After the first 2-h cycle of the wear test, the damaged surface of both types of coatings exhibited grooves parallel to the direction of the sample sliding movement. The span between grooves was approximately 100μm. At magnification from 1000× to 5000×, dense net of microcracks in splats, intersplat cracks [5] and smoothened edges of splats were observed. The residues of fractured splats had dimensions in plane perpendicular to the spraying axis from 20 to 50μm whereas the splat dimensions in the same plane prior to wear tests were up to 150μm.

Typical morphology of the damaged surface is presented on Figs. 4a, 4b. In several cases voids created by pull-out of spherical particles were found. The abrasive particles did not penetrate in the interior of such voids and the non-damaged splat structure of the coating [6] was observed. It was thus proved that the structure inside the coating is identical to that on the surface of the coating.

The damaged surfaces of both gray alumina and cromia coatings after the second, third and fourth 2-h cycle exhibited the main morphological features as observed after the first cycle, i.e. a dense net of microcracks in splats, delamination and smoothened edges of splats. Average dimensions of the residues of fractured splats after the later cycles were smaller than the dimensions of such residues formed in preceding cycles.

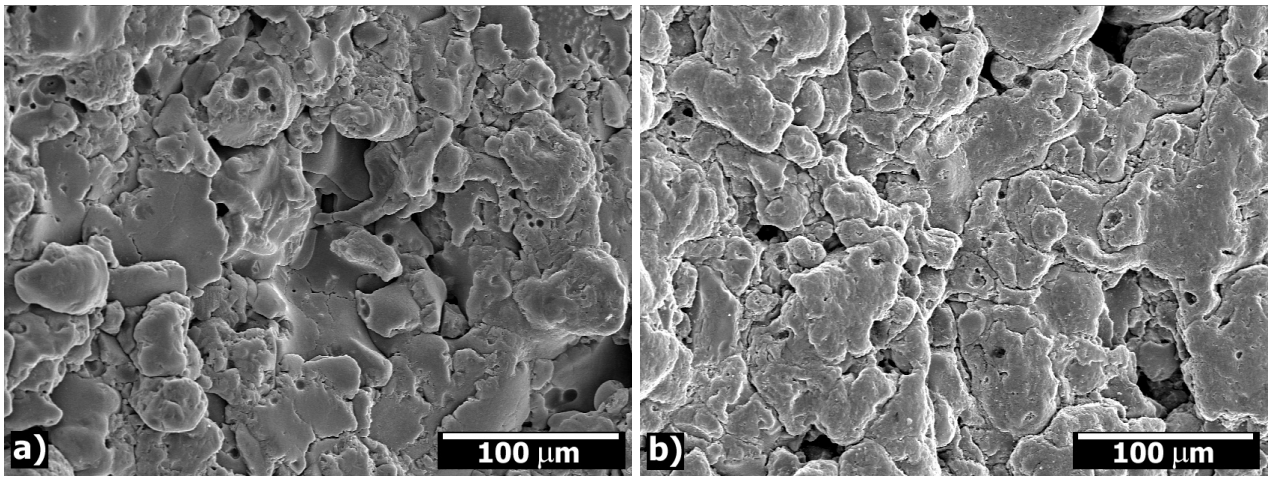

Figure 4 – SEM image of the damaged surface of Al_2O_3 coating **(a)** and Cr_2O_3 coating **(b)** after 4 hours of the wear test.

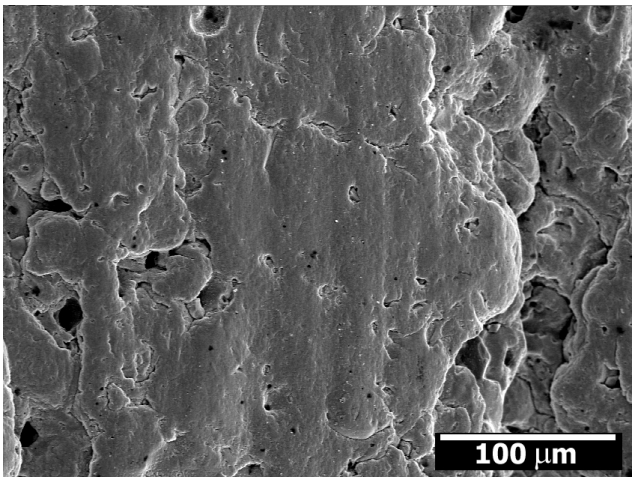

Figure 5 – SEM image of a flat area on the damaged surface of the cromia coating after 6 hours of the wear test.

During the second and third 2-h cycle large areas (2-D dimensions up to few hundreds of micrometers) with only minor vertical variation were created in the Cr_2O_3 coating (see Fig. 5). Such areas were not observed on the damaged surface of the gray alumina coating.

After the third cycle complete removal of the gray alumina coating from substrate was observed in several areas. It was decided in such cases to abandon the fourth cycle of the test because it would yield non-relevant values of the wear rate.

Fractographic analysis of the scratch test results

The results of the scratch test on the AL (gray alumina) and CR (cromia samples) served for SEM evaluation of the damaged surfaces and consequent determination of the main wear mechanisms of the ceramic coatings sprayed by WSP®.

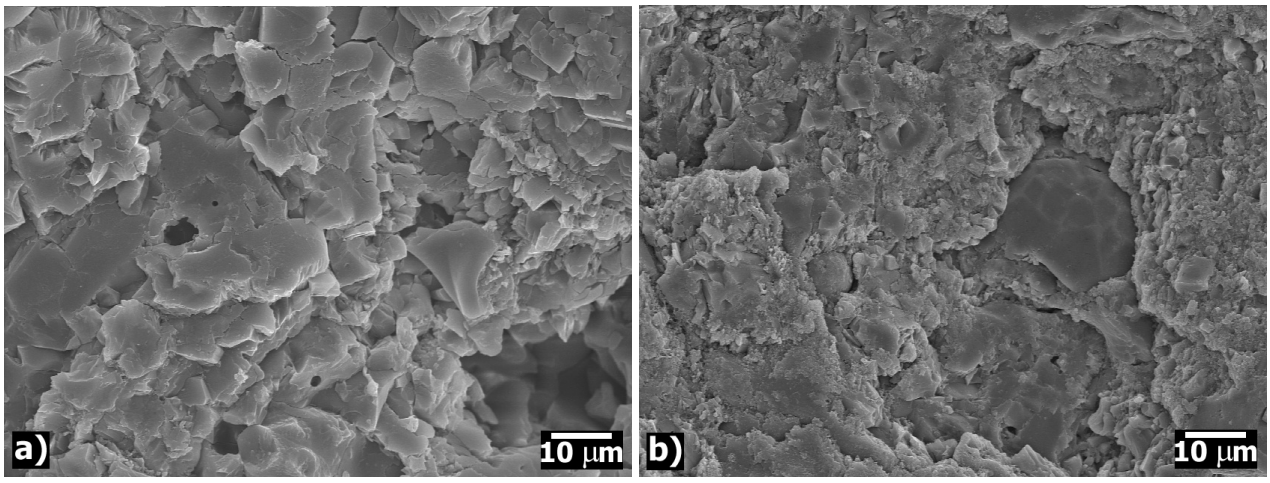

Figure 6 – SEM image of the interior of the scratch on **(a)** Al_2O_3 coating, **(b)** Cr_2O_3 coating.

The fractographic analysis of scratches on AL and CR samples confirmed the results of the fractographic analysis of the coatings subjected to the wear tests. The main morphological features found were:

- microcracks in splats,
- splats delaminated from neighboring splats and spherical particles,
- debris from the fractured splats re-deposited in the scratch.

However, several significant differences between the scratch morphology on the gray alumina and cromia coatings were found:

- the net of microcracks in the gray alumina splats was more dense than that in the cromia splats.
- the residues of fractured splats were in dimensions of approx.:
  - 10 to 30μm in the case of gray alumina coating (Fig. 6a),
  - 2 to 10μm in the case of cromia coating (Fig. 6b).

3. Discussion

The results of the wet slurry abrasion tests confirmed excellent wear resistance of the WSP®-sprayed Al_2O_3 and Cr_2O_3 coatings: cromia coating has the lowest wear rate, followed by gray alumina coating [7, 8]. The metal coatings exhibited higher wear rates than the ceramic coatings. The AISI 316L steel coating has wear rate comparable to that of gray alumina coating and can thus be considered for wear resistant applications, too. The results of the wear tests proved that WSP® can be used for spraying of large area wear resistant protective coatings such as cromia or gray alumina.

Direct comparison of the wear rates of WSP®-sprayed coatings with the results of other authors is difficult to carry out due to various experimental methods used by different authors. However, a good agreement between wear resistance of atmospheric plasma sprayed alumina and cromia determined by rubber wheel test [9] and WSP®-sprayed gray alumina and cromia coatings determined by slurry abrasion test was found (see Tab. 2).

Tab. 2 – Volume loss of alumina a cromia coatings deposited by different spraying techniques.

Coating	Volume loss in [mm^3] (atmospheric plasma spraying) [9]	Volume loss in [mm^3] slurry abrasion test (WSP®)
Al_2O_3	89.7	42.6
Cr_2O_3	22.3	18.6

The SEM analysis lead to determination of the main wear mechanisms of the WSP®-sprayed ceramic coatings:

- pull-out of spherical particles, thus creating areas with high stress concentration, susceptible to fracture [10],
- delamination and removal of entire splats [11],
- splat fracture and consecutive removal of the splat residues.

The different wear rates of cromia and gray alumina coatings are believed to be due to different internal microstructure of the splats. The gray alumina splats exhibit mainly columnar microstructure whereas cromia splats reveal fine and randomly oriented microstructure. Formation of microcracks perpendicular to the surface of the splats, which may result in splat fracture, is more favorable in the columnar microstructure. Fine and randomly oriented microstructure of cromia splats prevents formation and growth of vertical microcracks due to higher energy needed for crack propagation through the splat. The microcrack in cromia splat is forced to alternate its propagation plane, which is energy consuming process.

Removal of coatings material in the case of fine, randomly oriented microstructure is realized by smaller particles (corresponding to the size of microstructural units, i.e. 1 to 10μm) than removal of the material with columnar microstructure. The fine and randomly oriented microstructure of cromia splats resulted in superior wear resistance of cromia coating compared to gray alumina coating.

The removal of the gray alumina coating is thus supposed to be faster, which resulted in wear rate higher than that of the cromia coating.

4. Conclusion

Wet slurry abrasion and scratch tests of coatings sprayed by WSP® proved that this spraying technique can successfully be applied for deposition of wear resistant coatings. Due to high throughput and high temperature is this technique suitable for spraying of various large grain powders on large areas allowing complete melting of powder particles. The wear resistance of protective WSP®-sprayed coatings is comparable to that of coatings sprayed by other technologies and in some cases may be even higher. Wear

rates of the WSP®-sprayed coatings in ascending order were (see Fig. 2): Cr_2O_3, Al_2O_3, AISI 316L, Ni20Cr, Ni.

Fractographic analysis of the coatings damaged by wet abrasion and scratch tests allowed to identify the main morphological features of WSP®-sprayed gray alumina and cromia coatings. Comparison of the main wear mechanisms with wear mechanisms of coatings sprayed by other technologies indicated that both wear mechanisms are similar. Different micromorphology features and wear mechanisms lead to explanation of different wear rates of gray alumina and cromia coatings.

On the HMDSO dissociation paths in an Ar-fed expanding thermal plasma

M. Creatore, Y.Barrell, M.C.M. van de Sanden

Equilibrium and Transport in Plasmas, Department of Applied Physics

Abstract
Recently, it has been reported on the use of the expanding thermal plasma (ETP), a remote configuration, for the deposition of carbon-free dense SiO_2 films by means of hexamethyldisiloxane (HMDSO)/O_2 mixtures, at a very competitive growth rate of 7-10 nm/s. Because of its geometry, the ETP configuration has also proven its suitability for studies concerning the fragmentation paths of the HMDSO molecule and the reactions occurring in the plasma phase. In this framework, very recent results obtained by means of a very sensitive, high spectral resolution- absorption technique, Cavity Ring Down Spectroscopy, are presented.

Introduction
Organosilicon-based Plasma Enhanced Chemical Vapour Deposition (PECVD) is nowadays widely spread in the technological fields where $SiC_xH_yO_z$ films are employed, as IC/MEMS devices, optics, tribology, and packaging [1]. It is the possibility of tuning and controlling the degree of organic/inorganic character that eventually allows tailoring the physical-chemical properties of the coating (density, refractive index, dielectric constant, surface energy, internal stress, hardness…). However, this technology, mainly aimed to find out the "right recipe" for the film at competitive deposition rates, is not accompanied yet by a clear picture of the plasma phase reactions and the species responsible of the deposition process.
Recently [2-3], it has been claimed that the Expanding Thermal Plasma (ETP) leads to an entirely step-by-step chemistry-controlled deposition process (e.g., no ion bombardment involved), due to the geometrical separation between the plasma source and the deposition chamber.
In this paper we address the expanding thermal plasma (ETP) technique as a simplified approach to get better insight into the hexamethyldisiloxane (HMDSO) chemistry. In this framework, a very sensitive plasma diagnostic tool, as Cavity Ring Down (CRD) Spectroscopy, has been coupled to the ETP set-up. Absorption measurements of CH_3 and CH radicals, coupled with Mass Spectrometry investigations, have pointed out to the HMDSO dissociation mechanism.

Experimental
The ETP [4,5] is an example of remote plasma: plasma production, active species transport and substrate surface treatment (deposition/etching) are geometrically separated. Its advantage over other conventional remote plasma sources is that the downstream properties have no influence on the plasma production zone, due to the huge pressure difference between the two zones. This means that, for example, we can change the deposition precursors flow rates and/or the working pressure without affecting the plasma source characteristics. The Ar (Φ_{Ar}=25-100 sccs) plasma is ignited in a dc cascaded arc, operating at currents (I_{arc}) of 25-75 A and pressure range of 0.15-0.4 bar. The thermal plasma expands supersonically through a nozzle into the deposition chamber kept at the pressure (P_{vessel}) of 0.1-0.3 mbar. At 5 cm from the arc outlet, the HMDSO is injected in the plasma by means of a ring. Because of the expansion, the electron temperature drops to about 0.3 eV [6]: electron-induced molecule dissociations are very unlikely to occur and the chemical activity in the ETP deposition chamber is dominantly controlled by the (Ar^+, e^-) flow from the arc; furthermore, ion bombardment can be neglected.
CRDS and Mass Spectrometry (MS) measurements have been performed. CRDS, an absorption technique which is rapidly spreading as a diagnostic tool for the plasma phase investigation is highly sensitive, as it is characterized by a long effective path length due to high reflectivity (>0.99) of the mirrors defining the cavity. The principle of this technique and one of its applications when coupled to the ETP set-up, can be found in Refs. [7, 8] (see Figure 1a). In this paper we report on CH and CH_3 radicals. CH absorption has been detected within the 430.1 nm system ($A^2\Delta$ (v=0)←$X^2\Pi$ (v=0)) [8] and CH_3 at 216.6 nm ($\widetilde{B}^2A_1 \leftarrow \widetilde{X}^2A_2$, 214 -218 nm [9]). The broad spectrum, due to the pre-dissociative state of CH_3, is shown in Figure 1a. The detection region for the radicals is 3 cm above the substrate, placed at a distance of 60 cm from the nozzle.

MS investigation has been performed by means of an AccuQuad Residual Gas Analyser 200D (resolution of 10 pts/amu and detection sensitivity of 10^{-17} A), placed at the side of the substrate holder, at about 5 cm lower than the substrate.

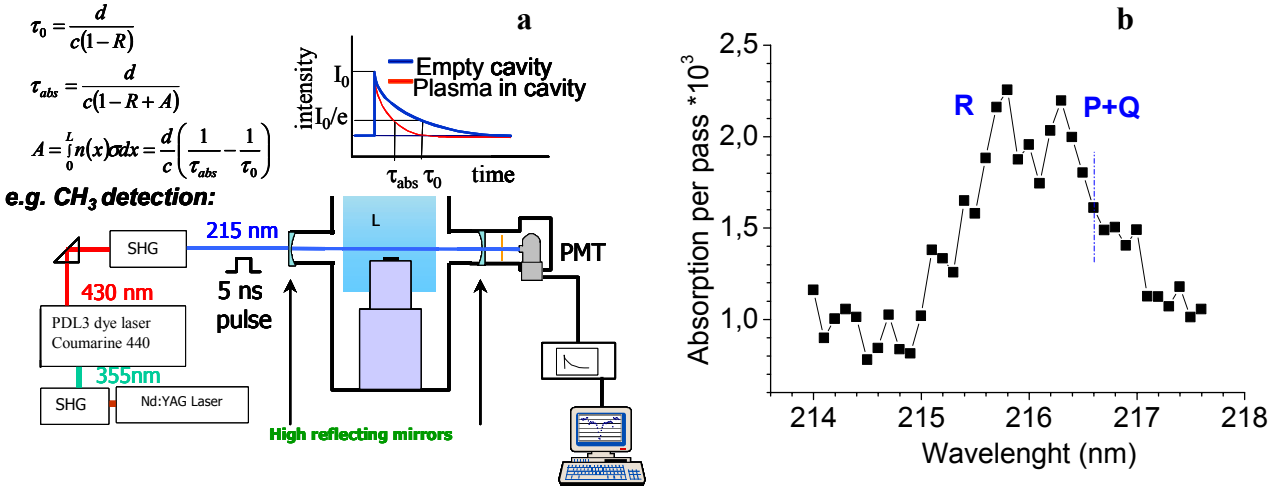

Figure 1: a) Cavity Ring Down Spectroscopy (and its principles) coupled to the ETP set-up. The particular case of CH_3 absorption is shown. b) Broad spectrum of CH_3 radical, due to its pre-dissociative character.

Results

In order to understand the dissociation paths of the HMDSO molecule in an expanding Ar plasma (Scheme I), the absorption of CH_3 radical has been measured by means of Cavity Ring Down Spectroscopy (CRD). The methyl radical, in fact, is a direct product of one of the possible dissociation routes which $[HMDSO]^+$ can undergo. The HMDSO reacts with an Ar^+ by means of charge exchange, which is then followed from a fast dissociative recombination with an electron.

Scheme I- Dissociative paths for the HMDSO molecule in an expanding thermal plasma

$$Me_3SiOSiMe_3 + Ar^+ \rightarrow [Me_3SiOSiMe_3]^+ + Ar$$

$$[Me_3SiOSiMe_3]^+ \xrightarrow{e^-} \begin{cases} Me_3SiO + SiMe_3 \rightarrow Me + Me_2SiO + SiMe_3 \\ Me_3SiOSiMe_2CH_2 + H \\ Me_3SiOSiMe_2 + Me \end{cases}$$

Figure 2 reports the measured CH_3 density divided by the total HMDSO density, e.g., the amount of methyl groups detected per HMDSO molecule. This ratio is compared, always in Figure 2, with the amount of Ar^+ available (from Langmuir probe measurements) per HMDSO molecule. One can conclude that the CH_3 production is leveled by the Ar^+ availability.

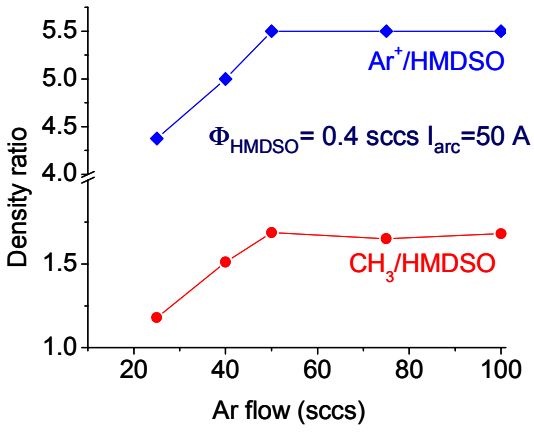

Figure 2: Ar^+/HMDSO density ratio compared with CH_3/HMDSO density ratio, as a function of the Ar flow rate.

Figure 3 reports the measured CH_3 density per HMDSO molecule, as a function of the arc current. When compared to the amount of Ar^+ available per HMDSO molecule, the CH_3/HMDSO decreases as the arc current increases, i.e., as more Ar^+ per HMDSO molecule are available.

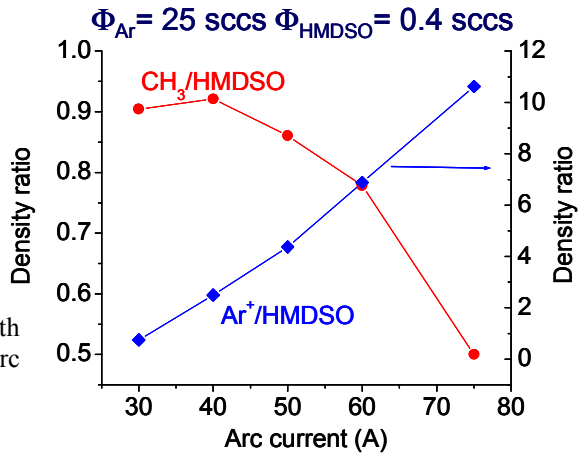

Figure 3: Ar^+/HMDSO density ratio compared with CH_3/HMDSO density ratio, as a function of the arc current.

The CH_3 radical can undergo dissociation as well, if enough Ar^+ are available. In particular, CH_3 can dissociate to give CH, according to Scheme II.

Scheme II- Dissociative path for the CH_3 radical in an expanding thermal plasma

$$CH_3 + Ar^+ \rightarrow CH_3^+ + Ar$$

$$CH_3^+ \xrightarrow{e^-} CH + H + H$$

The CH radical was monitored as a function of the arc current and its density is reported in Figure 4.
The CH density increases as function of the arc current, as more Ar+ are available for the path described in Scheme II.

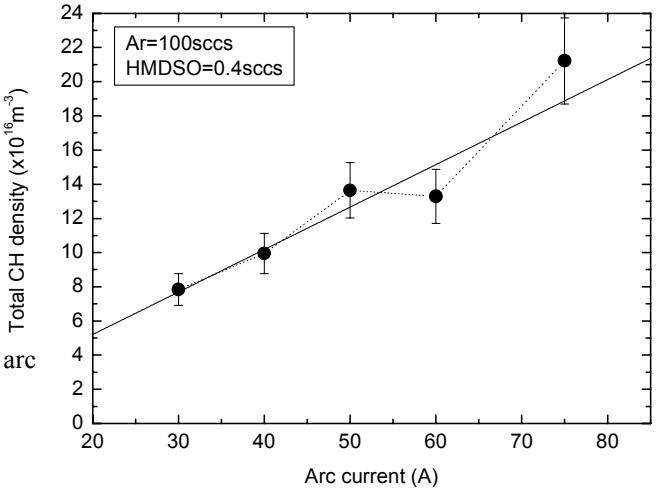

Figure 4: CH radical density as a function of the arc current.

The data shown in Figure 3 and 4 point out to dissociation paths of the HMDSO molecule where the formation of CH_3 radicals are involved. However, they cannot provide information whether the scission occurs at the Si-C bond or at the Si-O bond. Mass spectrometry studies were, therefore, performed in condition of similar Ar^+ produced (according to the arc efficiency and to the data collected by means of Langmuir probe) and amount of HMDSO available (at 50 A from 25 sccs Ar, the efficiency in Ar^+ production is estimated around 10% and the HMDSO injected downstream was 2 sccs). In these experimental conditions, we can highlight the most probable dissociation mechanism for the HMDSO molecule.

Figure 5 compares the ratio of the intensity of the 173 amu peak-to-the intensity of the HMDSO parent ion (*m/e*=147) when the plasma is off or on. The mass 173 amu corresponds to the $Si^+(CH_3)_3$ detected in the mass spectrometry, which corresponds to the neutral species $Si(CH_3)_4$ or to the radical $Si(CH_3)_3$, if this is characterized by a very low sticking probability, so that it can survive to the walls during its path to the mass spectrometer.

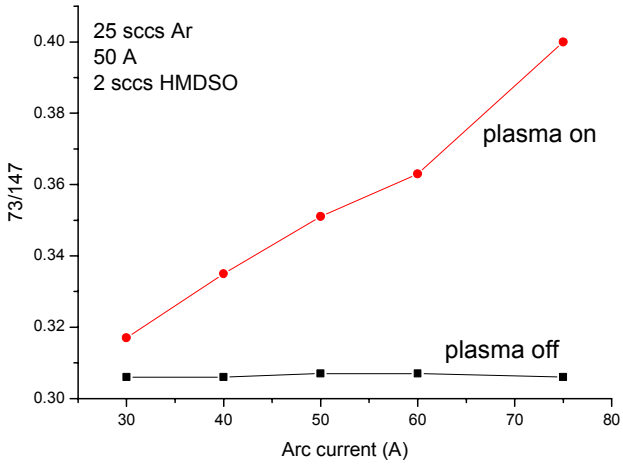

Figure 5: 73 amu signals normalized to the HMDSO parent ion (147 amu) as a function of the arc current, in the gas (plasma off) and in the plasma phase.

When this ratio is higher in the plasma phase, we can argue that the $SiMe_3$ radicals are also produced in the plasma phase (beside the MS), thus, suggesting that the preferred HMDSO dissociation route is at the Si-O bond.

Conclusions

The coupling of CRDS and MS to the ETP set-up looks promising in order to get better insight into the HMDSO dissociation paths. Under mild arc conditions (e.g., Φ_{Ar}=25 sccs, I_{arc}=50 A) the Si-O bond is preferred in the dissociative recombination of the $[HMDSO]^+$with an e^-. This shows totally different dissociation paths when comparing the ETP chemistry with more conventional plasma system, e.g., capacitively coupled, where the Si-C is unstable under electron impact.

Expanding thermal plasma for low-k dielectrics deposition

M. Creatore, Y.Barrell, W.M.M. Kessels, M.C.M. van de Sanden

Equilibrium and Transport in Plasmas, Department of Applied Physics
Eindhoven University of Technology, P.O. Box 513, Eindhoven, The Netherlands

Abstract
As the need for low-k dielectrics in the ULSI technology becomes urgent, the research primarily focuses on the deposition of novel materials with appropriate electrical properties and on the challenges concerning their integration with later processing steps. In this framework we introduce the expanding thermal plasma as a novel remote technique for the deposition of low-k organo-silicate glass materials from argon/oxygen/hexamethyldisiloxane mixtures.

Introduction
As the device dimensions of the ULSI chips shrink [1,2], it is necessary to reduce propagation delays, cross-talk noise between metal wires and power dissipation due to RC coupling. This is the reason why Cu (lower resistivity) has substituted Al and the research is now focused on the inter-metal dielectric (IMD) materials, which should have a dielectric constant lower than the one of SiO_2 in order to reduce the capacitance.
The spin-on deposition (SOD) has been the first to be adopted (IBM: SILK, k=2.65). On the other hand, chemical vapour deposition (CVD) is nowadays acknowledged for the possibility of using existing toolsets. Moreover, when the choice for a low-k dielectric falls on the siloxane (OSG) class, simpler process integration is expected because of the chemical structure similar to SiO_2.
Among the materials investigated, carbon-doped SiO_2 (SiOC) is considered a promising candidate in the 0.13 μm technology and beyond. The origin of the low dielectric constant of SiOC films has been investigated in literature [3] and mainly attributed to the decrease of the ionic component of the dielectric constant due to the replacement of Si-O bonds with $Si\text{-}CH_3$ bonds. Moreover, the presence of terminal groups increase the porosity, which inevitably decrease k. Also, a change in the dipolar component of the k value has to be considered since the $Si(O)_4$ tetrahedron is symmetric and does not have a dipolar component, while the insertion of methyl groups induces asymmetry, which promotes dipole generation.
The introduction of organic terminal groups in the silica network reduces necessarily the density of the dielectric, but also affects other properties. This brings up challenges on how to integrate the dielectric characteristics with later processing steps. In general, the main issue is related to the mechanical stability of the film, affected by the porosity. Residual gases from etch/ash processes can be trapped in the pores. High levels of porosity can lead to moisture uptake, which eventually leads to degradation of the dielectric constant. Films, which are mechanically weak, are prone to damage during processes, which induce stress (e.g., CMP, assembly, thermal processes…), and they are quite sensitive to wet/dry clean chemicals.
These considerations lead to conclude that a "successful" dielectric is a balance of material properties: the introduction of C-containing groups in the SiOSi network is limited by the negative impact of the porosity on the mechanical strength. In general, it has been observed [2] that the best compromise between electrical (k value) and mechanical (hardness) properties is obtained when deposition is performed from precursors with 2 Si-O and 1 Si-C bonds per Si atom. Two examples are DMOMS $(CH_3O)_2SiH(CH_3)$ and DEMS $(CH_3CH_2O)_2SiH(CH_3)$. The films deposited by these precursors shows a k value in the range of 2.75-2.95, as measured at 1 MHz and hardness around 1-3 GPa. Therefore, hexamethyldisiloxane (HMDSO) may not appear suitable as deposition precursor, due to the high $Si\text{-}CH_3$: Si-O bond ratio, which could lower far beyond the density of the film, and thus its mechanical stability. However, the expanding thermal plasma (ETP) set-up allows selecting different fragmentation paths for HMDSO, which eventually can be turned to the progressive cleavage of Si-C bonds. Therefore, the tuning of the process parameters, as it will be shown later, allows tailoring the organic functionalities in the film.

Experimental
The ETP (Figure 1) is an example of remote plasma [4,5]: plasma production, active species transport and substrate surface treatment (deposition/etching) are geometrically separated. Its advantage over other conventional remote plasma sources is that the downstream properties have no influence on the plasma

production zone, due to the huge pressure difference between the two zones. This means that, for example, we can change the deposition precursors flow rates and/or the working pressure without affecting the plasma source characteristics. The Ar (Φ_{Ar}=25-100 sccs) plasma is ignited in a dc cascaded arc, operating at currents (I_{arc}) of 25-75 A and pressure range of 0.15-0.4 bar. The thermal plasma expands supersonically through a nozzle into the deposition chamber kept at the pressure (P_{vessel}) of 0.1-0.3 mbar. At 5 cm from the arc outlet, the HMDSO is injected in the plasma by means of a ring. Because of the expansion, the electron temperature drops to about 0.3 eV [6]: electron-induced molecule dissociations are very unlikely to occur and the chemical activity in the ETP deposition chamber is dominantly controlled by the (Ar^+, e^-) flow from the arc; furthermore, ion bombardment can be neglected. O_2 was injected through the nozzle.

C-doped SiO_2-like films were deposited at a substrate temperature of 50°C on *c*-Si (100) having a resistivity of 7-21 Ω·cm. The dielectric constant at 1 MHz was obtained by a C-V meter on metal-insulator-semiconductor (MIS) structures. The values were confirmed by means of the Hg probe. Hardness/Young modulus values were obtained by means of nano-indentation measurements. Spectroscopic ellipsometric measurements (Woollam M-2000F rotating compensator ellipsometer, 245 – 1000 nm) were carried out on the deposited films in order to evaluate their optical constants and thickness.

Film chemical characterization was carried out by means of X-ray Photoelectron Spectroscopy, after sputtering with Ar ions in order to remove the carbon contamination due to sample exposure to the ambient air.

Plasma characterization was carried out by means of Cavity Ring Down Spectroscopy (CRDS) [7,8] and Mass Spectrometry (MS). In the first case, radicals could be detected 3 cm above the substrate (which is placed at a distance of 60 cm from the nozzle). MS investigation of the background gas has been performed by means of an AccuQuad Residual Gas Analyser 200D (resolution of 10 pts/amu and detection sensitivity of 10^{-17} A), placed at the side of the substrate holder, at about 5 cm lower than the substrate.

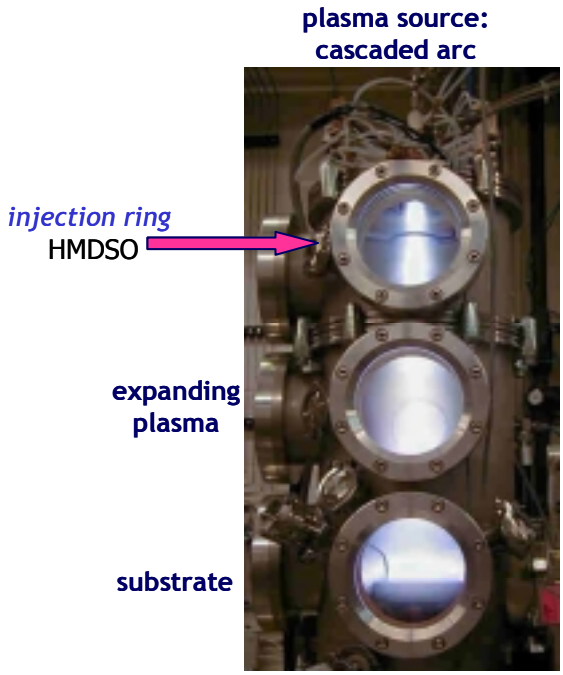

Figure 1: The expanding thermal plasma set-up.

Results

As already mentioned in the Introduction, the ETP set-up leads to a more rationalized approach to the deposition process, since the downstream properties have no influence on the plasma parameters. The HMDSO molecule dissociates in expanding Ar plasma [9,10], according to Scheme I: first, a charge exchange with an Ar ion occurs, followed from a fast dissociative recombination with an electron.

Scheme I- Dissociative paths for the HMDSO molecule in expanding thermal plasma

$$Me_3SiOSiMe_3 + Ar^+ \rightarrow [Me_3SiOSiMe_3]^+ + Ar$$

$$[Me_3SiOSiMe_3]^+ \xrightarrow{e^-} \begin{cases} Me_3SiO + SiMe_3 \rightarrow Me + Me_2SiO + SiMe_3 \\ Me_3SiOSiMe_2CH_2 + H \\ Me_3SiOSiMe_2 + Me \end{cases}$$

Figure 2a shows the depleted (e.g., consumed) HMDSO flow rate, as a function of the arc current, i.e., the Ar^+ flow rate as calculated from Langmuir probe measurements. The consumed HMDSO flow is proportional to the Ar ion flow, which emanates from the arc. Figure 2b compares the ratio of the intensity of

the 173 amu peak-to-the intensity of the HMDSO parent ion (*m/e*=147) when the plasma is off or on, as a function of the arc current. The mass 173 amu corresponds to the $Si^{+}(CH_3)_3$ detected in the mass spectrometry, which relates to the neutral species $Si(CH_3)_4$ or to the radical $Si(CH_3)_3$, if this is characterized by a very low sticking probability, so that it can survive to collisions with walls during its path to the mass spectrometer. When this ratio is higher in the plasma phase, we can argue that $SiMe_3$ radicals are also produced in the plasma phase (beside the MS), thus, suggesting that the preferred HMDSO dissociation route is at the Si-O bond.

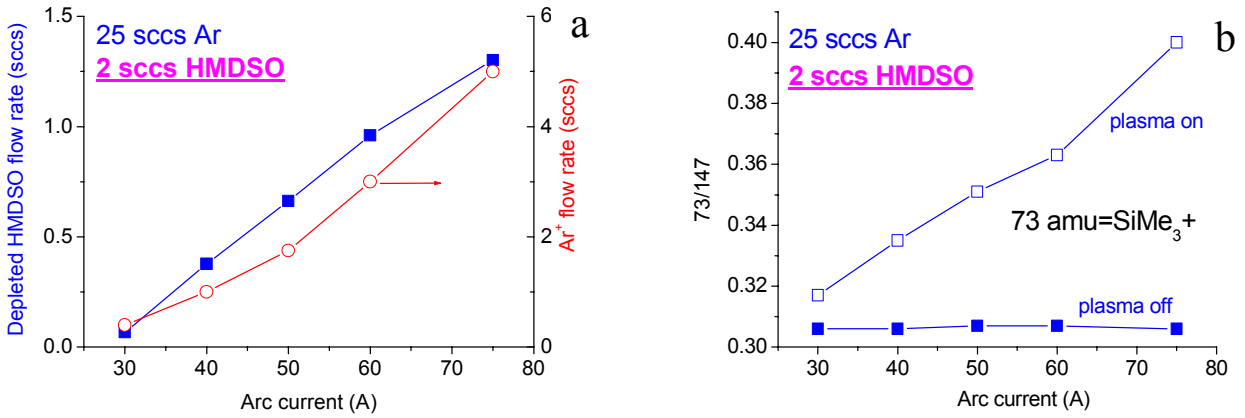

Figure 2: a) Depleted HMDSO flow rate as a function of the arc current. The Ar ion flow rate (as calculated from Langmuir probe measurement) has been reported for comparison. b) 73 amu signals normalized to the HMDSO parent ion (147 amu) as a function of the arc current, in the gas (plasma off) and in the plasma phase.

From Figure 2 it appears clear that the most favourite dissociation path occurs at the Si-O bond, in conditions where the HMDSO flow rate is similar to the Ar^{+} flow rate. These conditions, however, will presumably lead to the "wrong" film stoichiometry, as the film will be oxygen-deficient. XPS analysis of the films deposited in the same experimental conditions reported in Figure 2 show that the composition varies a little with the arc current and it can be expressed as $SiC_1O_{0.6}$.

In order to rebuild the SiOSi network, it is therefore necessary to "dilute" HMDSO in O_2. Figure 3a shows the depleted HMDSO and O_2 flow rates, as a function of the O_2 addition. Figure 3b, in particular, shows that the HMDSO depletion is "almost" independent from the O_2 depletion: even in the presence of O_2, Ar^{+} "prefers" to react with HMDSO, presumably due to the very low reaction constant of the charge exchange reaction of Ar^{+} with O_2 ($4.6 \cdot 10^{-11}$ cm^3/s). However, we cannot neglect, for the moment, reactions of HMDSO fragments with O_2.

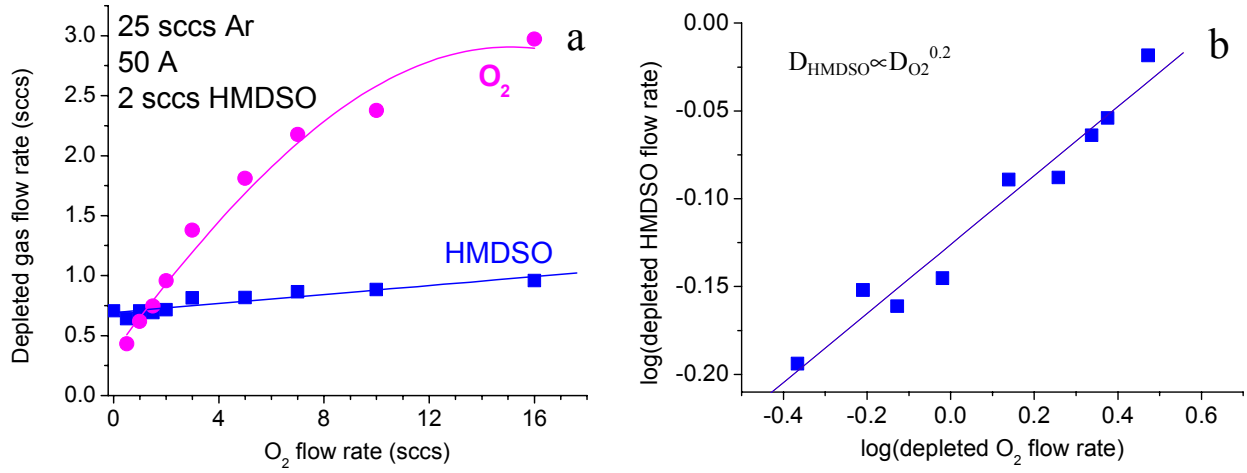

Figure 3: a) Depleted HMDSO and O_2 flow rate as a function of the added O_2 flow. b) Logarithm plot of the depleted HMDSO flow rate as a function of the depleted O_2 flow rate.

Films deposited in the above-mentioned conditions do show a refractive index (as measured at 633 nm), which decreases as a function of the O_2 flow rate and reaches values below 1.46 (thermal silica), as shown in Figure 4a. Since films deposited even at high dilution of HMDSO in O_2 still contain carbon (Figure 5), we can conclude that the low refractive index is due to the presence of porosity. Figure 4b reports the imaginary part of the dielectric function, which is correlated with the presence of carbon in the film, as the absorption in the low wavelength range witnesses: the absorption in the film decreases as the O_2 addition increases.

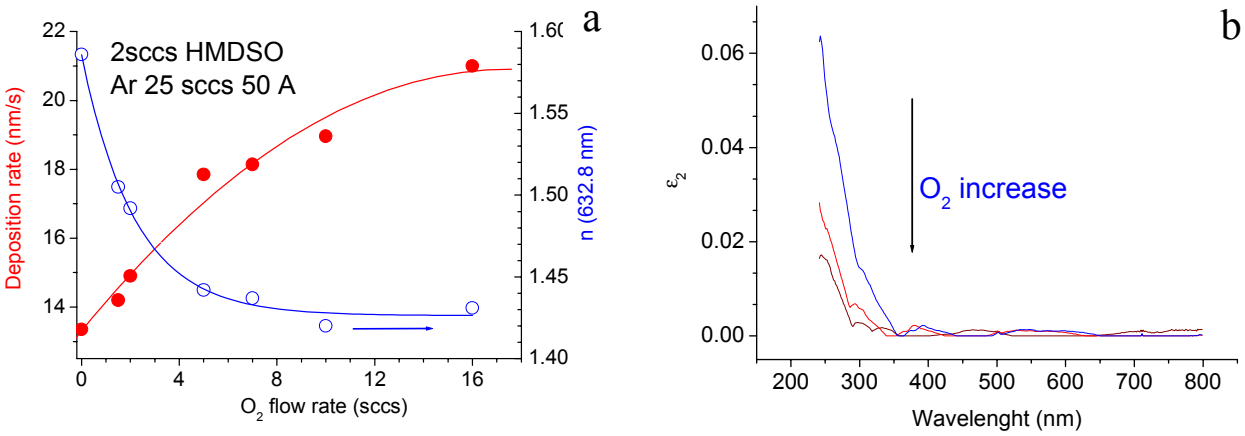

Figure 4: a) Deposition rate and refractive index of the deposited films as a function of the O_2 flow rate. b) Imaginary part of the dielectric function as a function of the O_2 flow rate.

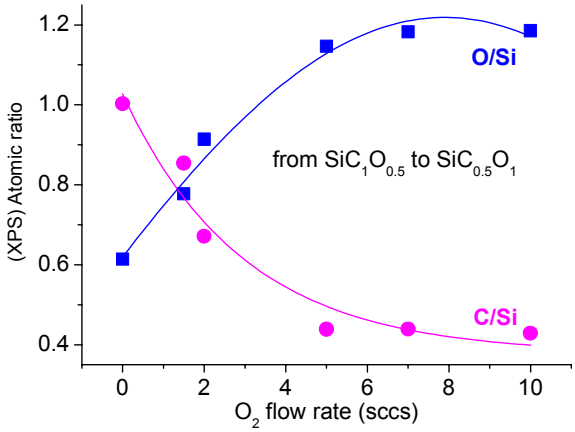

Figure 5: Chemical composition of the deposited films as a function of the O_2 flow rate, as determined from XPS measurements.

Films deposited in these conditions reach a dielectric constant if 3.44±0.15 for O_2=10 sccs. However, as the chemical composition suggests, the films are expected to be mechanically weak due to the fact that they are still deficient in oxygen content. The films show a hardness of 0.4 GPa and a modulus of 4-4.5 GPa.

We can conclude from this first investigation that a higher dilution of HMDSO in O_2 is necessary. In particular, by keeping constant the Ar ion flow rate expanding from the arc and decreasing the HMDSO flow rate, more Ar^+ per HMDSO molecule will be available. We could, therefore, use these Ar^+ in a selective way in order to "strip" methyl groups from the HMDSO molecule and O_2 for controlling the inorganic SiOSi structure.

Figure 6 shows reports the measured CH_3 density divided by the total HMDSO (0.4 sccs) density, e.g., the amount of methyl groups detected per HMDSO molecule. This ratio is compared, always in Figure 6, with the amount of Ar^+ available (from Langmuir probe measurements) per HMDSO molecule. One can conclude that the CH_3 production (stripping) is leveled by the Ar^+ availability.

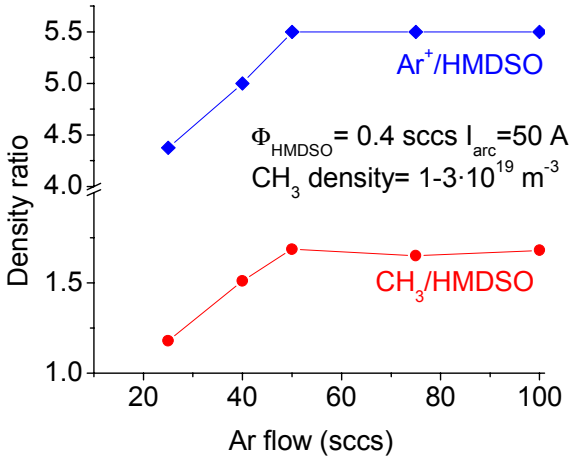

Figure 6: Ar^+/HMDSO density ratio compared with CH_3/HMDSO density ratio, as a function of the Ar flow rate.

Figure 7a shows the refractive index as a function of the O_2 flow rate: the *in situ* values are found lower than the *ex situ* measurements due to the water up-take when porous films are exposed to ambient air. Figure 7b shows the dielectric constant as a function of the O_2 addition, which reaches a value as low as 2.9. The hardness and modulus of these films are 1GPa and 10 GPa, respectively.

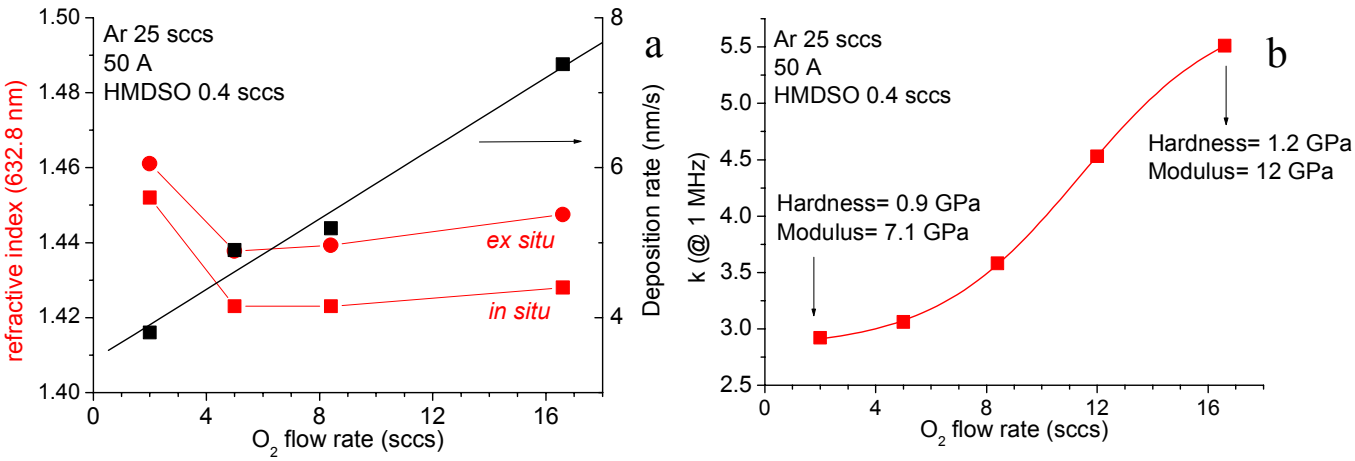

Figure 7: a) Deposition rate and refractive index of the deposited films as a function of the O_2 flow rate. b) Dielectric constant (as measured at 1 MHz) as a function of the O_2 flow rate. The hardness and modulus values are also reported.

Conclusions

Low-dielectric constant films were deposited by means of the expanding thermal plasma set-up: a minimum of 2.9, as measured at 1MHz, was found with an acceptable hardness of 1 GPa. The investigation of the plasma phase by means of Cavity Ring Down Spectroscopy and Mass Spectrometry has been helpful for tailoring the organic/inorganic content of the deposited films.

The future work will deal with a better insight into the deposition of low-k materials and their further characterization (e.g., porosity evaluation).

The $N_2(A^3S_u^+)$ density produced in atmospheric-pressure nitrogen streamers: experimental determination by time-resolved emission spectrometry.

M.Šimek

Institute of Plasma Physics, Department of Pulse Plasma Systems,
Academy of Sciences of the Czech Republic, Za Slovankou 3, 18221 Prague , Czech Republic

Abstract
Newly developed spectrometric method was applied to determine absolute densities of $N_2(A^3\Sigma_u^+)$ metastable species produced by positive streamers. Streamers were generated in high-purity, atmospheric-pressure nitrogen with NO traces by applying short, high-voltage pulses to wire anode in coaxial wire-cylinder electrode geometry. The $N_2(A^3\Sigma_u^+)$ densities in the range 10^{14}-10^{15} [cm^{-3}] were found close to the central wire anode during early post-discharge time.

1. Introduction
In the physics and chemistry of non-equilibrium nitrogen or N_2-O_2/air discharges, the fundamental role is played by the lowest electronically excited and metastable $A^3\Sigma^+_u$ state of N_2. Except for a very long (~2s) radiative lifetime, the $N_2(A^3\Sigma^+_u)$ molecule possesses enough energy (~6 eV) to initiate many energy transfer and chemical reactions [1]. Recently, we have proved that the post-discharge populations of $NO(A^2\Sigma^+)$ and $N_2(^3\Pi,^5\Pi)$ states in atmospheric-pressure nitrogen streamers have a common $N_2(A^3\Sigma^+_u)$ precursor [2,3]. The experimental evidence is based on the fact that the intensity of $N_2(C^3\Pi_u \rightarrow B^3\Pi_g)$, second positive system (2.PG) emission varies quadratically with the intensity of the $NO(A^2\Sigma^+ \rightarrow X^2\Pi)$ system (NO-γ) and on the study of the $N_2(C^3\Pi_u, v=0\text{-}4)$ state vibrational distributions during both discharge and post-discharge phases. An independent confirmation of the former scheme was provided through the observation of the $N_2(C''^5\Pi_u \rightarrow A'^5\Sigma_g^+)$ Herman infrared (HIR), $N_2(C'^3\Pi_u \rightarrow B^3\Pi_g)$ Goldstein-Kaplan (GK), and $N_2(B^3\Pi_g \rightarrow A^3\Sigma_u^+)$ first positive (1.PG) systems populated by the $N_2(A^3\Sigma_u^+)$ energy pooling as well. The quantitative $N_2(A^3\Sigma^+_u)$ determination is obviously the next step for further study of nitrogen streamer properties.
To determine absolute $N_2(A^3\Sigma^+_u)$ densities we applied newly developed method suitable to investigate atmospheric-pressure nitrogen streamers [4,5]. The method originates from the correlation of emission intensities of the $NO(A^2\Sigma^+)$ and $N_2(C^3\Pi, C''^5\Pi)$ states observed in a decaying streamer channel with the $N_2(A^3\Sigma^+_u)$ state evolution through a simplified kinetic model:

- $N_2(A^3\Sigma_u^+)+N_2(A^3\Sigma_u^+) \rightarrow N_2+N_2(C^3\Pi_u)$ & $N_2(C^3\Pi_u) \rightarrow N_2(B^3\Pi_g) + h\nu_{2.PG}$,
- $N_2(A^3\Sigma_u^+)+N_2(A^3\Sigma_u^+) \rightarrow N_2+N_2(C''^5\Pi_u)$ & $N_2(C''^5\Pi_u) \rightarrow N_2(A'^5\Sigma_g^+) + h\nu_{HIR}$,
- $N_2(A^3\Sigma_u^+)+NO(X^2\Pi) \rightarrow N_2+NO(A^2\Sigma^+)$ & $NO(A^2\Sigma^+) \rightarrow NO(X^2\Pi) + h\nu_\gamma$.

Assuming atmospheric-pressure, post-discharge conditions under which the excitation of $N_2(C''^5\Pi_u, C^3\Pi_u)$ and $NO(A^2\Sigma^+)$ states is governed by the above mentioned energy transfer processes, one can expect that $NO(A^2\Sigma^+, X^2\Pi)$ and $N_2(C''^3\Pi_u, C^3\Pi_u, A^3\Sigma_u^+)$ populations go rapidly towards the steady-state which is determined by a balance between the pooling, resonant transfer, radiative and quenching processes. A stationary solution of corresponding rate equations then provides simple correlation between $NO(X^2\Pi)$, $NO(A^2\Sigma^+)$, $N_2(C^3\Pi_u)$ and $N_2(A^3\Sigma^+_u)$ state densities. The diagnostic procedure is then based on the modelling of NO-γ and N_2-2.PG emissions controlled by $N_2(A^3\Sigma^+_u)$ species through the pooling and resonant energy transfer reactions, and on establishing suitable calibration procedure [4]. Figure 1 shows synthetic bands occurring in the region of Δv=-1,-2 sequences of N_2-2.PG system. Each of synthesised band components contributes to the final spectrum with a specific weight, which depends on $N_2(A^3\Sigma^+_u)$ density. An example of the spectrometric representation of $N_2(A^3\Sigma^+_u)$ density through the blend of NO-γ and N_2-2.PG emissions is given in figure 2. All spectra shown in figure 2 were normalised so as to equal 2.PG-(0,1) band intensities. Finally, the concentration of $N_2(A^3\Sigma^+_u)$ metastables can be determined from experimental data by analysing time evolutions and relative intensities of emissions driven by the pooling and resonant energy transfer

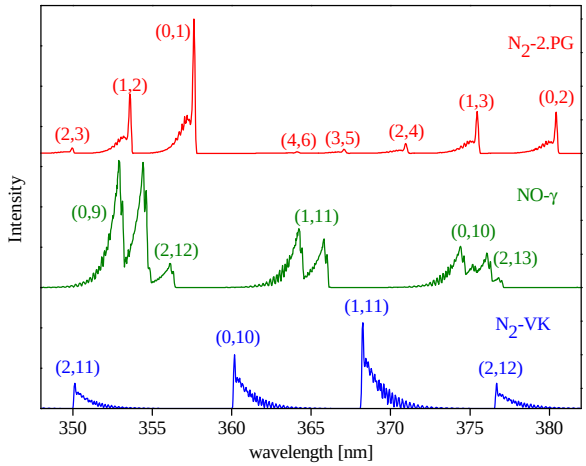

Figure 1: Synthetic bands of N_2-2.PG, N_2-VK and NO-γ systems.

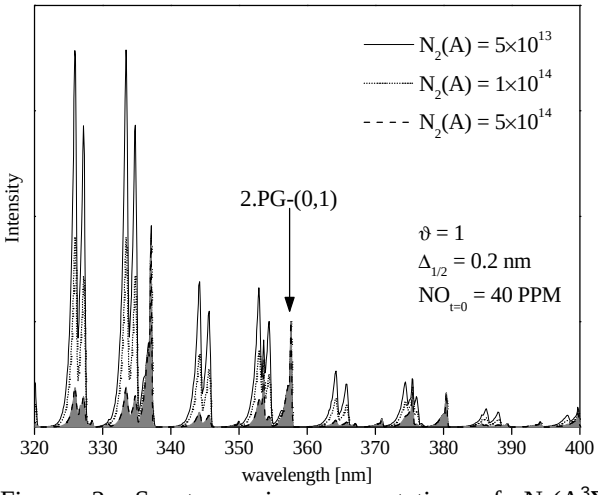

Figure 2: Spectroscopic representation of $N_2(A^3\Sigma_u^+)$ concentration via N_2-2.PG, N_2-VK and NO-γ emissions.

reactions [5]. The application of the method requires that concentrations of predominant $N_2(A^3\Sigma^+_u)$ quenchers are known and stable during the acquisition of spectrometric data. This can be fulfilled by adding a well defined quantity of an efficient $N_2(A^3\Sigma^+_u)$ quencher to the nitrogen stream so that the influence of the trace impurities (O_2, H_2O) as well as of species produced during the discharge phase (mainly $N_2(X,v\geq5)$ and $N(^4S)$ atoms) remains minor or not competitive. The former is well fulfilled, in our case, by adding small quantity of NO to the main N_2 stream and by limiting the amount of energy ($\leq 10^{-3}$ Wh/l) that is dissipated in the discharge volume [5].

2. Experimental setup

Investigated streamers (see figure 3) were generated in coaxial wire-cylinder geometry at atmospheric pressure in high-purity nitrogen with quantified NO traces. The experimental corona device consists of an Ag-coated Cu central wire anode (2r = 0.75 mm) and a grounded stainless-steel cylinder (2R=56 mm). The pulsed high-voltage power supply with maximum ratings, 100 kV/1kA/ 7 ns rise time/ ~100 ns fall time, delivers up to 2 J per pulse with up to a 10 Hz repetition rate at atmospheric pressure into the discharge volume ~ 1500 cm^3. Stable flow of nitrogen with defined quantity of NO is maintained by Bronkhorst mass flow controllers. The GA-60 flue gas analyser equipped with electrochemical cells was used to monitor volumetric concentration of nitrogen oxides (NO and NO_2).

The ISA JobinYvon and Chromex spectrometric systems, equipped either with multi-channel detectors or with a photon-counting system monitored the emission coming out along the symmetry axis of the discharge through quartz optics and colour glass filters. High time resolution has been obtained by synchronising the data acquisition systems with HV circuitry for the corona discharge. Because streamer parameters alter during the propagation between electrodes and the strongest emission can be expected from the high field region, we focused on emission generated close to wire anode (indicated by white dash circle in figure 3). The space resolution in radial direction was obtained by using a collection system composed of two lenses and three apertures.

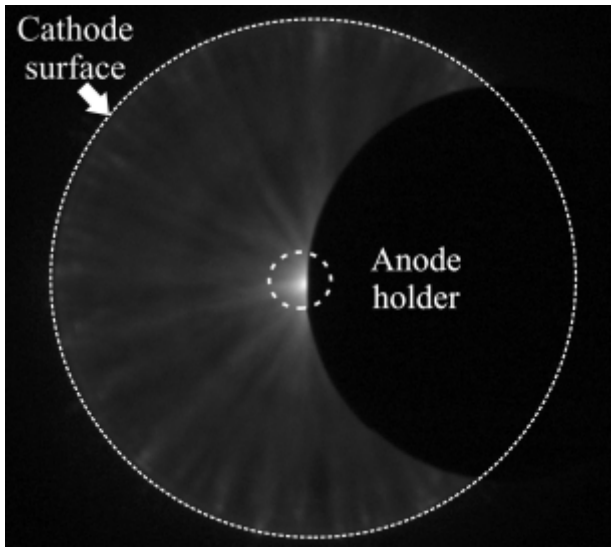

Figure 3: Digital photograph of the discharge area registered by a fast CCD camera.

3. Results

In order to follow time evolution of emission intensities we used two complementary data acquisition approaches. The first approach makes use of an ICCD detector, fixing the delay of the CCD intensifier opening gate with respect to the master trigger controlling corona pulsing. Multichannel ICCD spectra were used to evaluate relative emission intensities of selected molecular bands at given post-discharge time. The second approach uses PMT with a multichannel

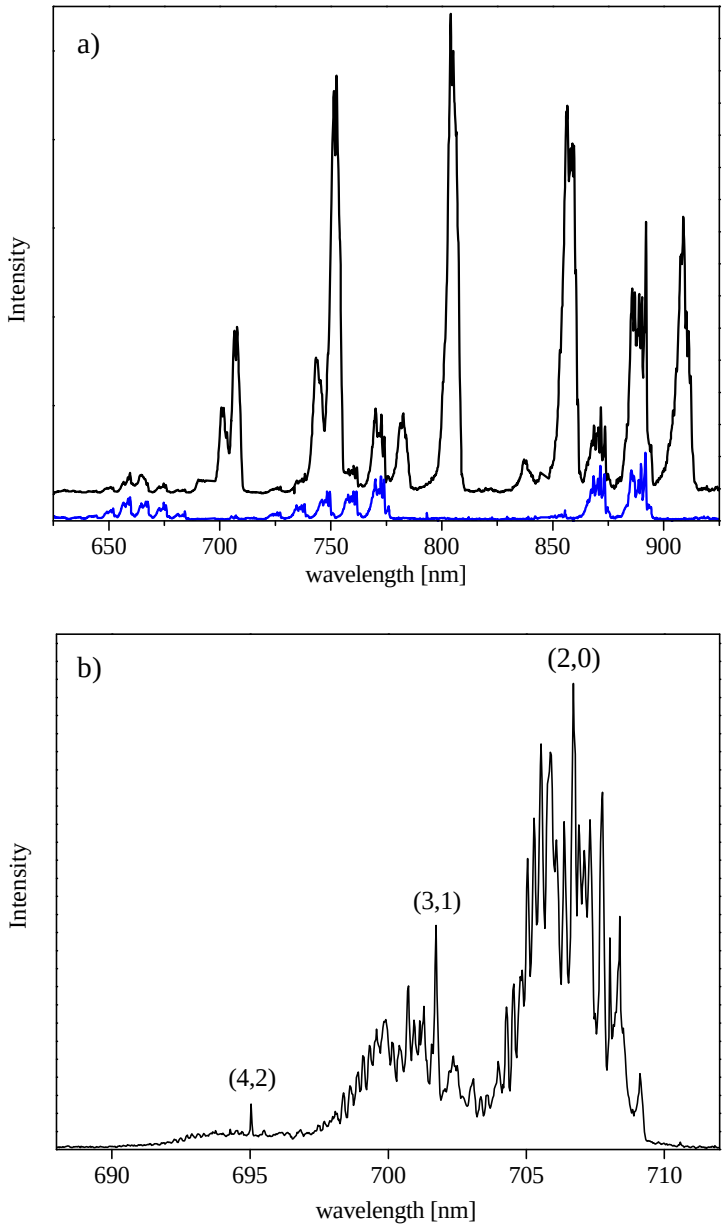

Figure 4: Characteristic streamer-induced emission observed in high-purity nitrogen at atmospheric pressure. Spectra acquired by multichannel ICCD data acquisition technique show a) the blend of bands of N_2-1.PG and N_2-HIR systems in the VIS-NIR spectral region and b) the $\Delta v=2$ sequence of N_2-HIR systems. Lower (blue) trace in the upper figure acquired as a discharge average, other (black) traces acquired without time resolution.

photon-counting system to obtain "continuous" time courses at fixed wavelengths. In the case of the photon-counting technique we selected appropriate wavelengths and entrance/exit slit widths of monochromator in order to obtain bandwidths well matching selected peaks. Finally, the composition of the gas mixture after passing the discharge chamber was studied by means of the flue gas (NO_x) analyser.

A number of ICCD spectra were taken during the post-discharge period to evaluate relative emission intensities between selected bands. Basically, data were acquired in two regimes; a) by fixing the initial N_2+NO composition (and all other discharge conditions) and varying the delay of the ICCD gate with respect to the corona HV pulse onset, and b) by fixing the ICCD gate and varying the NO concentration in the mixture.

Characteristic examples of ICCD spectra obtained in VIS-NIR spectral region from the discharge in high purity nitrogen are shown in figure 4. The upper trace in figure 4a (acquired without any time resolution) is given by the superposition of N_2-HIR and N_2-1.PG emissions. The lower blue trace (acquired as the average over the 150 ns discharge period) is given exclusively by N_2-1.PG emission, which is excited by streamer head electrons. Because N_2-HIR emission is excited exclusively by the pooling energy transfer, the square root of its intensity ($\ddot{O}(I^{HIR})$) describes relative evolution of $N_2(A^3\Sigma^+_u)$ density. To obtain $\ddot{O}(I^{HIR})$ curves, we utilised HIR emission occurring via the $\Delta=+2$ sequence, which is shown with better spectral resolution in figure 4b. The normalisation of relative $\ddot{O}(I^{HIR})$ curves was performed by analysing the $(I^{2.PG}/I^{g})$ intensity ratio of N_2-2.PG and NO-γ emissions [4,5]. Resulting normalised $\ddot{O}(I^{HIR})$ curves, obtained for several N_2+NO mixture compositions, are shown in figure 4.

4. Conclusions

The potential of the spectrometric method to determine $N_2(A^3\Sigma^+_u)$ metastable concentrations was investigated in the environment controlled by specific energy transfer processes. The method is based on the N_2-2.PG, N_2-VK, N_2-HIR and NO-γ emission analysis and its performance was inspected by analysing post-

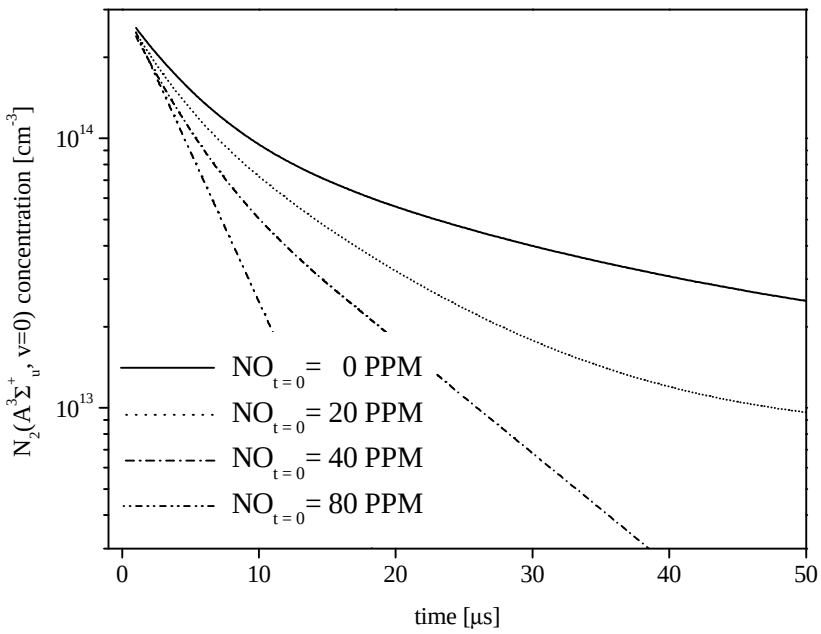

Figure 4: The $N_2(A^3\Sigma_u^+)$ concentrations determined through normalised $\ddot{O}(I^{HIR})$ curves. The time on the *x*-axis means the delay t_D between the onset of the HV corona pulse and the centre of an opening gate for the MSA counting channels.

discharge emission induced by pulsed positive streamers generated in coaxial wire-cylinder geometry in high-purity nitrogen with quantified NO traces.

After verification that all necessary conditions for correct application of the method were satisfied, we evaluated concentrations of $N_2(^3\Sigma^+_u)$ metastables from spectroscopic data acquired close to the central wire anode.

According to the method, the aggregate concentration of $N_2(A^3\Sigma^+_u)$ metastable species in the two lowest v=0,1 vibrational levels reaches as much as $\sim 5\times10^{14}$ [cm^{-3}] during early post-discharge time (~1 μs). Our data represent, to our knowledge, the first experimentally determined $N_2(A^3\Sigma^+_u)$ densities produced by nitrogen streamers at high (atmospheric) pressure, which are reported in the literature.

Absorption measurements of OH radical in sterilization plasma by means of Cavity Ring Down Spectroscopy

M. Creatore[1], R. Groenen[1], R. De Mitri[2], F. Rossi[2], M.C.M. van de Sanden[1]

Abstract
A highly sensitive laser-aided diagnostic tool, Cavity Ring Down Spectroscopy (CRD) is used to study the OH (integrated) absorption in a MW (2.45 GHz) sterilization plasma, operating at a power of 500-1500 W and fed by O_2/H_2 mixtures. Two different groups of lines of the broad OH absorption were detected: their intensity ratio gives a good indication of the rotational temperature of the radical, in general very close to the gas temperature.

1. Introduction

Plasma-based techniques to achieve sterilization represent an alternative, safer and versatile (especially indicated for moisture- and heat- sensitive polymer-made devices) route to conventional techniques, as those using autoclaves, ovens or wet chemicals (e.g., ethylene oxide). The main reason for using plasmas in sterilization is the presence of highly reactive species (more reactive than "conventional" chemicals), which have been identified in ultraviolet radiation and radicals. It is still unclear whether and how radicals or photons play a fundamental role in the destruction of micro-organisms; yet, a rationalization of these processes is necessary in order to develop more efficient plasma-aided sterilization tools.
In this framework, preliminary investigation has been carried out on a MW (2.45 GHz) sterilization plasma, operating at a power of 500-1500 W and fed by O_2/H_2 mixtures. A highly sensitive laser-aided diagnostic tool, Cavity Ring Down Spectroscopy (CRD) [1,2] which is commonly-used at Eindhoven University of Technology [3,4,5], has been coupled to the reactor in order to detect the absorption of the OH radical (3064 Angstrom system, $A^2\Sigma^+$ (v=0)-$X^2\Pi$ (v=0)).

2. Experimental

Figure 1 shows the CRD spectroscopy set-up (and its principles) coupled with the MW reactor. CRD requires an optical cavity defined by two highly reflective mirrors (>99%). A laser pulse (5 ns) is produced using the Nd-YAG laser-pumped dye laser (PDL2 Spectra Physics) and sent into the optical cavity. The laser pulse undergoes hundreds of reflections in the cavity and a detector, placed behind the cavity, records the succession of pulses transmitted from the cavity after each round trip. Because the intensity of the pulse confined within the cavity undergoes attenuation at each round trip (a combination of losses caused by the mirrors themselves, as well as scattering and absorption from the *sample* present in the cavity), the detector records a waveform with a time decay theoretically fitted by an exponential. The time required for the intensity to decay to 1/e of its original value is defined as ring down time. Its value is related only to mirror losses (as shown in Figure 1) when the cavity is empty (τ_0), e.g., in our case no plasma or no OH is present. In the presence of an absorbing species (e.g., OH) the ring down time decreases to τ_{abs}. The absorption of the species can be, therefore, calculated from the measured ring down times and the length of the cavity.
The detection region for the radicals is 7 cm from the microwave source. Depending on the operative pressure, the OH absorption has been sampled in the glow (low pressure regime) or in the immediate afterglow (high pressure regime).
The two plano-concave mirrors (radius of curvature of 100 cm) are mounted on the reactor and bellows allow for fine adjustment; the cavity length is 97 cm. An Ar flow is supplied to protect the mirrors from possible contamination due to H presence. For an empty vessel a ringdown time of ≈400 ns has been recorded. At the exit of the dye laser a 2 mJ light pulse is obtained with a bandwidth of 0.28 cm^{-1}. The frequency of the output beam is then doubled, from 616 nm to 308 nm, by means of a KDP (Potassium Deutero-Phospate) crystal. A LabView program controls the wavelength stepping of the dye laser and reads out the transients via a GPIB interface. For every wavelength 64 transients are averaged and the average is then fitted to an exponential decay function.

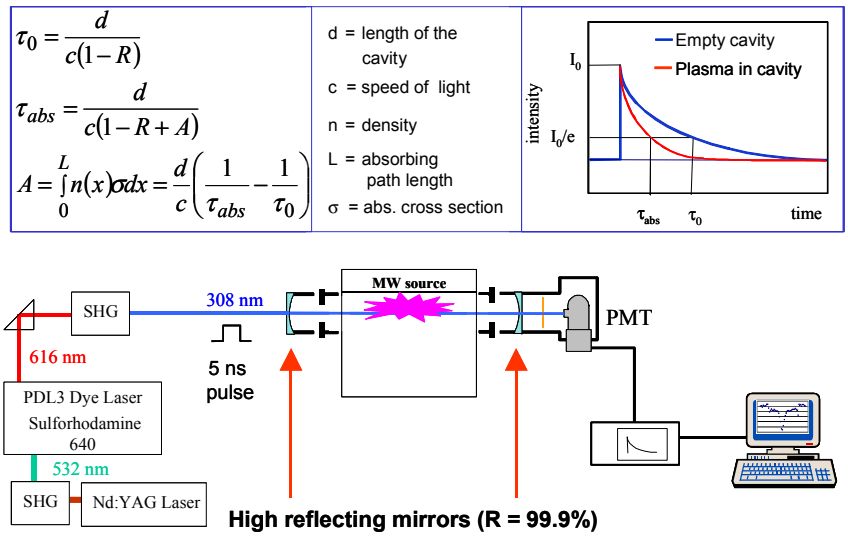

Figure 1: Cavity Ring-Down Spectroscopy set-up coupled with the MW source. Principles of CRDS are also reported.

3. Results and Discussion

The OH system which has been investigated is the 3064 Angstrom system, $A^2\Sigma^+$ (v=0)-$X^2\Pi$ (v=0). According to literature [6,7], the UV OH spectrum can be used as a *molecular pyrometer*, namely, the rotational temperature of OH can be determined as a function of the experimental conditions and approximated to the gas temperature in the plasma. Therefore, two different regions for OH absorption were monitored: the $I0_2$ lines (3064.95 and 3065.10 Angstrom) belonging to the G_0 group and the $I2_3$ lines (3081.54, 3081.62 and 3081.66 Angstrom) belonging to the G_2 group. These regions are shown in Figure 2.

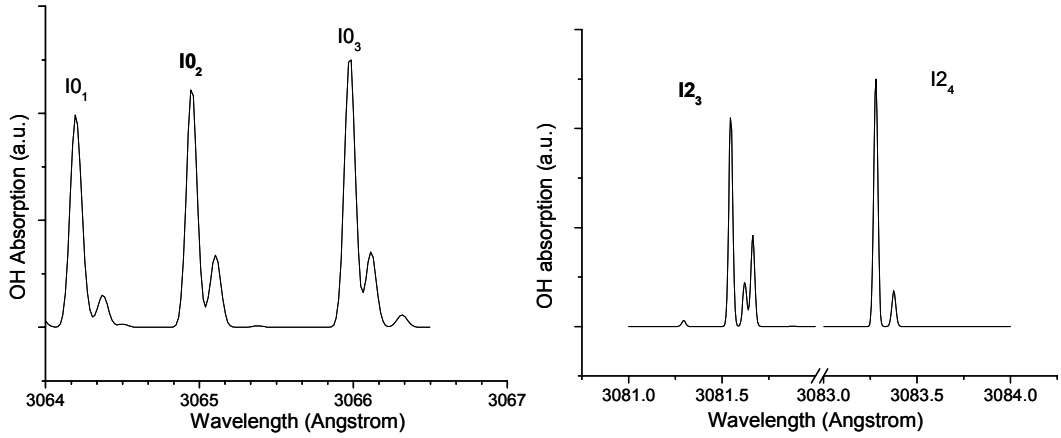

Figure 2: OH band spectra in the two regions chosen for the data acquisition, the G0 and G2 groups.

The OH (integrated) absorption is studied as a function of the different experimental parameters, e.g., power, pressure and gas feed composition (H_2/O_2 mixtures). Figures 3 and 4 show that OH production increases with the power as molecule dissociation becomes more efficient. As the pressure increases, the absorption decreases, probably due to the fact that the discharge becomes more confined, e.g., the CRD starts detecting in the afterglow region. At 350 mTorr (not shown), the absorption becomes quite noisy and estimated around $2 \cdot 10^{-5}$ per pass. The error is estimated around $5 \cdot 10^{-6}$ for the absorption measured in the G_0 group and $1 \cdot 10^{-6}$ for the absorption measured in the G_2 group. Figure 4 shows also the good agreement between the two data series, as collected in different OH absorption regions.

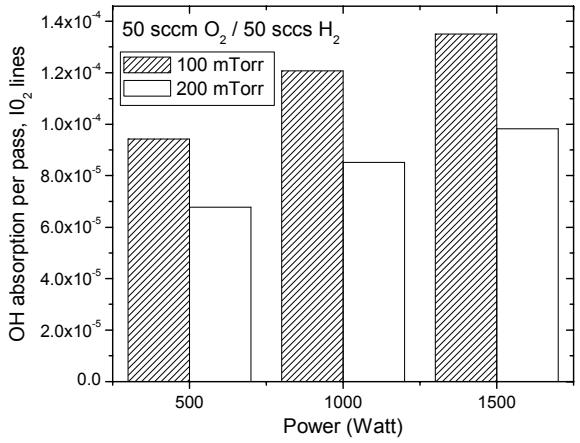

Figure 3: OH integrated absorption (from measurements on the $I0_2$ lines) as a function of the power, for two different pressure values, at constant gas feed composition.

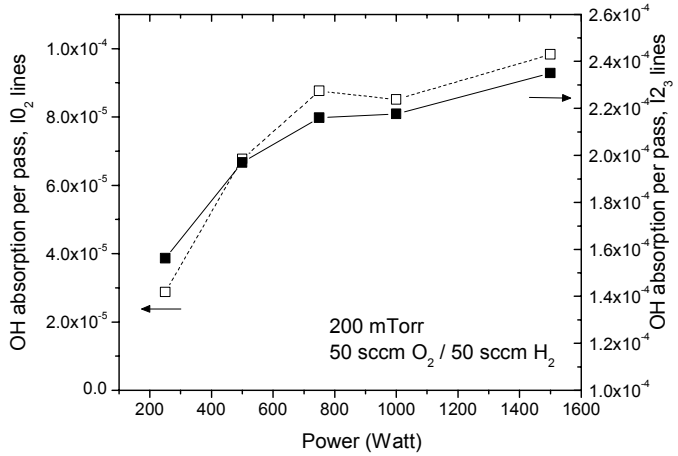

Figure 4: OH integrated absorption (from measurements on the $I0_2$ lines and $G2_3$ lines) as a function of the power, at constant pressure and gas feed composition.

Figure 5 shows the OH absorption as a function of the total flow rate. Any interpretation of this outcome is affected by the error on the absorption measurement, which is estimated around $5 \cdot 10^{-6}$. In Figure 6 the effect of the gas flow rate ratio on the OH absorption is shown. Again, a good agreement between the two data series as collected in different OH absorption regions, is found out. The OH production appears to reach a maximum at about H_2:O_2=0.3, which could be explained in terms of better dissociation efficiency of H_2 molecule compared with O_2 molecule.

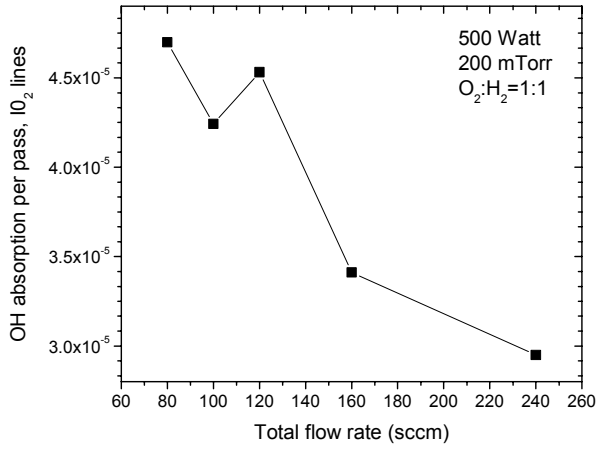

Figure 5: OH integrated absorption (from measurements on the $I0_2$ lines) as a function of the total gas flow rate, at constant pressure and power.

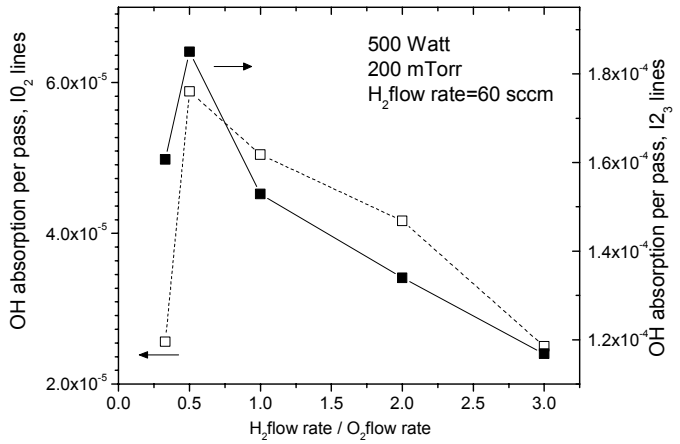

Figure 6: OH integrated absorption (from measurements on the $I0_2$ lines and $I2_3$ lines) as a function of the gas flow rate ratio, at constant H_2 flow rate, pressure and power.

From the ratio of the integrated absorption recorded in the two spectral regions it is possible to estimate the rotational temperature of the OH radicals. Simulations of the two spectral regions by means of the LIFBASE program [8] were run at different rotational temperatures, and the ratio $A(I0_2)/A(I2_3)$ was then calculated. The experimental ratio, as calculated from the absorption values reported in Figure 4 for the power series, was then compared with this simulation and rotational temperatures values were then determined and shown in Figure 7. The rotational temperature is found to increase with the power and the error is estimated around 150 K.

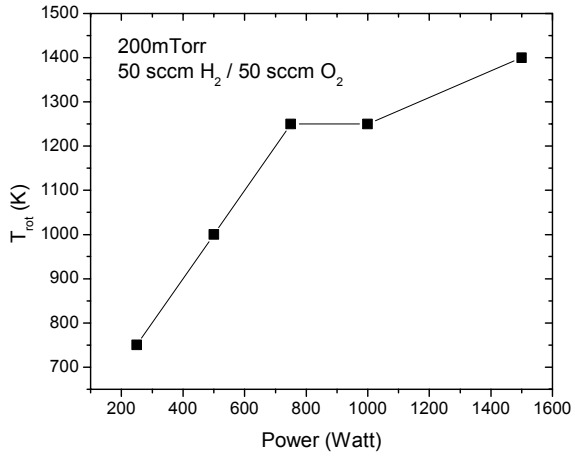

Figure 7: Rotational temperature of the OH radical, as calculated from the ratio of the integrated absorption lines ($I0_2/I2_3$), shown in Figure 4, as a function of the power.

4. Conclusions

The OH (integrated) absorption is studied as a function of the different experimental parameters, e.g., power, pressure and gas feed composition (H_2/O_2 mixtures) using a highly sensitive laser-aided diagnostic tool, Cavity Ring Down Spectroscopy (CRD). OH production increases with the power as molecule dissociation becomes more efficient. As the pressure increases, the absorption decreases, probably due to the fact that the discharge becomes more confined, e.g., the CRD starts detecting in the afterglow region. The OH production appears to reach a maximum at a gas feed composition of about $H_2:0_2=0.3$, which could be explained in terms of better dissociation efficiency of H_2 molecule compared with O_2 molecule. The rotational temperature of the OH radicals is found to increase with the power and the error is estimated around 150 K.

Abstract
The main object of the contribution is to report an extension of earlier papers focused on a more detailed study of the physical pulse diaphragm discharge properties and H_2O plasma parameters. Namely, for various solutions (NaCl, $FeCl_2$, $NaNO_3$ and others) the electron number density calculated from H_α spectral line profile as a function of solution conductivity and speed of cord movement for fixed applied voltage, diameter of hole in the dielectric diaphragm, thickness of the diaphragm were measured.

1. Introduction

Preliminary results on physical characteristics of pulsed underwater diaphragm electrical discharge [1, 2] have shown that the discharges burning in tap water, water-chelaton solutions, and some other water-based solutions can be used as a potential atmospheric-pressure H_2O - plasma source for surface activation various material in the form of fabrics, films, fibers, etc. The discharge burning at atmospheric pressure can substitute low-pressure plasma sources [3 - 6], when atmospheric pressure on-line surface treatments of polymer products with the low added value in large amounts are required.

Underwater pulsed corona discharges generated in liquid water matrix at atmospheric pressure have been demonstrated to be effective in the production of hydrated electrons and hydroxyl radicals [7 - 11, 13, 15]. Following the pioneering work of Clements et al. [7] on pulsed streamer corona generated using point-to-plane geometry of electrodes in water, various types of underwater electrical discharges producing hydrated electrons and hydroxyl radicals in liquid water-based media have been tested for the removal of low levels of non biodegradable organic pollutants from ground water and industrial waste water [14]. Very few results, however, have been published on interactions of the active species generated in pulsed electrical discharges in water with polymer materials [1, 15, 17].

In contrast to other types of underwater electrical discharges, in diaphragm electrical discharge the discharge plasma is not in a direct contact with the metallic electrodes, which helps to eliminate potential problems with electrode oxidation and erosion due to a direct contact of the electrodes with highly reactive H_2O plasma.

While in [1] and [2] the common features and chemical effects including hopeful application of this discharge for surface treatment of polymer materials are presented and discussed, the main object of the present paper is to report a more detailed study of the discharge physical properties. Using optical emission spectroscopy the electron number densities have been determined from broadening of hydrogen lines (H_α) vs. solution conductivity, frequency of high voltage pulses, speed of fiber movement for fixed applied voltage, diameter of the hole in dielectric diaphragm, and the diaphragm thickness.

2. Experimental set-up

The atmospheric pressure H_2O-plasma was generated using the diaphragm discharge arrangement described in more detailed in [1]. Its schematic drawing is shown in Fig.1. The discharge occurred in the vicinity and inside of the hole in the diaphragm made from a plexiglas desk (in the following the diameter of the diaphragm and its thickness are denoted as R and h), which was inserted in the gap between two metallic planar electrodes in conductive water - based solution. Several salts as NaCl, $FeCl_2$, $NaNO_3$, KBr, maleic acid were tested with five different conductivities σ. One of the electrodes was connected with a HV pulse power supply. The power supply of variable voltage U consisted of 60 kV DC source, a low inductance storage capacitor of 3 nF capacitance, and a rotating double spark gap similar to that described in [12]. The double spark gap was used to separate the charging and discharging phases of the storage capacitor. The polyester cord threads moved in the hole with a speed v from 16 to 64 mm/s. The HV pulse power supply was operated at fixed frequencies f = 20, 28, 35, and 43 Hz. As illustrated by Fig.2, many bubbles and turbulence are observed near the plasma channel. The discharge plasma took the form of streamers propagating on the thread surface to the distance of several millimetres from the diaphragm.

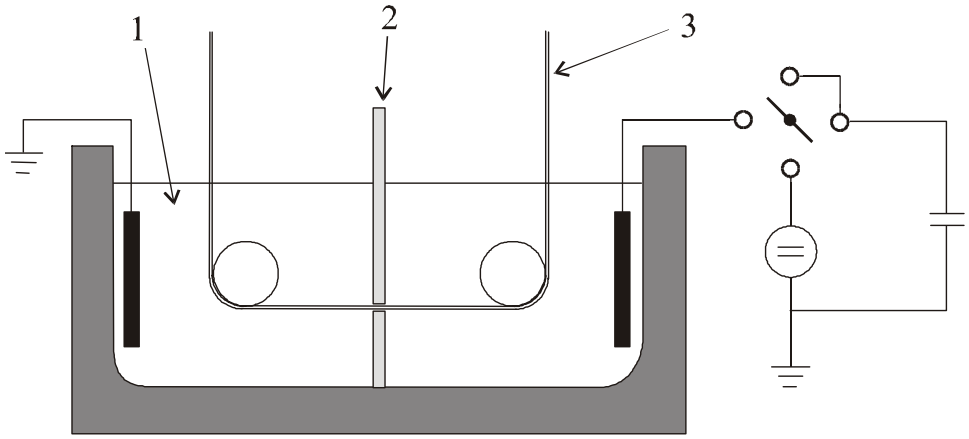

Fig.1: A schematic block drawing of the experimental set-up driven by the HV pulse power supply using the double spark gap: 1 - water based solution, 2 - plexiglas diaphragm, 3 - treated fiber.

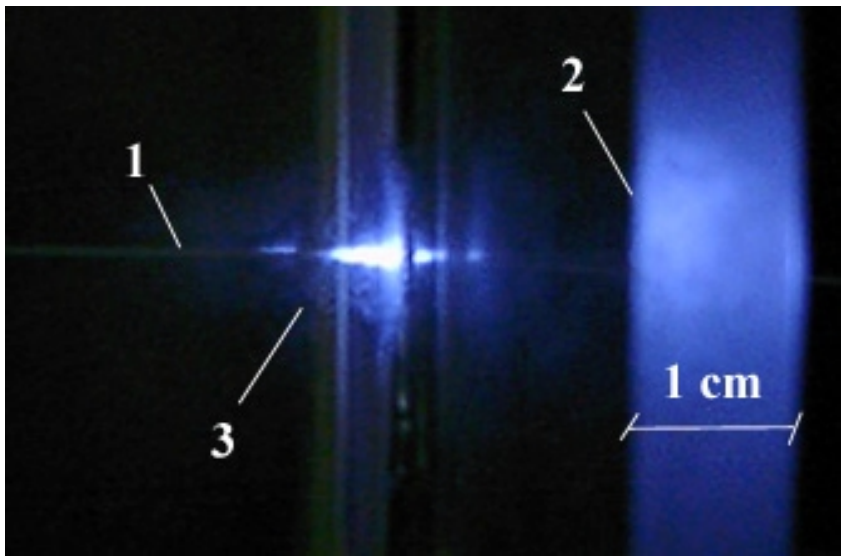

Fig.2: The snapshot of the discharge channel: 1 - treated fiber, 2 - plexiglas diaphragm, 3 - discharge.

Spectral analysis of the light emitted by the discharge was done using TRIAX 550 spectrometer by Jobin - Yvon with the CCD detector (cooled by liquid nitrogen, 2000 x 800 pixels) using a grating with 1200 gr/mm.

3. Results and discussion

To determine electron temperatures and densities the standard Griem's table (which takes into account the impact broadening by electron and quasi-static broadening by ions) of H_α line profile [17] and the procedure for data processing presented in [1] were used. The effect of individual parameters of the experimental set-up on the electron number density is summarised in Tabs.1 - 3. The electron density changes from 1.10^{16} cm^{-3} to 1.10^{18} cm^{-3} while the electron temperature was practically constant $\approx 4.10^4$ K in all experimental conditions studied. The error of the measured electron density was less than 5 %. The error of electron temperature was much higher, which is due to the weak dependence of the line profile on the electron temperature.

For different rate constants for reactions of OH radicals with ions and compounds used in the previous contributions [1, 2], the KBr solution (the rate constant for Br^{-1} is 1100 while for Cl^{-1} the rate constant is 430 in units of 10^7 l $mol^{-1}s^{-1}$, taken from [11]) was also measured. Moreover, maleic acid, which has been used treatment of polymer materials, was also tested.

It was found that for lower conductivity (less than 100 μS/cm) the electron number density changes slightly from 4.7 – 5.1 10^{16} cm^{-3}. It is interested that the electron number density is about 2 times higher for the solution with Br^{-1} ions than for solutions with Cl^{-1} ions (see the ratio of rate constants given above). Next, in case of maleic acid the electron density is relatively high (see the last line in Tab.1).

Salt	conductivity[a] [μS/cm]					frequency[b] [Hz]			
	100	200	300	400	500	20	28	35	43
NaCl	4.0	9.1	15.6	12.0	22.0	15.6	16.8	59.2	71.0
$FeCl_2$	4.1	5.9	12.0	15.3	20.9	12.0	13/7	19.2	18.6
$NaNO_3$	3.4	8.7	11.5	16.8	23.5	11.5	14.5	16.1	19.2
KBr	5.2	18.5	20.5	24.4	44.0				
Maleic Acid	6.2	16.5	33.0	51.3	48.5				

Table 1: The electron number density in 10^{16} cm^{-3} vs. conductivity and frequency for different water - based solutions of salts with treated fiber. Other parameters are fixed: U = 40 kV, h = 2 mm, R = 1.2 mm, v = 33 mm/s, a) f = 20 Hz, b) σ = 300 μS/cm.

Salt	speed [mm/s]							
	16	33	49	64	77	97	120	140
NaCl	7.7	15.6	10.7	9.1	10.2	16.8	42.1	58.9
$FeCl_2$	9.0	12.0	9.9	10.5	17.9	17.0	72.1	53.9
$NaNO_3$	10.6	11.5	13.3	11.3	14.7	15.9	21.6	31.4

Table 2: The electron number density in 10^{16} cm^{-3} vs. speed of treated fiber for selected water - based solutions of salts with treated fiber. Other parameters are fixed: U = 40 kV, h = 2 mm, R = 1.2 mm, f = 20 Hz, σ = 300 μS/cm.

U [kV]	conductivity[a] [μS/cm]					thickness[b] [mm]			diameter[c] [mm]			
	100	200	300	400	500	2	3	4	1.2	1.5	2.0	2.5
40	4.0	9.1	15.6	12.0	22.0	1.2	4.7	8.6	15.6	4.5	1.2	1.1
45	4.6	20.4	80.3	16.5	51.7	10.8	8.6	7.4	80.3	5.9	10.8	6.1
50	5.1	21.4	96.5	43.5	57.4	21.1	24.5	13.3	96.5	12.2	21.1	6.7
55	6.9	63.8	104.7	71.4	77.5	32.1	64.4	28.1	104.7	15.9	32.1	19.8

Table 3: The electron number density in 10^{16} cm^{-3} vs. conductivity, thickness and diameter of the diaphragm for various input voltage, water - based solution of NaCl and for fixed parameters as follows: f = 20 Hz, v = 33 mm/s, a) h = 2 mm, R = 1.2 mm, b) R = 2 mm, σ = 300 μS/cm, c) h = 2 mm, σ = 300 μS/cm.

In a contrast to the previous measurement [2], where surprisingly no OH bands were observed in the emission spectra at 305 - 311 nm, in these experiments the OH lines have been found. Their intensities, however, were low and comparable with the noise. The rotational temperature of OH radicals changed from 950 to 1600 K for parameters given in Tabs.1 - 3. For high level of noise the errors were not lower than 30 %.

If a higher electron number density corresponds to the higher production of OH radicals, the electron number density could be taken as a parameter that characterises chemical efficiency of the discharge. Of course, this conclusion should be supported with simultaneous measurements of OH radicals and surface properties of treated fibers. From the Tabs.1 - 3 one can deduce that the electron number density increases with increasing voltage and frequency. This is valid for all solutions. In case of $FeCl_2$ and $NaNO_3$ it seems that the electron number density increases with increasing conductivity σ. Among used salts and parameters

of the experimental set-up the solution with NaCl has produced the highest values of electron density 1 x 10^{18} cm^{-3} for σ = 300 μS/cm, U = 55 kV, f = 20 Hz, v = 33 mm/s, h = 2 mm, and R = 1.2 mm.

It is evident that the present experiments, even if many measurements were realised, do not cover all experimental possibilities. Also, as indicated the results in Tabs.1 - 3, some results deviate from the expected trends. It evokes possible problems, e.g. for the diaphragm with diameter of hole below 1 mm there is difficult to realise the precise diaphragm with given thickness and diameter. For example it was observed that the discharge changes its colour. Or, as shown in Tabs.1-3, the electron number density depends significantly on conductivity of solution.

The visual appearance of the discharge indicate that the discharge mechanism is identical with those described in [22, 23] where, however, diaphragm discharges without any fibrous dielectric material, such as a PES cord thread were studied. A general picture of the discharge development is relatively complicated since the water vapour generated there is mixed with air bubbles trapped in cavities inside the cord thread. In such a way a gas-filled region inside the hole and in its immediate vicinity is formed. Neglecting a voltage drop on the water layers between both electrodes and the diaphragm, nearly whole HV pulse applied to the electrodes appears on the gas region surface, resulting in its electrical breakdown and creation of a highly conductive plasma streamers propagating along the cord thread surface.

The physical picture (see also [1]) indicates that all gas discharge processes occur in a water vapour/air mixture with dependence on the conductivity, parameters of the diaphragm and chemical composition of the solution used. It is possible that because of a complex chemistry involved in the generation and decay of various radicals in atmospheric pressure plasmas [11], the solution chemical composition can have a significant effect on the radicals densities and, consequently, on chemical effects of the discharge plasma. Also, at the moment we have no plausible explanation for the observed sensitivity of H_α line to composition of the solution used. Such effects apparently can result from a very complex chemistry of the active species in water vapour plasma. A detailed study of the discharge plasma chemistry is beyond the scope of this article and could be an interesting subject for some future studies.

Abstract
The work focuses on the experimental determination and critical comparison of ozone formation efficiencies by several non-equilibrium discharges in synthetic air at atmospheric pressure. The experiments were performed in one site by using identical gas handling system, as well as the same instrumentation used for sampling and analysis of the discharge products. We found the maximum ozone concentrations ~2000 PPM. The highest ozone yield and the lowest energy cost reached ~80 g/kWh and ~20 eV/O_3, respectively.

1. Introduction

To reduce the cost of ozone based technologies (*e.g.*, treatment of drinking and wastewater, decomposition of hazardous organic wastes, medical applications) the design of efficient ozone generators has always been the focus of many researchers. Even though industrial ozonizers based on electrical discharges are in use for a long time, the design of an ideal plasma-chemical ozonator is a difficult task. To produce ozone from air efficiently, an ozonator should produce, first of all, large quantities of oxygen atoms at reasonable cost. When nitrogen is present in the feeding gas, the ozone production can not be separated from the generation of nitrogen oxides. Taking into account the mechanism of ozone formation from air [1] it is therefore obvious that for efficient ozone production it is necessary to suppress the excessive production of nitrogen atoms. Due to the fact that ozone loss processes are significantly enhanced by increasing the gas temperature [2] then to reduce ozone destruction channels it is necessary to keep the temperature as low as possible.
This work focuses on the experimental determination and comparison of ozone formation efficiencies by several non-equilibrium discharges in synthetic air at atmospheric pressure. Similar efficiency studies are usually performed for one single ozonator. Therefore it is often difficult to compare directly results obtained on one ozonator type presented by different research groups, and it is even more difficult to compare results concerning different ozonator types. It is usually because of various methodologies used for ozone concentration and energy density measurements. We eliminated the most important drawbacks by applying identical methodology to investigate different ozone-generating devices. The experiments were performed in one site by using identical gas handling system, as well as the same instrumentation used for sampling and analysis of the discharge products [1].

2. Experimental setup

The efficiency of ozone production was determined for five different plasma generators, namely for:

- pulsed positive corona discharge in wire-cylinder geometry (PPCD) [1],
- DC hollow needle-to-plate discharge enhanced by the gas flow (GFCD) [2],
- low-current DC gliding discharge (DCGD) [3],
- surface dielectric barrier discharge (SDBD) [4],
- diffuse coplanar surface discharge (DCSD) [5].

The experimental PPCD device (figure 1a), consists of an Ag-coated Cu central wire anode and a grounded stainless-steel cylinder. The pulsed high-voltage (HV) power supply with maximum ratings, 100 kV/1kA/ 7 ns rise time/ ~ 100 ns fall time, delivers up to 2 J per pulse with up to a 10 Hz repetition rate at atmospheric pressure into the discharge volume ~ 1500 cm^3. The power supply is connected to the discharge chamber through the diagnostic interface. The matching of the discharge chamber to the power supply and formation of the HV pulse is accomplished by means of the resistive load.

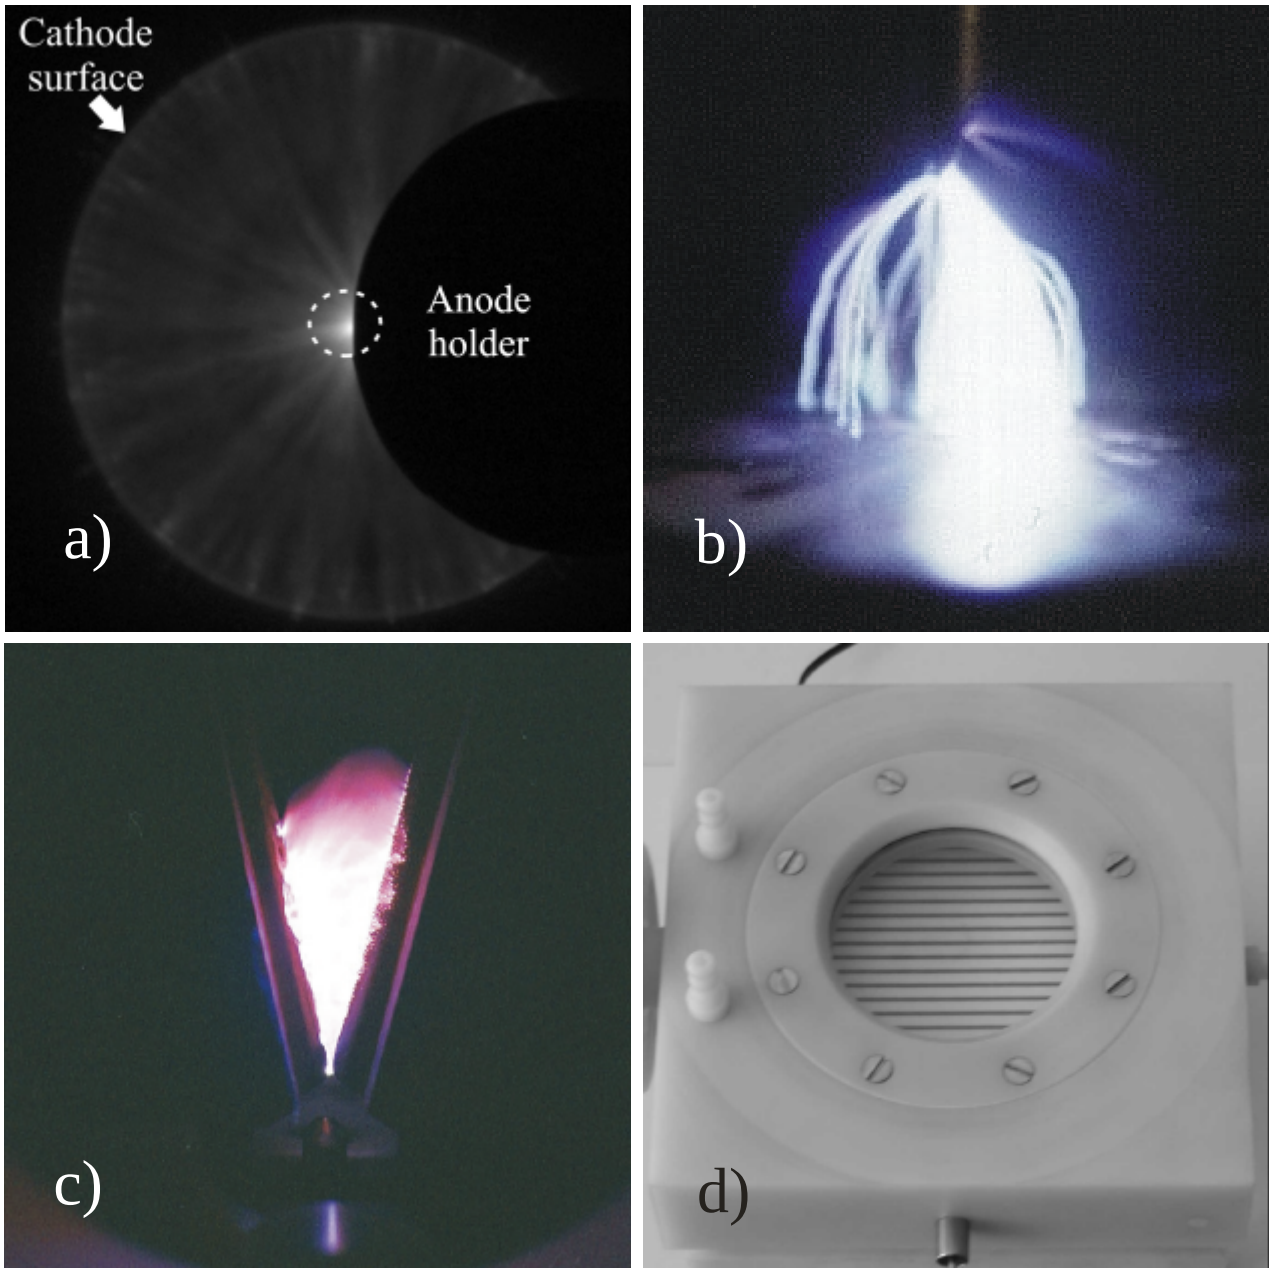

Figure 1. Photographs of experimental discharge devices: a) PPCD, b) GFCD, c) DCGD and d) reactor for both SDBD and DCSD discharges with currently inserted SDBD electrode system.

The second discharge tested for ozone generation is a needle to plate corona discharge. Classical DC corona is not suitable for efficient ozone generation with reasonable production rate. To achieve this aim it is necessary to enhance both the discharge power and air flow through the discharge region. For this purpose we used the gas flow through the needle electrode [2]. The electrode arrangement of this GFCD device (figure 1b) consists of stainless steel needle situated perpendicularly to the stainless steel disc. The needle is used as an anode and the disc as a grounded cathode. The outer and inner diameter of the needle is 1.2 mm and 0.7 mm respectively. The tip of the needle is sharpened at an angle 15°. The distance between the tip of the needle and the disc electrode is 3.2 mm. Both electrodes are placed inside a quartz tube. The air into the discharge is supplied through the needle only. A DC regulated HV power supply provides voltage up to 10 kV.

The DCGD device (figure 1c) consists of two diverging electrodes placed in a fast gas flow created by the nozzle [3]. When powered with sufficient voltage (several kV), the breakdown occurs in the point of a minimum distance between the electrodes and the plasma filament is carried away in the direction of the gas

flow increasing its length. The gliding discharge period can be roughly divided into three phases. The first breakdown or ignition phase is characterized with a fast decrease of electrode voltage simultaneously with an increase of the discharge current (followed with an increase of the gas temperature). The second intermediate phase is characterized with rather slow changes of all discharge parameters. The third extinction phase is characterized with a thermodynamic instability of the plasma filament with fast decrease of the gas temperature and discharge current. As soon as the length of the plasma filament reaches certain value, the filament snaps and the current is interrupted. Consequently, the electrode voltage increases as long as a new breakdown occurs initiating a next discharge cycle.

The SDBD device consists of two electrodes separated by a 100x100 mm^2 alumina dielectric plate. The thickness of alumina plate is 0.5 mm. The alumina plate has a discharge electrode on its upper surface and an induction electrode on its lower surface. The discharge electrode consists of 21 interconnected parallel strips made from tungsten. The induction tungsten electrode serves to produce a tangential electric field component on the upper dielectric barrier surface. The electrode system is energized by a sinusoidal HV (up to 6 kHz and 8 kV peak-to-peak). This arrangement produces a stable surface discharge starting from both edges of each strip electrode and covering uniformly the ceramic surface [4].

The electrode arrangement of DCSD device consists of two parallel strip-like molybdenum electrodes embedded in alumina using a green tape technique. The thickness of the ceramic layer between the plasma and electrodes is 0.4 mm. A sinusoidal high-frequency HV (1-15 kHz, up to 10 kV peak-to-peak) was applied between the electrodes. Such an electrode geometry and discharge energization arrangement generates visually almost uniform plasmas in air (or in nitrogen) at atmospheric pressure. The discharge consists of numerous H-shaped elementary discharges developing with a high intensity and running on the electrode system surface along the embedded strip electrodes. The density and the movement velocity of the elementary discharges increase with the gap voltage [5].

The O_3 and NO_x concentrations were monitored outside the discharge chamber by a non-dispersive UV absorption technique and by electrochemical cells, respectively. The pyrex probe (30 cm long, 6 mm i.d.) and Teflon tube (1.5 m long, 4 mm i.d.) was used for sampling the discharge products at the end of the discharge region with a constant speed of 1 l/min. The API 450 and API450M (Advanced Pollution Instrumentation) non-dispersive UV photometric O_3 analyzers were used to determine the ozone concentrations in the discharge products. Both instruments use mercury line 254 nm as the light source for the absorption and selective MnO_2 ozone scrubber that minimizes the influence of other potential absorbers. Covering ranges from 0-1000 and 0-5000 PPM respectively, the two analyzers assured high precision over several orders of O_3 concentration measurements. The GA-60 flue gas analyzer (Madur Electronics) equipped with electrochemical cells (O_2, CO, SO_2, NO, NO_2) was used to monitor volumetric concentration of nitrogen oxides covering ranges from 0-5000 and 0-800 PPM for NO and NO_2 respectively. Linearity of the NO sensor was verified in the range 0-900 PPM by defined mixture of Pulmonix® forte (Messer Austria, 900 PPM NO in N_2, with main impurities H_2O< 3 PPM, O_2<1 PPM and NO_2<1PPM).The production of ozone and NO_x was investigated as a function of energy density delivered to the discharge volume.

3. Results and conclusions

For each single measurement (*i.e.,* for given airflow and discharge conditions), the discharge ran continuously for 20-30 minutes until a steady-state ozone level had been indicated by both ozone analyzers. After each single measurement, the discharge was turned off until ozone monitors reported zero ozone level. Then the new discharge conditions and/or airflow were fixed and the discharge turned on again for the new measurement. Following such a procedure we found detected ozone and NO_x levels highly reproducible. Ozone generation was investigated for typical operation conditions, *i.e.* for conditions that were determined by the capability of available power supplies to assure stable and long-lasting discharge. For explored range of parameters we found the maximum ozone concentrations approaching 2000 PPM. From ozone concentration measurements we evaluated the ozone production, yield and production energy cost. Calculated ozone production and yield (figure 2) reached as much as 1 g/h and 80 g/kWh, the minimum ozone production energy cost (figure 3) approached 20 eV/O_3. Figure 2 and figure 3 do not show results obtained for the gliding discharge because corresponding numbers are significantly out of the range covered by other discharges. In the case of DCGD, the ozone generation was inspected, for fixed electrode geometry; in the energy density range 0.1-0.3 Wh/l. Calculated DCGD ozone yield does not exceed 0.1 g/kWh. In the case of DCGD ozone production energy cost, the minimum value does not go below ~9×10^3 eV/O_3.

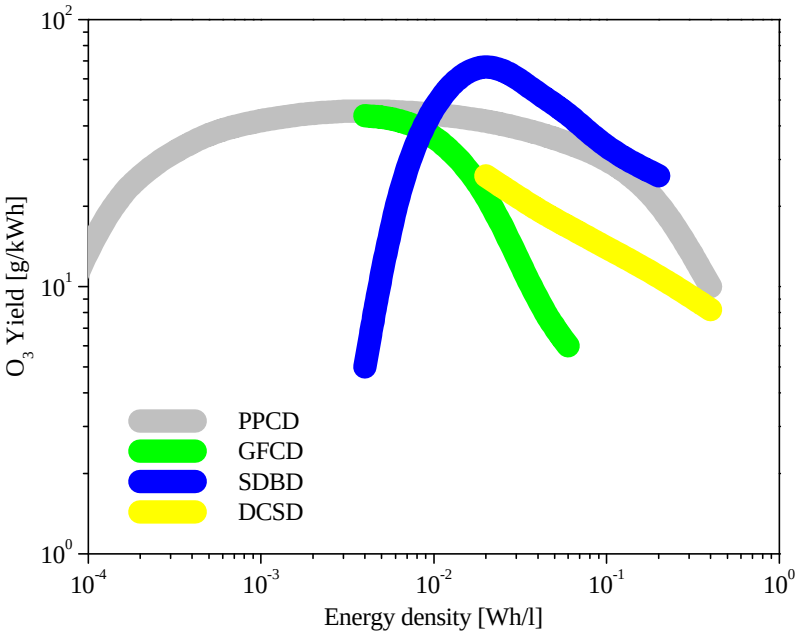

Figure 2. Ozone yield versus energy density

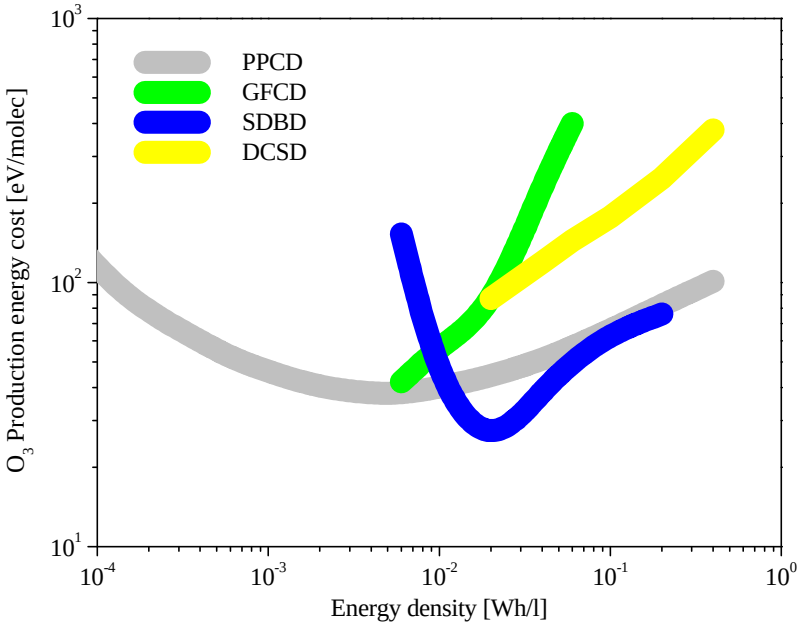

Figure 3. Ozone production cost versus energy density

Efficiency of ozone formation was explored for several non-equilibrium plasma generators in atmospheric pressure synthetic air in a wide range of applied energy densities by appropriately combining the discharge parameters and airflow rate. From the ozone concentration measurements, we evaluated ozone production, yield and production energy cost. Both the ozone production yield and energy cost show quite large variations. The best performance from the point of view of ozone generation efficiency show plasma generators based on streamers homogenously distributed either over the dielectric surface (SDBD) or inside the inter-electrode space (PPCD). Lower performance then shows the GFCD plasma generator based on self-repetitive streamers localized in a relatively small part of the whole reactor volume. The lowest efficiency then shows the DCGD plasma generator, which is based on one predominant plasma filament. The DCSD device is supposed to have a performance similar to the performance of the SDBD device. Measured DCSD characteristics are however significantly below the SDBD numbers. Unfortunately, for given electrode design and the energization, we were not able to obtain the DCSD characteristics at low energy densities. An attempt to decrease energy density resulted in large discharge instability (with streamers covering only randomly varying fraction of the electrode surface). Another kind of instability limited the inspection of the GFCD device towards low energy densities. With increasing air-flow rate (decreasing energy density), a regular discharge burning was progressively replaced by irregular bursts of pulses, or even with the discharge blow-out.

The performance of all generators is strongly limited by the presence of nitrogen oxides ($NO+NO_2$). For the SDBD, DCSD and PPCD devices we always observed the quantity of NO_2 species comparable with detected ozone levels, while NO species remained bellow the detector sensitivity. For the GFCD and DCGD devices, NO species can be detected. The former results are not surprising as a distributed dissipation of electrical power

(through well distributed plasma filaments) prevents an excessive heating of the gas. On the other side, a local release of energy through one (or few) plasma filament leads to the local increase of the gas temperature (ΔT=50-250 K in the case of the GFCD, ΔT=500-1500 K in the case of the DCGD) and consequently to the enhanced decomposition of ozone molecule through both thermal and plasma-induced (NO_x) chemical processes.

Abstract

We analyse the energy dissipation of cold reactive neutrals (Ar*) on surfaces using metal-insulator-metal (MIM) tunnel junctions. By this means we detect and perform energy spectroscopy of hot charge carriers injected into the metal bulk. This process occurs in addition to and in competition with the well known secondary electron emission into the vacuum. MIM sensors may be used as very sensitive detectors for excited and/or reactive cold species in a plasma environment.

Introduction

Depending on the plasma parameters metastable excited neutrals can be a very prominent species in the plasma. They can thus play an important role in the electron particle balance of discharges, influence the electron energy distribution function (EEDF) and, via the ionisation balance, the electric fields. When ions, excited neutral species or reactive radicals strike a surface, the particles are usually de-excited and/or a chemical bond is formed (chemisorption). If the excess energy between initial and final state exceeds the work function of the material (minimum energy required to emit an electron from the solid), electrons can be emitted into the vacuum. A prominent example is the de-excitation of metastable atoms on metal surfaces. This is especially important for plasmas where the secondary electron emission from the metal electrodes plays a key role in the maintenance of the discharge. For some systems this process has been well investigated, e.g. for Ar* on pure metal surfaces [1,2]. In addition to the electron emission into the vacuum an accompanying process is the electronic excitation of the metal. Excited defect electrons or excited electrons with energies below the work function can be injected into the bulk of the electrode. In this paper we investigated the latter processes for the first time by exposing a metal / insulator / metal junction (further called MIM) to the spatial afterglow of a surface wave sustained discharge producing Ar* metastable atoms predominantly in the $3p^5\,4s^1$ state [3].

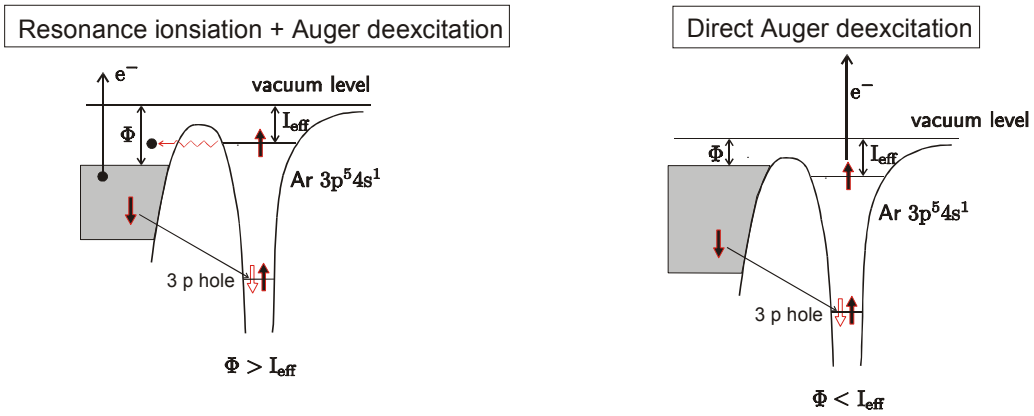

Fig. 1 : Schematic view of the two basic de-excitation schemes of metastable atoms at metal surfaces. Left view graph: Workfunction bigger than first ionization potential. Second view graph: Workfunction smaller than first ionization potential.

The basic processes of de-excitation of excited species approaching a metal surface, namely resonance ionisation and subsequent Auger de-excitation or direct Auger deexcitation are shown in more detail in fig. 1 at the example of the Ar $3p^5 4s^1$ excited metastable state [1].

In a potential energy diagram the potential well of the excited metastable (filled electronic states are represented by bold arrows) is separated from the metal bulk by a thin potential barrier. In the case of resonance ionisation the excited electron of the metastable atom (for Ar: 4 s^1) tunnels into the unoccupied states of the metals conduction band. Subsequently the resulting Ar^+ ion is neutralised by an electron from the conduction band of the metal. The excess energy of this process is disposed to an Auger process in the metal (left view graph of fig.1). In the case of direct Auger de-excitation an electron emission into the metal is not possible. The first step in this process is the transfer of an electron from the conduction band of the metal to the metastable atom. Subsequently the resulting Ar^- ion is neutralised by an Auger process in the atom. The excess energy in this scheme is transferred to the free electron originating from the Ar atom.

Auger de-excitation is the most probable process on adsorbate covered metal surfaces and on (111) noble metal surfaces [4] . It occurs when the work function Φ of the material is smaller than the effective ionisation energy I_{eff} of the metastable atom. In any of the two de-excitation schemes an excited defect electron remains in the metal. Practically nothing is known so far about the excited defect electrons produced by metal – metastable interactions. It is known from 2 photon photoemission experiments that the lifetime of excited defect electrons or electrons embraces a range of several 10 fs [5]. The corresponding mean free path is in the order of 20-30 nm. Defect electrons produced at the surface can thus be transported into the metal bulk within a range of this mean free path.

This point is exploited in our new approach for the detection and spectroscopy of the metastable caused excitation. As a sample we use a 20 nm thick gold film which is separated by a 2.3 nm thick oxide film from a 30 nm thick aluminium electrode. The excited defect electrons stemming from the afterglow / gold interface migrate to the inner gold / oxide interface of the MIM layer system. Here they can tunnel into the aluminium electrode and can thus be detected as a tunnel current.
This process is illustrated in more details in figure 2. Ar metastables striking the gold surface produce excited defect electrons. These defect-electrons migrate to the oxide / gold interface. There they can be neutralised by electrons originating from the aluminium which are tunnelling through the oxide layer to the gold film. A competing process for this neutralisation is the de-excitation of the defect electron by an Auger process. The partitioning between neutralisation by tunnelling and Auger de-excitation can be tuned by the bias voltage applied to the MIM system. For defect electrons with weak excitation energy the neutralisation by tunnelling can be prohibited by a small bias voltage. In this case the defect electrons in the gold film do not find corresponding electrons in the aluminium electrode. Consequently the detected tunnel current must decrease. If the bias voltage is increased and the Fermi level of the aluminium is lower than the energetic level of the hottest defect electron the metastable induced tunnel current should reduce to zero (bottom view graph in figure 2) .

It should be mentioned that the application of a bias voltage induces a DC tunnel current. To distinguish this DC current from the current induced by the metastables it is necessary to work with a chopped gas beam.

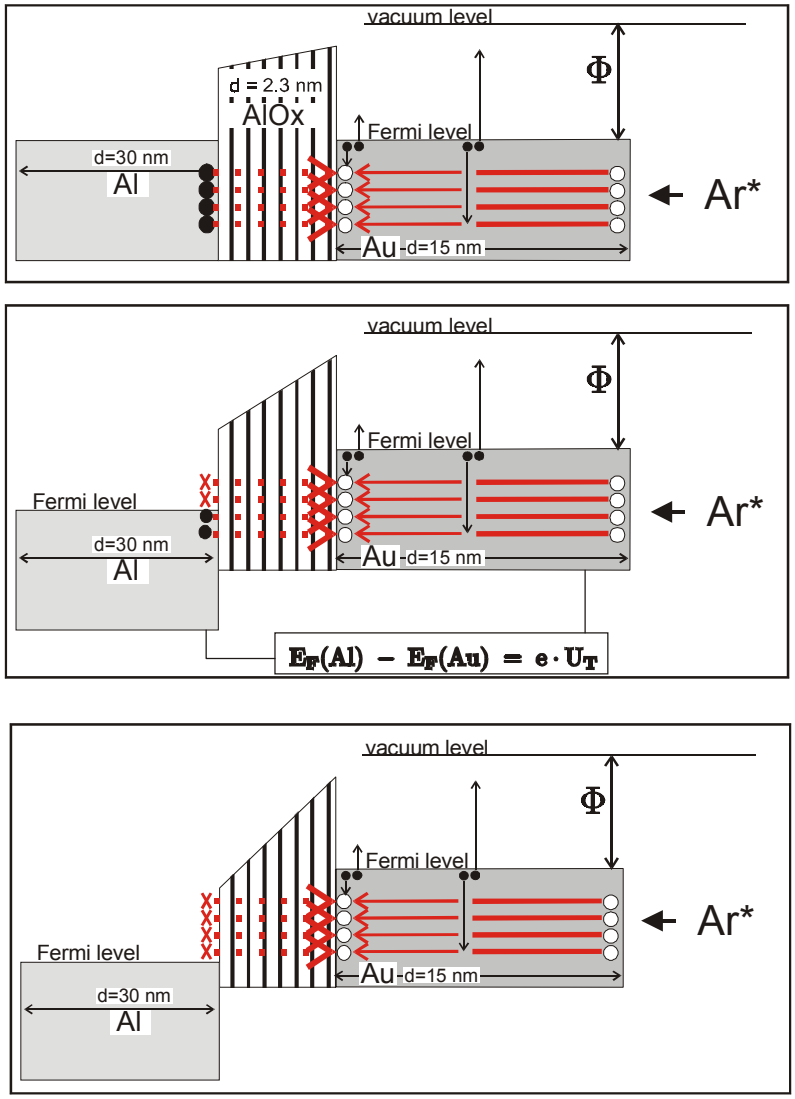

Fig. 2 : Energy level diagramm of a MIM tunnel junction in contact with metastable Argon atoms. Open circles represent defect electrons, closed circles represent electrons. Top view graph: Applied tunnel voltage 0 V. Middle view graph: Small tunnel voltages decrease the metastable induced tunnel current. Bottom view graph: The threshold voltage reduces the metastable induced tunnel current to zero.

Experimental set-up

Figure 3 shows a sketch of the experimental set up. A surface wave produced discharge is used as source for metastable noble gas atoms. The discharge is produced in a quartz tube of 10 mm inner diameter and 12 mm outer diameter by a travelling surface wave (2.45 GHz), which is excited by a Waveguide-Surfatron. The quartz tube is surrounded by a metal cylinder with a diameter of 5 cm. A microwave generator (Marconi signal source type 6056B) is driving a Thomson-CSF TH 2404 Klystron at 2,45 GHz, which supplies the power (ranging up to 1 kW) to the launcher. The transmitted and reflected powers, are measured with two HP 436 A powermeters. The gas flows through the quartz tube are regulated by mass flow controllers (MKS flowmeters), allowing a maximum flow rate of 500 sccm. The upstream pressure is measured by a pressure transducer (Baratron® type 626 A), and ranges from 1 to 3 mbar, depending on the flow rate. Downstream the quartz tube is penetrating through an O-ring seal into a vacuum vessel which is pumped by a turbomolecular pump with a pumping

speed of 1600 l/s. Depending on the gas flow, the pressure in the reaction chamber ranges between 10^{-2} and 10^{-4} mbar. The MIM-detector (together with a chopper disc) is placed in this reaction chamber approximately 5 cm from the end of the glass tube

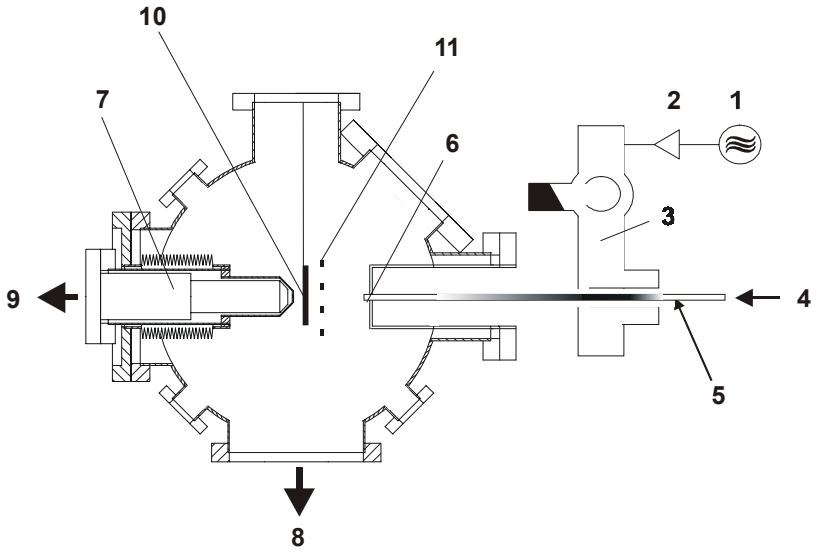

Fig. 3 : Experimental Set-up - 1. Microwave Generator, 2. Klystron and Pre-amplifier (+70 dB), 3. Waveguide-Surfatron, 4. Gas inlet, 5. Quartz tube (d_{in}=10 mm, d_{out} = 12 mm), 6. Post-discharge / Plasma, 7. Mass Spectrometer, 8. Turbopump (1500 l/s), 9. Turbopump (50 l/s), 10 MIM-detector, 11 chopper disk

An important property of surface wave sustained discharges is that the plasma length and thus the distance from the discharge to the substrate/ MIM-detector is not fixed. It depends on several parameters, such as gas mixture, total tube pressure and the applied power. In the present experiment the active plasma zone is ending about 30 cm before the end of the glass tube. Close to the end of the glass tube we have installed three metal grids. By applying appropriate voltages to these grids ions and electrons are prevented from reaching the MIM-detector.

The metal / insulator / metal layer system is produced in three steps. A 30 nm thick aluminium base electrode is evaporated an a glass slide in a high vacuum chamber. A localised anodic oxidation is performed in an electrochemical droplet cell. The procedure is described in detail elsewhere [6,7]. The gold electrode is evaporated across the aluminum / aluminum oxide layer and contacted by additional gold pads. In previous experiments we investigated the lateral conductivity of 20 nm thick gold, copper and aluminium films in contact with Ar afterglows [8]. No sputtering effects could be found. The conductivity of the films remained unchanged. The temperature at the sample position was found to be close to room temperature [9]. In the present experiments the conductivity of the gold electrode was controlled permanently during the experiments.

The samples used in the experiment have a preferential 111 orientation of the gold surface. These surfaces show a band gap at energies above the Fermi level. Thereby an electron injection normal to the surface on 111 terraces is not possible [10]. We therefore do not expect a remarkable amount of resonance ionisation processes. Moreover the gold film was not sputtered before exposure to the metastable atoms. Thereby a submonolayer coverage with oxygen cannot be excluded. There are several reports in literature that molecular adsorbates suppress the process of resonance ionization [11].
The tunnel currents were detected using an in house developed potentiostat [6] containing an autoranging current voltage converter. The sample was galvanostatically separated from the

vacuum chamber. The chopper disk enabled a 33 % beam on time and a 66 % beam off time for the clear distinction between DC tunnel current and chemically induced tunnel current.

Experimental results:

In figure 4 typical examples for the transient shape of metastable induced tunnel currents are shown at different bias voltages. The right side view graphs show the internal band structure of the MIM system. The left side figures show the AC component of the tunnel current as a function of time.

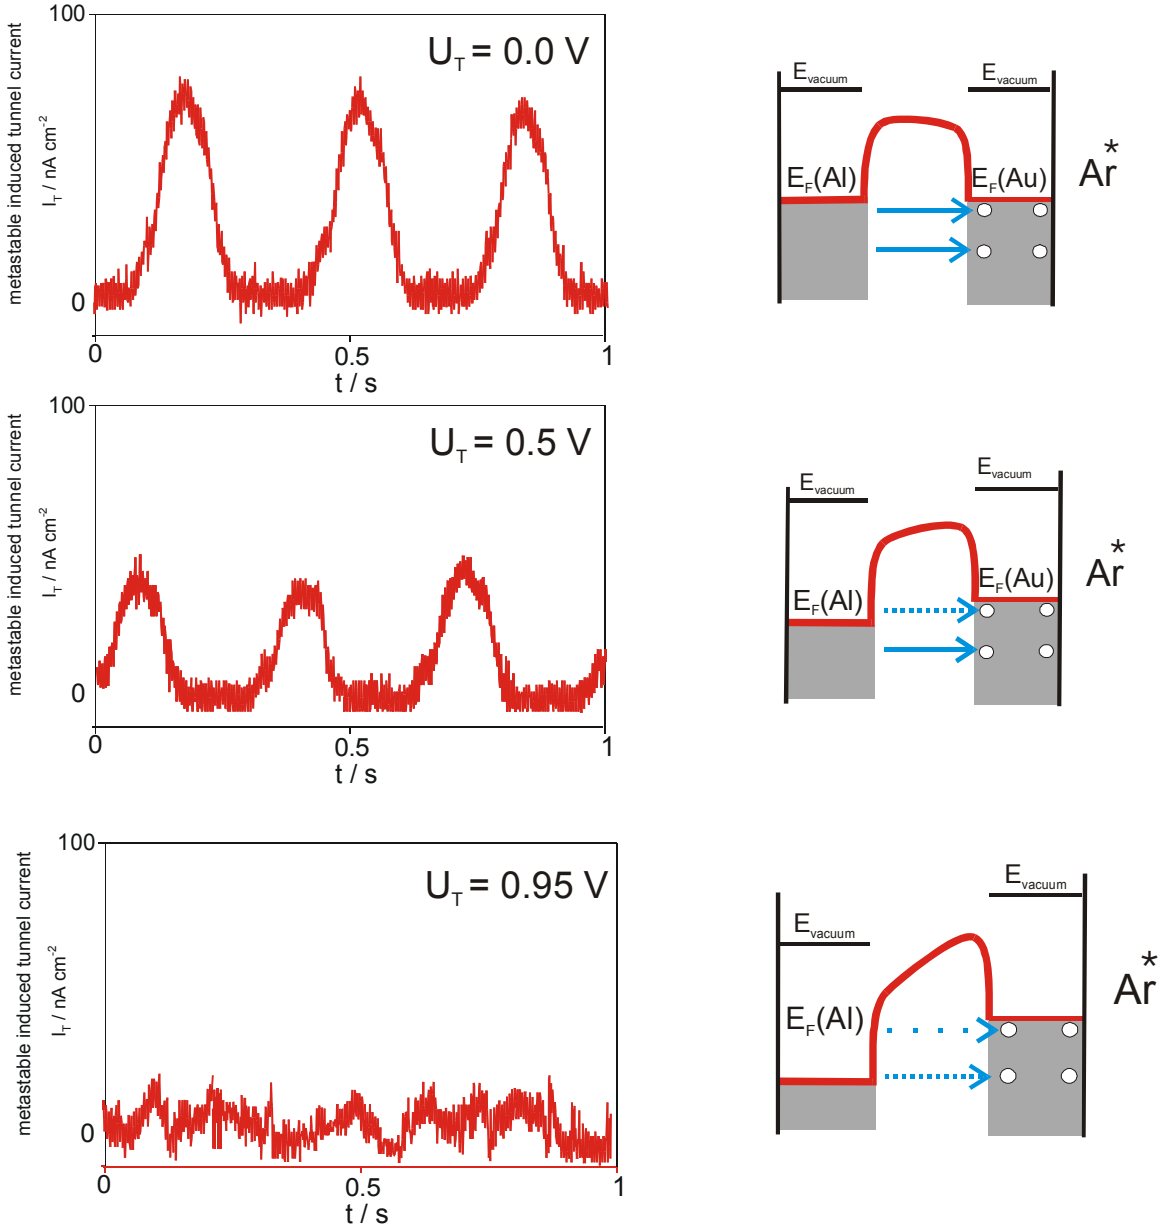

Figure 4: Left side view graphs show the AC part of the tunnel current for different bias voltages. The right side view graphs show the corresponding change of the internal band structure of the MIM system due to the bias voltage.

The typical shape results from the geometric design of the chopper disk leading to an asymmetric signal. At a tunnel voltage of 0 V (means Fermi level of the aluminum and the gold electrode on the same level) 70 nA peak to peak current density can be detected. The peak to peak signal drastically depends on the bias voltage. For a bias voltage of 0.5 Volts the metastable induced tunnel current is reduced by almost a factor of 2. The signal parishes nearly completely at a bias voltage of 0.95 V. This means that the excited defect electrons have at least an energy of 0.95 eV.

Conclusion

It could be shown that tunnel junctions with thin (d < 3 nm) oxide films are stable in the spatial afterglow of a surface wave sustained discharge. Plasma induced tunnel currents in the order of several 10 nA could be easily detected by using an optimized current voltage converter. We could not observe an electron injection from the afterglow into the MIM junction. The transient shape of the induced tunnel current depends on parameters as chopper frequency and gas flow. This clearly shows that the tunnel currents are not induced by electrons or photons emitted from the discharge. MIM sensors are obviously a new sensitive diagnostics for fluxes of metastables.

We report a novel technique for deposition and implantation of 10-20 nm layers of metals by Ablation Plasma Ion Implantation (APII). This process is based upon KrF laser ablation of a solid, metal target. The ablated ions are accelerated to a substrate by a negative voltage of magnitude up to 10 kV. In principle, ions can be ablated and accelerated from any solid target material. When the target is oriented parallel to the substrate, one obtains ion-beam-assisted-deposition (IBAD) of thin films; Ti thin films are 10's of nm thick with an implanted damage layer of 15 nm in Si substrates. For target orientation perpendicular to the substrate, pure ion implantation is achieved with Ti implantation-damage layers some 20 nm deep in Si and no overlying film. The perpendicular orientation reduces arcing and particulate deposition on the substrate. Extensive plasma diagnostics have been performed on the ablation plasma utilizing resonant laser interferometry and Langmuir probes, yielding total ion populations in the range of 10 14 per pulse. Implanted ion doses were estimated by electrical diagnostics and materials analysis including, X-Ray Energy Dispersive Spectroscopy (XEDS) and X-Ray Photoelectron Spectroscopy (XPS), yielding implanted doses in the range 10 12 per square cm per pulse. This yields an ion-utilization efficiency on the order of 10% over the implanted area.

Abstract

The time behaviour of Ar (750nm), O (844nm), OH (306nm), H (486nm) and CO (296nm) emissions has been studied by time-resolved optical emission spectroscopy in pulsed oxygen/tetraethoxysilane (TEOS) plasmas. In TEOS/O_2 1:9 mixture, the O and H lifetimes are deduced from the time variations of their intensities normalised to the Ar line intensity. O and H lifetimes are found to be equal to 17 and 23ms, respectively, which means that they are active and long time species and can thus interact with the surface in plasma-off time. A different time behaviour has been observed for O in pure O_2 (τ_O = 5ms) and has been related to a drop of their loss probability on the reactor walls from 0.06±0.01 in pure O_2 to 0.02±0.01 upon TEOS addition.

1. Introduction

New technological applications of low-pressure plasma often demand precise control of the plasma parameters in order to optimize various process characteristics. A promising approach is the use of pulsed plasmas, which allows to enhance some wanted species. For example, for the deposition of Teflon-like films, it was shown that using a plasma pulsed with a short plasma-on time, the fragmentation of the feedstock gas was reduced yielding a film composition much closer to Teflon than with a continuous plasma [1]. In oxygen/organosilicon plasmas, pulsed plasma can be used to emphasize the action of oxygen atoms, which are known to be responsible for the oxidation of hydrocarbon compounds and then to improve the quality and the roughness of the film [2]. Pulsed plasma can also be used to increase the neutral to ion flux ratio on the substrate in order to reduce the compressive stress in the deposited film [3]. In this context, we have studied by time-resolved optical emission spectroscopy the different active species created in pulsed oxygen/tetraethoxysilane (TEOS) plasma.

The work presented hereafter was performed in pulsed oxygen/TEOS plasmas created in a low-pressure reactor, operated at 13.56 MHz. In continuous plasma mode, both plasma and film properties have been deeply investigated as a function of the organosilicon to oxygen flow rate ratio [4]. Inorganic transparent and hard SiO_2-like films are obtained in oxygen-rich plasmas whereas the plasma polymerized $SiO_xC_yH_z$ films obtained in organosilicon-rich plasmas are soft and absorbent in UV.

2. Experimental setup and diagnostic

Helicon reactor. The pulsed experiments were carried out in a helicon reactor, described previously [5]. In brief, it is composed of a source, a Pyrex tube surrounded by a helicon antenna, and a diffusion chamber, where the silicon substrate is located. The base pressure of the reactor is less than 7.10^{-4} Pa. The oxygen and argon are introduced on the top of the source, whereas TEOS was injected via a gas ring located in the diffusion chamber, 8cm above the substrate. The organosilicon flow rate was controlled by MKS 500C massflow. To achieve good operating conditions, liquid TEOS was heated at 40°C. Experiments were performed in pure oxygen and in a TEOS/O_2 1:9 mixture. In both conditions, the total gas flow was fixed at 16 sccm, which corresponds to a pressure of 2.5mTorr before the plasma ignition.

The magnetic field (60G) inside the source is generated by an electromagnet coil around the antenna. The radio-frequency (13.56MHz) power is capacitively coupled up to about 100W and inductively coupled at higher powers. The plasma is generally operated in the inductive mode using a rf power of 300W. In pulsed mode, the power is 100% rectangular-wave modulated with a modulation frequency

varied from 1 to 500 Hz. The duty cycle, defined as the T_{on} period to the total period ratio, is varied from 14 to 50%.

Time-resolved optical emission spectroscopy. The light emitted by the discharge was sampled through a quartz window, using an optical fiber. The emission spectrum was detected by a Jobin-Yvon monochromator (HR460) equipped with two gratings (2400 and 1200 g/mm gratings used for the 180-420 and 420-850 nm spectral range, respectively) and a photomultiplier (R928 Hamamatsu). Argon was used as an actinometer.
For each pulsed condition, an emission spectrum was first recorded in the spectral range 180-850nm, with a resolution of 0.3 nm in order to locate the exact position of the maximum intensity of the line. Then, the temporal variations of the intensity at this fixed wavelength, were recorded during the plasma-on period using a digital oscilloscope (TDS 340).. The time behaviour of Ar^* (750nm), O^* (844 and 777nm), H_β (486nm), OH^* (306nm) and CO^* (296nm) emissions were more especially studied. Whatever the plasma conditions, the decay time of Ar line measured when the plasma is switched off is less than 50 µs. This time is expected to be close to the characteristic switch off time of both the generator and the detection system.
Experiments were carried out with the optical fiber positioned in the mid-height of diffusion chamber, so that the collected light is emitted from the plasma located between the injection ring and the substrate-holder.

The actinometry principle. The collected light intensity is given by : $I = C_{exp}.C(\lambda).A.[M^*]$, where C_{exp} is a geometrical parameter which accounts for the observed volume and the solid angle of the emission, $C(\lambda)$ is the spectral response of the system, A is the probability of the radiative transition, and $[M^*]$ is the concentration of the excited state of the M species.
The actinometry principle is to record the intensities of the studied species M and of an actinometer A. This actinometer is a gas introduced in a low and known concentration in the studied plasma. It is chosen to not react with the other gas. Actinometry can be used if several hypotheses are verified:
(1) The actinometer addition doesn't modify the discharge.
(2) The excited species M* and A* are produced by direct electron impact from their fundamental state. The excitation coefficient denoted K_{exc}, depends on the electron temperature and on the excitation cross section.
(3) The excited species is lost by radiative emission.
If these hypotheses are fulfilled, the intensity ratio can be related to the concentration ratio as follows :

$$\frac{I_M}{I_A} = \frac{C(\lambda_M)}{C(\lambda_A)} \cdot \frac{\lambda_A}{\lambda_M} \cdot \frac{K_{exp}{}^M}{K_{exp}{}^A} \cdot \frac{[M]}{[A]}$$

To get free from the electron temperature and from the excitation cross section, the actinometer has to be chosen so that the excitation threshold and excitation cross sections are similar for A and M. To monitor the oxygen atom concentration in oxygen plasmas, several authors have shown that the argon line at 750 nm, and the oxygen line at 844 nm were the best suited [6]. Nevertheless, if using these lines is necessary, it is not sufficient and actinometry can be invalid, for instance when the oxygen dissociation degree is low and the mean electron energy is high [7].

3. Results in oxygen plasmas
Figure 1 displays the time variations of Ar* line intensity. The initial spike, corresponding to the plasma breakdown, occurs after around 90µs and the emission reaches stability after about 100µs. The same plasma stabilization time is observed in all explored pulsed conditions. The observed initial peak corresponds to a rise of the Ar excitation coefficient, related to a higher electron temperature for the plasma breakdown [7].
The excited oxygen atoms can be created upon electron impact on either O or O_2 :
(1) $O + e^- \rightarrow O^* + e^-$ direct excitation of atomic oxygen
(2) $O_2 + e^- \rightarrow O^* + O + e^-$ dissociative excitation of O_2

Since molecular oxygen is the feedstock gas, its concentration is high before the plasma ignition. If reaction (2) is the dominant one, then the emission intensity is expected to increase as fast as the

electron density when the power is switched on. Figure 2 shows the temporal behaviour of the O*(844nm) to Ar*(750nm) intensity ratio measured in pure O_2 plasma for different modulations. At long power-off periods ($t_{off} \geq 75$ms), I_O/I_{Ar} is close to zero at the intercept. This behaviour suggests that the excited $O(3p^3P)$ atomic oxygen is not significantly created by dissociative excitation of O_2 but mainly by direct excitation of atomic oxygen.

When the same experiment is carried out at 50W, namely in the capacitively coupled plasma, I_O/I_{Ar} is weak and almost independent of the time. In these plasma conditions, the electron density is not high enough to efficiently dissociate O_2 into oxygen atoms so that the excited atoms are mainly produced by dissociative excitation of O_2. In addition, it can be noted that the I_O/I_{Ar} value measured at 50W is very close to the value measured at the intercept at 300 W (e.g. in inductive mode). Hence, it can be concluded that the initial value of I_O/I_{Ar} corresponds to the dissociative excitation of O_2, whereas the slower rise of I_O/I_{Ar} is due to the direct excitation of atomic oxygen, which is slowly produced. After several milliseconds, it reaches a stable value equal to the one obtained in continuous mode.
As the power-off period is decreased below 75ms, the value of I_O/I_{Ar} measured at the intercept increases, due to the increase in the residual atomic oxygen concentration which is only partially lost during the plasma-off period.

The same experiments were performed with the oxygen line at 777 nm. In all the pulsed plasma conditions, the intercept value of the O*(777nm) to Ar*(750nm) intensity ratio was always significant. In other words, $O(3p^5P)$ (the upper state of the 777nm transition) is always created in significant amount by dissociative excitation of O_2, which agrees with all the studies devoted to actinometry in oxygen plasmas [6-7].

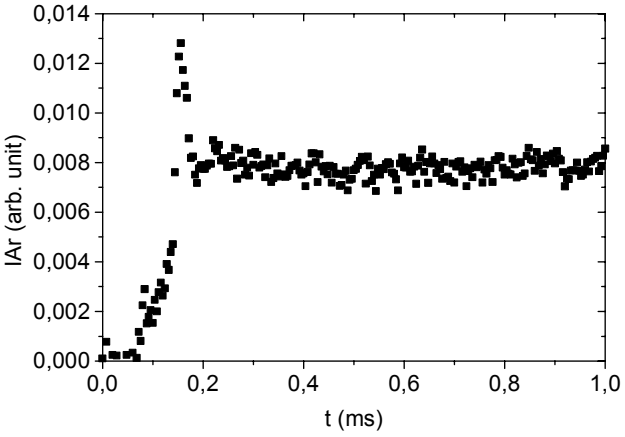

Figure 1: Argon line (750 nm) intensity in an inductively coupled O_2 plasma pulsed at 1Hz 2.5 mTorr-300W, t_{on}=130ms and t_{off}=860ms.

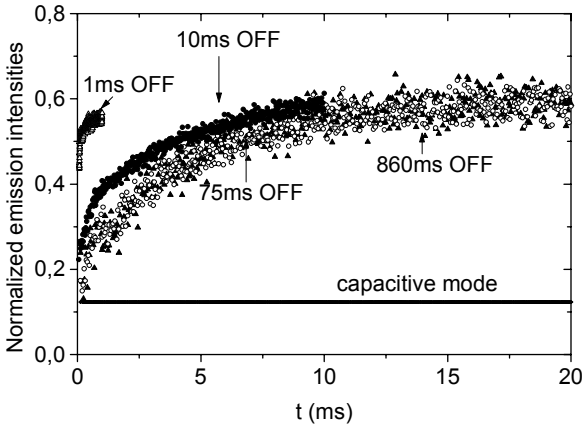

Figure 2: Normalized emission intensity of O in pulsed O_2 plasma for different conditions:*
(—) capacitive mode (50 W)
(symbols) : inductive mode (300 W) :
(Δ) $t_{on}=t_{off}$=1ms ; (●) $t_{on}=t_{off}$=10ms ;
(○) t_{on}=25ms, t_{off}=75ms ; (▲) t_{on}=130ms, t_{off}=860ms

At 1Hz, I_O/I_{Ar} can be modeled by an exponential law [7]:

$$\frac{I_O}{I_{Ar}} = \left(\frac{I_O}{I_{Ar}}\right)_{max}\left[1-\exp\left(-\frac{t}{\tau_O}\right)\right] \quad (3) \quad \text{and} \quad \ln\left[1-\left(\frac{I_O}{I_{Ar}}\right)\Big/\left(\frac{I_O}{I_{Ar}}\right)_{max}\right] = -\frac{t}{\tau_O} \qquad (1)$$

where τ_O is the rise-time of oxygen atoms.

The rise-time was assumed to be equal to the decay-time, which is likely to be reasonable in the case in low-pressure plasmas where gas-phase recombination is unimportant [7]. However, we can notice that at higher pressure (around 50 Pa), experiments carried out in both plasma-on and plasma-off periods by laser induced fluorescence have shown that the decay-time of O atom in O_2 plasma is much higher than the rise-time [2]. Hence, the lifetime deduced from relation (1), represented in figure 3, is likely to be a minimum value.

The oxygen atom lifetime τ_O is found to be equal to 5ms. By using the Chantry formalism [8] to describe the diffusion of O to the reactor walls, the atom recombination probability on the reactor walls, denoted γ_O, can be deduced from the oxygen lifetime. A value of 0.06±0.01 is found, corresponding to those already obtained in continuous mode [9], and in the same order of those reported in the literature [7]. This value is much higher than those measured in spatial post discharges [10]. However, it has been shown [11-15] that loss probabilities are largely higher on surfaces submitted to ion bombardment (continuous discharges and pulsed discharges) than on surfaces not submitted to ion bombardment (spatial post discharge).

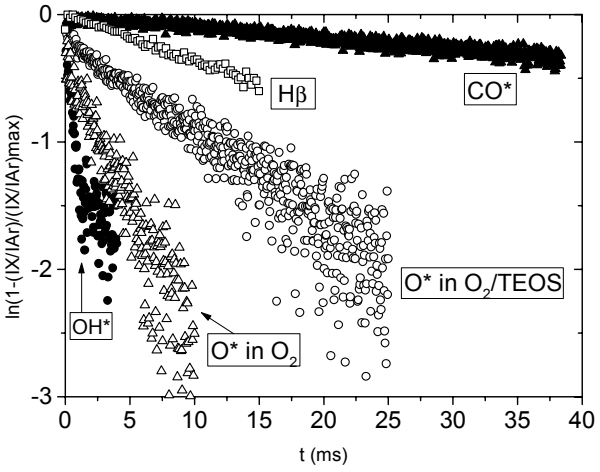

Figure 3: Time variations at 1Hz (t_{on}=130ms, t_{off}=860ms) of different species plotted under the form of Relation (1) in pure O_2 plasma : (Δ) O, and in O_2/TEOS plasmas : (○) O*, (●) OH*, (□) H_β, (▲) CO**

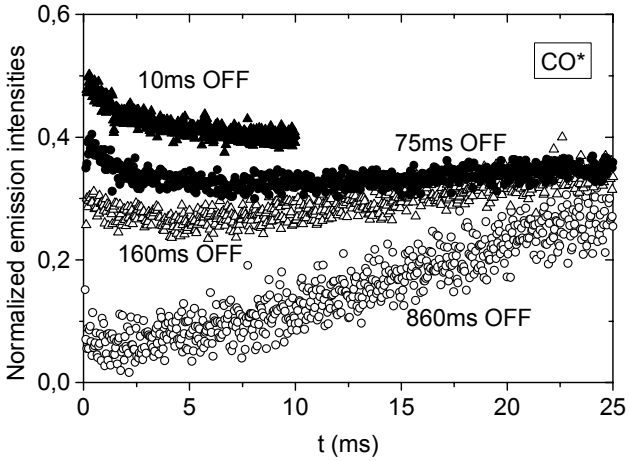

Figure 4: Normalized emission intensity of CO in TEOS/O_2 1:9 plasma (300W) for different modulation conditions :*
(▲) t_{on}=t_{off}=10ms ; (●) t_{on}=25ms / t_{off}=75ms ;
(Δ) t_{on}=25ms, t_{off}=160ms; (○) t_{on}=130ms, t_{off}=860ms.

3. Results in O_2/TEOS plasmas

All the results presented hereafter were obtained in a TEOS/O_2 1:9 plasma operated in the inductive mode (2.5mTorr – 300W). The optical fiber was located on the diffusion chamber. Previous measurements carried out by mass spectroscopy in a continuous plasma created in the same mixture, power and pressure conditions, have shown that more than 95% of the TEOS molecules were dissociated and that H_2, H_2O, CO and CO_2 were the main stable by-products of the dissociation and oxidation reactions [16]. Since these species are stable molecules, they are only lost by pumping. Their lifetimes are expected to be equal to the residence time in the reactor, which was estimated to be 330ms. We followed O*, CO*, OH* and H_β emissions by time-resolved optical emission spectroscopy.

3.1. Oxygen atoms

The time variation of I_O/I_{Ar} measured at 1 Hz is plotted in Figure 3. I_O/I_{Ar} and τ_O (17ms) are both higher than in the O_2 plasma, which indicates a higher oxygen concentration, and corresponds to a lower value of the O-atom loss probability γ_O (= 0.02). The same trends have already been observed in the case of continuous

plasmas [5]. As TEOS is added, new radicals are created and compete with O at the reactive sites of the surface. The oxygen loss rate drops so that its lifetime and its concentration in the plasma rise.

3.2. CO molecules

Figure 4 shows that the initial value of the normalized CO* emission rises when the plasma-off time drops. It is zero only for a time-off (860 ms) much higher than the residence time. Hence, it can be concluded that CO* is produced by electron impact upon the stable CO molecule.

3.3. OH radicals

The normalized OH* intensity behaviour, plotted in figure 5, is very different. For all the pulse frequencies investigated, its initial value is very low and it reaches its steady state value within a few ms. Hence, it can be concluded that OH* is not significantly created from a stable species but from OH radicals. The OH lifetime, determined using the method previously described for O, is equal to 1ms, which confirms that OH is a very reactive species.

3.4. H_β time variation

The time behaviour of the normalized H_β line for the different modulation conditions are plotted in figure 6. $I_{H\beta}/I_{Ar}$ time variations strongly depend on the rf-on time and rf-off time conditions. When the rf-off time is equal to 860ms, namely when all the stable species created by the plasma have disappeared during the rf-off time, $I_{H\beta}/I_{Ar}$ is almost zero at the intercept. Hence, H_β is not created by dissociative excitation of TEOS. This result was expected, since the electron energy threshold for this reaction was measured to be equal to 17eV by Kurunczi et al [17]. Since the electron temperature in O_2/TEOS 9:1 plasma was measured to be about 4eV [5], H_β emission by dissociative excitation of TEOS is not efficient.

When the rf-off time is decreased to 160 or 75ms, the value of $I_{H\beta}/I_{Ar}$ at the intercept increases, which can be attributed to the presence of residual H atoms from the previous pulse or emission of H_β by dissociative excitation of H_2 and/or H_2O. Since the rise time of H_β is equal to 23ms, which is much smaller than the residence time, it is likely that H_β is mainly created upon excitation of H.

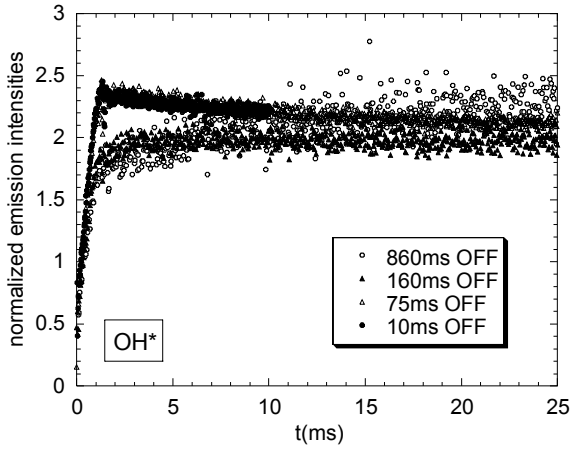

Figure 5: Normalized emission intensity of OH in TEOS/O_2 1:9 pulsed plasma (300W) for different modulation conditions :*
(●) $t_{on}=t_{off}=10ms$; (Δ) $t_{on}=25ms$, $t_{off}=75ms$;
(▲) $t_{on}=25ms$, $t_{off}=160ms$; (○) $t_{on}=130ms$, $t_{off}=860ms$

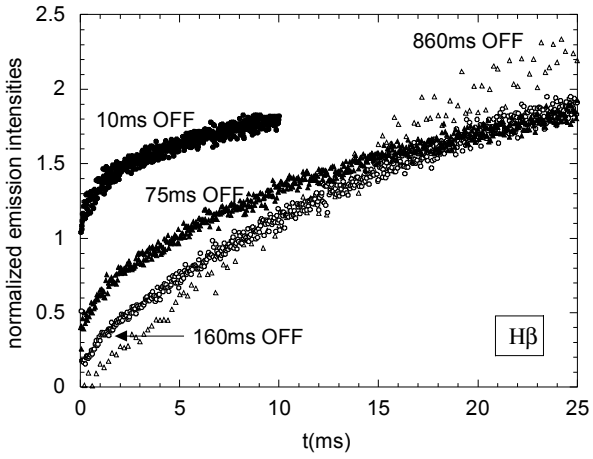

Figure 6: Normalized emission intensity of H_β in TEOS/O_2 1:9 pulsed plasma(300W) for different modulation conditions :
(●) $t_{on}=t_{off}=10ms$; (Δ) $t_{on}=25ms$, $t_{off}=75ms$;
(○) $t_{on}=25ms$, $t_{off}=160ms$; (Δ) $t_{on}=130ms$, $t_{off}=860ms$

Conclusion

Time-resolved optical emission spectroscopy is a suitable method to determine species kinetics in pulsed plasma and to verify the actinometry validity. This technique was used to determine the relative importance of the different mechanisms of the species creation. The oxygen atom loss probabilities on the reactor walls are determined to be: 0.06 in pure O_2 and 0.02 in TEOS/O_2 1:9 plasmas. This difference

may be due to a saturation of reactive sites on the walls by new radicals coming from TEOS dissociation. The lifetimes of studied species were also determined and give indications on the plasma composition for both power-on and power-off period.

Mass Spectroscopy Study of the Formation of Ammonia in Iron Nitrocarburizing Process by Using a dc Glow Discharge

H.R.T Silva, P. Egert[1], A.S. da Silva Sobrinho, A. Casaril, and C.V. Speller

Materials Sc. Laboratory/EMC/UFSC - 88040-900 - Florianópolis - SC - Brazil
[1]Environmental Engineering - Unisul - 88130-000 - Florianópolis - SC - Brazil

Mass spectroscopy was used to study the evolution of the ammonia formed during the iron nitrocarburizing process by using a dc glow discharge in different $N_2/H_2/CH_4$ gas concentration mixtures. The experiments were performed in two different configurations [1-2]: the volume configuration was used to collect ammonia that is formed in all the reactor volume, including that formed in the sample surface, while the surface configuration was used to enhance the collection of ammonia formed on the plasma/sample surface interface. The technique proved to be an efficient tool to investigate the mechanism of the physical chemistry of the plasma nitrocarburizing process. Results obtained using the surface configuration showed that the formation of ammonia in the nitrocarburizing process present a maximum for nitrogen rich gas mixture (about 75% N_2 - 22% H_2 - 3% CH_4) that decreases as the treatment time increases, giving rise to a new maximum in hydrogen rich gas mixture (about 22% N_2 - 75% H_2 - 3% CH_4). This shows that the ammonia formation is related with the formation of the compound layer, probably by a mechanism similar to that proposed by Szabo and Wilhelm [3] for the nitriding process. In the case of volume configuration where the collected gas contain ammonia formed in all plasma reactor (reactor walls and sample surface), the results show a very broad maximum for the ammonia, which is the convolution of the two maximum: one for the ammonia formed in the hot sample surface (high nitrogen consumption) and the other one for the stoechiometric ammonia formed in the reactor walls (high hydrogen consumption).

Preparation of hard coatings employing non-equilibrium plasma under atmospheric and reduced pressure

V. Valinčius, P. Valatkevičius, L. Marcinauskas

Plasma Processing Laboratory of Lithuanian Energy Institute, Kaunas, Lithuania

Abstract
The plasma spray system has been developed for deposition of wide range of coatings. Two types of plasma torches were developed for operating by feeding air, nitrogen or hydrocarbon containing gases mixed with dispersed particles using the possibility of injection directly into the reacting arc zone. Thick and thin carbon containing films suitable for further plasma treatment and diamond phase nucleation process have been deposited employing non-equilibrium atmospheric and reduced pressure plasma.

1. Introduction

Due to distinctive characteristics of plasma, low temperature plasma flows and jets have been widely used in a variety of fields: plasma chemistry, metallurgy, material processing, waste treatment, laser and space technology and the scientific research goals. Plasma technology processes take place at high temperatures of gas flows created by the specific equipment. Usually, gas retains its dielectric properties there, however, with certain amount of electrons it becomes a conductor and a suitable power source creates in it the electric current, even electric arc discharge.

Amorphous carbon films appeared as very important means for technological applications, presenting a variety of unique properties. Among of the applications plasma polymerization [1,2] and diamond phase nucleation in micro channels of high electrical conductivity of hydrocarbon films [3,4,5] should be mentioned. The creation of suitably arced coatings for that purposes is a very important task, because microarcing plays an essential role in the initiation of electric breakdown that enable and influence diamond nucleation. Despite the large amount of scientific work, several aspects of the deposition process, especially in the conditions of atmospheric pressure, are still a matter of controversy.

The plasma spray deposited diamond and hard ceramic coatings are attractive in many fields of industry. It is well known that high or low pressures are required for synthesis of them. During last years, significant progress has been made in the development of atmospheric pressure plasma technology. There appeared a possibility to realize plasma deposition of diamond, diamond like carbon and other hard coatings under atmospheric or slightly reduced pressure conditions [6,7,8].

We conclude that synthesis of plasma polymeric coatings in atmospheric pressure plasma possibly can be performed in two ways: 1) synthesis of polymer coatings directly in atmospheric pressure plasma jet under effect of ion bombardment and with presence of the catalyst; and 2) treatment and polymerisation of earlier deposited coatings employing low-pressure discharge.

In the first case reactive species, generated by the dissociation of gas precursors, react with heated injected particles and the resulting material splats to form the chemical compounds of polymeric precursors. Reactions may occur in flight with the solid and liquid species (the flight time is about $1 \cdot 10^{-3}$ s), and at the splat surface. The second case is based on different methods of release of energy in the local areas of coatings, such as external irradiation of precursor by concentrated beams of electrons, ions, photons, stress, etc. In that case especially prepared coatings are necessary.

However the essential condition in both cases is a synthesis of coatings suitable for the further treatment process. The early deposited coatings could be prepared by low temperature non-equilibrium plasma at atmospheric pressure employing two different approaches: 1) plasma enhanced spray deposition of coatings using partly or fully melted phase of dispersed particles, and 2) plasma chemical condensation of films employing evaporated substances. In the last case raw materials used can be compounds that make up the coating itself. So, the deposition of the carbon film suitable for the further plasma treatment and diamond phase nucleation process is in the main focus of present studies, where coating samples were formed employing the direct plasma spraying technology. In present paper we report on the technology of forming such coatings employing plasma jet at atmospheric and reduced pressure on the metallic, silicon, quartz glass or ceramic-based material. The ingredients are introduced directly into reactive arc zone. The condensed-phase preparation of coatings can be realized at conditions of both, equilibrium and non-equilibrium plasma.

The plasma technique is also used for activation of the substrate surface and sprayed species, which reaches the surface in liquid or vapour phase. Plasma nonequilibrity plays a very important role in film formation therefore the distribution of electron temperature and density is analyzed here.

2. Experimental equipment and technical details

Experimental installation (Fig.1.) consists of the power, gas and cooling systems, plasma torch (PT), feeders, measuring devices, auxiliaries and airing devices. The PT and gas dynamic system was modified so, that major part of dispersed carbon particles and jet forming gas were supplied directly into the reacting zone of arc. This allows forming very active vapour and melted particles jet in no reacting gas plasma, which could condense and adhere on the especially prepared substrate surface. The thickness of coatings may be adjusted in wide range due to ratio of the flow rate of evaporated and melted particles.

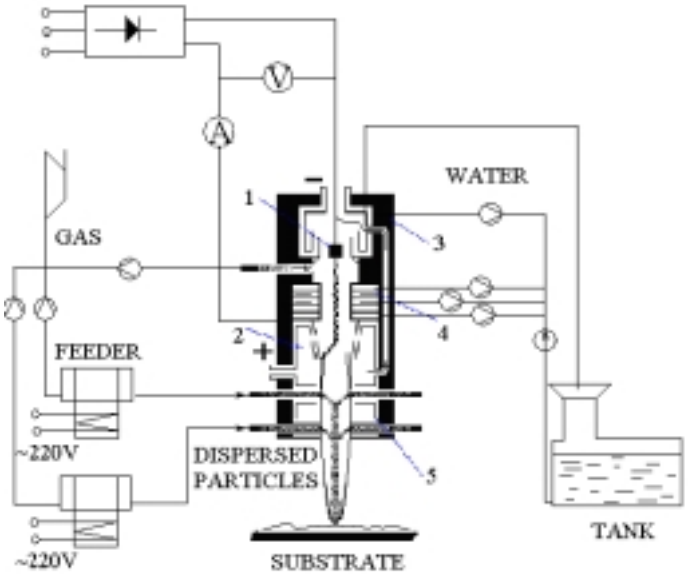

Fig. 1. The schematic presentation of plasma system for deposition of coatings in reduced and atmospheric pressure. 1 – cathode, 2 – anode, 3 – cooling rings, 4 – gas injection rings, 5 – injection of dispersed particles

Two constructions of plasma sources were used. The first one – a linear dc PT of 35 kW of power with hot cathode and step-formed anode with tangential gas injection was designed especially to produce non-equilibrium plasma jet. The schematic presentation of the PT is shown in Fig. 2. It consists of a cathode junction 1 with hafnium emitter, insulation-injection rings 3, and cathode-coupled section for arcing 4, neutrode 5, and step-formed anode 6. In the case when magnetic stabilization of flow is necessary, the magnetic coil may be useful. Each ring 3 contains blowholes of tangential air supply (G_1, G_3 and G_3) for the arc stabilization and to obtain a possibility to introduce the stock and plasma forming gas directly into the arc. The G_1 under investigation is of the order of 0,54 – 1,27, G_3 – 1 – 3,45, and G_5 – 1 – 3,45 10^{-3} kg·s^{-1}. At the constant total gas flow, G_1, G_2 and G_3 are defined as diverse ones. The current can be varied in the range of 150 - 200 A in the experiments described here. The voltage drop depends on the gas flow rate and gas composition and ranges from 180 to 250 V.

One of the simplest and acceptable ways to influence the arc for production of non-equilibrium plasma was the injection of thin stream of gas circular directly into different cross section of rechargeable chamber. The mass flow of the source gases as air or nitrogen was regulated by mass flow controllers. The flow in the air lines was controlled by diaphragm and differential pressure gauge with electrical output signal. The nitrogen flow rate was controlled by critical jet up to maximum of 3.5 10^{-3} kg·s^{-1}.

The voltage-current characteristics of the plasma torch are slowly decreasing and may be presented analytically in the following way:

$$\frac{Ud_2}{I} = c\left(\frac{I^2}{Gd_2}\right)^m \cdot \left(\frac{d_2}{I}\right)^{0,5} \cdot \left(\frac{G_1}{G}\right)^{-0,12}, \qquad (1)$$

where U is voltage, I - the arc current, G - the flow rate, d - exhaust nozzle diameter, m=0,8.

The efficiency coefficient η is calculated according:

$$\frac{1-\eta}{\eta} = c\left(\frac{I^2}{Gd_2}\right)^m \cdot \left(\frac{G_1}{G}\right)^{0,12} \cdot \left(\frac{G}{d_2}\right)^{0,2} \cdot \frac{d_2}{I} \cdot \left(\frac{l}{d_2}\right)^{0,95}, \quad (2)$$

where l - the characteristic arc distance, $c = 0{,}71 \cdot 10^{-4}$, $m = 0{,}8$.

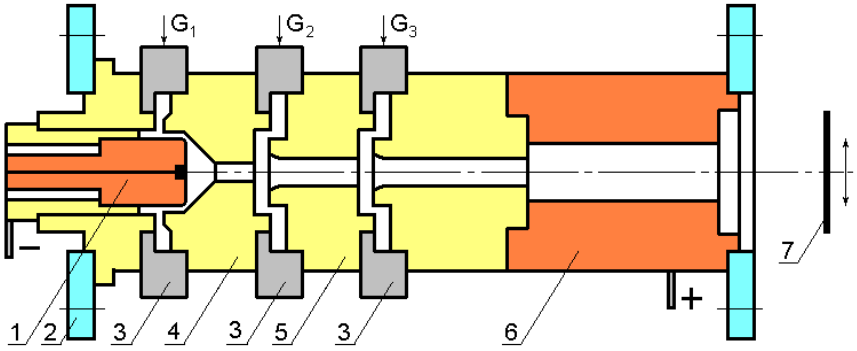

Fig. 2. Plasma torch for deposition of coatings. Explanation see in the text.

Before being introduced into working gas, the dispersed particles is mixed in vibrating feeders with controlled dosage. The gas and powder were injected trough a 4,5 mm diameter cylindrical tube with a flow rate about $0{,}4 \cdot 10^{-3}$ kg·s^{-1}. The distance between the plasma torch and substrate was equal to 0,09-0,12 m ($x/d \approx 12$).

Stainless steel sheets, silicon plate, ceramics and quartz glass tubes have been used as substrate. The substrate was cooled by air or water so, that surface temperature couldn't exceed 650 K. During deposition, the substrate was rotated and its linear velocity was equal to 5 m·s^{-1}. The surface of the substrate was nitrogen cooled during all process of deposition. Simultaneously, the plasma torch moved horizontally and parallel to the substrate with a velocity equal to $(3\text{-}5) \cdot 10^{-3}$ m·s^{-1}.

The propane-butane gas was injected into non-equilibrium nitrogen plasma to get carbon-containing the plasma forming flow. A mixture of propane-butane gases is fed into the space between the two electrodes at $(0{,}15 - 0{,}45) \cdot 10^{-3}$ kg·s^{-1} (at 10^5 Pa and 293 K). For deposition thick films carbon particles are added to air carrier gas. The aluminum layer on metallic surface is deposited for subsequent synthesis of hard coating and for protection of metal surface from oxidation during deposition process.

To estimate the charged particle flux and temperature in the jet effluent, double planar Langmuir probe was placed in the exhaust plasma jet. The probes are circular, water cooling, of $4 \cdot 10^{-3}$ m diameter and made of oxygen free copper. The edges of the probe are shielded off by a ceramic (Al_2O_3) coating.

For large area application the similar of new types of plasma sources were developed. The other PT, 5 kW of power, consisting of similar parts, was designed and specially constructed to improve plasma spray quality employing high velocity plasma jet. PT fitted with an orifice used to generate the supersonic plasma jet. Plasma forming gas was injected only tangential in two places. The latter plasma source has been placed in a vacuum chamber together with its belonging auxiliaries. A series of films were deposited with different N_2 and dispersed carbon particles flow rates each for 100 s duration.

3. Results and discussion

The plasma jet parameters at the exhaust nozzle of plasma torch were also strongly regulated and fixed. Results of plasma diagnostics showed that temperature and velocities profiles in plasma jet are axi-symmetrical and parabolic shaped. The diameter of the jet slightly increases.

An electron flux of 5 x 10^{13} particles cm^{-2}·s^{-1} was collected on the probe when 100 V to the floating potential positively biased it. The electron temperature was several times of magnitude higher than temperature of heavy particles (Fig.3.). The electron density (Fig.4.) in the plasmas under our investigation is of the order of $10^{16} - 10^{17}$ cm^{-3} and the temperature is 0,5 – 1,8 eV.

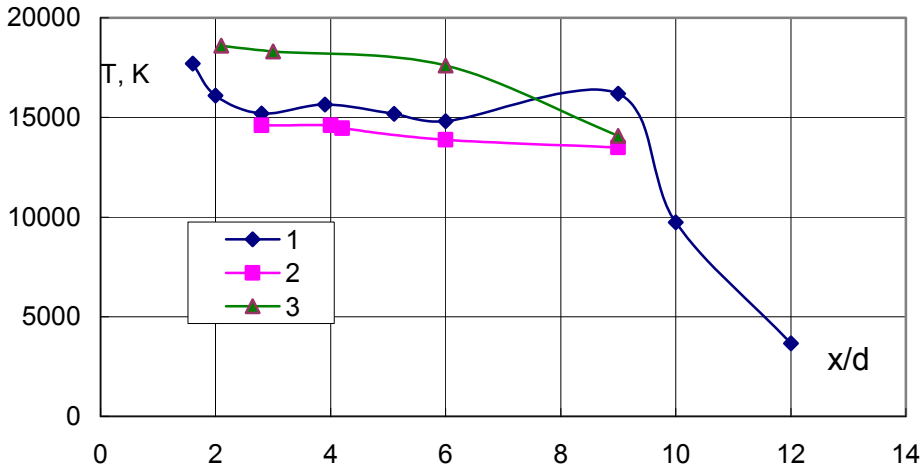

Fig. 3. Distribution of electron temperature in plasma jet. 1,2 – PT developed by authors, 3 – PT of Sankt-Petersburg colleagues

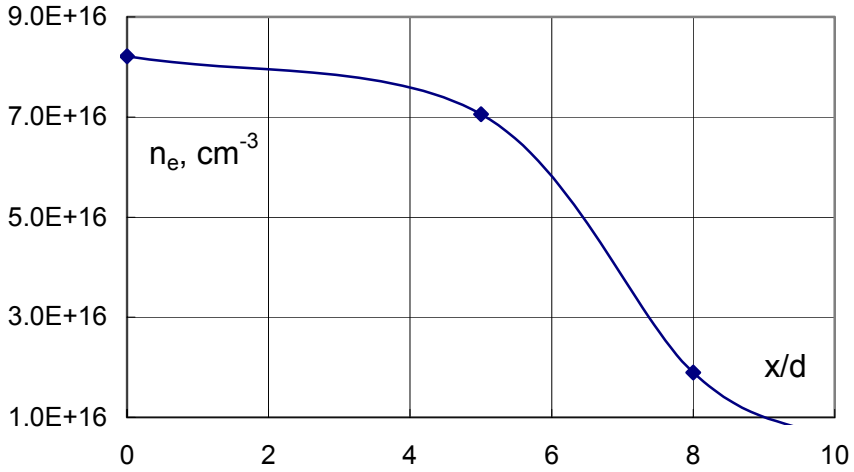

Fig. 4. The electron density as a function of distance

The subject of this paper is the application of plasma spray torch for deposition of carbon derivative coatings on metal and ceramic substrates of different configuration and composition. In the present study carbon derivative films were formed from carbon containing gas, carbon dispersed particles and their mixtures by the direct plasma spraying technology with or without evaporation of solid fraction.

In many cases coatings have been deposited without any sub layer and intermediate layers. At first the deposition process was performed according to our previously developed methods [9,10], when dispersed particles were injected into the plasma jet inside or outside the stream reactor, connected to the exhaust nozzle of PT. Carbon containing coatings were thick and rough. SEM images allow investigation of the film morphology and estimation of deposition rate as function of plasma forming gas rate and location of injection place. From the SEM studies, on the samples it can be observed that the coating consists of large ($(5 – 10)\cdot10^{-6}$ m) different shaped (spherical, hollow, broken, sphere within a sphere, tubular, and some other irregular shaped) particles (Fig.5a.). After modification of plasma source, when there appeared a possibility to inject particles simultaneously with plasma forming gases directly into the reaction zone of arc, the view has substantially changed (Fig.5b). Dispersed particles have evaporated and after transportation to the substrate they condensed again on the cold surface of substrate. The particles size on the coating could be changed by the change of arc length, its electric parameters, also plasma jet parameters. By the way the dissociation and ionization of substances is possible and the rest particles become as highly activated. The high velocity of plasma accelerates ions and heavy particles, which take part in film growth and the DC self-bias between the plasma and the substrate has been rapidly quenched on reaching the growing film. Because

of the shock, so activated particles impacts the surface atoms passing a part of energy to them. In that reason, atoms of the growing film become also activated and amorphous carbon is deposited on the surface.
Upon propane-butane addition, the film growth rate in the central area of the deposits initially increases from 50 to $150 \cdot 10^{-6}$ m/h. With further increasing gas flow rate, the film growth rate drops again while the material particles in the layer start to deteriorate. The structure of the film is fine and homogeneous; particles on the film become a streamline shape (Fig. 6.).

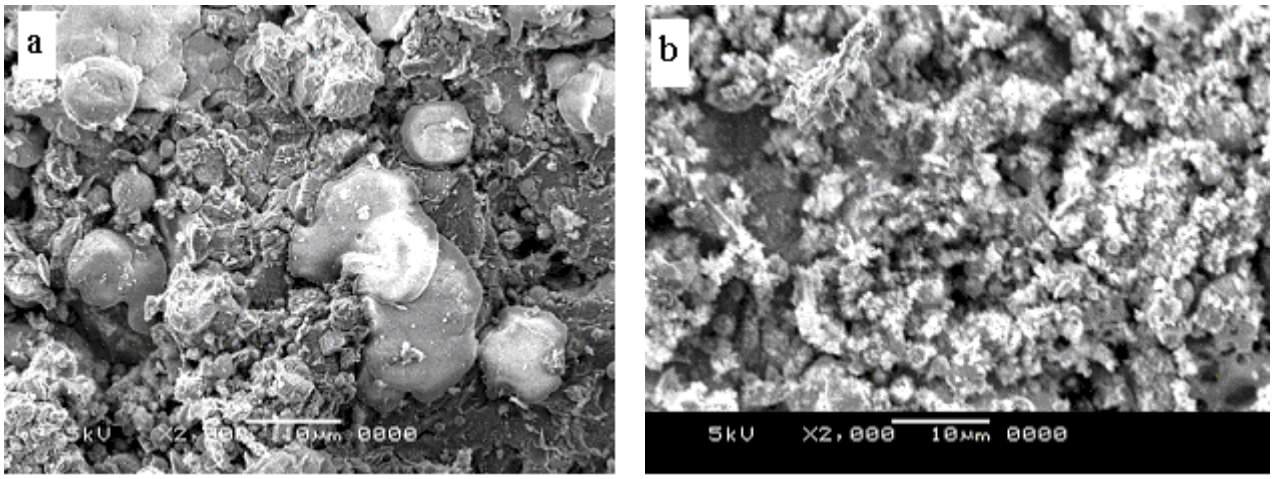

Fig. 5.The surface structure view of carbon coatings. a) dispersed particles injected in the stream reactor; b) particles injected directly into reaction zone of arc

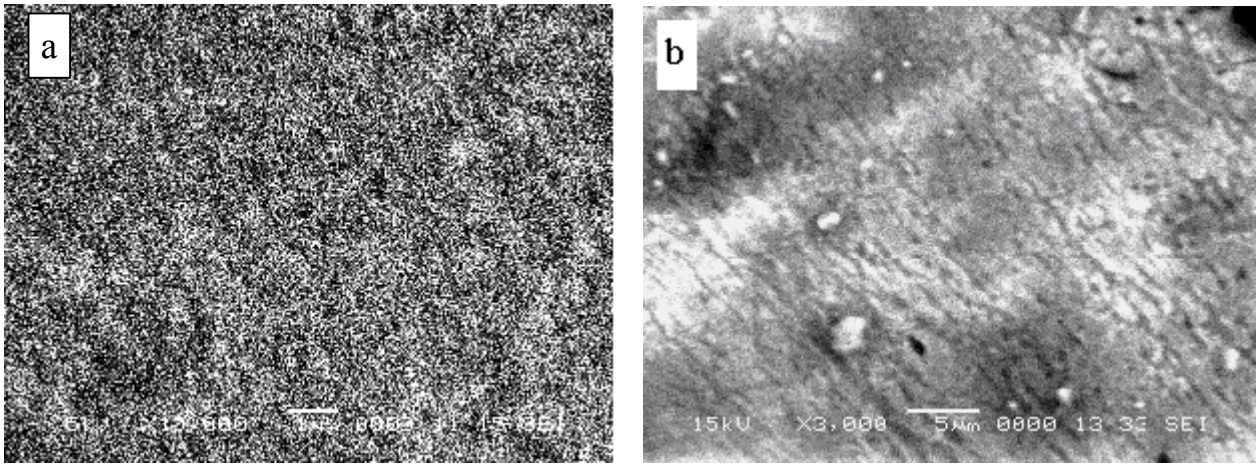

Fig. 6. The surface structure view of carbon coatings in the support of propane-butane gases. a) dispersed particles and gas injected into the reaction arc zone; b) the same, after additional plasma treatment at reduced pressure

Based on the results of the present study, the structural properties of deposited films on different surfaces (Fig.6.) display their suitability for further polymerization and diamond nucleation processes. For reproducible plasma deposition of fine carbon derivative coatings as a recipe could be given the use of special plasma torch with injection of dispersed carbon particles and propane-butane gases into the reaction zone of arc. SEM images of films grown with propane-butane and N_2 mixture of, respectively, 6 and 91% illustrated that propane-butane gas addition to the process gas mixture affects the film morphology. Films grown with no added propane-butane gas are predominantly faceted and twinning, while with addition of these gas the coating became even structure distribution with facets approaching ~10-50 nm in size. The addition of dispersed carbon particles into process mixture promotes the growth of large type of surface particles features.
The variation of N_2 or hydrocarbons containing gas flow rate has only low influence to the film growth rate. Significant film growth increases increasing dispersed particles injection rate and reaches the maximal value of 1 $\mu m \cdot s^{-1}$ in a 35 kW DC arc jet system operating with N_2/propane-butane at atmospheric pressure. The deposition rate in vacuum chamber employing 5 kW DC arc jet system was less than 0.1 $\mu m \cdot s^{-1}$ at the pressure of 10^{-3} Pa operating with the same gas mixture. Hardness values of deposited films estimated

employing Vicker's identification technique were in the range of 10,9 to 12,5 GPa. Films deposited employing 5 kW plasma spray system at reduced pressure after additional plasma treatment showed the 15,7 – 18,4 GPa hardness.

Conclusions

Finally we note that the present work supports the suggestion that DC plasma jet correlates with deposition of high quality hard coatings suitable for further plasma treatment, plasma polymerization, microarcing and diamond phase nucleation in microchannels of high electrical conductivity.

The DC-arc jet provides an excellent environment for plasma assisted deposited of thick and thin hard amorphous carbon films. Shape and size of particles on deposited coatings strongly depend on the localization of injection place. Fine-grained structures obtained after injection of dispersed particles directly into the reaction zone of the arc.

Significant differences in size and shape were observed during deposition process when carbon particles were injected directly into the arc together with non-reacting gas.

Carbon film particles deposited on quartz glass surface with addition of propane gases, assume the minimal size and streamline shape.

Plasma chemistry aspects of fullerenes and carbon nanotubes (CNT) production in arc discharge plasmas are reviewed. Two main ways of thermal decomposition of graphite, resulting in fullerene (nanotubes) containing soot generation are considered and compared in detail. The first one is the arc discharge with graphite electrodes in helium, where the soot is generated as a result of thermal decomposition of graphite anode (Kraetchmer scheme). The second one is based on usage of an arc plasmatron, where small size amorphous graphite particles are admitted. The conditions favorable for fullerenes and carbon nanotubes formation in plasma are analyzed on the basis of experimental data. The kinetics of vaporization of a small size carbon particles in plasma medium is investigated theoretically, on the basis of the heat conductivity equation with taking into account the temperature dependence of the heat conductivity coefficient.
The work is supported by the CRDF through the REC "Plasma".

Correlation of Optical Emission Parameters and ZnO:Al Film Properties in Reactive Magnetron Sputtering from Ceramic and Metallic Targets

Abstract

Aluminium doped zinc oxide (ZAO) layers are used as transparent conductive layer (TCO) in thin film solar modules. A significant cost reduction of TCO thin film production is expected by use of much less expensive metallic alloy targets.

The preparation of ZAO films with good TCO properties from ceramic targets with low amounts of oxygen gas inlet is well established due to low effort of process control means.

ZAO films with good TCO properties can also be deposited from metallic target in the transition mode of the reactive sputter process. To control the discharge in the transition mode by adding varying amounts of oxygen gas using a combination of a Plasma Emission Monitor PEM®05 and a fast optical emission spectrometer AOS-4, which allows multi wavelength control was applied.

The optical emission spectroscopy investigations were carried out in DC mode with metallic and ceramic targets at varying discharge power and gas pressure. The properties of the ZAO films obtained are correlated with optical emission data. It was investigated, if the optical emission parameters obtained in ceramic target process can be used as a measure for the control of the reactive metallic target process.

Introduction

Aluminium doped zinc oxide films (ZAO) are used as combined window and contact layer for thin film solar modules [1, 2, 3]. Commonly these films are DC sputtered from ceramic ZAO targets [4, 5]. However, a reduction of the high deposition costs can be expected, if reactive sputtering of metallic alloy targets will be applied. To deposit high quality TCO coatings special requirements are needed to stabilize the process. It has been shown that single wavelength Plasma Emission Monitoring (PEM) can be used to meet this requirements [6].

In further works we have shown that dual wavelength control by use of a simple intensity ratio can be used to improve the stability and reproducibility of the process parameters, which results in high transparency and low resistivity of the films grown [7, 8]. For this dual

wavelength control we successfully used a combination of an AOS spectrometer produced by IfU GmbH and a PEM®05 Plasma Emission Monitor which is produced by VON ARDENNE ANLAGENTECHNIK GmbH.

The AOS 4 spectrometer is a fast optical measurement system, based on AOTF technology, where the wavelength is selected by a fast switching Acousto Optical Filter [9]. Its wavelength calibration is stable over several years due to special internal stabilization. The robust design works without any moving parts and combines a wide wavelength range of 250-800 nm with an excellent wavelength resolution of 0.5nm@800nm and 0.05nm@250nm. The random wavelength access is carried out by full electronic control within a few milliseconds maintaining both, wavelength resolution and wavelength range.

The AOS 4 spectrometer supports 3 modes of operation:

Spectral scanning mode (called spectrum mode): The spectrum mode delivers complete intensity information from a wavelength range. The wavelength range is scanned by stepping through with acquisition time of minimum 5 milliseconds per step. Characteristic emission lines can be found in the spectrum using an automatic peak search tool. An advanced emission library tool based on data from the N.I.S.T. library [10] supports the identification of the lines found in the spectrum.

Chronogram / time tracking mode: The chronogram mode uses the advantage of fast random wavelength access. The AOS spectrometer control software supports the quasi simultaneous watching of up to 16 spectral emission lines with an acquisition time of down to 5 milliseconds each. The total time resolution depends from the number of selected emission lines. This mode is connected with an analog output, which can be set to values calculated by a user defined algorithm from the measured intensities. The chronogram mode can be used to monitor or to control a plasma process.

Microchronogram mode: The microchronogram mode combines the fast random wavelength access with a fast acquisition of the photomultiplier signal. It is specially intended for investigation of pulsed plasma applications. The measurement can be triggered by an external digital or analog signal, which may be derived from the pulse plasma power supply voltage or from the plasma power generator. The AOS spectrometer control software allows to take optical data from up to 16 preselected wavelength's, with a time resolution of downto 200ns.

Experimental

In [7] we have shown that dual wavelength control can easily be established with a combination of the AOS spectrometer and a PEM®05 Plasma Emission Monitor in DC and MF power supply mode as well. As the preparation of ZAO films with good properties using ceramic target is well established, it seems to be worth to compare the plasma emissions coming from a ceramic target process and from a metallic target process.

For our experiments we used the same setup and diagnostics for the films grown, as in [6]. We have shown that the metallic target allows to cover the complete film property range from totally metallic via transition to totally oxygenic behaviour only by controlling the reactive gas flow. The transition range has been investigated more detailed using metallic targets.

In a second step we recorded spectra from the plasma emissions using ceramic targets. As it has been shown in earlier work, very small amounts of oxygen have to be added to the discharge region to obtain the optimum in film properties without advanced process control.

Results

An emission spectrum of the metallic target magnetron discharge taken under single wavelength control is shown in fig 1. The operating condition are choosen close to metallic mode, where the transparency of the films grown is zero.

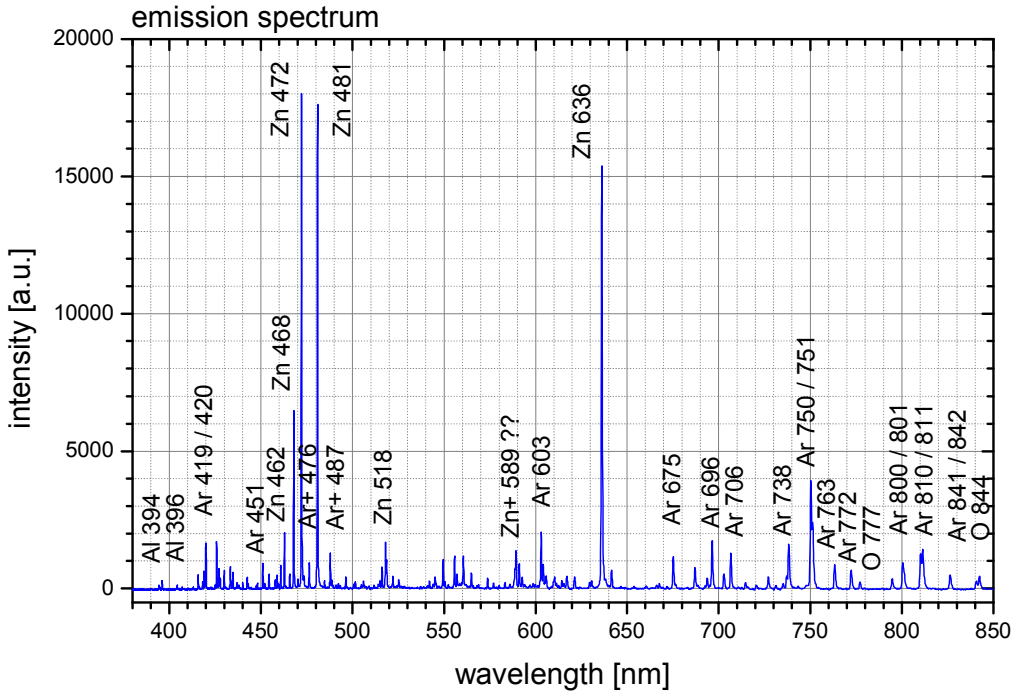

Fig. 1 Visible part of an emission spectrum taken with AOS under near metallic conditions with small amounts of oxygen

The most interesting emission lines have been selected and coordinated to the following specimen using data from the N.I.S.T. emission line library [10]:

Al	394, 396 nm
Ar	419, 420, 451, 603, 675, 696, 706, 738, 750, 751, 763, 772, 800, 801, 810, 811, 841 and 842 nm
Ar+	413, 454, 461, 476, and 488 nm
O	777 and 844 nm
Zn	307, 328, 330, 334, 462, 468, 472, 481, 518 and 636 nm
Zn+	491, 492 nm, overlayed with Ar+ emission lines, 589nm

A quiet intensive emission line at 589nm was identified as single charged Zn^+ ion line using the N.I.S.T. library. As the ionisation degree of the magnetron discharge may be low, only

very few ion lines could be observed. Considering the remarkable intensity of this 589nm line it may be used to monitor the ionic Zn^+ species.

To investigate the behaviour of different emission lines the AOS was used in chronogram mode. Following emission lines have been selected to be viewed under film deposition experiments with varied discharge set point:

Ar	750 nm
O	777 nm
Zn	472, 481, 636 nm
GND	657.5 nm, where no emission lines have been observed.

For the deposition experiments in metallic mode we used a simple ratio of the intensities from the O 777 and the Zn 636 emission line. As it has been shown in [6] the AOS output signal is highly sensitive to the mode of operation and allows the adjustment of the setpoint needed for deposition of ZAO films with TCO properties by reactive sputtering.

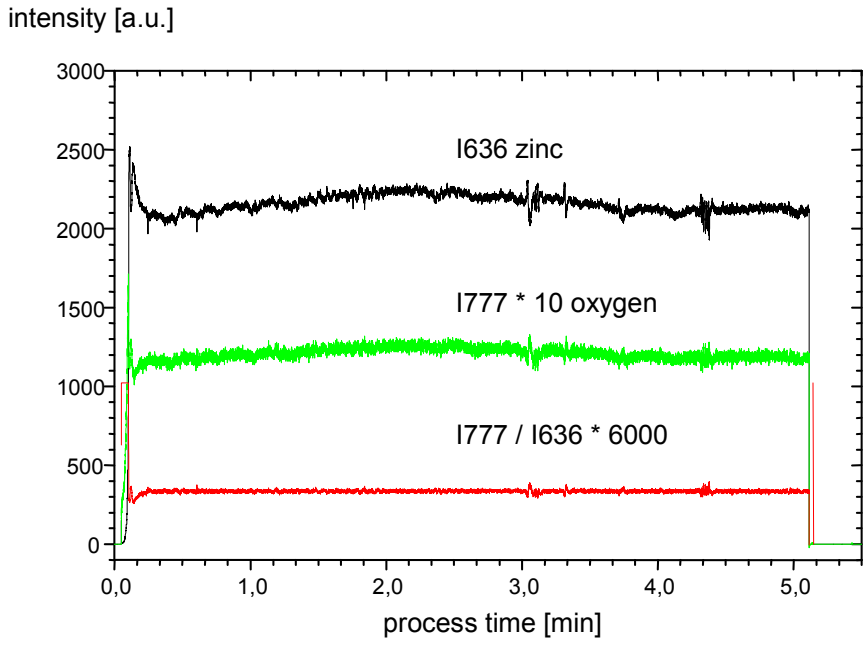

Fig. 2 Chronogram taken during the process dual wavelength control using AOS and PEM.

Fig. 4 shows a chronogram taken during the process control of the deposition of a ZAO layer under dual wavelength control. Plasma power was turned on at process time = 3 seconds. Approximately at 15 seconds the discharge had been stabilized to the setpoint (65% are related to S =325 digits due to signal conversion from digital to analog). There are changes in intensity visible at both emission wavelength 636nm and 777nm, but the ratio was held very constant.

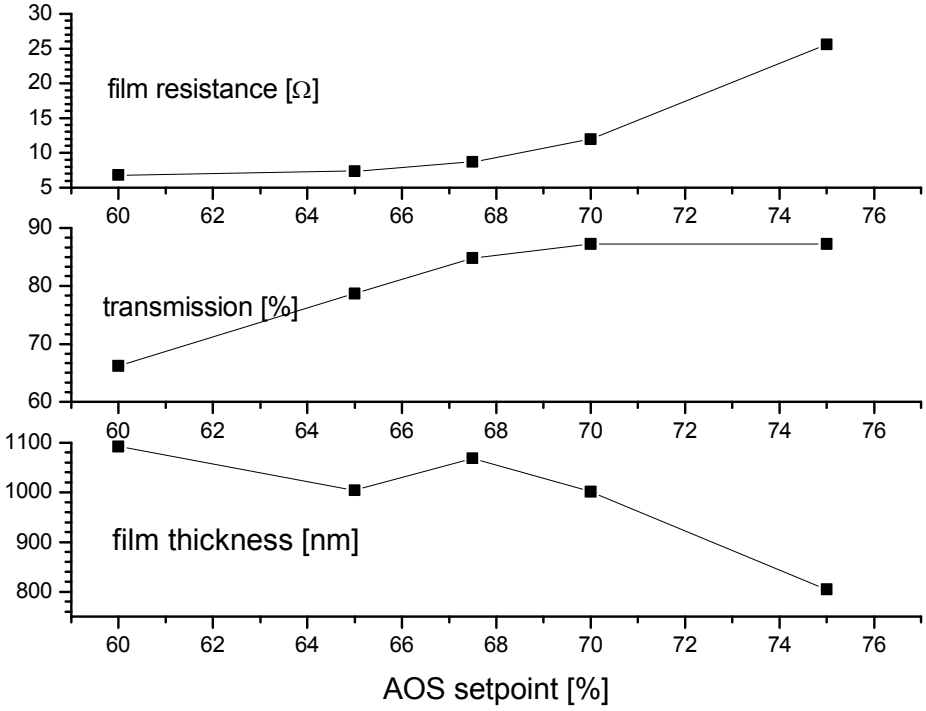

Fig. 3 Properties of ZAO layers grown at room temperature from metallic target with dual wavelength control

In fig. 2 there are shown properties of films grown with different AOS setpoints from metallic target. Higher values for the AOS setpoint correspond to higher content of Oxygen in the gas. The best film of this series was deposited at a gas pressure of 2.7 μbar with an AOS setpoint equal to 67.5%. Its transmission was as high as 84.8% with a film resistance of 871μΩcm.

Several film deposition experiments have been carried out with ceramic target. During deposition we recorded several emission spectra. The point of interest was to determine the intensity of the O 777 line. For this collection of emission data we used the same optical setup as for the optical measurements from metallic target.

target	Ar flow	O_2 flow	Remarks	Ar 763 counts	O 777 counts	O / Ar ratio
metallic	300 sccm	140 sccm	metallic films	930	103	0.11
metallic	300 sccm	188 sccm	very good TCO films	960	115	0.12
metallic	300 sccm	200 sccm	oxide films	960	245	0.26
ceramic	300 sccm	1 sccm	very good TCO films	13400	90	0.0007
ceramic	300 sccm	10 sccm	R > 300 Ω oxide films	13400	350	0.0261

Tab. 1 Selected optical emission data from ceramic and metallic target

The intensity of the O 777 line was very small in all experiments carried out with ceramic target. Only if large amounts of oxygen of 30 sccm are added to the gas discharge, a remarkable intensity of the O 777 line could be observed. At these reactive gas flows the properties of the films obtained are strongly oxygenic already. Selected emission data from both targets are shown in tab. 1.

As it can be seen in the right column, the intensity ratio measured from ceramic and from metallic target do not agree. The idea of using the plasma emission intensities from ceramic target as a reference value for metallic target set-point optimisation is not valuable for Aluminium doped Zinc Oxide layers.

Conclusion

ZAO layers can be produced from metallic targets by reactive magnetron sputtering. This process is expected to be much less expensive in the case of mass production due to low target costs and higher deposition rates.

The advanced process control needed for the metallic process can be established with a combination of a fast scanning AOS spectrometer and a PEM®05 plasma emission monitor using a simple ratio calculated from emission lines of the reactive gas and the metal used.

The optical emissions for the optimum ZAO properties set-point of the metallic target process cannot be optimised using the optical emissions from the the optimum set-point of the ceramic target process.

Diagnostics of dust structures in a gas discharge plasma

Olga S. Vaulina, Oleg F. Petrov and Vladimir E. Fortov

Institute for High Energy Densities, Russian Academy of Sciences, Moscow, Russia

Dusty plasma consists of neutral gas, ions, electrons, and micron-sized particles (dust grains). The particles are typically charged negatively in gas-discharge plasmas. The combined effect of interaction between the particles and the ambient plasma as well as between the particles themselves leads to the formation of various complex plasma states ranging from "gaseous plasma" to "liquid plasma" (or plasma fluid) and "plasma crystals". These states are distinguished by the level of ordering in the particle system. Since the particles can be visualized and analyzed at the kinetic level, complex plasmas are recognized as valuable model system for the study of phase transitions and other collective processes including transport properties and wave phenomena. Results are presented for a set of experiments performed in different types of gas-discharge plasma.

Effective structural (pair correlation function) and transport (diffusion constant) characteristics of the system of microparticles (dusty plasma) have been measured in a set of experiments in dc- and rf gas-discharge plasmas. The comparison between these measurements and numerical simulations were used for complex plasma diagnostics. Specifically, the effective coupling parameter, which mainly governs structural and dynamical properties of the system, was determined for different experimental conditions. The application of these measurements to estimate the particle charge and the plasma screening length is discussed.

First we report on the experiment performed in dc discharge plasma. More details about the experimental apparatus can be found for example in Ref. [1]. The basic plasma parameters were: Ne gas at pressure p = 0.4-1 Torr, the current I = 3 mA, the electron temperature $T_e \approx$ 2-5 eV, plasma number density $n_i \sim n_e \sim 5\times10^9$ cm^{-3}. Basic purpose of these experiments was to study the properties of dust structures in a state close to gaseous one. The diffusion constant measurements were performed for small iron particles with the radius a = 1-3 μm, which formed quasi 3D cloud even in gravity conditions. The measured particle temperature was practically independent of neutral pressure, $T_p \approx 1$ eV. The interparticle distance was slightly decreasing from $\Delta \approx 250$ μm at $p \approx$ 56 Pa to $\Delta \approx 190$ μm at $p \approx$ 128 Pa. The effective coupling parameters Γ^* retrieved from these measurements as a function of neutral pressure were obtained. The complex plasma was in a weakly coupled "gaseous" state in this case as Γ^* was in the range from ~10 to ~20.

We studied dynamics of small (a =1-2.5 μm) aluminum oxygen (Al_2O_3) particles in a single dust lay, which was formed above the ground electrode of rf- discharge (P = 10-40 Pa, the power W= 2-7 W, $T_e \approx$ 1-3 eV, n_i ~ 10^9 cm^{-3}) in argon. The effective coupling parameters were also estimated. Nevertheless the application of our three-dimensional simulation for analysis of effective characteristics can be not valid in this case.

Abstract

Carbon dioxide is a waste gas which disturbs the atmospheric thermal equilibrium of our planet. Therefore techniques for reducing the industries Carbon dioxide emission plays an increasing role worldwide.

A special technique was developed to activate the Carbon dioxide. Due to low reactivity of the Carbon atom depending on the oxidation number of +IV thermal activation methods are not expected to work efficiently. A microwave plasma (up to 6kW) at atmospheric pressure allows the efficient activation of Carbon dioxide continuously up to flow rates of 10 m³/hr.

Optical emission spectroscopy is used to investigate the aggregation of Carbon atoms to specimen containing up to four Carbon atoms. An Imaging Spectrometer based on Acousto Optical Tuneable Filter technology is used to visualize the spatial distribution of excited particles inside of the plasma source. Especially the Oxygen emission at 777.3 nm and the C_2-band head at 516.5 nm were investigated varying the gas flow and discharge power.

Introduction

Causing the green house effect Carbon dioxide becomes a really interesting raw material for chemical synthesis. Carbon dioxide is a molecule with low reactivity [1]. Therefore plasma activation is good chance to prepare the CO_2 molecule for following chemical and plasma chemical reactions.

The observation of CO_2 activation was carried out by **o**ptical **e**mission **s**pectroscopy (OES). First experiments were performed with an AOS 4 (**a**cousto**o**ptic **s**pectrometer) [2] produced by IfU GmbH, Germany. The most important emission structures of activation process were determined. In second step the spatial distribution of excited particles inside of the plasma was recorded by imaging spectroscopy based on AOTF-technique (**a**cousto**o**ptic **t**unable **f**ilter) [3] to visualise the efficiency of activation in plasma volume [4].

The experiments were carried out at the University of Dortmund, Germany, in a special developed plasma synthesis reactor. The plasma activation was supplied by micro wave and could be performed at a pressure ranging from some mbar up to somewhat more than atmospheric pressure. It was possible to handle flow rates up to 10m^3/h.

Experimental

Plasma Synthesis Reactor

The plasma synthesis reactor is divided into three main parts (fig.1): the plasma source, the reaction tube and the reactor head. By using the CYRANNUS® I plasma source from Iplas GmbH, Germany, it is possible to activate carbon dioxide continuously up to flow rates of 10 m³/h and a microwave power up to 6 kW. The maximum flow rate of the plasma source in inefficient mode is 200 m^3/h. Causing the high flow rates the CO_2 activation inside of the plasma source has to perform at atmospheric pressure [5].

The gas supply of the reactor can handle five different gases simultaneously. Besides Carbon Dioxide during all experiments also Argon, Methane, Hydrogen, Ethene, Nitrogen, and Butadiene were used as reaction partners to enforce chemical conversions in the reaction tube. The gas inlets could be switched between three positions: before the plasma source (complete activation of reaction partners), directly after the plasma source (partial activation and additional cooling) or in reaction tube (partial activation and first reaction partner contact near the catalysators). In reaction tube there is a possibility to place some catalysators. Causing the high temperatures only pure metals are useful established.

Inside of the reactor head a cooling system and the outlet for gas chromatic analysis is realised.

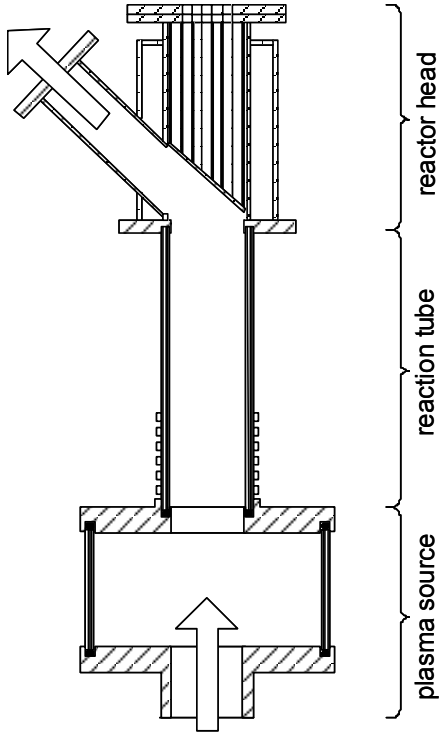

figure 1: plasma synthesis reactor

The measurement of plasma emission was possible at the plasma source and at the beginning of the reaction tube. All here represented spectroscopic measurements were performed only at the plasma source. For better realisation of imaging spectroscopy the ring of plasma source was modified with parallel arranged holes (fig.2). The emitting light is forming parallel light beams between plasma source and imaging spectrometer.

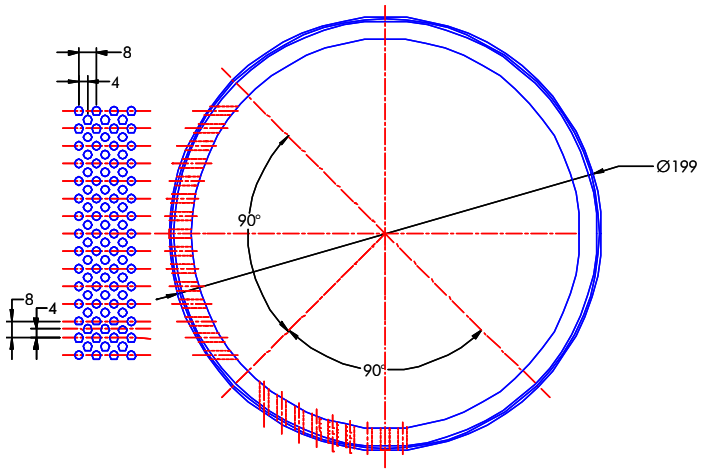

figure 2: preparation of plasma source ring for imaging spectroscopic diagnostics

Acoustooptic Imaging Spectroscopy

Through exploitation of the two-dimensional aperture of the AO spectrometer, it becomes to prosecute possibly imaging spectroscopy. Similar applications are already known for the NIR and IR range. The use in UV/VIS range demands special requests to all components of the AO spectrometer, e.g. the radio frequency driver, the AO crystal and the belonging optical components. To use a quartz crystal in UV/VIS range a particular adaptation is necessary [3].

The resonance condition for the diffraction of the light wave depends strongly on the angles of the propagation direction of the light wave and the propagation direction of the ultrasound wave as well as the crystal orientation [2]. The incoming linear polarised light beam is diffracted into two partial beams: **n**ot tuned **o**rdinary (NO – same polarisation, broad band light) and **t**uned **o**rdinary (TO – vertical rotated polarisation, narrow band light at resonance wavelength). In case of divergent light complies the resonance condition at different places in the crystal with same ultrasound frequency for different wavelengths. The reproduction of a single wavelength image can take place only deficiently. Therefore, divergence and dispersion of the ray of light must be as small as possible in the entire spectral range. This demands high requests at all optical components. In and out coupling objectives are achromatically (non disperse) and from high quality. An accurate mapping of approximately 150x300 pixels can be guaranteed with in the spectral range from 400 nm till 800 nm. The transmission wavelength bandwidth has excellent 0.5nm in the near infrared at 800nm, and 0.15nm in the near UV at 400nm, respectively. The millisecond random wavelength access of the AO spectrometer system is seen as an essential benefit against commonly used interference filter technology. The sampling time for a single wavelength image is 120 milliseconds

As first result the measurements at continuous light emitters appear that the contrast (TO - to NO beam) which is precipitated of the final polariser is not enough, in order to extract the wavelength separated picture. The intensity of the TO beam consists of one small spectral range only, $T(\lambda)\approx 0$, besides $T(\lambda-\Delta\lambda<\lambda<\lambda+\Delta\lambda)>0$, and that of the NO beam of the entire spectral range:

$$\int i(\lambda)d\lambda = \int T(\lambda)i(\lambda)d\lambda + \int [1-T(\lambda)]i(\lambda)d\lambda$$

$$I_{ges} = I_{TO} + I_{NO}$$

The pictures of both partial beams are overlapping, because the integral intensity is approximately equal at continuous light sources. In the present arrangement (fig.3), the TO beam possesses an diffraction angle of approximately 2° to the NO beam. Therefore, an optical diaphragm system is brought in here to suppress the disturbing NO beam additionally.

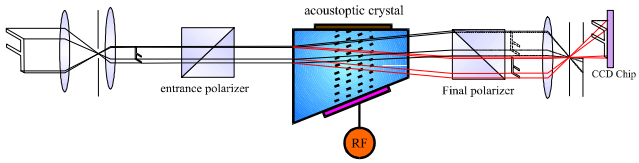

figure 3: optical arrangement of imaging spectrometer

Results

Optical Emission Spectroscopy

At atmospheric pressure there were found following specimen in emission spectrum (fig.4): C, C_2, C_3, C_4, O, H, OH and CH [6,7].

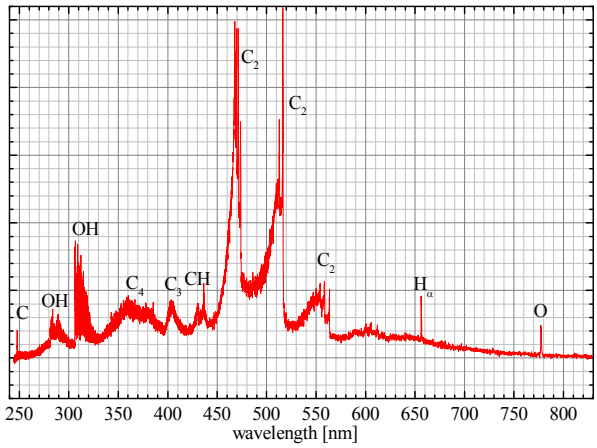

figure 4: typical emission spectrum of CO_2 activation at atmospheric pressure adding Hydrogen containing raw materials

A chance to get valuable products is the addition of natural gas to carbon dioxide to produce synthesis gas which is a gas mixture of hydrogen and Carbon Monoxide:

$$CH_4 \Leftrightarrow C + 2H_2 \qquad +84\ kJ/mole$$

$$CO_2 \Leftrightarrow C + O_2 \qquad +406\ kJ/mole$$

$$2C + O_2 \Leftrightarrow 2CO \qquad -246\ kJ/mole$$

$$CH_4 + CO_2 \Leftrightarrow 2CO + 2H_2 \qquad +244\ kJ/mol$$

In this reaction system the formation of soot and water can also be observed. These side products decrease the conversion rates and the yield of synthesis gas strongly and are strongly to be avoided. In case of oversupplying Hydrogen this effect is increasing and it is visible in emission spectrum by increase of the OH bands in UV at 280 nm to 330 nm. To produce

stoichiometric synthesis gas the hydrogen content should be reduced. In this case the disturbing OH bands are missing (fig. 5).

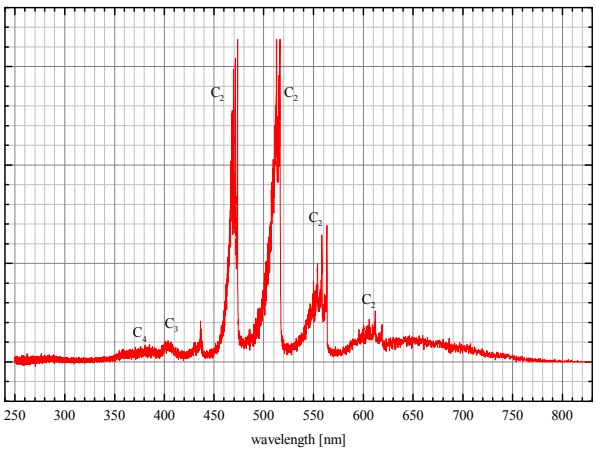

figure 5: typical spectrum of synthesis gas production at atmospheric pressure

Imaging Spectroscopy

During the experiments with natural gas ($Ar/CO_2/CH_4$-mixture) the emissions of Oxygen (777.3 nm), C_2 (516.5 nm) and the H_α-line (656.2nm) were investigated. The plasma volume was observed through the hole mask in plasma source ring (fig.6).

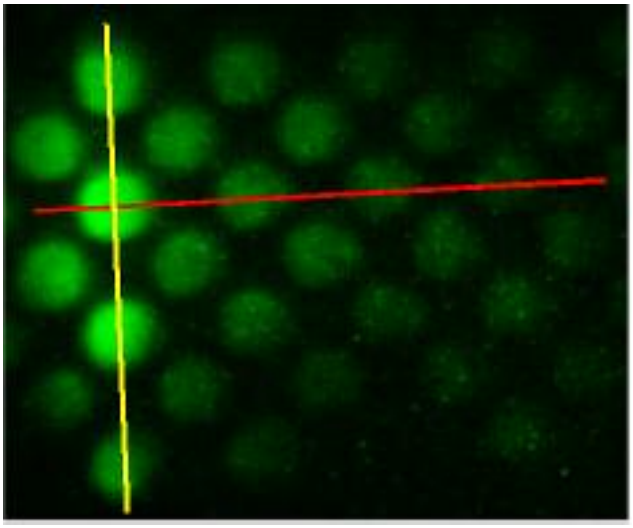

figure 6: spatial distribution of the C_2 band head emission at 516.4nm through the hole mask of the plasma source

The mathematical interpretation of following results was done in radial direction (redline in fig. 6) and in main stream direction (yellow line in fig.6). Firstly a three dimensional visualization with mathematical diameter correction was enforced.

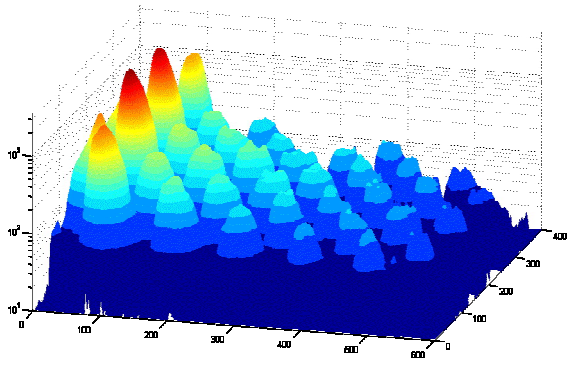

figure 7: intensity distribution of the O-Triplets during the Methan experiments

The radial specimen distribution shows an essentially smaller inhomogeneity, as which of the gone ahead pure CO_2 activation experiments (fig.8). This circumstance improves the efficiency of the entire system so.

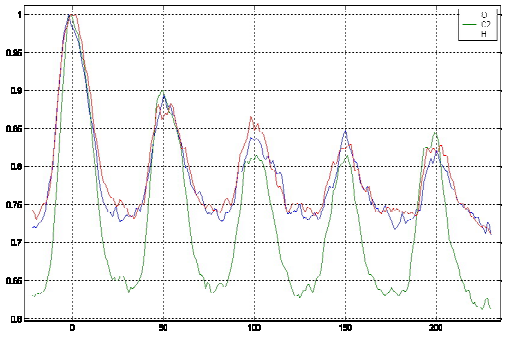

figure 8: radial distribution of exited specimen

The behaviour of Hydrogen and Oxygen in main stream direction is quiet similar. This results from the fact that both atoms can decompose relatively easy. (binding energy: C-H: 3.5EV; OC-O: 5.5eV). Atomic carbon is set free in both cases (CH_4, CO_2), only in a second step and isn't available immediately for the recombination to C_2. Therefore the emission of the C_2 start more slowly than the emission of H and O at the source entrance (fig.9).

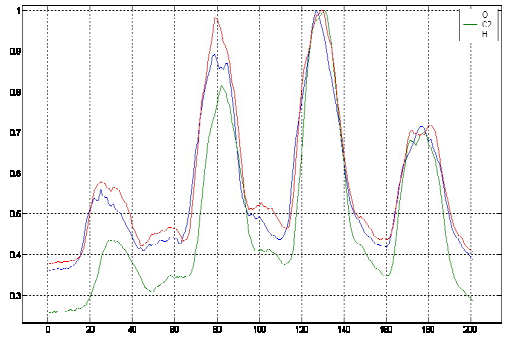

figure 9: distribution in main stream direction of exited specimen

Clear postponements of the maximum C_2 Excitation appears through variation of the gas composition. With low argon content, one finds circumstances the pure CO_2 activation similarly. An increase of the argon content leads to one noticeable shift of the stimulation-maximum to the stream exit and can be used with it as optimisation value (fig.10).

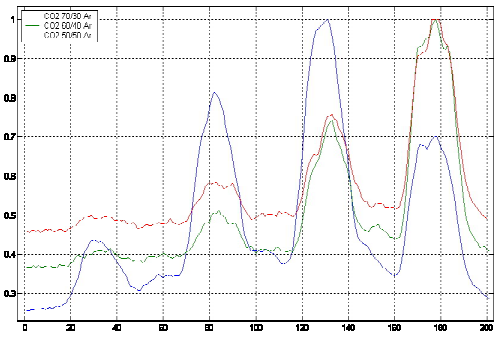

figure 10: distribution of C_2-emissions in main stream direction at different streaming conditions

The argon content a drastic influence to the radial distribution of the C_2 emission. An inferior Ar content leads here to better homogeneity (fig.11). These are best conditions for an upscaling to an industrial application without any Argon.

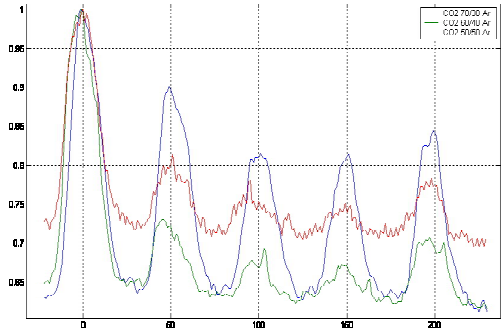

figure 11: radial distribution of C_2-emissions at different streaming conditions

Conclusion

The presented plasma activation of Carbon Dioxide adding Methane is able to produce synthesis gas, a 1:1 mixture of CO and H_2. The developed plasma synthesis reactor can handle up to 10 m^3/h gas flow.

Acoustooptic imaging spectroscopy is a useful method to investigate large area or volume plasma phenomena. The simultaneous capture of whole images at a single wavelength and the fast access to another wavelength allows a fast sampling of time and spatial resolved distributions of excited specimen in plasma volume.

In present work it was shown that CO_2 plasma activation for chemical synthesis can be optimised by imaging emission spectroscopy.

Control of energy input at ignition of fuel-air mixtures by nanosecond discharge

S.A.Bozhenkov, E.I.Mintoussov, S.M.Starikovskaia, S.V.Pancheshnyi, A.Yu.Starikovskii

Physics of Nonequilibrium Systems Laboratory, Moscow Institute of Physics and Technology, Dolgoprudny Moscow Region, Russia

Abstract

The present work is devoted to the details of the energy input control in nanosecond discharge. The discharge is used for the ignition of hydrogen-air and methane-air mixtures in a temperature range of 800-2200 K. Gas mixture is heated by the shock wave. We represent results of the energy input measurements in the fast ionisation wave at different gas temperatures. Possibilities to decrease significantly the temperature threshold of the ignition using gas discharge are analysed.

1. Introduction

Process of combustion is described from the point of view of chemical kinetics as a chain mechanism. Chain propagation in a condition of high temperatures takes place at a high velocity. The slowest stage is the initiation of a chain which is often combined with increased activation energy. For this reason, the reaction rate is in fact higher with artificial chain initiation [1]. For example, for hydrogen-oxygen combustion at a pressure of 1 atm and temperature of 750 K reaction rate for the process $O_2+M=O+O+M$ is about of 10^{-40} cm^3/s, which is extremely low value. Reaction of the dissociation have an extremely high activation energy (59380 K for the mentioned reaction [2]), so, they become efficient at higher temperatures. In a region of low temperatures gas discharge low temperature nonequilibrium plasma can be used as an efficient source of the radicals for the chain reaction initiation.

In this paper, the homogeneous ignition method is discussed, which is fast in comparison with the characteristic times of combustion processes and gas dynamics. The method is based on the use of a nanosecond high-voltage discharge in the form of a fast ionization wave (FIW) producing atoms, radicals, and excited molecules. The fast ionization wave originates at very high – hundreds of percent – overvoltage on the electrode system, that is the case where the voltage, at the moment of the discharge initiation, significantly exceeds the threshold of the initiation of a stationary glow discharge. From the point of view of the experiment, this means a high rate of voltage rise: 1 kV/ns and higher. A typical pulse amplitude is tens - hundreds of kV and a duration is 10-100 ns. The most distinctive features of this type of discharge are the high propagation velocity (10^9-10^{10} cm/s), the good reproducibility of the discharge parameters, and the spatial homogeneity over a large gas volume. The fact that electric fields behind the discharge front are high enough and may be used for the gas dissociation is also of a great importance. These properties may be interesting for different applications, such as hypersonic combustion or the ignition of lean mixtures. A review of our papers concerning the kinetic approach to this discharge is given in [3].

2. Experiment

The apparatus used to investigate the fast homogeneous ignition of combustible mixtures (Figure1) consists of a shock tube (ShT), discharge cell (DC) connected to the shock tube, the gas evacuation and supply system, the system of discharge initiation, and the diagnostic system.

The shock tube is made of stainless steel and has a square cross section of 25x25 mm with a 1.6 m working channel length. The high pressure cell (HPC) length is 60 cm. There are 2 pairs of diagnostic optical windows along the stainless steel working channel. The windows were aligned with respect to inner shock tube walls and walls were polished to decrease disturbances of flow. The last section of the shock tube is made from a transparent dielectric material. We used two different sections in our experiments. The first one is made from a 10 mm thick quartz plates surrounded by an organic glass 20 mm in thickness and has twelve quartz optical windows for an emission output. The second one is made from an organic glass and has eight optical windows (6 of them are made from quartz and 2 are made from MgF_2). Both sections have 25x25 mm the inner square cross-section and are 20 cm in length. The results were the same for both sections, therefore we shall not specify which of sections was used. The uniform nanosecond discharge in the form of the fast ionization wave was organized in the dielectric section; the end plate (EP) of the shock tube is a high-voltage

electrode of the discharge system; the electric circuit is closed via grounded stainless steel driven section of the shock tube.

The nanosecond discharge initiation was synchronized with the reflected shock wave coming to the observation point (point A in the figure) by means of a microsecond pulse generator (PG). To obtain high-voltage pulse we used Marks-type generator. The GIN-9 high voltage Marks generator (HVG) consists of 10~stages. To provide the spark gap operation, the pulsed voltage generator is filled with nitrogen at a pressure of 3 atm, which provides a starting voltage range from 100 to 160 kV. To sharpen the voltage impulse coming from the generator to the discharge gap, a forming ferrite line of wave resistance Z=40 Ohm is used. At the forming line output, the voltage rise rate is 8 kV/ns, which provides the formation of gas discharge in the form of a fast ionization wave in the dielectric section of the shock tube.

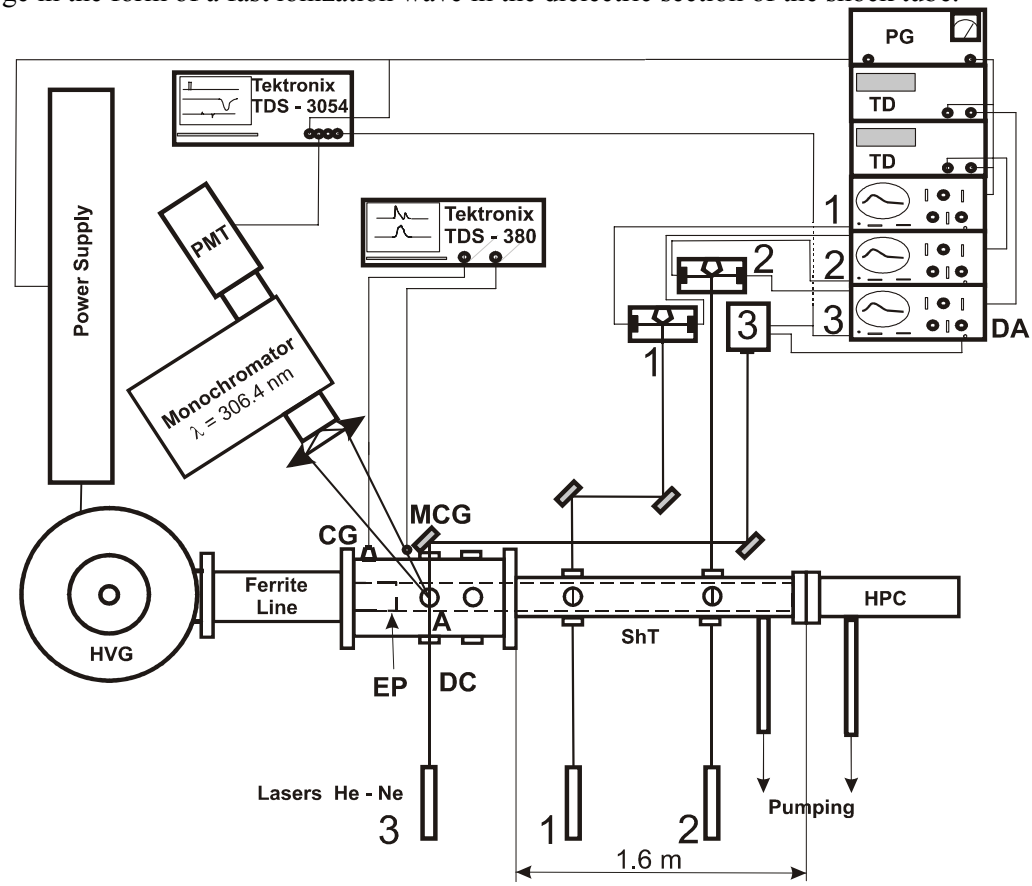

Figure 1. Experimental setup

To evacuate the system, rotary and diffusive pumps were used. Having been pumped the system was filled with investigated gas mixture. We used gas mixtures of methane or hydrogen with air or oxygen diluted with Ar or He in order to reach the desired pressure and temperature behind the reflected shock. The initial pressure in the driven section was varied from 5 to 40 Torr. Dilution by Ar or He increased the specific heat ratio, and allowed higher temperatures to be reached behind the reflected shock wave. He, dry air, or CO_2 were used as driver gases. In some experiments special perforated flow plate was inserted between high pressure section and driven section before the diaphragm. This plate allowed us to decrease the shock wave velocity at the same initial conditions.

Diagnostic system consists of three parts. They are the system monitoring shock wave parameters, the system monitoring the nanosecond discharge electrical parameters and the system registering ignition. The system monitoring the shock wave parameters includes the system measuring the incident and reflected shock wave velocity by the laser schlieren technique and the system controlling the initial pressure. The schlieren system consists of 3 He-Ne lasers mounted along the shock tube at different points and 3 pairs of photodiodes with differential analysers (DA); the time delays between points 2-1 and 1-3 along the tube were registered by time-delay analyzers (TD) and monitored by the Tektronix TDS3054 oscilloscope. From the initial gas mixture composition, the initial pressure and velocity of the incident shock wave, we determined the pressure, gas density and temperature behind the reflected shock wave by solving the conservation laws, assuming a full relaxation and no chemical reactions. Thermodynamic data were taken from [4].

The system monitoring the nanosecond discharge electrical parameters includes a calibrated magnetic current gauge (MCG) to control current pulse and a capacitance gauge (CG) over the high-voltage electrode to monitor the high-voltage pulse shape and amplitude. We placed an additional capacitive gauge near the observation point (12 cm apart from the CG) to measure the velocity of the discharge development. The signals from electrical gauges were monitored by using a Tektronix TDS~380 oscilloscope. All cables were additionally screened and oscilloscopes were placed into the shielded room to diminish high-frequency electrical noise.

The combustion process was investigated by using emission spectroscopy. Emission originating due to the combustion process was monitored in the direction perpendicular to the shock tube axis at a distance of 55 mm from the end plate (point A) with the use of a MDR-23 monochromator (1.2 nm/mm, 1.2 m focal length, 1200 1/mm, LOMO), a FEU-100 photomultiplier (MELZ), and a Tektronix TDS3054 oscilloscope. The observation point is rather far from the end plate. To decrease influence of boundary layers it is more usual for kinetic measurements to be made in the vicinity of end plate. However we had to choose position of the observation point in such way to avoid electric field disturbances caused by high voltage electrode. We measured the OH emission (306.4 nm) in a wide range of experimental conditions: mixtures of various compositions, temperature variations from 750 to 2250 K, pressure variations from 0.3 to 2.3 atm. The same experiments were repeated under a discharge action, at high-voltage pulse amplitude variations from 100 to 160 kV on the electrode and a pulse duration of about 30-40 ns at a half-height of an amplitude (FWHM). For all the cases, the ignition delay time τ_{ign} was determined as a time delay between the last physical action (that is, the reflected shock wave signal in a case of autoignition or the discharge initiation when the nanosecond discharge being used) and the start of OH emission. The ignition delay decreases under the action of the FIW. The operating time of our shock tube was about of t_{max} = 400-500 μs. In the figures we have represented all obtained points, even those for which ignition delay time $\tau_{ign}>t_{max}$, to give reference points for the comparison with the ignition by the nanosecond discharge.

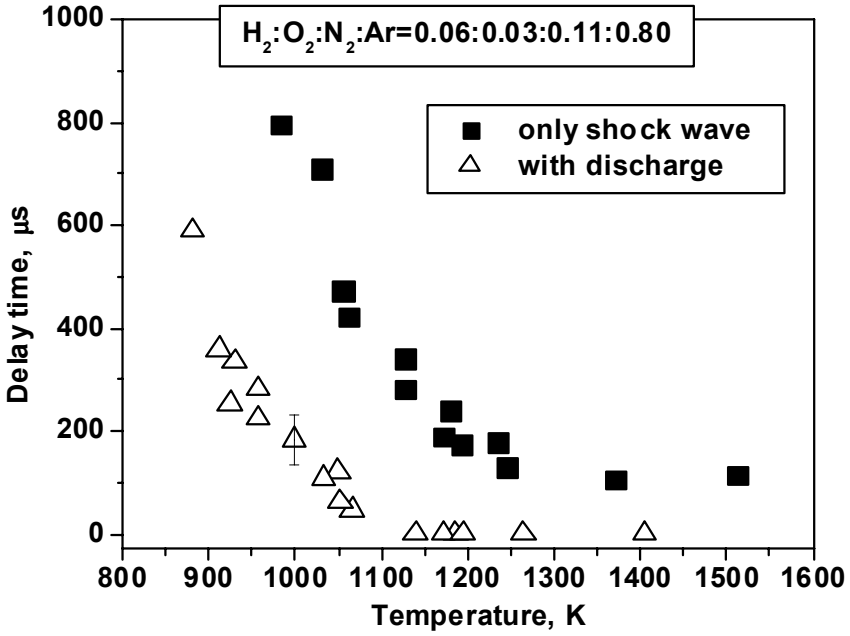

Figure 2. Ignition time delay *vs* temperature for hydrogen-air stoichiometric mixture diluted with Ar

It is very important to analyse the power input into plasma during the discharge. To do that we developed special technique based on the measurements of voltage signal in two adjacent points along the discharge cell together with the current signal. All signal are registered synchronously with the time resolution of 2 ns. To obtain the total energy input, the integration by time takes place.

3. Results of the experiment. Ignition delay.

We determined the dependence of ignition delay upon the temperature at fixed voltage U=160 kV. The measured time delays of the ignition of the H_2-air-Ar mixture are shown in Figure 2. The decrease in time delay for ignition under the action of plasma and the decrease of the temperature threshold (minimum temperature where the ignition is possible) are clearly seen. For example, at T=1000 K, the energy input in

the discharge decreases the ignition delay time by a factor of 4.8, from 860 to 140 μs. It should be noted that in this figure and in the next figures devoted to the experimentally measured ignition delay, zero delay time means some conventional value. We were not able to measure delay time less than 2 μs, which actually gives the typical duration of the electrical noise from the discharge. The numerical analysis of the ignition delay time and comparison with the experiment is described in [5].

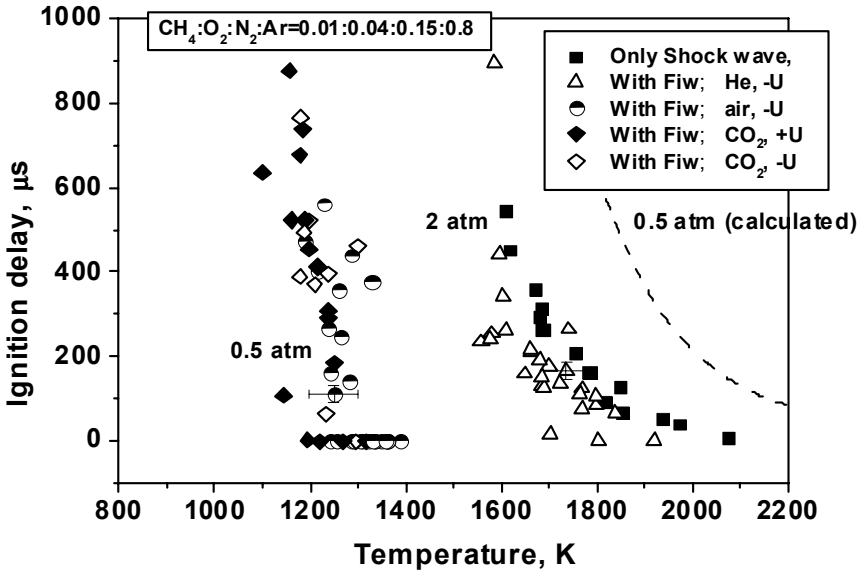

Figure 3. Ignition time delay *vs* temperature for methane-air stoichiometric mixture diluted with Ar

We observed the same tendency for ignition delay for methane-air mixture (Figure 3). He, air or CO_2 were used as high pressure chamber gases, and this is indicated in the Figure. The ignition delay time changes dramatically under the action of the discharge. We were able to provide the ignition of highly diluted methane-air mixture at a pressure of 0.3-0.5 atm and a temperature of 1100-1200 K. The dashed line on the right represents calculated autoignition delay time for the initial pressure of 0.5 atm, it was impossible to get these parameters in our experiments.

3. Results of the experiment. Energy input.

From the Figure 3 it is clear that for the initial pressure of 2 atm and initial temperature within the range of 1600-1900 K the shift in the ignition delay is relatively low. At the same time experiments at a pressure of 0.5 atm demonstrate significant (about of 700 K) shift in the ignition threshold.

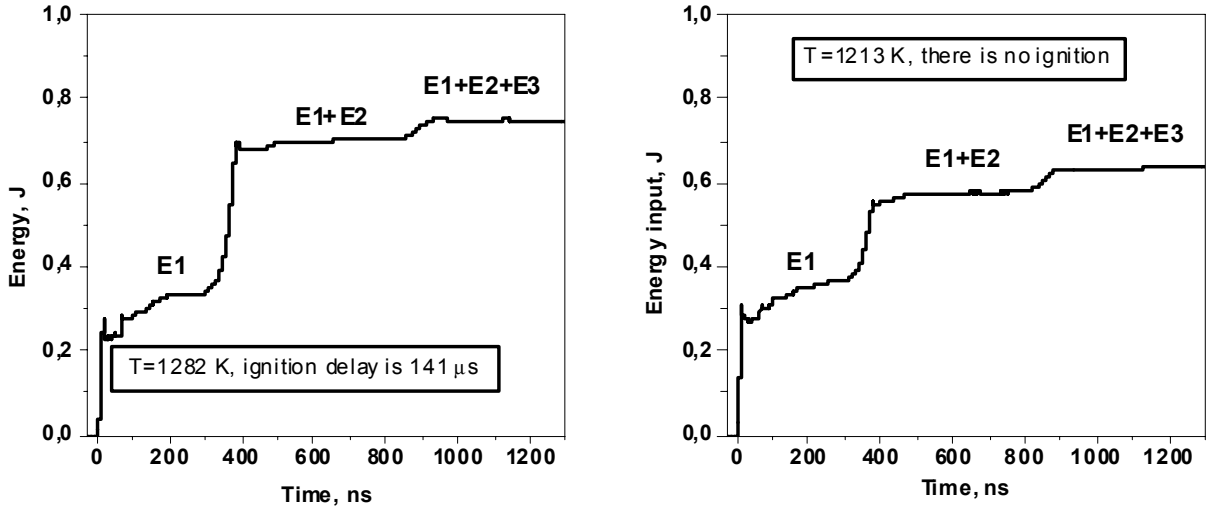

Figure 4. Typical energy input into plasma of the discharge *vs* time

To understand the reason we analysed the energy input into the plasma under the action of a nanosecond high-voltage discharge. All experiments were performed for the mixture mentioned in the Figure 3. Typical energy input in the experiment *vs* time is represented in the Figure 4. We obtained one or two pulses reflecting form the high-voltage generator and coming back to the discharge cell, so, the total energy input consisted of three separated in time portions: the first one, marked as E1 in the Figure, and one or two from reflected pulses, E2 and E3 respectively. It is interesting that the energy input in experiments with ignition is practically the same as in the experiments without ignition.

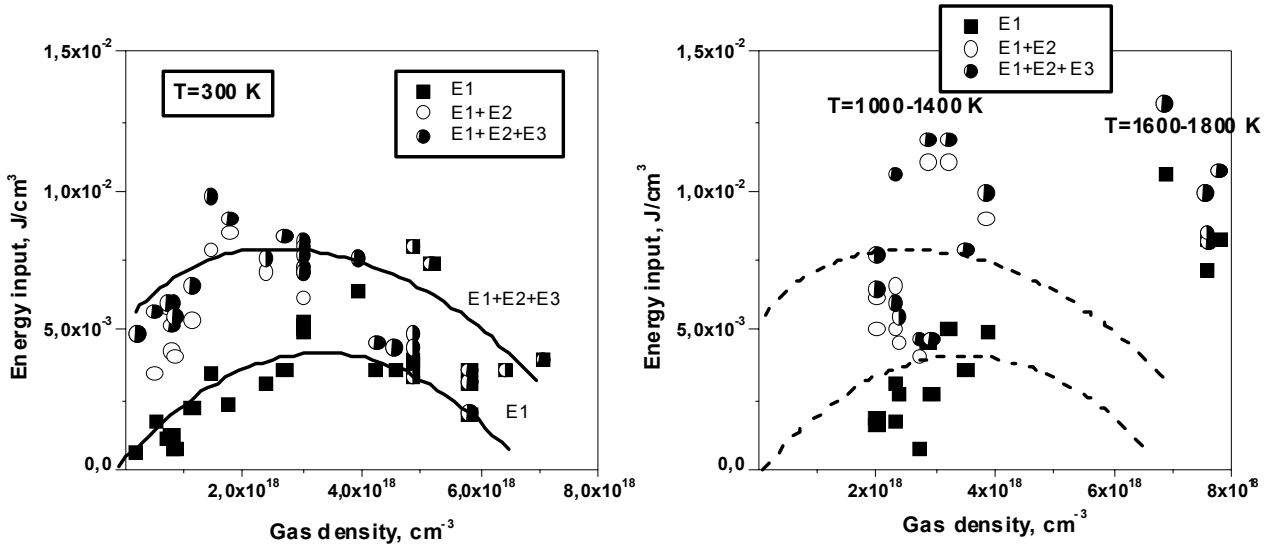

Figure 5. The energy input *vs* gas density. Comparison of the energy input at ambient and high temperature

We compared the energy input at ambient temperature and at combustion temperatures in the same methane-air mixture diluted with argon. The results are represented in the Figure 5, "cold" experiments in the left graph, and high temperature experiments in the right one. As for the "cold" experiments, the behavior of the energy input dependence upon the gas density is qualitatively the same is in well-known experiments on the energy input in repetitive high-voltage nanosecond discharge (see, for example, [6]). From these experiments it is known that the nanosecond discharge propagates uniformly in space within the region of this cupola-shape dependence. With the density increase discharge loses its uniformity and transforms to a streamer corona.

At the high temperatures we obtain practically the same values of the energy input at given gas density. The only difference is the strong data scattering for the E2 and E3 (that is for the energy input in reflected pulses).

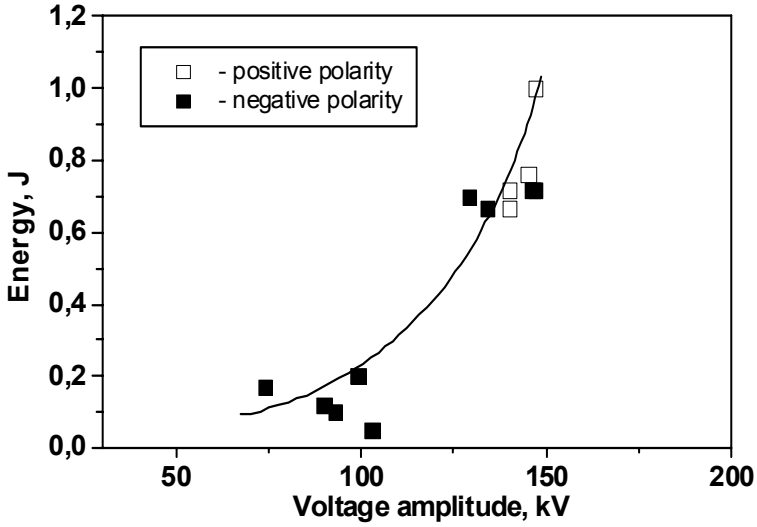

Figure 6. The energy input *vs* voltage amplitude on the high-voltage electrode

We used different voltage amplitudes of the high-voltage pulse to initiate the discharge, and total energy input upon the voltage peak value on the high-voltage electrode is represented in the Figure 6. The gas parameters are the following: gas number density is (2-3)x10^{18} cm^{-3}, temperature is 1000-1400 K. In spite of the fact that we have difference of the order of magnitude between the energy input in the discharge all this experiments have not dramatic difference in the ignition delay time dependence upon pressure. To understand this fact we have to analyse the dynamics of voltage and current in the discharge cell to make a conclusion about electric field value and efficiency of radicals production.
In part, coming back to the Figure 5, it was possible to conclude from such an analysis, that at high pressure (and, consequently, at relatively high gas densities) we have not nanosecond uniform discharge. We have made the detailed analysis of results which correspond to the group of points T=1600-1800 K. Oscillograms of the current and voltage rather fit to those in the nanosecond pulsed corona. So, we concluded that, even higher initial energy input for the temperature range of 1600-1800 K does not lead to significant shift in ignition delay time because of too gas high densities for the uniform nanosecond discharge development at given experimental conditions. To decrease the ignition delay significantly under those experimental conditions it is necessary, for example, to increase the amplitude of the high voltage pulse.

5. Acknowledgements

This work was partially supported under grants No. 01-02-17785, 02-03-33376, and 02-02-99305 of the Russian Foundation for Basic Research; Projects No.1474 and No1440 of International Science and Technology Center; grant YSF 2001/1-138 of INTAS; and by Award No. MO-011-0 of the U.S. Civilian Research and Development Foundation (CRDF).

6. Conclusions

So, the experimental scheme for testing the ignition delay time under the successive action of a shock wave and a nanosecond discharge is described. The shift in the ignition time delay is obtained experimentally for hydrogen-air and methane-air stoichiometric mixtures diluted with Ar.
Energy input into a gas due to the action of nanosecond gas discharge is analysed for the ambient gas temperature and for the temperature range of 1000-1800 K for the methane-air-argon mixture. It was demonstrated that such an analysis provides additional tools to analyse and to optimise the ignition by pulsed nanosecond discharge.

Abstract

The purpose of this paper is to describe a relatively unused approach in plasma physics, but which allows to apprehend fluctuations and turbulence phenomena in electric arcs. The Burgers equation is considered as a simplified model of the Navier-Stokes equation to treat fluctuations of a velocity field plunged in a fluctuating field of strength. This point of view arises as an alternative method to numerical simulations.

1 Introduction

In 1939, J.M.Burgers introduced his famous equation (see [1]) which turned out to be an useful model in many fields of physics : growth of interfaces, driven diffusion, flame fronts or directed polymers [2, 3] ...

The first idea of this equation was to progress in the comprehension of turbulent flows. As we will see later, Burgers equation contains several similarities with the Navier-Stokes equation, and this will allow the description of a velocity field in time and space. This way of using the Burgers equation, relatively unused in comparison to fluid equations for numerical simulations, is the starting point of our approach. One of the reason leading to the present study is the rather small time necessary to obtain results in comparison to the time of computation. Among the most comprehensive codes treating electric arcs, we can underline the ESTET 3.4 CFD code developed by Delalondre & al.[4, 5]. Some important results have been found from this numerical computations of about 100 hours of CRAY computer corresponding to 0.01 second of real time. This comes from the fact that, in magnetohydrodynamic model (MHD), many Partial Derivative Equations (PDE) have to be taken into account, and this is in this context that arises our approach, which should allow to simplify calculations while treating fluctuation problems.

The paper is built as follow : in the next section, generalities about the Burgers equation are presented. The treatment of fluctuation problems is described in the third section. Then a conclusion will resume the mains ideas and will give a survey to the continuation of this work.

2 The Burgers equation

The initial value problem of the Burgers equation for the velocity field u is presented in the following form :

$$\left| \begin{array}{l} \partial_t \mathbf{u} + (\mathbf{u}.\nabla)\mathbf{u} - \nu\ \nabla^2\mathbf{u} = \mathbf{f}(\mathbf{r},t) \\ \mathbf{u}(\mathbf{r},0) = \varphi(\mathbf{r}) \end{array} \right. \tag{1}$$

with an evolution term $\partial_t u$, an advective term $(u.\nabla)u$, a diffusive term $\nu\ \nabla^2 u$, $\mathbf{f}(\mathbf{r},t)$ a the term of forces, and where ν stands for the viscosity.

So we use this equation as a simplified model of Navier-Stokes equation, where the term of force represents all forces which are linkable to fluctuations : it can be as well a pressure gradient than exterior force or Maxwell term (Laplace force). This is a non linear diffusion equation, where no-linearitie can be evaluate, as for Navier-Stokes equation, by the way of the Reynolds number Re, which is proportional to $1/\nu$. However, on the contrary to shock models, the diffusive term does not have to be neglected, because turbulence does not appear only in the inviscid limit $\nu \to 0$. So we have an equation which is closely related to Navier-Stokes equations.

We use now the well known Hopf-Cole transformation (HC) [6] from which the Burgers equation may be transformed into a linear PDE :

$$\mathbf{u}(\mathbf{r},t) = -2\nu \frac{1}{\psi(\mathbf{r},t)} \nabla\psi(\mathbf{r},t). \tag{2}$$

This leads to the heat equation with a source term, which is easier to handle than the Burgers equation.

3 Analytic resolution of a fluctuation problem

We present here the analytical resolution of the Burgers equation for two different terms of force. First we examine the case of a constant force as a random variable, where we show that we obtain the result in term of Airy functions. Then the case of a time dependent force is studied, by the way of two equivalent methods. We restrict the solution to this problem to one dimension.

3.1 Constant force

Let us consider the following Burgers equation with a constant force

$$\left| \begin{array}{l} \partial_t u + u\partial_x u - \nu\ \partial_{xx} u = f \\ u(x,0) = \varphi(x) \end{array} \right. \tag{3}$$

where f is a random variable which represents for example the effect of the electric field. It means that for one realisation of f we have one solution u_f obeying the previous equation.

At all events, the HC transformation leads to the heat equation with a linear source term proportional to x :

$$\partial_t \psi(x,t) = \nu\ \partial_{xx}\psi(x,t) - \frac{fx}{2\nu}\psi(x,t). \tag{4}$$

This equation being linear with respect to ψ, it can be solved by a variable separation method such as $\psi(x,t) = \Phi(t)\theta(x)$. From this, the analytic expression of the velocity field $u(x,t)$ can be obtained. We first have :

$$\frac{\dot{\Phi}(t)}{\Phi(t)} = \nu \frac{\theta''(x)}{\theta(x)} - \frac{fx}{2\nu}; \tag{5}$$

where the dot indicates the derivative with respect to t, and the prime $'$ the derivative with respect to x. Then, for the time variable we find $\Phi(t) = e^{rt}$ and for the space variable, we recognize the Airy differential equation :

$$\theta'' - \frac{f}{2\nu^2}\left(x + \frac{2\nu r}{f}\right)\theta = 0. \tag{6}$$

The solution is found by putting $X = \left(\frac{f}{2\nu^2}\right)^{1/3}(x + \frac{2\nu r}{f})$,

$$\theta(X) = a_1 Ai(X) + a_2 Bi(X). \tag{7}$$

But $Bi(X) \to \infty$ as $X \to \infty$, then we would have $u \to \infty$, so we get $a_2 = 0$. Thus the solution of (4) now reads

$$\psi_f(x,t) = a_1 e^{rt} Ai\left[\left(\frac{f}{2\nu^2}\right)^{1/3}\left(x + \frac{2\nu r}{f}\right)\right]. \tag{8}$$

However, this solution leads to a stationary solution for the velocity field u, but we can avoid this situation by developing $\psi_f(x,t)$ on the Airy functions basis [7], with the conditions :

$$\psi(0,t) = 0 \quad \text{and} \quad \lim_{x\to+\infty} \psi(x,t) = 0\ .$$

Then we choose r such as $\left(\frac{f}{2\nu^2}\right)^{1/3}\frac{2\nu r}{f}$, is a zero of the Airy function. Noting Ω the countable set of values taken by r, we obtain successively :

$$\psi_f = \sum_{\Omega} \Phi_r(t)\theta_{r,f}(x) = \sum_{\Omega} a_r e^{rt} Ai[X_{r,f}] \; ; \tag{9}$$

and :

$$u_f = -2\nu \frac{\sum_{\Omega} a_r \left(\partial_x X_{r,f}\right) e^{rt} Ai'[X_{r,f}]}{\sum_{\Omega} a_r e^{rt} Ai[X_{r,f}]} \; . \tag{10}$$

Then, since $u_f(x,t)$ is the fluctuating quantity, we are able to compute mean quantities as :

$$\begin{array}{l} \langle u(x,t)\rangle_f \\ \langle u(x,t)u(x',t')\rangle_f, \; \ldots \\ \langle \partial_x u(x,t)\rangle_f \end{array} \tag{11}$$

These quantities appear in particular in the $k-\epsilon$ model, via the diffusion turbulent term, the viscous dissipation term,... This resolution is treatable in three dimensions.

3.2 Time-dependent force

Fluctuations may arise also under the action of a random force, such as Langevin force, and taking the form of a time-dependent function in the Burgers equation :

$$\left| \begin{array}{l} \partial_t u + u\partial_x u - \nu \, \partial_{xx} u = f(t) \\ u(x,0) = \varphi(x) \end{array} \right. \tag{12}$$

An interesting theorerical result resides in the possibility of solving analytically this equation by two different methods.

Time Space Transformation method : The Time Space Transformation method (TST) have been used to solve the Schrödinger equation with a linear potential [8]. Now, the HC transformation applied to (12) leads to :

$$\partial_t \psi = \nu \, \partial_{xx}\psi - \frac{1}{2\nu}\big[x f(t) + c(t)\big]\psi, \tag{13}$$

which is nothing but a Schrödinger equation with an imaginary time, and with a linear potential. Then, the TST method for (13) is composed by a transformation of the form

$$\psi(x,t) = \Phi(y,t) e^{x \int f(t)\mathrm{d}t}, \tag{14}$$

followed by the shifting of variables

$$\mathrm{TST} \left| \begin{array}{l} y = x + \iint f(t)\mathrm{d}t \\ t' = t \end{array} \right. \tag{15}$$

Just notice that in the case of a Langevin force, the term $\int f(t)\mathrm{d}t$ has to be taken either from the Itô point of view, or from the Stratonovich's one.[10]

From these transformations, we arrive to a well known heat equation :

$$\partial_{t'} \Phi(y,t') = \nu \, \partial_{yy} \Phi(y,t'). \tag{16}$$

Thus, from a given initial condition and inverting the latest transformations according to :

$$\Phi(y,t') \rightarrow \Phi(x,t) \rightarrow \psi(x,t) \rightarrow u(x,t), \tag{17}$$

we can express analytically the velocity field. We can also note that the solution is only defined when we have imposed an initial condition.

The Orlowsky-Sobczyk method (OS) This method [9] enable to proceed directly from an inhomogeneous Burgers equation with a force term $f(t)$, to an homogeneous Burgers equation. Then the Hopf-Cole transformation yields to the heat equation.

Let us start again with the equation :

$$\left| \begin{array}{l} \partial_t u + u\partial_x u - \nu\, \partial_{xx} u = f(t) \\ u(x,0) = \varphi(x) \end{array} \right. \tag{18}$$

The OS method will consist on to carry out the following shifting of variables :

$$\mathrm{OS} \left| \begin{array}{l} y = x - \iint f(t)\mathrm{d}t \\ t' = t \\ v(y,t') = u(x,t) - \int f(t)\mathrm{d}t \end{array} \right. \tag{19}$$

where $v(y,t')$ is the new velocity. These transformations lead to

$$\partial_{t'} v + v\partial_y v - \nu\, \partial_{yy} v = 0. \tag{20}$$

The expected equation is then obtained from the HC transformation. We arrive as for TST method to the heat equation

$$\partial_{t'} \Phi(y,t') = \nu\, \partial_{yy} \Phi(y,t'). \tag{21}$$

Giving us an initial condition, we go up to the analytic expression of the velocity field according this time to :

$$\Phi(y,t') \rightarrow v(y,t') \rightarrow v(x,t) \rightarrow u(x,t)\ . \tag{22}$$

The two latest methods (TST and OS) can be compiled by the following commutative diagram, where IBE means the Inhomogeneous Burgers Equation, HBE the Homogeneous Burgers Equation and $Heat - S$ the heat equation with a source term.

$$\begin{array}{ccc} IBE : f(t) & \xrightarrow{OS} & HBE \\ {\scriptstyle HC}\downarrow & & \downarrow{\scriptstyle HC} \\ Heat - S & \xrightarrow[TST]{} & Heat \end{array}$$

FIG. 1 – Commutative diagram showing the equivalence between the two methods.

4 Conclusion

We have shown that the analytical solution of Burgers equation allows the treatment of fluctuations. We started from the inhomogeneous Burgers equation presenting the same non-linearities as the Navier-Stokes equation. From this, two axes have been developed :

(i) From a mathematical point of view, we have seen the possibility to simplify the Burgers equation (into the heat equation with a source term) and solving it for particular values of the force. The complete solution depends narrowly on the form of this term. For a time dependent force $f(t)$, we have obtained the heat equation by two methods (Eq. (16) and (21)). These methods have been then gathered into a commutative diagram.

(ii) These results have led to the study of fluctuations, by mean of appropriate terms. Naturally, the resolution of the Burgers equation, by the nature itself of this equation, allows the study of fluctuations of a velocity field when the system is plunged into a fluctuating field of force.

An interesting work would consist now on studying the case of an elastic force in order to treat the trajectory of an arc column. The calculations are under way and should be achieved soon.

Abstract
In the present work detailed theoretical and experimental studies of the plasma-chemical reactor, which consists of two parts: 1) generator of active particles based on volume barrier discharges; 2) work chamber, are accomplished for widely used plasma generating medium – dry and wet air. It is shown that the essential amount of active molecules, such as O_3, H_2O_2, N_2O_5, HNO_3, HNO_2, NO_3, is possible in work chamber volume with concentrations depending on flow rate and water vapor percentage.

1. Introduction

In the last ten years nonthermal discharges at one atmosphere pressure find more and more applications in the technology. Particularly, possibilities of the use of corona and barrier discharges for efficient cleaning of industrial gases from nitrogen oxides NO_x and N_xO_y, sterilization of medical articles, in modification of surface features of polymer materials and chemical warfare agent decontamination were demonstrated. For solving the last three tasks the most optimal is the use of plasma-chemical reactor, which consists of two parts: 1) generator of active particles based on one or several discharges; 2) – work chamber with relatively big volume containing articles or materials to be processed. Such design enables elimination of the influence of processed articles on the discharge operation regime and, consequently, on the component content of active particles.

Purpose of the present work consists in theoretical and experimental investigation of the component content and concentration of active particles in work chamber of developed by us reactor of the type mentioned above at the use of ambient air with various humidity as working medium. Calculations were performed both for the discharge gap, where formation and decomposition of radicals and molecules occurred under action of electrons, and for the chamber, where only chemical reactions between the particles formed in the discharge took place.

2. Experimental setup and methods of measurements

Generation of active particles was performed in sixteen volume barrier discharges placed evenly on top wall of work chamber made of polymethylmethacrylate with 80 liters volume (430x430x430 mm). Internal chamber walls were covered by glass plates for diminishing losses of active particles. The active particles formed in the discharges came to the chamber, where articles to be processed were placed, and then left the chamber via the system of filters through the hole placed in a center of the chamber bottom plane. Air was supplied to the discharges via the system for moistening/desiccation, which enabled relative humidity (RH) variation in 20-90% range at temperature 20-22^{0}C. Volume rate of air purge could be adjusted in range 1-8 l/min (at that transient time of working medium in barrier discharge volume changed in range 5÷0.6 s, and linear velocity of particles at entrance to the chamber – in range 1.5÷12 cm/s). For performing optical measurements of the component content windows made of KU-1 quartz were placed at side walls of the chamber at distances of 65, 215 and 365 mm from top chamber wall. For powering the discharges high-voltage AC source with 15 kV maximum amplitude and 400 Hz frequency was used. Total active power introduced into the discharges comprised 120 W, and specific power value was 1.5 W/cm^3.

For researches of mixture component content in the chamber absorption spectroscopy method was implemented with the use of hardware-software complex based on monochromator MDR-23 (having 0.1 nm spectral resolution). Detection of light beams was performed by means of photomultiplier tube (PMT) FEU-100. For measuring digitized values of PMT electric signal specially developed hardware-software complex with 16-bit conversion and 11025 Hz sampling rate was used. NO_3 concentration was calculated

from measurements of absorption by this component at wavelengths $\lambda = 662$ nm and 623 nm. Component concentrations of O_3, NO_3, N_2O_5, HNO_3, HNO_2, H_2O_2, HO_2NO_2 were calculated from measurements of total absorption curve in wavelength range 200-300 nm. For that purpose values of component densities were chosen by means of automatic curve fitting software, so that resulting absorption curve would coincide with measured one. Use of such method was possible due to fact that characters of spectrum dependencies of absorption cross sections for studied components in wavelength range 200-300 nm are essentially different. For validation the method, O_3 concentration values obtained by procedure described above were compared with results on O_3 concentration measurements by its absorption at 296.5 nm wavelength, when it was possible to neglect absorption contributed by the other components. O_3 concentration values obtained by two those methods coincided with precision of concentration measurement (that is, scatter values for different measurements). Precision of the measurements was not worse than 5% for ozone, and 10-15% for the other components. Absorption cross sections for O_3, NO_3, N_2O_5, HNO_3, HNO_2, HO_2NO_2, H_2O_2 were taken from references given in [1].

3. Methods of numeric modeling the plasma component content in barrier discharge and work chamber

As it was already noted in the introduction, the most optimal plasma-chemical reactor for many technological tasks is one consisting from two independent parts – generator of active particles based on the discharges at atmosphere pressure and work chamber intended for placement of articles to be processed. Such design leads to significant complication of the calculations, because it is necessary at first to calculate component content of active particles in the discharge space, and then to take into account changes of content and concentrations of particles immediately in the chamber only due to chemical reactions. The second complexity of the calculations results immediately from specificity of barrier discharge, which represents a set of filamentary micro-discharges stochastically spread in space and time between the electrodes, so that each of micro-discharges has ~10^{-8} s duration and ~0.1 mm diameter. Normally [2], at determining concentrations of particles in discharge, initially plasma kinetics is calculated in separate current channels of micro-discharges, and then after time of the order of diffusion time value (~10^{-3} s) averaging of concentrations of all components over the whole discharge space is performed. In such approach there exists a set of parameters (dimensions, density per discharge electrode square unit and rate of formation the current channels) that are not well known and essentially depend on design of the discharge space and gas type. Such parameters are usually fitting ones.

Calculations represented in the present work are based on another approach, in which power introduced into the discharge is immediately averaged over the discharge volume. In such approach valid consideration is assured for the processes, that are linear on specific power, and also for non-linear processes with typical reaction time longer than diffusion time ($\tau > 10^{-3}$ s). This condition is fulfilled good enough in the system under study, because typical durations of chemical reactions between dissociation products in current channels normally exceed 10^{-2} s. Advantage of such approach consists in the absence of free parameters, and thus exactly this approach was used in our calculations. At performing the calculations, processes at barrier discharge electrodes and those at work chamber walls were not taken into consideration.

In calculations of the plasma component content and concentrations of molecules and radicals formed in barrier discharge volume, kinetic equation were used as follows:

$$\frac{dN_i}{dt} = S_{ei} + \sum_j k_j N_j + \sum_{j,l} k_{jl} N_j N_l + \ldots \qquad (1)$$

Here N_i are concentrations of molecules and radicals; k_j, k_{jl} are rate constants of molecular processes; S_{ei} is rate of formation of the products of electron-molecular reactions, which was calculated from the equation:

$$S_{ei} = \frac{W}{V}\frac{1}{\varepsilon_{ei}}\frac{W_{ei}}{\sum_j W_{ej} + \sum_j W_j}. \qquad (2)$$

W is power introduced into barrier discharge; V is barrier discharge volume. W_{ej} is specific power spent for electron-molecular process of non-elastic scattering with threshold energy ε_{ej}:

$$W_{ei} = \sqrt{\frac{2q}{m}} n_e N_i \varepsilon_{ei} \int_0^\infty \varepsilon Q_{ei}(\varepsilon) f(\varepsilon) d\varepsilon, \qquad (3)$$

where $q = 1.602 \cdot 10^{-12}$ Erg/eV; m and n_e are electron mass and concentration; Q_{ei} is cross section of respective non-elastic process; $f(\varepsilon)$ is electron energy distribution function (it was calculated from Boltzman equation). W_i is specific power spent for heating the gas:

$$W_i = \frac{2m}{M_i}\sqrt{\frac{2q}{m}} n_e N_i \int_0^\infty \varepsilon^2 Q_i(\varepsilon) f(\varepsilon) d\varepsilon \,, \qquad (4)$$

where M_i is mass of respective type of molecules, Q_i is transport scattering cross section.
Electron distribution function was calculated from Boltzman equation in two-term approximation [3].

$$\frac{1}{n_e N}\left(\frac{m}{2e}\right)^{1/2} \varepsilon^{1/2} \frac{\partial(n_e f_0)}{\partial t} - \frac{1}{3}\left(\frac{E}{N}\right)^2 \frac{\partial}{\partial \varepsilon}\left(\frac{\varepsilon}{\sum_i \frac{N_i}{N} Q_i} \frac{\partial f_0}{\partial \varepsilon}\right) - \qquad (5)$$

$$-\frac{\partial}{\partial \varepsilon}\left[2\sum_i \frac{m}{M_i}\frac{N_i}{N} Q_i \varepsilon^2 \left(f_0 + T\frac{\partial f_0}{\partial \varepsilon}\right)\right] = S_{eN}$$

where ε is energy (eV); T is gas temperature (eV); e is electron charge; E is electric field strength; N is total concentration of the molecules; N_i is concentration of respective type of the molecules; m is electron mass; S_{eN} and S_{ee} are integrals of non-elastic collisions of electrons with neutral particles and electrons, respectively.
The integral of non-elastic collisions of electrons with gas molecules was chosen in form

$$S_{eN} = \sum_i \frac{N_j}{N}\left[(\varepsilon - \varepsilon_i) Q_{ei}(\varepsilon + \varepsilon_i) f_0(\varepsilon + \varepsilon_i) - \varepsilon Q_i(\varepsilon_i) f_0(\varepsilon)\right], \qquad (6)$$

Q_{ei} are cross sections of excitation and ionization of O_2 and N_2 molecules with threshold energy ε_j.
Electron-electron scattering was not taken in consideration, because, as it was shown by our test calculations, at fulfilling inequality $n_e/N \le 10^{-6}$ e-e scattering does not have significant effect on rate constants of electron-molecular processes. Absence of e-e scattering integral in equation (5) leads to fact that stationary electron distribution function becomes independent on electron concentration. For that reason, for determining densities of neutral plasma components there is no necessity to solve kinetic equations for electrons and ions. It was assumed in the calculations that electric field in the discharge did not change in space and time, and it was taken to be equal 20 kV/cm, which is mean field value in barrier discharge on air, as it follows from [4]. At solving equations (1) 105 elementary processes were taken in consideration. Equations (1) were solved together with Boltzman equation by numerical techniques analogous to [3].

At second stage of the calculations it was assumed that the whole mixture acquired in barrier discharge volume (excluding charged plasma components) comes to work chamber in spatially uniform way with rates:

$$S_{ir} = \frac{N_{i\tau}}{\tau_r}\frac{V_r}{V_a}, \qquad (7)$$

where τ_r and V_r are pump-through time and volume of barrier discharge space, respectively, $N_{i\tau}$ are concentrations of particular components of the mixture in time point τ_r, V_a is work chamber volume.
Calculation of concentrations of molecules and radicals in work chamber was performed on a basis of equations:

$$\frac{dN_i}{dt} = S_{ir} - S_{ia} + \sum_j k_j N_j + \sum_{j,l} k_{jl} N_j N_l + \ldots \qquad (8)$$

Here $S_{ia} = \frac{N_i}{\tau_a}$ is rate of coming the plasma components out of work chamber due to gas purge, τ_a is time of gas purge through work chamber.

4. Results of numeric modeling of the component content of active particles in work chamber volume

In Fig.1 calculated values of concentrations of gas mixture components in work chamber with dry (20% RH, light bars) and wet (80% RH, black bars) air for purge rates of 2, 4 and 8 l/min. Such purge rates correspond to average time of mixture presence in the chamber of 40, 20 and 10 minutes, and average time of mixture presence in barrier discharge volume of 2.5, 1.25 and 0.5 s, respectively. As one can see from Fig.1, concentrations of particular components of the mixture possess different dependencies on purge rate. For that reason, by varying purge rate one can change ratio between concentrations of particular components in rather wide range.

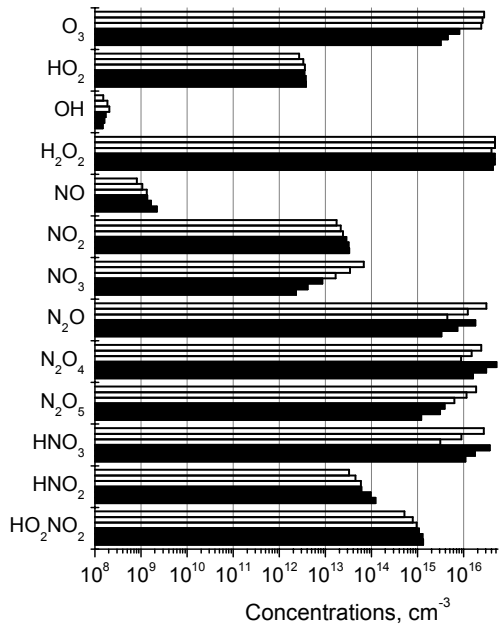

Fig.1. Calculated quasi-stationary concentration values of gas mixture components in work chamber in dry (20% RH, light bars) and wet (80% RH, black bars) air at purge rates 2, 4 and 8 l/min (purge rate increases from top to bottom).

In Fig.2 temporal dependencies of the component concentrations of gas mixture in work chamber with dry (20% humidity) air for 8 l/min purge rate are presented. Mentioned concentrations have practically linear dependence on time in the interval before approximately 1 minute. It is due to fact that the rate of their coming from the discharge does not change in time, and chemical reactions in the chamber volume do not have enough time to change ratios between concentrations of the components. Thus, only after big enough time interval ($\tau >> 1$ min) quasi-stationary values of the component concentrations are reached, that gives evidence to steady in time income of these components, that is, the income is determined by processes of carrying the molecules out of barrier discharge volume. Ozone concentration reaches its

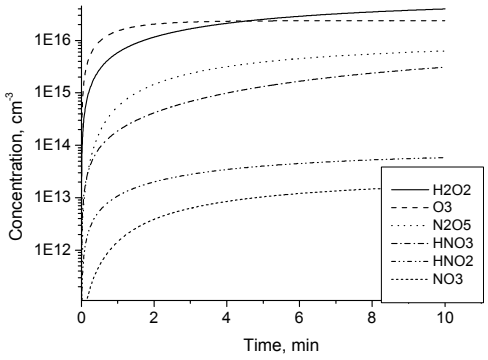

Fig.2. Calculated dependencies of component concentrations of H_2O_2, O_3, N_2O_5, HNO_3, HNO_2, NO_3 in work chamber on time at 8 l/min purge rate of dry air (20% RH)

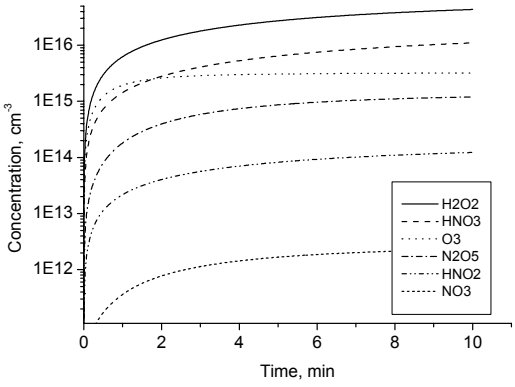

Fig.3. Calculated dependencies of component concentrations of H_2O_2, O_3, N_2O_5, HNO_3, HNO_2, NO_3 in work chamber on time at 8 l/min purge rate of wet air (80% RH).

quasi-stationary value for the time of about 100 – 250 s. Hydrogen peroxide concentration is practically independent on time, because in our calculations it is limited by value of saturated vapor concentration.

At increase of air humidity (Fig.3) concentrations of acid components (HNO_3, HNO_2) grow up due to increase of concentration of hydrogen-containing molecules in the mixture. At that ozone concentration decreases by about one order of magnitude due to fact that in barrier discharge volume increase of ozone decomposition at collisions with OH and HO_2 molecules occurs. For the same reason NO_3 concentration decreases in wet air, and since main channel of N_2O_5 formation is represented by reactions with NO_3 participation, N_2O_5 concentration is respectively decreased.

5. Experimental results for dry air (RH≈25%)

Measurements of component concentrations of O_3, NO_3, N_2O_5, HNO_3, HNO_2, H_2O_2, HO_2NO_2 in the chamber were performed at three volume rates of the purge (8, 4 and 2 l/min) at distances of 65, 215 and 365 mm from top wall of the chamber. HO_2NO_2 was not detected in any operation regime of the setup. It agrees with fact that calculated values of HO_2NO_2 concentration do not exceed $1\cdot10^{15}$ cm^{-3}, and sensitivity threshold of measuring technique does not exceed that value. The experiments have shown that characters of the dependencies of quasi-stationary concentrations of O_3, N_2O_5, HNO_3, HNO_2, NO_3 in the chamber on purge rate are in good agreement with calculated ones: concentrations of O_3, NO_3, N_2O_5, HNO_3 grew up with decrease of purge rate, and HNO_2 concentration decreased at that. However, for correct comparison of experimental results with calculated ones, one should determine, to which extent an assumption about uniform distribution of active particles in work chamber volume is fulfilled. Measurements of concentrations of active particles in three cross sections of the chamber have demonstrated the following. Heterogeneity of the distribution of measured densities of the particles on the chamber height is minimum at 8 l/min supply rate (minimum scatter about 10% was observed for O_3, and maximum about 30-40% - for HNO_2), and increases essentially with the rate decrease, reaching 200-300% for NO_3 and N_2O_5 at 2 l/min supply rate. As it was shown by experiments with smoke supply to gas route, such character of the dependence of homogeneity of particle distribution in the chamber volume on purge rate, first of all, is due to peculiarities of the process of mixing active particles coming from the discharges with air in the chamber. It was determined that at low rates of air supply (1-2 l/min) process of filling the chamber by active medium in the first approximation can be imagined as motion of gas "plunger" from top to bottom. That is, mixing of active particles with air occurred only in top part of the chamber, and then formed mixture moved downward and extruded residual air out of the chamber. But in case of volume supply rate of 8 l/min flows of active particles passed through the whole chamber due to higher initial velocity, then they were reflected from the bottom and returned to the chamber, thus providing good mixing of active particles with air present in the chamber volume. Thus, one can see that the most correct comparison of calculated and experimentally measured concentration values is possible at high purge rate.

Fig.4 exhibits dependencies of averaged over chamber height densities of O_3, NO_3, N_2O_5, HNO_3, HNO_2 on time for 8 l/min purge rate. (Starting values of component concentrations in Figs. 4 and 5 correspond to sensitivity thresholds of measuring technique.) One can see from the figure that, as in case of calculations (see Fig.2), concentrations of all components practically reach quasi-stationary values in short time. Concentrations of O_3 and HNO_3 comprise $2.6\cdot10^{16}$ cm^{-3} and $2.6\cdot10^{15}$ cm^{-3}, respectively, and are essentially higher than densities of other components. Comparison of experimental data with calculated ones at 10-th minute shows that discrepancies between theoretical and experimental concentration values do not exceed 5% for O_3 and 25-100% for HNO_3, NO_3, HNO_2. In case of N_2O_5, the difference is essentially greater - experimentally measured concentrations are lower than calculated ones approximately by factor of 20. The most probable reason of the discrepancy between theory and experiment may consist in intensive precipitation of N_2O_5 at surfaces of the chamber walls, because their temperature is lower than that of dinitrogen pentoxide sublimation (32.4^0C). Another essential difference between experimental results and the theory is the absence of H_2O_2 in the chamber, although calculated values of hydrogen peroxide concentration are $\geq 5\cdot10^{16}$ cm^{-3}, which is almost one order of magnitude higher than sensitivity threshold of used measuring technique.

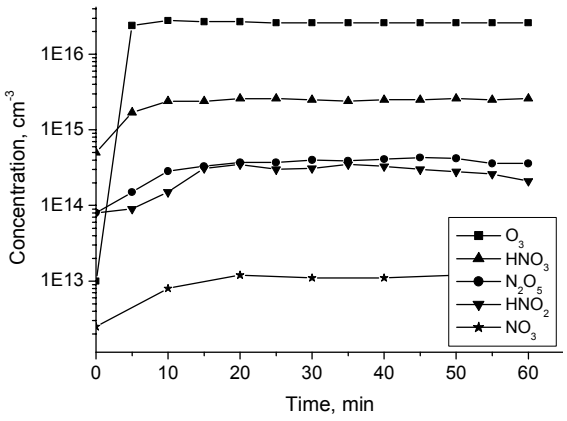

Fig.4. Dependencies of experimentally measured concentrations of O_3, HNO_3, N_2O_5, HNO_2, NO_3 averaged over the chamber volume on time at 8 l/s purge rate of dry air (RH≈ 25%).

6. Experimental results for wet air (RH ≈ 80 %).

As in the case of dry air, heterogeneity of distribution of component concentrations of O_3, NO_3, N_2O_5, HNO_3, HNO_2 on chamber height is minimum at 8 l/min and increases essentially at rate decrease down to 2 l/min. However, homogeneity degree is worse than in previous case. Particularly, for the rate of 8 l/min maximum difference in concentration values of NO_3, N_2O_5, HNO_3, HNO_2 measured at top and middle windows comprised about 100% (at that homogeneity of O_3 distribution remained high enough – concentration difference in those cross-sections did not exceed 10%). Unlike previous case, at the use of wet air and purge rates of 8 and 4 l/min hydrogen peroxide was also detected. In Fig.5 the dependencies of averaged over top part of the chamber (only measurements at top and middle windows were considered) component concentrations of O_3, NO_3, N_2O_5, HNO_3, HNO_2, H_2O_2 on time for 8 l/min purge rate are given. One can see from the figure that component concentrations of O_3, HNO_3, NO_3, N_2O_5, HNO_2 reach their quasi-stationary values till 10-20 minutes of filling the chamber. Hydrogen peroxide concentration reaches quasi-stationary value $\approx 8 \cdot 10^{16}$ cm^{-3} only at 55-60 min after the start of chamber filling. Comparison of theoretical and experimental data at 10-th minute shows that agreement between calculated and measured component concentration values of O_3, NO_3, N_2O_5, HNO_3, HNO_2 in case of wet air is essentially worse than that in case of dry air. Whereas theoretical and calculated concentrations of N_2O_5, HNO_2 and NO_3 differ approximately twice, in case of O_3 and HNO_3 this difference is significantly more. Particularly, theoretical values of O_3 concentration are about 6 times less than experimental ones. As to HNO_3, on the contrary, theoretically obtained concentration values are 6-7 times higher than measured ones. The most possible reason for such effect may be increased HNO_3 exit out of the chamber volume at air humidity growth due to solving nitrogen acid molecules in water layer at chamber walls.

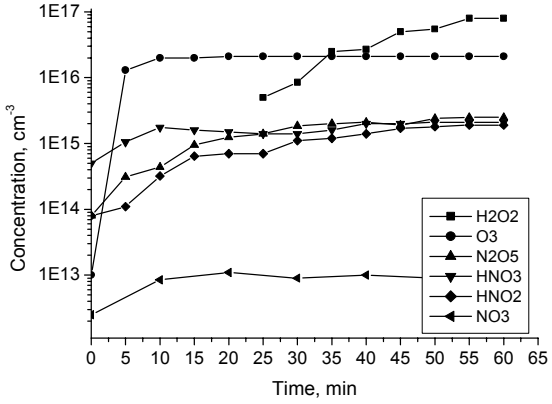

Fig.5. Dependencies of experimentally measured concentrations of H_2O_2, O_3, N_2O_5, HNO_3, HNO_2, NO_3 averaged over volume of upper half of the chamber on time at 8 l/s purge rate of wet air (RH≈80%).

7. Conclusions

Accomplished comparison of calculated and experimentally measured concentrations of O_3, NO_3, N_2O_5, HNO_3, HNO_2, H_2O_2 in the work chamber at different air humidity shows that proposed by us approach to calculation of concentration of the particles in most cases gives good agreement between the theory and the experiment. Noticeable discrepancies observed in certain cases may be reasonably explained by factors that can not be correctly taken into account in the theory. The most important of those is the influence of discharge electrode surfaces and work chamber walls, and inhomogeneity of component distribution in the chamber.

Prediction of droplets desolvation in an rf inductively coupled plasma

Yanguang Shan, J. Mostaghimi

Centre for Advanced Coating Technologies
Department of Mechanical and Industrial Engineering, University of Toronto, Canada

Abstract
A mathematical model for the desolvation of solvent droplets has been implemented into a time-dependent rf-ICP code. Plasma-droplet interactions and droplets collisions are considered. Simulations have been performed for various droplet sizes under typical ICP operating conditions. Effects of the local cooling, droplets collisions, central gas flow rate and plasma power, as well as sample uptake rate have been investigated. Some results agree quite well with the experiment.

1. Introduction

In ICP atomic spectrochemical analysis, the samples are commonly introduced into the ICP as an aqueous aerosol via a spray. Studies [1-3] have shown that the efficient desolvation process can significantly improve the overall performance of the spectrometry. Signal fluctuations due to individual incompletely desolvated droplets can be significant [4-9]. Each incompletely desolvated droplet affects the plasma ionization and excitation within 1-2 mm of the droplet, acting as a local heat sink [9]. The region near desolvated analyte particles is also affected [7]. A few numerical studies have been done by several groups to study the droplets desolvation in an ICP [10-12]. These studies have led to a better understanding of the desolvation process. However, these models deal with the plasma temperature and velocity and the droplets desolvation and trajectories separately. The coupling effect of the droplets desolvation and trajectories on the plasma gas was not included. The droplet-droplet collisions, which may lead to coalescence of droplets, also were not considered. In this paper, we present a mathematical model to study droplet desolvation and trajectories within the ICP torch. This model is based on the spray model used in KIVA II [13-15]. It was implemented into a two-dimensional, time-dependent radio frequency ICP code. Interactions between plasma gas and the droplets injection as well as droplet-droplet collisions are included.

2. Mathematical models

Mathematical models of the rf-ICP have been very successful in predicting plasma properties and in studying a variety of plasma phenomena. The model used in this paper was developed by Mostgahimi *et al*. and the details of this model can be found elsewhere [16].

2.1. Spray model

To simulate the behavior of the spray droplets, a droplet probability distribution function is defined.

$$f = f(\vec{x}, \vec{v}, r, T_d, t) \tag{1}$$

where $\vec{x}$ is the droplet position, $\vec{v}$ is the droplet velocity, r is the equilibrium radius of droplet, T_d is the droplet temperature which is assumed to be uniform within the droplet.The time evolution of f is obtained by solving the spray equation.

$$\frac{\partial f}{\partial t} + \nabla_{x_i} \cdot (f\dot{\phi}_i) = \dot{f}_{coll} \tag{2}$$

where x_i are $\vec{x}, \vec{v}, r, T_d$, and ϕ_i are $\vec{v}$ $\vec{F}$, R, $\dot{T}_d$ which are time change rates of x_i for an individual droplet. The expressions for $\vec{F}$, R, and $\dot{T}_d$ will be given later. $\dot{f}_{coll}$ is the source term due to droplet collisions.

2.2. Droplets collisions

When a large number of droplets travel in a flow, there exists a possibility that the droplets may collide. During collisions, droplets may coalesce or graze each other depending on droplets' properties. In droplet collision model, collisions are considered only when a pair of parcels (each parcel contains a number of droplets with same properties) locate in the same computational cell [21]. The droplets within the same parcels are not allowed to collide since they are moving with the same velocity. The probability that no collision occurs between the droplets of this pair of parcels is calculated as following

$$P_{nocoll} = e^{I_{coll}\Delta t} \tag{3}$$

where I_{coll} is the collision frequency the larger droplet experiences, given by

$$I_{coll} = \frac{N_1}{V_c}\pi(r_1 + r_2)^2\left|\vec{v}_1 - \vec{v}_2\right| \tag{4}$$

where N_1 is the number of droplets in the parcel with the smaller radius droplets, V_c is the volume of the computational cell. To specify the collision types, the collision impact parameter b is defined [13].

$$b = \sqrt{xx}(r_1 + r_2) \tag{5}$$

where xx is a random number, b_{cr} is the critical impact parameter. b_{cr} is given by

$$b_{cr}^2 = (r_1 + r_2)^2 \min(1.0, \frac{2.4g(\gamma)}{We_d}) \tag{6}$$

$$g(\gamma) = \gamma^3 - 2.4\gamma^2 + 2.7\gamma \quad (\gamma = r_2 / r_1, r_1 \le r_2) \tag{7}$$

$$We = \frac{\rho_d\left|\vec{v}_1 - \vec{v}_2\right|^2 r_1}{\sigma(\overline{T_d})} \qquad (\overline{T_d} = \frac{r_1^3 T_{d_1} + r_2^3 T_{d_2}}{r_1^3 + r_2^3}) \tag{8}$$

If the impact parameter is less than the critical impact parameter, then the droplets coalesce. If the impact parameter is greater than the critical impact parameter, then the droplets in the parcel pair just graze. In this case, droplets maintain their sizes and temperatures but undergo velocity changes in the resulting semi-elastic collision. The velocities of droplets after collision are given by

$$\vec{v}_1^{'} = \frac{r_1^3\vec{v}_1 + r_2^3\vec{v}_2 + r_2^3(\vec{v}_1 - \vec{v}_2)\dfrac{b - b_{cr}}{r_1 + r_2 - b_{cr}}}{r_1^3 + r_2^3} \tag{9}$$

$$\vec{v}_2^{'} = \frac{r_1^3\vec{v}_1 + r_2^3\vec{v}_2 + r_1^3(\vec{v}_2 - \vec{v}_1)\dfrac{b - b_{cr}}{r_1 + r_2 - b_{cr}}}{r_1^3 + r_2^3} \tag{10}$$

2.3. Trajectories of individual droplets

To simulate droplet trajectories, we assume: (1) the droplet is spherical; (2) the gas film around the droplet is quasi-steady and has uniform physical properties; (3) the pressure around the droplet is uniform; (4) the droplet surface is under thermal equilibrium state; (5) no droplet dispersion since the plasma gas is assumed to be laminar, and (6) rarefied gas effects are neglected.

The governing equations for the motion of a droplet can be expressed as

$$\frac{d\vec{x}}{dt} = \vec{v} \qquad \text{and} \qquad \frac{d\vec{v}}{dt} = \vec{F} \tag{11}$$

The aerodynamic drag force is given by the expression

$$\vec{F} = \frac{3}{8}\frac{\rho_g}{\rho_d}\frac{\left|\vec{u} - \vec{v}\right|}{r}(\vec{u} - \vec{v})C_D \tag{12}$$

where ρ_g and ρ_d are the densities of surrounding gas and droplet respectively, $\vec{u}$ and $\vec{v}$ are the velocities of surrounding gas and droplet respectively. The drag coefficient C_D is given by

$$C_D = \begin{cases} 0.424 & \mathrm{Re}_d > 1000 \\ \dfrac{24}{\mathrm{Re}_d}(1 + \dfrac{1}{6}\mathrm{Re}_d^{2/3}) & \mathrm{Re}_d \le 1000 \end{cases} \tag{13}$$

$$\mathrm{Re}_d = \frac{2\rho_g\left|\vec{u} - \vec{v}\right|r}{\mu_g(\overline{T_g})}, \ \overline{T_g} = \frac{T_g + 2T_d}{3} \tag{14}$$

The evaporation of the droplet results in a change of droplet radius and droplet temperature. The rate of droplet radius change R is given by the Frossling correlation [20]

$$R = -\frac{(\rho D)_{dg}(\overline{T}_g)}{2\rho_d r}\frac{Y_1^* - Y_1}{1 - Y_1^*}Sh_d \tag{15}$$

where Y_1^* is the liquid vapor mass fraction at the droplet surface, Y_1 is the liquid vapor mass fraction in the gas. $(\rho D)_{dg}$ is the liquid vapor diffusivity in gas. We use the formula suggested by R. B. Bird *et al.* [17] to estimate the liquid vapor diffusivity in plasma gas. The Sherwood number is given by

$$Sh_d = (2.0 + 0.6\,\mathrm{Re}_d^{1/2}\,Sc_d^{1/3})\frac{\ln(1+B_d)}{B_d} \tag{16}$$

$$Sc_d = \frac{\mu_g(\overline{T}_g)}{(\rho D)_{dg}(\overline{T}_g)}\ ,\ B_d = \frac{Y_1^* - Y_1}{1 - Y_1^*} \tag{17}$$

The surface mass fraction Y_1^* is given by

$$Y_1^*(T_d) = \frac{W_1}{W_1 + W_0\left(\frac{p_g}{p_v(T_d)} - 1\right)} \tag{18}$$

where W_0 is the local average molecular weight of all species except the liquid vapor; $p_v(T_d)$ is the equilibrium vapor pressure at T_d.

The rate of droplet temperature change is determined by the energy balance equation.

$$\rho_d \frac{4}{3}\pi r^3 c_d \dot{T}_d - \rho_d 4\pi r^2 R L_d(T_d) = 4\pi r^2 Q_d \tag{19}$$

where c_d is the liquid specific heat, $L_d(T_d)$ is the latent heat of vaporization, and Q_d is the rate of heat conduction to the droplet surface per unit area. Q_d is given by the Ranz-Marshall correlation [20].

$$Q_d = \frac{K_{gas}(\overline{T}_g)(T_g - T_d)}{2r}Nu_d \tag{20}$$

$$Nu_d = (2.0 + 0.6\,\mathrm{Re}_d^{1/2}\,\mathrm{Pr}_d^{1/3})\frac{\ln(1+B_d)}{B_d} \tag{21}$$

$$\mathrm{Pr}_d = \frac{\mu_g(\overline{T}_g)c_p(\overline{T}_g)}{K_g(\overline{T}_g)} \tag{22}$$

2.4. Coupling source terms and initial and boundary conditions

The exchange of mass, momentum, and energy between plasma gas and the spray are given by following.

$$S_c{}^s = \sum_{N=1}^{NP}\frac{dm_d}{dt}\delta(\vec{x} - \vec{x}_d) \tag{23}$$

$$\vec{S}_m{}^s = \sum_{N=1}^{NP}\frac{d(m_d\vec{v})}{dt}\delta(\vec{x} - \vec{x}_d) \tag{24}$$

$$S_E{}^s = \sum_{N=1}^{NP}\frac{d(m_d h_d)}{dt}\delta(\vec{x} - \vec{x}_d) \tag{25}$$

The spray is continuous and the initial properties (sizes, velocities, temperatures) of injected droplets are specified, then distributions of these properties are calculated according to appropriate distribution functions. Two types of droplet size distribution are available: (1) mono-disperse distribution and, (2) x-squared distribution. The temperatures of all injected droplets are same. Whenever a liquid droplet impinges on a rigid wall, we assume it completely evaporates near the wall, and there is no heat transfer between the droplet and the torch wall. The plasma model was solved using the SIMPLER algorithm [18].The method used for solving the spray equation is based on the ideas of Monte Carlo method and of discrete particle method [13]. The parcels are introduced into the computation domain during the time of injection. Each parcel is composed of a number of droplets with same location and properties. We sample randomly from

assumed probability distributions that govern droplet properties at injection and droplet behavior after injection. To realize this method, the continuous distribution f is replaced by a discrete distribution $f^{'}$.

$$f^{'} = \sum_{p=1}^{NP} N_p \delta(\vec{x} - \vec{x}_p)\delta(\vec{v} - \vec{v}_p)\delta(r - r_p)\delta(T_d - T_{d\,p}) \tag{26}$$

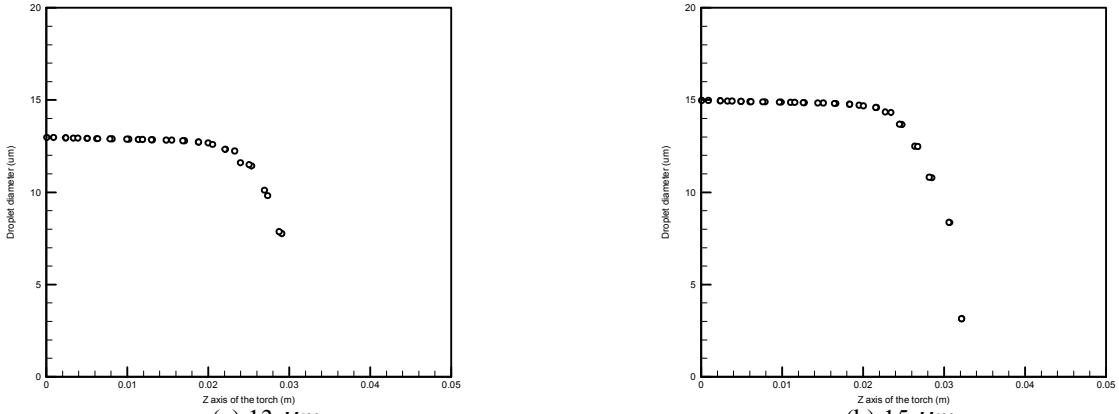
The discrete distribution is then simulated stochastically by tracking the parcels' positions and properties in the solution domain.

3. Results

The plasma is operated at 1.0 kW power and 0.9 l/min central flow rate, Sample uptake rate is 1 ml/min. The inner diameter of the center tube is 1.0 mm. Other operating parameters are same as those in Table 1 in Ref. [9]. The operating parameters used in this paper are same as the above description unless mentioned.

3.1. Desolvation profiles for mono-disperse droplets

Desolvation profiles of mono-disperse solvent droplets are shown in Fig. 1. A train of mono-disperse droplets are introduced into the plasma in this calculation. It can be seen from Fig. 1 that the desolvation rate sharply increases after the droplets reaching above the load coil where the maximum gas temperature on the torch axis is predicted by models and experiments. The profiles also show that the height in the ICP where vaporization begins for a particular size of droplets is almost fixed. This characteristic is helpful to improve the precision of the ICP spectrometry.

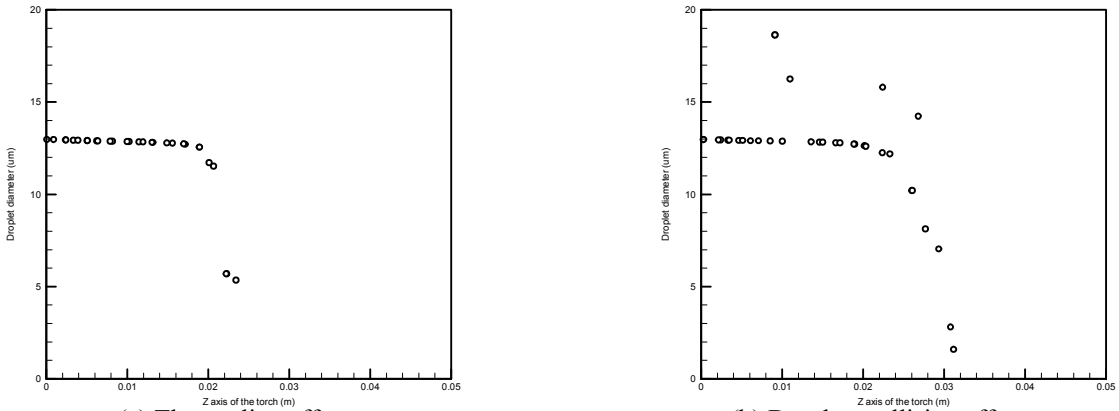


(a) 13 μm (b) 15 μm

Figure 1 Desolvation profiles for mono-disperse droplets

3.2. Effects of the local cooling and droplets collisions on droplets desolvation

Figure 2a shows the desolvation profile of a train of 13 μm mono-disperse droplets without considering the local cooling effect. Compare it with Fig. 1a (the cooling effect is included), it is obvious that the local cooling effect leads to a delay of droplets desolvation. The height of complete desolvation for 13 μm mono-disperse droplets increases from 3.4 mm ALC (Above the Load Coil) to 9.2 mm ALC when the cooling effect is considered.



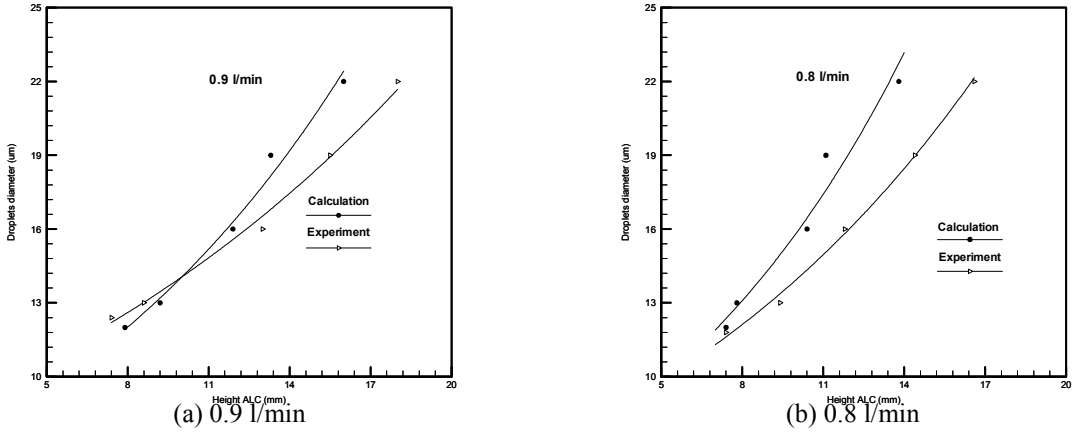
(a) The cooling effect (b) Droplets collision effect

Figure 2 Effect of the local cooling and droplets collisions on droplets desolvation

Fig.2b shows the desolvation profile of mono-disperse (13 μm) droplets with considering droplets collisions. Compare it with Fig. 1a (droplets collisions are not included), it can be seen the droplets coalescences are predicted. The height of complete desolvation for droplets increases from 9.2mm ALC to 11.2 mm ALC due to droplets collisions. The effect of droplets collisions is slight compared to the effect of local cooling.

3.3. Height of complete desolvation for droplets of different initial diameters

Heights of complete desolvation for mono-disperse droplets of different initial diameters are presented in Fig. 3a, Fig. 3b. The central gas flow rates are 0.8 l/min, 0.9 l/min respectively. For 1 kW ICP, the experimental prediction of the height of complete desolvation for a 14.8 μm diameter droplet is 11.4 mm ALC [9]. The model here predicts a height of 10.9 mm ALC for a train of 14.8 μm mono-disperse droplets to be completely evaporated. When we compare Fig. 3a here with Fig. 10a in Ref. [9] and Fig. 3b here with Fig. 10b in Ref. [9], it is found that the prediction results by the simulation agree quite well with the experimental results. The differences between simulation results and experimental results are probably due to an inaccurate prediction of plasma fields and an inaccurate calculation of the cooling effect. For a fixed sample uptake rate, the cooling effect could be over estimated for smaller droplets while underestimated for bigger droplets. Besides possible inaccurate predictions of models, the operating conditions for the experiment and the simulation are not exactly same. The experiment determined the minimum diameter of the droplets at the exit of the spray chamber that survive at a particular height in the plasma by introducing a distribution size of droplets while the simulation determined the height of complete desolvatation for a train of mono-disperse droplets.

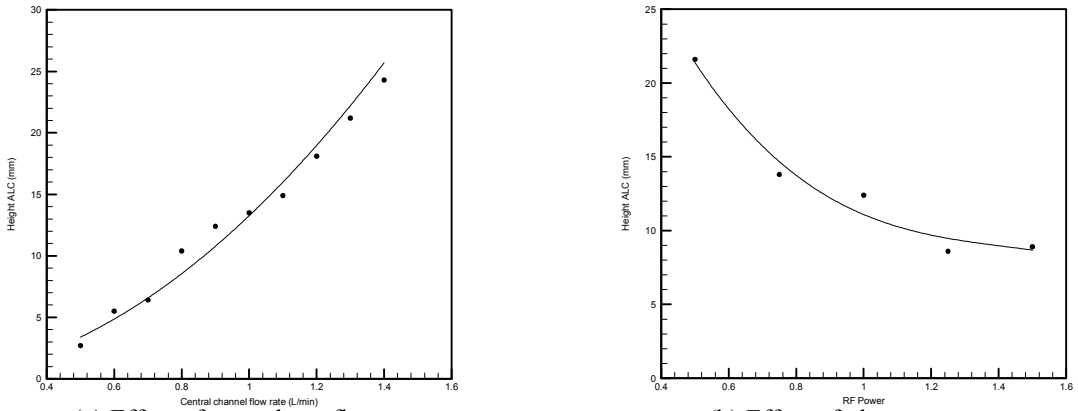


(a) 0.9 l/min (b) 0.8 l/min

Figure 3 Height of complete desolvation for droplets of different initial diameters

3.4. Effects of central gas flow rate and plasma power on the desolvation

Fig. 4a and Fig. 4b show the effects of central gas flow rate and plasma power on the height of complete desolvation for 15 μm mono-disperse droplets. It is seen from Fig. 4a that the height of complete desolvation increases as the central gas flow rate increases. This is because the increasing of central gas flow rate leads to further cooling of the plasma center temperature. As can be expected, the height of complete desolvation for droplets decreases when the power of ICP increases.



(a) Effect of central gas flow rate (b) Effect of plasma power

Figure 4 Effect of central gas flow rate and plasma power on the desolvation

3.5. Effect of sample uptake rate on the desolvation

The effects of central flow rate and ICP power on droplets desolvation are widely reported both numerically [11] and experimentally [9]. However, little consideration is put on the effect of sample uptake rate on the desolvation of droplets. As mentioned previously and reported in reference [7], the local cooling can significantly affect the plasma conditions and droplets desolvation. It is reasonable to conclude that the sample uptake rate, acting as the main cooling source, could affect the desolvation of droplets. Fig. 5 shows the effect of sample uptake rate on the desolvation of droplets. It can be seen the relationship between sample uptake rate and droplets desolvation height is nearly linear. The increase of sample uptake rate can lead to a delay of droplets desolvation.

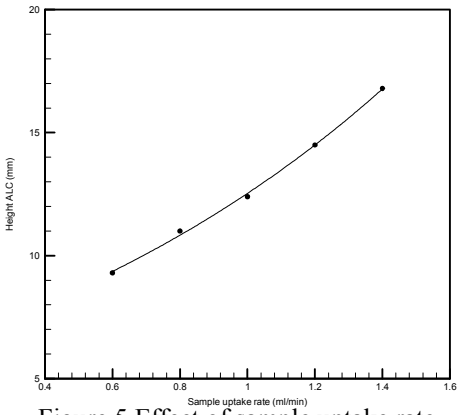


Figure 5 Effect of sample uptake rate

4. Conclusion

A mathematical model was developed to study desolvation of solvent droplets within ICP. The model is used to predict the height of complete desolvation for mono-disperse droplets within the rf-ICP. Calculations have been performed for various droplet sizes under a variety of ICP operating conditions. Effects of the local cooling, droplets collisions, central gas flow rate and plasma power, as well as sample uptake rate have been investigated. It is found that the local cooling effect can greatly delay droplets desolvation. It is also found that: as the droplet size increase, the height of complete desolvation for droplets increases; as the central gas flow rate increase, the height of complete desolvation for droplets increases; as the ICP power increase, the height of complete desolvation for droplets decreases. The predicted heights of complete desolvation for different droplet diameters in a 1 kW ICP operated at different central gas flow rates are compared with experimental results. The agreement is quite good. It is also concluded that the sample uptake rate can be a factor affecting the droplets desolvation process. Increasing of sample uptake rate can delay the droplets desolvation.

Abstract
Optical emission spectroscopy provides a tool to determine the vibrational population in the ground state of hydrogen molecules up to relative population densities $n(v)/n(v=0) > 1\%$, i.e. the first four to five vibrational levels. The vibrational temperature in hydrogen plasmas changes if an additional surface is placed into the discharge. Results for quartz, copper, aluminium, tungsten and graphite are presented and a dependence on the surface temperature is observed. A correlation with the atomic hydrogen density is discussed.

1. Introduction

The vibrational population in the ground state of hydrogen molecules ($H_2(v)$) is an important parameter in hydrogen plasmas. One example is the formation of negative ions (H^-) due to the dissociative attachment process which is resonant with v=4 for H_2 and v=6 for D_2. Other examples are the enhancement of ionisation and dissociation rates and the modification of the electron energy distribution function. In order to calculate the vibrational distribution both electron impact collisions and heavy particle collisions have to be considered. This includes electron impact excitation in electronically excited states followed by spontaneous emission which causes re-distributions of vibrational populations in the ground state. Furthermore, the vibrational population can be affected by wall collisions, either directly ($H_2(v)$ + wall $\rightarrow$ $H_2(w)$) or by recombining hydrogen atoms/ions ($H_{ads\ or\ gas} + H_{ads} \rightarrow H_2(v)$, Langmuir-Hinshelwood or Eley-Rideal mechanism). For these processes the data base is scarce and often not determined from plasma-material interaction experiments.
The paper reports on investigations of the vibrational populations of hydrogen and deuterium molecules in low pressure plasmas where an additional surface is placed into the plasma chamber. Several materials (steel, quartz, aluminium, copper, tungsten and graphite, all of them plasma treated) are tested in two types of discharges, i.e. microwave and radio-frequency plasmas. To obtain a possible correlation with surface temperature, the substrate holder can be cooled actively. The atomic hydrogen density is determined as well as the electron density and electron temperature. Thus, a dependence of measured vibrational populations on plasma parameters can be discussed also.

2. Experiments and diagnostic method

Two different types of plasma experiments were used to study plasma wall interaction with respect to a modification of the vibrational population of hydrogen molecules. One necessary experimental requirement was to have a homogeneous plasma in direct contact with an additional surface. For diagnostic purposes, lines of sight should be arranged to be parallel to the surface with the possibility to vary the distance to the surface. Furthermore, the surface should be large enough to satisfy predominant observation of surface processes in proportion to volume processes. Since laboratory plasmas are general limited by chamber walls, mostly steel surfaces, different configurations were chosen: a surface wave excited microwave plasma (Duo-Plasmaline®) with chamber walls far away from the plasma generation volume and an inductively coupled plasma source (ICP) with a plasma being always in contact with chamber walls. The geometry is shown in Fig. 1. In both experiments, the plasma is directly in contact with a quartz surface, in consequence of the plasma generation, i.e. the coupling of the generator power into the chamber volume.
The microwave plasma, based on the principle of the Duo-Plasmaline® (f = 2.45 GHz, $P_{max} = 2 \times 1.2$ kW), has a cylindrical symmetry which provides axial homogeneous and radial variable plasma parameters [1]. The cylindrical chamber is 420 mm in diameter and 700 mm in length. The plasma column is about 300 mm long, the radius varies from about 30 mm to vessel dimensions, depending mainly on pressure. As the plasma is investigated along the axis, the large vessel dimensions reduce effects of the wall material (high-grade steel) on the observed plasma volume. However the central column is a quartz tube and the plasma is always in direct contact with this quartz surface, as sketched in Fig. 1. Electron temperatures and densities of 2 - 4 eV and 0.5 - 5 $\times$ 10^{17} m^{-3}, respectively, can be achieved, depending on pressure (6 to 100 Pa) and the

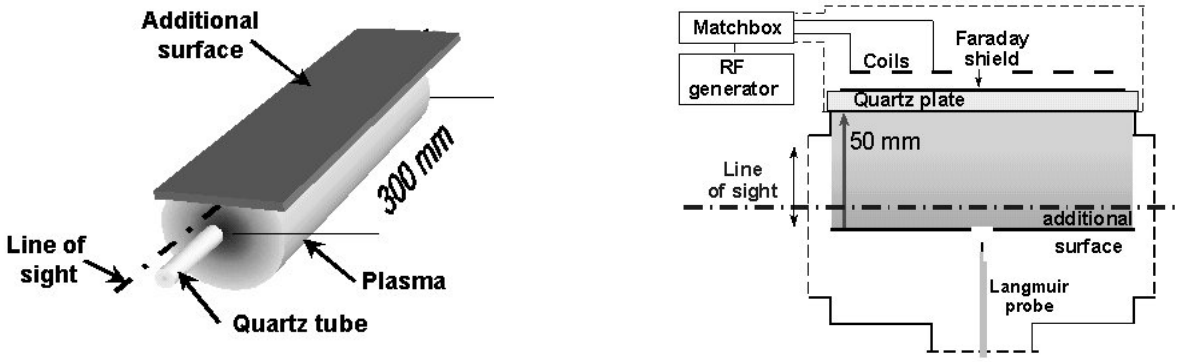

Figure 1. Geometry and lines of sight for both plasma experiments. Left: surface wave excited microwave plasma. Right: planar inductively coupled plasma.

percentage of helium admixture. Gas temperatures range from 550 K at low pressure to 750 K at high pressure. The line of sight for diagnostic purposes is arranged to be parallel to the central axis (homogeneous plasma) at a distance of 20 mm to the quartz tube and 6 mm to an optionally exposed surface which has typically a size of 300 × 70 mm. Since the surfaces are exposed to the plasma the surface temperature is assumed to be in equilibrium with the gas temperature of the plasma. The large area and the long path of the line of sight directly above the surface should guarantee a maximum signal for the measurements.

The planar inductively coupled plasma source (f = 27.12 MHz, P_{max} = 600 W) is 150 mm in diameter and 100 mm in height [2]. To avoid capacitively coupling a Faraday shield is placed between the coils and the quartz plate. The plasma is heated mainly below the quartz plate. The chamber walls (high-grade steel) are water cooled. As a consequence the plasma in the ICP interacts with cooled steel surfaces and a hot quartz plate. This has to be kept in mind when discussing the effect of additional surfaces in the chamber on the vibrational population of hydrogen. However, relative variations of vibrational populations with several surfaces should be reliable and steel and quartz are investigated first. Due to planar coils and cylindrical symmetry of the chamber, the plasma parameters were homogeneous above an additional surface located in the center of the discharge (Fig. 1). Langmuir probe measurements are carried out through a hole (10 mm in diameter) in the additional surface along the z-axis of the reactor. Electron temperatures and densities are 2 - 5 eV and 10^{16} -10^{18} m^{-3}, respectively, due to a wide pressure range (1 -100 Pa) and a variation in input power. Gas temperatures are 450 – 800 K. The additional surface is 150 mm in diameter and can be cooled actively to 300 K, otherwise the surface temperature reaches gas temperature. Because of large diagnostic windows, which are 80 mm in height, the lines of sight for diagnostics can be arranged to be parallel to the surface with variable distance to the surface. Measurements are taken every 5 mm from 1 - 40 mm.

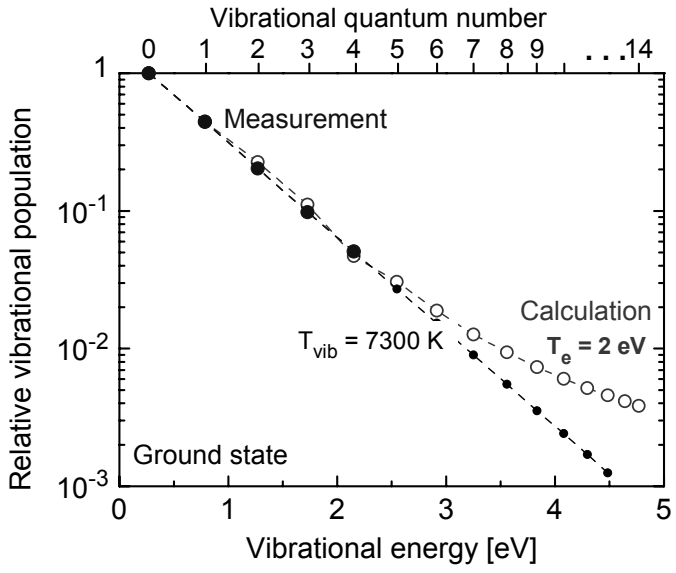

Figure 2. Boltzmann plot for relative vibrational populations of molecular hydrogen. Open symbols: collisional radiative model. Filled symbols: populations accessible by measurements. Small filled symbols: population according T_{vib}.

The spectroscopic method for determination of the ground state vibrational population is based on the measurement of the radiation of the Fulcher transition and the application of the Franck - Condon principle. It was already established for H_2 and D_2 in laboratory plasmas as well as in fusion edge plasmas [3, 4]. Beneath Franck - Condon factors, branching ratios, effective lifetimes, vibrationally resolved excitation rate coefficients as well as quenching corrections are considered for the interpretation of the radiation. It has to be mentioned that this method is sensitive for the first four (five) ground state vibrational levels of H_2 (D_2). For these levels the vibrational distribution is

characterised by a vibrational temperature $T_{vib}(X)$. However, it is not expected that vibrational levels higher than quantum number four (five) follow this Boltzmann distribution. It is well known, that electron impact excitation to the first electronically excited states in the singlet system ($B\,^1\Sigma_u^+$ and $C\,^1\Pi_u$) followed by spontaneous emission into the ground states leads to an overpopulation of higher vibrational quantum numbers. These volume processes can be described in simplified collisional radiative models. The result of such a calculation is shown in Fig. 2, together with a population according to a vibrational temperature (small filled symbols) [5]. The comparison shows, that the assignment of a $T_{vib}(X)$ to the first four to five quantum numbers is justified. The vibrational populations which are accessible with this simplified diagnostic method are shown for clarity by the filled symbols. It should be noticed that all results presented here refer to variations in vibrational populations of these first four to five levels. In order to obtain changes in higher vibrational states other diagnostic techniques must be applied, such as active laser diagnostics.

3. Results

For the investigations of the influence of additional surfaces on the vibrational population of hydrogen molecules, a gas mixture of 10%H_2 in helium was chosen. Helium was used to enhance electron temperature and electron density in comparison with pure hydrogen discharges. Thus, the intensity of the Fulcher band emission increases. Additionally, the molecular density decreases and consistently depopulating heavy particle collisions of molecules are reduced. To obtain a change in vibrational populations due to interaction with surfaces, mixing heavy particle collisions (volume processes) should be diminished as much as possible. Furthermore, the mean free path of the molecules, which penetrate from the surface into the plasma, should be in the range of some millimetres. This should be fulfilled for pressures below 20 Pa.

In the Duo-Plasmaline® the influence of steel, quartz, tungsten and graphite on the vibrational population of hydrogen and deuterium, characterised by $T_{vib}(X)$, was measured as a function of the discharge pressure. A comparison with plasmas without an additional surface is presented in Fig. 3. The pressure was varied from 6 to 100 Pa which yields molecular densities of 7×10^{19} to 1×10^{21} m^{-3}. The isotopes show similar dependence on pressure and materials. Except for graphite, $T_{vib}(X)$ ranges from 4600 to 6800 K (H_2) and 3000 to 4500 K (D_2). Furthermore, the isotopes show similar vibrational population densities, which is manifested in lower temperatures for D_2 due to lower energy separation of D_2 in comparison to H_2. Above a pressure of 20 Pa an enhancement of $T_{vib}(X)$ by the additional surface ($T_s \approx 500$ K) is clearly observed. Since the plasma is always in contact with the quartz tube only a relative enhancement with respect to quartz is measured. The fact that even the additional quartz surface leads to an increase of $T_{vib}(X)$ could lead to the statement that this variation is due to a change in plasma parameters, i.e. increase of electron temperature and decrease of electron density before the surface. However the radiation of a helium line remains stable. A considerable enhancement is observed in case of a carbon surface (graphite). Graphite is of special interest for investigations on plasma wall interaction for fusion experiments. In hydrogen plasmas chemical erosion of carbon occurs due to the bombardment of atoms and low energy ions. Hydrocarbons are released from the surface and penetrate into the plasma. Radiation of radicals such as CH and C_2 can be used to monitor the formation. In the underlying experiment the evaluation of the measured CH radiation yields a methane

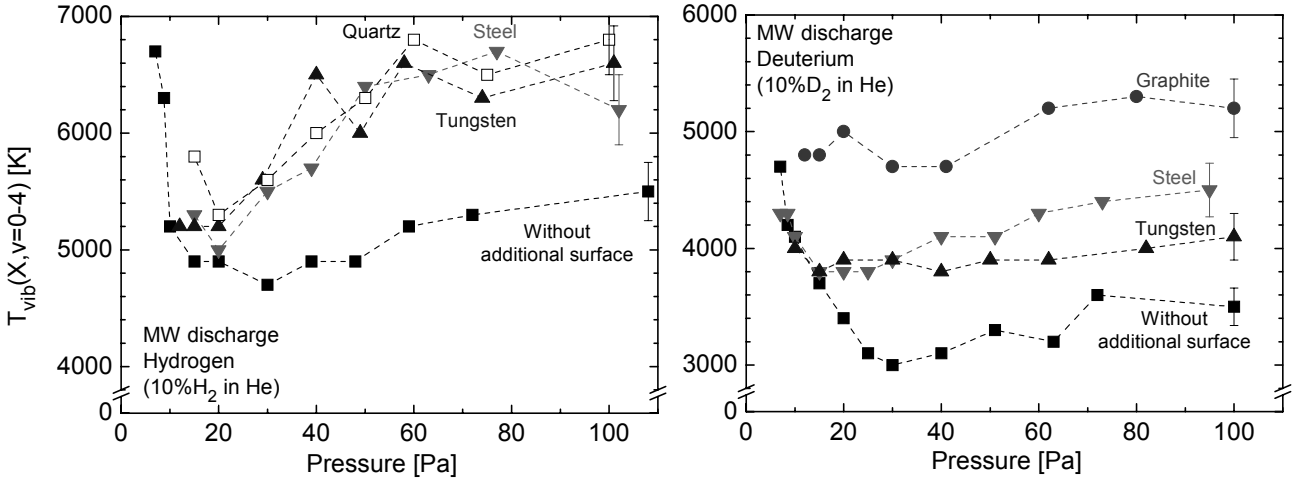

Figure 3. Vibrational temperatures in the microwave discharge with and without additional surfaces in hydrogen (left) and deuterium (right) plasmas as a function of discharge pressure.

density in the plasma of one percent. Since C_2 radiation is detected, higher hydrocarbons, such as the C_2H_y family are also present. As a consequence the enhancement in the vibrational population of hydrogen could be due to dissociation of hydrocarbons in the plasma. Measurements of vibrational population of hydrogen in methane plasmas indicated higher $T_{vib}(X)$ than in hydrogen plasmas under same conditions[6].

The inductively coupled plasma source provides the advantage to obtain spatially resolved vibrational populations and offers a comparison of surfaces at gas temperature with actively cooled surfaces (T_s = 300 K). Since the experiments run with similar gas mixture and discharge pressure electron temperatures and densities are comparable. Therefore, the relative dependence of the vibrational population on the additional surface is expected to be identical. However, in contrast to the Duo-Plasmaline®, the plasma is always directly in contact with cooled chamber walls, i.e. steel surfaces. First of all the profile of vibrational temperature in an empty chamber was measured at a pressure of 10 Pa and 5 Pa. Data were taken each 5 mm, covering a range of –35 to +35 mm from the discharge centre (z = 0). Flat profiles are obtained for both pressures, the temperatures are $T_{vib}(X)$ = 5000 K at 10 Pa and $T_{vib}(X)$ = 2800 K at 5 Pa with an error of approximately 500 K. Gas temperature is 560K and 500 K for 10 Pa and 5 Pa, respectively. Profiles of the atomic hydrogen density are obtained from the analysis of the absolute value of the radiation of the Balmer line, i.e. H_y, based on a collisional radiative model. Details of such an analysis are given in [7]. The atomic densities are in the range of some 10^{18} m^{-3} increasing a factor of three from a pressure of 5 to 10 Pa. Furthermore, a profile is observed, i.e. the density increases towards the coupling region, i.e. the quartz plate. Since the profile is given by diffusion, the slope in density can be used to yield the atomic hydrogen flux in the centre of the discharge [8]. Thus, a atomic hydrogen flux of $\Gamma_H = 2.6\times10^{21}$ $m^{-2}s^{-1}$ is obtained (10 Pa). For 5 Pa the slope indicates a lower flux but the small increase in density yields high error bars. Therefore, further measurements are carried out at the gas pressure of 10 Pa.

For reference, steel and quartz were tested first. At a distance of 5 mm from the surface no influence of steel on the vibrational population of hydrogen was measured. Active cooling of the surface yields the same results within the error bars. A large enhancement of $T_{vib}(X)$, from 5000 K to 8400 K, was detected in case of quartz (T_s = 560 K). It has to be mentioned that the surface was taken from the manufacturer and was exposed approx. one hour to the hydrogen plasma before the measurements have been started. Previous investigations indicate a time dependence, on a scale of several hours plasma operation, on the results. The longer the quartz surface was exposed to the plasma, the lower is the influence on $T_{vib}(X)$. The quartz plate at the top of the chamber is assumed to be in a steady state, full plasma operation time was several weeks.

Cooper, aluminium and tungsten surfaces lead to similar results as for the additional steel surface, i.e. no influence on $T_{vib}(X)$ in the plasma due to these metallic surfaces is observed at 5 mm distance. However, $T_{vib}(X)$ increases from 5500 K to 6500 K if the temperature of tungsten decreases, from 560 K to 300 K, respectively. This enhancement is clearly outside the error bars of the measurements. In case of graphite, the enhancement is much larger, i.e. from 6700 K to 9000 K or even higher, since the method is not sensitive for these high temperatures. Thus, similar statements for the material dependence are obtained in both plasma experiments, with the additional information that graphite temperature is an important parameter. This might be correlated to additional chemical processes, the formation of hydrocarbons, which can occur in contrast to metallic surfaces. However, in case of chemical erosion processes, it is known that the carbon flux from a graphite target has a maximum around 800 K. This means, less hydrocarbons are released from the surface at 300 K graphite temperature than at 560 K. It should be mentioned that the graphite material investigated in both experiments is pressed polycrystalline carbon, commonly used in fusion experiments. However, the surface is modified due to plasma treatment, i.e. the eroded hydrocarbons are re-deposited and form amorphous hydrocarbon films (a-C:H).

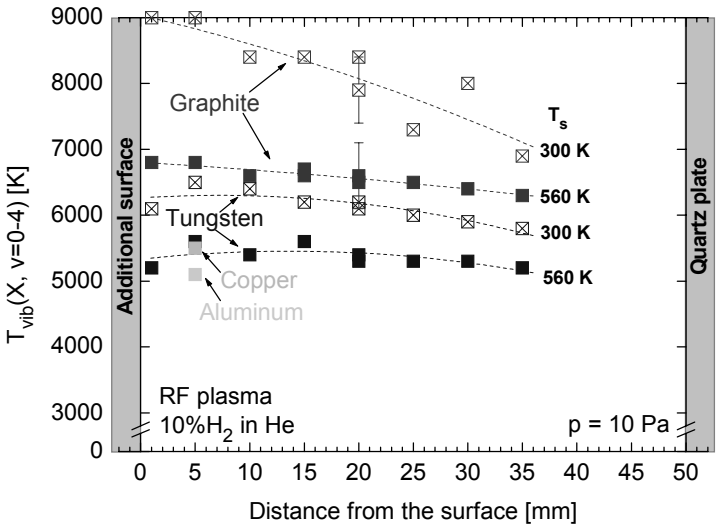

Figure 4. Spatially resolved vibrational temperatures of hydrogen in the ICP discharge with several additional surfaces.

For graphite and tungsten at 560 K and 300 K spatially resolved results are presented in Fig. 4. For comparison, the measured data for copper and aluminium at 560 K is shown also. In order to clarify the geometric set-up, the location of the additional surface and of the quartz plate are indicated. Except for graphite at 300 K, the profiles of $T_{vib}(X)$ are relatively flat. The large enhancement of $T_{vib}(X)$ for short distances from the graphite surface at 300 K indicate direct surface processes followed by collisions in the plasma volume. From the point of view of the surface the number of adsorbed atomic hydrogen particles can vary with substrate temperature. In case of the recombination of two particles, either the particles are adsorbed both, i.e. the Langmuir-Hinshelwood mechanism, or one atom in the gas phase recombines with a adsorbed atom, i.e. Eley-Rideal mechanism. Both processes depend on substrate temperature and the latter in particular on the atomic hydrogen density. The surface itself should be saturated with adsorbed particles, which is a reasonable assumption.
The atomic hydrogen densities are determined by optical emission spectroscopy, i.e. the analysis of the H_γ radiation, at a distance of 5 mm from the surface. In comparison to an empty chamber the density ($n_H = 3\times10^{18}$ m^{-3}) decreases a factor of 1.5 by implementing the metallic surfaces. In case of graphite, the density increases and the highest density is observed using the quartz surface ($n_H = 6\times10^{18}$ m^{-3}). The decrease in substrate temperature of tungsten does not affect the atomic hydrogen density, however an enhancement of a factor of 1.5 is measured for graphite. This is explained by different reflection coefficients for the materials being also a function of substrate temperature. Comparing these results with the variation of $T_{vib}(X)$ a correlation can be obtained, i.e. the higher the atomic hydrogen density the larger is the enhancement of $T_{vib}(X)$. This might indicate that the formation of molecules by the Eley-Ridal mechanism is preferred for the formation of already vibrationally excited hydrogen molecules.

4. Conclusions

The influence of several materials on the vibrational population of hydrogen in two types of hydrogen discharges was measured by optical emission spectroscopy. This diagnostic method offers an easy and fast method to determine the vibrational population of the first four to five quantum numbers which was characterised by a vibrational temperature. Since in both discharges, the plasma is always in contact with a quartz surface and, additionally, in one case, with cooled steel surfaces, only relative variations are obtained. For metallic surfaces, such as steel, cooper, aluminium and tungsten, which are exposed additionally to hydrogen and deuterium plasmas no change in $T_{vib}(X)$ was detected at low pressures, within the error bars of the method. Of course, the surfaces themselves were plasma treated and it was assumed that the substrate temperature is close to the gas temperature ($T_s \cong 600$ K). For tungsten, a decrease of substrate temperature leads to an enhancement of $T_{vib}(X)$. The largest effect was obtained in case of quartz. However, additional investigations have shown that the absolute value depends on the plasma exposure time of quartz. Furthermore, polycrystalline graphite surfaces, which are chemically active due to the chemical erosion process, were investigated. This surface has the highest influence on $T_{vib}(X)$ depending also on substrate temperature. Spatially resolved measurements showed the strongest influence near the target. This might be explained by the formation of hydrocarbons which penetrate into the plasma and dissociate in already vibrationally excited hydrogen molecules. A correlation of $T_{vib}(X)$ influenced by an additional surface with the atomic hydrogen density could be noticed.
These investigations on plasma wall interaction show clearly that the vibrational population of hydrogen molecules can be influenced by surfaces. As a consequence it is not sufficient to consider just plasma volume processes for plasma modelling. Detailed investigations on a dependence on material and substrate temperature have to follow to provide a data base for these kind of processes. Thus predictions of $H_2(v)$ will be improved which is necessary for example to increase negative hydrogen ion densities in plasmas.

Can Langmuir Probe be used for the Diagnosis of Atmospheric Thermal Plasmas with Gas Motion?

M T C Fang, J L Zhang and J D Yan

Department of Electrical Engineering and Electronics
The University of Liverpool, Liverpool L69 3GJ, UK

Abstract

The disturbance caused by the insertion of a Langmuir probe into a 5mm long, free burning 200A argon plasma at atmospheric pressure is investigated. It has been found that the disturbances are so severe that probe measurements cannot refer to an undisturbed plasma. The difficulties in interpreting the results of a sweeping probe are also discussed.

1. Introduction

This paper is concerned with the use of Langmuir probes in free burning, thermal plasmas at atmospheric pressure. The temperature range of interest is from 25,000K to 10,000K. Due to the interaction of the current sustaining the discharge with its own magnetic field a maximum velocity of around 150m/s on the axis of the discharge can be attained. The length of the discharge does not usually exceed 1cm. In such a hostile environment, the survival of the probe requires that the residing time of a probe is sufficiently short in order to avoid electron emission and ablation of the probe. Sweeping probes are therefore often used [1].

It is well-known that the derivation of the plasma parameters from probe measurements solely depends on the theoretical model with which the probe V-I characteristics are interpreted. A necessary condition for the meaningful use of probes is that the plasma is not disturbed sufficiently far away from the probe surface (usually a probe diameter). This is in fact the starting assumption of any probe theory. Earlier theory on probes in high pressure plasmas up to 1975 has been summarised by Chung et al [2]. Much work on probes assumes collision dominated space charge sheath (although it can be thin [2]) and the plasma is weakly ionised. The latter decouples the fluid dynamic aspects of the problem from the electrical characteristics of the flow. Thus, gas velocity and heavy particle temperature are assumed to be known although electron temperature may be different from that of heavy particles under the influence of the probe bias [2, 3]. The effects of ionisation and chemical reactions within the region of electrical disturbance are usually not considered.

The application of probes to the thermal plasma conditions indicated above has an added complexity. That is that the Debye length is usually smaller than the smallest mean free path calculated using LTE composition for the temperature range of interest. Thus, the space charge sheath is collisionless. The matching of a collisionless space charge sheath with a collision dominated quasi-neutral pre-sheath is extremely difficult. It can only be done if a kinetic approach is adopted for the region (commonly known as the Knudsen layer, [4]) between the continuum pre-sheath and the collisionless sheath. However, this is yet to be done for probes.

The objective of the paper is to investigate by computer simulation the validity of the necessary condition for the application of probes to flowing thermal plasmas within the temperature range of interest. Attention is paid to the thermal and fluid dynamic disturbances caused by a spherical probe situated on the arc axis. The probe surface temperature is assumed at the melting temperature of the material and a non-slip velocity boundary condition is imposed along the surface. Since sweeping probes are often used, we also investigate the characteristic time required for the plasma and probe to reach steady state.

This paper is not concerned with the situation where the use of Langmuir probes is restricted in the region near a wall or the probe being flush with a large cold electrode (e.g. [5,6]). For such an arrangement, the presence of a probe does not introduce additional thermal and fluid dynamic disturbances.

The paper is organised as follows. In Section 2, we present the temperature and velocity fields of a 200A free burning arc in argon in the absence and in the presence of a spherical probe. The time required for the plasma and the probe to reach steady after the insertion of a probe is investigated in Section 3. Finally, in Section 4 appropriate conclusions are drawn.

2. The Influence of the Probe on the Temperature and Velocity Fields

The arc burns in a 5mm gap between a shaped cathode and a water-cooled copper anode (Figure 1). The argon gas is fed in through an annular nozzle at a fixed flow rate of 10*l/min*.

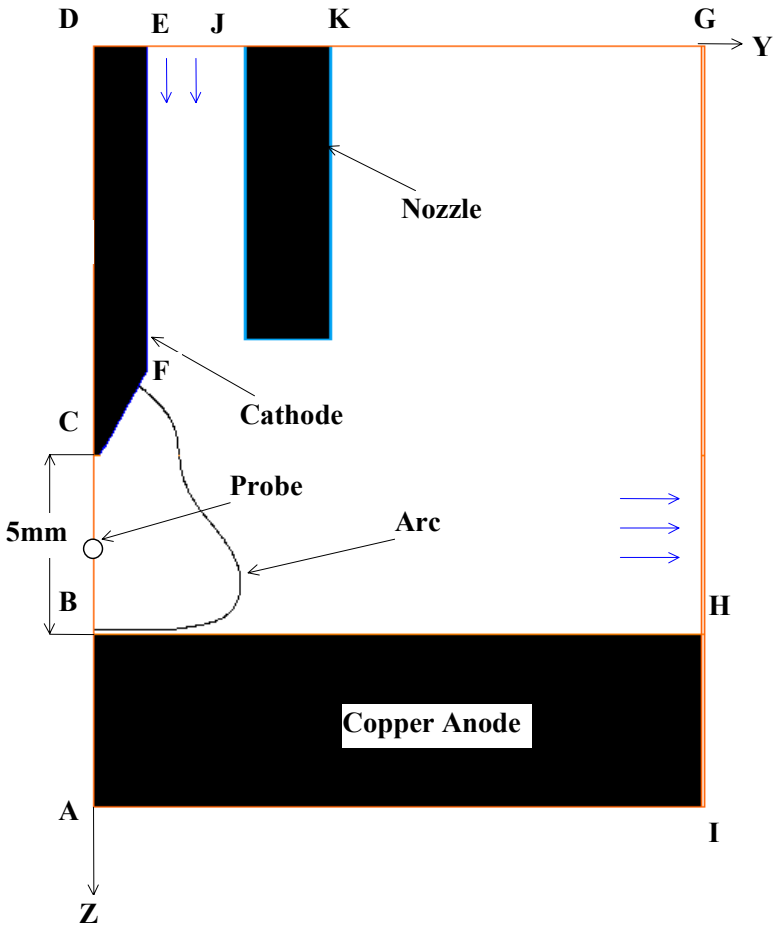

Figure 1 Schematic diagram showing the electrodes, nozzle and the dimensions. The same length scale is adopted.

The axisymmetric arc under LTE and steady state can be described by the conservation equations, which can be written in the following form:

$$\nabla \bullet \left(\rho \Phi \vec{V}\right) - \nabla \bullet \left(\Gamma_{\Phi} \nabla \Phi\right) = S_{\Phi} \tag{1}$$

where Φ is the dependent variable, ρ is the gas density, and $\vec{V}$ is the velocity vector. The source term S_{Φ} and the diffusion coefficients Γ are given in Table 1 where all symbols have their conventional meaning.

Table 1

Equation	Φ	Γ	S_{Φ}
mass of mixture	1	0	0
z-momentum	w	μ	$-\partial P/\partial z + J_r B_\theta$+ viscous terms
r-momentum	v	μ	$-\partial P/\partial r - J_z B_\theta$+ viscous terms
enthalpy	h	k/c_p	$\sigma E^2 - q + dP/dt$ + viscous dissipation

The electrical field is obtained by solving the current continuity equation:

$$\nabla \cdot (\sigma \nabla \varphi) = 0 \tag{2}$$

where φ is the electrical potential.

The net radiation loss per unit time and volume, q, is calculated by a semi-empirical radiation transport model [7]. The transport model requires the net emission coefficients, which are given by Menart et al. [8]. Transport properties as a function of temperature and pressure are provided by Murphy [9]. The boundary conditions required for solution are listed in the Table 2.

Table 2 Boundary Conditions

	DE	EJ	KG&GH	BH	BC	CD	Probe surface
v	---	0	$\partial v/\partial n = 0$	v=0	$\partial v/\partial y = 0$	---	v=0
w	---	w_{in}	$\partial w/\partial n = 0$	w=0	$\partial w/\partial y = 0$	---	w=0
h	---	T=500K	$\partial h/\partial n = 0$	T=1355K	$\partial h/\partial y = 0$	---	T=1355K
φ	$\partial\varphi/\partial z = j_0/\sigma$	$\partial\varphi/\partial z = 0$	$\partial\varphi/\partial n = 0$	φ=const	$\partial\varphi/\partial y = 0$	$\partial\varphi/\partial y = 0$	$\partial\varphi/\partial n = 0$

Where j_0 is the total current divided by the cross section of the uniform section of the cathode and n denotes the normal direction to a surface.

PHOENICS [10] is used to solve the conservation equations and the current continuity equation. The temperature and axial velocity fields are shown in Figure 2. The highest temperature, 27,000K, is near the cathode and the maximum axial velocity is about 130m/s. The calculated temperature is in good agreement with that measured [11], thus gaining confidence in computed results.

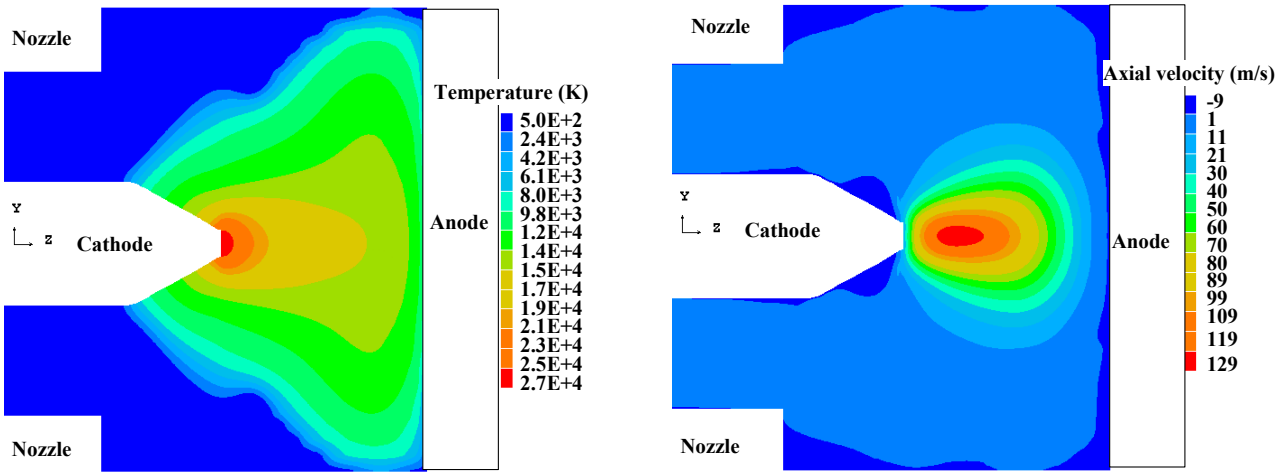

Figure 2 Temperature and axial velocity fields of a free burning argon arc at 200A.

The influence of a probe inserted in such an arc discharge is investigated by placing a spherical probe of radius of 0.125mm made of copper on the arc axis, which is 2.5mm away from the cathode tip. The surface temperature of the probe is set at 1,355K and the non-slip condition for velocity along probe surface is imposed. The computed results with a probe inserted are given in Figure 3, which shows severe disturbance affecting a large part of the arc, especially the velocity field. A detailed comparison of axis temperature and velocity in the absence of a probe with those in the presence of a probe is shown in Figure 4. The thermal disturbance in the upstream region of the probe extends 3 probe diameters from the probe surface. The size of the thermal disturbance downstream of the probe is twice that of the upstream. The disturbance on the velocity field is even more severe, which extends to the cathode and anode region. It is therefore obvious that

the disturbance caused by the presence of a probe is not localised, and, hence, the very foundation for the application of Langmuir probes does not exist for the thermal plasma under investigation. Since there are no "localised" un-disturbed upstream conditions, the use of the knowledge of the local plasma parameters in the absence of a probe to estimate the thermal, viscous and electrical boundary layer thickness would be in serious error.

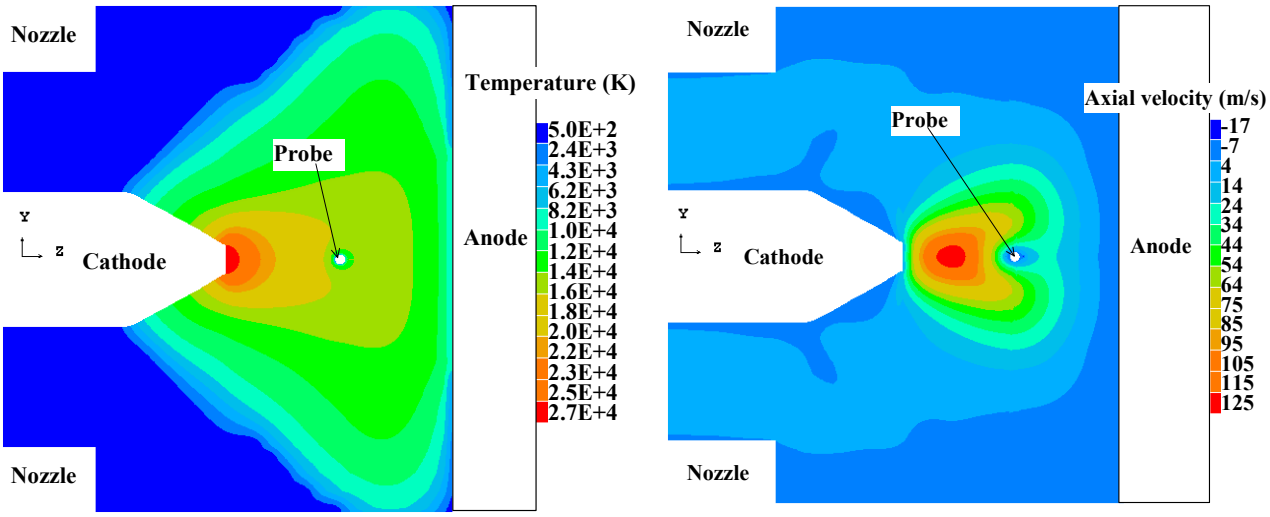

Figure 3 Temperature and axial velocity fields of a free burning arc at 200A with a spherical probe inserted on the axis.

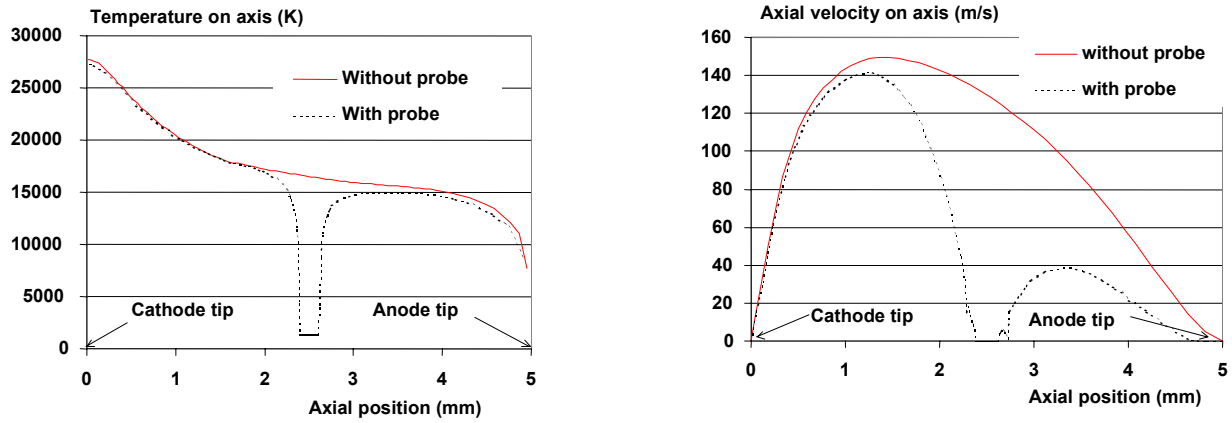

Figure 4 Thermal and fluid dynamic disturbances caused by the insertion of a spherical probe of radius of 0.125mm.

It is not surprising that the insertion of a probe could cause such a severe disturbance. The temperature boundary conditions imposed along the probe surface force the surrounding gas to become electrically non-conducting, which deprives Ohmic input in the region. This further reduces the temperature close to the probe. The increase in gas density due to the reduced temperature results in a decrease in velocity. Thus, the energy convected into the near probe region from high temperature upstream region is reduced. Through thermal conduction and the effects on the velocity field the cooling effects due to the probe spread into neighbouring regions, thus resulting in a severe disturbance extending to the whole arc.

The results shown in Figures 3 and 4 are obtained by assuming that the whole system is still in local thermal equilibrium. LTE assumption would no longer be valid in the region where temperature is below 8,000K. This renders the situation even more complex. However, for the demonstration of the effects of the insertion of a probe the LTE model serves the purpose.

3. On the Use of a Sweeping Probe

The use of a sweeping probe is necessary in practice in order to avoid the destruction of the probe by the high temperature plasma. The interpretation of the results obtained by a sweeping probe requires, in addition to the assumption of localised disturbance, that the plasma and the probe are in quasi-steady state when the probe sweeps across an arc cross section. The validity of this assumption is investigated by observing the transients caused by the insertion of a cylindrical probe into a uniform flow perpendicular to the probe. The upstream temperature and velocity correspond to the local un-disturbed conditions given in figure 2. Typical results are shown in Figure 5. The time required to obtain the steady state solution is approximately 4-5ms, which is comparable to the residing time of the probe in the arc. It is therefore unlikely that a quasi-steady state could be established on every point of the trajectory of the sweeping probe. The current method of computing the time required for the establishment of steady state tends to underestimate the time as the disturbance caused by the probe affects the whole arc.

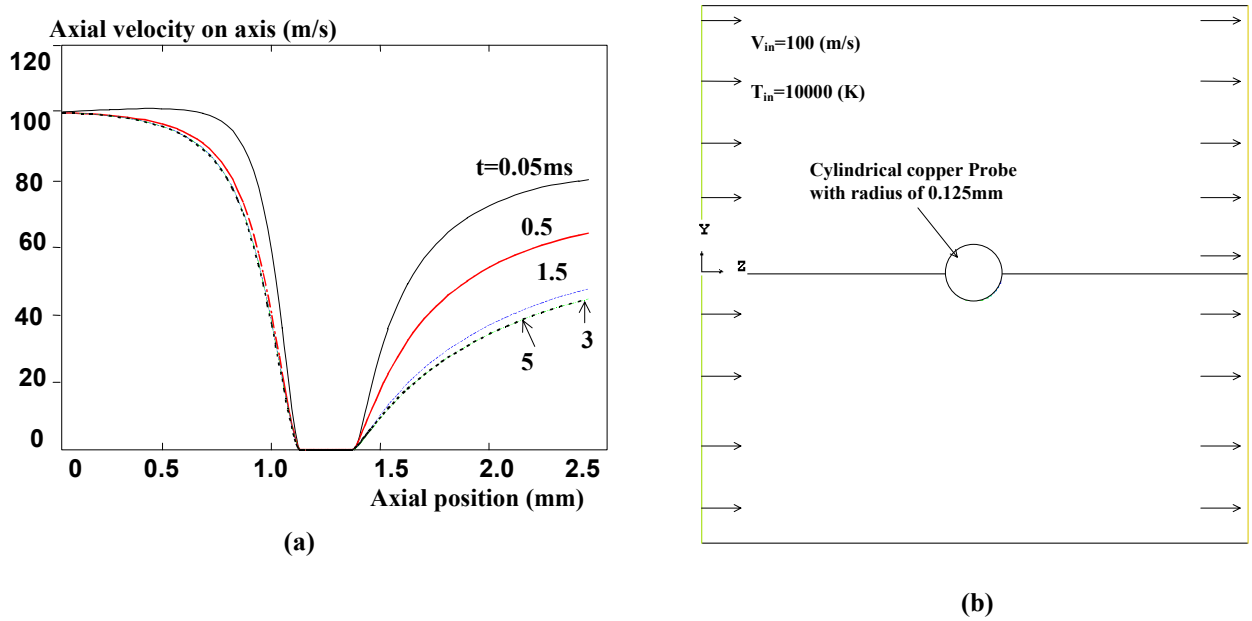

Figure 5 (a) The change of axis velocity after the insertion of a probe at t=0. (b) The simulation domain which is twenty times of the probe radius.

4. Conclusions

The application of Langmuir probe for the measurement of plasma parameters requires that the disturbance caused by the probe be localised. The validity of this very basis for the interpretation of Langmuir probe characteristics has been examined by using computer simulation. It has been found that, for the thermal plasma conditions under investigation, the presence of the probe severely affects the temperature and velocity fields of the whole arc. It is therefore not possible to refer probe measurements to an un-disturbed plasma. Probe measurements in the fringes of arc plasmas (such as anode boundary layer) may be feasible. The added difficulty in elucidating the characteristics of a sweeping probe is that the plasma and the probe are not in quasi-steady state.

Abstract
DC unbalanced magnetron was employed for the deposition of composite Ag/C:H (hard plasma polymer) films. Gaseous phase products of the discharge were characterized by FTIR spectrometry. Absorption bands of C_2H_2, CH_4 and C_2H_4 were identified for the working gas argon/*n*-hexane. For the case of working gas argon/*n*-hexane/air CO, CO_2, HCN, CH_4 and C_2H_2 were found. Only CO lines were observed in emission spectra. Non-equilibrium of rotational and vibrational states became evident from these spectra.

1. Introduction

Tunable diode laser absorption spectroscopy (TDLAS) and Fourier transform infrared (FTIR) spectroscopy are the most common techniques for infrared diagnostics of plasma. Because of its high sensitivity and resolution power, TDLAS can detect molecules in very low concentrations (including direct detection of short living intermediate species). This method is very useful for investigation of chemical reactions in plasma. On the contrary, FTIR is able to monitor much wider spectral region but with lower sensitivity and usually with much worse spectral resolution. Monitoring of stable end-products of reactions by FTIR spectroscopy gives indirect information about reactions in the plasma.

Applications of FTIR spectroscopy for detection of many various species in plasma or in discharges have been reported (see [1] for a review). This technique has been used for investigation of hydrocarbon plasma as well [2-6]. Methane CH_4 and acetylene C_2H_2 are the most abundant products detected. Spectral resolution is an important parameter; the resolution in the order of 10^{-3} cm^{-1} or better is used in high-resolution FTIR or laser spectroscopy of molecules. The necessary equipment is not common in laboratories not specialized in this field. In the most cases, FTIR spectroscopy is routinely used for characterization of liquid or solid samples. A resolution of the order of several cm^{-1} is adequate for this purpose. On the other hand, a high resolution measurement is time-consuming (investigated object can change its properties) and problem with signal/noise ratio appears in the case of low sample concentrations. Therefore resolution of 1 cm^{-1} or several cm^{-1} is often used for plasma diagnostics [2,4-6]. Of course, the better resolution the higher peak intensity of the narrow rovibrational bands; computer modelling (taking into account apparatus function of the spectrometer and correct parameters of absorption lines) has to be used for determination of molecule concentration [5].

Nanometer-sized metallic particles in various matrixes have been studied extensively in recent years because of their interesting properties and their possible applications. From the spectroscopic point of view, effects like surface enhanced Raman scattering (SERS) and surface enhanced infrared absorption (SEIRA) in systems containing silver particles are well-known. Composite material Ag/C:H based on polymer-like hydrocarbon matrix is one of many investigated systems containing silver nanoparticles. The composite materials can be prepared by a plasma polymerization with simultaneous metal sputtering, e.g. using a planar magnetron [7-9]. In our experiments the working gas was a mixture of argon and *n*-hexane vapour. Properties of the deposited films depend on concentration, size and shape of silver inclusions. Recently we reported dependence of deposition rate and properties of the films on the coverage of the silver electrode (i.e. magnetron target) by solid products of reactions in gaseous phase [10]. We employed both *in situ* and *ex situ* infrared spectrometry for characterization of the films deposited on mirror substrates (infrared reflection – absorption spectroscopy IR RAS) or on silicon wafers (transmittance measurements). In this paper we report infrared transmittance and emission measurements of the gaseous phase during the film deposition.

2. Experimental

Plasma polymerization and co-sputtering of silver proceed in a small vacuum chamber (inner diameter 190 mm, volume 4.7 dm^3). The silver target (diameter 75 mm) is a component of an unbalanced magnetron equipped with a ring of ceramic permanent magnets and with a mild steel magnetic circuit [11]. The chamber was pumped by rotary and diffusion pumps, pressure was measured by MKS Baratron 626 gauge and the

discharge was powered by an Advanced Energy MDX500 DC supply. Typical parameters of the discharge were: mixture of argon and n-hexane vapour as the working gas (air added in some cases); typical total flow rate 5 ccm(STP)/min., total pressure 3 – 30 Pa; current 0.1 A, power 30 – 45 W. Films were deposited on glass substrates and silicon wafers for IR transmittance measurement. The substrates were placed on a holder at a distance 80 mm from the magnetron target. Before each deposition the silver target was cleaned mechanically by an emery paper, washed by ethanol and additionally cleaned by an intensive sputtering in argon plasma (magnetron current 0.5 A for 5 minutes).
The infrared spectra were measured by Bruker IFS 66S spectrometer (beamsplitter KBr, detector MCT with cutoff wavenumber 800 cm^{-1}, the best resolution 0.15 cm^{-1}). The vacuum chamber was equipped with two KRS5 windows protected against film deposition by conical-shaped covers. Both transmittance and emission measurements were performed using focusing optics. The focus was localised in the centre of the chamber, 20 mm above the substrate. The transmittance spectra of the films were measured *ex situ* several minutes after the samples were taken out of the chamber.

3. Results and discussion

Absorption in gaseous phase

In our previous deposition experiments we usually used pressures 1 – 2 Pa. However, the higher pressure in the chamber the better spectra can be obtained. The spectra measured at the pressure 4 Pa of the mixture argon : *n*-hexane = 85 :15 with spectral resolution 0.2 cm^{-1} and 2 cm^{-1}, respectively, are shown in Fig. 1. The spectra for the total pressure 30 Pa in Fig.2 measured with resolution 0.2 cm^{-1} give more informations. About 80 - 90 % hexane is decomposed in the discharge. Absorption bands of methane CH_4, acetylene C_2H_2 and ethylene C_2H_4 can be distinctly recognized in the spectra. Methane, acetylene, carbon monoxide CO, carbon dioxide CO_2 and hydrogen cyanide HCN were identified in the discharge products for mixtures argon/hexane/air. HITRAN molecular spectroscopic database [12] was used for the identification. The absorption bands created by overlapping of many molecular transitions (not resolved in our spectra, e.g. 729 cm^{-1} for acetylene, 712 cm^{-1} for hydrogen cyanide or 3018 cm^{-1} for methane) are the most distinct lines for resolution 2 cm^{-1}. The strongest simple rovibrational lines of the small molecules can be seen in the spectra measured with 0.2 cm^{-1} as well.

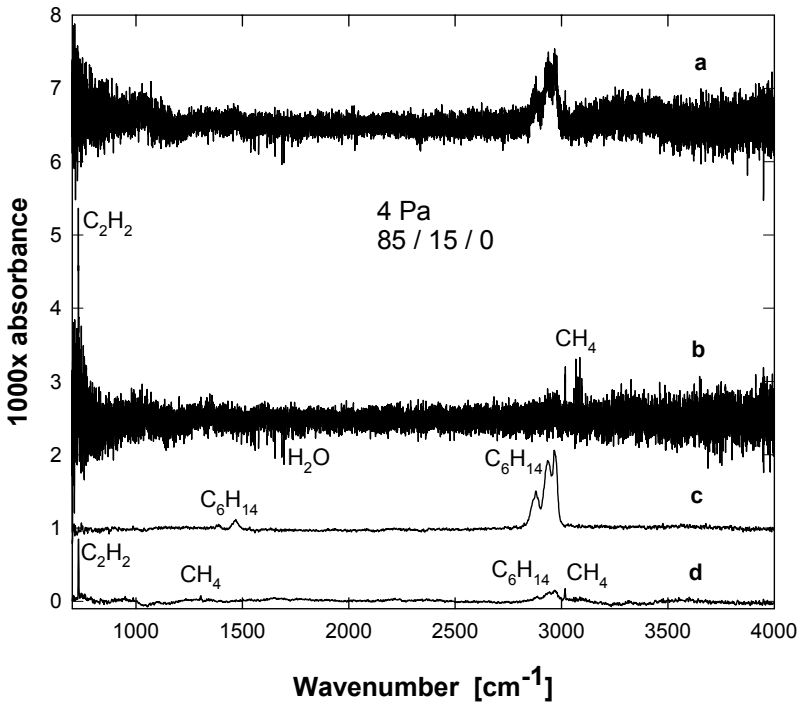

Fig.1. Absorption spectra of the gaseous phase measured with resolution 0.2 cm^{-1} (curves a,b) and 2 cm^{-1} (c,d) without the discharge (a,c) and during the discharge (b,d). The total pressure 4 Pa, composition argon : hexane = 85 : 15, discharge current 0.1 A, input power 32 – 36 W. Time of measurement 5 minutes in all cases.

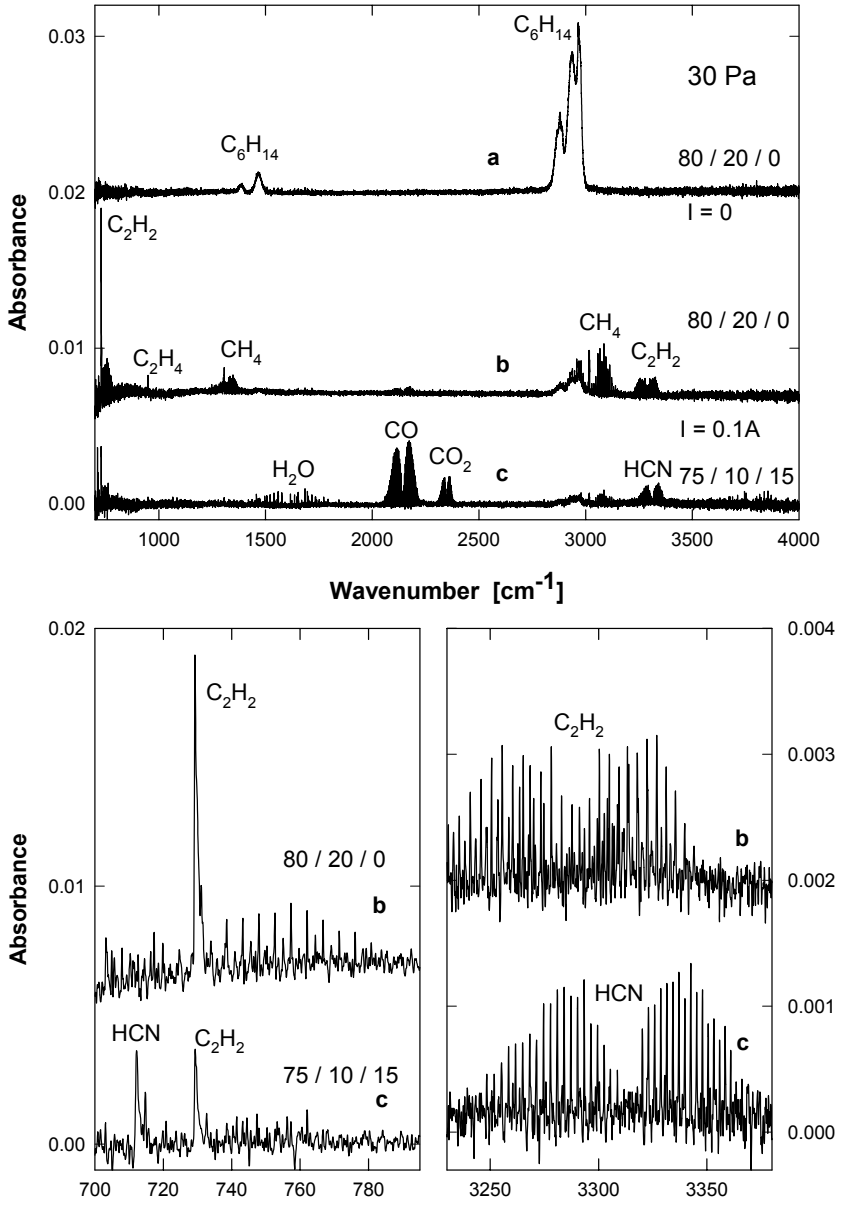

Fig. 2. Absorption spectra of the gaseous phase without discharge (a) and during the discharge (b, c). The composition of the gas is shown in the form argon / hexane / air. Total pressure is 30 Pa, electric current 0.1 A.

Emission of IR radiation by CO

We observed a line emission in the range 2000 – 2200 cm^{-1} superimposed on a background continuous room temperature thermal radiation. The absorption in this range (see Fig. 3a) is due to rovibrational transitions from the lowest vibrational state ν=0 of CO molecules to the first excited one ν=1 with the change of rotational quantum number $\Delta J=-1$ (branch P) and $\Delta J=+1$ (branch R). The emission corresponds to the inverse transitions from ν=1 to ν=0 (e.g. spectra d, h in Fig. 3), but a relatively strong contribution of transitions from ν=2 to ν=1 can be recognized in many spectra (e.g. c, i in Fig. 3). The vibrational temperature can be estimated to be higher than 2000 K if we take value 1/2 for the ratio of intensity of the transitions from higher vibrational level (from ν=2 to ν=1) to the intensity of transitions from ν=1 to ν=0. The estimation is based on Boltzmann distribution function taking into account that matrix elements for transition ν=2 to ν=1 are almost twofold than those for ν=1 to ν=0 transitions. On the contrary, the rotational temperature does not differ from 300 K remarkably. It should be emphasized that the emitted radiation was collected from the space near the substrate, relatively far from the magnetron electrode.

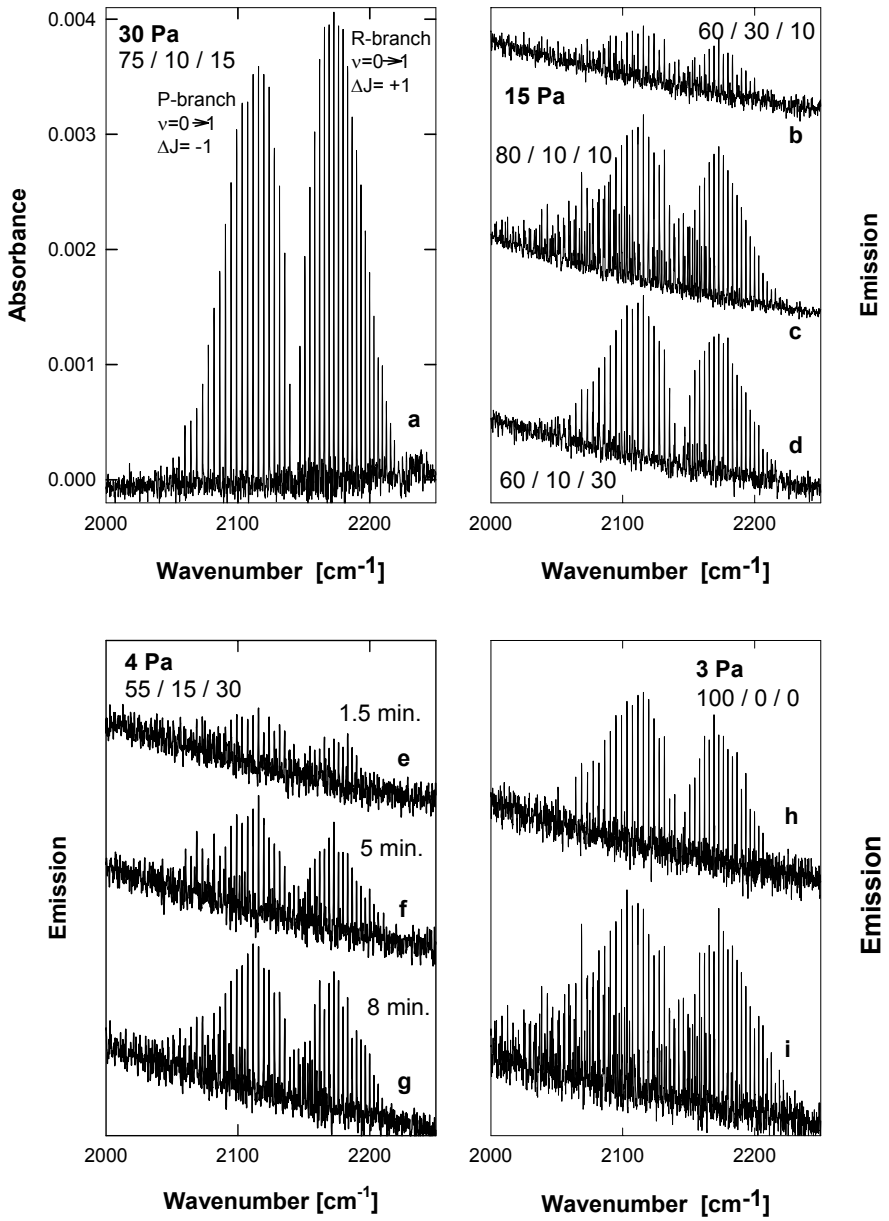

Fig. 3. Absorption and emission of carbon monoxide. Spectra a – d were recorded for various gas mixtures. Spectra e, f, g illustrate an evolution of the emission during one deposition. Spectra h, i were collected during initial stage of target cleaning in argon discharge with current 0.5 A (h - target with thick carbon cover, i - mechanically cleaned target); this emission was disappearing during several minutes.

The emission spectra are changing during the discharge on the time scale of minutes. Their intensity increases at lower pressures with air excess in the mixture (curves e, f, g in Fig. 3). On the contrary, their weakening or gradual vanishing is observed for *n*-hexane-rich mixtures. It seems that hexane and/or products of its reactions suppress all emission transitions (spectrum b), while air inhibits only transitions from the higher vibrational states $\nu = 2$ (spectrum d).

Spectra of the films

"Surface enhanced infrared absorption" (SEIRA) is well-known effect observed in various systems containing nanoparticles of some metals, including silver. Absorption bands caused by vibrations of atomic groups placed tightly near the metallic inclusions and with dipole moment perpendicular to the surfaces of metal particles are greatly enhanced. It is also the case of the composite films Ag / C:H. Vibration spectra of the deposited films were deduced from the transmittance measurements. Silicon substrate absorption was

subtracted and a subjectively chosen background correction was performed to eliminate contributions of an antireflection effect and a broad absorption tail of the silver – plasmon absorption with maximum in the visible region. The treated spectra are shown in Fig.4. Time of deposition was 10 minutes and the silver target of magnetron was cleaned before each deposition. All spectra were measured immediately (in 5 minutes) after removing the sample out of the chamber. A decrease of deposition rate with increasing pressure is considerable: from 30 nm/min for total pressure 4 Pa to 3 nm/min for 15 Pa.

As shown in our previous *in situ* investigation of samples deposited at a pressure 1 – 2 Pa, the spectra are very quickly changing just during first several minutes when the films are exposed to the ambient air. Namely the following absorption bands strengthen:

a) bands near 830 cm^{-1} (carbonate ions CO_3^{2-} bonded to silver particles with their plane parallel to metallic surface),

b) broad band around 1400 cm^{-1} (symmetric stretching of carboxylate ions OCO^- bonded to silver particles) and around 1550 cm^{-1} (antisymmetric stretching of the same ions),

c) bands in region from 1950 cm^{-1} to 2200 cm^{-1} (various types of carbonyl bonding to the silver).

Aging in the air (time scale days or weeks) caused some changes in the spectra:

1) carbonate groups oriented planparallel to the silver inclusions surface vanish,

2) absorption of carboxylate groups is strongly increased,

3) type of carbonyl bonding to silver is changed (possibly from a bridge configuration on the surface of Ag-inclusions to a linear one and/or to cations Ag^+ dispersed in the polymer matrix).

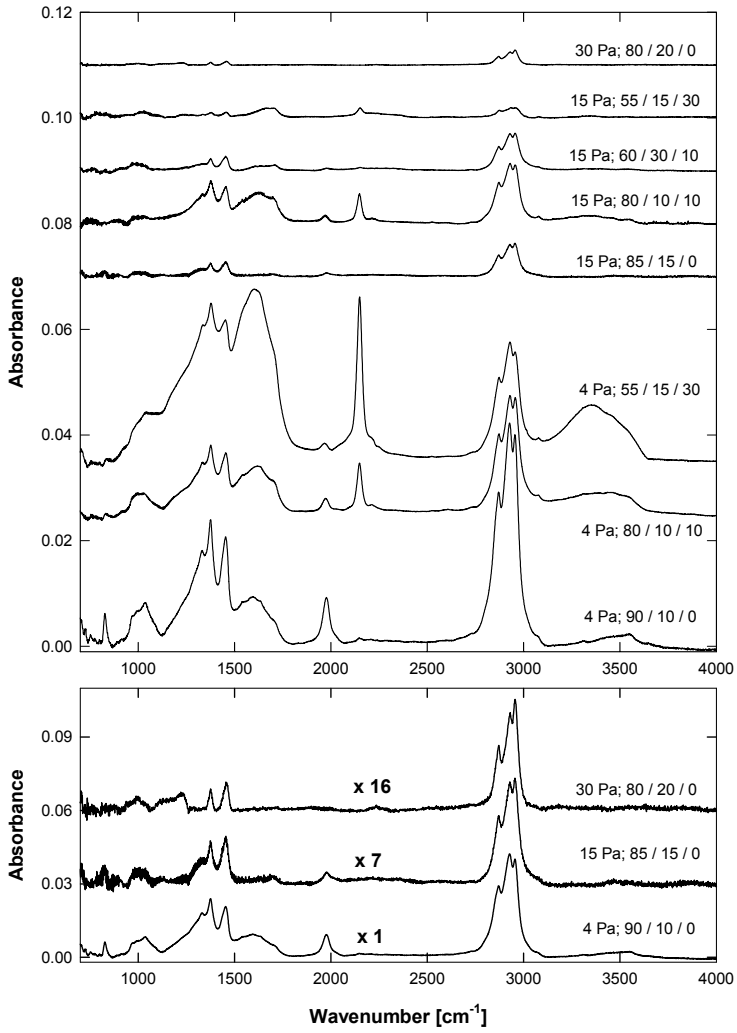

Fig. 4. Absorption spectra of the deposited films. The spectra are shifted in the upper part and normalized and shifted in the lower part of the figure. Total pressure and composition of the input gaseous mixture (argon/hexane/air) is given for the respective curves.

Similar bands are observed in the films deposited using the mixture argon/*n*-hexane/air. The effect of adding air into the gas mixture for discharge resembles the long-time aging of the films deposited from argon/*n*-hexane mixture. There is an exception: the films deposited in the mixture argon/*n*-hexane/air reveal much more intensive antisymmetric stretching band OCO^- ions. This can be explained by orientation of carboxylate groups which become more inclined relatively to the silver particle surface. It may be a consequence of a changed surface geometry and composition resulting from a higher oxidation of the silver inclusion surfaces.

It seems that role of the silver particles in the observed spectra becomes less important with increasing the total pressure. Absorption bands caused by hydrocarbons constituting polymer matrix prevail in these films. The absorption of CH_3 groups (near 2960 cm^{-1}) becomes stronger comparing to CH_2 groups (2930 cm^{-1}). This may be caused by creation of shorter molecular chains at higher pressures. Moreover, deposition rate is reduced substantially as mentioned above.

Another question is the incorporation of nitrogen in the films. Gaseous phase spectra showed a production of HCN in the discharge containing air. Unfortunately, the observed broad band infrared absorption (typical for disordered systems like plasma polymers) is not able to resolve oxygen- and nitrogen-containing groups because of an overlap of characteristic wavenumbers (e.g. OH and NH stretching above 3000 cm^1 or many possible types of vibrations in spectral region 1500 – 1700 cm^{-1}).

Conclusions

About 80 - 90 % *n*-hexane is decomposed in the discharge. The most IR-active gaseous products of reactions in plasma are methane CH_4 and acetylene C_2H_2 for gaseous mixture argon/hexane. The absorption of carbon monoxide CO, carbon dioxide CO_2, hydrogen cyanide HCN, acetylene C_2H_2 and methane CH_4 was observed in the discharge spectra in the mixture argon/*n*-hexane/air. Remarkable non-equilibrium between vibrational and rotational states occupation was found in the emission spectra of carbon monoxide. It depends not only on composition of the mixture but also on the cover of the magnetron target by solid products of plasma reactions. Rate of deposition of the films becomes lower with increasing total pressure. Spectra of the films deposited from mixture argon/*n*-hexane/air reveal some similar features to the aged films of Ag/C:H.

Energy dispersive X-ray diffraction (EDXRD) is a well-established method for the investigation of phase changes of powdered materials under high pressure and/or high temperature [1]. Recently, this technique was introduced by us for the in situ-investigation of thin film growth during reactive magnetron sputtering [2].
In the present work this method is used for the investigation of nucleation and growth of thin molybdenum and tungsten disulfide films, which are of interest as absorber materials for thin film solar cells [3]. These semiconducting materials belong to the class of layer-type van der Waals compounds, like graphite or mica.
For these experiments an situ-magnetron sputtering chamber was installed at a bending magnet beam line of the synchrotron radiation source DESY-HASYLAB in Hamburg (Germany). White synchrotron light hits at a small angle the growing film on a silicon substrate. The diffracted beam, observed under diffraction angles between 3 and 10 ° exits the chamber via a Kapton foil and is energy analyzed by a high purity Ge detector. The whole diffraction spectrum can be measured in short data collection times of between 10 to 30 sec, thus allowing time-resolved growth studies.
The balanced magnetron sputtering source at a distance of 6 cm from the substrate was excited either by DC or RF (13,56 MHz). For the characterization of the film growth the following quantities are used, which can be extracted from the EDXRD spectra:

- pattern of the diffraction peaks (phases, texture)
- energetic positions of the peaks (lattice constant, mechanical strain and stress)
- width and form of the diffraction lines (grain size, micro stress in the grains).

Furthermore, the fluorescence lines of Mo or W can be used to monitor in situ the growth rate of the films (in atoms/cm^2).
We found, that the growth of the layer-type compounds depends significantly on the deposition conditions, especially on the deposition rate and on the substrate temperature. At low growth rates and/or high temperatures the films exhibit a pronounced (001) texture, where the van der Waals planes are oriented parallel to the substrate surface. By varying the total sputtering pressure it was investigated if the energy of the sputtered or reflected particles (neutral argon) contributes significantly to the growth mode. It turned out, that the energy of the particles does not influence the film formation to a large extend in the pressure region investigated (0.5 to 9 Pa). At high deposition rates and/or low substrate temperatures the growth starts again with the (001) orientation. But after some 10 nm a texture cross-over occurs and a combined (100)(101) texture dominates the EDXRD spectra, where the van der Waals planes are vertically oriented, leading to a pronounced dentritic film structure. It is assumed that the vertically oriented lamella originate at defects (dislocations, stacking faults), which are likely to be formed in these materials due to the weak van der Waals bonding along the (001) direction. Due to the much higher growth rate along the (100) direction compared to the (001) direction, this cross-over can not be reversed once it occured.
In order to prepare (001)-textured films of these van der Waals compounds the orientations of the nuclei have to be preserved up to the desired film thickness by a low growth rate at high temperatures. The EDXRD method is a powerful tool for the in situ-investigation of thin film growth. The EDXRD results are complemented by morphological results obtained by scanning and transmission electron microscopy.

Abstract
Composite films were deposited by rf co-sputtering of Ag or SiO_2 and PTFE or PE(PP) targets, respectively. Characteristics of sputtered Ag/hydrocarbon plasma polymer films correspond to the properties of composite metal/dielectric films. Composite SiO_x/fluorocarbon plasma polymer films reveal various wettability (static contact angle of water from 41° to 68 °) and hardness (from 3100 N/mm^2 to 720 N/mm^2). Composite SiO_x/hydrocarbon plasma polymer films have similar properties - the hardness seems to be generally lower.

1. Introduction
Composite films with plasma polymer matrix have been studied for several decades [1,2]. In the most cases – metal/plasma polymers have been in the center of the attention [1-3]. These can be prepared by several techniques – one of them is co-sputtering from composite metal/polymer target. Metal/fluorocarbon plasma polymer films [1-3] and metal/hydrocarbon plasma polymer were prepared using Pt-10 %Rh or Au or Cu/PTFE composite target [4]. In the other case Ekonol - (trade name of Carborundum Co) that is an aromatic polyester was used instead of PTFE [4].
More complex composites such as SiO_x/fluorocarbon plasma polymer were prepared by ion beam co-sputtering [5] and by plasma polymerization [6,7]. The intention was to apply the composite films mainly as protective coatings. Recently, these films were deposited using rf magnetron equipped with a composite SiO_2/PTFE target [8]. Composite films SiO_x/hydrocarbon plasma polymer or a-C:H prepared by plasma polymerization of HMDSO and a hydrocarbon gas have been investigated [9-11]
In this contribution rf co-sputtering from the two magnetrons equipped with Ag or SiO_2 and PTFE (Polytetrafluoroethylene) or PE (Polyethylene) and PP (Polypropylene) targets, respectively, was used in order to prepare composite films Ag/hydrocarbon plasma polymer, SiO_x/fluorocarbon plasma polymer and SiO_x/hydrocarbon plasma polymer. Deposition processes and basic characterization of the composite films are discussed below.

2. Experimental
The composite films were deposited in argon as a working gas at a pressure 5 Pa and a flow rate 25 cm^3 (STP)/min. The experimental set-up consists of two balanced magnetrons 78 mm in diameter each, sitting next to each other with the 90 mm distance between their centres. Ag and PE (PP); SiO_2 and PTFE (Goodfellow LTD); SiO_2 and PP (Goodfellow LTD), targets in the form of the disks were placed on the top of respective magnetrons.
The substrates were located 40 mm above the magnetrons. The specially designed substrate-holder enabled us to move (oscillate) the substrates in a horizontal plane above the magnetrons and thus to deposit the films with improved thickness homogenity in contrast to the previous case [8].
The parameter that controls the amount of respective component (Ag and PP, SiO_x and PTFE and etc.) in the film, is the deposition rate of the respective material given by the applied power to the magnetron. The deposition rate of each magnetron was controlled by quartz crystal microbalance heads (QCM) sitting above the magnetrons at the same level as the substrates. The calibration measurement was carried out earlier and it is described in [8].
The films were characterized by X-ray Photoelectron Spectroscopy (XPS), Fourier Transform Infrared Spectroscopy (FTIR), Atomic Force Microscopy (AFM), microhardness, and static contact angle of water.
Wettability was examined on composite films deposited on glass substrates. The contact angle of the water drops (about 2 mm in diameter) was measured with a contact angle meter (self built) by a sessile drop method at a temperature 18-20 °C in the air. The contact angle was measured in the the static mode when the

constant time (1 min) passed after dropping of water. The average angle values have been estimated from the three different points measured in the middle of the samples.
XPS measurements were performed using Kratos Axis 165 apparatus in a monochromatic Al K_α hybridmode, which means that both electrostatic and magnetic lenses were used.
The FTIR-RAS was performed on Nicolet Impact 400 spectrometer. For this measurement the films were deposited on Au precoated glass substrates. The film hardness was measured by an ultra-microindenter Fischerscope H-100 B.

3. Results and Discussion

Composite Ag/hydrocarbon plasma polymer

The films Ag/sputtered PP were deposited at 5 Pa of Ar, flow of Ar cm^3STP/min and powers ranging from 3 to 15 W for Ag and 30 to 60 W for PP targets, respectively. The films were deposited on glass substrates and carbon foils supported by Cu grid for TEM measurements.
Morphology of composite films Ag/sputtered PP or PE resembles those found for Ag/hydrocarbon plasma polymer prepared by dc magnetron sputtering of Ag in a working gas mixture of Ar and n-hexane[12] i.e. the film consists from Ag clusters embedded in a hydrocarbon plasma polymer matrix. The same optical anomalous absorption was found and dc electrical behavior. The dc electrical conduction increases with the filling factor f (volume fraction ratio) of Ag by several orders of magnitude revealing the percolation threshold approx. at f =0.4. The films are futher considered for antibacterial effects.

Composite SiO_x/fluorocarbon plasma polymer

The most attention was paid to composite SiO_x/fluorocarbon plasma polymer films. The deposition parameters are shown in Table 1.

Table 1. The deposition conditions.

Parameter	Value
Pressure of working gas: p	5 Pa
Flow rate of working gas: F	25 ccmSTP/min
Working gas	Ar
Power delivered to the magnetron with SiO_2 target: P_{SiO2}	25-160 W
Power delivered to the magnetron with PTFE target: P_{PTFE}	35-145 W
Deposition time: t	20 min
Substrate-target distance: d	4 cm

The deposition experiments were performed at different ratios of the applied powers to the magnetrons (P_{PTFE}/P_{SiO2}) (see Tab.1) at a constant oscillation velocity of the substrates.
The static contact angle of water measured on the resulting composite films increases steadily from 41° for film prepared at a power ratio P_{PTFE}/P_{SiO2} = 1/12 to the value 68° for film prepared at P_{PTFE}/P_{SiO2} = 10/1 (the contact angle on silica is ~27° and on PTFE it is ~109°). As it can be seen from Fig.1 the hardness values were found from 3100 N/mm^2 (1 mN load) to 720 N/mm^2 (1 mN load) in the above mentioned range of the power ratio. The films are rather smooth according to AFM – the roughness R_a is between 2 and 6 nm.
The infrared spectra of the fluorocarbon films are shown in Fig. 2. The spectra of the films prepared at the low P_{PTFE}/P_{SiO2} contain mainly the absorption bands coming from silicon-oxygen bond formations. The intensive asymmetric Si-O-Si as well as less intensive O-H, Si-O stretching vibrations are detected at 1080 cm^{-1} , 950 cm^{-1} and 795 cm^{-1} [13], respectively (see Fig. 2A, B).
With increasing PTFE content in the investigated samples, the asymmetric and symmetric CF_2 bands appear at 1230 cm^{-1} and 1150 cm^{-1}, respectively (Fig. 2C). At the moderate fluorocarbon concentrations the contributions from both SiO_x and CF_2 vibrations produce the total peak envelope in the range 900-1200 cm^{-1} (see Fig.2C). The following increase of fluorocarbon content leads to the disappearance of SiO_x response. Thus, only peaks related to CF_2 contributions are dominant over the whole spectrum (see Fig. 2D). In

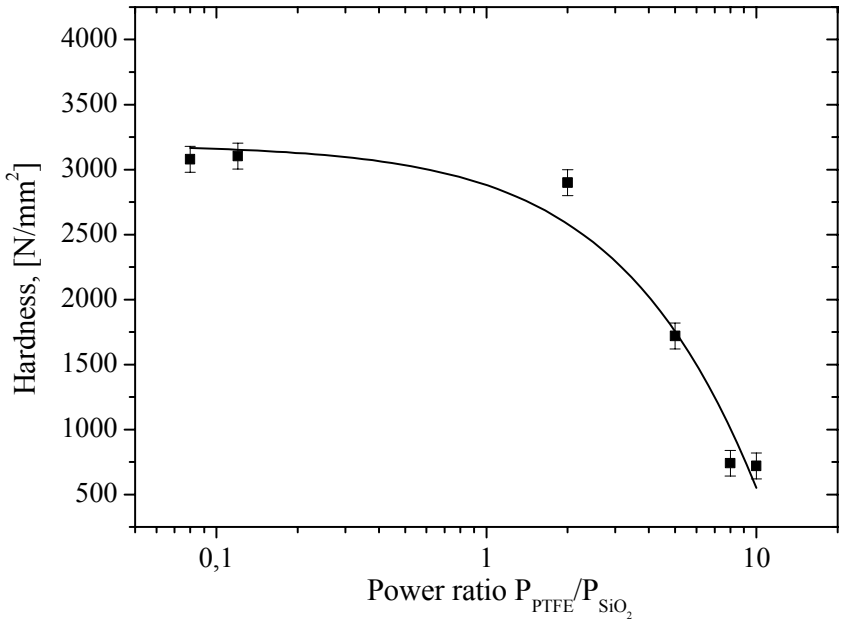

Fig.1. The dependence of film hardness on the applied power ratio.

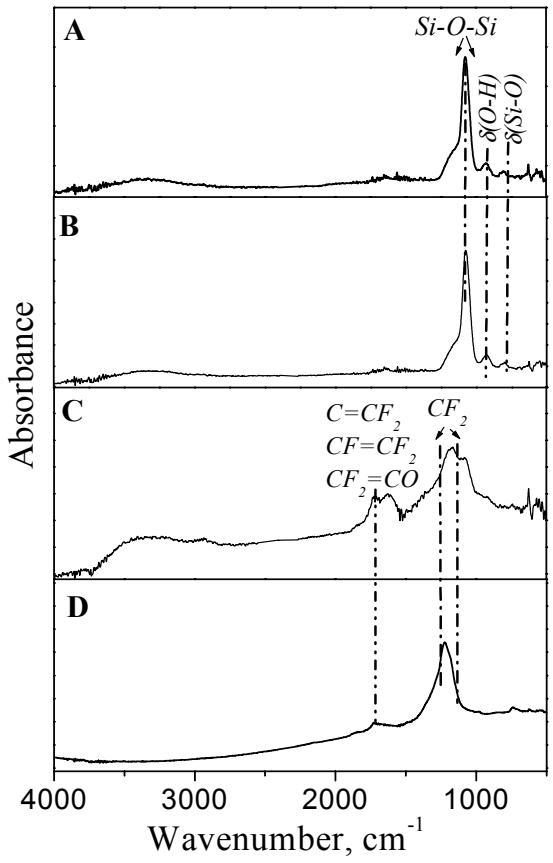

Fig.2. FTIR spectra of the films deposited at different P_{PTFE}/P_{SiO2} power ratios: 0.08 (A), 0.5 (B), 2 (C), 10 (D).

addition, the peaks corresponding to C=CF, $CF=CF_2$, CF=O vibration groups contribute to the FTIR spectrum.

The elemental composition obtained by XPS analysis is shown in Fig.3. One can see that the samples prepared at power ratios from P_{PTFE}/P_{SiO2} = 1/12 to P_{PTFE}/P_{SiO2} = 1/2 are composed from the two distinct components SiO_x and a fluorocarbon plasma polymer that is very deficient in fluorine (C:F ~ 4). However, part of carbon is likely bonded also to oxygen as may be seen from high resolution C1s spectra. It has been formerly observed that in some composite films with fluorocarbon plasma polymer matrix – namely gold/fluorocarbon plasma polymer the deficiency in fluorine increases with the increase of gold concentration and also it increases from the film bulk towards the surface [1]. In addition during the deposition process a reaction between Si and F may be expected that leads to creation of SiF_4 that is volatile at a room temperature and is removed from the reactor by pumps. This may also explain remarkable decrease of Si for power ratios P_{PTFE}/P_{SiO2} = 2/1 and 5/1 and occurence of only traces of Si for 8/1. The decrease of fluorine concentration is also seen. For power ratio 10/1 sudden increase of F was found that is not yet explained. Therefore these films prepared at higher ratios of powers (fluorocarbon dominated) can be viewed as a very oxidised fluorocarbon plasma polymers deficient in fluorine. However, some post deposition oxidation especially on the sample surface my happen at ambient atmosphere when transferring the samples for XPS measurements.
High resolution Si2p spectra show the peak at 103.5 eV that indicates that Si is bonded to oxygen. No Si-F bonding environments at higher binding energies or Si-C at lower energies was found. This suggests together with some AFM and EFM observations that especially for power ratios P_{PTFE}/P_{SiO2} from 1/12 to 1 the structure of the composite film is not homogenous but has a heterogeneous character probably regions of SiO_x dispersed in a fluorocarbon plasma polymer matrix that is also partly oxidised. However, bulk

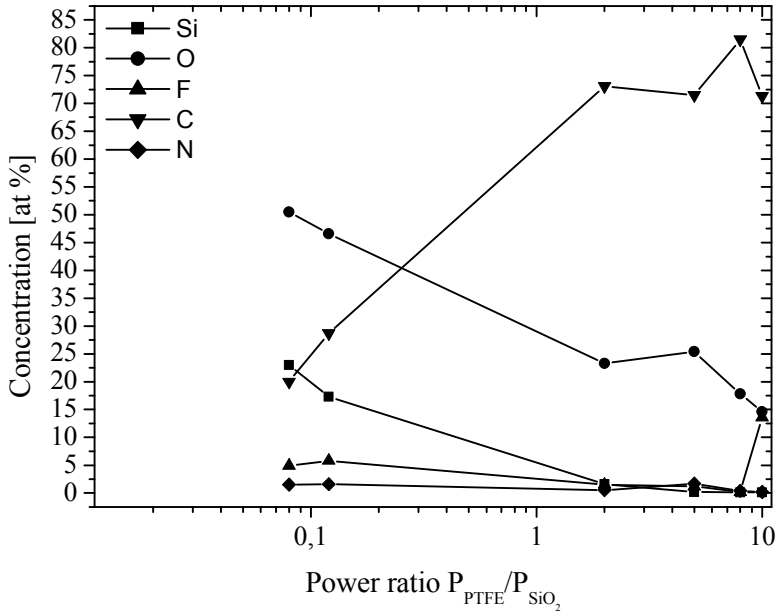

Fig.3. XPS elemental composition of composite SiO_x/fluorocarbon plasma polymer

elemental profiles by RBS/ERDA will be attempted in order to confirm if the XPS surface analyses is valid for the whole bulk of the film.

Composite SiO_x/hydrocarbon plasma polymer
These films were deposited as described above. The infrared data showed similar results as those for SiO_x/fluorocarbons. AFM observations showed similar roughness as before – the films are more or less smooth. Static contact angle is presented in Fig.4. It changes from 33° to 80° and this reflects the ratio of SiO_x and

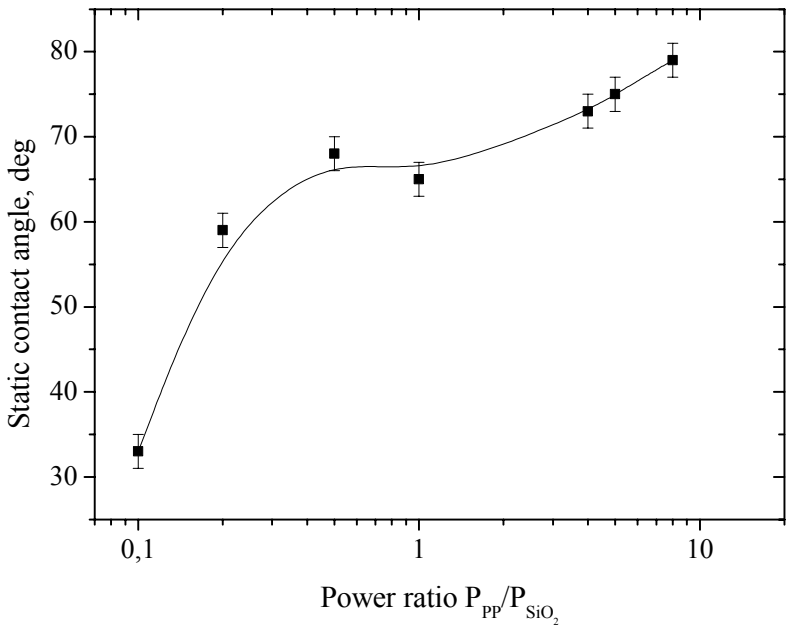

Fig.4. The dependence of static contact angle on the applied power ratio

hydrocarbon plasma polymer components in the composite. The hardness measured at the load 1 mN was found from 1000 N/mm^2 to 1800 mN/mm^2 .

4. Conclusions

Composite films with plasma polymer matrix were prepared by rf magnetron sputtering. Sputtered PP or PE films containing silver were found to be a type of composite Ag/hydrocarbon plasma polymer films. Composite films SiO_x/fluorocarbon plasma polymer were found to have very likely a heterogeneous structure. Contact angle of water increases from 41 ^{o} (high SiO_x contents) to 68 ^{o} (low SiO_x contents). Hardness decreases from 3100 N/mm^2 to 720 N/mm^2. Composite films prepared by co-sputtering of PP and SiO_2 possess various hardness (in the range from about 1000 N/mm^2 to 1800 N/mm^2) and vettability (static contact angle from 33 ^{o} to 80^o).

Abstract

Acoustic waves produced by the filamentary discharges developing in a point-to-plane dielectric barrier discharge in air at atmospheric pressure are used for an evaluation of the mean gas temperature in the discharge volume at its lowest level, just before the ignition of new filamentary discharges. Of crucial importance for the chemistry developed by the discharge, as it is typically the case for ozone production, this temperature exhibits values for instance ranging from room temperature to 780 K while the plasma temperature varies between 450 K and 1020 K.

1 Introduction

A thermal macroscopic equilibrium is obtained in a plasma reactor when a balance is reached between the heat input and the heat losses.

Let us here consider the case of dielectric barrier discharges traditionally used for ozone production. Heat losses depend on the external parameters such as the feed gas (air) temperature, flow rate, velocity and injection mode on the one hand, and as the reactor walls and dielectric barrier thermal conductivities on the other hand. Note that a feedback mechanism of the electrodes and of the dielectric temperatures on the electrical and physical properties of the discharge is often observed. The heat input comes from the energy injected in the discharge. In a dielectric barrier discharge, the gaseous gap is alternatively heated and cooled. When the discharge parameters, such as the injected energy, its current characteristics, its plasma temperature, its gaseous products concentrations, exhibit steady state values, a local thermal equilibrium is reached. The plasma temperature can be evaluated through rotational temperature measurements performed inside the transient filamentary streamers by means of emission spectroscopy [1], but the reactive volume temperature is periodically evolving between an upper limit, the plasma temperature measured during the emissive phase, and a lower limit, the neutral gas temperature just before the occurrence of any filamentary discharge. Focussing on a filamentary discharge developing in a gaseous gap with a 10 kHz repetition rate, it is worthy of note that the plasma phase (≈ 100 ns duration) only represents 0.1% of the period duration.

Since the time scale for ozone formation at atmospheric pressure is higher (5-15 µs) [2], the temperatures to be taken into account for the reactions kinetics are intermediate between both of the two limit values.
Results presented in this paper correspond to an attempt to evaluate the lower limit value for different repetition rates of the current pulses of the discharge, i.e. different local thermal conditions, through the analysis of the acoustic waves emitted by the filamentary discharges. The current interpulse duration will be controlled, independently of the applied electrical field value, by using pulsed high voltage signals with different repetition rates.

2 Experimental set-up and measurements

2.1 Experimental set-up

A schematic block diagram of the complete experimental set-up is given in Fig. 1. Three groups of measuring devices take place around the discharge cell itself, allowing the simultaneous monitoring, each one with its own time resolution constant, of the (i) discharge voltage/current signals, (ii) plasma temperature and (iii) discharge acoustic signal.

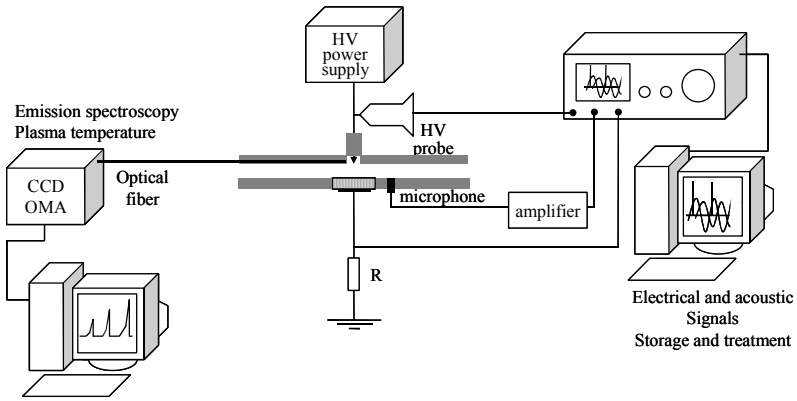

Figure 1 : Experimental set-up

The discharge reactor (Fig. 2) consists of a point-to-plane electrode system (Fig. 2). The high field electrode (point of ~ 50 µm radius of curvature) made of stainless steel is connected to the high voltage power supply. The plane grounded electrode made of brass is covered with a dielectric barrier (alumina-silicate ceramics 3 mm thickness). The gas gap length between the active electrode and the dielectric barrier surface is fixed to 2 mm. Experiments are performed in ambient air at room temperature.

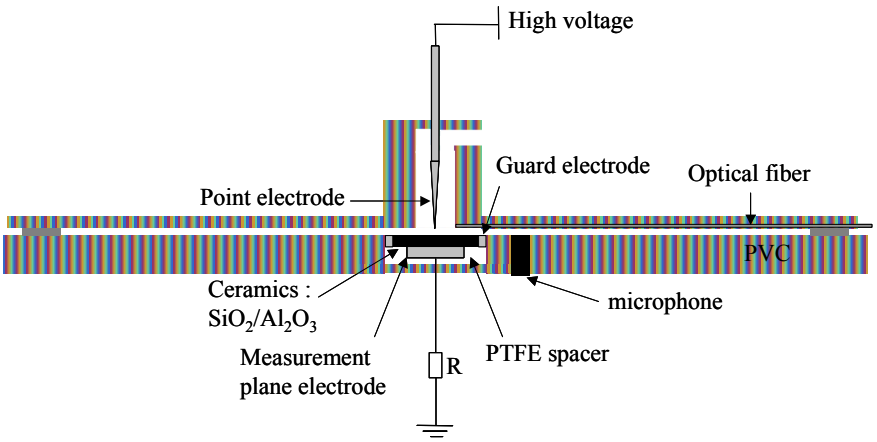

Figure 2 : Discharge reactor

2.2 Electrical measurements

Electrical measurements are carried out using a Lecroy LC347A 500 MHz - 2 GS/s numerical oscilloscope. A Lecroy 1000:1 100 MHz high voltage probe provides the voltage signal $v_1(t)$ applied to the high field

electrode. The measurement brass plane electrode is connected to ground through a 50 Ω resistor ; so the discharge current signal corresponds to the time resolved voltage $v_2(t)$ obtained on this resistor. The dielectric surface is limited by a guard electrode connected to ground. For the study of the discharge current signal itself, an accurate electrical analysis is realized with a numerical data treatment [3] which after eliminating the capacitive current, allows a fine analysis of the active components of the discharge current : the pulsed current and the pseudo continuous current - sometimes qualified of synchronous current (synchronous with the applied voltage).

2.3 Temperature measurements

Temperature measurements are performed by emission spectroscopy using a CCD detector coupled to an Optical Multi-channel Analyzer (OMA). This technique allows the evaluation of the rotational temperature reached in the filamentary discharge plasmas developing in air at atmospheric pressure by the excited molecular nitrogen. The $C^3\Pi_u$ excited state used for this purpose is produced through direct electron impact with the nitrogen molecule in its fundamental state :

$$e + N_2(X^1\Sigma_g^+) \rightarrow N_2(C^3\Pi_u) + e \qquad (1)$$

As this transition is quasi-instantaneous in our working conditions, the population distribution on the rotational level of the $C^3\Pi_u$ state can be considered as representative of the population distribution on the rotational level of the $X^1\Sigma_g^+$ state. Due to quenching effects with the neutral gas, the molecular excited state has, at atmospheric pressure, a lifetime of the order of 0.5 ns. The radiative desexcitation corresponding to the $0 \rightarrow 1$ band of the second positive system, i.e. the transition

$$N_2(C^3\Pi_u) \rightarrow N_2(B^3\Pi_g) + h\nu \qquad (2)$$

is used to determine the rotational temperature of the $C^3\Pi_u$ state, and by identification, the rotational temperature of the fundamental state, i.e. the neutral gas temperature. These measurements so provide an evaluation of the temperature of the plasma gas itself, in the filamentary discharge, where thermodynamic equilibrium does not exist.

2.4 Acoustic measurements

For measuring the acoustic pressure, a Brüel and Kjaer (B&K) 1/4 inch condenser microphone type 4938 (pressure field response) is used with a B&K microphone amplifier (Nexus). The microphone is flush-mounted and measures the actual sound-pressure level at the plate surface.

3 Results - Discussion

3.1 The acoustic signals

In a first approach, the interpulse duration is chosen long enough to minimise overlapping effects of the acoustic signal from a period to the following one. This is obtained with a pulsed voltage signal working at low frequency (≈ 3.5 kHz) and inducing the development of a single discharge channel per period, to which a single current pulse is associated, as it can be seen in Fig. 3.

Now focussing on the acoustic wave signal, it is worthy of note that this signal is resulting from the overlapping of the source phenomenon with reflection waves : as a matter of fact, the first overpressure peak is associated to the primary acoustic wave, the following overpressure peaks corresponding to reflection waves strongly dependent on the geometry of the upper part of the reactor. Furthermore, in the same figure, one can observe that the magnitude of the first overpressure peak is linked to the amplitude I of the current pulse. This first phenomenon here observed in unstable conditions will be now more systematically investigated for a steady state discharge regime.

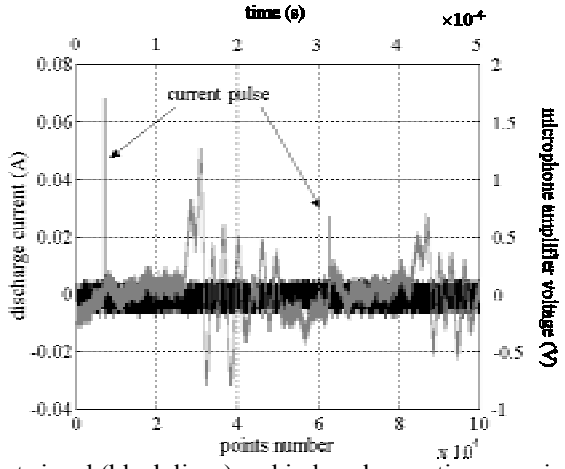

Figure 3 : Discharge pulsed current signal (black lines) and induced acoustic wave signal (grey lines). Acoustic pressure A_a(Pa) = 2.61 × microphone amplifier voltage (V). (V_p = 6.4 kV, F = 3.5 kHz, ambient air atmospheric pressure).

3.2 The acoustic signal as a function of the discharge current at a fixed "low" frequency (3.5 kHz)

For a same discharge repetition rate, governed by the pulsed high voltage repetition rate and inducing the development of a single discharge per period, one can increase the current pulse amplitude I by increasing the peak voltage amplitude V_p. When plotting the overpressure magnitude ΔP, i.e. the acoustic wave amplitude A_a, as a function of the current pulse amplitude I, as shown in Fig. 4, a linear correlation is obtained.

A consistent theoretical and experimental work has been done in the years 1980 on the acoustic emissions of atmospheric pressure arc discharges [4]. The acoustic equations are obtained from a first order expansion of the fundamental equations of dynamics for neutral particles. Assuming the neutral particles gas as an ideal gas, adiabatic conditions and first-order of the acoustic quantities, a propagation equation for the pressure can be obtained by use of the set of linearized acoustic equations (continuity, Euler and Fourier equations) in which the source terms appear :

$$\nabla^2 P - \frac{1}{c^2}.\frac{\partial^2 P}{\partial t^2} = -\frac{\gamma - 1}{c^2}.\frac{\partial H}{\partial t} + \mathrm{div}\vec{F} - \frac{\partial Q}{\partial t} \quad (3)$$

where P, Q, F and H are respectively the acoustic pressure perturbation, the particle mass source term, the vector force per unit volume and the energy per unit volume dissipated by Joule effect, c being the adiabatic sound speed and γ the specific heat ratio (7/5 for diatomic gases). This equation shows that three different mechanisms can potentially induce the excitation of acoustic waves : momentum transfer, energy transfer and mass transfer. It is stated by the authors that, in the case of atmospheric pressure arc discharges, energy transfer is predominating, namely through thermal transfer. The acoustic wave magnitude A_a can so be correlated to the energy transferred to the discharge according to the following equation :

$$A_a = K \times \frac{M}{k_B T_g} \times \frac{\partial H}{\partial t} \quad (4)$$

where M is the mass of gas in which the arc is burning, T_g the initial temperature of this mass of gas, k_B the Boltzmann's constant and K a constant proportionality coefficient.

Experiments on arcs burning in air performed at atmospheric pressure by Fitaire et al. [4] permitted to obtain a linear correlation between the acoustic wave amplitude A_a and the electric power (transferred to the discharge) derivative ∂W/∂t, assuming that cathode and anode voltage drops are not modified by an applied voltage modification. The theoretical approach was so validated by the experiments.

Coming back to our results of Fig. 4, it is noticeable that for the discharge regime under investigation, the characteristics of the current pulses are very similar : whatever the amplitude value I, constant values of rise time (≈ 10 ns) and amplitude/duration ratio are observed, with a current pulse duration never exceeding 100 ns. In turn, comparing our experiments results obtained in a thermodynamic non-equilibrium system at atmospheric pressure to the arc experimental results, it can be assumed :

(i) since all filamentary discharges here under consideration propagate with negligible voltage drops and for very akin onset voltage values, that the amplitude I of the current pulses of our non disruptive discharges can be here assimilated, with a K' factor proportionality, to the arc discharge $\partial W/\partial t$ power term.

(ii) since a linear correlation can be found between A_a and I, that the overpressure wave corresponding to the acoustic wave may be attributed to a local transient temperature variation.

Adapted to our experimental conditions, the Fitaire's equation may be written :

$$A_a = K.K' \times \frac{M}{k_B T_g} \times I \qquad (5)$$

implying that the gas volume involved in the discharge propagation is remaining constant, i.e. that the gas mass M and temperature T_g value remain constant for the pulsed current amplitude I range investigated. Plasma temperature values obtained by spectroscopic measurements in the vicinity of the point electrode range from 420 K to 480 K with increasing values of I. The transient heating of the gas gap volume by the discharge propagation is balanced by different cooling mechanisms : slow phenomena (conduction, diffusion) enhanced by the electrical wind effects, and rapid phenomena such as an adiabatic expansion [5]. The relaxation time (here ≈ 280 µs) is widely sufficient in this case (3.5 kHz case) to allow a cooling of the gas down to room temperature (300 K).

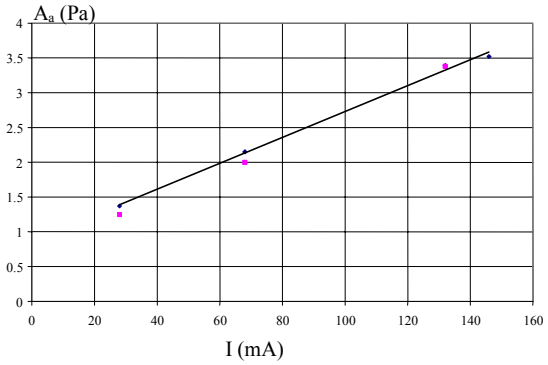

Figure 4 : Evolution of the acoustic wave magnitude A_a as a function of the current pulse amplitude I (F = 3.5 kHz, ambient air atmospheric pressure).

3.3 Effect of the frequency

Different working conditions have been investigated, adjusted through the high voltage pulsed signal frequency and a control of the current pulses amplitude ; the corresponding electrical and physical experimental data are summed up in Table 1. Increasing the frequency for a constant pulsed current amplitude ideally leads to reduce the cooling phase duration while keeping a same heat input phase. As a result, the mean temperature of the point-to-plane gas gap will increase, leading to :

(i) an increase of the local plasma temperature when the discharge will develop in this medium (injecting its own thermal contribution in a pre-heated gas)

(ii) to a decrease of the magnitude of the overpressure wave due to the decrease of the variation between plasma temperature and neutral gas temperature at the end of the relaxation phase.

Table 1 : Electrical and physical parameters of the discharge for 4 working points.

Frequency F (kHz)	Pulsed current amplitude I (mA)	Acoustic pressure A_a (Pa)	Plasma temperature T_{pl} (K)
3.5	140	3.38	480
15	50/140	1.7	540
30	225	2.7	920
50	225	1.3	1020

This is illustrated by Fig. 5 which shows that for equivalent current pulses, the acoustic pressure decreases when the high voltage frequency is raised. Note that the 3.5 kHz point (blank mark in Fig. 5) is calculated

using an extrapolation of the linear curve of Fig. 4. In other respects, the 15 kHz case in Table 1 exhibits a non consistent acoustic pressure value because two types of current pulses were obtained during two consecutive periods, so prohibiting a proper treatment of the acoustic signal.

Now focussing on the 50 kHz case, frequency condition for which thermal effects are not negligible [6], one can apply the equation (5) using as a constant coefficient the one found for the 3.5 kHz case (neutral gas temperature reference being room temperature). The gas gap temperature so calculated reaches 780 K, which is lower than the plasma temperature near the point electrode (1020 K). So it can be inferred that in the 50 kHz case, ozone is mainly produced in the volume surrounding the discharge channel and not inside the volume of the discharge channel between two current pulses. In the other cases, both possibilities seem to be valid.

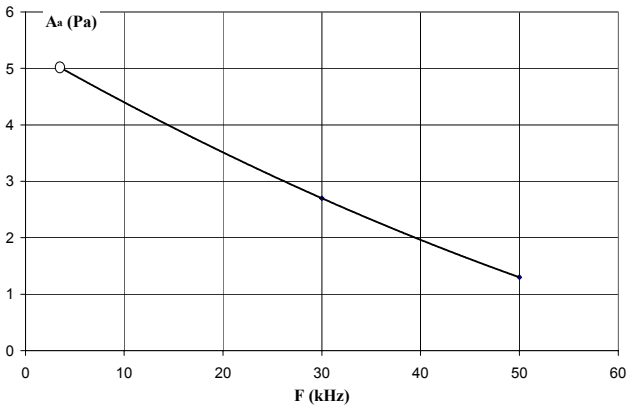

Figure 5 : Evolution of the acoustic wave magnitude A_a as a function of discharge frequency F (I = 225 mA, ambient air atmospheric pressure).

4 Conclusion

The paper shows how lower values of the temperature in the volume of intermittent electrical discharges in air at atmospheric pressure can be determined during their non emissive phases by means of acoustic pressure measurements, while emission spectroscopy allows to get upper values with the determination of rotational temperatures during their emissive phases. This is of particular interest for gas phase chemical reactions kinetics, such as ozone formation/destruction kinetics.
So, using pulsed high voltage signals of frequencies ranging from 3.5 kHz to 50 kHz, we were able to obtain a significant concentration of ozone with temperatures inside the discharge channels always higher than for instance 780 K, temperature of the gas at the end of the relaxation phase, immediately preceding the development of a filamentary discharge. It is typically a case for which it can be concluded that ozone formation reactions can only take place externally to the discharge volume and not in it during the time intervals between successive intermittent discharges.

Epitaxial Growth of Doped and Undoped Zinc Oxide Films on Sapphire Substrates: Influence of Substrate Orientation and Pretreatment

G. Vollweiler, K. Ellmer

Hahn-Meitner-Institut, Solare Energetik, D-14109 BERLIN, Glienicker Str. 100
phone: ++49-30-80622770, fax: ++49-30-80622434, e-mail: ellmer@hmi.de

Aluminium-doped zinc oxide (ZnO:Al) films have been grown on c-plane (001) and a-plane (110) sapphire by RF magnetron sputtering from a ceramic target. The films grew epitaxially, even at room temperature. However, the crystalline quality depends both on the substrate temperature as well as on the sapphire orientation. The best films, proved by X-ray diffraction (rocking curves and pole figure measurements) were grown on (110)-oriented sapphire in the temperature range 473 to 773 K. The minimum rocking curve half width was about 0.75°. By Rutherford backscattering analysis it could be shown, that the films exhibit a significant variation of the defect density over the film thickness. The highest density, as expected, is observed at the interface sapphire/ZnO:Al. Films grown on (001)-oriented sapphire have higher rocking curve half widths (about 1.3°) and exhibit sometimes two types of domains in the same film rotated by 30°.

Low temperature plasma treatment on the empress tree seeds observed through pH factor

Abstract
In this paper we present result of studies of low-temperature plasma treatment of Empress tree (*Paulownia tomentosa* Steud.) seeds. Treatments were carried out in capacitively coupled RF discharge for various powers given by RF power supply and various pressures. Significant improvement of germination was achieved and optimal plasma treatment conditions were determined. Decreasing of pH values of treated samples implied deposition of some bioactive nitrogenous compounds in/on seed coat.

1. Introduction

There are different types of pretreatments (chemical, mechanical or physical) for seeds that have small percentage of germination. Low-temperature plasma treatment is a serious alternative due to high efficiency, low consumption of power. Also, this treatment is environmentally friendly. Increasing percentage of seed germination is very important for fundamental studies and for practical use. In addition, such studies may provide further understanding of biochemical and biophysical processes involved in seed germination.
In this paper we present result of studies of low-temperature plasma treatment of *P. tomentosa* seeds. The treatments were carried out in low pressure non-equilibrium RF discharges previously used for treatment of polymers and wool fibers. The reactor was designed in such a way to minimize the energy of ions that hit the surface exposed to the plasma so the geometry is cylindrical with a large ratio of areas of central, powered and outer grounded electrode. Special probes were designed to monitor voltage and current immediately before the discharge and power was calculated from those measurements.
Our goal was to determine the influence of glow discharge parameters (power given by RF power supply, pressure and treatment time) on germination of seeds and to find optimum procedure for plasma treatment. Treatments were carried out in air and argon plasma. After determining optimal plasma treatment conditions, pH values of treated samples under these conditions were measured. This enabled us to establish some of the mechanisms responsible for improvement of germination.

2. *Paulownia tomentosa* Steud.

Empress tree seeds belong to the group of light-requiring seeds. To induce germination of empress tree seeds it is necessary to illuminate the samples with red light (λ=660 nm). On the other hand light with wavelength of λ=730 nm inhibits germination. Photoreceptor responsible for plant germination is phytochrome, which changes its conformation and initiate germination when illuminated.
Germination process of *P. tomentosa* consists of three stages. The first stage is imbibition where distilled water was added to the seeds and then seeds were held in dark for 72 hours. After that, samples were irradiated with pulse (5 min) of red light (λ=660 nm) and the second phase of phytochrome activity started. This phase lasts for three days and after that begins the last phase-radical elongation. Seed samples were held at constant temperature of 24 ± 1 °C at all time.
One of the main reasons for using empress tree seeds was short process of germination, small dimensions (approximately 4x3 mm) and the fact that it is not liable to pathogen attack and infections. Also, very important was the fact that characteristics of this seed is well known and what effect does different factors, like

temperature, light [1,2] and organic nitrates [3] have on seeds. Figure 1. shows the electron scanning microscopy *of P. tomentosa.*

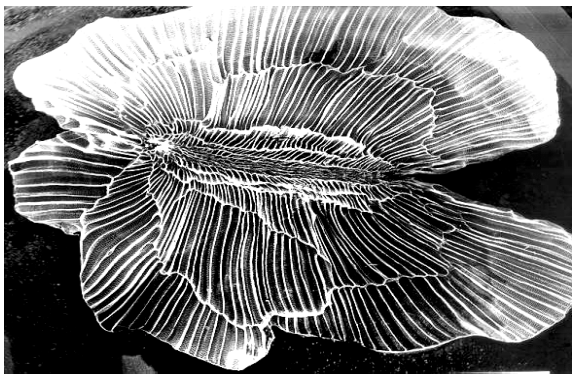

Figure 1. *Paulownia tomentosa* electron scanning microscopy

3. Experimental

Glow discharge treatment was carried out in capacitively coupled, radio-frequency (13.56 MHz) induced air and argon plasma. RF system used in this experiment is highly asymmetric and therefore the sheath potential against the walls of reactor is very small and damage by ion bombardment is minimal so organic products and natural fibers may be treated [4]. It consists of a constant RF power supply, matching box, vacuum pump, chamber, gas supply with appropriate pressure gauges, current and voltage probes, digital oscilloscope and computer as shown in Fig. 2. The chamber is a cylinder made of stainless steel with central electrode (14 mm in diameter) which is the powered electrode and the wall (37 cm in diameter) which is the grounded electrode. At the bottom of the chamber there is a flat platform (33 cm long and 24.5 cm wide) where we put the samples. Stability of the system is very important and was checked before every treatment. It was maintained by adjusting matching box so the reflected power would be minimal.

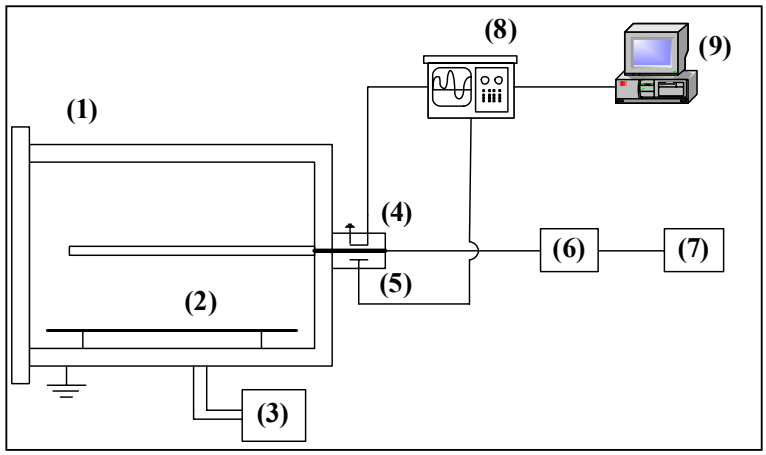

Figure 2. Experimental setup: (1) discharge chamber; (2) platform; (3) vacuum system; (4) current probe; (5) voltage probe; (6) matching box; (7) RF power supply; (8) digital oscilloscope; (9) PC

The experiments were performed by using the Empress tree seeds. Tree different groups of seeds were used: the first, which germinates up to 25 %, after 5 min of red light pulse, the second, which germinates up to 40 % after 5 min red light pulse, and the third, which germinates up to 80 % after the same light treatment. Lots of 100

seeds were placed in 6 cm diameter petri dishes before plasma treatment. Four petri dishes were set on the platform and treated by air or argon low temperature plasma. Power was maintained at constant levels of 50 W, 100 W, 200 W and pressure of 200 mTorr for different treatment times. In addition, for power of 100 W treatments were also carried out for pressures of 100 mTorr and 400 mTorr. One control group were samples of seeds held under a constant pressure of 200 mTorr without igniting plasma. This was the vacuum control group. Also, for every set of conditions (power, pressure, type of gas), 400 untreated seeds were used for control group and their percentage of germination was determined. After the plasma treatment seeds were imbibed with 2 ml of distilled water. Germination was counted seven days after the light treatment. All experiments were repeated 2 times, each with 3-5 replicates. The data points represent means; standard errors are not shown since they never exceeded 3%. Also, pH values of treated seeds were determined. Germination of seeds, counting of germinated seeds and determining of pH values of treated samples was done at the Institute for Biological Research "Siniša Stanković".

4. Results and discussion

Plasma treated samples have a higher percentage of germination than the untreated samples. The curves for the power of 50 W and 200 mTorr and for the vacuum control sample are shown in Fig.3. Untreated control group of this set of samples germinate up to 3%. Percentage of germination for treated seeds is increased for shorter treatment times while for longer treatment times it is decreasing. The other curve representing vacuum control is almost constant at the untreated control group value and it shows that vacuum has almost no effect on seed germination.

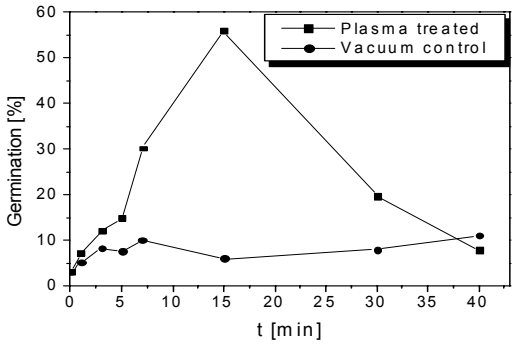

Figure 3. Germination curve for a constant power of 50 W and a constant pressure of 200 mTorr.

We can see that germination curve increases, reaches its maximum value and then decreases. For longer treatment times and higher powers given by RF power supply germination curve falls to zero. Fig. 4. shows germination curves for constant powers of 100 W and 200 W and pressure of 200 mTorr. The percentage of germination for control groups for the samples used are 25 % and 23 % for power of 100 W and 200 W, respectively. Obviously, we can see that with the increasing power given by RF power supply maximum of germination curve shifts towards shorter times. This implies that the overall effect of plasma is proportional to the integral effect of the flux of particles reaching its surface. Also, plasma treatment by ion bombardment damages the seed's surface and therefore after longer treatment times seeds cannot germinate.

If we reduce pressure, germination curve widens and for the same power given by RF power supply we have a larger range of times where germination is increased. Inhibition in this case occurs only for the longest treatments times. For larger pressures germination curve is narrow, maximum occurs for shorter treatment times and inhibition is significant even for 5 min treatments (see Fig. 5.). Control group values for both pressures is 77.25 % and feed gas was air.

One set of samples (2 Petri dishes) was covered by a glass cover (square shape, 10 cm wide, 30 cm long and 2.5 cm high) and was treated at the same time with another set of samples (2 Petri dishes) which was uncovered. In Fig. 6. we show germination curves for both cases. The glass cover, obviously, shielded the samples and the total flux of particles reaching the surface was smaller than in the case of uncovered samples. Therefore, the curve representing the covered samples is wider, for shorter treatment times less stimulation occurs, but, in this case, the seed survived longer treatment times. On the other hand, glass cover prevented UV photons from reaching the surface so maintenance of a relatively high improvement indicates the importance of active radicals from the plasma.

Besides air we have also used argon as the feed gas and the curves representing data for these two gases are shown in Fig. 7. Both curves are normalized to their control group values. For argon the percentage of germination for the control group is 59 % and for air it is 25 %. The stimulation for argon is much smaller than for air. This implies that there is another mechanism, besides ion bombardment of seed surface, involved in improving germination.

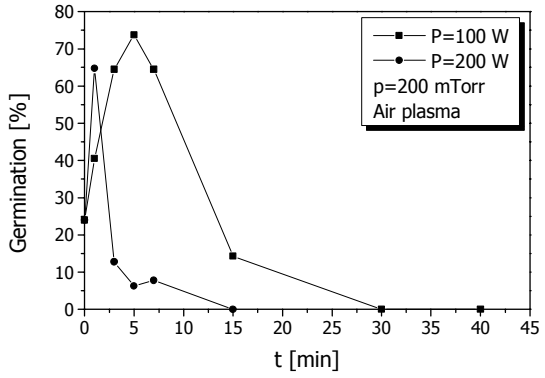

Figure 4. Germination curves for a constant power of 100 W and 200 W a constant pressure of 200 mTorr.

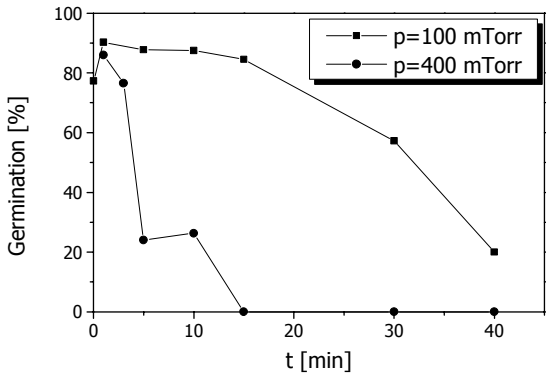

Figure 5. Germination curves for constant power of 100 W and pressures of 100 mTorr and 400 mTorr.

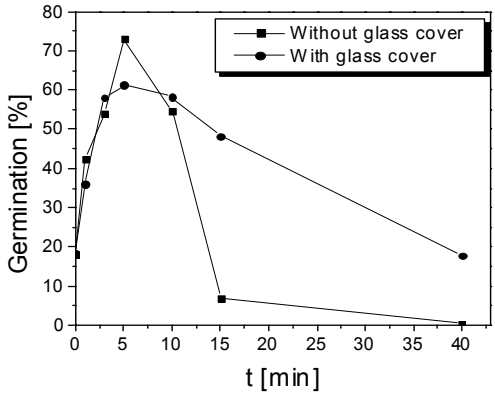

Figure 6. Germination curves for a constant power of 100 W and a constant pressure of 200 mTorr. Control group value: 18.25 %

Interaction between active species from plasma and seeds surface leads to a change of seed's surface topography. This implies that plasma treatment causes the destruction of surface layer and it also activates the surface. Activated surface is now capable of bonding active nitrogenous compounds. These compounds reduce pH values of samples and play important role in increasing the germination of seeds [5,6].
In Fig 8. we show pH values of samples treated by air and argon plasma for power of 100 W and pressure of 200 mTorr. pH values measured one hour after imbibition started decreases with increasing treatment times. pH of the samples treated by air plasma reduces from 6.8 (1 min treatment) to 3.8 (40 min). We should expect that for longer times percentage of germination should be at a maximum. However, that is not the case and the reason is significant damage of seed and its germ due to ion bombardment.

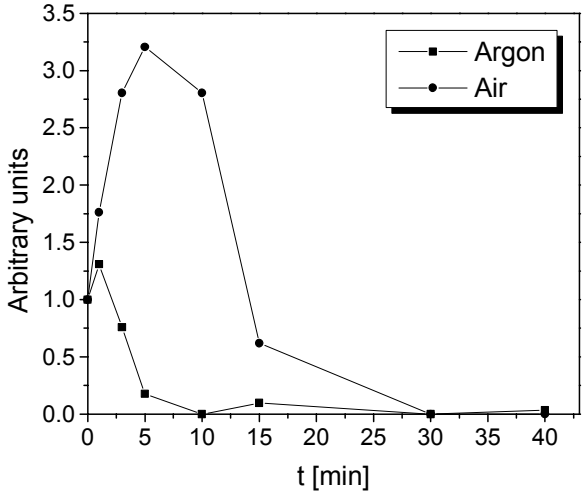

Figure 7. Normalized germination curves for air and argon at a constant pressure of 200 mTorr and a constant power of 100 W.

In case of argon plasma decrement of pH is not so significant and this concurs with germination curve for argon plasma. For 1 min treatment pH=6.8 and decreases to 4.8 for 40 min treatment. This small change in pH values of samples treated by argon plasma can be explained either with the fact that argon used in this experiment is not completely clean or the fact that there is some effect of vacuuming on pH factor. Also, it is not impossible that

argon metastables are the active species which can interact with surface of seeds and change pH values. Control in Fig 8. represents pH value of distilled water.

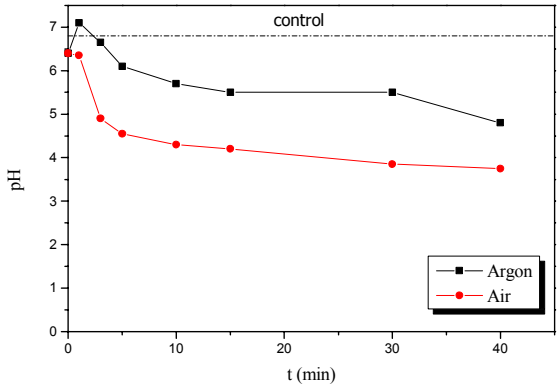

Figure 8. The pH of water solution in which seeds were imbibed after air and argon plasma pretreatments.

5. Conclusion

Percentage of germination of seeds used in the present study is increased by non-equilibrium RF plasma treatment. The effect increases with pressure and power, so it seems that the overall effect is proportional to the total flux of reactive particles reaching the surface.

Stimulatory effect on germination of seeds *P. tomentosa* treated by low temperature plasma can be explained by several mechanisms. The first mechanism is etching of seed's surface by ion bombardment. Damaged surface is now better absorbent of water and gases necessary for germination. This is not the main mechanism but can be relevant for seeds with hard surfaces.

Activation of surface is very important because plasma treatments can change physical and chemical characteristics of seed's surface and therefore change its dormancy. Activated surface is now capable of bonding active nitrogenous compounds. Although there is no direct evidence, generation and deposition of nitrogenous oxides in/on the seed coat [3] may be the clue for understanding the stimulatory effect of air-derived cold plasma in *P. tomentosa* seed germination.

Influence of chemical non-equilibrium on the simulation of a D.C. plasma jet

I. Choquet, A. Boussagol, P. Nylén

University of Trollhättan/Udevalla, Box 957, 461 29 Trollhättan, Sweden

This paper presents a comparison of the numerical simulations of a d.c. plasma jet (similar to [1]) assuming chemical equilibrium and chemical non-equilibrium. The calculations are done with the 3D commercial computational fluid dynamics code Fluent [2].

Numerical simulations can be of great help in the optimization of plasma spraying conditions for a specific material. The quality of the coating is indeed governed by the particle parameters before impact (such as temperature, molten state, velocity, and size), and thus the plasma-particle interaction. The prediction of the plasma flow field is thus essential. The plasma jet is generally simulated assuming, as in [1], that the plasma is:

- optically thin,
- in thermal equilibrium, and
- in chemical equilibrium.

In this work, we investigate the influence of chemical non-equilibrium, while keeping the assumption of local thermal equilibrium as well as optically thin plasma. Arc root fluctuations are not considered and, therefore, the flow is assumed to be in steady state. We study an argon plasma jet flowing into a cold air environment and simulate numerically two cases:

- The reference test case is at chemical equilibrium.
  The gas flow is then supposed to be made of two (also three) gases: the plasma-forming gas and the ambient gas (also the powder carrier gas). The thermodynamic and transport properties of the gas mixture are calculated using mixing laws and the data of pure gases derived from kinetic theory in [3].
- The test case with chemical non-equilibrium.
  We then retain the chemical species with a number density larger than $10^{21} m^{-3}$ in the range of temperature we consider (from 300 to 15000K) at atmospheric pressure. Concerning the air for instance we take into account N_2, O_2, NO, N, O, N^+, O^+, Ar, Ar^+, and the electrons. The forward reaction rates are expressed in an Arrhenius form. The equilibrium constants of reaction have the following temperature dependence:

$$K(T) = \exp\left[AT + B + C\ln\left(\frac{10^4}{T}\right) + \frac{D}{T} + \frac{E}{T^2} \right],$$

  where A, B, C, D and E are constants characteristic of the chemical species involved in the chemical reaction under consideration.
  The transport coefficients of the pure gases are, as for the reference test case, derived from kinetic theory with the same order in the expansions. The collision cross sections are taken from the data base T&Twinner [4]. The reaction rates and transport coefficients are implemented in the Fluent code in the form of 'user defined functions'.

The density, velocity, and temperature flow fields computed for these two test cases are then compared and the assumptions concerning chemical equilibrium and non-equilibrium are discussed.

Abstract
In this paper we study a partially ionized plasma that corresponds to the plasma column of an arc discharge of moderate pressure. We derive an inviscid hydrodynamic/diffusion limit from a system of Boltzmann type transport equations modeling that plasma problem. The original property of this system is that impact ionization is a leading order collisional process. As a consequence, there is no evolution equation governing the density of electrons.

1. Introduction

This work is concerned with the derivation, from a kinetic framework, of an inviscid diffusion/hydrodynamic limit for a plasma problem. Let us recall that the case of a binary gas mixture can be found in [1] for instance. The ternary gas mixture corresponding to a very weakly ionized plasma, such as a glow discharge where ionization occurs very seldom, is studied in [2].
Here, we consider the partially ionized plasma investigated in [3]. Its electrons, ions and neutral molecules are subject to elastic binary collisions as well as ionization and recombination reactions. We assume that the ionization level is several orders of magnitude larger than in [2]. It lies within the range 10^{-3} to 10^{-1}, which corresponds to an arc discharge problem. A typical arc discharge, investigated in [4] for instance, consists of electrodes interacting with a thermal plasma through non-equilibrium boundary layers. Here we do not consider the cathode and anode layers, and focus the study on the modelling of the plasma column. We assume that impact ionization-recombination dominates radiative ionization-recombination, excluding thus very high pressure arc discharges. The activation energy Δ of ionization reactions is supposed to be constant and given by the impacting electron.
We start this study from a system of Boltzmann type transport equations governing the distribution functions of electrons, ions and neutral molecules. This system, presented in section 2, is coupled through collision operators that involve three collisional processes: i) elastic binary collisions where at least one particle is neutral (Boltzmann), ii) elastic binary collisions between charged particles (Fokker-Planck), and iii) inelastic collisions with impact ionization and its reverse recombination. Notice that the study of charge carriers giving rise to impact ionization can be found in [5] for semiconductor devices.
This system is scaled in section 3, based on its two small parameters. The first parameter ϵ measures the relative smallness of the electron mass with respect to the neutral particles. The second parameter δ measures the ionization level of the plasma. For an arc discharge we have $\delta \approx \epsilon$. The main consequence of this scaling is that impact ionization gets a leading order collisional process.
A macroscopic limit is then derived in section 4.

2. A system of Boltzmann equations modelling an arc discharge

We study a gas partially ionized whose electrons, ions and neutral molecules are subject to elastic binary collisions as well as ionization and recombination reactions. To that purpose, we assume that:
• (**2.1**) *The external forces applied to the particles do not depend on the velocity variable, excluding thus magnetized plasmas.*
• (**2.2**) *The interaction potentials associated with the nonreactive collisions only depend on the distance between the particles.*

• (**2.3**) *Radiative ionization and recombination are negligible, excluding thus very high pressure arc discharges.*
• (**2.4**) *The activation energy of impact ionization reactions is given by the electron, and not by the neutral particle.*
• (**2.5**) *The charge level of ions is of order one.*
To avoid confused notations, we restrict the presentation of this study to a single neutral species and the related single charged ion species. The extension of the forthcoming results to several molecular species characterized by masses of similar order of magnitude, and to ions of charge $Z < 10$ is indeed straightforward. We thus investigate the following system of Boltzmann transport equations:

$$\begin{aligned}
&\partial_t f^e + v_e \cdot \bigtriangledown_x f^e + \frac{F_e}{m_e} \cdot \bigtriangledown_{v_e} f^e = (\partial_t f^e)_c \ , \\
&\partial_t f^i + v_i \cdot \bigtriangledown_x f^i + \frac{F_i}{m_i} \cdot \bigtriangledown_{v_i} f^i = (\partial_t f^i)_c \ , \\
&\partial_t f^n + v_n \cdot \bigtriangledown_x f^n + \frac{F_n}{m_n} \cdot \bigtriangledown_{v_n} f^n = (\partial_t f^n)_c \ .
\end{aligned} \tag{1}$$

The indexes e, i and n denote quantities associated with electrons, ions and neutral particles, respectivelly. The distribution functions $f^\alpha = f^\alpha(t, x, v_\alpha)$, where $\alpha = e, i, n$, depend on time $t \geq 0$, space $x \in I\!R^3$ and velocity $v_\alpha \in I\!R^3$. F_α represents the external forces acting on the paticle α of mass m_α; it satisfies the assumption 2.1.
The system of Boltzmann equations (1) is coupled through the collision operators $(\partial_t f^\alpha)_c$. These operators involve three collisional processes detailed below: i) elastic binary collisions where at least one particle is neutral, ii) elastic binary collisions between charged particles, and iii) inelastic collisions with ionization and its reverse recombination. Thus

$$(\partial_t f^\alpha)_c = Q^{\alpha\alpha}(f^\alpha, f^\alpha) + Q^{\alpha\beta}(f^\alpha, f^\beta) + Q^{\alpha\gamma}(f^\alpha, f^\gamma) + Q^{\alpha,ir}(f^\alpha, f^\beta, f^\gamma), \tag{2}$$

where the superscript *ir* stands for ionization-recombination, and $\alpha, \beta, \gamma = e, i, n$ with $\alpha \neq \beta \neq \gamma \neq \alpha$.
Let us first consider binary elastic collisions between the two particles α and β. When one of these particles (or both) is neutral, the binary collisions are described by Boltzmann operators of the form:

$$Q^{\alpha\beta}(f^\alpha, f^\beta)(v_\alpha) = \int_{I\!R^3 \times S^2_+} \sigma^{\mathcal{B}}_{\alpha\beta} \ |v_\alpha - v^\star_\beta| \Big(f^{\alpha\prime} f^{\beta\prime}_\star - f^\alpha f^\beta_\star \Big) d\Omega \ dv^\star_\beta \ , \tag{3}$$

where $\alpha = n$ and $\beta = e, i, n$ or $\alpha = e, i, n$ and $\beta = n$. The distribution functions $f^{\alpha\prime}$ and $f^{\beta\prime}_\star$ stand for $f^\alpha(t, x, {v_\alpha}')$ and $f^\beta(t, x, v^{\star\prime}_\beta)$, respectivelly. S^2 is the unit sphere of $I\!R^3$ and $S^2_+ := \Big\{ \Omega \in S^2; (v_\alpha - v^\star_\beta) \cdot \Omega > 0 \Big\}$. The post-collisional velocities ${v_\alpha}'$ and $v^{\star\prime}_\beta$ are defined from the pre-collisional velocities v_α and $v^\star_\beta$ by:

$${v_\alpha}' = v_\alpha - 2 \ \frac{\mu_{\alpha\beta}}{m_\alpha} \Big((v_\alpha - v^\star_\beta) \cdot \Omega \Big) \Omega \quad \text{and} \quad v^{\star\prime}_\beta = v^\star_\beta + 2 \ \frac{\mu_{\alpha\beta}}{m_\beta} \Big((v_\alpha - v^\star_\beta) \cdot \Omega \Big) \Omega, \tag{4}$$

where $\mu_{\alpha\beta} = m_\alpha m_\beta / (m_\alpha + m_\beta)$ is the reduced mass. From assumption 2.2, the scattering cross section $\sigma^{\mathcal{B}}_{\alpha\beta}$ is a function of two variables: $\sigma^{\mathcal{B}}_{\alpha\beta} = \sigma^{\mathcal{B}}_{\alpha\beta}(\mathcal{E}, \chi)$, where $\mathcal{E} = \mu_{\alpha\beta} |v_\alpha - v^\star_\beta|^2$ is the reduced kinetic energy and χ denotes the angle $\Big(\frac{v_\alpha - v^\star_\beta}{|v_\alpha - v^\star_\beta|}, \Omega \Big)$. While the former belongs to $I\!R_+$, the latter lies within the range $[0, 1]$.
Elastic collisions between two charged particles α and β are modelled by Fokker-Planck-Landau operators:

$$\begin{aligned}
Q^{\alpha\beta}(f^\alpha, f^\beta)(v_\alpha) = \frac{\mu^2_{\alpha\beta}}{m_\alpha} \ \bigtriangledown_{v_\alpha} \cdot \int_{I\!R^3} &\sigma^{\mathcal{F}}_{\alpha\beta} \ |v_\alpha - v^\star_\beta|^3 \ S(v_\alpha - v^\star_\beta) \\
&\times \Big(\frac{1}{m_\alpha} \bigtriangledown_{v_\alpha} f^\alpha \ f^\beta_\star - \frac{1}{m_\beta} \bigtriangledown_{v^\star_\beta} f^\beta_\star \ f^\alpha \Big) \ dv^\star_\beta \ ,
\end{aligned}$$

where $\alpha, \beta = e, i$ and $\bigtriangledown_{v_\alpha} f^\alpha = (\bigtriangledown f^\alpha)(v_\alpha)$. $S(w)$ is the matrix $S(w) = \mathbf{Id} - \frac{w \otimes w}{|w|^2}$ where $\mathbf{Id}$ is the identity matrix. Here, due to assumption 2.2, the scattering cross section for grazing collisions $\sigma^{\mathcal{F}}_{\alpha\beta}$ only depends on the reduced kinetic energy: $\sigma^{\mathcal{F}}_{\alpha\beta} = \sigma^{\mathcal{F}}_{\alpha\beta}(\mathcal{E})$.
From assumption 2.3, radiative ionization and recombination are supposed to be negligible. The ionization process we shall consider is thus impact ionization. Its mechanism can be schematized by the following direct and reverse reactions:

$$e + A \xrightarrow{\sigma^d} e + e + A^+ \qquad \text{and} \qquad e + A \xleftarrow{\sigma^r} e + e + A^+ ,$$

where e represents an electron, A^+ a single charged ion, and A the related neutral atom. σ^d and σ^r stand for the direct and reverse reaction cross sections. They are supposed to be positive. Applying the principle of detailed balance, we assume in the sequel that these cross sections are linked through $\sigma^d = \mathcal{F}_0\ \sigma^r$, where $\mathcal{F}_0$ is a positive constant. The ionization-recombination operators are then given by:

$$\begin{aligned} Q^{e,ir}(f^e, f^i, f^n) = &\int_{I\!R^{12}} \sigma^r\ \delta_v\ \delta_{\mathcal{E}} \left(f^{e\prime}\ f^e_\star\ f^i - \mathcal{F}_0\ f^e\ f^n \right) dv_e{}'\ dv^\star_e\ dv_i\ dv_n \\ &+2 \int_{I\!R^{12}} \sigma^{r\prime}\ \delta_{v'}\ \delta_{\mathcal{E}'} \left(\mathcal{F}_0\ f^{e\prime}\ f^n - f^e\ f^e_\star\ f^i \right) dv_e{}'\ dv^\star_e\ dv_i\ dv_n, \end{aligned} \tag{5-a}$$

$$Q^{i,ir}(f^e, f^i, f^n) = \int_{I\!R^{12}} \sigma^r\ \delta_v\ \delta_{\mathcal{E}} \left(\mathcal{F}_0\ f^e\ f^n - f^{e\prime}\ f^e_\star\ f^i \right) dv_e\ dv_e{}'\ dv^\star_e\ dv_n, \tag{5-b}$$

$$Q^{n,ir}(f^e, f^i, f^n) = \int_{I\!R^{12}} \sigma^r\ \delta_v\ \delta_{\mathcal{E}} \left(f^{e\prime}\ f^e_\star\ f^i - \mathcal{F}_0\ f^e\ f^n \right) dv_e\ dv_e{}'\ dv^\star_e\ dv_i. \tag{5-c}$$

Due to assumption 2.4, the reverse reaction cross section writes $\sigma^r = \sigma^r(v_e{}', v^\star_e, v_i; v_e, v_n) = \sigma^r(v_e{}', v^\star_e; v_e)$, and $\sigma^{r\prime} = \sigma^r(v_e, v^\star_e; v_e{}')$. $\delta_{\mathcal{E}}$ and δ_v hold for the energy and momentum conservation during the ionization-recombination process:

$$\begin{aligned} \delta_{\mathcal{E}} : &\qquad m_e|v_e|^2 + m_n|v_n|^2 = m_e(|v_e{}'|^2 + |v^\star_e|^2) + m_i|v_i|^2 + 2\Delta, \\ \delta_v : &\qquad m_e v_e + m_n v_n = m_e(v_e{}' + v^\star_e) + m_i v_i, \end{aligned} \tag{6}$$

where the ionization energy Δ is a constant.
Notice that the factor 2 in Eq. (5-a) is a consequence of the indistinguishability of electrons. This indistinguishability and the principle of detailed balance imply that $\sigma^r(v_e{}', v^\star_e; v_e) = \sigma^r(v^\star_e, v_e{}'; v_e) = \sigma^r(v_e, v^\star_e; v_e{}')$.
The reference values of the problem are now introduced in order to scale the system of Boltzmann transport equations (1).

3. Scaled system of Boltzmann equations

We first introduce the reference dimensions of the problem (such as time t_0, length x_0) in order to scale the previous system. In that aim, let ϵ denote the parameter measuring the relative smallness of the electron mass with respect to the neutral particle:

$$\epsilon = \sqrt{\frac{m_e}{m_n}} = \sqrt{\frac{m_e}{m_i + m_e}} << 1.$$

We assume that:

• (**3.1**) *Electrons, ions and neutral species have temperatures of the same order of magnitude* T_0.

Their reference velocities $(v_\alpha)_0$ will be defined from the thermal velocity, $(v_\alpha)_0 = \sqrt{kT_0/m_\alpha}$, with $\alpha = e, i, n$, k being the Boltzmann constant. Consequently, we obtain the following ordering:

$$(v_n)_0 = \sqrt{1-\epsilon^2}\ (v_i)_0 = \epsilon\ (v_e)_0.$$

Besides, we shall choose $x_0 = t_0\ (v_e)_0$ as reference length. The reference time t_0 is specified later on.

• (**3.2**) *The densities of the charged particles have the same order of magnitude:* $(\rho_e)_0 = (\rho_i)_0$.

We introduce a second parameter measuring the ionization level,

$$\delta = \frac{(\rho_e)_0}{(\rho_n)_0} = \frac{(\rho_i)_0}{(\rho_n)_0},$$

where $(\rho_n)_0$ is the typical density of neutral particles. The distribution function scales are determined from the previous characteristic quantities according to $(f^\alpha)_0 = (\rho_\alpha)_0 (v_\alpha)_0^{-3}$ where $\alpha = e, i, n$.

• (**3.3**) *The force field F_α with $\alpha = e, i, n$, derives from a potential and is relatively weak, i.e. the force term $(F_\alpha m_\alpha^{-1}) \cdot \bigtriangledown_{v_\alpha} f^\alpha$ involved in (1) is supposed to be of lower order than the collision operator $(\partial_t f^\alpha)_c$.* The force scale is related to the length scale by $(F_\alpha)_0 = kT_0 x_0^{-1}$.

To specify the typical values of the elastic collision operators $Q^{\alpha\beta}$ we assume that:

• (**3.4**) *The interaction potentials associated with binary elastic collisions between the various species of charged particles have the same order of magnitude: $\sigma^{\mathcal{F}}_{\alpha\beta} = \sigma^{\mathcal{F}}_0$ for any $\alpha, \beta = e, i$. A similar property is supposed to apply to elastic binary collisions involving a neutral particle (or two), thus: $\sigma^{\mathcal{B}}_{n\alpha} = \sigma^{\mathcal{B}}_{\alpha n} = \sigma^{\mathcal{B}}_0$ where $\alpha = e, i$ or n.*

The variables involved in (1)-(2) can now be expressed in dimensionless variables as:

$$t = t_0\ \bar{t}\ , \quad x = x_0\ \bar{x}\ , \quad v_\alpha = (v_\alpha)_0\ \bar{v}_\alpha\ , \quad f^\alpha = (f^\alpha)_0\ \bar{f}^\alpha\ , \quad \ldots\ .$$

Further details can be found in Ref [3]. In the sequel we shall only use reference values and dimensionless variables. To simplify the notations, the bar above dimensionless variables will therefore be omitted from now on.

We now need to specify the characteristic time t_0. We first notice that choosing the time scale $t_0 = \tau_{en} = \epsilon^2 \tau_{ir} = \delta\ \tau_{ee}$ while $\delta \to 0$, we recover the dimensionless system studied in [2]. This corresponds to a very weakly ionized plasma, such as a glow discharge, where ionization occurs very seldom and the ionization level δ lies within the range 10^{-8} to 10^{-5}, such that $\delta << \epsilon$.

In an arc discharge, the ionization level lies within the range 10^{-3} to 10^{-1}, implying that $\delta \approx \epsilon$.

• (**3.5**) *We thus assume in the present study that: $t_0 = \tau_{en} = \epsilon\ \tau_{ir} = \delta\ \tau_{ee}$* and $\delta = \epsilon$.

The scaled version of the system of Boltzmann transport equations writes then,

$$\begin{aligned}
&\partial_t f^e + v_e \cdot \bigtriangledown_x f^e + F_e \cdot \bigtriangledown_{v_e} f^e = Q^{en}_\epsilon(f^e, f^n) \\
&\qquad\qquad + \epsilon\ \left[Q^{ee}(f^e, f^e) + Q^{ei}_\epsilon(f^e, f^i) + Q^{e,ir}(f^e, f^i, f^n)\right], \\
&\partial_t f^i + \frac{\epsilon}{\sqrt{1-\epsilon^2}} \left(v_i \cdot \bigtriangledown_x f^i + F_i \cdot \bigtriangledown_{v_i} f^i\right) = \frac{\epsilon}{\sqrt{1-\epsilon^2}}\ Q^{in}_\epsilon(f^i, f^n) \\
&\qquad\qquad + \epsilon\ Q^{i,ir}(f^e, f^i, f^n) + \epsilon^2\ \left[\frac{1}{\sqrt{1-\epsilon^2}}\ Q^{ii}(f^i, f^i) + Q^{ie}_\epsilon(f^i, f^e)\right], \\
&\partial_t f^n + \epsilon\ \left(v_n \cdot \bigtriangledown_x f^n + F_n \cdot \bigtriangledown_{v_n} f^n\right) = \epsilon\ Q^{nn}(f^n, f^n) \\
&\qquad\qquad + \epsilon^2 \left[Q^{ne}_\epsilon(f^n, f^e) + \frac{1}{\sqrt{1-\epsilon^2}}\ Q^{ni}_\epsilon(f^n, f^i) + Q^{n,ir}(f^e, f^i, f^n)\right].
\end{aligned} \tag{7}$$

In this system, collisions of electrons, ions and neutral particles with neutral particles are leading order collisional processes, as in any weakly ionized plasma. However, contrary to the very weakly ionized

problem studied in [2], the leading order operators of neutral particles and ions are also coupled with electrons. Besides, the collision operators for elastic electron collisions Q^{ee} and ionization $Q^{e,ir}$ have now the same order of magnitude. But the main novelty comes from the ionization-recombination operator for ions, which is here among the leading order operators.

The properties of the collision operators, required to derive the hydrodynamic/diffusion limit, are studied in [3].

4. Inviscid hydrodynamic/diffusion limit

To derive the macroscopic limit, we start from the dimensionless system (7) and replace the collision operators $Q_\epsilon^{\alpha\beta}$ by their expansions with respect to ϵ (cf. Ref. [3] for more details). Then we introduce the diffusion scaling of small parameter ϵ: $t \to \epsilon^2 t$, $x \to \epsilon x$, and obtain:

$$
\begin{aligned}
&\partial_t f_\epsilon^e + \epsilon^{-1}\left(v_e \cdot \bigtriangledown_x f_\epsilon^e + F_e \cdot \bigtriangledown_{v_e} f_\epsilon^e\right) = \epsilon^{-2}\, Q_0^{en}(f_\epsilon^e, f_\epsilon^n) \\
&\qquad + \epsilon^{-1}\left[Q_1^{en}(f_\epsilon^e, f_\epsilon^n) + Q_0^{ei}(f_\epsilon^e, f_\epsilon^i) + Q^{ee}(f_\epsilon^e, f_\epsilon^e) + Q^{e,ir}(f_\epsilon^e, f_\epsilon^i, f_\epsilon^n)\right] \\
&\qquad + Q_2^{en}(f_\epsilon^e, f_\epsilon^n) + Q_1^{ei}(f_\epsilon^e, f_\epsilon^i) + \epsilon\left[\, Q_3^{en}(f_\epsilon^e, f_\epsilon^n) + Q_2^{ei}(f_\epsilon^e, f_\epsilon^i)\right] + \mathcal{O}(\epsilon^2), \\
&\partial_t f_\epsilon^i + v_i \cdot \bigtriangledown_x f_\epsilon^i + F_i \cdot \bigtriangledown_{v_i} f_\epsilon^i \\
&\qquad = \epsilon^{-1}\Big[Q_0^{in}(f_\epsilon^i, f_\epsilon^n) + Q^{i,ir}(f_\epsilon^e, f_\epsilon^i, f_\epsilon^n)\Big] + Q^{ii}(f_\epsilon^i, f_\epsilon^i) + Q_0^{ie}(f_\epsilon^i, f_\epsilon^e) \\
&\qquad + \epsilon\left[\, \tfrac{1}{2}\, Q_0^{in}(f_\epsilon^i, f_\epsilon^n) + Q_2^{in}(f_\epsilon^i, f_\epsilon^n) + Q_1^{ie}(f_\epsilon^i, f_\epsilon^e)\right] + \mathcal{O}(\epsilon^2), \\
&\partial_t f_\epsilon^n + v_n \cdot \bigtriangledown_x f_\epsilon^n + F_n \cdot \bigtriangledown_{v_n} f_\epsilon^n = \epsilon^{-1}\, Q^{nn}(f_\epsilon^n, f_\epsilon^n) \\
&\qquad + Q_0^{ne}(f_\epsilon^n, f_\epsilon^e) + Q_0^{ni}(f_\epsilon^n, f_\epsilon^i) + Q^{n,ir}(f_\epsilon^e, f_\epsilon^i, f_\epsilon^n) + \epsilon\, Q_1^{ne}(f_\epsilon^n, f_\epsilon^e) + \mathcal{O}(\epsilon^2).
\end{aligned}
\tag{8}
$$

Next, we expand the solutions in powers of ϵ: $f_\epsilon^e = f_0^e + \epsilon\, f_1^e + \epsilon^2\, f_2^e + \mathcal{O}(\epsilon^3)$ and $f_\epsilon^\alpha = f_0^\alpha + \epsilon\, f_1^\alpha + \mathcal{O}(\epsilon^2)$, with $\alpha = i, n$. Then, we insert these expansions in the system (8) and identify terms of equal powers of ϵ. This leads to systems of equations of order ϵ^{-2}, ϵ^{-1}, ϵ^0, etc, to be successively solved (these systems are also detailed in Ref. [3]).

From the lower order systems we prove that:

• The equilibrium distribution functions of neutral particles f_0^n and ions f_0^i are Maxwellians characterized by the same mean velocity u and temperature T.

• The equilibrium distribution function of electrons is the centered Maxwellian of temperature T_e.

• The electron density ρ_e is governed by the ion density ρ_i, the density of neutral particles ρ_n and the electron temperature T_e, according to:

$$
\rho_e = \frac{\mathcal{F}_0\ \rho_n}{\rho_i}\ (2\pi T_e)^{3/2}\ \exp\Big(-\frac{\Delta}{T_e}\Big)\ . \tag{9}
$$

Notice that this relation can be compared to a Saha law generalized to a plasma characterized by two temperatures: a temperature for heavy particles and another temperature for light particles.

Then we introduce the conservative variable $\mathbf{u} = (\rho_n, \rho_i, \rho_n u, \rho_n E, \rho_e E_e)$: $I\!R^3 \times I\!R^+ \to \mathcal{U}$ where $\mathcal{U}$ denotes the open set $\big\{\mathbf{u} \in I\!R^7, \rho_n \in I\!R^+, \rho_i \in I\!R^+, \rho_n u \in I\!R^3, T \in I\!R^+, T_e \in I\!R^+, \big\}$. The density ρ_n, the momentum $\rho_n u$ and the energy $\rho_n E = \rho_n(|u|^2 + 3T)/2$ of neutral particles are defined such that:

$$
\begin{pmatrix} \rho_n \\ \rho_n u \\ \rho_n E \end{pmatrix} = \int_{I\!R^3} \begin{pmatrix} 1 \\ v_n \\ \frac{1}{2}|v_n|^2 \end{pmatrix} f_0^n(v_n) dv_n \tag{10}
$$

The ion density ρ_i and the electron internal energy $\rho_e E_e = \frac{3}{2}\rho_e T_e$ are defined by:

$$
\rho_i = \int_{I\!R^3} f_0^i(v_i)\ dv_i \quad \text{and} \quad \rho_e E_e = \frac{1}{2}\int_{I\!R^3} |v_e|^2\ f_0^e(v_e)\ dv_e\ . \tag{11}
$$

Using these notations we successively establish the solvability conditions for defining the first order corrective terms $f_1^\alpha(v_\alpha)$, with $\alpha = n, i$, and the second order corrective term $f_2^e(v_e)$ (refer to [3] for more details). These conditions give the inviscid hydrodynamic/diffusion system governing the time evolution of the neutral particle and ion densities ρ_n and ρ_i, the velocity u and the temperature T of the heavy particles, and the electron temperature T_e. This inviscid hydrodynamic/diffusion system derived from Eq. (8) is:

$$
\begin{aligned}
&\partial_t \rho_n + div(\rho_n u) = 0, \qquad t > 0,\ x \in I\!R^3,\\
&\partial_t \rho_i + div(\rho_i u) = \rho_i\ Y^{ir},\\
&\partial_t(\rho_n u) + div[\rho_n (u \otimes u)] + \bigtriangledown_x(\rho_n T) - \rho_n F_n = 0,\\
&\partial_t(\rho_n E) + div[\rho_n u\,(E + T)] - \rho_n u \cdot F_n = 0,\\
&\partial_t T_e + u \cdot \bigtriangledown_x T_e + \frac{2T_e^2}{3T_e + 2\Delta}\left(div\,(u) - \frac{1}{\rho_e} \bigtriangledown_x \left[\rho_e D_1\Big(\frac{\bigtriangledown_x \rho_e}{\rho_e} - \frac{F_e}{T_e}\Big) + \rho_e D_2 \frac{\bigtriangledown_x T_e}{T_e}\right]\right)\\
&\qquad\qquad = \left(1 + \frac{\rho_i}{\rho_e}\right)\ \frac{2T_e^2}{3T_e + 2\Delta}\ Y^{ir},
\end{aligned}
$$

with the energy $E = \frac{1}{2}\ |u|^2 + \frac{3}{2}\ T$. The diffusion coefficients are

$$
\begin{aligned}
D_1 &= \int_{I\!R^3} M_{0,T_e}(v_e)\ \Psi_1(|v_e|)\ v_e \otimes v_e\ dv_e\ ,\\
D_2 &= \int_{I\!R^3} M_{0,T_e}(v_e)\ \Big[\Big(\frac{3}{2} + \frac{\Delta}{T_e}\Big)\ \Psi_1(|v_e|) + \Psi_2(|v_e|)\Big] v_e \otimes v_e\ dv_e\ .
\end{aligned}
$$

The ionization-recombination source term Y^{ir} and the functions Ψ_1 and Ψ_2 are detailed in [3]; M_{0,T_e} is the normalized and centered Maxwellian for electrons. This system is supplemented by the closure relation defining the electron density (9).
We thus observe that due to the important difference in masses between heavy particles and ions, and to the collisions with impact ionization, this inviscid macroscopic limit does not lead to the standard Euler equations for a plasma problem. An important property of this new macroscopic model is that the electron density is governed by a generalized Saha law rather than a conservation equation.

The extension of this study to a viscous plasma flow is under progress.

Expanding Thermal Plasma Deposition of Hydrogenated Amorphous Carbon Films

J. Benedikt, R.V. Woen, M.C.M van de Sanden

Department of Applied Physics, Eindhoven University of Technology, Eindhoven, The Netherlands

Abstract
Ar/C_2H_2 expanding thermal plasma (ETP) is used for hydrogenated amorphous carbon (a-C:H) deposition. The ETP plasma is able to produce good quality a-C:H (hardness 14 GPa) at very high growth rates (up to 70 nm/s) without ion bombardment involved. The remote nature of the plasma is suitable for the study of plasma chemistry by means of laser spectroscopy and mass spectroscopy in combination with plasma chemistry modelling. The reactive species in ETP are identified and their role in the growth is discussed.

Introduction
As summarised recently by Robertson [1] most of the good quality a-C:H films (and diamond-like carbon films in general) prepared by plasma enhanced chemical vapour deposition techniques requires an ion bombardment (ion energy typically 100 eV) during the growth. This presence of ion bombardment leads to a growth process that is physical in nature and the chemical identity of the growth precursors is suppressed.
On the contrary, good quality a-C:H films are grown by means of Ar/C_2H_2 ETP without ion bombardment involved. In the remote part of the ETP the electron temperature is low and the plasma behaviour is ruled by the heavy particle kinetics, e.g. hydrogen abstraction or ion induced reactions [2]. In other words the generation of precursors for growth is dominated by the chemistry and not by physical processes such as electron impact dissociation or ionisation in direct plasmas. The chemistry in remote plasmas could therefore be more selective and lead to the dominant production of one specific precursor. These conditions can possibly leads to different material properties allowing e.g. to achieve better electronic properties.
For understanding the growth mechanism under Ar/C_2H_2 ETP conditions it is essential to study plasma chemistry. Cavity Ringdown Spectroscopy (CRDS) and Mass Spectrometry (MS) was used to measure densities of hydrocarbon radicals (C, CH and C_2), consumption of acetylene gas and production of stable molecules (C_4H_2, C_6H_2). Next to it, also broadband absorption was observed and can be most probably assign to the C_2H radical and C_2H functional group in C_4H_2 molecule. Remote nature of the ETP is very suitable for successful modelling of obtained results. Simple plug down model was build and has shown very good agreement with experimental results. The influence of plasma composition on the film properties (determined by single wavelength ellipsometry) will be discussed.

Experimental Setup
A schematic view of the deposition system is shown in Fig.1. A cascaded arc creates Ar plasma (0.2-0.5 bar), which expands into a low-pressure vessel (0.3 mbar). This expansion is first supersonic and than, after the shock, subsonic [2]. Because of this high pressure difference between the arc and the vessel, there is no influence of the conditions in the vessel on the performance of the arc, and the amount of argon ions and electrons, emanating from the arc is fully determined by cascaded arc settings (argon gas flow and applied arc current). Acetylene is injected into the ETP beam and different radicals (and ions) are created. The substrate holder is positioned 60 cm downstream from the nozzle where the deposition takes place. The temperature of the substrate is well-controlled ($\Delta T < 10°C$ when exposed to plasma) [3] and is kept at 250°C. Pressure in the reactor is not kept constant and increases slightly (up to 10% of its starting value) with increasing acetylene flow. The setup is described in more detail elsewhere [3,4,5].
The CRDS setup is described in Refs. [6,7]. All the measurements were done 30 mm above the substrate with the laser beam crossing the ETP axis. Saturation effects are checked carefully in all the measurements. It should be noted that with CRDS line integrated densities are obtained. It is assumed that all the species have similar radial density profiles. The details of the CRDS measurements and the description of the CRDS principle are given elsewhere [6,7,8].

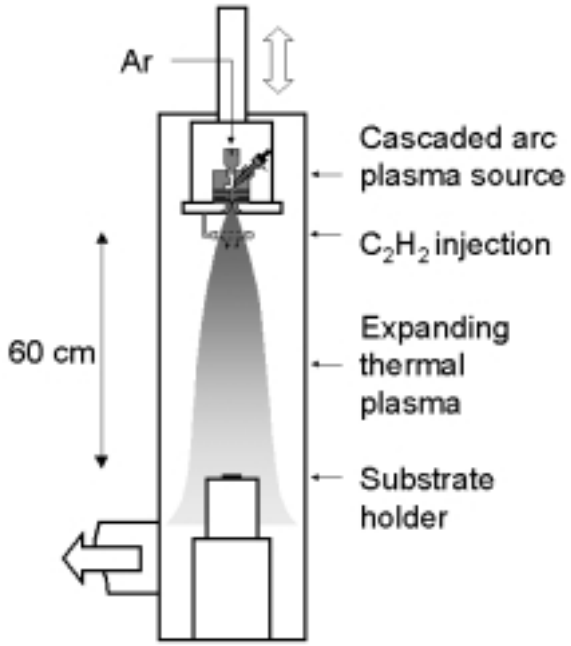

Fig. 1: Experimental Setup

Results and discussion

Experimental results

The MS measurement of acetylene and diacetylene in the background of the plasma at the arc current of 48A are shown in Fig. 2. Since arc current is fixed, also the amount of argon ions and electrons emanating from the cascaded arc is constant. Than varying the acetylene flow into the reactor, we vary the $C_2H_2/(Ar^+,e^-)$ ratio. At small acetylene flows all the acetylene is consumed in the plasma and transformed into different reaction products. On the contrary for high acetylene flows the consumption is saturated and does not increase as demonstrated by the fact that the difference between measurement at plasma off and plasma on conditions is constant. The C_4H_2 measurement shows absence of diacetylene for small acetylene flows and saturated values for high acetylene flows.

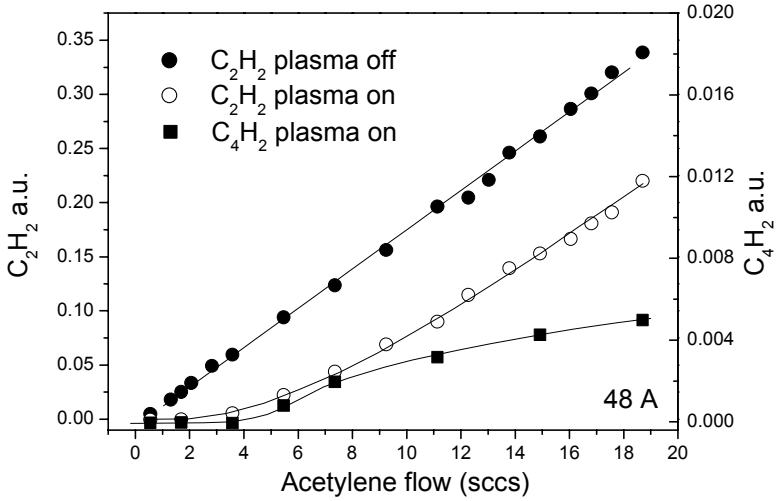

Fig. 2: Mass spectrometry measurement of C_2H_2 and C_4H_2 molecules as function of acetylene flow at fixed arc current of 48A. No C_4H_2 was observed under plasma off conditions.

To understand the results in Fig. 2 we need first to discuss the dissociation process of the acetylene injected. The first step is a charge transfer reaction between acetylene and an argon ion [9]:

$$Ar^+ + C_2H_2 \rightarrow Ar + C_2H_2^{+,r,v} \qquad k_1 \approx 4.2 \times 10^{-16}\ m^3/s \qquad (1)$$

This step is followed by a dissociative recombination of the molecular ion with an electron [10]:

$$C_2H_2^{+,r,v} + e^- \rightarrow C_2H^* + H \qquad k_2 \approx 3 \times 10^{-13}\ m^3/s \qquad (2)$$
$$\rightarrow CH^* + CH^*$$
$$\rightarrow C_2 + H + H$$

Since we are dealing with remote plasma and the reaction rate constants k_{CE} and k_{DR} are relatively large, for low acetylene flows there are more argon ions than acetylene molecules and acetylene can be fully consumed in reaction (1). On the contrary for high acetylene flows all the argon ions and electrons are consumed in reaction (1) leaving some acetylene unconsumed. The constant acetylene consumption at high acetylene flows indicates that polymerisation does not take place in the plasma chemistry. It was already argued, that C_2H radical is the dominant product of reaction (2) [11]. Main source reaction for the diacetylene molecule is than the reaction of C_2H radical with acetylene [12]:

$$C_2H + C_2H_2 \rightarrow C_4H_2 + H \qquad k_3 \approx 1.3 \times 10^{-16}\ m^3/s \qquad (3)$$

The C_4H_2 molecule is a stable molecule and will most probably not react with acetylene. Since C_2H production is limited by amount of available argon ions and electrons the C_4H_2 measurements saturates at high acetylene flows.

In Fig. 3 the C metastable state, CH and C_2 radicals absorption together with broadband absorption (BBA) are shown as measured by CRDS. The CH, C_2 and C radicals are created in a secondary reaction of C_2H radical with another argon ion and electron pair:

$$Ar^+ + C_2H^{e,r,v} \rightarrow Ar + C_2H^{+,r,v} \qquad (3)$$

$$C_2H^{+,r,v} + e^- \rightarrow CH^* + C^* \qquad (4)$$
$$\rightarrow C_2^* + H(n=1,2,\ldots)$$

This reaction takes place only when there are enough Argon ions and electrons in the plasma (two Argon ions and two electrons per acetylene molecule are needed). For this reason the highest C, CH and C_2 absorption is measured at low acetylene flows.

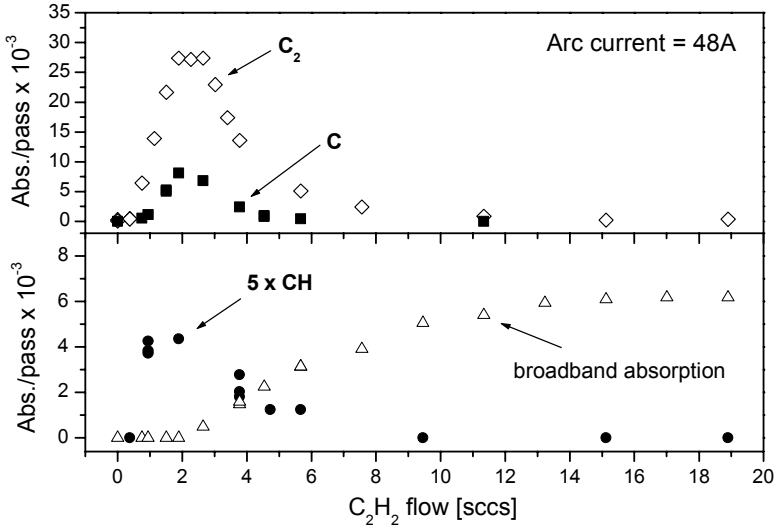

Fig. 3: C, CH, C2 and broadband absorption (BBA) as measured by CRDS.

Modelling of the plasma chemistry

The geometry of the expanding thermal plasma with the nozzle and injection ring followed by the expansion region allows modelling of the plasma chemistry with a rather simple plug-down 1D-model [13]. To the reactions mentioned above the loss processes of C [14], CH [15] and C_2 [16] radicals has to be added:

$C + C_2H_2 \rightarrow$ products $\quad k_4 \approx 2.8 \times 10^{-16}$ m^3/s (4)

$CH + C_2H_2 \rightarrow$ products $\quad k_5 \approx 3 \times 10^{-16}$ m^3/s (5)

$C_2 + C_2H_2 \rightarrow$ products $\quad k_6 \approx 1$ to 5×10^{-16} m^3/s (6)

More details about the model can be found in [17]. Comparison of experimental results (C_2 radical, C_4H_2 molecule) and modelling is shown in fig. 4:

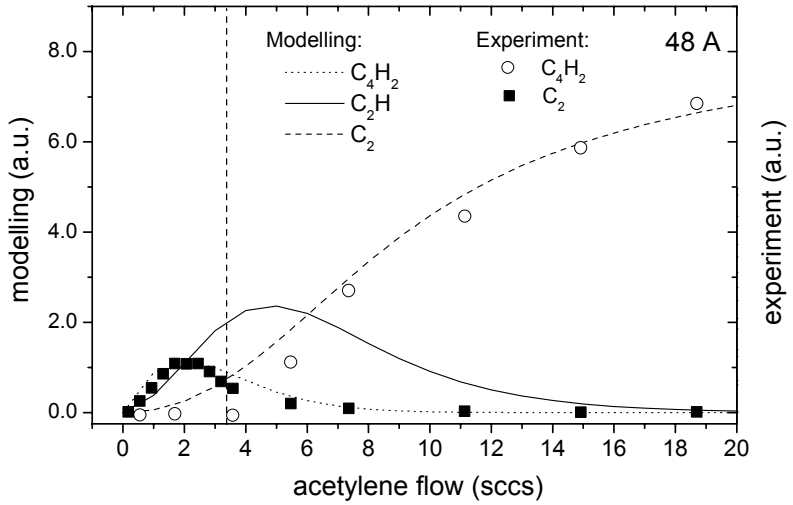

Fig. 4: Comparison of experimental and modelled result. Vertical dashed line indicates argon ion and electron flow used in the model.

Argon ion (and electron) flow was used as a variable parameter. The value of 3.3 standard cubic centimetres per second (sccs) gave the best agreement between the measurements and the model. Both experimental results and modelling shows, that ETP beam composition changes as the $C_2H_2/(Ar^+,e^-)$ ratio changes. At low flows mainly C, C_2 and CH radicals reach the substrate, at higher flows with ratio close ore slightly higher than unity C_2H radical is dominant species in the beam. At very high acetylene flows the radicals react away in the gas phase and C_4H_2 molecules arrives to the substrate.

Broadband absorption

A broadband absorption (BBA) was observed together with C, CH and C_2 absorption (in the wavelength regions 248nm, 431nm and 517nm). Its values at 248 nm and 431 nm as a function of acetylene flow are shown in Fig. 5. It is clear that more than one species contributes to the BBA since it behaves differently at different wavelengths (seen also at 517 nm). The most remarkable change is around 5 sccs of acetylene flow, where the plasma chemistry model predicts highest C_2H radical density. The BBA measured at the wavelength of 248 nm has the feature around 5 sccs much less pronounced and resemble more the C_4H_2 data. Insert in Fig. 5 shows BBA as function of wavelength at highest acetylene flow of 18.7 sccs. It shows exponential dependence with exponent of –6.4. Similar BBA behaviour (with exponents ranging between –2.7 and –9.2) was observed in flames in not sooting conditions [18] and was attributed to aromatic functionalities or chromophoric groups containing not more than two aromatic rings.

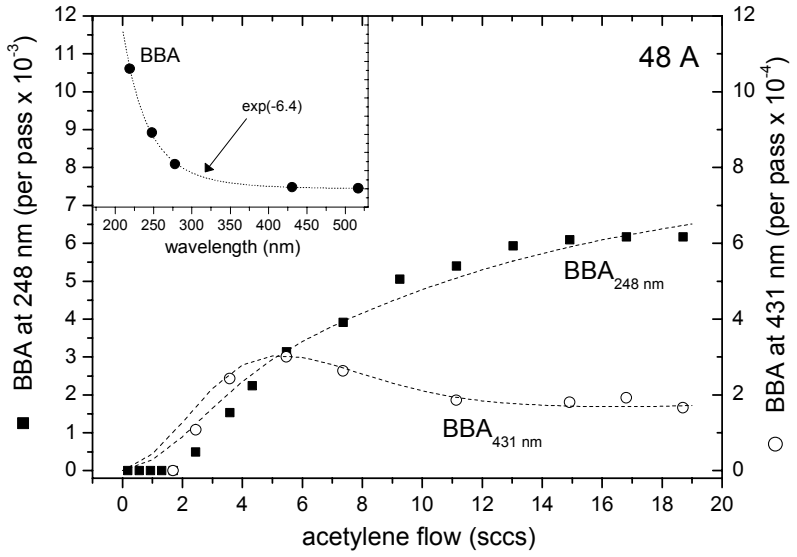

Fig. 5: BBA at two different wavelengths. Dashed lines were constructed as combination of C_2H and C_4H_2 densities as predicted by the model. Insert shows BBA at highest acetylene flow as function of the wavelength.

On the basis of obtained experimental data, modelling and the fact that -C≡C-H group is a chromophoric group we suggest that this group is a cause of BBA in our Ar/C_2H_2 ETP. Than both C_2H radical and C_4H_2 molecule can contribute to BBA. The supporting argument is the fact, that we were not able to detect any of reported spectral features of the C_2H radical or C_4H_2 molecule [19], probably due to broadening of their spectra as a result of their high ro-vibrational excitation.

A-C:H films growth

Fig. 6 shows refractive index and film growth rate as determined by real-time in situ single wavelength ellipsometer. It was shown that in the case of our a-C:H films the refractive index is the measure of mechanical properties of the films [4]. The dashed line indicates the argon ion and electron flow given by the model.

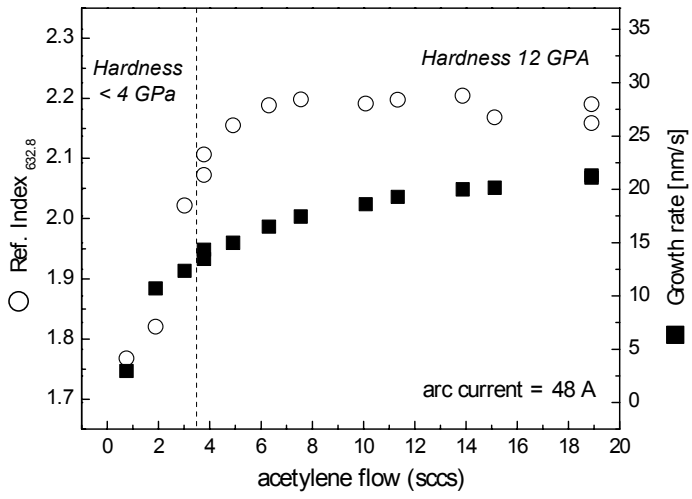

Fig. 6: Refractive index and growth rate of a-C:H films as determined by real-time in-situ single wavelength ellipsometer.

Comparing now ETP beam composition with results in Fig. 6 we can conclude that first C, CH and C_2 radicals do not lead to the deposition of hard a-C:H films. Second that highest refractive index is reached at the acetylene flow in which C_2H density above the substrate is expected to be maximal. Third good quality a-C:H films are also grown under the conditions, where C_4H_2 molecules are dominant in the ETP beam and, next to it, BBA scales very well with the film growth rate, both indicating that C_4H_2 molecules contribute to the film growth. As a deposition mechanism of C_4H_2 molecule we suggest its braking under impact onto the plasma activated surface into two C_2H radicals.

Aerosol Production by Dielectric Barrier Discharges in air at atmospheric pressure

N. Jidenko[1], J.-P. Borra[1]

1 Laboratoire de Physique des Gaz et des Plasmas (CNRS –Univ. Paris XI)
Equipe Décharges Electriques et Environnement, SUPELEC, France

Abstract
This work focuses on sub-micrometer aerosol production in DBD by nucleation in air of very locally saturated vapour produced when filamentary discharges reach the surface. Two hypotheses on the source of condensable vapours (sublimation by Joule effect or ion sputtering) are discussed by comparison of aerosol frequency (part/s) for constant electrical energy flux, related to constant charge per filament with different surface temperatures. Then, the air flow rate is varied to discuss of competition between production and collection in this plane-to-plane DBD arrangement.

1. Introduction

As already observed with point to plane arrangements in clean air at atmospheric pressure, either with metallic electrodes polarised in DC or with AC Dielectric Barrier Discharges (DBD), the increase of the applied voltage induces the same succession of the same electrical discharge regimes (auto-stabilisation, glow, filamentary streamer and spark). Whatever the symmetry and the polarisation waveform, i.e. whatever the geometry and the related distribution of filaments in time and space are, production of nanometer aerosol is observed when filamentary discharges reach the surface [4, 5, 6]. Particles are produced by gas to particle conversion i.e. nucleation of sursaturated vapour produced either (i) from surfaces by plasma-surface interaction in carefully conditioned air at atmospheric pressure, (as proven by size distribution measurements and chemical analysis of particles electro-precipitated on the electrodes [10] as well as collected in the effluents of DBD [5]) ; or (ii) from combustion like mechanisms in depollution plasmas of Volatile Organic Compounds (polluted air), where condensable species are produced by plasma-gas interaction in volume [5, 6]. This paper focuses on surface erosion in clean air characterised by particles frequency between 10^2 and 10^9 part/s (with a few l.p.m), depending on geometry, humidity and voltage in terms of experimental parameters and related to the impulse component of the electrical power injected in the plasma (P_{imp}) and on gas flow rate for dilution factor.

$P_{imp} = \frac{1}{nT}\int_{nT} i_{imp}(t).u(t).dt$, $i_{imp}(t)$: impulse current, u(t): applied voltage, T: period and n: an integer.

To deal with the origin of vapour from surfaces submitted to filamentary discharges, sublimation by Joule effect and/or on ion sputtering in the spot can still be considered because the energy flux is related to both charge per filament and ionic sputtering as well as to the spot temperature at the feet of the filament and sublimation. To check the mechanism of production, we work with silent discharges (plane to plane), where the discharges only occur in numerous micro-discharges (filaments) [1-3] so that all the electrical power is injected in the gap through impulse filamentary discharges i.e. power and energy flux on surface (in $Watt.m^{-2}$ or $J=.s^{-1}.m^{-2}$) are directly proportional. The reduction of the discharge gap length enables us to reduce the charge per filament and to control independently the surface temperature, as experimentally observed [5] and confirmed by considerations about the ratio d/ε_r (d: gap and ε_r: relative dielectric permitivity [7]). Assuming that the kinetic energy of ions reaching the plane is related to charge per filament, this short gap configuration allows us to carefully control the surface temperature via heat exchanges on surfaces for constant electrical energy flux i.e. the "decoupling" of kinetic energy (assumed to be related to charge per filament) and surface temperature.

In the first part, from particle production rate (part/s) versus electrical characteristics and from aerosol size distributions, we confirm the nucleation mechanism induced by interaction of filamentary discharges with dielectric plane in a plane-to-plane geometry. Two hypotheses on the source of condensable vapours (sublimation by Joule effect or ion sputtering) are discussed versus surface temperature by particle production rate measurement during the transient initial phase to reach the quasi-steady-state surface temperature and particle production rate (QSS). Then, when surface temperature is stable at the QSS the air flow rate is varied. Results are coherent with a competition between production and collection in the DBD arrangement considered as an AC Electro Static Precipitator, as already described by [5, 9, 10].

2. Experimental set-up

The dielectric media is a single stage of honeycomb monolith between two plane electrodes constitutes the discharge cell. Their area is about 3 cm2. The discharge gap (pore diameter) measures 1 mm. The electrical discharges occur in numerous filaments distributed in time and space.
A 1 to 60 kHz signal is derived from a function generator, fed through a 2 kW amplifier, and then stepped up with a high voltage transformer. This sinusoidal AC high voltage is applied across the cell electrodes and measured by high voltage probe. The current crossing the cell is measured through a 50 Ω adaptive line to prevent from deformation and reflection. Dry air flows are controlled with mass flow controllers between 1 and 3 L/min. Using an oscilloscope (LeCroy LC374A, 500 Mhz, 2 Gs/s), both current and tension are treated as described in previous paper [8]. The current measured is an influence or displacement current underestimated in our conditions (represents only 85% to 95% of the current crossing the gap).

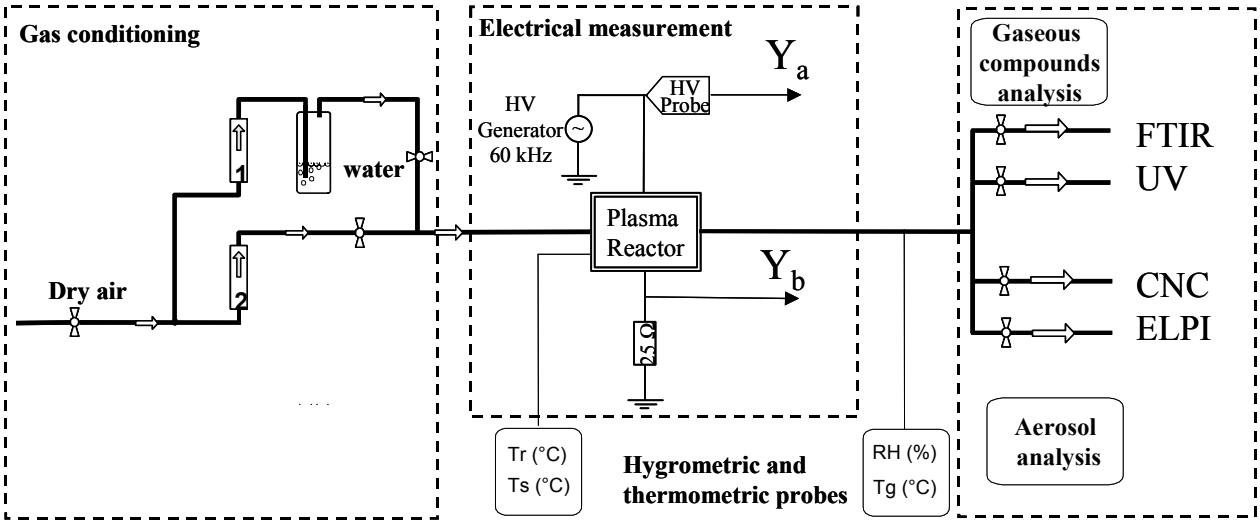

Figure 1: Experimental set-up

The aerosol concentration in the outlet gas is characterised by a Condensation Particle Counter (model CPC 3022 TSI) for all the particles whose diameter are higher than 5 nm. An Electrical Low Pressure Impactor (ELPI Dekati) gives its size distribution with 11 trays between 30 nm and 10 µm. The outlet gas and the metallic electrode temperatures (Tg and Te) are measured with thermocouples in order to evaluate the mean dielectric surface temperature (Ts). Tg and Te depend on gas flow rate and on thermal exchanges around the dielectric. The more representative temperature to deal with Ts, is the Te of the metallic electrode less than 200 µm from the dielectric surface.

3. Results and discussion

3.1 Quasi-steady state equilibrium

For a given operating condition (frequency 60kHz, peak to peak voltage from 12 kV to 17 kV, air flow rate 2 L/min), when the quasi-steady state equilibrium is reached, the concentration of particles as well as all the characteristic temperatures are related to the impulse component of the electrical power injected in the plasma (depending on the applied voltage). On Figure 2, the aerosol frequency (number of particles per second) at the output of the reactor is plotted versus the energy flux on surface (ϕ_e=P/S where P the input power and S is the area of an electrode, expressed in Joule by cm^2 per second or Watt /cm^2).

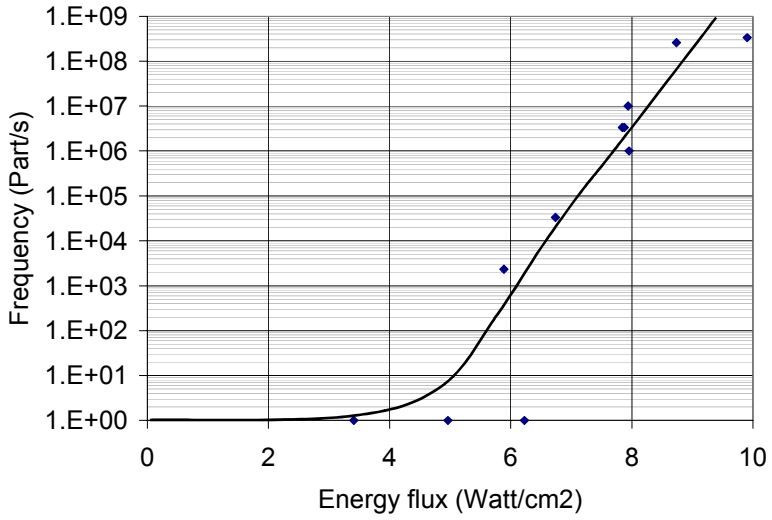

Figure 2: Aerosol frequency (part.s-$^{1)}$ at the reactor output versus energy flux (J/s.cm^2)

The first remark lies on the existence of a threshold effect when dealing with particle production rate versus impulse input power. This has never been observed in longer gap, probably because of the higher minimum impulse energy flux per filament reaching the plane on longer distances. Assuming that the kinetic energy of ions reaching the plane ("pushed" by the primary streamer charge density) is related to charge per filament measurements, this apparent electrical threshold would tend to support ions sputtering rather than sublimation effect (even with small filaments with lower charge per filament than 10 pC/filament, the aerosol production is null); but for lower energy fluxes than the apparent threshold value reported on figure 2, and constant charge per filament lower than 10 pC/filament with different surface temperatures (controlled by heat exchanges), this threshold energy is rather related to a corresponding threshold surface temperature of 140°C with alumino-silicate and 160°C with aluminium oxides dielectric barriers, in air at atmospheric pressure (cf. Fig 4b).

3.2 Nucleation confirmed by aerosol size distribution

Prior to any discussion about the mechanism of vapour production through ion sputtering or sublimation we first confirmed from aerosol size distribution that the nano-particle production arises from nucleation i.e. from gas-to-particle conversion (90 % of the aerosol is smaller than 30 nm, [8]). The operating conditions are: gas flow rate Q=3 L/min, peak-to-peak applied voltage Vpp=17 kV, input power P=30 Watt and temperature of the metallic electrodes Te=170 °C. In those conditions, the aerosol concentration is about 2^{E7} part/cm^3. The aerosol size distribution in plotted on Figure 3, the different trays are in dashed line and the real size distribution is in dotted line.

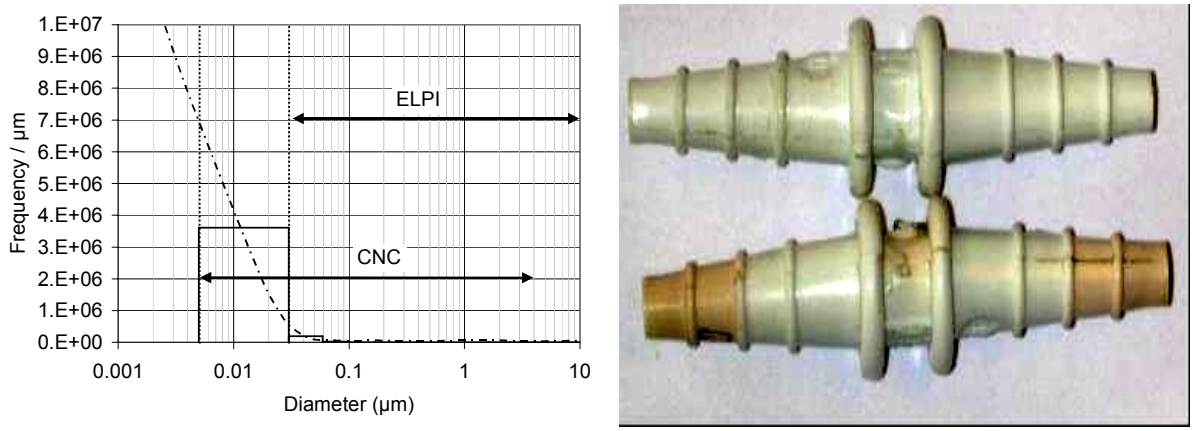

Figure 3: Aerosol size distribution and picture of the tube connector before (above) and after (below) the reactor

Three major arguments tend to show that this vapour comes from the dielectric planes and is produced by plasma-surface interaction: (i) the same phenomenon is observed in different clean gases (without volatile organic compound, such as N_2). The gas does not seem to be important for the particles production. (ii) The gas flow rate does not modify neither aerosol size distribution nor aerosol frequency (for gas flow rate higher than 2 l.p.m as discussed in §3.4). This means that the vapour concentration is not modified by the gas flow rate because if it would come from condensable species created by interaction plasma gas, the partial pressure (inversely proportional to the gas flow rate) and thus the frequency of nucleation and size distribution would be affected. So the vapour and the subsequent nucleated nano particles do not seem to be produced in the volume but locally before homogenisation of the concentration in the whole reactor volume (constant aerosol frequency independently of dilution); iii) after few tens hours of work the air connector at the output is coated by particles of the same colour than the dielectric (see picture of the lower connector in figure 3).

3.3 Transient state: Influence of the surface temperature

When the DBD is turned on, the mean surface temperature evolves from ambient to a final equilibrium temperature depending on the discharge current and on thermal exchanges around the dielectric, while both electric characteristics and the temperature of neutral species in filaments are constant. It is thus possible to discuss about the transition observed in § 3.1 with an energy flux nearly constant. Figure 4 a) depicts the evolution of electrode temperature (dotted line) and particles frequency (dashed line) since the lighting on to the quasi-steady-state (Q=2 L/min, Vpp=14.2 kV, Ps=7 Watt/cm^2). On the right is plotted the aerosol frequency versus the temperature for the transient initial phase (dotted line) and the aerosol frequency at the quasi-steady-state (dashed line). The discrepancy between the final steady states (temperatures and aerosol frequencies) can be explained by taking into account different thermal conditions (ambient temperature 20 °C and 26 °C and dielectric thickness 150 µm and 300 µm).

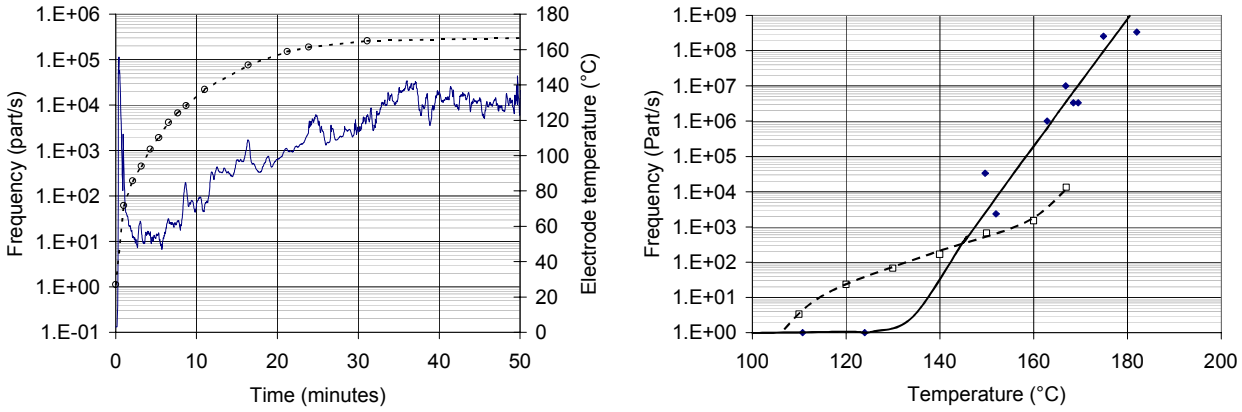

Figure 4: (a+b) Evolution of aerosol concentration and electrode temperature

- At first, when the discharge is switched on, there is a particle's puff. This initial puff can come from the suspension of unadherent particles already deposed on surfaces.

- Then the production of nucleated particles follows the mean surface temperature. For lower electrode temperature than 110°C there is no particle counted at the output. This temperature is different than the transition one at the QSS (140°C) because of the heat dynamic: the difference between surface and electrode temperatures is higher during the transient state than during the quasi steady state (the thermal capacitance of the metallic electrodes slows the temperature rising).

    - Aerosol frequency dependence on surface temperature for constant filament properties tends to support the sublimation process rather than ionic sputtering for the vapour production. For a constant energy flux related to constant charge per filament, the production of particles evolves with the mean surface temperature that is the more reliable measured temperature to deal with the spot temperature at the feet of the filament. This is confirmed by another experience, starting of the QSS and observing the evolution of the concentration and the temperature with an external cooling. The diminution of the surface temperature without modifying the energy flux and the related filament properties, induces a decrease of aerosol frequency.

Even if the mean surface temperature (less than 500 K) is under dielectric fusion temperature (about 2 000 K), one has to emphasise that this mean temperature results on thermal energy transfers to the surface occurring through the spots. Thus, this mean surface (temperature characterised through Te measurements), is related to individual thermal contribution of single filaments multiplied by the number of filament per second. However the spots last about 20 ns and on a surface of about 0.01 mm^2 so the local temperature is probably above sublimation temperature of the surface with the corresponding energy flux per filament estimated from 10^9 to 10^{16} J/s.m2 in our conditions, even if only a part of this total energy flux per filament is involved in heating of the surface.

3.4 Gas flow rate influence: 5 phases between production and the output of the reactor

The gas flow rate changes transit time and surface temperature without modifying significantly the plasma conditions. On Figure 5, the evolutions of the aerosol frequency with the gas flow rate (between 1 and 3 L/min) are plotted for four voltages (from 14 kV to 15.5 kV).

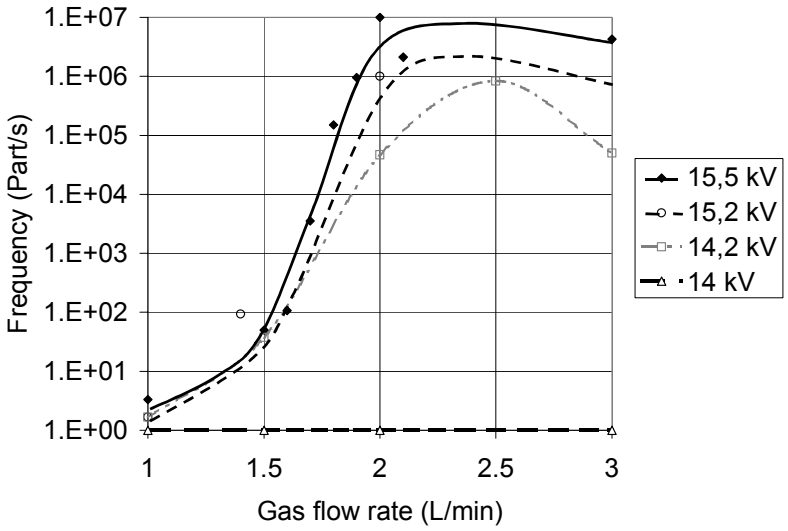

Figure 5: Aerosol frequency versus gas flow rate for different voltages

Except for the lower voltage, where there is no aerosol at the output whereas the input power is about 15 Watt (i.e. 5 Watt/cm^2) all the curves have the same shape. The output aerosol frequency increases with the gas flow rate until a maximum frequency depending on the input power. After this maximum the output aerosol frequency decreases.

- For the lower voltage, there is no aerosol at the output whereas the input power is about 15 Watt i.e. 5 Watt/cm^2 probably because surface temperature lies under the threshold temperature discussed in §3.1.
- At 1 L/min there is no aerosol whatever the energy flux or the electrode temperature are, probably related to longer transit time of charged particles in the polarised gap enabling collection of particles, as discussed below.
- The shape of aerosol frequency versus gas flow rate could be explained by the fact that even if there is no aerosol counted at the output, production of aerosol could occur in the reactor. Actually, between the production of vapor by the interaction of filament on the surface and the output of the reactor there are at least five phases: nucleation, growth, transport, charge, and exit/collection. Nucleated aerosol is produced as described before. Once created, they can grow by heterogeneous nucleation and coagulation. Then the ions produced by the discharges can charge the particles. So that they can be collected on the surfaces by electro-precipitation mechanism like. Before the maximum aerosol frequency (for low air flow rate), longer transit times allow the growth, the charge and the electrostatic collection of all the particles formed: the electrostatic force is dominant. But with transit time smaller than 10 ms (gas flow rate > 1.5 l.p.m), particles have less time to grow up, to get charged and to be collected: the training force becomes greater than electrostatic one. After the maxima, nearly constant aerosols frequencies are observed independently of the gas flow rate; this means that all the particles produced can reach the output of the

reactor without being collected because nearly only a dilution effect is dominant. Nevertheless, the small decrease of aerosol frequency can be explained by a better surface cooling all the more noticeable at lower voltages inducing lower energy and resulting heat fluxes on surfaces and lower surface temperature.

As a conclusion, surface temperature can modify vapour production, transport through thermophoresis, charge, Brownian and coulombian coagulation, as well as the reduced field (~E/P). Thus, for a given energy flux and related charge per filament, the dielectric surface temperature and residence time play on each process involved in the sequence from vapour production to exit of nucleated aerosol from the reactor (vapour production, nucleation, growth, charge and transport i.e. exit/collection).

4. Conclusion

Even if under certain conditions no particle is counted at the output of the reactor whereas the discharge mode is filamentary, it seems that filamentary discharges always produce particles. “Small filaments” (charge per filament from 1 to 100 pC/filament) produced by DBD in shorts gaps does not prevent from nucleated aerosol production. This tends to show that with “small filaments”, either (i) the kinetic of ions reaching the plane is still higher that the minimum kinetic energy required for ion sputtering or (ii) the sublimation is the dominant process to account for vapours arising from plasma-surface interaction in the feet of the filament when it reaches the plane. Moreover, this sublimation hypothesis is supported by the reported effects of surface temperatures (related to spot temperature) on nucleated aerosol frequency.

Then, from flow rate influence for a given energy flux and related charge per filament, the dielectric surface temperature and residence time play on each process involved in the sequence from vapour production to exit of nucleated aerosol from the reactor (vapour production, nucleation, growth, charge and transport i.e. exit/collection). Nevertheless, great experimental efforts have still to be done so as to define surface temperature influence on vapour production and/or charging, growing and collection after the production during the transit time in the reactor.

However, silent discharges at atmospheric pressure could be used either as nano-particles production tool or as well as filtering devices for particle collection.

Abstract
The influence of the dielectric barrier discharge regime on the dust nucleation and growth is studied in a plasma formed in a $N_2/SiH_4/N_2O$ mixture at atmospheric pressure. Two kinds of dielectric barrier discharges are compared : the filamentary and the glow discharges. The formation of large aggregates is more important and more rapid and reactive gases dissociation is quicker in the case of a filamentary discharge. However kinetics of formation of particles seem to be the same in the two regimes.

1. Introduction

Whatever the pressure, the use of silane in a plasma easily leads to the formation of powders or particles. This formation was first considered as disastrous in particular in micro-electronics industry where dust contamination can severely reduce the yield and performance of fabricated devices. Also the effort essentially aimed at avoiding particle growth in order to control the contamination level in industrial reactors. Since thirty years more and more studies have been led and some positive aspects of dusty plasmas have progressively emerged and now particles are not anymore considered as only unwanted pollutants. Control of the properties of plasma produced particles allows the development of new technologies or new materials [1,2,3].

The aim of this study is to understand the particles formation in a silane plasma containing an oxidizing gas, at atmospheric pressure. After a brief description of the experimental set-up and the discharges used, results will be presented and discussed.

2. Experimental set-up

The discharge is produced between two parallel and rectangular electrodes, both covered by a dielectric layer (alumina). A silicon wafer, used as a substrate, is placed on the lower electrode (figure 1).
After a primary vacuum of 10^{-1} Pa is achieved, the vessel is filled to atmospheric pressure (10^5 Pa) with a mixture of N_2, SiH_4 and N_2O . During the discharge, gases are introduced laterally, on one side of the reactor. The pressure is maintained constant by slight pumping. The flow of each gas is controlled by mass flow controller. An alternative voltage is applied to the electrodes. The frequency is about few kHz and the amplitude reaches 10kV. The discharge current is measured thanks to a 50Ω resistance in series with the mass electrode.

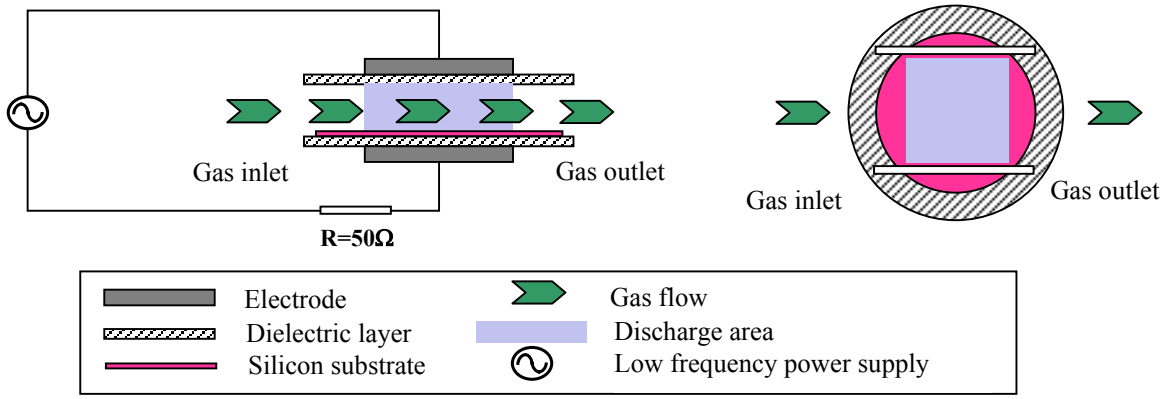

Figure 1 : schematic diagram of the reactor

Some of the particles formed during the discharge deposit on the substrate. Ex-situ analysis by optical or scanning electron microscopy allow to determine the size and the localization of these particles.
As the gas flow injector is on one side of the discharge, the decomposition of the reactive gases and particles growth can be studied relatively to their residence time in the discharge.
The gas phase is studied by optical emission spectroscopy (OES). Measurements are made through a quartz window using an optical fiber and a 27cm focal length monochromator (SPEX 270M) equipped with a 1200 lines mm^{-1} grating coupled to an intensified CCD camera (Jobin Yvon, i-spectrum one).This system works in the range of 200-800nm with a wavelength resolution of 1nm. A collimator system allows a space resolution in the discharge equal to 5mm. The acquisition of spectra was synchronized to the discharge current, permitting time resolution.
Appearance of particles in the gas phase is studied by laser light scattering. A laser diode (Stocker Yale, Lasiris SNF 501-L, 680nm, 70mW) is used. The beam is focused and pass trough one side of the discharge to the other, in the opposite way of the gas flow. When the beam meets a cloud of particles, a part of the light is scattered and detected at 90° by the same equipment as for OES.
Powders deposited on the substrate are studied by optical and Scanning Electron Microscopy (SEM).

3. Two kinds of discharges

At atmospheric pressure, two kinds of dielectric barrier discharges can develop : the glow discharge and the filamentary one.
The glow discharge is characterized by the appearance of a single discharge canal covering the whole surface of the electrodes. We observe a single current peak by half period of the applied voltage (figure 2b). It lasts a few hundreds of microseconds.
On the contrary, during a filamentary discharge, a large numbers of micro-discharges develop simultaneously and randomly in the gap. Each micro-discharge has a diameter of about 100µm and lasts a few tens of nanoseconds. In a half period of the applied voltage many current peaks can be observed, each one corresponding to the sum of the currents through the filaments developing at the same moment between the electrodes (figure 2a).

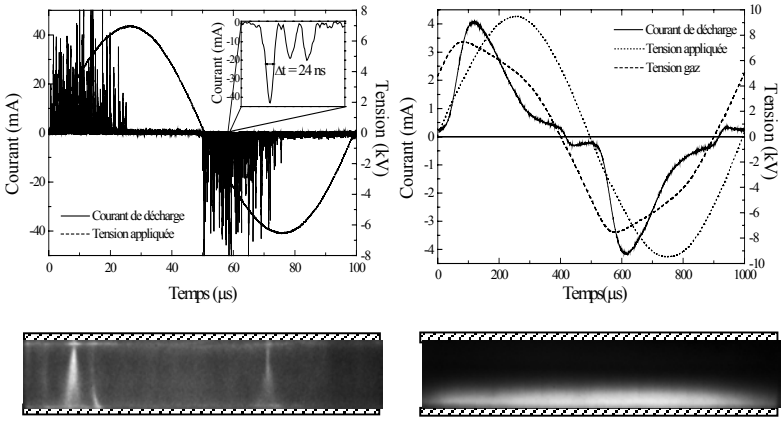

Figure 2 : electrical characteristics and photographs (10ns exposure time) of (a) a filamentary discharge and (b) a glow discharge

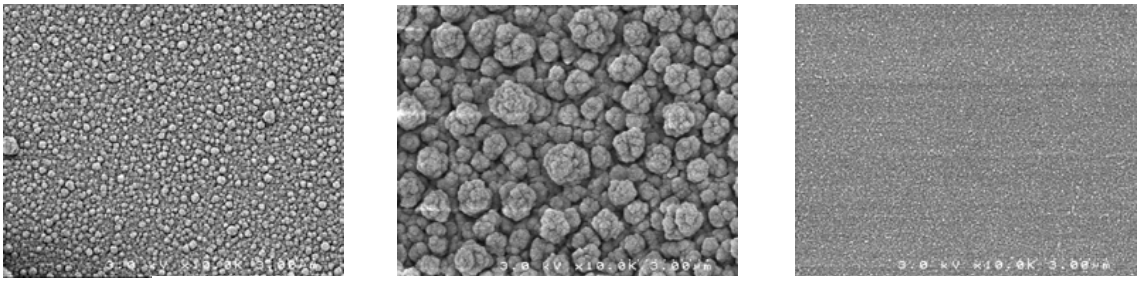
In some specific conditions of gas flow and excitation frequency, it is possible to obtain, by simply increasing the applied voltage, a low power filamentary regime (30mW/cm² at 10.5kV), a glow discharge (0.4W/cm² at 11.5kV) and a high power filamentary regime (1.2W/cm² at 15kV). The comparison of the powder formation in these three discharges allows to distinguish the influence of the discharge regime, glow or filamentary, and the power on the formation and growth of particles.

4. Observations on the substrate

The sample obtained with a glow discharge presents a whitish band of 0.5cm at 1cm from the gas inlet. Nevertheless, powders cannot be observed with optical microscope.

Whatever the power, filamentary samples look much more dusty, with a high concentration of powders even at the first beginning of the discharge area (0.5mm). Analysis with optical microscope leads to the conclusion that these powders are in fact aggregates of smaller particles. The smallest particle discernible with the optical microscope is 1µm in diameter.
We can also conclude that the glow discharge does not form such big particles, whereas the filamentary discharges create powders of about 1µm in diameter.

Analysis of these samples with a Scanning Electron Microscope confirms these observations.
On the filamentary sample obtained at high frequency, big clusters of particles can be observed. These aggregates grow rapidly up to 800nm at 2.5mm from the beginning of the discharge area (figure 3, a and b). Then they disappear suddenly : the deposit is only made of an accumulation of small grains of about 40 nm in diameter (figure 3c).



(a) (b) (c)

Figure 3 : SEM photographs of the surface of a high power filamentary sample at different distance from the beginning of the discharge area : (a) at 1.25mm, (b) at 1.75mm, (c) at 4.75mm.

Observations have also been made with a sample obtained with a glow discharge. They lead to the same behavior as the one observed on a filamentary substrate : the size of the grains quickly increases when moving from the gas inlet and then reduces (figure 4). However the size of the aggregates is much smaller (150-200nm) with a glow than with a filamentary discharge. This explains the fact that it was not possible to observe them with the optical microscope. Moreover, the kinetics of clusters and particles formation is much less rapid in a glow discharge than in a filamentary one : about 2 times more discharges are necessary to obtain the clusters with the maximum size. Another point is the fact that in the glow discharge, deposit growth is accelerated when there is no more large aggregates on the substrate.
A common point between the two discharges is that the elementary grain constituting the aggregates at the beginning of the discharge area or the deposit at the end has the same size for the two regimes that is to say, about 40 nm in diameter.

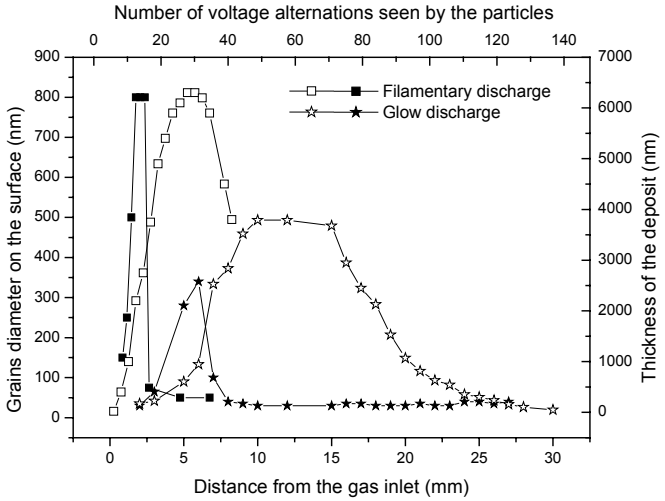


Figure 4 : Grains diameter (full symbol) and thickness of the deposit (open symbol) in a glow (star) and in a high power filamentary (square) discharge determined by analysis of the SEM photographs.

5. Study of the gas phase

5.1. Glow discharge

Experiment of laser light scattering in a $N_2/SiH_4/N_2O$ mixture has been carried out during a glow discharge (figure 5 a and b).

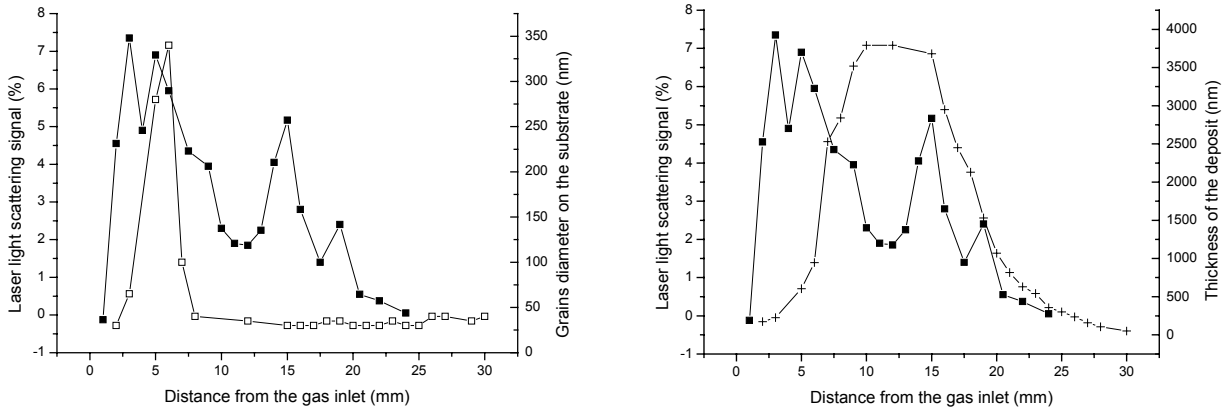

Figure 5 : laser light scattering in a glow discharge (full square) and (a) diameter of the aggregates on the surface (open square) in the $N_2/SiH_4/N_2O$ mixture, (b) thickness of the deposit (cross).

We observe that the scattering intensity reaches its maximum at about 3mm from the gas inlet. That means that about twenty half periods of the voltage are necessary to create the maximum number of particles which have a size large enough to diffuse the laser light.

Scattering intensity is proportional to the particle radius to the power of 6 and to the particle density. So, even a little change in the particle radius leads to an important variation of the scattering intensity. The fact that the scattering signal never varies significantly leads to the conclusion that in the gas phase, particles have roughly the same size (40 nm as we can observe on the SEM photographs). So the scattering variation is mainly attributed to a change in particle density. The scattering intensity has been compared with the diameter of the aggregates on the substrate surface (figure 5a). We observe that the region of the largest aggregates on the substrate is not linked with the maximum intensity of laser light scattering. This means that these aggregates are not formed in the gas gap but on the surface of the substrate. Scattering signal decreases as the thickness of the deposit increases : a possible explanation is that particles created in the gas gap are consummated on the surface to form the deposit more rapidly than they are created which induces a decrease of laser scattering. The scattering peak at 15mm can be due to the fact that the discharge pulls particles from the surface.

The decomposition of the gases during the glow discharge is studied in a N_2/SiH_4 mixture by OES. The excitation conditions and N_2 and SiH_4 flows are the same as previously. Decomposition of the gases is studied in terms of the distance from the gas inlet, that is to say as a function of the number of discharges seen by the gases (figure 6a).

Emissions of Si (251-253nm), SiN (401nm), SiH/SiN (412nm) and NH (336nm) have been observed.

Si and SiN radicals are created in important quantity at the very first beginning of the discharge area. More interactions may be needed to create SiH or SiN species, that could explain the delay needed to reach the maximum intensity of emission. Radiative state of NH ($NH(A^3\Pi)$) can be obtained by four main ways described by equations 1, 2, 3 and 4 :

$$SiH_4 + N(^2D) \rightarrow SiH_3 + NH \quad \text{Eq. 1}$$

$$SiH_x + N(^4S) \rightarrow SiH_{x-1} + NH \quad (x=1,2,3) \quad \text{Eq. 2}$$

$$NH + N_2(A^3\Sigma_u^+) \rightarrow NH(A^3\Pi) + N_2 \quad \text{Eq. 3}$$

$$N(^2D) + H(^2S) \rightarrow NH(A^3\Pi) \quad \text{Eq. 4}$$

So, the emission amplitude of NH depends on SiH_x, N or H densities. Atomic nitrogen is essentially created by electronic dissociation of N_2 and dissociative recombination of N_2^+. As nitrogen is the main gas, atomic nitrogen must be produced all along the discharge, whatever the distance from the inlet. Moreover, hydrogen comes essentially from silane dissociation. So the variations of NH emission are mainly linked to the

variations of SiH_x densities. Beyond 8mm from the gas inlet, all the emissions are decreasing. That means that the radicals linked to the dissociation of silane are consummated to form powders in the gas phase or a deposit on the substrate, or are transformed in other radicals.
The inter-electrode gap can also be divided in two regions. The first one goes from the gas inlet to 8mm : in this region the silane radicals are numerous. In the second region beginning around 8mm from the inlet, silane radicals have drastically reduced.

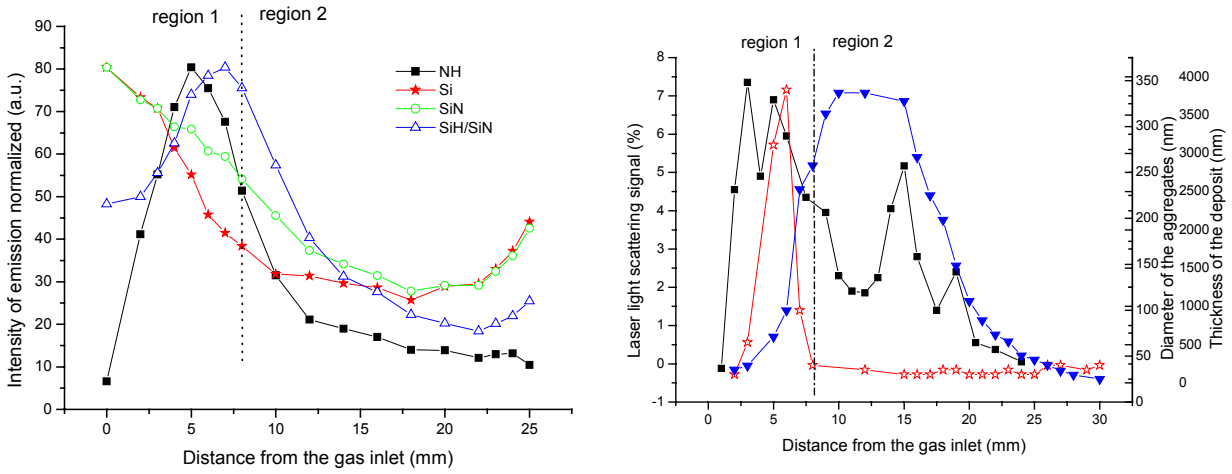

Figure 6 : (a) evolution of emissions intensity as a function of the distance from the gas inlet ; Si at 251-253nm (full star), SiN at 401nm (open circle), SiH/SiN at 412nm (open triangle), NH at 336nm (full square)
(b) comparison of OES, laser light scattering (square), diameter of the aggregates (star) and thickness of the deposit (triangle).

The different observations made with laser light scattering, OES and SEM can be correlated. One discharge is enough to create Si, SiH, SiN radicals but the particles density increases up to 4mm. This delay can be attributed to the time needed to form a particle large enough to induce laser light scattering. For larger distance, particles begin to arrive at the substrate surface and aggregate. This happens in the region 1, where there is a large quantity of silane radicals which act like binding agents between the particles (figure 6). When there is no more binding agents, particles that arrive on the surface do not bind together and the size of the structures on the surface is much smaller (40nm).

5.2 Filamentary discharge
Similar experiments have been undertaken for the high power filamentary discharge.
Figure 7a shows the results of OES in a the N_2/SiH_4 mixture. The same behavior as the one in glow discharge can be observed : two regions can be distinguished, the first one being correlated with a high presence of silane radicals and the second one with an important decrease of these species. The first region is correlated with the presence of large aggregates on the surface, wich confirms the role of binding agent of SiH_x radicals (figure 7b). As we can see on the SEM photographs, a large amount of powders are created and rapidly fixed on the substrate : at 1.7 mm, deposit is constituted by large aggregates (800nm) of smaller particles (40nm). Beyond 3mm, particles on the surface have the same size of 40nm. As laser light scattering signal does not vary drastically, we can again conclude that the signal is rather proportional to the density of particles than to a change in their size (figure 7b). The signal increase is comparable to that of the glow discharge, but the peak width is smaller. The scattering signal grows up like the deposit thickness, therefore scattering intensity seems to be controlled by the creation rate of particles and not by their loss on the surfaces. So many particles are created that their deposit on the substrate does not influence the scattering signal. Beyond 4mm, density of particles decreases : they are sufficiently numerous to make the deposit grow for 2mm more. And then both scattering intensity and thickness decrease.

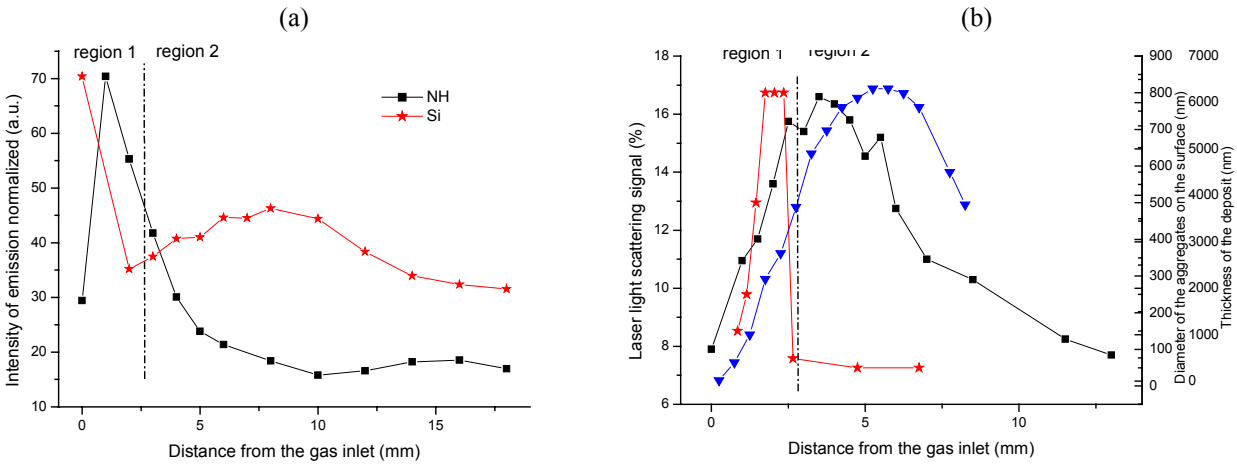

Figure 7 : (a) evolution of emissions intensity as a function of the distance from the gas inlet ; Si at 251-253nm (full star), NH at 336nm (full square)
(b) comparison of laser light scattering intensity (square), diameter of the aggregates (star) and thickness of the deposit (triangle)

7. Conclusion

Whatever the power delivered by the filamentary discharge, the quantity of big powders (about 1µm) produced in this kind of discharge is more important than in a glow discharge. However, the same two regions can be defined in the two regimes : at the beginning of the discharge area, important presence of SiH_x radicals, playing the role of binding agent, seems to lead to the formation of large aggregates of particles on the surface of the deposit ; farther in the discharge, these radicals have disappeared and the deposit is made of powders of 40nm in size that are not linked together. In another hand, dissociation of reactive gases, growth of aggregates and deposit are 2 to 3 times more rapid in the case of the high power filamentary discharge. Then the slowdown of the mechanism allows to get an area without powder at the really entrance of the discharge in the glow discharge case. As laser light scattering experiments show, formation of powders seem to happen as quickly in the glow discharge than in the filamentary. An explanation could be that filamentary discharge form more powders and that these powders are more rapidly driven on the surfaces.

Electrotechnical approach of a process based on glow dielectric barrier discharge

N. Naudé, J-P Cambronne, N. Gherardi, F. Massines

Laboratoire de Génie Electrique de Toulouse, Université Paul Sabatier, Toulouse, France

Abstract

The aim of this work is to improve the working domain of a glow dielectric barrier discharge at atmospheric pressure (GDBD) thought a better understanding of the power supply and the discharge coupling. A model of the GDBD and its power supply is presented. This model is based on the use of equivalent electrical circuits and is taking into account the main phenomena of the GDBD and the main parasitic elements of the power supply. It permits to have a general view of the process and to study the influence of the electrical circuit and its parasitic elements on the discharge and on the working domain.

1. Introduction

Because of their homogeneity, GDBD are very interesting for surface treatment. Industrial processes using a few amount of reactive gases diluted in N_2 to reach the atmospheric pressure would be very useful. One of the main difficulties to reach that goal is that a GDBD at atmospheric pressure in nitrogen can only be obtained on limited working domain. This domain depends of the excitation form and the electrical characteristics of the power supply. The development of an industrial process supposes an optimization of the coupling between the discharge and the power supply. A possible approach to achieve this goal consists in developing an electrical model of the power supply and the GDBD [1]. After a brief description of the experimental set-up, we will describe the modeling of the GDBD and of its power supply, then we will study the working domain of the GDBD as well as one reason of destabilization of the GDBD.

2. Experimental set-up

The experimental arrangement used for this study is shown in figure 1. GDBD are generated between two parallel plane electrodes, coated on ceramic plates, to which an a.c. high voltage is applied in the frequency range from 200 Hz to 20 kHz with a magnitude up to 24 kV peak to peak. The discharge is obtained in an atmospheric pressure of nitrogen. To limit impurities, a pumping system is used to reach a secondary vacuum (10^{-6} mbar). The electrodes are rectangular with the dimension of 10 mm in length and 60 mm in width. The gap between the two electrodes is currently 1 mm. A flow of nitrogen in the direction of the electrode width is used to renew the gas and eliminate the species etched from the surface.

The power supply is made of a low frequency generator providing the reference signal which is then amplified by a linear amplifier whose output is applied to the primary winding of a transformer, the discharge system being connected with its secondary. The discharge current, I_d, is measured via a 50 Ω resistance connected to the ground in series with the discharge by a 2 GHz bandwidth digital oscilloscope. The applied voltage, V_{ps}, is measured by a high voltage probe. The voltage applied to the gas, V_g, is calculated from I_d and V_{ps}.

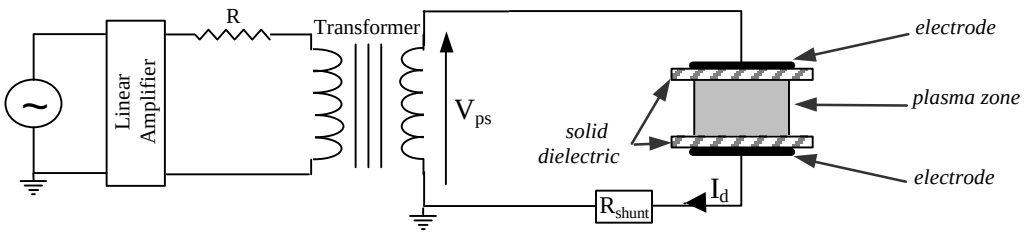

Fig. 1 : Schematic diagram of the experimental set-up

3. Power supply model

The figure 2 presents the model of the power supply experimentally studied [3]. The principal element of the power supply is the transformer. Indeed, the amplifier can be modelled by a constant gain.

This model is composed of six elements : R_T is the resistance of the copper winding, X_T accounts for the flux leakage, R_M represents the core loss of the magnetic core material due to hysteresis, X_M is the magnetizing inductance and finally C_1 and C_2 model the coupling capacitor of the primary and secondary windings.

In order to determine this parameters, we realized different tests without connecting the GDBD to the power supply. We measured the impedance seen from the primary with the secondary with no-load then in short-circuit. To measure the impedance (modulus and argument) in high frequency (from 50 kHz to 1 MHz), we used an impedance analyzer (HP 4284A). As the magnetic circuit (modelled by X_M and R_F) is nonlinear, it is necessary to determine its parameters for nominal conditions : the reference signal is amplified by the linear amplifier whose output is applied to the primary winding of the transformer. Therefore, to measure the impedance in low frequency (from few Hz to 50 kHz), we determined the impedance (modulus and argument) from experimental measures of the primary current (measured by a current probe) and voltage (measured by a differential probe voltage).

To check the validity of this model, the measured and calculated free and short-circuit impedance of the transformer seen from the primary have been compared (fig. 4). This model fairly describe the behavior of the transformer until 300 kHz. This model permits to consider the inductive and capacitive parasitic elements of the power supply (mainly of the transformer [2]) as well as the parasitic elements of measurement (high voltage probe, current measurement).

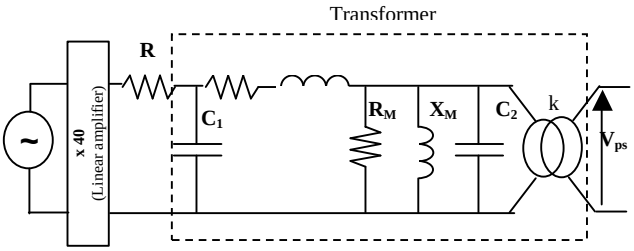

Fig. 2 : Electrical equivalent circuit of the power supply

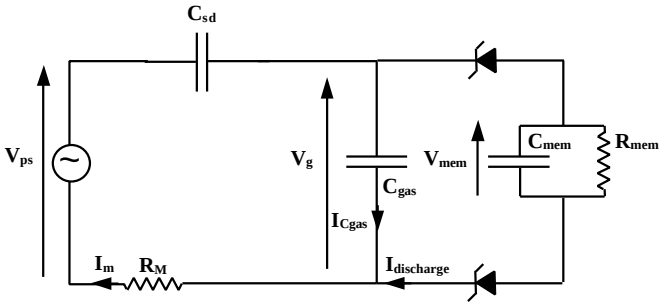

Fig. 3 : Electrical equivalent circuit of the discharge

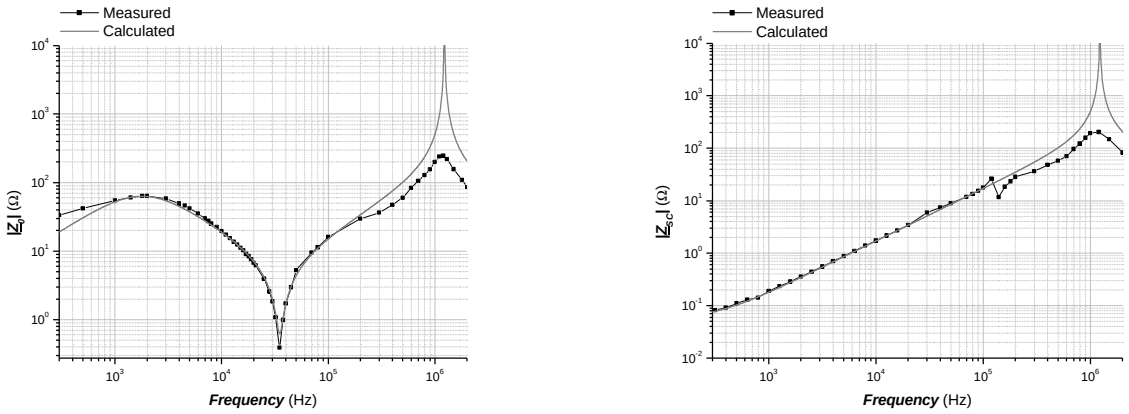

(a) (b)

Fig. 4 : Comparison between experimental and simulated of the modulus of free and short-circuit impedance

4. Electrical glow dielectric barrier discharge model

Unlike the models usually used in plasma, this model based on electrical components is macroscopic. The figure 3 present the electrical schema of the GDBD experimentaly studied (fig. 1). It does not directly describe the physics of the discharge but it holds account of it. However, it calculate in a simple way and with very short calculating times the discharge current and voltage, which are also measured. The

interest of this electrical circuit is to model in a simple way the discharge by using elements having a physical signification.

C_{sd} and C_{gas} capacitors model respectively the dielectric layer and the gas gap between the two electrodes. When the discharge is in off-state, the gas behave like an insulator, and the system can be modelled as the C_{gas} capacitor.

The two zeners diodes model the breakdown of the GDBD in nitrogen (Townsend breakdown). The choice of diodes to model breakdown is not trifling, in fact the effect of avalanche observed in the semiconductors [5] is comparable with gas avalanches occurring during the Townsend breakdown in the case of the GDBD. The figure 5 represents the layout of the discharge current according to the gas voltage for one period. During the rise of discharge current (fig. 6), the characteristic is exponential and can be modeled by the inverse characteristic of a diode. The inverse characteristic of a diode is defined by three parameters, which determine the equation 1. BV symbolize the reverse breakdown voltage, IBV the current at the reverse breakdown voltage and NBV the reverse breakdown ideality factor. In fact, NBV determine the slope of the characteristic of the discharge current according to the gas voltage. The lower NBV is, the quickest the discharge current increases is.

Finally, the elements C_{mem} and R_{mem} have been introduced to describe a specific behavior of GDBD : as shown in figure 7, for a given voltage amplitude, higher the frequency is lower the breakdown voltage is. Previous studies explained this by the fact that the gas remains excited from a discharge to the following one. The specie responsible of the memory effect is $N_2(A^3\Sigma_U^+)$ metastable which are created during a discharge and partly quenched between two discharges [4]. If the frequency increases the time between two discharges decrease then the metastables are less destroyed which induces a decrease of the breakdown voltage. In our model, during the discharge, the C_{mem} capacity is charged (equivalent to the creation of $N_2(A^3\Sigma_U^+)$ metastables) whereas between two discharges, the C_{mem} capacity discharge in R_{mem} resistance (destruction of $N_2(A^3\Sigma_U^+)$ metastables).

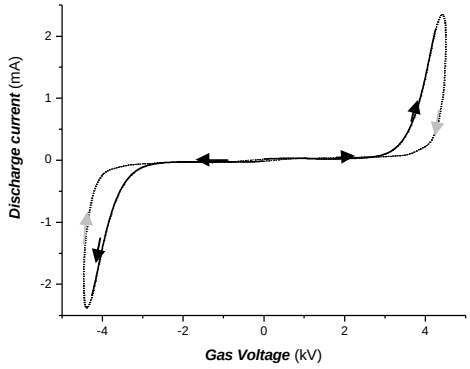

Fig. 5 : Discharge current versus gas voltage during one period (f=2 kHz, V_{ps}=15 kV_{pk-pk})

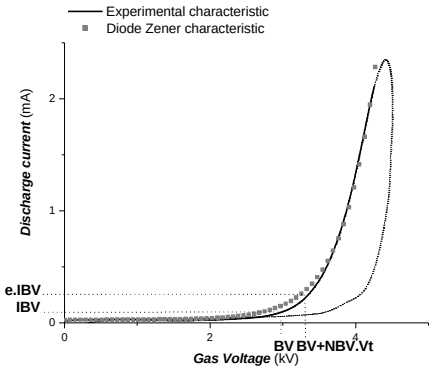

Fig. 6 : Rise of the discharge current (2 kHz, 15 kV_{pk-pk})

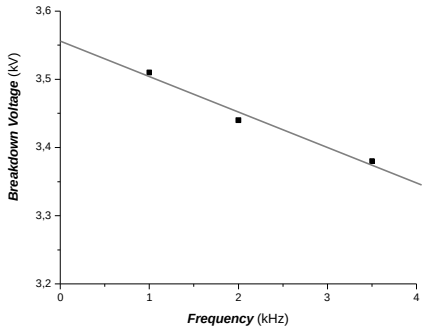

Fig. 7 : Breakdown voltage versus frequency (V_{ps}=13 kV_{pk-pk})

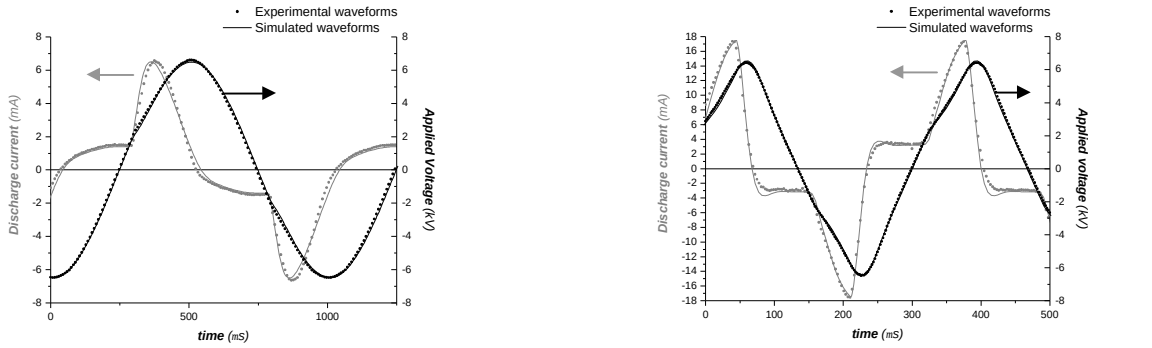
$$i(t)=IBV\times\exp\left(\frac{-V-BV}{NBV\times\frac{k\cdot T}{q}}\right) \qquad \text{Eq. 1}$$

To check the validity of this model, the calculated and measured discharge current have been compared for excitation frequencies ranging from 1 and 4 kHz and for sinusoidal or triangular voltages. As example, figure 8 shows the results of simulations and experiment concerning the waveforms of the discharge current (I_d), the applied voltages (V_{ps}). Then, all the model component values being fixed, the model fairly describe the GDBD electrical behavior.



(a) (b)

Fig. 8 : Comparaison between experimental and simulated waveforms for sinusoïdal voltage (a) V_A=13 kV_{pk-pk} and f=1 kHz, and triangular voltage (b) V_A=13 kV_{pk-pk} and f=3 kHz,

5. Working domain of GDBD and destabilization

The GDBD works only for a limited range of amplitude and frequency of the applied voltage [6]. The fact of being slightly apart from these limits of operation is characterized by the propagation of instabilities in the glow discharge, instabilities which lead to a pure filamentary discharge if the amplitude or the frequency of the applied voltage is increased even higher.

When the frequency is too much increased, pulses are observed in the rise of the current. These pulses develop too slowly to be streamers [7]. As shown figure 11, when the frequency increases, the current increases more quickly, it involves a reduction of NBV (fig. 12). As described previously [7], for frequencies higher than 3 kHz, the speed of the current rise allowing to keep a glow discharge is limited. The figures 13 represents the experimental and simulated discharge current and applied voltage during a destabilization for a frequency of 5 kHz. To understand this behavior, it is necessary to carefully consider the variation of the power supply load due to the discharge development.

During the ignition of the discharge, the load seen by the power supply varies [7]. In fact, if no discharge occurs (part a in figure 9), the current is defined by equation 2. When the gas voltage reaches the breakdown voltage, the current increases quickly and stops while the gas voltage becomes constant (part b in figure 9). The rise of the current is controlled by the ionization occurring in the discharge [6]. After the rise of the discharge current (part c in figure 9), the calculated gas voltage (eq. 4 and fig. 10) is constant thus all the voltage fluctuations are applied on C_{sd} and the current is defined by equation 3. During the rise of the current, the load seen from the power supply varies from $(C_{sd}.C_{gas})/(C_{sd}+C_{gas})$ to C_{sd} (eq. 2 and 3). Higher is C_{sd}/C_{gas} ratio larger the load variation is.

The destabilization in high frequency comes from a too fast variation of the load seen from the power supply that involve oscillations [7] of the electrical circuit (parasitic elements). In order to limit the risks of destabilizations in the rise of the glow discharge current, there are two solutions : act on the speed of this variation (which depends on the conditions of excitation of the GDBD, therefore of the frequency) or on the amplitude (which depends on the ratio of the capacitors C_{sd} and C_{gas}). A solution to limit the risks of destabilization in high frequency, is to reduce the C_{sd}/C_{gas} ratio. For that, we can decrease the gas gap (to increase the value of C_{gas}) or decrease the value of C_{sd} (by using a dielectric which have lower relative permittivity or increase the thickness of the dielectric). The figure 14 represents the simulated discharge current for low and high C_{sd}/C_{gas} ratio all the other parameters being constant. For a C_{sd}/C_{gas}=7.5, we observe a pulse in the rise of the discharge current whereas in the case of the lower ratio C_{sd}/C_{gas}=3.6, the discharge current do not comprise pulses. The reduction of this ratio permits to increase the working domain of the GDBD in term of maximum frequency. This has been checked experimentally by determine the working domain of the GDBD for low and high C_{sd}/C_{gas} ratio (fig. 15). It is interesting to notice that a reduction in a factor 2 of the C_{sd}/C_{gas} ratio permits to increase GDBD working domain as presented figure 15 of a factor 6.

6. Conclusion

Glow dielectric barrier discharge and its power supply have been modeled. This model based on electrical components permits to have a general point of view of the process and it fairly describes the GDBD electrical behavior. It has been first show that decreasing the C_{sd}/C_{gas} ratio permits to significantly increase the working domain of the GDBD, a reduction in a factor 2 of the C_{sd}/C_{gas} ratio (from 7,5 to 3,6) permits to increase GDBD working domain of a factor 6 and the maximum frequency of a factor 3.

This electrical model can be used as predictive one to study different power supply, and to define the type of excitation that produces a maximal ignition time of the discharge and a maximum transmitted power which will determine the treatment rate. It is also an interesting tool for the power supply design and the process optimization. This will be checked soon.

Abstract
This paper deals with the study of the fragmentation process of $CH_3O(CH_2CH_2O)_2CH_3$ diethylene glycol dimethyl ether (diglyme) molecule in low-pressure RF excited plasma discharges utilizing mass spectrometry. The results showed that for a fixed pressure, the increase of the RF power coupled to the plasma chamber from 5 to 45 W produced a plasma environment very reactive that reduces the population of the heavier chemical species and increases the population of the lighter one.

Keywords: Molecular fragmentation, Mass spectrometry, Diglyme Plasmas, Biomaterials

1. Introduction

Materials processing using low-pressure RF excited plasmas are of great importance in many current scientific and technological issues encompassing microelectronics, optical and biomaterials industries [1-10]. The main reason is that within such kind of plasmas electrons may attain an energy excess of some eV in comparison with the heavy particles present in the discharge. This unusual thermal non-equilibrium situation is very profitable in molecular fragmentation through electronic impact. This feature of such plasmas gives rise to a very reactive chemistry in a relative cold environment [4-8] whose kinetics is not easily controlled. Therefore is of paramount importance to set many plasma diagnostics in order to probe the trends of chemical species as well as the electrons behavior for different plasma parameters such RF power coupled to the plasma chamber, gas pressure, gas flux and so on [11-14].

In the field of biomaterials science and technology, plasma polymerized polyethylene glycol dimethyl ether is a material that has been keeping the attention of the scientific community due to its non-fouling properties [15-19]. If the appropriate plasma parameters are set these films may be synthesized keeping a molecular structure quite similar to the polyethylene oxide-like (PEO-like) with the advantage that these films are not soluble in water. The aqueous solubility of PEO makes it less appropriate in many biomaterials applications. In order to retain the monomer structure within the plasma deposited films and consequently its functionality, many different issues have been addressed in recent literature as for instance the film deposition under low mean RF power level by controlling the power supply on/off ratio [11,20], the decreasing of monomer residence time and consequently the reduction of its interaction with the plasma environment [20], the cooling of substratum with liquid nitrogen [13], the energy reduction of the ions reaching the substratum [14], and so on.

In order to set the appropriate experimental parameters that would result customized film structures in plasma polymerization of PEO-like coatings this paper deals with the study of the RF power dependence of different chemical species resulting from diglyme fragmentation for different values of the pressure inside the plasma reactor. The trends of chemical species were followed by mass spectrometry [21,22].

2. Experimental Setup and Plasma Diagnostics

The glow discharges were generated by a RF power supply operating in the range from 5 to 45 W in $CH_3O(CH_2CH_2O)_2CH_3$ (diglyme) atmospheres ranging from 16 Pa (120 mTorr) to 40 Pa (300 mTorr) within a stainless steel cylindrical, 210 mm of internal diameter and 225 mm long, parallel plate electrodes plasma reactor. This reactor is provided with eight lateral entrances, positioned at the mid plane between the electrodes, that may be used for setting optical, electrical and mass diagnostics and the low (mechanical pump) and high (turbo-molecular pump) vacuum systems. The vacuum inside the plasma chamber is

monitored by pirani™ (thermocouple) and penning™ (inverse magnetrom) gauges. The turbo-molecular pump is coupled to the chamber through a gate valve and is used for cleanness purposes. The pressure is pumped down to 1.33 x 10^{-4} Pa (10^{-6} Torr), being the chamber purged with argon several times before each running of the experiment. The inner side of the plasma chamber was polished up to the optical quality (roughness of 0.5 microns or less) in order to minimize the retention of impurities and facilitate the cleaning process. The plasma chamber walls were heated with a temperature- controlled belt in order to minimize the monomer's condensation as well as the humidity. Diglyme was placed inside a stainless steel bottle and was fed into the plasma chamber through a needle valve. The plasmas were excited by a RF power supply operating in 13.56 MHz whose output intensity could be varied from 0 to 300 W (Tokyo HY-Power model RF-300™). The RF power was coupled to the plasma reactor through an appropriate matching network (Tokyo HY-Power model MB-300™) that allows one to minimize the reflected RF power. The mass spectrometry was realized using a mass spectrometer and energy analyzer (Hiden Analytical model EQP-300™), operating in the mass and energy range from 1 to 300 amu and from 0 to 100 eV respectively. The background mass spectra with the plasma turned off were carried out at the same pressure conditions of each diglyme plasma polymerization processes. These spectra allowed one to control the number of chemical species resulting from the fragmentation within the mass spectrometer as well as to control the presence of contaminants resulting from the plasma chamber cleaning process. The block diagram of the experimental setup is presented in figure 1.

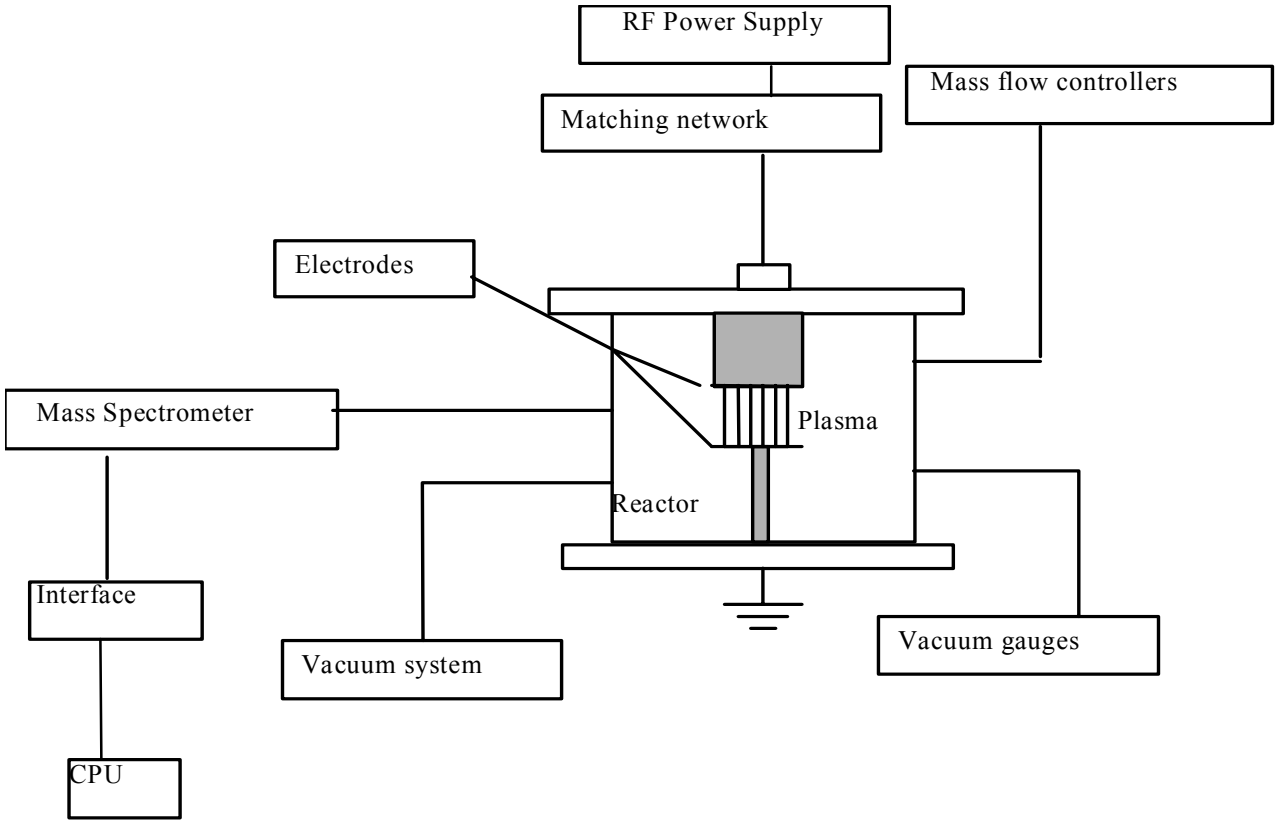

Figure 1. Block diagram of the experimental setup used in plasma polymerization of diglyme for different values of pressure and RF power coupled to the reactor.

The photograph of the stainless steel plasma chamber with the mass spectrometer coupled to it is shown in figure 2.

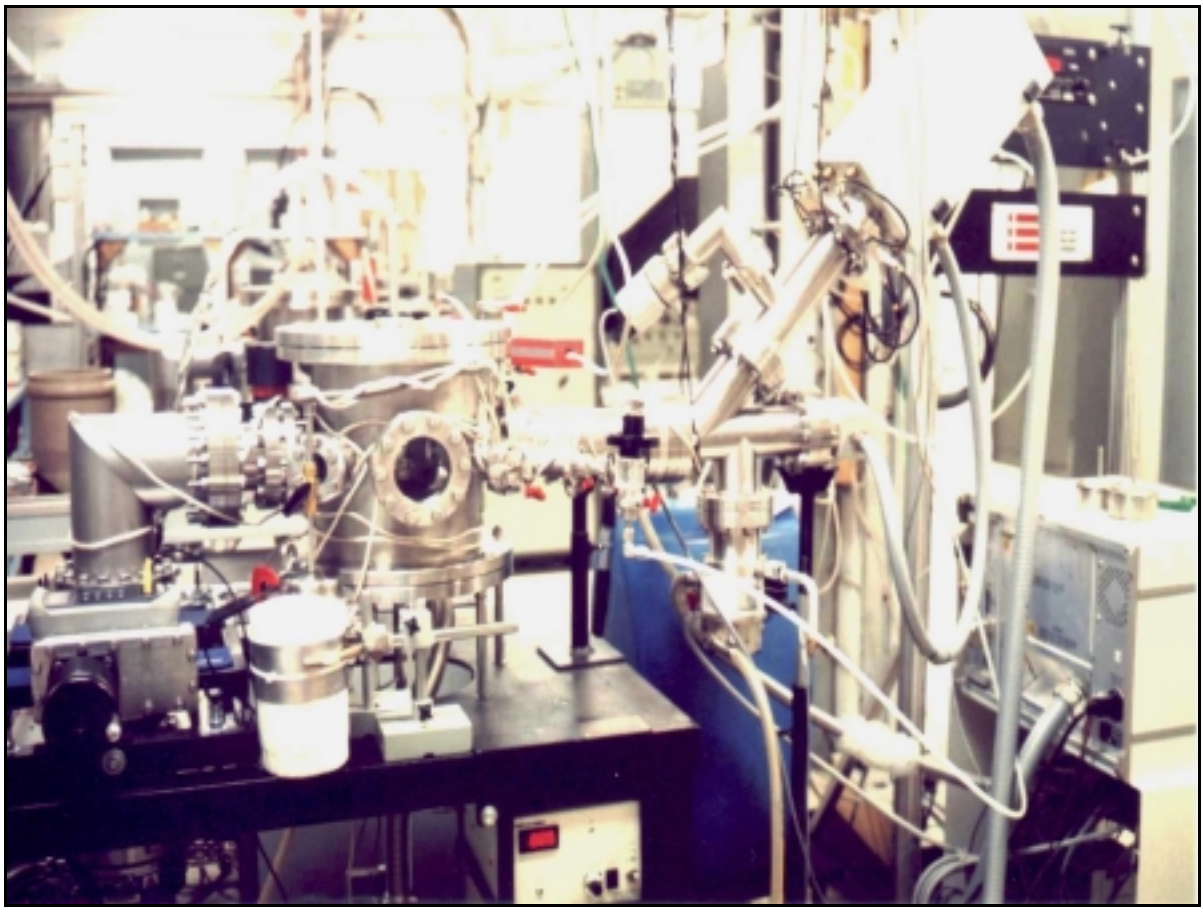

Figure 2. Photograph of the experimental setup used in plasma polymerization of diglyme for different values of pressure and RF power coupled to the reactor.

3. Results and Discussions

It is presented in table 1 all possible primary fragments of diglyme molecule (134 amu) resulting from the disruption of the chemical bonds between carbon-carbon and carbon-oxygen atoms. Since the molecule is central symmetric to the oxygen atom located in ethylene-glycol group one may identify only four different points of molecular disruption involving the above mentioned chemical bonds which results the fragments listed in table 1.

Table 1. Primary Diethylene glycol dimethyl ether fragments

fragment	chemical structure	mass (amu)
1	CH_3	15
2	CH_3O	31
3	CH_3OCH_2	45
4	$CH_3OCH_2CH_2$	59
5	$CH_3OCH_2CH_2O$	75
6	$CH_3OCH_2CH_2OCH_2$	89
7	$CH_3OCH_2CH_2OCH_2CH_2$	103
8	$CH_3OCH_2CH_2OCH_2CH_2O$	119

It may be pointed out that all the molecular fragments presented in table 1, with the exception of the number 8 (119 amu), may result from secondary or higher fragmentation process of the heavier fragments of the diglyme molecule. The number of possibilities contributing for the population of a fragment increases inversely proportional to its mass. From the point of view of the non-fouling characteristic of the plasma deposited diglyme films the ethylene-glycol structure, e.g., CH_2CH_2O (44 amu), is one the most important

structure to be retained within the film composition if one wants to keep its functionality [4,21,22]. Therefore is important to keep under control the plasma parameters that enhance the presence of heavier fragments within the discharge.

Figure 3 shows typical mass spectra of neutrals and ions resulting from a RF excited diglyme plasma taken at a pressure of 12.6 Pa (95 mTorr) and 5 W of RF power coupled to the plasma chamber. It may be seen the presence of several primary fragments of diglyme molecule resulting mainly from inelastic electronic collisions. It also may be appreciated that the number of neutrals is much higher than the ions due the low degree of ionization of such kind of discharges.

Figure 4 shows the RF power dependence of diglyme fragments within the plasma, for a fixed pressure of 13.3 Pa (100 mTorr). It can be seen that as the RF power coupled to the plasma chamber increases the concentration of heavier species decreases indicating the predominance of electronic inelastic collisions resulting in molecular fragmentation. It also can be appreciated that the concentration of lighter species like CH (13 amu), H (1 amu), and O (16 amu) increases with the increasing of the RF power. This result is in close agreement with the decreasing of the concentration of heavier species within the plasma discharge.

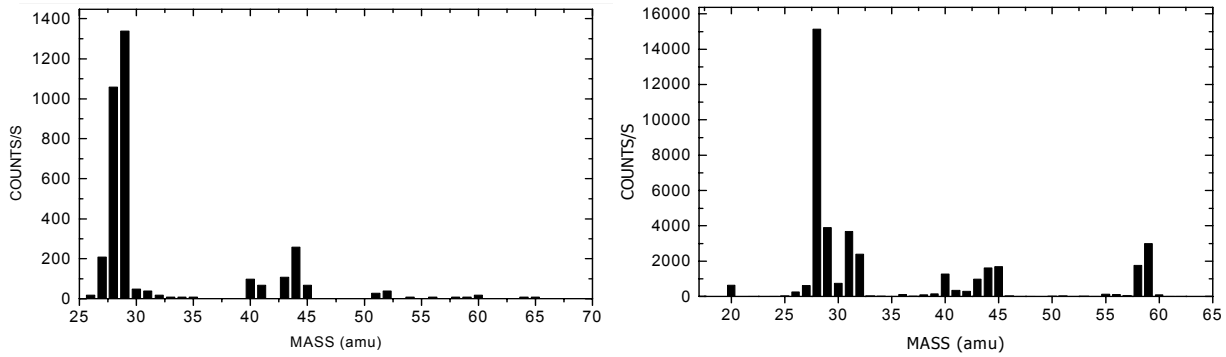

Figure 3. Typical mass spectra of ions (left) and neutrals (right) of RF excited diglyme plasmas taken at 12.6 Pa and 5 W of pressure and RF power respectively.

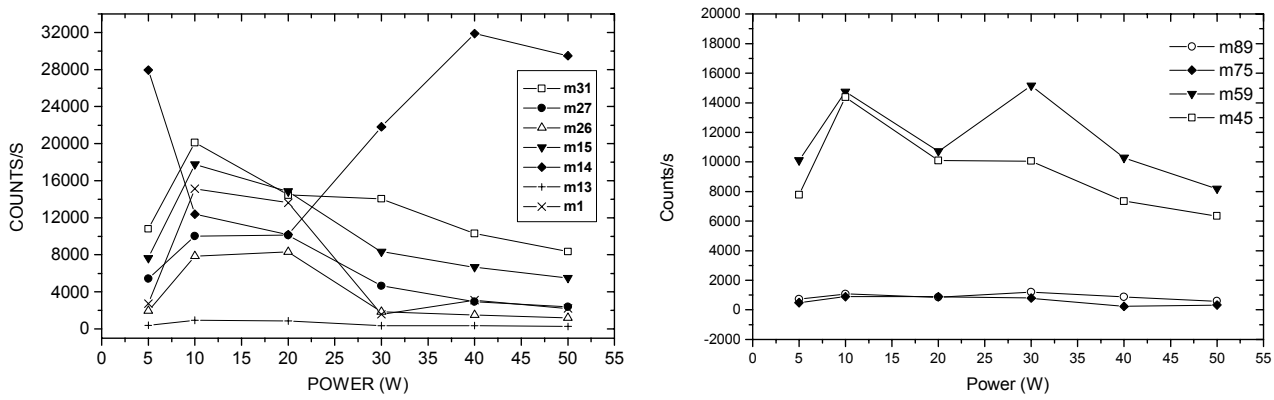

Figure 4. Power dependence of diglyme fragments products at a fixed pressure of 13.3 Pa.

4. Conclusions

One can conclude from the presented results that the operation of the plasma reactor at low RF power levels is appropriate if one wants to preserve the monomer functionality since it enhances the predominance of heavier chemical species within the discharge. The control of the plasma reactivity would be improved if one used a RF power supply whose output could be modulated by a square waveform in order to vary the plasma on/off ratio. This approach was already used with great success in current literature for others monomers [11,20]. The presented results also showed the effectiveness of mass spectrometry as plasma diagnostic for monitoring the diglyme plasma polymerization process.

Bacterial Adhesion onto Plasma Modified Polymer Surfaces

G. Z. Gadioli, E. C. Rangel, R. Y. Honda, M. C. Pereira, N. C. Cruz

Department of Chemistry and Physics, UNESP, Guaratinguetá, Brazil

Bacterial adhesion onto polymers used in prosthesis and clinical devices is of great concern. For instance, the most efficient solution to overcome the biofilm formation onto silicone voice prosthesis is by surgically substituting the prosthesis. In many cases, such replacement has to be done ever three months. Therefore, surface modifications to prevent bacteria attachment are highly desirable. In this sense, plasma treatment is of particular interest because it allows strong surface modifications without altering bulk properties.

The present work describes an investigation on the adherence of *Escherichia coli* onto silicone (SI) and polyurethane (PU) surfaces as-received and after exposure to SF_6 or O_2 plasmas.

Treatments were performed in a vacuum chamber by applying radiofrequency power (13,56 MHz) to two external electrodes. During the treatments the chamber was continuously pumped by an 18-m^3/h rotary vane pump. The admission of the gases was controlled by needle valves while the chamber pressure was monitored by a Pirani gauge. After the treatments the samples were immersed for 24 hours in water contaminated with *E. coli*. Afterwards they were individually taken to an ultrasonic bath for 5 minutes in 5 ml of sterile water. The rising water was inoculated in agar EAM in Petri dishes and incubated for 24 hours at 37°C. The number of colony forming units (CFU) was counted using pictures taken of the dishes.

Some of the results obtained are shown in figure 1. According to the figure, one can be observed that the exposure to any of the plasmas caused the decrease of bacterial adhesion. It is interesting to mention that the contact angles, θ, immediately after the exposure to O_2 and SF_6 plasmas were, respectively, 20° and 140° for silicone and 40º and 135º for polyurethane samples while both pristine materials presented θ around 110°. Therefore, the results show no straight relationship between surface wettability and bacterial adhesion. Further studies are under development to clarify the real effect of plasmas on the surfaces causing the inhibition of biofilm formation.

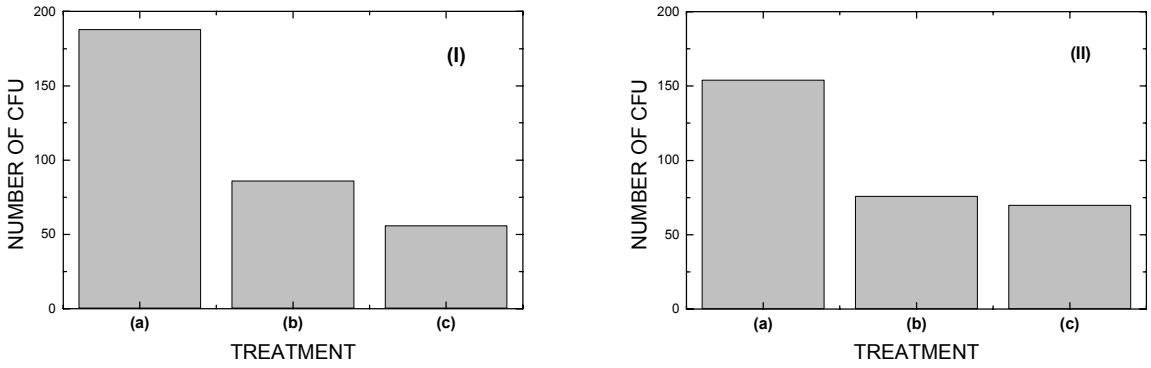

Figure 1 – Number of colonies forming units obtained from (I) polyurethane and (II) silicone surfaces as-received (a), and after exposure to O_2 (b) or SF_6 (c) plasmas.

Glow Dielectric Barrier Discharge for nitrogenous functions grafting on polymer surfaces

Nicolas Gherardi, Eric Croquesel and Françoise Massines

Laboratoire de Génie Electrique de Toulouse, Université Paul Sabatier, Toulouse, France

Abstract
The aim of this work is to confirm the understanding of the mechanisms governing the obtaining of atmospheric pressure glow dielectric barrier discharge (GDBD) in rare gases and to study the effect of GDBD in various atmospheres on the polypropylene surface activation.

1. Introduction

In order to improve surface energy and adhesion of polypropylene film, corona treatments in atmospheric air are often used in the industry. However, such a process leads to surface transformations based on oxygen chemistry and presents a lack of homogeneity. An alternative process is to treat the film with a Glow Dielectric Barrier Discharge (GDBD) in a controlled atmosphere. It is now well known that the GDBD structure from the anode to the cathode depends strongly on the atmosphere in which the discharge is ignited. In He, the discharge is a subnormal glow one while in nitrogen, it is closer to a Townsend one. The mechanisms responsible for these discharge structures are closely related to the metastable properties in these two gases. This knowledge has been extended to another rare gas, argon, in order to check the validity of these conclusions. By adding some hundreds ppm of ammonia in argon, a GDBD can be obtained. The characteristics of this GDBD are compared to He and N_2 GDBD ones. Then, the different atmospheres used (He, He/N_2, N_2, N_2/NH_3, Ar/NH_3) are compared relative to their effect on a polypropylene film, taking into account the amount of energy dissipated in the discharge during the treatment.

2. Experimental set-up

The discharge is ignited between two ceramic-coated electrodes, in a "roll-to-roll" configuration (figure 1) allowing online treatment with film speeds up to 500 cm/min. The treatment duration of the polypropylene film can be as low as 0.5 sec. The gas gap can be varied from 1 to 5 mm. To ascertain control of the treatment atmosphere, the cell is kept inside a vessel which is pumped down to 1 Pa before introducing of the desired gas up to 10^5 Pa. The gases used are N60 Air Liquide quality with less than 1 ppm of impurities. In order to continuously renew the atmosphere, a gas flow can be added (up to 6 slpm), maintaining the atmospheric pressure by a slight pumping. The electrical excitation is a sinusoidal voltage ranging from 0 to 24 kV peak to peak. The frequency can be adjusted between 200 Hz and 35 kHz, independently of the voltage amplitude.

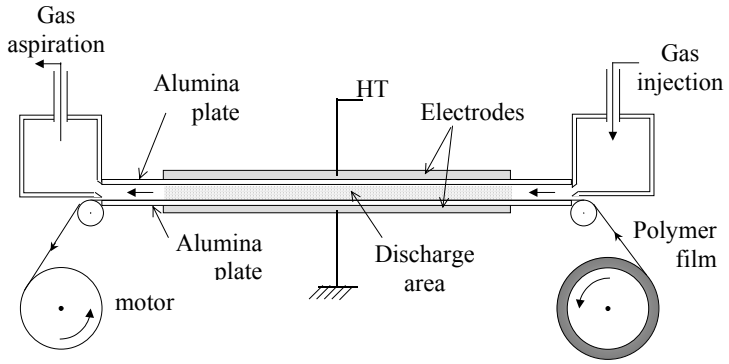

Figure 1: experimental set-up

The discharge is analysed by electrical measurements and through the light emitted (short exposure time photography and spectroscopy). The discharge current is measured through a 50 Ω resistor in series with the grounded electrode. The current and the voltage applied to the electrodes are visualized on a numerical oscilloscope (Tektronix 784A - 1GHz). The gas voltage actually applied on the gas and the power dissipated in the discharge are deduced from these two measurements via calculations detailed elsewhere [1]. The discharge light is observed through a quartz window. An optical lens is used to obtain the image of the plasma on the intensifier of a CCD camera (PRINCETON Instruments LN/CCD-1100-PB/UVAR) for recording photographs. A pulse generator, which is triggered by the power supply used to excite the discharge, governs the intensifier. An adjustable delay is introduced via the programmable pulse generator to synchronize the intensifier with the discharge current. Exposure time varies from 10 ns to 1µs.

The polymer is a 20 µm thick polypropylene (PP) film of capacitor grade. The surface transformations are characterized by static contact angle measurements and X-ray Photoelectron Spectroscopy.

3. Results

3.1. Discharge features

As it has already been written elsewhere [2], glow discharge properties depend on the main gas in which the discharge is ignited. Hence, the discharge current of a GDBD depends on the atmosphere. Comparing GDBD in He and in N_2 with the same power supply frequency, it appears that although there are some similarities in the two gases (the current is composed of only one peak per half cycle and the duration of this peak is in the range of microseconds, which is very long compared to a micro-discharge one), the current peak is 5 times higher in He than in N_2 while its duration is 5 times shorter in He [2]. Figures 2 shows that the gas voltage variations with time during the discharge also depend strongly on the atmosphere. In He (Figure 2a), as soon as breakdown occurs, the gas voltage, V_g, decreases and reaches a value close to 0 at the end of the discharge peak. On the other hand, in N_2 (Figure 2b), the gas voltage continues to increase after the breakdown and stays high until the end of the current peak, which corresponds to the instant at which the voltage delivered by the power supply, V_a, is maximum.

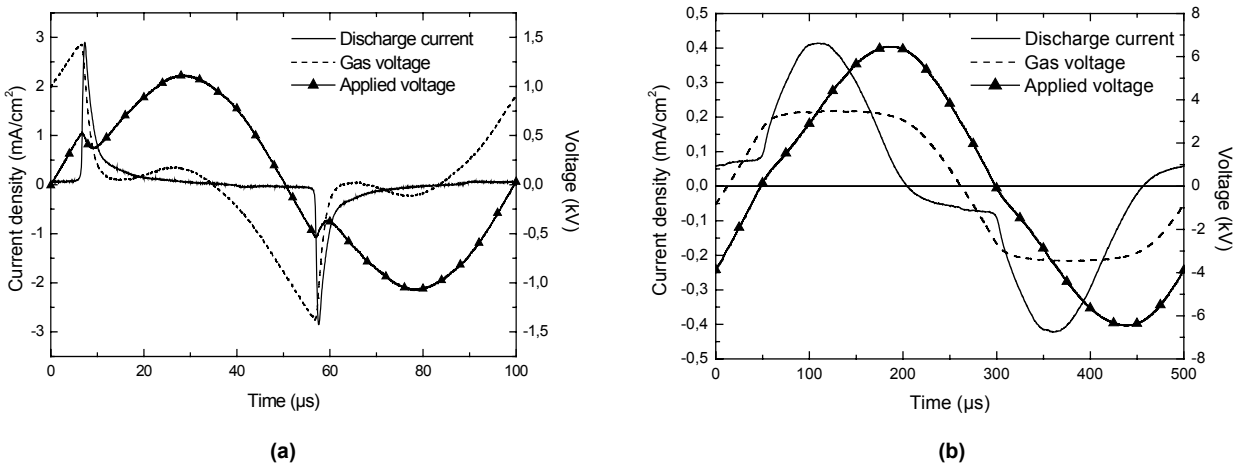

Figure 2: Discharge current, gas voltage and applied voltage of a GDBD (a) in He and (b) in N_2

The associated light distribution in the gas gap presents also some differences. Figure 3 represent 10 ns exposure time photography taken at the maximum of the GDBD current peak in the two atmospheres. In the two gases there is only one discharge canal covering uniformly the whole electrode surfaces.

Nevertheless, the light distribution depends on the gas nature. In He (Figure 3a), three areas can be distinguished: from the anode to the cathode, there is first a large luminous area, then a dark space and finally a highly luminous zone near the cathode. Such a structure is that of a glow discharge [3], the three areas being respectively a positive column, a Faraday dark space, and cathode and negative glows which cannot be separated at high pressure. This structure, which is that of a low-pressure glow discharge, is not observed in N_2 in which the light is localised close to the anode (Figure 3b).

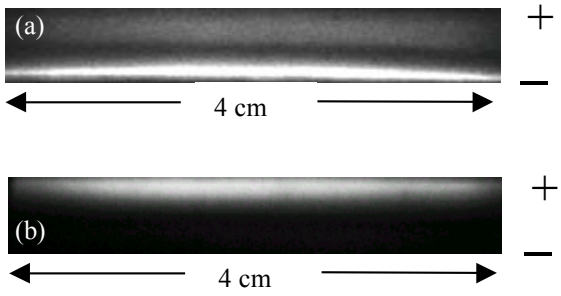

Figure 3: 10 ns exposure time photographs of the gas gap during a GDBD in He (a) in N_2 (b)

Some comparisons with numerical models developed by P. Ségur team [4,5] allow showing that these differences are due to the fact that the GDBD in He is a subnormal discharge close to a normal glow discharge, while the GDBD in N_2 is a subnormal discharge close to a Townsend discharge.

The mechanisms responsible for the obtaining of the GDBD have been discussed previously [2]. A critical point is that the memory effect from one discharge to the following one has to be high enough in order to have a high seed electron density. In the glow case (GDBD in He), the memory effect is based on electrons and ions trapped in the positive column while in the Townsend case (GDBD in N_2), the metastables which stay in the gas create electrons through cathode secondary emission. This last effect is possible in N_2 due to the long lifetime of the $N_2(A)$ (as long as there is not too much additive gas which quenches $N_2(A)$). This is not possible in He because even in pure He, at atmospheric pressure, the He(2^3S) metastables interact very rapidly to form the He_2 excimer [6]. Penning ionisation plays also an important role in He by lowering the breakdown field. Indeed, He(2^3S) metastable state is able to ionise almost every other gases. In a mixture of He/N_2, Penning ionisation on N_2 is very efficient and then a GDBD can be obtained up to 1.6 % of N_2 added [7]. When the percentage of N_2 becomes higher, the discharge physics changes and the discharge is no longer a glow one. It has to be pointed out that even in "pure" He, it has been shown that Penning ionisation occurs between He metastables and impurities present in the vessel, coming from the residual air, from the filling gas impurities and from the gaseous products desorbed or etched from the surface. Some optical measurements have shown that N_2 is one of these main impurities [8].

This being understood, it is of interest to see how the discharge develops in another gas. Ar has been chosen in order to confirm some of the previous conclusions. The first result is that in pure Ar, using a millimetric gas gap and in the frequency range used here (up to 35 kHz), we did not succeed to obtain of a GDBD covering uniformly the entire electrode surfaces, which is in accordance with the literature [9]. We attribute that to the fact that as in He, Ar metastables have a very short lifetime at atmospheric pressure due to the formation of Ar_2 [10]. Then these metastables cannot induce a secondary emission which lasts long enough to play a role like in N_2. Moreover, unlike He(2^3S), Ar(4^3P) (11.55 eV and 11.7 eV) cannot ionise the impurities which still exist in the vessel, as for instance N_2 (ionisation potential: 15.6 eV).

Then, the Penning ionisation has to be enhanced by the adding of an appropriate gas. This can be for example acetone [11], methanol (IP: 10.85 eV), oxygen peroxide (IP: 10.9 eV), or ammonia (IP: 10.15 eV). Although ammonia does not seem to be the most efficient considering the ionisation potential, it has been chosen here, the aim being the grafting of nitrogenous functions on polymer. By adding some 100 ppm of NH_3, a GDBD can actually be obtained. Its electrical characteristics are represented in figure 4 and a 1 µs exposure time photography taken at the maximum current peak is shown in figure 5. As it could be envisaged by comparing the metastable properties of Ar(4^3P) and He(2^3S), the GDBD in an Ar/NH_3 mixture is similar to the one obtained in He or He/N_2 mixture. Indeed, the current peak is high and narrow, and the gas voltage decreases during the current peak, which is the signature of the formation of the cathode fall. However, one can note that the gas voltage drop is not as marked as in He, which indicates that the cathode fall is may be less contracted. This could be attributed to the less efficient Penning ionisation as compared to He. The photography taken at the maximum current peak (figure 5) confirms the fact that the obtained

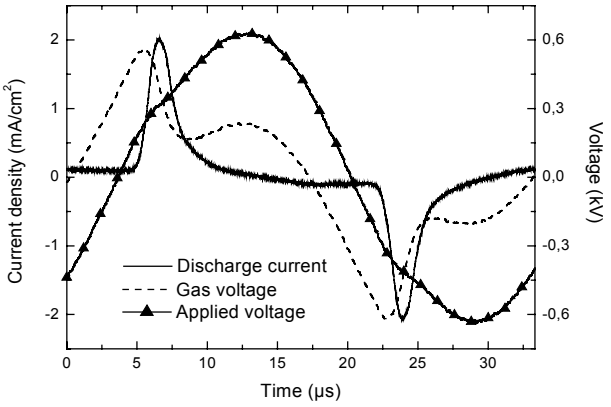

Figure 4: Discharge current, gas voltage and applied voltage of a GDBD in Ar/NH_3

discharge has a structure similar to the one in He, with three distinct areas: the positive column, the Faraday dark space and the cathode and negative glows which cannot be distinguished at high pressure. The thicknesses of these areas are similar to He ones.

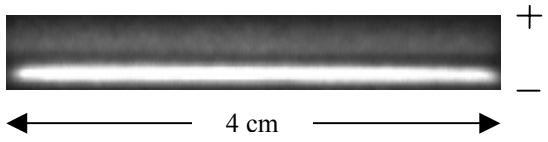

Figure 5: 1 µs exposure time photographs of the gas gap (4 mm) during a GDBD in Ar/NH_3

3.2. Surface transformations

Gas	Gap (mm)	Voltage (kV_{pk-pk})	Frequency (kHz)	Surface power density (W/cm^2)	Volume power density (W/cm^3)
He	5	3	10	0.15	0.3
He + 1% N_2	5	3	10	0.15	0.3
N_2	1	13	2	0.45	4.5
N_2 + 80 ppm NH_3	1	13	2	0.41	4.1
Ar + 370 ppm NH_3	4	1.2	30	0.11	0.28

Table 1: Discharge conditions used for the polypropylene surface treatment

The discharge conditions used for the surface treatments are shown in table 1. In figure 6, all the water contact angle results are reported as a function of the energy density dissipated in the gas during the treatment. The discharge energy density is the calculated mean power density multiplied by treatment duration. In all the cases, the water contact angle decreases with increasing the energy dissipated in the gas during the treatment. However, the optimum water contact angle, the energy for which this angle is reached, and the kinetics of the decrease, depend on the atmosphere used.

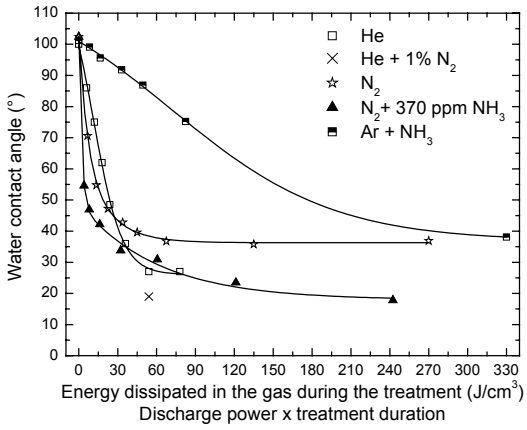

Figure 6: Water contact angle vs. energy dissipated in the gas during the treatment for the different discharge atmospheres

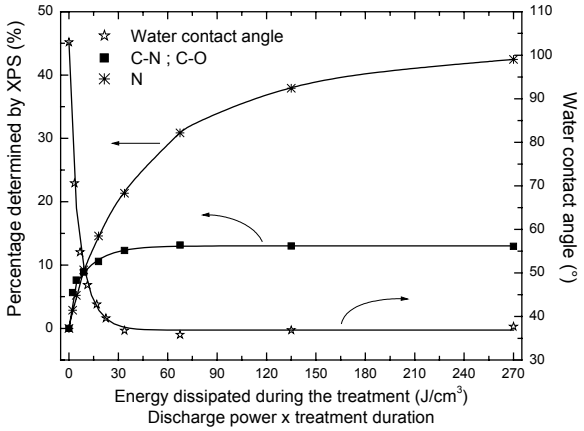

Figure 7: Correlation between water contact angle measurements and chemical composition determined by XPS, for N_2 GDBD treatment

3.2.1. GDBD in He, He/N_2 and N_2

Comparing the results obtained in He and N_2, it appears that the GDBD in He is more efficient than the one in N_2. In He, the water contact angle reaches 28° with 54J/cm^3 dissipated in the gas while GDBD in N_2 leads to a water contact angle of 37° with 68J/cm^3 dissipated in the gas. This can be surprising taking into account the fact that He is a non-reactive gas. In fact, XPS measurements after He and N_2 GDBD treatments show that He GDBD incorporates N atoms like a N_2 GDBD (table 2 [7]). This rather high N incorporation has been attributed to the creation of N_2^+ ions through Penning ionisation in He GDBD [12], the N_2 coming from the residual air present in the gas cell, the filling gas impurities and from the gaseous products which the plasma desorbs or etches from the surface. Considering a few ppm of N_2 in He, the relative contribution of Penning ionisation becomes as high as the direct ionisation [2], and about 10^{11} cm^{-3} N_2^+ ions are created [13]. Moreover, the recombination of N_2^+ ions with the surface is an exothermic reaction, which has a high probability of being dissociative ($N_2^+ + e_{surface} \rightarrow 2N + 4eV$ [14]), and the energy released is high enough to break polypropylene chemical bonds. Therefore, the N due to N_2^+ recombination at the surface efficiently reacts with the polypropylene surface, because radicals are created at the same time and the same place in the gas and on the polymer. The effect is enhanced if a small amount of N_2 is added in He. Indeed, the minimum angle reached after the treatment decreases from 28° in "pure" He to 19° in a mixture of He added with 1% of N_2.

Treatment	C (%)	O (%)	N (%)	Water contact angle (°)
Untreated polypropylene	100	0	0	102
GDBD N_2	71	4	25	37
GDBD He	87	4	9	28

Table 2: Chemical composition of the polypropylene surface determined by XPS and associated water contact angle for the N_2 and He treatments

Another surprising point is that 25% of N grafted by N_2 GDBD leads to a water contact angle of 37° when only 9% of N grafted by He GDBD leads to a lower value of the water contact angle (28°). This may be due to the transformation depth induced by the two discharges. Indeed, N_2 GDBD leads to a very deep incorporation of N atoms in the polymer, up to more than 6nm [15]. As He is a gas known for its crosslinking properties, it can be suggested that He GDBD leads to a grafting which is more localised on the top surface of the polymer. Moreover, it has been shown [15] than the water contact angle measured after a GDBD treatment in N_2 is not correlated with the percentage of N atoms grafted on the polymer but with the amount of C-N functions (amines). Indeed, the water contact angle decreases when the percentage of C-N grafted functions increases and saturates when this percentage saturates, even if heavy nitrogened functions (C-C≡N, N-C≡N et N_2C=O) are still incorporated (figure 7). By looking at the decomposition of N1s XPS peak, for a water contact angle of 38° (25% of N), 32% of the N bonds are amine bonds, which means that 8% of atoms are N atoms in amino groups. The fact that 9% of N atoms grafted by He GDBD is enough to have such a low water contact angle may be due to the fact that these N atoms are mainly grafted under amine forms. This will be checked in the near future by making a decomposition of the C peak following He GDBD treatment.

3.2.2. GDBD in Ar/NH_3 and N_2/NH_3

In Ar/NH_3 mixture, the kinetics of the decrease of the water contact angle is very slow. However, the fact that the discharge is a glow one clearly shows that Penning ionisation occurs between Ar metastable and NH_3, and so that NH_3^+ and NH_4^+ ions are created [16]. Then, the water contact angle results indicate that these ions would be much less efficient than N_2^+ ions for the incorporation of N atoms. This may be due to the fact that the recombination of NH_x^+ ions with electrons from the polymer surface is not sufficiently exothermic to break a chemical bond on the polypropylene and then to lead to the production of radicals on the polymer and in the gas, at the same instant and the same place, as it occurs in He GDBD.

The addition of NH_3 in the N_2 GDBD has an interesting effect. Indeed, despite the very small amount of NH_3 added (80 ppm), the water contact angle that can be reached is lowered compared to N_2 GDBD, especially for long treatment duration (fig 6). In fact, it looks as if the kinetics of decrease observed with N_2/NH_3

treatment is the convolution of the N_2 kinetics and the Ar/NH_3 one. However, looking at the very strong N incorporation occurring in N_2 GDBD, the fact that the water contact angle still continues to decrease in N_2/NH_3 has to be related to the incorporation of functions different to those grafted by N_2 GDBD. As in N_2 GDBD, the water contact angle is connected to the amount of C-N functions grafted on the polymer, and as NH_3 would preferentially lead to the formations of amino groups [17], this lowering of the water contact angle in N_2/NH_3 mixture may be caused by a higher incorporation of these amino groups compared to the N_2 GDBD. Obviously, this has to be checked by doing some XPS measurements on these treatments.

4. Conclusion

Atmospheric pressure glow dielectric barrier discharge can be generated in argon if Penning ionisation is enhanced by the adding of an appropriate gas. Ammonia can be used for that purpose, the $Ar(2^3P)$ metastable states being able to ionise it. The GDBD in Ar/NH_3 mixture is then similar to the one in He, i.e. a subnormal glow close to a normal glow discharge.

GDBD in various atmospheres (He, He/N_2, N_2, N_2/NH_3, Ar/NH_3) have been compared relative to their efficiency on polypropylene wettability. Taking into account the energy dissipated in the gas during the treatment, it appears that the GDBD in He/N_2 mixture is the most efficient discharge to lower the water contact angle. In fact, N_2 GDBD grafts much more N atoms than He GDBD, but the associated water contact angle is higher. This result may be attributed to two phenomena: (i) N is bonded deeper in the material with N_2 GDBD than with He GDBD, due to the crosslinking ability of He (ii) He GDBD grafts mainly amino groups while N_2 GDBD leads to higher valency nitro bonds for long treatment durations. GDBD in Ar/NH_3 mixture is the least efficient discharge, but the adding of NH_3 in N_2 GDBD increases the N_2 GDBD efficiency, probably due to a higher level of amino grafting.

Probabilistic modeling of the spot displacements on a high-pressure arc cold cathode

Sylvain Coulombe

CRTP/Department of Chemical Engineering, McGill University, Montréal, Québec, Canada

Abstract
A probabilistic model for the description of the type-A cathode spot (*macro-spot*) displacement dynamic is applied to a high-pressure rotating arc configuration for which experimental observations exist. Such system shows a $1/f^{\sim 1}$ (flicker noise) signature in the arc voltage signal for cathode surface conditions leading to arc anchoring. The cathode spot displacement conditions leading to such signature and computer simulations of the principal figures of interest (arc elongations, Fourier spectrum, and erosion trace) are presented.

1. Background

The dynamic of the arc attachment points on the electrodes is, in general, seen as detrimental to the operation of high-pressure arcs. Of particular interest with low current arc systems is the cathode macro-spot dynamic (the type-A spot [1]). The very existence of spots on non-refractory cathodes is associated with the requirements for a self-sustaining operation [2] and thus, such spots are essential. An obvious drawback of these requirements is the cathode erosion phenomenon leading to the release of copious amounts of metallic vapors into the arc. The movement of the cathode spot is erratic, and shows periods of momentarily attachment over confined regions (local diffusion) and jumps over longer distances (re-strike events). The later are a source of significant arc elongations causing arc voltage and temperature variations. The arc length elongations between re-strike events lead to the characteristic "saw-teeth" in the voltage signal. The local diffusion events add a high-frequency noise component to this signal.

The arc elongation dynamic associated with the electrode attachment effects is particularly problematic for the plasma spraying process since the thermal and acceleration history of the particles is affected, which in turns affects the uniformity of the coating. In plasma torches, the gas dynamics add to the arc attachment effects, leading to stronger instabilities. A significant research effort is now dedicated to the development of tools to monitor those instabilities and to relate them to the coating quality ([3] and references therein). A less significant effort is dedicated to the understanding of the relationship between the surface state and the movement of the arc attachment points, which lead to arc length and voltage fluctuations. Experimental observations made in our laboratory ([4,5] and references therein) revealed the intimate relationship between the contamination state of the cathode surface (i.e. electron emissive properties) and the erosion rate and smoothness of the cathode spot displacement. Arc anchoring conditions observed with copper cathodes in an argon or argon+nitrogen plasma gas atmosphere are associated with a $1/f^{1}$ voltage fluctuations signature while conditions leading to a smooth movement of the cathode spots (ex. Ar + 1vol% CO arc on Cu cathode) are associated with a white noise signature.

We recently presented a probabilistic modeling approach for the description of the cathode spot displacement dynamic [6]. We then demonstrated the ability of the model to qualitatively reproduce the experimentally obtained voltage signature for a range of cathode surface conditions giving rise to smooth and anchoring arc movements. We now present the results obtained for conditions leading to a *1/f* signature.

2. Description of the model

The probabilistic cathode spot displacements model was described in detail in a recent study [6] and only the essential details are presented here. A rotating arc geometry consisting of a center anode surrounded by a concentric water-cooled cathode is considered (figure 1). In such an arrangement, the attachment of the arc on the anode is confined to a plane while the cathode spot displacements are not as constrained. In a real experimental arrangement, the arc gap is small (a few mm) and the arc is forced into a rotating motion through the use of a magnetic field or tangential gas injection. Our model geometry for the cathode surface consists of an elongated rectangue where the shortest direction corresponds to the axis of the electrode assembly while the longest, to the azimuthal direction (the direction along the main arc motion). The arc

rotation is modeled assuming a uniform movement of the anode attachment (constant velocity) while the cathode spot is allowed to diffuse locally and jump in re-strike events. The arc elongations are thus only due to cathode spot displacements.

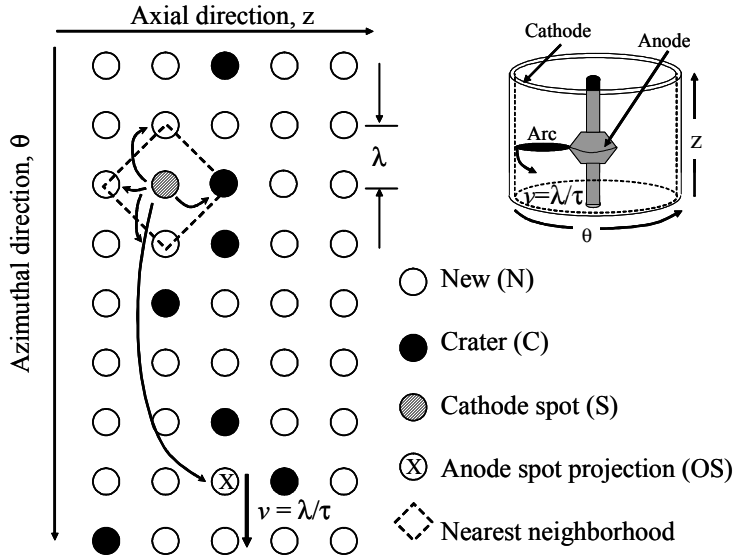

Figure 1. Schematic of the arc gas heater assembly and model geometry

The cathode spot has a residence time τ at a given location on the model surface (characteristic burning time). After this lapse of time, the new location of the cathode spot is predicted using a probabilistic scheme: i) the spot has a probability p_S to stay at the current location and burn for another time period τ. ii) the spot has a probability p_N to diffuse locally and move a distance λ (characteristic diffusion distance) to a neighboring lattice position located in either one of the cardinal directions. iii) the spot jumps with a probability p_J to the current position of the anode attachment point projected on the cathode lattice. The total probability is normalized: $p_{TOT} = p_S + p_N + p_J = 1$. In the present study, we assume $p_N = 4p_S$ with equal diffusion probabilities in each cardinal directions. The later assumption implies that the probability for the cathode spot to move into one of the local neighboring sites equals its probability to stay at the present location. This definition of probabilities is introduced in order to reproduce a local random diffusion process. A uniformly distributed random number $0 \le R \le 1$ is drawn after each time step τ and the actual event that takes place is determined using the following decision scheme:

Jump under the anode attachment point if:	$R \le p_J$
Move one λ North if:	$p_J < R \le p_J + p_S$
Move one λ South if:	$p_J + p_S < R \le p_J + 2p_S$
Moves one λ East if:	$p_J + 2p_S < R \le p_J + 3p_S$
Moves one λ West if:	$p_J + 3p_S < R \le p_J + 4p_S$
Stay at current location if:	$p_J + 4p_S < R \le 1$

Periodic boundary conditions are used to close the computational domain and thus, reproduce the cylindrical geometry of the cathode surface. The calculated arc elongation corresponds to the linear distance between the actual cathode spot position and the anode spot position projected onto the cathode plane. The frequency signature of the arc elongations dynamic is obtained by calculating its frequency power spectrum (FPS). The "depth" of the erosion trace is calculated by adding the number of times the cathode spot visited a given location on the model lattice. Numerous arc rotations are used in order to reproduce the erosion trace left on the cathode surface. The dimensions of the model cathode surface lattice are 101λ x 2048λ (axial and azimuthal directions).

3. Results and discussion

In [6] we determined the conditions leading to a *1/f* arc elongation dynamic: $p_J = p_N + p_S = 0.5$, meaning that in a displacement event the cathode spot is as likely to diffuse locally than to jump in the arc movement direction in a re-strike event. Those conditions are used in the present study.

Arc Elongation dynamic

Figure 2 presents the temporal evolution of the normalized arc elongation (top) and the corresponding power frequency spectrum calculated for one arc passage over the cathode surface. The arc elongation signal consists in a series of "saw-teeth" (low frequency) on top of which is added a weak higher frequency signal. The saw-teeth are characteristic of the momentarily arc anchoring on the cathode surface between re-strike events which leads to a stretching of the arc, thus a voltage increase, as the anode attachment point moves. The arc length increases in an essentially linear fashion before to suddenly shrink to its nominal length (arc gap distance) in a re-strike event. The higher frequency component of the signal is attributed to the local diffusion of the cathode spot between re-strike events. This simulated signal, though considerably less noisy than experimentally obtained ones [4], is nevertheless is good qualitative agreement.

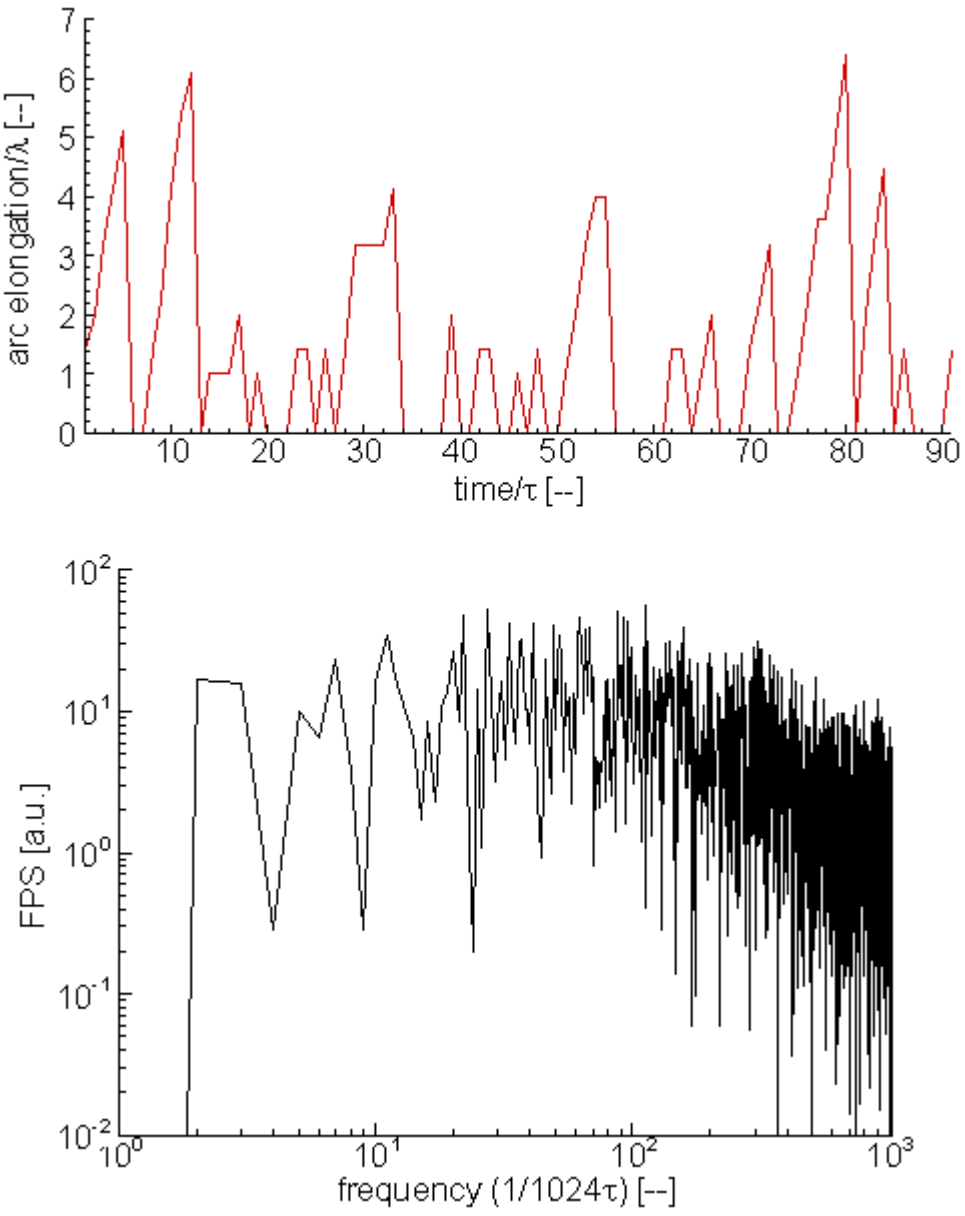

Figure 2. Closed-up view of the simulated temporal evolution of the arc elongation and corresponding Fourier spectrum obtained for conditions leading to a *1/f* signature (p_J=0.5, p_S=0.1) and one arc passage.

Figure 3 reveals the cathode spot displacements over a few time steps. The anode rotation plane is defined by $z = 51\lambda$. The cathode spot momentarily wanders out of the anode rotation plane before to jump back to this plane in a re-strike event. It is important to note that this jumping condition corresponds to a re-strike event at the minimum anode-cathode distance and thus, was not arbitrarily chosen. Without such condition, the cathode spot drifts out of the anode rotation plane causing an increase of the *rms* arc length and eventually, leaves the cathode surface. For the conditions leading to a *1/f* signature, the cathode spot rarely wanders more than 2-3λ out of the anode rotation plane before to jump in a re-strike event. As the jumping probability decreases, significantly more wandering out of the plane of rotation is observed [6].

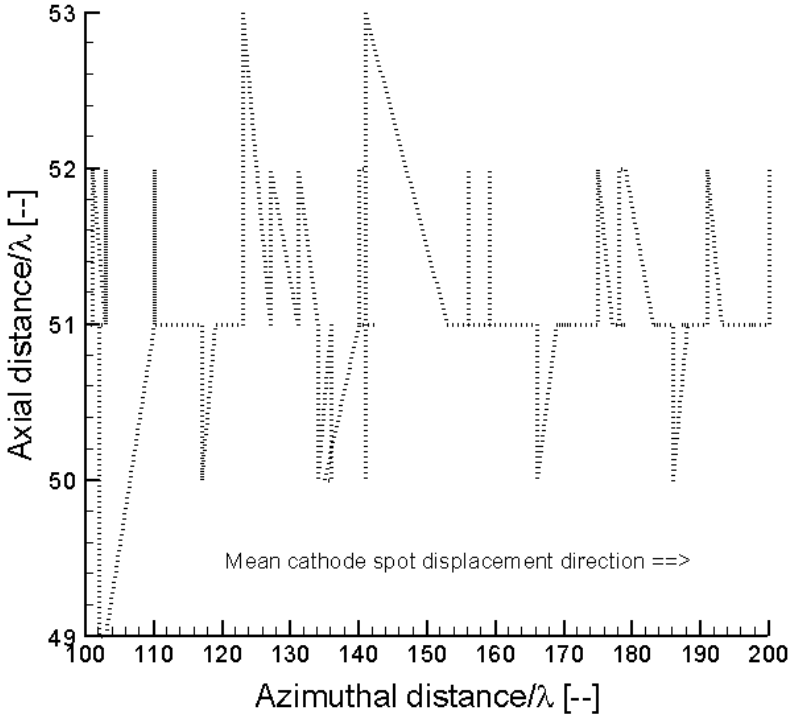

Figure 3. Close-up view of the simulated cathode spot displacements (p_J=0.5, p_S=0.1).

Erosion trace

The local diffusion of the cathode spot between re-strike events leads to the formation of an erosion trace on the cathode surface. Figure 4 shows a close-up view of the simulated erosion trace left by the cathode spot following respectively, 1 (top) and 10000 (bottom) arc passages. The gray scale used is such that the lighter the gray tone at a given location on the model cathode lattice, the higher the number of times the cathode spot visited this specific location. To some extent, this contour plot can be interpreted as the erosion trace where the gray tone represents the local depth of the trace. The depth of the erosion trace is obviously more significant in the anode rotation plane. When the jumping probability is increased, the cathode spot residence time in a given area of the surface decreases and thus, the extent of local damage to the surface is less significant [6].

4. Concluding comments

The results presented in this study complement our initial investigation of the type-A cathode spot (*macro-spot*) displacement dynamic in high-pressure arc systems. We attributed the experimentally observed *1/f* electrical signature (flicker noise) to the cathode spot dynamic and showed that this signature can be qualitatively reproduced using a simple probabilistic displacement model which uses local displacement rules based on the cathode surface conditions. This tool will potentially find a useful application in the monitoring and control of the cathode erosion process.

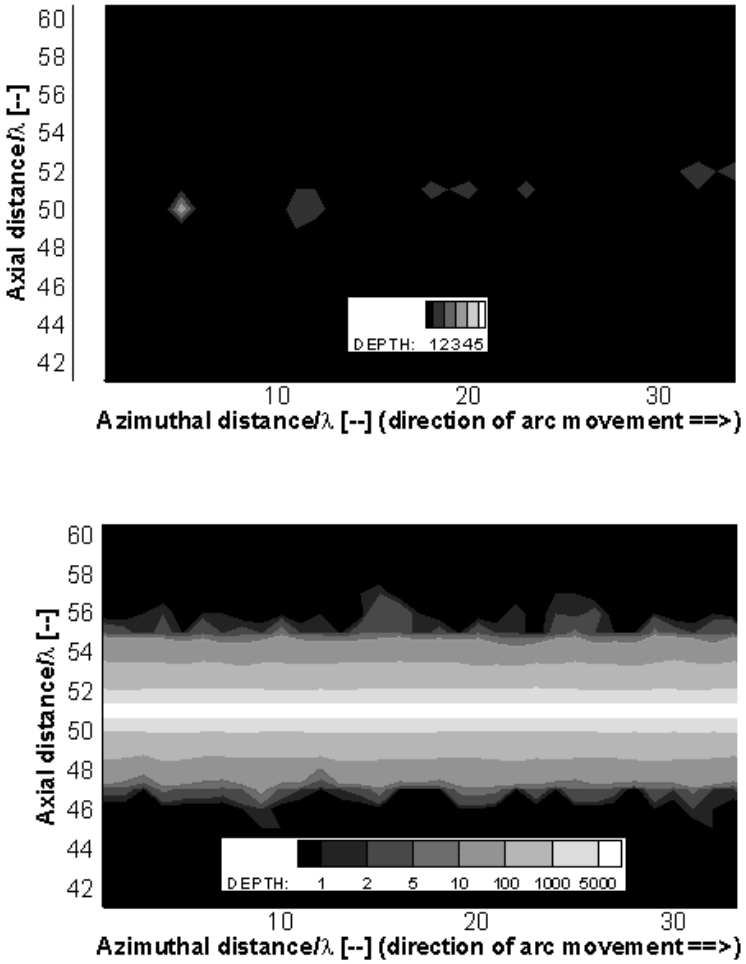

Figure 4. Closed-up view of the simulated erosion trace left on the model cathode surface for *1/f* conditions (p_J=0.5, p_S=0.1). Top: 1 arc passage. Bottom: 10000 arc passages.

Abstract
This paper reports the results of a model aiming to describe the characteristics of a chlorine high-density plasma. The model allows in particular to determine the pressure-dependence of the concentration of neutral and charged species. Comparison of this model to experimental measurements achieved in a high-density plasma sustained by an electromagnetic surface wave shows an excellent agreement for the neutral atomic and molecular species. As far as charged species are concerned, the model reproduces well experiments for atomic chlorine ions and electrons, but some discrepancy occurs for molecular positive ions and negative ions. The cause of this discrepancy remains to be clarified but might result from an underestimation of the creation rates of Cl_2^+ and Cl^-. The results also demonstrate that diffusion can be ignored above 1 mTorr.

1. Introduction

Chlorine- and fluorine-containing plasmas are routinely used for the etching of a vast class of materials, including materials with novel applications such as ferroelectrics [1-2]. While intense research efforts are devoted to the use of such plasmas for etching purpose, there is comparatively little information available concerning the gas-plasma phase and its interaction with surfaces. However, to be efficient, the optimization of etching processes requires a good understanding of the discharge chemistry. In addition, while high-density plasmas (i.e. low pressure plasmas (1 mTorr or so) with relatively high ionization degrees) are now finding their way as the most promising solution for the next generation of integrated circuits, important efforts still need to be devoted to the development of models that would allow optimizing the characteristics of such discharges in complex chemistries.

In this context, we have developed a 1-dimensional fluid model describing a high-density chlorine plasma. Among other quantities, the model allows to determine the radial structure of the plasma, including various neutral and charged species in the pressure regime ranging from 0.1 to 10 mTorr (in the following, gas pressure means pressure in the vessel before plasma ignition). The calculated densities of electrons, Cl, Cl_2, Cl^+, Cl_2^+ and Cl^- are compared to experimental measurements achieved in a low-pressure surface-wave sustained plasma.

2. Overview of the model

The model is based on fluid equations, in which the particle balance equations for electrons, Cl, Cl_2, Cl^+, Cl_2^+ and Cl^- are solved together with the corresponding flux equations and the energy balance equation. For simplicity, the model is isothermal, which means that power deposition is considered as spatially uniform. In addition, since chlorine is an electronegative gas, a simple quasi-neutral model cannot be used so that the plasma sheath needs to be treated in detail by solving Poisson's equation. In these conditions, the set of equations to be solved takes the following form

$$\frac{\partial n_k}{\partial t} + \nabla \cdot \mathbf{J}_k = S_k , \tag{1}$$

$$\mathbf{J}_k = \pm n_k \mu_k \mathbf{E} - D_k \nabla n_k , \tag{2}$$

$$P_V = \bar{n}_e \Theta , \tag{3}$$

$$\nabla \cdot \mathbf{E} = e\left(-n_e - n_{Cl^-} + n_{Cl_2^+} + n_{Cl^+}\right)\Big/\varepsilon_0 , \tag{4}$$

where k=1-6 indicates one of the 6 species considered, n_k being the density of the species k, $\mathbf{J_k}$ its flux, S_k its source term (volume creation minus volume losses), D_k and μ_k its free diffusion coefficient and mobility, $\mathbf{E}$ the space-charge electric field, P_V the average power absorbed by the plasma per volume unit and Θ the average power dissipated per electron [3]. In chlorine plasmas, the parameter Θ depends on the cross-section average values of both neutral atomic and molecular chlorine densities and on the electron temperature T_e. It

is calculated by summing all the power losses for electrons. In the range of pressures considered here, only inelastic collisions such as ionization and excitation play a significant role. A list of reactions affecting the electron power loss in chlorine discharges with their corresponding rate is given in [4]. Note that under steady-state conditions, Θ is also equal to the average power absorbed per electron [5].

In cylindrical coordinates, Eq. (1) can be written as

$$\frac{\partial n_k}{\partial t} + \frac{1}{r}\frac{\partial (r J_{kr})}{\partial r} + \frac{\partial J_{kz}}{\partial z} = S_k \,. \tag{5}$$

To avoid the problem of solving a 2-D model, the axial contribution of the flux in Eq. (5) is treated as an adjustable constant of the form $-(D_a/\Lambda^2)n_k$ where D_a is taken as the classical ambipolar diffusion coefficient and Λ an axial diffusion length. Such an approach allows to address in an approximate but simple way problems in which axial diffusion cannot be neglected, for example when the plasma is subjected to a magnetic field.

The radial component of equation (2) can be expressed as

$$J_{kr} = \pm n_k \mu_k E_r - D_k \frac{\partial n_k}{\partial r}\,, \tag{6}$$

while neglecting the axial component of the electric field in Poisson's equation (4) yields

$$\frac{1}{r}\frac{\partial (r E_r)}{\partial r} = \frac{e}{\varepsilon_0}\left(-n_e - n_{Cl^-} + n_{Cl_2^+} + n_{Cl^+}\right). \tag{7}$$

The source terms appearing in Eq. (5) are generally expressed as

$$S_k = \sum_j \beta_j n_k n_j\,, \tag{8}$$

where summation is performed on all the reactions involving a density change of the species k. For example, in the case of electrons

$$S_e = \beta_1 n_e n_{Cl_2} + \beta_2 n_e n_{Cl} + \beta_3 n_e n_{Cl_2} + \beta_4 n_e n_{Cl^-} - \beta_5 n_e n_{Cl_2^+} - \beta_6 n_e n_{Cl_2}\,, \tag{9}$$

where the coefficients β_j are given in Table 1, together with the whole reaction set considered in the model.

No	Mechanism	Reaction	Rate (cm^3/s)
(1)	Electron-impact ionization of Cl_2	$Cl_2 + e \rightarrow Cl_2^+ + 2e$	$\beta_1 = 9.214\times10^{-8}\exp(-12.9/T_e)$
(2)	Electron-impact ionization of Cl	$Cl + e \rightarrow Cl^+ + 2e$	$\beta_2 = \sqrt{T_e/12.96}\,\exp(-12.96/T_e)\sum_{i=0}^{5} a_i \left[\log(12.96/T_e)\right]^i$
			$a_0 = 1.419\times10^{-7}$ $a_1 = -1.864\times10^{-8}$ $a_3 = 3.306\times10^{-8}$
			$a_4 = -3.54\times10^{-9}$ $a_5 = -2.915\times10^{-8}$
(3)	Dissociative ionization of Cl_2	$Cl_2 + e \rightarrow Cl^+ + Cl + 2e$	$\beta_3 = 3.881\times10^{-8}\exp(-15.5/T_e)$
(4)	Electron-impact detachment	$Cl^- + e \rightarrow Cl + 2e$	$\beta_4 = 2.627\times10^{-8}\exp(-5.375/T_e)$
(5)	Dissociative recombination	$Cl_2^+ + e \rightarrow 2Cl$	$\beta_5 = 5.1\times10^{-7}(0.025/T_e)^{0.43}$
(6)	Dissociative attachment	$Cl_2 + e \rightarrow Cl^- + Cl$	$\beta_6 = 3.69\times10^{-10}\exp\left(\sum_{i=1}^{5} a_i/T_e^i\right)$ $a_1 = -1.68$;
			$a_2 = 1.457$; $a_3 = -0.44$; $a_4 = 0.0572$; $a_5 = -0.0026$
(7)	Ion-ion recombination	$Cl_2^+ + Cl^- \rightarrow Cl_2 + Cl$	$\beta_7 = 5\times10^{-8}$
(8)	Ion-ion recombination	$Cl^+ + Cl^- \rightarrow 2Cl$	$\beta_8 = 5\times10^{-8}$
(9)	Polar dissociation	$Cl_2 + e \rightarrow Cl^- + Cl^+ + e$	$\beta_9 = 8.549\times10^{-10}\exp(-12.65/T_e)$
(10)	Charge transfer	$Cl^+ + Cl_2 \rightarrow Cl_2^+ + Cl$	$\beta_{10} = 5.4\times10^{-10}$
(11)	Electron-impact dissociation	$Cl_2 + e \rightarrow 2Cl + e$	$\beta_{11} = 3.80\times10^{-8}\exp(-3.824/T_e)$

Table 1: Reactions considered in the model and corresponding rates (from [6,7])

The equation system is solved using usual boundary conditions

$$J_{kr}(0)=0;\ n_i(R+\delta)=0;\ J_{er}(R)=\frac{1}{4}\sqrt{\frac{8T_e}{\pi m_e}}n_e(R);\ J_{Clr}(R)=\frac{\gamma}{4}\sqrt{\frac{8T_n}{\pi m_{Cl}}}n_{Cl}(R);\ J_{Cl_2r}(R)=-\frac{1}{2}J_{Clr}(R)\,, \qquad (10)$$

where R is the vessel radius, n_i the total positive ion density, T_n the neutral temperature and γ the surface recombination coefficient characterizing the interaction of Cl with the wall. The value of γ depends on the wall characteristics. For example, in the case of anodized aluminum, γ is equal to 0.15 [8,9].

3. Results of the model and comparison with experiments

The model was tested through comparison with experimental data obtained from a high-density plasma produced by an electromagnetic surface wave at 190 MHz in a cylindrical structure made of two abutting cylinders of different diameter [6]. This plasma can be subjected to an axial magnetic field B_0. Details on the plasma reactor and diagnostics can be found in [6,10]. Measurements of the neutral density of atomic and molecular chlorine were performed using mass spectrometry and actinometry on Cl_2 molecules according to the zero-power extrapolation technique suggested by Donnelly [11]. The total ion density was determined by electrostatic probe and the Cl^+/Cl_2^+ ratio by ion mass spectrometry. The negative ion density was measured by laser photodetachment and ion acoustic waves. Finally the electron density was calculated using the neutrality condition.

In its present state of development, since the model is one-dimensional and isothermal, it does not allow to fully take into account the whole complexity of the reactor geometry and of the spatial distribution of species. Testing of the model was thus performed by comparison of the cross-section average densities of the various species with the experimental values in the larger of the two cylinders (processing chamber, R=14 cm). The parameters used for calculations were chosen to match the experimental conditions presented in reference [6]: P_V = 2.5 mW/cm^3 (250 W absorbed power), T_n = 300 K, Λ=150 cm, B_0 = 900 G.

3.1. Characteristics of neutral species

Figure 1 presents the Cl_2 dissociation degree τ_d as a function of the gas pressure for different values of the Cl surface recombination coefficient γ. It can be seen that for all values of γ, τ_d is decreasing with increasing pressure. In addition, when the surface recombination coefficient increases, the dissociation degree decreases as noticed in [7,12-13]. In our experimental conditions, the value of γ that provides the best agreement with the experimental data is found to be 0.02. This value lies between those of pure anodized aluminum (γ~0.15) and pure quartz (γ~0.008) [9,14]. Figure 1 shows that for γ=0.02, even in the moderate power conditions investigated, the dissociation degree exceeds 80% when operating at or below 1 mTorr while it decreases at about 25% at 10 mTorr. A similar decrease of the dissociation degree was also observed in [15,16].

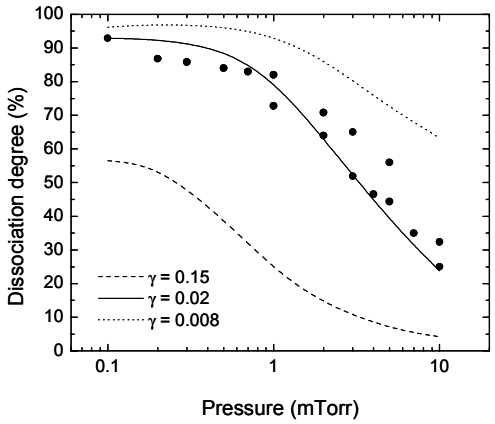

Fig. 1: Dissociation degree as a function of the gas pressure for different values of the surface recombination coefficient γ. The full circles correspond to the experimental values.

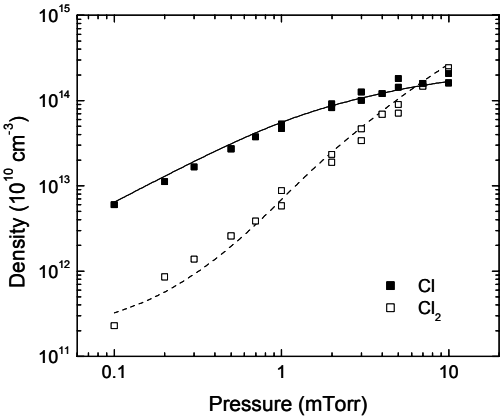

Fig. 2: Density of atomic and molecular chlorine neutrals as a function of the gas pressure for γ=0.02. The full and dotted lines correspond to the calculated densities of Cl and Cl_2 respectively.

The dependence on the gas pressure of the atomic and molecular chlorine neutral densities is presented in Fig. 2. These data were deduced from Fig. 1 assuming a gas temperature of 300 K as discussed in [6]. Clearly, at low pressure, the plasma is dominated by Cl while as soon as the pressure exceeds about 7 mTorr, Cl_2 takes advantage over Cl. Clearly, the model reproduces very well the experimental values, thereby indicating that for neutral species, the use of a 1-D isothermal model is quite suitable.

3.2. Characteristics of charged particles

Figure 3 shows the Cl and Cl_2 positive ion densities as a function of the gas pressure. The model predicts that Cl^+ increases up to a pressure of about 0.5 mTorr and then decreases like p^{-2}. As for Cl_2^+, its density increases with p, significantly up to 1 mTorr and slowly above this pressure. Overall Cl^+ dominates the positive ion population below 1 mTorr while the main ion species is Cl_2^+ above a few mTorr. Comparison with the experimental results shows an excellent agreement for the Cl^+ population. However, the model does not correctly predict the pressure dependence of the Cl_2^+ density, the experimental data showing a nearly pressure-independent behavior.

Figure 4 shows the electron and negative ion densities as a function of the gas pressure. As can be seen, the negative ion density is much smaller than the electron density at lower pressure, while Cl^- becomes the dominant negative charge carrier at higher pressure (i.e. above 2 mTorr). However, the model strongly underestimates the negative ion population in the lower pressure region while it slightly overestimates it at higher pressure.

It is worth mentioning that both model and experiment yield a similar pressure-dependence of Cl^+ and electrons on one hand, and of Cl^- and Cl_2^+ on the other hand. In addition, over the whole range of pressures investigated, the absolute values of Cl^+ and electrons are very close each other. The densities of Cl^- and Cl_2^+ are also very similar except at very low pressure for the calculated values. Similar observations were reported in [17]. In order to understand the reasons of this behavior, we have investigated the importance of the various reactions in the particle balance equations (1).

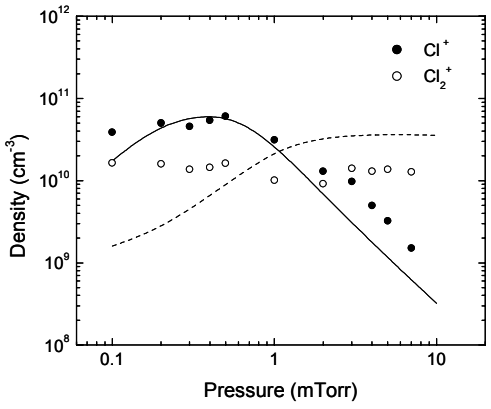

Fig. 3: Density of atomic and molecular positive chlorine ions as a function of the gas pressure. The full and dotted lines correspond to the calculated densities of Cl^+ and Cl_2^+ respectively.

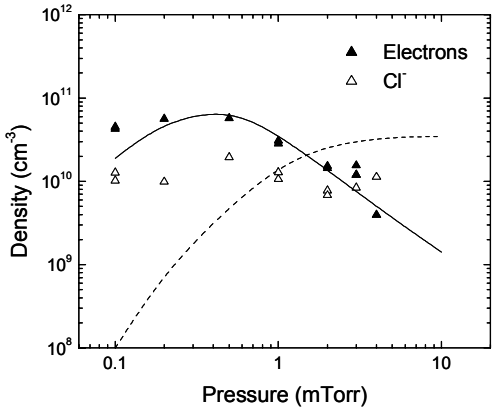

Fig. 4: Density of electrons and negative chlorine ions as a function of the gas pressure. The full and dotted lines correspond to the calculated densities of electrons and Cl^- respectively.

Figures 5a to 5d shows the volume creation and loss rates (i.e. the number of particles created or lost per volume and time unit) of Cl^+, e^-, Cl^- and Cl_2^+ through the various mechanisms that appear in Table I. In the case of Cl^+ (Fig. 5a), the creation is clearly governed by electron-impact ionization, while polar dissociation is everywhere negligible. On the other hand, the main losses occurring in the plasma volume are due to charge transfer, ion-ion recombination being lower by at least one order of magnitude over the whole range of pressures investigated. Charge transfer is however ignored in most publications. A close analysis of the results presented in Fig. 5a shows that volume creation and losses do not exactly balance each other. The difference is taken into account by the diffusive term $\nabla \cdot \mathbf{J}_k$ appearing in Eq. (1). Interestingly, for Cl^+, this term is positive at lower pressure, thereby representing a net loss term (when averaged over the radius, the

flux is directed towards the wall), while at higher pressure, it becomes negative (i.e. on the average the flux is directed inwards). A similar behavior is observed for electrons as can be seen in Fig. 5b. Indeed, the total creation term (mainly electron-impact ionization) is larger than the loss terms (dissociative recombination + attachment) at lower pressure, while the reverse situation occurs at higher pressure. In addition, note that the contribution of detachment to the creation term is negligible over the whole range of pressures investigated.

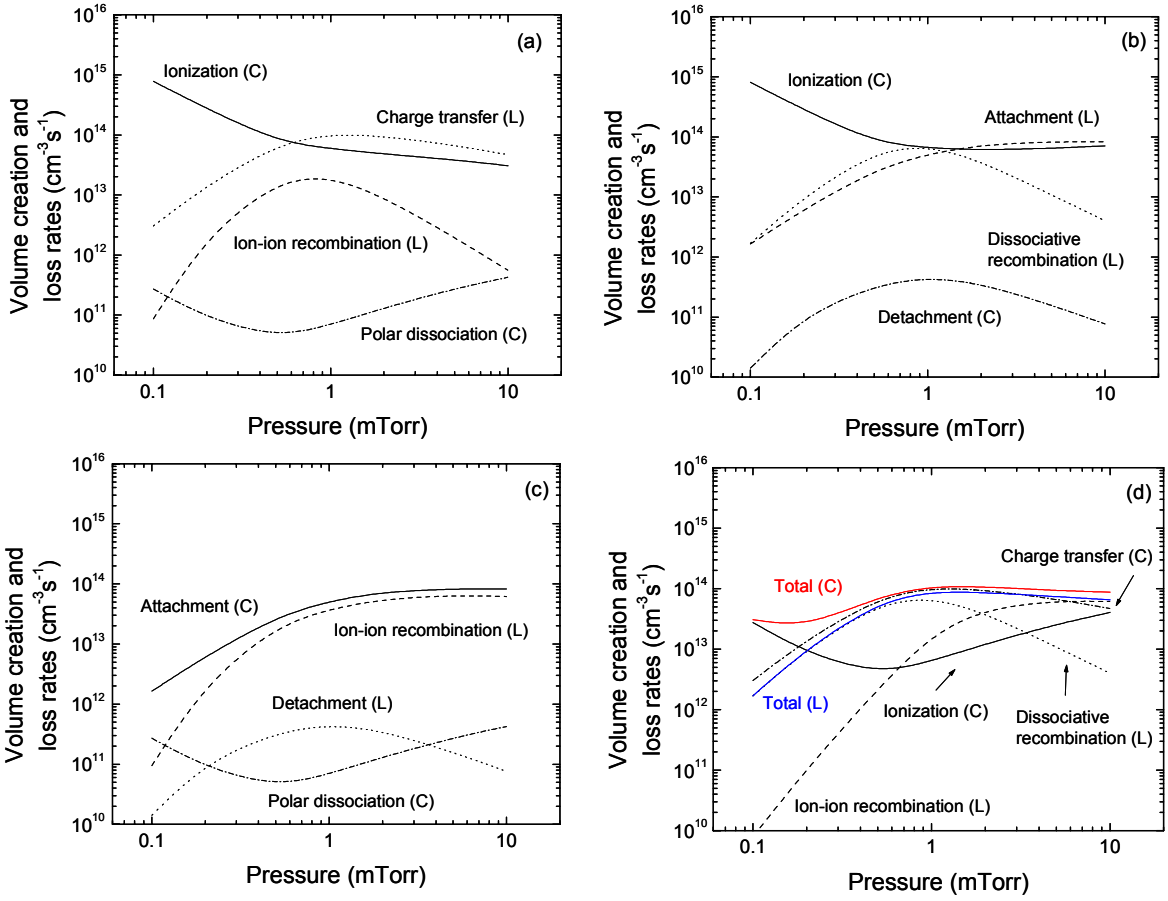

Fig. 5: Pressure dependence of the volume creation and loss rate of charged species through various mechanisms. (a) Cl^+, (b) electrons, (c) Cl^-, (d) Cl_2^+

Figure 5c shows the results obtained for negative ions. In this case, creation is largely dominated by attachment and volume losses by ion-ion recombination, the other mechanisms playing only a minor role. It can also be seen that creation is everywhere larger than losses, the difference being compensated by an outward diffusive term. However, the relative weight of this term with respect to volume losses is less important than for Cl^+ and electrons. In the case of Cl_2^+ (Fig. 5d), the situation appears a little bit more complex. For this reason, we also show on Fig. 5d the total volume creation and loss terms. Creation is essentially governed by charge-transfer except at very low pressure (0.1 mTorr) where electron-impact ionization dominates. The volume losses are mainly due to dissociative recombination below 2 mTorr and to ion-ion recombination beyond. Note that for Cl_2^+ the diffusive term is also outward.

It is quite remarkable in Figs. 5a to 5d that the creation rate shows a similar pressure dependence for Cl^+ and electrons on one hand, and for Cl_2^+ and Cl^- on the other hand. Since the total volume losses behave similarly with pressure for the 4 species, it is suspected that the pressure dependence of the creation rate is the key factor explaining the final pressure dependence of the densities. That would explain why molecular chlorine ions closely follow negative ions both theoretically and experimentally. In these conditions, the discrepancy observed between model and experiments for Cl_2^+ and Cl^- might be resulting from an underestimation of either the Cl_2^+ or the Cl^- creation in the lower pressure region. This remains however to be investigated in more detail before definitely concluding.

Finally, one notes from Figs. 5a to 5d that the total creation and volume losses become very similar above a typical pressure value of 1 mTorr. This indicates that under the conditions investigated here, the diffusion processes can reasonably be ignored when one is interested by plasmas operating above such a pressure. This allows considerable simplification of modeling.

4. Conclusion

The fluid model that was developed for describing a high-density chlorine plasma reproduces very well a number of observed characteristics. In particular, the pressure dependence of the dissociation degree and the absolute value of the Cl and Cl_2 neutral density are correctly described by the model. As for the charged species, the density of Cl^+ and electrons is correctly predicted. However, the model underestimates the density of Cl_2^+ and Cl^- in the lower pressure region.

Abstract
This article is devoted to the understanding of the gas-phase chemistry in a glow dielectric barrier discharge at atmospheric pressure in a $N_2/N_2O/SiH_4$ mixture. The main goal of this work is to identify the particle precursors. A detailed chemical kinetics model based on homogeneous nucleation is used, and it is found that SiO and SiH_2O species play an important role in the initiation of the clustering mechanism.

1. Introduction

Dielectric barrier discharges (DBD) at atmospheric pressure are widely used for surface treatment, depollution or ozone production. These discharges are usually filamentary in nitrogen but, under some specific conditions, a glow discharge can be obtained [1]. This feature is very interesting for surface purposes. The addition of SiH_4 and N_2O in nitrogen DBDs enables specific chemical functions to be grafted on a polymer surface, thus enhancing wettability. Nevertheless, particles form in the gas phase during the process and this is a limitation for such applications. Furthermore, experimental observations made in LGET show that particle formation is greater in a filamentary discharge than in a glow discharge [2]. Since there is a great advantage in avoiding particle formation, it is important to understand why clustering depends on discharge regime. Our aim is to identify the main powder precursors by means of numerical modeling, and to determine the different clustering processes involved in filamentary and glow discharges.
As a first step towards this, we studied the primary chemistry occurring in a glow dielectric barrier discharge in a mixture of $N_2/N_2O/SiH_4$. A brief description of the numerical model and chemical clustering mechanism used is made, and the first results obtained are presented.

2. Description of the model

2.1 Numerical modeling

The discharge was obtained between two plane parallel electrodes coated with a dielectric layer (Al_2O_3). An alternating voltage of about $11kV_{pk-pk}$ was applied. The frequency was 4 kHz.
The numerical model of the discharge is presented in detail elsewhere [3], therefore only a brief description will be given here. Our one-dimensional electrical model is based on the solution of the continuity equations for every species (electrons, ions and excited states) coupled to the Poisson equation. This model is used to describe the transport of electrons, ions and early products of electron impact processes (ionization, dissociations, excitation).
A zero-dimensional model was added to the electrical one in order to study the kinetics of heavy neutral particles. This zero-dimensional model consists in solving the space-integrated convection diffusion equation:

$$\frac{\partial \overline{N}_k(t)}{\partial t} = \overline{S}_k(t) \qquad \text{(Eq.1)}$$

where $\overline{N}_k(t)$ is the space-averaged density of species k and $\overline{S}_k(t)$ is a source or sink term due to chemical reactions.

2.2 Chemical kinetics

The glow discharge was produced in a mixture of nitrogen with a few ppm of silane and nitrous oxide. The chemistry occurring in a nitrogen glow discharge has already been studied in another work [3]. The initial set of reactions listed in nitrogen was completed by accounting for the chemistry of silane and nitrous oxide.

The one-dimensional electrical model includes 16 neutral species, 15 charged species and 5 excited states. The electron impact reactions include electronic excitation, ionization, dissociation and attachment. The corresponding reactions rates were determined using a numerical solution of the equilibrium form of the Boltzmann equation, and appropriate cross sections sets found in the literature. The model also includes electron-ion recombinations, ion-ion neutralization, ion-neutral reactions, reactions between neutral species and reactions with metastable states.

The reaction scheme describing the early stages of silane oxidation is mainly based on the work of Kushner in SiH_4 [4] and in a SiH_4/N_2O mixture [5].

The clustering mechanism considered in this study is based on the work of Suh et al [6] who built a model describing particle formation during low pressure silane oxidation.

In the model of Suh et al, the clustering of SiO and SiO_2 occurs through four main pathways : SiO self-clustering, insertion of SiH_2O and its dimer into SiO clusters, SiO_2 self-clustering and insertion of HSiOOH and its dimer into SiO_2 clusters (see table 1). Suh et al calculated the related reaction rates at 0.8 Torr by using the QRRK theory[7]. However, since we operated at atmospheric pressure, we must carefully make use of the rate constants reported by Suh et al.

In the case of unimolecular decomposition reactions (reactions 1-9, 20-28, see table 1), the rate constant increases with pressure up to the high pressure limit k_∞. Suh et al. reported the high pressure limit rate constants for these reactions together with the related correction factors taking into account pressure dependence. For correction factors close to one, we can assume that the rate constants are equal to the corresponding high pressure limits at atmospheric pressure. This is the case for most of the unimolecular reactions except reaction 1. For this reaction, the rate constant at atmospheric pressure was extrapolated from data published by Zachariah et al. [8].

For bimolecular reactions leading to dissociation of the intermediate complex (reactions 10-19, 29-38 table 1), the pressure dependence is inverted compared to unimolecular reactions (that is, the rate coefficient is pressure independent at low pressure and inversely proportional to the pressure at high pressure[7]). Since we had no reliable information about the value of the rate constants at atmospheric pressure, we used the low pressure limit constant as a first approximation. Further more, a few QRRK calculations made by ourselves showed that these reactions rates should remain more or less in this pressure domain at P=1atm. All reactions selected are presented in table 1, with the corresponding values of the rate constants.

It must be mentionned that another clustering pathway has been reported in [9], which consists in the self-clustering of SiH_2O. No accurate kinetic data were available to calculate the corresponding rate constants. For this reason, this clustering pathway was not considered in this work, neither in [6], but further investigation will be required to conclude that it is negligible or not.

3. Results

3.1 Electrical characteristics

Figure 1 shows the time evolution of the measured electrical characteristics: discharge current, applied and gas voltages. Figure 2 presents the electrical characteristics obtained from the model.

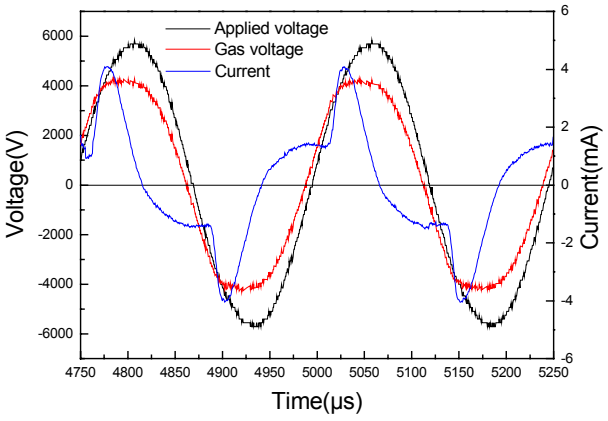

Figure 1 : Measured discharge current, applied voltage and gas voltage

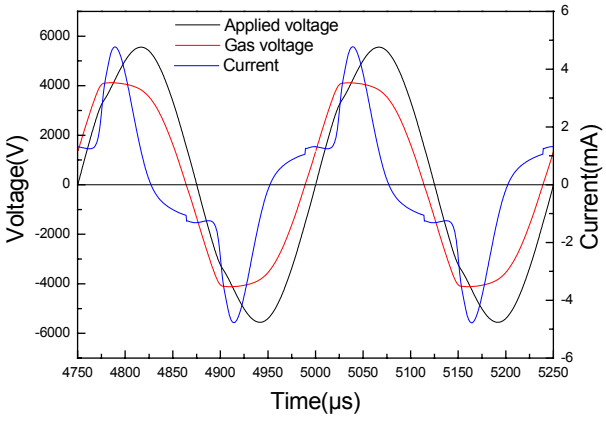

Figure 2 : Calculated discharge current, applied voltage and gas voltage

The good agreement (shape and amplitude) between calculated and measured values indicates that realistic physical mechanisms are included in the model.

3.2 Results of the kinetic model

Figures 3 to 7 present the species concentration calculated by using the kinetic model over sixty periods (which is equivalent to 120 discharges). Figure 3 is related to the clustering of SiO while figure 4 concerns the clustering of SiO_2.

There are two main pathways for SiO polymerization: SiO self-clustering and insertion of SiH_2O and $(SiH_2O)_2$ into SiO clusters. SiO, SiH_2O and $(SiH_2O)_2$ concentrations are rather high: about $10^{11}cm^{-3}$, $10^{13}cm^{-3}$ and $10^{12}cm^{-3}$ respectively (figure 5). This means that powder formation can be efficiently initiated via SiO clustering.

On the other hand, clustering of SiO_2 is found to be quite inefficient (figure 4). $(SiO_2)_n$ clusters are formed by SiO_2 self-clustering and insertion of HSiOOH and $(HSiOOH)_2$ into SiO_2 clusters. We can observe that SiO_2 creation is very slow (figure 4) and that HSiOOH concentration is rather low compared to SiH_2O and $(SiH_2O)_2$ (figure 5). $(HSiOOH)_2$ concentration is even lower and was not represented on the figure. Hence, it seems rather unlikely that particle formation could be significantly initiated from SiO_2 clustering reactions.

Based on the above remarks, SiO and SiH_2O appear as the most probable particle precursors, and the particle created in the gas phase mostly result from $(SiO)_n$ clusters.

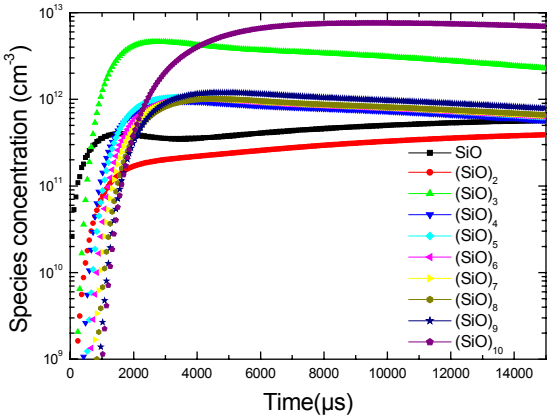

Figure 3 : Time-dependent concentrations of $(SiO)_n$ clusters (over 60 periods)

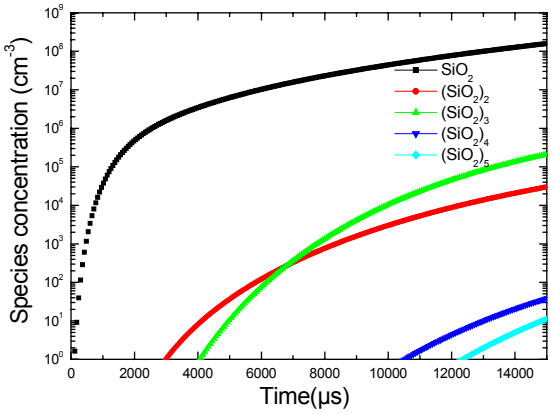

Figure 4 : Time-dependent concentrations of $(SiO_2)_n$ clusters (over 60 periods)

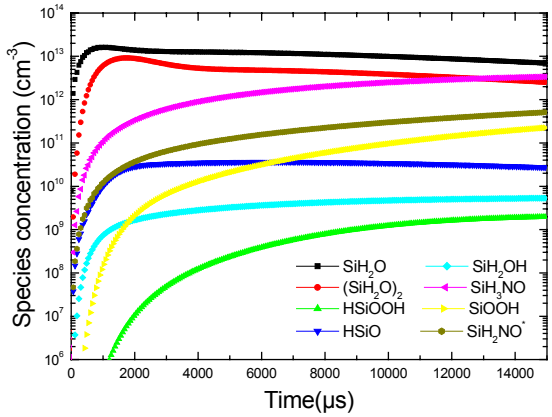

Figure 5 : Time-dependent concentrations of oxidized species of silane (over 60 periods)

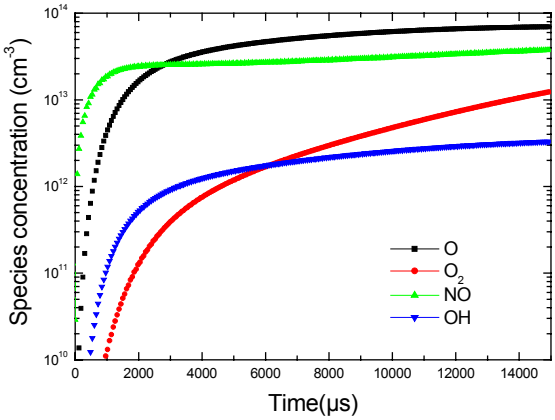

Figure 6 : Time-dependent concentrations of O, O_2, NO and OH (over 60 periods)

In figure 6, the time variations of the oxidizing species concentrations (O, O_2, OH, NO) are presented. The densities of O and NO are quite high. NO is mainly created by collision of N_2O with the nitrogen metastable state $N_2(A^3\Sigma_u^+)$ the density of which is high in the discharge (between $2.10^{12}cm^{-3}$ and $2.10^{13}cm^{-3}$) (Eq.2). Then, NO reacts with atomic nitrogen to produce oxygen (Eq.3).

$$N_2(A^3\Sigma_u^+) + N_2O \rightarrow N + NO + N_2 \quad \text{(Eq.2)}$$

$$N + NO \rightarrow O + N_2 \quad \text{(Eq.3)}$$

As a result, creation of oxidizing species by electronic dissociation of N_2O is very weak.
The high density of NO leads to the creation of SiH_3NO and SiH_2NO^* via the following reactions:

$$SiH_3 + NO + N_2 \rightarrow SiH_3NO + N_2 \quad \text{(Eq.4)}$$

$$SiH_2 + NO \rightarrow SiH_2NO^* \quad \text{(Eq.5)}$$

This result is rather surprising because our experimental results have shown that there is no nitrogen in the deposited layer. Chu et al [10] pointed out that the dissociation of SiH_2NO^* into $SiO+NH_2$ would be highly exothermic, then it would be possible that the molecules dissociate. However, no data are available and this dissociation pathway was not taken into account in our model.
In figure 7, concentrations of SiH_2, SiH_3, SiH_4 and Si_2H_6 are plotted. SiH_2 and SiH_3 radicals are created by collision between SiH_4 and $N_2(A^3\Sigma_u^+)$ (Eq.6-7), and also by electronic dissociation of silane (Eq.8-9). Oscillations on the densities of SiH_2 and SiH_3 confirm this strong connection with the discharge.

$$N_2(A^3\Sigma_u^+) + SiH_4 \rightarrow SiH_2 + H_2 + N_2 \quad \text{(Eq.6)}$$

$$N_2(A^3\Sigma_u^+) + SiH_4 \rightarrow SiH_3 + H + N_2 \quad \text{(Eq.7)}$$

$$e^- + SiH_4 \rightarrow SiH_2 + 2H + e^- \quad \text{(Eq.8)}$$

$$e^- + SiH_4 \rightarrow SiH_3 + H + e^- \quad \text{(Eq.9)}$$

Si_2H_6 is mainly formed by the following reaction:

$$SiH_4 + SiH_2 \rightarrow Si_2H_6 \quad \text{(Eq.10)}$$

The time variation of the nucleation rate is presented in figure 8. The nucleation rate is defined as the rate at which particles containing more than ten silicon atoms are created. We can observe that this rate is maximum after about 48 discharges. This result is in rather good agreement with measurements [2].

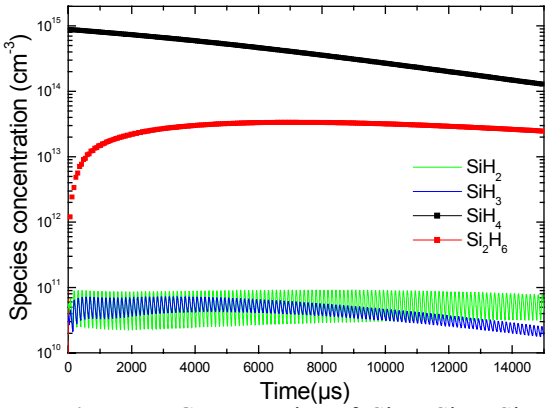

Figure 7 : Concentration of SiH_2, SiH_3, SiH_4 and Si_2H_6 (over 60 periods)

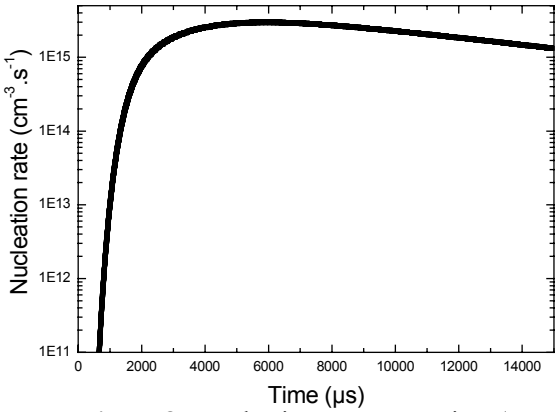

Figure 8 : Nucleation rate versus time (over 60 periods)

3.3 Discussion

The above results show the most probable clustering pathways in the case of the homogeneous nucleation model developed by Suh et al. However, it would be interesting to compare the results obtained with a heterogeneous model (ie., a model based on ion-induced nucleation). Indeed, in figure 9, we note that electron density is high while electric field is low between two discharges. At this time, electron attachment on particles is likely to occur.

Another drawback of our model is that we only considered chemistry in the gas phase, but surface chemistry might significantly influence the concentration of species in the gas phase. Surface reactions will be included in our model in the future.

4. Conclusion

In this paper, the preliminary results of our model of particle formation in a mixture of $N_2/N_2O/SiH_4$ at atmospheric pressure have been presented. The clustering mechanism is based on the work done by Suh et al [6]. Using this clustering mechanism, we found that SiO and SiH_2O were the most probable powder precursors.
In future studies, this model will be coupled with an aerosol model in order to study growth and coagulation of the primary clusters. The next step of our work is to introduce this chemical kinetics mechanism into our model of filamentary discharge. The kinetics involved in a filamentary discharge is likely to be very different. The energy injected is highly localized and many reactive radicals are then created in the filament, which will probably induce rapid cluster growth.

Abstract

The agressivity of CW-PECVD is of such magnitude that not even working with low power, PPy-like and films are obtained. In order to improve the structure, morphology and properties of PPy and PTh, pulsed-PECVD and HFCVD were used. With pulsed-PECVD, almost all aspects are improved. With HF-CVD the catalytic effect of the filament results in the co-deposition of tungsten oxide. With the information given by AFM, XPS and IR techniques, a comparative study of the films is attained.

.

1. Introduction

Conventional polymers consist of chains with a regular repeat unit but polymers obtained by plasma-enhanced chemical vapor deposition (PECVD) tend to form non regular three-dimensional cross-linked networks. The use of continuous wave-PECVD (CW-PECVD) produces a continuous ion bombardment of the growing film that can result in the formation of trapped free radicals in the film. Upon exposure to atmosphere, these free radicals can be oxidized leading to changes in the film structure and properties. In the polimerization of polypyrrole (PPy) and polythiophene (PTh) by CW-PECVD this changes show up mainly in the formation of C=O and –OH[1-4]. To reduce the formation of oxygenated groups, pulsed-PECVD can be used[5]. In this technique, electrical power is repeatedly turned on and off, making it easier to modulate plasma excitation to favor deposition from reactive neutral species rather than from ions. An alternative to PECVD is hot filament-CVD (HFCVD). RecentlyHFCVD[6-8] has been use successfully to develop fluorocarbon films with very close structure to bluk polymer. In this technique, pyrolisis of the monomer is achieved using a resistively heated filament. Then, polimerization reactions take place on the cooled surface of the substrate. The absence of plasma excitation in HFCVD minimizes the potential structural damage of the film from ion bombardment and electron irradiation.

In a previous work done by our research group[9], it was demonstrated that pyrrole is a more labile monomer than thiophene. For this reason, polymers derived from thiophene show closer structure to monomer than those derived from pyrrole. Also, the agressivity of CW-PECVD makes it impossible, even working with low power,to obtain PPy-like films because the main structure of the monomer is broken by the irradiation. These films have a poor doping capacity and therefore the exhibit a low conductivity upon doping[10]. Furthermore, the growth rate of PPy is much slower than that of PTh. This means that a greater amount of time is needed in the case of PPy to obtain pin-hole free films. In order to improve the structure (presence of C=O and OH, N/C or S/C ratios...), morphology (thickness, roughness, grain size and aspect, porosity...) and properties (conductivity upon doping, solubility, adherence to substrate, thermal stability...) of PPy and PTh, pulsed-PECVD and HFCVD were used.

2. Experimental section

Plasma-polymerized films were prepared using pyrrole (Sigma, as supplied) and thiophene (Sigma, as supplied) by radio-frequency plasma polymerization.

2.1 Plasma reactor system

The plasma polymerisation apparatus consists of a stainless steel discharge vessel (diameter 30 cm; width 25 cm). The RF power supply (27MHz) is capacitively coupled to the internal electrode. The vapour container with the monomer is attached to the deposition chamber through a vacuum cock and a needle valve. The reactor chamber was evacuated to a base pressure of 0,15 mbar and then the chamber was filled with monomer vapour until the pressure reached the desired level. 10 minutes later, when the pressure was stabilized, the power source was turned on. The films were deposited onto cleaned and degreased glass slides.

2.2. Hot Filament Reactor

Hot Filament enhanced polymerization was done in a stainless steel vessel (diameter 20 cm, 15 cm width). The hot filament is heated using a DC power supply. The distance between the filament and the sample was varied between 2 and 3 cm during the experiments. Temperature was measured with a pyrometrer. The reactor pressure was evacuated to a base pressure of 0.5 torr and the the chamber was filled with monomer vapour. Pressure was then kept automatically at 0.5 torr.

Films were deposited on oriented silicon wafers. The wafers were continously cooled inside the reactor at 25ºC using a recirculation bath. Nicrom and tungstene filaments were tested.

2.3 Infrared Spectroscopy

For IR studies specimens were scraped from the glass substrate and pelletized after mixing with KBr; these pellets were used to record IR spectra.. For recording IR spectra we used a FTIR Nicolet Magna 560 under identical conditions.

2.4 AFM

The surface morphology of the films has been studied with a Nanoscope III (Digital Instruments, Santa Barbara, CA) equipment with an extended electronic module. All images were collected on tapping mode and treated with Nanoscope software. The images for the morphological studies had a scan size of 5 m x 5 m. For thickness measurements images of a scan size of 10 m x 10 m were done onto scrapped films.

2.5 XPS

The XPS analysis were performed using a Perkin Elmer PHI 5500 spectrometer. The operating conditions were as follows: the X-ray source [Al K (1486.6eV)] was operated at a power of 350W. The spectrometer was operated in the fixed analyser transmission mode at a pass energy of 23.50 eV and a take off angle of 45ºC. The base pressure in the sample chamber was maintained below $5x10^{-9}$ Torr. Total spectral acquisition times per sample were typically 10-15 minutes. Spectral analyses were carried out using Multipak software for quantification and peak-fitting. The energy scale of the spectra is corrected to the C-H (1s) at 285.0 eV.

3. Results

3.1.-Deposition Rate

The deposition rate of the films has been calculated from thickness measurements done using the AFM technique onto scrapped films at different deposition times over a range between 30 seconds and 1 hour (fig 1).

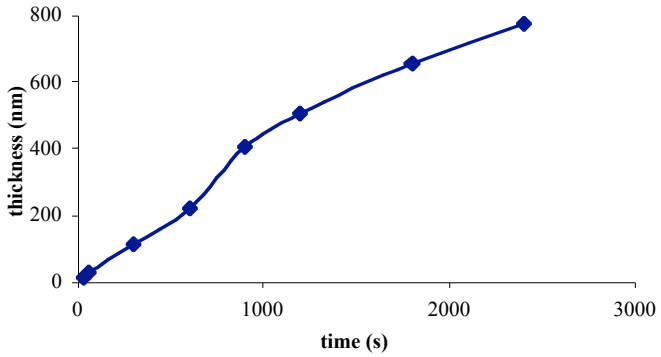

Fig. 1. Calculation of the deposition rate of polythiophene (continuous plasma, 10W, 0.4mbar of monomer pressure)

For all the samples, the power was maintained at 10 W (and 15kHz for the pulsed plasma) and the monomer pressure at 0.4 mbar. The results are summarized in table 1.

Table 1. Deposition rate of different samples

Sample	Monomer	Type of plasma	Deposition Rate (nm·min-1)
PyrC	Pyrrole	Continuous	11.5
PyrP	Pyrrole	Pulsed	2.2
ThioC	Thiophene	Continuous	21.4
ThioP	Thiophene	Pulsed	4.8

The fact that pyrrole is more labile than thiophene explains its lower deposition rate. Instead of activating the pyrrole, the exposition of the monomer to the RF power has a predominant effect of breaking its bonds and forming stable molecules such as CH_4 that leave the system without depositing onto the substrate. For this reason, after 1 hour of deposition, PPy films are absolutely transparent whereas PTh films present a brownish colour.

On the other hand, as it could be expected, the use of pulsed plasma greatly decreases the deposition rate.

3.2.-Morphology

The images obtained with AFM (fig. 2) show that pulsed plasma polymerized films have better morphological characteristics.

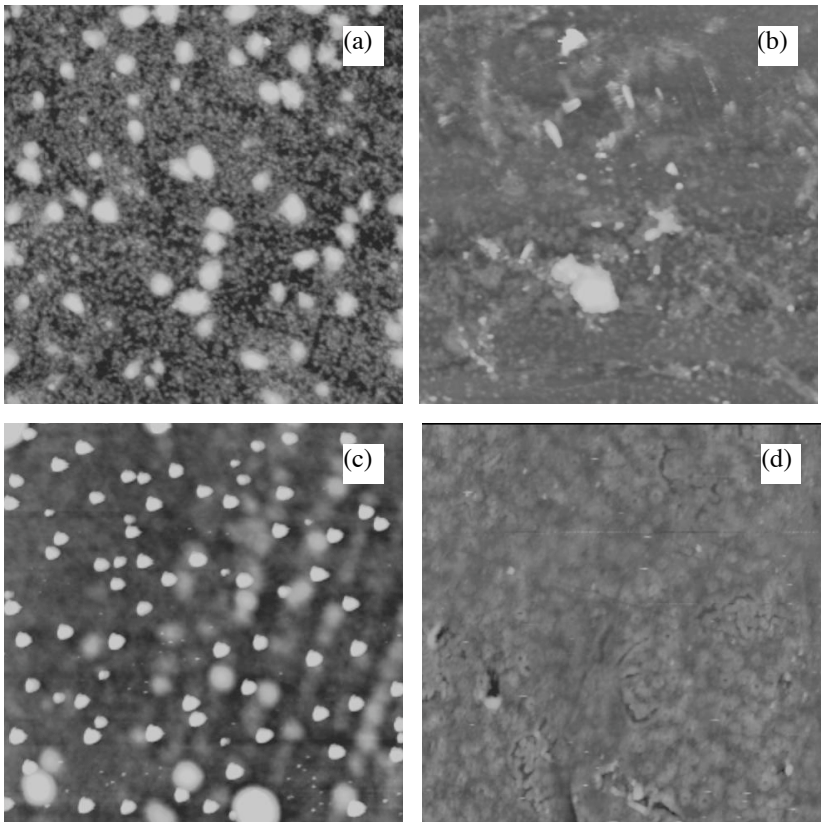

Fig.2. AFM images, 5□m x 5□m, of (a) PyrC, (b) PyrP, (c) ThioC and (d) ThioP

The effect of the use of pulsed plasma can be seen in the first place in the reduction of the roughness. Roughness measurements were performed on several images taken from the same sample in order to assure homogeneity. PPy films reduce their roughness from 4.85 nm to 2.99 nm and PTh show a greater reduction from 5.52 nm to 1.84 nm. However this reduction is not very impresive. The effect that has a greater impact on the visual appearance of the films is the reduction in grain size combined with a narrower distribution of grain size (fig.3), which provides these films with greater uniformity.

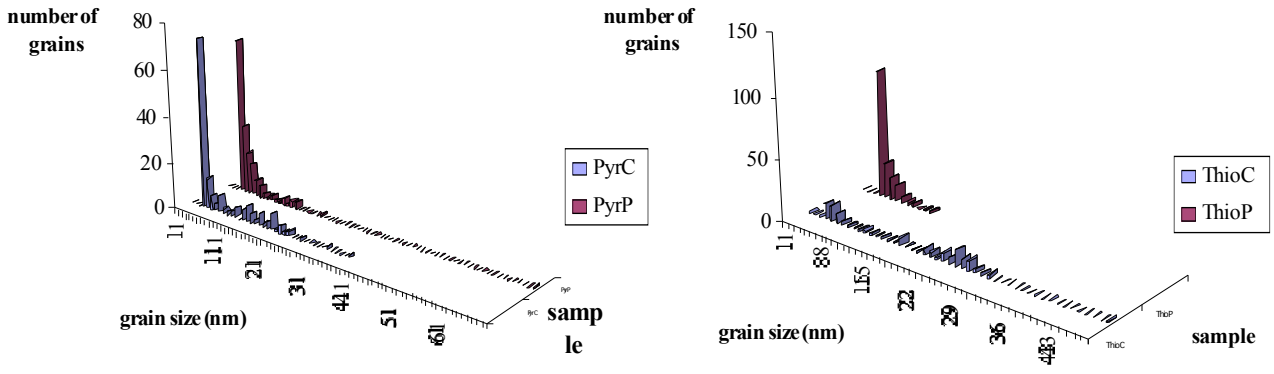

Fig 3. Grain size distribution

In continuous plasma films the size distribution is less uniform because the grain growth versus nuclei formation ratio is greater than in the pulsed plasma films. This affirmation is supported by the fact that the number of grains increases when pulsed plasma is applied. In PyrC the average number of grains is 156 and in PyrP is 160 and this trend is even stronger with thiophene films, with ThioC having 114 grains and ThioP 176. Also, as it can be seen in figures 2 and 3, continuous plasma films present bigger grains.

3.3.-Composition

The use of continuous plasma produces two negative effects on the chemical structure of the films. The first one is that the constant ion bombardment of the growing film that results in some extent in the formation of trapped free radicals in the film. Upon exposure to atmosphere, these free radicals react with oxygen forming C=O and O-H moieties. The second one is that the constant irradiation produced by the glow discharge can lead to a massive bond cleavage thus breaking completely the monomer structure.

Both effects are clearly present in the plasma polymerization of pyrrole which is, as mentioned above, a more labile monomer. The structure of PPy and PTh films was investigated by IR and XPS. The IR spectra of PyrC samples consist of broad peaks due to the inhomogeneities in the structure. It should be noted also the presence of absorption peaks at 2930-2800 cm^{-1} (assigned to O-H stretching), 1750-1650 cm^{-1} (C-O stretching) and 1099 cm^{-1} (C-O-C asymmetrical stretching). This is consistent with XPS results which reveal an oxygen content of 36 %. Furthermore, the C/N ratio (which has been widely used as a fragmentation indicator) is 5.2, due to the loss of nitrogen atoms from the monomer structure.

The PyrP sample shows an IR spectrum with more defined peaks, revealing a more uniform structure. This is a direct consequence of the mild character of pulsed plasma, which is responsible for the ring retention. Another effect is the reduction in the formation in trapped free radicals. As a consequence, there is a reduction of the peaks of the oxidized forms (C=O, O-H and C-O-C). XPS results which reveal an oxygen content of 8 % and a C/N ratio of 4.6.

On the other hand, as thiophene is a less labile monomer, it was expected that its oxygen content would be inferior. This was demonstrated with the XPS spectrum (fig. 4), where a content of 13.4% was revealed.

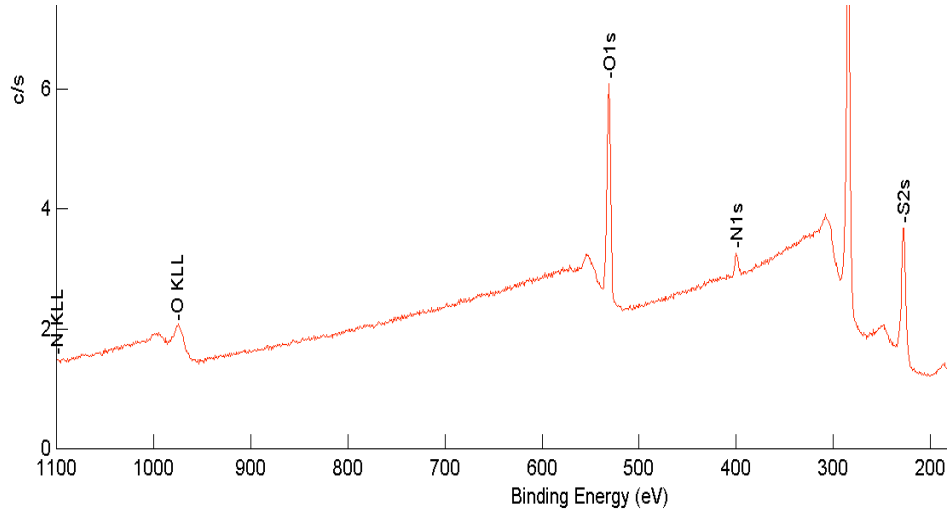

Fig. 4. XPS survey scan of ThioC

Regarding the IR spectra, the same effect as with pyrrole is observed: broad peaks when using continuous plasma versus narrow peaks and reduction of oxidized forms peaks when using pulsed plasma.

3.4.-Hot filament CVD

The use of Nicron filament did not give any film formation.even when filament was heated until 550C. Using tungstene film growing is observed at filament temperatures higher than 500ºC. The deposition rate was clearly higher (200nm/min) than when plasma polymerization was used. The HFCVD also leads to rougher films formation.

However unclear IR spectra resulted from the analysis of the films obtained. Significant signals corresponding to organic moieties could not be detected.

The XPS analysis showed the same trend. Intense signals corresponding to tungstene (W) and oxygen (O) were detected. The intensity of the W signal increased with the filament temperature.

It seems that a tungstene oxide film is deposited together with the polymeric film. The rate of such deposition is directly related with filament temperature.

4. Conclusions

To obtain monomer-like films without aging effects (oxidation of free radicals), the use of pulsed plasma CVD is recommended. However pulsed plasma polymerization has a slower deposition rate. Nevertheless, when very uniform films are desired, this technique is to be used because it enables better morphological characteristics.

Abstract

Composites make possible to obtain performance-improved materials, one example are filled polymers. The main factor involved in the final properties is the interaction between phases. Thus, surface modification of one of the components encourages us to obtain high performance composites. In this work cold plasma was used to change the surface characteristics of carbon black (CB). Many analytical techniques were used to evaluate the modified surface and filler treated samples were mixed and tested in terms of mechanical and viscoelastic properties.

Introduction

A CB filled elastomer can be regarded as a composite characterized by a "rubbery" continuous phase and a particulate "rigid" dispersed phase. The continuous phase is therefore responsible for the "rubbery" behavior of the composite, but the filler plays a specific and important role. The changes provoked by the presence of the filler in polymeric composites have been studied since a long time ago [1-3].

Polymer-filler interaction is known to be important to obtain good performance rubber materials and the approach of considering polymer composites as two interpenetrated networks is becoming popular. The polymer-filler interaction starts when the formulation components (polymer, curing agents and fillers) are introduced in the mixer to obtain a homogenous material that will be cured later. To obtain a good filler dispersion the polymer and the filler need to have some affinity for each other. Several techniques have been used to elucidate the CB conductive network structure; this is an important aspect as the majority of rubber compound properties are related to the CB dispersion degree [4-6]. In addition poor dispersion can itself give rise to certain detrimental effects. These effects can be summarized as follows: reduced product life, poor performance in service, poor product appearance, poor processing characteristics, raw-material waste and high finished product rejection rates. These inadequacies are generally result of the presence of rather large, undirspersed agglomerates that can act as failure-initiating flaws [7].

However it is worth to point out that filler particles tend to agglomerate forming clusters due to the filler-filler interaction, which can be also described as a poor micro-dispersion of the filler in the polymeric matrix. Some filler particles are not even separated during the compounding process while others come together especially during vulcanization or when exposed to high temperatures, this process is known as flocculation. A large difference between the polymer and the filler surface energy as well as a short filler-filler distance could result into high agglomeration. This agglomeration is strain and temperature dependent, as a consequence it has and important role in the mechanical and viscoelastic properties [8].

During the last 50 years many studies of CB as reinforcement filler have been published, many of them were focused on the morphology of the blacks (particle size and structure), [9,10]. However it has been admitted that the unique property that distinguishes CB from other fillers is its characteristic surface activity. Although surface activity is a poor defined term, it includes all the physico-chemical properties of the material, which can alter the behavior, the kinetics and the processes in which this material is involved. In a physical sense, variations in the surface activity determine the adsorptive capacity and energy of adsorption,

[1] Corresponding Author: Tel. +34 93 267 20 00; Fax. +34 93 205 62 66; E-mail: s.borros@iqs.edu

and therefore it represents the type and quantity of interactions that surface molecules can establish with their surroundings. The importance and some techniques to measure this property have already been described in a previous paper [11].

Two main factors seem to be involved in the surface activity level. One is CB's surface morphology, which is acquired during the filler formation process in the reactor. The presence of different amounts of crystalline and amorphous carbon domains on CB's surface, affect its energy distribution and consequently its surface activity [12] The effect of this parameter in the rubber-filler interaction has been studied in a previous work [13]. The other factor is the CB's surface chemical composition that can be responsible for changes on the surface polarity. Many authors consider that the presence of functional groups on CB is almost negligible [14]. Techniques such as plasma polymerization can be used to tailor this property introducing different functional groups that could improve both the reaction and interaction with the polymer matrix.

As a result of the above discussion the aims of this work are focused on CB surface chemistry modification in order to change the filler-filler as well as the polymer-filler interaction. The resulting filler has been characterized in terms of chemical composition and surface energy by means of different analytical techniques such as Raman Spectroscopy, Inverse Gas Chromatography, Thermal Programmed Desorption and Thermogravimetric studies. Finally, the changes that modification of CB surface energy provokes on the final properties of vulcanized filled compounds have been evaluated.

Experimental

Materials

The used CB was an experimental grade supplied by Sid Richardson Carbon Black Co, with a specific area of 121 m^2g^{-1} and a CDBP of 102 $cm^2/100g$.

Plasma treatment

In order to coat CB particles with a polymeric layer it was treated in a bell-jar cold plasma reactor at a frequency of 27 MHz and a power supply of 50 W. Pressure was maintained at 1mbar before the monomer gas was introduced in the reactor. The monomer used was acrylic acid, giving the plasma a light purple color. When the gas was introduced in the reactor the pressure increased up to 2mbar. Samples were treated for 4 hours.

Thermal Programmed Decomposition (TPD)

Modified and regular CB was submitted to a controlled increase of temperature inside an oven. A flow of helium carried the components inside a mass spectrum were the components that are desorbed from the sample or thermally destroyed can be detected. In order to place the sample inside the oven, a quartz vial with 30mg of CB is introduced in a quartz tube connected with the helium source and the mass spectrometer. To analyze CB samples temperature was increased from 30ºC to 600ºC at 10ºC/min. Helium flow was set at 60 cm^3/min.

Raman Spectroscopy

Raman spectra in order to study the CB surface morphology were performed at the Texas Christian University, Fort Worth. In order to perform the analysis, CB is compressed in a steel-stainless mold to achieve a uniform and smooth surface. Afterwards the spectrum is obtained. During the analysis a motor rotates the sample (14.000 r.p.m.), in order to avoid thermal decomposition due to the laser incidence.

Thermogravimetrical Assays

The Thermogravimetric Assay equipment was a Mettler Toledo TG50. Conditions are described in a previous paper [15].

Inverse Gas Chromatography

Measures were performed at infinite dilution with different polar and apolar probes to obtain the dispersive and specific component. N_2 was used as a carrier gas. Column temperature was 160ºC. Column length was 25 cm. CB was sieved between 250 and 300 μm. previous to column filling.

Low frequency viscoelastic properties

In order to study the CB behavior in rubber compounds at low strain results were obtained testing samples at 1Hz and 30ºC with strain measurements from 0.1 to 10% strain.

Bound Rubber

Approximately one gram of compound is weighted in a steel-stainless cage (25x25x50mm). The cage is introduced in a 200 ml beaker and covered with toluene for three days. The solvent is stirred for half an hour twice a day. After this period the cage is dried to constant weight.

Results and Discussion

The nature of the modified surface after the plasma treatment was evaluated. However, it is worth to point out, that first visual analysis gave evidence that changes on the surface had taken place inside the reactor. Already after 30 minutes of treatment both the inside of the reactor and the sample container were found to be sticky, which is one of the most common properties of polymers obtained by cold plasma polymerization.

On the other hand, CB surface polarity also presented clear differences. When untreated CB was introduced in a beaker containing water, the filler stayed on the liquid surface due to their differences in polarity and finally sank slowly. This was not the case of treated samples that sank almost immediately after they were introduced in the water. This effect could probably be due to an increase of the filler polarity by acrylic acid polymerization on its surface reinforcing the idea of successful surface modification. Moreover acrylic acid has a high water adsorption capacity that would facilitate the sinking process.

CB Surface Analysis

TPD

The abundance of different ions was screened during the increasing temperature ramp. These ions were mainly produced due to acrylic acid thermal desorption (mz= 27, 55, 72) and polyacrylate major decomposition ion (mz= 44) due to the decarboxylation of the polymer. Results for a modified sample were compared with an untreated sample and the analysis of the wool that holds the vial inside the quartz tube. For the ions resulting from the acrylic acid desorption a slight increase was observed near acrylic acid evaporation temperature (141ºC). Fig. 1 shows the case for mz = 27. On the other hand, when mz=44 abundance is analyzed a considerably increase of this ion is observed. The abundance of this fragment starts to rise from 150 ºC achieving a constant level, however it is above 500 ºC when the level of this ion increases steeply, fig. 2.

Therefore it can be said that the polymerization reaction took successfully place in the reactor since much higher levels are observed for the decarboxilation process than for thermal desorption even though some acrylic acid monomers may also be present (scales differ in one order of magnitude).

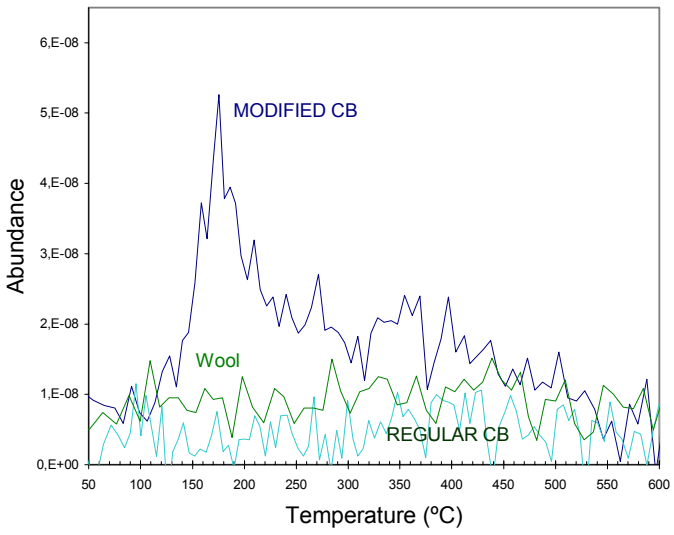

Fig.1 Acid acrylic desorption during TPD analysis

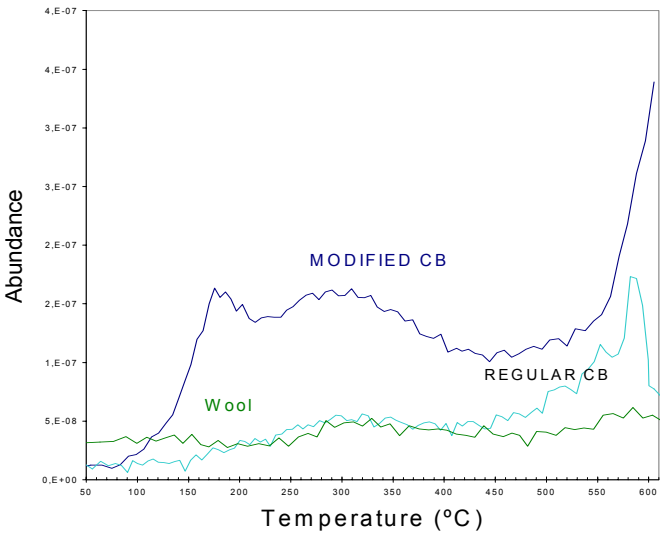

Fig.2 *Polyacrylate* decomposition during TPD analysis

Raman Spectroscopy

The Raman Spectrum of the regular and modified were obtained in order to evaluate any possible change in their surface structure since this technique allows to determine the amount of crystalline structure on CB. The values obtained from the spectrum were the same for both samples. None of the chemical changes were reveled by Raman spectroscopy suggesting that the bulk structure of the acrylic acid treated CB remained substantially unchanged and comparable to that of untreated CB, in contrast with the surface functionalization as already shown by TPD. Therefore, the temperature in the reactor was low enough to maintain the filler surface structure unaltered and only the chemical composition was changed during the treatment.

Thermogravimetrical Assays

Using samples that had been modified during different lengths of time (2 and 4 hours) a linear correlation between the weight loss and the plasma treatment duration was established, obtaining as expected higher weight loss for longer treated samples.

This technique can also be used to study surface activity by means of T15% (temperature when CB has lost a 15% of its weight) as shown in other literature works [11,13]. In this case the modified CB shows a higher T15% (590ºC) than the regular CB (568ºC), showing that surface activity had been modified. However, for T50% (temperature when CB has lost a 50% of its weight) the values were very close only differing 2ºC. This is an indication that the plasma treatment had only affected the surface (T15%) while the bulk part of CB remained unmodified (T50%).

Inverse Gas Chromatography

Inverse gas Chromatography is also used to study surface activity but it also allows dividing this parameter in two components, the dispersive and the specific one. The first is due to Van der Waals forces caused by carbon atoms interaction and the second is related with the interaction of specific chemical groups such as acids in our case. For the modified CB there was a dramatic change in the dispersive component. While the regular experimental grades showed values close to other CB grades with similar specific surface area (N-110 and N-220), the modified CB presented a lowe value that would correspond to CB's of much lower specific surface areas (around $20 m^2 g^{-1}$). Values are shown in table 1. This result was attributed to the presence of the acidic groups on the surface of CB.

Table 1. Dispersive component for several CB grades

CB grade	Dispersive component (mJ/m2)
N-110	580
N-220	575
Regular CB	608
Modified CB	250

Table 2. Specific component for several CB grades

CB grade	Dispersive component (mJ/m2)
N-110	156
N-220	----
Regular CB	143
Modified CB	82

However the same result was obtained for the specific component when a higher value was expected for basic probes, such as tetrahydrofurane, due to the presence of the acid groups. It is also worth to mention that CB modified for 2 and 4 hours presented practically identical results probably due to the complete coverage of CB particles. Several hypotheses to understand this phenomenon have been presented. Due to the high level of coverage with the plasma polymer the particles could trend to agglomerate together and preferably interact among themselves than with the injected probes. This process could be facilitated by the high pressures present inside the column at a 40cm3ml-1 flow. Moreover this high degree of coverage would give a completely new surface rather difficult to compare by IGC with the original CB surface.

In concluding the results so far show that CB surface has been strongly changed in terms of chemical composition shown by, TPD, TGA and IGC while its inner structure remains as the original filler. These facts present the cold plasma technique as a good treatment to obtain chemical changes on CB.

In-Rubber Properties

Both regular and modified CB were mixed at 50 phr with natural rubber. Low frequency dynamic properties, which give an idea of the filler-filler interaction and Bound Rubber, which is more related with polymer-filler rubber were determined.

Low frequency dynamic properties

This test shows the behavior of the filler network by means of G' and G'' modulus. The higher interaction between the filler particles the higher value for both parameters since it would be more difficult to break the CB network inside the polymer. High elastic modulus (G') is beneficial for the material performance contrary to high loss modulus (G'') that provokes high hysteresis due to the dissipated heat. In this case modified CB show a higher value for both modulus showing a higher interaction between CB particles (fig. 3 and 4).

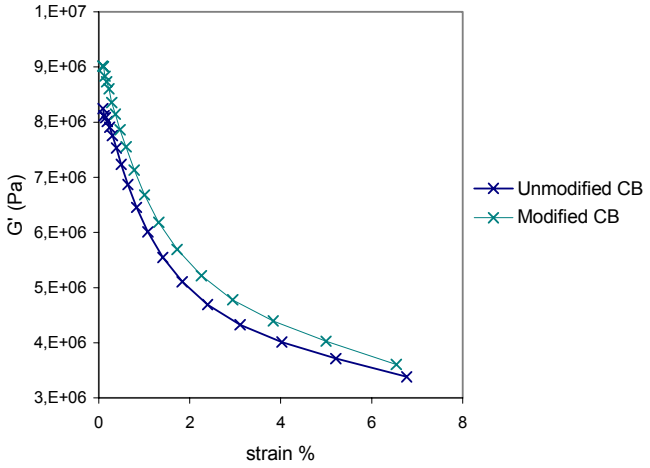

Fig.3 Elastic Modulus (G')

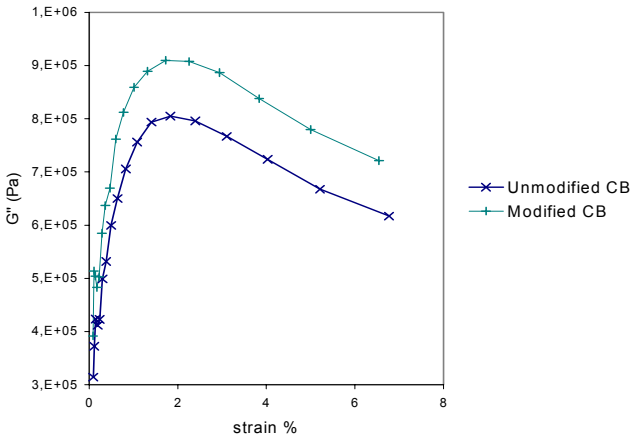

Fig.4 Loss Modulus (G'')

This would be in agreement with the hypothesis made from the IGC results showing a high degree of CB coating by a polymer film. As a result CB surface would be prevented to interact with the polymer chains leading to a higher filler-filler and probably to a lower filler-polymer interaction.

Bound Rubber

Plasma modified CB presented lower bound rubber level (46%) than the original filler (55%). This indicates that the chemical surface modification treatment had also affected the polymer filler interaction in agreement with the G' and G'' values. However, is difficult to compare this value with other CB since as it has been shown before the filler surface has been completely covered by the polymer and consequently the new surface does not resemble CB nature anymore.

Conclusions

Cold plasma has been presented as a suitable technique in order to modify the chemistry of CB surface without affecting CB bulk properties. Among other analytical techniques, TPD, TGA and Raman Spectroscopy have been presented as very useful techniques to characterize the plasma modified filler surface. From the surface activity point of view a diminishing of both the dispersive and specific component has been detected by means of IGC. On the other hand, G' and G'' obtained values show an increase of the filler-filler interaction causing a higher agglomeration of the filler inside the polymer. The obtained results show that CB has been completely covered by a polymer film forbidding CB surface to play any role in the polymer matrix. Nevertheless these results show that it is possible to selectively change CB surface chemistry. This should encourage to work with different monomers as well as with different plasma conditions in order to achieve tailored CB's to obtain high performance materials based on specific polymer-filler interaction.

Abstract
An experimental study has been made of thermal electron attachment to MoF_6, ReF_6, and WF_6 using a flowing-afterglow Langmuir-probe apparatus. The experiment is a thorny one because the molecules tend to form oxide impurities on feedline surfaces and because of thermal decomposition of MoF_6 on surfaces as the gas temperature is increased. The electron attachment rate constant for MoF_6 is $(2.3 \pm 0.5) \times 10^{-9}$ cm^3 s^{-1} and forms MoF_6^- exclusively for 297-385 K. The rate constant increases with temperature up to the point where decomposition becomes apparent. Electron attachment to ReF_6 occurs with a rate constant of $(2.4 \pm 0.5) \times 10^{-9}$ cm^3 s^{-1} at 297 K. WF_6 attaches electrons so weakly that it is difficult to measure the attachment rate constant at room temperature (ca. 10^{-12} cm^3 s^{-1}). Molecular structure calculations have been carried out for MoF_6 to aid in understanding the electron attachment process.

1. Introduction

It is often assumed that hexafluorides attach electrons efficiently because SF_6 is well known to do so, and indeed is widely used as an electron scavenger in plasmas and in electrical devices. But the transition-metal fluorides appear to be different. For one thing, their electron affinities have been calculated to be quite large—over 5 eV for MoF_6, compared to EA(SF_6) = 1.05 eV.

Electron beam studies of negative ion formation in MoF_6 and ReF_6 were carried out by Stockdale et al. many years ago, with an electron energy resolution of about 0.1 eV [1]. Electron attachment to MoF_6 near zero energy was found to produce mostly MoF_6^-, with some MoF_5^-. Electron attachment to ReF_6 near zero energy was found to produce mostly ReF_6^-, with very small amounts of ReF_5^- and ReF_3^-.

Stockdale et al. [1] also studied negative ion formation in the main-group hexafluorides SeF_6 and TeF_6, which are interesting because Se and Te lie directly below S in the periodic table. They found very weak signals from electron attachment to SeF_6, yielding the SeF_5^- ion exclusively, and no electron attachment at all to TeF_6, under essentially zero-pressure (single collision) conditions. The negative ions SeF_6^- and TeF_6^- exist, and can be produced by charge transfer from SF_6^-, but are not formed in single collisions with free electrons [1]. Jarvis et al. [2] have studied electron attachment to SeF_6 and TeF_6 under an atmospheric pressure of N_2 at 300 K and found that these pressures were adequate to stabilize the parent ions of SeF_6 and TeF_6, though some dissociative electron attachment takes place, producing SeF_5^- and TeF_5^-. Rate constants of $(8.0 \pm 1.2) \times 10^{-10}$ and $(8.2 \pm 1.1) \times 10^{-11}$ cm^3 s^{-1} were measured (in 1 atm N_2) for SeF_6 and TeF_6, respectively, values which are orders of magnitude below the attachment rate for SF_6 (2.3×10^{-7} cm^3 s^{-1}). Earlier work with SeF_6 and TeF_6 was discussed in [1] and [2].

We have used a flowing afterglow Langmuir probe (FALP) apparatus to study electron attachment to MoF_6, ReF_6, and WF_6, *viz*.,

$$MoF_6 + e^- \rightarrow MoF_6^- + 5.4 \text{ eV} \quad (1)$$

$$ReF_6 + e^- \rightarrow ReF_6^- + \sim 4.2 \text{ eV} \quad (2)$$

$$WF_6 + e^- \rightarrow WF_6^- + 3.5 \text{ eV} \quad (3)$$

in a helium buffer gas at 133 Pa. The respective energies released in the above reactions (the electron affinities of the molecules) were taken from Refs. 3-6. Some limited information is presented here as to the temperature dependence of the rate constants. In addition, the ion-molecule reaction

$$Ar^+ + MoF_6 \rightarrow MoF_5^- + F + Ar + 1.1\ eV \qquad (4)$$

was studied, for reasons that will be explained below. The energy released in this reaction was calculated from the heats of formation of the reactants.

2. Flowing-Afterglow Langmuir-Probe Experiment

The FALP apparatus is sketched in Fig. 1. Reactions take place in a weak plasma in a fast flow of helium carrier gas along the length of a flow tube (from left to right in the figure). Knowing the velocity of the flowing plasma allows us to convert the distance scale into a time scale and deduce reaction rate constants. In the FALP, a cylindrical, movable Langmuir probe is used to measure the electron density along the axis of the flow tube. In absence of an electron-attaching gas the only loss of electron density is through ambipolar diffusion to the walls of the flow tube. When an electron-attaching gas is added to the flow tube, the electron density decays much more rapidly, to the point where eventually a pure positive-ion/negative-ion plasma obtains. The FALP method [7] and this particular instrument at the U. S. Air Force Research Laboratory [8] have been described previously.

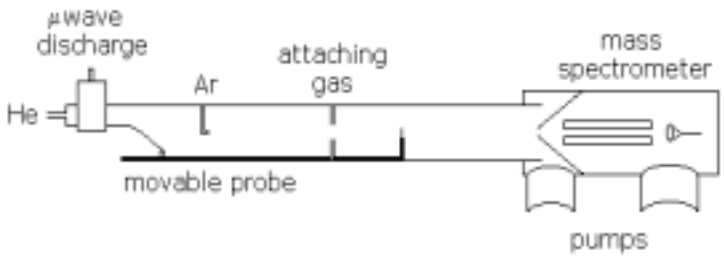

Fig. 1. A sketch of the FALP apparatus.

Helium gas flows in the FALP at typically 16 std. L min^{-1}, giving a bulk gas velocity of 63 m s^{-1} in a flow tube of 3.6-cm radius, at 133 Pa pressure and room temperature. The electron/He^+ source in the FALP is a 3.45-GHz microwave discharge at the upstream end of the flow tube. The discharge additionally creates metastable-excited He^*, which are undesirable because suprathermal electrons would be released in the reaction zone when reactant neutrals are Penning ionized by the He^*. Because of this, a small flow of 60 std. cm^3 min^{-1} of Ar gas is injected into the flow tube 10 cm downstream of the discharge for the purpose of deexciting the He^* via Penning ionization with Ar, well ahead of the reaction zone. Electrons created in the discharge and in Penning ionization thermalize readily in the He carrier gas prior to the reaction zone. The Ar also removes He_2^+ by ion-molecule reaction yielding Ar^+. Thus, following Ar reaction the plasma consists of electrons, He^+, and Ar^+, undergoing ambipolar diffusion.

Halfway down the flow tube, the electron attaching gas under study is added through a 3-radial-needle port with a known flow rate resulting in a known concentration n_r in the flow tube. At this point, the electron density $n_e(0)$ has been adjusted to be in the range 0.8-3 x 10^9 cm^{-3} : small enough that $n_e(0) << n_r$, so that first-order kinetics holds, and small enough that electron-ion recombination is negligible. (Thermal electron-ion recombination rate constants are only significant for molecular ions, such as those produced in ion-molecule reactions with the gas under study. However, since the recombination rate depends on the

square of the plasma density, that rate is entirely negligible at the low plasma densities used in the electron attachment experiments, provided the electron attachment rate constant is larger than ca. 10^{-10} cm^3 s^{-1}.)

The decay in the electron density following addition of the gas under study is due to the coupled effects of ambipolar diffusion and electron attachment. The solution to the relevant rate equation is [7,8]

$$n_e(t) = n_e(0)\,(\nu_a - \nu_D)^{-1}\,[\nu_a \exp(-\nu_a t) - \nu_D \exp(-\nu_D t)], \qquad (5)$$

where ν_a is the electron attachment frequency, ν_D is the diffusion loss frequency, and t is the reaction time. The electron attachment rate constant is k_a and is equal to $\nu_a\, n_r^{-1}$. The diffusion loss frequency ν_D is equal to the ambipolar diffusion coefficient divided by the square of the diffusion length characteristic of the apparatus, and is measured directly from the electron density decay along the flow tube axis in absence of the electron-attaching gas. The reaction time t is the distance between the gas inlet port and the movable Langmuir probe, divided by the plasma velocity. The plasma velocity (typically 100 m/s) is measured by pulse-modulating the microwave discharge and timing the arrival of the disturbance on the Langmuir probe, at different distances in the reaction zone. The plasma velocity as measured on the flow tube axis is greater than the bulk gas velocity by a factor of about 1.6 because of the way the parabolic velocity profile of the gas in laminar flow overlaps the fundamental diffusion mode of the plasma.

The Langmuir probe in these experiments is 25 μm in diameter, 4 mm long, and is made of tungsten. The diameter is much smaller than the plasma sheath diameter as required by orbital-limited cylindrical probe theory. Furthermore, the He pressure is kept low enough (usually 133 Pa) that the collisionless-sheath condition is satisfied. The probe potential is swept from about -2 to 2 V around the local plasma potential, and the current collected is typically a few μA. The electron-attracting portion of the probe I-V characteristic is parabolic in shape, as indicated by probe theory. A plot of the square of the probe current yields a straight line; the slope of this line is readily determined and yields the electron density at the position of the probe along the axis of the flow tube. Hysteresis in the probe characteristic is eliminated by cleaning the probe in the plasma to white-hot appearance through application of a high bias voltage (100-200 V).

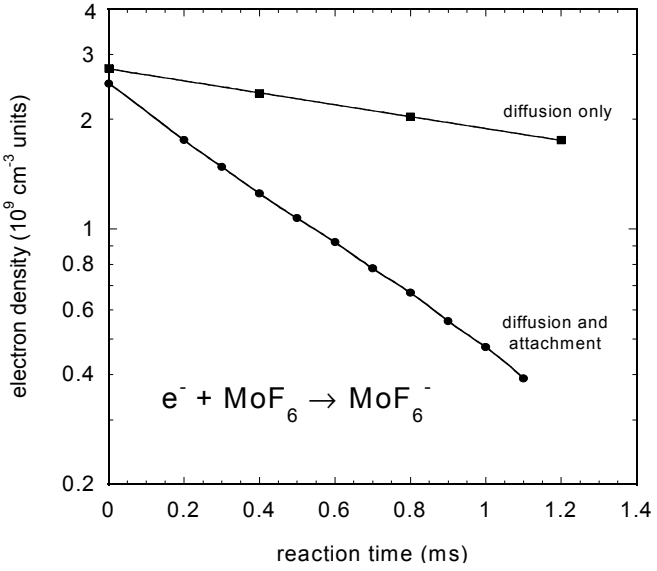

Fig. 2. Data obtained at 297 K for electron attachment to MoF_6 in 133 Pa of He gas and 13 ppmv of MoF_6.

We note that only relative electron densities are needed in electron attachment measurements, and the major uncertainty is the probe surface area. This uncertainty is mainly due to the question of where current collection terminates at the boundary between probe and a coaxial glass support. The relative electron density measurements are estimated uncertain to ±10%. The absolute electron attachment results are estimated uncertain to ±25%. The major uncertainty in the latter figure is measurement of the flow rates of the He, Ar, and electron-attaching gas. An example of the data obtained is shown in Fig. 2.

As electron attachment proceeds, the negative charge in the plasma becomes increasingly composed of negative ions. However, ambipolar diffusion is still determined by electron diffusion to the walls of the flow tube because of the high mobility of electrons. Negative ions are confined by the space charge field to the axial region of the flow tube as long as the electron density is at least 1/100th that of the negative ions. Eventually, the space charge field collapses and the plasma becomes a negative-ion/positive-ion plasma.

The data shown in Fig. 2 were obtained for a case where the negative ions are stable enough that thermal electron detachment will not take place at the temperatures of the measurement. If the electron detachment energy of the negative ion is low enough, thermal electron detachment will take place, and that process would have to be taken into account in the rate equations used to analyze the decay in the electron density [9].

At the downstream end of the flow tube there is an orifice leading to a high-vacuum region where an rf quadrupole mass spectrometer is used to determine the ion products and branching fractions for the electron attachment reactions studied.

3. Experimental Results

A. MoF_6

Electron attachment experiments with MoF_6 (reaction 2) were problematic because of decomposition on the walls of the feedlines carrying the neat vapor into the FALP flow tube. Decomposition apparently occurred in reaction with water vapor adsorbed on feedline surfaces, as evidenced by the appearance of oxides $MoOF_4^-$ in the attachment mass spectrum at very low flow rates. Higher flow rates of reactant results in only MoF_6^- in the mass spectrum. Positive-ion mass spectra were also obtained and did not show oxides; the spectra consisted almost entirely of MoF_5^+, even at low flows of reactant, from reaction of MoF_6 with the plasma ions Ar^+ (and some He^+).

There is some indication that the oxide attaches electrons more readily than does MoF_6. At very low flow rates of reactant, with $MoOF_4^-$ dominating the mass spectrum, the apparent rate constant was larger by a factor of ~2. With larger flow rates of reactant, and only MoF_6^- in the mass spectrum, a rate constant of $(2.3 \pm 0.5) \times 10^{-9}$ cm^3 s^{-1} was measured at 297 K in 133 Pa of He gas. This rate constant corresponds to an attachment efficiency on the order of 1%. At 340 K and 385 K, rate constants of $(2.9 \pm 0.6) \times 10^{-9}$ and $(3.5 \pm 0.8) \times 10^{-9}$ cm^3 s^{-1} were measured, respectively. These data may be said to be described by an activation energy of 47 meV over this very narrow temperature range. At higher temperatures, the apparent electron attachment rate constant fell in magnitude in a rapid manner characteristic of thermal decomposition. However, the bond enthalpy $D(MoF_5\text{-}F)$ is about 3.3 eV (using available heats of formation), so the decomposition is probably taking place on the walls of stainless steel feedlines, which travel half the length of the FALP flow tube inside of the heated region. The decomposition problem requires further study.

The reaction of Ar^+ with MoF_6 (reaction 4) was studied in order to use positive ion mass spectra as a diagnostic for the oxide and decomposition issues raised above. A rate constant of $(1.8 \pm 0.4) \times 10^{-9}$ cm^3 s^{-1} was measured for this reaction. An F atom was released in the reaction, as we have seen for other Ar^+ reactions with single-center hexafluorides [10].

B. ReF_6

We have studied electron attachment to ReF_6 (reaction 2) only at 297 K thus far. A rate constant of (2.4 ± 0.5) × 10^{-9} cm^3 s^{-1} was measured, comparable to that for MoF_6. The temperature dependence of the rate constant has not been studied at this writing.

C. WF_6

WF_6 was found to attach electrons so weakly that it is difficult to measure the attachment rate constant at room temperature (ca. 10^{-12} cm^3 s^{-1}). Even the ion product of the reaction is unclear when the attachment rate constant is so low, because ion-molecule reactions, which may be orders of magnitude faster, obscure the attachment mass spectrum. At this writing, it appears that WF_6^- is the product of attachment. WF_5^-, along with oxide impurities, appears in the attachment mass spectra at very low flow rates of WF_6. Production of WF_5^- is said to be approximately 4 eV endothermic [5], but appears in the attachment mass spectra at low flows of WF_6. However, as with MoF_6, oxides produced in the feedlines complicate the data analysis. The apparent rate constant for electron attachment to WF_6 increases rapidly with temperature, reaching about 2 x 10^{-10} cm^3 s^{-1} at 522 K. No decomposition problem was noted with the WF_6 gas. The apparent activation energy for electron attachment is ~0.3 eV.

It would be appropriate at this point to explain why the attachment rate constants for the single-center hexafluorides span so many orders of magnitude. But the information available is inadequate to do so. The usual picture of attachment is that the free electron becomes temporarily trapped in a resonant state of the parent anion in the continuum (the only way to explain the large size of attachment cross sections), and then the anion is stabilized either collisionally or radiatively, or autodetaches. The question of the size of the attachment cross section or rate constant is then tied up in the number of resonant states available to the electron and to the autodetachment width, plus the likelihood of collisional stabilization [11].

3. Calculations Using Density Functional Theory

We used the Gaussian-98W program package [12] to investigate the molecular structures of neutral and anionic MoF_6, primarily to obtain estimates of the energetics of the electron attachment process. We hope to be able to present some results of calculations for ReF_6 and WF_6 by the time of the meeting. The calculations should be viewed as tests of how well the Gaussian-98W program package can handle molecules for which a relativistic treatment would be more appropriate. Calculations of the total energies of the parent molecules and fragments were carried out using density functional theory, in particular Becke's three parameter hybrid functional denoted by B3LYP [13], which includes the Lee, Yang, and Parr correlation functional, which contains both local and non-local terms [14]. The Hamiltonian is non-relativistic, but the basis set denoted by LANL2DZ contains effective core potentials incorporating mass-velocity and Darwin relativistic effects [15].

The MoF_6 neutral and anion molecules were geometry-optimized using the B3LYP/LANL2DZ functional and basis set, and a harmonic frequency analysis was performed at the same level of theory to give the zero-point energies (ZPE). The vibrational frequencies were not scaled in calculating the ZPE. ZPE corrections were then applied to the total energies to give 0 K values. The results are given in Table 1. The B3LYP/LANL2DZ geometry optimization yielded an Mo-F bond length of 1.871 Å, which may be compared with the experimental result of 1.820 Å [16]. (The Re-F bond length is very similar, 1.832 Å [16].) The adiabatic electron affinity of MoF_6 was calculated from the difference in 0 K total energies of MoF_6 and MoF_6^-.

4. Conclusions

A flowing-afterglow Langmuir-probe apparatus was used to study electron attachment to MoF_6, ReF_6, and WF_6 in 133 Pa of helium gas. Measurement of electron attachment rate constants and ion products of attachment is difficult with these gases is difficult because they tend to form metal oxides on the surfaces of feedlines, and the oxides appear to attach electrons at least as efficiently as do the parent molecules. Furthermore, if the electron attachment reaction is very inefficient, as it is with WF_6, subsequent ion-

molecule reactions may obscure the actual ion product of electron attachment. Nevertheless, we conclude that MoF_6 and ReF_6 attach electrons with similar rate constants at 297 K, $(2.3 \pm 0.5) \times 10^{-9}$ and $(2.4 \pm 0.5) \times 10^{-9}$ cm^3 s^{-1}, respectively. The rate constant for MoF_6 is seen to increase with temperature.

Table 1. Total energies and zero-point energies (ZPE) for MoF_6 and MoF_6^-, in hartree units, calculated at the B3LYP/LANL2DZ level of theory, and the electron affinity (EA) derived from these calculations.

molecule	ZPE[a]	total energy[b] (0 K)
MoF_6	0.01376	-666.78340
MoF_6^-	0.01548	-666.97450

Present calculation, EA(MoF_6) = 5.20 eV
Ref. 3 calculation, EA(MoF_6) = 5.37 eV

The parent anion is the sole ion product of attachment in both cases. WF_6 attaches electrons at such a low rate at 297 K as to be immeasurable (a rate constant on the order of 10^{-12} cm^3 s^{-1}), but the rate constant increases rapidly with temperature to the point that the reaction is about 0.1% efficient at 522 K. Electronic structure calculations were carried out using density functional theory for neutral and anionic MoF_6. The calculated EA(MoF_6) is quite high (5.2 eV) and agrees with earlier estimates. The reaction between Ar^+ ions and MoF_6 was studied as a diagnostic for MoF_6 decomposition. The reaction produces $MoF_5^+ + F$, with a rate constant of $(1.8 \pm 0.4) \times 10^{-9}$ cm^3 s^{-1}.

Abstract

In order to improve the wheel life Moscow Railways use during the last 5-7 years a plasma technology for local surface hardening and nitriding of wheel flanges. Simultaneously the gathering of monthly measured data concerning the change in tires and flange thickness and kilometers of run for a great body of plain and plasma treated wheel sets was going on. The effect of the plasma treatment is analyzed using the measured data from the database.

1. Introduction

The resource of locomotive wheels is a great headache on the railways. They lose the regulated profile, mainly the flange thickness, due to the wear and must undergo the truing operation on the lathe. So during the exploitation process the diameter of the wheel goes down to the allowed limit. To save the bulk of wheel from wasting the outer part of wheel being under heavy duty is made as separate tire of 90 mm in thickness while the wheel diameter is 950 mm. When the tire loses the half of its initial thickness it is changed. These 45 mm of the tire thickness represent the tire resource what we mean speaking about the wheel resource. Even more exactly under "wheel resource" we mean the run of the locomotive until the change of tire, while looking further for the fate of the bulk of wheel is practically beyond the reach.

The wheel flange going thin was the most frequent cause of wheel failure, the driving force to introduce the plasma technology. It was only natural at the beginning to pay the main attention to the flange wear, evaluating the increased wheel life due to plasma treatment using the specific flange wear per 1000000 km as a criterion [1]. This criterion is easy to calculate knowing the run of the locomotive and the value of previous month measurement. The raw data from the database in an atomized form is suitable for this job. But it is more convenient to use a data model based on aggregated data units – measurement cycles, several sequential measurements between two truings. This data model excludes the greater part of fluctuations caused by data input errors. The same criterion used in this data model gets a solid and smoothed character. Easy, beautiful and convincing criterion of comparison in the measurement cycles data model is the number of truings per million kilometers of run. According to our database plasma treated wheel sets have this number half as much as plain wheel sets [1] (see Table 1).

Table 1. A comparison of plasma treated wheel sets with plain ones by the number of truings per 1 million km

	Number of measurement cycles in selection	Total run of selected wheel sets, 1000000 km	Total number of truings in selection	Number of truings per 1000000 km
Plain wheel sets	40580	1905.882	18056	9.47
Plasma treated wheel sets	5635	451.423	2158	4.78

But in spite of all convincing nature of the figures in the last column they don't prove ultimately the advantages of using the plasma technology to improve the field-performance characteristics of wheel sets of the rolling stock. The conditions of exploitation are different for engine houses of Moscow Railways, the tracks being rectilinear over the plains and with many curves through the mountains. The allowed minimal thickness of flange depends on the regulated velocity of motion of trains. These factors influence on the truing frequency not only through the objective variation of the intensity of wear but also through the subjective differences in the maintenance policy.

So we leave behind the easy solutions while in the long run as we pointed earlier the wheel resource is determined by the tire thickness going down due to the tread wear and during the truing process. For the

assessment of wheel resource a specific loss of the tire thickness per 10000 kilometers of run may be used as a criterion. This criterion has a sense only for the aggregated data such as a sequence of measurement cycles including at least one truing process because the truing is responsible for the most of loss of the tire thickness. We used this criterion in [1] too, selecting wheel sets having at least two measurement cycles. In those circumstances it had to be considered as a differential parameter. But time is going on and more data comes to the database, and we hope that the specific loss of the tire thickness per 10000 kilometers of run may be handled as an integral criterion based on the whole history of the separate tire from the mounting to dismounting (or that the situation is closer to this ideal one).

Regrettably the data coming from engine houses to our database has not the quality we would like it to have. There is a lack of the fullness of coverage, there are many errors, the locomotives emerge from nowhere and others disappear leaving no good-by message. But statistics goes through because of the really great number of measured data.

The wheel sets covered in the database are characterized (for the current analysis) by the number of measurement cycles, by initial and final tire thickness making the total loss of thickness and the total run. Those initial and final tire thickness values are not always maximal and minimal allowed ones, regrettably. Once more the hope is on the quantity of data - now the database contains 370 000 measurements concerning 19400 wheel sets.

2. Analysis

There are factors having an influence on the wheel life: lubrication, special profiling, and the flange thickness at the beginning of service. The skill is needed in the analysis to single one influence from the other lot. Actually other methods of improvement of the wheel life are friendly to the plasma treatment – the best results are provided using the lubrication over plasma-hardened surface. In this analysis we selected plasma treated and plain wheel sets in groups without distinction by above-mentioned factors. But we couldn't ignore the great difference between diesel and electric engines concerning the intensity of the wheel wear. The Table 2 justifies this approach.

Table 2. Specific loss of the tire thickness per 10000 kilometers of run for diesel and electric engines (without distinction between plasma treated and plain wheel sets).

Engine	Number of wheel sets in selection	Average loss of tire thickness, mm	Average run, km	Specific loss of the tire thickness per 10000 kilometers of run
Diesel	6989	9.2	65 675	3.03
Electric	5084	11.7	172 569	1.25

So further we are dealing with 4 groups of wheel sets: plasma treated and plain wheel sets for diesel and electric engines. The bold-faced averaging in the considered 4 groups of wheel sets all over the database results in the Table 3 and Fig. 1.

Table 3. Specific loss of the tire thickness per 10000 kilometers of run for plain and plasma treated wheel sets under diesel and electric engines.

Engine	Type of wheel set	Number of wheel sets in selection	Average loss of tire thickness, mm	Average run, km	Specific loss of the tire thickness, mm/10000 km of run
Diesel	Plain	5604	8.9	58 193	3.40
	Hard.	1385	10.4	95 945	1.59
Electric	Plain	4084	11.4	157 523	1.39
	Hard.	1000	13.1	234 016	0.68

The Table 3 shows that the number of data units in the considered selections nearly equal for diesel and electric engines and that the number of plasma treated wheel sets make a quarter of the number of plain ones. Wheel sets under electric engines have the greater average loss of tire thickness and more than twice average run per measurement cycle compared with ones under diesel engines. The explanation of this fact may be that the electric engines are used exclusively as main-line locomotives while the diesel engines are

used as local shunting engines. The last case is characterized by less run and more maneuvering, more use of brakes.

Table 3 and Fig. 1 show very favorable influence of the plasma treatment on the specific loss of the tire thickness per 10000 km of run – the main criterion of wheel resource according to the earlier mentioning.

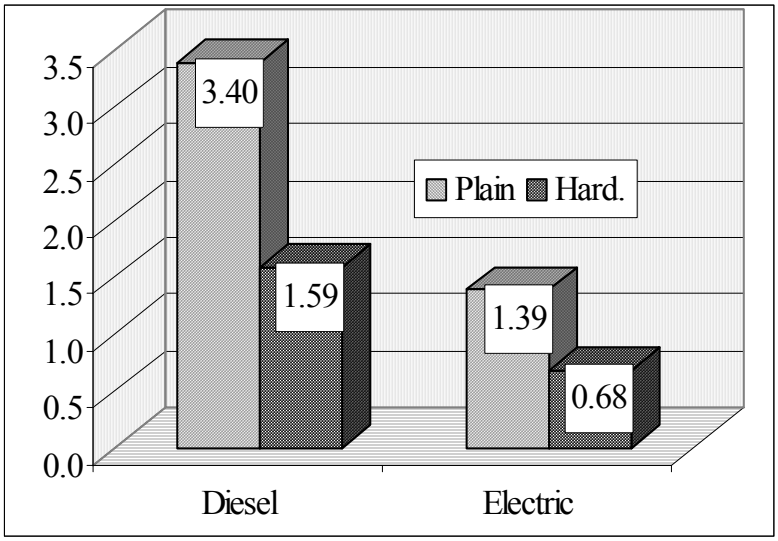

Fig. 1. Specific loss of the tire thickness per 10000 kilometers of run for plain and plasma treated wheel sets under diesel and electric engines.

The value of the specific loss of the tire thickness is diminished more than two times. This is true both for diesel and electric engines. This is true when diesel and electric engines are considered in one group together. The results of the averaging in this case are presented in the Table 4.

Table 4. Average run (R) and specific loss of the tire thickness per 10000 kilometers of run (S) for plain and plasma treated wheel sets.

	R, km	S, mm/10000 km of run
Plain	100 066	2.54
Hard.	153 837	1.20

Nothing unexpected is here after comparing two last columns of tables 3 and 4.

Following two figures illustrate the 4-group approach and the current state of our database. Fig. 2 shows that the majority of wheel sets is represented by one measurement cycle, the number of wheel sets being inversely proportional to the number of measurement cycles. The number of wheel sets under diesel engines (blank-marked) is greater than under electric engines (triangle-marked). The number of plain wheel

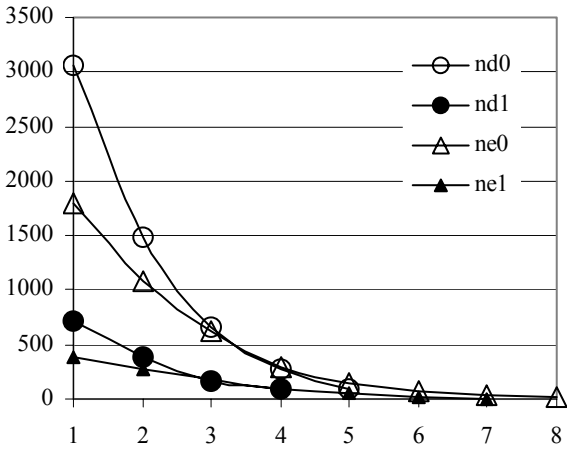

Fig. 2 Number of wheel sets in database as a function of number of measurement cycles for the following selections:
nd0-plain wheel sets, diesel engine
nd1-plasma treated wheel sets, diesel engine
ne0-plain wheel sets, electric engine
ne1-plasma treated wheel sets, electric engine

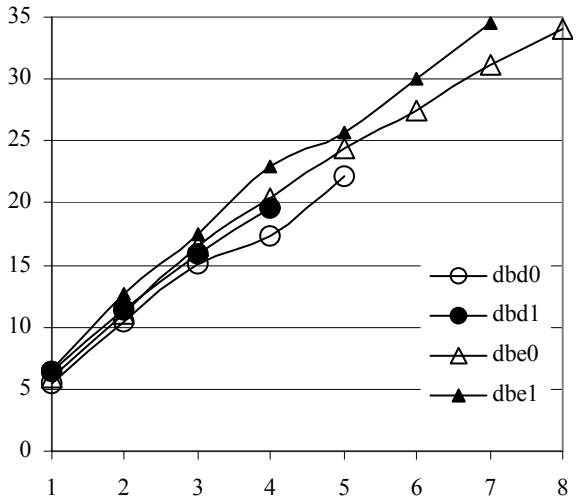

Fig. 3 Loss of tire thickness versus the number of measurement cycles for the following selections:
nd0-plain wheel sets, diesel engine
nd1-plasma treated wheel sets, diesel engine
ne0-plain wheel sets, electric engine
ne1-plasma treated wheel sets, electric engine

sets (circle-marked) is greater than the number of plasma treated ones (black-marked). Fig. 3 shows practically linear dependence between the number of measurement cycles and averaged loss of tire thickness with the derivative 4÷5 mm per measurement cycle. There is no distinction between any of groups.

Fig. 4 shows the time-varying results of specific loss of tire thickness per 10000 km run analysis displayed along the number of measurement cycles axis. As in the fig. 2 diesel engines are marked by circles and electric engines by triangles, plain wheel sets are marked blank and plasma treated ones are marked black.

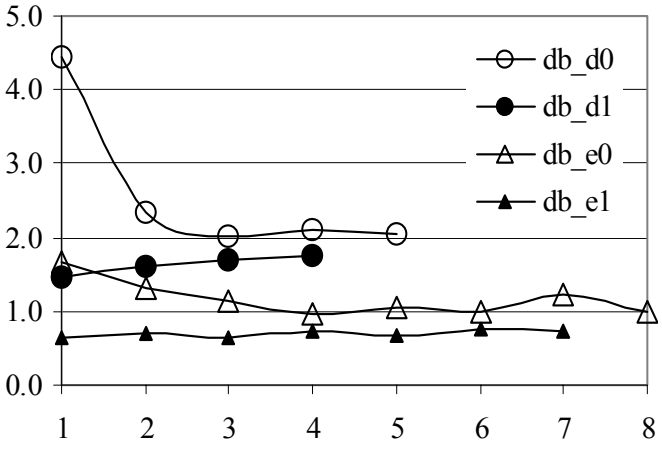

Fig. 3 Specific loss of tire thickness per 10000 km run versus the number of measurement cycles for the following selections:
db_d0-plain wheel sets, diesel engine
db_d1-plasma treated wheel sets, diesel engine
db_e0-plain wheel sets, electric engine
db_e1-plasma treated wheel sets, electric engine

The curves end at different points of abscissa due to lack of data to make a good statistics. The longest life as expected with good reason from the earlier mentioning have wheel sets under electric engines. One point less of the curves for plasma treated wheel sets compared with plain ones is due to the fact that they are outnumbered 4 times by the latters.

Plasma treatment until now is performed mainly for new wheel sets. The wheel sets identified as plasma treated ones in the considered selections actually keep their quality only until the first truing. After the truing the hardened layer is usually lost. Very seldom are they hardened second time. No wonder that the difference between the plasma hardened and plain wheel sets is maximal at the first measurement cycle disappearing altogether at the end of service.

For the plain wheel sets specific loss at the first measurement cycle exceeds the average value more than twice. This phenomenon, especially well pronounced for diesel engines, was amply discussed in our earlier publications [2]. On the contrary, the curves for plasma treated wheel sets show the tendency to be constant or to some growth. The mutual annihilation of two tendencies – the enhanced intensity of wear of new wheel sets with great initial flange thickness and the diminished intensity of wear of plasma treated wheel sets – is the trustworthy explanation of the behavior of latters.

3. Long-lived wheel sets

An interesting aspect of the wheel life problem is the direct measurement of the wheel run between the mounting and dismounting of separate tire. Due to some stochastic nature of measurements under industrial environment it is not easy to locate full-length working wheel sets in the database. A possible approach is to select them having initial and final tire thickness in the vicinity of allowed maximal and minimal values. These values are 75 and 40÷36 mm for diesel engines and 90 and 45 mm for electric engines. The results of averaging among the long-lived wheel groups in 4 groups are presented on the Table 5.

Table 5. Characteristics of the most long-lived plain and plasma treated wheel sets under diesel and electric engines.

Engine	Type of wheel set	Number of wheel sets in selection	Average loss of tire thickness, mm	Average run, km	Specific loss of the tire thickness, mm/10000 km of run	Average service time, year
Diesel	Plain	39	34	96229	4.05	2.70
	Hard.	19	37	147826	2.87	3.56
Electric	Plain	145	35	256 811	1.98	2.97
	Hard.	21	38	419 104	0.95	3.84

The figures on the Table 5 may be considered as a direct measurement of the run and service time of separate tire or a very close approximation to them after comparing the values of average loss of tire thickness with allowed ones – 45 mm for electric engines and 37 mm for diesel engines. The hope of

improvement is there for the characteristics of electric engines, and they are most interesting too because they are truly determined by wear and not by whatsoever it may be as in the case of diesel shunting engines.

Concerning the advantage of plasma treated wheel sets compared with plain ones it appears with greatest evidence in specific loss of the tire thickness per 10000 km of run for main-line locomotives. In this aspect quasi-direct measurement results of the Table 5 are in full agreement with purely statistical results of the Table 3.

4. Conclusions

For any selections of plain and plasma treated wheel sets the plasma treatment halves the specific loss of the tire thickness per 10000 km of run.

The perspective of the further improvement of the wheel life comes from the fact that up to now only new wheel sets are subjected to the plasma treatment, and in the group of so called "plasma treated wheel sets" this quality disappears for the second and further measurement cycles.

Abstract

Plasmatron with expanding anode channel used successfully for the hardening and nitriding railway wheel flanges, for the plasma treatment of rollers of the transport rollgang of the hot-saw workbench at the rolling mill, for the recovering of worn railway frogs using a plasma coating by the Mn-Cr-Ni powder in multiple layers with abrasive cleaning between them and a riveting of every single layer to eliminate residual stresses

1. Introduction

The problem of enhancement of resistance to metal fatigue and wear resistance of products of heavy engineering industry and ferrous metallurgy is becoming more important due to ever increasing demands to the reliability and durability of constructions and to the quality of articles. The conventional methods of volumetric hardening of construction components made of steels and alloys are approaching to the limits of their capability. Besides the production of massive details is characterized by complex manufacture and the need of replacement of components (rollers, transporting rollers, railway wheels and so on) [1]. So the promising way to the enhancement of working durability of steel products is the use of modern plasma technologies for the surface hardening and the coating [2].

These technologies make a new quality of the surface and enhance its properties keeping the properties of the bulk of the product unchanged, allow the recovering of worn items by means of plasma coating up to nominal geometry followed by subsequent surface hardening using highly concentrated heating sources (laser, electron beam, plasma)

The hardening of the ordinary material coating spares the expensive alloyed steels and other deficit materials, enhances the resource and reliability of the mechanisms, makes the production less power-hungry and solves many problems of the repair. The effective method of surface treatment is the use of low temperature plasma.

Fig. 1 Layout of the plasmatron with expanding channel of the outlet electrode (C – cathode, A – anode, I – insulating insertion).

A new technological process may reckon for the industrial application having stable output parameters and economic efficiency of the using the end product. So the optimization was performed for the construction parameters of the plasmatron with expanding channel of the outlet electrode [3], mainly the determination of the optimal angle of expansion (see Fig. 1). In the expanding channel the arc interacts with the gas flow in a different way compared with cylindrical channel. The drastic increase of the inlet velocity of the expanding channel intensifies the heat transfer between the arc and the cold gas. Main parameters of gas flow (the velocity, Mach number) are monotonous along the channel. The experimental investigations and field testing of this plasmatron prove it to be a stable device with enhanced resource and reliability [4].

2. Hardening of railway wheels.

The technology is developed for the hardening of wheel sets allow the simultaneous treatment of both flanges of wheel set in one pass. Over the whole treated area and in depth uniform structures appear characteristic of the hardening with smooth transition to the bulk of metal providing the strength of traction between the hardened layer and the bulk of metal [5]. Compared with the earlier technology using two pass plasma treatment this one makes in one pass deeper and wider (up to 70 mm) hardened layer with enhanced mechanical properties. The test results for wheel steel samples after these two technologies are presented in the Table 1.

The plasmatron of this kind has found many applications: for cutting copper molds of continuous casting devices and for the hardening and nitriding wheel sets for railway rolling stock. The technology developed for the hardening of wheel sets allow the simultaneous treatment of both flanges of wheel set in one pass. Over the whole treated area and in depth uniform structures appear characteristic of the hardening with smooth transition to the bulk of metal providing the strength of traction between the hardened layer and the bulk of metal [5]. Compared with the earlier technology using two pass plasma treatment this one makes in one pass deeper and wider (up to 70 mm) hardened layer with enhanced mechanical properties. The test results for wheel steel samples after these two technologies are presented in the Table 1.

Table 1 Dimensions and properties of the hardened area of the wheels treated using the old and newly developed technologies

Technology	Number of passes	Sample	Hardened layer thickness, mm	Average hardness of the treated area, HB	Microhardness, kg/mm^2		Impact strength		Components of the destruction work						Wear resistance	Delayed destruction
					Hardened layer	Transitional area	KC, J/cm^2	$\Delta KC/KC^0*L$	A_C, J/cm^2	$\Delta A_C / A_C*L$	Ap, J/cm^2	$\Delta Ap/ Ap*L$	A_Σ, J/cm^2	$\Delta A_\Sigma/ A_\Sigma$	mm^3	$\Delta t_{дл}//Vp*10^4$, min/mm/min
Old	2	No1	1.7	282	604	457	30.1	1.8	7.2	0.9	22.1	0.4	29.3	0.8	0.29	220/7.6
New	1	No2	4.0	435	599	500	11.7	0.4	3.3	0.75	15.7	0.4	19	0.7	0.17	450/1.6

The investigations show that the depth and the hardness measured in longitudinal and transversal directions in the hardened layer of the sample No2, treated by this technology, are greater compared with the ones measured in the sample No1 hardened by means of the previous technology. The average value of the hardness of the plasma treated area of the sample No2 is 435 HB, while the corresponding value of the sample No1 is no more than 282HB. Besides the hardness of the treated area of the sample No2 shows substantially greater stability compared with the one of the sample No1. The scatter of the hardness values of the treated area of the sample No2 is in the range 363÷530, while the corresponding range for the sample No1 is greater - 217÷499HB.

The lower hardness of the sample No1 is due to the two-pass hardening. This is proved by two overlapping areas ("tracks") on the surface. During the second pass the thermal unhardening of the previously hardened layer is going on (see Fig. 2).

Less stable hardness of the plasma treated area of the sample No1 may be also the result of lesser surface and depth of the hardened layer providing the greater share of transient areas in the dispersion of hardness values.

Impact strength of both samples is less compared with the original sample. The reduction is greater for the sample No2 first of all due to the greater thickness of the hardened layer. But the reduction may be caused by the higher level of hardness of the sample No2.To take this factor into account the evaluation was made of the change of impact strength per one unit of the thickness of the hardened layer:

$$(KC^0-KC^Y)/(L*KC^0) \quad (1)$$

where KC^0 - impact strength of the original sample, KC^Y - impact strength of the hardened metal, L - the thickness of the hardened layer.

It turned out that the change of the impact strength is caused not only by the increased hardness of the treated layer. The hardness bound change of impact strength is less for the sample No2 (0.4) than for the sample No1 (1.8). Additional factors are the peculiarities of the structural state of the hardened layer.

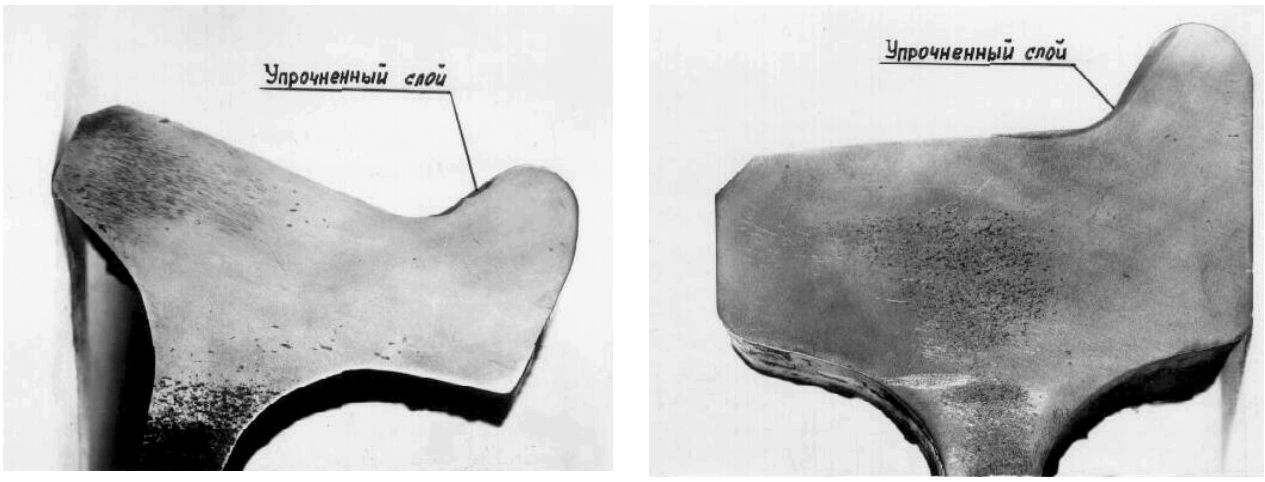

Fig. 2 Transversal ground edges of wheels hardened using the old (No1) and newly developed technology (No2).

Absolute values of the destruction work and its components for the hardened metal are not the same for the samples No1 and No2. But the specific values of the total destruction work A_{Σ}, of the crack creation work A_C and of the crack propagation work Ap, evaluated using expression (1) like criteria, are much alike for the greater values of the hardened layer thickness of the sample No2.

Wear test of the hardened layer was performed using "Skoda-Savin" device and plain-disc layout under the load 85H with the counter body made as disc of hard alloy Vidia XX 30 mm in diameter and 2.5 mm in thickness rotating at 675 rpm. The creation time of the wear hole was 270 s. The volume of the hole produced during the test time served as a measure of wear. Tests have shown that wear resistance of the second sample is twice as much as of the first one.

Test on the delayed destruction is capable to locate the week areas in the metal structure. This test was performed using the static stress a little less than the yield stress in the corrosive and hydrogen environment according to [6]. Besides this test allows the assessment of the frail destructibility of metal when hydrogenated.

Test has shown that the delay time of the crack creation in the hardened area of the sample No2 is greater two times compared with the sample No1. Average velocity of crack propagation Vp in the hardened area of this sample approximately 5 times less than in the sample No1.

So the newly developed technology makes the hardened layer of higher level of mechanical properties and of the resistance to wear uniformly distributed across the width of the treated surface. The analysis of field-performance characteristics of plain and plasma treated wheel sets shows the increase of the wheel life 2 times [7].

3. Hardening of rollgang rollers

The experience got in the broad band hardening of wheel steel was helpful for the development of the technology of hardening the rollers of transport rollgang of the hot-saw workbench of the Rolling Mill 700 of Oskol electrometallurgy integrated plant. The plasma treatment installation was modificated to fit the configuration and dimensions of the rollers. Two transport rollers 360 mm in diameter with barrel length 500 mm were delivered by the plant and were subjected to the plasma coating with chrome alloy.

In order to enhance the resistance of rollers to wear the heavy duty area in the central part of barrel 200-250 mm in width was subjected to plasma hardening. The roller was rotating during the process, and the plasmatron was moving along the roller. Two options were tested – the treatment in two bands 50 mm in

width overlapping by 3 mm and the treatment in two separate bands with the gap 3 mm between. The metal was heated up to ~1200 ^{0}C, to exclude the melted layer on the roller surface. The cooling was provided by the heat transfer to the bulk of roller and by air cooling of the surface. The hardness of rollers was measured before and after the hardening, and the corresponding values are 40.6HRC and 51HRC. The values of hardness measured along the roller are uniform in the 3 mm gap option, and in the overlapped option the tempering of the previously hardened layer occurs, so the hardness falls down to the original hardness of the coating.

The plasma treated rollers were installed into the rollgang section after the stationary saw for hot cutting immediately beside the first group of cages sequentially (Fig. 3).

The field testing was going on during 13.5 months (see Table 2). The actual surface wear was measured after 4.5 months of operation. The wear of the overlapped-option hardened roller was 1.95 mm; the wear of gap-option hardened roller was 1.75 mm, while non-treated rollers No 3, 4 have shown the corresponding values of wear 1.8 and 4.55 mm. The wear of the roller No 3 is close to the one of plasma treated rollers. The explanation is in the vicinity of hardened rollers overtaking a part of the load on them. The roller has substantially greater wear compared with hardened rollers, more so that it was coated only 1 month before the measurement. After 13.5 months of operation the second measurement was performed showing the wear for hardened rollers 5.5 mm, for non-hardened roller No 3 – 5.8 mm and for No 4 – 8.3 mm, worth to note that the roller No 3 was coated in 5 months before the measurement.

It turns out that the plasma hardening made the wear of transport rollers 1.5-2 times lower.

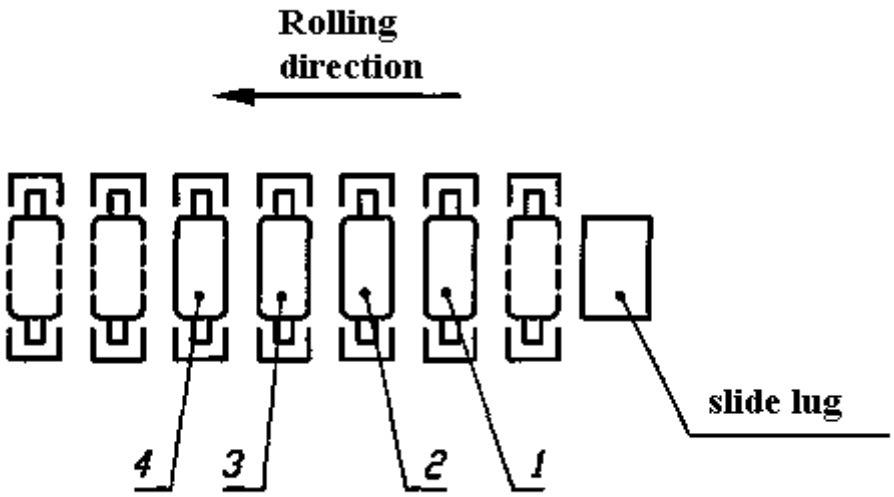

Fig. 3 Layout of the placement of rollers in the rollgang section: No1 – hardened with overlap, No2 – hardened with gap, No3 and No4 – non-hardened.

Table 2. Development of radial wear (mm) of hardened and non-hardened rollers in the course of time.

Time, month	Hardened		Non-hardened	
	No1	No2	No3	No4
4.5	1.95	1.75	1.80	4.55*
13.5	5.50	5.50	5.80**	8.30

* - the coating 1 month before the measurement

** - the coating 5 month before the measurement

4. Recovering of railway frogs

The recovering of the products of manganese steel (Hadfield steel) using plasma coating is not an easy job due to the peculiarities of properties of this steel: its structure is not stable enough during the heating and cooling processes. Its thermophysical properties – low heat conductivity and high coefficient of thermal expansion – are unfavorable enhancing its aptitude to the creation of thermal cracks [8].

Several methods are used to recover the worn products of Hadfield steel: acetylene-oxygen torch, electric arc, semiautomatic coating by powder wire, automatic arc coating under flux and so on. A method of

the explosive hardening is used to treat the surface of the new products before putting them into operation and after recovering the worn ones [9]. But the methods known up to now don't enhance substantially the resource of the recovered products, and further investigations on this line are needed.

Most important is the problem of the resource enhancement for railway frogs made of Hadfield steel. It is a commonplace that the resource of a frog cast of manganese steel is many times less than one of a railway switch as a whole. The life of the frog is limited mainly by the wear of the core between the sections from 20 to 40 mm. Depending on working conditions, wear tolerances are in the range 6-8 mm. The manufacture cost of these frogs is high (the content of manganese is high). Besides the change of worn frogs at the track is very expensive operation because the traffic is to be cut.

The properties of the coating layer material regardless of the method used depend mainly on the depth of melting of substrate and of the intensity of mixing of layer and substrate metals. Greater the depth and more intensive the mixing – worse layer properties.

Among of the most effective ways for surface hardening and coating of steel products are plasma treatment and plasma coating. For these operations a plasmatron is designed with expanding anode channel [10]. A powder is injected into argon which is simultaneously transporting, plasma forming and protecting gas. A coating of a real piece of new frog was performed using a Mn-Cr-Ni powder in multiple layers with abrasive cleaning between them and a riveting of every single layer to eliminate residual stresses [11].The core of the frog is wedge-shaped therefore during the coating process the amplitude of plasmatron motion is to be controlled according the layout sketched in the Fig. 4

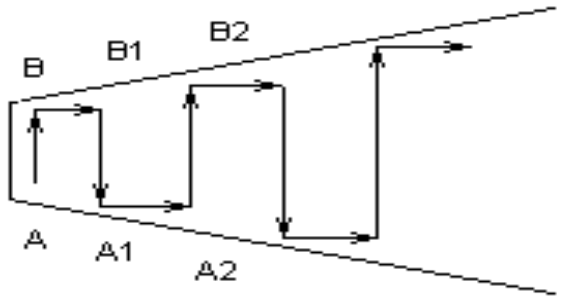

Fig.4. Layout of the plasmatron motion during the coating process

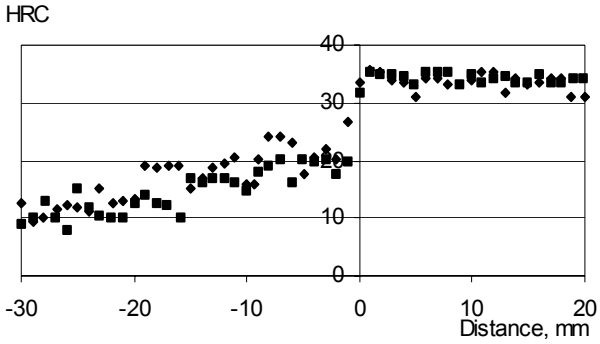

Fig. 5 Hardness HRC versus the depth in the layer and the substrate.

The coating was performed under the following parameters of technological regime: work current I=90-160 A, U=30-40 V, flow rate of argon G=1 m^3/hour, transversal motion velocity of plasmatron Vp=20mm/min, onward velocity of plasmatron Von=10mm/min, flow rate of the powder 0.2-0.3 g/s. The total thickness of the layer comes to 20-22 mm. The balance is made by the frog wear 6-8 mm after taking it from the track, besides there are surface defects to be eliminated.

The hardness HRC was measured 20 mm deep in the layer and 30 mm deep in the substrate (fig. 5). According to the plot at the depth 30 mm of substrate the measured hardness is 9-12 HRC. Towards the boundary the hardness grows evenly up to 17-20 HRC. At the distance ~2 mm from the boundary the hardness increases sharply up to 32-34 HRC. Further on along the thickness of layer the hardness stays constant at the level 32-35 HRC.

Two frogs recovered using the plasma technology were field-tested at the tracks of Moscow Railways. The first one was taken out fully worn after withstanding 115 million tonne brutto of load (worth to note that the new frog is expected to stand for 60 millions tonne), the second one withstood 144 millions tonne and was sanctified to continue the field-testing.

Conclusions

Plasma technology using the plasmatron with expanding channel of the outlet electrode enhances the quality of the surface treatment due to the elevated depth and width of the hardened layer.

Field-testing of the hardened railway wheels and rollgang rollers proves their doubled resource due to the plasma treatment.

Broad range investigations were performed of the plasma coated layer over manganese steel.

Abstract
In the paper the basic parameters of free jet in the "hot" zone just after the output of the arc heater and in the "cold" zone far from the output are studied. The determination of the water vapour flow rate and the total output momentum in the "hot" zone is based on spectroscopic measurements and calculation by means of conservation equations. In the "cold" zone the contact measuring methods (thermocouple, pressure sensor) in combination with calculation method are used.

1. Introduction

Temperature, velocity and composition are the most important parameters of hot gas free jet. The choice of measuring methods and instruments depends on many technical circumstances and demands, and it is influenced especially by the expected range of measured values. In the hot region near the arc heater output the method of optical emission spectroscopy is used to determine the temperature. Just after this hot region (T<10000 K) the molecular spectroscopy and schlieren methods are favourable for the jet investigation. The condition in the region with lower temperatures (T<2500 K, far from the arc heater output) enable the utilization of thermocouples and cooled dynamic pressure sensors for measurements of temperature and velocity fields in the jet plume. In this paper the results of investigation of hot and cold parts of jet plume are described.

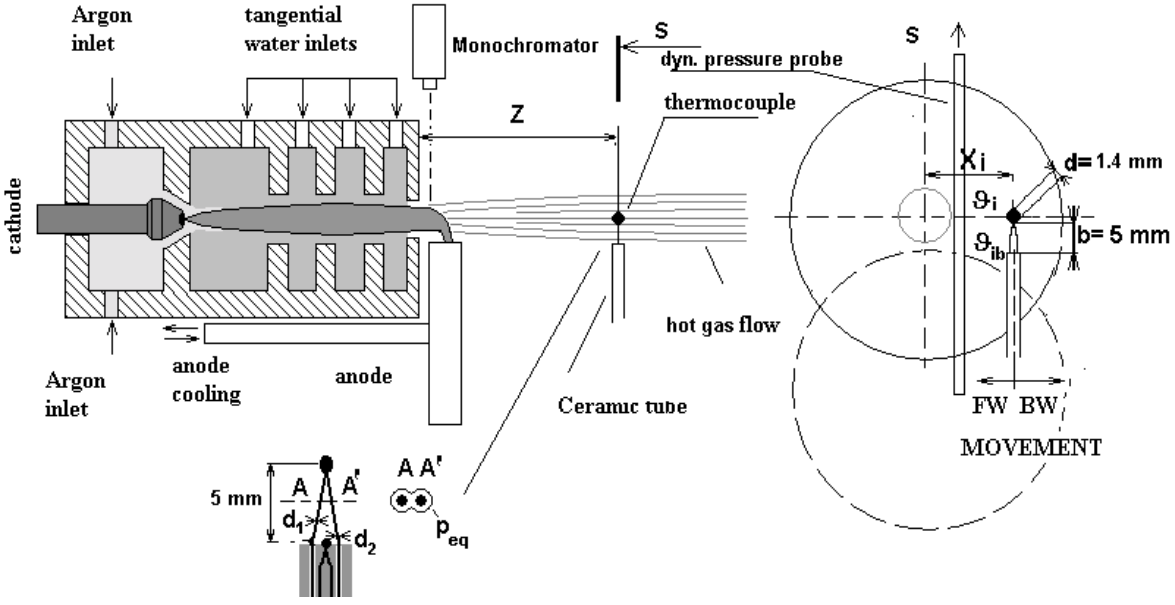

Fig.1 Scheme of the experimental device with hybrid water-argon plasma torch

2. Experimental and Measuring Arrangement

The arc in the arc heater is stabilised and cooled by the steam evaporated from the surrounding water swirl (Fig. 1). Water stabilised torch was modified by adding argon into the chamber. The main parameters of the experimental device were: output orifice diameter 5.6 mm, arc current 300 A, arc voltage 230 V (input power 69 kW), efficiency 0.55, argon flow rate 0.346 $.10^{-3}$ $kg.s^{-1}$.

The spectroscopic measurements were performed using the monochromator Jobin Ivon HR320 (Czerny-Turner configuration, f=0.32 m) with a grating of 1200 grooves per mm and with linear photodiode array.

Temperature distribution in the cold zone of jet plume was measured by Ir-IrRh thermocouple in ceramic protective tube. The thermocouple was inserted into the gas flow perpendicularly to its axis at the distance

z=365 mm from the output orifice (Fig. 1). The velocity field was measured by means of cooled dynamic pressure sensor inserted into the jet plume.

3. Output Parameters of the Arc Heater

The initial parameters of the jet at arc heater output are calculated by means of continuity, momentum, and energy equations using spectroscopically measured temperature distribution. From the continuity equation we obtain the total flow rate through the arc heater output orifice

$$G_M = \int_0^{r_T} \rho_M[T(r)].v(r)2\pi r dr \,. \tag{1}$$

From the momentum equation the initial momentum of plasma flow rate can be expressed

$$G_M.v_{out} = \int_0^{r_T} \rho_M[T(r)].v^2(r)2\pi r dr \,. \tag{2}$$

The energy equation can be written as

$$\eta UI = \int_0^{r_T} \{\ \rho_M[T(r)].v(r)\left[(h_M[T(r)] - h[373]) + \frac{v^2(r)}{2}\right]\}2\pi r dr + G_{WV} l \tag{3}$$

where $G_M = G_{Ar} + G_{WV} = G_{Ar}\left(1 + \frac{x_{WV}\rho_{WV}}{x_{Ar}\rho_{Ar}}\right)$; $x_{WV} + x_{Ar} = 1$ for the arc heater output.

G[kg.s^{-1}] is mass flow rate, ρ[kg.m^{-3}] specific mass, T[K]temperature, v[ms^{-1}] velocity, r[m] radial co-ordinate, η[-] efficiency, UI[W] input power, h[J.kg^{-1}] enthalpy, l[J.kg^{-1}] evaporation heat of water, x[-] molar fraction, lower indexes *M, T, out, Ar, WV* denominate values related to Ar+H_2O mixture, output orifice, argon, and water vapour.

The evaluation of the temperature distribution from spectroscopic measurements is based on Boltzmann diagram that uses relative emission coefficients of spectral lines of the same species and the same stage of ionisation [1]. The two groups of ArII lines were selected in the spectral regions around 420 nm and 482 nm. The obtained temperature profile at the arc heater output is given in Fig. 2.

The approximation of temperature radial profile by parabolic dependence obtained by means of the least squares method

$$T(r) = T_0 - (T_0 - T_T)\frac{r^2}{r_T^2}, \quad 2rdr = -\frac{r_T^2}{T_0 - T_T} dT \tag{4}$$

makes it possible to transform the integration over the co-ordinate r to the integration over the temperature T

$$G_M = \frac{\pi r_T^2 M}{T_0 - T_T} \int_{T_T}^{T_0} \rho_M(T) a_M(T) dT \tag{5}$$

$$G_M.v_{out} = \frac{\pi r_T^2 M^2}{T_0 - T_T} \int_{T_T}^{T_0} \rho_M(T) a_M^2(T) dT \tag{6}$$

$$\eta UI = \frac{\pi r_T^2 M}{T_0 - T_T} \int_{T_T}^{T_0} \rho_M(T) a_M(T)[h_M(T) - h_M(373)]dT + \frac{\pi r_T^2 M^3}{2(T_0 - T_T)} \int_{T_T}^{T_0} \rho_M(T) a_M^3(T) dT + G_{WV}\left[l + c_{pH_2O}(373 - 300)\right], \tag{7}$$

where a_M [m/s] is velocity of sound in heated gas, T_0 is the maximum temperature. This change of variables makes the solving of equation system easier because the integrals of thermodynamic quantities in equations (5), (6), and (7) can be calculated by the program for calculation of thermodynamic properties of gas mixtures [2]. Using the values UI=69000 W, ηUI=37950 W, G_{Ar}=0.346.10^{-3}kg.s^{-1} measured on the arc heater and the values T_0=18052 K, T_T=7930 K obtained from spectroscopic measurements (Fig. 2) the unknown values of water vapour flow rate G_{WV}=0.1903.10^{-3} kg.s^{-1} (G_{WV}/G_{Ar}=0.55), $G_M v_{out}$=1.21kg.m.s^{-2}, M=0.705, and v_{out}=2260 m.s^{-1} were obtained from the equation system (5), (6), (7). The process of calculation is given in Fig. 3.

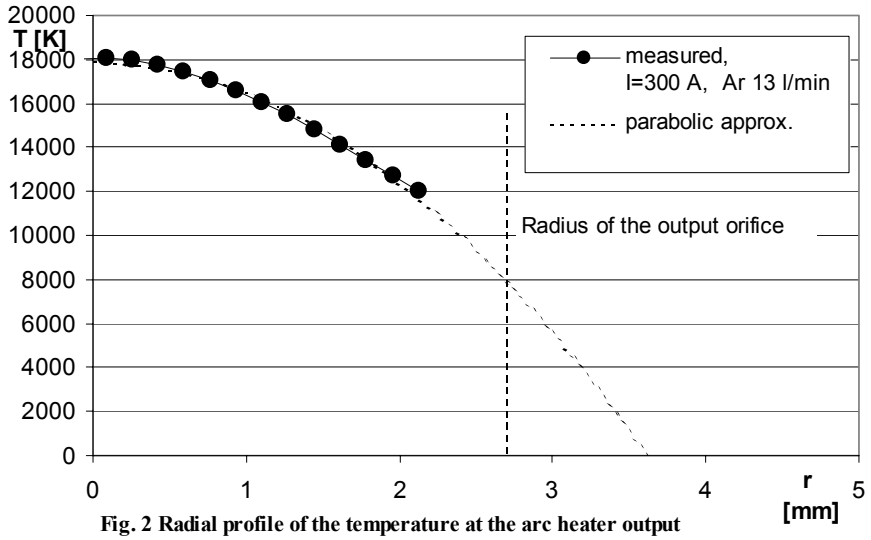

Fig. 2 Radial profile of the temperature at the arc heater output

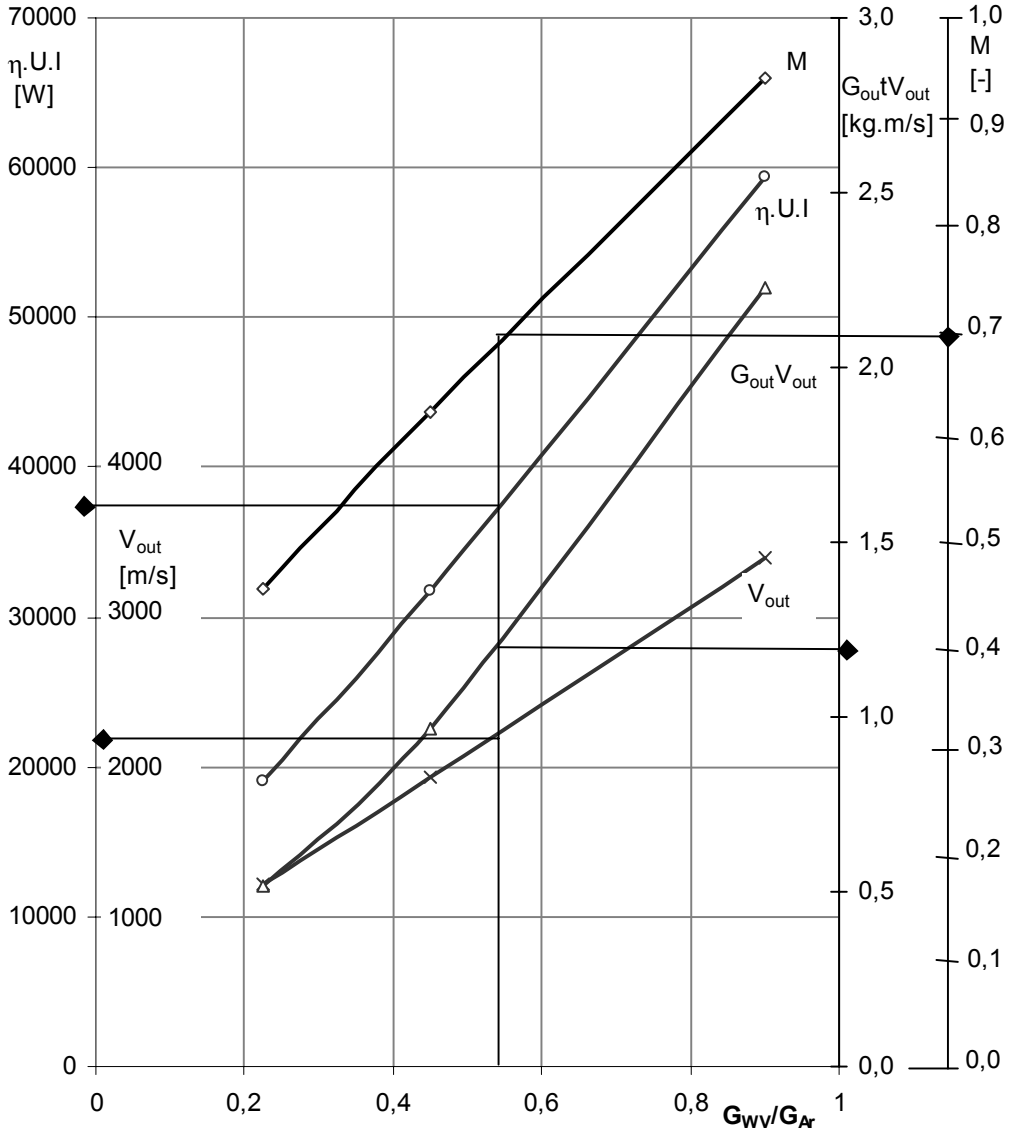

Fig. 3 The dependence of the calculated output quantities of the arc heater on the relation G_{WV}/G_{Ar}

4. Investigation of the Cold Part of the Jet Plume

The temperature distribution in the cold part of the free jet was determined by thermocouple inserted into hot gas. This measured temperature may differ from the real gas temperature because of energy loss by radiation and by heat conduction through the leads. These differences can be corrected using energy balance equation for thermocouple tip and the leads as it is shown in [3]. The corrected temperature profile with velocity profile measured by dynamic pressure sensor at z=365 mm are given in Fig. 4. The profiles were approximated by Gaussian distribution

$$\frac{T(r,z)-T_\infty}{T_{MAX}(z)-T_\infty}=e^{-\ln 2\left(\frac{r}{b_T}\right)^2}, \qquad \frac{v(r,z)}{v_{MAX}(z)}=e^{-\ln 2\left(\frac{r}{b_V}\right)^2} \tag{8}$$

where T_∞ is the temperature of the surrounding environment.

This substitution enables to determine the Prandtl number in the jet Pr = $(b_V/b_T)^2$=0.676 which is in very good agreement with the values given in [4], [5] for cylindrically symetrical jet. The determination of concetration of components in the gas mixture is based on the assumption that far from the output the components are completely mixed and the molar mass M_ρ of them is constant in the investigated temperature interval (T<2500 K). Then the molar fraction sum of the whole cross-section $\sum x_k$=1can be expressed by means of the component flow rates G_k

$$\frac{R}{p\int_{A(z)}\frac{v(r,z)}{T(r,z)}dA}\left[\frac{G_M}{M_{\rho M}}+\frac{G_{ON}(z)}{M_{\rho ON}}\right]=1. \tag{9}$$

From the momentum transfer law within the jet we obtain

$$k_t(z).G_M v_{OUT}=\frac{\int_{A(z)}\frac{v^2(r,z)}{T(r.z)}dA}{\int_{A(z)}\frac{v(r,z)}{T(r.z)}dA}\left[G_{WV}+G_{Ar}+G_{ON}(z)\right] \tag{10}$$

where R [J.kmol^{-1}.K^{-1}] is universal molar constant, p [Pa] pressure, M_ρ [kg.kmol-1] molar mass , $A(z)$ [m^2] the cross-section of jet in the distance z from the output , $k_t(z)$ [-] expresses the momentum loss and index ON means the values related to air.

Solving the equation system system (9), (10) for the gained output quantities of the arc heater and the determined quantities of the investigated cross-section at z=365 mm we obtain the values of the air flow rate $G_{ON}(365)=6.23.10^{-2}$kgs^{-1} and the coefficient of momentum radial loss $k_T(365)$=0.776.

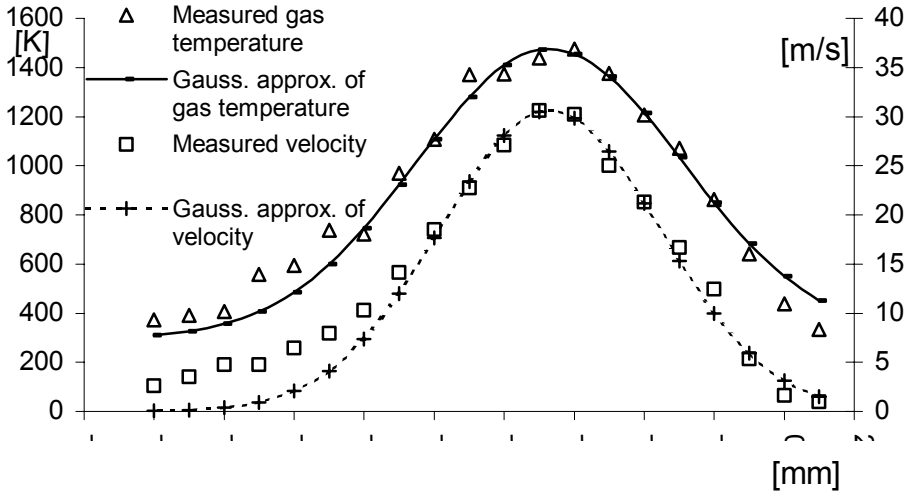

Fig. 4 Measured temperature and velocity profiles at z=365 mm approximated by gaussian curve

5. Conclusion

The calculated flow rates confirm our assumption that the shares of H_2O vapour (0,3 %) and Ar (0,6 %) in the total flow rate of the jet far from the arc heater output are very small. They are smaller than the relative content of this admixtures in atmosferic air at normal condition (it is 1,3 % Ar and 0,94 % H_2O vapour).
The significance of this insubstancial quantity is in the fact, that the flow rate $G_M=G_{WV}+G_{Ar}$ is the carrier of the original momentum of the jet.

Abstract
Different polyimide precursor monomers are deposited by Glow Discharge-induced Sublimation (GDS) in order to characterize the deposition process and to study the structure of the deposited coatings in terms of molecular damage and aggregation. The deposition process has been characterized with plasma sampling mass spectrometry and by measuring the time evolution of the deposition rate. The films have been studied by FT-IR and UV-Vis fluorescence. The results have been compared with vacuum-evaporated thin films.

1. Introduction

Fluorescent coatings are widely used in several application fields ranging from optical gas sensors to nuclear and high energy radiation detectors. Several techniques are currently employed in their manufacturing, such as liquid phase epitaxy, dip coating and the sol-gel method. The application of these fluorescent coatings in nuclear physics puts some limitations in the choice of the materials, which must be radiation-resistant, mechanically stable and low-weight. Fluorinated polyimides are a class of very interesting materials; they have already been used as highly transparent and radiation-resistant matrices in plastic scintillators [1,2]; moreover, these polymers are intrinsically fluorescent, as reported by Hasegawa and Horie in their recent review [3].

Recently, a solvent-free deposition technique, based on glow discharge-induced sublimation, has been developed for the preparation of thin organic coatings [4]. This method is based on a weakly ionized glow discharge produced with a standard radio frequency magnetron sputtering equipment. Low energy gas ions impinge on the solid precursor leading to the sublimation of the organic molecules and to their subsequent condensation onto the substrate.

This work is a feasibility study about the deposition of polyimide precursor monomers, both fluorinated and non-fluorinated, through glow discharge-induced sublimation (GDS). One of its previous applications is the successful growth of a thin coating of 3-hydroxyflavone employed as a wavelength shifter in a Cherenkov light detector for astrophysics [5].

Several precursor monomers have been selected for this work: 4,4'-(Hexafluoroisopropylidene)di-phthalicanhydride (6FDA), 3,4,3',4'-biphenyltetracarboxylic dianhydride (BPDA), 3,3'-diaminodiphenylsulfone (3,3'-DDS), 2,4,6-trimethyl-m-phenylenediamine (TMPD) and 4,4'-(Hexafluoroisopropylidene) dianiline (6FDAm). The plasma deposition of these monomers has been characterized by plasma sampling mass spectrometry while their deposition rate has been monitored with a quartz crystal thickness sensor. So as to better characterize the deposition process and the properties of the films, thin monomer coatings have also been deposited through vacuum evaporation (VE) to compare the

novel GDS deposition procedure with a standard thermal evaporation process. The chemical structure of the GDS and VE coatings has been studied by FT-IR analysis. In order to achieve a better understanding on both the aggregation states of the organic compounds in the coatings and on the molecular integrity after the deposition, UV-visible fluorescence analysis has been performed on both VE and GDS coatings. Fluorescence spectra have been also collected from the monomers dissolved in liquid THF at different concentrations in order to obtain the isolated molecule emission features to be compared with those collected from the coatings.

2. Experimental

6FDA, 3,3'-DDS and 2,4,6-TMPD were obtained from Lancaster at 99%, 98% and 98% purity, respectively; s-BPDA was obtained from Acros Chemicals at 97% purity; 6FDAm was obtained from Acros Organics at 98% purity. All the chemicals were used without further purification. In Fig. 1 are reported the chemical structures of the organic molecules studied in these experiments.

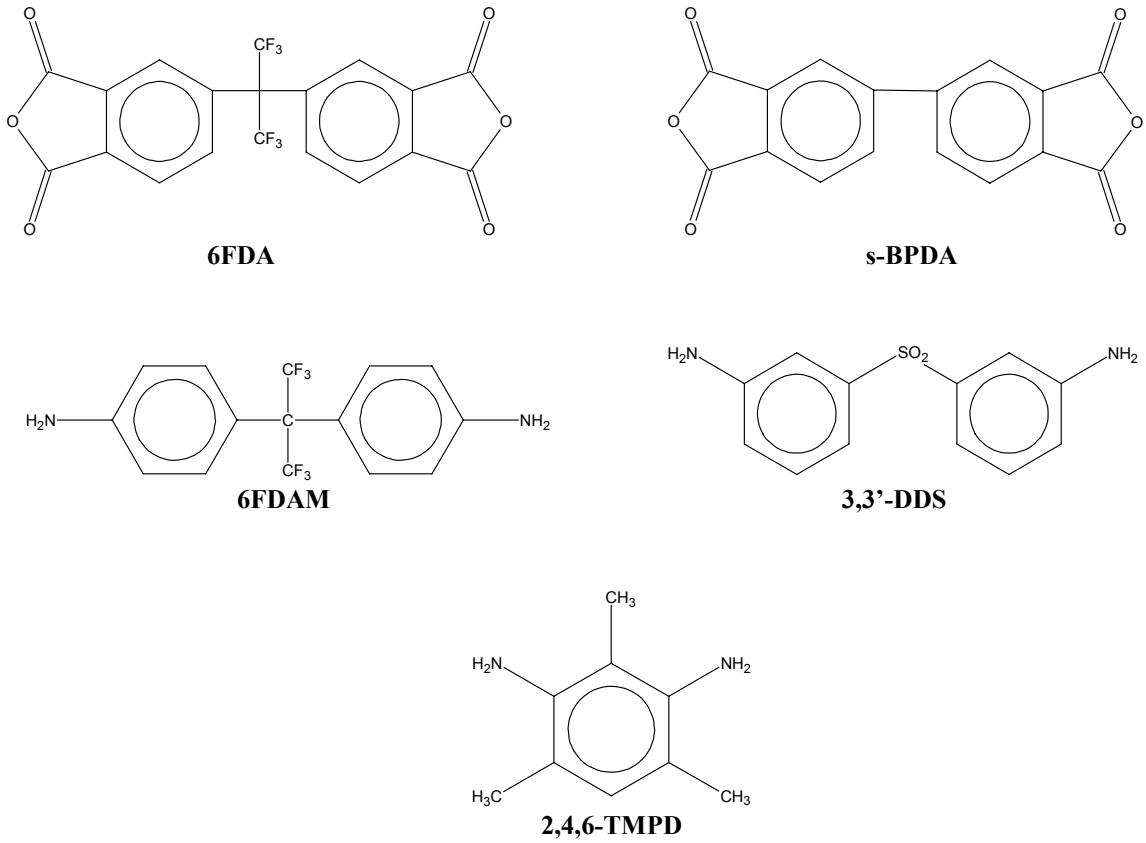

Figure 1. Chemical structure of 4, 4'-hexafluoroisopropylidene diphthalic anhydride (6FDA), 3,3',4,4'-biphenyltetracarboxylic acid dianhydride (s-BPDA), 4,4'- hexafluoroisopropylidene dianiline, (6FDAm), 3,3'-diaminodiphenyl sulfone (3,3'-DDS), 2,4,6 trimethyl m-phenylenediamine (2,4,6-TMPD).

The experimental apparatus used for the glow discharge deposition consisted in a stainless steel vacuum chamber evacuated by a turbomolecular pump to a base pressure of 10^{-4} Pa and equipped with a 1-inch cylindrical magnetron sputtering source connected to a radio frequency power generator (600 W, 13.56 MHz) through a matching box. The organic powders were put on the surface of an aluminum target, placed on the sputtering source. The glow discharge feed gas used in all the depositions was a 95% argon – 5% oxygen gas mixture. The oxygen gas was added to argon in order to promote the removal of the carbon-rich surface layer which is formed on the organic compound target owing to the ion bombardment [6]. The pressure inside the chamber was measured through a capacitance gauge. Typical values of rf power, target DC self-bias and working pressure were in the ranges 10-20 W, -20 to –200 V and 5.00±0.05 Pa, respectively. A quadrupole mass spectrometer (Hiden Analytical, model PSM 001) was connected to the deposition chamber through an electrically grounded sampling orifice (100 μm diameter) and evacuated by a turbomolecular pump to a base pressure of 10^{-6} Pa. The monomers were deposited on silicon substrates

lapped on both surfaces. The film thickness and deposition rate were measured by a quartz crystal microbilance.
Vacuum evaporated (VE) coatings were prepared with an apparatus specifically designed for the evaporation of organic compounds [7]. The powders were placed in copper crucibles wrapped with heating wires in a stainless steel vacuum chamber evacuated by a turbo molecular pump to a base pressure of 5×10^{-4} Pa. All the monomers were evaporated on silicon substrates, with the exception of TMPD due to its heat-induced molecular decomposition with the release of highly volatile molecular fragments.
FT-IR spectra of the samples were recorded using an evacuated Jasco FT-IR 660 Plus spectrometer with a resolution of 4 cm^{-1}. The transmittance spectra in the 4000-400 cm^{-1} range were collected from both the VE and the GDS coatings. KBr pellets containing the organic compounds were also inspected to obtain reference spectra.
The deposited films underwent fluorescence analysis at room temperature using a Jasco FP-770 spectrofluorometer equipped with a 150-W xenon lamp. The emitted light was collected at right angle from the sample surface. The data were corrected taking into account the spectral responsivity of the detection system (emission monochromator plus photomultiplier). So as to achieve a better understanding of the fluorescence behaviour of the molecules, emission spectra were also collected from liquid solutions prepared by dissolving each chemical in THF at two different concentrations, namely 10^{-2} and 10^{-4} M. These two concentrations were chosen in order to identify the fluorescence emission of insulated molecules and of fluorescent aggregates.

3. Results

The deposition rate of the different monomers follows a nearly exponential decay law which can be fitted by the expression

$$\log D = \log D_0 - Bt \qquad (1)$$

where D is the deposition rate in molecules cm^{-2} s^{-1} and t is the deposition time. The calculated values of $\log D_0$ and B are reported in Table 1.

Table 1: Deposition parameters for the different monomers. The first two rows refer to the GDS deposition, while the last row reports the vacuum evaporation rate. The temperatures for the vacuum evaporation procedure are also reported (T_{evap}). 6FDA powder sublimated completely in a few seconds when T_{evap} was reached.

Monomer	BPDA	6FDA	3,3'-DDS	6FDAm
log D_0	15.2	15.5	15.6	15.9
B (s^{-1})	$1.54\text{x}10^{-3}$	$1.61\text{x}10^{-3}$	$6.22\text{x}10^{-3}$	$1.96\text{x}10^{-3}$
T_{evap} (°C)	245	205	158	155
VE evap rate (molecules/cm^2s)	$1.4\text{x}10^{14}$	-	$1.1\text{x}10^{14}$	$2.2\text{x}10^{14}$

As far as TMPD is concerned, its deposition rate was nearly constant for about 500 s; afterwards it decayed following a nearly exponential law.

3.1 Dianilines

The dianilines mass spectra collected during the depositions show a different peak distribution and intensity with respect to the fragmentation patterns reported in literature [8]. In Fig. 2 is reported the TMPD mass spectrum; the molecular ion peak at 150 m/z shows a relative intensity with respect to the other fragmentation peaks lower than in the literature spectrum. 6FDAm mass spectrum exhibits a very small molecular ion peak together with other features not reported in literature, among which a peak at 69 m/z corresponding to the CF_3- group is noteworthy. Moreover, 3,3'-DDS shows neither the molecular ion peak nor any other fragment peak appearing in the literature spectrum. Among the different signals, a peak at 64 m/z ascribed to the SO_2 was visible.
FT-IR spectra of GDS, VE and KBr-dispersed samples exhibit nearly the same peak distribution with some little differences among them. The FT-IR spectrum of the TMPD sample deposited via GDS exhibits a small, sharp peak at 2160 cm^{-1}, which can be ascribed to the C≡C stretching vibration. The FT-IR spectrum collected from the GDS-deposited film of 3,3'-DDS shows a lower relative intensity between the peaks

placed at 1295 and 1150 cm^{-1}, ascribed to the C-SO_2-C stretching modes, and the peaks placed at 1600 and 1625 cm^{-1}, ascribed to the stretching vibration of the benzene rings. Moreover, a new small peak at 2210 cm^{-1} appears, due to the C≡N stretching vibration.

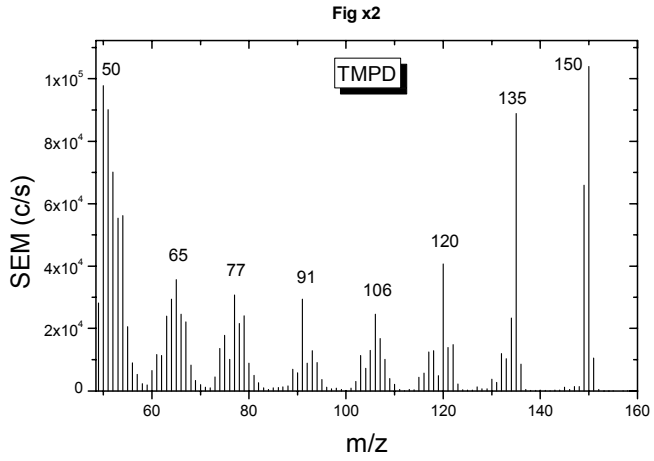

Figure 2: Mass spectrum of TMPD collected during the GDS deposition process.

As far as the fluorescence spectra are concerned, in Table 2 the main peaks collected from dianilines in liquid THF, VE and GDS samples are reported. In general, the fluorescence spectra obtained under UV excitation of the THF-dissolved and VE samples exhibit two kind of peaks: the former is placed at lower wavelengths and is ascribed to the isolated molecule, while the latter is placed at higher wavelengths, features a lower intensity and is probably due to dimers or aggregates. Some bathochromic shift can be observed owing to the different polar environments. Only the spectrum collected from the VE sample of 6FDAm shows a very faint band at 530 nm.

Table 2. Fluorescence peaks observed for the different dianiline samples.

Sample	THF (10^{-4} M)	THF (10^{-2} M)	VE	GDS
TMPD	335 nm (monomer) 415 nm (dimer)	340 nm (monomer) 415 nm (dimer) 475 nm (aggregates)	-	490 nm
6FDAm	330 nm (monomer) 420 nm (dimer/aggregates)	335 nm (monomer) 420 nm (dimer/aggregates)	330 nm (monomer)	500 nm 580 nm (shoulder)
3,3'-DDS	385 nm (monomer)	385 nm (monomer) 530 nm (very faint)	345 nm (monomer) 372 nm (monomer in more polar environment)	440 nm

GDS films show broad, faint emission bands at longer wavelengths. These fluorescence features are not directly connected to any of the emission peaks observed in THF-dissolved or VE samples.

3.2 Dianhydrides

The mass spectra of 6FDA and BPDA do not exhibit the molecular ion peaks and most of the high m/z features appearing in the literature spectra. In the case of 6FDA, the peaks corresponding to the CF_3- group at 69 m/z can be spotted.

As far as the FT-IR spectra are concerned, all the main molecule absorption peaks are visible in both VE and GDS samples. There is a significant broadening of these peaks in the latter with respect to VE and KBr samples.

In Table 3, the main fluorescence peaks collected from THF-dissolved, VE and GDS samples are reported.

6FDA exhibits two different emission features in THF at 10^{-4} and 10^{-2} M. In the first case two peaks are visible; the former is placed at 312 nm and is due to the monomer, while the latter is placed at 380 nm and is probably due to a dimer. In the second case only a broad band at 415 nm can be observed. On the other hand, the fluorescence spectrum of the VE sample shows a peak at 322 nm together with a structured band placed at about 500 nm. While the first peak can be clearly assigned to the undamaged monomer, the second band can be ascribed to some kind of aggregate formed during the condensation on the substrate. Finally, the fluorescence spectrum of the GDS sample shows a broad, faint band at 580 nm.
On the other hand, BPDA always exhibits the monomer emission peak, with some indication of dimer/aggregate formation in the GDS sample.

Table 3. Fluorescence peaks observed in the different dianhydride samples.

Sample	THF (10^{-4} M)	THF (10^{-2} M)	VE	GDS
BPDA	357 nm (monomer) 435 nm (dimer)	370 nm (monomer) 444 nm (dimer)	362 nm (monomer)	360 nm (monomer) 480 nm (faint emission)
6FDA	312 nm (monomer) 380 nm (dimer/aggregates)	415 nm (aggregates)	322 nm (monomer) 500 nm (aggregates)	580 nm

4. Discussion

The evolution of the deposition rates shown by the monomers during the GDS process points out the different mechanisms involved in the damage of the target. The exponential decrease observed after a few tens of seconds from the beginning of the deposition is ascribed to the progressive formation of a carbonised surface layer made of non-volatile species which cannot be removed from the target surface and hinder the further sublimation of the organic compound. The faster is the formation of the blocking layer, whose growth is only delayed by the reaction with the active oxygen species present into the plasma, the faster is the decaying rate. As far as TMPD is concerned, a possible interpretation of the different behaviour shown by this molecule is that the strong sublimation of integer species together with the emission of volatile fragments delay the formation of the blocking layer, which takes a much longer time (more than 500 seconds) than in the other chemicals.
Examining the VE-deposition procedure, 6FDAm, 3,3'-DDS and BPDA follow a similar pattern undergoing a gradual evaporation over a few minutes with comparable deposition rates, while 6FDA and TMPD suddenly "burst", evaporating completely in a matter of seconds once they reach a critical temperature. But while 6FDA deposits on the target surface, TMPD does not. This effect can be explained by supposing that the latter molecule undergoes a chemical decomposition on reaching the critical temperature, giving rise to the formation of very volatile fragments which do not adsorb on the substrate. From this fact, it can be concluded that the GDS deposition process allows to prepare coatings of organic compounds showing heat-induced decomposition during the standard thermal evaporation in vacuum.

4.1 Dianilines

The presence of the molecular ion peaks in the TMPD and 6FDAm mass spectra points out that the emission of undamaged monomer molecules takes place during the plasma-induced sublimation, so that their deposition onto the substrate can be expected. On the other hand, a further molecular fragmentation due to the interactions of the molecules with the plasma gives rise to ion peaks not appearing in the literature. It is possible to infer from this fact that weakly-damaged non-volatile molecules could adsorb on the substrate surface, becoming embedded in the film structure. FT-IR spectra points out that the GDS films are constituted mainly by integer molecules. This fact can be deduced by the presence of all the main fingerprint peaks, whose relative intensities correspond to those shown by the undamaged compounds. However, the presence of the features arising from the C≡C triple bond in the TMPD spectrum evidences that damaged molecules are also embedded into the film.
In the case of 3,3'-DDS, the absence of the molecular ion peak in the mass spectrum can be ascribed to the lower deposition rate of this chemical; the result is that in the deposition chamber the molecular concentration is lower than the detection limit of the mass spectrum analyzer. However, from the FT-IR spectra it can be deduced that the GDS-deposited 3,3'-DDS film is mainly made of undamaged molecules,

with some damaged structures as it is pointed out by the relative intensities between the stretching peaks corresponding to the SO_2 group and to the benzene rings. Besides, in the spectra is clear the presence of a feature ascribed to a $C \equiv N$ bond.
In the analysis of the film structure, UV-Vis spectroscopy plays an important role since it deals mainly with the delocalized molecular orbitals of the aromatic groups. Therefore, the fluorescence spectra can give more information both on the structure of the molecule as a whole and on its chemical surroundings. In fact, even if the mass spectra and/or the FT-IR spectroscopy give indications that GDS films are constituted by integer molecules, all the fluorescence spectra exhibit features which cannot be directly ascribed to the molecular orbitals of the undamaged, isolated molecules. On the other hand, the fluorescence spectra collected from VE films show the characteristic features of the monomers or the aggregates as observed in THF solutions.
At present, the nature of the new optically-active structures present in the GDS films is not clear. It must be pointed out that in the GDS deposition process the energy provided by the impinging ions gives rise to the formation of highly energetic species together with molecular fragments, which can produce a film structure different from the one obtained by means of a thermally-activated process like vacuum evaporation. In particular, the combination of energetic and weakly damaged molecules can induce the growth of molecular aggregates with new optical properties.

4.2 Dianhydrides
As far as 6FDA and BPDA are concerned, the absence of the molecular ion peak in the mass spectra can be attributed once again to the fact that the molecular emission rate during the GDS deposition process is below the detection limit of the mass analyzer. In fact, FT-IR spectra exhibit all the main molecular features, suggesting that the plasma-grown films are made of undamaged molecules for the most part. Moreover, the concentration of damaged structures is below the FT-IR detection limit, owing to the absence of any new peak.
The UV-Vis fluorescence emission spectra shows that the GDS-deposited 6FDA film exhibits a broad band centered at 580 nm, while the VE sample shows the monomer main peak together with a new feature at about 500 nm. This behavior can be ascribed, as for dianilines, to the formation of new optically-active molecular structures into the GDS-deposited coating. Moreover 6FDA, like 6FDAm, exhibits new fluorescence bands in VE samples. This finding can be explained with a more pronounced fragility of this kind of molecules caused by the $C(CF_3)_2$- group.
On the other hand, BPDA is the only monomer among those studied in this work that shows the molecular fluorescence peak in GDS films, thus confirming that undamaged molecules are deposited even in the absence of the molecular ion peak in the mass spectrum. In a previous work [5] the 3-hydroxyflavone dye molecule was deposited using the GDS procedure as an integer molecule, which preserved its optical properties. Therefore it can be concluded that some molecules, probably those characterized by a rigid structure, can be deposited via GDS to obtain films sharing the same optical properties of the isolated molecules.

5. Conclusions
Different organic thin films have been produced by means of the novel glow discharge-induced sublimation procedure. The deposition rate decreases with the time owing to the formation of a carbonaceous layer on the powder target surface which hinders further molecule sublimation.
From the analysis of mass and FT-IR spectra it can be deduced that the deposited films are mainly made of undamaged molecules with some weakly damaged structures. Moreover, the UV-Vis spectroscopy analysis evidences that the GDS deposition process gives rise to the formation of molecular structures with new optical properties compared to the starting monomers. This effect can be ascribed to a combination of energetic impinging monomers and damaged structures which form different kind of optically-active aggregates. The only exception is BPDA, which exhibits the monomer fluorescence features, indicating that it preserves its molecular structure also from the point of view of the electronic molecular orbitals.

The Method for Evaluation of Energy Processes in Intensively Blasted Electric Arc

J. Heinz[1], M. Hrabovsky[2], I. Jakubova[1], J.Senk[1]

[1]*Brno University of Technology, Faculty of Electrical Engineering and Communication, Purkynova 118, 612 00 Brno, Czech Republic*

The contribution presents a mathematical-physical model of intensively blasted electric arc burning in anode channel of arc heater. The model is used for evaluation of measurements on experimental arc plasma generator with argon as working gas. The calculation procedure based on mass and energy conservation equations and Ohm's law enables to determine the temperature and velocity fields and energy flows in the blasted electric arc. Main input data (arc current and voltage, mass flow rate of working gas, energy losses of the arc heater's anode channel etc.) were obtained from measurement on the arc heater described in [1].
For calculation purposes the whole channel area is divided into two zones - electrical arc zone and heated zone. In the heated zone temperature dependencies of thermodynamic quantities are rather simple (constant or linear) and the energy equation can be expressed in simpler way, while in the arc zone the non-linear temperature dependencies must be taken into account. The radial temperature profile in arc zone is approximated by modified parabolic dependence, and in heated zone by Gaussian distribution.
According to Reynolds number quantity, the gas flow is supposed to be laminar or nearly laminar. During the solution procedure of equation system it was found that the oscillations of the arc position and volume may be interpreted as local turbulence and can be included into thermal conductivity as its turbulence component.
By means of the mathematical-physical model the measurements on the experimental arc heater in the range of current values 80-200 A and flow rate 22 g/s are investigated. The obtained results of theoretical-experimental investigation enable to evaluate the energy flows (convection, conduction and radiation) from arc. The distribution of the anode channel losses (radiation, heat transfer to channel walls) and their dependency on arc current can be judged.

Abstract
Carbon nanotubes (CNT) are produced using a 100 kW dc non-transferred plasma torch and C_2Cl_4 as carbon precursor. Catalytic metallic nanoparticles are generated *in situ* using the tungsten metal vapours emitted by the electrode erosion process. Large quantities of multi-wall (MWNT), single-wall nanotubes (SWNT) and spherical onion-like carbon structures are observed under FE-SEM and TEM. Preliminary results are given here on the effect of some process parameter and electrode erosion.

1. Introduction

Carbon nanotube (CNT) structures are presently showing a vast interest throughout the scientific community and are finding their way into commercial applications. Applications particularly in the field of advanced materials are however strongly restrained not only by the price of CNT, but more importantly by the availability of large quantities of this material. A scalable approach for the synthesis of the fullerene cage-like molecules of C_{60} and C_{70} using a plasma torch based on the dissociation of tetrachloroethylene (C_2Cl_4) was described in previous ISPC conferences [1-4]. This paper presents an extension of the work on fullerenes to the nucleation and growth of carbon nanotubes. The objective of the project is first to demonstrate the possibility of large-scale production of CNT using thermal plasma torch technology [5], and to provide the design parameters enabling a scale-up to industrial power levels of the plasma torch system. These studies include an experimental component and modeling of the flow/energy/particle nucleation fields for a better understanding of the synthesis reactor.
As in fullerene experiments, the CNT growth is performed using a 100 kW non-transferred plasma torch. Long single-wall (SWNT) and multi-wall (MWNT) nanotubes were grown in various sections of the reactor. One key aspect of CNT synthesis is the need for nanoparticles of metal catalyst acting as a seed to anchor the tube structure and favouring growth at the tube-metal interface. Many techniques are pre-seeding the growth region with the nanoparticles of metal catalyst, while the conventional graphite arc technique uses metal particles imbedded within the anode and evaporated along with the carbon electrode [6-7]. One constraint of the graphite arc technique is the lack of independent control of the metal nanoparticle nucleation zone and the concentration/temperature fields of the carbon precursor species, these being coupled by the electrode erosion process and resulting local plasma composition responsible for the species concentration fields [6]. A plasma torch system provides some flexibility in trying to separate and provide a better *in-situ* control through the use of a catalyst nucleation zone followed by a CNT growth zone on the catalyst particles. We use in this study a simple and efficient method to induce such a two-step process by first producing metal vapour that condenses into nanoparticles within the plasma stream at a position of the carbon precursor injection. For simplicity of production and efficiency in generating the metal only in a vapour state within the plasma stream, we simply use the electrode erosion products within the plasma torch as the metal vapour source.

2. Experimental Setup

The water-cooled reactor (Figure 1) has a cylindrical geometry (ID=40 cm) and the flexibility to modify the length of the expanding plasma flame with a movable water-cooled disk plate (ID=36 cm) up to a possible total reactor length of L=100 cm. A quartz window provides optical access to the plasma jet for spectroscopy measurements. A 100kW non-transferred D.C. plasma torch is used for the dissociation of C_2Cl_4 injected in the torch nozzle with 20 slpm of helium or argon as the carrier gas. C_2Cl_4 is fed at flow rates of 0.15-0.54 mol/min at a temperature of 200°C ± 10°C. Helium or Argon are used as the plasma forming gas at 225 slpm for helium or 100 slpm for argon. Table 1 gives a summary of these experimental conditions. In the experiments presented in this paper, thoriated tungsten was used as electrode material and the erosion process within the plasma torch acted as the source of tungsten nanoparticles. A graphite cylinder of 30 cm long is added around the plasma jet in order to extend the hot section of the reactor and limit by-product formation by avoiding cold gas entrainment within the plasma jet. The operating pressure inside the reactor

is set at a value between 200 torr and 1 atm. It is controlled using a water-sealed vacuum pump and an automatic proportional valve. The chlorinated exhaust from the pump is treated through a packed column in which a caustic solution shower absorbs the chlorine gas. Observations of CNT were done using FE-SEM and TEM. Typical run durations were of 5 minutes.

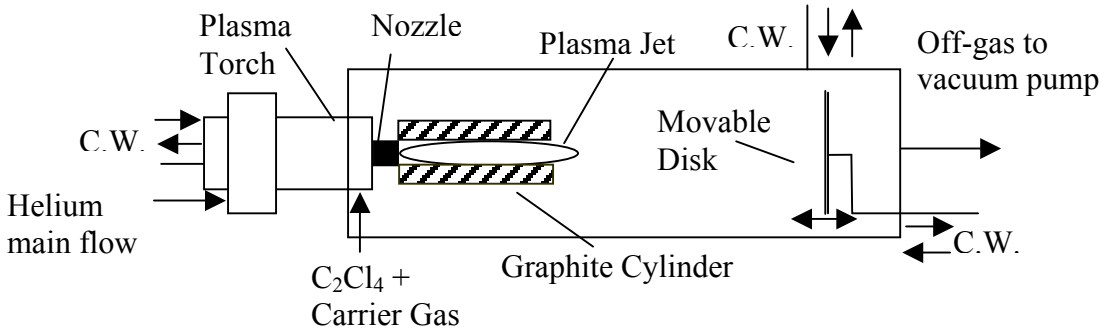

Figure 1: Experimental setup (C.W.=cooling water)

Table 1: Experimental conditions for fullerene/ nanotube soot production in present paper

Conditions	**Plasma-Forming Gas**	
	Helium	**Argon**
Torch Power (kW)	30 to 65	30
Main plasma gas flow rate (slpm)	225	100
C_2Cl_4 feed rate (mol/min)	0.15	0.15
Carrier Gas flow rate (slpm)	20	20
Reactor Pressure (torr)	200, 500	200
Reactor Length (cm)	100	100
Run Duration (min)	5	5

3. Results and Discussion

-3.1 Nucleation of Tungsten Nanoparticles

The plasma torch was designed with an inside diameter of the C_2Cl_4 injection nozzle that is enlarged with regards to the torch flow outlet at the downstream electrode (Figure 2). Modeling of the main plasma flow field indicated a recirculation zone is created with local cooling of the plasma stream. The thoriated tungsten electrodes generate tungsten vapours upstream of the injection nozzle within the plasma torch. The quench of the plasma stream occurring within the injection nozzle provides a nucleation zone into which tungsten nanoparticles acting as a catalyst for CNT nucleate. Depending on the operating conditions, carbon soot containing CNT condenses or grows within the nozzle at various positions upstream or downstream of the C_2Cl_4 injection and are collected either as a coating on the nozzle walls and/or downstream within the reactor itself. It was observed at the lower pressure for example that 10% of the total collected soot is condensed in the upstream region.

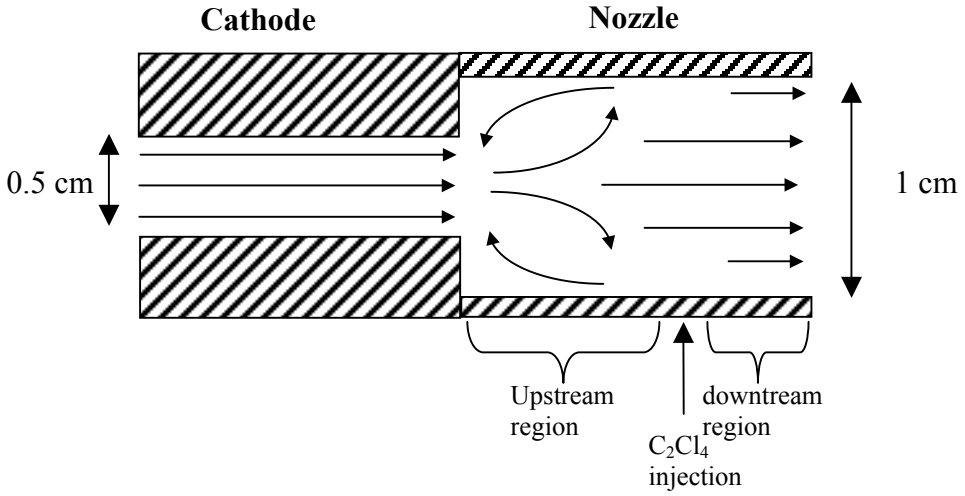

Figure 2: Sketch of the cathode/nozzle geometry and velocity streamlines

Tests were preliminary performed using helium as plasma-forming gas, 55 kW torch power and 200 torr reactor pressure. The resulting mixture of tungsten nanoparticles and carbon collected in the upstream region

of the nozzle was observed under FE-SEM and EDX (Figure 3a and b respectively). All electron microscopy images presented here are performed on raw unpurified samples.
The tungsten nanoparticles were found well-distributed within the carbon material which shows a cauliflower appearance at low magnification. The EDX spectrum confirmed that these nanoparticles are made of tungsten. The spectrum also shows the presence of chlorine in the sample coming from the chlorinated carbon precursor.

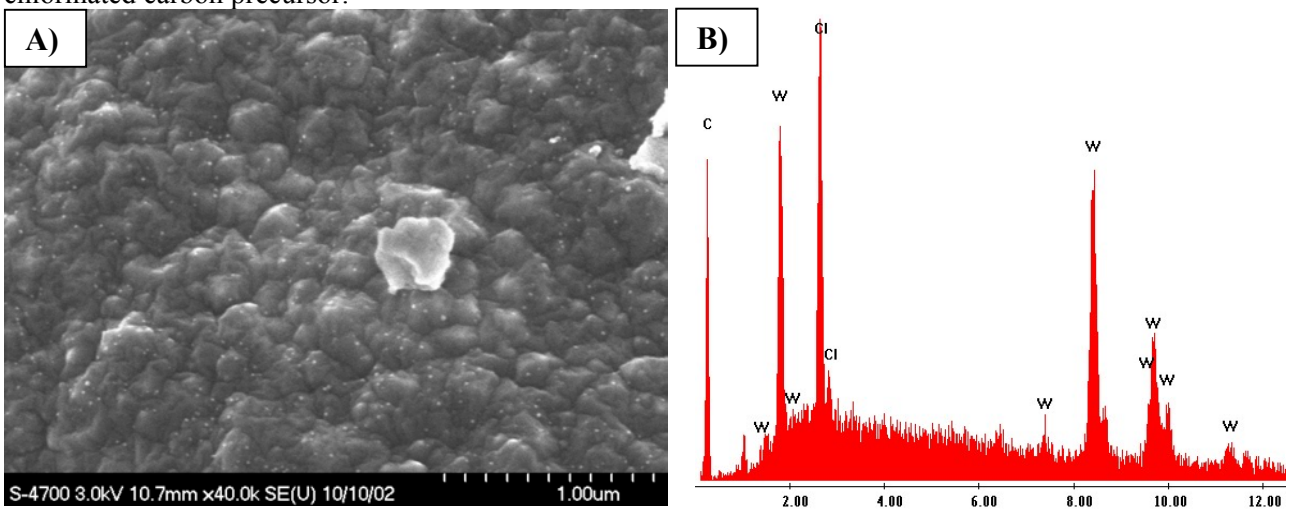

Figure 3: A) FE-SEM image showing nucleated tungsten nanoparticles (white dots, ϕ<20nm) well dispersed within the carbon deposit on the nozzle walls. B) EDX elemental analysis confirming the tungsten nature of these particles.

-3.2 Formation of CNT

At higher magnification using the FE-SEM, a well-distributed and high concentration of CNT can be seen in the carbon deposit within the nozzle. Both the deposit and CNT form a very stable structure in the nozzle during torch operation. Figure 4a,b respectively show that they are long (up to the 50 μm scale) and have relatively uniform diameters (≅20 nm range).

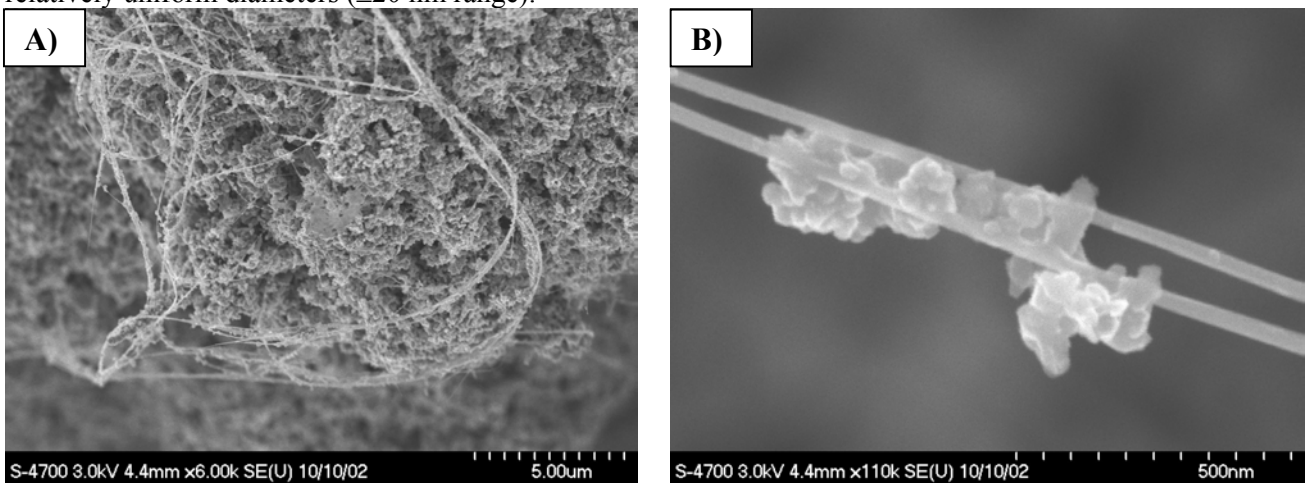

Figure 4: A) Large concentration of long and well-distributed CNT. B) Close-up of CNT with typical diameter in the 20-50 nm range.

Such structures are well distributed throughout the region upstream of the C_2Cl_4 injection at the lower reactor pressure, the downstream section typically showing larger CNT diameters. Increasing reactor pressure tends to push the smaller diameter CNT downstream of the nozzle towards the plasma tailflame. Under TEM, nanoparticles of tungsten having diameters in the 10-20 nm range are found encapsulated in the tip of the CNT (Figure 5a). The majority of the CNT observed correspond to MWNT, while a smaller fraction is seen as SWNT. Also present in large quantities are spherical onion-like carbon structures. The SWNT have diameters of 2-3 nm, while MWNT are characterized by an external diameter around 15-20 nm and internal diameters of 2-3 nm. One can see in Figure 5a that tungsten particles are effectively observed at the tip of the CNT, confirming that the tungsten vapours from the erosion process effectively promote CNT formation. A transitional metal at the CNT interface prevents an early closure and promotes an efficient elongation of the

carbon structure. The observations presented here indicate an excess of carbon to catalyst particles in the CNT synthesis region, and a size of the catalyst particles that seem to promote MWNT. The catalyst being produced by the electrode erosion process in the present experiment, section 3.3 shows the evolution of the erosion rate of the plasma torch.

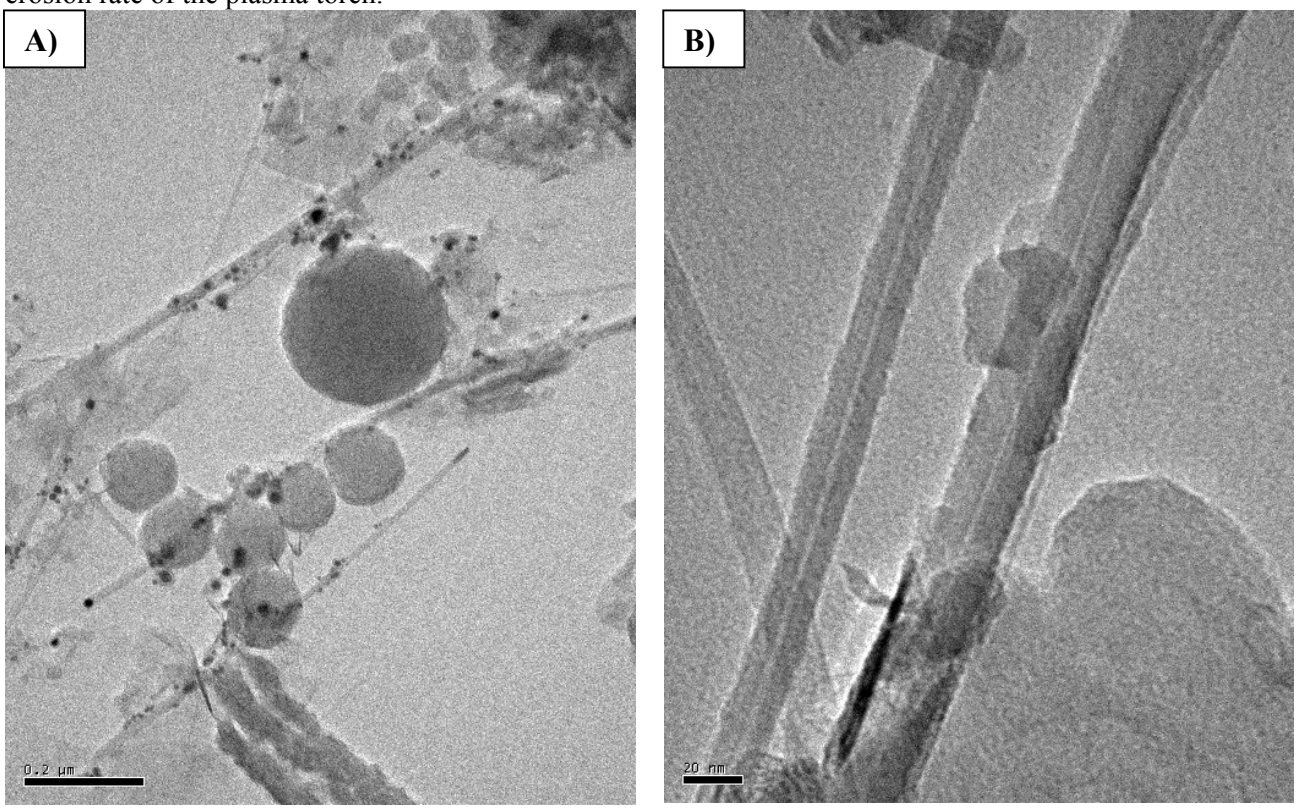

Figure 5: TEM images on carbon deposits collected in the nozzle after 5 minutes of operation using 55 kW torch power, 225 slpm helium, 0.15 mol/min C_2Cl_4 and 200 torr reactor pressure. Figure A shows tungsten particles (black dots) and a relatively large amount of spherical onion-like carbon structure. Figure B: close-up of some CNT structures. Scale lines: in A: 200 nm; in B: 20 nm.

-3.3 Erosion Rates of the Torch Electrodes

The relative quantity of available catalyst particles plays a crucial role in CNT growth and yield. Low quantities will yield by-products such as premature closed dome structures, whereas larger quantities will increase metal-carbon interfaces and yield more efficiently CNT [8-9]. Erosion rate experiments on the tungsten electrodes were thus performed at different torch currents in order to provide some knowledge and control on the amount of catalytic nanoparticles that can be provided into the system. The cathode for this evaluation was weighted before and after each experiment and erosion rate was calculated according to the duration of the experiment and the arc current used. Table 2 indicates the torch conditions used in this study and the values of current associated which each condition. Figure 6 presents the cathode erosion rates for the various torch conditions in Table 2. These are expressed in mass eroded/Coulomb of electric charge passing (10^{-5} mg/C) through the electrode during each experiment.

Table 2: Torch currents associated with their respective gas and power conditions

Torch Conditions	Current (Amps)
100 slpm Argon @ 30 kW	375
225 slpm Helium @ 30 kW	160
225 slpm Helium @ 45 kW	240
225 slpm Helium @ 55 kW	290
225 slpm Helium @ 65 kW	350

Depending on the torch current condition, the quantity of tungsten available in the system lies from 0.01% to 0.1% of the carbon fed. The plasma torch electrodes are made of tungsten to minimize erosion at higher power and to sustain the chlorine gas environment. One can see from Figure 6 that higher torch power provides enough electrode heating to reach thermionic "hot cathode" emission and relatively low erosion rate. On the contrary, the low power of 30kW in He is below a lower limit for this cathode arrangement having a tubular geometry. The cathode emission process in this case is most probably in the thermo-field "cold-cathode" mode leading to a strong increase of the erosion rate.

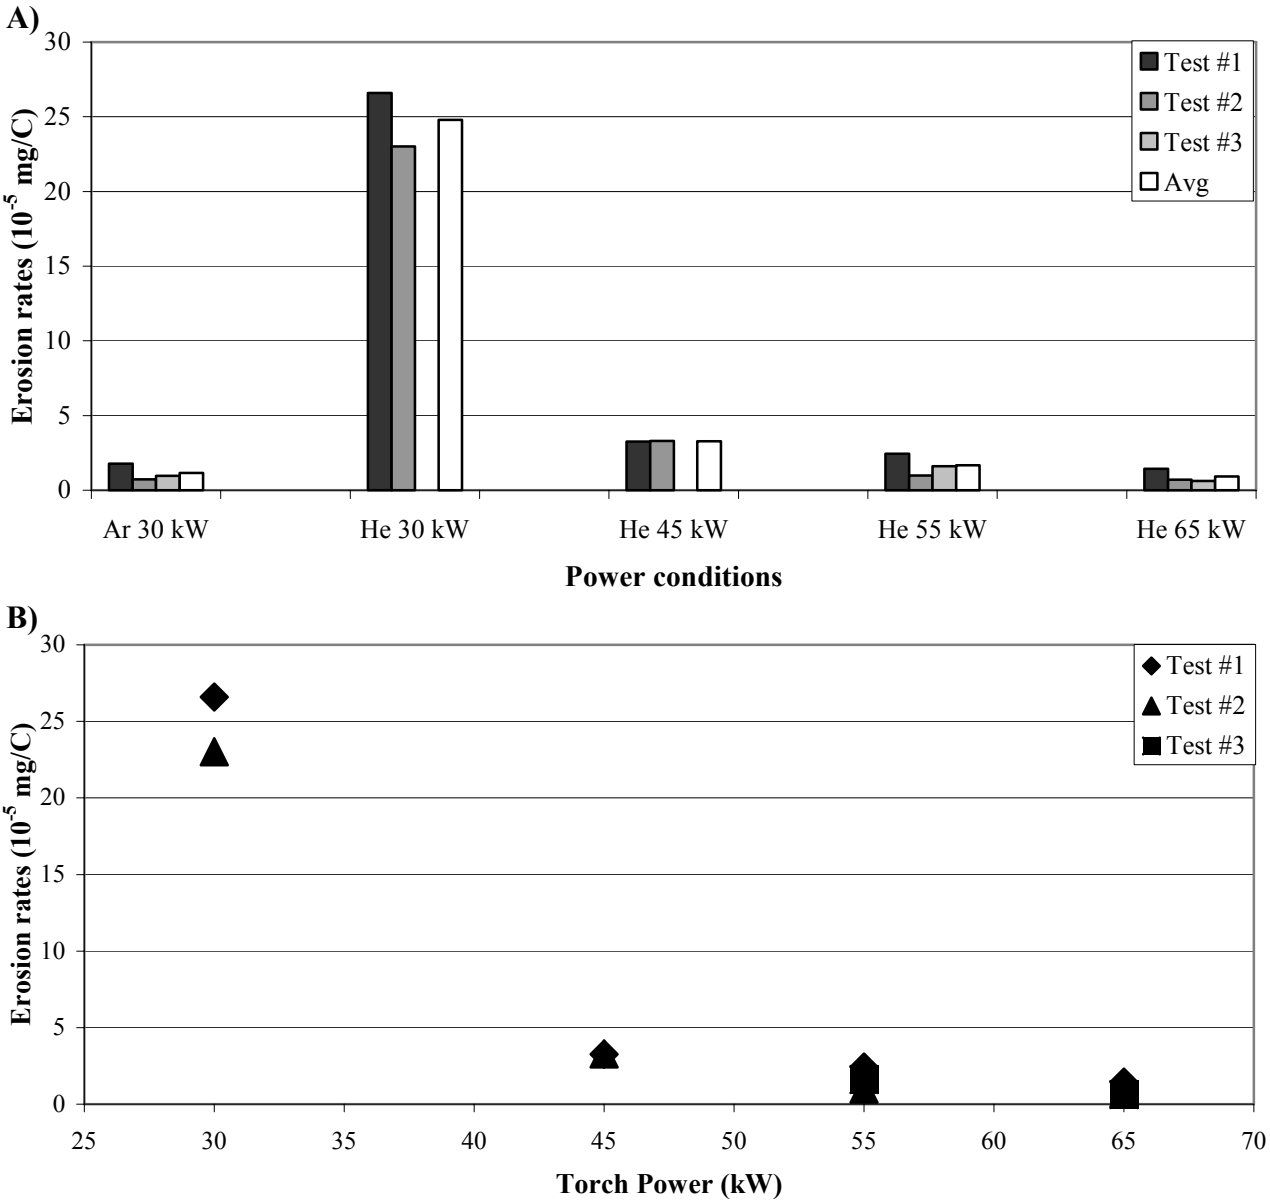

Figure 6: A) Erosion rate versus plasma conditions. B) Erosion rate versus torch power using 225 slpm of helium

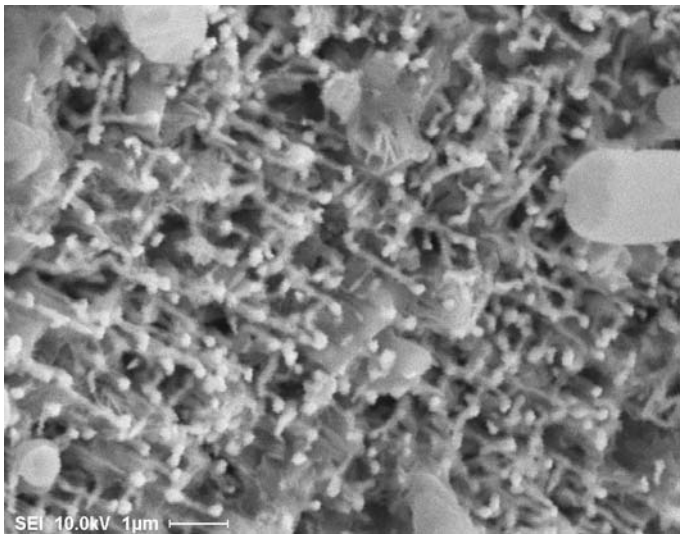

Figure 7: CNT produced at 500 torr pressure in the reactor on the movable disk.

-3.4 Effect of Reactor Pressure

In graphite arc systems, CNT are produced at pressures typically higher than fullerenes, for example in the 500-600 torr range [6-7,9]. The results presented above indicate CNT found in the upstream region of the nozzle when operating at 200 torr, while no CNT is observed further downstream in the reactor for this pressure. At 500 torr, observations made using FE-SEM revealed the absence of CNT in the upstream region of the nozzle, but their presence at the exit section of the nozzle and on the movable disk. The increase of pressure allowed the growth of CNT of comparable size and morphology to the ones produced at lower pressure, but in this case produced in the exit section of the nozzle. CNTs are also collected on the movable disk in the reactor. Some, as shown in Figure 7, are typi-

cally shorter (≅1μm long) than those seen in the nozzle itself and seem to have grown from the plate surface itself. The observations above suggest that an increase of reactor pressure produces flow and thermal conditions for catalyst nucleation with good adherence and CNT growth to occur further downstream in the nozzle and within the reactor. Soot accumulation within the nozzle gradually tends to a degradation of the plasma jet conditions. The transfer of CNT synthesis outside of the torch nozzle strongly favours implementation of a continuous process.

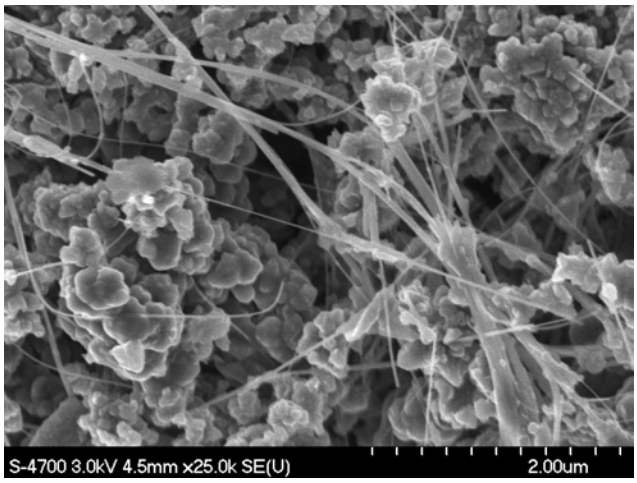

Figure 8: CNT's and soot collected using argon experimental conditions (Table 1)

-3.5 Tests in Argon

Typically, the carbon arc system does not provide conditions for fullerenes and CNT yields in argon. This is strongly linked to the physics of the arc-surface interaction leading to a small amount of carbon vapours being produced. Hence, this limitation should not necessarily be applicable to a plasma torch system aimed at separating plasma and atomic carbon production. Tests using argon as the plasma-forming gas were hence performed in view of the economical aspect of argon over helium. Conditions stated in Table 1 were used. The preliminary observations using FE-SEM (Figure 8) indicate important amounts of CNT are effectively produced; the concentration was fairly uniform in the torch nozzle deposit (upstream and downstream) and in fact appears to be higher in argon than for helium (Figure 3). This affirmation remains of preliminary nature at this time since soot was not analyzed for CNT quantification yet.

4. Conclusion

FE-SEM, TEM and EDX observations demonstrated the potential for a scale increase in CNT production using C_2Cl_4 as a carbon precursor in a process that could operate under a continuous production regime. In these demonstration experiments, the catalyst particles are generated *in situ* from the electrode erosion of a 100 kW D.C. plasma torch. The new process enables the synthesis of SWNT, MWNT, and onion-like spherical carbon structures. The CNT structures are produced both in helium or argon environment. At present, the experiments were limited to the use of thoriated tungsten electrodes showing low erosion rates. A change of the electrode material to thermo-field electrodes showing good catalyst behaviour such Ni/Co is expected to improve the CNT yield. The present study shows that CNT production is shifted downstream from the C_2Cl_4 injection nozzle at higher reactor pressure and using argon over helium as plasma-forming gas.

Abstract
The time evolution of a plasma produced by laser ablation of an aluminum target in ambient air at atmospheric pressure is investigated both experimentally and numerically. The space-averaged plasma temperature and electron density as a function of time are compared for (i) three laser pulse durations (100 fs, 270 ps and 8 ns) at a fluence of 20 J/cm^2 and (ii) for laser fluences up to ~30 J/cm^2 for 100 fs pulses. For fairly early times (< 1 μs), the plasma averaged temperature increases with the laser pulse duration and fluence, while for longer times the temperature is nearly independent of these parameters. The electron density also appears to be nearly independent of the plasma initial conditions for times greater than ~100 ns. Using our code, the results of which are in good agreement with experiments, this general behavior can essentially be explained by plasma's radiative losses and the work done on the ambient air for expansion.

1. Introduction

Laser Induced Plasma Spectroscopy (LIPS) is a spectrochemical analysis method based on the measurement of impurity line intensities emitted by plasmas created by laser-induced ablation from a target (for a review of LIPS, see Ref. [1,2]). While LIPS is already successfully used in several applications, there is a constant demand for improving the lower limit of detection of trace impurities. A step toward this goal is to improve our knowledge and understanding of the laser-created plasma characteristics as a function of the laser parameters such as pulse duration, laser energy per surface (fluence), wavelength, etc.

Several authors have investigated the influence of the laser parameters on the plasma emission, temperature and electron density (see [1-3] for ns pulses only). The conclusion which emerges from these investigations is that, for sufficiently short delays (typically less than a few hundred of nanoseconds), early temperature values increase with the fluence and pulse duration [4,5], while at later times the fluence has little influence on the temperature. Similar observations have been reported for the electron density as a function of the fluence. However, electron density has not been systematically investigated as a function of the pulse duration (except in [5] where 100 fs and 8 ns pulses were compared). Although these general trends emerge clearly from the experimental studies, to our knowledge the basic reasons for this behavior have not yet been discussed.

The main goals of this paper are to present measurements of the time dependence of the space-averaged plasma properties (temperature and electron density) for various pulse durations and laser fluences, and to compare the results with those of a numerical model. The objective of the modeling is to give a realistic interpretation of our measurements and to obtain physical insight. The code used here is a one-dimensional fluid model which is similar to the one used in our previous work [6-8]. The code includes a self-consistent treatment of hydrodynamics, laser energy absorption and interaction with the ambient medium. A novel feature of the code used here is the radiative cooling of the expanding plasma, which proves to play a major role in the plasma evolution.

We have considered three pulse durations (τ): one in the ultrashort regime (100 fs), one in the intermediate-pulse regime (270 ps) and one in the usual long-pulse regime (8 ns) for a laser fluence of 20 J/cm^2. We have also considered fluences from somewhat above the ablation threshold (~0.1 J/cm^2) [9] to ~30 J/cm^2 for a pulse duration of 100 fs. Our investigations were carried out using solid aluminum targets in air at atmospheric pressure and a 0.8 μm laser wavelength (Ti:Sapphire) for the 100 fs and 270 ps pulses, and a 1.064 μm laser wavelength (Nd:YAG) for the 8 ns pulse.

2. Experimental

All the measurements presented in this paper were performed at room temperature in air at atmospheric pressure. For the 100 fs and 270 ps pulses considered here the beam was focused on the target at an incidence angle of 20° from the normal using a quartz lens (f = 50 cm). The emission spectrum (from which the electron density and temperature were extracted) was measured by observing the aluminum plasma perpendicularly to the target surface, i.e., along the expansion axis of the plasma, using a gateable intensified charge-coupled device (Andor ICCD) coupled to a 50 cm Czerny-Turner spectrometer (Spectra Pro 500i, Acton Research Company) equipped with a 3600 gr/mm grating. Time-resolved emission spectra were obtained by controlling the time delay, denoted t_d (i.e., the time at which the plasma emission starts to be recorded), with respect to the laser pulse and the integration time (following the time delay, t_d), by means of an EG&G delay generator. The ICCD dark current was automatically removed from the emission signal for each measurement. The measurements consisted in accumulating the data for 100 successive laser shots. More details are given in Ref. [5]. The setup for the 8 ns pulse measurements is explained in Ref. [10].

The shape of the lines used for the diagnostics is well fitted by a Voigt profile, which suggests that self-absorption is negligible for the lines considered in this study. The peak intensity, the full width at half maximum (FWHM), and the center wavelength of each line were determined together with the continuum emission for each emission spectrum recorded. The excitation temperature and the electron density determined in our study are space integrated.

3. The numerical model

The code used here is a one-dimensional fluid model which includes a self-consistent treatment of: (i) absorption of the laser energy, (ii) hydrodynamics, (iii) thermal conduction, (iv) electron-ion energy coupling (implying that the ion temperature and the electron temperature are treated separately), (v) shock wave generation in ambient air and (vi) radiative transfer and losses at the interface between plasma and air.

Fluid equations for the conservation of mass, momentum and energy are solved through a one-dimensional Lagrangian scheme. The model also includes a realistic equation of state in order to describe thermodynamic properties (pressure and internal energy as a function of density and temperature) over the various states of the matter ranging from solid to plasma. In this paper, we have described the ablation step using the equation-of-state model QEOS (Quotidian Equation Of State) [11] while SESAME [12] is rather used for the expansion phase.

A particular feature of the code used for this paper is that radiative transfer and losses to the ambient medium are taken into account. Difficulties linked to the solution of equation of radiative transfer lead us to use the diffusion (or Eddington) approximation in which the radiative energy flux is proportional to the gradient of the radiative energy density u_v [13]. We have checked that the radiative energy flux thus obtained is always much smaller than the free streaming value cu_v (where c is the speed of light), this being a necessary condition for the validity of the diffusion approximation. We have used ten energy groups for photons, the absorption coefficient for each photon energy group being given by tables of Ref. [14]. Particle inter-diffusion between the plasma and the air has been neglected because the characteristic time scale for the diffusion process is much longer than that considered here.

The expansion of laser plasma plumes into the ambient gas is realistically an axisymmetric two-dimensional problem, but a full code for such a problem would be very costly and cumbersome for the long time scale of interest here (~10 μs). At very early times, one can assume roughly one-dimensional Cartesian expansion as long as the expansion distance is smaller than the focal spot diameter. At very late times, long after the laser has finished, the expansion can be reasonably considered as hemispherical expansion [15]. We ran the code with both geometries which can be seen as two limiting cases. The two cases are shown in Fig. 1, where the spot size on the flat target and the energy gives the fluence. In the spherical case the spot size has the same area on a hemispherical surface.

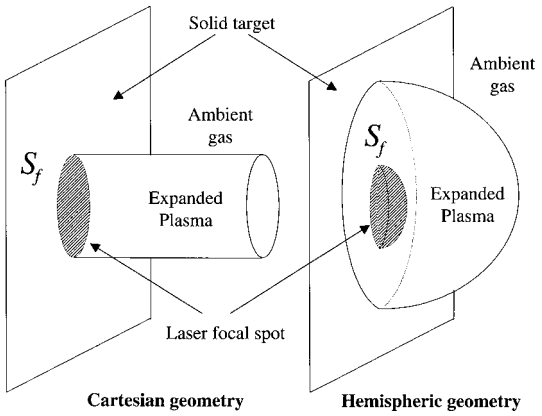

Fig. 1: The two plasma expansion geometries (Cartesian and hemispherical) used in our one-dimensional simulations.

4. Results

The plasma expansion is typically followed over times ranging from 100 ns to a few tens of μs. For light detection delay times shorter than 100 ns, the signal-to-noise (line-to-continuum) ratio is too small (i.e., the continuum emission dominates the lines) to provide useful spectroscopic information to determine the plasma properties. For longer delays (i.e., typically more than a few tens of μs, dependently of the emitted species of interest and of the pulse duration), the plasma emission has decreased so much as to be too small to provide usable results.

In order to make a comparison of the simulation results with our space-integrated measurements, we have replicated the experimental procedure on the model by integrating the appropriate line intensity emitted by each portion of the plasma. (We assumed that the plasma is optically thin for the lines considered and that the direction of observation has no importance.) We have then extracted from this space-averaged line signal the values used to infer the temperature and the electron density using the same methods as those used for treating the experimental data. To calculate the appropriate species densities, we solved the Saha equations and used as input parameters the atom density and the plasma temperature provided by the code.

4.1. Average plasma temperature as a function of the pulse duration

The average temperature was determined using a Boltzmann plot for a set of eight atomic lines of Fe(I) (element initially present with a concentration de 0.7% in the aluminum target). For optically thin plasmas, the intensity of a given line depends of the population of the excited level. For a plasma at LTE, the Boltzmann law links the total density to emitted species density (neutrals or ions).

Figure 2 shows the plasma space-averaged temperatures obtained from our measurements and from our code as a function of time, for the three pulse durations τ = 100 fs, 270 ps and 8 ns, and for the single fluence of 20 J/cm^2. A comparison of the measurements for all the pulse durations considered here shows that at early times, the plasma temperature is larger for longer pulses. Nevertheless, for sufficiently late times (more that a few microseconds), we observe that the laser pulse duration has little influence on the plasma temperature. At about 10 μs, the obtained temperatures for all pulse durations reach the common value 4000-5000 K, and therefore all the temperatures decrease together.

In Fig. 2, the code results are seen to agree well with measurements for the pulse durations presented here, considering the estimated experimental errors (about 20 %). For the average temperature, the choice of the expansion geometry proved to be irrelevant, since very similar results have been obtained in both cases. This result suggests that the calculation of the average temperature does not require a full two or three dimensional treatment and can be done using a one-dimensional model, as the one used here. The temperatures predicted by our model are however somewhat lower (a few percent) than the experimental results, for all times presented here. These discrepancies probably result from an overestimation in the code of the plasma radiative losses, due to the validity limits of the diffusion approximation for the plasma

studied and also from the opacities used, which could be underestimated. One observes a significant divergence of the temperatures obtained for the different laser pulses at short times. The fact that the temperature is initially higher for longer pulses is a consequence of the absorption of the laser energy in the expanding plasma. For short pulses, laser energy absorption occurs near solid density in strong electron density gradients and is less efficient for that reason [8]. The decrease of the temperature with time is naturally due to the fact that when the laser pulse has ended, no more energy is being supplied to the plasma which can then only cool down. In our simulations, the plasma can lose energy by pushing the ambient air (pressure forces work) and by emitting radiation. Radiative cooling rate decreases rapidly with decreasing plasma temperature. This is the main reason why the average temperatures evolves asymptotically in the same way for all pulse durations. This effect also explains why the temperature does not depend on the expansion geometry even though the spatial profiles differ considerably when considering one geometry or the other.

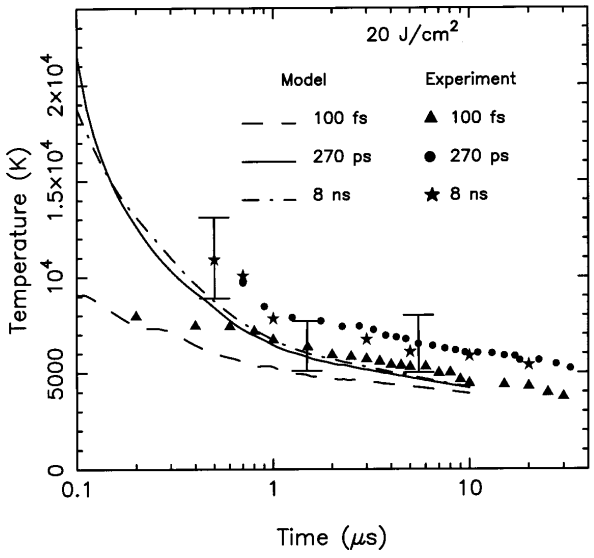

Fig. 2: Plasma space-averaged temperature as a function of time for several pulse durations. The simulation results were obtained using the Cartesian or hemispherical plasma expansion geometry. The laser fluence is 20 J/cm^2.

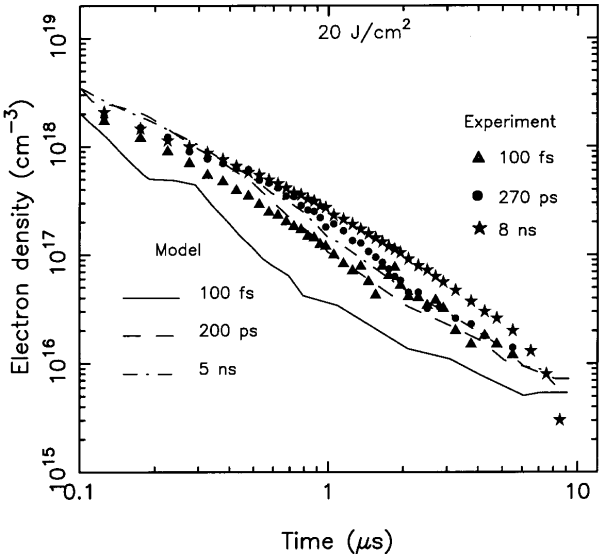

Fig. 3: Plasma space-averaged electron density for several pulse durations. The simulation results were obtained using the hemispherical plasma expansion geometry for the same laser parameters as in Fig. 2.

4.2. Average electron density as a function of the pulse duration

The average electron density was determined by using the Stark effect broadening formula $\Delta\lambda_{1/2} \approx 2Wn_e$, where $\Delta\lambda_{1/2}$ is the full width at half maximum of the Stark broadened line profile, n_e is the electron density and W is the electron impact parameter [16]. The Al II line at λ = 281.62 nm and the neutral Mg line at λ = 285.21 nm have both been used for determining the electron density [5].

Figures 3 shows the plasma electron density obtained from our measurements and from our code as a function of time, for the three same pulse durations as those used for temperature measurements (Fig. 2). A comparison of the electron density obtained for the various pulse durations shows that the plasma electron densities are so similar that we can conclude that for the delays considered here, the plasma electron density does not depend on the laser pulse duration. Typically, the electron density decreases quickly with time from a few 10^{18} cm^{-3} at 100 ns until a few 10^{15} cm^{-3} at 10 μs. This behavior was expected, since we have shown earlier that the temperature weakly depends on the pulse duration.

One observes in Fig. 3 good agreement between the measurements and the simulation results. As for the temperature, shown in Fig. 2, the electron density weakly depends on the expansion geometry chosen in the

simulations although the dependence upon this choice is more significant for the electron density than for the temperature. In Fig. 3 the hemispherical expansion geometry was selected since a somewhat better agreement with experiments is obtained than for the Cartesian geometry.

4.3. average plasma temperature as a function of the laser fluence

We investigate here the influence of the laser fluence on the average temperature for a given pulse duration. Since the temperatures given by our model are very similar for delays higher than a few hundreds of nanoseconds, whatever may be the pulse duration, we will only show results obtained for a 100 fs pulse.

Figure 4 shows the temperature as a function of the laser fluence obtained at several delays (t_d = 1, 5, 10 μs) after the laser pulse for a pulse duration of 100 fs.

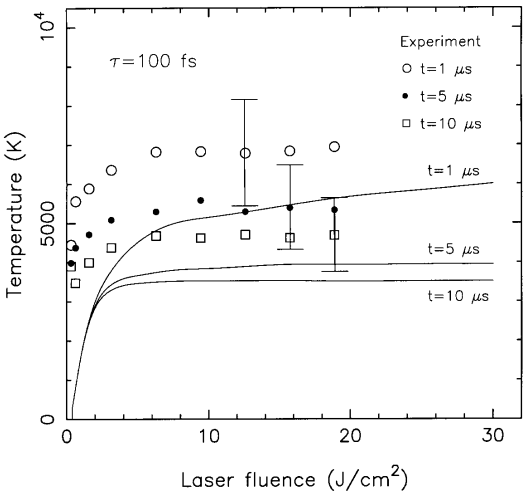

Fig. 4: Space-averaged temperature as a function of the laser fluence obtained from measurements and from simulations (full lines) at the delays t_d = 1, 5 and 10 μs after the laser pulse for a 100 fs pulse. Estimates of the experimental uncertainties are shown for each pulse duration.

One observes in Fig. 4 that the plasma temperature increases with the laser fluence and reaches a saturation value that depends on the observation delay. As the delay decreases, the temperature saturation value increases and occurs at an increasing fluence. This behavior is in agreement with other experimental investigations. In particular, in Ref. [4], it is shown that the temperature of a plasma created by ablation of a steel target with a 140 fs pulse increases with the laser fluence for delays of the order of 1 μs. In [3], experiments show that the temperature and electron density of steel plasmas are nearly independent of the laser fluence beyond a few microseconds, for 15 ns pulse.

In the framework of our model, the saturation of the temperature as a function of the fluence is basically due to the rapid increase of the radiation emission with the temperature. As the fluence increases, the plasma temperature tends to increase since more energy is absorbed in the plasma. However, radiative cooling strongly restricts this temperature increase. The temperature saturation values obtained from the simulations for the given delays are in qualitative agreement with measurements although, as mentioned in Sec. 4.1, the temperatures given by the code are always slightly underestimated. Moreover, the threshold fluence at which the saturation value is obtained is smaller in the experiments than in the code. The latter discrepancies could be simply due to the different definitions used for the fluence for radial Gaussian pulses since one notes that multiplying the experimental fluences by a numerical factor of about 4 (which could result from an overestimation of the focal spot diameter by a factor of 2) in Fig. 4 would improve the agreement.

5. Conclusion

In this paper, we have presented both measurements and results from our simulation code for the time-evolution of aluminum plasmas induced by laser ablation in ambient air at atmospheric pressure. The

simulations show that, for sufficiently long delays (typically more than a few hundred nanoseconds), the laser pulse duration and fluence have little influence on the temperature and the electron density obtained. This behavior, which is in agreement with experiments, can essentially be explained by an increase of the plasma radiative losses with the plasma temperature, and does not occur when radiation loss is neglected.

We have also observed that for short delays, the temperature increases with the laser pulse duration and the fluence while the electron density weakly depends on the pulse duration. Using our code, this observed behavior can be explained by the more efficient absorption of long pulses with respect to short pulses, which results in an initially hotter plasma. Despite the assumptions made in our one-dimensional model (simplified treatment of geometry rather than a full two-dimensional treatment, no exchange between the plasma and ambient air, etc.), the simulation results obtained are in good agreement with our experimental results and literature. Nevertheless, the calculated mean temperature seems to be slightly underestimated for long delays (more than a few microseconds) in comparison with experiments, which can be explained mainly by overestimation of the radiative losses in our model. It is interesting to note that the choice of the expansion geometry has little affects on the results obtained for space-average quantities. More insight in the plasma properties will be provided by taking into account the radial expansion in the framework of a two-dimensional model.

Temperature Effects in Nucleation and Transport of Particles in Silane Plasmas

U. Bhandarkar, S. Warthesen, S. Girshick, U. Kortshagen

Department of Mechanical Engineering, University of Minnesota, Minneapolis, USA

ABSTRACT

Novel properties of nanoparticles can be exploited if they can be generated to meet specific requirements. Towards this end, we have developed models to understand the growth and transport of particles in plasmas. In this contribution we discuss how the gas temperature of the discharge can be utilized to control nucleation as well as diffusive and thermophoretic transport in such plasmas. The results give valuable clues on methods to control particle size and direct their transport.

I. INTRODUCTION

For a long time particle formation in plasmas has been considered mainly as a contamination process that needed to be avoided. However, more recently a more favorable view of particles in plasmas has emerged with the realization that if particles are tailor-made to meet certain specifications, their novel properties can be exploited. One such example is the plasma deposition of silicon thin films that are used in the manufacture of solar cells. Amorphous hydrogenated silicon films – a standard material for thin film solar cells – are susceptible to light induced defect creation that leads to a deterioration of the solar cell efficiency on exposure to sunlight [1]. Roca i Cabarrocas and co-workers [2, 3, 4] have claimed that nanostructured silicon thin films deposited using a capacitive plasma show improved electronic properties due to the inclusion of silicon clusters (less than 1 nm in size) and nanoparticles in the 1-3 nm size range. The most significant aspect of the improved properties is that these films show increased stability against light-induced defect creation and are thus promising materials for solar cells.

However, the generation of particles with required size and composition is in itself insufficient. For maximum benefit, it is also necessary to selectively transport the nanoparticles once they have been generated. For example, Fontcuberta *et al.* [3] have claimed that the thermophoresis effect can be used effectively to transport particles in the 1-3 nm size range to the substrate.

This leads us to the conclusion that it is necessary to obtain a thorough understanding of particle growth and transport processes in plasmas. Significant experimental progress has been achieved in recent years. A particularly important observation is that particle formation in plasmas can be delayed with an increase in the neutral gas temperature [5, 6]. Similarly, the above stated example of thermophoresis is extremely important for transporting particles towards a surface. To help understand these processes from a fundamental point of view we are developing models to study the formation and transport of particles in low-pressure plasmas. In this contribution we describe recent progress on two models that were developed to address the above problems. A quasi 1-D plasma chemistry/particle model is used to study the delay of particle nucleation with increasing gas temperature. Particle transport is studied with a Monte Carlo code.

II. Plasma Chemistry/Particle Model

Our plasma chemistry/particle model is a quasi 1-D model (0-D with a diffusive loss term) that comprises three different modules coupled in a self-consistent scheme. These modules are:

1) A chemistry module that describes the clustering of silicon hydride species with up to ten silicon atoms. A detailed description of this module is available in a previous publication [7]. Silicon hydride species with more than ten silicon atoms are considered to be “particles” and are assumed to form irreversibly. Such particles form the source term for the next module.

2) A particle growth module that solves for the growth of particles due to coagulation and surface reactions. This model divides a particle volume range spanning six orders of magnitude into 180 sections based on a logarithmic scale. Such "sectional models" are common in the aerosol literature [8]. Our present module also takes into account the charging of particles in the plasma and the corresponding effect on coagulation. The basis of this model without surface growth has been described in ref. [9].

3) A plasma module that is coupled to both the modules described above. This module utilizes the plasma quasi-neutrality condition and also solves for the balance of positive ions and input power into the plasma. As a result we obtain plasma parameters such as electron density, positive ion density and the electron temperature.

Diffusion and pumping constitute loss terms for neutral silicon hydride clusters and particles. Diffusion coefficients are calculated using Chapman-Enskog theory [10] and assuming one predominant species in the background gas mixture (usually Ar and silane). Positive ions and positively charged particles are subject to ambipolar diffusion whereas the anions and negatively charged particles are assumed to be trapped in the plasma.

This model was used to study the effect of gas temperature on the nucleation of particles. To this end, we simulated the experiments performed by Boufendi *et al.* [5] using a capacitive discharge at 117 mTorr pressure utilizing an Ar-SiH_4 mixture in the ratio 96.2:3.8. Gas temperatures used were 20 ^{o}C, 80 ^{o}C and 120 ^{o}C. The authors used Laser Induced Particle Explosive Evaporation (LIPEE) to study the onset of nucleation as a function of gas temperature. This technique relies on evaporating small particles using an intense laser beam and measuring the emitted radiation. Using a simple model they concluded that the emission was proportional to the fourth power of the particle size. Figure 1 shows the results of the LIPEE experiments, which clearly show a delay of the LIPEE signal with increasing gas temperature. We used our model to study mechanisms that had previously been proposed as potential explanations for this effect, such as quenching of vibrationally excited species that propagate fast clustering [6], the temperature dependence of electron attachment to form anions [11], and gas density related effects [12]. In addition, we paid particular attention to the temperature dependence of diffusive losses and the surface growth of newly formed sub-nanometer particles. To distinguish between the contribution of previously proposed mechanisms and that of diffusion and surface growth, we performed two sets of calculations at the higher temperatures (i.e., 80 ^{o}C and 120 ^{o}C), one set wherein all calculations were carried out at the prevailing gas temperature (called "complete") and another set where the diffusion coefficients of all species and particles were calculated assuming a temperature of 20 ^{o}C while all other reaction rates were calculated at the prevailing gas temperature (called "fixed-D"). We found that the "complete" set of calculations led to a dramatic drop in particle density as gas temperature increased, whereas the "fixed-D" set showed only a small difference for the three gas temperatures. This immediately points to the fact that the temperature dependence of diffusion

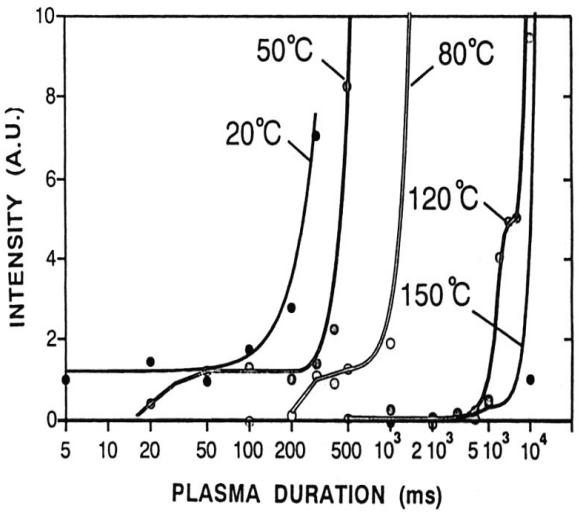

Figure 1: Temperature dependence of particle generation in 3.8 % silane in argon, 117mToorr from Ref 1.

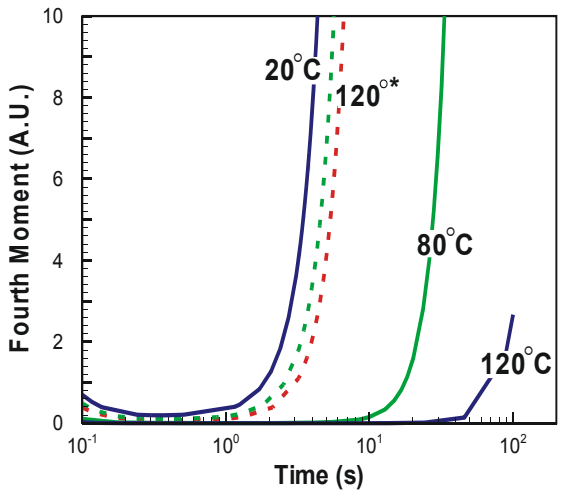

Figure 2: Simulated LIPEE signal for the same conditions as in Figure 1. Dotted lines represent "fixed-D" simulations, while solid lines indicate the "complete" results

coefficients plays a key role in the particle growth process since the only difference between the two sets is the manner of calculation of the diffusion coefficient. This is convincingly shown by comparing the simulations to the experimental data. We calculated the fourth moment of our simulated particle size distribution (Fig. 2) for comparison with the experimental LIPEE signal (Fig. 1). The "complete" simulations show qualitatively the same delay of nucleation as the experiments, while the agreement in the "fixed-D" calculation is poor.

A simple explanation for the drastic effect is as follows. Small particles in the sub-nanometer regime can be charged negative, neutral or even positive. The neutral and positive fractions are liable to be lost by diffusion whereas the negative fraction is trapped. To remain completely trapped in the plasma the particles need to achieve a "safe" size of around 2-3 nm at which point most of the particles become negatively charged. An increase in gas temperature (T_g) leads to an increase in the diffusion constant (D) of surface growth radicals as well as the subnanometer size particles ($D \propto T_g^{3/2}$). The increased loss rates of surface growth radicals slows the growth of particles to the safe size during which time the particles also experience an increase in loss rate due to an increase in their own diffusion coefficients. This dual effect of slower growth rate and faster loss rate leads to an exponential decrease in the particle concentrations that can participate in further growth processes. Thus temperature dependent diffusion plays a crucial role in the growth and transport of sub-nanometer particles and can be an effective tool to control particle sizes.

III. Monte Carlo Transport Simulations

To explore the transport of nanoparticles in a plasma a Monte Carlo transport model was developed. The Monte Carlo approach utilizes random numbers and probabilities to simulate individual collisions between a nanoparticle and surrounding plasma species. The nanoparticle velocity and position are recorded in time, and statistics are gathered over large numbers of particles to indicate general transport trends. The system modeled is a parallel plate reactor with gradients existing in the axial direction between the two electrodes, and the domain is modeled as radially infinite. The plasma species included in the model are electrons, positive ions, and neutral gas molecules. The electron and ion density profiles are determined by a fluid model and are undisturbed by the nanoparticles. The gas velocity profile is treated as one-dimensional stagnation-point flow, and is also unaffected by the presence of nanoparticles. Nanoparticles are assumed to be spherical and interaction among particles is not considered. The algorithm used in this Monte Carlo code is simply to move a particle in space for time *dt*, according to its known velocity components, then to simulate an instantaneous collision resulting in the transfer of momentum and/or charge to the nanoparticle.

The probability of a particle traveling for time *dt* between collisions is represented by a randomly generated number, R_1. The time between collisions is recalculated after each collision according to Equation 1.

$$dt = -\ln(1 - R_1)\left(\frac{1}{\nu_{\max}}\right) \qquad (1)$$

The maximum collision frequency, ν_{max}, is the sum of collision frequencies for a nanoparticle with each of the three plasma species. The electron-particle collision frequency is proportional to the electron current to the particle. This is determined by applying orbital motion limited (OML) theory, assuming that the nanoparticle behaves as a spherical probe. The particle potential required for this calculation is a function of particle charge. The collision frequency for an ion and a charged nanoparticle is calculated similarly, using the equation for ion current to a spherical probe [13]. Langevin collision rates are applicable to ion-molecule collisions, and thus are used to calculate charged particle-neutral molecule and neutral particle-ion collision rates [11]. One tenth of the Langevin collision rate is used in the simulation since the Langevin rate is an upper bound, which tends to overestimate collision rates by roughly an order of magnitude [7]. The collision frequency between neutral species is calculated using the Lennard-Jones collision diameter and potential in an equation for bimolecular reaction rates, treating the nanoparticles as large molecules [11].

After a particle has traveled for time *dt*, an instantaneous collision is simulated. A random number is generated to determine which species is colliding with the nanoparticle, based on their respective collision

frequencies. Collisions with an electron or an ion result in a transfer of one charge unit, neglecting the ion drag force. The charge on a particle is not allowed to exceed a calculated maximum charge based on the particle size [14]. When the nanoparticle collides with a neutral gas molecule, the result is a transfer of momentum between the species, changing the particle velocity components. In a momentum transfer collision, it is necessary to determine the direction and velocity of the incoming gas molecule. A gas molecule colliding with the particle is assumed to have traveled one gas mean free path since its last collision. Thus, the density and energy of the possible collision partners are determined by using the gas temperature at a location one mean free path from the nanoparticle, in any direction surrounding the particle. The temperature at this location is provided by the temperature profile. The probability of the nanoparticle being hit from a specific direction is proportional to the gas density calculated in that location. The pre-collision speed of the molecule is assigned as the average velocity of a Maxwellian distribution, $(8k_BT_g/\pi m_g)^{1/2}$, using the gas temperature at the appropriate location.

The location on the particle surface where the collision occurs is also based on probability and determined by using a random number. The reflection of the gas molecule off the surface can be either diffuse or specular (a ratio of 9:1, respectively, is applied here [15]). In a diffuse collision, the direction of the departing gas molecule is again determined through the use of random numbers. In a specular reflection, the angle of reflection is equal to the angle of incidence. The post-collision velocity of the particle is determined by conserving momentum and energy.

Diffusion is inherent in this method, and under conditions of pure diffusion (constant temperature and no directed gas flow), the particle is equally likely to be hit by a gas molecule from any direction, and the energy of the molecules, relating to the amount of momentum transferred, is the same regardless of their position. Thermophoresis is incorporated when a temperature gradient exists. The density of molecules is greater on the colder side of the particle; thus collisions from this side are more probable. However, the energy of the molecules on the hot side of the particle is higher, thus more momentum will be transferred to the particle from a gas molecule approaching from this direction. The net momentum transfer pushes particles towards lower temperatures. Gas drag is incorporated by adding a velocity component (varying spatially) to the gas molecules in the direction of gas flow, increasing the net momentum transfer in that direction. The electrostatic force is incorporated during the time between collisions. The velocity components of a charged nanoparticle change as it is accelerated by the electric field. The algorithm of moving the particle then allowing a collision to occur, is repeated for one nanoparticle until it has reached the upper or lower plate, or until the desired amount of time is simulated.

Using this code, we study the transport of particles in the 1-10 nm size range in the presence of temperature gradients. The parameters applied to the Monte Carlo transport model simulate the experimental conditions used by Fontcuberta *et al.* in a study of polymorphous film production [3]. In this study, the temperature gradient was varied between the upper and lower electrodes of a parallel plate reactor while holding other parameters constant, and the resulting film was characterized. At 1400 mTorr, with a gas flow rate of 140 sccm hydrogen and 3 sccm silane, the temperature of the film substrate was held, in almost every case, at 450 K while varying the temperature of the second electrode. The electrode separation distance was most commonly set to 2 cm. At weak (or positive) temperature gradients, deposited films were characterized as polymorphous and were found to contain nanocrystallites around 3 nm in diameter. As the strength of the temperature gradient increased, a critical temperature gradient of -50 K/cm was observed above which the resulting films no longer exhibited the properties of polymorphous films. This result has been partially attributed to the thermophoretic effect, that a strong temperature gradient will overcome the gas drag force to transport particles away from the hot film substrate, thus preventing their deposition.

A series of simulations have been carried out to investigate the transport properties under these conditions. In this series, the nanoparticles of interest are those deposited in the film. The following results consider only neutral particles since negatively charged particles are electrostatically trapped in the plasma, and are thus unavailable for deposition. Positively charged particles are not considered in this series. Figure 3 is a diagram of the model domain, describing the simulation input parameters. Nanoparticles are assigned the density of bulk silicon, 2.33 g/cm^3, and are initially distributed randomly between the upper and lower electrodes. Within a simulation time of 5 milliseconds, many particles have left the discharge by reaching

either the upper cold electrode or the lower electrode, the latter representing deposition of the particle into the film. Figure 4 shows the fraction of particles deposited on either electrode as the temperature gradient is varied, for particles of 1, 3, and 10 nm in diameter. Each symbol is an average over hundreds of particles, and lines connecting the symbols are drawn to guide the eye.

At weak (or zero) temperature gradients, particles of all sizes show relatively small preference for one electrode over the other. As the magnitude of the temperature gradient is increased, the particles are more likely to have been deposited on the cold (upper) electrode, indicating that the thermophoretic force has transported particles away from the hot substrate towards the cold electrode. This trend is most drastic for 10 nm particles, and the effect decreases with decreasing particle size. 1 nm particles are transported almost equally to both electrodes for all temperature gradients, showing only a slight variation in their distribution with the changing thermophoretic force. However, thermophoretic velocity is independent of size [14]. Gas drag is also included, but has a negligible effect on particle transport under these conditions. This indicates that Brownian diffusion, a size dependent transport mechanism, plays a large role in the transport of the smallest nanoparticles. For 3 nm particles, diffusion causes some particles to move against the thermophoretic force, but the influence of the thermophoretic effect is still apparent. Simulation results agree with those indicated by the experiments in ref. [3], that the transport of particles 3 nm and larger are controlled through the adjustment of the gas temperature gradient. Considerably fewer particles are deposited in the film as the temperature gradient becomes stronger. However, thermophoresis does not significantly influence the transport of 1 nm particles, which are dominated by diffusion.

IV. CONCLUSION

A quasi one-dimensional plasma chemistry/particle model has been developed to explore the experimentally observed temperature dependence of nucleation onset time. The simulations indicate that, with increasing temperature, an increased diffusion loss of surface growth radicals and sub-nanometer particles slows the growth of particles, thus delaying the onset of nucleation. The effect of temperature gradient has been studied in regards to particle transport using a one-dimensional Monte Carlo simulation, under the conditions of polymorphous film growth. These simulations indicate that thermophoresis can indeed be a dominant transport mechanism for particles larger than a few nanometers in size. However, as particle size decreases, diffusion becomes the dominant transport mechanism. These numerical investigations provide insight into the experimentally observed importance of both temperature and the presence of a temperature gradient, in controlling particle nucleation, growth, and transport in a low-pressure plasma.

Transport of nitrogen atoms in pure molecular nitrogen at atmospheric pressure

M. Ganciu [1,2], J. Orphal [3], M. Vervloet [3], A.-M. Pointu [1], M. Touzeau [1]

A new type of discharge [1] (high purity N_2 at atmospheric pressure, point-point electrodes in a special configuration, some 10 kV fast pulses of some 10 kHz, flow rate ≈ 500 cm^3/sec) able to generate a large flux of nitrogen atoms at atmospheric pressure, proved the possibility to transport nitrogen active species over long distances (more than 10 meters in a polyamide tube with an internal diameter of 6 mm). We report investigations concerning the mechanism that is responsible for this transport.

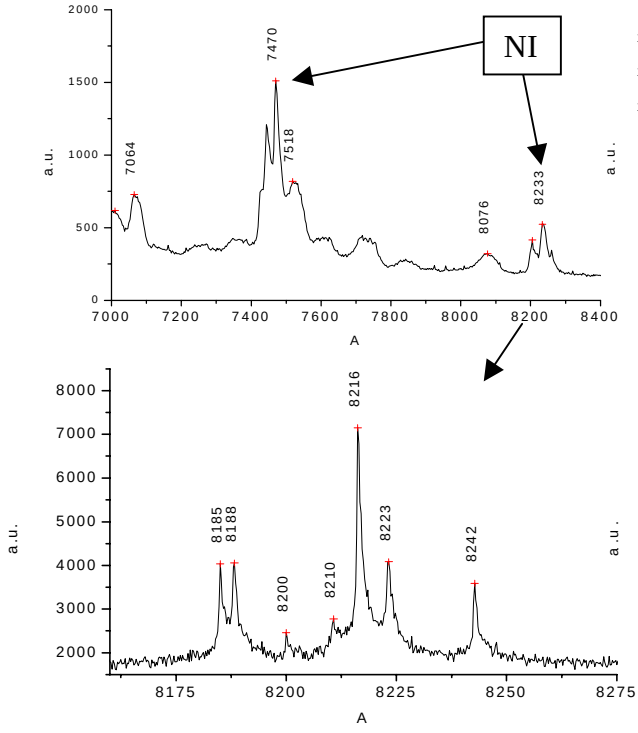

Fig 1. Emission spectrum of the discharge

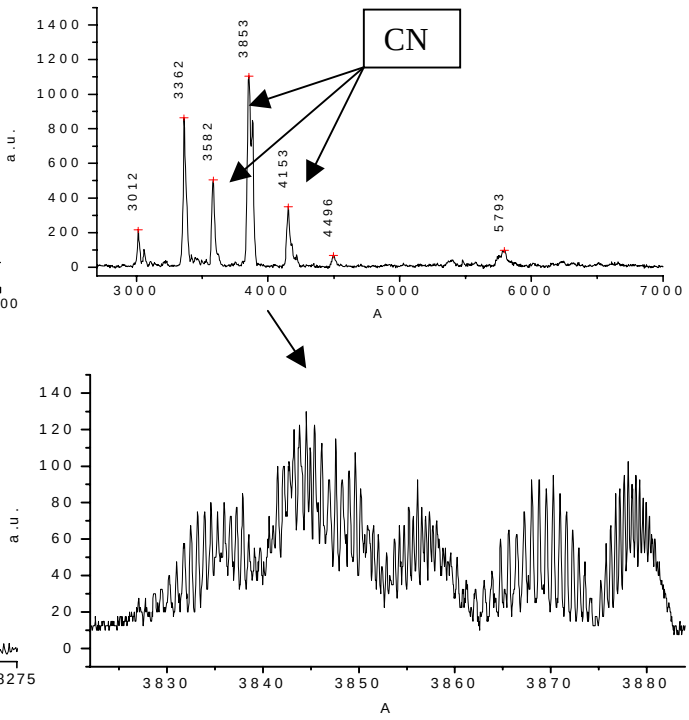

Fig 2. Emission spectrum of the post-discharge (1 m from the discharge)

Nitrogen atom concentrations are estimated by measuring the O_3 concentration when O_2 is introduced in the post discharge flow. For an N_2 (N50 purity) flux of about 500 cm^3 s^{-1}, using 15 W average power of applied electrical pulses, a nitrogen atom concentration of about 4×10^{14} cm^{-3} was estimated in the afterglow at 20 cm from the discharge. This measurement is compared with classical NO titration. The role of tube material, length, and internal diameter for nitrogen atom transport is discussed. The results are in agreement with main N atom losses by volume recombination and with the hypothesis that, at high pressure the surface recombination coefficient for N atoms is reduced [2]. The temperature of the post-discharge is about 300 K as shown by the CN rotational band (0-0) contour. A simple model of nitrogen atom transport is presented.

Abstract
Hydrogenated amorphous silicon thin films with nanocrystalline inclusions are synthesized via an RF capacitively coupled discharge using a mixture of helium and hydrogen diluted silane. Films with an increasingly nanocrystalline morphology show improvements in the optical absorption coefficient Urbach slope. However despite a sharpening of the band tail states, photosensitivity measurements indicate significant light-induced defect creation.

1. Introduction

One of the most promising materials for application in cost effective, efficient photovoltaic cells is plasma deposited hydrogenated amorphous silicon (a-Si:H). Amorphous silicon films can be deposited over large areas and have a higher optical absorption coefficient for visible light than that of crystalline silicon. However, extended illumination of a-Si:H solar cells results in the formation of metastable defects [1], known as the Staebler-Wronski effect, thereby dramatically decreasing the efficiency of the photovoltaic device. Hydrogenated amorphous silicon thin films with nanocrystalline inclusions (a/nc-Si:H), also sometimes referred to as "polymorphous", have attracted considerable attention recently due to reports of superior electronic properties combined with an improved resistance to light-induced defect formation [2-7].

In this study, a/nc-Si:H films are deposited by a radio frequency (RF) plasma enhanced chemical vapor deposition (RF-PECVD) using a mixture of helium and hydrogen diluted silane. Conditions are similar to those reported by Roca i Cabarrocas *et al.* [2, 5] in that they are at the edge of powder formation. In comparison, a-Si:H films are deposited by the same process without hydrogen dilution at a lower pressure and lower RF power. The optical absorption coefficient Urbach slope and the photoconductivity of the films are presented and discussed in relation to analysis of the structural morphology of the films obtained by high-resolution transmission electron microscopy (HRTEM).

2. Experimental Details

A series of films was synthesized using an RF (13.56 MHz) capacitively coupled plasma discharge. The schematic of the reactor is shown in Figure 1. The upper electrode is the RF powered showerhead electrode, through which the gas enters the chamber. The substrates rest on the lower grounded electrode. The electrode area is 200 cm^2. Both electrodes are independently heated to allow for control of the temperature gradient for the process. The various samples were synthesized under the conditions described in Table 1. The a/nc-Si:H films were deposited with an RF electrode temperature T_{RF} = 250^{0}C and substrate temperature T_S=250^{0}C. Nominally amorphous samples were deposited with T_S = 250^{0}C and an unheated RF electrode.

Table 1: Deposition conditions and resulting material

Pressure (mTorr)	Flow Rate SiH_4:He (5:95) (sccm)	Flow Rate H_2 (sccm)	Power (W)	Material
1800	40	100	20	a/nc-Si:H
1450	40	100	20	a/nc-Si:H
250	30	0	5	a-Si:H
100	19	0	5	a-Si:H

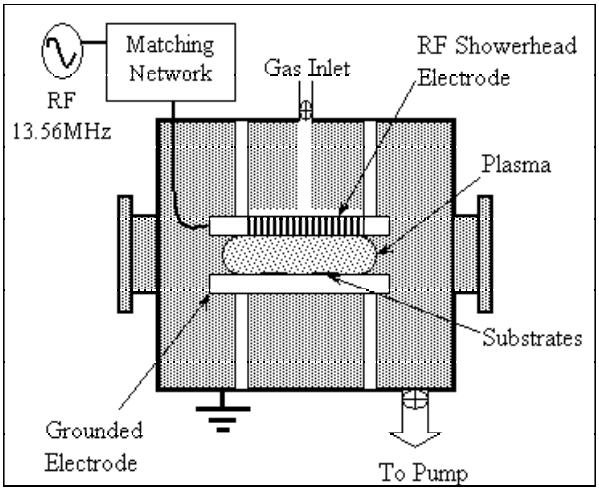

Figure 1: Schematic of RF capacitively coupled plasma reactor chamber

For the purpose of transmission electron microscopy (TEM) studies films with an approximate thickness of 100 Å were deposited on cleaved NaCl substrates. These films were floated off in distilled water and "caught" on a 3 mm copper TEM grid [8]. These samples were then allowed to dry in a dessicator and subsequently analyzed using a Philips CM30 TEM operating at 300 kV.

For the optical absorption coefficient and photoconductivity measurements, films with an approximate thickness of 3000 Å were deposited on Corning 7059 substrates. Two coplanar chromium electrodes either 2 or 4 mm apart were then evaporated onto the film samples. The optical absorption coefficient α of the samples was obtained by the constant photocurrent method (CPM). CPM measurements were performed at room temperature after dark annealing the samples at 170^0C for 1 hour. A tungsten-halogen light source was directed through a monochromator and focused on the sample. A bias of 10 V was applied to one electrode, and the photocurrent was measured from the other. At each incident photon energy hν, the light intensity striking the sample was adjusted to maintain a uniform value of the photocurrent. Thus any dependence of the photo-excitation intensity on the recombination lifetime is eliminated from the measured photocurrent. The optical absorption spectra are acquired by relating the photocurrent to the incident light intensity relative to the transmitted light intensity and film thickness.

The Tauc optical gap E_g is determined from the CPM spectra. The density of states in amorphous semiconductors varies continuously with energy, from a large density of filled or empty states, termed the conduction and valence bands, respectively, to an exponentially decreasing density of strained bond states tailing into the mobility gap, known as the valence and conduction band tails. Additionally, dangling bond states residing in the middle of the mobility gap can either accept or promote photo-excited charge carriers. The absence of a sharp gap in the density of allowed states in amorphous semiconductors results in a smoothly varying spectral dependence of the absorption coefficient. One common technique for extracting the optical gap from the wavelength dependence of the absorption spectrum involves constructing a 'Tauc plot'. In using Fermi's Golden Rule for calculating the absorption coefficient, one assumes that valence band to conduction band absorption predominates, that the density of occupied and empty states varies parabolically with energy, and that there is a constant momentum matrix element connecting optical transitions between bands. In this case, it can be shown that there is a linear relationship between $\alpha^*h\nu$ and the square of the incident photon energy $h\nu$, given by:

$$(\alpha^*h\nu)^{1/2} = B(h\nu - E_g). \quad (1)$$

Figure 2 shows a Tauc plot of the 1800 mTorr sample obtained using CPM. The data is well described by the Tauc expression, with an intercept value of 1.74 eV, the Tauc gap E_g. The absorption coefficient data

that tails off for photon energies less than E_g represents photon absorption due to band tail to band optical transitions. In this case the absorption coefficient can be expressed as

$$\alpha = \alpha_0 \, exp \, [(hv\text{-}E_1)/E_0] \tag{2}$$

where E_1 and α_0 are independent of both thermal and structural disorder. The value E_0 is referred to as the Urbach slope, which reflects the exponentially decreasing density of band tail states. With larger densities of strained Si-Si bonds, the band tail states extending into the mobility gap will be broader corresponding to a large value of the Urbach slope E_0. Therefore E_0 is sometimes used as a figure of merit for the intrinsic order in amorphous semiconductor films.

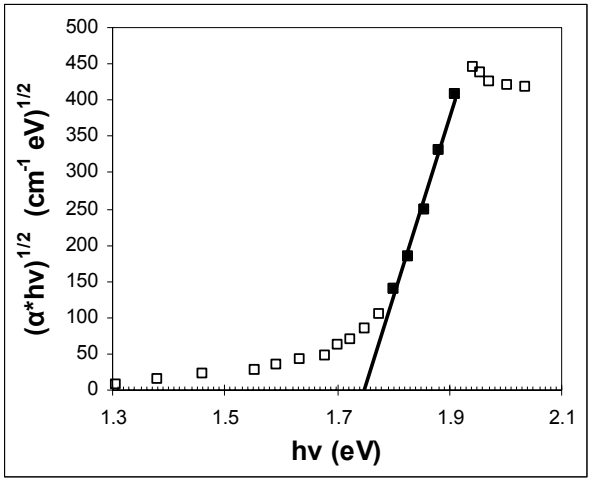

Figure 2: Tauc plot for the 1800 mTorr a/nc-Si:H sample showing a Tauc optical gap *Eg* of 1.74 eV.

The Staebler-Wronski effect was investigated through measurements of the photoconductivity and photosensitivity as a function of light exposure time (light soaking). The photoconductivity σ_{ph} is determined by the measured photocurrent divided by applied voltage and geometric factors. The photosensitivity is defined as the photoconductivity normalized by the dark conductivity: σ_{ph}/σ_d. Prior to measurement, the films were dark annealed at 177 ^{0}C for two hours and cooled at a controlled rate of one degree per minute. These measurements were performed under vacuum at 47 ^{0}C under ~100 mW/cm^2 of heat-filtered white light from a tungsten-halogen lamp.

3. Results

The identification and characterization of amorphous or nanocrystalline materials is a developing field. There are many techniques available for the analysis of structure and medium range order in the TEM [9-11]. The phenomena of scattering from ordered regions with dimensions comparable to the unit cell are still being understood. For this study, displaced-aperture dark-field (DADF) imaging is used to survey the crystalline material in the specimens [8].

A bright-field (BF) TEM image of the a/nc-Si:H sample deposited at 1800 mTorr is shown in Figure 3A. Several dark features are visible on the surface of the film; DADF was used to examine these features. Using DADF regions that satisfy the Bragg diffraction condition at the position of the aperture will appear bright [8]. Two such DF images using different objective aperture positions are shown in Figures 3B and 3C. Here, crystalline particles approximately 5 nm in size are apparent in an amorphous matrix; one such particle is noted in Figure 3B by an arrow.

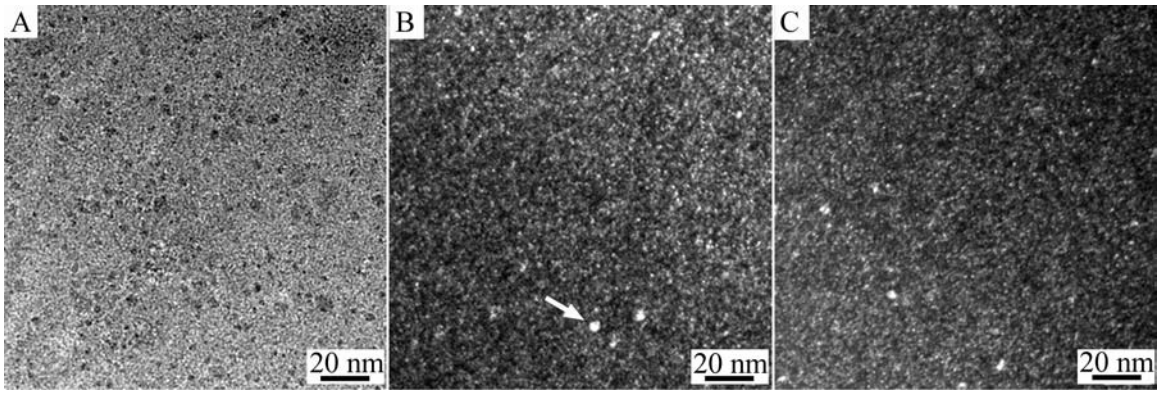

Figure 3: TEM images of the a/nc-Si:H sample deposited at 1800 mTorr. (A) is a bright-field image of a typical region of the film, showing irregular contrast not necessarily indicative of the presence of crystalline material. (B) and (C) are dark-field images using different objective aperture positions. In these images crystalline material appears bright, making crystals approximately 5 nm in size apparent. One such crystal is noted in (B) by an arrow.

A similar analysis is applied to the nominally a-Si:H sample deposited at 250 mTorr. Here, the BF image in Figure 4A shows some uneven contrast features. These are likely due to thickness variations in the film associated with the nature of the NaCl substrate. To examine evidence of crystallinity in the film, the DADF technique was again used. Figures 4B and 4C are images from different objective aperture positions. The lack of bright regions of contrast in these images suggests that if any crystallites are present, they are likely smaller than ~1 nm.

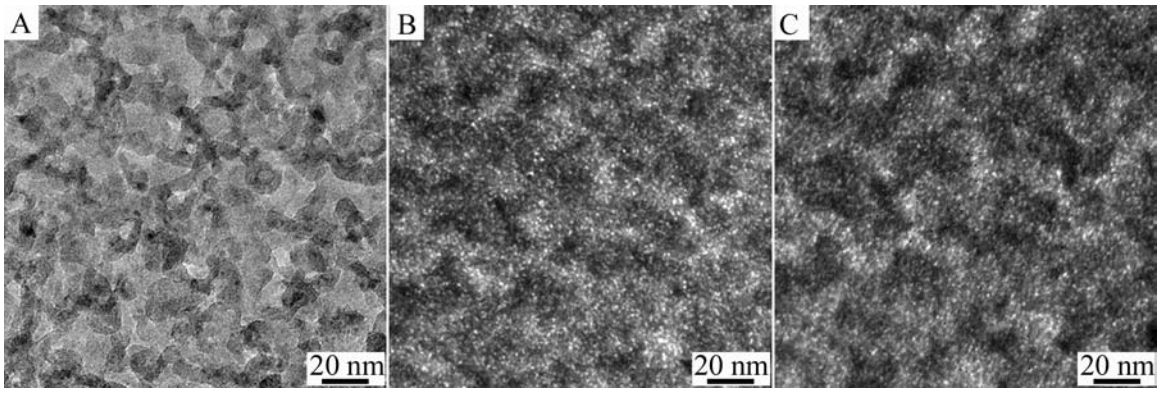

Figure 4: TEM images of the a-Si:H sample deposited at 250 mTorr. (A) is a bright-field image of the film, while (B) and (C) are dark-field images formed from different objective aperture positions. The contrast in the dark-field images suggest that if there is crystalline material present, it is approximately 1 nm or less in size. The contrast features in (A) are likely due to the NaCl substrate used for deposition.

Measurements of the optical absorption spectra Urbach slopes and Tauc optical gaps are presented in Table 2. In comparison to the a-Si:H sample deposited at 250 mTorr, the a/nc-Si:H samples deposited at 1450 mTorr and 1800 mTorr show a slightly smaller Urbach energy and a shrinking optical gap. This is consistent with other studies of a/nc-Si:H films [3].

The 100 mTorr film has an Urbach slope and Tauc gap comparable to a-Si:H, while the 250, 1450, and 1800 mTorr films have larger Urbach slopes and wider optical gaps. Though the 250 mTorr film was deposited with silane diluted only in He, not H_2, its similar optical properties to the 1450 and 1800 mTorr films (grown with H_2 dilution) suggest that there may possibly be ~ 1nm crystallites present in this film. Further studies of these films' properties are presently under way.

Table 2: Comparison of Urbach slope, Urbach energy, and Tauc optical gap of the samples

Pressure (mTorr)	Material	E_o (eV)	T_o (K)	E_g Tauc (eV)
1800	a/nc-Si:H	0.051	598.6	1.74
1450	a/nc-Si:H	0.054	625.8	1.77
250	a-Si:H	0.063	730	1.78
100	a-Si :H	0.038	438	1.69

The photoconductivity measurements as a function of light-exposure time for the 250, 1450, and 1800 mTorr samples are shown in Figure 5. It appears that the kinetics of light-soaking is similar for the three samples. All three films begin with a photoconductivity of a similar magnitude. But saturation occurs sooner for the 1450 and 1800 films in comparison to the 250 film. Not shown is the data for the 100 mTorr film, which had a photoconductivity magnitude and decay comparable to the other films.

Photosensitivity measurements as a function of light exposure time are shown in Figure 6. The a/nc-Si:H 1800 and 1450 mTorr films both show an initial magnitude of photosensitivity that is 2 and 5 times larger compared to the 250 mTorr film, which is in turn a factor of 4 higher than the 100 mTorr film. Additionally, the magnitude of the total decrease of the photosensitivity is smaller for the 250 mTorr film.

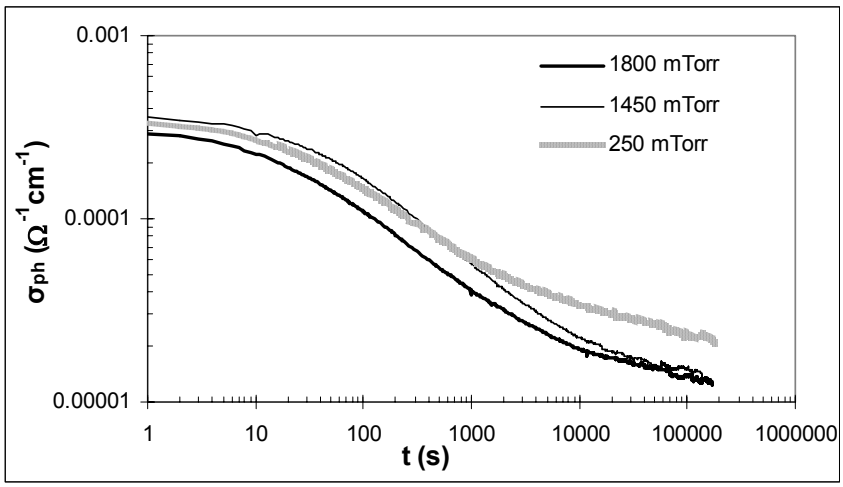

Figure 5: Photoconductivity σ_{ph} of the 1800 mTorr, 1450 mTorr, and 250 mTorr film samples measured against light-exposure time at 47 ^{0}C.

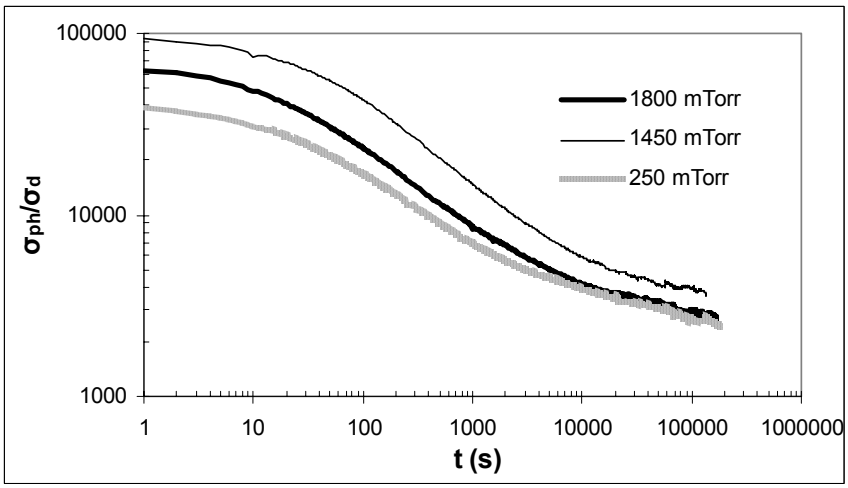

Figure 6: Photosensitivity σ_{ph}/σ_d as a function of light exposure for the 1800, 1450, and 250 mTorr films measured at 47 ^{0}C.

4. Discussion

Several characteristic of the a/nc-Si:H films are comparable with those observed for the a-Si:H film, specifically the Urbach slope and the Tauc optical gap. The Urbach slope of the optical absorption spectra reflects the band-tail density of states. A slight improvement of the Urbach slopes for the a/nc-Si:H films in comparison to the a-Si:H films could correspond to a reduction in the density of strained bonds. Although all three films show a decrease in both the photoconductivity and photosensitivity with extended light illumination, consistent with the Staebler-Wronski effect [1], there exist differences in the magnitude of this effect. The initial values of the photosensitivity of the films with nanocrystalline morphology, the 1450 and 1800 mTorr samples, are 5 and 2 times larger than that of the 250 mTorr sample. But the magnitude of the decrease in the photosensitivity over light-exposure time is larger for the a/nc-Si:H samples as well. Additionally, the a/nc-Si:H films saturate more quickly than the a-Si:H films. It possible that the nanocrystalline morphology of the a/nc-Si:H in comparison to the a-Si:H film is responsible for the variation in electronic properties and the increased rate of light-exposure saturation.

5. Conclusions

Hydrogenated amorphous silicon thin films with nanocrystalline inclusions have been deposited by RF-PECVD. Despite the inclusions of nanocrystallites, the a/nc-Si:H films show electronic properties comparable to the nominally amorphous film. Additionally, the a/nc-Si:H films do display a Staebler-Wronski effect and no significant enhancement of transport properties is observed.

Plasma – catalyst of combustion of low-reactive coals

Petrov S.V., Saakov A.G.

RPE TOPAS Ltd., Kiev, Ukraine

The consistent current trend is to deterioration of the quality of coals supplied to heat-electric generation plants, which is associated with increase in their ash and moisture content, decrease in volatile yield and combustion heat. Contrary to forecasts, this promotes growth of consumption of oil fuel (gas), especially at the coal-dust heat-electric generation plants, used for kindling of boilers and stabilization of burning of the coal dust even under rated loading. In this case, the combined combustion of fuel oil and coal, especially in kindling the coal-dust boilers, results in deterioration of all indicators of power-generating plants, i.e. increase in combustible loss, decrease in gross efficiency of a boiler, growth of yield of nitrogen oxides, increase in high-temperature corrosion of heating surfaces and ejection of sulphur dioxide, as the initial sulphur content of fuel oil is, as a rule, several times higher than that of the coal. In addition, vanadium pentoxide, which is an active carcinogen, is evolved in combustion of fuel oil.

Traditional methods for decreasing the consumption of fuel oil at heat-electric generation plants (increase in dust milling dispersity, high preheating of the air mixture and secondary air, etc.), used to improve fuel ignition and burning stabilization, have exhausted themselves. Therefore, a radical increase in the efficiency of utilization of fuel can be related only to development and mastering of absolutely new technologies. The plasma technology seems to hold the highest promise among the alternative technologies available for solving the above problems. This technology provides a substantial increase in cost effectiveness and improvement in environmental indicators of power-generating plants working with solid fuel.

As shown by numerical estimations, relative energy power of an electric lighter, related to the heat power of a gas stove burner, is 0.001 %, relative power of an electric candle is 0.01 %, relative power of the plasma torch in ignition of the fuel oil flame is 0.05 %, and that in ignition of the coal dust flame is 0.5-1.0 %.

Using such combined plasma-coal torch devices, it is possible to realize different sophisticated energy fuel-utilization technologies. They include:

- plasma ignition of the coal-dust flame (fuel oil free kindling of boilers, lighting of the coal-dust flame, stabilization of the liquid slag yield in furnaces with liquid slag removal);
- electric-thermochemical preparation of fuel (ETCPF) for combustion;
- coal distillation;
- plasma-steam coal distillation, production of synthesis gas;
- integrated processing of low-grade solid fuels in plasma reactors;
- processing of coal production wastes – coal slime.

The coal slime has hardly had any substantial application up to now, because of its high ash content and special requirements for its further utilization. It contains the Fe, Si, Al and Mg compounds, as well as other impurities. The use of plasma allows implementation of the waste-free technology for production of valuable products from a high-ash (low-grade) carbon raw materials. Thus, the air-water plasma conversion of coal provides a high-calorific synthesis gas containing the hydrogen and CO mixture at a temperature of 1500 ^{o}C, whereas an expensive ferrosilicium and fibrous warmth-keeping materials can be produced from a molten slag after reduction in the plasma reducing reactor.

Therefore, the use of plasma allows development of the waste-free and environmentally clean technologies which lead to reduction of import of scarce power supplies.

Tests of the combined plasma-coal torch devices at the Coal Energy Technology Center proved the high efficiency of lighting of the coal-dust flame.

Radical and Ion Behavior in Inductively Coupled, GEC Reference Cell C_4F_8/Ar Discharges.

Harold M. Anderson, Geoff Courtin, Marcus Barela

Department of Chemical and Nuclear Engineering
University of New Mexico, Albuquerque, New Mexico, USA 87131

Abstract

Diode laser absorption spectroscopy (DLAS), UV/visible absorption spectroscopy (UV/VIS), ion energy analysis and Langmuir probe measurements were performed to characterize both the fluorocarbon radical and ion behavior in inductively coupled C_4F_8/Ar discharges. The interpretation of these results is that the neutral radicals CF_2 and CF are key participants in the oxide etch process and that there is an ion flux and a reactant flux limiting regime in the etch, dependent on the C_4F_8/Ar ratio.

1. Introduction

The increased complexity of developing plasma processes for etching 300 mm wafers with critical feature sizes approaching 0.1 μm dimensions is fueling the need for more advanced plasma models that can aid in designing processes without costly experimentation. Before these models currently under development can be put to use, the predictive capability of the models must be verified by diagnostic measurements. One of the most challenging plasma etching operations is selective oxide etching using fluorocarbon based gases. The primary focus of this report is on diode laser gas phase density measurements of CF_x, SiF_x, CO_x and C_xF_y species made in the UNM GEC/ICP Reference Cell using DLAS and UV/VIS absorption spectroscopy. Concurrently, ion behavior was studied by ion energy analysis and Langmuir probe measurements. The work concentrated on etching of blanket bulk oxide and PR wafers in a tool parameter space defined by source power, bias power and pressure and correlating these results to radical and ion behavior in inductively coupled C_4F_8/Ar discharges. The work involved generating sets of statistically designed experiments used to characterize the gas phase plasma chemistry over a wide reactor operational parameter space. Routine post-etch measurements for etch rate and selectivity were performed. Diluting the C_4F_8 with Ar was used to illustrate the effect that greater ion current has on the etch rate. The interpretation of these results strongly suggest that the neutral radicals are key participants in the oxide etch process and that there is an ion flux and a reactant flux limiting regime in the oxide etch process window dependent on the C_4F_8/Ar ratio.

2. Technical details

A liquid nitrogen cooled diode laser based absorption spectroscopy system was used for these studies. The temperature of the diode and the current through the diode determines the wavelength of emission from the diode laser. With the diode temperature regulated, the current can be ramped to sweep the laser wavelength across a region of interest. Wavelength modulation spectroscopy (WMS) was used to increase the detection sensitivity [1]. This method involves simultaneously modulating the current ramp with a small sinusoidal wave. A lock-in amplifier is then used to demodulate the signal from the detector. This places the signal at a frequency above most of the laser and detector noise. The increased signal-to-noise ratio results in detection sensitivity that is usually limited by "accidental" etalons, which arise from multiple reflections off surfaces encountered by the primary beam. For the work presented here, the laser current was modulated at 50 kHz. The resulting high

frequency absorption signal was monitored with a lock-in amplifier set to observe at the second harmonic of the modulation frequency (100 kHz). A schematic of the detection system is shown in Figure 1. The processed signal from the detector resulted in a second derivative of the absorption spectrum due to demodulation at the second harmonic. This method has the added advantage that a single pass through the plasma is usually sufficient, eliminating the need for multipass optics. This method has previously been used in the past to successfully monitor fluorocarbon concentrations [2,3].

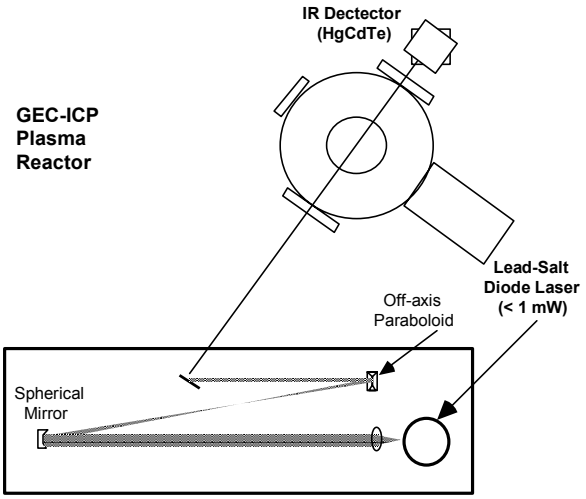

Figure 1 Schematic of GEC-ICP Cell and diode laser apparatus.

Diodes with a frequency around 1230 cm^{-1} were used for CF, CF_2 and COF_2 detection, diodes with a frequency around 870 cm^{-1} were used for SiF and SiF_2 detection, diodes with a frequency around 2120 cm^{-1} are used for CO detection and a diodes with a frequency around 1185 cm^{-1} are used for C_2F_4 detection. Details about the calibration of the absorption signal to absolute concentration of these species can be found in a previous work [4]. UV/VIS absorption measurements were made with a gated Xenon flash lamp and a Cetac EP-2000 spectrometer for comparison against diode laser measurements. Langmuir probe measurements were made with a conventional negatively biased single tip probe used to collect ion current. Ion energy analysis was performed using a high-resolution micro-engineered retarding field energy analyzer with sub-micron dimensions [5].

In the blanket oxide and blanket PR etch experiments using the GEC reference cell, the power was varied from 200 to 500 W, pressure was varied from 5 to 25 mTorr, and the bias was varied from 20 to 150 W power. The gas flow rate was maintained at 26.1 sccm and the wafer chuck temperature was maintained at 20^o C. The experiments were conducted using a central composite experimental design and the results are depicted as a response surface plot.

3. Results

Oxide etching in the inductively coupled GEC Cell is dominated by bias power rather than source power in pure C_4F_8. This is illustrated in figure 2 below which shows that at low bias power there is net deposition of polymer, while at high bias powers there is rapid etching of the oxide surface. However, the real variable that drives the oxide etch process is bias voltage rather than bias power, since bias voltage determines ion energy striking the surface. Langmuir probe measurement of the ion current density was used to estimate the bias voltage at the wafer at which this transition took place. For C_4F_8, this transition occurs at ~ 60 eV (75 W bias power) in the GEC Cell. The conversion was made based on a correlation made by Doemling, et al. [6] who showed that V_{DC} measured from

probe data as V_{DC}=P/ICD*A is the same as the self bias voltage measured directly using a wafer probe. In the above expression, P is the RF bias power, ICD is the ion current density and A is the area of the wafer.

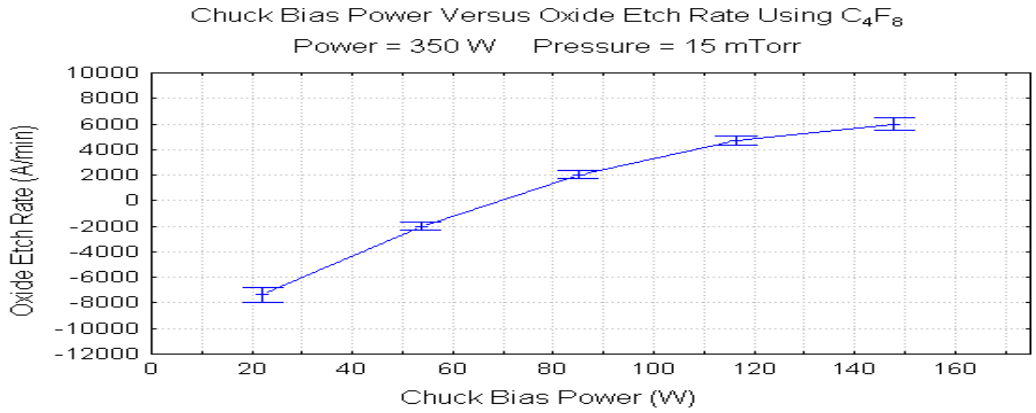

Figure 2. Oxide etch rate in C_4F_8 as a function of the chuck bias power.

DLAS has shown that C_4F_8 is largely dissociated to first form C_2F_4 (shown in figure 3), then further dissociate to form CF_2 and CF in the discharge. Over an oxide surface, CF_2 and CF are consumed in the oxide etch process, but only when the bias power is sufficient to keep the oxide surface clean through energetic ion bombardment. At higher bias powers (125 W) where oxide etching is fast (~600 nm/min.), CF_2 appears to be the key radical for the etch process since ~50 percent (2.7-3.0 mTorr in a 15 mTorr C_4F_8 discharge) is consumed. This is illustrated in figure 4 below. These values were obtained by comparing the CF_2 concentrations over non-reactive wafer surfaces versus blanket oxide wafer surfaces undergoing etching. CF is shown to display a similar trend, but its concentration is an order of magnitude less than CF_2. Also of interest to note, C_2F_4 has a similar trend with respect to bias power and active etching. Under high bias power and active etching, the concentration of C_2F_4 is also reduced by ~50 percent from those shown in Figure 3.

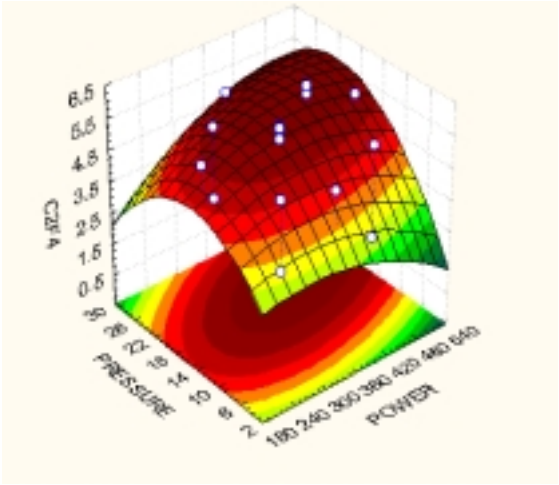

Figure 3 C_2F_4 concentration (mTorr) as a function of pressure and power in a 15 mTorr C_4F_8 discharge. Bias power constant at low setting (i.e. no etching).

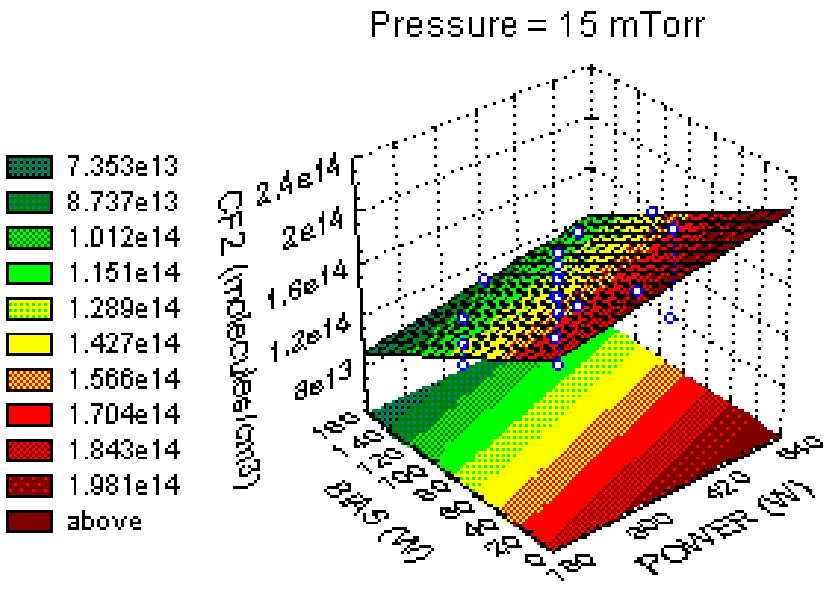

Figure 4. Oxide etch rate CF_2 behavior for bias versus power.

Given the fact that CF_2 is present in an order of magnitude greater concentration than CF, the CF_2 radical appears to be the primary radical constituent driving the oxide etch process. With both C_2F_4 and CF_2 concentrations depressed to only about 20 percent each of the total gas pressure, and with CF concentrations on the order of 1 percent or less, the remainder of the total gas pressure must be made up of etch product species like SiF, SiF_2, CO and COF_2. Previous measurements of CO concentrations by DLAS in the GEC Cell under steady-state blanket oxide etch conditions place the CO concentration at approximately 2 mTorr under relatively comparable etch conditions. Given the necessity of having to have a stochiometric balance for the evolution of SiO_2 etch products during the etch process, the appearance of CO in these quantities during active oxide etching appears to be in rough balance with the loss of CF_2 and C_2F_4 due to the underlying consumption of CF_2 during the etch process. C_2F_4 is presumably not directly consumed by etching, but its equilibrium concentration appears to be perturbed by the consumption of CF_2. However, this active participation of CF_2 in the etch process appears to only take place when the oxide surface is kept clean by energetic ion bombardment. CF, by merit of its order of magnitude lower concentration than that of CF_2, cannot be driving the oxide etch process in and of itself. There simply isn't enough CF available to account for the anticipated mass balance between reactant species and etch products.

Over a PR surface, neither CF_2 nor CF concentrations vary as a function of PR etch rate. Consequently, they do not appear to be involved in the PR etch mechanism. However, PR etching is also critically dependent on bias power. PR films etch presumably due to energetic ion bombardment that degrades the PR film, making it liable to attack by fluorine.

As C_4F_8 is diluted in Ar, the etch rate is first significantly enhanced by the additional ion current density provided by Ar, up to about a 20/80 dilution as shown in Figure 5. Beyond 80% the decline in etch rate is even more precipitous. DLAS measurements of CF_2 and CF concentrations show a near linear decline as the Ar fraction is increased from 0 to 80%, and CF_2 falls to less than 1 mTorr at 80% Ar dilution. Further increases in Ar show that CF_2 declines to the point such that these reactants for the oxide etch process could not sustain the etching rate. The interpretation of these results is that the neutral radicals CF_2 and CF are key participants in the oxide etch process and that there is an ion flux and a reactant flux limiting regime in the oxide etch process window dependent on the C_4F_8/Ar ratio. These regimes are illustrated in figure 5.

Langmuir probe measurements of ion density in this study show a significant increase in ion density in pure Ar as opposed to C_4F_8, and Li, et al. [7] have shown that at 90% Ar dilution of C_4F_8 more than 70% of the ion flux is attributable to Ar ions. This suggests that there is considerable synergism between Ar and C_4F_8 over that range, but the lack reactive flux beyond the 80-90% Ar range means the normal reactive ion process is surpressed. In the regime from 0 to 60% Ar in C_4F_8, there are sufficient fluorocarbon ions to keep the oxide surface clean and allow for continued etching, but the etch rate appears to be constrained by the overall lower ion density and ion flux to the surface. The function of this ion flux to the surface is consistent with a surface cleaning role for ions, keeping fluorocarbon deposits at a minimum and allowing for reaction of CF_2 radicals with a clean oxide surface, as has been suggested by Li, et al. [7]. Although the reactor used in this study is different from the inductive reactor used by Li, et al. [7], the etching performance of the GEC Cell is quite similar and adds to the credibility of this mechanism. In the no or low Ar addition regime, low ion flux (but energetic nonetheless) allows a finite thickness of fluorocarbon film to be present on the oxide surface, and this film constrains etching by interfering with CF_2 radical interaction with oxide bonds.

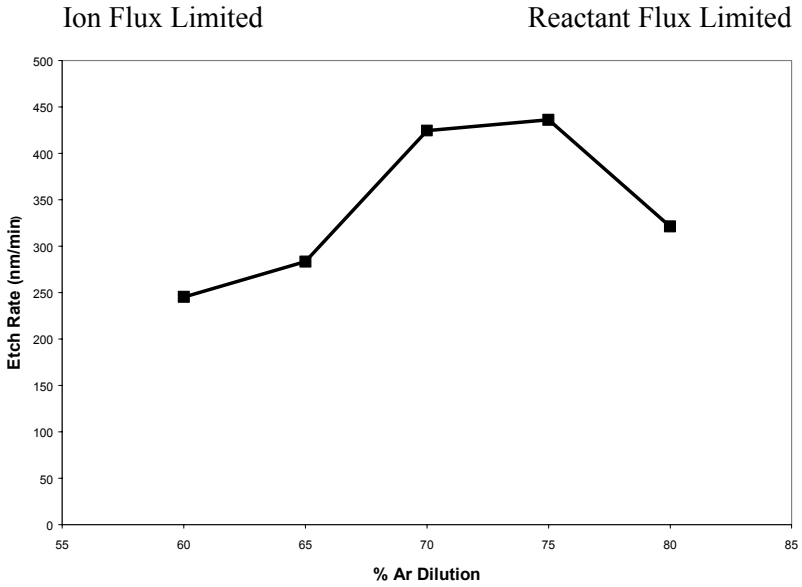

Figure 5. Etch rate versus Ar dilution for C_4F_8 (power 350W, bias power 100 W, pressure 20 mTorr)

4.0 Conclusions

The etch mechanism for both oxide and PR films has been clarified and the importance of CF, CF_2 and F to the etching of both these films has been established. C_4F_8 dissociation has been quantitatively characterized through the major electron impact, dissociation pathways involving C_2F_4 intermediates and CF and CF_2 radicals. The role of energetic ion bombardment in oxide etching has been clarified and it is clearly shown that fluorocarbon etching of oxide is not strictly ion driven. Rather, there is a regime in the reactive ion etching of oxide surfaces is ion flux limited and one that is neutral reactant flux limited, dependent on the dilution of the fluorocarbon with Ar. The role of CF_2 and CF neutral radicals in this complex interaction has been quantified by DLAS spectrometry.

This project was funded by SEMATECH and NSF.

Abstract

The motion of the anode attachment and the heat flux to the anode have been determined for a configuration where the arc axis is perpendicular to the anode surface with the plasma gas flowing along the arc axis, and with lateral injection of different gases parallel to the anode surface. The arc is stabilized by a constrictor except for a gap of 10 mm between the constrictor and the anode. The constrictor channel diameter is 10 mm, the arc current is 100 A, the plasma gas flow rate is 5 slpm of argon, and the lateral gas flow rate is 0 to 25 slpm, with argon or nitrogen gas injected laterally. High-speed videography and calorimetric measurements of the anode cooling water temperature rise have been used to characterize the anode attachment. The results show that different modes of anode attachment exist, including a steady deflected anode root, a randomly fluctuating attachment, and a periodically fluctuating attachment. When the anode spot appears, the lateral gas leads to an arc voltage increase. The total anode heat transfer changes with different lateral gas flow rates and for the different attachments modes. This effect may be explained by lateral gas flow causing a convective heat loss from the arc to the chamber walls.

1. Introduction

The arc - anode attachment and anode heat fluxes play an important role for the anode erosion characteristics and the anode lifetime. A better knowledge of these phenomena is required to optimize the anode performance. It had been shown previously that operation modes of plasma spray torches depend on the thickness of the cold gas boundary layer between the arc column and anode surface. The well known restrike and takeover patterns were correlated to end-on images taken with a video camera of high time resolution[1]. In this study we have addressed the question of the interaction of the arc with an anode when there is a cold gas flow parallel to the anode surface forming a cold boundary layer and leading to a constant motion of the anode attachment with a corresponding fluctuation in plasma power. This situation is encountered in many applications of non-transferred plasma torches such as plasma spraying where the fluctuation in plasma jet power can have a detrimental influence on the quality of the produced coating.

In this paper, the motion of the anode attachment and the heat flux to the anode have been determined for a configuration where the arc axis is perpendicular to the anode surface with the plasma gas flowing along the arc axis, and with lateral injection of different gases parallel to the anode surface.

2. Experimental Apparatus

The experimental apparatus of a DC plasma torch with lateral gas flow is shown in Fig.1. The arc is generated between a rod shaped cathode and a water-cooled flat anode situated perpendicularly to the arc axis. An assembly of water-cooled constrictor segments, each separated by ceramic discs, surrounds the arc. A gap between the constrictor and the anode allows observation and control of the fluid dynamic boundary layer in the stagnation region. The entire assembly is housed in a controlled atmosphere chamber. The distance between the cathode and anode is sufficiently large to minimize the effect of the cathode jet. The lateral gas distributor provides the parallel gas flow along the anode surface to deflect the arc. While the relation between the elastic modulus of the arc and arc voltage measurements were investigated[2,3], there are few reports[4] about the relation between the arc voltage, the attachment region and unstable arc modes for different lateral gases. The parallel gas flow to the anode surface from the lateral gas distributor cools the arc in the boundary layer leading to a constriction of the arc and to a deflection. A description of the oscillating phenomena requires diagnostic experiments with high time resolution. The voltage and current traces are recorded with a high-speed oscilloscope and correlated to the images of a color CCD camera with an exposure time as low as 222 μs, and with a high framing rate video system with frame rates at 4,500 frames per second. Appropriate zoom lenses, tele-microscopic lenses and neutral density filters allow matching to experimental conditions and provide the necessary optical resolution. The arc is stabilized by a constrictor except for a gap of 10 mm between the constrictor and the anode. The constrictor channel diameter is 10 mm, arc current is 100 A, the plasma gas flow rate is 5 slpm of argon, the lateral gas flow rate is 0 to 25 slpm of argon or nitrogen, and the background atmosphere in the chamber is argon with a pressure of 0.1 MPa. The high-speed videography and calorimetric measurements of the anode cooling water temperature rise have been used to characterize the anode attachment.

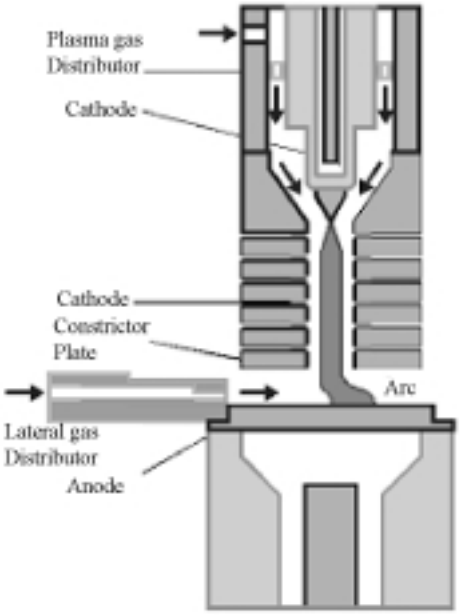

Fig.1 Experimental Apparatus of Plasma Torch

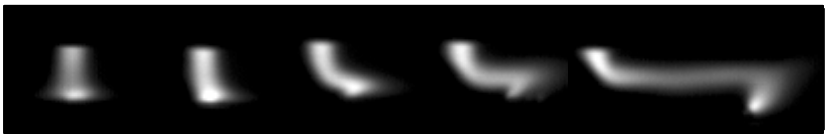
3. Arc Mode and voltage

Figure 2 (a) and (b) show the arc appearance mode as function of the lateral gases of argon and nitrogen, respectively. The mode 0 shows the stable attachment. Mode 1 shows a constriction of the arc in front of the anode. This mode is only observed with nitrogen. Mode 2 shows the lateral gas flow deflecting the arc. Mode 3 shows the appearance of a cold boundary layer. Mode 4 shows the appearance of an extended cold boundary layer and of an anode spot. Mode 5 shows the anode spot instability appearing.



0slpm Mode 0 | 15slpm Mode 2 | 18slpm Mode 3 | 20slpm Mode 4 | 25slpm Mode 5

(a) Argon

0slpm Mode 0 | 5slpm Mode1 | 10slpm Mode 2 | 15slpm Mode 3 | 16slpm Mode 4 | 18slpm Mode 5

(b) Nitrogen

Fig.2 Arc Mode.

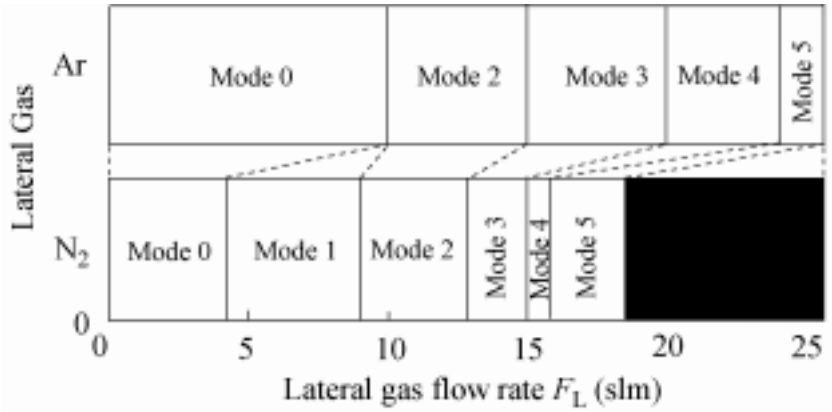


Fig.3 Relation of arc mode between current and lateral gas flow rate.

When the lateral gas flow increases from 4 slpm to 8 slpm, the arc constricts when the lateral gas is nitrogen. However, when the lateral gas is argon, there is little change in the arc diameter. When the lateral gas flow increases from 10 slpm of argon, and 9 slpm of nitrogen, the arc is deflected. A cold boundary layer appears when the flow rate reaches 15 slpm of the argon or 13 slpm of the nitrogen. An extended cold boundary layer and anode spot appears when the lateral gas flow reaches 20 slpm of argon or at 16 slpm of nitrogen. At these flow rates, the anode spot remains stationary and the arc becomes longer. The arc attachment becomes unstable when the flow rate reaches 24 slpm of argon or 17 slpm of nitrogen. The arc is extinguished when the nitrogen flow rate reaches 19 slpm. Figure 3 shows the arc mode as a function of lateral gas flow rate. Before the anode spot appears, the lateral gas just deflects the arc. However, after the arc spot appears, the effect of lateral gas increases. While the arc mode 4 and 5 can exist from 20-25 slpm in the case of argon as lateral gas, it can only exist from 16 to 18 slpm in the case of nitrogen. Also, the arc is longer with argon than with nitrogen. While the arc with nitrogen is extinguished immediately after the appearance of mode 5, the arc is not easily extinguished with argon flow.

4 Correlation of arc voltage and mode

Figure 4 shows the average, maximum and minimum values for the arc voltage as a function of the lateral gas flow rate. The voltage remains constant as long as there is no mode change or no movement of the attachment spot. Beginning of the arc attachment movement by increasing the lateral gas flow rate is seen also by voltage fluctuations. A change from mode 4 to mode 5 (attachment instability) is accompanied by a change in the maximum value for the voltage from 51.1 V to 56.2 V for a change of the lateral gas flow rate from 23 to 25 slpm in the case of argon flow, and from 52.9 to 54.5 V for an increase in the nitrogen flow rate from 16 to 17 slpm. There is a much smaller change in the average voltage. It can be seen that a similar deflection of the arc is obtained for a mass flow of 0.6 g/s of argon and 0.38 g/s of nitrogen. This is an indication that the deflection of the arc is not only due to the lateral gas momentum but also due to the higher energy losses encountered with the lateral flow of the molecular gas.

Figure 5 shows a voltage trace for conditions when a mode 5 attachment is established (100 A, 5 slm argon as plasma gas, 25 slm argon as lateral gas). It is seen that the voltage can remain constant for about 20 ms, but this period is followed by three restrikes in about 10 ms. In previous experiments under the approximately the same conditions, a restrike frequency of about 230 Hz has been measured [3]. It is clear from the present measurements that there is a random component in the restrikes. Also the magnitude of the voltage jump during the restrike can vary, being 3 V at location A in Fig. 5, 3.9 V at location B, 4.4 V at C and 6 V at D. Figure 6 shows the high speed images during the different restrike events. It is apparent that the time required for the arc to establish an upstream attachment in the case of a restrike is about 0.67 ms.

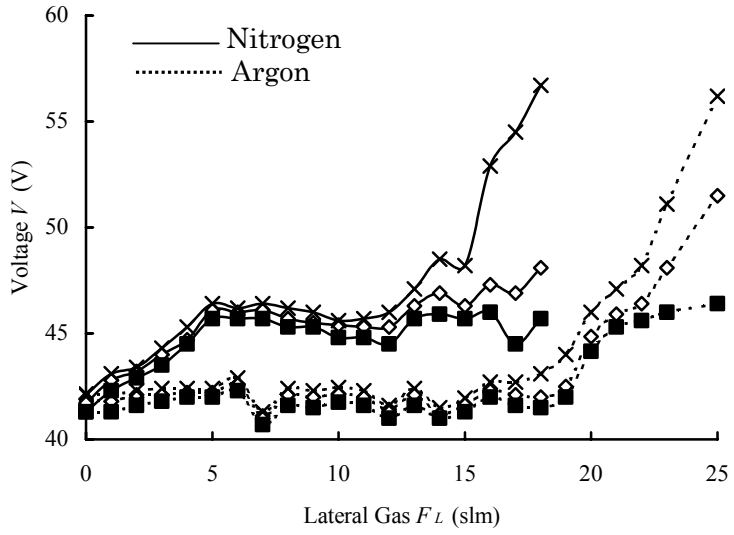

Fig.4 Voltage as functions of lateral gas.
(◇:Average, ■:Minimum, ×:Maximum)

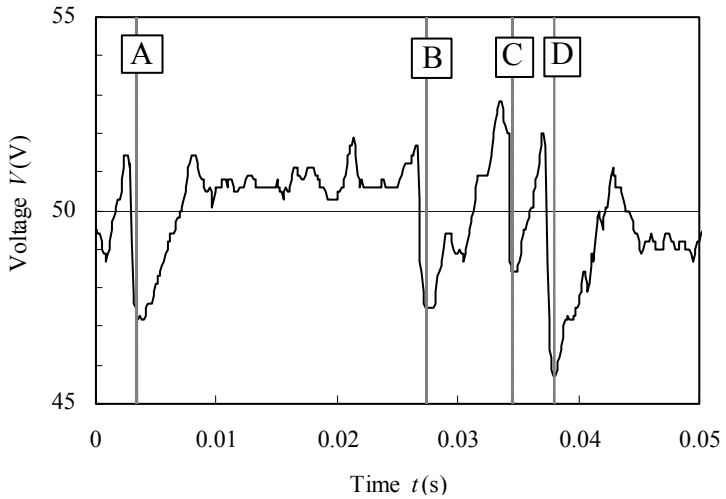

Fig.5 Correlation of restrike time and arc voltage.

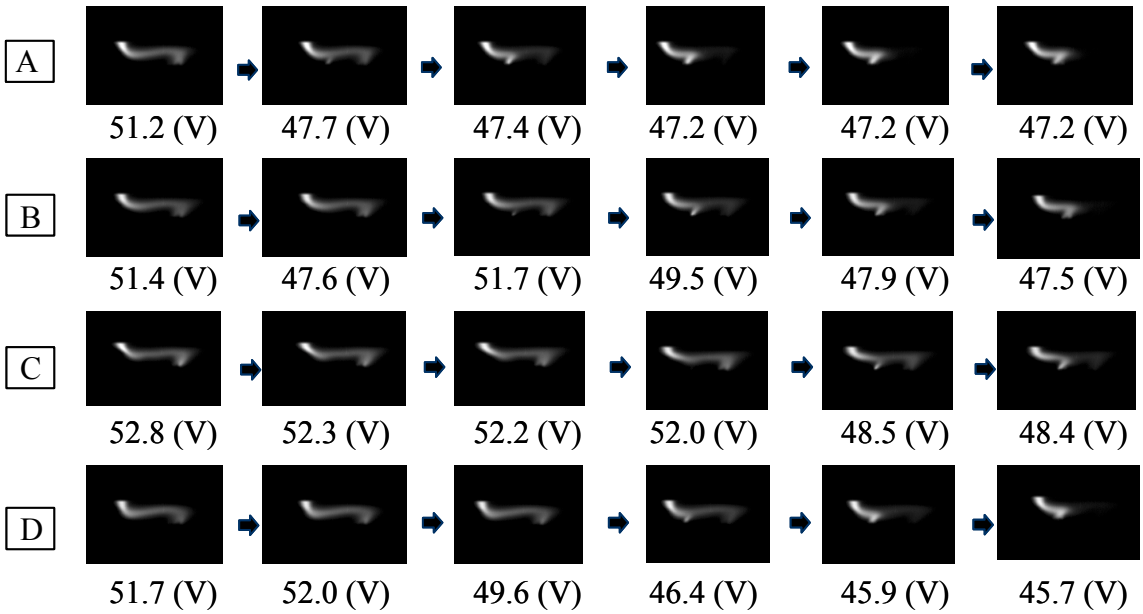

Fig.6 Arc mode with restrike.

5 Heat flux to anode

Figure 7 shows the total heat transfer to the anode as a function of the lateral gas flow rate for the two gases. The heat transfer shows a slight decrease with increasing lateral argon gas flow rate, indicating a convective loss from the arc to the chamber walls. With nitrogen, an initial increase is noticed during the period of arc constriction (mode 1). This increase in heat transfer indicates that the voltage increase during arc constriction and the associated increase in dissipated power are largely transferred to the anode.

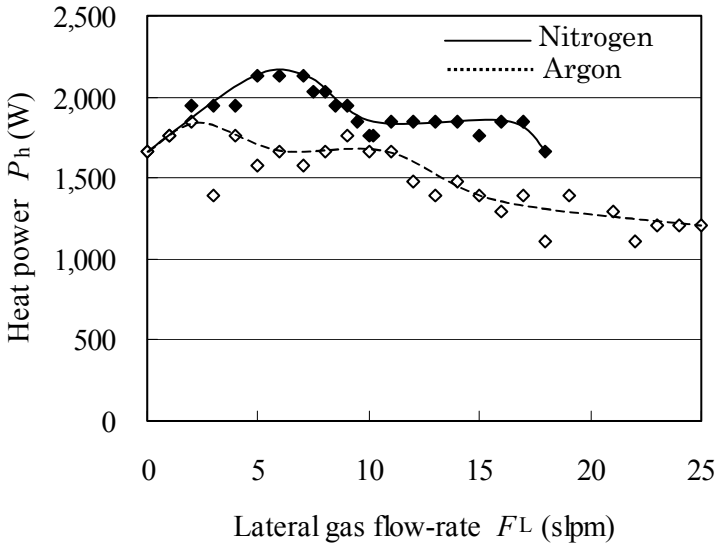

Fig.7 Heat flux to the anode.
(◆:Nitrogen,◇:Argon)

6. Summary

A lateral gas flow can result in distinctly different appearances of the arc-anode attachment, going with increasing mass flow from a diffuse to a constricted attachment, to a deflection and the establishment of an extended cold boundary layer between the deflected arc and the anode, and finally an instable attachment. The transitions occur at lower mass flow rates when nitrogen is the laterally blown gas compared with argon. An attachment mode change is accompanied by an increase in arc voltage in the case of nitrogen, but only an extended boundary layer build-up leads to a significant increase in arc voltage in the case of lateral argon flow. Arc instabilities usually lead to arc extinction in the case of nitrogen flow, and to voltage fluctuations with no specific periodicity in the case of argon. Anode heat fluxes initially rise with increasing lateral nitrogen flow indicating transfer of the increased energy dissipation to the anode. A further increase of the lateral flow leads to a decrease in heat transfer for nitrogen as well as for argon, indicating an energy loss to the surrounding chamber walls.

Abstract

Nanoparticles have attracted considerable interest for a wide array of potential applications [1]. Discrete, freestanding silicon nanoparticles are highly desirable for the fabrication of novel microelectronic devices. We employ a high-density inductive RF plasma in SiH_4 diluted in Helium and Argon for production of nanoparticles. Characterisation using Transmission Electron Microscopy (TEM) and X-Ray Energy Dispersive Spectroscopy (XEDS) suggests presence of defect-free crystalline particles.

1. Introduction

Amorphous silicon has been used for a wide variety of electronic applications including thin film transistors and energy conversion devices. However, these devices suffer strongly from defect scattering and recombination. Single-crystal semiconductor nanoparticles with their high carrier velocities and longer recombinative lifetimes are expected to be well suited for device fabrication. Potential applications of crystalline silicon nanoparticles as a substitute for amorphous silicon in optical and quantum effect electronic devices, have led to intense research efforts in that direction (see ref. [1] and references therein). These efforts mainly focused on particles in the 2-10 nm range for their unique confinement effects and ease of production. As a prominent example, microelectronic memory devices have already been built using silicon nanocrystals in this size range [2].

Out of a variety of synthesis methods, gas-phase synthesis of nanoparticles has been widely used for electronic applications due to the high degree of purity that can be achieved. A variety of gas-phase processes such as inert gas condensation [3], flame synthesis [4], furnace flow reactors [5] and thermal plasma particle synthesis [6] have been proposed for nanoparticle synthesis. These processes are relatively efficient in the synthesis of particles, however, they often produce either agglomerates or nanoparticles with broad size distributions that require post-synthesis size selection [2, 7].

The ability of plasmas to create highly monodisperse particles has been demonstrated on multiple occasions [8]. The monodispersity of the particle formation in silane plasmas can be explained by the fact that nanoparticles formed in the plasma scavenge precursors needed in the formation of new nuclei. After an initial nucleation and growth phase the nanoparticles seem to grow only by surface deposition. The particles get negatively charged due to the higher mobility of electrons as compared to ions in the discharge. This helps prevent agglomeration of particles once they reach a size of approximately 10 nm and carry enough negative charge [9]. The large electron mobility also leads to a negative charging of the reactor walls that cause the negatively charged particles to be trapped in the plasma region [8, 10].

Nanocrystals with size of the order of a few tens of nanometers having a monodisperse size distribution would be best suited for use with present day commercial lithography tools. A method for synthesizing single crystal, non-agglomerated silicon nanoparticles would be highly desirable, especially if particles can be remotely created and deposited on any kind of substrate. This could enable deposition on insulating substrates allowing high signal speeds or on other versatile substrates such as plastics. Recently several groups studying the formation of silicon particles in silane plasmas have reported generation of monodisperse, non-agglomerated distributions of particles [8,11-14]. However, particles observed in these studies were amorphous or polycrystalline.

Several studies of particle synthesis in low-temperature plasmas that focused on crystalline particles showed small crystallites, usually 2-5 nm in size [15-18]. In the present paper, we describe a synthesis route that allows the production of highly oriented, single-crystalline nanoparticles in the size range 20-80 nm.

2. Experimental set-up

Contrary to most studies reported, we employ a high-density inductively coupled low-pressure RF plasma for this work. This kind of plasma is known to produce plasma densities about one to two orders of magnitude higher than those of capacitively coupled plasmas [19] that were used in most of the aforementioned studies. Figure 1 is a schematic of the experimental setup. The inductive plasma is generated in a Pyrex tube with 5.1 cm inner diameter and 23 cm length. RF power of 150-200 W at 13.56 MHz is applied to a 5-turn induction coil. In the inductive mode, a bright ellipsoidal plasma forms inside the induction coil with an estimated local power deposition of 0.75-1 W/cm^3 . The Pyrex tube is attached to a high vacuum chamber. Particles are extracted through a 1mm orifice and deposited on amorphous carbon support film grids for transmission electron microscopy (TEM) at the end of the vacuum chamber. The process gas is 5% silane diluted in helium that can further be diluted by argon. During the plasma process, an operating pressure of 500-800 mTorr is maintained in the Pyrex tube. The total gas flow rate is 3.5-4 sccm. The pressure in the high vacuum chamber generally rises from 10^{-7} to 10^{-5} Torr during the deposition process. The plasma-on time normally is between 60-90 seconds. During this time, particles are likely negatively charged and trapped in the plasma. When the plasma is turned off, the particles are extracted through the extraction orifice by gas drag and are deposited on the TEM support films. A mask in front of the TEM gridholder permits the selective exposure of grids to varying plasma conditions and thus allows for a comparative study. A load lock system is employed to allow faster processing of substrates.

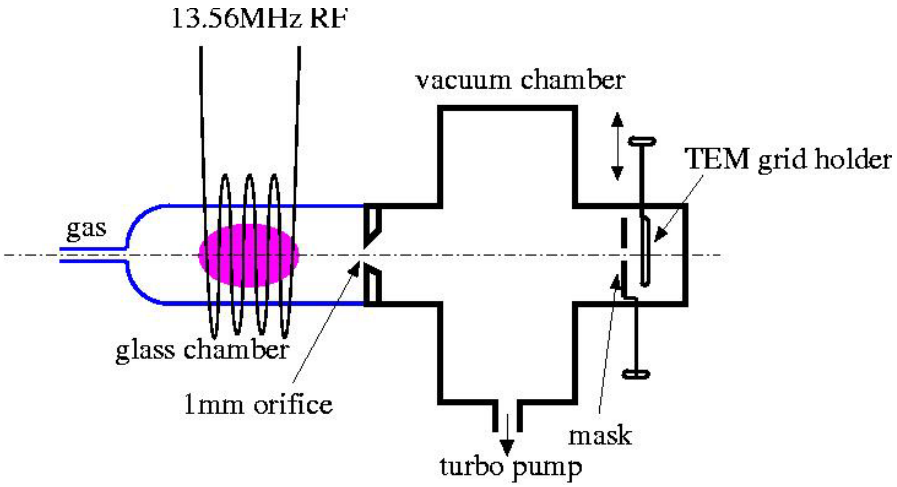

Figure 1: Sketch of Experimental Setup

Using this setup, experiments were conducted for varying plasma conditions in order to study the effect of plasma parameters on the particle formation process. TEM analysis was performed to study the particles deposited. The results presented here are only for a specific set of conditions, which lead to the formation of monodisperse crystalline particles. Process conditions for all results cited here were 0.72 sccm of silane (5%) in helium (95%) and 3 sccm of argon, leading to a total pressure of 700 mTorr, and a RF power input of 100 W applied for 90 seconds.

3. Preliminary findings

From preliminary studies performed, some trends can be inferred of the effect of plasma parameters on particle formation. The particle concentration is found roughly proportional to the silane partial pressure. Longer plasma-on times, higher power density, and higher total gas pressure favor formation of single crystal particles. Preliminary estimates of gas temperature in the plasma predict temperature values of the order of 1300K at the discharge center. Negatively charged particles are trapped in the plasma and can be assumed to reach at least the local gas temperature and then undergo a rapid annealing process leading to crystallization.

4. TEM analysis of deposited particles

Deposits of the nanoparticles on TEM support grids were examined using a Philips CM30 and JEOL 3010 TEMs; both were operated at 300 kV. The CM30 is equipped with a X-ray energy dispersive spectrometeter (XEDS) for chemical analysis. In order to image individual nanoparticles in the scanning electron microscope (SEM), the specimen was coated with Pt to enhance conductivity. All SEM studies utilized a Hitachi S900 field-emission SEM.

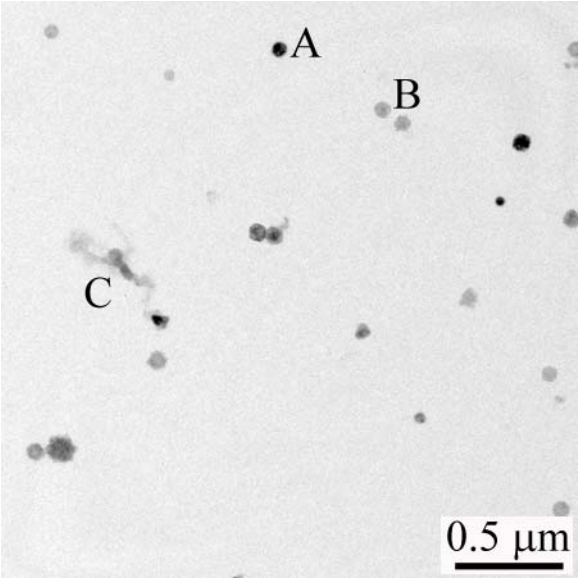

Figure 2: Bright field TEM image illustrating the spatial distribution of the nanoparticle deposit. The particle "A" is strongly diffracting and appears dark, while the particles at "B" are not in an appropriate diffracting orientation. A polycrystalline agglomerate is in the region "C."

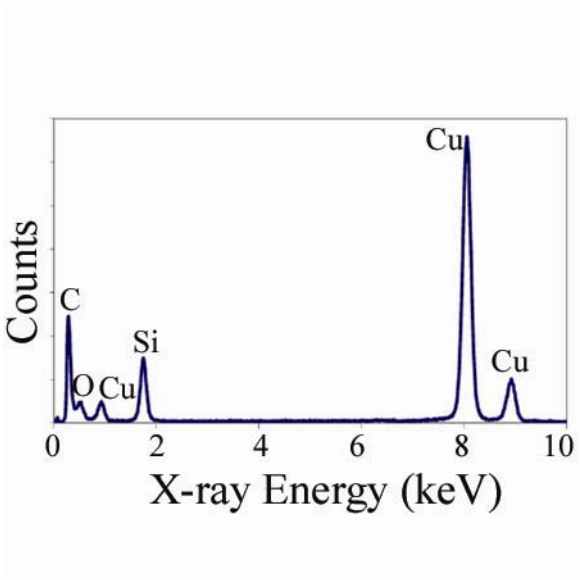

Figure 3: X-ray energy dispersive spectra showing the chemical species present. The Si and O peaks originate from the nanoparticles, and the Cu and C are from the TEM support grid and film, respectively.

Figure 1 is a bright-field (BF) TEM image of a typical area of the deposit. The size distribution of single-crystal nanoparticles is fairly uniform, with an average diameter of approximately 75 nm. Some particles in this image, such as the particle denoted "A," are in an appropriate crystallographic orientation to diffract strongly and appear dark. Conversely, the particles labeled "B" are not in a diffracting orientation and appear lighter. A polycrystalline agglomerate is noted in the region "C." The chemical identity of the deposit was confirmed using XEDS. The spectra resulting from the deposit is shown in Figure 2. The Si and O signals originate from the nanoparticles, while the Cu and C are from the TEM support grid and film, respectively.

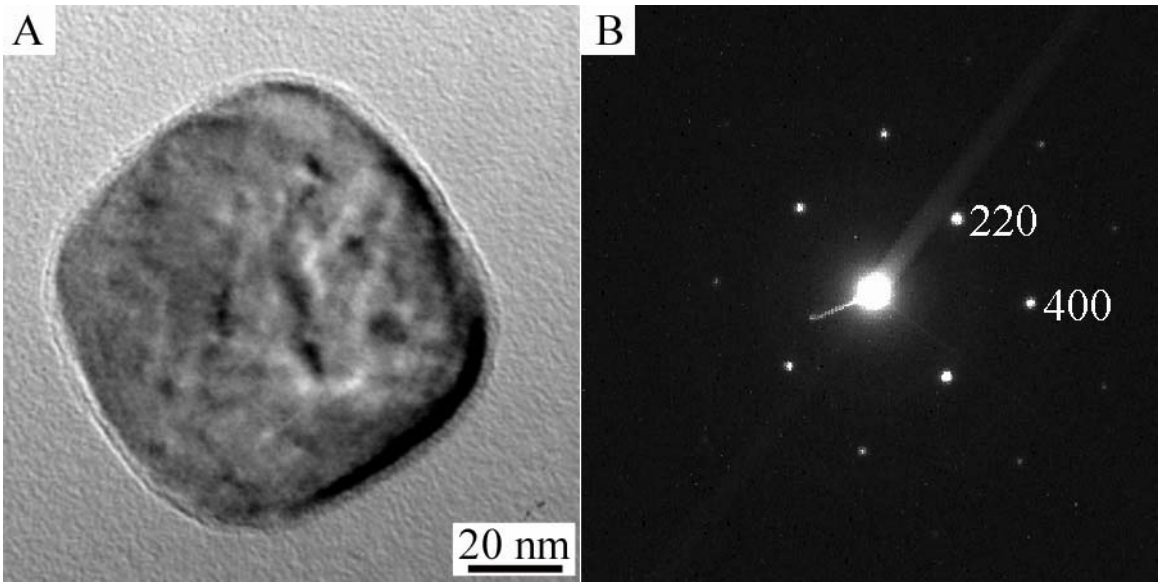

Figure 4: TEM observations of a nanoparticle with a "rounded square" appearance. (A) is a bright-field image of an individual nanoparticle, and (B) is the corresponding selected area diffraction pattern. This pattern is consistent with [001] single crystal Si.

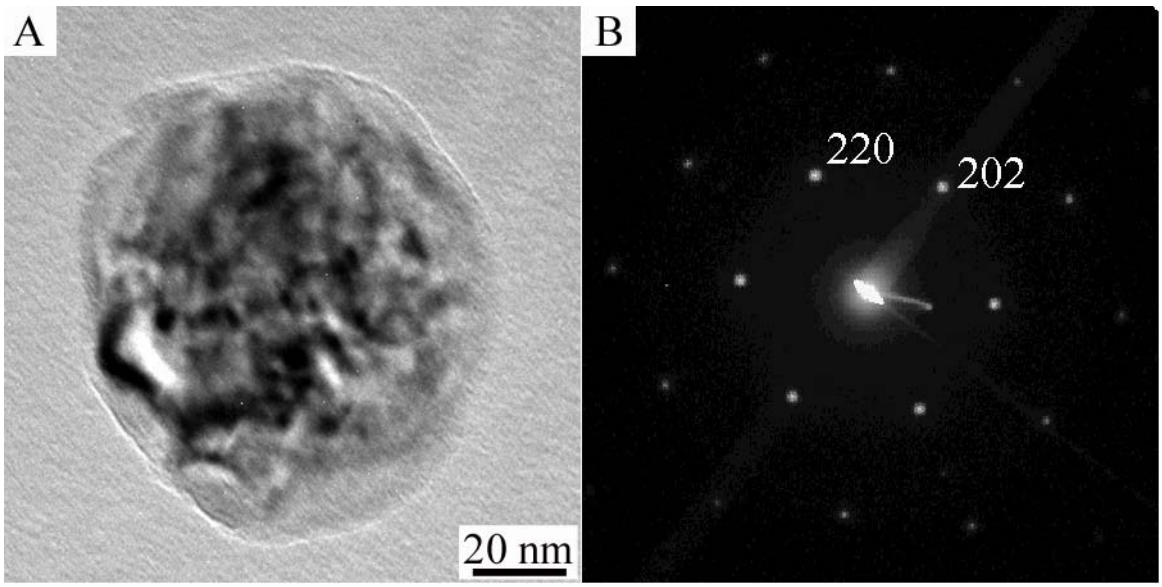

Figure 5: TEM observations of a nanoparticle with a "smoothed hexagon" appearance. (A) is a bright-field image of an individual nanoparticle, and (B) is the corresponding selected area diffraction pattern. This pattern is consistent with $[\bar{1}11]$ single crystal Si.

The use of the TEM for characterization of the nanoparticles provides the ability to identify the shape and crystallographic features of individual particles. Examination of nanoparticles at higher magnifications reveals shapes classified as "highly oriented." Figure 3A is a BF TEM image of a nanoparticle that has a "rounded square" appearance, while Figure 4A shows a particle with a "smoothed hexagon" appearance. Figures 3B and 4B are the selected-area diffraction (SAD) patterns from each particle. These diffraction patterns correspond to single-crystal diamond-cubic Si with [001] and $[\bar{1}11]$ orientations, respectively. Additionally, an amorphous surface layer is visible on each particle; this surface layer is likely an oxide layer.

Because the TEM images three-dimensional structures in two dimensions, the three-dimensional character of the nanoparticles can be difficult to discern solely from these images [20]. Imaging at different degrees of tilt has shown that the surface of the nanoparticles is not uniform and contains ledges and ridges [21]. Additionally, the apparent shape of the nanoparticles changed as the tilt was varied [21]. These obser-

vations agree with the TEM results, since the nanoparticles have different projected shapes when viewed along various crystallographic axes. The non-uniform surface of the nanoparticle will contribute to the contrast features visible in the TEM images [20].

5. Conclusion

In this paper we demonstrate a low-temperature plasma synthesis process for producing single-crystal silicon nanoparticles in the size range 20-80 nm. The XEDS and SAD analysis from the TEM confirm that the nanoparticles are crystalline diamond cubic Si of a highly oriented character. Future efforts are directed in the direction of better control of particle distribution with varying plasma parameters, modeling of particle trajectories in the plasma gas flow and electrical characterization of nanoparticles as a step towards building nanoparticle-based electronic devices.

Abstract

The effect of the introduction of species as nitrogen and oxigen in the helium microwave induced plasma created by the axial injection torch is radially studied by means of the Abel inversion procedure. The spectrum was scanned for atomic and ionic lines together with rotational bands of neutral and ionic molecules of such species. No ionic lines of any specie were detected at any plasma condition, neither were rotational bands of oxygen.

1. Introduction

Due to the high ionization potential of He, the He plasma produced by the axial injection torch (Torche à Injection Axiale or TIA)[1] is very useful as an excitation source for analytical chemistry [2]. The mixtures of helium with molecular gases are of great interest for a number of technological applications that take into account both physical and chemical processes. These plasmas are rich in active components, such as O, N and excited metastable species, which favour the different plasmochemical processes wich are necessary for such applications.

The different species present in the plasma, their radial distribution [3], and the possible mechanisms of creation and destruction have been studied. In order to do so, different percentages of N_2 and O_2 were introduced in the helium plasma produced by the TIA. The obtained results have been compared with those obtained with helium as the only component of the plasma gas, where the N_2 and O_2 are present in the TIA due to diffusion from the air surrounding the plasma.

2. Experimental

The axial injection torch produces a small (~1 mm diameter and 10-20 mm long) and very stable microwave plasma. It can operate with atomic and molecular gases, including air, which makes it a very versatile plasma. Its operating conditions range from 300 to 2000 W of incident microwave power and from 0.5 to 15 L min^{-1} of flow-rate of the plasma gas. In the present work, the plasma working conditions are 4 L min^{-1} of total gas flow-rate and 600 W of incident MW power.
The experimental set-up used in this work is aimed to the obtention of emission lines of the plasma for different lateral positions. Once these data are obtained, an Abel inversion can be performed on them in order to obtain the radial distribution of the emission intensity of the measured line. In Table 1 can be found the technical description of the instruments used in the set-up. The image of the flame produced by the plasma

Table 1: Technical description of the components of the experimental set-up

Microwave launcher	TIA (Montreal University)
Microwave generator	GPM 12K T/t (SAIREM) at 2.45 GHz
Material of the nozzle	Brass
Monochromator	THR-1000 (Jovin-Yvon) Grating 1200 grooves mm^{-1} Dispersion: Typically 0.8 nm mm^{-1} at λ=500nm Computer-controlled Spectralink system

Flow controller	Mass flow controllers FC280 Dynamass control system (Tylan General)

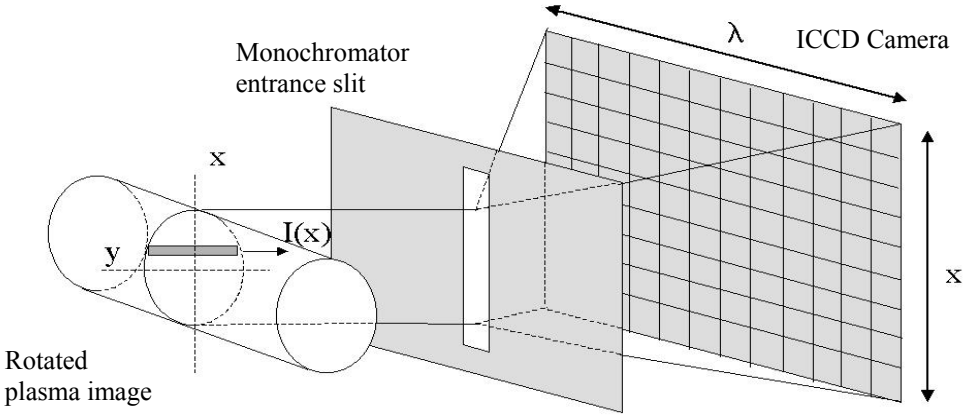

Fig. 1: The image of the flame, rotated 90º and integrated in the y-axis is dispersed in wavelength by the monochromator.

generator device is carried to the entrance slit of the monochromator by an optical system consisting of two convergent lenses and a Dove prism. The prism rotates the image 90º, allowing the selection of a transversal slice of the plasma, which is then focussed on the slit. The image of the slice is then dispersed in wavelength by the monochromator and focussed on the bidimensional array of photosensitive pixels of an intensified CCD camera. With this set-up, then, each row of the camera pixels collects an emission spectrum for a different lateral position of the discharge, and each column a lateral distribution of emission intensity for a different wavelength, as is shown in Fig. 1.

3. Data treatment

The measured emission intensity data are integrated along the plasma depth in the line-of-sight direction. The Abel inversion provides the radial distribution of the emission coefficient of a spectral line, $\varepsilon(r)$, from the lateral distribution of such integrated intensity, $I(x)$:

$$\varepsilon(r) = -\frac{1}{\pi}\int_r^R \frac{I'(x)}{\sqrt{x^2 - r^2}}\,dx \qquad (1)$$

where R is the plasma radius and $I'(x)$ is the first derivative of $I(x)$ respect to x. In order, eq. (1) has to be discretized. In this work the Hankel-Fourier method to Abel-invert discrete sets of data has been used, which was found in a previous paper to be more accurate than other methods present in the literature [3]. The $I(x)$ distributions were then Abel-inverted, and the radial distribution of the emissivity of such lines was obtained. The error of the Abel inversion is higher the closer to the plasma centre the radial positions are. This error has been calculated previously [3], yielding a relative error for the results of less than 8% for radial positions $r > 0.2\,R$.

4. Measurements and results

The measurements were performed for an input microwave power of 600 W and a constant gas flow-rate of 4 L min^{-1}. Five different plasma gas compositions were used in this work: pure helium, helium with 0.5% nitrogen added, helium with 2.5% nitrogen added, helium with 0.5% oxigen added and helium with 2.5% oxigen added. At each plasma condition, the emission spectra of the plasma was scanned in order to find atomic (N, O) or ionic (N^+, O^+) lines, and molecular (N_2, O_2) or ionized molecular (N_2^+, O_2^+) bands. Whichever was the plasma gas composition, only four of these eight species were found in the plasma: N, N_2, N_2^+ and O.

No ionic species from nitrogen nor from oxigen were detected in the discharge. This was to be expected, as although the helium ionization energy (24.587 eV) is higher than that of the oxygen (13.62 eV) and nitrogen (14.53 eV), the energy values of the excited levels of the O^+ and N^+ ions are still above the He ionization

energy [4], which probably causes these species to be mainly in their ground states, hence explaining the lack of emission from these species in our plasma.

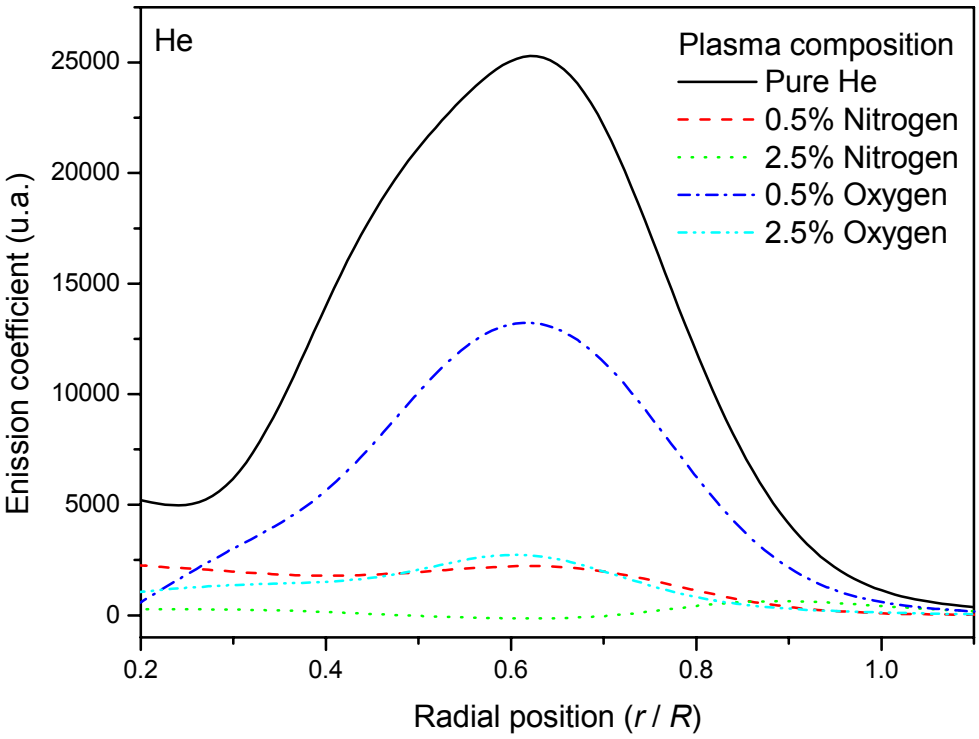

Fig. 2: Radial distributions of the emission coefficient of the 587.6 nm He line for different plasma gas compositions.

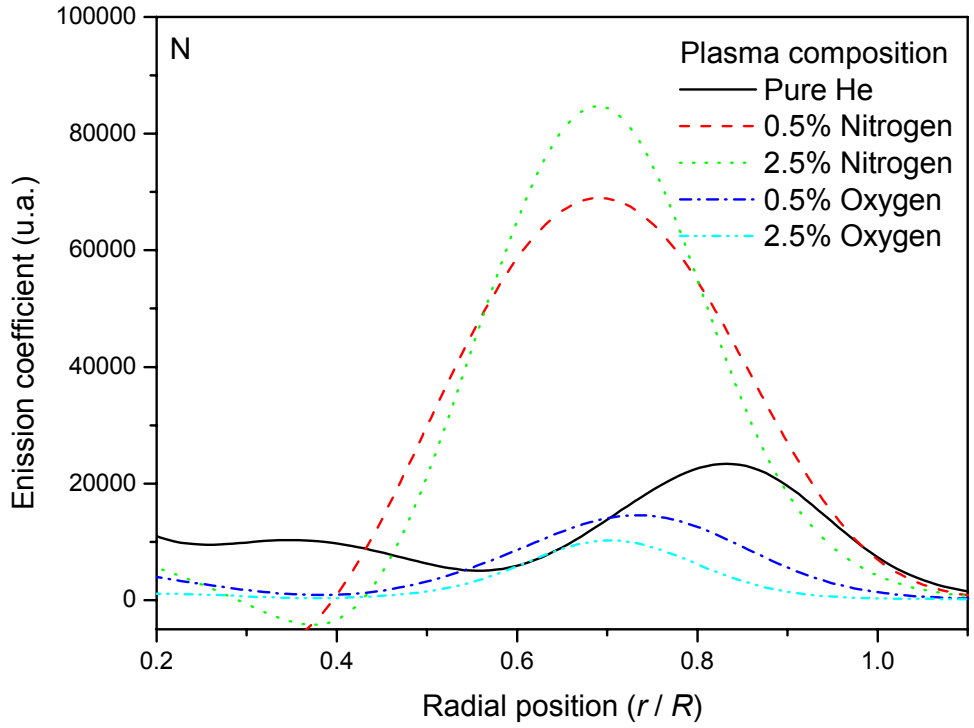

Fig. 3: Radial distributions of the emission coefficient of the 749.9 nm N line for different plasma gas compositions.

In the He-N_2 mixture a great profussion of N_2 and N_2^+ molecular bands were observed. In the He-O_2 mixture, however, no molecular bands (O_2, O_2^+) were detected. This behaviour was also found when the plasma gas is

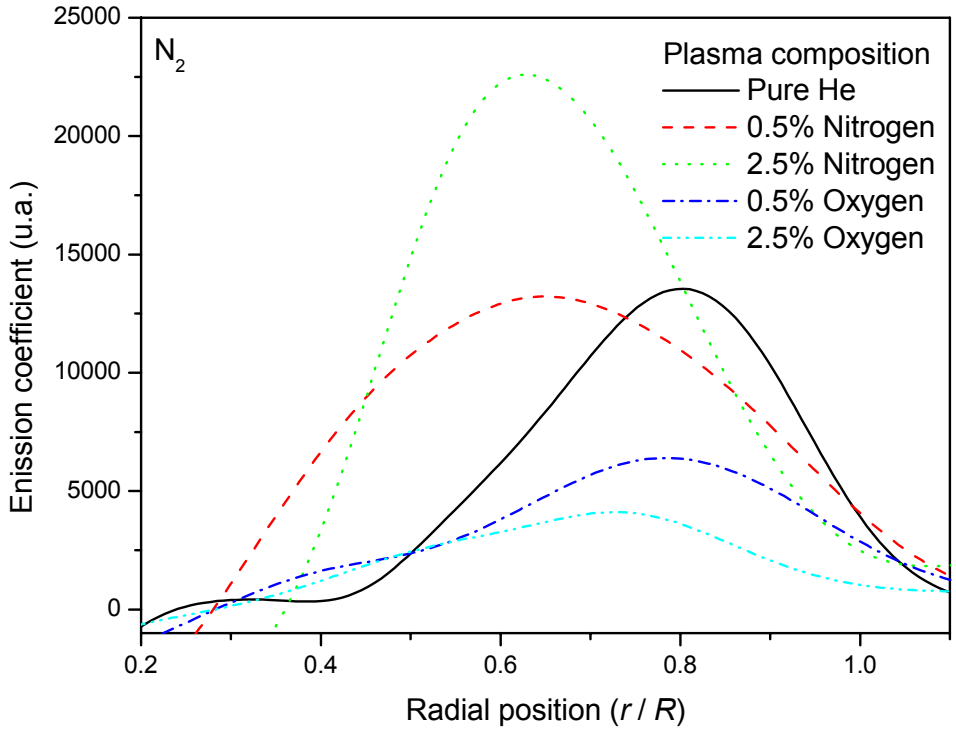

Fig. 4: Radial distributions of the emission coefficient of the 357.7 nm N_2 rotational bandhead for different plasma gas compositions.

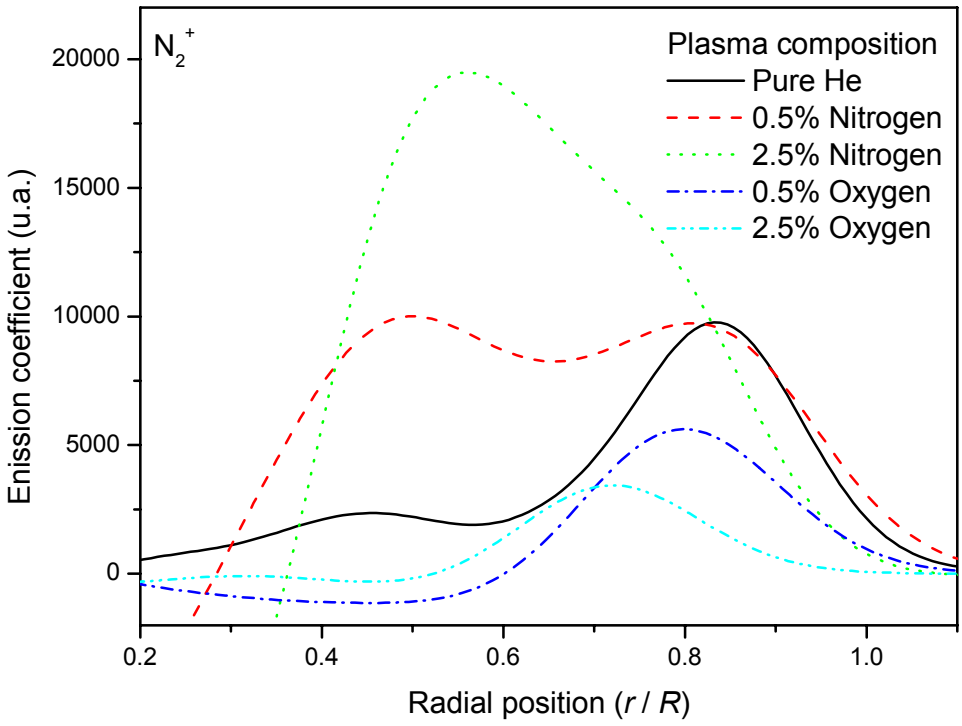

Fig. 5: Radial distributions of the emission coefficient of the 391.4 nm N_2^+ rotational bandhead for different plasma gas compositions.

pure helium, i.e. when the molecular gases come from the surrounding air that enters the discharge. The radial distributions of emission intensity of the measured species and that of a helium line are represented in Figs. 2 to 6 for every composition of the plasma gas.

5. Discussion of the results

The lack of O_2^+ can be explained by taking into account the charge transfer mechanisms proposed by Ricard [5] for a helium plasma, where molecular oxigen interacts with the ionized helium present in the plasma in these ways:

$$\begin{aligned} He^+ + O_2 &\rightarrow O_2^+ + He \\ He^+ + O_2 &\rightarrow O^+ + O + He \end{aligned} \qquad (2)$$

The occurrence ratio of these two processes is 0.03 and 0.97 respectively. As the most favoured process is, by far, the second one, this could explain the fact that no O_2^+ molecular bands were observed, while a number of atomic oxygen lines could be detected.
As to the lack of N_2^+ molecular bands, the charge transfer processes for molecular nitrogen are similar to that of molecular oxigen [5]:

$$\begin{aligned} He^+ + N_2 &\rightarrow N_2^+ + He \\ He^+ + N_2 &\rightarrow N^+ + N + He \end{aligned} \qquad (3)$$

but not the occurrence ratios, which are in this case of 0.4 and 0.6 respectively. This could explain the fact that N_2^+ bands were detected, but not O_2^+ bands, which have an occurrence ratio of only 0.03.

There is still another difference between N_2 and O_2 introduction: N_2 bands are visible all over the TIA spectrum, while no O_2 band could be measured, although the introduced quantities were the same for both gases. This is probably due to the difference in their respective dissociation energies, being 9.76 eV for N_2 and around half of that (5.12 eV) for O_2, which might indicate that O_2 is completely dissociated in the TIA plasma.

In Fig. 2 the radial distributions of a helium line are presented for every plasma gas composition. It can be seen that the line intensity decreases with the introduction of gases to the plasma, decreasing more with the added gas concentration, and being higher the decrease with oxygen than with nitrogen. This behavior can be explained if its taken into account that the dissociation energy of these gases is lower than the energy of the helium excited levels, the oxygen dissociation energy being lower than that of nitrogen.
Figs. 3 to 5 show radial distribution of nitrogen lines (N, N_2 and N_2^+ respectively), and a similar behaviour can be seen in all of them: the emission increases with the percentage of nitrogen introduced in the plasma and decreases with the percentage of oxygen. In the absence of extra nitrogen, the maxima of the distributions are close to the plasma edge, as the nitrogen comes then from the surrounding air. When nitrogen is introduced in the discharge, the radial position of the maxima shift towards the plasma centre.
In Fig. 6 can be seen the radial distribution of the atomic oxygen line for every plasma gas composition. The relative increase of the emission coefficient of this line is high when compared with the increase in the nitrogen lines. A reason for this could be the fact that, as can be seen when comparing the reaction rates of eq. 2, atomic and ionic oxygen are the main oxygen species present in the TIA plasma; not appearing molecular species and not existing enough energy to excite the ionized oxygen, atomic oxygen is the most excited oxygen specie.

Destruction of carbon tetrachloride in a microwave plasma produced at atmospheric pressure by the axial injection torch

S. Rubio, A. Rodero, M.C. Quintero

Department of Physics, University of Córdoba, Córdoba, Spain

Abstract
A novel plasma method and its application for destruction of carbon tetrachloride, using a moderate-power (several hundred watts) microwave torch discharge in atmospheric-pressure flowing helium are presented. This method can be extended to any other VOCs. The dependence on the destruction efficiency percentage was obtained for different values of the plasma conditions. The results show destruction and removal efficiencies greater than 99.999%.

1 Introduction

Some volatile organic compounds (VOCs), such as carbon tetrachloride (CCl_4) or trichloroethylene (C_2HCl_3), are typical emission gases of semiconductors and paint industries. These gases must be removed from the clean rooms not only to increase the product yield but also to protect human health. Specially, carbon tetrachloride has shown evidence of being very toxic in the water and a human carcinogen and teratogenic agent [1].

Therefore, efficient methods of destruction of these gases, which emitted to the atmosphere cause environmental problems, are in great demand. Different technologies have been investigated for decomposing the VOCs: catalytic oxidation and combustion, thermal decomposition, carbon adsorption and condensation.

Recently, several thermal and non-thermal plasma technologies have proved their potential for efficient removal of gaseous pollutants, including volatile organic compounds [2]. These plasmas are characterised by the electrons in the plasma having a higher energy than the ions or atoms and molecules, and this higher energy of the electrons can produce sufficient active chemical radicals and secondary electrons that decompose the pollutants molecules.

Non-thermal plasma techniques represent a new generation of air emission control technology that potentially could treat large-volume emissions containing dilute concentrations of pollutants. This work is focused on the study and optimisation of a destruction method of carbon tetrachloride (CCl_4), using a microwave plasma discharge. This system is a torch structure that produces a very stable high pressure (atmospheric) plasma flame at 2.45 GHz. Some modifications over the original design were made to obtain the maximum destruction percentage, like a reaction chamber design to isolate and analyse the products after destruction in the plasma.

A wide range of concentration of CCl_4 was studied, achieving destructions and removal efficiencies greater than 99.999% using an applied microwave power from 300 to 1000 W. This range of power is the one used by conventional microwave ovens.

2 Experimental set-up

The plasma was produced by the axial injection torch (Torche à Injection Axiale or TIA) [3]. This device provides a free expanding microwave plasma more resistant to impedance changes -that are caused by the introduction of samples- than other microwave plasmas [4].

A reactor was designed to be coupled to the wave-guide, in order to isolate and analyse the gases resulting from the destruction [5]. Gas samples can be taken from the reactor to be analysed by gas chromatography.

The conjunction TIA + Reactor is a good device to be applied to the destruction of volatile organic compounds.

The VOCs to be destroyed were introduced in the plasma by previously mixing them with the main gas, helium. The gas was saturated with CCl_4 vapour by forcing helium through a glass tube submerged in liquid CCl_4 at ambient temperature. The volumes of CCl_4 delivered into the plasma were determined by accurately measuring the weight differences before and after each experiment.

The concentration of CCl_4 in the final mixture was regulated by remixing with helium, before introduce the gas into the plasma. These concentrations were calibrated previously by gas chromatography.

The three main parameters and their variation range used in this work are:

- Total flow (helium + CCl_4 vapour) from 0.5 to 2.5 L/min.
- CCl_4 concentration of the gas from 0.01 to 10 %.
- Microwave applied power from 300 and 1000 W.
- Different internal diameters of the nozzle of the torch, in order to increase the energy efficiency.

A scheme of the experimental set-up is presented in Fig. 1.

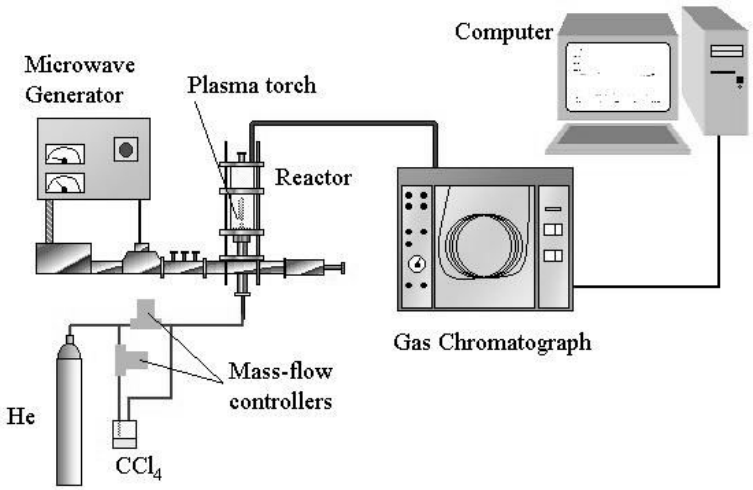

Fig. 1: Experimental set-up.

The gas mixture can then be led out through the exhaust in a fume hood via a $CaCO_3$ fluidised bed, to absorb the VOCs and their discharge products [6].

3 Carbon tetrachloride analysis

Quantitative analysis of CCl_4 was performed using an Agilent4890D gas chromatograph equipped with an electron capture detector (ECD) and a flame ionisation detector (FID). A calibration curve was generated in order to characterise the responses of these detectors to the analyte concentration. This calibration curve was carefully chosen to widely cover the concentration range of the samples injected.

The carbon tetrachloride mass density was measured before and after entering the plasma in order to compute the correspondent destruction and removal efficiency percentage (%DRE) from its standard definition [7]:

$$\%DRE = \left(\frac{W_{in} - W_{out}}{W_{in}} \right) \times 100 \qquad (1)$$

where W represents the weight of CCl_4 in the reactor chamber and the *in* and *out* subscripts denote the quantity before and after being processed.

Energy efficiency was calculated in terms of g(VOC)/kWh, as the mass of CCl_4 destroyed per hour, divided by the microwave power applied.

4 Results and discussion

The destruction of carbon tetrachloride depends on the plasma parameters, such as the electron density and the gas temperature. It is also very important to take into account the residence time of the CCl_4 in the plasma, that is computed as a function of the plasma volume. This volume and plasma parameters depend on the plasma conditions, i.e. the injected microwave power and the gas flow.

Destruction percentage was calculated for every different conditions of the TIA, such as gas flow, applied microwave power, and concentration of CCl_4. Different internal diameters of the nozzle of the torch were studied too.

The main gas flow is a fundamental parameter for the operation of the TIA. The gas flow affects considerably the destruction because the residence time of the CCl_4 in the plasma depends on the velocity of

the gas in the exit of the nozzle, and a high value of the flow reduces the residence time. Therefore it is interesting to obtain an optimum gas flow, which maintains stable the plasma in the reaction chamber and at the same time achieves good destruction percentages.

A fixed quantity of CCl_4 was destroyed using different flows of He, between 0.5 and 4.0 L/min. We can prove that the efficiency of destruction decreases when the total flow increases. But in this result two parameters are playing the same role: when the gas flow increases the time of residence decreases, and the concentration of CCl_4 decreases too (if a fixed mass of CCl_4 is used). Both effects produce a decrease of %DRE, so it is necessary study them separately.

4.1 Dependence of destruction efficiency with total flow

In order to study this dependence of %DRE when the total flow is changed, we have to maintain constant the concentration of CCl_4, which implies that the mass of CCl_4 must be increased as the flow of helium increases. We can observe only the dependence on the gas flow, if we have always the same concentration of CCl_4. This value is measured on-line by gas chromatography.

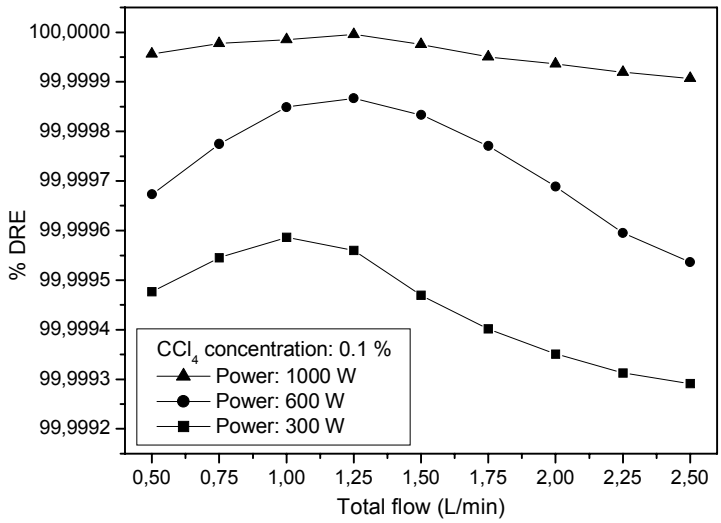

Fig. 2: Dependence of the %DRE with the gas flow for a fixed concentration of CCl_4, and three different applied microwave powers.

In fig. 2 it is shown a study with a concentration of 0.1 % of CCl_4. The total flow was changed and the %DRE measured for each value. Three applied microwave powers were used in this graph where we can observe that higher microwave powers achieve better destruction efficiencies. However the study of the influence of the applied microwave power will be discussed below.

It can be seen that there is an optimum gas flow value where the CCl_4 destruction is maximum. In this point the plasma has the best conditions to destroy a particular CCl_4 concentration with an applied microwave power. The %DRE decreases at higher values of helium flow. This is due to the decrease of the plasma gas temperature and to the reduction of the plasma volume, which implies lower residence times of the CCl_4 in the plasma.

On the other hand, the lowest flows of helium do not achieve the best destruction percentage because the TIA does not work correctly with total flows below 0.7 L/min.

4.2 Dependence of destruction efficiency with CCl_4 concentration

Another important parameter to characterise the destruction capability of this set-up, is the concentration of CCl_4 in the gas mixture used to generate the plasma. We have observed that higher destruction percentages were obtained when higher CCl_4 concentrations were used. This result implies that more CCl_4 molecules are decomposed, using a given energy and total flow, when CCl_4 concentration increases.

Similar results have already been found by T. Yamamoto [8] and B.M. Penetrante [9] and they suggested that secondary decomposition of CCl_4 could be induced by fragments of ions and radicals, from the initial decomposition of carbon tetrachloride.

Thus, if the concentration is higher, the quantity of molecules and collisions increases and the destruction efficiency is improved. It must exist a limit to this effect, but it is necessary very high concentrations, which is not possible because this value depends on the saturation of the gas with vapour of CCl_4, and we observe that concentrations above 20% are not possible.

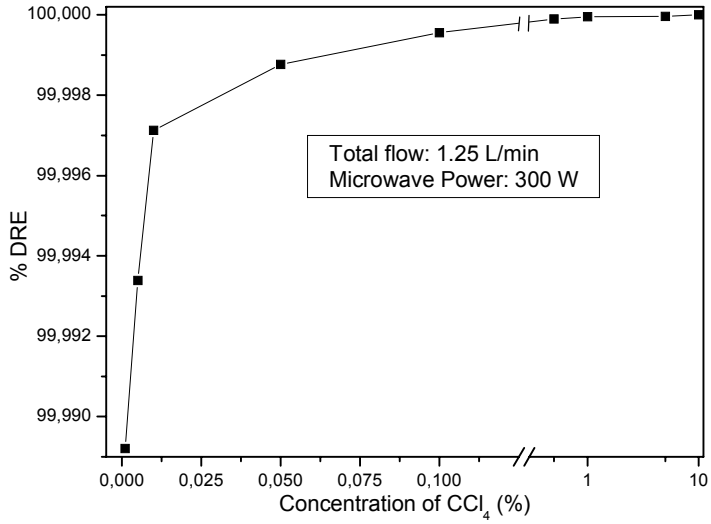

Fig. 3: Dependence of the %DRE with the applied microwave power for different CCl_4 concentrations.

Our data support this theory and in fig. 3 it is represented efficiency versus concentration of CCl_4, using a fixed total flow (1.25 L/min) and a constant applied microwave power of 300 W.

Higher concentrations seem to be the best solution because the energy efficiency is maximum. However lower concentration are of remarkable importance in some applications, such as the removal of air pollution. In this case, a good destruction percentage can be obtained by increasing the applied microwave power or decreasing the total flow. So it is possible to find the best conditions to destroy any quantity of CCl_4 with the proposed plasma-reactor system.

4.3 Dependence of destruction efficiency with applied microwave power

The electron energy increases when the microwave energy increases. Thus, the destruction capability improves when higher microwave power is used, but the energy efficiency decreases. We cannot use energies higher that are used in the actual method of processing, if we want show this system as novel.

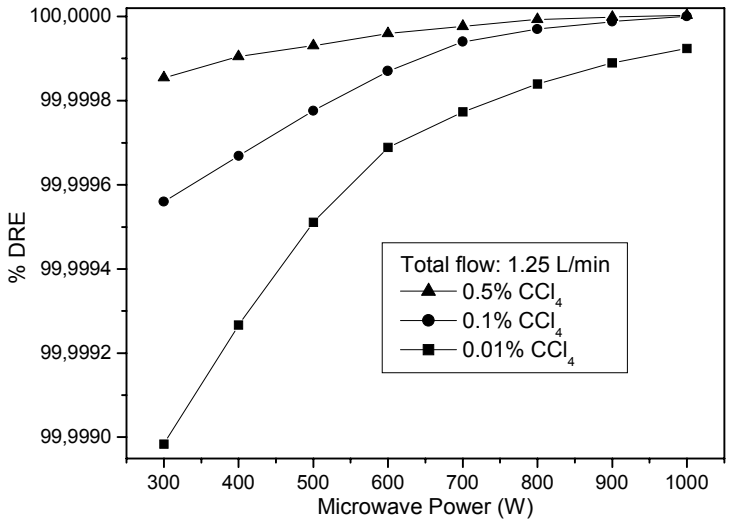

Fig. 4: Dependence of the %DRE with the CCl_4 concentration in the plasma gas.

In fig. 4 the dependence of the %DRE with the microwave power was studied using a helium flow rate of 1.25 L/min and different applied microwave powers, for three separate CCl_4 concentrations. These results clearly show that the %DRE increases as the microwave power until this raises 900 W, where the destruction efficiency exceeds 99.9998% for the highest concentrations. Beyond this value of injected power, no significant improvement of the %DRE was observed.

These results show 99.99985 % of destruction is obtained with 1000 W at 0.1 %. The same percentage is obtained with 400 W at 0.5 %. The conclusion is that we need lower microwave power to destroy the same percentage of CCl_4 if higher concentrations are introduced. The maximum possible concentration is given by the saturation of CCl_4 in helium.

4.4 Different cross-sections of the nozzle

Reduced energy efficiencies can be calculated from previous results, but in this set-up it is possible to achieve great values of this parameter only by changing the nozzle where the plasma is coupled.

We have already said that the destruction efficiency depends on plasma volume and residence time, but these parameters depend directly on the velocity of the gas in the exit of the nozzle. Thus, if we use a higher cross-section in the nozzle, a higher quantity of mass of CCl_4 will be destroyed with the same destruction percentage, because a higher flow is necessary to maintain the same velocity of gas in the nozzle, if we maintain a fixed concentration of CCl_4 in the gas.

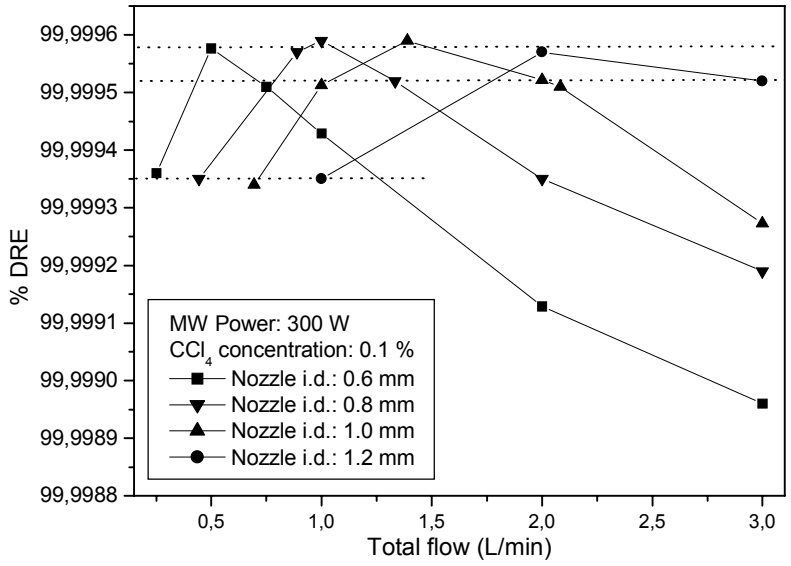

Fig. 5: Comparison of the destruction capabilities of four different nozzles of the TIA. "i.d." means "internal diameter"

Fig. 5 compares the results of experiments of 0.1 % of CCl_4 with four different internal diameters of the nozzles. The dash dot lines link points with the same velocity of gas in the nozzle, and we observe that these points have the same destruction and removal efficiency. This demonstrates that %DRE depends strongly on the velocity of the gas in the exit of the nozzle.

It is possible to observe that higher flows of helium+CCl_4 are necessary if we use higher internal diameters of the nozzle. If the system is completely scalable with internal diameters of 3 mm, flows above 15 L/min can be used. An application of these diameters would be the industrial treatment.

Energy efficiencies over 500 g/kWh were achieved in our apparatus with destruction and removal efficiencies above 99.999%.

Hence, it is necessary to say that the results previously presented, made in a laboratory scale, were measured using a nozzle with a small diameter, 0.8 mm of internal diameter. However, in an industrial processing, it would be interesting use bigger cross-sections.

5 Conclusions

This paper shows the effects of microwave power, gas flow rate, and CCl_4 concentration on decomposition efficiency:

- The conjunction TIA plus reactor seems to be a promising device to VOCs destruction.CCl_4 decomposition increases with microwave power supplied.
- At fixed CCl_4 concentrations and applied microwave power, its decomposition efficiency decreases as the gas flow rate increases.
- The decomposition efficiency was slightly higher with higher CCl_4 concentrations, which implies that more CCl_4 molecules are decomposed for a given energy when CCl_4 concentration is higher. This suggests that secondary decomposition of CCl_4 can be induced by some fragment ions and radical from the initial decomposition of CCl_4 [8,9].
- Energy efficiencies above 500 g/kWh can be achieved using higher cross-sections of the nozzle of the torch. The destruction efficiency depends on the velocity of the gas in the exit of the nozzle. More mass is destroyed per minute when higher cross-sections are used.
- It can be found the best parameters to maximize the destruction efficiency, for every concentrations of CCl_4.This method is useful in industrial processes, if we use higher internal cross-sections of the nozzle and the necessary flows and watts to destroy all that is needed.

Abstract
The aim of this work is to present the results of the spectroscopic caracterization made on two microwave plasma torch discharges with different construction geometry: the Axial Injection Torch (Torche à Injection Axiale or TIA) studied at the Cordoba University, and a microwave plasma torch used at the Masaryk University. Various discharge parameters have been measured for various operating conditions, such as different microwave power inputs and presence or not of extra H_2O in the discharge.

1. Introduction

Plasmas used in analytical chemistry are characterized mainly in order to relate their fundamental parameters with their analytical capability. Such characterizations are usually performed with the plasma working with a pure plasma gas, this is, with no analytes added. However, the introduction of liquid samples in the discharge causes some water to enter the plasma (unless the sample is not a dilution in water), which might modify the plasma parameters and hence its analytical capability. In this work the effect of the introduction of water in a microwave induced argon plasma has been studied. For that purpose two main plasma parameters such as the electron density (n_e) and the gas temperature (T_g) have been measured in two different microwave plasma torches. Both torches receive the input power via a waveguide, which enables them to stand more power that torches fed via a coaxial cable.

The TIA (Fig.1) provides a very stable plasma that can operate over a very wide range of operating conditions, (viz. incident powers between 150 and 3000 W, and gas flow-rates between 1 and 15 l min^{-1}),

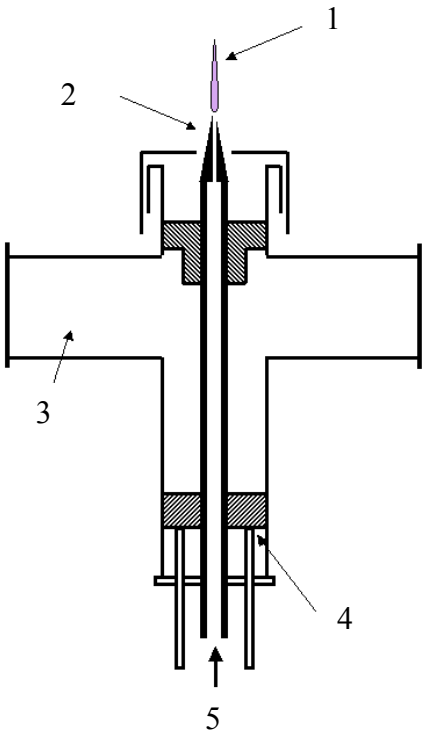

Fig.1: Scheme of the TIA

Table 1: Description of the instruments used in the TIA set-up.

Microwave launcher	TIA (Montreal University)
Microwave generator	GPM 12K T/t (SAIREM) at 2.45 GHz
Maximum generator power output	2000 W
Forwarded power	300–1000 W
Material of the nozzle	Brass
Argon flow rate	3.5 l min^{-1}
Monochromator	THR-1000 (Jovin-Yvon) Grating 1200 grooves mm^{-1} Dispersion: Typically 0.8 nm mm^{-1} at λ=500nm Computer-controlled Spectralink system
ICCD camera	Flamestar 2 (La Vision)
Flow controller	Bronkhorst mass flow controllers IB31 control unit (Iberfluid Instruments)

with no additional cooling. It requires no dielectric tube to hold the plasma and can operate with any type of gas, whether atomic (He, Ar) or molecular (O_2, N_2, air). The TIA therefore seems to be a promising alternative to the ICP as an excitation source for atomic and molecular spectroscopy; in fact, it has been experimentally found to provide strong emission lines for non-metals such as S(II) and halogens such as F(I), with helium as the plasma gas. Spectroscopic investigation of this discharge with helium as the working gas was described in [1]. The other microwave plasma discharge (Fig.2) has been studied at the Department of Physical Electronics of the Masaryk University at Brno as an environment for synthesis of boron nitride [2], and is actually being used as a plasma source for spectroscopic analysis.

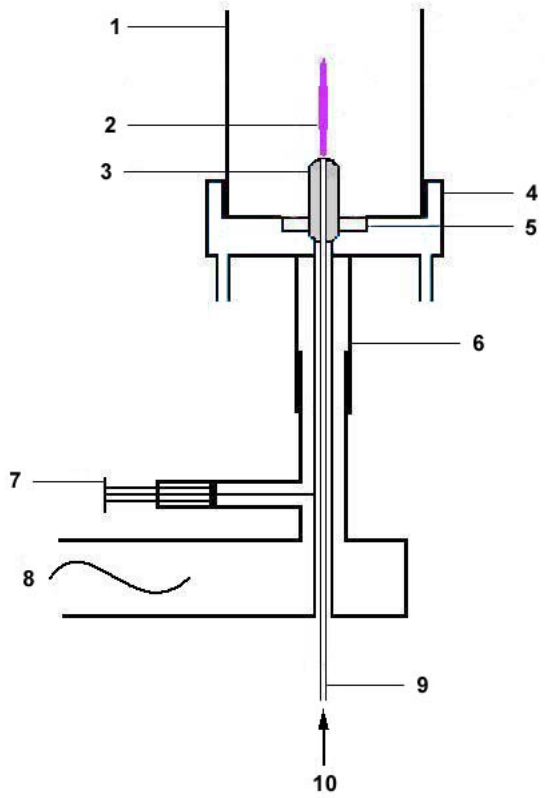

Fig. 2: Scheme of the Brno torch:
1- Wire shield; 2- Plasma torch; 3- Brass nozzle; 4- Aluminum holder; 5- Boron nitride underlay; 6- Cylindrical waveguide; 7- Movable plunger; 8- Waveguide; 9- Sample delivery quartz tube; 10- Argon input.

Table 2: Overview of technical parameters for the Brno torch.

MW generator working frequency (Muegge)	2.45 GHz
Maximum generator power output	2000 W
Forwarded power	300–1000 W
Reflected power	10–80 W
Inner diameter of the quartz tube	2.3 mm
Material of the nozzle	Brass
Argon flow rate	3.5 l min^{-1}
Sample flow rate	1.2 $cm^3.min^{-1}$
Nebulizer	Meinhard concentric
Scanning the spectra	Optical cable
Monochromator (Jobin-Yvon)	TRIAX 320, CCD detector

Rotational temperatures were measured from molecular species present in the discharge (OH and N_2^+) and T_g could be obtained by calculation of Boltzmann distribution law from the relative intensities of selected emission lines of these species. Electron number density was measured from Stark broadening of the hydrogen emission lines of the Balmer series.

2. Experimental

In order to compare the results obtained with the two different torches, their working parameters have been set as equal as possible. In tables 1 and 2 the technical description of the instruments used in both experimental set-ups can be found. The discharge produced by the TIA is sustained by the 2.45 GHz incident power suplied by the microwave generator, which ranges from 400 to 1000 W. The plasma gas flow was set to 3.5 l min^{-1}. The optical system consists of a Dove prism and two achromatic lenses, which respectively rotate 90º an image of the plasma and focus it at the entrance slit of the monochromator, hence allowing an axial position to be selected. The axial position of the measurements was the maximum emission position, i.e. 1 mm above the tip of the noozle. An intensified CCD camera at the exit of the monochromator was used for measuring the spectra. The water was introduced in the discharge by making the 15% of the argon flow through distilled water.

As to the measurements on the microwave plasma torch from Brno, the microwave plasma discharge is generated by means of the 2.45 GHz generator (Muegge) that delivers a maximum power of 2 kW. The plasma originates above the nozzle of the laboratory-constructed applicator. The same plasma gas and the same flow rate as the ones used with the TIA (argon, 3.5 l min^{-1}) flows through the inner quartz tube, and the discharge is also operated at a forward power of 400–1000 W, with a low reflected power (10–80 W). The radiation emitted from the plasma was collected using an optical fibre onto the entrance slit of a TRIAX monochromator (Jobin-Yvon) provided with a CCD detector. Spectra acquisition and treatment were performed by means of SPECTRAMAX software. When water was introduced, it was delivered into the Meinhard concentric nebulizer with the Scott spray chamber, which has a pump uptake rate of 1.2 cc min^{-1} and a nebulization efficiency of approx. 5%.

3. Spectroscopic measurement.

Rotational temperature measurement

The gas temperature measurement is performed frequently as an integral part of discharge investigation. Various techniques have been developed for this purpose (Langmuir probes, thermocouples, pyrometers); however, under the MW operating conditions only one approach is usually applied in the field of spectral methods. This techniques supports on the fact that the neutral gas temperature is taken to be nearly the same as rotational temperatures calculated from molecular spectra of some species (N_2, N_2^+, OH, CN…), because of the highly favourable exchange of energy between the kinetic energy of heavy particles and the internal rotational – vibrational states of the molecular species involved [1, 3].

In order to measure the gas temperature in the TIA plasma, seven lines of the R-branch of the first positive system (0-0) of the rotational band of the N_2^+ ionic molecule have been measured. The correlation of the Boltzmann plot is $R^2 \sim 0.7$ without adding water and $R^2 \sim 0.6$ when the water is introduced. No OH bands could be detected in this plasma.
In the plasma torch used in Brno, the gas temperature was determined from the relative intensities of the OH rotational lines (band 306.4 nm, branch Q_1). An important remark for this calculation is that one must select only the OH rotational lines of the Q_1 branch with rotational quantum number up to 13/2, which ensures the obtainment of reliable temperature (cold OH group). On the contrary, higher energy lines provide considerably higher temperatures, which are related to OH as a product of e.g. water dissociation (hot OH group) [4].

The R-branch of N_2^+ was measured too, but for this plasma torch the band does not provide good correlation in the Boltzmann plot ($R^2 \approx 0.2$-0.5), even if these lines are quite distincted in the spectra. That is why the Q_11, Q_12, Q_14, Q_15 and Q_16 OH lines were used, as described above. They are measurable and usable under any of the studied conditions and the correlation of their Boltzmann plot for this plasma is much better ($R^2 > 0.9$).

Electron density measurement:

Electron number density was measured from Stark broadening of the hydrogen H_β (486.13 nm) emission line, using the presence of hydrogen in the discharge. Lorentzian part of the line profile was calculated from this equation [3]:

$$\Delta\lambda_L = \frac{(\Delta\lambda_0)^2 - (\Delta\lambda_G)^2}{\Delta\lambda_0} \quad (1)$$

where $\Delta\lambda_0$ is the FWHM and $\Delta\lambda_G$ is the instrumental and Doppler broadening.

In the case of the Brno plasma, the H_β was observable in the discharge spectra both with and without water nebulization. However, in the case of the TIA, the emission intensity of the H_β line was too low to provide good measurements of the electron density. This problem was solved by making use of a previous calibration between the FWHM of the H_β and the H_α [1], which presents a higher emission intensity in the TIA discharge. Hence, from the FWHM of the H_α line it was obtained the FWHM of the H_β line, and from it, using the previous equation, its Lorentzian part $\Delta\lambda_L$.

The electron number density [m^{-3}] can then be calculated from the Czernichowsky and Chapelle formula [3]:

$$\log n_e = 22.578 + 1.478 \log \Delta\lambda_L - 0.144(\log \Delta\lambda_L)^2 - 0.1265 \log T_e \quad (2)$$

where $\Delta\lambda_L$ is in nanometers and the estimated electron temperature T_e is of 15000 K for the Brno plasma and of 20000 K for the TIA plasma. This values have been taken on basis of the respective MW discharge properties [1, 3]. However, the Czernichowsky and Chapelle formula is not very sensitive to small changes in the T_e.

4. Results

The values of the electron density for the two plasma torches, with and without water added to the discharge, are represented in the figure 3 as a function of the supplied microwave power. The first result that can be seen in the figure is that the n_e increases with the introduction of water for whatever the suplied power value or the plasma torch used. It can also be seen that the n_e increases with the power in the case of the TIA,

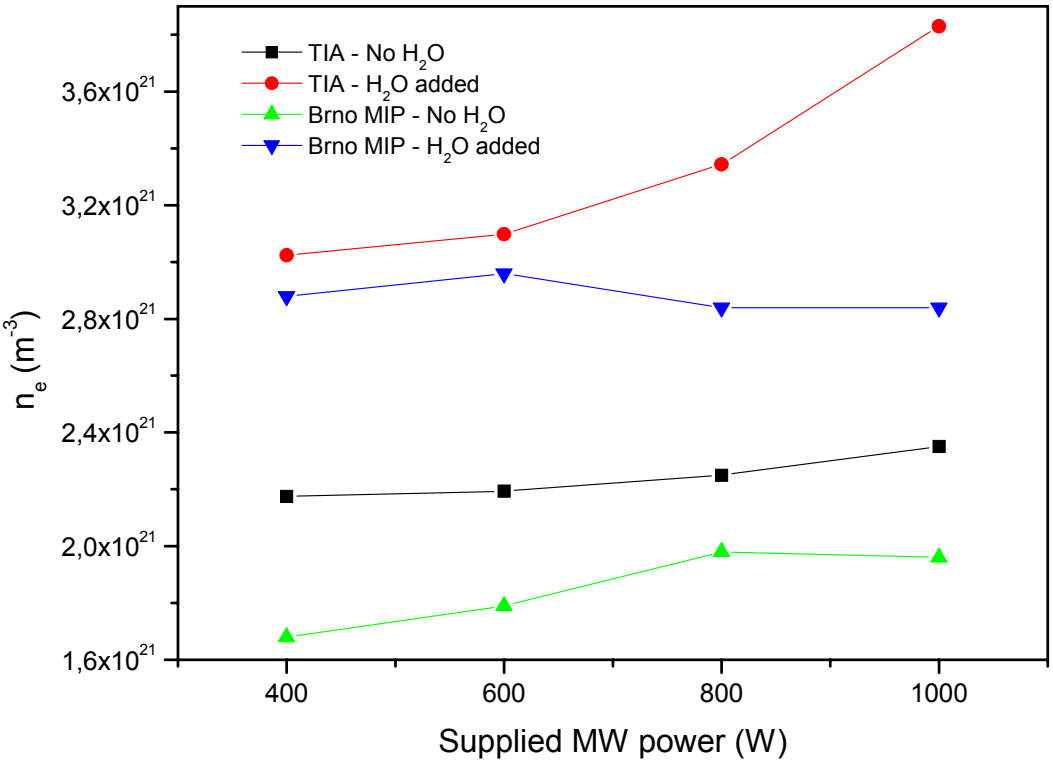

Fig. 3: Variation of the electron density with the suplied power for different torches, with and without adding water

although such variation is not so clear in the Brno plasma. The n_e values obtained for the TIA are above that of the Brno torch, although the order of magnitude of the results is the same in both torches.

The measured gas temperature values are depicted in Fig. 4, where, as in Fig. 3, there are the values corresponding to both torches, with and without adding water to the discharges, as a function of the supplied power. As the electron density, this parameter is also increased with the introduction of water for every possible case. However, the variation of the T_g with the supplied power is not as clear as that of the n_e in the case of the TIA, and the same happens for the Brno plasma. Furthermore, water makes the correlation of the Boltzmann plot to decrease in the calculation that uses the N_2^+ band, which difficults the apreciation of any dependence. The values of this parameter are higher for the TIA plasma than for the Brno plasma, which is not very conclusive due to the difference in the method of obtention of the T_g for the two plasmas.

5. Conclusions

The plasma parameters measured in this work, i.e. the electron density and the gas temperature, have been found to clearly increase when a small percentage of water is introduced in the discharge, not depending on the type of microwave plasma torch studied. This result implies that the introduction of water in a microwave discharge as a result of the introduction of liquid analytical samples is, rather than the cause of a decreasement of the analytical power of the discharge, a way of improving the plasma excitation capability. This increase of the parameters with the water presence may be related to the behavior of polar water molecules as a good MW energy absorber, followed by their dissociation on OH radicals and hydrogen, water products which would then transfer their energy to the other species present in the plasma. In the case of the TIA, no traces of OH were found, which suggests that in that plasma the OH radicals are dissociated, being hydrogen the cause of the increasement in the n_e and T_g values. The T_g and the n_e seem to increase with the supplied power, although that dependence is not always so clearly seen when water enters the discharge. The plasma produced by the TIA shows higher values of its parameters than the Brno plasma, although the order of magnitude of the measured parameters in both torches is the same.

Drag Coefficients for Spheres in Supersonic Argon Plasma Flow

A. Blais, A. Sirois, B. Jodoin

Department of Mechanical Engineering, University of Ottawa, Ottawa, Canada

Supersonic plasma flows are found in many industrial applications. They are generally obtained in Low Pressure Plasma Spraying (LPPS) processes, using plasma torches operated at reduced pressure. Plasma spray coatings benefits from the reduced pressure, higher velocities, and longer heating zone that exist in the supersonic core of the plasma jet [1,2]. This configuration accelerates particles to high impact speed. It leads to a higher density of the deposit than usual coating processes and less contamination due to the reduced operating pressure. Many different coatings have been successfully obtained using this technique [3]. Experimental and theoretical studies have been conducted to develop diagnostic tools and to characterize the supersonic plasma jet [4]. Those studies aimed at a better understanding of the various phenomena occurring in the supersonic plasma jet.

Because of the complexity of the supersonic plasma flow, one common goal of all the theoretical models developed is to get a complete and detailed model. Such a model should be able to predict the entire flow field and its interaction with the injected particles and the substrate. While many authors have focused their work on the prediction of the flow field in the plasma torch, others have developed models to predict the flow behavior in the free jet outside the torch. At the present time, those models are becoming more and more useful as predicting tools for the entire flow field. However, little work has been done so far regarding the injected particles behavior in the supersonic flow. Furthermore, all the modeling work done so far uses the drag coefficient (C_D) for spherical particles as measured in supersonic air flow. The fact that a different gas is used and that it is in plasma state has never been considered in the drag coefficients used to predict the particles trajectories. Since the time history of the in-flight particles is of crucial importance to predict the impact temperature and velocity of the particles, this drag coefficient may have a major influence in the prediction of the process performance.

The present work focuses on the prediction of the drag coefficients of spherical particles in a supersonic argon plasma. The approach used is to model a solid sphere injected in a supersonic argon plasma jet and to predict the plasma flow field around the particle to obtain the drag coefficient of the particle. The model is validated extensively with results from the literature on supersonic cold flows. The drag coefficient predicted by the model for supersonic cold flows is able to capture the proper physics and predict the drag coefficient within a few percent of error. The plasma model is then used to predict the drag coefficient in supersonic argon plasma flows for various Mach number and different pressures. A chemical non-equilibrium model is used, solving the mass, momentum, energy and species equations.

It is found that the drag coefficient is strongly influenced by the specific heat ratio, even at low temperature. Therefore, C_D is a function of the plasma temperature and pressure for a specific Mach number. It is also found that for supersonic flows, the drag coefficient is not function of the Reynolds number and that the drag force is mainly due to the pressure force on the particle created by the shock wave in front of the particle. It is expected that these new drag coefficients will help improve modeling the plasma-particle interactions in supersonic argon plasmas.

Synthesis of carbon single wall nanotubes by a microwave plasma torch

O. Smiljanic, F. Larouche, X. Sun, J.-P. Dodelet, B.L. Stansfield

INRS-Énergie, Matériaux et Télécommunications, Varennes, Québec, Canada

Abstract

Single wall carbon nanotubes have been produced via a gas-phase process using a plasma torch to dissociate a carbon-containing gas. Two different microwave plasma torches have been used successfully. Results show that both the plasma temperature and the temperature gradient play important roles in determining the efficiency of the process.

1. Introduction

The enormous interest in carbon nanotubes is due to the exceptional properties of these structures as well as the innovative applications which could arise[1,2]. Despite this potential, which could produce a technological revolution, progress in the field is slowed by the lack of raw material, due to the inadequate methods of synthesis (laser ablation, electric arc, CVD). The production of nanotubes in large quantities is thus an objective sought by many laboratories around the world. There exist two forms of carbon nanotubes: those with multiple walls (MWCNTs) and those with a single wall (SWCNTs). This latter form is much more interesting than the MWCNTs because of their properties. On the other hand, the level of production of SWCNTs is only a few grams per day, with prices approximately 1000$/g. A breakthrough in production technology is thus necessary to realize the many applications of SWCNTs.

Our objective is to demonstrate that there is an alternative to the existing methods for SWCNT synthesis: an approach based on the use of a plasma torch. As a first step, we have shown that the synthesis by plasma torch produces a product comparable to that produced by laser ablation and electric arc, the two most popular methods. As a second step, we have tested different torch configurations to solve certain problems, and finally we have studied the important parameters influencing the synthesis of SWCNTs.

2. Principle

The fact that the carbon and the catalyst are in solid form is a principal disadvantage of the laser and arc methods. In principle, these are discontinuous processes, because the carbon block must be changed once it is used up. In addition, the vaporization of graphite requires a lot of energy (716.6 kJ/mol), thus requiring a powerful laser or arc for a small rate of production, which partially explains the high cost of nanotubes produced by these methods. We have thus replaced the solid source by a gaseous one. Instead of using graphite, we use a carbon-containing gas, and an organometallic molecule containing carbon and metal as the catalyst: ferrocene. Other metallocenes exist, such as nickelocene and cobaltocene, which might be more efficient, but we have chosen in our experiments to use ferrocene because it is not as toxic as nickelocene or cobaltocene. Since the ultimate aim is the large scale production of nanotubes, it is difficult to foresee such a production using carcinogenic materials. The advantage of using a carbon-containing gas is the small amount of energy we need to supply to atomize it; for methane it is only 80 kJ/mol. Thus, the power necessary to produce the building blocks required for building the SWCNTs in a high temperature plasma is ten times smaller than in the case of laser or arc techniques. In addition, by using a carbon-containing gas the process can be continuous, which would favor the implementation of a large-scale industrial process.

Compared to the CVD methods, a significant advantage is provided by the plasma, which does the work of decomposing the gas, whereas in the CVD approach the role of the catalyst is double: the decomposition of the gas and the assembly of the nanotubes. In addition, in the CVD methods, the majority of the gas (greater than 90%) passes through the reactor without reacting with the catalyst particles, which thus requires a recirculation of the unreacted gas to avoid a loss of efficiency.

3. Methodology

We have tested two different types of microwave plasma torches: a tubular design where the plasma is generated within the body of the torch, and an axial design (the TIA)[3]. The schematic showing the operation of the first design is shown in Figure 1 (left). The mixture of carbon-containing gas, ferrocene and argon is injected into the torch and atomized by the plasma. In this way, the basic building blocks for the formation of the nanotubes (C_2, carbon clusters, atoms and clusters of metal) are created. The exhaust from the plasma is injected into a furnace at 900°C, where the growth of the nanotubes takes place. The deposits containing the nanotubes are collected from the walls of the reactor. The sheath gas is used to protect the plasma tube by forming a gaseous layer between the plasma and the wall. We also count on this layer to prevent the formation of carbon deposits on the surface. We have also injected the gaseous mixture at the exhaust of the torch to avoid the formation of deposits on the plasma tube.

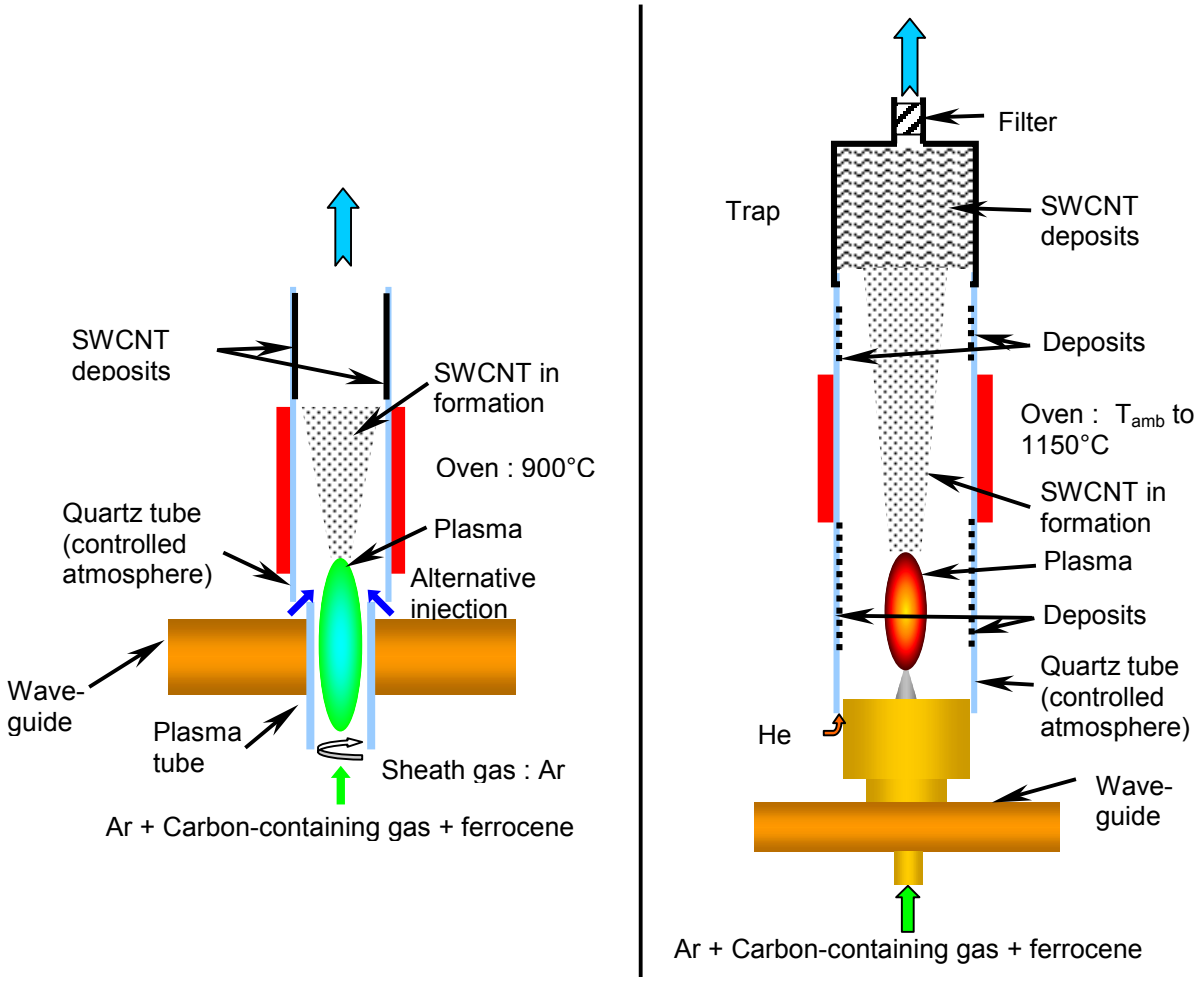

Figure 1 : (Left) Schematic showing the growth of single wall nanotubes in a tubular plasma torch. (Right) Overall view of the process based on the TIA.

In the second approach, the plasma is produced outside the structure of the torch, which has the advantage of making the torch less sensitive to carbon deposits (Figure 1 right). The plasma torch decomposes the carbon-containing gas and the ferrocene, again producing the building blocks necessary for fabricating the nanotubes. The other important points in the process are the control of the temperature gradient between the flame and the furnace and the temperature of the latter. To achieve this, the furnace is placed at a variable height above the torch. In addition, in order to minimize the carbon deposits on the

quartz tube, and to control the flow and the thermal gradient, helium is injected around the torch next to the quartz tube. The deposits form inside the quartz tube, at the exhaust from the furnace and in the downstream trap.

The operation of the torch is controlled by computer using Labview. We have used ethylene as the carbon-containing gas, with a throughput of 50 sccm. The program adjusts the argon throughput to obtain the desired metal to carbon ratio, typically 2%. The system is operated at atmospheric pressure, but under a controlled atmosphere of argon and helium. The furnace temperature is measured by an optical pyrometer. The samples are analysed by scanning electron microscopy (SEM), transmission electron microscopy (TEM), as well as by Raman scattering. The Raman spectra were taken using an irradiation wavelength of 782 nm.

To compare the samples, we have established what we call a quality factor Q. The main criterion used in the literature is the ratio between the peaks related to the graphitic structure (G) and the disorder (D): G/D. This allows us to determine the degree of graphitisation in the sample, and thus indicates its quality. To complement this criterion, we have added to this the ratio between the highest peak of the radial breathing mode (B) and the disorder peak (D): B/D. Figure 2 shows the relative positions of these peaks.

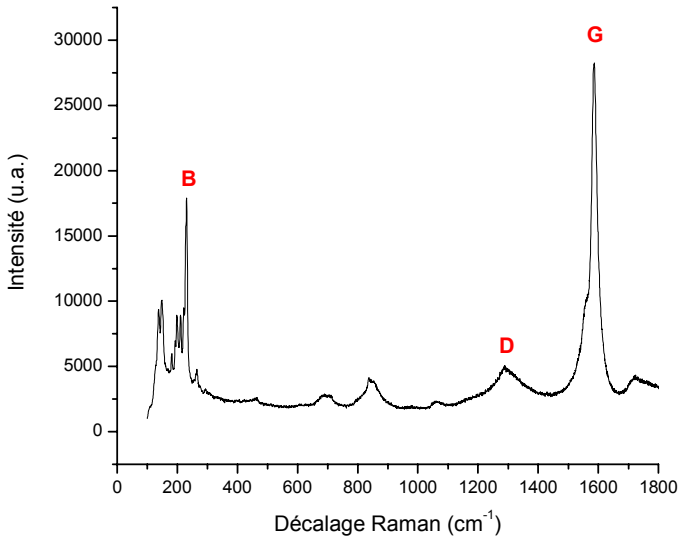

Figure 2 : Typical Raman spectrum of a sample containing a large proportion of nanotubes. The peaks G, D and B represent the graphitic peak, the peak related to the disorder, and the peak related to the nanotube diameter, respectively.

This latter ratio indicates the proportion of nanotubes in the deposit, but does not alone provide information on the overall quality. In practice, we should take into account the degree of graphitisation, the amount of disordered structures, and the proportion of nanotubes in the sample, to obtain a criterion representative of the quality. Thus, we have combined these two ratios G/D and B/D to obtain a parameter Q indicating the overall quality of the sample :

$$Q = \frac{G}{D} \cdot \frac{B}{D} = \frac{G \cdot B}{D^2}$$

The height of each peak is determined with respect to the background, which allows us to have a quality factor Q which is zero when there are no nanotubes in the sample, since in this case B=0. We have compared our results obtained using this parameter to our SEM observations, and we find a good qualitative correlation. The margin of error between samples is of the order of 20%. Emission spectra of the plasma were obtained using a ½ meter spectrograph (Acton Research) equipped with a grating having 1200 lines/mm, coupled to an ICCD multichannel detector (Andor). The resolution of this system is about 0,050 nm.

4. Results : the tubular plasma torch

We have tested two configurations with this set-up : with injection of the carbon-containing gas and the ferrocene either upstream or downstream from the plasma source. The aim was to stop the formation of carbon deposits in the plasma tube, which hinder a good coupling between the microwaves and the plasma.

When the mixture is injected upstream, a good production of nanotubes is obtained (Figure 3). We see in Fig.3a that the unrefined samples are basically composed of cords of single wall nanotubes (several of which combine to form a larger bundle), mixed with nanometer-size particles. The diameter of the cords is of the order of 20 nm, and the length exceeds 1 μm. In Fig.3b, we see clearly that the tubes are single wall, having diameters of the order of 1.5 nm. The tubes are surrounded by a matrix composed of amorphous carbon and nanoparticles of the catalyst having diameters of 1 to 3 nm. Thus, the nanoparticles of the catalyst, which are necessary for the formation of the nanotubes, are created spontaneously in-situ. The typical quality factor of the samples for this configuration is 11. Unfortunately, deposits form inside the plasma tube, and prevent good coupling between the microwaves and the plasma; this results in a degradation of the latter with time, and ultimately extinction after 15 or 20 minutes. We have thus attempted to inject the carbon-containing mixture downstream from the plasma source, at the exhaust of the torch.

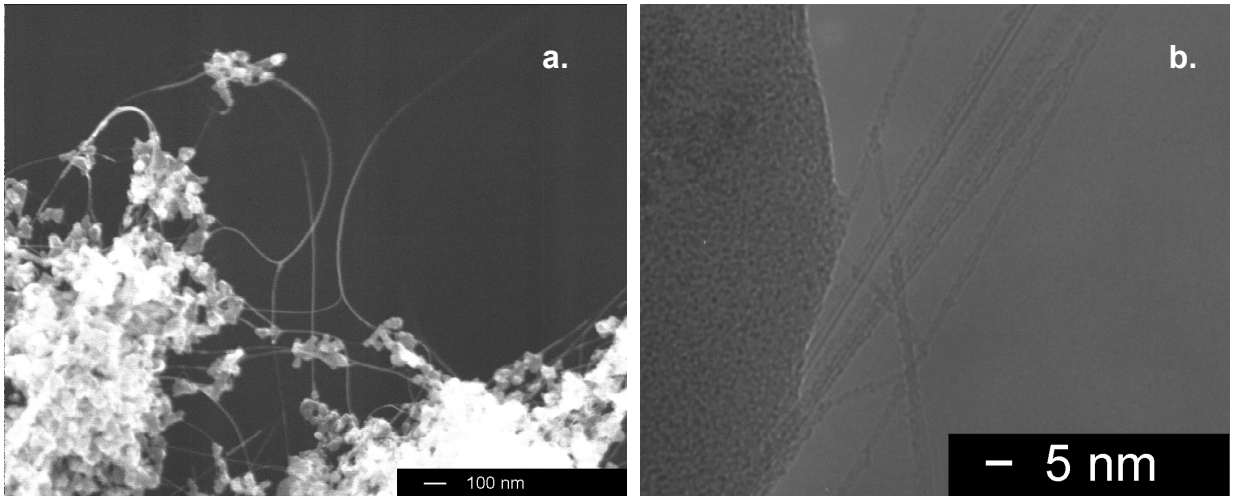

Figure 3 : a. SEM image of the deposits obtained with the tubular torch, with injection of the mixture upstream of the plasma source. b. TEM image of the same deposit.

In this case, SWCNTs are also obtained, but in a much lower proportion than in the previous case. The quality factor obtained for this configuration is only 1.8. Since the plasma is much less intense downstream from the source region, the temperature which the mixture attains must be lower than in the previous case. Since the temperature gradient is a key element in the gas phase synthesis of SWCNTs[4,5], the plasma temperature is very important, since it determines the initial point for the temperature drop. The importance of the temperature gradient as well as the growth temperature were verified in experiments with the TIA source.

5. Résults : the TIA

Emission spectroscopy of the flame allowed us to verify the presence of certain species necessary for the formation of single wall nanotubes. We were also able to determine certain important parameters defining the temperature profile during the growth of the nanotubes. The Swan band of C_2 is very intense, indicating that a significant density of these molecules is present in the plasma. The presence of atomic hydrogen in the plasma is confirmed by the observation of the H_α (656.3 nm) line; this indicates that at least some of the organic molecules are dissociated . Unfortunately, the H_β line could not be clearly distinguished from the background ; the width of this line is dominated by Stark broadening for our plasma, and it could have been used to calculate the plasma density. The fact that the H_α line is present, while that of H_β is not, is

somewhat mysterious, and will be studied further. We have also confirmed the presence of the following lines of FeI, thus indicating that the ferrocene is at least partially dissociated: 426.0 ; 427.1 ; 428.2 ; 430.7 and 432.5 nm. Finally, a spectroscopic analysis of the flame indicated no presence of the radical CH; the (0,0) band of CH, with band head at 431.4 nm, the most intense band, is absent. This last observation suggests a dissociation scenario for the ethylene in the plasma.

The presence of the C_2 molecules and the atomic hydrogen, and the absence of CH radicals in the plasma, suggests that the ethylene is dissociated by one of the following paths:

- $C_2H_4 \rightarrow C_2 + 4H$
- $C_2H_4 \rightarrow C_2 + 2H_2$
- $C_2H_4 \rightarrow C_2 + xH + yH_2$

We have not been able to determine whether the hydrogen is produced directly in the atomic form or in the form of molecules. The measurement of radiation from atomic hydrogen could also be due to the dissociation of the molecular hydrogen by the plasma.

The temperature of the flame is an important parameter in the process, since it largely determines the rate of dissociation of the carbon-containing gas and the ferrocene, as well as fixing initial point of the temperature gradient. We have determined the temperature of the flame during the synthesis of the nanotubes by analysing the spectrum of the (0,0) Swan band, taking into account the resolution of our instrument[6]. We obtain a rotational temperature of the C_2 molecules to be 5000 ± 1000 K. The uncertainty is relatively large, since it is strongly dependent on the spectral resolution of the system, which is relatively poor in our case.

We first studied the effect of the furnace temperature on the quality of the deposit (Fig. 5a.) in order to determine the optimum temperature for nanotube synthesis by our process. To do this, we placed the furnace both around and above the flame. Secondly, we placed the furnace only above the flame, to produce a greater temperature drop (Fig. 5b.) ; this enabled us to study the influence of the temperature gradient on the growth of the SWCNTs.

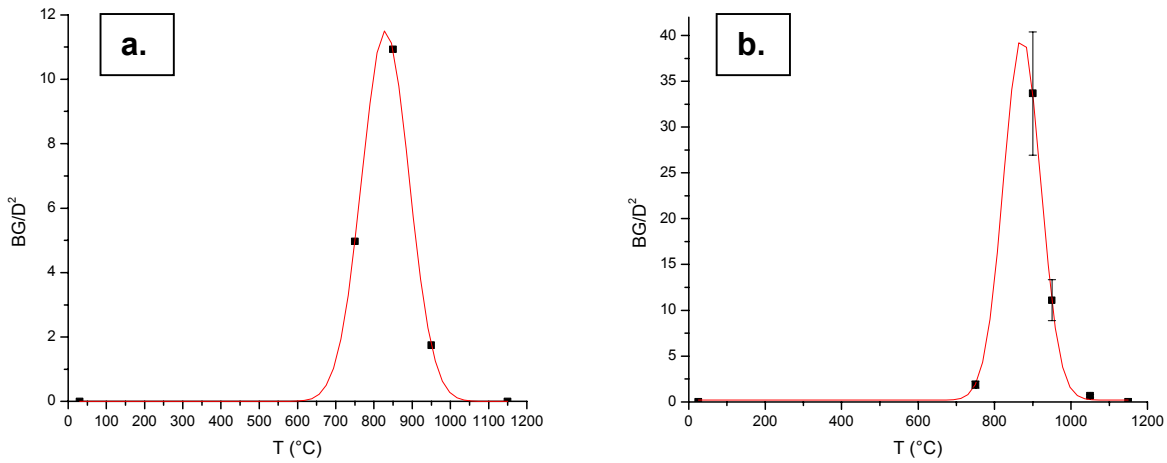

Figure5 : a. Influence of the furnace temperature on the growth of the SWCNTs, with the furnace around the flame (Q_{max} = 12). b. Influence of the furnace temperature on the growth of the SWCNTs with the furnace above the flame (Q_{max} = 40).

We see from Fig.5 that the temperature has an important influence on the quality of the sample ; there is an operational window around 850°C. These results are compatible with those from experiments on the production of nanotubes by pulsed laser ablation, where the presence of the nanotubes is related to the furnace temperature. Below 800°C and above 1400°C, the deposits don't contain nanotubes. It should be noted that the metal used as catalyst in our case is iron, whereas a mixture of nickel and cobalt is used in most laser experiments, which has an influence on the growth temperature[7].

The experiments carried out with the flame in the furnace produced deposits of relatively poor quality (Q = 12 at most), even at the optimum temperature, showing that the temperature is not the only

important parameter. By raising the furnace above the flame, we allow the plasma to cool more rapidly, thus establishing a larger temperature gradient at the exhaust of the torch. This gradient has an important effect, as can be seen in Fig. 5b, where the quality of the deposit is significantly increased. This improvement is seen for deposits recovered from all the regions in the reactor. For maximum production of SWCNTs, an optimum combination of temperature and temperature gradient must be established. In the case of the electric arc or continuous laser (CO_2), the heat in the arc plasma or in the laser-heated plasma is sufficient to maintain a temperature level high enough for the growth of nanotubes. To attain the temperature gradient in the arc, the graphite electrodes as well as the chamber are cooled, whereas for the continuous laser it is the ambient gas which provides such control. In the case of the pulsed laser, the gradient is formed naturally between the plasma and the furnace since the pulse is very brief (a few ns), and it produces little matter or heat. In summary, to increase the efficiency of our process, one must create the proper temperature gradient, all the while maintaining the particles at the optimum temperature, approximately 850°C, during the growth.

6. Conclusion

By comparing the quality factors obtained for the two torches, with different configurations, we can extract essential information about the growth of SWCNTs in a plasma torch. On the one hand, the plasma temperature must be sufficiently high, since it dissociates the carbon-containing gas and also determines the initial point of the temperature gradient. In the case of downstream injection in the tubular torch, the carbon-containing mixture is injected at the exhaust of the torch, where the plasma is less intense, resulting in a sample of poorer quality. On the other hand, although the temperature drop has an influence on the quality of the product, one cannot go below the growth temperature of the SWCNTs.

Abstract
Multi-walled carbon nanotube (CNT) was synthesized by short-wavelength laser ablation technique employing a metal-catalyzed graphite target. Focused ArF excimer laser (λ=193 nm) beam was irradiated on the target, then carbon and metal cluster vaporized and formed to CNT inside quartz tube operating at 1000°C. Transmission electron microscopy showed that the CNT was about 20 nm in diameter and more than 1 μm in length. Y-junction structure of the CNT was also observed.

1. Introduction

As carbon nanotube (CNT) shows unique structural and electronic properties, it is widely studied for applications of field emitter, electronic device and so on. Especially for the application of future electronic devices, CNT is used as quantum dots and molecular-scale wires connecting between the dots [1]. It is well known that laser ablation of metal-catalyzed graphite in Ar gas ambient is to synthesize CNT with a high yield [2]. However, the growth mechanism of CNT is not fully understood.

In the present study, we used ArF excimer laser (λ=193 nm) for CNT growth. As the short-wavelength laser generates more energetic carbon particles than infrared laser does, it is supposed that CNT growth process is different between them. It is possible to consider the growth mechanism in terms of behavior of ablated clusters. This difference is also expected to produce interesting nano-materials such as nanoballons [3]. To analyzed the CNT properties, transmission electron microscopy (TEM) and Raman spectroscopy was used. The CNT formation mechanism is discussed.

2. Experimental set-up

The present CNT growth set-up (AL039, SUGA Co., Ltd.) has basically the same configuration as that by Guo et al [4]. A schematic diagram of the set-up is illustrated in Fig. 1. It consists of a quartz tube (60 mm inner diameter, 620 mm length), an electrical furnace (360 mm length) operating at 1000ºC, and an ArF excimer laser. Inside of the tube, a target was mounted at 130 mm ahead of the rear end of the furnace and spun at 40 rpm. A water-cooled collector was mounted on the backside of the target. The temperature distribution inside of the tube is shown in Fig. 1 (b). The operating temperature is 1000ºC in the area of ~100 mm at the center of the furnace and decreases down to 600ºC at the front end. A 20-mm diameter graphite target containing 1 at. % Ni (TOYO TANSO Co., Ltd.) was used. However, in our analysis of the target by X-ray photoelectron spectroscopy (XPS), Fe and Y as well as Ni were detected. The laser beam (ArF excimer laser, LAMBDA PHYSIK COMPex 205: wavelength=193 nm; pulse duration=20 ns; fluence=3 J/cm^2; repetition rate=10 or 50 Hz) entered through a quartz window and was focused to the area of 1×5 mm^2 on the target surface. Ar gas flowed along the tube inner wall with a flow rate of 750 sccm, which was introduced from the window side, and pumped out through a butterfly valve by a rotary pump. Ar gas pressure was kept at 500 Torr. Although carbon soot was deposited on the area from (1) to (6) in Fig. 1, most soot was deposited on area (3). The soot was dispersed in ethanol using ultrasonic cleaner and collected on a metal mesh for TEM (JEM-2000FX, JEOL. Co., Ltd.) and Raman spectroscopy (Renishaw, Co., Ltd.) analysis.

3. Results and discussion

3. 1. TEM observation of carbon nanotube and Y-junction structure

After laser ablation of the target for 60 min., carbon soot was deposited mainly on area (3) of the inner tube wall. At the present moment, we are interested in the position where the carbon soot deposited. In previous reports by other groups, most carbon soot was obtained on a collector just located behind the target when a long-wavelength laser (e.g. YAG laser, λ=532 nm) was used [2, 4]. However, in the present experiment,

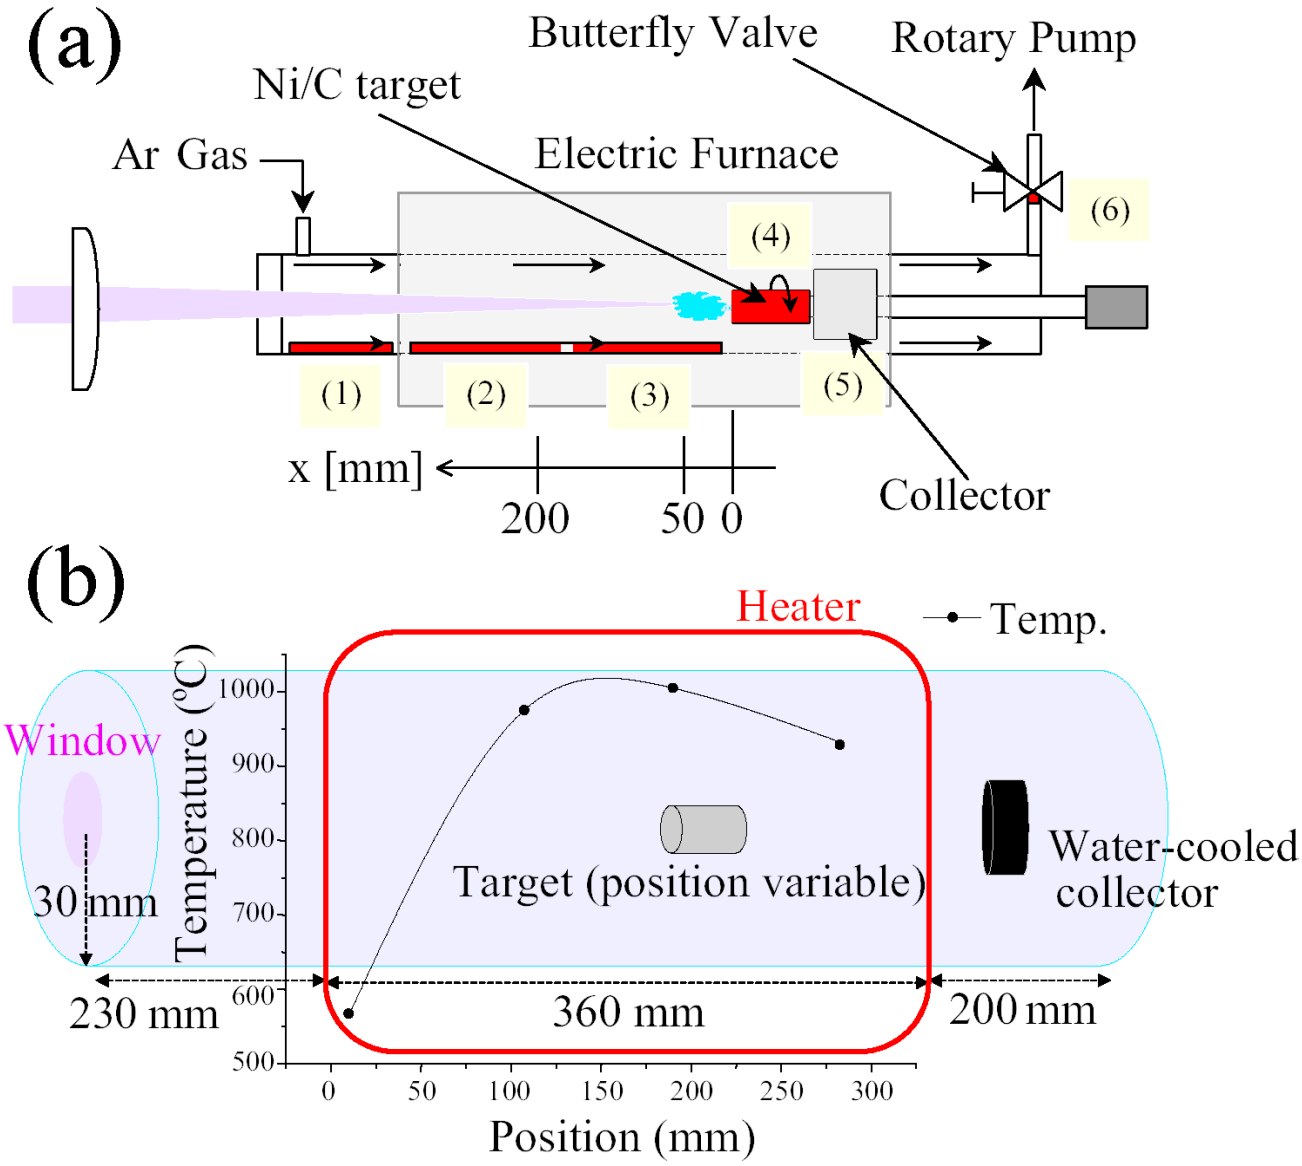

Figure 1. (a) A schematic diagram of the set-up. Parenthetic number shows the deposition area of carbon soot. (b) Temperature distribution inside the tube along the x-axis.

considerable amount of soot was obtained on the area in front of the target. To explain this difference, we have the following speculation.

Generally, as the laser light wavelength for ablation shortens, the size of carbon clusters (C_n^+) decreases and the kinetic energy of C_n^+ increases [6, 7]. In the ArF excimer laser ablation, the size of C_n^+ was mainly n=1-3 [6], and the kinetic energy of C_n^+ was ~80 eV at the laser fluence of 3 J/cm^2 [7]. This energy is much higher than that of heavier clusters. It may be reasonable that the lighter C_n^+ flew farther from the target against the direction of Ar gas flow and was deposited on area (3). However, the heavier C_n^+ is dragged backward by the Ar gas flow and is deposited on area (4)-(6).

Fig. 2 shows the TEM micrographs of the soot. It is clearly shown that many CNTs were synthesized. These tubes were approximately 20 nm in diameter and longer than 1 μm in length. The magnified photograph (b) reveals that the tube is of multi-wall structure with several layers. The spacing between tube walls is ~1 nm and several times larger than that shown in Ref. 5. The yield of CNT growth was high, and almost no catalytic metal particle was observed. It is interesting that CNT does not contain any catalytic particles. This was confirmed by XPS (ESCA-3400, Shimadzu Co., Ltd.) and EDX (Energy Dispersive X-ray Analyzer, H-700, JEOL. Ltd) analysis.

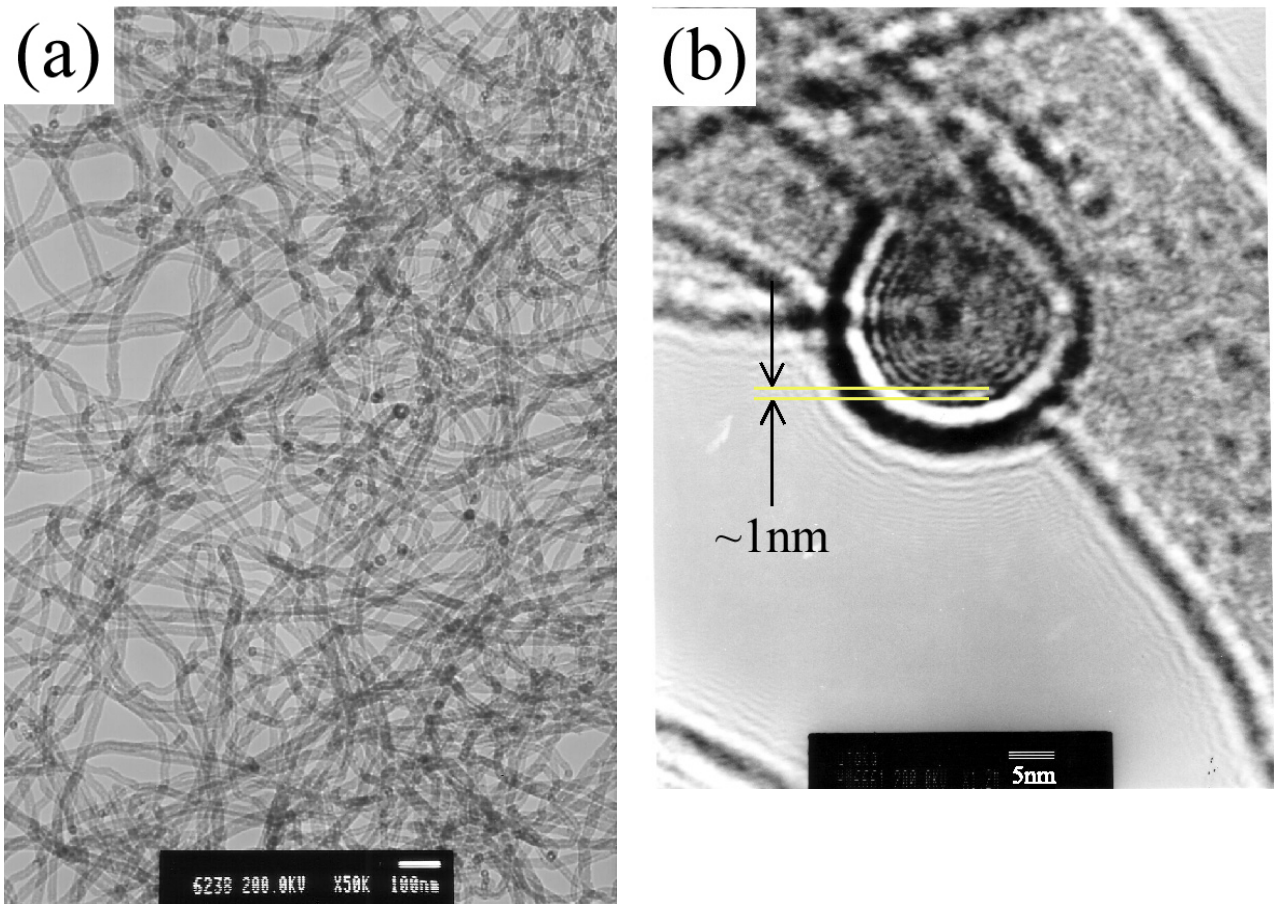

Figure 2. TEM micrographs of the soot deposited on area (3).

Some CNT contained Y-junction structure as shown in Fig. 3. The junction occurs at every several hundreds nm along the axial direction of CNT. At the junction, the axial direction bent, and very short branch grew out from the CNT stem. And it is clear that the hollow part of CNT was not so long and terminated by the wall like "bamboo gnarl". These structure are similar to that synthesized in a thermal chemical vapour deposition (CVD) system [8]. It was confirmed that this junction appeared when thiophene (C_4H_4S) was included in CH_4 gas. However, in the present experiment, we did not contain any sulfur in the graphite target. Further study to understand the Y-junction growth mechanism is required.

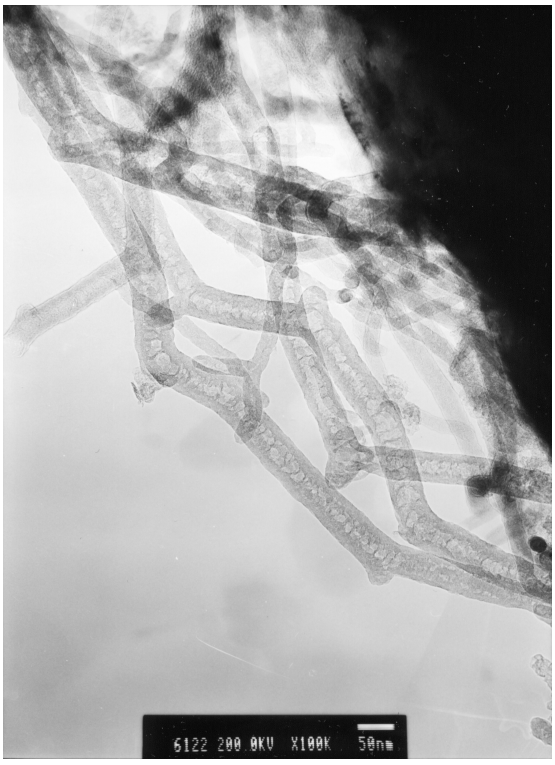

Figure 3. Y-junction structure of CNT.

3. 2. Raman Characterization

Raman spectroscopy is a convenient and strong tool for analysing CNT structure, for instance, diameter and chirality. Raman spectra of the carbon soot containing CNT supported on a metal mesh for TEM were shown in Fig. 4. Two peaks appear clearly and show the graphite structure. One peak that locates around 1581 cm^{-1} is called "G peak", which originates from the in-plane bond-stretching motion of pairs of sp^2 carbon atoms. The other peak that locates around 1360 cm^{-1} shows a breathing mode of six-fold graphite ring called "D (disordered) peak" [9]. As the D

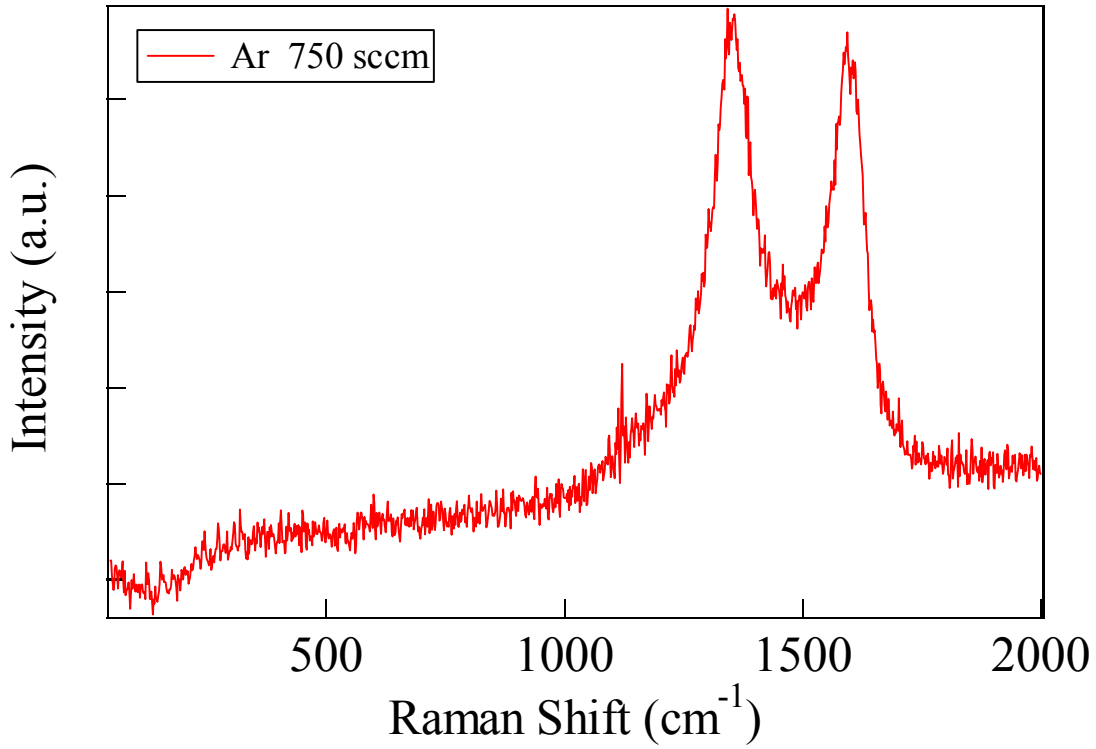

Figure 4. Raman spectra of the carbon soot

mode is forbidden in perfect graphite, the appearance of this peak shows that CNT contains some defect in crystalline structure. In this case, the ratio of D peak intensity to G peak one (I_D/I_G) is ~1, which is a similar value to that of multi-walled CNT synthesized in a plasma enhanced CVD system [11].

3. 3. Effect of ArF laser repetition frequency on CNT linearlity

To obtain high-quality CNT, we tried to increase the laser repetition rate. TEM micrograph of CNT synthesized at a repetition rate of 50Hz is shown in Fig. 5. Relatively long and linear CNT as well as graphite nano-balloon are obtained as shown in Fig. 5 (a). The CNT deposited on area (5) of low temperatures (a water-cooled collector), where the temperature is estimated to be 700ºC from the temperature distribution in Fig. 1 (b), shows similar feature to that synthesized at the rate of 10 Hz, which was deposited at the high temperature area (3).

It is speculated that CNT was formed in gas phase containing carbon and catalytic metal clusters below their eutectic temperature [10]. It may be important to increase the laser repetition rate, since successive energy input would heat up the ablated plasma and contribute to the stability and confinement of the plasma.

4. Conclusions

CNT was successfully synthesized in an electric furnace operating at 1000ºC by laser ablation technique with a short-wavelength pulsed laser (ArF). We confirmed that the CNT structure was multi-walled tubes by TEM and Raman spectroscopy. It was capable to improve the CNT structure (e.g. linearity) by increasing the laser repetition rate. We should study further to find the optimum synthesis condition of CNT.

Abstract

An atmospheric pressure ejected plasma(APEP) source has been developed to enhance the surface characteristics such as adhesion of polypropylene surface. With different gas species and compositions in the plasma source, surface characteristics as well as plasma properties are measured by optical emission spectroscopy(OES), X-ray photoelectron spectroscopy(XPS) and atomic force microscopy(AFM). Maximum lap shear strengths of about 4MPa are obtained in helium plasmas without any additional reactive gases such as O_2 or N_2.

1. Introduction

Polypropylene has been widely used in many different industries including automotive industry since it has good mechanical properties, light weight, low cost and readily-recyclable characteristics. However, it has inherently low surface energy so that its applicability has been limited by the difficulty in painting, coating, bonding, and metalization. To improve surface properties such as good bondability, pre-treatment of polypropylene surface has been studied. Not only wet chemical processes but also dry physical (or chemical) processes such as flame treatment, corona discharge, low pressure or atmospheric pressure plasma treatments are intensively studied and developed[1-5]. Among them, the atmospheric pressure plasma pre-treatment is considered to be most promising in real industrial applications since it is an environmentally preferential dry process applicable to in-line processes without any expensive vacuum system.

In this study, an atmospheric pressure ejected plasma source has been developed to modify the polypropylene surface for better adhesion property. To treat arbitrary shaped objects as well as flat shaped

ones the plasma source in plasma ejection configuration has been favored to the configuration of dielectric barrier discharge (DBD) plasma source. The main purpose of the study is to asses the mechanisms responsible for the increased adhesion as a result of atmospheric pressure plasma ejected plasma treatment.

To evaluate adhesion properties, bonding strengths are measured with lap shear strength tests and correlated with the change of plasma properties such as plasma radical line intensity measured by optical emission spectroscopy(OES). Also the chemical or physical changes of plasma-treated polypropylene surface are examined to understand improved bondability by X-ray photoelectron spectroscopy (XPS), secondary ion mass spectroscopy (SIMS)and atomic force microscopy (AFM), respectively.

2. Experimentals

2.1 Test material preparations

Two kinds of Homo-polypropylene (5mm thickness bulk) with other surface roughness (R_{rms}=110nm, $R_{rms=}$30nm) are prepared and cutted by pieces of 25.4×110×5 mm which are referred to ASTM3163-96. Before the plasma treatment, polypropylene surface is cleaned by acetone solution to remove the contaminant such as oil and dusts.

2.2 Plasma treatments

The schematics of overall experimental setups and the structure of the atmospheric pressure ejected plasma source are shown in Figs.1 and 2, respectively. Power electrode is made of aluminum with tapered-shape as shown in the fig.2 and ground electrode of 32mm inner diameter is made of stainless steel. Between them, boron-nitride insulator is inserted to generate the glow-like plasmas without arc channel. Atmospheric pressure plasmas are generated between two axial electrodes by applying RF power to the power electrode at the frequency of 27.12MHz up to 1kW. Generated plasmas are ejected from the discharge region along with the direction of gas flow. Discharge gases (helium and argon) mixed with a small amount of reactive gas (N_2 or O_2) are injected into the discharge region through the mass flow controller. Treatment distance between plasma source and polypropylene surface is defined as L as shown in Fig.1.

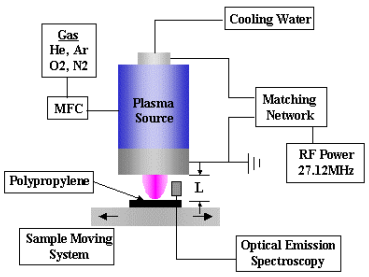

Fig.1 Schematics of overall experimental setup

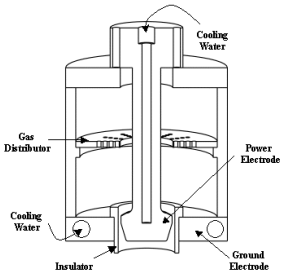

Fig.2 Structure of the atmospheric pressure ejected plasma source

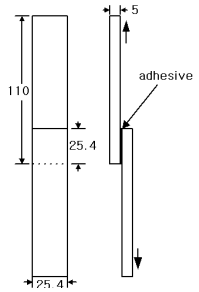

Fig.3 Assembled specimen for lap shear strength test with dimension

2.3 Adhesion Strength Tests

Adhesion strength is evaluated by the lap shear strength test, which is carried out using Instron Tensile Test Machine, at a pull-off speed of 1mm/min. Two polypropylene specimens treated by plasmas are adhered to each other immediately after plasma treatments using cyanoacrylate adhesive and stored at room temperature in air for 24 hours to ensure fully hardening between adherent and adhesive. Polypropylene assembly

adhered to cyanoacrylate adhesive for the lap shear strengrh test is shown in Fig.3. Tests for lap shear strength are performed as referred to ASTM3163-96. Each data points are averaged values of five identical measurements and error bars are obtained from the standard deviation of them.

2.4 Plasma Charaterizations

Plasma properties such as radical line intensity with gas compositions are diagnosed with a personal computer (PC) plug-in type spectrometer of AVS-PC2000S-ISA from Avantes with the spectral resolution of 0.4nm. And gas temperatures are measured by thermocouple. Principal emission lines of radicals in this experiment are summarized in Table.1.

Table.1 Principal emission lines

Species	Emission lines (nm)
He^* (3s→2p)	706.5
O^* (3p→3s)	777.2
N_2^+ ($B^2\Sigma_u \rightarrow X^2\Sigma_g$)	391.4
N_2^*($C^3\Pi_u \rightarrow B^3\Pi_g$)	337.1
Ar^* (4p→4s)	750.3

2.5 Surface Characterizations

The evolution of the surface characteristics is monitored by X-ray photoelectron spectroscopy(XPS) and Secondary ion mass spectroscopy (SIMS). The XPS study is performed with a VG-Scientific ESCALAB 250 spectrometer with monocromatized Al Kα X-ray source (1486.6eV) at Korea Basic Science Institute. Chemical compositions (atomic percent,%) are determined from the broad-scan XPS spectra with sensitivity factors for each atom. The SIMS study is performed with PHI 7200 TOF-SIMS/SALI with 8keV Cs+ ion source at Korea Institute of Science and Technology.

Changes of Surface morphology before and after plasma treatments are measured by SPA-400, Seiko Instrument with contact mode whose scan size is 50μm with 1line/sec scanning speed. Surface roughness values are expressed in terms of R_{rms} that is averaged roughness of three independent measurements for each specimen.

3. Experimental Results and Discussions

3.1 He plasmas with N_2 or O_2 gases

Lap shear strength variations with N_2 or O_2 flow rate (0.25%~6 %) for fixed helium flow rate of 5slm are shown in Fig.4. Maximum lap shear strength is obtained in helium plassma without N_2 or O_2. A small amount (0.25%) of N_2 or O_2 additoin to helium leads to the sharp decrease of lap shear strength. As shown in Fig.5 and 6, He^* line intensity and N_2^+/N_2^* line intensity ratio are also decreased with N_2 or O_2 addition. Because the N_2^+/N_2^* line intensity ratio represent the mean electronic temperature[6], high bondability in helium plasma in the absence of N_2 or O_2 can be related to the high population of He^* generated by high energy electrons. High energy He^* can contribute to bondability via excitation of polymer suface and creation of excited atoms or molecule such as O^* or N_2^* near the polypropylene suface. A small amount of oxygen or nitrogen added to helium plasmas results in the negative effects on the adhesion from the viewpoint of generating high energy He^*. Chain scission effect on the surface through helium plasma

treatment is verified as shown in Fig.7. Breaking of C-H bonds by plasma radicals and removal of hydrogen atoms from surface are confirmed by the decreased H/C ratio. This is so called creation of polymer radicals by plasma treatments, which leads to the absorption of excited species(O*, N_2^*) to the polypropylene surface.

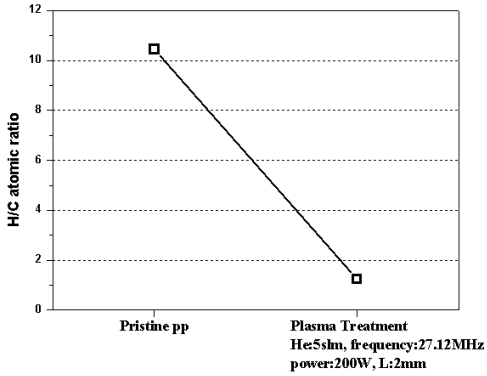

Fig.7 Variation of C/H ratio with He=5sm Plasma treatment (from SIMS results)

As shown in Table.2, high oxygen content on the surface is obtained in helium plasmas without N_2 or O_2. Figure 8 shows that C ls peak of polypropylene treated with helium plasma is expanded toward higher binding energy level corresponding to the ether (C-O), carbonyl (C=O) and ester (O=C-O) fucnctional groups which are favorable to adhesion [7]. From these results, generation of oxygen or nitrogen functoinal groups on the surface takes place sufficiently under ambient condition without additional injection of oxygen or nitrogen gases as reactive additives, which is contrary to vacuum-based plasma treatment. Variations of atomic percent with gas compositions are summarized in Table.2

Table.2 Atomic percent variations with gas compositions : Power:200W, Frequency:27.12MHz, L:2mm, Treatment time:20sec

For two kinds of polypropylene having different surface roughness, variations of lap shear strengths with different treatment times are shown in Fig.9. Surface roughnesses of two polypropylenes are 30nm and 110nm respectively, measured by AFM contact mode. As shown in Fig.9, steeper increase in lap shear strength with treatment time is observed in polypropylene having surface roughness of R_{rms}=110nm. Therefore, surface roughness can be considered as another important factor leading to the increase of adhesion. As shown in Fig.10, surface roughness of polypropylene treated by helium plasma without reactive gas is increased from 30nm to 50nm. Maximum adhesion in helium plasma can be explained not only by high population of He^* in discharge region, but also by rough surface imparted during the helium plasma treatment.

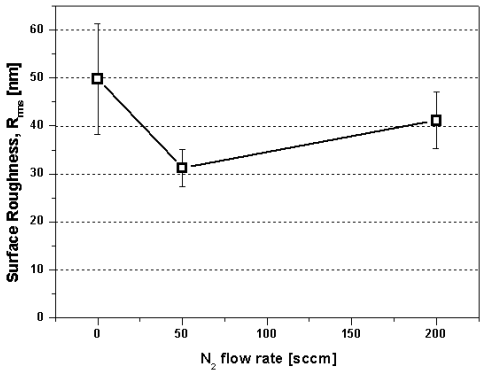

Fig.10 Surface roughness variations with N_2 flow rate : Power:200W, Frequency:27.12MHz, L:2mm, He:5slm

3.2 He/Ar plasmas

Due to the thermal problem, operations of He+Ar plasmas are limited at the relatively lower power level of less than 150W and with longer treatment distance of L=5mm. As shown in Fig.11, lap shear strength and gas temperature are increased as fractions of Ar gases are increased, and simultaneously ejection lengths of plasmas becomes longer.

OES measurements of Fig.12 show the decrease in He^* and Ar^* line intensity as the Ar/(Ar+He) ratio

increased. But lap shear strengths show completely opposite trend. Therefore, the increase of bondability with the increased Ar/(Ar+He) ratio cannot be explained only with high energy metastable species such as He^*. And XPS measurements for He+Ar plasmas shown in Table.3 do not provide any significant increase of oxygen and nitrogen concentrations on the surface. Putting above results altogether, bondability improvement with Ar/(Ar+He) ratio more likely seems to be combined effects of other factors such as gas temperature and plasma ejection length.

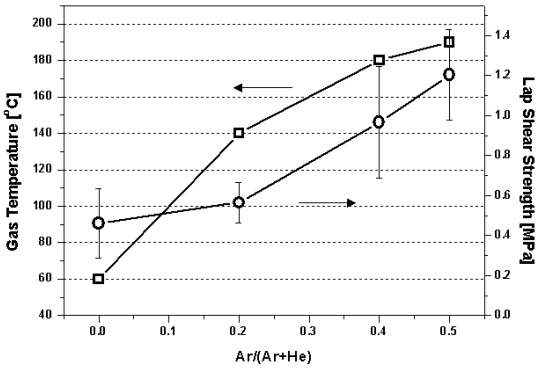

Fig.11 Variations of lap shear strength and gas temperature with Ar/(Ar+He) ratio: Power:150W, Frequency:27.12MHz, L:5mm, Treatment time:20sec

4. Conclusions and future work

Experimental results and future work can be summarized as followings:

(1) Maximum lap shear strength in helium plasma without adding reactive gases such as N_2 or O_2, which is correlated with high He^* line intensity instead of other reactive radicals. High energy He* seems to play an important role on adhesion improvement in He plasmas and need to be provided by maintaining good plasma discharge conditions.

(2) Surface roughness is another factor affecting the adhesion as shown in helium plasma tests.

(3) Increases of gas temperature and ejection length of plasma, induced by adding Argon gas to He gas as discharge gases, are identified to be another parameters to improve adhesion characteristics, which is identified from higher lap shear strength in spite of low He^* line intensity when Ar gas is added. But gas temperature effect is not verified yet and further studies are needed.

(4) Plasma characteristics such as electron densities and temperatures with different gas compositions may provide clues to understand adhesion improvements, which will be studied more in detail.

Self-consistent chemical and thermal non-equilibrium modelling of Ar-N_2 induction thermal plasma with a reaction chamber

Yasunori Tanaka and Tadahiro Sakuta

Department of Electrical and Electronic Engineering, Kanazawa University, 2-40-20, Kodatsuno, Kanazawa 920-8667, JAPAN

Abstract

A self-consistent two-dimensional thermally and chemically non-equilibrium model for Ar-N_2 inductively coupled thermal plasma (ICTP) was developed. Transport and thermodynamic properties were self-consistently calculated at each iteration step using the local particle composition, heavy particle temperature and electron temperature. Spatial particle composition distribution in the plasma torch and the reaction chamber was derived by solving simultaneously the mass conservation equation of each particle, considering diffusion, convection and production terms including thirty reactions.

1. Introduction

The inductively coupled thermal plasma (ICTP) can be found in various technology fields such as materials processing, plasma waste destruction and plasma spraying, because of its high temperature and high reaction activity [1]. Up to now, numerical modelling of such an ICTP has been made to understand the plasma internal state in detail on the assumption of local thermal equilibrium (LTE) in steady state [2, 3]. The use of this model enables us to understand the transport of mass, momentum, energy, gas flow and temperature fields in the ICTP. However, further understanding of reactions and particle density distributions in the ICTP has greatly been required for advanced material processings at non-LTE state. For this purpose, we have so far developed a one-temperature chemical non-equilibrium modelling [4, 5], in which reaction rates were considered for each of reactions. However, in some experimental cases, electron temperature T_e has been found to be higher than heavy particle temperature T_h especially near the wall of the ICTP, which means thermal non-equilibrium exists there. The thermally non-equilibrium can also affect the distribution of radicals and excited particles. Some two-temperature models for thermal plasma have been developed until now. However, many of the models are not self-consistent because they used transport and thermodynamic properties under equilibrium condition, and/or they neglected chemical non-equilibrium effect for example. Thus, a self-consistent model including thermal and chemical non-equilibrium effects has been greatly desired in the plasma material processing field. In this paper, a two-dimensional thermally and chemically non-equilibrium model for Ar-N_2 ICTP is proposed considering reaction rates and difference between electron and heavy particle temperatures. First, the proposed plasma model and the governing equations used are interpreted. Secondly, Ar-N_2 ICTP simulation is made by three different models i.e., the present two-temperature chemically non-equilibrium (2T-NCE) model, a one-temperature chemical equilibrium (1T-CE) model [3], and a one-temperature chemically non-equilibrium (1T-NCE) model [5]. Finally, by comparison of the results calculated by the three different methods, the effect of chemical and thermal non-equilibrium in the Ar-N_2 ICTP was discussed.

2. Modelling of Ar-N_2 induction thermal plasma

2.1. Hypothesis

In the present calculation, the followings were assumed in Ar-N_2 ICTP: (i) There are only seven particles Ar, Ar^+, N_2, N_2^+, N, N^+ and electron in Ar-N_2 ICTP. All the species are in the ground state. (ii) All the heavy particles has the same temperature with a Maxwellian energy distribution function. On the other hand, the electron energy distribution function also follows Maxwell-Boltzmann law, although its mean energy is not always the same to that of heavy particles. (iii) Electrons lose their energies through elastic collisions with heavy particles and through inelastic collisions involving ionization and dissociation reactions. However, inelastic collisions involving electronic, rotational and vibrational excitations are not taken into account in the present work. (iv) The reaction heat is supplied from or transferred to the electron kinetic energy if the electron is concerned with the reaction. (v) The plasma has an axissymetric structure. (vi) The optically thin assumption is established, and thus the effect of light absorption is negligible. (vii) Pressure in the ICTP is around the atmospheric pressure. (viii) All the particles moves together with gas flow.

2.2. Governing equations

On the basis of the hypothesis mentioned in the previous section, the Ar-N_2 ICTP behavior can be expressed by the governing equations described in Tab.1.

Tab. 1. Governing equations.

Mass conservation:

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho u)}{\partial z} + \frac{1}{r}\frac{\partial (r\rho v)}{\partial r} = 0 \tag{1}$$

Momentum conservation:

$$\begin{aligned}\frac{\partial (\rho u)}{\partial t} &+ \frac{\partial (u\rho u)}{\partial z} + \frac{1}{r}\frac{\partial (rv\rho u)}{\partial r} \\ &= -\frac{\partial p}{\partial z} + 2\frac{\partial}{\partial z}\left(\eta \frac{\partial u}{\partial z}\right) \\ &+ \frac{1}{r}\frac{\partial}{\partial r}\left[\eta r\left(\frac{\partial u}{\partial r} + \frac{\partial v}{\partial z}\right)\right] + \mu_0 \sigma \Re[\dot{E}_\theta \dot{H}_r^*]\end{aligned} \tag{2}$$

$$\begin{aligned}\frac{\partial (\rho v)}{\partial t} &+ \frac{\partial (u\rho v)}{\partial z} + \frac{1}{r}\frac{\partial (rv\rho v)}{\partial r} \\ &= -\frac{\partial p}{\partial r} + \frac{\partial}{\partial z}\left[\eta\left(\frac{\partial v}{\partial z} + \frac{\partial u}{\partial r}\right)\right] \\ &+ \frac{2}{r}\frac{\partial}{\partial r}\left(\eta r \frac{\partial v}{\partial r}\right) - 2\eta\frac{v}{r^2} + \mu_0 \sigma \Re[\dot{E}_\theta \dot{H}_z^*]\end{aligned} \tag{3}$$

Translational energy conservation of heavy particle:

$$\begin{aligned}\frac{\partial (\rho h')}{\partial t} &+ \frac{\partial (u\rho h')}{\partial z} + \frac{1}{r}\frac{\partial (rv\rho h')}{\partial r} \\ &= \frac{\partial}{\partial z}\left(\lambda_{\mathrm{h}}^{\mathrm{tr}}\frac{\partial T_{\mathrm{h}}}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\lambda_{\mathrm{h}}^{\mathrm{tr}}\frac{\partial T_{\mathrm{h}}}{\partial r}\right) \\ &+ \sum_{j\,(j\neq \mathrm{e})}^{N}\left[\frac{\partial}{\partial z}\left(\rho D_j' h_j' \frac{\partial Y_j}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\rho D_j' h_j' \frac{\partial Y_j}{\partial r}\right)\right] \\ &- \sum_{\ell\,(\beta_{\mathrm{e}\ell}^{\mathrm{f}}\beta_{\mathrm{e}\ell}^{\mathrm{r}}=0)}^{L}\Delta Q_\ell + E_{\mathrm{eh}}\end{aligned} \tag{4}$$

Energy conservation of electron:

$$\begin{aligned}\frac{\partial}{\partial t}\left(n_{\mathrm{e}}\frac{5}{2}\kappa T_{\mathrm{e}}\right) &+ \frac{\partial}{\partial z}\left(un_{\mathrm{e}}\frac{5}{2}\kappa T_{\mathrm{e}}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(rvn_{\mathrm{e}}\frac{5}{2}\kappa T_{\mathrm{e}}\right) \\ &= \frac{\partial}{\partial z}\left(\lambda_{\mathrm{e}}^{\mathrm{tr}}\frac{\partial T_{\mathrm{e}}}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\lambda_{\mathrm{e}}^{\mathrm{tr}}\frac{\partial T_{\mathrm{e}}}{\partial r}\right) \\ &- \frac{\partial}{\partial z}\left(\frac{1}{m_{\mathrm{e}}}\frac{5}{2}\kappa T_{\mathrm{e}}\Gamma_{\mathrm{ez}}\right) - \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{1}{m_{\mathrm{e}}}\frac{5}{2}\kappa T_{\mathrm{e}}\Gamma_{\mathrm{er}}\right) \\ &- \sum_{\ell\,(\beta_{\mathrm{e}\ell}^{\mathrm{f}}\beta_{\mathrm{e}\ell}^{\mathrm{r}}\neq 0)}^{L}\Delta Q_\ell + \sigma\dot{E}_\theta\dot{E}_\theta^* - P_{\mathrm{rad}} - E_{\mathrm{eh}}\end{aligned} \tag{5}$$

Mass conservation of species j (for N, $\mathrm{N^+}$, $\mathrm{N_2^+}$, $\mathrm{Ar^+}$):

$$\begin{aligned}\frac{\partial (\rho Y_j)}{\partial t} &+ \frac{\partial (u\rho Y_j)}{\partial z} + \frac{1}{r}\frac{\partial (rv\rho Y_j)}{\partial r} \\ &= \frac{\partial}{\partial z}\left(\rho D_j' \frac{\partial Y_j}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\rho D_j' \frac{\partial Y_j}{\partial r}\right) \\ &+ m_j \sum_{\ell=1}^{L}(\beta_{j\ell}^{\mathrm{r}} - \beta_{j\ell}^{\mathrm{f}})\left(\alpha_\ell^{\mathrm{f}}\prod_{i=1}^{N} n_i^{\beta_{i\ell}^{\mathrm{f}}} - \alpha_\ell^{\mathrm{r}}\prod_{i=1}^{N} n_i^{\beta_{i\ell}^{\mathrm{r}}}\right)\end{aligned} \tag{6}$$

Maxwell equation by vector potential:

$$\frac{\partial^2 \dot{A}_\theta}{\partial z^2} + \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial \dot{A}_\theta}{\partial r}\right) - \frac{\dot{A}_\theta}{r^2} = \bar{i}\mu_0\sigma\omega\dot{A}_\theta \tag{7}$$

$$\dot{H}_z = \frac{1}{\mu_0}\frac{1}{r}\frac{\partial}{\partial r}(r\dot{A}_\theta), \quad \dot{H}_r = -\frac{1}{\mu_0}\frac{\partial \dot{A}_\theta}{\partial z} \tag{8}$$

$$\dot{E}_\theta = -\bar{i}\omega\dot{A}_\theta \tag{9}$$

Reaction heat per unit volume and time:

$$\Delta Q_\ell = \psi_{\mathrm{reac}\ell}\left(\alpha_\ell^{\mathrm{f}}\prod_{i=1}^{N} n_i^{\beta_{i\ell}^{\mathrm{f}}} - \alpha_\ell^{\mathrm{r}}\prod_{i=1}^{N} n_i^{\beta_{i\ell}^{\mathrm{r}}}\right) \tag{10}$$

Translational enthalpy of heavy particles:

$$h' = \sum_{j\neq \mathrm{e}} Y_j h_j', \qquad h_j' = \frac{1}{m_j}\left(\frac{5}{2}kT_{\mathrm{h}}\right) \tag{11}$$

Energy transfer from electron to heavy particles:

$$E_{\mathrm{eh}} = \sum_{j\neq \mathrm{e}}\frac{3}{2}\kappa(T_{\mathrm{e}} - T_{\mathrm{h}})\frac{4m_j m_{\mathrm{e}}}{(m_j + m_{\mathrm{e}})^2} n_j n_{\mathrm{e}} \pi\bar{\Omega}_{\mathrm{e}j}\bar{v}_{\mathrm{e}j} \tag{12}$$

$$\bar{v}_{\mathrm{e}j} = \sqrt{\frac{8\kappa T_{\mathrm{e}}(m_{\mathrm{e}} + m_j)}{\pi m_{\mathrm{e}} m_j}} \tag{13}$$

Relation between mass density and mass fraction:

$$n_j = \frac{\rho Y_j}{m_j} \tag{14}$$

Equation of state:

$$\rho = \frac{p}{\dfrac{Y_{\mathrm{e}}}{m_{\mathrm{e}}}\kappa T_{\mathrm{e}} + \displaystyle\sum_{j\neq \mathrm{e}}\frac{Y_j}{m_j}\kappa T_{\mathrm{h}}} \tag{15}$$

Quasi-neutrality:

$$\frac{Y_{\mathrm{e}}}{m_{\mathrm{e}}} = \frac{Y_{\mathrm{Ar^+}}}{m_{\mathrm{Ar^+}}} + \frac{Y_{\mathrm{N_2^+}}}{m_{\mathrm{N_2^+}}} + \frac{Y_{\mathrm{N^+}}}{m_{\mathrm{N^+}}} \tag{16}$$

Balance of mass fraction:

$$Y_{\mathrm{Ar}} = Y_{\mathrm{Ar}}^{\mathrm{TOT}} - Y_{\mathrm{Ar^+}} \tag{17}$$

$$Y_{\mathrm{N_2}} = Y_{\mathrm{N_2}}^{\mathrm{TOT}} - Y_{\mathrm{N}} - Y_{\mathrm{N^+}} - Y_{\mathrm{N_2^+}} \tag{18}$$

Admixture ratio $\mathrm{N_2}$ to Ar:

$$Y_{\mathrm{N_2}}^{\mathrm{TOT}} = \frac{m_{\mathrm{N_2}} Q_{\mathrm{N_2}}}{m_{\mathrm{Ar}} Q_{\mathrm{Ar}} + m_{\mathrm{N_2}} Q_{\mathrm{N_2}}} \tag{19}$$

$$Y_{\mathrm{Ar}}^{\mathrm{TOT}} = 1.0 - Y_{\mathrm{N_2}}^{\mathrm{TOT}} \tag{20}$$

Effective diffusion coefficient of heavy particle:

$$D_j' = \frac{1 - Y_j}{\displaystyle\sum_{k\neq j}\frac{x_i p \Delta_{ij}^{(1)}}{\kappa T_{\mathrm{h}}}} \tag{21}$$

Electrical conductivity:

$$\sigma = \frac{e^2}{\kappa T_{\mathrm{e}}}\frac{n_{\mathrm{e}}}{\displaystyle\sum_{j\neq \mathrm{e}} n_j \Delta_{\mathrm{e}j}^{(1)}} \tag{22}$$

Viscosity:

$$\eta = \sum_{j=1}^{N}\frac{m_j n_j}{\displaystyle\sum_{i=1}^{N} n_i \Delta_{ij}^{(2)}} \tag{23}$$

Translational thermal conductivity of heavy particle:

$$\lambda_{\mathrm{h}}^{\mathrm{tr}} = \frac{15}{4}\kappa\sum_{i\neq \mathrm{e}}\frac{n_i}{\displaystyle\sum_j \xi_{ij} n_j \Delta_{ij}^{(2)}} \tag{24}$$

Translational thermal conductivity of electron:

$$\lambda_{\mathrm{e}}^{\mathrm{tr}} = \frac{15}{4}\kappa\frac{n_{\mathrm{e}}}{\displaystyle\sum_j \xi_{\mathrm{e}j} n_j \Delta_{\mathrm{e}j}^{(2)}} \tag{25}$$

$$\frac{1}{\Delta_{ij}^{(1)}} = \frac{3}{8}\sqrt{\frac{\pi\kappa T_{\mathrm{h,e}}(m_i + m_j)}{2m_i m_j}}\frac{1}{\pi\bar{\Omega}_{ij}^{(1,1)}} \tag{26}$$

$$\frac{1}{\Delta_{ij}^{(2)}} = \frac{5}{16}\sqrt{\frac{\pi\kappa T_{\mathrm{h,e}}(m_i + m_j)}{2m_i m_j}}\frac{1}{\pi\bar{\Omega}_{ij}^{(2,2)}} \tag{27}$$

$$\xi_{ij} = 1 + \frac{(1 - m_i/m_j)(0.45 - 2.54 m_i/m_j)}{(1 + m_i/m_j)^2} \tag{28}$$

where t: time (s), r: radial position (m), z: axial position (m), u: axial flow velocity (m/s), v: radial flow velocity (m/s), ρ: mass density ($\mathrm{kg/m^3}$), p: pressure (Pa), T_{h}: heavy particle temperature (K), T_{e}: electron temperature (K), P_{rad}: radiation loss ($\mathrm{W/m^3}$), n_j: number density of species j ($\mathrm{m^{-3}}$), Y_j: mass fraction of species j, x_j: mole fraction of species j, m_j: mass of species j (kg), Γ_{er}, Γ_{ez}: radial and axial electron flux due to ambipoler diffusion ($\mathrm{1/m^2/s}$), α_ℓ^{f}, α_ℓ^{r}: rate coefficients of forward and backward reaction ℓ, respectively, $\beta_{j\ell}^{\mathrm{f}}$, $\beta_{j\ell}^{\mathrm{r}}$: stoichiometric number of species j in forward and backward reaction ℓ, μ_0: permeability of vacuum (H/m), κ: Boltzmann constant (J/K), $\dot{A}_\theta$: vector potential (V·s/m), ω: angular frequency of coil current (rad/s), $\dot{E}_\theta$: electric field strength (V/m), $\dot{H}_z$: axial magnetic field strength (A/m), $\dot{H}_r$: radial magnetic field strength (A/m), $\bar{i}$: complex index ($\bar{i}^2 = -1$), $\psi_{\mathrm{reac}\ell}$: reaction heat for reaction ℓ (J), $\pi\bar{\Omega}_{ij}^{(1,1)}$: momentum transfer collision integrals ($\mathrm{m^2}$), $\pi\bar{\Omega}_{ij}^{(2,2)}$: viscosity collision integrals ($\mathrm{m^2}$), Q_{Ar}: Ar gas flow rate ($\mathrm{m^3/s}$), $Q_{\mathrm{N_2}}$: $\mathrm{N_2}$ gas flow rate ($\mathrm{m^3/s}$), N: total number of species, L: total number of reactions.

2.2.1. Energy conservation equation of heavy particle in two-temperature state

In two-temperature state, electron energy conservation equation should be separately treated from that of heavy particles. Moreover, in chemically non-equilibrium condition, energy transfer due to diffusion should be explicitly considered. Energy conversion through reactions also needs to be taken into account with considering whether the reaction is related with electron energy or not.
Equation (4) shows the translational energy conservation equation of heavy particle. In this equation, h' is the total translational enthalpy of heavy particles defined by Eq.(11). The left hand side of Eq.(4) includes the energy change and the energy transfer by convection. On the right hand side of Eq.(4), the first and second terms are the thermal conduction terms, the third is the energy transfer due to diffusion of heavy particles, the fourth is the energy conversion by the reactions, and the last term is the energy conversion between electron and heavy particle through elastic collision. In a conventional LTE or 1T-CE model, which is the extremely simplified model, the thermal conductivity has the translational, internal and reactional terms implicitly [1], which includes diffusion, excitation and reaction effect. However, in the two-temperature and chemical non-equilibrium (2T-NCE) condition, the thermal conductivity cannot have internal and reactional terms implicitly because the local particle composition is not determined only by temperature, and then they should be calculated with considering effect of diffusion, convection and reactions. Thus, translational thermal conductivity of heavy particles $\lambda_{\mathrm{h}}^{\mathrm{tr}}$ are used in the first and second terms, and the third and the fourth terms are added on the right hand side in Eq.(4) at the same time. In the fourth term, ΔQ_ℓ is the reaction heat per unit volume and time. This is defined by Eq.(10) considering reaction rates. For the heavy particle energy conservation, ΔQ_ℓ for reaction ℓ is summed unless there are electrons in both left and right sides in reaction equation. The energy conversion between electron and heavy particle through elastic collision E_{eh} is calculated through Eq.(12).

2.2.2. Electron energy conservation equation

Equation (5) indicates the electron energy conservation equation. In this equation, we took into account the heat conduction by electrons, the energy transfer by ambipoler diffusion, reaction heat, joule heating, radiation loss and the energy conversion between electron and heavy particle through elastic collision as described on the right hand side. The ambipoler diffusion terms were calculated through $\mathbf{\Gamma}_{\mathrm{e}} = -\rho D_{\mathrm{a}} \boldsymbol{\nabla} Y_{\mathrm{e}}$ where D_{a} is the ambipoler diffusion coefficient. In the present calculation, approximation $D_{\mathrm{a}} \sim 2D_{\mathrm{Ar^+}}$ was used because the electron are produced mainly by Ar ionization and difference between T_{e} and T_{g} is small in the wide area.

2.3. Reaction rates

Table 2 summarizes reactions in an Ar-N_2 plasma. Thirty reactions including the fifteen forward reactions in Tab.2 and their backward reactions were taken into account. The reaction rate α_ℓ^{f} for forward direction was given by Arrhenius' law $\alpha_\ell^{\mathrm{f}} = a_\ell T^{b_\ell} \exp(-c_\ell/T)$ where a_ℓ, b_ℓ and c_ℓ are constants. The values of a_ℓ, b_ℓ and c_ℓ for the reactions 1–9 in Tab.2 were given by Dunn [7]. For the tenth reaction, i.e. Ar three body recombination reaction, the reaction rate α_{10}^{f} were given by Owano et al.[8]. The reaction rate of the eleventh reaction α_{11}^{f} was computed using the collision cross section [9]. Others were predicted from values of the reactions 1–9. The reaction rates α_ℓ^{r} for the backward direction were calculated by the relationship $\alpha_\ell^{\mathrm{r}} = K_\ell(T)\alpha_\ell^{\mathrm{f}}$ where $K_\ell(T)$ is the equilibrium constant. The quantity $K_\ell(T)$ was calculated using internal partition functions and reaction heat $\psi_{\mathrm{reac}\ell}$. Here, the dependent temperature T in the above corresponds to T_{e} if one of colliding particles is the electron, but otherwise T_{h}. This dependent temperature for each reaction is indicated in Tab.2.

2.4. Transport properties

Transport properties such as electrical conductivity σ, viscosity η, translational thermal conductivity of heavy particle $\lambda_{\mathrm{h}}^{\mathrm{tr}}$, thermal conductivity of electron $\lambda_{\mathrm{e}}^{\mathrm{tr}}$ and effective diffusion of heavy particle D'_j were calculated at each position in the calculation space at each iteration step using the local particle composition, T_{h} and T_{e} derived. These transport properties were obtained by the first order approximation of Champman-Enskog method through Eqs.(21)–(28). Radiation loss P_{loss} was calculated taking account of atomic and ionic spectral lines and continuous spectrum including bremsstrahlung and recombination radiation. The absorption effect was not taken into account in the present calculation.

2.5. Calculation space and calculation conditions

Figure 1 shows the configuration of the ICTP system [5, 6] treated in this calculation. The ICTP system is composed of the plasma torch and the reaction chamber. The plasma torch on the left hand side in Fig.1 has two coaxial quartz tubes with a 330 mm length. The inner tube has an inside diameter of 70 mm. An eight turn

induction coil is installed around the plasma torch. The reaction chamber on the right hand side is made of SUS304 with a tapered shape. All the wall of the plasma torch and the chamber are cooled by water.

For this instrument, the calculation was performed in the *z*-*r* two-dimensional cylindrical space as hatched in Fig.1. This space was divided into 92×66 grids. The T_h of the inner wall side of the torch was determined by the thermal conduction through the 1.0 mm thick quartz. Non-slip condition was required at all the wall surface. The cold gas with T_h=T_e of 300 K is supplied along the inside quartz tube as a sheath gas from the area (*z*[mm], *r*[mm]) = (0,60)–(0,65). Its gas flow rate was set to 100/2.5 slpm for Ar/N_2 mixture. At outlet of *z*=910 mm, it was assumed that the gas flow and heat transfer occurs freely. The vector potential at any wall was calculated considering the coil current and the eddy current inside the plasma [2]. Input power into plasma is fixed at 27 kW. Pressure at (*z*, *r*)=(0,0) is set to 101 325 Pa. The SIMPLE method was adopted to solve simultaneously the governing equations described in the previous section. Steady state solution was obtained for the above condition.

3. Calculation results

3.1. Three different models for thermal plasma simulation

We have already developed a one-temperature chemical equilibrium (1T-CE) model [3] and a one-temperature chemically non-equilibrium model (1T-NCE) [5, 6]. In the present work, a two-temperature chemically non-equilibrium (2T-NCE) model is developed as described in the prior section.

The 1T-CE model corresponds to the LTE model in which chemical equilibrium is established under one-temperature condition. In this case, particle composition can be easily and previously calculated as a function of one-temperature through Gibbs free energy minimization method or Saha's equations, and then transport and thermodynamic properties depends only on one-temperature T(1T-CE) if the pressure is fixed. Thus, particle composition distribution was derived only from T(1T-CE) at each position of thermal plasma. The 1T-NCE model takes account of chemically no-equilibrium effect, in which reaction rates, convection and diffusion effect on particle composition distribution is considered. In this case, particle composition at each position was derived through mass conservation of each of species j as described in Eq.(6). Transport and thermodynamic properties depend on not only one-temperature T(1T-NCE) but also particle composition at each of position in thermal plasma. Thus, temperature and particle composition distributions are influenced by this chemical non-equilibrium effect. However, electron temperature is assumed to be the same to heavy particle temperature. The 2T-NCE model, the present work model, does not assume chemical equilibrium condition, and the electron temperature is not assumed to the same to the heavy particle temperature. For this model, transport and thermodynamic properties depend on local particle composition, T_e and T_h. In this

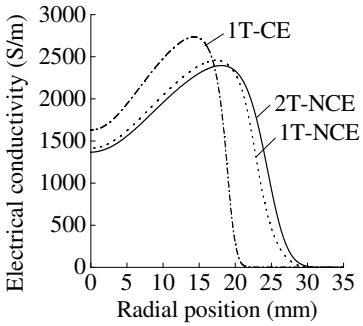

Fig. 5. Radial distributions of electrical conductivity at axial position of 155 mm by different models.

section, calculation results by these three models are compared to study the effect of chemically and thermally non-equilibrium.

3.2. Distributions of temperature and electrical conductivity

Figures 2 (a) and (b) demonstrates the two-dimensional distributions of T_e and T_h, respectively, by the 2T-NCE model. In the plasma torch, it should be noted that T_e is higher than T_h near the wall. This is because electric field strength $|\dot{E}_\theta|$ is high there, and also the energy conversion between the electron and heavy particles is low due to small collision frequency between them. On the other hand, in the reaction chamber, T_e is almost equal to T_h because of low electric field strength. For comparison, isothermal contours by 1T-CE and 1T-NCE models are also indicated in Figs.3(a) and (b). From these figure, it can be seen that the 1T-CE model predicts higher temperature around (z, r)=(155,15) and lower temperature around the torch wall than the 1T-NCE and 2T-NCE models. Figure 4 shows the radial distributions of T_e and T_h by the 2T-NCE model, T by the 1T-NCE and T by the 1T-CE model at axial position z=155 mm where $|\dot{E}_\theta|$ is highest. Radial temperature profile by the 1T-CE model is apparently narrower than that by the NCE models. This results from the fact that the 1T-CE model does not take into account radial diffusion of electron, which occurs particularly near the wall. On the other hand, temperature profile by the 1T-NCE model is similar to T_h by the 2T-NCE model. However, it should be noted that T_e is by 2000 K higher than T_h and T by the 1T-NCE model at r >22 mm.

Figure 5 represents radial distribution of electrical conductivity σ by the three models. It is found that σ by the 1T-NCE model has a peak around r=20 mm, while that by the 1T-CE model is around r=15 mm. This also arises from the fact that electron density in the NCE models has plainer radial distribution profile due to diffusion. The 2T-NCE model predicts a little higher σ around r >22 mm than that by the 1T-NCE. This is attributed to the high T_e by to high electric field near the wall.

From the above results, it can be found that chemical non-equilibrium substantially affects the temperature and electrical conductivity distribution.

3.3. Particle density distribution

For the advanced material processings, distribution of radicals such as the electron and the active atomic particles is of great importance to be understood. Figure 6 shows the electron density distribution by the three different models. The 1T-CE model has higher electron density n_e around (z,r)=(150,15) than the NCE models. However, the 1T-CE model predicts lower n_e near the wall. This is again attributed to no account of diffusion

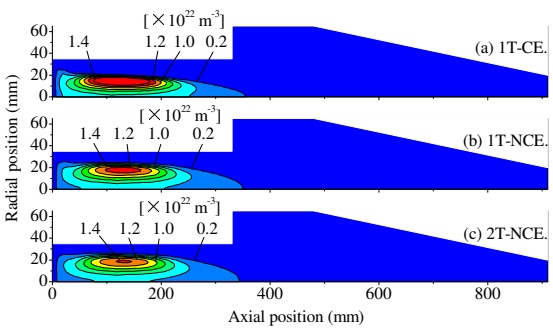

Fig. 6. Isocontours for electron density predicted by different models.

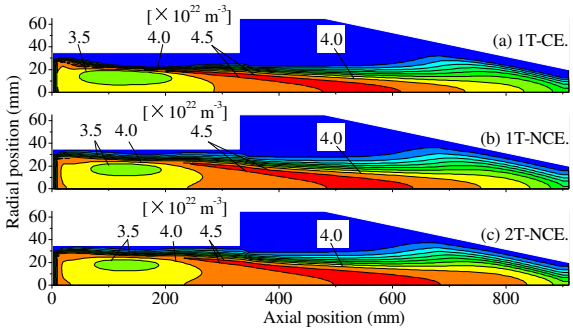

Fig. 7. Isocontours for nitrogen atom density predicted by different models.

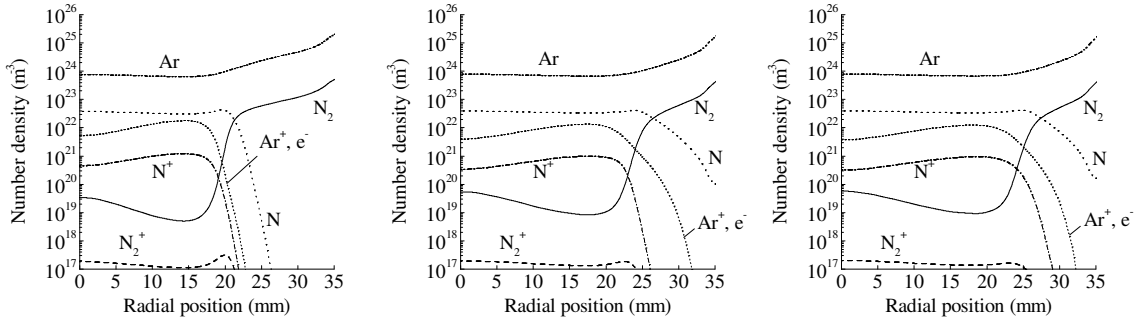

(a) 1T-CE model. (b) 1T-NCE model. (c) 2T-NCE model.

Fig. 8. Radial distribution of particle composition at axial position of 155 mm by three different models.

effect in the 1T-CE model. On the other hand, the 1T-NCE model has a similar electron density distribution to the 2T-NCE model although the 2T-NCE model has higher one near the wall.

Nitrogen atom density distribution is indicated in Fig.7. The existence of nitrogen atom is extended to the reaction chamber. The NCE models simulate wider radial distribution profile than the 1T-CE model. Figure 8 shows radial distribution of particle composition at an axial position of 155 mm. From this figure, it is seen that the two NCE models predict similar composition distributions. However, the 1T-CE model has much lower density of electron, nitrogen atom, and ions at $r > 22$ mm. For the simulation of spatial distribution of particle density, it is proved that chemical non-equilibrium effect cannot be negligible rather than thermal non-equilibrium effect in this calculation condition.

4. Conclusions

A self-consistent chemical and thermal non-equilibrium model for Ar-N_2 inductively coupled thermal plasma (ICTP) was developed considering effects of diffusion, convection, reaction rates in two-temperature state, without the local thermal equilibrium (LTE) assumption. As a result, it was found that chemical equilibrium state substantially affects the distribution of the particle composition and the temperature rather than thermally non-equilibrium effect. This deviation among the LTE and non-equilibrium models mainly arises from the diffusion in the radial direction. Therefore, the diffusion effect should be considered for accurate understanding in such the plasma processing condition treated in the present paper.

NOx and Soot Reduction Using Dielectric Barrier Discharge and Selective Catalytic Reduction in Diesel Exhaust

Min Suk Cha, Young-Hoon Song, Jae-Ok Lee, and Seock Joon Kim

Emission Control Group, Korea Institute of Machinery & Materials, Daejeon, Korea

Abstract

A combined De-NOx technique of non-thermal plasma and selective catalytic reduction (SCR) using NH_3 has been investigated to remove NOx from a 300 hp marine diesel engine exhaust under low temperature conditions (100–200 ^oC). As results, De-NOx efficiency for combined process was increased from 20 to 80 % at 100 ^oC compared to SCR sole process. From the measurement of smoke-meter, over 45 % of PM were reduced and the size distribution of PM was significantly altered after plasma process.

1. Introduction

Recently, we are faced with the elevated regulation of NOx from combustion exhaust gases, because it caused smog, an acid rain, and a respiratory disease. Available technologies for aftertreatment of NOx, for instance, are three-way catalyst and selective catalytic reduction (SCR) used for gasoline engines and stationary combustion systems, respectively. However, since the three-way catalyst should be operated in stoichiometry, it can not be adopted to lean burn engines such as diesel engines. For a SCR technique especially using NH_3 as a reducing agent, though it shows a good performance for oxygen contained flue gases, there is the limitation of operating temperature – normally its operating temperature is above 300 ^oC, so that de-NOx efficiencies are quite poor in low temperature range. In this reason, NH_3 SCR can not be used for low temperature flue gases in many stationary combustion systems as well as mobile engines which have a stop-and-go features. In these regards, catalytic processes combined with non-thermal plasma can be considered as one of the promising candidate for treating NOx from lean burn engines with low temperature exhaust, and recently many of researchers had a interest on this field [1-4]. Another main hazardous product in diesel engines is particulate matter (PM), which is generally formed from soot particles. Since diesel engines are operated with a diffusion flame, soot particles are inevitable.

In the present study, we investigated the effects of non-thermal plasma combined with conventional NH_3 SCR process on NOx treatment in marine diesel engine exhaust with emphasis on the increasing de-NOx efficiencies in low temperature range, i.e., 100-200 ^oC. The principles and illustrative test results of the combined De-NOx process of SCR and plasma techniques were well introduced in recent researches [1, 2]. A dielectric barrier discharge (DBD) was considered as the source of non-thermal plasma. We designed and constructed a planar type DBD, which showed a good performance even in humid and highly sooting conditions. Fundamental investigations, such as NO to NO_2 conversion characteristics with DBD, the effects of additives were also made with a simulated gas. In addition, the size variation and reduction of PM with the DBD reactor will be discussed.

2. Experiment

To investigate the basic characteristics of a non-thermal plasma and SCR processes, we first considered a lab-scale experiment with a diesel exhaust-like simulated gas. Figure 1 shows the schematic of lab-scale experimental setup. The apparatus consisted of a gas supply system, a mixing and preheating unit, a constant temperature furnace, a DBD reactor and a power supply, a SCR reactor, and measurement systems. To simulate a diesel exhaust, mass flow controllers were used for compressed air, N_2, CO_2, NO, and C_3H_6. Here, propylene was used for representing unburned hydrocarbons and the effect of water vapor was not considered for simplicity. The gas compositions are listed in Table 1, which correspond to 25 % load condition in marine diesel engine used in the present study. The flowrate of ammonia, as a reducing agent in SCR process, was also controlled with MFC, and it was fixed as much as the amount of NOx. Total flow-rate of simulated gas was fixed at 20 slpm for lab-scale test.

To identify the effects of operating temperature on each process, the DBD and SCR reactors were located in the constant temperature oven. The simulated gas was mixed and heated up to target temperature within the mixing and preheating unit, then it was introduced to the DBD reactor. The composition of gas was measured by Fourier transform infrared spectroscopy (FTIR, vector33, Bruker) at three different points – the inlet and outlet of the DBD reactor, and the outlet of the SCR reactor. These three points represent an initial condition,

the effects of plasma, and the role of a catalyst, respectively.

Table 1 Composition of diesel exhaust-like simulated gas

O_2 [%]	CO_2 [%]	NOx [ppm]	HC [ppm]
17.6	4.35	550	116

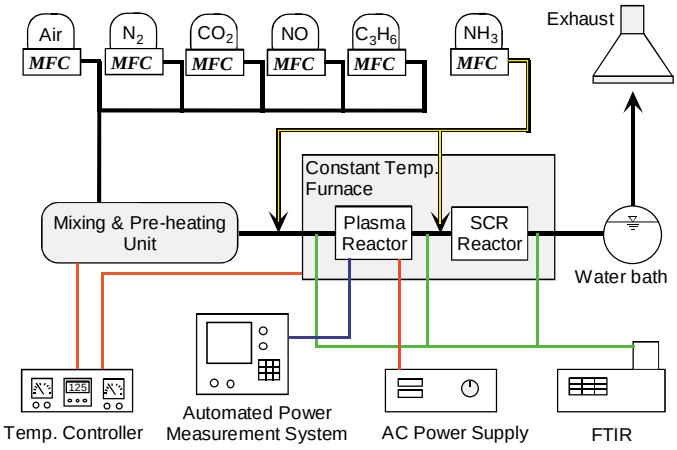

Fig. 1 Schematic of lab-scale experimental setup.

As shown in Fig. 2, the dielectric barrier discharge (DBD) reactor, which was constructed by stacking up a planar electrode together with spacers for gas flow, was used as a non-thermal plasma source. The planar electrode consisted of two α-Al_2O_3 ceramic plates bonded each other. At one of the attached surface, a silver paste was coated. AC power supplies with 60Hz and 10kHz frequencies were used separately for the lab-scale test and a pilot-scale test, respectively to supply adequate electric power in each experiment. The delivered electric power was measured by automated power measurement system using a charge-voltage diagram (Lissajous diagram) [5] with an additional capacitor of 2 μF. For SCR process, commercialized NH_3 SCR catalyst (SK Corp.) was used.

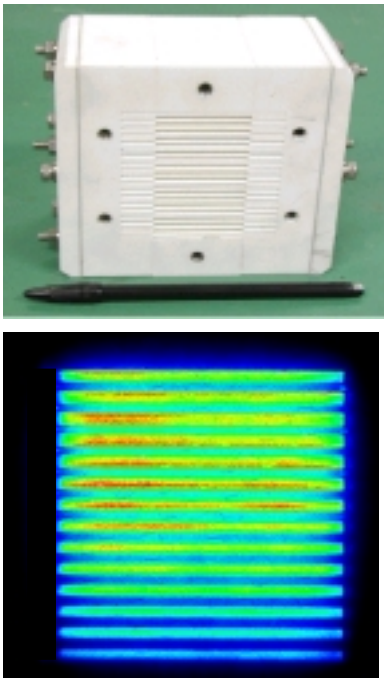

Fig. 2 Planar type DBD reactor and discharge images with ICCD camera.

Fig. 3 Pilot-scale plasma/SCR combined system with marine diesel engine.

To investigate the practical applicability of the plasma/SCR combined process to real diesel exhaust, 300 hp rating marine diesel engine (Yanmar) was used. 100 Nm^3/h was bypassed from a main exhaust stream, while the total flow-rate is about 1,000 Nm^3/h at full load condition. Note that at this flow-rate Q = 100 Nm^3/h,

space velocities are *S.V.* = 4,500/h and 450,000/h for the catalyst and the plasma reactor, respectively. NOx removal efficiencies were also measured with the FTIR spectrometer.

3. Results and Discussion

Effects of Non-thermal Plasma on NOx

In general, important chemical reactions relating to NO and NO_2 are as follows.

$$NO + N \rightarrow N_2 + O \quad (1)$$
$$NO + O + M \rightarrow NO_2 + M \quad (2)$$
$$NO + O_3 \rightarrow NO_2 + O_2 \quad (3)$$
$$NO + OH + M \rightarrow HNO_2 + M \quad (4)$$
$$NO + HO_2 \rightarrow NO_2 + OH \quad (5)$$
$$NO_2 + N \rightarrow N_2O + O \quad (6)$$
$$NO_2 + OH + M \rightarrow HNO_3 + M \quad (7)$$
$$NO_2 + O \rightarrow NO + O_2 \quad (8)$$

As can be seen in Eqs. 1-8, radicals or molecules such as O, O_3, OH, N, and HO_2 are needed in the reactions. Since non-thermal plasma was known to make lots of chemically active species, we used a DBD as the source of radicals.

In N_2/O_2 mixtures, much of input energy could be used for O_2 dissociation rather than N_2 dissociation [6]. Furthermore since Eq. 1 is relatively slow reaction, the reactions relating to N radical can not be considered for simplicity. In the present lab-scale experiment, we did not consider the effects of H_2O. In this regard, Eqs. 2, 3, and 8 can be important reactions. These O and O_3 involved reactions are composed with the oxidation of NO to NO_2 and the backward conversion of NO_2 to NO. In this point of view, one can conceive that at certain thermodynamic state including a concentration and temperature the reactions can be equilibrated, i.e., NO to NO_2 conversion can be saturated with the input power of plasma.

Figure 4 shows NO to NO_2 conversion efficiencies along with a SED (specific energy density) defined as input energy per the unit volume of a gas to be treated, i.e., SED = input power for plasma generation/gas flow-rate. Here, the rectangle and circle symbols indicate simulated mixtures with and without HC (C_3H_6), respectively, and conversion efficiency was defined by the volume fraction of NO_2 for the total amount of NOx. As shown in the figure, for the case without HC, NO_2 conversion rate is relatively insensitive to SED demonstrating saturated feature at about 13 %. However, owing to the addition of HC, the production of NO_2 is significantly increased, for instance 45 % of NO is oxidized to NO_2 at SED = 200 kJ/m^3. It is to be noted that the change of total amount of NOx ($NO + NO_2$) was negligible for both conditions, meaning that with the sole process of non-thermal plasma NOx can not be reduced to nitrogen.

The increase of NO to NO_2 conversion efficiency with the addition of propylene can be explained as follows. Propylene can be partially oxidized with the aid of O radical, and through this partial oxidation lots of reactive species can be produced with a chain reaction [7]. Chemical reactions relating these species are

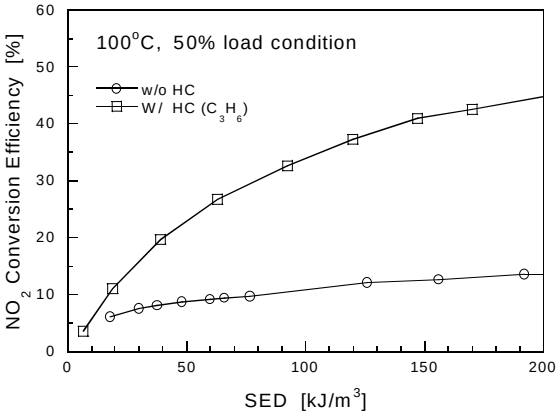

Fig. 4 NO_2 conversion rate with SED for 50 % load condition.

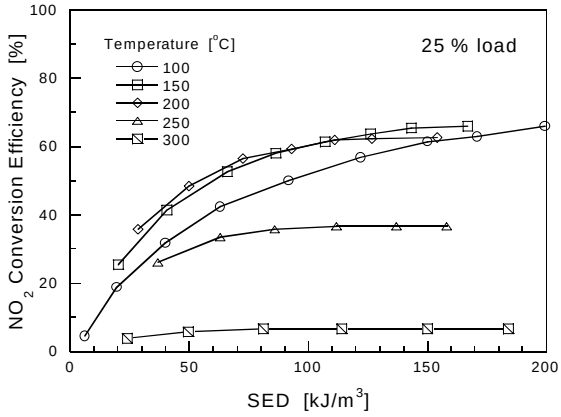

Fig. 5 NO_2 conversion rate with various operating temperatures for 25 % load condition.

$$NO + CH_3O_2 \rightarrow NO_2 + CH_3O \quad (9)$$
$$NO + O_2C_2H_4OH \rightarrow NO_2 + OC_2H_4OH. \quad (10)$$

Above reactions are known as faster than Eqs. 2, 3. Furthermore in defect of O radical, the backward reaction of NO_2 to NO in Eq. 8 can be decreased. In this reason, high conversion efficiency can be obtained with the addition of HC. In Fig. 5, we plotted NO to NO_2 conversion efficiencies for various operating temperatures with the simulated gas of 25 % load condition. As can be seen, at 150 and 200 ^oC NO_2 conversion exhibits its optimum, while the conversion became deteriorated as the temperature increases. It partly because the temperature sensitive characteristic of reaction 8 than Eqs. 2, 3, 9, and 10, i.e., NO_2 to NO conversion reaction prevail over the NO oxidation at high temperatures.

Characteristics of Plasma/SCR Combined Process

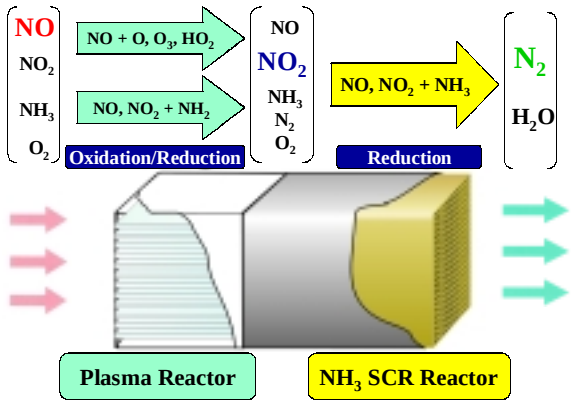

Fig. 6 Concept of plasma/SCR hybrid system.

As discussed in the previous section, NOx can not be reduced to nitrogen with non-thermal plasma process in the presence of oxygen. Some portion of NO was oxidized to NO_2 demonstrating negligible change of the total amount of NOx. In this regard, NH_3 SCR process was adopted after the plasma process to achieve the full reduction of NOx. In Fig. 6, the concept of plasma/SCR combined process was depicted. As shown in the figure, plasma and SCR reactors are connected in series. In combustion flue gases, over 90 % of NOx consisted of NO. A plasma reactor converts NO to NO_2 at certain amount. Some portion of NO can be reduced by NH_2 radical within the plasma reactor. Then $NO+NO_2$ reduced to N_2 in NH_3 SCR reactor, since NO_2 or $NO+NO_2$ mixture could be more easily reduced at low temperature [1]. Above arguments will be elaborated later.

Chemical reactions concerning NOx reduction in NH_3 SCR process are

$$4NO + 4NH_3 + O_2 \rightarrow 4N_2 + 6H_2O \quad (11)$$
$$6NO + 8NH_3 \rightarrow 7N_2 + 12H_2O \quad (12)$$

However, for the mixture of $NO+NO_2$, the below overall reaction is known as a dominant mechanism [1].

$$NO + NO_2 + 2NH_3 \rightarrow 2N_2 + 3H_2O \quad (13)$$

In addition, when NH_3 was injected before a plasma reactor, NH_2 radical produced from NH_3 by a plasma process also affects to NOx [1].

$$NH_2 + NO \rightarrow N_2 + H_2O \quad (14)$$
$$NH_2 + NO_2 \rightarrow N_2O + H_2O \quad (15)$$

From the reaction 15, undesirable N_2O formation occurred through a plasma process, however, in the present experiment, N_2O leakage can not be detected after SCR reactor.

Since over 90 % of NOx can be reduced to N_2 above 250 ^oC using a NH_3 SCR process, to identify synergetic effects with plasma process operating temperatures were varied from 100 to 200 ^oC. In Fig. 7, we plotted NOx reduction rates for the non-thermal plasma, the NH_3 SCR, and the plasma/SCR combined processes. As shown in the figure, for the plasma sole process with SED = 84 kJ/m^3, about 30 % of NOx is removed irrespective of temperature through Eqs 14 and 15. On the contrary, for the SCR sole process, it shows significant dependence on temperature. At 100 ^oC, NOx reduction rate is about 20 %, while it reaches about 85 % at 200 ^oC. However, the NOx reduction rate is dramatically changed for plasma/SCR combined process

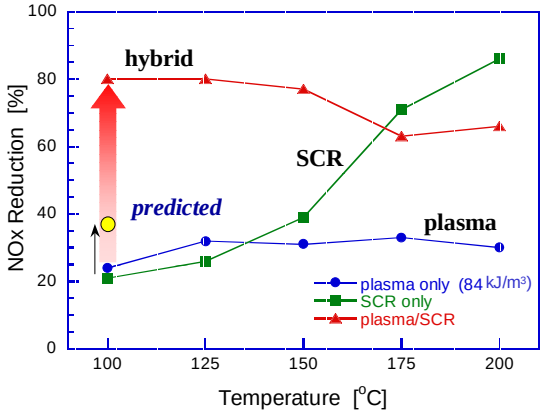

Fig. 7 NOx reduction efficiencies for various processes.

in relatively low temperature. About 80 % of NOx can be reduced through the plasma/SCR combined process in the temperature range of 100-150 °C. As depicted in Fig. 7 for 100 °C, the arithmetic sum of NOx reduction rate for plasma/SCR combined process is about 36 %, i.e., 20% (plasma) + 80% (remained portion of NOx relative to the initial amount after plasma reactor) × 20% (SCR performance) = 36%. While it reaches at 80% for combined process demonstrating synergetic effect of combining two processes. To clarify the synergetic result, we investigated de-NOx efficiencies for SCR sole process with NO and NO_2 separately. As results, NO_2 can be more easily reduced at low temperature compared to NO. In this reason, converted NO_2 within the plasma reactor can raise a reduction rate in SCR process. It is to be noted that a NOx reduction rate for a mixture of NO+NO_2 showed its optimum at around $[NO_2]/[NOx]$ = 0.4 to 0.6, which is agree with Eq. 13. However, de-NOx performance of combined process was deteriorated compared to SCR process over 170 °C. Through a parametric test with additives, we concluded that this result was originated from the HC addition. It was found that HC can serve as a reducing agent in catalytic process, while it reduced NO_2 to not N_2 but NO.

NOx Removal in Diesel Engine Exhaust

To investigate the applicability of the combined process in diesel engine exhaust, we construct the 100 Nm^3/h rating pilot-scale plasma/SCR combined system as shown in Fig. 3. The plasma reactor operated excellently with highly humid and sooting condition. Since the NO to NO_2 conversion in plasma reactor was mainly related to the amount of HC addition as well as input powers, first we investigated NOx reduction rates of combined system for various input powers and HC addition. Figure 8 shows the NOx reduction efficiencies along with the normalized C_3H_6 concentration for various input power conditions at 100 °C. As results, since de-NOx efficiency is saturated at about 80%, we chose the combination of SED = 40 kJ/m^3, which corresponds to 1.1 kW input power with flow-rate of 100 Nm^3/h, and $[C_3H_6]$ = 1.5[NOx] = 800 ppm as an operating condition. Note that to determine an operating condition in commercial applications the comparison of fuel cost between making electricity with engine and supplying HC should be made.

Figure 9 shows the NOx reduction rate for plasma/SCR combined system together with SCR sole process along with operating temperatures. Generally, combined process exhibits superior performance to SCR sole process. For instance, at 100 °C 20% NOx reduction occurs with SCR sole process, while 80% of NOx can be reduced with plasma/SCR combined system. Furthermore, contrary to the results in Fig. 7, even at 200 °C 90% of NOx is reduced with combined system, while 55% reduction is obtained using the SCR sole process. It is to be noted that the portion of converted NO_2 in total NOx is in the range of 60 – 70% as shown in Fig. 9.

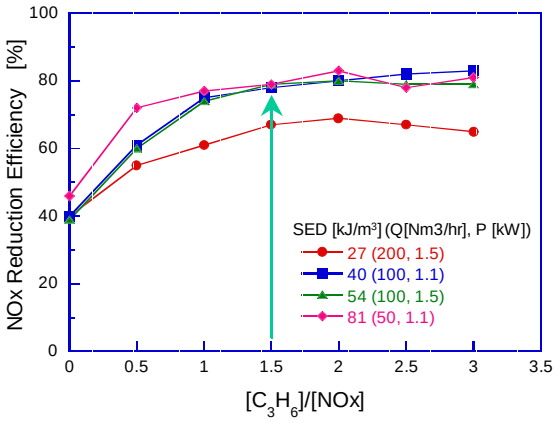

Fig. 8 NOx reduction efficiencies for various operating conditions.

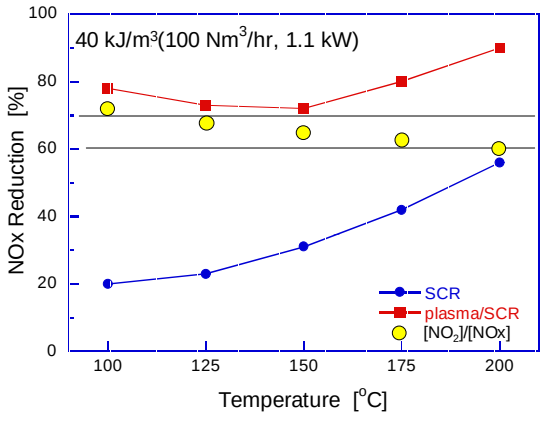

Fig. 9 NOx reduction efficiencies for SCR and combined system together with the percentage of $[NO_2]/[NOx]$ along with temperature.

To apply the combined system to the full-scale 300 hp rating diesel engine exhaust, we estimate the power consumption of the plasma reactor to be 5-6 kW approximately. This power can cover about 500 Nm^3/h, which can be enough for a warming up period considering that the exhaust flow-rate is about 1,000 Nm^3/h at full load. Since the estimated power corresponds to 2 % of the engine power, and moreover the plasma reactor should be turned off after exhaust temperature increases, probably the operating cost of the plasma reactor does not matter in practical applications. In addition, the degradation of catalyst from unwanted byproduct such as ammonium nitrate can be fixed by occasional high temperature (>250^oC) operations.

Effects of Non-thermal Plasma on PM

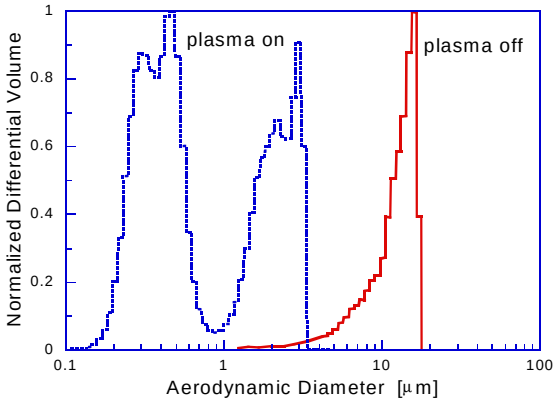

Fig. 10 Effect of plasma on the size distribution of PM in diesel exhaust.

Through the present pilot-scale test, it was also found that the present planar type DBD can be effective to change the emission characteristics of PM. The size distribution and blackness of PM were measured at the outlet of the plasma reactor using a particle size analyzer and a smokemeter, respectively. Figure 10 shows the size variation of PM. As shown in the figure, the initial distribution pattern (solid line) is significantly altered by the plasma process (dotted line). With the aid of the plasma process the average size of PM is quite reduced to the order of 1 μm demonstrating the double peak of its distribution. While the average size is in the order of 10 μm for the untreated PM. Since the reduction of average size means the increase of total surface area of PM, this result can be helpful to a continuously regenerative DPF system, which used NO_2 as an oxidizing agent for PM. Furthermore, 45% reduction in the blackness can be observed with the plasma process. From the above results, we can conceive that through the plasma reactor mass reduction can be possible as well as its average size reduction. However, at present, detailed mechanism of PM reduction is not clear, and further investigation will be a future study.

4. Concluding Remarks

Non-thermal plasma process combined with conventional NH_3 SCR process was successfully applied to the marine diesel engine exhaust. To treat 550 ppm of NOx from the diesel engine, we chose the flow-rate of 100 Nm^3/hr, electric power of 1.1 kW (SED=40 kJ/m^3), and 800 ppm C_3H_6 addition among the various optimal operating conditions. As results, de-NOx efficiencies for combined process were increased from 20 to 80 % and from 55 to 90% at 100 and 200 ^oC, respectively compared to SCR sole process. We estimated that the power consumption is about 2 % of engine power.

In addition to the NOx reduction, we found that PM in the diesel exhaust, mainly consisted of soot, was affected by the plasma process. From the measurement of smoke-meter, over 45 % of PM were reduced after plasma process. Furthermore, the size of PM is significantly decreased. It suggested that the non-thermal plasma process can be a viable method for PM reduction or assisted one for other DPF systems.

Comparison of PFCs Decompositions between Glow and Streamer Mode in Dielectric Barrier Discharges

Yongho Kim, Kwan-Tae Kim, Min Suk Cha, Young-Hoon Song, and Seock Joon Kim

Emission Control Group, Korea Institute of Machinery and Materials, Daejeon, Korea

Abstract

Using a dielectric barrier discharge (DBD), CF_4 removal characteristics are investigated for a N_2 streamer discharge and a He glow discharge. The optimal concentration of oxygen was ranged 500 ppm ~ 1 % for treating 500 ppm of CF_4. In N_2 streamer discharge, CF_4 can be more easily removed with 3 mm discharge gap, compared with 1 mm discharge gap. Helium glow was the most efficient one to remove CF_4. Experimental results were compared in view of an effective plasma volume.

1. Introduction

Perfluorocompounds (PFCs), such as CF_4 and NF_3, have been widely used in a semiconductor industry as a plasma etching gases. Since these PFCs are known to cause a greenhouse effect intensively, there has been a growing interest in reducing PFCs emissions. Among various PFCs decomposing techniques, a dielectric barrier discharge (DBD) is considered as one of a promising candidate because it has been successfully used for generating ozone (O_3) and decomposing nitrogen oxide (NO). In NO decomposition, energetic streamers in DBD produce numerous radical species, such as O and N in air. The O radicals oxidize NO to NO_2 ($NO + O \rightarrow NO_2$). The N radicals reduce NO to N_2 ($NO + N \rightarrow N_2 + O$). In CF_4 decomposition, however, CF_4 rarely reacts with radical species, even though dissociated fluorine compounds, such as CF_3, CF_2, and CF, show a good reactivity with O radicals [1, 2]. For a successful CF_4 decomposition, therefore, an electron interaction with CF_4, *primary reaction*, is essentially needed in advance of a radical reaction with CF_4, *secondary reaction*. Table 1 shows a CF_4 decomposing mechanism by the DBD plasma, where an electron is represented by "e".

Table 1. CF_4 decomposition mechanisms by DBD plasma [1]

Primary Reaction		Secondary Reaction		
$e + CF_4 \rightarrow CF_3 + F^-$	: 4.8 eV (1)	$CF_3 + O \rightarrow COF_2 + F$	: 3.16×10^{-11} cm^3s^{-1}	(4)
		$COF_2 + O \rightarrow CO_2 + F_2$	: 5.30×10^{-11} cm^3s^{-1}	(5)
$e + CF_3 \rightarrow CF_2 + F^-$	: 3.0 eV (2)	$CF_2 + O \rightarrow CFO + F$	: 2.17×10^{-11} cm^3s^{-1}	(6)
		$CFO + O \rightarrow CO_2 + F$	: 4.98×10^{-11} cm^3s^{-1}	(7)
$e + CF_2 \rightarrow CF + F + e$	: 4.55 eV (3)	$CF + O \rightarrow CO + F$	: 1.24×10^{-11} cm^3s^{-1}	(8)
		$CO + O \rightarrow CO_2$	: 6.52×10^{-11} cm^3s^{-1}	(9)

A first work in this experiment was to find how many primary reactions are associated with the streamer mode in DBD. Considering secondary reaction, finding the optimal concentration of oxygen was next. Finally, influences of an *effective plasma volume* (= plasma volume / reactor volume) on the CF_4 decomposition were studied by means of (1) varying a discharge gap distance of DBD reactor and (2) a glow mode operation with a helium gas.

2. Experimental Methods

Figure 1 shows the schematics of a coaxial-cylinder DBD reactor. A quartz tube with 27 mm diameter and 350 mm length was employed as a dielectric barrier. Outside of this quartz tube, a grounded mesh electrode was wrapped. The quartz tube and the mesh electrode was cooled by a flowing water. An inner metal electrode with 23 mm diameter was water cooled as well. A discharge gap distance between inner rod and outter quartz was 3 mm. Through the discharge gap, a nitrogen gas was supplied with 2 slpm. A 1000 ppm of an oxygen was added as for an O radical sources. Initial CF_4 concentration was fixed at 500 ppm. AC voltage, fixed at 10 kHz, was applied to the inner rod electrode. During this experiment, external electric power was varied from 0.75 kW to 1.5 kW. A discharge voltage and a current were measured with

Oscilloscope (LeCroy). A discharge power delivered into the DBD reactor was measured by means of the Lissajou diagram method. A FTIR (Brooker) was used for the measurements of species concentrations.

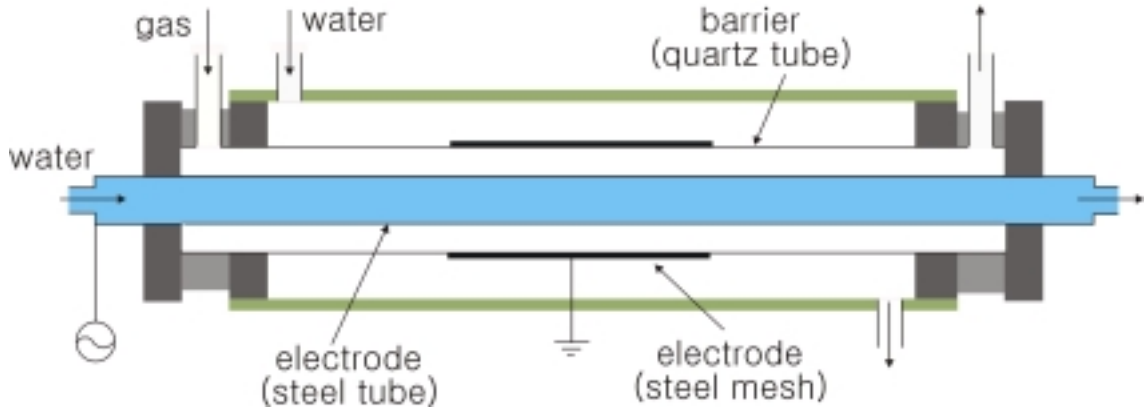

Figure 1. Schematic diagram of a coaxial-cylinder DBD reactor.

3. Results and Discussion

CF_4 Decomposition with Streamer in DBD

Figure 2(a) shows CF_4 removal efficiencies for various input powers in a pure nitrogen discharge (solid line) and a nitrogen discharge with 0.1 % of oxygen (dashed line). Each DBD reactor volume was filled with filamentary streamers at a tested input power from 0.75 to 1.5 kW. With these streamer discharges, 500 ppm of CF_4 was removed linearly with increasing input power. In a pure nitrogen discharge (solid line), 8.6 % of CF_4 was removed at 0.75 kW and 23.2 % at 1.5 kW. Considering 2 slpm of the nitrogen gas, a discharge energy density was reached up to 34 MJ/m^3 at input power of 1.5 kW. Though a great amount of discharge energy was delivered into the DBD reactor volume, the decomposition efficiency of CF_4 was quite low in streamer operation. Noting a similar dissociation rate between N_2 and CF_4, inefficient CF_4 decomposition can be caused by a poor *effective plasma volume* (= plasma volume / reactor volume) of streamer. In a nitrogen discharge with 0.1 % of oxygen (dashed line), about 10 % enhancement of removal efficiency was obtained. Though O radical does not react with CF_4 molecule directly, O radical can oxidize CF_3 to COF_2 (reaction 4, in Table 1). Owing to the stabilization of CF_3 by O radical, the recombination of CF_3 with F can be decreased, as a result, decomposition efficiency of CF_4 was increased. From the FTIR spectrum shown in Fig. 2, COF_2 is further oxidized by another O radical (reaction 5, in Table 1) and then it is converted into CO_2, of which spectra was increased during the oxidation process.

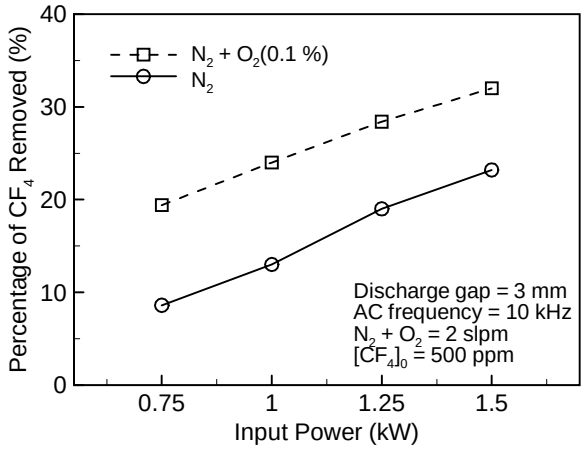

Figure 2(a). CF_4 removal in N_2 and N_2+O_2.

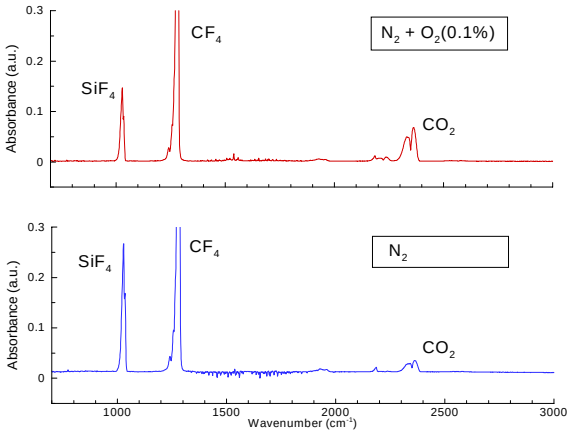

Figure 2(b). FTIR spectrum at 1.5 kW input power.

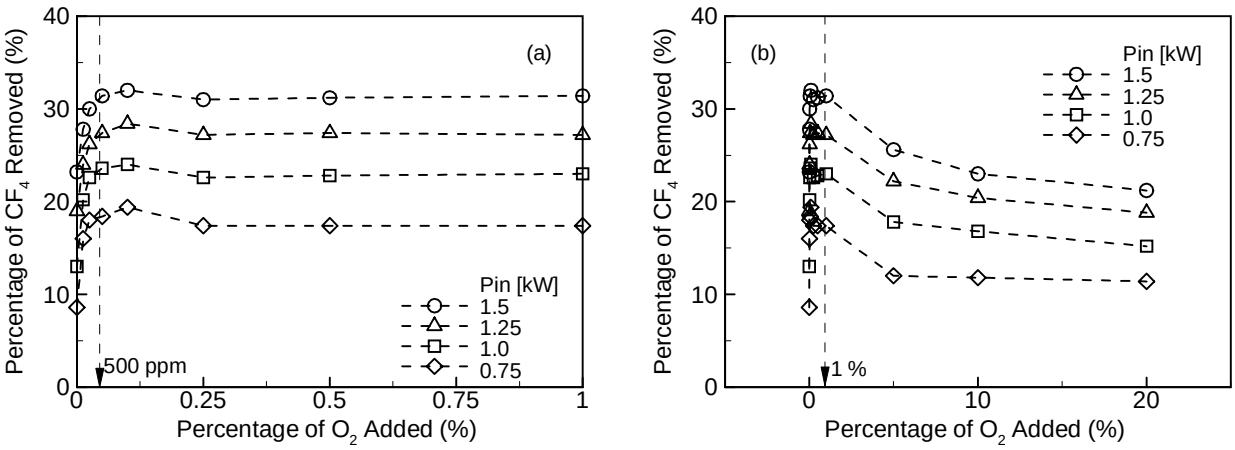

Figure 3. Percentage of CF_4 removed for various oxygen concentrations.

To find the optimal concentration of oxygen, which means the minimization of the recombination as well as the maximization of CF_4 decomposition, we investigated the effect of O_2 concentration. In Fig. 3(a), as O_2 concentrations increase until it reaches 500 ppm, CF_4 removal was gradually increased. For instance, at input power 1.5 kW (circle symbol), CF_4 removal reached 32 % at O_2 = 500 ppm, compared with 23 % at O_2 = 0 ppm. For further increase of O_2 in the range of 500 ppm ~ 1 %, CF_4 removal characteristics were insensitive to O_2 concentration. On the other hand, as O_2 concentrations increase over 5 %, CF_4 removal was decreased as decreased as shown in Fig. 3(b). Decreasing electron density due to excessive oxygen molecules can cause to decrease primary reactions of CF_4.

To clarify the dependence of initial CF_4 concentration, removal characteristics were investigated for various initial CF_4 concentrations. For all tested conditions, the amount of O_2 addition was fixed at 0.1 %. In Fig. 4(a), the removed CF_4 concentrations increased linearly with increasing initial CF_4 concentrations in the range of 100 ~ 500 ppm. Consequently, at the same input power, the same removal efficiency can be obtained regardless of initial CF_4 concentrations, shown in Fig. 4(b). This result means that electron density in streamer could be already enough to decompose both 100 ppm and 500 ppm of CF_4. At a given input power, the same effective plasma volume can result in the same decomposition efficiency even for different initial CF_4 concentrations. Moreover, it can also be considered that increasing input power plays a role to increase effective plasma volume rather to increase electron density.

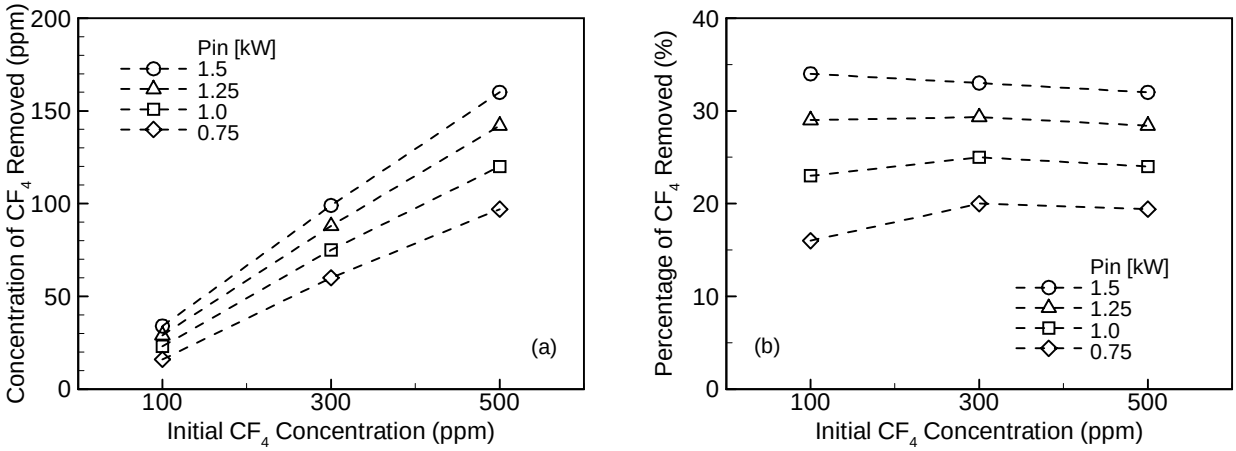

Figure 4. (a) Concentration of CF_4 removed, (b) percentage of CF_4 removed for different initial CF_4 concentration

Influences of Effective Plasma Volume on CF_4 Decomposition

Maintaining experimental conditions as the same as those in previous one, at first, discharge gap distance (*d*) of DBD reactor was reduced from 3 mm to 1 mm. In *d* = 1 mm operation, streamers were also observed to

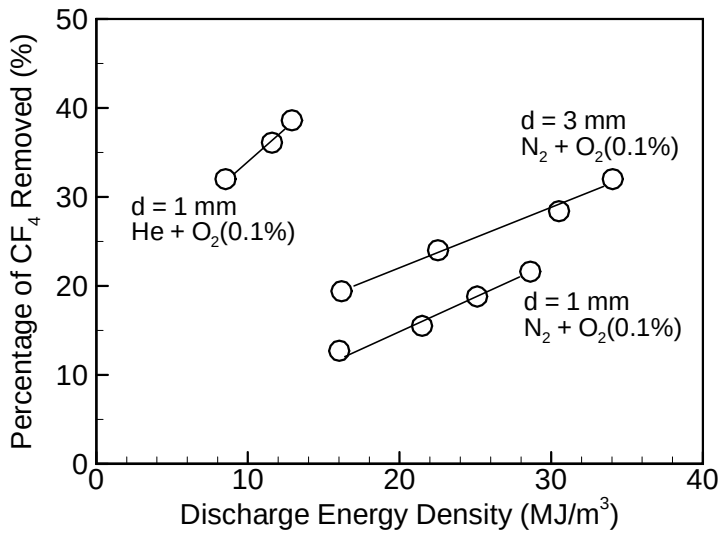

Figure 5. CF_4 removal for d = 3 and 1 mm, and for N_2 and He

fill up DBD reactor. In Fig. 5, CF_4 removal efficiencies are plotted as a function of discharge energy density in unit of J/m^3. As can be seen in Fig. 5, CF_4 removal efficiencies in d = 1 mm were decreased, compared with d = 3 mm. To analyze this experimental result, an effective plasma volume (V_s/V_r) was employed, which was originally derived by Rosocha [3] with considering an energy balance, $\varepsilon_r V_r = \varepsilon_r V_s$. Here, ε_r is total discharge energy per unit volume, V_r is a reactor volume, ε_s is streamer energy per unit volume, and V_s is a streamer volume. Defining the effective plasma volume as $F = V_s/V_r = \varepsilon_r/\varepsilon_s$, a ratio of F at d = 3 mm (F_3) to F at d = 1 mm (F_1) was represented as follows;

$$\frac{F_3}{F_1} = \frac{\varepsilon_{r,3}/\varepsilon_{s,3}}{\varepsilon_{r,1}/\varepsilon_{s,1}} \sim \left(\frac{\varepsilon_{r,3}}{\varepsilon_{r,1}}\right)\left(\frac{E_{s,1}}{E_{s,3}}\right).$$

In the above expression, we assumed ε_s mainly depends on average electric field at discharge gap, E_s. Measuring a discharge power using a Lissajou diagram, $\varepsilon_{r,3}$ was a little greater than $\varepsilon_{r,1}$. For instance, $\varepsilon_{r,3}$ = 23 kJ/ m^3 at 1 kW input power, compared with $\varepsilon_{r,1}$ = 22 kJ/ m^3. To estimate E_s, a gas gap voltage, V_g, was manipulated with applied voltage, V_a, and discharge current, I_d [4]. At 1 kW input power, Fig. 6 shows the measured V_a, I_d, and evaluated V_g at (a) d = 3 mm and (b) d = 1 mm, respectively. Though applied voltage at d = 1 mm was greater than that at d = 3 mm ($V_{a,1} > V_{a,3}$), the gas gap voltages evaluated for both cases were same ($V_{g,1} \sim V_{g,3}$). Based on the V_g measurement, we could estimate E_s ($=V_g/d$) for both cases, and we found $E_{s,1} \sim 3E_{s,3}$. Considering measured ε_r and evaluated E_s together, it could be concluded that F_3 is greater than F_1 in this experiment. An enhanced effective plasma volume ($F_3 > F_1$) can make the primary reaction of CF_4 increase, which result in higher CF_4 removal.

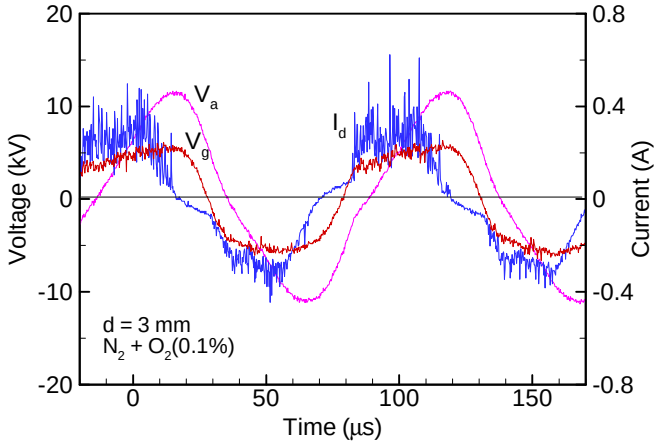

Figure 6(a). Waveforms of V_a, I_d, and V_g measeured at d = 1 mm

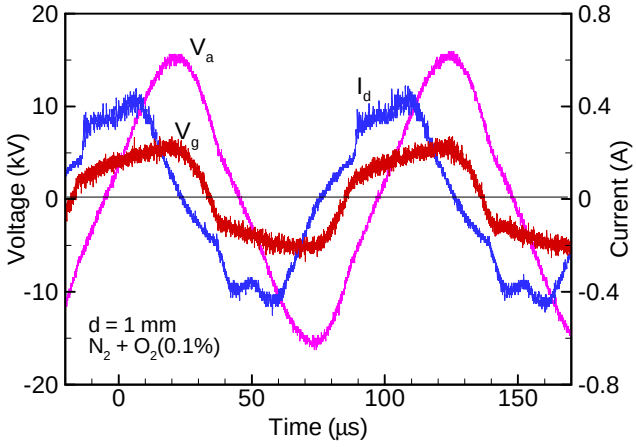

Figure 6(b). Waveforms of V_a, I_d, and V_g measeured at d = 1 mm

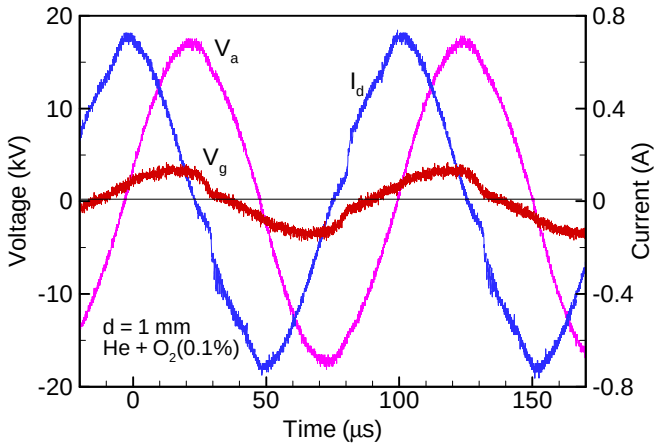

Figure 6(c). Waveforms of V_a, I_d, and V_g measeured at He discharge

Recently, there has been a growing interest in atmospheric glow discharge (AGD). Compared with streamer discharge, a spatial uniformity of AGD was one of merit for surface treatment of materials. In this CF_4 removal process, AGD is considered as a promising one because it has higher effective plasma volume. In this work, a N_2 gas was replaced with a He gas at d = 1 mm reactor. As shown in Fig. 6(c), the discharge current of He plasma did not show any current spike. Helium glow discharge with higher effective plasma volume resulted in higher CF_4 removal, as shown in previous Fig. 5.

4. Conclusion

Using a dielectric barrier discharge (DBD), CF_4 removal was examined for a streamer operation in N_2 and a glow operation in He. About 20 % of CF_4 was removed by the streamer discharge in N_2, spending 34 MJ/m^3. It was revealed that a primary reaction in streamer discharge, such as $e + CF_4 \rightarrow CF_3 + F$, is not so probable. Oxygen radical, reacting with CF_3, was helpful to inhibit a recombination (CF_3 + F), and resultantly to enhance CF_4 decomposition efficiency. However, excessive oxygen made an electron density decrease. An optimal concentration of oxygen was ranged from 500 ppm to 1 %, with which 30 % of CF_4 was removed in streamer discharge. Finally, influences of an *effective plasma volume* (= plasma volume / reactor volume) on the CF_4 decomposition were studied by means of (1) varying a discharge gap distance of DBD reactor and (2) a glow mode operation with a helium gas. As a result, higher effective streamer volume at d = 3 mm DBD caused enhanced CF_4 removal than d = 1 mm DBD in nitrogen. Helium glow was the most efficient one to remove CF_4 due to its highest effective plasma volume.

Abstract

Titanium dioxide was synthesized by in-flight oxidation of titanium nitride using inductive thermal plasma. The structure and phase composition of products depended mainly on the oxygen flow rate, and the formation mechanism of TiO_2 was investigated. The reaction was carried out initially by surface oxidation and melting, leading to core-shell structured composites with TiN cores and oxidized shells. At higher O_2 flow rate, the composites changed to anatase single crystal by rapid solidification of TiO_2 melts.

1. Introduction

Titanium dioxide has been used for a pigment, photovoltaic solar cell, photo-catalyst, gas sensor, biosensor, and optical material because of its high refraction index(>2.5), good photocatalytic activity, high resistance against chemical attack, and thermal stability. Recently, it has been a subject of interest as a photo-catalyst[1] or photonic crystal[2]. To improve the photocatalytic activity under visible light, the modification of TiO_2 has been tried to control by introduction of metal or reduction of TiO_2[3-6]. As a photonic crystal, highly ordered macroporous materials(inverse opals) or self-assembled opal-like structures[7], mono-dispersed single crystal TiO_2 spheres have been required. Many researchers reported that the structure, phase composition, and morphology relating to the key properties might be strongly influenced by synthetic conditions and additive compounds, but the mechanism was not yet cleared[8,9]. Titanium dioxide has been industrially produced by chloride and sulphate process, and recent research on the preparation of the powder tends toward sol-gel method[10,11], flame synthesis[4,12], sputtering[3], and plasma synthesis[5,6,13,14].

The present work is based on the thermal plasma process to prepare spherical titanium dioxide particles from titanium nitride particles. The purpose of this study is to prepare mono-dispersed spherical titanium dioxide and determine the main process parameter on the structure, phase composition, and morphology. We investigate the formation mechanism of anatase and rutile, and the effect of additive hydrogen in thermal plasma.

2. Experimental procedures

Fig. 1 shows the schematic diagram of experimental apparatus for preparation of TiO_2 powder by in-flight oxidation of titanium nitride. The water-cooled plasma torch(Model PL-50, TENKA Plasma System Inc., Canada) connected to a 2 MHz radio frequency power supply(Nihon Koshuha Co. Ltd., Japan) and attached a water-cooled cylindrical reactor. A water-cooled probe for injection of raw material was injected into the center of the plasma torch along the axis. As source materials, titanium nitride powder with diameter of ave. 28 ? (Nippon New Metal Co., Japan) was injected into plasma plum through the water-cooled probe using carrier gas, and the feed rate was adjusted to be about 1.5 g/min by controlling the motor speed of the powder feeder. Ar+He, Ar+O_2, or Ar+H_2 plasma was generated by mixing He, O_2, or H_2 in Ar-sheath gas, respectively. As the carrier gas, pure Ar was used in Ar+O_2 plasma, while Ar+O_2 mixing gas was used in Ar+He or Ar+H_2 plasma. The total flow rate of central and sheath gases were typically 30 l/min and 90 l/min, and the reactor pressure was controlled to about 500 torr because the filter could easily be blocked with product

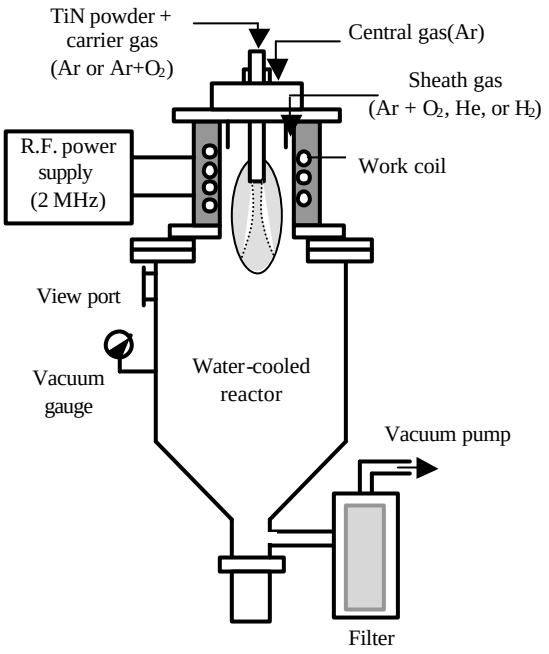

Fig. 1. Schematic diagram of a thermal plasma reactor for preparation of TiO_2 powder.

powders. The detailed experimental conditions were listed in Table 1.

Table 1 Experimental conditions

Plasma power	25kW, 40 kW
Pressure	500 torr
Plasma gas	Ar - 30 l/min
Sheath gas (total 90 l/min)	Ar + O_2(0 - 17.5 l/min) Ar + He(0 - 10 l/min) Ar + H_2(0 – 10 l/min)
Carrier gas (total 5 l/min)	Ar + O_2(0 – 2.5 l/min)
powder feed	1.5 g/min

The oxidized products were collected mainly at the reactor wall, and residual powders in exhausted gases were collected by porous metal filter. An X-ray diffractormeter(CuKa, RINT 2000, Rigaku, Japan) was used to analyze the phase compositions and particle size. Particle morphology was observed on the optical microscope and scanning electron microscope(Model S-5000, Hitachi, Japan). The internal structure of oxidized products was investigated for the cross-sectioned samples, which were embedded in polymer resin and polished with diamond paste. Micro Raman spectroscopy(NR-1800, JASCO, Japan) was used for structural analysis with a liquid nitrogen cooled CCD detector using a 100 mW Ar^+ laser.

3. Results and discussion

The synthesized powders typically consisted of micron sized bigger particles and nano-sized smaller particles: the bigger grained powders are solidified from molten species, while the smaller grained powders are derived by solidification of vaporized species. Two groups of particles could be separated from each other by sedimentation treatment after ultrasonic dispersion in a solvent where bigger powders easily sediment in short time. Fig. 2 shows the X-ray diffraction patterns of the bigger powders and smaller powders synthesized at a different O_2 flow using Ar-O_2 plasma. At a low O_2 flow rate(a), the diffraction pattern of bigger powders shows the peaks corresponding to TiN and rutile including Ti_4O_7[JCPDS 18-1402]. As the O_2 flow rate was increased, the peaks showed only the lines corresponding to TiO_2 in which anatase phase was dominated as shown in b. With the increasing O_2 flow rate, the anatase to rutile transformation might be promoted by increased exothermic reaction heat and heat transfer from plasma plum, but rutile phase was decreased. It is noted that the formation of anatase and rutile is strongly influenced by ambient oxygen pressure. Small powders are composed only of anatase and rutile regardless of O_2 flow conditions, and the size is calculated to be 50 nm by using peak patterns of Fig. 2c and d The nanopowders of anatase and rutile were derived by rapid solidification of gas mixture of TiO(g) and TiO_2(g), which are vaporized from the oxidized melts. At a higher O_2 flow rate, anatase content increased because the TiO_2(g) species dominate in the gas mixture as shown in Fig. 3.

Fig. 3 shows the chemical equilibrium compositions calculated for the systems of TiN/O_2 using the computer-based numerical method[15] in which Gibbs free energy is assumed to be minimum. In the low oxygen input system(a), Ti_4O_7 as well as TiO_2(rutile) with condensed phase exists at a range of temperature up to their boiling point. At a higher temperature of over 3000 K, TiO(g) is more stable than TiO_2(g) species, and it may cause the formation of the oxygen defect structure. With an increasing the oxygen input, TiO_2(g) become main product at the temperature range of 3000 K to 4200 K, while TiO(g) species is stable at the higher temperature exceeding 4200 K. It is interesting to note that the gas phase composition depends on the oxygen input condition, and the formation of nanopowder is derived by rapid quenching of mixture of TiO(g) and TiO_2(g) clusters.

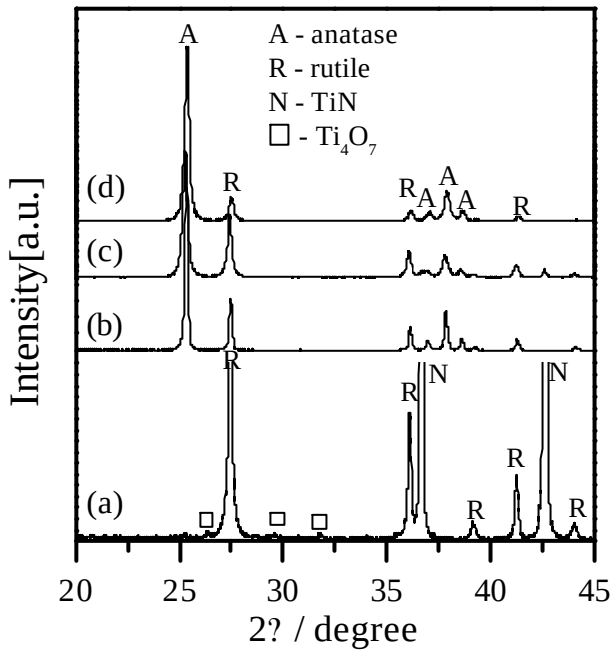

Fig. 2. X-ray diffraction patterns of separated powders from as-produced powders: (a, b) bigger powders; (c, d) smaller powder; (a, c) O_2 – 2.5 l/min; (b, d) O_2 – 17.5 l/min.

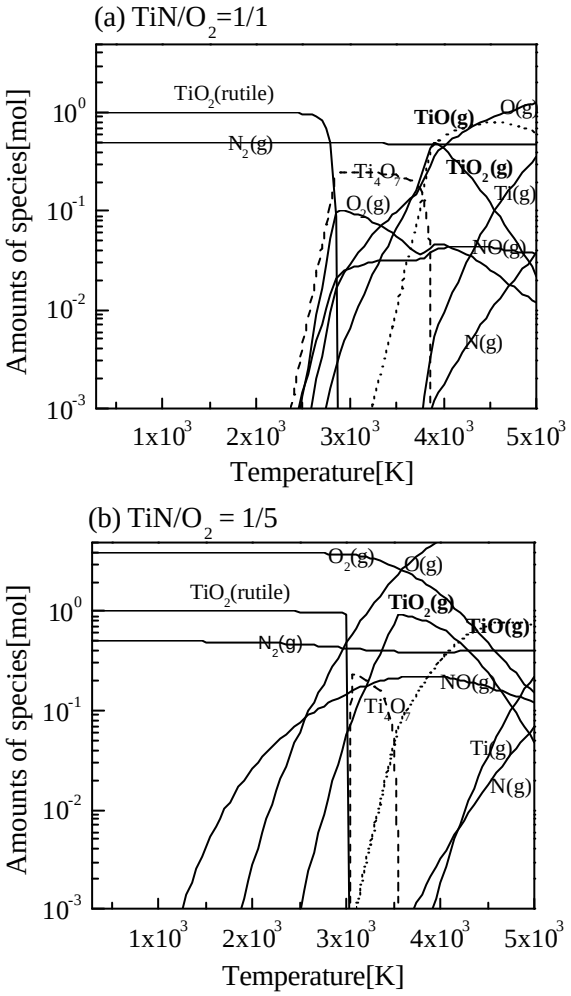

Fig. 3. Chemical equilibrium compositions calculated at different O_2 input conditions in TiN/O_2 systems.

Fig. 4 shows optical micrographs of raw powders and bigger powders synthesized at a different O_2 flow rate. The change of the color to black, blue, yellow, white, or transparent is relating to the degree of oxidation. The cross-section view in Fig. 4b reveals that the bigger powders formed of core-shell structured composites, TiN cores and oxidized shells, because the surface of the powders is rapidly oxidized to TiO_2 melts but oxygen did not fully diffused into TiN cores under low O_2 input conditions. The partially oxidized spherical powders consisted mainly of rutile as shown in Fig. 5, and the formation of rutile is attributed to the oxygen diffusion from molten TiO_2 shell into core because creation of oxygen vacancies enhance the formation of rutile[4]. With the increasing oxygen flow rate, the core-shell structured composites were more spherodized and reduced in size by enhanced oxidation and vaporization. At higher oxygen input conditions, mono-dispersed spherical crystals with diameters of several micrometers were produced as shown in Fig. 4c.

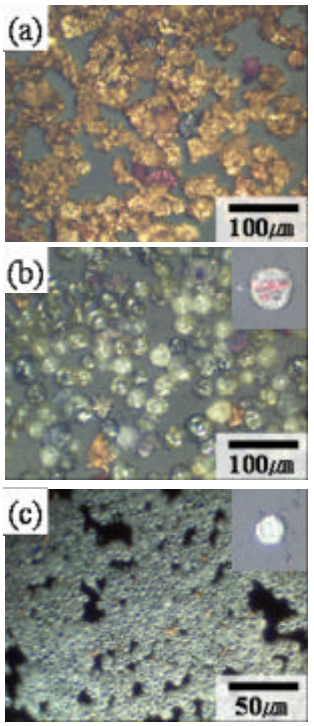

Fig. 4. Optical micrographs of raw powder(a) and oxidized powders(b,c): (b) O_2 – 2.5 l/min, (c) O_2 – 10 l/min.

The content of rutile was shown in Fig. 5 in which the relative weight fraction of rutile, excluding TiN, was calculated by using X-ray diffraction patterns. The rutile content of synthesized powders rapidly decreased with the increasing oxygen flow rate, and it implies that the formation of anatase and rutile is influenced mainly by oxygen flow rate. It is elucidated that the surface of the powders is rapidly oxidized and melted along the plum stream then the partially molten composites are rapidly solidified to anatase or rutile depending on the oxygen content in the melts. At low oxygen input, the molten surface of core-shell composites rapidly solidified to oxygen defect structure by diffusion of oxygen into the cores of composites, and TiN and TiO sub-oxides remain in the cores of composites. With the increasing oxygen flow rate, the powders become fully oxidized and melted, leading to anatase single crystal by rapid solidification under the oxygen rich atmosphere. For the smaller powders,

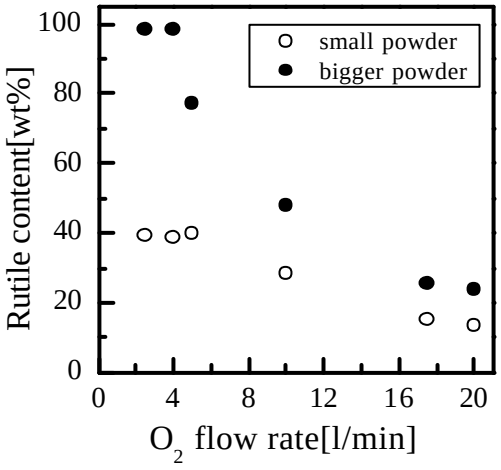

Fig. 5. Weight fractions of rutile for the powders synthesized by Ar-O_2 plasma.

anatase and rutile nanopowders are derived by quenching of the gas mixture of TiO(g) and TiO_2(g) species at high temperature as shown in Fig. 3. The formation mechanism of anatase and rutile was suggested that the anatase is formed by solidification of the oxygen-rich gas mixture under higher O_2 input conditions, while the rutile is derived from the oxygen-deficient gas mixture.

Raman spectra reveal the structure of the powders synthesized at different O_2 flow rate by Ar-O_2 plasma. At the low O_2 flow rate of 4.0 l/min, the peaks correspond to that of rutile as shown in Fig. 6a. The shifting and broadening of the spectrum is attributed to oxygen vacancies or lattice strain by rapid solidification[16,17]. The spectrum of the powder synthesized at the high O_2 flow of 20 l/min shows the peaks corresponding to the single crystal of anatase as in b[16,17]. It is similar to the results observed with X-ray diffraction as shown in Fig. 2.

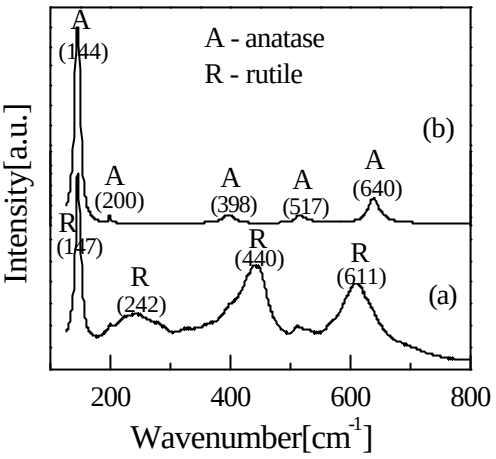

Fig. 6. Raman spectra of synthesized powders: (a) O_2 – 4.0 l/min and (b) O_2 – 20 l/min.

Fig. 7 shows the SEM images of separated powders from as-produced powders synthesized at the O_2 flow rate of 20 l/min. The bigger powders were well spherodized by solidification of TiO_2 melts, and the size significantly reduced by enhanced vaporization. The fully spherodized powders are associated to the anatase phase as shown in Fig. 6b. This has led us to conclude that the spherical single anatase crystal was synthesized by rapid solidification of fully oxidized TiO_2 melt under higher O_2 input conditions. In the case of gas phase synthesis, spherical nanopowders were grown from mixtures of TiO(g) and TiO_2(g) clusters, and the powders were evenly distributed by homogeneous nucleation and growth.

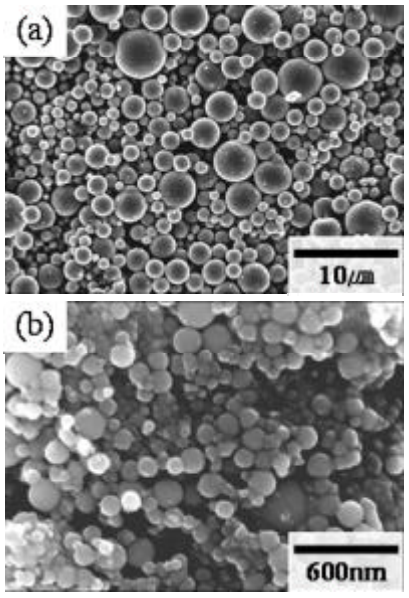

Fig. 7. SEM images of typical prolducts synthesized under higher O_2 input conditions: (a) bigger grained powder, (b) smaller grained powder.

To investigate the effect of H_2 addition, hydrogen was mixed into Ar-sheath gas, and oxygen injected into the center probe with the flow rate of 1 l/min. Fig. 8 shows the X-ray diffraction patterns of separated powders form as-produced products by Ar-H_2 plasma and Ar-He plasma. The patterns for bigger powders synthesized at low O_2 flow rate by Ar-He plasma reveal the peaks corresponding to TiN, rutile, and Ti_4O_7[JCPDS 18-1402]. The formation of rutile and TiO sub-oxides must have been caused by the ambient oxygen deficiency. Introduction of H_2 enhanced the reduction of partially oxidized powders, leading to ?-Ti_3O_5[JCPDS 40-0806], Ti_2O_3[JCPDS 10-0063], and $TiO_{0.34}N_{0.74}$[JCPDS 44-0951] as shown in (b). The pattern for nanopowders synthesized by Ar-He plasma shows the peaks corresponding to anatase and rutile in (c), because the powders are derived by the quenching of gas mixtures vaporized from TiO_2 melts. By introduction of hydrogen, the X-ray pattern reveals only the peaks corresponding to rutile , and the formation of pure rutile is attributed to the oxygen deficient clusters.

Fig. 9 shows a model for in-flight oxidation of TiN by thermal plasma. The surface of raw powders is rapidly oxidized and melted, because the m.p. of oxidized particle gets lower than that of TiN. Partial oxidization of the surface cause the powders to form core-shell structured composites, TiN cores and oxidized melts, and vaporized species forms nanopowder by rapid quenching. Under lower O_2 input conditions, the composites consist of TiN and black colored rutile, because oxidized molten shells is slightly reduced by oxygen diffusion into cores. With the increasing O_2 flow rate, the core is re-oxidized and transformed itself to yellow rutile or white grey anatase. Under higher O_2 input conditions, the powders are fully oxidized and melted, leading to spherical anatase crystals by rapid solidification. Nanopowder is derived from the gas mixtures which are consisted of TiO(g) and TiO_2(g) clusters, and the composition depends on the ambient oxygen

pressure. It was demonstrated that the formation of rutile phase is attributed to ambient oxygen deficiency because TiO(g) clusters are more stable than TiO_2(g) clusters under low O_2 input conditions.

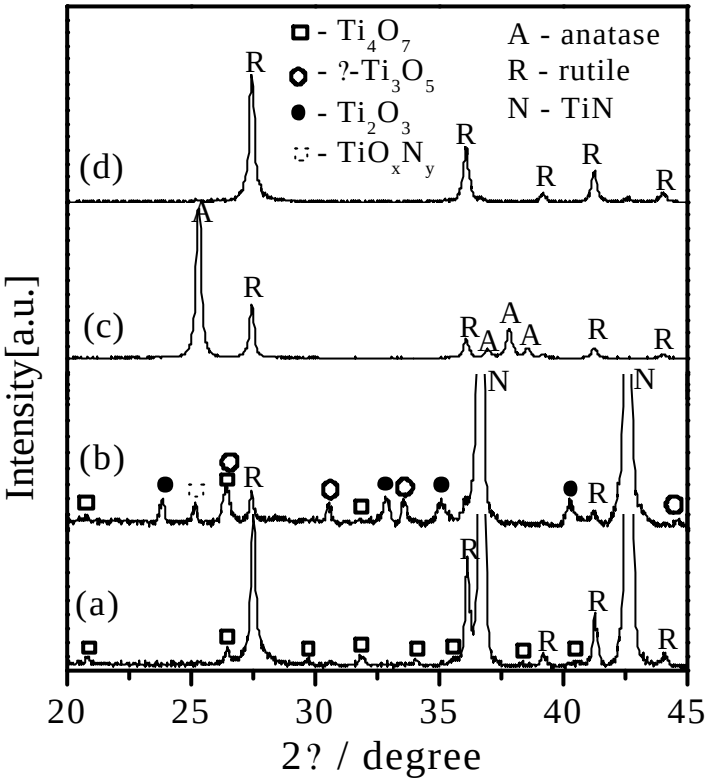

Fig. 8. X-ray diffraction patterns of powders synthesized by Ar-He plasma(a,c) and Ar-H_2 plasma(b,d): (a,b) bigger powders and (c,d) smaller powder.

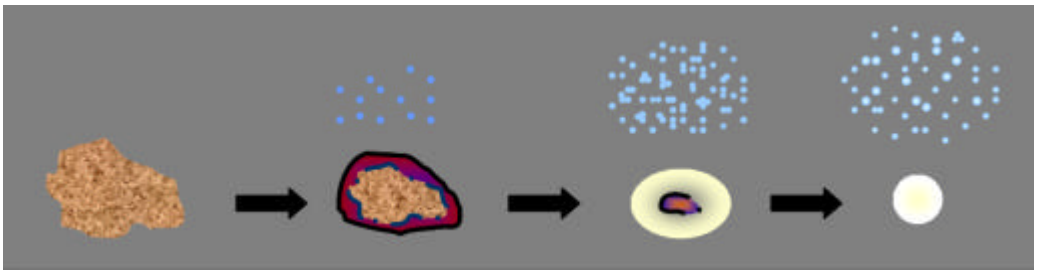

Fig. 9 Schematic model of preparation of spherical TiO_2 powders by in-flight oxidation of TiN powders.

4. Conclusions

We have synthesized spherical titanium dioxide from titanium nitride powders using r.f. thermal plasma. The products consisted of bigger grained powders and small grained powders: the bigger powders are derived by solidification of oxidized melts, and the smaller powders were derived by rapid solidification of vaporized species. Under low O_2 input conditions, the core-shell structured composites, TiN cores and oxidized shells, were produced by partial oxidization of surface. The composites were dominated by rutile because oxidized melts easily reduce to oxygen defect structures by the oxygen diffusion from oxidized shells to TiN cores. With the increasing oxygen flow rate, the composites became fully oxidized and melted to TiO_2 melts, leading to spherical anatase single crystals. The vaporized species from the oxidized surface

caused the formation of nanopowders with diameter of ave. 50nm, and the formation mechanism of nanopowders is associated to the composition of gas mixtures of TiO(g) and TiO_2(g). Under higher O_2 input conditions, TiO_2(g) species is more stable than TiO(g), thus the oxygen-rich clusters grow to anatase nanopowder. Introduction of hydrogen enhanced the reduction of TiO_2 species and the formation of oxygen-deficient clusters, leading to rutile nanopowder.

Numerical simulation of dielectric barrier-controlled glow discharge at atmospheric pressure

Dezhen Wang and Yanhui Wang

State Key Laboratory of Materials Modification by Laser, Ion and Electron Beams, Department of Physics, Dalian University of Technology, Dalian 116023, China

The space and time distributions of the electric field and the electron and ion densities, as well as the time evolutions of the discharge current density and the surface charge density of the dielectric layer in He dielectric barrier-controlled glow discharge at atmospheric pressure are calculated by solving one-dimensional continuity and momentum equations for electron and ion coupled to the current continuity equation. The properties of uniform atmospheric pressure glow discharge under the conditions of different driving frequency, voltage or dielectric layer are discussed and analyzed. When the driving frequency is high enough, a large number of ions are trapped and the induced space charge field makes a great many electrons stay in the discharge volume. These seed electrons lead to a Townsend discharge at atmosphere pressure. The structure of this discharge is similar to that of low- pressure glow discharge, i.e. there exist four specific regions: the cathode fall, the negative glow, the Faraday dark space and the positive column. The discharge current becomes small with decreasing the applied voltage amplitude. The secondary electron emission from the dielectric layer makes the discharge current increase. The thicker the dielectric layer is or the smaller the permittivity is, the smaller the discharge current is.

Abstract
A new electro discharge machining system employing a composite electrode fabricated a narrow and deep hole (diameter: 0.70 mm, depth: 150 mm) in a steel block. The composite electrode was a metal rod wearing a dielectric pipe jacket. The dielectric jacket prevents secondary discharges occurring between the sidewalls of the rod electrode and the fabricated hole, attaining a fabrication of a deep and narrow hole. The system design and setup, the operation, and the machining performance were described.

1. Introduction

A development of drilling of a narrow and deep hole in a metal contributes greatly to an extensive field of molding and assembly industries. One method to fabricate a narrow and deep hole in a metal is an electro discharge machining (EDM) utilizing transient arc discharges occurring between a work piece (drilled metal) and a tip of a metal electrode. Transient arc discharges inflict thermal shocks and intense impulse waves on the work piece, producing a hole and a waste metal. Working fluid injected from the rotating pipe-shaped electrode to the drilling portion has significant roles to maintain electrical insulation between the work piece and the electrode during arc-extinguishing, and to exhaust a waste metal. Dielectric oil is commonly used as working fluid. The waste metal makes negative effects reducing electrical insulation between the side of the formed hole and the side of the electrode. In addition to this, exhausting the waste metal requires a high pressure (up to 10 MPa) because of the small electrode bore diameter. Unexhausted waste metal reduces the drilling speed and accuracy, as well as the durability of the electrode. Oil disposal and inflammability, and its carbonization resulting from discharges reduce a function of the EDM method. New EDM drilling system being capable of overcoming faults of the above system has been developed. This system employs a special electrode wearing a dielectric jacket (composite electrode). The EDM system with a composite electrode may attain a high-speed, high-operationality, and low-cost fabrication of a narrow and deep hole. However, practical techniques for the system operation are insufficiently developed. A theoretical approach to a principle of the system, an evaluation of the machining speed and accuracy, and an optimization of the system operation are implemented.

2. Composite Electrode EDM System

2. 1. System Concept

EDM systems for a fabrication of a narrow and deep hole in a metal produce transient arc discharges at the drilling portion. The conventional EDM systems employ a metal pipe as an electrode and dielectric oil as working fluid. Fig. 1 shows drilling diagrams of the conventional and the composite electrode EDM systems. Both the electrodes rotate during the operation. The composite electrode is a rod electrode wearing a dielectric pipe jacket. Water is used as working fluid in the composite electrode EDM system. Water flows in a clearance between the rod electrode and the dielectric jacket in order to suppress uncontrolable arc discharges, to exhaust the waste metal, and to quench the discharge-drilling portion. Because a larger cross-section of water flow is possible compared to pipe electrodes, the composite electrode EDM system requires a lower pressure for pumping water. Electrical insulation between the side of the fabricated hole and the side of the electrode is steadily maintained. Thus, negative effects of a waste metal are restricted to the minimum.

2. 2. System design and setup

2. 2. 1. Elements of composite electrode

EDM allows transient arc discharges across a small gap between the work piece and the electrode, causing a fusion and/or a fragmentation of a metal work pieces and simultaneously causing a wear of the electrode. The distance between the tips of the electrode and the jacket shortens with developing the drilling. Thus, the jacket needs to move upward to maintain a specified distance between the tips of the electrode and the work

piece. The schematic diagram indicating the movements of the electrode and the jacket is shown in Fig. 2. The jacket is subjected to very severe atmosphere (high electrical stress, high temperature, and high reactivity) and should have low friction factor and high flexibility. Polytetrafluoroethylene (PTFE) is most likely to meet the above requirements [1] and is therefore employed as the jacket material. The distance between the tips of the electrode and the jacket is maintained during the drilling. A low-wear electrode facilitates a control of the jacket upward movement. Thus, a stiff and non-brittle electrode is suitable to this EDM system. Generally, copper, tungsten, or tungsten alloys are used as electrode materials of hole-fabrication EDMs. Tungsten rod is chosen because it is reported to be the most resistant to discharge-wear in the above electrode materials [2]. The diameter of obtainable tungsten rod electrodes is over 0.30 mm. The composite electrode consisting of tungsten rod (diameter: 0.30 mm, Nilaco Corporation, Japan) and PTFE jacket (bore diameter: 0.41 mm, external diameter: 0.56 mm, Zeus Industrial Products Inc., USA) is used.

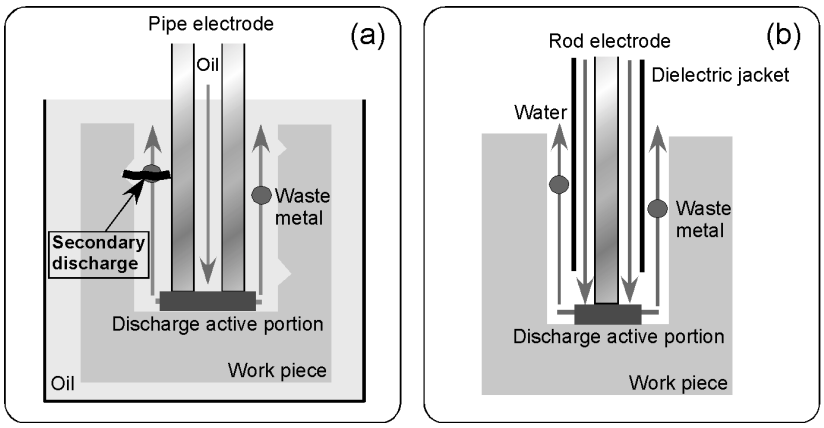

Fig. 1. Diagrams of convetional and composite electrode EDMs for a fabrication of a deep hole in a metal. (a) conventional EDM, (b) composite elctrode EDM.

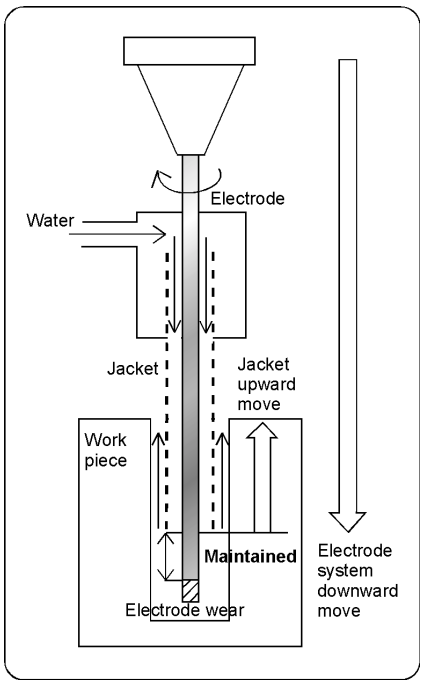

Fig. 2. Movements of the electrode and the jacket in the composite electrode EDM sysem.

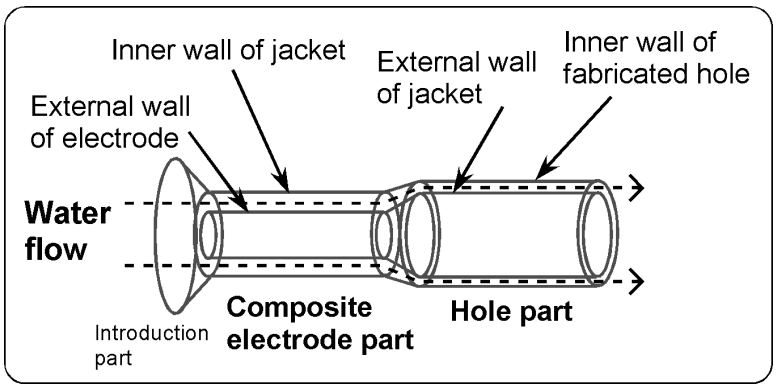

Fig. 3. A model of water flow in the composite electrode EDM system.

2. 2. 2. Required water pressure to exhaust waste metal

Working fluid of water is imposed to exhaust a waste metal produced as a byproduct of drilling and to quench a drilling portion. In the composite electrode EDM system, water flows first between the electrode sidewall and the jacket inner wall, then flows between the jacket external wall and the inner wall of the fabricated hole. The water flow rate and the related water pressure sufficient to exhaust a waste metal and quench a drilling portion should be understood. A series bi-cylinder model simplifies the path of water flow in the composite electrode EDM system (see Fig. 3). For fluid passing through a bi-cylinder, the relation between flow rate Q and pressure P is formulated (1) [3].

$$Q = \frac{\pi P}{8\eta l}\left\{(r_o^4 - r_i^4) - \frac{(r_o^2 - r_i^2)^2}{\ln(r_o / r_i)}\right\} \quad (1)$$

where, r_i, r_o, and l are radius of the inner cylinder, radius of the external cylinder, and length of the bi-cylinder. η is viscosity coefficient of fluid. When the actual dimensions and physical constants are given (electrode diameter: 0.3 mm, bore diameter of jacket: 0.41 mm, external diameter of jacket: 0.56 mm, length of jacket: 200 mm, viscosity coefficient of water: 0.00101 kg/(ms)), the relation between $Q_{comp.elec.}$ (m*l*/s) and $P_{comp.elec.}$ (MPa) for the composite electrode part is expressed by (2).

$$Q_{comp.elec.} = 0.076 P_{comp.elec.} \tag{2}$$

The equation (2) is verified by measuring the flow rate Q as a function of water pressure P. Fig. 4 shows the theoretical line based on (2) and the measurement result. The measurement result is consistent with the theory at 0-1 MPa. A higher water flow rate is observed than theoretically predicted at > 1 MPa. An expansion of PTFE pipe exposed to high pressure would be a primal reason. The actual water flow in the composite electrode exceeds the theoretical one, providing a margin safety in the system design.

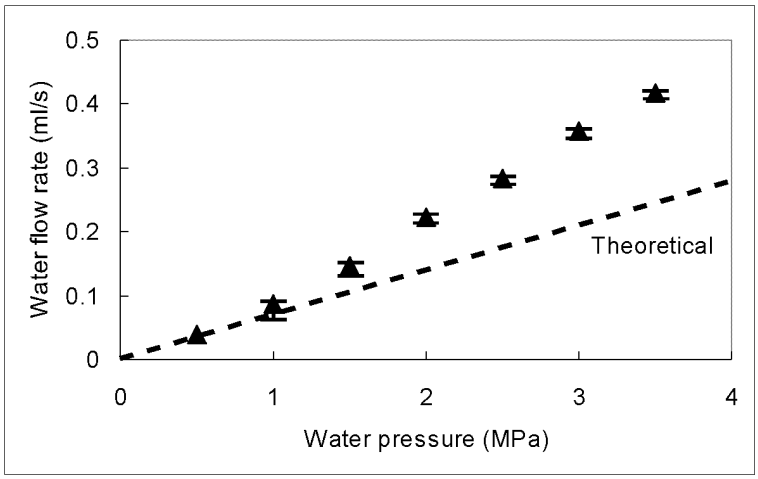

Fig. 4. A relation between water flow rate and pressure of the composite electrode. The theretical line is based on a bi-cylindrical model. Electrode diameter: 0.30 mm, bore diameter of jacket: 0.41 mm, external diameter of jacket: 0.56 mm, length of jacket: 200 mm, viscosity coefficient of water: 0.00101 kg/(ms)

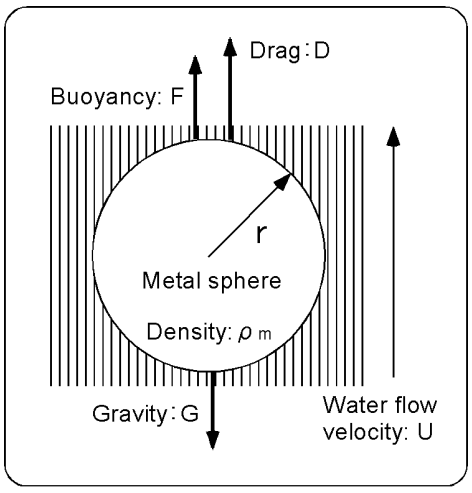

Fig. 5. A dynamic model of an exhaust of a waste metal assumed to be sphere.

A waste metal produced as a byproduct of drilling is exhausted through a clearance between the external wall of the PTFE jacket and the inner wall of the fabricated hole. While the waste metal is in water flow, it is assumed to be subject to dynamics presented in Fig. 5. For an upward movement of the waste metal assumed to be sphere (for an exhaust), the equation (3) should be satisfied.

$$D + F > G \tag{3}$$

D: drag, F: buoyancy, and G: gravity for metal sphere are written by the equation (4)-(6).

$$D = 6\,\pi\,\eta_w\,rU \tag{4}$$
$$F = 4\rho_w\,\pi\,r^3 g/3 \tag{5}$$
$$G = 4\rho_m\,\pi\,r^3 g/3 \tag{6}$$

where, η_w, r, and U are viscosity coefficient of water, radius of metal sphere, and water flow velocity, respectively. ρ_w, ρ_m, and g are density of water, density of metal, and gravitational constant, respectively. The equations (3)-(6) provide a condition for an exhaust of the waste metal (7).

$$U > \frac{2g(\rho_m - \rho_w)r^2}{9\eta_w} \tag{7}$$

The radius of the waste metal is actually measured to be 10-50 μm using a microscope, and is supposed to be 50 μm. The density of the waste metal is supposed to be 10000 kg/m^3 (Fe: 7860 and Cu: 8930 kg/m^3). The exhaust of the waste metal in the conditions given in the above should satisfy (8).

$$U > 0.0485 \text{ (m/s)} \tag{8}$$

In order to obtain the water flow velocity in the hole part U_{hole}, the depth and the diameter of the fabricated hole should be determined. Because the jacket pipe of which external diameter and length are respectively 0.55 mm and 200 mm is employed, the diameter and the depth of the hole are respectively assumed to be 0.70 mm and 150 mm. Under the given conditions, the relation between Q_{hole} (m*l*/s) and P_{hole} (MPa) for the hole part is

$$Q_{hole} = 0.373 P_{hole} \tag{9}.$$

The pressure generated by a pump is allocated to the composite electrode and the hole parts which are connected in series. The water flow rate in the composite electrode $Q_{comp.elec.}$ is equal to that of the hole part Q_{hole}. The equations (2) and (9) indicate that the most pressure is allocated to the composite electrode part. The relation between the water flow velocity in the hole part U_{hole} in unit m/s (= Q_{hole}/S_{hole}, S_{hole}: cross-section of water flow) and whole the pressure applied to the composite electrode part and the hole part P_{total} (MPa) is written by (10).

$$U_{hole} = 0.459 P_{total} \tag{10}$$

This equation suggests that at least water pressure 0.1 MPa is required for an exhaust of a waste metal.

2. 2. 3. Required water pressure to quench drilling portion

A drilling portion is quenched by water flow and, therefore, the quenching efficiency is strongly dependent on the water pressure. If the quench during the EDM system is simplified to an energy conversion, the required water flow rate can be correlated with the quenching ability. It is assumed that electricity energy provided from discharges is converted to thermal energy for water temperature increase without energy loss. The range of temperature increase of water T is assumed to be 25-95 ˚C. In addition to this, the discharge conditions are assumed to be voltage 100 V, current 1 A, and therefore power W, 100 W or J/s. A specific heat of water c is 4.18 J/(˚Cg). The required water flow for quenching Q_q in unit m*l/s* is calculated by (11).

$$Q_q = W/(Tc) \tag{11}$$

Q_q is calculated to be 0.342 m*l*/s. Using the equation (8), the water pressure required in the above-supposed conditions is estimated to be 0.9 MPa. The water pressure sufficient both to exhaust a waste metal and to quench a discharge-drilling portion is estimated to be ~1 MPa. But, it should be noted that higher water pressure promote an exhaust of a waste metal and quenching of a drilling portion

2. 2. 3. Power source equipment

In general EDMs, pulse voltage is applied to a gap between the work piece and the electrode. In this study, pulse-on 142 V for 112 μs and pulse-off 58 V for 5 μs are repeatedly applied to the gap in an open circuit using a pulse power source (5T, Sankyo Engineering Inc., Japan). This pulse voltage form creates the highest current level in the above power source. The pulse-off interval is necessary to extinguish arc, preventing excessive current leading to a circuit short and producing transient arc discharges suitable to EDMs. It should be noticed that the employed power source possesses a utility to stop voltage application when electrical insulation in the gap is extremely reduced (the voltage allocated to the gap is < 33 V). This utility protects a circuit short of the power source.

3. Operation Conditions Consideration

Other conditions to be determined for the system operation are water flow rate (water pressure), a polarity, a distance between the tips of the electrode and the jacket, and threshold gap voltage. An electrode movement (approaching or leaving the work piece) controls arc discharges during general EDMs. A determination of approaching or leaving is dependent on the voltage across the gap between the work piece and the electrode. When the gap voltage is higher than the threshold voltage level, the electrode approaches the work piece to generate arcs. When lower, the electrode leaves the work piece to extinguish arcs and to inhibit excessive current. This threshold gap voltage is determined to be ~90 V, which is the highest level in the system. A higher threshold gap voltage can fabricate a larger diameter-hole. The composite electrode requires a clearance for jacket insertion. Furthermore, it mitigates a deformation of the electrode tip or an insulating deposition at the electrode tip, both causing a cessation of drilling. However, a higher threshold voltage includes a negative profit of a lower drilling speed. On ahead, water pressure sufficient to exhaust a waste metal and to quench a drilling portion is estimated to be ~1 MPa. But, a higher water pressure is better for an efficient exhaust of a waste metal and an efficient quench of a drilling portion. The pressure test demonstrates that the PTFE jacket can resist water pressure up to 3.5 MPa. The water flow rate at 3.5 MPa is 0.42 m*l*/s (measured), referring to Fig. 2. A drilling test is performed to carbon steel (S50C) to find a better polarity. Table 2 shows the electrode wear rate and the drilling speed of the tungsten electrode as a cathode (-) or an anode (+). The results imply that the electrode-cathode polarity (40 %) is suitable to the composite electrode EDM system. The distance between the tips of the electrode and the jacket is also optimized to be 7.0 mm after several trials. The conditions determined for a fabrication of a narrow and deep hole by means of the composite electrode EDM system is determined as presented in Table 2.

Table 1. Wear rate and drilling speed of tungsten electrode (Elec.) at different polarity. The tests are carried out for 10 min. 40 % indicates 40 mm electrode wears for 100 mm hole fabrication. Work piece (WP) is carbon steel (S50C).

Polatity	Elec.: -, WP: +	Elec.: +, WP: -
Electrode wear rate	40 %	> 1000 %
Drilling speed	0.51 mm/min	0.59 mm/min

Table 2. Conditions determined for a steady operation of the composite electrode EDM system.

Item	Description
Electrode	Tungsten rod (diameter: 0.30 mm)
Jacket	PTFE pipe (bore diameter: 0.41 mm, external diameter: 0.56 mm)
Water flow rate (water pressure)	0.42 m*l*/s (3.5 MPa)
Polarity	Electrode: -, Work piece: +
Output voltage	Pulse, on 142 V for 112 μs and off 58 V for 5 μs.
Threshold gap voltage	~90 V (If gap voltage < 33 V, no output)
Distance between electrode and jacket tips	7.0 mm

4. Drilling performance of the composite electrode EDM system

Drilling to a rectangular steel block of which height is 150 mm is attempted under the conditions determined in Table 2. One of well-used carbon steels (S50C) is selected as the sample block. The current level during the drilling is maintained to be ~0.6 mA. The distance between the tips of the electrode and the jacket is constantly controlled to be 7.0 mm. Tap water (~100 μS/cm) is used as working fluid. When an undesirable deformation or an insulating deposition occurs at the tip of electrode leading to a cessation of drilling, the defective portion is cut and removed. Fig. 6 shows the depth and the electrode wear as a function of the operating time. A high linearity is observed in the data of the depth and the electrode wear. The average drilling speed is 0.37 mm/min and the average electrode wear rate is 92.7 % (the electrode wears 92.7 mm for 100 mm-depth hole). Fig. 7 shows a cross-sectional view of the fabricated hole. A good circle (diameter: 0.7 mm) is observed at the inlet of hole. But, the circle in the block enlarges (0.9-1.0 mm) and deforms to oval with the depth. The tungsten electrode is rotating during the drilling at 400 rpm for an aid of maintaining transient arc discharge. When the electrode is inserted in the fabricated hole, a force spent for a downward movement of the electrode enhances the electrode vibration. The electrode vibration caused by the rotation is tried to be restricted to the minimum. But, the vibration is likely to be a primal reason of the hole deformation. An insufficiency of the water flow rate (pressure) is a predominant reason. The electrode tip is not covered with the PTFE dielectric jacket. A residual waste metal induces more intense and more

geometrically non-uniform discharges at the tip of the electrode. The output voltage form, the threshold gap voltage, and the distance between the electrode and the jacket tips can control the electrode vibration and the undesirable discharge mode. The conditions preferred to a steady and safe drilling is chosen so far. But, a higher-speed and a higher-accuracy drilling require resetting of the above-presented items. An employment of a narrower tungsten rod to increase water flow rate is also one solution and seem interesting in upgrading the composite electrode EDM system.

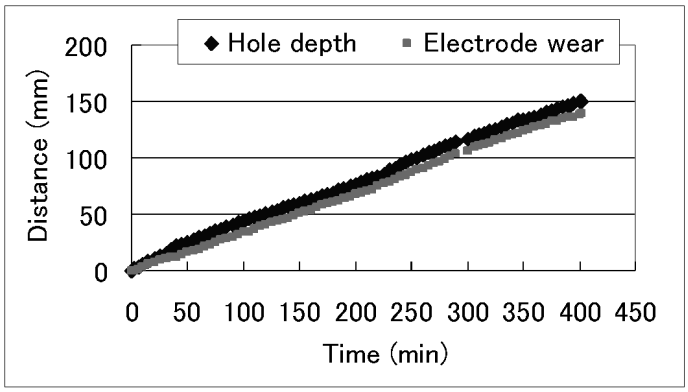

Fig. 6. Time variations of the hole depth and the electrode wear during the composite electrode EDM for carbon steel (S50C). The average drilling speed is 0.37 mm/min and the average electrode wear rate is 92.7 %.

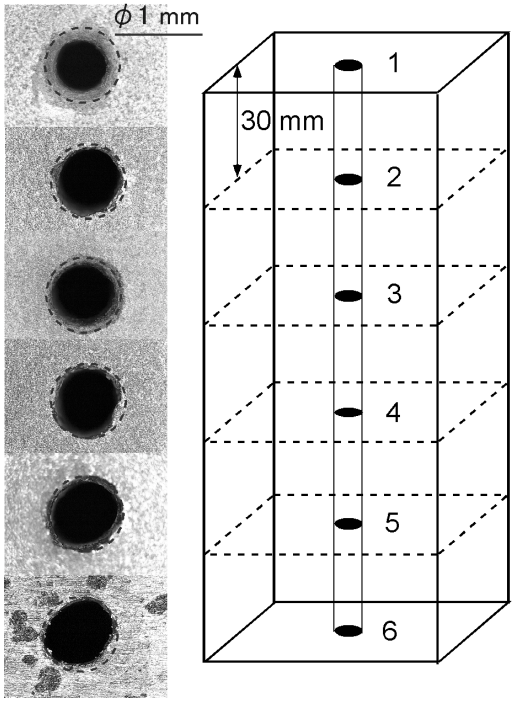

Fig. 7. The appearance of hole fabricated in the composite electrode EDM system. The fabracation process is shown in Fig. 6.

5. Conclusions

New EDM system with a composite electrode that is tungsten rod (diameter: 0.3 mm) wearing PTFE pipe jacket (bore diameter: 0.41 mm, external diameter: 0.56 mm) fabricated a narrow and deep hole in carbon steel block (S50C). The depth, the inlet diameter, and the outlet diameter of the fabricated hole are 150, 0.7, and 1.0 mm, respectively. The electrode wear and the drilling speed are 92.7 % and 0.37 mm/min, which are recorded under the steady and safe system operation. Tap water, flowing in a clearance between the sidewall of the electrode and the inner wall of the jacket, can be used as working fluid. The system concept, setup, and operation principle are in detail mentioned. A further improvement of the operation conditions is considered in regard to the output voltage form, the threshold gap voltage, and the distance between the electrode and the jacket tips. Those are likely to be relevant to the speed and the accuracy of the composite electrode EDM system.

Acknowledgement

This study was performed as a part of the project "H14 Sokkogata Chiiki Shinsei Konsosiamu Kenkyu Kaihatsu Jigyo" sponcered by Ministry of Economy, Trade and Industry of Japan. The authors appreciate the cooperation members of Collaboration and Industrial Advanced Fasclity of Honjo-Yuri, Sanei Kikai Inc., and Kobayashi Kogyo Inc. (all in Honjo, Japan) for thier experimatal supports and technical advice.
