaces, this changes under bombardment due to surface roughness, and also changes due to surface stoichiometry for compounds. Further, sputtering involves mostly the upper monolayer of the target. For targets such as copper the electronic energy loss of a target atom moving through the last monolayer is of the order of the surface binding energy, so even

monolayer roughness will change the sputtering yield. In spite of the arguments mentioned above, the values for the step estimated by SRIM programmes (270Å in the case of P/Cu and 45Å in the case of Cs/Cu), although slightly lower than the values obtained with KPFM, are still within the experimental error.

5. Conclusions

Two quite distinctive cases of ion implantation in copper were studied primarily in terms of surface composition and work function change; as substrate- copper polycrystalline sheets and deposited copper films were used, as ion specie- one light element (P) and one heavy element (Cs) were implanted with two different doses. The comparison between the surface composition analysis of implanted and non-implanted regions showed that there was no change in the concentration of contaminant elements (C, N, O, S, Cl) due to the ion implantation process and that the implanted ions were only present in the implanted regions, indicating that the adopted is appropriate for the experiments conducted in those studies. The detected concentration of phosphorus in P/Cu system was 2% and of caesium in Cs/Cu system was 6%. For both cases, work function changes were observed; for the case of polycrystalline copper sheets implanted with phosphorus, there was an increase of 50mV and for the case of thin copper films implanted with caesium, there was a decrease of 400mV. Topography analysis of the samples showed a lowering of the implanted regions (in comparison with the level of non-implanted regions) of 280Å for P/Cu system and of 70Å for Cs/Cu system and an increase in the surface roughness for the implanted region.

Using SRIM programmes, the value of sputtering yield was estimated and found to be close to the values found experimentally. However the ion range distribution, obtained with SRIM programmes cannot be used in a straightforward way to estimate the surface concentration of implanted specie; other considerations (Gibbsian segregation, radiation-induced processes, surface stoichiometry for compounds) should be taken into account.

Preliminary theoretical results, using TB-LMTO-ASA (CPA) programmes, show the decrease of the work function value of copper in presence of small amounts of Cs on the surface, with the value in relatively good agreement with one obtained experimentally. The agreement is even better if, in simulations, the increase of the surface roughness, which occurs in the implanted regions due to the process of sputtering, was taken into account. The studies are being continued, both theoretical and experimentally, for different elements, doses and substrate compositions.

Abstract
In the present work, electrode erosion studies were performed using a chamber that simulates a plasma torch. Several different types of gases and cathode materials were studied, as well as different magnetic fields and arc currents. The first results obtained on this on going project can be summarized as follows: i) preliminary results obtained here for similar conditions are almost identical to ones published by other authors, validating the equipment and procedures adopted here; ii) use of industrial argon resulted in the contamination of the surface; iii) Cu/Ni alloys showed similar behavior as pure when copper cathodes were used.

I. Introduction

Thermal plasma technology is playing an important role in the production of new materials, in the destruction of toxic wastes and in the development of safer and more efficient processes. One of the remaining problems inhibiting the further industrial application of plasmas is related to the plasma generator or plasma torch. Short electrodes lifetimes, unreliable torch performance, and lack of flexibility in torch operation are all directly or indirectly due to a still lack of fundamental knowledge of the role of the electrodes in the plasma generating process.

Although considerable advances have been made by torch manufacturers, electrode erosion still limits the application of thermal plasma technology to industrial processes. The erosion of the cathode is generally more severe (for non refractory materials) and therefore has been more studied. In the absence of direct chemical reaction, erosion is primarily due to the volatilization of electrode material by local overheating.

There are two significant classes of heat sources on the cathode surface: an external one, caused by particle impact on the surface (ion bombardment) and an internal one due to the passage of the electric current within the volume of the cathode (Joule heating). The other sources of heating, radiation from the arc and convection from the plasma gas have too low a flux to be important in erosion [1-3].

The erosion of the electrodes, in particular of the copper cathodes used in industrial plasma torches operating at atmospheric pressure, is probably the major problem for a broader use of plasma torches. Some of the factors suggested as important in determining cathode erosion rates are: arc velocity [4-7], water cooling rate for the cathode [8], transverse magnetic field strength [9], thickness of the oxide layer on the cathode [10], time duration of the experiment [11], plasma gas composition [12-14], and others. Previous studies [15-17] conducted by one of the authors, strongly appointed to the importance of the surface composition on cathode erosion rates; the composition of the electrode surface was directly affected by the type of plasma gas or mixture of gases used.

In the present work, an experimental chamber was built in order to simulate concentric electrodes of a plasma torch; experimental results were obtained for the effect of arc velocity, magnetic field strength, plasma gas composition and gas flow rate on copper cathode erosion in magnetically driven arcs.

II. Equipment and experimental procedures

A schematic representation of the test chamber is shown in Fig. 1. The DC arc was ignited by a high-frequency pulse and powered by a welding power supply. The arc was driven by an external magnetic field generated by a water-cooled coil external to the chamber and mounted coaxially with the electrodes. The arc rotation frequency was monitored using a light probe located in the chamber, and the mean arc velocity was calculated at the cathode surface. The current, voltage and velocity of the arc were monitored by an acquisition data program installed in a portable computer (one measurement per second).

The gas flow rate was 20 liters/min for all the experiments presented here; the pressure inside the chamber was always kept at 1.1 atm. Before an experiment, the electrodes were cleaned using a sequence of washings with dilute nitric acid and distilled water. The erosion rates reported here were obtained from the difference in weight of the electrodes before and after the experiments. Before the second weighing, the electrodes were again cleaned with the dilute nitric acid and distilled water to remove any contaminant layer that was formed during the experiments. After installing the test electrode, the chamber was purged with argon for 5 min. The electric arc was initiated in argon, and then after other gases could be used.

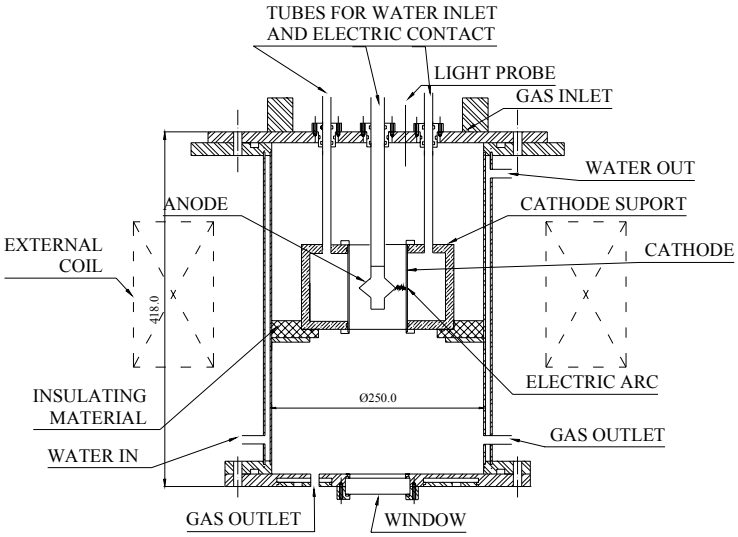

Fig. 1. Schematic representation of the test chamber

III. Results

The experimental results are summarized in the tables below. Each set of results is the mean value of at least three individual experiments carried out under identical conditions.

In the present work three different types of copper material were used (all of them were purchased as electrolytic quality copper from different suppliers). In Table I it is shown the composition of one of those materials, that was used more extensively for the experiments conducted here; the analysis were done using XRF.

Table I- Composition of the electrolytic copper obtained by XRF analyses.

ELEMENT	Electrolytic Copper (%)
Al	0.07
Si	0.15
P	0.07
S	0.03
Cl	0.06
K	--
Ca	<0.01
Fe	0.05
Cu	99.5
Pb	--
Sn	0.04

III.1 Preliminary results

In Table II it is shown two sets of results, one obtained here and a second one obtained by different authors using similar equipment and operating conditions. No difference was obtained when used industrial or ultra pure nitrogen (added to the argon main stream in the amount indicated in Table II).

Table II – Comparison of the results

---	Gas	Cathode Material	Erosion (μg/C)	Arc Velocity (m/s)	Magnetic Field (G)	Current (A)	Voltage (V)	Gas flow rate (l/min)
This work	Ar + 1.25% N_2	Cu 99.5%	3.5	43	1000	156	37-38	20
Ref. (16)	Ar + 1.25% N_2	Cu 99.9%	3.4	35	1000	100	39	20

In this work, the minimum value of current that can be obtained is 156 A for those operating conditions (arc voltage in particular). Since the arc current used in the other work was 100 A, in order to compared directly the arc velocities of the two studies is necessary to use a converting equation, proposed by Szente et al (16):

$$\text{Arc Velocity} \propto I^{0,56} \quad (1)$$

When that equation is used, the arc velocity of the experiment conducted here would be 34,4 m/s (instead of the value indicated in Table II, 43 m/s).

III.2 Formal Experimental results

Different experiments were performed, varying the composition of the plasma gas and of the copper material used for the cathode. In Tables III to VI the different results obtained for those various conditions are shown (the title of each Table characterizes the set of experiments conducted).

Table III – Results obtained varying the plasma gas composition.

---	Gas	Erosion (μg/C)	Arc Velocity (m/s)	Current (A)	Voltage (V)
1	Ar industrial	4.4	49	156	36
2	Ar Ultra Pure (UP)	7.6	16	156	38
3	Ar UP + 1.25% N_2 industrial	3.5	43	156	38
4	Ar UP + 1.25% N_2 UP	3.5	44	156	38
5	Ar UP + 0.3% N_2 industrial	3.6	38	158	36
6	Ar industrial + 0.3% N_2 industrial	4.2	39	158	36
7	N_2 industrial	1.7	104	200	65-70
8	He	1.2	190	210	49

All the results shown in Table III were obtained using a gas flow rate of 20 l/min, a magnetic field of 1000 G and for the cathode material, electrolytic copper (see Table I).

Table IV – Results obtained varying the cathode material .

----	Cathode Material	Erosion (μg/C)	Arc Velocity (m/s)	Current (A)	Voltage (V)
1	Cu	4.5	41	156	41-38
2	CuNi 90/10	4.3	26	158	36-32

All the results shown in Table IVI were obtained using ultra pure argon as the plasma gas, gas flow rate of 20 l/min and magnetic field of 1000 G.

Table V - Results obtained varying the gas composition for CuNi cathodes.

---	Gas	Cathode Material	Erosion (μg/C)	Arc Velocity (m/s)	Current (A)	Voltage (V)
1	Ar industrial	CuNi 90/10	3.9	37	158	30
2	Ar U.P.	CuNi 90/10	4.3	26	157	37-32
3	Ar industrial + 2.5% O_2	CuNi 90/10	5.5	22	196	40
4	Ar industrial + 0.3% O_2	CuNi 90/10	7.7	19	158	36
5	N_2	CuNi 90/10	1.9	93	200	52-58

All the experiments above (Table V) were conducted using a gas flow rate of 20 l/min and a magnetic field of 1000 G.

Table VI – Results obtained varying the magnetic field.

---	Magnetic Field (G)	Erosion (μg/C)	Arc Velocity (m/s)	Current (A)	Voltage (V)
1	160	15.8	23	180	34-35
2	1000	4.4	49	156	35.5

All the experiments were conducted using a gas flow rate of 20 l/min, industrial argon as the plasma gas and electrolytic copper for the cathode (Table I).

It is shown below, in Figure 2, photographs of the electric arc and plasma formed during different experiments, using a high speed photographic camera (exposition time of around 0.1 ms). In Figure 3 it is shown a schematic representation of the arc + plasma formed between the concentric electrodes, for different conditions (the representations shown in Figure 3 are based on high speed photographs).

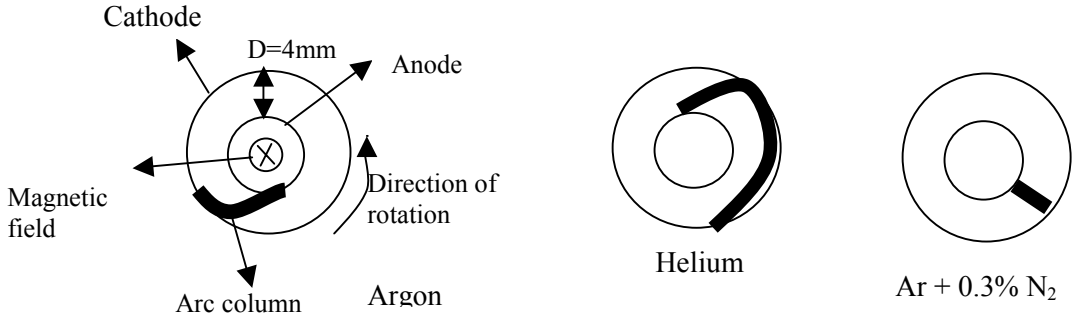

Fig. 3 Schematic representation of the electric arc and plasma between the electrodes, for different conditions

IV. Discussion

As it can be seen in Table II, the results obtained in the present work are very similar, for the same operating conditions, to the results obtained by other authors using similar equipment, validating the experimental procedures adopted here.

In general terms, the erosion of the cathode is higher for lower arc velocities (the arc stays longer over a same region, increasing the amount of material volatilized), which is affected by the surface conditions (work function in particular).

It has been reported [20], that the use of polyatomic gases or noble gases contamined with polyatomic gases contaminates the copper cathode surface and affects the arc caracteristics (arc velocity, arc residence time, arc voltage at the surface). In the present work, this has been also observed when comparing the results obtained using industrial and ultra pure argon, as well as when using argon + % of nitrogen (Table III).

The results obtained using industrial argon and electrolytic copper (experiment 1 in Table III) are very different than the ones reported by other researchers (19), who obtained, for otherwise similar conditions, an erosion rate of the cathode of 13.5 μg/C, arc velocity of 2 m/s and arc voltage of 44 V. The differences could be due to a contamination of the industrial argon used here or possible copper composition differences. The surface composition changes (caused by the use of mixtures of gases or copper alloys) would cause differences in work function among others, and this could change dramatically the behavior of the electric arc and plasma (see for instance Ref.19).

Comparing experiments 1 and 2, of Table III, it can be seen that the use of ultra pure argon indeed resulted in values closer to the ones obtained in (19), indicating that the industrial argon used here, although specified as 99.9 % pure, can have some contaminants that would cause a surface contamination (see above) which would result in a higher arc velocity, lower erosion rate (due to the high velocity) and lower voltage (less stretching of the electric arc, see for more details (16)). Analysis of the argon gases are current being conducted.

Comparing experiments 3 to 6 (Table III) it can be seen that the use of industrial or ultra pure argon, once % of nitrogen has been added to the argon main stream, did not result in significant differences, indicating that the level of contamination of the industrial argon is probably less than 0.3 % and that after a certain level of contamination of the surface is reached, the addition of more nitrogen did not cause substantial differences (up to a certain level, after what the nitrogen present in the argon stream would result in variations in all parameters, as it can be seen comparing experiments 3, 6 and 7 of Table III). The behavior of the arc adding nitrogen to a main argon gas stream observed here is similar to the ones obtained by other authors (19).

Experiment 8 (Table III) was conducted using industrial helium. The absolute values of the results obtained are different than the ones obtained by Szente (16) (who obtained lower arc velocity (20 m/s), similar erosion rate (1 μg/C) and higher voltage (110 V)), although the general trend, when comparing argon and helium was the same for both cases. Therefore comparing results 2 and 10 with the equivalent ones published previously (19), there is a strong indication that the copper material used here, although purchased as electrolytic copper, has composition differences when compared to the material used in the previous study. Analysis of the copper material used here, shown in Table I, indeed show the presence of several contaminants that could in principle cause variations in the properties of the surface (work function in particular) that would explain the differences found when comparing the results obtained here and the ones by Szente et al.

In Table IV it is shown the results obtained using different copper materials for the cathode, using ultra pure argon as the plasma gas. It can be seen that the use of copper-nickel alloy did not result in significant differences in erosion rate and arc velocity when comparing with the electrolytic copper. In Table V, the results obtained using the copper-nickel alloy for different gases, showed again similar results to the ones obtained using electrolytic copper. The use of the copper-nickel alloy may be important for other plasma gases, such as hydrogen; this is being investigated at the moment.

The decrease in the magnetic field strength (Table VI) resulted, as expected, in a decrease in the arc velocity (after correcting for the different arc currents used, the arc velocity for the lower magnetic field would be around 20 m/s) and an increase in the erosion rate.

The high speed photographs obtained in the present work show that the electric arc present similar characteristics to the ones published previously (19). The electric arc and plasma are longer for cleaner surface conditions (when using ultra pure argon, for instance), resulting in higher arc voltages.

V. Conclusion

Cathode erosion on copper electrodes by magnetically driven arcs was studied at atmospheric pressure by varying different parameters (B, I, type of plasma gas and purity of the electrode materials). The experimental results presented here will be used to further understand erosion phenomena. It was shown that the use of industrial gases affects the erosion rate and electric arc velocities due to contaminants present in the gases. The use of commercial electrolytic copper, for making cathodes, also revealed that there is an important level of contamination, which affects the overall behavior of the electric arc. Using copper-nickel alloys, as cathode material, did not result in significant differences when compared to electrolytic copper; however those alloys could be important for some plasma gases, such as hydrogen. Further experiments are being conducted in order to determine the effect of using industrial electrolytic copper and different plasma gases on the overall electric arc and plasma behavior.

A combined mass spectrometry and thin film deposition study of pulsed C_4F_8 plasmas

D. Theirich, F. Osenberg, J. Engemann

Forschungszentrum Mikrostrukturtechnik - fmt, University of Wuppertal, Wuppertal, Germany

Plasma polymerization of C_4F_8 was used to deposit teflonlike thin films. These films are used for example to control diffusion and the wettability of surfaces or as chemically inert and anti-sticking coatings. Besides other applications they are increasingly used in growing fields like biotechnological applications, sensors and nano systems. Important for theses films is the amount of CF_2 bonds inside the film which indicates how close the structure of the plasma deposited film comes to the structure of conventional teflon. Recently pulsed plasmas have been frequently used to influence and to control the plasma chemistry of molecular gas plasmas, especially pulsed plasmas have been used to control the degree of retention of the monomer structure during plasma deposition.

In this study pulsed C_4F_8 plasmas have been used to deposit thin films. XPS and FTIR analyses of these films were used to determine the film structure. A plasma monitor was used to perform neutral mass spectrometry, appearance mass spectrometry and time resolved mass spectrometry of C_4F_8 deposition plasmas in order to correlate the resulting film structure with the amount of different molecular fragments in the plasma. Mass spectrometry was also used to determine the essential reaction paths, which are influenced by pulsing the plasma. A capacitively coupled parallel plate rf plasma source (13.56 MHz) was used for the experiments. The upper electrode was a mesh connected to the rf generator. The lower electrode was grounded and used as substrate holder, which was held at a constant temperature of 20°C. The spacing between the electrodes was 3 cm. The monomer gas was supplied above the upper mesh electrode and transported to the mesh through a funnel shaped gas flow guiding.

The deposited films showed an increasing relative amount of CF_2 bonds under conditions of decreasing mean rf power, decreasing pulse-on times and increasing pulse-off times. Especially at constant mean power a decreasing pulse-on time results in an increasing CF_2 content in the films. Results from mass spectrometry showed the overall dissociation of C_4F_8 and the C_2F_6 content of the plasma is affected only by the mean rf power, whereas the content of fragments with larger carbon chains like C_4F_7 can also be influenced by the pulse parameters under conditions of constant rf power. Under these conditions the increasing C_4F_7 content in the plasma is correlated to an increasing relative amount of CF_2 bonds in the deposited films. Thus the results indicate that C_nF_{2n-1} fragments which may be produced by reactions of the type $C_3F_5 + nCF_2 \rightarrow C_nF_{2n-1}$ may contribute to the plasma deposition of fluorocarbon films with a large content of CF_2 bonds.

Modelling of a Microwave Flowing Post-Discharge in N_2-O_2 for Plasma Sterilization

Abstract
The aim of the present work is to give an insight into the kinetics of a low pressure afterglow of a microwave discharge in a N_2-x%O_2 mixture (x=0.2 and 2%). First, we calculate the conditions at the end of the discharge by solving the homogeneous Boltzmann equation for the electrons coupled with an appropriate set of rate balance equations. Once the concentrations of species are obtained, their temporal relaxation in the near afterglow is described by a 1D model. Then, we use a hydrodynamic 2D model to describe the flow in the sterilization vessel.

1.Introduction

Recently, gas plasma sterilization in hospitals has appeared as very promising alternative to conventional sterilization process, in particular for materials, essentially polymer based, that are heat sensitive. Among the proposed solutions to achieve sterilization using an afterglow plasma [1], it was shown that a N_2-2%O_2 mixture, within the pressure range 1-7 Torr and gas flow 0.5-3 slm, is a good candidate for such purposes [2]. In that paper an experimental study was realized on the operating conditions, pointed out the role played by O atoms and ultraviolet (UV) photons in spore inactivation. However, no modelling studies have been carried out to determine the concentrations of the various active species produced in the discharge, as well in the transport of the species in the post-discharge reactor. In this work, we present the results from a kinetic model for a microwave discharge at $\omega/2\pi$=915 MHz and its afterglow in a N_2-x%O_2 mixture with x=0.2 and 2%. The discharge model is based on the solution of the Boltzmann's equation for the electrons coupled to a set of rate balance equations for the various molecular and atomic species produced in the discharge, including ions and the vibrational distribution of $N_2(X^1\Sigma_g^+,v)$ molecules, in which the sustaining electric field is self-consistently determined [2]. Once the concentrations of the various neutral and ionic species are obtained, the time-evolution of the concentrations is analysed in the post-discharge by considering the relaxation of a set of coupled time-varying kinetic master equations for all heavy species. An analysis of the populating and depopulating mechanisms is then carried out for every species, with emphasis on $O(^3P)$ atoms, $NO(A^2\Sigma^+)$ and $NO(B^2\Pi_r)$ molecules, the later two being responsible for the UV emission of NOγ and NOβ system bands.
In parallel with this 1D analysis, a hydrodynamic 2D model for the afterglow taking into account the proper dimensions of the sterilizer vessel, has also been considered to determine the concentrations of O atoms and other active species near the sample to be sterilized. The hydrodynamic model is based on the solutions of the coupled transport equations, corresponding to the conservation of mass, the conservation of momentum and the conservation of heat.

2.Kinetic Model

Our work involves the kinetic study of two main different regions: the plasma source and the afterglow chamber, where the objects to be sterilized are placed (see figure 1). The plasma source includes the discharge tube and its connection to the sterilization chamber. In this intermediate zone a short-lived afterglow occurs. We start our analysis by the discharge, where we consider a steady-state kinetic model, based on the solutions to the homogeneous Boltzmann's equation coupled to a system of rate balance equations for the most populated neutral and ionic species present in a N_2-O_2 microwave discharge [2].

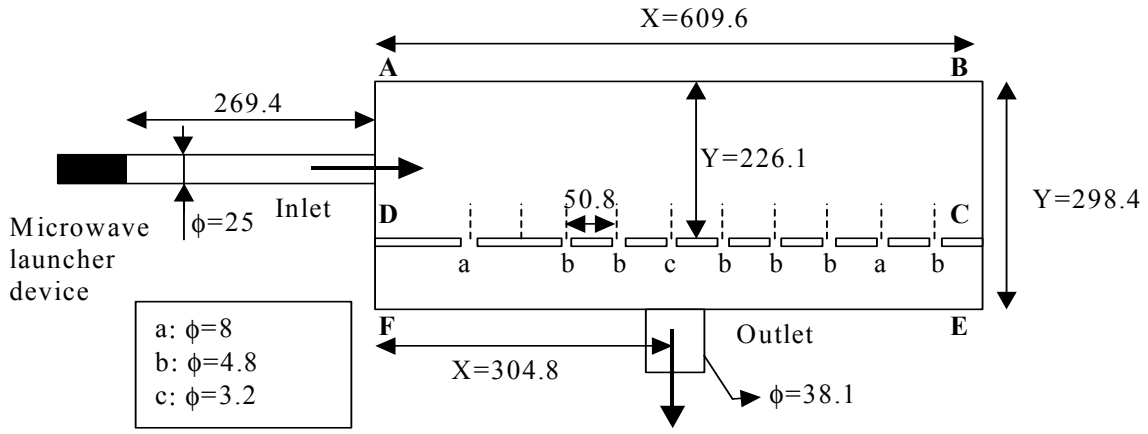

Fig.1 : Schematic of the sterilizer reactor. Units are in mm.

The reduced sustaining electric field in the plasma is self-consistently calculated using the requirement that under steady state conditions the total rate of ionization must compensate exactly for the rate of electron loss by diffusion to the wall plus the electron-ion recombination. In this analysis, we have considered two improvements in the model presented in [2]. First, we have included the kinetics of the atomic metastables $N(^2D,^2P)$, as it was recently proposed [3]. Secondly, within the purposes of this work, we have introduced the kinetics of NO(A) and NO(B) molecules, where we have added the reactions presented in table 1.

Table 1 : Reactions considered for the species NO(A) and NO(B).

$N_2(A)+NO(X) \rightarrow N_2(X,v=0)+NO(A)$	[4]	$NO(A)+N_2 \rightarrow NO(X)+N_2$	[8]
$N+O+O_2 \rightarrow NO(X)+O_2$	[5]	$NO(A)+O_2 \rightarrow NO(X)+O_2$	[8]
$N+O+(M) \rightarrow NO(B)+(M)$, $M=N_2, O_2$	[6]	$NO(A)+NO(X) \rightarrow NO(X)+NO(X)$	[9]
$NO(B)+N_2 \rightarrow NO(X)+N_2$	[7]	$NO(B) \rightarrow NO(X)+h\nu$	[9]
$NO(B)+O_2 \rightarrow NO(X)+O_2$	[8]	$NO(A) \rightarrow NO(X)+h\nu'$	[10]
$NO(B)+NO(X) \rightarrow NO(X)+NO(X)$	[8]		

Once the concentrations for the neutral and ionic species produced in the microwave discharge are obtained, we must investigate their temporal evolution until they reach the sterilization chamber. This is done by considering a system of coupled time-varying kinetic master equations for the most important heavy species, including ions and the vibrational distribution of $N_2(X^1\Sigma_g^+,v)$, where we assume the calculated concentrations in the discharge as initial conditions.

After these calculations, we can describe in detail the concentrations of active species in the sterilization vessel, by assuming the former as the concentrations at the entry of the reaction chamber. The modelling of this reactor has been done using or not the pumping grid (noted CD in Fig. 1). Thus, two geometries have been considered. They are represented by the two volumes ABCD and ABEF in Fig. 1. This 50-liter sterilizer (aluminum frame) is described as providing better spatial uniformity of the active species in the afterglow chamber [11]. A more detailed development of the equations solved, the boundary conditions and the finite volume method used herein is provided in [12].

3.Results and Discussion

The calculations of our work have been carried out for typical operating conditions of a microwave discharge at $\omega/2\pi$=915 MHz in a N_2-x%O_2 mixture (x=0.2 and 2) with p=8 Torr and a gas temperature T_g=1000K in a discharge quartz tube of inner radius R=1.3 cm. The electron density in the discharge is assumed to be equal to the critical value for surface-wave mode propagation, $n_e=5.196\text{x}10^{10}\text{cm}^3\text{s}^{-1}$, since the values calculated in the

discharge constitute the initial conditions at the beginning of the afterglow. Further, we have assumed a gas temperature T_g=500 K in the near afterglow.

The results concerning the temporal evolution in the near afterglow are presented in figures 2 to 5. Figure 2 and 3 report, respectively, the temporal evolution of the concentrations of $[N(^4S)]/[N_2]$,$[O(^3P)]/[N_2]$, $[NO(X)]/[N_2]$ and $[NO(A)]/[N_2]$, $[NO(B)]/[N_2]$ for N_2-0.2%O_2.

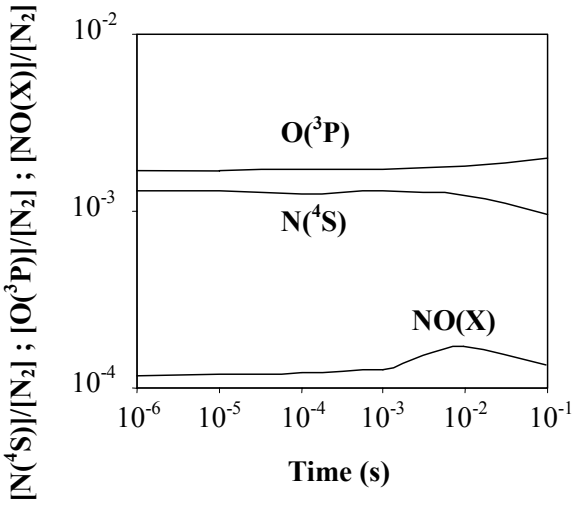

Fig. 2 : Temporal evolution of $[N(^4S)]/[N_2]$, $[O(^3P)]/[N_2]$ and $[NO(X)]/[N_2]$ in the near afterglow of a N_2-0.2%O_2 microwave discharge, with $\omega/2\pi$=915 MHz and p=8Torr.

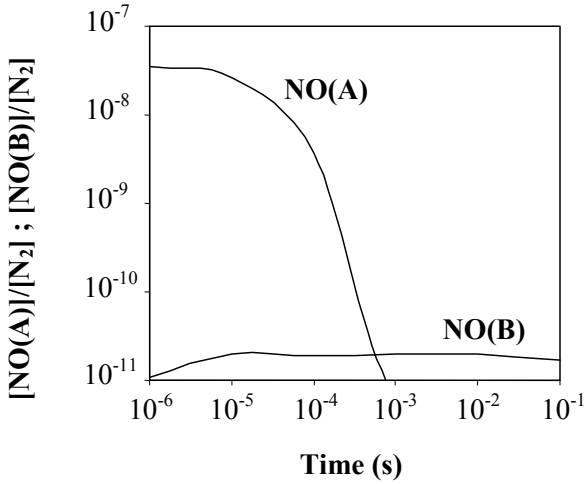

Fig. 3 : Temporal evolution of $[NO(A)]/[N_2]$ and $[NO(B)]/[N_2]$ in the near afterglow of a N_2-0.2%O_2 microwave discharge, with $\omega/2\pi$=915 MHz and p=8Torr.

Figs 4 and 5 show the same information as in Figs 2 and 3, but for the case of a higher O_2 initial concentration in the mixture, i.e. 2%O_2.

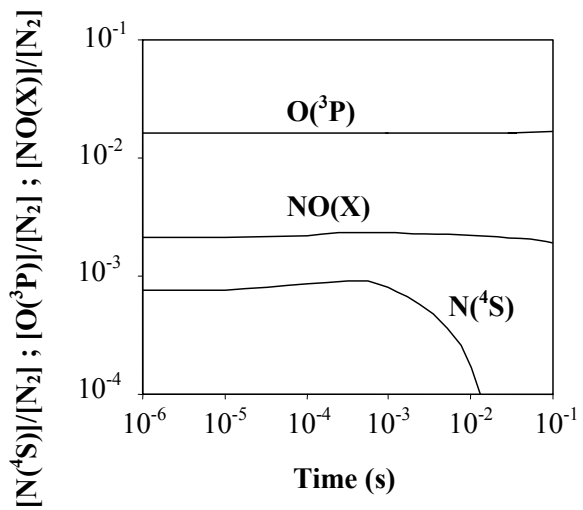

Fig. 4 : As in Fig.2, but for a N_2-2%O_2 mixture.

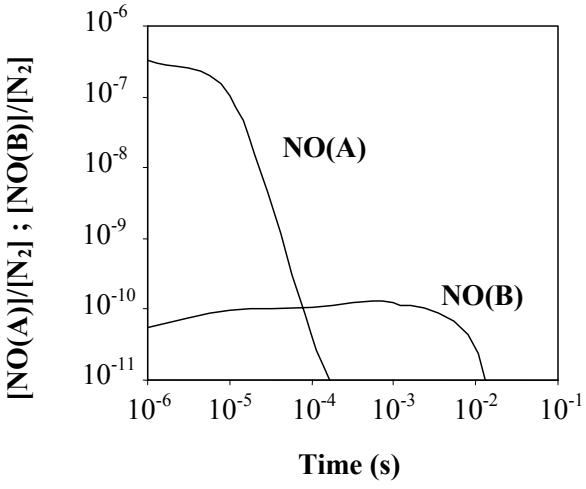

Fig. 5 : As in Fig.3, but for a N_2-2%O_2 mixture.

Figure 2 and 4 show that the relative concentrations $[N(^4S)]/[N_2]$, $[O(^3P)]/[N_2]$ and $[NO(X)]/[N_2]$ remain practically unchanged during the short-lived afterglow, with the exception of $N(^4S)$ for times $t \geq 10^{-2}$s in the case

of 2%O_2. For these larger values of *t*, the main mechanism of creation for N(^{4}S) is the reaction $N_2(X,v\geq13)+O\rightarrow NO+N$, whose rate becomes smaller in a N_2-2%O_2 mixture, as a result of a stronger depletion of the higher vibrational levels not shown here.

Figures 3 and 5 show a faster decay of NO(A) and NO(B) concentrations in the short-lived afterglow when the initial oxygen concentration increases. The NO(A) state is destructed more efficiently in a N_2-2%O_2 mixture via the reaction $NO(A)+O_2 \rightarrow NO(X)+O_2$. On the other hand, the NO(B) concentration remains almost constant in a N_2-0.2%O_2 afterglow and has a very fast decay for times $t\geq10^{-2}$s in a N_2-2%O_2 mixture. Since NO(B) is only created through the three body reaction, $N+O+M\rightarrow NO(B)+M$ (M=N_2 and O_2), and [O(^{3}P)] remains unchanged during the afterglow, we can conclude that the NO(B) decay follows that of N(^{4}S).

Using the data available from the 1D post-discharge model after a 0.1 s flow in the 25 mm ID quartz tube (see Fig. 1), calculations have been performed to understand the flow of the active species in the sterilization chamber. The set of chemical reactions considered in the present calculation is available in [12].

The chemistry of the post-discharge strongly evolves when the amount of oxygen in the initial gas mixture increases from 0.2 to 2%. For example, nitrogen atoms are no longer present at 2%. To account for such changes, the set of reactions considered in the late post-discharge has been adapted from the one presented in [12] to the two cases considered herein (0.2 and 2%). The influence of NO_2 has also been considered, contrary to the 1D model. Its concentration has thus been assumed to be null at the entrance of the reactor.

The temperature of the gas at the entrance of the sterilizer has been chosen equal to 500 K, whereas the temperature of the walls has been assumed to stay at room temperature. The pumping configuration being extremely important to distribute the active species around the samples, the two geometries previously presented have been studied using the two mixtures N_2-0.2%O_2 and in N_2-2%O_2. The velocity maps are depicted in Fig. 6 and 7. The improvement due to the grid noted (DC) in Fig. 1 is of major importance, since the flow no longer presents strong recirculation when it is used (only one remains in the upper right side of the vessel). Only this geometry will be retained hereafter.

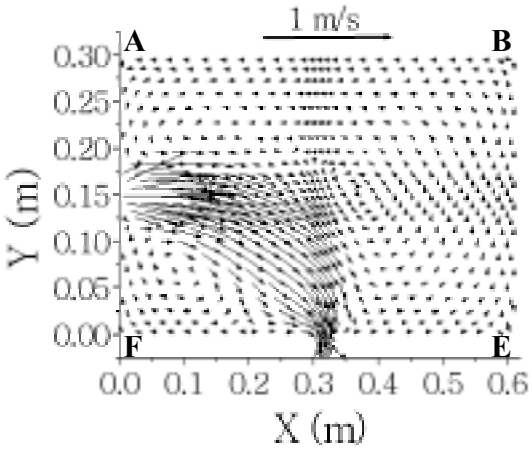

Fig. 6 : Velocity map in the (ABEF) volume of the reactor (see Fig. 1 for the meaning of the letters)

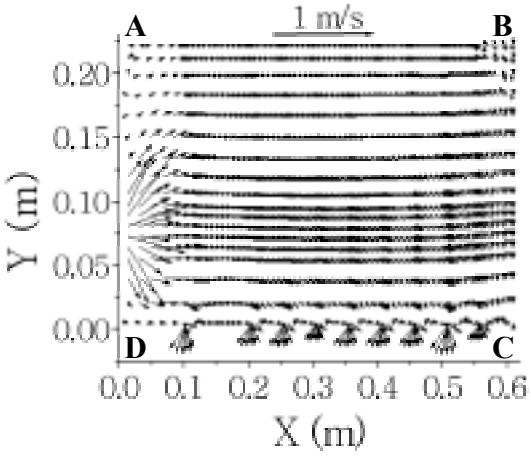

Fig. 7 : Velocity map in the (ABCD) volume of the reactor (see Fig. 1 for the meaning of the letters)

Only species with meaningful variations are represented in Fig. 8 to 11.

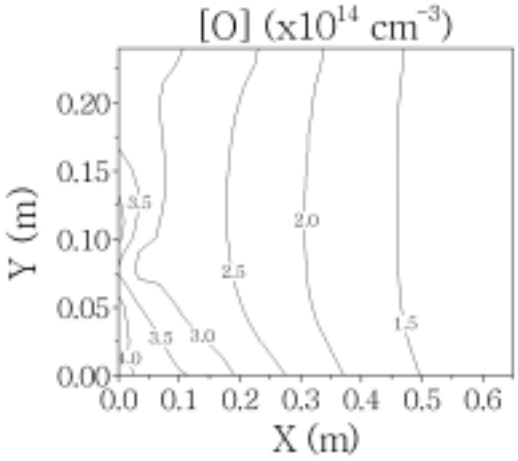

Fig. 8 : Density map of atomic oxygen in a late N_2-0.2%O_2. Reactor geometry : (ABCD).

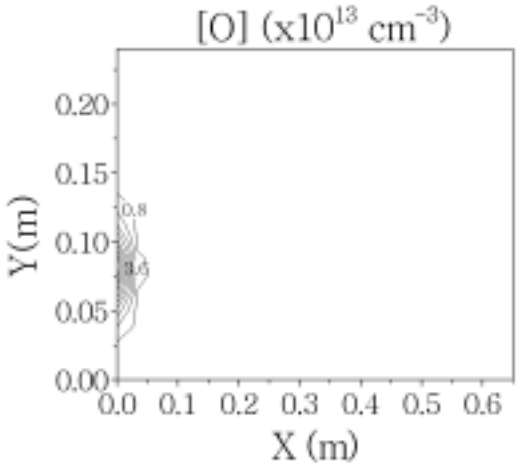

Fig. 9 : Density map of atomic oxygen in a late N_2-2%O_2. Reactor geometry : (ABCD).

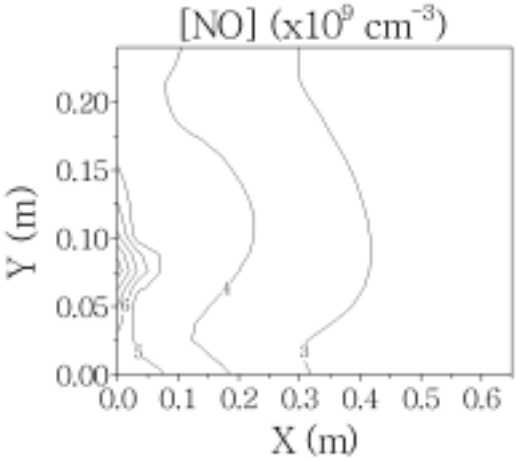

Fig. 10 : Density map of nitrogen monoxide in a late N_2-0.2%O_2. Reactor geometry : (ABCD).

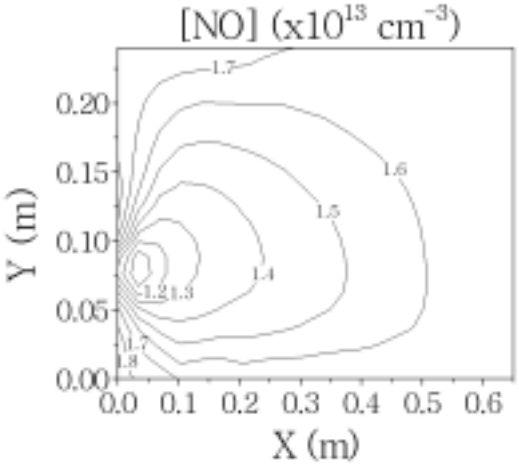

Fig. 11 : Density map of nitrogen monoxide in a late N_2-2%O_2. Reactor geometry : (ABCD).

The density of oxygen atoms strongly decreases at the entrance of the reactor. Their repartition is affected when the initial amount of oxygen in the gas varies. It is mainly due to the creation of NO_2 from NO molecules. This reaction is much less efficient in the N_2-0.2% O_2 mixture where the density of NO molecules is much lower (Figs. 10 and 11). The NO radical also evolves significantly from a N_2-0.2% O_2 mixture to a N_2-2% O_2 mixture but in an opposite way. To interpret the slight increase in NO density in Fig. 11, one must keep in mind that the temperature decreases in the reactor from 500 K at the entrance to 300 K at the walls. Thus, such an increase corresponds in fact to a weak consumption of matter in a temperature gradient. The evolution of the density of O_3, which is not represented herein, is not significantly affected by the change in the oxygen concentration. It is close to $2x10^{12}$ cm^{-3} mainly distributed near the walls. Thus, one can think from these results that the mechanisms responsible for the sterilization, which is efficient in both cases, are not the same. New experiments are in progress to confirm the first trends revealed by the present models.

Abstract
On long (30 – 60 sec.) plasma pre-treated polyimide (UPILEX) Cu/Cr films show high initial adhesion strengths, but also a significant loss in the adhesion strength of up to 40 % after thermal aging at 150°C and 250 hours. Short (3 – 6 sec.) plasma pre-treated samples have initially a 20% lower adhesion strengththan the long pre-treated samples, but show no reduction of the adhesion strength after thermal aging. The different long-term stability behavior of the short and long plasma pre-treated samples can be explained by relaxation processes inside the plasma modified surface layer of the polymer.

1. Introduction

The continuing trend towards miniaturization of electronic devices requires also development of cost-effective, environmentally friendly materials and processes for the interconnection techniques. The gap between chip production, now producing 80 nm lines and spaces, and the interconnection techniques able to producing electronic circuit boards with 60 µm structures, must inevitably shrink. Laser direct patterning (LPD) is a new possibility to structure ultra-thin metallic films laid onto polyimide foils [1]. By using a KrF UV eximer laser (λ = 248 nm) the light penetrates the ultra-thin (d ~ 50 nm) metal film and cracks the chemical bonds at the metal-polymer interface. The resulting plasma plume lifts off the metal film in a mini explosion. With this technique, structures less than 15 µm can be produced on 1 cm^2 by a single millisecond long laser shot.

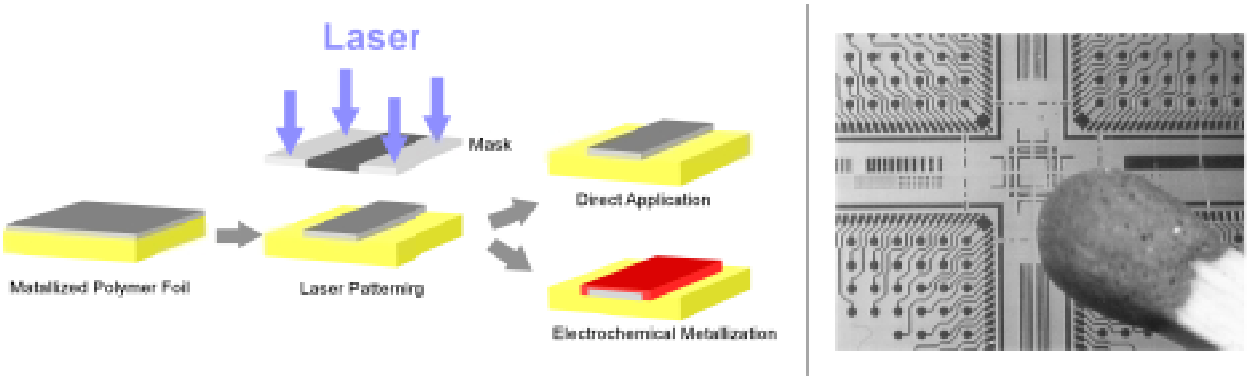

Figure 1
Principle of the direct laser pattering (LPD) process, together with a picture showing electronic interconnects produced by LPD on a thin polyimide foil. The finest lines and spaces are 15 µm wide.

For electronic applications very strong and durable adhesion of the metallization is required. The IPC-FC-241/18 norm dictates adhesion strength higher than 7 Ncm^{-1} after deposition and 5.2 Ncm^{-1} after thermal aging at 150°C and 1000 hours. These very strong adhesion requirements demand an activation of the polymer substrate surface. Plasma treatment is one of the more recent technologies to improve the adhesive properties of polymers. The plasma activation of a polymer surface is related to surface cleaning by ablation of low-molecular-weight materials, crosslinking and formation of polar functional groups, resulting in a

change of the surface energy γ. According to the Dupré relation an increase in surface energy will result in a higher reversible thermodynamic work of adhesion W_A given by:

$$W_A := E_i - E_f = (\gamma_A - \gamma_B) - \gamma_{AB} \qquad \text{Dupré relation}$$

Where E_i is the energy of the initial sate given by the sum of the surface energies γ_A, γ_B of the body A and B and E_f the energy of the final state given by the interface energy γ_{AB} of the two bodies in contact.
In the present contribution we will show that the adhesion performance between a metal film and a plasma modified polymer is in generally rather limited by the cohesion of the polymer near the plasma modified surface than by the adhesion at the metal-polymer interface. X-ray photoemission spectroscopy (XPS) data from the fracture surfaces after peel test reveal that the critical zone limiting the adhesion behavior of the metal film is located ~ 2 nm inside the polymer and not at the metal-polymer interface. A phase separation process of the plasma modified polymer chains and the bulk polymer can explain the formation of this new interface inside the polymer.

2. Experimental

The polyimide used was a commercial UPILEX foil. Figure 2 shows the XPS reference spectra together with the repeating structural unit of the UPILEX. Prior metallization the UPILEX surfaces was activated by Ar/O_2 RF-plasma at p = 2 x 10^{-2} mbar. Subsequently a 10 nm thin Cr adhesion layer followed by a 50 nm thick Cu film were sputtered onto the plasma activated polymer surface "in-situ". Finally a 50 µm thick Cu film was deposited electrochemically onto the sputtered Cu film. The adhesive strengths were determined by a standard 90° peel test. X-ray photoelectron spectroscopy (XPS) was performed in an Omicron Fullab equipped with an EA-125HR electron analyser. Analysis were carried out with non-monochromatized MgKα (hν = 1253,6 eV) radiation. The instrument was calibrated to the $Au4f_{7/2}$ signal at the binding energy of E_B = 84.0 eV and the $Cu2p_{3/2}$ signal at E_B = 932.7 eV. The mean free path λ_e for inelastic scattering of 1.0 keV electrons in polymers is about 30 Å [2], which results in a XPS probing depth of about 100 Å for electron emission normal to the surface. Charging of the samples, due to the photoemission process, was corrected by setting the binding energy of the main carbon component (-CH_2- component) in the C1s spectrum to 284.8 eV.

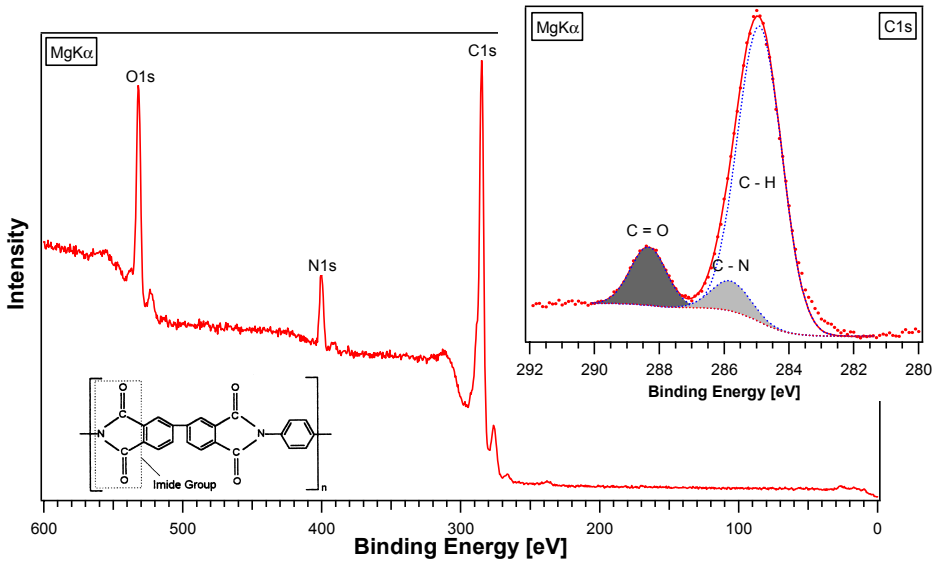

Figure 2
Reference XPS spectra together with the repeating structural unit of the untreated UPILEX surface.

3. Results and Discussion

For UPILEX treated for 30 – 60 sec. in Ar/O_2 RF-plasma we measured initial (as deposited) adhesion forces of 9.2 – 13.8 Ncm^{-1}. This is significant higher than the 7.0 Ncm^{-1} provided by the IPC-FC-241/18 norm. After thermal aging at 150 °C for 100 hours and 250 hours the adhesion forces reduce to 6.1 – 7.8 Ncm^{-1} and 4.6 – 5.9 Ncm^{-1} respectively. With this values we are not able to fulfil the 5.2 Ncm^{-1} after 1000 hours thermal aging provided by the IPC-FC-241/18 norm. XPS analysis of the fracture surfaces (Fig. 3) suggest that the loss in the adhesion force during thermal aging is associated to a change in the fracture behavior. The overview spectrum of the fracture surface from the Cu/Cr-side peel test fragment of the as deposited sample shows apart from the C1s, N1s and O1s signals from the UPILEX no additional signals from the underlying metal Cr adhesion layer. This indicates that the cohesive fracture is at least 100 Å (XPS probing depth) underneath the metal/polymer interface inside the polymer. After thermal aging Cr signals from the adhesive layer appear in the XPS spectra of the Cu/Cr-side peel test fragments, indicating that the fracture becomes closer and closer to the metal/polymer interface with increasing aging time, but still cohesive. For the 250 hours thermal aged samples we determined using the Toogaard procedure [3], we determined an average thickness of 20 Å for the polymer layer sticking on the Cr film, which indicates the cohesive nature of the fracture. The C1s detail spectra from the UPLEX-side fracture surfaces are for all samples identical with the reference spectrum of the untreated UPILEX (Fig. 2). In opposition to that shows the C1s detail spectra of the Cu/Cr-side fracture surfaces an increase in the intensity of the C = O component with increasing aging time. The increase of the C = O component indicates the presents of plasma modified polymer chains. From this observation we conclude that during the thermal aging process a new interface inside the polymer is formed by a phase separation of the plasma modified polymer chains from the bulk polymer, and the fracture propagates along this new interface.

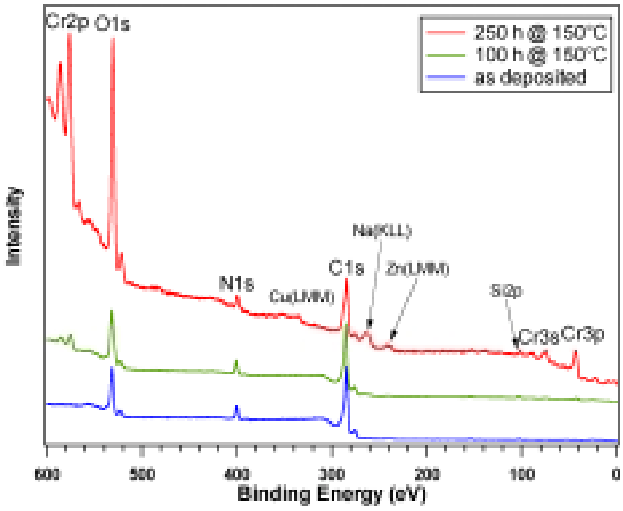

Figure 3

XPS overview spectra from the fracture surface of the Cu/Cr side peel test fragment, peel tested after deposition and after thermal aging at 150 °C for 100 and 250 hours, respectively. The UPILEX surface was pre-treated for 30 sec. in Ar/O_2 plasma.

On polymers the plasma treatment is not restricted to the surface. The thickness of the polymer surface layer strongly modified by plasma treatments is about 100 Å [4 – 6]. This plasma modified surface layer is initially in a highly excited state and tends to relax. In the presence of a reactive metal on the surface (Cr layer) the functional groups inside in the modified surface layer have the tendency to migrate at the surface and forming chemical bonds with the metal. This thermal driven process becomes equal to a phase separation process between the plasma-modified polymer chains and the bulk polymer, resulting in the formation of a new interface with low cohesive strength. The formation of this new polymer/polymer interface is in generally the limiting factor for the long-term stability of the adhesion of metal films on plasma modified polymers. As stronger the plasma modifications (polar bonds, chain secession) inside the polymer are as faster the phase separation process occurs. Consequently, in regard to the long-term stability of the adhesion, it is very important to reduce the plasma modifications in the surface region of the polymer as much as

possible. A confirmation of this conclusion can be found in the work of Gong et al. [7]. They studied the effect of sticker groups (–COOH) on the fracture energy of Al – cPBD interface (cPBD: carboxylated polybutadiene (PDB)) and found that a small amount of sticker groups improves the fracture energy considerably. They found a critical concentration around 3 mol% to give a maximum bond strength. Higher concentrations of sticker groups show lower bond strength. Further they showed that the concentration of sticker groups was much higher at the interface as in the bulk polymer, indicating the migration of the sticker groups to the interface. To proof our idea that relaxation processes inside the plasma activated polymer surface region are important for the long-tern stability of the adhesion we reduced the plasma pre-treatment time by a factor of ten to 3 – 6 seconds. The initial adhesion forces of the Cu/Cr film on such plasma pre-treated UPILEX was between 8.0 and 9.1 Ncm^{-1}. These values are about 20 % lower than for the samples with 30 – 60 seconds plasma exposure time, but still higher than the 7.0 Ncm^{-1} dictated by the IPC-FC-241/18 norm. The type of fracture for the short pre-treated samples is mixed adhesive/cohesive, indicated by the presence of the Cr signals in the overview spectrum and the Cr-C component in the C1s spectrum of the Cu/Cr side fracture surface (Fig. 4).

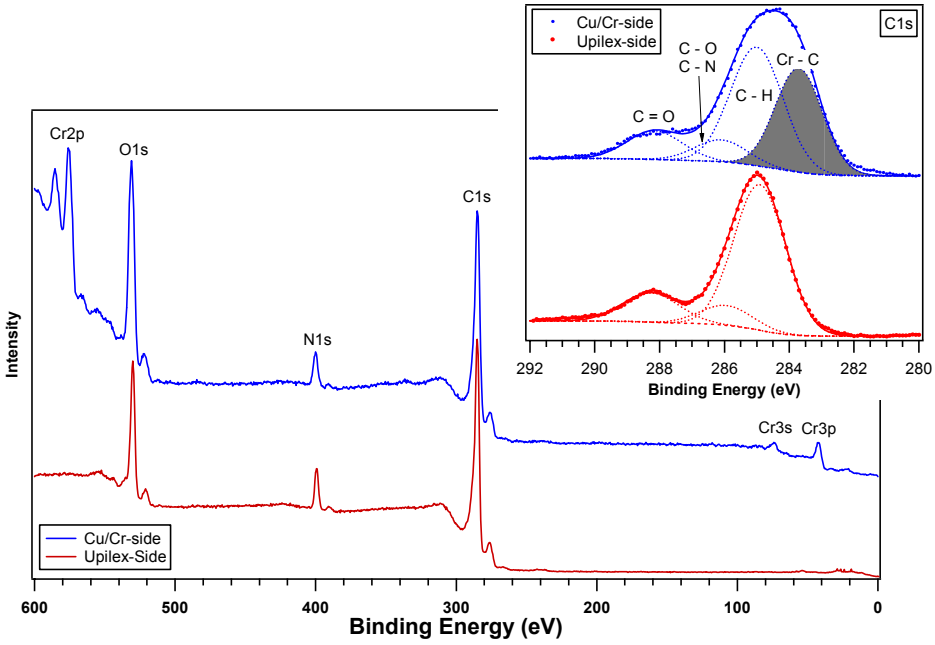

Figure 4
XPS spectra from the fracture surfaces from as deposited Cu/Cr-UPILEX sample.
The UPILEX surface was pre-treated for 5 sec. in Ar/O_2 plasma.

The mix-fracture can be associated to the structure of UPILEX consisted by crystalline and amorphous regions. Due to the stretching in the manufacturing of thin foils the crystalline regions are oriented parallel to the surface. The cohesive strength perpendicular to the surface is therefore very low for the crystalline regions at the surface. Consequently, the crystalline parts do practically not contribute to the adhesion of the metal film. The type of fracture in the crystalline regions is in generally cohesive. In the amorphous regions the type of fracture can be adhesive or cohesive depending on the surface activation. In our case the fracture is cohesive in the amorphous regions for long plasma pre-treatment and adhesive for short plasma pre-treatment. This explains the perfect cohesive fracture for the sample with long plasma pre-treatment and the mixed adhesive/cohesive fracture for the short plasma pre-treated samples (Fig. 5).
In contrast to the long plasma pre-treated samples show the samples with short plasma pre-treatment no losses in the adhesive strength during thermal aging. In the ideal case the adhesive strength even increases after thermal aging up to values of 10.5 Ncm^{-1}. Behind this effect are the same processes which are responsible for the weak layer formation in samples with long plasma pre-treatment. The migration of polar bonds inside the plasma modified surface region to the metal/polymer interface increases the number of

metal/polymer bonds and consequently the adhesion at the interface, but not to a phase separation and consequently to the formation of weak boundary layer as proposed for the long plasma pre-treated sample.

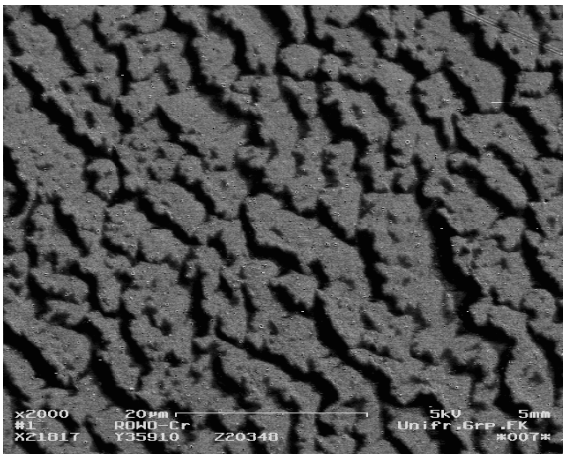

Figure 5
SEM picture of the Cu/Cr side fracture surface from a sample with short plasma pre-treatment.
The dark (polymer) and bright patches (Cr) illustrate the mixed adhesive/cohesive fracture of the sample.

4. Conclusion

For polymers, plasma treatments can not be considered as a classical surface effect. The surface region on polymer modified by plasma treatments is at least 100 Å thick. This plasma modified surface region is initially in a highly excited state and tends to relax. In the presence of a reactive metal on the surface (Cr layer) the functional introduced by the plasma have the tendency to migrate to the metal/polymer interface and forming chemical bonds with the atoms from the metal film. If the amount of adhesive sites inside the plasma modified surface region is to high the migration process becomes to phase separation process of the plasma modified polymer chains and the bulk polymer. This results in the formation of new interface inside the polymer with a low cohesive strength. For long plasma treated samples the formation of this new interface is factor limiting the long-term stability of the adhesion. For short plasma pre-treatments the amount of modifications inside the polymer is not high enough to trigger the phase separation process, which explains the good long-term stability of the adhesion. Our investigations have shown that the relaxation of the plasma activated polymer surface region may have strong effects on the long-tern stability of the adhesion of metallized films and must be considered in the optimization of the adhesion behavior of plasma modified polymer surfaces.

Plasma Functionalisation of the Carbon Nanofibres Surface

G. Marginean, W. Brandl

Department of Materials Science, University of Applied Sciences Gelsenkirchen, Gelsenkirchen, Germany

A selected plasmachemical treatment is utilised to improve the surface properties of carbon fibres used for fibre-reinforced composites. Compared to other methods for modifying the fibres surface the plasma treatment has many advantages [1]. Plasma processing presents, besides the advantage of a dry and clean process, also the advantage of the non-significantly diminishing of the fibre mechanical and physical properties [2].
In this study differerent plasma functionalisations of Vapour Grown Carbon-Nanofibres (VGCNF) surface are presented. The VGCNFs have a diameter of 50-200 nm and a length of 100-200 μm and are produced by the cathalytic decomposition of gaseous carbon precursors. Depending on the plasma parameters and functionalising gases (O_2, NH_3, N_2), an enhancement of the fibre surface energy occurs. Those surface treatments are doubly important in composites because they optimise the adhesion between the fibre and the polymer matrix which conducts to the improvement of the mechanical and physical properties of the composite. The morphology and the properties of the carbon nanotubes as well as of the fibre/polymer composites (before and after the plasma functionalisation) were characterised by scanning electron microscopy (SEM), contact angle measurements, electrical conductivity measurements and testing of the tensile strength of the obtained composites.

Prediction of anode arc root position in a DC arc plasma torch

He-Ping Li[1], E. Pfender[1], Xi Chen[2]

[1] *Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN 55455, USA*
[2] *Department of Engineering Mechanics, Tsinghua University, Beijing 100084, P. R. China*

Abstract
Modeling results are presented concerning the 3-D flow and heat transfer inside a non-transferred DC arc plasma torch using two different electric potential boundary conditions, i.e. anode iso-potential condition and the Steenbeck minimum principle. The computed results show that although the predicted anode arc root positions by the two approaches are almost the same, using the Steenbeck minimum principle can predict more precisely the anode arc root shape and the local high temperature region near the anode arc spot.

1. Introduction

Although DC arc plasma torches have been widely used over the past decades, understanding of the complex physical and chemical processes occurring inside plasma torches are still incomplete. The complex interactions between electromagnetic fields, gas flow and arc self-induced flow fields and temperature fields make modeling a formidable task. Transient behavior of the arc, non-local thermodynamic equilibrium (non-LTE) effects near electrodes, three-dimensional (3-D) effects inside the torch add further to this complexity [1]. In this paper, we will focus on the 3-D effects inside a non-transferred DC arc plasma torch.

The complex physical phenomena inside a DC arc plasma torch can be described by a complete set of magnetohydrodynamic (MHD) equations. Previously, many researchers used the two-dimensional (2-D) MHD equations to simulate the temperature, flow and electromagnetic fields inside the torch [2-7]. Although some useful information can be obtained by 2-D modeling, 3-D effects are entirely ignored. For example, the predicted arc voltage for the turbulent regime is much higher than measurement indicated, and the calculated anode arc root position at the anode surface is also much farther downstream than actually observed [6, 7]. A 3-D MHD model was proposed in Refs. [7, 8] to simulate heat and flow patterns inside a DC arc plasma torch. And physically reasonable anode arc root positions at the anode surface were obtained for a few operating parameters [7, 8].

As indicated in Ref. [4], the Steenbeck minimum principle [9] is a very useful tool to predict anode arc root positions at the anode inner surface. This principle is compatible with Maxwell's equations, and thus, it is not an independent law [10]. The goal of this paper is to compare the 3-D heat and flow patterns inside a non-transferred DC arc plasma torch by employing the Steenbeck minimum principle with those using the previous 3-D MHD model presented in Refs. [7, 8].

2. Mathematical model

2.1 Basic assumptions

In this paper, the following assumptions are employed for the 3-D modeling:

(1) The flow inside the plasma torch is quasi-steady, turbulent, having temperature-dependent properties;
(2) The plasma is in LTE state outside the electrode boundary layers and optically thin;
(3) The viscous dissipation and the pressure work terms in the energy equation are neglected;
(4) The working gas (argon) is injected into the plasma torch in axial direction, i. e., without any swirling velocity component of the gas at the torch inlet;
(5) The induced electric field $\vec{V}\times\vec{B}$ is negligible in comparison with the electric field intensity $\vec{E}$.

2.2 Governing equations

Based on the foregoing assumptions, the governing equations for the 3D quasi-steady numerical simulations can be written in (r,θ,z) coordinates as follows:

$$\nabla\cdot\left(\rho\vec{V}\right)=0 \tag{1}$$

$$\nabla\cdot\left(\rho\vec{V}\vec{V}\right)=\nabla\cdot\left(-p\vec{I}+\vec{\tau}\right)+\vec{j}\times\vec{B} \tag{2}$$

$$\nabla \cdot \left(\rho c_p \vec{V} T\right) = \nabla \cdot \left(\Gamma_T \nabla T\right) + j^2/\sigma + \frac{5}{2}\frac{k_B}{e}\vec{j} \cdot \nabla T - S_R \tag{3}$$

$$\nabla \cdot \left(\sigma \nabla \phi\right) = 0 \tag{4}$$

In the preceding equations, $\vec{V}$, p, T and ϕ are the velocity, pressure, temperature of the gas and the electric potential, respectively. $\vec{\vec{I}}$ and $\vec{\vec{\tau}}$ are unit tensor and shear stress tensor, respectively. The current density vector $\vec{j}$ relates to the electric potential ϕ as

$$\vec{j} = -\sigma \nabla \phi \tag{5}$$

$\vec{B}$ is the magnetic induction, which is obtained by

$$\vec{B} = \nabla \times \vec{A} \tag{6}$$

and by using this equation in the actual modeling work speeds up the iteration process [7]. In Equation (6), $\vec{A}$ is the magnetic vector potential, which satisfies the following equation

$$\nabla^2 \vec{A} = -\mu_0 \vec{j} \tag{7}$$

with

$$\vec{A}(x, y, z) = \frac{\mu_0}{4\pi}\int_{V'}\frac{\vec{j}(x', y', z')}{r}dV' \tag{8}$$

as the boundary conditions, where μ_0 is the permeability in vacuum. The boundary conditions for the magnetic vector potential employed in this paper are very different from those employed in Ref. [11].

The standard $K-\varepsilon$ two-equation turbulence model is employed in this study. The turbulent kinetic energy and its dissipation rate equations are

$$\nabla \cdot \left(\rho \vec{V} K\right) = \nabla \cdot \left(\Gamma_K \nabla K\right) + G - \rho\varepsilon \tag{9}$$

$$\nabla \cdot \left(\rho \vec{V} \varepsilon\right) = \nabla \cdot \left(\Gamma_\varepsilon \nabla \varepsilon\right) + \frac{\varepsilon}{K}\left(c_1 G - c_2 \rho\varepsilon\right) \tag{10}$$

The turbulent generation term G appearing in Equations (9) and (10) is expressed as

$$G = \mu_t\left\{2\left[\left(\frac{\partial v_z}{\partial z}\right)^2 + \left(\frac{\partial v_r}{\partial r}\right)^2 + \left(\frac{\partial v_\theta}{r\partial\theta} + \frac{v_r}{r}\right)^2\right] + \left(\frac{\partial v_z}{\partial r} + \frac{\partial v_r}{\partial z}\right)^2 + \left(\frac{\partial v_\theta}{\partial z} + \frac{\partial v_z}{r\partial\theta}\right)^2 + \left(\frac{\partial v_r}{r\partial\theta} + \frac{\partial v_\theta}{\partial r} - \frac{v_\theta}{r}\right)^2\right\} \tag{11}$$

where v_r, v_θ and v_z are the components of the velocity vector $\vec{V}$ in r-, θ- and z-directions, respectively. All the physical quantities in the foregoing equations are their time-averaged values. ρ, c_p, σ and S_R are the temperature-dependent mass density, specific heat at constant pressure, electric conductivity and the radiation power per unit volume of an argon plasma, respectively. k_B is the Boltzmann constant, e is the elementary charge. The effective 'diffusion' coefficients are the combination of laminar and turbulent values in the transport equations.

2.3 Calculation domain and boundary conditions

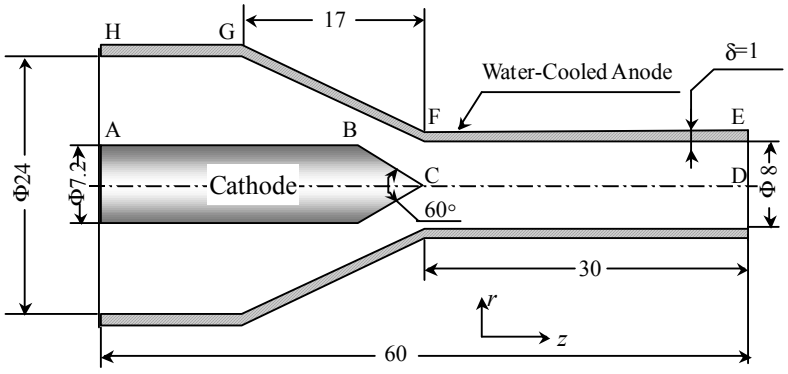

Figure 1. Calculation domain.

The calculation domain, as shown in Figure 1, is formed by the rotation of the region ABCDEFGHA about the torch axis with the indicated geometric dimensions. In this paper, the copper anode, the thickness of

which is in order of 1 *mm*, is included in the computational domain for getting a reasonable prediction of the temperature distribution on the anode. The boundary conditions are listed in Table 1, where Q is the volumetric flow rate of the working gas, A is the inlet cross-section area of the torch, while Φ_i are the values of the variable Φ at the grid points on the small circle nearest to the centerline ($\Phi = v_r, v_z, T, K, \varepsilon, \phi$). At the cathode surface, the temperature (T_c) and current density ($\vec{j}_0$) distributions are specified as shown in Figure 2 according to the experimental data presented in Ref. [12]. Then, the potential gradient is calculated as

$$\vec{j}_0(r) = -\sigma \frac{\partial \phi}{\partial n} \tag{12}$$

where $\vec{j}_0(r)$ is the current density vector at the location of the cathode arc root. This vector is perpendicular to the cathode surface and a function of the radial distance (r) and the axial distance from the cathode tip (z_c), while n indicates the normal direction of the cathode surface from the inner side to the outer side of the cathode. On the symmetry plane [$\theta = 0\,(2\pi)$], a periodic boundary condition is employed as follows [7]:

$$\Phi_{b_1} = \Phi_{b_2} \approx \frac{1}{2}\left(\Phi_{a_1} + \Phi_{a_2}\right) \tag{13}$$

where $\Phi = v_r, v_\theta, v_z, T, K, \varepsilon, \phi$. The subscripts b_1 and b_2 indicate the grid points located on the symmetry plane, while a_1 and a_2 indicate the nearest inner grid points to the symmetry plane located on both sides of this plane in the calculation domain.

Because the outer side of the anode is immersed in the cooling water, the third kind of boundary condition is employed in the present paper, i. e.,

$$-k \left.\frac{\partial T}{\partial r}\right|_w = h(T_w - T_\infty) \tag{14}$$

where the subscript "*w*" indicates the interface between the anode and the cooling water, h is the heat transfer coefficient, which is in order of $10^5\ W/\left(m^2 \cdot K\right)$, T_∞ is the temperature of the cooling water.

Table 1. Boundary conditions for 3D modeling of non-transferred DC arc plasma torch.

	ABC	CD	DE	EFGH	HA	$\theta = 0\,(2\pi)$
v_r	$v_r = 0$	$v_r\big\|_{r=0} = \frac{1}{N}\sum_{i=1}^{N} v_{r,i}$	$\partial v_r/\partial z = 0$	$v_r = 0$	$v_r = 0$	On the symmetry plane, periodic boundary conditions, [Eq. (13)], are employed.
v_θ	$v_\theta = 0$	$rv_\theta = 0$	$\partial v_\theta/\partial z = 0$	$v_\theta = 0$	$v_\theta = 0$	
v_z	$v_z = 0$	$v_z\big\|_{r=0} = \frac{1}{N}\sum_{i=1}^{N} v_{z,i}$	$\partial v_z/\partial z = 0$	$v_z = 0$	$v_z = Q/A$

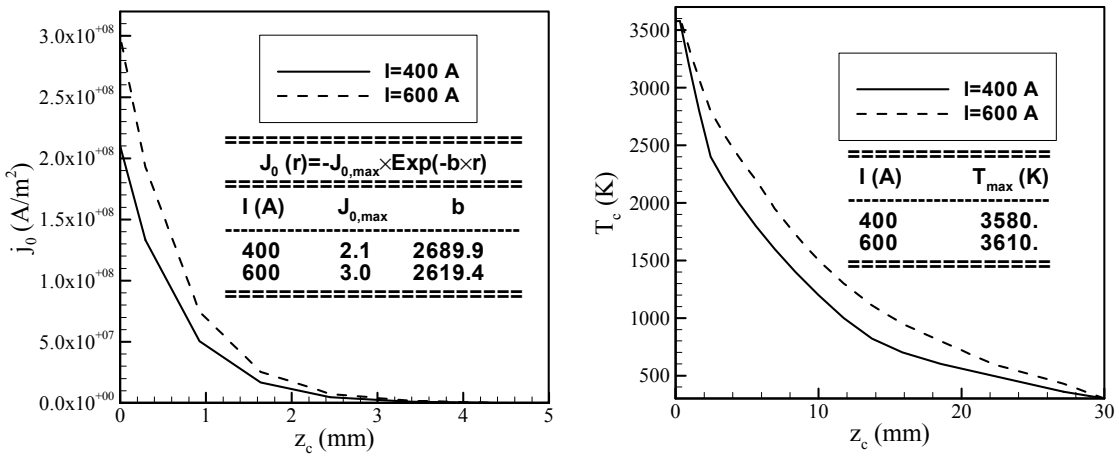
K	Wall Function Method	$K\big\|_{r=0} = \frac{1}{N}\sum_{i=1}^{N} K_i$	$\partial K/\partial z = 0$	/	$0.005v_z^2$	
ε		$\varepsilon\big\|_{r=0} = \frac{1}{N}\sum_{i=1}^{N} \varepsilon_i$	$\partial \varepsilon/\partial z = 0$	/	$0.1K^2$	
ϕ	$\vec{j}_0(r) = -\sigma\frac{\partial \phi}{\partial n}$	$\phi\big\|_{r=0} = \frac{1}{N}\sum_{i=1}^{N} \phi_i$	$\partial \phi/\partial z = 0$	See Section 2.3	$\partial\phi/\partial z = 0$	

In this paper, two approaches are employed to deal with the electric potential boundary condition on the anode surface, which are described as follows:

CASE I: Specified arc-root position boundary condition. With this approach, the anode arc-root position is specified in advance with $\phi = 0$ as boundary condition, and no current passes through the remaining parts of the anode. Thus, the total arc voltage can be obtained through solving the governing equations mentioned above. In our modeling work, we can obtain different arc voltages

by specifying different anode arc-root locations. And then, according to Steenbeck's minimum principle, the physically reasonable position of the anode arc-root should correspond to the position with minimum value of the arc voltage for a certain set of operation parameters.

CASE II: Iso-potential boundary condition. It means that the values of the electric potential are equal on the whole outer surface of the anode. This boundary condition is physically reasonable because of the very large electric conductivity of the anode material (copper), and was employed in Refs. [7, 8].



(a) (b)

Figure 2. The assumed current density (a) and temperature (b) distributions on the cathode surface.

3. Modeling results and discussions

In this paper, the SIMPLE algorithm [13] is employed to solve the non-linear equations (1)~(4), (7), (9) and (10) simultaneously with the new version of the non-commercial software FAST-3D (Fluid Analytical Simulation Tools—Three Dimensional) [14]. A 3-D, body-fitted, non-uniform mesh $32\,(z)\times 22\,(r)\times 11\,(\theta)$ is adopted for the 3-D modeling of a plasma torch in the present paper [7].

3.1 Modeling results and discussions

In CASE II, we assume that the anode arc-root positions are as L_{Arc}=2.32, 3.29, 4.47, 5.86, 7.53 and 9.54 *mm*. The calculated arc voltages as a function of the arc length L_{Arc} are plotted in Figure 3, which shows that for a given set of operation parameters (e. g., I=400 *A*, Q=2.0 STP m^3/hr), the arc voltage V_{Arc} varies with the increase of the arc length L_{Arc} as a V-shaped curve, and there exists a position corresponding to the minimum value of the arc voltage among the different assumed anode arc-root positions along the anode surface. Thus, according to Steenbeck's minimum principle, this position should be the real position of the anode arc-root attachment during torch operation. In our calculation, the arc length determined by Steenbeck's minimum principle is L_{Arc}=5.86 *mm*.

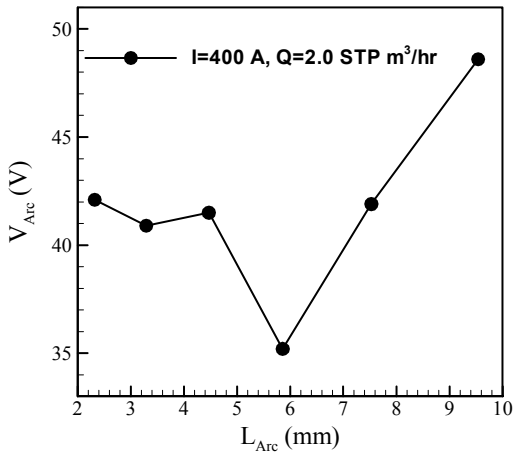


Figure 3. Arc voltage variations with different assumed anode arc-root positions.

The corresponding temperature distributions inside the plasma torch at $0-\pi$ plane and the iso-contours of the radial current density component at the inner surface of the anode are plotted in Figures 4(a) and 5(a), and compared with their counterparts for CASE I as shown in Figures 4(b) and 5(b), respectively. From Figures 4 and 5, we can find that although the predicted anode arc-root attachments in CASE I and CASE II are almost the same ($L_{Arc} \approx 5.9\,mm$), the temperature distributions near the anode arc-root attachment in Case I are very different from that in Case II. In CASE I, the anode arc root is confined to a certain spot, and

as a consequence, there is a higher temperature region near this spot, related to the anode jet formation as described in Ref. [15]. While in CASE II, such local characteristics of the arc cannot be predicted, and the maximum local current density is also much smaller than that in CASE I because the anode arc root distributes over a larger area in CASE II. The calculated average maximum values of the temperature and axial velocities at the torch exit are 12,650 *K*, 426 *m/s* and 12,738 *K*, 461 *m/s*, for CASE I and CASE II, respectively. The corresponding relative discrepancies for the averaged maximum temperature and axial velocity component between these two cases are 0.7% and 7.6%, respectively (both smaller than 10%). Similar results are also obtained for the case *I*=600 *A*, *Q*=2.0 STP m^3/hr.

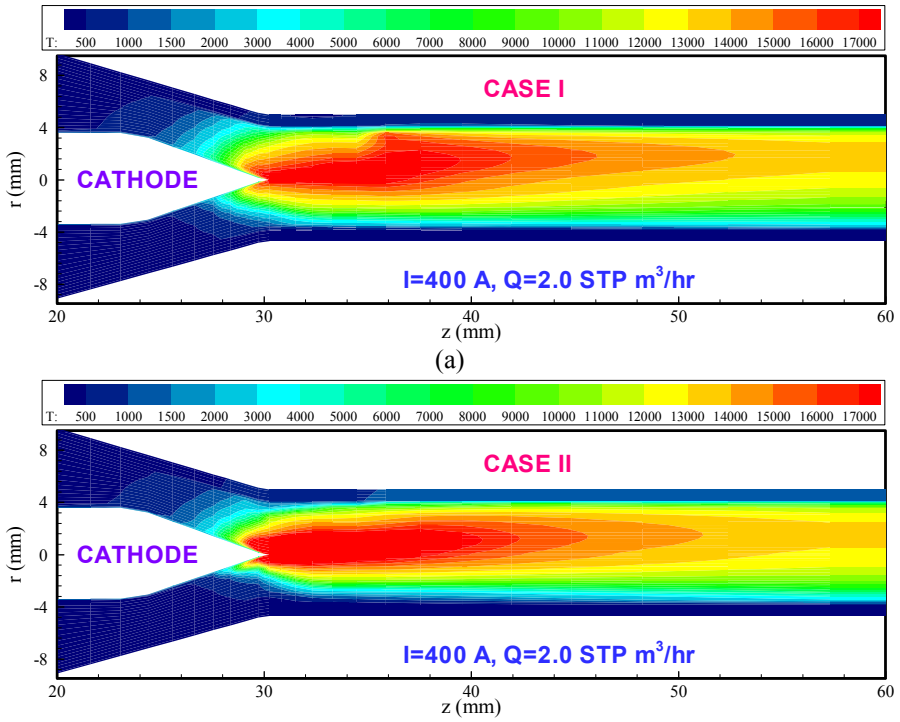

Figure 4. The temperature distributions inside the plasma torch for CASE I (a) and CASE II (b).

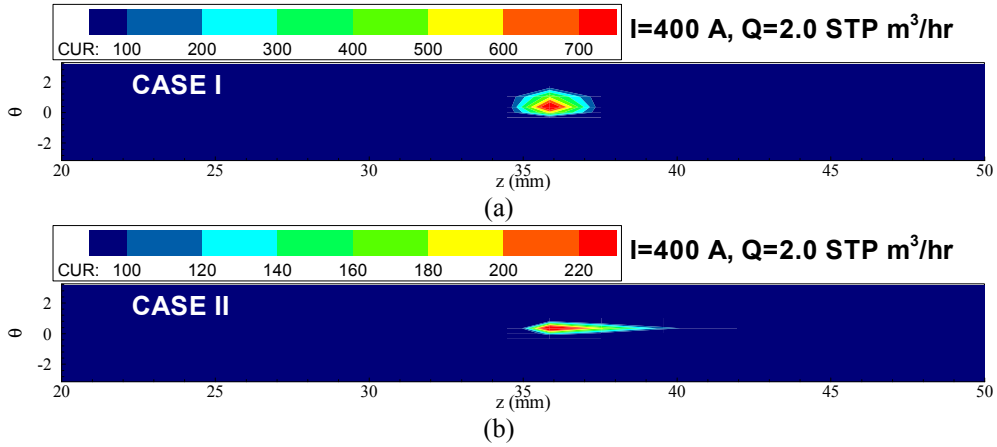

Figure 5. the iso-contours of the radial current density component at the inner surface of the anode for CASE I (a) and CASE II (b).

3.2 Comparison with experimental observations

As discussed in Section 3.1, Steenbeck's minimum principle used in this study can predict the anode arc-root position and the arc shape more precisely than the method with an iso-potential boundary condition.

The typically calculated arc contours for CASE I and II (*I*=400 *A*, *Q*=2.0 STP m^3/hr) and a photograph of the arc in steady mode of operation [15] are shown in Figure 6. The calculated arc shape (CASE I in Figure 6) is similar to the experimentally observed arc shape (lower part in Figure 6), while by using a uniform potential

boundary condition at the outer surface of the anode [7, 8], instead of using Steenbeck's minimum principle, the local characteristics of the arc near the anode arc-root cannot be well predicted.

4. Conclusions

In this paper, the 3-D heat transfer and flow patterns inside a non-transferred DC arc plasma torch are simulated. Two different electric potential boundary conditions are employed to determine the position of the anode arc root. The main conclusions are as follows:

(1) The 3-D effects inside the non-transferred DC arc plasma torch are significant.

(2) The predicted anode arc root positions by either the iso-potential boundary condition or the application of Steenbeck minimum principle are almost the same.

(3) The predicted anode arc root shape by using Steenbeck's minimum principle is more precise than that predicted by using an iso-potential boundary condition.

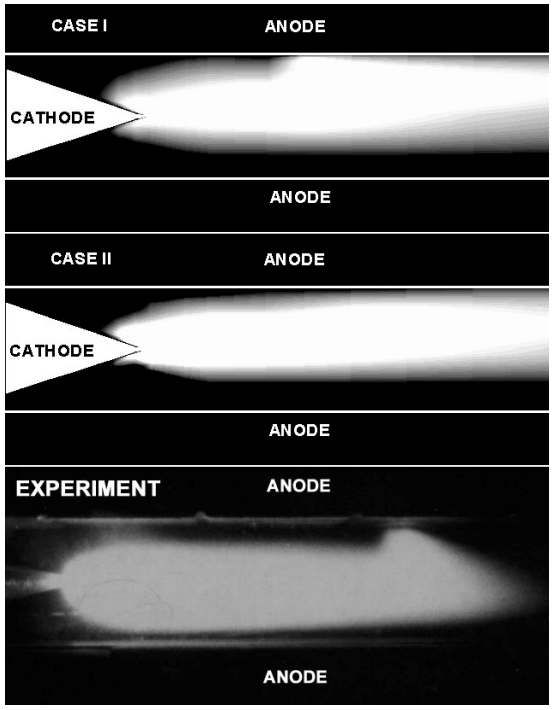

Figure 6. Comparison of the typically calculated arc temperature distribution inside the DC arc plasma torch (upper part) with the photograph of argon arc in steady mode of operation (lower part, [15]).

Wettability of Ion Bombarded Plasma Polymer Films

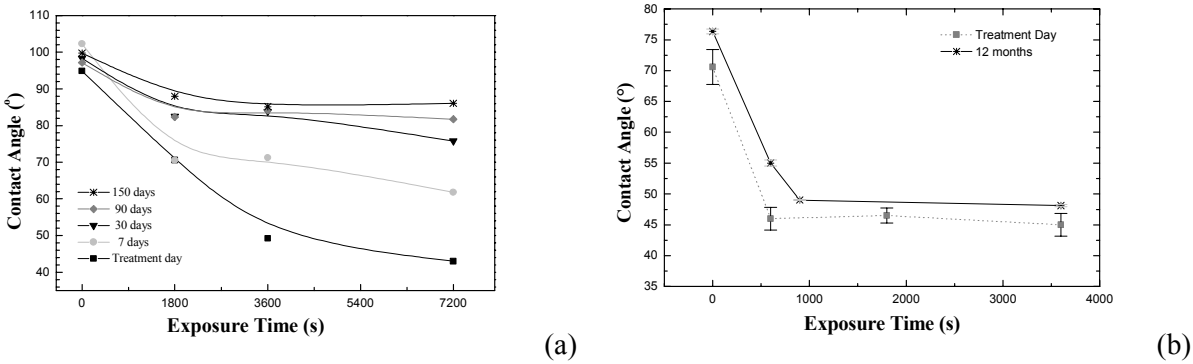
E. C. Rangel, R. Y. Honda, R. C. C. Rangel and N. C. Cruz

Departamento de Física e Química, UNESP - Guaratinguetá, SP, Brazil

The deposition of a film onto a surface can drastically alter its performance in certain applications. Thus, lubricating, hard, adhesive, biocompatible and wear resistant thin films are of great interest for mechanical and electronic engineering, food industry and biomedical devices [1-4]. In this work, the surface properties of plasma polymer films treated by PIII (Plasma Immersion Ion Implantation) were investigated. The effect of the treatment time on the wettability and free surface energy of the films was determined.

The system employed in the film deposition and PIII experiments is composed by a stainless steel vacuum chamber, fitted with two parallel plate electrodes. The upper electrode is connected to a radiofrequency (13.56 MHz) supply via a matching circuit. For the film deposition, the lower electrode is grounded and used as substrate holder. For the PIII experiments, chamber walls are grounded and the holder is biased with pulsed voltage (- 25 kV). Using this equipment, films were deposited from low-pressure acetylene/argon or hexamethyldisiloxane (HMDSO) glow discharges. Treatment plasmas were generated from nitrogen or helium, while biasing the samples with 25 kV negative tooth saw–like pulses. Exposure time to the plasma treatment (t) varied from 0 to 7200 s. Sample wettability was investigated by contact angle (θ) measurements, using de-ionized water. The stability of the modifications induced by ion bombardment was investigated through the temporal evolution of θ. Free-surface energy was derived from contact angle data acquired using water and methylene iodide.

Figures 1a and b show respectively, the contact angle of HMDSO and acetylene plasma polymer films as a function of the exposure time to the PIII. As can be noticed, θ drops after the bombardement for all the samples. However, the fall is more pronounced in films deposited from organosilicon compounds. Indeed, θ does not vary significantly with t in the hydrocarbon prepared samples.



(a) (b)

Fig.1. Contact angle of HMDSO (a) and acetylene-argon (b) plasma polymer films as a function of t. Different curves correspond to data acquired at different days after the treatment.

The evolution of θ with the aging can be accessed comparing the different curves in the pictures, which correspond to θ values measured at different days after ion implantation. Treated hydrocarbon samples demonstrated higher stability of θ than the bombarded organosilicon. Such behavior is ascribed to the different abilities to crosslink of each material.

Treatment of Conventional Polymers by Plasma Immersion Ion Implantation

E. C. Rangel, W. C. A. Bento, M. A. Algatti, R. C. C. Rangel and N. C. Cruz

Departamento de Física e Química - UNESP - Guaratinguetá, SP, Brazil

Polymeric materials are becoming increasingly attractive to a series of applications so far dominated by metals, semiconductors and ceramics. The main reason for that is the possibility of surface selective modification while keeping bulk characteristics unchanged. For instance, the adhesion of metal films to polymers, subject of great concern in food packaging, flexible cables and connectors in microelectronics, is fairly improved as the free-surface energy augment [1]. Besides, activated polymers are being used as base for tissue integration, cell seeding and bacterial growth [2-4]. In this work, polyurethane (PU) and polytetrafluoroethylene (Teflon) were submitted to plasma immersion ion implantation. It was investigated the effect of the ion mass on the wettability, surface energy and plastic resistance parameters of the polymers.

Commercially pure polymer sheets were first cleaned and then exposed to helium, nitrogen or argon glow discharges (13.56 MHz, 70 W, 0.53 Pa). Simultaneously to the plasma ignition, the sample holder was biased with 25 kV tooth saw-like negative pulses. Total exposure time to the PIII treatments was 3600 s. Contact angle measurements, using de-ionized water or methylene iodide droplets, allowed the determination of the wettability and surface energy of the polymers. The stability of the modifications was investigated monitoring periodically the contact angle (θ) after the treatment. Mechanical resistance of the treated layer (R) was evaluated through the plastic resistance parameter, using data acquired by nanoindentation.

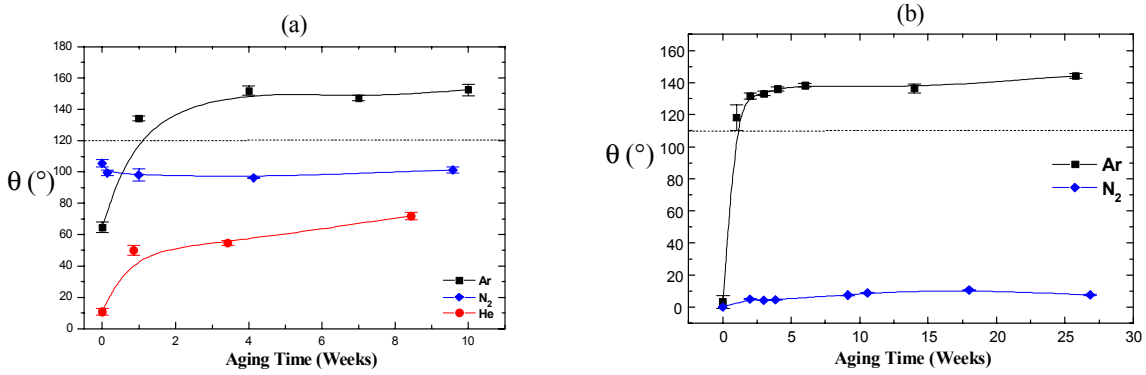

Fig.1. Temporal evolution of the contact angle of Teflon (a) and Polyurethane (b) bombarded with different ions.

In a general way, ion bombardment decreases the contact angle of the polymers. The reduction rate, however, depends on the mass of the implanted ion and also on the composition of the target material (Teflon or PU). In some cases θ was reduced to less than 1% of its original value. Despite of the intensity of such modifications, they were not stable, once θ tends to recover its initial character. Figures 1 (a) and (b) show respectively the temporal evolution of θ for Teflon and PU bombarded with different ions. It is interesting to note that the same material can become hydrophilic or hydrophobic depending on the mass of the implanted ion. After aging, Teflon implanted with argon and PU bombarded with nitrogen attained stable contact angles of 152 ° and 10 °, respectively.

There was improvement in the plastic resistance parameter of the polymer bombarded with argon. Treatments with helium and nitrogen, on the other hand, decreased R. Interpretation is proposed in terms of the ion energy loss mechanisms.

Highly crystalline 5H-polytypic form of sp^3-bonded boron nitride (BN) was grown by pulsed-laser-vaporization of BN, where synchronous reactive-plasma packets assisted the crystal growth in the vapor phase. The structure of the product crystallites (~5 micrometers) was confirmed by using transmission electron diffraction and electron energy loss spectroscopy. This material proved to have a sharp and dominant band at 225 nm by cathodeluminescence at room temperatures and corresponding monochromatic images revealed that they uniformly emitted the ultraviolet light. Considering that cubic BN has already been doped as p- and n-type semiconductors, this material may be applied to the light-emitting devices working at almost the deepest limit of the UV region that is functional without vacuum.

Abstract
Carbon films doped with nitrogen and oxygen were deposited on polytetrafluoroethylene (PTFE) support by hot wire plasma sputtering of graphite target in the mixture of Ar with 5% air. The composition and structure of carbon films were determined by XPS, FTIR and Raman spectroscopy. A comprehensive platelet adhesion analysis demonstrates improved haemocompatibility of doped carbon coatings in comparison with untreated PTFE.

1. Introduction

Plasma assisted deposition of amorphous carbon and diamond-like carbon (DLC) films on polymer substrates is one of the promising techniques for modification of the substrate surface. Due to a combination of superior mechanical and chemical properties including hardness, low friction coefficient, high wear and chemical resistance, carbon deposition holds promise in different applications and particularly in biomedical field [1]. Although amorphous and isotropic carbon as well as pyrolitic graphite have been applied for modification of implants for a long time [2], the potency of DLC films as a bio- and haemocompatible material has been proved only recently [3].
Fluorocarbon polymers are widely used now in the field of biomaterials for cardiovascular surgery. The haemocompatibility of polytetrafluoroethylene (PTFE) vascular grafts with small diameter (< 6 mm) is a problem that has to be resolved for wider applications. Our approach was to use hot wire plasma sputtering of graphite in the mixture of Ar with air to deposit carbon layer containing nitrogen and oxygen groups onto PTFE. The hot wire plasma causes heating and softening of the polymer surface layer thus stimulating the growth of carbon film with high adhesion to the polymer support. Doping of carbon layer with nitrogen and oxygen containing groups usually present in biological substances could improve haemocompatibility and used for further immobilization of biomoleculars.

2. Experimental details

2.1. Preparation of samples.
The substrate materials were polytetrafluoroethylene $-[CF_2\text{-}CF_2]_n-$ (PTFE) films (thickness 60 microns) and Si (100) wafers used as a witness samples. The size of PTFE and Si samples was 20 mm×10mm. All samples were cleaned in ultrasonic bath with methanol and distillate water before deposition.
2.2. Plasma deposition technique.
The PTFE samples were exposed to deposition in dc glow discharge plasma by sputtering a graphite target in the flow of Ar with 5% air. The gas flow and pressure in the plasma chamber were maintained at 25 sccm and 5×10^{-2} torr respectively. The square graphite target (25 mm × 25 mm) was located at 10 mm from round sample holder (diameter 50mm). The temperature of sample holder during deposition was measured by chromel/alumel thermocouple and ranged between 180-210 C depending on plasma conditions. The temperature of hot wire was controlled by Micro Optical Pyrometer (Pyrometer Instr. Co., USA) and varied in the range 1950 – 2100 K depending on the filament current. The deposition time was varied from 15 min to 3 hour. In each run, polymer and Si wafer were deposited simultaneously.
2.3. Surface characterization
The surface chemical composition before and after deposition were analysed by XPS spectroscopy (Kratos Axis Ultra spectrometer, USA). The XPS spectra were obtained with 90 degree take-off angle by using monochromatised Al K_α source. The charge neutraliser was on for all the analysis.

The Raman spectra were measured using 633 nm excitation wavelength of helium neon laser. The scattering light was collected in backscattering with CCD camera, using Renishaw Model 2000 Raman spectrometer. The incident laser power on the sample was 0.3 – 1.2 mW.
The surface morphology of the samples was examined by scanning electron microscopy (SEM) using secondary and backscattered electrons, 5 kV accelerating voltage, and magnification up to 5000 (JSM T330, JEOL, Japan).
The carbon films deposited on Si wafer were smooth enough and the crater depth after Ar^+ ion beam etching could be measured accurately using a profilometer Alpha Step 500 (Fencor Inc. USA). From these data the thickness of carbon films and the rate of deposition under typical deposition conditions (75 A/min) were determined.
2.4. Platelet adhesion technique.
The study of platelet adhesion was performed with informed consent of the donors. Five volunteers were included in the series of repeated experiments. Ten milliliters of blood was anticoagulated 1:9 with sodium citrate [4]. Platelet-rich plasma (PRP) was obtained by centrifugation of the whole blood at 100 g for 20 min at room temperature. The small PRP drops (50 μl) were placed onto sample surfaces and incubated in humid atmosphere for different periods (from 5 to 30 min). The samples incubated with PRP for 15 min were chosen for further analysis. The number of platelets adhered to the surface during this time interval was appropriate for quantification, and the platelets did not form large thrombus-like structures. The samples were rinsed in normal saline to remove unadsorbed plasma proteins and weakly adhered platelets and then fixed in 2.5% glutaraldehyde and dehydrated in a series of ascending ethanols by the standard technique [4].

3. Results and discussion
3.1. Characterization of deposited film
Figure 1 shows XPS survey spectra of PTFE film before and after deposition of carbon layer. For untreated PTFE film the XPS spectrum consists of F1s peak (688.2 eV) and less intensive C1s peak (291.4 eV). In the XPS spectrum of the film obtained after 15 min deposition one can see intensive C1s peak (285.0 eV) as well as O1s (532.1 eV) and N1s (399.8 eV) peaks.

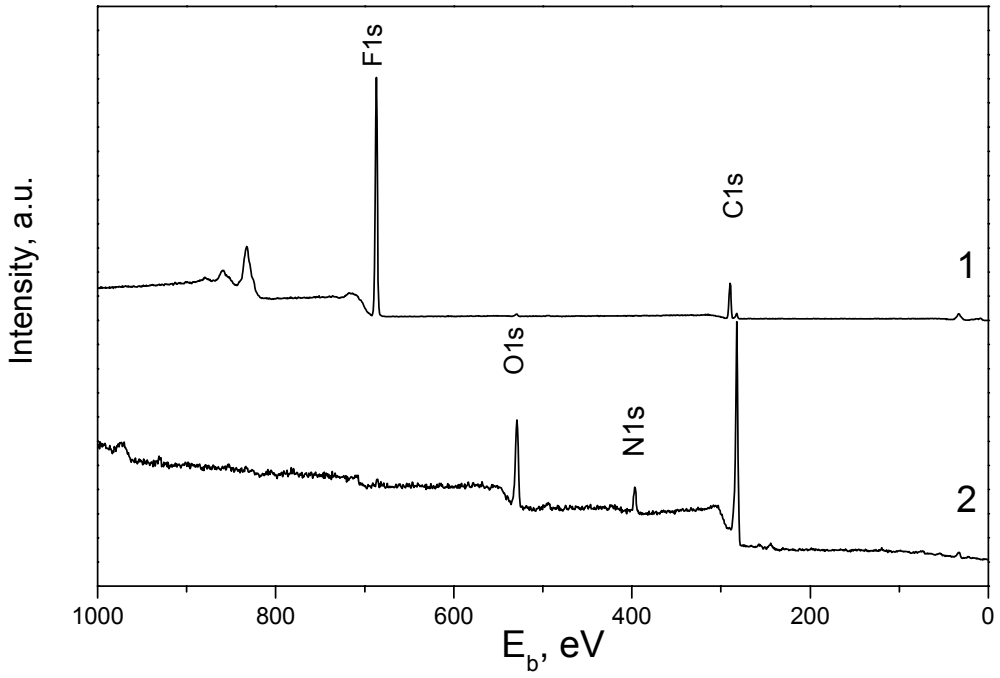

Figure 1 The XPS survey spectra of PTFE support before(1) and after plasma deposition of carbon film (2).

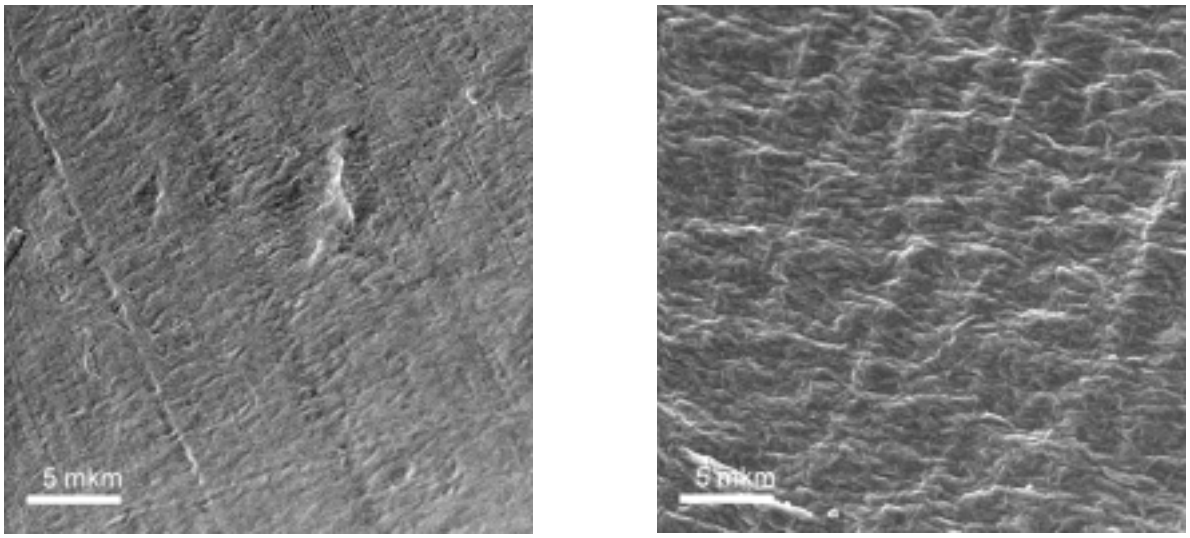
The important point is that no significant F1s peak was observed in the XPS spectrum of carbon film obtained after 15 min carbon deposition. It means that pin-hole-free carbon layer with the thickness more then 30 Å (depth of free electron path for 800 eV [5]) is formed on the PTFE surface already after 15 min of

graphite sputtering. The atomic surface concentrations calculated from measured integral intensities of XPS peaks for as deposited carbon film are: 72.2at% C, 10.5at% N and 14.0at% O. The appearance of relatively high concentration of oxygen on the surface of carbon layer may be explained by the surface contamination and/or bonding of oxygen in post reactions with carbon free radicals formed during plasma deposition. After a few minutes of Ar^+ ion sputtering oxygen content decreased in three times while the nitrogen concentration only slightly changed. The chemical composition measured after ion etching was: 86.8at%, 8.7%N, 4.5%O.
The surface morphology of PTFE support and carbon film formed on the support after 1 hour of deposition are shown in Fig.2. A complex fibril-type 1-2-micron regular structure could be observed on the surface of carbon layer.



a b

Figure 2 Scanning electron microscope images of PTFE support before (a) and after (b) 1 hour of carbon deposition.

The adhesion of carbon film was checked by scotch tape test [6]. No visible peeling of the deposited film was observed after scotch tape strip off.
The Raman spectra of PTFE films before and after deposition of carbon layer with different thickness are shown on Figure 3. The characteristic bands of PTFE support: at 734 cm^{-1} assigned to stretching vibration of C-F, and two bands at 387 cm^{-1} and 293 cm^{-1} attributed to deformation vibration of C-C in polymer chains, are still detectable through the carbon film with the thickness 225 nm deposited during 1 hour but did not appear in the spectra after deposition of carbon layer with the thickness 450 nm (2 hours of deposition). This result is in agreement with the optical probing depth for Raman spectroscopy d determined by absorption coefficient α for carbon layer at our excitation wavelength 633 nm $d=1/(2\alpha)$. Taking the optical constants for different carbons [7] we can estimate the Raman probing depth in our case as 100 – 200 nm that is much higher then XPS analyzing depth (about 3 nm [5]).
The Raman spectrum of our carbon film consists of two broad bands at 1575 cm^{-1} and 1360 cm^{-1} which are usually detected in amorphous and diamond-like carbon films [8,9,10]. According to Wagner's model [11] developed for Raman scattering of carbon and polycrystalline diamond films, peak at 1575 cm^{-1} has to be assigned to graphite-like sp^2 bonded carbon (G peak) while the scattering in low frequency region around 1300 cm^{-1} has to be interpreted in terms of scattering by sp^3 –bonded carbon plus possible contribution of disordered sp^2 -bonded carbon (D peak).
Figure 4 shows FTIR spectra for carbon films of different thickness deposited on Si wafer. Broad main band in the region 1000 – 1700 cm^{-1} increases with the increase of film thickness. The IR absorption in this range covers the frequency range of stretching vibration of both CN and CC bonds which is often observed in carbon nitride films [12]. Usually CC bonds in pure carbon films are not active in the IR absorption but only detected by Raman spectroscopy. Kaufman et al. [13] analyzed IR spectra of carbon films doped with different amount of nitrogen and have found that Raman-active G (1575 cm^{-1}) and D (1360cm^{-1}) CC bonds become IR-active due to the nitrogen replacement of carbon which breaks the symmetry in six-fold carbon

ring structure. The nitrogen replacement gives rise to a net dipole moment and makes active IR absorption. The presence of C-N groups is indicated by the small IR absorption at 1230 cm^{-1}. Liu et al. [14] found that Raman and IR spectra of nitrogen containing carbon films deposited by dc magnetron sputtering are almost identical, and attributed the peaks at 1557 cm^{-1}, 1337 cm^{-1} and 1269 cm^{-1} to the G peak, the D peak and the single C-N bond respectively.

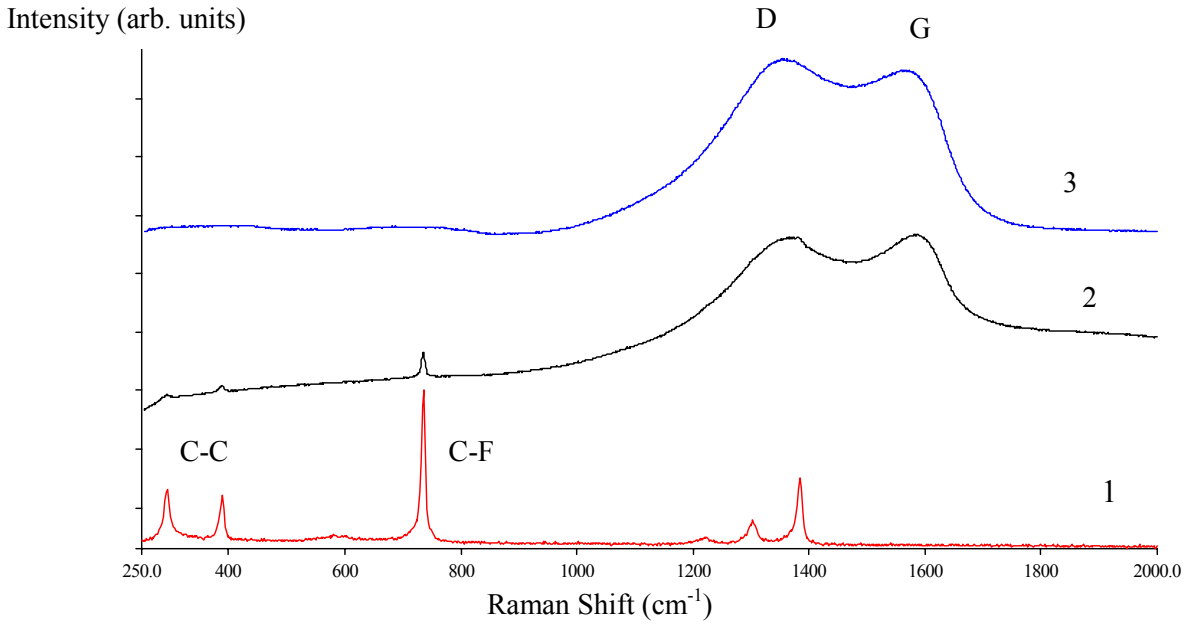


Figure 3 Raman spectra of PTFE support before (1) and after carbon deposition during 1hour(2) and 2 hour (3).

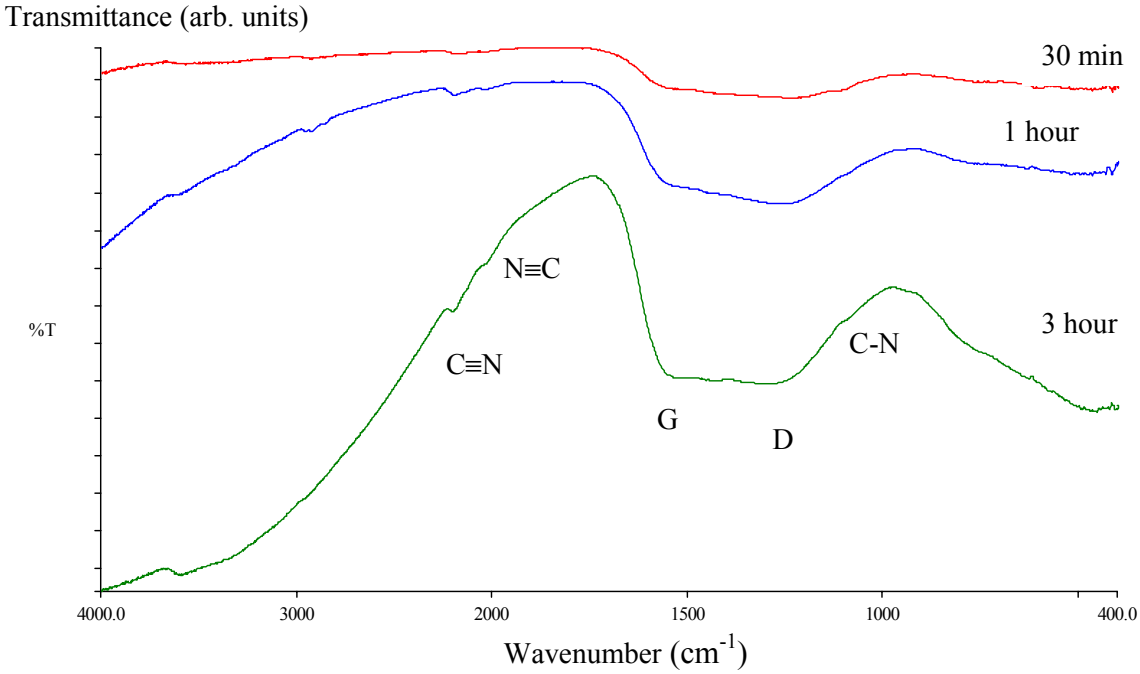

Figure 4. FTIR spectra of carbon film deposited on Si wafer

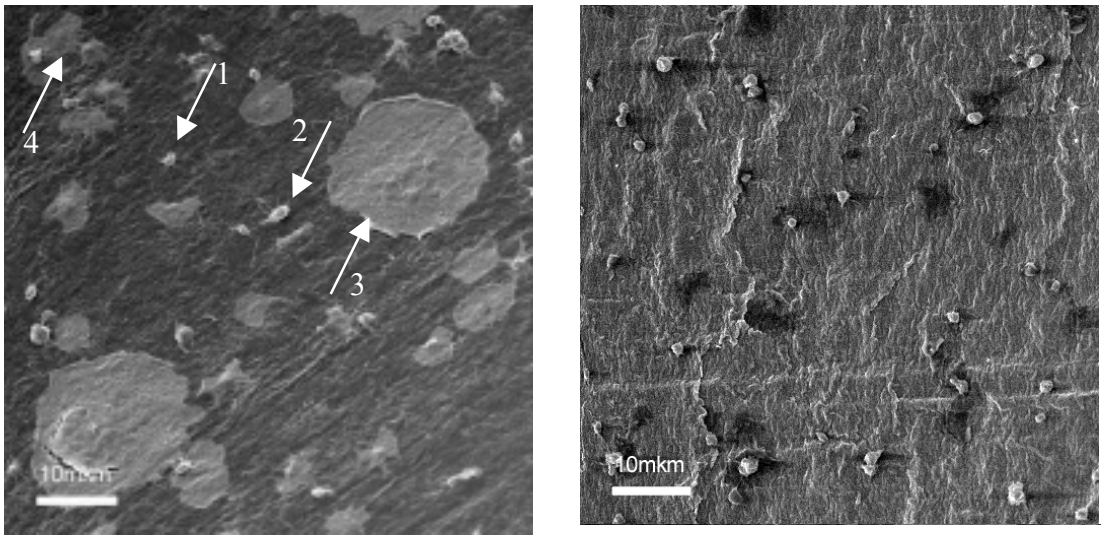
In the IR spectra range 1700 – 3000 cm^{-1} an additional bands at 2050cm^{-1} and 2200 cm^{-1} can be observed and assigned to the stretching vibration of nitrile -C≡N and isonitrile -N≡C groups respectively. A small amount of oxygen was detected in the film by XPS spectroscopy. But IR absorption bands in the range 1100-1300

cm^{-1} characteristic for C-O groups could not be observed due to the overlapping with the broad main carbon band at 1000 – 1700 cm^{-1}.

3.2. Platelet adhesion

Platelet adhesion patterns were investigated by SEM. All samples were decorated with copper (thickness~30 nm). For each sample 25 areas of 400 μm^2 were randomly chosen on the surface contacting with PRP. Then we qualified the total platelet number N_{tot} and platelet numbers N_i in the following four morphological classes [15] (Fig. 5a)



a b

Figure 5. Scanning electron microscope images of platelet adhesion on PTFE support before (a) and after (b) 1 hour of carbon deposition:

1. Single – non-activated cells
2. Slightly activated deformed cells and pseudopodical cells.
3. Spread – fully spread platelets.
4. Aggregates –aggregates of two or more platelets.

Adhesion process is believed to run in several stages: platelet attachment to the surface, activation, pseudopodia development, spreading and aggregate formation (see Fig. 5a) [16]. The release of intracellular components from adhered or fully spread platelets (ADP, Ca^{2+}, serotonin, etc.) promotes further platelet adhesion, aggregation and finally thrombus formation. [17]. One can estimate the activation of adhered platelet by their morphology. The more severe the impact of material on platelets, the more adhered cells are activated spread or aggregated. Usual approach for quantitative investigation of platelet adhesion consists in calculation of relative index of platelet adhesion (RIPA) for different morphological classes of adhered platelets. Presented on Figure 6 are RIPA values for carbon coatings in comparison with that of untreated PTFE. From this point of view, all carbon coatings seem more preferable for contact with platelets than untreated PTFE. Onto all coatings the numbers of slightly activated cells, spread cells and cell aggregates were lower but number of single cells was higher than that of the surface of unprocessed PTFE. It is noteworthy that the total number of platelets was also lower on carbon coated surface for all three samples. Assuming the existence of the adhesion stages, it can be suggested that platelet transition to later stages of activation was much slower on carbon coatings than on untreated PTFE.

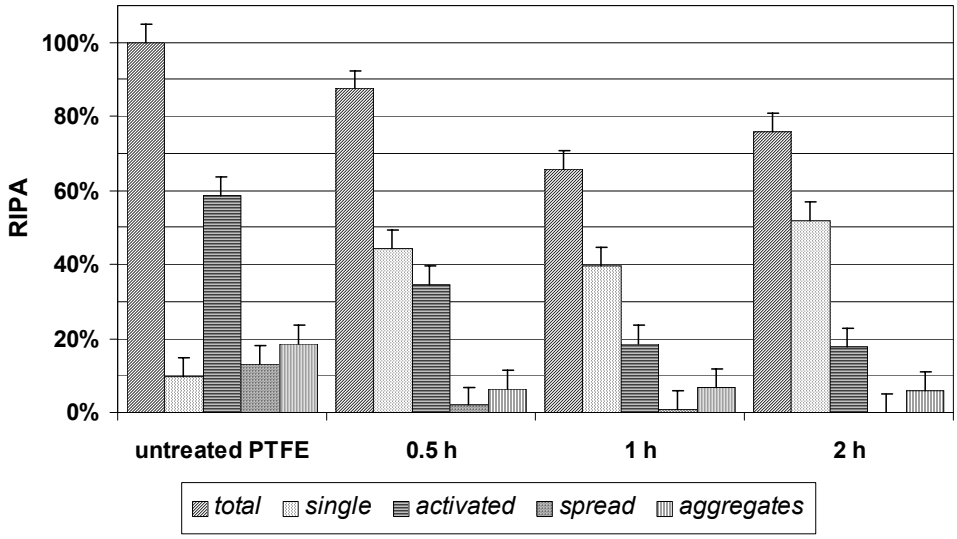


Figure 6. Diagram representing relative platelet quantities (RIPA) for different morphological classes observed by SEM for untreated and carbon coated PTFE (time of deposition 0.5, 1, 2 hours; RIPA=100% for the total number of adhered platelets on untreated PTFE)

4. Conclusions

The PTFE films were successfully modified with highly adhesive carbon layer using hot wire plasma sputtering of graphite in the mixture of Ar and 5% air. The platelet adhesion tests demonstrate that deposition of structured carbon layer containing oxygen and nitrogen groups promotes the minimization of platelet's reactions on foreign body thus considerably extending the haemocompatibility of PTFE film.

GlidArc-assisted removal and/or upgrading of Hydrogen Sulfide or Methyl-Mercaptan

A. Czernichowski[1], P. Czernichowski[2*], and M. Czernichowski[2]

Abstract
Diluted or concentrated (up to 100%) H_2S and air-diluted (up to 0.1%) CH_3SH are processed in various GlidArc discharge reactors at up to 70 m^3/h flow rate and 5 kW scales. These powerful high-voltage discharges produce non-thermal plasma directly generated in the processed gases. They activate some oxidation reactions in the case of air-diluted sulfides. Concentrated H_2S or H_2S+CO_2 mixtures are preferably dissociated into H_2 or H_2+CO (synthesis gas) at very low energy consumption.

1. Introduction

Hydrogen sulfide and mercaptans are unwanted compounds that have to be removed in many industrial processes. Moreover H_2S is also an abundant source for potentially the cheapest Hydrogen. Many hydrocarbon gas reserves contain large amounts of hydrogen sulfide frequently mixed with CO_2. The petroleum industry spends hundreds million of dollars per year to produce Hydrogen for Sulfur removal from crude oils and refinery products. This creates more than 6 million tons of concentrated H_2S in which very weakly bonded hydrogen is then stupidly burned to water (*via* 113-years old Claus process) making it unavailable for further use.
Burning of H_2S and/or mercaptans is also practices when their concentration is low. Such combustion gives another strong pollutant: SO_2. However at low concentrations the sulfides cannot burn themselves so that an extra fuel (and air) must be added. It brings the Nitrogen ballast into the flue gas and asks for much bigger washing installation in which SO_2 is removed in the presence of CO_2 issued from added fuel. Therefore several processes propose a low-temperature oxidation, particularly in aqueous phase, which end either in the production of water and Sulfur or sulfuric acid. Catalysts must often assist these reactions. All such processes require considerable volumes of equipment subjected to corrosion by aggressive solutions, hence high investment and maintenance costs. They present the further drawback of consuming a considerable amount of various chemical reagents that raises environmental problems created by some final products of these processes.
Since 1876' works of Marcelin Berhelot (France) the plasma-assisted H_2S destruction or upgrading has been quite largely studied. We are presenting that history in the papers [1] and [2] where our previous experimental contribution is also described. For more recent plasma-related works one can see contributions from ABB [3], Kurchatov Institute [4], or Argonne National Laboratory [5] – amongst others.

2. GlidArc-assisted processing of concentrated H_2S

2.1. Chemistry

It is worth to repeat that Hydrogen is very weakly bound in the H_2S molecule so it is so pity to convert it to water through the classical Claus process. In theory, the energetic requirement for 1 mole H_2 production from such dissociation:

$$H_2S \rightarrow H_2 + S \qquad (1)$$

is only 20.1 kJ, which is 14 times less than that of H_2 from an ideal water electrolysis. An extraction of Hydrogen would be therefore worthwhile when H_2S concentration in a waste gas is high enough. Also, the total upgrading of H_2S + CO_2 mixtures (called "acid" or "sour" gas) can be done *via* a low endothermic reaction:

$$H_2S + CO_2 \rightarrow H_2O + CO + S \qquad (2)$$

for the theoretical price of only 61.3 kJ per mole CO. Carbon monoxide is H_2-equivalent *via* the water-shift exothermic process:

$$CO + H_2O \rightarrow H_2 + CO_2. \qquad (3)$$

---

[*] *Presently with WESCO, Conroe, Texas 77301, USA*

From H_2S + CO_2 direct plasma processing one obtains therefore, after Sulfur and water precipitation, a mixture of the CO + H_2 (synthesis gas).

2.2. Our previous tests

First tests [6] were performed using a "controlled" transferred arc at 3 – 6 kW DC power, a kind of GlidArc precursor. Up to 71% of H_2S dissociation rate was observed but the energetic expense for 1 m^3(n) of Hydrogen was as high as 19 kWh. Some tests on simulated sour gas processing were also done: at 2 – 4 kW power applied to the gas containing 36 - 69% of H_2S (the ballast being CO_2) and at 0.75 - 0.83 m^3/h gas flow rate we got as high as 64 - 99% H_2S conversion rates. The energetic expense for 1 m^3(n) H_2+CO mixture was however in the 12 kWh range. Moreover, the cathode section of the reactor needed an Argon-flow protection that was a serious drawback for an industrial application of this proposed technology that we started to call "SulfArc".

The GlidArc reactors that we started developing in 1987 have largely opened a new way of a direct plasma-chemical processing of almost any gas mixtures. Our first results [7] on pure H_2S splitting in 6-electrode GlidArc reactor at 1.4 m^3(n)/h input flow rate and 0.73 kW AC power were quite encouraging as the energetic expense was equal to 7.9 kWh per 1 m^3(n) of produced Hydrogen. Too low (6.6%) H_2S dissociation rate was however observed for these conditions. Much better results were obtained at those time when processing a simulated sour gas containing 41% of H_2S and 59% of CO_2: at 2.6 m^3(n)/h input gas flow rate and 0.93 kW power: the energetic expense was equal to only 2.4 kWh per 1 m^3(n) of produced H_2+CO at quite reasonable 39% H_2S dissociation rate for one pass.

Further tests [8] were performed using another 3-electrode GlidArc reactor to split pure H_2S as well as some H_2S+CO_2 mixtures for different gas composition, pressure, flow-rate, dissipated power, electrode material and electrode gap. Up to 45% dissociation rate of pure H_2S was observed for that one-pass reactor without any gas preheating. The best result of 4.0 kWh per 1 m^3(n) of produced H_2 was obtained at 3-mm electrode gap but much lower energy expenses were expected with a complementary ignition system allowing a larger gap. Two sour gas mixtures containing 60 or 25% H_2S were also tested. The results indicated a minimal requirement of 5.5 kWh per 1 m^3(n) of H_2 + CO product in a pressure range of 0.5 - 0.7 bar.

Fig. 1. Three-step GlidArc-I reactor.

Figure 1 presents our 3-steps GlidArc pilot reactor built for an acid gas processing. The gas was issued from a natural gas cleaning plant near Zmigrod, Poland [9]. Figure 2 shows also the principle of the reactor implementation for the whole SulfArc process.

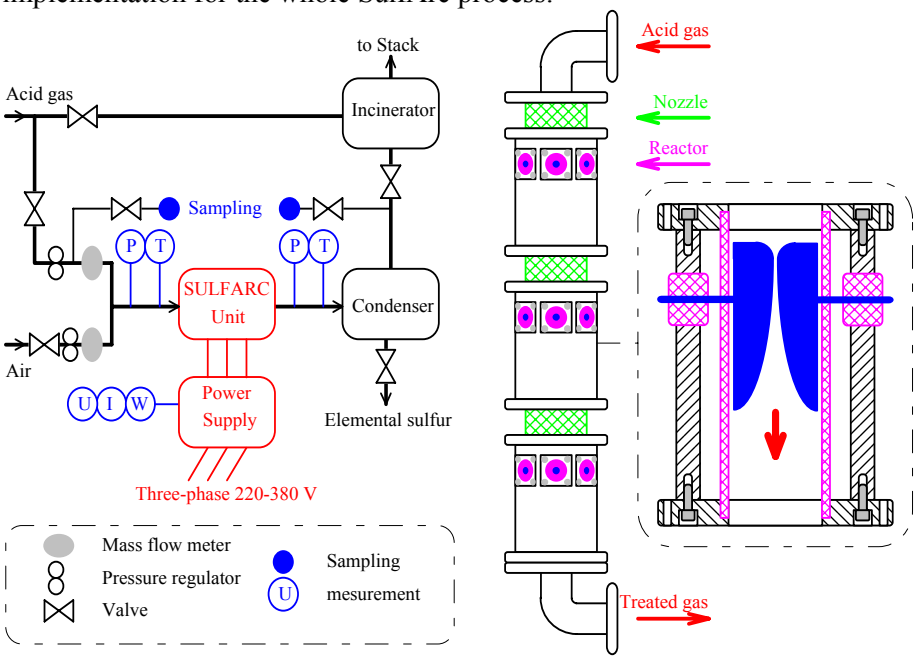

Fig. 2. Schematic view of a pilot installation of SulfArc for 60 m^3/h sour gas processing.

Some preliminary field tests of the sour gas (25% H_2S, 70% CO_2, and 5% light hydrocarbons) processing were satisfactory at 60 m^3/h scale: almost total destruction of H_2S was observed. No further field tests were however possible as the plant was going to close.
In 1997 we started to develop an alternative way of gliding discharges generation using so-called GlidArc-II principle. In an abstracts [10] we shortly mentioned this new reactor application for H_2S processing.

2.3. New developments
Using one or more rotating central electrodes and "connecting" them, *via* high-voltage AC discharges, to several stationary electrodes located around the central electrodes we have obtained a new GlidArc-II device. Figure 3 presents the principle of the GlidArc-II.

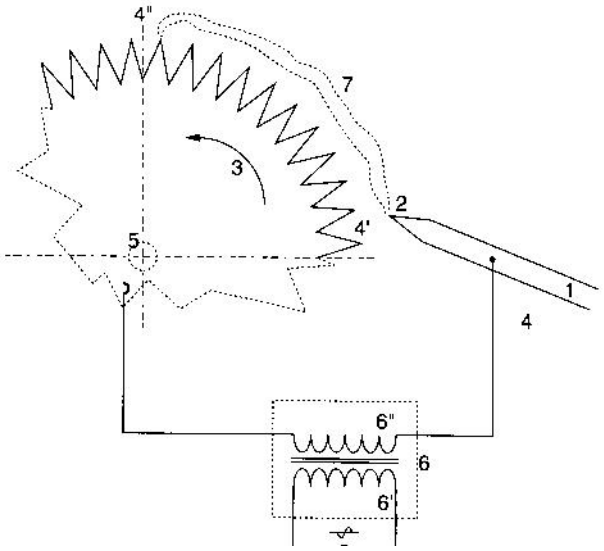

Fig. 3. Principle of the GlidArc-II device: 1 – stationary electrode, 3 – rotating electrode, 6 – power supply, 7 – high-voltage discharge filaments.

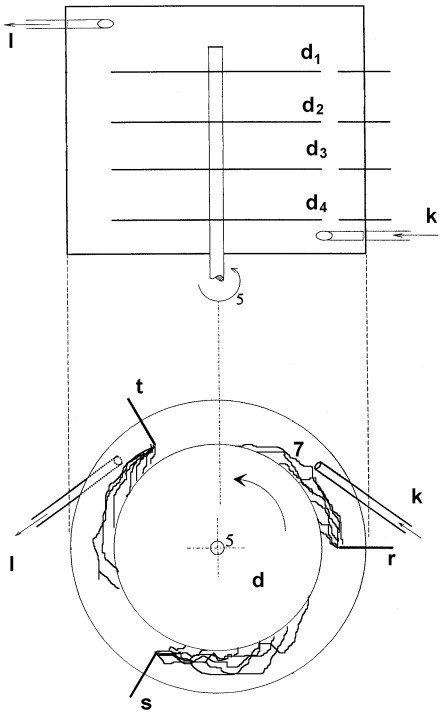

Fig. 4. Multiple-stages and multiple-electrodes GlidArc-II reactor: r, s, and t – three-phase-supplied stationary electrodes, k and l – input and output of the processed gas, d – rotating electrodes.

There are multiple advantages of the new structure. The high voltage discharges generation and the processed gas flow rates are no more self-dependent so that even a very low gas flow can now be accepted at any power as there is no more need to accelerate the gas at the proximity of electrodes. The mobile electrodes rotate in the range of 50 – 1000 rad/s, which are acceptable speeds. The discharges can "touch" several times the same gas flux without any obligation to push the gas between the stages (as it was previously needed for the reactor presented on the Fig. 1 and 2). The reactor is quite compact for even large gas flows. For example one can realize three 5 A and 2 kV = 30 kW discharges for one stage. When adding 4 stages it makes us a 120 kW reactor realized in a 0.3 m diameter cylinder of 0.5 m length (30 L of volume). Such reactor can process roughly up to 2400 m^3/h of gas.
The decomposition of pure H_2S has been first tested at the atmospheric pressure in relatively small GlidArc II reactor [11]. It has only one toothed steel disk of 15 cm diameter and three stationary steel electrodes (bent-knives-shaped) placed symmetrically around the rotating disk electrode. Every stationary electrode is connected to one of the three phases of a high-voltage transformer (5 kV, 50 Hz) and the disk is connected to the neutral point of the transformer. The processed H_2S is continuously introduced below of the vertical axis of the disk and the products are extracted above of the disk. A small electric motor rotates the disk (100 rad/s). A refractory glass closes the space in which our "cold" discharges strike the gas. This reactor can work under a pressure up to 1.5 bars and at the injected electric power of less than 1 kW. The power is controlled while activating one, two or three stationary electrodes, each one injecting the current limited to 0.12 either 0.25 A. We obtain the following performances:

- For an electric energy of 1 kWh injected into 1 m^3(n) of H_2S (initially at the ambient temperature) we are producing 0.31 m^3(n) of Hydrogen, which indicates an energy consumption of 3.1 kWh per 1 m^3(n) of Hydrogen.
- The conversion of a 40/60 mixture of H_2S/CO_2 has also been tested in the same reactor under 1 bar. For an electric energy of 1 kWh injected initially into this mixture at the ambient temperature we got the synthesis gas ($CO+H_2$) at the specific energy expense of 2.5 kWh/m^3(n). A side reaction towards the COS (3% in the products) should not present an obstacle for the process because it is sufficient to wash the products with water that splits COS towards initial H_2S and CO_2.

A 60-L stainless steel SulfArc reactor was recently built by ECP for H_2S-related streams processing. The reactor contains 9 stages, each of them being powered by 3 stationary electrodes so that 36 active electrodes are present. At the time of this ISPC-16 Poster Session we hope to present our first results on a larger scale H_2 extraction from pure H_2S and some sour gases.

3. GlidArc-assisted processing of air-diluted H_2S or CH_3SH

3.1. Chemistry

Direct injection of an active energy through our gliding discharges allows us to avoid the problem of additional fuel injection for conversion of so badly smelling sulfides into less smelling SO_2. Up to 100% conversion of the sulfides into SO_2 can be obtained at quite low energy expense … but we do not seek for such a high conversion! Using a very simple water-washing column, which saturates with the produced SO_2 (and some plasma-synthesized NO_x) and then captures unprocessed H_2S *via* a wet-Claus reaction, we are cutting the process' energy expense by factor of three, avoiding a SO_2 emission to the atmosphere and obtaining non-toxic elemental Sulfur as unique product of such depollution technology described by the following exothermal reactions:

$$3\ H_2S + 1.5\ O_2 = 2\ H_2S + SO_2 + H_2O = 3S + 3\ H_2O. \quad (4)$$

Indeed, the reactions (4) show that only 33% conversion rate of H_2S into SO_2 is needed for the full removal of the initial pollutant while the remaining amount of H_2S is simply destroyed by its oxidation product: SO_2!

3.2. Our previous tests [12]

3.2.1. One-stage reactor

Experiments were performed using a GlidArc-I reactor shown in Fig. 5. It contained three main electrodes (2 mm thick steel) as well as one central thin ignition electrode connected to a 50/150 Hz, 2/12 kV, 3-phase power supply. The electrodes were put inside a glass tube of 80/5 mm diameter and 50 cm length.

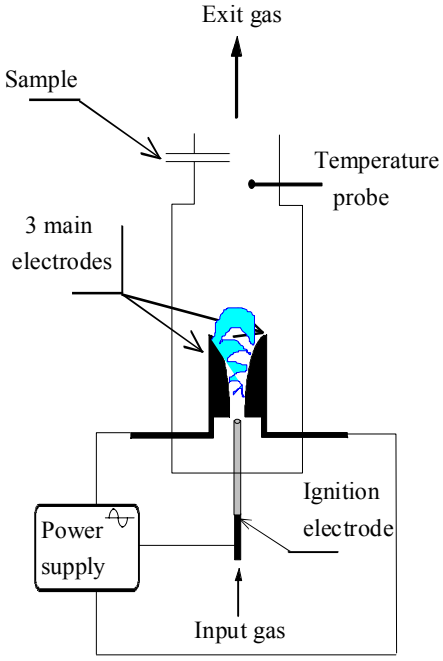

Fig. 5. Schematic view of the one-stage GlidArc-I reactor.

A stream of compressed air (about 20% RH at ambient temperature and pressure) was mixed with a controlled flow of a Nitrogen-diluted H_2S and then injected into the reactor through a nozzle. A Specific Energy Input (SEI, in kWh per 1 m^3(n) of the entering gas mixture) was determined for each run. Chemical analyses of entry and exit gas streams were performed using gas chromatography with a photometric determination of the S_2 emission at 394 nm; this provides detection and accuracy limits of 0.1 ppm.

Our washing tower is schematically shown in the Fig. 6. It consists of a 1.8 m height pipe of 8 cm of diameter. The tower is filled with a packing in order to enhance the gas-liquid contact. The liquid, initially tap water, flows into the top of the tower *via* a small pump (0.5 kg/min) and is recovered on the bottom. Only 2 kg of water is in continuous re-circulation.

More than 30 experiments were conducted to evaluate the influence of several parameters on H_2S destruction. We varied: the initial concentration of the H_2S (5 to 174 ppm), air flow rate (3.6 to 11 m^3(n)/h), power (1.1 to 1.7 kW), SEI (0.10 to 0.45 kWh/m^3(n)), and other.

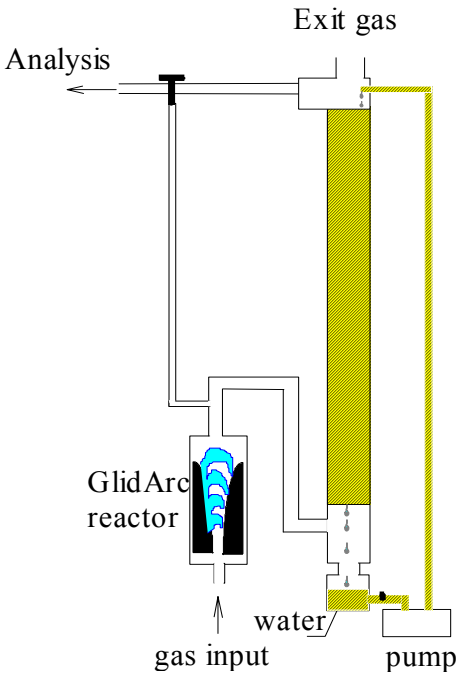

Fig. 6. Schematic view of the washing tower.

The reactor operated several hours without the electrodes deterioration. The destruction rate of H_2S was in the range of 60 - 100% so that complete removal of H_2S was possible even without using the water wash tower. The rate of the H_2S removal increased as a linear function of the SEI injected to the processed gas. The energy expense of pollutant removal was a strong inverse function of its initial concentration. It varied in the range of 0.77 – 44 MWh per kg of Sulfur, which seems very high. However, if related to the energy needed to cleanup 1 m^3(n) of polluted air we have obtained a very low value of around 0.05 kWh independently on initial pollutants' concentration in the range from 1 ppm to 1%.

The concentrations of NO_x at the reactor exit were at 0.3% level. Such strong oxidant plays a positive role in H_2S or mercaptan destruction in the plasma reactor as well as in the washing tower where a large improvement of the gas cleanup was observed: Initially neutral tap water becomes quickly acidified down to pH ~ 3 and stayed at that level up to the end of a run. After several runs we could observe opalescence due to colloidal Sulfur in water. Instead of 60 - 92% removal rate observed without gas wash we observed rather 93 - 98.5% removal with gas washing.

3.2.2. Four stages reactor

Experiments were also performed using a 4-stages serial reactor shown in Fig. 7. Each stage of that pilot contained the same GlidArc-I segment already described in the section 3.2.1. The gas transfer between the stages was organized through large nozzles, which allowed an acceleration of the gas near the electrodes. The exit gas washing was not applied. Four independent power supplies were used, each for one stage. A stream of ambient air was polluted with a controlled flow of pure H_2S or a CH_3SH-N_2 mixture and then injected to the reactor by the first large nozzle. The SEI was determined for each run. Gas flow rate metering and the chemical analyses at the entry and exit were based on gas chromatography.

Twenty runs were conducted in order to evaluate the influence of several parameters on H_2S or CH_3SH destruction. We varied: initial concentration of the H_2S (95 ppm to 1%) or CH_3SH (110 to 930 ppm), polluted air flow rate (from 48 to 67 m^3(n)/h), injected power (1.0 to 4.6 kW when one, two, three or four reactor's stages were running), and other.

As the results of the gas processing in this pilot we reported the destruction rates of H_2S or CH_3SH up to 39% or 65%, respectively. Removal rates of both H_2S and CH_3SH increased as linear functions of the specific energy (SEI) injected to the GlidArc-processed air.

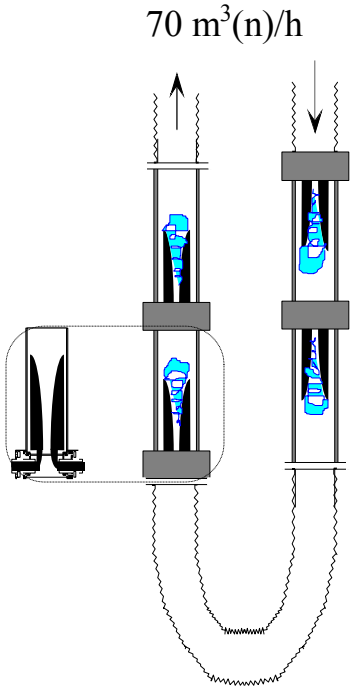

Fig. 7. Schematic view of the four-stage reactor.

Depending on initial pollutant concentration, roughly 1 MWh of energy was needed to withdraw 1 kg of converted Sulfur at 100 ppm of H_2S, and only 10 kWh for 1% initial H_2S in air. Similar energy expenditures were observed in the case of CH_3SH-air mixtures. Such energy expense for the unitary amount of pollutants removal is therefore a strong inverse function of their initial concentrations. But again, if accounted as the energy needed to clean 1 m^3(n) of polluted air, we have obtained a very low value of 0.05 kWh independently on initial pollutants' concentration in the range from 1 ppm to 1%.

3.3. New developments [11]

Several tests of air cleaning from sulfide molecules have been performed in GlidArc-II pilot reactor similar to that presented on Fig. 3 and 4. The reactor is composed of four toothed steel disks of 14 cm diameter and of 12 stationary steel electrodes placed symmetrically, three by stage, around the disks attached to the same rotation axis. For every stage of the reactor, each of the 3 stationary electrodes is connected to one of the three phases of a 5 kV, 50 Hz transformer. The disks are connected to the neutral point of the transformers (there are 4 identical transformers, one per disk). All mobile and stationary electrodes are inside a heat-resistant tube of the inner diameter of 20 cm and the length of 30 cm. Two plates close the tube and lodge: the system of the axis rotation (by a small electric motor), glass portholes, the entrance and the exit of the gas, and some probes (pressure, temperature). The reactor permits to work at pressures going from 0.1 to 5 bars. The regulation of the electric power injected to the reactor takes place while activating one, two or three stationary electrodes by stage (each electrode injecting the current limited to 0.12 or 0.25 A). The maximal electric power of the reactor is set to 4 kW.

All tests confirmed our previous results. The energy expense is weak, almost identical for various sulfide pollutants: while spending 1 kWh of electric energy we can completely clean out about 20 m^3 of air containing between 1 ppm and 1% of H_2S or CH_3SH.. Our observations indicate that the heavier sulfide molecules oxidize more easily thanH_2S.

Already mentioned 60-L GlidArc-II reactor, recently built by ECP for H_2S-related streams processing, is going to be used also for some tests on diluted H_2S and mercaptan destruction. At the time of this ISPC-16 Poster Session we hope to present our preliminary results.

4. Conclusion

Conditions are united to advance towards new GlidArc-I or -II processes of the concentrated H_2S upgrading into Hydrogen (or Synthesis Gas) as well as the destruction of diluted H_2S and/or mercaptans. We have demonstrated such feasibilities in laboratory as well as at the pilot scale of 70 m^3/h gas flow rate. An extrapolation of these reactors to process bigger flows will be easy as a result of very recent development of our so-called "Multi-Cluster" GlidArc (an electric powering system of dozens or hundreds of Gliding Discharges from unique ordinary High Voltage transformer) [13]. Advantages of the gliding discharges and here-described processes are the following:

- Utilization of the electricity as unique source of energy so that the process products do not contain ballasts of added reactants; it makes much easier all operations of their final treatment like washing, extraction, separation.
- No chemical reagents added (except water and air).
- No catalysts (except those generated spontaneously by the electric discharges).
- Final products are no poisonous nor pollutants: H_2O, Sulfur, and CO_2.
- Versatile treatment capacity (nature and quantity): the processes do not depend on the chemical composition nor the purity of products to treat. Accordingly, one can also treat weak quantities of sulfides produced by small industrial units that otherwise could not be valorized or cleaned out by the traditional processes.
- Energy expense of the pollutant processing is low.
- Very compact reactors and comfortable maintenance.
- Reactors have no thermal inertia and can therefore answer very quickly to control signals.
- Reactors have a good resistance of materials to corrosion.

The energy consumptions, already low, can certainly be further improved. All range of parameters asks for a further fine-tuning. Several further tricks can still be applied like heat recycling, Oxygen addition, and other. The compromise GlidArc + Claus could also present also some advantages…

* * * * *

Can one imagine plasma-chemical reactors and their powering simpler and cheaper?

Abstract
Natural gas, commercial propane, gasoline and various diesel oils as well as other carbonaceous feeds are converted into synthesis gas using GlidArc-assisted Partial Oxidation reactors. We produce up to 8 m^3(n)/h of Nitrogen-diluted syngas containing up to 26% of H_2 and up to 23% of CO. It corresponds to 9 kW of electric power when such syngas is converted in an ideal Fuel Cell (FC). Power requirement for GlidArc assistance of such non-catalytic reforming is below 2% of the FC output.

1. Introduction

Fuel Cell manufacturers have been concentrating on readying their products for commercial applications. In parallel, efforts have been made to supply these Cells with appropriate Fuels. Presently, only very pure Hydrogen can be consumed in so called Proton Exchange Membrane cells while two other FCs (Solid Oxide or Molten Carbonate referred as SOFC or MCFC) can also directly "burn" the syngas. Neither H_2 nor CO is naturally present on our Planet so that they need to be produced somehow. It appears that in the near- to medium-term future most of these applications will involve systems with FCs operating rather on fossil fuel derived CO and/or H_2. Some new horizons open as concerns a bio-derived syngas.

Reforming of fossil Hydrocarbons (HC) and bio-related feeds (carbohydrates, alcohols, vegetable oils, oils and gases from biomass pyrolysis, biogas from biomass or bio-waste fermentation, etc.) is therefore an important process for the FC and other Hydrogen- or syngas-related industries. Small-scale reforming would allow using of these feeds in widely distributed power generation systems and would require a development of small- and medium-scale reformers.

Conventional reformers' technologies require careful attention to heat management, feed introduction, specific catalysts as well as combustion know-how, and entails solution of a set of difficult problems. For example, diesel oil reforming is a problem; due to its complex composition (long HC chains and cycles) and Sulfur content it represents one of the hardest fuels to reform. Natural gas, propane, gasoline, quite "dirty" diesel oils and jet fuels are however the most available fuels through a very dense chain of distribution. One should add to this list a myriad of easily available vegetable oils, alcohols, sugars, molasses etc. So should one remove first all poisoning additives or molecules from such feeds to make them compatible as regards a catalyst? Or apply a non-catalytic reforming?

Instead of using a catalyst we run our reforming process in a presence of high-voltage and low-current GlidArc discharges that assist the Partial Oxidation (POX) of various carbonaceous feedstocks into the syngas without their prior cleaning. Electric power of this non-catalytic reformer can be as low as 5% of a typical FC electric power output so that a recycling of such a small portion of the electric power produced in a FC is, in our opinion, an acceptable compromise allowing an implementation of such a specific plasma-assisted technology into the FC chain. Very active (and also very simple) GlidArc discharges play there a role of igniters and homogeneous phase catalysts; they also stabilize a post-plasma zone of our reformer. For the sake of simplicity and economics, our unique oxidant source is atmospheric air.

This contribution firstly presents some of our initial tests with pure cyclohexane, heptane, toluene, and the tests with pipeline grade natural gas as well as commercial gasolines and diesel oils. The last ones can contain up to 4% of Sulfur. The ability to reform "dirty" diesels (and similar feeds like naphtha and jet fuel) for their use in FCs is critical for industrial and military operations in many parts of the world where only off-specification feedstocks are available.

More results are then presented here below on our newest detailed study on propane reforming while our current experiments on GlidArc-assisted reforming of such "green" carbonaceous fuels as rapeseed oil and

---

biogas (a mixture of CH_4 and CO_2 from anaerobic digestion of organic wastes) will be presented during this ISPC-16 Poster Session.

2. Experimental

2.1. GlidArc-assisted reformers

The GlidArc-assisted reformers for Natural Gas into syngas conversion, a part of our Gas-to-Liquid (clean diesel and gasoline) advanced technology [1], have proved to be also excellent reformers for other fuels. Our here-presented test work has been based on small reactors, similar to those described in [2]. The reformer is shown schematically on the Fig. 1.

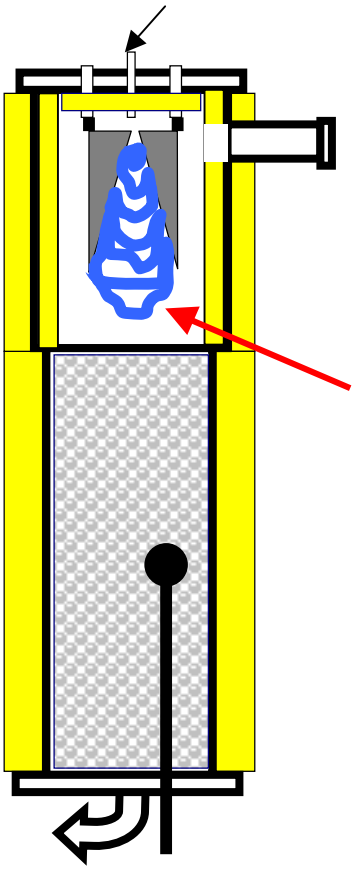

Fig. 1. Schematic view of GlidArc-assisted reformer.

The reactor contains three or six knife-shaped electrodes. The electrodes delimit a cone-shaped volume filled with gliding discharges. A feed + air premix is blown into that space through a simple tube and flows along the diverging electrodes. The plasma space (chamber) is thermally isolated in order to limit heat loses. Two flanges close the tubular reactor. The upper one supports the electrodes isolated electrically with high voltage connections. The other flange closes the reactor's bottom and comprises a product output tube. The entire structure is tight; it can support higher pressures but for the present runs we only worked at atmospheric pressure**.**

The gliding discharges ionize the gas mix. Given the moderate temperature of the electrodes (not cooled) and a very short contact time of the discharge roots with the electrodes, we do not observe any deterioration (even at a high Sulfur presence) that may prevent the gliding of these current-limited (0.1 A) discharges.

A perforated plate separates the plasma chamber and a post-plasma zone filled with packing. The plate makes it possible to transfer the products of partial reforming in plasma to the post-plasma zone. The whole reactor is externally insulated by a ceramic felt. In addition we thermally insulate the inner walls of the post-plasma zone of the reactor with a ceramic tube and a felt in order to keep it as hot as possible.

The total inside volume the reactor is 1 L (in our earlier experiments we also used a 2-L reactor). No part of the reactor is cooled in a forced manner. Two extra holes in the bottom flange provide for the insertion of two thermocouples measuring the post-plasma zone temperatures T_1 and T_2 respectively at 13 cm and 6 cm above the lower flange.

Almost punctual injection of the premixed feed + air between the electrodes provokes a phenomenon of re-circulation of the reactants in the plasma zone. The plate reinforces this recirculation. The flow of partially converted reactants containing long-living active radicals (and other catalytic species resulting from the gas excitation by gliding electric discharges) crosses the plate and, in the post-plasma zone, the conversion is thus completed in the presence of the packing where all the species deactivate. The luminous zone of the gliding electric discharges is observed through a window in order to verify the operation of the plasma chamber. A 10-kV power supply provides both ionization of the premix and then a transfer of electric energy into the discharges. The 3-phase supply is composed of commercial neon-light transformers. The time-averaged electric power is measured using a 3-phase kWh-meter and a chronometer. The averaged net GlidArc power during our runs was up to 0.8 kW.

A syngas sample crosses a white mineral wool in order to check if soot is present. Other sample is analyzed on-line using a 2-channels micro-gas chromatograph (μ-GC) dedicated to H_2, N_2, O_2, CH_4, CO for one channel, and CO_2 as well as some light HCs (C_2H_4, C_2H_6, C_2H_2, and C_3H_8+C_3H_6) for the second one. The gas product can be analyzed every 3 minutes.

2.2. Our previous preliminary tests [3]

As the test feeds we took several liquid HCs such as Cyclohexane, Heptane, Toluene, commercial Gasoline 95 and Diesel Oil (DO), and a pipeline-grade Natural Gas (NG). The reactor was fed by controlled flows of compressed air and HCs. Both flows were simply mixed together before their injection into the reactor. Some input/output data for these completely non-sooting experiments are presented in Tab. 1.

Table 1. Some input/output data of our first tests

Feed			C_6H_{12}	C_7H_{16}	C_7H_8	G-95[1]	DO[2]	NG[3]
Flow rate input	air	L(n)/min	42	35	47	77	91	81

kWh spent to produce 1 m^3(n) of H_2+CO			0.20	0.33	0.24	0.17	0.12	0.27
Output power* from syngas		kW	5.3	4.0	4.7	8.4	7.4	9.2
kW produced* per kW injected			19	11	20	19	26	12

* An ideal chemical-into-electric conversion of a FC is used; it takes into account the Lower Heating Value (LHV) of the produced H_2+CO mixture

[1] Gasoline: Aromatics 26.7%, Olefins 15.2%, Saturated 58.1%, and no Oxygenates; d = 0.73 g/cm^3; continuous run times of 6 h 31 min and 2 h 52 min

[2] d = 0.85 g/cm^3, 300 ppm of Sulfur; 3 main runs totalizing almost 11 hours

[3] CH_4 84.5%, C_2H_6 10.4%, C_3H_8 2.2%, C_4H_{10} 0.7%, C_{5+} 0.1%, N_2 1.6%, and CO_2 0.6%; continuous run times of 2 h 40 min and 9 h 20 min; the flow rate input is in L(n)/min

All feeds were totally reformed. We got a good energetic efficiency (defined in the bottom of the Tab. 1): always more than 10 times of chemical enthalpy contained in the syngas with respect to the electric energy injected into the GlidArc. We had no problem to reform such a cyclic compound as Toluene that is quite fragile. No soot was observed even in this case as well as when the commercial DO (containing a significant amount of Benzene, Toluene and Xylenes) was used as feed at a sufficient O/C ratio.

During the preliminary tests on the slightly Sulfur-polluted DO some H_2S in the syngas was detected. A simple way to remove it from the syngas can be, for example, a ZnO cartridge. We note therefore that our technology does not require clean feed and that our non-catalytic GlidArc-assisted reformer can accept some Sulfur-contaminated feeds. Based on that we performed a testing of some highly S-charged DO. Such fuels are widely spread over the world and therefore considered, for example, as logistic fuels for a local production of the electric energy on the battlefields. Our tests [presented orally as "Reforming of high-Sulfur diesel oil into synthesis gas in a plasma-assisted reactor", *3rd Department of Defense Conference on "Logistic Fuel Reforming"*, Panama City Beach, Florida, 2002] confirm that such dirty (up to 4% of S) and quite heavy fuel (end-point of distillation at 600°C) can be converted totally at no soot appearance and no harm to our compact reactor and electrodes (we worked several hours) at a 5-10 kW level of a FC output.

2.3. New detailed study of Propane reforming

2.3.1. Introduction

General availability of propane (also known as Liquefied Petroleum Gas LPG) designs it as an excellent candidate for an on-board or on-site POX reforming. Such process can provide the syngas for a direct feeding of the SOFC or MCFC. Otherwise, one can extract pure Hydrogen from the "water-shifted" syngas in which CO is partially or totally steam-converted to H_2. Hydrogen can then supply other types of FCs or can be used for other applications like chemical, petrochemical, metallurgical, and space. Small and medium size reformers running on propane/LPG can supply some FC powered buses, boats, homes, retail sales points etc. reducing therefore costs of the pure Hydrogen distribution. We contribute to such idea realization through our simply, GlidArc plasma-assisted reformer avoiding a need of poison-resistant catalysts or prior feedstock cleaner.

Generally, commercial propane can contain up to 300 ppm of Sulfur. Much higher Sulfur may be found in crude LPG or other light HC streams in refineries and gas processing plants. All such feedstock must be first cleaned (mostly desulfurized) in order to avoid the catalytic reformers poisoning (while some SOFCs can accept Sulfur-polluted syngas). For example only high purity propane (99.999%) can be reformed on a ceria-supported platinum catalysts [4].

2.3.2. Experiments

Our new experiments are performed using a short, 1-L, three-electrode GlidArc reactor. Commercial propane + air premix is blown into the plasma space through a simple 4-mm (I.D.) tube and flows along the diverging metallic electrodes. This time the averaged GlidArc assisting power was set to only 120 W.

Seven runs were preformed at various operating conditions. At the accumulated runtime of 25 hours we never changed any part of the reformer. The process was always very stable. When soot was starting to appear at an insufficient air/propane ratio we just put more air (or less propane) to establish the non-sooting conditions. Some characteristics of the runs are presented in Tab. 2.

When starting with a cold reactor it takes us less than 15 min to preheat it (a full combustion at a low propane flow) and then to collect the syngas at much stronger propane flow and proper reformer's temperatures. A regulation of the air/propane ratio and the GlidArc power are then applied as a function of reformer's temperatures during next fraction of hour after what the reforming could be left alone for an undetermined yet time. However we preferred to "play" various changes of input parameters to learn about the reformer productivity, efficiency, etc. To finish the run we simply cut all inputs letting the reformer to cool down in a natural manner.

Table 2. Some parameters of performed runs

Run	Air input $m^3(n)/h$	Propane input kg/h	H_2S added
A	1.9	0.41–0.49	0
B	1.9	0.35–0.42	0
C	3.0	0.46–0.72	0
D	4.2	0.86	0
E	3.0	0.53–0.78	0
F	1.9–4.2	0.5–0.83	0–8%
G	1.9–2.5	0.42–0.44	0 or 1000 ppm

Such hot reformer could be started again without any problem at a much shorter time. The reformer can also be left at reduced flows of air and propane as well as at limited electric assistance that keep it at appropriate temperature so that a re-start of reforming can be done in about 1 minute. Figure 2 shows an example of T_1 and T_2 temperatures evolution during the Run B.

The atomic ratio of Oxygen to Carbon in the feed should theoretically be equal to 1 according to the propane POX reaction:

$$C_3H_8 + 1.5\ O_2 = 3\ CO + 4\ H_2 \quad (1)$$

but such ideal POX cannot provide enough heat to keep the reaction going fast so that a combustion process must run in parallel. It may be presented as additional propane consumption:

$$C_3H_8 + 5\ O_2 = 3\ CO_2 + 4\ H_2O_{vap} \quad (2)$$

asking for extra Oxygen.

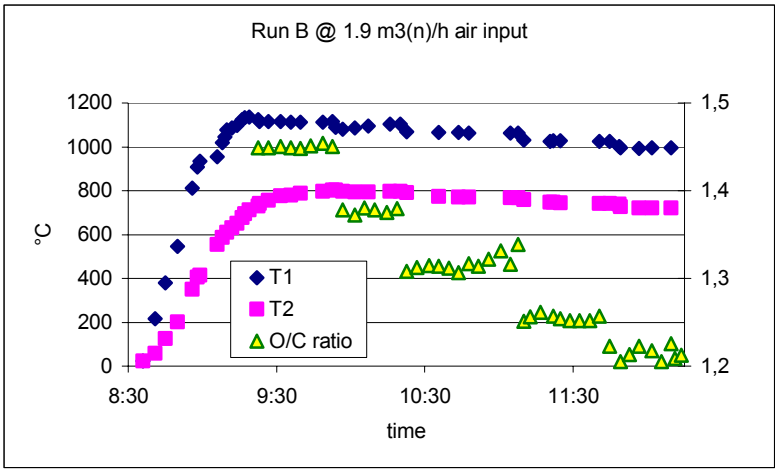

Fig. 2. T_1 (upper) and T_2 (lower) temperatures inside the post-plasma zone during the Run B as a function of time and air/propane input ratio (presented as an atomic O/C ratio on the right axis).

As shown on Fig. 2 (where for the constant flow rate of air a decrease of the O/C ratio means an increase of the propane input) the both temperatures decrease. We seek for a compromise between as low as possible O/C ratio and as fast as possible reforming kinetics that avoids at the same time the soot production according to exothermic parasite reaction:

$$2\ CO = CO_2 + C. \qquad (3)$$

Such a compromise is quite easy to find in the presence of the GlidArc. Moreover as the propane input increases the produced syngas flow increases at less pronounced reaction (2) due to a higher thermal loading of the reformer.

Precise mass balances show where the best compromise between the reactions (1) and (2) is located for the given reformer and wanted syngas outflow. The Figures that follow show some results of selected runs. The mass balances are based on the conservation of Nitrogen (totally inert gas in the reforming conditions) and total Carbon in the syngas (as no soot is present for an appropriate O/C ratio).

Figures 3 and 4 present the output flow rate of 100% syngas (H_2 + CO only) in m^3(n)/h and in kW units for Run B and integrated Runs C+E, respectively. In fact, the syngas is always diluted by Nitrogen as we use air to perform the reforming. The N_2 concentration at the output is typically in the range of 50-65 vol.% (dry basis), depending on O/C ratio applied for the given test. The H_2+CO flow rate in the output can also be presented as the potential thermal output power for the case this two components supply an ideal SOFC or MCFC where they are electrochemically converted into the steam and CO_2. Such a power is therefore assimilated to the LHV.

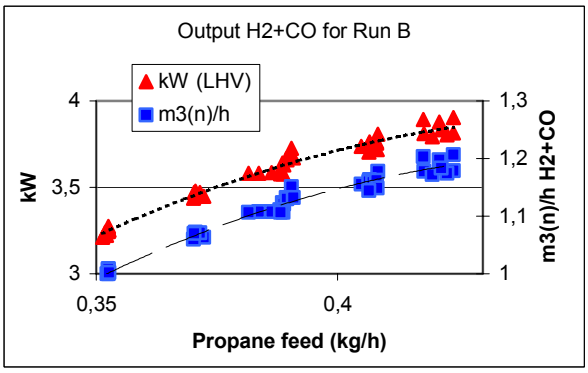

Fig. 3. Output flow rate of 100% syngas (H_2 + CO only) in m^3(n)/h and in kW units for Run B at constant air flow rate input of 1.9 m^3(n)/h.

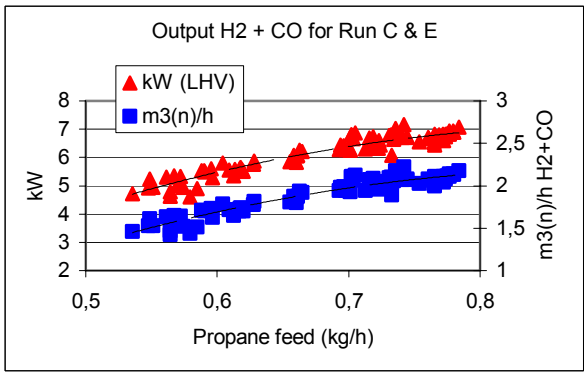

Fig. 4. Output flow rate of 100% syngas (H_2 + CO only) in m^3(n)/h and in kW units for integrated Runs C and E at constant air flow rate input of 3.0 m^3(n)/h.

In a short Run D at 4.2 m^3(n)/h air flow rate and 0.86 kg/h propane input we got the Nitrogen diluted syngas outflow corresponding to 2.7 m^3(n)/h of pure H_2 + CO mixture that is equivalent to LHV output power of 8.6 kW. This run was not yet optimized but it indicates that the maximal output of our 1-L reformer at atmospheric pressure is close to 9 kW or 3 m^3(n)/h of pure syngas. Higher outputs are expected for elevated pressures.

Having the output power we can calculate a thermal efficiency of the process. Such efficiency is defined here as a ratio of the LHV output power of the H_2+CO leaving the reformer with respect to the LHV input power of propane calculated from the reaction (2). The efficiency is shown on Fig. 5 and 6 as a function of O/C atomic ratio for the Run B and for integrated Runs C&E, respectively. On the same graphs we show also the H_2+CO concentration in the syngas as the function of O/C ratio deduced from relative flows of the air and

propane. At these O/C ratios the concentration of pure syngas in the output gas is around 36 to 44 vol.% (dry basis).

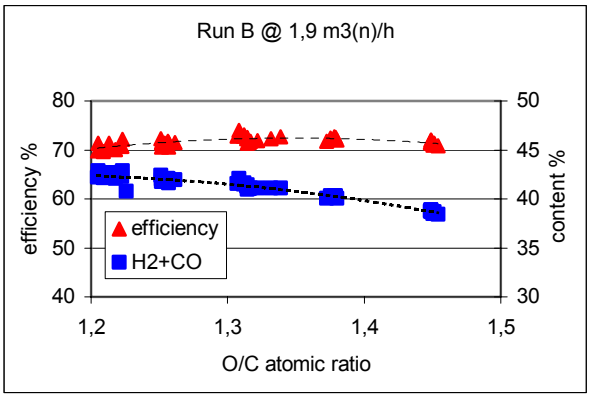

Fig. 5. Thermal efficiency of the propane reforming and the pure syngas concentration in output gas as a function of O/C atomic ratio for Run B at 1.9 m^3(n)/h air input flow rate.

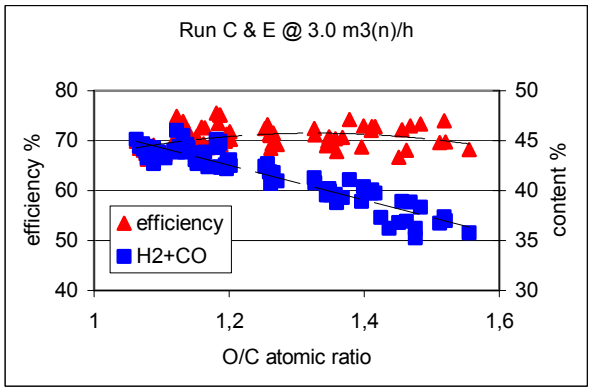

Fig. 6. Thermal efficiency of the propane reforming and the pure syngas concentration in output as a function of O/C atomic ratio for integrated Runs C and E at 3.0 m^3(n)/h air input flow rate.

Better than 70% thermal efficiency is obtained in the range of atomic ratio O/C ~ 1.2 to 1.4 (or otherwise O_2/C ~ 0.6 to 0.7 ratio) at no sooting conditions. Moreover, this quite high efficiency is based on only standard enthalpy heat (at 25°C) of output H_2+CO combustion to CO_2 and steam (LHV) with respect to the standard enthalpy heat of combustion (LHV) of entering C_3H_8. Such efficiency does not therefore take into account any sensitive heat content in the gas leaving the reformer at > 700°C. A part of that heat can certainly be reused to preheat entering HC feed and air so that a part of total propane combustion (2) could be limited and the thermal efficiency increased. No such heat exchange was however used in this study.
In order to show again our *pro*-Sulfur technology we have also performed Runs F and G adding a mass-controlled flow of pure H_2S into air/propane mixture. Especially Run G has simulated a quite dirty feed at 1000 ppm of H_2S. We did not observe any harm to our reformer and/or process. All collected reforming performances were the same when switching several times from "no H_2S" to "with H_2S" flows or *vice versa*. During the Run F where up to 8% of H_2S was added all went well but we could not yet make the full mass balances before identification of some unknown GC picks and their calibration.

3. Conclusion

This contribution presents firstly some of our preliminary tests on pipeline natural gas, gasoline 95 and diesel oils (including high-Sulfur containing ones) as well as some pure HC compounds: Heptane, Cyclohexane, and Toluene. These feeds were completely converted into syngas in our GlidArc-assisted reformer at atmospheric pressure and at low electric power assistance.
We are then appending these tests with more detailed study of propane as a representative of light HC feeds. The main operating parameters of the process: reforming temperature, air/propane ratio, GlidArc assisting power, etc. have been identified and set at their quasi-optimal levels. The results show the total propane conversion. No structural modifications of the whole converter or its parts are observed. As detailed and general conclusions we note:

- Propane is reformed at better than 70% energetic efficiency. Better efficiencies are expected when using heat exchangers.
- Soot is not produced if a sufficient O/C atomic ratio (and consequently some H_2O and CO_2 products) is accepted as compromise.
- 1000 ppm of Sulfur content in propane is not harmful for our reactor and process. Other high-Sulfur feeds were also successfully reformed so that GlidArc assisted technology opens the way for much simpler integrated reformer/SOFC units without prior removal of sulfur or other additives. This greatly expands the market potential to include military logistic fuels and/or other highly sulfur-polluted fuels.
- The flow rates of produced Hydrogen and Carbon Monoxide can be kept constant by fine-controlling the flow rates of entering propane and air. The syngas output can also match an actual need by regulating the rates of fuel and air.

- The temperature profile of the reactor is self-controlled by the process and by the GlidArc assistance. Frequent start-ups or quite drastic changes of syngas output can be done in a fraction of minute so that an integrated power-generation system can be much easier developed.
- Here presented 1-L (and not yet optimized reformer) can produce up to 3 m^3(n)/h of pure syngas (N_2 and other components not accounted). It can generate an amount of syngas corresponding to 9 kW of electric power (when syngas is fully converted in an ideal SOFC or MCFC). Further ECP's developments are in progress including systems to generate the syngas equivalent to 30 m^3(n)/h of pure H_2+CO mix corresponding to the LHV power of 100 kW.
- Electric power consumption assisting our reforming is less than 2% of the LHV power of produced syngas stream. Such a low power recycling level (or an import from outside) is, in our opinion, a worthy compromise. Instead of using a delicate catalyst that asks for a very clean fuel we dedicate an almost negligible part of produced syngas power to electrically support a non-catalytic reforming of almost any dirty fuel.
- No water or steam circuits, heaters, etc. are necessary. The process starts with compressed air (of any quality), a fuel, and the GlidArc. No special vaporizer/fuel injector unit is needed. The syngas appears after a short warm-up. If the reformer is kept hot than the full operation of our reformer can start after about 1 min.

These steps of ECP's self-financed project guarantees the development of a compact and reliable fuel processor fed by propane/LPG as well as other HC feeds. It can be used on-board of a SOFC vehicle or on-site for syngas or Hydrogen production for various applications.

* * *

Some qualitative tests were recently performed in our laboratory on the commercial rapeseed oil, 96% ethanol, and concentrated sugar solution in water. We got a soot-free syngas and the total feed conversion. It opens an opportunity to upgrade also other farm-issued products like molasses, residual or waste oils from various human activities. Other tests indicate that crude petroleum oils, heavy bitumen, and petroleum wastes can also be directly converted in our reformers… Large multiple-electrode ("GlidArc Multicluster", ECP's pending patent [5]) reformers are under development for a large-scale syngas production from almost any gaseous or liquid carbonaceous feed.

Thin films of amorphous, microcrystalline and epitaxial silicon are finding increasing application in solar sell fabrication. For industrial aims a deposition method are required which allows to grow both a-Si:H and μc-Si:H thin films under high rate on large area substrates for a-Si:H/ μc-Si:H tandem solar cells. Epitaxial Si growth at low temperatures of less than 650°C is required for production of thin-film monocrystalline solar cells. In this paper we present the results of the application of the gas-jet electron beam plasma CVD (GJ-EBP-CVD) method for deposition of amorphous, microcrystalline and epitaxial Si thin films. Our method has already demonstrated not only very high deposition rates for a-Si:H [1], μc-Si [2] and epitaxial Si [3], but also the capability of large area deposition [4].

The GJ-EBP-CVD method was described in detail elsewhere [2, 4]. The method is based on activation of gas mixture jet by electron beam plasma and fast convective transfer of generated radicals by the supersonic free jet to a substrate. The method has the following main features. Firstly, the electron beam plasma, in comparison to the discharge plasma, contains much more electrons with the effective energy enough for generation of radicals and ions. Secondly, a fast convective transfer of active particles from the activation zone to the substrate by the jet inhibits undesirable gas-phase processes. These two features ensure a high deposition rate of films and low power inputs on the process. At last, the jet protects the substrate from atoms and molecules of background gases, therefore one can use standard vacuum chambers and a low vacuum even for growth of epitaxial layers

In this work, the free jet of the gaseous mixture of 1-10 % of SiH_4 with Ar was activated by the electron beam with energy 1-2 keV and current 100-500 mA. The total flow rate of the mixture was up to 13500 sccm. Substrate temperatures were changed from 100 to 650 °C. A pumping system included booster oil-diffusion pumps. The base pressure in the growth chamber was about 10^{-4} Torr, the resulting pressure during growth process was $\approx 2\times10^{-2}$ Torr. Five kinds of substrate are used in the present work: stainless steel (20×20 cm^2), mono-Si wafers *n*-type (100)-oriented for homoepitaxy, mono-Si samples covered by SiO_2 layer for measure of photosensitivity, sapphire for optical absorption spectra study and ceramics.

The method was used for deposition of amorphous, microcrystalline and epitaxial silicon thin films under high rates up to 15 – 20 nm/s. The optical, electrical and structural properties of the films are systematically studied.

The structures of the films are significantly affected by the substrate temperature. Films deposited at 250 ºC were amorphous ones and have a low dark conductivity and a photosensitivity of 10^5. For samples deposited at 430 °C the crystalline fraction in the film is almost 100%. The films have a columnar structure perpendicular to the interface and the average grain size is about 300 nm [2]. SEM-investigation of the surface of μc-Si films shows that the surface roughness is in the range of 0.1-1 μm, that providing excellent light trapping as confirmed by spectroscopic ellipsometry measurement [2]. Carrier lifetime is measured in the range of 1-2 μs for μc -Si films deposited on ceramics substrate at 640 °C by means of microwave photoconductivity decay method at a bias light. Films deposited at 640 ºC on mono-Si wafers *n*-type (100)-oriented were epitaxial ones.

All results show that Si films grown by the gas jet method are suited for solar cell processing which is currently under development.

Abstract
An ion temperature in ECR plasma is measured with high-resolution optical emission spectroscopy of Doppler profiles of Ar and Ar^+ transition. It is found that the Ar ion temperature is about 0.6eV in pure Ar plasma, and it decreases drastically as the nitrogen gas concentration is increased. The radial profile of the electron density becomes flat with adding the nitrogen gas. These results suggest that the cooling of the ion temperature due to the decreasing of the radial electric fields.

1. Introduction

An electron cyclotron resonance (ECR) plasma [1-3] has been actively used in the field of plasma etching and deposition processes for semiconductor manufacturing, because of its attractive features that high plasma density (10^{13} cm^{-3}) can be obtained at low gas pressures (a few mTorr).

Especially in plasma etching process, an ion temperature in plasma is one of the most important parameters. The ion temperature affects the rate of surface reaction, the etch rate and the selectivity. Moreover, the ion temperature determines the quality of etching. If the ion temperature is low, the incident angle of ions is narrow and, as the result, most of ions hit the bottom of the feature. On the other hand, if the ion temperature is high, the incident angle of the ions broadens and degradations of the feature such as the mask undercut, bowing and so on, occur. Recently, the ultra large-scale integrated circuit becomes smaller and high aspect ratio features with narrower width (<0.25 μ m) is required from industry. Thus, the production of the low ion temperature plasma is one of the most important subjects in plasma processing.

In addition, there is a growing interest in the characteristics of nitrogen plasma because of their potential use in the synthesis of nitride thin films, such as GaN, and in the surface modification of various materials. In these plasma CVD processes, the ion temperature may also affect the quality of thin films. Thus, the measurement of the ion temperature in Ar/N_2 plasma is also necessary for understanding these processes.

However, there are few works about measurements of the ion temperature in plasma for application, since the high-resolution measurement system is necessary. An energy analyser is inappropriate for ion temperature measurements because its resolution is as low as 1eV. In the previous work, we measured the ion temperature in Ar ECR plasma with high-resolution optical emission spectroscopy and found that the ion temperature in low gas pressure plasma was considerably higher than that expected [4].

In this paper, we measured the ion temperature in Ar/N_2 ECR plasma and investigated the effect of adding the nitrogen gas.

2. Experimental set up

Fig.1 shows a schematic diagram of the experimental apparatus. The experiments were performed using a stainless-steel vacuum chamber with an inner diameter of 290 mm and length of 1200 mm. The chamber was evacuated using a rotary pump and a 2000 l/s turbo molecular pump to a base pressure of less than 10^{-7} Torr. The six magnetic coils with a thickness of 100 mm and inner diameter of 320 mm were placed adjacent to the chamber to form magnetic mirror fields. 2.45 GHz microwaves were launched into the chamber through a tapered waveguide and a quartz window as a circular TE_{11} mode. 915MHz microwaves were launched into the

chamber as a circular TM_{11} mode. The incident and refracted microwave power was measured using a power monitor connected to the directional coupler and the refracted microwave power was minimized by adjusting the three-stub tuner. The substrate holder was placed at 550 mm from the quartz window. The gases used were Ar and N_2. The flow rate of these gasses was adjusted by each mass flow controller. The plasma parameters were measured with a 1 mm-diameter cylindrical single Langmuir probe. The probe was connected to 2D motor drive and moved along pallarel and perpendicular directions to the magnetic fields.

The optical measurement system consisted of a Czerny-Turner type monochromator, a photomultiplier tube, an optical fiber and an electronics system for photon count processing. The monochromator was equipped with 2400-groove/mm grating brazed at 300 nm and scanned in 0.0002 nm steps. The focal length of the monochromator was 1.5 m and the slit width was kept at 14 μ m. The line broadening due to instrument was determined from the measurement of a spectral profile of Hg-lamp light (HAMAMATSU L937-02) at 313.18 nm. The measured instrumental broadening was 0.0030 nm. The effects of the instrument width were removed from the raw data through deconvolution calculations. Optical emissions in the ECR plasma were collected along the radial direction through a viewing port using a lens-optical fiber combination. The viewing port was positioned 170 mm downstream from the ECR point. The emissions entered monochromator were analysed by the photon counting method.

3. The measurement of ion temperature

The emission line profile observed in plasmas may be broadened by many factors, such as natural broadening and Zeeman broadening. The expected Zeeman effect was approximately 0.001nm at the presence of the static magnetic fields about 1kG [5]. The expected Zeeman broadening at measured point was less than the instrument broadening, and was neglected. In our experiment, the natural broadening was also neglected.

Assuming that the ion velocity distribution function is Maxwellian, the emission line profiles is as follows:

$$I(\Delta\lambda) = \frac{I_0}{\pi^{\frac{1}{2}}\Delta\lambda_D} \exp\left[-\left(\frac{\Delta\lambda}{\Delta\lambda_D}\right)^2\right] \tag{1}$$

Here I_0 is total intensity of the spectrum, $\Delta\lambda$ is the divergence from the wavelength of radiation λ_0. $\Delta\lambda_D$ is the width of the Doppler broadening and defined as follows:

$$\Delta\lambda_D = \frac{\lambda_0}{c}\sqrt{\frac{2kT_i}{M_i}} \tag{2}$$

Using a full width at half maximum $\Delta\lambda_{D\frac{1}{2}} = 2(\ln 2)^{\frac{1}{2}}\Delta\lambda_D$, we obtain

$$T_i = 1.67\times10^8 \times A\left(\frac{\lambda_{D\frac{1}{2}}}{\lambda_0}\right)^2 [eV] \tag{3}$$

, where A is the mass number. $\Delta\lambda_{D\frac{1}{2}}$ was obtained from a Gaussian fit of the experimental data.

4. Results and discussion

Fig. 2 shows the dependence of the Ar ion temperature on the nitrogen gas concentration. The measured spectrum was 434.81 nm. The nitrogen gas concentration α was determined as follows; $\alpha = S_{N2}/(S_{N2}+S_{Ar})$. Here S_{N2} and S_{Ar} mean the gas flow rate of Ar and N_2, respectively. The total gas pressure was kept at 2.0mTorr and the incident microwave power was 2.4kW. As shown in Fig. 2, the ion temperature is 0.6eV in pure Ar plasma and it decreases drastically as the nitrogen gas concentration is increased. Fig. 3 shows the dependence of the electron temperature and the electron density on the nitrogen gas concentration. It is found that the electron

temperature slightly increases with increasing the nitrogen gas concentration. This result is valid for physical picture that the loss of the plasma increases with increasing the nitrogen gas concentration because the mass of the nitrogen is lighter than that of argon and, as the result, the electron density decreases and the electron temperature increases to sustain the plasma. Usually, it is considered that ions are heated by electrons through electron-ion collisions. However, as shown in Fig. 2 and Fig. 3, the dependence of the ion temperature on the nitrogen gas concentration is different from that of the electron temperature. Thus, it is concluded that the decrease of the ion temperature is not caused by electrons.

Fig. 4 shows the dependence of the ion temperature on the nitrogen gas concentration for 915MHz microwaves. It is found that the ion temperature also decreases with increasing the nitrogen gas concentration and it is lower than that of 2.45GHz ECR plasma. It has been reported that the electron temperature in 915MHz ECR plasma is lower than that in 2.45GHz ECR plasma [6]. Actually, as shown in Fig. 5, the measured electron temperature in 915MHz ECR plasma is lower than that in 2.45GHz ECR plasma. These results suggest that the lower electron temperature leads to the lower ion temperature.

The charge exchange collision is thought of as the reason for decreasing the ion temperature. When the nitrogen gas is added, the following charge exchange is caused; $Ar^{+}*+Ar \rightarrow Ar^{+}+Ar*$. This charge exchange makes Ar ions cool and energetic Ar neutrals are produced. To verify this effect, we measured Ar neutral temperature. Fig. 6 shows the dependence of the neutral temperature on the nitrogen gas concentration, where the measured spectrum was 434.81 nm. The total gas pressure was 2.0mTorr and the incident power of 2.45GHz microwaves was 2.4kW. It is found that the neutral temperature slightly decreases with increasing the nitrogen gas concentration. This result indicates that the charge exchange collisions is not dominant and the decrease of the neutral temperature is due to the decrease of the ion temperature thorough ion-neutral collisions. However, the ionisation rate of the ECR plasma was so low as 2~3% that the number of neutral particle was much larger than that of ions. Therefore, the number of energetic neutrals was too small to measure.

There are many works about the acceleration of ions due to increase of the ambipolar electric field [7-9]. The same effect may occur along the radial direction. Fig. 7 shows the radial profile of the electron density with varying the nitrogen gas concentration. The measured point was the same as the viewing port position and the experimental condition was the same as Fig. 6. It is found that the radial distribution of the electron density becomes flat by adding the nitrogen gas. Usually, electrons in a magnetic mirror plasma behave as the Boltzman distribution. Therefore, the density distribution implies the plasma potential distribution. If the plasma potential distribution becomes flat, the radial electric field becomes small, and as the result, the transverse ion temperature is considered to decrease. Muta et al. calculated the ion temperature with self-consistent calculation using the hybrid model [10]. The simulation was run for the cases where radial density was peaking and relatively flat. It was found that, when the radial profile of the electron density was peaking, the average of the ion temperature was high, while it was low when the radial density profile was flat. From these results, it is concluded that the radial electric field is an influential factor for decreasing the ion temperature.

5. Summary

The dependence of the Ar ion temperature on the nitrogen gas concentration was investigated. It was found that the ion temperature decreased with increasing the nitrogen gas concentration, while the electron temperature slightly increased. In addition, it was found that the radial distribution of the electron density became flat by adding the nitrogen gas. This change of the plasma density may cause the change of plasma potential and, as the results, the decrease of the radial electric fields make the ion temperature lower.

Dissociation and hydrogen exchange reactions in water plasma monitored by emission spectroscopy

I. G. Koo, J. H. Shim, and W. M. Lee

Department of Molecular Science and Technology, Ajou University, Suwon, Korea

Abstract

We have studied the hydrogen exchange and water dissociation reactions in H_2/D_2O, D_2/H_2O, D_2O and H_2O plasma excited by hollow cathode discharge using emission and infrared spectroscopy. When the electrical power for the discharge, the flow rate of the gas system, and the reactor temperature were maintained at 1 W, 150 ml min^{-1}, and 100^oC, respectively, the reacting gas of one atmospheric pressure underwent about 30% of the hydrogen exchange reaction.

1. Introduction

Plasma, both thermal and non-thermal, is used as one of the major methods in removing environmental pollutants, replacing catalysts in many gaseous reactions, and altering chemical reaction paths [1-5]. Among many applications of the plasma method, we investigated the hydrogen isotope exchange reactions in water/hydrogen plasma [6].

Heavy water (D_2O) used as a coolant in nuclear reactors is partly transformed into DTO when the molecules capture neutrons. Among the many tritium recovery processes, the catalytic exchange of DTO with D_2 to produce DT and D_2O, or electrolysis of D_2O/DTO to D_2/DT and O_2 followed by cryogenic distillation of the hydrogen isotopes, appears feasible and promising [7,8]. But such exchange reactions require the use of expensive novel metals. When the hydrogen isotope exchange reactions occurring in (H_2O, D_2) or (D_2O, H_2) reacting system were carried out in a DC electrical discharge, it was revealed that the discharge method was far more effective in facilitating the exchange reaction than was the conventional catalytic method [6]. In this study the hollow cathode discharge method was employed instead of a typical DC discharge method relying on a point-plane geometry. Allowing gas flow through arrays of microhollow cathode holes and applying power between the electrodes could generate large area uniform and stable plasma [9-11]. The advantage of such large area plasma is obvious from the possibility of an increase in the energy efficiency defined by the extent of wanted chemical reactions per dissipated electrical energy. The advantage is even more pronounced considering a potential large increase in the treating capacity by the stable atmospheric plasma.

The plasma was monitored mainly using plasma emission spectroscopy (PES) and using the infrared spectroscopy (FTIR) as an auxiliary tool. The extent of the exchange reaction was determined by measuring in real time the OH or OD emission intensity or the IR absorbance of the HDO molecule, major products of the reaction. The progress of the reaction was studied as a function of the temperature, the current density and the composition of the reactants while the pressure of the system was maintained at the atmospheric pressure.

2. Experimental

The schematic experimental setup is illustrated in Fig. 1. The experimental setup used in this study consists of three major sections: the electrode assembly and the plasma reactor, the gas supply and regulating

lines, and the spectroscopic diagnostic system. The reactor included a thermocouple for temperature measurement, a pressure gauge, UV-grade quartz window for transmitting the emitted light, and CaF_2 windows (4000~1000 cm^{-1}) for transmitting infrared light. The emitted light from the plasma reactor was collected and transmitted through an optical fiber to the monochromator, the 750 mm Czerny-Terner monochromator (Model DM 702) attached to the Andor CCD camera (Model DB401-UV). The spectroscopic resolution of the emitted light for the 200-1000 nm ranges was made using a grating 1200 gr/mm, 2400 gr/mm with the resolution of 0.05, 0.01nm. The IR measurements of the reacting species were acquired using the FTIR spectrometer (Nicolet Magna-IR) in the form of a single beam with a resolution of 2 cm^{-1} and scan number of 1 in an IR detection range of 4000~800 cm^{-1}.

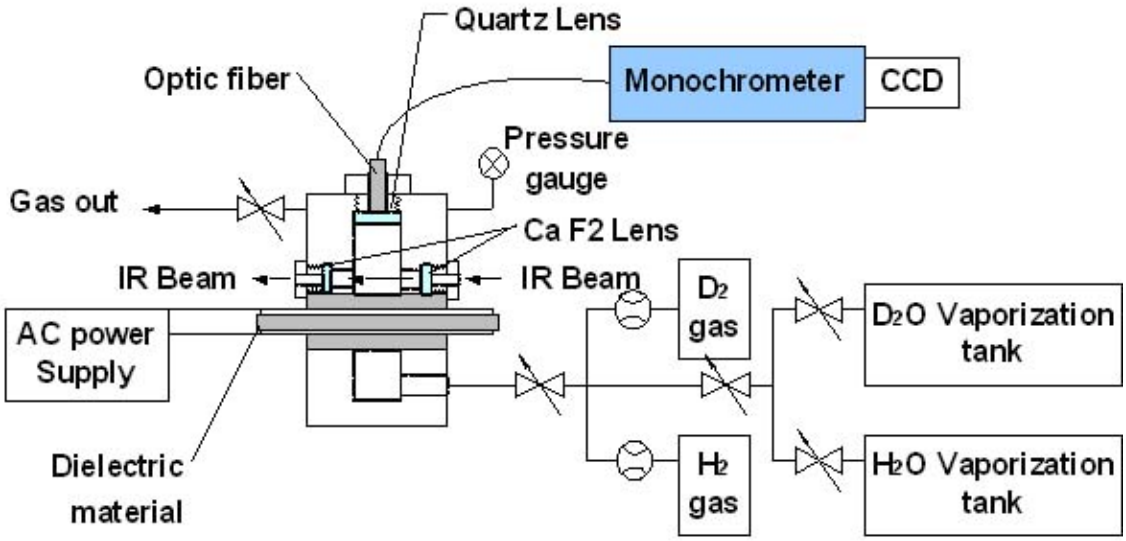

Fig. 1 Experimental setup

The electrode design for generating large-area atmospheric plasma is illustrated in Fig. 2. The electrodes basically consisted of two aluminum disks of 200 μm thickness separated by an alumina sheet of 1 mm thickness. A mechanical driller was used to bore many holes of 300 μm diameter through this electrode assembly. A 60 Hz AC power supply was connected to the cathode and the anode. Gas or gas mixture having composition such as He, H_2, D_2, H_2O, D_2O, H_2/D_2O or D_2/H_2O was allowed to flow through this assembly to generate atmospheric plasma.

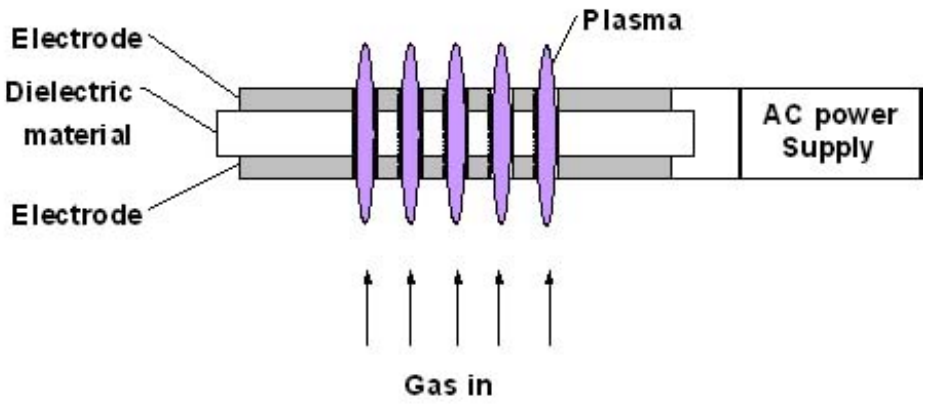

Fig. 2 Hollow cathode plasma generation

The transfer of the water vapor into the reactor and the regulation of its flow rate were accomplished by the following procedures. First, the reactor was pumped down to ~10^{-2} Torr by a cold-trapped rotary pump (Edward E2M1.5 double stage). The water reservoir was heated to reach a pre-set temperature and the saturated H_2O or D_2O vapor was introduced into the reactor. Second, during the reaction period the water loss at the reservoir was measured as a function of the temperature to determine its flow rate (250 sccm at 80°C). Concurrently with the introduction of water vapor the H_2 or D_2 gas was also allowed to enter the chamber with the help of a mass flow meter (100 sccm) and needle valve (Sierra series 820 Top-trak™). The total pressure of hydrogen gas plus water vapor and the chamber temperature were maintained at the atmospheric pressure and 100°C, respectively. The pressure was measured with the diaphragm manometer gauge (Baratron 268A model).

3. Results and discussion

AC discharge in pure hydrogen gas or water vapor or their mixture was able to generate stable large area plasma at a pressure of 760 Torr when the gas flew through the micro-cathode assembly. The success is quite remarkable in that no noble gas was used and the pressure reached the atmospheric pressure. It is quite well attributed to the unique geometry displayed in the micro cathode assembly. The characteristic α-emission line of atomic hydrogen obtained from pure hydrogen or deuterium gas plasma is shown in Fig. 3. The wavelength difference of the α-line between hydrogen and deuterium atom is about 0.3 nm that was also reported previously [12]. Such an extremely close occurrence of the atomic lines of the hydrogen isotopes makes it difficult to use such lines as the reference for monitoring the species containing H or D atoms.

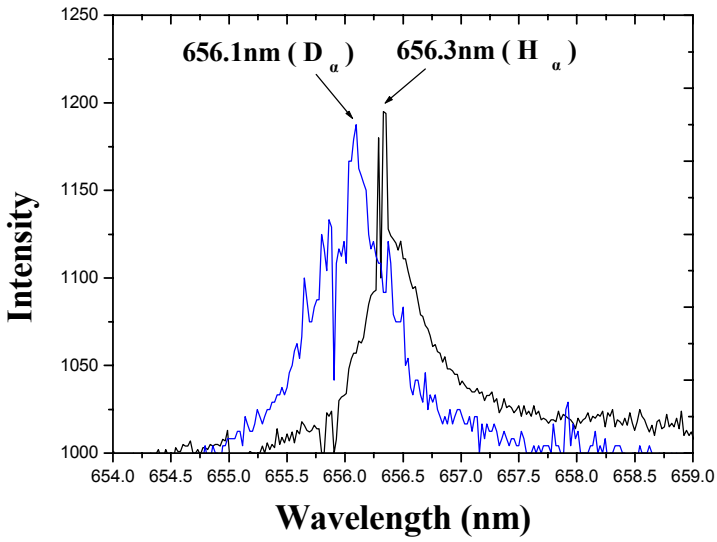

Fig. 3 The H-α or D-α line observed from the discharge in H_2 or D_2 gas

The emission spectrum of water vapor plasma is shown in Fig. 4. The characteristic lines of OH or OD radical are appearing in the range of 307 to 310 nm and much weaker hydrogen-α line is also showing up. But when the discharge was made in water/hydrogen gas mixture, the OH lines almost completely disappeared as shown in Fig. 5 while very weak hydrogen-α line appeared. It is surprising that OH or OD lines are almost completely subdued when hydrogen gas is added to the system. This is an indication that the lifetime of OH radical is very short during the discharge in the presence of hydrogen atom or molecule.

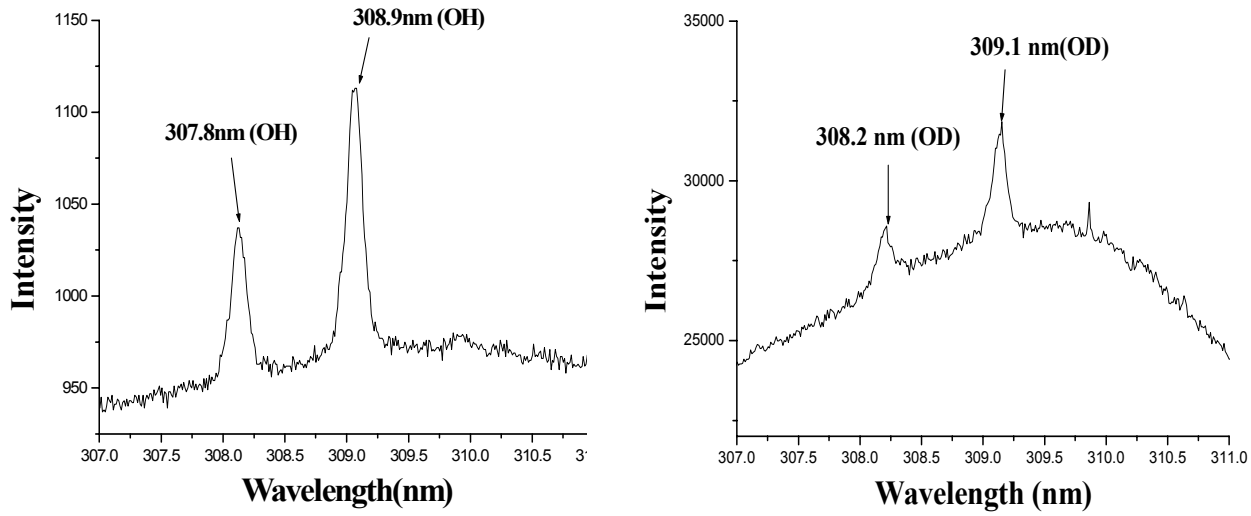

Fig. 4. The emission spectra of H_2O or D_2O plasma

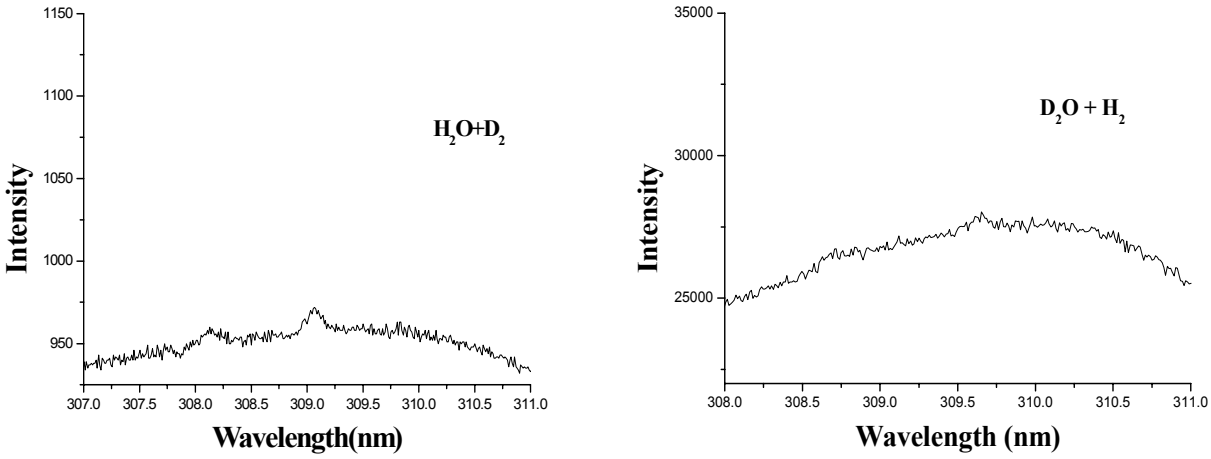

Fig. 5. The emission spectra of (H_2O/D_2) or (D_2O/H_2) plasma

But the emission spectra of water/hydrogen plasma obtained in a flowing system do not tell us directly the extent of the hydrogen isotope exchange reaction in a system such as (H_2O/D_2) or (D_2O/H_2). In order to determine the extent we have to resort to IR spectroscopy since this method renders it possible to obtain the information on the concentration of the exchange reaction product HDO. For example, measurements of the absorbency (or transmission) of the vibrational characteristic lines of D_2O or HDO molecules during the discharge in (D_2O/H_2) system gives out direct information on the advance of the exchange reaction. The exact determination of the advance of the exchange reaction in a flowing system requires that the reactor be closed at an arbitrary time during the steady discharge and then the measurement should follow in the closed system regarding the intensity of the vibrational peaks of the involved species. But in this study we assumed that the region of the reactor from which the optical signal was collected could represent the advance of the exchange reaction in the flowing system. Under this assumption the intensity of the flowing system can be compared with that measured in the closed system to determine the advance of the reaction. The vibrational

characteristic lines of HDO and D_2O molecules in D_2O/H_2 system are shown in Fig. 6. By comparing the intensity of the lines of D_2O in the flowing D_2O/H_2 system with those in the closed system, we were able to determine the advance of the reaction in the system. The advance of the exchange reaction in the closed D_2O/H_2 system, representable by the decrease in the number density of D_2O molecules, is plotted in Fig. 7 as a function of the discharge time. It turned out that the discharge with the given flow rate of the reacting gas accomplished about 30 % of exchange reaction when the power was maintained under 2 W.

Abstract

The results reported in this work have been obtained in HMDSO-O_2-Ar RF glow discharges, sustained in a capacitively coupled, parallel plate reactor. The exhaust gases has been sampled by means of a cold trap and analyzed using gas chromatography-mass spectrometry (GC-MS). The effect of feed composition, RF input power, and pressure on the concentration of unreacted HMDSO and of its conversion products has been investigated by means of qualitative and absolute quantitative analyses. HMDSO undergoes conversion to many different linear and cyclic compounds, containing from one to five silicon atoms. The results seams to indicate that under the experimental conditions investigated, HMDSO is not activated by reactions with oxygen but mainly by electron collisions. On the contrary, oxygen seams to have an important role in the plasma chemistry.

Introduction

Plasma Enhanced Chemical Vapor Deposition (PECVD) of silicon dioxide (SiO_2-like) thin films has many large-scale applications because of the interesting properties of the coatings: insulating characteristics[1], good abrasion resistance[2], low gas and moisture permeability[3,4,5], resistance to chemicals, optical transparency[3], etc... SiO_2-like thin films have been extensively applied in semiconductor industry and now they find applications in many other fields, like packaging, biomaterials, corrosion protection, etc.

In recent years, many organosilicon compounds like hexamethyldisiloxane (HMDSO) or tetraethoxysilane (TEOS) mixed with oxidants (O_2, N_2O) and/or noble gases (Ar, He), are used as SiO_2 precursors. Organosilicon monomer fed plasmas are complex reactive systems and a great deal of work has been produced to understand their chemistry, nevertheless the deposition mechanism is not yet completely known and for this reason many investigations are directed to the identification of the main film precursors and to clarify the plasma-surface interaction. An overall general deposition mechanism, reporting some of the possible reaction paths can be proposed according to Figure 1[6,7,8].

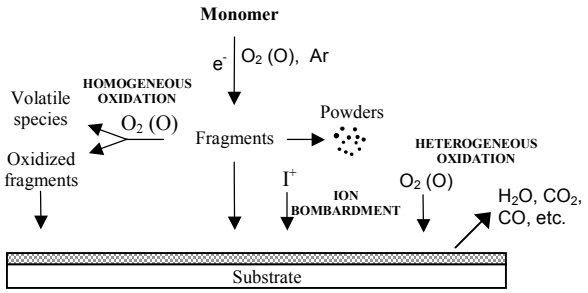

Figure 1. General deposition process in organosilicon plasma.

The organosilicon monomer is activated by electron collision and/or reaction with oxygen and/or excited Ar or He, the fragments can form powders or undergo homogeneous oxidation reactions with formation of partially or totally oxidized species. The intermediates are then adsorbed on the substrate surface where they can experience ion bombardment as well as heterogeneous (gas-surface) oxidations with release of water and other oxidized compounds.

The identification of the reaction steps relevant for the deposition process and the correlation with the chemical composition and properties of coatings is one of the most important research task.

Many diagnostic techniques such as Fourier Transform Infrared Absorption Spectroscopy (FTIR-AS), Optical Emission Spectroscopy (OES), Mass Spectrometry (MS), etc. have been utilized to study organosilicon containing plasmas[6,7,8,9,10], among them gas chromatography with mass spectrometric detection

(GC-MS) has shown to be a very powerful gas phase indirect diagnostic technique[11,12,13,14,15]. When coupled to other direct diagnostics, GC-MS can improve the understanding of organosilicon fed plasmas since it allows for the quali-quantitative determination of stable by-products formed by plasma activation. Unfortunately GC-MS does not allow a continuous monitoring of exhaust composition, since it is not compatible with on line continuous sampling, but requires a suitable discrete gas sampling system, such as a cold trap located between the plasma chamber and the pump.
GC-MS has been extensively utilized by Wróbel et al. to investigate PECVD and remote plasma chemical vapor deposition processes carried out with different organosilicon monomers (i. e. siloxanes, silanes and silazanes)[11,12,13,14].
In the present work we report the results of GC-MS investigation of RF glow discharges fed with HMDSO-O_2-Ar. The effect of the feed composition, input power and pressure on the monomer depletion and on the concentration of by-products have been investigated. The results allow for a clarification of some aspects of the overall deposition mechanism under the experimental conditions utilized for the study.

Experimental
The experimental apparatus consists of a stainless steel parallel-plate reactor with an asymmetric electrode configuration, at 13.56 MHz RF, pumped by a turbomolecular-rotary pumping system. The gas flow rates are controlled with MKS mass flow controllers while HMDSO vapor flow rate is controlled by means of MKS Vapor Source Controller (a commercial vapor delivery system maintained at constant temperature and equipped with a flow meter). A throttle valve allows the working pressure regulation.
Glow discharges were fed with HMDSO-O_2-Ar mixtures at the total flow rate of 23 and 78 sccm. HMDSO (Sigma Aldrich, 99 % purity) flow rate was kept constant at 3 sccm, while the O_2-to-HMDSO ratio was in the range 0 ÷ 25 (the Ar content in the feed gas was changed to keep the total flow rate at the selected value). The input power was changed in the range 50 ÷ 200 W and the working pressure was set at 100 and 500 mTorr. A stainless steel liquid nitrogen trap, located between the reactor and the turbomolecular pump (Figure 2), allows for the retention of the exhaust gases of the plasma process: i.e. unreacted HMDSO and products derived from recombination of plasma intermediates.
The exhaust gas was sampled at the liquid nitrogen temperature (78 K) for 20 minutes, then the trap was

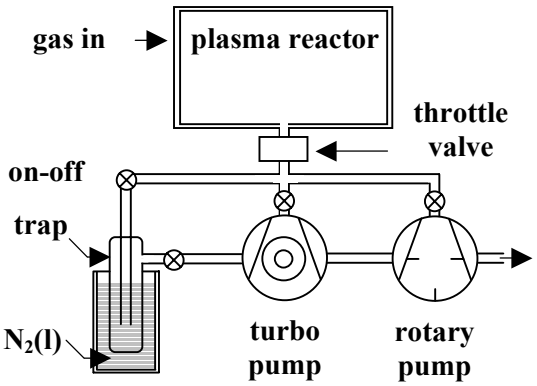

Figure 2. Schematic of the sampling apparatus.

isolated from the system and vented with Ar. The condensate was dissolved in acetone (50 ml), filtered and than analyzed with a GC 8000 Top GC-MS (Thermoquest Corporation) apparatus, equipped with an Alltech AT^{TM}-5MS capillary column of fused silica, coated with 0.25 μm of 5% phenyl and 95% methyl polysiloxane (length of 30 m, i.d. of 0.25 mm). The analyses have been performed with 2 sccm of He as carrier gas, injector temperature of 200˚C, and column temperature programmed from 30 to 200˚C (1 min at 30˚C, linear heating rate of 10 ˚C min^{-1}, 1 min. at 200˚C). Separated products were analyzed with a Voyager quadrupole Mass-Spectrometer, Thermoquest Corporation, at the interface and source temperatures of 250 and 200˚C respectively. Mass spectra were recorded in the m/z range: 15 ÷ 450 u.m.a. at the standard ionizing electron energy of 70 eV. The products were identified by means of available libraries[15] and, in particular for quantified products, by the comparison of retention time and mass spectra with standard compounds.

The quantitative analysis of some identified species was performed utilizing nonane (Sigma Aldrich, 99% purity) as internal standard (IS) through the calculation of calibration curves in the linear range. The amounts of quantified compounds have been converted in flow rate, Φ (sccm), by means of Eq. 1 assuming the ideal gas behavior:

$$\Phi(\text{sccm}) = \frac{\text{mass(g)}}{\text{MW}(\text{g}\cdot\text{mol}^{-1})} \cdot 22400\,(\text{cc}\cdot\text{mol}^{-1}) \cdot \frac{1}{\text{t}_{\text{sampling}}\,(\text{min})} \qquad (1)$$

where MW is the molecular weight and $t_{sampling}$ the collecting time of the exhaust in the LN_2 trap. The extent of monomer conversion has been evaluated by dividing the flow rate of HMDSO in the exhaust at plasma on with that introduced into the reactor at plasma off according to (2):

$$\%_{\text{HMDSO}} = \frac{\text{HMDSO}_{\text{plasma on}}\ (\text{sccm})}{\text{HMDSO}_{\text{plasma off}}\ (\text{sccm})} \cdot 100 \qquad (2)$$

The higher is $\%_{HMDSO}$ the lower is the monomer depletion. It is also verified that the collection of exhaust gases in the trap was quantitative and reproducible.

Result and descussion

Figure 3 shows two typical chromatograms of the by-products sampled with HMDSO containing plasma, the identified species are reported in Table 1.

Table 1. Identified species detected in HMDSO containing plasmas.

	Compound	**Formula**	**Molecular weight (u.m.a.)**
	Hexamethyldisiloxane (HMDSO) *	$Me_3SiOSiMe_3$	162
1	Tetramethylsilane (TMS)*	Me_4Si	88
2	Ethyltrimethylsilane (ETMS)	$EtMe_3Si$	102
3	Trimethylsilanol (TMSOH)*	Me_3SiOH	90
4	Pentamethyldisiloxane (PMDSO)	$Me_3SiOSiHMe_2$	148
5	Ethoxytrimethylsilane (EOTMS)	$EtOMe_3Si$	118
6	Trimethylsilylformate (TMSF)	$HCOOSiMe_3$	118
7	Ethylpentamethyldisiloxane (EPMDSO)	$EtMe_2SiOSiMe_3$	176
8	Hexamethylcyclotrisiloxane(HMCTSO)*	$(Me_2SiO)_3$	222
9	Octamethyltrisiloxane (OMTSO)*	$Me\text{-}(Me_2SiO)_2\text{-}SiMe_3$	236
10	Octamethylcyclotetrasiloxane (OMCTSO)*	$(Me_2SiO)_4$	296
11	Decamethyltetrasiloxane (DMTSO)*	$Me\text{-}(Me_2SiO)_3\text{-}SiMe_3$	310
12	Dodecamethylpentasiloxane (DMPSO)	$Me\text{-}(Me_2SiO)_4\text{-}SiMe_3$	385

(*) *absolute quantification with standard compounds available*

It is reasonably to assume that the heavier compounds are not sampled for their low volatility, while light species, e.g. CO, CO_2, CH_4, etc. are lost during manipulation of the condensed for their high volatility. It can be appreciated that HMDSO undergoes conversion to many different linear and cyclic compounds, containing up to five silicon atoms.

The simplest species detected, i.e. tetramethysilane (TMS) and trimethylsilanol (TMSOH), are very interesting because they give evidence of HMDSO fragmentation while the presence of species containing the dimethylsiloxane ($-Me_2SiO-$) repeating unit confirms the occurrence of oligomerization processes: e.g. chain propagation, ring formation and expansion, those bring to linear and cyclic compounds with general formulas $Me\text{-}(Me_2SiO)_n\text{-}SiMe_3$ (n = 1-4) and $(Me_2SiO)_n$ (n = 3,4), respectively.

The working conditions affect, both qualitatively and quantitatively, the composition of sampled mixtures along with HMDSO depletion; but in all the experimental conditions investigated, the most abundant species is the unreacted monomer.

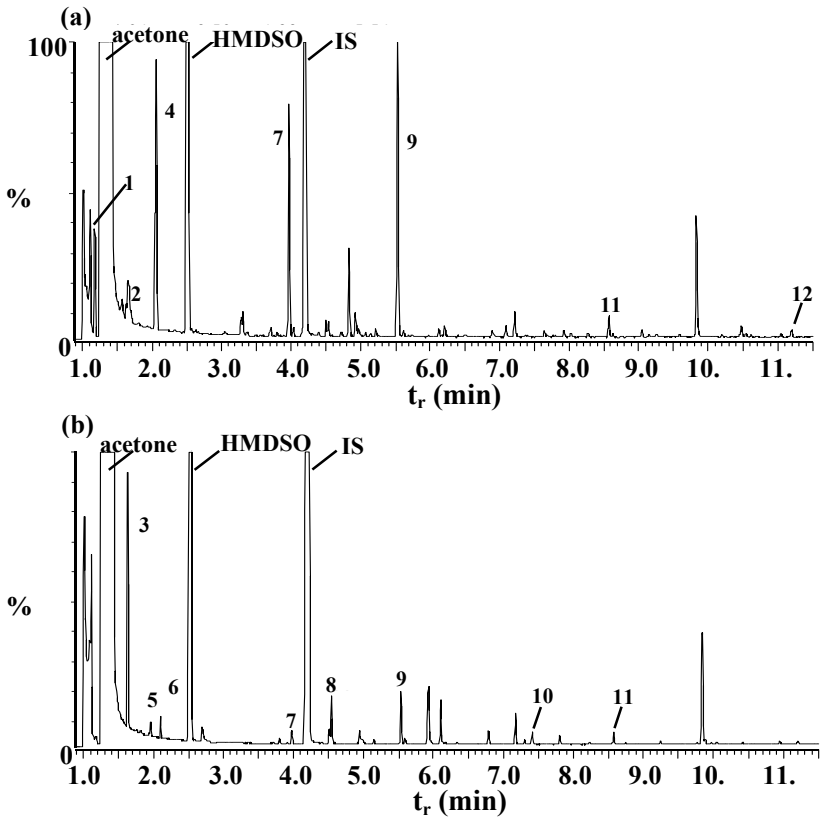

Figure 3. Typical gas-chromatograms of exhaust: (a) O_2/HMDSO = 0; (b) O_2/HMDSO = 25. The peaks without number indicate species not identified.

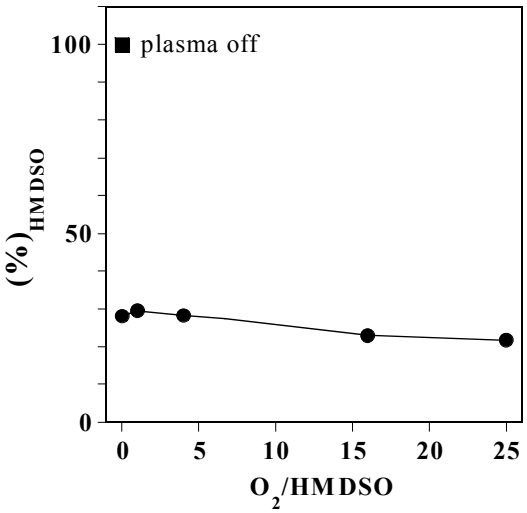

Figure 4. Concentration trend of (HMDSO) *vs.* the O_2-HMDSO ratio in the gas feed. Total flow rate = 78 sccm, 200 mTorr, 100 W).

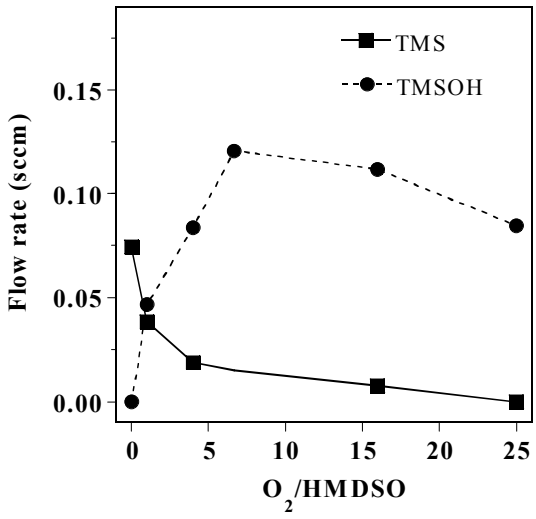

Figure 5. Concentration trends of (TMS) and (TMSOH) *vs.* the O_2-HMDSO ratio in the gas feed Total flow rate = 78 sccm, 200 mTorr, 100 W).

As shown in figure 4, $\%_{HMDSO}$ does not depend significantly on the feed composition even if the O_2-to-HMDSO flow rate ratio is varied in a wide range (0 ÷ 25).

By increasing the oxygen content of the feed the unreacted fraction of the monomer decreases very slowly: from about 28-30% for O_2/HMDSO = 0-1 respectively to about 20% for O_2/HMDSO = 25. This indicates

that under the experimental conditions explored, oxygen does not have a fundamental role in the activation of the monomer, a different conclusion respect to what reported by other authors under different conditions (see for instance ref. [14]).
On the contrary, feed composition affects the distribution of the by-products generated for plasma activation.

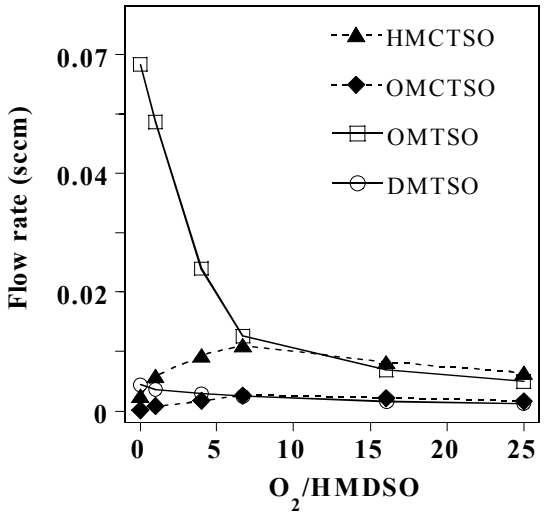

Figure 6. Concentration trends of OMTSO, HMCTSO, DMTSO and OMCTSO *vs.* the O_2-HMDSO ratio in the gas feed (total flow rate = 78 sccm, 200 mTorr, 100 W)

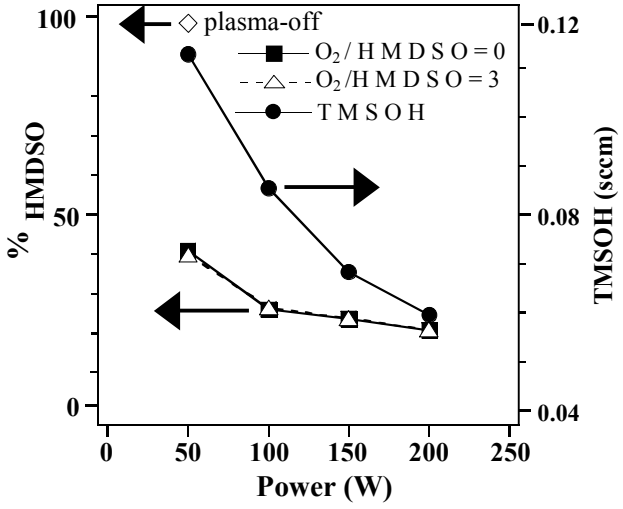

Figure 7. Concentration trends of HMDSO in the exhaust *vs.* the input power at O_2-to-HMDSO ratio of 0 and 3; concentration trend of TMSOH in the by-products *vs.* the input power at O_2-to-HMDSO ratio of 3 (total flow rate = 23 sccm, 100 mTorr).

Figures 5 and 6 show that increasing the oxygen content of the feed gas the trend of tetramethylsilane and of linear oligomers concentration decrease while the trends of trimethylsilanol and cyclic oligomers show a maximum at O_2-to-HMDSO ratio of 7, approximately.
The maximum can be reasonably explained considering that oxygen promotes the formation of trimethylsilanol and cyclic oligomers, but at high O_2 content the oxidation reactions prevail.
In order to study the effect of working pressure on the concentration of by-products, the total flow rate has been reduced to 23 sccm and consequently the O_2-to-HMDSO flow rate ratio has been varied in a narrower range (0 ÷ 7). Two sets of experiments have been performed at 100 and 500 mTorr. The trends of by-products concentration *vs.* O_2-to-HMDSO ratio are similar but the absolute values of concentration, as well as that of the $\%_{HMDSO}$, are always lower at 500 mTorr than at 100 mTorr. In particular, as a function of the other working conditions, the extent of unreacted monomer was found to vary in the range 40-30% and 15-10% at 100 and 500 mTorr, respectively. The effect of input power has been examined, at 100 mTorr, in the range 50 - 200 W at O_2-to-HMDSO ratio of 0 and 3.
The concentration of HMDSO in the exhaust decreases with the input power at both feed compositions without appreciable differences (figure 7), the main change is observed passing from 50 to 100 W. In oxygen containing feed, by-products concentration generally shows a decreasing trend with input power.

Descussion and conclusion
The results shown in the previous section allow a better definition of the general deposition scheme reposted in Figure 1, in particular for HMDSO activation (i.e. the first step of the overall reaction) which is directly linked to monomer depletion. When the organosilicon compound is fed directly into the plasma, as in the case under discussion, activation can occur through reactions with oxygen (atoms or excited molecules), with excited Ar, or by means of electron collisions. Since the variation of the feed composition results in modest changes of $\%_{HMDSO}$ (Figure 4), while input power has a more evident effect (Figure 7), it appears reasonable to assume that, under the experimental conditions explored, electron collision is the main monomer activation channel. Electron collision is more efficient when the input power is raised, i.e. when the electron

energy and density become higher. The importance of direct plasma dissociation by electron impact has been already reported by other authors.[16]

If oxygen addition has a negligible effect on monomer activation, on the contrary it seems to have an important role in plasma chemistry. In fact, oxygen addition affects the concentration of the organosilicons formed by recombination of reactive species in gas phase, although it has a remarkably different effect on linear and cyclic compounds. The important role played by oxygen addition in the overall discharge chemistry can be also stressed considering that the effect of power on by-products concentration is more evident when the feed gas contains oxygen.

The concentration trend of trimethylsylanol (TMSOH) is of particular importance. The marked decrease of trimethylsylanol concentration when the input power is raised (Figure 7) is in agreement with the concentration trend of Si-OH groups in the coating: by increasing the input power the content of Si-OH groups decreases and a more stable, inert and resistant film is obtained[16].

By considering the structure of the by-products revealed by GC-MS (Table 1) and the fact that many compounds in the gas chromatogram have not been identified by mass spectrometry, it can be concluded that despite the unit -Me_2SiO- is the most important building block for the formation of cyclic and linear heavy oligomers, other units shall also be considered. If -Me_2SiO- reasonably derives from the fragmentation of HMDSO (Me_3Si-O-Si Me_3), the other units (e.g. ethyl or ethoxy groups) are not contained in the structure of starting organosilion monomer and therefore the contemporaneous occurrence of different reactions should be considered.

The chemistry of the plasma phase and the distribution of by-products concentration is also affected by the working pressure. It has been reported in the previous section that at 500 mTorr the concentration of unreacted HMDSO and of by-products is lower than at 100 mTorr. It can be therefore concluded that at high working pressure by-product oxidation, and powder or deposit formation are favoured, otherwise as a consequence of the increased monomer depletion a higher concentration of by-product should be detected.

Further investigations by coupling GC-MS results with Infrared Absorption and Optical Emission Spectroscopies will be carried out for a better comprehension of the deposition mechanism.

Numerical Prediction of Population Inversion in a Fast -Axial- Flow CO_2 Laser

F. Siserir and D. Louhibi

Centre de Développement des Technologies Avancées,Baba Hassen BP17, Algiers, Algeria

Abstract
A six temperature kinetic model is used to predict the performance of a high power fast axial flow CO_2 laser, pumped by a longitudinal electric discharge. At an emission wavelength of $\lambda = 10.6$ µm, a typical output power of 1kW/m can be extracted from such lasers, with electrical efficiencies exceeding 30 percent. The spatial distributions of vibrational levels populations are determined through the numerical resolution of a set eight coupled differential equations. The results obtained are in satisfactory agreement with experimental data.

1. Introduction

The aim of the present paper is to apply a six-temperature kinetic model describing the behavior of fast- axial -flow CO_2 laser, electrically pumped by a longitudinal self-sustained glow discharge, in a linear cavity configuration. Quantitative predictions about laser operating characteristics are made. Such lasers generate more than 1 kW of 10.6 µm cw radiation per meter of tube length, with electrical efficiencies in excess of 30 percent. They are extremely useful in a number of industrial tasks involving materials processing like cutting, drilling, welding and surface treatment.

The model consists of a set of eight coupled differential equations [1]. It takes into account the effects of electrical excitation, energy transfer processes between vibrational and translational degrees of freedom, thermal energy transport, as well as laser light intensity amplification and losses inside the active medium. Using a numerical method to solve the system, we determine the distribution along the tube axis of the vibrational level population and population inversion in the laser process. We deduce the laser output power under given geometrical and pumping conditions [2]. The results of our simulation are compared to experimental performances achieved with devices described in the literature [3]-[4].

2. Presentation of the model

2.1. Geometrical configuration of the cavity

A linear cavity configuration was considered, as shown in Fig.1. The electric discharge region (positive column, lying between z= 0 and z = l_{pc}) is followed by a drift zone between z = l_{pc} and z= l_{flow} where population inversion, though decreasing, remains positive and contributes thus to additional light amplification.

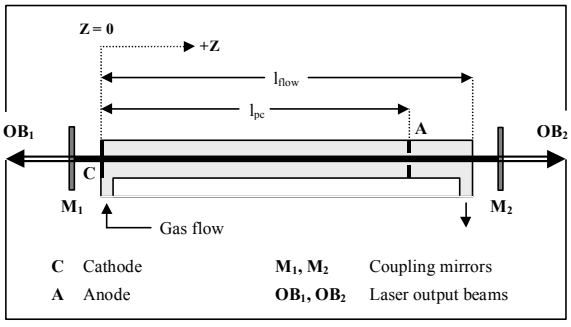

Figure 1. Geometrical configuration of the considered axial -flow CO_2 laser cavity.

2.2. Notations and assumptions

- Population distribution among the vibrational levels of a given mode β can be described by means of a Boltzmann vibrational temperature T_β. In fact, the energy redistribution process between those levels is fast enough for the mode to be considered in local Boltzmann equilibrium [5].

- The five Boltzmann factors $\mathrm{Exp}[-hc\nu_\beta / kT_\beta]$ which we will denote by β (β = s, b, a, n, w) thus constitute a good description of the state of population on the various vibration modes.
- The gas kinetic temperature T determines population distribution among the rotational sub-levels of a given vibrational level, because of the strong coupling between translation and rotation in the present operating conditions [6], [7].
- Our calculation is based on the P(20) laser transition in the $00^01 \rightarrow 10^00$ (10 μm) band, that particular vibration-rotation line being dominant in the considered gas temperature range.
- The high gas flow velocity (~100m.s^{-1}) is such tat one can neglect pressure variations along the tube, as well as molecular dissociation effects.
- All operating parameters are considered as functions of the only axial coordinate z, their dependence with respect to radial coordinates being neglected. There is experimental evidence that for this kind of lasers, the approximation is fairly good [8].

2.3. Differential equation system

The evolution along the tube axis of the five Boltzmann factors s, b, n, w, the gas temperature T and the light intensities I^+ and I^- can be modeled through a set of eight coupled differential equations [1]. The system reads as follows:

$$\frac{v}{(1-s)^2}\frac{ds}{dz} = R_{sb}\frac{(b^2 D_{s,b} - s)}{(1-b)^2(1-s)} + \Gamma + U_s \tag{1}$$

$$\frac{2v}{(1-b)^2}\frac{db}{dz} = -3R_{ab}\frac{(b^3 D_{a,b} - a)}{(1-b)^3(1-a)} - 2R_{sb}\frac{(b^2 D_{s,b} - s)}{(1-b)^2(1-s)} - R_{bw}\frac{(b D_{w,b} - w)}{(1-b)(1-w)} + 2R_b\frac{(\bar{b} - b)}{(1-b)} + U_b \tag{2}$$

$$\frac{v}{(1-a)^2}\frac{da}{dz} = R_{an}\frac{(n D_{a,n} - a)}{(1-n)(1-a)} + R_{aw}\frac{(w D_{a,w} - a)}{(1-w)(1-a)} + R_{ab}\frac{(b^3 D_{a,b} - a)}{(1-b)^3(1-a)} - \Gamma + U_a \tag{3}$$

$$\frac{v}{(1-n)^2}\frac{dn}{dz} = -R_{na}\frac{(n D_{a,n} - a)}{(1-n)(1-a)} + R_{nw}\frac{(w D_{n,w} - n)}{(1-w)(1-n)} + R_n\frac{(\bar{n} - n)}{(1-n)} + U_n \tag{4}$$

$$\frac{v}{(1-w)^2}\frac{dw}{dz} = -R_{wa}\frac{(w D_{a,w} - a)}{(1-w)(1-a)} - R_{wn}\frac{(w D_{n,w} - n)}{(1-w)(1-n)} + R_{wb}\frac{(b D_{w,b} - w)}{(1-b)(1-w)} + R_w\frac{(\bar{w} - w)}{(1-w)} + U_w \tag{5}$$

$$\frac{N_0}{N_A}\left(f_c C_c + f_n C_n + f_h C_h + f_w C_w\right) v_0 \frac{dT}{dz} = -h(\nu_a - \nu_n) N_a R_{an}\frac{(n D_{a,n} - a)}{(1-n)(1-a)} - h(\nu_a - \nu_w) N_a R_{aw}\frac{(w D_{a,w} - a)}{(1-w)(1-a)}$$

$$- h(\nu_a - \nu_b) N_a R_{ab}\frac{(b^3 D_{a,b} - a)}{(1-b)^3(1-a)} - h(\nu_s - \nu_b) N_s R_{sb}\frac{(b^2 D_{s,b} - s)}{(1-b)^2(1-s)} - 2h\nu_b N_b\frac{(\bar{b} - b)}{(1-b)} + F_e \tag{6}$$

$$\frac{dI^+}{dz} = \left(\alpha - \alpha_{sc}\right) I^+ \tag{7}$$

$$\frac{dI^-}{dz} = -\left(\alpha - \alpha_{sc}\right) I^- \tag{8}$$

2.4. Boundary conditions

At z=0, the gas temperature T is equal to T_0 , and Boltzmann factors are evaluated on the basis of Boltzmann temperatures equal to the gas kinetic temperature T_0, since no pumping has occurred yet . Hence:

$$\beta(0) = \exp[-hc\nu_\beta/kT_0] \quad \text{with } \beta = s, b, a, n, w. \tag{9}$$

As regards I^+ and I^- , they have to fulfil the following conditions, imposed by the output mirrors reflectivities:

$$I^+(0)=r_1 I^-(0)= (1-\alpha_1-\tau_1) I^-(0) \tag{10}$$

$$I^-(l_{flow})= \tau_2 I^+(l_{flow})= (1-\alpha_2-\tau_2) I^+(l_{flow}) \tag{11}$$

2.5. Computational method used

We use a numerical method where a set of equally spaced points $z= i\,\Delta z$($0 \le i \le N_p$ is generated along the interval $[0, l_{flow}]$ with a step size $\Delta z = l_{flow}/N_p$. Any z-dependent parameter p will be determined as an array of values $p_i=p(z_i)$, In differential equations $\frac{dp}{dz}(z_i)$ is replaced by $\frac{p(z_{i+1})-p(z_i)}{\Delta z}$ The step size Δz is progressively reduced, increasing the number N_p of data points to be handled. We stop the process when a stationary solution is reached, in the sense that any further reduction of Δz that any further reduction of doesn't change the obtained parameters distributions.

3. Results and discussion

The present simulation was performed using parameters listed in table.I. The gas mixture proportions, pressure and entrance flow velocity have been set identical to those in the experimental set-up described by Sugawara *et al* .[2], with slightly reduced tube dimensions.

We adopt a very commonly used value of $3\ 10^{-16}$ V cm^2 for the self-sustained reduced electric field strength E/N. it guarantees an optimal energy transfer from the discharge to the upper level (00°1 of CO_2) through efficient population of N_2 vibrational level v=1. In a such configuration, the discharge electrons have an average energy $E_{e(av)}$ of 1.2 eV. On that basis, their number density N_e can be estimated using formula $N_e = 4i/(\pi d^2 e v_{drift})$, where v_{drift} is the electrons drift velocity taken as $(2E_{e(av)}/m_e)^{1/2}$, m_e being the electron rest mass. Here, $v_{drift} = 6.5\ 10^5$ m s^{-1}, and $N_e = 5.910^8$ cm^{-3} , while the gas mixture number density N is $6.6\ 10^{17}$ molecules per cubic centimetre.

Table I: Operating specifications of the simulated setup

Considered laser transition line	P(20), 10,6 µm
Tube length l_{flow}	60 cm
Positive column length l_{pc}	50 cm
Tube diameter d	5 cm
Coupling mirrors transmittivities (τ_i) and absorptivities (α_i)	
$M_1 : \tau_1 = 0, \alpha_1 = 0$ $\quad M_2 : \tau_2 = 0.2, \alpha_2 = 0$	
Scattering loss per unit length α_{sc}	0
Entrance gas mixture pressure P_0	20 Torr
Entrance gas flow velocity v_0	100 m s^{-1}
Entrance gas mixture temperature T_0	293 K
$CO_2/N_2/He/H_2O$ gas mixture proportions	
$f_c = 0.04$ $\quad f_n = 0.4$ $\quad f_h = 0.56$ $\quad f_w = 5\ 10^{-5}$	
Discharge parameter E/N	$3\ 10^{-16}$
Discharge current intensity i	120 mA

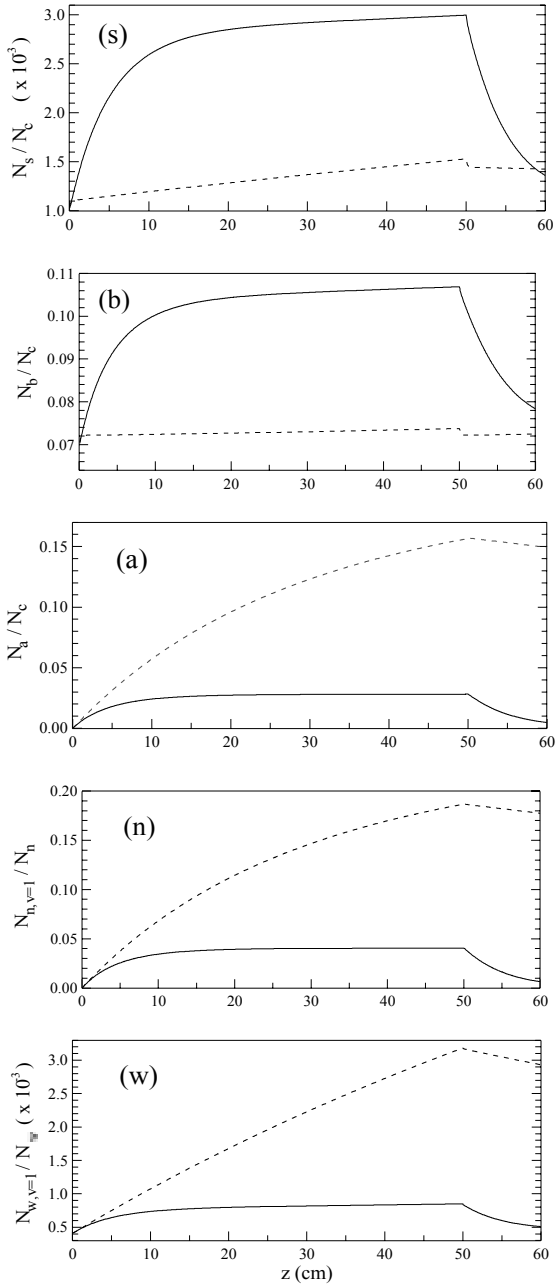

Figure 2. Relative first vibrational level population distribution along the tube, for each of five the vibrational modes s, b, a, n, and w. Dashed-line curves indicate the unsaturated regime case.

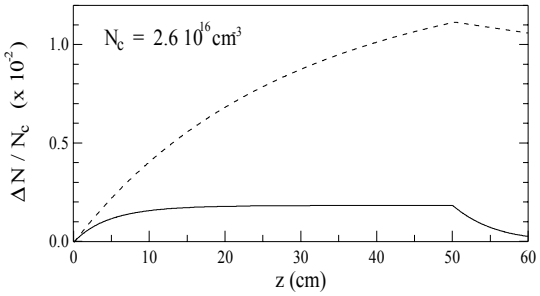

Figure 3. Distribution of CO_2 population inversion ratio along the tube, in both unsaturated (dashed –line curve) and oscillation (solid-line curve) regimes.

The obtained five Boltzmann factors distributions (s, b, a, n and w) lead to relative first vibrational level population profiles displayed in Figure 2. For each modeβ, the characteristic temperature $\theta_\beta = hc\nu_\beta/k$ is indicated. The relative first vibrational level populations $N_{\beta,v=1}$ /$N_{species}$ are respectively given by the expressions: $s(1-s)(1-b)^2$ (1-a), $2b(1-s)(1-b)^2(1-a)$, $a(1-s)(1-b)^2$ (1-a), n(1-n) and w(1-w).

The evolution along the tube axis of population inversion density ΔN between CO_2 laser levels 00°1 and 10°0, divided by the CO_2 number density N_c , is shown in Figure 3. Absolute population inversion density $<\Delta N>$ is $2.01x10^{14}$ cm^{-3} (resp. $3.90x10^{13}$), the average CO_2 number density $< N_c >$ being $2.61x10^{16}$ cm^{-3}. Our results concerning $< \Delta N >$ in the unsaturated regime compares to measurements performed by the authors of ref. [9], who found $2.5x10^{15}$ cm^{-3} in similar experimental conditions (3/38/59 $CO_2/N_2/He$ gas mixture with P= 50 mbar, d = 19 mm and i = 50 mA).

It is interesting to note the proportions of vibrationally excited molecules in the active medium. In the case of CO_2, the proportions is given by $[1-(1-s)(1-b)^2(1-a)]$, while it is simply represented by Boltzmann factors n and w for N_2 and H_2O. We find respective averaged proportions of excited CO_2 ,CO_2, N_2 and H_2O of 0.140, $3.46x\ 10^{-2}$ and $7.79x\ 10^{-4}$ (resp. 0.227,0161 and $2.10x\ 10^{-3}$) in the oscillation (resp. unsaturated) regime. The proportions of excited CO_2 molecules in pure vibration modes s, b are expressed as $s(1-b)^2(1-a)$, b(2-b)(1-s)(1-a) and a $(1-s)(1-b)^2$. Their respective average values, are found to be $2.59\ x10^{-3}$, 0.109 and $2.39\ x10^{-2}$ (resp. $1.34x\ 10^{-3}$, $7.83x\ 10^{-2}$ and 0.133) in oscillation (resp. unsaturated) regime.

Conclusion

We report on the application of six-temperature kinetic model predicting the operational characteristics of a fast –axial –flow CO_2 laser in a linear cavity configuration. The active medium consists of a $CO_2/N_2/He/H_2O$ Gas H_2O gas mixture and is pumped by a longitudinal self-sustained electric discharge.
We determine the evolution along the tube axis of the state of population in each of the five vibration modes involved in the laser process (the three normal modes of CO_2, the N_2 mode and the H_2O bending mode).
A system of eight coupled differential equations is numerically solved for that purpose. The gain spatial distribution and the laser power extracted from the cavity are deduced. Comparison of the results of our simulation to reported experimental performance achieved with similar lasers [2]-[4] is quite satisfactory.

Plasma processing at atmospheric pressure using a dielectric barrier discharge (DBD)

G. Borcia, N. M. D. Brown and C. A. Anderson

Surface Science Laboratory, University of Ulster, Coleraine, Northern Ireland, UK

Abstract

The effects of the air dielectric barrier discharge on surface treatment are reported for various polymer materials in the form of thin films and fabrics. XPS, contact angle/wickability measurement and SEM techniques were used in the study of the surface properties. The stability of the modified samples was monitored for two weeks after the treatment. The influence of the discharge parameters is discussed and related to the surface characteristics, allowing optimisation of the parameters used for treatment in the DBD.

1. Introduction

Chemical processes occurring in cold non-equilibrium discharge plasmas find increasing applications in various materials processing technologies. Among these techniques the dielectric barrier discharge (DBD) is one of the most effective non-thermal plasma sources, with an effective conversion of electric field to chemical and physical processes in gases or on surfaces for many applications. Importantly, it offers the major advantage of inducing significant surface chemical modifications on a material exposed to the discharge at atmospheric pressure.

For most of the industrial applications concerned barrier discharges are operated in the filamentary mode. In the past much effort has been dedicated to obtaining DBDs running in the homogenous glow regime. While it has been demonstrated that homogenous diffuse discharge behaviour can be obtained in barrier discharge configurations, special, quite restrictive conditions are required. Indeed, until recently it has been difficult and tricky to control reliably homogeneous glow discharges running at atmospheric pressure. Such diffuse discharges have obviously advantages over the more common filamentary type, especially for the uniform activation of material surfaces on the entire area exposed to the discharge.

However, the filamentary DBD is demonstrably an excellent source of microdischarges containing energetic electrons and ions. Discharges of this type, for which reliable control and significant average power densities can be achieved more easily, provide a chemically mild and mechanically non-destructive means of modifying surface properties targeting improved performance of materials. Moreover, ways can be found to ensure that the apparent inhomogeneity of the filamentary DBD does not lead to operational disadvantage.

Taking into account these issues, we describe here a surface treatment technique using a DBD of random filamentary type as a very convenient tool for the controlled activation of various categories of material surfaces. Remarkably uniform treatment and stable modified surface properties result on the entire treated area of the test surfaces. Moreover, the experimental set-up allows the simulation of continuous high speed processing of samples associated with in-line applications.

2. Experimental

The in-house designed and built dielectric barrier discharge system used is presented schematically in Figure 1. The sample is mounted on an electrically grounded, precision bearing mounted, aluminium cylinder. During the treatment a motor rotates the grounded electrode, so allowing the materials to be treated to pass through the discharge region between the electrodes with linear speeds in the range 60-9500cm/s. Experiments have shown that DBD treatments even as short as a few rotations (i.e. fractions of a second exposure time) can modify markedly the surface properties of the treated specimen.

The discharge is generated via a low frequency (80KHz) high voltage (peak-to-peak values in the 10-20KV range) power supply. The high voltage is applied between the cylinder and a spiral-shaped stainless steel electrode fitted inside a water-cooled quartz tube mounted above the grounded electrode. The inter-electrode gap is adjustable within a range $\leq$ 2.2mm. The latter is the practical upper limit that ensures a uniformly distributed random discharge over the width of the test sample.

The discharge region thus created ensures uniform treatment (as will be shown) over the entire surface (i.e. about 10 x 30 cm^2) of both porous and non-porous test samples, even though the DBD in the present electrode configuration is clearly of the random micro-filamentary type.

The discharge was characterised, when the power supply is optimally tuned, by means of the energy deposited at the electrodes during one cycle of the DBD. Measurements performed over the range of variation of the high-voltage input and for various values of the inter-electrode gap showed that the resulting energy surface density in the present experimental arrangement is of the order of $10\text{-}10^2 \mu J/cm^2$.

An extended series of treatments was performed on various types of commercial polymer films (Goodfellow Ltd., Cambridge), chosen from two main categories: a) polymers which do not contain oxygen in their chain: ultra-high density poly(ethylene) (UHMW PE), high density poly(ethylene) (HDPE), low density poly(ethylene) (LDPE), poly(styrene) (PS), poly(methylpentene) (PMP); poly(tetrafluorethylene); b) polymers which already contain structurally bonded oxygen in their chain: poly(amide) 6 (PA 6), poly(amide) 6,6 (PA 6,6), poly(amide) 12 (PA 12), poly(ethylene terephthalate) (PET). Woven commercial polyester (PET) and Nylon 6,6 fabrics (Clark & Sons, Ltd, UK) were also treated.

Treatments were systematically performed for two different values of the energy of the discharge (the energy deposited by the DBD during one cycle of the high-voltage), i.e. 3.5mJ and 5.0mJ, and various treatment times between 0.1s and 5.0s. A first series of treatments, on poly(ethylene) films, performed for different values of the inter-electrode gap, showed no significant influence of this parameter on the surface properties. For all other experiments the gap was fixed at 1.8 mm.

During treatment the samples were placed either directly on the grounded aluminium cylinder or on an additional thin polymer (polyethylene) film intimately contacting the cylinder. These two experimental configurations, as is shown later, led of to very different consequences in respect of the outcome of the treatment on samples of woven fabric.

The modification of the surface properties of the treated samples has been studied using X-ray photoelectron spectroscopy (XPS), contact angle/wickability measurement and scanning electron microscopy (SEM). The stability of the modified samples was monitored for two weeks after the treatment.

3. Results and discussions

Figure 2 shows an example of the values of the contact angle measured on a UHMW PE film treated for a set of fixed discharge parameters (5.0mJ energy, 1.8mm gap) and various treatment times, as a function of the ageing time. The contact angle observed is found to change from 103.6º for the untreated sample to the lowest value of 49.3º associated with the 5.0s treated sample, i.e. more than 50% reduction from the initial value.

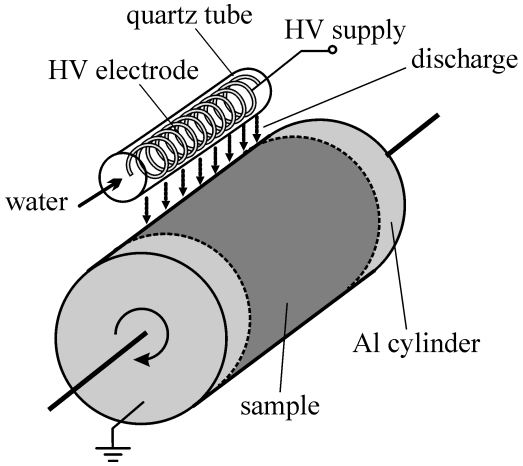

Figure 1. DBD set-up.

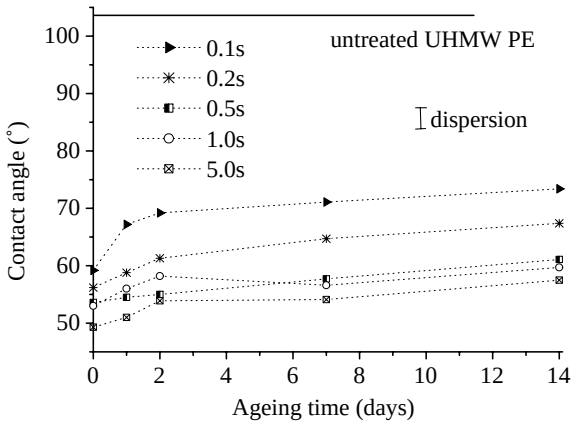

Figure 2. Contact angle of water on UHMW PE film vs. treatment time and ageing (5.0mJ discharge energy).

The steep diminution of the contact angles on treated samples compared to the non-treated PE shows the strongly increased wettability induced by the air-DBD even after such short treatment times. This behaviour can be attributed to strong surface oxidation. The molecular oxygen in the contacting air is activated, ionised and dissociated in the discharge to give extremely reactive oxygen species that react readily with the substrate surface.

The same behaviour is observed for all the various polymer films treated (Table 1). Even polymer surfaces that are quite “polar” before treatment, as with the polyamide (PA) or poly(ethylene terephthalate)

(PET) films (of intrinsically lower contact angles for the untreated surface compared to that of the other polymers examined), show much increased wettability after DBD treatment.

The surface modification reaches a steady level after only 0.1-0.2s of treatment, suggesting the modification of the outermost layer of the surface be extremely fast under the present experimental arrangement and discharge conditions. For most of the treated polymers the level of additional modification of the surface wettability achieved for treatment times greater than 1.0s is not significant. Even if lower contact angles were measured in a few cases after increased DBD exposure, i.e. 5.0s, the recovery of the surface, post-treatment, leads to comparable levels of wettability for all surfaces treated for more than 1.0s.

Here the particular behaviour of the PTFE films should be stressed, showing a rather low degree of wettability improvement after DBD exposure (Table 1). Complementary treatments on PTFE films extended up to 20s still showed a very low degree of modification. This is not too surprising, given that PTFE films generally are held to be very resistant to plasma modification.

It follows, therefore, that the DBD regime presented here induces significant modifications of the surface properties of the substrates so treated at a very high rate within the first few fractions of second. Treatments longer than 1.0s do not seem justified in terms of cost and duration of processing, as further modification at the surfaces examined takes place at a diminished rate and, thereafter, actual surface degradation processes are very likely to interfere.

Another important outcome concerns the spatial uniformity of the DBD surface treatment. The dispersion of the contact angle values measured over extended areas of all the treated polymer film samples is of only 3-4°, which is within experimental error, and leads to the conclusion that the surface treatment is remarkably uniform.

Referring to Figure 2, the treated poly(ethylene) film partly recovers after treatment. The contact angle reverted by 5º - 10º towards that of the untreated state over a period of several days. As expected, the material never fully returns to the untreated state, i.e. any necessary storage post-processing for significant times is not seen as an operational problem.

Moreover, since all the treated polymer surfaces show a notably low extent of recovery post-processing during ageing (with measured contact angles still having a similar low dispersion) it was concluded that the surface is not degraded after such short treatments and the resultant modification of the surface properties is stable with time.

Furthermore, topographical images obtained by atomic force microscopy (AFM), but not further discussed here, confirmed that treatments of up to a few seconds duration do not lead to damage at the surface by the etching effects alluded to above.

The XPS technique was used to elaborate the previous results, which suggested a strong oxidation level at the surface of the DBD treated samples, i.e. increased hydrophilicity followed DBD treatment in air.

Figure 3 shows, as an example, the C(1s) XPS band of a UHMW PE sample before and after surface processing for 1.0s in the DBD where the obvious changes in the band profiles reflect the effects of the oxidation of the sample surface.

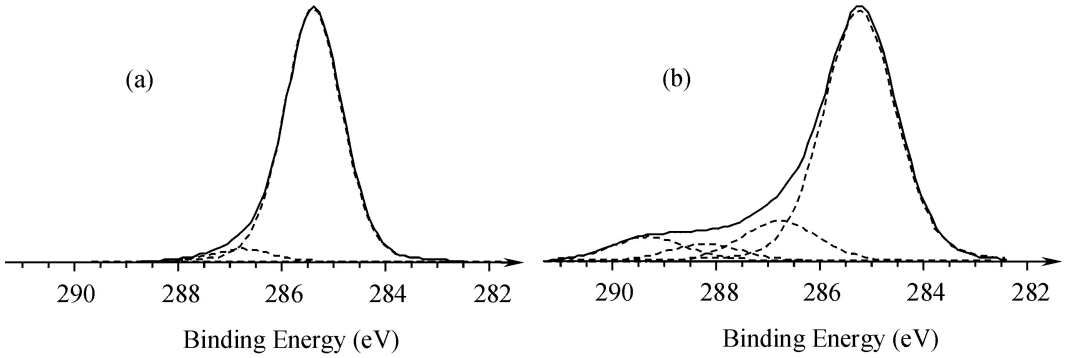

Figure 3. Carbon (1s) XPS spectra for (a) untreated and (b) 1.0s (5mJ energy) treated UHMW PE film.

The C(1s) band of the untreated sample can be fitted with two peaks. The hydrocarbon signal shows a peak at 285.0eV. The second peak at 286.5eV represents the intrinsic low-level oxidised carbon centres on the PE surface, attributed to carbon singly bonded to oxygen. The atomic elemental composition yields an O/C ratio of 0.05/1, ~5% carbon bound to oxygen.

Following DBD treatment, the higher binding energy carbon species increase and additionally oxidised species also start to appear. Thus, the C(1s) band now shows a long tail extending to ~291.5eV to the high-energy side. At the same time, the total oxygen content also increases, yielding an O/C ratio up to about 1/1. The C(1s) envelope of the modified surface can now be fitted with four peaks, by introducing two new, more oxidised, carbon species, i.e. ketone [-(C=O)-] and/or acetal [-(O-C-O)-] carbons at 288.0eV, and carboxyl carbon [-(C=O)-O-] at 289.6eV.

For the same duration of treatment the extent of oxidation further increases the higher the energy deposited by the discharge. Correspondingly, with increasing processing times the oxidised carbon components continue to increase then level off with overly extended treatment.

The same increase in the level of surface oxidation with increasing treatment parameters (energy and time) is observed for most of the other polymer films processed (Table 2). In all cases, the most marked parameter dependence is on the duration of the DBD treatment.

Surface oxidation after DBD processing is particularly strong in the case of polymers that do not initially contain oxygen in their monomer unit. As expected, the increase in the oxygen content is less important for the more "polar" polymers, i.e. those which already contain structurally bound oxygen before DBD treatment. Nevertheless, it is clear that the DBD treatment creates oxidised functional groups even on these surfaces.

Here again the particular behaviour of the PTFE film is noted. Very limited modification is apparent in the XPS data concerned, even less than that indicated by contact angle measurement. After treatment as extended as 20s the oxygen level on the surface is found never to reach more than 1%.

On all the other types of polymers addressed here (even those already containing oxygen in their monomer unit) the initial rate of bound oxygen uptake for the untreated surfaces processed for 0.1s is very high compared to the subsequent uptake for treatments of up to 5s.

This behaviour correlates with the contact angle measurements and confirms that treatments with duration of one second to maximum a few seconds represent an optimum for acquiring major surface modifications. Surfaces which cannot be processed within such short intervals arguably will not show further change in their surface properties after more extended treatment.

Table 2. Oxygen content (in atom %) on the various polymer films vs. treatment time (5mJ energy).

The conclusions drawn from the results obtained by wickability measurement on treated fabric samples (Table 3) were very similar to those obtained from the wettability data of polymer films.

For example, the water rise time on the polyester fabric (measured as the rise time of distilled water up to 2cm on the vertically positioned sample) is found to decrease from 19.0s for the untreated sample, to the lowest value of 7.0s associated with the 5.0s treated sample, representing about a 60% reduction from the initial value. The increase in wickability for the Nylon fabrics is even more dramatic, emphasised by water rise times of about 10-20s on the treated samples, in marked contrast to the rise level of not more than 0.5cm reached (over more than 15min) on an untreated vertically positioned sample. This steep diminution of the rise time compared to the non-treated fabric shows the strong increase of the wickability induced by the DBD exposure after very short treatment times and also confirms the very high rate of surface modification within the first 0.1-0.2s of treatment on fabric samples. Any subsequent modification for longer treatment (more than ~1.0s) is less important.

Wickability measurements repeated two weeks after the treatment on DBD-treated fabrics stored under ambient conditions showed no evidence of significant recovery of the surface properties in that the stored samples then having a wickability comparable with that evaluated immediately after DBD processing.

Note here again that during treatment the fabric samples were placed either directly on the grounded aluminium cylinder or on an additional thin polymer (polyethylene) film intimately contacting the cylinder. Importantly, XPS analysis was performed on both sides of the fabric samples, i.e. the one directly exposed to the discharge and the other side facing the grounded electrode during treatment.

As already noted, the polyester and the Nylon (PA 6) are intrinsically oxygen-rich materials prior to DBD treatment. Nevertheless, it is clear that the DBD treatment creates additional oxidised functional groups (not discussed further here) on the side of the fabric directly exposed to the discharge, i.e. the total oxygen content is shown to increase (Table 4). The initial rate of oxygen uptake of the untreated fabric for the 0.1s treated sample is very rapid, while the subsequent uptake for treatments up to 1.0s is practically negligible.

	polyester						nylon					
Substrate	untreated	0.1s	0.2s	0.5s	1.0s	5.0s	untreated	0.1s	0.2s	0.5s	1.0s	5.0s
on cylinder	19.6	11.5	9.0	8.5	7.5	7.0	>15min	57	48	42	22	19
on polymer	19.6	10.0	10.0	9.5	8.0	7.5	>15min	28	25	22	15	9

Table 3. Wickability of fabric samples (estimated as the water rise time to 2cm on the vertical positioned fabric, in seconds), vs. treatment time and the substrate placed (see text) on the grounded electrode (5.0mJ discharge energy).

The evolution shown in the behaviour of the side of the sample facing the grounded electrode during treatment is also very interesting. This side too is oxidised. In this case the amount of oxygen on the surface was found also to increase with increasing processing time. In contrast, when the fabric is processed with the additional polymer film in place, the degree of oxidation on the side directly exposed to the discharge levels out after 0.2-0.5s of treatment, behaviour mirrored in the fabric face contacting the electrode.

	Substrate	0.1s		0.2s		0.5s		1.0s		5.0s	
		top face	bottom face	top face	bottom face	top face	bottom face	top face	bottom face	top face	bottom face
polyester (34.9% at. O)	cylinder	43.2	34.0	45.4	35.7	46.8	39.6	48.8	43.6	49.4	45.2
	polymer	40.0	38.3	46.4	39.9	46.0	46.4	49.7	48.2	50.1	49.5

	polymer	27.4	22.5	32.1	28.4	33.5	31.8	34.0	33.3	34.9	34.2

Table 4. Oxygen content (in atom %) on the fabric surface, as a function of the treatment time and the substrate placed on the grounded electrode (5.0mJ discharge energy), with and without the interposed polythene film present (see text).

This behaviour is a consequence of the dielectric properties of the polymer film in contact with the aluminium cylinder. In this configuration, as alluded to above, the additional dielectric surface spreads the micro-discharge channels into surface discharges covering a much larger local area than do the original discharge channels present when the bare grounded aluminium alone supports the fabric.

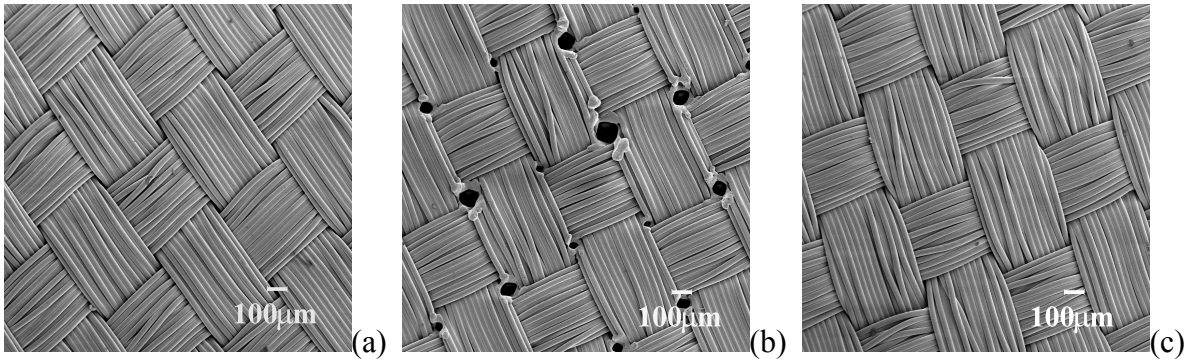
For porous materials, such as the textile fabrics, rapid treatment (fractions of a second) on both sides of the sample appears to be ensured, i.e. the discharge readily permeates the fabric weave.

It should be noted that the behaviour of the polyester and Nylon fabrics discussed here is very similar to the behaviour, under the same DBD treatment, of compact film variants of the same polymeric materials - polyester PET and Nylon 6,6 (PA 6,6) films, respectively - showing the same trend in the evolution of the surface composition.

The SEM analysis of the fabrics gave valuable supplementary information on the role of the additional polymer film placed on the grounded electrode during surface processing (Figure 4).

Images show that for samples placed during treatment directly on the grounded aluminium cylinder a very localised strong degradation of the fabric takes place, with fibres melting at the locations were the bundles of fibres are crossing each other (Figure 4.b). The effect is most probable due to the non-homogeneity of the discharge, with the micro-discharges tending to localise on spots where they can reach directly the grounded electrode directly. This behaviour can be seen as a type of corona effect where the channels at the

yarn crossover points in the fabric promote a localised more energetic discharge than the norm. The degradation is readily visible even using very short treatment times, showing locally the violent effect of the DBD discharge. For extended treatment, longer than about one second, the degradation is "complete", i.e. all crossing locations are attacked and the fibres in the yarn contiguous with these points melt (Figure 4.b).



(a) (b) (c)

Figure 4. SEM images of nylon fabric: (a) untreated, (b) 1.0 s air-DBD treated, placed directly on the grounded cylinder, (c) 1.0s air-DBD treated, placed directly on the additional polymer film.

The results are very different for the fabric samples placed on the additional thin polymer (polyethylene) film, so the grounded electrode is electrically isolated from the discharge. In this case no visible degradation of the fabric takes place. Samples show no visual difference compared to the untreated case (Figure 4.a), even for extended treatment duration, e.g. 1.0s (Figure 4.c).

This result offers a very attractive perspective for controlling the physical modification of non-compact materials and also shows that uniform, mild and efficient modification of surface properties can be obtained by DBD processing for samples with various texture, porosity etc.

4. Conclusions

The experiments show that air dielectric barrier discharge (DBD) surface treatments exert significant effects on the surface characteristics of various polymer films and on polymer fabric materials.

The results obtained underlined the utility of this type of surface processing for modifying the surface properties of materials, as the present experimental arrangement shows a highly efficient ability to modify in a very *uniform* way the surface of all the materials so far examined in detail. The surface properties, such as wettability, wickability and the level of oxidation appear to be increased markedly within the first 0.1-0.2s of treatment; moreover, any subsequent modification for longer treatment times (> 1.0s) is less important. The modification of the surface properties also appears to be stable with time, as minimal change (recovery) of the surface properties is shown on ageing post-exposure to the discharge.

The behaviour in respect of oxidation of the thin film polymers studied here in woven fabric form is found to be very similar under DBD treatment, to that of the same materials as thin films.

For porous materials, such as the textile fabrics examined, rapid, efficient and simultaneous treatment (fractions of a second) of both sides of the sample appears to be ensured.

The processing system also offers the attractive prospect of controlling the physical modification of non-compact materials of various texture, porosity etc., as the samples placed on an additional polymer film and treated in the DBD show no evidence of physical damage under the processing conditions used. In contrast, at higher power levels, evidence for a local melting phenomenon is found with woven materials if treated using a bare metal grounded electrode.

Taking into account the above commentary, the present surface treatment technique, using a DBD of random filamentary type, offers a convenient, reliable and economic alternative for the controlled surface modification (so far, largely dependent on surface oxidation) of different types of materials. Remarkably uniform treatment and markedly stable modified surface properties result over the entire area of test surfaces exposed to the DBD even at transit speeds simulating those associated with continuous processing expectations even at relatively high speeds. DBDs thus provide chemically mild and mechanically non-destructive means of altering surface properties targeting improved surface characteristics.

ON THE ROLE OF PLASMA FORMATION GAS AND DISCHARGE CHAMBER GEOMETRY ON CHARACTERISTICS OF THE D.C. ARC PLASMA TORCH WITH HOLLOW CYLINDRICAL ELECTRODES

A.F. Bublievsky[1], D.A.Bublievsky[1,2],. E.I. Urinok[1]

[1] *The Luikov Heat & Mass Transfer Institute NANB, Minsk, Rep. Belarus*
[2] *Instituto de Física, Universidade Estadual de Campinas, Campinas, São Paulo, Brazil*

In spite of wide application of the plasma torches with hollow cylindrical electrodes, the methods applied for their designing are imperfect due to the phenomena complexity. The methods of physical modeling, based on similarity theory, using an experimental data, are applied widely in this case. However, during the selection of similarity numbers, the sufficiently subjective methods of dominant processes determination are usually used. In present work, for this limitation overcoming, the statistical treatment methods together with a wide original selection of generalized parameters are applied, thus taking into account all processes affected on arc characteristics.

The data statistical treatments for air, nitrogen, hydrogen, helium and argon demonstrated that obtaining of single generalized characteristic for all gases with high accuracy is quite difficult. Reducing accuracy requirements, it is possible to find the arc generalized current-voltage characteristics (CVC) with one independent variable (convective heat transfer), with two ones (convection and turbulence) or, if discharge chamber geometry was considered, with three independent variables. The appropriate generalized CVC have next forms:

$$\frac{\sigma_0 UD}{I} = 2{,}5\left(\frac{\sigma_0 h_0 GD}{I^2}\right)^{0{,}610}, \text{ SE} = 0.335 \qquad (1)$$

$$\frac{\sigma_0 UD}{I} = 1{,}46\left(\frac{\sigma_0 h_0 GD}{I^2}\right)^{0.398}\left(\frac{\rho_0\sigma_0 h_0^{1.5} D^3}{I^2}\right)^{0.218}, \text{ SE} = 0.207 \qquad (2)$$

$$\frac{\sigma_0 UD}{I} = 1.475\left(\frac{\sigma_0 h_0 GD}{I^2}\right)^{0.400}\left(\frac{\rho_0\sigma_0 h_0^{1.5} D^3}{I^2}\right)^{0.208}\left(\frac{d}{D}\right)^{0.151}, \text{ SE} = 0.193 \qquad (3)$$

where U - voltage; I - electric current; G - gas flow-rate; D, d - internal and external electrode diameter, respectively; h - enthalpy; λ - heat conductivity; ρ - density; σ - electric conductivity; SE – regression standard error; index "0" means characteristic value.

In consequence of gas properties variation, the numerical estimate of inadequacy, using Fisher variances ratio, can be made for expressions (1)-(3). This parameter for expression (1) is $F_{inadeq} = 19.9$, for (2) $F_{inadeq} = 32.5$ and for (3) $F_{inadeq} = 30.2$. The values of allowed upper limits for combination of separated expressions into one are 1.95/2.53, 1.76/2.21 и 1.67/2.05, respectively, for case (1), (2) and (3) (numerator is referred to five-percentage probability level, denominator is referred to one-percentage one). Thus the combination into single generalized CVC of plasma torch with hollow cylindrical electrodes for different gases is inadequate.

The generalized dependences for every gas, having considerably higher accuracy then (1)-(3), are obtained too. The effect of discharge chamber geometry on CVC is analyzed.

EXPERIMENTALLY-STATISTICAL STUDY OF D.C. ELECTRIC ARC OPERATING IN THE PLASMA TORCH WITH TUBE ELECTRODES AND AIR

[2] *Instituto de Física, Universidade Estadual de Campinas, Campinas, São Paulo, Brazil*

The analysis of physical processes in d.c. plasma torches with two tube electrodes (one of electrodes is closed cathode with diameter D, anode diameter is d) is realized by the methods of physical modeling and mathematical statistic using ridge regression.

The selection of dominant processes is made by the statistical analysis methods using present-day software for PC compatible computer. The wide range experimental data for electrode diameter ($D(d) = 8 - 40$ mm), power ($N = 3.7 - 320$ kW), current ($I = 20 - 760$ A) and gas flow-rate $G = 0.8 - 40$ gs^{-1}) are analysed. Both same electrode diameters $D = d$ and different ones ($D/d = 1.0 - 4.375$) are used for experiments.

It is determined, that the heat transfer processes have dominant role for arc current-voltage characteristics (CVC) formation. The gas-dynamic factors, taken into account by Reynolds number, are insignificant (the standard regression coefficient is about 10 %). At the same time, heat transfer processes (convection, conduction, radiation, turbulent heat transfer) have strong correlation. It is possible to simplify generalized CVC, considering only most effective processes (convection and conduction). The discharge chamber geometry does not affect significantly on CVC, but make difficult generalized characteristic formation.

The generalized CVC, obtained by statistical analysis using ridge regression, have very complex form. If from three correlate independent variables (π_{turb}, π_{cond} and π_{rad}) use only single one, for example, π_{cond} and standard regression, it is possible to simplify expression. The standard error of such regression is SE=0.095, and Fisher variances ratio is $F_{(3.347)} = 6256.6$. The corresponding CVC have next form:

$$\frac{UD\sigma_0}{I} = 3.630\left(\frac{GD\sigma_0 h_0}{I^2}\right)^{0.516}\left(\frac{\sigma_0\lambda_0 T_0 D^2}{I^2}\right)^{0.120}\left(\frac{D}{d}\right)^{0.322}. \qquad (1)$$

By reducing accuracy, it is possible to obtain CVC with one independent variable:

$$\frac{UD\sigma_0}{I} = 1.835\left(\frac{GD\sigma_0 h_0}{I^2}\right)^{0.656}; \qquad \text{SE=0.192,} \qquad F_{(1,349)}=4328.5. \qquad (2)$$

Here, U - voltage; T - temperature; h - enthalpy; λ - heat conductivity; σ - electric conductivity; index "0" means characteristic value.

For quantitative comparison, two groups of experimental data, with the same and different electrode diameters, were separated. The corresponding generalized relations and their analysis are presented.

Non-equilibrium plasma processing of hydrocarbons

Keywords: Dielectric-barrier discharges; Methane conversion

Abstract

The methane transformation was examined under dielectric barrier discharge (DBD) conditions using a new developed laboratory reactor operated at frequency of 50 Hz. The growth of overall methane conversion and methane conversion rate was observed in the presence of granular dielectrics: quartz-glass and silica gel, in CH_4+Ar gas mixtures at ambient temperature. Ethane and hydrogen were found to be the main gas products. It was concluded that under the conditions of DBD, the methane transformations can be terminated after one of the first steps of the chain reaction where ethane is produced.

1. Introduction

The profits, gained by natural gas (NG) processing, are the reason for a number of searches undertaken on plasma techniques application in the field of hydrocarbon conversion. The hydrogen cyanide manufacturing (developed commercially by I. Mościcki in Switzerland and in Poland) [1] and the acetylene synthesis were the first plasma processes successfully used for the processing of gaseous and liquid hydrocarbons. The arc-process for acetylene production has been implemented in large scale, particularly in Germany (the Huels process) and in the United States (Du Pont). It was highly improved when the modern technique of plasma torch was applied. However, this production has lost some of its importance, over the recent decades, owing to the decreasing demand of acetylene from the industry of chemicals, and the increasing price of electric energy. Taking into account the high energy demand for hydrocarbon processing in arc discharges and plasma torches, other plasma sources, such as low frequency glow and microwave discharges, coronas and dielectric-barrier discharges (DBD), or gliding arc (Glid-Arc) have been investigated. In those discharges, under non-equilibrium plasma conditions, reaction rates are relatively high even at low gas temperatures. The energy of electrons generated in non-equilibrium plasmas is sufficient for transformation of stable hydrocarbon molecules [2-6].

In the last years, a number of investigations were performed on methane processing with DBD as a source of non-equilibrium plasma. The reactions of methane (both pure and in mixtures with helium or ethane were examined at ambient temperature [7] using a simple flat DBD reactor of capacity about 200 cm^3, at low frequency (50 Hz). Considerable methane conversion was observed (more than 20 % with pure CH_4, and about 30 % in mixtures with helium), ethane, ethylene, propane and butane being the reaction products. The methane transformation yield increased in the presence of ethane. It is to note that no acetylene formation was found in these experiments. Also the reactions of methane with carbon dioxide in DBD were studied [8-11]. The experiments [12] were performed in a tubular reactor 54 mm in diameter, 310 mm long, with the discharge space 1 mm wide, at frequencies of 15 to 20 kHz. Methanol was obtained (up to 0.5%) with traces of CH_3OCH_3 in CH_4+O_2 mixtures and ethane (2%) in CH_4+CO_2 mixtures. Various products, such as C_2 hydrocarbons (mainly ethane) and oxygenated ones (formaldehyde, ethylene oxide, dimethyl ether etc.) were obtained, depending on the CH_4/CO_2 ratio in the starting mixture [13]. As has been found [14,15], a direct synthesis of methanol from methane and water vapour may proceed in DBD when ultra-short voltage pulses were applied. The yield of this reaction was, however, very low (<1%). From those examples one can conclude that a number of valuable products may be obtained from methane under the DBD conditions, but it is difficult yet to attain satisfactory yield.

2. Experimental

The methane conversion into higher hydrocarbons was examined under DBD conditions using a new developed laboratory flow reactor operated at atmospheric pressure and the frequency of 50 Hz. The reactor (Fig. 1) was made of a quartz-glass tube (being a dielectric barrier) with an inner metal (aluminium) high voltage electrode. The discharge gap distance was about 3 mm. The outer grounded electrode was made of

aluminium foil adjacent to the quartz tube surface. Inter-electrode voltage was maintained constant at the 18 kV level and the temperature of the reactor was about 45 ^{O}C. The methane conversion was examined in the presence of dielectric materials in the discharge gap: granular quartz-glass and silica gel (the grain size of 1-2 mm). It was found that those materials did not influence the current-voltage characteristics of the discharge. Methane 99,5 % and argon 99,999% were the only components for the starting gas mixtures. The inlet and outlet gas compositions were determined using gas chromatography (GC Agilent 6890N).

3. Results and discussion

The results of experimental series with CH_4+Ar mixtures of 7.5 and 10% methane content, for the gas flow rate 2.7 - 16 Nl/h, are presented (Figs. 2- 6) using the following quantities:

W - flow rate of CH_4+Ar mixture [mmol/h]

$W[CH_4]$ - flow rate of CH_4 [mmol/h]

$W[CH_4]^*$ - flow rate of CH_4 in outlet [mmol/h]

P - discharge power [W], constant for all the measurements (5 W)

Overall methane conversion $$X = \frac{W[CH_4] - W[CH_4]^*}{W[CH_4]} \cdot 100\%$$

Methane conversion rate $$Y = X\, W[CH_4] \cdot \frac{1}{100}$$

Overall specific energy $$E_V = \frac{3600\,P}{W} \quad [J/mmol\ (CH_4+Ar)]$$

Specific energy per methane unit $$E_R = \frac{3600\,P}{W[CH_4]} \quad [J/mmol\ CH_4]$$

Energy efficiency $$\eta_E = \frac{Y}{3600\,P} \quad [mmol\ CH_4/J]$$

The growth of overall methane conversion X and methane conversion rate Y were observed using the packing of granular dielectrics: quartz-glass and silica gel. The energy efficiencies η_E were also increased in the presence of both packing materials. The influence of the packing on the overall methane conversion and conversion into C_2H_6 is shown in Table 1 for the CH_4+Ar mixture (7.5% CH_4) and flow rate 2.7 Nl/h.

Table 1. The influence of the packing on the overall methane conversion and conversion into C_2H_6 for CH_4 + Ar mixture (7.5% CH_4)

Packing	Overall CH_4 conversion X [%]	CH_4 conversion into C_2H_6 [%]
None	33.8	8.4
Quartz-glass	43.5	9.2
Silica gel	38.9	9.2

Under the action of barrier discharges in CH_4+Ar mixtures, ethane and hydrogen were generated as the main gas products with small addition of unsaturated hydrocarbons C_2 (C_2H_2 and C_2H_4). However, a significant part of methane was transformed into non-volatile products - macromolecular compounds or soot (not identified). The overall conversion of methane was evidently higher than the conversion into gaseous (C_2) hydrocarbons. From the fact that the contents of ethane in the gas products were found to be much higher than that of unsaturated hydrocarbons C_2, one may conclude that, for a part of methane involved, after the first steps of the chain reaction (shown in Table 2) while ethane was generated, the transformation path was terminated. There are some points to be considered as a reason for that. The filamentary feature of DBDs seems to be one of them taking into account the action of tiny, short-living microdischarges in surrounding cool gas reagents. On the other hand, it may be the solid surfaces (electrode, wall) acting as chain stoppers which take part in the deactivation of high-energy particles (radicals, excited molecules) in fast heterogeneous processes. It should be added that the high selectivity of ethane formation was observed earlier when methane was converted under the conditions of DBD [7,13] and corona [17].

When granular dielectric packing is present in the discharge gap, the current - voltage characteristics of the discharges are similar to those without packing. However, it should be taken into account that the feature of

the discharges may be modified because of surface discharges occurring on the packing grains. One can conclude that heterogeneous processes on the surfaces of quartz-glass and silica grains paticipate in the overall methane transformation, resulting in the growth of methane conversion rate (not neglecting the role of solid surface as a chain stopper).

Table 2. Chain reactionns of methane [16]

CH_3 radicals and atomic hydrogen formation	$CH_4 + e^- = CH_3^{\cdot} + H^{\cdot} + e^-$
Ethane generation	$CH_4 \rightarrow CH_3^{\cdot} + H^{\cdot}$ $CH_4 + H^{\cdot} \rightarrow CH_3^{\cdot} + H_2$ $2\,CH_3^{\cdot} \rightarrow C_2H_6$
Ethylene generation	$C_2H_6 \rightarrow 2\,CH_3^{\cdot}$ $C_2H_6 + H^{\cdot} \rightarrow C_2H_5^{\cdot} + H_2$ $C_2H_6 + CH_3^{\cdot} \rightarrow C_2H_5^{\cdot} + CH_4$ $C_2H_5^{\cdot} \rightarrow C_2H_4 + H^{\cdot}$
Acetylene generation	$C_2H_4 + H^{\cdot} \rightarrow C_2H_3^{\cdot} + H_2$ $C_2H_4 + CH_3^{\cdot} \rightarrow C_2H_3^{\cdot} + CH_4$ $C_2H_3^{\cdot} \rightarrow C_2H_2 + H^{\cdot}$

Abstract

In this paper a potential plasma source at atmospheric air is analyzed. The production of a corona discharge in air at atmospheric pressure is achieved by using a needle-plane configuration with a gap length of 1 mm. The needle-plane is surrounded by a hollow dielectric, which influences the plasma density, its shape and duration. The effect of the dielectric material and shape on the discharge development and stabilization is investigated using a model based on the drift-diffusion equations.

1. Introduction

Conventional plasma-processing tools are essentially based on parallel-plate discharges [1], in which a voltage is applied between two electrodes to break down the gas and sustain the generated discharge. Plasmas generated in this method are usually used in high-plasma-density processing at lower gas pressures needing specialized applicators [2]. Recently the study of atmospheric non-thermal plasmas has received much interest because of the elimination of expensive vacuum systems. This leads to system simplification and cost reduction. The possibility arises therefore to create low-power, cold non-equilibrium plasma at atmospheric pressure. At the moment the best-known example is a micro-discharge, i.e. plasma constricted to the size of 10 - 100 mm by using very small electrodes [3]. Although the power density in these plasmas is of the same order as in larger discharges, the total consumed power is very low (of the order of mW) due to the small volume involved. Moreover, since gas heating in plasmas is a volume effect, micro-discharges remain cold. These micro-plasmas, arranged in an array, are intended for applications in modern display technology, to obtain improved TV screens [4]. Another possibility of obtaining non-equilibrium plasma is limiting the plasma operation time to microsecond range (i.e. by pulsing the plasma power supply). In this case electrons in the plasma have enough time to gain energy and create active species, but not to heat the ambient gas.

In this paper we focus on the modeling and simulation of low power, cold non-equilibrium plasmas (micro-discharges) at atmospheric pressure, which may find many useful applications ranging from the treatment of skin cancer and removal of decayed dental surfaces [5] to material processing of low-cost polymers and semiconductors [6]. Another growth area is the use of mercury free excimer lamps employing dielectric barrier discharges [7]. The current major challenge is producing, stabilizing and controlling non-thermal plasma at atmospheric pressure in air, thus avoiding the use of expensive helium or argon gases at lower voltage and power levels. This challenge can only be overcome with a fuller understanding of plasma processes at atmospheric pressure and the factors that control their stabilization.

Modeling and numerical simulations of plasma processing can be useful in many ways. An improved understanding of a plasma-processing system can be achieved by comparing predictions from numerical simulations with experimental observations. The optimization of existing processes or the development of new plasma processes that offer better processing results may follow such an understanding. Additionally, such modeling and simulations can also be used in the computer-aided design (CAD) of new process systems and to optimize manufacturing processes within the framework of existing processing systems. The ultimate goal may be the numerical solutions of the Boltzmann equation under general conditions, which is a very difficult computational problem. One scheme that can be used to solve the equation exactly is the convective scheme [8]. A more widely used alternative method is the particle in cell (PIC) method [9]. However direct numerical simulations are very costly comparing with continuum models [10].

The solution of continuum models is predominantly carried out using the finite-difference (FD) method in conjunction with the Flux Corrected Transport (FCT) algorithm for the stabilization of the convective terms (coupled with the Poisson's equation). The structured nature of the grids used in FD results in a large number of unknowns for complex configurations which leads to long calculations. Unstructured

grid methods such as finite volume (FV) and finite element (FE) methods have been applied to discharge problems and their many advantages are reported in recent publications [11,12,13]. Due to the efficiency of FE method for the solution of Poisson's equation it is advantageous to use FE for the solution of the complete coupled system [12].

The aim of this paper is to present fundamental aspects of plasma-process modeling based on relevant physical/chemical mechanisms. The plasma generation of point plane structures is analyzed using the FE-FCT method in a two-dimensional (2D) axis symmetric model [11,13]. The effect of secondary processes such as photo-ionization, photoemission and background ionization on gas discharges is added to the numerical simulations very accurately using methods presented in [14]. More specifically, the avalanche and streamer phase of corona development is presented. For the control of plasma (homogeneity in density profiles) the effect of various dielectric configurations is added to the point plane configurations.

2. Numerical (Continuum) Model

If the neutral-gas pressure is sufficiently high, collisional processes dominate the dynamics of the plasma. The drift-diffusion equations are "condensed" equations derived from the well-known fluid equations (i.e., mass- and momentum-conservation laws) for ions and electrons under the assumption of high collision frequencies [14]. Within this framework the simplest set of equations containing the basic physics necessary for streamer formation and propagation are the continuity equations for particle species, coupled with Poisson's equation. If the values of the mobility and diffusivities are given, we need equations only for the electron and ion densities and the electric field E to fully define the system. This can be achieved by the following formulation:

$$\frac{\partial N_e}{\partial t} + \nabla \cdot (\Gamma_e) = S_e \tag{1}$$

$$\frac{\partial N_p}{\partial t} + \nabla \cdot (\Gamma_p) = S_p \tag{2}$$

$$\frac{\partial N_n}{\partial t} + \nabla \cdot (\Gamma_n) = S_n \tag{3}$$

where t is the time, N_e, N_p and N_n are the charge densities for electrons, positive ions and negative ions. Γ_e, Γ_p, Γ_n , S_e, S_p and S_n are the associated fluxes and source terms respectively and can be written as:

$$\Gamma_e = N_e W_e - D_e \nabla N_e \,,\; \Gamma_p = N_p W_p \,,\; \Gamma_n = N_n W_n \tag{4}$$

$$S_e = N_e \alpha |W_e| - N_e \eta |W_e| - N_e N_p \beta_{ep} + S_{sc} \tag{5}$$

$$S_p = N_e \alpha |W_e| - N_e N_p \beta_{ep} - N_n N_p \beta_{np} + S_{sc} \tag{6}$$

$$S_e = N_e \eta |W_e| - N_e N_p \beta_{np} \tag{7}$$

where W_e, W_p and W_n are the corresponding drift velocities and D_e is the electron diffusion coefficient. The symbols α, η, β_{ep} and β_{np} denote the ionization, attachment and recombination coefficients respectively. The value of the rate constants of these processes is taken [15] as a function of the local value of the reduced electric field and extracted from experimental data. The term S_{sc} is the source term due to secondary effects such as photo-ionization and surface emissions. Poisson's equation is given by:

$$\nabla \cdot (\varepsilon_r \nabla V) + \frac{e}{\varepsilon_0}(N_p - N_n - N_e) = 0 \tag{8}$$

where ε_0 is the dielectric constant of free space, ε_r the relative permittivity, e the electron charge and **V** the electric potential. The electric field E is computed using:

$$E = -\nabla V \tag{9}$$

In addition, ions and electrons are also lost at the walls and electrodes that contain the plasma. Some electrons are also created at the walls and the electrodes due to secondary-electron emission and photoemission. These effects must be incorporated in the boundary conditions. The other boundary conditions may be given as follows: for typical parallel-plate DC and RF discharges, the potential at the anode and wall boundaries may be set to zero, whereas the potential at the cathode may be set to the applied voltage. Depending on the physical conditions, there are a variety of choices for boundary conditions for electron and ion fluxes. Here we used the boundary conditions given in [14].

3. Numerical Results

It is well known that streamers and arcs move towards high field regions that generally occur on sharp metallic and dielectric material edges. Numerical modeling of high-pressure discharges considering the effects in the presence of dielectrics has been reported to a limited extent. Allen and co-workers [16] have studied the streamer propagation on insulator surfaces and have observed that for a given dielectric constant, the streamers spread along a dielectric surface with a constant separation layer between the dielectric surface and the streamer. The separation of the streamers varies with the dielectric strength of the material. This channeling effect reduces the damage caused by the streamer and eases the breakdown mechanism of the system by spreading charged particle species in close proximity to the dielectric surface.

Numerical simulation of such effects may be useful for the design of homogeneous distributed and stable plasma production systems. To demonstrate the effect the dielectric insertions have on streamer propagation, an axisymmetric model shown in figure 1 is employed. Numerical results were obtained for a 50 μm spherical radius point, 1 mm from a plane in air at atmospheric pressure, with a positive voltage of 3 kV applied to the needle. In this axisymmetric model the dielectric material has a hollow cylindrical geometry with curved edges to ensure numerical stability. From previous experience it has been observed that the numerical load increases proportionally with increasing dielectric constant. Four types of dielectric insertions have been simulated, namely, ε_r=2.2, 3.2, 4.2 and 6.2, as well as the case of no dielectric insertion.

The current characteristics are shown in figure 2. The magnitude of the current increases considerably with increasing dielectric constant. This is mainly due to the high electric field occurring at the dielectric material interface. This leads to high ionization rates and the spread of charged particles in a large area approaching the dielectric surface. It is also observed that the peak in the current characteristics occurs in earlier times as the dielectric constant increases. For example, with ε_r=2.2 the maximum peak is at t=1.2 ns whereas, for ε_r=6.2 it occurs at 0.75 ns.

The electron charge density distributions are shown in figure 3. From this figure it is clear that the streamer is not attached to the dielectric surface and there is a constant separation distance between the streamer and the dielectric. When the dielectric constant increases, this separation layer reduces. Moreover figures 3(f), 3(j), 3(k) and 3(l) show the calculated electron density when the streamer reaches the cathode and it is evident that the streamer bridges the gap at different times. Figure 4 shows a plot of the time the streamer takes to reach the cathode versus the dielectric constant. This clearly demonstrates that the streamer propagates faster as the dielectric constant increases, which may lead to corona discharges at lower voltages.

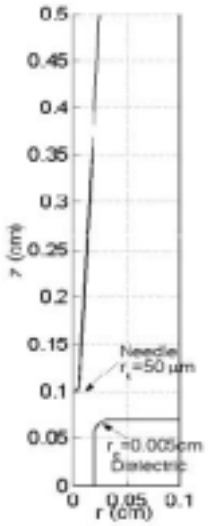

Figure 1: 2D axisymmetric model of a point plane dielectric model. Needle has a radius of curvature r_c = 50 μm and a dielectric edge of curvature r_c= 0.005 cm

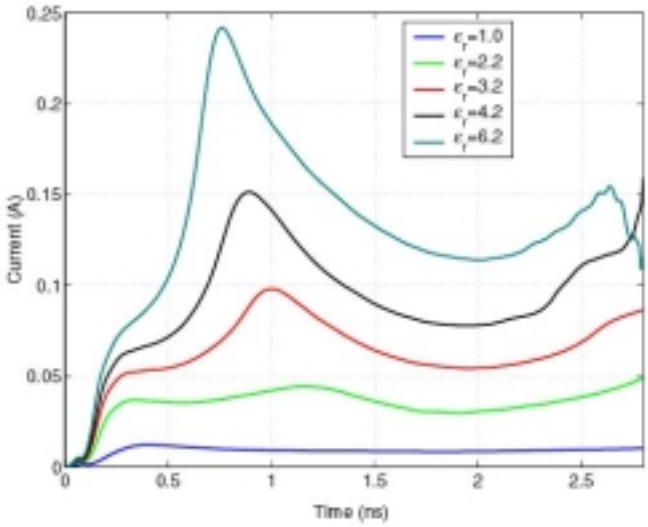

Figure 2: Current characteristic of four different types of dielectric when positive potential of 3 kV is applied to the needle.

(g) ε_r=3.2 at t=1.5 ns | (h) ε_r=4.2 at t=1.4 ns | (i) ε_r=6.2 at t=1.3 ns | (j) ε_r=3.2 at t=2.7 ns | (k) ε_r=4.2 at t=2.2 ns | (l) ε_r=6.2 at t=2.0 ns

Figure 3: Electron density distribution for point plane geometry. Applied voltage is 3 kV.

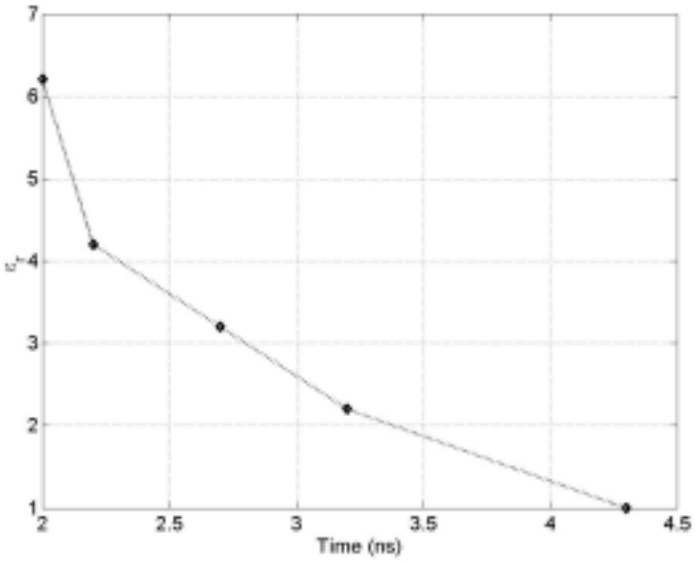

Figure 4: Time duration for the streamer to reach the cathode. The applied voltage is 3 kV for all dielectric materials.

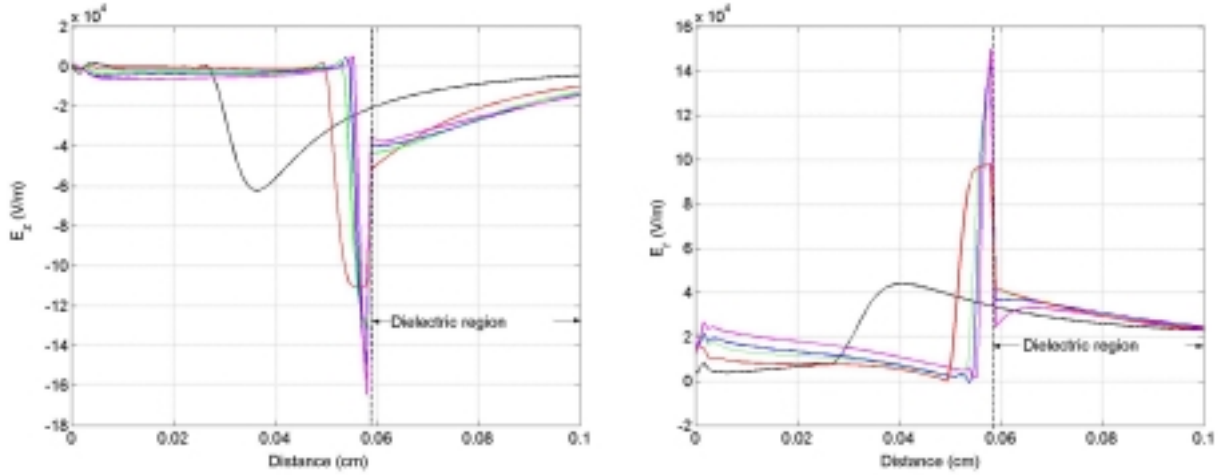

(a) (b)

Figure 5: 1D axisymmetric electric field distributions between point r=0 cm, z=0.1 cm and point r=0.07 cm, z=0 cm. (a) Axial electric field. (b) Radial electric field. Black: ε_r=1.0, red: ε_r=2.2, green: ε_r= 3.2, blue: ε_r=4.2 and magenta: ε_r=6.2.

Radial and axial 1D cross-section electric field distributions are shown in figures 5(a) and 5(b). It is interesting to note that, the electric field is nearly constant in the free space. A high gradient field occurs at the dielectric air interface, which increases the plasma density and the streamer speed.

4. Conclusion

In this paper the FE-FCT algorithm has been applied to the solution of high pressure gas discharge problems in the presence of dielectric insertions. Results suggest that the streamers spread along the dielectric surface with a separation layer, which depends on the dielectric permittivity and the applied potential.

Simulation of the streamer channel evolution for different dielectric constants shows that the streamer speed is not constant in the presence of dielectric material. This is a very important mechanism for the application of low tempareture plasmas to very small surfaces such as very small size biological tissues. The simulations suggest that carefully designed dielectric layer configurations may reduce the breakdown voltage.

Surface reactions in the presence of gas atoms: role of the vibrational excitation of the adlayers

E.Molinari and M.Tomellini

Dipartimento di Scienze e Tecnologie Chimiche, Università di Roma Tor Vergata, Roma,, Italy

Abstract. In the presence of gas atoms the reactive adlayer is likely to be found in vibrationally excited quasi steady states. Non-Boltzmann vibrational distribution functions of the adspecies characterize the adlayer, and exert a profound influence on the kinetics of the surface reaction by modifying rates and activation energies.

It has been shown, in a series of recent contributions [1-4], that the current, tacit assumption that adspecies present at a catalytically active surface, or at a reactive gas-solid interface, are in It has Boltzmann equilibrium at the surface temperature T_S , should be replaced, by a non-equilibrium picture of the reactive adlayer, where vibrational distribution functions (vdf) of the adspecies can be approximated by a Treanor vdf , well known in the chemical physics of gas plasmas and lasers[5],

$$\ln\left(\frac{n_\nu}{n_0}\right) = -\frac{\nu E_{10}}{RT_s}\left[\frac{T_s}{T_1} - \delta(\nu - 1)\right] \qquad (1)$$

which coincides with a Boltzmann vdf only if $T_1=T_S$. With the non-equilibrium parameter $(T_S / T_1) < 1$, vibrational levels with $\nu>0$ are over-populated with respect to an equilibrium distribution, the more so the lower the (T_S / T_1) ratio. The possibility of non-equilibrium quasi steady states in a reactive adlayer stems from the inclusion in a surface reaction scheme of fast (V-V) up-pumping processes, similar to those described by Treanor in the gas phase, and bound to the anharmonicity of the vibrational levels of mobile surface species. This up-pumping process competes with the vibrational relaxation of the adspecies $A_s(\nu)$ to the solid lattice ((V-L) relaxation), and the possibility of establishing a non-equilibrium quasi steady state at the surface is controlled by the ratio **K** between the constants of these competing processes.

The consequences of replacing a Boltzmann vdf by eq. (1) can be far reaching.

Let us select, as an example, the catalytic oxidation of CO by either molecular, $O_{2(g)}$, or atomic, $O_{(g)}$, gaseous oxygen on noble metal catalysts. It is a well-established fact that the surface reaction $CO_{(s)} + O_{(s)} \Rightarrow CO_{2(g)}$ is the rate-determining step of the heterogeneous oxidation of carbon monoxide on metallic surfaces [6] (subscript (s) denotes a chemisorbed species). Fig. 1 gives qualitative profiles for chemisorbed oxygen (a) and of chemisorbed CO (b) with the corresponding anharmonic vibrational levels $\nu=i$ and $\nu=j$ respectively. The very initial step of $O_{(g)}$ chemisorption corresponds to a *pump* process *populating the* upper i^* level of the $(S-O)$ species: $O_{(g)} \Rightarrow O_{(s)}(i = i^*)$, chemisorption of $O_{2(g)}$ pumps a lower i^+ level (fig.2a): $O_{2(g)} \Rightarrow 2O_{(s)}(i = i^+)$ chemisorption of $CO_{(g)}$ populates the upper j^* level of the vibrational ladder of the $(S-CO)$ species: $CO_{(g)} \Rightarrow CO_{(s)}(j = j^*)$(Fig.2b).

The vibrational energy pumped into these excited vibrational levels by the chemisorption processes is redistributed over the entire vibrational manifolds of the adspecies by (V-V) and by (V-L) processes.

For a non resonant (V-V) exchange among **mobile** surface anharmonic oscillators $O_{(S)}$ or $CO_{(s)}$, one writes:

$$O_{(S)}(\nu = 1) + O_{(S)}(\nu) \underset{P_r}{\overset{P_f}{\rightleftharpoons}} O_{(S)}(\nu = 0) + O_{(S)}(\nu + 1) \qquad (2)$$

and similarly for $CO_{(s)}$.. Application of detailed balancing to this reaction yields $P_f > P_r$, i.e. up--pumping, is

faster than reverse pumping, P_r, with the net result of over-populating the vibrational levels with respect to a Boltzman distribution.
For (V-L) relaxation one has:

$$O_{(S)}(v) + Lattice \underset{K_r}{\overset{K_f}{\rightleftarrows}} O_{(S)}(v-1) + Lattice^* \quad . \tag{3}$$

In this case $K_f > K_r$ and the system is driven towards a Boltzmann distribution. The condition for attaining a *quasi* steady state non-equilibrium vibrational distribution is that rate coefficients $P_{f,r}$ and $K_{f,r}$ in eqs.(3) and (5) respectivly, should obey the inequality $P_{f,r} n >> K_{f,r}$ with n total surface density of the adspecies, or $\mathbf{K} = (K_{fr} / P_{fr}\, n) << 1$. If this inequality is obeyed, the distribution functions at quasi steady state will be approximated by the Treanor vdf.
For a Langmuir-Hinshelwood mechanism involving vibrationally excited adspecies one writes

$$CO_{(s)}(j) + O_{(s)}(i) \xrightarrow{K(i,j)} CO_{2(g)}^* \langle i,j \rangle + 2S, \tag{4}$$

i.e. a reaction between the adspecies $(S-CO)$ in its jth vibrational level and the adspecies $(S-O)$ in its ith level , giving a vibrationally, rotationally and translationally excited gaseous $CO_{2(g)}^*$ molecule. The $\langle i,j \rangle$ symbol remarks that $CO_{2(g)}^* \langle i,j \rangle$ originates from the encounter of two adspecies in their ith and jth state respectively.
The rate of this reaction should be written:

$$\frac{dn_{CO_{2(g)}^* \langle i,j \rangle}}{dt} = K(i,j) n_1(i) n_2(j) \quad , \tag{5}$$

with $n_1(i), n_2(j)$ surface densities (molecule cm^{-2}) of $O_{(s)}$(i) and of $CO_{(s)}$(j) respectively.
The *total* rate of production of $CO_{2(g)}$ will then be given by:

$$\frac{dn_{CO_{2(g)}}}{dt} = \sum_{i,j} K(i,j) n_1(i) n_2(j) \tag{6}$$

The consequence of the presence of an activation energy $E^{\#}$ for the formation of the product $CO_{2(g)}$ from $CO_{(s)}$ and $O_{(s)}$ is that $\frac{dn_{CO_{2(g)}^* \langle i,j \rangle}}{dt}$, becomes appreciable only for (i,j) couples satisfying the condition $\left[E_1(i) + E_2(j)\right] \geq E^{\#}$. The sum over the *(i,j)* couples satisfying this constraint will be denoted $\sum_{i,j}^{\#}$ and contains a *lower cut-off*. With $\frac{dn_{CO_2}}{dt} = k(n_1 n_2)$, the expression for the overall rate constant is

$$k = \overline{K} \left[\frac{\sum_{i,j}^{\#} P_1(i) P_2(j)}{\sum_{i,j} P_1(i) P_2(j)} \right] \tag{7}$$

a function of $E^{\#}, T_s, (T_s/T_1)$, with $P(i) = n(i)/n(0)$

One can now analyse the dependence of the dimensionless rate constant for CO oxidation $\kappa = k / \overline{K}$, on $E^{\#}, T_s, (T_s/T_1)$ .Fig.2 shows log κ. for the reaction in atomic oxygen, plotted against (T_s/T_1) at different T_S and two different values of $E^{\#}$(95 kJ mol^{-1}, (full lines) and 50 kJ mol^{-1}, (dotted lines)). log κ at 300 K for the reaction in molecular oxygen is also shown for comparison (thick lines).The temperature dependence of log κ derived from fig,2 at constant (T_s/T_1), can be fitted by Arrhenius equations with slopes decreasing with decreasing (T_s/T_1). From these slopes one receives the 'non-equilibrium activation energies' $E_{NE}{}^{\#}$, which have been plotted in fig.3 vs. (T_s/T_1). Figs.2 and 3 allow a comparison to be made between non-equilibrium and Boltzmann dimensionless rate constants : the ratio between rate constants corresponding to 'true' activation energies $E^{\#}$ of 50 and of 95 kJ mol^{-1} are the following for Boltzmann vdfs ((T_s/T_1)= 1): (κ_{50}/κ_{95})=7 10^7, 8 10^3, 4 10^2 at 300 K, 600 K and 900 K respectively. At (T_s/T_1)=0.3 these ratios become (κ_{50}/κ_{95}) = 7, 3 , 1.5

The interpretation of these results is straightforward; it simply reflects the increased populations of (i,j) couples satisfying the constraint $[E_1(i)+E_2(j)] \geq E^{\#}$ and connected with a decrease of (T_s/T_1) in the Treanor vdfs of the $(S-CO)$ and$(S-O)$ surface species. The influence of T_S on these populations is therefore also expected to decrease with a decrease of (T_s/T_1), and κ becomes temperature independent ($E_{NE}{}^{\#}$=0) at values of $(T_s/T_1)$of about 0.1 because essentially all(i,j) couples will now satisfy the constraint in the whole range of temperatures considered (300-900 K). The influence on the reaction rates of oxygen atoms in the gas phase can therefore be attributed to a decrease of (T_s/T_1) with respect to the reaction in molecular oxygen, which follows from the observation that atomic oxygen populates, with no activation energy, the upper vibrational level *i**, while molecular oxygen pumps,with an activation energy, a lover level i^+ (fig 1).

The influence of oxygen atoms is nicely shown by the different vibrational distribution functions of the gaseous CO_2 molecules leaving the catalytic surface [7], which can be fitted [3] using the non-equilibrium scheme outlined above.(fig.4). Vibrational distribution functions of H_2 leaving the Ta surface after atom recombination [8] or abstraction can similarly be accounted for [2] (fig.5)

Impingement of energetic (4-8 eV) Xe atoms on coadsorbed $CO+O$ on Pt (111) at 100 K induces both formation of $CO_{2(g)}$ and desorption of O_2 below the surface temperature where any thermal reaction occurs and the reaction probability per incident Xe atom increases with the kinetic energy of the atom, above a 3-4 eV threshold [9]. When high energy gaseous Xe atoms hit the surface, efficient (T-V) energy transfer from the very fast Xe to coadsorbed $CO+O$ becomes possible and it has been shown in ref.[2] that additional pumping over all levels shifts the vdf's from a Treanor parabola to Treanor-like functions corresponding to higher degrees of vibrational excitation. In the low temperature (85 K) CO oxidation triggered by gaseous D-atoms incident on a $CO_S + O_S$ adlayer on Pt (111)[10] the pump process might well be represented by the highly exotermic reaction proposed by the authors $D_{(g)} + O_{2(s)} \Rightarrow O_{(s)} + OD_{(s)}$ and the oxidation reaction will again proceed at rates determined by the non-equilibrium vdf's of $O_{(s)}$, $OD_{(s)}$ and $CO_{(s)}$, pumped by this process.

An important observation stems from fig.2, namely that catalysts with widely different 'true' activation energies $E^{\#}$ can exhibit an equal κ, at the same T_S, provided (T_s/T_1) is properly selected for each system .In figs.2 and 3 Boltzmann rates represent but a limiting case, (T_s/T_1)=1, of a more general non-equilibrium picture showing that two parameters, besides T_S, are now necessary to define the non-equilibrium rate constant κ, namely $E^{\#}$ and (T_s/T_1).. Chemisorption of the reactants and the successive reaction steps on the surface, which are normally considered as independent from one another (one of them is rate determining), actually become closely coupled in this non-equilibrium picture in that the adsorption flux now controls the rate constants of successive steps via (T_s/T_1) [1,4].

Two examples of classical catalytic reactions influenced by the presence of atoms in the gas phase that can, at least qualitatively, be interpreted within the outlined framework of vibrational non-equilibrium, are the

following: 1)-*NH_3 oxidation on Pt -Rh and on Co O in the presence of $O_{(g)}$.[11]* .Oxidation of NH_3 on a *Pt -Rh* gauze was investigated in the temperature range 350 - 750 K in the presence of both $O_{2(g)}$ and of $O_{2(g)}$ + *10 % $O_{(g)}$* mixtures [11a]. *NO and H_2O* were, in both cases, the only reaction products . An ignition temperature marking the transition from a kinetic to a diffusional regime characterizes this reaction. First order kinetic rate constants can be extracted from the observed rates and plotted accoding to Arrhenius. The influence of $O_{(g)}$ is the following: a)-the ignition temperature is lowered from 525 K to 400 K, b) the activation energy derived from the Arrhenius plots is lowered from 54±12 to 29±4 kJ mol^{-1}, c)- these plots merge at a 'isokinetic temperature' Θ=890±20 K.The same technique was used with a cobalt oxide catalyst, grown on a copper gauze, in the temperature range 450-700 K[11b]. Reaction products are now N_2 and *NO* besides H_2O . The results parallel those obtained with a *Pt -Rh* gauze: in the presence of $O_{(g)}$ the activation energy is lowered from 125±16 to 38±4 kJ mol^{-1}, with an 'isokinetic tempe- rature' Θ= 750±20 K. The selectivity $s = [N_2]/[NO]$ decreases with increasing temperature and is systematically lower in the presence of $O_{(g)}$. 2) -*NH_3 decomposition on W in the presence of $H_{(g)}$ [12]*. Mixtures of NH_3 and H_2 of variable composition were flown across a tungsten wire spiral in a temperature range around 1300 K, yielding N_2+H_2 at rates *decreasing* with increasing partial pressure of H_2 . Addition of $H_{(g)}$ to these mixtures entrains an *increase* of the rate of NH_3 decomposition at all compositions and temperatures investigated.

One might then conclude that any analysis of surface reaction schemes in the presence of gas plasmas should duly take into account the existence of vibrational excitation in the reactive adlayer.

Collisional deexcitation of excited rare gas atoms by atoms and molecules is of great importance in both fundamental and applied sciences, which provides the essential features of chemical reactions, in particular, those including electronic energy transfer. The collisional deexcitation is a key also to understand fundamental processes in the interaction of ionizing radiation with matter and the phenomena in ionized gases such as reactive plasmas and upper atmosphere. Excited neon atoms have a large amount of internal energy enough to ionize Ar, Kr, Xe and N_2 at thermal energy.

Collisional deexcitation processes of excited neon atoms have not been extensively studied in comparison with those of excited helium atoms, the collisional deexcitation of Ne($^3P_1$) and Ne($^3P_2$) by Ar, Kr, Xe and N_2 has been studied in detail in this experiment. The temperature dependence of the rate constants for the deexcitation has been measured in the temperature range from 133K to 295K using a pulse radiolysis method and thus the collisional energy dependence of the deexcitation cross sections is obtained. The deexcitation cross sections are in the range of 10 -26 Å^2 and 6-20 Å^2 for Ne($^3P_1$) and Ne($^3P_2$), respectively, and increase slightly with increasing the collisional energy. The absolute experimental cross sections for the Ne($^3P_1$) deexcitation are larger than but close to those of Ne($^3P_2$). Moreover, the calculated optical model cross sections show that an electron-exchange interaction plays an important role in the deexcitation of Ne($^3P_1$) in collisions with Ar, Kr, Xe, and N_2. The comparison between the present experimental and calculated cross sections indicates that the deexcitation processes for Ne($^3P_1$) and Ne($^3P_2$) are dominated by collisional ionization induced by an electron exchange interactin, although the deexcitation cross sections for Ne($^3P_1$) are slightly enhanced by a weakly allowed dipole-dipole interaction. The details will be discussed at the conference.

Semicondactive polymer films obtained by plasma polymerization

A. Drachev, A.Gilman, and A. Kuznetsov

N. S. Enikolopov Institute of Synthetic Polymeric Materials, Russian Academy of Sciences, Moscow, Russian Federation

Polymerization of aniline, pyridine, and thiophene in the high-frequency discharge plasma was used for the preparation of the thin polymer films with semicondacting properties [1–4]. The bulk conductivity of the non-doped samples did not exceed 10^{-9}Ohm^{-1}cm^{-1} and only after doping reached 10^{-5}-10^{-4}Ohm^{-1}cm^{-1}.

In this work, polymer films based on 1-amino-9,10-anthraquinone (AAQ) were synthesized by polymerization in dc discharge.

Polymerization was carried out in vacuum tubular reaction chamber 30-cm long with a diameter of 10 cm. The upper part of the chamber was placed in an electric furnace, which provided heating to 400˚C controlled by a thermocouple. Two horizontal planar-parallel electrodes with a diameter of 50 mm were placed in the chamber, and a ceramic cup with the starting substance was placed on an anode. Polymerization was performed for 5-120min at 240°C in a discharge current of 5-15mA under pressure of 2.10^{-2}Pa.

Under DC discharge, a deposition of black polymeric layer with specific metallic luster on the cathode was observed. The thickness of polymeric layer could be varied from 1 to 9μ by changing duration of deposition. The cathode film did not dissolve in any organic solvents, acids and alkalis. The layer deposited on the anode was of red color and was easily soluble in acetone. The thickness of the layer deposited on the anode was less than 1μm.

Polymer films obtained on the cathode and the anode found to differ essentially in their electrical properties. The film deposited on the anode had the specific conductivity of 10^{-16}Ohm^{-1}cm^{-1} (20°C). The film deposited on the cathode had a conductivity of $\sigma = 10^{-5}$–10^{-4}Ohm^{-1}cm^{-1} (20°C). Repeated heating on air from 20 up to 300°C with a rate of 0,5 degree/min was found to have no effect on the value of conductivity.

In range of film thickness from 1 to 9μ, no dependence of the electrical resistance on the film thickness obtained on the cathode was found. This means that the basic part of electrical resistance of a sample falls to the near-electrode layer. The surface conductivity of the film deposited on the cathode was found to be equal $3{,}7.10^{-14}$ Ohm^{-1}, i.e. a value typical for dielectrics. These results are the evidence of pronounced electrical anisotropy of polymeric films deposited on the cathode.

Obviously, semi-conductive properties of polymeric film deposited on a cathode are due to polyconjugated structure. One could suppose two routes led to formation of polyconjugated chain from AAQ, the first one being the polycondensation of amino groups with AAQ carbonyl groups, the second one being 1,4–polyaddition, i.e. a process similar to an oxydative polycondensation of aniline [4]. If the first mechanism would be predominant, the content of the oxygen atoms in polymer should decrease compared to that in AAQ. This supposition is in a controversy with the ESCA data showed that the film from cathode did not differ in element composition from the monomer. So, the second mechanism seems to be more acceptable. In this case, polyconjugated chain can be formed by means of 1,4-polyaddition an AAQ cation–radical to the negatively charged end fragment of growing polymer chain and anthraquinone fragment is involved into main chain of polymer. Presence of strong C=N absorption bands and peaks of polycyclic quinone structure in a FTIR spectrum cathode deposition film are in accordance with hypothesis of 1,4-polyaddition reaction.

The results obtained by FTIR–spectroscopy suggest that the film deposited on a cathode has a polyconjugated structure and can be considered as polyaniline derivative containing in chain basically anthraqunone moieties.

Deposition of Amine Containing Films from Hyperthermal Silazane Ions

A. Choukourov[1], H. Biederman[1], E.R. Fuoco[2], S. Tepavcevic[2], and L. Hanley[2]

Abstract
This work examines films deposited from mass-selected 5 - 200 eV $Si_2NC_8H_{19}^+$ (silazane) ions onto aluminum and silicon substrates. Film chemistry including amine content, film aging, and film morphology are examined as a function of ion energy and fluence using x-ray photoelectron spectroscopy and atomic force microscopy

1. Introduction

Polyatomic ion deposition at ion impact energies below 200 eV is an effective method for the growth of thin organic films on polymer, metal, and semiconductor surfaces. We have previously shown that SO_3^+, CF_3^+, $C_2F_4^+$, $C_3F_5^+$, $Si_2O(CH_3)_3^+$, and $C_4H_4S^+$ ions can be employed for the growth and modification of organic thin films on polymer, semiconductor, and metal surfaces [1-4]. These films are often similar in chemical composition to plasma polymers, due at least in part the presence of large, hyperthermal positive ions in many plasmas. This work deposits beams of mass-selected 5 - 200 eV $Si_2NC_8H_{19}^+$ (silazane) ions onto aluminum and silicon substrates. Silazane ions are produced by electron impact ionization of 1,3-divinyltetramethyldisilazane. These ion-deposited films are analyzed by x-ray photoelectron spectroscopy (XPS) and atomic force microscopy. Chemical functionalization prior to XPS analysis permits the unique identification of primary and secondary amine groups. Secondary amine containing films are shown to form at low silazane ion energies whereas the higher ion energies lead to formation of more inorganic, silico-carbo-nitride-like films. Effects of film aging in air are also discussed.

2. Experimental

1,3-divinyltetramethyldisilazane, CH_2=CH-Si$(CH_3)_2$-NH-Si$(CH_3)_2$-CH=CH_2 (M=185), referred to below as silazane, was used as the ion precursor. The most abundant ion formed by electron impact appeared at m/z 170 ($C_7Si_2NH_{16}^+$) and was chosen for deposition. The m/z 170 silazane ion corresponds to the molecular ion minus one methyl group. Some deposition was also performed with the siloxane ion counterpart at m/z 171, formed from divinyltetramethyldisiloxane (CH_2=CH-Si$(CH_3)_2$-O-Si$(CH_3)_2$-CH=CH_2). The siloxane ion differs from the silazane ion in the replacement of the NH group by an oxygen atom ($C_7Si_2OH_{15}^+$). All ion depositions were performed with ion kinetic energies varying from 5 to 200 eV; ion currents of 25 to 35 nA; and ion fluences of 1.4 to 6.8×10^{15} ions/cm^2. Aluminum foil and silicon wafers were used as substrates, the latter after etching with 5% HF to produce a hydrogen-terminated surface with a minimum of oxide [3]. XPS of the aluminum substrate prior to ion deposition found an elemental content of 30% Al, 59% O and 11% C. The Si substrate prior to ion deposition displayed an elemental content of 10% C, 4% O, and 86% Si. Films noted "as-deposited" correspond to those directly transferred to the XPS without any air exposure. Initial XPS were recorded with monochromatic Al-Kα radiation and analyzed as previously described [5]. All XPS peaks are referenced to aliphatic C 1s (C-C, C-H) at 284.5 eV, chosen to take into account a considerable amount (~20%) of silicon in the coatings which shifts the carbon binding energy downwards slightly [6]. The peak positions vary with accuracy of 0.1 eV. Atomic force microscopy was recorded in air using the tapping mode, as previously described [3]. The average RMS roughness was calculated from 5 μm x 5 μm and 1 μm x 1 μm overlapping areas scanned for each sample. All work was performed at the University of Illinois at Chicago.

3. Results and Discussion

Fig. 1 displays the high-resolution Si 2p (left) and C 1s (right) XPS core levels of a silazane film deposited from 15 eV ions on a silicon substrate, without air exposure (as-deposited). The silazane film is thin enough to observe the substrate signal, consisting of the two Si 2p spin orbital peaks: $2p_{3/2}$ at 100.4 eV and $2p_{1/2}$ at 100.9 eV. The broad peak at 102.7 eV corresponds to silicon bound within the silazane film to carbon, nitrogen, and oxygen. Oxygen from the substrate appears in the films in the amount of several percent,

despite its absence in the silazane precursor ion. Unfortunately, the difference in the Si 2p chemical shift produced by nitrogen and oxygen is too small to be resolved here. Si 2p binding energies of SiN and SiC species range from 101.3 to 102.8 eV [7-13].

The broad Si 2p peak of the siloxane film appears at 103.2 eV (not shown), is 0.5 eV higher binding energy than the silazane film peak. This indicates that SiN is a major component of the silazane film, with smaller contributions from SiO and SiC environments. This SiN assignment is supported by elemental analysis (see below), which displays higher concentrations of nitrogen than oxygen across the entire range of the energies. The N 1s peak is centered at 396.9 eV, lower than usually found for many CN groups [6]. This lower N 1s binding energy is attributed to the predominance of nitrogen as Si_xN. The C 1s spectra in Fig. 1 (right) is featureless and is fit with an aliphatic and SiCN component (shown as solid underlying lines in Fig. 1), consistent with the above arguments and as discussed further below.

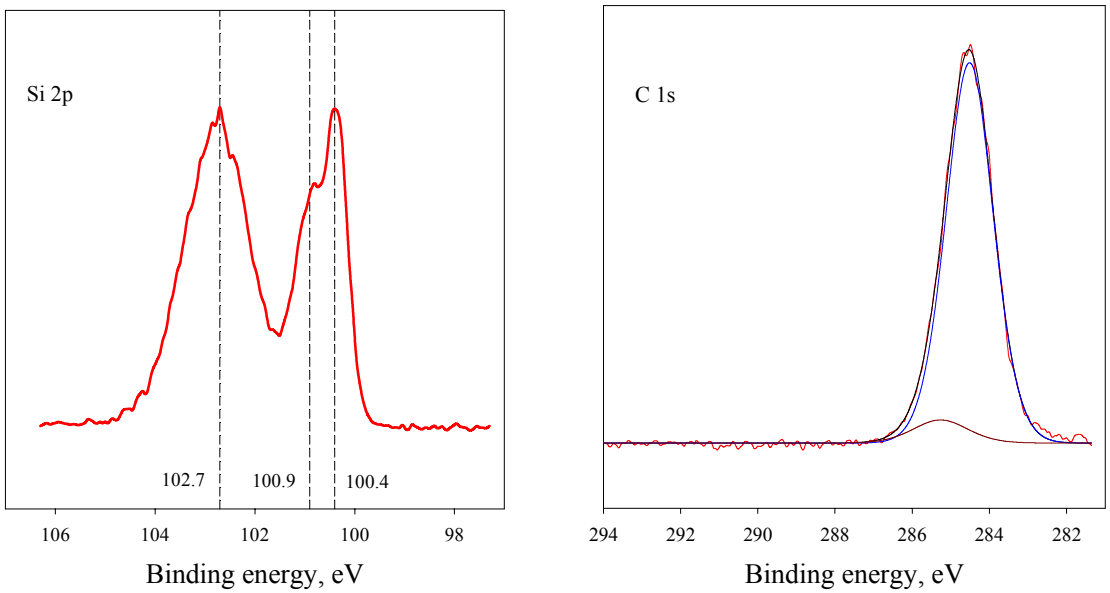

Fig. 1. The high-resolution Si 2p (left) and C 1s (right) XPS core levels of silazane films as-deposited by 15 eV ions on a hydrogen terminated Si substrate.

The elemental composition of the as-deposited silazane films on silicon is shown in Fig. 2a. The horizontal reference lines correspond to the element concentrations of the precursor ion $C_7Si_2NH_{16}^+$: 70% of carbon, 20% of silicon and 10% of nitrogen. There is evident dependence of the element composition on incident ion energy. With increasing ion energy the amount of carbon decreases and the concentration of silicon and nitrogen grows. The oxygen content for this set of experiments is nearly constant at ~4%. It has been reported that $Si\text{-}CH_3$ bonds are most vulnerable to cleavage in organosiloxane films deposited from plasmas [14]. It is similarly argued here that the $Si\text{-}CH_3$ dangling bonds are more easily broken than $Si\text{-}CH{=}CH_2$ or Si-NH-Si backbone bonds. It follows that the higher ion energy would favor cleavage of the $Si\text{-}CH_3$ bonds and formation of volatile CH_x species, leaving the film rich in silicon and nitrogen components. By contrast, low-energy ions should lead to films more similar to the monomer. The elemental contents in Fig. 2a are consistent with low-energy ions forming more organic polymer-like structures and the high-energy ions forming more inorganic SiCN coatings, as observed previously for $Si_2O(CH_3)_5^+$ ion deposition [2]. Slightly higher concentrations of carbon and lower concentrations of nitrogen and silicon are due to the initial carbon contamination of the substrate. The ion energy trend is similar in the case of the aluminum substrate (data not shown). However, the oxygen content of 10-18% is much higher, consistent with the high initial oxygen content on the aluminum substrate. The film thickness is on the order of several nanometers, allowing observation of oxygen signal from the aluminum substrate.

The elemental ratios vs. incident ion energy for the deposited silazane films are plotted in Fig. 3a. The broken lines at C/N=7, C/Si=3.5 and Si/N=2 ratios correspond to the precursor ion. The Si/N ratio remains nearly constant across the range of ion energies and is within experimental error of the precursor value. The decrease in C/N and C/Si ratios with ion energy at the expense of carbon is consistent with the loss of CH_x species. As mentioned above, the low binding energy of the N 1s peak confirms that nitrogen in the film

remains bound to silicon. Possible Si-N-Si structures include Si-NH-Si, Si=N-Si, Si=NH, Si-NH-C, Si-N=C, Si-NC-Si (the absence of primary amines will discussed below). The presence of SiCN binding environments is seen in a slight asymmetry of C 1s spectrum, shown for example in Fig. 1 (right). The small C 1s component is shifted ~0.8 eV below the primary aliphatic component, with ~7% of the total peak area. This minor component is assigned to SiCN species with some contribution from CO. Nitrogen bound only to carbon might also contribute to the C 1s, but there is no evidence of CN structures in the N 1s spectrum. Large fractions of SiC species are also unlikely.

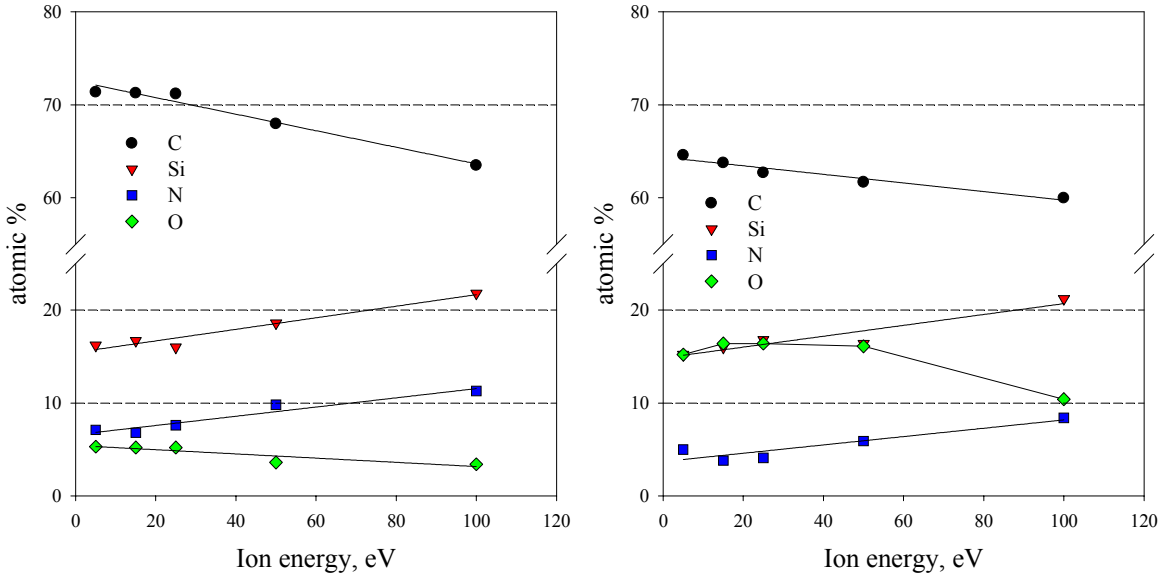

Fig. 2. Elemental composition of: a) as-deposited silazane films on Si; b) 7 day aged silazane films on Si.

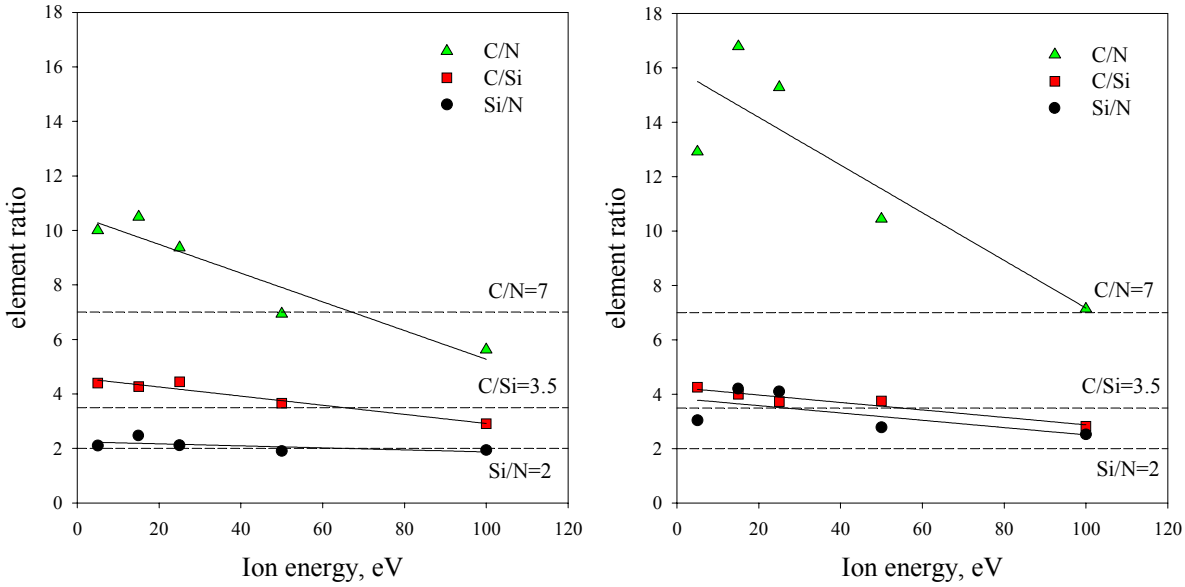

Fig. 3. Change of elemental ratios with ion energy for: a) as-deposited silazane films; b) 7 day aged silazane films.

The film samples were also stored in air for 7 days, then the XP spectra were again acquired. Chemical derivatization was applied to determine the concentration of primary and secondary amine on the aged samples. Trifluoromethyl benzaldehyde (TFBA, a) and trifluoroacetic anhydride (TFAA, b) were used as chemical agents to detect primary and secondary amines, as indicated in Fig. 4 [15]. XPS was immediately applied after treatment with TFBA or TFAA to determine the fluorine content, which was then related to the amine content. TFAA is also sensitive to hydroxyl groups, as discussed further below.

a) $-NH_2+O=CH-C_6H_5-CF_3 \rightarrow N=CH-C_6H_5-CF_3+H_2O\uparrow$ b) $-NH_2+(CF_3-CO)_2O \rightarrow -NH-CO-CF_3+CF_3COOH\uparrow$

$>NH+(CF_3-CO)_2O \rightarrow >N-CO-CF_3+CF_3COOH\uparrow$

Fig. 4. Derivatization reactions for primary (NH_2) and secondary (NH) amine analysis: a) NH_2 with TFBA; b) NH_2 and NH (and OH) with TFAA.

15 - 200 15 eV silazane films on aluminum were treated with TFBA and the lack of fluorine signal indicate an absence of primary amines. The same films on both on aluminum and silicon samples were then treated with TFAA, with the results shown in Fig. 5. The secondary amine content was calculated as [F]/3. TFAA may also react with hydroxyl groups which are likely present in the film as a result of oxidative reactions or hydrolysis during storage on air. So, the value of [F]/3 is referred to as the total amount of NH and OH on the film surface.

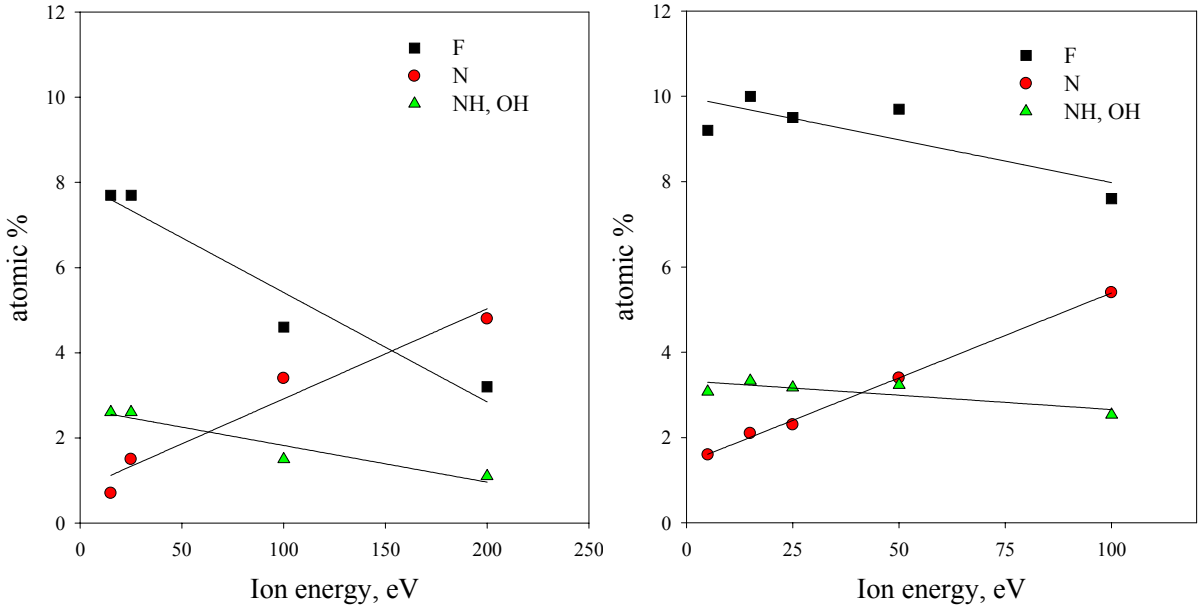

Fig. 5. Concentration of F, total N, and NH, OH (sum) after the derivatization with TFAA of films on a) Al and b) Si.

It is interesting to compare the behavior of the total nitrogen content (N) and the NH curves (NH, OH). The high-energy ions form films with higher nitrogen concentration, but the secondary amine concentration is the lowest. The collision of the silazane ions with the surface likely results in fragmentation of the secondary amine, leaving nitrogen bound mainly to silicon. In the case of 200 eV ions (aluminum substrate) the secondary amines constitute only ~20% of total nitrogen, but this rises to ~50% for 100 eV ions. The situation changes as the ion energy decreases. The values of [F]/3 are even higher than the nitrogen content for 15 and 25 eV ions. The curves follow the same trend for the films on the silicon substrates, except that the nitrogen and fluorine concentrations are slightly higher. However, [F/3] and total nitrogen curves intersect at about 50 eV ion energy for both substrates. The fact that the [F/3] values are higher than total nitrogen for the low-energy ions films is explained by the contribution from OH groups. A 15 eV film treated with TFAA immediately after extracting the sample from the vacuum system gave values of 2.5% total nitrogen and 2.7% [F]/3. This supports the argument that most nitrogen in the low-energy films is secondary amine, with oxidation in air leading to the formation of some surface hydroxyl groups.

The composition of the aged silazane films is shown in Fig. 2b. The aged samples have lower concentrations of carbon, silicon, and total nitrogen and much higher concentrations of oxygen than the as-deposited films. Aging effects were less for films deposited at higher ion energies. The oxygen content increased from 4% to 10% upon aging of 100 eV films, while it increased from 5% to 17% for aging of ≤25 eV films. The dependence of element ratios of the aged films on ion energy (Fig. 2b) reveals that C/N and Si/N ratios increase and C/Si stays at the same level as in the as-deposited coatings. Gengenbach [9] investigated the aging of plasma polymerized diaminopropane and considered the hydrolysis of imines with elimination of ammonia: $R-CH=NH + H_2O \rightarrow R-CH=O + NH_3\uparrow$. Given that the concentration of secondary amines is the highest for the low-energy ions films (see above), ammonia elimination can explain the unusual aging behavior of silazane films. The hydrolysis reaction runs slower in 100 eV films, in which only about half of the nitrogen atoms are in NH form.

The morphology of silazane films, kept after the deposition for 1-2 weeks on air, was investigated by AFM in tapping mode. To minimize the influence of substrate on resulted images silicon wafer with roughness of about 0.15 nm was chosen as a substrate (Fig. 6a).

e) 100 eV, 35 nA, 4.5 h Ra=0.73 nm

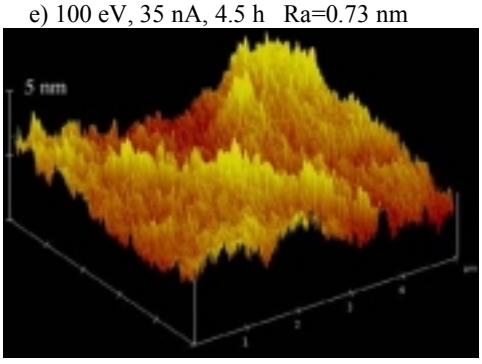

Fig. 6. AFM images of silazane films of equal thickness deposited by 15 and 100 eV silazane ions.

The films were deposited with 15 and 100 eV ions at 33-35 nA current with different deposition times. In order to analyze the morphology of different coatings, it is important to compare films of similar thicknesses. The very thin films yielded complex Si 2p XPS peaks, with both a silazane component (102.3 eV) and a substrate silicon component (100.0 - 101.0 eV), as depicted in Fig. 1 (left). Comparison of the relative peak areas of these different Si 2p components was used to grow films of similar thicknesses by 15 and 100 eV ions. The deposition rate for 100 eV silazane ions was thereby found to be ~2.3 times higher than that of 15 eV ions: deposition within 3 hours by 100 eV ions corresponded to 7-hour deposition by 15 eV ions; 4.5 hour, 100 eV deposition corresponded to 10 hours of 15 eV deposition.

The comparison of morphology of 15 and 100 eV ions films of equal thickness is given in Fig. 6. The only significant difference in roughness was observed for films of different thickness, with thicker coatings prepared at either energy (Figs. 6c and 6e) appearing rougher (~0.7 nm RMS) than thinner films (Figs. 6b and 6d, with ~0.5 nm RMS). Films of similar thicknesses at prepared at different energies displayed similar roughnesses, within experimental error.

4. Conclusion

The polyatomic ion deposition of 1,3-divinyltetramethyldisilazane occurs via fragmentation of the silazane ions colliding with the surface, followed by successive recombination of species in the film. The process occurs with preferential cleavage and elimination of methyl groups. The film composition depends strongly upon ion energy. Low energy ions produce more organic deposits with the highest concentration of carbon. As-deposited films are similar in composition to the original ion. Most of the nitrogen atoms in these films are in the NH form. The ions of higher energy form films with higher percentages of silicon and nitrogen, and reduced carbon content. Higher ion energy also leads to decomposition that reduces the amount of NH functionalities. The films deposited by the ion deposition of silazane are very smooth, with roughnesses less <1 nm (RMS). The roughness of the films depends more on their thickness, being higher for the thicker coatings. No strong difference in morphology between low- and high-energy films is found, in contrast to the case for films grown on polymer surfaces [16]. When exposed to air, silazane films age, which leads to oxygen concentration increase. One of the probable mechanisms of oxygen uptake is hydrolysis of imines with elimination of nitrogen as volatile ammonia. Low-energy ion films are more susceptible to aging because of higher NH concentration.

Plasma polymer coatings have been studied extensively on flat substrates such as paper, fabrics, glass and metal surfaces. Such coatings have been demonstrated to alter surface properties such as wettability and non-fouling characteristics. Applications of these coatings to powder surfaces, however, have additional challenges, and only limited studies have been done in applying these coatings to powders and particulates. This study focuses on the design and application of a plasma reactor for applying plasma polymer coatings on powders of various sizes. Plasma polymer coatings have been generated on powder substrates that provide such industrially important effects as moisture resistance, controlled dissolution and improved dispersion into solvent. The paper will discuss the process as well as chemistry used to generate various types of plasma polymer coatings on powders and particulates.

PLASMA POLYMERIZATION IN A MICROWAVE REACTOR AT ATMOSPHERIC PRESSURE

Microwave plasmas at low pressures have been extensively studied in the literature and are known for their high chemical activities due to the high generation rate of reactive species. In contrast Microwave discharges at high pressures is relatively new, and has been used mainly as excitation source for dissociative processes and spectrochemical analysis for use in environmentally oriented applications such as abatement of CFCs and NOx destruction, due to their high temperatures. In this paper we will investigate a new application of atmospheric microwave discharges, namely post-discharge plasma polymerization of Fluorocarbon monomers, for production of hydrophobic coatings. In our study the bulk chemistry of the coatings was determined by using FTIR analysis, while the surface chemistry and function retention was investigated by X-ray photoelectron spectroscopy XPS. The coatings were found to replicate the structure of the monomer as shown by FTIR analyses. The deposition thickness and topology of the coatings are estimated by AFM while surface energy determination using sessile drop technique exhibited hydrophobic polymer coatings with low surface energy. The variation of the surface energy as a function of the applied power is discussed in terms of the CF2/CF3 ratio and the functional retention.

FLUOROCARBON PLASMA POLYMER FORMATION IN A DIELECTRIC BARRIER DISCHARGE REACTOR AT ATMOSPHERIC PRESSURE

Dielectric Barrier discharges (DBD) are gaining increased attention as an economical and reliable method for generating non-equilibrium plasma conditions in atmospheric pressure gases. This has led to a number of important applications including industrial ozone generation, excitation of CO2 lasers, surface modification of polymers and large area plasma flat panel displays. This paper deals with a new topic in the spectum of applications of DBDs, namely plasma polymerization. Plasma polymerization of Fluorocarbons is studied in a parallel-plate dielectric barrier discharge (PPDBD) as a function of different plasma operating parameters. The chemical composition of the deposited films has been determined by X-ray photoelectron spectroscopy (XPS). The coating is found to be of a similar structure than the monomer as shown by FTIR analyses. The deposition thickness and topology of the coatings are estimated by AFM while surface energy determination using contact-angle measurements exhibits hydrophobic polymer coatings with very low surface energy. The retention of different functionalities and the influence of the ratio CF2/CF3 as a function of power are discussed and correlated to the surface energy of the coatings.

Combinatorial Synthesis of Conducting Oxides by Plasma-enhanced Chemical Vapor Deposition

C. A. Wolden, C. Fry, J. Esteban, and J. J. Robbins

Department of Chemical Engineering, Colorado School of Mines, Golden, CO 80401 USA

Abstract
Transparent conducting oxides (TCOs) are primarily doped oxides. Next generation applications require TCOs with improved conductivity and tailored properties. In this paper we will describe our combinatorial approach to rapidly evaluate new materials and process chemistries. The experimental reactor is described, as well as the characterization techniques used for both screening and formal evaluation. Examples are provided from a number of oxide systems, including tin–zinc, tin–antimony, and gallium–zinc.

1. Introduction (Times 11, bold)

Transparent conducting oxides (TCOs) are used extensively as transparent electrodes in photovoltaic and display applications. It is becoming clear that as photovoltaic, electrochromic, display and other technologies reliant on TCOs continue to advance the properties of existing TCOs are impacting the performance of the final device. To achieve superior performance the TCO community must discover new and improved materials since the existing ones have been highly optimized during the past three decades [1]. The TCO phase space is shown in Figure 1 [2]. The commercial TCOs are derived from the vertices of Figure 1: F-doped tin oxide (SnO_2:F), tin-doped indium oxide (ITO), and aluminum-doped zinc oxide (ZnO:Al). Despite some recent encouraging results, the elemental TCO phase space (Zn-In-Sn-Ga-Cd) remains largely uncharted.

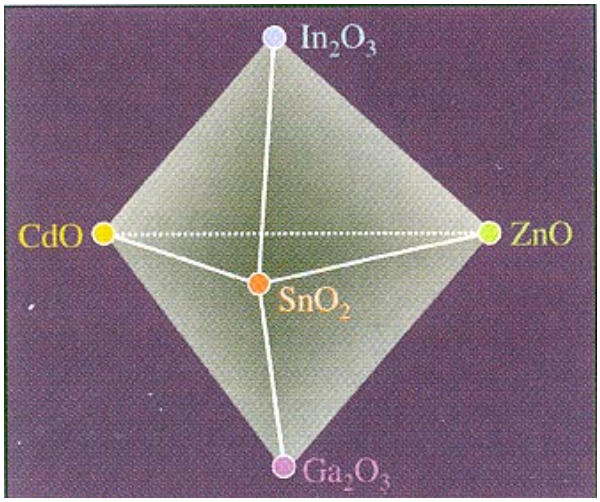

Figure 1. The TCO phase space [2].

The primary synthesis techniques for TCOs have been either physical vapor deposition (sputtering, pulsed laser ablation) or thermal chemical vapor deposition. Sputtering is the pre-eminent technique for the deposition of two widely used TCOs, ITO and ZnO. It has a demonstrated track record for producing high quality films at low temperature. It has some drawbacks, particularly the cost and reproducibility of forming new targets, which limits its suitability for exploring new compounds. An additional handicap is the inability to incorporate volatile compounds like N or F into targets. Atmospheric pressure chemical vapor deposition (APCVD) is an economical, high throughput technology that is employed for the synthesis of SnO_2:F. A kinetic process, it is capable of incorporating light atoms into film growth. Unfortunately APCVD has been restricted to tin oxide, mainly due to limitations on precursor volatility, reactivity, and compatibility. To make an alloy by thermal CVD is challenging since one must find precursors that have compatible volatility and reactivity. For example, the temperatures employed for CVD of ZnO [3] and SnO_2 [4] differ by several hundred degrees .

Plasma-enhanced chemical vapor deposition has a number of advantages over these techniques, particularly for the synthesis of alloys and functionally graded materials. In PECVD the initial chemistry is driven by electron impact reactions, which are very fast regardless of precursor. The low operating pressures ($P < 1$ torr) of the PECVD environment mitigate issues associated with low precursor volatility. To explore the phase space shown in Figure 1 by PVD would require numerous targets. In contrast, a wide range of compositions may be easily evaluated in a continuous manner through PECVD by simply adjusting flowrates. A further advantage of PECVD is that steps such as plasma cleaning and modification of surfaces may be performed *in-situ*. These steps are often used to improve adhesion on foreign substrates and to create

clean interfaces. In previous work we have established PECVD as an alternative technique for the synthesis of high quality tin oxide [5, 6] and zinc oxide films [7]. For both tin oxide and zinc oxide the best resistivity values achieved were $\rho \sim 10^{-3}$ Ω-cm, among the best values obtained for intrinsic films by any deposition method [1]. Further improvements in conductivity require the addition of dopants or alloy formation [8].

A drawback of plasma system is that the chemistry is complex, and not well understood. Combinatorial chemistry has established itself as the premier approach for the synthesis of materials as varied as new drugs and novel catalysts [9]. The essence of this approach involves the ability to *generate* and *evaluate* a large number of chemical compounds in an efficient manner. Originally developed by organic chemists to order peptide sequences into pharmaceuticals with therapeutic properties, the technique has recently been extended to solid-state materials synthesis. Particular success has been achieved with complex oxides, such as high temperature superconductors and ferroelectrics [10, 11]. For TCOs researchers have relied on sputtering to find new compounds using multiple targets [12, 13]. In this paper we describe a PECVD reactor that has been modified for combinatorial synthesis of TCOs. We also detail the techniques employed for both screening and detailed characterization. Results are presented from a number of materials systems.

2. Experimental

Since the plasma chemistry is quite complex and not well understood, an efficient means to screen potential precursors was developed. A custom-built, capacitively coupled PECVD reactor was used for this work. Additional details on the experimental setup may be found in the literature [5, 6]. The PECVD reactor was modified as shown schematically in Figure 2. Gaseous precursors were directed into the chamber through one of three sources: (*i*) a uniformly perforated showerhead, (*ii*) a single ¼" hole at the center of the showerhead, or (*iii*) through multiple ports on the exterior of the parallel plates. This combinatorial setup produced films with a radial gradient in composition. Figure 3 shows a photograph of a typical film produced with the combinatorial setup. Transparent throughout, the circular interference fringes are due to variations in thickness. The films all demonstrate radial symmetry, as one would expect from the setup shown in Figure 2. Three systems have been investigated to date: antimony-doped tin oxide (SnO_2:Sb) using $SnCl_4$ and $SbCl_5$, gallium-doped zinc oxide (ZnO:Ga) using diethyl zinc (DEZ) and trimethyl gallium (TMG), and alloy formation in the tin-zinc system using $SnCl_4$ and DEZ. In these studies the dopant was introduced through the center hole (Gas 2), and the base precursor was supplied through the showerhead (Gas 1).

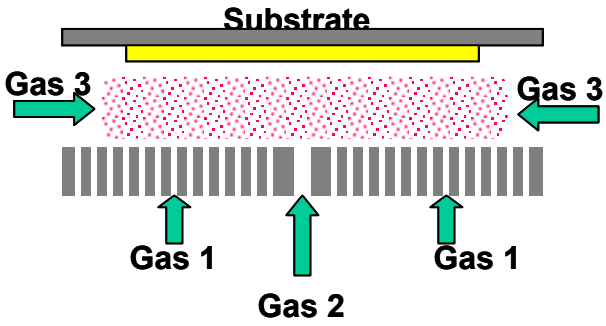

Figure 2. Schematic diagram of the PECVD setup.

The typical bottleneck to any combinatorial approach is property evaluation. For TCOs the primary metrics of interest are transparency and sheet resistance. Visual observation provided convenient screening of transparency, while a four point probe was used for expeditious evaluation of electrical properties with mm resolution. The sheet resistance is a function of both thickness and intrinsic resistivity, $R_s = \rho/t$. The thickness of the film across the glass substrate may vary by up to 50% in these combinatorial syntheses, which is the source of the interference fringes that may be seen in Figure 3. However, the electrical properties can vary by orders of magnitude. Thus, this technique provides an adequate first order assessment of electrical performance. As such a great range of process chemistries were examined with just a handful of deposition experiments. After screening, promising precursors and chemistries are examined in more detail.

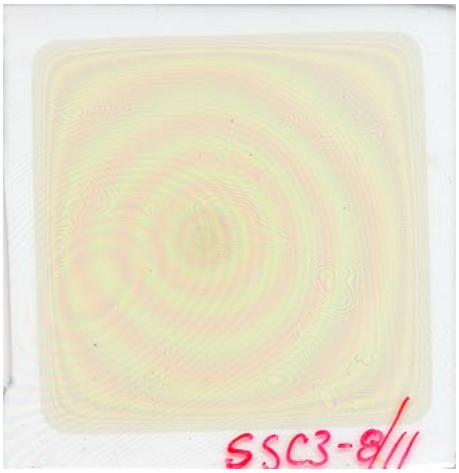

Figure 3. Optical photograph TCO film produced by the combinatorial setup.

The complete set of materials characterization included film, thickness, transmittance, resistivity, Hall mobility, and carrier concentration measurements, crystal structure, and film morphology. Film thickness was accurately measured using a Woolam WVASE32 variable angle spectroscopic ellipsometer. For our measurements the thickness and index of refraction the glass substrate were fixed; a standard file for Corning 7059 glass was used for the substrate index of diffraction. A parameterized Lorentz model was used for the film. Film transmittance was determined by a Cary 5G UV-VIS-NIR spectrophotometer over a wavelength range from 200 – 2500 nm. The values reported here reflect film properties only, since the contributions from the glass substrate were subtracted out during calibration. For visible transmission, the spectra were integrated over the 400-800 nm wavelength range, and the average value is reported. Film resistivity, electron mobility, and carrier concentration were determined using a Bio-Rad HL5500PC Hall Effect Measurement System using the square van der Pauw geometry. Structural measurements were made on several films using X-ray diffraction (XRD) and atomic force microscopy (AFM). XRD patterns were obtained by rotating the sample over a angle of incidence range of 20° to 70° using a Rigaku system. A Digital Instruments Nanoscope III scanning probe microscope was used to examine morphology and quantify surface roughness.

3. Results

The first property that was screened was optical transparency. The results were binary: either the film had excellent transparency (>85%), or it failed catastrophically. Figure 4 contrasts representative photographs of each case. Failure modes included both poor transmission or poor adhesion. The photograph on the left in Figure 4 is an example of a poor film that exhibited both failure modes. If a film had good transparency, it was next screened for electrical conductivity using the four point probe.

Figure 4. Comparison of films with poor (left) and good (right) optical transparency.

The three systems that have been investigated to date: antimony-doped tin oxide (SnO_2:Sb) using $SnCl_4$ and $SbCl_5$, gallium-doped zinc oxide (ZnO:Ga) using diethyl zinc (DEZ) and trimethyl gallium (TMG), and alloy formation in the tin-zinc system using $SnCl_4$ and DEZ. Figure 5 shows radial profiles of sheet resistance obtained for these three strategies. The dopant was highest in the center (r = 0), and in each case the electrical properties of the films at the edge of the substrate (r ~25 mm) were similar to that of undoped material.

In Figure 5 one can see antimony had a dramatic influence on the electrical properties of tin oxide. However the effect was detrimental, increasing the sheet resistance by more than 3 orders of magnitude. Similarly the electrical properties of alloys in the tin-zinc system were inferior to the individual oxides. However we did synthesize the ternary spinel, Zn_2SnO_4, which is also insulating. The most promising results were clearly achieved with gallium doping of zinc, and this system was investigated in more detail as described below.

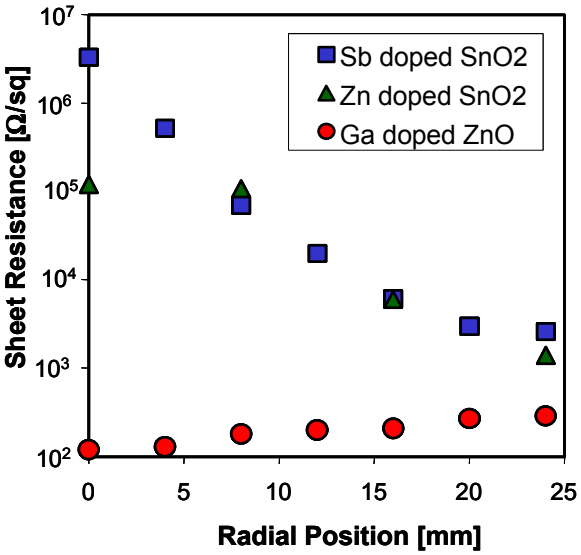

Figure 5. Radial profiles of sheet resistance from different screening experiment .

The structural features of the three films produced by combinatorial experiments are shown in Figures 6- 8. Figure 6 shows the XRD patterns from the tin-antimony systems. The major peak at 2θ ~26.6º is the (110) orientation of SnO_2. The crystallinity is best at the edge, and gradually deteriorates as one progresses towards the center of the film, where high levels of antimony were present. The structural data is consistent with the electrical properties shown in Figure 5.

The selection of dopant has a profound impact on the orientation of the base oxide. Figure 7 shows zinc-doped tin oxide. At the edge the two broad peaks at 34.5º and 52º correspond to the (101) and (211) orientations of tin oxide. Note that the prominent (110) peak that dominated the antimony-doped patterns is not present. At the center of the zinc-doped film the zinc stannate phase (Zn_2SnO_4) is formed, as identified by the (220) peak located at 2θ ~29.5º. The mixed oxide phases were not found to be beneficial for conductivity.

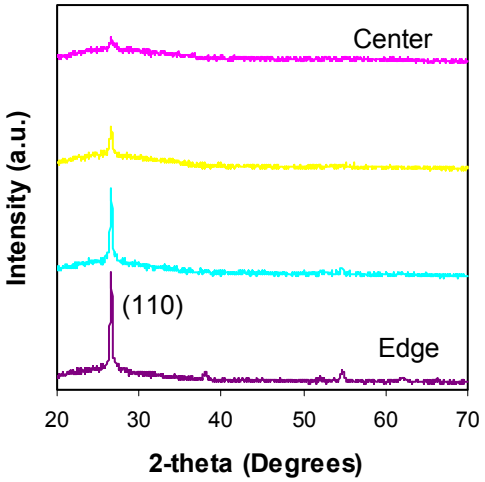

Figure 6. XRD patterns from a Sn-Sb-O film as a function of radial position.

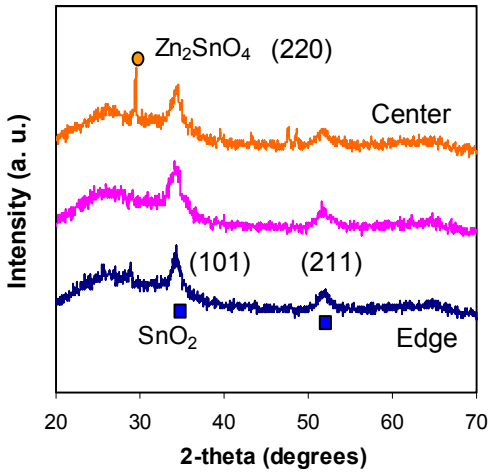

Figure 7. XRD patterns from a Sn-Zn-O film as a function of radial position.

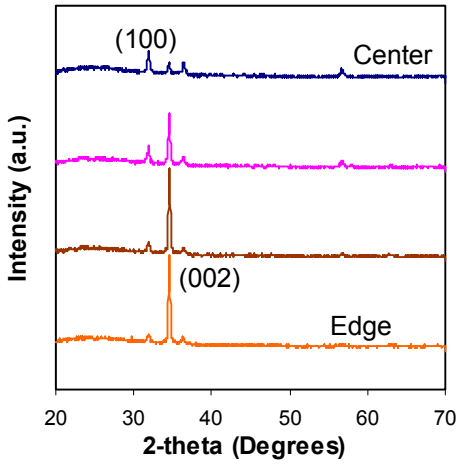

Figure 8. XRD patterns from a Zn-Ga-O film as a function of radial position.

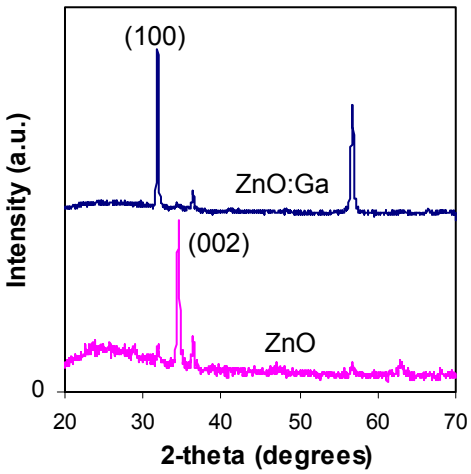

Figure 9. XRD patterns from optimized ZnO and ZnO:Ga films.

The final system examined was gallium-doped zinc oxide. The XRD patterns obtained from the screening experiments are shown in Figure 8. All of the peaks in Figure 8 were positively attributed to zinc oxide. At the edge of the film the ZnO demonstrated a preferred orientation in the (002) direction. As the gallium density was increased towards the center of the film it was observed that (002) at 2θ ~34.5º decreased, and the film shifted towards an (100) orientation identified by the peak at 2θ ~31.9º. As shown in Figure 5 the

inclusion of gallium was beneficial to the electrical conductivity. As such this reaction chemistry was pursued extensively. Films have been grown that span the ZnO – Ga_2O_3 phase space. The DEZ/TMG ratio was found to have a dramatic impact on the plasma chemistry, benefiting both rate and conductivity in a synergistic fashion. Details will be forthcoming [14], however at this point we have obtained commercial caliber TCO films with sheet resistance values ~ 15 Ω/square and visible transmission values > 85%. Figure 9 shows XRD patterns from undoped ZnO and gallium doped ZnO:Ga under optimal conditions. The undoped material is highly oriented in the (200) direction, while the doped film is dominated by the (100) orientation. These are the same features that were identified in the initial screening experiment shown in Figure 8. Work continues using this reactor to screen plasma chemistries for both oxide doping and alloy formation.

4. Conclusions

A system has been described for combinatorial synthesis of oxide films by plasma-enhanced chemical vapor deposition. It has been applied to examine doping and alloy formation for TCO thin films. Simple techniques were used to rapidly screen the optical and electrical performance of TCO films. A number of plasma chemistries were studied. This approach was used to identify the promising nature of diethyl zinc/trimethyl gallium mixtures. This system was further optimized to produce TCO films with very low sheet resistance and high optical transparency. Structural characterization of the films revealed the synthesis of the hard to form zinc stannate phase. It also showed that selection of dopant has a profound influence on the orientation of the base oxide.

This study utilized nitrogen downstream microwave plasma to react with the well-packed self-assembly monolayers (SAMs) of 1-Octadecanethiol ($HS-(CH_2)_{17}-CH_3$, ODT) adsorbed on Au(111) or Ag(111) substrate. Plasma processing was applied to create polarizable groups for subsequent graft copolymerization with diluted acrylic acid (AAc) monomer. The functional group of AAc, O=C-OH, was purposely formed on the plasma-treated surface without obvious damage to the S/metal bonds. SAMs of 11-mercaptoundecanoic acid ($HS-(CH_2)_{10}-COOH$, MUA) on Au or Ag surface was taken as the reference. Collagen type III was subsequently immobilized on these two types of surface under a custom-made well cell system (Fig. 1). Synchrotron soft X-rays combined with high-resolution X-ray Photoelectron Spectroscopy (XPS) were then utilized to characterize the variations of chemical structures. Experimental result has demonstrated that using MUA/Au, Ag as the substrates, collagen immobilization process in wet cell system or in atmospheric environment does not have significant difference, qualitatively or quantitatively. The well cell system is therefore feasible to carry out on-line collagen immobilization process in vacuum (Fig. 2). Similar result has been found as MUA/Au, Ag changed to the plasma-treated ODT/Au, Ag surface with subsequent AAc-grafting, but their collagen immobilized quantities. The most pronounced processes are the participation of oxygen to the plasma-treated ODT surface, highly oxidative groups, including O=C-OH group from AAc, are likely to bind with protein molecules. Overall, this work has completed a combined collagen immobilized process in the wet cell system with on-line XPS characterization. Fundamental studies on reactive mechanism for biomedical applications are perspective.

This work utilizes synchrotron light source to study self-assembled monolayers (SAMs) using thiols ($HS-(CH_2)_{11}CH_3$) as sulfur anchor group from solution onto Au(111) or Ag(111) surface. In this experiment, downstream N_2 microwave plasma is generated by 80W under 1torr; plasma-induced chemistries on the ODT/Au and ODT/Ag surface are studied. Using *Langmuir* probe, the state of electron temperature and the electron (or ionization) density are statically measured; it provides valuable information to adjust fluctuating condition in practical plasma applications. Experimental result has indicated that current downstream plasma provides plasma density of *ca.* $1.38\times10^6 N/cm^3$ or electron temperature of *ca*. 0.46eV; it is regarded as low-density plasma. Surface analyses using synchrotron base high resolution X-ray photoelectron spectroscopy has demonstrated that the alkyl chains are reactive with N_2/O_2 plasma species, the C-O, C-N and C=O bonds are identified (Fig. 1). The N, O-containing structures mostly result from chemical reactivity of free radials in plasma. Sulfur anchor onto Ag(111) surface is much resistant to the reactive plasma species, compared with that onto Au(111) substrate (Fig. 2). The consequences may result in relatively high binding strength of the S/Ag.

Carbon Metal Sulfide by Co-operation Process of Plasma CVD and Sputtering

Md. Abul Kashem, Shinji Goto, Masaki Matushita and Shinzo Morita
Department of Electronics, Graduate School of Engineering, Nagoya University
Nagoya 464-8603, Japan

Abstract
Carbon metal sulfide was synthesized by co-operation process of plasma CVD and sputtering with using CH_4, SF_6 and Ar mixture gas and metal plate discharge electrode. Gold (Au) and copper (Cu) plate was used as a discharge electrode to fabricate carbon gold sulfide (C-Au-S) and carbon cupper sulfide (C-Cu-S) film respectively. The maximum refractive indexes of both C-Au-S and C-Cu-S film were measured as 3.5. The gold and cupper atom in the carbon metal sulfide is considered to be uniformly distributing in the film.

1. Introduction

Photonic crystal is expected to be very important for optical devices like as optical wave-guides and others [1]. Optically transparent and large refractive index material is necessary to fabricate the photonic crystal with a wide photonic band gap. GaAs, SiO_2 and other materials are utilizing to form the crystal [2,3]. However, we are interesting in C-Au-S material for fabrication of photonic crystal, which is expected to be optically transparent and has a large refractive index and process compatibility.

CuS_2 is known as a superconducting material, which was synthesized at a high pressure of 50 kber and high temperature of 800^0K [4,5]. Recently Yahoo reported superconductor of carbon copper sulfide (C-Cu-S) material at a high temperature of 77^0K was applied for a patent to European patent office [6].

Whereas, polymer-metal films are attracted much attention due to their high potential in basic and technological applications. Metal species can dramatically influence on both chemical and physical properties of resultant polymer [7]. Metal atom can be incorporated into the plasma polymerized film matrices in several ways. The co-operation process of plasma CVD and sputtering is a well-known technique to fabricate metal containing carbonaceous film [8,9]. The carbonaceous gold sulfide is also formed by above process with using similar reactor with a parallel plate electrode system, where the upper electrode was connected to RF power source and the lower electrode was grounded with the stainless steel vessel. Therefore the upper electrode causes the development of negative self-bias potential with respect to plasma during the plasma CVD. The upper electrode materials are sputtered under negative self-bias potential condition and the metal containing film can be synthesized. When CH_4 and SF_6 were used as reactive gases, H and F atoms are dissociated from CH_4 and SF_6 by forming HF in the plasma, and then carbon sulfide was synthesized [10]. If the upper electrode material is metal, synthesized carbon metal sulfide can also be deposited on the lower electrode. The purpose of this paper is to study chemical and optical properties of polymer-metal film. An approach leading to the uniform dispersion of metal atom in the film is also discussed in this work.

2. Experimental

Carbon metal sulfide was synthesized by co-operation process of plasma CVD and sputtering with using CH_4, SF_6 and Ar mixture gas and metal plate discharge electrode. Where the discharge was performed by a parallel plate electrode system of 20 cm diameter and 1.5 cm gap distance between the electrodes. The upper electrode was a graphite plate connected to the RF power source at 13.56 MHz and the lower electrode was grounded with the reactor vessel of stainless steel. The graphite plate has a large number of holes to supply the gas uniformly. Sample substrates were set on the lower electrode. The graphite electrode was adopted to

eliminate the contamination, which is induced by sputtering the discharge electrode under negative self-bias potential. However the sputtering phenomenon was utilized to mixing metal atoms in the deposited plasma CVD film of carbon sulfide. Therefore carbon-gold-sulfide (C-Au-S) and carbon-copper-sulfide (C-Cu-S) were synthesized with using gold and copper sheet (50x50 mm^2) on a graphite electrode respectively. Si wafer and glass were used as substrates, where glass substrate was cleaned by ethanol and acetone and Si wafer was immersed into liquid HF for 5 minute to etch off the oxidized layer. The deposition was performed at two different discharge pressures of 0.07 or 0.1 Torr, which was kept constant by controlling evacuation rate. The discharge power and deposition duration were 100 W and 30 min respectively for the each cases. The characterizations of deposited films were performed using thickness and refractive index by ellipsometer, atomic compositions by ESCA apparatus, optical transmittance by spectro-photometer and X-ray diffraction data by X-ray diffraction analyzer.

3. Results and discussions

Thicknesses of the films were ranged from 1000 to 800 nm formed at the pressure of 0.1 and 0.07 Torr. The growth rate was decreased with decreasing the deposition pressure.

The atomic compositions for each sample were evaluated by ESCA measurements after cleaning the surface by Ar sputtering for 1 min. For C-S-Au film, C, S, Au, F and O atoms are identified by the C(1s), S(2p), Au($4f_{5/2}$) , Au($4f_{7/2}$), F(1s) and O(1s) photoelectron-energy chemical shift peak. Table 1 shows atomic compositions and refractive index "n" of C-Au-S film respectively formed at a pressure of 0.1 Torr. Oxygen was not included in the source gas but small amount of oxygen was detected in the films. Probably it will be referred to the contaminated oxygen, which was introduced by the reaction with leaked oxygen gas in the reaction vessel and/or by the oxidization in the air or the adsorption of water. The origin of F atom in the film was referred to the residual F atom, because, SF_6 was not dissociated perfectly by the reaction with hydrogen from methane in the plasma by forming HF [10]. However, the content of the F is negligibly small compare to C, Au and S atom.

For C-Au-S film formed at 0.1 Torr, Au atom content was only 1.9-2.1 atomic %, but the S atom was 8.1-9.5 atomic %, the maximum value of refractive index was measured to be 3.5.

The Au mixing with the film is referred to a sputtering of Au plate on the upper electrode, which is coupled to the RF power supply through a blocking capacitor and a matching circuit. The sputtering is induced by Ar ion bombardment under a negative bias potential, which is formed automatically in this discharge electrode configuration after the discharge initiation [11]. Our interest is a form of Au atom in the film. Previously Martinu reported existence of Au cluster in the film at a large Au content of 25-50 volume %, which was deposited at 10 mTorr. 10 mTorr is one order lower pressure than our experimental condition [11]. In order to increase the Au content, the deposition was performed at a lower pressure of 0.07 Torr. Table 2 shows the atomic compositions of C, S, Au, O and F atom of C-Au-S film formed at 0.07 Torr. Atomic % of Au was increased remarkably due to decreasing deposition. The maximum Au and S atom content were 10.5 and 3.6 atomic %. The maximum refractive index of C-Au-S film was 3.3, however the values are smaller than 3.4-3.5 for the film formed at 0.1 Torr.

Table 3 showed the atomic compositions and refractive indexes of C-Cu-S films formed at a deposition pressure of (a) 0.1 and (b) 0.07 Torr. Atomic % of Cu was increased with decreasing deposition pressure. The refractive index of C-Cu-S film was also decreased for the film of large Cu atomic compositions.

Table.1. Atomic compositions and refractive index of C-Au-S film

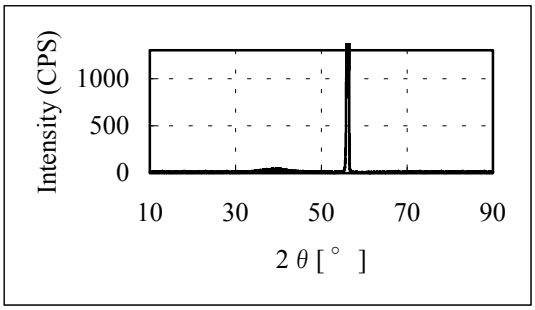
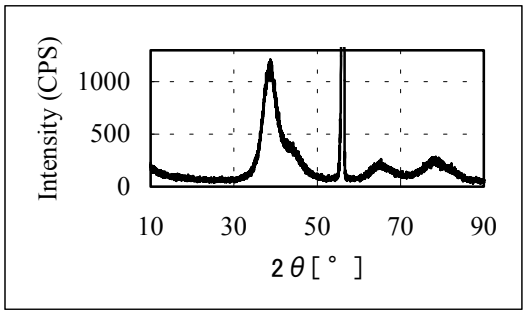
15	87.4	11.3	0.9	0.4	3.5	88.7	6.8	4.0	0.5	2.8

Martinu reported the calculated refractive index for a large Au containing film was only 2.8. Where the Au atoms were existed in the form of cluster. The refractive index of our C-Cu-S film formed at 0.1 Torr was larger than that of Martinue's C-Au film. In order to understand the difference, x-ray diffraction spectra on the C-Au and C-Au-S films were measured as shown in Fig.1 and 2 where the films were formed at 0.1 and 0.07 Torr. The x-ray diffraction spectrum measurements were carried out by using CuKα radiation source. Fig. 1 and 2 represents the x-ray diffraction (XRD) spectra of C-Au and C-Au-S film respectively, where big peak at $2\theta = 56.2^0$ is referred to Si wafer substrate. In Fig. 1, Peak at $2\theta = 38.2^0$ was increased with increasing Au atom density which is referred to Au cluster. Another peaks at $2\theta = 44.4^0$, $2\theta = 64.6^0$ and 77.6^0 in Fig.1(b) were also referred to Au cluster structure. However, there is no peak except the peak of Si wafer in Fig. 2. This means that the Au atom did not form polycrystalline structure in the C-Au-S film. X-ray diffraction spectra of the C-Cu-S film also showed similar tendency with the C-Au-S film.

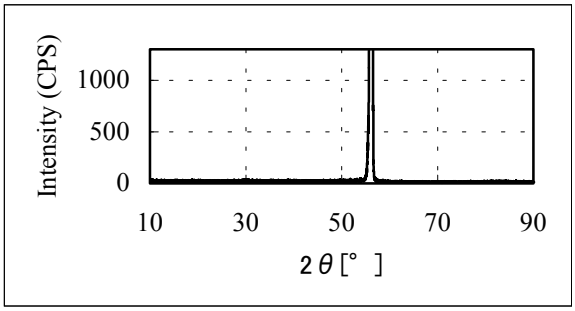


(a)

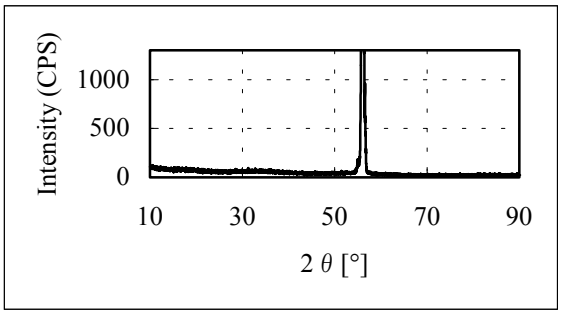


(b)

Fig.1. XRD spectra of C-Au films carried out by CuKα radiation source; (a) Pressure 0.1 Torr, Au: 5.5 %, (b) Pressure 0.07 Torr, Au: 12.3 %.



(a)

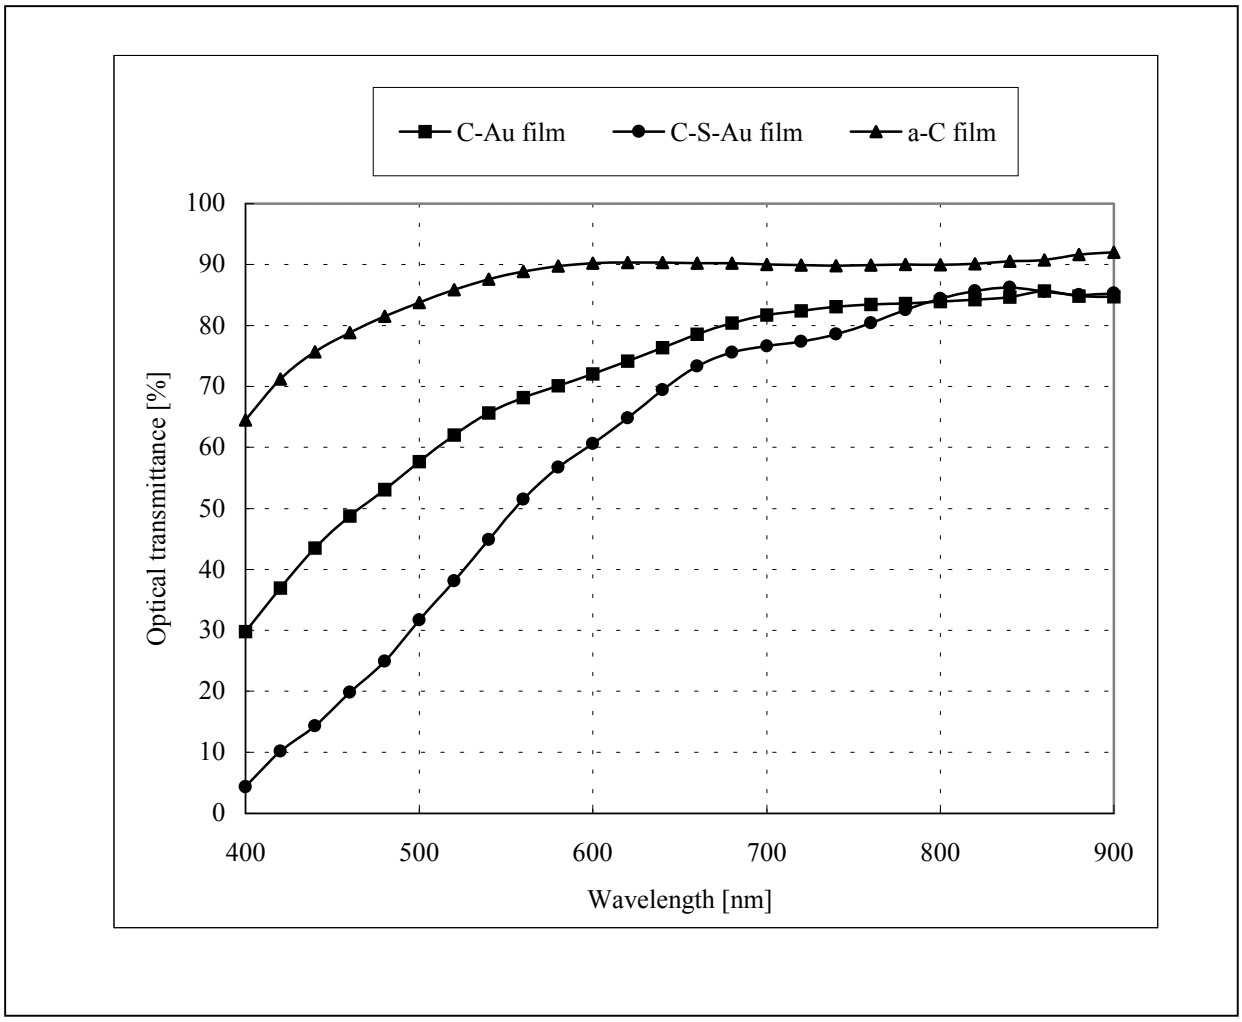


(b)

Fig. 2. XRD pattern of C-S-Au film carried out by CuKα radiation source; (a) Pressure 0.1 Torr, Au: 2.1 % (b) Pressure 0.07 Torr, Au: 10.5 %.

It is well known that the metallic atom have a tendency to form a cluster or crystallized structure when the metallic atom content is increased more than a few atomic % and the x-ray diffraction spectra shows broad peak usually [12]. It is also known that Au atom forms bonds with sulfur [13]. Therefore the Au atom in the C-Au-S film is considered to distribute uniformly by reacting with sulfur at a high Au atom content [14]. As shown in Table 1-3, the refractive indexes of metal containing film were decreased at a higher metal containing films. The smaller refractive index for the film of larger metal content is inconsistent properties on the carbon-metal-sulfide film. A possible explanation is referred to conductive properties of molecular structure like as C-Au-S or C-Cu-S. In the conductive molecules, each atom cannot contribute on the refractive index independently because the electronic polarizability of each atom is muffled by the electron cloud in the conductive molecules like as metallic cluster.

For the large refractive index properties of carbon-metal-sulfide film, fabrication of photonic crystal is more profitable applications. Figure 3 shows optical transmittance of C-Au, C-Au-S and a-C film. At a shorter wavelength region, the transmittance was decreased with sulfur and Au content. By optimizing transmittance and refractive index, carbon-metal-sulfide can be used as photonic crystal dielectrics.



4. Conclusion

C-Au-S and C-Cu-S film were formed by plasma CVD and sputtering. By decreasing deposition pressure, atomic % of Au and Cu in the film was increased. Larger refractive index was realized for a few atomic % of Au and Cu containing film. Au atom forms cluster structure when atomic % of Au increased more than a few atomic % in the C-Au film, but it was atomically distributed in the carbon metal sulfide film even at higher atomic % of Au, where chemical bond between S and metal atom was expected to be formed. The film is transparent in a visible light wavelength range but it shows an insulating property because the metal content is still small.

5. Acknowledgement

The works were performed partly at the Center of Co-operative Research in Advance Science and Technology (CCRAST), Nagoya University. The refractive index and optical transmittance was measured at Yasuda and Tsunashima laboratory respectively. We express our thanks to the respective persons at the laboratories.

Investigation of excited species in a carbon ablation plume in nitrogen gas environment

M.A. Bratescu, D. Yamaoka, Y. Sakai, Y. Suda and H. Sugawara

Hokkaido University, Division of Electronics and Information Engineering, Sapporo, 060-8628, Japan
maria@eng.hokudai.ac.jp

Abstract

In this work we investigate a carbon plasma plume produced by laser ablation of a graphite target in nitrogen gas environment. The XPS analysis of film deposited was explained in connection with the spatial distribution and velocities of excited particles (C, N, C_2 and CN) in the expanding plasma. The chemical reactions in the ablation plume in the vicinity of the Si substrate could be understood using spatial distributions of atoms, molecules and radicals.

1. Introduction

A laser ablation method for thin film deposition offers many advantages compared with traditional deposition techniques, due to the possibility to control the impurities and to deposit high refractory elements as well as different compounds with superior properties produced by chemical reaction.

In the last decade, interest in carbon nitrides was increased because this crystalline phase exhibits interesting properties like hardness combined with high elasticity [1]. Understanding of the mechanism of CN_x film formation could improve the film quality. The film quality depends on laser-induced plasma parameters, i.e. the velocity, temperature, number density of ablated species in the plume and chemical composition, and could be controlled if we measure these data. The quality of CN_x film is determined by the type of bonding between nitrogen and carbon atoms in connection with the plasma composition and dynamics of various species in the plume [2, 3].

2. Experimental set-up

Fig.1 shows the experimental set-up along with the arrangement of laser beams from excimer laser and diode laser (DL) on a target. A pulsed laser deposition (PLD) chamber is almost the same as the one given in Ref. [4]. An ArF excimer laser beam

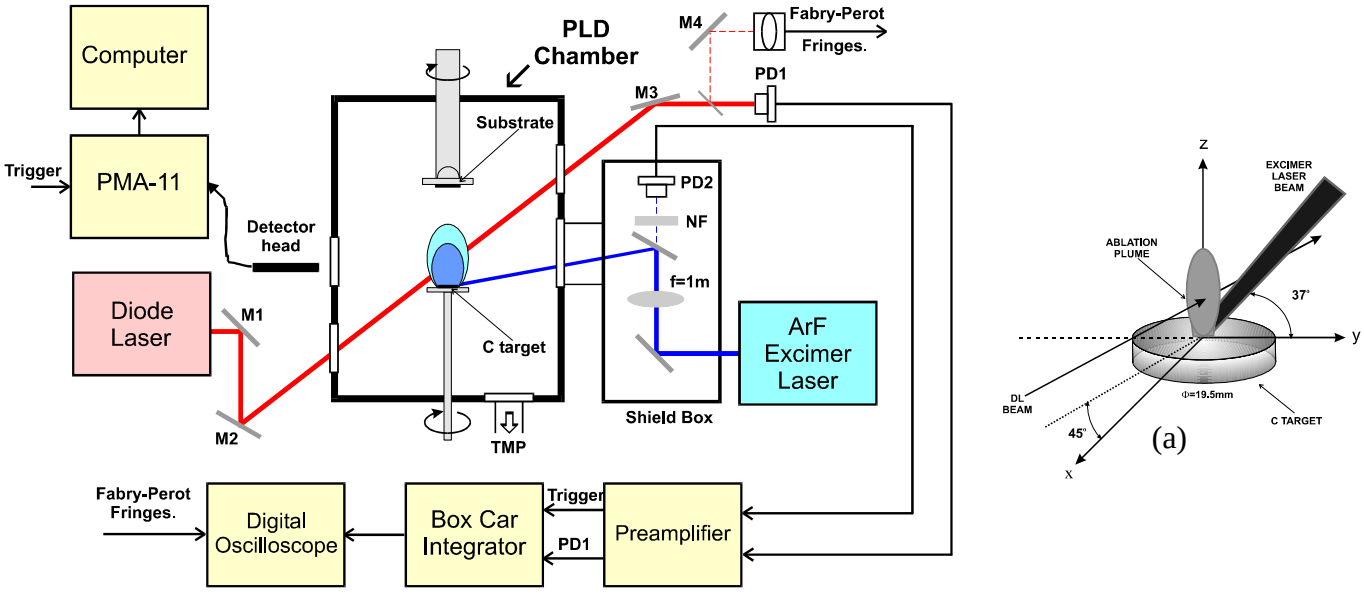

Fig. 1. Experimental set-up for carbon ablation plume diagnostics by laser absorption spectroscopy and by emission spectroscopy

(Lambda Physik COMPex205) was focused onto a crystal graphite target at an incidence angle of 53°. The pulse duration of the laser is 20 ns and the fluence is adjustable in the range of $E = 2 – 4.7$ J/cm^2.

A set-up for the laser absorption diagnostics of the number densities of excited atoms, C($3^1P_1^o$) and N($3^4P_{5/2}$) in a plume was realized with two distinct diode lasers (DL; Hitachi 8325G; 40 mW maximum output with the 830 nm central wavelength at 25°C). DL were tuned to the resonance absorption of C ($3^1P_1^0 \rightarrow 3^1S_0$) at λ_0^C = 833.7 nm or tuned to the resonance absorption of N ($3^4P_{5/2} \rightarrow 3^4P_{5/2}^0$) at λ_0^N = 821.859 nm. To acquire the absorption signal of excited atoms in the ablation plume we used a digital oscilloscope. The signal to noise ratio (*S/N*) of the absorption signals was about 10^3. The temporal absorption signal detected by PD1 simultaneously recorded with temporal signal of excimer laser light emission aquired by PD2 offers information about decay and expansion velocity of the excited atom in the plume.

DL beam was focused at different positions *z* from the target surface (see Fig. 1(a)). The spatial resolution of the DL beam was about 0.05 mm. A boxcar integrator (Standford SRS250) that is connected with an oscilloscope in acquisition mode to record the data accomplishes integration of the absorption signal of C and N by PD1.

When DL was scanned with a frequency of ~ 5 mHz over the resonance wavelength of the atomic transition, the time-integrated absorption signal was simultaneously recorded with the Fabry – Perot fringes of the 1.5 GHz free spectral range, in order to measure the line width of the absorption line ($\Delta\nu$).

The emission spectrum of the ablation plume was spectrally analyzed in a visible range between 300 and 800 nm using a Hamamatsu PMA-11 (Photodiode Multi-channel Analyzer). The PMA detector head was set in a (*y, z*) plane parallel with the (*y, z*) plane of the plume (fig. 1(a)). An XPS study characterizes the N and C bonds on the film deposited in different experimental conditions.

The nitrogen pressure (*p*) was varied from 0.1 to 13 Torr, the absorption signal and emission spectrum were measured at the vertical distance (*z*) from the carbon target surface from 0 to 25 mm. A Si(100) substrate was set in the plume at different distances *z* from the target. Measurements were done with and without substrate.

3. Results and discussion

From the absorption signal amplitudes the excited nitrogen N($3^4P_{5/2}$) number density (N_N) or the excited carbon C($3^1P_1^o$) number density (N_C) were calculated following the relation [4]:

$$N = \frac{8\pi^2 g_1}{g_2} \cdot \frac{\Delta\nu \cdot \ln\left(\frac{I_0(0)}{I_0(L)}\right)}{\lambda_0^2 \cdot A_{21} \cdot L} \qquad (1)$$

where $I_0(L)$ represents the DL intensity after passing through the plume, $I_0(0)$ the incident DL beam intensity, when the DL wavelength is fixed at the resonance absorption value λ_0 (λ_0^C or λ_0^N), $g_{1,2}$ are the corresponding statistical weights of the excited atom levels, A_{21} is the Einstein spontaneous emission coefficient, L is the mean absorption length through the plasma plume. $\Delta\nu$ is the absorption line width.

We measured the density of C excited atoms on $3^1P_1^o$ level at 7.5 eV and N excited atoms on $3^4P_{5/2}$ level at 10.3 eV in the carbon ablation plume in the vicinity of a Si(100) substrate introduced at different distances from the target surface. The presence of the substrate perturbs the density of nitrogen and carbon, as can be seen in Fig. 2. In the presence of substrate, an interesting effect, i.e. the increase of N_N with ~ 70%, was observed. This can be explained by a secondary plume excitation at the substrate surface, which may indicate film sputtering, and consequently an increasing of excited nitrogen in this region [3].

The N_2 pressure *p* can control densities of different species in different regions of the plume. The maximum number density of N($3^4P_{5/2}$) was $N_N = 7\times10^{10}$ cm^{-3} for p = 13 Torr at z = 1.8 mm (Fig. 3). Generally N_N increases as *p* increases and decreases with *z* if $z > 4$ mm. N_C was ~ 10^{11} cm^{-3} at z = 2 mm in vacuum, and decreases as *p* increases. In order to compare different results the laser fluence was kept at about E = 3.2 Jcm^{-2}.

From the delay (τ) of the absorption signal of the excited atom in the ablation plume, relative to the excimer laser light pulse, the mean expansion velocity of C($3^1P_1^o$) and N($3^4P_{5/2}$) atoms was calculated. Fig. 4 shows the delay of nitrogen atoms (τ_N) in the plume in different nitrogen pressures p = 1, 5 and 10 Torr.

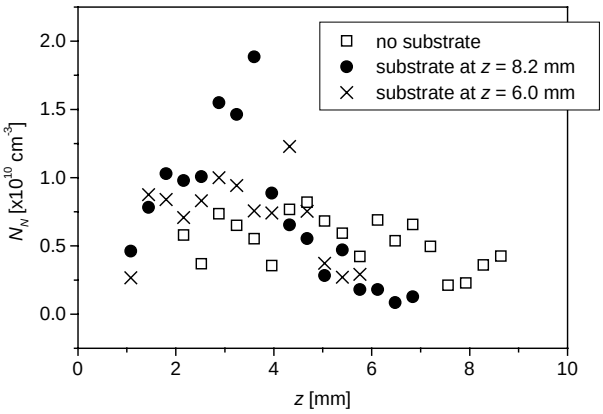

Fig. 2. N_N dependence on z with and without substrate, p = 1 Torr, E = 3.1 J/cm^2.

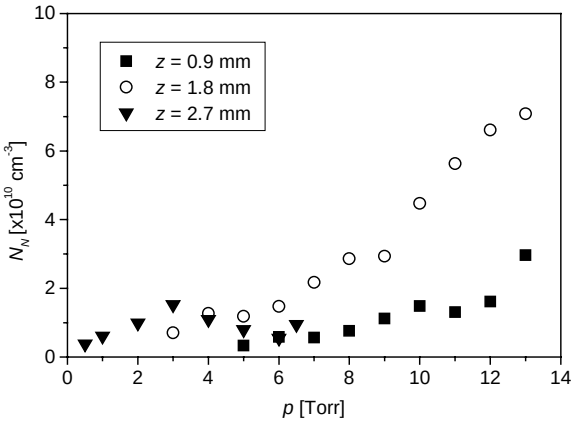

Fig. 3. N_N dependence on p for different z and E = 3.25 J/cm^2.

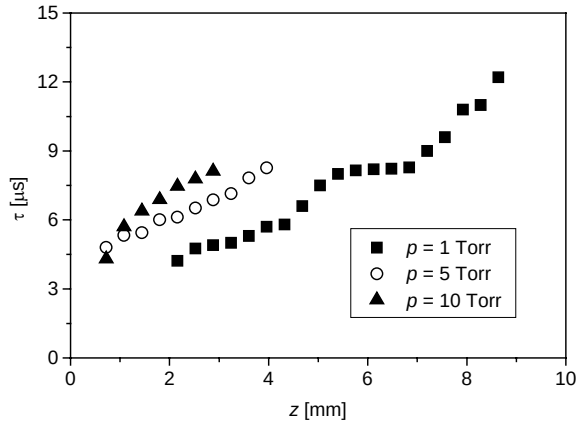

Fig. 4. τ_N dependence on distance in the ablation plume for different pressures p and E = 3.2 J/cm^2.

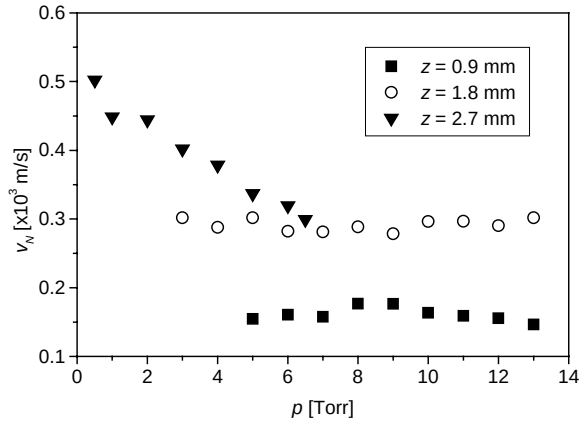

Fig. 5. v_N dependence on pressure for different z and E = 3.25 J/cm^2.

Space and pressure dependences of N($3^4P_{5/2}$) velocity (v_N) can explain expansion, collision and chemical reaction between N and C atoms. The N($3^4P_{5/2}$) velocity near the target surface was ~ 5×10^4 cm s^{-1}, while C($3^1P_1^o$) velocity was ~ 10^6cm s^{-1}, because carbon atoms were ablated from the target surface by ArF laser. The N($3^4P_{5/2}$) velocity near the target surface (~ 1 mm) was higher than that at z=~ 3 mm, and the N($3^4P_{5/2}$) velocity depended strongly on the pressure (Fig. 5). In the vicinity of the target surface the ablated particles have high kinetic energies and collide with the buffer gas molecules and atoms. Therefore N($3^4P_{5/2}$) atoms have higher velocity in this region than far. The excited atoms N($3^4P_{5/2}$) may be produced in the plume by N_2 dissociation and excitation. The N($3^4P_{5/2}$) velocity was slightly dependent on p for z > 2 mm. The N($3^4P_{5/2}$) velocity decreased with z due to plume expansion.

Expansion of laser-induced plasma could be described by a drag model for N($3^4P_{5/2}$) at p = 1 Torr, just after ablation, for z < 6 mm. For z > 6 mm, reaction between N and C atoms occurs [2] and this model is no longer valid.

In the vicinity of the surface substrate τ_N is almost constant as can be seen in Fig. 6. We can explain that by the release of nitrogen atoms from the substrate surface (as is shown in Fig. 2) produces an increased density of nitrogen atoms in this region (as is shown in Fig. 2).

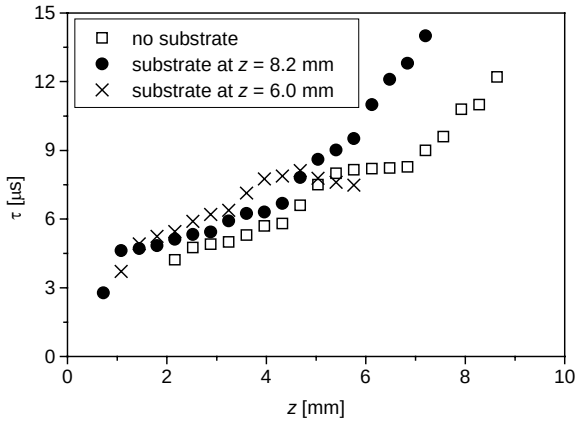

Fig.6. τ_N dependence on z in the ablation plume with and without substrate when p = 1 Torr and E = 3.1 J/cm^2.

CN radical molecular bands dominate the emission spectrum of the carbon ablation plume in nitrogen atmosphere. C_2 and N_2 molecules emission bands have intensities about five times less than CN emission bands intensities (Fig. 7).

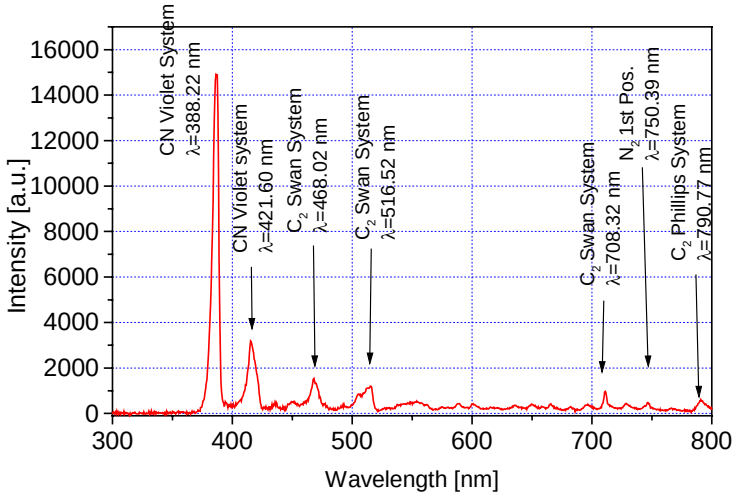

Fig. 7. Typical emission spectrum of C ablation plume in p = 5 Torr of nitrogen, E = 3.5 J/cm^2.

The highest density of C_2 excited molecule on $d^3\Pi_g$ level at 3 eV, produced by direct ablation from target surface is at z ~ 5 mm far from the target surface at pressures in the range of p = 1 – 5 Torr, where high density of N_2 excited molecule on $B^3\Pi_g$ level at 8 eV and CN radical on $B^2\Sigma$ at 3.2 eV could be found (Fig. 8). The appearance of CN radical excited on $B^2\Sigma$ level could be explained by the following chemical reactions in the plume:

$$C_2\left(d^3\Pi_g\right)\rightarrow C\left(^3P\right)+C\left(^3P\right)$$
$$N_2\left(B^3\Pi_g\right)\rightarrow N\left(^4S^0\right)+N\left(^2D^0\right)$$
$$C\left(^3P\right)+N\left(^4S^0\right)\rightarrow CN\left(B^2\Sigma\right)$$
$$C\left(^3P\right)+N\left(^2D^0\right)\rightarrow CN\left(B^2\Sigma\right)$$

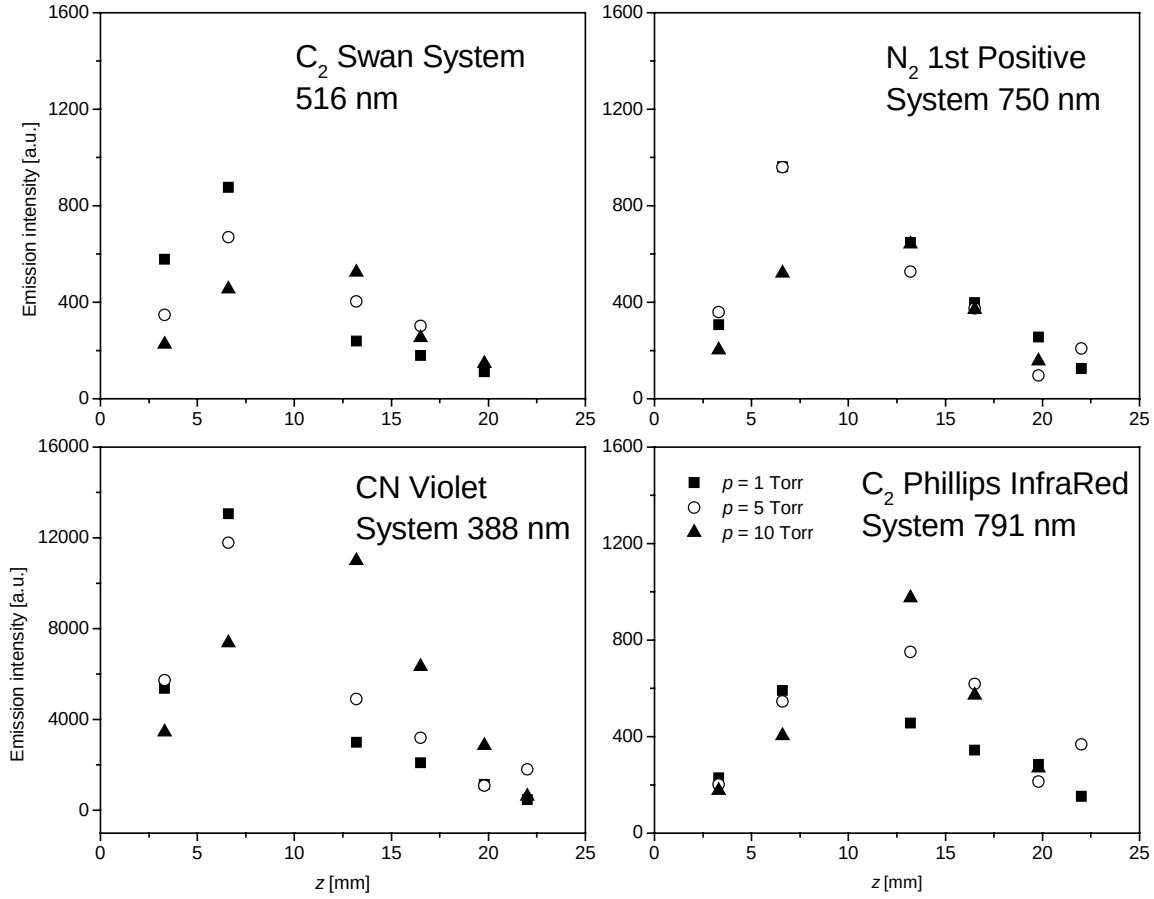

Fig. 8. Emission intensities of C_2 molecule at 516 nm (Swan system) and at 791 nm (Phillips infrared system), N_2 molecule at 750 nm (First positive system) and CN radical at 388 nm (Violet system), for different pressures in the carbon ablation plume (E = 4.5 J/cm^2)

C_2 molecular band at 791 nm (Phillips system) (Fig. 8), corresponding to the electronic level $b^1\Pi_u$ at 8 eV, has the maximum emission intensity at z = 13 mm in the plasma plume as explained by recombination of carbon atoms on excited electronic levels followed by de-excitation [5]. But laser absorption spectroscopy measurements of C($3^1P_1^o$) and N($3^4P_{5/2}$) densities shows a maximum at z = 2 mm far from the target surface due to the high electron density and electron temperature in this region [4]. Emission intensities in spectrum are higher if excimer laser fluence is higher because electron energy and temperature increase with E.

The results of XPS analysis of the film deposited on Si(100) substrate introduced in the carbon ablation plume are presented in Table I. The de-convolution of XPS spectra of carbon films deposited in nitrogen atmosphere in different conditions shows two main components: first component at 284.1 eV (line width ~ 1.0 eV) corresponding to

Table I

p [Torr]	z [mm]	A_{sp3}/A_{sp2}
1	6	0.046
1	10	1.439
1	15	0.512
10^{-8}	6	0.715
10	6	1.814

sp^2 carbon atoms (graphite) and the second component at 285.5 eV (line width ~ 1.1 eV) corresponding to sp^3 carbon atoms (diamond). A small intensity peak was also obtained by de-convolution of the XPS spectra, at 286.5 eV and corresponds to CO, which could be present on the film surface [6]. These results show that a high density on C_2 and CN is necessary to obtain high content of sp^3C by carbon ablation in nitrogen gas. In vacuum, sp^3C content relative to sp^2C content can be compared with the composition in the film obtained in p = 1 Torr nitrogen and z = 15 mm , but the substrate should be placed close to the target surface at z = 6 mm.

4. Conclusions

Optical methods, emission and laser absorption spectroscopy, are powerful tools for diagnostics of physical and chemical processes in plasmas used for thin films deposition.

The high content of sp^3C on the Si substrate set in the carbon ablation plume at 6 mm from the target surface, in 10 Torr nitrogen pressure, was explained by the high molecular (C_2, N_2, CN) density in this region. Close to the target surface the electron density and temperature are high and maximum values of atomic nitrogen and carbon were obtained. Here dissociation and excitation processes have higher probability than far to the target where de-excitation, diffusion and recombination processes become dominant.

Abstract
Wire arc spray is a process to produce coatings and forms structures through the deposition of metal droplets. Droplets are then produced at the arc heated wires end, they are eventually atomized and accelerated towards the substrate by the gas stream. Our research focuses on the investigation of the wire arc spray process trough an understanding of the interaction between the process parameters and the coating properties using the frequency and amplitude spectrums. Since arc fluctuations may have a strong effect on droplets formation and therefore on coating properties, such fluctuations were recorded by measuring arc voltages synchronized with current and luminosity signals. Some relationships between arc characteristics and coating properties can be pointed out.

Introduction
Electrical arc spraying with dual wires is an economical coating process which finds different industrial applications today. With this process, a cold gas jet across the arc atomizes and drives the molten droplets from the electrode tips [1]. Then, the melting behaviour of the consumable wire electrodes, giving rise to the formation of the droplets, is influenced by the arc stability which in turn is dependent on the input parameters, i.e. gas flow rate, current intensity and voltage [2]. It is now proved that arc fluctuations are due to the periodic removal of molten droplets from the wire tips by the atomizing stream. Because the dynamic forces of the atomizing air stream act on the arc, these fluctuations are characteristic of the wire arc spraying process and that leads to the formation of droplets with different sizes. That determines finally the coatings properties [3]. In this study, arc spraying of alumina wires is considered in order to establish correlations between input parameters and coating properties such as porosity, microstructure and adhesion in relation with the arc characterization too. Thus, the TAFA 9000^{TM} gun is used for these experiments; the air flow rates and current intensities were changed in order to understand the fundamental mechanisms of the wire arc spraying process. Concerning the arc characterization, the technique involves the recording of time resolved signals, i.e. arc voltage, current and luminosity. This way, the corresponding arc voltage across the consumable electrodes and the current have been simultaneously recorded by an oscilloscope as the luminous fluctuations of the jet have been recorded using a system including a photodiode and connected to the oscilloscope. After the process, the data processing has been performed using a specific application developed via Labview software. These fluctuations have been analyzed using the Fourier Transform for determining the frequency of the maximum peak as well as its corresponding amplitude. Because the turbulence can be estimated by the waveforms of the voltage fluctuations and the velocity of the droplets can be estimated by the frequency and the amplitude spectrum of the voltage fluctuations [4], the voltage spectral peak and voltage standard deviation have been correlated with operating conditions. That denotes the different phenomena occurring during this process. Finally, these analyses are combined with quantitative materials characterization to study the effect of each input parameter on the coating properties.

Experimental procedures

1. Operating conditions
The schematic of the TAFA 9000^{TM} arc spray system is represented in figure 1. On the TAFA equipment, voltage and current intensity can be adjusted independently and the current is directly related to wire feed rate. As a consequence, the feedstock increases with the current increase. For all the experiments, the voltage was fixed at 30V, compressed air was used as the atomizing gas, the flow rates were between 90 and 120 m^3/h and the current intensity was fixed at 100, 150 and 200 A. Alumina wires, referenced TAFA01T, were used as spraying materials and contain 99,5% in weight aluminium.

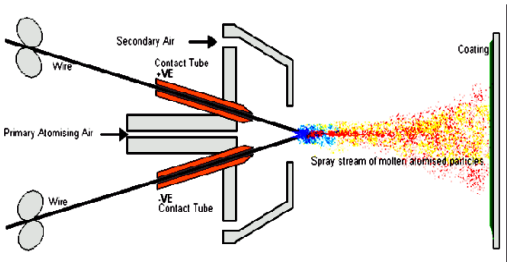

Figure 1 : Diagram of the wire arc spray process

2. Process diagnostics

During the spray, the corresponding arc voltage and current between the two consumable electrodes have been simultaneously recorded with an oscilloscope. The arc voltage is directly measured at the electrical connexions of the gun as the current intensity is measured using a Hall effect clip. The detection of light fluctuations of the jet was ensured by a PIN type photodiode. This photodiode with a 0,5 mm² surface was placed at the gun exit and connected to the oscilloscope as shown in the schematic of the experimental set up given in figure 2. Finally, the time resolved voltage signals were recorded giving directly the relationships with the intensity by the Ohm law.

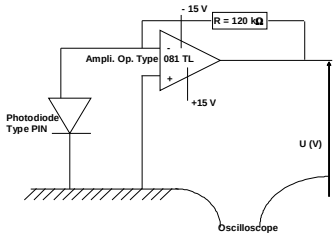

Figure 2 : Schematic of the set up used for the luminosity signals

For all these diagnostic methods, measurements are in real time. Time resolved traces are obtained using a digital oscilloscope connected to a PC operating with Labview® Software. During the process, the signals can be observed on the PC monitor control. Each signal contain 2500 points whatever the sampling rate. These signals can be real time processed and stored in the workstation in order to proceed to the future treatment of the data.

3. Data acquisition and treatment

All the data are then processed to find correlations between the arc parameters and the input conditions. For each set of operating conditions, the same data are collected several times in order to obtain an average value and a standard deviation of the characteristics of the wire arc spray process. Labview® software can conveniently perform Fourier Transforms from which the power and amplitude spectra can be determined.

4. Coatings analysis

The wire arc spray was fixed onto a ABB IRB4400^{TM} robot to ensure repeatable kinetic motion to build coatings. Coatings have been built onto a 316L steel plates, with dimensions of 2,5 cm diameter and 1 cm thick. Specimens were fixed on a drum with 380 mm in diameter, rotating with a speed 60 turns per minute. The transverse speed was 10 mm/s while the stand off distance was 250 mm. For each set of operating parameters, the same 300 µm thickness was obtained for the coating. For the resulting coatings, microstructure, porosity and adhesion have been determined. Optical micrographs are obtained on polished cross sections, using a reflected light microscopy. Image analysis are performed to determine porosity of polished coating cross sections. The analysis of grey levels enables to distinguish the different features of coating microstructures (Graftek^{TM} software). Average results have been obtained by measuring porosity at three random locations for each sample. The coating adhesion is also determined using the traction test method.

Results on arc characteristics

1.Time resolved measurements

Figures 3 and 4 represent the typical signals corresponding to real time measurements of arc voltage, current and luminosity obtained with a 90 m^3/h air flow rate and a 150 A current intensity.

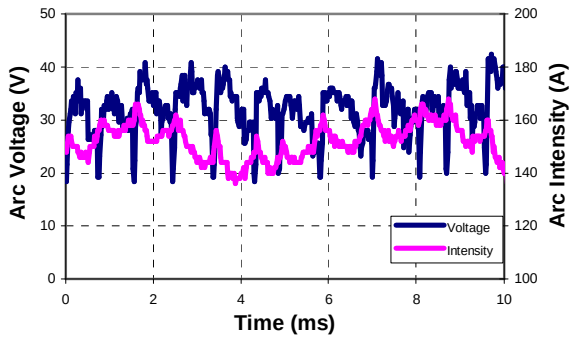

Figure 3 : Voltage and current fluctuations with a 90 m^3/h air flow rate and 150 A current intensity

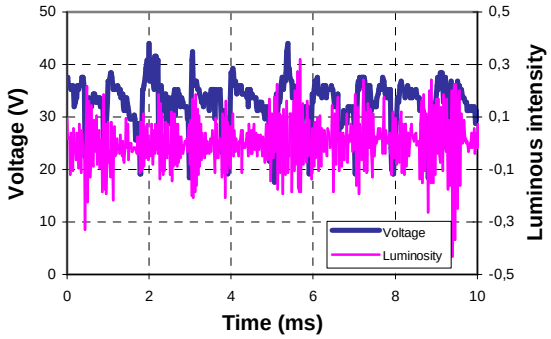

Figure 4 : Voltage and luminosity fluctuations with a 90 m^3/h flow rate and 150 A current intensity

One can notice that the arc voltage shows important and fast fluctuations, the current and the light display strong fluctuations as well. A repeating event is observed in the three signals : a sharp dip in the voltage occurs about every millisecond and is associated to a sudden variation in current and luminosity. Moreover, as it can be observed an important dip in luminous fluctuations directly related to voltage variation, some very rapid and small fluctuations follow this event, which are not present in voltage or current signals. According to what has been observed by Sheard & Co [5], it is assumed that this event is a key point in the droplet formation process. It can be assumed too that the voltage dip corresponds to the situation when the distance between the wire tips is a minimum value leading finally to the formation of large molten metal droplets. The molten wire tips are blown away by the compressed atomizing air flow leading to the renewed formation of the arc. It appears that at a certain instant, the compressed atomizing gas stream extends the arc voltage beyond a value which can not be sustained by the power supply. At this point the arc extinguishes and reignites after the advancing consumable wire tips make contact, leading initially to a high current flow and rapid melting of the consumable wire tips. This process leads to periodic fluctuations of the arc voltage, the arc current and the droplet size as shown previously and is also dependent of the input parameters. For example, in figure 5, time resolved signals of arc voltage are presented for the two different air flow rates, 90 m^3/h and 115 m^3/h.
It can be observed that the shape of the time resolved measurements is influenced by the experimental parameters. When the flow rate increases, the dips in voltage become in large number as their amplitudes become smaller. According to the phenomena involving in the wire arc spray process, the arc flow removes the droplets from the arc region and pushes the arc to the arc gun exit. Smaller droplets are then produced at higher flow rate of the atomizing gas because increasing the atomizing gas flow rate breaks the molten droplets more finely during the flight [6]. These results suggest that higher velocities of the atomizing gas can be correlated firstly with higher frequencies of the voltage fluctuations corresponding to smaller particle sizes and secondly with smaller amplitudes characteristic of more stable arcs. Then, the distance between the consumable wire and the arc nozzle determines the fluid velocity in the arc region.

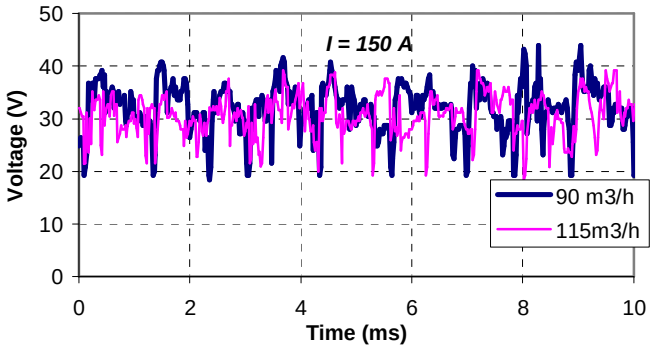

Figure 5 : Voltage fluctuations with a 90 m^3/h and a 115 m^3/h air flow rate

2. Power spectrum analysis

A typical example of the results of power spectrum obtained by Fourier Transform is given in figure 7. These results of respectively voltage, current and luminosity power spectrum correspond to 115 m^3/h air flow rate and a 200 A current intensity input parameters.

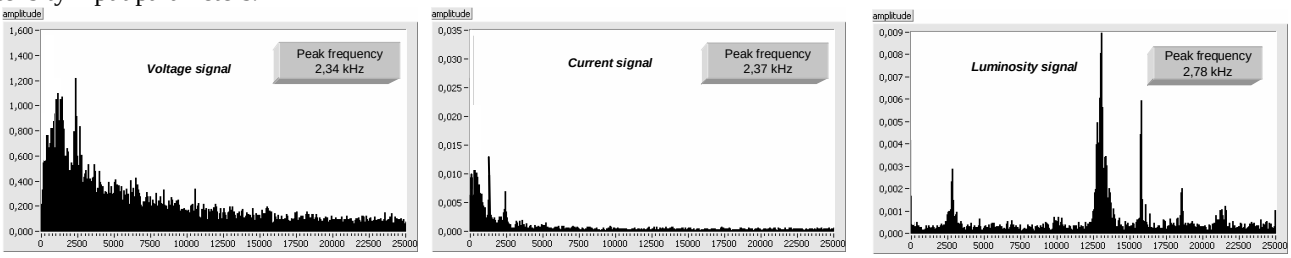

Figure 7 : Power spectrum of voltage, current and luminosity fluctuations at 115 m^3/h and I = 200 A

Very well defined peaks occur in all figures. The voltage waveforms indicate a clear periodicity at a dominant frequency, about 2,5 kHz in this case. This peak is detected in the power spectrum of current and light too but do not correspond to their maximum peak. Moreover, a group of peaks appears in the power spectrum of the light at much higher frequencies, around 12,5 kHz for the maximum peak frequency which do not appear in the voltage and current spectra. It can be thought that these peaks can be associated with a large scale turbulence of light due to numerous and different size particles which are produced using arc spray process [2].In order to point out the difference of the turbulence of the jet, the comparison of the power spectrum obtained with two different air flow rates is given in figure 8. As the peaks are really well defined in the case of the highest flow rate, a much larger dispersion appears when the flow rate is minimum. Because the light is due to the particles emission, that indicates why the particles produced by the spray are much more homogeneous in size with a high flow rate.

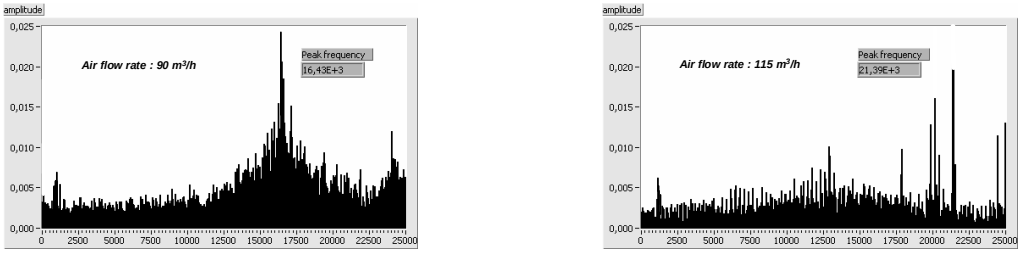

Figure 8 : Power spectrum of luminosity fluctuations at I = 150 A for 90 and 115 m^3/h

3. Average values of frequency and amplitude versus the input parameters

Several acquisitions of data have been performed for each set of input parameters. Figure 9 corresponds to the average value and to the standard deviation of the maximum peak frequency detected in voltage and intensity power spectrum in the case of a 150 A current intensity and air flow rates varying from 90 m^3/h to 115 m^3/h. Figure 10 gives the evolution of the corresponding amplitudes of voltage and intensity for the same input conditions.

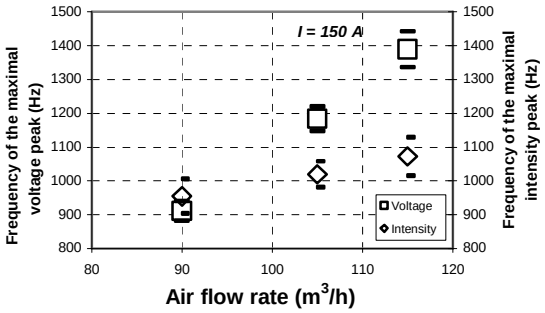

Figure 9 : Evolution of the maximum peak frequency of voltage and intensity versus air flow rate.

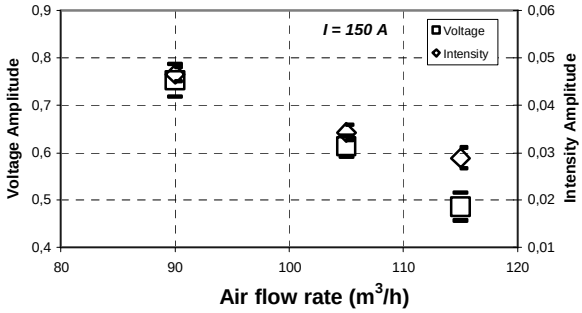

Figure 10 : Amplitude of voltage and intensity corresponding to the maximum peak detected versus air flow rate.

In figure 9, it can be noted an increase in voltage and intensity frequency respectively from 900 Hz to 1400 Hz and from 984 Hz to 1064 Hz versus the flow rate. As a consequence, the characteristic frequency of the voltage fluctuations corresponding to a periodic shortening of the arcing gap, higher frequencies with lower amplitudes can be associated to the generation of particles in a large number with smaller diameters. Then, it can be deduced that higher velocities and less turbulence in the wire arc spray process exist leading to more stable arcs when the flow rate increases. It is confirmed by the results obtained on the particles characteristics through the DPV measurements showing an important decrease in the standard deviation of in-flight particle characteristics as the flow rate increases [7]. More homogeneous arcs in terms of particles size and velocity are produced in such a case. Concerning the evolution of voltage and intensity frequencies and amplitudes, figures 11 and 12, corresponding to a variation of the current intensity from 100 to 200 A for a constant 115 m^3/h air flow rate, the rise of current intensity leads to increase the frequency of the maximum peak and to decrease the amplitude of this peak.

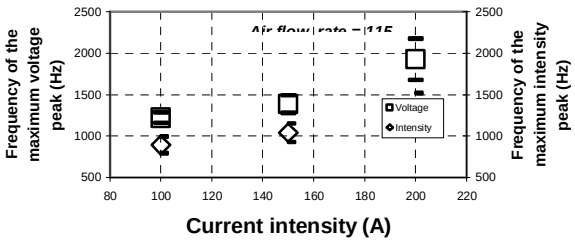

Figure11 : Evolution of the maximum peak frequency of voltage and intensity versus current intensity.

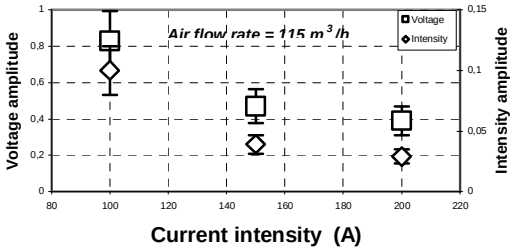

Figure 12 : Amplitude of voltage and intensity corresponding to the maximum peak detected versus current intensity.

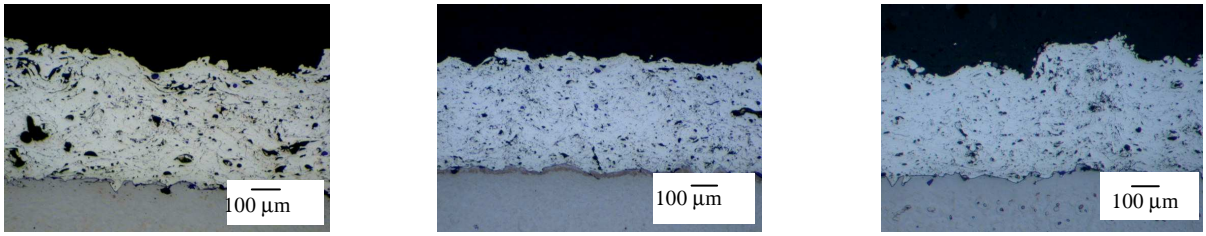
Results on coating properties

1. Coating microstructures

Figure 13 presents the micrographs of the cross section of aluminium coatings elaborated with a 100A current intensity and three different air flow rates : 90, 105 and 115 m^3/h



90 m^3/h and 100A *105 m^3/h and 100A* *115 m^3/h and 100A*

Figure 13 : Evolution of coating microstructures versus air flow rate

When the flow rate is changed, the coating lamellae are very different in terms of thickness and pores. According to the evolution of arc characteristics, higher frequencies with smaller amplitudes can be observed which can be associated to smaller particles with higher velocity when increasing the flow rate. Then, the quicker shearing of molten particles, the thinner lamellae. In such a case, all parameters contribute to a better accommodation of the particles to each other at the impact leading finally to smaller dimensions of the pores in the deposit [8]. Because the deformation on the impacted particles becomes better, the coating density increases.

2. Coating porosity

The determination of the coating porosity has been performed using images analysis obtained on the cross section of the deposits. The treatment, realized by Scion Image software, corresponds to the threshold presented in figure 14. The variations detected on the luminosity are due to the presence of pores (dark zone) and to the presence of oxydes (light zone).

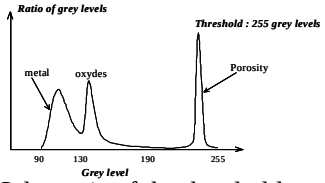


Figure 14 : Schematic of the threshold treatment

The evolution of the porosity versus the flow rates is given in figure 15.

A decrease of the coating porosity from 2,5 to 0,5 % can be noted when the flow rate increases. Then, higher air flow rates lead to lower coating porosity which can be attributed to higher impact particle velocities as well as smaller particle sizes. Then, higher gas velocities result in higher frequencies and smaller amplitudes of the voltage and in smaller molten droplets leading to coatings with lower porosity. Finally, lower turbulence levels at the electrode tips result in more periodic waveforms with a lower frequency content and in a lower porosity of the coatings.

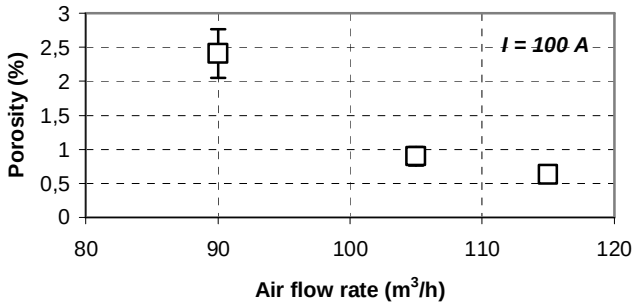

Figure 15 : Evolution of the coating porosity versus air flow rate

3. Coating adhesion

The adhesion measurements have been performed using ESCOTET^{TM}50 machine system following the ASTM C 663-79 standard. The 25mm diameter specimens are arranged like presented in figure 16 in order to avoid the shearing phenomena during the tests. The FM100 glue has been used due to its high mechanical resistance characteristic.

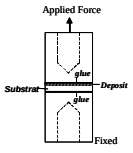

Figure 16 : Experimental set up for adhesion measurements

Figure 17 corresponds to the evolution of the coating adhesion in function of the air flow rate.

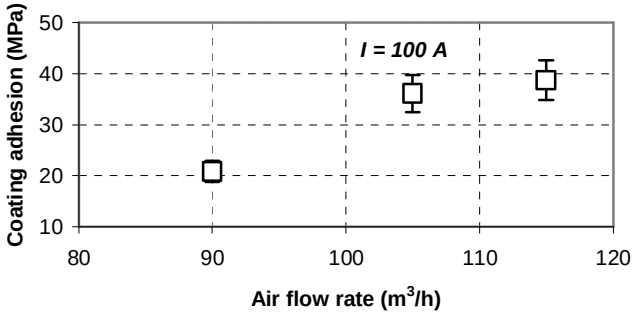

Figure 17 : Evolution of the coating adhesion versus air flow rate

In accordance with the previous results, the coating adhesion increases with the flow rate mainly due to the fact that higher velocity resulting in higher frequency and smaller amplitude of the voltage fluctuations leads to smaller molten droplets. Then, less turbulence at the electrode tips resulting in periodic waveforms of the voltage fluctuations leads to a lower porosity of the coatings in such a case.

Conclusion

Aluminium wires have been sprayed with air using the TAFA^{TM} 9000 gun. Arc fluctuations due to periodic narrowing and widening of the gap between the electrode tips have been investigated in order to point out the effects on the droplet formation therefore on the coating properties such as microstructure, porosity and adhesion. This way, arc characteristics i.e. voltage, intensity and luminosity were recorded using an oscilloscope for different input conditions. Accordingly, time resolved signals of voltage, intensity and luminosity fluctuations have been analyzed by Fast Fourier Transform and by amplitude analysis. The obtained results show that increasing the flow rate of the atomizing gas leads to increase frequency and to decrease amplitude of the voltage fluctuations. The same evolution was observed with the current intensity. As a consequence, the arc stability increases and a more homogeneous jet in terms of particle size is formed. In relation with the arc characteristics, the frequency and the amplitude as well as the waveform of the arc fluctuations are regarded as important parameters for the indication of the droplet characteristics : when increasing the flow rate, the higher the frequency, the smaller the amplitude corresponding finally to smaller particles with a higher velocity. Concerning the coating properties, a strong influence of air flow rates can be noted on the microstructure, porosity and adhesion. When increasing the flow rate, the coating becomes more dense which could be related to the particles size and velocity. In such a case, the porosity decreases due to a better accommodation of the particles between themselves at the impact. The coatings with a lower porosity are produced by the smaller droplets. Finally, velocity and turbulence are important functions for the coatings properties. In wire arc spray process, an increase in air flow rate leads to increase the homogeneity of the coating because the peaks of arc characteristics are well defined.

Non-equilibrium chemistry of Li atoms in laser-produced plasmas from ablation of $LiNbO_3$ crystals in gas atmospheres

F. J. Gordillo-Vázquez[1] and C. N. Afonso[1]

[1] *Instituto de Óptica (CSIC), Serrano 121, 28006 Madrid, Spain*

A precise knowledge of the non-equilibrium chemistry of the laser-produced plasmas typically found in Pulsed Laser Deposition (PLD) experiments is important for having a complete understanding of the growth process of thin solid films of technological interest. In particular, the homogeneous (plasma) and heterogeneous (plasma-surface) reactions partially control the plasma composition and, consequently, that of the growing films.

The use of PLD has proven to be one of the most successful techniques in growing complex oxide materials [1]. However, the thin films of $LiNbO_3$ (used in optoelectronic and photonic applications) deposited by laser ablation of $LiNbO_3$ in vacuum or low pressure (< 1 Torr) atmospheres are often found Li deficient [2]. However, when the films are grown at a pressure of about 1 Torr, independently of the nature of the used ambient atmosphere (either inert, Ar, or reactive, O_2), the $LiNbO_3$ films grow stoichiometrically [3]. Although the latter result has been understood in the frame of the blast-wave model [3], which describes the plasma expansion in a gas environment at a sufficiently high pressure, the detailed kinetics together with the species concentrations in the laser-produced plasma have not been modeled up to date.

The objective of this contribution is to develop a collisional-radiative model to determine the influence of Ar and O_2 atmospheres (at 1 Torr) on the electron-driven kinetics of ground and excited Li atoms (up to the 3^2D level) within the laser-generated plasma. It is found that whereas the Li atom population densities in the plasma produced in gas are, in general, higher than those found in vacuum, they are similar in vacuum and Ar close to the substrate, though lower than in O_2. In addition, it is suggested that the reabsorption of radiation by the plasma is more important within O_2 than in Ar since the absorber (ground Li) concentration is higher in O_2 environments. In this regard, a very reasonable qualitative agreement is found when comparing the Li I-670.8 nm spectral line emission intensity predicted by the model with that obtained experimentally in Ar and O_2 atmospheres.

Finally, the kinetic model proposed here provides quantitative information on the relative loss and gain electron-driven mechanisms contributing to, respectively, populate and depopulate the different energy levels of Li atoms present in the laser-produced plasmas of interest here.

Abstract
In this paper, a study of the PECVD of close-to-stoechiometry silicon oxide is proposed with a special focus on how the material structures itself. Indeed, depending on the operating conditions, a wide range of material properties can be achieved even for films close to stoechiometry. Based on physico-chemical analysis results (wet etch-rate, ellipsometry, XPS, FTIR, Raman spectroscopy) and on modeling results, the origin of such differences for almost similar materials is inferred from a structural point of view.

1. Introduction

Silicon oxide is a material of major importance for the microelectronics industry and is commonly used as an intermetal or interlayer dielectric. Among the various processes available to deposit silicon dioxide thin films, PECVD processes offer the possibility to operate at low temperature which is of great interest when the substrate is thermosensitive. Nevertheless, these processes have some drawbacks and often do not allow the reproducibility of thermal CVD. The properties of the material deposited using PECVD are changeable for a given process and changes from one process to the other as testify by the various results available in the literature. In this paper dedicated to films having a composition close to that of silica, i. e. SiO_2, a study of the structural properties of PECVD silicon oxide using various physico-chemical analysis tools is first proposed. More particularly, these properties are shown to depend on the position in the reactor. A mass transfer model has been used to establish which are the film precursors as a function of this position and so to propose relationships between the precursors and the film structure. At the end of this paper, the interest of helium dilution of the reactive gas mixture is also discussed and put in perspective with the help of the preceding analysis.

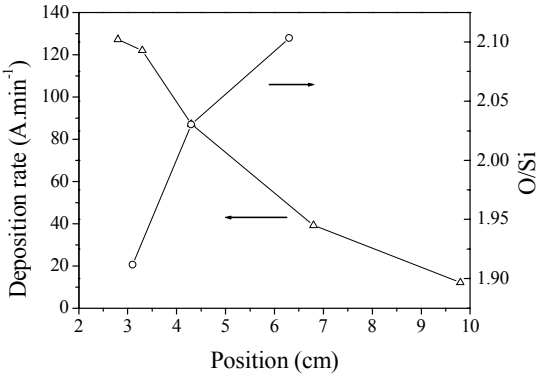

Figure 1 : Deposition rate and O/Si ratio as a function of the position

2. Experimental

Silicon oxide was deposited in a parallel-plate RF (13.56 MHz) reactor with the gas entrance on one end of the inter-electrode space and the exit on the opposite end. The utilized gas was a mixture of 1 % silane diluted in excess N_2O. With such a low dilution, the obtained films were close to the stoechiometry of silica in the reference condition (P= 0.5 Torr, T = 503 K) used throughout this paper as shown in figure 1. The O/Si ratio was measured by XPS. At the moderate power used under this reference condition (5 $mW.cm^{-2}$), an important decrease of the deposition rate is observed (figure 1).

3. Film analysis

Several analyses were carried out on our films. A special attention was dedicated to FTIR results. The spectra of our films presented the usual peaks of amorphous silica with some variations depending on the position in the reactor. First, Si-OH bonds were present in our films, but no Si-H bonds. Isolated Si-OH and associated ones can be distinguished as it was done by Theil [1]. In our reference conditions, it can be seen in figure 2 that the amount of associated OH decreases from the entrance of the reactor to its exit while that of isolated OH remains steady. Meanwhile, as shown in figure 3, the position of the peak corresponding to the stretching of Si-O-Si bridges changed from 1063 down to 1050 cm^{-1} and the Full Width at Half Maximum (FWHM) increases. The position of this peak is representative of the mean Si-O-Si angle and its FWHM of the angle distribution :the higher the position, the higher the angle and the higher the FWHM, the wider the

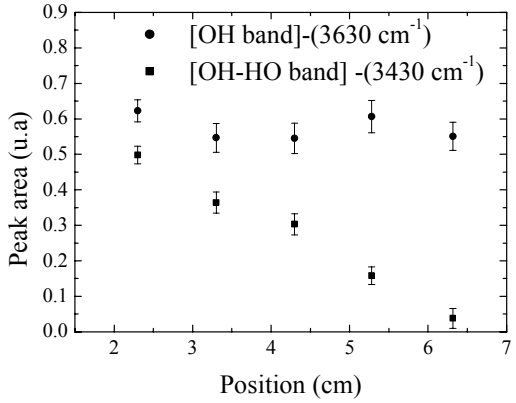

Figure 2 : Normalized area of isolated and associated OH IR peak as a function of position

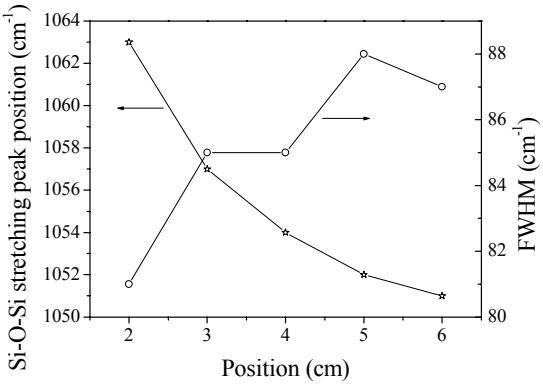

Figure 3 : Position of the IR Si-O-Si stretching peak and its FWHM as a function of position

distribution. First, it should be underlined that the normal position of this stretching peak in thermal silica is 1075 cm^{-1}. Therefore, the mean angle in our films is lower than in thermal silica and thus probably more constrained. The evolution along the position in the reactor of the energy of the IR peak is a signature of a lowering of this mean angle. Remarking that this decrease of the mean angle is accompanied by a similar evolution of the amount of associated OH makes us think that the material at the entrance is relaxed by water reaction with the more constrained bridges as suggested by Theil [1] and Brunet-Bruneau [2].

We suppose that these relaxation reactions open the more constrained Si-O-Si bridges to give birth to associated Si-OH bonds, which can explain that associated OH are present at the positions where the Si-O-Si mean angle is the highest. Such a process was also evidenced by Theil [1]. This hypothesis is supported by ageing experiments at the ambiant atmosphere which show that the films containing numerous associated OH are more prone to hydrolysis than the others. This leads us to think that the formation of associated OH is a post-venting effect.Then, it could be anticipated that before this ex-situ action of water, the mean angle of the film at the entrance and thus their peak position might be lower than the one we actually measured. The evolution of the FWHM is also coherent with the hypothesis of a relaxation by water. Indeed, the film which are the more relaxed have the narrower angle distribution.

At this stage, considering the preceding explanations, it can be quite surprising that the films around 6 cm are almost inert toward water, since they have a low mean angle and therefore Si-O-Si bridges which are potentially reactive. Nevertheless, these films have a wet etch-rate close to that of thermal silica and much lower than that of the films at the entrance (figure 4), which can result from a high compactness for these low-angle films. Several other facts come as a support to a higher compactness of these films. First, their refractive index is higher than the index of thermal silica (1.461 at 630 nm) as presented in figure 4. Besides, Raman spectroscopy showed that the behaviour of our films can be compared to pressure-densified silica. This matter is described more thoroughly in [3]. As far as the refractive index is concerned, most of our films have a refractive index higher than that of thermal silica, but in the case of the associated-OH containing films, this could be the result of a dense matrix containing pores partially filled by water, just as in [2]. Although none of our films when observed by TEM at a nanometric resolution presented pores and although no water was detected by FTIR, we think that subnanometric voids 'containing' the associated Si-OH bonds could give our films similar refractive properties as in [2].

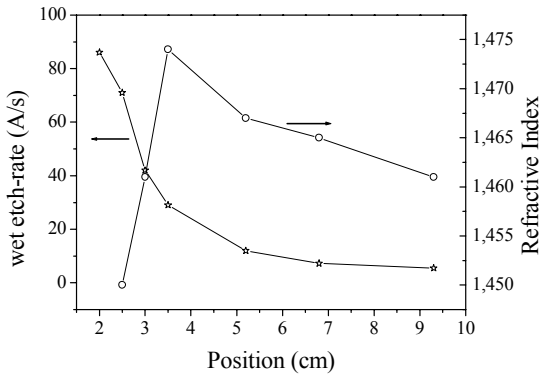

Figure 4 : wet-etch rate and refractive index as a function of the position

Back to the films which are almost associated-OH free, althought they are close to the stoechiometry of thermal silica, when compared to this last material, these films have a lower mean angle for the Si-O-Si bridges, the Si-O-Si angle distribution is larger (the

FWHM of thermal silica is about 65 cm^{-1}), their matrix seems to be denser and their wet etch-rate is comparable. The caracteristics of the Si-O-Si stretching peak of these films had already been observed in irradiated silica films [4, 5]. More particularly, Douillard and Duraud [5] attributed the evolution of this peak to a structural rearrangement process occuring during the ion implantation in silica which they studied. The energetic bombardment results in the creation of defects, mainly E' center and non-bridging oxygen centers. When reaching a sufficient amount of defects, new Si-O-Si bonds form. In fact, a steady state is reached between the defect creation and the rearrangement process which finally lead to a stable material with constrained bond. This process is called metamictization.

In the light of these information, we will now propose a film growth mechanism which could explain the observed structural properties of our films.

4. Film growth mechanism

It is well-known that in PECVD processes, the precursor species to the deposit are radical species. Moerover, at the low operating temperature used in this work, the sticking species have a reduced mobility and react with their immediate neighborood. In these conditions, defects can easily appear during the film growth. We just have explained how the presence of defects can lead to a deposit rearrangement which could explain the structure of the films around 6 cm. Nevertheless, the question of why the film structural properties are so changeable as a function of the position remains an open case. In order to answer this question, a mass transfer model coupled with an electrical model was used. The chosen chemical mechanism is quite simple and is described in details in [6]. In a nutshell, SiH_4 is mainly decomposed by $O\cdot$ which results from the electronic impact on N_2O. Afterwards, a radical propagation occurs and leads to SiH_xO species. This model allowed us to explain the drastic decrease of the deposition rate (figure 1) which is a direct consequence of the silane consumption along the flow. Indeed, the sticking silicon-containing radical are short-living species, which induces that the deposition rate at a given position is rather directly linked to the local silane concentration. Beyond that, in figure 5, the contributions of the different precursors to the film are given as a function of the position in the reactor. The analysis of this graph in combination with that of the deposition rate is a path toward the understanding of the obtained different structures. In the entrance zone, the silyl radical contributes substantially to the deposit and a large part of the oxidation occurs at the film surface. Moreover, at this place, the deposition rate is rather high, which implies that the time left to a deposited species to find a neighbor in a correct configuration is limited. In this condition, it can be anticipated that the defects can easily appear, may be rearrange in highly constrained bond and also that these defects and constrained bonds can be rapidly buried. Such a film can then be subjected to the water post-venting effect described above. When getting further in the reactor, the precursors become more and more oxided and the deposition rate decreases. As a consequence, the precursors which already contains an Si-O bond, have more time once sticked to the surface and before their burial to be oxided by gas phase $O\cdot$ or to react with other gas phase species. Then, the amount of defects is probably lower than in the entrance zone and gives place to a metamictization-like process. It should be also noticed here that due to the silane consumption, the $O\cdot$ concentration increases along the flow direction and so does the surface oxidation of the growing film. Besides, The higher contribution of SiH_3 in the entrance zone can also explain the lower O/Si ratio measured there (figure 1).

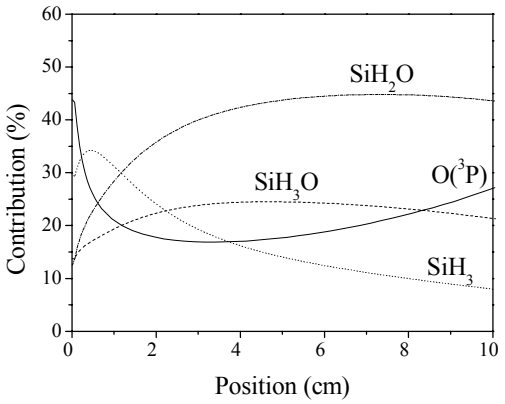

Figure 5 : Contribution of the deposit precursors as a function of position

Let us add a few words on SiH_2O which plays a major part in the deposition process, at least with the chemical mechanism we proposed. This species is known to react easily with itself with almost no activation barrier to form a species containing a $(Si\text{-}O)_2$ ring [7]. It is then possible that whether in the gas phase or directly on the surface SiH_2O could be at the origin of small $(Si\text{-}O)_n$ rings containing constrained Si-O-Si bridges in the material.

Based on the consideration given above on how the film structures itself, new conditions which could lead to associated OH free and stable material will now be studied. More particularly, our interest will focus on a

process where the SiH_4/N_2O mixture is diluted in helium. Indeed, diluting the reactive gas mixture results in a lowering of the active species concentration and by the way, of the deposition rate.

5. Effect of helium dilution

For these experiments, the pressure was set at 1 Torr and the N_2O and SiH_4 flow rates were kept at the same values as before. The dilution rate by helium was taken at 75 %. The consequence of this dilution was not only to decrease the reactant concentration but also to increase the gas velocity between the two electrodes. Both these effects reduces the deposition rate heterogeneity observed in figure 1. This is logical since silane is less rapidly consumed in the reactor. Also, the helium dilution lowers the wet etch-rate and increases the refractive index, probably due to an increase of the film compactness. More interestingly, the position of the Si-O-Si stretching peak stays about 1050 cm^{-1}, with a very low amount of associated Si-OH bonds. One can rapidly think that this is a direct consequence of the low deposition rate which let the time to the depositing species to be oxided. Nevertheless, we can wonder if the benefit of the helium dilution only comes from the lowering of the deposition rate. To investigate this, a film containing associated OH was exposed to a pure He plasma. This exposure results in the disappearance of the associated OH and to a shift the Si-O-Si stretching peak from 1063 cm^{-1} to 1055 cm^{-1}. This behavior could correspond to the formation of Si-O-Si bonds sharper than in thermal silica upon water departure from the film. Indeed, He plasma are known to produce energetic UV photons which could be at the origin of these modifications of the films. Obviously, such a process can also take place while the film is growing in SiH_4/N_2O/He plasma. Furthermore, two other experiments we carried out consisted in depositing films at 623 K in a SiH_4/N_2O mixture and in a diluted mixture, while keeping all the other parameters constant. Both the obtained films are under the detection limit of associated OH, which shows that at this temperature a thermal release of water happen. However, whereas the Si-O-Si stretching peak position in the diluted mixture is 1055 cm^{-1}, its position in the other case is 1065 cm^{-1}, closer to its position in thermal silica. This clearly shows that the water removal and the Si-O-Si bridge closure action of He is quite different from a thermal relaxation. This might explain why Batey [8] observed that when silicon oxide is deposited from He diluted plasma its electrical properties are improved as compared to process with no dilution. In fact, the helium dilution leads to structural modifications of the films.

6. Conclusion

In this work, the structural properties of silicon oxide films deposited using PECVD were studied using various physico-chemical analysis tools. Our interest mainly focused on films where the O/Si ratio is close to 2. It was shown that depending on the position in the parallel-plate PECVD reactor used for this work the properties of our films changed. The analysis of FTIR results and ageing experiments showed that the post-venting effect of water affect the amount of associated OH present in the films. It is inferred that the PECVD growth of the films lead to constrained Si-O-Si bridges which can interact with atmospheric water to form associated Si-OH bonds. Nevertheless, the films which have the highest O/Si ratio (around 2) are insensitive to water although their mean Si-O-Si angle is lower than in thermal silica. We proposed that during a film growth under plasma conditions, the growing films are subjected to a metamictization-like process. Metamictization is a rearrangement process which is caused by the defect induced when silica is irradiated. As the properties of our films are variable depending on the position in the reactor, a mass transfer model was used to identified the change of the deposit-precursor species with the position. This brought to the fore the role of the deposition rate on the film structure as well as that of the oxidation level of the precursor. The best conditions to obtain a stable material is to operate at a low deposition rate in order to let it the time to grow properly, which is easier when Si-O bonds already exist in the sticking species and to be oxided by O gas phase radicals. The effect of helium dilution have also been studied, since it led to low deposition rate. The structure of the films were actually interesting, and we found that this results not only from the low deposition rate but also from a possible action of the UV photons emitted by the helium-containing plasma. Future work will be dedicated to the electrical properties of our films essentially for those which are water-inert and more particularly for those obtained under helium dilution of the gas mixture. Besides, models will also be developed to reach a further understanding of the chemistry of the process, once again, especially under helium dilution.

RF plasma deposition of SiO_x and a-C:H as barrier coatings on polymers

D. Hegemann, H. Brunner, C. Oehr

Fraunhofer Institute for Interfacial Engineering and Biotechnology IGB, Nobelstr. 12, 70569 Stuttgart, Germany; www.igb.fraunhofer.de

Abstract

RF discharges of O_2/HMDSO and CH_4 were used to deposit SiO_x and a-C:H barrier coatings on PET foils using a symmetrical and an asymmetrical plasma reactor, respectively. Both processes were found to be radical-dominated since the reaction parameter *W*/*F* determines the film growth. Surface processes driven by ion bombardement result in rival ablation/deposition processes leading to a broadened interphase on PET. This inorganic/organic interphase was found to posses no barrier properties, whereas inorganic/inorganic interphases in two-layer systems of SiO_x/a-C:H contribute to the barrier properties.

1. Introduction

Siloxane- or hydrocarbon-based plasma films have been extensively studied, for example as protective or barrier coatings [1-4]. By using organic precursors like hexamethyldisiloxane (HMDSO) or methane (CH_4), the film properties can be varied from polymer-like to quartz- and diamond-like, respectively, at near room temperature. Thus, these films can be deposited on polymers for example with different wetting properties or gas permeation rates [5, 6]. However, optimized deposition conditions often depend strongly on the reactor geometry used. In particular for barrier coatings on polymers, surface roughness, adhesion, internal stresses, flexibility, and transparency – beside the permeation rates – must be considered. Barrier properties of flexible packagings are required for example in food packaging, for solar modules, LEDs and OLEDs.
Therefore, this work investigates the plasma deposition process of SiO_x and a-C:H films regarding deposition rate, plasma potentials, and film properties, using compact plasma reactors which can be scaled up. Moreover, the "interphase" formation (broadening of the substrate/coating transition) of inorganic, hard coatings on soft polymers during the first stage of film growth is examined. While this interphase enhances the adhesion of PECVD-derived coatings on polymers compared to PVD coatings, it seems to limit the critical film thickness needed for good barrier qualities. Therefore, OTR and WVTR values are compared for single layers and two-layer coatings of SiO_x and a-C:H on PET foils.

2. Experimental

Capacitively coupled RF discharges (13.56 MHz) with plane parallel electrode configuration were used in this study to deposit barrier coatings on polymers. For SiO_x films, a symmetrical reactor with an electrode size of 29 x 39 cm^2 was developed, whereas for the deposition of a-C:H films, an asymmetrical plasma reactor with an electrode size of 24 x 39 cm^2 was used to attain an additional bias voltage. Both reactors have a gas feeding system inside the top electrode to generate a uniform, vertical gas flow towards the bottom electrode where a homogeneous deposition over large areas is obtained. The lower (substrate) electrode is powered. A V/I probe (ENI Model 1065) measures applied voltage, current and phase angle.
The precursor hexamethyldisiloxane (HMDSO), $C_6H_{18}OSi_2$, used as obtained by FLUKA was thermo-stabilized and vaporized outside the apparatus. Oxygen as carrier gas is mixed with HMDSO and fed together into the plasma chamber. Power was varied between 50 and 400 W, HMDSO flow between 10 and 100 sccm, O_2 flow between 50 and 220 sccm and pressure between 10 and 35 Pa. SiO_x films were deposited near room temperature.
For the deposition of a-C:H coatings, methane, CH_4, was used as precursor alone. The parameter set was varied between 50 and 500 W for power, 20 and 100 sccm for CH_4 flow, and 10 and 35 Pa for pressure. Due to ion bombardement, the substrate temperature raised during deposition, but was always below 80° C.
To determine the deposition rate, Si wafers (100) were coated. The mass deposition is obtained by weighing the substrates immediately before and after the coating procedure (Sartorius Balance H110; precision:

0.1 mg). It was proven, that the deposition rate depends linearly on time. Additionally, thickness is measured on film edges via atomic force microscopy (PSI Autoprobe CP). Film density is calculated from mass and volume of the coatings. As substrate material 23 µm thick PET foils (Hostaphan RD) were coated.
X-ray photoelectron spectroscopy (KRATOS Axis Ultra) with Mg k_α excitation and a 110 µm spot and Auger electron spectroscopy (PHI 545C) were used to determine the chemical composition. For the depth profiles the samples were sputtered with 5 keV Ar ions at an incident angle of 90°.
Oxygen (OTR) and water vapor transmission rates (WVTR) were measured by Mocon Oxtran and Permatran devices at 23° C, 50% r.h. (DIN 53380-3) and 23° C, 85% to 0% r.h. (DIN 53122-1), respectively.

By measuring the excitation voltage V_0, bias potential V_{bias} and average thickness of the plasma sheath d_{sh} in front of the electrodes, the potential distribution can be given (Fig. 1) by using a simple model described in the literature [7, 8].

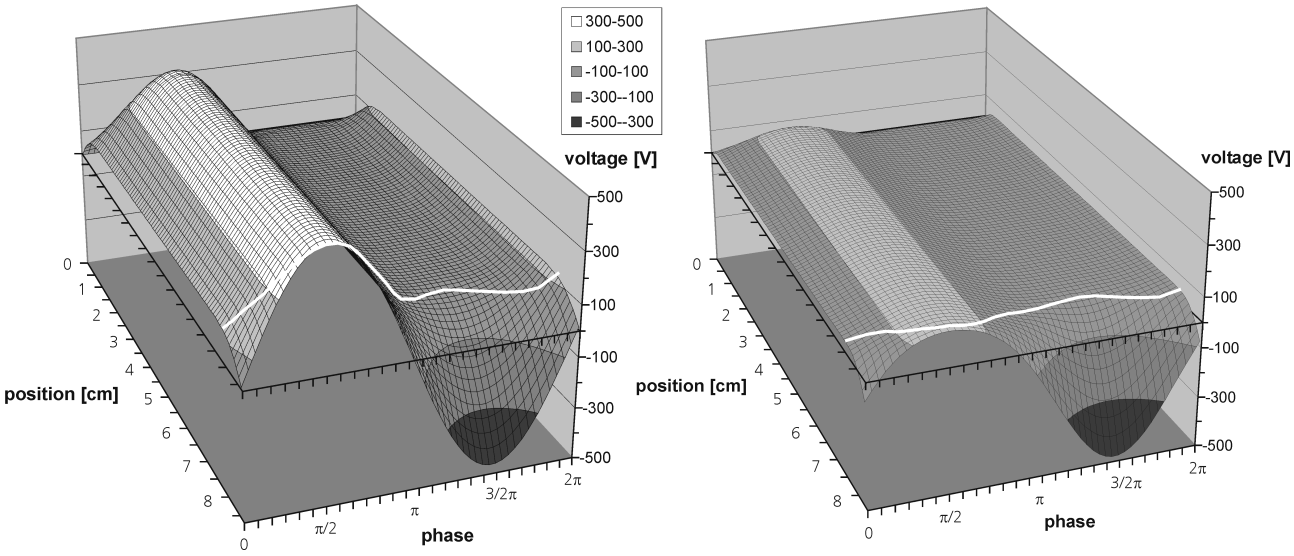

Fig. 1: Potential distribution over one RF cycle for the symmetrical (left; O_2/HMDSO 350 W 0.2 mbar) and the asymmetrical plasma reactor (right; CH_4 300 W 0.2 mbar). Both processes yield comparable potential drops across the plasma sheath (RF electrode in front). The white, bold line indicates the oscillation of the plasma sheath.

It can be seen that although there is no bias voltage in the symmetrical reactor, a sheath potential of about 190 V ($V_{sh} \approx 0.39\ V_0$) is applied on average in front of the powered electrode at typical parameters used to deposit SiO_x barrier coatings. On the other hand, the potential drop in the asymmetrical reactor is an addition of plasma potential and negative (average) bias potential ($V_{sh} \approx 0.39\ V_0 - 0.73\ V_{bias}$). Again about 190 V is obtained for typical conditions to generate a-C:H barrier coatings.

3. Results and Discussion

According to the work of Yeh, Shyy and Yasuda the mass deposition rate R_m for radical-dominated discharges depends on power input W, monomer gas flow F_m, and a geometrical, reactor depending factor G [9], thus that

$$\frac{R_m}{F_m} = G \exp\left(-\frac{E_a}{W/F_m}\right). \qquad (1)$$

It was found that W/F_m was the unique reaction parameter controlling the conversion of monomer in the gas phase to the plasma polymer in the solid phase primarily by activation of molecular bonds, where E_a is the apparent activation energy [10].

Only recently, it could be shown by our group that this concept also holds when oxygen is added to HMDSO as a reactive carrier gas [6, 11]. It was approved that power per gas flow still determines the deposition rate (Fig. 2), where the total gas flow F_{mc} is now an addition of monomer flow and carrier gas flow as

$$F_{mc} = F_m + aF_c \,. \tag{2}$$

The factor a was found to be 0.6, i.e. smaller than 1. This in turn means that keeping the total gas flow and the power input constant, the energy density W/F_{mc} raises with increasing O_2/HMDSO ratio. Thus, the addition of oxygen supports the film growth, since it contributes to the radical formation in the gas phase.

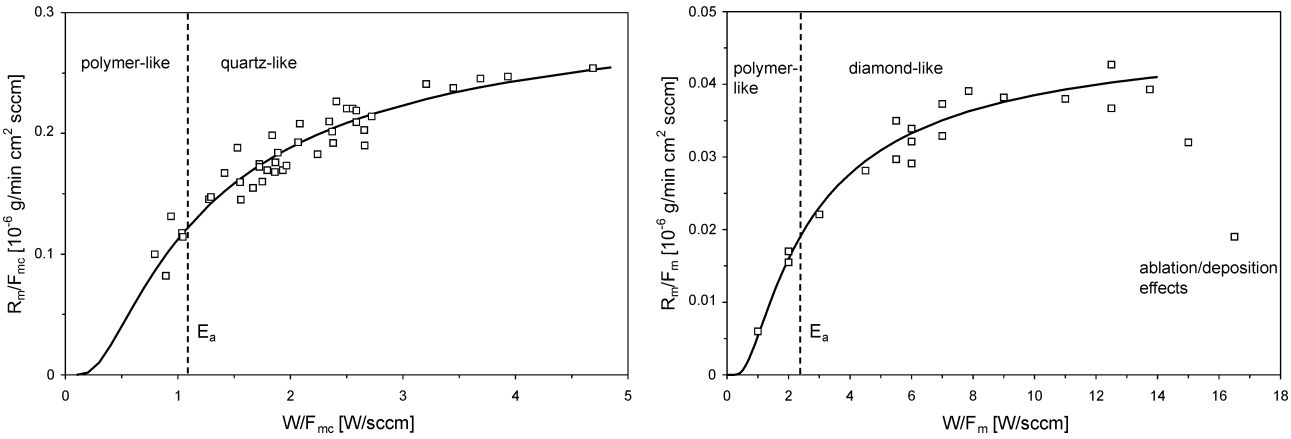

Fig. 2: Mass deposition rate per gas flow for O_2/HMDSO (left) and pure CH_4 (right) discharges depending on the reaction parameter W/F. The apparent activation energy E_a divides the energy density into a polymer-like and a quartz-like, respectively diamond-like, regime. A third regime occurs for a-C:H coatings at high energy densities due to rival ablation/deposition processes. The bold line represents the fit corresponding to eq. 1 and 2.

As long as ion bombardement does not prevail, the film growth is thus determined by gas phase processes such as fragmentation and generation of radicals. Nevertheless, ions accelerated across the plasma sheath by the potential drop V_{sh} supports cross-linking of the growing films. But V_{sh} also scales with the internal stresses in the SiO_x and most of all a-C:H films, whereby increased internal stresses result in a reduction of the barrier properties [6]. Hence, the two parameters, W/F and V_{sh}, which determine the plasma volume and surface processes, provide evidences for the optimum deposition conditions. It was found that an energy density of 2-3 times the activation energy E_a yields the optimum barrier properties (table 1). Compared to SiO_x films, a-C:H films are more flexible and smoother, but show higher oxygen permeation rates and internal stresses. Adhesion on polymers and transparency can be improved by applying the minimum film thickness required for barrier coatings.

Table 1: Oxygen (OTR) and water vapor (WVTR) transmission rates of SiO_x and a-C:H coatings on PET foil.

Material combination	OTR [cm^3/m^2 d bar]	WVTR [g/m^2 d]
23 µm PET	51	11
PET / 40 nm SiO_x	0.35	1.1
PET / 20 nm a-C:H	2.4	0.33
PET / 40 nm SiO_x / 20 nm a-C:H	0.21	0.29
PET / 40 nm SiO_x / 10 nm a-C:H	0.24	0.3
PET / 20 nm a-C:H / 40 nm SiO_x	0.23	0.28

Using the obtained deposition rates for SiO_x and a-C:H coatings, ultra-thin layers can be deposited. This can then be used to examine interphase formation of these coatings on polymers or in multi-layer systems. At first, ~14 nm thick SiO_x coatings were deposited on smooth Si wafers (R_{rms} = 0.5 nm; R_{ave} = 0.3 nm) using

the optimized plasma conditions for barrier coatings without a plasma pre-treatment. Depth profile analyses by XPS and AES were performed by sputtering through the SiO_x layer. As can be seen in Fig. 3 for both methods an interphase width of about 5.5 nm were detected. Due to the difficulty of getting the AES sensitivity factor of oxygen in oxide layers [12], the absolute chemical composition of the AES spectra was normalized with the XPS measurement, which was calibrated using a quartz standard. However, this has no influence on the sputtering depth. Assuming the real interphase width to be 1-2 nm due to Si–O bonds at the interface SiO_x/Si [13], a broadening of the interphase of about 4 nm occurs which can be assigned to the information depth of AES and XPS measurements [14]. Mixing effects might not play an important role with these ultra-thin coatings.

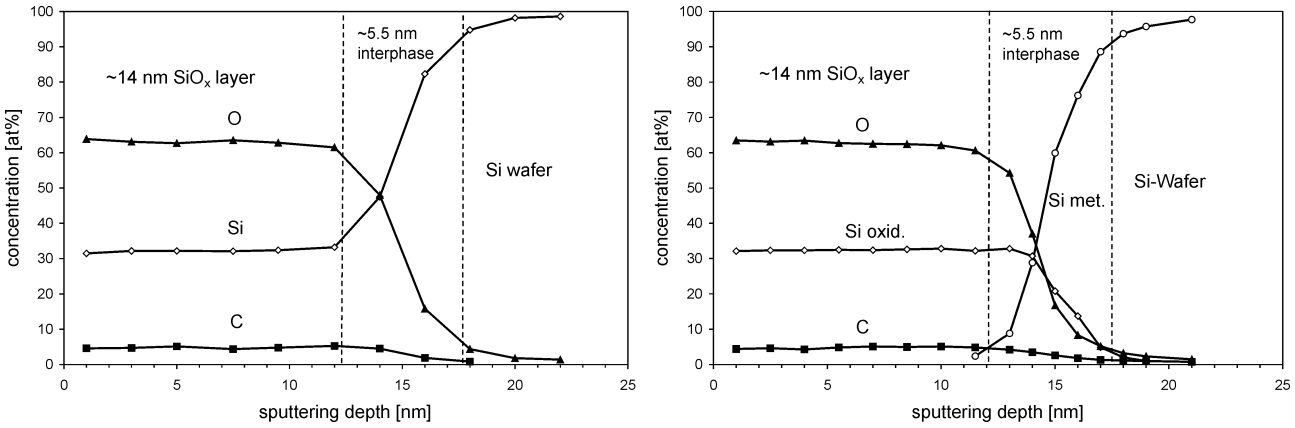

Fig. 3: Depth profile analyses by means of AES (left) and XPS (right) of ultra-thin SiO_x layers on Si wafers. With both methods the interphase width can be detected yielding comparable results. XPS can also differentiate the oxidic and metallic Si component.

With these findings, the interphase of a ~14 nm SiO_x layer on smooth PET foils (R_{rms} = 0.6 nm; R_{ave} = 0.45 nm) can be analyzed (Fig. 4). The apparent interphase width is around 8 nm, i.e. the real interphase might be ~4 nm derived in analogy with the SiO_x/Si interface. Hence, the deposition of SiO_x layers on PET leads to a broadened interphase formation due to ablation/deposition effects as long as the polymer surface is concerned through the plasma interaction [15]. To our understanding, the finding of thicker interphases might be attributed to an enhanced roughness of the polymer substrate [16]. This broadening of the interface yields a fairly good adhesion as long as the SiO_x layer does not become too thick. Then, the internal stresses of the films must be adopted to the polymer properties via a gradient layer [11].

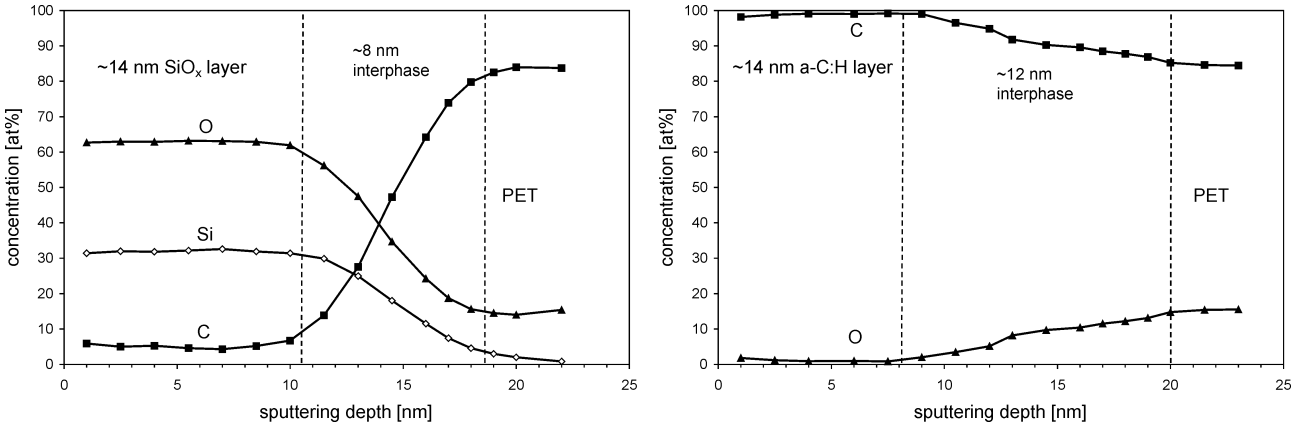

Fig. 4: Depth profile analyses by means of XPS of ultra-thin SiO_x (left) and a-C:H (right) layers on PET foils. The interphases are broadened due to rival ablation/deposition processes during the first stage of film growth.

Furthermore, it was found that a minimum thickness of about 15 nm is required to achieve barrier properties of the SiO_x coatings, that means to obtain dense, closed films [3]. Similar findings were obtained for a-C:H

barrier coatings. Nevertheless, due to an increased ion bombardement during deposition (mainly H^+ ions), a further broadening of the interphase (~8 nm) was detected and the minimum barrier layer thickness required is thus about 20 nm.

Next, two-layer systems of SiO_x and a-C:H were investigated. By depositing the a-C:H layer on top of the SiO_x layer, a corrected interphase width of about 6 nm was observed (Fig. 5). However, on inorganic SiO_x even 10 nm a-C:H were found to be sufficient to achieve good barrier properties (table 1). Therefore, it can be concluded that the inorganic interphase itself contributes to the enhancement of the barrier properties, whereas the organic/inorganic transition of the barrier layers on polymers does not.

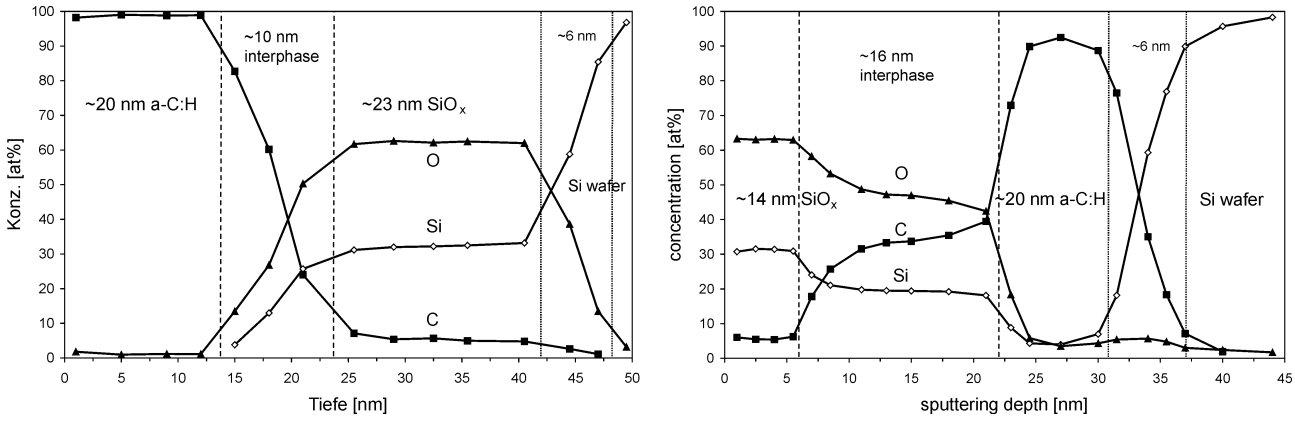

Fig. 5: Depth profile analyses by means of AES of a-C:H on top of SiO_x (left) and SiO_x on top of a-C:H (right) layers on Si wafers. The interphases are broadened due to rival ablation/deposition processes during the first stage of the second film growth. Due to chemical etching, this is particularly pronounced when depositing SiO_x on a-C:H.

When depositing the SiO_x layer on top of the a-C:H layer on the other hand, a noticeably broader interphase formation (~12 nm) can be observed (Fig. 5). Here, a strong interaction of the oxygen plasma with the a-C:H surface through chemical etching occurs, resulting in rival ablation/deposition processes. However, the adhesion of both two-layer systems were proven to be excellent. Moreover, since both combinations of SiO_x and a-C:H on PET exhibit comparable OTR and WVTR values (table 1), the interphase SiO_x/a-C:H can also be regarded to posses barrier qualities. However, considering the barrier improvement factors [17], these interphases add no additional or synergetical effects for improving the barrier properties, and WVTR (OTR) is hardly improved by SiO_x on top on a-C:H (a-C:H on SiO_x). The latter depends on the rather limited barrier properties of plasma polymerized a-C:H for oxygen and SiO_x for water vapor, respectively.

4. Conclusions

By evaluating the mass deposition rates of O_2/HMDSO- and CH_4-derived RF plasma coatings, it appears that the deposition of SiO_x and a-C:H barrier layers is a radical-dominated process since the reaction parameter power per gas flow W/F determines the deposition rate. The resulting apparent activation energy E_a gives hints to find the optimum deposition conditions. Nevertheless, the interaction of fast ions and neutrals with the growing film is needed to attain dense, closed films with a low defect rate. On the polymer substrate rival ablation/deposition effects thus lead to a broadening of the interphase SiO_x/PET and a-C:H/PET with an interphase width of about 4 nm and 8 nm, respectively. We suppose that these interphases do not contribute to the barrier properties, but enhance the adhesion of the layers. To obtain barrier properties on PET, a layer thickness of about 15 nm for SiO_x and 20 nm for a-C:H is required. On the other hand, when depositing a-C:H on top of a SiO_x layer, already 10 nm are sufficient to improve the barrier properties. Therefore, it can be concluded that the inorganic interphase itself contributes to the enhancement of the barrier properties, whereas the organic/inorganic transition of the barrier layers on polymers does not. However, synergetical effects, like healing of defects, did not occur in the two-layer system of plasma polymerized SiO_x and a-C:H coatings.

Abstract
This paper presents some issues on a novel atmospheric pressure pulsed plasma torch. A high-voltage pulse generator is used to induce transient plasma in a gas flow (air) under different conditions of pulse repetition rates, energizing levels and mass flow rates. A dedicated multi-torch reactor, with rod-to-rod electrode type, was built to perform studies on electrical behavior and thermal effects of the generated pulsed plasma.

1. Introduction

The efficient use of the energy sources and the feature of a low-impact on environment are crucial points for industrial production of most modern countries. Thus, the sustainable development of emerging processes or enhancement of traditional technologies, passes under restrictive conditions such as high efficiency, reduced waste products, affordable costs.
Plasma technology appears promising to satisfy the rules of potential sustainable new techniques for producing, processing and environmental protection applications [1].
Plasma generation processes are most widely performed using partial electrical breakdown of neutral gas in the presence of an external electric field. Depending on type of source and operational conditions, generated plasmas are differentiated in *thermal plasma* (*equilibrium plasma*) and *cold plasma* (*non-equilibrium plasma*), on the bases of thermal properties (ions temperature) of the gas ionized state. Traditional thermal plasma generation methods are high-frequency inductively coupled plasma torches, DC transferred and non-transferred arcs. These plasmas usually generate very high temperature or high heat flux. Cold plasmas are often produced under low-pressure conditions using low power radio frequency or microwave or dc sources. Both plasma types suffer from high costs for electrical energy consumptions and, often, their characteristics do not satisfy required fundamental processing conditions.
Pulsed plasmas technology seems to solve or reduce the reported problems [2]. Basically, a pulsed system is able to supply high-voltage to discharge phenomena in a discontinuous manner. Discharges can occur in very short time using a storage capacitor component, repetitively charged by a resonant circuit. Much attention, in the last ten years, was devoted to high-voltage pulsed power for many kinds of potential applications that this type of plasma source can perform [3], [4]. These applications extend from environmental purposes (gas and waste water cleaning, odor control), to biological treatments (inactivation of microorganisms) [5], and chemical processes and synthesis [6], [7]. In particular, non-thermal pulsed plasma appears as an emerging advanced technology especially for environmental and industrial chemistry applications [8], [9], [10]. The reasons of this increasing attention are the advantages that pulsed plasma systems show in comparison to continuous discharge plasma generators. Furthermore, the ability to obtain a non-thermal pulsed plasma at atmospheric pressure gives to this new technology a wide scientific interest.
The advantages of the pulsed technology over continuous arc discharges are to be further discussed in detail. They regard: costs/efficiency, spatial distribution of plasma parameters (homogeneity), output quality, reliability and size.
The main characteristic of plasma torches operating under arc discharge mode is the extremely high temperature (several thousand degree centigrade) confined in small volume. High temperatures during the discharge phenomena are very useful in some processes such as incineration treatments [11], [12] but in other applications, such as chemical processes, the impossibility (or the limitation) to control thermal effects can lead to undesired by-products. Often, the use of a non-reactive gas such as argon or a cooling system can reduce some of the problems related to high temperature (electrode-life and the reactor thermal stresses) but, at the same time, reduces the heating efficiency.

Pulsed technology presents the advantages of a tunable power supply with control by a variable duty cycle of active plasma and plasma afterglow (energy efficiency). The immediate consequence of this is the major homogeneity of the plasma characteristics since pulsed energization in conjunction with rapid gas exchange among pulses can promote heat and mass transfer between plasma boundary and the plasma center. This latter is an important feature especially in presence of chemical reactions since transport phenomena can play a key role in selectivity pattern (output quality).
Non-continuous discharges pulsed at high repetition rate are intrinsically stable and this together with the use of a new multiple switch concept for the realization of multiple plasma torches can give larger reactor volume for processing (reliability and size). Pulsed technology, thus, seems to solve the scale-up problems of the plasma sources since changing the linear dimension of conventional plasma sources, keeping the same proprieties, is not simple.
Finally repetitive pulsed power appears also able to generate a new kind of plasma, the *transient plasma* (not thermal plasma, not cold plasma), which the thermo-physic properties depend on the electric and temporal features of the discharge stages.

In this work a lab-scale plasma processing system, realized to observe transient plasma induced in a gas flow (air) at atmospheric pressure, is presented. The pulsed plasma torch is achieved in plug-flow like reactor under turbulent conditions of the gas flow. The electrical behavior of the induced plasma and the heat transferred to the gas stream under imposed discharge stages are also reported.

2. Bench-scale plasma torch equipment components

The realized lab-scale plasma processing system is composed of two main parts: repetitive pulsed power source and torch reactor. The pulsed power system consists of low-voltage and high-voltage circuits. The high-voltage capacitor C and the high-voltage transmission line with an impedance of Z are resonantly charged to around 20-30 kV in a three-step process described in the following. Figure 1 shows a circuit topology for a single transient thermal plasma torch. Detailed discussions on the circuit principle were reported in [13].

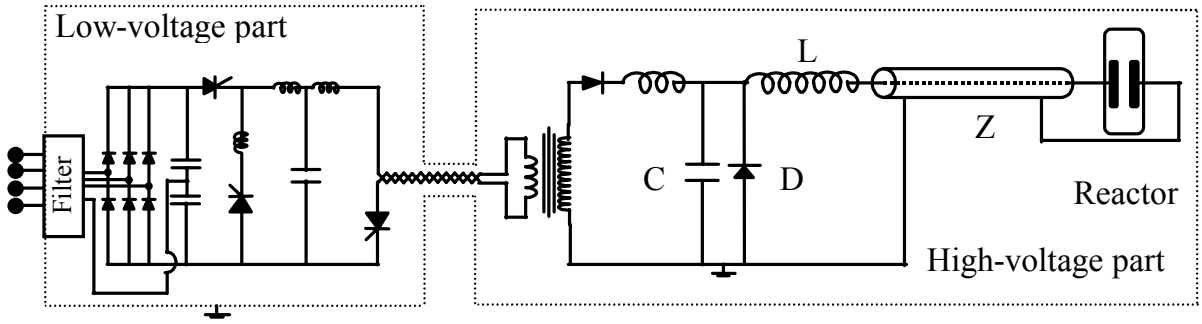

Figure 1. Schematic diagram of the main electrical circuit for a single transient thermal plasma torch.

For this study, a multiple plasma torch reactor is realized in a column (Figure 2). The plasma is induced in air flowing inside a channel with rectangular cross section. The column consists of ceramic walls (refractory material) and a transparent like-glass window. The torch electrodes, rod-to-rod type, are 60 mm long and are made in steel and mounted on the surface of the ceramic walls. The electrode pairs (four independent pairs) are connected to the high voltage and ground connection of four parallel transmission lines. The pairs are fixed at distance of about 100 mm in order to prevent interaction when powered.
The flow channel is 50 mm x 15 mm and 830 mm long. Gas flows in the reactor from the bottom side to reach the torch electrodes (Figure 2 (d)). It leaves the reactor at the top of the column via a tube which is connected to a temperature monitoring system.
Figure 2 shows the outline and the photo of the column reactor with the particulars of the channel cross-section and of the gas flow path.

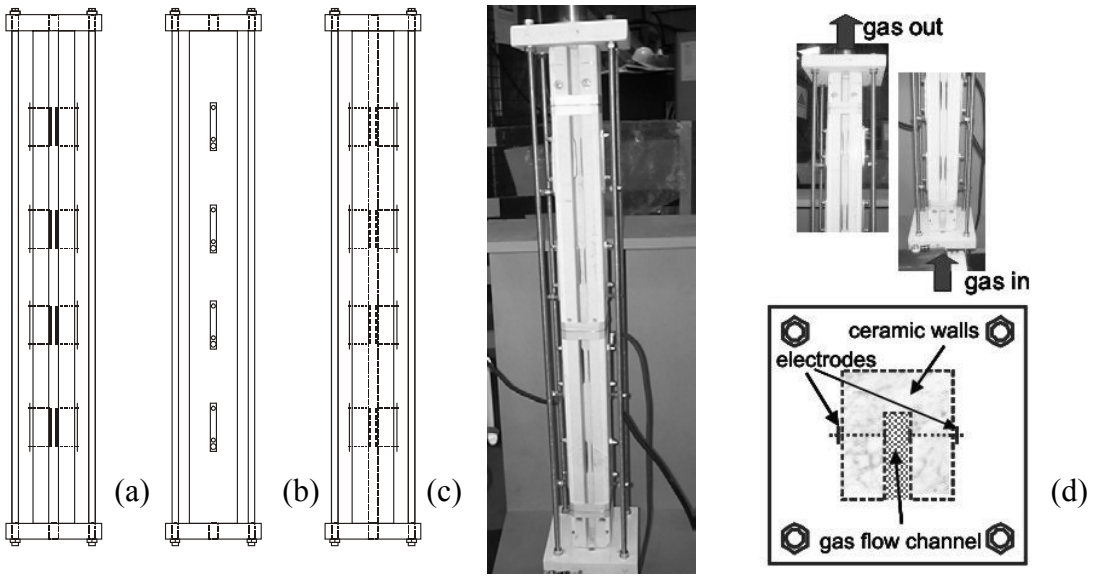

Figure 2. Scheme (*a,* front view; *b,* lateral view; *c,* back view; *d* top view) and photo of the multiple plasma torches.

3. Electrical behavior of the induced plasma

Initially the single plasma torch electrical behavior is investigated using the circuit scheme reported in Figure 1 (only one electrode is connected via one transmission line - Z -). Figure 3 shows the waveforms of the various electrical parameters collected during the transient plasma generation process. The electrical signals are recorded with a digital oscilloscope (*HP Infinium Oscilloscope*) having an analog bandwidth of 500 MHz and a maximum sampling rate of 1 GS/s. The measurements are performed at room temperature, atmospheric pressure and an electrodes gap distance of 8 mm.

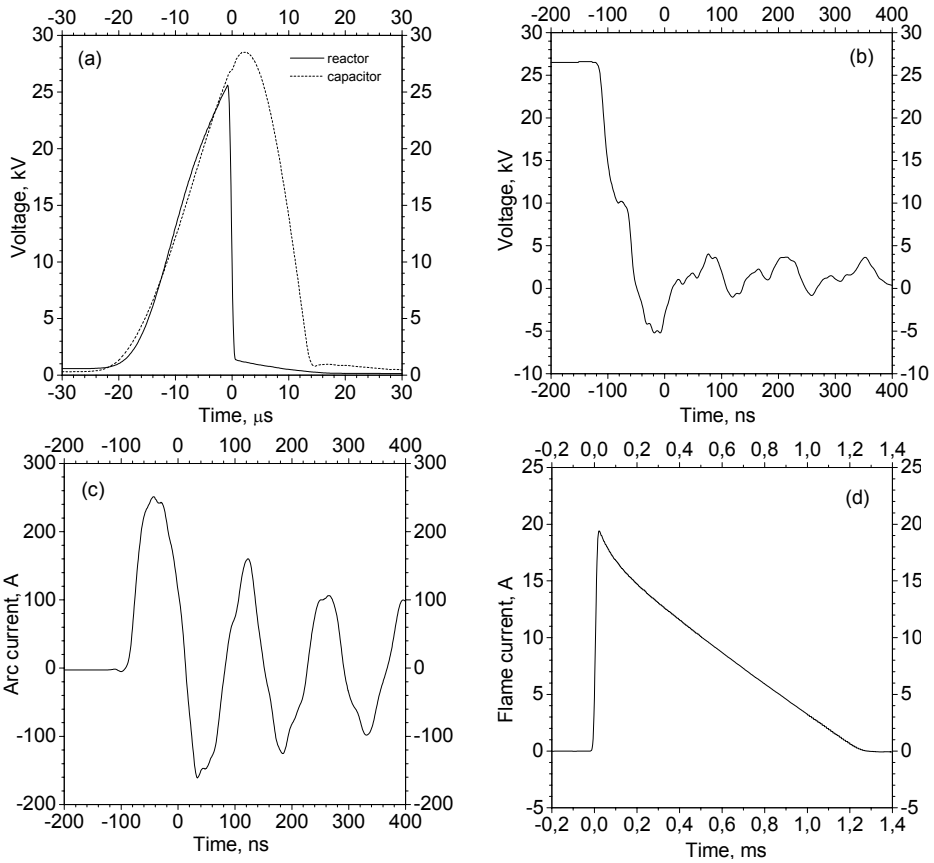

Figure 3. The voltage waveforms (a) on the plasma reactor and on the high-voltage capacitor; the voltage (b) and current (c) waveforms for arc discharge; the current waveform (d) for the flame like plasma.

Three stages are distinguishable in this kind of plasma generation process. Within the first stage, as shown in Figure 3 (a), the plasma reactor is resonantly charged to a maximum voltage of around 20-30 kV in about 20 μs. In a second stage, as shown in Figure 3 (b), (c) an arc discharge occurs inside the reactor. The voltage drops to about around 100 V in about 50-100 ns, and at the same time, the reactor is energized with a large peak current within a few hundred nanoseconds. In the last stage, called flame-like plasma, the voltage on the reactor is almost constant during about 1.2 ms with a peak current of around 20 A (Figure 3 (d)). The peak arc current, in the arc plasma, depends on the maximum charging voltage and the characteristic impedance of the transmission line where the energy is stored. During the flame-like plasma stage, the peak current depends on the maximum charging voltage on the capacitor and the circuit impedance $(L/C)^{1/2}$ since this stage is generated by the discharge of the high-voltage capacitor via the inductor L. Finally, the plasma duration depends on the plasma resistance and the inductor.

In order to transfer the transient thermal plasma process towards industrial applications, the possibility to achieve larger processing volumes must be considered. For this purpose a new circuit topology has also been developed and used to energize multiple plasma reactors.
Figure 4 shows the modified circuit topology reported in Figure 1 for two transient thermal plasma torches. Similar to the synchronization of multiple-switches [14], the two transmission lines synchronize the two transient plasmas. As a general circuit principle, multiple plasma reactors are inter-connected to a set of transmission lines, where the lines are connected in parallel at the input side. Investigations with two, three and four plasma reactors in air are performed. Coherent features of two pulsed plasma torch in terms of typical arc current waveforms are also shown in Figure 4. It is possible to observe that the two plasmas are generated within a time delay of around 2 ns.

4. Heat Balances of the Pulsed Plasma

To understand the relations between discharge properties and thermal effects of the transient plasma torch, a preliminary overall energy balance is carried out by temperature measurements of the flowing gas under different operational conditions. In particular, heat transfer phenomena are studied changing gas flow rate, pulse repetition rate and energy per pulse.
Five different gas velocities are imposed for the gas flow. Since the Reynolds number of the gas flow in the reactor channel is always near 4600, a turbulent regime is achieved. Pulse repetition rates are varied in the range of 10-100 Hz; energies of 1 to 5 J per pulse are obtained by changing the capacitor values.
Gas flow rate and temperature measurements are performed by a *Pitot tube* and by a K-thermocouple, respectively. The two different probes are inserted in the tube outside the torch reactor.
To avoid electromagnetic interference the temperature equipment is shielded. Electrical parameters (voltage and current) are also monitored by an oscilloscope.
In Figure 5 the results are reported about the temperature increase of the air flow, using a single plasma torch and an energy per pulse level of 2 J/pulse. As reported above, temperature measurements are performed in the exhaust about twenty centimeters from the discharge point. To minimize thermal losses this part of the gas flow path is thermally insulated.

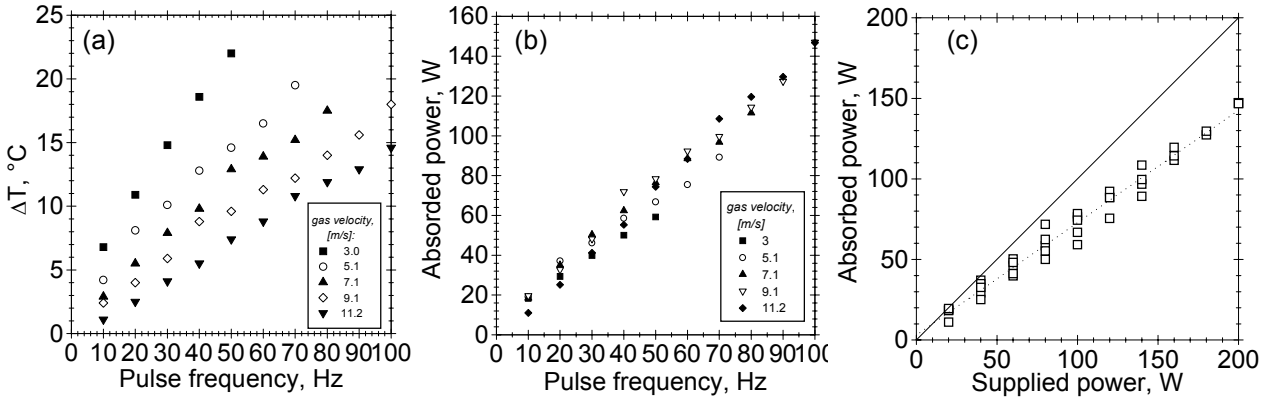

Figure 5. Temperature increase as a function of pulse repetition rates at different gas velocities (a); adsorbed power in different gas flows as a function of pulse repetition rate (b); thermal energy conversion as a ratio between absorbed and the supplied power (c).

Figure 5 (a) shows temperature increases in the gas for different air flow rate. Temperature increases have a linear trend with respect to the pulse repetition rates.

The absorbed power, plotted versus pulse repetition rates in Figure 5 (b), is calculated by the product $\dot{m} \cdot cp \cdot \Delta T$ where $\dot{m}$ is the mass flow rate [kg/s], cp is the specific heat [J/kg °C] and ΔT is the temperature increase achieved [°C]. Data collected show that, under the investigated hydrodynamic conditions, the absorbed power is independent from the flow rate.

The thermal effects of the transient plasma are studied by means of ratio between the absorbed and the supplied power at different conditions of mass flow rate (Figure 5 (c)). Supplied power is calculated on the bases of the supplied energy per pulse and the frequency value (pulse per second). For all performed runs, these ratio values are about 0.7. Overall consideration is that the main part of the supplied energy is transferred into temperature increases of the flowing gas.

Similar results in terms of: i) absorbed power proportional to frequency and independent upon hydrodynamics, and ii) absorbed energy at about 70% of input energy, independent upon hydrodynamics, have been also obtained when working with different values of the energy per pulse, in the range between 1 and 5 J per pulse.

5. Conclusions

In this work first studies on the physical characteristics of a novel atmospheric pressure pulsed plasma torch are performed. In particular, the realized high-voltage pulse generator system can induce a plasma torch in a gas flow at atmospheric pressure.

Electrical behavior studies on the torch energization process show that by changing either the high-voltage capacitor or the transmission line, the energy transfer ratio for the arc and flame-like plasmas can be easily controlled.

The thermal behavior of the transient plasma torch are studied by a preliminary overall energy balance. In particular, under different operational conditions, temperature measurements in the gas flow are performed. Preliminary runs have shown that the heating of the bulk flow is independent of the gas velocity and has a linear trend with respect to the furnished energy. Overall consideration on heat balances is that the main part (70%) of the supplied energy is transferred into temperature increases of the flowing gas.

Further work is in progress to equip the bench-scale plasma torch system with diagnostic instruments. In particular, studies on the active species produced (and temperature achieved too) during the plasma generation in the gas flow and on the composition of the exhaust flow are needed in view of industrial applications of atmospheric pulsed torch.

Electrochemical Estimation of Coverage of Oxide Layer at Platinum Metal Surface Treated by RF Plasma

Tatsuhiko Yajima[1], Mikio Akasaka[1], Naomi Harada[1], Yoshio Okabe[1], and Kazuo Sugiyama[2]

[1]*Department of Marerials Science and Technology, Graduate School of Engineering, Saitama Institute of Technology, Okabe, Saitama 369-0293, Japan*
[2]*Department of Applied Chemistry, Saitama University, Saitama 338-0825, Japan*

Platinum has promise as an ultra-micro electrode material because of it's intrinsic Nernstian potential response to pH [1-4]. As mentioned in previous paper,[5] such potential behavior may be due to the formation of an oxide layer at the platinum surface.

From thermodynamic considerations, the Nernst equation is given as eq (1), where R, F and T are the gas constant, the Faraday constant and the absolute temperature, respectively. Since pH is defined by -log[H^+], it can be rearranged to eq (2), which shows the pH-potential response of the electrode. The intercept E_o' in the eq (2), which is independent on pH, can be written as the eq (3). This equation can be rearranged to the eq (4) with the constant term of E_o" as the water concentration [H_2O] is approximately constant.

$$Pt + H_2O \rightleftharpoons PtOH + H^+ + e^-$$

$$E = E_o + 2.303(RT/F)\log([PtOH][H^+]/[Pt][H_2O]) \quad (1)$$

$$E = E_o' - 2.303(RT/F)pH \quad (2)$$

$$E_o' = E_o + 2.303(RT/F)\log([PtOH]/[Pt][H_2O]) \quad (3)$$

$$E_o' = E_o'' + 2.303(RT/F)\log([PtOH]/[Pt]) \quad (4)$$

$$E_o' = E_o'' + 2.303(RT/F)\log(\theta/1-\theta) \quad (5)$$

The ratio [PtOH]/[Pt] in the second term of the eq (4) can be represented as a function of θ which represents the coverage of the oxide layer at the uppermost surface of platinum, that is, [PtOH]/[Pt]= θ/(1-θ). Then, the eq (5) arises [5]. The last equation indicates that E_o' in the eq (2) is determined only by the surface coverage of oxide layer when T is constant. The slope of the eq (5) is theoretically calculated to ca. 59.2 mV at 25°C. In this study, the relationship of the eq (5) was verified quantitatively by X-ray photoelectron spectroscopy (XPS) especially with the Pt4f spectrum analysis involving peak separation between a pair of metallic $Pt4f_{5/2}$ and $Pt4f_{7/2}$ peaks and a pair of oxygen-binding $Pt4f_{5/2}$ and $Pt4f_{7/2}$ peaks and consequently the coverage of oxide layer at platinum surface could be estimated.

Platinum wires (0.5 mm in diameter by 5 cm length) with different oxidation states at their surface, which means θ values are different from each other, were prepared easily by low temperature plasma oxidation and reduction technique with O_2 and H_2 gases. The plasma apparatus used consisted of a 13.56 MHz radio-frequency (RF) generator (Creative Design Co. Ltd., type T847A), an RF power meter (TRIO, type PF-810), a tuner, a copper coil tubing and a Pyrex reactor tube. A platinum wire was set in the reactor tube in parallel with the O_2 gas flow to be treated by an inductive RF plasma. Typical plasma treatment parameters were RF power, P= 40 W; flow rate of gas, r_g= 2.0 mmol min^{-1}; gas pressure, p_g= 1-100 Pa and treatment time, t_{TR}= 2.0-6.0 min. A direct current (D.C.) microvolt ammeter (TOA Electronics Ltd., type PM-18U) was used to measure electric potentials of platinum wires versus a saturated calomel reference electrode (SCE) at 22±1 °C. The pH potential measurements involved preparing solutions with pH 5, 7 and 9 by adding 1.0 M acetic acid to 100 ml of 0.01 M NaOH aq., immersing the tip of the plasma treated or untreated platinum wires in those solutions prerviously prepared to measure their electric potentials. X-ray photoelectron spectroscopy (XPS) was carried out using PHI Quantum 2000 Scanning ESCA Microprobe spectrometer equipped with a spherical capacitor analyzer (SCA) with monochromatic 200 mm diameter Al Kα X-ray radiation (1486.6 eV). Sputtering for depth profile was performed under the following conditions: ion energy, 2 kV; sputtering rate, 9 nm min^{-1} reduced to SiO_2 basis; and total sputtering time, 10.2 min.

Abstract

ZnO particles were produced by dropping Zn powder on the heated boat which was set into the plasma in the mixture gas of argon (9.75 Torr) and oxygen (0.25 Torr). The structure of ZnO particle produced by the present method was the characteristic structure with tetrapod configuration having the [0001] short four needles.

1. Introduction

Zinc oxide (ZnO) is widely used in various applications such as cosmetic material [1], ultraviolet (UV) absorption substance [2] and gas sensors [3]. One of the problems on the production of ZnO particles is the size control and the shape control, or may be contained the ionic compound. By the use of flash evaporation technique in the gas evaporation, structure and morphology of ZnO particles can be controlled and elucidated the characteristic of infrared (IR) spectra [4]. Furthermore, it was found that the condition of the cubic ZnO particles predominantly produced by the flash evaporation method [4].

On the other hand, by using of the passing metal and/or semiconductor smoke particles through the plasma field, these particles were changed to the nitrogen particles in spite of the nitrogen gas pressure of 0.25 Torr [5]. The size of the order of 50 nm of these particles did not change after passing through the plasma field. Therefore, by using plasma field during production of the smoke particle, the compound particle of nanometer size can be produced in a low partial pressure of reactive gas.

In this study, the flash evaporation technique was used in the plasma field and ZnO particles were produced in the mixture gas of argon (9.75 Torr) and oxygen (0.25 Torr) by controlled evaporation of Zn. The comparison with and without plasma have been also presented.

2. Experimental method

The work chamber for the production of ZnO particle was a glass cylinder 17 cm in diameter and 33 cm in height. The plasma field which was set in the work chamber was shown in Fig. 1 schematically. The used electrodes were stainless steel of 5 cm in diameter and 5 cm in height. RF plasma with a frequency of 13.56 MHz was used. Zn powder was dropped into the heated boat at 1000°C which was set below the plasma field in a mixture gas of argon (9.75 Torr) and oxygen (0.25 Torr). The dropping rate of the Zn powder was about 10^{-2} m/sec. Dropped Zn powder into the heated boat was evaporated and passing through the plasma field with accompanying to the exothermic reaction of Zn vapor with oxygen gas. The color of the plasma field changed from the red-violet to the brilliant blue, i.e., oxidation of Zn vapor occurred [6]. The produced specimens were examined using transmission electron microscopic (TEM), high resolution TEM (HRTEM) method.

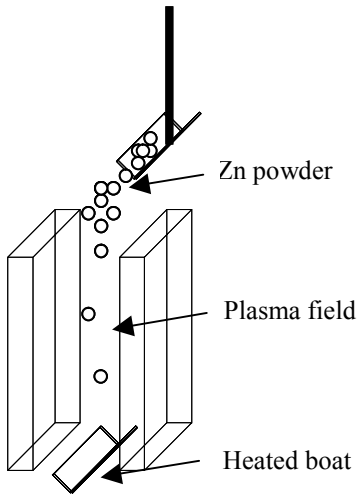

Figure 1: Schematic representation of the flash evaporation in plasma

3. Results and Discussion

Figure 2 shows the characteristic growth of ZnO particles produced by the general gas evaporation method of Zn in a mixture gas of argon (95 Torr) and oxygen (5 Torr) from nichrome boat. The characteristic needle crystal with the tetrapod shape can be seen. If the flash evaporation method was used in this gas pressure, the cubic ZnO particles with the size of 30 nm can be produced as shown in Fig. 3. The electron diffraction (ED) pattern shows clearly the growth of the cubic phase [4].

Figure 4 shows the characteristic ZnO particles produced by flash evaporation in plasma. Each particle can be seen spherical, but high magnified image showed tetrapod configuration. The size of ZnO was about 30 nm. As can be seen in Fig. 4, the dispersion state of ZnO particles was very good. The ED pattern of the present specimen showed the hexagonal structure of ZnO.

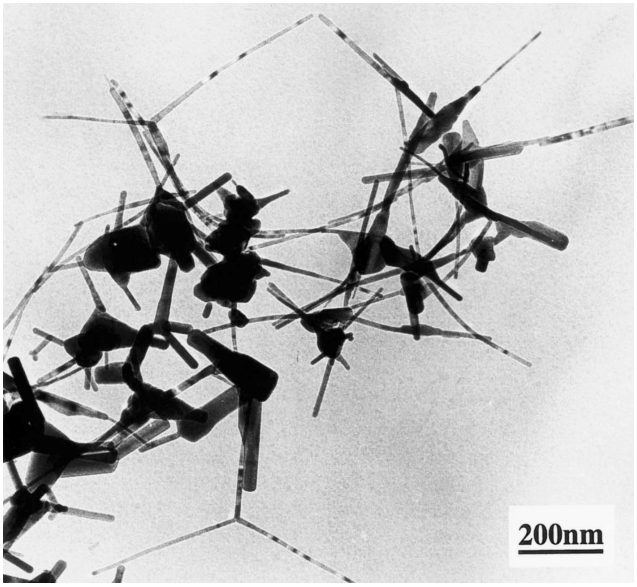

Figure 2: Elcetron microscopic image of ZnO produced by general evaporation method.

The HRTEM image of one ZnO particle is shown in Fig. 5. Lattice fringes of needle part are identified ($10\bar{1}0$) plane of the hexagonal ZnO particle as indicated by an arrow. The lattice image at the center of a particle is identified as crossed {$10\bar{1}0$} planes, as shown in Fig. 5. Therefore, the hexagonal [0001] axis for the central part is the incident electron beam direction. The dotted line as shown in Fig. 5 indicated {$11\bar{2}0$} planes of the interface between the central part of the ZnO particle and the needle parts. This corresponds to the projection of the {111} plane of the cubic nucleus, i.e., tetrapod growth starts from the cubic nucleus. Since ZnO particles were polar crystals, four {111} planes composed of Zn atoms at the top surfaces grew in Zn-rich atmosphere [7].

If the oxygen partial pressure were 0.25 Torr with the same total pressure as in Fig. 2, and only the flash evaporation technique were used without the plasma field, the morphology of the grown particle was drastically change and Zn crystals were included, as shown in Fig. 4. Therefore plasma is important factor on the growth of ZnO particles.

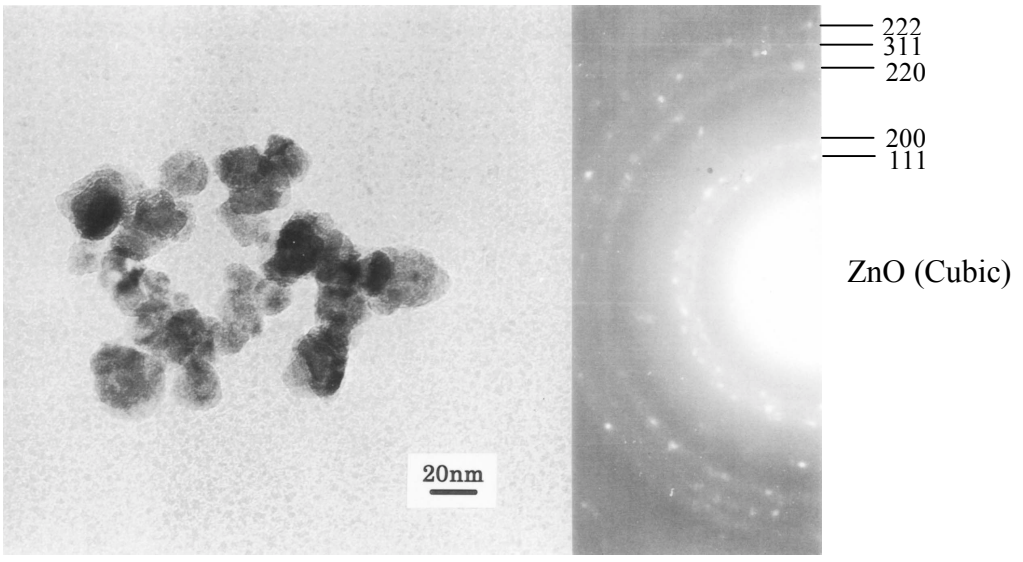

Figure 3: EM image and ED pattern of cubic ZnO particles

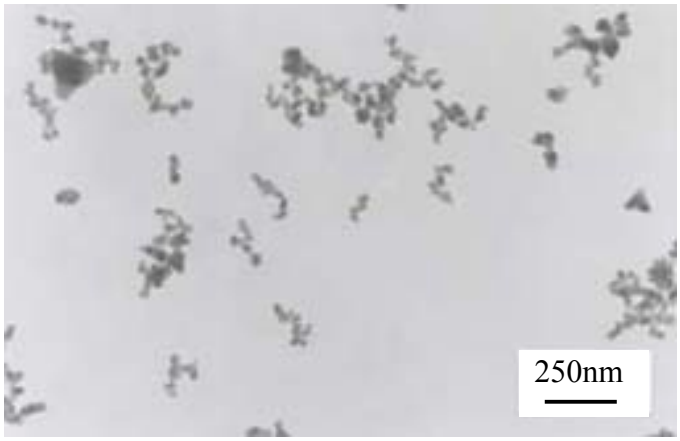

Figure 4: TEM image of the ZnO particles produced by flash evaporation in plasma

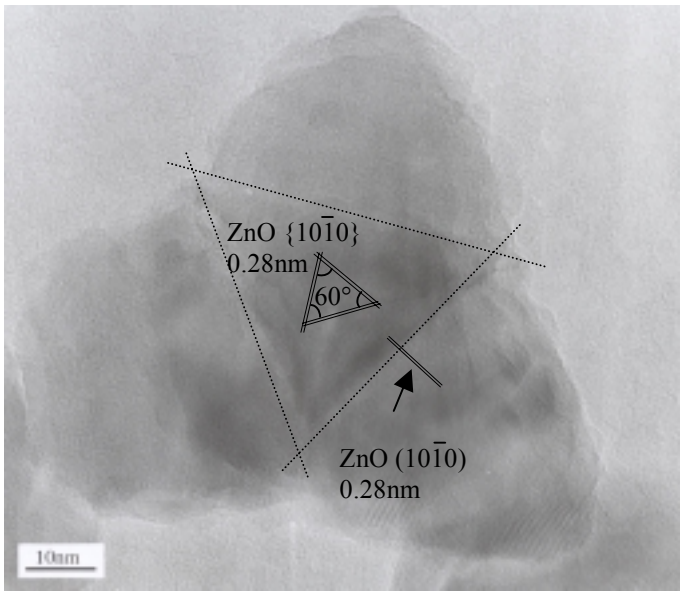

Figure 5: The HRTEM image of ZnO particle with tetrapod configuration

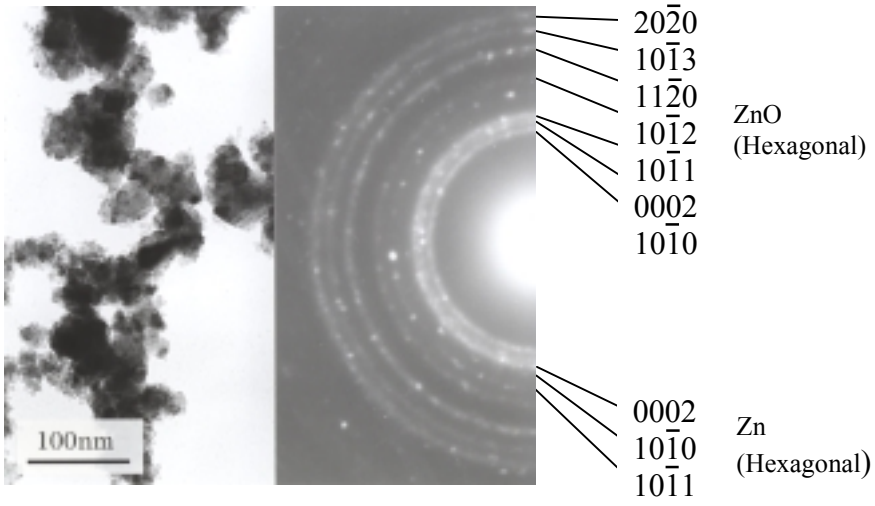

Figure 4: EM image and ED pattern of the particles produced by the flash evaporation technique

4. Summary

ZnO particle size, shape and dispersion can be controlled by preparation method. The morphology of ZnO particle shows the characteristic structure with very short needle parts and the dispersion state of each particle was very good in the plasma field. These results indicate that electric charge in the plasma field controlled by the coalescence growth of the particle and crystal growth of the particle was influenced by the plasma effect. By the flash evaporation method in the plasma field, the particles of the size of the nanometer can be obtained in the low gas partial pressure. The present particles may be used as the characteristic absorbance at 3.2 eV without Mie scattering.

Abstract

Stability of SiO_2 thin layer designed as the functional particles such as TiO_2 and ZnO have been elucidated by the heating experiment. When these particles were path through the plasma field in He gas at 80 Torr, SiO_2 layer were crystallized and broken due to the density change of the film. The heating experiment showed the crystallization at 650°C (TiO_2) and 600°C (ZnO). In the case of TiO_2, SiO_2 layer was dissolved into TiO_2 particle. In the case of ZnO, the small crystallites of Zn_2SiO_4 were formed on the surface.

1. Introduction

Titanium oxide (TiO_2) and Zinc oxide (ZnO) particles are able to use in various applications, for example, a white pigment of cosmetic material and ultraviolet (UV) absorption substance respectively. In order to improve safety and the dispersion of each particle, the method of covering the particle surface with thin SiO_2 layer has been developed with the aid of plasma treatment [1]. However, the stability and the state of the SiO_2 layer which was produced on the particle were hardly examined.

In this study, the stability by heating and the more RF plasma (13.56 MHz, 300 W) treatment process of the TiO_2 and ZnO particles which were covered with an amorphous SiO_2 layer of a few nanometers was examined by transmission electron microscopic (TEM) introducing the in situ observation method.

2. Experimental

In this experiment, two types of particles covered with an amorphous SiO_2 layer were prepared to compare the stability of heat treatment with plasma treatment. Commercial ZnO powder (ISI. Ltd.) was used as ZnO particles covered with thin amorphous SiO_2 layer, which produced by the aid of plasma [1].

TiO_2 particles were produced by burning Ti powder charged on a tantalum boat in a gas mixture of Ar (13.5 kPa) and O_2 (1.7 kPa). The Ti can be evaporated by heating the tantalum boat and Ti vapor was oxidized and condensed near the boat. Then, TiO_2 particles rise with convection flow like a smoke [2-5]. As same as TiO_2, SiO_2 particles were produced by evaporating SiO powder in the mixture gas [6]. The evaporation source of SiO_2 was set above 50 mm from the evaporation source of Ti. Since SiO_2 vapor existed around the evaporation source of SiO, produced TiO_2 particles passed through the SiO_2 vapor and were covered with an amorphous SiO_2 layer, as proposed in a previous paper [7]. In this experiment, these covered TiO_2 particles were dropped in a plasma field.

These samples were observed by Hitachi H- 7100 and H- 900NAR. In situ observation was done using a special heating holder in the high resolution electron microscope to confirm the stability of the SiO_2 layer on the TiO_2 and commercial ZnO particles. The dynamic behavior of the surface layer has been recorded directly on a video tape.

3. Results and Discussion

3.1 Stability of heat treatment of covered SiO_2 layer on TiO_2 and ZnO particles

Typical example of TiO_2 particles produced without SiO_2 vapor is shown in Fig. 1. Most of the particles are anatase, which is the low temperature phase, and small amounts of brookite and rutile are produced. When SiO_2 vapor introduced to the particles flow, TiO_2 particles uniformly covered with an amorphous SiO_2 layer were predominantly produced, as shown in Fig. 2. The SiO_2 layer is less than 10 nm on the TiO_2 particles with the size of the order of 100 nm. Using plasma at room temperature, the surface of TiO_2 particles was not covered uniformly by the SiO_2 layer [1].

These particles covered by the SiO_2 layer produced by this method were heated in the electron microscope. By heating at 650°C, the smooth surface layer of SiO_2 become rough due to the small black contrast on the particles with sizes of 5- 8 nm, as indicated by an arrow in Fig. 3. Lattice image of the contrast show the existence of β - quartz layer of 2 nm thickness which is stable phase at high temperature on the surface of

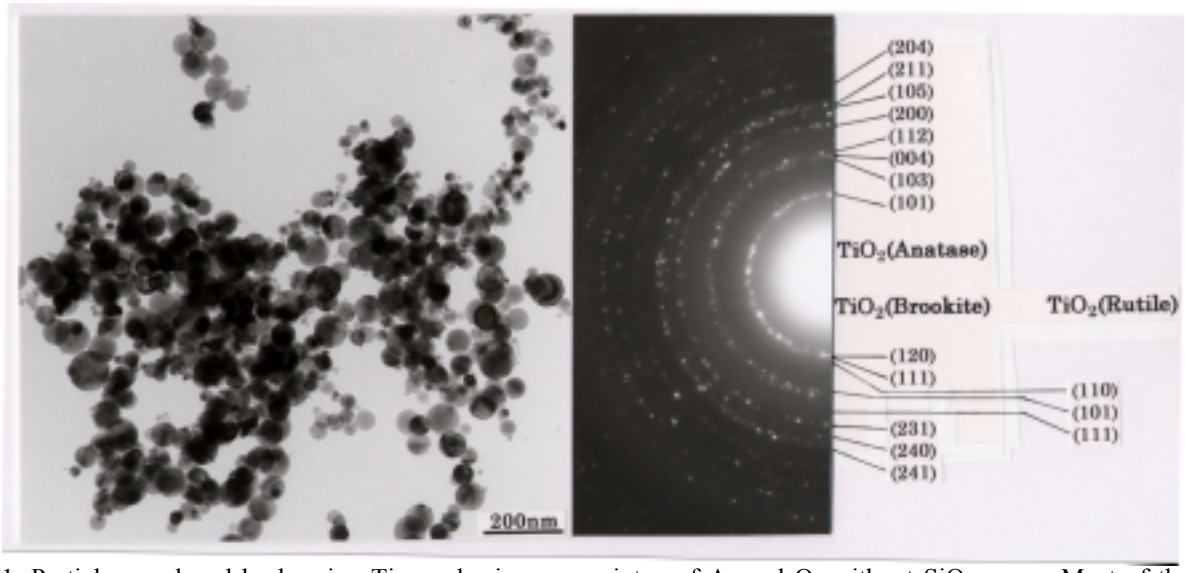

Fig. 1. Particles produced by burning Ti powder in a gas mixtue of Ar and O_2 without SiO_2 vapor. Most of the particles were rtile and a small amount of brookite and rutile partilces.

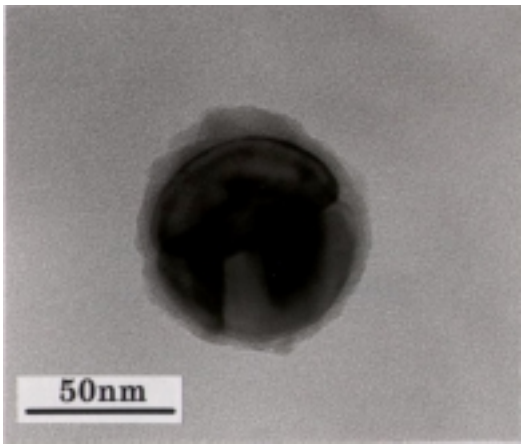

Fig. 2. TiO_2 particles covered with amorphous layer. Thickness of the layers is less than 10 nm.

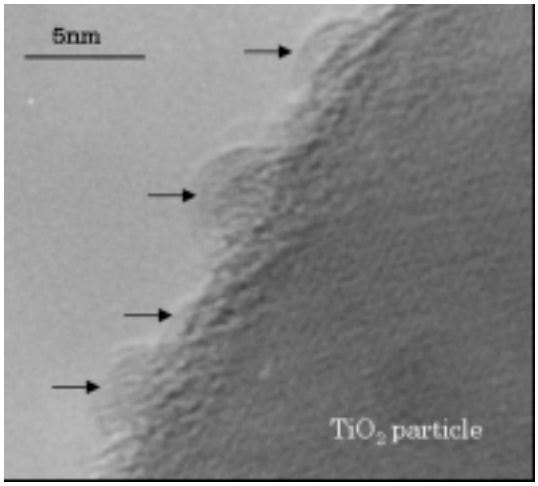

Fig. 3. HREM image of the surface of TiO_2 covered with SiO_2 layer which passed through plasma field. SiO_2 nanocrystallites are indicated by arrows.

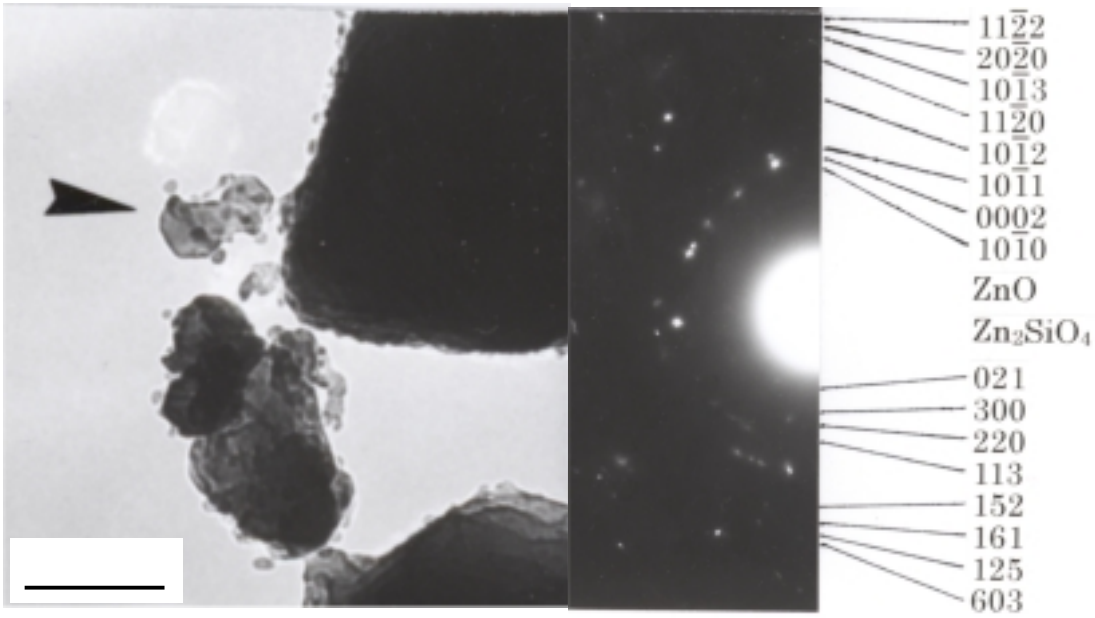

Fig. 4. Surface layer of ZnO particles produced by the aid of plasma became rough by heating at 700°C. Projections of the surface of ZnO were Zn_2SiO_4 crystallites indicated by arrow.

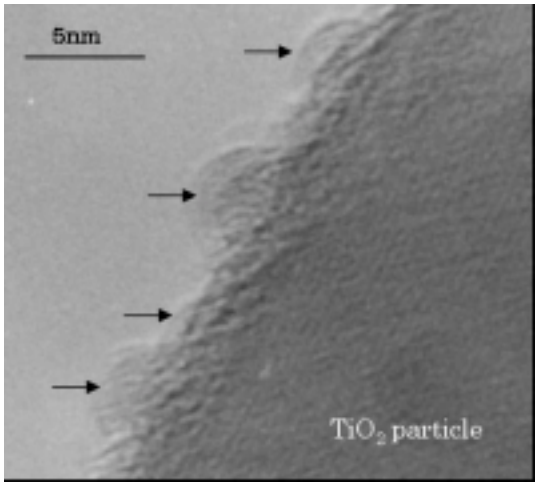

Fig. 5. HREM image of the surface of TiO_2 covered with SiO_2 layer which passed through plasma field. SiO_2 nanocrystallites are indicated by arrows.

TiO_2 particle. The β - quartz layer dissolved into TiO_2 particles on heating at 700°C and was disappeared completely on the particles at 750ºC [7]. This phenomenon means that the empty columns in TiO_2 are important in dissolving the SiO_2 molecules.

In the case of amorphous SiO_2 layer on ZnO particles, SiO_2 layer crystallized upon heating at 600°C. Upon heating at 700°C, the small crystallites of Zn_2SiO_4 were formed on the surface of ZnO particle, as shown in Fig. 4. This shows that the reaction of ZnO and SiO_2 also started above this temperature. Furthermore, the coalescence growth of these small crystallites started above 700°C.

3.1 Plasma treatment of covered SiO_2 layer on particles

TiO_2 particles covered with an amorphous SiO_2 layer was also crystallized by passing through the RF helium gas plasma field at 80 Torr. Fig. 5 shows the high resolution electron microscopic (HREM) image of the surface changed to the SiO_2 nanocrystallite of the order of 3 nm as indicated by arrows. The surface layer became uneven and didn't cover uniformly. Thus, the treatment of on the surface SiO_2 layer in plasma destroys the coverage of SiO_2, i.e., protected layer was destroyed.

In the case of heat treatment, the SiO_2 layer crystallized on heating at 650°C and dissolved into TiO_2 particles on heating at 700°C. Since the surface SiO_2 layer crystallized in the case of plasma treatment,

adequate energy to crystallize was accepted from plasma, i.e., the plasma treatment corresponded with over 650°C of the heat treatment. In the plasma field at high gas pressure, kinetic energy of electron is larger than the ion. Electric charge of electron in the plasma field accelerates the crystallization of amorphous SiO_2 layer.

In the case of ZnO particles, the small crystallites of Zn_2SiO_4 were formed on heating at 700°C. As same as TiO_2 particle, the surface SiO_2 layer on ZnO particles became rough and black contrast partly appeared on the particles in the case of plasma treatment. However Zn_2SiO_4 crystallites did not existed. Thus, the plasma treatment corresponds with less than 700°C. It is concluded that the plasma treatment corresponds between 650°C and 700°C of the heat treatment. If the power of the plasma becomes higher, the reaction growth of Zn_2SiO_4 may be occurred.

Abstract

In this contribution we focus on the formation of new molecules by wall association of atoms from atomic particle sources, investigating the efficiency and formation mechanism. We show that by using an atomic nitrogen and hydrogen source, ammonia can be formed efficiently, i.e. 11% of the total background pressure is measured to be ammonia. The measurements indicate that the ammonia is formed via plasma-surface interactions. The density of the produced ammonia is measured by cavity enhanced absorption spectroscopy.

Introduction

In applications in which plasma is used for chemical conversion, but also for surface treatment or deposition, newly formed stable molecules are often detected in the background gas. It has been acknowledged for quite some time that plasma-surface interactions are of great importance in the production of these new stable molecules. For example, in 1975 Eremin [1] reported that the synthesis of ammonia was increased by a factor of 3, when platinum was used as coating for the quartz wall of a plasma reactor in which discharges in N_2-H_2 mixtures were created. In 1989 [2], it was reported that zeolite added to the downstream plasma in high-frequency discharges facilitated the ammonia production, which was ascribed to the surface reaction of NH_x radicals adsorbed on the zeolite with hydrogen atoms. The formation of ammonia is still not completely understood and could depend on plasma conditions, but it is believed that it is due to plasma-surface interactions.

To gain a better knowledge of the plasma-surface interactions that take place during the formation of stable molecules, we have chosen to investigate the formation of ammonia in N_2-H_2 plasma in more detail. We show a new way of generating ammonia, i.e. via plasma-activated catalysis [3]. In this process fluxes of hydrogen and nitrogen radicals are produced in a high-density plasma source with high dissociation degree. The plasma then expands into a low-pressure vessel, where most of the atomic radicals will arrive at the surface at which they will adsorb. At the surface new molecules can be generated which subsequently may desorb. In this way the dissociation in the plasma source is geometrically separated from the production zone of the molecules. Since the plasma is used to produce the radicals for the ammonia production and the wall is used as a catalyst, the process is called plasma-activated catalysis.

We will present results of the production of ammonia in expanding plasma generated from mixtures of atomic hydrogen and nitrogen obtained by cavity enhanced absorption spectroscopy (CEA) [4]. In this technique, a narrow band (cw) light source is used in combination with a high-finesse optical cavity to perform sensitive high-resolution, direct absorption measurements. To study the influence of the geometry of the vessel on the ammonia production, measurements of the ammonia density obtained by mass spectrometry will be shown for a vessel with a larger surface to volume ratio. In the case the plasma is generated from a mixture of hydrogen and nitrogen, a significant amount of ammonia density is measured.

Experimental set-up

The plasma is created in a so-called cascaded arc source [5], which generates a direct current thermal plasma in mixtures of N_2 and H_2 at a typical pressure of 0.5 bar, a current of 55 A and a power of 5 kW. The plasma expands from the nozzle of the cascaded arc into a stainless steel vacuum vessel, which is kept at a pressure between 10 and 200 Pa. The expansion into the vessel is first supersonically and then, after a stationary shock, subsonically.

A scheme of the experimental set-up used in the cavity enhanced absorption measurements is depicted in Fig. 1. A continuous wave (cw) diode laser (New Focus, Model 6262, up to 5 mW) is used as a

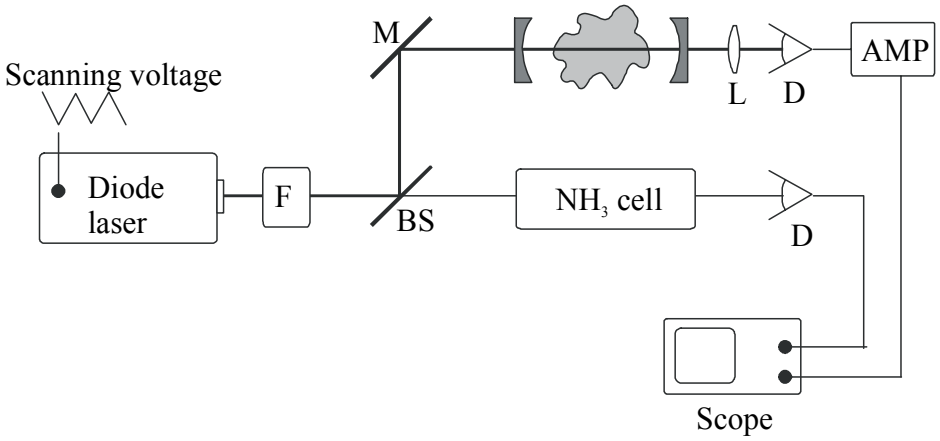

Figure 1: Scheme of the cavity enhanced absorption set-up.

light source, which is tunable in the 1520-1560 nm region. During all experiments, the laser is repeatedly scanned at a rate of 32 Hz over a spectral range of typical 1 cm^{-1}. A Faraday isolator is used to minimize the optical feedback to the laser. A beam splitter directs 10% of the laser light into a reference cell, which is filled with 5 mbar of ammonia. The absorption cell is used for absolute calibration of the frequency of the laser. The radiation that passes the beam splitter is coupled into a high-finesse, optically stable cavity with a length of 1.1 m, formed by two plano-concave mirrors with a diameter of 25 mm, a radius of curvature of -1 m and a reflectivity of R = 0.994. The mirrors are directly flanged onto the stainless steel vessel in which the plasma expands. The light that is leaking out of the cavity is detected by an InGaAs photodiode (New Focus, Nirvana 2017). The detector signal is amplified with a 0.1 ms rise time amplifier and integrated over 1 ms (spectral equivalent 0.06 cm^{-1}) and subsequently displayed on one of the channels of a digital oscilloscope (10 bits, 300 MHz). A second channel is used to record simultaneously the signal of the photodiode behind the reference cell. The data on the scope are transferred to a PC via GPIB for further analysis.

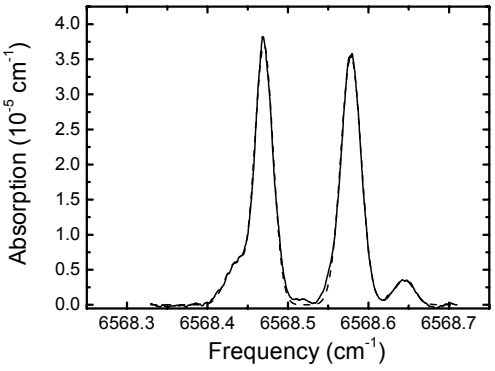

Figure 2: Typical NH_3 CEA spectrum measured in a vessel in which a N_2-H_2 plasma expands. The dashed line is a fit assuming four Gaussian line profiles. The background pressure was 20 Pa.

In the CEA technique the laser is continuously scanned over the same spectral range. Via accidental coincidences of the frequency of one of the cavity modes with the laser frequency light couples into the high-finesse optical cavity. During each scan different laser frequencies can be coupled into the cavity leading to a so-called interleaved sampling. After several scans, all frequencies will be sampled. The intensity of the light coupled into the cavity is determined by the overlap between the laser mode and the matching cavity mode, the scanning rate of the laser and the jittering and finesse of the cavity. Especially the scanning rate of the laser has a large influence on the measurements and is subject to several limitations. The maximum scanning rate is determined by the fact that the laser mode has to stay in resonance with the cavity mode sufficiently long, resulting in maximum intensity. The maximum intensity that can be reached inside the cavity is proportional to the overlap of the laser and the profile of the cavity mode. The spectral profile of the cavity mode is approximated by a Lorentzian profile with a width proportional to $1/\tau$, i.e. proportional to the total cavity losses, and the maximum of the Lorentzian profile is proportional to τ^2. The convolution of the laser profile and the Lorentzian profile has a maximum intensity that is directly proportional to the ring down time τ. One can show that the time-integrated intensity is also proportional to the ring down time τ, which is given by:

$$\tau = \frac{d}{c(1-R+\kappa(\nu)d)}, \qquad [1]$$

where d is the absorption path length, c the speed of light, R the reflectivity of the mirrors and $\kappa(\nu)$ the absorption coefficient.

There is also a lower limit to the scanning rate due to the requirement that all cavity modes should be in resonance with the laser frequency equally long. Therefore, the scanning rate of the laser must be significantly higher than the rate at which the cavity modes are changing.

An ammonia spectrum is measured in the plasma reactor and averaged over 1000 scans, i.e. about 30 s of acquisition time. The recorded spectrum however is a relative absorption spectrum expressed in loss of the empty cavity per round trip, i.e. (1-R)/d. The spectrum can be put on an absolute scale by measuring the CEA spectrum of a known amount of water. Using the transition strength [6] and the known density of the ground-state water molecules the factor (1-R)/d is determined as $(5.5 \pm 0.5)\cdot 10^{-5}$ cm^{-1}. The absolute absorption can be determined by using the formula:

$$\kappa(\nu) = \left(\frac{S_0(\nu)}{S(\nu)} - 1\right)\left(\frac{1-R}{d}\right), \qquad [2]$$

where $S(\nu)=I_0\tau$ is the time-integrated intensity with absorption in the cavity and $S_0(\nu)=I_0\tau_0$, is the signal in an empty cavity, i.e. the baseline, with I_0 the laser intensity inside the cavity. In Fig. 2, a typical measured ammonia spectrum is shown. The observed transitions of ammonia are strong lines from the combination band $\nu_1 + 2\nu_4$ reported by Lundsberg-Nielsen *et al.* [7]. Of the four transitions shown in Fig. 2, three are reported in literature with the line positions 6568.299, 6568.401, and 6568.463 cm^{-1}, and absorption coefficients, $7.556\cdot 10^{-4}$, $7.602\cdot 10^{-4}$, and $0.948\cdot 10^{-4}$ cm^{-1} Torr^{-1}

Results

Three different experimental situations have been studied. In the first experimental situation, the plasma is created with 2.0 SLM N_2 flowing through the arc, delivering a substantially dissociated and partially ionised (5%-10%) nitrogen flow. Simultaneously a varying hydrogen flow between 0 and 1.45 SLM is injected in the background of the vessel. The absolute density of ammonia as a function of the relative flow rate of hydrogen with respect to the total flow rate is shown in Fig. 3 for a background pressure of 100 Pa. The measured ammonia density first increases with increasing hydrogen flow and then saturates at a maximum of $2.5\cdot 10^{19}$ m^{-3}. This means that at T = 600 K, which is determined from the Doppler width of the measured ammonia transitions, 0.2% of the background gas is ammonia. The saturation of the ammonia density can be understood by noting that the hydrogen molecules, which are injected in the background, can only be

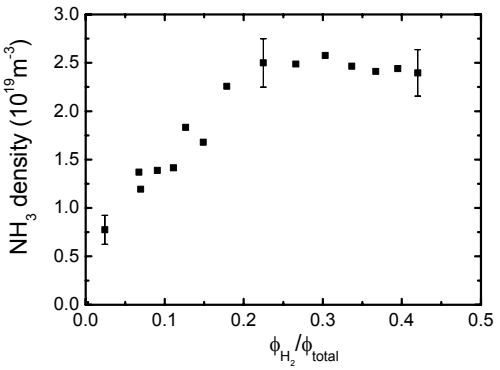

Figure 3: Ammonia density as function of the hydrogen flow rate relative to the to the total flow rate of nitrogen and hydrogen. The nitrogen is applied through the arc, while the hydrogen is injected directly into the vessel into which the nitrogen plasma expands. The background pressure is kept constant at 100 Pa.

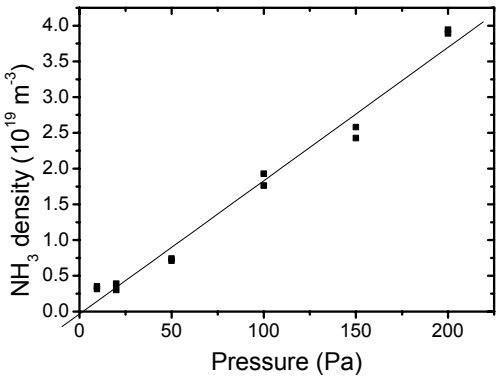

Figure 4: Ammonia density as function of the background pressure in the vessel. The plasma is created with 2.0 SLM N_2 flowing through the arc and 1.0 SLM H_2 injected in the background.

dissociated by the N^+ ions emanating from the arc. The H production will increase until all N^+ ions are consumed, which deliver two H atoms via the non-symmetric charge exchange reaction $N^+ + H_2 \rightarrow NH^+ + H$, followed by the dissociative recombination reaction $NH^+ + e \rightarrow N + H$. Adding more H_2 molecules will not lead to the production of more H atoms, and thus no extra NH_3 is produced.

In the second experiment, the ammonia density under the conditions of maximum NH_3 production, i.e. 1.0 SLM H_2 injected in the background, has been measured as function of the background pressure, i.e. from 10 to 200 Pa as shown in Fig. 4. The measured ammonia density shows a linear dependence on the pressure. Assume now that only N and H are necessary for the production of ammonia. Then the ammonia production rate is:

$$\frac{dn_{NH_3}}{dt} = n_H n_N k \,, \qquad [3]$$

where n_{NH3} is the ammonia density, n_N the atomic nitrogen density, n_H the atomic hydrogen density and k the reaction rate coefficient. The total ammonia density at a specific pressure in the vessel, i.e. at a certain residual time τ, can be calculated by:

$$\int_0^{\tau} \frac{dn_{NH_3}}{dt} = \int_0^{\tau} n_H n_N k dt \qquad [4]$$

This leads to:

$$n_{NH_3} = n_H n_N k \tau \qquad [5]$$

Under the experimental conditions used, n_N, n_H and k are constant and only τ is linear dependent on the pressure. In that case, the above shows that the ammonia density should be linear with the pressure. Starting from atomic radicals, volume production of ammonia would require reactions, i.e. three particle reactions, which are too slow to lead to any significant production under the experimental conditions used. Furthermore, the production would then show a stronger than linear dependence on the pressure, which is not observed. Moreover, under all conditions, the density of ammonia proved to be independent of the lateral position in the plasma jet at which the CEA spectrum was taken. All measurements have been performed at about 20 cm downstream from the exit of the arc. This shows that the ammonia is not produced in the plasma jet. This indicates that ammonia is mainly produced at the vessel wall.

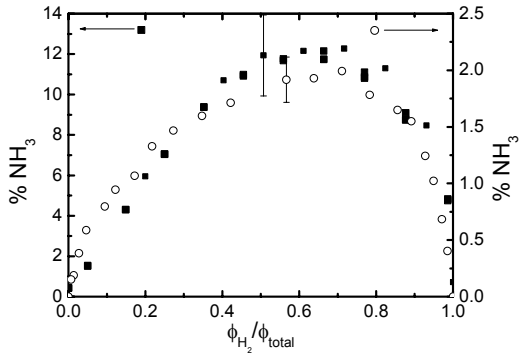

Figure 5: Density of ammonia as function of the hydrogen flow rate relative to the total flow of nitrogen and hydrogen (o CEA measurements, ■ mass spectrometry). Both nitrogen and hydrogen are applied through the arc at a total flow rate of 2 SLM. The background pressure is kept constant at 20 Pa.

In the third case, the plasma is produced while both nitrogen and hydrogen are flowing through the arc with a total flow of 2 SLM. In Fig. 5, the ammonia density as function of the relative H_2 flow rate to the total flow rate is presented as measured with cavity enhanced absorption spectroscopy. The maximum ammonia density under these plasma conditions is at $\phi(H_2)$ = 1.44 SLM and $\phi(N_2)$ = 0.56 SLM, which is close to the stoichiometric ratio of hydrogen and nitrogen in NH_3. The maximum density of NH_3 at 20 Pa background pressure is about $4 \cdot 10^{19}$ m^{-3}, which is 2% of the background gas at a temperature of 600 K.

If the production of ammonia is due to plasma-surface interactions a larger surface to volume ratio should lead to more ammonia production. This is confirmed by measurements on a different set-up, with a larger surface to volume ratio. The results are also depicted in Fig. 5, showing an ammonia density of 11%, measured with mass spectrometry. This is a remarkable result if one compares this with the total ammonia one could get under the conditions used. A maximum is detected around the stoichiometric ratio of hydrogen and nitrogen in NH_3. This means that one has 3 hydrogen atoms per 1 nitrogen atom. If one now takes all possible reactions into account leading to stable molecules, the maximum amount of ammonia one could make is 21%. The measured relative ammonia density as function of the relative hydrogen flow rate to the

total flow rate as shown in Fig. 5, is also measured in a low-pressure N_2-H_2 flowing discharge [8] and predicted fairly well from a self-consistent model assuming that NH_3 is mainly formed at the vessel wall [9].

The pressure in the vessel during the experiments is also monitored. With a starting background pressure of 0.220 mbar, a relative pressure decrease is found with a maximum of 11% as shown in Fig. 6. This decrease is not due to the pumping system as the pumping capacity is constant and independent of the gas type. Secondly, it is not caused by a temperature change, because the pressure is observed to change almost instantaneously after adjustment of the flows. The pressure is also observed to be equal for the pure hydrogen and nitrogen case. It seems that the decrease of the pressure as function of the relative H_2 flow rate to the total flow rate is a measure of the ammonia density. Consider the production of ammonia from nitrogen and hydrogen by the reaction: $N_2 + 3H_2 \rightarrow 2NH_3$. This means that if one molecule of NH_3 is formed from $\frac{1}{2}N_2$ and $1\frac{1}{2}H_2$, the total numbers of molecules decreases with one. Since the pressure in the vessel is linear dependent on the number of molecules, the pressure decrease in the vessel can be a measure of the ammonia density. Therefore, it is concluded that there is an ammonia density of 11% at a relative flow rate of hydrogen of 0.5 with respect to the total flow rate.

Now, we try to model the numbers of different molecules produced in the vessel with a very simple model using very basic statistics. It is assumed that just the relative amount of N and H determines the probability of a reaction. Furthermore, the formed N_2 or H_2 are assumed to undergo no further reactions and only four-atom molecules are considered as end product. So starting with one N or H will give N_2, NH, HN and H_2 with respectively a chance of $P_N^2P_H^0$, $P_N^1P_H^1$, $P_N^1P_H^1$ and $P_N^0P_H^2$, where P_N and P_H are the fractions of atomic nitrogen and atomic hydrogen, assuming a constant dissociation degree of the molecular hydrogen and nitrogen flows through the arc. This can be extended to statistics for all possible four-atom molecules. Now, two limitations are examined. In both H_2 and N_2 are formed, and in one case all possible four-atom molecules are formed and in the other only NH_3 is formed.

Both cases are plotted versus the measured ammonia production in Fig. 7. The model in which only N_2, H_2 and NH_3 are formed fits the measured ammonia density reasonable well. This indicates that at the wall the formation of NH_3 is favourable above the formation of other molecules. The calculated NH_3 fraction is rescaled because not all N_2 and H_2 molecules are dissociated, or because there are other processes that are not taken into account here. One possible cause is that due to the large difference in mass, a hydrogen plasma beam diverges more than a nitrogen plasma beam. This so-called mass-defocusing effect has been reported in Ar-H_2 and pure H_2 plasma expansion [10,11]. This mass-defocusing leads to an effective cross-section where both molecules are in a mixture, which is smaller than the total cross-section. In view of this effect the production efficiency of 11% is remarkably high.

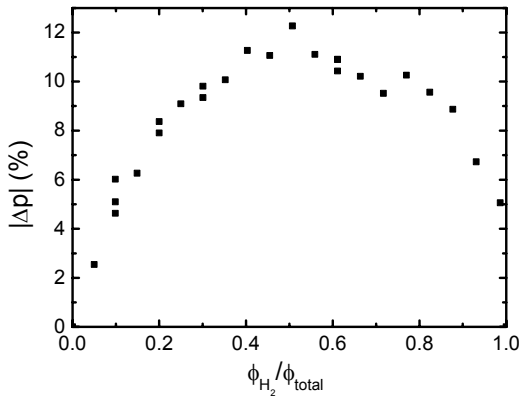

Figure 6: Relative decrease of the pressure as function of the hydrogen flow rate relative to the to the total flow rate of nitrogen and hydrogen.

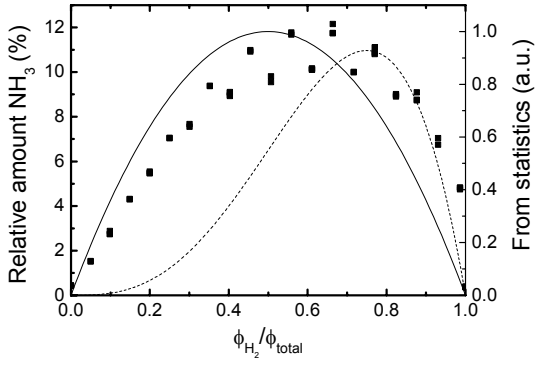

Figure 7: The ammonia density as measured with the mass spectrometer as function of the hydrogen flow rate relative to the total flow rate of nitrogen and hydrogen. The solid line is the calculated production from statistics assuming only reactions in which N_2, H_2 and NH_3 are formed. The dashed line is the calculated production assuming all possible reactions in which four-atom molecules are formed.

Conclusions

We have shown that by using high fluxes of atomic nitrogen and atomic hydrogen radicals, produced from N_2-H_2 plasma, ammonia is mainly produced at the vessel wall with high efficiency. Since the plasma is used to produce the radicals, and the wall acts as catalyst, the process is called plasma-activated catalysis. The results show that cavity enhanced absorption spectroscopy is a promising plasma diagnostic technique, which can supply fast and accurate density information.

Furthermore, Fourier transform (FT) spectroscopy with a thermal plasma as a broad-band light source, is currently installed on the set-up to be able to measure all different kind of molecules simultaneously. As FT spectroscopy is an absolute method, it can be used to complement the more indicative mass spectrometry technique and the absorption measured in a very narrow wavelength range with cavity enhanced absorption spectroscopy. The combination of these diagnostic techniques described above enables us to study the production of other molecules via plasma-activated catalysis.

By tuning the plasma parameters and choosing the right wall material, plasma-activated catalysis could be a promising new way for small-scale selective production of molecules, starting from their atomic constituents. It will be extended to hydrazine, N_2H_4, and later to organic molecules like methanol. In the latter example one could start from natural gas and oxygen [12].

CATALYCITY STUDY OF CNES/NASDA TPS SAMPLES AT THE CORIA INDUCTIVE PLASMATRON FACILITY

A. Desportes[1], P. Vervisch[1]

[1] *UMR 6614 CNRS CORIA, University and INSA of ROUEN, Saint Etienne du Rouvray, France*

Abstract

In the development of Reusable launchers technology, to explore the behaviour of TPS material in re-entry conditions is quite essential. At CORIA, an 100 kW class inductive plasmatron is implemented with a sample holder that allows tests on samples similar to Orex heat shield. Different working points are explored, simulating the whole area of the vehicle re-entry phase. To the date, the IPM method for γ determination is based on comparison between calculation of the boundary layer and measurements made on the surface sample. These measurements have been made on the OREX TPS material at CORIA. The final objective of this work is to contribute to the evaluation of the relevance of plasmatron facilities to determine the catalycity of thermal protection materials.

1. Introduction

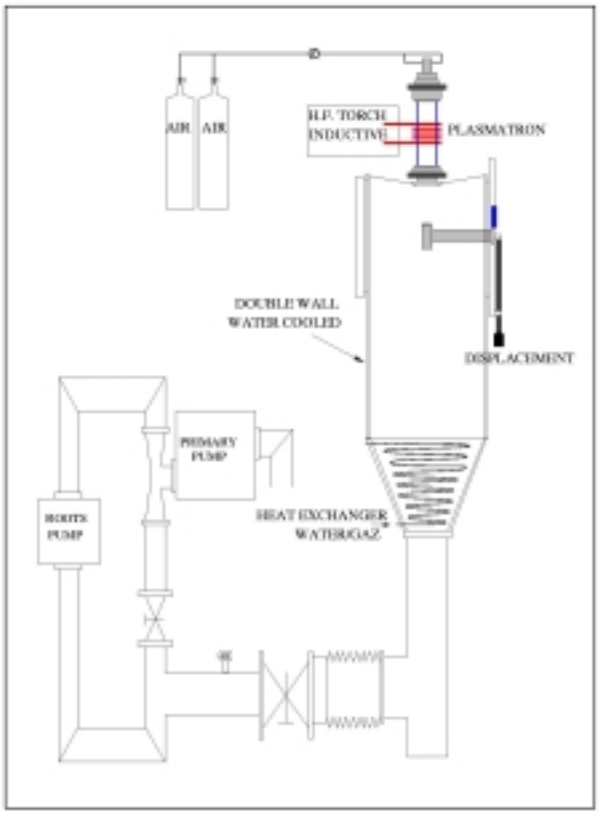

Fig 1. ICP torch at CORIA : IPWT

The catalycity parameters of a material cannot be obtained by direct measurements. In fact, this could be possible only with the knowledge of all the species concentration. Thus, the determination of the catalycity is a combination of experiments on the material and numerical simulations of the flow.

The samples that are to be tested are parts of heat shields of space vehicles. The aim of the tests is to prove that the material can resist or not to the atmospheric re-entry and reusability. In those conditions, the material has to be exposed to the same heat flux than the atmospheric re-entry.

These simulation conditions can be found in some plasma wind tunnels. One of the CORIA facilities was especially designed to produce such high enthalpy flows. The inductive 90 kW plasma generator can produce flows with various gases; the main interest of this kind of generator is the lack of electrodes which provides a high purity plasma jet.

1.1 Wind tunnel at CORIA : Description

The ICP torch is shown in Fig 1. There are three main parts :

- The generator : which can deliver a power up to 90 kW (9A 10 kV)
- The channel discharge : the place where the working gases confined in a quartz tube are ionised by the electro-magnetic field induced by the five turn coil.
- The test chamber : where is performed the interaction between the sample and the plasma. The pressure in the test chamber can vary from 1 mbar to 50 mbar.

2. Temperature and flux measurements on the samples

The total heat load of heat flux is one of the most important parameter during the atmospheric re-entry of the vehicle. It is primary determined by the convective part. Furthermore the catalytic behaviour of the surface of the thermal protection system can influence the heat flux to the vehicle.

The heterogeneous recombination of O and N atoms species and excited molecules can significantly increase the heat flux at the TPS material. The probabilities for wall recombination of O and N atoms γ_O and γ_N are the representative parameters to qualify this catalytic contribution. Information about these parameters are generally derived by the IPM procedure [2][3]. This method combine both experimental and numerical tools. The experiments give the sample surface temperature and the total heat flux received by the sample when it is placed in the plasma flow. These measurements are the input data to a numerical code that simulates the flow and the boundary layer around the sample. The gamma value is deduced for each tested material with a known gamma. Generally this reference sample is cold copper which is fully catalytic with $\gamma = 1$.

In this manner a macroscopic γ value is obtained where accommodation effects are integrated. However several hypothesis are underlying before to employ this method :

- Chemical equilibrium at the boundary layer edge
- $\gamma_N \cong \gamma_O$, weak variation with temperature and the ratio O/N

The deexcitations of metastable molecules at the wall are neglected.

To ascertain the reliability of theses assumptions, measurements in the boundary layer above the sample have to be performed. However in a first step, heat flux on the sample and its temperature level have to be primary determined.

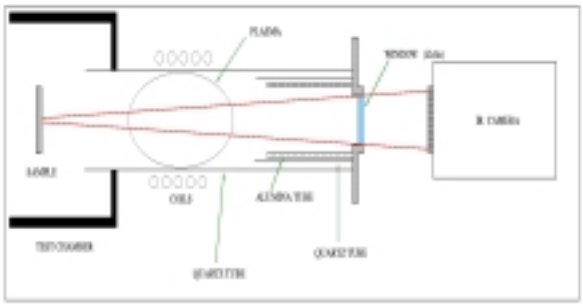

Fig 2. Experimental set-up for wall temperature and heat flux measurements

For surface temperature measurements, Infra-Red camera is used assuming a sample emissivity value. Experimental arrangements allow to explore the sample brightness at right angle, in order to prevent any mistakes due to the angle correction. Therefore the measurement is made in the axis through the plasma creation areas as shown in the **Fig 2**. This diagnostic is possible due to the specific wavelength used by the infrared camera (THERMACAM PM595 FLIR) which integers the emitted signal between 7 and 13 μm. Hopefully, there is no emission of the plasma in these wavelength.

The radiation Heat flux of the sample is given by the Stephan-Boltzmann laws as :

$$\Phi = \varepsilon.\sigma.T_w^{\,4} \quad (1)$$

The radiative flux focused on the camera can be written :

$$\Phi_{\,received} = \tau_{\,ZnSe} \,.\varepsilon\,.\sigma\,.T_{\,w}^{\,4} \quad (2)$$

Where σ is the Stephan-Boltzmann constant and τ_{ZnSe} the transmitivity of the ZnSe window equal to 0.68. The value of the heat fluxes are thus given thanks to the emissivity of the sample.
The total heat flux is the sum of the radiative flux and the transmitted flux on the sample.

$$\Phi_{TOTAL} = \Phi_R + \Phi_{TR} \quad (3)$$

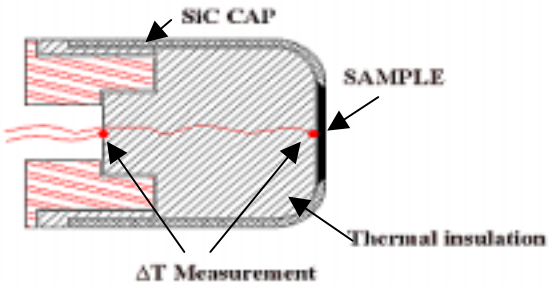

Fig 3. Experimental setup for transmitted heat flux measurements

Φ_{TR} is determined by the temperature difference between two thermocouples on the axis behind the sample (see **Fig 3**). This gradient depends on the thermal conductivity λ of the insulator holding the two sensors.
The ratio Φ_{TP}/Φ_R plotted against sample temperature is reported in **Fig 4**. The experimental point falls approximately on straight line. These measurements are able to estimate the loss of accuracy when Φ_{TR} is neglected. In the explored temperature range its contribution remains low.

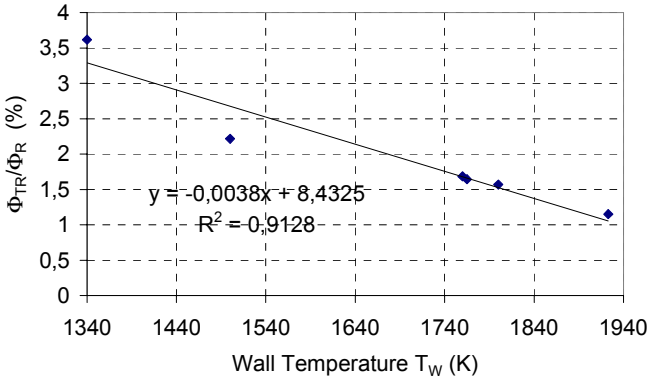

Fig 4. $\Phi_{TR}/\Phi_R = f(T_w)$

2.1 Infrared spectroscopy

As you can see on **Fig 4** the sample temperature range that have been explored is between 1340 and 1940 K. So the maximum intensity of the black body radiation for such temperatures is comprise between 1.5 and 3 µm. As discussed earlier, the infrared camera integers the wavelength between 7 and 13 µm. For example, we consider a black body with a temperature of 1500 K. The percentage of energy taken by the infrared camera is about 6 %. It is clear that an excellent calibration of the camera is needed otherwise the uncertainties will be so important that no temperature can be determined. In this way, we have replaced the camera by an infrared spectrometer. The experimental set-up is shown

on **Fig 5**. We use a parabolic off axis mirror rather than classical lens to get rid of the varying focal length with the wavelength. The spectrometer used is a Jobin-Yvon HR320 with a 300 grooves/mm grate. The wavelength range studied is 1-5µm. So the detector placed at the exit of the spectrometer is PbS or PbSe captor. The main drawback of this set-up is the time needed for a complete acquisition (description of the sample radiation between 1-5 µm will take about 10 min), whereas a picture taken with the camera is done in only 5 seconds. Furthermore the picture taken with the camera is a 2D picture of all the sample surface whereas with the spectrometer coupled with PbS or PbSe detector the information is 1D. On the other hand, the main advantage of this set-up, is the determination of the sample emissivity for plenty of wavelength comprised between 1-5 µm. In fact, ε_λ can be obtained by comparison between the black body radiation and the acquisition done. Furthermore, in order to obtained emissivity varying with temperature, this experimentation will be repeated for different wall temperatures. These measurements are underway.

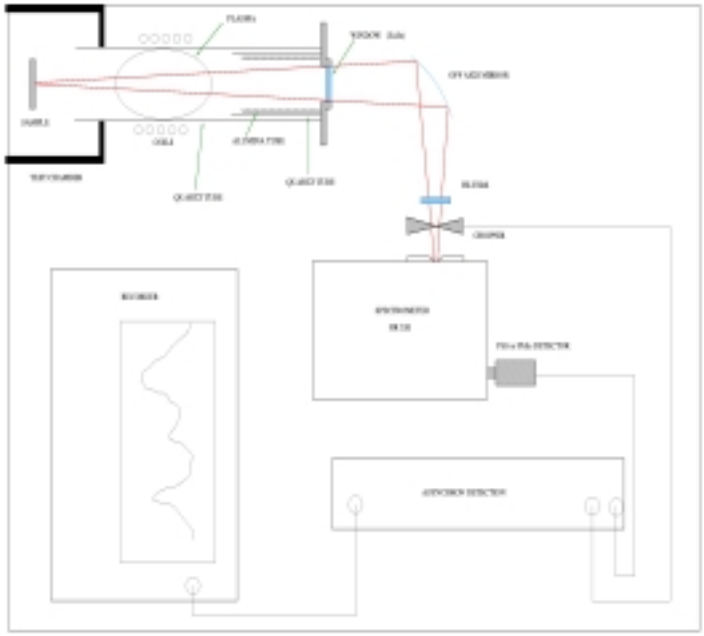

Fig. 5 Experimental set-up for infrared spectroscopy

3. Cold wall measurements

As discussed earlier, the IPM method for determination of catalycity needs a calibration with a material that has a tabulated gamma. In our case, this calibration is derived by the measured flux on a fully catalytic ($\gamma = 1$) copper sample.

The experimental set-up of the sample holder with the copper cold wall is described in **Fig 6**. The measured fluxes with this apparatus correspond of course to the highest fluxes available in our facility.

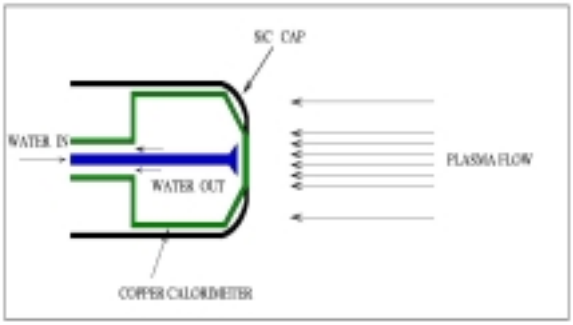

Fig 6. Copper calorimeter

Tab 1

Temperature measured on C/C sample	Φ_R	Corresponding heat flux on cold wall
3000 Pa		
1920 K	612.5 KW	1370 kW

To illustrate the abilities of the facility, typical results are reported in **Tab 1**. They are obtained for the following input conditions :

- 3.6 g.s-1 air mass flow rate
- 9 kV, 8 A anode power

4. Measurements technics : free jet and boundary layer

For an experiment-modelling comparison, the confidence of the deduced conclusions is related to the set of available measured parameters. In this direction, a special effort has to be made to measure as complete set of parameters as possible : temperature, velocity, species concentrations ….
For this purpose, several measurements techniques have been implemented on the experiment or are underway.

4.1 Spectroscopic measurement

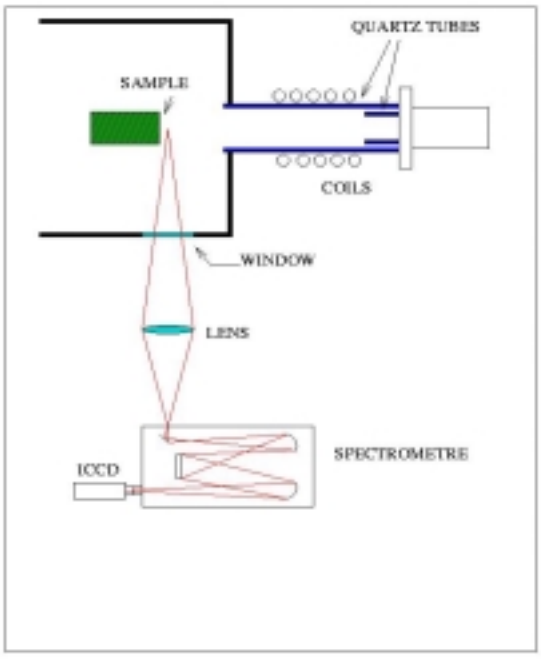

Fig 7. Experimental set-up for spectroscopic measurements

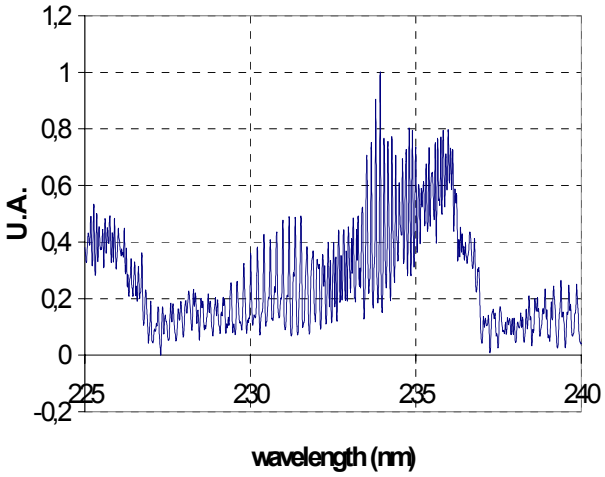

Fig 8. Emission spectra of the NOγ band.

For emission measurement, usual optical devices have been implemented on the experiment (**Fig 7**). The plasma image on the entrance slit of a 750 mm focal length Acton spectrometer, was produced by a quartz lens. An intensified CCD Camera (Princeton Instrument PI-MAX) designed for the UV wavelength range is used for the detection. The **Fig 8** shows the typical plasma emission in the wavelength range of the Noγ band. Temperature measurements can be achieved by fitting these experimental spectra with a calculation [1]. The experimental spectrum pictured in **Fig 8** correspond to a rotational temperature of about 5700 K. In present pressure conditions, rotational temperature can be equate to heavy particle temperature. The so measured axis temperature is reported on **Tab 2** for five typical working conditions. These measurements have been performed at 200 mm from the coil exit. To derive reliable γ value with IPM method, input conditions above the sample have to be as homogeneous as possible. Radial temperature behaviour (**Fig 9**) shows this required condition is approximately verified since the temperature change is about 10 % over 1.5 cm.

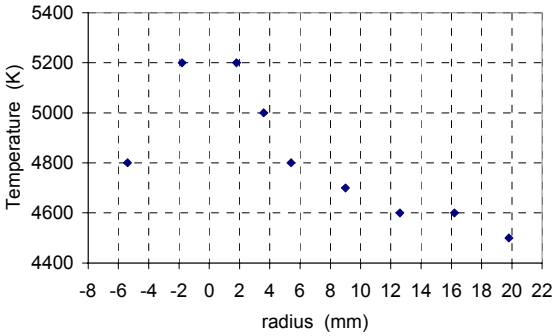

Fig 9. Temperature profile in the free plasma jet

Tab 2

Working Points			T_{kin} (K)
Pressure (mbar)	Anode Intensity (A)	Gas Mass Flow Rate (g/s)	
30	7,5	3,6	5300
30	6,8	3,6	5200
20	7,5	3,6	5600
20	6,7	4,3	4900
20	6,7	6,1	4800

4.2 Pitot probe measurements

In this kind of flow, difficulties are encountered to measure velocity. The velocity range being too low to derive its value by LIF (Doppler shift) and the temperature too high to employ PIV method. Then even if in plasma flow it is not easy to deduce reliable value with Pitot probe, this measurement technique have been implemented on the experiment. In the literature we find several theoretical works which study the determination of the velocity by dynamic pressure measurements [4][5][6]. But its are not available in our working conditions (low pressure, cone shape of the Pitot probe, low Mach number ……)

So, we assume that the impact pressure is :

$$\Delta P = \tfrac{1}{2}\rho_{\infty}U_{\infty}^{2} \qquad (4)$$

By this way, we have an order of magnitude of the velocity in a plasma jet section. An example is given for the same working point than the temperature profile (see **Fig 10**).

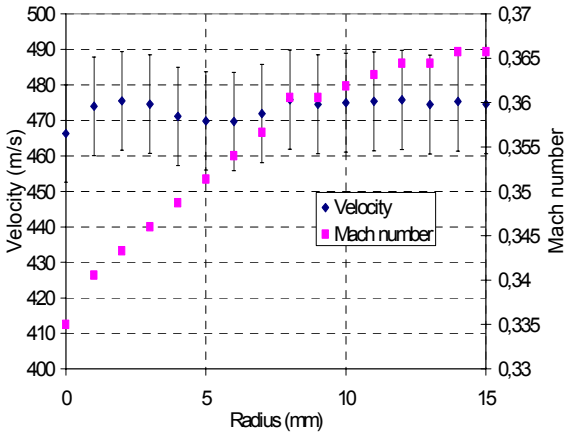

Fig 10. Velocity profile in the free plasma jet

We can see that the velocity profile is quite homogeneous on all the sample surface (the sample diameter is 26.5 mm).

4.3 LIF measurements

Thanks to an OPO laser, some LIF measurements are underway to obtain boundary layer profile for :

- NO, with a 226 nm excitation wavelength
- O , with a two photon LIF at 226 nm excitation wavelength
- N , with a two photon LIF at 211 nm excitation wavelength

5. Conclusion

We have seen that usual measurement techniques for γ determination have been implemented on IPWT. By the way of the IPM method (coupling between experimental results and a boundary layer numerical code) we are able to determine the γ parameter of TPS, like the OREX one. Furthermore, to complete the knowledge of the plasma jet, several measurement techniques have been used, like emission spectroscopy, Pitot probe and some LIF measurements are underway to get the species densities. This set of data will be very useful for the numerical code, and the so deduced γ will be more precise. In this way, we also want to improve the surface temperature measurement of the sample. This is a very important point, because this measurement is the base of the γ determination, and the new technique apply can lead us to the emissivity of the sample under re-entry conditions.

Simulation of the decomposition reduction in composite layers by computer supported optimisation.

E. Lugscheider, N. Papenfuss-Janzen, W. Varava
Material Science Institute, Aachen University of Technology, Aachen, Germany

Abstract
A multi-component APS powder spraying process is formalized and analyzed. A mathematical model to estimate the influence of the injector parameters on the powder's decomposition is built. The model is based on an optimization procedure of a multi-injector system, which maximizes the relative mass quantities of the powders in the intersection area of the powder spots. The decomposition optimisation allows layers designing with a desirable component mass distribution and should supply improving their thermo-physical properties.

1. Introduction

Application of multi-layer sprayed coatings, particularly graded coatings, plays more and more important role in industry and medicine. Metals, ceramics and synthetic materials can be used as components of powders, applied to produce a functionally graded coating. Among other things, these complicated coatings are used in implant medicine, production of abradables for turbine blades and corrosion protection of light weight constructions. Graded coatings are applied to substrates by atmospheric- and shrouded plasma spraying (APS/SPS) as well as by physical- and chemical vapour deposition (PVD/CVD). The component's mass distribution is one of the most important characteristic of a graded coating quality. A determined grading of a multi-component powder should supply desirable mass distribution to achieve decisive advantages, concerned to the most important physical properties of the coating.
Based on above consideration, building of a mathematical model for graded processes simulation, provided direct and inverse calculation of input and output parameters, plays an important role. A developed mathematical model should be put to the numerical and experimental tests in order to validate it.

2. Problem description

A determined powder mass distribution by the fabrication of abradables for gas turbine blades is required. The modern powders, widely used for the production of abradables, consist in majority of the three following components: MCrAlY, BN and Polyester. The thicknesses of the turbine blade abradable coating are usually in the range of 1,5 – 2 mm. Because of technical and exploitation reasons, the BN and polyester fractions in the coating must be increased and MCrAlY fraction must be decreased in the direction to the contact surface. Therefore, the coating's thermo-mechanical properties strongly change towards the thickness coordinate. Required mass fraction dependences can be obtained by a graded spraying process. The same problem takes place in medicine implant fabrication, where the grading of Titan (Ti) and Hydroxylapatit (HAp) supplies the necessary functional properties [2]. Therefore, the matters concerning optimal mass distribution are discussed in the presented article. In addition to above, the graded coatings should supply the following features [3]:

- Jump decreasing in thermo-mechanical characteristics in the system substrate – coating;
- Improving the chemical compatibility in the system substrate – coating;
- Supplying needed hardness.

Based on above discussion, the problem statement can be formulated as: to obtain a predetermined mass fractions distribution depending only on the thickness coordinate.

3. Mathematical Model

The presented mathematical model is developed for the simulation of APS graded processes exclusively (the other cases are not taken into account). The investigated physical system includes an unloaded plasma jet, particle injectors, and particles. Its parts have the following borders: plasma gun outlet, calculation domain surface, and substrate surface. The powder injection takes place at the same time by a number of injectors, located at different positions.

The following input parameters are used in the presented model:

1. Parameters related to plasma jet (field values):

They are the field values like temperature-, velocity- and pressure distributions at the outlet of plasma gun as well as inside unloaded plasma jet. These fields will be following considered as steady state and known. Besides of them, the particles' influence on the plasma jet is neglected. The accepted assumption very well corresponds to reality for a wide range of metallic and ceramic materials [4]. The interaction between the particles in the plasma jet can be considered as insignificant for technical applications, what is validated by a number of experimental and theoretical investigations. The fields are calculated for fixed plasma gun – **F4 - Sulzer Metco –** and for fixed cold plasma forming gas mixture – Argon 93%, Hydrogen 7% – in the ambient air under atmospheric condition by CFD software PHOENICS [1].

2. Parameters related to the particles:

The particle diameter is a random variable. Because of a great amount of particles (N > 7,5e+04 part/sec) in plasma spraying, it is possible to consider the particle diameter as a continuous random variable. Gauss probability density is assumed for this random variable approximately:

$$p_D(d) = \frac{1}{\sqrt{2\pi}\,\sigma(D)} \exp^{-\frac{(d - M(D))^2}{2\sigma(D)^2}}$$

$$d \in [d_{\min}; d_{\max}] = [M(D) - 3\sigma(D); M(D) + 3\sigma(D)] \quad , \qquad d_{\min} > 0 \qquad (1)$$

where: D is a random particle diameter; d is a realisation of random particle diameter; $d_{\min}$, $d_{\max}$ are the minimal and maximal realisation of a particle diameter, respectively; $\mathbf{M}(D)$ is the particle diameter mean value; $\boldsymbol{\sigma}(D)$ is the particle diameter standard deviation; $p_D\ (d)$ is the probability density of the particle diameter.

3. Parameters related to injector and particles:

The particle initial position is a random variable. Uniform probability density is assumed for this random variable:

$$p_{\underline{R}_0}(\underline{r}_0) = p_{R_0,\Phi}(r_0, \varphi) = \frac{1}{A_I} = \frac{1}{\pi R_I^2} \qquad (2)$$

where: $p_{\underline{R}^0}(\underline{r}_0)$ is the probability density of the particle initial position; A_I , R_I are the injector outlet area and injector radius, respectively.

The particle initial position and its diameter is assumed to be stochastic independent:

$$p_{D,\underline{R}_0}(d, \underline{r}_0) = p_D(d)\, p_{\underline{R}_0}(\underline{r}_0) \qquad (3)$$

where: $p_{D\ ,\underline{R}^0}(d, \underline{r}_0)$ is the common probability density of the particle diameter and of the particle initial position.

Particle initial velocity is assumed to be independent on the initial position and the particle diameter is a deterministic value. [5]:

$$\underline{V}_0 = \underline{V}_0(D, \underline{R}_0) = \underline{V}_0 = const \qquad (4)$$

In addition, the initial velocity is assumed to be perpendicular to injector outlet and depends linearly on the carrier gas flow rate [5]:

$$\underline{V}_0 = const \cdot \dot{m}_{TG} \qquad (5)$$

where: $\dot{m}_{TG}$ is the carrier gas flow rate. The carrier gas flow rate is a deterministic steady-state value.

4. Parameters related to injector:

The situation of the injector surface with respect to the plasma gun outlet position $\underline{\boldsymbol{C}}$, the injector outlet surface A_I and mass particle flow rate $\dot{m}$ are deterministic input parameters.

The following output parameters are used in the presented model:

1. Parameters related to particle

The particles are considered as a mass point in the frame of the presented model, and the assumption is used to solve the dynamic equation for the particle. The particle position vector depends continuously on the initial conditions and the coefficients of the dynamic differential equation, therefore it also continuously depends on input parameters like particle diameter, initial position and initial velocity. According to the consideration above, the particle-hit position on the substrate is introduced as output variable that follows from its trajectory. This variable is a random variable depending on input random variables.

2. Parameters related to coating

Because of the great amount of particles and the great area flattening rate (can reach 150-200 for ceramic particles at its melting point and velocities about 150-200 m/s), the average spot area is introduced as an output parameter, so it is possible to say that the material distributes continuously inside the spot.
An area of the coating on the substrate can be considered as the spot, obtained by a motionless plasma gun. The studying of input parameters influence shows that the particle diameter distribution, the initial velocity, the injector outlet area and its position strongly influence on spot area, but the particle flow rate and the initial particle position have no influence.
The common dependence of spot area can be presented as

$$A_F = A_F(p_D(d), \underline{V}_0, A_I, \underline{C}) \qquad (6)$$

The two following output parameters can be introduced because of continuous mass distribution in the spot: coating thickness (ρ_{su}) and normalized coating thickness (p_{Rsu}), both of them should be related in respect to a time unit. ρ_{su} depends on all input parameters introduced before; in the mean time p_{Rsu} doesn't depend on particle mass flow rate that plays a big role by the following model building. The common dependence of both output parameters considered before can be presented as follows:

$$\rho_{SU} = \rho_{SU}(p_D(d), \underline{V}_0, p_{\underline{R}0}(r_0), \dot{\Theta}, A_I, \underline{C}) = \frac{d\dot{\Theta}}{dA} \qquad (7)$$

$$p_{\underline{R}SU} = p_{\underline{R}SU}(p_D(d), \underline{V}_0, p_{\underline{R}0}(r_0), A_I, \underline{C}) = \frac{1}{\dot{\Theta}}\frac{d\dot{\Theta}}{dA} \qquad (8)$$

where: ρ_{SU} is the coating thickness related in respect to a time unit; p_{RSU} is the normalized coating thickness;

p_{Rsu} can be interpreted as a probability density of the particle hit position on the substrate for each of the powder component accordingly expression (8). For the chosen problem statement a mathematical model based on optimisation technique is proposed:

It is required to maximize all powder fractions in common coating spot.

In that way, the simultaneous probability of the particle hit position for all powder components will be used as a goal function. The following independent variables will be introduced as optimisation variables: the

particle diameter mean value **M**(D); the particle diameter standard deviation **σ**(D); the initial particle velocity $\underline{\mathbf{V_0}}$; the injector outlet position $\underline{\boldsymbol{C}}$ and the injector outlet area A_I.
In particular for two-injector design, the goal function can be expressed as follows:

$$\mathbf{P}\left(\tau_1 \wedge \tau_1 \in A_{12=21}\right) = \int_{A_{12}} p_1\, dA \bullet \int_{A_{12}} p_2\, dA \xrightarrow{\text{in Designvariables}} max \quad (9)$$

$$p_1 = \dot{\Theta}_1^{-1}\rho_1 = \dot{\Theta}_1^{-1}\frac{d\dot{\Theta}_1}{dA} \quad ; \quad p_2 = \dot{\Theta}_2^{-1}\rho_2 = \dot{\Theta}_2^{-1}\frac{d\dot{\Theta}_2}{dA} \qquad (10)$$

where: p_1, p_2 are the normalized coating thickness for the first and the second powder component, respectively; ρ_1, ρ_2 are the coating thickness for the first and the second powder component, respectively; $\dot{\theta}_1$, $\dot{\theta}_2$ the volume particle flow rate for the first and the second powder component, respectively.

4. Adaptation of PLASMA 2000 software and first results

At present PLASMA 2000 software is used to solve particle dynamic and heating problems with taking evaporation into account [6]. The software is adapted to solve the graded coating problem by the means of an optimisation model. The following modification steps was done:

- definition of variation range for all input parameters;
- extension up to two injection system;
- build a new program module in frame of PLASMA 2000 called TOPO-model;
- choosing the NELDER-MEAD method as restriction free optimisation procedure [7];
- looking for start point to optimisation with non zero goal function value (MODUL_START);
- finding of satisfying number of test particle (MODUL_PARTICLE).
-

The TOPO-model is used to define the area of each powder, the intersection area of the spots as well as to calculate the goal function. The operation results of TOPO-model are illustrated in Figure.1 for the input parameter set, defined in Table 1.

Table 1. Spraying design 1-2 (one injector – two powders)

Plasma design		Injection design		Powder properties	MCrAlY	BN
Current, A	650	Velocity , m/s	12	Density, kg/m^3	8000	2300
Voltage, V	50	Injector area, mm^2	1,78	Mean diameter, µm	70	110
Power (effective), kW	25,3	Axial distance, mm	6,3	Standard deviation, µm	10	20
Argon flow rate, slpm	41	Radial distance, mm	8,5	Number of test particles	30x30	30x30
Hydrogen flow rate, slpm	10	Angle, °	180			

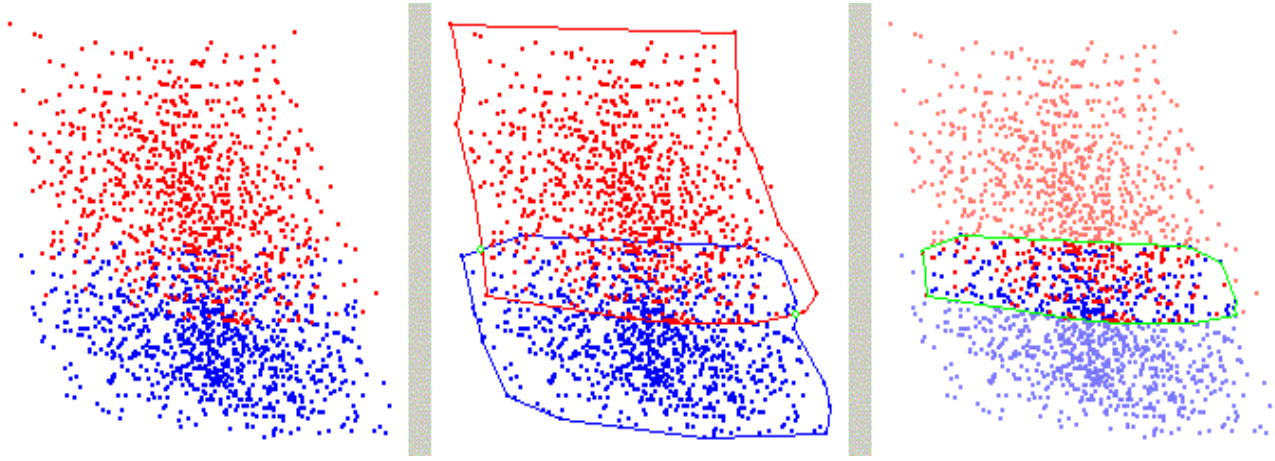

Figure 1. TOPO-model for spraying design 1-2

It is possible to observe quiet a big decomposition of the powders, which is represented by a relative little value of the goal function (P=0,057). It corresponds to the mean volume efficiency for each powder about 22%. The spot areas are equal to 8,55 mm^2 for McrAlY (red), 6,03 mm^2 for BN (blue) and 2,23 mm^2 for the intersection area.
Operation results of MODUL_PARTICLE are illustrated in Table 2.

Table 2. The deviation of spot areas and goal function (60x60 Particles)

Experiment, $N^{\underline{0}}$	**Goal, *P***	**Area 1, m^2 A_1 x 10^{-6}**	**Area 2 , m^2 A_2 x 10^{-6}**	**Intersection area, m^2 A_O x 10^{-6}**	**(MEAN ; STD), P , A_1 , A_2 , A_O , e**
1	0.9892	1.4783	1.5010	1.4419	μ (***P***) = 0.9869
2	0.9892	1.4835	1.5064	1.4454	
3	0.9844	1.5180	1.4098	1.3936	σ (***P***) = 0.0016 ; e = 0.16
4	0.9851	1.4725	1.4905	1.4220	
5	0.9856	1.4622	1.4637	1.4203	μ (***A1***) = 1.4683
6	0.9856	1.4134	1.4731	1.3696	
7	0.9869	1.4727	1.4767	1.4187	σ (***A1***) = 0.0261 ; e = 1.78
8	0.9855	1.4748	1.4828	1.4151	
9	0.9869	1.4468	1.4733	1.4089	μ (***A2***) = 1.4760
10	0.9875	1.4469	1.4796	1.4127	
11	0.9893	1.4583	1.4895	1.4335	σ (***A2***) = 0.025 ; e = 1.69
12	0.9868	1.4774	1.4897	1.4276	
13	0.9860	1.4650	1.4361	1.3870	μ (***AO***) = 1.4179
14	0.9873	1.5115	1.4730	1.4448	
15	0.9885	1.4428	1.4954	1.4268	σ (***AO***) = 0.0215 ; e = 1.42

The numerical results show, that the number of the test particles up to 4000 is enough to hold the deviation of the goal function in a 1% range.
Finally, the attention should be paid to the fact, that the particle heating part is neglected in the frame of the developed model, because the influence of the particle heating on particle dynamic process is insignificant and particle-heating calculation can be carried on separately for the optimal design. This assumption can hold the time for the calculation in reasonable limits.
In addition, some analytical expressions are obtained concerning graded spraying process.

Mean coating thickness:
$$\bar{h} = \bar{h}_1 + \bar{h}_2 = \kappa_1 \frac{\dot{\Theta}_1}{v_B \Delta x} + \kappa_2 \frac{\dot{\Theta}_2}{v_B \Delta x} = \frac{1}{v_B \Delta x}\left(\kappa_1 \frac{\dot{m}_1}{\rho_1} + \kappa_2 \frac{\dot{m}_2}{\rho_2}\right) \qquad (13)$$

Graded concentration ratio:
$$Q = \frac{\bar{h}_1}{\bar{h}_2} \qquad (14)$$

where: v_B is the plasma gun velocity; Δx is the maximal projection size in the direction perpendicular to the of plasma gun motion; $\bar{h}_1, \bar{h}_2$ are the mean coating thicknesses for the first an the second powder, respectively; $\dot{\theta}_1, \dot{\theta}_2, \dot{m}_1, \dot{m}_2$ are the particle volume and mass flow rate for the first an the second powder, respectively; κ_1 , κ_2 are the deposition efficiencies for the first an the second powder, respectively; ρ_1 , ρ_2 are the mass densities for the first an the second powder, respectively.
If the grading optimal design satisfies to technical requirements, the goal function is approximately 1. In this case it is possible to calculate particle mass and volume flow rates for defined elementary mean coating thickness and graded concentration ratio. The calculation and the spraying are carried on step-by-step up to the moment, when desirable whole thickness and concentration distribution will be reached.

5. Conclusion

The optimised graded spraying of few powders can improve thermo-physical properties of the coating. In this article, the mathematical model to calculate the controlled coating growth based on an optimisation technique developed by NELDER-MEAD is presented. This model is related to the problem formulation and shows advantages in the numerical solution procedure.

The optimisation procedure does not include the calculation of derivatives, only needs a limited amount of memory capacity and requires a small number of control parameters. The numeric testing of this procedure shows good stability and not sensibility to numerical errors, taking place at the goal function calculation [7].

The developed modules MODUL_START and MODUL_PARTIKEL allow to find an appropriate start design with a non-zero goal function value and to adjust the proper number of the test particles to hold the goal function deviations in a permissible range. The optimisation procedure combined with above described modules makes possible integrated numeric estimation of the optimal design for two or more powders, which helps to configurate appropriate graded spray equipment and to control the growing of the coating. High flexibility and possibility to vary the number of optimisation parameters are important advantages of the developed model too. The first presented numerical results combined with the analytic ones show the possibility to control the graded spraying by injector parameters.

Insignificant complication of the graded spraying process and injection equipment should lead to better coating quality.

In future work, some essential steps in order to develop further the model can be divided in the following groups: theoretical (taking into account particle influence on the plasma jet in the case of high loaded plasma; taking into account non stationery cases), numerical (extending and testing of the optimisation software, optimal design calculation for different material combination; dimension reduction of design variable space), and, the most important, detailed experimental investigations of the graded coating quality (metallography, radiography, hardness testing and tribology) to validate the developed model. It allows getting new knowledge and experience about the control and the structure of the graded coating process.

Transport coefficients in two-temperature argon-helium thermal plasmas

V. Rat, J. Aubreton, M.F. Elchinger, and P. Fauchais

SPCTS –CNRS UMR 6638, University of Limoges, 123 av. A. Thomas, 87060 Limoges cedex, France

Abstract

Transport coefficients in argon-helium plasmas at atmospheric pressure are calculated assuming that the kinetic electron temperature T_e is different from that of heavy species T_h. The influence on transport coefficients (electrical conductivity, viscosity and thermal conductivity) of the non-equilibrium parameter $\theta=T_e/T_h$ is investigated. The plasma composition shows that the increase of the non-equilibrium parameter θ gives rise to a shift of the ionisation of heavy species to lower heavy species temperatures. This results in a decrease of the viscosity at T_h fixed, as θ increases. Electrical conductivity is shown to be weakly dependent on θ, contrary to thermal conductivity.

1. Introduction

Departures from local thermal equilibrium (LTE) in many plasma processes have been highlighted, such as thermal plasmas in vacuum conditions, close to electrodes of electric arcs, in plasma jets as soon as a cold gas or a liquid is injected. Non-equilibrium plasmas, for which the kinetic electron temperature T_e can be different from that of heavy species T_h, are extensively studied and modelled.

Plasma processes modelling requires two-temperature transport coefficients in order to solve with accuracy conservation equations with their boundary conditions (see for example lately [i,ii,iii]). Very recently, Rat et al. [iv,v] proposed a modified approach of the Chapman-Enskog method applied to a two-temperature thermal plasmas in order to calculate non-equilibrium transport coefficients. Unlike Burm et al. [vi] who describe the plasma with reduced variables (depending on pressure and electron number density) and two non-LTE parameters, transport coefficients are basically obtained from the knowledge of plasma composition, the pressure, the temperature T_e and T_h. The non-equilibrium parameter $\theta = T_e/T_h$ is fixed for each calculation.

Many plasma processes use argon-hydrogen mixtures because argon and hydrogen respectively improve the momentum and energy transfers [vii,viii]. Argon-helium is also widely used because on the one hand, helium increase the plasma enthalpy and, on the other hand, the mixture exhibits a higher viscosity over 10000 K at equilibrium due its high ionisation energy [ix]. Besides its well known transport and thermodynamic properties, helium can present departures from LTE at atmospheric pressure, depending on experimental conditions as explained by Jonkers *et al.* [x], because of its high excitation potential of the first excited states and its light mass which facilitate its diffusion.

This paper is therefore aimed at calculating transport coefficients in argon-helium thermal plasmas, where the kinetic temperature of electrons T_e is different from that of heavy species T_h by using the approach of Rat *et al.* [iv,v]. First, plasma composition is calculated and the influence of $\theta = T_e/T_h$ on the latter is investigated. Second, results of two-temperature transport coefficients are shown and discussed as function of $\theta = T_e/T_h$.

2. Plasma composition

Considering a mixture of only atomic species, the modified equilibrium constant method of van de Sanden *et al.* [xi] is used to obtain the number density of each species up to T_e = 30,000 K.

Plasma composition is determined for 7 species, namely the electrons, Ar, Ar^+, Ar^{2+}, He, He^+ and He^{2+} using the conservation of pressure, the molar fraction ratio Ar/He and the electrical neutrality. The electron temperature T_e is used in the modified equilibrium constants for ionisation reactions of Ar, Ar^+, He and He^+.

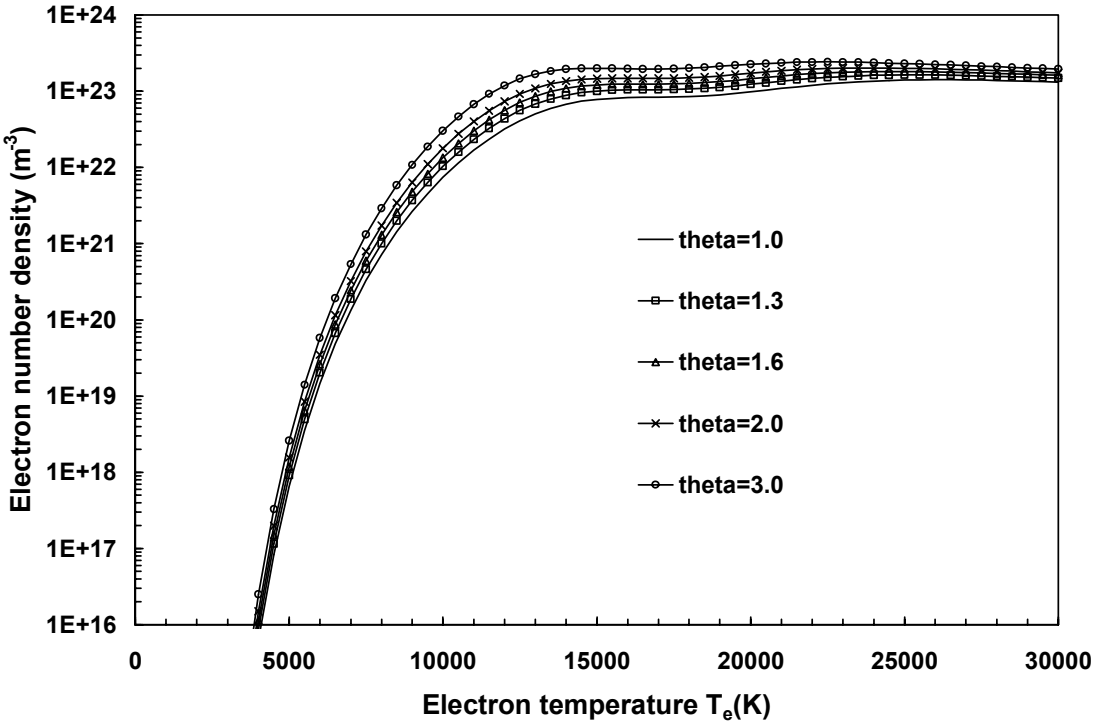

Figure 1: Dependence on electron temperature of the number densities of electrons of an argon-helium mixture (25mol % Ar) for different values θ at atmospheric pressure.

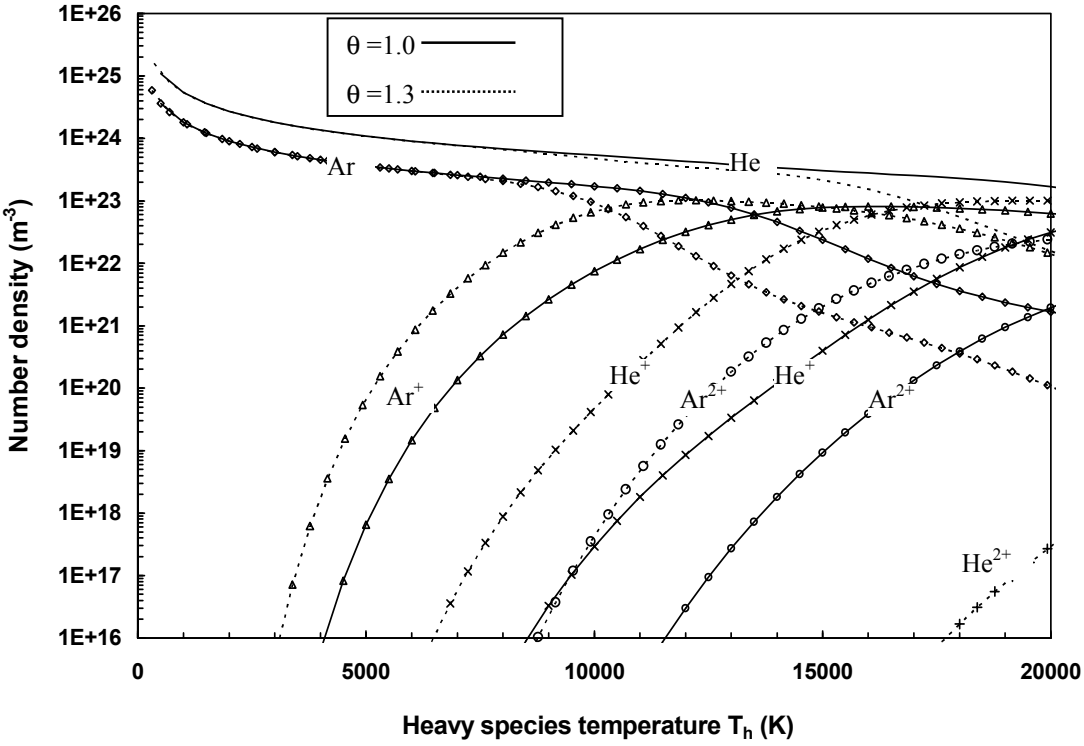

Figure 2: Dependence on heavy species temperature of the number densities of Ar, He, Ar^+, He^+, Ar^{2+} and He^{2+} species of an argon-helium mixture (25mol % Ar) for $\theta = 1.0$ and 1.3 at atmospheric pressure.

In order to illustrate the influence of the non-equilibrium parameter $\theta = T_e / T_h$ on plasma composition, Figure 1 shows the dependence on electron temperature of the number densities of electrons of an argon-helium mixture (25mol % Ar) for different values $\theta = T_e / T_h$.

It can be observed that electron density becomes almost constant over 15,000 K. The electron number density slightly increases with θ at fixed Te. However, in Figure 2, which depicts the dependence on heavy species temperature T_h of Ar, He, Ar^+, He^+, Ar^{2+} and He^{2+} species of an argon-helium mixture (25mol % Ar) for $\theta = 1.0$ and 1.3, the number densities of heavy species are strongly dependent on θ. For example, at 10,000 K, the number density of Ar^+ ions increases by one order of magnitude from equilibrium to $\theta = 1.3$. Similar observations can be carried out for He^+, Ar^{2+} and He^{2+} ions. Thus, it can be observed that the ionisation of heavy species is much more efficient in non-equilibrium conditions, resulting in a shift of ionisation to the lower heavy species temperatures. The non-equilibrium values are always higher than those obtained at equilibrium. Actually, plasma composition is dominated by the modified Saha equations calculated at T_e, which favour the ionisation of species.

Moreover, the number density of argon and helium atoms decreases over a heavy species temperature range smaller in the non-equilibrium case than at equilibrium. This means that the heavy species temperature range, over which the neutral-neutral and neutral-charged interactions dominate, decreases as θ increases, favouring the Coulomb interaction regime instead. Consequently, it is expected that transport coefficients should be deeply affected by the shift of ionisation to the lower heavy species temperatures, especially for the viscosity and combined diffusion coefficients, as it will be highlighted in section 3.

3. Plasma transport properties

Two-temperature transport coefficients are calculated at atmospheric pressure for different values of the non-equilibrium parameter θ.

Figure 3 shows the dependence on electron temperature of the electrical conductivity of an argon-helium mixture (25mol% of argon). It can be observed that, at electron temperature fixed, the electrical conductivity increases with θ. This behaviour is closely linked to that of the number density of electrons, which is also weakly dependent on θ as already shown in Figure 1. For a strong non-equilibrium parameter $\theta = 3.0$, the electrical conductivity indeed increases by only 17 % with respect to equilibrium.

However, the dependence on θ of the viscosity is much more pronounced, as shown in Figure 4, which depicts the viscosity of an argon-helium mixture (25mol% of argon) as a function of the heavy species temperature for different values of the non-equilibrium parameter θ at atmospheric pressure. The viscosity has been plotted as a function of heavy species temperature since it is well known that it is governed by heavy species. The part of non-equilibrium curves which overlap the equilibrium one corresponds to the neutral-neutral interactions regime, i.e. before a real efficient ionisation. The study of the plasma composition shows that ionisation is especially favoured as θ increases. This means that the ionisation temperature of heavy species is smaller than at equilibrium, inducing a shift to the lower heavy species temperatures of ionisation. A shift of viscosity curves to the lower heavy species temperature is therefore observed. It can be noted that the temperature range between both peaks of ionisation is drastically reduced as θ increases.

Figure 5 shows the dependence on electron temperature of the thermal conductivity of an argon-helium mixture (25mol% of argon) for different values of the non-equilibrium parameter θ at atmospheric pressure. It has to be emphasized that the thermal conductivity includes the translational (electrons and heavy species), reactional and internal contributions [xii]. This total thermal conductivity has been arbitrarily defined with respect to the temperature gradient of heavy species [viii]. At low temperature, the translational contribution of heavy species is dominant. Below 10,000 K, it can be seen that, at fixed T_e, the thermal conductivity, depending mainly on the heavy species temperature, decreases as θ increases due to a shift of curves plotting. However, as soon as ionisation occurs, above 10,000 K, a first peak corresponds to the ionisation of argon atoms, and a second one to the ionisation of helium atoms and Ar^+ ions. At high temperatures, the translational contribution of electrons seems to deeply dominate the behaviour of the thermal conductivity, especially as θ increases. However, it has to be focused that the translational contribution of electrons is θ times higher with respect to the heavy species temperature gradient than with respect to the electron temperature gradient.

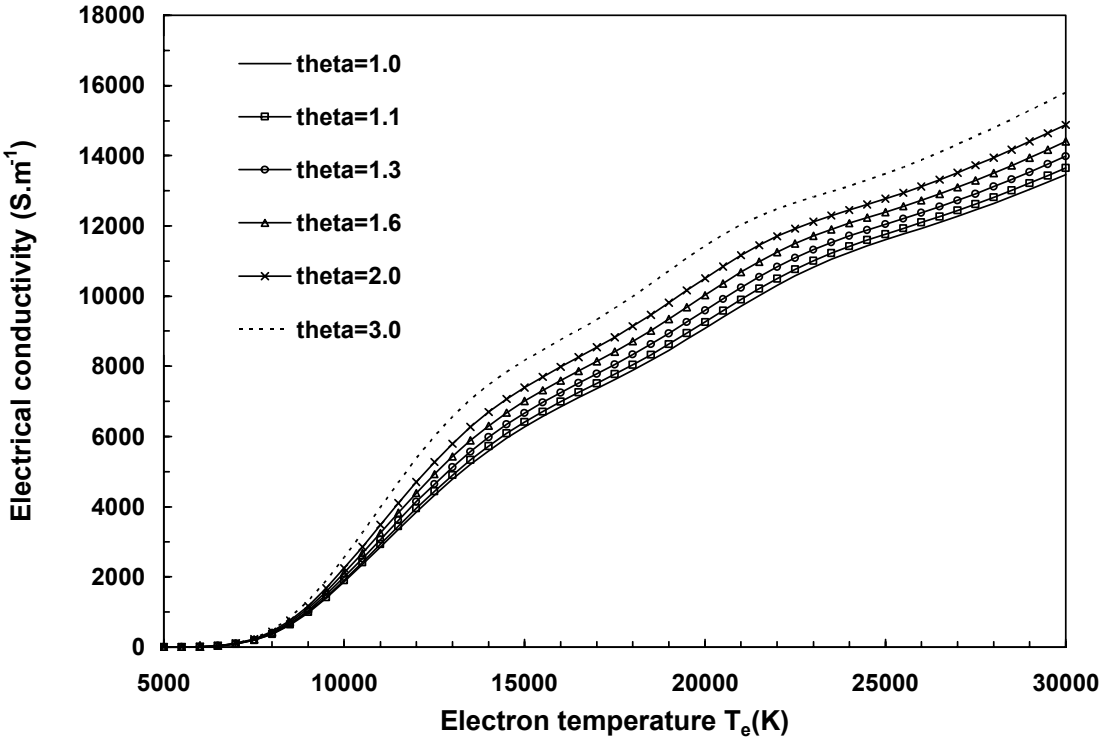

Figure 3: Dependence on electron temperature of the electrical conductivity of an argon-helium mixture (25mol% of argon) for different values of the non-equilibrium parameter θ at atmospheric pressure.

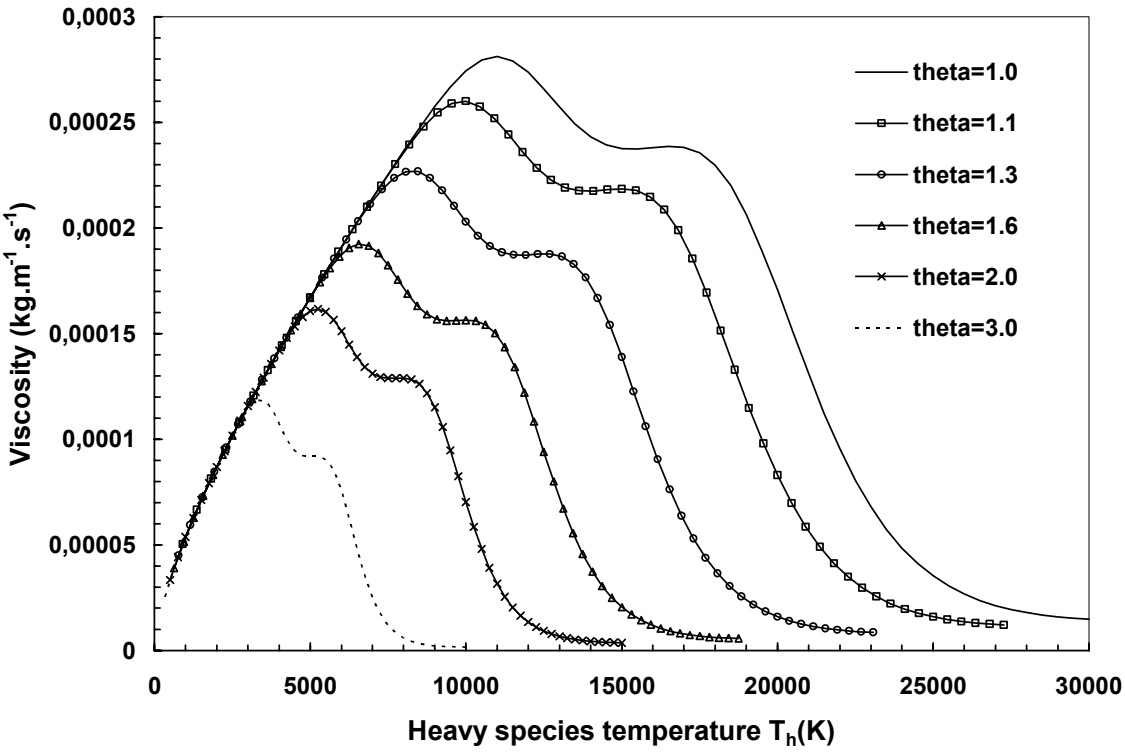

Figure 4: Dependence on heavy species temperature of the viscosity of an argon-helium mixture (25mol% of argon) for different values of the non-equilibrium parameter θ at atmospheric pressure.

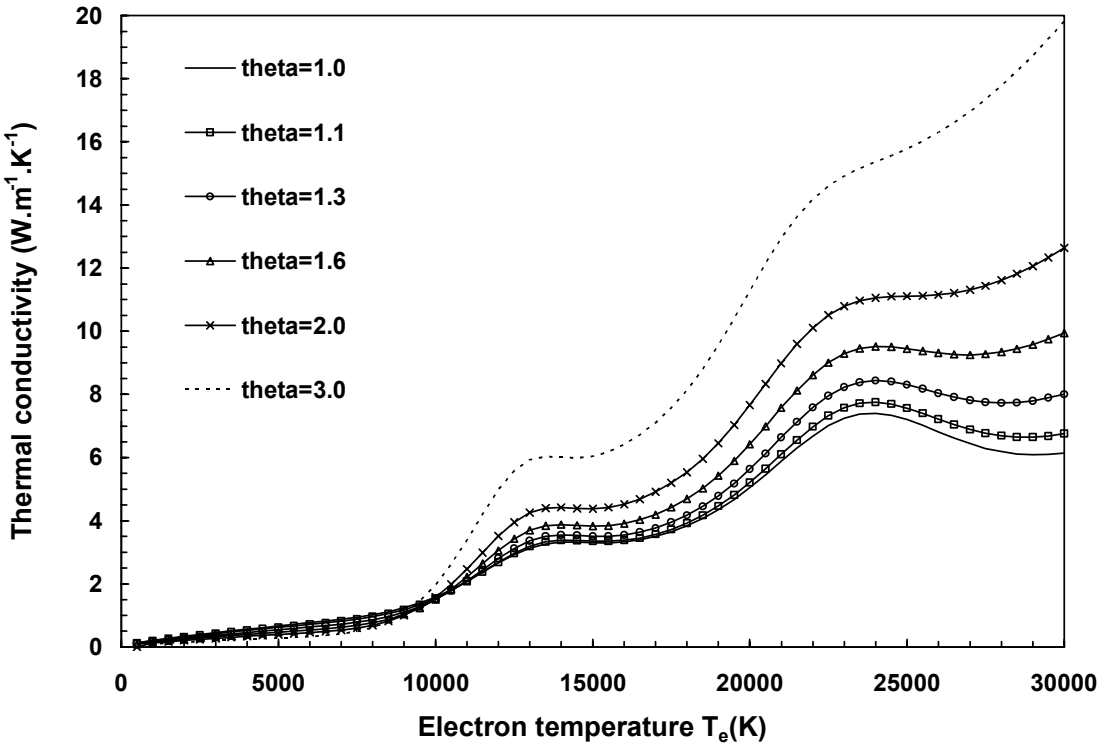

Figure 5: Dependence on electron temperature of the thermal conductivity of an argon-helium mixture (25mol% of argon) for different values of the non-equilibrium parameter θ at atmospheric pressure.

4. Conclusion

This paper is devoted to the calculation of two-temperature transport coefficients in argon-helium thermal plasmas at atmospheric pressure, where the kinetic electron temperature T_e is supposed to be different from that of heavy species T_h. To perform these calculations, first, plasma composition has been obtained using the modified equilibrium constants method of van de Sanden *et al.* [xi].

Two-temperature electrical conductivity, viscosity, and thermal conductivity have been calculated using a modified Chapman-Enskog method applied to a two-temperature thermal plasma [iv,v].

The analysis of the plasma composition has highlighted that the increase of the non-equilibrium parameter $\theta = T_e/T_h$ tends to shift the ionisation of atomic species to lower heavy species temperature. This behaviour is similar to that obtained by reducing the pressure. Numerous equilibrium calculations of transport coefficients (see for example [xii]) have indeed shown that a decrease of pressure moves dissociation and ionisation peaks to lower temperatures according to the Le Chatelier's law.

In a mixture consisted of only atomic species, an ions-dominated regime occurs all the more quickly as θ is high, and strongly influences transport coefficients, particularly through Coulomb collision integrals. The change of collision integrals from neutral-neutral interactions to charged-charged interactions drastically diminishes transport coefficients since the Coulomb integral collisions are two to three orders of magnitude higher than collision integrals of neutral species. The transport coefficients are then affected by displacing the maximum of viscosity and that of combined diffusion coefficients to the lower heavy species temperature. It can be noted that a shift of peaks of ionisation in thermal conductivity is expected if the latter is plotted as a function of heavy species temperature. Moreover, the electrical conductivity was observed to be weakly θ dependent.

Abstract
Low energy electron beams with an acceleration voltage of up to 14 kV were used to initiate methane reforming reactions with CO_2, O_2 and H_2O for hydrogen generation. Electron beams were generated in a compact electron gun system comprising a very thin electron extraction window, which separates the vacuum from the atmospheric pressure gas mixture to be treated. A maximum CH_4 conversion of about 6 % at a total flow rate of 5 ml/min was achieved with specific energy requirement of 2 MJ/mol H_2.

1. Introduction

Hydrogen is supposed to play a more and more important role in the world-wide energy supply. Hydrogen-fueled fuel cells offer the possibility for very efficient generation of electrical energy practically without contaminating emissions. Furthermore, hydrogen-enriched fuels for conventional combustion processes allow the operation under leaner conditions, increasing the efficiency of the process and at the same time reducing noxious emissions. However, due to the difficulties which still arise from hydrogen transport and storage, on-site hydrogen generation from hydrocarbons is preferred for the applications mentioned above.

In addition to conventional catalytic reforming processes for hydrogen generation from hydrocarbons, various plasma-based techniques have been described in literature [1-6], among them both thermal arcs and non-thermal plasma techniques such as dielectric barrier discharges (DBD), corona discharges, and microwave discharges. Plasma methods are characterised by a short response time on load change, and they are uncritical in terms of fuel impurities and soot deposition.

Steam reforming experiments with DBD have shown that the dissociation of methane in the discharge is strongly favoured. With the mean electron energy which can be achieved under DBD conditions the cross section for the electron collision dissociation of water is significantly lower than that for methane (Fig. 1). A great part of the electron energy is spent on vibrational excitation of water which is likely to be dissipated as heat during the relaxation of the excited molecules and does not contribute substantially to the formation of the desired reaction products. This results in a high energy requirement for hydrogen generation [7]. The mean electron energy in a DBD depends for a given gas mixture on the discharge gap and the gas pressure, i. e. to increase the electron energy it is necessary to reduce either the gap or the pressure. Both of these measures are unfavourable for a process scale-up with the need to increase throughput by high pressure and to reduce the flow resistance by increasing the flow cross section. Another disadvantage of DBD is the need for pulsed high voltage which is more challenging to obtain, especially for high power levels.

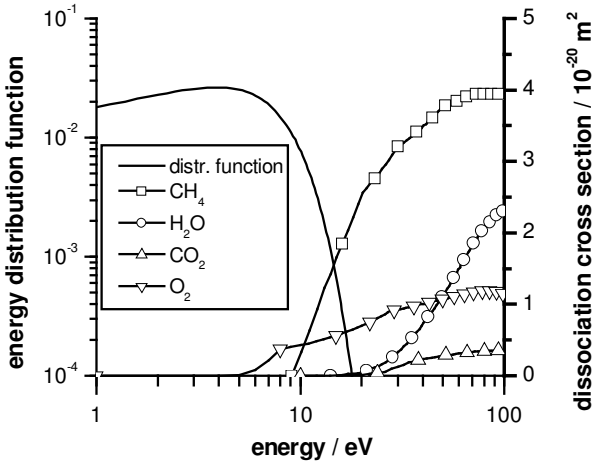

Fig. 1 Electron collision cross sections of CH_4, H_2O, CO_2 and O_2 as function of the electron energy and electron energy distribution function of DBD in a CH_4-H_2O-mixture at 400 °C at the moment of ignition.

Electron beams are an alternative method to gas discharges for the generation of a non thermal plasma. In a vacuum tube, free electrons are released from a suitable source, are accelerated in an electrical field and shot through a thin membrane into the gas phase, where they generate radicals, ions and secondary electrons and induce reactions of the gas components. The generation of accelerated electrons takes place outside the gas phase and is therefore independent of the conditions therein like gas composition, pressure and the reactor geometry. This means that it is easier to transfer the method to a large scale process. This is also true with regard to the power supply. Electron beams work with DC voltage and do not require pulsed power devices which are expensive and available only up to a certain power output level. Large scale electron beam systems with beam powers up to several hundred kW have successfully been tested for the treatment of large volume waste gases in power stations [8,9]. Surface treatment of various materials is another established industrial scale application of e-beams [10].

The transition from the vacuum into the gas mixture at atmospheric pressure requires an extraction window, which is on the one hand able to withstand the pressure difference and on the other hand sufficiently permeable for electrons in this low energy range to reduce the energy loss. For high energy electron beams (E > 100 keV) these requirements are fulfilled by thin metal foils, e. g. made of titanium. Low energy electron beams, however, require very thin window membranes to limit the energy loss in the material. Such thin membranes, which are at the same time mechanically and thermally stable, can be made of ceramic material like SiN using photolithographic techniques. These thin membranes have previously been used for e-beam ultraviolet light sources [11] and their application as ionisation method for mass spectrometry [12]. E-beam with an electron energy of 10-20 kV have a penetration depth in the order of 1 cm in gases composed of light elements at atmospheric pressure, and they generate a plasma zone with an approximately spherical shape. By that means a relatively high power density (~ 1W/cm^3) can be achieved.

In a first step we carried out experiments on e-beam activated methane reforming using a compact electron gun system generating a low energy electron beam with an acceleration voltage in the range of 10-14 kV and beam currents up to 30 µA.

2. Experimental

The electron beam was generated in the vacuum by a cathode ray tube which is built of a heated BaO cathode, various control and focussing electrodes and an electromagnetic system for beam alignment (Fig. 2). The transition of the electron beam from the vacuum into the gas mixture at atmospheric pressure required an extraction window, which is on the one hand able to withstand the pressure difference and which is on the other hand sufficiently permeable for electrons in this low energy range without a significant energy loss. A silicon plate containing a SiN membrane with a size of 1×1 mm and a thickness of about 300 nm was used in our electron gun system set-up to close the vacuum tube at the opposite wall. Due to the limited e-beam energy this system did not require any special X-ray shielding precaution.

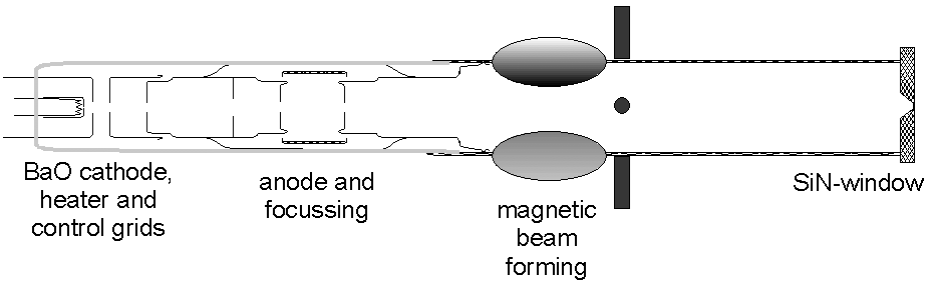

Fig. 2 Electron beam source

The gas to be treated passed the electron extraction window in a continuous flow. Two different gas flow cell designs were used, which are shown in Fig. 3. In the cell type A, the gas flow passed the electron beam in transverse direction. The reactor cell was divided into an inlet room and an outlet room separated by a wall with a small gap in front of the extraction window, which forced the all the gas to the volume reached by the electron beam. In the gas cell type B the gas flow entered the chamber radially nearby the extraction window and left axially opposite to the membrane. The cylindrical reaction chamber was formed by an exchangeable insert for easy change of the chamber diameter and length. Three different inserts were used with a diameter

d and a length l of 6, 8 and 10 mm. These inserts were electrically insulated from the reactor body for direct measurement of the effective beam current.
Methane reforming reactions were studied with three different oxidant components, particularly CO_2 (dry reforming), O_2 (partial oxidation) and H_2O (steam reforming). The gases were premixed with stoichiometric mole ratios regarding synthesis gas as reaction product including the water shift reaction in the case of steam reforming, in detail: CH_4:CO_2 1:1, CH_4:O_2 2:1 and CH_4:H_2O 1:2. Dry reforming and partial oxidation were carried out at ambient temperature with a total gas flow of 5 ml/min in the gas flow cell type A. The cell of type B was used for steam reforming with 15 ml/min at 110 °C and was therefore equipped with a heating coil. The reaction products were analysed with a gas chromatograph (Shimadzu GC14b) equipped with a thermal conductivity detector and a flame ionisation detector.

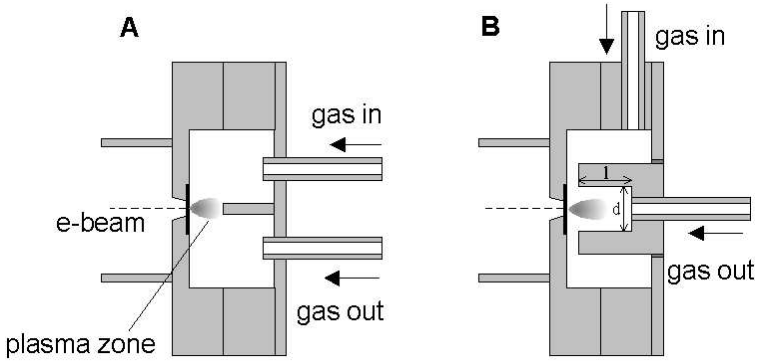

Fig. 3 Gas flow cells, type A: transverse flow, type B: radial/axial flow

3. Results and Discussion

Due to the low energy of the e-beam, the primary electrons penetrating the gas phase are retarded by ionising collision processes within a very low distance, typically a few millimetres in the voltage range of 10-15 kV at atmospheric pressure, and as a consequence, a very high power density in the reaction volume can be achieved, which results in a high density of reactive particles. The power density increases with decreasing acceleration voltage and with increasing pressure. The power output of the electron beam system is limited by the current density the extraction window can withstand without a destructive heat dissipation inside the membrane. With our system a maximum beam current of 33 µA could be achieved with an acceleration voltage of 14 kV. Thus the maximum e-beam power was 462 mW. On the other hand, the gas flow rate could not be reduced to any desired value in order to guarantee a precise gas manipulation and analysis. Therefore The conversions of methane and the oxidants achieved with this energy input are shown in Fig. 4, as a function of the e-beam power and the gas mixture. With dry reforming at 273 mW power (U = 13 kV, I = 21 mA), 5 % methane conversion was observed. However, the CO_2 conversion was lower by a factor 10. This can be explained by the significantly higher electron collision cross section of methane as shown in Fig. 1. By increasing the beam power to 462 mW the methane conversion rises to 6.6 % while the CO_2 conversion is nearly doubled. With partial oxidation the conversion ratio between methane and the oxidant is reverse. The oxygen conversion is about 8 %, almost twice as high as the methane conversion. According to Fig. 1 the oxygen cross section is significantly higher for low electron energy levels, i. e. between 5 and 10 eV. Thus one can suppose that the mean electron energy in the plasma zone is approximately in this energy range. Compared to dry reforming, the molar methane conversion is nearly the same, keeping in mind the higher methane concentration in the starting gas mixture. Steam reforming shows a similar behaviour to dry reforming, with the H_2O/CH_4 conversion ratio slightly higher than the CO_2/CH_4 conversion ratio, reflecting the proportions of the corresponding cross sections. The conversion rates increase linearly with the e-beam power, the maximum values at 420 mW are 1.6 % for methane and 0.4 % for water conversion.
the energy density in the gas was limited to 5.5 kJ/l.

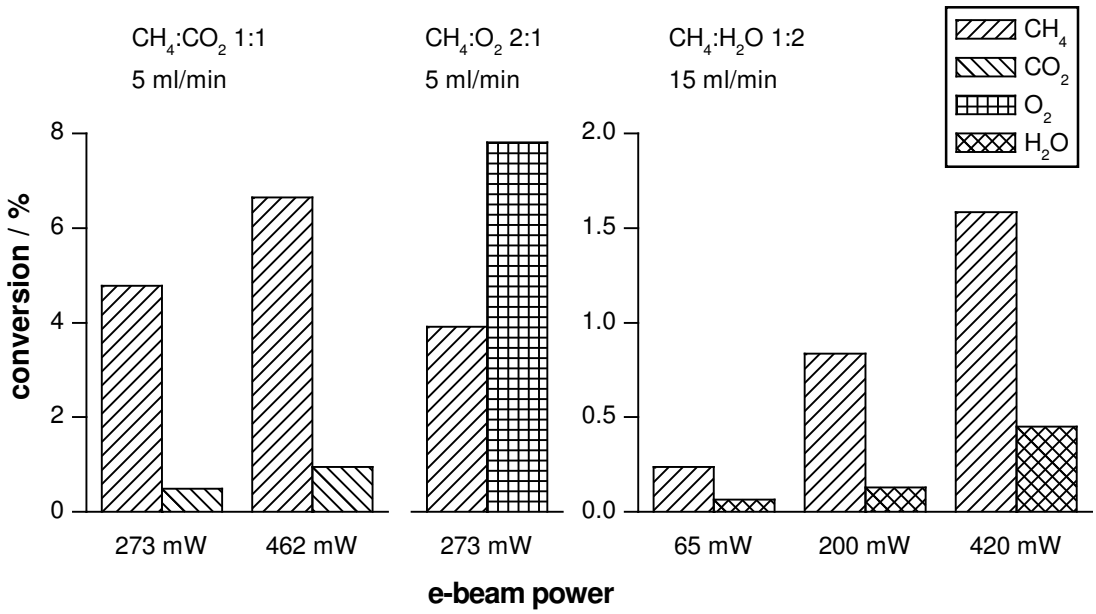

Fig. 4 Conversions of the starting compounds

The inhomogeneous activation of the different compounds by the electron beam has obviously also a strong influence on the secondary reactions and therefore on the composition of the reaction products. Fig. 5 shows the product yields depending on the e-beam power and the gas mixture. For dry reforming and steam reforming the main reaction products are hydrogen and saturated hydrocarbons, mainly ethane and propane. This is the consequence of the preferred methane dissociation which generates CH_3 and H radicals. The subsequent recombination reactions result in the formation of H_2 and C_2H_6, according to the following equations:

$$CH_4 + e^- \rightarrow H + CH_3 + e^- \quad (1)$$

$$CH_4 + H \rightarrow H_2 + CH_3 \quad (2)$$

$$CH_3 + CH_3 \rightarrow C_2H_6 \quad (3)$$

Compared to this the formation of oxygenated compounds like CO – and CO_2 in the case of steam reforming – plays a minor role due to the lower activation of CO_2 and H_2O. The e-beam power seems not to have a visible influence on the reaction pathways.

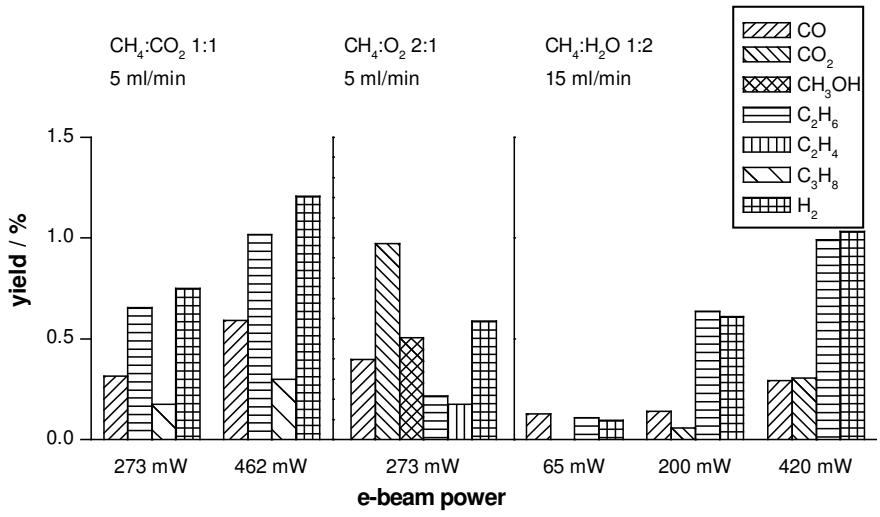

Fig. 5 Yields of reaction products

However, the product spectrum of partial oxidation is significantly different. The formation of oxygenated compounds is clearly favoured with CO_2 as the most important reaction product, due to the high dissociation rate of O_2. Also the hydrogen yield is lower than with dry reforming and steam reforming at the same power level. Although it was not possible to determine the amount of water in the product gas with the available equipment, one can expect that complete oxidation of methane plays an important role. An interesting aspect is the relatively high methanol yield, and also the formation of the unsaturated hydrocarbon ethylene.

In order to estimate the extension of the gas zone which is treated by the electron irradiation, another series of steam reforming experiments were carried out with the flow cell type B using various reaction chamber inserts. Both methane and water conversion increase by a factor 2 with the chamber diameter increasing from 6 mm to 10 mm keeping the specific energy unchanged. Apparently, with chamber diameters lower than 10 mm, a substantial fraction of the electron beam energy is dissipated directly to the chamber walls without inducing gas reactions. Thus, the diameter of the reactive plasma zone is estimated to be at least in the range of 10 mm, possibly even higher.

The specific energy requirement for hydrogen generation was in the order of 10 MJ/mol H_2 for dry reforming and partial oxidation, however, for steam reforming this value was only 2 MJ/mol H_2, and therefore by a factor 4 lower than the energy requirement of DBD steam reforming at low temperatures.

4. Conclusions

Hydrogen generation by methane reforming using low energy electron beams has been studied based on three different reforming reactions: dry reforming, partial oxidation and steam reforming. Electron beams were generated with a compact electron gun system including a ultra thin SiN membrane which allows the irradiation of the e-beam into the gas phase at atmospheric pressure with low energy loss.

The reaction products and therefore the preferential reaction path turned out to be quite different for partial oxidation on the one hand and for dry reforming and steam reforming on the other hand, due to the different electron collision cross sections of the corresponding oxidant molecule. While for partial oxidation the oxygen conversion is higher than the methane conversion and oxygenated reaction products prevail, in the case of steam reforming and dry reforming, the preferential reaction is the dissociation of methane and the formation of hydrogen and hydrocarbons. The energy requirement of the steam reforming reaction could be reduced by a factor 4 compared with previous DBD steam reforming experiment at low temperature.

Hydrogen yields were still relatively low – in the order of 1 % – due to the limited power output of the electron beam source and the small extraction window. The next experimental step should be to increase the cross section of the extraction window to be able to increase the power output while maintaining a low electron energy and hence high power density. Anyhow, there is the potential for scaling up to large reactor volumes, pressures and mass flows, as already demonstrated in power station flue gas cleaning applications.

Filamentary and homogeneous dielectric barrier discharges in He/N_2 mixtures at atmospheric pressure

N.K. Bibinov and K. Wiesemann

Ruhr-Universität Bochum, Experimentalphysik insbes. Reactive Plasmen, 44780 Bochum, Germany

Abstract

In He/N_2 dielectric barrier discharges at atmospheric pressure we studied the conditions for the appearance of filamentary and homogeneous (APGD) discharges. By analysing the emitted light measured time and space resolved we found that the afterglow phase is dominant for both types of discharges. We discuss our findings by means of a kinetic model of the processes occurring at the different conditions in a DBD.

1. Introduction

Dielectric barrier discharges (DBD) are high-pressure non-equilibrium discharges controlled by one or two dielectric barriers in the discharge gap. In the present work we discuss processes in He/N_2 DBD plasma. For this mixture the reaction model, the spectroscopic parameters of the excited particles and the rate constants for excitation and de-excitation processes are well known. Therefore, one can use efficiently spectroscopic methods for studying plasma processes in this discharge [1,2]. Two types of DBD modes in He/N_2 mixtures are known, namely filamentary and homogeneous (APGD) discharges [3]. Filamentary discharges are a consecution of short microdischarges ($\tau \approx 1$ μs in He/N_2) randomly distributed in space and time. The microdischarge radius is below 30 μm [1]. The APGD mode looks homogeneous along the electrodes. The discharge occupies sometimes totally sometimes only partly the gas gap. The spatial structure of the light emission from these discharges looks like the structure of glow discharges at low pressures [3]. The transition from the filamentary to the homogeneous mode occurs either at constant gas pressure when increasing the frequency of the applied voltage or at constant frequency of the power supply when decreasing the nitrogen partial pressure.

In the present work we study DBDs in both modes by means of spectroscopic measurements with time and space resolution.

2. Experiment

The discharge cell consists of two parallel plane electrodes (5.5×5.5 cm^2) with one single 0.2 cm thick dielectric glass plate on one of the electrodes. The He and nitrogen flows are controlled by mass flow controllers. The width of the gas gap is varied in the range 0.03-0.5 cm. The width of the gas gap is varied in the range 0.03-0.5 cm.

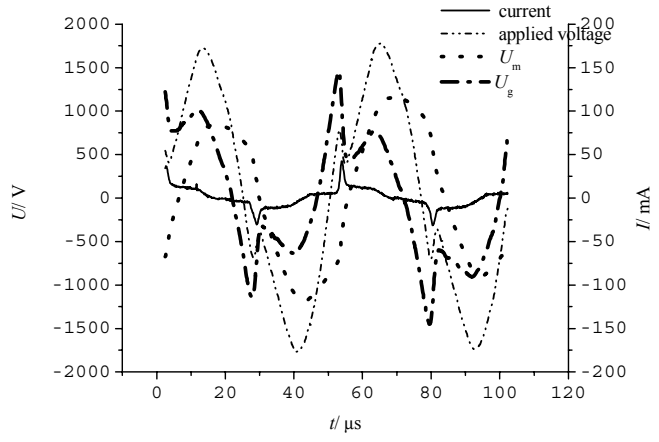

Fig.1 Measured applied voltage and current in the homogeneous mode of a He/N_2 DBD and calculated gas gap voltage .

An ac-generator with the frequency 19.7 kHz served as power supply. The applied voltage U_A and the current of the power supply I_d are measured by means of a digital oscilloscope TEKTRONIX 2440 either directly or via a 50 Ω resistor connected in series to ground. The voltage on the gas gap U_g is determined as

$$U_g(t) = U_A(t) - U_m(t) \quad (1)$$

$$U_m(t) = \frac{1}{C_d}\int_{t_0}^{t} I_d(t)dt + U_m(t_0). \quad (2)$$

One can see in fig. 1 that at our experimental conditions the gas gap voltage U_g at the time of discharge ignition is about two times higher than the applied voltage.
This difference U_m is caused by charges on the surface of the dielectric created during discharges in the previous half-cycle of the applied voltage.
For measuring emission spectra we used a SpectraPro-500i® spectrometer with up to 0.04 nm spectral resolution. From the rotational structure of the N_2^+(B-X) and OH(A-X) bands we determined the gas temperature. The resolution of the spectrometer allows determining the gas temperature with an accuracy of about ±5 K and ±10 K for N_2^+(B-X) and OH(A-X) respectively. By means of interference filters with a spectral resolution of $\Delta\lambda \approx 10$ nm we studied the emissions of N_2^+(B-X), N_2(C-B) and helium atoms space and time resolved. Time and spectrally resolved photographs of the discharge we obtained with an intensified CCD triggered by the discharge voltage – see fig. 2.

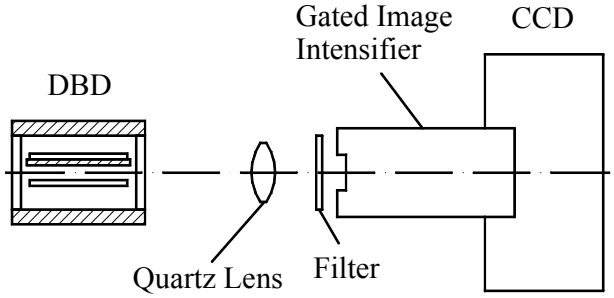

Fig.2 Experimental set-up for measuring space and time resolved distributions of the plasma emission for optical transitions of interest

3. Results

According to [1,2] the rotational temperature in the emission spectra of N_2^+(B-X) is 100-250 K higher than the rotational temperature in the N_2(C-B) and OH(A-X) bands. It was supposed in [1,2], that the emission of the nitrogen ions occurs in heated microdischarge channels, while the N_2(C-B) and OH(A-X) emissions are excited in the cool ambient gas by reactions of metastable nitrogen molecules:

$$N_2(A) + N_2(A) \rightarrow N_2(C) + N_2(X) \quad (3)$$

$$N_2(A) + OH(X) \rightarrow OH(A) + N_2(X) \quad (4)$$

For proving these assumptions we have measured the N_2^+(B-X) and N_2(C-B) emissions with spatial and time resolutions in the filamentary mode - see figs. 3 and 5. At relatively low nitrogen partial pressure the micro-

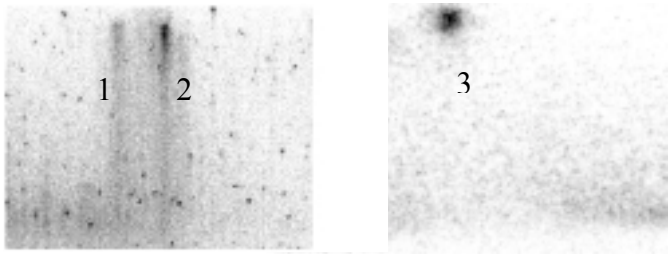

Fig.3 Photographs of He/N_2 DBDs in the light of the N_2^+(B-X) emission. The cathode is on top, the dielectric on bottom. Gas gap width 5 mm; p_{He}= 101 kPa, p_{N2}= 1.17 kPa.

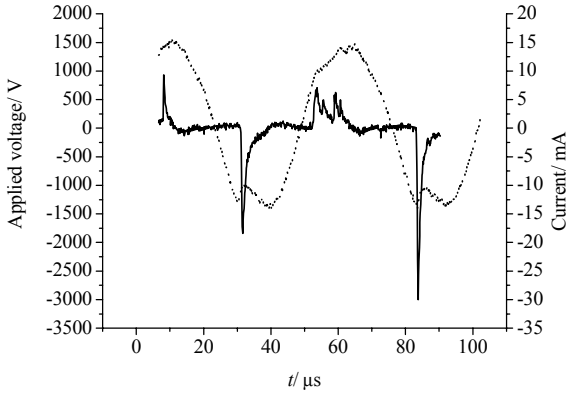

Fig. 4. Applied voltage (dotted) and discharge current (full line) in the filamentary mode (p_{He}= 101 kPa, p_{N2}= 1.17 kPa)

discharges are randomly distributed in space and time and one can detect in the photographs all discharge phases occurring simultaneously – see fig. 3.
For determining the order of the discharge phases we used photographs at 101 kPa He and 3.9 kPa nitrogen. At these gas conditions and for a low amplitude of the applied voltage only one microdischage is ignited per half-cycle of the applied voltage. It appears always at the same place. Thus we could determine the discharge phase order by varying the photographs' delay. Because of the high quenching rate at these conditions the intensity of the N_2^+(B-X) emission is very small while the intensity of the N_2(C-X) is so much higher that our filter was not sufficient selective for separating these emissions. Nevertheless we could work out the succession of the different discharge phases. We found three phases of the microdischarges in the filamentary mode - see the numbers in fig. 3. The first phase consists of an uniformly emitting narrow channel across the gas

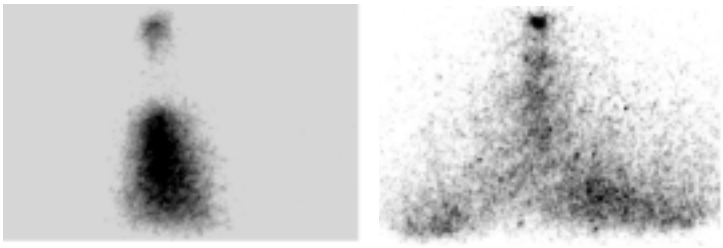

Fig.5. Photograph of a He/N_2 DBD in the light of the N_2(C-B) emission. The cathode is on top, the dielectric on bottom. Gas gap width 5 mm, pressure like in Figs. 3 and 4. The right photograph corresponds to a later phase.

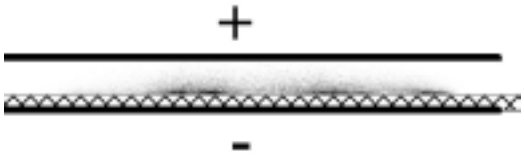

Fig.6. Photograph of a He/N_2 DBD in the light of the N_2^+(B-X) emission. Gas gap width 5 mm, pressures like in Figs. 3 and 4

gap. In the third phase the nitrogen molecular ions emit only from a point like area near the cathode. The second phase is an intermediate case - one can see there the transition between the two others.

The emission of N_2(C-B) originates from a broad area around the narrow channel defined by the emission of the nitrogen ions - see fig. 5. This area represents a cone with a base spreading out with time - similar to pictures published by Gherardi et al. [4] In the later phase the emission intensity exhibits a minimum near the anode in the middle of the discharge area. At this very position the intensity is maximum in the early phase.

The emission of nitrogen ions has a different temporal behaviour when the dielectric is on the cathode. One can see in fig. 4 that the discharge current has only one peak with a high maximum value. In time and space resolved photographs we find only an emission from a narrow area near the dielectric. This is shown in fig. 6.

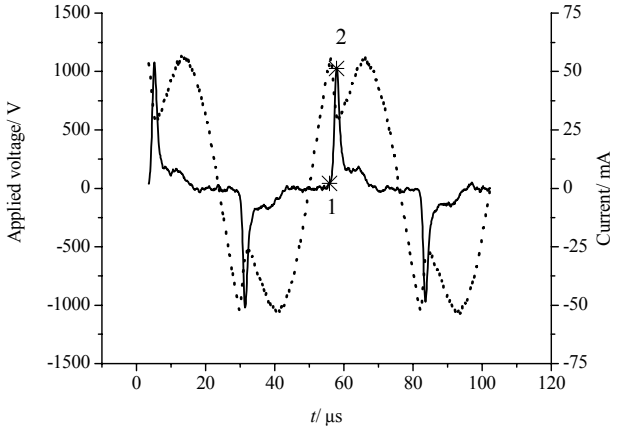

Fig.7. Applied voltage and discharge current in the homogeneous mode of a DBD (p_{He}= 101 kPa)

In the first phase of a homogeneous discharge (corresponding to the point number 1 in fig.7) the very weak emission of nitrogen ions and helium atoms extends along the total gas gap length - see fig.8. A photograph taken at the maximum of the current shows an intense emission near the cathode and no emission in the other areas - see fig. 9.

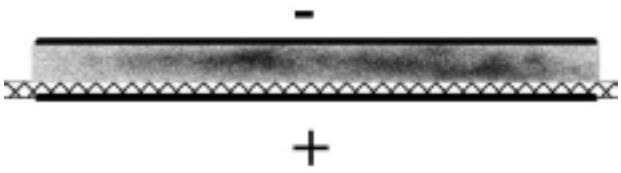

Fig.8. Photograph of a He/N_2 DBD in the light of the N_2^+(B-X) emission at the beginning of the discharge current pulse. Gas gap width 5 mm; p_{He}= 101 kPa. The grey background is caused by the high gain necessary to detect the low emission intensity.

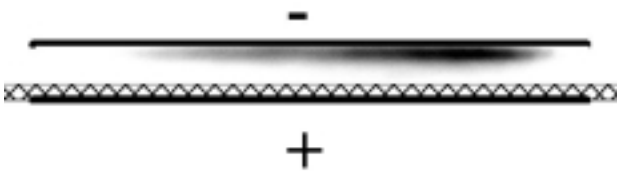

Fig.9. Photograph of a He/N_2 DBD in the light of the N_2^+(B-X) emission at the maximum of the discharge current. Gas gap width 5 mm; p_{He}= 101 kPa.

4. Discussion

The charge on the surface of the dielectric plays a key role for the filamentary mode as well as for the homogeneous mode. In the filamentary mode the charge density on the surface is irregular because of the random space distribution of the microdischarges. Because of this charge the gas gap voltage may locally increase

and microdischarges may ignite there at a value of the applied voltage below the ignition voltage. At very low amplitudes of the applied voltage this effect enables just one single microdischarge to ignite in every half-cycle again and again at the same place of the discharge gap.

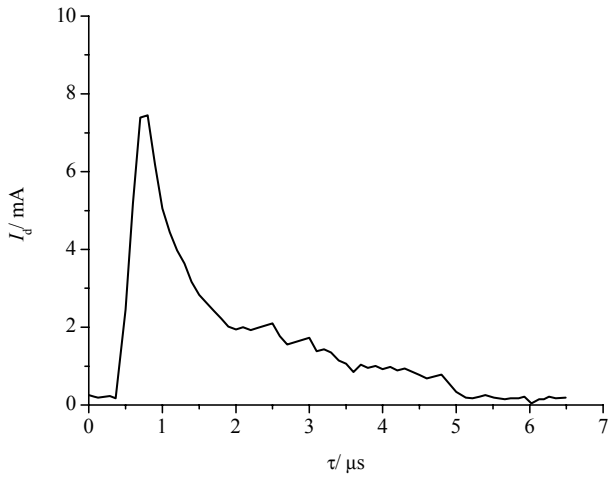

Fig.10. Measured discharge current in the filamentary DBD mode (p_{He}= 101 kPa, p_{N2}= 1.17 kPa).

From the characteristic time for a single transit of a primary electron from cathode to anode at a constant drift velocity the duration of a microdischarge in the filamentary mode can be estimated. For a free electron in a 101 kPa gas mixture predominantly consisting of He the drift velocity is about $2.1*10^6$ cm/s under the influence of a field strength of E≈3000 V/cm, the typical breakdown field at our experimental conditions. Thus the free electron transit time amounts to about $2.4*10^{-7}$ s for a 5-mm gap. This value agrees well with the time of the discharge current increase of about $3*10^{-7}$ s - see fig. 10.

For the conditions at discharge ignition we have calculated the excitation rates of He metastable and the ionisation rate. At our experimental conditions the rate of metastable excitation at the discharge ignition is about 60 times higher than the ionisation rate. At a nitrogen partial pressure of p_{N2}=1.17 kPa the characteristic time for Penning ionisation amounts to about $3*10^{-8}$ s. That is ten time shorter than the free electron transit time. When the primary electron avalanche reaches the anode, the electron density in the channel is maximum. Thus the gap field drops. The start of new avalanches in this area of the gap is inhibited because of a decrease of the surface charge density on the dielectric after surface discharges (Lichtenberg figures). But free electrons in the microdischarge channel drift to the anode and a region of high electric field, a cathode layer or "cathode fall" forms. When the electric field in this area reaches the ignition limit new avalanches start. Outside the high field region the electron drift more slowly to the anode. This finding is in agreement with model calculations of Braun et al. [5] for N_2 where the same succession was found, however, on a different time scale because the electron drift velocities are higher in the case considered there.

One can see in fig.10 that the discharge current decreases with a characteristic time of about 1 µs, which corresponds to a drift velocity of about $5*10^5$ cm/s. Such a drift velocity can be obtained from a field of about E≈300 V/cm. This field strength corresponds to a non-self-sustained discharge that is to afterglow conditions. These conditions correspond to the third phase of the filamentary mode shown in fig.3. Under these circumstances only lower excited states of nitrogen like N_2(A) can be populated and the emission due to the de-excitation of these states is observed – see fig. 5. During this discharge phase the dielectric surface is charged up. Due to the increase of the surface charge density the gap electric field changes and the surface charge saturates. Thus the discharge has to move to neighbouring areas otherwise the electric current stops. This produces the conical shape seen in fig.5.

When the polarity of the applied voltage reverses we observe only one intense current pulse during that half-cycle of the power supply. Probably, free surface electrons can be extracted from the dielectric. As a result of this "preionization" the formation of filaments in the gap is inhibited [6]. Primary avalanches produced by the extracted electrons reach the metal anode. Then a cathode layer forms and a discharge ignites near the cathode as seen in fig. 6.

To ignite a homogeneous DBD we stopped the nitrogen flow. However, adsorbed nitrogen atoms exist on the surface of the electrode and the dielectric. Because of the narrow and long shape of the gas gap nitrogen atoms move off very slowly even at the high He gas flow of 10^3 sccm. On the surfaces of the gas gap free nitrogen atoms recombine with adsorbed ones to form nitrogen molecules during the discharge. By a high Penning ionisation rate high nitrogen molecule concentrations cause an increase of the electron concentration and the ignition of filaments as mentioned above. Therefore, it is important to determine the nitrogen molecule concentration when studying the homogeneous DBD mode. For this purpose, we measured the temporal behaviour of the integral intensity of the emissions of nitrogen molecular ions and helium atoms. At our experimental conditions N_2^+(B) nitrogen ions are produced mainly by Penning ionisation.

The intensity distributions in the measured emission spectra of helium atoms testify that excited states of rare gas atoms are populated in the following recombination processes

$$He^+ + 2He \rightarrow He_2^+ + He, \quad (5)$$

$$He_2^+ + e \rightarrow He^* + He. \quad (6)$$

In the framework of this model (see Tab.1) we have calculated the temporal behaviour of the N_2^+(B-X) and He atom emissions and fitted these dependences to the measured ones - see fig.11. As fit parameters we used the duration of the active discharge (where metastables and ions are produced) and the partial pressure of nitrogen. From this fit we obtained partial pressures of nitrogen in the range 10-40 Pa and found that the measured discharge current reaches its maximum 0.5-1 μs later than the current of the active discharge. We conclude from these findings that the characteristic time of Penning ionisation is of the order of 1 μs – much longer than the transit time of free electrons. Thus the electron density in the channel of the primary avalanches increases only slightly and the low avalanche current cannot alter strongly the surface charge density on the dielectric. The small change of surface charging is compensated by the applied voltage increase and new avalanches start. Therefore, the discharge extends through the entire gap at the beginning of the current pulse and the emission intensity remains very low - see fig. 8. If the internal resistance of the power supply is high or the applied voltage rises too slowly to compensate for the changes of surface charging, starting of new avalanches is interrupted. In this case the discharge occupies only part of the volume between the electrodes. This latter case is shown in fig. 8.

Tab.1. Main processes and rate constants for excitation and de-excitation of molecular nitrogen ions and excited helium atoms

Process	Rate Constant
$He^+ + 2He \rightarrow He_2^+ + He$	$1.5*10^{-31}$ cm^6s^{-1}
$He_2^+ + e \rightarrow He^* + He$	$9*10^{-9}$ cm^3s^{-1}
$He^+ + N_2 \rightarrow$ quenching	$1.2*10^{-9}$ cm^3s^{-1}
$He_2^+ + N_2 \rightarrow N_2^+(B)$	$8.3*10^{-10}$ cm^3s^{-1}
$He_2^+ + N_2 \rightarrow$ quenching	$2.7*10^{-10}$ cm^3s^{-1}
$He^*(met) + N_2 \rightarrow N_2^+(B)$	$2.8*10^{-11}$ cm^3s^{-1}
$He^*(met) + N_2 \rightarrow$ quenching	$7.1*10^{-11}$ cm^3s^{-1}

When owing to Penning ionisation about 1 μs after ignition the electron density increases in the gap the electric field drops, free electrons drift to the anode, a cathode layer forms and new avalanches start near the cathode - see fig. 9. At our conditions the partial pressure of the nitrogen molecules is relatively low and thus the probability of the pooling reaction (3) is very low too. Therefore, we could not detect any emission from the area outside the cathode layer.

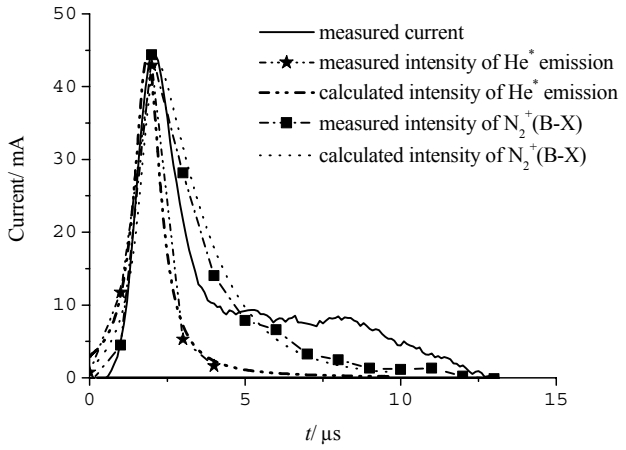

Fig.11. Measured and calculated emissions of nitrogen ions and helium atoms and discharge current of a homogeneous DBD; p_{He}=101 kPa, p_{N2}= 40 Pa (from fit).

In the channels of the microdischarges the gas is heated mainly when positive ions move rapidly. As the electric field strength is low in the area outside of cathode layer (in the "positive column") the gas temperature in this area is lower than in the cathode layer. We have measured the rotational structures in the N_2^+(B-X) and OH(A-X) emissions of nitrogen ions and OH-radicals. In the homogeneous DBD mode these structures correspond to the gas temperature in the microdischarge channel and in the ambient gas respectively - see fig. 12. Here the OH(A-X) emission is excited by absorption of the VUV helium emission by water molecules. Near the electrodes we measured about 400 K gas temperature. At the same time the temperature in the middle of the gas gap is notably lower- about 340 K and compares with the temperature of the ambient gas, which we determined to about 310 K by means of the OH(A-X) emission.

The drift velocity of the positive ions in the area of the cathode layer depends on the electric field strength, which in turn depends on the gas gap length in the following way [7]. The length of the cathode layer area and the electric field strength depend weakly on the distance between the electrodes if this distance is much longer than the thickness of the cathode layer area. But the field strength increases rapidly if the distance between the electrodes becomes comparable with this thickness. According to calculations of the spatial

evolution of the electric field in the homogeneous DBD mode in 101 kPa of helium [3] the cathode layer thickness amounts to about 0.03 cm.

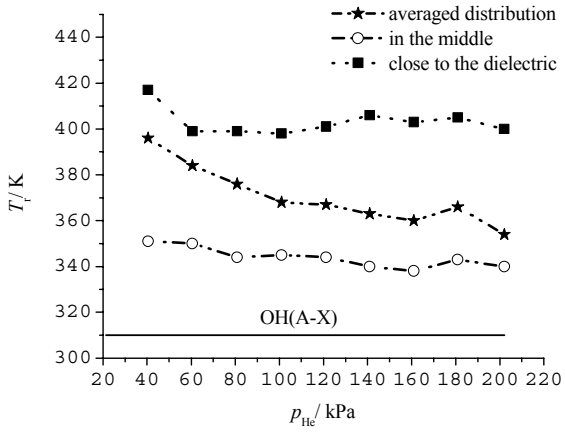

Fig.12 Rotational temperatures obtained from the nitrogen ion (curves with markers) and the OH–radical emissions in a homogeneous mode DBD. Gas gap width is 0.5 cm.

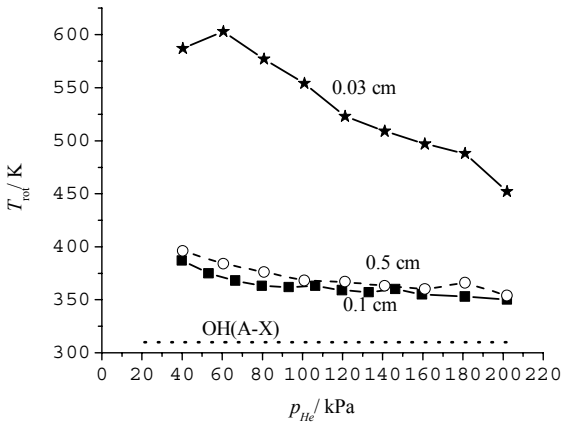

Fig. 13 Rotational temperatures obtained from the nitrogen ion (curves with markers) and the OH–radical emissions in a homogeneous mode DBD. Parameter is the gap width.

We have measured the gas temperatures at different gas gap widths. At large electrode separations the measured discharge gas temperature is practically independent of the gap width - see fig. 13 - but increases dramatically at small widths. At the same time the OH-radical rotational temperature and thus the temperature of the ambient gas is constant - about 310 K. Assuming the electrical energy of one current pulse to be totally dissipated we calculated the gas volume, which can be heated by this energy to the temperature corresponding to the nitrogen ion rotational temperature. This volume turned out to be more than two orders of magnitude smaller than the volume occupied by the cathode layer. Thus the difference between the values of the gas temperatures measured by means of the nitrogen ions respective the OH-radicals can be explained only if we assume that the homogenous discharge consists also of a multitude of microdischarges.

5. Conclusion

In atmospheric pressure He/N_2 dielectric barrier discharges (DBD) we have studied the conditions for the appearance of filamentary and homogeneous discharges. In both DBD modes we found an afterglow phase of the active discharges. During this phase the surface of the dielectric is charged. In both modes the active discharges consist of two phases: a discharge bridging the entire gas gap and a discharge restricted close to the cathode after formation of a cathode layer. From the temporal behaviour of the emissions of nitrogen ions and helium atoms we could determine the partial pressure of nitrogen in the rare gas flow. At our experimental conditions the homogeneous DBD mode consist of a multitude of microdischarges. The gas temperatures in the channels of these microdischarges are 50 - 300 K above the temperature of the ambient gas.

EXPERIMENTAL STUDY OF THE EFFECTIVE EFFICIENCY IN A CERAMIC COATED DIESEL ENGINE

[*]I. Taymaz, M.Gur and A. Mimaroglu.

The quest for increasing the efficiency of an internal combustion engine has been going on ever since the invention of this reliable workhorse of the automotive world. In recent times, much attention has been focused on achieving this goal by reducing energy lost to the coolant during the power stroke of the cycle. A cursory look at the internal combustion engine heat balance indicates that the input energy is divided into roughly three equal parts: energy converted to useful work, energy transferred to coolant and energy lost to exhaust The reduction in, or the elimination of, in-cylinder heat transfer to either the coolant and/or the environment does not violate the second law of thermodynamics and, moreover, according to the first law, has the potential of producing more work. Added to this, another important advantage of the concept is the great reduction in parasitic losses due to elimination of cooling system, thus increasing the brake horsepower of the engine. These prospects of improving the design and performance have generated impetus to active research on adiabatic or more appropriately, low heat rejection (LHR) or insulated engines.

Since the 1970s, substantial interest has been focused on the development of the low heat rejection engine (LHRE) and the use of ceramic materials to insulate the metals of the combustion chamber (pistons, valves, cylinder head). Insulating an engine is not simply the means to an end. Reducing heat losses from the engine cylinder makes minimal changes to the efficiencies of existing engines. It does reduce the need for cooling systems and their costs, reducing weight, and reducing the complexity of the system. As in any IC engine, a tremendous amount of energy escapes from a diesel engine. It has been estimated that up to an equivalent of 87% of the amount of shaft work exits the engine in the form of waste heat. In a standard engine a large percentage is wasted through the cooling system. By thermally insulating the engine's piston, cylinders, and cylinder heads this heat energy could be directed to the exhaust gases. It then can be harnessed to increase the net power output of the system, thus raising thermal efficiencies and decreasing specific fuel consumption.

The main purpose of this study is to evaluate the effective efficiency at different engine loads and speeds with and without ceramic coated diesel engine. Experiments were conducted with six cylinders, direct injected, turbocharged, intercooled diesel engine. First, this engine was tested at different speeds and loads conditions without coating. Then, combustion chamber surfaces (cylinder head, valves and piston crown faces) was coated with ceramic materials using plasma spraying technique. Ceramic layers were made of $CaZrO_3$ and $MgZrO_3$ and plasma coated onto base of the NiCrAl bond coat. The ceramic coated research engine was tested at the same conditions as the standard (without coating) engine. The results showed a reduction in heat losses to the coolant and an increase in effective efficiency.

Characterization of Atmospheric Pressure Mixed-gases TIG Arc Plasmas

C. Fanara[(1)], L. O. Vilarinho[(2)]

Abstract
Thermal plasma at atmospheric pressure used in industry are often made of inert gas mixtures. Changes in structure and properties of these arcs due to variation of the Ar-He mixture composition are presented for currents selected in the range 50-200 *A*. Emission spectroscopy provides temperature maps with isotherms variable in shape and location. Langmuir probes provide voltage, electrical radii whereas (Abel inverted) ion saturation currents give hints on changes of the width of the arc current carrying region.

1. Introduction

Thermal plasma technologies based on arcs at atmospheric pressure are used in industry for cutting, heat surfacing and welding. In these processes, multi-component plasmas are employed in form of inert gas mixtures. The structure and properties of the arc are altered with respect to pure gases. *Demixing* [1-4] from originally homogeneous mixtures takes place which separates the component gases in different regions of the arc. The present work is aimed at the characterization of the arc structure when two chemical species are present in form of an Ar-He mixture (1% to 10% He in mass fraction). Diagnostic techniques include Emission Spectroscopy and Langmuir probes. From the first, temperature maps are presented [5, 6], showing change of the argon isotherm shape and location upon variations in the impurity concentration. The use of Langmuir probes in atmospheric pressure plasmas, although problematic due to flow [7], high collisionality and spatial non-homogeneity [8], can still shed light on the electrical structure of the arc [9, 10]. A multi-probe apparatus for the study of TIG welding arcs constructed to operate in the range 50-200 *A*, provides voltage, axial electric field and electrical radii for pure argon and argon-helium mixtures as well as ion current densities obtained upon Abel inversion of the individual probe signals [9, 11]. The apparatus is summarized in section 2 whereas results are presented in section 3.

2. Experimental details and procedures

A detailed description of the apparatus, both the optical and of the probe system have been reported elsewhere [5, 6, 8, 10, 12]. Figure 1 left shows the vacuum vessel and some ancillary equipment.

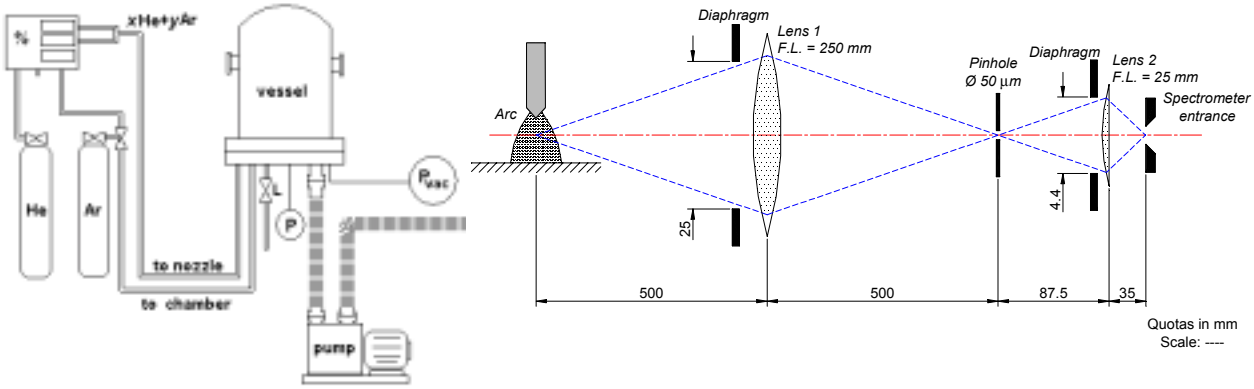

Figure 1 Chamber (left) and emission spectroscopy experiment Set up (right)

Of the two gas lines, one is dedicated to the filling of the chamber (usually with Argon), the other leads to the cathode nozzle (torch). The mass flow of the gases is controlled down to 1% by means of a mass flow controller capable of delivering up to 40 *slm* (full scale) on both the *Ar* and *He* channels (1 *slm* = 2.97 $\cdot 10^{-5}$

Kg s^{-1} of argon). The optical setup, leading to the Czerney-Turner 1 *m* focal length monochromator and CCD detector, is shown in figure 1 on the right. Figure 2 left depicts the complete probe system whereas on the right a photograph of the probe system is reported showing the torch and few probes (copper, Ø 250 µ*m*, length 58 to 60 *mm*). The arc is struck in the typical point-plane geometry and except where explicitly indicated the arc length is 5 *mm*.

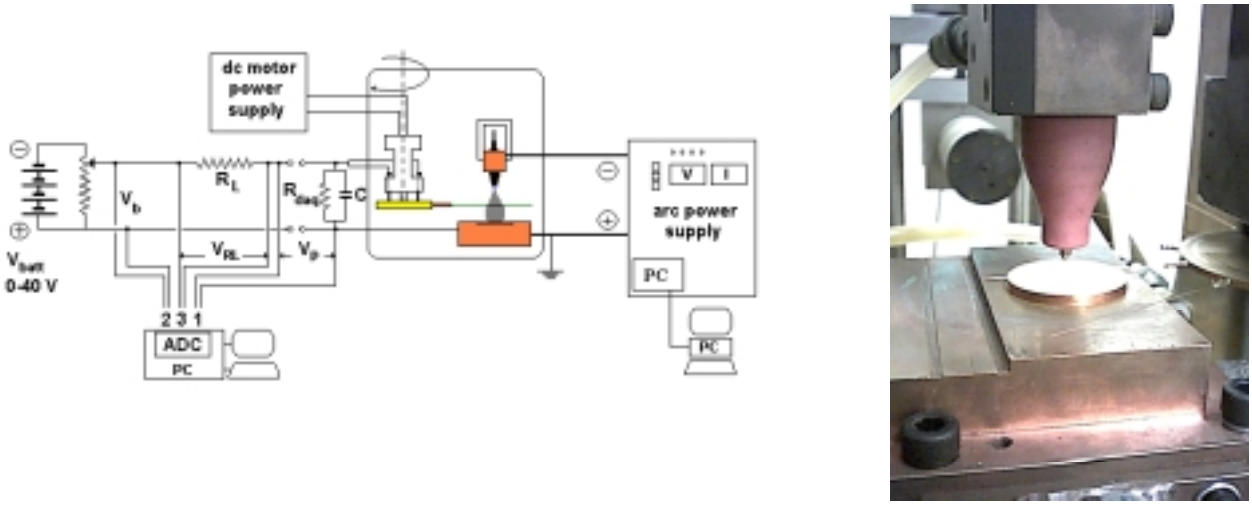

Figure 2, setup for the Langmuir probe. The probe disk sweeps probes through the arc (in between cathode and anode shown in orange). Right, torch nozzle with W tip, and copper anode. A portion of the multi probe disk with protruding probes is shown

3. Results

Effects of helium addition can be visualized by emission spectroscopy and electrical measurements. As an illustration, a selection of arc characteristic curves, optical temperature maps, probe characteristic curves (V-I), current distributions, electrical radii and probe voltages is shown.

3.1 Arc characteristic curves

Characteristic curves are shown (figure 3) obtained from the fixed arc current by measuring the total arc voltage fall for varying Ar-He mixture fraction. On the right, the corresponding electrical power input is also shown. Monotonicity in both the total arc voltage fall increase and in the electrical input power can be observed.

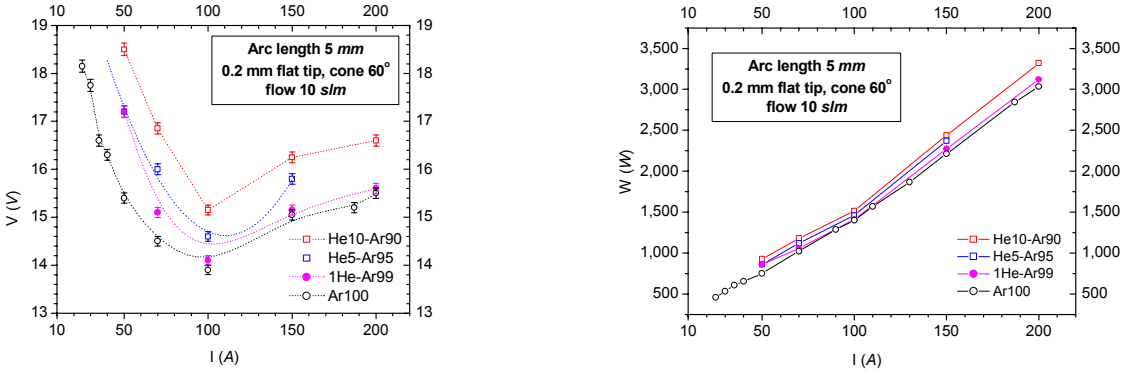

Figure 3, arc IV curve (left) and electrical power input (right) at varying Ar-He mixture compositions

3.2 Optical temperatures

Temperature maps obtained using the Fowler-Milne method are shown in figure 4. It was not possible to use the *modified* Fowler-Milne method [13] which requires separate measurement of emission lines for the pure argon and pure helium arcs. Limitations of the cooling system did not permit to record helium lines for more than few minutes before anode melt down. Therefore, the isotherms of figure 4 refer always to argon

emission lines. Limiting to high currents arcs, the assumption of a system not far form LTE, is sustainable even for mixtures [4] so that the argon electron temperature can be assumed to characterize the arc plasma as a whole. The difference between pure argon and 1*He*-99*Ar* in the upper half of figure 4 is at the limit of detectability.

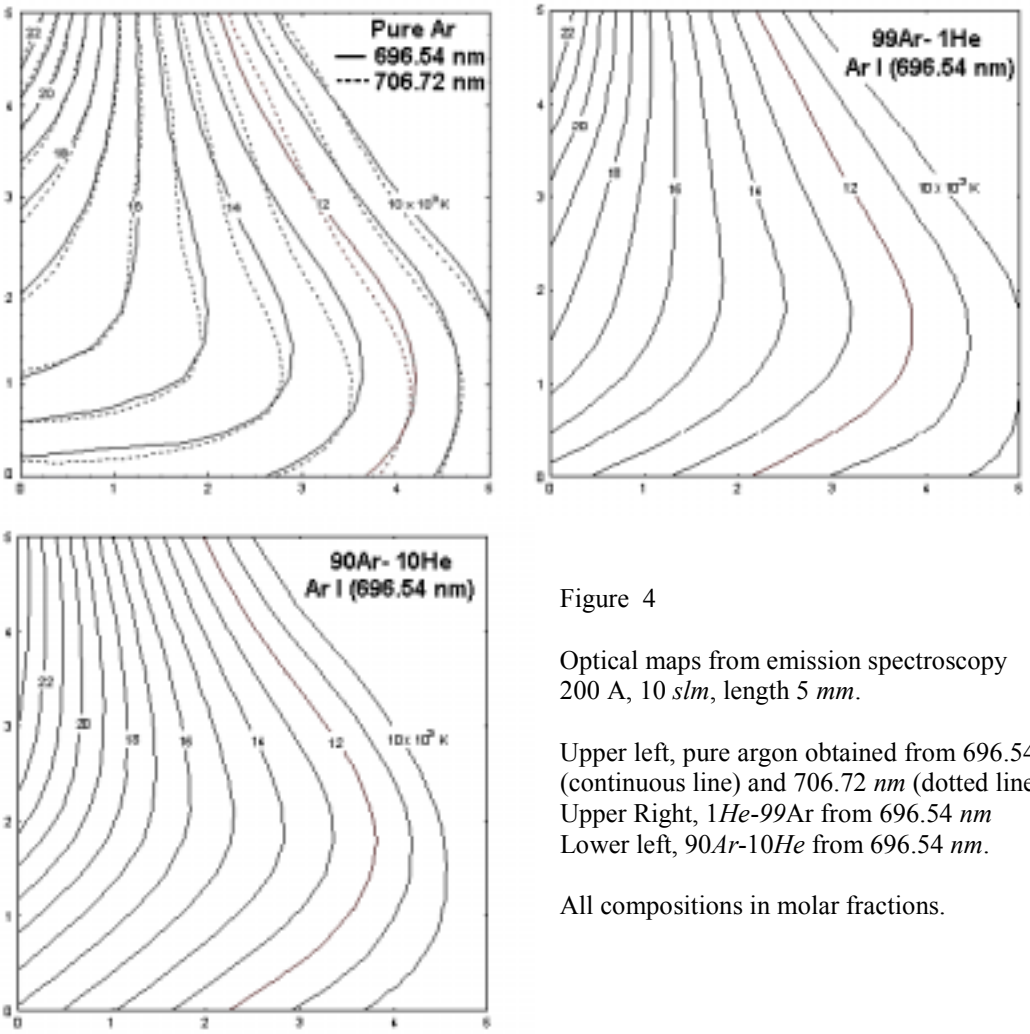

Figure 4

Optical maps from emission spectroscopy
200 A, 10 *slm*, length 5 *mm*.

Upper left, pure argon obtained from 696.54 *nm* (continuous line) and 706.72 *nm* (dotted line).
Upper Right, 1*He-99*Ar from 696.54 *nm*
Lower left, 90*Ar*-10*He* from 696.54 *nm*.

All compositions in molar fractions.

In fact, in this region the difference between the two pure argon determinations (lines at 696.54 and 706.72 *nm,* figure 4 left) is comparable with the difference between either of these two and the 1*He*-99*Ar* (figure 4 right). However, the isotherms for the pure argon show enhanced curvature towards the axis, especially in the lower region. The 10*He*-90*Ar* shows contraction of the outer part of the column at all arc heights. Extension of the highest isotherms toward the anode along the axis is also visible. This agrees with previous predictions and observations [2, 14]

3.3 Probes V-I curves

A selection of V-I curves is presented in figure 5 for some probes and increasing helium concentration. The effect of helium addition is to decrease the probe (ion) current at the same probe voltage especially close to the electrodes; whereas at mid arc (*cf z*=2.03 *mm*) the effect is minimal. Moreover, when ion saturation occurs (from mid arc downwards), the corresponding current decreases.

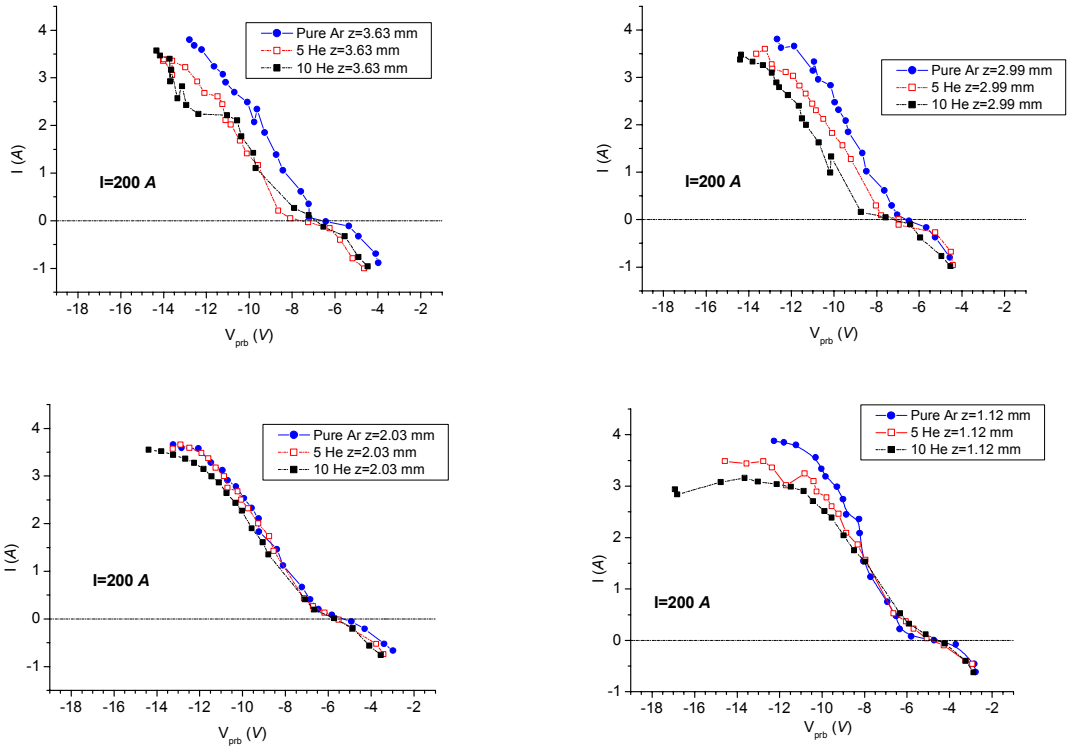

Figure 5, I=200 *A*. Central characteristic curves for selected probes for pure argon, 5He-95Ar and 10He-90Ar

Irrespective of the interpretative model chosen, this influences the electron temperature, when determined from the ion saturation portion of the V-I curve [11]. The current-temperature relationship is not monotonic over the range of interesting currents, therefore the prediction of whether an *apparent* cooling or heating occurs is not straightforward. Also, a reduction of the current could lead to a reduction of the number density and, within the appropriate temperature range, this implies a reduction of the electron temperature. The comparison with optical maps is possible only once corrections are performed that account for the recombinative cooling [11] occurring in the fluid flow perturbation region around probes [11, 15].
Figure 5 also suggests that helium additions change the location of the floating potential on the V-I curve (more exactly, the probe voltage in floating conditions). This change is monotonic with respect to helium addition.

3.4. Electrical radii

The notion of electrical radius has been anticipated in earlier works [10, 11, 16]. Helium addition tends to lower the absolute value of the ion current (figure 6 left), whose radial structure however, seems preserved. The radius of the current carrying region (*ccr*), defined by the intercept of the radial current distribution with the abscissa is enhanced for helium addition with respect to the pure argon case. This can be seen in figure 6 right in the *ccr* at high position in arc (errors on radii are 2.5% of the order of the symbols); this agrees with previous indications about dominance of the effect in the vicinity of the cathode region [17], although its *radial* dependency is shown for the first time here. The arc external boundary, corresponding to the interception of the peak edges in *floating conditions*, when the current is virtually zero, identifies the *halo* region. These radii correspond to a region where no current is flowing, although charge concentration is sufficiently high to be detected by probes. The apparent radial contraction of the halo upon helium increase is more difficult to assess due the scattering of the data.

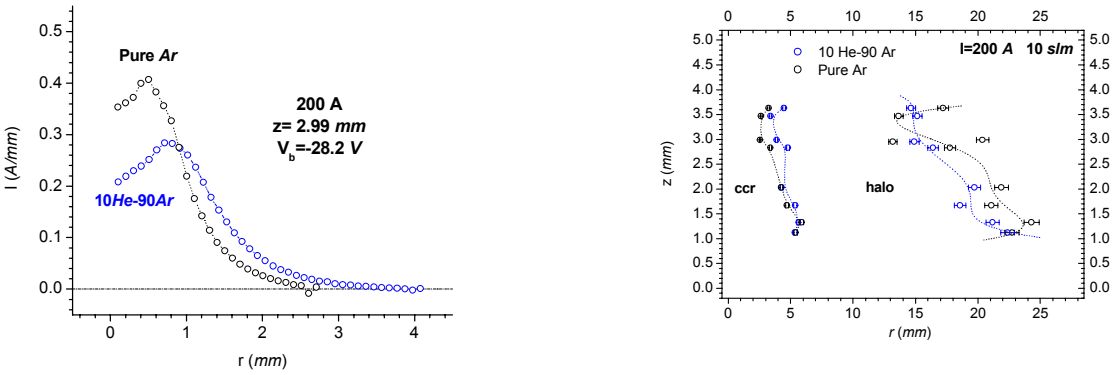

Figure 6 Left, comparison of the inverted current signals at ion saturation for pure Ar and 10He-90Ar. Right, comparison between the radius of the current carrying region, *ccr*, and of the arc external boundary identifies the electrical *halo*

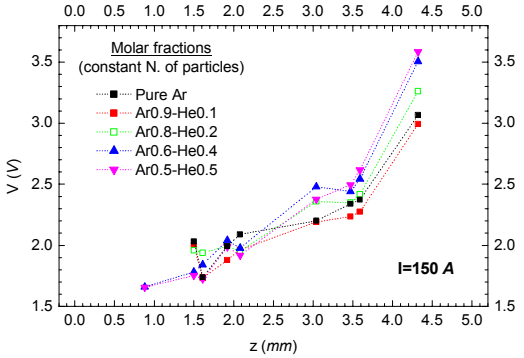
3.5 Probe voltages

The increase of the electric potential for a given current and height within the arc is clearly detected in figure 7. Note that here a range of mixture fraction is shown broader than in figure 5.

Figure 7

Probe voltages in unbiased (but not floating) conditions, versus probe height in 5.2 *mm* arc. Arc currents 150 A. He molar fraction from 0 to 50%



The voltage increases for increasing helium molar fraction. As previously indicated [17], there is a tendency for the phenomenon to occur in the cathode region, as shown by the highest He fraction. The effect is less clear in the column of the arc, so it is not possible to infer a voltage inversion which would suggest increased helium concentration along the arc height.

4. Summary and conclusions

Emission spectroscopy shows temperature maps variations for concentration variations of a few %. Perhaps 1% can be considered as the lowest limit as shown in the discussion following figure 3.

Contrary to previous beliefs, sensitivity of probes versus helium concentration appears of the order of 10% or less, as shown by the variation of several quantities: the shape of the V-I curves, the values of the ion saturation currents, the electrical radii (current carrying and halo), probe voltage along the arc height. The latter can be compared with previous values [17, 18]. For the V-I curves it is not known why only a limited portion of the retarding region was previously used [17].

These results require further analysis, in fact:

1. Quantitative analysis of the V-I curves (central as well as local) and attempts to obtain a probe determined temperatures, in analogy with work carried out for pure argon arcs [11], are currently under way at Cranfield
2. Careful analysis is required to verify variations in potential gradients and therefore in electric fields, once the way of determining the plasma potential is clarified.

3. The current carrying region structure obtained from ion saturation currents needs comparison with electron current density if the plasma potential can be attained experimentally by probes at all probe heights.
4. Finally, signals obtained in floating conditions [11], not shown here for reasons of space, suggest the possibility of unveiling charge distribution variations.

PLASMA EQUIPMENT and TECHNOLOGIES for HARDENING and REPAIR of WHEELSETS

Petrov S.V., Saakov A.G.

RPE TOPAS Ltd., Kiev, Ukraine

Abstract.

The work solves the package of problems associated with hardening and repair of wheelsets. Plasma equipment and technologies have been developed and tested. They meet contradictory requirements to different zones of a wheel during its life time. These are two methods which provide a constant shape of the wheel flanges, i.e. plasma surface hardening and deposition of wear-resistant coatings, plus tempering of the surface layer of increased hardness prior to re-profiling. All the three processes are applied using the UVPZ-2M machine.

1. Introduction

Local heat treatment is justifiable in many cases in terms of technology and cost effectiveness, where only the most loaded working surface is subjected to hardening, while the bulk of a material remains untreated. Plasma surface hardening allows wear to be decreased and service life of heavy-loaded machine parts to be extended 2-5 times. The novel method of plasma hardening is technically and economically preferable for heat treatment of a large number of parts. One example of its application is high-speed surface hardening of all types of passenger, freight and locomotive train wheelsets. Tests show that in all cases the amount of wear of the wheelset ridges after plasma hardening is much lower (2.5-3.0 times) than that of the ridges after standard heat treatment. The new approach to making machines for high-speed plasma surface hardening has been developed based on utilization of the variable-composition mixture of gas and air and the stabilized elongated electric arc that burns in a plasmatron and is adapted to meet the technology requirements.

2 Modelling of the plasma hardening process

The key task of the mathematical support realized in the form of the specialized software package based on modern computer facilities is to optimize the hardening process through selection of such heating-cooling conditions which would provide the desirable strength properties for a given material (steel grade) within the preset space area of heat treatment.

Fulfilment of this task is associated with a possibility of having a reliable prediction of the material structure to be produced, based on the selected thermal effect parameters. Considering complexity of the latter, the total work on development of the software was divided into three inter-related and, at the same time, sufficiently independent stages.

Stage 1 involved solution of the problem associated with computation of thermal cycles for an arbitrary micro-volume within the treatment area for the preset type of a material (density of a material, as well as temperature dependence of thermal conductivity and specific heat are considered to be known). External effects which can vary over a wide range include consumption, initial temperature and thermal-physical properties of the plasma, size of the zone to be heated, character of relative displacement, speed of displacement of the material treated, degree of preheating-cooling, cooling conditions upon leaving the plasma treatment zone, etc.

It should noted, however, that the latter approach is associated with a large scope of preliminary experimental studies, while reliability of the results obtained dramatically decreases even with a slight deviation of parameters outside the range studied.

Optimization of the technology is reduced to making special precautions to produce the preset configuration of the plasma flow and to proper selection of the required conditions of the hardening process. Reliable prediction of structures and residual stresses formed in the hardened layer can be made only in the case of using a non-linear mathematical model. Allowance for non-linearity of thermal-physical parameters of the plasma and material treated makes it possible to determine local extrema of rates of variations in temperature of certain micro-volumes within certain time intervals.

Further increase in level of service properties of a part being hardened can be achieved through improvement of the hardening technology, which is eventually reduced to ensuring the optimal thermal

cycle (heating-cooling), proceeding from regularities in structural, phase and polymorphic transformations of the material hardened.
Stage 2 of the work involved development of the software for modelling the processes of structural, physical and chemical transformations occurring in the material studied, under substantially non-equilibrium conditions of rapid heating and cooling, proceeding from the fundamental up-to-date concepts of the processes being investigated. In principle, occurrence of these processes and variations in thermal conditions of the material treated are a single process. Thus, they should be computed simultaneously, because structural, phase and chemical
transformations are related in this or that way to absorption or release of latent heat. However, based on the fact that the available reliable literature data on thermal-physical properties of the material treated implicitly make allowance for the above processes (e.g. the data on specific heat include values of the effective apparent heat capacity, and the same applies to thermal conductivity) as well as that under the considered conditions of rapid heating and cooling the diffusion processes substantially lag behind the thermal ones, the above separation of the procedures of computation of thermograms and transformations in the material treated seems justifiable.
Difficulties of stage 2 are associated firstly with the absence of a common opinion concerning the process of formation of austenite during heating and its decomposition during cooling. Secondly, in the majority of the available literature sources describing investigations into the hardening processes for certain classes of materials, the data given are in the best case the result of mathematical processing (plots, tables) of experimental studies. And as a rule it is very difficult to get from them the information concerning mechanisms of the processes occurring and quantitative estimates of the processes taking place in an individual micro-volume, which are important for description.
For this paper the authors selected as a reference point a relatively small number of works, where all variations taking place in micro-volumes are described on the basis of fundamental concepts of the material and energy conversion processes.
The problem of modelling of the heat treatment process consists in computation of the quantity of austenite formed during the period of heating (in compliance with the thermogram plotted for a given micro-volume) and, accordingly, the percentage of that quantity of austenite which remains non-decomposed by the moment of achieving the martensitic transformation temperature at a stage of cooling.
Mathematical description of these transformation processes is based on the diffusion equation of the following form:

$$\partial C/\partial \tau = \partial[D(t)\cdot\partial C/\partial x]/\partial x,$$

where C is the carbon concentration, D(t) is the carbon diffusion coefficient depending upon the temperature t, x is the space coordinate, τ is the time recorded for each of the micro-volume structures allowing for their boundary conditions.
The latter depend upon the type of steel considered, whether it is hypueutectoid (containing ferrite and pearlite), eutectoid (containing only pearlite) or hypereutectoid (containing pearlite and cementite). In this case the conditions for free ferrite and ferrite which is part of pearlite are different. This is equally true for cementite. In addition, the type of the boundary conditions greatly depends upon the a priori simplified assumptions of the morphological peculiarities of individual structural elements of the micro-volume.
As an example, consider the case of hardening of eutectoid steel following the preset thermogram:

$$t=t(\tau), \qquad 0\le\tau\le T$$

where T is the total hardening time. In this case τ_1 is the moment of achieving the martensitic transformation temperature at the stage of heating, τ_2 is the moment of achieving a temperature of 727 °C at the stage of heating, τ_3 is the moment of achieving a temperature of 727 °C at the stage of cooling and τ_4 is the moment of achieving the martensitic transformation temperature at the stage of cooling:

$$T\ge\tau_1 + \tau_2 + \tau_3 +\tau_4$$

For the process of formation of austenite as a result of decomposition of cementite of the pearlite grain ($\alpha-\gamma$ transition), the following boundary and initial conditions ($\tau_2 < \tau \le\tau_3$) are valid:

at the cementite-austenite boundary

$$C(\tau,\xi_1) = C_{max}(t),\ D(t)\cdot\partial C/\partial x|x = \xi_1 = (0{,}0667 - C_{max}(t))\cdot d\xi_1/d\tau,\ \ 0 \le x \le \xi_1$$

at the austenite-ferrite boundary

$$C(\tau,\xi_2) = C_{min}(t),\ \ D(t)\cdot\partial C/\partial x|x=\xi_2 = (0{,}0002 - C_{min}(t))\cdot d\xi_2/d\tau,\ \ \xi_1 \le x \le \xi_2 \le \xi_{2max}$$

$$\xi_1(\tau_2) = 0.5\cdot\delta Ce(\tau 2);\ \ \xi_2(\tau_2) = 0.5\cdot\delta Ce(\tau_2) + \delta A(\tau_2);$$

$$\xi_{2max} = 0.5\cdot(\delta F + \delta Ce + \delta A)$$

Here:
$C_{min}(t)$ is the equilibrium carbon concentration in austenite at the boundary with ferrite (GS curve in the constitution diagram);
$C_{max}(t)$ is the equilibrium carbon concentration in austenite at the boundary with cementite (SE curve in the constitution diagram);
ξ_1 is the austenite-cementite boundary coordinate;
ξ_2 is the austenite-cementite boundary coordinate;
D(t) is the coefficient of diffusion of carbon into austenite;
δF, δCe, δA, $\delta F(\tau)$, $\delta Ce(\tau)$, $\delta A(\tau)$ are the thicknesses of the ferrite, cementite and austenite layers within the pearlite zone at the initial moment ($\tau=0$) and arbitrary moment τ, respectively;
δA is determined from the value of the initial martensite content of steel.
For the stage of decomposition of austenite within the $\tau_1 < \tau \le \tau_2$ and $\tau_3 < \tau \le \tau_4$ ranges, it holds that:
at the cementite-austenite boundary:

$$C(\tau,\xi_1) = C^*_{max}(t),\ \ D(t)\cdot\partial C/\partial x|x = \xi_1 = (0{,}0667 - C^*_{max}(t)) - d\xi_1/d\tau,\ \ 0 \le x \le \xi_1$$

at the austenite-ferrite boundary:

$$C(\tau,\xi_2) = C^*_{min}(t),\ \ D(t)\cdot\partial C/\partial x|x = \xi_2 = (0{,}0002 - C^*_{min}(t)) - d\xi_2/d\tau,$$

$$\xi_1 \le x \le \xi_2 \le \xi_{2max},\ \ \xi_1(\tau_1) = 0.5\cdot\delta Ce;\ \ \xi_2(\tau_1) = 0.5\cdot\delta Ce + \delta A;$$

where $C^*_{max}(t)$ and $C^*_{min}(t)$ are the continuations of the SE and GS curves into the range of temperatures below 727 °C, respectively.
Problems of stage 3 concerning development of the software, associated with construction of correlation models of the type of "material structure - physical-mechanical properties" are not considered within the frames of this paper.

3 Process equipment

Milestones in improvement of equipment are associated primarily with development and realization of new approaches, and in recent years with using measurement and control digital devices. Based on the above ideology, RPE TOPAS Ltd. developed and started up manufacture of a number of new high-tech plasma machines to implement new technologies.
To realize this idea, the Company developed plasmatrons designed for different power levels, as well as hardware for high-speed surface hardening of various parts.
The set of equipment for plasma hardening includes:
1.High-speed surface hardening machine UVPZ-2M (Fig.1),
2. A semi-automatic line for hardening of wheelsets with wheeling out (Fig. 2)
The UVPZ-2M machine is equipped with an independent optimization unit to provide:
- in-process programming of conditions and parameters, indication of the current condition of the controlled process parameters, recording and storing of parameters of the process of plasma surface

hardening of wheelsets in permanent memory and output of the information accumulated to a personal computer;

- processing of analogue signals from the "TOPAS-Smotrich" pyrometer, the "Plasma-TOPAS" plasmatron power supply and pressure sensors, as well as input discrete signals from the final control mechanisms and formation of output commands for programmed control.

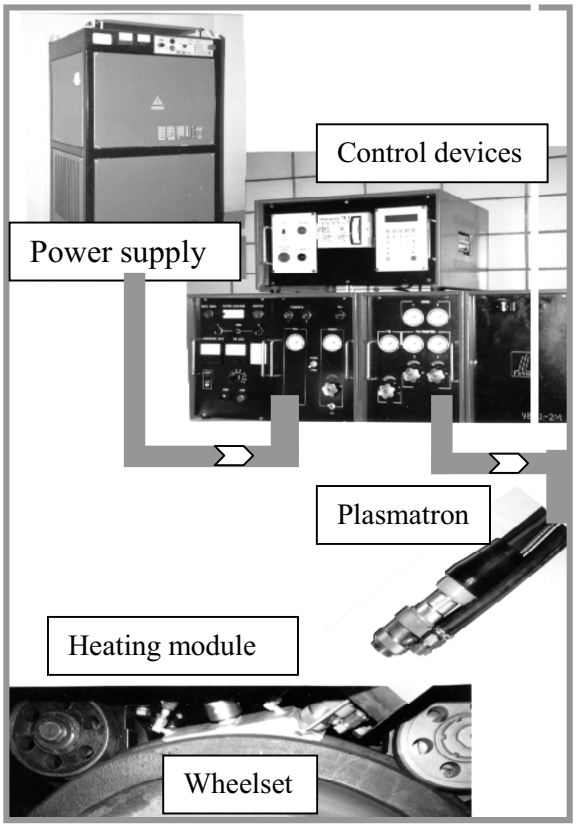

Fig. 1. High-speed surface hardening machine UVPZ-2M

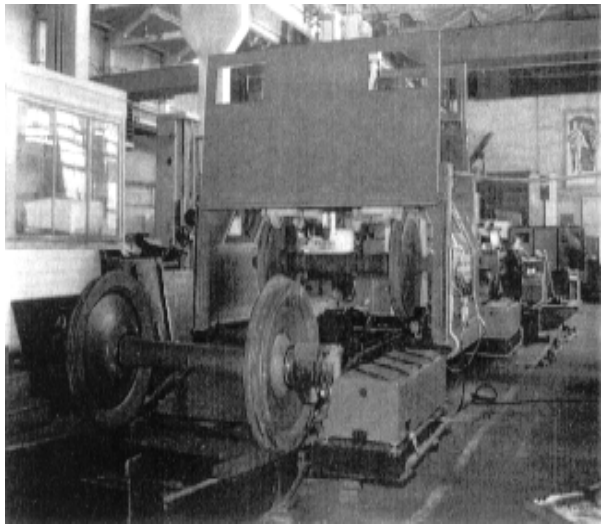

Fig. 2. A semi-automatic line for hardening of wheelsets with wheeling out

4. Results of wheelsets hardening

The technology of plasma surface hardening of TOPAS Ltd. is characterized by new capabilities in terms of increasing contact-fatigue strength and, therefore, increasing reliability of traction for locomotive wheelsets. Intensity of wear of the wheelset ridges after plasma hardening is much lower than that of the traditionally treated ones (2.5-3 times). The developed technology for hardening of the wheelsets has two peculiar features: 1.local (within the zone of the highest wear) surface hardening of the wheel ridge to a depth of 2.5-3 mm and width of 35 mm, ensuring an increase in hardness from 280 HB (in the base metal) to 450 HB. This provides an optimal relationship in hardness of the wheel and rail surfaces in contact; 2) change in structure of the hardened wheel zone from a ferrite-pearlite mixture with initial grain size of 30-40 μm to a mixture of fine-acicular or structureless martensite with a rosette-type troostite in a ratio of 50:50 %. This produces improvement of mechanical properties (including decrease in friction coefficient in contact of the ridge and the side surface of the rail) and increase in crack resistance of the wheel material within the plasma hardening zone.

Locomotives with the wheels plasma hardened by the TOPAS technology were first put into experimental operation at the Lviv-Zapad shed early in March 1996, and the cars - at the Kyiv-Passenger shed in summer that same year. Comparison of the plasma hardened wheel ridges of electric locomotives with the traditional ones under the same service conditions of the Lviv railway proved by the end of April 1996 the expected two-fold decrease in rate of wear. After that a decision was made to expand the scopes of application of plasma hardening of the wheelset ridges. It was for that purpose that the new specialized two-module high-speed plasma hardening machine UVPZ-2M was developed. Its application initiated the arrangement of workshops for plasma hardening of wheelsets without wheeling out from under a locomotive, which was completed in 1997. This was done using the KZh-20 machine tool at the Znamenka shed. Similar workshops for plasma hardening with wheeling out were arranged in Osnova,

Kharkiv. Workshops for plasma hardening of the wheelset ridges without wheeling out, based on the KZh-20 machine tool, were built at the Kazatin shed, those based on the K-40 machine tool were built at the Lviv-Zapad, Osnova (Kharkiv), Kotovsk, Nizhnedneprovsky junction, etc. (Fig. 3). The car wheels are hardened using the specialized production line with wheeling out at Kyiv, Kherson, Dneprodzerzhinsk and other car sheds.

The final outcome of more than 5 years operation of locomotives and cars with the plasma hardened wheelset ridges is as follows. 1.Plasma hardening is a highly productive efficient method for 2- or 3-fold extension of service life of the wheelsets, which can be applied under conditions of a typical car shed. The accepted technology provides a very high safety factor for operational reliability of the wheelsets. 2. The guaranteed reproducibility of the best indicators of operational reliability, and wear resistance is ensured by keeping precisely to the prescribed hardening parameters for every wheel.

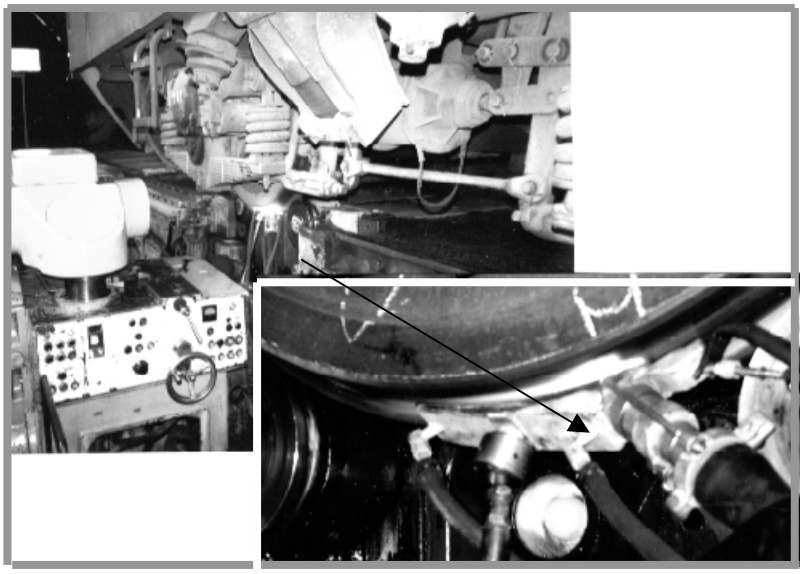

Fig.3. Plasma hardening of wheelsets without wheeling out from under a locomotive

5.Tempering of flats

A new technology for high-speed plasma tempering of cold-worked (hardened) roll surfaces of wheelsets has been developed on the basis of the UVPZ-2M machine. This technology has been successfully applied at a number of depots (Fig.4) Hardness of the surface layer of metal of wheels is increased due to cold working during movement from 285 HB to 350 HB, while on flats formed in braking with blocked wheels the hardness value may amount to 50-55 HRC.

In this situation tempering of the surface layer of metal prior to re-profiling the roll surface of wheels make the work of cutting tools and a lathe much easier. This enables the rate of turning to be increased and a substantial saving to be achieved.

6. Plasma Spraying of Resistant Coatings on Wheel Flanges

Constant shape of a wheel flange is ensured by deposition of wear-resistant coatings. This solves a contradictory problem, i.e. maintaining a sufficiently high coefficient of friction between the roll surface and rail to improve transfer of longitudinal forces and decreasing friction in the zone of pressing of the lateral face of the flange to the rail.

Wear-resistant coating of a self-fluxing material with an addition of carbides or carbonitrides (Fig.5) is deposited on the wheel flange in one pass with a simultaneous surface melting. Thickness of the coating is 1-2 mm, width of the coated strip is 25-30 mm. This is done using the TOPAS rotators, or rotators for wire deposition of the flanges, as the spray surface should be in a horizontal position. Wear-resistant coatings with simultaneous surface melting can be deposited using the UVPZ-2M plasma equipment for surface hardening, subjected to upgrading.

Materials which provide the following properties were selected for deposition of the coatings:

- high toughness and deformability of the deposited layer;
- special properties of the coating material the friction coefficient of which corresponds to a minimum probability of derailment;

- low wear of the rail-wheel system;
- high strength of adhesion of the coating to the substrate material;
- homogeneous structure of the coating;
- long service life of the coating;
- possibility of repeated deposition without preliminary machining.

Such a coating will provide a 5-10 times extension of life of the flange and a decrease of 50-100 % in the coefficient of friction of the working surface of the flange with the rail.

Plasma exposure of advanced resists during the pattern transfer step is often accompanied by resist surface roughening and line edge roughening due to factors which are not well understood. The roughness features so produced can be transferred into the underlayer and appear as sidewall striations. In the present work we have studied the evolution of surface roughening in advanced resists by ellipsometry in real time during plasma processing. We also have developed an optical model of the modified resist layer which is used to interprete the results of the real-time optical surface diagnostics. Using this methodology, we have investigated the relative importance of key plasma-surface interactions parameters, e.g. maximum ion energy, total energy flux, and plasma chemistry, in producing resist surface roughening, and also investigated chemical changes in the resist materials. A comparison of 248 nm resist with 193 nm resist shows that significantly more surface roughness is introduced in the 193 nm resist for all plasma processing conditions investigated. We also find a dramatic dependence of surface roughening on the chemistry of the plasma process, e.g. for Ar/C_4F_8 a rough resist surface layer with an extent of about 50 nm is produced in 193 nm resist, whereas for C_4F_8 discharges much less surface roughening is seen for otherwise similar conditions. We find that the thickness of the rough surface layer does not show a strong time dependence, but that the intensity of the roughness increases continuously with plasma exposure time. A comparison of the results of the real-time optical data with atomic force microscopy and x-ray photoelectron spectroscopy data obtained when interrupting the plasma process will also be reported. The mechanistic implications of the present results are discussed in the context of designing better resist materials/plasma processes, in particular for the development of 157 nm technology.

Characteristics of Broad-Band Frequency Low Pressure Inductively Coupled Plasma Used for Nanostructured Carbon Deposition

Katsuyuki Okada, Shojiro Komatsu, and Seiichiro Matsumoto

Advanced Materials Laboratory, National Institute for Materials Science
1-1 Namiki, Tsukuba, Ibaraki 305-0044, Japan; okada.katsuyuki@nims.go.jp

Abstract

We have developed a broad-band frequency (10-60 MHz) low pressure inductively coupled plasma system used for nanostructured carbon deposition by properly adjusting an antenna and an impedance matching network. The plasma characteristics {plasma potential (Vp), electron temperature (Te), plasma density (Ne), and electron energy distribution function (EEDF)} were investigated by an optical emission spectroscopy (OES) and an RF compensated Langmuir probe. We have found that the Vp and Te decrease with increasing pressure, whereas the Ne increases, and that the Vp and Ne also increase with increasing frequency, whereas the Te tends to be saturated in higher frequency. The EEDF at lower frequency exhibits a deviation from Maxwellian distribution, in which the population of electrons in the high-energy tail above 13 eV drops, whereas the high-energy tail grows at higher frequency and the almost straight line of the EEDF indicates Maxwellian distribution.

1. Introduction

Low pressure plasmas driven at very high frequency (VHF; 30-300 MHz) have recently attracted considerable attention [1] because they may have higher plasma density and lower electron temperature compared with those of conventional 13.56 MHz radio frequency (RF) plasma. In the VHF range, high plasma densities can be generated with low applied voltages, suggesting that high process rates can be realized with low damage. Sheath thickness also decreases with increasing frequency, reducing the number of collisions an ion experiences in the sheaths and improving anisotropy at a fixed pressure. These characteristics are considered to be appropriate for plasma process, e.g. deposition of thin films or etching. There are up to now many reports on capacitively coupled VHF discharge. In a conventional parallel-plate capacitive discharge, the applied voltage is essentially dropped across the electrode sheaths, and ion energies at the electrodes must increase along with the plasma density. This coupling between plasma density and ion energy is a serious limitation of conventional parallel-plate electrode reactors. On the other hand, in an inductively coupled discharge, the RF power is coupled to the plasma across a dielectric window, rather than by direct connection to an electrode in the plasma, as for a capacitive discharge. This noncapacitive power transfer enables one to achieve low voltages across all plasma sheaths at electrode, and independent control of the ion/radical fluxes and the ion bombarding energy is possible [2]. Therefore inductively coupled VHF discharge is considered to be the most suitable plasma source for processing. However there is few report on inductive VHF discharge.

We have recently developed a broad-band frequency (10-60 MHz) low pressure inductively coupled plasma (ICP) system used for nanostructured carbon deposition. We report on the plasma characteristics {plasma potential (Vp), electron temperature (Te), plasma density (Ne), and electron energy distribution function (EEDF)} measured with an optical emission spectroscopy (OES) and an RF compensated Langmuir probe [3,4] in this study.

2. Experiment

Figure 1 illustrates the schematic diagram of the experimental setup. A low pressure ICP was generated in a water-cooled quartz tube by applying VHF power to a loop antenna. The frequency was varied from 10 to 60 MHz. The maximum input power was 1 kW. The reflected power was always maintained at less than 10% of the forward power by properly adjusting an antenna and an impedance matching network consisting of two vacuum-dielectric variable capacitors. The total inductance of the antenna was always kept

less than 0.3 μ H.

The light emitted from a plasma was fed to an optical multi-channel analyzer (OMA) [Jobin Yvon HR-320 monochromator, 512 channels Photodiode-array] through an optical fiber. An RF compensated Langmuir probe [3,4] (Scientific Systems; Smart Probe) was mounted on the side flange of the chamber. The RF fluctuations of the plasma potential were compensated by self-resonant inductors, and the reference probe automatically compensated for the plasma-ground sheath impedance, fluctuations in the plasma sheath impedance, plasma potential shifts, and low frequency noise [3].

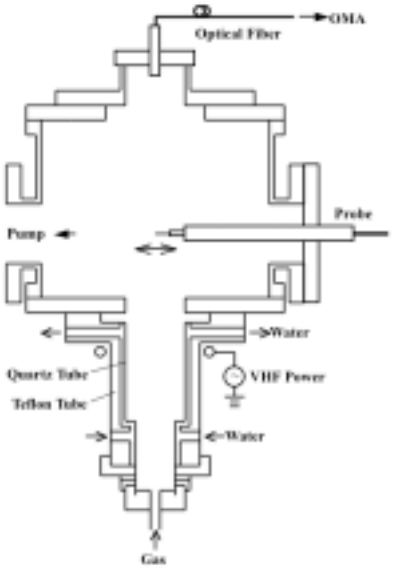

FIG. 1 Schematic view of the broad-band frequency low pressure ICP system.

3. Results and Discussion

Figures 2 and 3 show the OES profiles of an Ar and a H_2 plasma with 200 W in plasma power and 20 mTorr in pressure as a function of frequency, respectively. The absolute emission intensity of the both plasmas remarkably increased with an increase of frequency. The OES profiles of an Ar plasma exhibit that the relative intensities of ArI[4s'$(1/2)^0_1$-4p'$(1/2)_0$] at 750.4 nm become strong with an increase of frequency. The energy of the excited state of 4p'$(1/2)_0$ corresponds to 13.48 eV. Thus it is expected that the electron energy distribution around13.5 eV is relatively increased with increasing frequency. The OES profiles of a H_2 plasma exhibit that the relative intensities of H β at 486.1 nm become strong with an increase of frequency, and that the superimposed background due to H_2 molecules are lowered with increasing frequency. It was previously reported [5] that significant emission due to H_2 molecules appears in addition to H atomic transitions in a VHF H_2 plasma, and [6] that the intensity ratio of H_2/H α negatively correlates with the Te. The electron impact dissociation of hydrogen molecules is considered to proceed with increasing frequency. These features reveal that the excited states levels of chemical species in plasma largely depend on plasma driven frequency.

Figure 4 shows the radial distribution of the plasma potential Vp, the electron temperature Te, and the electron density Ne of an Ar plasma with 500 W in plasma power and 50 mTorr in pressure. The Vp and Ne have a similar shape, which has a peak at the center axis and decreases outward in the radial direction. The nonuniform profiles reflect the characteristics of diffusion-dominated plasmas [2,7]. On the other hand, the radial distribution of the Te is different from that of the Vp or the Ne. The Te is almost constant within the radius of 20 mm and then slightly decreases toward the chamber wall. The flatness of the Te around the

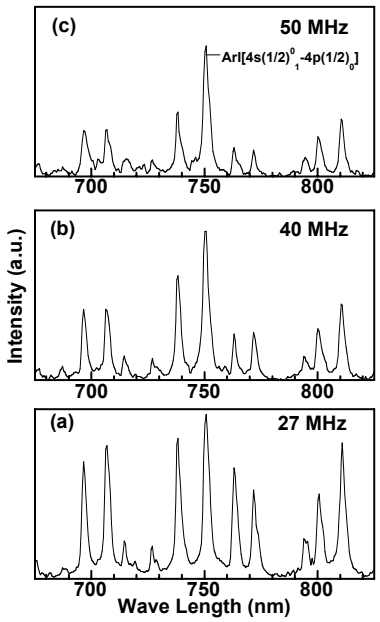

FIG. 2 OES profiles of an Ar plasma of 200 W at 20 mTorr as a function of frequency: (d) 27 MHz, (e) 40 MHz, and (c) 50 MHz.

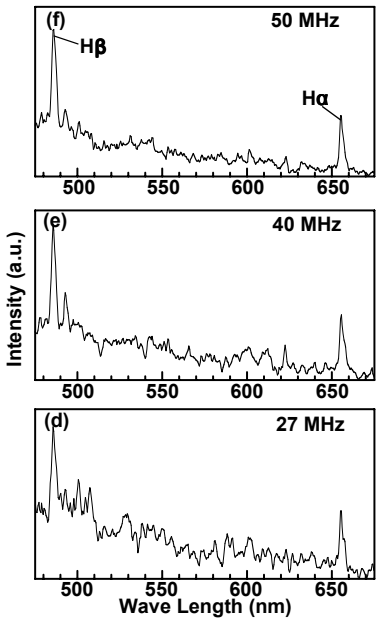

FIG. 3 OES profiles of a H_2 plasma of 200 W at 20 mTorr as a function of frequency: (d) 27 MHz, (e) 40 MHz, and (c) 50 MHz.

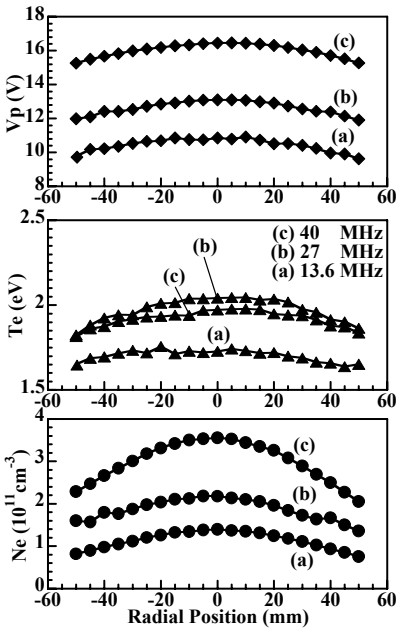

FIG. 4 Radial distribution of the Vp, Te, and Ne of an Ar plasma of 500 W at 50 mTorr: (a) 13.6 MHz, (b) 27 MHz, and (c) 40 MHz.

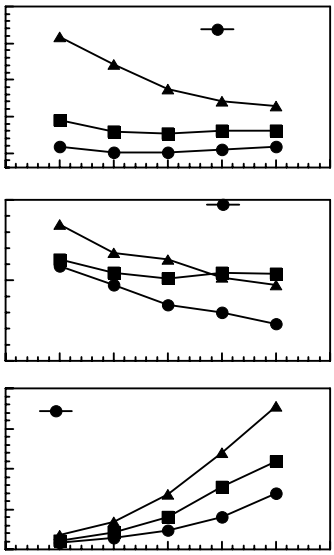

FIG. 5 Vp, Te, and Ne of an Ar plasma of 500 W at 13.6, 27, and 40 MHz as a function of pressure.

center axis is presumably due to the large mean free path of the electrons at low pressures [8], and the decrease of the Te at radii larger than 20 mm is caused by volumetric expansion [9]. The frequency does not affect these features of plasma parameters.

Figure 5 shows the Vp, Te, and Ne of an Ar plasma at 13.6, 27, and 40 MHz with 500 W in plasma power as a function of pressure. With an increase of pressure, the Ne also increases while the Vp and Te decrease. These variations with pressure are consistent with the previous results of 13.56 MHz ICP plasma [4,7]. The lower rate of inelastic electron-heavy particle collisions leads to the increase of the Te with decreasing pressure. This in turn increases the Vp because the rate of high-energy electrons escaping to the wall increases and brings about a loss of negative charge. The increase of Ne with increasing pressure is in agreement with the power balance relation [2], which indicates that the plasma density varies inversely with the effective plasma area.

With an increase of frequency, the Vp and Ne also increase, whereas the Te tends to be saturated in higher frequency. It was shown experimentally [5] that the electron density scales as the square of the frequency in an Ar VHF plasma. It was reported on a capacitive VHF plasma that the Vp decreases with an increase of frequency [10]. The opposite tendency in this study is presumably due to inductive discharge.

Figure 6 shows the EEDF of an Ar plasma with 500 W in plasma power and 50 mTorr in pressure. The population of electrons in the high-energy tail above 13 eV drops at lower frequency and the EEDF exhibits a deviation from Maxwellian distribution, whereas the high-energy tail grows at higher frequency and the almost straight line of the EEDF indicates Maxwellian distribution. This is consistent with the OES profile indicating that the electron energy distribution around 13.5 eV is relatively increased with increasing frequency. According to the theoretical investigation [11,12], the shape of the EEDF depends strongly on the ratio ν / ω, where ν is the frequency of energy transfer by electron-neutral collisions and ω is the angular excitation frequency of the applied VHF field. The EEDF tends toward a Maxwellian distribution as ν / ω decreases, whereas the EEDF is similar to a Druyvesteyn distribution in the low frequency limit ($\nu / \omega \rightarrow \infty$). Therefore, the high-energy tail of the EEDF is enhanced at higher frequency. The resultant EEDF profiles in this study are in agreement with the theory.

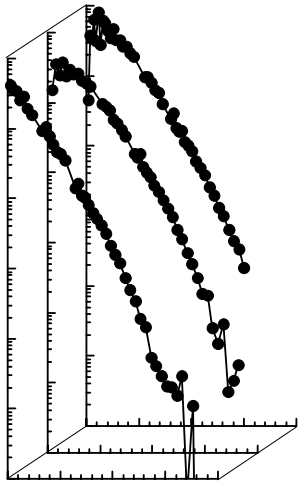

FIG. 6 EEDFs of an Ar plasma of 500 W at 50 mTorr as a function of frequency:(a) 13.6 MHz, (b) 27 MHz, and (c) 40 MHz.

4. Conclusions

We have investigated the plasma characteristics of a broad-band frequency (10-60 MHz) low pressure ICP. The OES profiles of an Ar plasma exhibit that the relative intensities of ArI[$4s'(1/2)^0_1$-$4p'(1/2)_0$] at 750.4 nm become strong with an increase of frequency. It suggests that the electron energy distribution around 13.5 eV is relatively increased with increasing frequency. The OES profiles of a H_2 plasma exhibit that the relative intensities of H β at 486.1 nm become strong with an increase of frequency, and that the superimposed background due to H_2 molecules are lowered with increasing frequency.

The Vp and Ne have a similar shape, which has a peak at the center axis and decreases outward in the radial direction, whereas the Te is almost constant within the radius of 20 mm and then slightly decreases toward the chamber wall. With an increase of pressure, the Ne also increases while the Vp and Te decrease. With an increase of frequency, the Vp and Ne also increase, whereas the Te tends to be saturated in higher frequency.

The EEDF at lower frequency exhibits a deviation from Maxwellian distribution, in which the population of electrons in the high-energy tail above 13 eV drops, whereas the high-energy tail grows at higher frequency and the almost straight line of the EEDF indicates Maxwellian distribution. This is consistent with the theory and the OES profile indicating that the electron energy distribution around 13.5 eV is relatively increased with increasing frequency.

Abstract
In this paper we present recent results of synthesis and deposition of Si/Ti/N nanocomposites using hypersonic plasma particle deposition (HPPD). The study analyzes individual nanoparticles as well as nanostructured films; particularly the chemistry, phase composition and morphology. It shows that complex crystallite phases seen in the film are not present in the particles prior to deposition. Moreover, the hardness of single Si nanospheres was evaluated and found to be several times higher than its bulk counterpart.

1. Introduction

A number of studies have reported that nanostructured materials have drastically increased hardness compared to conventional material of the same composition, suggesting that nanostructured parts or coatings might offer revolutionary improvements in applications requiring friction and wear resistance [1 and references therein]. Recently Si/Ti/N nanostructured films have shown good promise as potential candidates for high hardness and friction resistant applications [2].

Thermal plasmas are well adapted to synthesize such hard coatings, and they have the added advantage of high deposition rates [3]. The HPPD process has been used previously to synthesize binary component films (i.e. SiC) of high hardness [4, 5]. This paper analyzes Si/Ti/N films synthesized and deposited by inertial impaction with the HPPD process. Moreover, the mechanical properties of individual Si nanoparticles have also been examined.

After a description of the experimental process and the different characterization tools utilized, we present and discuss the results.

2. Experimental Process

The Si/Ti/N films were synthesized using the HPPD process as shown in Fig. 1 [2, 3]. The plasma gas consisted of a mixture of Ar and H_2 with an arc current of 200 A, and a voltage of about 45 V. In order to deposit films of Si/Ti/N nanocomposites, $SiCl_4$ and $TiCl_4$ vapors were premixed and injected in the hot plasma jet (about 4000 K) at the exit of the plasma torch, into a nozzle, whereas NH_3 is injected further downstream of the nozzle. Due to rapid quenching of the flow inside the nozzle, Si and Ti vapors reach supersaturated conditions and start to nucleate. The nucleus grows [6] to a few tens of nanometers in diameter. Due to rapid expansion into a chamber at a pressure of ~350 Pa the particles are deposited by inertial impaction on a temperature-controlled substrate made of molybdenum. Under these conditions a 20 nm diameter particle is predicted to hit the substrate with a velocity of about 1700 $m.s^{-1}$.

Several techniques have been employed in order to investigate both nanoparticles prior to deposition, and films constructed from these nanoparticles. A sampling probe interfaced with a differential mobility analyzer (DMA) allowed in-situ access to particles in the hot gas jet. The probe was connected to a hypersonic impactor to allow nanoparticle deposition onto TEM grids for off-line analysis (morphology, chemistry and crystallinity). The sampling system can be operated in chamber pressures as low as 533 Pa, with variable location along the jet axis.

The films were deposited on Molybdenum substrates and investigated using various characterization tools. X-ray diffraction (XRD) spectra were obtained with a Bruker AXS microdiffractometer (CuKα). The beam was collimated to a spot size of 0.8 mm. Rutherford back scattering (RBS) experiments were conducted in a MAS 1700 pelletron tandem accelerator (5SDH) equipped with charge exchange RF plasma by National Electrostatics Corporation (NEC). For each spectrum, 35 μC of 3.4 MeV He^{++} ions were collected. An Ortec Ultra ion detector, with an energy resolution of 12 keV, was placed at 165^o from the incident beam to collect the backscattered ions. X-Ray photoelectron spectroscopy (XPS) was carried out with a Physical Electronics model PHI-5400 equipped with an Al X-ray source. Scanning electron microscopy (SEM) was performed on a JEOL 6500 field emission gun microscope equipped with an energy dispersive spectrometer.

Transmission electron microscopy (TEM) was performed on a Philips CM30 with an operating voltage range of 50 to 300 kV. The CM30 was also equipped with energy dispersive x-ray spectroscopy analysis capabilities (EDAX PV9900).
Finally, the study of the mechanical behavior of individual Si nanoparticles was carried out with a scanning probe microscope-based nanoindenter (Hysitron TriboScope, Hysitron Inc., Edina, MN) equipped with a 1 μm radius diamond tip. The process of obtaining individual nanoparticles using the HPPD system is described elsewhere [7, 8].

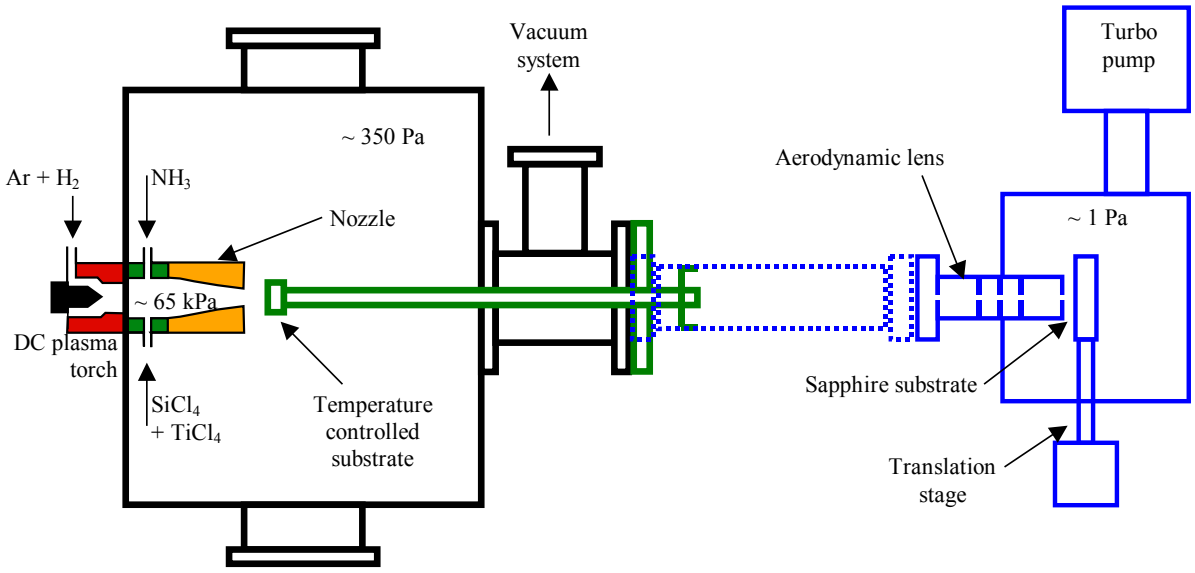

Figure 1. Schematic of the HPPD system.

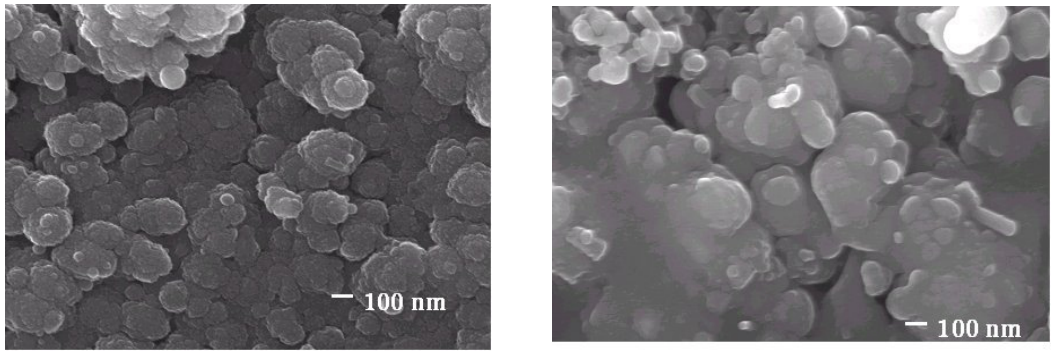
3. Results and Discussion

3-1. Film Deposition

Analyses of the films for which the $SiCl_4$ and $TiCl_4$ reactant vapors were premixed show the presence of crystalline phases of Si, TiN and $TiSi_2$ and amorphous phases of Si_3N_4. Veprek et al. recently concluded that films of nanocrystalline TiN and $TiSi_2$ in an amorphous Si_3N_4 matrix can have hardness values as high as 105 GPa [2]. The ratio of the different elements, phases and morphology of the film depended on the substrate temperature, reactant flow rates, and whether reactant premixing was performed. The effects of these parameters are discussed below.

3-2. Substrate temperature

Substrate temperature was varied during deposition of the Si/Ti/N films to gauge the effect of substrate thermal conditions on film quality. Two temperature ranges were selected for the experiments. The lower range was set at 320°C, which is the lowest temperature at which films can be deposited under stable conditions. The higher range was set to be ~800°C.
The morphology of the top and cross sections of the films from SEM images (Fig. 2) shows primarily a cluster like structure at high temperatures while clusters mixed with glassy splats were observed at the low temperatures.
XRD spectra show that films deposited at higher temperature are more crystalline than films deposited at low substrate temperatures. The substrate temperature affects the quench rate of the particle after impaction thus either freezing in an amorphous phase or allowing sufficient time for the atoms to order themselves into nanocrystalline phases of TiN, $TiSi_2$ and Si.



(a) (b)

Figure 2. SEM pictures of Si/Ti/N films. (a) Topography of a film deposited at 800°C. (b) Topography of a film deposited at 320°C.

3-3. Effects of Premixing

Experiments were conducted in which vapors of $SiCl_4$ and $TiCl_4$ were either premixed or unmixed before injection into the nozzle. Analysis of the films show that premixing the reactants before injection resulted in the formation of a crystalline $TiSi_2$ phase while unmixed injection was notable for the absence of crystalline $TiSi_2$ (see Fig. 3). This phenomenon is related to possible reaction chemistry between $TiCl_4$ and $SiCl_4$ before injection into the plasma jet, but the exact cause has not been determined yet.

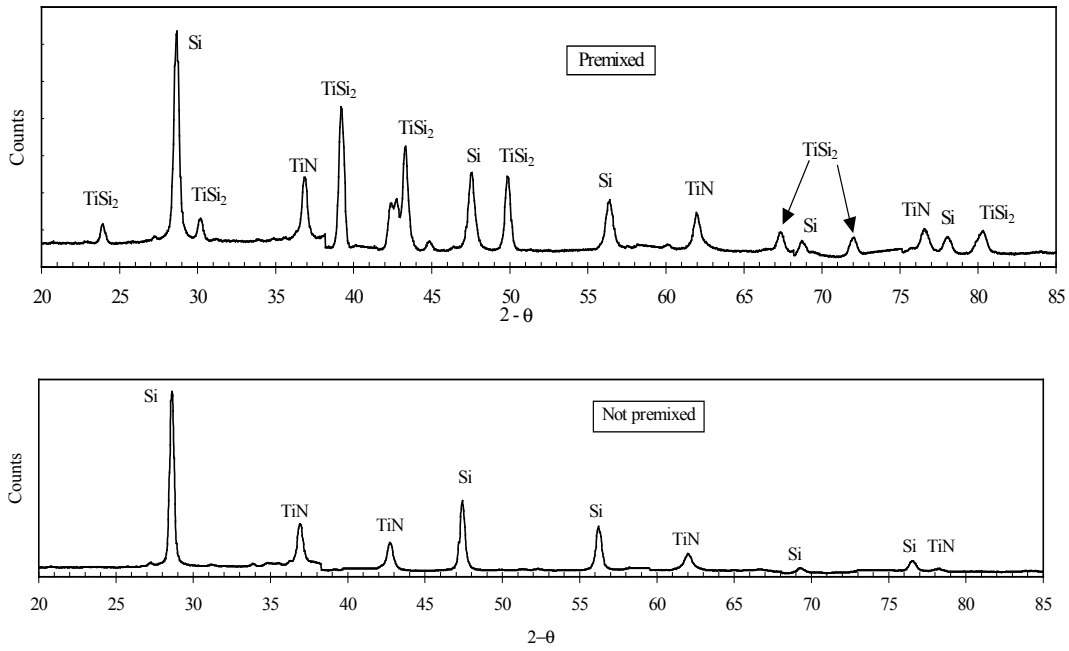


Figure 3. Micro XRD spectra of a premixed and unmixed film.

3-4. Effects of Reactant Flow Rates

Reactant flow rates were varied to determine the effect of $SiCl_4$, $TiCl_4$, NH_3 flow rates and their ratios. The atomic percentage ratios obtained from the RBS spectra (Fig. 4) show that to obtain a ratio of Si:Ti = 2 in the film the amount of $TiCl_4$ (volumetric) needs to be at least twice as that of $SiCl_4$. The presence of nitrogen was detected in RBS and XPS spectra only with ratios of $NH_3/(SiCl_4/TiCl_4) \geq 2.4$. Moreover, the high content of Si and N, the Si-N bond existence in the XPS spectra, and the weak Si_3N_4 peaks in the corresponding XRD spectra point to the presence of amorphous Si_3N_4 in the films. Interestingly, crystalline phases of Si_3N_4 were detected only when the $SiCl_4$ to $TiCl_4$ ratio was two or higher.

Also, the RBS spectra show that higher the NH_3 flow rate, lower the O contamination.

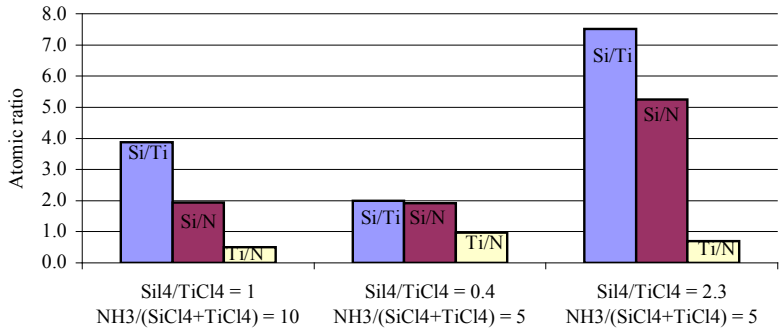

Figure 4. RBS atomic ratios of Si/Ti/N films for different reactant ratios.

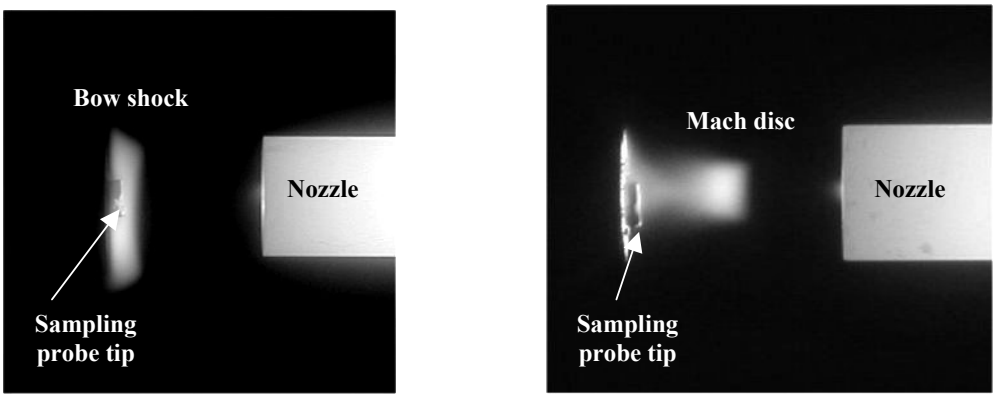
3-5. Particle Size Distributions

Particle size distributions were measured using the sampling probe for chamber pressures from 533 Pa to 11 kPa. The sampling probe distance from the nozzle was 2 cm, corresponding to the substrate standoff distance for film deposition (Fig. 5). This allowed us to compare the properties of the particles prior to films produced by impaction under the same conditions (other than differences in pressure).



(a) (b)

Figure 5. Sampling probe during actual experiment. (a) Chamber pressure = 800 Pa. (b) Chamber pressure = 3.7 kPa.

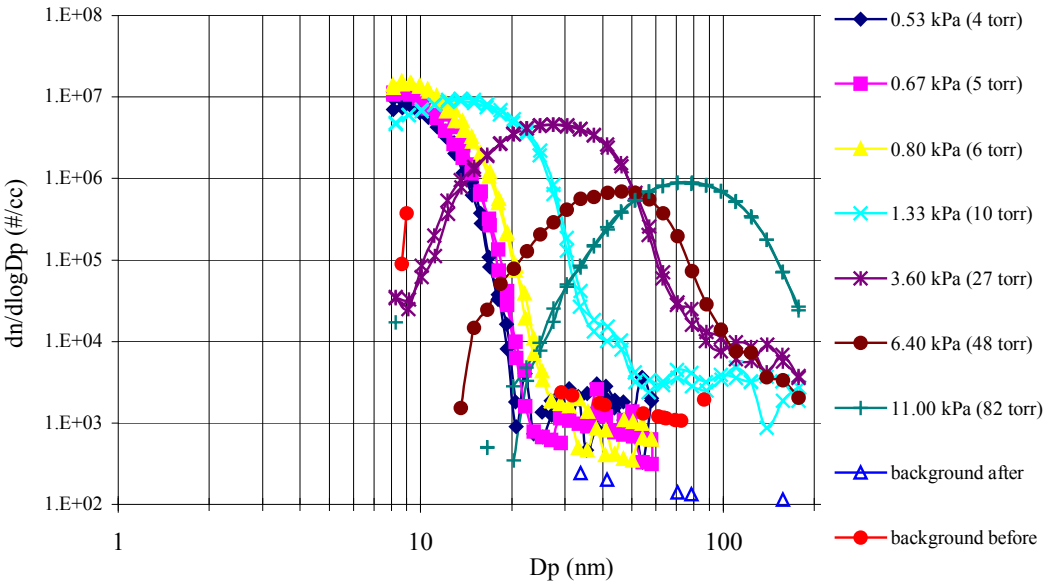


Figure 6. Pressure dependence of the particle size distribution (SiCl4: TiCl4: NH3 = 20:30:500 sccm).

The size distribution plot exhibits remarkably uniform peak behavior with respect to the chamber pressure (Fig. 6). For instance, the size distribution plot of particles sampled at 3.6 kPa (27 torr) shows a peak diameter of approximately 27 nm. Selected area diffraction patterns from a typical deposit obtained in the impactor show mainly amorphous material with isolated bright spots from polycrystalline material. EDS spectra from the same sample show the presence of both Si and Ti as expected. The EDS spectra of particles sampled from the free jet with the hypersonic impactor were consistent with the spectra obtained from the films.

TEM analysis of a randomly selected individual nanoparticle in the impactor shows a complex crystalline diffraction pattern with particle diameter of approximately 100 nm (Fig. 7 (a) and (b)).

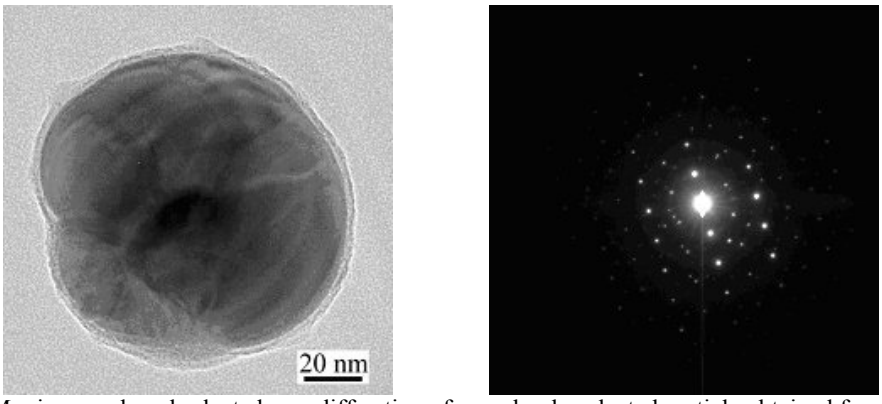

Figure 7. TEM micrograph and selected area diffraction of a randomly selected particle obtained from the impactor.

3-6. Individual Si Nanoparticle Hardness Measurements

A series of repeat loading experiments using the Hysitron Triboscope nanoindenter was performed on Si nanoparticles ranging from 20 to 70 nm in radius. The experiment started with small loads near 10 μN and was incrementally increased to a final value of 200 μN.

Hardness curves for spherical Si nanoparticles of various dimensions are given in Fig 8. The hardness values of the nanoparticles go up to 50 GPa, which is more than four times greater than the 12 GPa value for bulk silicon. It is interesting to note that the hardness increases dramatically as the particle size gets smaller. A particle with a radius of 46 nm has hardness values similar to bulk silicon while the hardness values of a 38 nm radius particle go up to 50 GPa. Extrapolation of this trend predicts hardness rivaling that of diamond for Si nanoparticles in the 5-10 nm range. The reader is referred to Gerberich et al. for detailed information on studies of superhard silicon nanoparticles synthesized in the HPPD system [8].

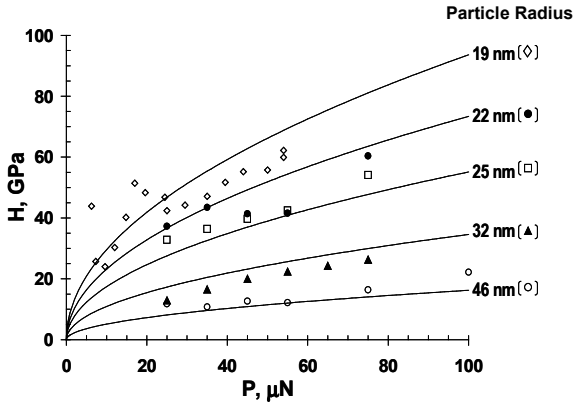

Figure 8. Hardness values of Si nanoparticles [8].

4. Conclusion

The work reported here presents preliminary results of using the HPPD process to deposit Si-Ti-N nanocomposite films. Phase distribution and stoichiometry in the films was studied as a function of process parameters. In-situ measurements of particle size distributions showed that the impacting particles were

mostly below 10 nm in diameter. It is also shown using the sampling probe that particle size distribution is well-behaved with the peak particle diameter linearly related to the sampling pressure.
The way nitrogen reacts with the nanoparticles and/or the film is not yet well understood: whether the particles contain N prior to their impaction onto the substrate or does nitrogen deposit on the film by a chemical vapor deposition route.
Nanoindentation studies of single Si nanoparticles showed that their hardness increases dramatically as particle size decreases, reaching several times the bulk material values for diameters below 40 nm. Work is in progress to determine mechanical properties of the films by nanoindentation.

Three-dimensional modeling of the long laminar plasma jet with transverse particle and carrier-gas injection

Dong-Yan Xu and Xi Chen

Department of Engineering Mechanics, Tsinghua University, Beijing 100084, China

Abstract

Modeling results are presented concerning the characteristics of a long laminar plasma jet with transverse particle and carrier gas injection. It is shown that the long laminar plasma jet has well enough stiffness to endure the impact of the laterally injected carrier gas, although the laminar jet assumes slight deflection from its geometrical axis. The three dimensional effects caused by the lateral carrier-gas injection on the jet characteristics and on the particle moving trajectories and heating histories are shown to be appreciable.

1. Introduction

In various applications of thermal plasmas (e.g. plasma spraying, plasma cladding and remelting, etc.), the plasmas are usually issued from thermal plasma torches in the form of plasma jets. Long laminar plasma jets have been successfully produced by use of elaborately designed plasma torches in recent years [1-3]. In comparison with the turbulent jet widely used in materials processing, the long laminar plasma jet has a few marked advantages including adjustable high-temperature region length, small axial gradients of temperature and velocity, low-level noise emission and weak entrainment of ambient air into the jet. Those advantages make the long laminar plasma jet very attractive from the materials processing viewpoint, since low-noise working surroundings, reduced oxidation degree of processed metallic materials and enhanced process controllability or repeatability can be achieved.

So far, our understanding on the characteristics of long laminar plasma jets is still far from completeness. Preliminary modeling results reported in Refs. [1, 4] showed that the laminar plasma jet assumed much longer high-temperature region length than that for the turbulent jet, in consistence with the experimental observation [1, 3]. Although it is expected that the entrainment of ambient air into the laminar jet is weaker than that for the case of turbulent jet, up to date there is lack of detailed information about the species diffusion in the long laminar plasma jet. On the other hand, since the mass velocity of the laminar plasma jet is relatively small compared with that for the turbulent plasma jet, there often exists a doubt about whether the laminar plasma jet can endure the impact of laterally injected carrier gas. For this reason, in experiments sometimes researchers turned to rely completely on the gravity (instead of carrier gas) to feed the material particles into the laminar plasma jet. In order to clarify the foregoing problems, modeling work is conducted in this paper to study the characteristics of the long laminar plasma jet with lateral injection of carrier gas and particles, using the laminar argon plasma jet issuing into ambient air as the calculation example.

2. Modeling approach

2.1 Modeling of the long laminar plasma jet

The assumptions employed in the jet modeling include: (i) the plasma flow is laminar and steady; (ii) the plasma is optically thin, in LTE state and with temperature- and composition-dependent properties; (iii) the pertinent Mach number is small (e.g. less than 0.3), and thus the viscous dissipation and the pressure work terms in the energy equation can be neglected; (iv) only the effect of the laterally injected cold carrier gas on the plasma jet is considered, i.e. ignoring the effect of the particle injection on the jet characteristics.

Based on the foregoing assumptions, the continuity, momentum, energy and species conservation equations in the cylindrical coordinate system (r, θ, z) can be written as follows:

$$\frac{1}{r}\frac{\partial}{\partial r}(r\rho v_r)+\frac{1}{r}\frac{\partial}{\partial \theta}(\rho v_\theta)+\frac{\partial}{\partial z}(\rho v_z)=0 \tag{1}$$

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\rho v_r^2\right)+\frac{1}{r}\frac{\partial}{\partial \theta}(\rho v_r v_\theta)+\frac{\partial}{\partial z}(\rho v_r v_z)=-\frac{\partial p}{\partial r}+\frac{\partial}{\partial r}\left(2\mu\frac{\partial v_r}{\partial r}\right)+\frac{1}{r}\frac{\partial}{\partial \theta}\left[\mu\left(\frac{1}{r}\frac{\partial v_r}{\partial \theta}+\frac{\partial v_\theta}{\partial r}-\frac{v_\theta}{r}\right)\right]$$
$$+\frac{\partial}{\partial z}\left[\mu\left(\frac{\partial v_r}{\partial z}+\frac{\partial v_z}{\partial r}\right)\right]+\frac{2\mu}{r}\left(\frac{\partial v_r}{\partial r}-\frac{1}{r}\frac{\partial v_\theta}{\partial \theta}-\frac{v_r}{r}\right)+\rho\frac{v_\theta^2}{r} \tag{2}$$

$$\frac{1}{r}\frac{\partial}{\partial r}(r\rho v_\theta v_r)+\frac{1}{r}\frac{\partial}{\partial \theta}(\rho v_\theta^2)+\frac{\partial}{\partial z}(\rho v_\theta v_z)=-\frac{1}{r}\frac{\partial p}{\partial \theta}+\frac{\partial}{\partial r}\left[\mu\left(\frac{\partial v_\theta}{\partial r}-\frac{v_\theta}{r}+\frac{1}{r}\frac{\partial v_r}{\partial \theta}\right)\right]+\frac{1}{r}\frac{\partial}{\partial \theta}\left[2\mu\left(\frac{1}{r}\frac{\partial v_\theta}{\partial \theta}+\frac{v_r}{r}\right)\right]$$
$$+\frac{\partial}{\partial z}\left[\mu\left(\frac{\partial v_\theta}{\partial z}+\frac{1}{r}\frac{\partial v_z}{\partial \theta}\right)\right]+\frac{2\mu}{r}\left(\frac{1}{r}\frac{\partial v_r}{\partial \theta}+\frac{\partial v_\theta}{\partial r}-\frac{v_\theta}{r}\right)-\rho\frac{v_r v_\theta}{r} \quad (3)$$

$$\frac{1}{r}\frac{\partial}{\partial r}(r\rho v_z v_r)+\frac{1}{r}\frac{\partial}{\partial \theta}(\rho v_z v_\theta)+\frac{\partial}{\partial z}(\rho v_z^2)=-\frac{\partial p}{\partial z}+\frac{1}{r}\frac{\partial}{\partial r}\left[\mu r\left(\frac{\partial v_z}{\partial r}+\frac{\partial v_r}{\partial z}\right)\right]+\frac{1}{r}\frac{\partial}{\partial \theta}\left[\mu\left(\frac{1}{r}\frac{\partial v_z}{\partial \theta}+\frac{\partial v_\theta}{\partial z}\right)\right]+\frac{\partial}{\partial z}\left(2\mu\frac{\partial v_z}{\partial z}\right) \quad (4)$$

$$\frac{1}{r}\frac{\partial}{\partial r}(r\rho v_r h)+\frac{1}{r}\frac{\partial}{\partial \theta}(\rho v_\theta h)+\frac{\partial}{\partial z}(\rho v_z h)=\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{k}{c_p}\frac{\partial h}{\partial r}\right)+\frac{1}{r^2}\frac{\partial}{\partial \theta}\left(\frac{k}{c_p}\frac{\partial h}{\partial \theta}\right)+\frac{\partial}{\partial z}\left(\frac{k}{c_p}\frac{\partial h}{\partial z}\right)-U_r-\frac{\partial}{\partial z}[(h_A-h_B)J_z]$$
$$-\frac{1}{r}\frac{\partial}{\partial r}[r(h_A-h_B)J_r]-\frac{1}{r}\frac{\partial}{\partial \theta}[(h_A-h_B)J_\theta]-\frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{k}{c_p}(h_A-h_B)\frac{\partial f_A}{\partial r}\right]$$
$$-\frac{1}{r^2}\frac{\partial}{\partial \theta}\left[\frac{k}{c_p}(h_A-h_B)\frac{\partial f_A}{\partial \theta}\right]-\frac{\partial}{\partial z}\left(\frac{k}{c_p}(h_A-h_B)\frac{\partial f_A}{\partial z}\right) \quad (5)$$

$$\frac{1}{r}\frac{\partial}{\partial r}(r\rho v_r f_A)+\frac{1}{r}\frac{\partial}{\partial \theta}(\rho v_\theta f_A)+\frac{\partial}{\partial z}(\rho v_z f_A)=\frac{1}{r}\frac{\partial}{\partial r}\left(r\Gamma_f\frac{\partial f_A}{\partial r}\right)+\frac{1}{r^2}\frac{\partial}{\partial \theta}\left(\Gamma_f\frac{\partial f_A}{\partial \theta}\right)+\frac{\partial}{\partial z}\left(\Gamma_f\frac{\partial f_A}{\partial z}\right)+S_f \quad (6)$$

In these equations, v_r, v_θ and v_z are the velocity components in r-, θ- and z-directions, p and f_A the gas pressure and the mass fraction of argon in the argon-air mixture, whereas ρ, μ, h, k, c_p and U_r are the temperature- and composition-dependent density, viscosity, specific enthalpy, thermal conductivity, specific heat at constant pressure and radiation power per unit volume of the plasma, respectively. The combined diffusion coefficient method proposed by Murphy [5, 6] is employed in this study to treat the diffusion of argon in the argon-air mixture. Since both argon and air are involved in this study, the source terms in the energy equation (5) are much more complicated than those for the case only one gas species is involved. In equation (5), h_A and h_B are the specific enthalpy of species A (argon) and B (air). J_r, J_θ and J_z are the r-, θ- and z-component of the following diffusion flux vector of argon species [5, 6]:

$$\vec{J}_A=-(n^2/\rho)\overline{m}_A\overline{m}_B\overline{D}_{AB}^{x}\nabla X_A-\overline{D}_{AB}^{T}\nabla\ln T \quad (7)$$

where n is the total gas particle number density, $\overline{m}_A$ and $\overline{m}_B$ are the averaged gas particle mass for all the heavy particles (excluding electrons) coming from argon (i.e. species A) and from air (i.e. species B), X_A is the mole fraction of argon in the argon-air mixture, whereas $\overline{D}_{AB}^{x}$ and $\overline{D}_{AB}^{T}$ are the combined ordinary diffusion coefficient associated with the mole-fraction gradient ∇X_A and the combined thermal diffusion coefficient associated with the temperature gradient ∇T, respectively [5, 6]. The transport coefficient in equation (6) can be expressed as $\Gamma_f=\left[\overline{m}_A\overline{m}_B/(\overline{M}\overline{M}_A)\right]\rho\,\overline{D}_{AB}^{x}$, in which $\overline{M}$ and $\overline{M}_A$ are the averaged gas particle mass for all the gas particles (including electrons) of the gas mixture and that for the gas particles coming from argon, respectively. The source term S_f in equation (6) can be expressed as

$$S_f=\frac{1}{r}\frac{\partial}{\partial r}\left(r\Gamma_f\frac{f_A}{\overline{M}}\frac{\partial\overline{M}}{\partial r}\right)-\frac{1}{r}\frac{\partial}{\partial r}\left(r\Gamma_f\frac{f_A}{\overline{M}_A}\frac{\partial\overline{M}_A}{\partial r}\right)+\frac{1}{r^2}\frac{\partial}{\partial\theta}\left(\Gamma_f\frac{f_A}{\overline{M}}\frac{\partial\overline{M}}{\partial\theta}\right)-\frac{1}{r^2}\frac{\partial}{\partial\theta}\left(\Gamma_f\frac{f_A}{\overline{M}_A}\frac{\partial\overline{M}_A}{\partial\theta}\right)+\frac{\partial}{\partial z}\left(\Gamma_f\frac{f_A}{\overline{M}}\frac{\partial\overline{M}}{\partial z}\right)$$
$$-\frac{\partial}{\partial z}\left(\Gamma_f\frac{f_A}{\overline{M}_A}\frac{\partial\overline{M}_A}{\partial z}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(r\overline{D}_{AB}^{T}\frac{\partial\ln T}{\partial r}\right)+\frac{1}{r^2}\frac{\partial}{\partial\theta}\left(\overline{D}_{AB}^{T}\frac{\partial\ln T}{\partial\theta}\right)+\frac{\partial}{\partial z}\left(\overline{D}_{AB}^{T}\frac{\partial\ln T}{\partial z}\right) \quad (8)$$

The computational domain used in this study is shown in figure 1 with domain sizes as follows: $0\le z\le 450$ mm, $0\le r\le 50$ mm, $0\le\theta\le 2\pi$. The mesh on the longitudinal section (θ = constant) and that on the cross section (z = constant) are also shown in figure 1. 24 (r-) × 35 (θ-) × 60 (z-direction) grid points are employed in the computation and are arranged to be finer near the jet axis and near the jet inlet.

The following boundary conditions are used in the modeling: (i) At the jet inlet (z=0 and $r\le$4 mm), we use

$$v_z(r)=U_0\left[1-(r/R)^2\right],\quad v_r(r)=0,\quad v_\theta(r)=0,\quad T(r)=(T_0-T_W)\left[1-(r/R)^2\right]+T_W,\quad f_A=1 \quad (9)$$

It is noted that the inlet enthalpy profile can be readily calculated from the given temperature profile. In equation (9), R is the jet inlet radius (4 mm), T_0 and U_0 are the maximum temperature and axial velocity at the jet inlet. T_0 = 15835 K and U_0 = 146 m/s are taken, corresponding to the argon flow rate 120 STP cm^3 / s

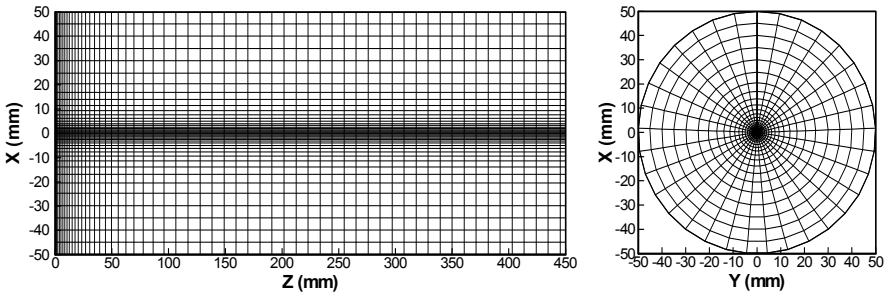

Figure 1. Computational domain and meshes on the $r-z$ section and the $r-\theta$ section.

and torch current 160 A (the measured jet power is 1.59 kW [2]). The other part of the upstream boundary (with z = 0 and 4 mm< r ≤50 mm) is assumed to be solid wall with zero velocity components, zero diffusion flux and fixed temperature (wall temperature T_W =300 K). (ii) One-way boundary conditions are adopted at the downstream boundary (with z = 450 mm), i.e. $\partial\phi/\partial z = 0$, ($\phi = v_r, v_\theta, v_z, h, f_A$). (iii) At the outer boundary of the jet (r = 50 mm), the following free-boundary conditions are used:

$$\partial(\rho r v_r)/\partial r = 0,\ \ \partial(r v_\theta)/\partial r = 0,\ \ \partial v_z/\partial r = 0,\ \ \begin{cases} T = 300\ \text{K},\quad f_A = 0 & \text{for}\quad v_r \le 0 \\ \partial T/\partial r = 0,\ \ \partial f_A/\partial r = 0 & \text{for}\quad v_r \ge 0 \end{cases} \tag{10}$$

(iv) Along the geometrical axis of the jet (r = 0), rv_θ =0 and the averaged values of ϕ_i (i = 1, 2, …, N) at all the N grid points on the small circle nearest to the axis in the mesh are employed for other variable ϕ, namely,

$$\phi|_{r=0} = \frac{1}{N}\sum_{i=1}^{N}\phi_i\ , \quad (\phi = v_z, v_r, h\ \text{or}\ \bar{f}_A) \tag{11}$$

(v) At the longitudinal section with θ = 0 or $\theta = 2\pi$, the value of variable ϕ at a boundary point is taken as the average of the ϕ values at its two neighbour grid points in θ direction. (vi) If there is radial carrier-gas (argon) injection, $v_r = V_{in}$, v_θ =0, v_z =0, T = 300 K and f_A =1 are taken at the exit of the injection tube, here V_{in} is the injection velocity of carrier gas.

2.2 Particle motion and heating in the laminar plasma jet

The following assumptions are employed in the study of particle behavior: (i) The particle is spherical. (ii) The pertinent Biot number is small (e.g. less than 0.02) so that the temperatures within the injected particle can be treated as everywhere uniform. This assumption is expected to be good for metal particles. (iii) The particle-particle interaction is negligible. (iv) The initial velocity of the particle is identical to the carrier gas velocity at the exit section of the injection tube.

Many factors may affect the motion and heating of the particle injected into the plasma jet. Drag and thermophoretic forces are expected to be the most important among the forces governing the particle motion. Hence, particle motion is described by the following equations:

$$m_p\frac{d\mathbf{V}_p}{dt} = \mathbf{F}_d + \mathbf{F}_t\,, \qquad \frac{dx_{pi}}{dt} = V_{pi}\,, \quad (i = 1,\ 2,\ 3) \tag{12}$$

where x_{pi} , m_p and t are the ith component of particle location vector, particle mass and time, whereas $\mathbf{V}_p$, $\mathbf{F}_d$ and $\mathbf{F}_t$ are particle velocity, particle drag force and thermophoretic force vectors, respectively. Using the drag coefficient and thermophoretic force expressions [7], equation (12) can be rewritten as

$$\frac{dV_{pi}}{dt} = \left(\frac{3\rho C_D}{8 r_p \rho_p}\right)\cdot\left|\mathbf{V}-\mathbf{V}_p\right|\left(V_i - V_{pi}\right) - 9\left(\frac{\mu^2}{\rho\rho_p r_p^2}\right)\cdot B\cdot\left(\frac{1}{T_\infty}\frac{\partial T_\infty}{\partial x_i}\right) \quad (i=1, 2, 3) \tag{13}$$

for a spherical particle with radius r_p . In equation (13), C_D is the drag coefficient, $\mathbf{V}$, T_∞ and $\partial T_\infty/\partial x_i$ are the plasma velocity vector, the plasma temperature and the temperature-gradient component in x_i-direction at the particle location if the particle is absent, whereas

$$B = C_s\,\frac{\left(k/k_p\right) + C_t\left(\lambda^*/r_p\right)}{\left[1+3C_m\left(\lambda^*/r_p\right)\right]\times\left[1+2\left(k/k_p\right)+2C_t\left(\lambda^*/r_p\right)\right]} \tag{14}$$

where ρ_p and k_p are the density and thermal conductivity of particle material, whereas C_s, C_t and C_m are three constants equaling to 1.17, 2.18 and 1.14, respectively. λ^* is the effective mean-free-path length of gas particles and can be calculated by $\lambda^* = \bar{k} \cdot \mathrm{Pr}_w/(2\psi_w \bar{C}_p)$ [7, 8], in which ψ_w is the gas particle flux incident upon the particle surface [8], and is calculated by $\psi_w = \rho_w \bar{v}_w /[2 \cdot (1+\sqrt{T_j/T_w})]$. Here ρ_w and $\bar{v}_w$ are the gas density and average thermal speed of gas particles evaluated at particle surface temperature T_w, whereas the average value of the gas thermal conductivity and specific heat within the Knudsen layer around the suspended particle are respectively calculated by

$$\bar{k} = \frac{1}{T_j - T_w}\int_{T_w}^{T_j} k dT = \frac{S_j - S_w}{T_j - T_w}, \qquad \bar{C}_p = \frac{1}{T_j - T_w}\int_{T_w}^{T_j} C_p dT = \frac{h_j - h_w}{T_j - T_w} \tag{15}$$

T_j is the jump temperature and is calculated by use of the relations $q_0 = (S_\infty - S_j)/r_p$, $(dS/dr)_w = q_0$ and $S_j = S_w + z^*(dS/dr)_w$ starting from a guessed value of T_j. Several iterations are enough to get a convergent value of T_j [7].

The drag coefficient C_D in equation (13) is calculated by $C_D = \alpha_1\alpha_2 f(\mathrm{Re}_\infty)(\mathrm{Re}_\infty/\mathrm{Re}_w)^{0.1} = \alpha_1\alpha_2 f(\mathrm{Re}_\infty)(\nu_w/\nu_\infty)^{0.1}$ [7, 8]. Here $f(\mathrm{Re}_\infty)$ is the standard drag coefficient of a sphere based on the Reynolds number evaluated at plasma temperature T_∞ (i.e. $\mathrm{Re}_\infty = 2\rho_\infty r_p |\mathbf{V} - \mathbf{V}_p|/\mu_\infty$) and the detailed piecewise expressions [7] are used. The factor $(\nu_w/\nu_\infty)^{0.1}$ is introduced to correct the great temperature-difference effect [8], whereas α_1 and α_2 are for the corrections due to, respectively, the Knudsen (rarefaction) effect and particle evaporation (if exists) [7] and can be calculated by

$$\alpha_1 = \left[1 + \left(z^*/r_p\right)\right]^{-0.45}, \quad \alpha_2 = \frac{L_v}{S_\infty - S_w}\int_{T_p}^{T_\infty} \frac{k dT}{h - h_w + L_v} \tag{16}$$

where $S = \int_{T_0}^{T} k dT$ is the so-called heat conduction potential, L_v is the evaporation latent heat of particle material, whereas z^* is the jump distance and is calculated by $z^* = [(2-a)/a][\gamma/(1+\gamma)](2\lambda^*/\mathrm{Pr}_w)$. Here a and γ are the thermal accommodation factor (a = 0.8 is used in this study) and specific heat ratio, whereas Pr_w ($= \mu_w C_{pw}/k_w$) is the Prandtl number evaluated at particle surface temperature.

The specific heat flux q from the plasma to the suspended particle is calculated by $q = \beta_1\beta_2 q_c$, in which q_c is the heat flux without accounting for the Knudsen (rarefaction) effect and particle evaporation and calculated using the following expression [7, 8] for the Nusselt number defined as $Nu_s = 2q_c r_p/(S_\infty - S_w)$:

$$Nu_s = 2\left[1 + 0.63\,\mathrm{Re}_\infty\,\mathrm{Pr}_\infty^{0.8}\left(\frac{\mathrm{Pr}_w}{\mathrm{Pr}_\infty}\right)^{0.42}\left(\frac{\rho_\infty\mu_\infty}{\rho_w\mu_w}\right)^{0.52} C^2\right]^{0.5} \tag{17}$$

in which factor $C = \left[1-(h_w/h_\infty)^{1.14}\right]/\left[1-(h_w/h_\infty)^2\right]$. The factors β_1 and β_2 are introduced to correct the Knudsen effect and particle evaporation (if exists) [7], and calculated by $\beta_1 = [1 + z^*/r_p]^{-1}$ and $\beta_2 = \alpha_2$.

For the case with small Biot numbers, the calculation of particle heating can be significantly simplified [7]. The temperature rising rate for the solid-phase heating of the injected particle is calculated by

$$dT_p/dt = 3(q - q_r)/(\rho_p C_{ps} r_p) \tag{18}$$

in which q_r is the radiation heat loss from the particle surface and $q_r = \varepsilon\sigma T_w^4$, whereas C_{ps} is the solid-phase specific heat of the particle material. During the melting period, the metallic particle temperature (T_m) would remain unchanged and the liquid-phase fraction (F) increment within the ith time step (Δt_i) is calculated by $\Delta F_i = 3(q - q_r)\cdot\Delta t_i/(L_m\rho_p r_p)$, in which L_m is the melting latent heat. The temperature rising rate for the liquid phase heating of the injected particle is also calculated using equation (18) but C_{ps} should be replaced by C_{pl} (the liquid-phase specific heat). As the injected particle has been heated to the period of intense evaporation, particle radius will reduce with the time as $dr_p/dt = -(q - q_r)/(\rho_p L_v)$ [7].

Sometimes, the moving particle may pass through the high-temperature core region of the plasma jet and reach the region with plasma temperatures less than the particle surface temperature. For this case, the heat flux from the plasma flow to the particle will be negative and the particle temperature will decrease gradually. The cooling of the heated particle can still be calculated using above equations.

3. Modeling results and discussions

3.1 Characteristics of the long laminar plasma jet with lateral carrier-gas injection

The carrier-gas (argon) injection tube is taken to be directed to the jet center and normal to the geometrical axis of the jet. The inner diameter of injection tube is 1.5 mm with a distance between the exit section of the carrier-gas injection tube and the geometrical axis of the plasma jet being 4 mm, whereas the distance between the carrier-gas injection tube and the jet inlet is 1.5 mm. Figure 2 presents computed isotherms within the laminar plasma jet on the plane formed by the plasma torch axis and injection tube axis (i.e. the $\theta = 0 - \pi$ section, this plane will be called injection plane hereafter) with the carrier-gas injection velocity of 5 m/s (or carrier-gas / plasma mass-flow-rate ratio being 0.074). Corresponding computed iso-contours of axial-velocity and argon mass fraction on the injection plane are shown in figure 3 and figure 4, respectively. The computed isolines of the temperature and argon mass fraction on the cross section at the axial distance z = 253 mm are shown in figures 5. In those figures, Z represents the axial distance from the plasma jet inlet, whereas X is the coordinate in radial direction with $X>0$ expressing the upper semi-plane (i.e. with $\theta = 0$) and $X<0$ denoting the lower semi-plane (i.e. with $\theta = \pi$). Examination of figures 2–5 shows that the lateral injection of carrier gas causes appreciable three-dimensional (3-D) features of the plasma jet. The carrier-gas injection induces marked deformation of the temperature, concentration and velocity fields near the carrier-gas injection port on the injection plane, and the 3-D effects of carrier-gas injection preserved in the downstream region of the plasma jet. Appreciable non-axisymmetry of the jet can be clearly seen in figure 5. The plasma jet assumes slight deflection on the injection plane due to the impact of the injected carrier gas, but the stiffness of the laminar plasma jet is still good. Namely, the long laminar plasma jet still assumes well enough stiffness to endure the impact of the laterally injected carrier gas. This predicted result implies that the particulate matter can be injected into the long laminar plasma jet with the aid of the carrier gas.

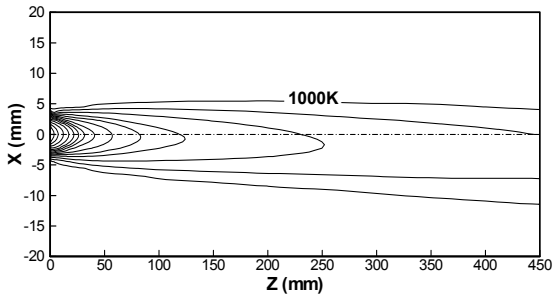

Figure 2 Computed isotherms in the laminar plasma jet on the injection plane ($\theta = 0$ -- π). Interval – 1000 K.

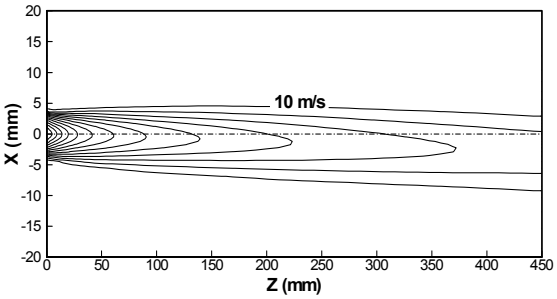

Figure 3 Contours of the axial velocity in the plasma jet on the injection plane (θ=0--π). Interval – 10 m/s.

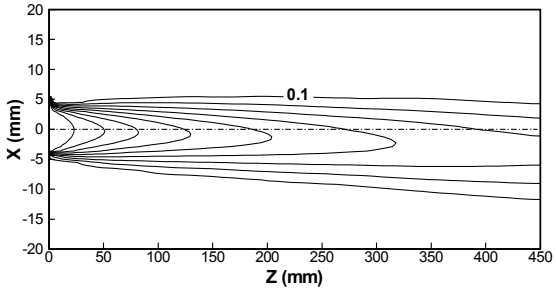

Figure 4 Computed contours of the argon mass fraction on the injection plane ($\theta = 0 - \pi$). Interval – 0.1.

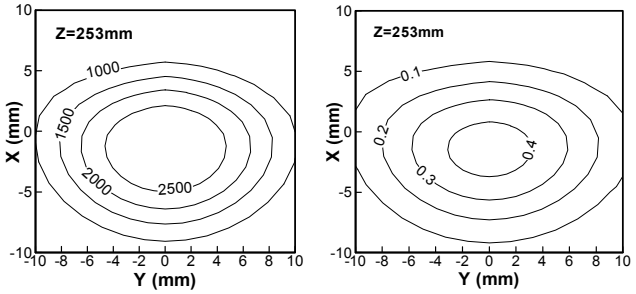

Figure 5 Computed isolines of the temperature and argon mass fraction on the cross section at z =253 mm.

3.2 Motion and heating of particles injected into the laminar plasma jet

Since the feedstock particles are injected into the plasma jet with the aid of the carrier gas, the 3-D features of the plasma jet flow caused by the lateral carrier-gas injection will cause the moving trajectories and heating histories of the particles somewhat different from those for the 2-D case ignoring the influence of the carrier gas injection. In the present study, metallic (nickel) particles have been employed and the counter-action of heated and accelerated particles on the plasma jet has been neglected for simplicity.

Figure 6 compares the moving trajectories of 10 μm and 20 μm nickel particles in the plasma jet with initial inward injection velocity of 5 m/s. Figure 7 compares the typical calculated heating histories of a 15 μm

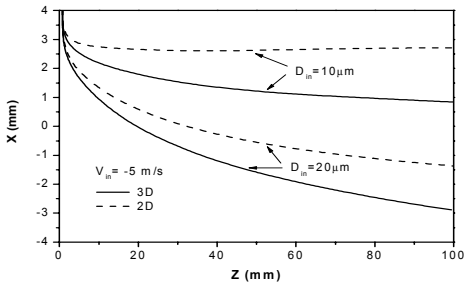

Figure 6 Comparison of the calculated trajectories of 10 μm and 20 μm particles injected into the 3-D plasma jet with their 2-D counterparts. V_{in} = – 5 m/s.

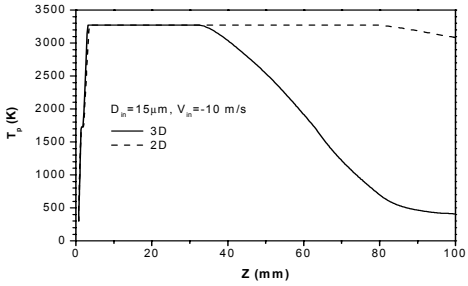

Figure 7 Comparison of the calculated heating history of a 15 μm particle moving in the 3-D plasma jet with its 2-D counterpart. V_{in} = –5 m/s.

particle. It is seen from figure 6 that the lateral injection of carrier-gas injection affects significantly the particle trajectories due to its appreciable influence on the temperature, velocity and concentration fields of the plasma jet. As expected, the particle with larger diameter will assume deeper penetration distance for both the 3-D and 2-D cases, with the 3-D penetration depth larger than its 2-D counterpart. Those calculated results can be readily understood, since the carrier gas not only makes the particle gaining an initial inward velocity, but also interacts with the plasma stream itself, resulting in the formation of an injection gas channel. The injected particles will move within the injection gas channel during the initial period of their movement, resulting in different predicted results from the 2-D case for the particle trajectories and also for the particle heating histories. For the case shown in figures 7, since the particle assumes a deeper penetration in the 3-D flow field than that for the 2-D case, the particle passes through the high temperature core region and reaches the region with lower gas temperatures in the 3-D jet. Consequently, the temperature of the injected particle is appreciably lower than that for the 2-D case at the later stage of its heating.

4. Conclusion

Main conclusions obtained from the present study are as follows.

(1) The lateral injection of the carrier gas will induce appreciable 3-D effects in the long laminar plasma jet. The jet will be deflected from its original geometrical axis, and the temperature, argon mass fraction and velocity distributions on the jet cross sections will assume appreciable non-axisymmetry. These 3-D effects also affects appreciably the moving trajectories and heating histories of the injected particles.

(2) However, the long laminar plasma jet still has well enough stiffness to endure the impact of the lateral carrier-gas injection for the carrier-gas injection velocities within a reasonable range from the viewpoint of materials processing. Hence, feedstock particles can be injected into the long laminar plasma jet with the aid of carrier gas.

Improved analysis of the noise emission from a turbulent plasma jet

Kai Cheng and Xi Chen

Department of Engineering Mechanics, Tsinghua University, Beijing 100084, China

Abstract

This paper improves the previous analysis concerning the turbulent plasma jet noise emission presented in Ref. [1] by using the computed temperature fluctuations from solving a second-order turbulent Reynolds heat flux equation. It is shown that the temperature fluctuation is still the dominant source of plasma jet noise emission. The predicted noise emission intensities are reasonably consistent with available experimental data.

1. Introduction

As is well known, strong noise emission is always generated in thermal spraying and has been harassing researchers since the atmospheric plasma spraying (APS) technology was employed in modern industry many years ago. However, so far our knowledge concerning the noise emission under plasma conditions is very pool. In Ref. [1], the approach originally proposed by Fortuné and Gervais [2] for predicting the noise emission from a hot non-ionized gas jet was extended to the study of the noise emission from a turbulent plasma jet with the atmospheric plasma spraying as the research background.

Pertinent two-dimensional continuity, momentum, energy, species, turbulent kinetic energy and turbulence dissipation rate equations were simultaneously solved in Ref. [1] to determine the turbulent plasma jet characteristics and then the noise emission intensity-frequency spectrums and noise levels were calculated. It was found that the noise intensity is roughly proportional to the square of the velocity at the plasma jet inlet. Among the noise emission sources due to, respectively, velocity fluctuation, temperature fluctuation and their mixed effect, the temperature fluctuation was the dominant one for the turbulent plasma jets.

In Ref. [1], however, the local temperature fluctuation in the turbulent plasma jet was simply calculated from the velocity fluctuation at the same location by assuming that there exists a directly proportional relation between the temperature fluctuation and the velocity fluctuation. Due to the extreme importance of the temperature fluctuation in determining the jet noise emission, such a simplified treatment is obviously unsatisfactory. Hence, this paper presents an improved approach to predict the plasma jet noise emission by using a more sophisticated method to calculate the temperature fluctuations in the turbulent plasma jet.

2. Modeling Approach

Main assumptions employed in the present study include (i) the turbulent plasma jet is axi-symmetrical and steady; (ii) the plasma is in the local thermodynamic equilibrium (LTE) state and is optically thin to radiation; (iii) all the current-related terms in momentum and energy equations, including the Lorentz force, Joule heating rate and electron enthalpy transport, can be ignored in the whole plasma jet region; (iv) swirling velocity component can be neglected; and (v) the argon plasma jet is issuing into ambient air.

The governing equations in a cylindrical coordinate (*x*-*r*) system concerning the continuity, momentum, energy, species, turbulent kinetic energy and its dissipation rate and the temperature fluctuation can thus be written as follows.

$$\frac{\partial}{\partial x}(\rho u)+\frac{1}{r}\frac{\partial}{\partial r}(r\rho v)=0 \tag{1}$$

$$\frac{\partial(\rho uu)}{\partial x}+\frac{1}{r}\frac{\partial(r\rho uv)}{\partial r}=-\frac{\partial p}{\partial x}+2\frac{\partial}{\partial x}\left(\Gamma_u\frac{\partial u}{\partial x}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left[r\Gamma_u\left(\frac{\partial u}{\partial r}+\frac{\partial v}{\partial x}\right)\right] \tag{2}$$

$$\frac{\partial(\rho uv)}{\partial x}+\frac{1}{r}\frac{\partial(r\rho vv)}{\partial r}=-\frac{\partial p}{\partial r}+\frac{2}{r}\frac{\partial}{\partial r}\left(r\Gamma_u\frac{\partial v}{\partial r}\right)+\frac{\partial}{\partial x}\left[\Gamma_u\left(\frac{\partial v}{\partial x}+\frac{\partial u}{\partial r}\right)\right]-2\Gamma_u\frac{v}{r^2} \tag{3}$$

$$\frac{\partial(\rho uh)}{\partial x}+\frac{1}{r}\frac{\partial(r\rho vh)}{\partial r}=\frac{\partial}{\partial x}\left[\Gamma_h\frac{\partial h}{\partial x}\right]+\frac{1}{r}\frac{\partial}{\partial r}\left[r\Gamma_h\frac{\partial h}{\partial r}\right]-U_r-\frac{\partial}{\partial x}\left[(h_A-h_B)J_x\right]$$
$$-\frac{1}{r}\frac{\partial}{\partial r}\left[r(h_A-h_B)J_r\right]-\frac{\partial}{\partial x}\left[\frac{k}{C_P}(h_A-h_B)\frac{\partial f_A}{\partial x}\right]-\frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{k}{C_P}(h_A-h_B)\frac{\partial f_A}{\partial r}\right] \tag{4}$$

$$\frac{\partial(\rho uf_A)}{\partial x}+\frac{1}{r}\frac{\partial(r\rho vf_A)}{\partial r}=\frac{\partial}{\partial x}\left[\Gamma_f\frac{\partial f_A}{\partial x}\right]+\frac{1}{r}\frac{\partial}{\partial r}\left[r\Gamma_f\frac{\partial f_A}{\partial r}\right]+S_f \tag{5}$$

$$\frac{\partial(\rho uK)}{\partial x}+\frac{1}{r}\frac{\partial(rv\rho K)}{\partial r}=\frac{\partial}{\partial x}\left(\Gamma_K\frac{\partial K}{\partial x}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left[r\Gamma_K\left(\frac{\partial K}{\partial r}\right)\right]+G-\rho\varepsilon \tag{6}$$

$$\frac{\partial(\rho u\varepsilon)}{\partial x}+\frac{1}{r}\frac{\partial(rv\rho\varepsilon)}{\partial r}=\frac{\partial}{\partial x}\left(\Gamma_\varepsilon\frac{\partial\varepsilon}{\partial x}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left[r\Gamma_\varepsilon\left(\frac{\partial\varepsilon}{\partial r}\right)\right]+\frac{\varepsilon}{K}(C_1G-C_2\rho\varepsilon) \tag{7}$$

$$\frac{\partial\left(\rho u\overline{v'T'}\right)}{\partial x}+\frac{1}{r}\frac{\partial\left(r\rho v\overline{v'T'}\right)}{\partial r}=\frac{\partial}{\partial x}\left(\Gamma_T\frac{\partial\overline{v'T'}}{\partial x}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(r\Gamma_T\frac{\partial\overline{v'T'}}{\partial r}\right)-\frac{2}{3}\rho K\frac{\partial T}{\partial r}$$
$$-C_{T1}\rho\frac{\varepsilon}{K}\overline{v'T'}+(C_{T2}-1)\rho\overline{v'T'}\frac{\partial v}{\partial r} \tag{8}$$

Here u and v are the axial (x-) and radial (r-) components of velocity vector, J_x and J_r the x- and r-components of argon diffusion flux vector, ρ, T, h and p the density, temperature, specific enthalpy and pressure, whereas f_A is the mass fraction of argon in the argon-air mixture. They are all the time-averaged values. K and ε are the turbulent kinetic energy and its dissipation rate. $\overline{v'T'}$ is the radial component of the so-called turbulent Reynolds heat flux, which represents the correlation of the radial velocity fluctuation and the temperature fluctuation. All the transport coefficients are their combinations of pertinent values for molecular and turbulent transport. For example, the transport coefficient Γ_u in momentum equations (2) and (3) is calculated by $\Gamma_u = \mu + \mu_T$, where μ and μ_T are the temperature- and composition-dependent viscosity of gas mixture and the turbulent viscosity, and $\mu_T = C_\mu\rho K^2/\varepsilon$. The empirical constants in standard two-equation turbulence model are used here, i.e. $C_\mu = 0.09$, $C_1 = 1.44$, $C_2 = 1.3$, and 1.0, 1.3, 0.9 and 0.9 are for the turbulent Prandtl numbers in the equations for turbulent kinetic energy, its dissipation rate, energy and species. In Eq. (8), $C_{T1} = 3.2$ and $C_{T2} = 0.5$ are used [3]. h_A and h_B in Eq. (4) are the specific enthalpies of pure argon and pure air, respectively, whereas U_r is the temperature- and composition-dependent radiation power per unit volume of the plasma. The combined-diffusion-coefficients method suggested by Murphy [4] has been employed here to treat the diffusion of argon in argon-air mixture, but here turbulent effect is also added. The source term in Eq. (5) is calculated by

$$S_f=\frac{\partial}{\partial x}\left(\Gamma_f\frac{f_A}{\overline{M}}\frac{\partial\overline{M}}{\partial x}\right)-\frac{\partial}{\partial x}\left(\Gamma_f\frac{f_A}{\overline{M}_A}\frac{\partial\overline{M}_A}{\partial x}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(r\Gamma_f\frac{f_A}{\overline{M}}\frac{\partial\overline{M}}{\partial r}\right)$$
$$-\frac{1}{r}\frac{\partial}{\partial r}\left(r\Gamma_f\frac{f_A}{\overline{M}_A}\frac{\partial\overline{M}_A}{\partial r}\right)+\frac{\partial}{\partial x}\left(\overline{D}_{AB}^T\frac{\partial\ln T}{\partial x}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(r\overline{D}_{AB}^T\frac{\partial\ln T}{\partial r}\right) \tag{9}$$

where $\overline{M}_A$ and $\overline{M}$ are the mean mass of the gas particles coming from argon and that of all the gas particles, whereas $\overline{D}_{AB}^T$ is the turbulence-enhanced combined thermal diffusion coefficient associated with the temperature gradient. The turbulence generation term in Eq. (6) and (7) is expressed as

$$G = \mu_t \left[2\left(\frac{\partial v}{\partial r}\right)^2 + 2\left(\frac{\partial u}{\partial x}\right)^2 + 2\left(\frac{v}{r}\right)^2 + \left(\frac{\partial u}{\partial r} + \frac{\partial v}{\partial x}\right)^2 \right] \tag{10}$$

As in Refs. [1,2], the following expression is used to calculate the noise intensity-frequency spectrums:

$$\mathbf{I}(\mathbf{x},\boldsymbol{\omega}) = \frac{1}{16\pi^2 |\mathbf{x}|^2 \rho_0 c_0} \left\{ \frac{\omega^4}{c_0^4} \iint_{VV} \hat{A}(\mathbf{y}') \hat{A}(\mathbf{y}'') \Gamma(\mathbf{y}', \xi, \omega) d\mathbf{y}' d\xi \right.$$

$$\left. - \omega^2 \iint_{VV} \hat{S}(\mathbf{y}') \hat{S}(\mathbf{y}'') \Gamma(\mathbf{y}', \xi, \omega) d\mathbf{y}' d\xi - j \frac{2\omega^3}{c_0^2} \iint_{VV} \hat{A}(\mathbf{y}') \hat{S}(\mathbf{y}'') \Gamma(\mathbf{y}', \xi, \omega) d\mathbf{y}' d\xi \right\} \tag{11}$$

where ρ_0 and c_0 are density and sound speed for the surrounding gas, ω the circular frequency, $\boldsymbol{x}$ or $\boldsymbol{y}$ ($\boldsymbol{y}'$ or $\boldsymbol{y}''$) are the distance vector from a far-field observer or a noise source position to the coordinate origin at the jet inlet center. $\boldsymbol{\xi}$ is also a position vector. $\hat{A}(\boldsymbol{y}) = \overline{\rho}(2K/3)(\boldsymbol{y})$ and $\hat{S}(\boldsymbol{y}) = \rho_0 \frac{1}{\overline{T}} \frac{\partial \overline{v'T'}}{\partial r}(\boldsymbol{y})$ are root-mean-square of the noise sources due to, respectively, velocity fluctuation and temperature fluctuation. Γ in Eq. (11) is the so-called space-frequency coherence function, which denotes the interactions between the source terms in the spectral domain, and is given by [2]

$$\Gamma(\mathbf{y}', \xi, \omega) = \pi \exp\left(\frac{-\pi \xi_x^2}{L_x^2}\right) \exp\left(\frac{-\pi \xi_r^2}{L_r^2}\right) \left[\beta \omega_t \cosh\left(\frac{\pi C \omega}{2\beta \omega_t}\right) \right]^{-1} \tag{12}$$

Here L_x, L_r, β and ω_t are all empirical constants, whereas C is a parameter linking with the observer's position and the velocity at the jet inlet [2]. The three terms in the parentheses on the right-hand side of Eq. (11) represent the contribution to the noise emission due to velocity fluctuation, temperature fluctuation and their mixed effect, respectively.

After Eqs. (1) – (8) have been simultaneously solved using the SIMPLE-like algorithm [5], the spatial distributions of the turbulent kinetic energy K and the velocity-temperature fluctuation correlation $\overline{v'T'}$ can be obtained, and thus the source terms $\hat{A}(\boldsymbol{y})$ and $\hat{S}(\boldsymbol{y})$ as well as $\mathbf{I}(\mathbf{x},\boldsymbol{\omega})$ can be calculated. The noise intensity can then be predicted from the integration of $\mathbf{I}(\mathbf{x},\boldsymbol{\omega})$ with respect to the frequency.

3. Computational Domain and Boundary Conditions

The computational domain is shown in Fig. 1. The inner radius (R_0) of the torch exit or the jet inlet (AB in Fig. 1) is 4 mm, whereas torch wall thickness BC is 15 mm. The axial length AF is 200 mm, while the radial width AD is 50 mm. In our numerical simulation, a 62 (x-direction) × 40 (r-direction) rectangular non-uniform mesh is adopted with finer spacing near the jet inlet and the axis.

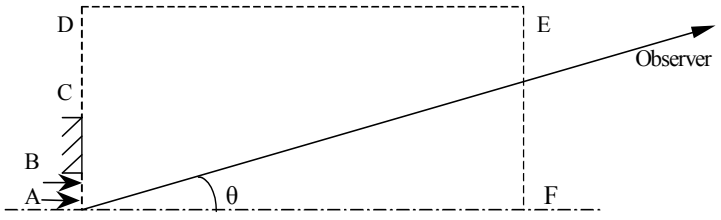

Fig. 1 Computational domain

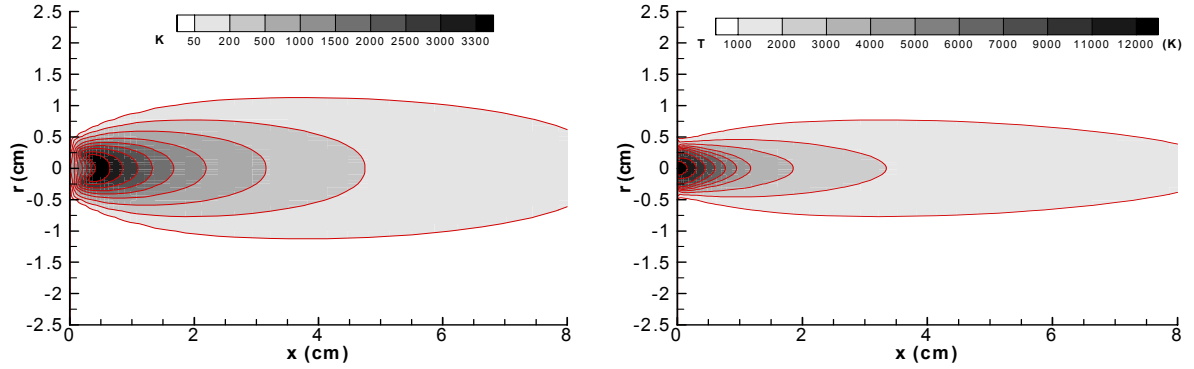
In the modeling, the following axial velocity and temperature profiles are adopted at the jet inlet (AB):

$$u = U_0\left[1-(r/R_0)^2\right], \qquad T = (T_0 - T_w)\left[1-(r/R_0)^2\right] + T_w \tag{13}$$

where T_w=500 K is the torch wall temperature. In addition, $v = 0$, $f_A = 1.0$, $K = 0.005u^2$, $\varepsilon = 0.1K^2$, $\overline{v'T'} = -(C_\mu / P_{rt})(K^2/\varepsilon)(\partial T/\partial r)$ with $C_\mu = 0.09$ and $P_{rt} = 0.9$ are used at the jet inlet; turbulence-wall-functions used along BC, one-way conditions used at the downstream boundary (EF), free boundary conditions used along CD and the radial outer boundary DE, whereas axi-symmetrical conditions are used along the jet axis (AF).

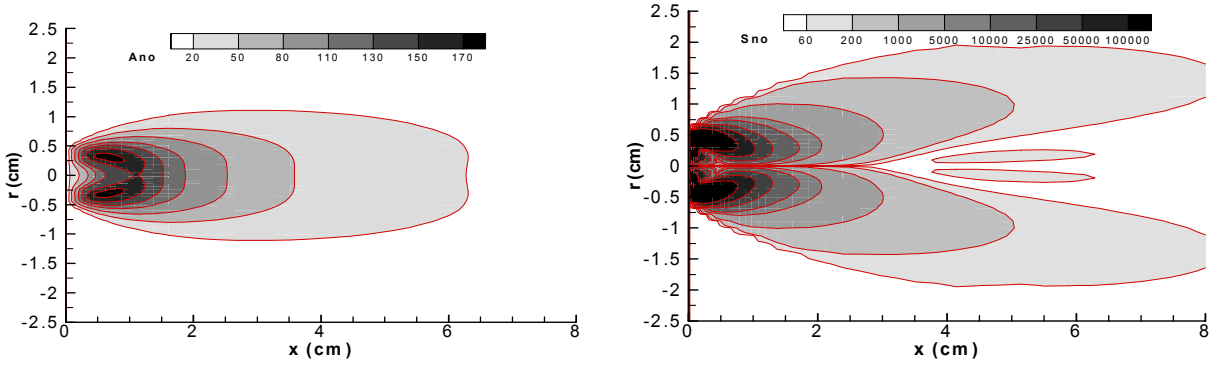
4. Results and Discussion

For a typical case with U_0 =300 m/s and T_0=13000 K, the computed spatial distributions of the turbulent kinetic energy and temperature in the plasma jet are shown in Figs. 2(a) and 2(b), respectively. It is seen from Fig. 2 that both the turbulent kinetic energy and the temperature gradient assume their maximum values near the jet inlet, and decrease rapidly with increasing distance from the jet inlet. Hence, it is expected that the most important contribution to the jet noise will come from the region near the jet inlet or torch exit. Corresponding computed results concerning the spatial distributions of the noise sources due to velocity fluctuation and temperature fluctuation demonstrate this expectation, as shown in Figs. 3(a) and 3(b). From Figs. 3(a) and 3(b) one can find that both the noise sources are mainly distributed within a narrow region near the plasma jet inlet, and the noise emission due to the temperature fluctuation is much larger than that due to the velocity fluctuation.



(a) (b)

Fig. 2 (a) Turbulent kinetic energy distribution, (b) Temperature distribution in the plasma jet



(a) (b)

Fig. 3 Noise source distributions. (a) Due to velocity fluctuation, (b) due to temperature fluctuation.

The computed noise intensity spectrums of the plasma jet are shown in Fig. 4, with the reference intensity being $I_0=10^{-12}$ W/m^2 and for an observer located at 0.4 m distance from the center of jet inlet and at observation angle of 90 deg ($\theta=90^o$) with respect to the jet axis. Here the individual contributions due to the different noise sources including velocity fluctuation, temperature fluctuation and their mixed effect are all presented besides their summation. It can be clearly seen from Fig. 4 that, similarly to that obtained in Ref. [1], the temperature fluctuation is the dominant noise source (i.e. its contribution is much greater than that due to the velocity fluctuation or due to the mixed effect of velocity and temperature fluctuations). However, we find that the computed summated noise intensities using the new modeling approach are about 10 dB higher than their counterparts given by Ref. [1]. This fact implies that the noise model employed in Ref. [1] somewhat underestimated the APS noise emission.

Fig. 5 compares the computed noise intensity spectrums for three different plasma jets with the same inlet temperature (i.e. T_0=13000 K) but different inlet velocities, i.e. U_0 =300, 600 and 900 m/s. It is found that with the increase of the jet inlet velocity, both the maximum noise intensity and the frequency corresponding to the maximum noise intensity increase. And the total noise intensity (or power, W/m^2) also increases approximately proportionally to the square of inlet velocity.

Although not shown here as separate figures due to the paper space limit, our computational results show that the noise emission increases with increasing inlet plasma temperature and decreasing observation angle.

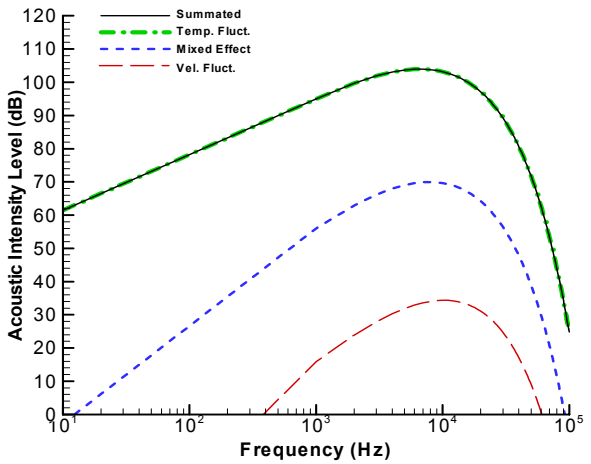


Fig. 4 Computed noise intensity spectrums of turbulent plasma jet with U_0 =300 m/s and T_0=13000 K

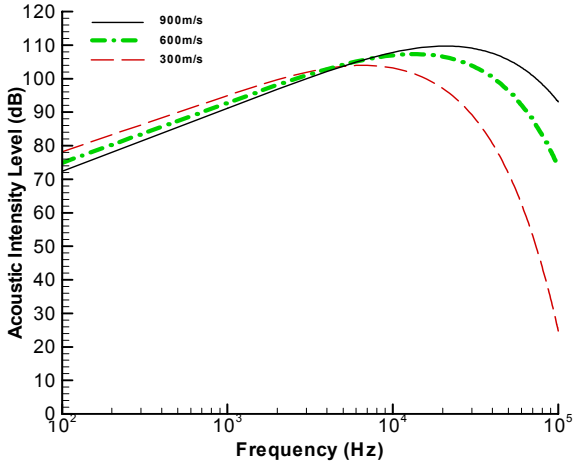

Fig. 5 Comparison of computed noise spectrums for 3 plasma jets with U_0 =300, 600 and 900 m/s. T_0=13000 K

Recently, the emitted noise intensity levels for plasma spraying were measured by Gross [6] using a real-time sound analysis meter. It was found that the cold gas flowing into the plasma torch could only produce a noise level below 80 dB, but the operating 30 kW plasma spraying torch with argon and helium as the working gas could enhance the noise levels to about 112 dB [6].

Fig. 6 presented our computed noise intensity-frequency spectrum characteristics for a turbulent plasma jet with U_0 =300 m/s and T_0=16000 K, which are roughly corresponding to the Gross' experiment. In Fig. 7, the predicted noise intensity-frequency spectrums are compared with Gross' experimental data for the 30 kW plasma torch. Totally, the agreement is reasonable. The experimental data are somewhat higher than the predicted values, partially due to that our modeling does not consider the existence of chamber which may increase the noise level. Moreover, the maximum velocity at the plasma jet inlet encountered in the Gross' experiment may be higher than 300 m/s employed in the computation.

In addition, our modeling results show that a great deal of the noise power is due to high frequency noise emission, which cannot be heard by the workers. This predicted result demonstrates that it is necessary for us

to pay more attention to the ultrasonic emission in plasma spraying.

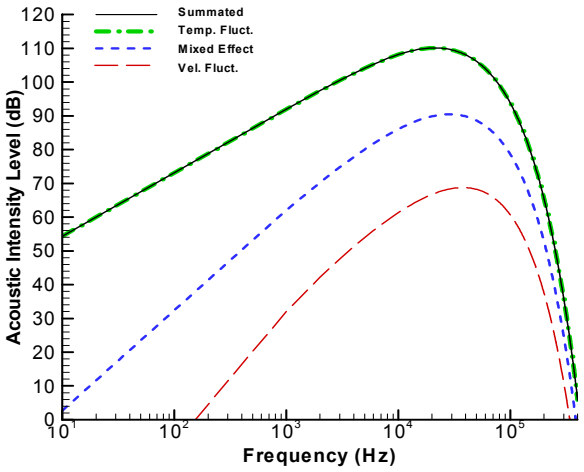

Fig. 6 Computed noise intensity spectrums of turbulent plasma jet with U_0 =900 m/s and T_0=16000 K

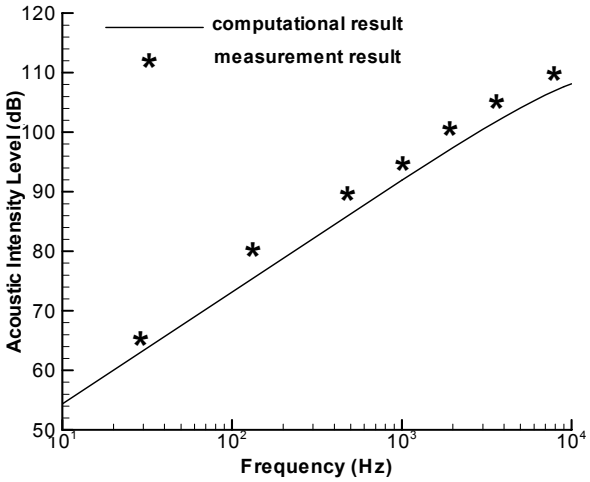

Fig. 7 Comparison between the computational noise intensity spectrums and experimental data [6]

5. Conclusions

As the improvement of the noise emission analysis, an improved modeling approach has been employed to predict the APS noise emission, in which the temperature fluctuations are computed by solving the second-order turbulent Reynolds heat flux equation. Main conclusions obtained from this study are as flows.

(1) Although the approach used in Ref. [1] somewhat underestimated the noise emission levels, the temperature fluctuation in the turbulent plasma jet is shown still to be the main source of noise emission, similarly to that obtained in Ref. [1].

(2) With the increase of the jet inlet velocity, the noise intensity increases approximately proportionally to the square of inlet velocity, and the frequency corresponding to the maximum noise emission intensity shifts towards the direction of high frequency.

(3) We should pay attention to the fact that the noise emission intensities at ultrasound frequencies may be high.

Abstract
Modeling results are presented concerning the effects of Joule heating on the characteristics of laminar plasma jet issuing from a DC arc plasma torch. It is shown that the Joule heating effect is dependent on the combination of torch operation parameters. For the case with arc root attachment near or at the anode nozzle exit of the torch, the Joule heating effect may not be ignored. On the other hand, the Joule heating rate can be neglected for the case that the anode arc root stays upstream far away from the anode nozzle exit.

1. Introduction

Thermal plasmas are widely used as the high temperature sources in many applications, such as the thermal plasma spraying, the ultra-fine powders synthesis, etc. In actual applications, usually the high-temperature partially-ionized gas is issuing from the plasma torch as the form of plasma jet. Studies of DC arc plasma jets have been conducted extensively in the past a few decades. Because of the existence of complex magneto-hydrodynamic effects inside the plasma torch and the interactions between the plasma jet and its environment, complicated physical phenomena may be involved in the studies. For example, the arc may assume unsteady behavior leading to the fluctuation of plasma jet, whereas the transverse injection of particulate matter and its carrier gas will cause appreciable three-dimensional features of the plasma jet characteristics [1]. So far our understanding on the arc plasma jet is incomplete. Many researchers studied the plasma jet characteristics by treating the jet separated from the plasma torch. They used the assumed (e.g. [1]) or computed (e.g., [2]) profiles obtained from the modeling of DC arc plasma torch as the jet-inlet boundary conditions, and solved the pertinent continuity, momentum, species and energy equations (and turbulent kinetic energy and its dissipation rate equations if turbulent flow is involved). In those studies it was assumed that no current-related effect (will be called Joule heating effect hereafter) existed in the plasma jet. Some other researchers simulated the heat and flow fields by combining the DC arc plasma torch and the plasma jet as a whole, i.e. solved the complete set of magneto-hydrodynamic (MHD) equations [3-6] for both torch and jet regions. Temperature and flow fields inside and outside the plasma torch were presented, but no clear description was given concerning whether or not the Joule heating effect is important in the plasma jet region. In addition, Ref. [6] mentioned that that electric potential equation was solved only for the plasma torch region, i.e. the Joule heating effect was not considered in the jet region. Another aspect should be pointed out is that the length of anode nozzles used in Refs. [3-5] is comparatively long (~29 *mm*), while the length of anode nozzle used in Ref. [6] is only 6.5 *mm*. So it is interesting to study the Joule heating effect on the plasma jet characteristics under different operation conditions (e.g. arc current, working-gas flow rate, etc.).

In this paper, for simplicity a two-dimensional (2-D) modeling for the DC arc plasma torch and plasma jet in laminar regime is conducted by solving the pertinent MHD equations in the computational domain including both the plasma torch and the plasma jet. By comparing the computed results with and without accounting for the current-related terms (i.e. Joule heating, electron enthalpy transport and Lorentz force) in the plasma jet region, the effect of Joule heating on the plasma jet characteristics can be revealed.

2. Mathematical models

2.1 Basic assumptions

The assumptions employed in this study are as follows:
(1) The flow is quasi-steady, laminar and with temperature-dependent properties.
(2) The plasma is in local thermodynamic equilibrium (LTE) state and optically thin to radiation.
(3) The pertinent Mach number inside and outside plasma torch is small (e.g. less than 0.3), and thus the viscous dissipation and the pressure work terms in the energy equation can be neglected.
(4) Argon is used as the working gas of plasma torch and as the ambient cold gas.

(5) The induced electric field $\vec{V} \times \vec{B}$ is negligible in comparison with the static electric field intensity $\vec{E}$.

2.2 Governing equations

Based on the foregoing assumptions, the governing equations for the 2D quasi-steady numerical simulations can be written in cylindrical coordinates (z, r) as follows:

$$\frac{\partial}{\partial z}(\rho v_z) + \frac{1}{r}\frac{\partial}{\partial r}(\rho r v_r) = 0 \tag{1}$$

$$\frac{\partial}{\partial z}(\rho v_z v_z) + \frac{1}{r}\frac{\partial}{\partial r}(r\rho v_z v_r) = -\frac{\partial p}{\partial z} + 2\frac{\partial}{\partial z}\left(\mu\frac{\partial v_z}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left[r\mu\left(\frac{\partial v_z}{\partial r} + \frac{\partial v_r}{\partial z}\right)\right] + j_r B_\theta \tag{2}$$

$$\frac{\partial}{\partial z}(\rho v_z v_r) + \frac{1}{r}\frac{\partial}{\partial r}(r\rho v_r v_r) = -\frac{\partial p}{\partial r} + \frac{\partial}{\partial z}\left[\mu\left(\frac{\partial v_r}{\partial z} + \frac{\partial v_z}{\partial r}\right)\right] + \frac{2}{r}\frac{\partial}{\partial r}\left(r\mu\frac{\partial v_r}{\partial r}\right) - \frac{2\mu v_r}{r^2} - j_z B_\theta \tag{3}$$

$$\rho c_p v_z \frac{\partial T}{\partial z} + \rho c_p v_r \frac{\partial T}{\partial r} = \frac{\partial}{\partial z}\left(k\frac{\partial T}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(kr\frac{\partial T}{\partial r}\right) + \frac{j_z^2 + j_r^2}{\sigma} - S_R + \frac{5}{2}\frac{k_B}{e}\left(j_z\frac{\partial T}{\partial z} + j_r\frac{\partial T}{\partial r}\right) \tag{4}$$

$$\frac{\partial}{\partial z}(\sigma\frac{\partial \phi}{\partial z}) + \frac{1}{r}\frac{\partial}{\partial r}(r\sigma\frac{\partial \phi}{\partial r}) = 0 \tag{5}$$

where ρ, μ, c_p, k, σ and S_R are the temperature-dependent mass density, viscosity, specific heat at constant pressure, thermal conductivity, electric conductivity and radiation power per unit volume of argon plasmas. v_r and v_z are the components of the velocity vector in r-, and z-direction, while j_r and j_z are the r- and z-components of the current density vector $\vec{j}$, respectively. T, p and ϕ are the gas temperature, pressure and electrical potential, respectively. k_B is the Boltzmann constant, and e is the elementary charge. The current density components can be calculated from the electrical potential by

$$j_r = -\sigma\frac{\partial \phi}{\partial r}, \quad j_z = -\sigma\frac{\partial \phi}{\partial z} \tag{6}$$

B_θ is the circumferential component of the self-induced magnetic induction vector due to the existence of arc current, and is calculated by

$$B_\theta = \frac{\mu_0}{r}\int_0^r j_z \xi d\xi \tag{7}$$

in which μ_0 is the permeability in vacuum.

In this study, two different sets of governing equations are employed in order to reveal the effect of current-related terms on the plasma jet characteristics, namely,

G. E. I: Equations (1)~(7) are solved simultaneously in both torch and jet regions, i. e. the effects of Lorentz force, Joule heating and electron enthalpy transport on the plasma jet characteristics are taken into account.

G. E. II: Equations (1)~(7) are only solved in torch region. In the plasma jet region, the current-related terms $j_r B_\theta$, $-j_z B_\theta$, $\frac{j_z^2 + j_r^2}{\sigma}$ and $\frac{5}{2}\frac{k_B}{e}\left(j_z\frac{\partial T}{\partial z} + j_r\frac{\partial T}{\partial r}\right)$ are all not included in the momentum or energy equations, i. e. the effects of Lorentz force, Joule heating rate and electron enthalpy transport on the plasma jet characteristics are not taken into account.

2.3 Computational domain and boundary conditions

Figure 1 shows the computational domain (ABCDEFGHIA) used in this study, which includes the plasma arc, the plasma jet and the anode region. The geometrical sizes are also shown in this diagram. The inner diameter of the anode nozzle is 8 *mm*, and the length of the cylindrical nozzle part is 10 *mm*. It should be noted that the physical properties c_p, k and σ, appearing in Equations (4) and (5), should be the values of anode material (copper) instead of those of argon plasmas in the anode region.

The boundary conditions used in this 2-D modeling are listed in Table 1. At the inlet section of the torch (BC), we assume that the cold gas is admitted in axial direction uniformly, i. e.

$$v_z = Q/A, \; v_r = 0 \tag{8}$$

where Q is the volumetric flow rate of the working gas (STP m^3/s), A is the inlet cross-section area of the torch (m^2). On the cathode surface, no-slip boundary condition is employed for velocity components. The temperature (T_c) and current density ($\vec{j}_0$) distributions are specified as shown in Figure 2 according to the experimental data presented in Ref. [7]. The electric potential gradient is thus calculated by

$$\vec{j}_0(r) = -\sigma \frac{\partial \phi}{\partial n} \tag{9}$$

where $\vec{j}_0(r)$ is the local current density vector at the cathode arc root. This vector is normal to the cathode surface and is a function of the radial distance (r) and the axial distance from the cathode tip (z_c), while n is the normal at the cathode surface directed from the inner side to the outer side of the cathode.
Lines GH and HI represent the free boundaries and mass conservation should be satisfied. Line IA represents the extended outer surface of the anode region with zero electric potential and constant temperature (500 K).

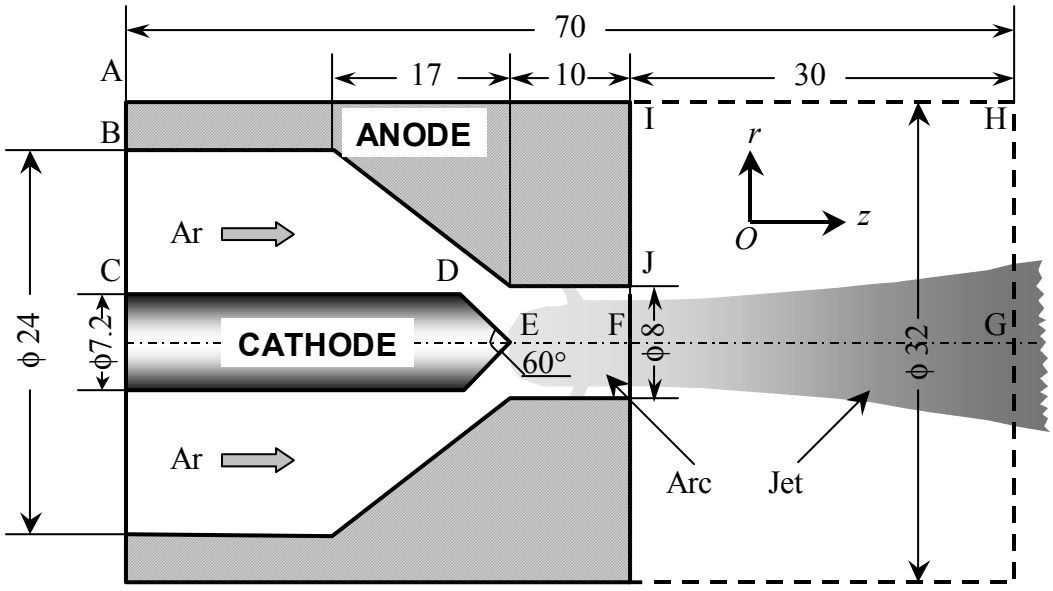

Figure 1. Schematic diagram of the computational domain.

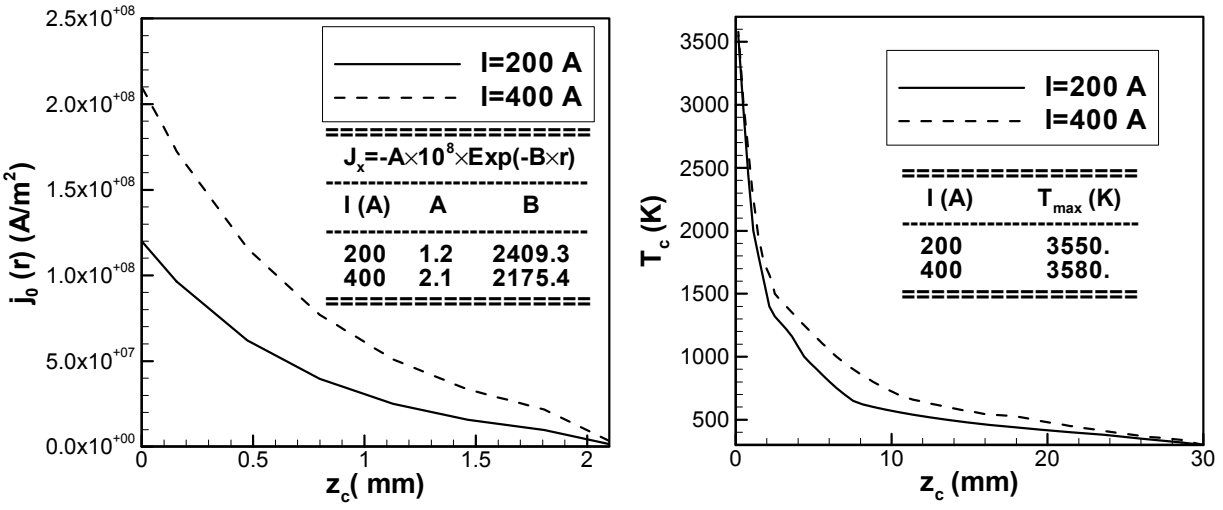
Table 1. Boundary conditions used for the governing equations along the boundaries shown in Figure 1.

	AB	BC	CDE	EFG	GH	HI	IA
v_z (m/s)	0	Q/A	0	$\partial u/\partial r = 0$	$\partial u/\partial z = 0$	$\partial u/\partial r = 0$	0
v_r (m/s)	0	0	0	$v = 0$	$\partial v/\partial z = 0$	$\partial(\rho v r)/\partial r = 0$	0
T (K)	300	300	Fig. 2	$\partial T/\partial r = 0$	$\partial T/\partial z = 0$	$\begin{cases} v > 0, \partial T/\partial r = 0 \\ v \le 0, T = 300 \end{cases}$	500
ϕ (V)	$\partial\phi/\partial z = 0$	$\partial\phi/\partial z = 0$	$\vec{j}_0(r) = -\sigma \frac{\partial \phi}{\partial n}$	$\partial\phi/\partial r = 0$	$\partial\phi/\partial z = 0$	$\partial\phi/\partial r = 0$	$\phi = 0$

3. Modeling results and discussions

In this modeling work, the SIMPLE-like algorithm [8] has been employed to solve the non-linear equations (1)~(5) simultaneously with a new version of the non-commercial software FAST-2D (Fluid Analytical Simulation Tools—Two Dimensional) [9]. This software has been employed to simulate 2-D heat and flow patterns of plasma arc and plasma jet [10]. The detailed description of the features of this modified computer code FAST-2D was presented in Ref. [10]. A 2-D, body-fitted, non-orthogonal, non-uniform mesh $67\,(z) \times 41\,(r)$, as shown in Figure 3, is adopted for the 2-D modeling of the plasma torch and plasma jet in this paper.

In this section, the influences of current-related terms (Joule heating, electron enthalpy transport and Lorentz force) on the plasma jet characteristics with different arc currents ($I = 100\ and\ 200\ A$) and working gas flow rates ($Q = 0.35\ and\ 0.5\ \mathrm{STP}\ m^3/hr$) are studied, which are listed in Table 2.



(a) (b)

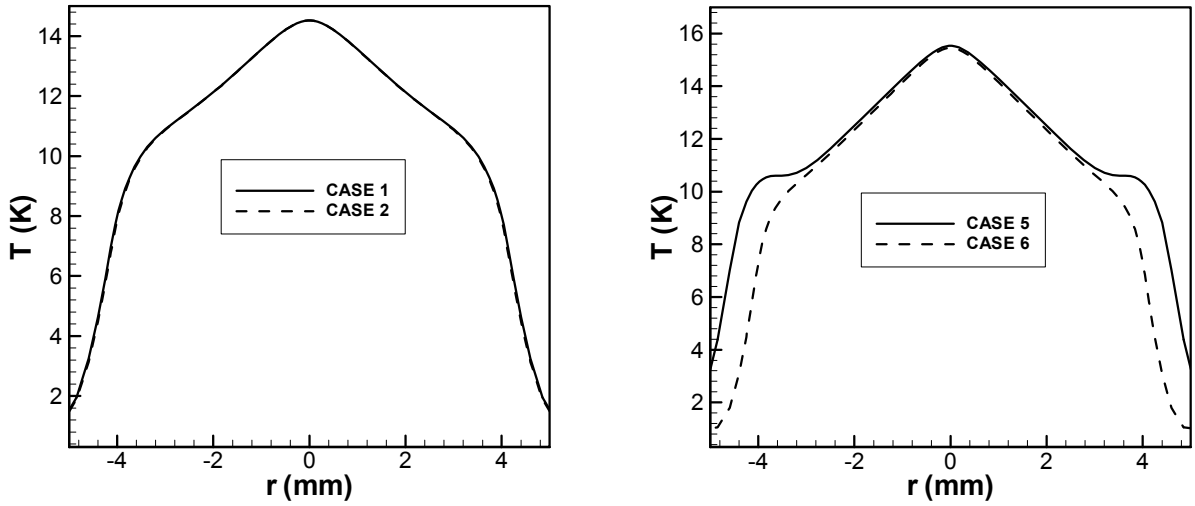
Table 2. Different cases studied in the present paper.

Case No.	I (A)	Q (STP m^3/hr)	Governing Equations
1	200	0.35	G. E. I
2	200	0.35	G. E. II
3	400	0.35	G. E. I
4	400	0.35	G. E. II
5	200	0.50	G. E. I
6	200	0.50	G. E. II
7	400	0.50	G. E. I
8	400	0.50	G. E. II

3.1 Modeling results

The radial temperature profiles in the cross section located at 0.8 *mm* downstream of the torch exit for Case 1, 2, 5 and 6 are shown in Figure 4, respectively. It can be seen that for Cases 1 & 2, the influence of the current-related terms (Joule heating rate, electron enthalpy transport and Lorentz force) on the plasma jet temperature fields can be ignored completely. But for Cases 5 & 6, the effects of current-related terms cannot be neglected, especially for the region near the plasma jet edge. The maximum relative discrepancy at the location $r = 4\,mm$ is about 30% between Case 5 and Case 6. Additionally, comparisons of the computed results for Cases 3 & 4 and Cases 7 & 8 show that the influence of current-related terms in the jet region can be neglected for those cases.

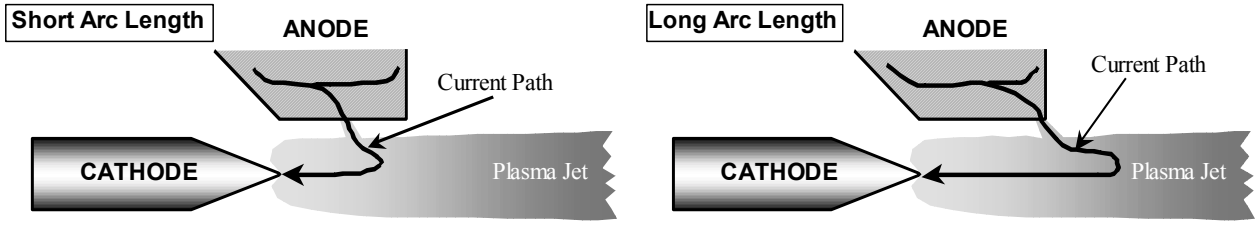


(a) (b)

Figure 4. Temperature profiles in radial direction at the section located at 0.8 *mm* downstream of the torch exit.

3.2 Discussion

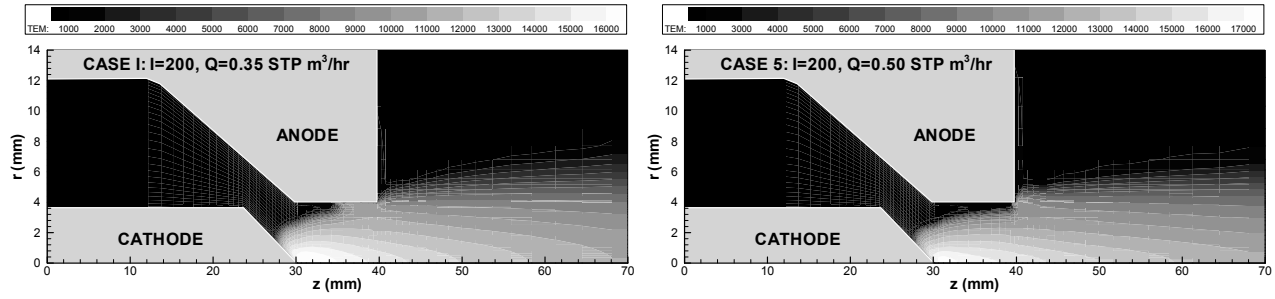
Based on the foregoing computed results, we can analyze the related mechanism of the current-related effects on plasma jet characteristics as follows: As indicated in Ref. [11], the gasdynamic force acting on the anode column should be balanced by the magnetic body force in order for the anode terminus of the arc to assume a stable axial location. With an increase of the working gas flow rate, the location of anode arc-root attachment will move downstream due to the enhanced gasdynamic drag force, leading to a longer arc length; while with the increase of the arc current, the location of anode arc-root attachment will move upstream due to the enhanced magnetic body force, leading to a shorter arc length, where arc length is defined as the axial distance between the cathode tip and the point of the anode arc root (with the maximum radial current density at the inner surface of the anode). The possible current path in the partially ionized high temperature gas region is shown in Figure 5. It can be seen that for a long arc length [Figure 5 (b)], the current path possibly exists in the plasma jet region, which will influence the characteristics of the plasma jet in the pertinent region; while for a short arc length [Figure 5 (a)], the current path will dominantly appear inside the plasma torch, and thus there is almost no effect of the Joule heating on the plasma jet characteristics.



(a) (b)

Figure 5. Schematic diagram of the possible current paths in the plasmas for short (a) and long (b) arc length.

The computed temperature distributions for Case 1 and Case 5 are shown in Figures 6 (a) and (b), respectively. From Figure 6, we can see that the arc length for Case 1 is 8.2 mm, i. e., the axial distance between the anode arc root and the exit of the anode nozzle is 1.8 mm; while for Case 5, the anode arc root just stays at the exit plane of the anode nozzle. Based on our preceding analysis, Case 1 and 5 should correspond to the "short arc length" case and the "long arc length" case shown in Figures 5 (a) and (b), respectively.



(a) (b)

Figure 6 Isotherms inside and outside of plasma torch for Case 1 (a) and Case 5 (b)

4. Conclusions

In this paper, the effects on the plasma jet characteristics are studied of current-related terms, including the Joule heating, the electron enthalpy transport and the Lorentz force. Main conclusions obtained are as follows:

(1) The extent of effects of the current-related terms on the characteristics of a plasma jet, issuing from a DC arc plasma torch, depends on the axial distance between the location of anode arc root attachment and the anode nozzle exit, i. e. on the magnitude of current density in the plasma jet region at the downstream of the anode nozzle exit.

(2) If the anode arc root stays upstream far away from the anode nozzle exit (e.g. operating at high arc current and low working-gas flow rate), i. e. the current density in the plasma jet region is very small, the influence of the current-related terms on the jet characteristics can be neglected completely.

(3) If the anode arc root stays at a location near the anode nozzle exit (e.g. operating at lower arc current and high working gas flow rate), the current density in the plasma jet region could be large enough and the influence of the current-related terms on the jet characteristics should be taken into account.

Analysis of the laser-induced plasma plume characteristics in laser welding

Hai-Xing Wang and Xi Chen

Department of Engineering Mechanics, Tsinghua University, Beijing 100084, China

Abstract
Typical computed distributions of temperature, velocity and some other parameters within the plasma plume are presented with the CO_2 laser welding of an iron workpiece as the calculation example. The computed results show that the height of the plasma plume is dependent on the vapor / shielding-gas momentum ratio. The laterally injected assisting gas may also significantly affect the plasma plume and thus can be used to control the effect of the laser-induced plasma plume on the laser welding process.

1. Introduction

In many laser welding processes, a continuous wave (CW) CO_2 laser beam is focused on the surface of a metallic workpiece with a sufficient high power density (e.g. higher than 10^{10} W/m^2) at the light spot, causing the localized heating and evaporation of the workpiece material and the formation of a keyhole in the wrkpiece. The vapor evaporated from the keyhole wall will be partially ionized due to its interaction with the incident laser beam, resulting in the formation of laser-induced plasma. A plasma plume appearing above the workpiece surface may affect the welding process through its absorption and refraction to the laser beam.
Herziger [1] summarized some research results up to the middle of 1980's concerning the plasma plume characteristics in laser welding. The measured electron (or plasma) temperatures by various authors differ significantly. For example, the reported values of the measured plasma plume temperatures are from around 8000 K to over 14000 K. Szymański et al [2] indicated that since iron atom spectral lines usually assume their maximum intensities near the temperatures around 10000 K. The approach that employs only the relative intensity ratio of two atom spectral lines to determine the plasma plume temperature is not suitable when higher plasma plume temperatures are involved. Instead, they suggested to us the ion spectral line intensity ratio for the measurement of the plasma temperature. They showed that when the intensity ratio of two different atom lines was used in their spectroscopic temperature measurements, the plasma temperature around 8000 K was obtained (Szymański and Kurzyna [3], Szymański et al [2]). However, when the intensity ratio of an ion line to an atom line was used to determine the plasma temperature, 11000 K was obtained for the same experimental conditions (Szymański et al [3]).
In the recent work of Kim and Farson [4], the plume-beam interaction is studied by applying an axi-symmetrical, high-temperature gas-dynamic model to the plasma plume formed above an iron workpiece surface. However, due to the inherent limitation of two-dimensional model itself, they could not well treat the actual three-dimensional problem concerning the effect of laterally injected assisting gas on the laser-induced plasma, although the laterally injected assisting gas might significantly affect the heat transfer and fluid flow within the plasma plume. In addition, the radiation energy loss from the plasma plume was not included in their 2-D model.
This paper presents a more generalized 3-D modeling approach to study the plasma plume characteristics. The plasma plume parameters including the spatial temperature distribution and the flow field are investigated in some detail. Laser absorption and refraction are then evaluated based on those modeling results of plasma plume characteristics.

2. Mathematical model

2.1 Basic assumptions

In this paper, the following assumptions are employed for the plasma plume modeling:
(1) The welding process and the plasma plume are steady in the coordinates fixed with the laser beam;
(2) The gas flow is laminar;
(3) The plasma is in the local thermodynamic equilibrium (LTE) state;
(4) The plasma plume absorbs part of the incident laser energy through the inverse Bremsstrahlung and radiates energy to the surroundings;

(5) Pure iron is used as the workpiece, the coaxially injected shielding gas and the laterally injected assisting gas (if any) are pure argon, whereas the plasma plume consists of the mixture of argon and iron vapor.

2.2 Governing equations

Based on the foregoing assumptions, the governing equations used for the 3D quasi-steady numerical simulations can be written in a cylindrical coordinate system (r, θ, z) as follows:

$$\frac{1}{r}\frac{\partial}{\partial r}(r\rho v_r)+\frac{1}{r}\frac{\partial}{\partial \theta}(\rho v_\theta)+\frac{\partial}{\partial z}(\rho v_z)=0 \tag{1}$$

$$\rho\left(v_r\frac{\partial v_r}{\partial r}+\frac{v_\theta}{r}\frac{\partial v_r}{\partial \theta}+v_z\frac{\partial v_r}{\partial z}\right)=-\frac{\partial p}{\partial r}+\frac{\partial}{\partial r}\left(2\mu\frac{\partial v_r}{\partial r}\right)+\frac{1}{r}\frac{\partial}{\partial \theta}\left[\mu\left(\frac{1}{r}\frac{\partial v_r}{\partial \theta}+\frac{\partial v_\theta}{\partial r}-\frac{v_\theta}{r}\right)\right]+\frac{\partial}{\partial z}\left[\mu\left(\frac{\partial v_r}{\partial z}+\frac{\partial v_z}{\partial r}\right)\right]+\frac{2\mu}{r}\left(\frac{\partial v_r}{\partial r}-\frac{1}{r}\frac{\partial v_\theta}{\partial \theta}-\frac{v_r}{r}\right)+\rho\frac{v_\theta^2}{r} \tag{2}$$

$$\rho\left(v_r\frac{\partial v_\theta}{\partial r}+\frac{v_\theta}{r}\frac{\partial v_\theta}{\partial \theta}+v_z\frac{\partial v_\theta}{\partial z}\right)=-\frac{1}{r}\frac{\partial p}{\partial \theta}+\frac{\partial}{\partial r}\left[\mu\left(\frac{\partial v_\theta}{\partial r}-\frac{v_\theta}{r}+\frac{1}{r}\frac{\partial v_r}{\partial \theta}\right)\right]+\frac{1}{r}\frac{\partial}{\partial \theta}\left[2\mu\left(\frac{1}{r}\frac{\partial v_\theta}{\partial \theta}+\frac{v_r}{r}\right)\right]+\frac{\partial}{\partial z}\left[\mu\left(\frac{\partial v_\theta}{\partial z}+\frac{1}{r}\frac{\partial v_z}{\partial \theta}\right)\right]+\frac{2\mu}{r}\left(\frac{1}{r}\frac{\partial v_r}{\partial \theta}+\frac{\partial v_\theta}{\partial r}-\frac{v_\theta}{r}\right)-\rho\frac{v_r v_\theta}{r} \tag{3}$$

$$\rho\left(v_r\frac{\partial v_z}{\partial r}+\frac{v_\theta}{r}\frac{\partial v_z}{\partial \theta}+v_z\frac{\partial v_z}{\partial z}\right)=-\frac{\partial p}{\partial z}+\frac{1}{r}\frac{\partial}{\partial r}\left[\mu r\left(\frac{\partial v_z}{\partial r}+\frac{\partial v_r}{\partial z}\right)\right]+\frac{1}{r}\frac{\partial}{\partial \theta}\left[\mu\left(\frac{1}{r}\frac{\partial v_z}{\partial \theta}+\frac{\partial v_\theta}{\partial z}\right)\right]+\frac{\partial}{\partial z}\left(2\mu\frac{\partial v_z}{\partial z}\right) \tag{4}$$

$$\rho c_p\left(v_r\frac{\partial T}{\partial r}+\frac{v_\theta}{r}\frac{\partial T}{\partial \theta}+v_z\frac{\partial T}{\partial z}\right)=\frac{1}{r}\frac{\partial}{\partial r}\left(rk\frac{\partial T}{\partial r}\right)+\frac{1}{r^2}\frac{\partial}{\partial \theta}\left(k\frac{\partial T}{\partial \theta}\right)+\frac{\partial}{\partial z}\left(k\frac{\partial T}{\partial z}\right)+\alpha I-U_r \tag{5}$$

$$\rho\left(v_r\frac{\partial f}{\partial r}+\frac{v_\theta}{r}\frac{\partial f}{\partial \theta}+v_z\frac{\partial f}{\partial z}\right)=\frac{1}{r}\frac{\partial}{\partial r}\left(rD\frac{\partial f}{\partial r}\right)+\frac{1}{r^2}\frac{\partial}{\partial \theta}\left(D\frac{\partial f}{\partial \theta}\right)+\frac{\partial}{\partial z}\left(D\frac{\partial f}{\partial z}\right) \tag{6}$$

In the preceding equations, v_r, v_θ and v_z are the velocity components of the gas mixture in *r*-, θ- and *z*-directions, *T* and *p* the gas temperature and pressure, whereas *f* is the mass fraction of iron vapor in the gas mixture. ρ, μ, *k*, c_p and *D* are temperature- and composition-dependent gas density, viscosity, thermal conductivity, specific heat at constant pressure and iron-vapor diffusion coefficient, respectively, for the iron-argon plasma, and the property database given by Samsonov and Shambetov [5] is employed in the present modeling study. In Eq. (5), the source terms U_r is the temperature- and composion-dependent radiation power per unit volume of plasma, and the data presented by Menart and Malik [6] and Essoltani et al [7] are used for the U_r calculation. *I* is the local laser intensity, whereas α is the local laser absorption coefficient. For the case of CO_2 laser, the absorption coefficient is calculated by [8]

$$\alpha = 1.63\times10^{-42}\,\frac{N_e^2}{T_e^{1/2}}\times\left[1-\exp\left(\frac{-1.36\times10^3}{T_e}\right)\right] \qquad \left(m^{-1}\right) \tag{7}$$

2.3 Computational domain and boundary conditions

The computational domain used in the modeling is the cylindrical region shown in figure 1 with sizes $0 \le r \le 5$ mm, $0 \le \theta \le 2\pi$ and $0 \le z \le 10$ mm. Altogether 22 (r-direction) × 22 (θ-direction) × 42 (z-direction) grid points are employed in the modeling. Boundary conditions are as follows. Metal vapor with fixed temperature (T_{va}) and upward velocity (U_{va}) enters into the plasma plume from the small circular area AB (light spot) on the bottom boundary shown in fig. 1, and thus the boundary conditions at AB are $v_z = U_{va}$, $v_r = 0$, $v_\theta = 0$, $T = T_{va}$ and $f = 1.0$. For the other part of the workpice surface except for the small circular area AB (i.e. along JA and BC), $v_r = 0$, $v_\theta = 0$, $v_z = 0$, $T = T_f$ and $\partial f/\partial z = 0$ are used. At the outer boundary (r = 5 mm) of computational domain for the gas-phase region (i.e. CD or GJ in figure 1), free-boundary conditions are used, i.e. $\partial(\rho r v_r)/\partial r = 0$, $\partial(r v_\theta)/\partial r = 0$, $\partial v_z/\partial r = 0$, $\partial T/\partial r = 0$ and $\partial f/\partial r = 0$. For the case including the effect of laterally injected assisting gas on the laser-induced plasma, the argon is assumed to be injected from the region HI on the western boundary in figure 1 with a fixed velocity U_{as} and

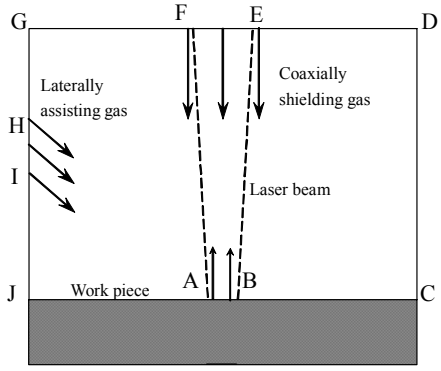

Figure 1. Computational domain.

inclination angle of 45°, and thus $v_z = -U_{as}/\sqrt{2}$, $v_r = U_{as}/\sqrt{2}$, $v_\theta = 0$, $T = T_f$ and $f = 0$ are employed, where T_f is the ambient gas temperature (i.e. 300 K). Along the geometrical axis of the computational domain ($r = 0$), $rv_\theta = 0$ and the averaged values of ϕ_i (i = 1, 2, …, N) at all the N grid points in the θ-direction and on the small circle nearest to the axis in the mesh are employed for other variable ϕ. Namely,

$$\phi|_{r=0} = \frac{1}{N}\sum_{i=1}^{N}\phi_i \qquad (\phi = v_z, v_r, T \text{ or } f) \qquad (8)$$

At the vertical section with $\theta = 0$ or $\theta = 2\pi$, the value of variable ϕ at a boundary point is taken as the average of the ϕ values at its two neighbour grid points in θ direction.

In order to protect the laser head from thermal damage by the high temperature plasma plume, the shielding gas is injected from a nozzle (i.e. EF in figure 1) coaxially placed with the laser beam. For the region EF on the top boundary where the laser beam and shielding gas enter into the computational domain, the boundary conditions $v_z = -U_{sh}$, $v_r = 0$, $v_\theta = 0$, $T = T_f$ and $f = 0$ are used, where U_{sh} is the shielding gas velocity. The boundary conditions for other part (except for EF) on the top boundary (i.e. GF and DE in figure 1) are $v_z = 0$, $v_r = 0$, $v_\theta = 0$, $T = T_f$ and $\partial f / \partial z = 0$.

3. Modeling results and discussions

One of the difficulties encountered in the modeling is how to determine the vapor temperature (T_{va}) and velocity (U_{va}) on AB region at the bottom boundary of computational domain. Although many studies have been conducted (e.g. Dowden et al [9], Tix and Simon [10], etc.), so far no reliable analysis is available concerning the vapor flow and heat transfer within the keyhole since very complex physical phenomena are involved there. Hence, as the first step to treat such a complicated problem, the vapor velocity and temperature at AB region of the bottom boundary are treated as parameters in the present modeling study, and their effects on the plasma plume characteristics are revealed by the parameter study.

3.1 Effects of the coaxially injected shielding gas velocity on plasma plume

Figures 2(a) and 2(b) show the computed flow fields (expressed using uniform vector length for clarity) on the middle vertical section for two different shielding gas velocities, i.e. 5 and 35 m/s. The metal vapor velocity (U_{va}) and temperature (T_{va}) are fixed in the computation, i.e. 100 m/s and 10000 K, whereas there is no laterally injected assisting gas. Corresponding computed isotherms are shown in Figs. 3(a) and 3(b) with isotherm range 1000 *K*~13000 K and isotherm interval of 1000 K. It is seen from the computed results that there always exist vortexes in the flow fields. In addition, the present modeling results clearly demonstrate that the coaxially injected shielding gas can significantly affect the plasma plume characteristics besides its original function to protect the laser head from thermal damage. With the increase of the shielding gas velocity, the plasma plume height (e.g. represented by the isotherm 2000 *K*) and the distance from the bottom boundary to the stagnant point at the plume axis (the location with zero axial velocity) decrease. However, it is found that the computed maximum temperature at the plasma plume core is always about 13800 K and less dependent on the shielding gas velocity.

We can compare our modeling results with some available experimental data. The conditions employed in the present modeling study are quite similar to those for the experiment of Szymański et al [2]. In their experiment, CO_2 CW laser with intensity of 3.76×10^{10} W/m^2 at the laser spot and diverging angle of 1.7 mrad were used in the welding of stainless steel and titanium. Argon was employed as the coaxially injected shielding gas with average injection velocity of 23.7 m/s. Using the intensity ratio of an ion spectral line to an atom spectral line, they measured the averaged electron temperature distribution above the stainless steel workpiece. The maximum value of the measured electron temperatures was about 11000 K with a location near the workpiece surface. Although this measured maximum temperature (~11000 K) is lower than our predicted value (~13800 K), the agreement between the modeling results and experimental data can still be considered to be reasonable. It is because that Abel inversion is not employed in the experiment of Szymański et al [2] and the ion / atom spectral intensity ratio is employed for the temperature measurements (they did not succeed in using the spectral intensity ratio of two ion lines). It is expected that if the Abel inversion was employed, the actual value of the maximum temperature in the plasma plume core region would be somewhat higher than the measured average maximum temperature 11000 K. In addition, it is also expected that if ion / ion (instead of ion / atom) spectral intensity ratio could be used to determine the plasma

temperature, somewhat higher value of the measured plasma temperature would be obtained. Our modeling results show that the plasma temperature decreases rapidly within the distance of a few millimeters from the workpiece surface. This prediction is also roughly consistent with the experimental observation of Szymański et al [2]. They showed that the measured electron temperature decreased appreciably with increasing distance from the workpiece surface within the height range of 0 – 1.25 mm. In addition, in their experiment Miller and DebRoy [11] found that the increase of the shielding-gas flow rate reduced the plasma sizes but did not affect the measured values of the electron temperature. Those results are also consistent with our modeling predictions, although their measured plasma temperatures are much lower than those predicted by the present modeling. Their measured plasma temperatures are also much lower than those reported by Szymański et al [2], although are consistent with the earlier results of Szymański and Kurzyna [3].

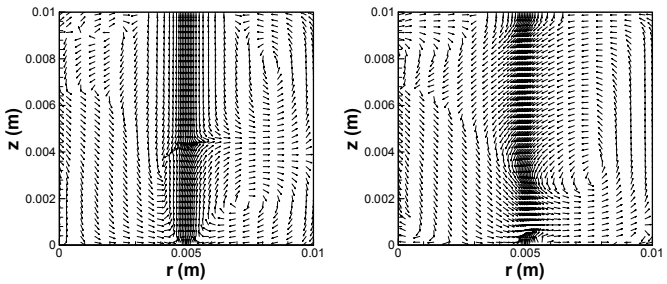
Figure 3 Computed isotherms on the vertical section ($\theta = 0 - \pi$) for different velocities of the axially injected shielding gas.

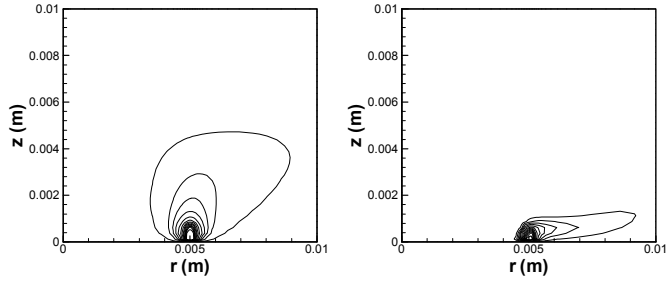
3.2 Effects of the laterally injected assisting gas on plasma plume

It is expected that the laterally injected assisting gas can significantly affect the plasma plume characteristics. In fact, the laterally injected assisting gas has often been employed to suppress the unfavourable effect of the plasma plume on the laser welding process. In the present parameter study, the injection port at the left boundary is 5 mm above the bottom boundary and directed to the center of the laser spot on the workpiece surface. The injection angle of the assisting gas is thus 45^o with respect to the workpiece. In this subsection, the metal vapor velocity (U_{va}) and temperature (T_{va}) at AB on the workpiece surface are assumed to be fixed, i.e. 100 m/s and 10000 K respectively, whereas the shielding gas velocity is 5 m/s. Typical 3-D modeling results are presented in Figs. 4(a) and 4(b) and Figs. 5(a) and 5(b) for two different assisting gas velocities, i.e. U_{as}= 5 and 50 m/s. Figs. 4(a) and 4(b) show the computed flow fields (denoted with uniform vector length) on the middle vertical section (i.e. on the $\theta = 0 - \pi$ plane). Corresponding



(a) U_{sh}=5 m/s (b) U_{sh}=35 m/s

Figure 4 Computed velocity vector fields on the vertical section ($\theta = 0 - \pi$) for different velocities of the laterally injected assisting gas.



(a) U_{sh}=5 m/s (b) U_{sh}=35 m/s

Figure 5 Computed isotherms on the vertical section ($\theta = 0 - \pi$) for different velocities of the laterally injected assisting gas.

computed isotherms are shown in Figs. 5(a) – 5(b) with isotherm range 1000 K~13000 K and isotherm interval of 1000 K. It is seen from the computed results shown in Figs. 4(a) and 4(b) and in Figs. 5(a) and

5(b) that the velocity of the laterally injected assisting gas significantly modifies the temperature and flow fields of the plasma plume. The plasma plume is blown away from its original location along the geometrical axis by the laterally injected assisting gas, showing an appreciable deflection. However, the present modeling results show that the maximum temperature of the plasma plume is less influenced by the laterally injected assisting gas. The maximum temperature of plasma plume decreases only from about 13800 K for the case with U_{as} = 0 (i.e. without the laterally injected assisting gas) to about 13100 K for the case with U_{as} = 50 m/s.

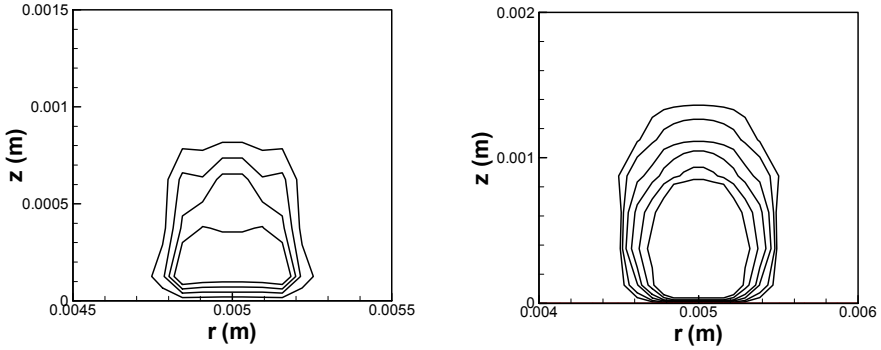
Comparison of these computed results to those without including laterally injected gas (e.g. the results shown in Fig. 2 and Fig. 3) reveals that due to the cooling effect of the laterally injected assisting gas, the dimensions of plasma plume become smaller. It is expected that the laser absorption and refraction caused by the plasma plume can be appreciably suppressed if the injection velocity and angle of the assisting gas are adjusted appropriately.

3.3 Laser absorption and refraction

The local values of the absorption coefficient of plasma plume are calculated using Eq. (7), whereas the complex refraction index is calculated using the following expression (Beck et al [12])

$$\hat{n} = 1 - \frac{\omega_p^2}{\omega(\omega_p + i\omega_e)} \tag{9}$$

In Eq. (9), ω_p is the plasma frequency， ω_e the electron collision frequency whereas ω is the frequency of CO_2 laser. As an example, the calculated results are presented here for the case that the metal vapor temperature (T_{va}) and velocity (U_{va}) at AB on the bottom boundary are 10000 K and 100 m/s, respectively, and the velocity of coaxial shielding gas is 5 m/s. Laterally injected assisting gas is not considered here.



(a) Absorption coefficient (b) Real part of refraction index

Figure 6 Computed distributions of the absorption coefficient (a) and the real part of refraction index (b) at the middle vertical section (θ = 0 – π).

The computed spatial variations of the absorption coefficient and the real part of the refraction index within the plasma plume are shown in Figs. 6(a) and 6(b), respectively. Fig. 6(a) shows the computed contours of the absorption coefficient in the range of 15~75 m^{-1} with interval 20 m^{-1}, whereas Fig. 6(b) plots the computed contours of the real part of refraction index in the range of 0.999~0.989 with interval −0.002. Changing from the non-ionized gas region outside the plume to the core of the plasma plume, the absorption coefficient increases from 0 to larger than 75 m^{-1}, whereas the real part of refraction index decreases from 1.000 to less than 0.989.

Using the computed spatial variations of the absorption coefficient and the refraction index within the plasma plume, we can further calculate the absorption and refraction of the laser beam when it passes through the plasma plume. After passing through a control volume, the laser energy will be partially absorbed and the fraction of absorbed power can be calculated by

$$\frac{I_{in} - I_{out}}{I_{in}} = 1 - \exp(-\alpha \Delta x) \tag{10}$$

where I_{in} and I_{out} are the laser intensity as the laser beam enters into and departs from the control volume, respectively, Δx is the axial size of the control volume, whereas α is the local absorption coefficient. Using

Eq. (10) and repeating the calculation for all the control volumes along the laser beam path, the total fraction of absorbed laser power is easily obtained. For the case as shown in Figs.6(a) and 6(b), the evaluated fraction of the laser power absorbed by the plasma plume is about 6 %.

The variation of the laser beam radius due to refraction can be estimated by the ray-tracing method. The deflection angle increment $\Delta\theta$ for the outermost ray at the edge of the laser beam as it passes through a control volume in the plasma plume with non-uniform refraction index can be calculated by (Eckert and Goldstein [13])

$$\Delta\theta = \frac{1}{n}\frac{\partial n}{\partial y}\Delta x \tag{11}$$

where n is the local value of the refraction index, $\partial n/\partial y$ the lateral derivative of the refraction index, whereas Δx is the axial size of the control volume. Repeating the calculation for all the control volumes along the ray path, the calculated deflection angle of the outermost ray at the edge of the laser beam is $\sim 3^0$ with respect to the laser beam axis and its lateral displacement is $\sim 0.3\times 10^{-4}\, m$ as it reaches at the workpiece for the present case. Hence, considering the refraction, the laser beam radius (originally 0.15 mm) at the spot will become $1.8\times 10^{-4}\, m$, and thus the laser beam intensity at the light spot will decrease by 30 % after the laser beam passes through the plasma plume and arrives at the workpiece surface.

4. Conclusions

A 3-D variable-property modeling approach is employed in this paper to study the laser-induced plasma plume characteristics with the CO_2 laser welding of iron workpiece as the calculation example. The modeling results show that the velocity of the coaxially injected shielding gas may appreciably affect the plasma plume characteristics. The height of the plasma plume is dependent on the metal-vapor / shielding-gas flow momentum ratio. Complicated flow pattern always exists in the plasma plume, but the maximum temperature in the plume core is always 13100–13900 K for the iron-argon system. Although laser absorption is important for the maintenance of plasma plume, its effect on the laser intensity attenuation is not significant. On the other hand, refraction may appreciably affect the laser intensity at the light spot. It is also shown that the laterally injected assisting gas can significantly affect the plasma plume characteristics. In order to obtain good welding quality, the velocity of the coaxially injected shielding gas and that of the laterally injected assisting gas should be carefully adjusted. Modeling results concerning plasma plume temperatures are shown to be reasonably consistent with available experimental data.

Abstract
We have carried out the comparative study of the luminescent spectra of plasma during different carbon film deposition in MW CVD system using CH_4/H_2 gas mixture in a wide range (0.5-17%) of CH_4 concentrations. It was found out that there is abnormally high rotational temperature of carbon dimers of up to 5000 K. The model of the C_2 molecule formation process was constructed to explain the observed phenomenon.

1. Introduction

The plasma of microwave discharge in methane-hydrogen mixtures is widely used for various carbon films deposition. Increase of the methane concentration from fractions of percentage up to tens of percent results in a fundamental change in the structure and in the composition of the deposited films. In low methane concentration range of 0.5-1% there is a high quality diamond film growth (both polycrystalline and single-crystalline ones – depending on the substrate type). In the next range (2-4%), as a rule, a nanodiamond film growth is observed. In this case the film contains a great share of amorphous carbon in addition to diamond nano-crystals. When we increase the methane concentration further, the result of the deposition process basically depends on the chemical composition and morphology of the substrate surface. In particular, when the methane concentration reaches 15% and there are catalytic particles (Ni, Fe etc.), the formation and growth of carbon nanotubes or nanowhiskers occur. Thus, physical and chemical properties of substrate surface substantially determine the characteristics of the deposited carbon materials at high methane percentage. However, the substrate having "optimal" for the growth of the required structure characteristics is necessary but insufficient for this structure deposition. Another necessary condition is the "required" plasma-chemical composition of the discharge to provide the required flux of radicals and ions with the required energy upon the substrate.

The density of radicals and ions in plasma, as well as their energy, depends not on the initial gas composition only, but also on the absorbed microwave power, the gas pressure, the rate of the gas pumping, and on many other parameters. This is the reason why the control of plasma-chemical composition and temperature of plasma during the deposition process is of fundamental importance for the reproducible production of the films with the required properties. Optical emission spectroscopy is a most available and noncontact method of control, however this method is the most complicated in the view of quantitative interpretation of results.

The present work is devoted to comparative study of luminescent spectra of microwave plasma in CH_4–H_2 mixtures. These spectra were obtained during the deposition of different carbon materials, from diamond to nanotubes. To explain the revealed spectra behavior the model of C_2 molecule formation was developed.

2. Experiment

Experimental setup. The experiments were carried out using the microwave setup having a 2.45 GHz magnetron as a microwave generator with spectroscopy system connected to the reactor's view port.

Electromagnetic energy generated by magnetron capable to produce up to 6 kW of the microwave power, comes through the waveguide to the resonator-type reactor and ignites the discharge in the reactor volume over the Mo substrate holder where the maximal energy concentration is situated. The plasma position just near the substrate is provided by reactor configuration and waveguide tuners set. To enable plasma spectroscopy and substrate temperature measurements the reactor has two inspection ports. For checking the substrate temperature we used Williamson Pro 90 dual-wavelength pyrometer.

Working gas mixture is injected directly in the discharge area from the top of the reactor. Fluxes of the hydrogen and of the carbon source (methane) were controlled with flow-meters. Gas evacuation carries out near the bottom of the reactor.

For plasma diagnostics we used the specially developed home made spectroscopy system which can control the wavelength range from 350 nm to 800 nm. System resolution was 0.05 nm that was achieved with B&M Spektronik BM-100 monochromator having 100 cm focal length and 0.83 nm/mm dispersion. The light-sensitive element was a Toshiba TCD1201 CCD linear sensor. Spectroscopy system was connected to the inspection port by way of quartz optical fiber equipped with the system of focusing lens. Spectra were collected and processed by the computer having spectral data analyzer program.

Substrates preparation. For diamond film growth we used Si(100) (4.5 Ω·cm) with the suspension of nanodiamond in photoresist put upon Si surface. This nucleation method allowed us to get 10^{10}-10^{11} cm^{-2} nucleation density. In the other case, to grow the carbon nanotubes the Ti layer (100 nm thick, as a diffusion barrier) under either Ni or Co layer (20 nm, as nanotube growth catalyst) was deposited upon Si(100) (4.5 Ω·cm).

Experimental conditions. In our experiments we operate with H_2 and CH_4/H_2 gas mixtures under the pressure in a chamber within 40-80 Torr. The CH_4 concentration in the methane/hydrogen mixture was varied from 0.5% (diamond film growth regime) to 16% (carbon nanotube growth regime). Microwave power absorbed by plasma was in the range of 0.5-1.5 kW. During the deposition process the substrate temperature was 700-800 °C.

Every process began with sample annealing in hydrogen atmosphere for five minutes to eliminate any possible sign of organic contamination on the substrate's surface to improve film's uniformity and quality. After the above procedure the methane was added to the feed gas and the film deposition process began. During this step the plasma spectrum was recorded. After the deposition process was over, in case of diamond film growth, the sample was annealed in hydrogen for 5 min. to remove the sp^2 phase, inevitably formed on the surface.

Films characterization. In our experiments in the methane concentration range indicated above we obtained a wide variety of carbon materials, from diamond to nanotubes. Films' phase and morphological properties were studied with Raman spectroscopy and scanning electron microscopy. Typical SEM-images and Raman spectra of the samples grown in both low and high methane concentration conditions (diamond and nanographite growth respectively) are presented in Fig. 1(a, b) and Fig. 2(a, b).

3. Results and Discussion

For the case of methane density varied from 0.5 to 16% the behavior of the following most high intensity molecular band systems C_2 ($d^3\Pi_g \rightarrow a^3\Pi_u$, 516.5 nm) and CH ($A^2\Delta \rightarrow X^2\Pi_r$, 431.4 nm), as well as of H_α (n=3→n=2, 656.3 nm), H_β (n=4→n=2, 486.1 nm) and H_γ (n=5→n=2, 434.0 nm) hydrogen atom lines was studied.

One of the fundamental characteristics of the weakly ionized plasma is the temperature of the neutral gas, determining either expressly or by implication practically all the processes in plasma. This characteristic determines the rates of physical and chemical processes, the direction and the intensity of heat fluxes, reduced electrical field strengths and mean electron energies, line widths, etc. The method of relative intensities of electronic-vibrational-rotational lines (EVR) [1] for diatomic molecules is widely used for the evaluation of the gas temperature. To apply this method it is necessary that the distribution of molecules over the rotational levels of the excited electron state should be of Boltzmann behavior with some rotation temperature, which, it should be noted, can be different from the gas temperature. If the typical time of the rotation relaxation in the excited state τ_{rot} exceeds the radiation life time τ_{rad} of this state, that is,

$$\tau_{rot} \gg \tau_{rad}$$

if the excitation of the upper state occurs by the electron strike and there is Boltzmann rotation distribution in the basic state, then the rotation temperatures T^0_{rot} and T'_{rot} of the basic and excited states are in the following ratio:

$$T'_{rot} B' = T^0_{rot} B^0 \quad (1)$$

where B^0 and B' are the corresponding rotation coefficients. And if the opposite inequality

$$\tau_{rot} \ll \left(\tau^{-1}_{rad} + k_q n_q\right)^{-1}$$

is true, then it is possible to conclude that within the considered system the rotation relaxation has been completed and the rotation temperature of the upper excited state is equal to the gas one. Here k_q is the rate coefficient of the collision quenching, n_q is the density of quenchers.

The present work is devoted to studying the $d^3\Pi_g \rightarrow a^3\Pi_u$ Swan band system of C_2 molecule and the $A^2\Delta \rightarrow X^2\Pi$ band system of CH molecule. The spectroscopic data and the radiation lifetime of these states are shown in table 1 [2-6]. The both studied transitions are associated with low states, therefore, the assumption can be made that in the studied mixtures, where the basic component is a light hydrogen molecule having abnormally large rotation constant, the rate of collision quenching is greater than that of the rotation relaxation. Therefore, the rotation distribution in the spectra of these bands most likely depends on the

excitation mechanism. If the electron excitation from the basic state prevails, then the temperatures are connected by ratio (1).

Under the Boltzmann distribution within the rotation levels with the temperature of T'_{rot} the intensities of the spontaneous radiation of the individual EVR line are determined according to the following expression [6-8]:

$$I_{n'\upsilon'J'\to n''\upsilon''J''} = const \cdot \left(\nu_{n'\upsilon'J'\to n''\upsilon''J''}\right)^4 S_e q_{\upsilon'\upsilon''} S_{J'J''} g_{s,a} \exp\left(-\frac{hcF'(J')}{kT'_{rot}}\right), \quad (2)$$

where $\nu_{n'\upsilon'J''\to n'''\upsilon'''J'''}$ is the wave number of the EVR transition $n'\upsilon'J'\to n''\upsilon''J''$, n indicates the electron state, υ is the number of the vibration level, J is the total momentum of the rotation level, the values with one prime refer to the upper state, those with two primes to the lower state; S_e is the electron momentum of the transition, $q_{\upsilon'\upsilon''}$ is the Frank-Condon factor, $S_{J'J''}$ is the Holn-London coefficient, $F'(J')$ - is the rotation term of the upper state, $g_{s,a}$ is the parameter taking into account the statistical weights symmetrical and anti-symmetrical states of homonuclear molecules, h is the Planck's constant, c is the velocity of light, k is the Boltzmann constant.

The rotation terms of duplet and triplet states were determined according to the relationships in [7]. In fig.3 contains the schemes of the studied transitions for C_2 and CH molecules. Only the transitions of basic branches are shown. Besides the basic branches, there 6 more satellite branches for $CH(A^2\Delta)\to CH(X^2\Pi_r)$ and 18 ones for $C_2(d^3\Pi_g)\to C_2(a^3\Pi_u)$. The Honl-London factors were calculated according to [7].

In fig.4 there is comparison of the experimental spectrum with the calculation one for different rotation (the first number in the legend) and vibration (the second number) temperatures of the upper state of the $CH(A^2\Delta)\to CH(X^2\Pi_r)$ system, 0-0, 1-1, 2-2 и 3-3 bands. No agreement with the experiment was achieved under any rotation temperature. It is seen that the temperature of high rotation levels is close to 2000 K (the sizes of peaks corresponding to individual rotation levels in the calculation and in the experiment practically coincide in the value), but in the range of low rotation levels the temperature is lower. The figure also shows the emission of C_2 molecules in the Swan system, the 2-0, 3-1 and 4-2 bands of $\Delta v=2$ sequence.

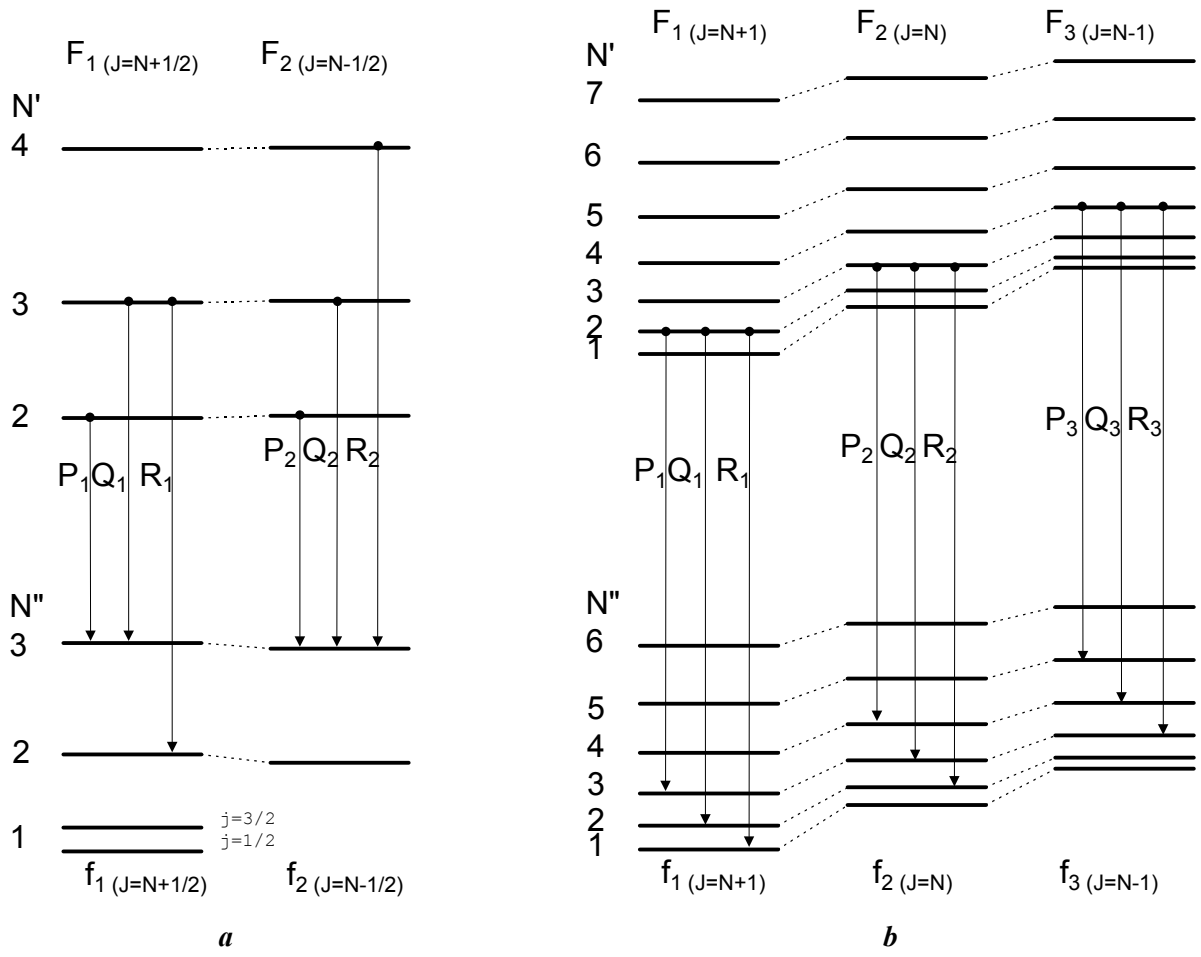

Fig.3. The rotation levels and the transition schemes of the basic branches for $CH(A^2\Delta)\rightarrow CH(X^2\Pi_r)$ and $C_2(d^3\Pi_g)\rightarrow C_2(a^3\Pi_u)$ band systems.

In fig.5 there is comparison of experimental and calculation spectra within the Swan band system for C_2 molecules, $\Delta v=0$ sequence in the mixture of H_2+C_2H_5OH with a small addition of $(CH_3O)_3B$, and also in the mixture of H_2+CH_4. The H_2 percentage in the mixtures exceeded 90%. It is seen that the rotational temperature of the upper state is close to 5000 K. Energy estimation and independent measurements result in the gas temperature, not exceeding 1000°C. Therefore, we can conclude that the rotation temperature determined by the emission within the Swan band system does not correspond to the gas temperature, but indicates the fact that the mechanism of exciting the $d^3\Pi_g$ is non-electron.

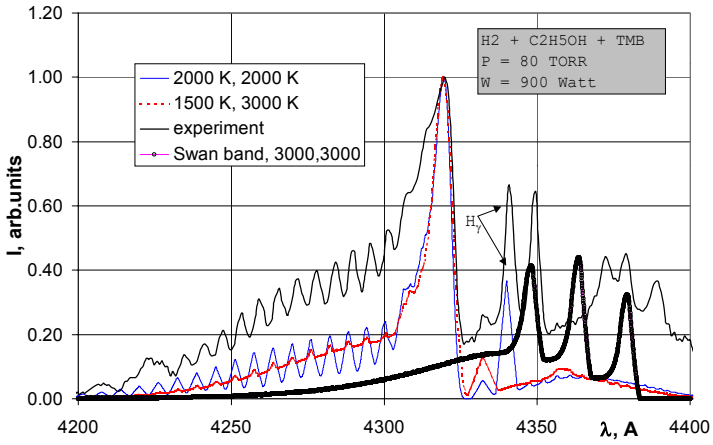

Fig.4. Experimental and calculation glow spectra of CH molecules within the $A^2\Delta\rightarrow X^2\Pi$ band system of the $\Delta v=0$ sequence.

The analysis of the processes with the participation of methane and hydrogen radicals shows that the excitation of high rotation levels can result from the following:

$$CH + CH_2 \rightarrow C_2H^*(E\approx 4.6\ eV) + H_2 \qquad (R1)$$
and/or
$$C_2H + e \rightarrow C_2H^*(E\approx 4.6\ eV) + e; \qquad (R2)$$

$$C_2H^* + H \rightarrow C_2(d^3\Pi_g) + H_2 + \Delta E\approx 1.0\ eV \qquad (R3)$$
and/or
$$C_2H^* + C_2(a^3\Pi_u) \rightarrow C_2H + C_2(d^3\Pi_g) + \Delta E\approx 2.1\ eV. \qquad (R4)$$

A share of the extra energy ΔE is spent for the excitation of rotation levels. In this case the process (R3) most likely occurs within the migration mechanism, when the hydrogen atom collides with one of the carbon atoms of the C_2H complex, and then "migrates" to the hydrogen atom, which is followed by the hydrogen molecule escape. According to [9] the migration mechanism is characterized by a high degree of rotation excitation of the reaction products. At present there occurs the creation of the complete chemical model for the discharge processes in the mixtures containing hydrogen and methane to explain the results revealed in this work.

Abstract
A new monomer has been synthesized, a pentafluorophenyl acrylate, that has been polymerised by plasma techniques. The polymer leaves labile groups on the surface, which facilitate a fast reaction with biotinylated molecules. Other monomers, such as acrylic acid and allylic alcohol, have also been polymerised by plasma, leading to a surface with functional character that would result into a versatile platform for further linkage of biotinylated biomolecules to promote cell attachment.

1. Introduction

Our research group is involved in the development of biomaterials that facilitate new tissue in-growth for bone and cartilage restoration. To this end, improvement of surfaces is crucial, so that they become attractive to cells so that their adhesion, growth and proliferation are enhanced. Initial cell adhesion can be induced by bioactive surfaces, obtained by linkage of biological ligands, which enable control of cell-substrate interactions. The main approach to immobilize ligand motifs on biomaterial surfaces consists of creating covalent attachments to reactive polymer side chains [1]. Surface modification techniques have been shown to be suitable, because a thin film may be deposited onto substrates of complex geometry [2] with a uniform distribution of functional groups.
Our goal was set in covalently linking biotin to a polymer surface. Subsequent assembling of streptavidin with the biotin-coated surface would result into a versatile platform for further linkage of other biotinylated biomolecules of interest to promote cell attachment [3].
µcontact printing methods are attractive for micropattering of biomolecules like biotin because of their simplicity and ease of use [4]. For applying this method it is necessary to have a very reactive surface, which is achieved by having labile groups like pentafluorophenyl. In consequence, the monomers developed untill now for getting these coatings having this kind of labile groups, are complicated and have long and complex synthesis [3]. The aim of this study is to get an easy way to synthesise different kinds of small acrylate derivates to be used afterwards as monomers for plasma polymerization, leaving a functionalized surface with this labile group. In the present work pentafluorophenyl methacrylate has been synthesized. Although methacrylate derivatives of pentafluorophenol are well known [5], their use as monomers for plasma polymerisation hasn't been studied in deep.
For the implementation of other methods for biotin linkage, polymerisation other kinds of monomers have also been studied.

2. Experimental section

2.1 Pentafluorophenyl methacrylate synthesis
2.1.1 General
Florosil® (60-100 mesh, Aldrich), Methacryloyl chloride (+98%, Aldrich), 2,6-lutidine (97%, Aldrich), 2,3,4,5,6-pentafluorophenol (99%, Aldrich), THF, Pentane.
^{1}HNMR and ^{13}CNMR spectra were determined in $CDCl_3$ as solvent on a Gemini 300 Varian spectrometer at 300.1 and 75.5 MHz, respectively. Chemical shifts are reported in δ (ppm) from internal TMS. IR spectra were made on a Nicolet Magna 5600 spectrophotometer.

2.1.2 Typical procedure [5]
Methacryloyl chloride (8ml, 82mmol) is added drop wise to a stirred solution of pentafluorophenol (7.6g, 41mmol) and 2,6-lutidine (6.6g, 62mmol) in THF (100ml) at 0ºC. After 10 min stirring at the same temperature, the precipitate is filtrated and washed with THF (50ml). Then, the solvent is removed under reduced pressure and the residue was purified by chromatography on a Florosil® column (Aldrich 60-100mesh), using pentane as eluent. The pentafluorophenyl methacrylate is stored at 4ºC.

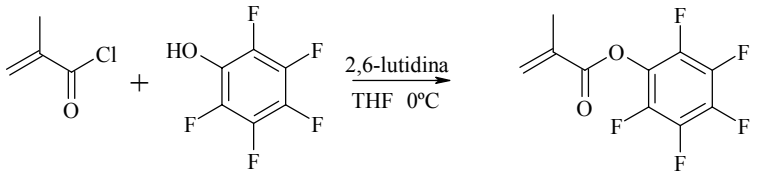

Fig.1 Monomer synthesis

2.2 Plasma reactor system
The plasma deposition apparatus consisted of a stainless steel discharge vessel (diameter 26 cm, length 24 cm) with internal electrodes which were connected to a RF power source (13,56MHz). The gases or monomers were supplied via a standard manifold with gas fluxes adjusted with needle valves. A pressure meter positioned between the reactor and the cold trap before the vacuum pump, measured the system pressure. The two stages mechanical pump (Edwards, RV12 903) evacuates de vessel. The reactor chamber was evacuated to a base pressure of 0,1mbar.
Each polymer was deposited on a square of silicon wafer (100) oriented 250-350µm thickness and on 25µm polyethylene. The RF power was around 10W. Deposition times were within two and eight hours.
Pentafluorophenyl methacrylate (PFM) was used as synthesized. It was necessary to heat the monomer to reach the desired pressure to polymerise. The monomer flow rate was set so that the pressure within the reactor was 0.3mbar.
Acrylic acid (99%, Aldrich), 1,7-octadiene (98%, Aldrich) and allyl alcohol (98,5%, Aldrich) were used as supplied. The pressure within the reactor for the DACH was typically 0.4mbar (it was also needed to heat the monomer). Acrylic acid and allyl alcohol were polymerized at a pressure of 0.4mbar and 0.8mbar each. They were also copolymerized with 1,7-octadiene, with a relationship between the monomers of $3_{Octadiene}/4_x$.

2.3 Infrared (IR) Sprectroscopy
IR spectra were collected by the transmittance mode with the plasma polymers deposited on the polyethylene by the use of an FT-IR spectrophotometer (Bormen MB-120). In the reflectance mode a microscope (IR-Plan-Spectra Tech) was attached to the spectrophotometer.

2.4 XPS
The XPS analysis were carried out using a Perkin Elmer PHI 5500 spectrometer, fitted with a monochromatic Al X-ray gun, operated with a gun of 350W. The pass energy for the acquisition of C 1s narrow scans was 23.50 eV. All XPS spectra were recorded at a take off angle of 45ºC relative to the surface normal. The pressure in the main UHV chamber was maintained below $5x10^{-9}$ Torr for all analyses. Data analyses were carried out using Multipax software (PHI) with the C1s component of the aliphatic hydrocarbon set a 285.00 eV as a reference.

3. Results

3.1 Monomer synthesis
Pentafluorophenyl methacrylate is obtained as a colourless oil (7.0g, 35%).
1H NMR: 6.454ppm (1H, dq, H_b), 5.914ppm (1H, dq, H_a), 2.093ppm (3H, dd). See figure 2.
13C NMR: 162.910ppm (1C, s, CO), ca.139.6ppm (5C, m, C-F), 133.626ppm (1C, s, H2C=C), 129.786ppm (1C, s, H2C=C), 18.272ppm (1C, s, C-CH3).

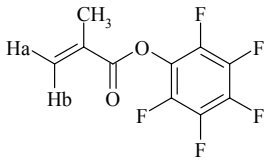

Fig.2 pentafluorophenyl methacrylate

IR spectra (figure 3):
The IR spectrum of the pure PFM shows some characteristic peaks. Around 2950 cm^{-1} there are peaks that reveal hydrocarbon activity, the peak at 1764 cm^{-1} shows a carbonyl stretch of a carboxylate ester. Between 1625 and 1475 cm^{-1} there are some peaks for the skeleton vibrations. Around 1100-1000 cm^{-1}, there are some peaks characteristics for C-F stretching.

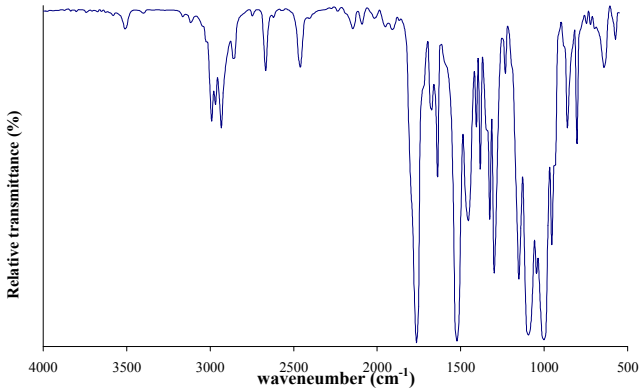

Fig.3 IR spectra of pentafluorophenyl methacrylate

3.2 Plasma polymerisation
3.2.1 FT-IR
In the FT-IR spectra of the continuous plasma acrylic acid films appeared some characteristic peaks. There is a broad absorption peak around 3200 cm^{-1}, assigned to the stretching vibration of O-H in the carboxylic acid, and around 2950 cm^{-1} there is a peak that reveals hydrocarbon activity, the peak at 1738 cm^{-1} shows a carbonyl stretch of a carboxylic acid. [6]
The FT-IR spectra of the allyl alcohol films show retention of hydroxyl functional groups. The peak around 3350 cm-1 is due to the stretching vibration of the polymeric O-H, the presence of hydrocarbon activity is also shown by the peak at 2935 cm-1, additionally there is a peak which shows C-O presence at 1050 cm-1. It is to be shown, that there is a presence of carbonyl groups with peaks around 1650 cm-1, that is created under the high energy conditions of the plasma polymerisation. [7]

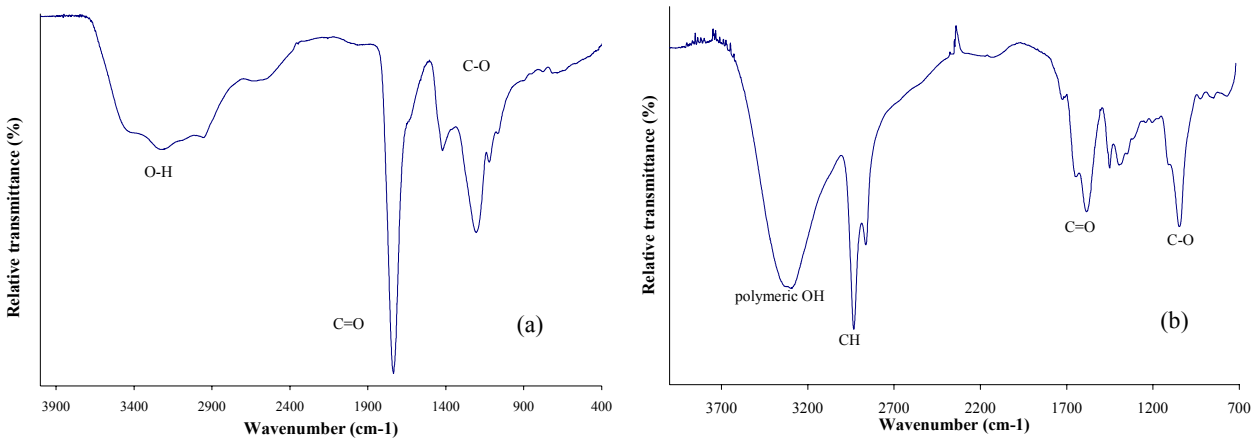

Fig.4 (a) IR spectrum of plasma polymer of acrylic acid, (b) IR spectrum of plasma polymer of allyl alcohol

3.2.2 XPS

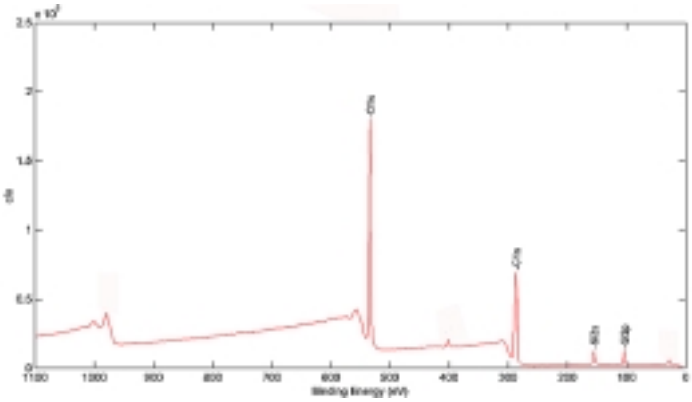

Fig.5 Survey spectrum of allyl alcohol plasma polymer

The different XPS spectra revealed the presence of silicon, oxygen and carbon. Additionally the spectrum of the PFM revealed fluorine. The presence of silicon is due to the nature of the bracket, a silicon wafer. The C 1s core level spectra were peak fitted on various oxygen-containing functionalities, except the PFM C 1s core level, that was peak fitted on oxygen-containing functionalities and also on fluorine-containing functionalities. First, spectra were corrected for sample charging, setting the hydrocarbon signal to 285 eV, and the position of the others centroids adjusted accordingly. The 1s levels of oxygen and carbon occur at 528 and 280 eV, respectively, and fluorine in the PFM occurs at 690 eV.

Figure 6 shows the C 1s core-level spectra of plasma polymerised pentafluorophenyl methacrylate and the copolymerised allyl alcohol and octadiene.

In the XPS spectrum prepared from acrylic acid and 1,7-octadiene carbon environments of the form C-R, C-O, C=O and COOR (R = C or H) are expected to be present, each exhibiting a characteristic chemical shift. This spectrum has been fitted using three peaks corresponding to hydrocarbon (C-C/H) set a 285 eV, an alcohol or ether carbon (C-O) at 286.5 eV, and carboxyl/carboxylate COOH/R at 289.2 eV [8]. The existence of carbonyl functionalities is not to be noticed, but other functionalities like alcohol/ether are present as expected.

For allyl alcohol and 1,7-octadiene samples, carbon environments of the form C-R, C-O, C=O and COOR (R = C or H) are also expected to be present, with its characteristic chemical shift. This spectrum has been fitted using four peaks corresponding to hydrocarbon (C-C/H) set a 285 eV, an alcohol or ether carbon (C-O) at 286.5 eV, carbonyl (C=O) at 288 eV, and carboxyl/carboxylate COOH/R at 289.2 eV.

The PFM spectra, it is expected, that carbon environments like C-R, COOR (R = C or H), C-F are present, each exhibiting a characteristic chemical shift. The XPS spectrum reveals the presence of fluorine. This spectrum has been fitted using three peaks corresponding to hydrocarbon (C-C/H) set at 285 eV, an ester carbon at 286.6 eV, and fluorinated carbon (C-F) at 288.9 eV.

XPS data are summarized in Table 1.

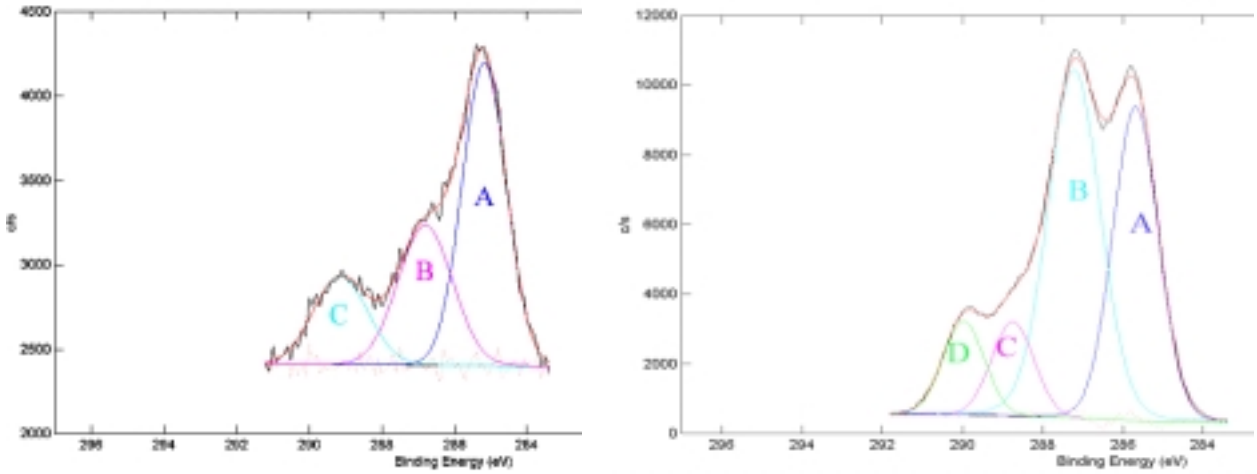

Fig.6 (a) Peak fitted C 1s core levels of pentafluorophenyl methacrylate. A: C-C/H, B: COOR, C: C-F (b) Peak fitted C 1s core levels of allyl alcohol + octadiene. A: C-C/H, B: C-O, C: C=O, D: COOR/H

Table 1. Results of quantification of the XPS spectra of plasma polymerised monomers

		percentage of functionality in the C 1s core level (%)				
	O/C ratio	C-C/H	C-O	C=O	COOH/R	C-F
PFM	0,48	51,84	-	-	29,5	18,7
Acrylic acid + Octadiene	0,49	52,95	24,85	-	22,2	-
Allyl alcohol + Octadiene	0,65	35,1	45,97	9,58	9,35	-

4. Discussion

The synthesis of the PFM is made following a general synthesis way for acrylate derivatives. The use of a hindered pyridine as proton acceptor is to limit the side Michael addition of the pyridine to the acrylate. Moreover, an excess of the base is used to prevent the addition of hydrogen chloride onto the activated double bond of the acrylate. The high basicity of he 2,6-lutidine compared to pyridine increases the extent of deprotonation of the phenol [5]. The reaction product is purified by a chromatography column filled with Florosil®, which allowed its isolation in a very pure form, as it is seen in the MNR spectra. The product has to be stored at 4ºC, to avoid its degradation.

The FT-IR analysis for the plasma polymerisation of acrylic acid and allyl alcohol already showed a retention of functional groups on the surface. But these surfaces were not stable with the contact of water. As the surfaces were desired to react in water, these monomers were let to copolymerise with 1,7-octadiene, to get a bigger cross linking of the end-polymer. The results of the FT-IR and XPS analysis showed that the retention of the functionality was also achieved.

In the plasma copolymerisation of octadiene and acrylic acid the retention of carboxylic groups is to be seen, but also the presence of other oxygen-containing functionalities like ethers or alcohols. These can arise as a result of the fragmentation of the monomer in the plasma and can be assigned to side products formed during polymerisation. Reaction between the deposit and the water desorbed from the walls of the plasma vessel (during polymerisation) and the atmospheric oxygen and the water (after polymerisation) can also contribute [9,10].

In the case of the copolymerisation of allyl alcohol and octadiene, it can be noticed that there's a big retention of the alcoholic functionality. The functionalities like carboxyl/carboxylate are less important and are the ones which can arise as a result of the fragmentation of the monomer in the plasma and, as previously, they can be assigned to side products formed during polymerisation. Once more, reaction between the deposit and the water desorbed from the walls of the plasma vessel (during polymerisation) and the atmospheric oxygen and the water (after polymerisation) can also contribute [10,11].

Regarding the polymerisation of the pentafluorophenyl methacrylate, the existence of other oxygen-containing functionalities besides to carboxylates is not to be noticed. The atomic content of fluorine reveals a relation between carbon and fluorine (C/F=3,7), higher than theoretical It could be explained if some the labile groups are supposed to fragmentise during the plasma treatment. Nevertheless, it is confirmed by the analyses that the fluorinated group on the surface is mainly retained.

5. Conclusions

Pentafluorophenyl methacrylate has been synthesized by a general derivatization method for acrylates.. It has been possible to get a simple monomer in an easy way that afterwards has been polymerised by plasma. It has been proved that labile groups are staying on the surface. These labile groups enable a fast reaction with molecules containing a primary amine groups making possible the use of microcontact printing technique.

Surface has also been activated by polymerization of other commercial monomers achieving hydroxyl and carboxylic groups that could react subsequently with molecules of interest.

These functionalities allow the covalent linkage of biotin or other biomolecules that permit substrate-cell interaction. Hence, the possibility of easy surface modification is of great interest to improve the control of cell attachment.

Abstract
This work presents a theoretical and experimental investigation of the dissociation rate and N(^4S) atom concentrations in a nitrogen DC discharge operating at gas pressures p = 0.5 – 4 Torr and discharge currents I = 10 – 80 mA. It is shown that electron impact dissociation controls nitrogen dissociation only at the lower pressures considered in this study. For p > 1 Torr, dissociation proceeds essentially via reactions involving the long-lived metastable heavy-particles $N_2(X\,^1\Sigma_g^+,v)$ and $N_2(A\,^3\Sigma_u^+)$, such as $2N_2(X, 10<v<25) \rightarrow N_2(X) + 2N$ and $N_2(X, 14 \le v' \le 19) + N_2(A) \rightarrow N_2(X) + 2N$.

1. Introduction

It is well known already for a long time that the high dissociation degrees observed experimentally in nitrogen discharges at pressures above ~1 Torr and low values of the reduced electric field, E/N, typically below 8×10^{-16} V.cm^2, cannot be explained by electron impact dissociation only [1]. Several authors have then proposed dissociation to occur by a vibration-dissociation (V-D) mechanism, in which the vibration-vibration (V-V) and vibration-translation (V-T) energy exchanges would induce transitions into a pseudo-level above the last bound vibration level [2,3]. However, the vibrational distribution functions (VDFs) of ground-state N_2 molecules considered in those works were unrealistically overpopulated in the very high v-levels, since they were calculated neglecting both the deactivation of the vibrationally excited molecules at the discharge tube walls [4] and the strong quenching of vibrations in V-T N_2-N collisions [5]. Although the direct V-D mechanism cannot be effective under discharge conditions, these early works have pointed out the importance of vibrationally excited $N_2(X,v)$ molecules in nitrogen dissociation.

The problem of lack of dissociation in nitrogen discharges was recently stressed in [6-8], which have proposed, respectively, additional channels of dissociation according to reactions

$$N_2(A) + N_2(A) \rightarrow N_2(X) + 2N\,, \quad (1)$$

$$N_2(X, v>10) + N_2(X, v>10) \rightarrow N_2(X) + 2N \quad (2)$$

and

$$N_2(X, 13<v<20) + N_2(A) \rightarrow N_2(X) + 2N\,. \quad (3)$$

Reaction (1) was abandoned soon later due to difficulties in the explanation of experimental data, but anyway the need for an extra source of dissociation was clearly pointed out in [6].

In this report we present a theoretical and experimental study of nitrogen dissociation in a N_2 DC glow discharge, operating at gas pressures p = 0.5 – 4 Torr and discharge currents I = 10 – 80 mA. In order to investigate the contribution of reactions (2) and (3) to the total rate of dissociation, we have developed a kinetic model coupling in a self-consistent way the electron Boltzmann equation and the rate balance equations for the populations of the most important neutral and charged heavy-particles, in which the maintaining electric field is self-consistently calculated. The calculated densities of ground-state atomic nitrogen are then compared with absolute measurements performed using the method of electron spin resonance (ESR), for the same conditions as in the calculations.

2. Experiment

The measurements were performed in a flow system using the setup described in [9]. Briefly, the discharge was produced in a borosilicate glass molybdenum sealing cylindrical tube with inner radius R = 7.5 mm. The gas flow rate was measured by a capillary rotameter calibrated at atmospheric pressure and room temperature. The electric field sustaining the discharge was measured by the voltage of current compensation in a circuit of two cylindrical probes, each of diameter of 20 μm. The gas temperature at the positive column axis and the wall temperature were determined using a copper-constantan thermocouple. The concentration of ground-state N(^4S) atoms was determined by electron spin resonance (ESR), using a RE1301 radio spectrometer. The atomic nitrogen ESR spectrum consisted of three symmetric equidistant lines of equal

intensity and was registered for a magnetic field intensity H_0=3100 Oe. The absolute concentrations of N(^4S) were determined with an uncertainty of less than 40%. The main plasma parameters corresponding to the conditions of the present investigation can be found in [7]. The series of experiments carried out in [7] allowed to determine not only the stationary concentration of nitrogen atoms in the zone of the positive column, but also the probability for heterogeneous loss of N(^4S) atoms in the plasma zone γ and the rate of dissociation of nitrogen atoms W.

3. Kinetic model

In order to investigate the effect of reactions (2) and (3) on nitrogen dissociation, we have used a self-consistent kinetic model, that has already proved in many different conditions to be a powerful predictive tool (see ref [8] and refereces therein). This model is described in detail in [10,11], but a brief outline is given below. Essentially we solve the homogeneous electron Boltzmann equation, coupled to a system of equations describing the creation and loss of the most important neutral and ionic heavy-particles, $N_2(X\ ^1\Sigma_g^+$, v), $N_2(A\ ^3\Sigma_u^+$, $B\ ^3\Pi_g$, $C\ ^3\Pi_u$, $a'\ ^1\Sigma_u^-$, $a\ ^1\Pi_g$, $w\ ^1\Delta_u$, $a''\ ^1\Sigma_g^+$), N(^4S, ^2D, ^2P), N_2^+ and N_4^+. The electric field sustaining the discharge is determined from the requirement that the total rate of ionization must compensate exactly the total electron loss rate due to ambipolar diffusion and electron-ion recombination. The ionization rate includes both direct and stepwise electron impact ionization, as well as Penning/associative reactions involving the metastable species $N_2(A\ ^3\Sigma_u^+)$ and $N_2(a'\ ^1\Sigma_u^-)$ [10]. Reactions (2) and (3), not considered before, were added to the kinetic scheme described in [10,11].

The input parameters for the model are the ones usually controled in a real experiment, namely the gas pressure p, discharge current I, and tube radius R. The gas temperature can be calculated from the model [12], but was taken here as an input parameter as well. It is still worth to note that we have used the constant value $\gamma = 10^{-3}$ for the probability of recombination of N(^4S) atoms at the wall. This approximation is well justified by the measurements of γ reported in [7] for the conditions of this investigation, which did not exhibit any significant dependence of the recombination probability with the pressure (and thus with the wall temperature).

Looking for mechanisms that could provide additional dissociation in N_2 discharges at low reduced electric fields, we have only considered reactions (2) and (3). On one hand, these reactions had already been proposed in the literature; on the other hand, both require an important role of vibrationally excited molecules, as it was suggested in the early works [1-3]. Reaction (3) seems a natural candidate, since it is likely to occur via the excitation of the predissociative v' ≥ 13 levels of the $N_2(B\ ^3\Pi_g$, v') state [13],

$$N_2(X, 13 < v < 20) + N_2(A) \rightarrow N_2(X) + N_2(B, v' \geq 13) \rightarrow N_2(X) + 2N\ . \quad (4)$$

We note that this reaction is known to be very efficient in the excitation of the bound v' < 13 levels, in collisions involving $N_2(X, 4<v<14)$ and $N_2(A)$ states [10]. At first sight reaction (2) seems to bring more problems. However, the direct excitation of different states in similar processes is often invoked in the literature, such as [13,14]

$$2N_2(X, v > 16) \rightarrow N_2(X) + N_2(a') \quad (5)$$

and

$$2N_2(X, v > 13) \rightarrow N_2(X) + N_2(B)\ , \quad (6)$$

reported with rate coefficients of the order of 10^{-15} cm^3/s. Process (5) can be followed by a reaction very similar to (3), like

$$N_2(X, v \geq 7) + N_2(a') \rightarrow N_2(X) + N_2(a, v' \geq 6) \rightarrow N_2(X) + 2N\ . \quad (7)$$

In this case the mechanism (2) would in fact represent formally the sequence of reactions (5) and (7). Another possibility is the direct excitation of the predissociative levels $N_2(B\ ^3\Pi_g$, v' ≥ 13) and/or $N_2(a\ ^1\Pi_g$, v' ≥ 6) in reactions of type (5) and (6). At the present stage it is not possible to determine which is the actual mechanism leading to dissociation.

4. Results and discussion

All the calculations have been carried out for the conditions described above, p = 0.5 – 4 Torr, R = 0.75 cm and three values of I, 20, 50 and 80 mA. For this set of conditions, the gas temperature varies between 330 and 680 K [7].

To illustrate the effect of reaction (2) on nitrogen dissociation, figures 1 and 2 show the measured and calculated concentrations of N(^4S) atoms for I = 20 and 80 mA, respectively, when reaction (3) is neglected and reaction (2) is considered with a rate coefficient k_2 of zero (full curves, A), $k_2 = 10^{-15}$ cm^3/s (dashed

curves B), $k_2 = 5\times10^{-15}$ cm^3/s (dotted curves C) and $k_2 = 7.5\times10^{-15}$ cm^3/s (dash-dot curves D). Next, figures 3 and 4 show the effect of additional dissociation only according to reaction (3), considered with a rate coefficient k_3 of zero (full curves, A), $k_3 = 10^{-12}$ cm^3/s (dashed curves B), $k_3 = 5\times10^{-12}$ cm^3/s (dotted curves C) and $k_3 = 6.5\times10^{-11}$ exp (-1765/T_g) cm^3/s (dash-dot curves D). Finally, the conjoint effect of both reactions can be evaluated and compared to the former cases in figures 5 to 7, where we depict the results when the following situations are considered: dissociation occurs by electron impact only, $k_2 = k_3 = 0$ (full curves A); the best case considered when additional dissociation results from reaction only (2), $k_2 = 7.5\times10^{-15}$ cm^3/s and $k_3 = 0$ (dashed curves B); the best case considered when additional dissociation results from reaction only (3), $k_2 = 0$ and $k_3 = 6.5\times10^{-11}$ exp (-1765/T_g) cm^3/s (dotted curves); both reactions are considered, with rate coefficients of $k_2 = 3.5\times10^{-15}$ cm^3/s and $k_3 = 4.5\times10^{-11}$ exp (-1765/T_g) cm^3/s. From figures 1 – 6 we can immediately confirm that electron impact dissociation cannot provide a satisfactory explanation of the experimental data for pressures above ~1 Torr. Furthermore, reaction (2) can conciliate the calculations with the measurements at low discharge currents, but is unable to do so for the higher values of I. On the contrary, reaction (3) provides the correct amount of dissociation for high currents, but fails in the opposite limit. Finally, the results are quite acceptable in the full range of values of I and p considered in this investigation when both mechanisms are taken into account as extra sources of dissociation (curves D in figures 5 – 7).

The results from the previous figures can be quantified in figure 8, where we plot the relative contribution of each of the dissociation mechanisms to the total dissociation rate, for I = 20 mA (full curves) and I = 80 mA (dashed curves). Thus, curves A correspond to the contribution of electron impact dissociation on N_2 molecules, curves B to the contribution of reaction (3), and curves C to the percentage contribution of reaction (2). It can be seen that electron impact dissociation is the major channel of dissociation only at the lower pressures considered in this study. For p ≥ 1 Torr the mechanisms (2) and (3) start to be dominant, their contribution to the total dissociation reaching values as high as 90%. Figure 8 confirms as well that reaction (2) is more important at lower values of I, while reaction (3) has the opposite behavior. The reason for this is related to the effect of superelastic electron-vibration (e-V) collisions, which significantly heat the electron energy distribution function. The effect is more dramatic at low values of E/N and, therefore, for the higher pressures. We recall that the vibrational temperature of ground state N_2 molecules, T_V, increases with the discharge current, while the reduced electric field remains practically unchanged, as it has been determined experimentally in [7] and theoretically in [15].

5. Conclusions

In this work we have presented a theoretical and experimental study of the mechanisms of nitrogen dissociation in N_2 DC discharges. The calculated densities of ground-state atomic nitrogen were compared with absolute measurements performed using the method of electron spin resonance (ESR), for the same conditions as in the calculations.

It has been shown that electron impact dissociation is the dominant mechanism of dissociation only at pressures below ~1 Torr. The results of this investigation suggest that reaction (3) may control nitrogen dissociation for p≥1 Torr and I≥50 mA, whereas reaction (2) may be important at lower discharge currents. The rate coefficients for these two reactions were estimated to be of the order of 10^{-15} cm^3/s and 10^{-12} cm^3/s at T_g = 500 K, respectively for reactions (2) and (3).

Removal of NO_x from Flue Gas by Non-thermal Plasma-Catalyst System

J. Mizeraczyk and M. Dors

Centre of Plasma and Laser Engineering, Institute of Fluid Flow Machinery, Polish Academy of Sciences, Fiszera 14, 80-231 Gdańsk, Poland, e-mail: jmiz@imp.gda.pl

Abstract

The objective of this work was to investigate NO_x removal with a hybrid system consisting of a DC corona discharge and a catalyst at a room temperature (22ºC) in the presence of ammonia. In the hybrid reactor a positive DC corona discharge was generated between a hollow needle and a flat mesh. The catalyst was a layer of V_2O_5 and TiO_2 deposited on Al_2O_3 globules. The catalyst surface was either free of NH_3 or saturated with NH_3. A gas mixture of N_2(80%):O_2(5%):CO_2(15%):NO(200ppm), simulating a flue gas, flowed through the tube with a flow rate of 1 l/min. NH_3 was added to the gas mixture through the hollow needle.

The obtained results showed that the proposed hybrid reactor consisted of the corona discharge and NH_3-saturated catalyst is attractive for NO_x removal and may be an alternative to other non-thermal plasma methods used for NO_x removal.

1. Introduction

Investigations carried out in laboratories and pilot plants showed that removal of NO_x from flue gases by corona discharges may be efficient [1, 2]. However, the energy consumption in this new technology is still not acceptable for commercial use and is to be improved.

A technology competitive to the corona discharge processing is the selective catalytic reduction (SCR) which has proved its efficiency in NO_x removal [3]. In the SCR process, ammonia (NH_3) and a catalyst operating at a relatively high temperature range of 280-430ºC are used to reduce NO_x to N_2 and H_2O which are harmless products. The efficiency of NO_x removal using the SCR method is up to 90 %.

In the corona discharge processing, the dominant mechanism of NO_x removal is its oxidation to gaseous HNO_3 which then is converted to NH_4NO_3 solid particles by adding NH_3 [4-9]. Among many corona discharge types, the most efficient in NO_x removal is a corona radical shower (CRS) [6, 7]. In the CRS reactor, NH_3 is introduced through a hollow needle electrode into the corona discharge zone where NH_3 molecules dissociate to NH_2 and NH radicals. These radicals react with NO_x molecules converting them into NH_4NO_3 solids. The record NO_x removal energy yield of the CRS method is 15 g/kWh at NO_x removal efficiency of 90 % [7].

In recent years hybrid plasma-catalyst systems have been proposed because of their capability to reduce NO_x into N_2 and other harmless molecular gases [10-18]. A typical hybrid system consisted of a corona discharge and a catalyst operating at temperature over 120°C. In some hybrid systems, first the corona discharges were used for oxidizing NO into NO_2, and then the SCR processing with NH_3 was used to convert NO_2 into N_2 and H_2O [10-12]. The efficiency of NO_x removal using hybrid plasma-catalyst systems was up to 98 % at an energy yield up to 55 g/kWh [12]. In other hybrid systems, hydrocarbons were added to the flue gas polluted with NO_x to improve its removal [14-16].

This work was aimed at studying NO_x removal in a hybrid system consisted of a DC streamer corona discharge with a catalyst operating under low temperature (22ºC) in the presence of NH_3. In our reactor a catalyst typical of the SCR method, but operating at low temperature, interacted with a corona discharge. Gaseous NH_3 was introduced into the corona discharge zone either conventionally through a hollow needle electrode, similarly as in the CRS reactors, or using a novel method. In this new method, the gaseous NH_3 diffused into the discharge zone after releasing it by the corona discharge from an NH_3 phase, which has been earlier adsorbed on the catalyst surface. The performance of our hybrid corona discharge–catalyst reactor is described below.

2. Experiment

The hybrid corona discharge-catalyst reactor used in this experiment is shown in Fig. 1. The positive DC corona discharge was generated between a stainless steel hollow needle electrode and grounded flat mesh electrode (1 mm x 1 mm) made of brass. The outer and inner diameter of the hollow needle was 2 mm and 1.6 mm, respectively. The hollow needle-mesh spacing was 40 mm.

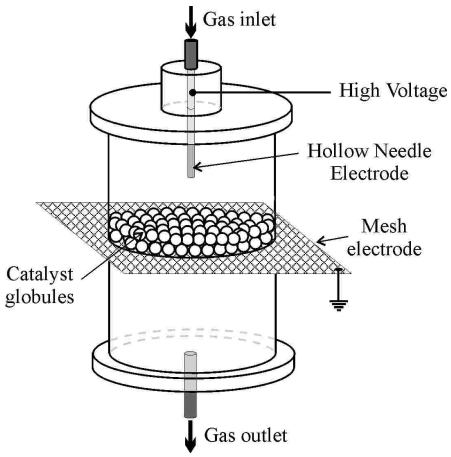

Fig. 1. The hybrid corona discharge-catalyst reactor.

The catalyst used in this investigation was a layer of V_2O_5 and TiO_2, as in the SCR processing, deposited on Al_2O_3 globules of 5-6 mm in diameter. The catalyst globules were placed on the mesh in the form of 2 layers. The hollow needle-catalyst spacing was about 30 mm.

The catalyst layer deposited on Al_2O_3 globules was used to play two roles. The first one, when a "pure" catalyst-covered globules were used, was the typical role of a catalyst. The another role, which is a new approach in this investigation, resulted from using the catalyst-covered globules as an adsorber of NH_3 before placing the globules into the reactor. We expected that the NH_3-saturated globules could become a gaseous NH_3 source in the reactor, when subjected to the corona discharge.

The positive polarity DC high voltage (15-38 kV) was applied through a 10 MΩ resistor to the hollow needle electrode. The time-averaged discharge current varied in the range of 50-200 μA.

A gas mixture of N_2(80%):O_2(5%):CO_2(15%):NO(200ppm), simulating a flue gas, was supplied through the hollow needle and then flowed through the reactor with a flow rate of 1 l/min.

When the performance of the reactor with the "pure" catalyst was investigated, gaseous NH_3 was first mixed with the N_2:O_2:CO_2:NO mixture, forming the working gas. Then the working gas was introduced through the hollow needle electrode into the reactor. The NH_3 concentration in the working gas was 400 ppm, which corresponds to a molar ratio of NH_3 to NO equal to 2:1 [7].

When the performance of the reactor with NH_3-saturated catalyst globules was tested, gaseous NH_3 (30 ppm) was introduced into the reactor, after mixing with the N_2:O_2:CO_2:NO mixture. This additional gaseous NH_3 was supposed to make up a loss of NH_3 released from the globules and sustain steady concentration of NH_3 in the reactor with a minimum slip in the outlet gas (at an NH_3 level of 1 ppm). As the concentration of NH_3 adsorbed on the globules layer was expected to decrease with elapsing time of the discharge operation, this part of the investigation had a time-dependent character.

Concentrations of NO, NO_2 and NH_3 in the working gas at the reactor inlet and outlet were measured by absorption spectroscopy method using a Perkin-Elmer 16 PC FTIR spectrophotometer.

The investigation of performance of the hybrid corona discharge-catalyst reactor for NO_x removal from the flue gas was carried out for the following cases:

a) without catalyst [without or with gaseous NH_3 (400 ppm) supply],
b) with NH_3-free catalyst [without or with gaseous NH_3 (400 ppm) supply],
c) with NH_3-saturated catalyst [without or with gaseous NH_3 (30 ppm) supply].

3. Results

Corona discharge processing without catalyst and gaseous NH_3 supply

The removal efficiency of NO from the working gas by processing it with the corona discharge without catalyst and NH_3 was no higher than 25 % (at 200 μA, 34 kV, Fig. 2). The processing was accompanied with production of NO_2 (up to 50 ppm). As a result, NO_x removal was not higher than 8 %.

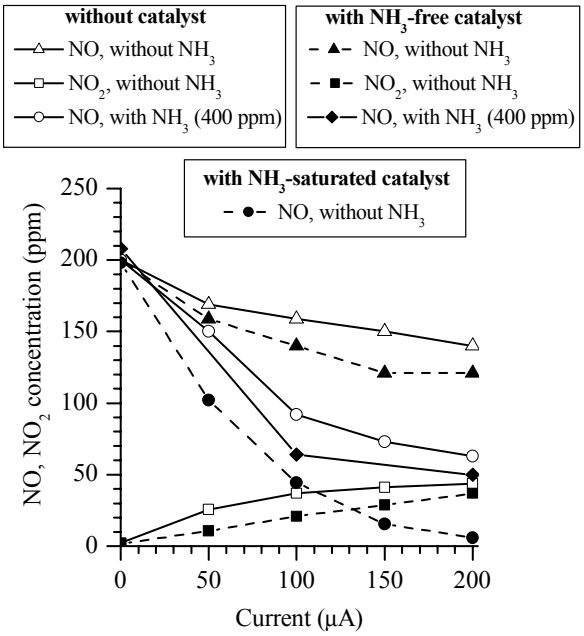

Fig. 2. Concentrations of NO and NO_2 in the working gas at the reactor outlet as a function of time-averaged corona discharge current. Cases: a) processing without catalyst [without or with gaseous NH_3 (400 ppm) supply], b) processing with NH_3-free catalyst [without or with gaseous NH_3 (400 ppm) supply], c) processing with NH_3-saturated catalyst [without gaseous NH_3 (30 ppm) supply].

Corona discharge processing without catalyst and with gaseous NH_3 (400 ppm) supply

NH_3 (400 ppm) added to the working gas increased NO removal to 66 % (at 200 μA, 31 kV) and resulted in the absence of NO_2 molecules in the outlet gas (Fig. 2). Deposits of white NH_4NO_3 solids, produced during the corona processing, could be found on the reactor wall and mesh electrode. Only a small fraction (about 15 %) of the introduced NH_3 was consumed during the corona discharge processing. This resulted in a high slip of NH_3. It seems that the initial concentration of NH_3 used in this experiment after [7] was too high.

Corona discharge processing with NH_3-free catalyst and without gaseous NH_3 supply

In the presence of the NH_3-free catalyst in the reactor, NO removal from the working gas without NH_3 was higher (about 40 % at 200 μA and 32.5 kV) than that without catalyst and NH_3 (Fig. 2). The NO removal was accompanied with NO_2 production, which is, however, lower than that without catalyst and NH_3. As a result, NO_x removal increased up to 25 %. The higher efficiency of NO removal in the presence of the catalyst seems to be caused by the lower concentration of NO_2 molecules, which easily reduce to NO.

Corona discharge processing with NH_3-free catalyst and gaseous NH_3 (400 ppm) supply

When 400 ppm of NH_3 was introduced into the reactor with NH_3-free catalyst globules, removal of NO and NO_x increased up to 75 % at 200 μA and 29 kV (Fig. 2). Like in the case without catalyst, NH_3 in the working gas caused absence of NO_2 in the outlet gas. Consumption of NH_3 in the

processing increased with increasing corona discharge current and reached 60 % at 200 μA and 29 kV.

Deposits of NH_4NO_3 solids were found on the catalyst globules and reactor wall. After 5 min. of processing, the number of NH_4NO_3 solid deposits on the catalyst surface was relatively low. The NH_4NO_3 solids had the form of irregular conglomerates (like incipient crystals), the size of which was approximately 5 μm. However, after longer time of the processing the catalyst surface became considerably deteriorated with NH_4NO_3 deposits, which resulted in a progressive decrease of NO removal. Eventually, the deteriorated catalyst surface stopped acting as a catalyst.

Corona discharge processing with NH_3-saturated catalyst without gaseous NH_3 supply

When the NH_3- saturated catalyst without any additional supply of gaseous NH_3 was used, removal of NO and NO_x increased to 96% (Fig. 2). NO_2 molecules were not present in the outlet gas, which, however, contained 2 ppm of NH_3. This NH_3 slip was formed by those NH_3 molecules, which released from the catalyst surface, were not consumed in reactions with NO, NO_2 and HNO_3.

The very high efficiency of NO (and NO_x) removal recorded in this case suggests that the surface reactions leading to NO (and NO_x) removal are very efficient when the interaction of the corona discharge with the NH_3-saturated catalyst takes place.

The NO removal efficiency of 96 % at a discharge power of 4.8 W resulted in the energy yield of 3.4 g NO/kWh. This is superior to the other cases tested in this experiment (Tab. 1). However, better results were obtained in other hybrid plasma-catalyst [12] and CRS systems [7].

Tab. 1. Parameters of NO_x removal processing in selected systems using corona discharge (CD) and ammonia.

System	Initial NO concentration	Flow rate	Specific energy	NO_x removal efficiency	Energy yield	Ref.
	[ppm]	[l/min]	[Wh/m^3]	[%]	[g NO/kWh]	
CD (wire-to-cylinder)	400	2	333	90	0.6	[4]
CD (wire-to-plate)	300	10,000	12	60	20	[5]
CD (needle-to-plate)	200	60	230	90	0.2	[9]
CRS	200	5	18	90	15	[7]
Hybrid CD-catalyst	430	2-6	8.3	75	21	[10]
Hybrid CD-catalyst	198	1314	2.5	60	55	[12]
Hybrid CD-catalyst	200	1	80	96	3.4	This work

The number and shape of NH_4NO_3 solids deposited on the catalyst surface were similar to those of the case of NH_3-free catalyst and gaseous NH_3 supply.

After some time, the NH_3-saturated catalyst started to loose its properties due to either NH_3 depletion on the catalyst surface or deterioration of the catalyst surface by NH_4NO_3 solids. This was investigated in the following experiment.

Temporal performance of the hybrid reactor

Fig. 3 illustrates temporal performance of the hybrid reactor for the cases listed in Chapter 2. In all the cases the discharge current was fixed at 100 μA.

As expected, NO concentration at the reactor outlet remained constant when the corona discharge processing was carried out either without catalyst or with NH_3-free catalyst without gaseous NH_3 supply.

When the NH_3-saturated catalyst without gaseous NH_4 supply was used, NO (and NO_x) removal efficiency was relatively high (78% at a discharge current of 100 μA) and remained constant over the

first 20 hours. After that time, the NH_3-saturated catalyst started to loose its activity and NO removal efficiency decreased. After the next 10 hours, the NO removal efficiency remained steady at a level corresponding to the corona discharge processing without catalyst but with gaseous NH_4 (400 ppm) supply.

When the corona discharge processing was performed in the presence of NH_3-saturated catalyst with gaseous NH_3 (30 ppm) supply, NO removal efficiency was equal to that without gaseous NH_4 supply (78%) but it remained constant longer (during about 30 hours). After that time the catalyst lost its activity. As a result, NO removal efficiency started to decrease and NO concentration increased during the next 20 hours until it leveled at a concentration typical of the processing without catalyst but with gaseous NH_3 (400 ppm) supply. After leveling at a time of 50 hours, the performance of the hybrid reactor became unchanged over the next 20 hours.

The significant changes of the catalyst surface due to NH_4NO_3 deposits after 67-hour corona discharge processing were revealed by scanning electron microscopy (SEM) imaging. The catalyst surface exposed to the corona discharge was almost completely covered with NH_4NO_3 solids, which formed relatively large crystals.

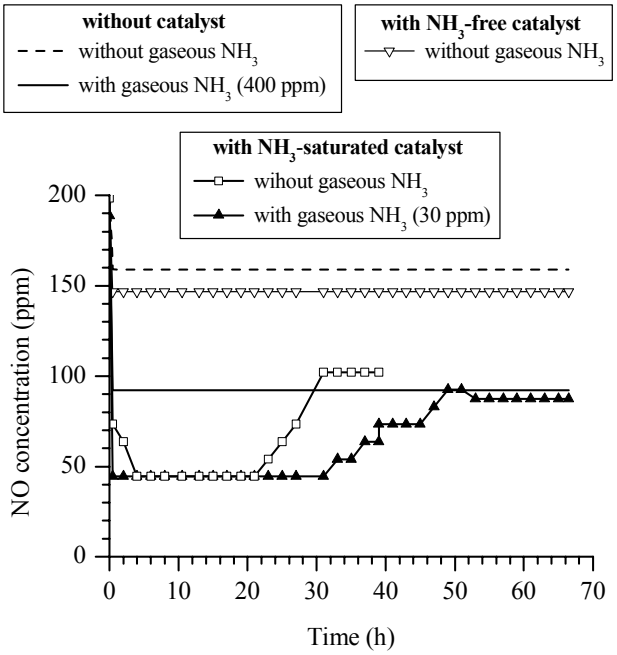

Fig. 3. Time dependence of NO concentration in the working gas at the reactor outlet. Corona discharge current 100 μA. Cases: a) processing without catalyst [without or with gaseous NH_3 (400 ppm) supply], b) processing with NH_3-free catalyst [without gaseous NH_3 (400 ppm) supply], c) processing with NH_3-saturated catalyst [without or with gaseous NH_3 (30 ppm) supply].

Taking the above into consideration, we conclude that the NH_3-saturated catalyst (without or with gaseous NH_4 supply) lost its activity not due to releasing NH_4 from its surface but due to NH_4NO_3 deposits. The surface-deteriorated catalyst still was able to release NH_3 molecules enough to remove NO molecules on a level typical of processing with gaseous NH_3 (400 ppm) supply.

From the weight balance analysis of the NH_3 and NH_4NO_3, we found that only a small fraction of NO and NO_2 was transformed into NH_4NO_3. This may mean that considerable part of NO and NO_2 molecules was decomposed to N_2 and H_2O, which is mostly desired.

4. Summary and conclusions

In this paper results of investigation of the performance of a hybrid corona discharge-catalyst reactor to be used for NO_x removal from the flue gases are presented. The catalyst was a layer of V_2O_5 and TiO_2 deposited on Al_2O_3 globules. The gas mixture, which simulated a flue gas, was

N_2(80%):O_2(5%):CO_2(15%):NO(200ppm). The corona discharge processing of the gas mixture was carried out: without catalyst, with NH_3-free catalyst, and with NH_3-saturated catalyst, all either without or with gaseous NH_3 supply.

The investigation showed that:

- The catalyst increased significantly NO_x removal efficiency. The highest NO_x removal efficiency (96 % at a corona discharge current of 200 μA and operating voltage of 24 kV) was observed when NH_3-saturated catalyst was used [without or with gaseous NH_3 (30 ppm) supply];
- In the presence of NH_3, the corona discharge produced solid particles of NH_4NO_3 which depositing on the catalyst surface shortened the active life of the catalyst (due to poisoning of the catalyst). The life-time of the catalyst due to its poisoning was about 30 hours;
- NO_x removal energy yield in the presented hybrid reactor with NH_3-saturated catalyst without or with gaseous NH_3 (30 ppm) supply was up to 3.4 g/kWh (at 96 % of NO_x removal) compared to 1.8 g/kWh in the "pure" corona discharge processing with gaseous NH_3 (400 ppm) supply;
- The hybrid reactor with NH_3-saturated catalyst operated efficiently over 30 hours without additional gaseous NH_3 supply.

The obtained results showed that the proposed hybrid reactor consisted of the corona discharge and NH_3-saturated catalyst is attractive for NO_x removal and may be alternative to other non-thermal plasma methods used for NO_x removal. The processes which occur when the corona discharge interacts with NH_3-saturated catalyst are not known and need further investigation to improve the performance of the reactor.

Abstract

The first steps in the development of a new method to interpret enthalpy probe measurements in supersonic plasma jets is presented. This method relies on a special post-shock probe which allows measurement of the (unknown) static pressure downstream of the shock induced by the probe. Conservation equations are used to infer the jet parameters in two steps: backwards from stagnation to post-shock, and then to free stream. The assumptions of this new method are less restrictive than previous ones. The new method will also allow for inclusion of non-LTE effects. Comparison with previous approaches shows the improved accuracy of the described technique.

1. Introduction

Low Pressure Plasma Spraying (LPPS) processes, using plasma torches operated at reduced pressure, have emerged as reliable technologies with broad industrial successes for the deposition of numerous coatings [1]. However, the majority of advances in LPPS have been made by empirical means and have reached their limit [2]. To further improve the control and quality of the processes, and to develop new applications, a more quantitative approach is required in which the fundamental physics of the process should be investigated. In particular, the phenomena controlling the expanding plasma jet should be studied both experimentally and by numerical simulations. This requires the knowledge of key parameters such as the temperature, pressure, chemical composition, velocity or local heat flux.

To measure these parameters, the enthalpy probe measurement technique has been extensively applied in Atmospheric Plasma Spraying (APS) jets assuming Local Thermodynamic Equilibrium (LTE) and incompressible flow [3]. However, the latter is not valid in low-pressure plasma jets and the formation of a normal shock wave (NSW) in front of the probe must be accounted for. Although specific technological constraints (low gas density) have been recently overcome [4], there are still severe conceptual complications in the use of enthalpy probes for low-pressure plasma jets.

First, the Pitot tube technique commonly used for the determination of the flow velocity cannot be directly applied because these jets are usually not in aerodynamic equilibrium with the surrounding atmosphere [5]. This means that the free stream local static pressure (P_1) can differ strongly from the chamber pressure. Erroneous results are obtained if the latter is used to approximate P_1 [4, 6], which is not directly accessible by measurement. A second complication comes from the required assumptions about the stagnation process that have been made in order to infer the free-stream jet properties from the quantities measured downstream of the shock [7]. Third, the low collisionality and high velocity of these flows can lead to deviations from LTE, which cannot be accounted for with the usual approaches [4, 6, 7].

In a previous attempt to solve the aerodynamic non-equilibrium problem, P_1 has been determined from numerical simulations of the plasma flow, which were then back-validated by the enthalpy probe results [8]. This approach, although valid, is complex and inconvenient to use.

The new enthalpy probe measurement approach presented here improves the accuracy of the technique by introducing a new way to deal with and interpret the data provided by the probe. It does not require the knowledge of the jet static pressure P_1, which is a major advantage over existing methods. It is also less restrictive in the assumptions used and can be modified to include non-LTE effects. As before, the stagnation pressure and enthalpy (P_{02} and h_{02}) behind the NSW induced by the probe are measured and used to compute the flow properties of the free plasma jet in front of the NSW (P_1, T_1, M_1, V_1). To achieve that,

the jet static pressure behind the NSW (P_2) is required and a special post-shock static pressure probe (PSSPP) is developed and used as presented in the next section.
The experimental technique is described in section 3. In section 4, our new approach is demonstrated for the interpretation of enthalpy probe measurements performed on an argon plasma jet at 10 mbar. These results are discussed and compared with those obtained by previous approaches [4, 6 - 8].

2. Description of the method

The deceleration of the free supersonic plasma jet towards the enthalpy probe can be seen as two separate evolutions (figure 1). The first evolution, from state (1) to state (2), represents the strong deceleration from the free stream conditions (1) to the post-shock conditions (2) through the NSW present in front of the enthalpy probe. The second evolution, from state (2) to state (02), represents the deceleration of the flow after the NSW to the stagnation condition in the probe. The proposed method consists of solving the governing flow equations for the two evolutions, starting backward from (02) to (2) and then from (2) to (1). The required data are obtained from the enthalpy probe (P_{02} *and* h_{02}) and the post-shock static pressure probe (P_2) described below.

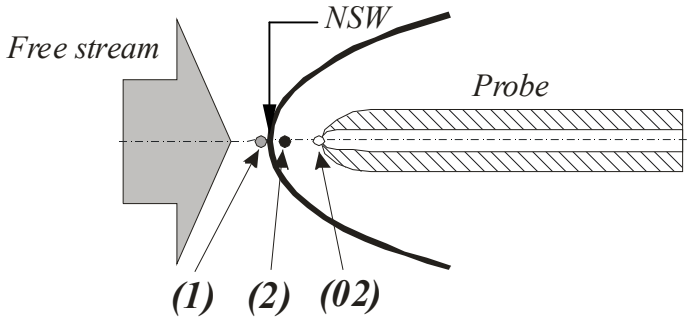

Figure 1 : Schematic representation of the free plasma jet deceleration by the probe.

Evolution (02) to (2)

Knowing from the enthalpy probe P_{02} and h_{02} and assuming that at stagnation the plasma is in local thermodynamic equilibrium (LTE), it is possible to find the plasma stagnation composition (ω_{Ar02}, ω_{Ar+02}, ω_{e02}), temperature (T_{02}) and entropy (s_{02}). Assuming that the flow is steady and reversible, the mass and energy conservation can be combined to give:

$$h_{02} = h_2 + \frac{V_2^2}{2}$$

In the same way the mass conservation and the second law can be combined to give:

$$s_{02} = s_2.$$

Assuming that the plasma is in LTE at location (2), and since s_2 (from the second law) and P_2 (from the post-shock static probe) are known, it is possible to find the plasma composition (ω_{ar2}, ω_{ar+2}, ω_{e2}), temperature (T_2) and enthalpy (h_2) behind the NSW [9, 10]. Using the energy equation, one can then find the velocity (V_2) behind the NSW. The flow properties are then all known at location (2).

Evolution (2) to (1)

The fundamental governing laws are again applied for this evolution and are expressed as:

$$\rho_1 V_1 = \rho_2 V_2 \quad \text{(mass conservation)}$$

$$p_1 + \rho_1 V_1^2 = p_2 + \rho_2 V_2^2 \quad \text{(momentum conservation)}$$

$$h_1 + \frac{V_1^2}{2} = h_2 + \frac{V_2^2}{2} \quad \text{(energy conservation)}$$

$$s_2 > s_1 \quad \text{(2nd law of Thermodynamics)}$$

This system of equation is closed with a state equation, $s=s(P,T)$. Due to strong non-linearity, a graphical Fanno-Rayleigh line solution method [11] was preferred to a classical iterative one. A general representation of the Fanno and Rayleigh lines is presented in figure 2. The Fanno line represents solutions to the mass, energy and state equations on a Mollier (enthalpy *vs* entropy) diagram. The Rayleigh line represents solutions to the mass, momentum and state equation on the same diagram. The flow going through the NSW must obey all three mass, momentum and energy conservation equations as well as the state equation. Therefore, the solutions ((1) and (2)) of the system must lie on the intersections of the Fanno and the Rayleigh lines.

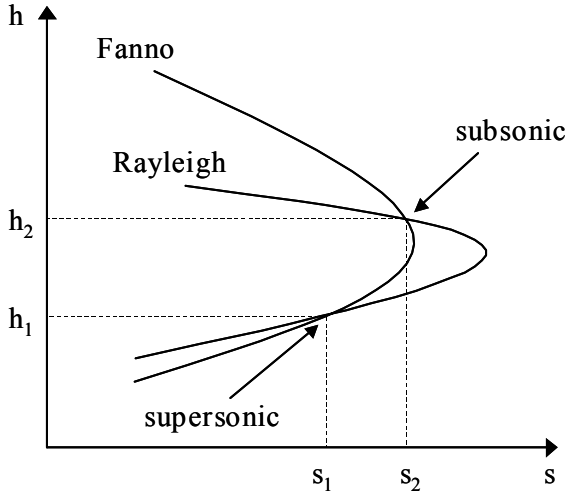

Figure 2 : General representation of the Fanno and Rayleigh lines on a Mollier diagram.

As shown, two (*h,s*) combinations lie on both lines. To determine which is condition (1) and which is condition (2), the second law of Thermodynamics is used : s_2 should be larger than s_1. Therefore it becomes clear that the intersection of the Fanno and Rayleigh lines at the smallest entropy value represents the flow at location (1). The flow properties at location (1) are then found by reading the Mollier diagram.

3. Experimental

The plasma jet under investigation is produced by a Sulzer Metco F4-VB gun operated in a vacuum chamber. The operation conditions are 40 SLPM of pure argon flow with a 400 A current. For the 10 mbar chamber pressure used here the plasma jet flow is under-expanded, as shown in figure 3. Further details about the experimental set-up and phenomenology of under-expanded plasma flows are described elsewhere [5, 8]. The enthalpy probe system, described in more detail in [4], is a specially designed version [12], which allows measurements down to a pressure of 2 mbar. Two different types of probe tips are used in the present study. The first type is a usual, water-cooled, stainless steel Pitot tube (3.2/0.8 mm external/internal diameter, see Fig. 4a). The second type is a specially designed graphite appendice, the Post-shock static pressure probe (PSSPP), which is plugged in the orifice of a probe (Fig 4b). The first probe allows measurement of the stagnation quantities P_{02} and h_{02}. The second one is equipped with a 0.5 mm diameter static pressure tap that allows measurement of the static pressure behind the NSW (P_2) using the enthalpy probe system (Fig 4c).

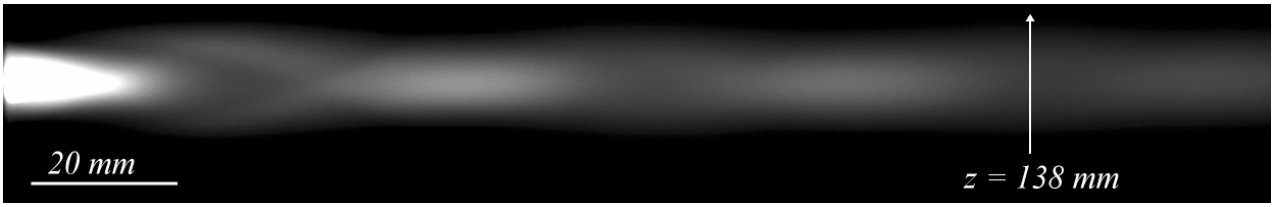

Figure 3 : Image of the investigated plasma jet (400A, 40 SLPM Ar, 10 mbar). "z =138 mm" indicates the axial position of the probe measurements presented below.

The design of the PSSPP is made as follows: First the profile and angle of the graphite probe have been determined in order to insure that the NSW-probe distance and the stagnation pressure are similar to those obtained with the enthalpy probe. This ensures that the PSSPP induces the same shock strength as the enthalpy probe. Second, numerical simulations of the flow around the PSSPP were conducted to get a mapping of the static pressure after the NSW. These simulations show that the static pressure behind the NSW (P_2), is recovered at a given location on the PSSPP surface, due to the flow re-acceleration. The pressure tap was then tuned to this location, obtained from the numerical simulations. Finally it was checked that P_2 obeys the condition : $0.6\ P_{02} < P_2 < P_{02}$, ensuring that the flow has undergone a NSW [11].

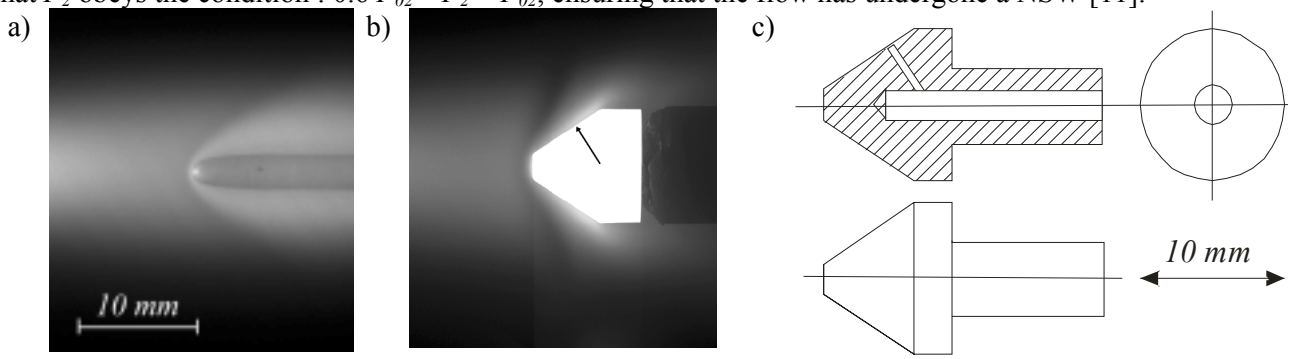

Figure 4 : Images of (a) the enthalpy probe tip and (b) one of the PSSPP developed for the p_2 measurement, both located on jet axis at 138 mm from nozzle exit. (c) shows a drawing of the PSSPP geometry with the pressure tap.

Measurements have been made at different locations in the plasma jet, and tuning of the PSSPP has been made with various shapes and pressure tap positions. The experimental error on the measured pressure is estimated to be within 2% of the measured value. For every measurement location an image of the probes has been acquired with a CCD camera equipped with a band-pass filter to reduce the bright emission from the heated PSSPP in favor of the emission from the plasma jet.

4. Results and discussion

The new approach is tested in the supersonic plasma jet described in the previous section and shown in Figure 3. Measurements are taken at the location z = 138 mm, shown on figure 3, for 5 radial positions, (r = 0, 2, 4 and 8 mm). The choice of this location is justified as follows: It is desired to test the new approach in a zone where the jet is not in aerodynamic equilibrium and where the static pressure changes radially. Such a region would allow testing of the sensitivity of the new probe. By looking at Figure 3, it is possible to deduce that the location z = 138 mm corresponds to the beginning of an expansion zone (where the pressure near the axis of the jet is higher than the chamber pressure) and that it well suits the requirements to test the method. Table 1 presents the raw data *(h_{02}, p_{02}* and *P_2)* as measured.

Table 1 : Raw data as measured, used in the new method

r (mm)	h_{o2} (kJ/kg)	p_{o2} (Pa)	p_2 (Pa)
0	9556	5941	3943
2	10982	5905	3731
4	8009	5752	3519
8	3236	4471	3085

The results of the new approach are then compared with the results obtained using the classic approach [4, 6, 7, 8]. Figure 5 presents a comparison of the static pressure (P_1), temperature (T_1) and velocity (V_1) profiles across the plasma jet as computed using both methods.

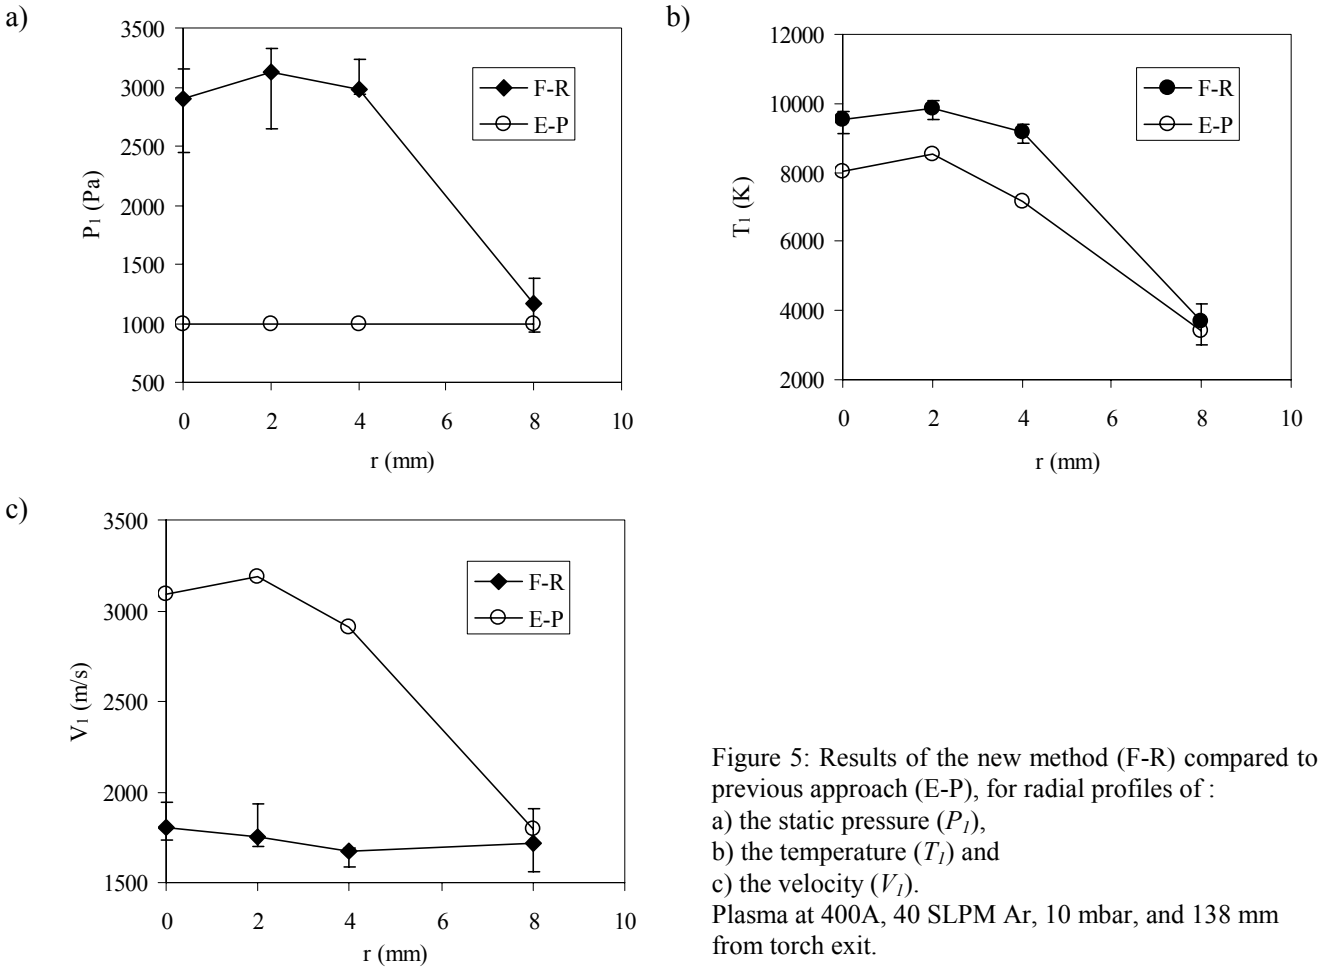

Figure 5: Results of the new method (F-R) compared to previous approach (E-P), for radial profiles of :
a) the static pressure (P_1),
b) the temperature (T_1) and
c) the velocity (V_1).
Plasma at 400A, 40 SLPM Ar, 10 mbar, and 138 mm from torch exit.

In figure 5a, the pressure distribution given by the new approach differs strongly from the one assumed by the classic method (chamber pressure). The new method predicts a higher static pressure than the chamber pressure on the axis, which was foreseen since this axial location is before full expansion (see Fig 3). It is well known that in an expansion zone, expansion waves reduce the jet static pressure radially from a maximum on the axis down to the level of the chamber pressure in the fringe of the jet. This behaviour is captured by the new approach since it predicts a pressure very close to the chamber pressure used in the classic method at the jet fringe where it is close to aerodynamic equilibrium.
The two temperature distributions have the same general trend (Fig 5b), showing a radial temperature drop. An important feature is that both methods predict the same temperature at r = 8mm, where both static pressures are identical. However, the new method gives a higher temperature in the core of the jet.
The two velocity profiles are very different as shown in figure 5c. The new method presents a relatively flat profile compared to the classic method which significantly overestimates the jet velocity on axis (a factor of 1.7 higher). This is due to the fact that the classic method underestimates the core jet static pressure. The flatter profile given by the new approach follows better the free jet boundary layer behaviour predicted by the jet boundary layer theory [13]. Again, the two methods give the same velocity at r = 8mm, due to the aerodynamic equilibrium at this location and provides a validation test case for the new method.

5. Conclusions

The first steps of a new approach have been presented to interpret enthalpy probe measurements performed in supersonic plasma jets which are not in aerodynamic equilibrium. This technique is based on the resolution of the fundamental governing flow equations throughout the NSW induced by the probe and towards stagnation. It uses the second law of Thermodynamics to include non-isentropic effects and relies on the measurement of the post shock static pressure using a specially developed probe. The advantages of

this new approach over previous ones are the less restrictive assumptions and the possibility to include non-LTE effects. In addition, the unknown static pressure of the free jet (usually wrongly approximated by the chamber pressure) is not required as an input, but is obtained as a result of the method.
This new technique has been tested and compared with previous approaches for the case of an under-expanded argon plasma jet produced by a DC plasma torch operated at 10 mbar. The results obtained, in terms of static pressure, temperature and velocity profiles, are consistent with the jet flow phenomenology. Moreover, agreement is found with previous methods at the fringe of the jet where non-aerodynamic equilibrium effects are negligible.
Work is underway to further improve the post-shock static pressure probe developed here, and will allow to extensively characterize the plasma jet flow topology. Inclusion of non-LTE is also foreseen.

The treatment of incineration wastes in a pilot-scale plasma reactor

A. Huczko, H. Lange, J. Golimowski

Department of Chemistry, University of Warsaw, Warsaw, Poland

Abstract
Different solid residues resulting from the incineration of municipal solid wastes (MSW) were processed in a pilot-scale /100 kW/ arc plasma reactor. Depending upon the specific energy of the processed material (within 0.8 ÷ 10.7 kWh / kg) the melting degree varied between 9.7 and 97.4 %

1. Introduction

Current regulations impose the stabilization of much of the wastes before dumping [1]. Containing significant amount of leachable heavy metals (i.e., Cd, Pb, Zn and Cr) and chlorine, the solid residues from MSW incineration are classified as toxic (fly ash) and noxious (bottom ash and slag) wastes [2]. Thus, many techniques hare been tried to neutralize them. Since the incineration has been commonly accepted as the only basic safe and reliable technique to process various wastes, the problem of further utilization, remediation, recycling and management of incineration residues is currently of high interest. One of a proposed solution is plasma processing [3] which profoundly changes the physical and chemical nature of these "wastes resulting which from wastes". As a matter of fact, there has been growing interest in the application of plasma techniques in environmental engineering recently [3]. While non-thermal plasmas (mostly corona discharge) have been tried to process gaseous reactants [4], the thermal plasmas (DC and RF) have been widely applied to process various solid and liquid wastes [5].
Earlier we reported [6,7] the results of a low-power thermal plasma processing of different solid residues resulting from the incineration of domestic waste. A DC plasma jet, RF plasma and a rotating arc ware tested and the highest melting degree was achieved using a high-volume, low-velocity conical and rotating plasma. Thus, in the present study a higher power rotating plasma was used to assess the economical validity of the process.

2. Experimental

A 100 kW plasma reactor, in which solid matter was caused to interact with a thermal plasma comprised spaced stationary electrode (graphite rods, 60 mm dia) structures. (Fig.1). An arc was established by a power supply between annular cathode and anodes (5) in a star-like configuration. The arc was caused to orbit at high angular velocity (15000 rpm) round the anode structure to form a conical plasma zone between the cathode and the anodes. It is worth mentioning that the thermal efficiency of this plasma system is very high since only the anode holders are water-cooled. Thus, practically all arc power is transformed into plasma enthalpy. Particulate solids were introduced through the feeding probe to enter the interelectrode zone and interact with the plasma therein. The arc could be circulated by electromagnetic force with the help of coils fitted outside the anode structure. Downstream of the plasma head is a reacting chamber and a bottom collector. The tests were carried out under atmospheric pressure and the flow of plasma gas (Ar) was equal to 1800 dcm^3/h.
The starting material to be plasma processed was the post-incineration solid waste from the Municipal Incinerator in Warsaw (Table 1).

Table 1. Particulate size characteristic of processed wastes

Origin	Granulation
Crushed slug	below 3 mm[a]
Bottom ash	below 1 mm[b]
Fly ash	below 0.060 mm[c]

[a]49 per cent of total [b]87 per cent of total [c]100 per cent of total

The solid products were collected and analyzed using different techniques: SEM, XRD, ICP-MS, and sieve analysis. The melting degree was evaluated, too.

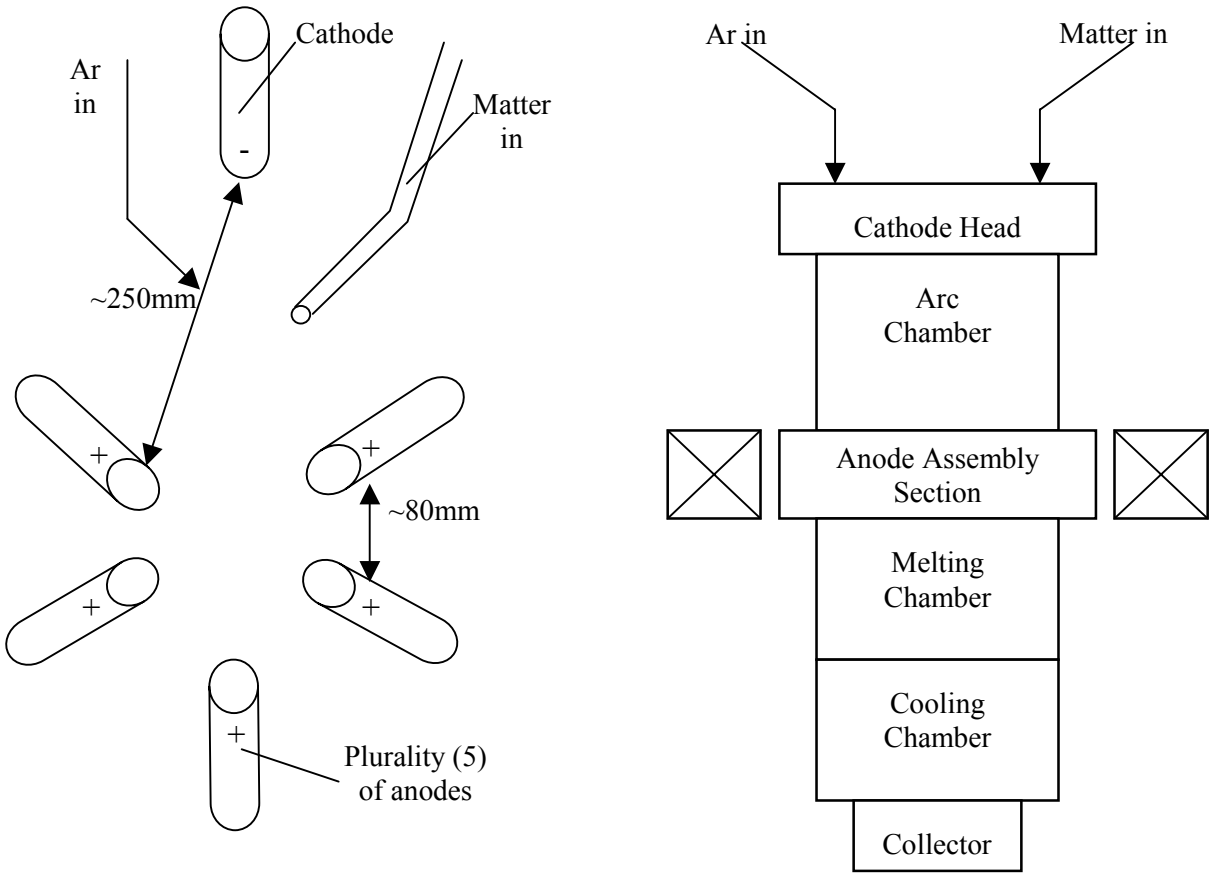

Fig.1. The scheme of the plasma reactor

3. Results and discussion

The operational parameters and the results of a plasma melting of different wastes shown are in Table 2.

Table 2. Operational parameters and results of plasma processing of incineration wastes

Run No	Processed Waste	Feeding Rate [kg/h]	I [A]	U [V]	Power [kW]	Energy Consumption [kWh / kg]	Melting Degree[a] [%]
1	Crushed slug	17.1	300	270	81	4.7	83.2
2	Crushed slug	51.6	320	300	96	1.9	38.2
3	Bottom ash	32.5	300	300	90	2.8	51.0
4	Bottom ash	94.7	250	300	75	0.8	9.7
5	Fly ash	13.6	450	325	145	10.7	97.4

[a]calculated from the mass and the sieve analysis of solid products

A high power of an arc plasma and a very low flow of plasma gas resulted in a high plasma temperature and a long reaction time. Consequently, the high melting degree of processed solids , close to 100 %, was obtained. Fig.2 shows the plasma melted incineration waste (fly ash).

Fig.2. Starting fly ash (left) and the plasma melted product (right)

Surprisingly, the size of the processed solid particulates does not seem to influence the melting efficiency. As it can seen from Fig.3 the specific energy of the processed matter defined as the arc power divided per feeding rate (see the energy consumption in Table 2.) is clearly the operational parameter characterizing the process efficiency.

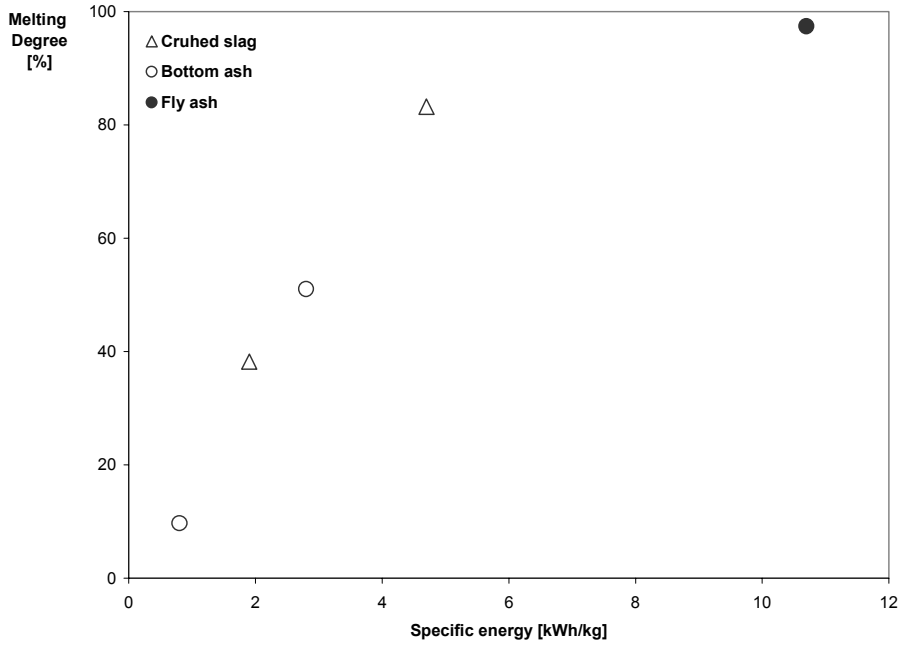

Fig.3. Melting efficiency of incineration residues vs. specific energy

It is also worth mentioning the relatively low energy consumption for the melting of wastes, much lower comparing to the tests in a laboratory-scale plasma systems [6,7].
The analysis are under way to evaluate the chemical transformation of wastes during plasma processing and, above all, the change in the leachability of heavy metals.

Plasma polymer adhesion and interfacial hydrolytic stability

R. Prikryl, V. Cech, L. Kripal, and J. Vanek

Institute of Materials Chemistry, Brno University of Technology
Purkynova 118, CZ-612 00 Brno, Czech Republic

Abstract

Adhesion of plasma-polymerized films on planar glass substrates has been tested using a micro-scratch tester and an optical polarizing microscopy. Plasma-polymerized films of vinyltriethoxysilane were deposited by helical coupling pulsed plasma system. Adhesion tests has revealed that the interfacial hydrolytic stability of plasma-polymerized films has been much better with respect to polycondensed films prepared from the same monomer by wet chemical process.

1. Introduction

Thin films are deposited on surface of various materials to change (increase or decrease) wettability, surface roughness, chemical functionality, and mechanical or electrical properties, which could be utilized for adhesive bonding, corrosion and scratch protection, and electronic applications. Films prepared from organosilicon monomers by wet-chemical processes (sol-gel) (e.g. silane coupling agents) are of good adhesion to glass substrates due to forming of siloxane bonds at the glass/film interface. However, the siloxane bond is hydrolytically unstable [1] and the film adhesion therefore decreases if water molecules diffuse to the interface, which results in splitting of chemical bonds. The siloxane bonds are only partially reformed upon removal of the water during the drying process. In industry, silane coupling agents are applied for surface modification of glass reinforcements (fibers, particles) in order to form a thin interlayer. Modified glass fibers or particles are used as reinforcements for polymer composites. The interlayer has to provide a strong and simultaneously tough bonding between the reinforcement and the polymer matrix. Degradation of a composite material due to the interfacial hydrolytic instability may result in worsening of its mechanical properties or even collapse of composite if it is used in humid or aqueous environment [2]. An improvement of interfacial hydrolytic stability in polymer composites enables an expansion of composite applications.

Plasma polymerization has been utilized for surface modification of fibers mainly since 1980s. Most studies were aimed at an improvement of surface properties of carbon, aramid and polyethylene fibers for advanced composites [3]. Thin layers of plasma polymer deposited on fibers result in an increase of composite strength and modulus [4,5]. The world market is dominated by glass reinforcements with appropriate mechanical properties and low costs. Organosilicones are potential compounds for successful surface modification of glass fibers and particles. Plasma polymer films prepared form organosilicon monomers may be of good adhesion to glass substrates due to strong siloxane bonds at the glass/film interface, which was formed in vacuum and so without occurrence of water molecules. Organosilicon monomers are very popular and often utilized for thin film deposition [6,7].

Of all the properties of a thin-film system, adhesion is one of the most important but difficult to measure. We can describe fundamental adhesion in terms of the energy per unit area needed to separate a thin film from its substrate. This energy is known as the work of adhesion. Practical adhesion refers to a thin film's ability to resist delamination in a practical setting, under stresses appropriate to the application [8]. Although there are no ways to directly measure the work of adhesion, there are a number of tests, which characterize adhesion practically. Three basic types of tests can be distinguished as follows: tensile-type adhesion tests, shear-type tests, and scratch tests [9]. Practically, hard films and coatings are easily characterized, as measured responses and delamination are more evident. Thin films deposited from organosilicon monomers belong among softer materials and adhesion measurements and their evaluations are more complicated [6]. Adhesion measurements of such softer films are the aim of this paper. Interfacial adhesion and its stability is compared for films prepared by plasma polymerization and wet-chemical process using the same monomer.

2. Experimental

2.1. Materials

Monomer for thin-film deposition was vinyltriethoxysilane $CH_2{=}CH{-}Si\ (-O-CH_2-CH_3)_3$ (VTES, ≥ 98% purity, Fluka). Glass substrates were special microscope slides without flaws (1.0×26×76 mm^3, refractive index n = 1.518, Knittel Glaser, Germany).

2.2. Plasma process

Plasma polymerized films of VTES were deposited on glass substrates using helical coupling plasma system (13.56 MHz); details on the apparatus have been described in Ref. 10. The deposition process is very important to control interfacial adhesion with high reproducibility. Vacuum system was evacuated to a pressure of 5×10^{-3} Pa and then flushed by argon gas (10 sccm) for 10 min. Glass substrate was placed into a side vacuum chamber and the chamber was evacuated by an independent vacuum system. Basic pressure of 2×10^{-3} Pa was established in the deposition chamber after flushing. Argon gas was again introduced (10 sccm) into deposition system. The glass substrate was placed into the deposition chamber using a manipulator and was cleaned by Ar plasma (continuous or pulsed plasma) for a given treatment time. Then the substrate was saved in the side chamber, the plasma was switched off, and argon gas was evacuated. Monomer vapor at a given mass flow rate was introduced into deposition chamber using a dose valve and then the plasma was ignited at a chosen power (pulsed plasma). When the pressure in deposition chamber was stabilized, the fresh substrate was placed into the chamber and thin film was deposited on its surface during a given time. Finally, the deposited specimen was saved in the side vacuum chamber, the deposition process was finished and all the apparatus was flushed by argon gas. After 30 min the side chamber was flooded by air up to the atmospheric pressure and the prepared specimen was conveyed from the side chamber into a desiccator to avoid contamination before measurements.

Pulsed plasma: The plasma was switched on (switched off) during the time denoted as t_{on} (t_{off}). Sum of them represents a period $P = t_{on} + t_{off}$. The effective power used for thin film deposition may be evaluated as follows: $W_{eff} = W_{total} \times (t_{on}/P)$, where W_{total} = 50 W.

2.3. Wet-chemical process

VTES monomer belongs among organofunctional silane coupling agents recommended for surface modification of glass fibers applied as reinforcements for unsaturated polyester resin. The silane molecule is a multifunctional one, which reacts at one end with the glass surface and at the other end with the polymer matrix. The ethoxy group ($-O-CH_2-CH_3$) represents a hydrolysable unit and so the silane is hydrolyzed to the corresponding silanol in the aqueous solution to which the glass substrate is exposed. These silanol molecules compete with water molecules to form hydrogen bonds with the hydroxyl groups bound to the glass surface. When the glass substrate is dried, the free water is driven off and condensation reactions then occur, both at the silanol/glass interface and between neighboring silanol molecules. The result is a polysiloxane layer bonded to the glass surface, presenting an array of vinyl groups ($CH_2{=}CH-$) to the environment.

Glass substrates were twice rinsed by fresh acetone in an ultrasonic bath for 10 min and dried at room temperature (cleaning procedure). 3 ml of VTES was hydrolyzed for 60 min in 100 ml of deionized water using a magnetic stirrer. The initial VTES concentration was about 3% by weight. The pH value of the solution was adjusted to about 4 by adding acetic acid. Aqueous solution was poured into a Petri dish where the cleaned substrates were placed. The dish was brought to a vacuum oven and the solution was concentrated at room temperature for 6 hr so that free water molecules were eliminated during the condensation process. Glass substrates coated by the polycondensed film (pc-VTES film) were removed from the Petri dish and were dried in a vacuum oven at 60 ^{o}C for next 20 min. Prepared samples were saved in a desiccator to avoid contamination before measurements.

2.4. Scratch test

Scratch testing is widely used to evaluate film adhesion since it can provide fast qualitative, semi quantitative, or quantitative information. The test consists of drawing a stylus (Rockwell ball or diamond tip) with known radius of curvature over a film under increasing normal (vertical) loads and the value of the load, at which adhesion failure (delamination between the film and the substrate) is detected, is known as the critical load, L_C. The acoustic emission signal and the tangential (friction) force are monitored as a function

of the progressively increased load. Scratch lines are also investigated by means of optical and scanning electron microscope to determine the critical load (normal force).

Soft polymeric films produce negligible acoustic emission during scratching and so the signal cannot be utilized for evaluation of the critical load. Special low-load micro-scratch tester has to be used for adhesion measurements of soft films. Such a micro-scratch tester was developed at the Institute of Materials Chemistry. A description of the instrument has been reported in Ref. 11. Three Rockwell diamond tips with an apex radius of 50, 90 and 120 μm worked with the apparatus. A special instrument arrangement enabled the normal load ranging from 20 mN to 10 N at the scratching speed ranging from 1 to 20 mm/min. Scratch lines were observed by an optical polarizing microscope (BX-P 50, Olympus) using a digital video camera.

3. Results and discussion

Aqueous solution of VTES monomer is frequently used for surface modification of glass fibers by glass manufactures. It is known that the silanol molecules tend towards self-condensation, forming siloxane oligomers, rather than complete bonding with the glass surface and so, there is only a low density of siloxane bonds at the glass/film interface [12]. Plasma treatment and plasma polymerization are processes that could improve interfacial adhesion in the examined system.

Plasma-polymerized vinyltriethoxysilane (pp-VTES) was deposited by a mass flow rate of 0.5 sccm and a corresponding pressure of 1 Pa. Pulsed plasma was maintained at a constant t_{on} = 1 ms. The effective power used was ranging from 0.05 to 25 W. So, a relatively low power was used in order to prepare tenacious material with low modulus (10^9 Pa), which is appropriate as the interlayer for polymer composites.

Thin polymer films deposited by plasma polymerization and wet-chemical process were characterized by scratch test under a loading rate of 500 mN/min and a scratch length of 5 mm. Every specimen was tested using four scratch lines and the critical load was determined as the mean value with standard deviation. All measured scratch lines are characteristic of the stylus reaching the substrate and then recovering due to pile-up of material, which is typical for soft materials and in contrast to hard films.

Typical scratch recordings and a corresponding microphoto of scratch lines in pp-VTES film are depicted in Fig. 1. The critical load, L_C, is marked out in the graph. We can distinguish three important levels of critical loading; L_{C0} corresponds to the beginning of visible path, L_{C1} denotes a level of the first local failure, and L_{C2} corresponds to the beginning of permanent failure.

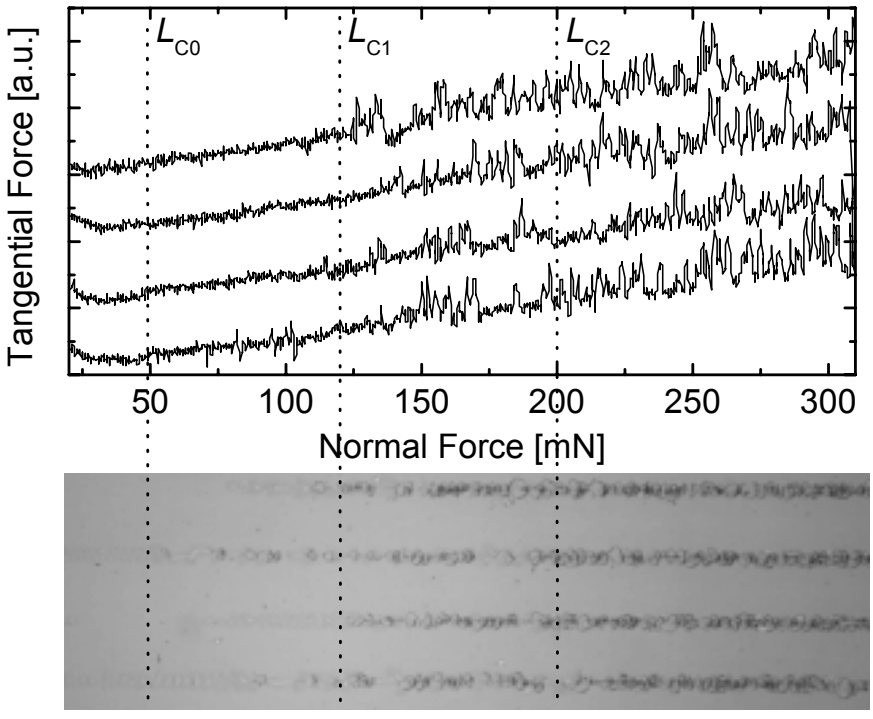

Fig. 1. Typical scratch recordings and a corresponding microphoto for pp-VTES film on glass substrate. Critical loads, L_c, are marked out in graph.

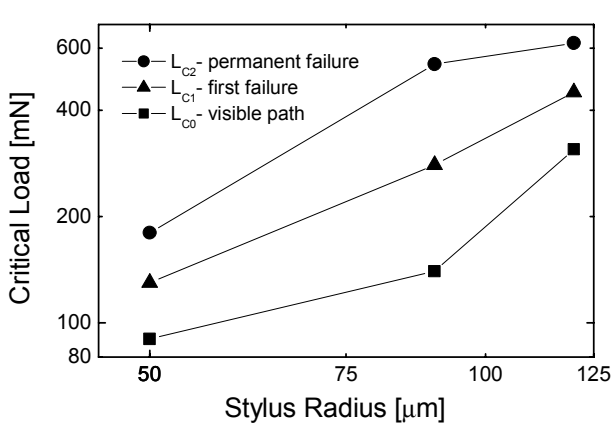

Fig. 2. Critical load versus stylus radius for three levels of film failure.

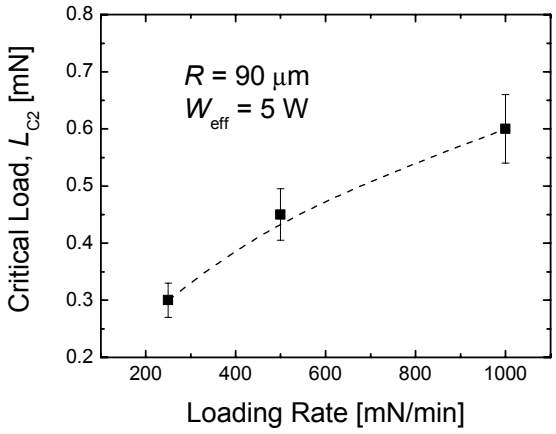

Fig. 3. An influence of the loading rate on critical load for pp-VTES film.

The glass/film interface was subjected to an impact of the stylus changing the stylus radius, R (50, 90 and 120 μm). The critical loads (L_{C0}, L_{C1}, and L_{C2}) versus the stylus radius for the same plasma-polymerized film are depicted in Fig. 2. A value of the critical load L_{C2} (permanent failure) is more reproducible than that of the first failure (L_{C1}) and therefore, we use L_{C2} as a measure of adhesion in next text. According to Ohring [9], theoretical analyses relating the critical load, stylus geometry and material parameters of the film lead to a relation $L_C \sim R^n$, where $n = 2$. Martinu found out that $1 < n < 2$ for hard films on polymer substrates [13]. The log-log scale in Fig. 2 enables to determine the degree $n = 1.48$ for the L_{C2} dependence. All our measurements confirmed results obtained by Martinu and $1 < n < 2$ is valid for the soft films (pp-VTES) on the glass substrates as well.

The critical load is intensely dependent on the loading rate as evidenced from the dependence in Fig. 3. The critical load increased twice with the loading rate ranging from 250 to 1000 mN/min. Changes in the critical load are a consequence of different response in visco-elastic behavior of the material. Obviously, we use a loading rate of 500 mN/min in our measurements.

Thin films of different thickness were deposited at the same deposition conditions using an effective power of 5 W. Critical loads evaluated from scratch recordings and scratch lines are plotted as a function of the film thickness in Fig. 4. The critical load corresponding to the film of thickness 190 nm is much higher than the remaining data, likely due to a lower internal stress in the film of lower thickness. Therefore, the critical load decreases with the increasing film thickness of pp-VTES films. This trend of the dependence was observed for oxide thin films by Ottermann *et al.* [14] as well. They found out that increasing the film stress the critical load decreased.

A set of pp-VTES films was prepared at different effective power using a constant t_{on} = 1 ms and changing t_{off} (1, 9, 99, 999 ms). Remaining process conditions (flow rate, pressure) were the same and all prepared films were of similar thickness about 1 μm. The critical load versus the effective power is shown in Fig. 5. One can see that adhesion slightly increases with the power. However, the reason of adhesion enhancement is not quite clear, as many film properties could be different (internal stress, film density and related Young's modulus and hardness) due to different growth conditions. For example, Ottermann *et al.* [14] observed that the critical load increased with increasing Young's modulus of the film.

Pp-VTES and pc-VTES films on glass substrates were subjected to scratch tests under dry and wet conditions to investigate hydrolytic stability of adhesion bonding at the glass/film interface. Pp-VTES films were deposited on untreated and Ar-plasma treated (10 min) glass substrates and pc-VTES films were prepared on acetone pretreated glass substrates, see Chapter 2. The film thickness of pp-films was about 1.2 μm and that of pc-films was about 7 μm. Thinner pc-films were inhomogeneous and not appropriate for scratch measurements, which gave results of bad reproducibility. Specimens stored in a desiccator were tested under dry (as prepared) and wet conditions. Wet conditions mean that specimens were dipped into distilled water at a temperature of 22 or 100 ^{o}C for a given time and after removing them they were dried at a temperature of 60 ^{o}C for 2 hr. Critical loads corresponding to specimens tested under dry and wet conditions are depicted in Fig. 6. All pp-VTES films on untreated glass substrates started to delaminate and were completely separated from the substrate during the wet test and so the critical load is assigned to be zero.

Adhesion of pc-VTES films did not change if the film was immersed into water (22 ^{o}C) for 1 hr but decreased by 45% after 21 hr (22 ^{o}C water) and 60% after 2 hr (100 ^{o}C water). The decrease of film adhesion is connected with a scission of siloxane bonds [1] at the glass/film interface. The diffusion of water molecules to the interface can be enhanced increasing the temperature and so the degradation process was accelerated using boiling water. Pp-VTES films on Ar-plasma pretreated glass substrates exhibited a higher adhesion with respect to the pc-VTES films and the interfacial hydrolytic stability of plasma-polymerized films was much better. Critical loads of pp-VTES films immersed in cold and boiling water did not change towards that obtained for dry conditions. The reasons could be a higher density of siloxane bonds at the glass/film interface and/or a higher crosslinking of plasma polymer and resulting lower diffusion rate of water molecules.

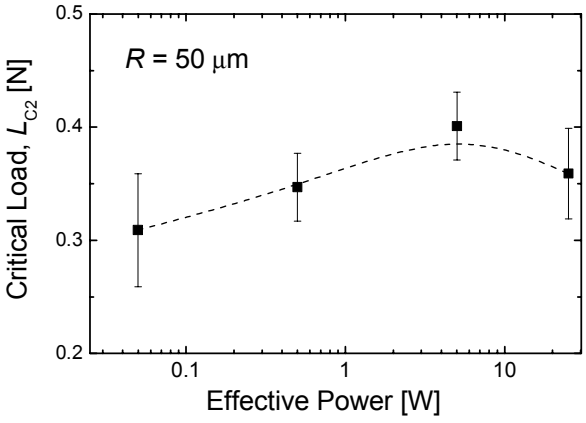

Fig. 5. Dependence of critical load on effective power for pp-VTES films.

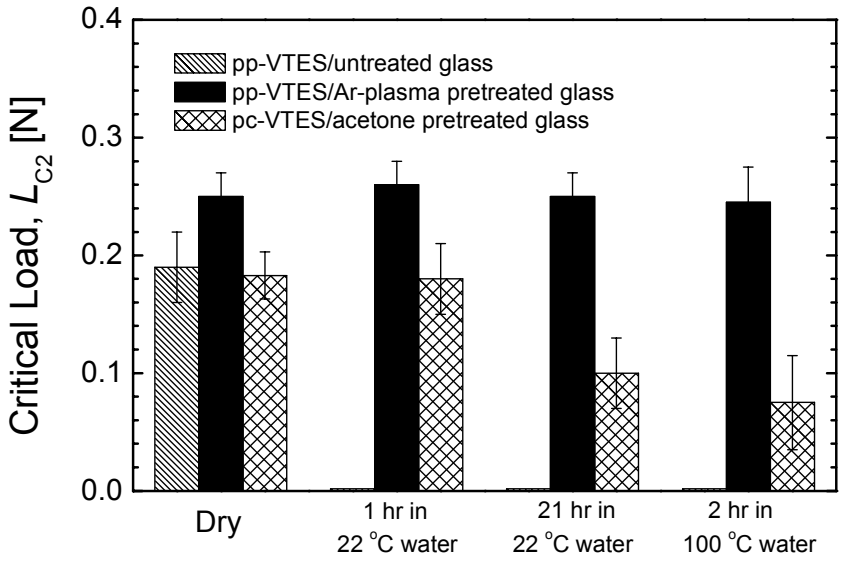

Fig. 6. Interfacial adhesion of plasma-polymerized and polycondensed films under dry and wet conditions.

4. Conclusion

Plasma-polymerized films of vinyltriethoxysilane were deposited on planar glass substrates using RF pulsed plasma. Polycondensed films were prepared on glass substrates using the same monomer. A micro-scratch tester and an optical polarizing microscopy enabled to analyze a scratch path together with normal and lateral force recordings. Our study has pointed out to an influence of the stylus radius and the loading rate on measured data. The critical load, L_C, increased with the increasing stylus radius according to a relation $L_C \sim R^n$ with the degree $1 < n < 2$. The loading rate has to be maintained constant so that we could compare scratch data, as the critical load is intensely dependent on the loading rate. Our results has confirmed that adhesion of thin films could be improved depositing films of lower thickness, probably due to a lower film stress. Plasma-polymerized and polycondensed films were tested under dry and wet conditions. While interfacial adhesion of polycondensed films immersed into cold and boiling water decreased with time, the adhesion of plasma-polymerized films was unvarying. Therefore, interfacial hydrolytic stability of plasma-polymerized films was very good, probably due to a higher density of siloxane bonds at the glass/film interface and/or a higher crosslinking of plasma polymer.

Abstract

Plasma-polymerized thin films of vinyltriethoxysilane have been prepared by plasma-enhanced chemical vapor deposition using an RF (13.56 MHz) helical coupling pulsed-plasma system. Thin films of the thickness ranging from 80 nm to 1.5 μm were subjected to nanoindentation measurements. The Young's modulus determined from the indentation load-displacement curve has increased with the effective power used from 4 GPa to 11 GPa. Thin films have exhibited an abrupt increase of the hardness at the film surface.

1. Introduction

Silane coupling agents (e.g. vinyltriethoxysilane) are utilized for surface modification of glass fibers, which are embedded in polymer matrix forming the fiber-reinforced polymer composite. The fibers are coated by thin film during a wet-chemical process (sol-gel) in order to prepare the interlayer (thin film) that forms a strong but tough link between the fiber and the polymer matrix. Recently, it has been found out that the interlayer seems to be the most important part in composite materials [1]. The interlayer properties (elastic modulus) can influence or even control performance of composite material, i.e. the composite strength and the composite toughness [2]. However, thin films of various moduli cannot be prepared from a given monomer using the wet-chemical process. What are the possibilities of plasma-enhanced chemical vapor deposition (PE CVD) using RF plasma?

In an effort to determine mechanical properties (elastic modulus, strength, hardness, internal stress, adhesion) of thin films a number of methods has been evolved [3]. However, different methods resulted in different values of mechanical parameters. For example, the elastic modulus of plasma-polymerized hexamethyldisiloxane (pp-HMDSO), calculated from internal stress measurements, was found to be of order 10^6 Pa, as it was published in 1980s. At present we know that such a value is unreal low. A rough estimation of the film modulus can be done using a two-layer or three-layer sandwich structure [4]. This simple method enabled an estimation of the elastic modulus to be 1 GPa for pp-HMDSO [5]. Similar values were obtained for pp-tetramethylsilane (2 GPa) [6], pp-tetraethylsilane (3 GPa) [6] and pp-dichloro- (methyl) phenylsilane (6 GPa) [4].

Nanoindentation is a modern technique, which is able to estimate modulus and hardness at the nano scale and so it is helpful for probing of sub-micron films. The aim of our study was to deposit plasma polymer films of vinyltriethoxysilane (VTES) under different RF power and to find out if the elastic modulus of film differs.

2. Experimental

Plasma-polymerized films were prepared by plasma-enhanced chemical vapor deposition (PE CVD) employing an RF (13.56 MHz) helical coupling pulsed-plasma system [7]. Vinyltriethoxysilane (VTES, purity ≥ 98%, Fluka) was used as a precursor with a vapor flow rate of 0.45 sccm, which corresponds to a process pressure of 2 Pa. Thin films were deposited on silicon (100) wafers pretreated by Ar plasma (10 sccm, 10 Pa, 25 W) for 10 min so that the activated surface could improve interfacial adhesion between the wafer and the film. Plasma-polymerized VTES (pp-VTES) was prepared at different effective power in a form of thin film of a thickness ranging form 80 nm to 1.5 μm. The effective power (W_{eff}) of pulsed plasma can be controlled by changing the ratio of the time when plasma is switched on (t_{on}) to the time when plasma

is switched off (t_{off}), $W_{eff} = W_{total} \times t_{on}/(t_{on} + t_{off})$, where W_{total} = 50 W. Plasma polymers were prepared at three (effective power) values of 0.05, 5.0 and 25 W with t_{on} = 1 ms. Employing a mechanical manipulator the pretreated silicon wafer was placed into the plasma zone after plasma reached the steady state monitored by mass spectroscopy. The film thickness was measured by a Profiler Talystep (Taylor-Hobson) and the mean deposition rate was determined as the film thickness divided by the deposition time.

The mechanical properties of the films were determined from load-displacements curves obtained using a Nanoscope III A (Veeco Instruments Inc). A three-sided pyramid Berkivich indenter was employed in our study. Measured data were obtained from one complete cycle of loading and unloading. The unloading data were then analyzed according to the equation

$$S = \frac{2}{\sqrt{\pi}} E_r \sqrt{A}, \tag{1}$$

where the experimentally measured stiffness (S) was determined as a slope ($S = dP/dh$, P is the applied force, h is the displacement) of the upper portion of the unloading curve. A is the projected area of the elastic contact and E_r is the reduced modulus defined through the equation

$$\frac{1}{E_r} = \frac{(1-\nu^2)}{E} + \frac{(1-\nu_i^2)}{E_i}, \tag{2}$$

where E and ν are Young's modulus and Poisson's ratio for the specimen and E_i and ν_i are the same parameters for the indenter with E_i = 1141 GPa and ν_i = 0.07 for the diamond indenter used. A description of the indentation procedure and the apparatus is reported in Ref. 8. The hardness is determined from measured data using the equation

$$H = \frac{P_{max}}{A}, \tag{3}$$

where P_{max} is a maximum of the applied force. Nine up to fifteen indentations were made on each sample into a penetration depth of 30% of the film thickness. The elastic modulus was estimated by averaging the values measured up to 10% of the film thickness, where the measurements are not influenced by substrate properties [9]. The Poisson's ratio, ν, used in (2) for all samples was 0.3.

3. Results and discussion

Deposition conditions and mechanical properties of pp-VTES films are summarized in Table 1. H_{max} denotes the maximum value of the hardness at the film surface and H_{bulk} is a bulk value of the hardness estimated as an average one of data obtained down from 20 nm of the film thickness.

Table 1. Deposition conditions and mechanical properties of pp-VTES films.

Effective power	Film thickness	Mean deposition rate	Young's modulus	Hardness [GPa]	
[W]	[nm]	[nm/min]	[GPa]	H_{max}	H_{bulk}
0.05	112	5	4.9	1.7	1.2
0.05	240	6	3.7	1.2	0.7
5.0	180	180	7.4	2.0	1.1
5.0	390	181	6.8	2.2	1.0
5.0	1480	148	6.6	2.1	1.1
25	80	107	11.3	2.5	2.1

Plasma polymers behaved almost as the true elastic material as it is evidenced from the load-displacement recording, see Fig. 1. Deformation of the film material induced by the indenter at the loading part of measured cycle is almost completely removed after unloading. So, there is practically no visual footprint of the indenter in the film after measuring cycle.

The only deposition parameter, the effective power, was changed at preparation of a set of samples. The Young's modulus of pp-VTES as a function of the effective power is depicted in Fig. 2. In spite of different

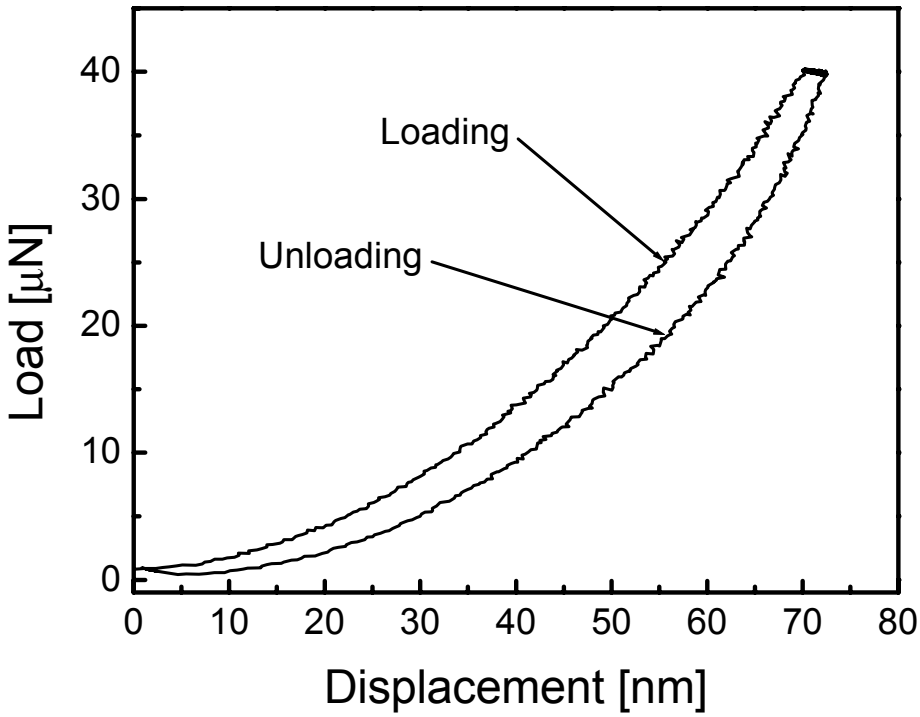

Fig. 1. Load (unload) versus indenter displacement for plasma-polymerized vinyltriethoxysilane (pp-VTES).

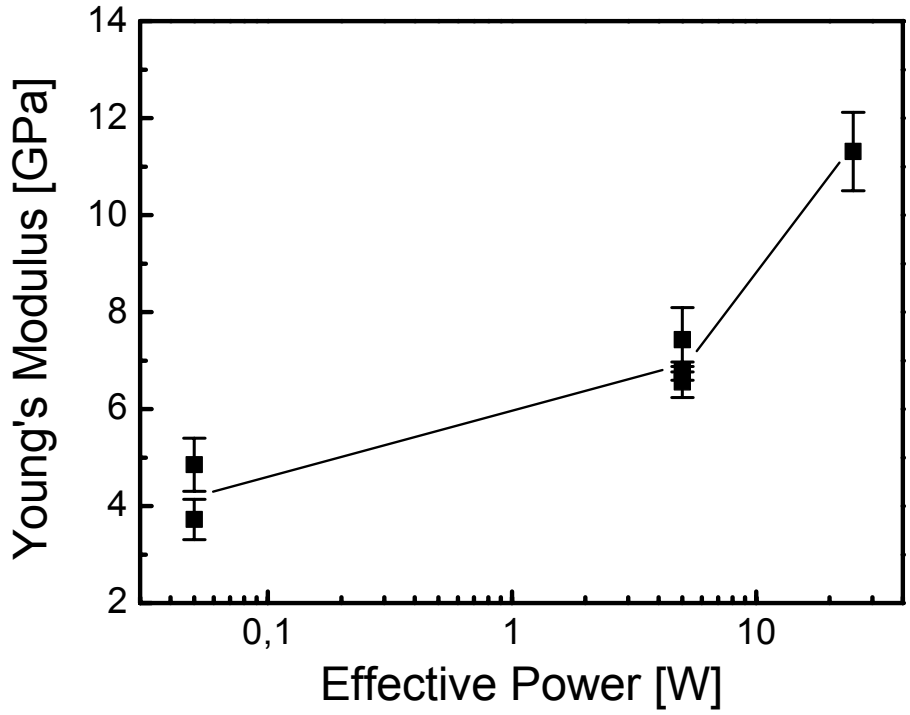

Fig. 2. Young's modulus of pp-VTES as a function of the effective power.

film thickness, it is evident that the modulus increases with the increasing power from about 4 GPa to 11 GPa. This change represents an enlargement of the modulus by 175%. It means that we are able to control film modulus very simply changing the effective power. Values of the modulus (pp-VTES) are relatively small with respect to those estimated for other amorphous hydrogenated films prepared by plasma techniques, i.e. hydrogenated silicon (a-Si:H, 60-100 GPa [10]), hydrogenated carbon (a-C:H, 40-145 GPa [10,11]), hydrogenated silicon carbide (a-SiC:H, 130-160 GPa [12]) hydrogenated silicon nitride (a-SiN:H, 140 GPa [13]) and hydrogenated silicon oxide (a-SiO_2:H, 85 GPa [13]). For a comparison, the modulus of silicon wafer is 170 GPa. Our films were prepared at relatively low power and the low plasma energy seems to be the reason of reduced modulus. Monomer molecules are more activated and fragmented forming higher density of free radicals if the plasma energy increases, and the reactive species result in a highly cross-linked polymer. A cross-linking of material may be supported by ion bombardment as well. It has been shown that the ion energy effectively enhances the film packing density [14].

We prepared thin films of different thickness purposely to investigate a variation of elastic modulus. There is the modulus dependent on the film thickness in Fig. 3. The Young's modulus slightly decreases with the film thickness for both sets of samples prepared at the different power. It is known that the kinetics of film growth changes during thin film deposition [6]. At the beginning of deposition process the film growth is very fast and decelerates with an increasing film thickness as a result of competition between the plasma polymerization and ablation processes. Therefore, a value of the mean deposition rate (determined as film thickness/deposition time ratio) is lower for thicker film as it is evident for the sample (1480 nm) in Table 1. A modulus descent with the film thickness could be a consequence of lower material compaction.

A dependence of the mean deposition rate on the effective power is not a trivial function, see Fig. 4. The kinetics of film growth changes with the effective power and can be faster for an optimal t_{on}/t_{off} ratio. The infrared spectroscopy did not reveal differences in chemical structure of films prepared at different power [15]. However, differences could be expected in microstructure of film material and the plasma polymer deposited at high deposition rate could be more porous. Porosity of films will be investigated in our next research.

Figure 5 shows a development of the hardness along the contact depth [8], which is the distance (from film surface) along which contact between the indenter and the film is made. Simply, there is the depth profile of the hardness in Fig. 5. One can see that the hardness decreases from the film surface (H_{max}) to the bulk value (H_{bulk}) within the range of 20-30 nm for most of samples. This phenomenon could be a consequence of post-deposition oxidation at the film surface. The surface layer of films stored in the open air can react with atmospheric humidity and the reaction results in oxygen incorporation into the polymer network. The oxygen is able to diffuse into the film material increasing the cross-linking of plasma polymer [16].

4. Conclusion

Plasma-enhanced chemical vapor deposition was used to prepare thin and ultrathin films of vinyltriethoxysilane employing an RF helical coupling pulsed-plasma system. Plasma-polymerized films of the thickness ranging from 80 nm to 1.5 μm were deposited on silicon substrates at a flow rate of 0.45 sccm, a process pressure of 2 Pa and an effective power ranging form 0.05 to 25 W. Prepared films were subjected to an investigation of mechanical properties using nanoindentation. It means that the elastic modulus and the hardness of plasma polymers were evaluated from the indentation load-displacement behavior of materials tested with a Berkovich indenter. Plasma polymers behaved almost as the true elastic material and the Young's modulus increased with the effective power from 4 GPa to 11 GPa. The relatively low values compared to similar material data published by other authors were explained as a result of low power used. The modulus of VTES films slightly decreased with the film thickness for the films prepared at the same deposition conditions. Nanoindentation measurements revealed an abrupt increase of the hardness at the film surface form about 1 GPa in bulk to 2 GPa at the film surface. Investigation of mechanical properties in context with preparation of thin film of controlled properties could enable progress in performance of composite materials.

Recent Development of Waste Treatment by Reactive Thermal Plasmas in Japan

Takayuki Watanabe

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Tokyo, Japan

Abstract
Attractive waste treatments by plasmas under atmospheric pressure have been proposed, because atmospheric pressure plasmas offer unique advantages. In this paper, the application for destruction of hazardous and waste materials, such as low-level radioactive waste, ion-exchange resin waste, and ozone-depleting substances, will be reviewed. Also selective separation mechanism by reactive thermal plasmas will be discussed for waste treatment.

1. Introduction

Attractive material processes by thermal plasmas have been proposed especially for waste treatments, because thermal plasmas offer unique advantages; these advantages include high enthalpy to enhance reaction kinetics, high chemical reactivity, oxidation and reduction atmospheres in accordance with required chemical reactions, and rapid quenching (10^6 K/s) to produce chemical non-equilibrium materials. However, thermal plasmas have been simply used as high temperature source. This indicates that thermal plasmas may have more capability for waste treatment, if thermal plasmas are utilized effectively as chemically reactive gas. In this paper, the application for destruction of hazardous and waste materials will be discussed. Melting and solidification of incineration ash by thermal plasmas will not be discussed in this paper, because these systems have been already commercially operated at several sites.

2. Low-Level Radioactive Waste Treatment

Low-level radioactive wastes (LLW) are generated from nuclear power plants and will be generated from decommissioning of nuclear power plants in future. In Japan, there are three facilities for volume reduction of LLW by thermal plasmas. Thermal plasma process offers attractive advantages for treatment of LLW because of high heat transfer rate from plasmas to wastes.

Two facilities of LLW treatment by thermal plasmas are being conducted at Tokai Research Establishment of Japan Atomic Energy Research Institute (JAERI). One is twin torch transferred arc system with the capacity of 4 tons/day, and another is induction thermal plasmas with induction melting furnace [1]. The melting furnace with induction thermal plasma torch is presented in Fig. 1. Three torches of induction plasmas (200 kW x 3) with an induction furnace up to 800 kW are used for melting and volume reduction for LLW. Capacity of LLW treatment is 4 tons/day. Compared with DC transferred and non-transferred arc, air and oxygen can be used as the plasma gas of induction thermal plasmas. Therefore, complete combustion of the waste can be achieved, resulting in stabilization of radionuclide.

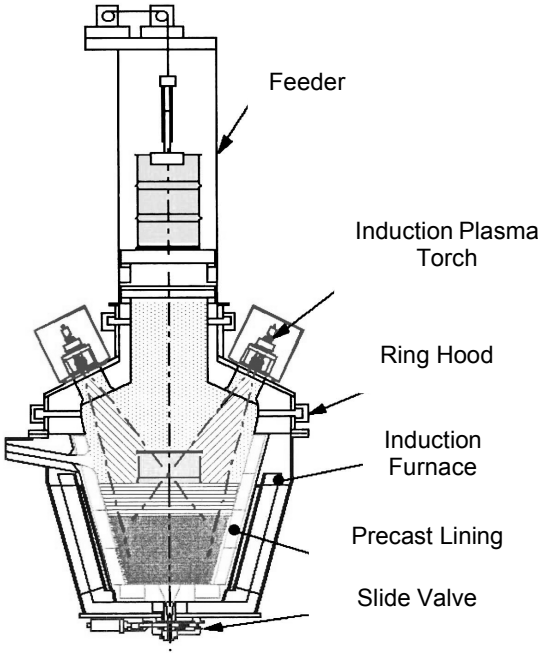

Fig. 1 Plasma – induction melting furnace [1].

The Japan Atomic Power Company (JAPC) has decided to construct LLW treatment facility by the Plasma Arc Centrifugal Treatment (PACT) system at the Tsuruga Power Station [2]. The PACT system with an 8 ft rotating hearth and 1.2 MW transferred arc torch was developed by Retech, Inc., USA. The treatment capacity for LLW is 600 kg/hr.

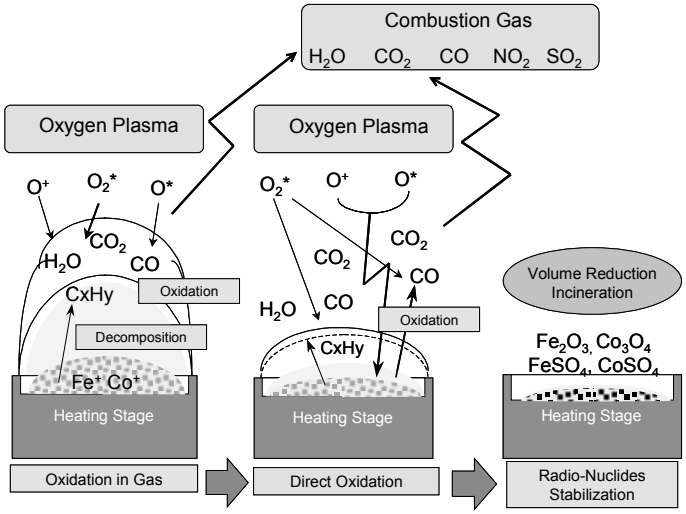

Fig. 2 Ion-exchange resin treatment mechanism by induction oxygen plasma generated at low pressure [4].

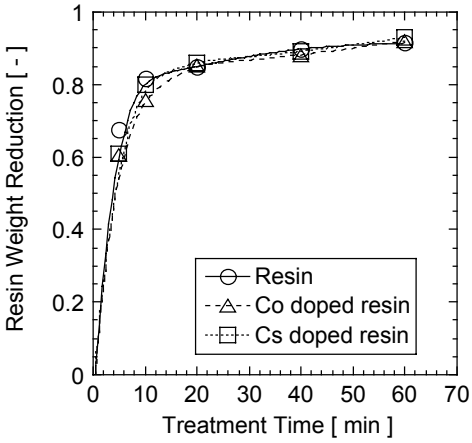

Fig. 3 Weight reduction of ion-exchange resin by thermal plasma treatment.

Radionuclide can be stabilized in the slag generated from the melted LLW by the thermal plasma treatment. Especially cesium entrapment in slag layer is important for LLW treatment. The effect of waste components on the vaporization behavior of Cs was investigated using simulated waste materials [3]. The vaporization rate of cesium increases with an increase in the slag basicities defined as (CaO+FeO+MgO) / (SiO_2+Al_2O_3). Entrapment of Cs into the slag can be enhanced by an increase in the content of Al_2O_3 or SiO_2 in the waste.

3. Treatment of Waste Ion-Exchange Resin

The amount of the waste ion-exchange resins adsorbing of radionuclide is increasing, therefore the effective method to reduce the volume of the waste is required. Fuji Electric Co. Ltd. developed volume reduction system for resin waste using low pressure plasma [4]. The concept of ion-exchange resin by an oxygen plasma is shown in Fig. 2. The process consists of two stages; the first stage is the low volume-reduction (1/4-1/5) by gas-phase plasma oxidation, and the second stage is the high volume-reduction (1/10-1/20) by direct oxidation on the ion-exchange resin. The reduction ratio achieved is 1/20 of the original volume at the treatment rate of 2 L/hr. The migration ratio of radionuclide in the exhaust gas generated in the process is below 10^{-6} under the pressure of 1-10 kPa..

The reactive thermal plasmas were also used to reduce the weight and volume of ion-exchange resins [5]. In the experiment, cation exchange resins (SKN-1) doped with Co and Cs were used as simulated waste resins. Oxygen or air used as reaction gas was injected in the downstream of the anode under atmospheric pressure. Figure 3 shows the weight reduction of waste resins by thermal plasma treatment. The weight was reduced to 80 % after 10 min treatment. After 40 min treatment, the weight was reduced to 95 %. Small difference in the weight reduction was found among the undoped resins and Co and Cs doped resins. XRD analysis indicates that Co in resins remains as CoO and Co_3O_4, while Cs in resins remains as Cs_2SO_4. Retention of Co after the treatment was approximately 100 %. Retention of Cs was approximately 100 % except for large flow rate of oxygen injection. Thermal plasma treatment provides the effective and rapid reduction in weight and volume of ion-exchange resins. The treatment has also good advantages for the stabilization of radionuclide.

4. Plasma Direct Melting Furnace

Waste treatment requires dioxin destruction, landfill-site life extension, material recycling and effective use of waste heat from high-temperature off-gas. A system of gasification of waste with ash melting should meet those requirements. A plasma direct melting furnace for waste gasification was developed by Hitachi Metals, Ltd [6]. Figure 4 shows the pilot-scale of 24 tons/day for municipal solid waste by thermal decomposition and melting using a vertical shaft furnace. This system meets environmental requirements for slag recycling and dioxin destruction. The advantage of this system is smooth and continuous extraction of melted waste with quick starting-up. In this system, crushing, drying and other waste pretreatment are not

necessary. The melting section of the furnace maintains at 1,500-1,700°C through the injection of a flame from a plasma torch. The condition of the plasma torch can be controlled to respond the fluctuations in the waste quality, and the coke bed maintains a high temperature in the melting section, enabling stable operation.

The plasma torch consists of a closely spaced pair of tubular water-cooled electrodes. The generated arc discharge is magnetically rotated at extremely high speeds. During operation, a process gas is injected into the heater through a space between the electrodes.

5. Selective Separation by Reactive Plasmas for Waste Treatment

Plasma enhanced vaporization is well-known method for production of ultrafine particles of metal. The plasma-enhanced vaporization can be applied to the selective separation for waste treatment. Hydrogen in arc plasmas enhances the vaporization of particular metals on the anode. In Si-Ti system, the vaporization rate of Ti is enhanced selectively by hydrogen in the arc [7]. An increase in H_2 concentration in the arc leads to an increase in Ti fraction in the prepared particles.

The dissociated hydrogen in arc plasmas enables the dissolution of a large amount of hydrogen into molten metals as well as the generation of metal vapor from the molten metals. The vaporization enhancement is attributed to the following four factors; recombination of hydrogen atoms in molten metals; high thermal conductivity of hydrogen; formation of intermediate products such as hydride; activity modification by hydrogen in molten metals. The first and second factors have small effect on the vaporization enhancement, therefore the third and/or fourth factors were considered to be the main factors. However hydride produced from molten metals with hydrogen arcs has not been identified yet. Instability and unknown properties of hydride give rise to difficulty in the quantitative examination.

Investigation of reaction mechanism of molten metals with chlorine or fluorine in arc plasmas would lead to the alternative solution, because chloride and fluoride are more stable and their properties have been known compared with hydride. Arc plasma reactions with chlorine was investigated for the separation of particular elements from alloys since chlorine atoms react with particular elements to form chlorides that have high vapor pressures and are especially separated from alloys [8,9]. The components of the fumes produced by changing O_2 flow rate are shown in Fig. 5. The component using Ar plasmas is almost identical to the initial KOVAR alloy (Fe=53, Co=17, Ni=29 mass %). The concentration of Fe in the fumes is highest by Ar-Cl_2 and Ar-Cl_2-O_2 (0.25 NL/min) plasma treatments. The concentration of

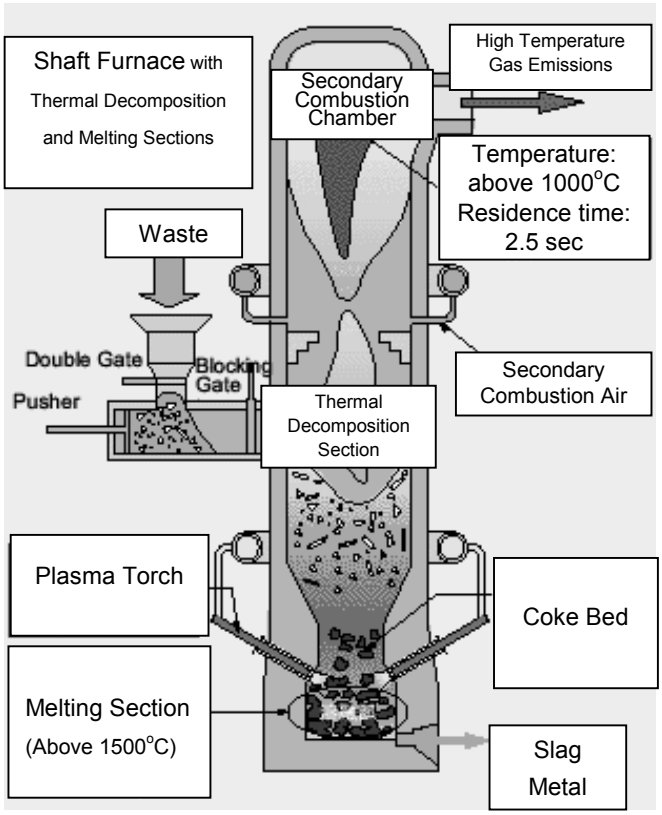

Fig. 4 Schematic diagram of plasma direct melting furnace for waste gasification [6].

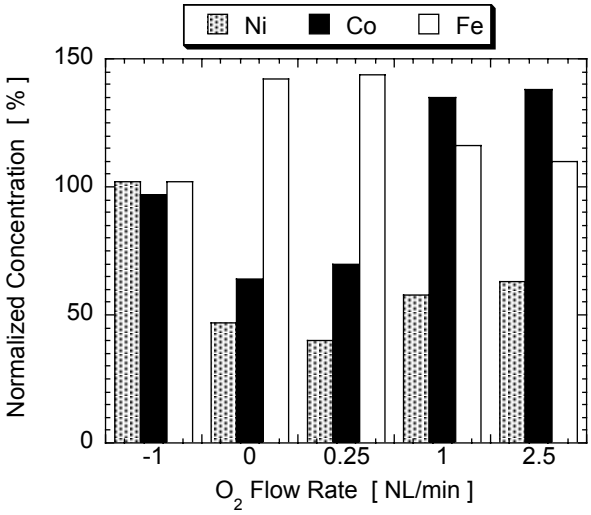

Fig. 5 Selective separation of particular elements from alloy by chlorine thermal plasma with oxygen addition.

Co increases with O_2 flow rate of the plasma gases, while the concentration of Ni using Ar-Cl_2 and Ar-Cl_2-O_2 plasmas is low since Ni compounds are difficult to vaporize. The reaction mechanism using these plasmas with Cl_2 and O_2 can be correlated to Gibbs free energy changes of chlorination and oxidation.

6. Plasma Decontamination

The highly effective decontamination process is required for the treatment of material generated from a decommissioned nuclear reactor as well as from the nuclear reprocessing plant and nuclear waste processing plant. Many wet processes for the decontamination have been proposed, but the wet process has the drawbacks due to the large volume production of secondary waste such as the contaminated solvent and ion-exchange resin. Therefore the plasma methods were proposed owing to the small secondary waste production. The decontamination researches have been carried out under the low pressure plasma conditions, however the low pressure condition is not favorable considering the practical application.

Decontamination process by microwave plasma under atmospheric pressure was developed for the removal of deposition of radionuclide on the surface of stainless steel [10]. The decontamination reaction is based on the formation of volatile compound such as fluoride produced by CF_4/O_2 plasma. Using the stainless steel sample prepared in water in autoclave simulated BWR condition, the surface oxide film was removed by irradiation of CF_4/O_2 plasma, resulting from the fluorination of the oxide.

7. Fly Ash Detoxification

Incineration of municipal waste generates incineration ash and fly ash. Induction thermal plasma system for fly ash treatment was proposed to recover the useful metals and materials from fly ash generating from melting furnace [11,12]. Fly ash fed into the induction thermal plasma was completely vaporized and decomposed during thermal plasma process.

After thermal plasma treatment of fly ash, the components were recovered separately owing to the difference of each condensation temperature. The H_2 injection into the induction thermal plasma strongly influences the difference of each condensation temperature, especially Zn compounds. The atomic fractions of the heavy metals of Zn and Pb included in the recovered materials increase under 800°C with Ar-H_2 plasma treatment, as shown in Fig. 6. More amounts of heavy metals than initial fly ash are included in the materials recovered at lower temperature. On the other hand, the materials recovered at higher temperature are detoxified because they contain extremely less heavy metal components than in initial fly ash.

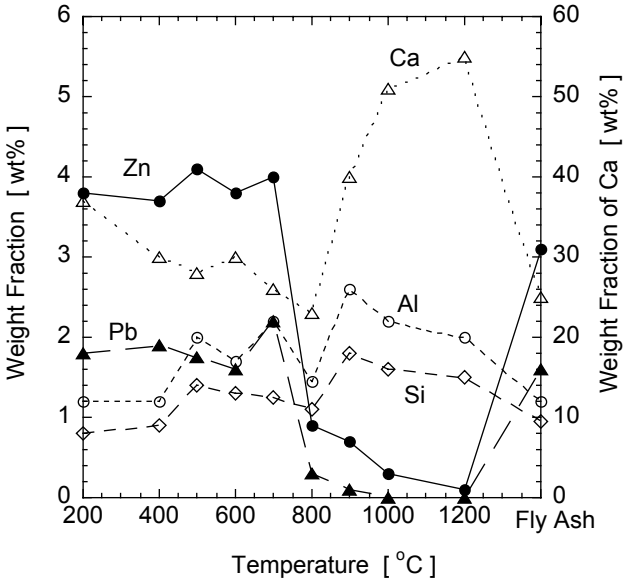

Fig. 6 Recovered materials with changing of the temperature after induction Ar-H_2 plasma treatment.

8. CFC and Halon Destruction

The destruction of ozone-depleting substances (ODS) such as chlorofluorocarbons (CFCs) and halons was developed by using steam thermal plasmas. The use of steam as oxidizing gas has the advantage for the destruction of CFCs and halons. Steam plasmas are successfully utilized to decompose ODS. In Japan, there are two commercial facilities for ODS decomposition by induction thermal plasmas with 100%-steam. The total system for ODS decomposition is shown in Fig. 7. In the first facility, a 200 kW plant under reduced pressure is operated by the Clean Japan Center [13]. ODS fed into a 100%-steam plasma are completely decomposed and converted to CO_2 and hydrogen halides. The feeding rate for CFC-12 and halon 1301 is more than 50 kg/hr under the pressure at 26 kPa. The second facility in Japan, ODS has been decomposed by atmospheric pressure induction plasmas. The second system has important technology for waste treatment;

generation of 100%-steam plasma under atmospheric pressure at 70-90 kW with the steam feeding rate at 14-20 kg/hr. The treatment capacity for CFCs is 30-40 kg/hr.

The small commercial facilities for CFCs decomposition were developed by Mitsubishi Heavy Industries [14]. The CFCs are decomposed by a 100%-stream microwave plasma. In the plasma, The CFCs are injected into the plasma at the concentration of 23-33 vol% under atmospheric pressure. The treatment capacity is 2 kg/hr at the power of 1.8 kW for CFC-12, 1.4 kg/hr at 2.0 kW for HCFC22, 1.5 kg/hr at 2.0 kW for HFC134a. Besides, the destruction of ODS by DC plasmas have been already operated at several sites in Japan. An Ar plasma jet is generated with the injection of oxidizing gas such as steam and oxygen to suppress the formation of soot [15,16]

Treatment of exhaust gas after the decomposition of CFCs and halons is the major concern, because the exhaust gas contains toxic and corrosive gas such as fluorine, chlorine, bromine, fluorohydride, chlorohydride and bromohydryde. In the above-mentioned process, hydrogen halides are quenched and neutralized in a scrubber to convert into calcium halides. Recently, dry process to recover these corrosive gases was developed [17]. Solid alkaline carbonate and hydrate made from dolomite were used as the reactant to adsorb these gases. This dry process of hydrogen halides into calcium halides would be applied to ordinary exhaust gas treatment for combustion.

9. Medical Waste Treatment

Medical waste treatment system for volume reduction and detoxification was developed by several companies in Japan. Figure 8 shows the schematic diagram of the medical waste treatment system by non-transferred arc developed by Chubu Electric Power Co. Inc [18]. This system can treat medical wastes containing a large volume of polyvinyl chlorides, which may cause production of dioxins. This system heats waste without oxygen until the waste breaks down. Then thermal plasma (50 kW) is applied to remaining injection needles, bottles, and other unburned substances to melt and solidify them into stable slag. The volume reduction ratio is 1/250 for treatment capacity of 100 kg/day. The field test has been conducted at Nagoya Daini Red Cross Hospital for a year to check the operability, durability, economy, and other properties of the product.

Another field test of medical waste treatment was conducted at The University of Tokyo Hospital by Koike Sanso Kogyo Co. Ltd. Twin Torch system, which uses two electrodes of opposite polarity connected in series to form a single circuit, was adopted in this system.

10. Conclusions

Thermal plasmas have been simply used as high temperature source. If thermal plasmas are utilized effectively as chemically reactive gas, thermal plasmas would provide more capability for waste treatments. The advantages of thermal plasmas, such as high enthalpy to enhance reaction kinetics, high chemical reactivity, oxidation and reduction atmospheres in accordance with required chemical reactions, and rapid quenching rate, should be utilized effectively for waste treatment. The researches about the reaction mechanism in the plasmas as well as sophisticated numerical analysis of reactive plasmas are important for the development of attractive waste treatment.

DNA adsorption on NH_2-functionalized plasma polymer films

R. Förch[1], Z. Zhang[1], Q. Chen[1], W. Knoll[1], Rob Holcomb[2], Daniel Roitman[2]
Max Planck Institut für Polymerforschung, Ackermannweg 10, 55128 Mainz
Agilent Technologies, Palo Alto, California, USA

Abstract

Surface Plasmon Resonance techniques were used to study the properties of NH_2-functionalized plasma polymer coatings and their applicability for oligonucleotide/ DNA binding as a function of molecular architectures and amine group density. Low duty cycle films with a relatively high $–NH_2$ group density, low contact angle and low degree of cross-linking showed optimal properties for DNA probe attachment.

1.Introduction

The controlled attachment of biological molecules on plasma polymerized thin organic films has received increased attention over the past years. In the past, we have described the use of impedance spectroscopy (1) and optical methods such as Surface Plasmon Resonance spectroscopy (SPR) (2) and waveguide mode spectroscopy (WaMS) (3) to study the properties of plasma films in solution. These electrochemical and optical measurements of plasma films in solution have shown that plasma polymer films deposited at low DC swell considerably and exhibit hydrogel-like character when submersed in aqueous solution. This property decreased with increasing DC and was not observed for high power plasma deposits. If the plasma polymer contains ionizable groups such as amines or anhydrides the films show polyeletrolyte behaviour in aq. solution (1, 4) and the reactivity of the functional groups can be influenced by the pH of the solution used.(5, 6) These unique properties of functional plasma polymer films makes them particuarly attractive for use as supports for biological material.

The present work describes the fabrication, characterization and optimization of NH_2-derivatized polymer coatings prepared by pulsed plasma polymerization for applications as adhesion layers in DNA immobilization. In situ Surface Plasmon Resonance (SPR) (2, 7) measurements were used to study the behaviour of the pulsed plasma polymerized allylamine films in solution and to correlate DNA adsorption to the chemical nature of the plasma films as observed by FTIR and contact angle goniometry.

2.Experimental

The substrates used throughout the work were LaSFN9 optical glass slides coated with approximately 50 nm gold. A monolayer of octadecanethiol was allowed to self assemble on the gold surface and used as an adhesion layer between the plasma polymer and the gold surface. The plasma polymers were prepared in a cylindrical (300mm long, ∅ 100mm) 13.56 MHz rf plasma reactor under pulsed plasma conditions. The samples were placed half way between the electrodes, which consisted of two concentric rings wrapped around the outside of the chamber and separated by 12 cm.(3)

The plasma polymers were prepared either using a high duty cycle (DC= t_{on}/ t_{on}+ t_{off}) of 10/50 using a P_{peak} of 100 W or a low DC of 10/200 at a P_{peak} of 50 W. The equivalent power (P_{eq}=P_{peak} x DC)

during the pulsed experiments were thus 20 W and 2.5 W respectively. The process pressures used were 0.06 mbar and 0.1 respectively. Deposition times ranged between 30 seconds and 15 minutes.

The adsorption of single stranded DNA (25 mer) was monitored using a SPR spectrometer equipped with a wet cell made of teflon and sealed with a viton O-ring. Measurements were made using a continuous flow of buffer or buffer/DNA mixtures over the polymer surface. The DNA solutions were made up using phosphate buffer solutions consisting of (A) 0.2 mol/L NaH_2PO_4 (27g in 1L H_2O) and (B) 0.2 mol/L Na_2HPO_4 (53.65 g $Na_2HPO_4 \cdot 7H_2O$, or 71.7g $Na_2HPO_4 \cdot 12H_2O$ in 1L H_2O. Depending on the pH required these were mixed as follows: (i) dilute (A) to give 0.1 mol/L buffer at pH 4.5, (ii) 93.5 ml of (A) and 6.5 ml (B) plus 100ml H_2O give 200ml of 0.1 mol/L buffer of pH 5.7, (iii) 39.0 ml of (A) and 61.0 ml (B) plus 100ml H_2O give 200ml of 0.1 mol/L buffer of pH7, (iv) dilute (B) to give 0.1 mol/L buffer at pH 9.

For comparative experiments, poly-L-lysine (500 WG, Dg16, MW 3400) was self assembled onto the gold coated glass substrates from a solution of 5mg/L in PBS. This typically lead to a PL- film thickness of approximately 2 nm.

3.Results and Discussion

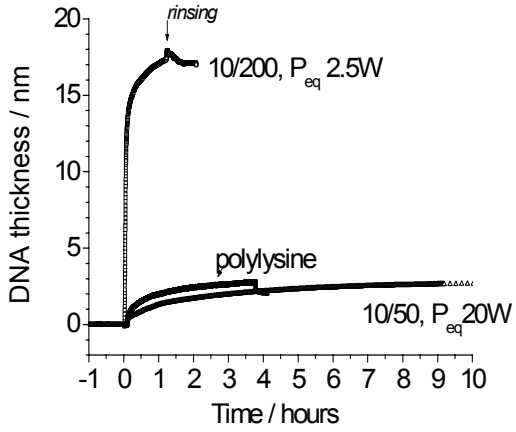
The chemical structure of plasma polymerized allylamine in air and in solution has previously been discussed in the literature.(3, 5) With decreasing duty cycle the deposited films show increased retention of the amine functionality within the film, as can be seen in Table 1 for two different preparation conditions.

Table 1 FTIR and contact angle data for different pulsed plasma polymerized allylamine films

Duty cycle	**Pressure / mbar**	**P_{peak} / W**	**P_{eq} / W**	**Rel. area from 3100-3500 cm^{-1} (NH_2 – band) ± 1%**	**θ_A / ° ± 3°**
10/50	0.06	100	20	16%	60°
10/200	0.13	50	2.5	26%	33°

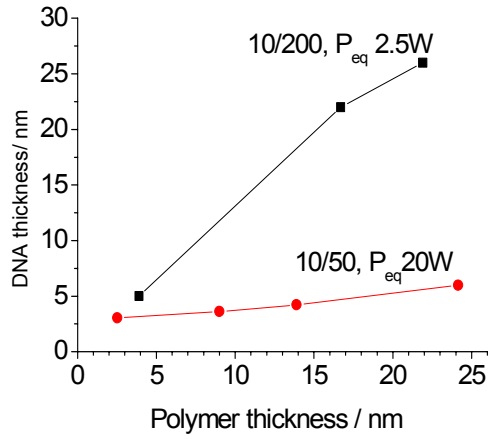
After equilibration of the polymer films in PBS buffer, the kinetics of DNA probe attachment were studied using a probe concentration of 100 nMol. After adsorption appeared to be complete the surfaces were rinsed with four cell volumes of buffer to remove any unspecifically bonded DNA from the surface. The kinetic scans of DNA adsorption as measured by the SPR techniques, Figure 1, show that adsorption was more efficient for the low DC films with the high -NH2-group density, than for the high DC (high P_{eq}) films which characteristically have a lower –NH2 functional group density. The data was compared to the immobilization of DNA on poly-L-lysine keeping all other conditions constant. As is evident from the data in Figure 1, the high DC plasma polymer appears to exhibits similar binding properties as the polylysine film, both showing an optical thickness increase of approximately 3 nm. The thickness of the DNA layer measured for the low DC film, however, showed a 6-fold improvement and a typical DNA thickness of approximately 17 nm.

Figure 1 SPR kinetic measurements of DNA binding on low DC (d ≈ 18 nm), and a high DC (d ≈ 10 nm) plasma polymerized allylamine compared to that on a polylysine film (d ≈ 2 nm), C_{DNA} 100nMol, PBS buffer at pH 7.4



DNA adsorption was found to be depend not only on the DC, but also on the polymer film thickness, Figure 2. With increasing polymer thickness, the low DC films indicated a much higher affinity for DNA probe attachment. For films with d > 20 nm the measured DNA thickness was approximately 4-5 times greater for the low DC, low cross linked films than for the highly cross linked films, high DC films.

Figure 2 Dependence of the DNA optical thickness on the plasma polymer thickness for DNA adsorption on high and low duty cycle plasma films, C_{DNA} 100nMol, pH 7.4



The increase in the probe sensitivity is believed to be related to the cross link density and thus the swelling characteristics of the low P_{eq} films. Since the low P_{eq} polymers are less cross linked and the chains have a greater freedom of mobility, the network can expand in solution making the functional groups within the bulk of the swollen polymer network more accessible to the DNA molecules possibly allowing the DNA molecules to penetrate into the bulk of the film.

In solutions of low pH the amine functional groups exist predominantly in the protonated form ($-NH_3^+$) following the reversible reaction:

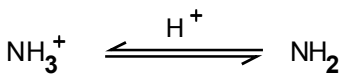


Figure 3 Effect of pH on the DNA adsorption on plasma polymerized allylamine films using P_{eq} of 20 W and 5W.

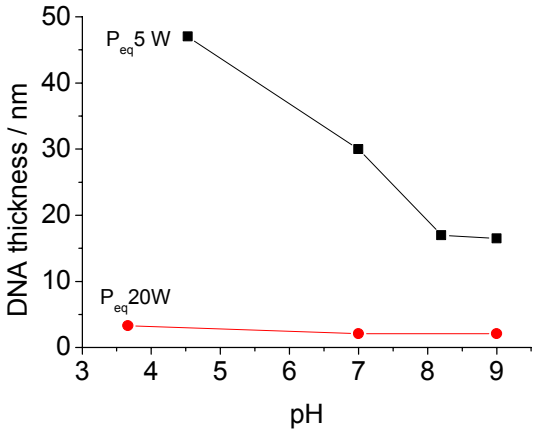

An increase in positive charge on the plasma polymer will lead to improved binding of the negatively charged DNA to plasma polymer film. Keeping all other conditions constant and only changing the buffer pH, the thickness of DNA probe measured on low DC plasma polymers was found to increased significantly, Figure 3. In contrast, the pH effect was significantly less on the highly cross-linked, high DC films even though the general trend was the same. This appears to be in agreement with the relative, estimated functional group densities and the accessibility of the groups within the two types of films as discussed above.

4.Summary

Plasma polymerized, amine functionalized films appear to exhibit properties, which render them suitable for DNA adsorption. DNA probe immobilization was found to be optimal for low duty cycle films with a relatively high density of $-NH_2$ groups, low contact angles and a low cross link density. When in solution, polyelectrolytic and hydrogel characteristics of low DC films seem to enhance DNA probe adsorption. Probe thicknesses observed on these films were up to 6 times greater than on the highly cross linked films and on polylysine.

PROTECTIVE PROPERTIES OF ORGANIC COATINGS ON PLASMA TREATED COLD ROLLED ALUMINIUM

Tullio Monetta and Francesco Bellucci

Department of Materials and Production Engineering, Piazzale Tecchio 80142 Napoli Italy

Abstract

The adhesion and protective properties of organic coatings on cold rolled aluminium alloy, treated by NH_3 radio frequency plasmas, were tested using the Electrochemical Impedance Spectroscopy (EIS) technique. Epoxyphenolic, and epoxypolyester solvent based, and water based epoxyphenolic resins deposited on 8011 aluminium alloy were investigated in presence and in absence of plasma treatments. Plasma treatments were carried out in a parallel plate reactor using pure NH_3 as a gas feed and three treatment time (i.e. 3-30-300 s) were used. Results obtained suggest that plasma treatment produce significant modification onto the metallic surface enhancing or decreasing adhesion.

1. Introduction

Aluminium alloys exhibit a large number of interesting properties such as (i) high thermal conductivity, (ii) light weight, (iii) mechanical strength (iv) moderate production costs and so on. Such properties make Al alloys suitable for its use in a large number of applications. Indeed, aluminium alloy foils are largely employed in both the automotive and home commodity industry (refrigerators and air conditioners) [1]. Currently, in order to withstand the large plastic deformation occurring during the lamination process high ductility alloys (containing high amount of Fe, Cu, Mn, Mg and Si), 8000 series, are employed [1, 2]. The relatively high concentration of alloying elements, however, reduces the corrosion resistance of these alloys. To improve corrosion resistance of this series an on-line chemical conversion process and a subsequent coil coating treatment is necessary [3,4].

Conventional treatments used for aluminium alloys as those mentioned above, are very polluting requiring large area for the storage of liquids used in the conversion treatment. In this work an attempt is made to use cold plasma treatments to modify the surface chemical structure of aluminium alloys in order to enhance adhesion in the coil coating treatment. In this investigation, plasma treatments were carried out on samples that were neither cleaned nor washed (as received samples).

Cold plasma treatments are widely used in a large number of industrial applications and an enormous number of papers appeared in the scientific and technological literature dealing with such applications. In the field of corrosion protection plasma treatment was addressed mainly to investigate the effect of treatment on cold rolled steel [5-9]. Specific issues investigated were (i) the cleaning of the metallic surface, and (ii) the application of a protective layer via plasma polymerisation [10].

2. Materials and methods

The plasma reactor used in this work to treat the metallic surface, was an internal parallel plate electrode type in which the plasma was generated at 13.56 MHz. During the treatments the pressure chamber was held at 200 mTorr, the flow rate was 20 sccm using pure NH_3 and power was set at 20 W. Treatment time were 3, 30 and 300 s, respectively. Cold rolled aluminium (8011 alloy) was used as the metallic substrate in the form of square panels of 100 cm^2.

The following three types of commercial resin (kindly furnished by Eco-Polifix) were used in this work: (i) a waterborne epoxyphenolic system, (ii) and epoxyphenolic solvent-based coating, and (iii) an epoxypolyester solvent-based system (see Tab. 1). Coated aluminium samples were prepared, immediately

after the plasma treatment, by adopting the following procedure. Samples were first dipped in the liquid resin, dried in air and cured in an oven at the cured temperature as determined via Differential Scanning Calorimetry (DSC) analysis. (see Table 2 for details). The average thickness of the coating was 10 μm. Three samples were prepared for each system, and experimental data reported in this work are the "best performance" observed for each system. It is important to stress that the resins used in this work were commercial grade and their formulation is proprietary.

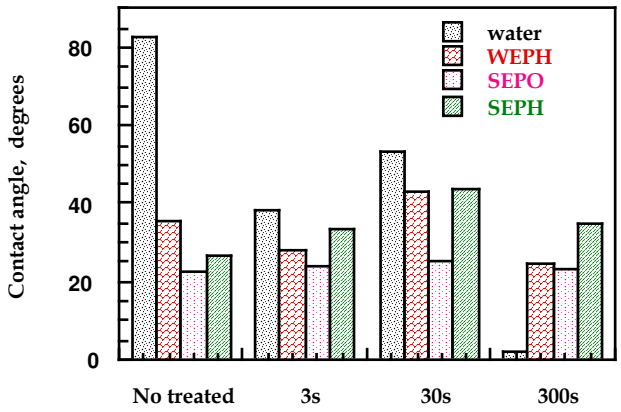

Fig. 1 Contact angle values obtained using water, WEPH, SEPO, SEPH resins on treated and untreated aluminium substrate.

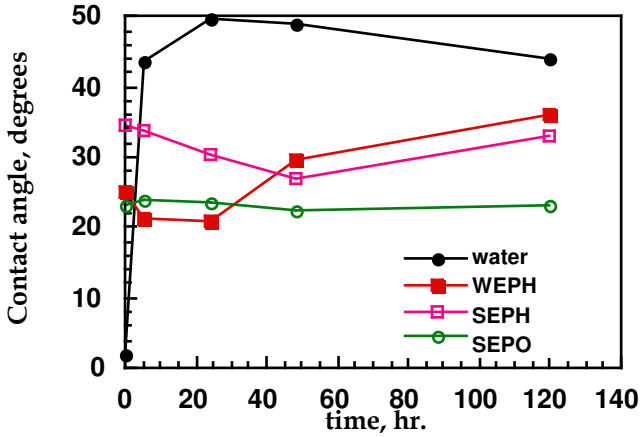

Fig. 2 Ageing of plasma treatments evaluated using contact angle.

The experimental apparatus for the electrochemical investigation is described in ref. [13] Contact angle measurements were performed using Imass Inc. contact angle analyser. The data reported is an average of five measurements on five different samples. DSC measurements were performed using a Mettler Toledo DSC12E calorimeter.

3. Results and discussion

One of the main problems in the characterisation of organic coatings is related to the structural properties of the cured materials. DSC measurements and permittivity data were used in this work for evaluating the initial properties of the coating and their reproducibility for all the samples investigated.

The effect of plasma treatment on the aluminium surface was evaluated by measuring the contact angle for both water and resins used in this study. Measurements were performed on both treated and untreated substrates. As shown in Fig. 1, NH_3 plasma significantly affect the water contact angle; in fact it decreases from 83° for

the untreated sample, to 3° for the sample treated for 300 s. Opposite behaviour was exhibited by the SEPH sample. The value for the untreated sample was 26°, while a maximum value of 42° was observed after 30 s of treatment. On the other hand, this treatment does not modify the contact angle (a constant value of (22-24°) for both the treated and untreated sample) when the SEPO resin is employed. The WEPH contact angle reveals an initial value of 35° reaching a maximum value of 44° for the sample treated for 30 s. The ageing of the plasma treatment was addressed by measuring the contact angle as a function of time of exposure to laboratory atmosphere. Results are reported in Fig. 2 for sample after 300 s of treatment. As can be seen from this figure, a sharp increase of water contact angle is observed after few hours of exposure to the test atmosphere, and a maximum value is reached after about 20 hours. The subsequent decrease observed at late exposure is of minor significance. In this case, however, the maximum value reached (50°) is far from that of the untreated sample (83°) as shown in Fig. 1. No ageing was observed for the SEPO resin. The SEPH contact angle returns to the value of the untreated material (26°) after 50 hours of exposure, before a subsequent increase observed at late exposure. Finally, the contact angle for the WEPH resin comes to the value of the untreated sample after 120 hours of exposure.

In this work, an attempt is made to estimate the ratio of delaminated area between the treated and untreated coated samples. If C_t and C_{coat}^{t} are the total (interface and coating) and coating capacitance at time t, respectively, one has:

$$C_{t=t'} = C_{coat}^{t=t'}(1-x) + xC_{dl}^{t=t'} \qquad (1)$$

Where $x = A_{dl}^{t}/A_t$; $C_{t=0} = C_{coat}^{t=0}$; C_{dl}^{t} is the double layer capacitance, while A_t and A_{dl}^{t} are the total and delaminated area, respectively.

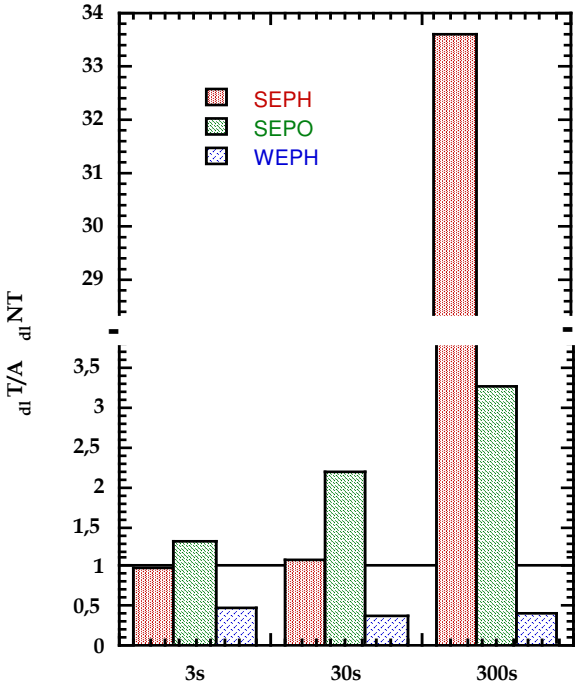

Fig. 3 Ratio between the delaminated area of the treated and the untreated samples as a function of treatment time.

$$\%\Delta C = \frac{C_{t=t'} - C_{t=0}}{C_{t=0}} \times 100$$

$$\%\Delta C = \frac{C_{coat}^{t=t'}(1-x) + xC_{dl}^{t=t'} - C_{coat}^{t=0}}{C_{coat}^{t=0}} \times 100$$

If the delaminated area is small (1-x) ≈ 1 and the coating and the double layer capacitance variation with ageing can be neglected, one has:

$$\%\Delta C = \frac{xC_{dl}^{t}}{C_{coat}^{t=0}} \times 100 = \frac{C_{dl}^{t}}{C_{coat}^{t=0}} \frac{A_{dl}^{t}}{A_t} \times 100$$

If A_{dl}^{t} NT and A_{dl}^{t} T are the delaminated area of he untreated and treated coated sample, respectively; and %ΔCT and %ΔCNT are the values assumed by the previous equation at time t, then:

$$\frac{\%\Delta CT}{\%\Delta CNT} = \frac{A_{dl}^{t}T}{A_{dl}^{t}NT} \qquad (2)$$

Equation 2 indicates that if the ratio %ΔCT/%ΔCNT is less than 1, the delaminated area of the treated samples is smaller than that of the untreated one.

Fig. 3 shows the ratio $A_{dl}T/A_{dl}NT$ evaluated for samples investigated in this paper at the same ageing time. The frequency at which C was evaluated is in the range 10-60 Hz depending on the type of resin employed. As can be seen from Fig. 3, SEPO resin exhibits a ratio $A_{dl}T/A_{dl}NT$ is >1 for all treatments time.

Thus, the delaminated area is always larger than for the untreated sample. Plasma treatment does not improve adhesion of this resin to the aluminium metallic substrate. For the system SEPH, with the exception of the sample of the 300s of treatment in which a complete cracking of the coating occurred, the delaminated area for both treated and untreated samples is approximately the same. It is interesting to observe that for the water borne coating the above ratio is less than 1 indicating an effectiveness of the plasma treatment.

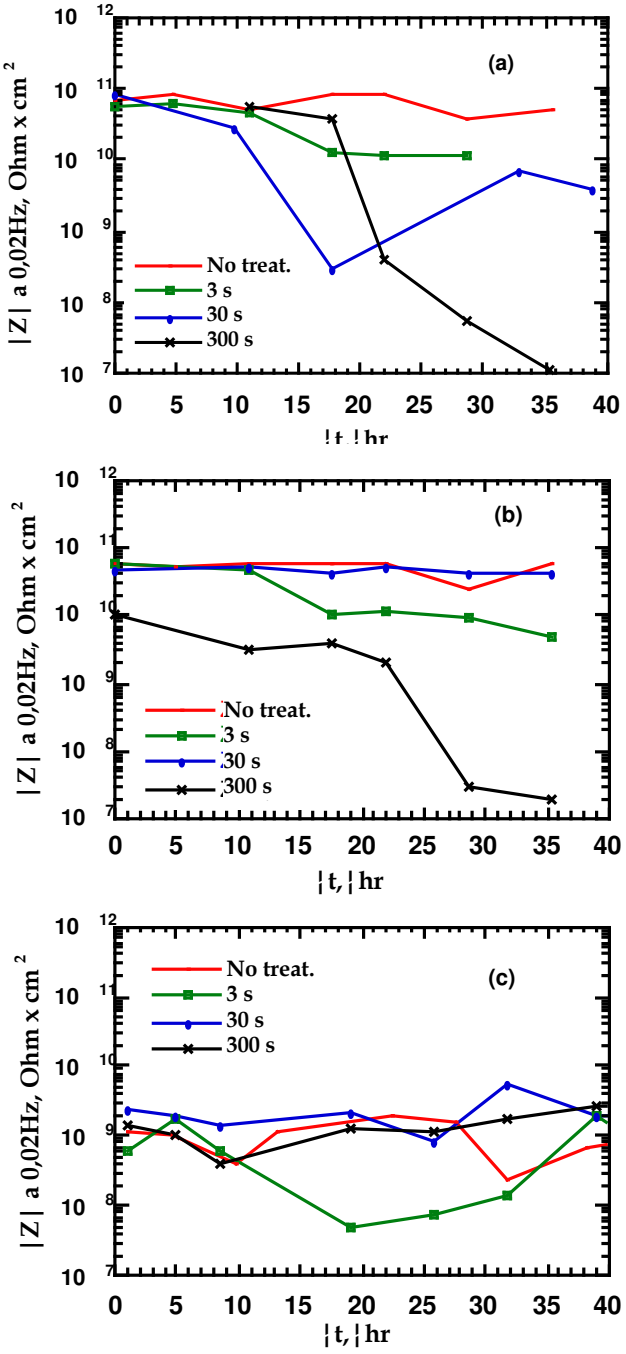

Fig. 4 Modulus of impedance, |Z|, as a function of time evaluated at 0.02 Hz for the system SEPO (a), SEPH (b), WEPH (c).

The value of modulus of impedance, |Z|, calculated at 0.02 Hz, is reported in Fig. 4, as a function of time of exposure to the test solution (aerated synthetic seawater). As can be seen from this figure, the untreated SEPO system exhibits better performance when compared to the treated one. It is worth to mention, however, that the sharp decrease of |Z| after about 16 days of exposure, for the 300s treated sample, is in good agreement with the time required t o Cl^- ions to reach the metallic substrate by diffusion [13]. Similar conclusions can be drawn by analysing the behaviour of the SEPH system as represented in Fig. 4b. Finally, no major differences were observed between the treated and untreated WEPH samples (see Fig. 4c).

It is often reported in the literature that contact angle values furnish an indication of the extent of adhesion. Experimental data reported in this investigation do not support such evidence. In fact, while contact angle measurements suggest that the SEPO system is not affected by the NH_3 plasma treatments (see Fig. 1), impedance data (see Fig. 4) show that an effect is observed. In addition, the worst performance for the SEPH system should be expected after 30 s of treatment, while data in Fig. 4 show an excellent behaviour for such system. Finally, data for WEPH system furthers support the view that low values of contact angle are not predictive of good adhesion. At the same time, however, these data seem to be promising as far as the use of friendly coatings is concerned. It is, thus, possible to conclude that: (i) "total" contact angle value does not allow us to forecast the adhesion strength, and (ii) a plasma treatment may improve adhesion between coating and substrate when a water based resin is used. Then, for some applications, it could be of interest to choose a low cost and less pollutant resin together with a plasma treatment to increasing paint/substrate adhesion and thus performance of the system.

4. Conclusions

In this paper the effect of NH_3 plasma treatment on "as received" aluminium alloy sample has been evaluated. Results obtained in this investigation further support the view that contact angle does not correlate to adhesion strength.

Cold plasma could be an effective *clean* technology to improve adhesion for painted aluminium systems for water based resins. However further experimental data must be collected to optimise the process.

Abstract

Potatoe starch was hydrophobized in a rotating reactor, using a capacitively coupled RF glow discharge. Two working media were used, one was tetramethylsilane(TMS)/argon mixture, and the other was methane. Water capillary elevation measurements showed that the best results were obtained for TMS/Ar system at relatively mild RF power of 20 W. FTIR studies revealed an absence of Si bonding. Instead, an increasing (CH)/(CH_2) ratio strongly suggests a crosslinking of starch surface.

1. Introduction

One possible approach to the manufacture of biodegradable polymer materials concerns a use of starch as a biodegradable filler in composites with typical thermoplastic polymers, such as polyethylene or polypropylene. In these materials, degradation of the filler should be subsequently followed by a disintegration of the entire piece into environmentally harmless polyolefine powder. However, the main problem with a manufacture of composite materials, comprising a polyolefine as a matrix and starch as a filler, is a mixing difficulty. A polyolefine, such as polyethylene, with a very low polar component of its surface energy [1], does not sufficiently wet the surface of starch grains, characterized by a relatively high polar component. As a result, agglomerates of starch in polymer are easily formed in the extrusion process. An obvious solution to this problem is a minimization of the surface energy of the interface polymer/starch [2]. One way to realize this process is through such a modification of the surface energy of starch, which will significantly lower the polar component of this energy and, consequently, improve the conditions of matrix-filler interactions. Plasma processes are well known to be effective in hydrophobization of polymer surfaces [3-5]. The principal difficulty with a modification of materials remaining in a fine particulate form, such as starch, is comprised of the fact that the surface of each particular grain has to be modified with similar efficiency. One technological solution to this problem consists in a use of a fluidized bed reactor [6]. An approach of this work comprises an application of a rotating RF plasma reactor for that purpose, and particularly for the purpose of hydrophobizing potatoe starch.

2. Experimental

The rotating RF plasma reactor is schematically represented in **Figure 1** below. The main part of this

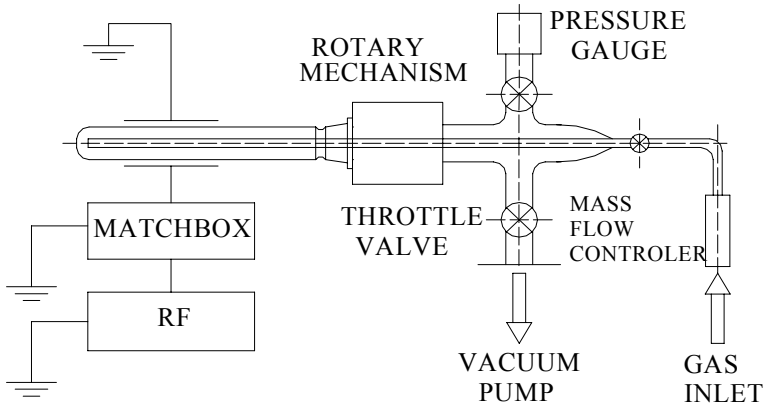

Figure 1. Schematic representation of the rotating RF plasma reactor

reactor is a 450 mm long tubular element, that may be rotated with frequency ranging from 0 RPM to 60 RPM. The reactor is equipped with a set of external electrodes, to which the RF power is supplied from the

Plasma Products RF5S power generator through a self-designed matching circuit. MKS 1179 AX mass flow controllers are used to control the flow rates of gaseous media. The flow rate of a vapour of liquid medium (TMS) is controlled by both the temperature and the pressure of a liquid container, and the *rate-of-rise* technique is used to measure its magnitude. A starch modification cycle starts with setting the flows of working media, then the rotation of the tubular element with a selected RPM value is introduced, and finally radio frequency plasma is generated in the reactor. Powdered starch contained in this reactor is stirred very efficiently, thus enabling an effective plasma deposition or modification of the surface of each grain.

As working media, two different systems were used: a) saturated hydrocarbon such as methane and b) TMS/Ar mixture. Methane plasma modification was performed at two different magnitudes of flow rate, namely at 2 sccm and 6 sccm, while TMS/Ar plasma modification was carried out at the total flow rate of 7 sccm, with the TMS to Ar ratio amounting to 1:6. In each case the RF power was used as an operational parameter in the process optimization. Process pressure was maintained at the 400-420 mTorr level.

An assessment of the modification process efficiency is comprised of measurements of capillary rise of water in glass tubes filled with starch. Since the principal aim of the modification process has been a surface hydrophobization of starch, i.e. a substantial decrease of its water contact angle (a direct measurement of which is impossible) the above method, although very simple, is thought to be a sufficiently good assessment tool. In practice, the measurement was realized in the following way. Into a glass tube of an ID of 1.8 mm, starch was compressed in such a way that its weighted amount of 0.2 g always corresponded to 55 mm of height. The tube was then immersed in a beaker filled with water and water capillary elevation was measured, using a cathetometer, as a function of time. A result that did not exhibit any changes within 100 minutes was taken as a maximum capillary elevation of water.

FTIR studies of selected starch samples (both native and modified) were performed with the help of a BioRad, model 175C, FTIR spectrometer, equipped with a Harric Sci. split-pea attachment and a silicon crystal. Such an experimental configuration allows one to record IR absorption spectra from the surface layer of starch grains, down to the depth of approximately 200 - 1800 nm, depending on the radiation wavelength. Each spectrum was constructed by collecting 64 consecutive scans, with a resolution of a single scan amounting to 4 cm^{-1}. Finally, SEM imaging of starch particles was carried out, using a Hitachi F 3000 N scanning electron microscope.

3. Results

Subjected to capillary water elevation measurements described above, a sample of native starch exhibit a maximum water elevation of 62 mm. **Figure 2** presents a set of water elevation results for starch modified with methane plasma, for the methane flow rate of 2 sccm. Since they all remain within the range of 16- 20 mm, the water capillary elevation results shown in this figure indicate much higher hydrophobicity than those obtained for an unmodified starch.

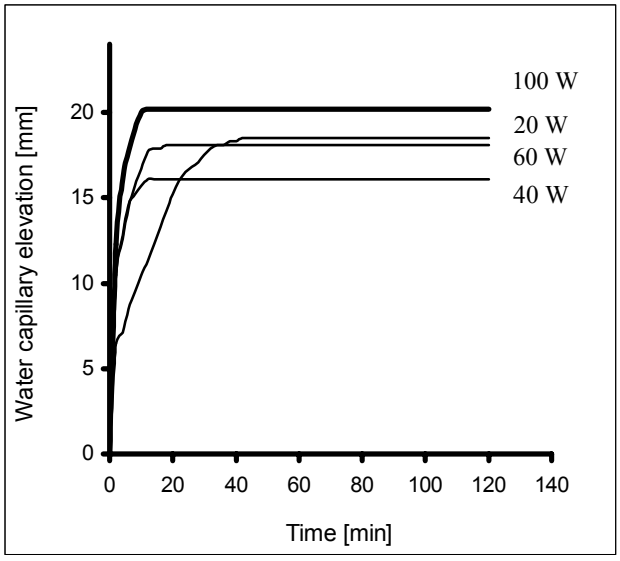

Figure 2. Results of water capillary elevation for starch modified with methane plasma at the flow rate of methane of 2 sccm and different values of RF power.

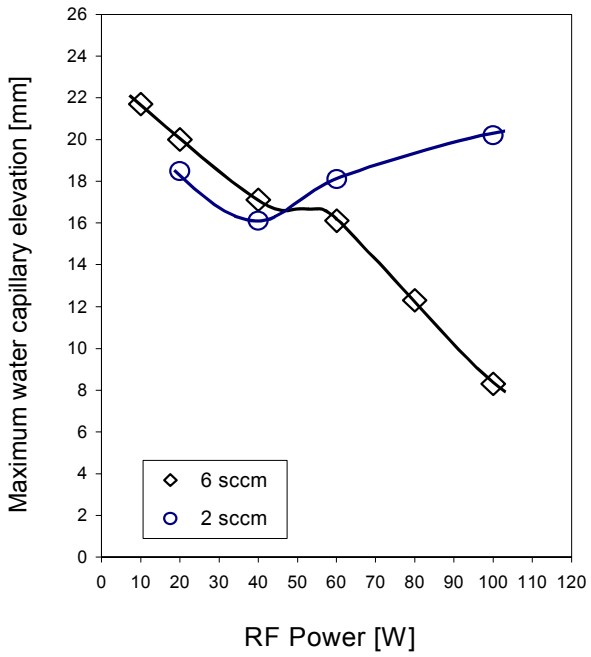

Figure 3. Maximum water capillary elevation for starch modified with methane plasma as a function of the RF power of modification

In **Figure 3**, the maximum values of water capillary elevation from **Figure 2** are plotted against the RF power. Data collected for the methane flow rate of 6 sccm are also presented in the same plot. As seen in the figure, the results obtained at the lower value of flow rate pass a minimum, while those obtained for the higher one exhibit a decreasing tendency within the entire range of power values used. The course of this line very likely constitutes a left wing of another minimum reaching dependence, which cannot be tracked along higher RF power values due to starch degradation. In other words, under these conditions the RF power of 100 Watt is the highest power level at which no visible signs of degradation take place.

The dependence of maximum water capillary elevation for starch modified using the TMS/Ar plasma on the RF power of modification is presented in **Figure 4**.

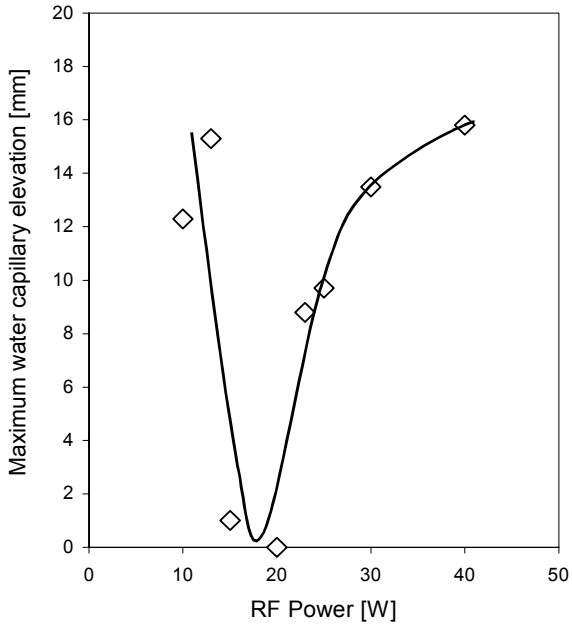

Figure 4. Maximum water capillary elevation for starch modified with TMS/Ar plasma as a function of the RF power of modification

In the above relationship, there is evident and sharp minimum at approximately 20 Watt of RF power, for which the practical value of water capillary elevation, under the measurements conditions, amounts to zero. It is the best result of this work and, indeed, the macroscopic tendency to agglomerate for TMS/Ar plasma modified starch is much lower than that observed for the native material. What this tendency looks like at the microscopic level, is presented in **Figure 5** in the form of SEM micrographs.

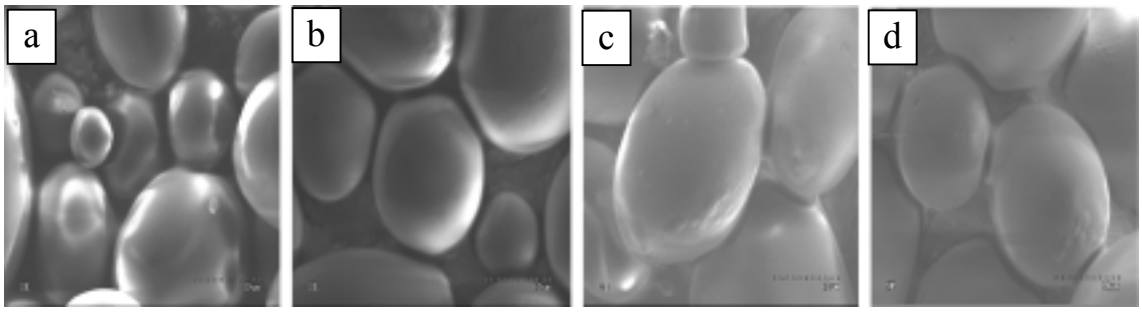

Figure 5. SEM micrographs of starch grains modified with TMS/Ar plasma at different RF power values: 10 Watt (a), 20 Watt (b), 25 Watt (c) and 30 Watt (d)

As seen in the above micrographs, it is only the starch sample modified with TMS/Ar plasma at RF power of 20 Watt (sample b), that exhibits a clear separation of its grains. It is the same sample that shows practically no water capillary elevation in the hydrophobicity measurements.

In order to look for structural changes responsible for the presented increase of starch hydrophobicity, IR absorption spectra have been recorded for selected samples. Principal structural features that constituted a subject of interest were: 1) potential changes in the carbonous network of starch (in both cases: methane and TMS/Ar plasma modification) and 2) grafting of any silicon containing surface functions, reflected in the presence of such bonds as Si-C, Si-O or Si-H bonds (in the case of TMS/Ar plasma modification).

First of all, it has to be stated that no silicon bonding was observed in TMS/Ar plasma modified starch. Fingerprint region of IR absorption (where Si-C stretching, Si-O stretching and Si-H bending vibrations should be observed) for these samples was identical with that of native starch. In addition, no traces of Si-H stretching band were observed in the vicinity of 2000 cm^{-1}.

The main changes take place in the C-H bond stretching IR absorption region, shown in **Figure 6**.

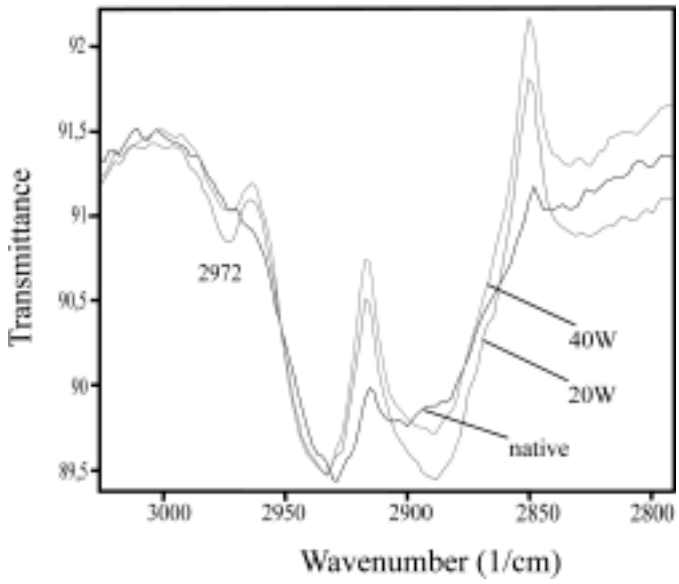

Figure 6. C-H bond stretching IR absorption region for native and TMS/Ar plasma modified starch

As seen in **Figure 6**, the main changes in C-H bond stretching region comprise a rise of the 2972 cm^{-1} band, corresponding to C-H asymmetric stretching vibrations in methyl groups, and an even stronger increase of the intensity of 2883 - 2906 cm^{-1} band, corresponding to C-H stretching vibrations in isolated carbon-hydrogen bonds. Both these features strongly suggest that it is the hydrocarbon part of a tetramethylsilane molecule that is responsible for the surface modification in this case. Indeed, similar to the changes observed for TMS/Ar plasma modification of starch, are those presented in **Figure 7**and recorded for starch samples modified with methane plasma.

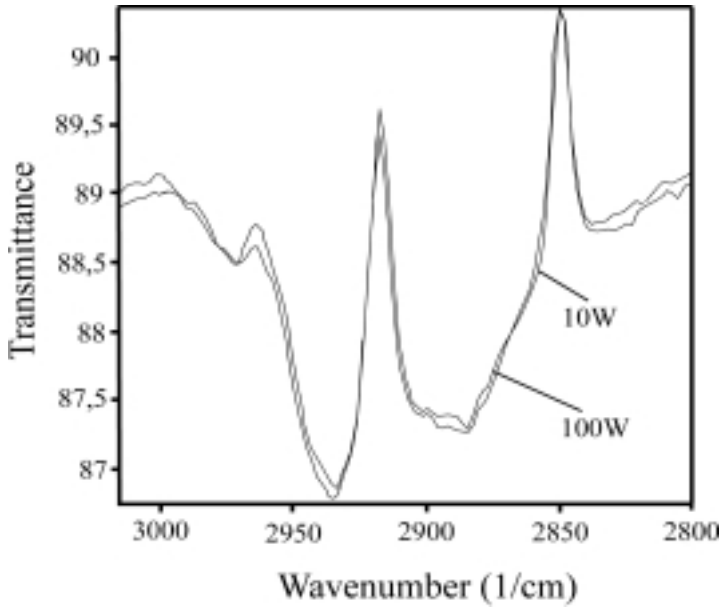

Figure 7. C-H bond stretching IR absorption region for starch modified with methane plasma.

A brief comparison of the presented spectra reveals extended similarities between the results of plasma modification of starch with both types of working media. These results are predominantly present in the structure of carbon bonding, reflected in the proportions between integrated absorption of stretching vibrations of C-H bonds in different environment. Other absorption ranges remain to a large extent unaltered and, in particular, no silicon containing bonding has been found in the IR spectra of TMS/Ar plasma modified samples. Since a molecule of tetramethylsilicon contains four methyl groups, splitting these groups off the silicon atom should have similar effect as breaking a C-H bond in methane. The fact that silicon carbon bond has a lower bond energy (301 kJ/mole) than hydrogen-carbon bond (416 kJ/mole) [7] explains why the respective magnitudes of RF power necessary to introduce required changes in the starch structure are substantially lower for TMS than for methane.

In **Figures 6** and **7**, the band at 2972 cm^{-1} is assigned to asymmetric stretching vibrations of C-H bond in methyl groups, the bands at 2940 cm^{-1} and at 2927 cm^{-1} to asymmetric stretching vibrations of the same bond in methylene groups, and those at 2906 cm^{-1} and at 2883 cm^{-1} to the stretching vibrations of this bond in methine systems. In a first approximation, symmetric vibrations of both methyl and methylene group originating C-H bonds have been disregarded. As mentioned above the particular changes taking place within the scope of C-H bonding as a result of plasma modification consist in an increasing number of both methyl groups and trifunctional methine moieties, as compared to the concentration of methylene groups. While grafting methyl groups should directly lead to an increased hydrophobicity of the surface, an increase of methine/methylene ratio suggests a process of surface cross-linking. Table 1 presents the values of ratio of integrated absorption of methyl group and methine group originating C-H bonds to that of integrated absorption of these bonds vibrations (asymm.) in methylene groups, for native starch as well as for starch samples modified with TMS/Ar and with methane plasmas.

Table 1. A ratio of integrated absorption of C-H bonds in methyl group and methine groups to that of integrated absorption of C-H bonds (asymmetric vibrations) in methylene groups, for native starch as well as for starch samples modified with TMS/Ar and with methane plasmas.

	CH_3/ CH_2	CH/ CH_2	Maximum water capillary elevation [mm]
Unmodified starch	0.121	0.87	62
Modified (CH_4 10 W)	0.082	1.15	22
Modified (CH_4 100 W)	0.313	1.31	7
Modified (TMS 40 W)	0.276	1.57	16
Modified (TMS 20 W)	0.293	1.87	0

In **Table 1**, results of surface hydrophobicity for respective samples, obtained with water capillary elevation measurements, are also presented. There is a sound correlation between the values of maximum water capillary elevation of starch, and the CH/CH_2 ratio in the samples. It appears that an increase of this ratio, most likely connected with an enhancement of surface cross-linking of starch, has an effect of lowering its water capillary elevation potential, i.e. of increasing its hydrophobicity.

4. Conclusions

Out of the experimental results the following conclusions may be drawn:

1. RF plasma modification of particulate materials may be effectively carried out in a rotating plasma reactor, presented in this work.
2. The described process is well suited for the purpose of hydrophobization of potatoe starch.
3. The best hydrophobizing effect has been achieved in the case of tetramethylsilicon/argon plasma modification of starch under relatively mild conditions of RF power (20 Watt).
4. An alteration of starch structure responsible for its hydrophobization appears to be a surface cross-linking combined with grafting with non-polar methyl groups.

RF Plasma Synthesis and Deposition of SOFC Materials

G. Schiller, M. Müller, E. Bouyer, M. v. Bradke

German Aerospace Center (DLR), Institute of Technical Thermodynamics, Stuttgart, Germany

Abstract
Thermal spray technology is considered to be a suitable mass production method for solid oxide fuel cells. A thermal plasma chemical vapour deposition process (TPCVD) using inductively coupled RF plasma was applied to synthesise and deposit porous perovskite-type SOFC cathode coatings from liquid precursors such as aqueous solutions of the nitrates of the relevant elements. Results on the phase purity, the microstructure and the growth rates of perovskite-type cathode coatings $La_xSr_{1-x}MO_3$ and $Pr_xSr_{1-x}MO_3$ (M = Mn, Fe, Co) are presented that prove the suitability of this method for the preparation of highly efficient SOFC cathodes.

1. Introduction

Solid oxide fuel cells (SOFC) are electrochemical converters that convert chemical energy of fuel gases (hydrogen, natural gas, other hydrocarbons) with oxygen directly into electrical energy in an environmentally friendly way, thereby also exhibiting higher overall efficiency than conventional combustion processes for power generation. Thermal spray technology is considered to be a suitable mass production process for SOFC as an alternative method to conventionally used sintering processes. These processes such as tape casting of the electrolyte layer and screen printing or wet powder spraying of the electrodes and subsequent sintering are widely used for SOFC fabrication [1, 2], but they are time-consuming and they require high sintering temperatures partly far above 1000 °C which can give rise to undesired solid state reactions. Thermal spray techniques, on the other hand, such as atmospheric or vacuum plasma spraying are very rapid processes with a moderate temperature regime at the substrate surface and needing no further thermal post-treatment after deposition. Additionally, these processes can be fully automated to a production line. DLR pursues a planar SOFC concept for a metallic substrate-supported thin-film SOFC which is based on vacuum plasma spray technology as manufacturing process for the entire membrane-electrode assembly (MEA), the core element of SOFC stacks. Specially further developed and adapted DC and RF plasma deposition processes are applied for the manufacture of SOFC cells to be integrated in a stack assembly [3].

Conventional thermal spray techniques require particular powder conditioning being a considerable cost factor that should be reduced or even avoided. A promising approach for the preparation of SOFC components such as dense electrolyte and in particular porous cathode layers is given by the in situ synthesis and deposition in an inductively coupled RF plasma from liquid precursors. Perovskite coatings from aqueous solutions were deposited in a thermal radio-frequency (RF) plasma with a "plasma expanded through a nozzle" (PETN) technique achieving a growth rate of about 1 µm/min [4]. Similar precursors were injected into a plasma generated by a triple direct current (DC) torch reactor with growth rates of about 7 µm/min [5]. Using suspensions as well as aqueous solutions of suitable salts, two methods – suspension plasma spraying (SPS) [6] and thermal plasma chemical vapour deposition (TPCVD) [7] – have recently been developed for the deposition of SOFC components. Deposition rates of 30 – 100 µm/min were achieved but the phase purity of the cathode coatings was not sufficient for SOFC application. This paper focuses on the preparation of highly porous and pure perovskite-type cathode coatings by applying the TPCVD method.

2. Experimental

2.1 Set-up and Process Conditions

The experiments were performed using a vacuum reactor and a PL50 induction plasma torch from TEKNA Plasma Systems, Sherbrooke/Canada which is operated with a radio frequency generator from Himmelwerk, Germany, at 500 kHz (Fig. 1). The RF power was varied in the range from 20 to 30 kW, the chamber pressure was between 12 and 38 kPa and spraying distance between 150 and 600 mm. The plasma gas composition was varied over a wide range from argon/hydrogen mixtures to plasma mainly consisting of oxygen. The precursors were fed with a rate between 1.5 and 3 ml/min by a peristaltic pump using two channels to avoid pulsing. The material was directly injected into the hot plasma core by means of a gas-

assisted atomiser. Argon flow rates in the range of 2-10 slpm were used to atomise the precursors. Slabs of the SOFC bipolar plate material 94Cr5Fe1Y_2O_3 were used as substrates in order to match the thermal expansion coefficient of the ceramic SOFC components.

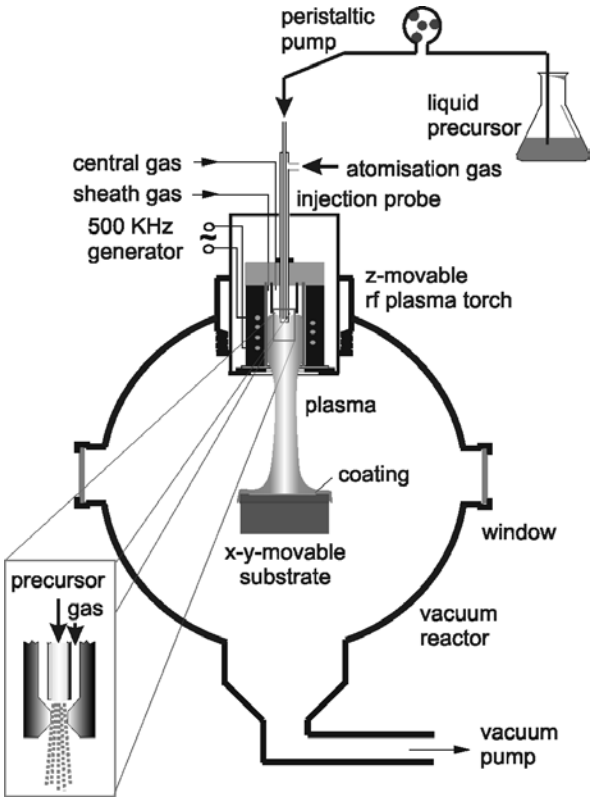

Fig. 1: Experimental set-up, detail in left corner: principle of gas-assisted atomisation

2.2 Precursors

Aqueous solutions of metal nitrates of different concentrations were used as precursors for the preparation of perovskite-type cathode coatings by means of TPCVD. A summary of the main precursor solutions applied and the desired synthesis products is given in Table 1.

Table 1: Summary of the precursor solutions applied and the desired synthesis products

	Synthesis product	Precursor	Concentration
A	$La_{0.9}Sr_{0.1}MnO_3$ (LSM)	$La(NO_3)_3 \cdot 6\ H_2O$ $Sr(NO_3)_2$ $Mn(NO_3)_2 \cdot 4\ H_2O$	0,9 M 0,1 M 1,0 M
B	$La_{0.5}Sr_{0.5}MnO_3$ (LSM)	$La(NO_3)_3 \cdot 6\ H_2O$ $Sr(NO_3)_2$ $Mn(NO_3)_2 \cdot 4\ H_2O$	0,5 M 0,5 M 1,0 M
C	$La_{0.65}Sr_{0.3}MnO_3$ (ULSM)	$La(NO_3)_3 \cdot 6\ H_2O$ $Sr(NO_3)_2$ $Mn(NO_3)_2 \cdot 4\ H_2O$	0,65 M 0,3 M 1,0 M
D	$Pr_{0.65}Sr_{0.3}MnO_3$ (UPSM)	$Pr(NO_3)_3 \cdot 5\ H_2O$ $Sr(NO_3)_2$ $Mn(NO_3)_2 \cdot 4\ H_2O$	0,65 M 0,3 M 1,0 M
E	$La_{0.8}Sr_{0.2}FeO_3$ (LSF)	$La(NO_3)_3 \cdot 6\ H_2O$ $Sr(NO_3)_2$ $Fe(NO_3)_3 \cdot 9\ H_2O$	0,8 M 0,2 M 1,0 M

	Synthesis product	Precursor	Concentration
F	$La_{0.8}Sr_{0.2}Co_{0.5}Fe_{0.5}O_3$ (LSCF)	$La(NO_3)_3 \cdot 6\ H_2O$ $Sr(NO_3)_2$ $Co(NO_3)_2 \cdot 6\ H_2O$ $Fe(NO_3)_3 \cdot 9\ H_2O$	0,8 M 0,2 M 0,5 M 0,5 M
G	$La_{0.58}Sr_{0.4}\ Co_{0.2}Fe_{0.8}O_3$ (LSCF)	$La(NO_3)_3 \cdot 6\ H_2O$ $Sr(NO_3)_2$ $Fe(NO_3)_3 \cdot 9\ H_2O$ $Co(NO_3)_2 \cdot 6\ H_2O$	0,58 M 0,4 M 0,8 M 0,2 M
H	$Pr_{0.58}Sr_{0.4}Co_{0.2}Fe_{0.8}O_3$ (PSCF)	$Pr(NO_3)_3 \cdot 5\ H_2O$ $Sr(NO_3)_2$ $Fe(NO_3)_3 \cdot 9\ H_2O$ $Co(NO_3)_2 \cdot 6\ H_2O$	0,58 M 0,4 M 0,8 M 0,2 M

2.3 Coating Evaluation

The phase content of the coatings was determined by XRD using a STOE Stadi P diffractometer and MoKα radiation. Polished cross sections and fracture surfaces were prepared by standard metallographic procedures to study the coating microstructure by optical and scanning electron microscopy (SEM) as well as EDX mapping.

3. Results and Discussion

Lanthanum manganite doped with 20 % Sr ($La_{0.8}Sr_{0.2}MnO_3$, LSM) is the preferred cathode material for high operating temperatures with SOFCs. It has reasonably good electronic conductivity but the oxide ion conductivity is very low even at 1000 °C. Therefore, mixing of LSM with yttria-stabilised zirconia (YSZ) which is used as electrolyte material is a common approach to overcome the oxygen transport limitation. But at temperatures below 800 °C which is a general goal in present SOFC development such two-phase cathodes cannot support high current densities. Ferrites, cobaltites and nickelites have better oxide ion conductivities than manganites [8], hence these perovskite phases promise high electrochemical performance at reduced SOFC operating temperature. Particularly strontium doped lanthanum ferrite (LSF) and cobaltite ferrite (LSCF) achieve low areal resistances and stable performance probably due to the higher ionic conductivity compared to LSM.

In previous investigations suspension plasma spraying was applied for LSM preparation by using suspensions of MnO_2 particles in saturated aqueous and ethanolic solutions of La salts [6]. The perovskite phase was formed as the main phase but also La_2O_3 was observed as an additional phase in significant extent in the coating. Post-treatment with an 80 % oxygen plasma improved the coating purity but the occurrence of detrimental La_2O_3 which reacts to $La(OH)_3$ causing severe volume change and destruction of the coating could not completely be suppressed. Furthermore, the coatings exhibit a layered microstructure resulting from impinging molten particles which is known from conventional thermal spraying processes. Although porosity can be affected by the solid content of the suspension SPS coatings showed a porosity which is too poor for gas migration in SOFC cathodes. Much more porous microstructures of LSM coatings were observed when using the TPCVD process, but phase purity remained still a problem to be solved [7]. The development of perovskite-type cathode coatings by using TPCVD is reported in more detail in the following chapters.

3.1 Phase composition

A key parameter governing the purity of the coatings appears to be the radial temperature gradient within the plasma jet. When using lanthanum and manganese nitrates (precursors A, B, C), the high temperature along the axis of the jet combined with the high volatility of Mn results in a non-stoichiometric composition with regard to La and Mn in the central part of the coating on a stationary substrate. The deviations from stoichiometry are larger than the perovskite structure con tolerate, thus, the presence of surplus La causes La_2O_3 to appear in the coating beside the desired LSM phase. The cooler outer regions of stationary substrates were always covered with pure or almost pure perovskite phase. Fig. 2 shows an extreme example of the different phase content obtained in the centre and in the outer region of a stationary substrate.

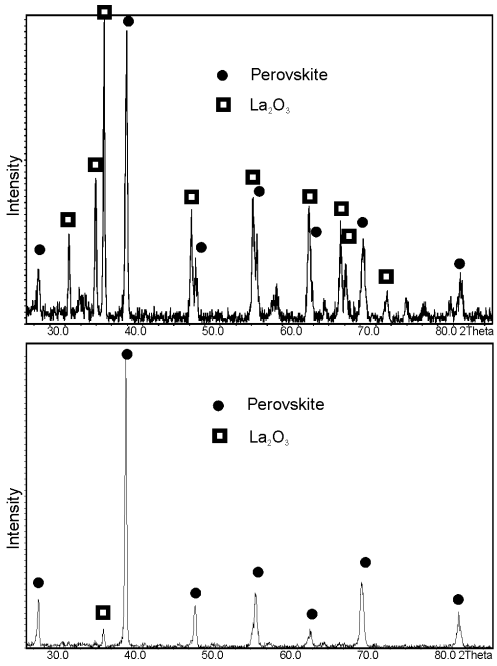

Fig. 2: XRD patterns of a TPCVD coating of LSM (precursor A) top: centre, bottom: margin of the sample

Scanning of the substrate results in the simultaneous deposition of the two main phases La_2O_3 and LSM. The homogeneity of the perovskite phase could be substantially improved by using precursors with lower lanthanum content, e.g. $La_{0.5}Sr_{0.5}MnO_3$ (precursors B and C) or by replacing lanthanum by praseodymium (precursor D), but a completely single-phase, large area perovskite coating could not be achieved. The synthesis of LSM, LSF (precursor E) and LSCF (precursor F) showed the same tendency concerning the formation of La_2O_3 but to a different extent. A semi-quantitative method was applied to compare the phase purity of different compounds by calculating the percentage of pure perovskite phase from the intensities of the main XRD peaks of the perovskite and La_2O_3. Table 2 depicts the phase composition of different perovskite layers.

Table 2: Phase purity of different TPCVD perovskite coatings

Precursor	ULSM		UPSM		LSCF		PSCF	
Position	centre	margin	centre	margin	centre	margin	centre	margin
Phase purity	85 %	100 %	92 %	100 %	65 %	100 %	100 %	100 %

It is concluded that the volatility of the manganese cannot be the only reason for the non-stoichiometric incorporation of the elements into the central part of the perovskite coating. Regarding the melting points of the simple oxides of the considered elements, La_2O_3 and SrO show far higher values than the other oxides of Mn, Fe and Co. This leads to the consideration that clusters of La_2O_3 or La-Sr-oxide might form in the hot zone along the plasma jet by homogeneous nucleation similar to the observation made in the system with yttria-stabilised zirconia [7]. These clusters might then be deposited and cannot completely be transformed to the perovskite phase due to the limited interdiffusion of Mn, Fe and Co. A break-through concerning phase purity was achieved when using precursors where La is substituted by Pr (precursor H). With the slightly non-stoichiometric composition $Pr_{0.58}Sr_{0.4}Co_{0.2}Fe_{0.8}O_3$ (PSCF) absolutely pure perovskite phase could be observed by XRD measurement both in the centre and on the margin of the layer as can be seen from Fig. 3. An explanation of this behaviour cannot be given at present and needs further investigation.

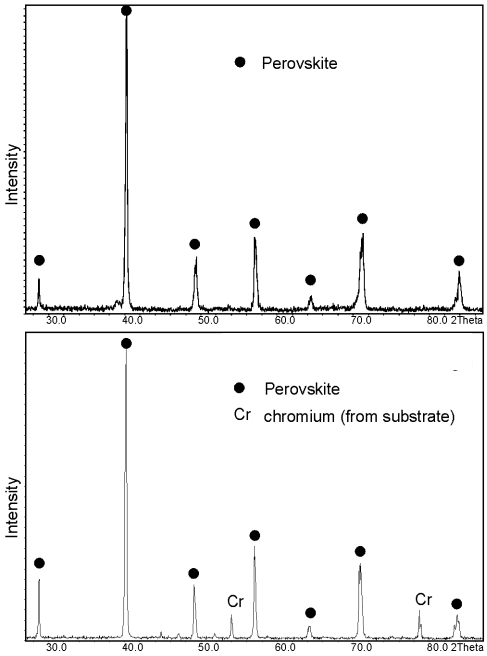

Fig. 3: XRD patterns of a TPCVD coating of PSCF (precursor H), top: centre, bottom: margin of the sample

Microstructure of TPCVD coatings

The coatings prepared from the precursor solutions A to H show a columnar or cauliflower-like microstructure as it is shown in SEM images of fracture surfaces in Fig. 4. Obviously they are a result of heterogeneous nucleation of the material on the substrate surface as it is well known from conventional CVD. During growth of the perovskite layer needle-shaped single crystals are initially formed. The substrate is in a temperature range that provides enough surface diffusion of the impinging species. Therefore the needles can coalesce resulting in a columnar growth. The resulting microstructure is of high open porosity offering efficient vertical as well as horizontal gas migration paths. This is an ideal microstructure for application as SOFC cathode enabling excellent gas permeability and creating a lot of reaction zones. Improved electrochemical performance is expected with this cathodes compared to conventionally DC plasma sprayed ones which suffer from a limited porosity due to their splat-shaped microstructure [3]. By depositing such TPCVD cathode coatings on half cells consisting of DC plasma sprayed anode and electrolyte layers on porous metallic substrates, full cells will be prepared and electrochemically characterised in the near future to prove their electrochemical performance.

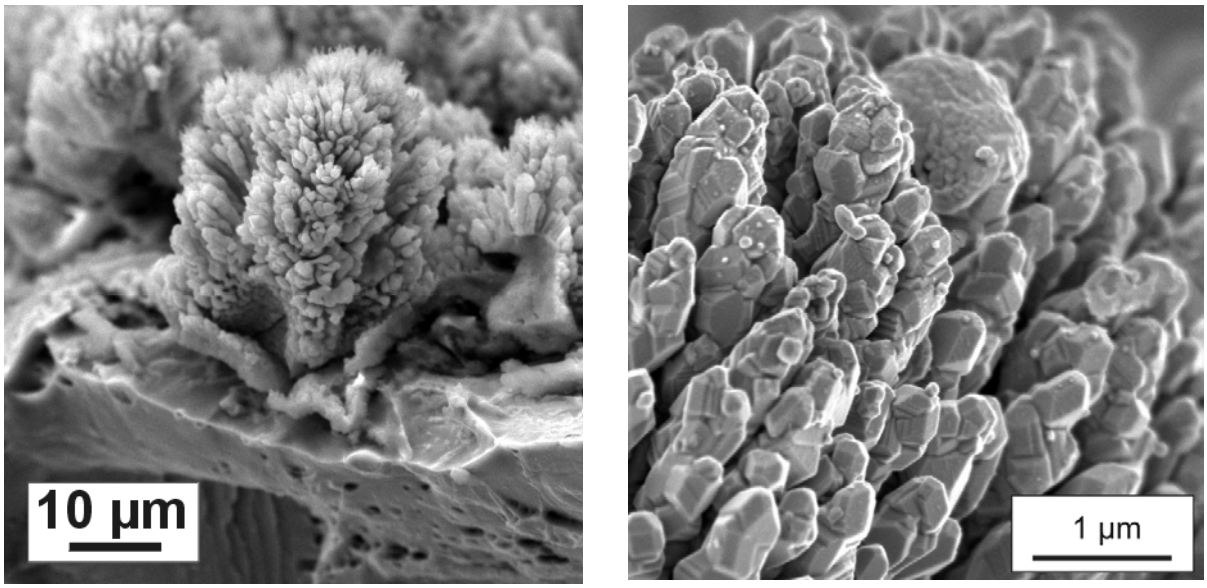

Fig. 4: SEM images of a fracture surface of a TPCVD perovskite coating

3.2 Growth Rate and Deposition Efficiency

The deposition of perovskite coatings by means of the TPCVD process from aqueous solutions resulted in growth rates of up to 25 µm/min on substrates with a size of 25 cm² that were scanned with the plasma jet. Depending on the process conditions and the precursor composition approximately 10 to 40 % of the theoretical oxide content of the precursors contributed to the coating growth. With optimisation of the plasma parameters and application of larger substrates the deposition efficiency of the TPCVD process may achieve the range of about 100 µm/min which is typical for plasma sprayed ceramic coatings.

4. Conclusion

Thermal plasma-assisted chemical vapour deposition (TPCVD) was applied to produce perovskite-type cathode coatings for solid oxide fuel cells from liquid precursors such as aqueous solutions of the relevant metal nitrates. The solutions completely vaporise in the plasma and condense through heterogeneous nucleation on the substrate surface forming a columnar structure. This microstructure provides an open porosity that is very advantageous for gas migration in SOFC cathodes. Deposition rates of up to 25 µm/min were achieved which is orders of magnitude higher than most of the comparable values found in the literature for TPCVD of oxide layers. Phase purity of the perovskite coatings is not easy to be achieved but we succeeded in preparing pure perovskite phase PSCF, checked by XRD, by replacing La by Pr in the perovskite structure. The expected improvement in electrochemical performance by applying these TPCVD cathodes in comparison to conventional DC plasma sprayed ones remains to be proven.

Abstract
The highly sensitive attenuated total reflection Fourier transform infrared spectroscopy technique (ATR-FTIR) has been used for *in-situ* measurements of amorphous (a-Si:H) and microcrystalline silicon
(μc-Si:H) film growth. A data analysis procedure for the ATR-FTIR measurements has been developed to obtain quantitative information on the hydrogen (H) concentration and bonding in the films. Contrary to
a-Si:H films, μc-Si:H films shows a non-homogeneous distribution of the hydrogen throughout the film, which suggests columnar growth of the μc-Si:H.

Introduction
Hydrogenated amorphous (a-Si:H) and microcrystalline silicon (μc-Si:H) thin films have important applications in semi-conductor devices and solar cell fabrication. In particular, a-Si:H and μc-Si:H are used in thin film transistors (TFTs) and the next generation thin film solar cells. Over the last few years, μc-Si:H has gained a lot of interest, because it exhibits important advantages compared to a-Si:H. Hydrogenated microcrystalline silicon has a lower bandgap (1.1 eV) than a-Si:H (1.7 eV), which enables a better use of the solar spectrum in tandem solar cell configurations [1]. Furthermore, it shows less light induced degradation [2] and a higher electron mobility. Future industrial applications of a-Si:H and μc-Si:H require deposition processes with a high growth rate (> 1 nm/s) and high film quality. High growth rate deposition of a-Si:H and μc-Si:H films is possible with the expanding thermal plasma (ETP) deposition technique.
The H concentration and bonding in a-Si:H and μc-Si:H films plays a key role in determining the film properties such as defect density, film structure and optical absorption. In this work, attenuated total reflection Fourier transform infrared (ATR-FTIR) spectroscopy [3] is used to measure the H concentration and bonding in very thin films (< 200 nm). For the quantification of the ATR-FTIR measurements, a data analysis method that includes interference effects has been developed.
The evolution of the H concentration and bonding as a function of the film thickness is measured for a-Si:H and μc-Si:H films. These experiments provide more insight in the growth mechanism of the film, especially for μc-Si:H that is not isotropic and grows in a non-uniform way [4,5]. The evolution of the H concentration and bonding in a-Si:H and μc-Si:H film growth has been studied.

Experimental setup, procedures and results
The expanding thermal plasma (ETP) setup consists of a thermal plasma source and a low pressure deposition chamber (~ 20 Pa). The plasma source is a DC cascaded arc discharge operated on a mixture of argon and hydrogen at a sub atmospheric pressure (~ 400 kPa). After creation, the plasma expands into the low pressure deposition chamber, where it dissociates the injected silane (SiH_4) gas. The deposition setup and the cascaded arc plasma source have been described in detail elsewhere [6].
The plasma species cause the deposition of a film on a substrate holder whereon an internal reflection element (IRE) is placed. The substrate holder is actively temperature controlled at 250 °C and a helium back flow ensures a proper thermal contact between substrate holder and IRE. During the starting of the plasma, deposition on the substrate holder and IRE was prevented by a shutter that was situated approximately 5 cm from the substrate holder.
The films are deposited on a GaAs IRE, which is a trapezoidal substrate with the dimensions 50 x 20 x 0.7 mm^3 and edges beveled at 60 °. Furthermore, the refractive index of GaAs is almost equal

to that of a-Si:H and μc-Si:H films, which has advantages in the analysis of the data. Infrared light from a Bruker Vector 22 FTIR spectrometer is focused onto the beveled edge of the IRE. In the IRE, the light undergoes 21 total internal reflections on both sides of the IRE, enhancing the sensitivity of the measurement technique. The light exiting the IRE passes a polarizer and falls on a MCT detector that detects the intensity of the light.

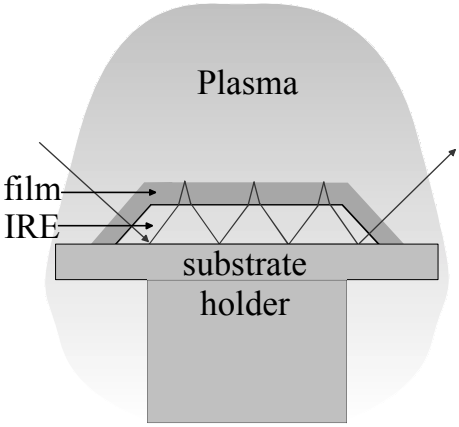

Figure 1: An IRE on the substrate holder.The film is probed by infrared light in the MTIR mode.

To obtain spectra with a good resolution 1000 scans of the FTIR spectrometer are integrated, which takes approximately 7 minutes. The combination of the long integration time and the fast deposition rate (3 – 10 nm/s) prevent real time measurements of the spectra during film growth. Therefore, the evolution of the H concentration and bonding as a function of the film thickness is obtained in a step-by-step deposition scheme.

The refractive index of the film on the IRE determines the way (mode) in which the film is probed. Two modes of probing are distinguished, the attenuated total reflection mode (ATR-mode) and the multiple total internal reflection mode (MTIR-mode). The MTIR mode, which is depicted in Fig. 1, occurs when the condition for total internal reflection (TIR) is not fulfilled at the interface IRE-film. Now the electromagnetic wave traverses into the film and TIR occurs at the film vacuum interface (if the condition for TIR is fulfilled there). In this work, all the films are probed in the MTIR mode.

In order to quantitatively analyze the ATR-FTIR measurements, an optical model has been constructed. The model takes into account several effects, including interference in the film, the influence of a deposited film on the bevels and the influence of multiple passes in the IRE that can occur when a part of the infrared beam is reflected back into the IRE at the bevels. Absorption in the film is taken into account by the introduction of a complex refractive index of the film: $\tilde{n}_f = n_f + ik$. Here n_f is the real part of the refractive index and k is the extinction coefficient that is related to the absorption coefficient $\alpha = 4\pi k/\lambda$, with λ the wavelength of the infrared light.

The transmission through the IRE can be described with the following equation:

$$T_{IRE}(d,\alpha) = \frac{T_{in} R_{ATR}^{M} T_{out}}{1 - R_{out}^{2} R_{ATR}^{2M}} \tag{1}$$

In this equation T_{in} is an expression for the transittance of the input bevel, T_{out} for the transmittance at the output bevel and R_{out} for the reflectance at the both bevels when the beam is incident from the inside of the IRE. R_{ATR} is an expression for the reflectance at the top surface of the IRE and includes possible interference effects and the absorption in the film on top of the IRE (dependent on absorption coefficient of the film and film thickness). M is the number of reflections at the top surface of the IRE. Because all the transmittances and reflectances are based on the Fresnel equations that are polarization dependent, also T_{IRE} is polarization dependent. Therefore, it is essential for a quantitative data analysis to use polarized light in the measurements. More information on the measurement technique and data analysis method is given elsewhere [7]

As a measure for the amount of absorption in the film on the IRE the quantity absorbance is used. Absorbance is defined as:

$$A(d) = -\log \frac{T_{IRE}(d,\alpha)}{T_{IRE}(0)} \tag{2}$$

Because of the complexity of the expressions in Eq. 1 a mathematical inversion is required to obtain the absorption coefficient from Eq. 2. In this work an iterative numerical procedure has been used to extract the absorption coefficient from the measurement.

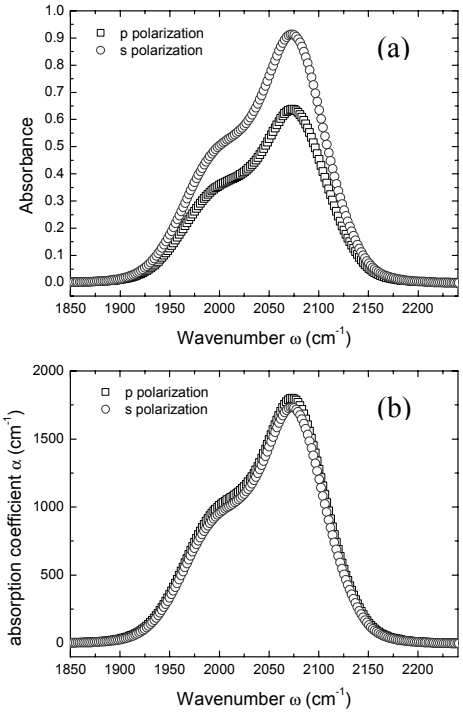

Figure 2: (a) The absorbance spectra for measurements with s and p polarized light of a 200 nm thick a-Si:H film. (b) The calculated absorption coefficient for the same film.

In Fig. 2(a) the absorbance for measurements with *s* and *p* polarized light of a 200 nm thick a-Si:H film is given. Clearly a large difference between the measurements observed. By the application of the optical model, the resulting absorption coefficient can be calculated. In Fig. 2(b) the calculated absorption coefficient is shown, also for measurements with *s* and *p* polarized light. The calculated absorption coefficients are equal for *s* and *p* polarized measurements. This is expected for an isotropic material like a-Si:H, which verifies the validity of the used model.

Absorption in a film depends linear on the density of absorbing species, which means that the total density in a specific infrared bonding mode N_i can be expressed in terms of the absorption coefficient α:

$$N_x = P_x \int \frac{\alpha}{\omega} d\omega \approx \frac{P_x}{\omega} \int \alpha d\omega \qquad (3)$$

where P_x is the proportionality constant for the silicon hydride bonding mode *x*. The proportionality constant has been set to 9.0 x 10^{19} cm^{-2} for all bonding modes [8]. Now the H concentration $C_{H,x}$ in atomic percent can be calculated for the bonding mode *x* according:

$$C_{H,x} = \frac{N_x}{N_{tot}} \times 100\% = \frac{P_x}{\omega N_{tot}} \int \alpha d\omega \times 100\% \qquad (4)$$

where N_{tot} is the total atomic density of the film (5.0 x 10^{22} cm^{-3} for c-Si). The hydrogen concentrations determined from the ATR-FTIR measurements are in good agreement with *ex-situ* FTIR measurements of similar films.

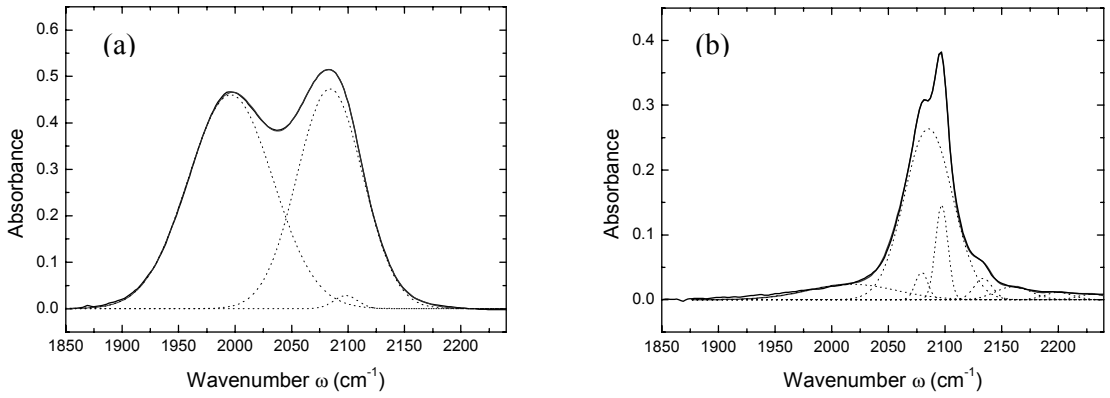

Figure 3: (a) The ATR-FTIR spectrum of a 200 nm thick a-Si:H film. Three peaks can be distinguished, the LSM, HSM and a small peak corresponding to surface-like modes. (b) The ATR-FTIR spectrum of a 200 nm thick μc-Si:H film.

In Fig. 3 (a) the ATR-FTIR spectrum of a 200 nm thick a-Si:H film is shown. In the spectra two main peaks are present, the lower stretching mode (LSM) and the higher stretching mode (HSM). The LSM is assigned solely to SiH bonds in the material and the HSM to SiH_2 bonds and SiH bonds on internal surfaces. Furthermore, a small peak is present that is assigned to surface-like modes of SiH bonds. In Fig. 3 (b) ATR-FTIR spectrum for a 200 nm thick μc-Si:H film is shown.

Apart from the LSM and HSM that are also present in the spectrum of the a-Si:H film, several well-defined surface-like peaks can be seen that are essential for fitting the spectrum properly.

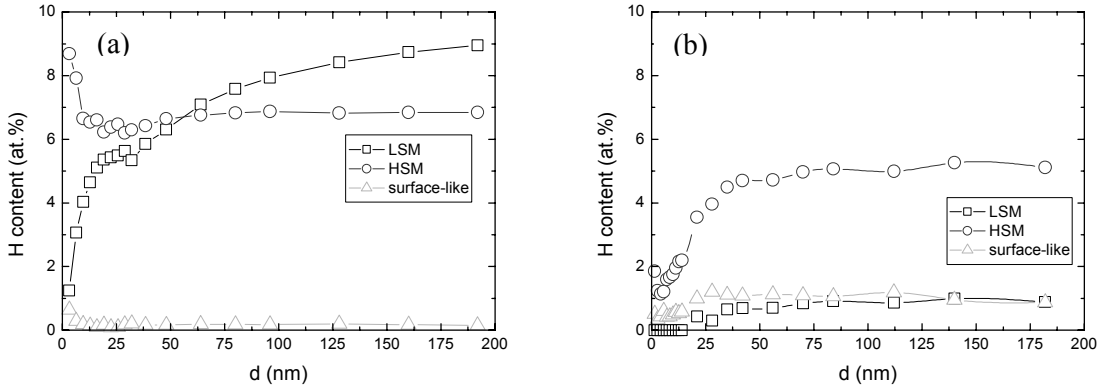

Figure 4: (a) The ATR-FTIR spectrum of a 200 nm thick μc-Si:H film. Apart from the LSM and HSM that were also present in the spectrum of the a-Si:H film, several surface like peaks are necessary to fit the spectrum properly. (b) The evolution of the H concentration and bonding in a μc-Si:H film as a function of the film thickness.

In Fig. 4 (a) the evolution of the H concentration and bonding as a function of the film thickness is shown for the a-Si:H film. The initial phase of the a-Si:H growth is characterized by a high H concentration in the HSM. When the film thickness increases, the H concentration in the HSM decreases sharply and becomes constant, while the H concentration in the LSM gradually increases. Eventually the LSM becomes dominant over the HSM and the total H concentration is ~ 16 at. %.
Fig. 4 (b) shows the evolution of the H concentration and bonding for the μc-Si:H film growth. Initially the H concentration in the HSM and surface-like modes increases, while the H concentration in the LSM remains zero. Eventually the LSM increases slightly. After 25 nm the film growth reaches a steady state and the HSM is dominant in the film. The total H concentration in the μc-Si:H film is ~ 7 at. %.
The well defined surface-like modes in the μc-Si:H film have been assigned to hydrogen on the boundaries of crystallites in the material. These measurements, combined with spectroscopic ellipsometry measurements of the μc-Si:H film growth [9,10], suggest the following growth mechanism. Initially small crystallites are formed in the material. The crystallites grow in size, which corresponds to the increase in surface-like modes. After approximately 25 nm, the crystallites make contact and from there columnar growth of the μc-Si:H is observed. This columnar growth is characterized by a constant H concentration in the surface-like modes (on grain boundaries).

PLASMA TECHNOLOGY AND TECHNIQUE IN NUCLEAR FUEL CYCLE

I.N.Toumanov

Russian Research Centre "Kurchatov Institute"-HEPTI, Moscow, Russia

1. Traditional nuclear fuel cycle includes the next stages: opening up and enrichment ores, leaching and purification of uranium, producing of uranium and uranium compounds designed for synthesis of uranium hexafluorides, uranium enrichment, producing ceramic nuclear fuel, generation of power in a nuclear reactor, regeneration of uranium, recovery of plutonium, processing and burial of nuclear waste. Plasma, direct inductive heating and laser technology in combination with new purification technologies (sorption, liquid extraction, counter flow distillation) enable to reconstruct the nuclear fuel cycle efficiently and to solve a lot of specific economic and social problems of nuclear power engineering.
2. Technical basis include: DC plasmatrons generating air, nitrogen, steam, hydrogen plasma streams; high frequency plasmatrons supplied with slotted water – cooled discharge chamber made of non-magnetic metal; all metal microwave plasmatrons; combined plasmatrons supplied with reinforcement of coupling a basic power supply with plasma. Laser technique used for uranium enrichment includes technological and auxiliary lasers equipped in AVLIS and MLIS technologies.
3. Large scale plasma processes realized on the level of plasma plants, at least, are following:

- plasma processing of ores for destruction of crystallic lattice of resistive ores for more efficient hydrochemical opening up and leaching of valuable components;
- plasma conversion of disintegrated liquid nitric raw materials (predominantly re-extracts or melts) to disperse oxide materials and nitric acid solutions;
- producing of the MOX – fuel;
- plasma steam conversion of low enriched uranium hexafluorides to uranium oxides for following making of oxide nuclear fuel and hydrofluoric acid solution;
- plasma steam conversion of depleted uranium hexafluorides to uranium oxides and anhydrous hydrogen fluoride in combination with counter flow distillation;
- high frequency technology for reactant free reduction of uranium from uranium hexafluorides in combination with processes of separation of uranium and fluoride;
- plasma reduction of metallic uranium from oxide raw material accompanied with plasma - electronic refining;
- plasma conversion of gas exhausts of hydrogen fluoride production;
- high frequency synthesis of ceramic materials used in the nuclear fuel cycle: carbides, borides, nitrides, solid solutions etc.;
- low frequency reduction of rare metals (zirconium, hafnium, scandium etc.);
- calcination of aqueous nitric radioactive waste;
- plasma processing of condensed nuclear waste.

4. There are several approaches for reconstruction of the nuclear fuel cycle both based on plasma and frequency technique and on combination of the technique aforesaid with laser technology used for uranium enrichment:

- plasma technology of producing of nuclear materials in combination with high frequency and low frequency direct inductive heating;
- plasma technology of producing of nuclear materials in combination with AVLIS technology for uranium enrichment and with frequency direct inductive heating;
- plasma technology of producing of nuclear materials in combination with MLIS technology for uranium enrichment and with frequency direct inductive heating.

SIMPLIFIED MODEL FOR GENERATION OF ARC COLUMN IN A PLASMA SPRAYING TORCH.

E. Meillot, D. Guénadou

C.E.A. LE RIPAULT, B.P. 16, 37260 MONTS, France
Erick.Meillot@cea.fr

Symposium topic number 3 : Modeling in plasma chemistry.

In the plasma spraying process, the influence of the gas flow dominates to determine the state of the particles at impact onto the substrate. To better comprehend this influence, 2 D. numerical simulations are carried out with the C.F.D. ESTET code using the k-? turbulent model.
A simple model generating the plasma in the anode is proposed and analyzed. The model leads to simulate the arc generation in a simplified way : it mainly depends on the macroscopic operating parameters of the plasma torch and so allows the numerical simulations of the process for industrial applications without expecting high level measurement diagnostics such as velocity or temperature of the flow at the nozzle exit.
The plasma is simulated by a volume energy source inside the nozzle. Several designs of torch are investigated. The main parameters are discussed and comparisons with experiments are done in the steady state of the plasma flow.

The discussed model of plasma column permits the correct simulation of the plasma spraying process with only operating conditions and design parameters of the torch.

Relationships between induction plasma spraying parameters and TiO_2 particle characteristics at impact.

Abstract
Many studies have been devoted to the effect of the plasma spray process parameters on the in-flight particle velocity and temperature because of the recognized relationships between the latter and the quality of the coating. The objective of this work is to link the main operating parameters of the induction plasma spray process with the impact parameters of titania particles. The use of inductive plasma torches working under subsonic or supersonic conditions makes it possible to get particles with velocity ranging between 40 and 730 m/s and temperature between 2000 and 2150°C.

1. Introduction

Over the past 15 years, the **I**nductive **P**lasma **S**praying (IPS) technology has gained important credibility for the manufacturing of plasma-sprayed coatings of metals and ceramics. Its main advantages are the low velocity and large volume of the plasma plume that result in an increase of the particle residence time compared with the particle residence time in d.c. plasma spraying and, therefore, in an improvement in their melting state before impact. Moreover, the absence of electrodes involves the possibility to operate under a wide range of conditions at atmospheric and low pressure, with inert, reducing or oxidizing gases [**1**].

At the end of the eighties, a specific effort was made to measure the velocity of particles before impact onto the substrate under typical IPS conditions [**2-3**]. Measurements were carried out using Laser Doppler Anemometry that is a well established diagnostic tool under plasma conditions. Also, Coulombe et al [**4**] examined the correlations between the morphology of the splats obtained by IPS and particle characteristics thanks to the simultaneous measurement of particle velocity by a time-of-flight technique and surface temperature by two-color pyrometry. They showed that the uniform radial distributions of particle temperature and velocity gave rise to a high deposition efficiency (up to 90 %) and homogeneous quality of coatings.

The objective of this work is to correlate the operating conditions of an IPS spray process with the particle parameters that are measured using a commercial diagnostic system (DPV-2000, Tecnar-Canada) [**5**]. Two operating modes of the inductive plasma spray torch are investigated: subsonic and supersonic. The latter results from the use of a "de Laval" nozzle. This convergent-divergent nozzle presents a critical throat diameter that brings about particle velocity equal or higher than the velocity reached under d.c. plasma spray conditions [**6-7**].

This study deals with titania coatings that are mainly used in photo-electric energy applications [**8**] and wear-resistance applications [**9**]. The first part of the paper gives a description of the plasma-sprayed materials and experimental procedure. The second part refers to the effect of the main parameters of the IPS process on the in-flight particle characteristics. A special section examines the relationships between particle velocity and coating stoichiometry.

2. Materials and experimental procedure

Materials

The commercially available powders (H.C. Starck) had a particle size distribution ranging between 22 and 45 µm when working with subsonic IPS conditions and between 5 and 20 µm with the supersonic conditions. In order to obtain the pure rutile phase, the powders were heat-treated in air for a period of three hours at 1000°C before plasma processing. After this treatment, the Magneli phases (Ti_nO_{2n-1} with n = 4-10), present in the original powders, were eliminated.

Plasma conditions

Plasma spraying was performed with a 3-MHz induction plasma unit (Figure 1). An inductive plasma torch (Model PL 35 - Tekna Plasma Systems Inc., Canada) with a ceramic plasma-confinement tube of 35 mm in internal diameter, was used to study the effect of the subsonic IPS parameters on the in-flight particle characteristics. In supersonic IPS, a convergent-divergent nozzle with a critical throat diameter of 10 mm was used as a substitute for the convergent nozzle of the standard PL-35 plasma torch.

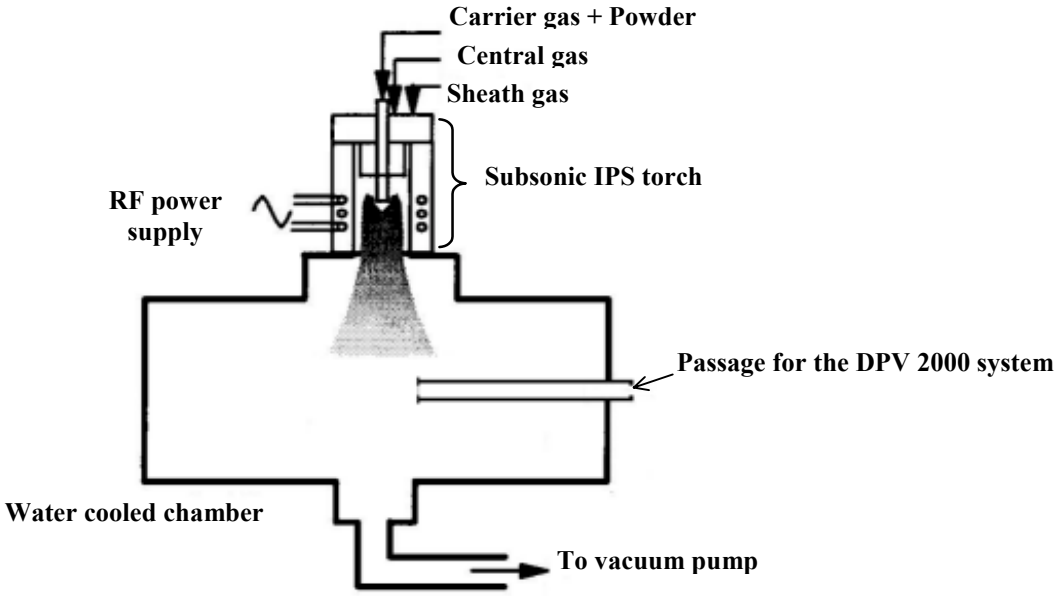

Figure 1 : Schematic illustration of the IPS setup.

In subsonic IPS, the powder was injected axially into the plasma flow through a water-cooled stainless steel probe with an exit tip located at 40 mm upstream of the exit plane of the torch nozzle. The external and internal diameters of the powder-feeding probe were 4.8 mm and 2.5 mm, respectively. The powder feed rate was 11 g/min. In supersonic IPS, the powder feed rate was 3.5 g/min and the probe was located 90 mm upstream of the exit plane of the torch nozzle.

In both modes, oxygen, at 70 NL/min, was used as sheath gas in order to limit the reduction of titania particles in the plasma flow while argon was used as plasma and powder carrier gases at flow rates of 40 and 4 NL/min, respectively.

The torch power, the spraying distance and the expansion chamber pressure were varied as shown in Table 1. These parameters were expected to affect the residence time of the particles in the plasma flow and, consequently, the momentum and heat transfer between the plasma gas and particles. It must be noted that in subsonic IPS, the pressures were the same in the expansion chamber and coil region while in supersonic IPS, the pressure was higher in the coil region and varied between 40 and 60 kPa.

In order to study the effect of oxygen and particle velocity on the decomposition of titania particles during plasma processing, coatings were deposited on stainless steel substrates (X13M), 25 mm in diameter and 5 mm in thickness, prepared by grit blasting and degreasing before spraying. The coatings were subjected to metallographic preparation before observation by cathodoluminescence.

Table 1 : Variation range of the induction plasma spraying parameters.

Process	Powder size range	Spraying Parameters	Variation range
Subsonic mode	22-45 µm	Torch power	35 to 50 kW
		Spraying distance	150 to 200 mm.
		Expansion chamber pressure	33.3 to 79.9 kPa
		Coil chamber pressure	33.3 to 79.9 kPa
Supersonic mode		Powder granulometry	[5 –20 µm] and [22-45 µm]
	5-20 µm	Expansion chamber pressure	3.3 to 13.3 kPa
		Coil chamber pressure	40 – 60 kPa

In-flight particle velocity and temperature

Particle temperature and velocity were measured using a DPV-2000 diagnostic system. The measurements were carried out on the torch axis at 100 mm from the DPV-2000 sensor head. The accuracy of measurements was estimated to be about 5 % for particle velocity and 20 % for particle temperature [**5**]. However, it can be noticed that temperature measurements give a correct trend of the effect of spray parameters on particle behaviour.

3. Results and discussion

3.1 Subsonic IPS

Spraying distance

The spraying distance is defined as the distance between the torch exit and substrate surface. As the total distance covered by the particles is the distance between the tip of the powder feeding probe and the substrate, 40 mm for the subsonic torch and 90 mm for the supersonic one must be added to the spraying distance.

The study of the effect of the spraying distance on particle parameters was carried out at a torch electric power of 40 kW and a pressure of 53.3 kPa.

An increase in spraying distance results in a longer residence time in cooler zones outside the plasma plume. Therefore, the particles decelerate and cool down gradually in this part of their trajectory. It was observed a decrease in particle velocity by 15 % (from 48 to 40 m/s) for an increase in spraying distance of 70 mm while the particle temperature difference was only 20°C (from 2120°C to 2100°C). It should be noticed that, first, the particle temperature was higher than the melting point of titania (Tm = 1850°C) and, second, the accuracy of the DPV 2000 for temperature measurement is not high enough to observe any effect of the spraying distance on particle temperature.

The spraying distance also affects the flattening behaviour of the particles impinging onto the substrate : a short spraying distance (150 mm) limits the cooling of the particles and results in thinner splats (about 3 µm instead of 10 µm for a spraying distance of 200 mm).

Torch power

The spraying distance was fixed at 150 mm and the chamber pressure at 53.3 kPa.

The electric power input to the torch has an effect on the plasma discharge volume and enthalpy. An increase in the plasma power causes a slight rise in the degree of ionisation of the gas and results in a higher plasma enthalpy and a larger discharge volume. Consequently, the heat transfer between plasma and particles is enhanced. However, it was found that an increase in torch power by 29 % resulted in an increase in particle temperature by 100°C while, as generally observed, the particle velocity was, by far, more sensitive to the gas enthalpy (Figure2).

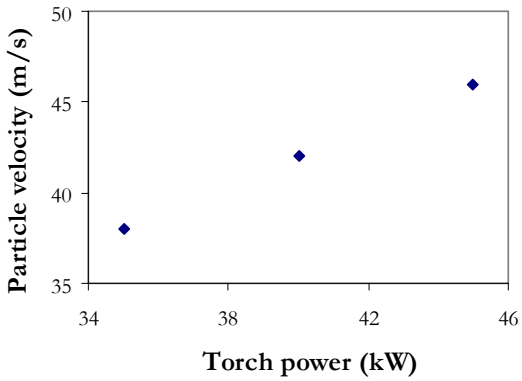

Figure 2 : Variation of the mean particle velocity with the torch power.

Chamber pressure

The study of the effect of the pressure in the expansion chamber on particle acceleration and heating was carried out at a spraying distance of 150 mm and a torch power of 40 kW.

The expansion chamber pressure affects the plasma discharge volume and length. Indeed, an increase in the chamber pressure causes a decrease in the length and velocity of the plasma plume as a result of the mixing with the denser environment gas. The higher the expansion chamber pressure, the lower the velocities of particles at impact as shown in Figure 3.

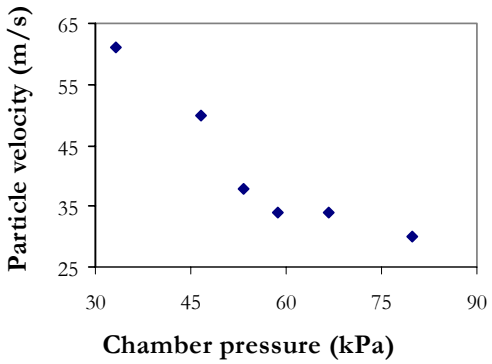

Figure 3 : Variation of the mean particle velocity with the chamber pressure under subsonic IPS conditions.

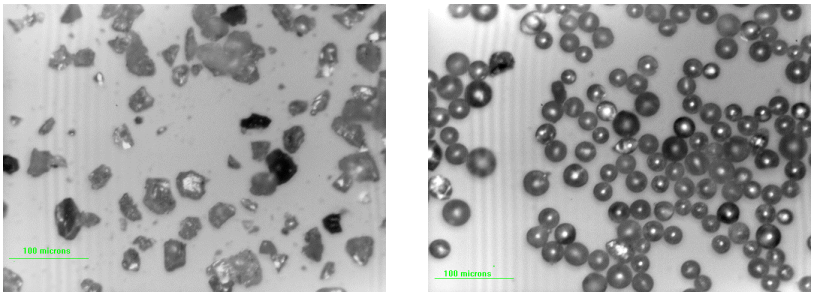
However, when the chamber pressure decreases, the heating of particles is less efficient because of shorter particle residence time in the gas flow and Knudsen effect. As seen in Figure 4, the particles collected in the chamber at 13.3 kPa, had an irregular shape similar to that of the titania powder feedstock. Whereas, at a chamber pressure around 53.3 kPa, particles exhibited a spherical shape highlighting a good melting state.



p = 13.3 kPa **p = 53.3 kPa**

Figure 4 : Optical micrographs of titania particles collected in the spraying chamber at two different pressures.

3.2 Supersonic IPS

Powder granulometry

The effect of the powder granulometry on the particle characteristics is shown in Table 2. The pressure in the expansion chamber was kept constant at 13.3 kPa and the spray distance at 200 mm whereas the torch power was varied between 35 and 50 kW resulting in a coil chamber pressure between 40 and 60 kPa.

Table 2 : Effect of the powder granulometry on the in-flight particle characteristics at different torch powers.

	Particle size range : 22-45 µm		Particle size range : 5-20 µm	
Torch power (kW)	Mean particle temperature (°C)	Mean particle velocity (m/s)	Mean particle temperature (°C)	Mean particle velocity (m/s)
35	1690	330	2020	440
40	1720	355	2040	435
45	1710	350	2050	485
49	1715	380	2100	495

Because of the high plasma and particle velocity compared to that in subsonic IPS, finer particles are generally used in supersonic induction plasma spraying as the heat required to melt the particles is proportional to the cube of the particle diameter. Under the conditions of this study, the heat transfer to the powder with particle size ranging between 22 and 45 µm was not sufficient to melt them and particle surface temperature at impact was less than the titania melting point (T_m = 1850°C) against more than 2140°C in subsonic IPS.

Chamber pressure

The effect of the expansion chamber pressure was studied at a spraying distance of 200 mm and a torch power of 35 kW.

In supersonic IPS, the effect of the expansion chamber pressure on the in-flight particle behaviour was similar to the effect observed in subsonic IPS : an increase in the chamber pressure results in a decrease in the length and velocity of the plasma plume as a result of the mixing with the denser environment gas. Consequently, the increase in the expansion chamber pressure brings about a decrease in particle velocity.

In addition, the decrease in the expansion chamber pressure enhances the supersonic conditions because of a larger difference between the pressure in the coil region (about 60 kPa) and the pressure behind the torch, i.e. in the expansion chamber. Consequently, the lower the expansion chamber pressure, the higher the velocity of the particles. The latter ranged between 440 and 730 m/s for an expansion chamber pressure varying from 13.3 to 3.3 kPa

3.3 Effect of particle velocity on coating stoichiometry

As previously shown, the use of a supersonic nozzle leads to particle velocities ranging between 330 m/s and 730 m/s whereas under subsonic IPS conditions, particle velocities were in the order of 40-60 m/s.

The distinctive characteristic of titania is that the plasma-sprayed coatings exhibit large variations in stoichiometric composition depending on the operating conditions of the deposition process. The coating stoichiometry affects its electrical properties [**7**]. When titania is plasma-treated, the insulating rutile is changed in a n-type semiconductor because of some oxygen loss during the spray process. To quantify this effect, the coatings were observed by a cathodoluminescence (CL) technique [**10**] that is often used to study semiconductor materials.

Figure 5 shows that the subsonic IPS coatings present a less luminous response because of a less marked presence of semiconductor zones contrary to the supersonic IPS coatings. In both IPS processes, oxygen was used as sheath gas to limit the de-oxidation of the in-flight particles. However, in the case of subsonic IPS, the lower particle velocity favours the chemical equilibrium between the particles and plasma environment. Consequently, the oxygen loss is compensated explaining why there are less semiconductor zones.

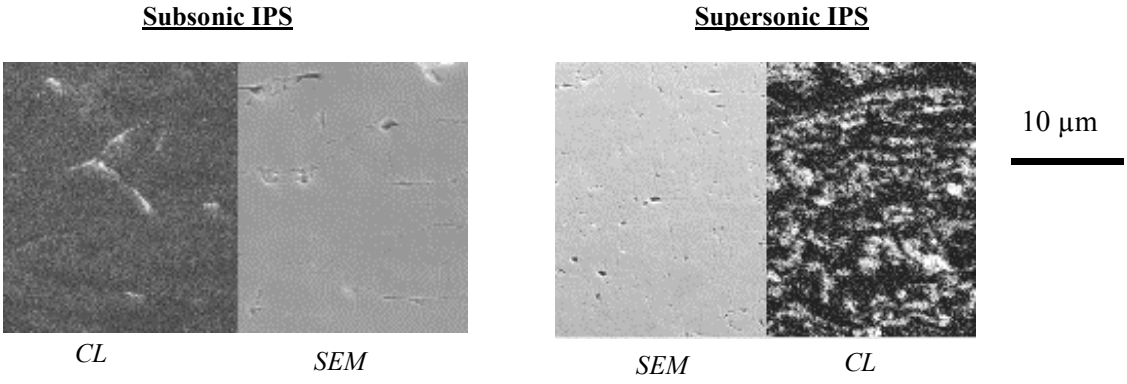


Figure 5 : CL and SEM micrographs of titania coatings prepared by subsonic IPS and supersonic IPS.

4. Conclusion

This work deals with the study of the heating and acceleration of titania particles in Inductive Plasma Spraying. The objective was to limit the decomposition of titania particles by using oxygen as sheath gas and a convergent-divergent "de Laval" nozzle to increase particle velocity.

The measurement of particle velocity and temperature made it possible to link the plasma spraying parameters and in-flight particle characteristics prior to impact on the substrate. For the powder with particle size between 22 and 45 µm, the particle temperatures ranged between 2100 and 2240°C and velocities between 30 and 60 m/s under IPS subsonic conditions, while they ranged between 1690 to 1715°C and between 330 to 380 m/s, respectively, under IPS supersonic conditions. For the powder with particle size between 5 and 20 µm, the measurements showed that the particle velocity was comprised between 440 and 730 m/s and the particle temperature between 2050 and 2150°C. The pressure in the chamber was found to be the factor that affects the most particle velocity whatever the inductive plasma spraying process was.

Moreover, thanks to the analysis of the titania plasma-sprayed coatings by a cathodoluminescence method, it was observed that the use of oxygen is not the only necessary condition to limit the decomposition of titania. The oxygen gas must be combined with a low particle velocity, obtained under subsonic IPS conditions, to favour the chemical equilibrium between the particles and plasma environment.

MEASUREMENTS OF COOLING AND HEAT FLUXES IN A CRYOGENIC ATOMIZATION AND PLASMA SPRAYING PROCESS

E. Meillot
C.E.A. LE RIPAULT, B.P. 16, 37260 MONTS, France
Erick.Meillot@cea.fr

Abstract. This paper is devoted to heat flux measurements in a plasma spraying process to which a cooling system by liquid cryogenic atomization is added. The heat fluxes are measured for both systems and the interactions between the two jets are investigated via these fluxes. The goal of this study is to analyze the heat received by the substrate to determine the cooling, avoiding an increase in the local substrate temperature and therefore the damage of the substrate.

Key words : Plasma spraying, cooling, heat flux, cryogenic atomization.

Introduction. Plasma Spraying heats and accelerates sub-micron particles which crash onto a substrate. This results in a coating by the piling up of particles which improves the performance of the substrate. Generally, the substrate temperature grows due to the heating by the melted particles and by the enthalpy plasma gas which reach the substrate. The coating properties depend on the thermocinetic state of the particles impacting onto the substrate, but also on the cooling speed of the particles spreading out on the substrate while spraying /1/. The increase in temperature has high importance due to the consequences in the coating properties. The residual stress distribution within coatings depends mainly on the temperature distribution within coatings during spraying /2/ /3/. At the end, this increase could lead to the destruction of the substrate, or the piece to be coated, by thermal dilatations (for example) or by chemical behavior, if the temperature over grows the changing phase temperature. So several methods were followed to cool the substrate while spraying : high velocity cold gas cooling /4/, cryogenic spray cooling /5/…
At the beginning of the 80's, the CEA patented this last cooling : argon liquid at low temperature (≈ 84 K) pulverized by spraying nozzles onto the substrate /6/. This process is called Atmosphere and Temperature Control (A.T.C.) Plasma Spraying. This involves a high cooling by low temperature droplets impacting the substrate simultaneously with the deposition formation. So high melting temperature particles can be deposited onto low destruction temperature substrates (less than 100°C).
This paper is devoted to the heat and cooling flux measurements from both plasma spraying torch and cryogenic cooling device. The goal of this work is to compare the fluxes obtained by different operation parameters of the cooling nozzles and to quantify the interactions of the cooling droplet jet with the plasma flow near the substrate.

I – Experimental System.

Plasma operating parameters. An F100 CONNEX SULZER METCO plasma torch is equipped with a 6 mm diameter anode and stands on a 6 axis robot arm. The operating parameters, summarized in table 1, were determined to spray ceramics or metals such as TIO_2 /7/ for example. These conditions lead to an effective power at the torch exit of about 9.5 kW resulting in gas enthalpy of 13.8 MJ/kg. In the L.T.E. assumption, the average off-gas temperature is more than 10000 K.
Cooling operating system. The robot arm is also equipped with the cooling system. In case of important heat to evacuate, several cooling devices stand around the plasma torch (cf. figure 1).
The first one concerns the cooling with high speed argon gas flow rate through two rods each side of the torch at 18 mm from the torch axis. The argon flow rate is typically 15 sm^3h. These two rods are copper tubes with an inside diameter of 4 mm and a length of 80 mm. Five holes of 2 mm diameter are spaced 10 mm from each other. The 3rd hole is at the same centerline as the torch axis. This configuration produces a vertical barrier of cold gas in each part of the torch.

The second one is composed of two atomizers 40 mm from the axis of the torch. These atomizers are SPRAYING SYSTEMS referenced 100150. They are assisted atomizers because of the injection of high speed gas around the liquid jet.

Table 1 : Plasma operating conditions

Parameter	Value
Argon flow rate (slm)	20
Helium flow rate (slm)	30
Intensity (A)	50
Spraying distance (mm)	120
Electric power (kW)	15.75

The front face of the global apparatus (torch, nozzles, rods) stands in the same plan at 120 mm from the substrate.
Let us closer describe the nozzles with their two feed networks. The liquid flows in a central pipe. With the 100150 nozzle, the exit diameter is 2 mm but it has been drilled at 2.9 mm for a higher flow rate.
To feed the nozzles in liquid, the pressure is regulated from 1.2 10^5 to 1.8 10^5 Pa in the feedstock. The liquid flows in vacuum isolated pipes from the feedstock to the nozzles.
Around this network exit, the first circuit of the assistance gas takes place. It has a smaller diameter of 3.9 mm and an upper one of 4.9 mm. The goal of the assistance gas is to destroy the liquid jet in small droplets due to the high speed difference between the two jets. In this kind of nozzle , the goal of the second gas network is to put in shape the droplet jet: so two lateral holes take places in each part of the jet at some millimeters after the exit (3 mm). With this configuration, the droplet jet is in shape as a vertical plan, normally avoiding the interactions with the plasma or the sprayed particles. The two gas networks are in connection: so it is impossible to determine the gas flow rate passing in each part. We only know the global gas flow rate, around 22 sm^3h in nominal operating conditions. A remark : the central assistance gas network can be closed. In this case, the gas passes through the second circuit by the two lateral holes. This configuration is a particular motivation for this study.

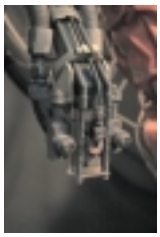

Figure 1 : Torch and cooling systems.

Figure 2 : Flux measurement device.

Heat flux measurement device. To quantify the plasma and atomized cooling fluxes, a heat flux measurement has been developed. First measurements have shown the opportunity to quantify the fluxes but also to determine the fluctuations of the plasma /8/ impacting the substrate due to the movement of the arc foot in the anode.
Eleven sensors are attached to a copper support (figure 2), and linked to a data acquisition computer. These sensors are copper/constantin multi-layers. The small sensor size (10 mm x 10 mm x 70 µm) gives them a high sensitivity (about 0.50 $\mu V/W/m^2$) and a short reaction time (less than 1 ms). The signal is directly proportional to the heat flux, positive for heating and negative for cooling. Moreover, three thermocouples measure the surface temperature of the copper sheet. The system drawback, due to the varnish protecting the probes, is the operating temperature, which must range between -200 and +200 °C.
Operating procedure tests have shown that the results are reproducible with an acquisition data frequency less than 350 Hz. In fact, for each sensor, an average of five consecutive measurements is

made: this averaged value is recorded in a file and corresponds to one measurement point. The error is around 10% in steady state.

II – Experimental Conditions.

The plasma conditions of table 1 remained constant in surrounding air. The stand off distance between the torch exit and the substrate was 120 mm. This distance was also kept for the cooling devices.
The translation movement of the robot arm, equipped with the global apparatus, was regulated at 1000 mm/s which is a usual velocity for this kind of applications.
Let us have a look of the cooling conditions. First, the atomizers were analyzed alone without the two gas rods. Four liquid pressures were investigated to feed the atomizers : 0.12 ; 0.14 ; 0.16 ; 0.18 MPa. According to the exit diameter of the atomizers and the BERNOUILLI law, neglecting the charge looses in the pipes, the liquid flow rates were respectively 7.24, 7.82, 8.36 and 8.87 kg/mn. Three gas pressures (0.4 ; 0.6 ; 0.8 Mpa) were also used to destroy the liquid jet; they lead respectively to 18, 22, 25 sm^3h gas flow rates.
All these conditions were explored in two designs of the atomizers : firstly in normal configuration with the two opened gas networks (It will be called case I in the following paragraphs). Secondly, with the central assistance gas network closed (It will be called case II in the following paragraphs). After that the gas rods were under pressure. The experiments were carried out with the highest gas pressure (0.8 MPa) and with the four liquid flow rates.

III – Results And Discussion.

For all the investigations, references are necessary. So, the single plasma heat flux received by the substrate will be analyzed first. Then the plasma flux will be investigated with the substrate cooling by the two ways, firstly with the single atomizers, secondly with the addition of the gas rods. At the end, the interactions between the two different kinds of jet will be analyzed to conclude this work.

The plasma flux.

The plasma flux without cooling. First of all, let us have a look at the heat generated by the plasma and received by the substrate without any cooling. Figure 3 shows the heat flux recorded by one captor during time. The maximal average flux is around 15 W/cm². In figure 4, the space distribution of the maximum flux is rather extensive : the half-height width gets a surface with a radius of 25 mm. This result will be kept as reference for the following comparisons.

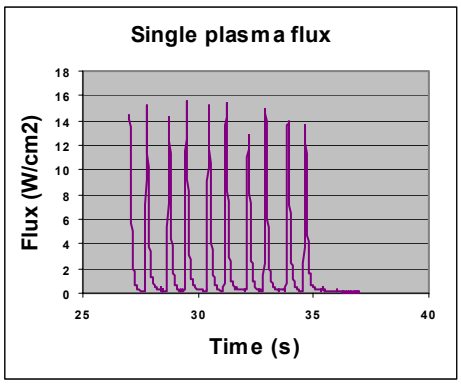

Figure 3 : Plasma flux measured by the central captor versus time.

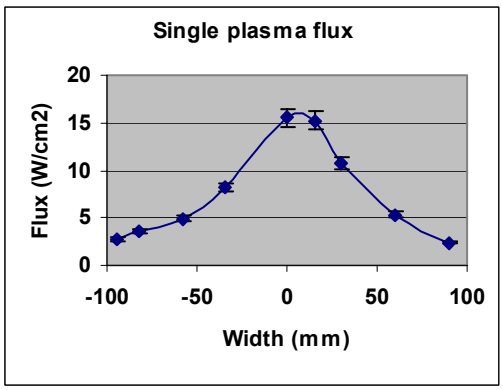

Figure 4 : Plasma flux spatial distribution.

The plasma flux with cryogenic atomization. After measurements of the single plasma flux, the cooling of the substrate is introduced by cryogenic atomization. The liquid flow rate (7.24 kg/mn) and the gas pressure (0.4 Mpa) lead to a decrease in the plasma flux to around 9 W/cm² (figure 5).

The plasma flux decreases with an increase in the assistance gas of atomization (figures 5 and 6). When the central assistance gas network is closed, it brings about a strong decrease in the flux (figure 6). Similar behaviors are noticed for every liquid flow rate.

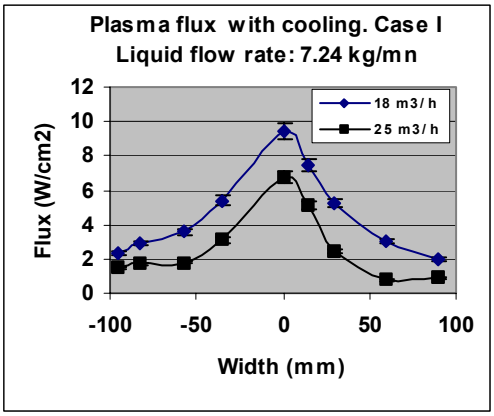

Figure 5 : Plasma flux with cooling in case I (Liquid flow rate: 7.24 kg/mn; Gas flow rate: 18 and 25 sm^3h)

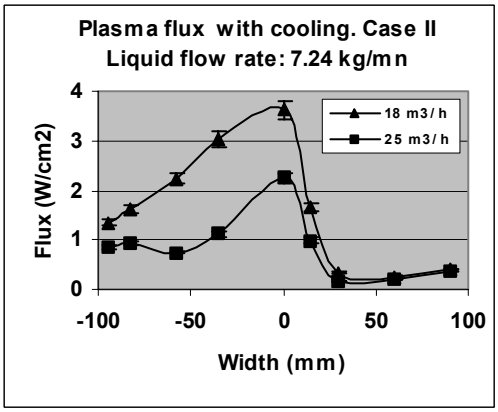

Figure 6 : Plasma flux with cooling in case II (Liquid flow rate: 7.24 kg/mn; Gas flow rate: 18 and 25 sm^3h)

In figure 6 (case II), the two curves show a asymmetry of the flux which is present for every experiment. We assume this is due to a bad position of the lateral holes on either side of the liquid centerline. In fact, the first goal of these lateral holes is to put in shape the liquid jet, not to destroy it.

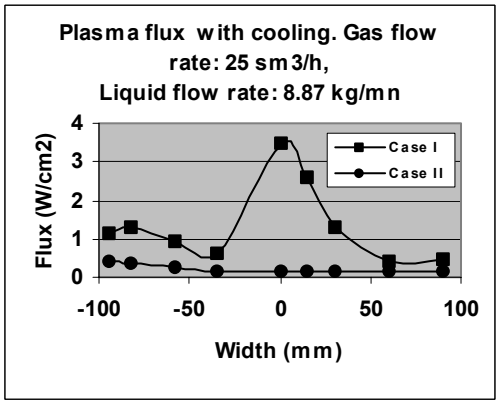

Figure 7 : Plasma flux with cooling by single nozzles in cases I and II (Liquid flow rate: 8.87 kg/mn; Gas flow rate: 25 sm^3h)

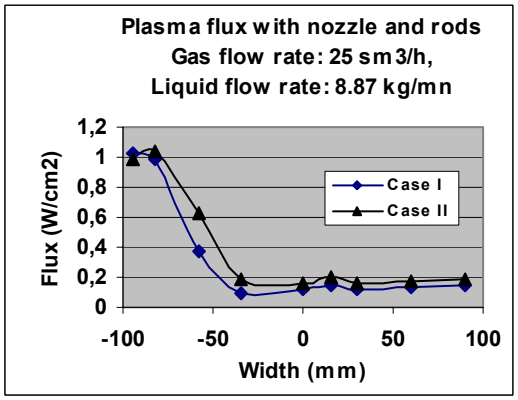

Figure 8 : Plasma flux with cooling by nozzles and rods in cases I and II (Liquid flow rate: 8.87 kg/mn; Gas flow rate: 25 sm^3h)

These experiments show strong interactions between the plasma and the cooling flows as if the cooling jet acts as a screen between the plasma and the substrate. The interactions could be due to the low distance (40 mm) between the plasma and the two atomizers. These interactions increase strongly with the liquid flow rate (figure 7): the flux reduces to less than 4 W/cm² in case I and less than 1 W/cm^2 in case II. This has a high consequence on the substrate temperature increase and certainly on the deposition efficiency by the elimination of the finest particles before impacting the substrate. This cannot be investigated in this study.

The plasma flux with cryogenic atomization and the gas rods. To conclude the measurements of the plasma flux, the second device with the gas rods is active with an argon gas flow rate of 15 sm^3h for both rods (figure 8). The previous conclusion about the interactions between the plasma and the cooling gas flows is strongly amplified : the plasma flux impacting the substrate is less than 1 W/cm² and presents a strong asymmetry.

The cooling flux. Let us consider different argon liquid flow rates.
The first one is called case A for low liquid flow rate (7.24 kg/mn) and for the three gas flow rates. Comparisons are made with the central atomization gas network opened (case I) or closed (case II).

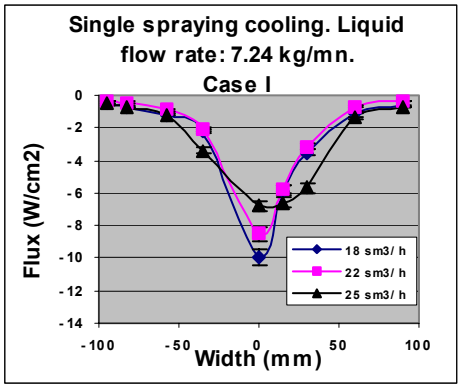

Figure 9: Single spraying cooling case I
(Liquid flow rate: 7.24 kg/mn)

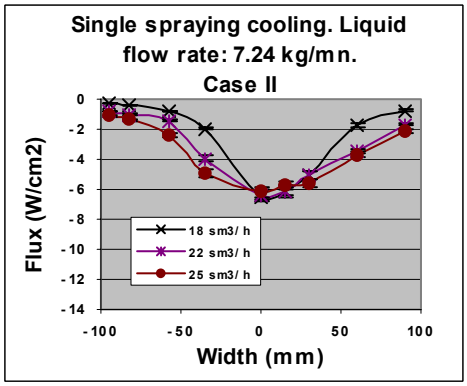

Figure 10: Single spraying cooling case II
(Liquid flow rate: 7.24 kg/mn)

Figures 9 and 10 show the space flux distributions for both cases I and II. In figure 9, the two higher fluxes (around –9 W/cm2) are due to the lower gas flow rates passing through the central atomization gas network. The decrease in the flux is due to the increase in the gas flow rate : over 22 m^3/h, the gas flow is too important and breaks the liquid sheet in very small droplets which can evaporate before impacting the substrate. This trend is a standard: the flux always decreases with an increase in the gas flow rate for every condition but this evolution is more or less important depending on the liquid flow rate. In case II (figure 10), the flux intensities are in the some order independent of the gas flow rate but with a tendency to spread. The half-height width leads to a 40 mm radius. This spreading is observed each time the central atomization gas network is closed.

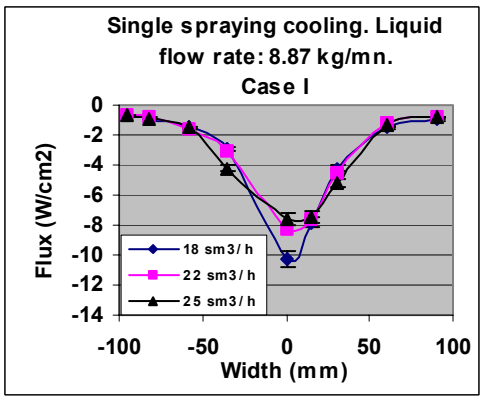

Figure 11: Single spraying cooling case I
(Liquid flow rate: 8.87 kg/mn)

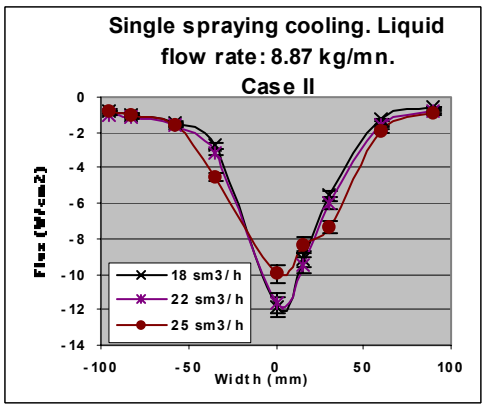

Figure 12: Single spraying cooling case II
(Liquid flow rate: 8.87 kg/mn)

Let us consider case B with the highest liquid flow rate (8.87 kg/mn) and for the different gas flow rates. Figures 11 and 12 present the comparisons with the central atomization gas network opened or closed. Of course, the maximum flux increases (around –12 W/cm²) but the droplet jet spreads less than in the previous case for any parameters. Moreover, the higher fluxes are obtained when the central atomization gas network is closed: there is an inversion of the cooling efficiency in comparison with the case A. The asymmetry is weaker and does not depend on the introduction way of gas flow rate : We only notice it with the highest gas flow rate (figure 12).
Different conclusions can be extracted from these experiments :

- The maximum flux diminishes with an increase in the gas flow rate.
- This flux increases with the liquid flow rate, but with the lowest flow rates (7.24 kg/mn and 7.82 kg/mn) the measured flux leads to an asymptote around – 8 W/cm².
- The central atomization gas network must be closed or not, depending on the liquid flow rate. For the low liquid flow rate, the closing is not approved : it leads to a liquid spreading and to lower cooling flux. For the high liquid flow rate, the closing is approved : there is no significant step of spreading by comparison with and without closing, but the cooling flux is higher when the network is closed.

Plasma-Cooling flux interactions. In this part, the interactions between the two sources of heat and cooling are further investigated. The following assumption is set down: the devices are in steady state so that the flux measurements are still correct at the same point independent of time. So the way to identify these interactions uses the difference between fluxes from the plasma and the cryogenic atomization without and with the gas rods.
In the general way, the main conclusions are :

- The difference is positive for nearly every case and less than 1 W/cm² on the edges.
- This difference becomes negative in the center of the measurement area: the higher liquid flow rate, the higher difference. This is amplified when the central atomization gas network is closed. So the plasma produces less calories than the pulverization can extract (but the sprayed particles have to give their energy to the substrate too).

The minimum of the difference is slightly displaced for the low liquid flow rate as seen in figure 13. This gap is also noticed, but in less of a way, without closing the central atomization gas network. An increase in the liquid flow rate in both configuration (closing or opening the central atomization gas network) leads to a complete reduction of the displacement (figure 14). This could be explained by the difference in momentum between the plasma and the liquid argon jets. This last one becomes stronger with the increase in the mass flow rate and so less sensitive to hydrodynamic forces of the plasma jet.

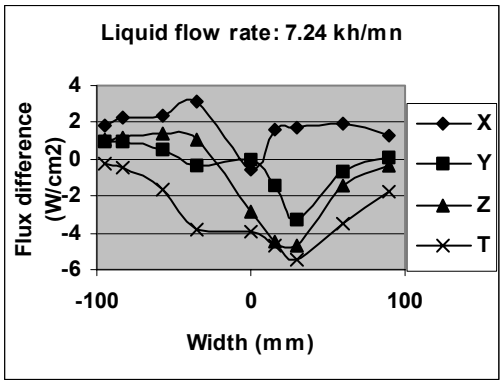

Figure 13 : Flux difference. Liquid flow rate : 7.24 kg/mn for different configurations :
X : case I and 18 sm^3h gas flow rate
Y : case I and 25 sm^3h gas flow rate
Z : case II and 18 sm^3h gas flow rate
T : case II and 25 sm^3h gas flow rate

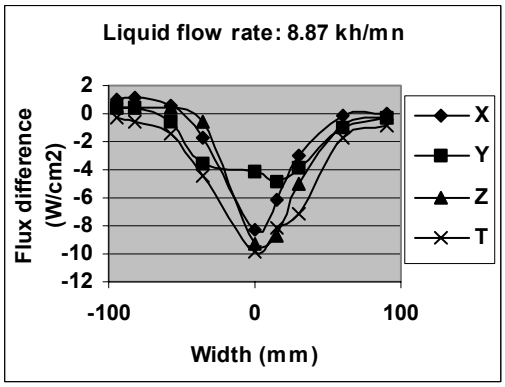

Figure 14 : Flux difference. Liquid flow rate : 7.24 kg/mn for different configurations :
X : case I and 18 sm^3h gas flow rate
Y : case I and 25 sm^3h gas flow rate
Z : case II and 18 sm^3h gas flow rate
T : case II and 25 sm^3h gas flow rate

Now, let us introduce the gas rods in the experiments. The presence of the argon gas flow replaces the maximum in the difference in the center of the measurement area. This trend is always true for every experiment (comparison between Y and X or Z and T in figures 15 or 16). So the first consequence of the argon gas rod is to separate well the two heat and cooling sources. The second one concerns the cooling efficiency. The cooling flux changes from –4 W/cm² to –6 W/cm² without and with the argon gas rods. This efficiency trends to slightly diminish with an increase in the liquid flow rate.

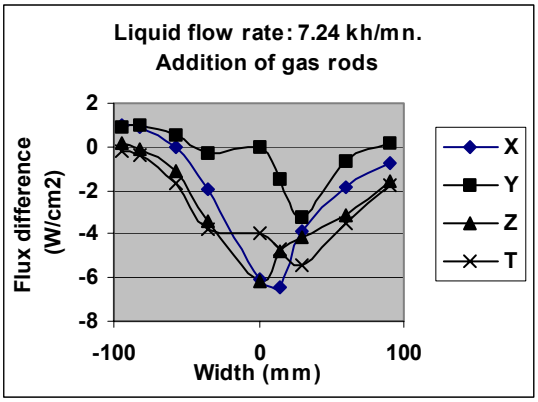

Figure 15 : Flux difference. Liquid flow rate : 7.24 kg/mn and addition of gas rods for different configurations :
X : case I and 18 sm^3h gas flow rate
Y : case I and 25 sm^3h gas flow rate
Z : case II and 18 sm^3h gas flow rate
T : case II and 25 sm^3h gas flow rate

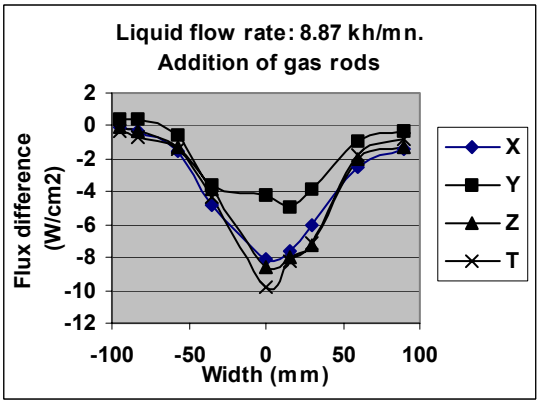

Figure 16 : Flux difference. Liquid flow rate : 8.87 kg/mn and addition of gas rods for different configurations :
X : case I and 18 sm^3h gas flow rate
Y : case I and 25 sm^3h gas flow rate
Z : case II and 18 sm^3h gas flow rate
T : case II and 25 sm^3h gas flow rate

When the central atomization gas network is opened (case I), the cooling flux increases strongly from 0 W/cm² to –6 W/cm² (figure 15) when the liquid flow rate is rather low (comparison Y and Z in figure 15). The same conclusions can be extracted from figure 16 for higher liquid flow rate (comparison Y and Z in figure 15).

Conclusion. Measurements of plasma heat and pulverized argon liquid cooling fluxes impacting a substrate have been carried out in several configurations. For the plasma, the maximum heat flux is up to 15 W/cm² but with cryogenic atomization cooling, it goes down to 9 W/cm² and the adding of argon gas rods on both side leads to less than 6 W/cm². These first measurements show strong interactions between the plasma and the cooling jets.
For the cryogenic atomization cooling, two ways were investigated :

- firstly in standard configuration, with the central atomization gas network opened (case I)
- secondly this one closed (case II).

The best configuration in term of cooling fluxes received by the substrate depends on the argon liquid flow rate. For low argon liquid flow rate, the standard configuration leads to higher cooling fluxes. For high argon liquid flow rate, the closing of the central atomization gas network shows a better efficiency of cooling.
The addition of two argon gas injection rods in each part of the torch and between it and the spraying system leads to well separate the plasma and the droplet jets and so diminishes the interactions between the two jets. In this case, the cooling efficiency is upper.

Abstract

New gas-phase model of silane decomposition during plasma enhanced chemical vapor deposition with formation of stable negative hydrogenated silicon ion clusters is suggested. The kinetics equations describing time dependent cluster formation are computed.

Introduction

The simulation of particle growth kinetics requires a time-dependent modeling of the gas-phase plasma chemistry. Currently negative ions are believed to be the precursors of silicon dust in a SiH_4 plasma. Mass spectroscopy reveals that negative ions can grow up to 60 Si atoms. We have suggested a generalized model of gas-phase reactions of silane decomposition initiated by the electron impact with formation negative, containing up to 30 silicon atoms, and positive, containing 5 silicon atoms, hydrogenated ion clusters following [1-2].

In the kinetics scheme of silane decomposition 219 reactions were included.

The mathematical model of the task comes to a set of stiff ordinary first-order-differential equations with the given initial conditions, which describe in time the processes of the production of both stable products and fast-reacting species:

$$\frac{dN_i}{dt} = \sum n_e K_{ij} N_j + \sum_{jl} K_{ijl} N_j N_l - N_i \left(\sum n_e K_{ji} + \sum_{jl} K_{ijl} N_l \right)$$

Results and discussions

The computed kinetic curves of the negative hydrogenated silicon ion clusters behaviour for the silane density $N=10^{15}$ cm^{-3}, the electron density $Ne=10^9$ cm^{-3} and electron temperature Te=1.0 eV are presented on fig. 1-4. The cluster growth mechanism considered involves initiating, growth and suppressing spices.

Numerical results on negative hydrogenated silicon ion clusters point out forming of stable negative molecular cluster groups: $Si_6H_{13}^-$, $Si_7H_{15}^-$, $Si_8H_{17}^-$, $Si_9H_{19}^-$, $Si_{10}H_{21}^-$, $Si_{11}H_{23}^-$, $Si_{12}H_{25}^-$, $Si_{13}H_{27}^-$, $Si_{14}H_{29}^-$, $Si_{15}H_{31}^-$, $Si_{16}H_{33}^-$, $Si_{17}H_{35}^-$, $Si_{18}H_{37}^-$, $Si_{19}H_{39}^-$, $Si_{20}H_{41}^-$, $Si_{21}H_{43}^-$, $Si_{22}H_{45}^-$, $Si_{23}H_{47}^-$, $Si_{24}H_{49}^-$, $Si_{25}H_{51}^-$, $Si_{26}H_{53}^-$, $Si_{27}H_{55}^-$, $Si_{28}H_{57}^-$, $Si_{29}H_{59}^-$, $Si_{30}H_{61}^-$. The threshold of the appearance of main stable group of high-mass negative ions $Si_{15}H_{31}^-$ up to $Si_{30}H_{61}^-$ is in time limit $1.5 \cdot 10^{-5}$ s and $1.1 \cdot 10^{-4}$ s. Their concentration ranges from $7 \cdot 10^7$ cm^{-3} up to $8 \cdot 10^3$ cm^{-3} for the time $5 \cdot 10^{-4}$ s.

In conclusion we have simulated plasma enhanced silane decomposition on base of the generalized model of gas-phase reactions. The calculation performed with the account for recent experimental result indicate formation of study negative hydrogenated silicon ion clusters at high concentrations. They have masses bigger than those of positive ion clusters. It allows us to state confidently that the formation of a silicon dust with the particle more than 10 nm is connected with a continuum of negative clusters in a silane plasma.

Finally, we have developed theory of the negative hydrogenated silicon ion clustering in corpuscle deposition processes.

Etching of organic compounds by oxygen plasma

M. Mozetič[1], U. Cvelbar[1], A. Zalar[1], D. Babič[2]

[1] *Plasma laboratory, Institute of Surface Engineering and Optoelectronics, Ljubljana, Slovenia*
[2] *Department of Physics, University of Ljubljana, Ljubljana, Slovenia*

The etching rates of different polymers versus the dose of neutral oxygen atoms was measured in an oxygen plasma postglow reactor. The source of neutral oxygen atoms was an inductively coupled RF oxygen plasma with the electron temperature of 5 eV and the density of about 10^{16} m^{-3}. The density of oxygen atoms in the postglow reactor was measured with a catalytic probe. The O density was up to $4x10^{21}$ m^{-3}. It was found that the activation of a polymer was completed after the O dose of $6x10^{21}$ m^{-3}. Further exposure to O atoms caused continuous etching of polymers. The combination of rather precise measurements of both the oxygen atom density and the thickness of polymers allowed for the determination of the etching rate. It was found that the oxidation probability did not depend on the density of the O atoms in the vicinity of samples but rather on the dose of oxygen atoms. The etching rate was found to be of the order of $1nm/10^{20}$ cm^{-2}. The etching rate depended on the type of polymer. The highest etching rate was measured for alkyd resin, a polymer often used as the basis of different paints. The lowest etching rate was detected for polyether sulphone – a pretty stable plastic that is widely used in electronic industry.

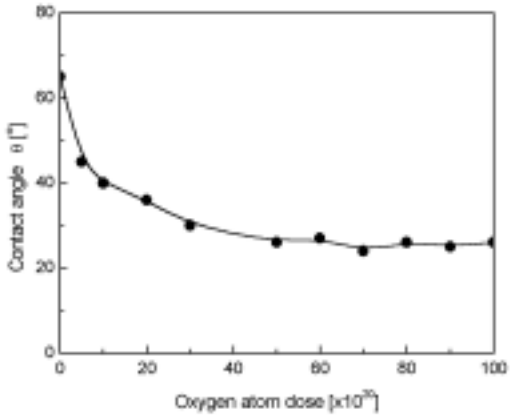

Fig. 1. Contact angle of a water drop versus oxygen atom dose.

Plasma treated polymers as supports for structured antibacterical materials

T. Yuranova, A. Bozzi, J. Kiwi

Laboratory of Photonics and Interfaces, Institute of Molecular Chemistry and Biology, EPFL, Lausanne, Switzerland

Abstract.

The bacterial inactivation efficiencies of silver metal and oxides and their combinations on textile plasma treated fabric was investigated to evaluate the disinfectant action on airborne bacteria. The inactivation performance was seen to depend on the amount of silver on the textile surface and RF plasma treatment conditions.

1. Introduction

Silver has been known as a disinfectant for many years and is being used in many forms in the treatment of infectious diseases [1-3] and has a broad spectrum antibacterial activity while exhibiting low toxicity towards mammalian cells. In a very low concentration silver-ions are effective against bacteria in water systems [4-5].

This investigation is directed towards the fixation and catalytic performance of Ag-clusters on polyamide-polystyrene textile fabrics. After a long series of preliminary experiments the most suitable experimental conditions for the RF-plasma activation of the fabric surface were found. Then the chemical deposition of Ag-clusters was carried out on these activated surfaces checking subsequently each Ag-deposit against the antibacterial activity observed. Once the optimization of the Ag-clusters was completed the latter clusters were characterized by complementary surface techniques like: elemental analysis, X-ray photo-electron spectroscopy (XPS) and transmission electron microscopy (TEM).

2. Experimental section

2.1. Materials

Reagents like $AgNO_3$, ammonia, isopropanol, Ag_2CO_3 were Fluka p.a. and used without further purification. De-ionized water was employed throughout this work. Industrial textile fabric consists of polyamide blended polyester was received from Tissupor AG, St.Gallen, Swiss.

2.2. Functionalization of textile fabrics by RF-plasma

The textile polymer fabric surface was treated in a RF-plasma cavity (Harrick Corp, 13.56 MHz, 100 W) at an air pressure of 0.1 torr. RF plasma was created in a quartz reactor where textile samples

were placed. A variety of oxygen functional groups: >C-O, >C=O, -O-C=O, -COH, -COOH, were produced on the fabric through the reaction between the active species induced by the plasma in the gas phase and the C-surface atoms [2-5]. These oxygen functionalities obtained by oxygen plasma are located are in the topmost layers and increase with longer treatment time, but remain constant with treatment time > 30 minutes. This is why the latter time has been chosen for RF-plasma treatment.

2.3. Loading of silver on activated textile fabrics

After functionalizing the textile surfaces by RF-plasma or vacuum-UV the fabrics are immersed in solutions with different concentrations of $AgNO_3$. Afterwards the silver is reduced at a suitable pH with mild reducing agent [6] and the final fabric presenting a dark yellow color is dried in air at room temperature.

2.4. Bacterial growth testing

Textiles with silver attached and textiles without silver that have not been previously sterilized are incubated for 24 hours at 37 °C in Luria Bertani media (LB) plates under controlled conditions. After the latter time period the assessment of partial or total bacterial inhibition by the Ag-loaded fabric is observed and compared with the non-loaded fabric. To determine bacterial survival in water, *E coli* K-12 was used as a bacterial model. Cultures in the exponential phase of growth were obtained using an aliquot part of the inoculum grown overnight in 20 ml of Luria Bertani media at 37°C. After centrifugation, the cells were re-suspended in tryptone (Merck AG) solution. Finally the cell suspensions were diluted with Milli-Q de-ionized water to the required cell density corresponding to 10^4 (CFU/ml) colony forming units (CFU/ml).

In a typical experiment bacterial suspensions were contacted with the textile fabric for 24 hours in the dark and samples were plated on agar PCA (plate count Agar Merck AG, Germany). The plates were incubated at 37°C for 24 hours before counting and the reported results were the media of 3 experimental runs.

Additional tests were carried out using *Pseudomonas Aeruginosa* following Swiss EMPA Norms 2003 and for *Bacillus subtilis* and *Aspergillus niger* according to Swiss EMPA Norms 510. The bacterial growth inhibition followed the same pattern as observed for the case of *E coli* K-12.

2.5. X-ray electron spectroscopy (XPS)

Measurements were carried out in a Leybold-Heraeus instrument calibrating the binding energies (BE) to the Au $f_{7/2}$ level taken as 84.0 eV. The evaluation of the binding energies of the Ag-clusters was carried out following the DIN norms [7] and after taking into consideration the sensitivity factors allowed a reproducibility of ±5% in the measurements. The spectra were analyzed in a DS 100 data set after X-ray satellite subtraction and smoothing of the polynomial fit. The relative sensitivity factors used were: O1s 0.78; Cls 0.78: S2p 0.84; Ag3d5/2 3.23. The quantitative evaluation of the

experimental data was carried out with a Shirley type background correction due to the electrostatic charging of the particles during the measurements [8]. Electrostatic charging effects were referenced calibrating to the C1s signal.

2.6. Transmission electron microscopy (TEM)

Electron microscopy was carried out with at the Philips CM 120 microscope to observe the Ag-clusters on the textile surface. The instrument used for electron microscopy (120 kV, 0.35 nm point resolution) was equipped with energy dispersive X-ray analysis EDAX to identify the deposition of Ag-clusters on the textile fabric.

3. Results and discussion

3.1. Biological testing of the Ag-loaded textile prepared by RF-plasma activation

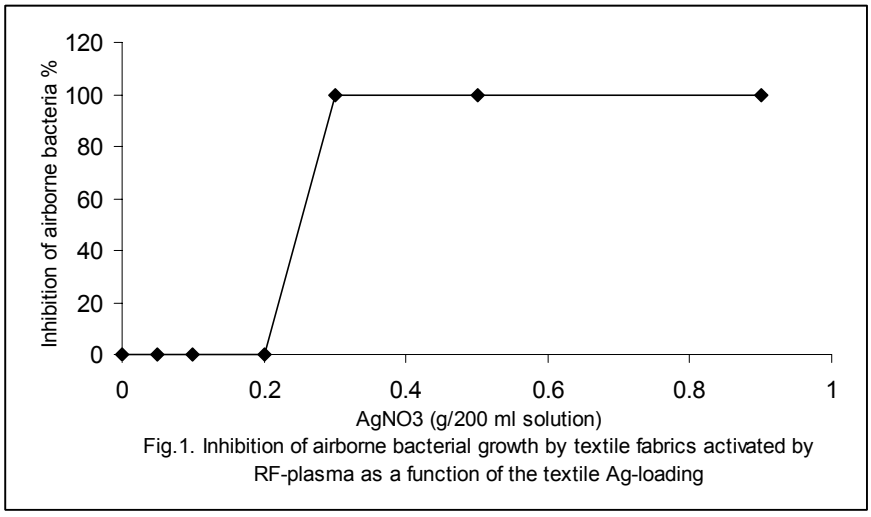

Fig.1. Inhibition of airborne bacterial growth by textile fabrics activated by RF-plasma as a function of the textile Ag-loading

Figure 1 shows the effect of Ag-loaded textiles surfaces activated by RF-plasma on the airborne bacteria after 24 hours. The antibacterial effect reported in Figure 1 was carried out in the dark. Adsorption of bacteria on the textile was observed on the unloaded fabric and as well as on the Ag-loaded fabric. The abscissa refers to the $AgNO_3$ grams in 200 ml solution used in the silver loading after the RF-plasma treatment. After the relative index of 0.3g Ag/200 ml solution (Figure 1), the inhibition of bacterial activity at 24 hour seems to be complete. This suggests that a direct contact between the bacteria and the textile having an adequate density of silver clusters is necessary for the bacterial abatement process to proceed. The latter observation is consistent with some recent work on the mechanism of bacterial abatement due to metal/oxides and ions [1,2,9]. Lower levels of silver loading in the textile do not allow the formation of a sufficient number of Ag-clusters necessary for the total inhibition of bacterial growth.

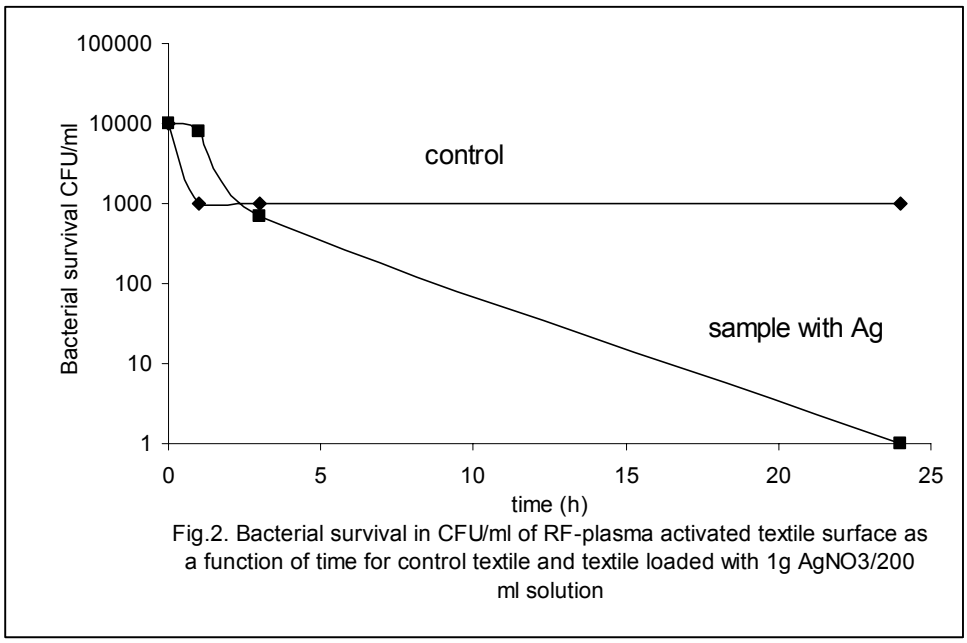

Fig.2. Bacterial survival in CFU/ml of RF-plasma activated textile surface as a function of time for control textile and textile loaded with 1g AgNO3/200 ml solution

Figure 2 shows the decrease in the number of *E coli* K-12 colonies suspended in Milli-Q water as a function of time in contact with a textile sample activated by RF-plasma with ($AgNO_3$ 1g/200 ml) and for a second control fabric without silver loading. It is readily seen from Figure 2, that during 24 hours the Ag-loaded fabric inhibits any bacterial growth. Moreover, a bacterial decrease from 10^4 CFU/ml to a non-detectable level below 10 CFU/ml was detected within 24 hours. The control fabric shows only a modest reduction of one order of magnitude due to adsorption of *E coli* K-12 on the textile fabric surface.

3.2. X-ray photoelectron spectroscopy (XPS) of RF-plasma activated surfaces loaded with silver.

The percentage surface composition of RF-plasma loaded silver textiles by XPS spectroscopy is presented in Table 1. The silver content of topmost layer surface of the textile increases with the concentration of the silver solution used to react this metal with the functional groups introduced on the textile by RF-plasma. The reference for the values obtained has been carried out according to reference [8] comparing the spectra obtained with related spectra of silver found in the scientific literature. The background correction for the obtained signals was carried out according to reference [7]. The values reported in Table 1 do not represent bulk or deeper layer content of silver that can be treated as integral value for the attached silver. This observation will be discussed with the right perspective in relation to the Ag found by elemental analysis in the last section below.

The binding energies (BE) of the silver were quantified for the silver species deposited on the textiles for the different concentrations of silver used. For 0.05, 0.3 and 1g $AgNO_3$ / 200 ml, the BE was close to 368.2 eV which is the reference value for metallic Ag[10]. The reference values for the BE of Ag_2O were 367.8 eV and AgO 367.4 eV.

Table 1. Percentage surface composition of RF-plasma loaded silver textiles.

	0.05 g $AgNO_3$/200 ml	**0.3 g $AgNO_3$/200 ml**	**1 g $AgNO_3$/200 ml**
C1s	63.2	63.3	69.7
N 1s	1.13	0.82	0.92
O 1s	33.0	33.6	26.7
Na 1s			0.59
Si 2p	2.70	1.85	1.45
Cl 2p			
Ag $3d_{5/2}$	0.06	0.40	0.62

3.4. Transmission electron microscopy (TEM) of Ag-loaded fabrics activated by RF-plasma

The data of the TEM for the thick polyamide fiber component of the textile fabric allow to estimate the size of Ag-clusters varied between 50 and 500 nm. The spacing between the fibers was observed to be highly irregular. The heterogeneous deposition of the Ag-clusters on the textiles is probably due to the numerous oxygen gas species produced during RF-plasma leading subsequently to different anchoring groups on the textile surface. The analysis of Ag-clusters on thinner poylester fibers demonstrates a more regular spacing on the fiber surface. The size of the clusters was seen also to vary widely between 8 and 40 nm counting around 100 Ag-clusters.

4. Conclusions

This study has shown the beneficial antibacterial activity of silver grafted on textile fabrics by RF-plasma followed by chemical treatment of the silver salt on the fabric surface. A minimum loading of silver was seen to be necessary to inhibit the airborne bacterial growth depending on the method used to activate the textile surface. This effect was also investigated and reported for aqueous suspensions of *E coli* K-12 taken as a bacterial model. The electron microscopy carried out shows different clusters of silver in size and distribution depending on the type of surface activation of the textile surface.

Decomposition of isooctane using a Dielectric Barrier Discharge reactor

K.Bouamra, N. Blin-Simiand, F. Jorand, S. Pasquiers, C. Postel

Laboratoire de Physique des Gaz et des Plasmas, Bat.210, Université Paris-Sud, 91405 Orsay Cedex, France

Abstract:
Decomposition of isooctane is investigated in a nonthermal plasma reactor under atmospheric pressure. The highest isooctane consumption, obtained at an electrical power of 12 W, is around 93 % in wet air and 85 % in dry air. Identification of reaction products is done by a GC/MS. Acetone, dimethoxypropane and dimethoxyethane are identified.

1. Introduction

Non-thermal atmospheric plasmas are under study since the beginning of the eighties for decomposition of Volatile Organic Compounds with different chemical structures, for application in pollution control [1,2]. Some experiments [3], as well as kinetic modelling [4], have been performed on conversion of hydrocarbon molecules.
The aim of this study is to investigate the decomposition of isooctane (iC_8H_{18}), a primary reference fuel with n-heptane, using a Dielectric Barrier Discharge reactor (DBD).

2. Experimental description

The experimental setup was schematically illustrated in Figure 1. The plasma-chemical reactions took place in a cylindrical DBD reactor, which was made of a quartz tube (14 mm inner diameter and 2 mm wall thickness) surrounded by a copper tape as the outer electrode. The outer electrode connected to the earth was 14.5 cm length. On the inner electrode, which consisted of a central stainless-steel rod (e.d. 5 mm), was applied a high voltage pulse (up to 40 kV) with a repetition frequency value up to 120 Hz. The discharge volume was about 19.5 cm^3.
The isooctane liquid was injected with a syringe through a vaporizer producing gaseous isooctane. The hydrocarbon streamed along a glass rod located at the center of a heated tube through which air, either dry or with water vapor, flowed. At the outlet of the vaporizer, the homogeneous gas mixture was continuously carried through the DBD reactor at different frequencies. The gases resulting from these discharges passed through a U-tube cooled to –40°C, where condensable products were trapped during 20 min. All these experiments were carried out at ambient temperature and atmospheric pressure.

Chemicals

In the experiments reported here, about 1000 ppm of iC_8H_{18} balanced with air N_2/O_2 (80/20) was introduced into the reactor. Air flow rate was adjusted with a flowmeter at 1 L/min and the residence time in the reactor was about 1.2 s. Moisture was added to the mixture by bubbling the sample gas through a small volume water bath. The water vapor concentration was 3 %.

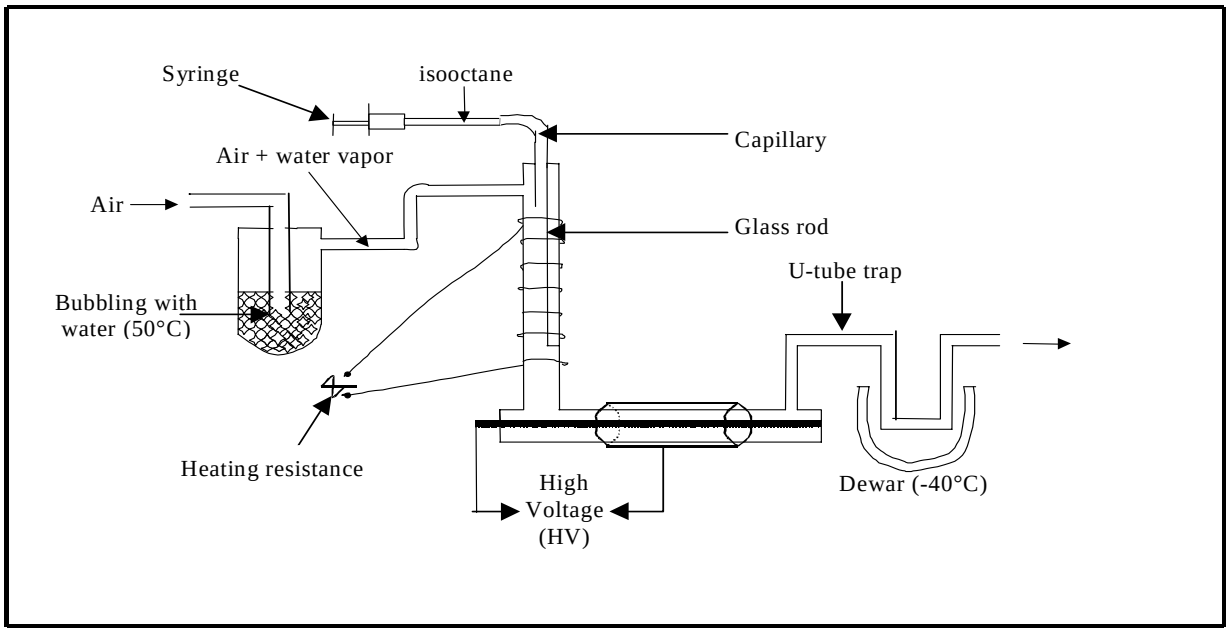

Figure 1: Schematic representation of experimental setup.

Techniques used for the identification

Analysis by GC/MS was performed using a Varian 3800 gas chromatograph, coupled to an ion trap mass detector Varian Saturn 2000. The mass spectrometer operated in the *m*/*z* range of 20–350, and it was used either with Electron Impact (EI), with an ionisation energy of 70 eV, or with Chemical ionisation methanol (CI) mode. The separation was performed on a fused silica column (VARIAN CP-SIL 5 CB, 30 m×0.25 mm I.D., 0.39 mm O.D. and 0.25 μ m film thickness, 1 ml/min). The carrier gas was helium with flow-rate of 1.0±0.1 ml/min. The gas chromatograph was equipped with a split/splitness injection port operating in the split mode with a split ratio equals to 60. The column temperature program was: 45°C for 6 min, 45–160°C at 30°C/min, and 10 min at 160°C. Injector, transfer line and ion trap were at 100°C, 170°C and 150°C.

3. Results and discussion

3.1 Effect of frequencies on decomposition efficiency

As shown in table 1 and figure 2, consumption of isooctane increased with frequency. The highest isooctane decomposition, was obtained at 120 Hz, which corresponds to a maximum electrical power consumption in the discharge circuit of about 12 W. Many products issued from the discharge were observed on chromatograms. These products were analysed by GC/MS.

Frequencies (Hz)	1	20	50	70	120
% of consumption (mixture air/isooctane)	26	62	67	74	**85**
% of consumption (mixture air/isooctane/ water vapor 3 %)	20	45	71	70	**93**

Table 1 : Effect of frequencies and moisture on consumption rate.

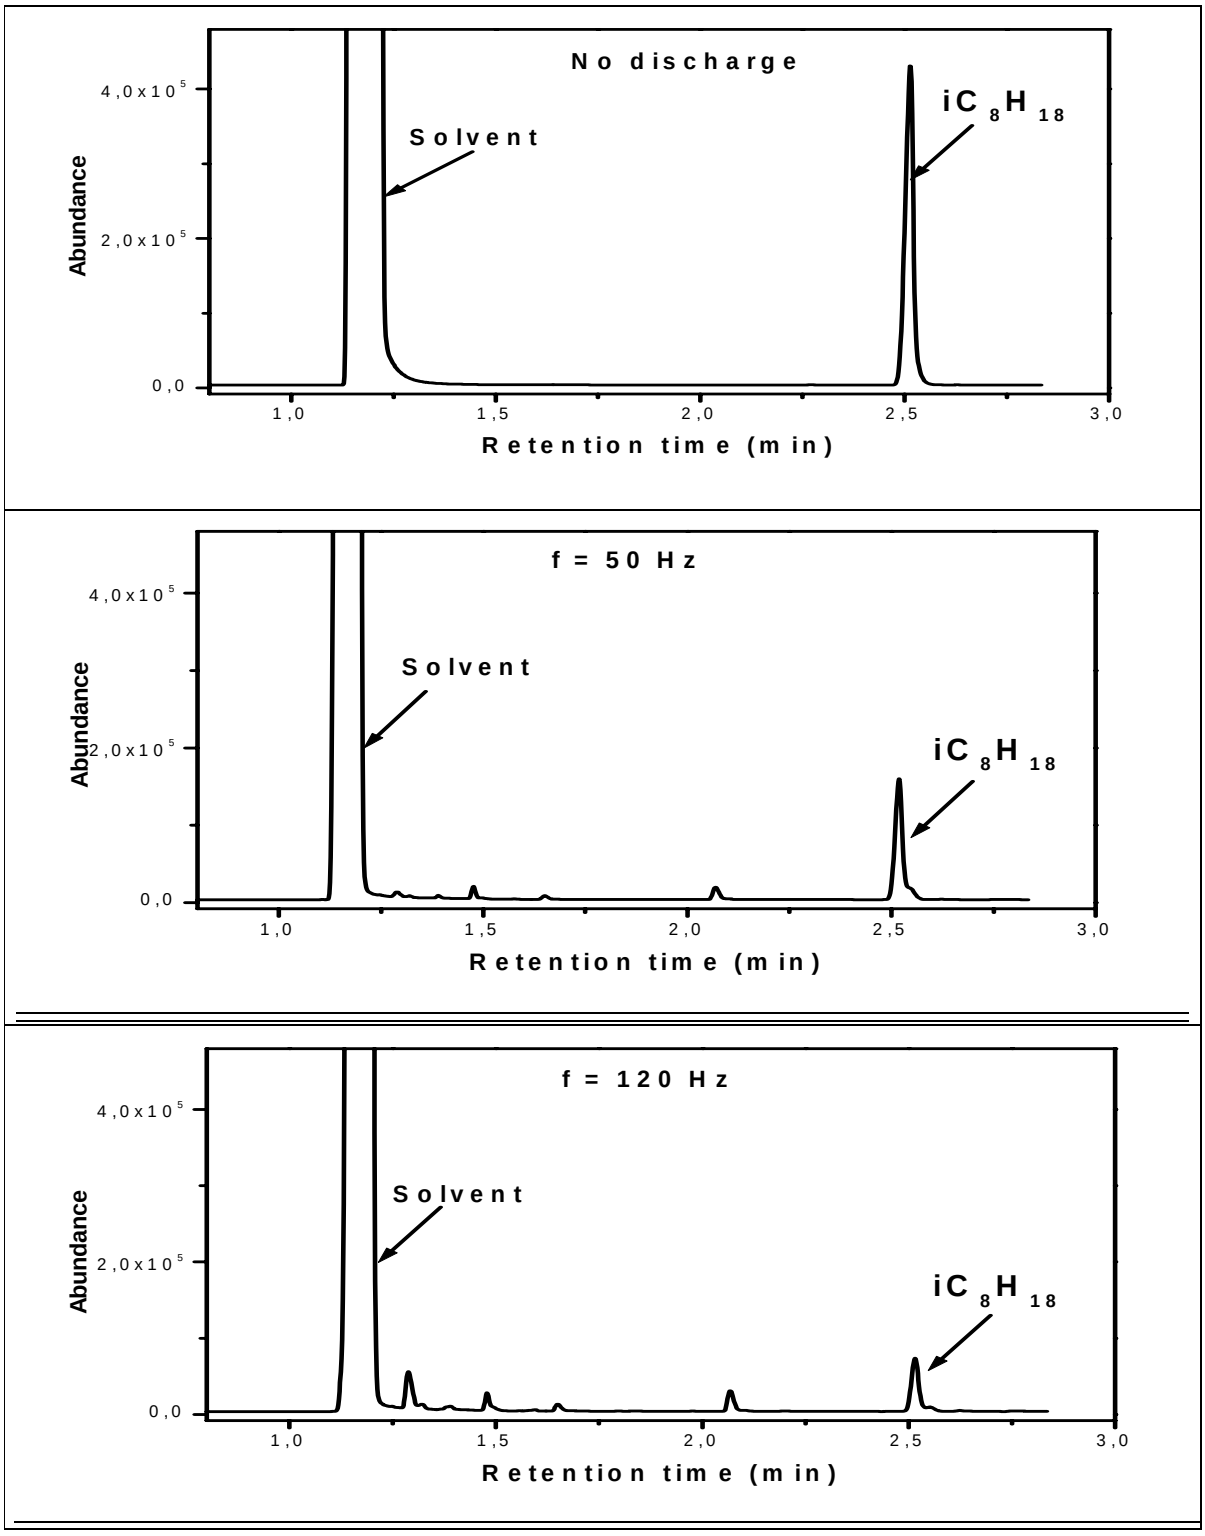

Figure 2: Chromatograms of isooctane consumption at different discharge frequencies.

3.2 Effect of water vapor on consumption of iC_8H_{18}

The highest isooctane decomposition was around 93 % in wet air and 85 % in dry air. Decomposition seems to be easier in wet air than in dry air (Figure 3, table 1).

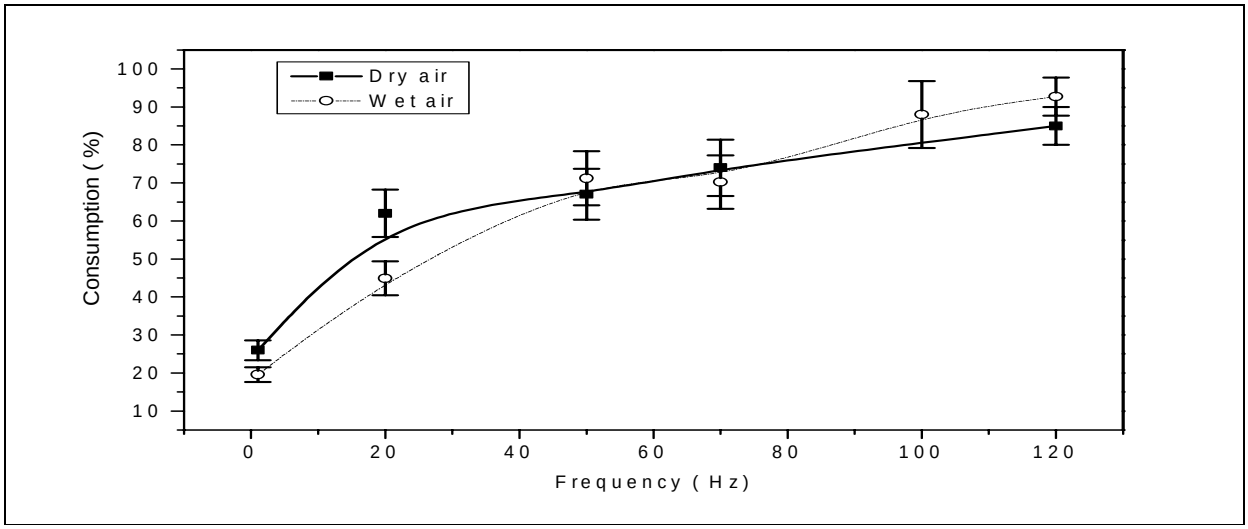

Figure 3 : Effect of frequency and water vapor (3 %) on consumption of 1000 ppm of isooctane in 1L/min air

However, wet air had negative effect on isooctane decomposition under low frequencies. These observations suggested that isooctane can decompose in a DBD reactor, at atmospheric pressure and ambient temperature without initiation by active oxygen species issued from water at high frequencies.

Products identified by GC/MS

Products obtained during the isooctane decomposition in dry air and at 120 Hz were analyzed by GC/MS. The chromatogram shown in figure 4 includes many peaks. They correspond to molecules issued either from decomposition of iC_8H_{18}, or from recombination processes between the various products. Molecules were analyzed both with EI and CI modes.

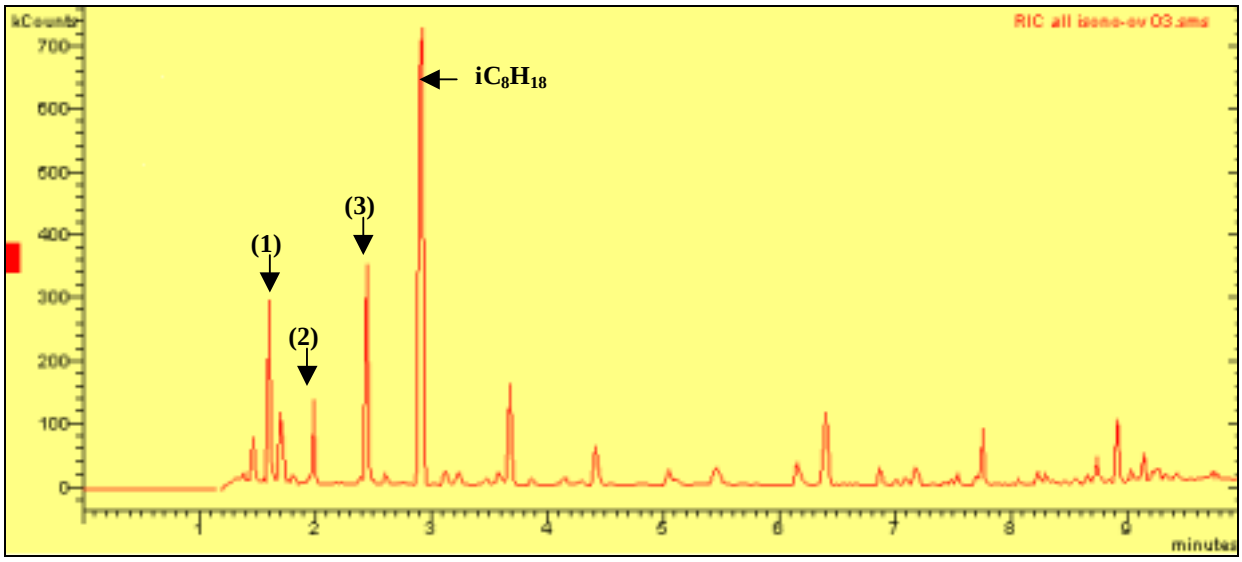

Figure 4 : GC/MS chromatogram of products obtained in dry air (1L/min) and 1000 ppm of isooctane at 120 Hz.

Three molecules, with a weak retention time (Figure 4), were identified:
- Acetone C_3H_6O (Molecular Weight (MW) = 58)
- Dimethoxyethane $C_4H_{10}O_2$ (MW = 90)
- Propane 2,2 dimethoxy $C_5H_{12}O_2$ (MW = 104)

3.3 Effect of temperature

The temperature effect on isooctane decomposition without discharge was investigated at 200, 400 and 600°C. Gases CO, CO_2, O_2 and N_2 were analyzed by gas chromatography VARIAN CP-4900 Micro-GC, using molecular sieves (10 m × 0.32 mm I.D) and a PoraPlot U column. Hydrocarbon was analyzed by a GC/MS. It was found that isooctane consumption was near zero at 200 and 400°C. However, experiments shown a weak decomposition at 600°C. CO and CO_2 were only detected at this temperature.

4. Conclusion

The experiment showed that DBD plasma reactor can lead to a high decomposition of iC_8H_{18} in dry or wet air. The conversion of the hydrocarbon molecule led to production of various species. GC/MS spectra enabled to identify some of them.

At atmospheric pressure, no conversion was observed for isooctane under temperatures of 200 to 400°C without plasma. Effect of plasma, under high temperature, on hydrocarbon conversion will be treated in next works. Identification of more species will allow us to understand isooctane degradation kinetic mechanism.

Reduction of oxides and chlorides of metals in low pressure plasma-beam discharge.

V.M. Atamanov, L.I. Elizarov, A.A. Ivanov, A.V. Pereslavtsev, G.V. Povolotskaya

Russian Research Centre "Kurchatov Institute", Moscow, Russia

Abstract
Low pressure beam–plasma discharge in hydrogen and deuterium was used to obtain the pure metals from the pure oxides or chlorides: Fe_2O_3, $FeCl_3$, $CuCl_2$, $LaCl_3$, Sc_2O_3. The series of the experiments on the reduction of oxides and chlorides in low pressure beam-plasma discharge were carried out in the "Oratoria-10" installation. The decreasing of purity degree of the metal reduced in the comparison with initial oxide (or chloride) was not observed.

1. Introduction

The beam-plasma discharge was proposed for plasma chemistry in 1975 [1-3]. The discharge is initiated in a gas of low density in the magnetic trap known as mirror machine when electron beam of moderate energy penetrates gas along the magnetic force lines. Due to the collisions with neutral atoms or molecules the electrons of the beam produced ions and the secondary electrons. Then the plasma of very low density due to beam-plasma instability brings about the non-collision losses of beam energy in plasma thus heating the plasma and increasing essentially the degree of ionisation. The density of plasmas achieved 10^{13} cm^{-3} the neutral pressure of the order of several tenths of millitorr. The discharges of various configurations were studied when various type of the cathode of electron guns were used. The plasma produced was suitable for processing however the optimisation of equipment was not done. As known, the beam-plasma discharge can be successfully used in plasma chemical studies [1-3]. Recently the attention was drawn again to this problem [4, 5]. According to the analysis done in the papers cited electron beams can generate processing plasmas with greater process control and larger areas than present plasma generation techniques such as capacitive or inductive discharges, electron cyclotron resonance (ECR), surface wave or helicon reactors.
In the cited papers a plasma configuration early known as "ribbon" beam configuration [1-3] is described. This beam has been shown to generate 60x60 cm^2 sheets of high density (10^{12} cm^{-3}), cold (<1eV) plasma this system is called Large Area Plasma Processing System (LAPPS). Study of those configurations earlier has given us the criterion of plasma-beam discharge ignition, however the main factor for this discharge to be so interesting is the second study of the discharge, viz. the development of Langmuir waves and their role in plasma heating. Nevertheless the fact of development of technique of beam plasma discharge is very important despite of different interpretation of experiments. We have used the beam plasma discharge for direct reduction of metals from oxides and chlorides. The chemistry of the process of metal reduction from the oxides or chlorides by hydrogen is well known. There are the hydrogen atoms and ions besides the molecular hydrogen in the beam-plasma discharge. At the presence of hydrogen atoms and ions the process of metal reduction from oxide can take place at the room temperature. The hydrogen was injected in the working chamber; the reaction products were removed with the rest of hydrogen by the pumping-out system. The process of metal reduction from oxide or chloride by hydrogen in beam-plasma discharge is non-equilibrium. It means, that the fixation of the reaction products can be simplified. When the process of treatment is over the neutral gas such as argon or nitrogen is introduce into the working chamber up to the atmospheric pressure and the products can be taken from the system.

2. Experimental Device

The experiments are performed on the device "Oratoria10", the scheme being shown at Fig.1. The installation «Oratoria-10» is intended for the plasma chemical researches. The working vacuum chamber (1) of radius 252,5 mm and the length of 1m is made of stainless steel. All the chamber was immersed in magnetic field created by the coils (2), the voltage 100 V and the current 200A. The constant magnetic field in the centre of chamber can be varied from 300Gs up to 600Gs. The magnetic system of a "mirror-like magnetic trap" type produces magnetic field of maximum strength 800 Gs and magnetic mirror (max/min) ratio R~3.5. The electron beam of a cylindrical geometry of maximum diameter up to 4 cm is formed by means of an electron gun (3) with a beam current of up to 2 A and of its energy up to 6 keV. The electron

beam penetrates chamber via small orifices that lead to the electron gun (3) from one side and to the electron beam receiver (4) on the other side. To provide the necessary high vacuum conditions for the electron gun to operate the system of differential pumping (5) was used. Differential pumping system consists of three groups of thin diaphragms with the intermediate pumping out between the two ending diaphragm groups and through the middle group. The holes in the diaphragms are equal to a diameter of the electron beam. The necessary vacuum conditions in the electron gun chamber are provided by the oil vapour high vacuum diffusion pump (6) with liquid nitrogen-cooled trap. The working chamber (1), the differential pumping system (5) and the volume of electron beam receiver (4) are pumping out by the oil vapour booster vacuum pumps (7) with liquid nitrogen-cooled traps. The residual gas pressure is not more than 1.10^{-5} Torr in the working chamber and not more than 5.10^{-7} Torr in the electron gun chamber with the using of nitrogen cooled traps. The maximum working pressure in working chamber is about ~ 10^{-1} Torr and is about 10^{-5} Torr in the electron gun chamber. The "Oratoria -10" installation enables to carry out the researches of non equilibrium plasma with the density of $10^{10} – 10^{13}$ cm^{-3} produced in a beam-plasma discharge.

1 - vacuum chamber; 2 - magnet coils; 3 - electron gun; 4 - electron beam receiver; 5 – the diaphragms of differential vacuum pumping out system; 6 – oil vapour high vacuum diffusion pump; 7 – oil vapour booster vacuum pump.

3. Experiments

The scheme of the experiments on the reduction of metals from oxides or chlorides is shown on the fig.2. The electron gun produces the electron beam (1) of power W=2-4 kW, the voltage being up to 2kV and the current up to 2 A. The electron beam penetrates the working chamber from one side another side (from the electron gun to the electron beam receiver) through the cylinder tube (2). There is the working table (3) with the small volumes (4) with powder metal oxide (or chloride) on it in the tube (2). The internal diameter of the tube (2) is 95 mm. The hydrogen is supplied into the reaction zone through the inlet nozzle (5). The temperature of the small volume (4) walls was measured by the thermocouple (6) that had the diapason of measurement from 100C up to 1000C. The small volumes (4) have the shape of a parallelepiped with the area 10x30 mm and height of walls 3 mm. Volume is made of a tantalum. The surface of a reduced metal oxide (or chloride) powder was at the distance 18-25 mm from the boundary of the electron beam. The bottom of volume is made corrugated with the corrugations along the long side. Powder of metal oxide studied is filled in small volume (4) up to height of 1 mm. The intermixing of a powder can be carried out by the rotational displacement of the tube (2) around of a long axis in limits of angle ±90°. The experiments on the reduction of metals were executed in non-equilibrium hydrogen or deuterium plasma produced by the beam-plasma discharge in plasma chemical installation “Oratoria-10”. The study the process of metal reduction from oxides or chlorides was executed with the compounds in powder form.

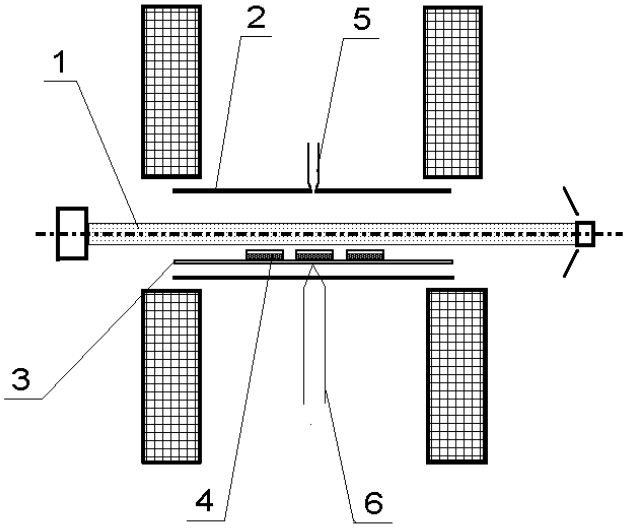

Fig. 2. The scheme of the experiment on the reduction of oxides and chlorides of metals.
1 – electron beam; 2 – tube; 3 – working table; 4 – small volume with powder oxide; 5 – inlet gas nozzle; 6 – thermocouple.

The studied powders were filled in small volume (4) that was fixed on the table (3) and was positioned in the tube (2) in the working chamber (1) of the installation (Fig.1). Then the pumping-out up to the minimal pressure of residual gas was executed. The working chamber was pumped out first up to 10^{-5} Torr and then the hydrogen or the mixture of argon and hydrogen were delivered into the chamber by a nozzle up to the pressure 4.10^{-2} - 6.10^{-2} Torr. The initial gas pressure was supported at stationary value; at that there was the equilibrium of the inlet gas supply and the pumping-out. The pressure of hydrogen (or the intermixture of hydrogen and argon) in the working chamber (or in the reaction zone) was controlled by the quantity of inlet gas flow through the nozzle. After the achieving of the working pressure the discharge was ignited. The exposition time of the hydrogen plasma interaction with studied materials was from two up two and one half hours. The powder was stirred up by a special mechanism for the interaction of hydrogen with treated material to improve. Moreover to improve stirring the walls of volumes were corrugated. The studied substance in small volumes was heated by the effect of beam-plasma discharge up to the temperature 400C – 500C. In several experiments the addition of argon to the hydrogen was used to increase the plasma electron density. The mixture argon and hydrogen was fifty-fifty. The deuterium was used to decrease the plasma losses thus increasing of the electron density as well. In the experiments with the argon addition the total gas pressure before the discharge ignition was ~(6.10^{-2} - 9.10^{-2}) Torr. The argon was used for the discharge in the electron gun to evade for relative high pressure of the order of 10^{-3} Torr. For lower pressures of the order of 10^{-4} Torr the addition of argon was not necessary. The initial compounds to be treated were Fe_2O_3, $FeCl_3$, $CuCl_2$, $LaCl_3$, and Sc2O3. The treatment time was from two up to two and a half hours and treatment was repeated four times. On having finished treatment we supplied the chamber by a nozzle with dry nitrogen to evade the oxidation processes of reduced metal powder obtained. The dry nitrogen was supplied into the "Oratoria-10" vacuum volume up to the pressure equalled to one atmosphere. Thus the dry nitrogen permitted to open the chamber having isolated the product (reduced metals) from air. The product obtained was studied by optical spectral method and by the X- ray analysis.

A typical experiment with iron oxide was as follows. All the small volumes were filled with Fe_2O_3. The initial pressure of residual gas in chamber corresponds to 10^{-5} Torr. Then the hydrogen in chamber was delivered up to the pressure 4.10^{-2} Torr. Argon was added up to the total pressure 9.10^{-2} Torr. The beam power was 1,9 kW. The total time of exposition was eight hours (four times for two hours). The temperature of powder during the experiment was 225C. The X-ray structure analysis showed: 10% of Fe_2O_3; 10% of Fe_3O_4; 10%; the rest 70% was pure iron represented in two forms, viz., 60% of α - Fe modification and 10% of β - Fe modification.

The second experiment was executed with the powder of $CuCl_2$. The sequence of the operations in the experiment was the similar to the above. The initial pressure and the pressure of hydrogen were the same. The adding gas was the mixture of Ar and He up to the total pressure $8.2 \cdot 10^{-2}$ Torr. The electron beam power

was 3,5 kW. The time of exposition was two hours and ten minutes. The temperature of powder was 470C. The obtained powder was consisted of 10% $CuCl_2$, 20% CuCl and 60% pure Cu.
The third experiment was the reduction of Sc from Sc_2O_3. The experiment was carried out by the analogy the experiments on the reduction of iron and copper. The adding gas was argon. The total pressure was the same as in the experiment with iron. The electron beam power was 2.2 kW. The time of exposition was one hour and forty-seven minutes. As a result we had the reduction of one half from the initial scandium oxide (50% of Sc and 50% of Sc_2O_3).
The fourth experiment was executed with the powder of $LaCl_3$. The experiment was the similar to the three above. The adding gas was helium. The total pressure of gas mixture was $7.4 \cdot 10^{-2}$ Torr. Two expositions were executed. In the first one the electron beam power was 2.25 kW during the time of one hour and forty-seven minutes. In the second one the electron beam power was 2.25 kW during the time of two hours. The product result contained 20% of $LaCl_3$, 15% of LaCl and 65% of pure La.
The last fifth experiment was the reduction of scandium from $ScCl_3$. This experiment was the similar to the above too. The adding gas was helium and the total pressure was same as in the fourth one. The electron beam power was 2kW. The total time of the exposition was one hour and forty minutes (five times for twenty minutes). As in the experiment on the reduction of scandium from the scandium oxide we had in a result the reduction of one half scandium chloride (50% of pure scandium, 20% of $ScCl_3$ and 30% of Sc_2Cl_3).

4. Results

It was shown, that the reduction of metals (iron, copper, scandium, lanthanum) from its oxides and chlorides in hydrogen plasma of the beam - plasma discharge was good enough, not less than 50 %. As a rule the reduced metals were obtained in the powder form, the special attention was being to be drawn to the problem of transportation of the obtained metal samples to avoid their oxidation. Usually the total gas pressure was 10^{-2} Torr, the hydrogen pressure being 10%, argon pressure being 90%. The other mixtures were used as well. The transition to the lower pressure when the soft X-ray emission appeared was performed and the comparison of results for high pressure (10^{-2} Torr) and low pressure (10^{-4} Torr) was done. The low pressure permits to dispense with argon and deuterium. The processing studied can be of interest for the direct reduction of the oxides of the rare earth metals.

5. Discussion

The obtained result confirms the opportunity to use the method of direct reduction of metals from oxides and chlorides in hydrogen plasma for the production high pure metals from high pure oxides (chlorides). We have not achieved the complete reduction of metals oxides (and chlorides). The possible reason could be the excessive thickness of the sheet of an initial powder and poor intermixing. Because of it is difficult to speak about reaction rate and the productivity of the process. In any case the obtained results confirm the opportunity to create the technology of direct reduction of high pure metals from oxides (or chlorides). There are two main ways of the further researches: to extract the reduced metal from oxide (or chloride) and to achieve the complete reduction of metal oxide (chloride) up to metal. The solution of a problem of complete reduction of metal oxide up to metal is possible by the increasing density of hydrogen ions in plasma for example by the decreasing of argon addition and the using of only hydrogen plasma. Now, the reconstruction of device is in progress. The minimal residual gas pressure in the working chamber is 10^{-6} Torr. Beam-plasma discharge is stable ignited and burns in wide pressure range of hydrogen from 5.10^{-5} Torr up to 10^{-3} Torr and higher at the energy of beam electrons from 2 keV up to 6 keV and current of the beam from 0,5 A up to 2 A. In this regime there is the X-ray generation with the energy up to 250 keV is observed. The presence of X-ray generation testifies the existence of a group of "hot" electrons with energy much more than energy of beam electrons in the discharge. The hot electrons appear in the beam - plasma discharge at equality of plasma oscillations frequency to doubled Larmor oscillations frequency. The existence of such mode also is the confirmation that the process of reduction of metal from oxide is carried out with the most efficiency in the beam-plasma discharge. It is necessary to take into account the opportunity of X-rays generation in the experiments with beam-plasma discharge from the view point of a safety of the operative personnel. It is of interest to carry out the experiments at more thin layers of studied compounds at smaller pressures of initial gas and without the use of argon additions. With this respect it should be pointed out that the beam-plasma discharge is rather turbulent heating phenomenon rather than support of discharge only due to pair collisions [3]. The outcome of X- ray radiation from the beam plasma discharge is well known in the physics of hot plasma since 1963. It should be noted that the appearance of the hot electron and of X-ray

emission should be taken into account very seriously. From one side it demonstrates the possibility of this type of discharge from the other side it calls for certain accuracy.

Abstract
The condensation mechanism of rare-earth boride in thermal plasmas was investigated experimentally. In the thermal plasma, the premixed powder of rare-earth boride with boron was evaporated immediately and nanoparticles were produced through the cooling process. The nucleation temperature of boron, lanthanum and cerium have wide liquid range between the nucleation and melting temperature, resulting in better preparation of boride.

1. Introduction

Induction thermal plasmas have been used for production of high-quality and high-performance materials, such as synthesis of nanoparticles, deposition of thin films, plasma spraying and treatments of powders. Induction thermal plasmas have been also applied for treatment of harmful waste materials and recovery of useful material from wastes [1, 2]. These attractive material processes with induction thermal plasmas result from unique advantages; these advantages include high enthalpy to enhance reaction kinetics, high chemical reactivity, large volume with low velocity, oxidation and reduction atmospheres in accordance with required chemical reactions, and rapid quenching (10^6 K/s) to produce chemical non-equilibrium materials. These advantages increase the advances and demands in plasma chemistry and plasma processing, such as preparation of various kinds of nanoparticles in metallic and ceramic systems.

The purpose of this paper is to prepare rare-earth boride nanoparticles by induction thermal plasmas. Rare-earth boride is attractive materials because of their high melting temperature, high electrical conductivity and low work function. Therefore these nanoparticles would be applied for the electromagnetic shielding, and solar control windows with interaction with IR and UV light. Some reports about the preparation of boride nanoparticles were published previously; YB_{66} nanoparticles were prepared by plasma chemical process using starting powders of YB_4 and B [3]. TiB_2 nanoparticles were synthesized in the vapor-phase reaction of sodium with $TiCl_4$ and BCl_3 [4].

Another purpose is to investigate the condensation mechanism of mixture vapor of rare-earth metal and boron in thermal plasmas. Investigation of physical and chemical processes in thermal plasma processing is indispensable for production of nanoparticles. Co-condensation process of metal vapors was investigated for Nb-Al and Nb-Si systems [5], Nb-Si and V-Si systems [6]. Formation mechanism was investigated for silicide nanoparticles [7,8]. Vaporization process for Ti-Si, V-Si and Mo-Si systems were also investigated [9]. For nanoparticle preparation with stoichiometric composition, the vaporization and condensation rates of the constituent metals should be controlled in the case of large difference in the vapor pressure.

2. Experimental Set-ups

Figure 1 shows a schematic illustration of experimental set-ups for the production of nanoparticle preparation. Induction thermal plasmas were used for preparation of rare-earth bride nanoparticles. The set-ups consist of a plasma torch, a reaction chamber, a

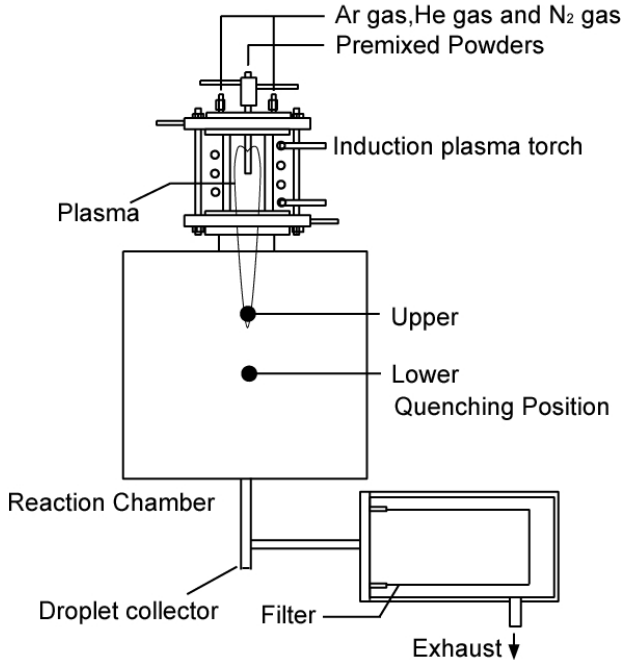

Fig. 1 Experimental set-up for nanoparticle preparation.

prepared particle collection filter and a power supply (4 MHz) at 25 kW. The plasma torch (45 mm i.d., 128 mm length) consists of a water-cooled quartz tube and a working induction coil (3 turn). The reaction chamber was set below the torch. Total system was evacuated and then Ar was introduced up to a pressure of 101 kPa. Premixed powders of La_2O_3, B and C were introduced into the thermal plasma from the top of plasma torch at the feed rate of 0.1 g/min. Premixed powders of $La(OH)_3$, B and C were also used for the preparation of LaB_6. For the preparation of CeB_6, premixed powders of CeO_2, B and C were used. Raw material powders used in this study are La_2O_3 (average: 14.4 μm), $La(OH)_3$ (average: 1.34 μm), CeO_2 (average: 20.2 μm), B (average: 15.0 μm), and C (average: 1.34 μm). In the thermal plasma, injected powders were evaporated and reacted with boron. After the evaporation and reaction, the vapor was rapidly cooled after the plasma flame. Through the cooling process, metal vapor condensed and boride nanoparticles were produced. The prepared nanoparticles were collected at quenching condition by the water-cooled coil.

The structures of the prepared nanoparticles were determined by X-Ray Diffractometry (XRD, Mac Science MXP3TA). Concentrations of La and B in the prepared particles were determined by Inductively Coupled Plasma Spectrometry (ICP, Seiko Instruments SPS4000), while that of C were measured by Carbon Determinator (LECO EC12). The size distribution of the particles was measured from the photographs of Transmission Electron Microscopy (TEM) for about 1000 particles. TEM observations as well as Electron Diffractometry (ED) were performed on JEOL JEM-2010 operated at an accelerating voltage of 200 kV.

3. Experimental Results

a) La-B-C system

The TEM photograph of the prepared nanoparticles for La_2O_3-B-C system was shown in Fig. 2. The particle size distribution shown in Fig. 3 presents the average particles size of 15.0 nm with the geometrical standard distribution of 1.58. The XRD spectrum charts of the prepared nanoparticles for La_2O_3-B-C system with the Ar plasma are demonstrated in Fig. 4. LaB_6 and La_2O_3 were identified from the XRD spectrum peak of the as-prepared particles. The as-prepared particles were separated to nanoparticles in suspension and agglomerated particles in precipitate by ultrasonic dispersion. Nanoparticles are mainly composed of LaB_6 with small fraction of $La(OH)_3$ made from La_2O_3 at ultrasonic dispersion. The agglomerated particles are identified as LaB_6, $La(OH)_3$, $LaBO_3$ with unreacted B from XRD and ED analysis. Induction thermal plasmas provide a powerful tool for the preparation of functional nanoparticles because the phase and composition in nanoparticles can be well controlled.

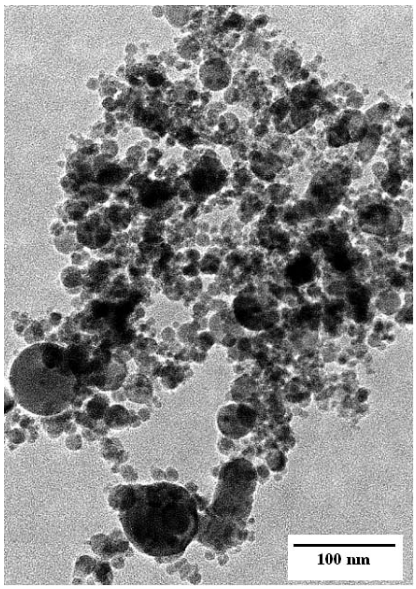

Fig. 2 TEM photograph of nanoparticles for La_2O_3-B-C system; La_2O_3:B:C = 1:12:3; powder feed rate: 0.1 g/min.

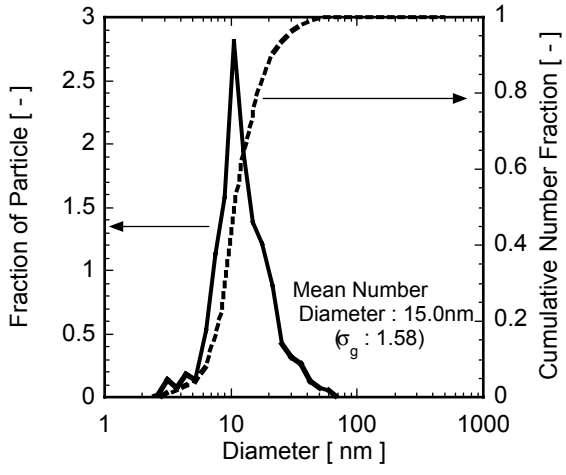

Fig. 3 Particle size distribution for La_2O_3-B-C system; La_2O_3:B:C = 1:12:3; powder feed rate: 0.1 g/min.

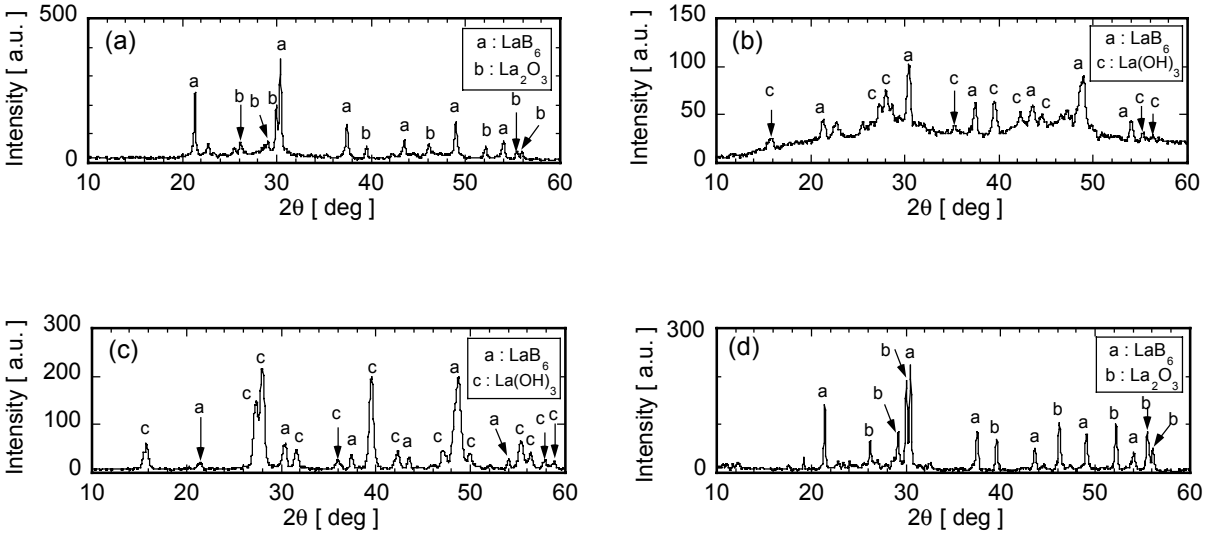

Fig. 4 XRD spectrum charts of nanoparticles for La_2O_3-B-C system; La_2O_3:B:C = 1:12:3; powder feed rate: 0.1 g/min. (a) as-prepared particles, (b) nanoparticles in suspension, (c) particles in precipitation, (d) unvaporized particles.

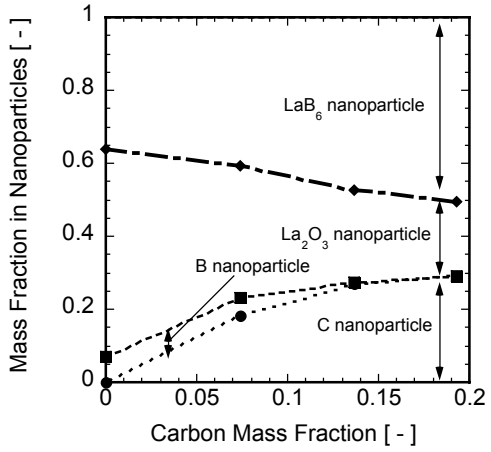

Fig. 5 Effect of carbon mass fraction in the injected powders on the nanoparticle composition for La_2O_3-B-C system.

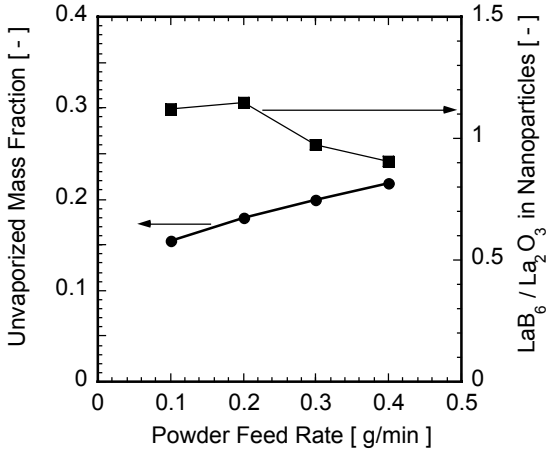

Fig. 6 Effect of powder feed rate on the unvaporized fraction and on the nanoparticle composition for La_2O_3-B-C system.

Figure 5 shows effect of carbon mass fraction in the raw powders on the nanoparticle composition. The prepared amount of LaB_6 increases with the carbon content, because the injected La_2O_3 is easily reduced by carbon in the plasma. Increasing in the carbon content in the feed powder also causes the increase in the carbon content in the prepared nanoparticles. However the carbon in the nanoparticles can be separated by hydrochloric acid treatment; 3 N hydrochloric acid during 20 min at room temperature.

Effect of powder feed rate on the unvaporized fraction of the particles was shown in Fig. 6. The composition of the nanoparticles was also shown in this figure. The unvaporized fraction deceases with a decrease in the powder feed rate, resulting in the enhanced vaporization of boron powders. Therefore the prepared amount of LaB_6 nanoparticles are larger at smaller powder feed rate.

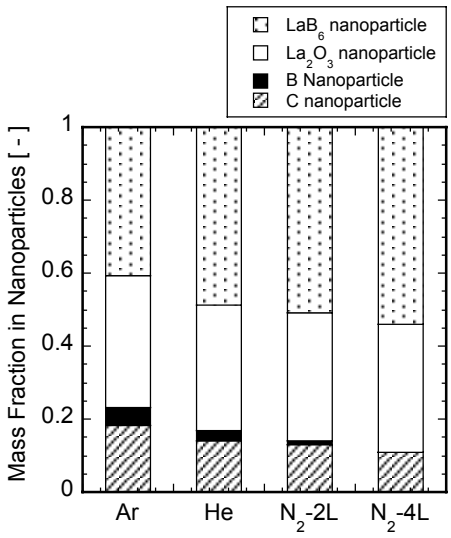

Fig. 7 Effect of plasma gas composition on the nanoparticle composition for La_2O_3-B-C system.

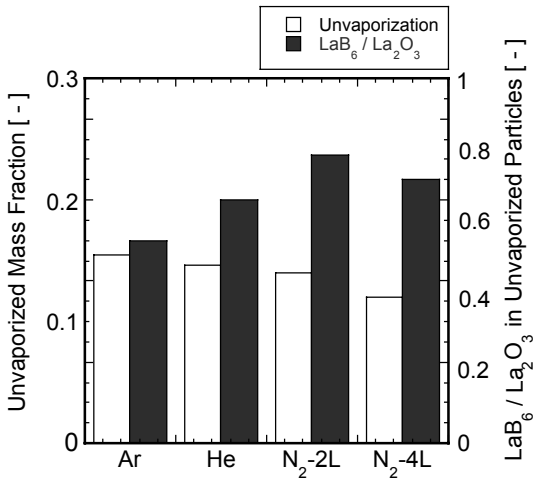

Fig. 8 Effect of plasma gas composition on the unvaporized fraction and on the composition of unvaporized particles for La_2O_3-B-C system.

Plasma gas composition has important role on the nanoparticle composition, because the heat transfer rate as well as the reaction mechanism are influenced by the plasma gas composition. Nitrogen (2 or 4 NL/min) or helium (3 NL/min) was added to argon induction plasmas. From the XRD analysis, no peaks due to BN and LaN were not found because ΔG of La nitridation is higher than that of boridation. Effect of plasma gas composition on the nanoparticle composition was shown in Fig.7. Prepared amount of LaB_6 nanoparticles were increased by helium or nitrogen plasmas. Addition of helium or nitrogen enhances the heat transfer rate to the injected powders as shown in Fig. 8. The unvaporized fraction of the injected powders is reduced by helium or nitrogen plasma.

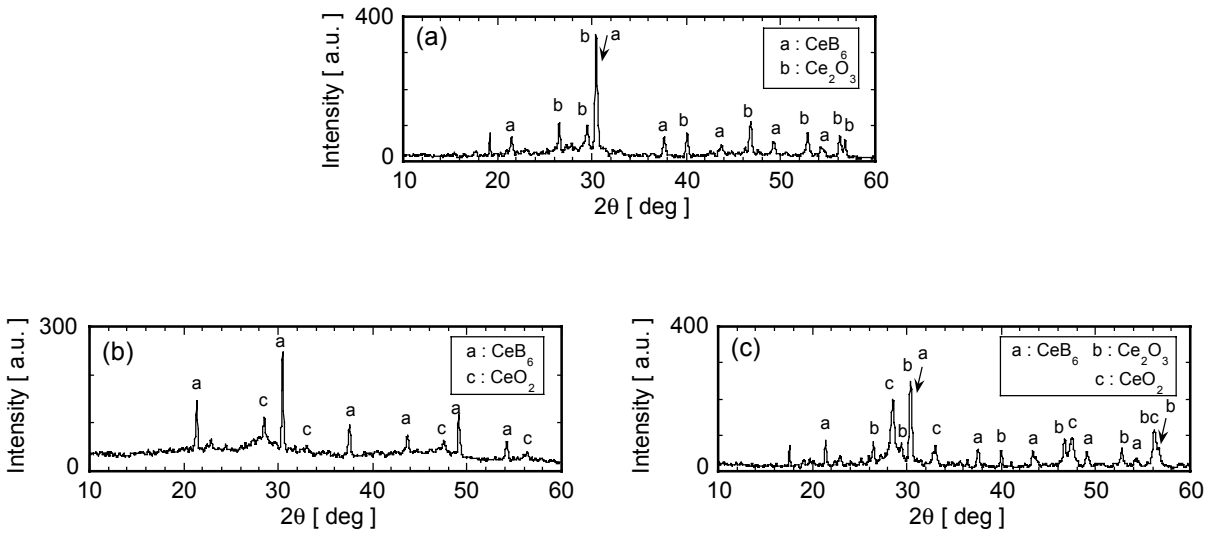

Fig. 9 XRD spectrum charts of nanoparticles for CeO_2-B-C system; CeO_2:B:C = 1:12:3; powder feed rate: 0.1 g/min. (a) as-prepared particles, (b) nanoparticles in suspension, (c) unvaporized particles.

b) Ce-B-C system

The XRD spectrum charts of the prepared nanoparticles for CeO_2-B-C system with the Ar plasma are demonstrated in Fig. 9. CeB_6 and Ce_2O_3 were identified from the XRD spectrum peak of the as-prepared particles. The as-prepared particles were separated to nanoparticles in suspension and agglomerated particles in precipitate by ultrasonic dispersion. Nanoparticles are mainly composed of CeB_6 with small fraction of CeO_2 made from oxidation of Ce_2O_3 at drying.

Figure 10 shows the comparison of nanoparticles composition for La_2O_3-B-C and CeO_2-B-C systems. The ratio of LaB_6 to La_2O_3 is larger than the ratio of CeB_6 to Ce_2O_3 in the as-prepared particles. The better preparation of LaB_6 than that of CeB_6 is attributed to lower ΔG of lanthanum boridation than that of cerium boridation.

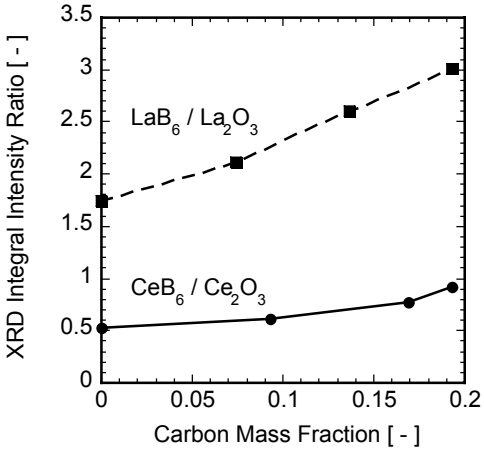

Fig. 10 Comparison of nanoparticle composition for La_2O_3-B-C and CeO_2-B-C systems.

4. Discussions

a) Vapor pressure

Vapor pressure difference of boron and rare-earth is the important factor for the controlled composition of the prepared rare-earth boride nanoparticles. The vapor pressure ratio of lanthanum to boron is 13, while that of cerium to boron is 18 at the melting point of born. Small difference in vapor pressure of the constituent components leads to better preparation of boride nanoparticles.

b) Nucleation Temperature

Homogeneous nucleation rate has been proposed by Girshick et al. [10]. They derived the expression as an extension of kinetic nucleation theory. The proposed expression can be used over a wide range of physical conditions. Furthermore, the expression for homogenous nucleation, J, was consistent with experimental data. Therefore Eq. (1) was used for the estimation of critical saturation ratio.

$$J = \frac{\beta_{ij}\, n_s\, S}{12}\sqrt{\frac{\Theta}{2\pi}}\exp\left[\Theta - \frac{4\Theta^3}{27(\ln S)^2}\right] \tag{1}$$

where n_s is the equilibrium saturation monomer concentration at temperature T, β_{11} the collision frequency function between monomers, and S the saturation ratio. The dimensionless surface tension Θ is given by

$$\Theta = \frac{\sigma s_1}{kT} \tag{2}$$

where σ is the surface tension, and s_1 the monomer surface area. The collision frequency function β_{11} can be estimated by Eq. (3) when the Knudsen number is more than 10 [11].

$$\beta_{ij} = \left(\frac{3v_1}{4\pi}\right)^{1/6}\sqrt{\frac{6kT}{\rho_p}\left(\frac{1}{i}+\frac{1}{j}\right)}\times\left(i^{1/3}+j^{1/3}\right)^2 \tag{3}$$

where ρ_p is the particle mass density and v_1 the monomer volume. In this model, the particle nucleation is due to the monomer collision, therefore $i = j = 1$.

Relationship between the nucleation rate and saturation ratio is shown in Fig. 11. The nucleation rate is strongly dependent on the surface tension and saturation ratio. When the nucleation rate is over 1.0 cm^{-3} s^{-1}, particle formation can be conveniently observed experimentally. Therefore the corresponding value of saturation ratio is defined as the critical saturation ratio [11]. The critical saturation ratio of boron was estimated to be 2, while lanthanum and cerium have the critical saturation ratio of 14 and 16, respectively. Carbon has the highest critical saturation ratio of 42.

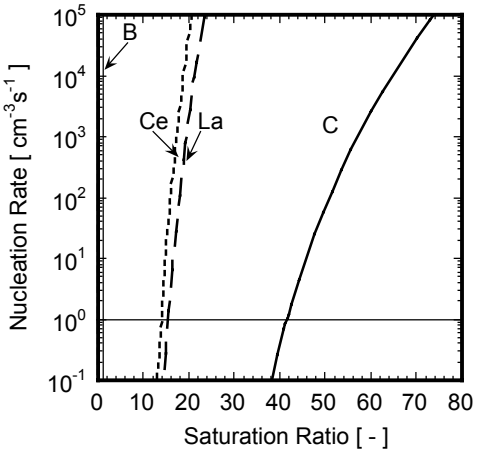

Fig. 11 Relationship between homogenous nucleation rate and saturation ratio for La, Ce, B and C.

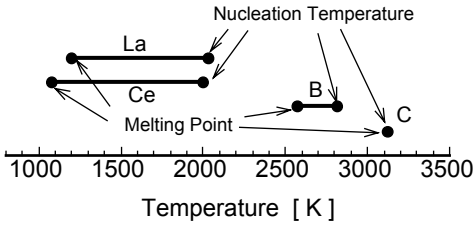

Fig. 12 Nucleation and melting temperature of La, Ce, B and C.

The nucleation temperature at the critical saturation ratio is presented in Fig. 12 for constituent components of boride. The nucleation temperature of carbon corresponds to the melting temperature, while boron, lanthanum and cerium have wide liquid range between the nucleation and melting temperature. The wide liquid range combination of boron with rare-earth metals leads to better preparation of rare-earth boride nanoparticles.

5. CONCLUSIONS

Experiments were performed to investigate the condensation of mixture of rare-earth metal with boron in thermal plasmas for the preparation of LaB_6 and CeB_6 nanoparticles. The nucleation temperature of boron, lanthanum and cerium have wide liquid range between the nucleation and melting temperature, resulting in better preparation of boride. Induction thermal plasmas provide a powerful tool for the preparation of functional nanoparticles because the phase and composition in nanoparticles can be well controlled.

Plasma sputtering technique for problems to solve by making use of environment at the outdoor conditions

V.S. Blokhin[2], A.A. Ivanov[1], A.V. Pereslavtsev[1]

[1] *Russian Research Centre "Kurchatov Institute", Moscow, Russia*
[2] *Center of Ecological Technologies – "Intellect of Creation", Moscow, Russia*

Abstract
The plasma sputtering technology of decorative and moisture-proof coatings on the base of natural sand is developed. The direct current arc plasmatron is applied for the sputtering of coatings. The air is used in plasmatron as the plasma forming gas. The plasma equipment complex for the coating producing may be made as in stationary or in the mobile variant for the using at the outdoor conditions. The technology can be applied for the producing of corrosion resisting and wear-resistant chemically proof coatings.

1. Introduction

One of the perspective trends in the modern technologies development is the wide using of various types of coatings such as decorative coatings, moisture-proof coatings, anticorrosive coatings, wear-proof coatings, chemically resistant coatings, and also various multipurpose coatings. Rather complicated stationary equipment required for the application of plasma sputtering techniques is the main problem for its wide application. The modern materials in plasma equipment make it possible to develop new advanced techniques for the production of protecting coatings based on natural materials. The using of air, water aerosols or natural gas in plasma sputtering techniques simplifies the plasma equipment and increases its mobility. The application of natural sands as the base component of plasma ceramic coatings in sputtering process decreases the cost of the technological process and the cost of coatings simultaneously. The development of the new approach to the interaction of powder particles with the flow of high temperature plasma allows to increase the efficiency of the powder heating in plasma flow in 2.5 - 3 times. This approach makes it possible to decrease the power consumption of the plasmatron sputtering equipment about two times.

2. Technology

The scheme of plasmatron for the producing of protective coatings on the base of natural materials is shown on the fig.1.

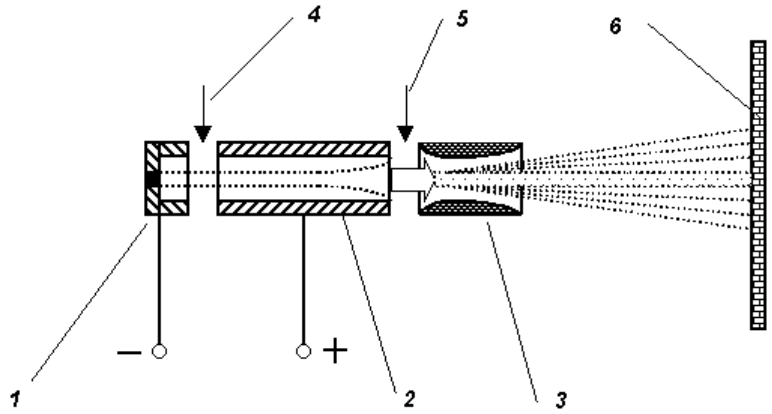

Fig. 1. Special plasmatron for plasma sputtering deposition on the base of natural materials. 1 – cathode; 2 – anode; 3 – sputtering nozzle; 4 – plasma forming gas; 5 – working intermixture; 6 – handled surface.

The direct current arc plasmatron is applied as the source of low temperature plasma for the plasma sputtering process. The plasma forming gas is being supplied to the inter-electrode space, between the cathode (1) and anode (2). The air is used as the plasma forming gas in the presented technology. The gas heating and the plasma flow formation take place in the plasma filament of arc discharge of plasmatron. The

heat content (enthalpy) of gas flow is determined by the parameters of arc discharge (arc current and arc voltage) and gas flow. The spraying nozzle (3) is set at the outlet of the plasmatron anode. The working intermixture being the base for the coating is supplied to the space between the anode (2) and the spraying nozzle (3).
The heating of the working intermixture particles up to the required temperatures and their transportation up to a handled surface is carried out by the high temperature gas-plasma flow. The temperature of the working intermixture particles depositing on a handled surface, their phase state and their velocity are determined by the following parameters:

- the heat content (enthalpy) of gas-plasma flow,
- the relation of the plasma forming gas flow and working intermixture flow,
- the composition of the working intermixture,
- the configuration of the spraying nozzle.

The main problem in the development of presented technology is the choice of the working intermixture composition, the temperature and the velocity of the particles at the interaction with the handled surface [1,2]. The characteristics of the coating obtained (the composition and the structure of the coating, the adhesion with the handled surface) depend on the above parameters of the working intermixture and the gas-plasma flow produced by plasmatron.
The above approach allows us to form the coatings of the required composition and structure on the base of rather various materials. It makes it possible to obtain the composite coatings [3,4,5].

3. Application

The above principle of the interaction of working mixture particles with the gas-plasma flow is applied in the plasma sputtering technology for the producing of decorative protective coatings. The developed technology is based on the using of natural sands and it is intended for the application in the building construction. The gas for the plasma formation is the air. The features of the produced coatings and their characteristics depend on the composition of the working mixture. One can obtain the coatings of different colours mixing natural sand with the different inorganic dyes. The use of widely accessible natural materials and the rather low requirements to their preparation allow us to realise the technology not only in the stationary variant, but as the mobile complex of equipment, too. The scheme of the mobile complex of plasma sputtering equipment for the application in the building construction is shown on the fig.2. The process of the plasma sputtering deposition is realised by the specially designed plasmatron. One can use the air, water vapour, and the natural gas as the plasma forming gas in the plasmatron. The composite materials are used in the construction of plasmatron [6,7]. The spraying nozzle is manufactured with the using of composite materials. The durability and the lifetime of plasmatron and spraying nozzle are determined first of all by the application of these composite materials. The complex of equipment is intended for the producing of coatings of any types, including the decorative and moisture-resistant coatings by the method of plasma sputtering on the surfaces of concerts and on the other constructional materials.
The complex of plasma equipment consists of:

- the power supply system (autonomous electric generator and voltage transformation unit);
- compressor;
- the system of working intermix supply (receiving bunker with disintegrator and the dispensing mechanism of the mix supply: sand + admixture);
- water-cooling system;
- plasmatron;
- control system.

The plasma equipment complex can be transported by the automobile or may be installed on the automobile chassis or auto trailer.
At the use of computer control and monitoring system two operators can serve the plasma equipment complex.
Some technical parameters of the plasma equipment are as follows:

- the power of plasmatron is 30 kVA;
- the productivity of process per square unit is about 3 - 6 m^2/hour;
- the productivity of plasmatron is about ~ 1.5 kg/h;
- small dimensions of the plasma device.

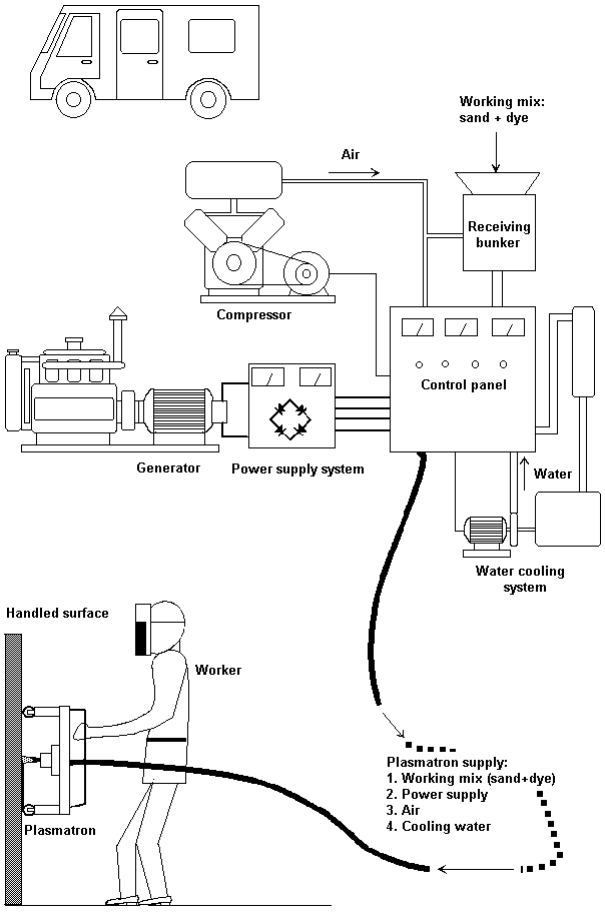

Fig. 2. Structure of the mobile complex of plasmatron equipment for the plasma sputtering of coatings on the base of nature sands in the buildings construction.

The presented technology allows to produce the ceramic coatings of the thickness 0.15 – 0.3 mm with waterproof glassy (fused) structure. Also the presented technology allows to create the facing details with any thickness.

The process of preparation of working intermixture for plasma sputtering technology is not very complicated and there is no need to organise the special industrial productions.

The manufacturing equipment intended for the preparation of the working intermixture can be mobile. One can use the equipment as in industrial variant or in the variant for outdoor conditions. One can see the possible variant of the scheme of manufacturing equipment for the preparation of working intermixture on the base of natural sand on the fig.3.

The technology of the working sand mixture preparation includes the following operations:

- sand drying;
- sizing, and the grinding up to the size of 50 - 150 microns;
- the mixing with the admixtures (inorganic colour dye and some others).

One preparation equipment complex can be utilised to serve several plasma sputtering equipment installations for the coating producing. This example of use of the above-stated approaches to the application of plasma sputtering technologies demonstrates us the new opportunities of plasma methods to improve and to get the new qualities of large-sized products.

4. Discussion

The technology of the deposition of coatings by plasma sputtering method based on the using of air, water aerosols, and natural sand allows us to obtain the "ceramic" or “cermets” coatings. Ceramic or cermets coatings have high durability and the resistance to external actions in outdoor conditions. The approach based on the above principles may be used for the creating of the techniques for the sputtering of protective

chemically resistant and corrosion-proof coatings for trunk pipelines, for the sea ship bottoms exposed to action of aggressive environment and for other objects and the directions of technique.

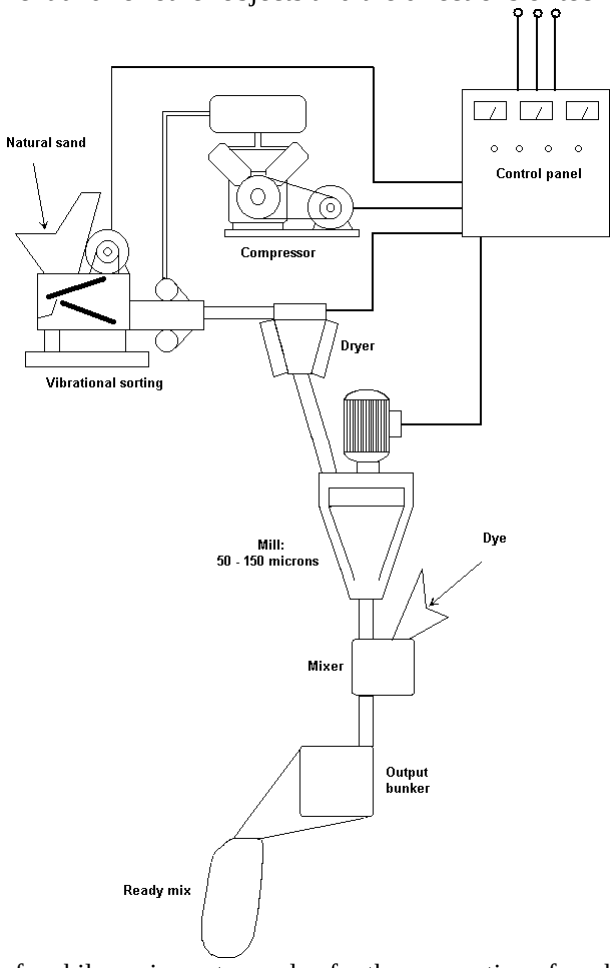

Fig. 3. The structure of mobile equipment complex for the preparation of working intermixture for the deposition of coatings by plasma sputtering method on the base of using of natural sand.

The presented technology accords to the modern ecological requirements and makes it possible to decrease the man-caused influence on the environment.

One can successfully apply the plasma sputtering technique for the producing of more complicated ceramic coatings on the metal surfaces with required characteristics. So, for example, the new approach to the formation of plasma jet containing the depositing material can be applied for the development of wider spectrum of products and to increase the operation resource of these products.

The simplicity and the cheapness of this technology make us hope on its wide application.

Abstract

This paper presents results about time evolution of OE spectra in a pilot 3-phase AC plasma reactor for nanotubes synthesis. Experiments are related to the injection of powder mixtures of carbon black with nickel or cobalt (or both metals). The following is commented: (1) He, Ni, Co, CN atomic lines and spectrum are observed when carbon, nickel and cobalt are injected together in the He plasma; (2) The mean plasma temperature is about 5200 K; (3) There is a strong influence of Ni on Co emission.

Introduction

In-situ diagnostics of high temperature processes for nanotubes synthesis is a critical issue addressing process monitoring and control in the view of the increase of selectivity. Nevertheless available data are very poor in the literature. Scott et al. [1] and Puretsky et al. [2] have published data about the laser ablation method. Concerning the arc and the solar methods data were given in the fullerene synthesis configuration, i.e. without catalysts, in [3] and [4] respectively. The C_2 emission is generally used as a temperature probe. Very recently results were obtained at CPAT (Toulouse, France) in conditions of single wall nanotubes (SWNT) synthesis by the arc method [5], Ni and Co lines were observed and analysed.
The data presented in this paper are related to an original plasma process in which carbon vapors are obtained from the evaporation of carbon powder in plasma whereas they are produced by electrode erosion in the standard electric arc process. Time evolution of the emission spectra is emphasized.

Experimental

The Reactor. The principle of this process consisted in introducing carbon particles, with or without metallic powders (Ni, Co), in a reactor equipped with 3-phase AC plasma torches. Both gas and solid were carried away in a filtration device where the carbon products were separated from gases. The gas was again injected at the bottom of the reactor. Inert or reducing plasma gas was used.
The complete system shown in Figure 1 was mainly composed of:

- A 200 kW 3-phase AC plasma source with consumable graphite electrodes, located at the top of the reactor;
- A high temperature reaction zone in which the carbon particles were injected. This top zone was separated from the rest by a graphite nozzle
- An insulated hot wall reacting chamber with graphite walls placed downstream the nozzle
- A circulation loop equipped with a bag-filter (PTFE bags) where carbon and gas were separated and collected
- An external vessel double-walled and water-cooled.

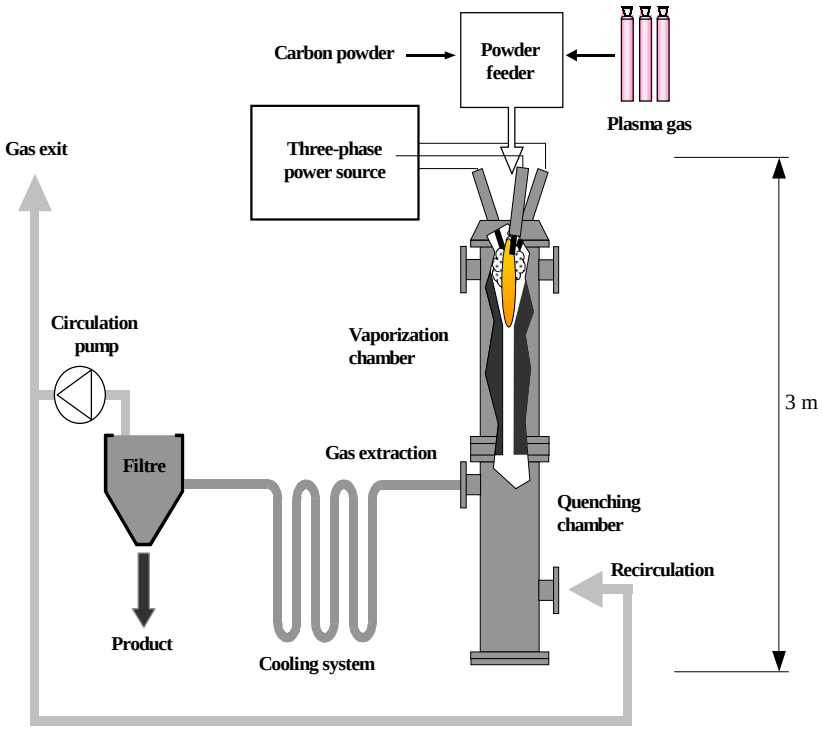

Figure 1: Scheme of the experimental system

Spectroscopic equipment:

The light emitted from the plasma was analysed by a monochromator (320 mm focal distance, with a 1200 lines/mm grating and 50 µm inlet slit). The detector was a 1024 x 128 photodiodes matrix. This device permitted a quasi-instantaneous analysis in a spectral range of about 60 nm. The duration time for the acquisition of an entire spectrum was 1 second. The spectral resolution was about 0.12 nm. An axial exploration of the plasma was performed using an optical device composed of:

- A lens: focal distance; 19 mm, diameter; 12.7 mm,
- An optical fiber: silica-silica, core diameter: 200 µm, length: 20 m,
- A measurement bench allowing 25 mm x and y displacement, and 1 meter z displacement.

The volume integrated by the fiber was perpendicular to the z-axis and centered on this axis. It was considered as a cylinder (4 mm diameter and 280 mm length).
The plasma gas was helium with a flow rate of 3 Nm^3/h. OES diagnostics of such plasma, seeded with cobalt and nickel powders, were performed in the arc zone through a window located at Z_1 = 15 cm. The mass flow rates of graphite powder and of metal (single or mixture of Ni + Co) were 100 g/h and the 10 g/h respectively. Standard electric characteristics were: U=80 V, I=250 A.

In this paper the comments will be focused on the time evolution of the emission spectra observed just underneath the arc zone during a injection sequence where pure carbon is first injected, then carbon plus cobalt powder and finally carbon plus nickel powder without cobalt.

Results

The walls of the reactor were first heated using nitrogen plasma. The nitrogen was then replaced by helium to perform the OES experiments. The Ni and Co powders were injected using Helium as carrier gas. Figure 2 shows a typical spectrum recorded in the arc zone during experiments without metallic powder injection. This Figure shows that the main lines are due to the bands of the violet system $B^2\Sigma$-$X^2\Sigma$ of CN. This species is produced from carbon and residual nitrogen coming from the preheating phase of the reactor.

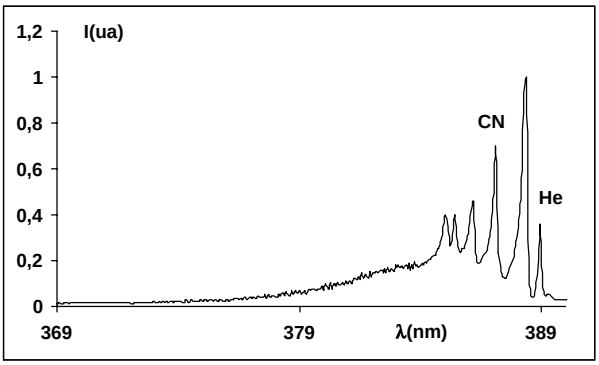

Figure 2: Typical OES spectrum without metallic powder injection

The head of the CN most intense band (0,0) for this system lies at 388.34 nm. The molecular spectrum of CN was observed for all our experiments. An atomic line of helium can also be observed at 388.86 nm, close to the CN band head.
Of course when pure cobalt powder is introduced in the plasma one can detect the emission of some atomic lines of this element mainly evidenced by the line at 389.4 nm (see Figure 3). But at the same time the intensity of the He line decreases.

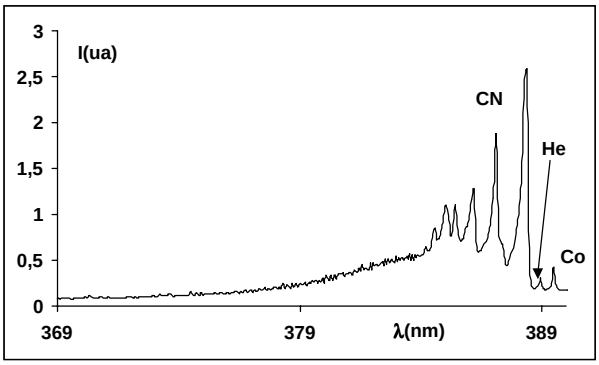

Figure 3: Typical OES spectrum with pure Co injection

Figure 4 shows the spectra obtained when the feeding of pure cobalt was stopped and replaced by pure nickel at the same flow rate. The spectrum shown in Figure 4 was obtained ten minutes after the spectrum in Figure 3. The feeding of Co was stopped five minutes before the introduction of pure nickel. Considering the time of nickel introduction as t= 0 one can deduce that the spectra on Figure 4 was recorded at t=2 mn.

In Figure 4 an emission of Ni atomic lines is clearly evidenced by the Ni line at 372.25 nm and three lines respectively at 377.56nm, 378.35 nm and 380.71 nm. More surprisingly is the important increase of the cobalt line intensities while there is no Co feeding.

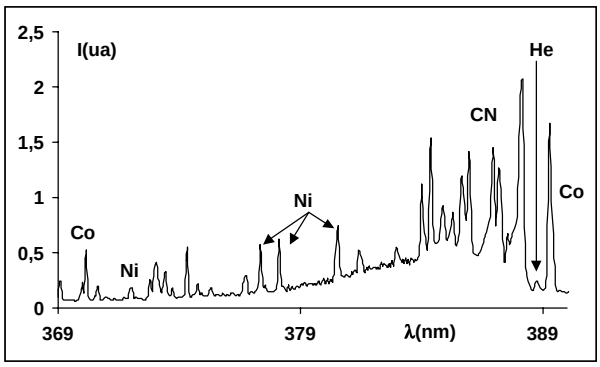

Figure 4: Typical OES spectrum with pure Ni injection at t=2 mn (Co injection stopped)

Moreover this Figure indicates an enhancement of the intensity of the 389.4 nm cobalt line with respect to the intensity of the helium line. Otherwise two atomic cobalt lines, respectively at 370.22 nm and 370.41 nm, can be observed in this Figure while they are almost undetectable for the experimental conditions of Figure 3.

A temperature can be derived from the relative intensities of these two lines assuming that the population of the upper level of the corresponding transition obeys a Boltzmann distribution (Local Thermodynamic equilibrium assumption). The temperature determined from the ratio intensities of the Co lines lead to a mean value of about 5200K ±200 K. This result agrees with data from [5].

Figure 5 shows the spectra recorded one minute after the experiment corresponding to the Figure 4. It is very surprising to observe a relative decrease of the same time of the Co and Ni lines intensities with respect to the helium line intensity.

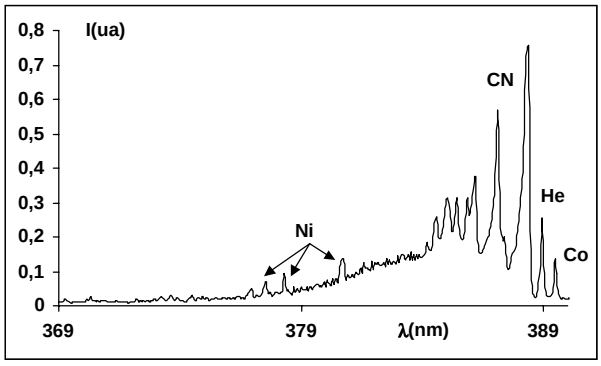

Figure 5: Typical OES spectrum with pure Ni injection at t=3 mn (Co injection stopped)

Figure 6 summarizes the intensity evolution of the Co, Ni, and He atomic lines for the three situations corresponding to the time sequence from Figures 3 to 5. The relative density of gaseous species Ni and Co in the arc zone is calculated assuming LTE, i.e. a same temperature for Co and Ni species.

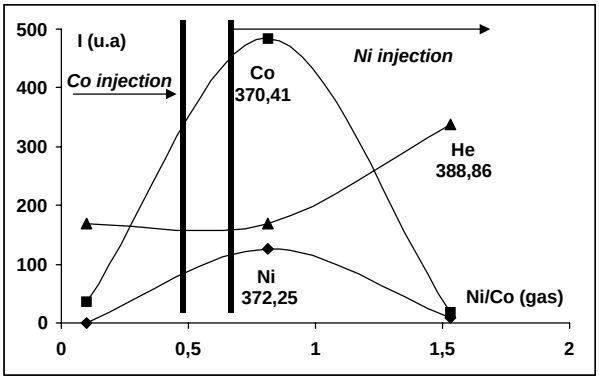

Figure 6**:** Line intensities evolution vs density ratio Ni/Co in the arc zone

The abscissa axis of Figure 6 gives the calculated Ni/Co ratio from the measured intensities and the calculated temperature. The obtained results are consistent: it is obvious that the ratio Ni/Co in the plasma (deduced from the intensity analysis) increases when pure Ni is introduced while the Co feeding is stopped.

When pure Co is injected the Ni/Co ratio is obviously small, the lines emission is weak meaning that the partial pressures of gaseous Co and Ni are low in the plasma. On the contrary it is difficult to explain the peak intensity mainly for the Co line while the helium intensity remains constant (constant temperature) and there is no Co injection inside the reactor, the only source of cobalt may be due to residual powder in the feeding pipes.
We have no satisfactory explanation for such behaviour and more experiments would be necessary for a better understanding of this phenomenon.

Conclusion

The main conclusions of this study are:

- He, Ni, Co, CN atomic lines and molecular spectrum are observed in the plasma flow during injection of powders.
- The derived plasma temperature assuming LTE is about 5200 K.
- An enhancement of Co emission is observed if Ni is present, this point is not explained but is perhaps related to the good performance of nanotubes synthesis observed when both catalysts are used.

Abstract
The experimental technology of the thermal synthesis of ozone is developed. The technique can be applied in the systems of drinking water conditioning on the base of the ozonization and for the utilisation of different kinds of industry waste and domestic waste. The water vapour is supplied in plasmatron as the plasma-forming gas. It results in the thermal dissociation and ionisation water molecules with subsequent recombination and formation of atomic oxygen. The synthesis of ozone occurs in the freezing plasma jet.

1. Introduction

The ecological problems are the essential problems of our civilisation. The problem of drinking water conditioning is one of them today. The ozonization process, which is applied in drinking water conditioning, requires certain amount of ozone. The main modern method of ozone production is based on the oxygenation air passing through the barrier discharge. The plasma thermal synthesis of ozone is the essentially new method of ozone producing. The ozone synthesis is based on the use of water vapour dissociation in thermal plasma onto the atoms of hydrogen and oxygen with the subsequent partial ionisation up to the ions of oxygen and hydrogen. The system of ozone thermal synthesis is equipped by the reactor that provides the recombination of oxygen ions into ozone molecules with simultaneous freezing of plasma jet to the temperature 10 - 12°C. The obtained ozone may be used in the processes of water ozonization and in the technologies of utilisation of different kinds of waste.

2. Technology

The scheme of process of the ozone thermal synthesis is shown on the fig.1. The water vapour is chosen as the parent material for the ozone synthesis. The water vapour is the plasma-forming gas in the plasmatron. The arc discharge burns in the direct current arc plasmatron. The water vapour decomposes at the heating in the arc discharge:

$$H_2O \rightarrow OH + H \rightarrow O + H + H.$$

There is the partial ionisation of atomic oxygen and atomic hydrogen in the plasma filament of arc discharge. The equilibrium between the charge carriers is established: between positively ionised atoms of hydrogen, electrons and negatively ionised atoms of oxygen. Heat content (enthalpy) and the freezing rate of plasma jet determine the output of reaction products.

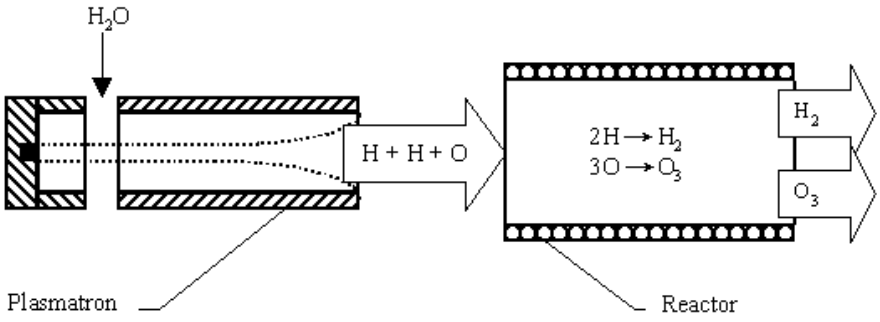

Fig.1. The scheme of the ozone thermal synthesis.

One can see the ideal scheme of ozone thermal synthesis on fig.1. There is the possibility of the opposite process to the initial process:

$$O + H + H \rightarrow OH + H \rightarrow H_2O.$$

It takes place with the heat evolution. There is the possibility of formation of molecular hydrogen and molecular oxygen. Only the existence of the atomic oxygen and its interaction with oxygen molecules results in the ozone formation in the process. As known, the interval of ozone thermal stability corresponds to the temperatures below the 16 - 18°C. To fix ozone it is required "to freeze" the plasma jet coming out of a plasmatron. The process is realised in the reactor that has a form providing to the cooling of gas flow. The cold walls carry off the heat from the reaction zone. At the same time the molecular hydrogen is formed simultaneously with the molecular oxygen and ozone in such process too. It requires to solve the problem of the selection of reaction products. The choice of water vapour as the plasma-forming gas is explained by that the alternative to it is the atmospheric air. The choice of air as the parent material for the ozone producing results in the necessity to remove the nitric oxides nascent in the freezing plasma jet. It results in more complexities, than in the case of water vapour.

The unstable burning of arc discharge is the other essential problem when the water is used in plasmatron as plasma-forming gas. This problem is caused first of all by the phase change of water that takes away the considerable amount of heat in the discharge thereby the temperature of plasma filament of arc iss decreased. To solve this problem it is necessary to supply the plasmatron by water vapour instead of the water. On the other hand the using of water vapour in plasmatron as plasma-forming gas requires to design the special plasmatron. Namely, it is necessary to provide the stable plasmatron operation at the temperature higher than 100°C on its internal parts to avoid the water condensation on the cold details. The problem becomes complicated by the presence of rather aggressive oxidising atmosphere containing atomic oxygen in the plasmatron. To solve these problems the special plasmatron is designed on the base of the application of high temperature constructional materials such as cermets and metal-composites [1,2]. It operates at the temperatures of internal surfaces about 140 - 150°C.

The preparation of water vapour for the supply of plasmatron (evaporation and vapour heating up to the temperatures 140 - 150°C) is carried out in gas generator.

As it was mentioned above one can see the ideal scheme of ozone thermal synthesis on fig. 1. In reality the plasma jet contains H, O, H^+, O^-, OH^- at the plasmatron outcome. There is the displacement of thermal equilibrium in the association – dissociation reactions with the formation of water vapour, molecular hydrogen, molecular oxygen and ozone at the cooling of plasma jet. The process of plasma jet cooling is realised in the refrigerator-cooler where the heat of plasma jet is taken away and it is utilised in a gas generator for the preparation plasma forming gas. Then the cooled gas flow comes in a reactor, where the necessary requirements for synthesis of ozone are provided at constant temperature about 15 - 18°C. The main requirement to the process is to provide the stationary temperature and required conditions for the interaction of atomic and molecular oxygen with the formation of ozone in a gas phase. The gas-water intermixture coming out of the ozone reactor-synthesizer is secondary cooled in the refrigerator-cooler, where there is a final ozone fixing. The heat taken away in the refrigerator-cooler is utilised in the first step of a gas generator for water preheating. Further, the cooled gas-water intermixture is moved in the gas-water separator, where molecular hydrogen, molecular oxygen, and ozone are selected from the intermixture. The hydrogen is removed from gas mixture at last stage of the technological process of ozone production by the method of thermal synthesis. The problem of hydrogen removal is solved on the base of use of hydrogen catalytic oxidizing with the addition of atmospheric air.

The scheme of technological process of ozone producing by the method of thermal synthesis is shown on the fig.2.

The experimental study of the ozone thermal synthesis from the water vapour was executed on the experimental plasma installation with the plasmatron by power 50 kVA. The stable output of ozone was obtained in the experiments. It was planned to carry out the work on the creating of complete cycle of ozonization of drinking water on the base of the executed experimental studies. One can use special small dimensional plasmatron by power from 50 up to 250 kVA designed on the assumption of the above-stated requirements for the ozone thermal synthesis in the systems of water conditioning.

Thus, the following equipment is required to produce ozone by the method of thermal synthesis:

- gas generator (It prepares the water vapour with the temperature 140 - 150°C),
- the special plasmatron (It carries out the thermal dissociation of water vapour and ionisation of hydrogen and oxygen atoms),
- refrigerator-cooler I (It cools gas-plasma jet),
- the reactor for ozone thermal synthesis,
- refrigerator-cooler II (It cools gas-water mixture and fixes the ozone obtained),

- gas-water separator (It separates gas mixture from water),
- gas separator (It separates oxygen and ozone from hydrogen).

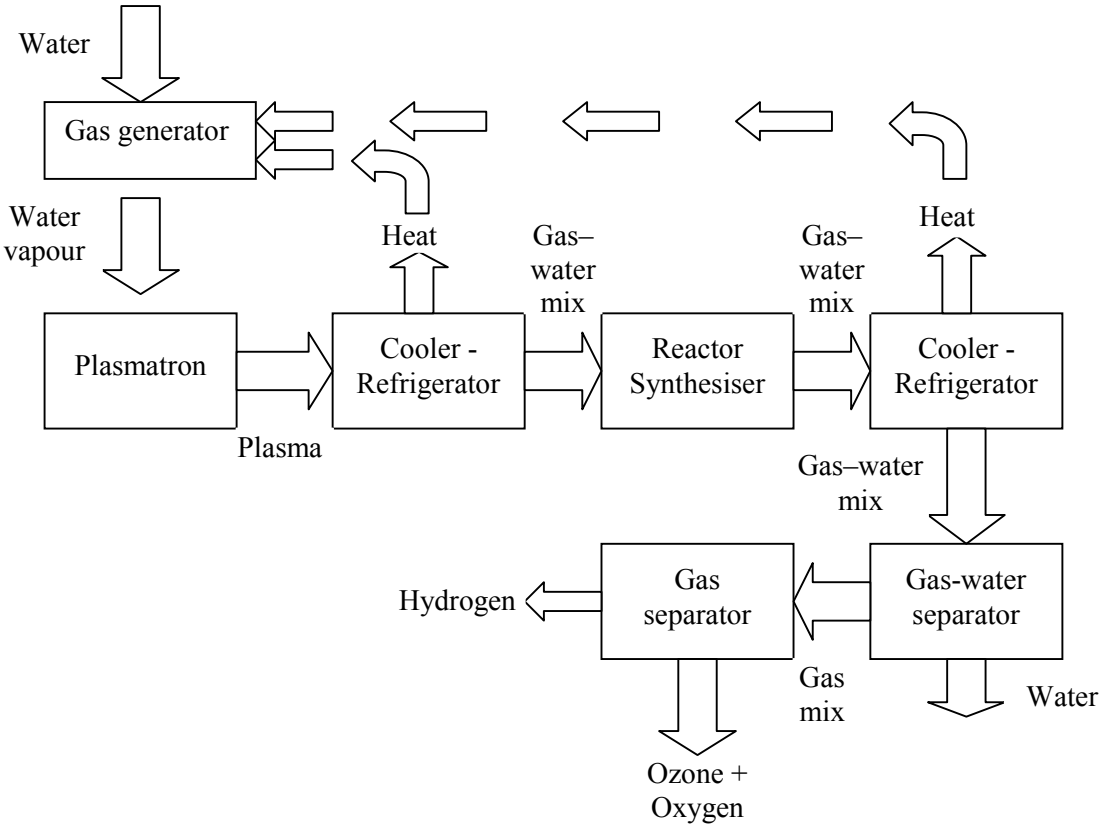

Fig.2. Scheme of technological process of the ozone obtaining by the method of thermal synthesis.

3. Discussion

The method of ozone thermal synthesis with the use of special plasmatron has some advantages before a widely used method based on barrier discharge. The ionisation degree of the arc plasma discharge is about 2 - 3 times higher than in the barrier discharge. It allows to increase the concentration of oxygen ions in plasma and to increase the probability to get ozone as the reaction product consequently. The feature of plasma thermal synthesis of ozone is that this method of the ozone producing does not require the special preparation of plasma-forming gas, namely, drying, compression and refinement off oil vapours being in air as a result of compression. The equipment for the ozone producing by the thermal synthesis method has no lengthy details with precision gaps, as it takes place in the case of the barrier discharge. All this gives in the essential decrease of metal consumption and energy consumption. It gives also, both the decrease of equipment cost, and the decrease of operating costs.

The perspective direction in the application of presented method of ozone production is its using in the technological processes of treatment of various types of waste. As known the oxidising processes are basic for the treatment of various types of waste excepting radioactive waste. Ozone is the second strongest natural oxidising agent after fluorine. Ozone oxidises other chemical agents and decays, thus it superimposes the minimal damage of the environment. It means that the ozone using in the technologies of waste treatment is safe for the environment.

Ozone has strong bactericidal activity and it can be successfully applied in the treatment of domestic and industrial wastewater. It can be used in the technologies of treatment of toxic agents and dangerous medical drugs and waste. It is possibility to use ozone in the technologies of the treatment of bacteriological and chemical weapons.

Other perspective application of the method of plasma thermal synthesis of ozone is use of ozone in technological processes of waste treatment in chemical industry, pulp and paper industry, timber industry, and petrochemical industry.

It is necessary to note the opportunity to create the mobile devices of plasma thermal synthesis of ozone for the treatment of oil spills on water and land by means of disintegration of lengthy hydro carbonaceous chains (–CH–CH–) with the formation of carbon oxide (CO) and water (H_2O).
The plasma thermal synthesis of ozone is extremely perspective to use it for the desalination of seawater and producing of drinking water by an oxidising of the dissolved salts with their subsequent deposition.
The plasma thermal synthesis of ozone in XX1 century will define the ecological face of our planet.
The compactness of the plasma thermal sources of ozone gives the unique opportunity to make the mobile ozonization devices for the application in the places of ecological distresses, number of which continuously grows on a planet.

Gas Temperature Effects on CF_x Kinetics in a CF_4 Inductively Coupled Plasma

J.P.Booth[1], H.Abada[1], P.Chabert[1] and D.B. Graves[2]

[1] *Laboratoire de Physique et Technologie des Plasmas, Ecole Polytechnique, Palaiseau, France*
[2] *Department of Chemical Engineering, UC Berkeley, USA*

Abstract
CF and CF_2 absolute number density profiles have been determined in steady-state and pulse-modulated inductively-coupled plasmas in pure CF_4, allowing their production and destruction mechanisms to be investigated. In the steady state plasma there is net production of the CF radical in the gas phase (probably by electron impact dissociation of CF_x species), and CF is destroyed at the reactor surfaces with a probability of about 4%. In the afterglow CF stops reacting at the walls, but is destroyed by a rapid gas phase reaction. The CF_2 radical is produced in large quantities at the reactor walls, probably by conversion of incident CF_x^+ ions, and is destroyed in the gas phase (probably electron-impact dissociation). The emission of CF_2 continues for a few milliseconds into the afterglow, indicating the existence of a long-lived intermediate, possibly CF_2 physisorbed in a polymer layer. This mechanism is largely responsible for the observed sharp rise in CF_2 density in the initial afterglow, when gas-phase CF_2 destruction mechanisms have stopped. The central plasma volume is significantly above ambient temperature in the steady state (about 900 K), and gas temperature and density gradients must be taken into account in transport calculations. In the afterglow the gas cools (and contracts) in a few milliseconds, causing gas to flow back towards the central region, also contributing to transient increases in the CF and CF_2 number densities.

1. Introduction

Radio-frequency discharges in low-pressure fluorocarbon gases are widely used for the etching of SiO_2 layers in microelectronics circuit fabrication. By careful adjustment of the gas composition (using mixtures of CF_4, H_2, CHF_3, C_2F_6, C_4F_8, Ar, O_2 etc.) and external plasma parameters it is possible to etch sub-micron features in SiO_2 with vertical side-walls and without etching the underlying silicon. This etch selectivity occurs due to the selective formation of a protective fluorocarbon polymer film on the Si surface. Polymer film formation has been found to be well correlated to high concentrations of CF and CF_2 radicals, motivating studies of the kinetics of these species in plasmas.

Previously [1, 2] time and space resolved LIF has been used to investigate CF and CF_2 production and destruction mechanisms in capacitively-coupled radio-frequency plasmas in pure CF_4. Although industrial processes use more complex gas mixtures, pure CF_4 was used as it is the most "simple" fluorocarbon gas, allowing the basic reaction pathways producing and destroying CF and CF_2 radicals to be elucidated. These studies showed the power of comparing steady-state to afterglow number density profiles in separating electron and ion induced processes from neutral chemistry. One of the major findings of these studies was that, under many conditions CF and CF_2 radicals are produced predominantly by neutralisation and backscattering of CF_x^+ ions (either instantaneously or via deposition and sputtering of a fluorocarbon film) at the strongly-biased RF electrode, rather than by direct electron-impact dissociation of feedstock.

In this study[3] the same methodology has been applied to an inductively-coupled plasma in pure CF_4. This system differs from the capacitively-coupled case in that the plasma density is higher (as are the associated electron-impact dissociation and ionisation rates) and the gas pressure is somewhat lower. In addition, there is no intentional RF biasing, so the ion flux to all the walls is large in magnitude but everywhere low in energy. Furthermore, a number of studies [4] have shown that significant gas heating occurs in these systems, leading to strong gas temperature and number density gradients in the reactor. One of the aims of this paper is to elucidate the effect this has on radical transport and kinetics. As before, we have used the comparison of density profiles in the steady state to those in the afterglow to separate electron- and ion-induced processes from neutral chemistry. However, in this case it is essential to take into account the gas cooling before drawing conclusions: indeed it was necessary to simultaneously model the heat and mass transfer and chemistry, as presented elsewhere [5].

2. Experimental

The experimental set-up is shown schematically in Fig. 1. The inductive plasma is created in a cylindrical aluminium chamber which is 5.3 cm high and 30 cm in diameter. Pure CF_4 is flowed at 25 sccm through the reactor and pumped by a turbo-molecular pump via a throttle valve. In all experiments presented here the pressure was maintained at 33 mTorr. At the bottom of the reactor there is a 25 cm diameter aluminium grounded electrode. At the top is a 1.5 cm thick alumina window, cooled by forced air. The plasma was excited with a 3 turn flat spiral copper coil, placed on this window. Radio-frequency power at 13.56 MHz (up to 400 W) was supplied via a classical L-Type matching network, which could be switched on and off in 5 μs. Before data was taken the reactor was run for 30 minutes in order to reach thermal equilibrium and for any wall passivation processes to reach steady state.

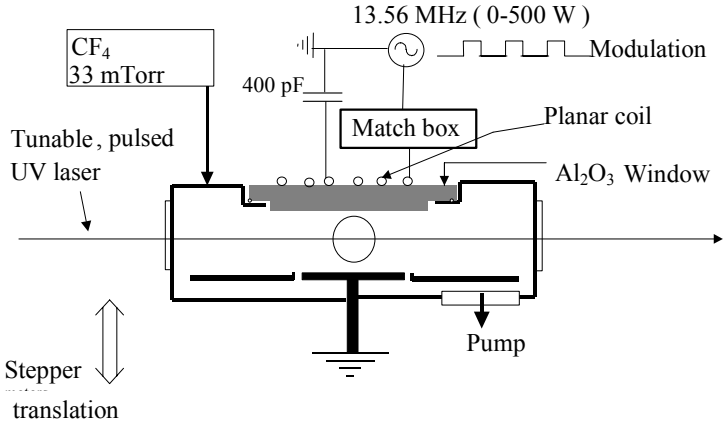

Fig. 1. Experimental Layout

The CF and CF_2 radicals were detected by Laser Induced Fluorescence using a frequency-doubled dye laser pumped by a XeCl excimer laser. Three fused silica windows allow the passage of the probe laser beam at any position between the grounded electrode and the alumina window, and detection of the induced fluorescence perpendicular to it. The fluorescence was focused onto the entrance slit of a 60 cm monochromator and detected with a photo-multiplier. Axial temperature and radical density profiles between the alumina window and the grounded electrode were obtained by translating the reactor relative to the laser beam and the detection optics. To achieve this, the whole reactor and pumping system was mounted on three stepper-motor driven lead-screws. Measurements in the afterglow were obtained by stopping the RF power for 20 ms at a repetition rate of 10 Hz, and triggering the laser shot accordingly.

Relative CF radical densities were determined by exciting the P_{11} band-head of the A-X (1,0) transition at 223.89 nm, with detection of the (1,1) fluorescence at 230.6 nm. The profiles were corrected, as before [6], for variations in the solid angle by normalising to the signal profile obtained from LIF of NO molecules introduced at known static pressure into the reactor. The gas temperature was determined as a function of position and time from the relative intensities of the CF P_{12} bands in the spectral region 224.20 nm to 224.25 nm [4] allowing for partial optical saturation of the transitions [7].

The relative CF_2 number densities were obtained by exciting at the peak of the A(0,5,0)←X(0,0,0) transition at 251.989 nm, with detection of the A(0,5,0)→X(0,3,0) fluorescence at 264.9 nm. Previously[1] CF_2 density profiles were determined by exciting the A(0,11,0) level at 234 nm, using the same laser dye as for CF. However, here it was necessary to use a band that has been characterised spectroscopically, so that the temperature correction factors could be calculated. A further complication of using this (longer wavelength) band was that the solid angle normalisation could no longer be accomplished with NO LIF. Instead we filled the reactor with a static pressure of benzene vapour: this molecule can be laser excited at 252.94 nm, with observation of the fluorescence at 264.9 nm.

For the sake of experimental convenience, number density profiles are generally determined from the LIF signal, I(λ), taken at a *single* wavelength, λ. If the gas temperature is constant in time and space then this signal is representative of the variations in the *total* ground state density, n_{tot}. However, if the temperature is not constant then it is necessary to add a correction factor that accounts for the change of the relative fraction of the molecules that are in the particular ground state rotational quantum level that is excited by the laser. We calculated these correction factors by simulating the spectra (for both CF and CF_2) over a range of rotational temperatures and comparing the intensity of the relevant peak to the integrated band intensity. The

spectroscopic constants for CF_2 were taken from Mathews [8], and for CF they were taken from Porter et al. [9]. As the temperature is increased, more population is transferred from the probed lower level into higher rotational states, lowering the overall detection sensitivity; therefore the correction factors C increase with temperature. Finally, the corrected profiles were put on an absolute scale by broad-band UV absorption measurements[10, 11]. This technique gives absolute line-integrated radical densities. Combined with the radial density profiles determined by LIF we could then determine the absolute radical number density at the reactor centre.

3. Gas temperatures

The measured gas temperature axial profiles, along with model results [4] are shown in Fig. 2. The steady state gas temperature in the centre of the reactor is of the order of 900 K, dropping sharply towards the walls. At constant gas pressure this implies, from the ideal gas law, that the total gas number density at the reactor centre is about one half of that close to the walls. In the afterglow the gas cools quickly, dropping to within 100 K of the wall temperature after 1 ms. The reactor walls are somewhat above ambient temperature (measured by thermocouple, 370 K at the bottom and 340K at the top (alumina) surface), due to the significant power dissipated.

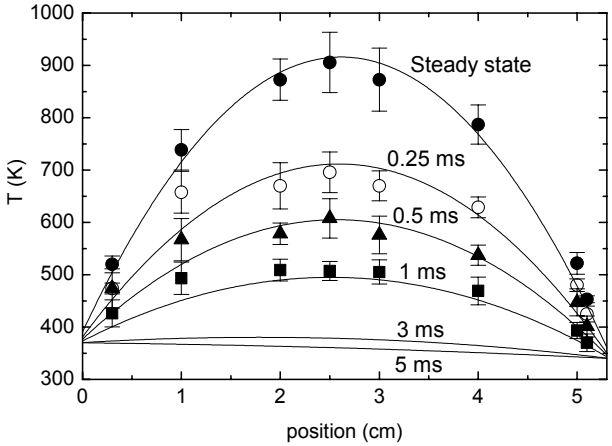

Fig. 2. Measured and modelled axial gas temperature profiles in the steady state and in the afterglow. 250W nominal RF power, 33 mTorr total gas pressure. Zero corresponds to the lower surface, the alumina window is at 5.3 cm.

4. CF number density

Fig. 3 shows the raw LIF signal profiles in the steady state and in the afterglow; also shown is the effect of correcting for the temperature coefficient. Even after correction, the steady-state number density profiles are markedly concave, suggesting that there is a flux of CF radicals produced at the surface and destroyed in the gas phase (but see below). In the afterglow the profile becomes flat, and the number density drops rapidly.

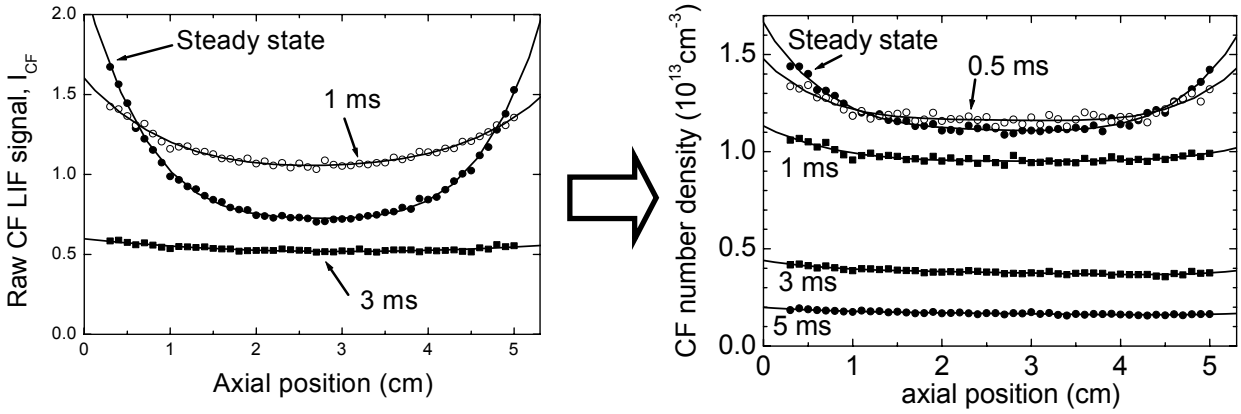

Fig. 3. Raw LIF signal and corrected absolute axial density profiles for CF in the steady state and afterglow.

The absence of significant number density gradients in the afterglow indicates that *surface production or loss* of CF are negligible in the afterglow. The diffusive flux, *Ji* (molecules.m^{-2}s^{-1}) of a radical *i*, (diluted in a bath gas) is related to the gradient of the number density, n_i, by Fick's law:

$$J_i = -D\nabla n_i \quad , \tag{2}$$

where D is the diffusion coefficient. However, in the presence of a temperature gradient the flux must be calculated from the *mole-fraction* gradient, y_i. For a binary mixture the flux can be estimated from [12]:

$$J_i \approx -\frac{P}{kT} D\left(\nabla y_i + \alpha_T y_i (1 - y_i) \frac{\nabla T}{T} \right), \tag{3}$$

where P is the total gas pressure. The mole-fraction gradient can be calculated from :

$$y_i = n_i \frac{kT}{P} \quad . \tag{4}$$

The second term in equation (3) is the thermo-diffusion term, with α_T being the (dimensionless) thermo-diffusion factor. For a light molecule in a heavier carrier gas α_T is negative: assuming that the majority gas is (un-dissociated) CF_4, the thermo-diffusion effect will cause a flux of CF from cold regions (edges) to hotter regions (the reactor centre). The CF mole-fraction profile in the steady state is shown in Fig. 4. The CF mole-fraction is maximal at the reactor centre, suggesting that there is a net flux of CF *from* the reactor centre *towards* the reactor walls: however, this component is opposed by the thermo-diffusion term. For CF in CF_4 we estimated a thermo-diffusion factor of -0.18.

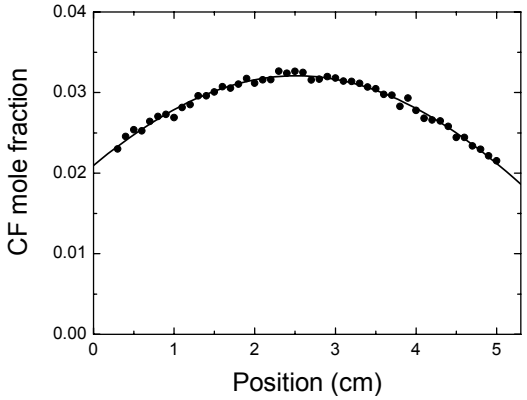

Fig. 4. CF mole fraction axial profiles in the steady state and in the afterglow.

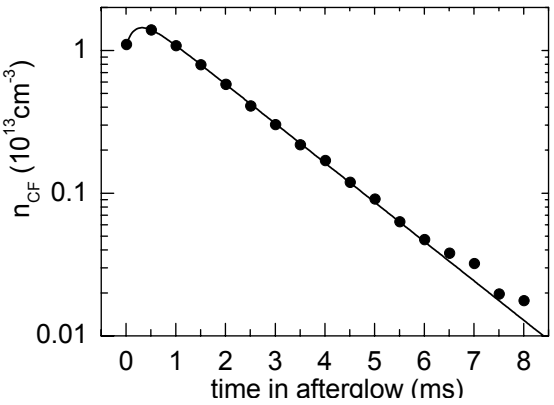

Fig. 5. CF number density decay in the afterglow at the reactor centre.

The relative importance of the two terms in equation (3) can be evaluated by comparing $\nabla y_i / y_i$ to $\alpha_T . \nabla T/T$. We find that the thermo-diffusion term is about one half of the mole-fraction gradient term, but opposite in sign: there is still a net flux of CF to the walls. We estimate a diffusion coefficient of 4400 $cm^2 s^{-1}$ for CF in CF_4 at 33 mTorr and 370 K (based on the value for N_2 in CF_4 at this temperature[13], corrected for the reduced mass and for the slightly smaller collision cross-section). This gives a flux of CF destroyed at the surface, Φ_{loss}, of $1.6 \times 10^{16} cm^{-2} s^{-1}$. We can estimate the reaction probability, β, from:

$$\Phi_{loss} = \frac{1}{4} n \bar{v} \beta , \tag{6}$$

where $\bar{v}$ is the kinetic mean velocity, giving a value $\beta_{CF} = 3.7\%$. Interestingly, in the afterglow this reaction probability appears to drop to near zero, as noted above. It may be that the CF radical can only become chemisorbed at the polymer surface at sites that have been previously activated by ion impact; in the afterglow these sites rapidly become saturated.

These observations are very different to the findings in a capacitively-coupled plasma in CF_4[1], where there was strong production of CF at the powered electrode, and strong destruction of CF (β_{CF} close to unity) at the grounded reactor surfaces (and, in the afterglow, also at the powered electrode). However, the energy of ions hitting the surfaces is much lower in the present case (= plasma potential = a few tens of eV), and is inadequate to dissociate CF_3^+ ions into CF radicals: the majority of the incident CF_x^+ ions are either incorporated into C/F film on the surface, or are returned to the gas phase as CF_3 or CF_2. Indeed, in the present experiments the central top and bottom surfaces of the reactor were coated with a black polymer layer. This polymer surface appears to have a much lower reactivity to CF than the clean Al surfaces in the capacitive reactor (kept clean by high energy ion bombardment).

In the steady state there is therefore a net production of CF in the plasma centre, which flows to the walls where it is destroyed. This net production, however, is the difference between simultaneous production and destruction processes. Fig. 5 shows the CF number density variation at the centre of the reactor as a function of time in the afterglow. There is a small initial rise for the first half millisecond, followed by a rapid exponential decay (rate 640 s^{-1}). One possible explanation for the initial rise is an influx of CF-rich gas

towards the reactor centre as the gas cools and contracts in the first millisecond [5]. The rapid subsequent decay of the CF number density in the afterglow must be due to a gas-phase reactions: the axial number density profiles show that the flux to the reactor top and bottom is negligible. At this point we can only speculate as to the identity of this process. The only processes that are sufficiently rapid are (exothermic) bimolecular exchange reactions of the type:

$$CF + F_2 \rightarrow CF_2 + F. \quad (8)$$

or

$$CF + CF_3 \rightarrow 2CF_2, \quad (9)$$

The rate constant for reaction (9) has been measured[14] to be $3.9\text{x}10^{-12}\text{cm}^3\text{molecule}^{-1}\text{s}^{-1}$. An F_2 density of $1.6\text{x}10^{-14}\text{cm}^{-3}$ would be necessary to account for this observed CF loss rate, or some 15% of the total gas composition: this seems unlikely. The rate constant for reaction (10) is not known; however, exothermic exchange reactions typically have rate constants of the order $10^{-11}\text{cm}^3\text{molecule}^{-1}\text{s}^{-1}$. Singh et al. [15] found a density of $4\text{x}10^{13}\text{cm}^{-3}$ under similar conditions, which would give a CF loss rate of the correct order of magnitude. One consequence of these reactions is the production of a significant quantity of CF_2 in the afterglow. This CF loss process indeed occurs in the steady state, but is exceeded by rapid production of CF (for example, electron-impact dissociation of higher CF_x species). This production process stops immediately in the afterglow, leaving the gas-phase reaction process to destroy the remaining CF.

4. CF_2 number density

The CF_2 steady state axial number density profile is seen in Fig 6. This profile is more strongly concave than was observed for CF. When this is converted to mole-fraction, we observe a profile that is essentially flat, with CF_2 representing about 6 % of the total gas composition. However, when the thermo-diffusion term is included in equation (3), we see that there is a strong net flux of CF_2 emitted by both the top and bottom surfaces of the reactor, and that there is net destruction of CF_2 in the plasma centre. Taking a value of 0.076 for the thermo-diffusion factor, α_T, and a diffusion coefficient of 3060 cm^2s^{-1} (from the experimental value of $65\text{cm}^2\text{s}^{-1}\text{Torr}$[16] for CF_2 in CF_4, corrected for the pressure and assuming a $T^{1.823}$ temperature dependence[12]) and using equation (3), the value obtained for the flux of CF_2 emitted by the surfaces is of the order of $1\text{x}10^{16}\text{cm}^{-2}\text{s}^{-1}$.

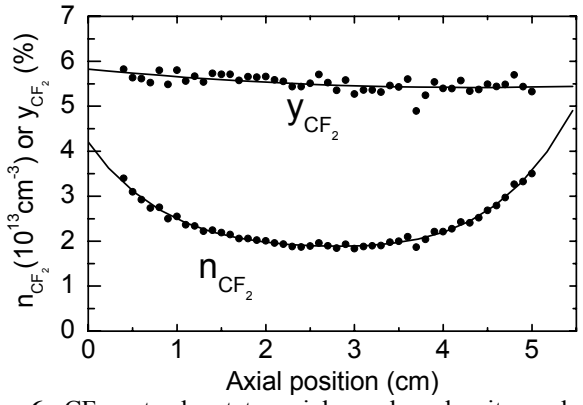

Fig. 6. CF_2 steady state axial number density and mole-fraction profiles

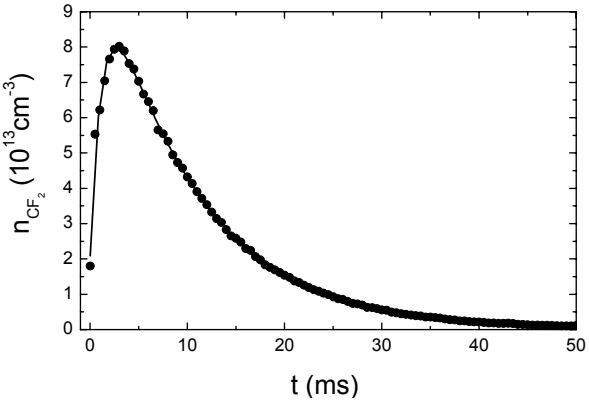

Fig. 7. CF_2 number density decay in the afterglow at the reactor centre.

We measured an ion flux density at the reactor centre of about 1.1 mAcm^{-2}, or $7\text{x}10^{15}\text{cm}^{-2}\text{s}^{-1}$. Considering the uncertainties involved, it is reasonable to postulate that the major source of CF_2 produced at the surface is neutralised ions, and that the majority of the ions return as CF_2 . It is also possible that the CF which is destroyed at the surfaces returns as CF_2 after recombining with a fluorine atom.

The afterglow behaviour of the CF_2 number density at the reactor centre is shown in Fig. 7. A very marked initial *increase* in the CF_2 density is observed, peaking at four-times the steady state density after three milliseconds. Subsequently the CF_2 density decays away exponentially at a rate of about 100 s^{-1}. A number of mechanisms can be advanced to explain this "initial rise" phenomenon. Firstly, it should be stressed that our data are corrected for the partition function dependence on gas temperature, so that Fig. 7 indeed shows the variation of the total ground state CF_2 density. One possible mechanism is the return of CF_2 –rich gas into the central region as the gas cools and contracts in the afterglow. However, the gas temperature changes from 915 to 360 K, a factor of only 2.6 in temperature and gas density, so it would appear that this phenomenon cannot account for all of the initial rise. A quantitative evaluation of the relative importance of

this contribution can only be made from a full model of the gas transport [5]. Further information can be obtained from the CF_2 number density profiles in the afterglow (shown in Fig. 8).

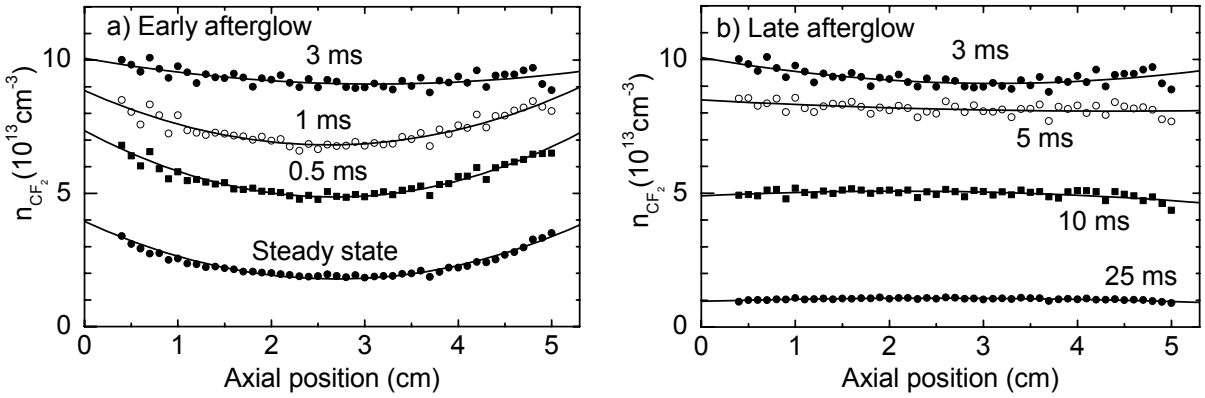

Fig. 8. CF_2 axial number density profiles, a) steady state and early afterglow, b) late afterglow

It can be seen that the CF_2 density profiles remain *concave* until about 3 ms. After 1 ms the gas temperature (and density) has almost fully relaxed, so the radical diffusive flux can be deduced directly from the number density gradient: the data shown in Fig 8 (a) gives clear evidence that the surface emission of CF_2 *persists for a few milliseconds after the incident ion flux has ceased*. This mechanism therefore makes a strong contribution to the CF_2 "initial rise" phenomenon. This result is similar to that observed in capacitive discharges in fluorine-poor gases[2], where it was concluded that there was formation of a porous fluorocarbon layer containing sub-surface physisorbed CF_2 that takes a few milliseconds to diffuse to the surface.

In the late afterglow (after 3 ms, Fig. 8 (b)) the CF_2 density decays, and relaxes to a convex profile, indicating diffusion of CF_2 to the reactor top and bottom surfaces, where it is destroyed by (an unidentified) chemical reaction. The gradient adjacent to the surface allows the effective reaction coefficient to be estimated (equations 2 and 6), giving a value of 2.7%. With this reaction coefficient we estimate[17] a value of 100 s^{-1} for the CF_2 loss rate due to diffusion and loss at the reactor top and bottom surfaces, in excellent agreement with the observed late afterglow CF_2 decay rate. From this we can conclude that CF_2 is lost by principally by reaction at the surfaces in this period, gas phase reactions being negligible (the gas flow rate is slow, accounting for only about 3 s^{-1}).

Abstract
Bonding characteristics of low dielectric constant (low k) cyclic organosilicon films ($Si_xC_yH_w$) prepared by Plasma Enhanced Chemical Vapor Deposition technique were investigated. Reducing film density study, by incorporating more void in the bulk, has been developed to overcome negative effect caused by macroscopic porosity in spin-on film. A cyclic structure and deposition conditions appear as important parameters to reduce the dielectric constant of the material.

1. Introduction

With the miniaturization of silicon ultra-large-scale integrated circuits (ULSI), the increase in interconnect delay time exceeds the delay of the transistors. Therefore, the interconnect delay begins to control the performance of the entire ULSI chip [1]. One way to overcome this problem is the dielectric constant reduction of the material between the interconnected layers. Current technologies in low k dielectric materials propose intermetal dielectric (IMD) below k=3,0. Including porosity in the bulk open a large perspective in ULSI future circuit, and, is expected to reach integrable films permittivity lower than 2,0. However, the pore structure of these low-k dielectric materials strongly affects some material properties other than the dielectric constant such as mechanical strength, moisture uptake, coefficient of thermal expansion, and adhesion to different substrates [2]. All this problems prevent any integration in manufacturing processes.

In previous study, we highlighted a polar kind effect in the dielectric constant evolution [3]. A best control of Si-O and Si-C densities in a bulk appear as interesting parameters to reduce the permittivity. Hence, reducing films density was emerged as a determinant factor to improve our films quality and decrease the dielectric constant.

This work is devoted to elaborate, via PECVD technique, a low k film from a new cyclic organosilicon precursor. PECVD technique is proposed as substitute solution than spin-on process to grow low k film ($k \leq 2,5$). Film properties such as chemical bonding structure, density and refractive index, are investigated. The new cyclic organosilicon behavior is observed to look into the deposition conditions and their effect on the dielectric properties.

2. Experiment

The plasma is generated in Multipolar Microwave Plasma (MMP) (2,45 GHz) reactor excited by Distributed Electron Cyclotron Resonance (DECR). A Diphenylmethylsilane (DPMS) precursor is used to deposit the $Si_xC_yH_w$ films on intrinsic silicon Si (100) substrates.
In the deposition chamber, the total pressure was maintained at 1 mTorr of DPMS. The microwave power was varied from 50 to 400 watts. The chemical bonding states of the $Si_xC_yH_w$ films were characterized by Fourier Transform Infrared spectroscopy (FTIR) in the absorbance mode using a Bio-Rad (FTS60A) spectrometer. The thickness (d) was estimated by profilometer (TENCOR). The density of the films were measured by ellipsometry. The films composition was determined by XPS analysis. Metal-insulator-metal (MIM) structures (the insulator is constituted by the deposited film) and a HP4280A LCZ-meter have been used to measure the films capacitance C. The total dielectric constant was evaluated from the equation (1):

$$\varepsilon = \frac{C.d}{\varepsilon_0.S} \qquad (1)$$

Where ε_0 is the vacuum permittivity ($\varepsilon_0 = 8,854.10^{-12}$ F.m^{-1}) and S the electrode surface area.

Diphenylmethylsilane monomer ($SiC_{13}H_{14}$) contains two aromatic structures bonded on central silicon. One hydrogen and methyl group (CH_3) are also connected to the silicon atom. The molecular weight is 198,34 g/mol.

The boiling temperature of DPMS is 366 °C at 760 Torr. Therefore, the organosilicon is putting on bottle heated (Mary's bath) at about 130°C, to obtain a sufficient pressure to correctly injected the vapour inside the plasma chamber.

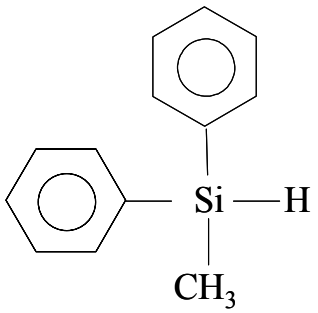

Figure.1 Diphenylmethylsilane monomer structure (DPMS).

The organosilicon vapour was injected close the substrate, while the oxygen or argon were used to initiate the plasma in mixture condition. The film thickness are maintained in the range of 2000 Å and 2500 Å.

3. Results and discussion

The semiconductor industry is aggressively investigated electrical insulators with dielectric constant less than that SiO_2 (k<3,9). Material which includes porosity can achieve k values below 2,2, these are the so called "ultra low k" dielectrics. The ultra low dielectric constant results from the incorporation of pores. Such materials are more fragile than non-porous dielectrics, and suffer from several integration problems. Porous structure is very sensitive to air exposure and includes moisture inside the material structure, which causes an increase of the dielectric constant. The idea is to include high rate of microscopic void without making any macroscopic porosity.

Figure 1 shows the growth rate evolution of films deposited from DPMS/ Ar (3:1) and DPMS/ O_2 (3:1) mixtures as function of injected power. We can distinguish two growth modes separated at 200 watts. At low injected power, the deposition rate increases linearly for the both cases. This means that the deposition process is activated mainly by monomer reaction in plasma and no difference can be noticed between the two mixtures. The growth rate increases from 155 Å/min at 50 watts to 905 Å/min at 200 watts.

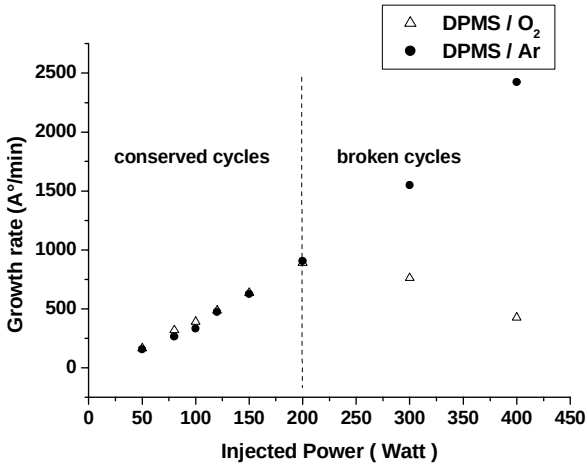

Figure 2 : Growth rate evolution for DPMS/O_2 and DPMS/Ar mixtures vs. injected power.

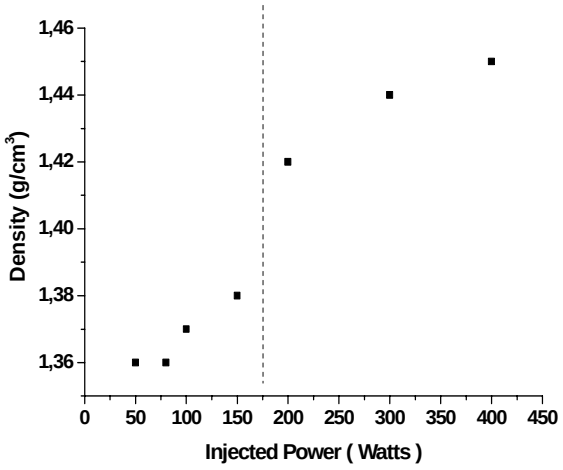

Figure 3: Density evolution of pure DPMS films vs. injected power

Beyond that, the deposition rate increases for DPMS/Ar films. This later go up from 905 Å /min to 2400 Å /min. This suggests the increase of the monomer fragmentation. Indeed, as the injected power increases, the Ar addition involves the increase of the electronic density as can be seen in equation (1) [4]:

$$Ar + e \rightarrow Ar^{+} + e + e \quad (1)$$

The precursor dissociation is improved with the electronic density. This is in agreement with the increase of the deposition rate [5].

In the DPMS/O_2 case, the decrease of the growth rate traduces a stronger effect of the etching process. The oxygen molecules dissociation produces more atomic oxygen in the plasma which affects the surface as described below. The interaction of the atomic oxygen with the surface produces volatile species as O-H and C=O [6]. Beside the dissociation and the etching phenomena, the deposition rate change beyond 200 watts can be also attributed to the break of cycle structures into the films.

We have studied the density evolution as function of power input. The shape is similar to the deposition rate evolution with the change at 200 watts. This suggests that the cycle structure conservation is governed by the input power. As the input power increases, the monomer dissociation increases and the cycle density decrease. So more smaller fragments are deposited on the surface and then the density increases.

Electrical analysis reveals that the films deposited at low power have a lower dielectric constant. In fact, the permittivity tends to increase as a function of the power input (figure 4). In previous study, we have shown the density change induces a permittivity evolution in our film and, the dielectric constant of the structure is a function of different polarization kind [3].

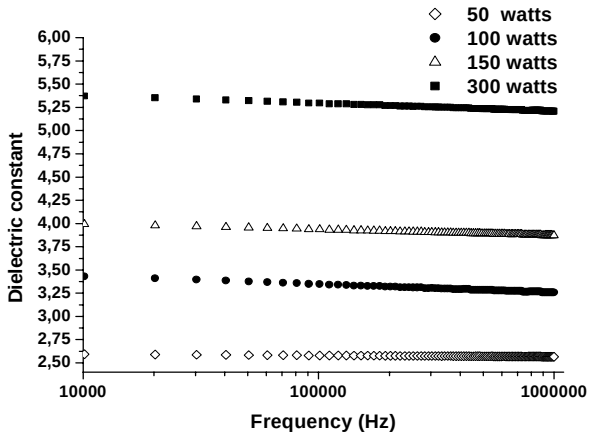

Figure .4 Dielectric constant evolution vs. injected power
for films deposited from pure DPMS

X-ray photoelectrons spectroscopy was used to determine the relative amounts of C, and Si at the film surface. The atomic ratios of carbon and silicon are evaluated from the relative peaks areas of C (1s), and Si (2p) peaks of the XPS spectrum. It is found that pure DPMS film possesses oxygen in addition to constituent elements of the monomer.

Figure 5 shows the composition evolution of pure DPMS films elaborated at different microwave power. The carbon percentage decreases slightly with the injected power, while the silicon and oxygen increase. This tendency results from the etching effect of oxygen by removing some carbon and hydrogen atom from the surface. Nevertheless, these little changes do not affect the carbon, silicon and hydrogen relative amount in the film. This composition stability suggests that the atomic ratio at the film surface was the same for each injected power condition. Hence, the dielectric constant change can not arise from polar group kind modification. We can clearly show this effect on the infrared spectrum made on the films from pure DPMS. The IR spectrum of pure DPMS films shows the main absorption bands features of diphenyl monomer [6] (figure 6).

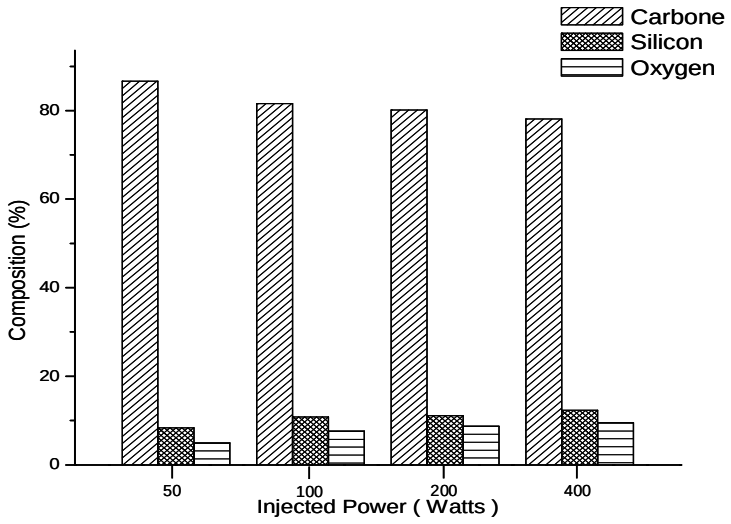

Figure.5 Evolution of pure DPMS films composition for different power condition.

FTIR spectrum shows at 689, 734, 787, 832 and 875 cm^{-1} peaks corresponding to the =C-H out-of-plane phenyl ring bending vibrations. We can also observe the peaks at 3050 cm^{-1} (aromatic C-H), at 1595 cm^{-1} (aromatic C=C) and at 1118 cm^{-1} (Phenyl group), which constitute a serious proofs of aromatic cycles integrity in the film. Absorption bands correlated to vibration of aromatic $Si-CH_2$ are also observed at 1429 cm^{-1}. The symmetric bending of cyclic $Si-CH_3$ appears at 1262 cm^{-1}, and the stretching mode of cyclic dimmers of carboxylic (C=O) group at 1720 cm^{-1}. The Si-H peak intensity at 2140 cm^{-1} decreases at high power input. The OH band can be seen in the range of 3200 to 3700 cm^{-1}.

By following the evolution of these spectra as function of injected power we can notice a reduction in intensity from peaks associated to the presence of DPMS cycle structure. Figure 6 shows a comparison between spectra of films elaborated at different power. We can observe that the aromatic structure intensity of C-H at 3050 cm^{-1} decreases with injected power, while the $C-H_x$ intensity increases. This fall is also observed for the phenyl group at 1118 cm^{-1} and the remainders peaks which reveal the cycle structure presence. These evolutions are serious indications which inform us about cycle structure destruction.

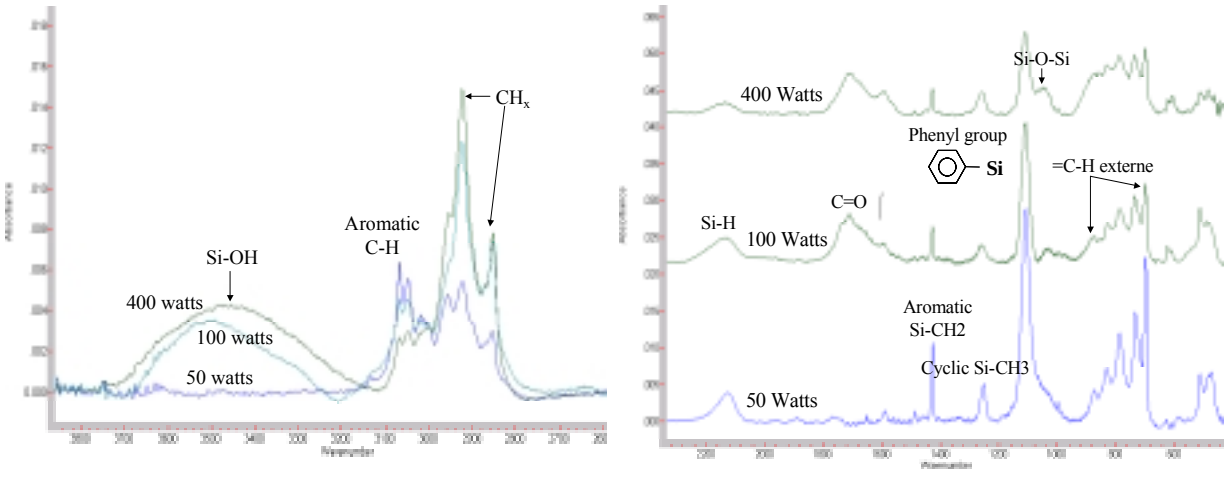

Figure .6 Spectra evolution of DPMS pure films as function of injected power.

At high power we can observe Si-O-Si stretching peak vibration, probably due to more interaction of oxygen in plasma and/or in the deposited film. The origin of the oxygen incorporated into the pure DPMS film, which is not a constituent element of the starting material used, may either be from the reaction chamber and/or due to exposure in air. At low power (50 watts) the film exhibits a good resistance to moisture absorption. This can explain the low permittivity that we have obtained. Besides this, the cycle conservation at low power improves the low dielectric value of the elaborated films.

Figure 7 shows the dielectric evolution vs. exposed to air time for film deposited from pure DPMS and pure HDMSO (hexamethyldisiloxane). HMDSO films have bad ageing, due to the moisture uptake. We can observe a slight increase of the dielectric constant for pure DPMS films, which indicates that the permittivity do not shows a big change on its values. These results reveal that the film has a good barrier properties to moisture absorption.

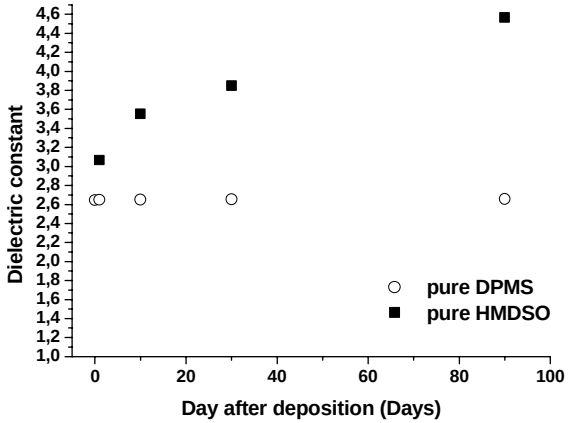

Figure 7. Ageing effect on the dielectric constant

4. Conclusions

This work demonstrated the ability of our PECVD technique to propose stable film with low dielectric constant ($k \approx 2.5$). For that reason, Plasma process could be an interesting alternative solution to overcome problems met with instable pores in spin-on process.

The pure DPMS films deposited at low power and high pressure can offer permittivity as low as 2.5.

Decrease films density without making any macroscopic porosity appears as a real answer to improve the dielectric properties of our films.

Abstract
An on-line reference OH source based on a pulsed N_2-H_2O RF discharge is described. Its operation principles are demonstrated together with its stability with respect to variations of discharge conditions and laser energy. Such stability is the basis for the operation of the source at less controlled conditions, i.e. with simple ambient air gas feed that greatly simplifies the source apparatus. This is an important requisite for operation in field instruments.

1. Introduction

The detection of OH is a difficult issue in atmospheric research, due to the low OH concentration found in the troposphere. The Laser Induced Fluorescence (LIF) has been employed to this end [1], but it suffers of the not easily solvable problem of its calibration, and, in particular, of the disposal of a simple and robust calibration method available in field and airborne instruments. We have recently proposed [2] a N_2-H_2O low-pressure, low-power pulsed RF discharge as a calibrated source of OH, based on:

a. the observation that the $OH(A^2\Sigma^+)$ and $NO(A^2\Sigma^+)$ states have the same excitation precursor, $N_2(A^3\Sigma_u^+)$, in this kind of discharges [3].

$$N_2(A^3\Sigma_u^+)+OH(X^2\Sigma) \xrightarrow{k_{OH}} N_2(X^1\Sigma^+)+OH(A^2\Sigma^+) \qquad (1)$$

$$N_2(A^3\Sigma_u^+)+NO(X^2\Sigma) \xrightarrow{k_{NO}} N_2(X^1\Sigma^+)+NO(A^2\Sigma^+) \qquad (2)$$

Therefore the OH density can be quantitatively correlated to the NO density through the intensity ratio of $OH(A^2\Sigma^+)$ and $NO(A^2\Sigma^+)$ emissions. The OH density can then be brought back to the NO density.

b. a novel LIF scheme by which OH and NO can be detected simultaneously by the use of one laser only, in which OH and NO are detected by the second and third harmonic respectively of the same dye laser output [4].

The simultaneous detection of the LIF from OH and NO in the post-discharge, the LIF from NO in a static cell, the post-discharge emission from the (0,0) band of the OH 3064 Å system and from one of the NO γ-system bands, provides a reliable real-time calibration that is intrinsically stable with respect to variations of the production of OH and NO in the discharge and laser energy and wavelength drifts.
The stability of such OH source allows its use without a strict control of the discharge conditions. In this contribution we demonstrate the operation of the source obtained by a discharge gas feed of ambient air through a needle valve, in which the water vapor is supplied by the natural air humidity. This greatly simplifies the apparatus, avoiding the need of a gas bottle and a water vapor generator. Furthermore the source is operated at a discharge pulse frequency in the kHz range, i.e. close to the laser repetition rate in use in FAGE field instruments, thus matching the FAGE operation conditions and increasing the measurement statistics.

2. Experimental

The scheme of the OH reference cell apparatus is shown in fig.1. The discharge is a cylindrical external electrodes discharge in a 4 cm dia. quartz tube. The discharge is operated in a N_2-H_2O mixture by a 13.56 MHz RF supply pulsed at controlled T_{ON} and T_{OFF}. The NO cell is filled with a 300-ppm N_2-NO mixture from a bottle with a certified NO concentration uncertainty < 3%.
The laser is a pulsed dye laser pumped by a Nd-YAG at 10 Hz. The laser wavelength in the region 303 - 311 nm, that is the initial part of the OH(A--X) (0,0) band, is obtained by the R640 dye output doubled by a BBO crystal. The third harmonic of the dye is obtained by a second BBO crystal, and falls in the region 204-207 nm that corresponds to the spectral region of the (2,0) band of NO γ system. In particular for our purposes we have

used OH LIF excitation by both $R_{11}(1.5)$ at 3072.01 Å or $R_{11}(2.5)$ at 3070.32 Å lines [4]. The fluorescence light is revealed by photomultipliers preceded by interferential filters.

The self-calibration on-line procedure is based on the formula:

$$[OH]_{source} = \frac{I_E(OH(A))}{I_E(NO(A))} \frac{k_{NO}}{k_{OH}} \frac{I_{LIF}^{disch}(NO)}{I_{LIF}^{cell}(NO)} [NO]_{cell} \quad (3)$$

and requireres the simultaneous measurement of:

1. the LIF from OH and NO in the post-discharge;
2. the LIF from NO in the cell;
3. the post-discharge plasma emission from the (0,0) band of the OH 3064 Å system and from one of the NO γ-system band, $I_E(OH(A))$ and $I_E(NO(A))$ respectively; these quantities are measured by the photon counter by the same photomultipliers used for the LIF, in a gate opened for 10 μs immediately before the laser pulse.

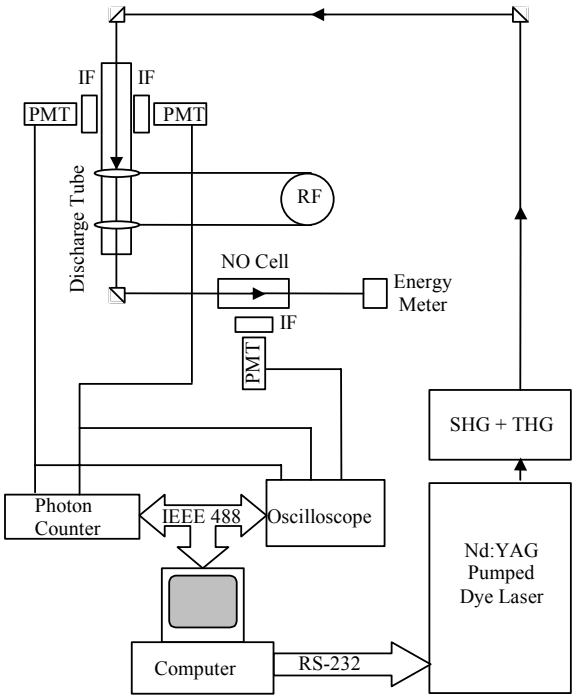

Fig. 1 Scheme of the OH reference source apparatus. IF: interferential filter; PMT: pulsed photomultiplier

The measurements are made in the post-discharge since the (0,0) band of the OH 3064 Å system is overlapped by the strong Δv=1 sequence of the N_2 SPS emission. Such SPS emission is dominant in the discharge while, being mainly due to electron impact excitation, it rapidly falls down to a negligible intensity in the post-discharge, leaving a clean OH emission after few hundreds of microseconds [3].

As a whole, then, [OH] in the source is continuously measured by formula (3) and monitored by LIF. In other words, the OH LIF signal in the source is always correlated to a measured OH density. Placing the sample (the FAGE [1], for example) in the laser beam path, the OH LIF signal from the source then constitutes a reference signal for the sample OH LIF, always tied to a measured OH density.

This scheme is intrinsically robust with respect to:

a) variations of the production of OH and NO in the discharge reference source;
b) laser energy drifts, i.e. it is not necessary to monitor the laser energy and to correct for its fluctuations according to *ad hoc* saturation curves;
c) small wavelength drifts of the laser.

Such a robustness was demonstrated in [2], in a N_2-H_2O discharge, in which the water vapor was supplied by an *ad hoc* generator. It was shown in practice that the scheme is valid whatever the discharge conditions, and in particular the gas composition, provided the OH(A) and NO(A) excitation by $N_2(A)$ is still the dominant mechanism.

3. Validation of the source with ambient air gas feed

The discharge in this new configuration is fed with ambient air through a needle valve that regulates the air flux. No bottles and flux meters/regulators are needed. In order to verify that processes (1) and (2) are still the dominant ones in the post-discharge, we have investigated the new discharge by the same method as that applied in [3]. That is to look for a correlation between the decay of the OH(A) and NO(A) emissions in the post-discharge. To this end we have measured:

1. the time-resolved emission by the digitizing oscilloscope, through a monochromator with wavelength at 308 nm for OH(A) and at 227 nm for NO, and 1 nm bandwidth;
2. the time-resolved LIF on OH(X) and NO(X). The NO(X) practically does not change in the post-discharge, so we will not report NO(X) LIF results.

In Fig 2 we report some such measurements, taken at 0.1 Torr, 1W average discharge power, and at different T_{ON} and T_{OFF} values, all with $T_{ON} << T_{OFF}$. The combination low power – small duty cycle ensures that the gas temperature in the discharge does not exceed the ambient one.

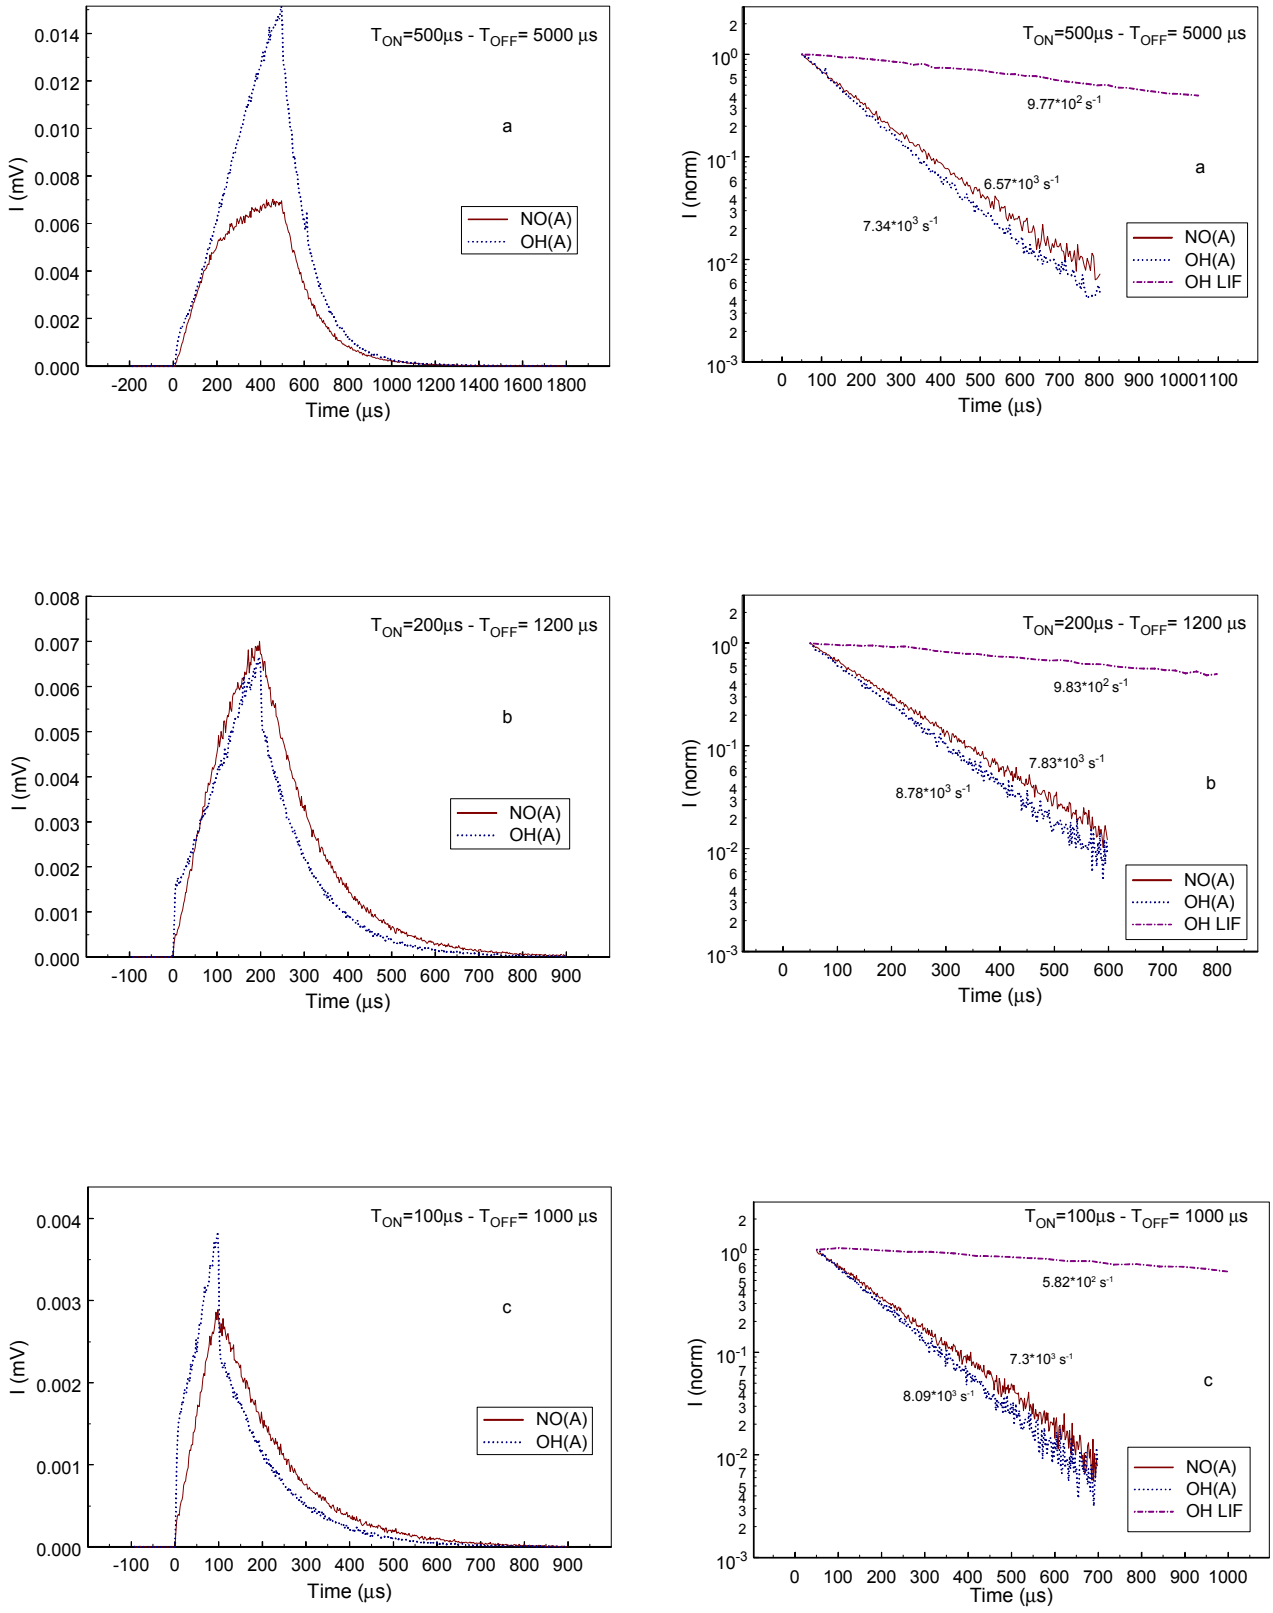

Fig. 2 Time resolved emissions and OH LIF at 0.1 Torr, various T_{ON}, T_{OFF} times. In the right figures the measurements are restricted to the post-discharge and plotted in log scale.

It is shown that in all the cases presented, the decays are single-exponential, and that the following relationship is satisfied, within the experimental error:

$$K_{OH(A)} = K_{NO(A)} + K_{OH(X)}$$

where K is the post-discharge decay time constant. This means that both OH(A) and NO(A) have the same excitation precursor, and that this is the nitrogen triplet metastable (see the discussion in [3] and also [5]).

In the figures containing the emission in the discharge pulse, it is worth noting that, on decreasing the discharge time both OH(A) and NO(A) emission intensity decrease. In the OH(A) emission a fast component, both at discharge ON and at discharge OFF, is increasingly recognizable on decreasing T_{ON}, due to the superimposed SPS emission and an eventual OH(A) excitation by electron impact, that becomes relatively more important when the long-time-constant component decreases. It is clear, then, that, increasing T_{ON}, the $N_2(A)$ density increases, with a corresponding rise of the OH(A) and NO(A) emission.

The next step is to test the source principle robustness with respect to variations of the discharge conditions and laser operating conditions. To this end we have artificially caused such variations. Discharge conditions are varied by detuning the matching network or increasing the applied RF voltage. The laser energy output is instead varied by detuning the TH generator: this causes both a large variation of the TH energy and a smaller variation, of the order of 30%, of the SH, since a low TH conversion results in an increase of SH energy passing through the TH BBO crystal. The results of the test at T_{ON}=100μs, T_{OFF}=1000 μs, are shown in Fig.3. The test is made of 100 runs, each of which is the result of 256 laser shots statistics for the LIF, and 5000 openings of a 10μs photon counter gate for the emissions. The measurements are made at 700 μs in the post-discharge. In Fig. 3a it is reported the OH LIF signal, corrected for the SH energy according to a measured saturation curve. The SH energy is measured by a pyroelectric energy meter simultaneously to the LIF measurements.

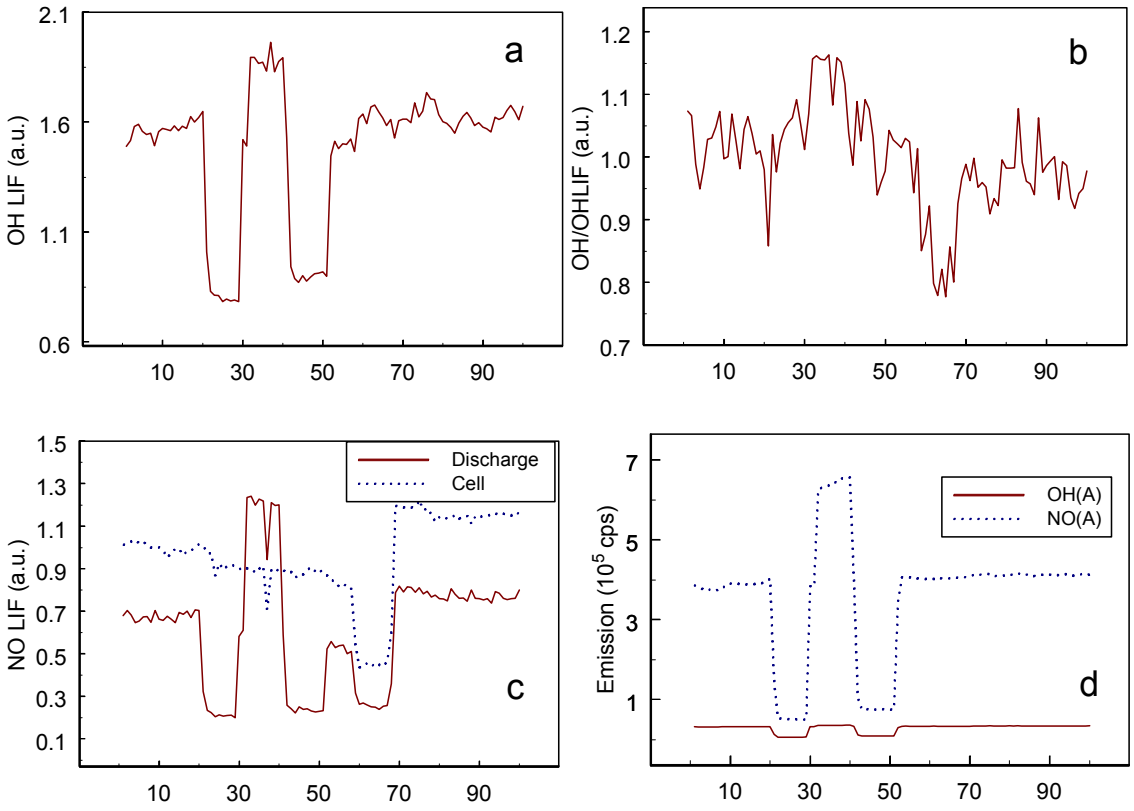

Fig. 3 Test runs of the source scheme robustness with respect to discharge and laser operating conditions variations. On the x-axis the run number is reported. For the details of each figure see the text.

In Fig. 3c it is reported the NO LIF in the post-discharge and in the reference cell. The LIF variations induced by the TH generator detuning are of the order of a factor 6. Roughly the same factor six, or more, is the range of variation of the emission intensities, reported in Fig. 3d, induced by discharge power changes. Finally the result of the test is shown in Fig. 3b, in which the ratio of the OH density calculated by formula (3) and the OH LIF (Fig. 3a) is plotted against the run number, after normalization to the mean value of the ensemble. The standard deviation of the ensemble of Fig 3b is about 8%. A large contribution to the standard deviation comes from the measurements between runs 30-40 and runs 60-70, corresponding to the large TH energy variations and is due to an identified cause. The LIF on NO is made in partial saturation conditions, in spite of the quite low laser energy (about 200 μJ per pulse). This is due to the spatial non-homogeneity of the laser beam, characterized by the presence of a "hot spot". The TH energy in the discharge vessel is not the same as that in the NO cell, since the beam passes through two windows and one prism before reaching the NO cell. This means that the LIF in the discharge and in the cell are made at different points, with different slopes, of the saturation curve. On reducing the TH energy the "relative slopes" of the two LIF measurements slightly change. This is a very small effect, about 10% when changing the LIF signal by a factor 3, but it is visible in Fig. 3b. The way out of this problem is to reduce as much as possible the windows number by an appropriate design of the discharge-NO cell system, to use very high optical quality windows, and to work with a TH that does not change as much as in our tests.

As a whole, the result of Fig. 3b is very satisfactory. It is the combination of six measurements, each of which changes very much in the ensemble. Furthermore the measurements statistics is not high. We are using a 10 Hz repetition rate laser, while in actual FAGE systems the laser operates at repetition rates in the kHz range. This means that, in the same measurement time the LIF statistics can be increased by a factor 100. Furthermore, as already pointed out, the problem of the NO LIF saturation can be drastically reduced by an appropriate design of the apparatus. It is then reasonable to estimate that the source can operate at a statistical precision of 1-2%, whichever the discharge and gas feed conditions are.

4. Discussion and conclusions

The data shown in the preceding paragraph are a striking evidence of the correctness of the method. Furthermore the scheme we have proposed is only apparently complex: it in fact opens the possibility for a simple, robust and small reference cell. A key role in the miniaturization of the source is played by the LIF spectroscopic scheme, detailed in [4], that allows solution of the laser scattered light elimination from the OH LIF signal by the use of a precision multi-cavity interference filter. This eliminates the need of long arms with baffles on the laser beam path. With the aid of up-to-date miniature photomultipliers, one can envisage a source apparatus 10-20 cm long, and supplied by a very low power (< 1W) pulsed RF generator. The other key for miniaturization and portability of the apparatus is the fact that it uses ambient air as gas feed. This is the field where our scheme shows the major advantage with respect to the other method actually available for the generation of a known OH density. This latter is based on the well known reaction[6], [7]:

$$H + NO_2 \rightarrow OH + NO \qquad (4)$$

H atoms are generated in an Ar/H_2 microwave discharge and NO_2 is added downstream the discharge in a flow tube. The OH density is classically obtained by a volumetric measurement of NO_2, provided the H density is well known in the flow tube. Alternatively, and perhaps more easily, the measurement of OH can be reduced to the measurement of NO, since equal amounts of OH and NO are produced by reaction (4), provided the ratio of OH and NO density remains constant in the measurement region. The big practical drawback of this method compared to our scheme is the need for hydrogen and nitrogen dioxide bottles, i.e. hazardous/harmful gases, in the apparatus, that is not desirable in an on-line reference source for a portable field instrument.

A further development of our scheme could be a "local" application of the pulsed discharge in the same region as the sample one, with an time alternation of the "sample" and "reference cell" measurements instead of a simultaneous "sample" and "reference" measurements, but with the reference cell physically located in a different space position. In the FAGE case this could be done by switching-on a small confined pulsed discharge close to the nozzle of the sample air expansion. Two important advantages of such a "local reference cell" would be:

1. the “reference” measurements are made in the same pressure and temperature conditions as the sample ones;
2. the “reference” signals are measured by the same optical collection-measurement system as the sample signals.

Abstract
In the present work, cobalt nanoparticles have been stabilized by coating RF plasma polymerized C_6F_{14}.SEM and Transmission Electron Microscopy and have been used to study the morphology and thickness of the coating. The protective property of the coating was studied by TOFSIMS. The degradation over time in magnetic behavior of the coated cobalt nanoparticles at room temperature were studied using Vibrating sample Magnetometry

Introduction
There has been an increased interest in ferromagnetic nanoparticles of Cobalt because of their potential use in magnetic data storage as well as in sensors. Co nanoparticles have been synthesized by colloidal chemistry [1], and by a modified arc discharge method [2]. The stability of nanoparticles has long been a concern for useful applications. Some advances have been made towards this end by encapsulating them in graphitic layers [3, 4]. Specifically for cobalt nanoparticles, the sensitivity of the magnetic properties to oxidation [5] points towards the necessity for stabilization of the nanoparticles. One method of achieving this has been to form and coat the nanoparticles insitu in microwave plasma [6, 7].
In the present work we have synthesized Co nanoparticles from Cobalt carbonyl and coated with a stabilizer plasma polymer layer of C_6F_{14}.

Experimental
Chemicals Cobalt carbonyl (1-5% hexane as a stabilizer) and perfluorohexane were purchased from alfa-aesar.
Apparatus The reactor consists of a 2 piece Pyrex glass set consisting of a flask at the bottom of diameter 7.5 cm, a vertical tube of 25 cm length and 2.5 cm diameter. Two inlets are provided in the top portion for monomer and carrier gas if required. The inductively coupled plasma was excited by means of an RF generator operating at 13.56 MHz. The reactor was subjected to oxygen plasma cleaning to ash any organic matter from previous depositions, followed by argon plasma treatment for 15 minutes.

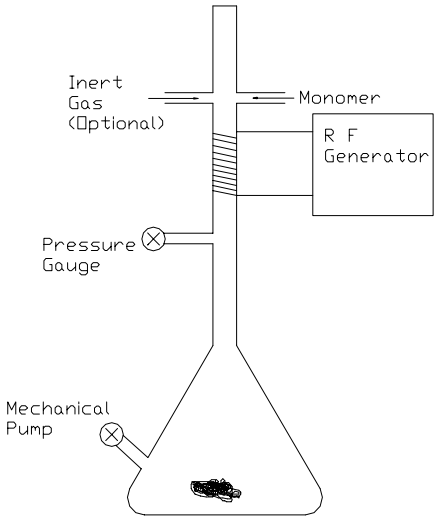

Figure 1 The RF plasma reactor used to make and coat cobalt nanoparticles

The cobalt carbonyl, in the form of crystals, is introduced in the bottom flask of the reactor in a vial. Typically, 0.2-0.3 g is taken so that the yield may be at least 10-20 mg. The reactor is pumped to a base vacuum of 80 mtorr. The cobalt carbonyl is then heated so as to decompose it to form metallic cobalt. This is followed by introduction of the perfluorohexane monomer at a pressure of 200 mtorr over base pressure in the reaction chamber where it is polymerized by the plasma. The plasma power was between 115 and 120 W. The deposition time of the polymer was 30 minutes.

Scanning Electron Microscopy The coated samples were studied for the aggregation in a Hitachi 3200 N variable pressure SEM.

Transmission electron microscopy Transmission electron microscopy was done in a Phillips CM-20 TEM. The samples were suspended in methanol and ultrasonically shaken to concentrate the particles. The solution was then placed on a Ni grid and evaporated under a nitrogen atmosphere. The operating voltage was 20 KV.

Time of Flight Secondary Ion Mass Spectrometry (TOFSIMS) The particles where characterized in an ION-TOF IV Time of flight SIMS system. The primary ion source consists of 25 KV Ga^{3+}. The typical raster area is 75 µm * 75µm. The pressure in the analysis chamber is kept below 10^{-8} mbarr.

Vibrating sample Magnetometry (VSM) The magnetic property studies were carried out in an EG & G PAR model 4500, Vibrating Sample Magnetometer system equipped with a 1 Tesla Electromagnet.

Results

The synthesized nanoparticles were found to have an average size of 60 nm in the agglomerated form as seen from the SEM micrograph in figure 2.

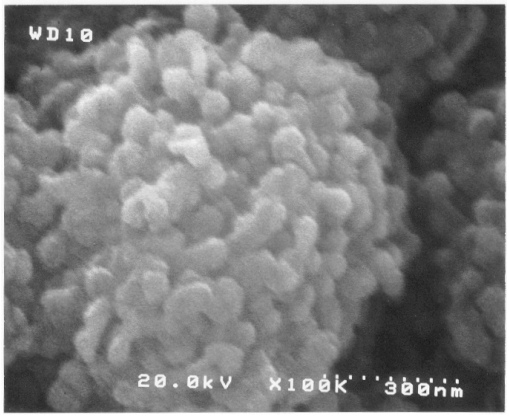

Figure 2 The agglomerated cobalt nanoparticles

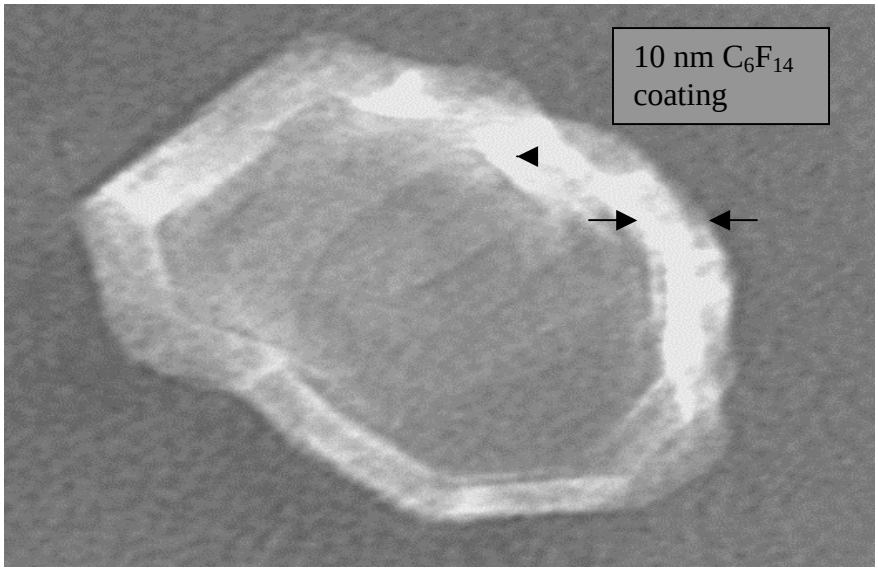

Figure 3 TEM micrograph of C_6F_{14} coated cobalt particle

The TEM micrograph shown in figure 3 clearly shows the coating of C_6F_{14} of 10nm thickness on a cobalt particle of about 100 nm thickness.
Time of Flight-Secondary Ion Mass Spectroscopy (SIMS) was done to determine the protective property of the stabilizer coating. The intensity ratio of Co and various oxides of cobalt to that of the total ion intensity is a tool which can quantify the amount present. SIMS was done in the same sample under two different conditions:
a) As prepared condition
b) Exposed to moisture for 3 months.

Table 1 The intensities of Co and various Co oxides as compared to the total ion intensity for SIMS

Condition	Co	CoO	Co_2O_3	Total Ion Intensity
As prepared	446657	748	0	1451160
Exposed to moisture	135422	1436	111	814380

Table 2 The Intensity ratios of Co, CoO and Co_2O_3

	Intensity ratio in as Prepared Sample	Intensity ratio in sample exposed to moisture
Co	0.31	0.17
CoO	0.0005	0.0010
Co_2O_3	0	0.00007

It is observed that there is a significant decrease in the Co content but not much of an increase in the oxide content. The increase may be attributed to the formation of hydrated cobalt oxides because of the reaction with moisture.

The magnetic property of Cobalt was measured using Vibrational Sample Magnetometry (VSM) and also after exposure to moisture after 3 weeks.

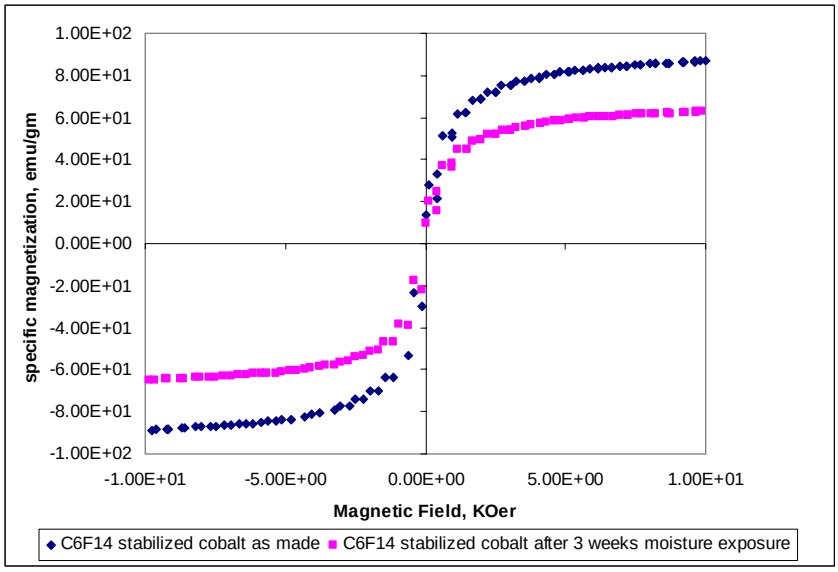

Figure 4 The Magnetic Hysteresis curves of C_6F_{14} stabilized Cobalt

Table 3 The various magnetic properties of the 2 samples under consideration

	As made Sample	3 weeks moisture exposed Sample
Retentivity, M_r (emu/g)	18.80	18.74
Coercivity	192.5	191.01
Saturation Magnetization, M_s, (emu/g)	88.73	87.34
Mass (gm)	0.0158	0.0213

The retentivity value of the C_6F_{14} stabilized Co is 18.80 in as prepared condition and reduces to 18.74 after a 3 week exposure to moisture which is not a very significant reduction. This comapares well with that of Sun etal [2]. The Saturation Magnetization, M_s is rising in the as made case even on application of 10 KOer field. This may be due to super- paramagnetic property. This will be verified further with Mossbauer spectroscopy studies. However, after exposure to moisture for 3 weeks there is a slight decrease indicated by the less sharp slope in the curve. This may be due to the nonmagnetic nature of moisture and also some increase in oxide content as discussed in SIMS analysis.

Conclusion

It has been shown that nanoparticles of the order of 100 nm have been formed and coated insitu with a 10 nm coating in RF plasma. The protective nature of the perfluorohexane plasma polymer has been shown by the SIMS analysis. The magnetic properties of the stabilized particle are comparable to that of only cobalt nanoparticle. There is also not much of a change in these properties in the time period considered. This further indicates the protective nature of the coating.

Abstract
It is shown; there are the conditions of heating of electrons in a beam - plasma discharge up to high energies. The experimental studies of electrons heating in beam-plasma discharge in mirror magnetic trap are executed. The experimental spectra of X-rays quanta energy from the discharge plasma are given. The maximum of X-ray quanta energy distribution is in the area of energies 200 - 250 keV. The results may be used for the creating of X-ray source on the base of beam -plasma discharge.

1. Introduction

There is the interest to the advantages of beam-plasma discharge in recent years [1]. There are the conditions in beam-plasma discharge when there is the group of hot electrons with energies much higher, than the energy of beam electrons. These high-energy electrons may produce high energy X-rays. The possibility of X-ray generation by the electrons heating in plasma discharge and to create the X-ray sources on this basis for the practical application in the technology and medicine was been demonstrated by the series of experiments that were executed at 60-th - 70-th. First off all we should mark the experimental work by Alexeff and others [2]. An electron temperature of 32 keV and an electron density of $4 \cdot 10^{11}$ cm^{-3} was obtained in beam-plasma discharge in mirror magnetic trap in the stationary mode. The electron beam current was 0.5 A, the energy of beam electrons was 5 keV. It was shown in work [3] that the high-energy electrons are generated in a mirror magnetic trap with high mirror ratio at the interaction of pulse electron beam with the plasma density $2 \cdot 10^{10} cm^{-3}$ in volume of 20 litres. The energy of electrons was 200 keV at the magnetic field 1.65 kOe in the centre of the trap and the electron energy was 40 keV when the magnetic field was 0.5 kOe [3]. The plasma with electron temperature 550 keV and density of 10^{11} cm^{-3} in volume of 4.2 litres was produced in installation PN-2 by means of adiabatic plasma compression [4]. The intensive X-ray radiation in the experiments was up to 1 MeV. The hot plasma was confined by mirror magnetic field without decay for a few seconds in the experiment. The powerful beam-plasma amplifier is described in work [5]. The amplifier is manufactured as a separate vacuum device. In the amplifier the accelerating voltage of electron beam was U_0=15 - 25 kV, the beam current was I= 3 - 5 A, the strength of magnetic field of a solenoid was 2 - 3 kOe, the pressure range of working gas (hydrogen) in the interaction space was $10^{-6} \div 10^{-3}$ Torr. This experiment confirms the possibility of hot electron generation in the separate device. The actual selection of method to get X-ray generation by beam-plasma discharge in a mirror trap is based on its energy-economical capability, simplicity for realisation, possibility to create a compact device for generating hot electrons which can be used as a source of X-ray without the using of high energy power supply (5 ÷ 6 keV, but not 100 keV). Meanwhile, for the tropical countries, due to humidity, high voltages occur such accident like fire. Replacing X-ray tubes (feeding voltage ≅ 100 kV) by our experimental device (feeding voltage≅ 6 kV) can consider this loss. The series of experiments are going on the plasma chemical installation "Oratoria-10" to generate X-ray from the non-equilibrium plasma by beam-plasma discharge [6]. The experiments are carried out in the stationary mode with continues electron beam injection. The X-ray generation was obtained in argon and in hydrogen plasma. During the stationary process some parameters (like magnetic field, electric beam energy, pressure of working gases, Type of gases) were changed to get the optimal results on the X-ray generation. The outcome of X-ray was formed through the aluminium diaphragm with the thickness of 1.4 mm. The dose rate of X-ray was measured by the using of the sandwich of two thermo-luminescence tablets *LiF* with the thickness of 1 mm. The first one absorbed the doze and it's the filter for the second tablet at the same time. The measurements showed that the doze rate measured was 1.7 R/h in the experiments with argon plasma and 3.7 R/h in the experiments with hydrogen plasma. The doze rate measured by the second tablet of the sandwich was 82-84% of the doze rate measured by the first tablet. In the assumption of the mono energy distribution the energy of X-ray quanta was about 20 keV. In the assumption of the Maxwell distribution for the fluid of hot electrons the obtained energy of thermal

electrons was about 30 keV. One can obtain more reliable results with the measurements of X-ray spectra from plasma by using of scintillation detector.

2. Mechanism of electron heating

The analysis of the experimental and theoretical researches of the beam heating of electrons in mirror magnetic trap is resulted in work [7]. When the electron beam is injected in a mirror magnetic trap [7] the strong beam-plasma interaction takes place and it results in the growth of the cross size of plasma and in the strong heating of the hot electrons confined by the trap. The electron beam excites the Langmuir oscillation at the interaction with plasma [8]. The heating of hot electrons takes place because of its interaction with the electron Langmuir oscillations $\omega_{pe} > \omega_{He}$. The width of the beam in the space of velocities Δv becomes to the initial velocity of the beam u at the distance of 20 ÷ 30 cm from the beam input in the system. The characteristic increment of instability is $\gamma \sim \omega_{pe} n_{0b}/n_0$. The electron beam excites the oscillations mainly with the wave vectors parallel to its axes. The spectrum of Langmuir oscillations is essentially non-isotropic. If the electrons at interaction with noise will not get in a cone of losses in the space of velocities, they will diffuse in usual space to the periphery of installation and its energy will slowly increase. The cone of losses in the space of velocities is the function of mirror ratio R. Thus to obtain hot electrons it is necessary to satisfy the series of conditions for the confinement of electrons in mirror magnetic trap and for their heating up to high energies, namely:

$\omega_{pe} > \omega_{He}$,

$\gamma \sim \omega_{pe} n_{0b}/n_0$,

$R > 1/\cos^2\theta_0$,

where $arctg\theta = k_\perp / k_{//}$, and θ_0 is some limiting angle.

If to take into account, that the radius of a beam $a \sim 1$, and characteristic wave vector of raised oscillations $\boldsymbol{k} \sim \omega_{pe}/u \approx 5$ cm^{-1}, that $k_a >> 1$. It means, that for estimations it is possible to use outcomes of the theory of a boundless beam.

Energy of oscillations in a transverse direction is transferred with formation speed

$$\frac{\partial \omega}{\partial k} \sim \left(\frac{\omega_{He}^2}{\omega_{pe}^2} \right) v_\phi .$$

The time of propagation of oscillations up to diaphragms limiting plasma is much less then decay time on hot particles. At on frequency, wave number k and the speed of hot electrons v is superimposed a condition

$$\omega_{pe} = kv\cos\varphi ,$$

where φ is an angle between k and v. The vigorous electron will be effective to interact only with those oscillations, which wave numbers are almost perpendicular to their velocities.

On the base of the above one can observe the dependence of the energy of hot electrons on the strength of the magnetic field. The electrons involved in process of acceleration increase the energy and diffuse from a beam to an exterior wall of the trap. The energy of electrons is determined by the time of its life in the trap τ, that it is possible to write as:

$$\tau \sim \left(\tau_D^{-1} + \tau_S^{-1} \right)^{-1} ,$$

where τ_S is the time of dispersion in a cone of losses, and τ_D is the time of a diffusion of an electron up to the external boundary of plasma. Thus, the time of leaving of an electron in a cone of losses is defined by the configuration of magnetic field (mirror ratio) and does not depend on its strength. The time of electron diffusion across the magnetic field is proportional to a quadrate of plasma radius and it is in inverse proportion to an effective diffusion constant or proportionally to quadrate of the magnetic field strength. Thus, in the area of "small" magnetic fields, while $\tau_D < \tau_S$, the lifetime is determined by the time of diffusion and increases proportionally to quadrate of a magnetic field strength. At some value of a magnetic field strength the diffusion time is compared to the dispersion. At the further magnification of a magnetic field the lifetime ceases to depend on a magnetic field strength and it is defined only by the leaving of "hot" electrons in a cone of losses.

3. Experimental device

The experiments on plasma producing and electron heating in beam-plasma discharge were executed on plasma chemical device “Oratoria-10”, the scheme being shown at Fig.1. The "Oratoria -10" device enables

to carry out the researches of non-equilibrium plasma with the density of $10^{10} \div 10^{13}$ cm^{-3} produced in a beam-plasma discharge. The working vacuum chamber (1) of diameter 0.5 m and the length of 1m is made of stainless steel. All the chamber is immersed in magnetic field created by the coils (2). The magnetic system of a "mirror-like magnetic trap" type produces magnetic field of strength 600 Oe in the centre of the magnetic mirror trap and accordingly in the centre of the working chamber (1) and magnetic mirror (max/min) ratio R~3.5. The strength of magnetic field can be varied from 300 Oe up to 600Oe. The maximum magnetic field strength is about 800 – 900 Oe in short time regime (10 – 15 minutes). The electron beam of a cylindrical geometry of maximum diameter up to 4 cm is formed by means of an electron gun (3) with a beam current of up to 2 A and of its energy up to 6 keV. The electron beam formed by the electron gun is injected into the working chamber (1) along the axis of the magnetic field and through the system of diaphragms (5) with the small orifices. The electron beam penetrates the chamber from one side to the electron beam receiver (4) on the other side. The system of differential pumping is used to provide the necessary high vacuum conditions for the electron gun operating. Differential pumping system consists of three groups of thin diaphragms with the intermediate pumping out between the two ending diaphragm groups and through the middle group. The orifices in the diaphragms are equal to a diameter of the electron beam. The necessary vacuum conditions in the "Oratoria-10" chambers are provided by the oil vapour high vacuum diffusion pump (6) with liquid nitrogen-cooled trap. The residual gas pressure is not more than $3 \cdot 10^{-7}$ Torr with the using of nitrogen-cooled traps and not more than 5.10^{-6} Torr without the using of nitrogen cooled traps. The maximum working pressure in working chamber is about ~ 10^{-3} Torr. High-energy electrons heated by beam-plasma interaction in the discharge produce the X-ray quanta at Coulomb scattering in plasma and at the electron - wall collisions. X-ray quanta attain the scintillation detector (7) passing through the thin beryllium diaphragm and the orifice in the lead collimator. X-ray quanta are registered by the detector (7) on the base potassium-iodine crystal. Photo multiplier tube enables us to measure the signal and determine the X-ray spectrum. 1024 channel amplitude analyser is used to measure X-ray spectrum. The plasma density was measured by the using of Langmuir probe (8). The working plasma forming gas is supplied into the working chamber through the piezoelectric inlet valve (9).

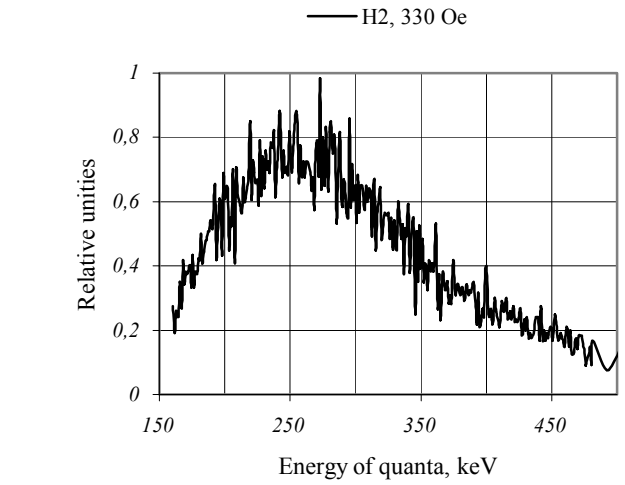
6 - vacuum pump; 7 - X-ray diagnostic; 8 - Langmuire probe; 9 – piezoelectric inlet valve.

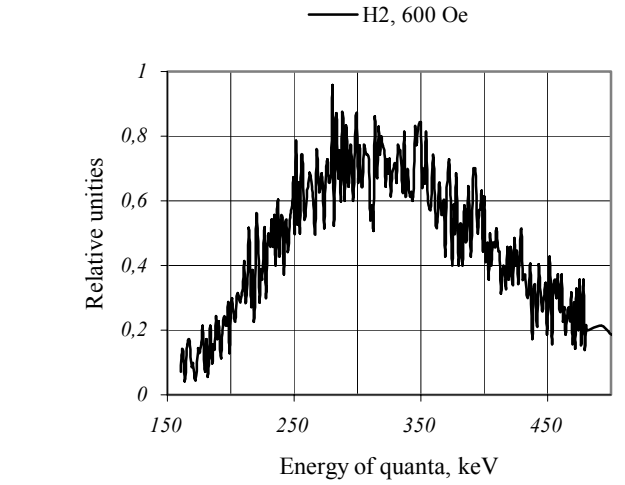
4. Experimental results

The experiments were carried out for two aims – to measure integral intensity of X-ray radiation and to find out the dependence of spectral distribution of X-ray energy on the strength of magnetic field, electron beam parameters, initial gas pressure in the working chamber and the composition of plasma forming gas. In our

researches we used two gases for the plasma forming: argon and hydrogen. One can explain our choice to study the X-ray generation in the plasma of gas with minimum excite states of the molecules and to study the plasma of more complicated composition with plenty of excite states of atoms.
A typical experiment to study the X-ray generation in plasma beam-plasma discharge in "Oratoria-10" device was as follows. The initial pressure of residual gas in working chamber is about $5 \cdot 10^{-6}$ Torr. The magnetic field is switch on. Nominal current in magnet coils is about 200 A corresponds to the strength of magnetic field about 600 Oe in the centre of magnetic trap. The electron beam is injected into the working chamber along the axis of magnetic field. The electron beam current is about 1 A, the energy of beam electrons is about 3 – 4 keV. The hydrogen is being supplied through the piezoelectric inlet valve into the working chamber. The hydrogen inlet flow is adjusted concerning to the maximum of integral intensity of the X-ray radiation. The inlet hydrogen gas flow corresponds to the total gas pressure in the working chamber about $(7 – 9) \cdot 10^{-5}$ Torr. Then the spectrum of the X-ray radiation is measured by the using of scintillation detector, photo multiplier tube and amplitude spectrum analyser. The experiments on the study of X-ray generation was carried out in the accordance with the above operation sequence at the variable parameters of the discharge: the strength of magnetic field, the electron energy and the current of electron beam, the plasma forming gas pressure. The typical experimental spectrum of the X-ray generation in hydrogen plasma of beam-plasma discharge is shown on fig.2 and fig.3.



a)



b)

Fig. 2. X-ray spectrum in hydrogen plasma. Initial pressure $\sim 8.5 \cdot 10^{-5}$ Torr, beam current ~0.75A, electron beam energy 3 keV : a) H=330 Oe; b) H=600 Oe

One can see the maximum of X-ray energy distribution in the experiments with hydrogen plasma is about 230 - 250 keV at the strength of magnetic field *H=330 Oe* and about 270 - 300 keV at *H=600 Oe*.

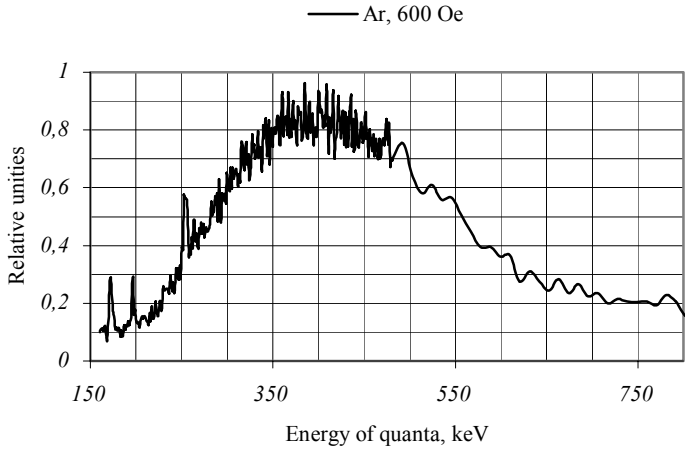


Fig. 3. X-ray spectrum in argon plasma
H=600 Oe, initial pressure ~$8.5 \cdot 10^{-5}$ Torr, beam current ~0.75A, electron beam energy 3 keV

The typical experimental spectrum of the X-ray generation in argon plasma of beam-plasma discharge in the "Oratoria-10" device one can see on fig. 3.
In the case of argon plasma maximum of X-ray energy distribution is about 350 keV.
The X-ray registration system (scintillation crystal, photo multiplier tube and amplitude spectrum analyser) was calibrated against the isotopes ^{241}Am, ^{60}Co and ^{137}Cs.
We carry out the series of experiments with argon and hydrogen plasma. All these curves were Maxwell-like. Our experiments demonstrate some interesting dependence: integral intensity is the highest in the experiments with hydrogen plasma and maximum energy of quanta is reached when argon was used as plasma forming gas.

5. Discussion

First of all we must mark some new physical results of our experiments.

- In our experiments we obtained rather high energy of hot electrons that is about 250 – 350 keV in the maximum of the energy distribution.
- There is the X-ray emission in hydrogen plasma at the strength of magnetic field about 300 – 330 Oe.
- The energy of hot electrons and its quantity depends on the kind of plasma forming gas.

One can explain the increasing of X-ray energy distribution maximum at the higher magnetic field in the experiments with hydrogen plasma by the dependence of hot electrons transverse velocity on the strength of magnetic field.
If it is possible to explain the smaller intensity of X-rays in the experiments with argon plasma from the point of view of a lot of excitation levels of argon atoms and accordingly more losses of energy, this mechanism does not explain the increasing of "temperature" of hot electrons in argon plasma. Thus it is necessary to assume the presence of other mechanism responsible for this phenomenon. It is possible to assume the existence of dependence of transverse diffusion velocity of hot electrons on the kind of ions in the plasma (the relation of mass to a charge). In the case of heavier ions in plasma the velocity of transverse electron diffusion is less, the time of the transverse diffusion is accordingly more, the lifetime in a trap is more too. It results in the decrease of amount of hot electrons i.e. more part of electrons leaves in a cone of losses and simultaneously to the increasing of hot electrons energy in a trap.
On the other hand the executed experiments demonstrate the opportunity to obtain hot electrons in plasma of beam - plasma discharge. The temperature of hot electrons in plasma is much higher than the temperature of electrons in a beam. To compare the obtained experimental results with the earlier experiments on installations working in the pulse mode it is interesting to continue the study of electron heating in beam - plasma discharge and to find the time of formation of electron acceleration mode at the pulsing injection of electron beam in the same conditions as at the continuos injection of the beam. The other direction of the researches is the obtaining of high temperature relativistic electrons at the adiabatic compression of plasma of the beam - plasma discharge containing hot electrons. The existing of hot electrons in the experiments with hydrogen plasma at the strength of magnetic field about 300 Oe enables us to assume the possibility to

obtain rather high-energy electrons by the adiabatic plasma compression. One more perspective direction in the study of heating of electrons in the beam-plasma discharge is the researching of plasma decay after the termination of electron beam injection into the mirror magnetic trap and first of all the study of hot electrons that leave the magnetic trap through the magnetic mirror.
All these results will be very useful for the application in the science, technology and medicine.
There is the possibility to create X-ray source with the variation of X- ray quanta energy and the intensity of the X-ray generation. Such X-ray source may be used in medicine for the X-ray therapy. The hot electrons produced in beam-plasma discharge may be used to obtain the multi charged ions. The sources of multi charged ions are applied in science and industrial technology.
The electron bunch leaving the hydrogen plasma through the magnetic mirror of the trap in the processes of plasma decay can carry away the hydrogen ions. Taking into account the high velocity of hot electrons and the relation of proton mass to the electron mass (equal to 1840) one can assume the possibility to accelerate the protons by the electron bunch in the process of collective acceleration. It opens the perspective to create the collective proton accelerator on the base of the obtained results and above-mentioned processes.
It is necessary to take into account the presence of X-ray generations in beam plasma discharge devices is the indicator of the existence of beam-plasma instability in the discharge.
The opportunity to heat electrons in beam - plasma discharge has also the own back, namely, practically in any device with the beam - plasma discharge exists a mode, at that the X-rays radiation may be intensive enough. It is the problem of operation personal safety.

6. Acknowledgement

The generation of high energy X-rays in beam-plasma discharge in mirror magnetic trap was studied by our team with the support of INTAS (grant 97-0094) and Federal Programme “Integration of Science and High Education” (grant И0602/1378 and Я0068/2137).

Measurements of Local Plasma Parameters for an Ionized Inert Gas Flowing in a Magnetic Field

E.D.Roach, R.V.Vasil'eva, A.V.Erofeev, T.A.Lapushkina, S.A.Poniaev

Gasdynamic Laboratory, Ioffe Physico-Technical Institute RAS, St.Petersburg, Russia

Abstract
Method of measuring electron temperature and concentration in fluctuations of ionization unstable inert gas plasma in presence of regular plasma structures is presented. Experiment was made in a disk magnetohydrodynamic channel in Xe. Maximum magnetic induction value was 1.4T. Local electron temperature and concentration are measured. Evolution of plasma inhomogeneities is analyzed. Average values of plasma parameters are estimated.

1. Introduction

It is known that ionization (electrothermal) instability is the type of instabilities that earlier than others occurs in closed-cycled magnetohydrodynamic (MHD) generators [1-3]. Therefore, such type of instability has more influence on MHD channel characteristics and generator performance. Traditionally, pure inert gases with alkali seed use as a working substance for closed-cycled MHD generators. Effective conductivity decreases in the MHD channel with developing ionization instability at using traditional working substance. There is an opposite result when using pure inert gas without alkali seed as a working gas. The development of ionization instability in plasma of pure inert gases without alkali seed leads to increasing effective conductivity and, therefore, to growing extracted power, as it was discovered in our previous studies [4-6]. The major purpose of this work is to study ionization instability in great detail for deeper understanding this phenomenon, which will lead us to presenting the accurate physical model of increasing effective conductivity in unstable plasma flow when there are regular plasma structures. Our main goal of this study is to determine electron temperature and concentration in plasma fluctuations for determination of the relationship between the structures of inhomogeneities, distributions of plasma parameters, and integral characteristics of MHD channel.

2. Experimental setup

The experiment was performed in a disk MHD channel 0.32 m in diameter and 0.01 m high. Ionized gas flow was produced in a shock tube. Xenon was used as a working gas. The experiment was made at a Mach number of the incident shock wave of 6.9 and under initial pressure of 26 Torr. The maximum value of magnetic induction was 1.4T. The channel is shown in fig.1.

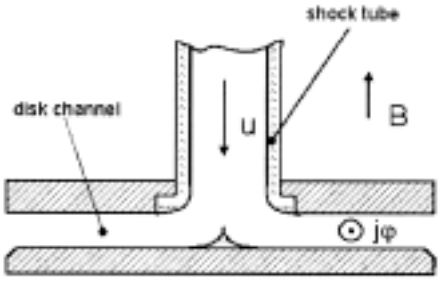

Fig.1 Scheme of disk MHD channel with shock tube.
j_φ – azimuthal Faraday current , B – magnetic field, u – velocity of gas flow.

In a disk MHD channel, MHD interaction gives rise to an azimuthal Faraday current (j_φ) and a radial Hall field. The more detailed descriptions of setup and measuring methods are contained in the Refs. [4-6]. In our terminology, instabilities or strata are names for regular structures with high electron temperature and concentration, which occur in the plasma flow at ionization instability at magnetic induction greater than 0.57 T for this experiment. Plasma parameters at the inlet of the disk MHD channel (at r=0.04 m) are: u_0 $=1.27 \cdot 10^3$ m/s, ρ_0 =0.45 kg/m^3, T_{ao} =2600 K, T_{eo} =3100 K, α_o $=2.6 \cdot 10^{-4}$, M=2.45.

3. Plasma state

Presence of MHD interaction leads to a temperature separation between electrons (T_e) and heavy component (T_h). This separation can be presented by an expression similar to the Kerrebrock formula (1):

$$(T_e-T_h)/T_h=\gamma k_\sigma \beta^2 M^2 (1-k)^2 (3\delta)^{-1} \qquad (1)$$

where $\gamma=c_p/c_v$; M – the Mach number of the flow; k_σ – correction multiplier used in conductivity calculations [7]; δ - inelastic loss factor which is mainly associated with the energy spent on gas ionization; β - Hall parameter; T_e and.T_h – temperature of electrons and heavy component, respectively. The temperature separation was $T_e/T_h=4$. At B=0, the gas ionization degree (α) in the recombining plasma proves to be higher than the equilibrium value (α_0) because of slow recombination. In the presence of a magnetic field, the process of ionization began to dominate due to selective electron heating. The ratio between the nonequilibrium and equilibrium ionization degrees became less than 1, $\alpha / \alpha_0<1$. The electron velocity distribution can be considered as Maxwellian for the gas ionization degrees in our MHD channel, $2\cdot10^{-4}<\alpha<2\cdot10^{-3}$. The increase of ionization degree due to selective heating leads a change of ratio between collision frequencies with atoms and ions. In the experiment, the ratio is between 0.2 and 1. According to ionization kinetic theory [8] of inert gases, the basic ionization mechanism is the following: ionization rate is determined by the rate of excitation of lower energy levels by an electron impact. The reverse process determines the recombination rate. For example, at T_e=8000K the three-particle recombination coefficient in Xe is $Kr=5\cdot10^{-41}$ m^6/s. If $n_e=10^{21}$ m^{-3}, the characteristic recombination time under these condition is $2\cdot10^{-2}$ s. In the experiment, the flight time was the order of 10^{-4} s.

4. Theoretical basis

The method of determination of electron concentration and electron temperature in an inert gas is based on continuum radiation peculiarities of the inert gas. There is a wide range of wavelengths for Xe, where radiation intensity drop is as an exponential function. The measurements of electron concentration (n_e) and electron temperature (T_e) are based on recording the absolute and relative intensities of the continuous radiation. A.Unsold and Kramers [9] established the general mechanism of the continuous emission. Corrections due to the nonhydrogen-like nature of the complex atoms were taken into account in the Biberman-Norman theory [10]. The energy distribution in continuous spectrum of Xe was studied in work [11]. It was shown that there is dependence on the intensity of the continuum radiation (I_ν) from frequency in some areas of xenon continuous spectrum:

$$I_\nu = \begin{cases} 4.3\xi(\nu)\frac{2h}{c^2}\cdot\frac{N_e N_i}{(kT_e)^{1/2}} = A & \nu \leqslant \nu_I \\ A\cdot\alpha\cdot\exp(-h\nu/kT_e) & \nu_I < \nu < \nu_{II} \\ A\,(1-\beta\cdot\exp(-h\nu/kT_e)) & \nu > \nu_{III} \end{cases}$$

$$\alpha = \exp(h\nu_I/kT_e), \qquad \beta = \exp(h\nu_{II}/kT_e) - \exp(h\nu_I/kT_e),$$

$$\gamma = \exp(h\nu_I/kT_e) - \exp(h\nu_{II}/kT_e) + \exp(h\nu_{III}/kT_e);$$

$$\nu_I = 3\cdot10^{14}\,s^{-1}, \quad \nu_{II} = 4.5\cdot10^{14}\,s^{-1}, \quad \nu_{III} = 6\cdot10^{14}\,s^{-1}. \qquad (2)$$

The radiation intensity drop is as an exponential function for wide range of wavelengths (470-300 nm) in xenon radiation at $\nu>10^{14}$ s^{-1}. Therefore, as shown in work [11], electron temperature can be determined based on the results of comparison of I_ν for two frequencies as following:

$$T_e=h \bullet (\nu_1-\nu_2) \bullet [k \bullet \ln(I_1/I_2)]^{-1} \qquad (3)$$

The major question with using this method is what is reasonable to use as standard values for intensity of radiation, electron temperature and electron concentration in MHD channel. Studies of other authors, for instance work [12], show that at M≥10, the measured parameters of a shock-compressed gas plug in shock tubes match well with their computed values. The part of shock-compressed gas plug with thermodynamic equilibrium (Mach number of shock front M_1=10.5 and p=7.7 mm Hg) served as the standard for the intensity of radiation I_ν, electron temperature T_e and electron concentration n_e. In the experiment it was area

with maximum radiation of shock-compressed plug, close to the shock wave front. Under these conditions, radiation intensity, electron concentration and electron temperature are close to calculated equilibrium values of these parameters. Standard electron temperature is determined to within 2%. This accuracy determines the absolute accuracy of measurements. The relative value of electron temperature is obtained with the ratio of a noise to a signal and is 1.5%.

Electron concentration was determined with radiation intensity and electron temperature. For this purpose, the area with wavelength 566 nm was extracted with an interferential filter. In this wavelength range the correct formula is the following:

$$I_\nu = 8.6 \bullet (h/c^2) \bullet \xi(\nu) \bullet n_e^2 \bullet (kT_e)^{-0.5} \qquad (4)$$

where $\xi(\nu)$ is a multiplier taking into account non-hydrogen nature of atoms [10].

Radiation of a shock-compressed gas plug from the volume with thermodynamic equilibrium was taken as a standard value of radiation. All plasma parameters are calculated with good accuracy for this part of shock-compressed gas. If we are taking absolute electron temperature values to within 2%, then absolute values of electron concentration are within 25% using this method of determination.

5. Optical scheme of measurements

The optical scheme of continuum radiation registration for two wavelengths from the disk MHD channel and shock tube was designed. Ultra-violet (UV) monochromator was designed with a concave diffraction grating (R=1m) as shown in fig.2.

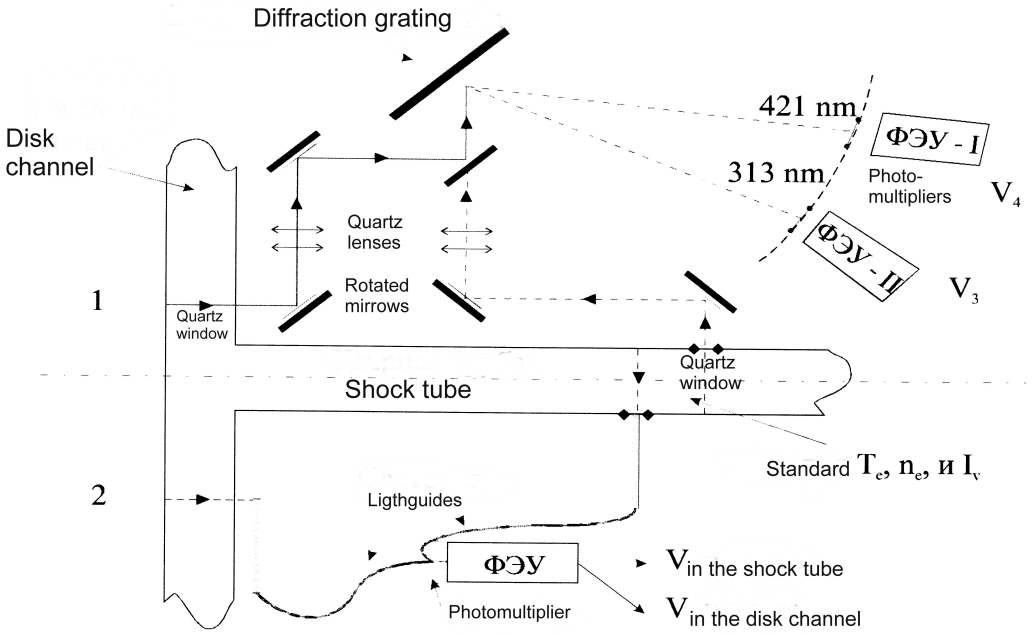

Fig.2 Schemes for measuring electron temperature (1) and absolute intensity of radiation (2)

The solving ability of the monochromator was 0.8 nm/mm and was determined with the distance between mercury lines using standard mercury lamp. Two quartz windows with diameter 0.01 m were installed in plexiglass disks in MHD channel at radii r_1=0.07 m and r_2=0.096 m. Plasma radiation from the disk channel was directed on a diffraction grating with rotated mirrors and quartz lenses. Two areas of xenon spectrum λ_1=423±1.5 nm and λ_2=313±1.5 nm were extracted at the same time. Radiation from these two areas was registered with two identical photomultipliers. Signals from photomultipliers were transferred to a digital oscilloscope. Computer analysis was used for obtaining data.

6. Fluctuations of electron concentration and temperature

Our previous study [13] shows that luminous inhomogeneities (magnetic strata) are shaped as spokes, oriented at 20-30^o with an azimuthal direction, placed in the distance of 0.03m from each other in the azimuthal direction. At the same time there are 3 strata in the length of the channel. In the channel, they appeared with the same time interval ($2\cdot10^{-5}$ s – $3\cdot10^{-5}$ s), their propagation velocity was close to flow velocity, i.e. it was as if the strata were frozen to the flow. While strata were moving in the channel, they become more luminous, wider and more oriented with the initial current direction. Once formed, the strata do not decay. They have a lifetime longer than a flow time. It is possible to follow the strata evolution in more detail by detecting temporal variations in electron concentration at different fixed locations in the channel. To this end, photomultypliers were used to measure plasma luminousity through windows in the disk channel wall. Fig.3 demonstrates how the electron concentration changes at distances r_1 and r_2 as different volumes of plasma move past the measurement window. It can be seen that the time interval between the first electron concentration maxima is close to the time difference between the shock wave arrivals at r_1 and r_2, which suggests that the same strata are observed at r_1 and r_2. The electron concentration in the strata grows as they propagate downstream. The electron concentration distribution shown in Fig.6 is seen to have large-scale inhomogeneities with duration of 20-50 μs. During a flow time of 400 μs, about eight large-scale strata pass through the channel. On their background, small-scale inhomogeneities, which are more pronounced at larger radii, are present. We find a certain analogy with the development of classical turbulence [14] when small-scale pulsations are regarded as a fine structure superimposed on large-scale inhomogeneity.

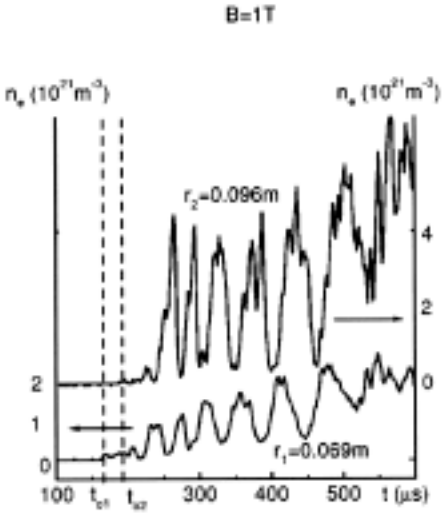

Fig.3 Electron concentration for two radii along the channel radius at B=1T.
t_{01} and t_{02} are times of the shock wave arrives into the first and second measuring locations.

Fig.4 shows electron concentrations and temperatures in the inhomogeneities that move past the measurement window at r=0.096 m for B=1T. It can be seen that, in general, large-scale regions with higher temperatures (strata) have higher electron concentrations and, conversely, that lower-temperature regions are characterized by lower electron concentrations, although the positions of the n_e and T_e maxima and minima are somewhat shifted. In the large-scale inhomogeneities, the highest and lowest electron concentrations differ by approximately a factor of 3-3.5, the electron temperature varies from 8500 to 7000K. In the small-scale inhomogeneiteies, variations in the electron concentration are weaker by about 50%, while the temperature may rise as high as 10000-11000K. The average value of T_e over fluctuations $<T_e>$is 7800K. Measurements of electron temperature T_e at radii r_1 and r_2 revealed that average temperatures at these radii were nearly equal.

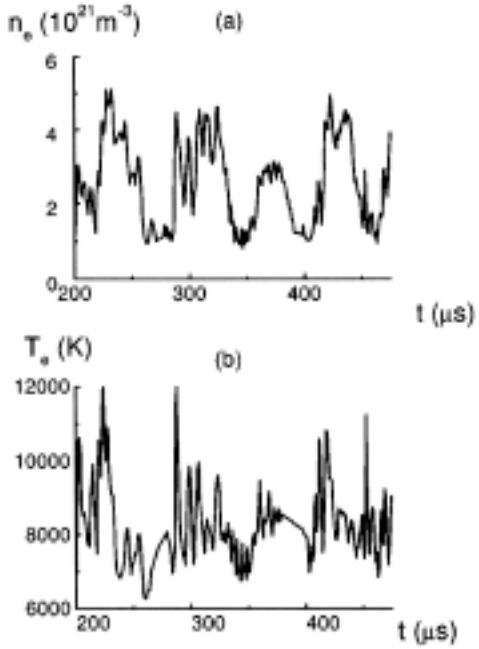

Fig. 4 Fluctuations in luminous inhomogeneities of electron concentration and electron temperature at B=1T, r_2=0.096m.

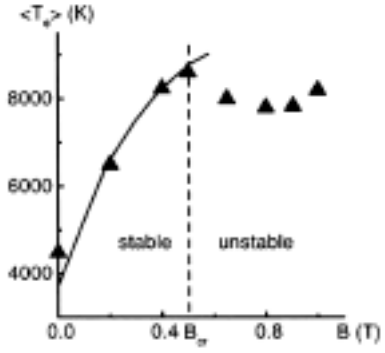
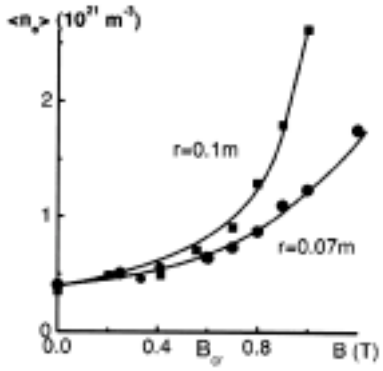
7. Average values of T_e and n_e

The average value of electron temperature over fluctuations in the region (r_2-r_2) was obtained by averaging the results of several experiments, fig.5a. The picture also shows calculated values of electron temperature for magnetic induction lower than critical magnetic induction value, i.e. for stable plasma. The measured values of T_e in ionizational unstable plasma proved to be lower than those calculated on the assumption of stable plasma. Fig.5b presents electron concentration values, which were averaged over fluctuations for different magnetic fields at two radii. Each point was determined by processing several measurements.



(a)



(b)

Fig. 5 (a) - Average electron temperature for different magnetic induction values. Curve is the temperature calculated on the stable plasma assumption. Points are experimental data. (b) - Average electron concentration for different values of magnetic induction at two radii.

8. Conclusions

The lifetime of plasma strata is longer than their flight time in the MHD channel and the strata are "frozen" in the flow. Therefore, plasma flow consists of volumes with lower and higher electron temperatures and electron concentrations. Among the plasma parameters considered, the most significant changes were observed in electron concentration. Average values of electron concentration and their modulation depth increase with increasing magnetic induction values.

Abstract
In this paper, a model is presented describing the dynamics and motion of the electric arcs in a three-phase AC configuration without neutral point. The model considers that the arcs are conducting filamentary wires that carry a given current. Incorporated into a conventional computational fluid dynamics (CFD) simulation of the entire plasma system in the form of an arc sub-model, this new approach will allow a more detailed definition of the reactor inlet conditions.

1. Introduction

An original three-phase AC plasma arc technology has been developed over the last 10 years for the production of carbon nanostructures such as carbon black, nanotubes or fullerenes [1]. In this technology, the discharges do not transit via a star neutral point as commonly found in metallurgical applications but the arcs change in time between delta and star configurations showing complex motions caused by interactions between arcs themselves and the crossing gas flow. As the arc region plays a crucial role in the transfer of energy and momentum to the plasma gas inside the plasma reactor, a better understanding of the phenomena occurring in the arc zone is needed in order to improve the control of the process as well as the CFD modelling of the plasma system.

In an earlier approach by Ravary and co-workers [2, 3], analytical expressions describing the Lorentz forces were presented. Ravary assumes small arc displacements with respect to an initial (star or triangle-type) arc configuration. For that reason the geometry is mainly fixed even if the current in the electrodes and the arcs change in time. Finally, a model of the arc is described which is used in the CFD simulation. The model assumes that time-averaged Lorentz forces are distributed homogenously inside a torus whose radius is set to be equal to the radial position of the electrode tips. The value of the Lorentz force is derived from the average in the space of the analytical expressions determined previously. Although the essential characteristics of the arc forces are given by this model, that means the presence of a positive radial force and the S-shape arc observed by high-speed camera analysis, the films also show that the arc deflection displacements are as large as the distance between the electrode tips. Moreover, in the previous approaches the location of the momentum and energy sources is only justified within the small volume of the arc region compared to the reactor volume.

To overcome these inconveniences, a more sophisticated model of the electric arc is proposed in this work. The force distribution used in the CFD calculation is obtained after direct calculation of the arc positions in time.

2. Theoretical model

Figure 1 shows the electrode configuration. Three cylindrical electrodes of length L and radius r_c are arranged with a 120° symmetry around the vertical z-axis in such way that their tips are on a circumference of diameter D and their axis form an angle α with respect to the z-axis.

The arcs are established between the electrode tips and they are assumed to be conducting wires with uniform properties along their length and having constant cross section S. No constraint is imposed on the arc shape whereas its maximum length is limited. This assumption is justified by energy balance considerations: the electric power dissipated in the arc must achieve a certain value to sustain the discharge and simultaneously it must be lower than the maximum electric power supplied by the electric source.

The arc deformation is governed by the dynamic equation that takes into account the magnetic interaction of the arc with itself, the other arcs and the electrodes or Lorentz force $\mathbf{F}_L$ and the drag force $\mathbf{F}_D$ due to the

relative motion of the arc with respect to the gas surrounding it. Thus, the forces applied on an element of the arc with length *dl* is written as:

$$\rho\, dlS\ddot{\mathbf{x}}=\mathbf{F}_L+\mathbf{F}_D\,, \tag{1}$$

where the Lorentz force is given by

$$\mathbf{F}_L=I\,(\mathbf{dl}\times\mathbf{B}) \tag{2}$$

with *I*, the electrical current across the arc and **B** is the magnetic field.
The drag force $\mathbf{F}_D$ is expressed as

$$\mathbf{F}_D=-C_D\frac{1}{2}\rho_g\,\dot{\mathbf{x}}_2\,A\mathbf{n}\,. \tag{3}$$

In this formula, C_D is the drag coefficient, ρ_g is the density of the cold gas surrounding the arc, *A* is the cross-sectional area of the element of the arc and **n** is a unitary vector in the direction of the element motion. An explicit scheme of equation (1) is used to calculate the evolution in time of the arc motion.
The algorithm is described as follow: At a given initial time t_0, the arc configurations (positions and velocities) are defined and a cold gas velocity distribution is fixed as well as the thermodynamical properties of the fluid and the arcs. In each time step, the intensities are estimated, the Lorentz and Drag forces along the arcs are calculated and the arc position is updated by solving equation 1.
Once the new position and velocities are known, the extinction condition is verified using the arc power which is expressed in terms of the product of the current intensity and the arc length. If the extinction conditions are satisfied, the position and velocity of the arc are restarted setting the arc geometry as a straight segment joining the corresponding electrode tips and the velocity distribution from the corresponding one of the cold gas.
After each time step, the points composing the arc are rearranged equidistantly along the arc improving the accuracy of the algorithm.
In order to obtain a Lorenz force field, the volume which contains the arc region is discretised in small cells $\Delta r\Delta\theta\Delta\phi$. In each time step, the Lorentz force along the wire is mapped on this discretised space and stored as a function of the index (*i*, *j*, *k*) of the cell. Once the time evolution is finished, the spatial distribution of density of the Lorentz forces is obtained by time averaging of the storage data and dividing by the cell volume. The field is expressed in terms of spherical harmonics to better show the angular dependence:

$$\langle\mathbf{F}_L\rangle=\frac{1}{T}\int_0^T\mathbf{F}_L(\mathbf{r},t)dt=\sum_{l=0}^{\infty}\sum_{m=-l}^{l}\mathbf{f}_{lm}(r)Y_{lm}(\theta,\phi) \tag{4}$$

where the coefficients $\mathbf{f}_{lm}$ are calculated by the expression:

$$\mathbf{f}_{lm}=\int_{4\pi}d\Omega\langle\mathbf{F}_L\rangle Y_{lm}^{*}(\theta,\phi) \tag{5}$$

At present stage, experimental values have been used to close the model. The maximum arc length and the arc density was determined after examination of the ultrahigh-speed camera films [3].
A previous sensibility study has been made with the aim to establish the dependence of the final Lorentz force distribution with the initial conditions, with the number of points that compose the arcs and electrodes and with the number of cells used to obtain the distribution.

3. Results

Figure 2 (left) shows a typical arc picture seen from the bottom of the reactor (plane *XY*) obtained by an ultrahigh-speed cine-camera 'NAC' (7000 frames/s) in argon plasma. The theoretical calculation obtained assuming that the gas involving the arcs remains stationary is plotted in figure 2 (right). In the case of argon, the calculation compares very well with the experimental data in spite of the simplicity of the model.

Moreover, theoretical results allow to take a tri-dimensional outlook of the motion of the arcs which is impossible to obtain under experimental conditions due to the inaccessibility to the plasma region. This idea appears clearly illustrated in figure 4 which contains two projections of the same calculation than in figure 3 on the planes *XZ* and *YZ*. We have observed that the elongation of the arcs in the vertical direction is at least as important as the radial displacement originating very complex forms whose XY projection shows S-shapes and occasionally the presence of boucles justified by a helicoidal pattern. Another characteristic is the strong curvature of the arc around the electrodes due to the strong magnetic interaction in the vicinity of the electrode tips.

The series in spherical harmonics show the angular dependence of the force distribution. As example, figures 5 and 6 show the series at l = 0, 1, 2 and 3 for the radial and axial Lorentz forces obtained as explained above versus the radial distance divided by the parameter *D*. The figures correspond to high (10^3 kg/m^3) and low (10^{-1} kg/m^3) arc mass densities, respectively. Hence, the first one represents an ideal case with a quasi-stationary triangle-type arc configuration and it should be compared with the results published by Ravary *et al* [2].

In the quasi-stationary case (fig. 5), the functions take non-zero values for radial values between 1/4 and $3^{1/2}/4$. The radial force distribution is mainly positive with a maximum centered around 0.29 whereas the axial force distribution is negative showing a minimum at the same position. When the density decreases, the arc deflection is increased and the distribution is spread to a larger radius. Simultaneously, the sign of the terms f_{lm} oscillate with the parameter *l* being positive when *l* is even for the radial force and negative for the axial component distribution.

4. Conclusions

An improved model describing the motion of the arcs has been reported which allows to generate a time-averaged Lorentz forces field. The results derived let us described more accurately the momentum transfer in the arc region. The model shows good agreement with the experimental data, however some improvements are needed in terms of energy balance. So far, the model does not take into account the temperature description along the arcs and the radiative emission. In a next step, this arc submodel will be implemented in a CFD code in order to better describe the momentum sources due to the arc presence in the arc zone.

Abstract
NRL has developed a number of hollow cathodes to generate sheets of high energy electrons, culminating in a 'Large Area Plasma Processing System' (LAPPS) based on the electron beam ionization process. In this work, we discuss (1) a large area (0.5 m x 1 m) plasma with a comparably large substrate stage and (2) various materials modification tests on smaller (20 cm x 30 cm) systems, both complemented by time-resolved, *in situ* plasma diagnostics (mass spectrometry, Langmuir probes, cathode currents). The materials' modification tests consist of polymeric material (photoresist) and silicon removal, and also nitriding of stainless steel. Results of *ex situ* materials analysis are used to qualify the processing capability and plasma source.

1. Introduction

Conventional discharges (such as dc/rf glows, capacitive, ECR, ICP) directly heat electrons with externally applied fields to ionize the gas, which results in a significant loss of input power to low-energy gas excitation processes rather than plasma production (ionization or dissociation). Hence, plasma electron temperatures are typically multiple electron volts, which translates to an environment of high plasma potentials (> 10 V), sheath drops and ion isotropy at surfaces. Plasmas produced by electron beams (e-beams) are quite different than conventional discharges. When a high energy beam of electrons passes through a gas, its dominant energy loss process is ionization of the gas followed by dissociation and finally inelastic excitations. Secondary electrons are created over a wide energy spectrum but cool rapidly through collisions with the background gas and thus the plasma electron temperature is low. Moreover, the direct ionization mechanism makes this plasma production process extremely efficient when compared to conventional plasma discharges. These attributes coupled with the independence of plasma gas composition and uniform scalability make e-beam produced plasmas well suited for materials applications, from surface activation of fragile polymer substrates to high energy reactive ion etching of hard semiconductor materials.

Electron beam ionization has been shown to be both efficient at producing plasma and scalable to large area (square meters). Fernsler [1] and Manheimer [2] *et al.* have discussed the detailed physics behind the plasma production mechanisms, which agree with *in situ* experimental measurements [3,4]. More recently, a broader view of e-beam produced plasmas was presented [5] to illustrate both the fundamental aspects and the range of plasma source configurations being investigated for various applications. This work reports on the recent experimental progress of some of the applications that are being pursued for materials' surface modification, and the development of a large area plasma processing system (LAPPS).

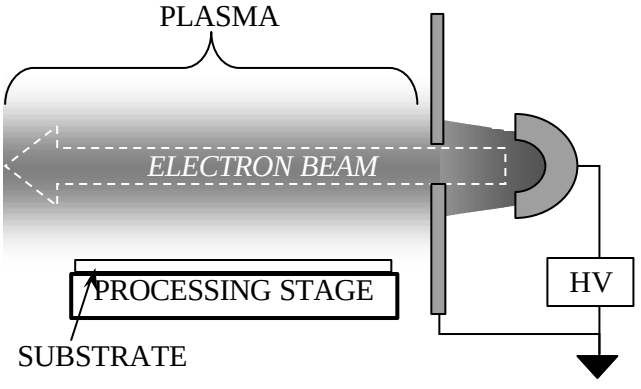

Figure 1 Electron-beam generated plasma in materials' processing arrangement.

2. Experimental Details

Generally, these systems consist of a pulsed, planar plasma generated by a magnetically collimated sheet of 2-3 kV, < 1 mA/cm^2 electrons injected into a neutral gas background (oxygen, nitrogen, sulfur hexafluoride, argon) with typical operating pressures in the range of 20 to 150 mtorr. The arrangement of the planar plasma processing

* Email: darrin@ccs.nrl.navy.mil
† ONR/ASEE Postdoctoral Research Fellow

system is shown in Fig 1. The processing stage (or substrate holder) was introduced laterally, to the 'face' of the plasma sheet. In the application tests, the stage was introduced at the middle of the 25 cm x 50 cm plasma sheets. Stage construction consisted of a 13 cm diameter electrode with grounded support structures, rf-bias and temperature control capabilities. All construction materials were stainless steel and machinable ceramic. Linear hollow cathodes operating at –2 kV with 0.5-10 ms pulse lengths and various duty cycles generated the electron beam, as described previously [6]. External magnetic fields of 150-165 Gauss collimated the e-beam to maintain a localized ionization region. All chambers were metal in construction and had base pressures below $2x10^{-6}$ Torr.

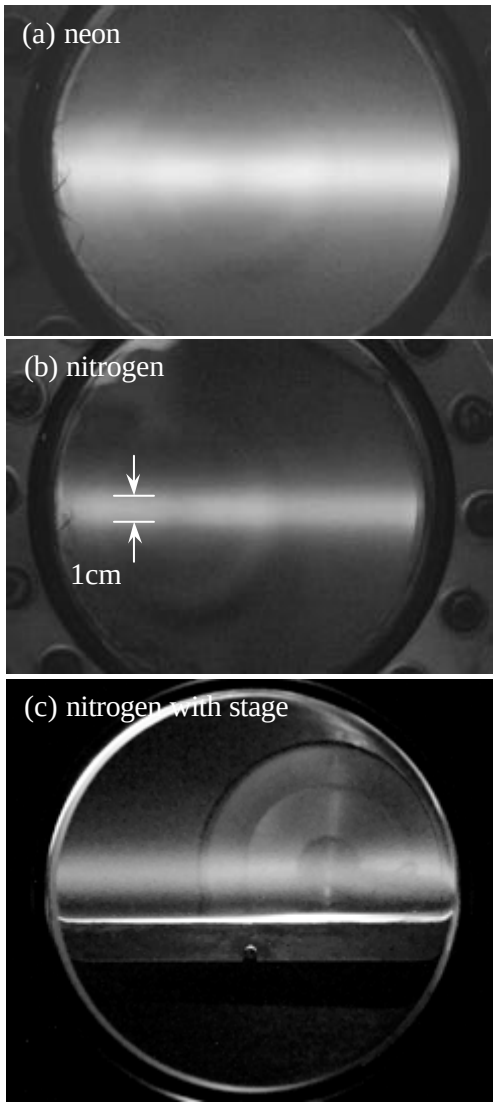

Figure 2 Large area plasma without stage (a) neon (b) nitrogen and with stage in (c).

The LAPPS hollow cathode was 50 cm long, providing a 50x1 cm^2 electron beam source which traveled the length of the chamber (~ 100 cm). Figure 2 shows a portion of this plasma source, photographed through a 20 cm viewport. In these photos, the 50 cm dimension goes into the page surface while the 100 cm dimension was along the page. The 1 cm beam thickness is marked in (b). Figure 2 shows a (a) 75 mT neon plasma, (b) 55 mT nitrogen plasma, and a (c) 55 mT nitrogen plasma with the large processing stage introduced. The processing stage was slightly wider than the plasma surface (~60x90 cm^2), and made similar to the smaller stages previously discussed. The stage is grounded in Fig 2c. With a cathode operating current of <100 mA/pulse, these plasmas had densities of $2\text{-}6x10^{11}$ cm^{-3} in the beam channel.

Applications

Polymeric and semiconductor samples were cut into ~ 1cm^2 pieces and mounted on the processing stage, which was positioned 1 cm from the e-beam edge. The processing stage was water cooled to keep the temperature at 20±4°C. In the etching tests, an rf-induced dc bias level (bias voltage) was applied to the processing stage to vary the incident ion energies during the plasma pulse. Etch rates (ER) were determined through stylus profilometry (Tencor P-10) or scanning electron microscopy (SEM) analysis and are calculated from the total plasma exposure time and not the actual laboratory time. The polymeric materials were industry standard negative or i-line photoresists, etched in O_2/Ar gases. Figure 3a shows the ER dependence for a negative resist as the bias voltage was varied. In these tests, plasmas were formed in 55 mTorr of pure oxygen (80 sccm). A moderately linear relationship between bias voltage and ER was seen, which increased strongly at higher voltages. Diluting the working gas with argon (keeping a fixed bias voltage of –50 V) resulted in the ER behavior shown in Fig 3b. From this data, the ER remained fairly constant until the oxygen percentage dropped below 20%. The total pressure of the mixtures was 65 mT, increasing to 70 mT for pure Ar.

Figure 4 shows the results from a feature cleaning test carried out in a pure O_2 plasma with a –50 V bias on the processing stage. The samples came from a commercial ashing process for Cu vias on i-line resist, shown by the SEM photo in Fig 4a. This photo shows residual spires coming from around the edges of a 300 nm via, left behind after the [cleaning] ash process. The SEM photo in Fig 4b shows removal of the residual spires after the 3-minute e-beam plasma exposure.

Mixtures of Ar or O_2 with SF_6 gas were used to etch crystalline <100> silicon. Figure 5 shows the measured etch rates with respect to the bias voltage for O_2/SF_6 mixtures (55/8 sccm) and Ar/SF_6 mixtures (35/15 sccm). Operating pressures were 60 and 70 mT, respectively. The O_2 plasma shows an increase in ER at V_{bias} > -100 V, but was generally an order of magnitude smaller than the Ar plasma for lower energies.

The Ar plasma ER varies strongly with the applied bias level, starting out slowly before rapidly increasing to ~ 1 micron/min at V_{bias} = -125 V.

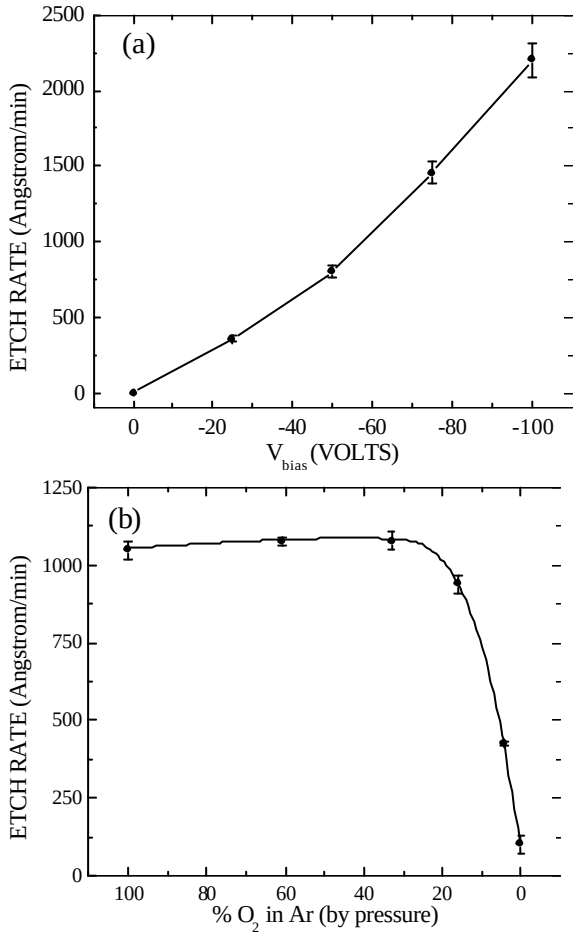

Figure 3 Etch rates of resist material with respect to (a) V_{bias} and (b) % O_2.

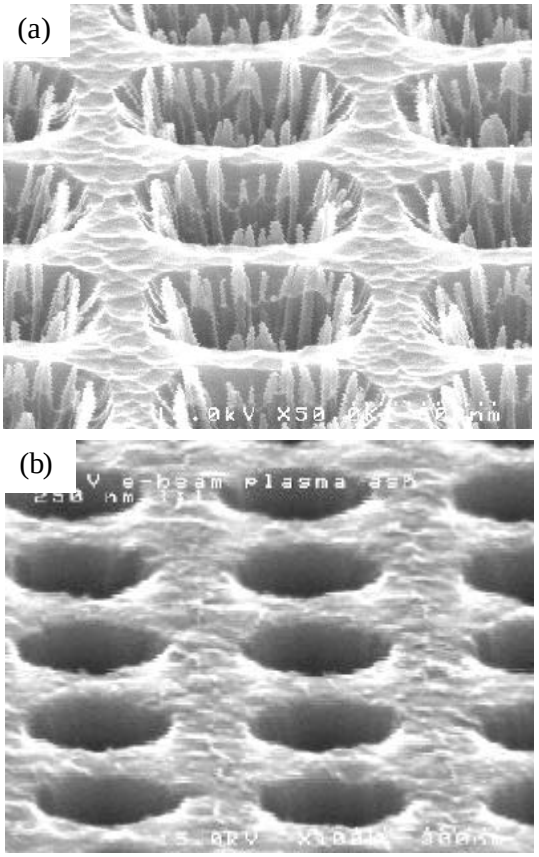

Figure 4 300nm via structures after standard ash process (a) before and (b) after a –50V_{bias} etch in O_2 plasma.

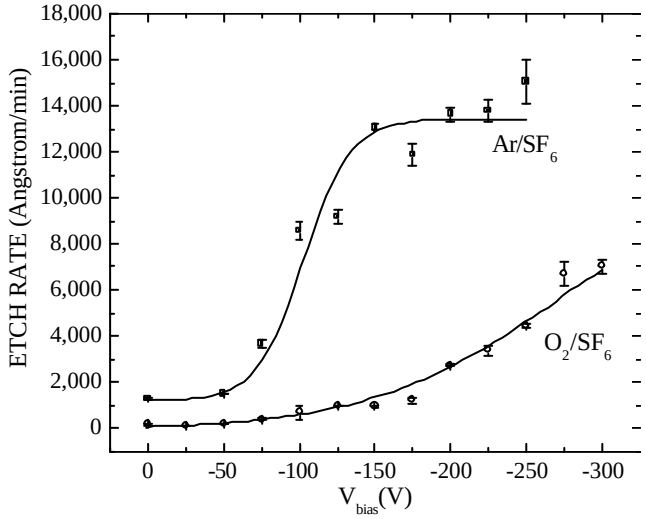

Figure 5 Silicon etch rate with respect ot bias voltage for O2/SF6 (55:8) and Ar/SF6 (35:15) mixtures.

Plasma nitriding experiments were carried out on 316 stainless steel substrates. Sample tiles, approximately 5x5 cm^2 were cut from a 02 cm thick plate and polished to a surface roughness of 7 nm. Samples were then heated to 340-440°C and cleaned in an Ar/H_2 plasma for 30 minutes before being exposed to a 60 mTorr N_2 plasma for 1.4 hours of plasma exposure. A constant –100 Vdc signal was applied to the processing stage for the cleaning and nitriding periods. Samples were allowed to cool, removed from vacuum and analyzed in the SEM to determine the surface nitride thickness. At 340°C, a 0.75 micron thick layer was observed, increasing to 1.3 microns at 400°C and 2.1 microns at 440°C. An Arrhenius plot of these growth rates and temperatures, gives a surface activation energy of 85 kJ/mole (0.90 eV) for this process.

The plasma diagnostics presented here consist of Langmuir probe and ion mass spectrometry measurements as discussed in References [3] and [4], respectively. The ion mass spectrometry provides information of the relative ion fluxes and their energies at the substrate, while the Langmuir probe data, taken at the center of the e-beam, provides plasma density, electron temperature and plasma potential. For the nitrogen plasma discussed previously, the temporally resolved plasma characteristics from these measurements are shown in Fig 6 for a 3 ms e-beam pulse with the grounded sampling stage (mass spectrometer in this case) located 1 cm away from the e-beam. The data shown in Fig 6 illustrates: (a) a rapid ion flux build up, particularly for the more energetic ions; (b) low energy atomic ions with a long decay after the e-beam was turned off but a rapid decay of molecular ion flux; and (c) a steady-state plasma electron densities of $2x10^{11}$ cm^{-3} and temperatures of 0.4 eV. The variation in ion flux with gas composition was also measured and is shown in Fig 7 for mixtures of argon and nitrogen. This data was time averaged and integrated over the entire ion energy distribution before normalized to the total ion flux. The dominant ion fluxes (N^+ and Ar^+) show a linear relationship with the concentration of their parent gas pressure.

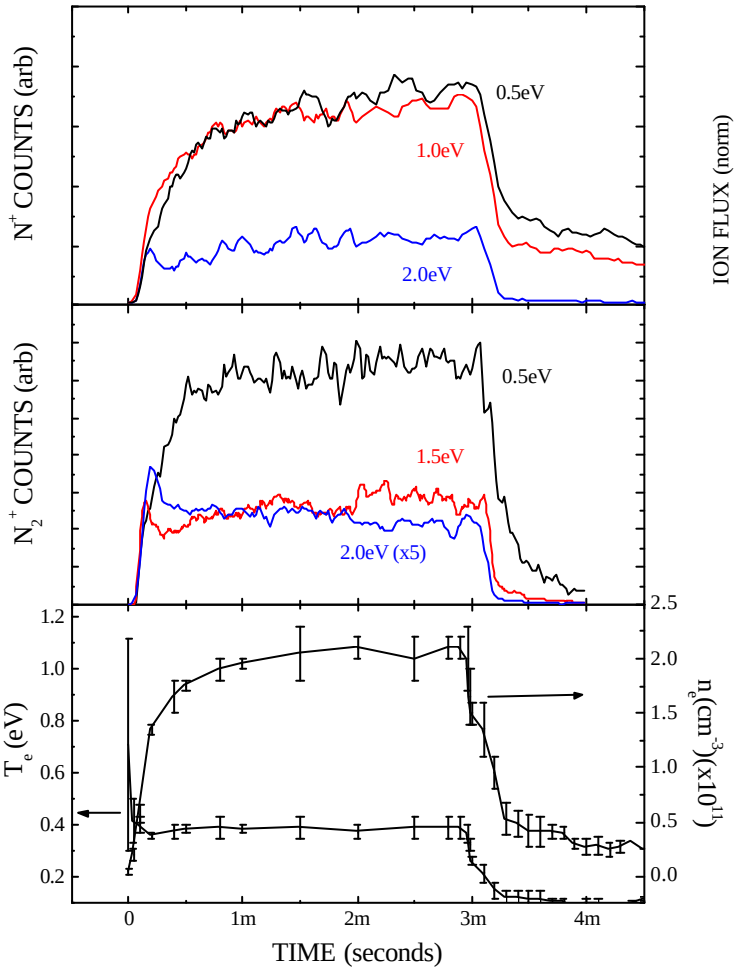

Figure 6 Temporally resolved ion fluxes and bulk plasma characteristics. Flux measurements are made at fixed energy analyser settings. The plasma pulse length was 3 ms.

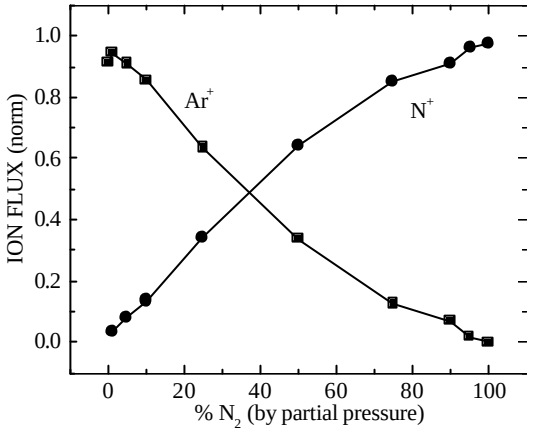

Figure 7 Normalized fluxes of dominant ions to a grounded stage for mixtures of Ar and N_2.

3. Results and Discussion

The photographs in Fig 2 illustrate the plasma localization, differences due to gas composition and the independence of the processing stage location in e-beam produced plasmas. Since the e-beam is the ionization source, the plasma is independent of the chamber and stage design (as long as the e-beam isn't intercepted). The visible light emission from the Ne plasma shows a diffusive nature of the emission while the N_2 plasma is strongly confined to the e-beam channel. Uniformity tests on this LAPPS are presently underway. The additional plasma characterizations shown in Fig 6 illustrate the plasma characteristics of very low electron temperatures, which result in a high density plasma with low plasma potentials and ion energies. From Fig 6, an abrupt peak in the electron temperature and the higher energy ion fluxes characterizes the ignition of the plasma, before the steady-state condition is reached.

The demonstrated reactive ion etching of polymer materials shows strong promise in terms of precise control of a typically isotropic, uncontrollable process that relies strongly on the desorption of carbon monoxide (CO) from the surface. From the data shown in Figs 3 and 4, etching of the resist material was an ion-driven process in an environment that contained an abundance of atomic oxygen neutrals. The direct

correlation between ion energy and material removal in Fig 3 shows that some ion energy was in fact necessary to remove material and the removal was not automatic (exothermic) in the presence of atomic oxygen (especially since the ER drops to nearly zero with no bias energy). In other plasma sources, organic material removal is considered a chemical process dependent only on the atomic oxygen flux to the surface. Thus, ion energy is not considered important in sources where the plasma potential exceeds 10 V. However, plasma potentials in e-beam produced plasmas are only 1-5 V, so initial ion energies are greatly reduced. Without some sort of additional activation (ion energy, temperature) the desorption of volatile etch species does not progress at measurable rates. This control of ion energy down to extremely low values provides additional benefits, as shown by the via residue removal in Figure 4. These test structures provided a much more rigorous test for process anisotropy and showed submicron feature evolution in an otherwise isotropic process. With only very fine (~ 50 nm) residues within small features, any process isotropy would quickly destroy the feature profile. Instead, a clean removal of the residuals left behind was seen, leaving the via structure intact. The results of Figure 3b suggest the plasma source produced a large reactive neutral flux, as the ER remained constant while the feedstock gas source of atomic oxygen was reduced. The ER was therefore not neutral-limited, until the molecular gas percentage fell below 20%.

The reactive ion etching of silicon also showed promising results in terms of material removal rates. At a moderate bias voltage of –125 V, the ER of ~ 1 micron/min for the Ar/SF_6 mixtures is comparable to other high density plasma etchers, although the ER for the O_2/SF_6 mixtures was much remarkably lower. Although the amount of SF_6 was lower in the O_2/SF_6 plasmas, the order of magnitude difference in ER at low energies was surprising, since a strong chemical etch component was expected. This lower ER is more indicative of a SiO_2 sputter yield at these energies, which is reasonable for the more dilute SF_6 plasmas. In this case, the flux of etchants was dominated by oxidizing species, which caused the surface to become more like SiO_2 prior to etching. In addition, the selectivity of SiO_2 over Si using SF_6 at these ion energies should be appreciable, although preliminary tests using an SiO_2 mask showed no selectivity in this plasma chemistry further suggesting SiO_x removal as the limiting step. The Ar/SF_6 plasma chemistry conversely showed a strong chemical and reactive ion etch components from 0-50 V and 50-150V, respectively, and then leveled out at the –275 V energy threshold.

While the present plasma nitriding experiments require further composition analysis, the results are impressive for an non-optimized plasma process. These growth rates are comparable with standard techniques[7] using rf and dc discharges, but the activation energy is low, making this process attractive from the thermal management standpoint. This low activation energy is believed to be due to the large fluxes of atomic nitrogen ions and neutrals produced in these plasmas. With the additional kinetic energy from the applied dc voltage, the atomic ions are the likely critical species for this process, considering that it is atomic nitrogen that adsorbs and diffuses into the bulk. These preliminary results along with the ion specie control demonstrated in Fig 7 makes the development of this process very lucrative from a materials standpoint.

Summary and Conclusion

Electron-beam produced plasmas were readily produced and used in various materials processing applications. The etching of photoresist in O_2/Ar chemistries demonstrated a high degree of control over a predominantly chemical process. This control is attributed to the low incident ion energy from the plasma source, which resulted in better ion energy control with an externally applied rf bias. Similarly, the silicon etching in O_2/SF_6 and Ar/SF_6 mixtures showed a stronger ion-driven component than expected. The limiting step in the O_2/SF_6 mixtures was the removal of an SiO_x layer, due to the large amounts of atomic oxygen generated by the plasma. The use of Ar/SF_6 mixtures eliminated the SiO_x layer as a limiting step and dramatically increased the Si etch rate, at both low and high ion energies. Further tests will focus on feature evolution and anisotropy of these etching conditions. The stainless steel nitriding experiments were encouraging, resulting in both high growth rates (~ 1 micron/hr) and low activation energy (85 kJ/mole), for a large area process. The fact that e-beam produced plasmas in diatomic gases supply predominantly atomic ions to the workpiece makes it an attractive system for plasma nitriding of materials.

The reactive ion etching and nitriding experiments discussed here were proof-of-concept tests for the practicality of applying e-beam produced plasmas to more widespread applications. In order to take full advantage of the versatility of these plasma sources, a more comprehensive design-of-experiments is necessary to optimize the processes. The fact that modulated plasmas offer additional process space not always accessible with continuous plasma sources is another area to be further explored. These plasma sources offer considerable flexibility for modifying materials, although only a few of the attributes have been

investigated thus far. The absence of high plasma electron temperatures (and therefore large plasma potentials) allows a variety of processing conditions without sacrificing flux of reactive charged or neutral species. This work demonstrated important attributes of ion energy control and damage-free etching possibilities, versatility of ion flux through gas composition, competitive nitriding rates and scalability within an actual plasma processing environment.

Plasma-solid interaction in electronegative plasma: comparison of self-consistent particle modelling and experiments

R. Hrach, V. Hrachová, M. Vicher, J. Šimek

Department of Electronics and Vacuum Physics, Faculty of Mathematics and Physics
Charles University, Prague, Czech Republic

Abstract
The contribution presents results of the computer experiment describing the interaction of electronegative plasma with immersed substrates. The simulation was performed under several approximations; the most important was the simplified geometry of substrates. The results of simulation were compared with experimental data obtained in mixtures of oxygen with rare gases.

1. Introduction

The inert gas plasma-solid interaction is of fundamental importance for the understanding of plasma properties and also of a great interest in plasma diagnostics. Especially the electrostatic probes are indispensable diagnostic tools in low-pressure weakly ionised plasma. On the other hand, the interaction of chemically active plasmas with immersed substrates takes part in many plasma technological applications such as plasma processing of materials or plasma-assisted deposition processes. The resulting influence of the both inert gas and chemically active plasmas on immersed materials depends not only on plasma properties but also on properties of processed solid substrates.

In various plasma chemical technologies electronegative gases are widely used. The presence of negative particles, i.e. the application of three-component plasma containing electrons and both positive and negative ions, significantly alter the formation of sheath and in this way modifies the fluxes of charged species to the substrate. However, the detailed description of physical and chemical processes taking part during plasma-solid interaction in such kind of plasma is very difficult. The same holds for the interpretation of results of probe diagnostics in plasmas containing negative ions, especially for higher pressures and/or for dynamic measurements.

For these purposes the computational approach seems to be very convenient. Typical method of modelling used in such studies is the fluid simulation technique (e.g. [1]-[4]), however more detailed results can be obtained with the help of various particle simulation codes (e.g. [5]-[7]). In our laboratory the combination of two types of particle simulation codes, i.e. the molecular dynamics and Monte Carlo methods, PIC-MC, was used for the modelling of the spatial and energy distributions of charged particles during the plasma-solid interaction. Results of the modelling were compared with experimental data obtained in our laboratory, too. The present contribution is devoted to the discussion of these problems.

2. Experimental technique

The structure and properties of the discharges in oxygen are intensively studied for a very long period. In our laboratory the measurements were performed in a positive column of the dc glow discharge, as this part of discharge is often used in various plasma technologies as oxidation, etc. The plasma consisted of oxygen both pure and in the mixtures in rare gases – argon, neon and helium. Main parameters of our experiments were the total pressure of the mixture, the composition of mixtures and the discharge current. In recent measurements an attention was devoted to the properties of substrates/walls, as it was found that they influence the plasma properties profoundly. For the study of plasma properties various diagnostics were used – optical, microwave and probe diagnostic. Some experimental results obtained in our laboratory can be found e.g. in [8]-[11].

It is well known that in the positive column of glow discharge in oxygen there exist at higher pressures two forms of discharges – so-called T and H forms. These two forms differ in the axial electric field (H-form with higher value of this parameter and T-form with the lower one), in the plasma parameters, in the instabilities and in the emitted spectrum. In order to simplify further computer analysis only such experimental data were used, where due to the discharge parameters the transition between these two forms was not observed.

3. Experimental results

In our experiments the positive column of dc glow discharge was studied in the mixtures of rare gases containing oxygen in the pressure range 67 to 800 Pa. All plasma parameters were measured in the dependence on the discharge current 5-30 mA (for discharge tube with diameter 0,02 m).

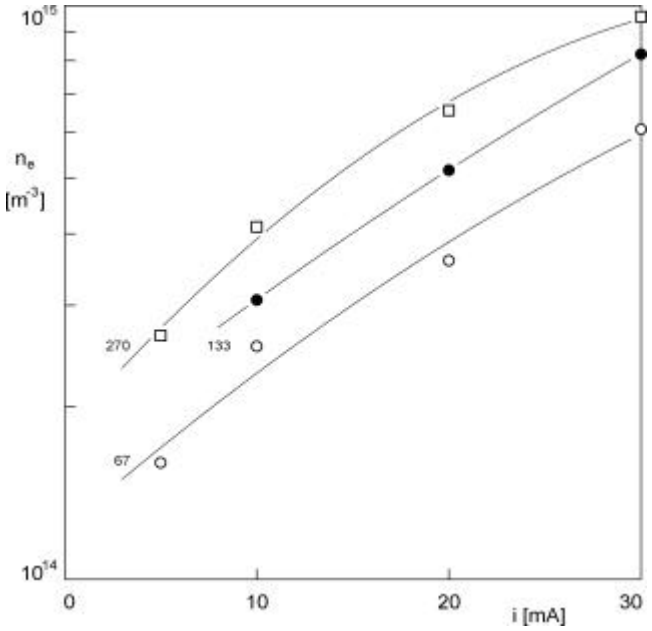

Fig. 1: Measured electron density n_e in the pure oxygen plasma in the dependence on the discharge current. Parameter: pressure of oxygen in limits 67-270 Pa.

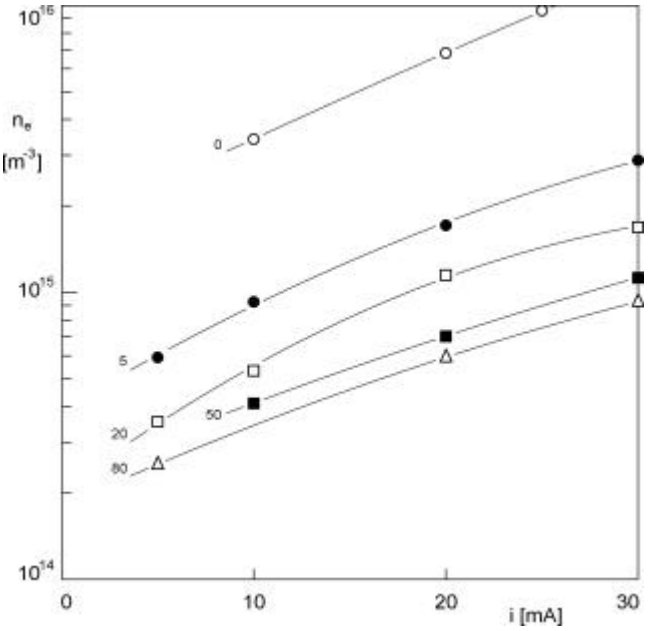

Fig. 2: Measured electron density n_e in the O_2-Ne plasma in the dependence on the discharge current i. Pressure 800 Pa. Parameter: concentration of neon in the mixture (0-80 %).

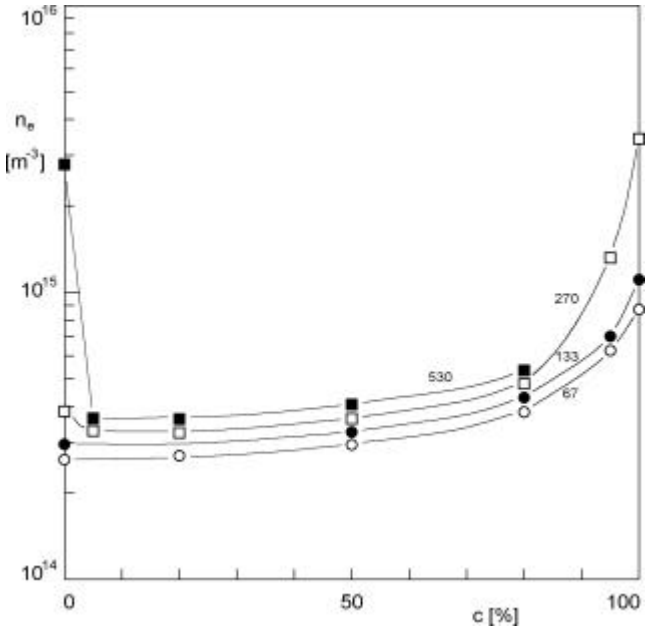

Fig. 3: Measured electron density n_e in the O_2-Ne plasma in the dependence on the concentration of neon in the mixture c. Discharge current 10 mA. Parameter: pressure of the mixture in limits 67-530 Pa.

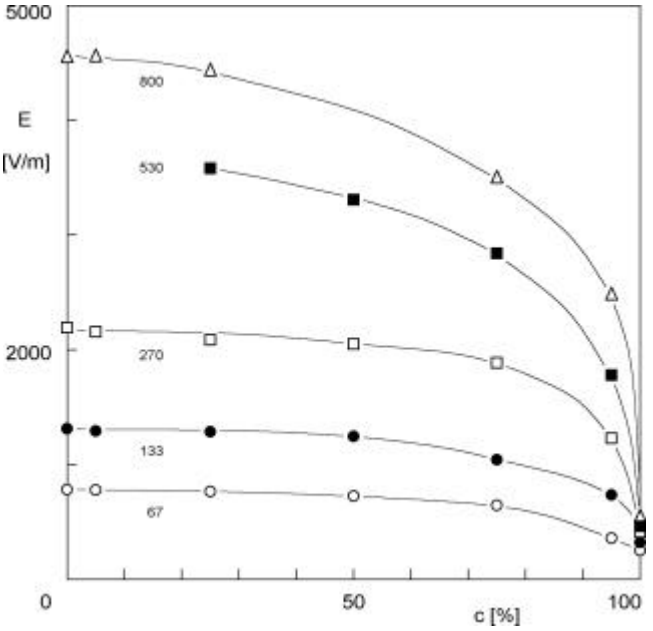

Fig. 4: Measured intensity of axial electric field E in the O_2-Ar plasma in the dependence on the concentration of argon in the mixture c. Discharge current 20 mA. Parameter: pressure of the mixture in limits 67-800 Pa.

In Figs. 1-3 the dependences of electron densities n_e determined by microwave toroidal resonator method on various experimental parameters are shown. The measurements were performed both in the pure oxygen and in the mixtures of oxygen with rare gases, the composition of the mixture being one of experimental parameters.

In Fig. 3 (characteristics for 530 Pa and partially for 270 Pa) it can be seen the starting transition between the T and H forms. Influence of this transition can be observed in the change of axial electric field and collision frequency. Except of the mentioned curves in Fig. 3 all other characteristics in Figs. 1-4 correspond to the H form of the oxygen discharge.

In Fig. 4 the dependence of the intensity of electric field in the positive column of discharge is presented in the dependence on the pressure and composition of oxygen-argon mixture.

The experimental results shown in this section as well as some other characteristics were used as input data and data for testing of results of our computer experiment described in the following section.

4. Computer experiment

In our computer experiment the main attention was devoted to the role of negative ions in the formation of sheath region in the vicinity of metal substrate immersed into plasma. For this purpose several models were prepared. All models are based on the particle simulation approach, i.e. on the combination of deterministic molecular dynamics simulation (for the determination of movement of charged particles in both external and local electric fields) and stochastic Monte Carlo simulation (for the description of interactions between charged and neutral particles). The models differ in the geometry and in the techniques of calculation of self-consistent local forces.

The standard model (see e.g. [12] and [13]) is limited to very simplified geometries of studied problems. There exist three modifications of this model: all modifications are one-dimensional in space and differ in geometries – planar, cylindrical or spherical – corresponding to various forms of probes or substrates. The coordinates used in these modifications are either *1d2v* (planar geometry) or *1d3v* (cylindrical and spherical geometry), where *d* denotes the number of spatial and *v* the number of velocity coordinates. The coordinate system consists of the *x*-axis, perpendicular to the surface of metal substrate (zero being on the surface of substrate), and two or three velocities – v_x and either v_r (i.e. $[v_y^2 + v_y^2]^{1/2}$) or v_y and v_z.

The simulation technique used in this standard model was PIC-MC. The simulations were performed for O_2-Ar plasma in the positive column of dc glow discharge. The model consists of following parts:

Source of particles:

Undisturbed plasma consisting of individual species with concentrations obtained from the macroscopic kinetics model of plasma chemistry of the mixture oxygen-argon. Present simulations were performed for the Maxwell distribution of charged particles with different temperatures of electrons and ions, T_e and T_i.

Interactions:

For electrons elastic collisions in the plasma were supposed, charge transfer interactions for Ar^+ ions and inelastic interactions for all other particles. The interactions were characterised by mean free paths $?_j$, different for various species *j*, the data were taken from [14].

Trajectories of particles:

The trajectories of particles between scattering events were simulated by the molecular dynamics technique, i.e. the Newton´s equations of motion were solved by means of a leap-frog scheme. The scattering of particles was simulated by the Monte Carlo technique – random free paths were derived from the mean free paths $?_j$ with the help of null-collision method and the types of individual interactions were generated statistically, too.

Force calculations:

The most time consuming part of molecular dynamics simulations is the self-consistent calculation of the force $\boldsymbol{F}_i$ acting on the *i*-th particle. This force generally consists of two parts, $\boldsymbol{F}_i^{ext} + \boldsymbol{F}_i^{loc}$. The external force $\boldsymbol{F}_i^{ext}$ is given by voltage bias of the probe/substrate, the local force $\boldsymbol{F}_i^{loc}$ is a sum of Coulomb forces of all interacting particles. The direct summation depends on the number of particles *N* as $O(N^2)$, therefore in our standard model the PIC method was applied with the linear interpolation of resulting space charge. The distribution of electric potential was derived by solving the Poisson equation with boundary values equal to plasma potential (undisturbed plasma) and probe potential (metal electrode).

Time steps:

The leap-frog method handles the problem discretely in time with constant time step $?t$. In order to speed-up calculations, in static regime different time steps for electrons and heavier particles were used, 10^{-11} to

10^{-12} s and 10^{-8} s. However, in dynamic regime this technique cannot be used and all calculations ought to be performed with the electron time step and thus the simulation was extremely time consuming.

Advanced computational techniques:

In order to obtain more efficient code some rather complicated techniques were used – variable numbers of particles increasing during the simulation (especially in dynamic regime) and variable statistical weights of particles depending on their positions (for cylindrical and spherical geometries).

The model was written in FORTRAN 90 programming language and processed by the PC computer. The total number of particles in the model treated simultaneously was $1 \cdot 10^5$ to $6 \cdot 10^6$ (in some special cases even more than $1 \cdot 10^7$) and the number of time steps was about $1 \cdot 10^5$.

5. Results of modelling

The simulations were performed both in static and dynamic regimes. As a result of simulation the spatial and temporal evolutions of velocity and angular distributions of basic types of charged species in the plasma were derived. The studied questions were: the influence of negative ions, the influence of gas pressure and the influence of probe form in the discharge tube versus the properties of sheath region.

Influence of negative ions:

In order to study the influence of negative ions on the plasma properties in the vicinity of the substrate various relative concentrations of oxygen negative ions were introduced – ranging from 0 to 100 %. The steady-state potential distribution in the sheath is shown in Fig. 5. The spatial distributions of basic charged species in the discharge (electrons, Ar^+ and O^-) are demonstrated in Fig. 6. It can be seen, first, that the presence of negative ions influence profoundly the sheath thickness, and second, that the electrons and negative ions behave diversely in the sheath region

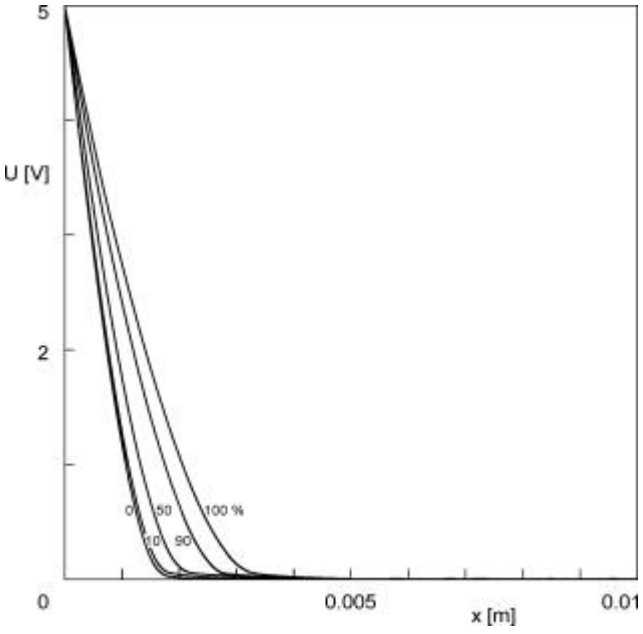

Fig. 5: Distribution of electric potential U(x) in the distance *x* from the substrate. Relative concentrations of negative species Γ^-/e: from 0 % (only electrons) to 100 % (only oxygen ions).

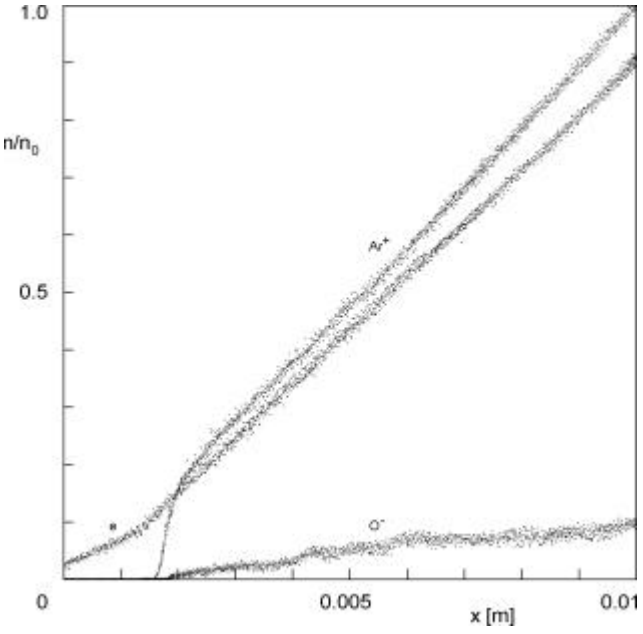

Fig. 6: Distributions of normalised concentrations of individual charged species *n(x)* in the distance *x* from the substrate. Relative concentration of negative particles Γ^-/e: 10 %.

Dynamic properties:

Further studied problem was the dynamics of processes in the sheath, i.e. the temporal evolution of the sheath region after the application of step voltage, both without and with the presence of negative ions in the mixture. Some preliminary results are shown in Fig. 7. When changing from negative to positive bias, as a response the positive ions are ejected from the vicinity of the substrate and the negative charge is attracted.

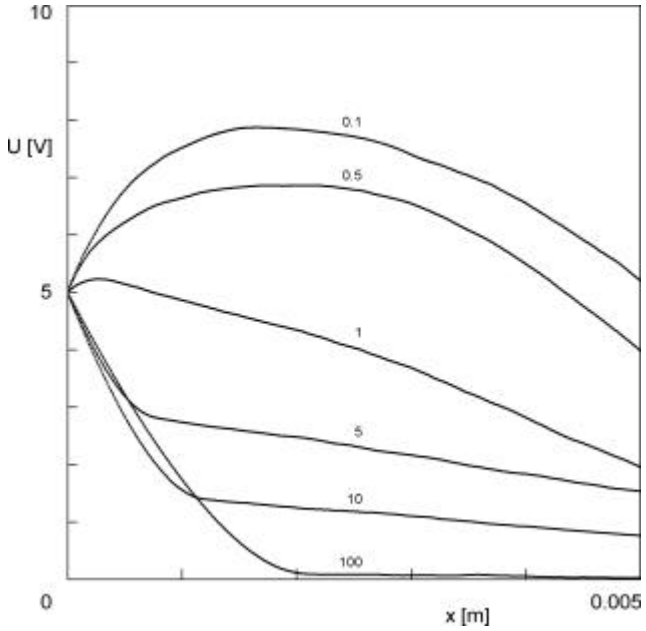

Fig. 7: Dynamics of the potential distribution near the substrate *U(x)* for positive bias. Parameter: time of simulation in microseconds – in limits 0.1 to 100 μs. Relative concentration of negative species 50 %. Total number of charged particles $2 \cdot 10^7$.

Dynamical simulations were performed for various composition of plasma. It was found that the sheath dynamics is extremely sensitive to the concentration of negative ions. For electropositive plasma the typical switching time was found to be in the order of nanoseconds, while in the case of electronegative plasma the process is slowed down – see the time scale in Fig. 7. It was observed that due to strong electrostatic interaction, even the electrons in electronegative plasma reach their stable positions in several tens of microseconds, the switching process being dependent on the relative concentration of negative ions.

Pressure dependence:

Most simulations were performed at 133 Pa. Beside them some results were obtained at higher or lower pressures. It was found that both the composition of the mixture and its total pressure influence the sheath region and the fluxes and distributions of particles striking the substrate. The computer experiment enabled us to discuss the importance of various physical mechanisms and processes influencing the plasma-solid interactions by means of the macroscopic characteristics of plasma.

6. Discussion

The main part of simulations was performed with the help of standard one-dimensional models in three geometrical modifications. However, due to the basic physical restrictions only the simulation of plasma-solid interactions with spherical geometry of substrate enables us to obtain quantitative results, for another two geometries only qualitative results can be derived and the relative changes of plasma parameters can be discussed.

For this purpose an attempt was made to extend the simulation of plasma-substrate interaction to more complex systems. Two new models with geometries both spatially two-dimensional (*2d2v* and *2d3v*) and fully three-dimensional both in space and velocities (*3d3v*) were prepared. These models differ from the previous one-dimensional models only in their geometries, other parameters of the models were standard ones: Maxwell distribution of charged particles in undisturbed plasma with superimposed drift, movement of charged particles influenced by self-consistent electric field created by these particles and by bias of metal substrate, limited set of interactions for electrons, positive ions and negative ions consisting of elastic scattering, inelastic scattering, charge transfer interactions and Coulomb interactions. The simulation was performed again for the O_2-Ar plasma with changing concentration of oxygen and changing total pressure of the mixture.

Besides the particle simulation methods another simulation technique is tested in our laboratory – the hybrid modelling combining the particle techniques with fluid modelling. We hope that this approach can help to create more efficient computer codes without significant loss of their preciseness.

During the modelling it was observed that the pressure of the gas mixture influences the sheath region in two opposite ways (see Fig. 8):

?? due to the increase of the pressure the mean free paths of all particles are reduced and their concentrations are increased, the change in mean free paths becoming more significant – approx. linear compared to slower dependence of charged particle concentrations observed experimentally and demonstrated in Figs. 1-3

?? the decrease of mean free paths enlarges the region of disturbed plasma (1), while the increase of particle concentrations reduces it (2).

However, in accordance with known experimental data it was found that the sheath thickness is decreasing with increasing pressure of the gas mixture in the discharge (3). From it follows that the sheath region is more sensitive to changes of particle concentrations than to other parameters.

In similar way the dependence of other characteristics of the sheath region on the parameters of simulation can be found. Although the basic results can be obtained with the help of 1D models, the more precise analysis can be performed on the basis of models in more dimensions only.

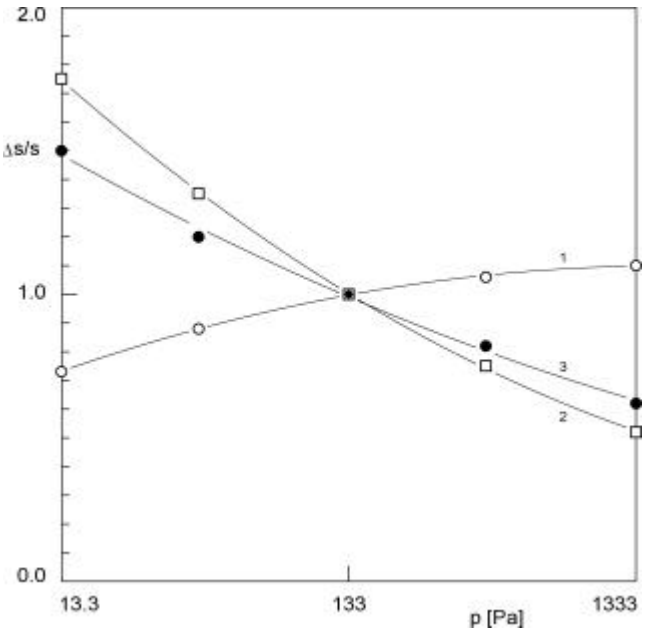

Fig. 8: Dependence of the relative sheath thickness *?s/s* on some plasma parameters – mean free paths (1) and concentrations of charged particles (2).

Abstract: Porous SiO_2 (PS) is being investigated as a low dielectric constant material for the insulator in interconnect wiring due to its inherent low mass density. In this paper, the results from a computational investigation of the fluorocarbon plasma etching and post etch processing (polymer stripping and seed layer deposition) of PS and non-porous SiO_2 will be discussed. We found that mass normalized etch rates of PS depend on L/r_0 (the ratio of polymer thickness to pore size). Polymer removal is less efficient for materials having larger pores due to the shadowing of ion fluxes.

Introduction

As microelectronics device sizes continue to shrink, there is a propensity for increased delay in signal propagation in interconnect wiring due to higher resistances in the lines and larger capacitance between the lines.[1] In this regard, low dielectric constant (low-k) materials are being investigated as the insulator in interconnect wiring. Low-k dielectrics can be broadly classified as organic and inorganic.[2] Organic materials such as polytetrafluoroethylene (PTFE) and parylene are etched in oxygen based high plasma density systems (O_2/Ar and O_2/N_2).[3,4] Inorganic dielectrics typically use SiO_2 based materials which are etched in fluorocarbon plasmas. Porous SiO_2 (PS) is one such inorganic low-k material. PS typically has pore sizes of 2-20 nm and porosities of 20-70%.[5] The dielectric constant is reduced in proportion to the mass density, which in turn is proportional to the porosity.[1,5] The residual polymer layer which remains after etching in fluorocarbon plasmas results in high contact resistance and defects at the metal-silicon interface and so needs to be removed.[6] Oxygen containing plasmas are extensively used for such post-etch cleaning and for photoresist stripping.[7,8]

In this work the etching of PS will be discussed using results from a two-phase algorithm incorporated into the Monte Carlo Feature Profile Model (MCFPM).[9,10] The MCFPM was integrated with the reactor scale Hybrid Plasma Equipment Model (HPEM), which provides the energy and angular distributions of the neutral and charged species incident on the wafer.[11] A surface reaction mechanism was developed for fluorocarbon etching of SiO_2 and was applied to the investigation of etching of PS in fluorocarbon plasmas. Dielectric etching is the first step of process integration, which includes polymer and resist removal, and metal deposition. In this regard, surface reaction mechanisms for etching of organic polymers in oxygen plasmas were developed and applied to the stripping of the residual fluorocarbon polymer. Copper ionized metal physical vapor deposition (IMPVD) was then investigated as a surrogate to deposition of a barrier coating or seed layer.

Reaction Mechanism

A schematic of the reaction mechanism for etching of SiO_2 in fluorocarbon plasmas is shown in Fig. 1. Etching of SiO_2 proceeds through the formation of an overlying fluorocarbon polymer layer [nominally $(C_2F_4)_n$)] on the SiO_2.[12] C_xF_y radicals are the precursors to polymer formation following low energy ion activation of surface sites.[13] Upon delivery of activation energy to the polymer-SiO_2 interface the SiO_2 reacts with the fluorocarbon species in the polymer to release etch products such as COF_x. In

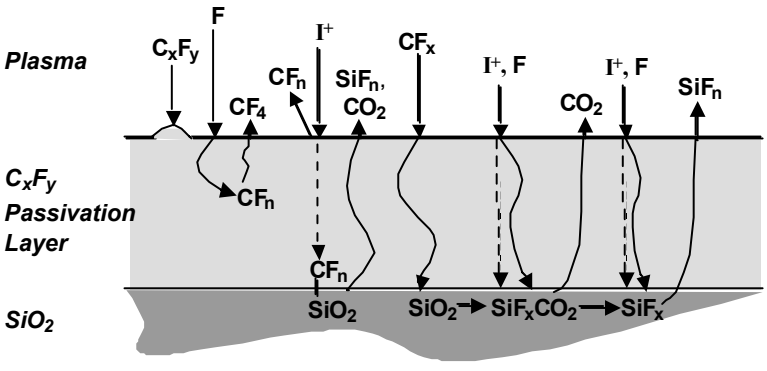

Figure 1 – Schematic of the surface mechanism for etching of Si and SiO_2 in a fluorocarbon plasmas.

this process, the polymer is consumed.[14] The polymer layer is also consumed by energetic ion sputtering and F atom etching.[15] The polymer layer is the main inhibitor for the transport of species and activation energy to the SiO_2 interface. As such the etch rate generally scales inversely with the polymer thickness.[16] A very thin polymer layer also produces low etch rates due to the lack of reactants in the overlying layer. Si is less reactive with the polymer, being unable to consume the carbon, and so produces thicker films and lower etch rates.

The removal of organic materials using oxygen plasmas has widespread applications in semiconductor processing.[3,17,18] The primary etching specie in oxygen plasmas is the O radical. Molecular oxygen has little effect on the etch characteristics at low temperatures.[8] The primary etch products are CO_2, CO, COF_x in the case of fluorocarbons and CO_2 and H_2O in the case of hydrocarbons. [7] Little etching of fluorocarbon polymers occurs in the absence of ion bombardment even with plentiful oxygen radicals.[3] This suggests an ion-activated pathway for the etching of these materials.[8,19] For example, the etching of photoresist by an oxygen ion beam is limited by the availability of oxygen radicals at low pressures and by ions at higher pressures.[17] Generally etch rates increase with increasing oxygen mole fraction in mixtures and substrate bias. Joubert *et al* suggested a reaction pathway whereby oxygen radicals first adsorb on the polymer interface. The etch reaction on the surface is then initiated by the impact of energetic ions.[7] The etch mechanism was modeled here as a multi-step ion-assisted process. When the polymer is passivated by oxygen radicals, ion activation produces volatile etch products,

$$P(s) + O(g) \rightarrow P^*(s) \quad (1)$$
$$P^*(s) + I(g) \rightarrow COF_x(g), \quad (2)$$

where P is the polymer, P* is the activated polymer complex, I is the ion, O is the etchant and COF_x is the volatile gas product.

Calibration and validation of the fluorocarbon surface reaction mechanism was performed for three fluorocarbon chemistries; C_2F_6, C_4F_8 and CHF_3. The logic is that the reaction mechanism is an intrinsic property of incident gas phase reactant species and surface resident species, and so should not depend on the source of gas phase fluxes. The choice of the fluorocarbon plasma (e.g., CHF_3 vs. C_4F_8) may determine the magnitude and energies of individual species fluxes but the reaction mechanism should be the same. The reaction mechanism was validated by comparison to experiments by Oehrlein *et al* using an inductively coupled plasma, with an rf substrate bias.[5] Validation for the oxygen reaction mechanism was performed varying compositions Ar/O_2 gas chemistries. The reaction mechanism was validated by comparison to experiments by Standaert *et al* using an inductively coupled plasma, with an rf substrate bias and is discussed elsewhere.[3]

PS is modeled as stoichiometric SiO_2 having vacuum pores, characterized by an average pore radius and porosity. The pore locations were randomly distributed in the numerical mesh used by the MCFPM with a Gaussian distribution of radii having probability $p(r) \sim \exp(-((r-r_0) / \Delta r)^2)$, where r is the radius of the pore in, r_0 is the average pore radius and Δr is the standard deviation. Algorithms were developed to distribute the pores so that the network of pores was independent until the desired porosity was achieved. We acknowledge that many PS films incorporate some organic groups and may have interconnecting pores. We intend to address these issues in future work. For brevity only CHF_3 plasma etching will be further discussed here.

Etch, Clean and Fill of Solid and Porous SiO_2

Process conditions for the ICP reactor used for the cases discussed here are 10 mTorr CHF_3 at 50 sccm flow rate, and 1400 W ICP power at 13.56 MHz with a substrate bias at 3.4 MHz, producing a self-bias from 0-150 V. Fluxes to the center of the wafer obtained from the HPEM were used as input to the MCFPM. The ions included in the mechanism are CF_3^+, CF_2^+, F^+, F_2^+, $C_2F_4^+$, $C_2F_5^+$ and CHF_2^+, H^+ and H_2^+. The polymerizing radicals are CF_2, CF, C_2F_3 and C_2F_4. Typical reactor properties (power deposition, and density of CHF_3 and CF radicals) as obtained from the HPEM are shown in Fig. 2. Power deposition is restricted to the top of the reactor to within the skin depth of the electromagnetic field, a few cm. The large electron density (10^{11} cm^{-3}) highly dissociates the CHF_3 feedstock, which is injected through an annular nozzle and is pumped at the bottom of the reactor. As a result of the high degree of dissociation, the major fluorocarbon radicals are CF and CF_2.

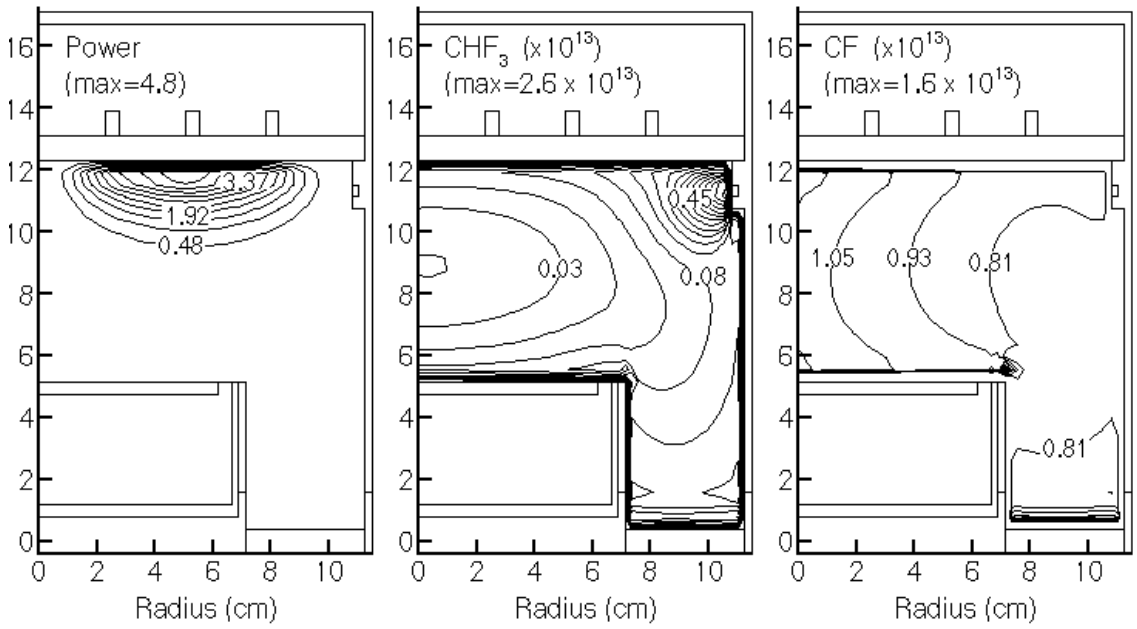

Figure 2 – Power deposition (W/cm^3); and density (cm^{-3}) of CHF_3 and CF radicals for base case operating conditions. (10 mTorr CHF_3, 10 mTorr, 50 sccm, 1400 W).

Etch rates as a function of self-bias for PS and solid SiO_2 are compared to experiments in Fig. 3. Three materials are examined: solid SiO_2; PS having 2 nm pores and 30% porosity; and PS having 10 nm pores and 58% porosity. The solid SiO_2 etch rates were used to validate the reaction mechanism. The etch rates generally increase with increasing self-bias voltage as the incident ion energy increases. The onset of etching at around 40 eV for both solid SiO_2 and PS occurs as the polymer thins and energy is delivered more efficiently through the polymer to the SiO_2 interface. At low biases and low ion energy the polymer thickness is large as there is insufficient ion energy to sputter the polymer and low energy ion activated polymer deposition is rapid. The polymer thickness is large and etching is negligible. At large biases the polymer thickness is sub-monolayer and there is insufficient passivation to etch the SiO_2 layer and hence the increase in etch rate flattens out. The etch rates for the PS are typically higher than that of conventional SiO_2 due to the inherent lower mass densities of the porous materials. The threshold bias is similar for both solid and porous materials, an indication that the fundamental reaction chemistries are the same.

To. isolate the effect of pores on etch rates, a corrected etch rate is defined as C = ER(1-p), where p is the porosity of the substrate and ER is the gross etch rate. C is, effectively, the etch rate per unit mass. If pores had no kinetic effect on etching, the C of PS should be the same as the ER of solid SiO_2. Corrected etch rates as a function of self-bias are shown in Fig. 3(c). For a pore radius of 2 nm and porosity of 30%, the C of PS is greater than the ER of solid SiO_2, which implies that the presence of pores enhances the etch rate. In contrast, for 10 nm pores and 58% porosity, C of PS is less than the ER of solid SiO_2, which implies that the

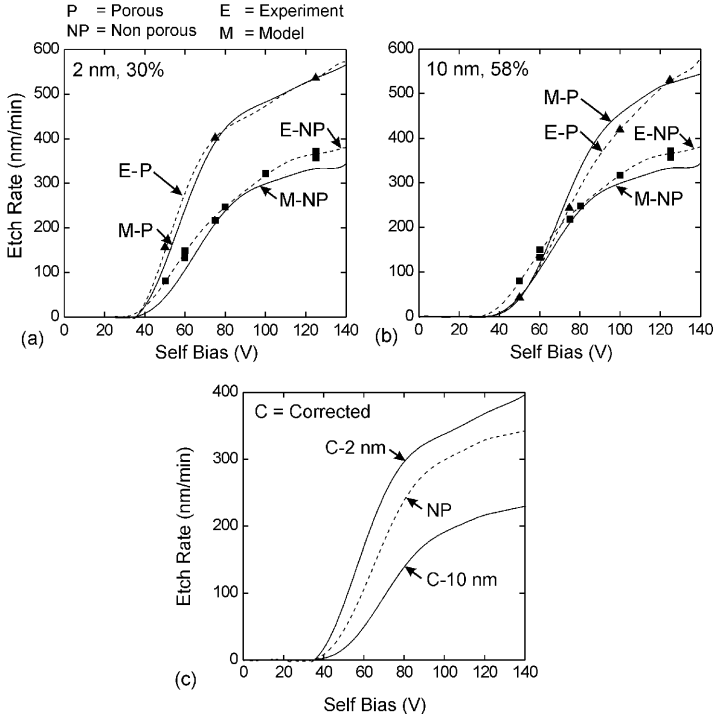

Figure 3 – Etch rates as a function of self-bias voltage for 2 nm and 10 nm porous SiO_2 compared to the solid material. C denotes the mass corrected etch rate.

presence of pores decreases the mass removal rate. Similar dependencies were obtained in the experiments.[5]

In highly polymerizing environments, such as fluorocarbon plasmas of this type, the steady state polymer thickness, L, can be many nm. As the PS is etched, pores are exposed and are filled with polymer. If $(L/r_0) > 1$, as in the 2 nm case, then the increase in local polymer thickness due to pore filling is fractionally small. The end result is that C is not significantly different from the ER of solid SiO_2. The increase of C above ER is likely due to the angle of incidence for chemically enhanced sputtering, on the average, being closer to the optimum at $\approx 60^{\circ}$ due to the non-planar surfaces of the exposed pores. If $(L/r_0) < 1$, as is the case for the 10 nm pores, pore filling produces significantly thicker polymer at local sites. This effect is more pronounced for larger pores and larger porosities. The increased polymer layer thickness decreases delivery of activation energy to the SiO_2 interface and hence reduces the etch rates. The larger pores also have SiO_2 – polymer interfaces at shallow angles to the ion-flux or which do not have line-of-sight to the incident ions. These locations therefore rely on reflected species for activation, which typically have lower energies. The end result is a reduced etch rate per unit mass and C is less than the ER of solid SiO_2.

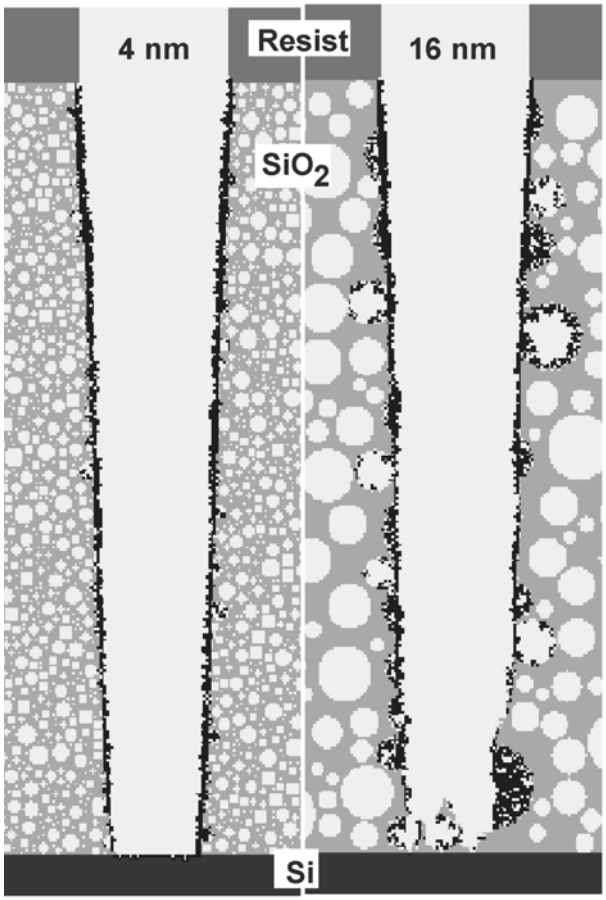

Figure 4 – High Aspect Ratio features (0.1 μm width) etched through 4 nm and 16 nm PS to a Si layer below. The dark material on the SiO_2 is polymer. The larger pores fill with polymer as they are exposed.

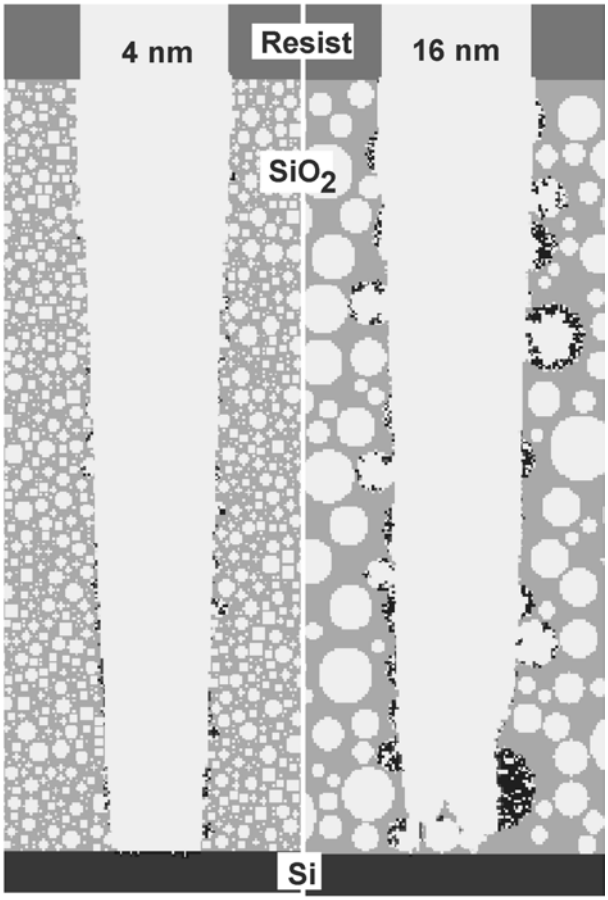

Figure 5 – High Aspect Ratio features (0.1 μm width) in 4 nm and 16 nm PS following stripping of post-etch polymer using an Ar/O_2 plasma. The dark material on the SiO_2 is polymer. The larger pores are more difficult to clean due to unfavorable view angles to the ion flux.

These trends are shown in Fig. 4 where high aspect ratio trenches (0.1 μm width) of SiO_2 having a hard-mask and Si underlayer are shown for 4 nm and 16 nm PS having 50% porosity. The large pores exposed at the surface by the etch fill with polymer, producing, on the average, a thicker overall polymer layer. These scalings depend both on the pore size and the porosity and are discussed elsewhere.[20] Note that a few marginally opened pores are lined with polymer, providing additional challenges to later removal of the polymer.

Stripping of the fluorocarbon polymer was investigated for Ar/O_2 plasmas in an ICP reactor having a substrate bias. Process conditions for the case discussed here are 4 mTorr, Ar/O_2=99/1 at 40 sccm, and 600 W ICP power at 13.56 MHz with a 20 W substrate bias at 3.4 MHz. The stripping was performed long enough for the cleaning process to reach asymptotic limits. The profiles from Fig. 4 after cleaning are shown in Fig. 5. The stripping was more efficient with the smaller pores, whereas significant polymer remained with the larger pores where ≈24% of the residual polymer remained. The cleaning was ineffective with the larger pores at the bottom of the trench due to the lack of view angles for the incident ions. This results in poor activation of the polymer preventing subsequent removal of the polymer. On the other hand, the formation of polymer at these sites during fluorocarbon etching results from low ion energy activation and is more dependent on the neutral fluxes. The neutral flux being more isotropic in nature is less sensitive to the pore morphology. The complex pore morphologies are easily filled with polymer but the cleaning of PS using traditional dry etching techniques is less efficient.

To complete the interconnect wiring, following cleaning, vias are lined with a barrier coating, deposited with a seed layer and finally, in the case of copper, filled by electrodeposition. Copper IMPVD onto the cleaned vias was modeled as a surrogate to deposition of a barrier coating. Surface reaction mechanisms developed by Lu *et al* were adapted to address filling of PS materials.[21] Process conditions for the case discussed here are 1.0 kW ICP power, 0.3 kW magnetron power, 40 mTorr Ar buffer gas and 150 sccm flow rate.[21] The coated vias for solid SiO_2 and PS with 16 nm average pore radius are shown in Fig 6 for equal deposition times. The process conditions were maintained such that a void-less uniform coating is obtained for the solid SiO_2. In the case of PS, there was no conformal coverage leading to the creation of gaps and voids in the barrier coating. This effect was more pronounced for PS with larger pores. Non-uniform coverage, similar to inefficient stripping, was due to the unfavorable view angles of the incident reactant fluxes caused by the complex pore morphologies.

Figure 6 – High Aspect Ratio features (solid SiO_2 and 16 nm PS) lined with copper following IMPVD. The dark material on SiO_2 is copper. Presence of pores creates or initiates voids. This effect is pronounced for larger pores.

Concluding Remarks

Etching mechanisms for solid and porous SiO_2 were discussed based on results from a computational investigation using reactor and feature scale models. Predictions for etch rates as a function of self-bias were validated by comparison to experiments for porous and solid SiO_2. The functional dependence of etch rate on porosity in large part depends on the ratio of L/r_0, polymer thickness/pore radius. Kinetically inhibited etch rates result when this ratio is small as pore filling increases the average polymer thickness. The limiting value of L/r_0 is a function of both porosity and average pore radius. Stripping of residual fluorocarbon polymer for solid SiO_2 and PS was studied in Ar/O_2 plasmas. Unfavorable view angles for incident ions in complex porous structures lead to inefficient cleaning. Copper IMPVD inside vias was investigated following cleaning as a surrogate for deposition of barrier coatings or seed layers. The presence of pores created or initiated gaps or voids in the barrier coating.

Abstract:

Cathode erosion in a plasma arc cutting system using oxygen as the plasma gas was investigated. Ejection of molten cathode material was the major erosion source. Proposed erosion mechanisms are high ion flux during ignition and aerodynamic drag forces during arc shutdown. Copper and silver were both used as cathode sleeve materials and had very similar erosion characteristics, however, silver sleeved cathodes had a much longer lifetime. The long lifetime appears to be due to different cathode failure mechanisms.

Introduction:

Cathode lifetime in plasma arc cutting, especially oxygen cutting, is limited because of erosion of the cathode material [1,2]. This limited lifetime increases cutting costs due to part replacement, maintenance, and potential damage to the processed material. Experiments were conducted in an attempt to identify major erosion sources as well as their causes. Several parameters of the cutting system were varied and effects on the erosion were determined qualitatively with high-speed video imaging and quantitatively by collecting eroded material. Once the cathode erosion sources and their physical causes have been identified, steps can be made to reduce the erosion rate and extend the overall lifetime of the cathode.

Experimental setup:

The cutting system used for this investigation is a Hypertherm HT2000 system. Major components of this system are a 200 amp power supply, a high frequency arc starter, a gas flow control console, and the torch. The cutting torch cathode consists of a 1.8-mm diameter hafnium cylinder set in a water-cooled copper sleeve. Plasma gas is introduced into the torch through a ceramic swirl ring at the base of the electrode. A copper nozzle directs the gas flow and shield gas cap completes the cutting torch. These standard cutting components are run with a rotating anode that is water-cooled to allow operation without the cost or byproducts from cutting material. Measurement of the arc voltage and current during operation is recorded. This setup is very similar to that used by Yin [1]. All of the major components and the electrical diagnostics are shown in Figure 1.

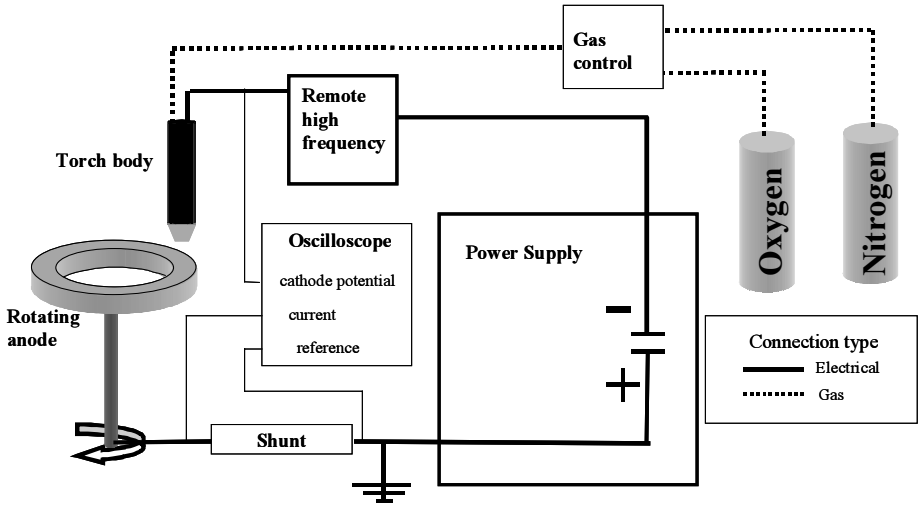

Figure 1. General experimental setup.

Modifications were made to the standard nozzle design to aid in the study of the cathode during arc operation. The first modification allows optical access to the cathode. In this modification scheme the shield gas cap is removed and 2 small holes are drilled into the nozzle. Sapphire windows are then cemented into the nozzle holes. These windows are placed nearly flush to the nozzle wall to minimize the effect on the gas flow through the nozzle. The windows have a diameter of 2.5 mm and are angled at 45 degrees to show the entire cathode surface [1]. A standard nozzle is shown next to this nozzle modification in Figure 2.

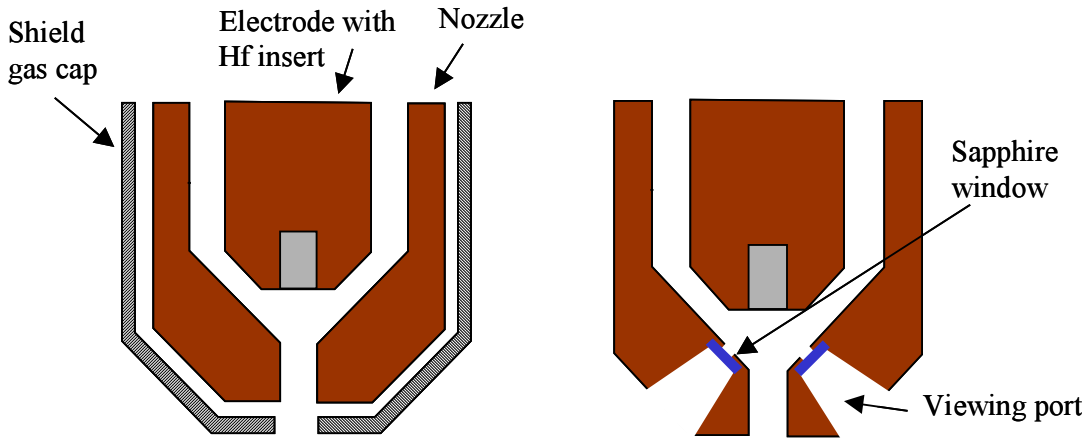

Figure 2. Nozzle modification for optical access to cathode.

Using this imaging system, pictures of the cathode during operation were obtained using a high framing rate system as well as a short exposure time system. A typical image of the cathode is shown in Figure 3. The round hafnium insert appears as an ellipse under the viewing angle. In the figure the hafnium surface is the bright ellipse, the extinguishing arc is visible and the round viewing window is highlighted.

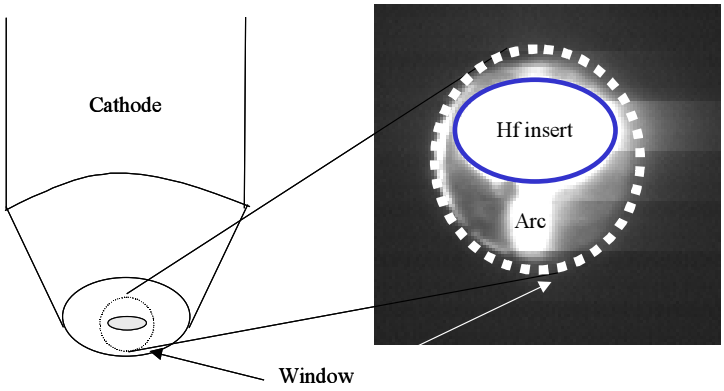

Figure 3. Typical cathode image during operation.

The qualitative erosion information from the cathode images was quantified using another nozzle modification to allow collection of eroded material. This modification has one window in the side of the nozzle. This window leads to a collection surface. Material eroded from the cathode should deposit on the collection surface if the ejected droplet has a radial velocity and hits the window. The collection surface is a segmented stainless steel tube that is moved during torch operation to allow time-resolved measurements of the erosion. The nozzle modification for mass collection and the collection surface are shown in Figure 4.

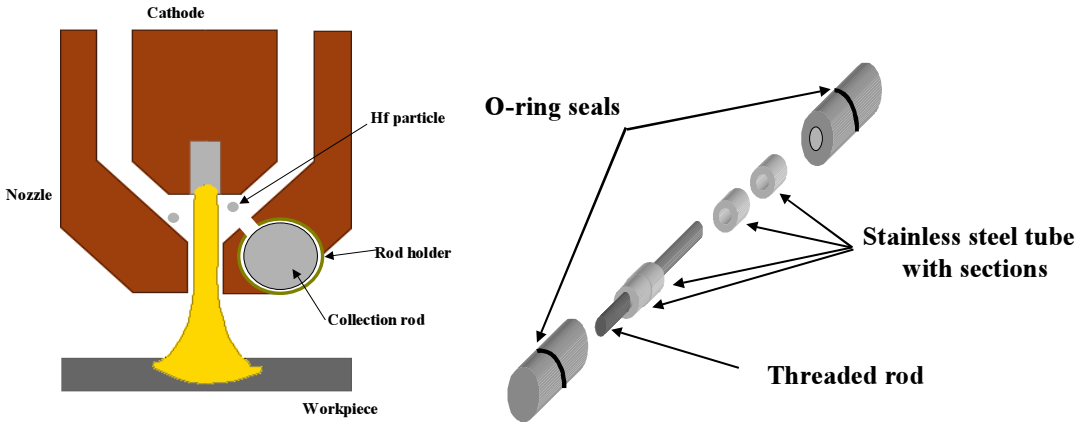

Figure 4. Mass collection system

This setup requires many starts of the torch to obtain a measurable amount of eroded material on the collection surface. We used 4 sections on the collection surface so we could look at 4 discrete time intervals. Once the deposit was collected for 400 torch starts, the mass of each section was determined with the deposit, then the deposit was removed and the mass of the cleaned collection section was measured. The difference was the mass of eroded cathode material.

The total cathode pit depth and the total mass lost from the cathode were also recorded as a means of measuring the erosion rate. Pit depth is the distance the hafnium insert has receded into the copper. It is measured as the distance from the lowest point on the hafnium surface to the top surface of the copper. Pit depth is similar to the cavity depth used by Nemchinsky [2].

The cathode imaging system was used to investigate the sources of the cathode erosion during arc operation. This system was used to study the effect of transients in the cutting cycle, such as arc start, arc shutdown and gas flow changes, on erosion. For the imaging experiments the arc was started, run for 2.5 seconds then shut down. This time was long enough for the voltage, current and nozzle pressure to reach steady values. Parameters that were investigated using this experimental technique were the current ramp-down during arc shutdown and the pre-flow gas type and flow rate. There were 2 available shutdown methods. The normal shutdown procedure for the cutting system has a current ramp down over a few hundred ms before the arc is completely extinguished. The other shutdown method is a fast current stop where the current decay occurs over the course of a ms. Standard torch operation begins with a pre-flow gas mixture of nitrogen and oxygen. The pre-flow mix is then switched to pure oxygen after 0.65 seconds. The pure oxygen is the cut flow gas. Mixtures of the pre-flow gas have been varied from pure oxygen to pure nitrogen; the total flow rate of the gases was also changed.

For the mass collection experiments, effects of specific operating parameters were considered and were based in part on observations of the cathode with the imaging system. The pre-flow gas configurations tested were the standard N2 and O2 mix and a low flow rate of O2 that showed the minimal number of ejections during the second and third time intervals. Normal and fast current shutdowns were compared using this characterization method and different cathode sleeve materials were investigated because of field observations that silver sleeved cathodes have extended life characteristics when compared to copper cathode sleeves.

Results:

A sequence of images from the high-framing rate camera is shown in Figure 5. These images have been taken immediately after the arc was extinguished using the fast current shutdown with a camera frame rate of 9000 frames per second. The frame when the arc is first completely extinguished was labeled as time zero. The first frame in the sequence shows the arc as it is extinguishing. As the pool cools, the bright spot representing the molten hafnium shrinks. There are three distinct droplet ejection events from the molten pool at 2.3 ms, 5.8 ms and 7.5 ms after arc extinction. This image sequence shows a typical erosion event. The erosion event shows distinct bright flares caused by the ejected molten particle.

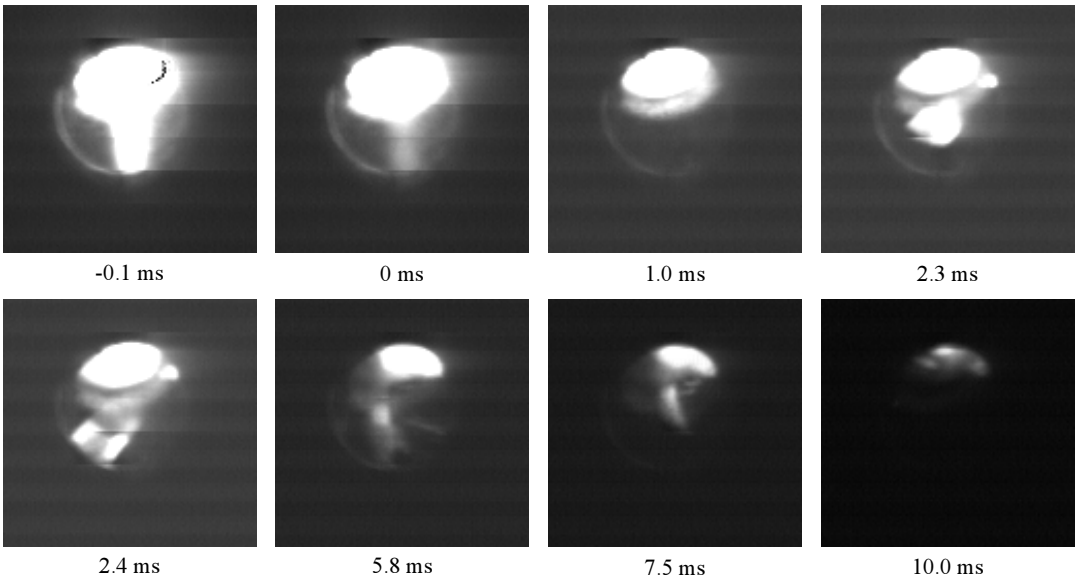

Figure 5. Cathode erosion after arc shutdown using 9000 fps.
Eroded droplets appear at times 2.3, 2.4, 5.8 and 7.5 ms.

These ejection events occurred at specific times during arc operation. For any arcing sequence, four specific ejection events have been identified. The first ejection occurs during the arc ignition within the first 0.2 seconds of operation. This ejection occurs when the arc root is very small and the current is being increased and the cathode just begins to melt. The second ejection occurs about 0.35 seconds after the arc is ignited. At this time the molten pool under the arc root is nearing the end of its expansion. The third ejection occurs at 0.65 seconds after the arc start and corresponds to the change in gas flow from the pre-flow to the cut-flow. The final ejection event occurs during the arc shutdown immediately after the arc has been extinguished. There were no observed ejections during the steady operation of the torch [1].

A significant difference was observed in the size and number of droplets that were ejected depending on the current shutdown method. The fast current shutdown produced many large particles while the normal shutdown was very clean. There was also an effect of the gas flow on the second and third ejections. As the pre-flow composition approached pure nitrogen the second ejection was no longer observed and the third ejection increased. When the composition was pure oxygen, the second ejection increased and the third ejection decreased. A pre-flow of pure oxygen at a flow rate of less than 19 slm led to the fewest number of particle ejections. There was no observed effect on the start up erosion events from the pre-flow gas that was chosen.

Mass collection experiments were performed based on the observed droplet ejection times from the imaging results. The collection surface was divided into four sections. The corresponding time intervals were 0.0 to 0.2 seconds which included the ignition ejection, 0.2 to 0.6 seconds which included the second observed ejection event, 0.6 to 1.0 seconds which would include the ejection during the gas flow change and 1.0 to 2.5 seconds which captured the steady state operation and arc extinction ejections. The results are shown in Figure 6 and are labeled according to pre-flow gas – shutdown type – sleeve material. The fast current shutdown is the dominant erosion source. If the controlled shutdown is used the arc ignition becomes the most important source.

Another interesting observation is shown in Figure 6. The collected particle sizes from the start and the stop erosion events are quite different. The particles collected during shutdown are much larger while the particles eroded during the arc start are more numerous and smaller.

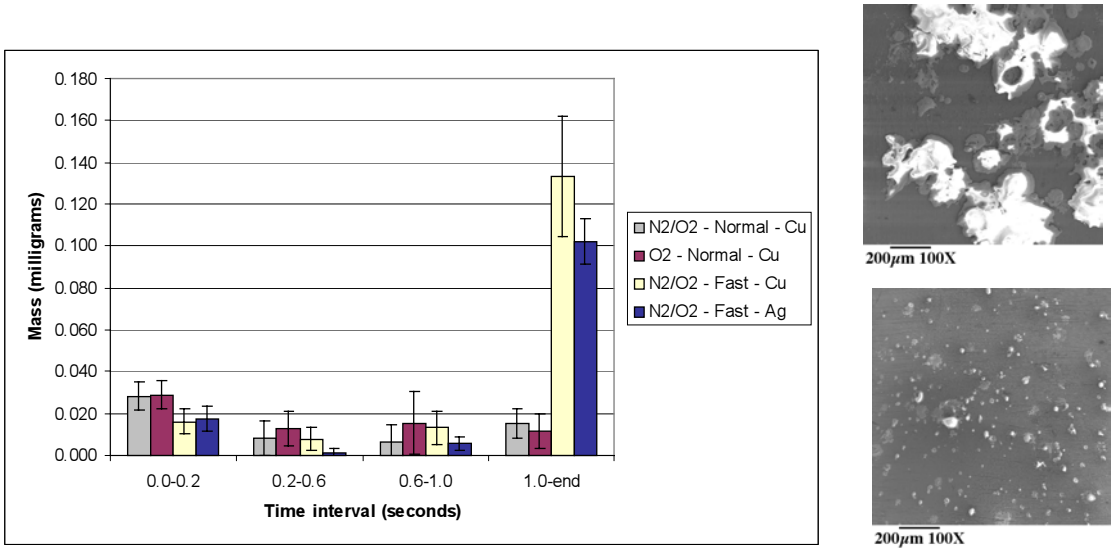

Figure 6. Mass collection results. Graph of cathode erosion using mass collection system (left). Legend shows pre-flow gas type – shutdown type – cathode sleeve material. Pictures of the large particles collected during arc shutdown (top – right) and the small particles collected during arc start (bottom - right)

For the silver and copper sleeved cathodes with fast current shutdown the pit depth erosion rate was very similar up to about 500 starts. At this point the copper sleeved cathode experienced rapid copper erosion that destroyed the cathode and the nozzle, erosion measurements were stopped at this point. Silver sleeved cathodes did not experience this rapid destructive erosion and the pit depth increased steadily for many more starts. In fact the rapid erosion of silver was never observed with this experimental method. The erosion rate determined from the pit depth is shown in Figure 7.

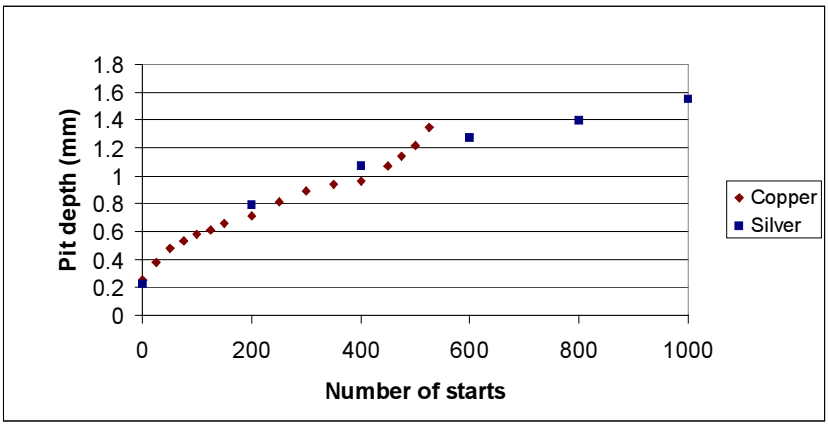

Figure 7. Silver and copper sleeved cathode erosion comparison

Discussion:

Ejection of droplets from the molten cathode surface is a major component of the total cathode erosion. From the visual observations there appear to be four important times during arc operation at which these ejections are occurring. Quantitative measurements show that the dominant erosion periods are the arc start and fast current shutdown. There were no measured effects of the pre-flow gas on the middle two ejection events as was observed with the imaging system. It may be that the total size of the ejection event is too small to be detected or the ejected particle trajectory may not lead to deposition on the nozzle wall.

The varied size and trajectory of the ejected droplets, as well as the arc conditions present during the various ejection times, point to different mechanisms causing the different ejection events. Yin proposed hypothesis for the two major sources of erosion [1,3]. During fast current shutdown the erosion is a result of aerodynamic forces and during the arc ignition the erosion is a result of high ion backpressure.

During the arc shutdown the primary difference between the normal and fast current ramp-down is the pressure in the nozzle. Aerodynamic drag forces from residual gas flow in the nozzle after current shutdown cause motion of the molten pool and droplet ejection from the cathode pool surface. When a controlled current ramp-down is used, the gas flow is reduced simultaneously with the current, as indicated by a comparison of the pressure decay in the nozzle with the current decay. The molten pool is not affected by the gas flow when the arc is present due to the arc's high viscosity and low density.

The second most important erosion interval is the arc start. A static force balance applied to the region of the cathode arc attachment has been used to formulate a hypothesis for this ejection [3]. Major forces acting on the molten cathode pool are the surface tension, ion flux pressure and electromagnetic force. Surface tension acts on the edges of the molten cathode material to keep the material together. The ion flux pressure acts on the surface of the molten pool and works to spread the material out. Electromagnetic or j x B forces also act on the molten pool. During arc ignition the arc root is very small leading to a very high current density. This high current density can lead to a very high ion flux pressure and will push particles out from the edge of the small molten pool. When the arc is in steady operation the pressure acting to push particles out from the edge is reduced because of the reduced current density and a reduction in the fraction of the current carried by the ions.

The observed reduction in the first erosion event using the fast current shutdown is most likely caused by the deep pit that rapidly develops and keeps the molten droplets that would normally be ejected from the edge of the pool during arc ignition in the hafnium pit.

Although there is slightly less mass eroded during the fast current shutdown for the silver sleeved cathode, this difference was not significant for the available sample size, and the erosion mechanisms at the start and shutdown appear to be the same for both cathode sleeve materials. Even though the erosion of hafnium from both of the sleeve materials is similar, there is a significant difference between the lifetime of the cathodes. Rapid erosion of the cathode sleeve material indicates cathode failure. For the copper sleeved cathodes the critical parameter for failure was a pit depth of 1.3 mm. As seen in Figure 7, this depth was usually reached around 600 starts. Silver sleeved cathodes could be operated to pit depths greater than the critical value for those with copper sleeves. This greater operational pit depth translated into an additional 400 starts for the experimental operating conditions. There appears to be a difference in the failure mechanism between the two cathode sleeve materials.

Conclusion:

In order to identify means to extend cutting torch life, the cathode erosion mechanisms and torch failure have been studied. Erosion occurs as the ejection of droplets of cathode material and is strongest during the transients of the cutting process. Causes of droplet ejection appear to be aerodynamic drag forces during shut down and high ion pressure during the start-up. Reduction of erosion may be achieved by different current ramp up methods and controlling the gas flow during arc shutdown. Because the erosion rate is so dependent on the transients of arc operation, design of the cutting process to avoid arc starts and stops may be beneficial in cathode life extension. Erosion leads to cathode failure when a certain pit depth is reached. Failure of the cathode is significantly postponed when silver is used as the cathode sleeve material because of a different failure mechanism, or a deeper value of pit depth necessary for failure to occur.

Abstract

We have investigated the deposition of SiO_2 films from alkoxysilane/O_2 and alkoxysilane/N_2O plasmas using a number of novel precursors, i.e., 1,3,5,7-tetramethylcyclotetrasiloxane (TMCTS), dimethyldimethoxysilane (DMDMOS), trimethylsilane (TMS), and hexamethyldisiloxane (HMDSO). Plasma parametric effects on film characteristics, gas phase, and gas-surface interface were examined. The combination of these studies leads to a better overall understanding of the molecular-level chemistry occurring in these plasma systems.

1. Introduction

SiO_2 is ubiquitous in manufacturing semiconductor devices, primarily as gate oxides, interlayer dielectrics, or passivation layer over devices.[1] Plasma-enhanced chemical vapor deposition (PECVD) of SiO_2 films using organosilane precursors, such as tetraethoxysilane (TEOS), is commonly used. Other organosilane precursors such as 1,3,5,7-tetramethylcyclotetrasiloxane (TMCTS), dimethyldimethoxysilane (DMDMOS), trimethylsilane (TMS), and hexamethyldisiloxane (HMDSO) have also drawn much attention.[2,3] Similar to TEOS, these novel precursors are noncorrosive and non-pyrophoric. Moreover, they all have much higher vapor pressures than TEOS, making controlled source delivery easier.

Plasma parameters that affect deposition of SiO_2 films using organosilane-based plasmas include oxidant addition, applied rf power, and substrate temperature. Here, we explored PECVD of SiO_2 films using TMCTS, DMDMOS, TMS, and HMDSO precursors. O_2 or N_2O was used as the oxidant. The effects of oxidant addition, applied rf power, substrate temperature, and substrate position in the reactor were studied. The films were analyzed with FTIR, x-ray photoelectron spectroscopy (XPS), spectroscopic ellipsometry, and scanning electron microscopy (SEM). The gas phase species were examined with optical emission spectroscopy (OES) and mass spectrometry (MS), and correlated with film deposition and characteristics. In addition, the surface interactions of small molecules in the plasma, such as OH, during film deposition were also studied with our Imaging of Radicals Interacting with Surfaces (IRIS) technique.[4,5] The overall deposition processes in these plasma systems were explored by correlating film characterization, gas-phase composition, and gas-surface interactions.

2. Experiments

The inductively coupled rf plasma reactor used in these experiments was described in detail previously.[6] The pressures of TMCTS, DMDMOS, and HMDSO in the reactor were controlled with a Nupro bellows-sealed metering valve and TMS was introduced into the reactor through an MKS mass flow controller. In all systems (except for 100% precursors), O_2 or N_2O was also introduced into the reactor through an MKS mass flow controller and allowed to stabilize prior to the addition of the precursors. The total pressure in the reactor was maintained at 100 mtorr (± 2%) and the ratios of precursor to O_2 or N_2O were calculated from partial pressures.

Substrates of Si wafers (p-type, ⟨100⟩) with ~25 Å of native oxide (scribed to ~20 mm × 15 mm) and KBr pellets were placed on glass slides oriented parallel to the gas flow. Unless otherwise noted, the distance of the substrates from the plasma discharge region was 5 cm. The following plasma parameters were varied: ratio of precursor to oxidant (from 1:0 to 1:30), applied rf power (P = 20–150 W), substrate temperature (T_s = 373–573 K). To distinguish the ambient T_s from elevated T_s, the ambient T_s is defined as the temperature the substrate achieves simply through plasma heating, without specifically heating the substrate with a substrate heater. The deposited films were analyzed *ex situ* using FTIR spectroscopy and XPS for film composition, spectroscopic ellipsometry for film thickness, and SEM for film morphology. Gas phase species were studied with OES and MS.

The surface reactivity of OH was measured with our IRIS apparatus.[4,5] In the IRIS experiment, the plasma is expanded into a differentially pumped high vacuum chamber through a 10-mm orifice of the tubular glass reactor and two collimating slits, creating a near-effusive molecular beam containing virtually

all the species present in the bulk plasma. A laser beam tuned at 307.853 nm intersected the plasma molecular beam downstream at a 45° angle and excited the ground-state OH. Spatially resolved laser induced fluorescence (LIF) images of OH $A^2\Sigma^+ - X^2\Pi$ (0,0) transition were collected with a gated intensified charge-coupled device (ICCD) camera located perpendicular to both the laser beam and the plasma molecular beam. An Si substrate oriented parallel to the laser beam was rotated into the path of the plasma molecular beam and the LIF images were again collected. The difference between LIF images collected with the substrate in and out of the path of the molecular beam was attributable to the OH scattered off the substrate surface. Comparisons between the spatial distribution of scattered and incident molecules were used to determine the surface reactivity of OH. To quantify the spatially-resolved LIF data, one-dimensional cross-sections were created by averaging 15 pixel columns along the laser axis and plotting signal intensity as a function of distance along the laser path. A numerical simulation[4,5] was used to obtain the surface reactivity. It is based on known experimental geometry and calculates the spatial distribution of molecule number density along the laser beam in the molecular beam at the interaction region as well as those for molecules scattered from the substrate surface. The scattering coefficient, *S*, defined as the ratio of the flux of scattered molecules to that of incident beam, is adjusted to best fit the experimental data. The surface reactivity, *R*, is defined as $1 - S$.

3. Results

3.1 Film Characterization. The composition and properties of SiO_2 films deposited from TMCTS, DMDMOS, TMS, and HMDSO with the addition of O_2 or N_2O, are very similar. All precursors can produce high quality SiO_2 films provided that sufficient oxidants are added to the systems. The general trends observed are similar for these precursors. In addition, the two oxidants, O_2 and N_2O, yield nearly identical results.

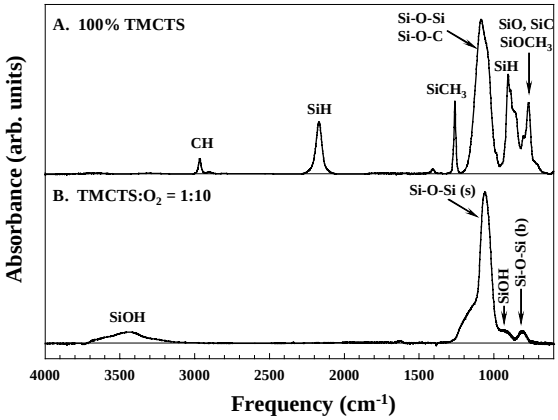

Figure 1. FTIR transmission spectra of films deposited from plasmas of (A) 100% TMCTS and (B) TMCTS:O_2 = 1:10 at P = 50 W.

The addition of oxidants to alkoxysilane plasmas reduces the hydrocarbon incorporation in SiO_2 films. Figure 1 shows representative transmission FTIR spectra for SiO_2 films deposited from TMCTS-based plasmas at P = 50 W and ambient T_s. The amount of hydrocarbon and SiH decreases with increasing O_2 addition. At a 1:10 ratio of TMCTS:O_2, only the Si–O–Si and silanol species were observed. The reduction of carbon and hydrogen demonstrates that a more stoichiometric and higher quality SiO_2 film is produced. Similar trends were observed for N_2O as the oxidant and for other precursors.

The XPS composition results correlate with the FTIR results. The Si concentration appears insensitive to the addition of oxidant, while the O concentration increases and the C concentration decreases with addition of oxidant. The Si bonding environment also changes with oxidant addition. High-resolution XPS analyses show that Si_{2p} peak position increases with addition of oxidant. The Si_{2p} peak width also narrows with increasing oxidant. These trends indicate that with different oxidant addition to the precursor, the structure of SiO_2 network of the deposited films also changes. Alexander *et al.*[3] proposed that the number of O atoms bonded to Si varies from 1 to 4, denoted by $Si(-O)_1$, $Si(-O)_2$, $Si(-O)_3$, and $Si(-O)_4$ with the binding energies of 101.5, 102.1, 102.8, and 103.4 eV, respectively. Figure 2 shows representative fitting of Si_{2p} peak for films deposited from plasmas of 100% TMCTS and TMCTS:O_2 of 1:10. For film deposited from

100% TMCTS, the distribution of Si_{2p} peak is: 40% $Si(-O)_1$, 35% $Si(-O)_2$, 25% $Si(-O)_3$, and 0% $Si(-O)_4$. As oxidant concentration increases in the plasma, the contribution of higher binding energy Si environments increases. For films deposited from TMCTS:O_2 of 1:10, the distribution is simply 34% $Si(-O)_3$ and 66% $Si(-O)_4$.

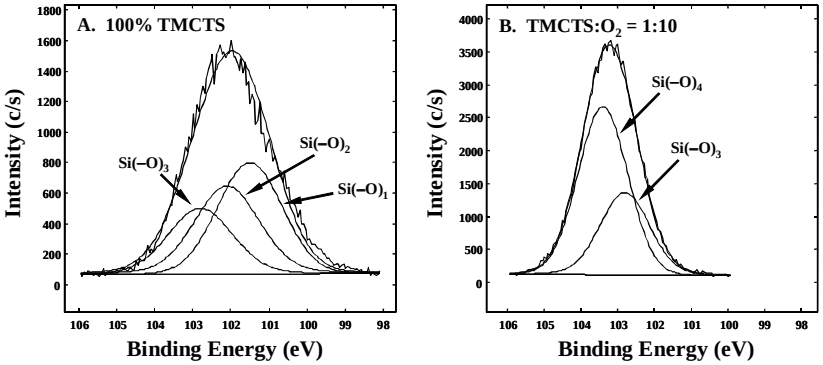

Figure 2. Curve fit of the Si_{2p} high resolution XPS peak for films deposited from plasmas of (A) 100% TMCTS and (B) TMCTS:O_2 = 1:10 at P = 50 W.

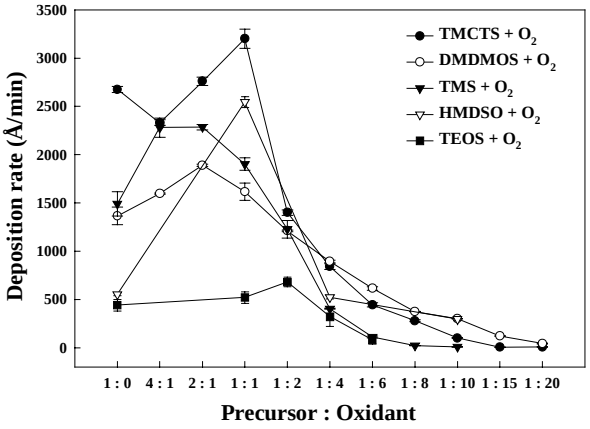

Figure 3. Dependence of deposition rate on oxidant addition for films deposited from plasmas of TMCTS + O_2 (closed circles), DMDMOS + O_2 (open circles), TMS + O_2 (closed triangles), HMDSO + O_2 (open triangles) at P = 50 W, and TEOS + O_2 (closed squares) at P = 85 W.

Deposition rate is another important factor in film deposition. Figure 3 shows the deposition rate of the SiO_2 films as a function of oxidant addition at P = 50 W for TMCTS-, DMDMOS-, TMS-, and HMDSO-based plasmas. The results from TEOS/O_2 plasmas at P = 85 W[7] are also plotted as a comparison. With increasing amount of oxidant, the film deposition rate initially increases to a maximum and then declines sharply, ultimately approaching zero. The position of the maximum varies with different systems. The deposition rate for TMCTS-based plasmas is significantly higher than those for other precursors when the ratio of precursor to oxidant is higher than 1:1. Deposition rate is also strongly affected by substrate temperature. The deposition rates were found to decrease with increasing T_s. From the Arrhenius plots of the logarithm of deposition rate as a function of $1/T_s$, the apparent activation energy, E_a, can be calculated. The values of E_a for TMCTS- and DMDMOS-based plasmas at P = 50 W and for TEOS/O_2 and other alkoxysilane/O_2 plasmas[7] are listed in Table I. All the E_a values are negative. For TMCTS- and DMDMOS-based plasmas, the E_a values for films deposited from plasmas of 1:1 ratios are generally more negative than those for the ratios of 1:10. For the other alkoxysilane/O_2 plasmas, the E_a values for P = 22 W are generally more negative than those for P = 85 W. Furthermore, the E_a values for films deposited from the other alkoxysilane/O_2 plasmas are significantly more negative than TMCTS- and DMDMOS-based plasmas.

[a]Errors represent the standard deviation, as determined by linear regression analysis. The linear correlation coefficients are listed in parenthesis.
[b]Values from ref.[7]

The effects of other plasmas parameters on film deposition are summarized as follows. Increasing applied rf power decreases the hydrocarbon incorporation in the film and the deposition rate. The amount of silanol species decreases with increasing T_s and disappears at $T_s \geq 473$ K. The film deposition rate decreases and silanol species increases with increasing distance from the plasma discharge region. It also should be noted that all the deposited SiO_2 films are very smooth.

3.2 Gas-phase Composition. Our OES results indicate the presence of CO, CO_2, OH, O, O_2, and H species in the gas phase. This is also confirmed by the mass spectrometry results. In addition, larger molecules of fragments of the precursor molecules were also observed. From the MS data, we observed that the dissociation percentage of the precursor molecules increases with increasing *P* and oxidant addition. In addition, smaller fragments and molecules of OH, H_2O, CO, and CO_2 also increase with increasing *P* and oxidant addition. Moreover, the relative LIF intensity of OH molecules also has the same trend.

3.3 OH Surface Reactivity. As mentioned in Section 2, the surface reactivity *R* is measured by comparison of the ICCD images obtained with the substrate surface in and out of the path of the plasma molecular beam. Figure 4 shows a typical set of cross sections (solid curves) of the OH LIF images along

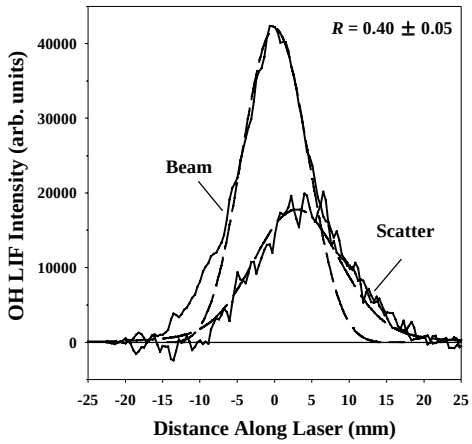

Figure 4. Cross-sectional (solid curves) data for the LIF of OH in the incident plasma molecular beam and scattered from the Si substrate for plasma of TMCTS:O_2 = 1:10 at *P* = 100 W. The laser-surface distance is 3 mm. Dashed curves represent the simulation results assuming *S* = 0.60, which gives *R* = 0.40.

the laser axis for a 1:10 TMCTS/O_2 plasma at P = 100 W and T_s = 300 K. The simulation results (dashed curves) yield a scattering coefficient, S = 0.60 ± 0.05, which gives a surface reactivity R = 0.40 ± 0.05. Averaging 3 sets of data gives R = 0.40 ± 0.03 for OH from 1:10 TMCTS/O_2 plasma at P = 100 W at the surface of a depositing SiO_2 film. The effects of P and the precursor-to-oxidant ratio on OH surface reactivity have been studied and the R values are about the same: R = 0.40 ± 0.10 at T_s = 300 K under all conditions, for TMCTS- and DMDMOS-based plasmas. This value is identical to the surface reactivity of OH for TEOS/O_2 plasmas.[5,8] However, the reactivity of OH decreases with increasing T_s. For 1:10 TMCTS/O_2 plasma at P = 100 W, R = 0.21 ± 0.03 at T_s > 350 K. For 1:10 DMDMOS/O_2 plasma at P = 100 W, R = 0.33 ± 0.07 at T_s > 350 K. Similar results were observed for TEOS/O_2 plasmas, in which R decreases to 0.15 ± 0.05 at T_s > 350 K.[5]

4. Discussion

The deposition of SiO_2 films from these precursors have similar dependencies on oxidant addition, P, T_s, and substrate position in the reactor. Among these parameters, the effect of T_s on deposition kinetics provides insight into the deposition mechanism. The deposition rate decreases with increasing T_s. The negative apparent activation energies of deposition indicate that the adsorption of precursor and its fragments on the substrate surface is the rate-determining step.[9] Increasing oxidant addition and P improves the quality of the SiO_2 films through a better precursor dissociation in the gas phase and oxidation on the gas-surface interface. With increase in oxidant addition and P, the gas-phase homogeneous reactions with O atoms improve the precursor fragmentation. In addition, the heterogeneous reactions between O atoms and adsorbed precursor fragments also increase, and thus reduce hydrocarbon incorporation into the deposited SiO_2 films. OH is an important oxidation product and reactant of the reactions of oxygen with hydrocarbon species. In both gas phase and gas-surface reactions, O atoms react with hydrocarbons typically through H-atom abstraction to form OH.[10] In TEOS/O_2 plasmas, using isotopically labeled $^{18}O_2$ as the oxidant, we have previously identified that the oxygen source of OH is from the O_2 gas, not from the oxygen in the TEOS precursor.[5] For the plasma systems studied in this work, we believe that the oxygen source of the OH is also from the oxidants, O_2 and N_2O. This is supported by the observation that no OH LIF signals were detected for 100% precursor plasmas and the direct correlation of the OH LIF intensities with oxidant addition.

The OH surface reactivity of ~0.40 at T_s = 300 K during SiO_2 film deposition indicates that 40% of the incident OH molecules in the plasma react with the surface and 60% scatter or desorb from the surface. As the IRIS experiment does not track individual molecules, the reactivity value could be the result of combinations of gas-surface interactions that consume and generate OH. The OH molecules may adsorb on the surface and the adsorbed OH may desorb subsequently. OH may also react with other surface species such as H atom to form H_2O or Si to form –SiOH. Reactions that produce OH include surface H-atom abstraction by gas-phase and/or surface O atoms. This process will be enhanced by increasing oxidant addition or P, which increases the O-atom concentration in the gas phase. Therefore, the apparent OH surface reactivity will decrease with increasing oxidant addition or P. However, the R-values are unaffected by changes in oxidant addition or P. This suggests that the overall OH surface reactivity is mainly governed by the chemistry of OH alone and the O-atom reaction with surface to produce OH is not significant compared to overall interactions of OH with the surface. However, the OH surface reactivity could be dramatically different for different systems due to difference in the surfaces. On the other hand, the reactivity of OH during SiO_2 film formation in the plasma systems of TMCTS/O_2(N_2O) and DMDMOS/O_2(N_2O) is identical to that in TEOS/O_2 plasma system,[5] i.e., R = 0.40. This is not surprising as these systems are all depositing systems with similar deposition processes that can deposit high-quality SiO_2 films. Therefore, the surfaces that OH molecules interact with during film formation are very similar. However, at elevated substrate temperature, these systems show slightly different OH surface reactivity: R = 0.15 ± 0.05, 0.21 ± 0.03, and 0.33 ± 0.07 at T_s > 350 K for TEOS/O_2, TMCTS/O_2, and DMDMOS/O_2, respectively. This indicates that the concentrations of active species on the surface that react with OH have different T_s dependence. At elevated T_s, the concentrations of surface-active species decrease, (but not to zero even at 573 K), which leads to decreased R-values. During SiO_2 deposition, reactions of OH with surface Si atom produce undesirable –SiOH species. Increasing T_s leads to a decrease in the surface reactivity of OH, thus a

decrease of the possibility of the reaction to form surface –SiOH. This is consistent with the observation that increasing T_s decreases or eliminates silanol species in the SiO_2 films.

5. Conclusion

We have deposited SiO_2 films from TMCTS-, DMDMOS-, TMS-, and HMDSO-based plasmas. Addition of O_2 or N_2O to the feed gas is essential to deposition of high quality SiO_2 films. Parametric studies have shown that the film quality is improved with increasing oxidant addition, P, T_s, and distance from discharge region. Negative apparent activation energies for film deposition have been observed, suggesting a deposition mechanism dominated by adsorption/desorption processes. Gas phase studies have shown that the dissociation percentage of the precursor molecules, the fragments, and oxidation products such as OH, H_2O, CO, and CO_2 increase with increasing oxidant addition and P. We have also measured the surface reactivity of OH during film deposition, which is ~0.40 at T_s = 300 K and is independent on changes in the precursor-to-oxidant ratio or P. The OH surface reactivity decreases to 0.21 ± 0.03 for TMCTS/O_2 system and to 0.33 ± 0.07 for DMDMOS/O_2 system at elevated T_s (from 350 to 573 K). Comparisons with previous results for TEOS/O_2 plasma systems suggested that OH participates in SiO_2 film deposition and contributes to hydrocarbon removal, precursor fragmentation, and surface silanol formation.

Low Dielectric Constant Porous Organosilicate Glass Films via Plasma Enhanced Chemical Vapor Deposition

Qingguo Wu, Daniel D.Burkey, April Ross, and Karen K. Gleason

Department of Chemical Engineering, Massachusetts Institute of Technology
Cambridge, MA 02139, USA

Abstract

Chemical vapor deposition (CVD) of nanoporous dielectric films was achieved using multilayer assemblies of polystyrene spheres as the template for creating the pore structure. The polymer beads were dispersed from aqueous suspension onto a silicon wafer and then dried to remove the water. Next, the CVD dielectric matrix was grown in the interstitial spaces between the beads using a dimethylsilane/oxygen mixture. Subsequent annealing at 300 to 500 ºC resulted in depolymerization of the labile polystyrene phase, leaving spherical pores behind in the more thermally stable CVD matrix. The lowest dielectric constant achieved was 1.4. The refractive index of this film was 1.067.

Introduction

As semiconductor feature sizes decrease, ultra low-k interlayer dielectric materials are needed to minimize transmission delays[1]. Presently, the standard manufacturing methods for interlayer dielectrics include the chemical vapor deposition (CVD) of SiO_2 and organosilicate glass (OSG, Si:O:C:H). The dielectric constant, k, of fully dense SiO_2 layer is 4.0 while for OSG, k values are typically 2.7. The inclusion of pores is an evolutionary pathway for reducing k. Indeed, a variety of porous materials have achieved dielectric constants in the ultra low-k region (2.5-1.5)[2-4]

In this work, a nanoporous CVD matrix is created having extremely low values of dielectric constant, 1.4, and refractive index, 1.067. Assemblies of polymer nanospheres 15 hm. to 96 nm. in diameter serve as templates for the pores. The precursor for the CVD matrix are dimethylsilane and oxygen.

The CVD step fills the interstices of the colloidal crystal to form the OSG matrix. The CVD process for OSG matrix must satisfy three simultaneous criteria. First, the fully dense OSG films must be hard as soft films collapse when the template is removed. A CVD matrix material that is mechanically robust will leave behind spherical pores. Second, the OSG layer should be chemically stable. In particular, incorporation of Si-H bond is undesirable as these bonds are susceptible to attack by water[5]. Finally, the CVD process must exhibit excellent gap fill in order to deposit OSG material into the void spaces within the multiple layers of the polystyrene beads. Thus, the CVD feed gases and conditions selected must generate reactive species having low sticking coefficients. Conditions that enhance the sticking probability of the film forming species and promote deposition on the top surface of the colloidal crystal are undesirable, as channels needed to fill the interstices within the template structure become blocked.

With subsequent annealing at 300 to 500 ºC the labile polymer beads depolymerize, resulting in a nanoporous thin film. To enable three-dimensional crystal templates to form on substrate areas larger than 10 cm^2, a rapid evaporation-induced self-assembly of labile polystyrene (PS) nanospheres was developed. Colloidal crystallization can yield either two or three dimensional crystals of polymeric beads onto a substrate[6-8].

Results and Discussions

First, an aqueous suspension of the polymer nanospheres was diluted to 0.1-0.5 w/v % and dispensed over the surface of a rectangular silicon piece by a syringe. Two opposing edges of the rectangular substrate were heated to 60-70 ºC. The polymer suspension of nanospheres at the two heated edges dried and crystallized first. Then, the two crystal domains propagated towards the cooler center of the wafer. Arrays as large as 10 cm^2 containing multiple layers of polymer beads were obtained in less than 60 minutes. Figure 1 shows scanning electron micrograph (SEM) of a three-dimensional crystal of monodisperse polystyrene beads of 96 ± 4 nm diameter assembled using this rapid, large-area process.

The top down view (Fig. 1a) reveals well-ordered hexagonal arrays of the polymer beads. Five layers of beads can be seen in the cross sectional view (Fig. 1b). Varying the concentration of the polymer microspheres in the suspension provides precise control over the number of layers formed, from two to over 15.

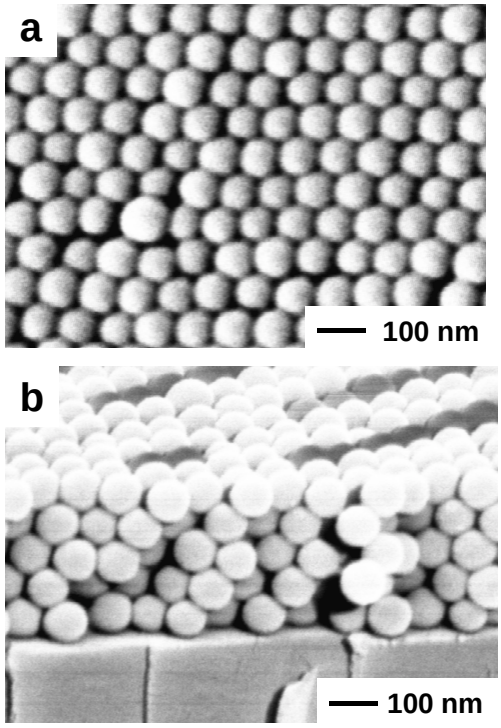

Fig 1. SEM images of a five-layer polystyrene template assembled on Si wafer from 96 nm polystyrene nanospheres : (a) Top view; (b) Oblique view.

This approach is remarkable for simplicity, speed, and effectiveness in producing large area crystalline templates of well-defined thickness. The degree to which the OSG matrix infiltrated the voids between the template beads was inferred from ellipsometric measurements of refractive index of the composite film.

The substrate temperature, vapor pressure, and peak RF power of the CVD OSG process were varied 25°C to 100°C, 200 to 110 mTorr and 200 to 120 W, respectively, resulting in composite films with degrees of infiltration ranging from 0% to 100%. The degree of infiltration was observed to increase with increasing substrate temperature, decreasing vapor pressure, and decreasing plasma power.

The highest degree of infiltration was achieved using pulsed plasma enhanced CVD from dimethylsilane (2MS) at 4 sccm mixed with argon at 15 sccm and oxygen at 2.5 sccm at a total pressure of 110 mTorr. For excitation cycle, the plasma was pulsed on at a peak rf power of 120 W for 10 ms followed by an off time of 600 ms.

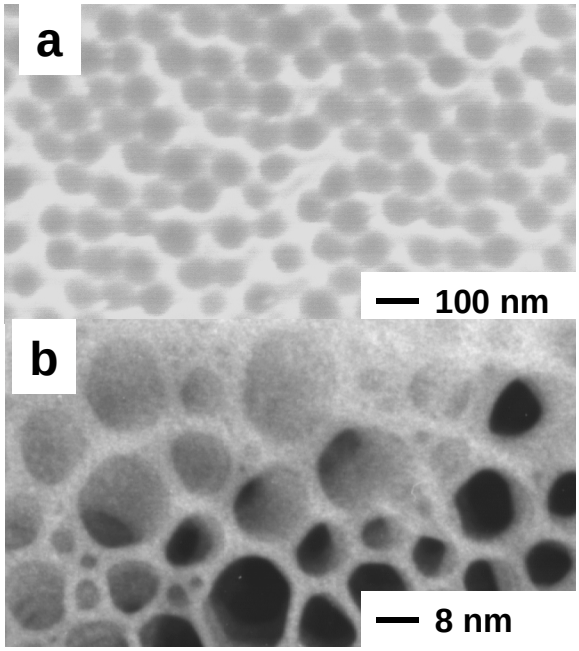

Fig 2 (a). SEM images of the nanoporous OSG film using the template beads of 96 nm mean diameter. (b) TEM image of nanoporous OSG film using the template beads of 15 nm mean diameter.

The filling of the OSG matrix at a substrate temperature of 95 ºC is superior to that for 20 ºC substrate temperature This observation is consistent with the expected decrease in the sticking coefficient with increasing temperature for an adsorption limited process. A lower sticking coefficient increases the probability that the OSG precursor is able to traverse the small channels within the template of polymer beads prior to reacting to form film.

The generation of the nanoporous organosilicate glass was accomplished by thermal treatment to remove the template of polymer beads from the composite film. The polystyrene is expected to decompose at temperatures above 280 ºC[9]. Annealing was accomplished under N_2, ramping the temperature at approximately 8°C/min. A ramp to 500°C followed by isothermal anneal at 500 °C for one hour resulted in complete removal of the polymer. A ramp up to 300 °C, an 1 hour isothermal anneal at 300 °C for 1 hour.

The C-H stretch region of the FTIR associated with the polystyrene appears from 2844-3091 cm^{-1}. Additionally, the CH_3 stretching bands from OSG are centered at 2960 cm^{-1}. After annealing, only the 2960 cm^{-1} band remains, clearly demonstrating the complete removal of the polystyrene template and retention of the OSG matrix material and porous structure.

Control over the pore size is critical for obtaining materials with suitable properties for different insulator feature sizes in microelectronic devices[10]. To obtain different pore sizes in the nanoporous organosilicate glass, templates were assembled using polystyrene beads of 96 nm, 19 nm and 15 nm mean diameter. Figure 2c shows cross-

sectional SEM image of resultant nanoporous OSG film produced using 96 nm polystyrene beads while Figure 2(b) shows transmission electron micrograph (TEM) image of resultant nanoporous OSG film produced using 15 nm polystyrene beads. Spherical ordered pores created by the decomposition of the 96 nm beads are clearly visible in Fig. 2(a) and spherical pores created by decomposition of the 15 nm beads can be also seen in Fig. 2(b) although pore sizes are very different due to high standard deviation of diameter for 15 nm beads. The porosity is also attested by the extremely low values measured for the refractive index, 1.067, and dielectric constant, 1.4.

Conclusions

Nanoporous organosilicate via CVD onto a colloidal template is a new approach to the synthesis of extremely low-k dielectric materials. The technological steps of CVD and annealing are standard semiconductor manufacturing techniques. Control over the template area for polymer bead assembly and control over bead shape and size are key issues remaining for the development of this material for practical application.

Microwave Plasma Barrier Coating Technology for PET Beverage Containers

Christopher Weikart, Todd Smith

The Dow Chemical Company
Chemical Sciences, 1776 Bldg
Midland, MI 48674

The PET packaging environment remains competitive in the development of commercial barrier solutions for extending the shelf-life of beverages and ensuring the quality of products such as beer, carbonated soft drinks and juice. Among the many different technologies that exist today, plasma-based barrier coating technology is an attractive solution due to the high performance properties, ease of recyclability and competitive cost compared to other technologies. Research and development work conducted at The Dow Chemical Company has demonstrated high barrier coatings on PET containers with a microwave PECVD device. The device deposits thin (10-30nm) barrier coatings on plastic containers to provide enhanced barrier performance to small gaseous permeants such as oxygen and carbon dioxide. A bi-layer coating, composed of a patented organosiloxane layer and a SiOx layer, was deposited uniformly over the interior surface of the container. The organosiloxane layer acts as a flexible interfacial layer before depositing the brittle SiOx barrier layer. The nature of the microwave deposition process, the challenges of coating a complex-shaped container and the barrier performance properties as they relate to the coating properties will be addressed.

Thermodynamic and Kinetic Study of Black Liquor Treatment by the Submerged Plasma Technology

V. Yargeau, B. Marcos and G. Soucy

Department of Chemical Engineering, Université de Sherbrooke, Québec, Canada, J1K 2R1

Abstract

A novel technology, the submerged plasma reactor, is used to study the kinetic and thermodynamic model of thermal treatment of black liquor. An innovative kinetic approach is proposed and validated: the severity factor, a phenomenological kinetic approach developed for lignocellulosic fractionation. Thermodynamic modeling of plasma treatment is improved by the use of Pitzer's parameters. Key characteristics of this use of submerged plasma technology are identified as the influence of the catalyst on organics decomposition and the lignin decomposition.

1. Introduction

Several industries, such as the Pulp and Paper industry, experience problems with the treatment of caustic solutions used in their processes. Better kinetic and thermodynamic predictions would be beneficial in the optimization of the actual treatment and in the development of new treatment technologies such as the submerged plasma system that could address the need of incremental solution treatment capacity.

The global kinetic approach, the simplest model of kinetic behavior [1], gives poor results for complex systems having kinetic parameters varying with the operating conditions. On the other hand, a detailed model can be developed by a mechanistic approach [2] but the complete reaction mechanism must be known, which is not the case for the complex black liquor system. Between those two approaches lies the phenomenological approach that has given rise to the severity factor kinetic model for the complex system of the decomposition of the lignocellulosics fractionation [3], [4]. This study evaluates the suitability of this kinetic model for thermal treatment of black liquor. The ideal solution model is often used in the thermodynamic analysis of solutions thermal treatment. This approach is not adequate however for concentrated electrolyte solutions such as black liquor. This present study evaluates the potential gain in using a real solution model, based on Pitzer's parameters. The last objective of this study is to identify key characteristics of the submerged plasma for the treatment of black liquor.

2. Thermodynamic study

The relevance of the real solution model in thermodynamic prediction was verified by the introduction of available Pitzer's parameters as reported in the following Tables, in a new version of FactSage program.

TABLE 1 Binary Pitzer's parameters [6]

	BINARY PARAMETERS			BINARY PARAMETERS DERIVATIVE[1]		
ION PAIR	β_o	β_1	C^ϕ	β_o	β_1	C^ϕ
Na[+] HCOO[-]	0,0820	0,2872	-0,00523

3. Kinetic study

SEVERITY FACTOR KINETIC MODEL

The severity factor kinetic model, as applied to the lignocellulosics fractionation, demonstrates that it is possible to predict the kinetic behavior of a complex system by the use of a severity factor; a descriptor of the importance of operating conditions on the extent of conversion of the input material as products. This severity factor *(Ro)* is a parametric combination of temperature *(T)*, time *(t)* and catalyst concentration *(C)*.

The phenomenological approach was first introduced in 1930 by Geniesse and Reuter [7], followed by Brash and Free [8] and Whitehurst [9]. In 1990, Montané, Overend and Chornet revised this literature and proposed the use of the severity factor combining temperature and residence time. In 1992, Abatzoglou et al. [3], unified these two approaches and introduced the catalyst effect to the severity factor. From the hypotheses set out below and the mathematical development presented in [4], the severity factor is defined as follow:

$$R_0 = \exp\left(\frac{1}{\omega_0}\left(1-\frac{T_{ref}}{T}\right)\right)\frac{t^{\gamma}}{\gamma} \quad \text{.....(1)}$$

The conversion, *f*, is then expressed as a function of the severity factor means of the following equation, where *m* is the reaction order for the catalyst:

$$\ln(1-f) = -k_{Tref,Cref}\left(\frac{C}{C_{ref}}\right)^{m} R_0 \quad \text{.....(2)}$$

Parameters γ, $k_{Tref,Cref}$

To determine the parameters γ, $k_{Tref,Cref}$ of the model from experimental data, equation (1) and (2) are combined, the catalyst concentration is fixed at the reference and $\omega_0 T$ is replaced by ω to obtain the linearized equation:

$$\ln(-\ln(1-f)) = \ln\left(\frac{k_{Tref,Cref}}{\gamma}\exp\left(\frac{T-T_{ref}}{\omega}\right)\right) + \gamma \ln t \quad \text{.....(3)}$$

From which the least square function indicates gamma as the slope and the rate constant as a function of the y-intercept, *b* :

$$k_{Tref,Cref} = \gamma \exp\left[b - \frac{T-T_{ref}}{\omega}\right] \quad \text{.....(4)}$$

Parameter m

To determine the parameter m of the model from experimental data, the catalyst contribution term is linearized through a series expansion around C_{ref}, truncated to the first term to obtain:

$$\ln(-\ln(1-f)) = \ln(\frac{k_{Tref,Cref}}{\gamma}\exp\left(\frac{T-T_{ref}}{\omega}\right)\exp\left(\frac{m(C-C_{ref})}{C_{ref}}\right)) + +\gamma\ln(t) \quad \text{.....(5)}$$

from which the least squares function indicates that the parameter *m* can be estimated from y-intercept, *b* and the following equation:

$$m = \frac{C_{ref}\left[\omega(\ln\gamma - \ln k_{CrefTref}) + \omega * b + T_{ref} - T\right]}{\omega(C - C_{ref})} \quad \text{.....(6)}$$

HYPOTHESES OF THE MODEL

§ Reaction rate doubles for a specified temperature increment.
§ Temperature dependence of reaction rate follows the Arrhenius equation.
§ Process is isothermal and irreversible.
§ Catalyst concentration is constant with time.
§ Reaction rate is independent of the conversion.

REFERENCE CONDITIONS

The model is based on a reference temperature and a reference catalyst concentration. The reference temperature chosen is 25^0C since no significant reaction occurs at this temperature. The catalyst concentration is chosen to lie midway in the interval of catalyst concentrations studied, 0.033 ml/L.

4. Experimental set-up and procedures

SUBMERGED PLASMA TECHNOLOGY

The technology used during this study, shown in Figure 1, is based on a submerged plasma system designed for fluids treatment (*US Patent* 6187 206 B1: February 13, 2001 and *Patent Cooperation Treaty* (PCT) WO9722556: December 20, 1996) adapted for this study as described in [5]. The solution to be treated **(1)** is pumped **(2)** into the reactor **(3)** prior to plasma ignition. To place energy in direct contact with the solution to be treated, thermal plasma generated by a 45 kW DC plasma torch **(4)** is submerged in the solution, at the bottom of the reactor. The torch, fed with plasma gas **(5),** is cooled by tap water **(6)**. To control both the liquid and gases flow patterns in the reactor and to obtain adequate contact between the gas and liquid phase, a draft tube **(7)** is placed above the torch. Visual observations of the treatment are possible through the porthole **(8)**. During the reactor operation, make-up water is added, using the reservoir **(1)** or a tap water line **(9),** at a flow rate known to keep the solution volume constant at 15 L. The volume level is verified by the magnetic indicator located in a side tube **(10)**. Treatment is carried out under pressure (445 kPa) to reduce foaming problems and to increase the boiling temperature of the system. Liquid samples are taken by the sampling line at the half-height level of the reactor **(11)**, the reactor being drained by a line at the bottom **(12)** while the gases leaving the reactor at the top are cooled by heat exchangers **(13)**. The condensate from the gases is recuperated in a reservoir **(14)** and the cooled gases are sampled and sent to a scrubber **(15)** before exhaustion.

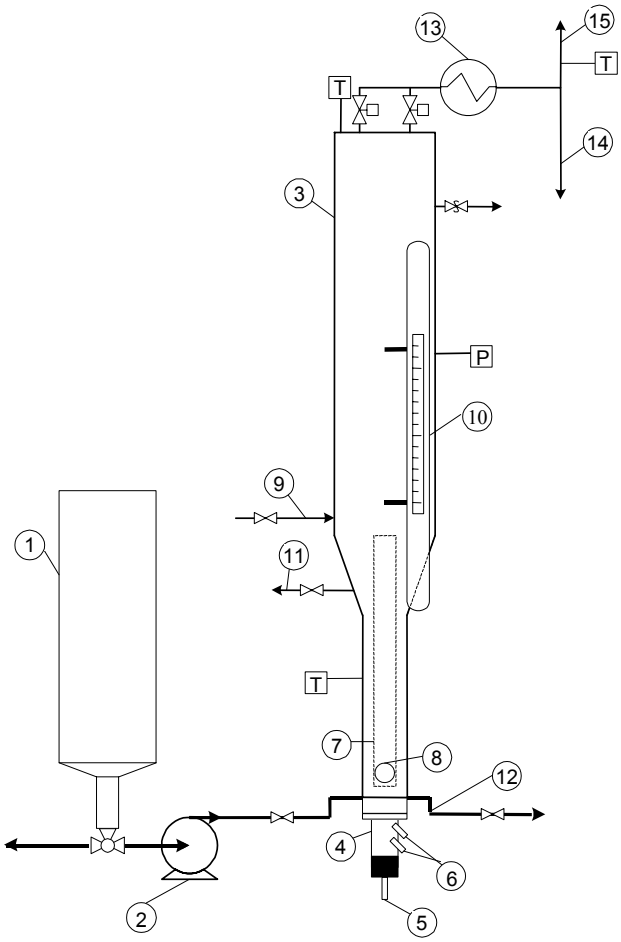

Figure 1 Experimental set-up

BLACK LIQUOR SOLUTION

To streamline the chemical analysis and to focus the analysis on major compounds, a synthetic solution is used as a surrogate for the black liquor for most of the experimental runs. The compounds introduced into the test solution are summarized in Table **Errore. L'origine riferimento non è stata trovata.** along with the concentration interval studied. Fifteen liters of solution are prepared and treated for each experiment.

TABLE 3 Solution concentration

SPECIES	CONCENTRATION
NaOH	0.23 mol/L
Na_2CO_3	0.13 mol/L
Lignin	[0.0 , 15.0] g/L
HCOOH	[0.14 , 0.28] mol/L
CH_3COOH	[0.07 , 0.14] mol/L
Na_2S	[0.07 , 0.14] mol/L

EXPERIMENTS

The main set of experiments, structured by a partial factorial analysis 2^{4-1}, are described in Table 4.

TABLE 4 Experiments from a Factorial 2^{4-1} to evaluate the parameters $k_{Tref,Cref}$ and γ

TEST #	PLASMA GAS	Na_2S (mol/L)	ORGANIC ACIDS (mol/L)	CATALYST (ml/L)
01	Air	0.07	0.21	0
02	O_2	0.07	0.21	0.033
03	Air	0.07	0.42	0.033
04	Air	0.14	0.21	0.033
05	O_2	0.14	0.21	0
06	O_2	0.07	0.42	0
07	Air	0.14	0.42	0
08	O_2	0.14	0.42	0.033

To determine the value of the third parameter of the severity factor, *m*, the reaction order for the catalyst, additional experiments, as described in Table 5, are undertaken. Knowing the parameters $k_{Tref,Cref}$ and γ, it is then possible to calculate the reaction order for the catalyst by means of equations (5) and (6).

TABLE 5 Experiments to evaluate the reaction order for the catalyst

TEST #	PLASMA GAS	Na_2S (mol/L)	ORGANIC ACIDS (mol/L)	CATALYST (ml/L)	PRESSURE (kPa)

SAMPLES ANALYSIS

Liquids

During each 20 minute treatment, samples are taken from the reactor just over the reactor elbow (see #11 on Figure 1) at various times: 0, 3, 8, 13, and 20 minutes. Samples are analyzed, for the anions; SO_3^{2-}, SO_4^{2-}, $S_2O_3^{2-}$, $HCOO^-$ and CH_3COO^- by ionic chromatography, using method based on TAPPI standard methods, T699 om-87.

Gases

During each 20 minute treatment, gas samples are drawn off in front of the scrubber entrance (see #15 on Figure 1) at various times: 7 and 20 minutes. The analysis performed is limited to the qualitative identification of the most probable "sulphurated" gases products: SO_2(g) and H_2S(g). Analysis are conducted with the aid of a CP-3800 Varian chromatograph equipped with a Porapack QS Teflon column and a TCD detector.

5. Results and Discussion

EVALUATION OF PARAMETER $K_{TREF,CREF}$ AND γ

Kinetic parameters $k_{Tref,Cref}$ and γ are calculated for each test through the use of equations (3) and (4). The mean parameter $k_{Tref,Cref}$, obtained for formic acid decomposition, is 1.5E-05 min^{-1} and is 3.32E-05 min^{-1} for sulfur oxidation. The parameter γ for formic acid decomposition seems to be quite variable with respect to the operating conditions. It has been statistically verified by factorial analysis that the plasma gas type influences the parameter γ for acid decomposition. The dependence of this variation with operating conditions is not

statistically significant for sulfur oxidation, for which and the mean value obtained is γ = 0.44 [10]. The variation of these γ parameters with temperature is analyzed in the following section.

Variability of γ with temperature

To verify the variability of the parameter γ with temperature, test 03 is replicated and another test is performed under higher pressure condition (Test 03Pd: 585 kPa) to increase the treatment temperature. The results obtained at different temperatures indicate that the variation of parameter γ with operating conditions is significant, as is shown on Figure 2, for both formic acid decomposition and sulfur oxidation.

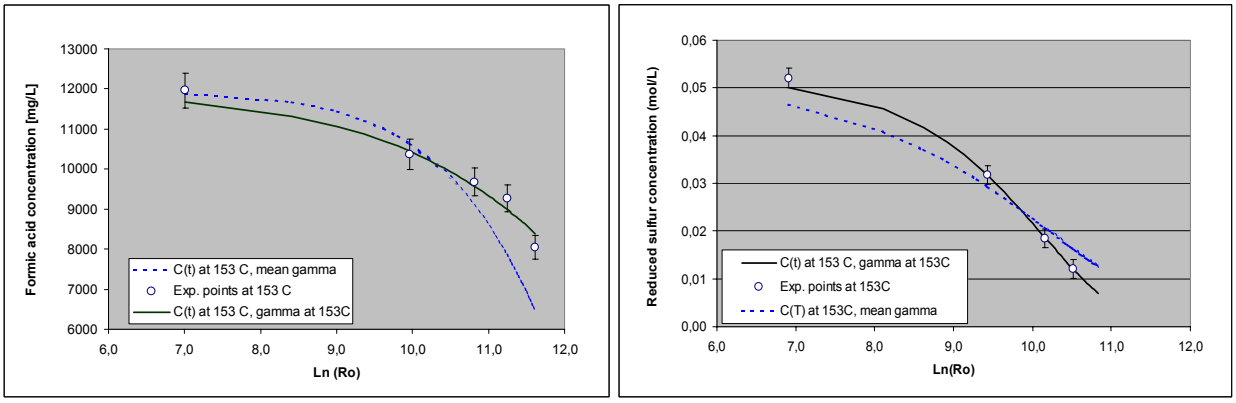

Figure 2 Significance of variability of γ with temperature

EVALUATION OF PARAMETER *m*

The calculation of the reaction order for the catalyst, using equations (5) and (6), indicates that the reaction order for the catalyst, in the formic acid decomposition, is 0.85 and almost 0 for the sulfur oxidation. The conclusion that the oxidation of sulfur is not catalyzed is also statistically validated by the results of factorial analysis [10].

VALIDATION OF THE KINETIC MODEL

Figure 3 demonstrates that the model is adequate for the prediction of formic acid decomposition and also for sulfur oxidation in the plasma treatment of black liquor. The information so obtained can be used to optimize the conventional thermal treatment or to design new ways of treatment.

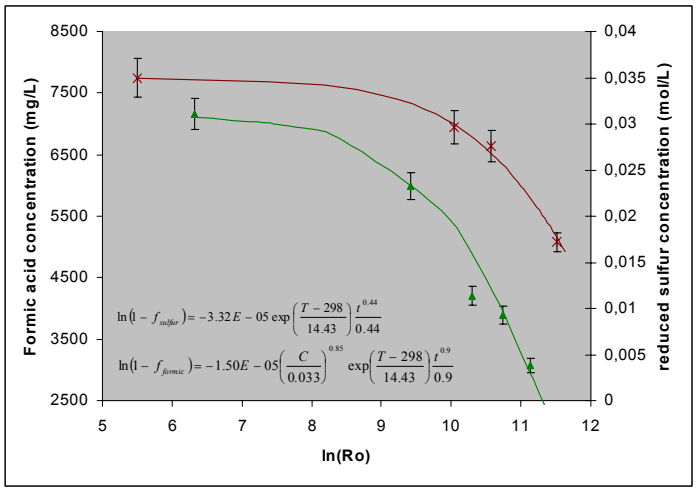

Figure 3 Kinetic model validation

KEY CHARACTERISTICS OF THE TECHNOLOGY

The factorial analysis demonstrates that the influence of a catalyst is significant on the decomposition of black liquor organics. It also reveals that it is possible to decompose the lignin content even if it remains in a bulk solution at a mean temperature lower than the lignin decomposition temperature, 220^{0}C [11]. No "sulphurated" gases were analyzed from these tests.

VALIDATION OF THE THERMODYNAMIC MODEL

The comparison of the models' predictions (ideal and real solution) to the experimental observations, as summarized in Table 6, indicates that the real solution model provides improved results.

TABLE 6 Comparative results between models' predictions and experimental observations

CRITERIA	PREDICTION IDEAL SOLUTION	PREDICTION REAL SOLUTION	EXPERIMENTAL OBSERVATION
Precipitation temperature for Na_2CO_3	143^0C	155^0C	No precipitate observed at 153^0C
Solution pH	7,5	6,9	6,0
Oxidized sulfur after solution preparation	none	none	15% of initial sulfur
Formic acid residual percentage	0%	0%	42% à 74%
Acetic acid residual percentage	0%	0%	51% à 110%
Carbonates	0,7 g/L	8,9 g/L	3,3 à 6,4 g/L
Oxalates	0 mol/L	0 mol/L	50 à 350 mg/L

6. Concluding remarks

The submerged plasma technology, described above, offers considerable advantages for practical lignin decomposition and kinetics. The real solution model improves thermodynamic predictions. The phenomenological severity factor kinetic model, developed for the decomposition of cellulose, is adequate to predict the kinetic behavior of complex systems such as those formed during the thermal treatment of black liquor and to optimize the submerged plasma treatment operating conditions. However, the results obtained in this work indicate that the severity factor kinetic model might be more efficient through the optimization of the gamma parameter to adapt the model to the more homogeneous molecular composition of black liquor. This optimization will be evaluated in further work.

Molecular Dynamics Calculations of Carbon/Hydrocarbon Reflection Coefficients on Hydrogenated Graphite Surfaces

D.A. Alman, J.P. Allain, D.N. Ruzic

Department of Nuclear, Plasma, and Radiological Engineering, University of Illinois, Urbana, Illinois, USA

Abstract

Reflection coefficients for carbon and hydrocarbon atoms/molecules on carbon-based surfaces are critically needed for plasma-surface interaction analysis in fusion devices, as carbon will continue to be used in next step devices like ITER. These have been calculated at different energies and angles with a molecular dynamics code using the Brenner hydrocarbon potential [1]. Hydrogen saturated graphite was prepared by bombarding a pure graphite lattice with energetic hydrogen, until a saturation at ~0.42 H:C. Carbon at 45° has a reflection coefficient (*R*) of 0.64 +/- 0.01 at thermal energy, decreasing to 0.19 +/- 0.01 at 10 eV. Hydrocarbons reflect as molecules at thermal energies and break up at higher energies. The total reflection via these fragments decreases with energy, and increases with hydrogen content. The results compare reasonably well with trend in VFTRIM-3D [2] modeling and experimental sticking data of A. von Keudell [3]. A second surface, representing a "soft" redeposited carbon layer formed by the deposition of hydrocarbons onto a graphite surface, is also analyzed. In general, reflection is lower from the "soft" surface (0.2 vs. 0.4 at 1 eV). These reflection coefficients, together with the energy and angular distribution of reflected particles, can be incorporated in erosion/redeposition codes to allow improved modeling of chemically eroded carbon transport in fusion devices.

1. Introduction

The use of carbon-based surfaces, structures, and materials has led a wide range of scientific development and technological applications, in particular the use of hydrocarbons [1]. Examples include the application of nanotubes, diamond-like amorphous carbon films [2], and nanocrystalline diamond films and their production from low-temperature hydrocarbon plasmas [3]. An understanding of the chemical processes and physical mechanisms governing the interaction of carbon-based surfaces and hydrogenic/hydrocarbon environments is necessary to further advance hydrocarbon technology applications. One particular application of carbon-based materials is their use as plasma facing surfaces in magnetic confinement fusion reactors [4-6]. The uptake and release of hydrogen species at the plasma boundary in fusion devices is an important issue that requires vast knowledge of the nature of chemical and physical phenomena in hydrocarbons [7]. In a fusion device an understanding of how hydrocarbon surfaces erode and how impinging hydrocarbon and hydrogenic species reflect is vital to assess fusion plasma performance.

Carbon has been a leading candidate for use as a plasma-facing component for some time. As such, carbon-based materials, in such forms as graphite or CFC (carbon fiber composites), have been widely used in fusion devices. This typically means covering the surface of the walls with carbon tiles, especially in regions where a large flux of heat or particles to the wall is expected, e.g. on the *divertor*. The divertor is a place where the magnetic field lines that confine the plasma ions intentionally intersect a material surface. Carbon based materials are attractive because carbon has a low atomic number (Z=6), which is critical to keeping radiation power losses from the core to a minimum. Additionally, they have good thermomechanical properties [8]. Most notably, carbon materials can withstand the large heat fluxes of a tokamak without their structure being degraded. Carbon will not melt, and seems to be the material best suited to dealing with the required heat load, especially during off-normal events (e.g. disruptions) characterized by unusually large heat and particle loads.

However, carbon is not a perfect choice. Carbon is more susceptible to *physical sputtering* (defined as the release of one or more target atoms due to an incident particle) than higher Z materials (e.g. tungsten, molybdenum) and has a lower energy threshold for physical sputtering. The major problem with carbon comes from the special chemical relationship between carbon and hydrogen, the main component of a fusion plasma. The chemical affinity between the two causes carbon-based materials to be susceptible to chemical sputtering in the presence of a hydrogen plasma. The result is the release of hydrocarbon impurities into the plasma. These hydrocarbons are dominated by methane, but have been shown to contain significant amounts of heavier hydrocarbons, i.e. C_2H_x and C_3H_x species, which can account for up to 50% of the total chemical erosion of graphite under hydrogen impact [9].

Another important issue related to the erosion of hydrocarbons is the sticking of impinging hydrocarbon or hydrogenic species on the carbon-based surface. An eroded particle released into the plasma boundary of a fusion device will undergo a number of reactions, in some cases leading to ionized states. Due to the sheath potential in the plasma boundary and collisions with the background plasma these ionized species (atomic and/or molecular) are drawn back to the carbon-based surface[10]. This process has been successfully modeled by erosion/redeposition codes such as WBC and REDEP[11,12]. The energetic incident particles/molecules will either be implanted (stick) or reflected. This outcome will be dependent on a variety of parameters including: the incident energy, angle, mass and the surface chemical and thermodynamic state. Therefore, a critical improvement to erosion/redeposition codes (e.g. WBC, REDEP) would be the inclusion of realistic carbon/hydrocarbon reflection/sticking coefficients. The work presented here attempts to provide such reflection/sticking data using a molecular dynamics code to provide a realistic model for carbon/hydrocarbon interaction with carbon-based surfaces.

2. Modeling description

2.1. Description of computational models

A molecular dynamics (MD) code, MolDyn [13], was modified to study reflection of carbon and hydrocarbon molecules on a hydrogenated carbon (C:H) film. The code uses parameter set II of the Brenner hydrocarbon potential [14], an empirical many-body potential based on the Abell-Tersoff covalent bonding formalism [15,16]. This potential describes reasonably well the chemical bonding in graphite and diamond lattices, as well as hydrocarbon molecules. The second parameter set was chosen because it gives more accurate C-C bond stretching force constants. Temperature is controlled in the simulations with the velocity scaling method of Berendsen [17]. The simulation cell begins as a pure graphite lattice that is 39.1 Å by 40.2 Å and 20.1 Å deep, containing 4032 carbon atoms, and is modified as described below. Boundary conditions were chosen to simulate a small region of a much larger bulk material. The atoms within 2 Å of the bottom surface are held fixed, the top surface is free, and the sides of the cell have periodic boundary conditions.

VFTRIM-3D is used to compute the reflection coefficient as a function of incident particle energy [18]. In this paper the cohesion energy calculated from molecular dynamics is applied to the surface binding energy (SBE) in VFTRIM-3D. The bond energy is taken as 10% of the surface binding energy. Two layers are used in the VFTRIM-3D simulation with input data from the molecular dynamics code. The first layer has a SBE equal to 6.98 eV, the mass density as 1191 kg/m^3 and a 0.2 H-C composition. The second layer has a SBE equal to 7.04 eV, mass density of 1286 kg/m^3 and a 0.3 H-C composition.

2.2. Surface preparations

The MolDyn code was originally able to generate a carbon lattice in either graphite, diamond, or zinc-blende configuration. In order to study a surface more relevant to fusion devices, the original pure graphite surface was modified in one of two ways. Because a carbon surface in a fusion reactor will be bombarded by large fluxes of hydrogen, graphite will quickly become saturated with hydrogen. Therefore, the original pure graphite surface was bombarded with hydrogen atoms incident at at 20 eV and 45°, roughly what may be expected to occur in a tokamak. This process was carried out for over 4000 individual atom impacts, during which hydrogen is primarily implanted in the lattice but may also reflect or later be evolved

from the surface. The process leads to the evolution of the surface's hydrogen content as shown in Figure 1. The resulting surface is a hydrogenated graphite surface with 0.42 H:C, near what is typically found in experiments. The surface is near steady-state, as the H:C ratio is not completely constant at the end of the process shown in Figure 1. The CPU time requirements were the limiting factor in how long the preparation of the surface could be carried out.

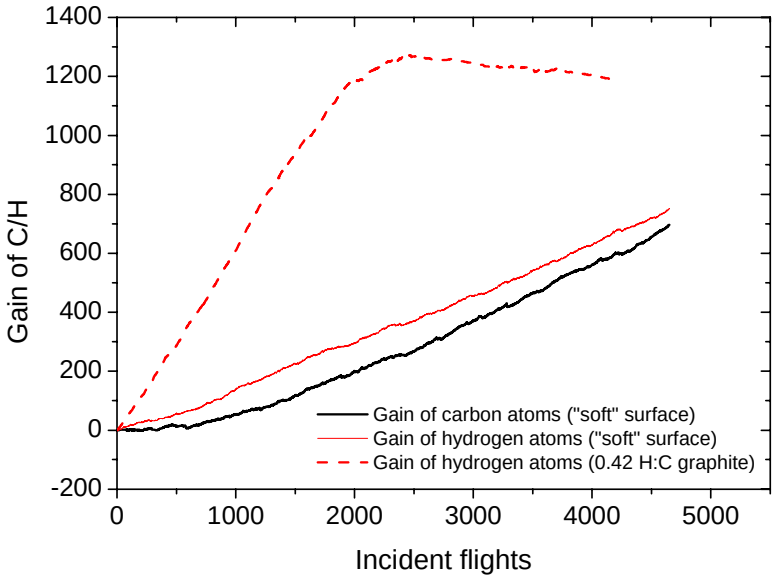

Figure 1. The gain of carbon and hydrogen atoms during surface preperation to get (1) a hydrogen saturated graphite surface [dashed line] and (2) a "soft" redeposited layer [solid lines]. For the 0.42 H:C graphite, saturation is reached as the line levels off. The "soft" layer, however, continually grows.

The second surface that has been developed is meant to go a step further to replicate real carbon PFCs. It also began as pure graphite, but instead of bombarding it with hydrogen only, as in the first process, both hydrogen and hydrocarbon molecules were launched at the surface. This emulates the redeposition of chemically sputtered hydrocarbons on the surface of PFCs in fusion devices. As in the prior case there were over 4000 flights run, with the effects of each being cumulative. Unlike the first case, however, the surface did not reach a steady-state. Instead, the number of carbon and hydrogen atoms comprising the surface both continued to grow, as shown in Figure 1. As such, the thickness of the surface grew from the original 20.1 Å to 47 Å – representing the deposition of a redeposited carbon layer almost 27 Å thick. This matches what occurs in experiments, as do some of the qualities of the layer; namely a lower density, higher H:C ratio, and less strongly bound carbon atoms in the "soft" layer.

2.3. Reflection calculations

The pre-prepared surfaces described above were used as input to all of the following reflection calculations. Carbon at 45° and 60°, and some hydrocarbon molecules (CH, CH_2, CH_3, and CH_4) at 45° were incident on the surface at 300 Kelvin. Incident energies ranged from thermal to ~10s of eV, coinciding with the upper end of the energy range where the potential is valid. Molecules were rotated randomly so that they struck the surface in a different 3D orientation each time. Thousands of separate flights were run for each incident species and energy to develop good statistics, giving reasonably small errors in the reflection coefficient of generally under 5%.

3. Results and Discussion

Molecular Dynamics simulations of carbon and hydrocarbon reflection were initally performed using the first (0.42 H:C graphite) surface, and were reported in detail in [19]. To summarize the results, carbon was found to reflect nearly 70% of the time at thermal energies, with the reflection coefficient decreasing to only 0.2 at 10 eV. It was found that the reflection coefficient was slightly higher at 60° incidence (from normal) than at 45°. The angular dependence on reflection probability was more pronounced at the upper end of the energy range. Reflected carbon atoms at 45° incidence came away with ~32% of their original energy. Also, they tended to reflect with a distribution of elevation angles peaked at 45°, and tending to continue in their original direction parallel to the surface. Carbon atoms at 60° incidence showed some evidence of a specular component in the reflected elevation angle distribution, and a more definite tendency to continue in their original azimuthal direction.

The reflection behavior of hydrocarbon molecules was more complicated, as the molecules tend to break up upon hitting the surface at significant energy. The result is that various fragments can be reflected from the surface. For example, an incident methane molecule can come back as CH_4, CH_3, CH_2, CH, C, H_2, or H. In order to effectively summarize these type of results, the total carbon recycling was calculated as the sum of all carbon atoms reflected in various fragments, divided by the number of incident carbon atoms. Comparison of such a calculation for carbon and all of the methane family of hydrocarbons (CH_x) is shown in Figure 2 and demonstrates that the reflection coefficient tends to increase with the hydrogen content of the molecule. Methane, a saturated molecule, shows almost no sticking over most of this energy range. However, at higher energies the molecule breaks up, allowing the fragments to stick. As one goes from CH_4 to CH_3 to CH_2 to CH the reflection coefficient decreases. The behavior of molecules, in terms of reflected energy and angle, was similar to that of carbon atoms, although this is complicated by their tendency to break apart upon impact.

An attempt was made to compare these results to those of a Monte Carlo BCA-based code, such as VFTRIM-3D. This data is shown in Figure 2, and seems to agree reasonably well with the results of the MD code. It is somewhat difficult to directly compare the two, mainly because they are valid at different energy ranges. A similar comparison was made between the MD code and some experimental data on hydrocarbon sticking/reflection at thermal energy for CH_2 (reflection coefficient $R \approx 0.972$-0.975) [20] and CH_3 ($R \approx 0.986$-0.999) [21-24]. The data presented here shows good agreement to these reflection coefficients.

The second type of surface analyzed is a “soft” redeposited carbon layer, formed by the process described in Section 2.1. As mentioned briefly above, this surface is characterized by a lower density, higher H:C ratio, and less strongly bound carbon atoms. Figure 3 shows some of these characteristics. First, the ratio of hydrogen atoms to carbon atoms reaches over 0.6 in the redeposited layer, increasing toward the very top of the layer. It is possible that this ratio would continue to increase if the redeposited layer was allowed to continue to grow. Second, there is a dramatic decrease in density (proportional to the number of atoms in each slice of volume) as one approaches the surface. Additionally, carbon atoms very near the surface have an average potential energy of -6.0 eV, compared to -7.4 eV on a pure graphite surface. It has been theorized that the existance of such layers on plasma facing components, which would cause them to erode more easily[25], may help to better explain some experimental findings[26].

Reflection measurements on this “soft” surface were performed for CH_3, CH_2, CH, and C at 1 eV and 45° incidence. The resuling data points are shown in Figure 2, allowing for comparison to the data on the previous surface. In each case, reflection was less likely on the “soft” layer. This effect was the largest for carbon atoms, for which the reflection coefficient decreased from 0.42 to 0.18 (a 57% decrease). CH went from the previous value of 0.37 to 0.21, CH_2 declined from 0.63 to 0.42, and finally CH_3 decreased from 0.86 to 0.63. Simulations at a full range of incident energies, as well as for other incident hydrocarbon molecules, are currently underway.

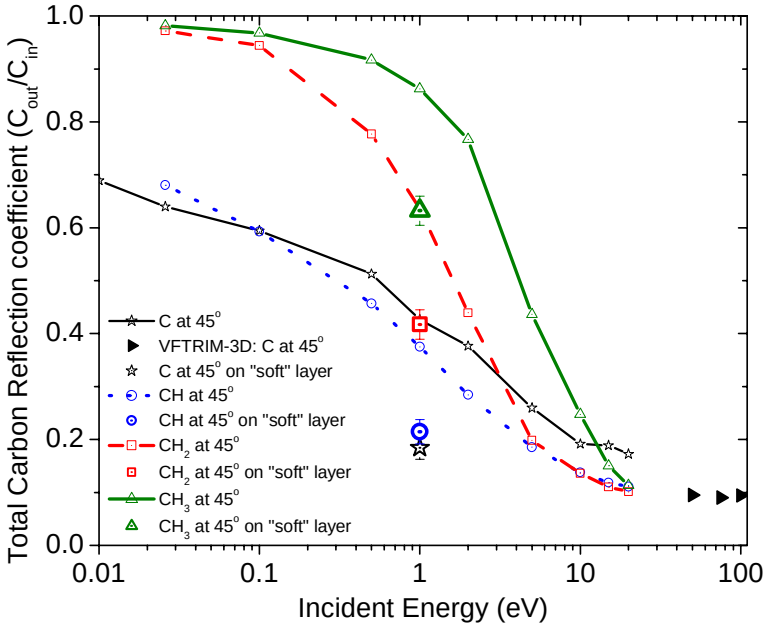

Figure 2. The total carbon reflection coefficient for C, CH, CH_2, CH_3 at various energies on the 0.42 H:C graphite surface (lines) and at 1 eV on the new "soft" redeposited layer (data points at 1 eV). For comparison, VFTRIM-3D data for carbon incident at 45 degrees is also shown.

4. Conclusions

A molecular dynamics code has been optimized for studying surface interactions between carbon and hydrocarbon molecules and carbon-based surfaces. Reflection data for carbon and several hydrocarbon molecules (CH, CH_2, CH_3, and CH_4) has been calculated. There appears to be a definite trend in the data, i.e. molecules with a higher hydrogen content are more likely to reflect. The data is compares relatively well with VFTRIM-3D modeling at the higher energies and with experimental hydrocarbon sticking data at thermal energy.

The information gained from these simulations, namely reflection coefficients and reflected energy and angular distributions, have been included in erosion/redeposition codes to improve the capability of modeling chemically sputtered carbon transport in fusion devices [26]. One remaining unknown is the chemical erosion yield, which is thought to vary depending on the type of surface in question. For example, the "soft" redeposited layers that are thought to erode more easily. Additional modeling and experimental work is required to resolve certain discrepancies between modeling and experiment, e.g. the codeposition problem in JET [26]. In terms of the MD modeling presented here, future work includes studying more hydrocarbon molecules (including C_2H_y and C_3H_y species) and looking a larger range of incident energies.

Acknowledgements

The authors would like to thank Jeffrey Brooks, whose work with erosion/redeposition modeling provided the motivation for this work, and Robert Averback for providing the MolDyn code used as a starting point for the modeling discussed herein. This work was supported by the United States Department of Energy, under a subcontract from Argonne National Laboratory.

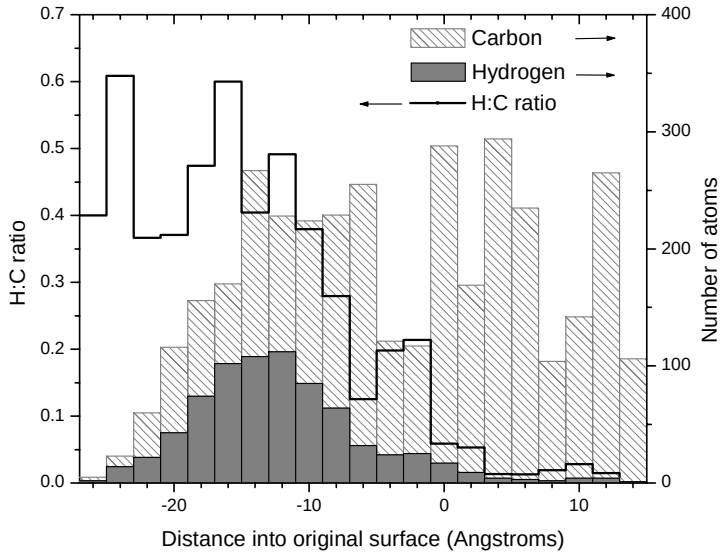

Figure 3. Properties of the "soft" redeposited carbon surface showing the hydrogen to carbon ratio (line) and the concentration of carbon (cross-hatched) and hydrogen (gray) atoms versus depth. A depth of zero represents the original surface, and the deposited layer extends in the negative direction.

Global Model of High/Low Frequency Decoupling in Dual Frequency Capacitive Discharges

M.A. Lieberman and Jisoo Kim

Department of Electrical Engineering and Computer Science, University of California, Berkeley, CA 94720

Abstract

Large area capacitive discharges driven at two frequencies, one of which is is higher than the usual industrial frequency of 13.56 MHz, have attracted recent interest for dielectric etching on large area substrates. In the ideal case, the high frequency controls the plasma density n (ion flux) and the low frequency controls the ion bombarding energy $\mathcal{E}_i$. A global (volume averaged) model of dual frequency discharge operation is described, and the conditions for the decoupling of the high and low frequencies are obtained.

1. Introduction

Large area plasma processing systems capacitively driven at frequencies higher than the conventional industrial frequency of 13.56 MHz, and dual frequency capacitive reactors with one high and one low frequency drive, have attracted much recent interest from researchers and equipment manufacturers for silicon wafer and flat panel display processing [1–14]. Larger areas are required as semiconductor manufacturers increase wafer sizes from 200 mm to 300 mm, and also for processing large (1 meter $\times$ 1 meter) glass panels for active matrix LCD flat panel computer and TV screens. Higher frequency produces a reduced ion bombarding energy for a given ion flux to the substrate [1, 3, 6, 15–17]. A reduced bombarding energy is required in the near future, to process integrated circuits with smaller critical dimensions (gate widths) and to increase reactor throughput. Higher frequency also permits the addition of a second, low frequency bias voltage, for additional flexibility. With both a high frequency and a low frequency drive, independent control of *both* the ion flux and ion bombarding energy can be achieved in capacitive reactors [8, 9, 11–14, 18].

2. Dual Frequency Discharges

Dual frequency capacitive reactors can have desirable properties for dielectric etch: low cost, robust uniformity over large areas, and control of dissociation (F-atoms). In the ideal case, the high frequency controls the plasma density n (ion flux) and the low frequency controls the ion bombarding energy $\mathcal{E}_i$. Typical operating conditions are: discharge radius $R \sim$ 15–30 cm, length $L \sim$ 1–3 cm, pressure $p \sim$ 50–300 mTorr, high frequency $f_1 \sim$ 27.1–160 MHz, low frequency $f_2 \sim$ 2–13.6 MHz, high frequency voltage amplitude $V_{\rm rf} \sim$ 250–1000 V, low frequency voltage amplitude $V_B \sim$ 500–2000 V, and powers of 500–3000 W for both low and high frequency sources.

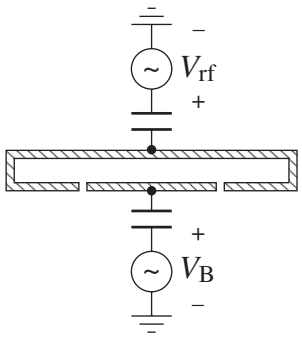

Figure 1. Diode model (two electrodes).

The two main types of dual frequency discharges are shown in Figs. 1 and 2. The diode configuration has the high frequency voltage applied to the larger area electrode and the low frequency voltage applied to the smaller area electrode. However, components of both high and low frequency voltages appear across the sheaths at both electrodes. The triode configuration has an added ground electrode.

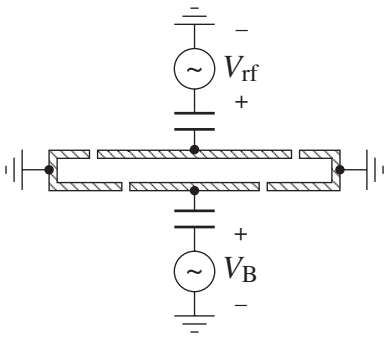

Figure 2. Triode model (three electrodes).

If the area of this ground electrode is large compared to the areas of the two driven electrodes, then the high frequency can mainly appear across the upper electrode sheath, and the low frequency across the lower electrode sheath. However, for both diodes and triodes, it is possible to achieve a good decoupling of the effects of the high and low frequencies, such that the high frequency mainly controls the plasma density (ion flux) and the low frequency mainly controls the ion energy at the lower electrode.

To understand the decoupling, let us consider a cylindrical (radius $R >>$ length L) discharge model in a simple gas (argon). We use a global (volume-averaged) model. In the steady state, the production of electron-ion pairs in the volume by electron-neutral ionization must be balanced by the loss of pairs to the walls. It is well known [19, Sec. 10.1] that this particle (ion) balance relation sets the electron temperature T_e of the plasma, independent of the plasma density n. Typically $T_e \sim$ 2–5 eV, depending weakly on the pressure. The corresponding electron power balance relation is

$$P_e = enu_B\, 2A\, \mathcal{E}_e \tag{1}$$

where P_e is the electron power absorbed, $u_B = (eT_e/M)^{1/2}$ is the ion loss (Bohm) velocity, $A = \pi R^2$ is the discharge plate area, and $\mathcal{E}_e$ is the total electron energy loss per electron-ion pair created (typically $\mathcal{E}_e \sim$ 30–100 eV for argon, depending on the pressure). We see that the density is simply proportional to the electron power absorbed P_e.

To understand why the high frequency controls the density, let us consider the ohmic heating of the plasma $P_e = \frac{1}{2} I_{rf}^2 R$ for the usual "sandwich" structure of a capacitive discharge carrying an rf current I_{rf}, with sheaths of thickness s each having capacitance C, and with a plasma resistance R, as shown in Fig. 3.

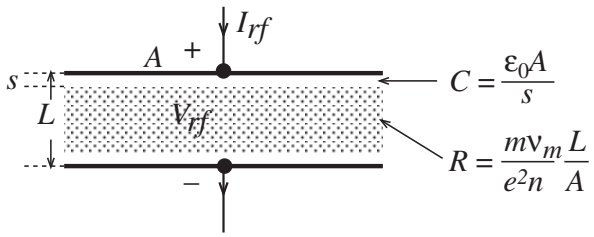

Figure 3. Sandwich structure of a capacitive discharge.

Since the current $I_{rf} \propto \omega C V_{rf} \propto \omega V_{rf}/s$ and the resistance $R \propto n^{-1}$, we have the scaling for ohmic power

$$P_e \propto \frac{\omega^2 V_{rf}^2}{s^2 n} \tag{2}$$

On the other hand, the Child law scaling for the sheath thickness is

$$n \propto \frac{V_{rf}^{3/2}}{s^2} \tag{3}$$

Eliminating s from (2) and (3) yields

$$P_e \propto \omega^2 V_{rf}^{1/2} \tag{4}$$

Since $n \propto P_e$ from electron power balance, a high frequency source at moderate voltage yields a high density, while a low frequency source even at fairly high voltage has almost no effect on density. *Hence, the high frequency power controls the density.*

For a diode (Fig. 1), the ion energy is controlled by the amplitude of the *total* voltage (high + low frequency) across the lower electrode:

$$\mathcal{E}_i \sim 2\,|V_{\rm rf} + V_B| \tag{5}$$

If the low frequency is at a high voltage V_B compared to the high frequency voltage $V_{\rm rf}$, *then the low frequency voltage controls the ion energy.* For a triode (Fig. 2), one can make the ground area large for additional control of ion energy by V_B. Hence the two conditions for good decoupling of high and low frequencies are:

$$\omega^2 V_{\rm rf}^{1/2} \gg \omega_B^2 V_B^{1/2} \tag{6}$$

$$V_B \gg V_{\rm rf} \tag{7}$$

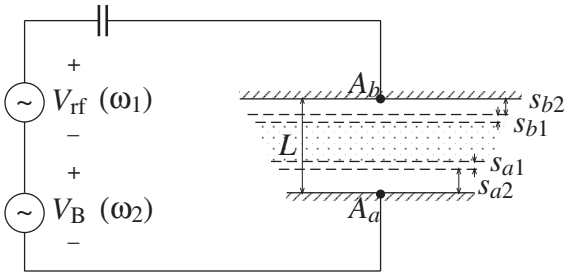

Figure 4. Global model of dual frequency diode discharge.

Let us examine a typical global model result for the dual frequency asymmetric diode model shown in Fig. 4. The discharge conditions are plate areas A_a = 544 cm^2, A_b = 707 cm^2, length L = 1.6 cm, high frequency f_1 = 27.1 MHz, low frequency f_2 = 2 MHz, and pressure p = 190 mTorr in argon. The physics incorporates Child law sheaths at the low frequency (thicknesses s_{a2} and s_{b2}) and homogeneous sheaths at the high frequency (thicknesses s_{a1} and s_{b1}).

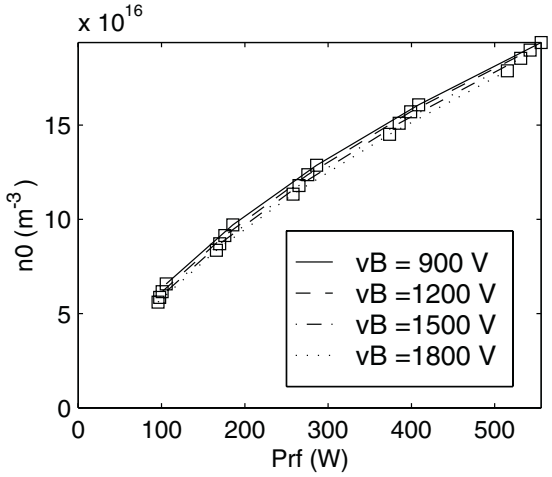

Figure 5. Central density versus high frequency power.

Homogeneous sheaths are used at high frequencies because the low frequency sheath thicknesses are generally larger than the high frequency sheath thicknesses. The low frequency sheaths act like capacitors that vary on the low frequency timescale, limiting the flow of high frequency current through the discharge. The model physics incorporates all ohmic and stochastic heating terms for both high and low frequencies, as well as the usual particle balance relation for ions.

The results for the central density n_0 versus the high frequency power absorbed $P_{\rm rf}$ are shown in Fig. 5 for four different low frequency voltages V_B. We see a good decoupling of low and high frequencies, with almost

the same central density n_0 at the same high frequency power $P_{\rm rf}$ over the range of low frequency voltages V_B = 900–1800 V.

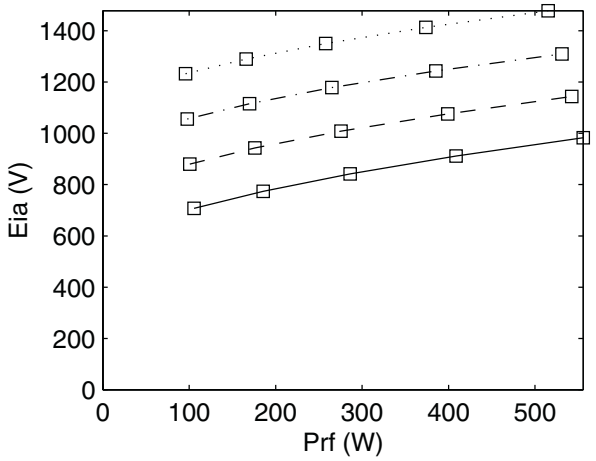

Figure 6. Ion bombarding energy versus high frequency power at electrode a.

The results for the ion bombarding energy $\mathcal{E}_i$ at electrode a are shown in Fig. 6. We see a reasonably good decoupling, with reasonably flat curves for $\mathcal{E}_i$ versus $P_{\rm rf}$ for each value of V_B. There is some slope to each curve, showing the influence of $P_{\rm rf}$ on $\mathcal{E}_i$. Ideally, for perfect decoupling, the curves would have zero slope everywhere.

3. Conclusions

We have described work in progress aimed at understanding and modeling dual frequency capacitive discharges for dielectric etch applications. A global (volume-averaged) model has been developed to determine the discharge parameters and to investigate the influence of the high and low frequency drives on the plasma density (ion flux) and ion bombarding energy. The conditions for decouping the effects of the high and low frequencies were examined.

We have previously examined the standing wave and skin effects due to the high frequency drive [20]. We showed that the discharge is excited at the high frequency by the propagation of surface and evanescent waves from the discharge periphery into the center. We showed examples of discharges where skin effects and standing wave effects could be important, and we found the conditions for which standing surface wave effects, surface wave skin effects, and evanescent wave effects can be neglected.

Abstract
A convenient way to synthesize aluminum nano particles is to evaporate the metal, direct this vapor into a tubular reactor and quench it with a radial flow of cold gas. The supersaturated vapors nucleate and grow into the desired nano particles. For small scale operations, because of the high temperatures and relatively low flow rates involved, the conditions of operation are usually laminar. As the units are scaled up to higher production rates, the flows become transitional or even fully turbulent. This work reports on the use of a Low Reynolds Number (LRN) turbulent model to simulate this system and its scale up for the synthesis of pure aluminum powders. The dynamic behavior of the particulate system was modeled in terms of the leading moments of a log-normal particle size distribution.

1. Introduction

The unique properties associated to nano size metal particles, thanks to the high fraction of atoms that reside at the grain boundaries, make them very attractive for different applications such as super alloys, thick film conductors, catalysis for the chemical industry, coatings, and others. A common method of production of metal powders is the Inert Gas Condensation (IGC). Pure product due to the inert atmosphere, relative ease to control by adjusting operation parameters, and possible continuous operation are the main features that make the IGC method appropriate for the production of aluminum nano particles.

The objective of this work was to develop a model to study the growth and transport of nano size metal particles inside a tubular reactor with radial injection of a quenching gas. The model is used to study the effect of the different operation parameters on the particle properties and to assist the scale up of the system. In this paper two cases are studied, the effect of the injection flow rate and the scale up of the process.

2. Mathematical model

Figure 1 shows a schematic drawing of the process, the plasma chamber and the particle generator. The particles are collected at the end of the particle generator by a filter. It is assumed that the particles are only formed inside the particle generator. This permits the separation of the model for the particle generator from

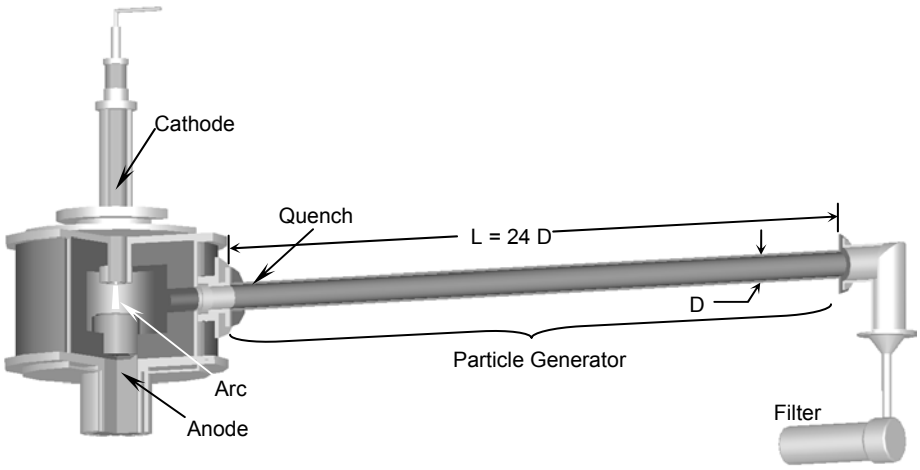

Figure 1: Schematic of the process of generation of nano size particles from the quench of a superheated vapor. The plasma chamber uses a transferred arc to evaporate the metal placed as the anode.

that for the heat source [1]. The particle generator is 60 cm in length and 5 cm in diameter. The quenching gas is injected through a slot 2.5 mm wide, located 5 cm from the entrance. The model has been developed for dilute systems, where the concentration of metal vapor in the gas phase is small (~ 10^{-3} kg Al/kg gas). The properties of the metal vapor and carrier gas mixture are assumed those of the carrier gas [2].

The Jones-Launder LRN $\kappa-\varepsilon$ turbulence model [3] was selected for its simplicity and low computational expense. This model also can be integrated to solid walls without fixing an artificial point below which a laminar sublayer is expected to exist. It uses a series of damping functions to force the desired behavior near the wall. It can also be used for both, laminar and turbulent flows as well as transitional flows [2, 4].

The metal vapor concentration is modified by convection, diffusion, nucleation and condensation and therefore it is coupled to the moment equations. The form of the conservation of metal vapor is presented in Eq. (1). The last two terms of this equation represent the amount of vapor being condensed by nucleation and by condensation, respectively.

$$\nabla\cdot\left(\rho\,\vec{u}\,w_{Al}\right)=\nabla\cdot\left[\left(\rho D_{Al,Ar}+\frac{\mu_t}{\sigma_w}\right)\nabla w_{Al}\right]-I\,\rho_p v^{*}-\rho_p^{1/3}B_1\left(S-1\right)\hat{M}_{2/3} \tag{1}$$

The moment equations are derived from the General Dynamic Equation (GDE) for turbulent flow [5]. The fluctuating sources of growth, coagulation, and nucleation rate are neglected (Eq. 2). The turbulent diffusion term is taken to be proportional to the gradient of the mean value of the transported quantity, by analogy with turbulent transport of momentum, since both phenomena are due to the same mechanism, eddy mixing [6].

$$\begin{aligned}\underbrace{\nabla\cdot\rho\,n_m\,\vec{v}}_{Convection}=&\underbrace{\nabla\cdot\left(\rho\left(D_p+\frac{\mu_t}{\sigma_t}\right)\nabla n_m\right)}_{Diffusion}-\underbrace{\nabla\cdot\rho\,n_m\,\vec{v}_{ther}}_{Thermophoresis}+\underbrace{I\left(v^{*}\right)\delta\left(v-v^{*}\right)}_{Nucleation}-\underbrace{\frac{\partial\left(G\,\rho\,n_m\right)}{\partial\,v}}_{Condensation}\\&\underbrace{+\frac{1}{2}\rho^2\int_0^{v}\beta\left(\tilde{v},v-\tilde{v}\right)n_m\left(\tilde{v}\right)n_m\left(v-\tilde{v}\right)d\tilde{v}-\rho^2\,n_m\left(v\right)\int_0^{\infty}\beta\left(\tilde{v},v\right)n_m\left(\tilde{v}\right)d\tilde{v}}_{Coagulation}\end{aligned} \tag{2}$$

The first step in deriving the moment equations is to define the moments of the particle size distribution. The particle size distribution is normalized by a constant n_0 [2], which represents the number of monomers at a certain location in the reactor, as presented in Eq. (3). Using this definition of the moments, a conservation equation for the k^{th} moment can be obtained by multiplying Eq. (2) by m^k and integrating over the entire particle size. The result of this procedure is presented in Eq. (4)

$$\hat{M}_k=\int_0^{\infty}m^k\,\frac{n_m\left(v,t\right)}{n_0}dv \tag{3}$$

$$\begin{aligned}\underbrace{\nabla\cdot\rho\vec{u}\hat{M}_k}_{Convection}=&\underbrace{\nabla\cdot\left(\rho\left(D_k+D_{turb}\right)\nabla\hat{M}_k\right)}_{Diffusion}-\underbrace{\nabla\cdot\rho\,\vec{u}_{ther}\hat{M}_k}_{Thermophoresis}\\&\underbrace{+I\left(v^{*}\right)\delta\left(v-v^{*}\right)v^{*k}\rho_p^k}_{Nucleation}+\left[\dot{\hat{M}}_k\right]_{Condensation}+\left[\dot{\hat{M}}_k\right]_{Coagulation}\end{aligned} \tag{4}$$

D_k represents the Brownian diffusion coefficient for the k^{th} moment, and D_{turb} is the diffusivity due to the turbulent motion. The Brownian diffusion coefficient is calculated using the simplified expression presented by Chiu [7]. The thermophoretic coefficient K_{Th} can be assumed to be independent of particle size for large Knudsen numbers, since it approximate an asymptotic value of 0.55. The nucleation term can be easily integrated since it is independent of the particle size distribution. I is calculated from the expression for the self-consistent nucleation rate [8]. The condensation [9] and coagulation [9, 10] terms in the Free Molecular Regime (FMR) are used in this work [5].

The integration of some of the terms in Eq. (4) requires the assumption of a particle size distribution function. In this work the distribution is approximated by a lognormal function which fits the observed size distributions reasonably well and its mathematical form is convenient for dealing with weighted distributions

[11]. Any moment of the size distribution is related to the zero moment, the geometric mean volume, and the geometric standard deviation. These parameters can be calculated from the first three moments of the distribution, Eq. (5) [9].

$$v_g = \frac{\hat{M}_1^2}{\hat{M}_0^{3/2}\hat{M}_2^{1/2}} \cdot \frac{1}{\rho_p}; \qquad \ln^2 \sigma_g = \frac{1}{9}\ln\left(\frac{\hat{M}_0\hat{M}_2}{\hat{M}_1^2}\right) \tag{5}$$

The equations are discretized using the Finite Volume Finite Difference Method (FVFDM). The set of algebraic equations is solved using the Gauss-Seidel line-by-line iteration scheme using a Tri-Diagonal-Matrix-Algorithm (TDMA of Thomas algorithm) to solve for each line. Moreover, the SIMPLER algorithm (Semi-Implicit Method for Pressure-Linked-Equations Revised) was used to solve the fluid flow field coupled to the continuity equation [12]. Here, the Power Law scheme for the diffusion-convection problem was used. The thermophoretic term also needs an interpolation function to calculate consistent fluxes at the interfaces; in this case, the Upwind scheme was implemented [6]. The solution of the equations is an iterative procedure that is manipulated in two different forms, relaxation factors or the method of false transients.

The equations are solved in a two dimensional axi-symmetric domain. The boundary conditions of the model are presented below; otherwise they are set to zero. At the entrance of the reactor the axial velocity, the temperature (2000 K), and the metal vapor concentration are specified (10^{-3} kg/kg). At the injection only the radial velocity and the temperature are specified. The turbulent quantities at these two positions are calculated from the relationships presented by Launder and Spalding [6] and a turbulent intensity parameter of 6%. The wall temperature is set to 1000 K. The different moments are set to zero at the entrance, the wall and the injection, indicating that no particles exist at these locations. At the outlet straight out boundary conditions are used, the axial gradients are zero. At the centerline standard symmetry boundary conditions are used.

3. Results and discussion
