Abstract

PTFE nanocrystallines with different morphology and crystal structures were rapidly formed by an Atmospheric Plasma Polymerization without any catalysts or templates. TEM and XRD results indicated single crystal phase of the nanocrystallines. FTIR and Polarization optical micrographs display their polymer properties. The atmospheric oriented plasma polymerization can serve as a common method for nanofabrication of many other single crystalline polymer systems.

Keywords: Atmospheric oriented plasma polymerization, PTFE, nanocrystallines, characterization

1. Introduction

1-D single crystalline nanostructure polymer could exhibit mechanical strength reaching its theoretical bonding strength [1]. Some novel optical and electronic properties could also be expected due to its high charge density, high carrier mobility, and unique quantum confinement effect [2-3]. The 1999 International Technology Roadmap for Semiconductors has set a goal to reach an effective dielectric constant of 1.6–2.2 for the 0.1 μm technology node by the year 2005, and fluoropolymers are a potential candidate [4]. PTFE has many desirable properties, including a low refractive index and dielectric constant, low coefficient of friction, excellent chemical resistance, and high thermal stability [5-7]. Thin films of PTFE offer advantages for applications as diverse as optical coatings [8], biopassivation coatings for implantable devices [9-10], and interlayer dielectrics in integrated circuits [11-12]. However, bulk PTFE's high melt viscosity and poor solubility make it difficult to process into thin, conformal, and uniform films[13]. Deposition of PTFE films has been explored in a number of other ways. Pulsed laser deposition from PTFE targets produced high quality films showing the structure and thermal stability characteristic of bulk PTFE [14-15]. Ionizationassisted evaporation of low molecular weight PTFE powders also yielded similar films [16].

Synchrotron radiation ablative photodecomposition of PTFE targets yielded films much like PTFE, although in that case CF3 chain ends were observed [17]. This is comparable to films produced by downstream plasma deposition using tetrafluoroethylene [18] and HFPO [19] as precursor gases. Thermolysis of bulk PTFE produced films consistent with the source material [20-21]. Films spin coated from aqueous nanoemulsion PTFE and commercialized by W. L. Gore as SPEEDFILMTM, have undergone several evaluation studies as a potential low dielectric constant material [22]. By contrast, OPP is capable of providing good control over film structure and morphology on a substrate. OPP provides yet another promising alternative. In this paper, rapid formation of single nanocrystallines of PTFE-Like polymer was achieved on a glass substrate by a novel synthesis, the so-called Oriented Plasma Polymerization (OPP) at atmospheric pressure. The entire process was completed within a short period of time ranging between a few seconds to several minutes. The surface morphology of the coated organic crystal film was controlled through the conditions such as discharge time, ratio of the monomer to carrier gas and power

2. Experimental

For the fluorocarbon films, a mixture of fluorocarbon (atom ratio of C: F is 1:1~1:4) and Argon were used as the precursor gases and fed into the reactor at a constant flow rate. The reactor used for the "oriented plasma polymerization" (OPP) was a home-made system. In this system, a gradient electric field with a high voltage of 10—50 KV and frequency of 10—100 KHz was applied to deposit the single nanocrystallines on the ordinary glass slides. Filament plasma streamers were generated between a high voltage strip electrode and a grounded plane electrode, both were covered with a dielectric barrier, the filament-to-substrate distance was maintained at 1.5 cm. After an initial period (a few seconds to several minutes), a uniform thin film was deposited onto the entire substrate.

3. Results and Discussion

Fig. 1 shows the TEM images of the nanocrystallines film on glass slide. As can be seen in Fig. 1a and Fig. 1b the ratio of the monomer to carrier gas is 3:100 and 7:100. The synthesis time needed for growing these nanocrystallines was only three minutes. The nanocrystallines on the substrate appear massive in quantity. Some of them tend to lie in parallel with the background particulate layer. Some of them grow vertically from the layer. There are a lot of uniformity of nanorods and nanotubes in Fig. 1a, c. These nanorods and nanotubes are about 10 m in length and 100 nm in diameter. In Fig. 1b, however, the nanorods are about

800nm in length and 250 nm in diameter. The morphology is dependent on the ratio of monomer to feed and reaction time. When the reaction time shortened from 3 minutes to 15s, the amount of the nanorods and nanotubes decreased obviously. The electronic energy inside the discharge core must be high enough to dissociate the monomers into active particles such as ions, radicals, metastable neutrals, and electrons. So the power of the discharge was very important to the form of the nanocrystallines. As can be seen in Fig. 1d, there were hardly any nanorods or nanotubes on the fluorocarbon polymer film. It was believed that the growth on the glass of fluorocarbon nanocrystallines effected by discharge conditions such as discharge power, time, ratio of the monomer to carrier gas on the nanocrystallines morphology.

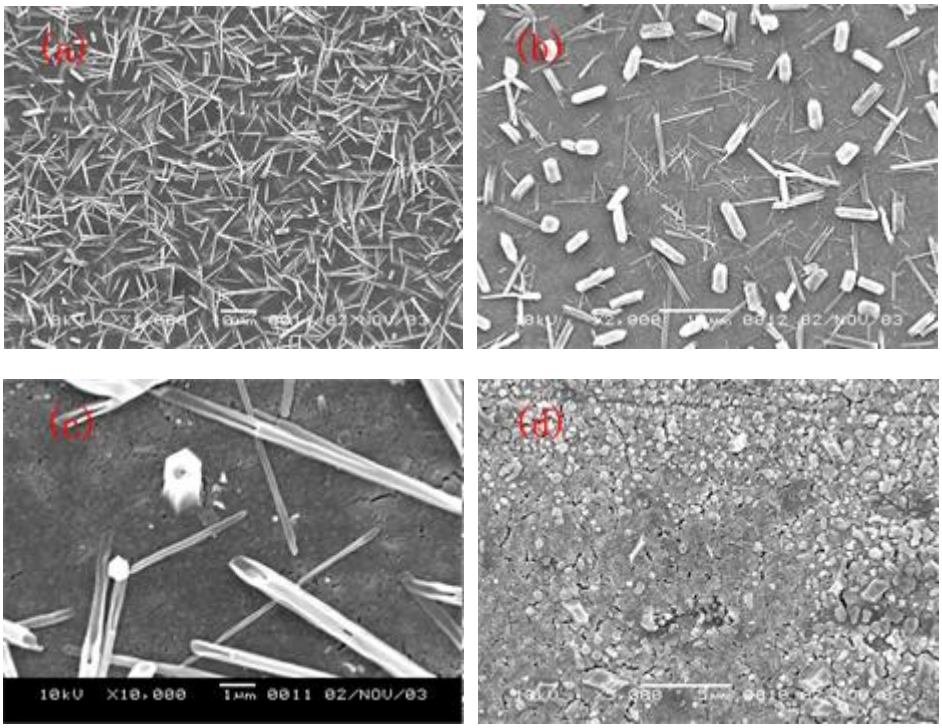

Fig 1 SEM images of fluorocarbon nanocrystallines

(a), (c) the ratio of the monomer to carrier gas is 3:100, for 3min at high power

(b) 7:100, for 3min at high power (d) for 3min at low power

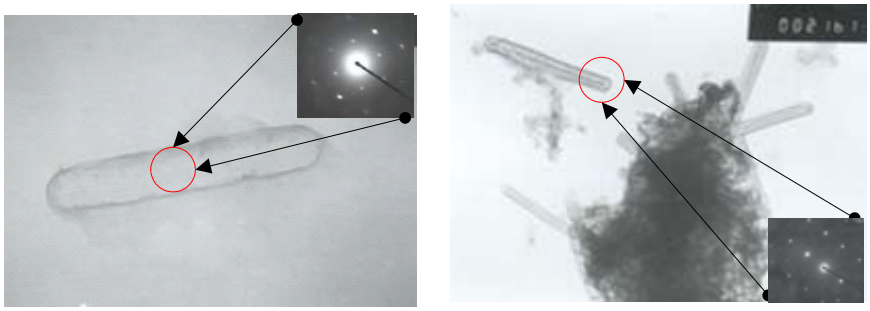

Fig 2 Transmission electron micrograph images and typical electron diffraction diagram

corresponding to single crystal (a) nanofibers, (b) nanotubes

Electron diffraction measurement in these nanotubes and nanofibers indicates that they are all single crystals. Fig 2a and Fig 2b shows diffraction pattern that the crystals growing on the substrate. Single crystals of fluorocarbon were prepared by a novel synthesis method--- Oriented Plasma Polymerization at Atmospheric Pressure. Each crystal yields a sharp electron diffraction pattern as shown in the images. Based on the d-spacing of the electron diffraction pattern, it was determined that the reflections corresponded to the hkl planes of a close-packed hexagonal (cph) structure.

The X-ray diffraction pattern of fluorocarbon films is presented in Fig. 3. The diffracted area also includes the background nanoparticulates on the substrate. Five main reflections sharp peaks can be found at 2θof about 18.620°, 15.520°, 21.099°, 20.100°and 31.3°. It can be index to a close-packed hexagonal (cph) structure.

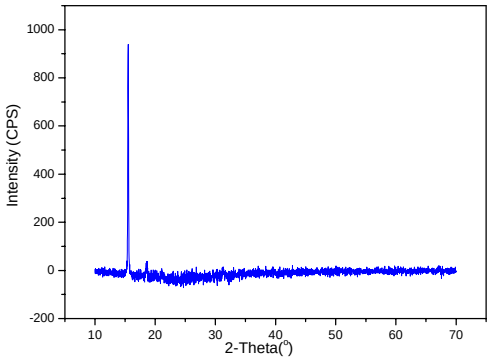

Fig.3 XRD diffraction pattern of nanocrystallines film

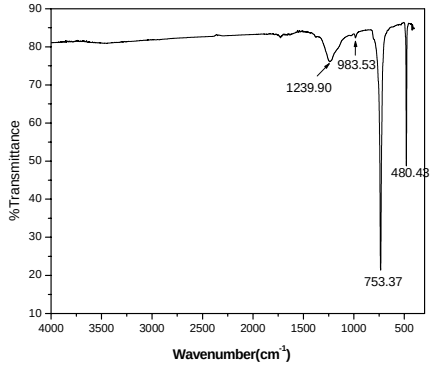

Fig.4 IR spectrum comparison of nanocrystallines film

The chemical composition of the coating is investigated through FTIR in Fig.4. The FTIR spectrum is shown in Figure 4. The feed gas is an unsaturated monomer. The peaks at 481 cm^{-1} and 735 cm^{-1} due to the CF deforming vibration are very strong. But the peak at 1368 cm^{-1} due to the CF stretching vibration in $-CF_2$ CF_3 group is only observed in the film deposited for 4 min., There is one new peak appearing at 983cm^{-1} attributed to –O-O- stretching vibration in aryl peroxide and another new peak at 1700cm-1 attributed to C=C stretching vibration in $–CF=CF_2$. These changes display that the C=C band is still remained in the deposited film. Besides, aryl peroxide group is combined into the film because of the strong oxidation during the deposition.

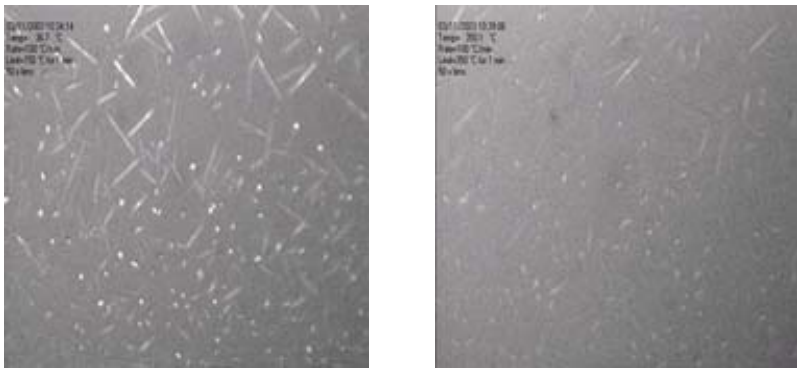

Fig.5 Comparison of thermal stability of observable nanotubes polymer slices through polarization micrographs at different testing temperatures (a) nanotubes at 36.7 °C; (b)nanotubes at 350.1 °C

The thermal stability of the as-obtained nanotubes was observed through the hot-stage polarized optical microscopy. As shown in Figure 5, the observable nanotubes with large size retain a needle-like morphology at 36.7°C (Fig. 5a) and exhibit high birefringence in the crystal edge region. Upon heating up to 350°C (Fig. 5b), the nanocrystallines layer appears melted and mobile in the vision field. But the nanocrystallines still display clear birefringence although not as strong as at 36.7°C.

4. Conclusion

The rapid formation of nanofibers or nanotubes is dependent on the monomer types and associated with plasma conditions. Discharge time, power and ratio of the monomer to carrier gas strongly influence the structure and morphology of fluorocarbon films. The “Oriented Plasma Polymerization” method opens a novel way of one-step fast formation of single crystal fluorocarbon nanotubes at Atmospheric Pressure. As a result, the physical morphology and structures of nanorods and nanotubes could be controlled through the conditions of the oriented plasma polymerization to some extent.

Abstract

Efficient production of fullerenes, endohedral metallo-fullerenes and single walled carbon nanotubes is realized by using the ***J***x***B*** arc-discharge method. By applying steady-state magnetic field perpendicular to the DC arc current, the ***J***x***B*** force jets out the sublimated carbon clusters and considerable increase of the production efficiencies is obtained, which would reduce the production cost of these new materials.

Keywords: production of fullerenes and carbon nanotubes, ***J***x***B*** arc discharge, efficient production, magnetic field, carbon clusters

1. Introduction

Recently, fullerenes and carbon nanotubes (CNTs) attract much interest in many branches of chemistry, physics and material science. [1] Applications of higher fullerenes and endohedral metallo-fullerenes are increasing, [2, 3] while production rates of these fullerenes are still very low with respect to that of C_{60}.

Therefore, high efficiency production of higher fullerenes and metallo-fullerenes should be developed. High quality single-walled carbon nanotubes (SWNTs) are also desired to supply good and cheap SWNT-materials for many kinds of applications. Here, in order to improve the normal arc-discharge method, the ***J***x***B*** arc discharge method has been developed to increase the production efficiencies of fullerenes [3, 4] and good-quality SWNTs. [5] Various production conditions are examined by this discharge method to obtain the high performance production.

2. Experimental setup and method

Fullerenes are produced by a revolver injector type fullerene producer (***RIT-FP machine***) [3] as shown in Fig. 1. It consists of three parts, (a) a cylinder-type arc-discharge chamber of 27 cm in diameter and 70 cm high made of stainless-steel, (b) a revolver-type carbon rod magazine of 35 cm in diameter and 45 cm long and (c) a control panel. A block type ferrite-magnet is set at outside of the middle chamber, which makes steady-state magnetic field of 10-50 Gauss perpendicular to the DC arc current and makes the ***J***x***B*** arc discharge. An anode carbon rod is 300 mm x 8 mmϕ and a carbon cathode is 30 mmϕ. For a standard arc condition, He pressure, $\boldsymbol{p}$(He)= 40 kPa, discharge current, $\boldsymbol{I}_d$= 120 A and gap distance $\boldsymbol{d}_G$ ~ 5 mm. In order to produce La metallo-fullerenes and Gd metallo-fullerenes, metal-oxide mixture carbon rods are used. [6] Carbon soot deposited on the chamber wall is collected and fullerenes in the carbon soot are extracted by the Soxhlet method with hot tri-chloro-benzene. A high pressure liquid chromatograph (HPLC) is used to measure fullerene contents in the extracted solution, and collection rates of fullerenes are obtained. A laser desorption TOF mass spectrometer is used to confirm separated

species. [7]

Carbon nanotubes are produced using a similar arc-discharge machine (RPX-machine), which consists of simpler configuration with a cylindrical arc chamber (18 cm in diameter and 20 cm high). [5] Metal-composite carbon rods (6x6x100 mm rectangular type, Ni/Y included carbon) are used to produce SWNTs.

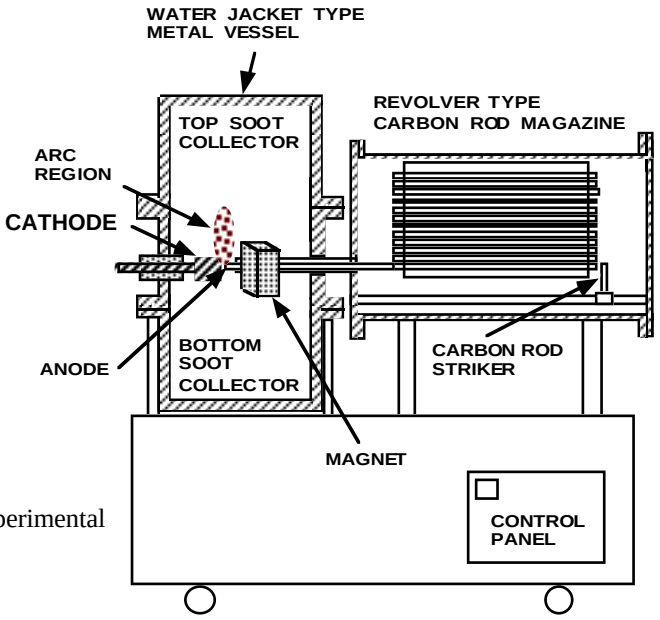

Fig. 1 Schematic of the experimental setup (***RIT-FP machine.)***

3. Experimental results and discussion

Collection rates of higher fullerenes (C_{60}, C_{70}, C_{76}, C_{78} and C_{84}) under the $\boldsymbol{J}$x$\boldsymbol{B}$ and $\boldsymbol{B}$= **0** conditions are measured and shown in Figs. 2 (a) and (b), where $\boldsymbol{I}_d$= 120 A, $\boldsymbol{p}$ (He)= 40 kPa and $\boldsymbol{d}_G$ ~ 5 mm. By applying the magnetic field, significant increase of the production rates is successfully obtained. [7] The effect of discharge current is examined. Collection rates of higher fullerenes as a function of discharge current ($\boldsymbol{I}_d$= 60-160A) are measured, where $\boldsymbol{p}$ (He)= 40 kPa, $\boldsymbol{d}_G$ ~ 5 mm with the $\boldsymbol{J}$x$\boldsymbol{B}$ arc. At $\boldsymbol{I}_d$= 120 A, optimum collection rates of higher fullerenes are obtained. Collection rates of higher fullerenes as a function of He pressure ($\boldsymbol{p}$ (He)= 5-95kPa) are measured where $\boldsymbol{I}_d$= 120 A, $\boldsymbol{d}_G$ ~ 5 mm with the $\boldsymbol{J}$x$\boldsymbol{B}$ arc. The collection rates become maximum at $\boldsymbol{p}$= 40kPa. In this experiment, collection rates of higher fullerenes to that of C_{60} are $\boldsymbol{C}(C_{70})$~ 0.3$\boldsymbol{C}(C_{60})$, $\boldsymbol{C}(C_{76})$~ $\boldsymbol{C}(C_{78})$~ 0.03$\boldsymbol{C}(C_{60})$ and $\boldsymbol{C}(C_{84})$~ 0.05$\boldsymbol{C}(C_{60})$. It can be confirmed that the production rates of these fullerenes increase about twice by the magnetic field. Pressure dependence and discharge current dependence of the production rates of C_{70} and C_{84} are shown in Fig. 3(a) and (b). It is confirmed that the relative collection rates of C_{70} and C_{84} have similar parameter dependence. They become maximum when the collection rate of C_{60} is maximum.

By using the La_2O_3 mixture carbon rod (15 mm in diameter), La metallo-fullerenes are produced by this method where $\boldsymbol{p}$ (He)= 40 kPa, $\boldsymbol{I}_d$= 300 A and $\boldsymbol{B}_0$= 12 Gauss. In this case, the collection rate of La@C_{82} is about 11 mg/h and the content is about 0.047w% (C_{60} content is 3.2 w%), where $\boldsymbol{p}$ (He)= 40 kPa and $\boldsymbol{I}_d$= 120 A. [6]

By using a catalyst-carbon mixture rod, SWNTs are produced [5] The discharge voltage gradually increases with increasing applied magnetic field. The discharge voltage also increases with increasing the gap distance as shown in Fig. 4. Production rate of soot including SWNTs versus applied magnetic field is shown in Fig. 5, where $\boldsymbol{p}$ (He)= 60 kPa and $\boldsymbol{I}_d$= 50 A. Clear monotonic increase of the production rate is obtained. Figure 6 shows a typical photo of SWNTs observed by a TEM, where $\boldsymbol{B}_0$= 0 Gauss. SWNTs, amorphous-like carbon and metal particles are observed. In order to make clear the quality of the samples, the Raman analysis is carried out and shown in Fig. 7. The radial breathing mode

(RB mode), G-band and D-band of the carbon soot are measured for the two magnetic-field conditions. From the RB mode, diameter distribution of the SWNTs can be confirmed. Form these figures, it is confirmed that SWNT of 1.40 nmϕ is predominantly produced by applying the magnetic field. From the ratio of the G-band intensity and the D-band intensity, content of disordered carbon in the soot is estimated, and it can be described that the disordered-carbon does not increase by applying the magnetic field.

4. Summary

It is shown that collection rates of higher fullerenes dramatically increase by means of the ***J***x***B*** discharge method. At the discharge current of 120 A, gap distance $\boldsymbol{d}_G$ ~ 5 mm and the He pressure of 40 kPa for 8 mmϕ rods, the production rate is optimum. SWNTs are also efficiently produced by this method and the SWNTs with 1.40 nmϕ are predominantly produced.

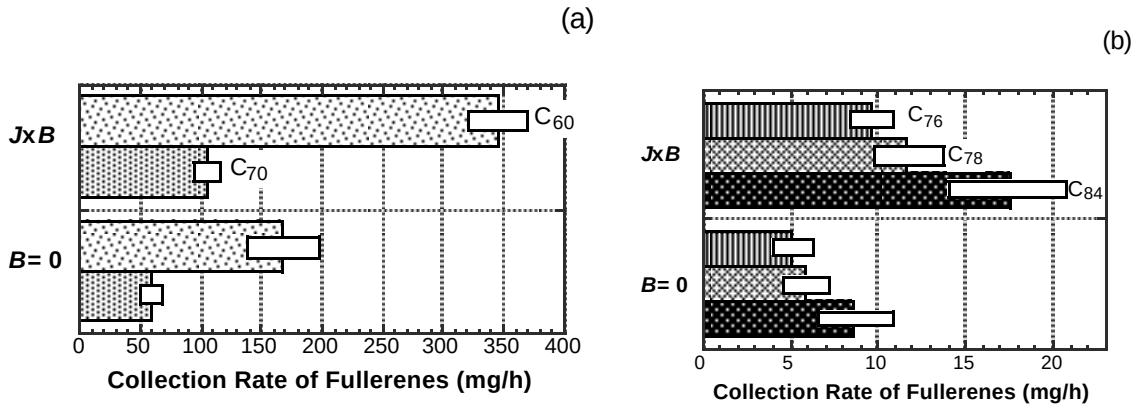

Fig. 2 Collection rates of (a) C_{60}, C_{70}, and (b) C_{76}, C_{78}, C_{84} for the two discharge methods from the produced soot. $\boldsymbol{I}_d$= 120A, ***p***(He)= 40 kPa, $\boldsymbol{d}_G$ ~ 5 mm.

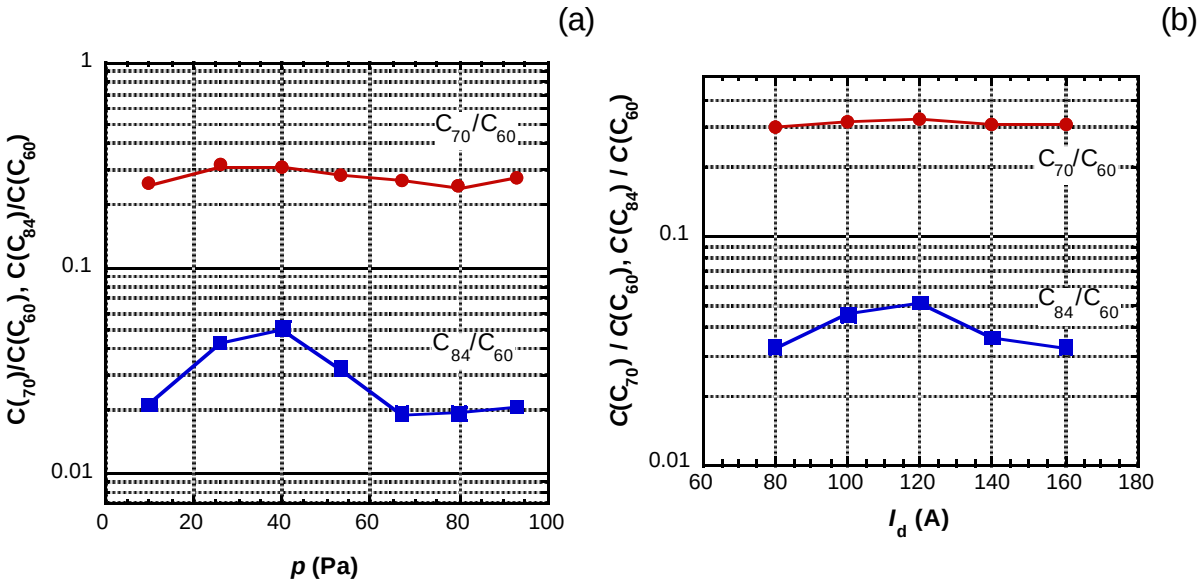

Fig. 3 Relative contents of C_{70}/C_{60} and C_{84}/C_{60} in the soot versus He pressure (a), where $\boldsymbol{I}_d$= 120 A. These contents versus discharge current (b), where ***p***(He)= 40 kPa.

Abstract

The key information about the mechanisms of the generation of structures of coherent character may be obtain from the time sequences of experimental data on the changing radiation intensity in the plasma. The variations of the radiation in time allow us to understand the dynamics of the structure movement in the plasma domain where the fluctuations of the radiation energy reach their maximum values.

Keywords Heat flow, vortex structure, radiation intensity, plasma jet

1. Introduction

The analysis of the vortex dynamics of the free stream is one of the exceptionally difficult problems of transition from laminar to turbulent flow. The transition between these two types of flow proceeds with a certain degree of organization (order) in the non-equilibrium working environment within the plasma generator. The degree of the organization of the movement in the free plasma stream depends on the gas throughput and on the energy supplied to the gas by the electric arc. The mathematical apparatus as well as the physical diagnostics tools must be designed in such a way as to respect the conditions under which the free plasma stream is generated. Therefore, it is desirable to select for the basic research such configurations of the plasma generating process that lead to the support of symmetric types of flow. The anisotropy of the processes is an inevitable complement of the interaction of the free plasma stream with the environment. The energy transport away from the central regions of the jet is influenced by the processes taking part in the outer regions of the free stream. These facts lead us to conclusions that the analysis of these processes must be performed by methods describing them in a certain spatial and temporal interval – i.e. not locally but globally.

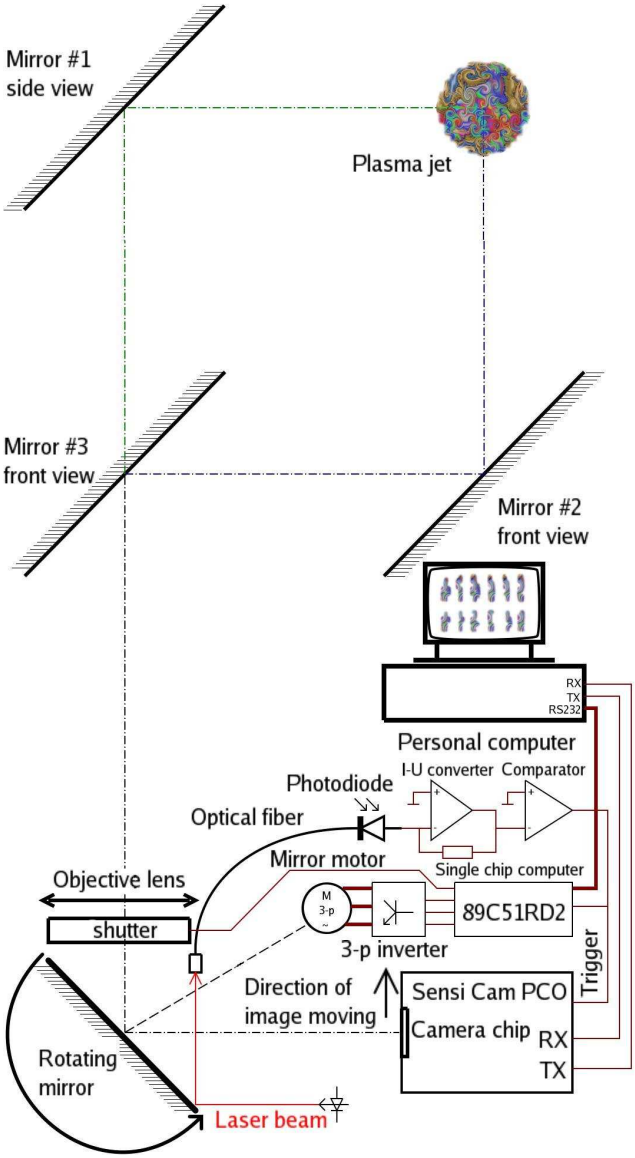

Fig. 1. Experimental setup.

Vortex motions make plasma flows fully three dimensional and complicated in general, and they play a dynamically important role in kinetic energy production and dissipation, mixing, diffusion and transport of mass, heat and momentum, plasma instabilities, and so on. Understanding of the dynamics of vortex structures in plasma, such as their generation, interaction and evolution mechanisms, is a prerequisite for flow prediction and control.

The basic components of the transport of the thermal energy in a flowing plasma are the heat flux and the tensor of the shear stresses of the velocity field. These two vector and tensor quantities, respectively, determine the dynamics of the development of the fluctuations of the velocity field and of the free energy in the plasma stream. The key information about the mechanisms of the generation of structures of coherent character may be obtain from the time sequences of experimental data on the changing radiation intensity in the plasma. The variations of the radiation in time allow us to understand the dynamics of the structure movement in the plasma domain where the fluctuations of the radiation energy reach their maximum values.

2. Experimental setup, imaging, and graphical representation methods of radiation structures in plasma

The heat flux in the free plasma jet depends on a number of thermodynamic and hydrodynamic quantities, first of all on the enthalpy and the vector of the macroscopic gas velocity. To determine it, we use the information about the radiation variation in the interval of 100 μs as captured on eight CCD snapshots. The image is swept through the CCD chip by a fast rotating mirror. An eightfold exposition produces a series of eight snapshots on a black background. The radiation intensity is used to identify the enthalpy values in the jet core where the jet possesses the highest internal energy and enthalpy. The shear layer region is characterized by fluctuations in the radiation intensity. These fluctuations result from macroscopic vortexes and, subsequently, from the fluctuation of the macroscopic velocity field. The instabilities of the velocity field thus become the source of the heat flux fluctuations.

In this situation, it is complicated to construct components of the three-dimensional heat flux vector from the CCD snapshots. The side view and the frontal view represent the image of the radiation dynamics in two directions. However, the determination of the radiation intensity in the horizontal projection is difficult and has not been performed by the CCD technique yet. Therefore, we have estimated the radiation values in the ground plane in the form of a square matrix from the values obtained in the vicinity of the nozzle orifice. The ground plane matrix is computed as a product of two vectors that are given by the radiation intensities in the side plane and the frontal plane in the nozzle vicinity. This method has several drawbacks that will be studied later.

The enthalpy of the gas mixture is strongly dependent on the mixture composition not only in the sense of chemical composition but, in the case under consideration, on the hydrodynamic processes that are related to macroscopic fluctuations resulting from the intense jet mixing. This means, in the same time, that the stress tensor also influences significantly the heat flux. The combination of these two factors focuses our attention to tomographic methods for the reconstruction of the radiation body of the free jet, ire. to the processing of the radiation signal based on Radon transformation. In this considerations, it is necessary to respect the differences between the vector and the scalar potentials.

We assume in the proposal for the phenomenological construction of the jet body that the changes in the radiation intensity are strongly influenced by the electric field in the chamber of the plasma generator, and, as far as the location of the vertical axis of the jet is concerned, also by the buoyancy forces. This leads to a break down of the isotropy of the heat transfer in the vertical direction as a consequence of the shear forces generated by the environment. Under these conditions, the location of the maximum radiation intensity in the side and frontal planes determines the coordinates of the maximum radiation intensity in the horizontal plane of the three-dimensional jet body. Via the determination of these couples of the locations of the maximum values we obtain the information about the location of the maximum radiation intensity along the axis of the jet. The three-dimensional matrix obtained from the multiplication of the side and frontal planes, resp., may be considered as a substitution of the spatial distribution of the radiation intensity in the vicinity of the maximum luminosity in the individual horizontal planes. Subsequent thoughts about the distribution of the heat flux vector are strongly determined by its dependence on the product of the velocity vector and the enthalpy of the working gas.

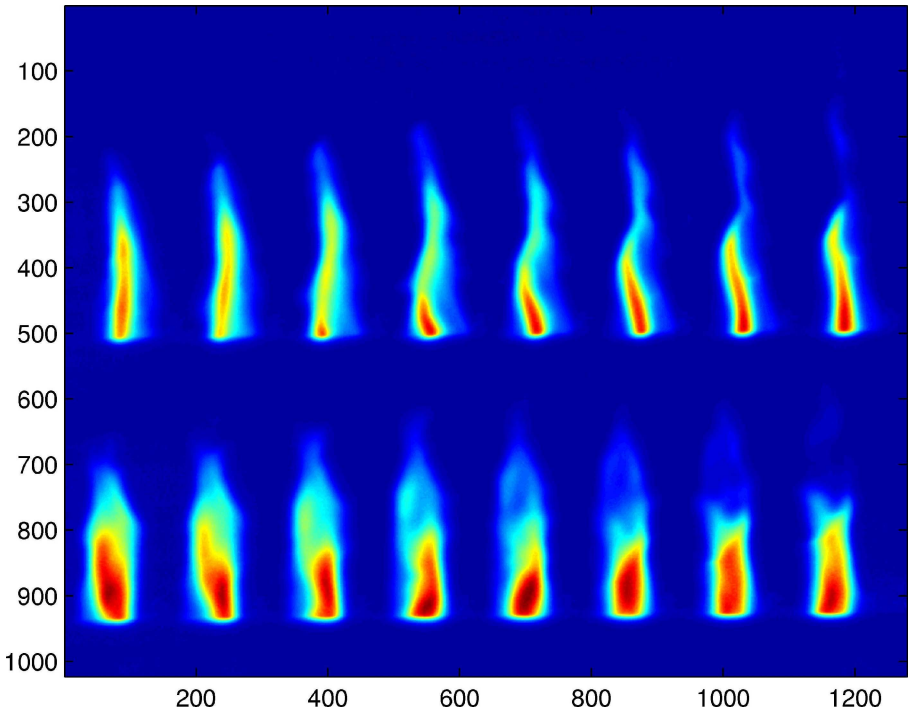

Fig. 2. Original image captured from CCD camera, 80 slm, 150A.

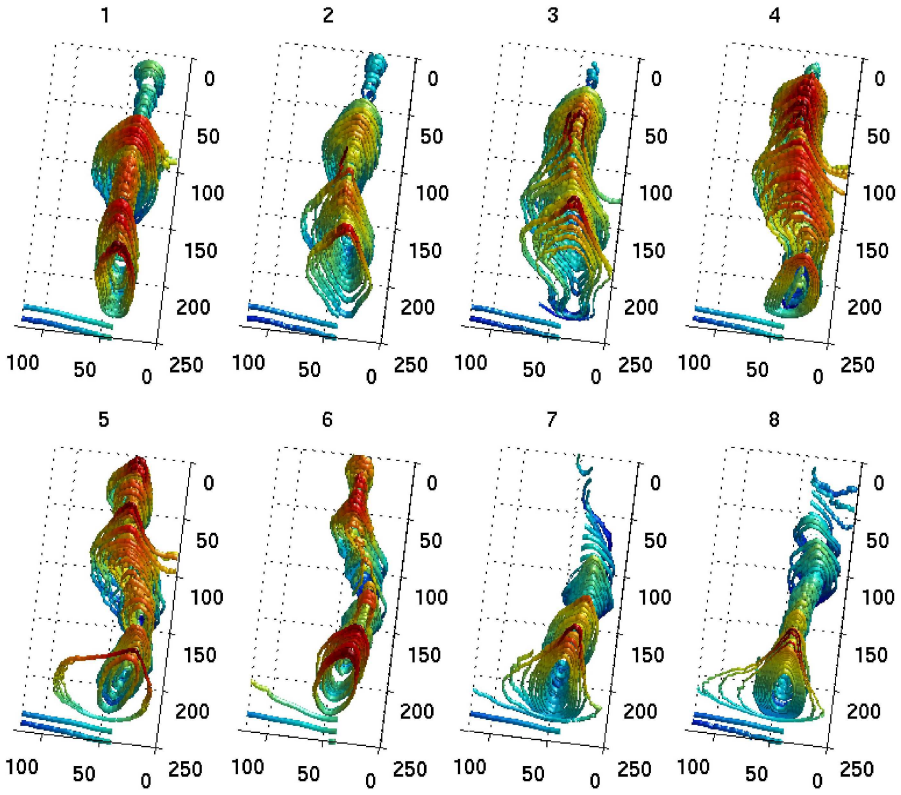

Fig. 3. Analysis of vortex structures, 80 slm, 150A.

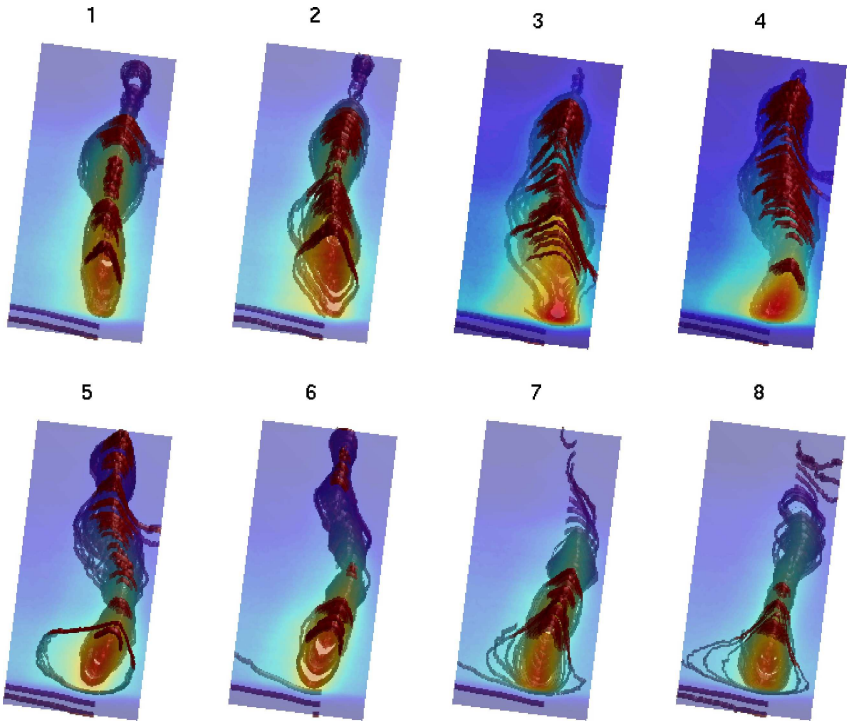

Fig. 4. Analysis of vortex structures together with a plane representating luminosity, 80 slm, 150A.

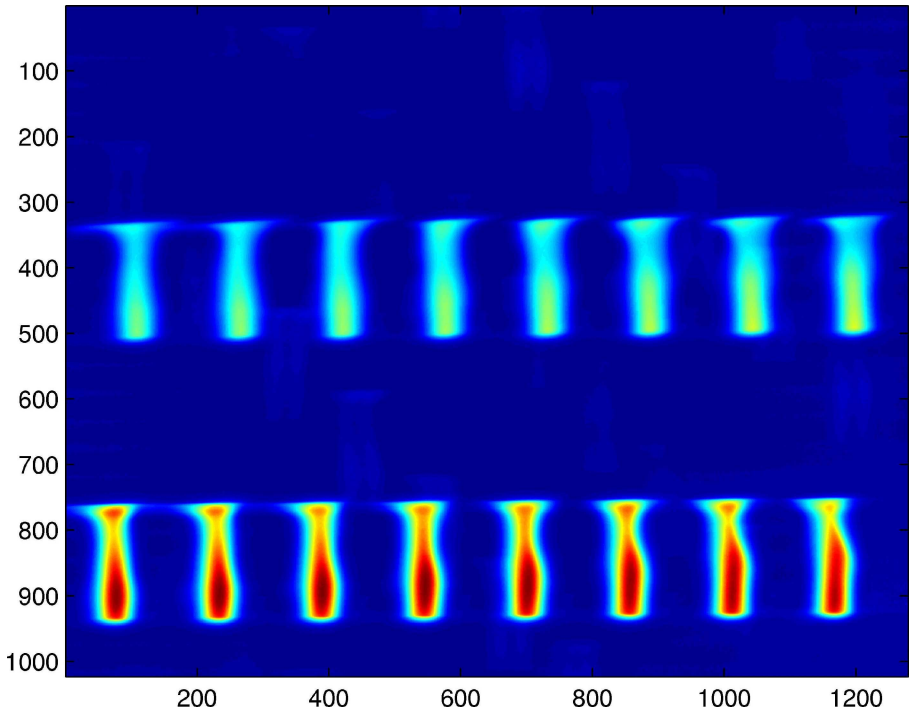

Fig. 5. Original image captured from CCD camera, 40 slm, 200A.

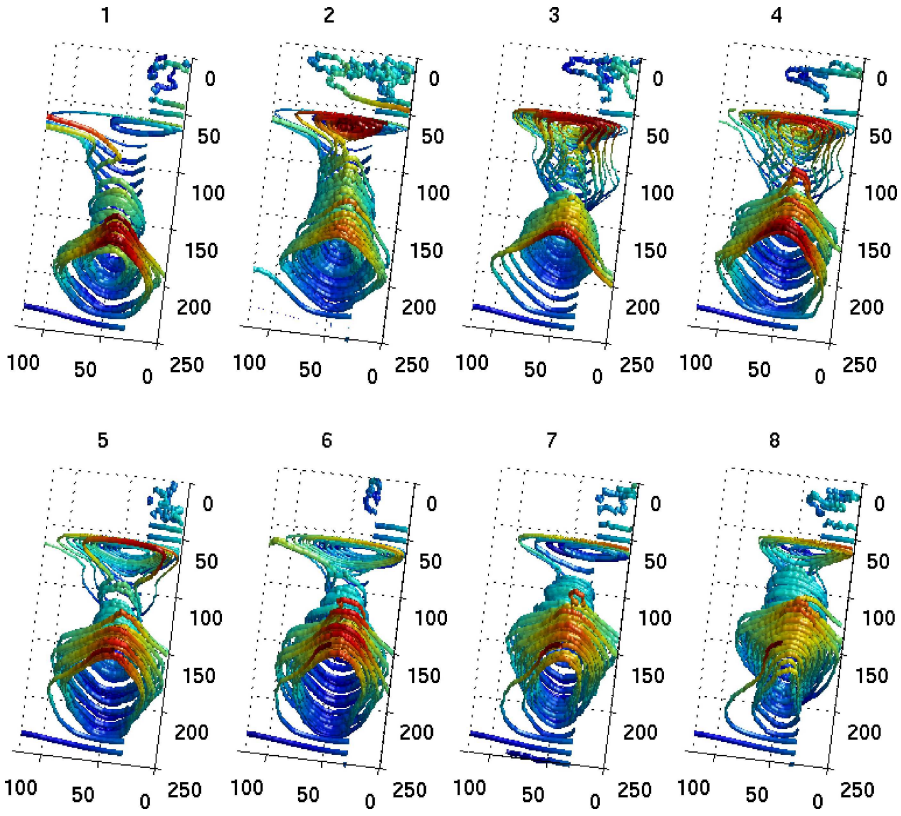

Fig. 6. Analysis of vortex structures, 40 slm, 200A.

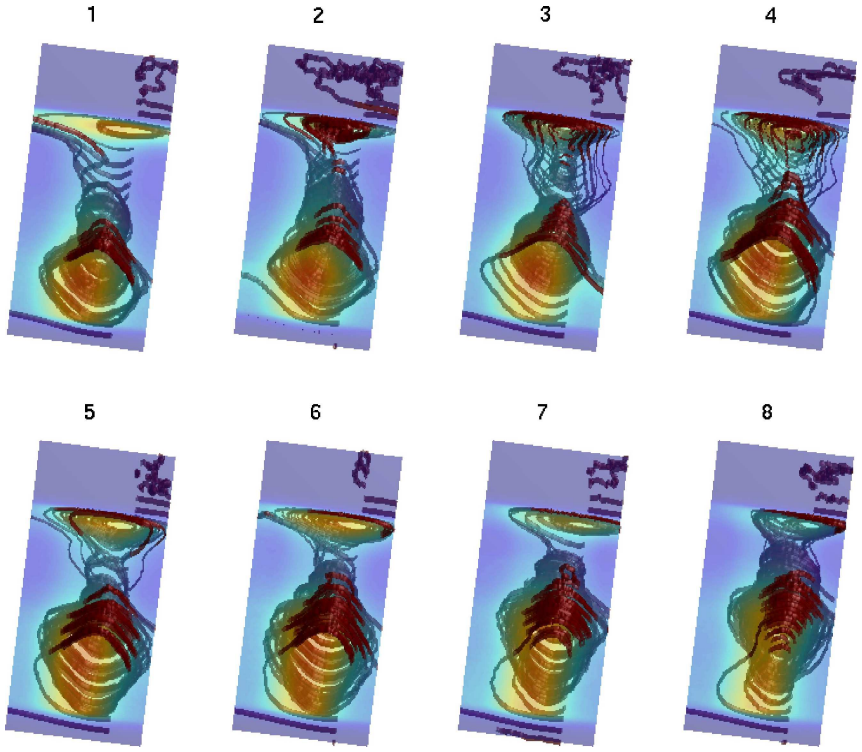

Fig. 7. Analysis of vortex structures together with a reconstructed plane, 40 slm, 200A.

Figures 5 - 7 show movement of heat flow vortex structures between the plasma jet and the barrier inserted into plasma flow. Snapshots 2, 3, and 4 in figures 5 - 7 illustrate the grow of vortex structures under the barrier, including the interaction of plasma jet with the vortex under the barrier. The barrier has a stabilising effect on the plasma jet, radial movements are minimized, in vertical direction we can see the movement of the vortex structure. Radial movements are influenced mainly by the presence of macroscopic scale vortexes in plasma jets outer shell, observed on figures 2 - 4 . The intensity of vortexes is increased if the mass flow rate of working gas goes up. For illustration we choose snapshot 5, figure 3 (mass flow rate 80 slm, current 150A). Radial transfers are dominant in structure dissipation, which is moving vertically (see snapshots 1 – 4). If we place a plane into plasma jet reconstruction in vertical direction, we obtain information about the stability changes in radial direction, and the velocity of movement of the structure in vertical direction.

The vector relations of the differential geometry for vorticity do not allow us, due to the properties of the scalar potentials, to perform such matrix transformations that rectify the measured values through scalar potentials as it holds that $rot(grad\phi)) = 0$ (ϕ is a scalar potential). Therefore, in the first phase of the application of the method based on the vorticity vector of the heat flux, we have retained only the components obtained as a product of the radiation body of the free jet – i.e. three-dimensional matrices – with two-dimensional matrices representing ground plane, frontal plane and side plane. Thereby we obtain a three-dimensional vector whose components contain the information about the enthalpy changes in the core and that modify the radial part of the free jet by the information about the stress tensor. The presence of the macroscopic vortexes in the vicinity of the jet body exercises the crucial influence on the stress tensor. This method as applicable namely to the identification of the different movement of the plasma features. We study structures of two types – emerging horizontal partitions, and structures of the free plasma jet whose dynamics is determined by the momentum in the closest vicinity of the nozzle exit. The discussion of the results is facilitated by drawing a plane through the jet body which allows to portray complex movements of the jet as opposed to the slower movement of the plasma features hold by the partitions. The selection of the planes intersecting the jet is done via a visual evaluation the graphical records shown in selected images. The selection is realized with Matlab.

3. Conclusion

The motion of heat flow vortex structures illustrated in Figs. 2 to 7 is influenced by forces of buoyancy, by shear forces due to macroscopic vortexes and by velocities corresponding to flow rates of gas. The value of the electric power input determines the stability of the system – with increasing the power input , the enthalpy of the system is on increase. The enthalpy is represented by the intensity of radiation in the central region of the jet , which allows for the reconstruction of the heat flow. A heat flow is considered as a vector whose anisotropy actuates towards establishing dynamic equilibrium. Experimental results need substantiating in terms of non-linear thermodynamics and kinetic theory [1] and are based on the changes of the radiation intensity of the jet. The geometrical correspondence between the volume features of the jet and the vorticity tubes of heat flow is from experimental results acceptable. Presented methods are very usefull for vorticity identification, and for velocity measurements. As non-contact method does not influence the plasma jet behavior, we are able to observe changes if a barrier is inserted into plasma flow.

Abstract

The formation, the analysis, and reactions of radicals is reviewed briefly with respect to plasma processes. Polyethylene films were treated with an atmospheric pressure glow discharge. The formation of radicals and hydroperoxides was investigated by the derivatization with NO and SO_2, respectively, and XPS. It was found that the concentration of alkoxy radicals increases constantly with the treatment time to 4.2% of the C-atoms (5 min). A maximum of 0.7% C-atoms with a hydroperoxide group was measured.

1. Inroduction

Radicals play important roles in the plasma treatment of materials and in particular of organic materials. Some of the reactive particles in the plasma are radicals. They alter the surface chemistry of materials or form coatings. Oxygen atoms (biradicals) are crucial in cleaning and etching processes. On the other hand, most of the reactions that are initiated by a plasma in a solid are radical reactions. These radicals induce cross-linking or fragmentation and they readily react even with traces of oxygen in a chain reaction. But they also can be used to initiate graft polymerizations. In many plasma processes they are important intermediates.

In the present paper, we will briefly review the basics of radical chemistry before we will focus on reactions in solids. We will discuss methods for the analysis of radicals, which can be used for plasma-processed materials. Finally, we will show examples for the determination of radical concentrations and the radical structure in polyolefin surfaces after a plasma treatment.

1.1 Radical formation

Molecules or atoms are called radicals if they have one or more unpaired electrons. Usually they are formed by a homolytic scission [1] of a chemical bond. The energy necessary for the scission can be introduced thermally, by photons, or by a reactive chemical agent. This energy must be at least as high as the dissociation energy E_{dis} for the bond. The value of E_{dis} depends on the atoms that form the bond but also on the chemical environment of these atoms (see Table 1, [2]). If a molecule comprises different types of bonds, the ones with the smallest E_{dis} tend to be broken first. For example, the E_{dis} of a C-H bond of the methyl group at the end of a hydrocarbon polymer chain is higher by 27 % compared to the C-H bond at the tertiary carbon atom of a branch or linkage. Therefore, the hydrogen atom at the tertiary carbon atom is split off easier than others. Similarly, it

Table 1. Bond energies (E_{bond}) and dissociation energies (E_{dis}) of bonds in organic molecules [2]

Bond	E_{bond} kJ/mol	E_{dis} kJ/mol	eV
H–CH_3		436	4.52

CH_3–F		453	4.70

[a] calculated as difference between the bond energy of the double bond and the single bond.
[b] calculated as difference between the bond energy of the triple bond and the double bond

takes less energy to produce radicals from multiple bonds than from single bonds because of the π-bond's smaller E_{dis}. C-O bonds and C-N bonds tend to break before C-C bonds and C-H bonds.

These purely energetic considerations are most important in the case of an excitation by photons. In the case of an attack by a reactive atom or molecule there are sterical influences, too.

In a plasma, there are particles and radiation which possess sufficient energy to break bonds and to form radicals. While the action of particles at polymer surfaces is mostly limited to a very shallow surface layer, photons can penetrate deeper. Vacuum ultraviolet radiation (wavelength between 100 nm and 200 nm) is usually absorbed in the outer 50 nm (90 % intensity loss [3]) of an organic material. It can produce radicals efficiently. Radiation with a longer wavelength can penetrate deeper into the material. However, the efficiency of initiating reactions in the solid is often small compared to the other plasma components and the contribution can be neglected. Many of the particle induced reactions and virtually all photon initiated reactions involve radicals.

1.2 Analysis of radicals

In general, the unpaired electrons are characterized by the spin. Electron spin resonance spectroscopy (ESR) is mostly used to analyze them. However, ESR analysis of real-world plasma treatments and plasma treated samples is difficult because the geometry of the spectrometer does not allow in-situ measurements. (There are reports in literature about experiments with plasma treatments in ESR cuvettes [4].) Experiments with quenching reactions which convert the radicals into stable structures are closer to real treatments. Diphenylpicrylhydrazyl (DPPH) was used for that purpose [5]. DPPH is an intensely colored and relatively stable radical which recombines with other radicals forming colorless products. The discoloration of a DPPH solution is used to quantify the amount of radicals in a sample. However, there are reports about DPPH not being useful for radical determination [6] because it reacts with other functional groups, too.

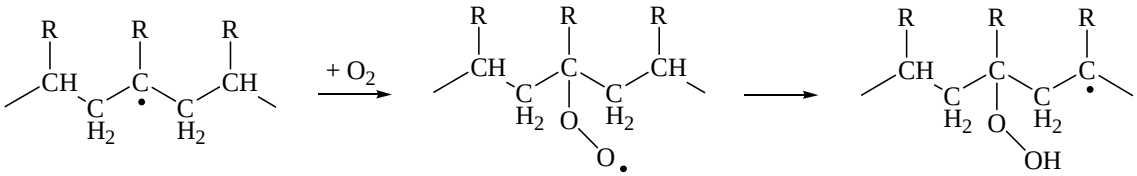
In previous papers we reported about the use of gaseous scavengers like iodine and nitric oxide (NO) for the analysis of radicals [7, 8]. These gaseous substances do not alter the surface in an unspecific way like a solvent does. Iodine can be determined very sensitively using XPS which provides the opportunity to identify small variations of the radical concentration. Unfortunately, the small iodine vapor pressure at room temperature limits the diffusion into the surface. If the radicals are not sufficiently stable and they diminish before there is iodine to react with, the absolute quantification is difficult. For example, the decay of radicals in the surface of polyethylene (PE) and polypropylene (PP) was investigated with iodine [8]. The radical decay rate was found to be in the same order of magnitude like the gross reaction rate with iodine. Consequently, the shape of the radical decay evolution was determined correctly while the absolute concentrations values were too small.

Nitric oxide is a gas under normal conditions and, therefore, it is easier to use. The reaction condition can be selected to meet the demands for the radical quenching at solid surfaces. These experiments provide absolute numbers for the radical concentration. Moreover, the reaction can be used to obtain information about the structure of the original radicals [7]. In the case of oxygen-free hydrocarbon polymers, the recombination of the carbon centered radical with NO is followed by rearrangement reactions. Depending on the structure, these reactions form different NO_x structures which can be distinguished by N1s-XPS.

1.3 Radical reactions

In general, we have to distinguish reactions which preserve the unpaired electron and such which result in the loss of the unpaired electron.

The addition of molecular oxygen starts a series of reactions that is called oxidation. From a practical viewpoint, it is the most important example for the first reaction type. For the understanding of the oxygen reactivity and the pathways of the reactions, it is important to note that molecular oxygen (O_2) is a biradical, i.e. the molecule has two unpaired electrons, one at each atom. The recombination rate of the carbon-centered radicals with O_2-radicals is several orders of magnitude higher than the value for the reaction with other molecules. Therefore, even traces of oxygen in a plasma chamber suffice to incorporate oxygen into the surface.



The reaction of a carbon radical with an oxygen molecule forms a peroxy radical. In the next step, the abstraction of a hydrogen atom preferably at the β-carbon atom results in a hydroperoxide and a new carbon radical, which again can react with O_2. This chain reaction continues until there are no more hydrogen atoms available. This means that several oxygen molecules are incorporated into the surface at the place of one single radical initiation site. For example, radicals which were produced by VUV photolysis in PE and PP result in the incorporation of about 20 and 10 oxygen atoms per radical, respectively [9].

Hydroperoxides degrade under the influence of heat or UV light. Depending on their structure, they can decay also at room temperature with a considerable rate. In the result, alkoxy radicals and hydroxyl radicals are formed. They react readily with neighboring molecules or parts of molecules in consecutive steps and form a variety of different functional groups. The type of these functional groups and their relative concentrations depend only partly on the structure of the first original radical, the initiation site.

There are two reaction types that result in the loss of the radical function: recombination and disproportionation. In recombination reactions the two unpaired electrons form a new bond. The disproportionation describes the transfer of a hydrogen atom from one radical to a second according to the following reaction scheme.

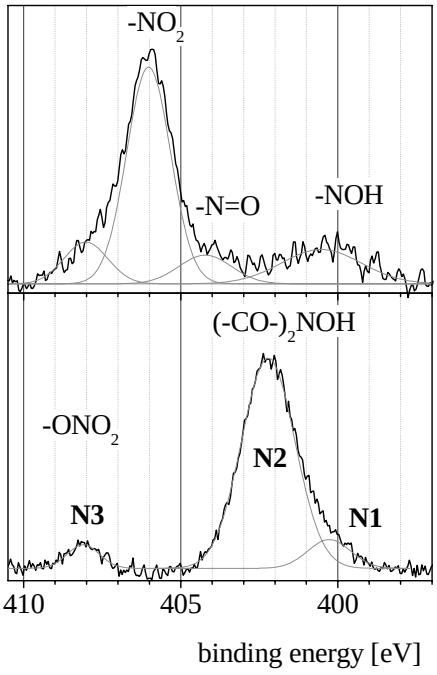


Figure 1. N1s-XPS of NO labeled PE which was treated with VUV (top, [8]) and with an atmospheric pressure glow discharge (bottom, 60 s).

While the recombination results in an increase of the molecular mass, the disproportionation tends to decrease it. In the case of a plasma treatment of polymers, the ratio between the two reactions decides whether the material gets cross-linked or etched. For example, a branched structure favors the disproportionation over the recombination. As a result of this tendency, in a plasma treatment polyethylene tends to be cross-linked while polypropylene forms low molecular weight volatile products. The etch rate is higher in the case of PP.

2. Radicals in the plasma treatment of polyolefins

In previous investigations [8] we studied the formation of radicals in VUV photolysis reactions of PE and PP and their decay in high vacuum (HV). With these experiments we were able to prevent oxygen from reacting with the radicals. This was a simulation of the subsurface conditions during a plasma treatment. With the NO reactions, it was found that at extended treatment times (60 min) the majority of radicals are located at tertiary carbon atoms (see upper part of Fig. 1), which is an indication for a substantial cross-linking. In the N1s X-ray photoelectron spectrum we observed highly oxidized nitrogen atoms, which are formed by multi-step reactions of the tertiary radicals with NO.

In the presence of oxygen, the reaction pathways during the treatment are much more complex. Considering what was discussed in the chapter above, the probability to find a carbon centered radical is rather low. We have to expect hydroperoxides and alkoxy radicals instead. In fact, we observe a completely different N1s-spectrum (Fig. 1, bottom) with samples, which were treated in an atmospheric pressure glow discharge (APGD) and then with NO. There is a

rather small fraction of oximes (400.4 eV) which are usually formed from radicals at secondary carbon atoms. The component at a binding energy of 402.2 eV suggests a nitrogen atom with one bond to an oxygen atom and two bonds to carbon atoms having one or two bonds to oxygen each [10]. Nitrogen in such a binding state has never been found in our experiments in HV. Therefore, we conclude that it is a result of the reaction of NO with an oxygen containing species. If we consider the evolution of this N1s component with the treatment time (see below), it seems reasonable to assume that alkoxy radicals are the origin of this feature.

Nitroso groups and nitro groups which are formed from tertiary radicals and which are prominent in the samples of HV experiments, were not found at all in the APGD experiments. This virtually complete absence of tertiary radicals suggests that there are no carbon based linkages at the polymer backbone within the analysis depth. If there is any cross-linking, it must be via oxygen bridges like ethers or esters.

The component at 408.1 eV must be attributed to nitrates [11]. In the HV experiments we observed nitrates, too. They were thought to be formed by the reaction of NO with nitroso groups. In the present samples, there were no tertiary radicals that could form nitroso groups and we did not find any nitroso groups. The source of the nitrates must be different. Comparing the two types of experiments, we see that the presence of O_2 gives rise to peroxy radicals and hydroperoxides which are both good candidates for the nitrate formation.

A typical evolution of the fractions of the 3 nitrogen components as a function of the duration of the APGD treatment is shown in Fig. 2. A short treatment time of some seconds gives rise to a relatively high concentration of the nitrate N3 component. Its concentration decreases at longer treatment times. The component N2 is formed more and more over all the treatment at least up to 300 s. N1 is small in all the samples but there might be a slight tendency to an increasing concentration value. These evolution characteristics fit reasonably well with the proposed structural features behind these components and their probable fate during an APGD treatment. In the very beginning of the treatment, the surface radicals react with O_2 and form peroxy radicals and hydroperoxides (N3). In the course of the treatment, the peroxy structures are destroyed and form alkoxy radicals (and other stable products). But the O_2 addition to carbon radicals continues although with a decreasing rate. The resulting peroxy structures decompose to alkoxy radicals which gives rise to a quasi-equilibrium concentration of the peroxy structures and to a steadily growing alkoxy radical concentration.

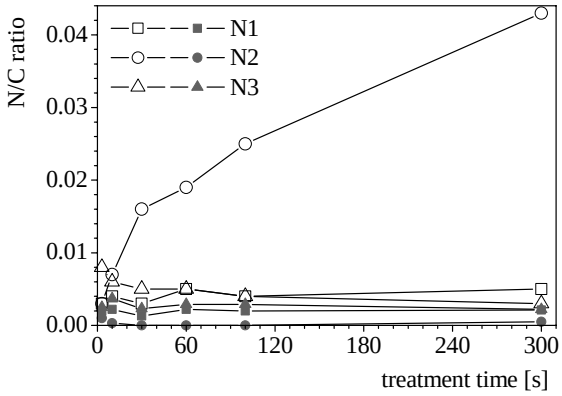

Figure 2. Evolution of the N1s component concentrations after the NO reaction as a function of the APGD treatment time of a PE film. open symbols: NO treated; filled symbols: NO treated and washed

A total of 2.3 at% of nitrogen from the NO reaction was found in the sample after the 300 s treatment. The oxygen concentration accounted for 20 at%. Washing the samples in ethanol reduced the oxygen concentration of all samples with treatment times > 10 s to about 8 at%. A maximum nitrogen concentration of 0.7 at% was found after washing the NO treated samples. It is worth noting that the component N2 is removed completely by the washing (filled symbols in Fig. 2).

In literature, there are reports about using sulfur dioxide for the investigation of hydroperoxides [12]. The sulfur inserts between the oxygen atoms and forms a hydrogen sulfate which can be determined by XPS. It was found that in a 30 s APGD treatment a hydroperoxide concentration of 0.7 % of the carbon atoms is present in the sample surface. This value is slightly higher than the one obtained from the NO reaction (N3: 0.5 %).

The hydroperoxides decompose during storage (Fig. 3). A 4 h heating to 89°C reduces the sulfur concentration to 0.29 % of the carbon atoms. At room temperature the decomposition is slower but still considerable. After a 24 h (1440 min) storage, we measured a value of 0.36%C.

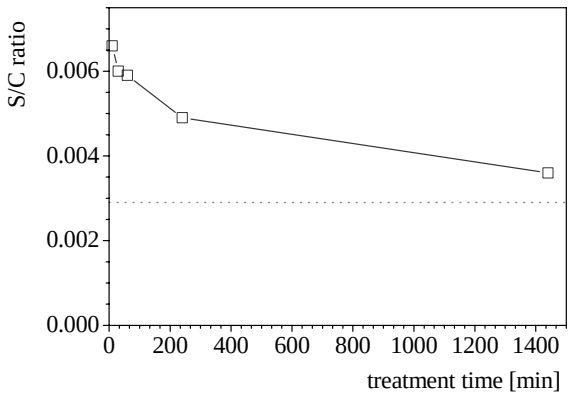

Figure 3. Sulfur concentration of SO_2 derivatized samples of PE films as a function storage time between APGD treatment and SiO_2 treatment. Dotted line: value for a 4 h storage at 89°C.

3. Conclusions

Gas phase derivatization reactions with nitric oxide NO and sulfur dioxide SO_2 can be used to obtain information about the concentration and the structure of radicals and the concentration of hydroperoxides at the surface of polymers.

Compared with previous studies in a strictly oxygen-free process, the reaction paths are more complex in the presence of oxygen. They are not completely understood yet and it requires further investigations on the reliability of the quantification data.

4. Experimental

The APGD equipment is described in detail elsewhere [13]. Briefly, a DC discharge (110 W) is generated between metal pin electrodes and a metal grid while blowing air through the discharge zone (250 m^3/h, 20 °C, 52 % rel. humidity). The sample film (polyethylene, 30 µm, Orbita-Film GmbH, Germany) located at a distance of 5 mm away from the discharge zone.

For the derivatization we used a 0.8 l stainless steel chamber which was pumped to < 1 mbar before filling with NO (99 % Linde AG, Germany) or SO_2 (99.98 %, Linde AG, Germany) to 200 mbar. After 15 min the chamber was pumped again to remove the gas. Then it was filled with argon and the samples were transferred to the XPS instrument.

Some samples were washed in ethanol in an ultrasound cleaner for 5 min.

The XPS spectra were recorded using an AXIS 165 instrument (Kratos Analytical, UK). A monochromatic Al Kα was used for excitation. The instrument was operated in hybrid mode (with magnetic and electrostatic lenses).

Introduction of irregularities into plasma polymers by radiative and auto-oxidative processes

S. Krüger, R.-D. Schulze, K. Brademann-Jock, J. Friedrich
Bundesanstalt für Materialforschung und –prüfung (BAM), 12200 Berlin

Abstract
Thin plasma polymer films were deposited using the pulsed plasma (pp) mode. These plasma polymers should possess a more regular structure because of the lower monomer fragmentation during the plasma pulses and the chemical chain propagation during the plasma-less periods than those produced by the conventional continuous-wave (cw) mode. In addition to the use of the classic thin film characterization method XPS the new method of thermoluminescence was applied to characterize defects and structural specifics in the polymer films produced by pp or cw plasma mode. The thermoluminescence method was applied to functional groups-carrying plasma polymer layers, which are used in medical technology for forming biocompatible and bioactive coatings or in metal-polymer composites as adhesion-promoting interlayers.

1 Introduction

The process of plasmapolymerization was investigated in detail by Jesch, Yasuda, Westwood, Poll, Denaro, Shen, Bell, Tiller etc. [1-10]. It was recognized soon that plasmapolymers differ strongly in structure and composition from their classic reference polymers. Firstly, a complete fragmentation of monomers in the plasma phase was detected before the deposition occurs [10]. Secondly, it was observed that all fragments and atoms recombine randomly [8], so that the real structure of plasma polymers is far from that of classic analogues. Moreover, the deposited thin film is exposed to short-wavelength UV and to a bombardment of energetic plasma particles during the whole plasma process. These processes are responsible for the introduction of C-radical sites and irregular structures into the deposited polymer films. These trapped radical sites are points of initiation of auto-oxidation when the layers are exposed to the ambient air.

Using the pulsed plasma (pp) mode, the plasmapolymer deposition exhibits a new formation mechanism. Now, the plasma specific polymerization via fragmentation and polyrecombination is suppressed in favour of chemical chain propagation within the plasma-less periods of the pulsed mode. Here, short plasma pulses (100 µs-1000 µs) shall initiate the classic chain propagation of classic monomers as vinyl or acrylic monomers. By this way a more defined structure and composition were expected similar to those of classic polymers. This new quality could be confirmed using the above mentioned well-suited monomers, low power-input and short plasma pulses and long dark (plasma-less) periods (known as duty cycle $dc=t_{on}/t_{off}+t_{on}$) and analyzing these layers by surface-sensitive methods as XPS, NEXAFS, ATR etc. [11]. However, the use of integral (bulk) methods (UV, IR-transmission, FFF, TG or dielectric relaxation spectroscopy) had indicated stronger differences between pulsed plasma polymers and classic reference polymers. Thus, it was detected that more defined structures are formed at the surface whereas more irregular structures occur in the bulk, modified probably by the UV irradiation during each plasma pulse.

For the first time, pulsed plasma polymerized ethylene showed in its IR spectrum a weak doublet (721 and 738 cm^{-1}) characteristic for regularly structured sequences as occurring in classic polyethylene [11]. Using continuous-wave (cw) plasmas these bands could not observed anywhere [1]. The situation is improved when using allyl monomers as allylamine and allyl alcohol. It could be shown that the polymerization for these substances is more close to classic polymerization than that for ethylene [11].

Here, ethylene and allylamine plasmapolymers should be investigated for the retention of monomer structure or functional groups during the deposition process and vice versa for the formation of irregular structures in the layers. For this purpose, the thermoluminescence is well suited because of its sensitivity towards defects, irregularities and radical sites. Especially the comparison between continuous-wave and pulsed plasma polymerized layers and the influence of power-input were of interest.

Thermoluminescence from irradiated polymers is a powerful means widely used to investigate molecular motions with respect to the occurrence of phase transitions [12-14]. Recent reports have pointed out that the behaviour of light emission is related to and varies with the structure of materials [15]. Thus, thermoluminescence furnishes a new measure for the structural perfection of materials, i.e. in terms of the mode of releasing trapped electrons.

So far two references are found to deal with plasma, polymers and thermoluminescence [16,17]. However, structural changes of polymers caused by exposure to plasmas were investigated. Here, for the first time, thermoluminescence measurements of spectral distribution under isothermal conditions as well as measurements after exciting by irradiation in dependence on temperature were applied to pulsed plasma produced polymer layers.

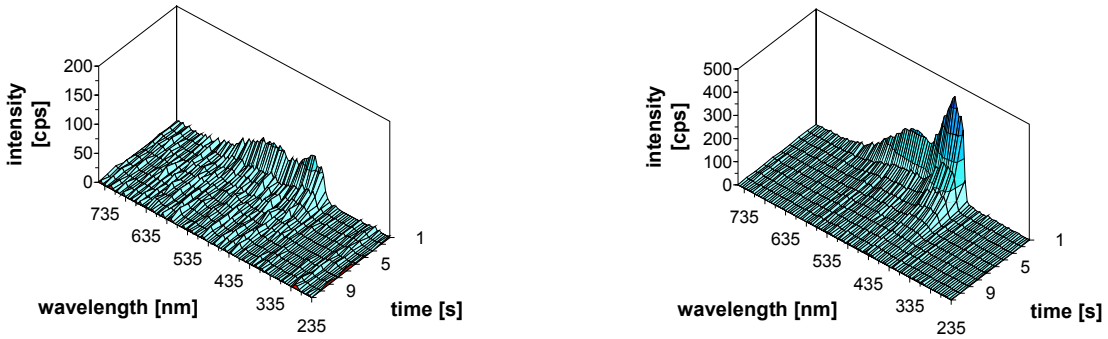
2 Experimental

For measuring after the ITL-method (isothermal thermoluminescence, recording of decay-curves, spectral resolution in dependence on time) the samples are subjected to a vacuum chamber, which was pumped down to a pressure of 10^{-4} Pa and the polymer sample was cooled down to 30 K. For the irradiation of the polymer sample a low-pressure mercury-UV source (185, 248 nm; Hg-lamp HBO 200 W/4, Osram) equipped with a tunable shutter was used. After 3 min excitation the irradiation was stopped and the emitted radiation from the sample was collected and transmitted by flexible fibre optics to the monochromator connected with a cooled CCD cell. By this way the signal could be spectrally and temporally deconvoluted. Moreover, different temperature regimes could be adjusted (e.g. 30, 110, 150, 180 and 230 K).
Using the TL-Methode (thermally stimulated luminescence, glow curves, heating-up) a similar apparatus was used as described before. Only a new excitation source was introduced, an electron beam gun (7.5 keV; electron gun EGPS-14 B, Kimball Physics Inc.). In the same way as before, after 3 min electron-beam irradiation at 80 K, the decay curves were recorded. After slowing down of emission the heating-up process was started at 80 K up to room temperature and the glow curves were measured.
Plasma polymer layers were deposited in a cylindrical plasma reactor of 50 dm³ volume. The design of the plasma reactor has been described in detail in [11]. The reactor was equipped with a pulsed radio-frequency (r.f., 13.56 MHz) generator and an automatic matching unit as well as an r.f. bar antenna (length: 35 cm). The substrate foil was mounted on a continuously rotating, grounded steel cylinder (Ø= 10 cm, length= 35 cm, rotating frequency= 0.5– 1 s^{-1}) at 10 cm distance to the r.f. powered electrode. The duty cycle of pulsing was adjusted to 0.1 and the pulse frequency to 10^3 Hz. The power input was varied between P = 100 - 300 W. Mass flow controllers for gases and vapours, a heated gas/vapour distribution in the chamber, and control of pressure and monomer flow by varying the speed of the turbomolecular pump were used. The gas flow was adjusted to 75 - 125 sccm and the pressure was varied between 10 to 26 Pa depending on the respective polymerization or copolymerization process. The deposition rate and the film thickness were measured by a quartz microbalance.
These thin plasma polymer layers (thickness ≈ 125 nm) were deposited onto glass slides and analyzed by the thermoluminescence methods. Both continuous-wave and pulsed plasma mode were applied to produce the plasma polymers and deposit them onto glass slides. The plasmapolymer layers were produced from ethylene and allylamine to compare layers without functional groups and those with amino functionalities. The thickness of investigated layers ranged from 125 nm to 200 nm. TL investigations were performed immediately after finishing the plasma deposition, after 6 weeks and after 5-month exposure to the ambient laboratory air.

3 Results

3.1 Polyallyamine layers – isothermal TL, spectral resolution in dependence on time

At first the influence of the plasma polymerization mode, cw- or pp-plasma, on the spectral emission was investigated. The time-dependent ITL spectra of cw- and pp-plasma polymerized polyallylamine show significant differences, which are presented in Figs. 1 and 2.



Figs. 1 and 2 Time-dependent ITL spectrum of polyallyamine that was deposited in the pulsed (left) and the cw-plasma mode (right)

The cw-plasma polymer shows a broad and continuous emission between 450-650 nm. Also in the range between 250 to 355 nm a very weak background emission is observed. Two broadened, not clearly resolved peaks at $\lambda \approx 435$ and 535 nm appear with moderate intensity (cf. Fig. 2). These two peaks are better resolved and much more intense if the polyallylamine was produced in the pulsed-plasma mode (Fig. 3). The intensity ratio of $peak_{435}$ and $peak_{535}$ is also changed if using the pulsed plasma. Applying the cw-mode the ratio 435/535 is roughly 1.2 : 1 and 2.1 : 1 for the pulsed mode.
In Fig. 3 the difference between the ITL-spectra of polyallylamine, produced in the cw-plasma mode or in the pulsed plasma mode, are obvious.

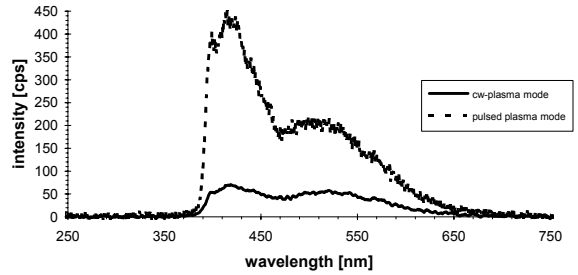


Fig. 3 ITL spectra of polyallylamine layers produced in the cw-plasma mode or in the pulsed plasma mode measured immediately after 3 min UV-irradiation at 30 K

The sharp peak at 435 nm and the broad peak at 535 nm are clearly pronounced. This behaviour is surprising because it means that using the pulsed plasma mode significantly higher concentrations of chromophores were formed. As described before the UV emission fraction is much higher than with the cw-plasma mode. Additionally, a shoulder at 375 nm becomes more intense whereas that at 445 nm shows slightly less intensity. The whole UV emission peak is slightly slimmer than that of the cw-plasma mode. Generally, the same emitting species are present in the two layers, which can be deduced from the shape and location of bands within the spectra.
The exponential decrease of light-emission in dependence on time ("fading") is presented in Fig. 4.

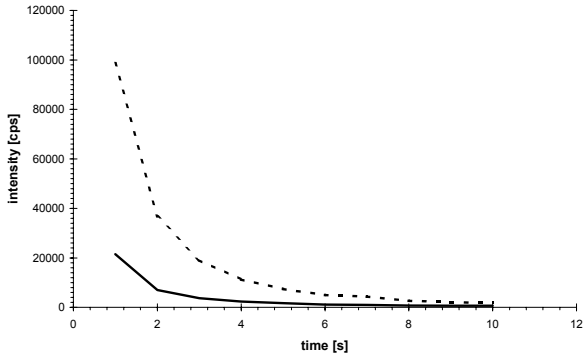

Fig. 4 Fading of total emission of polyamine layers produced in both the cw- and the pulsed plasma at 30 K and 3 min UV irradiation

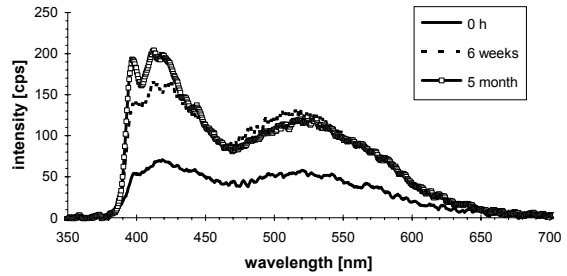
Also in this case the two different produced polyallylamines show the same behaviour if the different start intensities are normalized. Therefore, it is to assume again that in both layers the same emitting species exist and the same decay rules are valid. Further work to this topic is in progress.

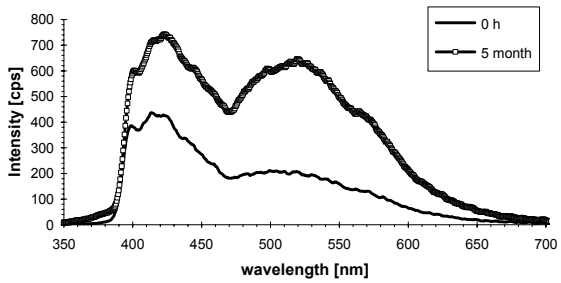
3.2 Storage of polyallylamine layers

The plasmapolymers were stored in a dark room with constant room temperature and humidity (20°C, 60%) and inspected by thermoluminescence in defined intervals. The ITL spectra of the cw-plasma mode produced polyallylamine exhibit a significant increase in intensity during the storage. The most important intensity increase is observed within the first 6 weeks of storing (Fig. 5).

Most likely this phenomenon is generated by the slow post-plasma auto-oxidation at exposure to the air. It should be remembered that there is a fast (primary) oxidation of trapped C radical sites at contact to oxygen [18]. This fast oxidation exceeds immediately during the transport of the samples from the reactor to the TL cell involving the contact to the air. At longer exposure of the plasmapolymer to air the slow auto-oxidation of the layer dominates [18]. After 5-month exposure to the air the intensity of emitted light only increases slightly in the UV range, however, the wavelengths of emitting species in the plasmapolymer do not change. The increase of the peak intensity at λ=398 nm to the dominant emission is obvious as presented in Fig. 5.

Figs. 5 and 6 ITL spectra of polyallylamine produced in the cw (left) and pulsed(right) plasma mode after 3 min UV irradiation in dependence on time of storage



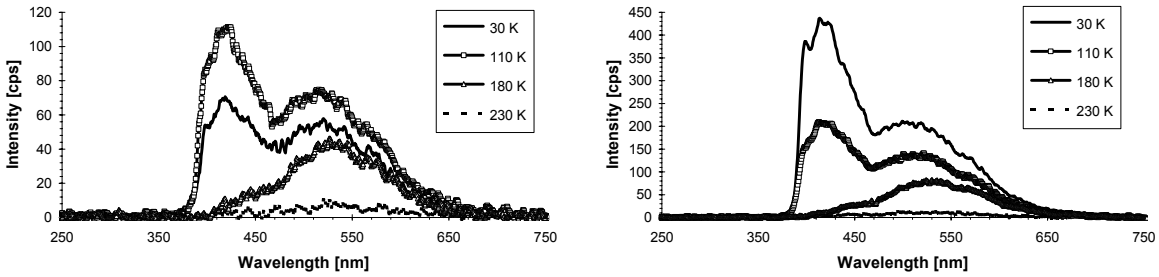


Investigating the pulsed plasma polymerized polyallyamine also the intensity of emitted light is increased, however, in this case in the visible range (λ>480 nm; $\lambda_{max}\approx$525 nm) more than in the UV region (Fig. 6). Moreover, the structure of the UV peak is different from that of the cw-plasma mode. The peak λ=398 nm does not increase so much as in the case of the cw-plasma mode produced sample. In contrast to it the emission at λ=420 nm increases super proportionally (cf. Fig. 6).

3.3 Time-dependence of ITL spectra

ITL spectra of cw-plasma mode produced polyallylamine are presented in dependence on the isothermal temperature used for measuring (Fig. 7). The temperature used varied between 30 and 230 K. The isothermal luminescence fading curves were recorded each after 3 min UV irradiation. With growing temperature the intensity increases in the first step (30→110 K) and then decreases dramatically (110→180→230 K) up to total quenching of emission (230 K). This behaviour is not surprising because the relaxation possibilities grow with temperature and, therefore, the radiation-less deactivation processes increase also. Moreover, the emission shifts to the visible (red-shifting) while the UV emission is completely quenched (cf. Fig. 7). This behaviour was prevailed for all investigated polymer layers. In the same manner the ITL spectra of cw-plasma mode produced polyallylamine are presented in dependence on the isothermal temperature using the UV activation but exposure the samples 6 weeks to the air. In contrast to unaged samples these layers show an unambiguous succession of decrease in intensity in dependence on increasing temperature (30→110→180→230 K). After 5-month exposure to the air the total emission in the ITL spectra of cw-plasma mode produced polyallylamine increases again for the measurements at 30 and 110 K, while the measurements at higher temperature lead to lower emission intensity.

Figs. 7 and 8 ITL spectra of polyallylamine produced in the cw (left) and pulsed (right) plasma mode and irradiated by UV for 3 min in dependence on isothermal temperature



ITL spectra of pulsed plasma mode produced polyallylamine are also presented in dependence on the isothermal temperature (Fig. 8). A significant higher intensity was measured compared to the species those were produced in the cw-plasma mode and measured under the same conditions. These layers show a succession of decrease in intensity in dependence on increasing temperature (30→110→180→230 K). The peak at λ=398 nm decreases with growing temperature much more than that at λ=425 nm (30→110). At higher temperatures the two peaks disappear nearly completely and the broad visible peak λ=515 nm remains in lowered intensity. After 5 month exposure of the pulsed plasma produced polyallylamine layers to the air the global intensities become much more intense for each temperature. In general, the same situation exists as before without storage, the UV peak disappears with growing temperature and the broad peak in the visible range at λ=515 nm remains in lowered intensity

In the same manner the ITL spectra of cw- and pp-plasma mode produced polyallylamine are presented in dependence on the isothermal temperature using the electron beam activation before and after exposure the samples to the air. In Fig. 9, the decay curve is shown in dependence on the isothermal temperature at 80 K using the electron beam activation before and after exposure the samples to the air. As shown in Fig. 9 the exponential decrease in light emission of the cw-plasma mode produced polyallylamine is comparable for immediately measured and 6 weeks aged layers, however, starting with the twofold of emission in the case of the non-stored sample. The total intensity is low compared to that of Fig. 6.

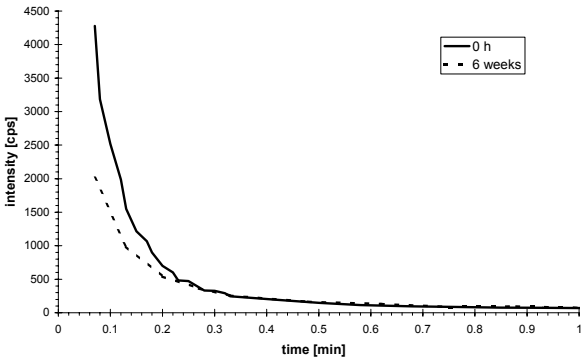


Fig. 9 Fading of the total emission of cw-polyallylamine before and after ageing

The glow curves of the two samples are also of low intensity. Both the non-aged as also the 5 weeks aged sample show a broad peak at about T≈130 K. The two curves differ insignificantly and do not change further at storage in air.

The type of traps (e.g. charge carrier traps) responsible for this luminescence emission is unknown. However, it is known from plasma chemistry that trapped radical sites play an important role. Obviously, considering Fig. 10, the types of traps and their "breaking" are identical for un-aged and aged. Thus, also the decaying of these traps is similarly, however, no concrete assignment to their nature is possible.

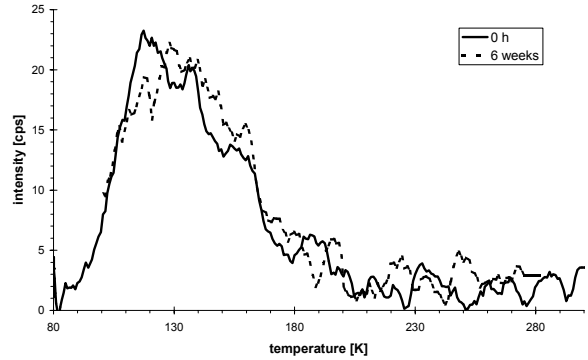

Fig. 10: Glow curve of emission from polyallylamine produced by the cw-plasma mode after 3 min electron beam irradiation (7.5 keV, 80 K)

In dependence on the mode of layer deposition different time-lag and intensities behaviours were found. The light emission obeyed kinetics of first order for the pulsed plasma mode produced species (lnI~t) and the cw-plasma mode produced layer was not unambiguously assignable to a defined kinetics.

The glow curves of the two species show also significant differences (Fig. 11). The cw-plasma produced species exhibit only a weak intensity and a broad diffuse peak at λ≈120 K.

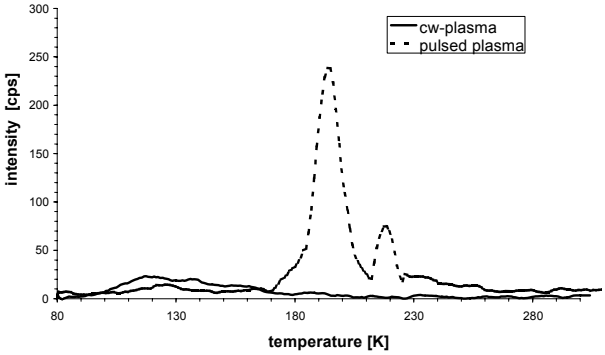

Fig. 11: Glow curves of polyallylamine produced by cw- or pulsed plasma mode after 3 min electron irradiation (7.5 keV) at 80 K

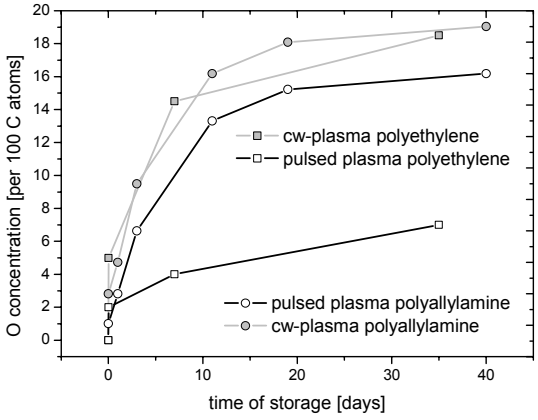
High intensities and characteristic peaks are manifested investigating the pulsed plasma polyallylamine (cf. Fig. 11). Obviously, complete different trap states were present, which are broken at higher temperatures (190 and 210 K). Together with the time dependence of total light emission and the glow curves the existence of significant different trap types can be derived and thus different chemical structures in the two layers can be concluded [19].

3.4 Polyethylene layers

Polyethylene sequences should be inserted as comonomer sequences in pulsed plasma polymerized allylamine-ethylene copolymers. By this way and varying the allylamine/ethylene proportion in the precursor mixture different concentrations of primary amino groups in the resulting polymer layers should be adjusted [20]. However, pulsed plasma polyethylene should be regularly structured and defect-free.

The intensity of light emission in dependence on time ("fading") showed a linear dependence when plotting it with 1/t. Thus, a tunnelling process was proposed as mechanism for the emission because of the 1/t dependence as described in [21-22]. The glow curves did not show significant emission before and after ageing. Around 130 K a broad maximum was visible.



3.5. Results of XPS

It should be added that XPS measurements of these investigated polymer layers were performed to identify a correlation between ageing processes expressed in post-plasma attached oxygen and thermoluminescence features.

The two plasmapolymers, polyallylamine and polyethylene, are sensitive towards ageing. However, those one polymerized in the pulsed plasma mode pick up much lower amounts of oxygen as shown in Fig. 12.

Fig. 12 Introduction of oxygen into plasmapolymers during their exposure to the air measured by XPS

Primary amino groups containing polymers are generally sensitive towards oxygen. Thus, the broad shoulder at the high binding energy (BE) side of the C1s peak is attributed to the post-plasma formation of OH and ether groups (BE=286.3 eV), ketones and aldehydes (BE≈288 eV), esters and carboxylic acids (BE≈289 eV) as well as carbonates and peroxyacids (BE≈290 eV).

Now, it is assumed that the radiatively decaying centres in the plasmapolymers are connected with the post-plasma introduction of oxygen. Thus, the increasing emission after ageing of samples can be explained. Also the insignificant luminescence of pulsed plasma polyethylene is obviously resulted by the lower oxygen introduction if produced in the pulsed plasma mode.

4 Conclusions

The two investigated polymer layers, polyallyamine and polyethylene, show a noteworthy thermoluminescence. The original aim for production of such layers was to form structurally more perfect layers. However, the plasma process itself, known as "fragmentation-polyrecombination" polymerization, involves the co-formation of irregular structures and defects in the polymer layer. Using the pulsed plasma with short plasma pulses (a few hundred microseconds) and long plasma-off periods (a few milliseconds) these irregularities and defects should be minimized [20]. This was confirmed by XPS and NEXAFS measurements of the surface composition and structure of such layers [20]. On the other hand bulk-detecting analysis show more irregularities and defects. So, it is assumed that the deposited plasma polymers cover a number of analytically hidden defects, which are manifested at exposure to the air. These hidden defects may be C radical sites and other anomalities within the bulk of polymer layer. The other possibility of forming structural imperfections is the irradiation, which secondarily changes the structure of the growing plasma polymer by short-wavelength (λ<200 nm) UV from the plasma at each plasma pulse. Thus, C radical sites and cross linking were introduced into the deposited layer. In Toto the C radicals, wherever they come from, are source of post-plasma auto-oxidation. The results of thermoluminescence measurements confirm these earlier findings generally. Because of the high content of anomalous structures in plasma polymers an assignment of thermoluminescence (TL) features was not tried yet. The UV activated TL (ITL spectra) showed no principle differences in spectral intensity distribution. Generally, the pulsed plasma polymerized polyallylamine films emit with higher intensity compared to polyethylene. The ageing progression of both the pulsed and the cw-plasma species could be followed clearly when exposing the samples to the air. The longer aged the more intense are the ITL spectra in the case of polyallyamine. Here, a correlation of ITL spectra with the post-plasma XPS-measured introduction of oxygen is given when comparing Figs. 5 and 6 with Fig. 12. Therefore, the auto-oxidation of films during their storage seems to play an important role for the behaviour of ITL spectra. On the other hand, the concentration of implemented oxygen alone does not play the exclusive role because the intensity of ITL spectra of pulsed plasma produced polyallylamine is much stronger than that of the cw-plasma produced species and the XPS-measured O content is lower (cf. Fig. 12). Here, further investigations are in progress.

Chemical synthesis at plasma modified polymer surfaces

Jörg Friedrich, Gerhard Kühn, Renate Mix
Bundesanstalt für Materialforschung und –prüfung, 12200 Berlin

Abstract
Polymer surfaces were modified in low-pressure glow discharge plasmas for introduction of monotype functional groups of different type and density. For this purpose three ways are selected, (**i**) oxygen plasma treatment followed by wet-chemical reduction of O functional groups to OH groups, (**ii**) plasma bromination for introducing C-Br groups and (**iii**) coating by deposition of thin plasma (co-) polymerized layers of functional groups-carrying monomers with OH, NH_2, COOH, epoxy etc. functionalities. Subsequently, these groups were used as anchoring points for chemical grafting of spacer molecules, oligomers, prepolymers, fluorescence labels, ionic and nucleic acid residues. This chemical grafting of organic molecules uses different simple chemical reactions. The yield in monosort functional groups at polymer surfaces ranged from 10-14 (process (**i**)), 20-45 (process (**ii**)) and 18-31 groups per 100 C atoms (process (**iii**)). The consumption of functional groups amounts 40-90% of all functional groups present at the surface and depending on the dimensions of grafted molecules. For infinitely variable tuning the number of functional groups process **iii** was executed as copolymerization of a functional group-carrying comonomer with a non-functionalized ("chain-extending") comonomer.

1 Introduction

Aim of this work was to introduce monotype functional groups at polymer surfaces and using them for subsequent chemical grafting of molecules, oligomers and polymers. The introduction of functional groups onto most often chemically inert polymer surfaces can be preferentially performed using plasmachemical processes. Such low-temperature glow discharge plasmas are well suited to attack the polymer surface, forming reactive sites, which are able to attach functional group-forming atoms or radical fragments from plasma. First attempts were made by Hollahan who used NH_3 plasma for introducing primary amino groups onto polypropylene surfaces and thus using these surfaces for interacting with heparin [1]. Later on it could be shown that the reaction of ammonia plasma with polymer surfaces always lead to the formation of co-existing N-functionalities of different types among them NH_2 groups not exceed a threshold concentration greater than 1-3 NH_2 groups per 100 C also for a total N-concentrations $\geq$ 20 N/100 C [2]. Attempts to unbalance this product distribution by feeding additional hydrogen to NH_3 yield without success [3]. The same is valid for introduction of O-functional groups onto polymer surfaces [4]. Also in this case a broad variety of O-functional groups is produced among them 2-4 OH groups/100 C are present. The formation of OH groups demands the preceding abstraction of H from the polymer thus the enormous rearrangements of the polymers well documenting. Also in this case an improvement in selectivity of the formation of only one type of O-functional groups is not realistic, otherwise the O-functionalization passes into polymer degradation and etching. Therefore, only a two-step process can be considered that repairs the unsatisfying result of the O_2 plasma modification by using a wet-chemical reduction process. This was firstly presented by Nuzzo and Smolinsky [5] and later perfected [6]. By this way 10-14 OH groups/100 C were synthesized (process **i**) with a maximum selectivity of about 60% within all O-functionalities [7].

An elegant one-step process was introduced by our group consisting of the polymer surface bromination by $HCBr_3$ (process **ii**) [8]. The tuning of the Br-concentration was reached by varying the treatment time. Thus, 20-45 covalently bonded Br-groups/100 C could be introduced onto the surface, with selectivities near 100%. Only traces of Br-anions were found as side-product.

A more complicated but very variable process (**iii**) was the pulsed plasma-initiated polymerization or copolymerization. Here, the wished monotype functional groups are provided by the monomer, which becomes polymerized in the pulsed plasma. The art of producing such 50 nm thick monotype functionalized polymer coatings consists in carrying out the plasma process so soft as possible to avoid fragmentations of monomers and to preserve and remain the functional groups of the respective monomer. This process uses short plasma pulses (0.1-1 ms), needed for monomer activation, and long plasma-off periods (1-100 ms), needed for a pure chemical chain propagation instead of the random recombination of fragments. Together with minimizing the plasma power-input the monomer fragmentation should be suppressed and the number of retained functional groups in the deposited plasma polymer layer should be maximum in comparison to the number of functional groups originally present in the monomer molecules. 60-95% of functional groups could be recovered at the polymer surface [9]. Now, the variety of

monomers suited for this "plasma-initiated" polymerization is similar to that of ordinary polymer chemistry. Thus, allyl alcohol, allylamine or acrylic acid produce OH, NH_2 or COOH groups, however, with the anomaly that under low pressure conditions the degradative chain transfer is absent, so that is possible to produce high-molecular weight allyl polymers. The same reaction principle is valid for copolymerization used to adjust the number of functional groups. Nevertheless, to a smaller content, the known disadvantages of all plasma techniques, as occurrence of trapped radical sites, auto-oxidation, crosslinking, irradiation defects etc. remain [10].

Now, the functional groups are open for derivatization and grafting for example using dioles and diamines (Br groups), silanes and isocyanates (OH groups), aldehydes (NH_2 groups) or alcohols (COOH groups).

2 Experimental

Plasma polymer layers were deposited in a cylindrical plasma reactor of 50 dm³ volume. The design of the plasma reactor has been described in detail in [11]. The reactor was equipped with a pulsed radio-frequency (r.f., 13.56 MHz) generator with an automatic matching unit and an r.f. bar antenna (length: 35 cm). The substrate foil was mounted on a continuously rotating, grounded steel cylinder (Ø= 10 cm, length= 35 cm, rotating frequency= 0.5– 1 s^{-1}) at 10 cm distance to the r.f. powered electrode. The duty cycle of pulsing was adjusted to 0.1 and the pulse frequency to 10^3 Hz. The power input was varied between P = 100 - 300 W. Mass flow controllers for gases and vapours, a heated gas/vapour distribution in the chamber, and control of pressure and monomer flow by varying the speed of the turbomolecular pump were used. The gas flow was adjusted to 75 - 125 sccm and the pressure was varied between 10 to 26 Pa depending on the respective polymerization or copolymerization process. The deposition rate was measured by a quartz microbalance.

Surface functionalization of PP foils in the O_2 plasma was performed in the continuous-wave (cw) mode. PP films, which were coated with plasma polymer layers of functional groups-carrying monomers, had been used without any additional plasma pretreatment. PTFE films were exposed first to H_2 r.f. plasma (continuous-wave mode) for 1 - 1800 s at a pressure of p = 6 Pa and a power of P = 300 W followed by deposition of adhesion-promoting plasma polymer layers.

The XPS and IR analyses have been described in detail elsewhere [12]. Here, only some important facts are summarized. The XPS data acquisition was performed with a SAGE 150 Spectrometer (Specs, Berlin, Germany) using a non-monochromatized MgK_α or AlK_α radiation with 12.5 kV and 250 W settings at a pressure $\approx 10^{-7}$ Pa in the analysis chamber. XPS spectra were acquired in the constant analyzer energy (CAE) mode at 90° take-off angle. Peak analysis was performed using the peak fit routine from Specs.

The FTIR spectra were recorded with a NEXUS instrument (Nicolet, USA) using the ATR (Attenuated Total Reflectance, 45° angle of incidence) technique with a diamond or a Ge cell ('Golden Gate', Specac, Kent, UK). The IR signal comes from a near-surface layer of the polymer film. The information depth depends on the material used as ATR crystal and amounts about <1.5 µm using Germanium and 2.5 µm applying diamond.

All solvents used were of analytical reagent grade. Toluene and THF were refluxed under N_2, and over sodium and benzophenone. Pyridine was distilled and stored over KOH pellets. Water was doubly distilled before use. All silanes were vacuum-distilled and all reactions were performed under N_2 atmosphere. Reactions on the polypropylene film were performed with pieces of 5 x 5 cm or for industrial applications with foils of 35 x 24 cm. Details of chemical synthesis are described in [6-10].

3 Results

3.1 Monotype functionalization

3.1.1 Reduction of oxygen plasma introduced O functional groups on PP and PE surfaces to OH groups by diborane

Using the oxygen r.f. pulsed-plasma modification the oxygen incorporation onto the surface of PP was identified by ATR-FTIR spectra. A strong carbonyl band (≈ 1700 cm^{-1}), alcoholic structures (≈ 1100-1200 cm^{-1}), a broad OH peak and adsorbed water related features (≈ 3100-3500 cm^{-1}) appear. Surfaces with an O/C ratio of about 0.2 were used for further chemical processing. The XP spectra of PP confirmed the plasma production of a strong O1s peak. After TFAA derivatization of plasma generated OH groups a small F1s peak at a binding energy of 689 eV is detected at the PP surface. The origin of this limited OH group formation in the oxygen plasma can be attributed to the largely absence of additional hydrogen sources, only abstracted hydrogen from the polymer backbone and hydrogen from dissociation of desorbed water are available. The diborane reduction strongly increases the yield of OH groups. Quan-

tification of this optimized process shows an improvement in OH yield from about 2-4 OH/100 C without further chemical post-plasma treatment to 13-14 OH/100 C maximum after chemical reduction with diborane under the best conditions. These conditions were the hydrolysis with NaOH and the oxidation of C=C in the presence of H_2O_2. $LiAlH_4$ increases slightly the yield in OH further.

3.1.2 Bromination

Polymer surface bromination using the bromoform plasma emphasized as a highly selective functionalization. Only negligible side-reactions were observed as the deposition of polymer layers, which was detected with a microbalance, as well as the formation of small quantities of bromide anions and traces of oxidized bromine as detected by means of XPS. The percentage of surface bromination could be varied between 0 and 45 Br per 100 C. Exposure to air causes a post-plasma addition of oxygen.

3.1.3 Williamson's ether synthesis to introduce spacers with OH end groups

Using the brominated PP surface, the C-Br groups reacted with sodium ethylene glycolates with n = 2,3,4,5 and 22 (PEG 1000) glycol units. Thus, this process forms spacer bonded OH groups. The concentration of these terminal OH groups can be compared to those, which are directly bonded to the surface (cf. with results presented in Sections 3.1-3.3) (Fig. 1). In the same way it is also possible using sodium hexamethylene diamine to produce a C_6 spacer with an amino end group (Fig. 1). Both end groups, OH and especially NH_2, are important for further biochemical synthesis. The synthesis was followed and controlled by XPS. In all these syntheses only 2 % Br was not consumed and remained at the PP surface. It was assumed that either steric problems played a role or these bromines were not situated directly at the surface. For all glycolate spacers a "functionalization density" of about 5 spacer bonded OH groups per 100 C was measured. Additionally, two directly at the surface bonded (without spacer) OH groups per 100 C atoms were also detected.

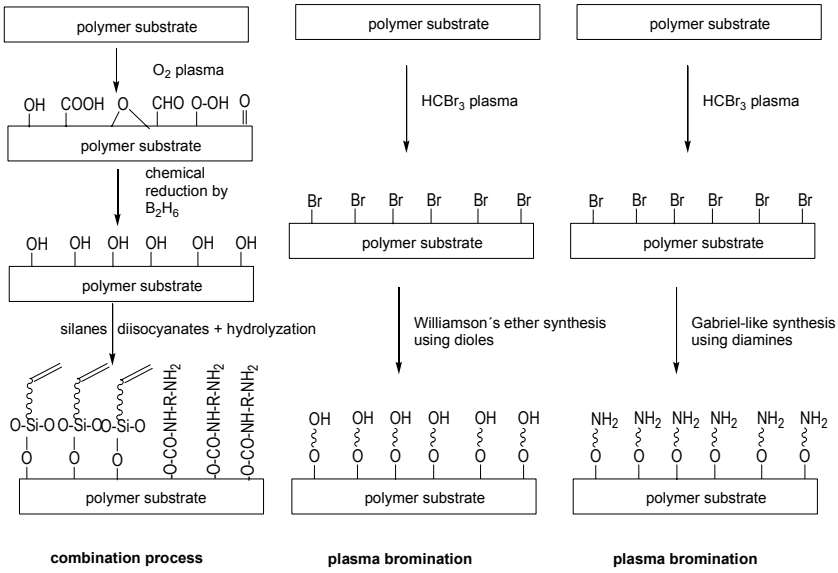

Fig. 1 Scheme of synthesis at brominated or hydroxylated polymer surfaces

3.1.4 Silane spacer

Undecenyltrichlorosilane was reacted with OH groups produced by oxygen plasma modification and hydroboration (B_2H_6/H_2O_2) (cf. Fig. 1). The yield of this reaction (attachment of C_{11} spacers) amounts to about 7. This means a selectivity of about 70% starting with 10 OH groups per 100 C. Additionally two OH groups directly bonded at the surface per 100 C atoms were also present. Subsequently, the undecenyl spacer was subsequently modified and now bearing bromo, cyano or amino groups in comparable yields and selectivities.

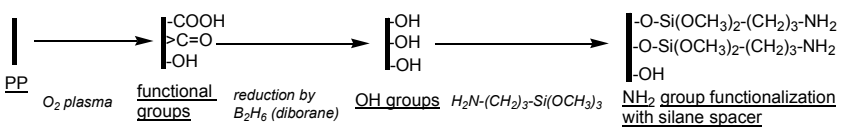

Fig. 2 Reaction scheme of covalent alanine grafting onto polypropylene surfaces

3.1.6 Azomethine group containing spacers and coupling of amino acids

Another synthesis, based on a hydroxylated polymer surface, consists in the attachment of γ-aminopropyltrimethoxysilane. This results in a polymer surface coated with primary amino

groups. These groups reacted with glutaraldehyde acting as a spacer. The spacer can facilitate the attachment of bioactive molecules such as phospholipids or amino acids and also can be used as a starting-point for biochemical synthesis. Therefore, simple amino acids, alanine and cysteine, were attached to the spacer (cf. Fig. 2). 4 to 6 carboxylic end groups were formed by this reaction pathway starting from 10 OH/100 C produced by oxygen plasma treatment and diborane reduction.

3.1.5 Isocyanate grafting

The consumption with diisocyanates (hexamethylene diisocyanate (HDI), methylene-di-*p*-phenylene isocyanate (MDI) and toluylene-2,4-diisocyanate (TDI)) is schematically shown in Fig. 3. Subsequently, different fluorescence labels (dansylchloride (DNS), dansylhydrazine (DNH) and dansylcadaverine (DNC)) were grafted. However, the reaction with HDI was too slow and the hydrolysis (Fig. 3a) not clearly reproducible. Using MDI and TDI the reactions 3b and 3c result in the attachment of ca. 1 fluorophore/100 C and in satisfying absorbance-fluorescence spectra.

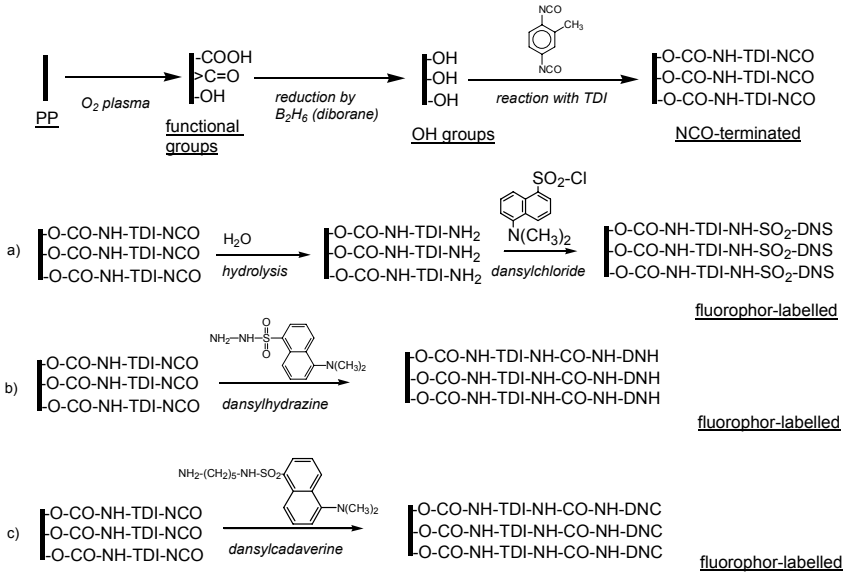

Fig. 3
Schematics of the reactions of hydroxylated PP surfaces with diisocyanates and fluorophores

3.2 Deposition of functional groups-carrying plasma polymers as anchoring points for grafting

3.2.1 Pulsed plasma polymerization

Allyl alcohol, allylamine and acrylic acid were pulsed plasma polymerised to retain a maximum in functionalities in the resulting plasma polymer. The respective pulsed plasma polymers were investigated for the retention or yield in functional groups. This retention was primarily measured by XPS including the chemical derivatization of these groups as described in Section 2. These layers were checked for side-products by respective IR spectra (Table 1).

Tab. 1 Absolute and relative yields in functional groups at the surface of deposited pulsed plasma polymer layers measured with XPS after derivatization (cf. Section 2, 100 W)

Group	Monomer	Theoretical stoichiometry	Measured stoichiometry	Yield in functional groups (per 100 C)	Characteristic side-products
OH	Allyl alcohol	100 C / 33 O	100 C / 3 O	31 (95%)	>C=O
NH_2	Allylamine	100 C / 33 N	100 C / 36 N / 4 O	21 (65%)	C-N-C, C≡N, C-O
COOH	Acrylic acid	100 C / 67 O	100 C / 60 O	26 (79%)	>C=O
-	Ethylene	100 C	100 C / 3 O	-	>C=O, C-O, C=C

3.2.2 Copolymerization

Exemplified with OH and COOH groups containing plasma polymer layers the qualification of these layers as models for monotype functionalized substrates with variable concentrations of functional groups should be proved. The plasma-initiated copolymerization of acrylic acid with ethylene or 1,3-butadiene is shown in terms of measured COOH- and OH-concentration as a function of the composition of the respective comonomer mixture (Fig. 4). Depending on the comonomer reactivity, a more linear correlation between precursor composition and produced COOH groups (butadiene) or a parabolic behaviour (ethylene) was observed. For each type and concentration of functional groups its concentration was determined by chemical derivatization followed by XPS analysis as described in Section 2. As shown in Fig. 4, similar tendencies were detected considering the allyl alcohol copolymerization with ethylene, butadiene or styrene. Here, different curve progressions are observed depending on the types of comonomers, their ratio in the precursor mixture and the plasma parameters. These deviations were attributed to the different copolymerization tendencies, for example expressed in copolymerisation parameters, which are also valid for the plasma-initiated gasphase copolymerization. Taking these curves as calibration it was possible to

adjust a defined concentration of functional groups in the deposited layer (Fig. 4). In the same way allylamine-copolymer and pure polyethylene-like layers were deposited. Also the nature and the quantity of side-products of these polymers were investigated. Generally, the number of side-products was minimum using low power values (cf. Tab. 2).

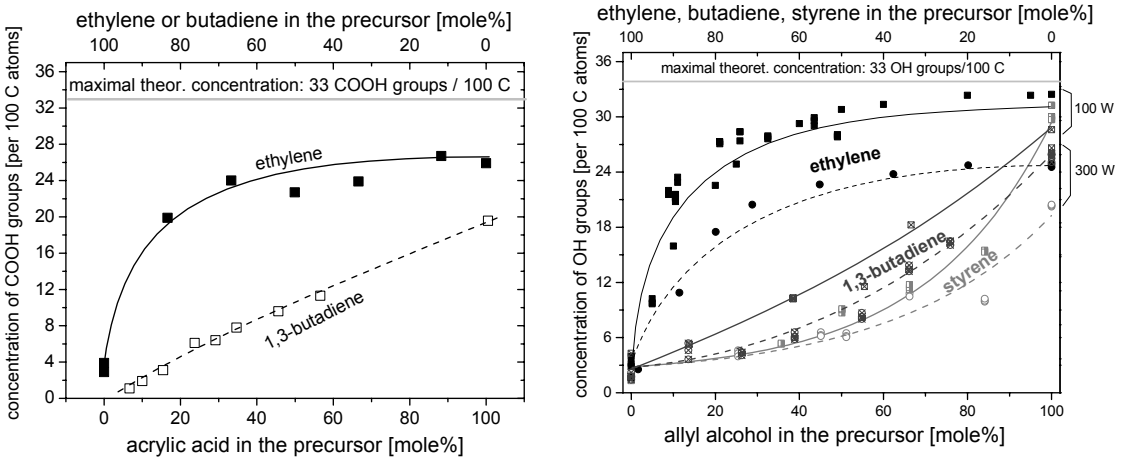

Fig. 4
Yield in COOH groups (a) and OH groups (b) in dependence on the composition of the precursor mixture and the types of comonomers (a – acrylic acid + ethylene or butadiene; b – allylalcohol + ethylene or butadiene or styrene)

Tab. 2 Comonomer pairs and yield in functional groups

Group	**Monomer**	**Maximum concentration (X per 100 C)**	**Suited comonomers**	**Range of concentration (X per 100 C)**
OH	Allyl alcohol	31	C_2H_4, C_4H_6, C_8H_8	0 - 31
NH_2	Allylamine	18	C_2H_4, C_4H_6, C_8H_8	0 - 18
	Diaminocyclohexane	12	C_2H_4	0 - 12
COOH	Acrylic acid	25	C_2H_4, C_4H_6, C_8H_8	0 - 25
Epoxy	Glycidylmethacrylat	10	-	-

The aim of this work was to produce defined layers with monosort functional groups, which can be used for grafting. Now, in contrast to the irregularly structured continuous-wave plasma polymers the structure of pulsed plasma polymers was so much improved that partial or complete solubility was observed. Therefore, the further chemical processing in solvents and water led to dissolving the layer. Here, also chemically crosslinking copolymers as butadiene, divinylbenzene and trivinylcyclohexane were necessary.

3.2.3 Introduction of fluorescence labels onto the surface of plasmapolymer layers

Fluoresceinisothiocyanate should be covalently bonded to polymer surface. For this purpose allylamine (and allylamine-butadiene copolymers – in process) polymer layers were deposited onto polypropylene foils (cf. Fig. 5). These layers were relatively stable at processing in aqueous solution or in THF. By means of derivatization of NH_2 groups with pentafluorobenzaldehyde or p-trifluoromethylbenzaldehyde their concentration was calculated to about 12 NH_2/100 C.

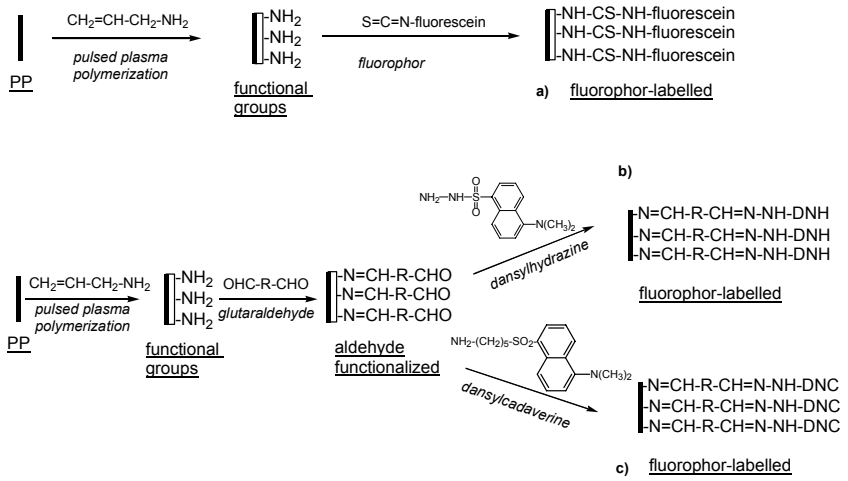

Fig. 5 Covalent bonding of fluorophores onto primary amino groups of allylamine pulsed plasma polymer layers (a-fluorescein bonding; b-dansylhydrazine bonding; c-dansylcadaverine bonding)

Two reaction pathways follow, the consumption with the thioisocyanate (a) and with glutaraldehyde and dansylhydrazine or dansylcadaverine (Fig. 5). Immediate transfer to wet-chemical processing avoided problems with the auto-oxidation of the amino group containing plasmapolymers, when exposed to air.

4. Conclusions

A few ways were presented for preparation of inert polymer surfaces with chemically reactive functional groups as Br, OH, COOH, NH_2 etc. It could be demonstrated that these functional groups are chemically available and, therefore, can easily react with organic molecules and prepolymers. The same is true for their reactivity towards metal atoms. First time, these functional groups are provided as more or less monotype functional groups. This monosort functionalization on polymer surfaces is a helpful pre-requisite for both to start graft reactions as well as to investigate metal-polymer interactions.

The functional groups could be formed by a combination process (plasma oxidation + chemical reduction, process **i**), by bromination (process **ii**) and by coating with monotype functional groups carrying polymer layers (process **iii**). The combination process leads to moderate yield in OH groups formation (10-14 OH/100 C) and shows moderate selectivity (60% of all O-functionalities appear as OH groups). On the other hand, this process allows it to covalently bond the OH groups directly onto the polymer molecules. The OH modification was stable if stored and exposed to air over longer periods (> 1 year). An adjusting of the OH group density at polymer surface was not reproducibly possible. The bromination was very selective and high concentrations could be introduced onto the polymer surface. The functional groups were also directly bonded to polymer backbones. Nearly all Br-sites were situated at the surface and, therefore, were open for chemical graft reactions. The concentration of C-Br groups was maximum compared with the other functionalization methods. Up to 40 C-Br/100 C could by produced with only negligible amounts of side-products. The concentration of C-Br groups could be slightly tuned by variation of the bromination time. Plasmapolymers from functional groups-carrying monomers allow a broad range of variation of both the type of monosort functional groups and the concentration. The concentration could be infinitely varied by copolymerization from 0 to 31 groups per 100 C atoms. In such a way OH and COOH groups carrying layers could be easily produced. They were resistant to long-time exposure to air. In contrast to that NH_2 groups containing layers show generally low yield in NH_2 formation, indications for reactions at the amino groups and a pronounced tendency of post-plasma oxidation. This oxidation during exposure to air may be ascribed to the auto-oxidation with oxygen from air initiated by trapped C radical sites in the layer.

Applications of these layers as targets for fluorescence sensor devices and biocompatible materials as well as for adhesion promotion have illustrated the ability of polymer surface chemistry.

Control of the metal catalyst particles for CNT production in a supersonic DC thermal plasma torch

L. Guo, J-L. Meunier and D. Harbec

Department of Chemical Engineering, McGill University, Montreal (QC), Canada

Abstract

The existence of metal particles plays an important role in the carbon nanotube synthesis process. Not only the coexistence of the carbon and metal catalyst is a crucial requirement for the successful growth of CNT, but also the size of the metal catalyst has a very important impact on the morphology of the nanotubes. In order to have some insights of the production of CNT in a DC thermal plasma reactor, modeling work concerning the evolution of fine metal catalyst has been carried out. The results of an analysis on operating parameters are presented.

1. Introduction

It has now been over ten years since the first confirmation of the existence of single-walled carbon nanotube(SWNT) [1]. These SWNTs have many proposed applications in super-strong fibers, composites, catalysts, molecular wires, straws, gears, switches, nano-electronic and photonic materials [2]. However, success in most of these applications will be base on the ability to synthesize large-scale coherent, defect-free nanotubes or nanotube assembly. In recent years, many studies have been made to investigate methods of mass production of this fascinating novel material. From the published papers on the synthesis of CNT, we could tell that no matter how these are produced, the existence of metal particles plays an important role in the process. Zhang and Iijima [3] reported their results of using different components as target using a Nd:YAG laser. Their results indicated that when there was no metal catalyst used in the system, no CNT was produced. Metals used for the synthesis of CNT include for example transition metals Fe, Co, Ni and Cu and lanthanide metals Gd, Y, and La. Because the coexistence of carbon and a small percentage of metal is required in the CNT growth zone, catalytic growth is believed to be the mechanism of the CNT formation [4]. A widely accepted concept is that the metal particles satisfy the dangling bonds of carbon caps and stop the premature closure of the CNT. It is also highly believed that the size of the particles is one of the key parameters for determining the morphology of the CNT [5].

D. Harbec et al developed an approach of producing CNT based on the dissociation of carbon containing gas(carbon tetrachloroethylene, (TCE), C_2Cl_4 in this case) using a DC thermal plasma torch [6]. Experimental results showed that a large amount of CNT can grow inside the torch itself. In this system, though no external supply of metal species were added, CNT was produced. The erosion of the cathode and anode provided the source of metal catalyst. The metal vapor are transported by the main plasma flux to the torch exit nozzle. The geometry of the nozzle provides sudden expansion in its upstream section. This expansion produces a strong quench of the plasma gas and the metal vapor it contains, forming a zone of nucleation of metallic nanoparticles. These are rapidly brought in contact with carbon injected in a radial direction within the same nozzle. Due to the extremely high local temperature, the size and geometry of the nozzle, it is practically impossible to perform in situ diagnostics on the nucleation inside the nozzle. This paper presents modeling work on the evolution of the metal catalyst and the distribution of the carbon containing gas in the nozzle based on computational fluid modeling and fine particle nucleation modeling. The arc region is not investigated, we concentrate on the phenomena occurring within the nozzle only. The FLUENT and FPM codes were used as modeling platforms. In this report, we focus on finding appropriate operating conditions for attaining the desired size distribution of fine metal particles in this DC plasma torch system. The operating parameters include plasma gas flowrate, operating pressure and power level of the torch. These are connected with experimental results obtained on the plasma torch system [6,7,8].

2. Description of the Computational domain

The schematic of the computational domain is showed in Figure 1. The nozzle is water-cooled, cylindrical and shows a sudden expansion before the carbon-containing gas injection. The metal vapor, in the present case tungsten vapor, comes from the erosion process of the electrodes and enters the nozzle along with the plasma gases (argon or helium). The carbon containing gas comes into the system with the same carrier gas as the plasma gas. It will dissociate in the nozzle and provide C and Cl atoms and molecular species. In this paper we do not model the dissociation reaction of TCE, we consider instead the molecule as non-breakable and only consider its mass. The nozzle has a 100% change in diameter, changing from 0.5cm to 1cm upstream of the TCE injection. The high velocity of the plasma gas and the sub-atmospheric operating pressure in the reactor generates on the axis of the nozzle at node A a mach number as high as 5.37 (500 torr), and 1.52 (200 torr) in the case of helium plasma gas. We are in a supersonic region and the compressibility of the gas can not be neglected.

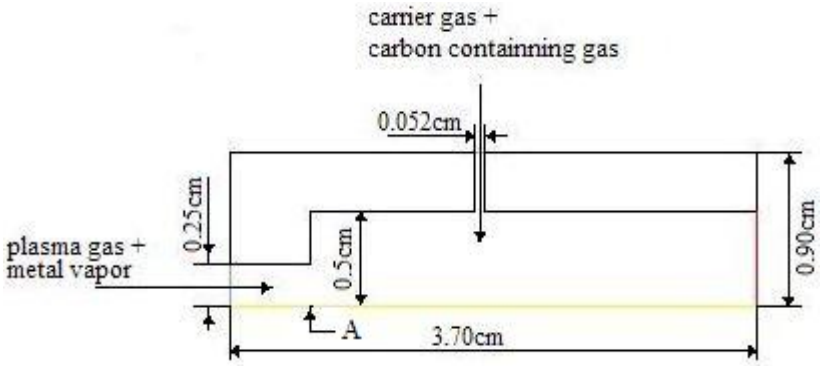

Figure 1. Computational domain.

3. Modeling work

3.1 Assumptions

In the modeling work, some major assumptions used are as follows:

(a) Plasma is at LTE, the process is operated under steady state, the nozzle is axisymmetric
(b) The radiative heat losses are negeleted
(c) The physical properties of the mixture follow the ideal gas mixing law, the fluid follows ideal gas law
(d) The particle size distribution is approximated by a lognormal distribution
(e) The particles are in thermal equilibrium with the plasma gas

3.2 Modeling approach

FLUENT(6.1.22) has been used to perform the modeling of the flow and temperature field, FPM is used to take care of the particle formation part. Classic K-ε model is chosen to calculate the effect of turbulence in sets of conservative equations. The conservative equations are solved with strong coupling to represent the effects of compressibility of the flow. Since the tungsten vapor comes from the erosion of the electrodes and has a very low concentration in the flow, the diffusivity of tungsten vapor in the gas phase is based on constant dilute approximation and is set as 2.88×10^{-5} (default value of FLUENT). In the case of TCE, the diffusivity is evaluated using [10]:

$$D_{AB} = \frac{2}{3}\left(\frac{k_B}{\pi}\right)^{3/2}\left(\frac{1}{2m_A}+\frac{1}{2m_B}\right)^{1/2}\frac{4T^{3/2}}{p(d_A+d_B)^2} \qquad (1)$$

In this equation k_B is Boltzmann's constant, p is the pressure in Pa, m_A and d_A are the mass and equivalent diameter of species A, respectively species B. In order to obtain a conservative estimate of the diffusion of the TCE, the molecular weight of TCE in non-dissociated form was applied in this equation. But since in this specific model the flow is turbulent, the laminar diffusivity should not influence the diffusion process very much.

In the modeling of particle formation, the carbon containing gas was not been taken into account, only the mass flowrate value of TCE was considered. Coagulation is calculated using Dahneke kernel function, Girshick model [11] has been chosen to deal with the particle nucleation, and particle condensation, thermophoresis and Brownian diffusion are all included in the calculation.

3.3 Calculation conditions

The chosen calculation conditions are as follows, based on experimental parameters:

The power added to the plasma gas is 45KW or 35KW, and the static pressure at the outlet of the nozzle is 200torr or 500torr. The mass flow inlet condition has been assigned to both plasma gas inlet (6.09×10^{-4} kg/s for helium plasma gas and 2.726×10^{-3} kg/s for argon plasma gas) and carbon containing gas with carrier gas. The torch efficiency is 75%, and the walls of the nozzle have a static temperature of 300K since they are all water-cooled. The mean mass ratio of tungsten vapor with respect to 225slpm helium plasma gas is 7.8095×10^{-5}, the molar flowrate of the carbon containing gas is 0.15 mol/min, while the flowrate of the carrier gas is 20slpm.

4. Calculation Results and discussion

Calculation results of static temperature fields are presented in Figure 2 for the case of helium plasma gas, plasma power level of 45KW, plasma gas flow rate of 225slpm, operating pressure 200torr and 500torr respectively. We can clearly see that there are shock waves inside of the nozzle. We see that under different operating pressures, the position of the first shock, the distance between each shock core and the number of shock waves in the nozzle is different. Since each expansion and compression of the gas correspond to regions of transfer between thermal energy and kinetic energy [3], the temperature and velocity fields vary enormously under different operating pressure and strongly influence the evolution of metal particles in the nozzle.

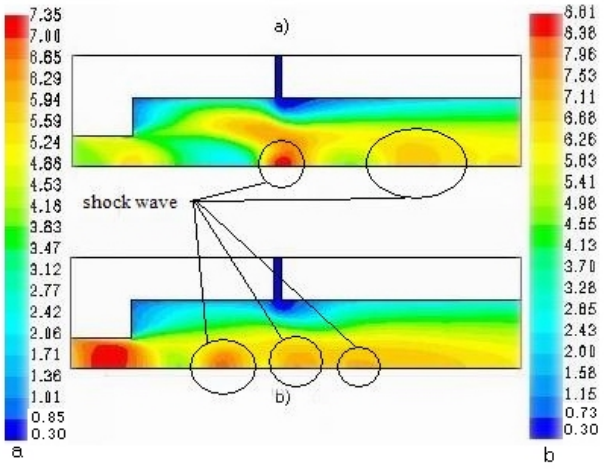

Figure 2. Static temperature contour for helium(10^3K)
(a. 200torr, b. 500torr)

The critical cluster size is defined as follows[12]

$$d_p^* = \frac{4\sigma_m v}{k_B T \ln S} \qquad (2)$$

where d_p^* the critical cluster size, σ_m the surface tension of the metal species, v the volume of a single metal atom, T is the local temperature. Parameter S is the saturation ratio of the metal vapor.

$$S = x_m * p / p_m \qquad (3)$$

where x_m is the molar ratio of metal vapor, p the local pressure, and p_m the saturated pressure of the metal.

In the model of the particle formation, we made the assumption that the particles which are smaller than the critical sized particles will not stay stable. From Equation 1 we can easily tell that the particle size and number distribution will change enormously in the supersonic area. This change could be favorable for maintaining the particle size to small values. Every compression area will have an extremely high temperature and particles coming into this area will re-vaporize to metal vapor or smaller particles and will re-grow in the following expansion zone. So the existence of the shock waves actually gives us opportunity to control the nucleation of the particles. As we can see in Figure 2, the position and number of the shock waves can be influenced by the operating pressure, which is a controllable parameter. And since the supersonic flow is also very closely related to the flowrate and energy of the flow, we will estimate the possibility of controlling the shock waves by adjusting these parameters so as to control the fine particle formation inside of the nozzle.

4.1 Changing operating pressure

As presented in Figure 2, the shock waves travel in the nozzle as the operating pressure changes. Figure 3. presents the contours of particle number density and particle size distribution in the nozzle under the same operating conditions as Figure 2. The expansion of the gas and the cold carrier gas generate a strong quenching for the plasma gas and create a strong temperature gradient inside of the small nozzle. The local partial pressure of the metal vapor also increases due to the decrease of the local pressure in the expansion area. These explain the reason why we obtained particle nucleation near the centre of the nozzle although the temperature is relatively high in this zone. However in the area of compression that follows, the formed particles vaporize because of the high local temperature and high local pressure in this zone. We can see from Figure 3 that there are "particle number shock waves", the density of the particles decreases and then increases again following the shock wave pattern. From Figure 2, we can see that strong temperature gradients exist near the water-cooled nozzle wall, this location providing favorable conditions for the nucleation of particles. From the calculation results of the tungsten particle number density and the mass distribution of carbon containing gas (as given in Figure 4), the area which is very close to the nozzle wall has a high tungsten particle concentration and a high ratio of carbon species. This correlates with experimental results showing a large quantity of carbon nanotube growing on the wall of the nozzle. Comparing the tungsten particle number density distribution under 200torr and 500torr, the formation of the particles is being pushed downstream with increasing pressure. This enables the possibility for producing the CNT inside the reactor instead of in the nozzle itself. This correlates with the results on the experimental reactor. One may note from Figure5 the relatively difficult penetration of the carbon precursor inside the main plasma flow. Under this configuration, 80% of TCE is mainly confined along the cold nozzle wall and induces and important carbon deposition in this zone, as observed experimentally [6]. Changing other parameters as mentioned can also change the size distribution of the particles inside the nozzle.

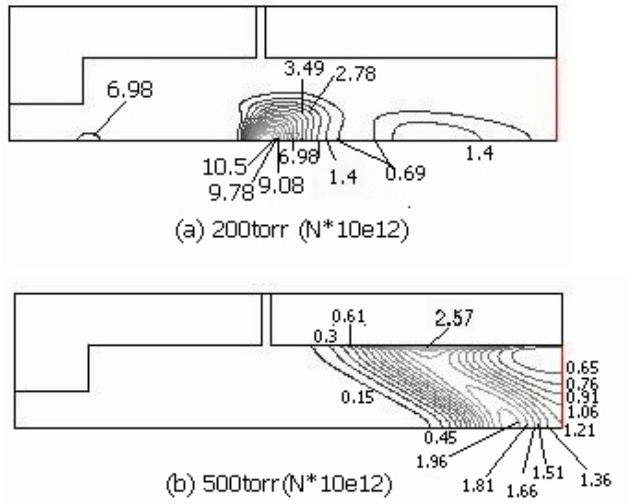

Figure 3: The number density distribution of particles in the nozzle(N/m^3).

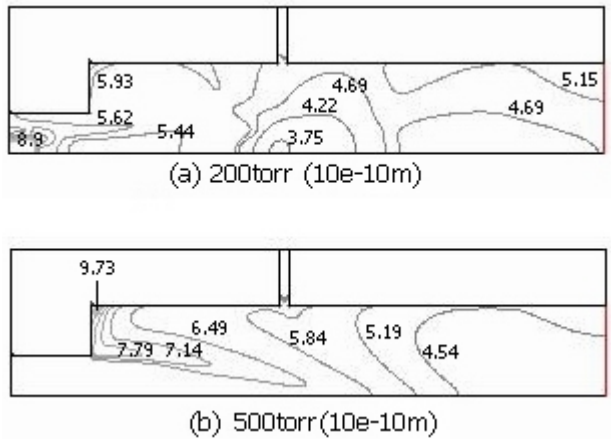

Figure 4: Size distribution of particles in the nozzle (m).

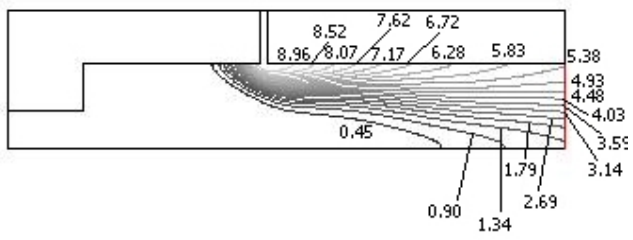

Figure 5: TCE mass ratio contour (45kW, 200torr)($x10^{-2}$).

4.2 Results with different plasma gas flowrates

Assuming all other conditions stay constant, we can study the effects of the plasma gas flowrates. Figure 6 shows the static temperature field, particle number density contour and particle size distribution field when the nozzle is operating under 200torr with a reduced helium plasma gas flowrate of 150slpm. Comparing with Figures 2(a), 3(a) and 4(a), we see first that the temperature is higher at this reduced flow rate since the power level is kept constant. As a

consequence, the particle number density is also lower, the high temperature is helping in this case to keep the metal species in the gas phase. There is not a strong difference between the two particle size distribution fields. Lowering the flow rate while keeping the power level constant can increase the energy of the plasma gas. It therefore helps to decrease the number of particles in the nozzle. More metal vapor would then be available to enter the reactor and grow catalyst particles outside of the nozzle.

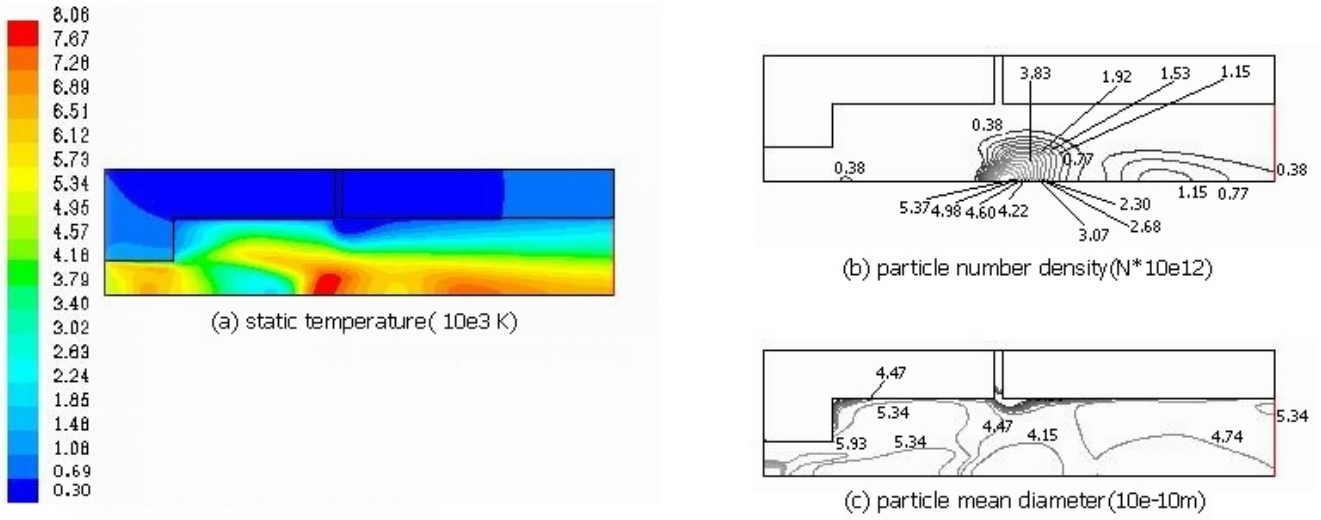

Figure 6. The temperature field (a), particle number density (b) and particle size distribution (c) under 200torr pressure, with a plasmas gas flow rate of 150slpm, and a power of 45kW.

4.3 The effect of change of the power level

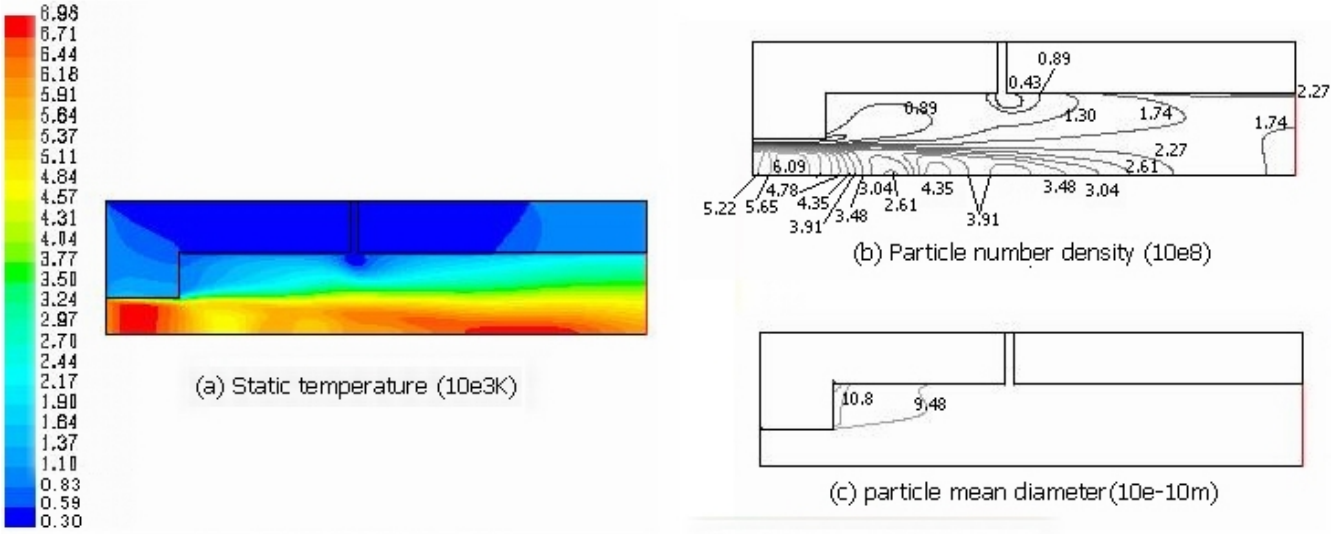

Figure 7. The temperature field(a),particle number density(b) and particle size distribution(c) under 500torr, with plasmas gas flowrate 225slpm, 35KW

Figure 7 shows the static temperature field, particle number density contour and particle size distribution field when the nozzle is operating under 500torr with a helium plasma gas flow rate of 225 slpm, a power level of 35KW. From the temperature field we can see that the shock waves are not as strong as what is observed at 45kW(Figure 2b). The position is pushed downstream, and both the temperature and temperature gradient are lower. When the power level is 35kW, the number density of the particles is quite low compare to the 45kW case. We can see from the temperature field that the high temperature area moves towards the outlet of the nozzle. As a consequence, the number density of the particle decreases along the main plasma gas flow. This is a favorable

condition for preserving the metal vapor into the reactor.

5. Conclusions:

The objective of this paper is to perform a parameter analysis with the aid of a CFD numerical model coupled to a particle nucleation model. Comparing the computational and the experimental results, one has a possibility to adjust operating parameters such as the pressure, power level and flow rate of the plasma gas, to modify the number and position of the shock waves inside the nozzle and the resulting evolution of the particles. Metal particles nucleate and grow in the expansion area but re-vaporize in the compression zone. From the calculation results, we come to a conclusion that higher operating pressures are favorable for pushing the formation of finer particles into the reactor along with the formation of CNT. This correlates well with experimental result [6]. From similar calculations, lower torch power is also favorable for preserving the metal vapor. The calculated particle sizes are smaller than the values obtained experimentally [6]. This could be attributed to the exclusion of the reaction energy term from the TCE dissociation. This contribution could also be an important factor behind the formation of nanometer-sized particles in the nozzle.

Abstract

This work will present the experimental results of our investigations of the electron heating in Thomson scattering experiments obtained for atmospheric-pressure argon thermal plasma. The spatially and temporally (in time of the laser pulse duration) resolved LTS spectra enabled us to follow the evolution of T_e. These experimental results will be compared to the theoretical ones obtained with the model of Murphy.

1. Introduction

Thomson or incoherent scattering is the process of scattering of low energy photons ($\hbar\omega \ll m_e c^2$) on free electrons present in a plasma. These electrons, in a plasma, are not completely free but they are exposed to the electric microfields. This weak coupling causes coherent or collective scattering events. All electrons located in a sphere with the size of a Debye length λ_D oscillate in phase yielding a coherent scattered signal if, for the scattered wave $\lambda = \lambda_L/(2\sin(\theta/2))$ (see Fig. 1a), the condition $\lambda \gg \lambda_D$ is valid. In the opposite case, $\lambda \ll \lambda_D$, the scattering process is incoherent. The character (incoherent/coherent) of the scattering is measured by the so called scattering parameter $\alpha = \lambda/(2\pi\lambda_D)$ which determines the shape of the scattered spectrum (see Fig. 1). The theory of Thomson scattering has been presented in detail in many publications [1, 2, 3]. The interpretation of the experimental Thomson-scattered spectra is, in most cases, straightforward and gives direct access to the electron density n_e and the electron temperature T_e.

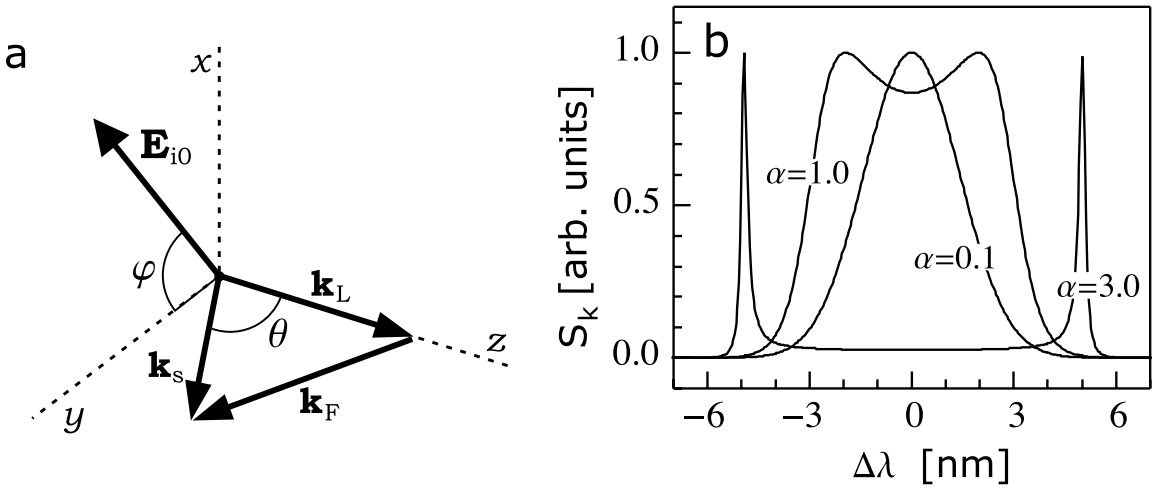

Figure 1: a). The Thomson scattering geometry and definition of the scattering angle θ and the angle φ between the plane of scattering and the polarisation vector $\mathbf{E}_{i0}$ of the incident laser beam. $\mathbf{k}_L$ and $\mathbf{k}_s$ are the wave vectors of the incident laser beam and the scattered light while $\mathbf{k}$ is the scattering vector ($\mathbf{k} = \mathbf{k}_s - \mathbf{k}_L$). b). The electronic part of the spectral density S_k calculated for $\theta = 90^o$, $\lambda_L = 532$nm and for different values of scattering parameter α.

The determination of n_e and T_e of thermal plasmas by spectrum analysis of the Thomson scattered light is attractive because it does not require any assumption about local thermodynamic equilibrium and, unlike optical emission spectroscopy, gives the spatially-resolved results. Moreover, since in thermal plasmas $k_B T_e > 1$ eV and $n_e > 10^{22}$ m^{-3} so $\alpha > 1$ and the electron temperature and density can be simultaneously determined based on the individual Thomson scattered spectrum. On the other hand, due to very low cross section for the Thomson scattering process ($\sigma_{Th} \equiv r_e^2 = 6.6 \times 10^{-25}$ cm^2), measurements require high power pulsed lasers in order to obtain a detectable signal level. However, it can result in significant disturbance of the plasma state predominantly due to electron heating by the laser pulse in the inverse bremsstrahlung process. The corrections of T_e for the laser power are commonly based on estimations made by Kunze [1]. According to these calculations the relative change in electron temperature is directly proportional to the laser power. Such dependence suggests measurements of Thomson-scattered spectra at different laser powers and then simple extrapolation of the determined electron temperature to the zero laser power. Such a linear extrapolation, in the case of thermal plasmas, yielded T_e well in excess of the expected values. These discrepancies were observed in many experiments with the laser Thomson scattering as a diagnostic tool [4, 5, 6].

The problem of the electron heating by the incident laser beam has been recently studied by Murphy [7]. He solved one-dimensional equation for the electron heating by absorption of laser radiation and cooling due to such processes as: electron thermal conduction, energy transfer to heavy particles by elastic and inelastic processes and by radiative emission. These calculations show highly nonlinear dependence of the derived electron temperature on the laser power and that the usual linear extrapolation leads to an overestimatation of T_e in thermal plasma.
The goal of our work was to give, at least qualitatively, some experimental evidence for plasma disturbance by the laser pulse. We also studied an evolution of the Thomson scattered spectra within the spatial and temporal profile of the laser beam which enabled to determine evolution of n_e and T_e.

2. Experimental setup

In our experiment we used a second harmonic of a Nd:YAG laser ($\lambda_L = 532$ nm) which delivered laser pulses of energy E_p up to 200 mJ and of about 6 ns duration time. The beam was passing through the beam attenuator and then it was focused to the spot of 150 μm on the plasma axis and a few millimeters z above the cathode tip. The scattered light was collected at a angle of 79.2^o with respect to the laser beam. The investigated plasma volume was imaged onto the entrance slit of a spectrograph (1.6 nm/mm reciprocal dispersion) with an enlargement factor equal 1. In order to improve S/N ratio the polarizer with the polarization axis parallel to the laser beam polarization vector was placed on the path of the scattered light beam. Finally, the scattered spectrum was registered using a gated two-dimensional intensified charged-coupled (ICCD) array with the gate width as short as 2 ns. The gate was delayed with respect to the triggering laser pulse.
In the experiment we can only measure the intensity of the scattered light integrated along a line of sight e.g. across the laser beam. In order to obtain some local values (spatially resolved Thomson spectra across the laser beam) we applied the Abel inversion transformation. The final spatial resolution across the laser pulse was limited by the pixel size of the ICCD camera which was $20\,\mu m \times 20\,\mu m$.
The details concerning plasma generator one can find in [8]. In the following presented results, the gate width of the ICCD camera was 2.5 ns and the arc was generally operated at I=100 A.

3. Results and Conclusion

Figure 2 shows the Thomson scattered spectra obtained from the plasma across the laser beam. The experiment was performed for the arc discharge current of 100 A and the axial region of plasma 4.0 mm above the cathode tip was studied. Energy of the laser pulse was set to 150 mJ while the gate width of the ICCD camera was 2.5 ns with 0 ns delay time with respect to the center of the laser pulse.
It is observed that both the distance between two peaks and their width increase while approaching the center of the laser beam. It follows that plasma parameters (n_e and T_e) vary with the laser beam which implies the disturbance of the plasma state by the laser pulse.

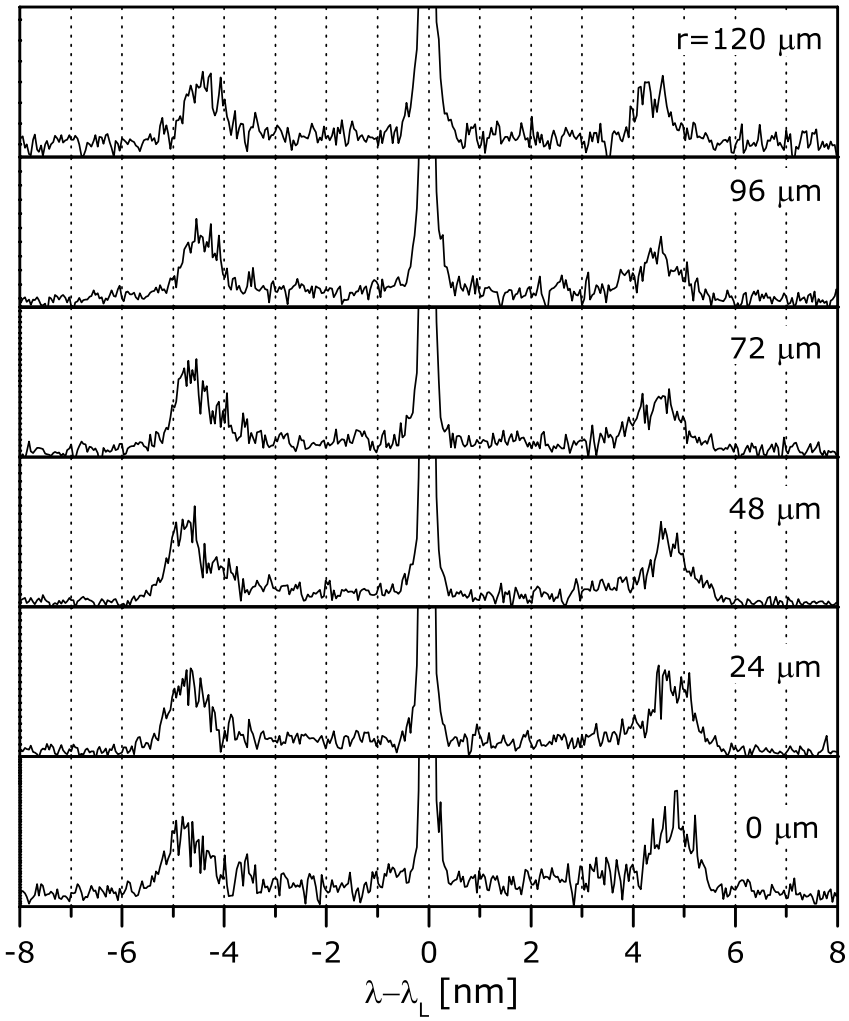

Figure 2: The Thomson scattered spectra determined for different positions across the spatial profile of the laser beam. Distances $r = 0\,\mu$m and $120\,\mu$m correspond to the center and the wing of the pulse, respectively [I=100 A; z=4.0 mm; E_p=150 mJ].

Under similar discharge conditions as in Fig.2 we investigated the temporal evolution of the Thomson scattered spectra setting the ICCD gate width to 2 ns and measuring the scattered light at different moments of the laser pulse. Figure 3 shows the Thomson scattered spectra determined for the central part (with the use of Abel transformation) of the laser beam. The delay of 0.0 ns corresponds to the maximum of the laser pulse while negative and positive delays correspond to its front and wing, respectively.
As one can observe the spectrum of the scattered light changes during the laser pulse. The spectral distance between two peaks and their width first increase with rising the pulse and then start to decrease at the delay time of +6.0 ns. This is the direct result of plasma temperature and electron density variations due to the interaction of plasma with the laser pulse.

The temporal evolution of plasma parameters (n_e and T_e) during the laser pulse was determined from the registered Thomson scattered spectra and is presented in Figures 5a-b. The gate width was set to 2.5 ns and the axial volume z=6.0 mm above the cathode tip was investigated at the discharge current of 100 A and at different energies of the laser pulse.

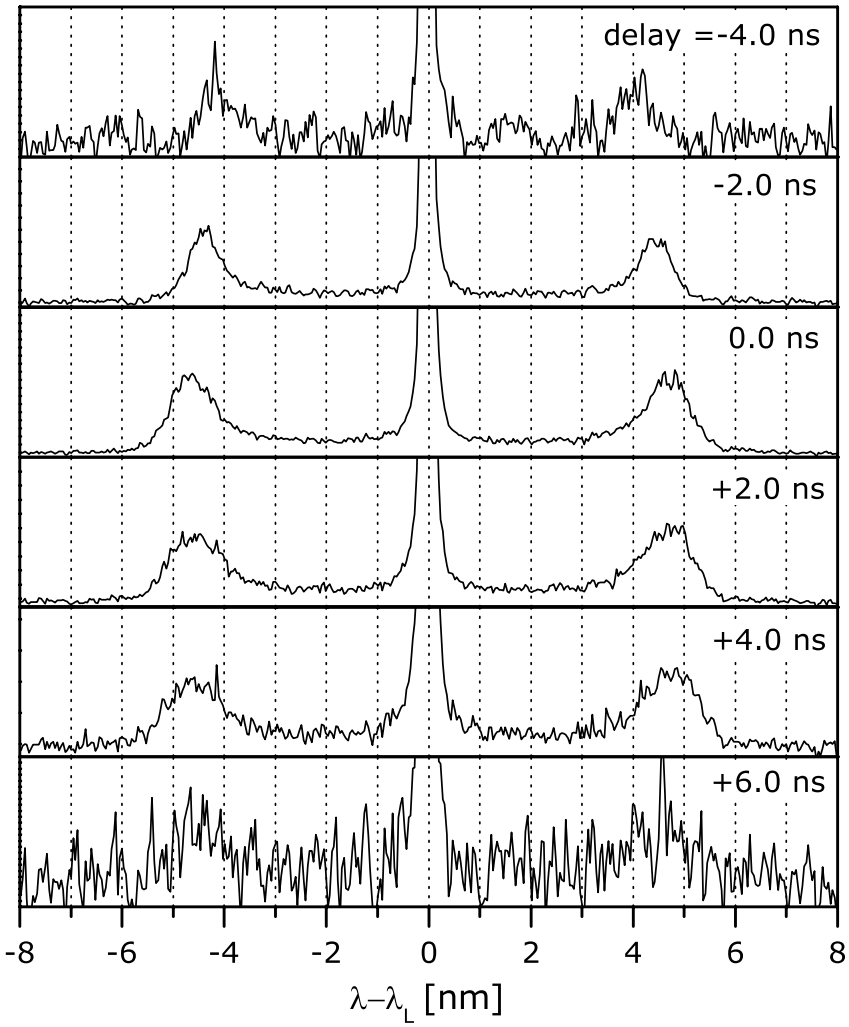

Figure 3: The Thomson scattered spectra determined at different moments of the laser pulse. Delay of 0.0 ns corresponds to the center of the laser pulse while negative and positive delays correspond to the front and the wing of the pulse, respectively [I=100 A; z=4.0 mm; E_p=150 mJ].

For the range of investigated energies of the laser pulse, T_e rapidly growths when the laser pulse is switched on. The higher laser energy the higher final temperature can be reached at given initial plasma parameters. Since the decay of T_e is slower than the decay of the laser pulse it follows that plasma processes are not fast enough to make it thermal at each moment of the laser pulse. At the same time the rapid increase of the electron density is observed only in the case of the highest laser energy ($E_L = 150\,\mathrm{mJ}$). No significant variation of n_e is observed during the laser pulse for the pulse energies E_p of 50 mJ and 20 mJ. It implies that for these lower energies photoionization processes are of minor importance unlike the electron heating by the laser pulse.

Abstract
Quartz-like deposition tracks were produced from HMDSO/O_2 gas mixture (1:120) by means of micro-jet plasma chemical vapor deposition (MJPCVD) with a moving capillary. Virtually carbon-free quartz-like depositions were obtained at high power input. SEM analysis revealed a compact structure with some fine cracks. At a lower power input, uniform and densely packed nanospheres are produced and there are some traces of hydrocarbons in the deposition.

Keywords
Quartz-like deposition, micro-jet, plasma CVD, XPS

Introduction
The plasma deposition of SiO_2 using hexamethyldisiloxane (HMDSO) or tetraethoxysiloxane (TEOS) as precursor mixed with oxygen has been investigated extensively [1]. RF HMDSO/O_2 plasma deposition is widely used to produce a stable and long-life quartz-like deposition for gas barrier applications in packaging industries or for scratch resistance coatings of optical components. Such a SiO_2 deposition might possibly be used as an optical wave guide. However, a major source of attenuation of the wave propagation results from the morphology of the deposition. The chemical composition influences the optical quality, as well. Thus, a hazy layer will scatter the light [2, 3]. Plasma parameters as the oxygen flux or the power input influence the deposition of SiO_2 films, too.
Most of the plasma techniques target large area coatings. The preparation of a structured coating usually requires several steps such as the use of an appropriate mask followed by the dry-etching. A novel plasma technique for well-defined and localized deposition with extremely high deposition rate, called micro-jet plasma chemical vapor deposition (MJPCVD), was developed [4, 5, 6, 7]. This technique is based on the process gas injection through a capillary into a vacuum chamber and the RF plasma excitation of the jet. In this study, we report about our investigations of localized depositions of quartz-like coatings by means of MJPCVD as a function of the power input.

Experimental part
The MJPCVD experimental apparatus consists of a 4.63 dm³ stainless steel vacuum chamber with a home-made symmetric copper electrode configuration [7]. A shielded electrode which was powered by a 13.56 MHz RF generator and the grounded electrode were used to ignite the glow discharge. The chamber was pumped with a two stage rotary pump (Trivac DB16 from Leybold), and the pressure was measured with an absolute pressure transducer MKS Baratron (type 62A). A mass flow controller was used to control the gas mixture flow rate. The gas mixture comprises the organosilicone precursor hexamethyldisiloxane ($C_6H_{18}OSi_2$ 98.5% for gas chromatography from Fluka) and oxygen 3.5 (99.95 Vol. % pure). The oxygen was injected into a 0.785 dm³ stainless steel bubbler which contained the precursor liquid. The pressure in the bubbler was adjusted with the oxygen gas to p_1=5 bar. The resulting HMDSO concentration in the mixture was fixed at 120:1. The HMDSO, which has a vapor pressure of 4457 Pa at 20°C, was transported by the oxygen carrier gas.
The capillary position was accurately adjusted in front of the substrate and between the two electrodes, using an ultra-high vacuum motorized x-y-z manipulator (Huntington MPM-275). The 125 µm inner diameter and 5 cm length capillary, positioned normal to the substrate, was used to inject the reactive gas mixture into the vacuum deposition chamber and through the glow discharge. During the experiments, the capillary was maintained at 8.75 mm on the x-axis, corresponding to the injector-substrate distance. It was moved vertically along the substrate (y-axis) with a velocity of 175 µm/s to produce a one centimeter deposition track on the substrate.

The power input was varied up to 80 W, while the other parameters were maintained constant, namely the chamber pressure at 0.72 mbar and the flow rate at 50 sccm.
The deposition process was carried out onto substrates made of glass, aluminum or KBr. Except for the KBr, the substrates were cleaned in a solution of ethanol during 15 min in an ultra-sonic bath and then pre-treated with oxygen plasma for 1 min at 0.60 mbar with 60 W and 100 sccm O_2.
The Dektak³ST stylus surface profilometer was used to determine the surface topography of the deposition track. For the chemical characterization of the deposition we used Fourrier-transform infrared spectroscopy (FTIR) (in transmission mode with coated KBr), x-ray photoelectron spectroscopy (XPS), and scanning electron microscopy (SEM). FTIR spectra were obtained with a Perkin Elmer FTIR microscope system 2000 by means a 100 µm blind aperture. XPS spectra were obtained by using an Axis165 (Kratos Analytical, UK) with monochromatic Al Kα radiation (20 mA at 15 kV) in hybrid mode (with electrostatic and magnetic lenses). The spot size of approximately 0.3×0.7 mm^2 was applied to determine the relative concentration of elements from the integral intensities of photoelectrons. The sampling spot size was reduced to 120 µm in diameter for the laterally resoled measurements. The high resolution spectra were fitted with Gaussian curves after the subtraction of a linear background.

Results and Discussions

Profile

Figure 1 shows a profile of quartz-like deposition track. The width of the profile is approximately 2.6 times the inner diameter of the capillary. Less than 1 min is required to produce 1 cm long and 63 µm high quartz-like track with an extremely high deposition efficiency of 84 %. The average deposition efficiency reflects the conversion of the monomer to silicon oxide and can be expressed as follows:

$$Eff.(\%) = \frac{Quartz-like\ mass\ deposited}{SiO_2\ mass\ from\ the\ flow\ rate} \times 100$$

Eq. 1: Average deposition efficiency

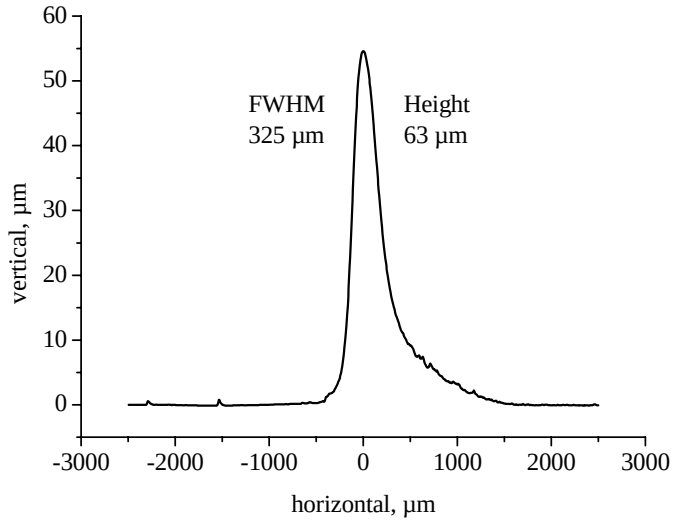

Fig. 1: Profile of a quartz-like deposition track (0.72 mbar, 50 sccm, 70 W)

Chemical composition

A XPS spectrum of quartz-like depositions from a O_2/HMDSO (120:1) mixture is shown in figure 2. Peaks of O1s, C1s, Si2s and Si2p core levels are distinguished. The high-resolution spectra of Si2p and C1s were fitted with Gaussian functions. Si2p peak was fitted only with the doublet $Si2p_{1/2}$ and $Si2p_{3/2}$ at 103.6 and 104.2 eV, respectively. There is no signal at 102.4 eV, which would be assigned to silicon atoms with bonds to carbon atoms like in methyl groups of the HDMSO molecule $(CH_3)_3$-Si-O-Si-$(CH_3)_3$. According to the peak fit, silicon atoms are surrounded by oxygen atoms only. The major component of the C1s spectrum was found at 284.91 eV (C-H/ C-C units). Minor quantities of C-O and O-C=O were detected, while there is no sign of carbon atoms with bonds to silicon C-Si (binding energy 284.5 eV). The carbon found in the spectrum (Fig. 1) is assumed to originate from surface contamination.

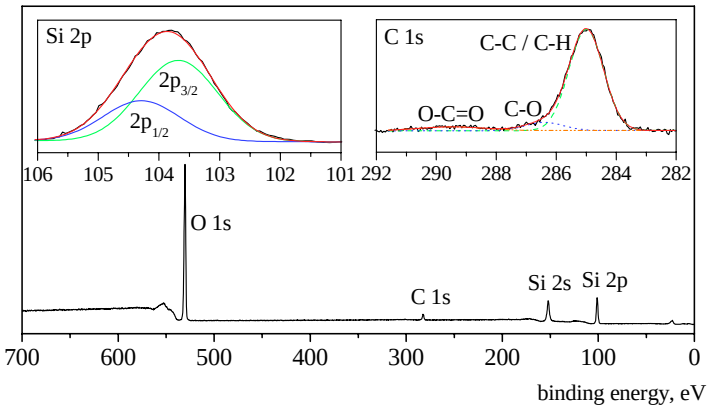

Fig. 2: Wide spectrum of a quartz-like deposition (capillary 125 µm × 5 cm, 0.72 mbar and 50 sccm O_2/HMDSO (120:1), 70 W and 7.95 mm injector distance)

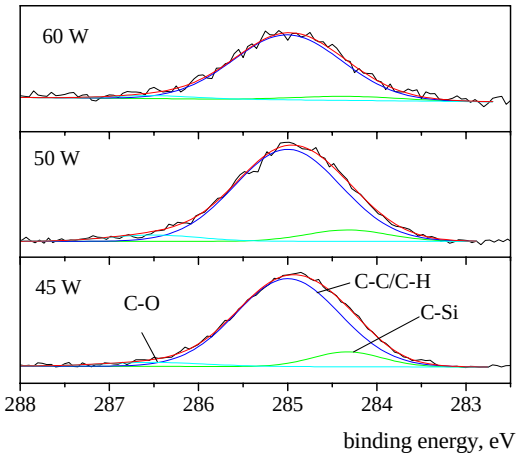

Fig. 3: C 1s spectra of quartz-like depositions prepared at varying power input.

The elemental surface compositions of the deposition track prepared at different power inputs reveal that the carbon content in the deposition decreases when the power input increases (Tab. 1). The ratio [C]/[Si] decreases from 0.29 to 0.06 for 45 and 70 W, respectively. The C 1s spectra show the various binding state components (Fig. 3). Most of the carbon atoms are bonded to carbon or hydrogen atoms and fewer to oxygen atoms. However, at low power input, the spectrum shows a small amount of C-Si bonds, which decreases when the power increases and it disappears completely at higher power (P>70 W). A low power input (P<70 W) results in the production of a more polymer-like deposition C-Si features in the C1s spectrum.

Table. 1: Element composition of the quartz-like deposition

	45 W		50 W	
	B.E. (eV)	%	B.E. (eV)	%
Si 2p	103.67	29.75 ± 0.1	103.67	30.19 ± 0.1
C 1s	285.01	8.82 ± 0.1	284.99	7.82 ± 0.1
O 1s	532.00	61.43 ± 0.1	532.00	61.99 ± 0.1
	60 W		70 W	
Si 2p	103.67	30.61 ± 0.1	103.67	33.01 ± 0.1
C 1s	284.96	6.81 ± 0.1	284.96	2.06 ± 0.1
O 1s	532.00	62.58 ± 0.1	532.00	64.93 ± 0.1

The FTIR spectra (Fig. 4) show the typical features of a quartz-like deposition. There are the major Si-O-Si stretching and bending absorption bands at 1090 and 1020 cm^{-1}, respectively (Tab. 2, V2). The silanol Si-OH stretching and bending bands at 3450 and 930 cm^{-1}, respectively, are present, too.
While the XPS spectra did not indicate the presence of Si-C bonds in the deposition track for a power input above 70 W, the V8 band at 804 cm^{-1} in the FTIR spectra clearly show a non-negligible amount of Si-C bonds from $Si(CH_3)_3$. The presence of $Si(CH_3)_3$ is supported by the wagging vibrations of methyl groups in $Si(CH_3)_3$ which cause the shoulder V5 on the absorption band V6 and by the CH stretching (V2). It is difficult to appraise the different results from the two techniques. The IR data represent all of the many microns thick deposition while with XPS we see the top-most layer only. But under the high vacuum conditions of a XPS measurement we remove a part of the adsorbed contaminants while they can remain on the high energy quartz surface during the recording of the FTIR spectra. It is quite possible that a material with a cauliflower surface morphology can adsorb substantial amounts of hydrocarbon contaminants from the ambient atmosphere.

Table. 2: List of bands observed in the quartz-like deposition

Notation	Wavenumber, cm^{-1}	Function
V8	804	Si-C from $Si(CH_3)_3$
V7	930	Si-OH bend
V6	1090 + 1020	ν_{as}(Si-O-Si)
V5	1277	Si-CH_3 wagging
V4	1633	
V3	2358	H_2O from air
V2	2981	$\nu_{as}(CH_3)$ stretching
V1	3450	OH stretch

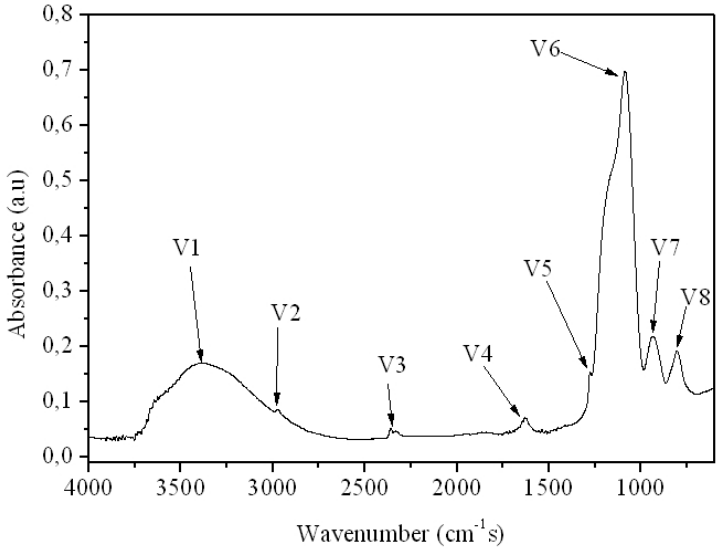

Fig. 4: FTIR spectrum of a quartz-like deposition (125 µm × 5 cm capillary, 0.72 mbar, 50 sccm O_2/HMDSO, 70 W)

Morphology
SEM images of the quartz-like depositions prepared at 60, 70 and 80 W show remarkable differences (Fig. 5). The 60 W sample is composed of mostly uniform and densely packed nanospheres. The average diameter of the nanoparticles measured on the SEM image accounts for about 30 nm. At 70 W, a cauliflower-like structure is obtained. However, the cauliflower-head is composed of nanoparticles, which have a about the same size as the nanospheres obtained at 60 W. At 80 W, a particle-free, compact structure with some fine cracks was produced.

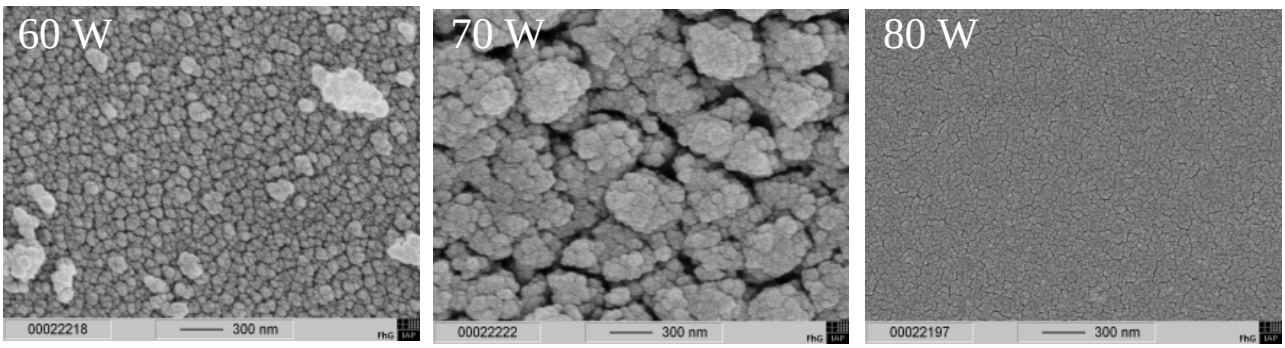

Fig. 5: SEM picture of quartz-like depositions at various input powers (0.74 mbar, 50 sccm O_2/HMDSO (120:1) employing the 125 µm × 5 cm capillary positioned 8.75 mm away from the substrate.

Conclusion

A localized quartz-like track deposition was produced by a micro-jet plasma CVD with a moving capillary. A parameter study has shown that the film quality is improved with increasing the applied energy. A transparent track which is either compact or it consists of nanoparticles, can be produced with a high efficiency.

Aknowledgements

We wish to thank Dr. Pinnow for the SEM images and Dr. Regenstein for microscopy FTIR spectra.

Spectroscopic measurement of plasmas generated in supercritical carbon dioxide environments

T. Tomai, M. Sawada and K. Terashima

Department of Advanced Materials Science, Graduate School of Frontier Sciences,

The University of Tokyo, Chiba, Japan

Abstract

We applied optical emission spectroscopy (OES) to plasmas generated in high-pressure CO_2 environments up to supercritical condition. Two types of plasmas, namely, dielectric barrier discharge (DBD) and DC discharge were employed. Up to supercritical conditions, the spectra of C_2 molecule and atomic O were remarkable in intensity by optical emission spectroscopy of both types of discharge. Rotational temperature of C_2 was estimated as approximately 4000 K in DBD at 2.0 MPa.

Keywords: supercritical fluid (SCF), dielectric barrier discharge (DBD), optical emission spectroscopy (OES) and rotational temperature.

1. Introduction

Supercritical fluid (SCF) has attracted much interest in scientific and engineering fields due to its unique characteristics such as its transport properties intermediate between gas and liquid [1] and its high solubility. From the microscopic viewpoint, SCF consists of clusters of various sizes [2]. It results in the above-mentioned characteristics.

Up to present, we have succeeded in generating DC discharge [3] and dielectric barrier discharge (DBD) [4] in supercritical carbon dioxide ($scCO_2$, the critical point: 7.38 MPa, 304.2 K, the critical density: 0.46 g/cm^3) environments and observed unique phenomena such as a drastic decrease in breakdown voltage near the critical point [3]. Additionally, we have applied discharge in $scCO_2$ to fabricate nanostructured materials at temperatures lower than those in conventional $scCO_2$ processings [4, 5]. These interesting phenomena and chemical reactions are supposed to be caused by radical and ion clusters in SCF plasmas. Understanding its microscopic feature might bring an important indication for controlling its unique chemical reactions. However, there have been few reports on the microscopic features of this novel plasma.

In this study, we diagnose SCF plasmas by optical emission spectroscopy (OES). OES provides microscopic feature of plasmas, such as existence of species excited by plasmas and temperature of such species. In our previous work, we had measured emission spectra of DBD at high-pressure CO_2 environment up to the supercritical condition [4]. In present work, to investigate dependence of microscopic features of high-pressure CO_2 plasmas on pressure and type of discharge, we compared DC discharge, which might raise gas temperature, and DBD, which might maintain low temperature. In addition, to diagnose temperature of excited species in high-pressure CO_2 plasma, we attempted to estimate rotational temperature of C_2 from the emission spectrum of C_2 (0,0) Swan band taken from DBD.

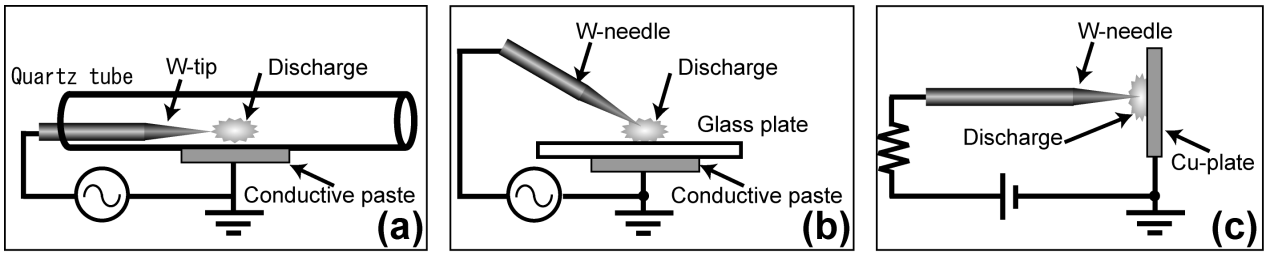

Figure 2. A schematic diagram of electrodes for (a), (b) dielectric barrier discharge and (c) DC discharge.

2. Experimental

Figure 1 shows a schematic diagram of the apparatus for generating discharge in a high-pressure environment. A stainless-steel cell, which has an internal volume of approximately 100 ml and can withstand conditions up to 10 MPa and 373 K, is employed as a reservoir. Electrodes are fixed in a sapphire tube connected with the reservoir. Liquefied CO_2 condensed in a condenser is pumped up to the reservoir and the sapphire tube. The reservoir and the sapphire tube are heated by cartridge heaters and band heater coiled around sapphire tube, respectively, to generate a high-pressure environment including supercritical conditions. Pressure and temperature in the reservoir and in the vicinity of sapphire tube are monitored using sensors and thermocouples, respectively, and controlled. The emission spectra of plasmas can be measured through the sapphire tube and optical fiber with a charged-coupled device (CCD) camera (Spec-10: 2KB/LN, Princeton Instruments Inc., NJ, USA) and a 500 mm spectrometer (SpectraPro-500i SP-556, Acton Research Corp., MA, USA). The spectra were recorded with a computer (PC).

A schematic diagram of the electrodes for identification of excited species in DBD is shown in Figure 2(a). The electrodes consist of a thin (outer diameter: 1 mm, and inner diameter: 700 μm) quartz tube as a dielectric barrier, conductive paste on the outside of the tube as the first electrode and a W-needle inserted into quartz tube as the second electrode. To generate DBD easier, the discharge gap, which is equal to the distance between the top of the W-needle and the tube, is reduced to approximately 100 μm. The details of

the electrodes are mentioned in Reference 4. The discharge is generated at the tip of the W-needle. In this study, applied ac voltage for generation of DBD was 0-15 kVp-p (frequency: 3 kHz, offset voltage: 0 V).

On the other hand, for measurement of rotational temperature of C_2, more accurate measurement is needed. Therefore, another type of electrodes for DBD is employed to remove optical obstruction such as quartz tube covering plasma. A schematic diagram of the electrodes is shown in Figure 2(b). The electrodes consist of a thin glass plate (thickness: approximately 150 μm) as dielectric barrier, conductive paste on one side of the glass plate as the first electrode and a W-needle, the tip of which is fixed ~100 μm away from the another side of the glass plate, as the second electrode.

A schematic diagram of the electrodes for DC discharge is shown in Figure 2(c). The electrodes consist of a W-needle and a Cu-plate. The distance between the W-needle and the Cu-plate is approximately 100 μm. Applied dc voltage for generation of discharge was 0-10 kV through a resistor (15 MΩ). The register is used to generate stable discharge.

3. Results and discussion

3.1 Identification of excited species in high-pressure CO_2 plasma

Before OES for CO_2 plasmas, we attempted to generate DBD and DC discharge in a high-pressure N_2 environment and measured the emission spectra of nitrogen to estimate the rotational temperature of N_2. The rotational temperature of N_2 can be measured from the intensity distributions in the rotational structure of the second positive system of nitrogen N_2 ($C^3\Pi_u$ (v' = 0) → $B^3\Pi_g$ (v'' = 2) transition) [6].

The rotational temperature of N_2 (nearly equal to gas temperature) in DBD is estimated as approximately 400 K under a various pressure (1-4 MPa) [4]. For example, in the case of our DC micro-discharge, in high-pressure N_2 environment (4.0 MPa), the rotational temperature of N_2 is estimated as approximately 800 K. Figure 3 is a schematic representation of gas temperature in various types of plasmas and environmental pressure. From Figure 3, it is found that our DBD, the distance of which is reduced to approximately 100 μm, can realize generation of low-temperature plasma in higher-pressure environment, compared to usual methods.

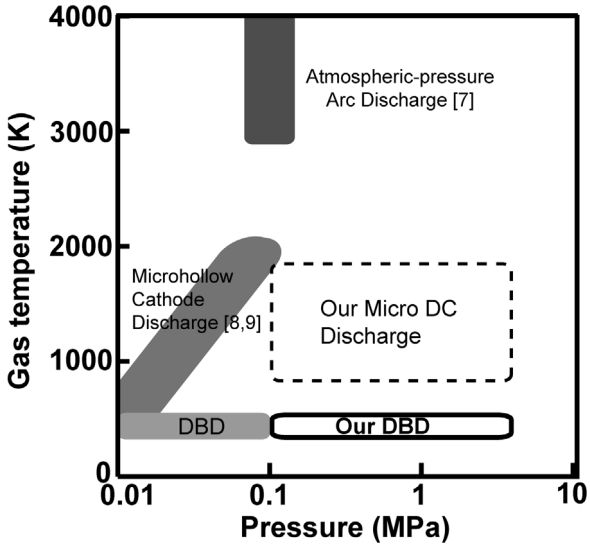

Figure 3. A schematic representation of gas temperature in plasmas and environmental pressure.

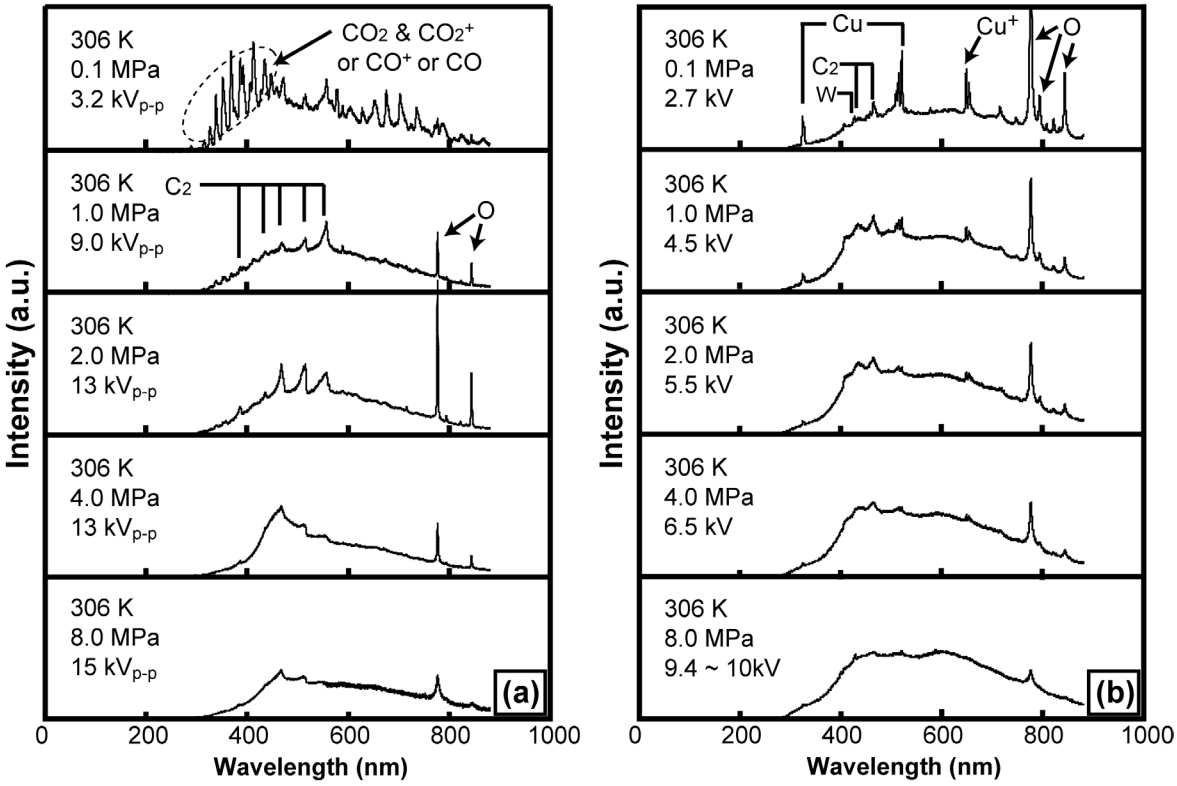

Figure 4. The emission spectra taken from (a) dielectric barrier discharge [4] and (b) DC discharge in high-pressure CO_2 environment up to the supercritical condition.

Figure 4 (a) and (b) show the typical emission spectra taken from DBD of previous work [4] and DC discharge in present work in high-pressure CO_2 environment up to supercritical condition, respectively.

At atmospheric pressure (0.1 MPa), the spectra taken from DBD and DC discharge are different obviously. In the case of DBD, the spectra of CO, CO^+, CO_2 and CO_2^+ are remarkable in intensity, in addition to the spectra of C_2 and O. On the other hand, as DC discharge, the spectra of C_2 and O are remarkable in intensity, in addition to the spectra of electrode materials, Cu and W. At higher than 1 MPa up to the supercritical condition, the spectra of C_2 molecule and atomic O become remarkable in intensity by OES of both types of discharge. In the case of DBD, the transition pressure from CO, CO+, CO_2 and CO_2+ to C_2 and O emissions probably exists in the range from 0.1 to 1 MPa. Generally, it shifts to a lower-pressure region with increasing gas temperatures. For example, it is approximately 500 Pa in the case of microwave induced plasma (MIP), whose gas temperature (600-1400 K) is higher than that of our DBD [10]. This transition pressure confirms that the gas temperature of our DBD is kept lower than 600 K in this DBD under a high-pressure CO_2 environment at least 1 MPa.

On the other hand, between the upper and lower sides of the critical point, any remarkable changes, which may result from the appearance of clusters in SCF, have hardly been observed. One of the conceivable reasons is as follows; With increasing pressure, collisional broadening of emission spectral lines becomes remarkable and the emission line tends to overlap neighbor lines. Therefore, the emission lines are difficult to identify, except for the emission line whose intensity is very strong, such as C_2 and O. Even if a tiny change between the upper and lower sides of the critical point exists, it may be hard to capture it.

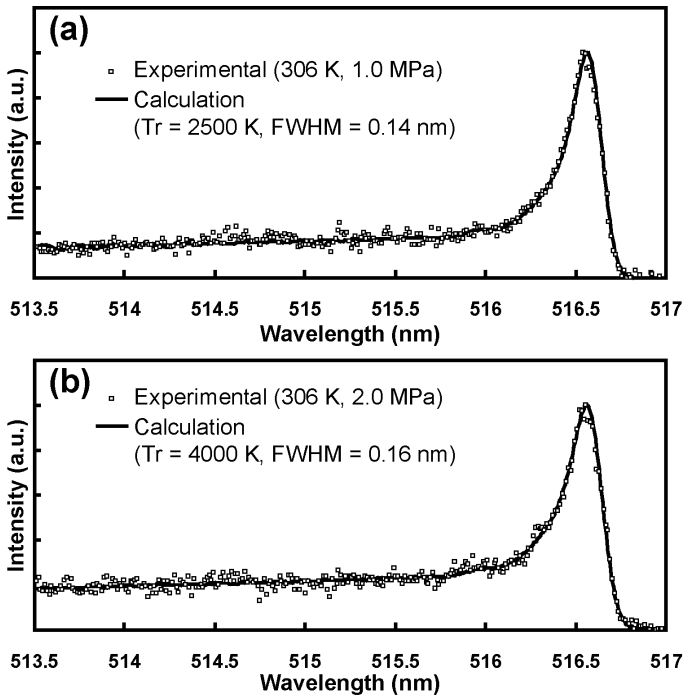

Figure 5. Observed and calculated spectra of C_2 (0,0) Swan band taken from dielectric barrier discharge in high-pressure CO_2 environments ((a) 1 MPa, (b) 2 MPa, environmental temperature: 306 K).

3.2 Measurement of rotational temperature of C_2

The determination of the temperature of excited species by OES gives valuable information on plasma processings. In this study, we attempted to estimate the rotational temperature of C_2 from the intensity distributions in the rotational structure of C_2 (0,0) Swan band, which was remarkable in intensity under the higher-pressure CO_2 environment than atmospheric pressure.

The C_2 (0,0) Swan band consists of P-, Q- and R-branches, and these bands belong to triplet transition. However, because the emission spectra taken by DBD under the higher-pressure CO_2 environment were noisy and broadened by collision with other particles, it was difficult to resolve these triplets sufficiently. Hence, to estimate the rotational temperature of C_2, we simulated these spectra with broadening by apparatus function and collisional broadening, and compared the calculated spectra with experimental spectra [11].

An observed spectra and calculated spectra of C_2 (0,0) Swan band taken from DBD at 1 and 2 MPa are shown in Figure 5. We revised FWHM (full width of half maximum) with increasing pressure, considering collisional broadening. In the case of DBD (applied voltage: 8 kVp-p) at 1 MPa, the rotational temperature of C_2 is estimated as 2500 ± 500 K (FWHM = 0.14 nm). In the case of DBD (applied voltage: 10 kVp-p) at 2 MPa, the rotational temperature of C_2 is estimated as 4000 ± 500 K (FWHM = 0.16 nm). At higher-pressure environment (more than 4MPa), the emission spectra of C_2 taken by DBD were noisier and spectra became broader, and it was hard to estimate the rotational temperature of C_2.

In general, DBD generates non-equilibrium plasma streamer: during the discharge hot electrons are created, while most of the gas stays at a temperature close to the environmental temperature. For example, Pellerin et al. reported that, in atmospheric pressure CH_4/CO_2-DBD plasma, the rotational temperature of C_2 was around 3000 K, which gave the temperature of the plasma streamer, while wall temperature was close to

the environmental temperature (≤ 350 K). In the case of our DBD, whereas the rotational temperature of C_2 was estimated as several thousands K under a high-pressure CO_2 environment (1, 2 MPa), melting of the electrodes employed for generation of DBD under a high-pressure CO_2 environment up to the supercritical condition, was not observed and the rotational temperature of N_2 was estimated as 400 K under high-pressure N_2 (1-4 MPa, 313K) environment up to supercritical condition (the critical point of N_2: 3.39 MPa, 126 K). Therefore, it is speculated that, in the case of our DBD, the temperature of plasma streamer is several thousands K, while most of the gas stays at several hundreds K under a high-pressure CO_2 environment up to the supercritical condition.

4. Conclusion

We applied optical emission spectroscopy to DBD and DC discharge generated in high-pressure CO_2 environment up to the supercritical condition. Under supercritical conditions, the spectra of C_2 molecule and atomic O are remarkable in intensity by optical emission spectroscopy of both types of discharge. We attempted to estimate the rotational temperature of C_2 from the emission spectra of C_2 (0,0) Swan band taken from DBD to diagnose temperature of excited species in high-pressure CO_2 plasma. The rotational temperature of C_2 was estimated as approximately 4000 K for DBD at 2.0 MPa. It is expected that the temperature of plasma streamer is several thousands K in the case of our DBD under a high-pressure CO_2 environment.

The Conversion of Natural Gas to C_2 Hydrocarbons via Cold Plasma Technology*

Genhui Xu, Baowei Wang, Zhenhua Li , Yang Li, Changjun Liu

School of Chemical Engineering , Tianjin University,
Tianjin, 300072, P. R. China

Abstract

The focus of this research is to develop a process to convert methane to C_2 hydrocarbons (ethane、ethylene & acetylene) via cold (non-equilibrium)plasma technology at the room temperature and atmospheric。The experiments were carried out in the plug flow DBD reactor equipped the high voltage plasma generator, the feeding gas and reaction products were analyzed by GC on –line.

The experiment was found the power was enhanced the methane conversion was increased and the selectivity of C_2 hydrocarbons was decreasing. The experimental results show that the methane conversion was 47% and the selectivity of C_2 hydrocarbon was 40% under the proper condition using an atmospheric cold plasma technology for the natural gas convert to C_2 Hydrocarbons, it is possible.

Keywords: Natural gas, C_2 hydrocarbon, cold plasma

1. introduction

Natural gas reserves are found in abundant quantities in the world, natural gas is not only an increasing important role in energy and chemicals supplies but also the second major greenhouse gases. Natural gas, with methane as the primary constituent, has been paid more attention as a main source in chemical industry and energetic industry for several decades, with the lack of crude oil and the influence of greenhouse global warming effect . It is a deep significance of strategy that the development of natural gas utilization as the feedstock instead of crude oil for the production of chemical engineering. Industrial usage of natural gas is still limited to primarily a combustion fuel in China, the present industrial processes for the production of methanol and other hydrocarbons from methane are economically feasible in areas where large reserves of natural gas are available. The commonly considered and extensively researched direct conversion methods are:

Catalytic oxidative coupling	$2\ CH_4 + O_2 \rightarrow C_2H_4 + 2\ H_2O$
Partial catalytic oxidation	$CH_4 + 1/2\ O_2 \rightarrow CH_3OH$

The reactions above require the high temperatures with catalyst, because of the C-H bond in molecule of methane is very stable, however the high temperature required for methane activation drive the reaction to unavailing complete oxidation reaction at high methane conversion.

Selective activation from methane to C_2 hydrocarbons is very difficult due to the high dissociation energy of methane C-H bond, the reaction is an unfavorable reaction at the thermodynamics. The plasma

- **The Research Foundation of Tianjin Science & Technology Committee support**

technology served as an unconventional catalysis has been used in natural gas conversion, because of the traditional catalytic research h of methane (the main component of natural gas) oxidative coupling must be required the high temperature, this stability of methane molecule causes difficulty in activating methane, so the high temperature with catalyst for methane activation drives the unavailing reaction to complete oxidation. The focus of this research is to develop a process to convert methane to C_2 hydrocarbons (ethylene and acetylene) with cold (non-equilibrium) plasma technology at the room temperature and atmospheric。

The preliminary studies have great contributions: Steven L.S. et al. studied the methane conversion to higher hydrocarbon using microwave plasma under the low pressure. [1] Oumghar A. et al. studied methane conversion by air microwave plasma. [2] Zhu A.M. et al. and Marafee A.,et al. studied with pulse corona plasma and DC corona discharge respectively for methane conversion. [3、4] Kozlov K.V. et al. and Yao S. L. et al. investigated the methane conversion using dielectric-barrier discharges (DBD) and high-frequency pulsed plasma respectively. [5、6] . In the present study is to develop a process of methane conversion to C_2 hydrocarbons (ethane、ethylene and acetylene.) via non-equilibrium plasma technology with DBD reactor under the without oxygen condition at room temperature and atmospheric, the reaction of methane coupling dehydrogenation as follows:

$$2CH_4 \rightarrow C_2H_6 + H_2$$

$$2CH_4 \rightarrow C_2H_4 + 2H_2$$

$$2CH_4 \rightarrow C_2H_2 + 3H_2$$

Above reactions are an electron & radical chain – reaction in the electric field enhanced plasma catalysis condition. This route of natural gas conversion to C_2 hydrocarbons via cold plasma technology could be offer an effective、simple and clean green chemical technology.

The experimental results show that the methane conversion was 47% and the selectivity of C_2 hydrocarbon was 40% under the proper condition using an atmospheric cold plasma technology for the Natural Gas convert to C_2 Hydrocarbons. This process is possible.

2. Experiment

The experiments were carried out in the dielectric-barrier discharges （DBD） plug flow reactor equipped the high voltage alternating current (AC) electric discharge plasma generator, the reactants were subjected to varying conditions of voltage (input power) and flow rates (reaction times), the range for the voltage under which the experiments were carried out was 20 – 200V. (power source), the voltage was controlled by a voltage regulator, the range of feed methane flow rate was 10 – 200 ml/min., the flow rate was controlled by an electronic mass flow controller. The gaseous product stream was analyzed using the HP 5890 GC, the GC was programmed to

take the gas samples automatically in-situ.

The experimental apparatus used for the steady state runs is shown in Figure 1.

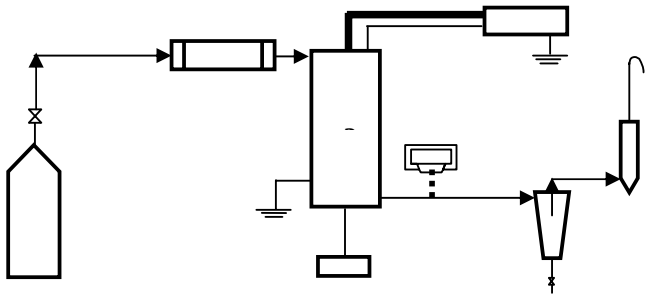

Fig. 1 Experimental Schematic Diagram

1.CH_4 Tank ; 2. Mass flow controller (MFC); 3. DBD Plasma Reactor ; 4. HV Plasma Generator ; 5. GC Analyzer 6. Thermocouple meter ; 7. Condenser ; 8. Flow meter;

The raw material methane from CH_4 tank 1. via MSC 2. was flowed to plasma reactor 3. which is consisted of a 10 mm ID quartz tube of 250 mm length, the gas methane molecule was excited to conversion C_2 hydrocarbon in the zone of plasma reaction, the outlet from the reactor through the condenser 7.

3. Results and Discussions

The experimental results were found that the parameters of electric field and the reaction conditions were effect on the conversion of methane and selectivity of C_2 hydrocarbons under the DBD plasma condition.

3.1 Effect of input power on the reaction results

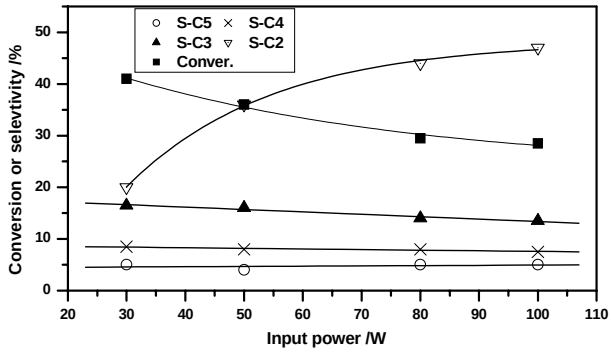

Figure 2. Effect of input power on the conversion of methane & Selectivity of Light hydrocarbons

Reaction temperature of 323K; Flow rate of 20ml/min

The experiment was found the characteristic of micro-discharge in DBD plasma condition for methane conversion, according to the Lissajous Voltage – Charge figure recorded by experimental data was obtained: the micro-discharge life of 20ns, current-diameter of 0.03mm, peak current of 0.4A., current density of 40000 A/cm^2, charge amount of 0.6 nC. , therefore the studies on above plasma parameters were helpful to understand the process of DBD plasma for methane conversion. The effect of input power on the conversion of methane and the selectivity of reaction were shown in Fig.2 and Fig.3.

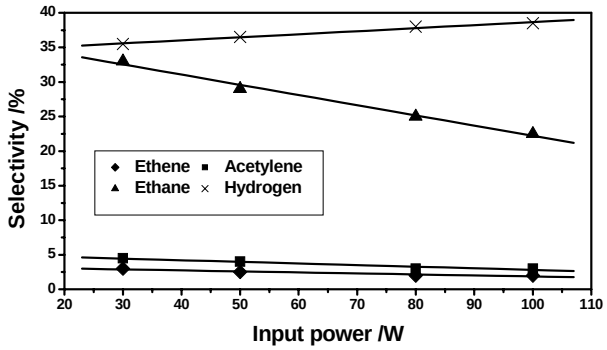

Figure 3. Effect of input power on the selectivity of C_2 hydrocarbons & H_2

Reaction temperature of 323K; Flow rate of 20ml/min

When the voltage was enhanced the methane conversion was increased and the selectivity of C_2 hydrocarbons was decreasing. The suitable voltage was provided 40-80 V. (input AC power 50W – 100W),. The experimental results show that the methane conversion was most to 47% and the selectivity of C_2 hydrocarbon was most to 40%

3.2 Effect of residence time on the reaction results

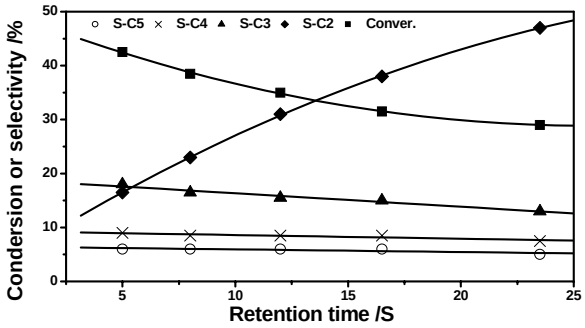

Figure 4 Effect of residence time on the conversion of methane & Selectivity of Light hydrocarbon

Reaction temperature of 323K; Input power of 100W

The experiment was varied in feed flow rate of methane, the methane conversion was decreased and the selectivity of C_2 hydrocarbons was increased with increasing of the inlet flow rate of methane in the above power condition. The proper extent of flow rate was 20-40 ml /min (corresponding residence time was 10 – 20 s) ,the experimental results were shown in Fig. 4 and Fig. 5.

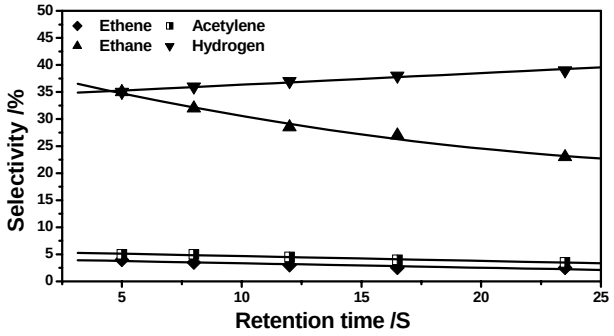

Figure 5. Effect of residence time on the selectivity of C_2 hydrocarbon & H_2

Reaction temperature of 323K; Input power of 100W

3.3 Effect of reaction temperature on the reaction results

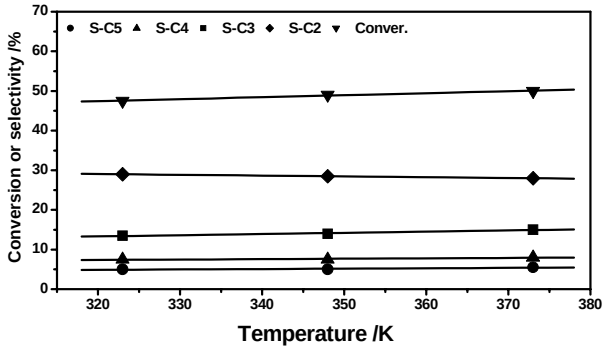

Figure 6 Effect of reaction temperature on the conversion of methane & Selectivity of Light hydrocarbon

The reaction temperature from the room temperature to 373K, but the experimental results were found the Effect of reaction temperature on the reaction results was not obviously at the condition of experimental range, in other words, the influence of temperature can be neglected for DBD plasma reaction. the experimental data were drawn in Fig. 6 and Fig. 7

Flow rate of 20 ml/min; Input power of 100W

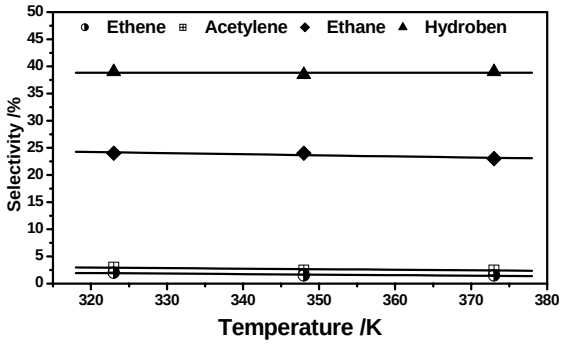

Figure 7. Effect of reaction temperature on the selectivity of C_2 hydrocarbon & H_2

Flow rate of 20 ml/min; Input power of 100W

The temperature action of DBD plasma reaction differs greatly from the traditional catalytic reaction, the

latter, on the contrary, the influence of temperature was very important.

3.4 Discussion

3.4.1．The breakdown voltage of methane under the AC cold plasma condition

As is known to all, the gas breakdown voltage $V_{B,min}$ is the minimal required voltage when the gas is beginning discharge, under the atmospheric and AC cold plasma condition the experiment was found that the breakdown voltage of methane $V_{B,min}$ was decided by the type of electrode and the discharge gap width, obviiiously, it can be used the Paschen law equation from the DC gas discharge deduced, the CH_4 breakdown voltage $V_{B,min}$ was alike at DC and AC plasma discharge condition.

Where: $V_{B,min} = BPd/\ lnAPd/\ ln[1+1/\gamma]$

P is the pressure of gas discharge

d is the distance between electrodes (the discharge gap width)

γ is Townsend's second ionization coefficient

A、B are the constants depending on the type of gas

Therefore, the breakdown voltage of methane under the experimental AC cold plasma condition, the $V_{B,min}$ equation was established:

$$V_{B,\min} = 26.186 \ln\left[1+\frac{1}{\gamma}\right]$$

γ is Townsend's second ionization coefficient, which is experimental volume also concerned with the type of gas. The $V_{B,min}$ volume is very important parameter in the conversion of natural gas to C_2 hydrocarbons with cold plasma reaction.

3 .4.2. The reaction route

The reaction of methane conversion to C_2 hydrocarbons (ethane、ethylene and acetylene.)

is very difficult at the normal condition due to the high dissociation energy of methane C-H bond, the reaction is an unfavorable reaction at the thermodynamics. Using non-equilibrium plasma technology under the without oxygen condition, the reaction route is the dehydrogenation & coupling reaction of methane, first the electron is accelerated by an electric field enhanced to turn into then high-energy electron e^*. The high-energy electron e^* with gaseous methane molecules react by means of the inelastic collisions and they are excited (or dissociation) to activity methyl、methylene、methine (CH_3^*、CH_2^*、CH^*)etc. radicals in silent discharge reaction area

$$CH_4 + e^* \rightarrow CH_3^* + H^* + e$$

$$CH_3^* + e^* \rightarrow CH_2^* + H^* + e$$

$$CH_2^* + e^* \rightarrow CH^* + H^* + e$$

The several activity radicals are associated each other to attract coupling to C_2 hydrocarbon as follow :

$$2\ CH_3^* \rightarrow C_2H_6$$

$$2\ CH_2^* \rightarrow C_2H_4$$

$$2\ CH^* \rightarrow C_2H_2$$

$$2\ H^* \rightarrow H_2$$

Above reactions are an electron & radical chain – reaction in the electric field enhanced plasma catalysis condition. This route of natural gas conversion to C_2 hydrocarbons was supposed

4. Conclusion

1. The experiment of the DBD plasma reaction for methane conversion was found that the input power and the residence time of reaction were key factor of influence reaction result, the suitable AC input power was 50 -80 W and the proper residence time of reaction was 10 -20 sec.

2. The experiment was considered the Effect of reaction temperature on the reaction results was not obviously under the DBD plasma reaction condition.

3. The experimental results show that the methane conversion was 47% and the selectivity of C_2 hydrocarbon was 40.0% under the proper condition using an atmospheric DBD cold plasma technology, this process of the natural gas convert to C_2 hydrocarbons was possible.

Abstract
The enormous radiation energy emitted from plasma arc is utilized as a heating device without combustion for the treatment of waste. In order to realize high radiation efficiency, precise controls of the radiation power and the spectrum of the radiation are required. In this paper, the MHD simulation of the dependence of plasma arc temperature and it's radiation power density on input current to the device is carried out in order to know the basic relationship of plasma torch between temperature distribution and radiation power. As a result, the temperature and the radiation power of plasma arc become higher near the cathode. The radiation power of this calculation agrees with it of experiment at the arc column.

Keyword : Numerical simulation, Radiation power, Plasma arc, Temperature

1. Introduction

The enormous radiation energy emitted from plasma arc is utilized as heating device without combustion for the treatment of waste. In order to realize high radiation efficiency, precise controls of the power and the spectrum of the radiation are required. In this paper, the MHD simulation of the dependence of plasma arc temperature and it's radiation power density on input current to the device are carried out in order to know the basic relationship of plasma torch between temperature distribution and radiation power.

2. Simulation model

In this simulation, 2-dimensional calculation domain in cylindrical co-ordinates is defined as shown in Fig. 1. The temperature of plasma arc and it's radiation power are evaluated using MHD equations and radiation equations. The flow is assumed to be laminar, steady and incompressible.

(a) mass continuity

$$\nabla \cdot (\rho \vec{u}) = 0$$

(b) momentum equation

$$\nabla \cdot (\rho \vec{u}\vec{u}) = -\nabla p + \vec{j} \times \vec{B} + \nabla \cdot \tau, \quad \tau_{\alpha\beta} = \eta \left(\frac{\partial u_\alpha}{\partial x_\phi} + \frac{\partial u_\beta}{\partial x_\alpha} \right)$$

(c) electron energy equation

$$\vec{u} \cdot \nabla \left\{ n_e \left(\frac{5}{2} k T_e + \varepsilon_i \right) \right\} = \nabla \cdot \left(k_e \nabla T_e \right) - \left\{ \varepsilon_i + \left(\frac{5}{2} + \frac{e}{k} \frac{\phi}{\sigma} \right) k T_e \right\} \dot{n}_e + \left(\frac{5}{2} + \frac{e}{k} \frac{\phi}{\sigma} \right) \frac{k}{e} \vec{j} \cdot \nabla T_e + \vec{j}\vec{E} - \frac{3 m_e}{m_i} n_e (\overline{\upsilon}_{ei} + \overline{\upsilon}_{en}) k (T_e - T) - \dot{R}$$

(d) heavy-species equation

$$\vec{u} \cdot \nabla \{ (n_e + n) k T \} = \nabla \cdot \left(k_a \nabla T \right) + \frac{3 m_e}{m_i} n_e (\overline{\upsilon}_{ei} + \overline{\upsilon}_{en}) k (T_e - T)$$

(e) diffusion equation

$$\vec{u} \cdot \nabla n_e + \nabla \cdot \left\{ \frac{e n_e D_{in}}{k T} \left(\vec{E} - \frac{1}{e n_e} \nabla p_i \right) \right\} = \dot{n}_e$$

(f) charge continuity

$$\nabla \cdot j = 0$$

(g) generalized ohm's law

$$\vec{j} = \sigma\left(\vec{E} - \frac{1}{en_e}\nabla p_e \right) + \phi \nabla T_e$$

(h) electric field strength

$$\vec{E} = -\nabla \phi$$

(i Maxwell equation

$$\nabla \times \vec{B} = \mu_0 \vec{j}$$

(j) Dalton's law

$$p = (n_e + n_i + n_n)kT$$

(k) quasi-neutrality condition

$$n_e = n_i$$

In addition, the anode sheath property is calculated using the method adopted in Ref[1]. The maximum temperature of the plasma arc is approximately 15000K. Therefore the plasma is assumed to be optically thin [2]. The simulation region is the plasma torch which has the cathode diameter 6.4mm, the inner diameter of nozzle 8.6mm and the electrode gap 20mm as shown in Fig. 1. The region is filled with 0.1MPa Ar gas. Input mass flow of 12NL/min. is introduced through a cylindrical area of radius 3.2-4.3mm in the face B-C. The gas flows out through the face D-F. Input current density distribution is defined on the boundary E-H. The current and potential distributions are calculated only in the region E-F-G-H. The temperatures of the anode and the cathode are set to be 1000K and 3000K, respectively. The boundary conditions of tye whole region are listed in Table 1.

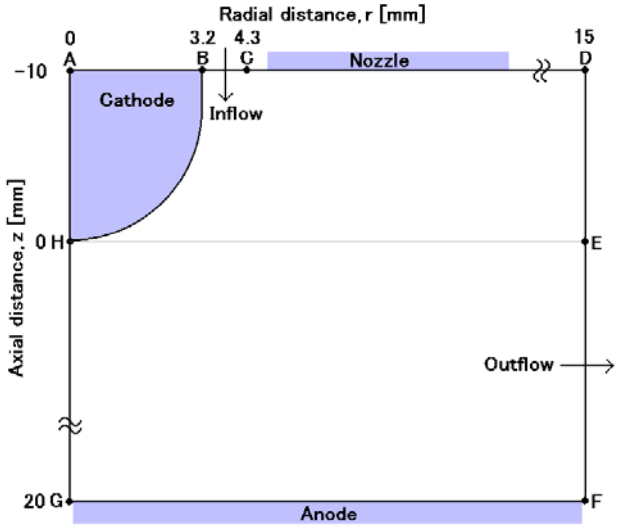

Fig. 1. Simulation region.

Table 1. Boundary conditions.

	T	φ	flow
A-B (Cathode)	3000K	-	u=v=0
B-C (Inflow)	1000K	-	v=0
C-D (Nozzle)	1000K	-	u=v=0
D-F (Outflow)	dT/dr=0	φ=0	u=0
F-G (Anode)	1000K	φ=0	u=v=0
G-A (Axis)	dT/dr=0	dφ/dr=0	v=0

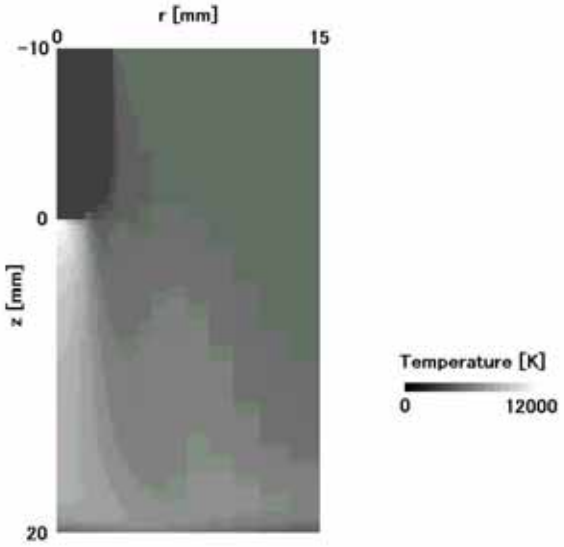

Fig. 2. 2-dimensional temperature distribution (I=100A).

3. Simulation results and discussion

The plasma arc temperature and radiation power density distributions of plasma arc are calculated in the case of 80, 100, 120A. Figure 2 shows 2-dimensional temperature distribution in the case of 100A. It is found that high temperature and small arc radius near the cathode are produced as a result of the arc column squeezed due to the inflow. Figure 3 shows temperature and radiation power density distributions along the axis(A-G). The experimental values by about 1,000 - 2,000K are cited from Ref. [4]. It is clear that calculated temperatures between z = 3mm - 20mm nearly agree with the experimental values. On the other hand, the experimental values near the cathode (z = 0 - 3mm) become higher than calculated values. One of the reasons for the difference is the strong dependence of the temperature near the cathode on the input current density distribution defined as the boundary condition. For more accurate calculation, it is necessary to define this boundary condition inside the cathode (A-B) to calculate current density distribution near the cathode. The temperature decreases gradually from the cathode to the anode. On the contrary, the radiation power density near the cathode decreases steeply apart from the cathode, because the radiation power density is reduced steeply when the temperature is lower than 10,000K [5] as seen near z=3 - 5mm. The radiation power of this calculation agrees with it of experiment at the arc column.

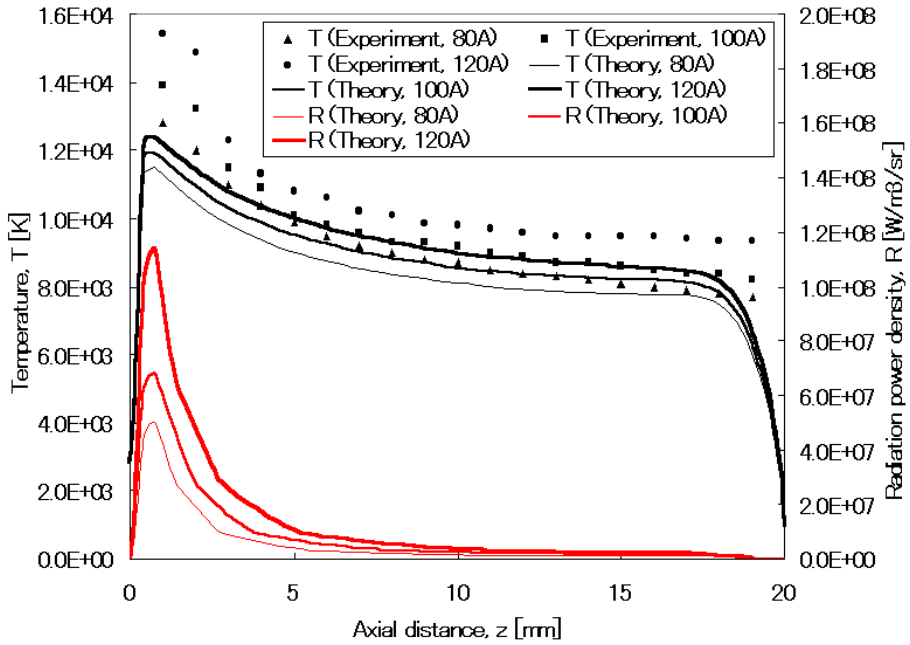

Fig. 3. Temperature and radiation power density distribution along the axis.

4. Summary

(1) The temperature and the radiation power of plasma arc become higher near the cathode.

(2) The radiation power density of this calculation agrees with it of experiment at the arc column.

(3) The axis temperature in calculation agrees with the experiments.

Abstract

When a reduction of the waste and dissolution of the iron are carried out by using a high temperature medium, the radiant power emitted from the medium should be suppressed. On the contrary, it is useful for lighting and treatment of hazardous wastes because it has a highly intense radiant energy. In this paper, we tried to calculate the radiant power density under consideration of atmospheric high temperature pure argon(Ar) which is frequently used for a plasma arc to know the basic theory of radiant power density for the development of the plasma treatment by using radiant power. The radiant power density of Ar I - Ar III is calculated with each rays and wavelength at 1,000 - 30,000 K and 200 nm - 1,000 nm in wavelength. The total radiation power density increases with increasing the temperature up to 15,000K and almost levels off over 15,000K. The continuum spectrum of Ar I increase up to 14,000 K with increasing the temperature. However, it decreases after 14,000K. The continuum spectrum of Ar II is ten times as high as the line spectrum of Ar I. The line and continuum spectrum of Ar III increases with increasing the temperature, and the latter levels off at 26,000K. The recombination radiation of Ar II-u_{fb} and Ar III-u_{fb} is higher than the bremsstrahlung Ar II-u_{ff} and Ar III-u_{ff}, respectively. The bremsstrahlung emitted from Ar I-u_{ff} is dominant in the continuum spectrum of Ar I. The u-Ar II is higher than u-Ar I and u-Ar III in UV rays. However, the u-Ar I reverses u-Ar II in IR rays. The Ar II-u_{fb} is higher than other continuum spectrum under 25,000K. Therefore, the recombination radiation is dominant with wavelength. The UV rays is to be 50% and the UV and VR:visible rays are dominant at 15,000K. Most UV and VR rays are emitted from Ar II-u_{fb}. Therefore, the radiation emitted from the UV rays of argon is dominant due to recombination radiation. The radiation emitted from argon could apply to waste treatment because of highly intense UV rays.

Keyword : Plasma Arc, Radiation Power, Radiation component, UV rays

1. Introduction

The plasma arc has a lot of excellent characteristics such as the high temperature, highly intense radiation[1-3] and high energy. When a reduction of the waste and dissolution of the iron are carried out by using a high temperature medium, the radiant power emitted from the medium should be suppressed. On the contrary, it is useful for lighting and treatment of hazardous wastes because it has a highly intense radiant energy. In this paper, we tried to calculate the number density and then the radiant power density under consideration of atmospheric high temperature pure argon(Ar) which is frequently used for a plasma arc to know the basic theory of radiant power density for the development of the plasma treatment by using radiant power.

2. Number Density and Radiation Power Density

Figure 1 shows the radiation power density with the temperature. The total radiation power density increases with increasing the temperature up to 15,000K and almost levels off over 15,000K. The continuum spectrum of Ar I increases up to 14,000 K with increasing the temperature. However, it decreases over 14,000K. The line one of Ar II does do. The continuum spectrum of Ar II is ten times as high as the line spectrum of Ar I over 12,000K. The line spectrum of Ar II goes to its maximum at 26,000K. The line and continuum spectrum of Ar III increases with increasing the temperature, and the value of the latter levels off at 26,000K. Figure 2 shows the component of continuum radiation power density. The recombination radiation of Ar II-u_{fb} and Ar III-u_{fb} is higher than the bremsstrahlung Ar II-u_{ff} and Ar III-u_{ff}, respectively. The bremsstrahlung emitted from Ar I-u_{ff} is dominant in the continuum spectrum of Ar I.

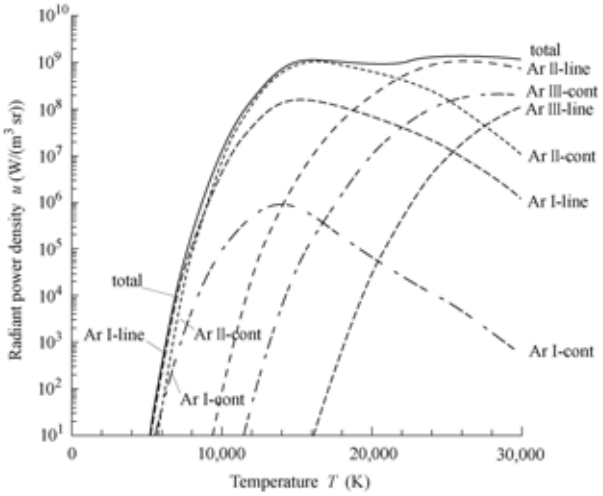

Fig. 1 Radiation power density with the temperature.

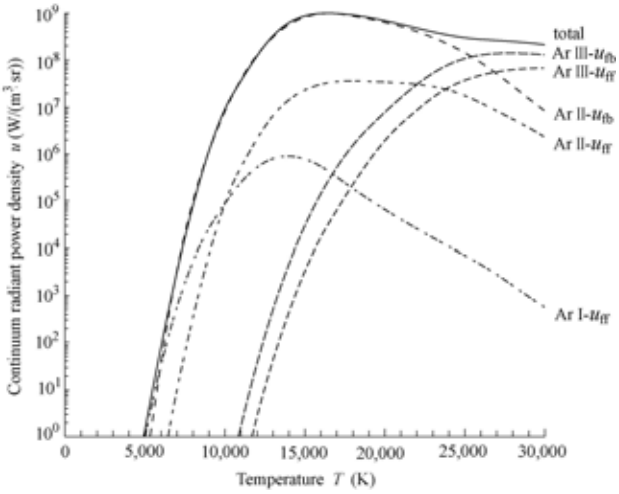

Fig. 2 Component of continuum radiation power density

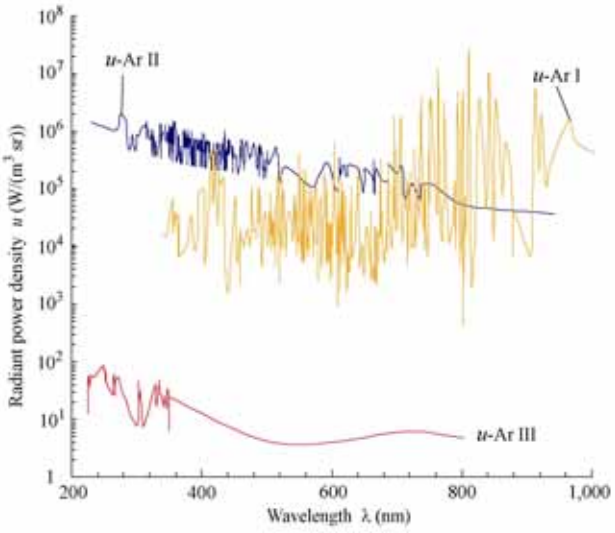

Fig. 3 Radiation power density emitted from Ar at each state as function of wavelength. (15,000K)

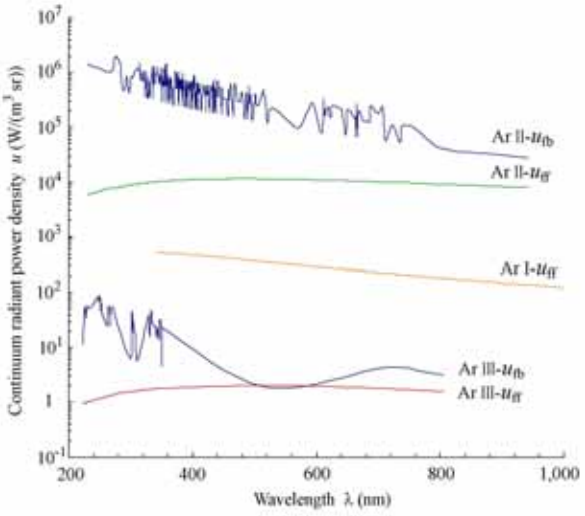

Fig. 4 Component of continuum radiation power density with wavelength. (15,000K)

3. Total Radiation Power in Wavelength

Figure 3 shows the radiation power density emitted from Ar at each state as a function of wavelength at 15,000K and 0.1MPa. The radiation power has a peak value at 15,000K. The UV rays under 380nm emitted from *u*-Ar II is about 10^6 W/(m^{3}sr) and higher than *u*-Ar I and *u*-Ar III. The VR rays between 380-780nm emitted from *u*-Ar I and *u*-Ar II is almost same value. The IR rays between over 780nm emitted from *u*-Ar III is almost constant to be 10 W/(m^{3}sr) and lower than it from *u*-Ar I and *u*-Ar II by 10^4 times. The UV rays emitted from *u*-Ar II is higher than *u*-Ar I and *u*-Ar III. However, the *u*-Ar I reverses *u*-Ar II in IR rays. Figure 4 shows the component of continuum radiation power density with wavelength at 15,000K. The Ar II-u_{fb} is higher than other continuum spectrum. Especially there are few Ar III-u_{fb} and Ar III-u_{ff}. Therefore, the recombination radiation is dominant with wavelength.

4. Component ratio of Radiant Power in Wavelength Region

Figure 5 shows the ratio of ultraviolet, visible and infrared rays emitted from Ar at 15,000K in order to know the component ratio of radiation power density in wavelength region. The UV rays is to be 50% and the UV and VR:visible rays are dominant. Most UV and VR rays are due to recombination radiation emitted

from Ar II-u_{fb}. The ratio of radiation power density becomes 48.6 % in UV(200-380nm), 38.6% in VR(380-780nm) and 12.8% in IR(780-1,000nm). The radiation power density emitted from u_{line}-*Ar I* is dominant in the IR region as shown in Fig.3, while the ratio of radiation power emitted from u_{fb} is dominant as shown in Fig.5.

Figure 6 shows the spectrum component of radiation power density from Ar at 15,000K. The UV component emitted from Ar II-u_{line} , Ar I-u_{ff}, Ar II-u_{ff} is dominant such as more than 60%.

Figure 7 shows the ratio of line and continuum to the total radiation power density about Ar I, Ar II, and Ar III. The IR rays are dominant due to the line radiation from Ar I. Although there is a little Ar II-u_{ff}, it is not effective and the ratio of other radiation component is to be less than 1%.

The UV radiation emitted from argon is dominant due to recombination radiation. The radiation emitted from argon could apply to waste treatment because of highly intense UV rays.

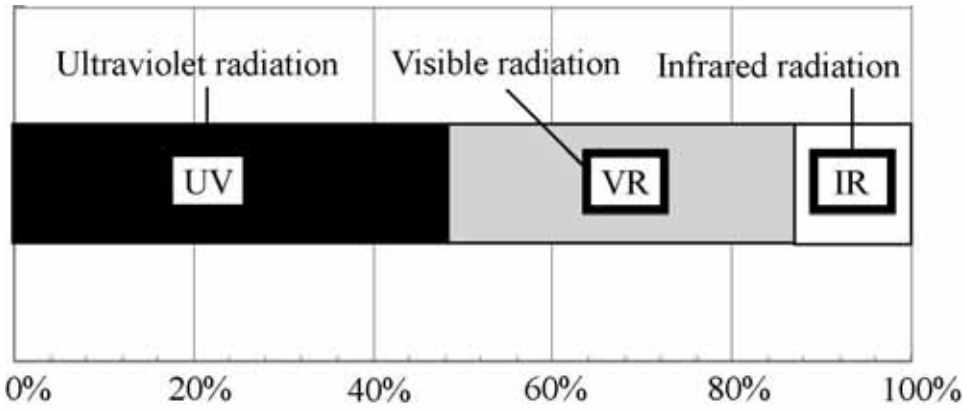

Fig. 5 Ratio of ultraviolet, visible and infrared rays emitted from Ar. (15,000K)

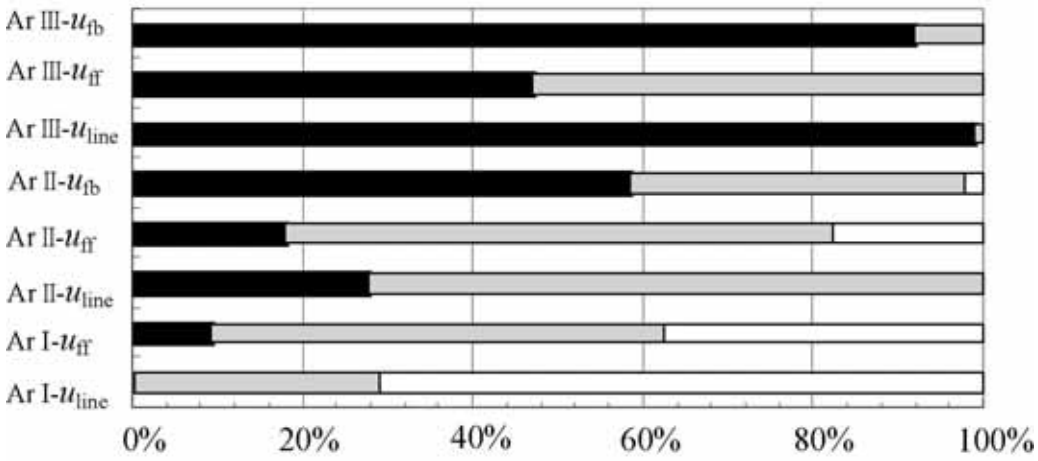

Fig. 6 Spectrum component of radiation power density emitted from Ar. (15,000K.)

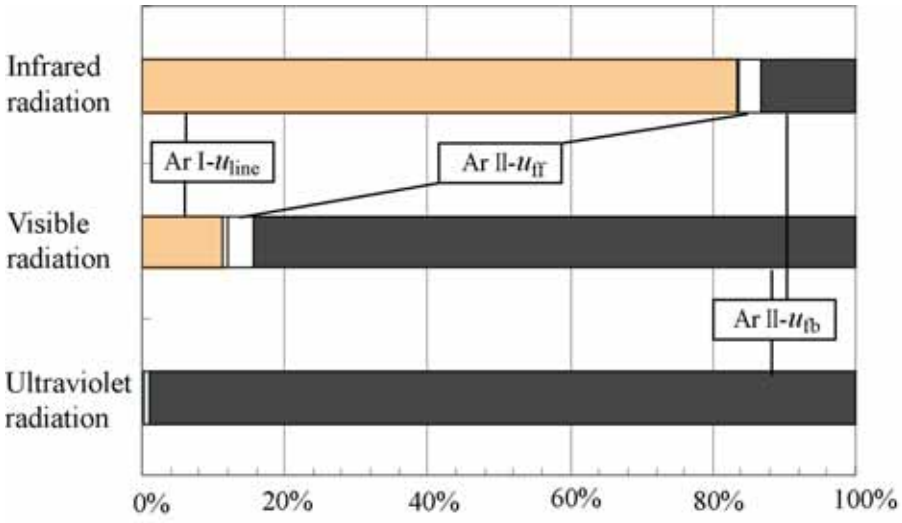

Fig. 7 Ratio of line and continuum to total radiant power density about Ar I, II and III.

5. Summary

The number density and radiant power density under consideration of atmospheric high temperature pure Ar which is frequently used was calculated for a plasma arc to know the basic theory of radiant power density for the development of the plasma treatment by using radiant power. The main results are shown below.

(1) The total radiation power density increases with increasing the temperature up to 15,000K and almost levels off. The continuum spectrum of Ar I increases up to 14,000 K with increasing the temperature. However, it decreases over 14,000K.
(2) The continuum spectrum of Ar II is ten times as high as the line spectrum of Ar I. The line and continuum spectrum of Ar III increases with increasing the temperature, and the latter value levels off at 26,000K.
(3) The recombination radiation of Ar II-u_{fb} and Ar III-u_{fb} is higher than the bremsstrahlung Ar II-u_{ff} and Ar III-u_{ff}, respectively. The bremsstrahlung emitted from Ar I-u_{ff} is dominant in the continuum spectrum of Ar I. The *u*-Ar II is higher than *u*-Ar I and *u*-Ar III in UV rays. However, the *u*-Ar I reverses *u*-Ar II in IR rays.
(4) The Ar II-u_{fb} is higher than other continuum spectrum under 25,000K. Therefore, the recombination radiation is dominant with wavelength. The UV rays is to be 50% and the UV and VR:visible rays are dominant. Most UV and VR rays are emitted from Ar II-u_{fb}.
(5) The UV radiation emitted from argon is dominant due to recombination radiation. The radiation emitted from argon could apply to waste treatment because of highly intense UV rays.

Abstract

The twin torch plasma arc can generate the high temperature and also treat non-conducting material, because it has a higher temperature arc column, even if it is a non-transfer type. Therefore, the twin torch plasma arc has been a more effective device for the treatment of hazardous waste. However, in the twin torch plasma arc, the arc mode is not easy to control. In this paper, the temperature distribution of twin torch plasma arc near 100A was measured. The high temperature region of the twin torch plasma arc is larger than that of a conventional single plasma torch. The plasma arc length can be changed as a function of plasma gas flow rate. The arc voltage is also changeable as function of current and plasma gas flow rate. The temperature of twin torch plasma was measured to be about 14,000K near the cathode, and 13,000K at the center point between the electrodes and near anode at 100A. The neutral bar under the arc column received the heat power of the amount of 280-500W, and the fraction of the total power transferred to the neutral bar of the total dissipated power is 12-18%.

Keyword : Twin Torch, Plasma Arc, Temperature Distribution

1. Introduction

The plasma arc has a lot of excellent characteristics such as the high temperature[1-5], highly intense radiation[6][7] and high energy. The conventional plasma torches have been developed, previously. However, they have some problems of ignition and generation of high temperature and highly intense arc for hazardous waste treatment[8-12]. Although the plasma jet in a non-transfer type can treat non-conducting material, it is difficult to generate the high temperature arc. In the case of the plasma torch in a transfer type[5], although it can generate the high temperature arc, it is difficult to treat the non-conducting material. Therefore, it is important to solve this problem immediately. Especially, the medical waste has complex such as knives, injectors, injector needles, diaper, blood etc.. Normally, the plastic is non-conducting material. Therefore, they should be treated and the off-gas should be clean. The twin torch plasma arc can generate the high temperature and also it can treat the non-conducting material, because it has a higher temperature arc column, even if it is a kind of non-transfer type. Therefore, the twin torch plasma arc is a more effective device for the treatment of hazardous waste. In this paper, the temperature of twin torch plasma arc near 100A is measured for the treatment of hazardous waste[1][2]. Metals such as knives and injection needles are electrically conducting materials. Therefore, they are treated easily by the electrical arc. However, the twin torch plasma arc is one of the non-transfer type arcs, i.e. it is not producing Joule heating of materials themselves. Therefore, the temperature of arc column must be high enough to treat the metals. Because the injector needle is very sharp, it is dangerous for workers and citizens. It is not enough to treat the injector needle by the normal incinerator, because the temperature is too low to treat the injector needle made of stainless steel.

2. Experimental arrangement

Figure 1 shows the experimental arrangement of twin torch plasma arc. And figure 2 shows an arrangement of nozzle electrodes. The angle between cathode and anode is 98 degrees. The argon is filled in the chamber at 0.1MPa. The twin torch plasma arc is generated between the cathode and anode. The conventional twin torch plasma arc has only two gas flow from the nozzle, and the twin torch plasma arc has more than three gas flow from the nozzle. The plasma gas is also argon and its flow rate of cathode, F_c, is 15slpm and 20slpm from nozzle electrode of cahode, and gas flow rate of anode, F_a, is constant to be 15slpm. The DC arc current of the twin torch plasma arc is varied from 30 to 100A. The neutral bar arranged at the middle point between the cathode and anode is used to measure the received power and derive the gas heating efficiency. The left electrode is anode and the right one is cathode. The neutral bar for a tentative treatment plate consists of a Th-W tip and a copper stem which is cooled by forced water.

L=4cm, F_a=15slpm, (a) F_c=15slpm, (b) F_c=20slpm

Fig. 3 Conventional twin torch plasma arc mode.

3. Arc mode

The arc mode is changed by the gas flow surrounding the arc[13]. Figure 3 shows the conventional twin torch plasma arc modes. When the current increases, the arc appearance changes from a V to a Y mode. This means the high temperature region increases. When the gas flow rates of cathode and anode are the same, the arc modes don't become V and Y mode completely. However, when the gas flow rate from the cathode is 20slpm and it from the anode is 15slpm, the arc appears a V mode. This indicates that the electrode jet from the anode is bigger than that from the cathode.

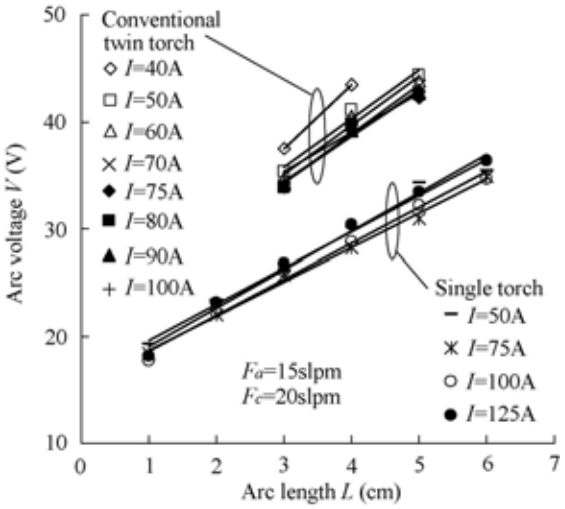

Fig. 4 Arc voltage as function of arc length.

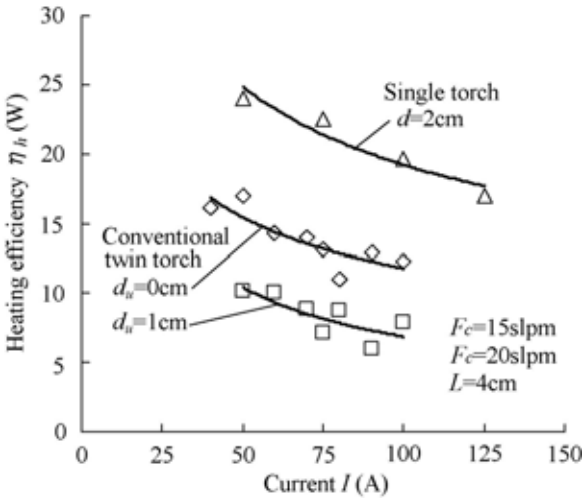

Fig. 5 Heating efficiency.

Therefore, the arc mode from anode is always strong. When the current increases from 40 to 80A, the high temperature region of arc expands. The anode spot was observed to be bigger than the cathode spot.

4. Arc Voltage

The arc voltage as a function of arc length as shown in Fig.4. The arc voltage of single torch plasma arc is almost constant around 30V. However, that of the twin torch plasma arc decreases with a current. These characteristics are similar to a wall-stabilized arc. Because the anode electrode has a nozzle, the radius of plasma arc is constricted due to the pipe type gas flow. Therefore, the voltage of twin torch plasma arc is larger than that of single torch plasma arc. However, the twin torch plasma arc can obtain more voltage and input power. The voltage and input power of twin torch plasma arc is 1.1, 1.4 times that of the conventional twin torch plasma arc and the single torch plasma arc, respectively, in the case of L=3cm and 100A. Figure 6 shows the arc voltage as a function of arc length. The arc voltages of single and twin torch plasma arc increase almost linearly with the arc length and the voltage gradients are almost constant at 4.5V/cm in the twin torch plasma arc and 3.4V/cm in single torch plasma arc in a range of 50-125A. They are almost the same when the current changes.

5. Heating efficiency

The flow rate of cooling water in the neutral bar, A, equals 233.3 g/s. Together with the temperature difference between input and output cooling water, $T_{\text{out}} - T_{\text{in}}$ (K), they indicate the quantity of heat power to the neutral bar, Q_{water} (W), as follows[14]:

$$Q_{water} = 4.185A(T_{out} - T_{in}) \qquad (1)$$

The received heat increases with the current. The received heat in the case of the twin torch is a little bit bigger than that of the single torch plasma arc. However, that of the twin torch plasma arc sharply decreases when the downward distance is bigger as d_{u}=1cm. The received heat is measured to be 280-500W at d_{u}=0cm. Figure 5 shows the heating efficiency, which is defined as the ratio of the received heat Q_{water} to the input power of the arc. The heating efficiency of the twin torch decreases with current and 18-12% at 40-100A, d_u=0cm. It is smaller in the case of the twin torch plasma arc than in the case of the single torch, because the Joule heating of materials exists in the case of single torch. When the heating efficiency is large enough, the twin torch plasma arc can treat the waste easily. If the neutral bar is changed into actual materials or a melting pot, the heating efficiency is expected to become double or more.

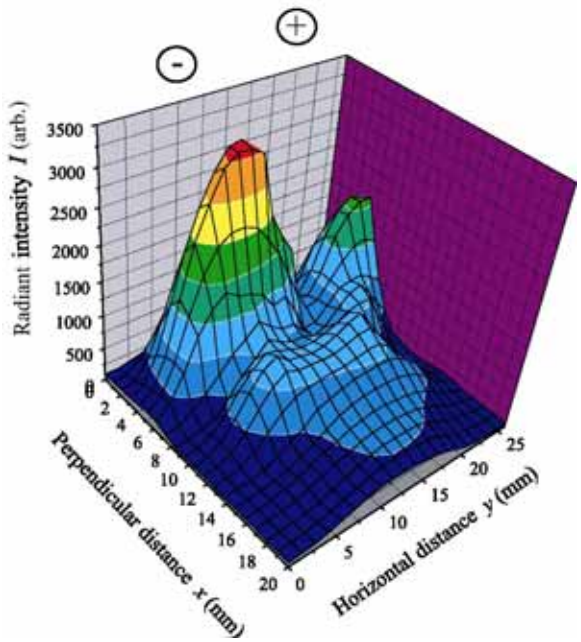

Fig. 6 Intensity distribution of spectrum (Ar I 706.7nm)

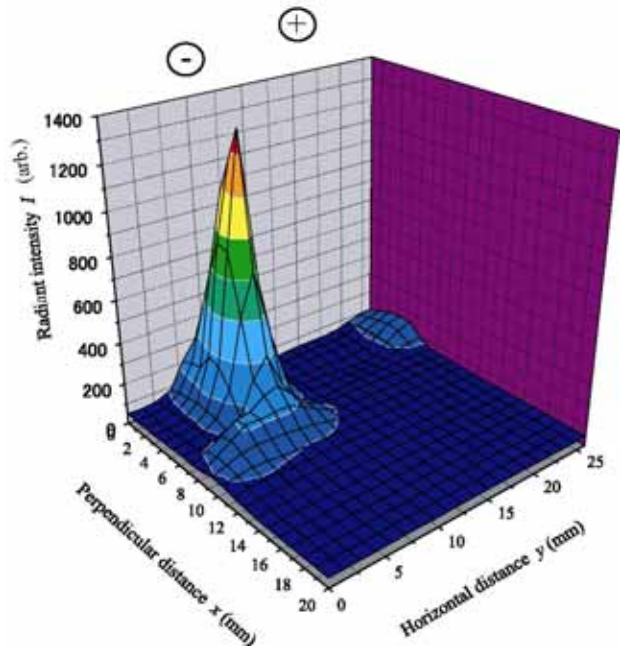

Fig. 7 Intensity distribution of spectrum (Ar II 434.8nm)

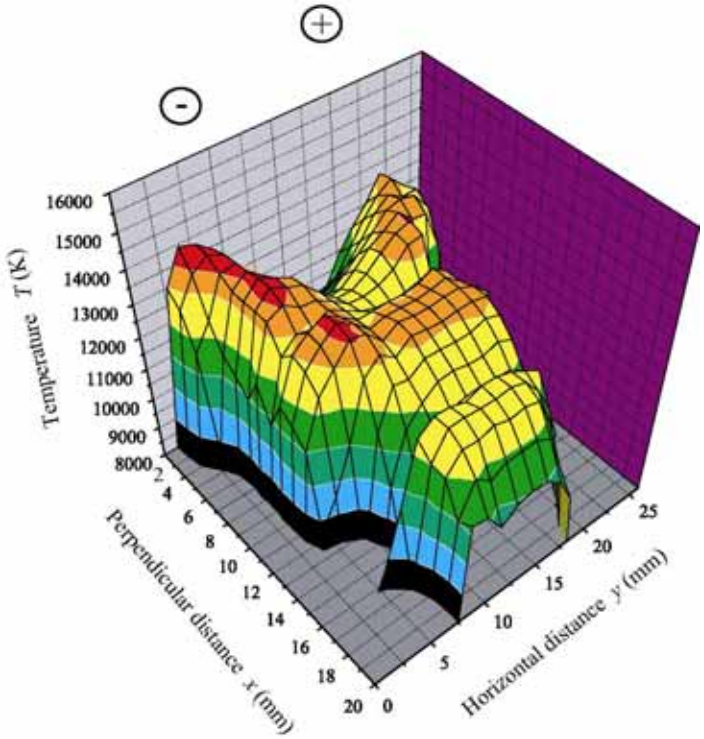

Fig. 8 Temperature distribution of twin torch plasma arc.

6. Temperature of Plasma arc

The temperature of twin torch plasma arc at 100A was measured by using spectroscope and line pair method. The intensity of spectrum Ar I(706.7nm) and Ar II (434.8nm) are shown in Figs. 7 and 8, respectively. The intensity of Ar I is higher than it of Ar II, and the intensity near cathode is higher than it near anode because the ionization and electron are dominated from 13,000K. The temperature becomes 14,000K near cathode. The center point of plasma arc, which is attachment point between the plasma arc from cathode and anode, and near anode is 13,000K.

7. Summary

The temperature distribution of twin torch plasma arc near 100A was measured for the treatment of hazardous waste. The main results are shown below.

(1) The high temperature region of the twin torch plasma arc is larger than that of a conventional single plasma torch and twin torch plasma arc.
(2) The plasma arc downward length can be changed by changing the plasma gas flow rate. The voltage is also changeable as function of current, plasma gas flow rate and arc length. The voltage gradient of twin torch plasma arc is about 4.5V/cm compared to 3.4V/cm in the case of the single torch.
(3) The temperature of the twin torch plasma was measured to be 14,000K near the cathode, and 13,000K at the center point between the electrodes and near anode at 100A.
(4) The heat power transferred to a neutral bar is 280-500W and its heating efficiency or the fraction of the total input power is 12-18% at d_u=0cm, 40-100A.

Abstract

The type of the applied shielding gas has a strong influence on quality of the welding process. In particular, increase of the percentage of carbon dioxide in argon, involves increase of the transition current value from the globular to spray mode of metal transfer. These results show that the observed effects could be linked to the microstructural modifications of the anode tip during the MIG-MAG welding process as a function of the gas composition, and especially to the existence and disappearance of an insulating oxide "gangue" at the wire extremity.

The spectroscopic diagnostic of the welding arc is also necessary to understand the observed changes in the mode of droplet transfer. The use of an original diagnostic method allows to estimate the temperature and the electronic density distributions in the plasma without hypothesis on its equilibrium state.

1. Introduction

In the MIG-MAG ("Metal Inert Gas"-"Metal Active Gas") welding process, the plasma arc burns between the extremity of a fusible electrode (usually anode) and metal plate (usually cathode). The transfer mode of the metal melted in the arc depends mainly on nature of the used gas, electrode dimensions and composition, and the density of the welding current. Following the arc current and gas mixtures, the metal transfer can be made of three manners: the regime of transfer by short-circuits ("short-arc"), the "globular transfer" and the "spray-arc".

Composition of the applied shielding gas has a strong influence on physical properties of the plasma and parameters of the welding process. In particular, increase of the percentage of carbon dioxide in argon, results in increase of the transition current value while changing from the globular to spray mode of metal transfer during the welding process. In order to explain this phenomenon, the MIG/MAG welding arc plasma was investigated at different mixtures of argon and carbon dioxide in the shielding gas. Applying a fast camera, recording distribution of spectral lines of the plasma components, we have noticed some phenomena not described yet in the literature [1]. Particulary, results show in a very clear way that there is a limit of the percentage of relative concentration CO_2/Ar beyond which the shape of the arc is significantly modified.

Furthermore, the metal transfer mode can be characterized qualitatively by the shape of the plasma column and its attachement on the wire tip [1]: indeed, pictures show clearly in spray-arc a conical arc shape with a narrow attach zone on the anode, while the arc shape in globular transfer is rather like a bell with an attach zone largely increased on anodic wire, including the drop in the process of formation.

The current distribution inside the pendant attached droplet plays a decisive part on the drop behaviour due to the magnitude and sign of the induced electromagnetic force. The Lorentz force can act, either as a force of detachment (if current lines diverge), or on the other hand, as a force attaching the droplet to the wire electrode (if current lines converge) [*2*, *3*]. In this second case, the repelled metal transfer was observed during welding process using CO_2 shielding gas [4]. Detailed calculations made by Haidar [*5*] indicate that in dependence on welding conditions, the axial component of the electromagnetic force can perform this double function and its radial component is the dominant detaching force and directly determines the transition from globular transfer mode to the spray transfer mode. These results seem to show that the observed effects could be linked to the microstructural modifications of the anode tip during the MIG-MAG welding process as a function of the gas composition.

Also study of the anode erosion (detaching of electrodes pieces), formation of metallic droplets, their shape and their distribution in the discharge volume, are very valuable from the point of view of welding. One of the objectives of the present research was to identify microstructural characteristics for each transfer mode.

But a good knowledge of the welding arc plasma is also necessary to understand the observed changes in the mode of droplet transfer. The use of an original spectroscopic diagnostic method allows to estimate the temperature and the electronic density distributions in the plasma without hypothesis on its equilibrium state.

2. Experimental setup

The scheme of the experimental system is presented on Figure 1, and has been partially described in [1]. It is organized around a welding set SAFMIG 480 TRS PLUS [6, 7]. The welding was performed under reverse-polarity (wire-anode, workpiece-cathode) direct current in the constant current mode. The wire-anode was a mild steel consumable electrode (AWS A5.17) with 1.2 mm diameter. The distance between the contact-tube and the metal plate amounted 20 mm. The thickness of the workpiece was 8 mm for all measurements. The gas mixture based on the argon and the carbon dioxide, was provided by two bottles of industrial gas. Two mass flow meters allow measurement and control gas output. The measurements of voltage between the electrodes and arc current were carried out by a differential voltage and current probes, respectively.

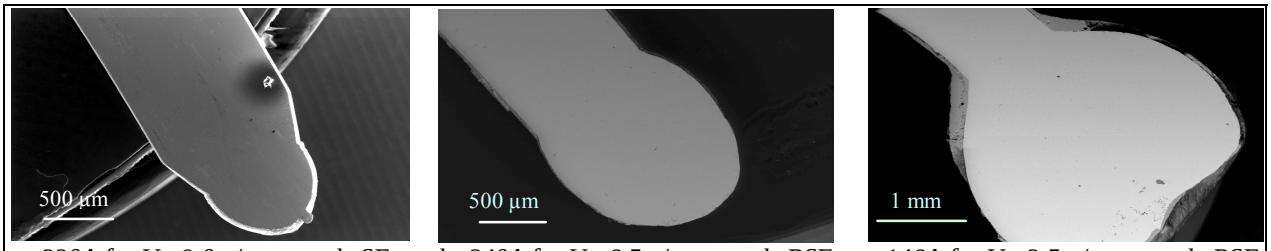
3. Microstructural analysis

Working conditions of the process, such as the nature of the protective gas, the current, the wire moving speed, have direct consequences on the plasma, what induces an evolution of its shape and composition. So, they will give rise to some physicochemical transformations of the anode wire. We have studied in particular the microstructure and the elementary chemical composition of the drop derived from the steel quench into the working gas.

Microstructures have been examined by scanning electron microscope SEM (PHILIPS XL 40) coupled with an EDS (Energy Dispersive X-ray Spectroscopy) analysis. Observations are made on polished cross-sections according to wire axis. Chemical composition measurements are qualitative, with an incertitude in the order of 1% for metals and 5% on oxygen. Carbon detection is rather indicative. These measurements have been completed by quantitative analysis with an electron microprobe (CAMECA SX 50 microbeam).

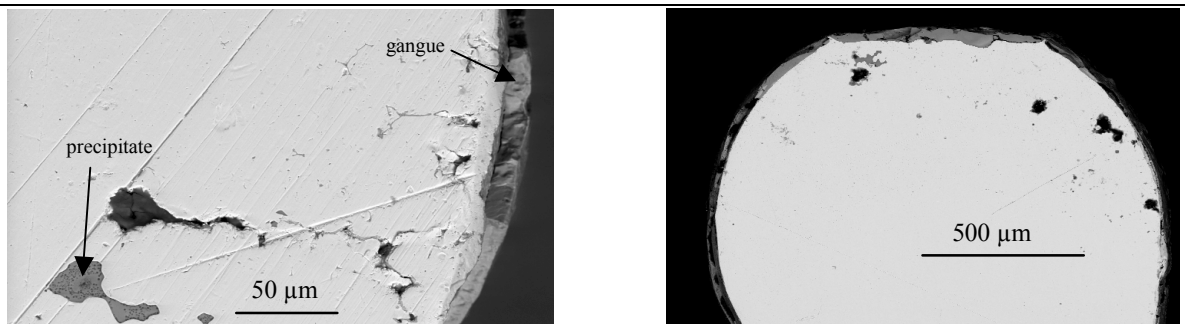
Experiments in argon atmosphere allow to attain a spray-arc above 240 A in the case of steel anode wire 70S (cf composition in table). Decreasing the current, the arc behavior corresponds first to globular transfer mode then to short-arc for lowest currents (for 146 A for example). In spray-arc, the drops formed in quenching are very small and then can be supported at the tip of the wire on a section inferior to the normal wire section [Cf. Figure 2a]. Indeed, on the images of working arc, we can observe the tapering of the wire tip which discharges the drops. At the time of the quench, the liquid wire tip takes an equilibrium shape corresponding to a pendant drop which minimizes its surface energy, considering surface tension of the liquid. Reducing the current, more and more voluminous drops are obtained, and supported by the total wire section [Cf. Figure 2b and Figure 2c]. The largest are associated with the short-arc. However, remark that drop volume can be more or less important for same experimental conditions, in agreement with the kinetics of the drop formation and the time of the quench.



a: 330A for V_f=9.0m/mn - mode SE (Spray-arc) — *b: 240A for V_f=6.5m/mn - mode BSE (Globular transfer)* — *c: 146A for V_f=3.5m/mn – mode BSE (Short-arc)*

Figure 2 - Drop size comparison at different currents for MIG experiments in pure argon – SEM micrographs

When CO_2 is present in the protective gas, it is difficult to maintain the spray-arc. For low CO_2 contents (< 10 %vol) the current increase still allows to recover the spray transfer mode, but for higher CO_2 contents, we are limited by the available currents on the experimental device. At 330 A for example, spray-arc is maintained for 5 %vol CO_2, while the transfer mode is globular at 15.4 %vol. The microstructural analysis of drops formed in protective gas mixture Ar+CO_2 at different current values show that they have overall the same characteristics than in MIG experiments : precipitates, porosities and cracks, oxide gangue [Cf. Figure 3]. But in this case, the gangue presence is more systematic. It is constituted of oxides and its thickness increases when CO_2 content is higher at fixed current, or when the current decreases at constant CO_2 content in the protective gas. The trend is then the gangue disappearance towards the spray-arc.



a: at 20% CO_2 vol. — *b: at 40% CO_2 vol. [V_f=9m/mn]*

Figure 3 - Drop microstructure for MAG experiment at 330A in gas mixture – SEM micrograph in BSE mode

In presence of oxide gangue, which is bad conductor, arc will need an attach zone larger to transfer the same current value. In globular transfer mode, we have effectively observed that arc attach zone includes largely the drop in the process of formation. This can explain the bell shape observed in globular transfer or short-arc, compared to conical shape characterizing the spray-arc.

To confirm these hypothesis, new recent experiments with another wire composition have been made. Very promising results have been obtained, and in few cases the transfer mode is observed close to spray at 330 A with 15 %vol CO_2.

4. Optical emission spectroscopic of the welding arc

The experimental diagnostic of the welding arc is necessary to understand the observed changes in the mode of droplet transfer. But the temperature measurements available in the literature, are dispersed, and do not seem to validate proposed models, for example by Haidar [8, 9]: from metallic lines emitted in the central region of the plasma, Lancaster [10] obtains temperatures in the order of 7000 K reaching 11000 K on the column axis with a mild steel consumable wire-anode, and closed to 17000 K on axis with an aluminium electrode. Haidar [8] puts these differences, that are not anticipated by the theoretical models, on the account of experimental uncertainties. It is therefore necessary to obtain precise informations on the plasma column behavior, and the not-intrusiv diagnosis methods of optical emission spectroscopy seem to be the alone methods adapted to the problem.

Spectral distribution of emitted light was measured in spectral range [260nm-760nm] using an Ebert type grating spectrometer equipped with a intensified two-dimensional CCD array of 512×512 contiguous photodiodes (19×19µm – effectiv size: 24×24 µm) designed by ROPPER SCIENTIFIC. The used CCD array recorded a spectral range of about 4 nm of the spectrum; therefore, the line profiles were measured up to their far wings.

The side-on measured intensity was converted into a radial emission distribution, pixel by pixel, using the numerical Abel inversion procedure with a cubic Spline data smoothing [11]. Then, the Voigt function on a linear continuous background was fitted to each inverted line profile, and allowed to determine automatically the total emission line profile (including line wings) and to obtain the Stark contribution to the effective line broadening, if the Doppler and instrumental broadening are known. Other broadening mechanisms, such as Van der Waals and resonant broadening, appeared to be negligible in the pressure and temperature range ($P \approx 1$atm, $T \leq 15000$K) of our experiments.

The use of an original method based on comparison of stark broadenings of the 696.543nm ArI line and 538.337nm FeI line spectral lines [12, 13], has allowed to estimate the temperature and the electronic density distributions in the plasma without hypothesis on its equilibrium state [14, 15]. So, the plasma diagnostic has been done on differents distances h from the cathodic plate for pure argon and for two Ar-CO_2 gas mixtures (Ar + 5.4% vol CO_2 and Ar + 20.2% vol CO_2), with a total gas flow rate D_g=20 l/min, and identical parameters of the process: wire speed V_f=9 m/min, $I_{ArcOrigine}$=330 A and average current I_{Mean}=326 A. An exemple of obtained results is given in Figure 4.

The temperature lowering in the center of the arc column, observed in the MIG-MAG arc under pure argon and with poor mixture in carbon dioxide, is well explained by the metallic vapours in the plasma that increase its electrical conductivity, but also of its emissivity [16, 17] and induces an increase of energy losses by radiation. Indeed, measurements realized in an TIG type's arc prove that the addition of less than 0.07% iron vapours to an argon plasma, lows its temperature approximately of 1500K [18].

Then, the temperature in the central part of the arc never seems to exceed the value of 15000 K, contrary to the values given in literature (T>20000 K on the axis). On the basis of these results, it is clear that the modelisations available in the literature [8, 9] do not represent the real situation: they are generally established in the local thermodynamical equilibrium (LTE) hypothesis in the case of the pure argon, and they do not take into account the metallic vapours influence and the induced temperature lowering.

Actually, to estimate the distribution of relative concentrations in argon and iron in the arc column, we try to verify the equilibrium state of the plasma using differents crossed diagnostic methods (Boltzmann plot, atomic to ionic lines ratio…). But the zone of most intense iron line emission is limited to the center of the arc column, and possibilities of MIG-MAG plasma diagnostic based on the emission spectrum of other metallic elements are limited.

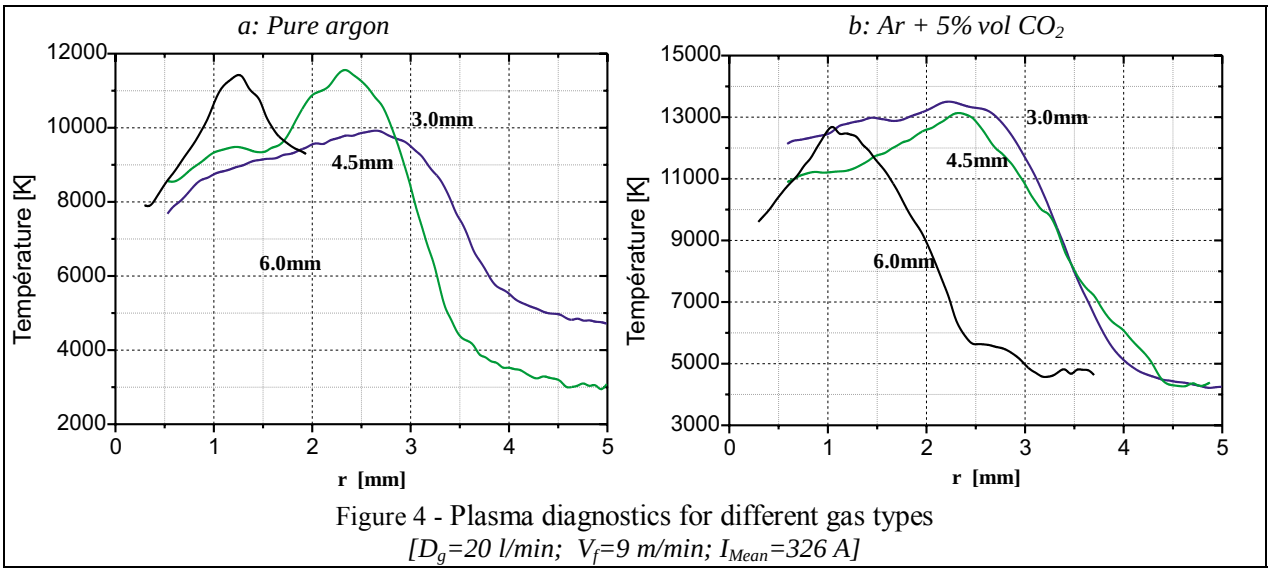


Figure 4 - Plasma diagnostics for different gas types
[D_g=20 l/min; V_f=9 m/min; I_{Mean}=326 A]

5. Conclusion

The comparison of metal transfer modes for experiments MIG in argon and MAG in argon+CO_2 shielding gas mixture shows an evolution from the short-arc to the globular transfer and then to the spray-arc when current values are increased. The transition between globular and spray transfer modes is observed towards 240 A in pure argon, and towards 410 A in gas mixture with 15%vol. CO_2.

SEM microstructural observations and EDX analysis, on quench drops for MIG-MAG experiments have allowed to characterize the physicochemical transformations of the anode wire, according to working conditions of the process, such as the nature of shielding gas and the arc current. The presence of oxide gangue, comparable to slag in iron metallothermy is typical of globular transfer and short-arc. CO_2 in protective gas favors its formation by chemical oxidation-reduction reactions. This bad conductor gangue hinders the current transfer and the arc needs a larger attach zone. That explains the bell arc shape associated to globular transfer or short-arc. The thickness of this gangue is decreasing when current value increases or CO_2 content decreases. So, it has not been observed in spray transfer mode for pure argon shielding gas. In this conditions, the plasma column has a well defined conical shape and the curvature on the current lines is clearly modified.

The plasma column diagnostic done by optical emission spectroscopy without hypothesis on the LTE state, show that, in the central part of the arc, the temperature never seems to exceed the value 15000 K, contrary to the values given in literature (T>20000 K on the axis). Among other results, we can note especially the deficit in excited argon close to the axis of arc when the amount of CO_2 in the shielding gas is less than 5%, the relative weakness of iron lines on the edge of the column, but also the increase of the FeII spectral lines in periphery of the arc. This work must be continued to study the LTE state in the plasma, and try to estimate the distribution of relative concentrations in argon and iron, and then the principal transport and thermodynamic characteristics (thermal and electrical conductivity, viscosity…) in the arc column.

Abstract

The etching of the DLC films deposited on the PET has been investigated by Atomic force microscopy (AFM), Raman spectroscopy, and infrared spectroscopy (IR). The DLC films were effectively etched by the reactive radicals in the glow discharge plasma of oxygen gas. The etching of the DLC films was easily carried out by the treatment of the plasma. The end point of the DLC etching was estimated by the plasma diagnostics because the damage of PET was given by the overexposure. The intensity of the optical emission was rapidly changed at the end of the etching treatment and it was able to monitor the etching process.

1. Introduction

The diamond-like carbon (DLC) films are coated at inner wall of the polyethylene terephthalete (PET) bottles because the DLC films protect degradation of inner soft drink against irradiation of ultra violet light and penetration of carbon dioxide gas through the PET[1]. By these advantages, the number of PET bottles with the DLC films is significantly increased for carriers of beverages with carbon dioxide gas such as soda, cola, and beer. These PET bottles become resource materials as synthetic fiber and resins. However, the DLC films act as contamination during recycling process of PET materials. Therefore the quality of regenerated PET is extremely deteriorated by the inclusion of the DLC residue. The removal of the DLC films is essentially required for recycling industry because it is big environmental problem against civil life. In order to recycle the PET bottles with DLC films, it is quite necessary to eliminate the DLC films before the treatment of recycling process. Furthermore, the base PET has to be analyzed after the removal of the DLC films from the PET substrates.

2. Experimental

Since the DLC films are easily deposited on the PET by using capacitive coupled radio frequency (r.f.) plasma discharge, the same r.f. plasma system is utilized for etching of the DLC films[2]. In this work, the oxygen gas was utilized for etching because radicals of oxygen plasma are very reactive with the carbon films. The power of the r.f. generator was kept constant at 100 W during etching. Optical emission

spectroscopy (OES) was used to obtain the end of the plasma etching treatment, and the results were applied to discuss the relationship between the etching treatment and the plasma diagnostic.

The etching of the DLC films on the PET has been investigated by atomic force microscopy (AFM), and Raman spectroscopy. The etching rate was calculated by the film thickness and plasma treatment time. It needs that the optimized time should be investigated for the etching because the PET is received the some damages by corrosion of ionic species for extra etching treatment. Therefore the end point of the etching treatment was estimated by the plasma optical diagnostic.

3. Results and discussion

The thickness of the DLC films was monotonously reduced with increase of the etching time as shown in Fig. 1. At the etching pressure of 10 Pa, the DLC films with thickness of 300 nm were completely removed by oxygen plasma for the treatment time of 6 minutes. The complete etching of the DLC films was also confirmed by Raman analysis. The etching of the DLC films in PET bottles is quit easy by using this technique. The etching time is estimated about 1 minute because the thickness of the DLC films in PET bottles is about several nanometers. The etching rate is approximately 50 nm/min by the etching time and thickness of the DLC film. The etching rate was dramatically decreased at 1 Pa because of the decrease of plasma density. The surface topography of the samples before and after the etching treatment was observed by AFM.

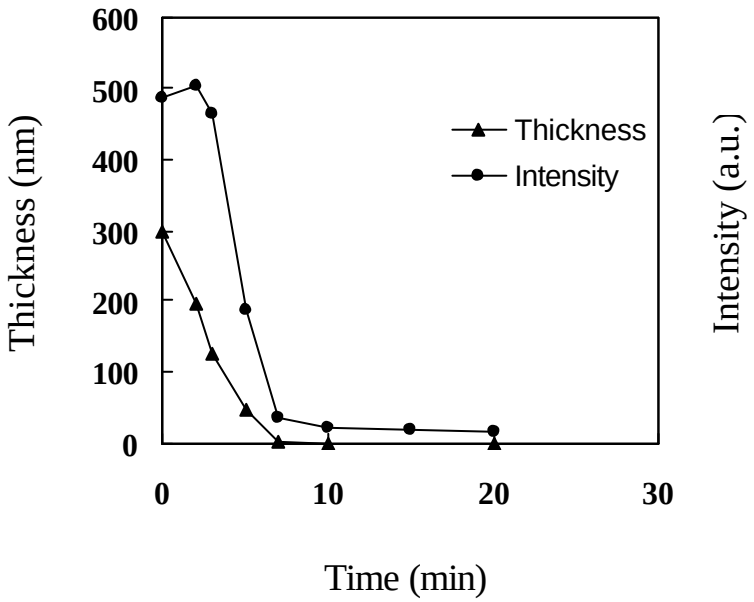

Fig. 1 The thickness of the DLC films and the intensity of CH optical emission at 430 nm as a function of the etching time. Both results of the thickness and the emission intensity obtained at pressure condition of 10 Pa.

In order to obtain the relationship between the etching result and plasma condition, the spectra of the OES measurements were recorded during etching. The emission intensity of CH at 430 nm as a function of the etching time is shown in Fig. 1. The optical emission peaks of the plasma were rapidly changed at the

end of the etching treatment. The intensity is dramatically decreased with the increase of the etching time and then it approaches to the saturation point. In particular, the intensity of the peak is the saturation value around the goal of the etching. The intensity of CH peak may be able to monitor the end point of the DLC etching by oxygen plasma.

Table I Etching rate and peak intensity ratio of optical emissions at each condition

Condition (Pa)	Intensity ratio CH/Hα (a.u.)	Etching rate (nm/min)
10	8.61	50.8
100	2.48	14.7

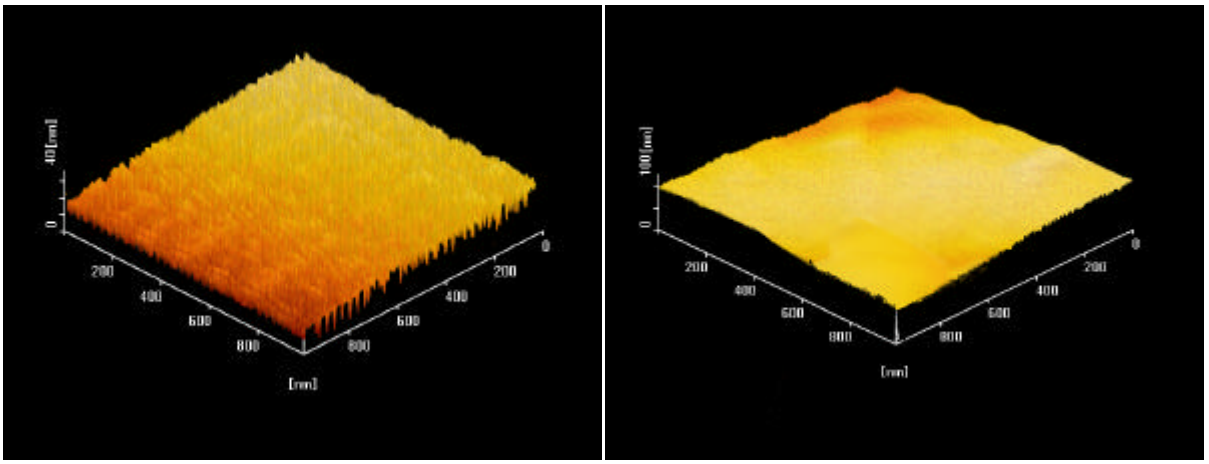
The etching rate is reduced at the higher pressure condition. At the etching pressure of 100 Pa, it needed for 20 minutes for etching of the DLC films with thickness of 300 nm. The etching rate in case of higher pressure condition (100 Pa) was a factor of one fourth lower than that of a low pressure condition (10 Pa). The etching rate at the pressure condition of 100 Pa is 15 nm/min. This decreasing effect can be explained by sputter removal through ions accelerated towards in the electrical field of bias voltage. Etching and deposition products are extremely influenced by the negative dc self-bias voltage which occurs on the powered electrode. The dc self-bias voltage is generally increased with decrease of the pressure in case of r.f .plasma. The relationship between the negative bias potential and the etching and deposition of some films is reported in detail[3,4].

The many peaks were observed from the OES of the oxygen plasma. The OES has intensive three peaks at 431.4, 486.1, and 656.3 nm. The peaks at 486.1 and 656.3 nm correspond to Hα and Hβ in hydrogen plasma, respectively. The peak at 431.4 nm is originated from CH radicals in the plasma. In order to monitor the etching process, the emission intensity ratio CH/Hα was measured at different pressure condition of 10 and 100 Pa. Table I shows the etching rate and peak intensity ratio of the optical emissions at different pressure condition. The intensity ratio CH/Hα of low pressure condition was higher than that of high pressure condition because the strong emission of CH peak was observed in case of 10 Pa. At lower pressure condition, the DLC films are exposed by the ionic species in the plasma that are accelerated to the film surfaces. The etching is enhanced by both ionic species and neutral radicals in the plasma.

On the other hand, the electrical neutral radicals are dominant at high pressure condition of 100 Pa. Since the etching of chemical reaction is mainly forwarded by the dominant radicals, the etching rate is decreased in comparison with lower pressure condition. The emission intensity ratio CH/Hα in case of high pressure is also greater than that of lower pressure condition. There is good agreement between both results of the etching rate and plasma optical diagnostic.

The root-mean-square (rms) roughness values used throughout the paper have been determined on areas of 1 μm x 1 μm. Figure 2 shows AFM images of the DLC film topographies obtained at different etching pressure. In the lower pressure region (10 Pa), pronounced protrusions were observed on the film surface. The estimated thickness is about 150 nm because of half time (3 min) of total etching time. The rms roughness was about 3.7 nm. In case of the high pressure condition (100 Pa), such pronounced features can not be observed at the surface. At this condition, the estimated thickness is about 150 nm from the etching rate of 15 nm/min because the etching

treatment is 10 min. The fine pronounced features can not be observed on the sample surface as shown in Fig. 2 (b). The decrease of the roughness with increase of pressure is obtained. The roughness at high pressure is approximately half than that of sample at low pressure. The decrease of the rms roughness from 10 Pa to 100 Pa is originated by the difference of the dc self-bias voltage and the energy of the ionic species. At low pressure condition, both weak and strong bonds of the films are sputtered and milled by the ionic species with high acceleration energy, and most of the ionic species attack to the surface without collision to any other molecules in the chamber. High etching rate was obtained at low pressure condition whereas the surface roughness was increased after the etching treatment.



(a) etching time: 3 [min], pressure: 10 [Pa] Roughness: 3.7 [nm]

(b) etching time: 10 [min], pressure: 100 [Pa] Roughness: 1.9 [nm]

Fig. 2 AFM images showing the morphology of the sample surfaces.

4. Conclusion

The etching of the DLC films deposited in PET bottles has been investigated by using plasma process and optical emission spectroscopy. The etching thickness was increased with etching time of oxygen plasma and the etching rate at optimum condition is about 50 nm/min. The emission intensity of the plasma was proposed for monitoring the etching of the DLC films. The end of the etching is confirmed by the intensity ratio CH/Hα during etching. At high pressure condition, the etched surface of the substrate PET is smooth than that at low pressure condition with dependence on the dc self-bias voltage.

Abstract
A two-dimensional magnet-gas-dynamic model for numerical calculation of the microwave discharge in argon at atmospheric pressure of co-axial waveguide with a short-cut internal electrode is offered. The output qualitatively agrees with experimental data.

Introduction

The microwave discharges with a co-axial electromagnetic power supply find a wide application in different scientific, technical and technological tasks [1-3]. The practice of different schemes of microwave discharges realization has shown that that plasma generation strives to "elongate" a short-cut electrode. For example, in a standard scheme of the co-axial microwave plasmatron the discharge is excited on the end of a short-cut internal water-cooling electrode. The stability of the plasma torch spatial localization is reached by a straight-jet or vortex work of gas flow supplied between the internal and external electrodes of co-axial line [2].

In Institute of General Physics RASc a new variant of the plasma torch generation is offered, where a short-cut internal electrode represents a tube, ensuring a plasma-generating gas flow (fig.1). The length of the internal electrode from entry in the co-axial part is taken so that the tube end was in maximum electric field of a standing wave, which arises without any discharge at reflection of a running wave from a zone of round below-cutoff waveguide. At relatively low microwave power (~ 1 kWt) the disruption is possible, that ensures generation of torch in different gases at different pressures, including the atmospheric. New modifications in the construction allowed an essential prolongation of generated microwave torch to 10-20 cm and perfection of the torch gas-dynamic stability. Experimental study of the discharge has shown that in every new power supply pulse (magnetron of 2.45 HHz) the torch passes stages of initialization, flaming, and propagation along the waveguide axis up to a certain end size. Visually, in atomic gas near a nozzle of the internal electrode a bright luminescence in a shape of a rod ("core") with a diameter of 1-2 mm and length 1-2 cm is realized; an expanded area of less luminescence follows it. In molecular gases the core as a sharply outlined area of bright luminescence is absent. The concentration of electrons in the core is 10^{16} cm^{-3}, and in the torch body outgoing from the core – 10^{14} cm^{-3}. Main part of the torch, elongated along axis of the waveguide system, is formed by the internal surface wave, which necessary condition for existence and propagation is increased critical concentration of plasma electrons.

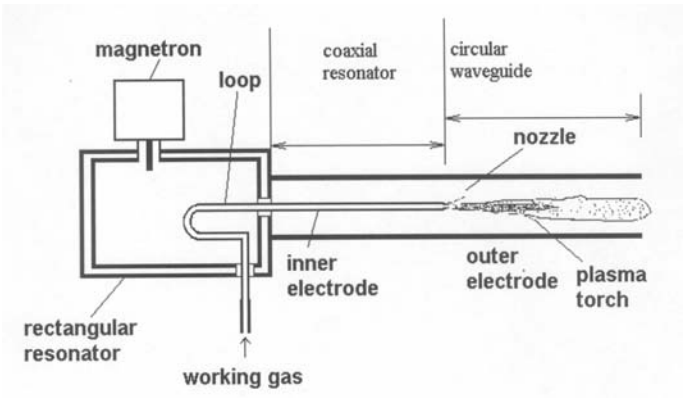

Figure 1. Microwave plasma torch launcher.

This model offers two-dimensional magnet-gas-dynamic (MGD) model of equilibrium microwave discharge in the co-axial wave-guide with a short-cut internal electrode. The discharge characteristics are calculated in argon at atmospheric pressure. The assessment of the numerical model adequacy to experimental properties of the discharge is carried out.

Model

Burning of the microwave discharge is considered in a driven by TEM-wave co-axial waveguide with a short-cut internal electrode made in a shape of tube for transporting plasma-generated gas with the discharge G_0 (fig.2). It is guessed that the electrodes material is ideally conductive, and a cylindrical wall of

the external electrode with the radius R_e is "transparent" for gas inflow and outflow. The axis-symmetrical equilibrium plasma jet, generated in a zone of a round below-cutoff waveguide, is guessed ensuring conditions for existence of electromagnetic field with components $\vec{E}(E_r; 0; E_z)\exp(i\omega t)$, $\vec{B}(0; B_\varphi = B; 0)\exp(i\omega t)$. A period of electromagnetic field change is much less than the time for establishing thermal gas-dynamic characteristics of the discharge.

Equations. The gas-dynamic, thermal and electromagnetic characteristics of the microwave discharge in axis-symmetrical MGD approximation are described on the basis of a set of stationary equations continuity, motion (Navies-Stokes), energy balance and wave equation:

$$\frac{1}{r}\frac{\partial}{\partial r}(r\rho v)+\frac{\partial}{\partial z}(\rho u)=0,$$

$$\rho\left(v\frac{\partial v}{\partial r}+u\frac{\partial v}{\partial z}\right)=-\frac{\partial p}{\partial r}-\frac{1}{4}\sigma\left(E_z B_\varphi^*+E_z^* B_\varphi\right)+\frac{2}{r}\frac{\partial}{\partial r}\left(r\eta\frac{\partial v}{\partial r}\right)-\frac{2\eta v}{r^2}+$$

$$\frac{\partial}{\partial z}\left[\eta\left(\frac{\partial u}{\partial r}+\frac{\partial v}{\partial z}\right)\right]-\frac{\partial}{\partial r}\left[\frac{2}{3}\eta\left(\frac{1}{r}\frac{\partial rv}{\partial r}+\frac{\partial u}{\partial z}\right)\right],$$

$$\rho\left(v\frac{\partial u}{\partial r}+u\frac{\partial u}{\partial z}\right)=-\frac{\partial p}{\partial z}+\frac{1}{4}\sigma\left(E_r B_\varphi^*+E_r^* B_\varphi\right)+2\frac{\partial}{\partial z}\left(\eta\frac{\partial u}{\partial z}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left[r\eta\left(\frac{\partial u}{\partial r}+\frac{\partial v}{\partial z}\right)\right]-$$

$$\frac{\partial}{\partial z}\left[\frac{2}{3}\eta\left(\frac{1}{r}\frac{\partial rv}{\partial r}+\frac{\partial u}{\partial z}\right)\right],$$

$$\rho C_p\left(v\frac{\partial T}{\partial r}+u\frac{\partial T}{\partial z}\right)=\frac{1}{2}\sigma\left(E_r E_r^*+E_z E_z^*\right)-\varphi_e+\frac{1}{r}\frac{\partial}{\partial r}\left(r\lambda\frac{\partial T}{\partial r}\right)+\frac{\partial}{\partial z}\left(\lambda\frac{\partial T}{\partial z}\right),$$

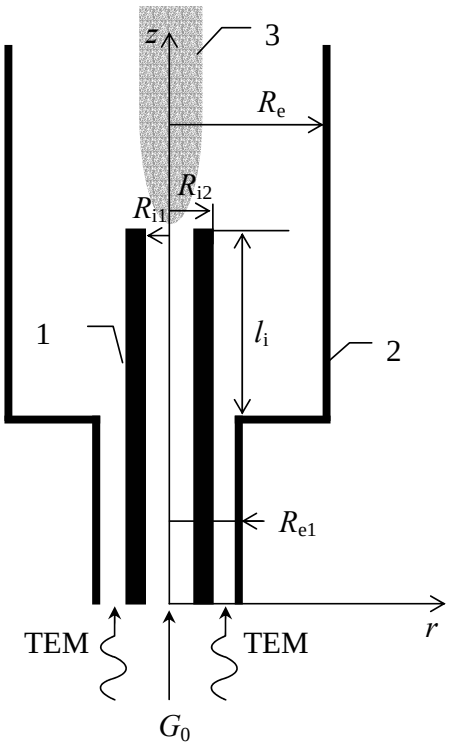

Figure 2. Schemes of accounted area of co-axial wave-guide with a short-cut internal electrode and electromagnetic power supply by TEM-wave: 1 – internal el.; 2 – external el-de; 3 – plasma; R_e, R_{e1}, R_{i1}, R_{i2}- radiuses of exterior and interior electrodes; l_i- length of the internal electrode emerging part; G_0- gas flow.

$$\frac{\partial}{\partial r}\left(\frac{1}{r\varepsilon_k}\frac{\partial rB}{\partial r}\right)+\frac{\partial}{\partial z}\left(\frac{1}{\varepsilon_k}\frac{\partial B}{\partial z}\right)+\frac{\omega^2}{c^2}B=0.$$

Components of the electric field intensity are found from the Maxwell equations:

$$E_r=\frac{i}{\omega\mu_0\varepsilon_0\varepsilon_k}\frac{\partial B}{\partial z},\qquad E_z=-\frac{i}{\omega\mu_0\varepsilon_0\varepsilon_k}\frac{1}{r}\frac{\partial rB}{\partial r}.$$

Notations: $\vec{V}(V_r=v,\ V_\varphi=0,\ V_z=u)$- velocity; T - temperature; p - pressure; $\omega=2\pi f$-frequency; ρ, λ, C_p, η, φ_e- density, thermal conductivity, thermal capacity, viscosity, emittance; $\varepsilon_k=\varepsilon-i\sigma/\omega\varepsilon_0$; $\varepsilon=1-\sigma/\varepsilon_0\nu_e$- dielectric permeability; $\sigma=K_\sigma e^2 n_e\nu_e/m_e(\omega^2+\nu_e^2)$- electro-conductivity; K_σ- kinetic correction; ν_e, n_e, e, m_e – effective collision rate, electrons concentration and mass; c – velocity of light; ε_0- electric constant; μ_0- magnetic constant; i – imaginary unit; upper index * means complex conjugate value.

Boundary conditions are given on all the contour of the accounted area (fig.2): for velocity – an adhesion on solid surfaces, radial gas inflow-outflow through the surface of the exterior electrode with radius R_e, poise flow in entry profile of the internal electrode tube; pressure in outflow profile is atmospheric; for temperature – conditions of coupling

with given temperature of exterior contour, excluding outflow boundary, where thermal equilibrium condition is given; for magnetic field induction – conditions of ideally conducting electrodes (tangential to the wall component of the electric field intensity is equal to zero), radiative conditions in ring profile of TEM-wave supply and in outflow profile. Boundary conditions are as follows:

$z = z_{\min}$, $R_{i2} < r < R_{e1}$: $\dfrac{\partial B}{\partial z} - ikB = -2ikB_I \dfrac{R_{i2}}{r}\exp(-ikz)$;

$z = z_{\max}$, $0 < r < R_e$: $\dfrac{\partial B}{\partial z} + ikB = 0$.

We guess that sizes of the co-axial R_{i2}, R_{e1} "ensure" for given field frequency the propagation only of the TEM-wave $B = B_I \dfrac{R_{i2}}{r}\exp(-ikz) + B_R \dfrac{R_{i2}}{r}\exp(+ikz)$: falling with amplitude $B_I = \sqrt{\dfrac{\mu_0 \omega P_I}{\pi k c^2 R_{i2}^2 \ln R_{e1}/R_{i2}}}$ and power P_I and reflected with amplitude $B_R = -\left.\dfrac{\partial B/\partial z + ikB}{\partial B/\partial z - ikB}\right|_{R_{i2}<r<R_{e1}}$ and power $P_R = \dfrac{B_R B_R^*}{B_I B_I^*} P_I$; $k = \omega/c$. On the outflow boundary a condition corresponds to the passed wave propagating along the plasma torch in positive direction of axis z with a number of longitudinal propagation k.

The integral balance of electromagnetic power was checked in accounts by the condition:

$P_I = P_R + P_T + P_d$,

where power of the "passed " wave and dissipated power are determined by the equations:

$$P_T = \frac{\pi}{\mu_0}\int_0^{R_e} E_r B^* r dr; \qquad P_d = 2\pi \int_0^{R_e}\int_0^{z_{\max}} \frac{1}{2}\sigma(E_r E_r^* + E_z E_z^*) r dr dz .$$

For *numerical solution a set of equations* is sampled by control volume method on a rectangular nonuniform grid. For velocity components the offset grids are used, and the pressure field is determined by the method SIMPLER [4]. On every pitch of the iteration procedure the discrete analogs of amendments for dependant variables are solved by the exclusion method of Gauss. Restriction conditions (less than 0.01%) for Euclidean norms of discrete analogs residual vectors made up on all control volumes for desired dependent variables are used for end criterion.

Results

The Characteristics of the microwave discharge in argon at atmospheric pressure are calculated as follows: f = 2.45 HHZ, R_{i1} = 1 mm; R_{i2} = 2 mm; R_e = 10 mm. Coefficients of the argon equilibrium plasma at atmospheric pressure are used from [5]. Particles concentrations are taken from calculation of equilibrium composition; electrons impingements frequency are calculated by the formula $\nu_e = \sqrt{\dfrac{8k_B T}{\pi m_e}}\left(n_a Q_{ea} + n_i Q_{ei}\right)$, where the impingements profile as in [5] are given by functions of temperature and concentrations. The output at $l_i = 3\lambda/4$ ($\lambda = 2\pi/k$); P_I = 800 Wt; G_0 = 10 l/min are shown in fig.3-4.

Following the accounts, the discharge is excited near the internal electrode profile (fig.3-4) because of high electric field concentration. The outflowing from the internal electrode plasma-generating gas results in formation of plasma torch front separated from the nozzle cut by "cold" space, which thermo-isolates the internal electrode. The isotherms field expands down the flow and then narrows with heat generation reduction (reduction of electromagnetic field intensity dissipation) and heating of surrounding gas at the expense of thermal conductivity and convective heat exchange. The electromagnetic field spreads up to area of plasma conductivity, which ensures conditions for further propagation and consequent dissipation of electromagnetic field energy in the thermal along the torch. In fig.3-4 is viewed that behind the internal electrode cut a complex electromagnetic field structure is formed. A zone of electromagnetic field energy dissipation: area with significant axial component of electromagnetic field intensity and radial vector

component of Umov-Pointing as well as area with prevailing radial electric field and axial electromagnetic energy flow, are distinguished. The periodicity of electromagnetic field structure along the discharge axis is considered. The isolines of the module of the electric field intensity

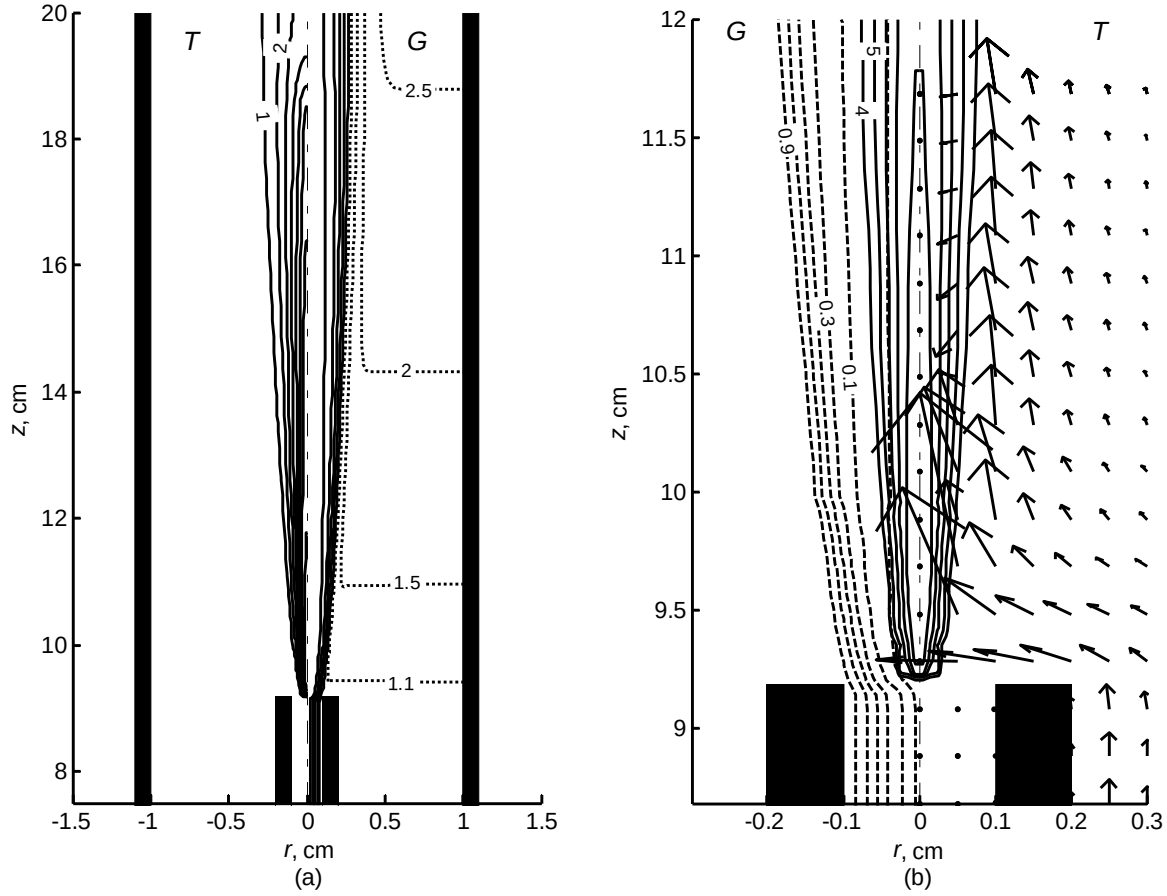

Figure 3. (a) Isotherms T/T_0 (pitch 1 kK) and gas flow lines G/G_0 (from 0.1, pitch 0.2); (b) field fragments of gas flow lines, isotherms and vector of Umov-Pointing (T_0 = 1kK, G_0 = 0.27g/s, S_m = 9.9 kW/cm^2, P_I = 800W, P_R = 493 W, P_d = 307 W, P_T = 0).

along the torch point to available concentration of the field near boundary of a zone of dissipation.

The picture corresponds to the mode of prevailing gas flow around discharge region: main amount of the transported on the internal electrode cold gas (more than 90%) flows around a high-temperature region (the isotherm 4 kK). The pressure increases sharply and goes down near the internal electrode cut on axis. On end surface of the electrode cut the pressure decreases and a surrounding air inflows (fig.3). The flow gasdynamic structure promotes spatial stabilization of the discharge (localization of main part and cross-section sizes fixation along the torch axis).

At power input increase or gas flow decrease, one consider a tendency to growth of radius of energy dissipation area along the torch axis.

When length of the internal electrode is $l_i = \lambda/2$ (fig.2) the numerical solution corresponds to a cold gas outflow from the internal electrode in free space at electromagnetic field energy dissipation absence and at full wave reflection from a zone of round below-cutoff waveguide ($z > l_i$). At $l_i = \lambda/4$ the account gives a solution, which is qualitatively similar to case $l_i = 3\lambda/4$. According to the scheme (fig.1, 2) a critical condition for the discharge existence is a choice of the internal electrode length that agrees with the experiment data. If the internal electrode length is equal to uneven number of quarters of wavelength, the electrode's end is in standing wave's electric field maximum, generated at reflection of TEM wave running from a zone of round below-cutoff waveguide. This choice of the internal electrode length can be considered as a necessary condition of the discharge burning.

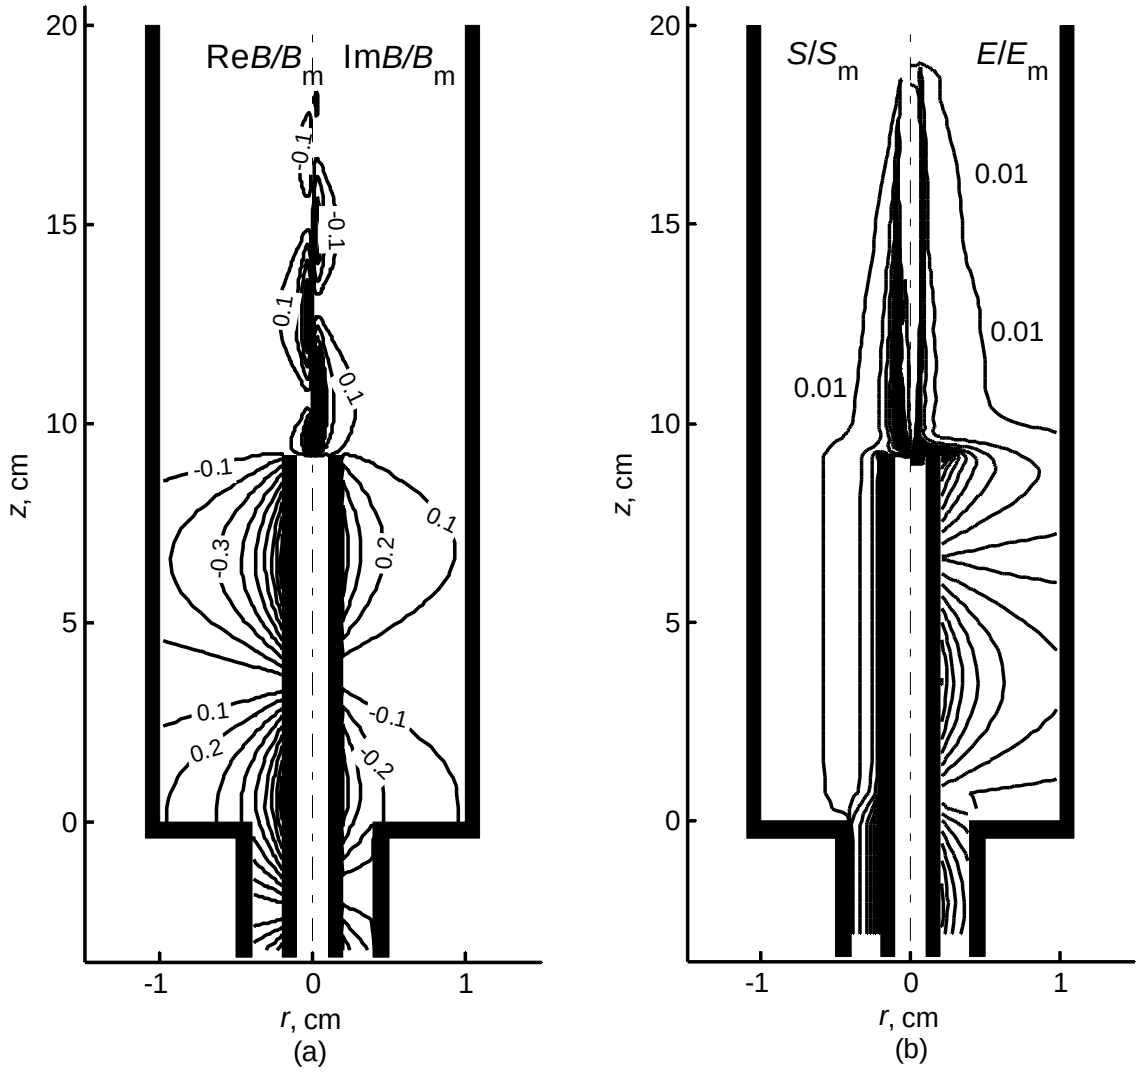

Figure 4. Given isolines of (a) magnetic field induction B/B_m (pitch 0.1); (b) vector of Umov-Pointing S/S_m (pitch 0.02) and electric field intensity E/E_m (pitch 0.02) (B_m = 1.09 mT; S_m = 9.9 kW/cm^2; E_m = 21.66 kV/cm).

Abstract
Aluminium oxide films were deposited by a dc pulsed reactive sputtering using a dual magnetron. High deposition rates (~100 nm/min) of Al_2O_3 films at the substrate-to-target distance $d_{s-t} = 100$ mm were achieved when the film deposition was carried out in a transition mode of sputtering. To avoid the hysteresis effect and to maintain the film deposition in the transition mode the process was controlled by the discharge voltage U_d. Transparent Al_2O_3 films with amorphous structure and smooth surface were successfully deposited. Optical and mechanical properties of Al_2O_3 films were determined.

Keywords: Al_2O_3 films, High deposition rate, Sputtering, Dual magnetron, Optical and mechanical properties

1. Introduction

At present, similarly as nitride films, the oxide films are a subject of great interest not only for their excellent properties such as a high chemical inertness, high thermal stability and corrosion resistance but also for their functional properties and particularly due to their enhanced mechanical, optical, electronic and catalytic properties. To understand fully the enhanced properties of oxide films, these films are intensively investigated in many world leading laboratories [1–7]. Simultaneously, a great attention is devoted also to the increase of a deposition rate a_D to ensure their low-cost industrial production. This concerns mainly the transparent oxide films which are usually produced in the oxide mode of sputtering with very low a_D.

The industry requires the transparent oxide films to be deposited with a_D of films at least 50 nm/min. However, this requirement is very hard to meet because (1) there is a jump transition from the metallic mode of sputtering (opaque films) to the oxide mode of sputtering (transparent films) and (2) the deposition rate of transparent oxide films in the oxide mode is very low $a_{D\,oxide} \leq (1/10)\, a_{D\,Me}$, where $a_{D\,Me}$ is the deposition rate of metallic films produced in the metallic mode of sputtering [8]. The transparent oxide films can be produced also in the transition mode of sputtering. However, due to the jump transition from the metallic to the oxide mode a special control system, which stabilizes the sputtering process, e.g. the system based on a plasma emission monitoring [6, 7], is needed. In addition, in the reactive magnetron sputtering of Al_2O_3 films, which are electrically insulating, a very serious problem is the charging of insulating islands and/or layers forming on uneroded areas of a sputtered target. The charging results in arcing on sputtered target that needs to be eliminated. A pulsed dual magnetron is an efficient tool which eliminates the arcing. It enables to produce insulating transparent oxides in the transition mode of sputtering without the arcing on sputtered target. This article reports on a high-rate deposition of the transparent Al_2O_3 films in the transition mode of sputtering using the magnetron discharge voltage U_d.

2. Experimental

The experiments were carried out in a deposition device schematically shown in Fig. 1. The dual magnetron, equipped with Al (99.99) targets of 50 mm in diameter, consists of two single unbalanced magnetrons tilted at 20° to the axis of substrate holder. In this system, both magnetrons were electrically insulated from the deposition chamber. The dual magnetron was supplied by a dc pulsed Advanced Energy 5 kW power supply and operated in a symmetrical bipolar mode at the pulse repetition frequency $f_r = 100$ kHz and pulse off time $t_2 = 5$ μs, i.e. the duty cycle $t_1 / T = 0.5$; here $T = 1 / f_r$ and t_1 is the pulse length. This means that each magnetron target acted alternatively as an anode and a cathode during the pulse cycle. Other deposition parameters were the

following: substrate-to-target distance $d_{s-t} = 100$ mm, substrate bias $U_s = U_{fl}$, substrate temperature $T_s = RT$ (unheated substrate), total gas pressure $p_T = p_{Ar} + p_{O2} = 0.5$ Pa and partial pressure of oxygen $p_{O2} = 0.06$ Pa; here U_{fl} is the floating potential. Ar and O_2 were introduced into the chamber at constant flow rates controlled by mass flow controllers MKS (type 1179 A). No automatic adjusting of the flow of O_2 was used when a film deposition was carried out. The microscopic glass slides (26x12x1 mm^3) and Si (100) (12x4x0.5 mm^2) plates were used as substrates. The thickness of films varied between 1000 and 5000 nm.

The film thickness and surface roughness were measured by a profiler Dektak 8 of the Veeco Instruments Inc. The structure of films was characterized by X-ray diffraction (XRD) in the Bragg-Brentano configuration with CoKα (λ=0.179021 nm) and the mechanical properties (hardness and Young´s modulus) were measured by computer controlled microhardness tester Fischerscope H 100. The optical properties (refractive index and optical transmittance) were measured by UV-vis spectrometer Specord M400.

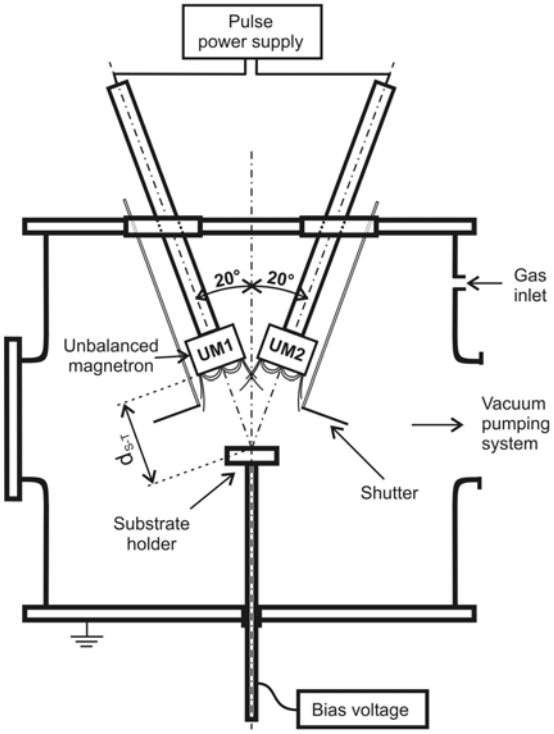

Fig.1. Schematic diagram of the experimental device.

3. Results and discussion

3.1. High-rate sputtering in transition mode

The dependence of p_{O2} on ϕ_{O2} measured prior to the film deposition at constant average discharge current I_{da} (average current over the pulse) and automatic regulation of the reactive gas (oxygen) flow rate ϕ_{O2}, which maintains the total gas pressure constant ($p_T = p_{Ar} + p_{O2} = const$), is displayed in Fig. 2. In this control of reactive sputtering, there is a jump transition from point A to point B when ϕ_{O2} increases, i.e. no stable operation in the transition mode is possible. This jump occurs due to an avalanche target poisoning, i.e. a conversion of the surface of Al target to Al_2O_3; for more details see, for instance, the reference [8]. From Fig. 2 it is clearly seen that this change in the chemical composition of sputtered targets is accompanied also by a jump change of the average discharge voltage U_{da} from 500 V (metallic mode) to approximately 300 V (oxide mode).

The difference in U_{da} occurring when films are sputtered in the metallic and oxide mode offers a possibility to ensure a stable sputtering in the transition mode. To achieve it, the magnetron must be supplied with the power supply with controlled output voltage, i.e. in the case when U_{da} is kept constant. This control makes it possible to adjust every value of p_{O2} from the interval between 0.025 Pa and 0.085 Pa, corresponding to the interval between points A and B (Fig. 2). The stable sputtering of Al_2O_3 films in this interval of p_{O2} is illustrated in Fig. 3. All film depositions in the transition mode of sputtering were carried out at a constant value of p_{O2} = 0.06 Pa. No change in p_{O2} with increasing ϕ_{O2} is due to a sorption of oxygen by sputtered Al atoms and formation of Al_2O_3 films.

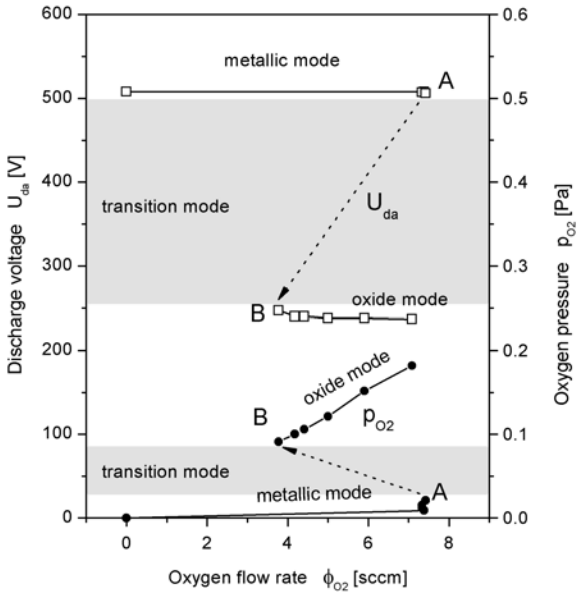

Fig. 2. Jump transition from the metallic to the oxide mode of sputtering due to p_{O2} control by ϕ_{O2} at I_{da} = 1.5 A and $p_T = p_{Ar} + p_{O2}$ = 0.5 Pa

Fig. 3 shows stabilized working points in the transition region with corresponding values of (i) the discharge voltage U_{da} and (ii) deposition rates of transparent Al_2O_3 films on substrates located at $d_{s\text{-}t}$ = 100 mm. As it is expected, U_{da} decreases and a_D increases with decreasing p_{O2}. The sputtering process controlled by U_{da} is more stable than that controlled by the discharge current I_{da}. Besides, it is worthwhile to note that the deposition rate of transparent Al_2O_3 oxide films produced in the transition mode is more than ten times higher than a_D of those produced in the oxide mode of sputtering, see Figs. 3 and 4. The increase of a_D of transparent Al_2O_3 films with increasing ϕ_{O2} up to a very high value $a_D \approx$ 100 nm/min at ϕ_{O2} = 7.8 sccm and p_{O2} = 0.6 Pa is clearly seen in Fig. 4. To increase a_D it is necessary to increase the magnetron target power loading to prevent full oxidation of its surface. To sputter transparent Al_2O_3 films with the high deposition rate $a_D \approx$100 nm/min, the magnetron must be operated at high target power loadings achieving up to 30 W/cm^2 (the average over the whole surface of a sputtered target during the sputtering pulse).

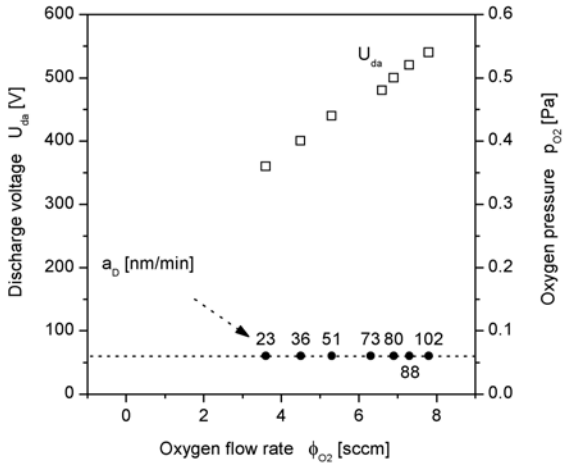

Fig. 3. Stable operation points in the transition mode of sputtering when p_{O2} is controlled by discharge voltage U_{da} at p_T = 0.5 Pa.

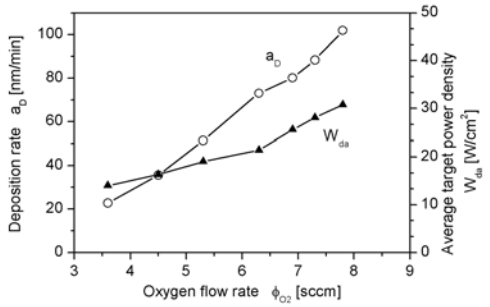

Fig. 4. The deposition rate of transparent Al_2O_3 films and the average target power density ($W=I_dU_d/S$) on oxygen flow rate at p_T = 0.5 Pa; S is the total area of target surface.

3.2. Mechanical and optical properties of transparent Al_2O_3 films

The Al_2O_3 films were deposited on unheated substrate. This is a reason why sputtered films exhibited an amorphous structure and relatively low hardness H of about 11 GPa. These results are in a good agreement with literature data which show that (1) amorphous Al_2O_3 films exhibit low (11 GPa) hardness and (2) $T_s \geq 500$ °C is necessary to produce crystalline alumina films [3]. All measured properties of sputtered Al_2O_3 films are summarized in Table 1.

Our measurements show that the hardness H and effective Young´s modulus E^* do not depend on the deposition rate a_D of their production, see Table 1. This fact indicates that mechanical properties of the films are determined by its structure which is amorphous in the whole range of a_D used in our experiment. The increase in a_D cannot stimulate the film crystallization because the energy of ions bombarding the growing film is inversely proportional to a_D and so decreases with increasing a_D [10].

Transparent Al_2O_3 films with amorphous structure have very smooth surface and excellent transmittance in visible spectrum, see Table 1. We report the index of refraction n at 550 nm for comparison with other author's studies. If we consider n = 1.70 at 550 nm of polycrystalline Al_2O_3 [11] as the bulk refractive index, we find that our sputtered amorphous Al_2O_3 films exhibit almost the bulk density. Also, the transmittance of sputtered Al_2O_3

films is very high and, in the system Al_2O_3 film/glass substrate (1 mm thick microscope glass plate), achieves approximately the same value of 87.5% for two (1140 and 5080 nm) very different thicknesses of Al_2O_3 films, see Fig. 5. This indicates that losses of light intensity inside the Al_2O_3 films are very low.

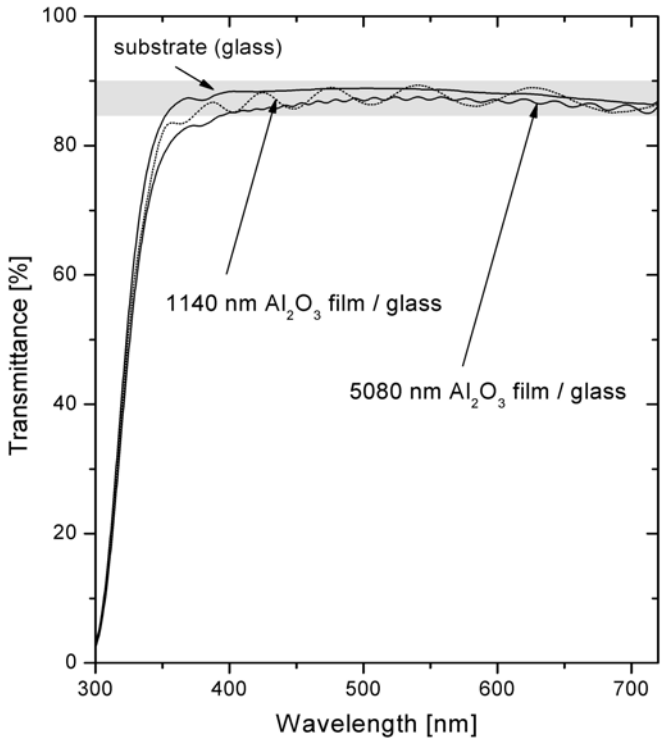

Fig. 5. Transmittance of the Al_2O_3 film/glass system with differnt film thickness h and sputtered with different a_D. a) h = 1140 nm, a_D = 22.8 nm/min and b) h = 102 nm/min.

4. Conclusions

Main conclusions of our study can be summarized in two points.

1. The operation of dual magnetron with discharge voltage control makes it possible the stable reactive sputtering of transparent Al_2O_3 oxide films in the transition mode of sputtering with a high deposition rate $a_D \approx 100$ nm/min. This deposition rate is more than ten times higher than that of transparent oxide films produced in the oxide mode of sputtering.
2. Transparent Al_2O_3 oxide films sputtered on unheated substrates are X-ray amorphous and their mechanical and optical properties do not depend on the deposition rate a_D of their production.

Table 1. Mechanical and optical properties of transparent Al_2O_3 films with amorphous structure sputtered in the transition mode.

Abstract
Using pin-on-disc wear testing machine, wear and tribological characteristics of nano and conventional zirconia coatings were studied. Friction coefficient and weight loss were determined. Coatings were characterized before and after wear tests. Effects of wear distance, applied load, and pin materials were investigated. Results obtained revealed a pronounced effect of test variables and coating characteristics on the wear behavior of these coatings.
Keywords: Zirconia, Nanostructured, Air plasma spray, Wear, Tribology

1. Introduction

During the last decades, ceramic materials have been widely studied, developed, and applied as effective Thermal Barrier Coatings (TBC). The main application of thermal barrier coatings such as Plasma Sprayed Zirconia-base coatings (PSZ) are combustion system components such as: pistons, valves, piston fire decks in diesel engines, and piston rings, as well as cylinder liners [1-3]. These applications could extend durability of engine, increase engine efficiency, and reduce fuel consumption. The main advantage of plasma-spayed zirconia-base materials as TBC, stems from their unique properties such as: high hardness and wear resistance, high strength, excellent resistance to erosion, hot corrosion, and oxidation, as well as high thermal insulating characteristics and a thermal expansion coefficient close to that of the most metallic materials.
Regarding the development of TBCs for the above-mentioned applications, one of the main problems involved is the wear behavior. In this respect, the combined effects of intrinsic properties such as chemical composition, microstructure, and grain size, as well as the environmental parameters such as wear testing variables would be important [4-9]. Comparing the nanostructured and conventional 8wt.%yttria-partially stabilized zirconia coatings, it has been reported that at long wear distances such as 10km the former one showed better wear resistance and lower friction coefficient than the latter one [5]. Yang et al have shown that the wear resistance of tetragonal zirconia polycrystalline coating decreases with increasing grain size. They showed that the weight loss can be expressed in form of $R=nG^{-n}$, where G is the average grain size. The value of n is equal to 0.5 and 1.0 for fine and large grain size samples respectively [6]. Chen and his coworkers have reported a wear rate for nanostructured zirconia coating equal to two-fifths and half of traditional zirconia under applied load of 20-80N, dry and distilled water lubrication condition respectively. They have attributed the improved wear resistance of plasma-sprayed nanostructured zirconia coating to the optimization of microstructure and enhancement of mechanical properties [7-8]. Furthermore, Li et al have reported that the friction coefficient of the coatings spayed using the nanostructured powder were almost the same as those of the coatings spayed using the conventional powder. However, the former coatings were more wear resistant than the latter one [9].
The aim of this paper is to investigate and compare the wear and tribological behavior of Air Plasma Sprayed (APS) nanostructured and conventional 8wt% Yttria-Partially Stabilized Zirconia (Y-PSZ) coatings on stainless steel substrate.

2. Material and experimental techniques

Using Air Plasma Spraying (APS), and processing parameters shown in table 1, conventional and nanostructured 8wt.%Yttria Partially Stabilized Zirconia (Y-PSZ) coatings were deposited on pre-bond coated austenitic stainless steel (AISI 304) disc shape (75x4mm) substrates**.** Thickness of bond coat and topcoat were around 150µm and 250µm respectively**.** Conventional zirconia powder with particle size of 45-75 µm, and Ni-based bond coat powder with the particle size of 56-106 µm (purchased from Sulzer Metco Company) and

nanostructured powder consisted of agglomerated particles of 15-150μm in diameter (purchased from Inframeat Corporation) were used.
Using an X-ray diffractometer (Philips model PW2273) with Cu-k_α tube, phase analysis of powders and coatings produced were determined. Employing a computer controlled machine the coated substrates were subjected to pin-on-disc wear tests using silicon nitride (Si_3N_4) and zirconia balls (10mm in diameter) as the pin (Fig. 1). The coefficient of friction was recorded in real time. The weight loss of coated substrates was measured using initial and the final weight of coated substrates just before and after the wear tests, respectively. Coatings were characterized before and after subject to wear tests by various techniques including optical microscopy, scanning electron microscopy (SEM), energy dispersive X-ray spectrometry (EDX), and X-ray diffraction (XRD). Effects of experimental parameters such as wear distance, and applied normal load, were investigated.

3. Results and discussion

The XRD patterns obtained from coatings produced showed clearly the presence of tetragonal phase in the both coatings (Fig. 2). This phase is the most suitable phase for these types of ceramic coatings. Optical and scanning electron microscopy observations revealed an almost uniformly deposited bond and top coatings on the stainless steel substrates (Fig. 3)
Effect of wear distance on the weight loss for both coatings against silicon nitride and zirconia balls is shown in figures 4A and 4B respectively. As is observed, increasing the wear distance would increase the weight loss of both coatings. However, the wear rate of conventional coating against wear distance is higher than that of the nanostructured coating. This is more pronounced for coatings tested against silicon nitride ball. The lower weight loss (wear rate) obtained for nanostructured coating could be due to the finer microstructure as well as superior physical and mechanical properties of nanostructured zirconia compared with the conventional one. All worn tracks of coatings tested against silicon nitride and zirconia balls were examined using scanning electron microscopy. In the case of coatings tested against silicon nitride ball, a silicon containing film was observed on the worn surfaces (Figs. 5A and 5B). This film is less pronounced for short wear distances such as $\leq$ 5km. Conversely, for long wear distances such as 10km, a thick but very brittle silicon containing film is formed. Particles and wear debris produced due to cracking, fracturing and delaminating of this film at long wear distances could act as abrasive wear agents. The higher weight loss obtained for coatings tested for long wear distances against silicon nitride ball is believed to be due to presence of these wear debris.
Effect of applied normal load on the weight loss of nanostructured and conventional zirconia coatings against silicon nitride and zirconia ball is shown in figures 6A and 6B. As is observed, the effect of applied normal load on weight loss of coatings against silicon nitride and zirconia balls is quite different. In the case of silicon nitride ball (Fig. 6A), the rate of increasing the weight loss for applied normal loads greater than 40N is more than that of applied normal loads less than 40N. This is believed to be due to fracture and delaminating of silicon oxide containing film on the worn track surface at high-applied normal load. AS previously mentioned, these particles in the worn debris could act as abrasive wear agents, and therefore increase the wear rate of coatings. In the case of zirconia ball the weight loss of nanostructured and conventional coatings against applied load, for applied normal loads less than 40N increased. The rate of increase was more than that of coatings against silicon nitride ball. Conversely, for applied normal loads greater than 40N, the weight loss of nanostructured coating decreased while that of conventional coating remained almost constant. It is believed that at applied normal loads less than 40N, the wear debris act as abrasive wear agents. However, at applied normal loads greater than 40N, wear debris trap between the contact surfaces of ball and coating and redeposit on the worn track surface. This would reduce the weight loss measured.
In all cases, friction coefficients recorded for both coatings under various conditions tested in this paper represented a lower friction coefficient for nanostructured coating than that of conventional coating. However, the differences observed for various experiments were different from each other and were depended on the wear test conditions applied (wear distance, applied load, and ball material). Examples of friction coefficients recorded for nanostructured and conventional coatings are shown in figures 7A and 7B. As it is observed, under the conditions applied in figures 7A and 7B, the initial friction coefficient for both coatings is almost the same. However, in the case of nanostructured coating the friction coefficient against wear distance decreased more rapidly.

4. Conclusion

Under the wear conditions tested in this paper, the weight loss of nanostructured zirconia coating was observed to be lower than that of conventional zirconia coating. However, the difference obtained was observed to be a function of wears conditions applied, such as wear distance, applied normal load, and counterface material. Although the friction coefficients recorded for nanostructured coatings were observed to be lower than those of conventional coatings, the difference in some cases was negligible.

UV absorbance of titanium oxide-like films by plasma assisted deposition from mixtures of oxygen and titanium-tetrakis-isopropoxide

Abstract
A radio frequency (RF) low pressure non-thermal plasma was used to deposit films by mixtures of oxygen and titanium(IV)isopropoxide (TTIP) at powers of 0.2 kW on polyethylene-terephthalat (PET). As to XPS, films deposited consist of TiO_x ($x \approx 2$). Spectral absorptance (309 to 500 nm) of films was studied. At 310 nm, the absorption coefficient obtained was 0.3% nm^{-1}. While keeping other parameters constant, the coefficient decreased by 0.05% nm^{-1} with an increase of the concentration of TTIP from 2% to 8%.

Keywords Titanium oxide, Plasma assisted chemical vapour deposition (PACVD), UV absorption, XPS

1. Introduction

Thin films of titanium oxide have many potential applications due to high dielectric constant, high refractive index and good chemical as well as thermal resistance of the material [1, 2]. Good quality films of titanium oxide are obtained in high temperature processes. However, as plastics are the material of choice in many domains of industrial production, this work addresses the deposition of titanium oxide-like films obtained by means of plasma assisted chemical vapour deposition (PACVD) in a low temperature environment.
Several polymers provide also excellent optical transmission in the visible range, and thus are convenient materials for substituting glass. However, polymers absorb very effectively ultraviolet (UV) light causing chain degradation and crystallization, accompanied by loss of flexibility and translucence.
In this regard, the absorption properties of films deposited by means of TTIP in mixtures with oxygen in an RF discharge are studied in the present work. Films were deposited in varying the concentration (the molar fraction) of TTIP in the discharge gas. In addition, chemical composition of films deposited was investigated by X-ray photoelectron spectroscopy.

2. Experimental

Experimental set-up for PACVD
Films were deposited in the set-up schematically shown in figure 1. Unless described differently, all parts of the set-up were made of stainless steel. The heart of the set-up is a double-walled chamber built on the basis of a T-piece pipe fitting for clamping flange (DN 250 ISO-K). Its side-flange is shut by a blanking flange acting as porthole. It is double-walled as well and gives access to the deposition chamber for maintenance and substrate exchange. The bottom flange of the chamber is sealed by a special flange which supports the feedthroughs of the annular gas shower and of the powered electrode. Inside the chamber, at 13 cm height from the chambers bottom, the cylindrical electric feedthrough meets the electrode, a circular plate of a diameter of 14 cm. Fitted into the dark space shield, gaskets of polytetrafluorethylen (PTFE) with fluorelastomer o-rings seal and centre the electric feedthrough as well as the electrode. The dark space gap obtained is 0.3 mm. The shield is fixed and grounded by thread-connection at the inner side of the blanking flange. Outside the vacuum chamber, the electric feedthrough of the powered electrode forms the pin of a plug shaped coaxial connector integrated in the blanking flange.This plug connects to the output socket of a LC-matching network (DRESSLER, VM 1500) right beneath the vacuum chamber. The matching is used to adapt the load impedance of the discharge configuration to the out-put impedance of the electric generator (DRESSLER, Cesar 1312). The generator supplies sinusoidal voltages of a frequency of f = 13.56 MHz and is connected to the matching unit by a coaxial cable. The gas throughfeeds support the annular gas shower which has a diameter of 23 cm. Since they are sealed by tube fittings with PTFE gaskets at the bottom of the vacuum chamber, the vertical position of the gas shower is variable. Gas throughfeeds and shower are made of ∅ 6 x 4 mm tube. By means of 24 holes (∅ 0.6 mm) in the shower, the gas is dispersed toward the center of the reactor and the substrate holder. The substrate holder is electrically

grounded and of the same diameter as the powered electrode. It is supported by a rod with rocket tail-shaped plates, which are fixed to the top flange of the vacuum chamber. By this means, the substrate holder is centre-positioned right beneath the exhaust gas exit of the chamber.

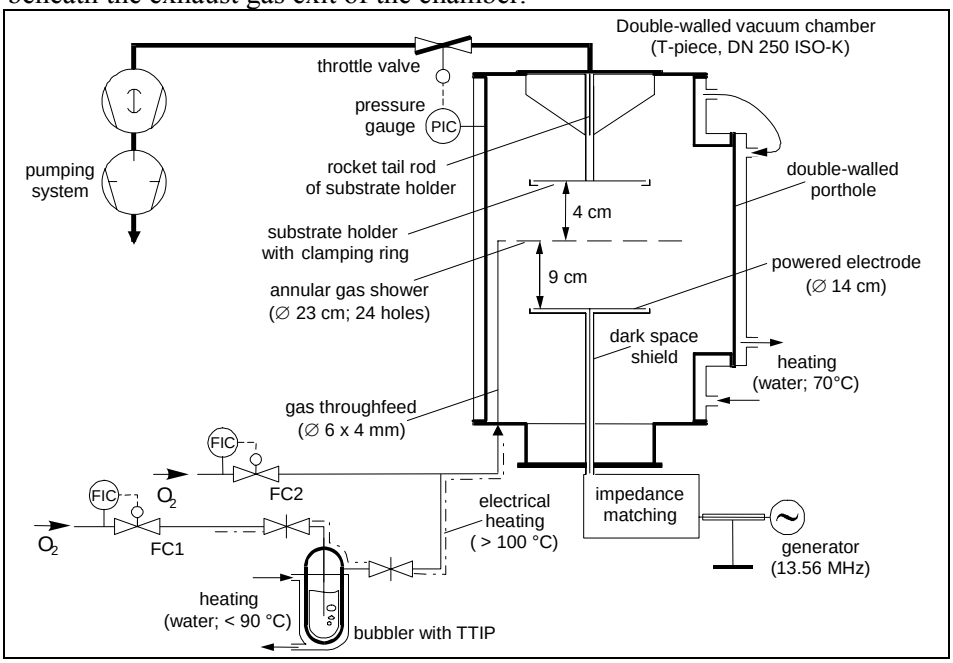

Figure 1 Scheme of the experimental set-up.

A triple stage pump system with a double stage pre-vacuum rotary pump (LEYBOLD, Trivac D 65 B) and a roots pump (LEYBOLD, RUVAC WS 1001) generates and maintains low-pressure environment. The base pressure of the chamber obtained is less than 10^{-3} mbar. The chamber pressure is measured by a capacitance diaphragm gauge (MKS, Baratron 626A, 10^{-3} – 10 mbar). It is connected to a pressure controller (MKS, 651C), and by means of a butterfly exhaust throttle valve (MKS, 653B, DN 100 ISO-F), the pumping speed is regulated. Therefore, the chamber pressure could be adjusted independently form gas flux.

The two mass flow meters (MKS, 1179B), in fig. 1, designated as FC1 ($Q_{FC1,max}$ = 10 sccm (N_2)) and FC2 ($Q_{FC2,max}$ = 100 sccm (N_2)) are controlled by a PR4000 (MKS). The gas flux delivered by FC1 is admixed to the gas flux of FC2 after passing through the bubbler containing the deposition precursor TTIP (purchased from SIGMA-ALDRICH with a purity of 97%). According to the dependence of its vapour pressure on temperature, a partition of TTIP is diluted in the through-streaming gas. Therefore, the precursor temperature T_{TTIP} has been controlled by means of a thermostat which pumps constantly water through the double-mantle of the bubbler. Since reference specifications concerning the vapour pressure are fragmentary and sometimes contradictory [3, 4, 5], we estimated the precursor concentration c_{TTIP} (molar fraction) in measuring the diminution of its volume ΔV_{TTIP} over time Δt at fixed values of T_{TTIP}:

$$c_{TTIP} = \frac{[TTIP]}{[TTIP] + Q_{tot}} \text{ with } [TTIP] = \frac{\sigma_{TTIP}}{M_{TTIP}} \frac{\Delta V_{TTIP}}{\Delta t} \qquad (1)$$

Here, Q_{tot} is the total flux of the diluting gas, i.e. oxygen, M_{TTIP} = 284.25 g/mol is the molar mass of TTIP, and σ_{TTIP} = 0.96 g/cm^3 its mass density. Hence, the resulting calibration function depending on Q_{tot} and T_{TTIP} is the basis for the values of the precursor concentration of TTIP given later on. All experiments described were conducted with an initial gas mixture of oxygen with TTIP admixed. Variation of c_{TTIP} = 0.4 to 8% was obtained by varying T_{TTIP} = 60 to 85°C at constant flux Q_{tot} = 50 sccm, and at constant value of T_{TTIP} = 80°C by varying Q_{tot} = 10 to 50 sccm. In order to prevent condensation of TTIP, the inner surface of the vacuum chamber was heated to 70°C by pumping water of a thermostat through the double-walled mantle of the chamber. The gas supply, however, was heated electrically to a temperature of more than 100°C.

During experiments the working pressure has been kept constant at $p = 4\times10^{-2}$ mbar. Comparing it to the base pressure of less than 10^{-3} mbar it would contribute to approximately 3% of residual gas in the initial gas

mixtures. But, purging with the process gas at the nominal pumping speed of several hundred cubic metres per hour reduces the residual gas to negligible amounts within seconds. Preliminary, pure streaming tests with different O_2/TTIP mixtures did not result in any detectable deposition although the sticking coefficient of TTIP below 300 K is nearly equal to unity [6]. This could only be achieved by operating the plasma. Experiments were conducted at a constant forwarded power of $P_f = 200$ W. The reflected power was adjusted to $P_r = 25$ W ± 3 W. By this means, an asymmetric RF discharge was operated between powered electrode and substrate holder (see fig. 1). The self bias voltage varied from experiment to experiment between 300 and 600 V. During a single experiment, however, it slightly increased by approximately 50 V. Films were deposited on PET films with a thickness of 12 µm. The PET films were attached to the substrate holder by a special clamping ring put to the edge of the substrate holder. Since in this orientation, substrates have been coated up side down, powder agglomeration on the substrate surfaces could be reduced. PET films were used as substrate for investigations of the light absorptance of films deposited. For XPS and ellipsometric analyses small pieces of Si(100) wafers have been fixed onto the surfaces of the PET films.

X-ray Photoelectron Spectroscopy

In order to determine the concentration and the chemical status of titanium, oxygen and carbon in the films deposited on pieces of Si(100) wafers, spectra were acquired on a Physical Electronics (PHI) Quantum 2000 photoelectron spectrometer. The samples were exposed to a monochromatized X-ray beam (Al-Kα: hν = 1486.6 eV). Low-energy electrons and argon ions were used simultaneously to compensate for electrical charging of insulating surface areas during analysis. Emitted photoelectrons were analyzed with a hemispherical electron energy analyzer equipped with a channel plate and a position sensitive detector. The electron take-off angle was 45°. The analyzer was operated in the constant pass energy mode at 58.7 eV giving a total energy resolution of 1.05 eV. The binding energy scale of the analyzer was calibrated for the Au 4f electrons to be at 84.0 eV ± 0.1 eV. The base pressure of the spectrometer was less than 5×10^{-9} mbar. Elemental concentrations are given in atomic percent (normalized to a total of 100%) using the photoelectron peak areas after Shirley background subtraction (Multi-Pack, Version 6.1, Physical Electronics Inc., Eden Prairie, MN, USA) and the built-in PHI sensitivity factors for the calculation. To remove adventitious carbon as well as surface oxide layer, prior to analysis the sample surfaces have been cleaned by 4 kV argon ion bombardment for 30 s. Due to residual charging of the samples during analysis, the actual peak positions had to be referenced to the Ar 2p peak at 241.9 eV.

Ellipsometry and Profilometry

A variable angle spectroscopic ellipsometer (J.A. WOOLLAM INC., M-2000F) was used to measure the film thickness. Measurements were performed at three different incident angles (65°, 70°, 75°) in the range of 245 nm to 995 nm. Best fit of the measured spectral dependencies of Δ and ψ have been found by adapting the spectral dependencies of the refractive index n and the extinction coefficient k of the deposited films.Film thicknesses obtained by ellipsometry could be validated by masking a portion of Si substrates during deposition and then measuring the resulting steps by profilometry (TENCOR P10).

UV-Vis spectroscopy

Spectral absorption of the films deposited on PET was determined by a double-beam spectrometer (PERKIN-ELMER, Lambda 35) operative in the ultraviolet and visible spectral range. The spectrometer is equipped with a deuterium (D_2) lamp for the UV range and a tungsten lamp for the visible spectrum. Spectral dispersions is obtained by a grating of 1053 lines/mm. Deposited films were investigated at a beam cross-section of 2 mm × 7.5 mm in the focal length of the sample compartment. Therefore, samples of 1.5 cm × 3.5 cm were cut out of the PET films coated. At these samples, spectra from 500 nm to 200 nm have been acquired and compared to the spectral absorption of the uncoated substrate material, namely PET film of 12 µm thickness.

3. Results

Chemical composition of the films

While keeping the temperature of TTIP constant at 80°C ± 1°C, the oxygen flow rate Q_{tot} was varied such as to vary the oxygen-to-TTIP ratio *q* in the range from 58 to 12. With regard to the chemical composition of the films deposited on PET, Si-wafer sample coated under these same conditions have been examined by XPS.

The obtained spectra reveal that oxygen, titanium and carbon are the major constituents in the films deposited. Apart from these elements, traces of nitrogen, chromium and silicon were observed at some coated samples. On the basis of the O1s, Ti2p and the C1s photo-electron peaks, their atomic concentrations were determined. In table 1, these values are listed in dependence on the concentration of TTIP during the plasma deposition process.

Table 1 Elemental composition (atomic-%) of films deposited at different precursor concentrations

c_{TTIP} [%]	1.7	1.9	2.6	3.8	7.4
O_2/TTIP ratio q [-]	57.8	51.6	37.5	25.3	12.5
C(1s) [%]	6.7	7.0	6.7	7.9	8
O(1s) [%]	58.8	58.5	59.7	58.5	57.9
Ti(2p) [%]	34.5	34.5	33.6	33.7	34.1
[O]/[Ti]	1.70	1.70	1.78	1.74	1.70

Despite a quadruplicating concentration of TTIP from approximately 2% to 7%, the resulting elemental composition of deposited films remains virtually unchanged. In comparison to the stoichiometry of TTIP, the carbon content is drastically reduced from nearly 74% to 8%. Consequently, the concentrations of oxygen and titanium have increased. However, the ratio [O]/[Ti] = 1.7 (tab. 1) is too low for being TiO_2.

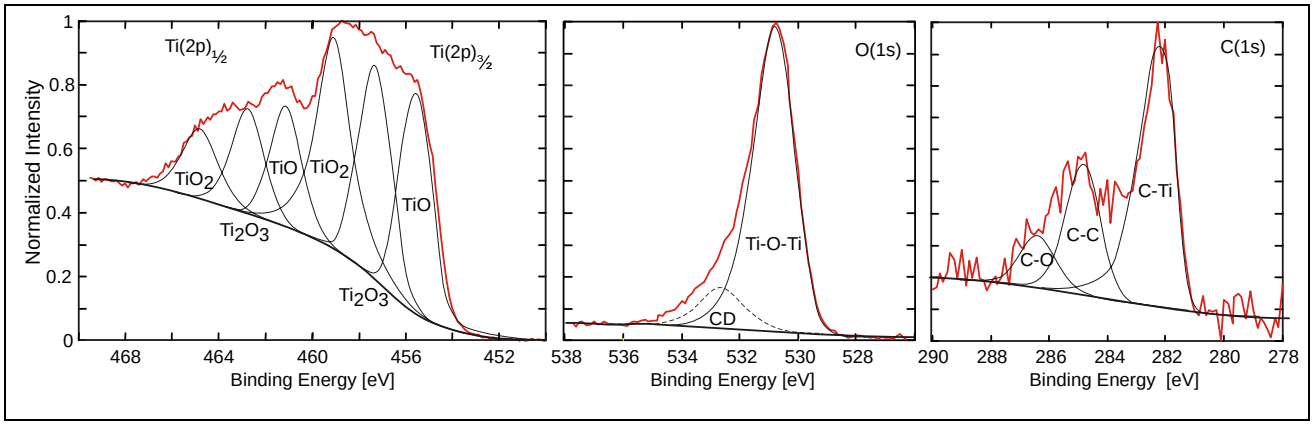

Figure 2 Spectra of the $Ti(2p)_{1/2}$ and $Ti(2p)_{3/2}$, O(1s) and C(1s) core level peaks. Peaks attribution to chemical structures has been done after [7, 8, 9].

Since peaks of the $Ti(2p)_{1/2}$ and $Ti(2p)_{3/2}$ core level are broad and overlapping each other (see fig. 2), the films seem to consist of a mixture of the oxides of titanium: Ti_2O_3, TiO_2 and TiO [7]. Further, the C(1s) spectrum features the chemical formations Ti-C, C-C, respectively C-H and C-O at binding energies of 282.2 eV [8], 285.0 eV and 286.2 [9].

The O(1s) spectrum, however, accounts for the presence of Ti-O-Ti structures typically observed of pure TiO_2. Indeed, the feature forming the shoulder of the O(1s) peak (at 535.3 eV) could represent Ti-O-C. However, considering the C(1s) spectrum, the occurrence of Ti-O-C seems to be rather improbable. Since the entire amount of carbon is always lower than 8%, the portion of C-O bonds attributable to the presence of Ti-O-C is too small to account for the shoulder in the O(1s) spectrum. In fact, it must be taken into account the effect of the argon ion bombardment which was applied to clean the film surfaces before spectrum acquisition.

Its influence has already been addressed in an earlier study [7]. It showed that (initially existing) TiO_2 becomes reduced due to preferential sputtering of oxygen at even lower ions energy of 2 kV. The by such means modified material showed the same characteristic XPS spectra as described above.Furthermore, it should be noted, that the effect of sputtering is not as noticeable in the O(1s) spectrum. In this case, the small peak shoulder accounts for charge transfer in TiO_x [7]. Consequently, it is likely that under the deposition conditions investigated all films obtained consist of TiO_2. Under this premise, the detected carbon is likely to descend from surface contaminations which become re-deposited and recombined under the influence of the argon sputtering.

Film thickness and growth rate

Apart from the chemical composition of the films deposited at different values of c_{TTIP}, the film thickness has

been derived by ellipsometry. In general, film thickness and growth rate were found to increase with precursor concentration. In figure 3, two deposition series at t_P = 5 and 10 min of deposition are compared. For the shorter deposition time, the growth rate increases linearly from 32 nm/min at c_{TTIP} = 2% to 48nm/min for c_{TTIP} = 8%.
In the sample series for 10 min deposition time, the deposition rate follows the characteristics for 5 min up to 4% of TTIP. However, at doubled concentration, the rate is by 8 nm/min smaller. This finding can be explained by the increase of powder formation with increasing precursor concentration, virtually observed in the gas phase. Gas phase nucleation reduces the flux of species contributing to deposition on the substrate.

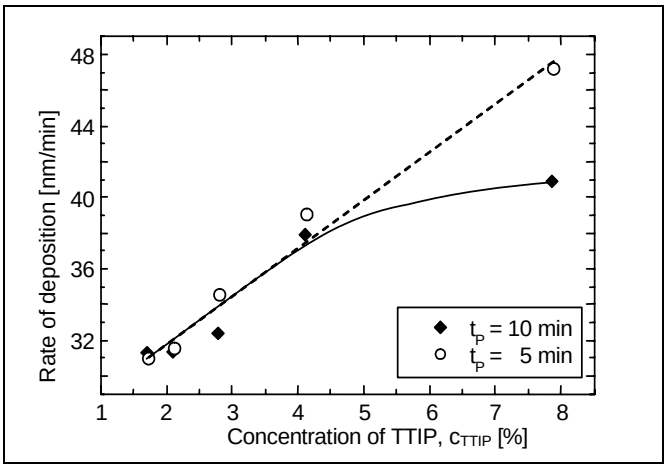

Figure 3 Dependence of the film growth rate on precursor concentration at different deposition times (t_P = 5 and 10 min) in O_2/TTIP gas mixture.

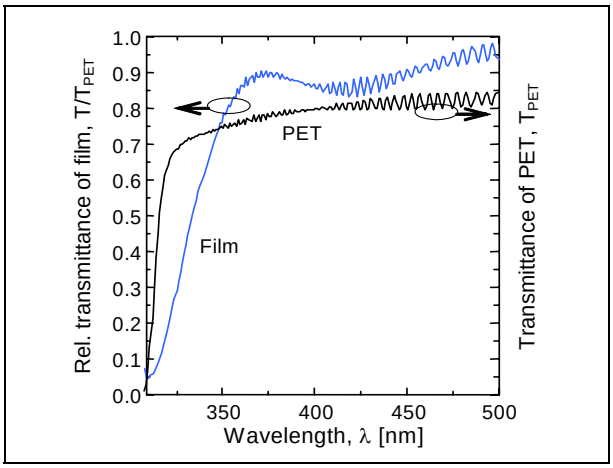

Figure 4 Relative transmittance of a film deposited at c_{TTIP} = 1.9% (t_P = 10 min in O_2/TTIP) compared to the transmittance of PET substrate.

Since number and size of particles will increase with progressing deposition time, the reduction of the film growth rate is inevitable. Surface profiling conducted to validate ellipsometric measurements, in addition, indicate the increasing role of gas phase nucleation with precursor concentration since a qualitative increase of surface roughness was observed.

UV and visible light absorption by deposited films

A typical transmittance spectrum of a film relative to the PET substrate is shown in figure 4. Due to the strong absorption of PET below 310 nm only the upper part of the spectral range acquired is presented here.

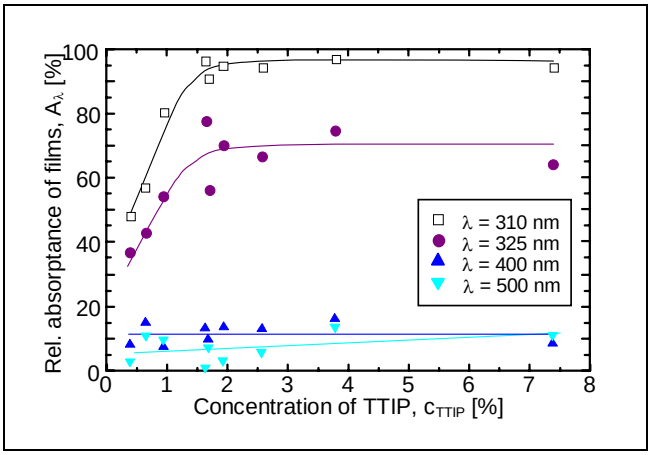

Figure 5 Dependence of the spectral absorptance on precursor concentration at different wavelengths.

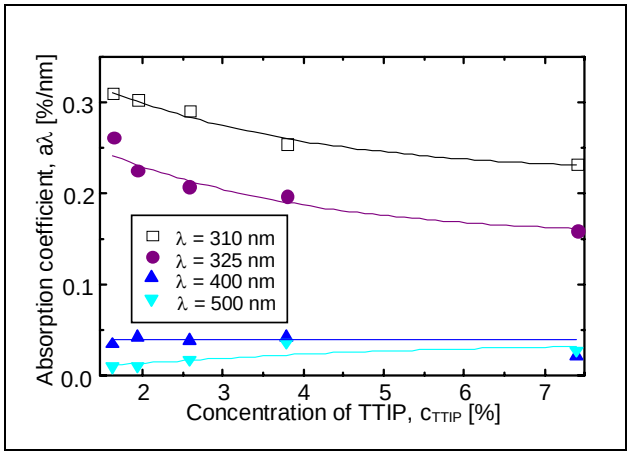

Figure 6 Absorption coefficient of films versus precursor concentration at different wavelengths.

Compared to PET, the relative transmittance of films deposited at c_{TTIP} > 0.6% is generally lower in the spectral range from 325 nm down to lower wavelengths. Therefore, cut-off (transmission reduced to the level of -3dB) occurs at higher wavelengths than 313 nm in the case of PET. The exact cut-off wavelength, however, has been found to alter in the range from 320 nm to 325 nm. Moreover, no cut-off was obtained for films deposited at

c_{TTIP} < 0.6%, although a reduction of transmission could be observed. In the spectral range from 350 to 500 nm, the relative transmittance of films is generally higher than that of PET, although it is not 100%. In this range the transmittance characteristics is strongly affected by interference effects as it can be seen in figure 4.
In order to study the influence of c_{TTIP}, spectral absorptance A_λ and absorption coefficient a_λ have been determined for λ = 310, 325, 400 and 500 nm. As shown in figure 5, absorptance at 310 nm and 325 nm rise with increasing value of c_{TTIP} up to an approximate concentration of 1.8%. Whereas the relative absorptance at 325 nm attains approximately 70% (cut-off value), the absorptance at 400 and 500 nm remains nearly constant at a level of 10%. Above c_{TTIP} = 1.8%, spectral absorptance remains nearly constant at all wavelengths. However, since the film thickness has been found to increase with precursor concentration, the efficiency of UV absorption of films deposited decreases with increasing precursor concentration above c_{TTIP} = 1.8%. This can be seen in figure 6, where the absorption coefficient is depicted. At λ = 310 nm, the absorption coefficient drops from 0.3% nm^{-1} (virtually 30% for a 100 nm thick film) to 0.25% nm^{-1} by an increase of the concentration of TTIP from 2% to 8% when keeping other parameters constant. In the same time, $a_{400\ nm}$ and $a_{500\ nm}$ appear to increase slightly.

4. Conclusions

As derived from XPS analyses, films deposited from oxygen-TTIP mixtures on PET films resemble the chemical structure of TiO_2 with small quantities of carbon containing inclusions. The origin of such contaminants could not be fully enlightened, and remains to further investigations. However, with respect to chemical properties of films, it was shown that good quality titanium oxide is also obtainable in a low-temperature process environment being preferable for coating of polymeric materials.
Since TTIP provides titanium already in chemical liaison to oxygen (at a ratio of 1:4), chemical composition of oxide films was found to be chemically invariant against the variation of precursor concentration (2% to 8%), and the variation of the mixing ratio of oxygen to TTIP (58 to 12), respectively.
Consequently, the cut-off wavelength of films analysed by UV-visible absorption spectroscopy showed little variation around 325 nm. However, detailed study of spectral absorptance and absorption coefficient of films shows an influence of the precursor concentration on optical properties. Accordingly, best UV absorptance the films deposited (at 310 nm more than 95%) was obtained above 2% of TTIP. Evaluation of the absorption coefficient revealed that the absorption effect of thicker films deposited at higher precursor concentrations is decreasing. Since chemical composition of films did not change significantly (see above), and profilometry showed increasing surface roughness with increasing precursor concentration, a decrease of the film density causing diminution of the absorption coefficient ($a_{310\ nm}$ from 0.3% nm^{-1} to 0.25 % nm^{-1}) is likely.

Acknowledgement

The authors wish to thank L. Feuz and Prof. M. Textor (ETH Zurich) for providing opportunity of and their support in ellipsometric measurements. Furthermore, access to the surface profiler used has been offered by U. Lang (ETH Zurich), whose helpfulness is gratefully acknowledged.

Abstract.

In the present work the results of an experimental research of the measurement of heat flows from the plasma generator with the external electrical arc which are controlled by magnetic fields are represented. Because of these data hardening the surfaces, subject to wear, of railway wheels and rails is conducted. The practical application of the given technology has shown it high efficiency.

1. Introduction.

The theoretical analysis of process of distribution of heat in a material [1] has shown, that for hardening of the surface it is necessary to create heat flows $(2\text{-}3)\cdot10^7$ W m^{-2}. And for want of heat flows more then $2\cdot10^7$ W m^{-2} the phase structure should consist in main of martensite. Using more "soft" conditions of heat treatment by the plasma generator it is possible to receive structures of metal practically without martensite, namely with troosomartensite, troostite, sorbite. This circumstance is extremely important for creation of a hardening stratum on details, which are subject to significant mechanical loads. For example, strengthening of crests of railway wheels or working surface of rails take place the formation of martensite. There are additional residual voltages [2], which can result in formation of cracks. The hardening of a surface of details without getting martensite creates conditions of their safe operation.

2. Experimental researches.

For deriving required structures in a hardened stratum of metal details it is necessary to select an appropriate source of plasma heat – plasma generator. After a selection of a construction plasma generator it is necessary to determine it of a regime parameter, which ensure required heat flows on a surface of an item for creation of required structures in a hardened stratum.

There are methods of determination of high intense heat flows, namely stationary and non-stationary. The non-stationary methods are based on a measurement of temperatures in the copper cylindrical gauge (or on an end face, or on a distance of several mm from it). After that the method of a solution of a return problem of a thermal conduction determines magnitude of a heat flow. In gauges of a stationary type by a way of calorimetric of water which is flowing past through the gauge determine magnitude of a heat flow. Restriction for gauges of such type are the heat flows 10^8 W m^{-2} and more, since melting a surface of the gauge.

In our researches the plasma generator with the born electrical arc was applied. The electrical arc in this construction "burns" between the tungsten cathode and rotated copper water-cooled anode. A breadth of processing, and intensity of heat of a surface are ensured with a system of constants and variable magnetic fields, which influence an electrical arc.

As the thermal effect on a surface is cyclical with magnitude of thermal impulse 10^8 W m^{-2} that application of non-stationary gauges of heat flows not probably because of reaching temperature of melting it by a surface for want of operation already of several thermal impulses (approximately 0,4 c)

The gauge of a stationary type was applied to definition of fields of heat flows in our experiments which found room (are located) in various points for want of working plasma generator.

The anode spot of an electrical arc of this construction of the plasma generator makes reciprocating movements on a surface of the electrode. Accordingly gauge of a stationary type measures the average integral for period magnitude of a heat flow.

The high-speed filming of movement of an electrical arc was made for determination of magnitude of a heat flow at the moment of passing an electrical arc (impulse heat flow).

The magnitude q_0 settled up under the formula

$$q_0 = QTV/2d, \quad (1)$$

where Q – an average integral heat flow, T - period of effect, d - it is the diameter. The magnitudes V and d were determined by a method of high-speed filming.

The field of heat flows Q represented in a fig. 1.

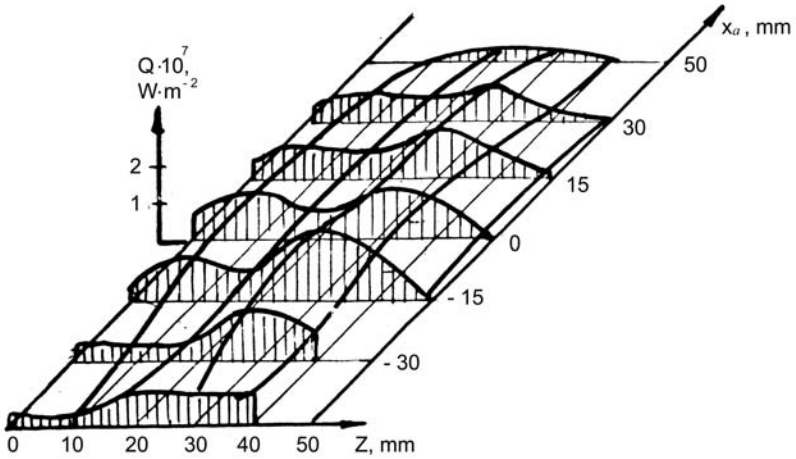

Fig.1. The field of heat flows

This field is uniform enough on a breadth of processing (x_a). The magnitude Q achieves $2 \cdot 10^7$ W m^{-2} for want of current of an electrical arc 400 A.

Influence of frequency of a variable magnetic field to heat flows Q and q_0 are indicated in a fig. 2.

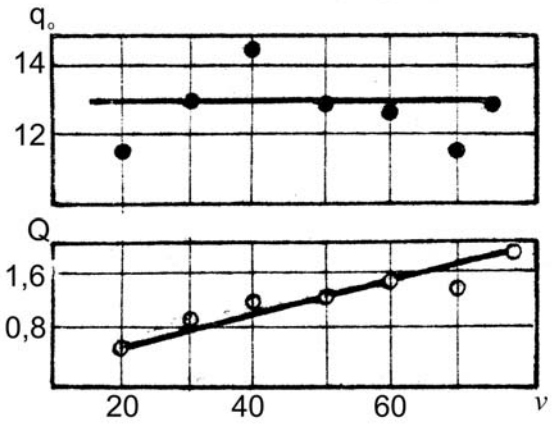

Fig.2. Influence of current frequency of magnetic field to the heat flows
in the point Z=0; Xa=0; I=400A;
q_0, $Q \cdot 10^7$, $W \cdot m^{-2}$; ν, Hz.

From Figures it is visible, that Q is increased approximately in 5 times for want of magnification of frequency n with 20 up to 100 Hz. On the other hand magnitude impulse of the heat stream remains practically constant $1{,}3 \cdot 10^8$ W m^{-2}. In the given construction of the plasma generator by a variation by a velocity of movement of an electrical arc, magnitude it of a current and degree of it approaching to a surface

of processing details is possible for changing magnitude of a heat flow in some times, that ensures technological flexibility of the given construction.

Leaning on data of a measurement of heat flows given to a construction of the plasma generator was applied to hardening crests of sprockets of locomotives with the purpose of magnification of term of their service.

The purpose was the hardening of a surface without formation of martensite .
The outcomes of such hardening are indicated in a fig. 3.

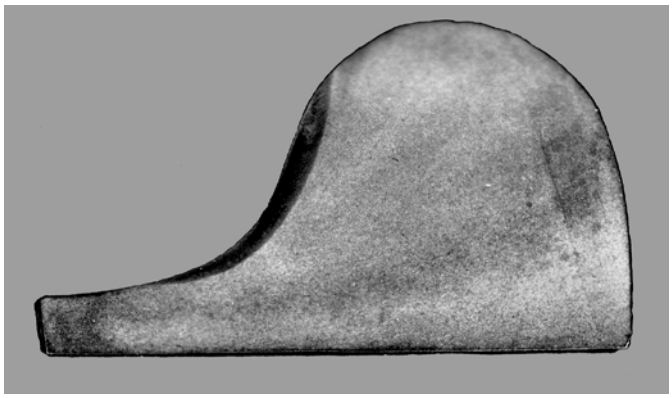

Fig.3 The structure of crest of the railway wheel.

Distributions of hardness on depth are given in a fig. 4.

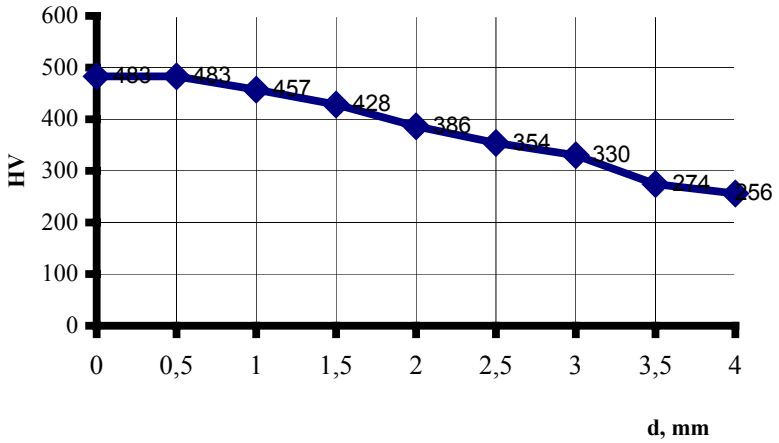

Fig.4 The dependence of hardness of treatment lays from depth of lays.

The data outcomes are obtained for want of optimum heat flows.
The current of an electrical arc made 270 A.

From Figures it is visible, that the obtained stratum has a thickness of 3 mm.
For want of it was hardened all surface of a crest, which is subject to wear. The phase structure of this stratum represented by: troosomartensite , troostite, sorbite .

For a diminution of defects on a surface of a rolling of carload sprockets it was hardened on a breadth up to 45 mm (fig. 4)

For want of magnification of a breadth of processing up to 45 mm the current of an electrical arc in this process was accordingly increased up to 400 A, and the frequency of a variable magnetic field made 50 Hz. Accordingly middle of the integrated heat flow in a material remained practically at the same level. The maximum hardness for want of hardening of a surface of a rolling made 520 HV. The depth of a hardened stratum made 3 mm.

With the purpose of a diminution of wear of a working surface of rails the processing by the plasma generator of the given construction was made it.

The outcomes of such hardening are indicated in a fig. 5.

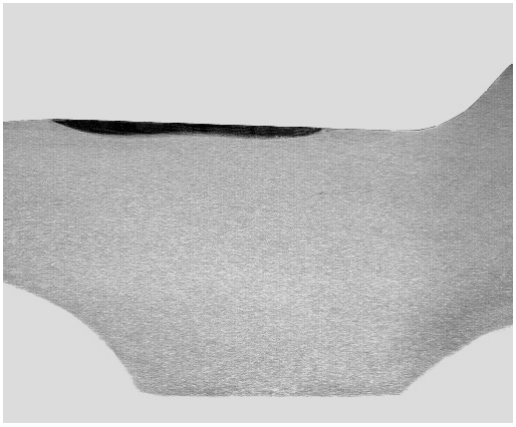

Fig.5. The structure of the running surface of the railway wheel.

The depth of a stratum makes 4 mm. The structure of metal in for heat treatment to a zone represented:
released martensite with hardness 670-592 HV (at a surface),
troosomartensite and troostosorbite with hardness 554-464 HV (in an average zone),
sorbite (at the basis of metal) with hardness 429-339 HV.

For the heat treatment of a horizontal and vertical surface of rails (fig.6)

Fig.6. The structures of the surface of the rail.

movement to an anode spot of an electrical arc added a Γ-figurative trajectory at the expense of an additional system of magnetic fields.

3. Practical application

The outcomes of researches were used for want of hardening of crests of sprockets of locomotives by the Far East railway. The wear of crests with plasma hardening has decreased in 1.5-3.0 times.

Abstract
The paper introduces an experimental work on surface-wave discharges, produced and sustained in a coaxial structure. Planar probes are used to investigate the existence and the directionality of a high-energy electron flux, which is expected to be generated within electron-plasma resonances. Emission spectroscopy measurements of argon line intensities are compared to the populations of different excited argon states, calculated using a Collisional-Radiative Model coupled to a 1D-moment method radial code.

Keywords Surface-wave, Electron-plasma resonance, Directional Langmuir probe, Emission spectroscopy, Collisional-Radiative Model.

1. Introduction

This paper analyses a microwave discharge sustained in a coaxial structure, which was initially developed as an additional ionization device for an Ionized Physical Vapor Deposition (IPVD) system [1]. We have decided to carry out a fundamental study on the electron population of low-pressure argon discharges produced in this device, as results may be extrapolated to similar high-density microwave discharges produced in large-scale planar reactors [2]. Such devices are interesting for material processing [3] specially because they may produce hot-electron fluxes, as reported in [4,5,6,7].
A definite advantage of this azimuthally symmetric structure was evidenced by the self-consistent description obtained in [8,9], which reported the development of an electron-plasma resonance in the vicinity of sheath regions. These resonances occur wherever $\omega_p \sim \omega$ (ω is the microwave excitation frequency; $\omega_p = \sqrt{n_e e^2/\varepsilon_0 m_e}$ is the electron-plasma frequency; e and m_e are the electron charge and mass, respectively; n_e is the electron density; and ε_0 is the vacuum permittivity), as a result of the strong radial gradient of n_e in sheath regions. The main interest with the coaxial configuration is that it leads to a resonance located near the centre of the discharge, where the local field is higher, thus enhancing its effect upon the local electron energy.
A preliminary experimental characterization of this discharge was previously reported in [10]. Cylindrical probe measurements yielded typical electron densities of 10^{11} to 10^{12} cm^{-3} and temperatures around 2 eV, for argon gas pressures ranging from 10 to 100 mTorr. Further probe measurements are presented in [11], where a planar probe configuration was used to investigate the anisotropy of the electron fluxes generated within field resonant regions. The projet also includes a numerical simulation analysis that uses a self-consistent 1D-moment method model to describe the radial deposition of energy in the plasma. Here, this model is coupled to a Collisional-Radiative Model (CRM), to compare calculated excited state populations with measured line intensities of argon gas.

2. Presentation

The coaxial structure presented in *Figre 1* is given by the superposition of 3 cylindrical layers - a 5 mm radius copper tube, a flowing air layer of 13 mm radius at atmospheric pressure and a 2 mm thick quartz tube - which act as propagation media for the surface-wave. A low-pressure chamber, delimited

by the quartz tube and an outer metalic shield, hosts a plasma with more than 60 mm radius. It is assumed that only the fundamental plasma mode TM_{00} propagates to sustain the discharge. The reactor is approximatively 70 cm long and operates for injected powers up to 1 kW.

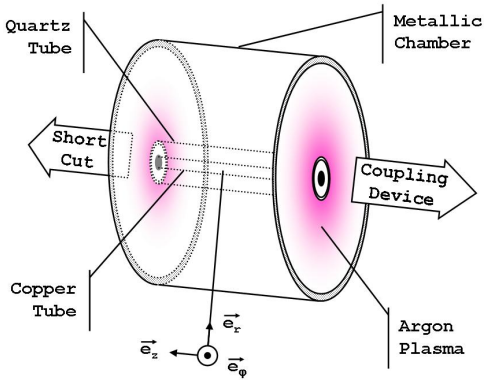

Figure 1. Longitudinal cut of the experimental setup.

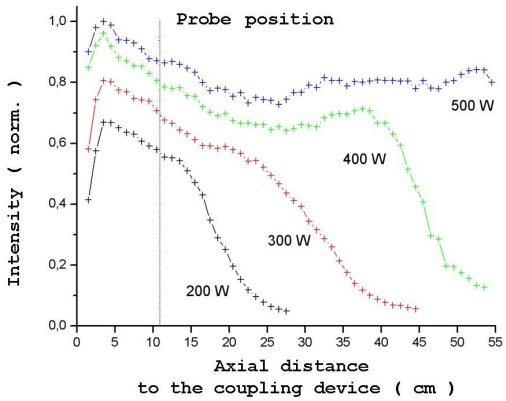

Figure 2. Experimental axial variations of the 3948.9 $\AA$ argon line at 30 mTorr pressure, and for different injected microwave powers (200, 300, 400, 500 W).

The experimental setup was designed as to allow Langmuir probe measurements across the discharge radius $\vec{e_r}$, for different positions along the axis $\vec{e_z}$, and emission spectroscopy measurements through a quartz window, set along the discharge axis on the outer metallic chamber. The probe measurements presented here were performed 11 cm away from the coupling device. As shown on *Figure 2*, emission spectroscopy measurements at 30 mTorr pressure reveal that, for low injected powers, the wave power is completely transferred to the plasma before reaching the ending shortcut, as the radiation intensity presents a rapid decrease with the axial distance.

The discharge radial description is given by a 1D - moment method code [8,9], which couples charged particle and energy transport equations to Maxwell's equations for the TM_{00} mode (taking into account the electron-plasma resonance) and to Poisson's equation for the electrostatic space-charge field. The local mean energy approximation [9] is adopted to introduce a radial dependence for the electron transport parameters and rate coefficients. The latter are calculated from the electron energy distribution function (EEDF), assumed Maxwellian, and are tabulated as a function of the electron mean energy ε. The radial map of the electron parameters is obtained by resorting to the profile $\varepsilon(r)$, as obtained from the charged particle transport model.

The calculated radial distribution of the electromagnetic field components is shown in *Figure 3*, where one can observe the resonance peaks of the radial electric field, located within the space-charge sheaths (near the quartz tube and near the outer metallic cylinder).

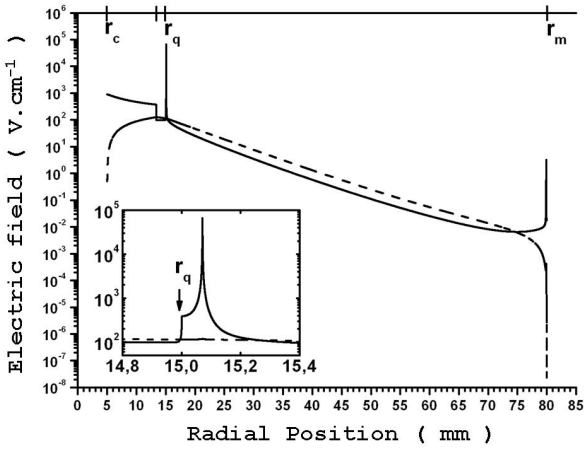

Figure 3. Calculated radial distribution of the wave electric field components, at 30 mTorr pressure and 5.7×10^{11} cm^{-3} radially averaged electron density. E_r : solid line, E_z : dashed line. The lower left graph is a blow-up of the inner resonance region

3. Planar probe directional measurements

Assuming as valid that the electric field in the plasma has no azimuthal component, presenting high intensity ratios of its radial to axial components in the resonance region near the quartz tube, we decided to check the possible anisotropy of the electron fluxes generated within this region. The study involved probe measurements that used Tungsten planar probes with 1 mm radius, as detailed in [11].

Two different planar probes were inserted at different axial positions, where they could move in the radial direction. The normal vector to the collection surface of the first probe (see *Figure 1* for axis references) was radially oriented (rad) $+\overrightarrow{e_r}$. The tip of the second probe was bent, so that the normal to its collection surface could point at different directions, by rotation around $+\overrightarrow{e_r}$: axially towards the coupling device (ax-cd) $-\overrightarrow{e_z}$; axially towards the short-cut (ax-sc) $+\overrightarrow{e_z}$; azimuthaly (azim) $\pm\overrightarrow{e_\varphi}$.

Figure 4 shows typical deformations of the probe characteristics, obtained at a fixed radial position of 2 mm away from the quartz tube, and for different probe orientations. The (azim) characteristic clearly corresponds to the case where only cold electrons are collected, with typical maxwellian temperatures that range between 1.5 and 2 eV, depending on the gas pressure. The different curves in this figure show very close plasma potentials V_{plasma} (see the inflexion points on the right), and a similar behaviour for the region of cold electron collection (at $V_{probe} \lesssim V_{plasma}$). At more negative probe potentials, we observe a strong increase in the characteristics obtained at both axial and radial directions (when compared to the corresponding azimuthal measurement), that can indicate an increase in the *number* of high-energy electrons overcoming the repulsive potential barrier of the probe sheath. Note that although such deformations may be associated to the existence of high-energy electrons, generated within the electric field resonance near the quartz tube, it is also possible to have the intense electric field in this region affecting current collection, or the probe itself modifying the local field.

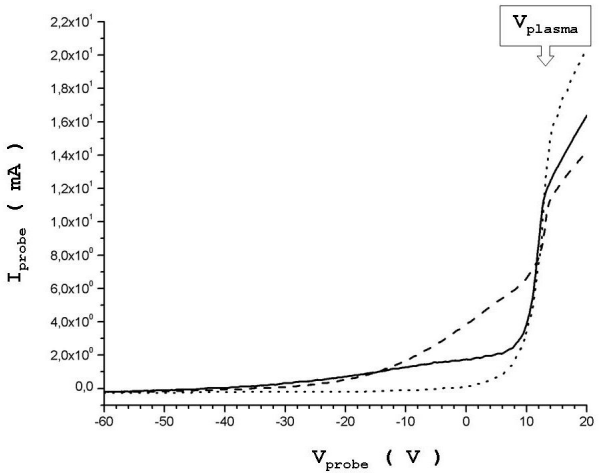

Figure 4. Planar probe characteristics at a constant radial position of 2 mm, for 30 mTorr gas pressure and 200 W injected power, and for different probe orientations: solid line (rad), dashed line (ax-sc) and dotted line (azim).

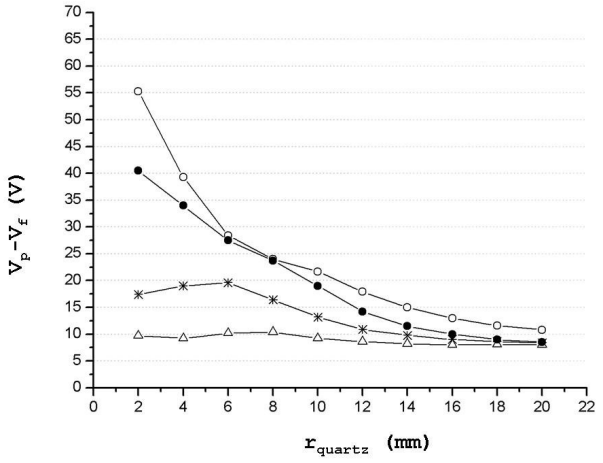

Figure 5. Deviation of the floating potential V_{float} with respect to the plasma potential V_{plasma}, as a function of the radial position, at 30 mTorr pressure and 200 W injected power, and for different orientations of the probe collection surface: empty circle (rad), star (ax-cd), triangle (azim) and full circle (ax-sc). Note that r_{quartz} is defined with respect to the outer radius of the quartz tube.

Further confirmation about the existence of high-energy electrons in the discharge is given by the radial evolution of V_{float} with respect to V_{plasma}. The floating potential V_{float} is defined as the potential at which the electron current exactly compensates the corresponding ion current. Considering that no external perturbation is affecting current probe collection, the quantity $\Delta V \equiv V_{float} - V_{plasma}$ is a simple parameter that relates to the *energy distribution* of electrons. *Figure 5* plots ΔV as a function of radial position, for different orientations of the probe collection surface. Far away from the quartz tube, the values of ΔV are independent of the probe orientation, which is consistent with the existence of a cold electron population, assuming that the plasma potential is constant across the radius. Near the quartz tube, however, one observes a strong increase in ΔV, for measurements carried out in all directions except the azimuthal one. In fact, the values of ΔV obtained in the azimuthal direction remain constant for all radial positions, thus indicating that probe measurements are not perturbed. Note that although the values of ΔV are comparable for measurements obtained at both axial (ax-sc) and radial (rad) directions (hence, suggesting similar electron energies), the number of cold electrons is higher is the latter case (see *Figures 4* and *5*).

4. Simulation results. Inclusion of the CRM

Preliminary comparisons have been carried out between simulation results and experimental measurements, obtained with both Langmuir probe and (radially averaged) emission spectroscopy diagnostics. It was shown [10,12] that the model predicts the correct trends of plasma density and electron mean energy profiles - see *Figure 6*, at various gas pressures and averaged electron densities. However, model predictions for the values of the electron mean energy were found to be systematically overestimated with respect to measurements, which was mainly attributed to the fact that stepwise electron-neutral (e-N) ionisation collisions were not taken into account.

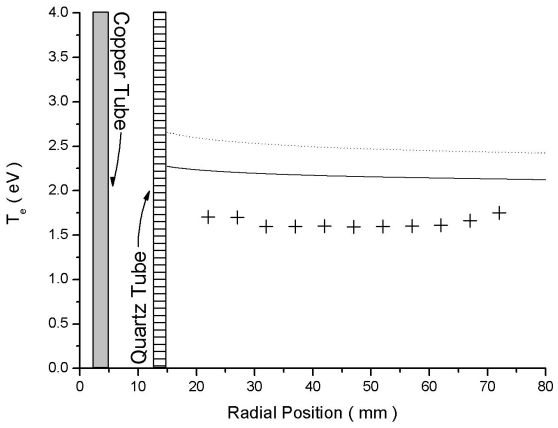

Figure 6. Radial mean electron energy profile (experimental - *cross*, calculated without CRM - *dotted line* and calculated with CRM - *full line*) for a gas pressure of 30 mTorr and injected power 700 W. Averaged electron density $< n_e > = 5.14 \times 10^{+}11\ cm^{-3}$.

In fact, the first excited levels of argon are expected to play a significant role in the electron energy balance, as they participate in stepwise e-N ionisation collisions that can contribute to lower the values of the electron mean energy required to sustain the discharge. In order to clarify the influence of these species, we have self-consistently coupled a CRM for argon gas to the 1D-moment method radial code, describing charged particle and energy transport. The CRM uses an updated set of cross-sections [13], taking into account 31 real and effective argon atomic levels - see *Fig.8*. The balance equation for each species includes electron impact inelastic processes (excitation and ionization, both direct and stepwise), radiative processes (taking into account resonant imprisonment effects) and diffusion of the two 3p5-4s metastable states toward the discharge walls. The flux boundary conditions assume total absorbing walls.

Figure 7. Atomic levels of argon considered in the Collisional-Radiative Model.

Emission spectroscopy measurements were used for comparisons with the calculated populations from the CRM. Measurements were performed at an axial position of a 3 cm away from the coupling device. This corresponds to the position of the maximum of intensity of the plasma column, which does not change with pressure nor injected power, to ensure a similar spatial electromagnetic field configuration for comparisons. Injected power was set to 400 Watts.
Measurements are integrated over the discharge radius. Excited states populations are obtained from experimental line intensities using

$$n_p = \frac{4\pi}{V_p - V_q} \frac{I_{p \to q}}{A_p^q}$$

, where $I_{p\rightarrow q}$ is the experimental emission line corresponding to the transition from a level p to a level q, n_p is the excited state density, $V_{p,q}$ the respectively upper and lower state energy and A_p^q the corresponding radiative constant. Without the information of the spectral response of the acquisition system (optic fiber + CCD camera), only relative comparisons using the ratios of n_p excited states populations obtained from emitted lines which wavelengths are close to each other, are to be considered.

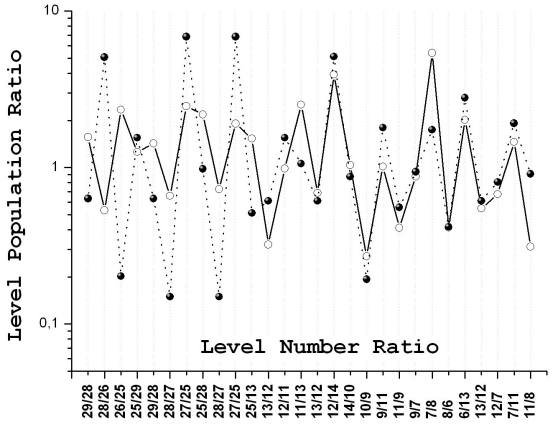

Figure 8. Ratio of excited states populations obtained from emitted radially averaged lines close to each other - *full line* - and from calculated radially averaged profiles using the CRM - *dotted line*. Gas pressure of 60 mTorr, injected power of 400 W. Corresponding averaged electron density $n_e = 7.0 \times 10^{+11}\ cm^{-3}$.

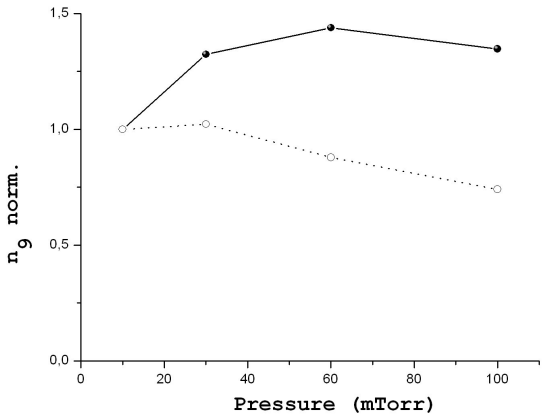

Figure 9. Normalized population of the level n° 9 as a function of gas pressure obtained from emitted radially averaged lines - *full line* - and from calculated radially averaged profiles using the CRM - *dotted line*. Averaged electron density $n_e = 7.0 \times 10^{+11}\ cm^{-3}$.

As one can notice on *Figure 8*, a good comparison between numerical and experimental results is achieved for the lower levels (ranging from number 6 to 14). This shows that the $4p$ levels are correctly described by the CRM. For levels ranging from number 25 to 29, a fair comparison is obtained as higher levels are not included in the model. The trend is similar for the different investigated pressures.
A typical evolution of both normalized calculated and measured populations as a function of gas pressure is shown on *Figure 9*. One can observe a similar qualitative trend for both cases where a maximum is reached around 30 mTorr for calculated populations and around 60 mTorr for measured populations.

5. Conclusion

Corroborating results obtained from a comparative study of planar probe characteristics show the existence of high energy electron fluxes [11] near the quartz tube of the coaxial structure of a low pressure microwave discharge. Still the global behavior of their generation process within the resonance regions is not clearly understood. The work indicates that an axial energetic electron flux is possibly generated along the discharge axis, which could induce changes in the radial energetic balance.
Despite a good qualitative agreement of both measured and calculated electron mean energy and low argon excited states description, one can notice a quantitative difference. Such discrepancy has been in part reduced by using a CRM, taking into account electron impact inelastic processes (excitation and ionization, both direct and stepwise). Further comparison work with experiment, including a precise spectral response of the acquisition system, is needed to evaluate the used cross sections relevancy.

As a first approximation, higher order terms have been neglected in the writing of the electrons and electron mean energy transport equations considered in the moment method model. A more complete description could result to an intensity increase in the regions of space charge separation and thus lead to a global diminution of the electronic temperature. It could also provide some usefull informations on the generation of more energetic electron fluxes in the resonance regions.

Aknowledgment The authors would like to express their most profound sadness as a result of the death

of G. Gousset. He was at the head of the *Laboratoire de Physique des Gaz et Plasmas*. This work is a consequence of the many projects he initiated. His enthusiasm, his rigorous analysis and his scientific vision will stay in our memories.

Abstract: In this paper atmospheric orientation plasma polymerization (APOP) has been selectively demonstrated, focusing on the controlling of crystalline phase structure and morphology of organic nanocrystals. We will concentrate on nanofabrication and crystallization of PTFE and pyrrole-like polymers through AOPP. Organic nanocrystallines with various shapes and crystal phase have been fast formed by AOPP. Special thermal or optical-active properties of the nanocrystallines were also found. This "oriented plasma polymerization" method opened another way for nanofabrication of crystalline polymers.

1. Introduction

Polymer nanostructures are mostly investigated for two purposes. One is to nanofabricate conjugated polymer structures with higher crystallinity for semiconductor or conductor applications such as FET's, LED's, molecular wires, molecular devices etc.. Another is to get nanostructures for insulating interconnections between other conducting or semiconduting nanostructures such as BCP's, nanocable shells, AFM tip coating, insulation coatings for biological implants such as integrated circuits, bond pads, wires, and neural probes etc.. PTFE-like polymers have many remarkable properties, including low dielectric constant, low friction coefficient, high thermal stability, good solvent or chemical resistance, low permeability constant, low surface tension and good biocompatibility etc..

Although there have been extensive efforts on the formation of polymer nanostructures with well controlled and specified nano dimensions, it is a great challenge to synthesize them with high crystallinity and purification. In most of the previous synthesis to get polymer nanostructures [1-6], it often requires confined templates, oriented polymerization catalysts, long and tedious post removing of the templates and catalysts after polymerization, and special requirement for monomers[7-11]. These post treatment process is usually not benefit to the purity and crystallinity of the nanostructures. It is therefore desirable to seek novel synthesis routes by which polymer single crystals with high purity can be formed reproducibly and efficiently.

Plasma method has been widely applied for etching or deposition in the microelectronics industry since 1960's. It has also played an important role in the fabrication of nanomaterials from the emerging of nanotechnology. Based on the strategy to assemble or etch small particles in the state of electrons, atoms, ions and excited molecules etc., it provides a convenient, effective, and low-cost vapor-solid or vapor-liquid-solid method for fabrication of nanomaterials. But most of the research concentrated on inorganic and metal nanostructures , especially on the fabrication of nanostructure arrays with the assistance of catalysts and templates. Only a few studies were related to its applications in the fabrication of organic or polymeric nanocrystalline structures. And it is normally considered that organic products by PECVD are pinhole-free and highly cross-linked amorphous structures[12].

Recently we have found that plasma discharge at atmospheric pressure with an inhomogeneous electric field and linear CxFy monomers could produce single crystalline PTFE-like polymer nanotubes. So in this paper, PECVD at atmospheric pressure (here it is called atmospheric orientation plasma polymerization (APOP)) has been selectively demonstrated, focusing on the controlling of the nanofabrication and crystallization of PTFE and pyrrole-like polymers through AOPP. Organic nanocrystallines with various

shapes and crystal phase have been fast formed by AOPP. Special thermal or optical-active properties of the nanocrystallines are also found. This “oriented plasma polymerization” method opened another way for nanofabrication of crystalline polymers.

2. Experimental

The apparatus used for the formation of single crystalline polymer nanoparticles was a home-made atmospheric plasma discharge reactor. In this reactor, a gradient electric field with a high voltage of 10—50 kV and a frequency of 10—100 kHz was applied to deposit the nanoparticles on ordinary glass slides or into water directly. Filament plasma was generated between a high voltage strip electrode and a grounded plane electrode, one of which was covered with a dielectric barrier at least. Perfluorocarbon compounds or pyrrole were used as the precursors and fed into the reactor through an argon carrier gas at a flow rate of 1:10. The flow rate of the mixture gas was controlled at 5 SLM through a mass flow controller. No vacuum was needed for the reactor system. After only a few seconds to several minutes, a thin film was deposited on the entire substrate, onto which a large quantity of nanoparticles were identified.

The morphology of as-grown nanoparticles was investigated by scanning electron microscopy (SEM) using a JSM-5600LV. Transmission electron microscopy (TEM) images were acquired at an accelerating voltage of 120 kV using a JEOL JEM-200CX. TEM samples of nanoparticles were prepared by dispersing them directly on a carbon film supported with Ni grids. The scattering selected area diffraction (SAD) pattern pictures were taken as soon as possible after focusing, otherwise the polymer nanoparticles experienced melting by the electron beam radiation. A Rigaku D/Max 2550V X-ray diffractometer (XRD) with Cu K radiation was used to characterize the synthesized film. The x-ray wavelength was 1.54 Å with a beam size of 3 mm. X-ray photoelectron spectroscope (American Physical Electronics, PHI 550) was used to characterize the chemical composition of the film containing nanoparticulates. FTIR measurement was carried out on a Nicolet NEXUS-670. Polarized optical micrographs were continuously taken by an Olympus B×51 with a hot stage at a constant heating rate. For comparing the thermal stability of the nanotubes with PTFE, small pieces of PTFE were cut off from PTFE polymer from 3F Company (melting point 310 °C) and also observed with polarized optical microscope. The heating rate was the same as in observing the deposition films. The UV-visible absorbency spectrum of the nanoparticle-water suspension solution was measured after 15 minutes ultrasonic treatment through a UV-3000 ultraviolet spectrophotometer (Shimadzu Corporation, Japan).

3. Results and discussions

3.1 Crystallization of PTFE-like Nanotubes by AOPP

Figure 1 shows the SEM images of the as-grown single crystalline nanotubes on a glass substrate. The synthesis time needed for growing these nanotubes was only three minutes. As can be seen in Fig. 1A and Fig. 1B, the nanotubes exhibit a hexagonal outer geometry with an open end. The outer diameter of these tubes is between 60-700 nm with a wall thickness of 50-120 nm. The maximum aspect ratio observed is on the order of 100:1. The nanotubes on the substrate also appear massive in quantity. Some of the nanotubes tend to lie in parallel to the background particulate layer. Portions of the nanotubes grow vertically from the layer. As can also be seen in Fig. 1C, these nanotubes protrude directly upward from the background film, indicating their close structural and compositional relationship with the background. Also observed in Fig. 1A and Fig. 1B is that the background film is composed of loosely-packed nanoparticles on the glass substrate. The loosely-packed nanoparticulates in the background have a mean particle size of about 50 nanometers.

Figure 2 shows the TEM image of the nanotubes (Fig. 2A) and the selected area diffraction pattern (SAD) within the nanotube (inset of Fig. 2A). Based on the sharp electron diffraction spots in SAD, it is clear that they

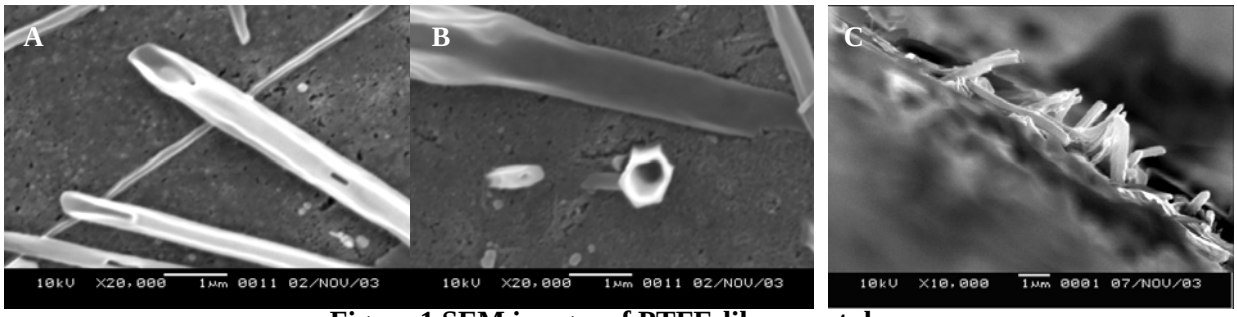

Figure 1 SEM images of PTFE-like nanotubes

A. PTFE-like nanotubes lying on the surface of a loosely-packed nanoparticulate layer
B. Cross-section of the broken PTFE-like Nonotubes, clearly showing hexagonal shape
C. Nanotube arrays grown from the nanoparticulate layer

have a single crystal phase, which is indexed to a hexagonal close-packed (HCP) structure with lattice constant of a=6.384 Å, c=10.231 Å and its axis direction of [011]. In sharp contrast, however, the diffraction pattern on the background nanoparticulates exhibits entirely different behavior. As shown in Fig. 2B, the ring patterns from these nanoparticulates on the substrate suggest a polycrystalline structure of a cubic structure with a unit cell parameter of 5.786 Å. Therefore there are two types of structures among the sample materials studied, namely, the HCP structure for the nanotubes and the cubic for the nanoparticulates, respectively. It should also be noted that both phases are well crystallized on the substrate.

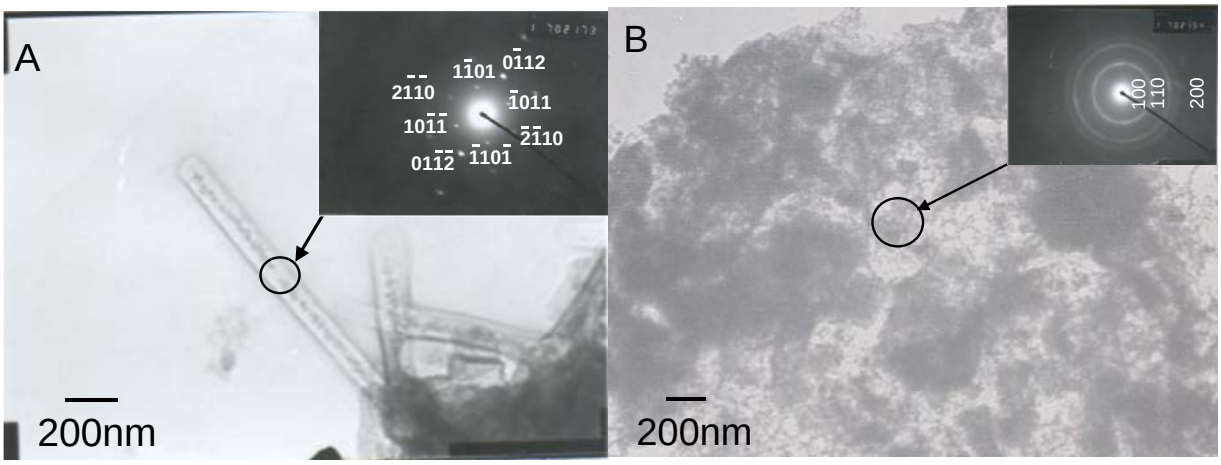

Figure 2 Crystal structure characterization of PTFE-like nanotubes through TEM

A. TEM image of PTFE-like single crystalline nanotubes and the SAD pattern (inset)
B. TEM image of PTFE-like polycrystalline nanoparticulates and the SAD pattern (inset)

The chemical structure of the film was characterized by Fourier infrared spectroscopy (FTIR). The FTIR spectrum is shown in Figure 3. As can be seen in this figure, the spectrum displays absorptions at 480.43 cm^{-1}, 753.37 cm^{-1}, 983.53 cm^{-1} and 1239.90 cm^{-1}, which can be assigned to CF_2 rock deformation, wag deformation, asymmetric stretch and symmetric stretch vibrations, respectively. Although the peak at 1750 cm^{-1} has considerably weak intensity, it is likely that it is associated with the oxygen-containing group. From the EDS experiment, the relative ratio of the C, O, F atom is about 51: 36: 13. Based on the FTIR and EDS results, the as-deposited film is identified to be a Teflon-like polymer structure .

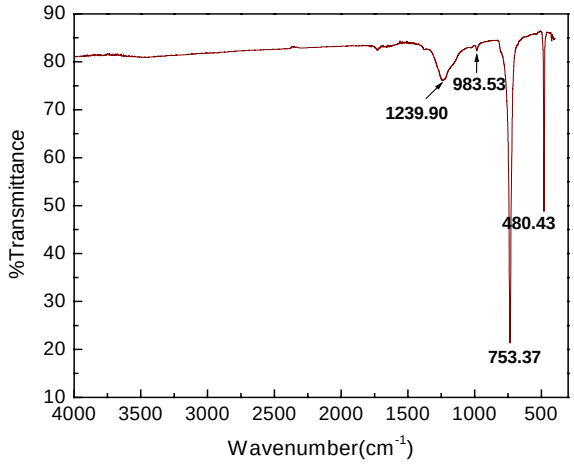

Figure 3FTIR spectrum taken from the as-deposited sample containing nanotubes and nanoparticulates on the glass substrate.

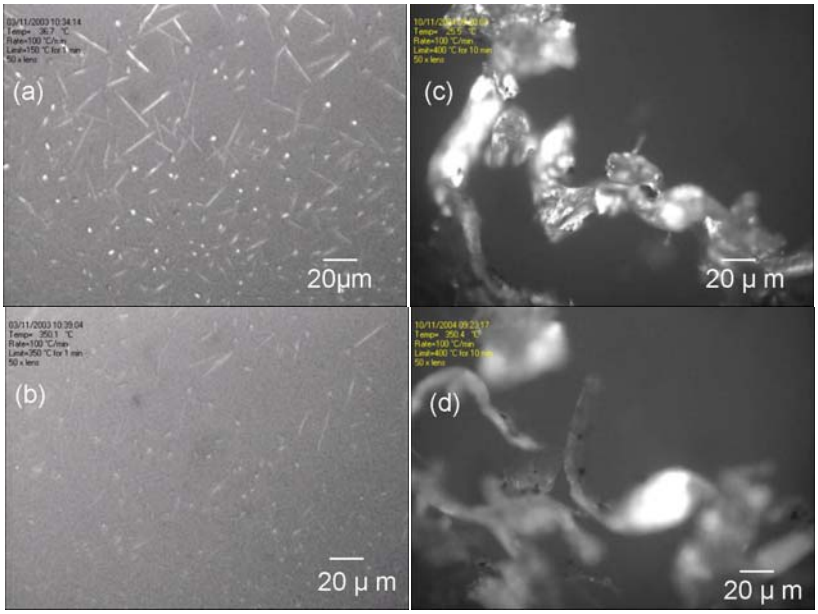

Figure 4 Comparison of thermal stability of observable nanotubes and PTFE polymer slices through polarization micrographs at different testing temperatures

A), Nanotubes at 36.7°C , B), Nanotubes at 350.1°C,

C) PTFE polymer slices at 25.5°C, D) PTFE polymer slices at 350.4°C

The thermal stability of the as-obtained nanotubes was observed through the hot-stage polarized optical microscopy. As shown in Fig. 4, the observable nanotubes with large size retain a needle-like morphology at 36.7 °C (Fig. 4a) and exhibit high birefringence in the crystal edge region. Upon heating up to 350 °C (Fig. 4b), the nanoparticulate layer appears melted and mobile in the vision field but the nanotubes still display clear birefringence although not as strong as at 36.7 °C. Small slices of PTFE exhibit high birefringence of polycrystalline at room temperature (Fig. 4c). Upon heating up to 350 °C, they also melt as the film(Fig. 4d). They completely melt when heating up to 370 °C. This implies significant thermal stability of the single crystal polymer nanotubes comparable to PTFE bulk polymer. The FTIR spectrum and XPS experiment data also display a PTFE-like polymer structure of the film (data not shown here).

3. 2Crystallization of Pyrrole-like Nanorods by AOPP

Figure 5 shows the SEM images of the as-grown single crystalline nanorods on glass substrates. The synthesis time needed for growing these nanotubes was only 2 minutes. As shown in Fig.5 A and Fig.5 B, the nanorods have a spindly shape. The diameter of the nanorods is between 300-400 nm and the maximum aspect ratio observed is about on the order of 8:1-2:1. The nanorods on the substrate also appear massive in quantity. As the same as observed in Fig. 1A and Fig. 1B there is also a background film which is composed of smaller nanoparticles on the glass substrate. The TEM of these nanorods displays that

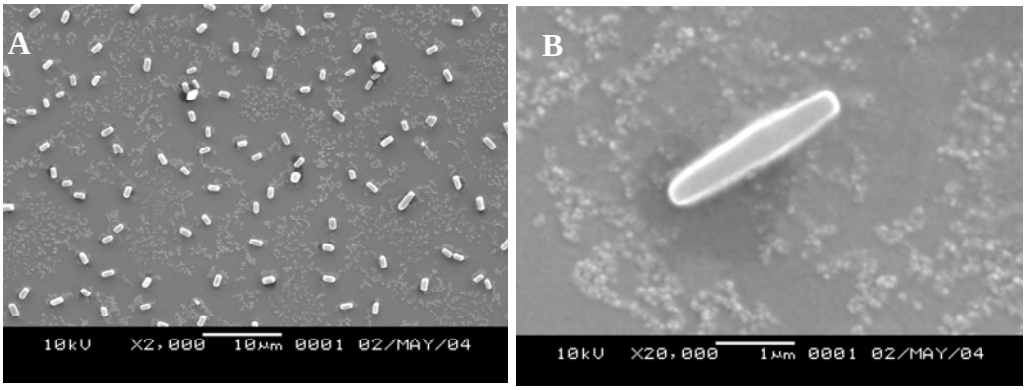

Figure 6 SEM images of pyrrole-like nanorods

When the product is led to water directly, the similar spindly shape nanorods are found in the suspension solution. Besides, the color of the nanorod-water suspension changes with time. As shown in figure 7, the color of

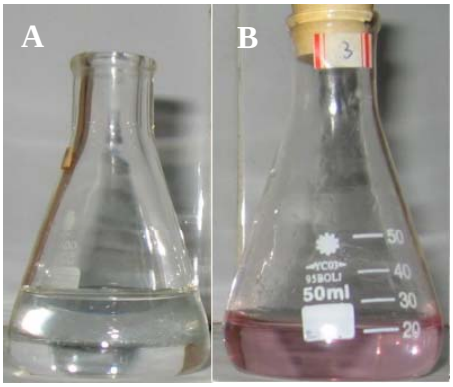

Figure 7 Color changes of pyrrole-like nanorod-water suspension after stored for 2 days

A) after reaction, B) after reaction for 2 days

the suspension changes to pink after stored for 2 days. No such phenomena is observed for pyrrole-water solution. The fluorescence intensity of the suspension increases with time, as shown in Figure 8. This demonstrates that these nanorods are optical-active.

3.3 Discussions

The atmospheric plasma discharge method has many unique advantages in nanofabrication of single crystalline polymer structures in comparison with other processes. It can be carried out at room temperature under atmospheric pressure on many kinds of substrates without any templates or catalysts at an exceptionally fast rate (within several minuets). The synthesized nanostructures by this method possess a high degree of crystallinity. It is suggested that the discharge streamers along the direction of the electric field act as temporary confined templates in the formation of the nanostructures and disappear after the discharge. The electron energy inside the discharge core is 2-5 eV and high enough to dissociate the monomers into active particles such as ions, radicals,

metastable neutrals, and electrons within the discharge channels. But compared with the plasma discharge in

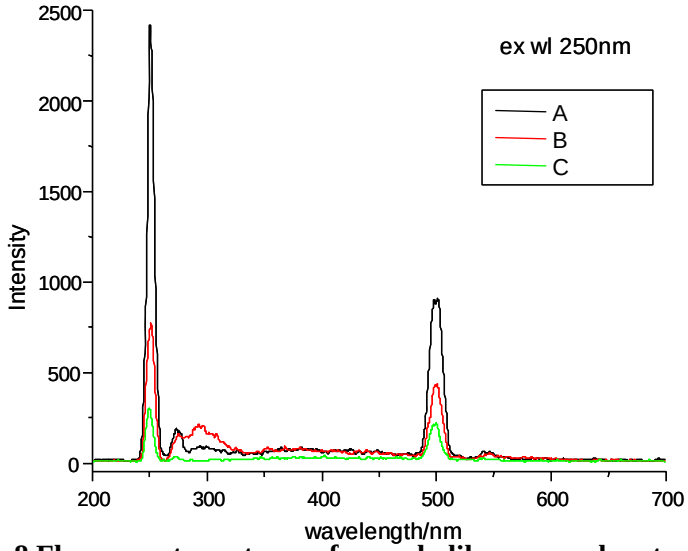

Figure 8 Fluorescent spectrum of pyrrole-like nanorod-water suspension

A) after reaction, B) after reaction for 1 day, C) after reaction for 2 days

vacuum, the mean free path of the electrons is only several micrometers. Therefore the dissociation of the monomers is not as severe as in vacuum plasma discharge. More organic functional groups containing oxygen, nitrogen, hydrogen or fluorine could be retained in the product. The density of the active species is also higher than that in vacuum plasma, leading to a high deposition rate. The initially formed active particles such as ions or radicals are polarized inside the numerous filament channels in the inhomogeneous electric field. Then they are oriented along the direction of the gradually-decreased electric field “head to tail”, react with each other and form the crystalline structures. So it looks like an “atmospheric oriented plasma polymerization”.

This AOPP method opens another approach in the one-step fast formation of single- or polycrystallines The rapid process is independent of monomer types and only associated with plasma conditions and the electric field gradient. Therefore, the novel plasma polymerization process can also be applied to the nanofabrication of other single crystalline polymers with potentially excellent properties and wide range of applications.

The treatment of Li-ion battery waste in a transferred arc plasma reactor

Vittorio Silla and Richard J. Munz[1]

[1]*CREPE Department of Chemical Engineering, McGill University, Montreal, Quebec, Canada*

Abstract
A transferred arc process for the treatment of lithium-ion battery waste to recover cobalt was examined in a laboratory scale transferred arc plasma reactor. Batch operation under oxidizing conditions gave a recovery of 38% of the cobalt in a consolidated metal phase composed of 50 % Fe, 28 % Co, 12 % C and 7 % Cu and 3 % Ni. Operation simulating a semi-continuous process resulted in a Co recovery of 60% and a Co concentration of 57% in the metal phase.

Keywords – Li-Ion battery waste, transferred arc, cobalt, recycling, treatment

1. Introduction

In the new millennium, over 500 million rechargeable battery-operated and miniaturized pieces of electronic equipment will be in circulation. A battery market survey showed that the average annual growth rate of Li-ion batteries will increase by 118%. The millions of spent Li-ion batteries will cause an environmental waste management problem. The cathode metals, which have a high market value (41 US$ / kg cobalt) will leach into the earth when land filled. There is thus a great need to develop processes to recycle these batteries or at least render them harmless. This paper reports on a preliminary study of a transferred arc process to accomplish this. In this process the Li-ion battery waste would be separated into volatile, slag and metal phases using argon and/or oxygen as the plasma gas. The cobalt would be recovered in a metal phase while other elements would be either concentrated into an inert slag or volatilized and recondensed. Thermodynamic simulations and experimental test were carried out in both inert and oxidizing atmospheres.

2. Thermodynamic Simulations

Thermodynamic simulation of the process was performed using the FACT-Sage software [1] with free energy minimization calculations. The process was simulated at 1 atm and between 1000 and 2000ºC in both inert and oxidizing atmospheres using spent Sony Enertec lithium ion batteries. These batteries are commonly used in portable instruments such as laptop computers, camcorders, and digital cameras. The molar composition of the battery was : C 1.047, H 0.756, O 0.205, Fe 0.149, Co 0.126, Li 0.114, Al 0.057, Cu 0.021, Ni 0.003 and to this was added 5 moles of argon for inert operation and various amounts of oxygen for oxidizing conditions. Lithium was always volatilized at temperatures above 1600^{o}C. Inert conditions were unsuitable since although the valuable cobalt reported to the metal phase, it could not be separated from the other metals in the presence of carbon. Figure 1 below shows the predicted behavior of the most important metals at a temperature of 1800^{o}C as the oxygen added is varied from 0 to 2 moles. With the addition of oxygen, cobalt remains in the metal phase while iron is oxidized and copper is vaporized. Nickel reports primarily to the metal phase. With the addition of 1.1 moles of oxygen per standard battery at 1800^{o}C, the simulation showed that 98% for the Co could be recovered in the metal

phase but with contamination by 10 % Cu, 4 % Fe and 2 % Ni. At a temperature of 1600^{o} C the concentration of Co in the metal phase is reduced form 84% to 81% while at 2000^{o} C Co starts to be lost to the vapor phase.

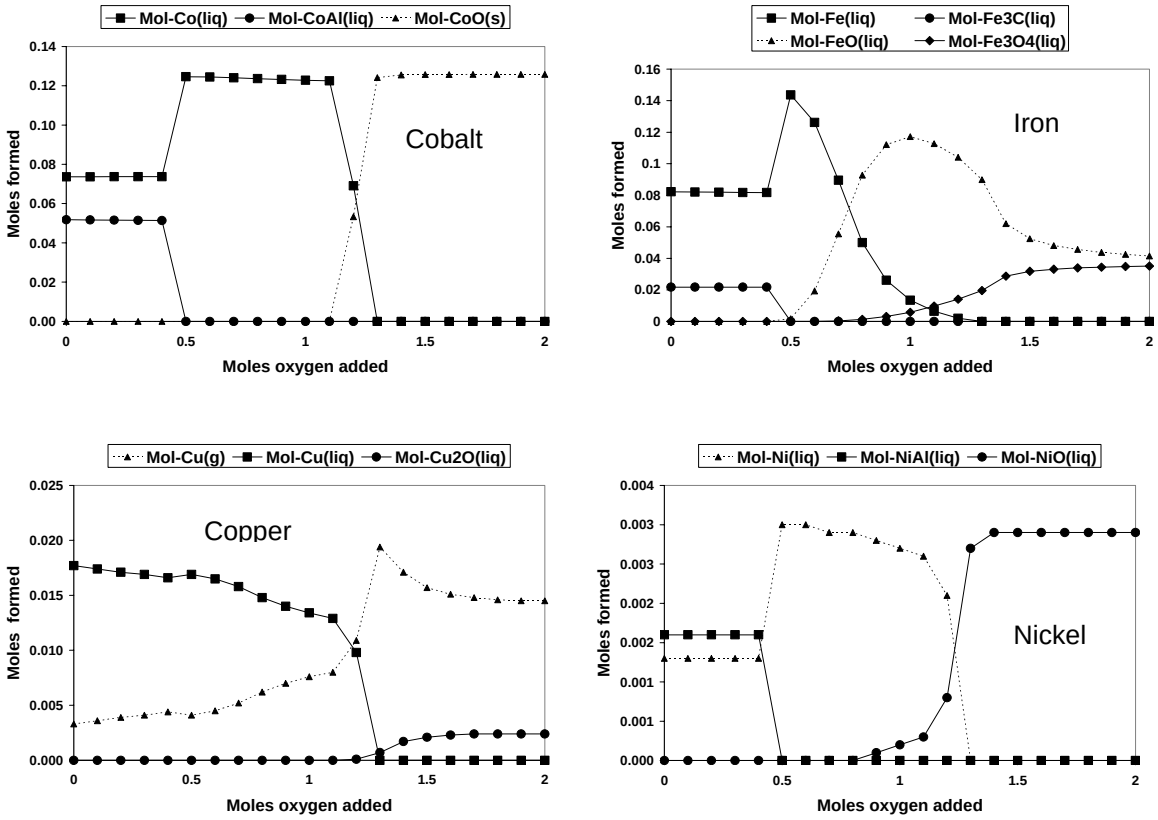

Figure 1: Predicted behavior of metals in system of ideal solutions at 1800^{o}C

3. Experimental Equipment

The experiments were conducted within a water-cooled stainless steel reactor vessel 30 cm in diameter and 38 cm long as shown in Figure 2. Further details are available elsewhere [2]. The vessel contained an inlet for oxygen at its midpoint and a gas exhaust as shown in the drawing. Two purged windows on the reactor lid were used for observations and pyrometric measurements. The arc was struck between a thoriated tungsten tip surrounded by an auxiliary anode and the crucible which contained the battery waste. The purpose of the auxiliary anode was to produce a non-transferred arc until the arc could be transferred to the waste. A data acquisition system monitored and logged the initial arc length, current, voltage, and bath temperature. A two wavelength pyrometer was used to obtain the reaction temperature after the arc was extinguished. The power was supplied by a DC power supply with an open circuit voltage of 600 V and a maximum power rating of 300 kW. The current supplied to the reactor was regulated using a remote control console. The arc was ignited with a high frequency generator in series with the dc power supply.

Two types of crucibles with identical interior dimensions were used. The cavity to receive the waste was in the shape of a truncated cone with a height of 2.54 cm, a bottom inner diameter of 2.54 cm and walls sloped at 21^{o} from the vertical. Graphite was used for inert gas operation while cast zirconia ceramic was used for oxidizing conditions. The graphite crucibles were placed in zirconia ceramic heat shield with an exterior diameter of 7.31 cm. The ceramic crucible bottoms contained a graphite rod with a diameter of 6.4 mm to provide conductivity to the charge.

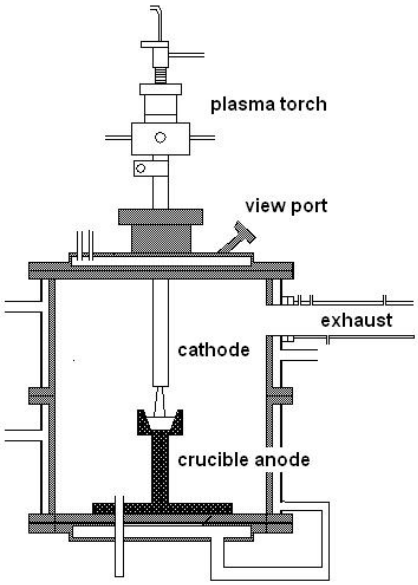

Figure 2: Transferred arc plasma reactor

4. Experimental Procedures

The batteries were first removed from their battery packs, and stripped of their plastic covering. They were then cut in two and dried in a vacuum oven for 24 hours at 80 ºC to eliminate the volatiles. After cooling, they were pressed in a stainless steel mould into 2.54 cm diameter by 2.54 cm high cylindrical pellets with a hydraulic press supplying 93 kN of force.

Before each experimental run the reactor was cleaned. The pellet was weighed and mounted in a weighed crucible. The reactor was then sealed and the torch adjusted to a position just above the pellet. The reactor was purged for 5 minutes at an argon flow of 9.3 slpm. For oxidizing runs, oxygen at a rate of 15.8 slpm was injected before igniting the arc. After arc ignition, the arc length and current were adjusted to the desired values to the appropriate run time. At the end of this time the arc current and gas were simultaneously stopped and an auxiliary stream of argon was injected into the reactor exhaust to avoid the inlet of air. This purging argon flow was continued for about 10 minutes during the cooling of the pellet and crucible to avoid any oxidation. The pellet temperature at shutdown was obtained by back-extrapolating the pyrometer readings after arc extinction to the time of extinction; pyrometer readings during arc operation were too biased by radiation from the arc to be reliable.

The treated samples were separated into their respective phases, weighed and analyzed by ICP emission spectroscopy, TOC, SEM-EDAX, and X-ray diffraction as was appropriate [2].

5. Experimental Results Inert Operating Conditions

The optimum operating conditions for inert conditions were treatment with 9.3 slpm of argon at 200 A for 20 minutes. The initial arc length was 3.0 cm and the voltage was 32.2±1.1V. The average temperature at the end of treatment was 1420^{o}C. Less current and time resulted in a less complete treatment while higher currents and time resulted in excessive vaporization. The combined results of four experiments are presented in Table 1 which gives the percentage of the initial elements reporting to each of the phases identified. These phases include a consolidated metallic phase, an essentially untreated hulk, a friable powder and the vaporized material. Only the first three phases were analyzed while the vaporized material behavior was obtained by difference. Overall 44±4% of the charge was vaporized and of the remaining material, 66±27% was consolidated, 23±26% was untreated while 11±1% remained as powder. The all important metallic phase contained 63% Fe, 16% C, 12% Co, 3% Ni, 4% Al and 0.68% Cu. The recovery of

the cobalt in this phase was only 19% and it was heavily contaminated. A comparison of the experimental results with the thermodynamic predictions suggested that the crucible contents were highly non-isothermal. It must be concluded that treatment under inert operating conditions is not successful.

Table 1: Inert operation - Elemental distribution among phases

Element	Consolidated (%)	Untreated (%)	Powder (%)	Vaporized (%)
Fe	87.89±5.91	10.82±1.89	0.97±0.07	0.33±7.98
Co	19.06±0.85	23.21±3.48	3.08±0.25	54.65±4.57
Cu	6.00±0.08	26.50±1.67	25.37±0.95	42.132.70
Al	26.79±0.12	19.85±0.57	6.74±0.14	46.62±0.83
Ni	93.02±2.06	5.81±0.22	2.22±0.01	0.00±2.29
Li	0.00±0	0.00±0	4.10±0.06	95.90±0.06
C	14.79±0.15	6.78±0.50	7.54±1.09	70.89±1.74

6. Experimental Results Oxidizing Operating Conditions

It was determined from exploratory experiments under oxidizing conditions that the optimum operating conditions were a current of 100 A, and initial arc length of 3.0 cm, an argon flow rate of 9.3 slpm, and a run time of 7 minutes. An oxygen flow rate of 15.8 slpm was used to reflect the thermodynamic simulations. The average arc voltage was 39.8±0.9 V and the average temperature at the end of treatment was 1510±210^{o}C. Lower arc currents were needed because of the insulating properties of the ceramic crucible and the heat of oxidation. The results presented below are based on three runs. Consolidated metal represented 31±11 % of the initial mass while 61±8 % was vaporized and 8±6 % formed oxides. The elemental distribution due to the oxidizing treatment is given below in Table 2. Because the amount of the oxidized phase was so small, it has been included with the vaporized material. The last column of Table 2 gives the composition of the product metal phase. The content of cobalt was much higher for oxidizing conditions but the product was still heavily contaminated with iron and copper. This is because the carbon was not sufficiently removed by oxygen. This was attributed to the poor mixing within the crucible and the nonisothermal conditions. Also, because the oxygen was not injected via the plasma gas, mass transfer resistances limited its contact with the product.

Table 2: Oxidizing operation – Elemental distribution among phases and composition of metal phase

Element	Consolidated Metal (%)	Vaporized and Oxidized (%)	Composition of Metal Phase (%)
Fe	62.0±6.2	38.0±6.2	49.63±4.93
Co	38.5±3.9	61.5±3.9	27.54±2.80
Cu	55.5±12.2	44.5±12.2	7.01±1.55
Al	2.2±1.3	97.8±1.3	0.32±0.20
Ni	100.0±37.6	0.0±0	2.77±0.31
Li	0.1±0	99.9±0	0.00±0
C	9.5±7.3	90.5±7.3	12.72±9.81

7. Experimental Results Oxidizing Operating Conditions with a Metal Heel to Simulate the Industrial Process

The experiments described above were necessarily batch while on an industrial scale the treatment was envisioned to be a semi-continuous process. Lithium ion battery waste would be continuously added to the system creating a large pool of liquid metal primarily composed of Co and an overlying slag layer. The metal and slag layers would be periodically tapped.

To better simulate the industrial scale process, a 10 g Co heel was added to the 40 g battery waste. During the treatment the Co heel would melt and act as a solvent, absorbing the liquid Co diffusing from the battery. It was found that because of the presence of the heel of Co, higher currents and oxygen injection rates could be used without damage to the crucible. Experiments were conducted at 100 A, 10 minutes of reaction, and oxygen flow rates of 15.8 as well as 23.3 slpm. This gave voltages of 42.3±2.5 V and 41.8 V respectively. As the flow rate of oxygen increased from 15.8 to 23.3 slpm, the percentages of consolidated metal, oxide and vaporized material changed from 41:8:51 to 25:11:64. Essentially the metal phase was reduced and the amount of material which was volatilized increased as more oxygen was added. The distribution of elements into the different phases and the compositions of the metal phases for the two operating conditions is given in Table 3 below.

It may be seen from the first set of conditions that the use of a heel improved the recovery of Co in the metal phase; it was increased from 39 to 59%. In addition, the contamination of the cobalt in the metal phase by other metals was less and the Co concentration increased to 57%. It is clear that there is still too much carbon in the product indicating poor mixing of the oxygen with the material in the crucible and within the crucible. Very little of the cobalt was lost to the oxide layer but a great deal, 40% was volatilized.

As the oxygen flow rate was increased to 23.3 slpm in the presence of a heel of cobalt, the overall recovery of cobalt decreased greatly from 59 to 35%; most of this was volatilized. The concentration of cobalt in the metal product increased marginally to 58% but the change was not statistically significant.

Table 3: Oxidizing operation with metal heel – Elemental distribution among phases and composition of metal phase at oxygen flows of 15.8 and 23.3 slpm

Element	Metal (%)		Oxide (%)		Vapourized (%)		Composition of Metal Phase (%)	
	15.8 slpm	22.3 slpm	15.8 slpm	22.3 slpm	15.8 slpm	22.3 slpm	15.8 slpm	22.3 slpm
Fe	64.9	15.1	0.6	1.0	34.5	83.9	30.87	32.43
Co	59.4	34.6	0.3	1.4	40.3	64.1	57.08	58.48
Cu	82.4	32.9	1.3	5.7	16.3	61.4	6.19	4.42
Al	1.1	0.1	8.0	10.9	90.8	89.0	0.10	0.03
Ni	98.8	100.0	0.0	0.0	1.2	0.0	1.82	1.96
Li	0.0	0.2	2.3	25.7	97.7	74.2	0.00	0.00
C	4.9	1.9	0.0	0.0	95.1	98.1	3.93	2.69

8. Conclusions and Recommendations

A transferred arc plasma process for the treatment of lithium-ion battery waste was examined using a thermodynamic simulation and a laboratory scale transferred arc reactor in the batch mode at power levels between 4.0 and 6.4 kW. Because of the small scale of the operation, a major challenge was to obtain a clean separation of the phases produced in the crucible. The system was nonisothermal in both time and space and this resulted in excessive vaporization in the vicinity of the arc and incomplete melting and consolidation at the edges. In experiments under oxidizing conditions, the flow of argon, which protected the tungsten cathode tip also partially, shielded the crucible contents from the oxygen injected into the reaction chamber.

The optimum operating conditions for oxidizing experiments gave a recovery of 38% of the cobalt in a consolidated metal phase composed of 50 % Fe, 28 % Co, 12 % C and 7 % Cu and 3 % Ni. The remaining Co was primarily volatilized.

To better approximate the proposed semi-continuous industrial process, experiments were also conducted with the addition of a 10 g Co heel. Operation the same conditions as above but for a run time of 10 minutes resulted in a consolidated metal phase of 41% of the original mass and a cobalt recovery of 60% and a Co concentration of 57% in the metal phase.

Future work should investigate possibility of moving the arc to improve treatment homogeneity and the use of an air or oxygen plasma to avoid the shielding effect of the argon plasma gas.

Abstract
A new apparatus that has two types of plasma generators (RF and microwave) is developed for depositing on a silicon substrate a DLC (diamond like carbon) layer embedded with tiny diamond particles. The substrate temperature during deposition can be kept at around 200 degC [473 K]. According to the evaluation with Raman spectrometry both spectra of DLC and diamond are identified in the layer.
Key words: plasma, nano diamond, diamond like carbon, ion implantation

1. Introduction

Some machine tools and dies are coated with DLC or poly-crystalline diamond layer to improve their mechanical properties like hardness, friction and wear resistance. DLC coating lowers the coefficient of friction to make it possible to machine even soft and cohesive materials like aluminum. But it also lowers the surface hardness of the coated tools and dies, resulting in making it hard to machine usual hard materials. On the other hand the diamond coating that is usually made by thermal- or plasma-CVD (chemical vapor deposition) enhances hardness, but it also enhances friction. We develop a new coating method that takes in both advantages of the two coatings, i.e., very low friction and very high hardness.

2. Experimental setups

Usually DLC coating is carried out by PVD (physical vapor deposition) using hydrocarbon gases like ethylene, ethane, acetylene and so on. We constructed a new apparatus that has two kinds of plasma generators. One is an inductively coupled-plasma source with one-turn loop antenna driven by 13.56 MHz RF power, and the other is a 2.45 GHz microwave-plasma source with slotted rectangular waveguide surrounding the plasma chamber made of quartz cylinder. Fig.1 shows the photograph of the apparatus. The RF loop antenna is inside the plasma chamber. The sample holder that is placed at the center of chamber is supplied with negative high voltage pulses for performing PBII (plasma-based ion implantation). Thus, this apparatus can control the energies of charged-particles in plasma for a wide range. Whether the deposited carbon layer becomes DLC or diamond

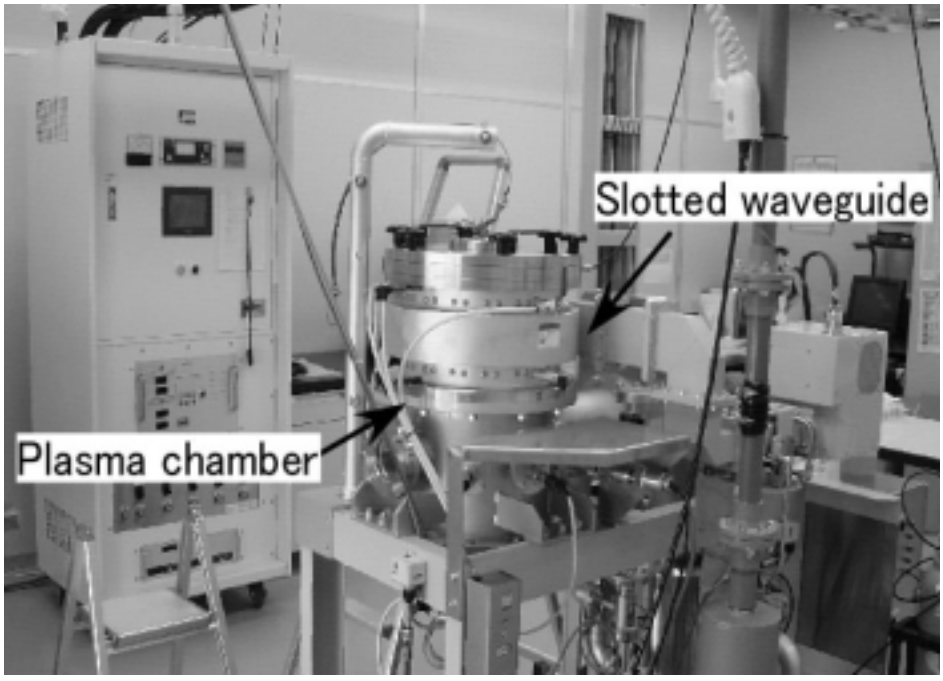

Fig.1 Experimetal apparatus

is considered affected by many factors such as gas pressure, energy distributions of particles, hydrogen-radical proportion in plasma and so on. High-density and high-electron temperature plasma is needed especially for depositing diamond films. Therefore, how efficiently microwaves are fed into vacuum is important. In order to find an appropriate microwave-feeding structure we made and compared two kinds of slotted waveguides as shown in Fig.2. Waveguide (a) in the figure has short slots on the H plane of rectangular waveguide. Since the waveguide end is short-circuited, standing waves exist in the waveguide. The slot positions coincide with where standing wave peaks of wall current are. On the other hand, waveguide (b) has a long slot on the E plane of rectangular waveguide. Since the waveguide end is not short-circuited, there are no standing waves. Microwaves that are progressing in the waveguide are emitted through any part of long slot on E plane into the plasma chamber. Plasma densities with waveguide (b) are more than 10^{11} cm^{-3} that are several times higher than those with waveguide (a). Thus, we adopt the waveguide (b) as the microwave plasma generator for this experiment.

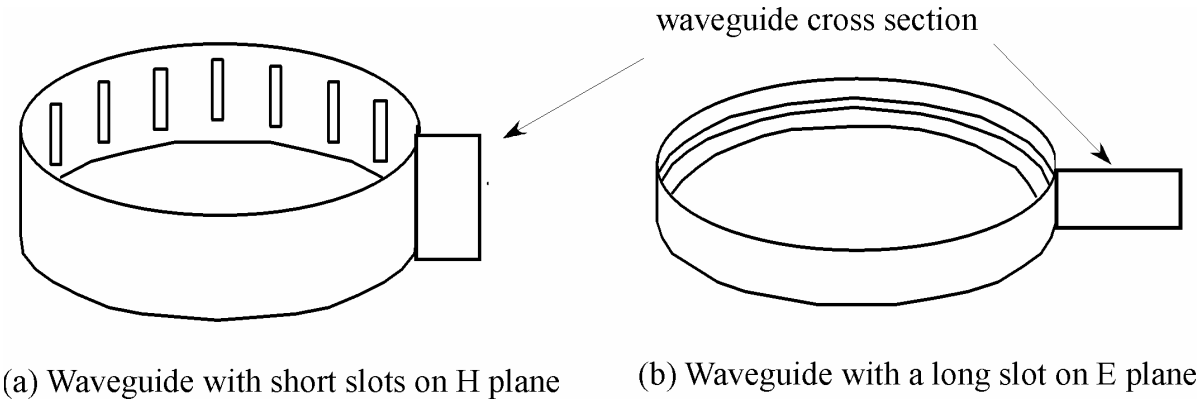

Fig.2 Selection of appropriate slotted waveguide

Another plasma generator, the RF plasma generator that is composed of 1 turn loop antenna, is placed under the microwave plasma generator around the sample holder.

3. Formation of DLC and diamond

3.1 DLC

DLC layer is easily deposited by either RF (13.56 MHz) or microwave (2.45 GHz) plasma with hydrocarbon gases like C_2H_2, C_4H_4 or C_6H_6 fed into the chamber [1]. In this case the gas pressure is around 1 Pa that is 1/100 the pressure for diamond deposition. Since ion bombardment at enegies of several tens to several thousands in eV is necessary in order to form DLC, negative-high voltage pulses of 1 to 2 kV are applied to the sample holder. Fig.3 shows comparison of Raman spectra from DLCs that are made with acetylene gas by both plasmas of RF and microwave (MW). The spectra are typical of DLC but have some differences each other. According

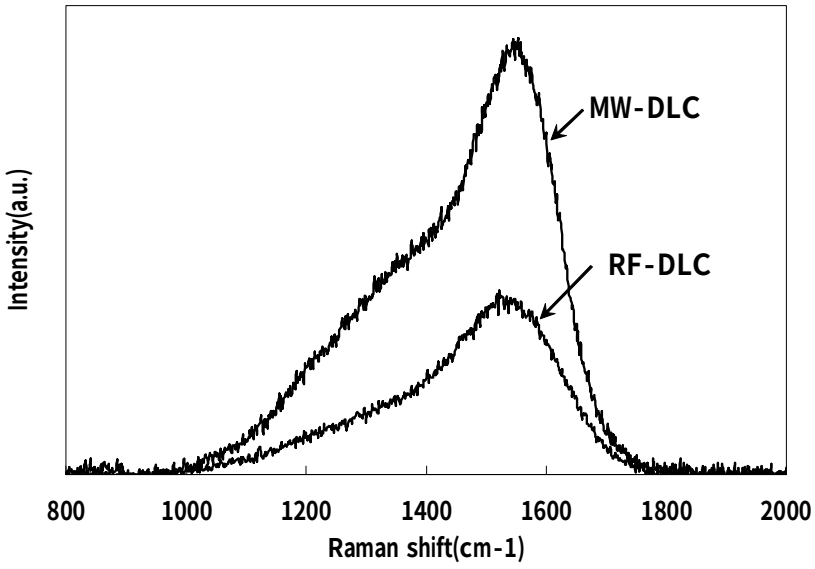

Fig.3 Raman spectra of DLCs made by different plasmas

to the component separation of the spectra by computer, microwave-plasma DLC contains larger percentages of small Raman shifts including disordered graphite component than RF-plasma DLC. Thus, the former has higher hardness as well as lower friction coefficient than the latter [2]. The typical hardness of DLC measured with super-micro hardness meter, Shimazu Co. DUH-W201, is about 25 GPa, and friction coefficient measured with CSEM Co. Tribometer is 1.0 to1.5.

3.2 Nano diamond

Diamond film has been usually formed on a substrate of higher temperature than 800 K by plasma process with methane and hydrogen mixture gas. In this case, the gas pressure is about 100 Pa. But since the percentage of methane is one to several %, the partial pressure of hydrocarbon (methane) is almost same as the presuure of acetylene for the above-mentioned DLC formation. For generating diamond, amount of CH_3 radicals or ions that have sp^3 mixed orbit for diamond combination must exist in the plasma [3]. Another difference of the diamond process from DLC is that the process needs low energies of plasma particles. Therefore, microwave plasma is advantageous over RF plasma. Because, microwave power of 2.45 GHz does not accelerate ions in plasma, but RF power of 13.56MHz does. For diamond formation high-voltage pulse bias is not applied to the sample holder from the same reason.

Using the new apparatus we deposited diamond layer that is composed of tiny particles of several to a thousand nm in grain size. Fig.4 shows the SEM image. We found out a new depositing condition where diamond particles are formed at a very low-substrate temperature of around 473 K (around 200 degC).

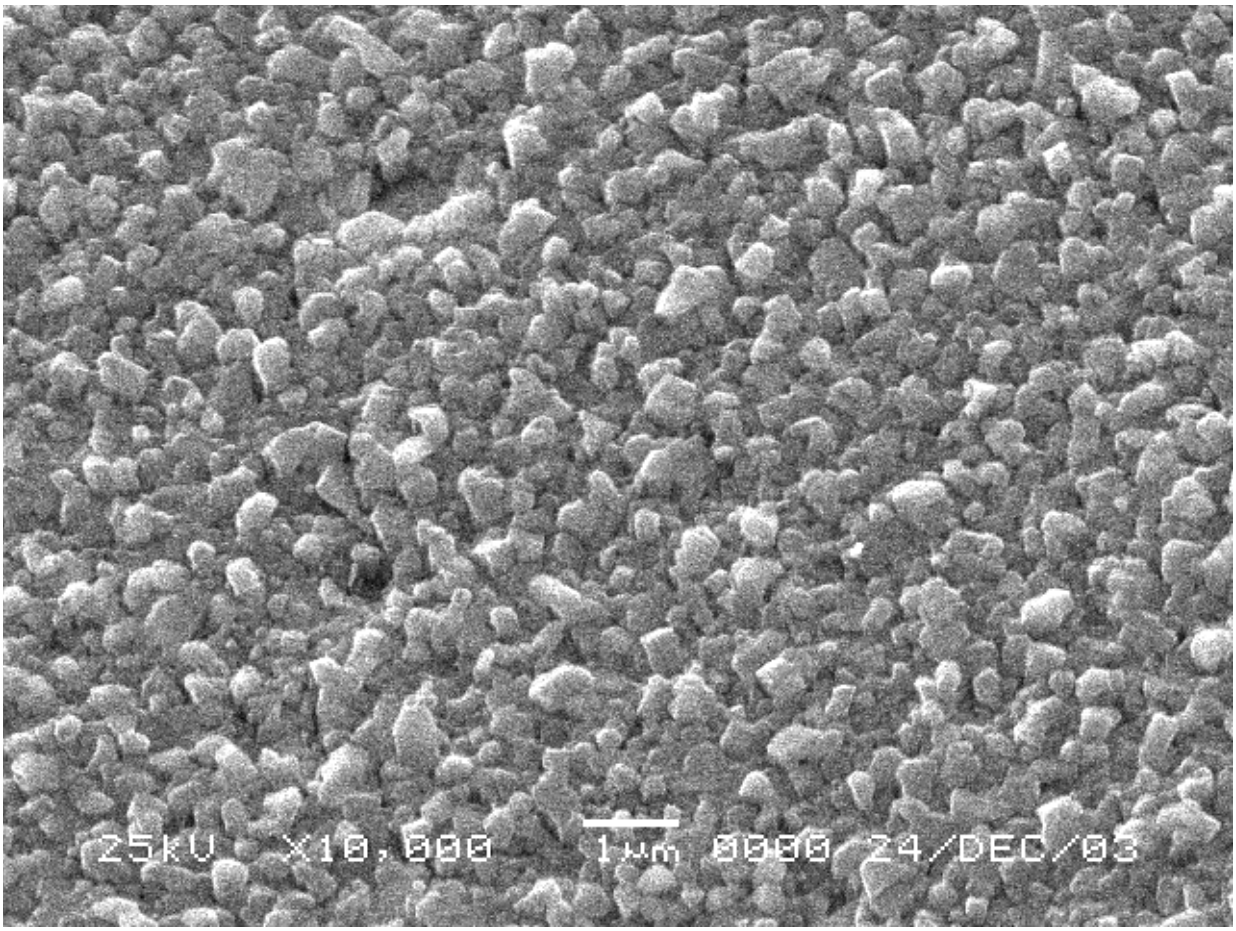

Fig.4 SEM image of nano-diamond deposit

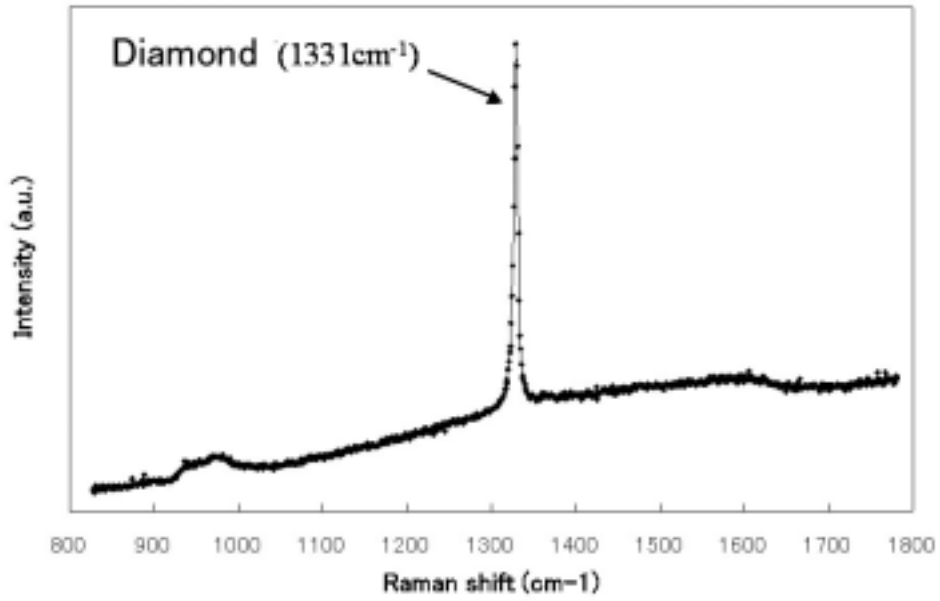

Fig.5 Raman spectrum of nano diamond deposition

The deposited material was measured with Laser-Raman spectrometer. Fig.5. shows a line peak at 1331 cm^{-1} that corresponds to diamond Raman shift. The slight inclination of base line implies that the deposition contains some amount of amorphous components of carbon. A lot of depositions are carried out by changing substrate temperature. It is found out that the grain sizes of nano diamond particles increase with substrate temperature as shown in Fig.6. Each black dot in the figure correponds to one sample datum. Even at a low temperature below 473 K [200 degC] nano deamonds of several tens of nm in grain size are deposited by this new plasma process, although diamond deposition has been until now carried out at a very high substrate temperature of over 1000 K.

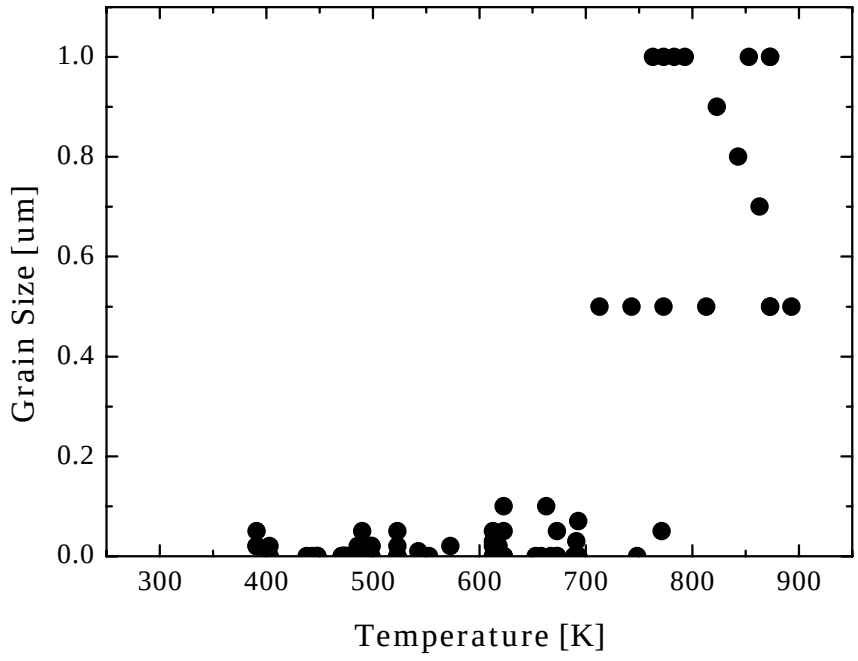

Fig.6 Dependence of nano-diamond grain size on substrate temperature.

Tribometric properties of nano diamond deposition are measured. The hardness is about 40 GPa, which is higher than that f DLC. But friction coefficient is about 4.0, which is 2 to 3 times higher.

4. Depositing DLC layer embedded with nano diamonds

In order to take advantages of both DLC and nano diamond we tried to combine both depositions. Two different plasmas are alternately generated; microwave plasma with methane-hydrogen mixture gas for nano diamond and RF plasma with acetylene gas for DLC. Resultantly, DLC layer that contains nano-diamond particles is deposited on a silicon substrate. Fig.7 shows the TEM (Transmission Electron Microscope) image of sliced sample of the deposited layer. The sample is sliced with a focused ion beam apparatus. The dark part on the left side of this figure is intermediate layer that is placed between Si substrate (not shown in this image) and the DLC layer embedded with nano diamonds. We can see a diamond particle of about 50 μm in grain size in the center. The part on the right side of this image is DLC deposition. The tribometric properties of this deposition are also measured. The hardness is almost same as that of the nano diamond deposition, and the friction coefficient is almost same as that of DLC.

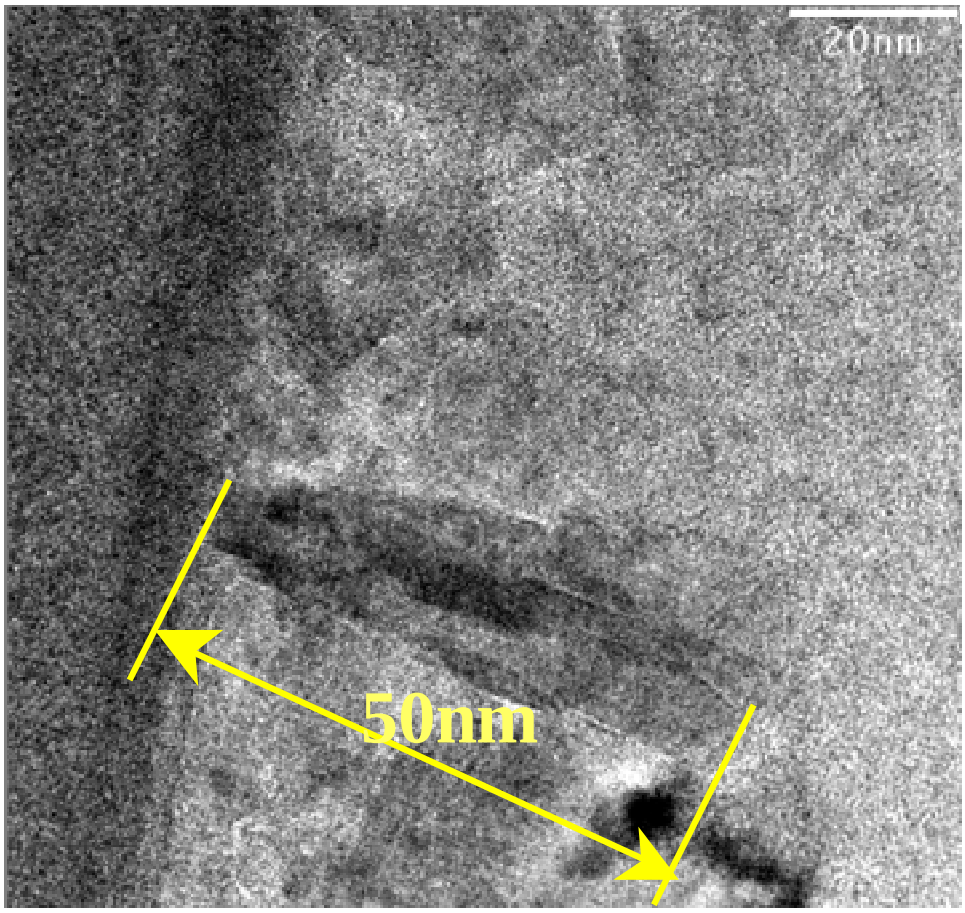

Fig.7 TEM image of sliced sample of habrid nano diamond layer

5. Conclusion

A new method to deposit a DLC layer embedded with nano-diamond particles is developed. The deposition is carried out at very low substrate temperature. The layer is expected to improve performances of machine tools and dies. It has low friction due to DLC as well as high local hardness due to diamond particle. Furthermore, the low temperature of substrate may enable the application of this new deposition to polymers that needs to be processed at a substrate temperature lower than 400 K.

Partial oxidation of fossil and renewable fuels into the Synthesis Gas

A. Czernichowski, M. Czernichowski, P. Czernichowski[1]
ECP – GlidArc Technologies, La Ferté St Aubin, France

Abstract
The mixture of CO and H_2 is produced in our GlidArc (a High-Voltage discharge) assisted reformers *via* partial oxidation of various fuels with atmospheric air. Such process accepts almost any feed at up to 4% of Sulphur content. The feed conversion is total. No soot, coke or tars are produced. The assisting electric power presents less than 1% with respect to the power of the processed fuel.
Keywords: Synthesis Gas, Syngas, GlidArc, Reforming, Partial Oxidation

1. Introduction

The Synthesis Gas (SynGas, a mixture of mostly CO and H_2) is widely used as source of Hydrogen (*via* a simple extraction or when CO is water-shifted to CO_2 and H_2), as feedstock for chemical syntheses or as gaseous fuel for power generation. The last application can be performed, for example, in the Solid Oxide Fuel Cells (SOFC) that are capable of operating directly with the SynGas containing light Hydrocarbons and even some H_2S. The SOFC operating at high temperatures allow also a heat recycling for the primary fuel processing or other uses.

Conversion of liquid fuels into gaseous reformate for SOFC feeding is however difficult. High Sulphur and aromatic content of certain fuels deactivates classical catalytic processors and/or creates a significant soot appearance. Instead of removing thousands of Sulphur-organic molecules from fuels we propose a very simple plasma-assisted conversion of almost any fuels into the SynGas containing all initial Sulphur converted into the Hydrogen Sulphide. Such SynGas can be then very easily cleaned from H_2S, if necessary. Our High-Voltage discharge called GlidArc [1] assists first the cold-start of such processors when the full combustion of fuel is performed at high turbulence conditions. Once the reformer is sufficiently hot the discharge starts to assist only partial oxidation of the fuels with a reduced amount of oxidant. Such assistance allows the feed pre-reforming in the plasma zone so that the process achievement in the post-plasma zone containing an activated solid material may occur. Our electrically assisted process of partial oxidation accepts almost any feed at up to 4% of Sulphur content. The feed conversion is total. No water (or steam) needs to be added so that the process is simple.

Our tests with natural gas, cyclohexane, heptane, toluene, gasoline and Diesel oil (DO) were first published in [2]. Then we have presented a study on propane (LPG) [3] and natural gas [4]. The Rapeseed oil (Canola) conversion into SynGas was then tested [5] as example of various renewable fuels processing.

2. GlidArc-assisted reformers

Some experiments are now presented with a military aviation fuel and Rapeseed oil. We return also to our previous studies on the Diesel oil reforming and show our recent results. Here-presented tests are performed in small or medium-size reactors. A 0.6-L (internal volume) reformer is shown on the Fig. 1.

The plasma zone contains two flat electrodes that delimit a space filled with the gliding discharges. A feed + preheated air are mixed, blown into that space and flows along the diverging electrodes. The discharges ionize the air + partially vaporised fuel. Given the moderate temperature of the electrodes (not cooled) and a very short contact time of the discharge roots with the electrodes, we do not observe any deterioration (even at a high Sulphur presence) that may prevent the gliding of these current-limited discharges.

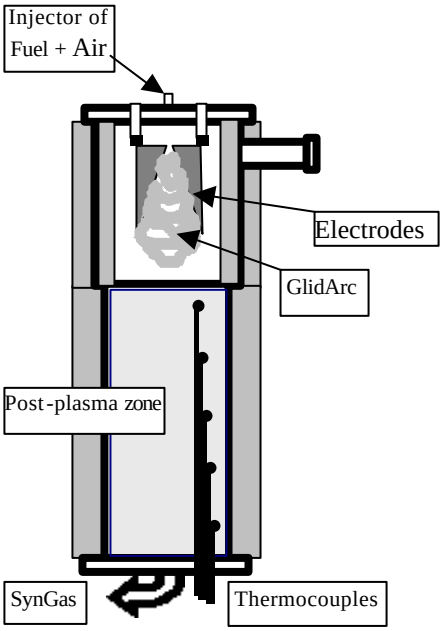

Fig. 1. Schematic of a 0.6-L GlidArc-assisted reformer.

[1] presently with Ceramatec Inc.

The plasma zone communicates with a post-plasma zone filled with activated packing (noble, rare or exotic elements are not used for activation). The flow of partially converted reactants containing long-living active radicals enters the zone where the conversion is completed by deactivation of all excited species. A 5 to 10kV power supply provides both ionisation of the air/fuel mix and then a transfer of the electric energy into the plasma. The time-averaged electric power is measured at the mains; it is less than 0.1kW for small reformers or up to 0.4kW for large ones.

The reformer is thermally insulated to keep it as hot as possible. Its total inside volume is 0.6L (1.8 to 6.6L for 20 or 80kW processor, the output power being accounted as the Lower Heating Value LHV of exiting reformate gas). No part of reactors is cooled in a forced manner. Some thermocouples measure the post-plasma zone temperatures. The output gas sample crosses white wool for soot presence checking. Other sample is analysed using a two-channel μ-GC dedicated to H_2, N_2, O_2, CH_4, and CO for one channel, and CO_2, C_2H_4, C_2H_6, C_2H_2, C_3H_8+C_3H_6, and residual moisture for the second one.

Figure 2 presents a picture of 6.6-L reformer that we are currently testing for up-to 1kg/h Hydrogen (+ roughly 14kg CO) production from the Soybean biodiesel or fossil Diesel oil. Such SynGas ($25m^3$(n) per hour equivalent to 80kW LHV) is devoted to clean up a NO_x-polluted exhaust from a 2MW Diesel engine. The GlidArc-assistance power is only 0.4kW.

Fig. 2. 6-L GlidArc-assisted reformer of various fuels.

3. Reforming

3.1.Aviation fuel

The JP-8 military aviation fuel can be considered as a logistic support for SOFC-based auxiliary power supply. The fuel has the following characteristics: relative density 0.800, average formula $CH_{1.94}$, aromatics 15.3 vol.%, total Sulphur 433ppm wt., initial BP 150°C, final BP 252°C, net heat of combustion (LHV) 43.2MJ/kg.

The explored ranges of inputs were: JP-8 @ 4.4–8.3g/min and air @ 23–41L(n)/min. The post-plasma zone of the processor contained 0.34L of activated refractory granules. The temperature of exiting SynGas (Reformate) reaches 725°C. As the result of various runs we have always observed the absence of soot, tar or non-reacted feed in the Reformate gas. The dry gaseous output (in vol.%) was:

H_2	10–16
CO	15–20
H_2+CO	6–35
N_2+Ar	5–68
CO_2	2.2–4.8
CH_4	0.7–2.8
C_2H_4	0.01–2.8
C_2H_6	0.00–0.19
C_2H_2, O_2, C_{3+}, others	absent

From the mass and enthalpy balances we deduce the output Reformate gas power (based on the LHV of all combustible components acceptable for SOFC): it can reach 4.4kW. Knowing the net heat of combustion (LHV) of the JP-8 we calculate the thermal efficiency of the JP-8 conversion into Reformate gas in our processor. This efficiency (defined as the ratio of the LHV of H_2+CO+light hydrocarbons at 25°C to the

LHV of the entering JP-8 fuel) is up to 78% for explored range of input parameters. Remaining energy content (chemical enthalpy) of the initial fuel is converted into the heat – but it is a compromise that we propose to accept for such a simple GlidArc-assisted soot-free and Sulphur-resistant technology.
The total GlidArc assistance power varied from 0.13kW at the cold-start of the process to some 0.05kW at the stabilized reforming conditions. The process power consumption related to the output Reformate gas power presents therefore only 1%. Figs. 3 and 4 show a typical composition of the Reformate gas (dry) and give an idea on the reformer output dynamics and its thermal efficiency.

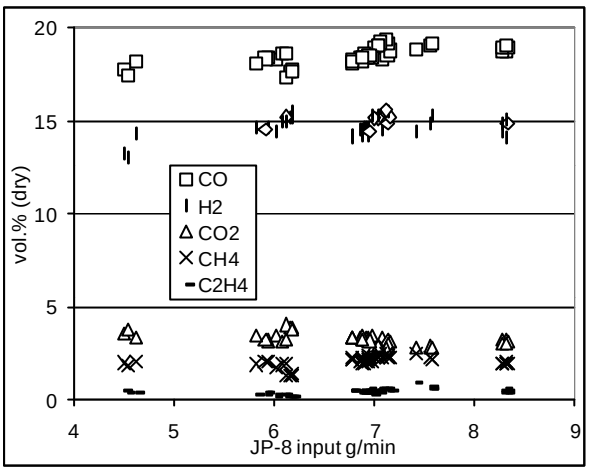

Fig. 3. Composition of the Reformate gas as a function of JP-8 fuel input rate.

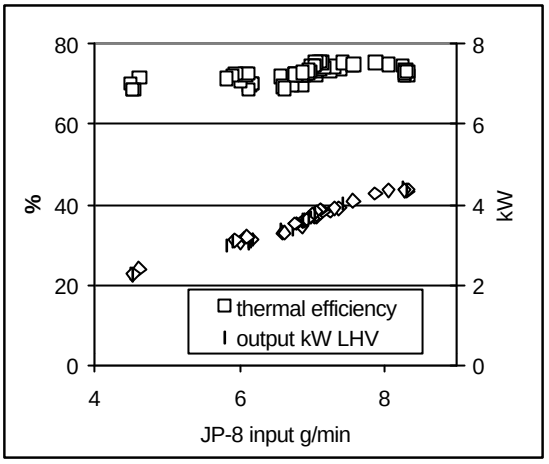

Fig. 4. Reformate output power and the thermal efficiency of the reforming as a function of JP-8 fuel input rate.

A 12-hours run at the constant air flow rate of 29L(n)/min and the constant fuel flow rate of 6g/min of JP-8 in 0.6-L processor at 3kW (LHV) output Reformate gas power and 60W GlidArc assistance was successfully preformed. No structural changes of the processor and its post-plasma zone after the run were found. Neither soot nor tars were produced.
We installed therefore this reformer for online feeding of a SOFC stack in a laboratory. Four series of tests were performed. No problems appeared after long runs during which several litres of this high Sulphur fuel crossed the reformer. Our 79 gas analyses showed a stable Reformate gas composition and the mass balance closure was typically 1%.The SOFC stacks were composed of a single 10-cell and then a dual 11-cell system. The stacks worked perfectly. Their performance were comparable to the Hydrogen baseline and the electric power output difference correlated well with higher steam content in our reformate gas. No soot was found in manifolds or electrodes after the stacks dismantling.

3.2. Diesel oil

Already in 2001-2 our feasibility tests with various road Diesel oils were successful [2] and further tests with a highly Sulphur-polluted heavy oil showed us that practically no harm is observed up to 4% Sulphur content. We performed then more detailed studies and long tests expanding the output Reformate gas power to >20-kW scale.
Our 1.8-L reformer is very similar to the previously described one. The plasma compartment (0.6L) contains two electrodes powered through one 10-kV power supply. The same activated material is used in the post-plasma zone of 1.2L volume. French road DO (from Total) is processed. Its average Carbon number is 15.6 (ranging from C_8 to C_{29}); an averaged formula can be written as $CH_{1.83}$, and the molecular mass is in the range of 210–220. This fuel has a quite high relative density of 0.826 and a high Sulphur content of 310ppm by weight. The DO (dosed by a metering pump) and compressed air (controlled by a mass flow meter) are simply mixed in a "T" connector and preheated up to 140-200°C before their injection to the GlidArc zone by an 8-mm (inner diameter) tube centred on the electrode axis. Through a porthole one can see the plasma discharge in the stream of the air + DO droplets. The droplets do not however affect our electric discharge. Explored inputs are:

Compressed air	48–146L(n)/min	Preheat	140–200°C
Diesel Oil	11–30g/min	GlidArc power	0.3–0.4 kW

As result we observe the following outputs at no sooting conditions and at total fuel conversion:

Bottom reformer temperature: ≤870°C

Reformate gas content (dry basis, vol.%):

H_2	16–20
CO	19–22
H_2+CO	38–41
CO_2	2.4–4.8
CH_4	0.8–3.3
C_2H_4	0.0–2.1
N_2+Ar	52–58
C_2H_2, O_2	absent

Reformate gas LHV power: 7-22kW.

Fig. 5 and 6 show the LHV power output of all combustibles (H_2, CO, CH_4, and C_2H_4) as a function of the DO input flow rate. They also illustrate the specific LHV energy output (in kWh per kg of DO) and the dry Reformate gas composition as a function of O_2/C molar ratio at the input (reflecting the air/fuel ratio).

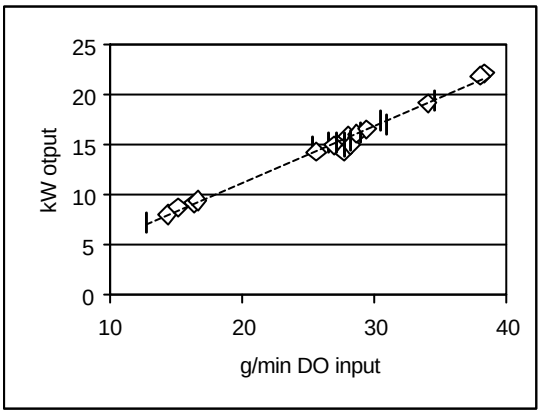

Fig. 5. LHV power output of 1.8-L processor as a function of the input flow rate of Diesel oil.

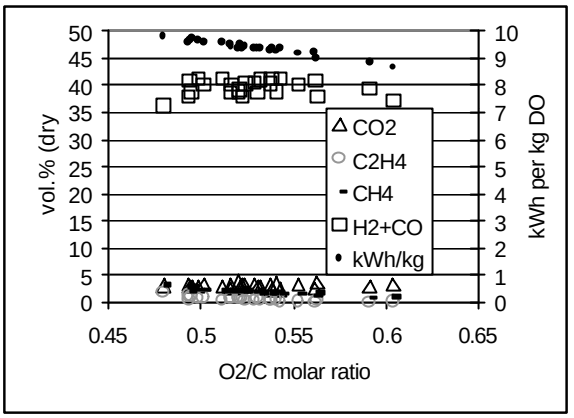

Fig. 6. Specific energy (LHV) output and the Reformate gas composition as a function of O_2/C at the input (right).

Our tests are successful: such quite highly Sulphur polluted Diesel oil is totally reformed at no water or steam added and at no soot or tars production (when checking the gas output with a white wool). To confirm that absence we dismantled several times our processor after its cooling and did not find any soot deposits inside. Our uninterrupted 24-hours test showed a good stability of the system. Other long-term tests are under way…

3.3. Rapeseed oil (Canola)

We use other 1-L reactor, similar to that shown on the Fig. 1. This processor contains three electrodes connected to 3-phase power supply 100 mA current to each electrode. No preheat is applied to any stream.

Several runs were preformed using an edible oil having the density of 913kg/m^3. At the accumulated runtime of 6 hours we never changed any part of the reformer. The process was always very stable. When soot was starting to appear at an insufficient air/oil ratio we just added more air (or reduced the oil flow) to establish the non-sooting reforming conditions. During these runs the air flow rate was comprised between 35 and 102 L(n)/min for the oil input flow rate between 11 and 30mL/min.

Fig. 7 shows temperatures T_1 (upstream) and T_2 (downstream, equal to exiting gas product temperature) such as observed when the thermal equilibrium of the reactor is achieved. Various tests are put together on the same graph showing therefore the explored range of the parameters. Fig. 8 presents the composition of the output gas (all successful tests are put into the same graph). In fact, the SynGas is always diluted by Nitrogen as we use air for reforming. The N_2 concentration at the output is typically in the 55–60 vol.% range (dry basis) depending on the air/oil ratio applied for the given test.

As results of the mass balances we calculate the output flow rate of 100% SynGas (H_2+CO only) for all runs as shown on the Fig. 9. The H_2+CO flow rate in the output can also be presented as the potential thermal output power. Such a power is therefore assimilated to the LHV. Our runs and reactor are not yet optimized but they indicate that we already obtain (at atmospheric pressure) as much as 11kW or 3.5m^3(n)/h of pure SynGas output. Higher outputs are expected for elevated pressures and/or preheat of the air and oil streams.

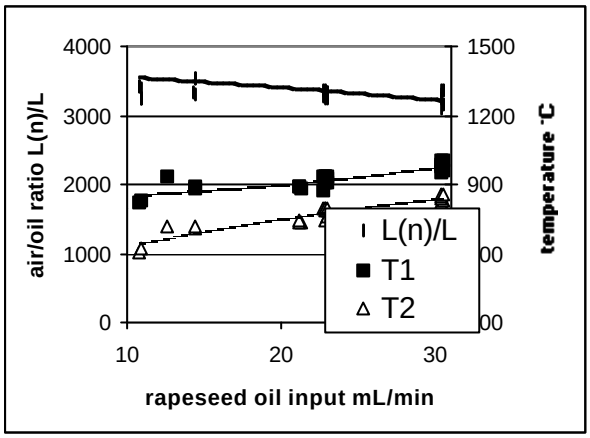

Fig. 7. Temperatures T_1 (upstream) and T_2 (downstream) inside the post-plasma zone as a function of the input flow rate of rapeseed oil. The left axis presents the air/oil ratio required for completely non-sooting reforming of the oil.

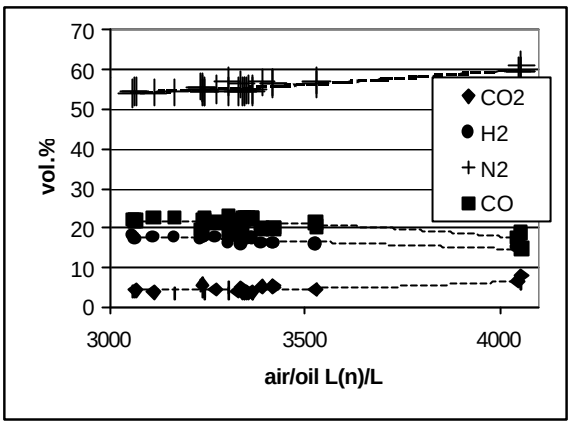

Fig. 8. Concentration of the main components (dry basis) in the output gas as a function of the air/oil ratio for all successful runs. Other gases are at minor concentrations: CH_4 0.5–1.0, C_2H_4 0.1–0.5, C_2H_6 0.01–0.03, and C_2H_2 0.001–0.005 vol.%.

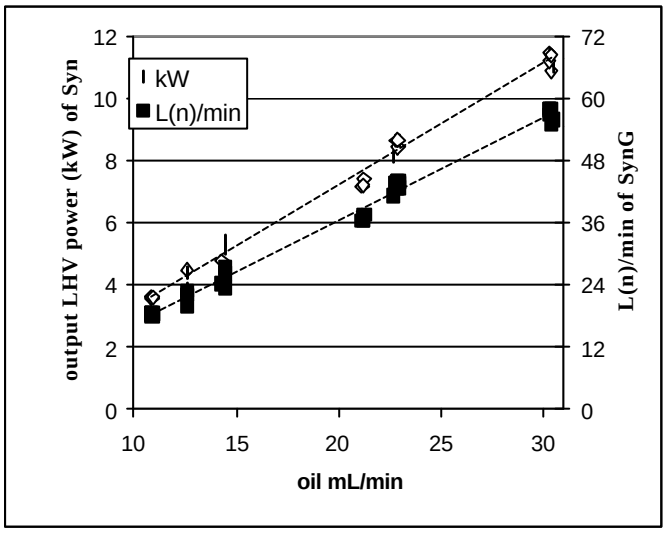

Fig. 9. Output flow rate of 100% SynGas (H_2+CO only) in L(n)/min and in kW for all runs at close-to the thermal conditions of the reformer.

The thermal efficiency of the reforming process can be estimated from these results. If one takes the LHV of the feed as 35MJ per kg then for our run at 30.4mL/min = 0.507mL/s = 0.463g/s the thermal input power corresponds to 16kW. For 11.4kW thermal power (LHV) output that we obtain as SynGas one finds therefore the thermal efficiency of the process at no sooting conditions equal to 70%. This quite high efficiency is based on only standard enthalpy heats (at 25°C) of the output H_2+CO combustion to CO_2 and steam (LHV) with respect to the standard heat of combustion (LHV) of entering oil. Such efficiency does not take into account any residual light hydrocarbon gas useful for SOFC or the sensitive heat content in the gas leaving the reformer. A part of that heat can certainly be reused to preheat entering feed and air so the thermal efficiency could be increased. No such heat exchange was used in this study.

3.4. Other feeds

We have already performed positive tests of reforming using 90% Ethanol, Glycerol, saturated Sugar/water solution, Soybean oil, Soybean diesel, and heavy bio-oil from the flash pyrolysis of wood. All that opens opportunities to upgrade some farm-issued products or waste biooils from various activities. ECP is presently fabricating a 30-L processor of about 0.5 MW output LHV power. Some last-minute results will be presented during the Symposium.

4. Conclusions

- Working hours or days we never changed any part of the reformer and/or its post-plasma zone loading. The technology is robust.

- Reformate gas appears after ~15min from a cold start or after ~2min when the reformer is kept hot. At such quick starts we do not obtain yet optimal performances – but the Reformate gas flow may be sufficient to start operate a SOFC (that also asks for a quite long heating and equilibration period).
- Thermal efficiency of the process is around 75%. An overall efficiency of our fuel processor + SOFC system can be increased thanks to some synergetic effects.
- Some methane and ethylene are present in the Reformate gas. They can be kept at quite low concentration, if necessary, by applying a higher O_2/C ratio at the input - but it would slightly lower the thermal efficiency of the reforming. These gases are however considered as good fuel for SOFC.
- Reformer works also when Sulphur is present in the feed. We proved it when reforming the JP-8 and Diesel oil at respectively 433ppm and 310ppm (weight) content. Our previous experiments show that even 4% of Sulphur in a heavy liquid carbonaceous feed (end distillation point of 600°C) is not harmful. In fact, even 100% H_2S can be processed using our GlidArc reactors for Hydrogen recovery from such waste gas [6].
- Conversion of the fuels is total, as we do not find any residual fuel or Oxygen at the exit. We do not produce soot, coke or tar and that is at no water or steam addition.
- Noble, rare or exotic elements are not used for activation of the solid mater present in the post-plasma zone of the reformer.
- Process is stable. The Reformate gas output flow and composition can be kept constant or match a required level by regulating the fuel and air flow rates. Drastic changes of the Reformate gas output flow and/or composition can be done in a fraction of minute.
- Electric assistance is low, around or less than 1% relative to the LHV of produced Reformate gas flow.
- According to our tests we can produce a flow of Reformate gas that is equivalent to 12kW LHV power per one Litre of inside reformer volume.

Here presented results show a simple way for a Reformate gas production from fossil or renewable matter. Our past tests show that pure Oxygen or O_2-enriched air can be used instead of atmospheric air. It opens some opportunities for more efficient GlidArc-assisted reformers and processes if such extra Oxygen is applied to reduce the Nitrogen content in the Reformate gas… One can also reduce the reformer volume or increase its output when working at higher pressures; we have some results at up to 6 bars.

ECP – GlidArc Technologies, La Ferté St Aubin, France

Abstract
A 45 years story of construction and development of various plasma sources for various applications is presented. It starts with a stabilized low-voltage but high-current intensity DC free-burning arc, a typical example of so-called "thermal plasma". Nowadays, we rather prefer our completely unstable AC high-voltage and very low-current plasma sources called "GlidArc". Third generation of this low-cost (and low-tech) devices is under development.
Keywords: GlidArc, plasma sources

1. Introduction

Since 46 years the first author has been involved in construction and/or development of various plasma sources for chemistry, metallurgy, atomic and molecular spectroscopy, deposition, assisted partial- or full-oxidation, and other. Under direction of Professor Wlodzimierz Trzebiatowski he started in 1959 with a DC free-burning low-voltage arc (up to 1500A in Argon) as a high-temperature source for some refractory minerals decomposition in Wroclaw's Technical University, Poland. Then he has successively built the first Polish DC plasma torch (1960) and started a study of the Argon plasma spectral emission. In 1962 he switched to an 800A DC arc in water- or Nitrogen-swirl; these plasma reactors were used for the Iron Titanate and Zirconium Silicate processing (Ph.D. thesis in 1966). Successively came a new DC torch having a Tungsten cathode and a segmented Copper anode (each segment actively power supplied at various electric potentials) for SiO_2, TiO_2 and ZrO_2 reduction in Hydrogen (1970). In turn a microwave torch for NO_x synthesis (3kW, 1973), an arc striking to the molten LiCl (1974), an induction-coupled torch (atmospheric pressure, 25kW, 1975), a metal-wall-stabilized arc for plasma spectroscopy (150A, 1975), a multiple-electrode and high intensity rotating/pulsating arc (1980), an unstable and very active transferred DC arc for Hydrocarbon or H_2S processing (1983), a high current circuit breaker (1983), an electro-burner for Methane flame over-heating (1985), and a semi-industrial 250kW DC transferred arc furnace (1987) took his attention…

In early 1980's the plasma-chemical community started to abandon the so-called "thermal plasma" devices for chemical applications, as it appeared that their high electric energy consumption cannot be accepted for most of industrial processes. Also the microwave and induction-coupled sources did not get a large approval because of their complex electric supplying, especially for higher power units. Other non-thermal ("cold" or "out-of-equilibrium") plasmas were demanded… Accordingly, the gliding arc device was proposed in 1988 [1]; it is now known under its short name "GlidArc".

2. Gliding Discharges

2.1. GlidArc-I

The GlidArc generates non-thermal plasma that enhances various processes through active catalytic species: electrons, ions, and excited atoms. This source has at least two diverging electrodes immersed in a fast gas or vapour flow. A high voltage and relatively low current discharge (up to 30kV, 0.05-5A, 0-20kHz) is generated across the flow between the electrodes as it is shown on the Fig. 1. The discharge forms at the closest point between the electrodes, glides along the electrode's edges, and disappears. Another discharge immediately reforms close to the initial spot. The discharge performs its own maintenance on the electrodes, preventing chemical corrosion and/or thermal erosion. The electrodes are not water-cooled so the electric power is directly and totally transferred to the processed feed. Any gas or vapour can be directly processed at 0.05-12bar range. Droplets, mists, and powders can be present. Feeds of any initial temperature are accepted.

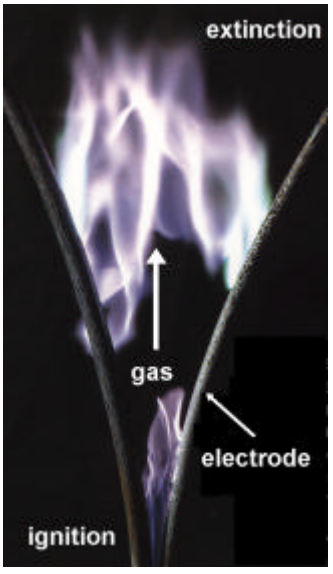

Fig. 1. The GlidArc-I

Gliding discharges of GlidArc-I type can be also installed between metallic electrodes and a conducting liquid [2]. Multiple electrode systems can be installed for large gas steams processing. Their electric powering is described in [3]. Structures of several dozens of electrodes can be organized as "clusters" forming some plasma heads for powerful AC plasma reactors supplied from unique 3-phase transformer [4].

2.2. GlidArc-II

In 1996 we started to develop an alternative way of gliding discharges generation using a rotating central electrode and "connecting" it, *via* high-voltage AC discharges, to several stationary electrodes located around the central electrode [5]. As result we have obtained a new GlidArc-II device. Figure 2 presents the principle of such cold-plasma source while the Fig. 3 shows a principle of multiple-stage reactor in which the processed fluid can cross several electric discharges to reach a suitable rate of conversion.

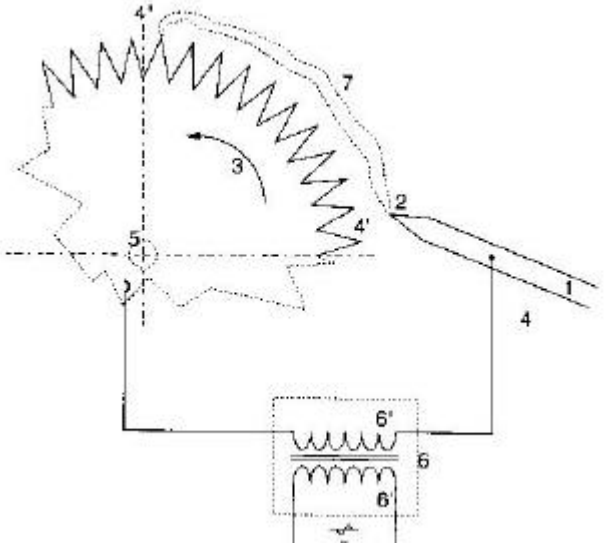

Fig. 2. Principle of the GlidArc-II device: 1 – stationary electrode, 3 – rotating electrode, 6 – power supply, 7 – high-voltage discharge filaments.

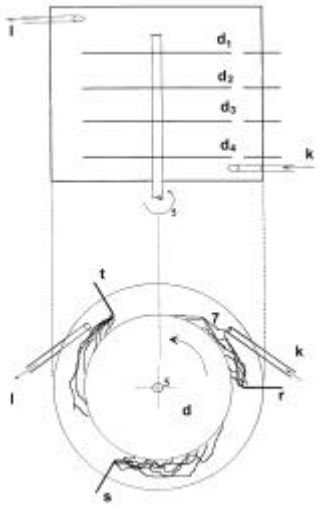

Fig. 3. Multiple-stages and multiple-electrodes GlidArc-II reactor: r, s, and t – three-phase-supplied stationary electrodes, k and l – input and output of the processed gas, d – rotating electrodes.

There are multiple advantages of the new structure. The high voltage discharges generation and the processed gas flow rates are no more self-dependent so that even a very low gas flow can now be accepted at any power as there is no more need to accelerate the gas at the proximity of electrodes. The mobile electrodes rotate in the range of 50–1000rad/s, which are acceptable speeds. The discharges can "touch" several times the same gas flux without any obligation to push the gas between the stages. The reactor is quite compact for even large gas flows. For example one can realize three 5A and 2kV discharges for one stage. When adding 4stages it makes us a 120kW reactor realized in a 0.3m diameter cylinder of 0.5m length (30L of volume). Such reactor can process roughly up to 2400 m^3/h of gas.

A 60-L stainless steel reactor was built by ECP for H_2S-related streams processing. This reactor presented on the Fig. 4 contains 9stages, each of them being powered by 3 stationary electrodes so that 36 active electrodes are present (including central electrodes).

First successive tests of this reactor were performed with an active participation of Piotr Czernichowski. We have obtained better than 50% conversion of an H_2S-rich acid gas into the SynGas.

Fig. 4. 60-L, 36-electrodes GlidArc-II pilot plant for Hydrogen Sulphide processing (SulfArc).

Several application tests and studies were performed in laboratory or pilot scale GlidArc-I and-II reactors for gases, vapours, liquids, and solids processing (decomposition, conversion, upgrading, activation) as well as for flames overheating or stabilization (flaring for example). More than twenty French and foreign patents protect some of GlidArc-I and -II principles, powering, and applications.

2.3. GlidArc-III

Since long time we have been also working on plasma assisted partial oxidation of various fuels into the synthesis gas [6]. During this process it appeared that soot or other solid particles could deposit on high-voltage insulators of the GlidArc-I electrodes. Generally, only two electrodes are needed for such application to ignite and then to support such partial oxidation at less than 1% dissipated electric energy with respect to the enthalpy of the SynGas. New GlidArc-III plasma source [7] solves this problem.

As shown on Fig. 5 we direct 5-20% of the air *(1)* to a vortex-like zone *(2)* that protects one central GlidArc-III electrode *(3)* while the remaining part of the oxidant is sent through *(4)*, together with the processed fuel, to the plasma zone *(5)* where the gliding and rotating high-voltage AC discharge strikes between the central electrode *(3)* and the surrounding metallic nozzle *(6)* being at the ground potential The fuel and its pyrolysis products cannot now harm the dielectric support *(7)* of the central electrode. A Diesel fuel conversion into Synthesis Gas was successfully performed this year.
Figures 5 and 6 present our GlidArc-III reformer for various fuels processing.

3. Conclusion

A 45 years in-house story of construction and development of various plasma sources for various applications indicates that GlidArc-type generators are the best solution for plasma-chemical applications.

They can be as powerful as classical plasma torches while avoiding specific power supplying, water-cooling, electrode erosion, and quite complicated manufacturing. GlidArc instabilities rather help progressing the chemical processes by creating strong fluid turbulences (mixing) and generating very active catalytic species at quite low processed fluid temperature. We are proud to submit already three generations of these low-cost and low-tech devices to the Plasma Chemistry Community.

Development of New Green Process for Methane Reforming Using Microwave Plasma / Solid Catalyst Combined Reactions

H.Nagazoe, M.Konuma, M.Kobayashi, T.Yamaguchi, K.Onoe

Department of Life and Environmental Sciences, Faculty of Engineering, Chiba Institute of Technology

Methane is irradiated with microwaves by using a microwave plasma reactor, and the selective synthesis of ethylene under the oxygen free condition is developed by the contact of active species with a Pt/Al_2O_3 catalyst, assuming that the concentration of the active species is sufficiently high. Furthermore, H-ZSM-5 is used as a zeolite catalyst, and oily matter can be produced with high yield.

1. Introduction

"Green Chemistry", namely the new chemical technology which does not give the load to the environments, has been promoted by many researchers. According to the suggestion of Anastas, the concept of reaction design with the aim of not only the consideration to the health but the lowering of environmental risk is summarized at twelve items [1]. From the viewpoint of the chemical reaction engineering, it seems to be necessary to carry out the development of the catalytic reaction process based on the new reaction mechanism. In a normal solid catalytic reaction, the material reaches the surface of the catalyst. However, the material is irradiated with microwaves, it will be converted to an active species before it reaches the surface of the catalyst. This suggests the possibility to develop a new reaction process by extracting higher performance from the catalytic activity.

Here, methane is attracting a great deal of attention as a next-generation carbon and hydrogen resources, and many researches have been investigated on the synthesis of C_2 hydrocarbon through oxidative coupling of methane (OCM) using solid catalysts since the early 1980's [2-5]. But the methane reforming to low-grade or long-chain hydrocarbons under the oxygen free condition is very important for an achievement of the clean process of non-discharging the unnecessary carbon oxides. If the advantage that "a raw material for a catalytic reaction is converted to appropriate active species before reaching the conventional catalysis field" outweighs the disadvantage that "external energy needs to be added", it leads to possibility of creating a new process.

In this study, a new oxygen-free green process combining the methane plasma decomposition with the solid catalytic reactions was developed. Features of this process reveal that three reaction zones exist. In the primary reaction zone, which is located in microwave-irradiated field, the supplied methane is decomposed into the hydrocarbon and hydrogen active species in the plasma state. In the secondary reaction zone, which is located between microwave irradiation field and packed bed zone of catalyst, the generated active species (mainly methine and hydrogen radicals) gradually convert to acetylene and hydrogen with an increase in residence time due to the individual progress of homogeneous couplings [6-10]. In the last reaction zone, the specified reactions among active species or between active specie and molecule are progressed on the surface of catalyst. In this paper, Pt/Al_2O_3 and H-ZSM-5 were chosen as catalysts. The concentrations of remaining hydrocarbon and hydrogen active species during the individual progress of homogeneous couplings are measured by the selective oxidation method using oxygen molecule, and the effects of the concentration of active species for the molecule on the catalytic activity are examined.

2. Experiment

2.1 Catalyst

0.5 wt% of Pt/Al_2O_3 pellet (2 mm in diameter with 3 mm in height, N. E. Chemcat. Co., Ltd. Japan) and a granular Al_2O_3 (Shinwa Kako Co., Ltd. Japan) were separately pulverized to 60-80 mesh and mixed together to produce a mixture with a Pt content of 0.05 wt%.

H-ZSM-5 (80 mesh under) was prepared by oxidation of NH_4-ZSM-5（Zeolyst Inter. Co., Ltd. US）under the air supplying. The ratio of Si/Al was 164.

2.2 Experimental apparatus

Figure 1 shows the experimental setup for the reduced-pressure continuous flow reactor, which consists of a gas supply system, a microwave-generator, a reaction tube and an analysis facility. Plasma was generated by irradiating a quartz reactor (an inside diameter of 25 mm, a thickness of 1.5 mm and a length of 500 mm) with microwave with a frequency of 2.45 GHz through a wave guide (a length of 54.6 mm and a width of 109.2 mm) installed horizontally. Non-irradiated gas was supplied from an alumina tube (an inside diameter of 4 mm) attached at the bottom of the quartz reactor. The catalyst was retained in silica wool and filled into the reaction tube (**Figure 2**).

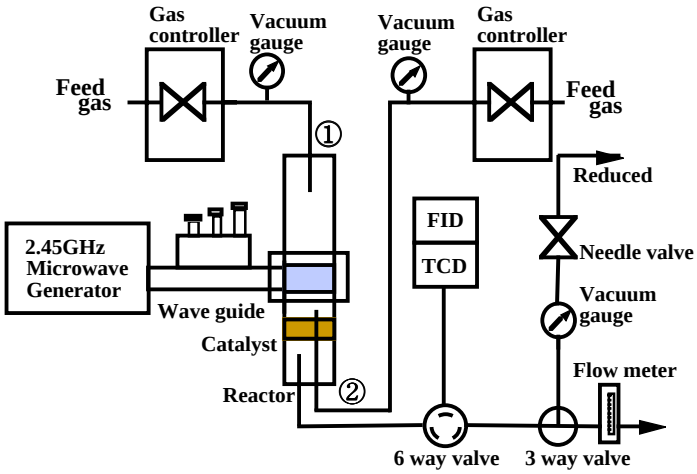

Figure 1. Experimental apparatus for combined reactions

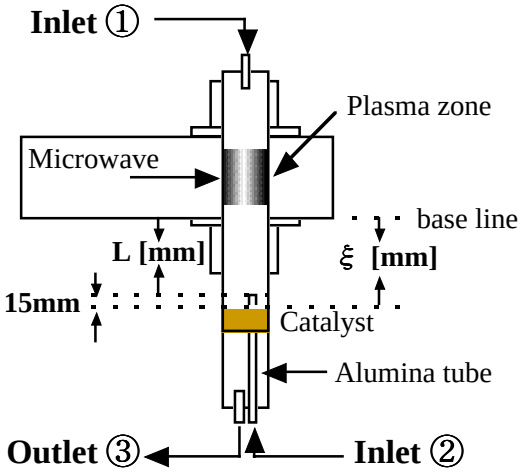

Figure 2. Detail of plasma reactor

2.3 Experimental procedures

2.3.1 Measurement of the concentration change of active species in the secondary reaction zone

The decreases in the concentrations of hydrocarbon species (HCS) and hydrogen species (HS) occurring

in the secondary reaction zone were estimated as follows: (a) The concentration decrease of hydrocarbon species was estimated on the produced amount of COx (CO and CO_2) using a set-up in which methane plasmas were contacted with the oxygen supplied from inlet ②, and the distance *L* from the lower-level of the waveguide to the inlet ② was changed. (b) Similarly, the concentration decrease of hydrogen species was estimated on the produced amount of water vapor when hydrogen and oxygen were supplied from ① and ②, respectively.

2.3.2 Combined reactions in the last reaction zone

Both the remaining active species and the generated molecules (acetylene and hydrogen) during the reactions in the secondary reaction zone were brought into contact with the surface of solid catalyst. Experiment was performed with varying the distance ξ between the lower-level of the waveguide and the upper-level of the catalyst bed.

When 5 g of Pt/Al_2O_3 catalyst was packed, the feed rate of methane was adjusted to 34.7 μmol/s and initial reaction pressure was set at 6.5 kPa. Microwave irradiation power was adjusted at 300 W. In the case of H-ZSM-5 (1 g) catalytic reactions, the methane feed rate was 4.95 μmol/s and initial reaction pressure was 4.0 kPa performed with keeping microwave irradiation at 150 W. The temperature of the catalyst layer was measured using a K-type sheathed thermocouple with its tip placed at 6 mm from the upper-level of the catalyst layer. The products were taken with an online sampler and analyzed by gas chromatography.

3. Results and discussions

3.1 Homogeneous reaction progress of active species into acetylene and hydrogen

When methane was supplied from inlet ① and the position of oxygen inlet ② was changed, the concentration of COx (mainly carbon oxide) formed by the selective oxidation of the carbon included in the hydrocarbon species was changed. **Figure 3a)** shows the concentration change of active hydrocarbon species (HCS) estimated from the yield of COx, where *L* means the distance between the lower-level of the waveguide and the upper of inlet ②. **Figure 3b)** shows the concentration of active hydrogen species (HS) estimated from the yield of water vapor measured when hydrogen was supplied from inlet ①. In both figures, "*" indicates that the supplied gas from inlet ① was converted to active species through the reaction induced by the microwaves. It was obtained that the concentration of hydrocarbon active species was decreased to 30 % at $L = 90$ mm, while that of acetylene increased with increasing *L*. The slight amounts of carbon dioxide and water vapor were detected. Assuming that the generation rate of carbon monoxide through a gas-phase reaction between the active hydrocarbon species and oxygen molecule is comparatively fast, which indicates that the molar fraction of carbon monoxide is positively correlated to the concentration of the reacted active hydrocarbon species. Similarly, the concentration of active hydrogen species was decreased to 35% at $L = 90$ mm, and it is assumed that the active hydrogen species turns into stable hydrogen molecules as it moves away from the microwave irradiation zone. These results in the secondary reaction zone are summarized that the concentrations of molecules (acetylene and hydrogen) which reaches the catalyst surface increases, while the concentration of the radical species decreases.

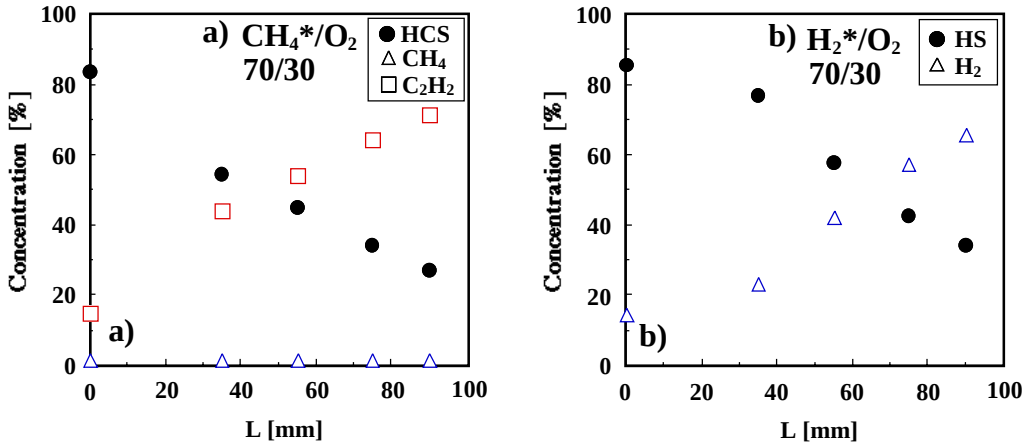

Figure 3. Concentration changes of a) hydrocarbon active species, and b) hydrogen active species

3.2 Comparison of products from the variation of solid catalyst

In the last reaction zone, microwave irradiated methane was introduced into the empty reaction tube [system I)] and the various packed bed zones [system II) Al_2O_3, III) Pt/Al_2O_3, and IV) H-ZSM-5], where the distance from the lower-level of the waveguide to the upper-level of packed bed (ξ) was set at -10 mm. **Figure 4** shows the comparison of the distribution of products in terms of the number of carbons. The trace amount of carbon deposition was observed in all experimental systems. In comparison with the experimental results in systems I) and II), the carbon distribution of the acetylene is almost equal, which indicated that the hydrogenation activity of alumina on the hydrocarbon active species is very low.d Meanwhile the yield of ethylene obtained in the system III) was up to 74.1%. This result indicates that active hydrocarbon and hydrogen species in contact with the Pt/Al_2O_3 catalyst can facilitate hydrogenation on the surface of catalyst. When H-ZSM-5 catalyst was used, the carbon distribution of oily product was remarkably increased (25.9 %).

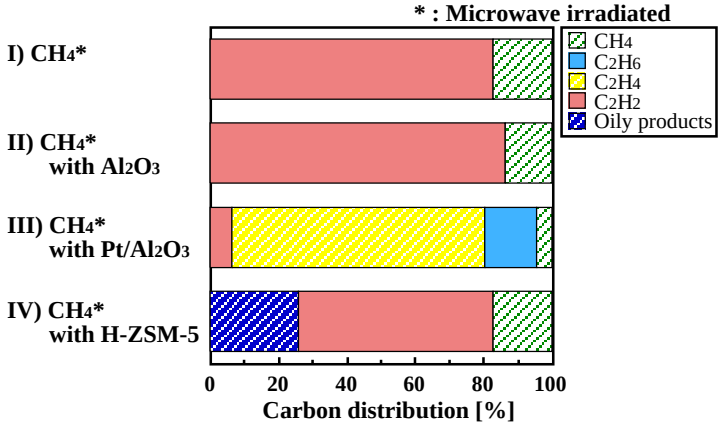

Figure 4. Comparison of carbon distribution in each system

3.3 Effect of the distance in the secondary reaction zone on catalytic activity of Pt/Al_2O_3

As described above, the concentrations of active species (active hydrocarbon and hydrogen species) produced in the primary reaction zone were decreased with increasing the distance in the secondary reaction zone. When Pt/Al_2O_3 catalyst was used, the effect of the distance ξ on the methane conversion (X_{CH_4}) and product yield are shown in **Figures 5a)** and **5b)**, respectively.

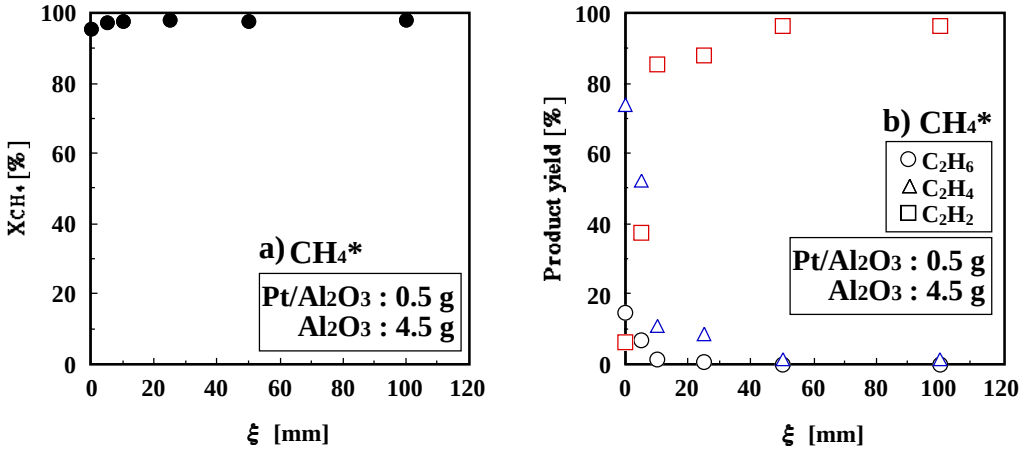

Figure 5. Effect of the packed position of catalyst on a)methane conversion and b)product yield

The methane conversion exceeded 90% in each experimental run. At ξ=0 mm, the yield of ethylene ($Y_{C_2H_4}$) was 78% and the temperature *T* of the catalyst layer was 785 K. These results are superior to the results obtained in the hydrogenation of acetylene using Pt/Al_2O_3 catalyst under microwave non-irradiated field (the maximum $Y_{C_2H_4}$ of 38.2% at *T* = 473K). At ξ= 100 mm, ethylene yield was 3% and *T* was 305 K. The decrease in ethylene yield with increasing ξ (*T* also decreases with increasing ξ) means that high yield of ethylene can be obtained by bringing into contact with the catalyst under high-density methane plasmas.

3.4 Effect of the distance in the secondary reaction zone on catalytic activity of H-ZSM-5

Figure 6 shows the effect of distance in the secondary reaction zone on product yield, where the methane conversion exceeded 80% in each experimental run. It was clear that the yield of the oily products exceeded 20% at ξ= -10 mm, which indicated that the catalytic activity of H-ZSM-5 for the production of oily compounds was increased with an increase in the concentration of active species. When the distance in the secondary reaction zone was set below –10 mm, the carbon deposition was remarkably observed on the surface of H-ZSM-5 catalyst.

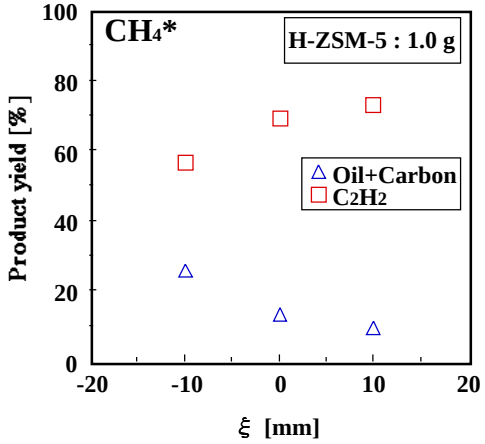

Figure 6 Effect of packed position of catalyst on product yield

Figure 7 shows the gas chromatogram of oily products (ξ=-10 mm). It was indicated by the measurement of the carbon number distribution of oily hydrocarbons that C_{14}-C_{45} of aliphatic hydrocarbons and C_{12}-C_{20} of aromatic hydrocarbons were obtained.

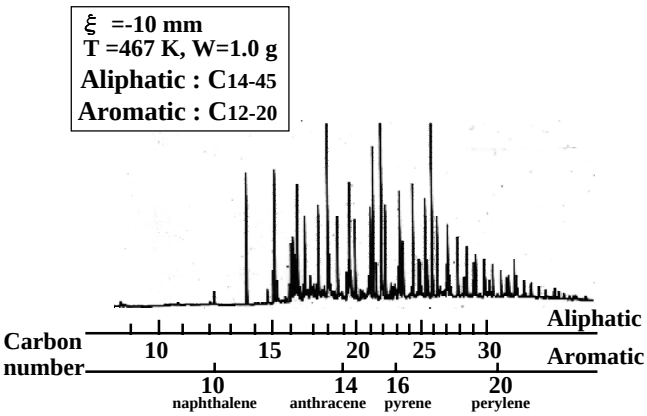

Figure 7 Gas chromatogram of oily product

4. Conclusions

Both active species of hydrocarbon and hydrogen produced by irradiating methane with microwaves were brought into contact with Pt/Al_2O_3 or H-ZSM-5 catalyst. From the results, the following findings were obtained.

a) In the primary reaction zone which is located in microwave-irradiated field,, the supplied methane is decomposed into the hydrocarbon and hydrogen active species (mainly methine and hydrogen radicals) in the plasma state.

b) In the secondary reaction zone which is located between microwave irradiation field and packed bed zone of catalyst, the generated active species gradually convert to acetylene and hydrogen with an increase in residence time due to the individual progress of homogeneous couplings.

c) When Pt/Al_2O_3 catalyst was packed in the last reaction zone, ethylene yield was increased with decreasing the distance in the secondary reaction zone. When H-ZSM-5 catalyst was used, the yield of oily product was increased compared with the Pt/Al_2O_3 catalytic reactions.

Multi-electrode gliding arc plasma reactors powered from special transformers

Henryka Danuta Stryczewska, Grzegorz Komarzyniec, Jarosław Diatczyk
Institute of Electrical Engineering and Electrotechnologies, Lublin University of Technology,
20-618 Lublin, 38A Nadbystrzycka St., Poland, http:/volt.pol.lublin.pl

Abstract
Multielectrode reactor requires simultaneous ignition and sustaining the gliding arc discharge between many pairs of electrodes what is a difficult task for its electric power system and makes it complex and expensive. The proposed in the paper systems based on specially constructed transformer can fulfill requirements of industrial arc discharge reactors while representing simplicity of construction with high efficiency and reliability.
Keywords: non-thermal plasma reactor, gliding arc discharge, power supply systems, special transformers

1. Introduction

Industrial plasma-based technologies for pollution control require the non-equilibrium atmospheric pressure plasma to be produced directly in the big volume of polluted gases at conditions similar to whose the gases are emitted to the atmosphere during the industrial processes. Gliding arc discharges can be produced at DC and AC power supply conditions at commercial or increased frequency in the multi-electrode systems and can treat large volume of polluted gases, cold or hot, with moisture or dry without any previous gas preparation. Moreover, the possibility to treat very diluted substances, like VOC or CFCs components, simultaneous treatment of gas mixtures containing several pollutants, not very sophisticated requirements to power supply, all these make the gliding arc technology very promising tool in the environment pollution control [1].
The gliding arc discharges in the multielectrode and multistage configurations are especially suitable in the industrial pollution control applications. The technology is based on the arc discharge that is forced to glide by fast gas flow along electrodes of diverge form. The more electrodes are put into the discharge chamber the bigger volume of polluted gases can be effectively treated. Multi-electrode configuration allows gliding arc discharge to penetrate and to treat large volumes of polluted gases at atmospheric pressure and conditions typical for industrial processes.
It is a power supply system that determines the reliability and efficiency of the whole plasma generation installation and very often it just decides if the process has the prospects for common usage in industry. Reliability and low investment and exploitation costs are important factors, which shall be taken into consideration during design and construction process of the industrial plasma reactors' installations. Paper presents chosen solutions of arc discharge reactors' power systems. Their construction is based on single- and three-phase transformers, which magnetic cores' nonlinearity is the source of ignition voltage, so the additional arc ignition systems are not required and what makes the proposed systems very simple and reliable. The proposed systems are suitable to energize not only reactors with gliding arc discharge but also for plasmatrons with arc discharges of similar to gliding discharge current-voltage characteristic.

2. Gliding arc discharges in multielectrode and multistage configuration

Basic configuration of plasma reactor with gliding arc discharge, presented in Figure 1, comprises two knife-shaped working electrodes, **B,** connected to the power system, **Z,** and put in the discharge chamber, **A,** through which polluted gas, **D,** to be treated flows with velocity greater than 10 m/s. To assure required non-thermal plasma conditions, working electrodes should be energized with voltage of about 1-2 kV and current value lower than 10 A. Such values of voltage and current are not typical for arc discharge and the produced plasma is at non-equilibrium state similar to glow discharge rather than to arc discharge plasma. Moreover, the interelectrode voltage lower than 2 kV is not sufficient for discharge ignition and therefore it is necessary to introduce the additional ignition electrode, **C,** to the zone in which the discharge starts to move through electrodes. Presented in the Figure 2 typical voltage–current characteristic of the gliding arc discharge between two electrodes shows that voltage required for the discharge ignition (10,5 kV) is more than sixth times greater than for the discharge

sustaining (1,5 kV) at nominal current (2 A) and explains how the power supply system characteristics should be constructed to fulfill the plasma reactor requirements.

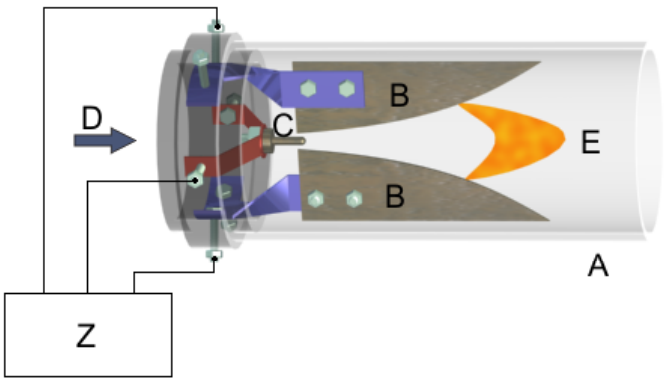

Fig. 1. Scheme of construction of the basic two–electrode gliding arc discharge reactor

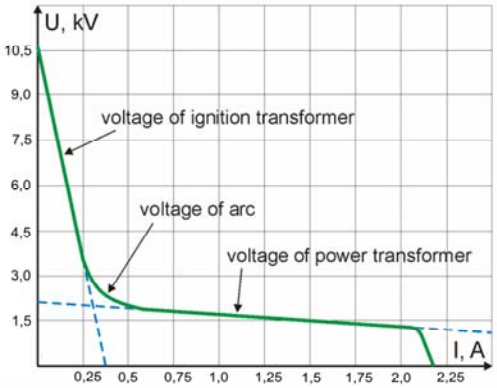

Fig. 2. Typical voltage–current characteristics of the gliding arc discharge

In industrial application, like for exhaust gas treatment, there is often the necessity to place more electrodes in the discharge chamber or more discharge chambers in parallel or in series to the flowing gas (e.g. inside the chimney). Multi-electrode and multi-stage configurations of the gliding arc reactors that could be applied in industrial practice are presented in Figure 3.

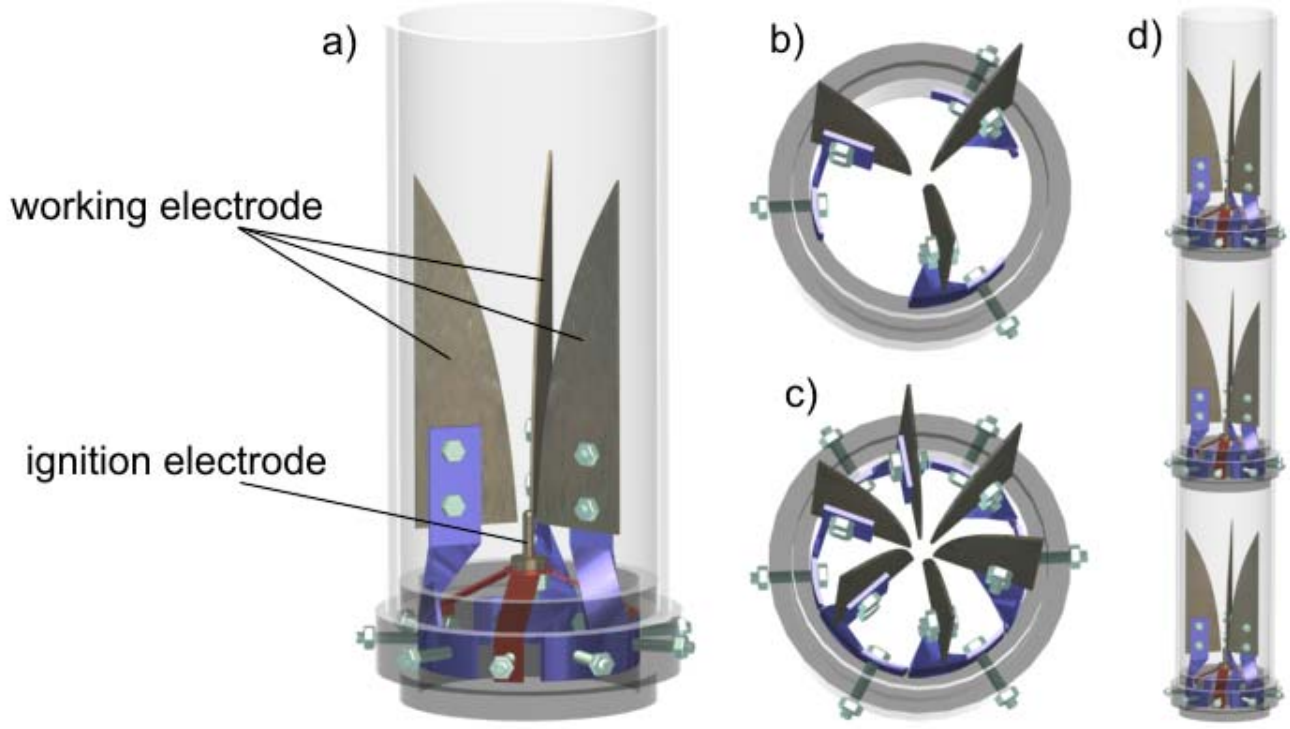

Fig. 3. Electrodes' configurations of gliding arc plasma reactor

Working plasma reactor with gliding arc discharge is strongly non-linear energy receiver of resistive nature. The multi-stage configuration loads power supply asymmetrically. Moreover, the interelectrode voltage is considerably distorted while current has close to sine form (Fig. 4a).

Voltage and current courses representative for two, (a), and three, (b), electrode configuration together with side view photo, (c), of the gliding arc discharge are presented in Figure 4.

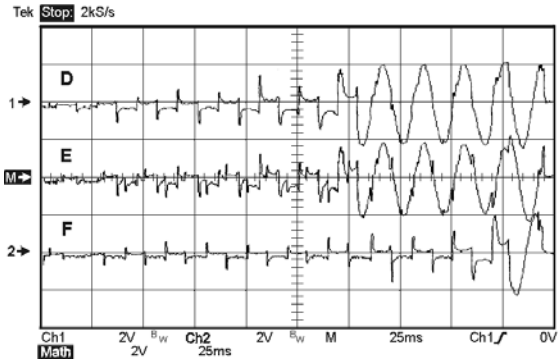
b)



c)

Fig. 4. a), b) Courses of voltage and current of the gliding discharge in two and three electrode reactor, respectively, c) side view of the discharge

3. Power systems

Gliding arc discharge reactor as an electrical energy receiver differs considerably from the other plasma reactors and its cooperation with supplying system requires suitable analysis. The inter-electrode resistance depends on the gas ionization degree and during a single cycle of reactor operation its value changes significantly. It is the largest before discharge ignition when the gas is not ionized and after the ignition rapidly decreases. The increasing of the gap distance and the arc discharge resistance, when the discharge is displacing from the area of ignition to the area of extinction, are not sufficient for the extinction of the arc discharge. The decreasing of the supplying voltage is necessary, which means that the electrical supply of the plasma reactor should have very soft output characteristic, i.e. the voltage of which quickly decreases with the current increasing, like it is presented in Figure 2.

In spite of soft output characteristic, the power supply system should fulfill also the following requirements:

- to supply electrical energy at a high voltage of mains or increased frequency,
- to ensure the voltage varies in the wide range which enables the regulation of the plasma reactor productivity,
- to present high efficiency of energy transfer to the plasma
- to have low power consumption, capital and maintenance outlay
- to present simple servicing and safe operation,
- to cooperate properly with power grid
- to have possibility of controlling the operation of the whole system performance.

The basic unit of each power system of the discharge plasma reactor is a transformer. Its task is to supply energy to the discharge chamber at parameters required by an industrial process. Specially constructed transformer's based system of our invention, so called integrated system [6], can fulfill plasma reactor's requirements while representing high efficiency with simplicity of construction. In integrated power supply systems the functions of

preliminary ionization, ignition and discharge maintaining during operation cycle as well as a limiting the short-circuit current value are integrated in one device. The system employs the nonlinearity of the transformer cores to generate the tripled frequency preliminary ionization voltage, therefore, in one supplier the function of arc ignition and its maintenance are performed that makes them much more efficient in comparison to other power systems for industrial applications. Moreover, the system permits the arc suppression at the end of the electrodes at relatively low extinction current, limited by the transformer internal reactance, and prompt arc ignition at the least electrodes' distance [7].

a. Three-phase ninth-electrode system

The integrated power system of the triple-stage ninth- electrode reactor is presented in Fig. 5. The discharge chamber of the system comprises three triple-electrode segments. One out of three electrodes in each stage are for the arc discharge ignition and they are connected in parallel and energized from the ignition transformer, while two others are connected to line voltages of the three-phase power transformer. Thanks to this connection, the ninth electrode arc plasma reactor can be energized form the three-phase grid with single ignition transformer.

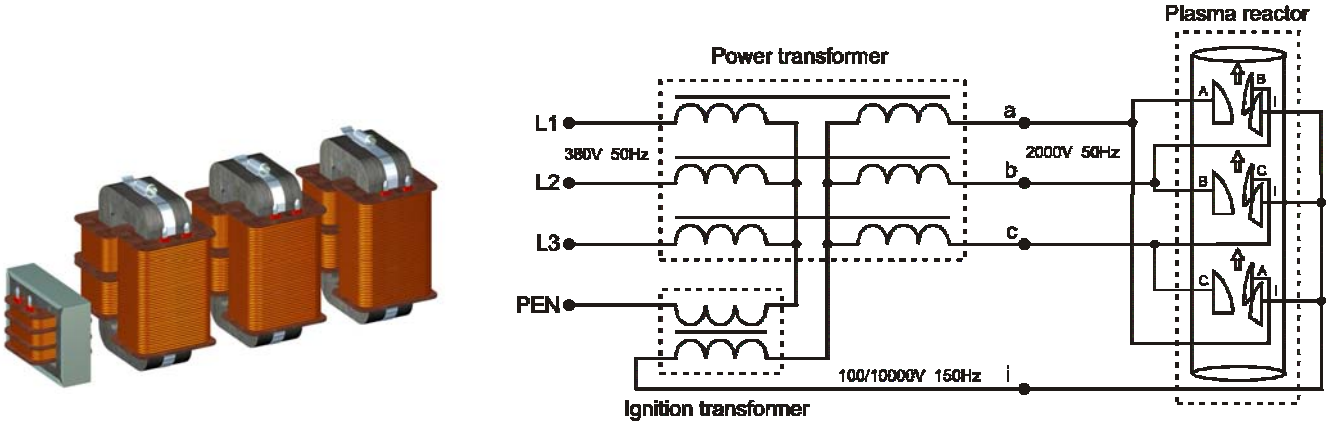


Fig. 5. The three-stage gliding arc reactor powered from integrated power supply system - one electrode in each stage operates as ignition electrode

b. Multi-stage system with individual ignition transformers

Sometimes, in the case of multi-stage systems, it would be better to detach the ignition system from the power supply and to equip each electrode system with separate ignition electrode, as it is presented in Fig. 6. In this solution, every ignition electrode of plasma reactor has its own power supply. The advantage of such solution is its high reliability, as when ignition power supply system breaks down only one segment of electrodes is out of operation.

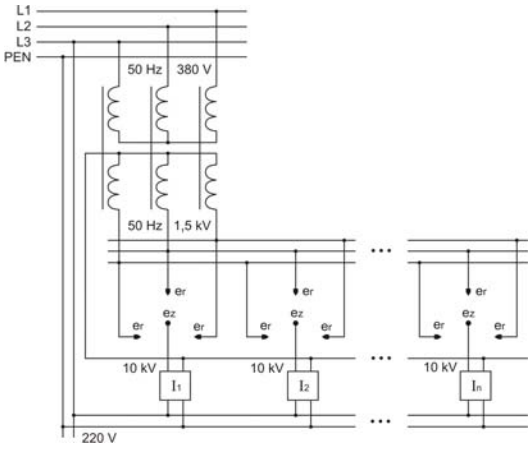

Fig. 6. Transformer–based power supply with separated ignition system, e_r-working electrode, e_z- ignition electrode, I_1, I_2, …I_n – discharge ignition systems

c. System based on five-limb transformer

Power systems, which have already been presented above, are based on the application of properly connected single-phase transformers. Solution presented in Figure 7 is taking advantage of the fifth-limb core of the three-phase transformer. The primary and secondary windings are put on three internal columns of transformer core and connected in star without neutral wire. The primary windings are energized from three-phase mains while the secondary supply the working electrodes of plasma reactor. In the connected in series windings, put on the core's external yokes, the ignition voltage is generated due to the magnetic flux distortion. The benefits of this solution are the tightness and simplicity of construction and the possibility to supply higher number of ignition electrodes compared to the other transformer-based systems.

a) b)

Fig. 7. Transformer with 5-limb core as a power system for triple-electrode gliding arc reactor

Experiments were carried out on the model of the power system from Figure 7a. Model consists of 4 rolled sheet metal cores with primary, secondary and ignition windings put on the core's columns as it is presented in Figure 7b. Magnetic flux and voltage induced in windings of the external columns' are distorted mainly by third harmonic (150 Hz) as it is shown in Figure 8.

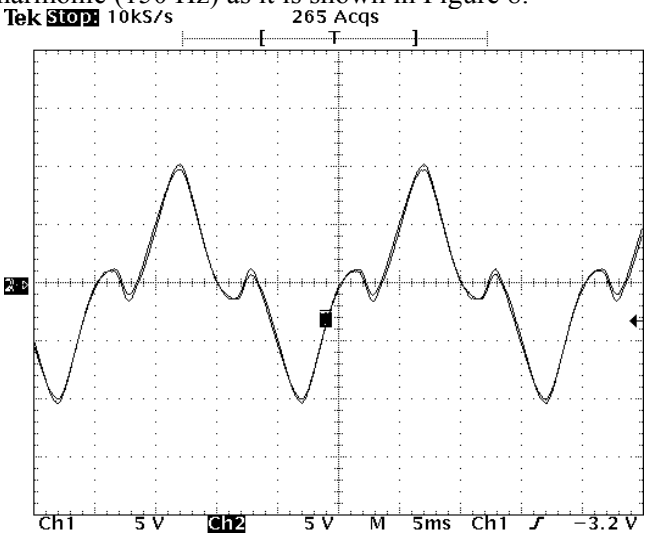

Fig. 8 Course of the voltage induce in the external columns of the 5-limb transformer under three-phase excitation

Voltage induced in the external columns' windings connected in series has enough value for pre-ionization of the interelectrode gap in the three-electrode reactor. It is possible to wind more ignition windings on the external columns which makes the system suitable also for multistage plasma reactors

5. Conclusion

Presented power supply systems for gliding arc plasma reactors are based on special construction single phase and three-phase transformers. The windings' connection and magnetic core construction assure proper operation of plasma reactor as well as expected plasma parameters. Proposed power systems take advantage of the three-phase power supply to energize multi-electrode and multi-stage gliding arc discharge reactors that are especially suitable treatment of large

volumes of polluted gases at atmospheric pressure, directly in the place of their emission. In the proposed power supply systems any auxiliary controls are not necessary which guarantees simplicity, reliability and low investment and exploitation costs of industrial plasma reactors with gliding arc discharge.

ATMOSPHERIC PRESSURE PLASMAS - ANALYSIS BY MODULATED MOLECULAR BEAM MASS SPECTROMETRY

Y. Aranda-Gonzalvo, M. E. Buckley, P. J. Hatton, J.A. Rees, D. L. Seymour, T.D. Whitmore

Hiden Analytical Ltd., 420 Europa Blvd., Warrington WA5 7UN, England
www.HidenAnalytical.com info@hiden.co.uk

1. Introduction

Atmospheric plasmas are increasingly used to process materials that are otherwise unsuitable for vacuum processing. Highly functional surfaces can be produced on a number of materials including textiles, plastics, polymers and nonwovens. Other applications include cleaning of polluted water, sterilisation of surgical instruments and localised treatment of biological tissues.

In all cases an understanding of the gas phase and surface chemistry involved is important in order to develop and refine a particular process. Compared with optical techniques, mass spectrometry has the distinct advantage of being able to provide simultaneous identification of the various plasma species that impinge on the substrate or workpiece. When coupled with energy analysis a detailed understanding of the process can be quickly achieved.

Molecular beam inlet systems consist of several differentially pumped stages coupled by sampling/collimating apertures and have been used previously to determine reaction kinetics of high pressure combustion and pyrolosis processes [1]. More recently they have been developed for accurate measurement of radical densities in low pressure plasmas [2,3]. In this work we describe a molecular beam mass spectrometer system for atmospheric plasma diagnostics. The instrument incorporates beam modulation in the form of a software controlled rotating disk chopper.

2. Diagnostic Apparatus

2.1. Molecular Beam Mass Spectrometer

The discharge was generated by a radio frequency driven atmospheric plasma source, based upon the design of Stoffels et al [4]. This original design was adapted to include a second, concentric gas inlet in order to study mixtures of gases. The low power discharge, around 7W, was produced between the plasma source and the entrance of the Molecular Beam Mass Spectrometer (MBMS) analyser.

Species created in the atmospheric discharge were sampled using a triple stage differentially pumped molecular beam inlet system and subsequently detected with the Hiden EQP mass/energy analyser. A schematic of the arrangement is shown in Figure 1. The chopper mechanism is omitted for clarity.

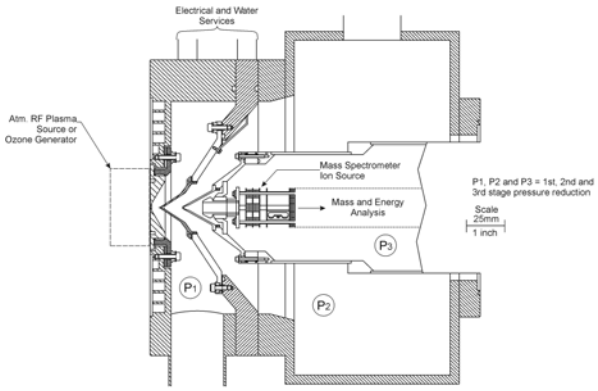

Fig. 1: Schematic of the MBMS Analyser.

2.2. Automated Beam Modulation Control

The beam chopper mechanism incorporates an opto-detector positioned on the opposite side of the rotating disk to the molecular beam aperture. This generates a synchronisation signal that is phase locked to the chopper movement and used by the mass spectrometer as two virtual detectors, *foreground* and *background*.

The mass spectrometer has one physical electron multiplier detector (SEM), which may be connected to either the foreground or background virtual detectors under the control of the gating system. The detectors are presented as separate inputs by the control software and related as follows;

$$\text{SEM} = \text{foreground} + \text{background} \quad (1)$$

$$\text{foreground} = \text{SEM} - \text{background} \quad (2)$$

$$\text{background} = \text{background} \quad (3)$$

The chopper synchronisation signal cannot be used to directly gate the mass spectrometer as its duty cycle does not exactly match the instrument's response to the beam chopper, and this would tend to reduce its differential sensitivity. To overcome this, two internal delayed pulse generators (100nsec resolution) are used to match the beam chopping cycle to the foreground and background gating, as shown in Figure 2.

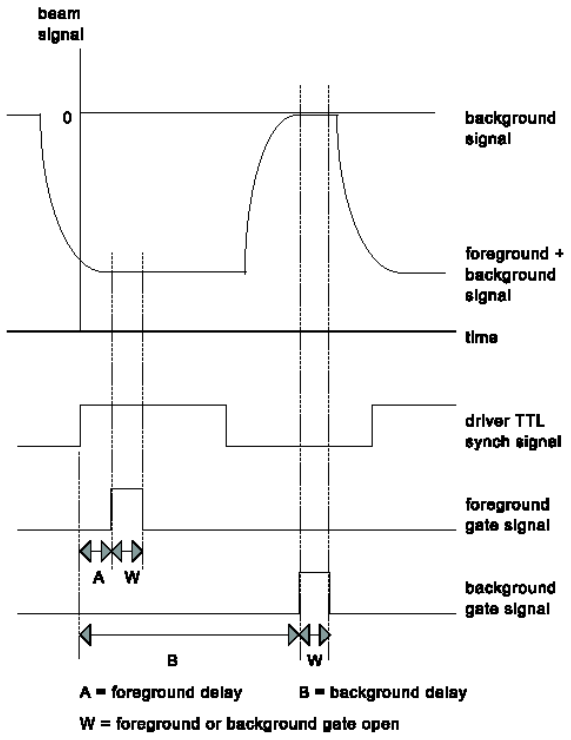

Fig. 2: Modulation timing diagram.

3. Results & Discussion

Figure 3 shows the measurement and display of SEM and background signals for N_2^+ for plasma on and off conditions. The foreground (beam) signal is derived in real time from (2).

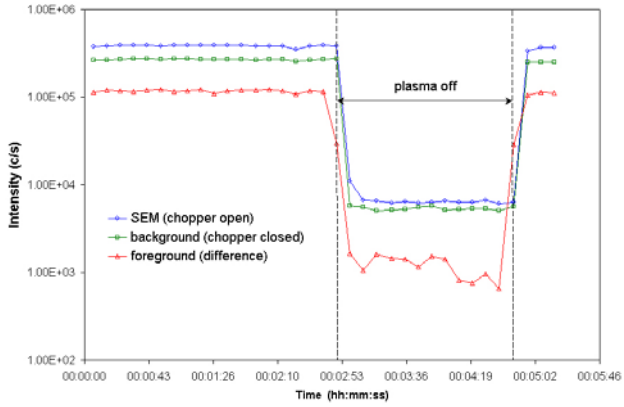

Fig. 3: Raw (SEM, background) and derived (foreground) signal intensities for N_2^+ for plasma on/off conditions.

Figure 4 shows the corresponding appearance potential scans for N^+ when the plasma is on. Again, the threshold ionisation foreground (beam) data is generated automatically. The two observed thresholds correspond to the direct and dissociative ionisation processes;

$N + e \rightarrow N^+ + 2e$ (Ei= 16.5 eV), and

$N_2 + e \rightarrow N^+ + N + 2e$ (Ei=25.2 eV)

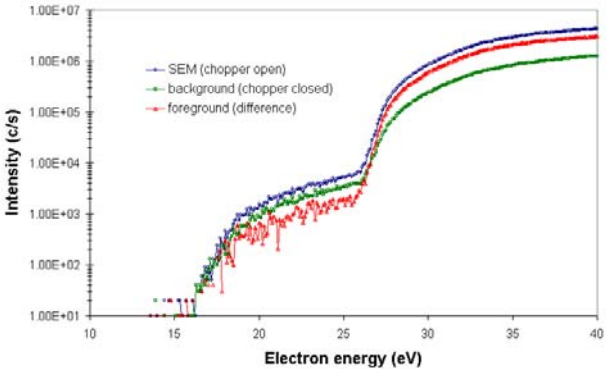

Fig. 4: Threshold ionisation curves for N^+ .

The beam-to-background ratio can be calculated from the slope of the linear fits between the above thresholds and gives a figure of merit for the sensitivity of the overall apparatus to the beam component [2]. This in turn determines the accuracy of absolute radical density calculations [3]. The value of 0.95 is obtained for the N^+ case above, clearly demonstrating the sensitivity of this apparatus for absolute radical density determination from atmospheric plasmas.

4. Conclusions

We have described a modulated molecular beam mass spectrometer that is suitable for diagnostics of atmospheric plasmas. Automatic control and processing of the modulated molecular beam signals allows rapid and accurate determination of beam/background components which are required to determine absolute radical densities.

Numerical Simulation of Low Pressure Inductively Coupled Plasma Sources for Nanocrystalline Diamond Deposition

Katsuyuki Okada, Shojiro Komatsu, and Takamasa Ishigaki

Advanced Materials Laboratory, National Institute of Materials Science, Tsukuba, Japan

Abstract
Numerical study on low pressure inductively coupled plasma (ICP) used for nanocrystalline diamond deposition has been performed with direct simulation Monte Carlo (DSMC) method and electron Monte Carlo simulation. Spatial distributions of electron density, electron temperature, and plasma potential are obtained. The electron energy distribution functions (EEDFs) are compared with the experimental results obtained with a Langmuir probe previously. The EEDFs of an Ar and a CH_4/H_2 plasma obtained from the simulation agree well with the measured data. The calculated EEDF of a CH_4/H_2 plasma at 50 mTorr exhibits a hump around 6 eV, which corresponds to a hump around 6 eV in the measured EEDF at the same pressure. It can be attributed to the resonant peak of the vibrational excitation cross section of CH_4 molecule.

Keywords
Low pressure inductively coupled plasma, Nanocrystalline diamond, Monte Carlo simulation

1. Introduction

We have applied a low pressure inductively coupled plasma (ICP) to deposit nanocrystalline diamond [1]. The sp^2/sp^3 bondings of the nannocrystalline diamond were evaluated with Raman spectroscopy [2] and electron energy loss spectroscopy [3]. Langmuir probe and mass spectrometric measurements were performed to characterize the ICP [4,5]. We obtained plasma parameters {electron density (N_e), electron temperature (T_e), and plasma potential (V_p)}, electron energy distribution functions (EEDFs), and ion energy distributions (IEDs). For better understanding of the ICP, we need a theoretical investigation such as modeling or numerical simulation. Economou et al. [6] used the direct simulation Monte Carlo (DSMC) method to demonstrate reactive neutral and ion flow in an ICP reactor. Nanbu et al. [7] also used the electron Monte Carlo method for obtaining the production rate of radicals. Takekida and Nanbu [8] reported the EEDFs of capacitively coupled Ar plasmas using particle-in-cell/Monte Carlo (PIC/MC) method.

In this study, we report on the numerical simulation of the ICP used for nanocrystalline diamond deposition using DSMC method and electron Monte Carlo simulation. Spatial distributions of N_e, T_e, and V_p are obtained. The calculated EEDFs are compared with the measured EEDFs.

2. Experiment and Simulation

Figure 1(a) illustrates the schematic diagram of the low pressure ICP-CVD system. The detailed description and the procedure of Langmuir probe measurement were reported previously [1,4]. To be brief, a low pressure ICP was generated in a growth chamber by applying 13.56 MHz rf powers of 1 kW to a three-turn helical antenna wound around a quartz tube. An Ar or a CH_4/H_2 (5:75 mixture) plasma was generated at pressures ranging from 10 to 50 mTorr. A Langmuir probe (Smart Probe; *Scientific Systems Inc.*) was utilized to measure plasma parameters and EEDFs.

The procedure of simulation is as follows. The flow, electromagnetic field, and plasma are assumed to be axisymmetric. The geometry of computational model is shown in Fig. 1(b). The height of the reactor is 110 mm. A three-turn helical coil wound around a quartz tube with 40 mm in diameter. The calculation was performed with DSMC method and electron Monte Carlo simulation. Collisions of e-Ar in an Ar plasma; e-H, e-H_2, e-CH_4, e-CH_3, e-CH_2, and e-CH are considered in a CH_4/H_2 plasma, respectively.

Surface reactions of radicals play a critical role in determining the concentrations and distributions of ions and radicals in a reactive plasma such as CH_4/H_2 plasma. The sticking of CH_3, CH_2, and CH radicals on the surface are taken into consideration in the calculation. The sticking coefficients of CH_4, CH_3, and CH_2 radicals are refereed to $1.0X10^{-4}$, $1.0X10^{-3}$, and $3.0X10^{-2}$ in the previous reports [9-11].

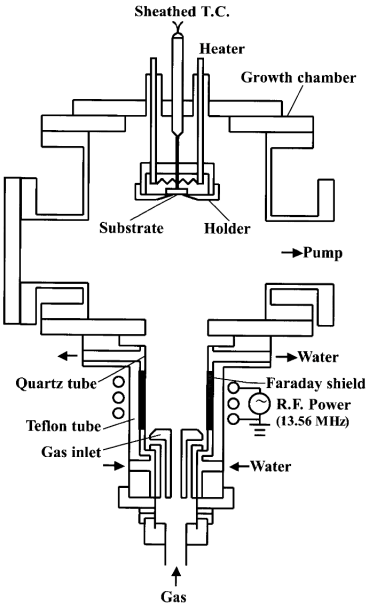

FIG. 1(a) Schematic diagram of low pressure ICP-CVD system.

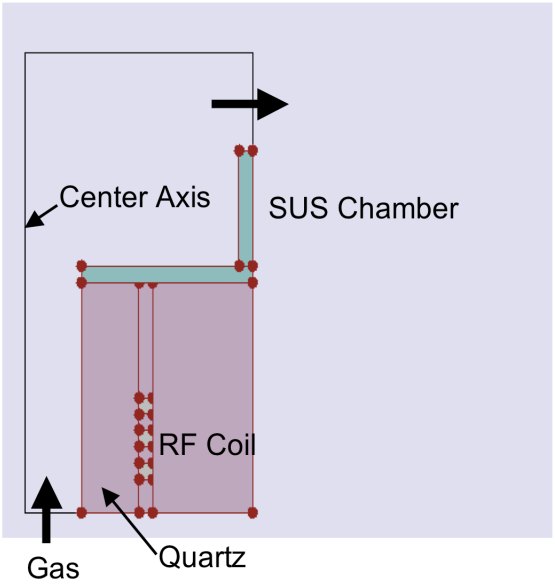

FIG. 1(b) Geometry of computational model.

3. Results and discussion

Figures 2(a) and 2(b) show the N_e and T_e of an Ar plasma at 50 mTorr, respectively. The N_e is concentrated near the rf antenna, and the T_e has a doughnut-shape distribution near the rf antenna. Figure 3(a) and 3(b) show the density of Ar^+ and Ar*, respectively. While the former has a similar distribution to the N_e, the latter spreads toward the growth chamber.

The N_e and T_e of a CH_4/H_2 plasma at 50 mTorr are shown in Fig. 4(a) and 4(b), respectively. The N_e is concentrated near the rf antenna similar to that of Ar plasma. The T_e is high along the quartz tube, which is different from that of Ar plasma. The density of H^+, CH_3^+, H*, and CH_3* are shown in Fig. 5(a), 5(b), 5(c), and 5(d), respectively. While the ion distributions are concentrated near the rf antenna, the radical distributions spread into the growth chamber. The distributions strongly depend on each radical.

Figure 6(a) shows the measured EEDF of an Ar plasma at 50 mTorr (closed circles) and the calculated one at the same pressure (open circles). The each EEDF is nearly a straight line, which means that the electron energy has a Maxwellian distribution. Although the calculated EEDF above 10 eV slightly deviates from a straight line, it is consistent with the measured EEDF.

Figure 6(b) shows the measured EEDF of a CH_4/H_2 plasma at 50 mTorr (closed circles) and the calculated one at the same pressure (open circles). They are different from the EEDF of an Ar plasma at the same pressure. There is a hump around 6 eV in both measured and calculated EEDF. Turner and Hopkins [12] reported the unusual structure of the EEDF. They found a dip around 4 eV in the EEDF of a N_2 plasma, which is interpreted as the electric absorption of N_2 molecule corresponding to the resonant peak of the vibrational excitation cross section. In the CH_4 vibrational excitation cross sections, $\sigma_v(1,3)$ and $\sigma_v(2,4)$ have a peak around 6 eV [13]. Therefore, the hump around 6 eV can be attributed to the electric absorption of CH_4 molecule analogous to the vibrational absorption of 4 eV electrons of the N_2 molecule.

The calculated EEDF of a CH_4/H_2 plasma agrees well with the measured one. Accordingly, the unusual structure around 6 eV in the calculated EEDF can also be attributed to the resonant peak of the vibrational excitation cross section of CH_4 molecule.

Acknowledgment

The authors would like to thank Mr. M. Tanaka and T. Takasaki of PEGASUS Software Inc. for their useful advice on the calculation.

Abstract

The characterization of a plain-jet air blast atomizer, as used for the pyrolysis of hydrocarbons in an induction thermal plasma reactor, has been performed. Experimental measurements of the mean droplet size, expressed as the Sauter Mean Diameter (*SMD*), were obtained using a light-scattering technique. A dimensionally consistent expression for the *SMD* estimation was determined as a function of the dimensionless numbers: *Re*, *We*, *ALR* and *X/do*. This empirical correlation permits the influence of the operating conditions of the liquids atomizer, on the quality of the atomization, to be described. Further, the final expression was subsequently and successfully used for the estimation of the size of droplets, produced during experimental tests of hydrocarbons pyrolysis by induction plasma.

Key words: liquid atomization, induction plasma, hydrocarbons pyrolysis.

Introduction

In an atomization process, a liquid is initially disintegrated by a gas stream into a multitude of small droplets, which are then dispersed into the gaseous medium, increasing the overall liquid phase surface area. As general rule, the performance of any given type of atomizer depends on its geometry and on the physical properties of the liquid and gas phases [1]. Various definitions of the mean droplet size are available [2], among them, the Sauter Mean Diameter (*SMD*) is one of those most widely used because it defines the volume/surface ratio of the spray and it has a special use in heat and mass transfer applications.

The majority of published investigations [3, 4, 5] into the droplet size distribution have been empirical in nature, and only a few of the more complex CFD models have been developed for large scale combustion processes. Very few reports have been published on the hydrodynamic performance of liquid atomizers when used under operating conditions typical of thermal plasma processes [6, 7]. Because the hydrodynamic performance of a liquid atomizer depends not only on the physical properties of the fluids employed, but also on the range of its operating conditions, a complete atomizer characterization becomes mandatory when it is desired to better understand the influence of vaporization on the physicochemical characteristics of the final products produced.

The primary purpose of this work is to evaluate the effect of the operating conditions, as well as the properties of the liquid phase, on the quality of atomization obtained for a new, plain-jet air blast atomizer. In addition, various experimental tests on the pyrolysis of hydrocarbons were performed in order to evaluate the influence of liquid droplet size on the type and quality of products, obtained in the plasma process.

Experimental

Experimental Set-Up

The experimental setup used in this study is shown in Figure 1. It consists of a liquid container, a liquids supply line, a pressurized air line, a specially designed air blast atomizer, a spray measurement system and a tunnel extraction system. The liquid flow rate was measured using precision flow meters, the air stream being separately introduced through a pressure regulator and a flow meter. The atomizer was horizontally oriented, thereby injecting the liquid into the collection system. It was designed to avoid undesirable droplet recirculation and to generate a quiescent environment.

The spray measurement system employed was a laser based, particle size analyzer (Malvern/Insitec Ensemble Particle Concentration and Sizes Instrument System) that measures suspended particles size distribution, via light scattering. The measurement error of this instrument is estimated to be ±2%, with an accuracy of 96% of the droplet size distribution. The experimental results were analyzed in terms of their *SMD* values, and the parameter known as Span (Δ), which is used as an indicator of the distribution width. The plain-jet air blast atomizer used in this study is an external-mixing-type nozzle. The liquid discharges

through a circular orifice of 6 x 10^{-4} m in diameter, while air is supplied through an annular slot of 1.2 X 10^{-4} m in diameter around the periphery, resulting in a conical discharge pattern.

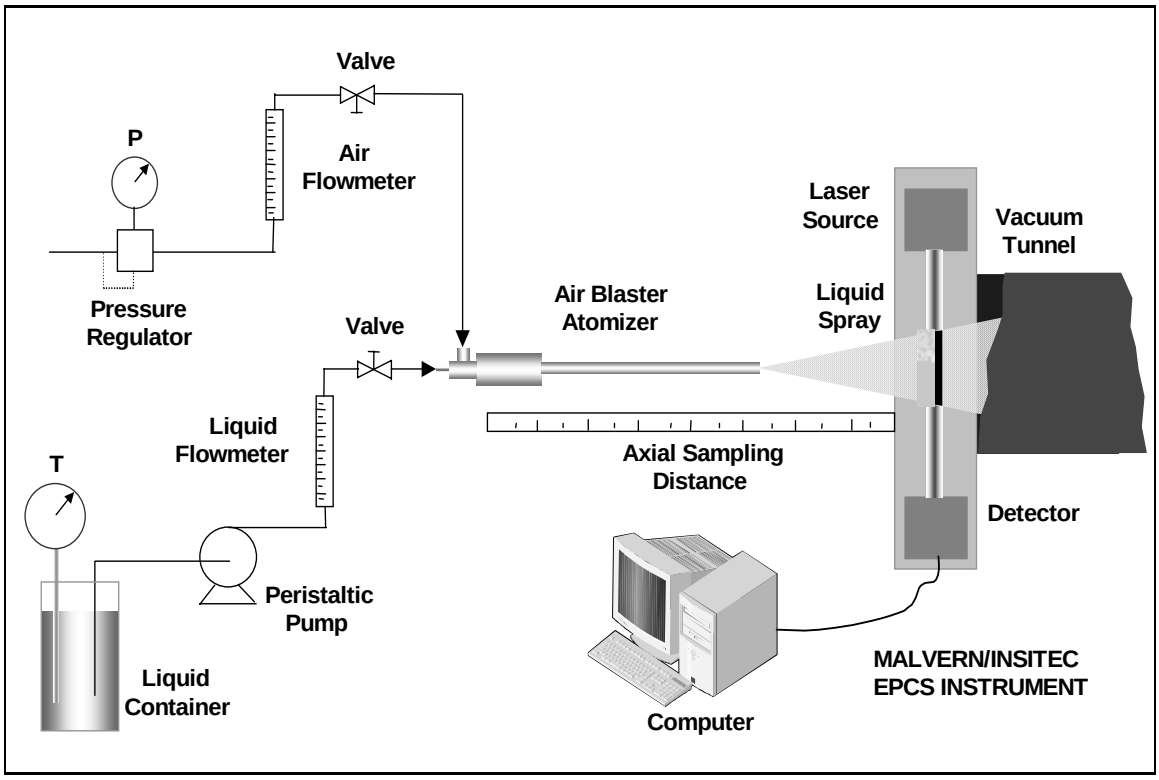

Figure 1. Experimental Setup for the Atomization Study

Continuing, the thermal plasma system used for the pyrolysis of hydrocarbons was composed of a Tekna PL-50 induction plasma torch, a water-cooled stainless steel reactor, and a filtration system. The complete experimental set up for the pyrolysis of hydrocarbons is described in more detail elsewhere [8, 9]. The final products, obtained after the plasma pyrolysis, were characterized by various techniques, including surface area, UV/Vis spectrometry and transmission electron microscopy.

Experimental Conditions

In the first series of experiments, an air-water system was used on which to conduct tests. The variable parameters were as follows: airflow rates (8.3, 12.5, 16.6, 20.8 slpm), liquid flow rates (*LFR*) (3.6, 9.0, 14.5, 20.5, 22.3 ml/min), and the axial distances from the nozzle exit (*X*) were (0.00, 0.04, 0.08, 0.12 m). In order to evaluate the influence of variations in the test liquid properties, a second set of experiments was performed, using dodecane ($C_{12}H_{26}$) and tetrachloroethylene (C_2Cl_4) as the test liquids. Due to safety considerations, a reduction in the overall number of tests performed with the two latter liquids was mandatory. Thus test conditions were; for the airflow rate, 8.3, 12.5 and 16 slpm, while for the liquid flow rate (*LFR*), values of 3.6, 9.0, 14.5 and 20.5 ml/min and 0,04 and 0.08 m for the axial distance (*X*) from the nozzle, were selected. All liquid flow rates were measured under ambient conditions (25°C and atmospheric pressure) and the delivered pressurized air was regulated at 412.7 kPa (60 psig).

On the other hand, the plasma operating conditions were maintained constant for all experimental tests conducted on hydrocarbons pyrolysis. Thus, flow rates of 8 and 25 slpm of argon, and 120 slpm of helium were used in the powder, central and sheath gas supplies, respectively. Plasma plate power was maintained at 40 kW, and the reactor pressure at 80 kPa. Various flow rates (5, 10 and 18 ml/min) of the liquids feeds were used to evaluate the effect of droplet size on the type and quality of the solid and gaseous products obtained in the plasma process.

Results and Discussion

Atomizer Characterization

The most important factor influencing the *SMD* is undoubtedly the air velocity. In general, *SMD* values decrease as the relative air velocity is increased. For instance, the influence of the relative air velocity on the *SMD*, for an axial distance of 0.04 m from the exit of the nozzle, is shown in Figure 2. It is clear that, for the three test liquids used, the *SMD* decreases when the air velocity is increased. Thus, for water, *SMD* values smaller than 25 μm are achieved at relative velocities greater than 220 m/s, while for $C_{12}H_{26}$ and C_2Cl_4, these values are already to be found at and above 160 m/s. This phenomenon can be explained by the differences in the physical properties of the various compounds examined.

It is generally accepted [3, 4, 5] that *SMD* be expressed in terms of dimensionless groups, such as the Reynolds (*Re*) and the Weber (*We*) numbers.

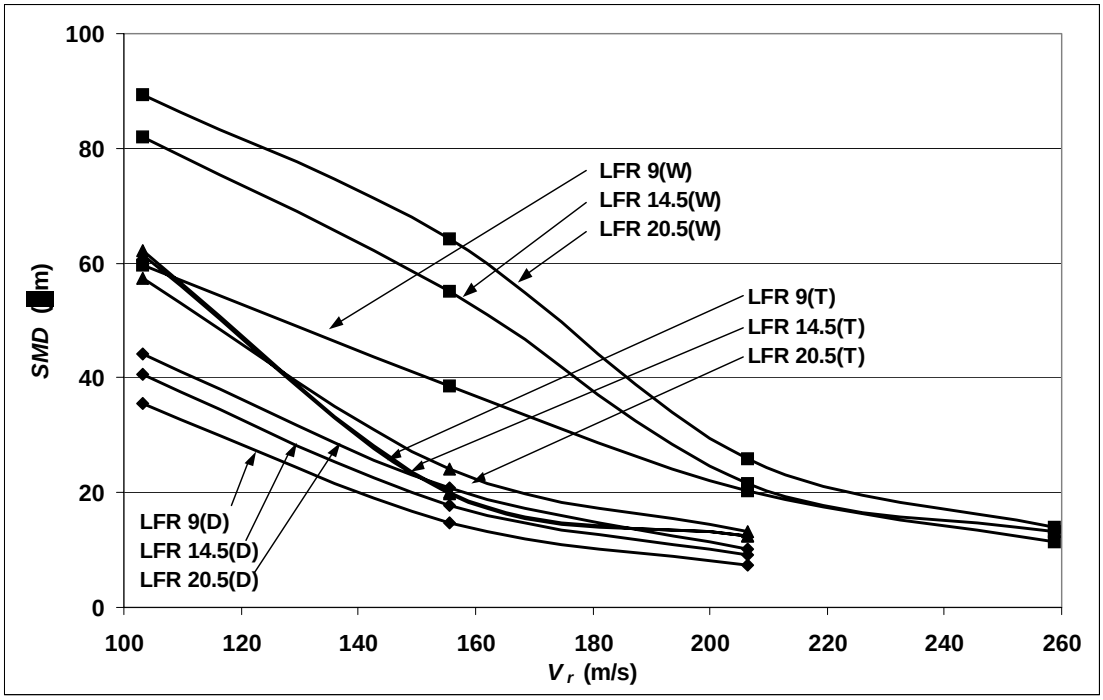

Figure 2. Variation in the Mean Droplet Size with the Relative Air Velocity (V_r)

In order to develop an empirical relationship, a dimensional analysis was performed by application of the Buckingham π-theorem method [10]. The variables used in this study are show in Table 1.

Table 1. Variables Used in the Dimensional Analysis

Variable	Symbol	Units	Dimensions
Air Mass Flow Rate	m_a	kg/s	m/t
Liquid Mass Flow Rate	m_l	kg/s	m/t
Liquid Density	ρ_l	kg/m^3	m/l^3
Gas Density	ρ_g	kg/m^3	m/l^3
Liquid Viscosity	μ	kg/ms	m/l t
Surface Tension	σ	kg/s^2	m/t^2
Discharge Orifice Diameter	d_0	m	l
Relative Velocity	V_r	m/s	l/t
Liquid Velocity	V_l	m/s	l/t
Axial Distance	X	m	l

There are ten variables and three reference magnitudes. Assuming that three dimensionless groups depend on one specific variable, the dimensional formula may then be expressed in terms of four dimensionless groups. The application of a multiple regression yields a regression coefficient of 96% and a standard error of 2.4 %.

$$SMD = 6.7 d_o \, Re^{-0.10} \, We^{-0.56} \, ALR^{-0.41} \left(\frac{X}{d_o} \right)^{0.003} \quad (1)$$

The range of the *Re* number for the operating conditions varies from 67 to 1376. It was observed that the effect of the *Re* number on the *SMD* strongly depends on the physical properties of the liquid. For instance, for liquids presenting smaller density/viscosity ratios, such as $C_{12}H_{26}$ (5.28 X 10^5 s/m^2), the *SMD* increases when the *Re* number values are increased. This means that, even when the liquid flow rate is increased, the inertial forces are not as strong as the viscous forces and the *SMD* values are thus increased. Here, the viscous forces control the disintegration process. In contrast, when a liquid, such as C_2Cl_4, with a higher density/viscosity ratio (1.9 X 10^6 s/m^2), is used, *SMD* values increase for small *Re* numbers.

The *We* number values varied from about 500 to 6500. In this case, surface tension of the liquid plays the most relevant role in determining the *SMD* value of the droplet. The surface tension force adversely affects the atomization process because it opposes the diffusion of air inside the liquid, preventing droplet disintegration. Additionally, *SMD* values decrease when the relative air velocities are increased. This result can be related to the high shear strengths produced at high values of relative air velocity.

In the case of the *ALR* effect, at a constant value of relative air velocity, the mean droplet size is inversely proportional to the *ALR* for values smaller than about 2, for any of the liquid compounds used. An increase in the *ALR*, and consequently in the *Vr* values, improves the atomization quality, due mainly to increases in the air mass, which favour the droplets' disintegration process.

According to equation 1, the modest value of the exponent (0.003) of the dimensionless number (X/d_o) indicates that *SMD* values are only slightly affected as the spray moves down wind. However, a narrowed droplet size distribution (decreasing Span (Δ) parameter), and hence a higher quality of atomization, is also achieved. Therefore, it is clear that atomizer position in the plasma torch plays a key role in the vaporization of further droplets and therefore, in determining the final energy consumption efficiency of the plasma process.

Hydrocarbons Pyrolysis Experiments

In order to evaluate the influence of droplet size on the synthesized product, four experimental tests of hydrocarbons pyrolysis were performed. Table 2 shows the liquid feed rates used in these experiments, along with the estimated *SMD* values and the most important experimental results for solid products.

Table 2. Experimental Tests for the Atomizer Performance Evaluation

Run	Compound	Feed Rate (ml/min)	Estimated *SMD* (μm)	Solid Product		
				Soot (wt%)	Surf. Area (m^2/g)	C_{60} (wt%)
1	$C_{12}H_{26}$	5.0	29	23	121	traces
2	$C_{12}H_{26}$	11.0	37	28	121	traces
3	C_2Cl_4	10.0	50	15	46	3.9
4	C_2Cl_4	18.0	60	21	58	2.1

Table 2 shows that higher liquid feed rates generate larger, average droplet sizes, which in turn, strongly affect the final composition of products. For example, results for $C_{12}H_{26}$ show that carbon soot yield increased when the $C_{12}H_{26}$ feed rate is greater, due in part to plasma cooling. The plasma temperature decreases because of the high-energy requirements required to vaporize the larger droplets and heat the gaseous species. According to thermodynamic and kinetic studies, found elsewhere [8, 9], lighter hydrocarbons, such as acetylene, are always favoured at higher temperatures.

Larger droplet sizes also generate products of incomplete $C_{12}H_{26}$ decomposition. In comparing Runs 1 and 2, it can be seen that both high $C_{12}H_{26}$ throughputs and large droplet sizes produced significant amounts of adsorbed polyaromatic compounds (PAHs), and some traces of C_{60} (MW = 720 uma) and C_{70} (MW = 840 uma) fullerene molecules. Richter et al. [11] suggested that acetylenic and olefinic compounds (C_2H_2 and C_2H_3) act as precursors in PAHs molecular growth.

In turn, the results of C_2Cl_4 pyrolysis tests also show that high liquid feed rates generate larger droplet sizes, which effectively quench the plasma tail, enhancing the formation of soot and favoring the synthesis of soot-adsorbed chloro-organic compounds. After toluene extraction, high concentrations of C_{60} and C_{70} fullerenes were observed. The formation of these higher molecular weight compounds may be similar to its non-chlorinated analogs, in which the small chlorinated species (C_2Cl_3 and C_2Cl_2) play key roles in the aromatic molecular growth.

Toluene extractions of soot samples were also analyzed by UV-spectrometry at 329 nm for the C_{60} determination. The results (Table 2) reveal that C_2Cl_4 enhances the formation of fullerenes, when compared with $C_{12}H_{26}$. This finding can be explained, taking into account the thermodynamic conditions at high temperatures. Equilibrium computations [8, 9] show that high concentrations of atomic hydrogen and small hydrocarbon radicals are found during the $C_{12}H_{26}$ pyrolysis. These radicals become competitive species for the C_2 and C_3 fullerene precursor molecules, inhibiting the fullerene growth-reactions.

The morphology and structure of the produced soot were evaluated by TEM. Figure 4 shows some of the typical synthesized carbon black aggregates. The shapes of these aggregates vary, from individual spheroidal particles to flat form particles, with some particles resembling crumpled paper. These forms are common in plasma-generated "blacks", reported earlier [12]. Figure 3(a), corresponding to $C_{12}H_{26}$ pyrolysis, shows the presence of "flat" forms of carbon particles. The high energy density of the induction plasma leads to the creation of growths of graphitized planar structure.

Interestingly, these flat particles were not observed (Figure 3(b)) in the soot collected when C_2Cl_4 was used as a raw material. Because of the higher flow rates and larger droplets generated in these tests, a greater plasma quenching effect was generated. Hence, the prevailing, lower plasma temperatures favored the formation of spherical amorphous carbon particles instead of the graphitized flat particles. The carbon black particle size also appears to depend on the particular feedstock used. The average spherical particle sizes are about 18 and 40 nm, for the $C_{12}H_{26}$ and C_2Cl_4 tests, respectively. Detailed inspection of the micrographs reveals the formation of hollow carbon shells, usually known as *giant fullerenes* [13], in $C_{12}H_{26}$ tests. While the pyrolysis of C_2Cl_4 mainly generated nanoparticles of amorphous carbon, the $C_{12}H_{26}$ tests produced a highly structured carbon black, which is usually characterized by its higher physicochemical properties [14].

Conclusions

The influence of the particular operating conditions of a liquid phase atomizer, on the quality of the achieved atomization, has been investigated. An empirical correlation, based on the relationship of *SMD* and dimensionless numbers, was also obtained, with a final correlation coefficient and standard error of about 96% and 2.4 %, respectively. While the *We* and *ALR* dimensionless numbers have the greatest influence on the final droplet product sizes, the dimensionless axial distance (X/d_o) has the smallest effect. However this term provides the opportunity for predicting the effect of the atomizer position on *SMD* values downstream

in the plasma reactor. The maximal *SMD* values were estimated for C_2Cl_4 atomization, while smaller values were estimated when $C_{12}H_{26}$ was used as the liquid feedstock, due to its particular physical properties. Experimental results also show that an increase in the liquid feed rate produces an increase in the *SMD* values. Both higher feed rates and larger droplet sizes strongly affect the composition and quality of the products finally obtained . When a higher *SMD* value of $C_{12}H_{26}$ was used, higher amounts of incomplete decomposition products were observed. Although the solid products obtained in all tests corresponded to the typical carbon black particles obtained at high temperatures, the morphology and particle size are strongly influenced by the *SMD* values of the liquid stream injected into the reactor. *SMD* values play a key role in both the hydrodynamics of the induction plasma torch reactor and in the thermochemistry of the system.

Abstract

We discuss five gas-phase surface treatment processes (flame, corona, plasma, UV/ozone and ozone) in terms of the speed of oxidation, the depth of treatment and the formation of low-molecular-weight-oxidized-material (LMWOM). These characteristics are then discussed in relation to the active species present in the initiation reaction, the gas-phase species available to react with the polymer radical and the ability of the treatment to generate alkoxy radicals. We derive a number of unifying concepts that assist in explaining the different effects on the surface of the polypropylene (PP) film**.**

Keywords: polypropylene, flame, corona, plasma, UV, ozone, surface oxidation, mechanism

Introduction

Oriented PP films ordinarily require some type of surface modification prior to commercial use. Surface oxidation is by far the most common type of modification imparted to PP. Oxidized PP surfaces have improved wetting and adhesion properties when compared with the unmodified polymer. There are five main gas-phase processes used commercially for the oxidation of PP: flame, corona discharge, air or oxygen plasma, ozone, and combined UV/ozone (UVO) treatments. Although all of these processes oxidize PP, there are significant differences between the surfaces formed by these techniques. Three major differences between the various surface-oxidation processes are the processing time required to generate a given amount of oxidation, the depth of that oxidation, and the extent of polymer chain scission that occurs during the oxidation process. Corona discharges, flames, and plasmas can rapidly oxidize PP surfaces, with characteristic processing times of < 1 s [1]. In contrast, the various UVO treatments appear to require exposure times that are orders of magnitude greater in order to achieve the same level of oxidation. Of the five techniques, flame treatment appears to incorporate the highest concentration of oxygen in the outermost surface of the polymer (~1-2 nm). Corona and plasma treatments appear to affect somewhat deeper areas of the PP(~3-10 nm). At the other extreme, the UVO treatments tend to modify considerably deeper into the bulk polymer (microns) [1].

Perhaps the most interesting difference between the five surface-oxidation processes is the propensity to form water-soluble low-molecular-weight oxidized material (LMWOM). LMWOM is the result of oxidation coupled with scission of the PP chains. The presence of LMWOM on PP can be detected by a number of analytical techniques performed in conjunction with washing of the treated surface. LMWOM is characteristically soluble in "polar" solvents such as water, alcohols, and ketones, but remains insoluble in non-polar solvents such as the alkanes and aromatics. More recently, we have demonstrated that LMWOM and other products of oxidative scission can be directly examined using atomic force microscopy (AFM). AFM images of unmodified biaxially oriented PP show a characteristic fine fibrillar network [2,3,4]. The presence of LMWOM on PP is characterized by a topography consisting of smooth, globular "mounds" that are completely removed by washing with water [2,3,4]. The size of these globular mounds often increases as the quantity of LMWOM increases, although this is not the only factor that influences the size of the mounds [2]. Of the surface-oxidation processes examined in this study, LMWOM is readily formed by corona discharge, air or O_2 plasma, and combined UVO treatment [2,3,5,6,].

In contrast, PP treated by flame or by ozone only has no detectable LMWOM within normal treatment-time regimes. Only after repeated treatments, in the case of flame treatment, or at abnormally long treatment times (1-2 hours), in the case of ozone-only treatment, can LMWOM formation be detected. Rather, a surface topography consisting of bead-like "nodules" is formed [2,7,8].

In this paper we will examine the similarities and differences between the PP surfaces treated using five gas-phase, oxidative processes and then attempt to rationalize these differences using our knowledge of the types of active species present in each of the gas-phase treatments and prior research into the mechanisms of oxidation. The comparison of the five surface-oxidation processes is facilitated by reference to two crucial portions of the overall oxidation mechanism, the initiation step and those reactions that lead to chain scission and the formation of LMWOM: the differences between the oxidation processes are most apparent when these two steps are examined.

The nomenclature of electrical discharges can be somewhat confusing. In this paper, we retain the historic "corona" terminology for atmospheric-pressure dielectric-barrier discharges that is overwhelmingly used in the polymer industry while we use the term "plasma" to denote high-frequency, alternating-current glow discharges sustained at reduced pressures.

Initiation Reactions

The initial step in the surface oxidation of PP is likely the formation of a polymer radical by hydrogen abstraction. Hydrogen can be abstracted from any of the primary, secondary, and tertiary sites on the PP chains to form an alkyl radical. The probability of abstraction scales as $H_{tert} > H_{sec} > H_{pri}$, with this ranking largely independent of the attacking radical [9,10,11]. As an example, H abstraction from atactic PP is approximately 20x faster at the tertiary site than at the secondary site [12].

We believe that all of the surface-oxidation processes are largely explained by free-radical chemistry. The rate-limiting step in surface-oxidation processes is probably the initial hydrogen-abstraction reactions. As implied by the data shown in Table 1, there are really only three effective gas-phase hydrogen-abstraction agents: OH, O, and H. Only these three species can account for the rapid reactions that occur in flames, coronas, and plasmas. UVO processes contain significant quantities of O but do not contain the OH or H reactive species. Ozone-only treatments do not contain significant quantities of any of the efficient hydrogen abstracting species. Much of the polymer-radical formation occurs through the reactions:

$$RH + OH \rightarrow R\bullet + H_2O \quad (1)$$

$$RH + O \rightarrow R\bullet + OH \quad (2)$$

$$RH + H \rightarrow R\bullet + H_2 \quad (3)$$

The excited state of atomic oxygen, $O(^1D)$, is extremely reactive and non-selective. Both OH and ground-state atomic oxygen, $O(^3P)$, are quite reactive but do tend to discriminate between the different types of C–H bonds[11]. PP is among the polymers most readily attacked by atomic O. Ozone and hydroperoxy radicals can also abstract hydrogen, but at rates that are orders of magnitude slower than H atoms. As shown in Table 2, given the relative concentrations of the hydrogen abstracting species in each of the gas-phase processes, one would expect treatment with UVO to be as effective as flame, corona and plasma in hydrogen abstraction.

Oxidation

Once a polymer alkyl radical ($R\bullet$) is formed, it will react with gas-phase species such as O_3, O_2, O, H, OH, $HO_2\bullet$, or H_2O_2. All of these reactions are likely to be fast, non-rate-determining reactions [10]. Therefore, the products formed by the reactions of surface alkyl radicals with these gas-phase species should be approximately proportional to the relative gas-phase concentrations of these various species. This is one of the key concepts that helps to explain the differing results obtained with each surface-oxidation method.

LMWOM

Each of the five gas-phase treatment processes produces an oxidized PP surface. LMWOM is not necessarily produced on the oxidized surface, indicating differing reaction mechanisms for each of the treatment processes.

For PP, it is widely accepted that chain scission and the lowering of the molecular weight of oxidized PP occurs primarily through the β-scission reaction [9,11]. The reaction rate constant for the β-scission of PP alkoxy radicals is ca. 10^3 L mol^{-1} s^{-1} [13]. Polymer alkoxy radicals should, therefore, be the main precursor to LMWOM. There are several routes to alkoxy-radical formation in PP oxidation mechanisms:

1. the direct formation of alkoxy radicals from the reaction of polymer alkyl radicals with atomicO:

$$R\bullet + O \rightarrow RO\bullet \quad (4)$$

2. the reaction of polymer peroxy groups with atomic O:

$$RO_2\bullet + O \rightarrow RO\bullet + O_2 \quad (5)$$

3. the reaction of peroxy groups to form hydroperoxy groups, which subsequently decompose to form alkoxy groups:

$$RO_2\bullet + R'H \rightarrow RO_2H + R'\bullet \quad (6)$$

$$RO_2H \rightarrow RO\bullet + OH \quad (7)$$

4. the reaction of ozone with alkyl radicals:

$$R\bullet + O_3 \rightarrow RO\bullet + O_2 \quad (8)$$

The reactions of either O or O_3 with polymer radicals are undoubtedly fast, with rate constants > 10^9 L mol^{-1} s^{-1} [14]. Gas-phase hydrocarbon alkyl radicals react with O_3 in the gas phase at rates of up to five times faster than the analogous reactions with O_2 [14]. When O_3 is present, route (4) to alkoxy formation is almost certainly important.

On the other hand, route (3) is quite slow. As shown by the kinetic data in Table 1, the formation and decomposition of hydroperoxides is considerably slower than the subsequent alkoxy β-scission reaction. The route to alkoxy formation from peroxy thus appears to be many orders of magnitude slower than the reactions involving atomic O or O_3. Therefore, extensive, rapid scission and the formation of detectable LMWOM may be strictly associated with reactions involving atomic O and O_3. If the scission process proceeds sufficiently, gaseous products such as H_2O, H_2, CO, and CO_2 will form, leading to the removal (ablation) of the polymer [15,16].

Process Comparisons

Based on this discussion of the routes and mechanisms available for the production of LMWOM, the five gas-phase modification processes were examined. Flame treatment does not result in the formation of LMWOM despite a high level of oxidation but the formation of nodules on the PP fibrils has been noted by AFM.

In a fuel-lean flame, hydrogen abstraction is primarily accomplished by OH radicals. Once the alkyl radical is formed, it reacts rapidly with O_2 and other gas-phase species in the flame. All of these reactions with the alkyl radical are fast, non-rate-determining reactions. Therefore, the mix of oxidized products that is formed on the PP surface should be in approximate proportion to the concentrations of the gas-phase species present at the PP surface. In a fuel-lean flame, O_2 is by far the most common oxidizing species and we will consider molecular oxygen as the species responsible for affixing most of the oxygen to the PP surface through the reaction:

$$R\bullet + O_2 \rightarrow RO_2\bullet \quad (9)$$

In earlier papers, we showed that, in flame treatment, the extent of surface oxidation best correlates with the gas-phase concentration of OH radicals near the PP surface [7,17]. Even though O_2 actually leads to most of the oxidation in flame treatments, the reaction of O_2 with alkyl radicals is not rate limiting. The rate-limiting step in the overall flame treatment process is hydrogen abstraction by OH radicals.

The reaction of PP in the ozone-only treatment process is a slow one, requiring many minutes of exposure to generate significant oxidation of the surface [18]. Even when the ESCA O/C atomic ratio of the ozone-treated PP becomes > 0.10 at long exposure times, no LMWOM is detected until the exposure times exceed 45-60 minutes [8]. Oxidation of PP by ozone is slow because there are no efficient hydrogen-abstraction agents present. The rate constant for the reaction of O_3 with PP is only 0.08 L mol^{-1} s^{-1}, which is many orders of magnitude slower than the reactions rates of O, OH, or H with PP (which are of the order of 10^8 – 10^9) [19]. The accepted reaction of O_3 with polyolefins is [18,19]:

$$RH + O_3 \rightarrow RO_2\bullet \quad (10)$$

The polymer peroxy radical ($RO_2\bullet$) subsequently reacts more slowly to form carbonyls, carboxylic acids, and hydroperoxides [18,19]. Only the formation of the carboxylic acid leads to chain scission:

$$ROO\bullet \rightarrow R{=}O,\ RCOOH,\ RO_2H \quad (11)$$

Flame treatment and ozone-only treatment do not show the formation of LMWOM within normal treatment regimes. The lack of LMWOM can be traced back to the fast formation of polymer peroxy radicals rather than alkoxy radicals at the surfaces of the PP in these two processes. Only one of the subsequent slow reactions of the polymer peroxy radical leads to chain scission. For the flame treatment, there is a fast hydrogen-abstraction reaction available which enables the reaction of the alkyl radical with O_2 to form the polymer peroxy radical. This set of reactions results in a high level of oxidation and no LMWOM formation. For the ozone-only treatment there is no fast route available for the formation of the alkyl radical: instead the oxidation of the surface proceeds slowly and directly from the reaction of the polymer with O_3 to form the polymer peroxy radical. This set of reactions leads to lower levels of oxidation and limited chain scission.

Study of the UVO treatment leads to some interesting observations. When PP is exposed to ozone in the presence of UV, LMWOM is formed readily and apparently to a great extent even though the O/C atomic ratio does not reach 0.12 quickly [18,20]. AFM images of PP treated with UVO show ample mounds of agglomerated LMWOM [3].

Léonard et al. suggest that an excess of oxygen atoms actually leads to limited stable functionalization (oxidation) of polyolefin surfaces because oxidative degradation and ablation of the polymer will predominate [21]. In other words, if scission initiated by O atoms is too vigorous, the polymer is etched away before a large number of oxygen-containing functional groups can be affixed to the surface. The UVO process is rich in O atoms, O_3 and O_2. The O atoms are available both for fast hydrogen abstraction and reaction to form polymer alkoxy radicals. Also freely available in the gas phase is O_3 at concentrations similar to the concentration of O atoms and O_2. The reaction mechanisms of all of these species have pathways that lead to the formation of polymer alkoxy radicals which are the precursors to the formation of LMWOM. The high concentrations of these reactive species, in conjunction with the observed formation of LMWOM before high levels of oxidation are reached, indicates that there may be an equilbrium process present that allows the formation of a large number of alkoxy radicals which in turn leads to massive amounts of LMWOM and ablation. This is consistent with the work of Holländer et al. in their study of the vacuum UV (VUV) induced oxidation of PP [10]. They suggest that the extent of surface oxidation can saturate at relatively low levels (as low as an ESCA O/C atomic ratio of 0.07) because of the continuous renewal of the PP surface by oxidative ablation. Low-molecular-weight products are continuously formed by the action of O atoms, then desorb from the surface, exposing new, less-oxidized PP molecules. A competition between oxidation, on one hand, and scission and desorption, on the other hand, leads to the behavior that we observe with UVO reactions.

The oxidation of PP by corona discharges is also primarily a free-radical process, with little contribution from ions or UV radiation. As shown by the modeling data in Table 2, a corona is characterized by high concentrations of O_3, O_2, O, HO_2, and H_2O_2, but a relatively low concentration of OH and virtually no H atoms. In a corona, as the RH increases, the concentrations of O_3 and O decrease while the concentrations of OH and H_2O_2 increase. In a corona, hydrogen abstraction is primarily accomplished by O with some contribution from OH, particularly at high RH:

$$RH + O \rightarrow R\bullet + OH \quad (12)$$

$$RH + OH \rightarrow R\bullet + H_2O \quad (13)$$

Once the polymer alkyl radical is formed, it will react with most gas-phase species in the corona at about the encounter frequency. Therefore, the oxidation of the PP occurs primarily by the reaction of R● with O_2 and O_3, which are present in large numbers relative to any of the other oxidizing species in the corona [22]:

$$R\bullet + O_2 \rightarrow RO_2\bullet \quad (14)$$

$$R\bullet + O_3 \rightarrow RO\bullet + O_2 \quad (15)$$

The reaction of O_3 with R● generates most of the RO● that then leads to scission and the formation of LMWOM. We now realize that there are simply not enough O atoms to accomplish all of the hydrogen abstraction and alkoxy formation that must occur in corona treatment, so that there must be another fast route to the formation of alkoxies. That route is through ozone reaction with alkyl radicals.

The smaller amount of LMWOM that is formed at higher RH is a result of lower [O_3], lower [O], more OH, and more H_2O_2. These trends in active species concentrations should reduce alkoxy formation and thereby reduce the amount of LMWOM formed. The concentration of O_2 should not be significantly affected by relative humidity, so O_2 must not have a major role in the formation of polymer alkoxy groups.

The reaction of PP in downstream air or oxygen plasmas has also been found to generate an oxidized surface similar to that of a corona. By locating the PP downstream of the plasma itself, the effect of the ions and electrons generated inside the plasma is negated. Downstream from the plasma, only the relatively long-lived electronically excited species exist long enough to react with the PP surface. Such species include atomic O which is efficient at hydrogen abstraction. Wertheimer and coworkers have shown that vacuum UV can cause hydrogen abstraction. They have also demonstrated that the action of UV and atomic O are synergistic [23]. Holländer et al. have observed that "the important step [in surface oxidation processes] is the formation of the alkyl radical in the presence of oxygen [24]. Whether this radical is formed by VUV photolysis, by hydrogen abstraction by any kind of radical including O atoms, or by an ion does not seem to be important for the following [oxidation] reactions."

Plasmas generate singlet O_2, O, various excited states of atomic O and vacuum UV, all of which can initiate the reaction sequence. Given the concentrations of the hydrogen abstracting species, it is likely that the O is the primary

abstraction species, possibly aided by VUV. A path to LMWOM formation involving primarily O seems easy to envision.

Summary

The rate-limiting step in all of the processes considered in this discussion is hydrogen abstraction. For a given process, the rate of overall oxidation is highly dependent upon which specific abstracting agent dominates the gas phase.

Once hydrogen is abstracted and a polymer alkyl radical is formed, the next gas-solid reaction step is fast, at about the encounter frequency. The specific reaction that occurs depends primarily upon the relative concentrations of all gas-phase species present near the PP surface.

Although reactions of alkyl radicals with O_2 may dominate the post-abstraction mechanism, the reactions of other species with lower gas-phase concentrations are also critically important. In fact, is it largely the reactions of these secondary gas-phase species that determine the differences between the various oxidation techniques. In particular, these secondary reactions determine whether or not LMWOM is formed during oxidation.

Abstract
Nitrogen-doped zinc oxide films were deposited in an $Ar/N_2/O_2$/DEZ expanding thermal plasma at different N_2/O_2 ratios. All films exhibit n-type conductivity, a high transmission in the visible and preferential *c*-axis orientation. For the ZnO films deposited at low O_2 flows the ERD/RBS measurements indicate a factor of 10 increase in the incorporated N and C levels, as compared to the undoped samples (from below 0.1% to about 1%). An explanation is given by the mass spectrometry results, which show high HCN concentrations in these working conditions. For high O_2 flows on the contrary, HCN is hardly present, while NO is predominantly formed. In contradiction with earlier predictions, the presence of NO in the deposition region leads to almost no N incorporation in the ZnO film.
Keywords nitrogen-doped ZnO, expanding thermal plasma, mass spectrometry

1. Introduction

Zinc oxide (ZnO) is a wide bandgap (3.2 eV) II-VI compound semiconductor, which gained a lot of interest in the last decades due to major advantages such as the low fabrication costs, the possibility of wet chemical etching, and stability during radiation exposure. Besides this, the large exciton binding energy (60 meV) makes ZnO a good alternative in terms of efficiency and stability to the widely used GaN (26 meV) for blue and UV solid-state emitters and in detector applications. For these applications, both high quality n- and p-type ZnO need to be fabricated.

Reproducible n-type ZnO material with high transmittance in the visible (>80%) and low resistivity (10^{-2}-10^{-4} Ωcm) has already been obtained using various deposition techniques, e.g. magnetron sputtering, atomic layer deposition, molecular beam epitaxy, and also expanding thermal plasma CVD [1-4]. This makes n-type ZnO a good alternative to the already commercially produced, but more expensive, indium tin oxide (ITO). Intrinsically, ZnO is n-type conductive, due to native donor defects, i.e. interstitial Zn/O vacancies and unintentional H incorporation [5]. The conductivity can be further increased by doping with Al, Ga, F. On the other hand, obtaining p-type ZnO is more complicated, because of the presence of native defects and a low dopant solubility [6]. Theoretical calculations have shown that nitrogen is the most suitable p-type dopant for zinc oxide [7]. Also other II-VI semiconductors, such as ZnTe and ZnSe, have been efficiently p-doped with nitrogen [8,9].

In this work the ZnO films are deposited using an argon-fed expanding thermal plasma, in which diethylzinc ($Zn(C_2H_5)_2$, DEZ) and oxygen gas are admixed downstream. This technique has the advantage of high deposition rates and has shown good reproducibility. Also, by adding nitrogen gas in the cascaded arc plasma source, the nitrogen molecules are dissociated to a high degree [10], leading to a high N radical density in the deposition chamber. For the p-type doping of ZnO the incorporation of nitrogen via N-radicals is desirable as N acts as an acceptor, while N_2 acts as a double donor [11].

Here we discuss the effect of nitrogen addition on the plasma chemistry and on the electrical and optical properties of the ZnO films deposited on glass substrates by expanding thermal plasma CVD, with the final aim of obtaining N-doped p-type ZnO.

2. Experimental

The ZnO films were deposited using an expanding thermal plasma, generated in an argon/nitrogen-fed high pressure (300-600 mbar) cascaded arc. The plasma expands supersonically in the low pressure (0.2-2 mbar) deposition chamber, where diethylzinc and O_2 are injected, via two separate injection rings, situated at 30 cm and 6.5 cm from the plasma source (figure 1). The diethylzinc is evaporated at constant rate by a control evaporating and mixing unit (CEM).

The substrate used for all films was 0.7 mm thick Corning 7059 glass. The deposition rate varied between 0.2 and 0.6 nm/s and the deposited films were between 400 and 600 nm thick. The substrate temperature was kept at 200^{o}C in all experiments. The experimental conditions are summarized in table I.

The film thickness was measured using a step profiler. The electrical properties, i.e. sheath resistance, carrier density and mobility, were measured at room temperature, using the van der Pauw method. The film crystallinity was studied by X-ray diffraction (XRD), while the film composition was determined by Elastic Recoil Detection (ERD) and Rutherford BackScattering (RBS) measurements. A double-beam spectrophotometer was used to acquire the transmission spectra in the 200-1100 nm range. The deposition process was monitored using a Balzers Prisma Quadrupole Mass Spectrometer (MS). The pressure in the MS measuring chamber was between $1.4 \cdot 10^{-5}$ and $2.2 \cdot 10^{-5}$ mbar. All the signals were normalised to the signal of He (4 amu) to account for variations in e.g. pressure or temperature. Before performing the measurements, the linear mass response with pressure in the chamber was checked.

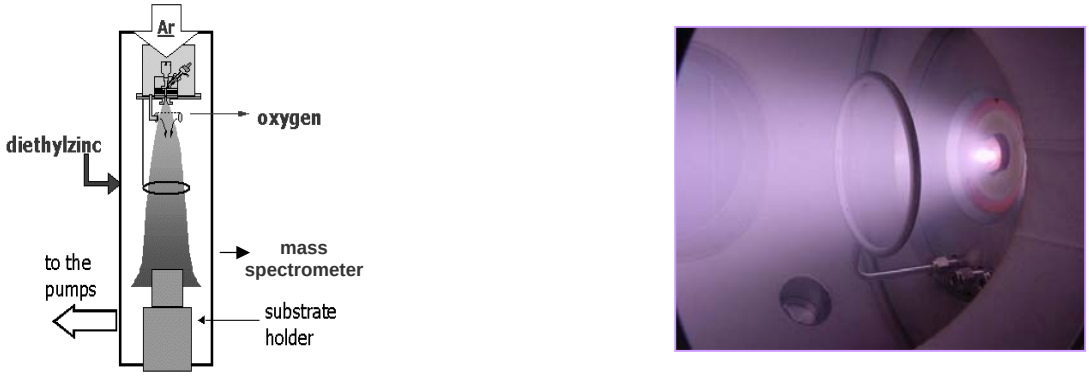

Figure 1. a) Schematic of the deposition reactor; b) Argon expanding thermal plasma (Φ_{Ar} = 1000 sccm, $p_{chamber}$ = 0.3 mbar); the O_2 ring and the arc nozzle are visible.

Table I. Overview of the experimental conditions

Plasma generation	
Argon gas flow (Φ_{Ar})	840-2000 sccm
Nitrogen gas flow (Φ_{N_2})	0-100 sccm
Arc current (I_{arc})	50 A
Plasma expansion & precursor injection	
Oxygen gas flow (Φ_{O_2})	20-150 sccm
DEZ flow (Φ_{DEZ})	2.5 g/h
Pressure in expansion chamber ($p_{chamber}$)	0.2-2 mbar

3. Results and Discussion

Hereby, we present our first attempts to incorporate molecular nitrogen in the expanding thermal plasma deposition process of ZnO. In order to understand how the interaction between species in the reactor takes place and how this influences the properties of the deposited films, preliminary studies of the stable species present in the reactor using mass spectrometry were performed. Their outcome is further correlated with the structural and electro-optical properties of the ZnO films.

3.1. Mass spectrometry

Mass spectrometry is used for monitoring the stable species present in the reactor. While the presence of atomic nitrogen in an Ar/N_2 expanding thermal plasma has already been demonstrated [10], it is not known what occurs in a more complex plasma chemistry, such as the $Ar/N_2/O_2/DEZ$ deposition plasma case. The aim of these measurements is therefore to investigate the presence of N-containing species when O_2 and DEZ decomposition products are present in the reactor.

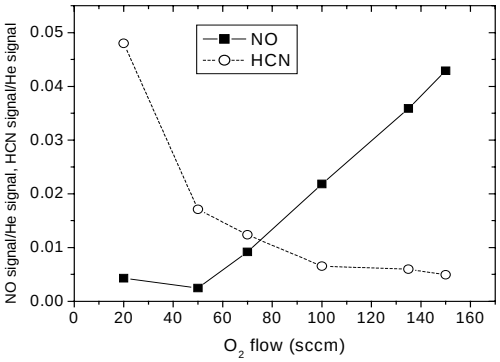

Figure 2. The NO and HCN relative intensities as a function of O_2 flow. The other conditions are Φ_{Ar} = 1000 sccm Ar, I_{arc} = 50 A, Φ_{N_2} = 50 sccm, Φ_{DEZ} = 2.5 g/h, $p_{chamber}$ = 0.6 mbar.

The only N-containing species which can be univocally identified in the mass spectra taken for an $Ar/N_2/O_2/DEZ$ plasma are hydrogen cyanide (HCN) and nitric oxide (NO). Their behavior with the O_2 flow shows two distinct regions (figure 2): for O_2 flow values lower than 60 sccm HCN is dominant, while for flow rates higher than 100 sccm, NO becomes dominant.

3.2. Film properties

The films are highly transparent (>80%) in the visible part of the spectrum for both undoped and nitrogen-mixed ZnO films, at all nitrogen mixing ratios (figure 3). The bandgap does not change significantly, the impurity concentration being probably too low for this effect to be detectable in a normal transmission measurement. Other more sensitive measurements, such as cathodoluminescence or photoluminescence at low temperature are necessary for the detection of the levels introduced by impurities inside the bandgap.

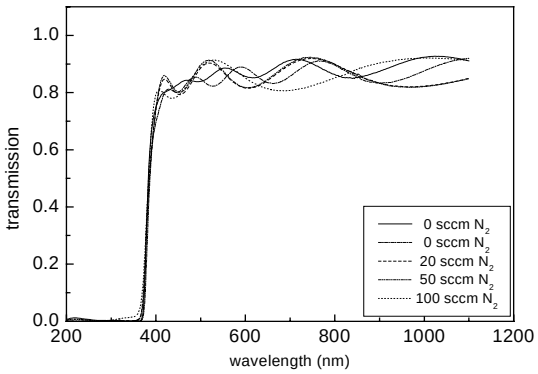

Figure 3. Transmission spectra for ZnO films deposited at different N_2 mixing ratios. The other conditions are Φ_{Ar} = 840 sccm, I_{arc} = 50 A, Φ_{O_2} = 50 sccm, Φ_{DEZ} = 2.5 g/h, $p_{chamber}$ = 0.6 mbar.

The XRD measurements (figure 4) show that all films are crystalline, with strong preferential orientation along the *c*-axis. The average crystallite size for all films was calculated from the (002) peak width using the Sherrer formula and is between 32 and 48 nm. This agrees with the values determined by other groups for polycrystalline ZnO [12].

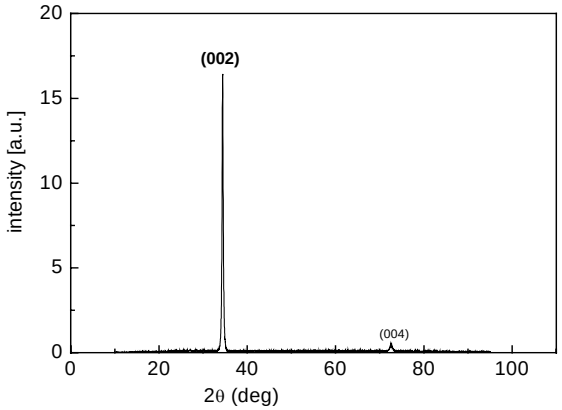

Figure 4. Typical XRD spectrum for an expanding thermal plasma-deposited ZnO film (for deposition conditions see table I).

The film resistivity gradually increases with higher nitrogen flow rates (figure 5a), while the carrier density is independent of the N_2 mixing ratio (figure 5b). The increase in resistivity can be attributed to a drastic decrease in mobility (figure 5c). This can be due to two effects: either a decrease in the grain size, the carrier scattering at grain boundaries being enhanced, or, very probable in our case, to an increased carrier scattering at impurities. These findings are in accordance with those of Sato *et al* [13]. For the sample deposited at 100 sccm N_2 flow and 50 sccm O_2 a Hall measurement could not be made with our system, probably due to a very low carrier mobility leading to a very low Hall potential. Also all samples deposited at high O_2 flow had resistivities outside the Hall measurement range.

The ERD/RBS measurements showed an N and C impurity level in the undoped ZnO films lower than 0.1%. For the films deposited at 50 sccm O_2 flow we observed an increase in the incorporated N and C to about 1%. On the contrary, for the films deposited at an O_2 flow of 150 sccm, no significant N and C incorporation is noticed.
Several articles already showed that NO potentially contributes to the growth of N-doped/p-type ZnO [14,15], while, to our knowledge, the influence of HCN on the ZnO film properties has not been reported yet.
After correlating the ERD results with the mass spectrometry measurements we can conclude that, for the films deposited at low O_2 flow, where the HCN concentration in the deposition region seems to be higher than the NO concentration, C and N incorporate easily, probably due to a high CN radical concentration. However, it is not clear what effect the additional carbon has on the N-doped ZnO films and what kind of bonds it forms in the material. Recent reports [16] give proves for CN incorporation in the ZnO film when similar mixtures are used. On the other hand, when NO is the dominant N-containing species in the plasma, almost no N or C are detected in our ZnO films. This seems to point out that, even when present in considerable amounts in the reactor, NO leads to almost no N incorporation in the ZnO film in these conditions.

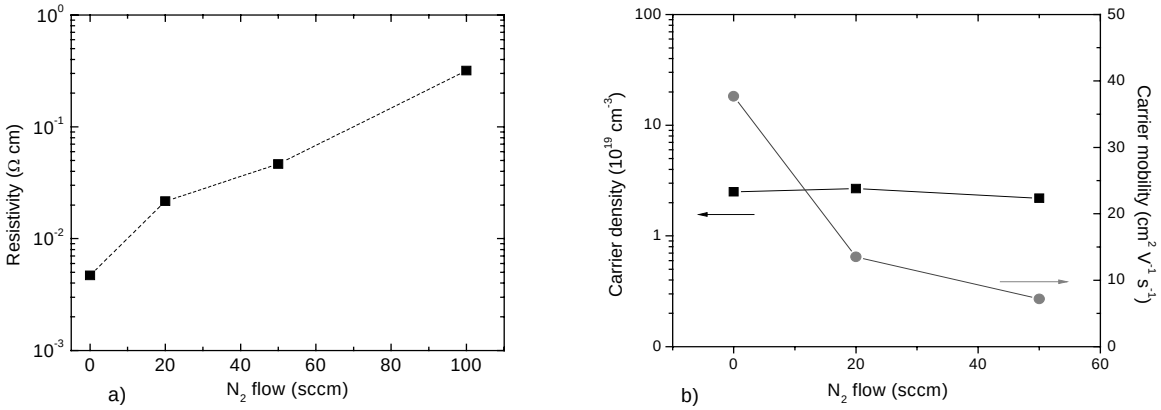

Figure 5. a) Resistivity of ZnO films as a function of the N_2 mixing ratio; b) The electron density and Hall mobility as a function of the N_2 mixing ratio; The other conditions are Φ_{Ar} = 840 sccm, I_{arc} = 50 A, Φ_{O_2} = 50 sccm, Φ_{DEZ} = 2.5 g/h, $p_{chamber}$ = 0.6 mbar.

4.Conclusions

We studied the N doped ZnO film deposition process in an $Ar/N_2/O_2$/DEZ expanding thermal plasma at different nitrogen mixing ratios. All films exhibited n-type conductivity, a high transmission in the visible and a preferential *c*-axis orientation. An increase of resistivity was also observed, probably caused by an increased carrier scattering at impurities. For the ZnO films deposited at low O_2 flows the ERD/RBS measurements indicated a factor of 10 increase in the incorporated C and N levels, as compared to the undoped samples (from below 0.1% to about 1%). This is in accordance with the mass spectrometry results, which showed considerable HCN concentrations in these working conditions. For O_2 flows higher than 100 sccm on the contrary, HCN is hardly present, while NO is predominantly formed. Working in these high oxygen flow-conditions, however, leads to almost no C and N incorporated, showing that, even when present in considerable amounts in the reactor, NO leads to almost no N incorporation in the ZnO film in these conditions.

OPTIMIZATION AND UP-SCALING OF PLASMA POLYMERIZATION PROCESSES

D. Hegemann, D.J. Balazs, M. Amberg, A. Fischer

EMPA Materials Science and Technology, Lerchenfeldstrasse 5, 9014 St.Gallen, Switzerland

Abstract
Progress in plasma polymerization processes can be made considering the reaction parameter power input per gas flow. This specific energy determines the plasma-chemical processes within the active plasma zone, known as concept of macroscopic kinetics. Regarding the geometry of plasma reactors and using well-defined, symmetric set-ups, a generalized activation energy is derived by evaluating the deposition rates of radical-dominated plasma polymerization processes. Thus, the presented concept enables the comparison of different processes such as HMDSO, methane, and acrylic acid discharges as well as their up-scaling.

Keywords: RF plasma, specific energy, activation energy, reactor geometry, pulsed plasma

Introduction

Plasma chemistry enables the deposition of thin films showing characteristics beyond wet chemical coatings. Using hexamethyldisiloxane (HMDSO), for example, chemical composition, cross-linking, and film thickness of SiOC:H films can be adjusted over a wide range [1,2]. Films with desired properties like wettability, elasticity, hardness, internal stresses, abrasion resistance, biocompatibility, and permeability can thus be designed. Different substrate materials and geometries like e.g. textiles, fibers, and membranes can be treated with high penetration [3]. However, the broad parameter range available as well as the distinct influence of reactor geometry complicates the process optimization and up-scaling. Therefore, a deeper understanding of process relevant correlations also on a macroscopic level is desirable.

As it is well-known, plasma polymerization – that means radical-promoted – processes are governed by the composite parameter power input per gas flow W/F, which relies on the concept of macroscopic kinetics [4]. This statistical approach considers the energy invested per particle within the active plasma zone yielding an excited state such as a radical and subsequent recombination in a passive zone yielding a stable product such as a deposition. A monomer depending activation energy E_a can be derived by evaluating the mass deposition rates R_m [1,2,5] considering that

$$\frac{R_m}{F} = G \exp\left(-\frac{E_a}{W/F}\right) \tag{1}$$

with a reactor depending geometrical factor G. An Arrhenius-type plot of Eq. (1) by variation of W/F parameters gives a straight line, where its slope corresponds to E_a (Fig. 1).

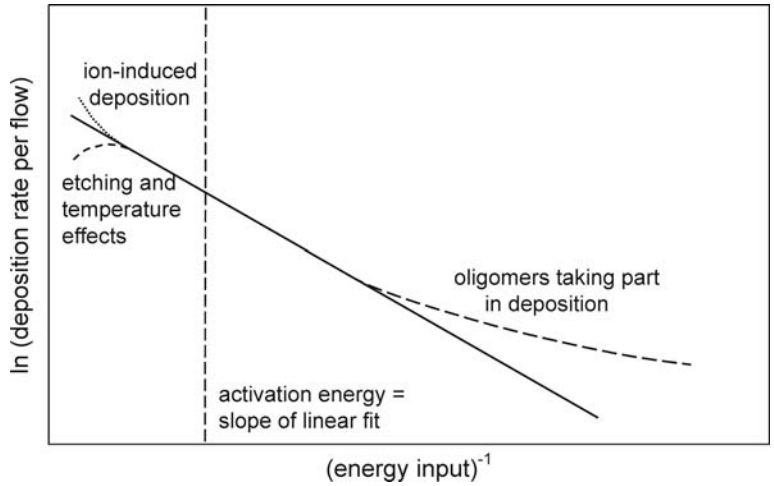

Fig. 1: Dependence of deposition rate (per gas flow) on (inverse) energy input. The straight line is given by Eq. (1) describing the deposition rates around the activation energy. Deviations might be found at low and high energy inputs.

While Eq. (1) agrees very well with experimentally found deposition rates at energy inputs around E_a, some deviations might be obtained at low power inputs due to different precursors or oligomers taking part in film growth and at high power inputs indicating ion-assisted or temperature effects. Hence, different effects can be observed using the evaluation of deposition rates.
At an energy input below the activation energy, for example, swellable hydrogel films can be deposited such as PEO-like coatings (Fig. 2). Increasing the energy input into the active plasma zone the degree of retention of functional groups can be controlled due to enhanced fragmentation at higher energies. While the hydrophobic properties of pp-HMDSO coatings slightly decrease at increasing energy input, the cross-linking and thus the mechanical properties can be enhanced. Further energy input leads to the formation of dense barrier coatings, when e.g. hydrocarbons are used as precursors.

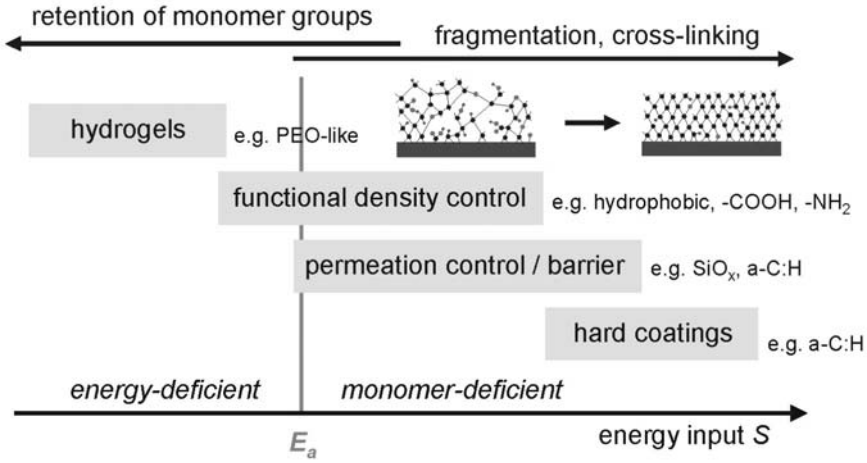

Fig. 2: Different regimes of functionality that can be covered by plasma polymerization.

Hence, the evaluation of the deposition rates to obtain the monomer-specific activation energy gives hints to find the optimum process parameters.
However, to obtain the generalized activation energy for a certain plasma polymerization process the real energy input within the active plasma zone that contributes to film deposition $S = W/F\,\big|_{dep}$ has to be known. Common plasma reactors often show power losses, e.g. due to the power coupling or secondary plasmas, and parts of the incoming particles might be pumped away without being activated, which might strongly affect the value of W/F. Therefore, geometrical considerations should be taken into account. Assuming a vertical flow of the gas particles towards the deposition area the real power delivered to the active plasma zone should be scaled by the expansion of the active plasma zone d_{act} above the electrode area A_{dep} to the total discharge volume V_{dis}, whereby the residence time of the monomer in the active plasma zone is regarded by

$$W\big|_{dep} = W\,\frac{A_{dep}\,d_{act}}{V_{dis}}\,. \tag{2a}$$

The real flow that contributes to film deposition should be scaled by the volume between gas inlet and electrode area $A_{dep}\,d_{gas}$ per total volume V_{gas} where the gas is flowing, using

$$F\big|_{dep} = F\,\frac{A_{dep}\,d_{gas}}{V_{gas}}\,, \tag{2b}$$

which finally leads to the similarity parameter [6]

$$S = \frac{W}{F}\,\frac{d_{act}\,V_{gas}}{d_{gas}\,V_{dis}}\,. \tag{3}$$

The derived geometrical correction is important e.g. for unconfined plasmas, corner-dominated discharges, where V_{gas} is larger than V_{dis}, and samples placed directly in the discharge (like in tubular reactors), where V_{gas} is smaller than V_{dis}. For volume-dominated discharges and small sheath length compared to the plasma expansion, on the other hand, the correction is close to one. In symmetric reactors, where the plasma fills the whole space between plane parallel electrodes, V_{gas} also equals V_{dis} and well-defined conditions are present. This work thus focuses on the evaluation of the deposition rates within different symmetric reactors using HMDSO, methane, and acrylic acid as monomers aimed for the optimization and up-scaling of plasma conditions.

Experimental

To obtain well defined plasma conditions capacitively coupled RF discharges (13.56 MHz) within symmetric reactor set-ups were considered. Three reactors with plane parallel electrodes which differ in size were compared. The two smaller reactors are cylindrical reactors, whereas the larger apparatus has rectangular electrodes. One electrode contains a gas shower yielding a vertical flow towards the counter electrode, where the substrates were placed at the distance d_{gas} from the gas inlet (Fig. 3a). Since the electrodes confine the vacuum chamber, the RF is directly coupled to the electrode without an electrical feed-through needed. V/I probe measurements thus reveal a 95% power conversion into the plasma. A small bias potential V_{bias} lower than 10% of the excitation voltage V_0 ($V_{RF} = V_0 \sin \omega t + V_{bias}$) was measured proving the symmetry of the set-ups. Moreover, homogeneous deposition rates over the entire deposition area A_{dep} were obtained. Due to the construction of the reactors, the whole vacuum chamber is filled by the discharge, and the gas volume V_{gas} equals the discharge volume V_{dis}. To obtain the length of the active plasma zone d_{act} the sheath widths can be observed, e.g. from the luminosity distribution (Fig. 3b). Some characteristics of the reactors are given in table 1.

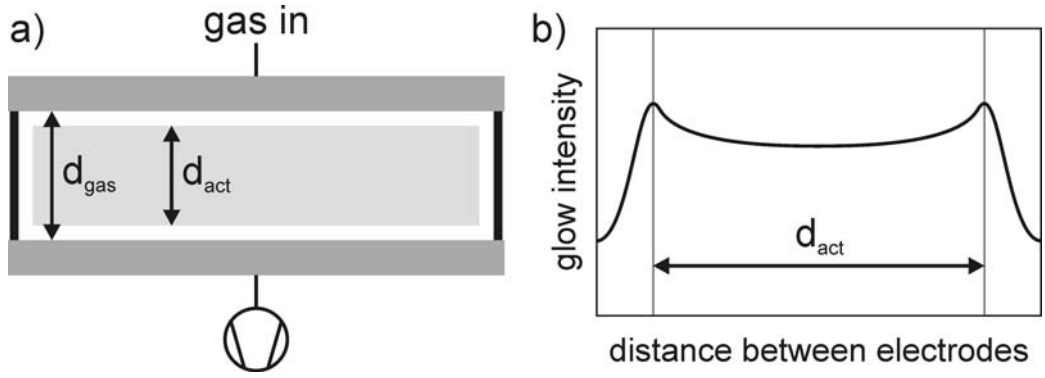

Fig. 3: (a) Schematic drawing of the reactor set-ups used. (b) The glow intensity indicates the plasma boundaries between sheath and bulk plasma and gives the length of the active plasma zone.

As monomers hexamethyldisiloxane (HMDSO), methane (CH_4), and acrylic acid (Aac) were used. Pure HMDSO and CH_4 discharges were run at a pressure of 10 Pa, while 30 Pa was used for the pure Aac discharge. The mass deposition rate was obtained by weighing the deposition on glass slides before and after plasma treatment.

Table 1: Characteristics of the used symmetric plasma reactors.

reactor	A_{dep} [cm^2]	$-V_{bias}/V_0$	d_{gas} [cm]	d_{act} [cm]		
				HMDSO	CH_4	acrylic acid
small	310	0.08	5.3	4.3		3.9
medium	700	0.05	5.0	4.0	3.2	
large	1150	0.05	8.5	7.5	6.7	

Results and discussion

At first HMDSO discharges were considered using all three symmetric reactors. Regarding the introduced similarity parameter $S = W\, d_{act} / F\, d_{gas}$ for $V_{gas} = V_{dis}$ it can be seen in Fig. 4 that the same slope of the mass deposition rates per monomer flow R_m/F in the Arrhenius-type plot was obtained for the different reactors. Thus, a generalized activation energy E_a can be derived which was found to be 55 J/cm^3 for HMDSO corresponding to 1230 kJ/mol (12.8 eV per molecule). This energy is exactly required to initiate HMDSO polymerization by breaking one Si-C (360 kJ/mol) and one Si-O bond (452 kJ/mol) and cross-linking by cleavage of a C-H group (435 kJ/mol). E_a is thus identified to be the minimum activation energy to start the polymerization process, i.e. to activate each monomer molecule and to avoid oligomerization [7].

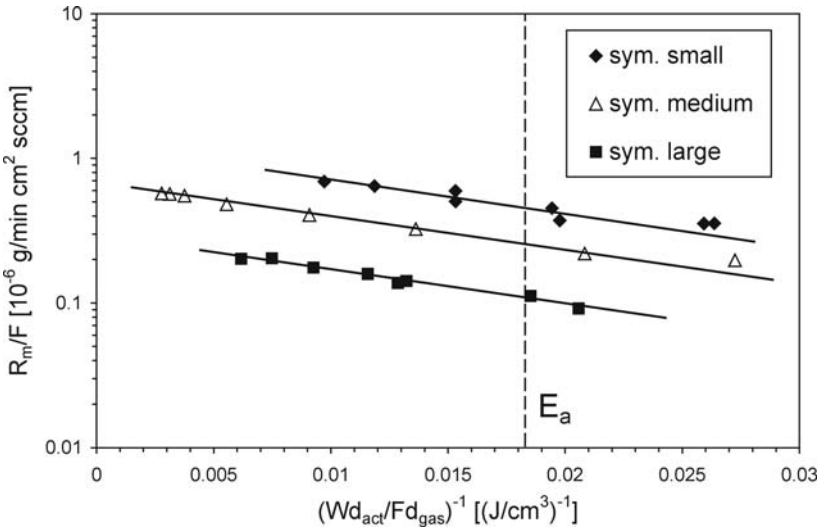

Fig. 4: Mass deposition rates per monomer flow depending on the similarity parameter (energy input) for pure HMDSO discharges within three different symmetric reactors.

Moreover, all three reactors were proven to show well defined deposition conditions. Note, that the proposed concept relates to the plasma chemistry taking place within the plasma zone determined by the activation energy. It is not related to the absolute deposition rate, which is further influenced by the interaction of energetic particles during film growth, by electric fields, conversion of monomer flow into film growth (by nucleation sites), and also by geometrical factors [2,3].

As a second monomer methane was used with two reactor set-ups (medium and large). Comparing both reactors, it can be shown that a generalized activation energy can be derived from the evaluation of the deposition rates (Fig. 5). E_a was found to be 23 J/cm^3 corresponding to 535 kJ/mol (5.3 eV per molecule).

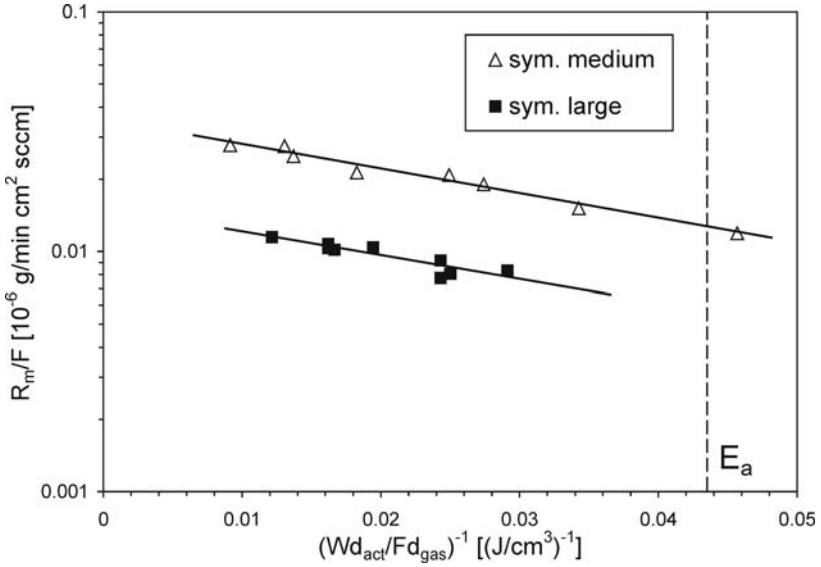

Fig. 5: Mass deposition rates per monomer flow for pure methane discharges within two different symmetric reactors.

To obtain CH_3 radicals in CH_4 discharges an energy of 435 kJ/mol is required. The additional energy might be used to break hydrogen molecules, since atomic hydrogen is considered to determine the hydrocarbon layer growth by transformation of higher hydrides into mono-hydrides yielding H/C ~1 for polymer-like films [8]. However, different precursors and growth zones (at different energies) are discussed for methane discharges [9]. As for the HMDSO discharges, higher absolute deposition rates were obtained for smaller reactors indicating a higher conversion of monomer flow into film growth.
The small reactor was also used to perform discharges with acrylic acid with the aim to retain carboxylic functional groups within the plasma. Therefore, not only continuous wave, but also pulsed plasma conditions were applied. While the on time was kept at 1 ms, the off time was varied between 1 and 40 ms to enable very low energy inputs into the plasma. At moderate energy inputs CW and pulsed plasmas can be compared. Regarding the deposition rate per flow a linear regime was obtained at energy inputs around the activation energy (Fig. 6). Here, Eq. (1) is applicable and E_a was found to be 33 J/cm^3 which corresponds to 740 kJ/mol (7.7 eV per molecule).

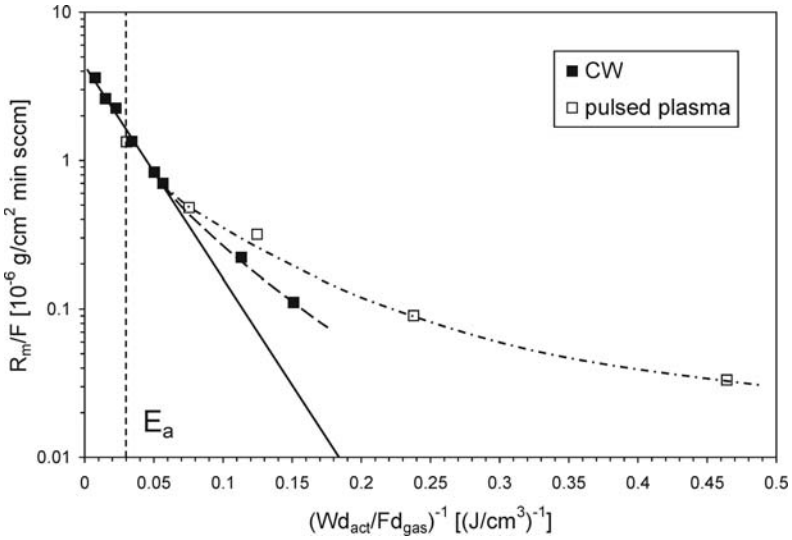

Fig. 6: Mass deposition rates per monomer flow for pure acrylic acid discharges for CW and pulsed plasma conditions. For pulsing the effective power input was used.

This energy is enough to open the double bond C=C in the acrylic acid molecule and to break one C-H bond for cross-linking reactions, while maintaining the carboxylic group in many molecules intact. For chemical and statistical reasons, however, the carboxylic group might also be dissociated. Therefore, many plasma groups investigate lower energy inputs by using power modulation. The usefulness of pulsed plasmas other than for reducing the average power input is controversially discussed within the literature. It is reported that deposition rates can be increased due to film growth during the off period [10,11], while others claim that no increase in the density of carboxylic groups can be obtained at comparable CW and pulsed plasma conditions [12]. As can be seen from Fig. 6, an increase in deposition rate can merely be observed at very low energy inputs for power modulated acrylic acid discharges. It can be assumed that oligomers strongly contribute to film growth (chain growth polymerization mainly during the off period). At moderate energies (around E_a), on the other hand, no difference in deposition rate is obtained and both CW and pulsed plasma conditions are comparable explaining the finding of similar functional densities [12]. While the highest retention of carboxylic groups can be obtained at energies around E_a [13], the stability of the films can be strongly enhanced using elevated energy inputs. More cross-linked films with a lower density of functional groups are able to withstand washing tests which is important for the use in bio applications [12,14].

Conclusions

In this work the introduced concept of a similarity parameter by considering the geometry of the discharge was proven for polymerizable gases such as a siloxane, hydrocarbon, and a vinyl-type monomer. Recently, we were able to show that the concept also works by addition of non-polymerizable gases such as O_2, N_2, Ar, NH_3, etc. by considering the modified flow $F = F_m + a\ F_c$ (F_m: monomer gas, F_c: non-polymerizable or

carrier gas), where the factor a (< 1) is experimentally determined [15]. A generalized activation energy for these different monomers can be derived by the evaluation of the mass deposition rates supported by the use of well-defined plasma conditions within symmetric reactors. For the use of asymmetric reactors it has to be regarded that the active plasma zone might expand into the plasma chamber at increasing energy inputs depending on gas flow and pressure [6,7]. Moreover, gas volume and discharge volume might differ and the true power absorption might not be known very accurately due to power losses within the reactor. Nevertheless, the evaluation of the deposition rates enables the identification of a process-specific activation energy that strongly facilitates up-scaling. Furthermore, the comparison of an asymmetric reactor with the well-defined symmetric set-ups increases the knowledge on the considered reactor with respect to power conversion and gas flow conditions using the introduced similarity parameter. For example, we demonstrated that the deposition of stable, hydrophobic pp-HMDSO coatings can be optimized using small, well-defined batch reactors, which was then scaled up to a large web coater to treat textile fabrics in a semi-continuous process [6].

We were able to demonstrate that the concept of macroscopic kinetics by evaluating the deposition rates depending on the specific energy shows many benefits:

- comparison and up-scaling of plasma polymerization processes [7,12]
- insight into plasma-chemical processes regarding the generalized activation energy [7,16]
- optimization of plasma polymerization processes with respect to the activation energy [1,6,7,16,17]
- detection of the influence of non-polymerizable gases on deposition or etching [15,17]
- detection of the influence of additional, e.g. ion-induced, effects [15]
- evaluation of pulsing conditions [12]
- design of functional gradient layers [2,18]
- optimization of power coupling and gas flow conditions (by comparison of activation energies) [7]
- conversion of monomer flow into film growth [2]
- advanced plasma reactor set-up [7]
- re-engineering (insights into old data sets or performed by different groups) [2]
- standard plasma process [7]

Abstract

We succeeded in electron emission from PVDF with C-Au-S ultra thin film by a polarization inversion method, where the C-Au-S film was deposited by co-operation process of plasma CVD and sputtering. With using the electron, it is expected to excite luminescence substance as light emitting element. To realize the light emission, 70 μm thick and 5×5 mm^2 area PZT plate is used in this experiment, where the electron emission window is composed with a tooth type electrode and 1 nm thick C-Au-S semi-conductive layer.

Keywords: PZT, Ferroelectric Substance, Polarization Inversion, Electron Emission, Electro Luminescence

1. Introduction

Electron emission from ferroelectric materials is interested as a new electron source since the emission current of 7A and emitted electron energy of 3KeV were measured at CREN in 1988 [1]. Recently the emitted current was increased up to 200 A [2]. All report were concerned on in-organic substances like as $LiNbO_3$, PZT and others. It is known that PVDF (polyvinylidene fluoride) with ß-type crystal structure shows ferroelectric nature. However there is no report on electron emission from the organic ferroelectric substance like as PVDF.

Electron emission from PVDF was not easy to realize, even if same manner device system was constructed because there is large difference on the physical properties between in-organic and organic ferroelectric substances. Generally in-organic ferroelectric substance has large dielectric constant and small coercive field, but organic ferroelectric substance has small dielectric constant and large coercive field. In order to realize electron emission for organic ferroelectric substance, several problems must be solved.

In this paper, succeeded methods for electron emission from the PVDF will be reviewed. Then our efforts to realize a new light-emitting device will be introduced.

2. Experiment

2.1 Electron emission from PVDF through C-Au-S film [3~5]

PVDF with ß-type crystal structure shows ferroelectric nature, which have a small dielectric constant, large coercive field, and an insulating property. PVDF used in this experiment is flexible sheet with thickness of 40 μm. Sample was cut into size of 30×30 mm^2 from the sheet. PVDF sample was sandwiched by vacuum-evaporated Al film, but one side of electrodes was processed to a tooth-type electrode (10×10 mm^2 window area) using a photo-lithography process. The space between the teeth electrodes of the

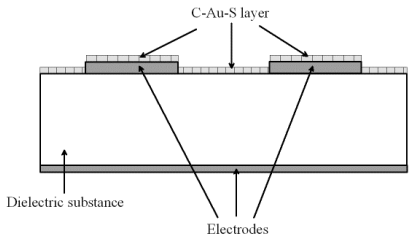

Fig.1. Cross section of sample with the C-Au-S layer.

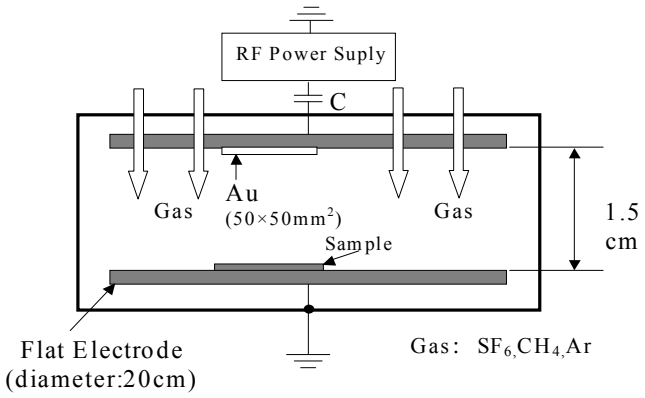

Fig.2 Cross section of sample holder in a vacuum

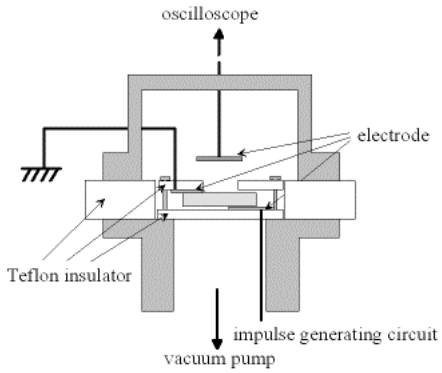

Fig.3 Cross section of sample holder in a vacuum chamber.

tooth-type electrode was set to 50 μm, similar to the PVDF film thickness. To prevent electrical contact between the electrodes on both sides, the rim of the Al film was etched off to maintain 15×15 mm^2 active area. When PVDF sample was polarized as flat-type electrode was negative and tooth-type electrode was positive, electric field induced along the surface of PVDF between teeth electrodes. However evidence of electron flow on the surface was not observed, the reason will be referred to high resistance of the PVDF surface.

To realize the current flow on PVDF surface, the surface with the tooth-type electrode was coated by semi-conducting film. From several candidates [3], the C-Au-S film was selected as a profitable semi-conducting film. As shown in Fig.1, the C-Au-S film, which is composed of C, Au and S atom at 63.7 10.5 and 25.8 atomic%, respectively, was coated on the PVDF surface by cooperation process of plasma CVD and sputtering at a pressure of 0.07 Torr for 3 sec. (Fig. 2) The film thickness was expected to be about 1 nm. Au atom disperses unanimously without forming a cluster in the film coated by this method. The semi-conductive C-Au-S film is adjustable by changing the content of Au in the film.

In the vacuum at 10^{-4} Torr or less, the sample was polarized at a voltage of 450 V. Thereafter, an opposite polarity impulse voltage of about –2400 V was added on the flat-type electrode to reverse the polarity, where the peak voltage was set higher than the voltage calculated by multiplying the coercive field of 50MV/m and

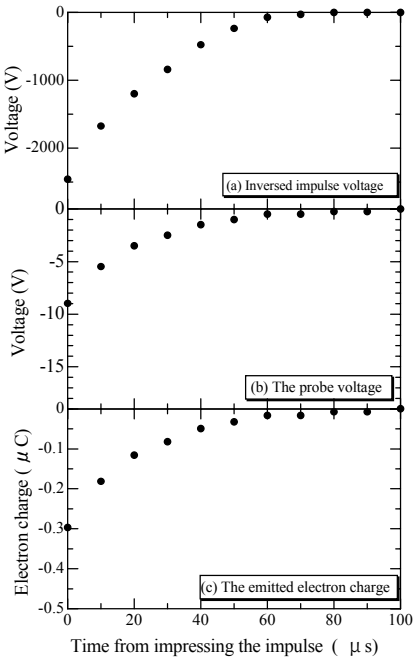

Fig.4 Time-dependence of applied impulse voltage, probe voltage and emitted electron charge for PVDF with the C-Au-S film

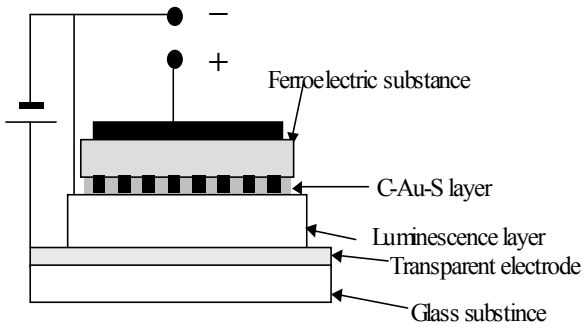

Fig.5 New light emitting device

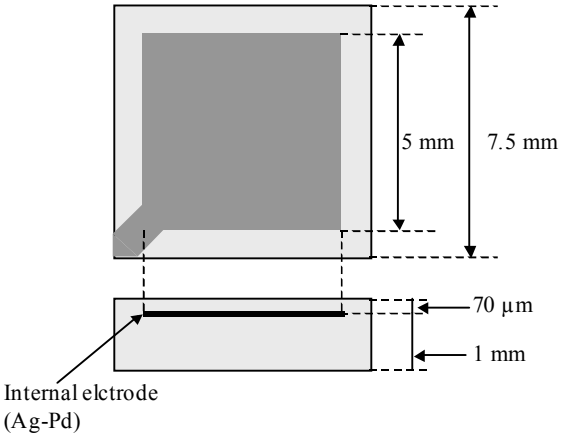

Fig.6 PZT Sample

a thickness of 40 μm. The prepared impulse voltage had a shape of 1-10 ns of wave front and 10-100 ms of wave tail. The electron emission was measured for the sample equipped in the vacuum chamber as shown in Fig. 3. The sample was placed on the Teflon holder while maintaining the tooth-type electrode side upward, where the probe electrode of copper plate (area 30×30 mm^2) was placed at 5 mm from the tooth-type electrode surface. The electron charges on the probe electrode were collected by a capacitor of 0.033 μF and the induced voltage on the capacitor was measured using a storage oscilloscope (Tektronix, 7834) with a memory system at response of sub-nanosecond. The applied voltage for reversing the polarization was used as shown in Fig. 4(a), which showed the peak value of 2400 V. The probe potential measured is shown in Fig.4(b), where the peak value is –9 V. By multiplying the capacitance of 0.033 μF, the emitted charge is shown in Fig.4(c). The total emitted electron charge was calculated to be 6.1×10^{-12} C, which is 5.2 % of the compensated charge on the PVDF surface.

2.2 Electron emission from PVDF through C-Au-S film

We propose a new light-emitting device, which has a new structure using ferroelectric electron emitter with C-Au-S layer. The device structure is shown in Fig.5. The electron will emit from a ferroelectric substance surface through C-Au-S 1nm thick film by a polarization inversion method and it is injected into the luminescence layer. If the electron energy is high enough to excite the luminescence substance, light will be emitted.

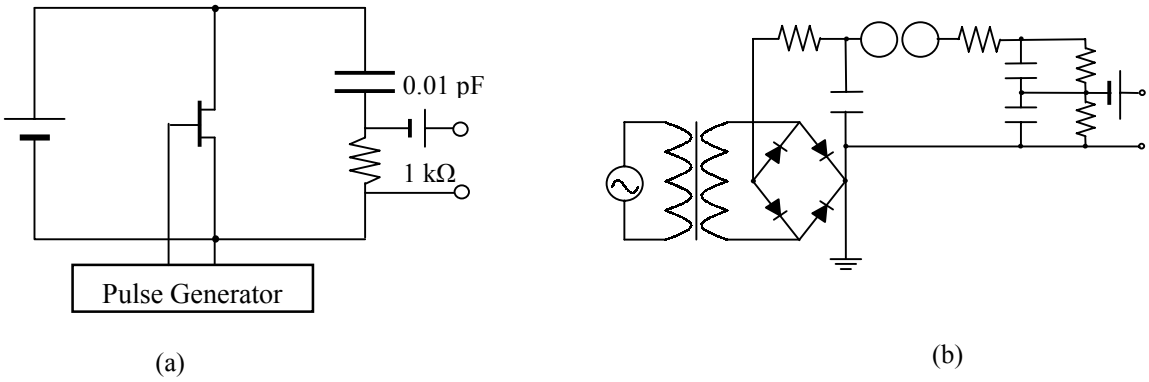

Fig.8 Impulse generation circuit

In this experiment, PZT was used as ferroelectric substance because of large dielectric constant. The PZT sample used for this experiment is shown in Fig.6. PZT has a dielectric constant of 1700 and small coercive field of 0.7 MV/m. Therefore, larger emitted electron charge and lower driving voltage are expected compared to the PVDF case. Ag-Pd flat-type electrode is sandwiched by PZT. The active PZT layer has 70μm thick in the are of 50×50 mm^2. Therefore, the coercive voltage is calculated to be 49 V. The tooth-type electrode was formed with evaporated Al film by photo-lithography processes. The line and space width of tooth type electrode was 50 μm. The C-Au-S film was coated on PZT surface with a tooth type electrode same as the PVDF at pressure of 0.08 Torr for 3 sec. The film thickness was 1 nm. ZnS and antracen were used as luminescence substances. These materials were coated on the C-Au-S film by a vacuum-evaporation method.

It needs to control emitted electron energy to excite luminescence layer, and two types impulse generator were prepared as shown in Fig. 8. The rise time of impulse voltage is estimated to be about 100 nsec for Fig.8 (a) and a few ns for Fig.8 (b), respectively. The poling voltage was 10-100 V, and the reversed polarization impulse voltage was 80-250 V.

The light emission has not been observed yet. The emission system and dimension must be optimized to realize the emission

3 Conclusion

Electron emission from PVDF could be observed by forming C-Au-S semi-conductive layer between the teeth electrode on the PVDF surface. With using same device system, a new electro luminescence device was proposed.

Acknowledgement

A part of experiments are carried out at the Center for Co-operation Research in Advanced Science and Technology, Nagoya University. Samples of PVDF and PZT were obtained from Kureha Chemical Industry Co. and NGK Spark Plug Co., respectively. We express our gratitude to all who contributed to this study.

Abstract

Polyethersulphone, polycarbonate and cellulose acetate membrane surfaces were modified in a glow-discharge plasma polymerisation system with a 13.6 MHz radio frequency using ethylenediamine and 2-hydroxyethyl methacrylate as monomers at a 20 W power and 10 min of exposure time. Surface properties were determined by AFM and contact angle measurements. Changes on permselective behaviours of the membranes were determined using a filtration system.

Keywords: Plasma polymerisation, sugar separation, glucose permeability.

1. Introduction

Sugar separation is a difficult and costly task in food industry. Among different separation methods, chromatography is the most used one for commercial sugar separation. Such methods are batch processes and imply expensive installations, low productivity and low yields of the desired products [1]. Alternative processes for sugar separation, such as zeolite adsorption [2], reverse osmosis [3], electro dialysis using borates to complex sugars[4], ion exchange membranes[5], plasticized cellulose triacetate membranes[6], liquid membranes[7], and supported liquid membranes [8-11] have been reported. Compared with the mentioned methods, the membrane processing has the advantages such as low energy demand, low capital and operating costs, easy scale up and continuous operation. Among membrane processes, supported liquid membranes are the most promising one but it is not commonly used in industrial applications because of the membrane instability due to the partition of the organic solvent/carrier to the aqueous phase [1].

The advantages of plasma processing of materials have been reported; it changes only the surface properties of the introduced material without affecting its bulk properties, it is a very efficient method and considered as environment friendly. When plasma is applied to a polymeric membrane, several kinds of reaction can take place on the polymer surface; breakage of covalent bonds along the chain, crosslinking, grafting, interaction of surface free radicals, alteration of existing functional groups and/or incorporation of chemical groups originated in plasma [12]. With the plasma polymerisation system, it is possible to prepare new membrane species, affinity membranes [13], reactive membranes [14], or membranes with brush-like surfaces [15].

Although plasma polymerisation technique is commonly used in the preparation and modification of different types of membranes for different purposes, to the best of our knowledge, no previous research studied on the effect of plasma polymerisation, so called glow discharge technique, modification of membranes for sugar separation. By plasma polymerisation technique we aimed to carry the separation technique of sugar beyond the state-of-the-art. In this paper, the effect of plasma polymerisation technique on the permselective behaviour of polyethersulphone, polycarbonate and cellulose acetate membranes to glucose by using ethylenediamine and 2-hydroxyethylmethacrylate as monomers was reported.

2. Materials and Methods

Cellulose acetate (CA) membranes were prepared by solvent casting method [12]. The composition of the casting solution was, 2% of cellulose acetate w/v (Acros organics, USA) in acetone (J.T Baker, Holland). Film formation was achieved by evaporation of acetone at room temperature (20ºC) and 80% relative humidity environment. Polyethersulphone (PES) membranes with a MWCO 100,000kDa and a diameter of 25 mm (Millipore Co., UK), Polycarbonate (PC) membranes, 0,03 µ pore size and 47 mm diameter (Poretics, USA) along with CA membranes were modified in a glass tubular reactor with the external plate electrodes and standard excitation frequency of 13.56 MHz (Fig.1). The reactor base pressure was 7x 10-2 mbar. The discharge power of the monomer gas (20 W), exposure time (10 min) and the flow rate were maintained constant for all of the modifications. Ethylenediamine (EDA) and 2-hydroxyethyl methacrylate (HEMA) (Sigma, Germany) were used as monomers.

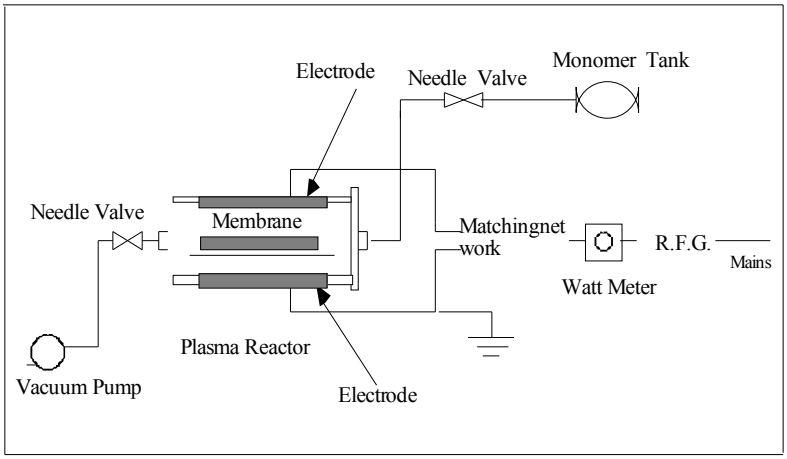

Fig. 1 Plasma Polymerisation System

Membranes, after storing in distilled water for 24 hr, were placed in filters (25 and 47 mm), filtration solution was fed to the system using an HPLC pump (Oriental Motor, Japan). A 0,1 M glucose (Acros organics, USA) solution in phosphate buffer (Sodium hydrogen phosphate, potassium dihydrogen phosphate, J.T Baker, Holland) at pH 7.5 and 50 ºC was used as the filtration solution. Glucose content of the permeates were determined using a sandwich type glucose electrode made in our laboratory. The preparation of the amperometric enzyme electrode is described elsewhere [12].

Contact angle measurements of the wetted membrane surfaces were performed by sessile bubble technique using an Intel®Play Q*3 Computer Microscope with distilled water and formamide (Sigma, Germany). Surface energies of the membrane surfaces were calculated using Young's and geometric mean equations [13].Atomic Force Microscopy (AFM) imaging was performed with using Topometrix TMX 200.

3. Results and Discussion

3.1 AFM

AFM images of PES membranes are given in Figure 2. Virgin PES membrane surface (Fig.2a) is rather smooth. After plasma treatment of membrane with both EDA (Fig. 2b) and HEMA (Fig 2c) at 20 W, 10 min some pores or pore like structures were appeared on the PES membrane surfaces. On the other hand no change on the porosity of the plasma modified PC membranes, when compared with virgin membrane (Fig 3a), occurred. AFM images of CA membranes showed a dense layer of deposition on the surfaces of both EDA and HEMA treated membranes (Fig4) making the surface smoother.

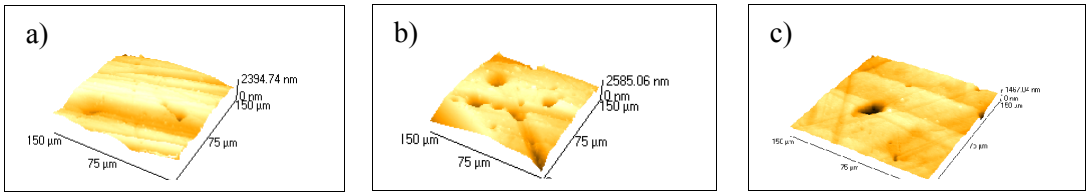

Fig.2. AFM images of PES membranes, a) virgin membrane, b)after modification with EDA 20 W 10 min, c) after modification with HEMA 20 W 10 min

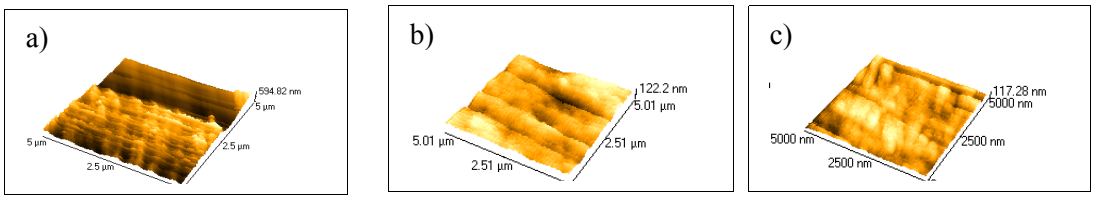

Fig.3 AFM images of PC membranes, a) virgin membrane, b)after modification with EDA 20 W 10 min, c) after modification with HEMA 20 W 10 min

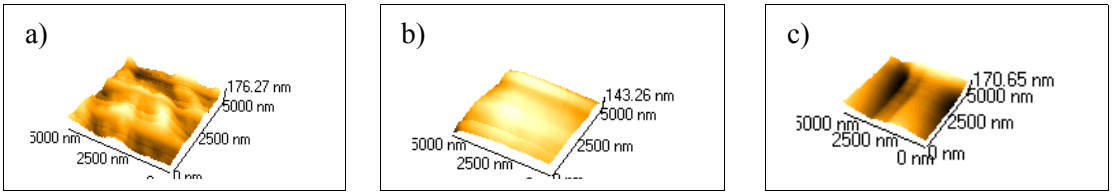

Fig.4 AFM images of CA membranes, a) virgin membrane, b)after modification with EDA 20 W 10 min, c) after modification with HEMA 20 W 10 min

3.2. Surface energies

Surface energy values of the virgin and modified membranes are given in table 1. After plasma treatment of PES membranes an increase in the surface energies is observed. The polarity of the EDA and HEMA treated PES membranes increased.

After plasma treatment, there was a little change in the SFE' s of the modified PC membranes, while their polarity decreased. The final SFE and polarity values of the EDA and HEMA modified membranes were close to each other.

Plasma treatment increased the SFE's and polarity of CA membranes. After treatment with EDA, the increase in the polarity was higher than the polarity of HEMA treated membrane while the SFE of EDA treated CA membrane was higher.

Membrane	γ^p_{pv}	γ^d_{pv}	γ_{pv}	**Polarity (%)** ($\gamma^p_{pv} / \gamma_{pv}$)
PES plain	15,6	28,2	43,8	35,62
PES EDA 20W 10'	37,7	5,24	42,94	87,8
PES HEMA 20W 10'	23,72	23,33	47,05	50,4
PC plain	26,73	9,55	36,28	73,7
PC EDA	16,32	18,23	34,55	47,24

CA plain	28,73	39,19	67,92	42
CA EDA 20W 10'	42,51	3,92	46,43	91,6
CA HEMA 20W 10'	46,38	7,56	53,94	86

Table 1. SFE's and polarities of virgin and modified membranes

3.3. Glucose permeabilities

Changes in the glucose permeabilities of the membranes are given in Fig.5. There were no significant changes on the glucose permeabilities of the PC and PES membranes (Fig.5.b). Since PC membranes have a porous structure and the density of the pores on the surfaces is high, plasma may not have caused a deposition around those pores so the plasma treatment was not efficient on the surface for the applied plasma parameters.

AFM images of the CA membranes showed that a dense coating layer was formed after plasma treatment with both EDA and HEMA. A dramatic decrease was observed on the glucose permeabilities of the treated membranes probably due to this layer (Fig.5.c). When the permeability values of EDA and HEMA treated membranes were compared, it was seen that the glucose permeability values of HEMA modified membranes were higher than the glucose permeability values of EDA treated membranes (Fig.5.d.).

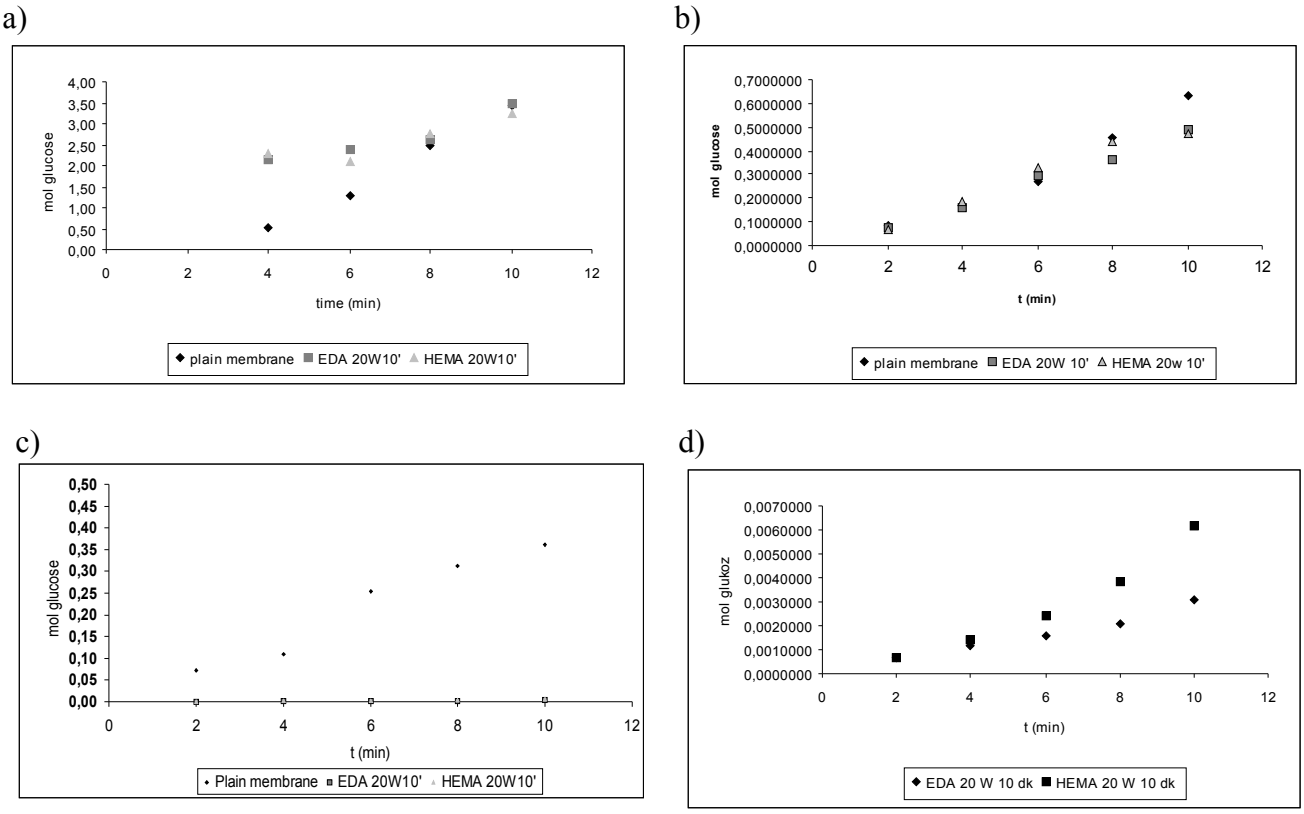

Fig.5. Changes on the glucose permeabilities of the membranes a)PES membranes, b)PC membranes c)CA membranes d)EDA and HEMA modified CA membranes.

4. Conclusions

The effect of glow discharge treatment on PES, PC and CA membranes at 20 W discharge power and 10 min exposure time was reported. Plasma treatment caused pore formation on the surface of PES membranes and making the surface more hydrophilic. The surface modification of PC and PES membranes was not efficient due to the membrane structures for the applied plasma parameters. Thus no significant change on the glucose permeabilities of the modified PC and PES membranes was observed. Glucose permeabilities of the EDA and HEMA modified CA membranes decreased compared to the virgin CA membrane, due to the coating layer formed after plasma modification. The hydrophilicity of EDA modified membrane was higher than the HEMA modified membrane but the permeability of HEMA modified membrane was higher. Monosaccharides are known to form complexes with OH groups. The reason of the glucose permeability value of the HEMA treated membrane was higher than EDA modified membrane may be the facilitated transport of glucose on the membrane surface due to the glucose-OH complex formation. For a better understanding of the transport mechanism on the membrane surface, XPS results are needed. Further studies will be performed using CA membranes as model membrane and with different monomers which are known to be carriers on sugar transport.

Modeling of Chemical Vapor Deposition System Cleaning by Remote Plasma Source and/or In-Situ Plasmas

A. Chirokov, K. Iskenderova, A. Gutsol, A. Fridman
Department of Mechanical Engineering, Drexel University, Philadelphia, USA

Abstract:
The numerical study intended to assess the effectiveness of CVD chamber cleaning technology is presented here. The chamber cleaning process is of great importance since it can affect the quality of deposited film. To study the main aspects of the clean process, CFD plasma chemical model of High Density Plasma Chemical Vapor Deposition (HPD-CVD) chamber was developed. It was found that the clean time could be dramatically reduced by controlling on /off cycles of plasma discharges in the chamber.

Introduction
In recent years, semiconductor manufacturers have put in a great effort to improve the production worthiness and the effectiveness of the equipments. Equipment qualification procedures are quite expensive and lengthy. For Chemical Vapor Deposition (CVD) systems, the chamber cleaning process is very important not only because it affects the quality of the final product but also because it time consuming and technically costly.

In a typical cleaning procedure an inefficiently high flow rates of expensive gas are supplied into the chamber. Excess, unreacted cleaning gas is wasted, resulting in unnecessary operational costs. Also, inadequate usage of plasma sources leads to low etching rates and poor gas utilization. All these issues demand a detailed optimization of cleaning conditions to achieve maximum utilization for cleaning gas, high cleaning rates (i.e. low cleaning times) and maximum hardware lifetime. The objective of this work is to concern the main aspects of the problems involved in remote clean process achieving both superior chamber cleaning performance and improved environmental friendliness.

Up-to-date HDP-CVD chambers have a capability to ignite several plasma discharges in a turned on / turned off regime during the cleaning process. In order to minimize the damage to the chamber components caused by plasma, the use of remote plasma source was proposed. The method has clear benefits compared to in situ cleaning: due to the high efficiency of the microwave/RF excitation, the NF_3 gas utilization efficiency can be as high as 99% in standard operating conditions [1]. This ensures an extremely efficient source of fluorine, while virtually eliminating global warming emissions. With this “remote” technique, no plasma is sustained in the main deposition chamber and the clean of the chamber components is much “softer”, compared to an in situ plasma cleaning technology. The disadvantage of the remote cleaning technology is that atomic fluorine after being generated in remote plasma source has to be delivered to the main chamber trough a transport tube. The recombination of the F atoms in the transport tube decreases the effectiveness of these applications [2-4]. The recombination is affected by various factors such as wall material, pressure, flow rate, residence time, etc. In order to overcome this problem, in situ plasma is used to recover F-atoms that recombine in transport tube. While the usage of in-situ plasma allow to recover F-atoms lost in the transport tube and thus increase efficiency of the remote plasma clean technology it also leads to damage of chamber components. Thus cleaning process should be optimized to reduce cleaning time, increase F-atoms utilization and reduce damage to the chamber. In this article the possibilities of optimization of in situ cleaning process was studied using Fluent CFD commercial software.

Description of HDP-CVD Chamber:
The entire model of HDP-CVD was build using Fluent CFD commercial software with additional compiled user-defined functions for plasma chemistry modeling.
The CVD chamber considered in this study (Figure 1) is roughly cylindrical with diameter of 50 cm and the height of 20 cm. The diameter of the substrate is 35 cm while the diameter of the wafer is 30 cm. The gas enters the chamber with the temperature of 300 K through 72 nozzles (ID = 0.057 cm) and has the following

proportion: NF_3/Ar = 1/2, where NF_3 flow rate can vary from 0.7 slm (standard liter per minute) to 1.5 slm and Ar flow rate can vary from 0.35 slm to 0.7 slm. The system operating pressure is constant and equals to 2 Torr. The walls of the reactor, wafer region and the substrate are covered with the silicon (Si) deposits with the film thickness of up to 0.6 mkm (highest thickness of the deposits is on top of the chamber). There are two types of radio frequency (RF) discharges that could be ignited inside of the system: inductively coupled plasma (ICP) and capacitively coupled plasma (CCP). The first ICP discharge can be ignited at the top of the reactor from the flat antenna located on top of the chamber. The flat antenna generates a plasma power up to 5 kW with the frequency 2 MHz. The second ICP is toroidal-like discharge generated by the RF coils surrounding the chamber wall. The second ICP can also generate a plasma power up to 5 kW and frequency 2 MHz. The CCP discharge could be ignited at the region close to the substrate and the outlet zone of the chamber. This discharge operates at the frequency of 13.65 MHz and can generate a power up to 10 kW. For more details see [5].

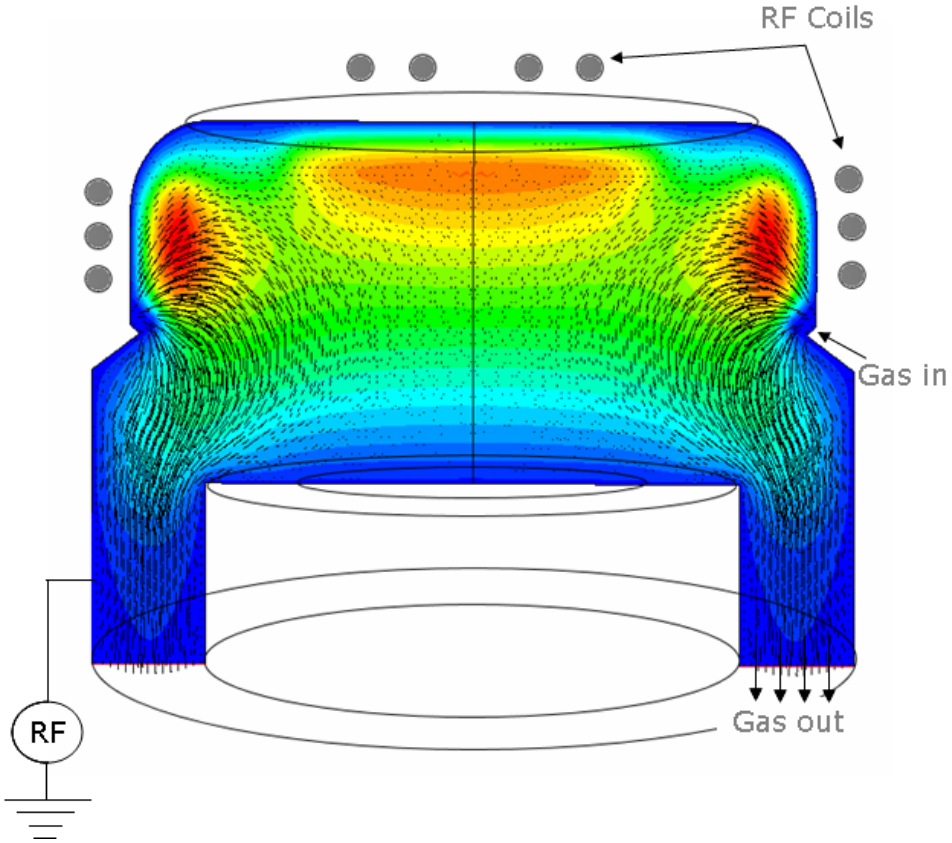

Figure 1: HDP-CVD chamber, with two ICP and one CCP discharge. Velocity vectors and temperature distribution are shown in case when all discharges are operational.

In Fluent CFD program, 2D steady-state laminar flow model was built and compiled together with the plasma-chemistry model. The analytically estimated energies and plasma volumes were implemented into CFD model as the source terms. ICP and CCP plasmas were represented in terms of heat sources and corresponding plasma-chemical reactions. Four global reactions describing overall plasma-chemical and etching process were selected and used in this model:

Reaction of electron-impact dissociation [6]:

$$e + F_2 \rightarrow F + F + e\,, \quad k_d = 1.18 \cdot 10^{-14} \exp\left(-\frac{6.88}{T_e} + \frac{1.11}{T_e^{\,2}} \right), \quad m^3/\sec \tag{1}$$

Reaction of thermal dissociation: [7]

$$F_2 \rightarrow F + F \quad (T > 1000K), \quad k = 7.52 \cdot 10^{-12} (cm^3/s) \cdot e^{-\frac{28.42(kcal/mole)}{RT}} \tag{2}$$

Reaction of volume recombination: [7].

$$F + F + M \rightarrow F_2 + M\ ,\ k = 2.76\times10^{-34}\ \mathrm{cm^6/s} \tag{3}$$

Surface etching reaction [8]:

$$Si + 4F \rightarrow SiF_4\ ,\ R = 2.91\cdot10^{-12}\cdot n_F\cdot T^{\frac{1}{2}}\exp\left(-\frac{0.108}{kT}\right),\quad \text{Å}/\min \tag{4}$$

Side Inductively Coupled Plasma: The Figure 2 (left) shows the contours of etch rates (4) in the side ICP discharge (main ICP discharge). In this regime the maximum etch rates are at the top of the chamber. The etch rates at the outlet walls are almost zero because of the shortage of reactive gas. Because of the high temperature in ICP discharge zone the volume recombination reaction rate of fluorine is very low having no effect on plasma volume kinetics and etching. The intermediate species formed with nitrogen atoms such as NF, NF_2 are very unstable and quickly decompose in a high temperature environment. The atomic fluorine mainly participates in the formation of SiF_4 molecules but still some amount of it recombines in the gas phase producing F_2 molecules. The main cleaning products outgoing from the system are F_2, N_2, Ar and SiF_4. The dilution gas such as argon (Ar) or helium (He) is always added to the plasma systems. The simulation results show that the highest etch rates comes with the minimum of dilution gas (Ar). On the other hand, the power consumption will increase dramatically without the presence of Ar. It was shown in [5] that for the reasonable result the ratio of etching gas (NF_3) and dilutant (Ar) should be 1/2.

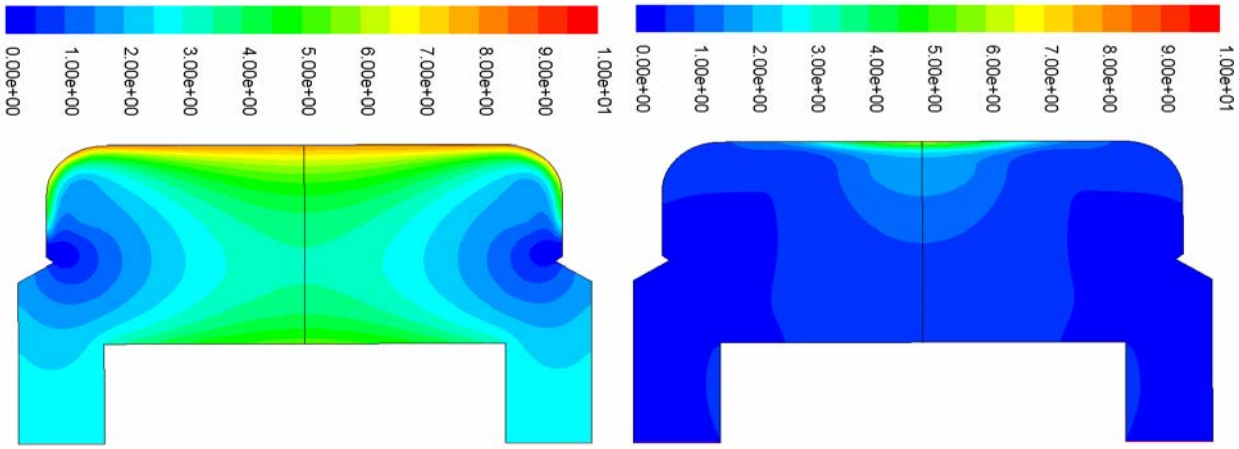

Figure 2: Contours of etch rates, kA/min. Only the side ICP is on (left). Only the upper ICP is on (right)

Upper Inductively Coupled Plasma. The abilities of secondary (upper) inductively coupled plasma are also explored in this study. The flow rates for the inlet gases are the same as is used for side ICP discharge. The corresponding contours of etch rates are shown in Figure 2 (right). As seen from the figure the upper ICP discharge is very local. The fluorine atoms produced in discharge do not propagate further through the system resulting in extremely low etching rates and overall cleaning efficiency. The low values of the flow velocity in the middle of the chamber result in discharge localization and low etch rates.

Side & Upper Inductively Coupled Plasmas. The results obtained from single side and upper ICP discharges show that the upper ICP can be used to increase the etch rates in the upper zones only (Figure 4). For this reason the simulation with both side and upper ICPs was performed. With both operational ICPs the etch time of upper chamber region could be essentially decreased. Although the upper ICP helps to decrease the etch time in upper region it has no effect on etch rates of lower zones.

Capacitively Coupled Plasma. The capacitively coupled plasma discharge is considered as low density (n_e = 10^8-10^9 $\mathrm{cm^{-3}}$) and high frequency (f = 13.56 MHz) discharge, used as a secondary discharge to increase etch rates in the lower zones of the chamber. The discharge is strongly non-equilibrium. The temperature of the gas in the discharge reaches only 600 K which means that thermal dissociation reaction of molecular fluorine will not

occur in this type of plasma. However, the fluorine recombination reaction is important here and affects the etching process. Due to strong influence of volume recombination reaction the optimal value for the flow rate should be investigated. For example, if we try to decrease the flow rate, the gas flows through the discharge slowly giving the time for proper dissociation, but once it passed the discharge zone it is also given a time for a proper volume recombination. If we try to increase the flow rate, the gas flows through the discharge quickly not having a time for proper dissociation, but once it passed the discharge zone it is also not given a time for proper volume recombination. In this situation there is an optimal solution for the gas flow rate and this solution is the maximum of some function depending on the flow rate or residence time. This function we are looking for is representation of the etch rates along the flow path. The highest value of the etch rate would give the most optimal value for the gas flow rate. The CFD modeling provides us with F-atoms concentration along the path line. The integral of F-atoms concentration basically represents the average value of the etch rate. The Figure 3 shows the integral of F-atoms over the flow path (etch rates) as a function of residence time (flow rates). The wide spectrum of flow rates was considered. The highest value of the residence time represents the lowest value of the flow rate and vise versa. The obtained function has the maximum value of the etch rate at the residence time of 5 sec. For the residence time of 5 sec the estimated total flow rate is 0.7 slm.

Figure **5** shows the contours of etch rates for capacitively coupled plasma discharge. Because CCP discharge is located near the outlet it affects only the lower zones of the chamber. Accordingly, the etch rates at the upper zones are very low while the etch rates at the lower zones have relatively high values.

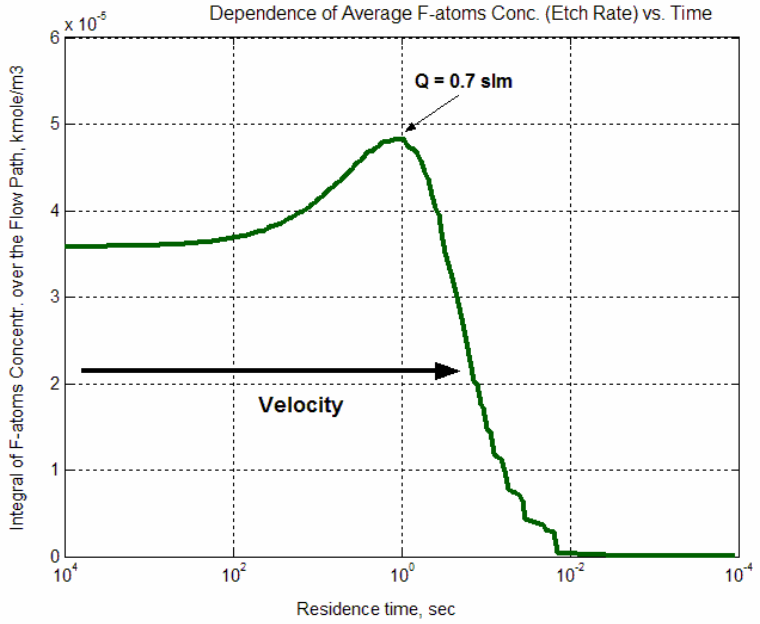

Figure 3: The dependence of average F-atoms concentration vs. residence time.

The Optimal Cleaning Regime: The control and manipulation of all considered discharges will give a reasonably optimal solution in overall cleaning time. It was found that for the system described above two stage cleaning procedure is the optimal solution. In a first time step which lasts 7 sec both side and upper inductively coupled discharges are operational. After that both inductive coupled discharges are turned off and the capacitively coupled discharge is turned on for additional 30 sec. Thus, the overall cleaning time of this process is about 40 sec. In the scope of the proposed method this can be the minimum time which could be achieved in remote cleaning technology with supported by *in situ* plasma.

Nowadays using NF_3-based remote cleaning technology without supported by *in situ* plasma the duration of cleaning time of HDP-CVD reactor reaches 2 min [9]. The multi-step plasma cleaning technology could save as much as 80 sec for each cleaning cycle. The cleaning time can be reduced further by igniting all three discharges

simultaneously, however, in this case due to the high etch rates in the upper reactor zones they will be cleaned off faster than the lower zones. Once the upper zones are cleaned the ICP discharges will continue to produce an excessive amount of F-atoms causing an overetching of upper zones resulting in equipment corrosion. Also igniting all three discharges simultaneously will significantly lower fluorine density in CCP discharge, since most of the fluorine will be dissociated in ICP discharges and F-atoms will be spent in upper zones [5].

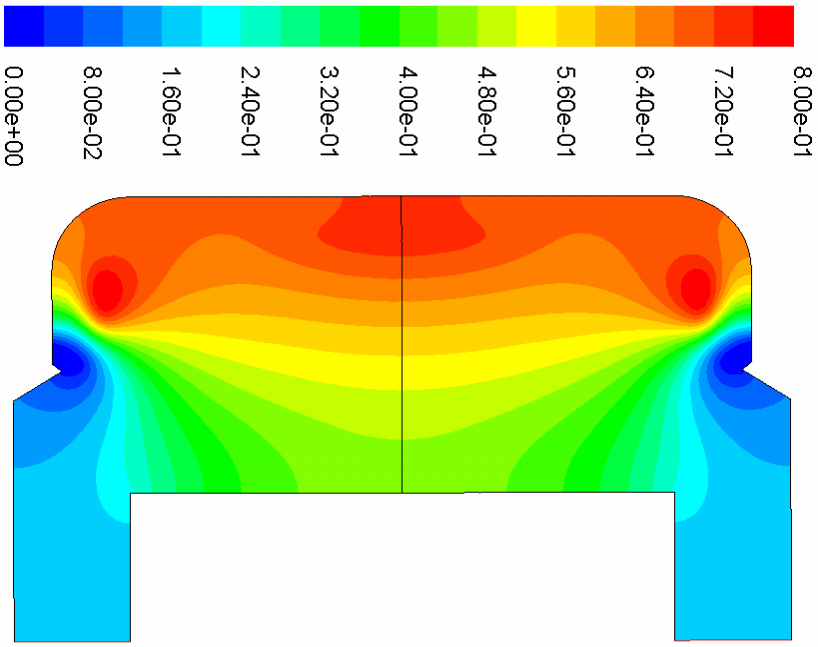

Figure 4: Contours of mole fraction of F atoms. Side and Upper ICPs.

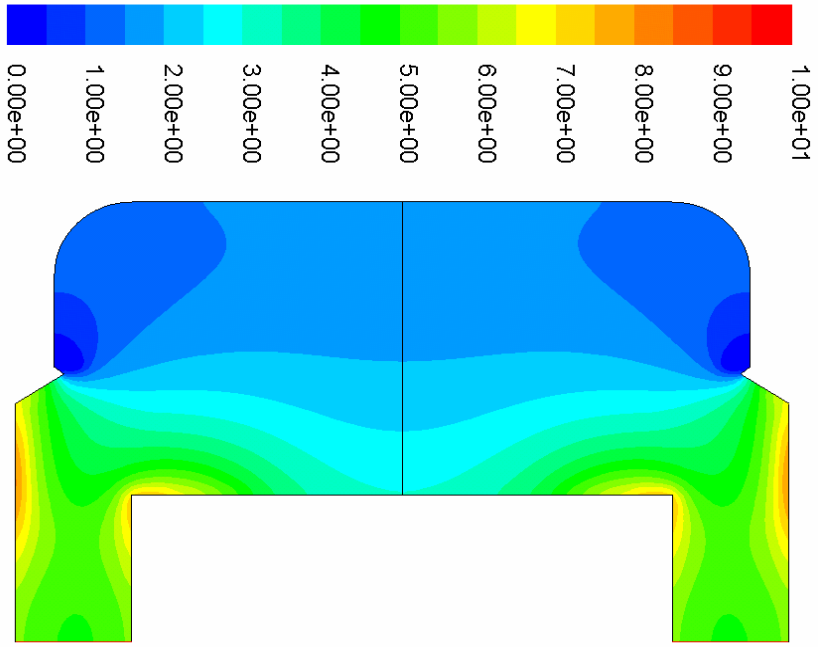

Figure 5: Contours of etch rate, kA/min. CCP discharge only.

In different HDP-CVD the optimal cleaning procedure can be different from the one proposed here, but it is clear that using multi-stage cleaning procedures instead of single strep procedures can dramatically lower cleaning time, reduce power consumption and significantly improve fluorine utilization.

Abstract:
Dielectric barrier discharges can exhibit two major discharge modes: filamentary mode and homogeneous or glow mode. Since stability of glow mode is very sensitive to gas composition, geometry, etc., most industrial DBD applications utilize filamentary mode despite the fast that glow discharge mode has obvious advantages over the filamentary one. Previously reported explanations of stability of glow DBD mode were inconsistent with experimental evidence. This article is an attempt to provide consistent explanation of glow mode stability.

Introduction
The dielectric barrier discharges (DBDs) are usually non-uniform and consist of many local microdischarges. Physics of these discharges is very sophisticated and is based on the initial avalanche-to-streamer transition that is followed by the formation of microdischarges and their arrangement in the specific pattern [1].
It was shown recently that dielectric barrier discharges can exhibit two major discharge modes: filamentary mode and homogeneous or glow mode [2]. The filamentary mode was a topic for active investigations in the past several years. A lot of experimental and theoretical work has been done in this area. Most industrial DBD applications utilize filamentary mode. However, for a homogeneous treatment of surfaces, or for the deposition of thin films, the glow discharge mode has obvious advantages over the filamentary one [3]. Unfortunately the glow mode is very unstable and prone to spontaneous transition to more stable filamentary mode.
Dielectric barrier discharges glow mode or atmospheric pressure glow discharges (APG) [4-6] with the average power densities comparable to those of filamentary discharges will be of enormous interest for applications if a reliable control over it could be achieved. Several approaches to generating stable APG were developed using helium as dilution gas and using special electrode structures [7]. Since usually use of helium is not practical due to its cost, alternative techniques of stabilizing APG are being actively researched. It is especially challenging to stabilize APG in electronegative gasses such as air. It was found in [8] that if concentration of oxygen in nitrogen discharge exceeds 0.1% the discharge can only operate in filamentary mode. Many APG stabilization criterion such as required preionization [9] and ion-trapping mechanism [10] were proposed but were inconsistent with experiment results [11, 12]. In this article we propose new explanation of the glow mode stability limitations based on the fluctuations of the local current densities.

Townsend Nature of APG:
Since streamer strike is immediately followed by formation of microdischarge, APG discharge operates when applied electric field exceeds Townsend criterion but is lower than Meek criterion [13] for the formation of streamers. The fact that in APG electric field must be below Meek and above Townsend criterion is consistent with experimental results [12]. Townsend breakdown criterion for the case of non-electronegative gas is well known and given by equation $(\exp(\int_0^d \alpha \cdot dx) - 1) \cdot \gamma > 1$, where γ is the coefficient of secondary electron emission (also known as the third Townsend coefficient) and α is ionization coefficient (also known as the first Townsend coefficient). In an electronegative gas the Townsend breakdown criterion becomes

$$\frac{\alpha}{(\alpha - \beta)} (e^{(\alpha-\beta)\cdot d} - 1) \cdot \gamma > 1 \qquad (1)$$

where β is an attachment coefficient (also known as the second Townsend coefficient). Most of APGs operate in the range of current densities of dark Townsend discharge (on the level of ~1 mA/cm^2), so electric field is not significantly disturbed by the space charge and is mostly affected by the charges deposited on the dielectric

surfaces. Deposited surface charge produces electric field which is opposite to the applied electric field. When voltage is higher then necessary for Townsend breakdown, electric current due to electron avalanches will grow exponentially until accumulation of charges on the dielectric surfaces collapses local electric field to the value below breakdown. So, there are similarities between DC and APG discharges and the major difference of APG from classical dark Townsend discharge [14] is that surface charges provide quenching mechanism for the discharge current.

Since positive ions are much slower than electrons, in addition to surface charge there is a positive space charge that form weak cathode layer and slightly increases electric field near the cathode. We do not consider space charge due to electrons since at typical APG operating frequencies 1-20 kHz electrons have enough time to leave the gap. Space charge due to electrons is important in discharge such as Atmospheric Pressure Plasma Jet (APPJ) since they operate at much higher frequencies [15]. Cathode layer formation leads to redistribution of the electric field and thus Townsend criterion can be satisfied for lower average electric field [14]. For more details about cathode layer formation in APG see [8].

The stability of APG can be considered as a balance between two effects: surface charges provide stabilization mechanism for the current density by collapsing local electric field while space charge provides destabilization by supporting discharge at lower average electric field. In order to simulate these effects detailed models based on drift-diffusion equations were developed [4]. Although these models can predict basic properties of APG discharge they fail to predict transition to filamentary mode. In these models discharge always appears to be stable, contradictory to experimental evidence. Thus there are physical effects that are not included in the model. We believe that this missing effect that influences the stability of glow mode is fluctuations of local current density. These fluctuations are the primary focus of this study. Also using a simple model the effect of these fluctuations on cathode layer formation and stability of APG was evaluated.

Effect of Electronegativity on Current Density:

Average number of electrons in an avalanche (avalanche "size") is $N = \exp((\alpha - \beta)d)$, and current density in given discharge location is proportional to the avalanche size. Multiplication of electrons in an avalanche and secondary electron emission from dielectric surface are statistical processes. Thus number of electrons in avalanche deviates from the average, causing fluctuation of the discharge current density (Figure 1). In order to estimate the standard deviation of the avalanche size from the average values we developed Monte-Carlo model similar to one described in [16]. In this model the electric field was assumed to be constant because the distortion of the electric field by the avalanche space charge becomes important at $(\alpha - \beta)d \approx 20$, and in the simulation $(\alpha - \beta)d = 5$. We choose to specify the value of $(\alpha - \beta)d$ instead of electric field in order not to be restricted by the particular gas mixture composition. The average size of avalanche in simulation is $\exp((\alpha - \beta)d) = \exp(5) \approx 148$ and Townsend criterion becomes $\gamma > 6.8 \cdot 10^{-3}$. Simulation results presented in Figure 1 and 2 clearly show the effect of attachment on the avalanche size distribution. An average size of avalanche is the same in both cases (with and without attachment) but standard deviation is much higher in the case with attachment, though it is very high (96%) even in the case without attachment. Also significant fraction ($\beta / \alpha = 3/8$) of the initial electrons in electronegative gas don't produce avalanches (Figure 1), because these electrons were attached on early stages of avalanche development.

Since current density at given discharge position is proportional to the total number of electrons in all avalanches at that position, fluctuations of current will be reversely proportional to the square root of number of avalanches and directly proportional to the standard deviation of the avalanche size:

$$\delta j \sim \frac{\sigma_{av}}{\sqrt{N_{av}}} \qquad (2)$$

where σ_{av} standard deviation of the avalanche size distribution and N_{av} is the total number of avalanches at given position.

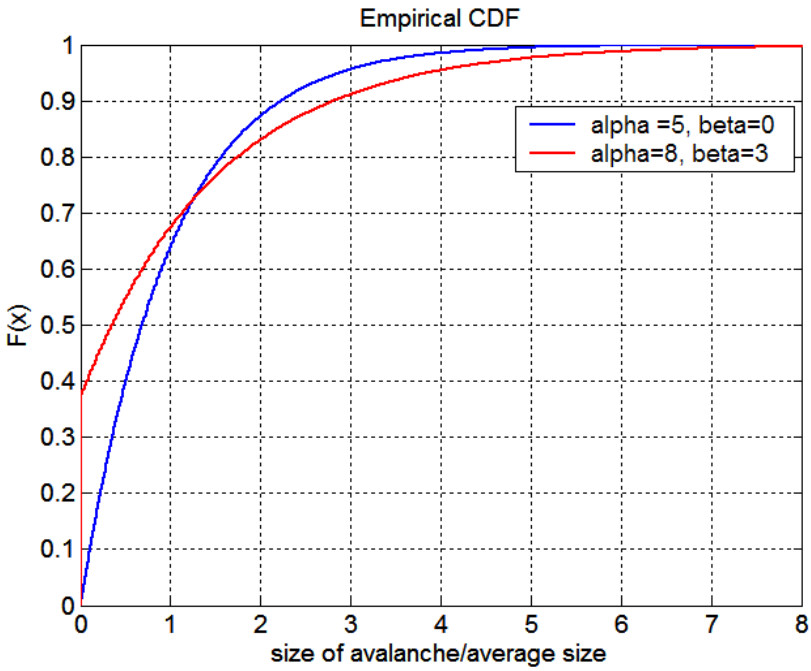

Figure 1: Empirical cumulative distribution function (CDF) of the avalanche size computed using Monte-Carlo simulation. Blue curve represent case without attachment, average avalanche size is $\bar{N} = 0.97 \cdot N_t$ while standard deviation is $s = 0.96 \cdot N_t$ where $N_t = \exp(5)$. Red curve represent the case with non dimensional attachment coefficient $\beta \cdot d = 3$, average size of the avalanche is the $\bar{N} = 0.96 \cdot N_t$ while standard deviation is $s = 1.41 \cdot N_t$.

Thus, for high current density these fluctuations become unimportant and this explains why these fluctuations are not usually considered for high current discharges. The stability limitations of high current discharges are usually related to thermal instability rather than to fluctuations of local current density and this is beyond the score of this study. In glow mode of dielectric barrier discharge typical peak current density is on the level of ~1 mA/cm^2 and can be as low as ~0.01 mA/cm^2 [4, 12].

Simple estimation shows that in case when $(\alpha - \beta)d = 5$, avalanche radius is about 0.1 mm in gap distance of 1 mm and electron drift velocity is 10^7 cm/sec, about 130 avalanches at a time needed to give electric current density of 1 mA/cm^2 and just one (1.3 on average) to give ~0.01 mA/cm^2. If there is only one avalanche on average at the same time at given location then fluctuations of current density will be proportional to fluctuations of the avalanche size at this location. Thus in this case standard deviation of local current density fluctuations will be equal to the average current density. In case when there are 100 avalanches at the same time standard deviation of the current density fluctuations will be according to (2) 10 times less than average current density. Accordingly local fluctuations of current density will be about 88% percent for current the density 0.01 mA/cm^2 in the conditions described above.

In non-electronegative gasses standard deviation of avalanche size is equal to the average avalanche size while in electronegative gasses standard deviation can be much higher (Figure 2). For example, if standard deviation is twice the average (Figure 2), number of avalanches in the same location has to be four time higher to have the same level of local current density fluctuations. Thus even small addition of electronegative gas to the APG can destabilize the discharge, by increasing local current density fluctuations and thus decreasing uniformity of discharge. It is clear that fluctuations of local current density in typical APG conditions can be very large and can not be neglected. Critical value of local current density fluctuations that causes filamentation of APG can not be specified based on this analysis alone because it obviously depends on the particular configuration of the discharge as well as parameters of external circuit.

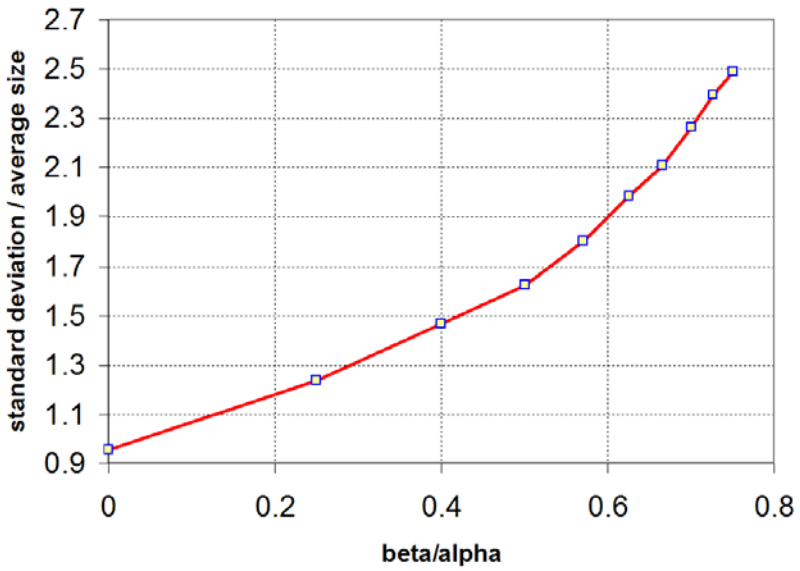

Figure 2: Standard deviation of the avalanche size distribution as a function of β/α parameter. Simulation was performed for $(\alpha-\beta)\cdot d=5$, parameter $\beta\cdot d$ was varied from 0 to 9 while parameter $\alpha\cdot d$ was varied accordingly. We found that variation of $(\alpha-\beta)\cdot d$ do not introduce any visible changes to this curve in the range from 3 to 5.

Effect of Current Density Fluctuation on Cathode Layer:

Although fluctuations of local current density disturb uniformity of the discharge they do not necessarily lead to the filamentation of the discharge, because current in the discharge gap can be stabilized by surface charges. The mechanism is the following: If current density at given location rises above the average, the amount of deposited surface charge increases. Since the surface charge decreases local electric field, thus it also decreases the non-dimensional parameter $(\alpha-\beta)d$. This lead to the decrease of the average size of electron avalanches and as a result to decrease of local current density, since average avalanche size exponentially depends on $(\alpha-\beta)d$. Stabilizing effect of surface charge can be canceled out by the formation of the cathode layer.

To illustrate the effect of current density fluctuations on the cathode layer, 1D steady–state model was developed. Space charge behavior can be understood with relatively simple model that consists of continuity equations for electrons, negative and positive ions (3) coupled with Poisson equation. Model does not take into account accumulation of surface charges. Flux of positive ions at the anode as well as flux of negative ions at the cathode was set to zero. Flux of the electrons from the cathode was equal to flux of positive ions to the cathode multiplied by the secondary emission coefficient. Simulation performed using MatLab boundary value ODE solver.

$$\begin{aligned}\frac{dj_e}{dx}&=(\alpha-\beta)\cdot j_e\\ \frac{dj_p}{dx}&=-\alpha\cdot j_e\\ \frac{dj_n}{dx}&=\beta\cdot j_e\end{aligned}\qquad(3)$$

Expression of ionization coefficient for helium as a function of electric field was taken from [12]; attachment coefficient was assumed to be independent on electric field and was specified as input parameter. Pressure in simulation was set to 1 atm, discharge gap was 1 cm and secondary emission coefficient was set to 0.01. Current density was specified as an input parameter while voltage drop in the gap was calculated during simulation for each value of current density.

Fluctuations of local current density were modeled by slightly changing input current density, and effect of fluctuation on voltage drop in the gap was recorded. Figure 3 shows how derivative of voltage with respect to current changes with different values of the attachment coefficient and different current densities. Expected voltage derivative is always negative, which means that lower voltage is needed to support discharge at higher current (falling voltage-current characteristic is typical for transition from dark to subnormal discharge). At low current densities, voltage derivative is much higher for electronegative gasses. This means that the same fluctuations of current density in case of electronegative gas produce higher 'overvoltage'. Term 'overvoltage' used here to describe the voltage that is higher than needed to satisfy Townsend criterion. Higher overvoltage in electronegative gas can be attributed to the much higher ionic space charge than in the case of electropositive gases. Comparing the effect of current density fluctuations on the cathode layer and the effect of surface charge accumulation the following relation can be obtained:

$$\Psi = j\frac{L_d}{\varepsilon\cdot\varepsilon_0} + U'\cdot\frac{\delta j}{dt} \qquad (4)$$

Here δj is current density fluctuation, U' is the derivative of voltage-current characteristics, L_d - total dielectric thickness, and value of Ψ described the balance between two effects mentioned above. For APG stability Ψ value should be higher than a certain "critical value" which depends on particular discharge configuration. It is clear from (4) that the higher value of current fluctuations and the slope of voltage current characteristics the harder it is to stabilize the discharge.

Concluding Remarks:

It was shown that fluctuations of local current density are important for understanding of APG discharge stability limitations especially in electronegative gasses and can not be neglected. These fluctuations strongly depend on the value of non-dimensional ratio of attachment over ionization coefficient. Combination of small average size and high density of avalanches results in less fluctuating current density and thus a favorable condition for obtaining APG. High density of avalanches means high number of initial electrons, so this condition is more general version of the "required preionization" condition [9, 16]. On the other hand, large size and low density of avalanches produces significant current density fluctuations and therefore such conditions should be avoided in order to obtain stable APG. Also it was found that in electronegative gases voltage-current characteristics is much more sensitive to current fluctuations than in non-electronegative gases. Our consideration shows that current fluctuations can be also a primary reason of instability of low current DC discharges.

It is important to emphasize that fluctuations are local with characteristic length scale equal to diameter of avalanche. So, fluctuations of total current in APG depend on the electrode area and can be negligibly small since usually this area is much larger than typical avalanche crossection (10^{-4} cm^2).

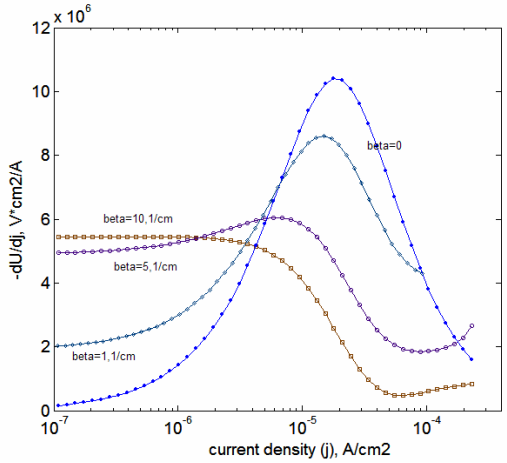

Figure 3: The plot of voltage derivative with respect to the current density as the function of current density, at different values of attachment coefficient.

Abstract:
Although natural gas is considered a cleaner source of energy than some solid and liquid fuels, there is still significant emissions emitted as a result of combustion that must be characterized and controlled. This research focuses on the treatment of simulated natural gas (NG) combustion exhaust gas by plasma-catalytic oxidation and reduction reactions produced by a trench type non-thermal plasma (NTP) reactor followed by a catalyst. The plasma-catalyst has been observed to be effective in the removal of NO_x using simulated NG exhaust gases.

1.0 Introduction

The development of an after-treatment technology for gas turbines (GTs) is critical since the large number of GTs being used today for commercial and industrial applications is only likely to increase over the next decade. The three pollutants of greatest concern for GTs are: nitrogen oxides (NO_x), carbon monoxide (CO) and volatile organic compounds (VOCs) including unburnt hydrocarbons. Although methods for controlling NO_x are available, none work efficiently in the oxygen rich, low temperature environment created by GTs. After treatment technologies for VOCs created by GTs are also limited, given the complexity of VOCs emitted by GTs and the overall cost of many of these technologies is too high to be cost effective. One of the technologies at the forefront of research for this application in non-thermal plasma in combination with a catalyst called a plasma-catalyst system.

It has been well established that non-thermal plasma reactors can efficiently reduce the NO concentration and convert NO to NO_2 by many researchers [1,2]. In order to convert the NO and NO_2 to elemental nitrogen and thus a harmless gas, research has focused on combining non-thermal plasmas with reduction or oxidation agents such as hydrocarbon additives [1, 2], ammonia [3, 4], hydrogen peroxide [9] and/or catalysts [1, 2, 10, 12].

The specific objectives of the present non-thermal plasma-catalyst experiments are to convert NO_x to less harmful substances such as N_2, O_2 and H_2O. The system also aims to convert CO to CO_2 and convert hydrocarbons and VOCs to aldehydes in order to activate the catalyst.

2.0 Experimental Facilities

Figure 1 shows the experimental set-up for the simulated gas test, where the test set-up capable of conducting real natural gas combustion with dust removal by the dust flow separated type electrostatic precipitator [13]. However, in the present work, a simulated combustion gas was used to investigate the potential to work at low gas temperature without soot generated from combustions. In this experiment N_2-NO 1.38% was introduced into the natural gas combustion test loop, with the combustor off, through an Edwards Datametrics 6100 flow controller. The air flow rate was controlled by a rotameter and introduced to the natural gas test loop. The air flow rate was set between 0-9.5 Nm^3/hr. The flow rate of the NO was accordingly adjusted to dilute the NO in the loop to approximately 20ppm. The non-thermal plasma reactor was then set to applied voltages between 10kV and 20kV, at a frequency of 60Hz. A Greenline combustion analyzer was used for exhaust gas analysis.

The sodium zeolite-Y catalyst coated on 400 cpsi cordierite monolith reactor was placed 30cm downstream of the trench type barrier discharge reactor [1] as shown in Figure 2. The sodium zeolite-Y reactor was then heated for a period of 2 hours by wrapping the catalyst chamber (steel) in standard electrical heating tape with an output of 300°C.

3.0 Experimental Results

3.1 NO_x removal in a N_2-O_2-NO System by Non-Thermal Plasma-Catalyst System

The NO_x removal efficiency of the trench type dielectric discharge non-thermal reactor followed by the sodium zeolite-Y catalyst is shown in Figure 3; where NO_x reduction versus the specific energy density (SED) for gas flow rates between 3.4-9.5Nm^3/hr at 23°C and 65°C, respectively is shown. Figure 3(a) shows that the NO_x removal efficiency increases with increasing SED and decreasing gas flow rates. The removal efficiency of NO_x increases with decreasing flow rates because the residence time is longer at lower flow rates. This increase in removal efficiency of NO_x occurs since there is a greater probability that the NO_x will interact with electrochemically excited nitrogen by reduction reactions, as well as further oxidation of NO_2 to N_2O, NO_3 and HNO_3 (with trace water content absorbed in the catalyst) by free radicals, [3,4] in the NTP reactor. Furthermore, the increase in residence time also increases the probability that the NO_2 formed by the NTP reactor will be absorbed in the catalyst surface and thus be removed by free radical reactions.

Figure 3(a) shows that the maximum removal efficiency of NO_x at flow rates 3.4 Nm^3/hr and 5.1 Nm^3/hr were the same at 65%, however the removal efficiency at 5.1 Nm^3/hr was achieved at a lower SED. This means that more gas was treated with the same electrical power injected into the plasma reactor, therefore the process was more effective at 5.1 Nm^3/hr than at 3.4 Nm^3/hr. By comparing Figure 3(a) to Figure 3(b) it can be observed that the NO_x conversion was greater at 23°C then at 65°C. The maximum NO_x removal at 23°C was 65%, whereas it was only 50% at 65°C. This is the opposite trend that was expected, as catalysts generally require elevated temperatures to operate effectively, however 65°C is still below minimum values for catalyst operation reported in literature. The test at 23°C may have been more effective for NO_x removal for two reasons. The cordierite monolith would have had a greater capacity to absorb at lower temperatures, thus resulting in more NO_x being absorbed at 23°C then at 65°C.

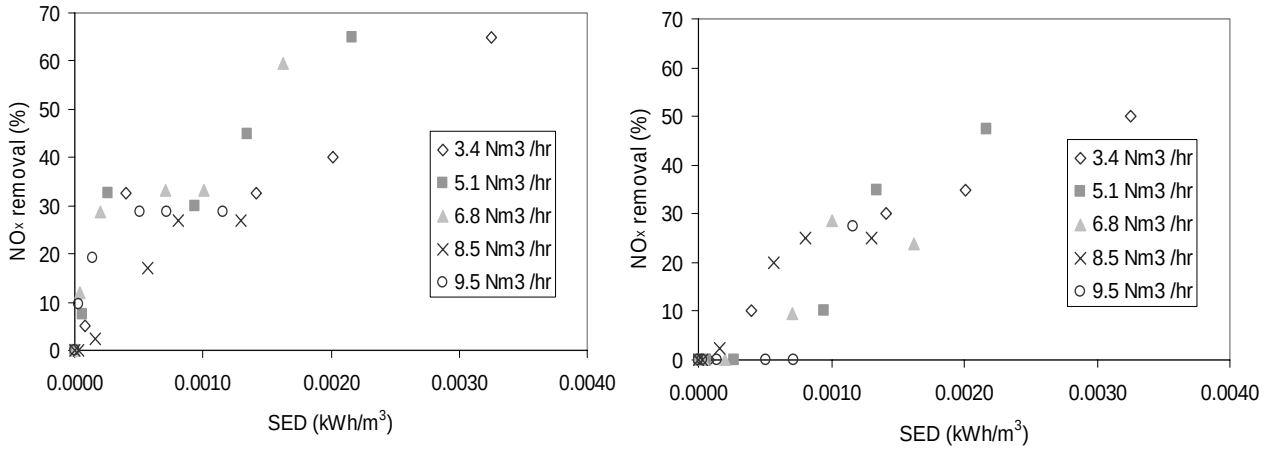

Figure 3: NO_x removal efficiency versus SED for trench-type non-thermal plasma-catalyst for gas flow rates between 3.4-9.5Nm^3/hr at (a) 23°C (left) and at (b) 65°C (right)

Figure 4 shows the energy efficiency of NO_x removal as a function of SED for various gas flow rates for gas temperatures of 23°C and 65°C, respectively. As can be observed from comparing Figures 4(a) and 4(b) the NO_x removed is greater for the test at 23°C than for 65°C at low SEDs. The maximum mass of NO_x removed at 23°C was 81g/kWh, whereas at 65°C the maximum NO_x removed was 8.5g/kWh. Again this large difference could be due to the effective mass of NO_2 and the other gas by-products absorbed on the surface of the catalyst, since absorption of gas decreases with increasing gas temperature. It can also be observed that at higher SEDs of about 0.001kWh/m^3 that the mass of NO_x removed is similar for both experiments. This trend can also be seen in Figures 3(a) and 3(b). This suggests that at higher SEDs there is not a significant difference between the NO_x removal efficiencies of the plasma-catalyst system.

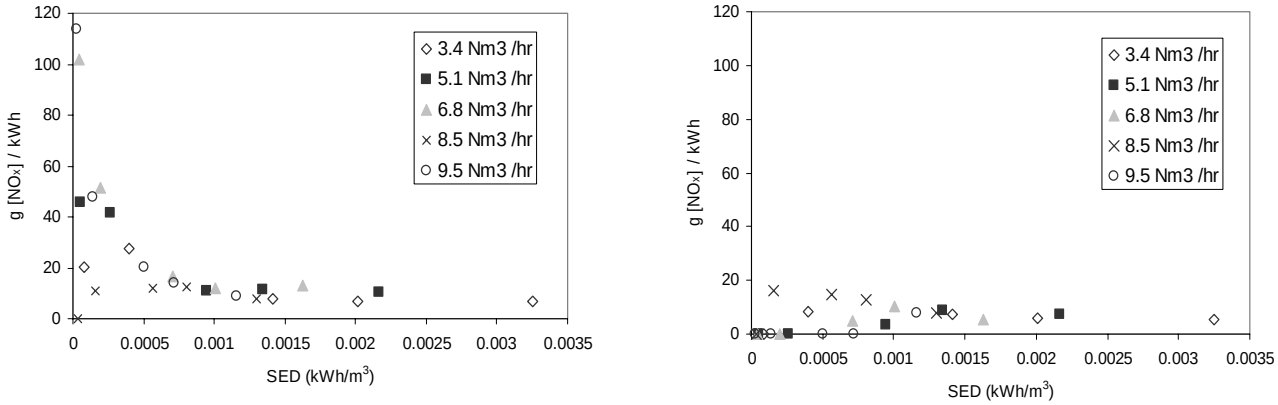

Figure 4: Energy efficiency of NO_x removal by mass versus SED for trench-type non-thermal plasma-catalyst for gas flow rates between 3.4-9.5Nm^3/hr at (a) 23°C (left) and at (b) 65°C (right)

3.2 NO_x removal in a N_2-O_2-NO-CH_4 system by Non-Thermal Plasma-Catalyst System

The NO_x removal efficiency of the plasma-catalyst system was examined during this test for various NO to CH_4 ratios at 23°C. Methane was injected into the system in order to create aldehydes to activate the catalyst [2]. The first large difference that was observed when compared to the previous test without CH_4, was the power injected into the NTP reactor. The power injected into the NTP reactor was approximately four times higher than the previous test. This was confirmed during the test and after with only air present in the NTP reactor. This change in the injected power may be due to the additional energy consumed by the CH_4 decomposition.

Figures 5(a) and 5(b) show the NO_x removal efficiency of the plasma-catalyst system for the addition of CH_4 for flow rates of 3.4 Nm^3/hr and 8.5Nm^3/hr, respectively. As can be observed from Figures 5(a) and 5(b), the NO_x removal efficiency increases with increases SED, as expected. As previously mentioned this

trend occurs both due to an increase in residence time in the plasma-catalyst system and because more power is being injected into the NTP reactor compared to the flow rate

The NO_x removal efficiencies are also lower than the previous test at 23°C without the addition of CH_4, as shown in Figure 5 ($[CH_4]/[NO]$ ratio = 0 for previous test). This result was expected as the addition of CH_4 should have allowed for the formation of aldehydes in the NTP reactor but could not activate the sodium zeolite-Y catalyst at low gas temperatures. As well, the plasma energy may be more effectively used to dissociate CH_4 then generating N* and N_2* radicals, hence NO_x removal may not be enhanced as has been observed by Ambridge et al [12].

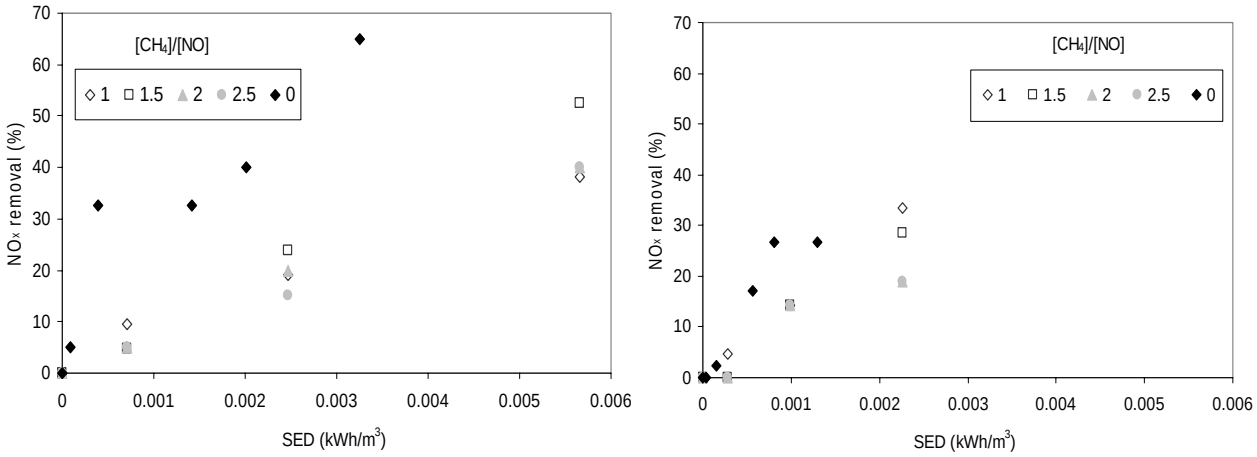

Figure 5: NO_x removal versus SED for non-thermal plasma-catalyst for gas a flow rate of (a) 3.4Nm^3/hr (left) and (b) 8.5Nm^3/hr (right) for various CH_4 to NO ratios

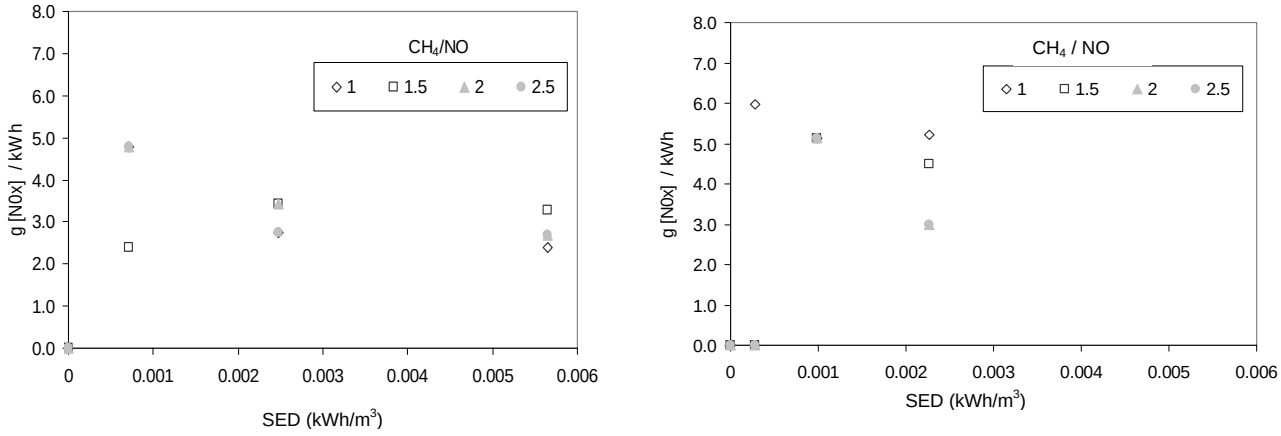

Figure 6: Energy efficiency of NO_x removal versus SED for non-thermal plasma-catalyst for gas a flow rate of 3.4Nm^3/hr (left) and 8.5Nm^3/hr (right) for various CH_4 to NO ratios

Figure 6 shows the energy efficiency of NO_x removed ($g[NO_x]/kWh$) versus the SED. The energy efficiency of NO_x removal decreases with an increasing CH_4 to NO ratio.

4.0 Conclusions

The plasma-catalyst system was observed to have a maximum NO_x removal energy efficiency of all experiments conducted was 120g/kwh at 23°C for the simulated exhaust gas without methane. The maximum NO_x removal energy efficiency observed at a gas temperature of 65°C was approximately 18 g/kwk. In the simulated exhaust gas treatment with methane, the maximum NO_x removal efficiency was observed to be 52% at 23°C with 30ppm of injected CH_4. It was observed during the test with NO and CH_4 that the removal of NO_x increased with increasing SED. It was also seen the concentration of CH_4 did not have a large impact on the NO_x removal efficiency in most cases at 23°C. At all flow rates, expect 8.5Nm^3/hr, the maximum

NOx removal occurred with a CH_4 concentration of 30ppm. The energy efficiency of NO_x removal decreases with increasing CH_4 to NO_x ratio.

[1] *Physics of Nonequilibrium Systems Laboratory, Moscow Institute of Physics and Technology, Institutskii lane,9, Dolgoprudny 141700 Russia*

Abstract

The comprehensive experimental investigation of processes of alkanes slow oxidation in mixtures with oxygen and air under nanosecond uniform discharge has been performed. We have investigated kinetics of alkanes oxidation from methane to decane in stoichiometric and some lean mixtures with oxygen and air at room temperature. The discharge current, electric field and input energy have been measured with nanosecond time resolution. Time of full oxidation of alkanes was determined.

1 Experiment

The scheme of experimental setup is represented in the figure 1. The electric pulses yielded to the discharge cell through 50-Ohm RF cable with 20 m length. The discharge cell consisted of thin-wall quartz discharge tube with 5 cm inner and 4.7 cm outer diameters, metallic screen, high and low-voltage electrodes. The screen was made of eight brass rods with 12 mm diameters uniformly installed on the 7 cm distance from the cell axis. The high voltage electrode had conical form with 60^{O} opening angle. The low voltage one was a ring connected to the screen directly. The distance between the edges of the electrodes was 20 cm.

Electrical characteristics of the discharge were measured by capacitive gauge movable along discharge cell axis and back current shunt mounted into the break of the supplying cable screen. The back current shunt was installed on the distance from the discharge cell at which incident to the cell and reflected from it current pulses are separated in time.

In all mixtures the emission intensity of the discharge was measured both in time resolved (band pass of signal route was 150 MHz) and in integral regimes. Emission intensities were measured through the optical CaF_2 window mounted in the low-voltage ring electrode with using monochromator MDR-23 and photomultiplier FEU-100 (rise-time of signal was not longer than 3 ns, spectral sensitivity bandwidth was 200-800 nm).

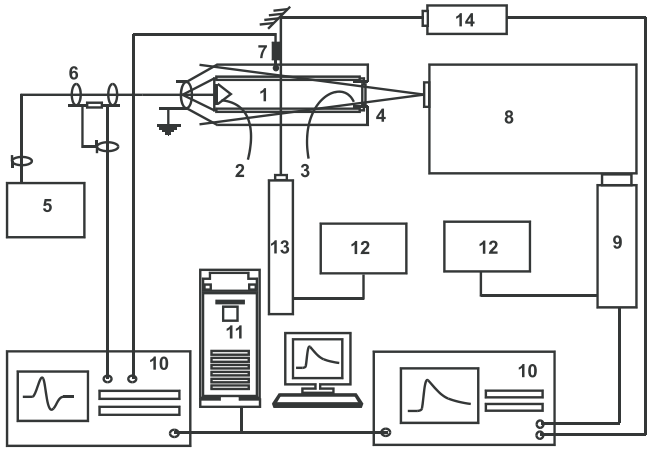

Figure 1: Experimental setup: 1 - discharge cell, 2,3 - electrodes, 4 - optical window (CaF_2), 5 - high-voltage generator, 6 - back current shunt, 7 - capacitive gauge, 8 - monochromator, 9 - photomultiplier FEU-100, 10 - oscilloscopes S9-8 and TDS-380, 11 - computer, 12 - power supplies, 13 - He-Ne laser ($\lambda = 3.3922\mu$m), 14 – photodetector Pb-Se.

In mixtures with methane absorption of He-Ne laser emission on 3.33922 μm was measured in addition to general set of parameters.

Time resolved signals were registered by oscilloscope Tektronix TDS 380 (band pass was 400 MHz). The integral measurements was fulfilled by oscilloscope S9-8 with 100, 200 and 400 s per scale.

Mixtures of heavy hydrocarbons were prepared under condition when partial pressure of an alkane lower than saturated vapor pressure at room temperature. A portion of an alkane was injected into the 10-liter vacuum-processed. The mass of the portion was smaller on 20% than mass of saturated vapor pressure of this alkane in this volume at room temperature. The control of pressure of gas in the volume allowed to measure the alkane concentration in the volume. Later we filled the volume by the oxygen up to the required pressure. The list of percentage of alkanes in all investigated mixtures is represented in the table 1.

2 Experimental methods

2.1 Finding of electric current, electric field and energy input

Typical oscillogram of the signal from the shunt is showed in the figure 2a. The first pulse of the current ("incident") is a pulse which moves from the high-voltage generator to the discharge cell. This pulse reflects from the discharge cell and returns to the shunt installation section in 100 ns. This is second pulse ("reflected") showed in the figure 2a. Further the pulse returns to the generator and reflecting from it returns to the shunt and later to the discharge cell. That is the process of pulse propagation repeats. Thus, the current shunt registers pair of pulses ("incident" and "reflected"), which come through it with period of 200 ns. The energy, which contributes in the gas in the first pulse, is equal to the difference of energies of "incident" and "reflected" pulses. The current, which passes through the discharge cell was obtained from the continuity equation of charge at the section of the high voltage electrode (figure 2). Taking into account directions of pulses propagation, which determine polarities of signals on the back current shunt:

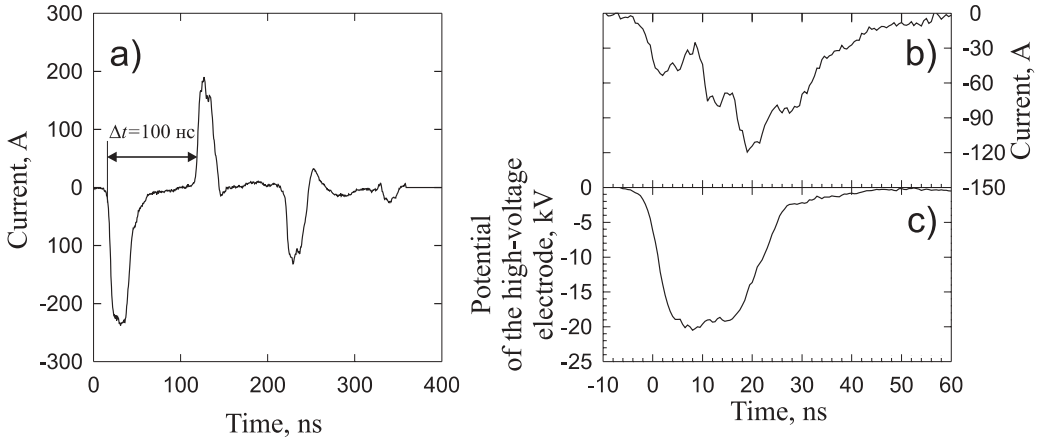

Figure 2: Characteristics measured by the current shunt: a) - the oscillogram of current in a cable, b) - the current through the high voltage electrode, c) - the high-voltage electrode potential. Initial pressure of the mixture CH_4+air is 1.51 torr.

$$J_0(t) = J_{\rm sh}(t) + J_{\rm sh}(t + 2\Delta t) \tag{1}$$

where $J_{\rm inc} = J_{\rm sh}(t)$ was the current in the incident pulse, $J_{\rm ref} = J_{\rm sh}(t+2\Delta t)$ is the current in the reflected pulse (figure 2), Δt is the time of the pulse propagation from the current shunt to the high-voltage electrode. Besides, the current shunt measurements allow to obtain as the current through the high electrode so the potential on the electrode U_0 (figure 2b), so electric field $E(t) = U_0(t)$ at the stage of short circuit.

Fulfilled analysis allowed to predicate that the main part of energy in the pressure range (0.76–10.6 torr), in which investigations were fulfilled, contributes in gas on the stage of short circuit in the first or the second pulse. At the same time nonuniformity of the discharge caused by cathode layer can be neglected. The noted feature allows measuring local electric field and current during the time of maximal energy contribution using only a back current shunt, that is especially important for investigation of chemical reactive mixtures, in which changes of a composition lead to the changes of electrodynamic characteristics. The electrical measurements,

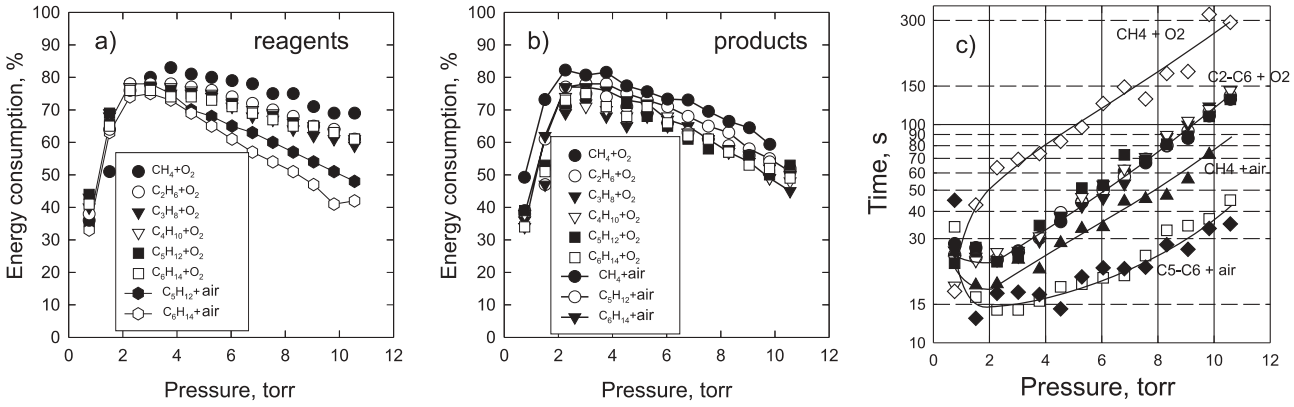

Figure 3: The sum of the energy input in the first and the second high-voltage pulses: a) in the initial mixture, b) in the mixture transformed by the discharge. Dependencies of alkanes full oxidation times on initial pressures of stoichiometric mixtures, obtained from $CO(B^1\Sigma \rightarrow A^1\Pi)$ band emission – c). The data for the stoichiometric mixtures of oxygen with alkanes from ethane to hexane are denoted as "C2–C6+O2", and data for the stoichiometric mixtures of oxygen with alkanes from ethane to hexane are denoted as "C5–C6+air" (see table 1)

which were fulfilled in the processed stoichiometric mixtures (from ethane to hexane) with oxygen or air, gave results, which are the same as the above-mentioned.

In the figure 3 the energy contribution is represented for all investigated mixture in the beginning of the discharge and after oxidation process. The total energy of the pulse reaches to 60 mJ. It is seen from the figure that in the beginning of the process of oxidation the energy contribution in any mixture with oxygen for pressures higher than 3 torr is systematically higher than for a mixture with air. With the growth of the pressure the difference increases and reaches 12% for the $p = 10.6$ torr. In processed mixtures variations of the energy contribution from a mixture to a mixture are negligible and even presence of nitrogen does not effect essentially. The energy contribution in the methane–oxygen processed mixture only is rather higher than one in other mixtures.

2.2 Experimental investigation of optical characteristics of the discharge

Full oxidation of alkanes in our conditions takes place under the action of a few thousands pulses (for tens and hundreds second), therefore integral over the time signal from the photomultiplier tube contains information about the hydrocarbons oxidation process. The control of emission intensity has been carried out for set of spectral transitions, at that some bands have been overlapped.

In addition in air-contained mixtures emission of $NO(A^2\Sigma \rightarrow X^2\Pi, \delta v = 3)$, $N_2(C^3\Pi, v' = 1 \rightarrow B^3\Pi, v'' = 7)$, $N_2(B^3\Pi, v' = 6 \rightarrow A^3\Sigma, v'' = 3)$ and $N_2^+(B^2\Sigma, v' = 0 \rightarrow X^2\Sigma, v'' = 2)$ have been controlled. It is necessary to note that intensities of the transitions of these molecules were so large that the emission of the overlapped bands was negligible.

In the case of essential overlap of the emitted bands to identify the band the emission intensities were measured in time-resolved regime for instants at the time when discharge switched on and when oxidation process was finished (when signal from the photomultiplier reached steady-state value). Also, measurements of emission intensities in time resolved regime were used for obtaining quenching constant rates in initial and final mixtures. Taking into account the constant rates of the quenching the excitation rates of higher states have been obtained.

Table 1: Investigated mixture.

Alkane	CH_4	C_2H_6	C_3H_8	C_4H_{10}	C_5H_{12}	C_6H_{14}
in mixture with O_2	33.3%	22.2%	16.6%	13.3%	11.1%	9.5%
n mixture with air	11.11%	–	–	–	3.03%	2.56%

2.3 Kinetics of alkanes oxidation in the discharge.

2.3.1 Stoichiometric mixtures

Time of full oxidation is defined as time at which the signal from photomultiplier reaches level of $0.95I_\infty$ for wavelengths (290 and 307,8 nm) corresponded to $OH(A^2\Sigma \rightarrow X^2\Pi)$ and $CO(B^1\Sigma \rightarrow A^1\Pi)$ transition and level $1.05I_\infty$ for wavelengths (430 and 518.6 nm) corresponded to $CO_2^+(B^2\Sigma \rightarrow X^2\Pi)$ and $CH(A^2\Delta \rightarrow X^2\Pi)$ transitions.

It is important to note that times of oxidation obtained from emission of different bands in the same experimental condition are rather different, owing to different influence of processes of excitation and quenching on different states during the mixture transformation, but times obtained from emission of the same band in different mixtures are practically the same within the experimental accuracy. Because of the fact that the experimental dispersion is minimal for the time obtained from $CO(B^1\Sigma \rightarrow A^1\Pi)$band emission, we designate time obtained from the emission of this band as the time of alkane full oxidation.

In the figure **??** times of full oxidation for different alkanes are represented. It is clearly seen, that time of methane full oxidation is nearly twice as large as times of full oxidation for other alkanes as in mixtures with oxygen so in mixtures with air. For other alkanes times of full oxidation are not differ with the experimental dispersion. In mixture with air times of full oxidation are twice or more as small as times in the same mixtures with oxygen. Taking into account that total quantity of alkanes smaller in stoichiometric mixtures with air than one in mixtures with oxygen, rates of allkanes in mixtures with oxygen oxidation are twice as small as one in mixtures with oxygen.

Thus, stoichiometric mixtures of alkanes with air and oxygen under nanosecond uniform discharge action at ambient temperature have been oxidized entirely. Oxidation of all alkanes beginning with ethane takes place for the same time in stoichiometric mixtures. The methane oxidizes in two times more slowly than other investigated alkanes.

2.3.2 C_4H_{10} oxidation in lean mixtures with oxygen under nanosecond discharge

As indicated above, oxidation of alkanes beginning with ethane under nanosecond discharge action proceeds for the same time under the same experimental conditions (initial pressure, energy input). One can explain this fact most logically in approximation of weak influence of excited and charged particles producing by electron impact to molecules of fuel in compare with influence of the impact to molecules of oxygen, intermediates and products, at first time water. It is known that electron impact thresholds of alkanes (in set methane–propane) dissociation reduce on 1 eV approximately with a increasing on a carbon's atom. Steric factor increases proportionally to a quantity of C atom in molecules of alkanes, at the same time a concentration of an alkane in stoichiometric mixture decreases inversely proportional to the quantity of C atom. Thus, it should be expected, that with change of stoichiometric mixtures from light to heavy alkanes the variation of an alkane concentration be compensated by variation of steric factor. However, with a quantity of carbon's atom in an alkane molecule increasing a dissociation threshold by electron impact is decreased. It should be expected, of course, faster oxidation of more heavy alkanes in compare with more lightly, which did not obtain in experiments. Let us consider possible explanation of this fact.

Excitation of molecular oxygen, its dissociation and ionization and so may be excitation and dissociation of products (at first time water) and intermediates entirely govern the alkanes oxidation. It is need to note, that in stoichiometric mixtures the quantity of oxygen is weakly varied from an alkane to another alkane and after processing in all mixtures the same quantity of water is produced. Difference in quantity of the carbon dioxide produced in oxidation process in all mixtures is negligible. So, the quantity of oxygen in stoichiometric mixture with ethane is 20% lower than it in mixture with hexane, on the same percents quantity of carbon dioxide produced in oxidation process is lower. It is necessary to note that water dissociates by electron impact more easily in comparison with carbon dioxide — water has lager absolute values of cross-sections of electron impact processes and essentially lowers thresholds; radicals generated from water are more active.

Thus, produced active particles of oxidant react with non-excited hydrocarbon's molecules, at that excitation, dissociation and ionization of hydrocarbons itself do not influence on oxidation rate. Using the methods described above, we have investigated oxidation of lean mixture of butane with oxygen. It has been shown that changes of energy input with equivalence ratio are not higher than 13% of pulse energy and specifically small for the range of maximum energy input in the initial mixture. And so we can assume that the discharge condition, which control excitation processes are not differ essentially for mixtures with different equivalence ratio from 0 to 1. In the figure 4 dynamics of the $CO(B^1\Sigma \rightarrow A^1\Pi)$ integral emission in the investigated mixtures is represented. It has clearly seen that with decreasing of the equivalence ratio the time of full oxidation decreases.

Time of full oxidation obtained from $CO(B^1\Sigma \rightarrow A^1\Pi)$ integral emission and time of of maximum of $CO(B^1\Sigma \rightarrow A^1\Pi)$ emission are represented in the figure 5. It is clearly seen that the time decreases linearly with

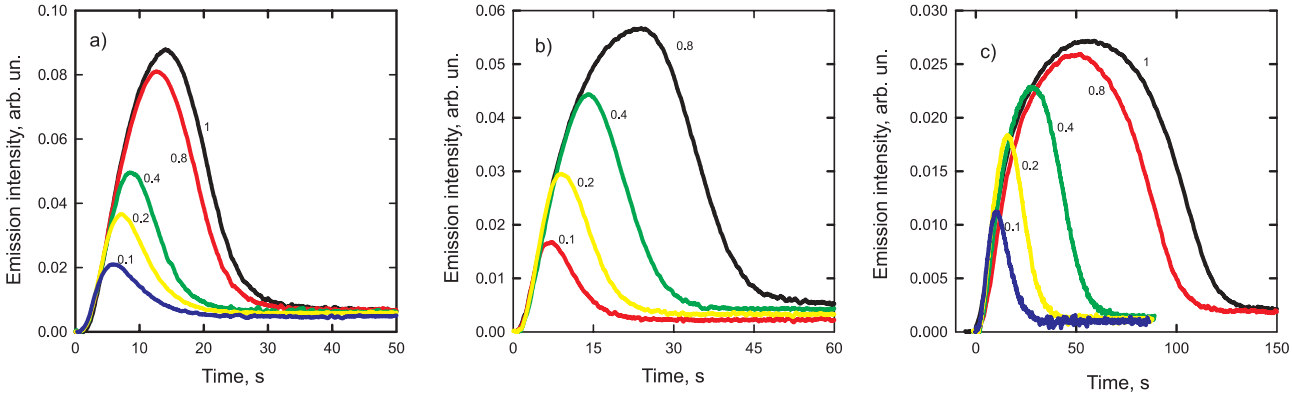

Figure 4: Integral over time emission intensities of transition $CO(B^1\Sigma \rightarrow A^1\Pi)$ in the discharge. The initial pressures of the mixtures are 1.51 torr for a), 5.29 torr for b) and 9.83 tor for c)

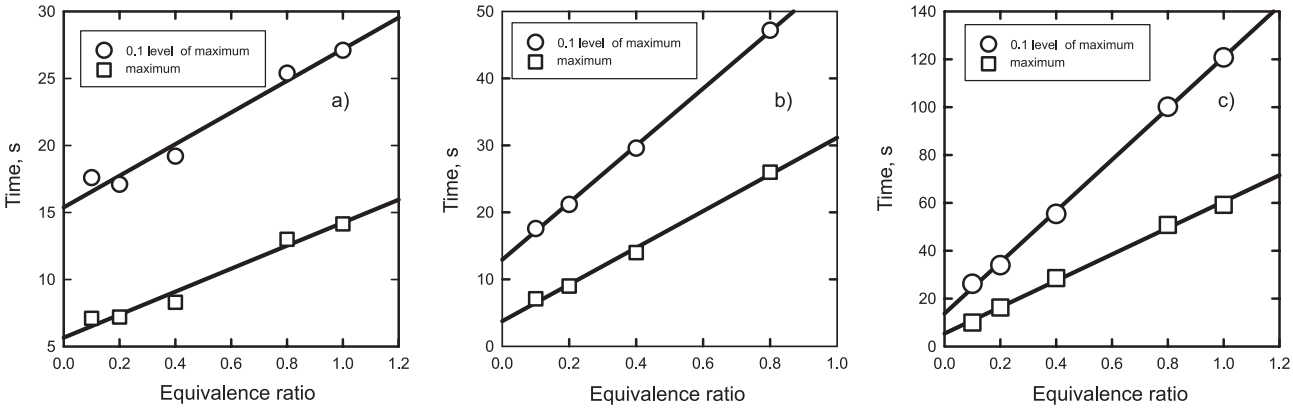

Figure 5: Time of full oxidation obtained from $CO(B^1\Sigma \rightarrow A^1\Pi)$ band emission - a) and time of $CO(B^1\Sigma \rightarrow A^1\Pi)$ band emission maximum versus initial pressure of butane with oxygen lean mixtures

decreasing the equivalence ratio that should be expected in the case of weak influence of excitation, dissociation and ionization of alkanes by the discharge. Really, the quantity of oxygen in stoichiometric mixture differs from it in mixture with equivalence ratio 0.1 on 11%, hence variations of concentrations of excited molecules, ions and atoms of oxygen no more than 11%. At the same time the concentration of butane changes in one order of magnitude, therefore dependence of time of full oxidation on equivalence ratio have to be linear with the good accuracy.

Thus, under our experimental condition, excitation, ionization and dissociation of an alkane by electron impact did not influence on the rate of the alkane oxidation.

2.3.3 $C_{10}H_{22}$ oxidation in lean mixture with oxygen under nanosecond discharge action

Real fuels used in internal-combustion engines consist of hydrocarbons C8-C16, therefore it should be examinate universality of above drawn conclusions on the example of alkane higher than C6. For this work we chouse n-decane $C_{10}H_{22}$. At 25^oC saturated vapor pressure of n-decane is equal 0.9 torr, and so the maximal pressure of stoichiometric mixture with oxygen is equal 18 torr. The preparation of the mixture was analogous as for hexane and pentane mixtures. A portion of decane was injected into the 10-liter vacuum-processed volume. The portion of decane was smaller than value of saturated vapor pressure of n-decane at 25^oC in 10-liter volume. Later we added oxygen into the volume. The mixture was mixed by ventilator. In spite of the forced mixing, concentration of decane increases very slowly, that we explained by very slow evaporation of decane under ambient temperature condition.

We controlled the concentration of decane by following method. The current mixture was oxidized in nanosecond discharge. The spectrum of emission of the mixture compared with spectra obtained in processed mixtures of butane and oxygen with different equivalence ratios. Emission intensities of OH and CO_2^+ bands in processed butane-oxygen mixtures upon equivalence ratio, which are used to obtain decane concentration depend on equivalence ratio essentially non-linearly. We explained this fact by the influence of concentration of

water on electron energy distribution function that is by changes of constants of excitation of these states by electron impact with water concentration changes. In this figure also emission intensities of processed decane oxygen mixture on the same wavelengths are represented. The emission intensities of different bands were interpolated between measured points and extrapolated to the zero point linearly. These dependencies allowed to obtain the equivalence ratio of the decane mixture. The concentration of n-decane obtained by this method amounted to 0.12 during 3 days of mixing. That is necessary 30 days to obtain the stoichiometric mixture of n-decane with oxygen.

Thus, there is no sense to prepare stoichiometric mixture of n-decan with oxygen in room temperature owing to very long preparation time, and so we investigated oxidation process in the mixture with 0.12±0.01 stoichiometric ratio. In the mixture was registered energy contribution and $CO(B^1\Sigma \rightarrow A^1\Pi)$ emission intensity. It is necessary to note that difference between energy inputs in initial and in processed mixtures is negligibly small owing to the oxygen is the main constituent of these mixtures.

The energy contribution in different mixture does not differ within the range of experimental data scattering. Thus, excitation of a gas occurred with the same intensity for all mixtures.

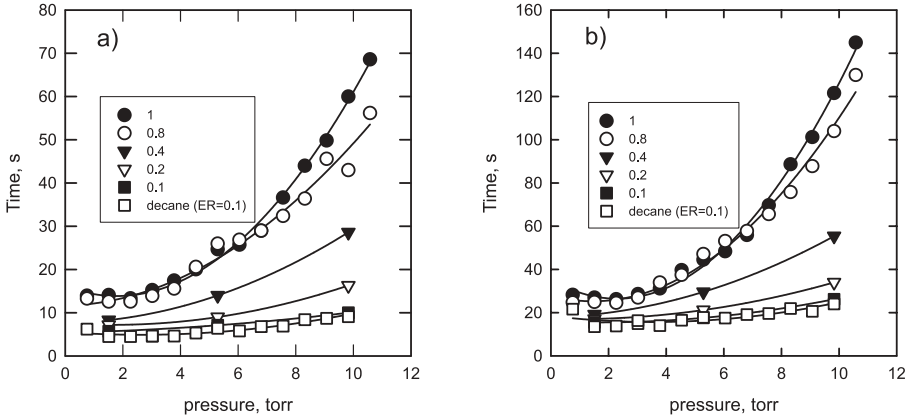

Figure 6: Time intervals between discharge beginning and $CO(B^1\Sigma \rightarrow A^1\Pi)$ emission maximum — a) and instants of full oxidation — b)

In the figure 6 times of full oxidation obtained by emission intensities of $CO(B^1\Sigma \rightarrow A^1\Pi)$ bands for butane-oxygen mixtures and for the decane-oxygen mixture are represented. It is clearly seen that time of full oxidation of n-decane is approximately equal to the time of full oxidation of butane in mixture with 0.1 equivalence ratio. Thus, the conclusions, which we have made for mixtures of alkanes C2-C6 early, can be extended on alkanes that are more heavy.

3 Conclusions

The kinetics of slow oxidation of alkanes under the action of the nanosecond pulsed-periodic discharge in stoichiometric and lean mixtures with oxygen and air at room temperature has been investigated experimentally.

It has been shown, that the alkanes under the nanosecond discharge action at ambient temperature are oxidized entirely. The times of the full oxidation with the same values of the energy contribution, mixture initial pressure and equivalence ratio were not differ for all alkanes large then methane. Methane was oxidized in two times more slowly than other alkanes. Alkanes oxidation in mixtures with oxygen passes approximately in two times more effectively than in corresponded mixtures with air. Times of full oxidation of alkanes are proportional to equivalence ratio under our conditions.

The Use of Nitrogen/Hydrogen Corona Treatment for the Surface Modification of Poly(tetrafluoroethylene)

Seth M. Kirk[1], Mark Strobel[1], Hyacinth Cabibil[1]

[1]*3M Corporate Research Laboratory, 3M Company, St. Paul, MN 55144*

1. Introduction

Fluoropolymer materials have many desirable properties such as low reactivity with chemical and biological compounds. However, these same non-reactive qualities also make it difficult to form an adhesive bond with a fluoropolymer surface to create a functional multi-layer construction. To successfully incorporate a fluoropolymer material into a multi-layer construction, a surface modification must be applied to the fluoropolymer.

Various processes are used for the surface modification of polymers, including solution-coating techniques, chemical etching, and the exposure of polymer surfaces to reactive gas atmospheres. The use of reactive gas atmospheres, such as plasmas and flames, is of significant interest for the high-speed industrial-scale surface modification of polymer films. Perhaps the most robust process for such surface modification is dielectric-barrier discharge treatment, commonly referred to as atmospheric-pressure plasma or corona treatment.

However, corona treatment technology has not been well developed for treating fluoropolymer films. Surface modification of fluoropolymer films has more typically been done with slow and costly wet-chemical etching or reduced-pressure plasma treatments. The use of commercial corona treatment technology for the surface modification of fluoropolymers is a lower-cost and higher-throughput process than other technologies. It is the aim of this paper is to demonstrate that by using a low-cost reactive atmosphere with commercial corona equipment, a robust and industrially viable polymer surface modification can be delivered to poly(tetrafluoroethylene) (PTFE) film.

2. Background

Although corona treating is a mature technology with multiple suppliers of commercial equipment, there has been limited work reported on the use of corona processing with controlled atmospheres. In particular, we are aware of no reported work on the use of corona treatment with hydrogen-containing atmospheres. Accordingly, the use of corona treatments in nitrogen/hydrogen atmospheres has been developed in 3M as a proprietary process [1].

There is a body of work that has examined reduced-pressure plasma treatment of fluoropolymers. Although the reactive environment of a reduced-pressure glow discharge is distinct from that of atmospheric-pressure corona, comparisons with the reduced-pressure work can be instructive. In particular, a comparison made by Inagaki [2] between “direct” plasma exposure and “remote” plasma exposure, shows that the remote plasma treatment, with diminished roles of ions and UV energy, produces a modified PTFE surface without a soluble surface component. Atmospheric-pressure corona discharges are understood to have minimal amounts of ions and reactive UV energy [3], and analysis of the samples reported here parallels the reported Inagaki results.

In work that directly compares hydrogen plasma to other reduced-pressure plasma chemistry, the use of hydrogen is noted to produce a uniquely high level of surface defluorination [4, 5]. However, defluorination of a PTFE surface followed exclusively by surface reaction with hydrogen does not result in the most reactive surface. Several researchers have demonstrated that a hydrogen plasma with other gaseous additives [6], including nitrogen [4], will produce a more functionalized surface than a pure hydrogen discharge.

2. Experimental

For the work reported here, we used a modified commercial corona treater. In this treater, PTFE film was transported on a grounded ceramic-covered water-cooled ground roll. The ground roll and two stainless steel shoe electrodes were enclosed in a housing that was purged with nitrogen and the optional addition of hydrogen. A sealing system on the treater enclosure enabled the polymer film to be transported into and out of the discharge while minimizing the amount of gaseous contaminants in the discharge atmosphere.

The most significant variables in corona processing are the composition of the atmosphere where the discharge occurs and the normalized energy. Normalized energy has units of Joules per square centimeter (J/cm^2) and is calculated from the net power P (in watts), the electrode width w (in cm) and the film velocity s (in cm/s):

$$\text{Normalized energy, } E = P/ws$$

All corona treatments reported here were done at 25 ºC, with a film velocity of 3.3 cm/s and a net power of 1870 watts delivered to 33-cm-wide electrodes, which corresponds to a normalized energy of 17 J/cm^2.

The surface composition of the films was analyzed by X-ray photoelectron spectroscopy (XPS), also known as Electron Spectroscopy for Chemical Analysis (ESCA). The ESCA spectra were obtained from a Kratos Axis Ultra system equipped with a monochromatic Al Ka X-ray source. The photoemitted electrons were detected at 90^o with respect to the sample surface. ESCA detected the presence of fluorine, carbon, oxygen, and nitrogen on the treated samples and only fluorine and carbon on the untreated sample.

Contact-angle measurements were made on the treated surfaces of the films using the Wilhelmy plate method on a ThermoCahn Radian DCA322 dynamic contact-angle instrument. Advancing and receding contact angles in air were made using deionized filtered water and high-purity hexadecane. A three-layer laminate was prepared using 3M Scotch Brand #666 double-coated tape to mount the treated sides of the film outward. The laminate was cut into a 2.5 x 2.5-cm square for analysis. The stage speed was 50 µm/sec with a travel distance of about 1 cm. At the position of the maximum travel, the motion of the stage was halted for 2 minutes prior to starting the retraction phase of the Wilhelmy cycle, thereby soaking the sample for a period of time. The contact angles were calculated using a software routine supplied with the ThermoCahn instrument that uses linear regression for the buoyancy correction. Typical standard deviations for the contact angles measurements were 2º.

3. Results

ESCA analyses show that corona treatments using nitrogen and nitrogen/hydrogen atmospheres result in the surface modification of the PTFE surface. The loss of fluorine is evident in Figure 1, which shows the changes in F/C atomic ratios as a function of the percent hydrogen in a nitrogen atmosphere. The use of a nitrogen discharge atmosphere with no hydrogen addition results in a surface with a F/C ratio just slightly lower that of the untreated PTFE surface, indicating a minor surface modification. The addition of increasing amounts of hydrogen results in a progressive loss of fluorine as shown by a substantial decrease in F/C ratios.

The defluorination is accompanied by the incorporation of nitrogen and oxygen to the polymer surface as shown in Figure 2, which plots the N/C and O/C ratios as a function of percent hydrogen in the nitrogen atmosphere. The incorporation of these atoms on the modified surface likely results from surface radicals (created by the removal of fluorine atoms) reacting with nitrogen and oxygen atoms formed in the discharge. Figure 2 also suggests that the maximum level of nitrogen and oxygen incorporation has been achieved at a hydrogen additive level of less than 1%.

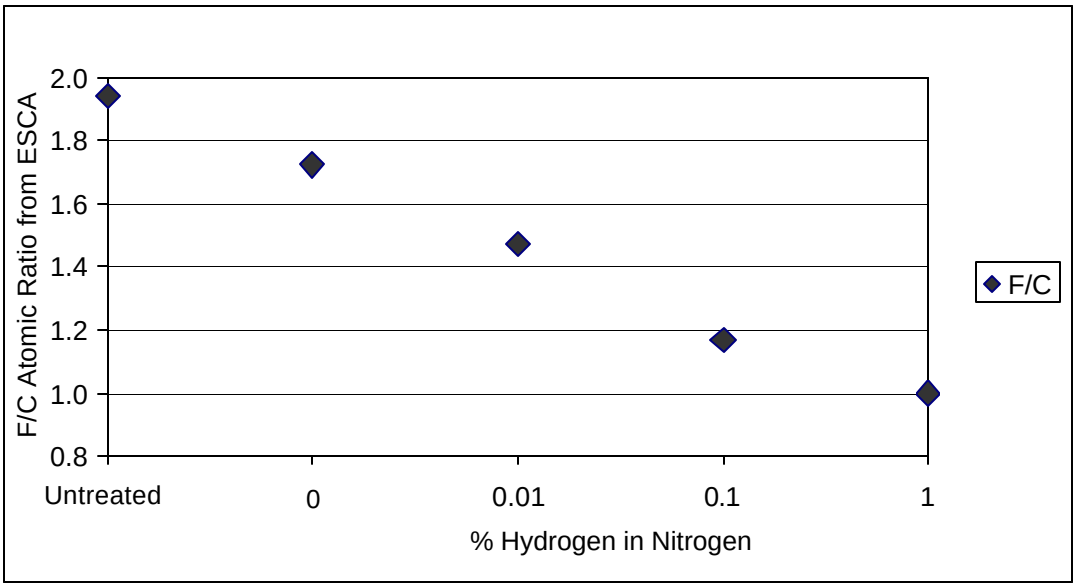

Figure 1. ESCA F/C atomic ratios of corona-treated PTFE

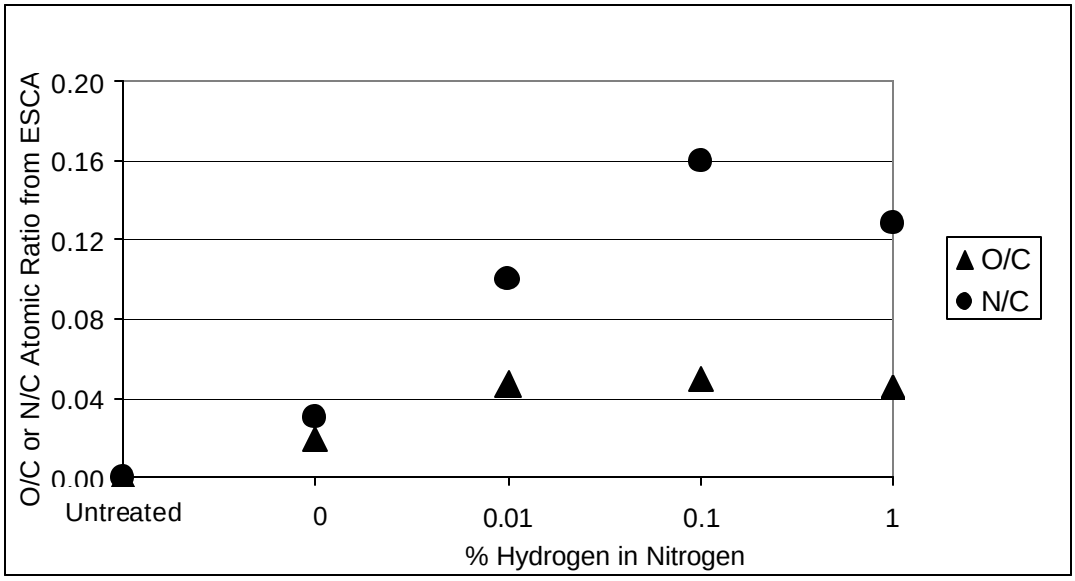

Figure 2. ESCA O/C and N/C atomic ratios of corona-treated PTFE

The loss of fluorine is also reflected in the ESCA carbon 1s spectra displayed in Figure 3, which shows the gradual decrease of the CF_2 peak from the untreated PTFE and the evolution of a broad peak on the lower-binding-energy side. The C 1s spectrum of the nitrogen corona treatment (no hydrogen added) is very similar to that of the untreated PTFE. A broad peak develops on the lower binding energy side of the C 1s spectra with the increasing addition of hydrogen to the nitrogen atmosphere. This broad peak includes contributions from carbon atoms in many different chemical environments. For example, –CF and C-CF_x bonding configurations may be present in addition to C-O, C-N, and C-C. The peak attributable to the C-C is most pronounced on the sample treated with the highest amount of hydrogen added to the corona atmosphere.

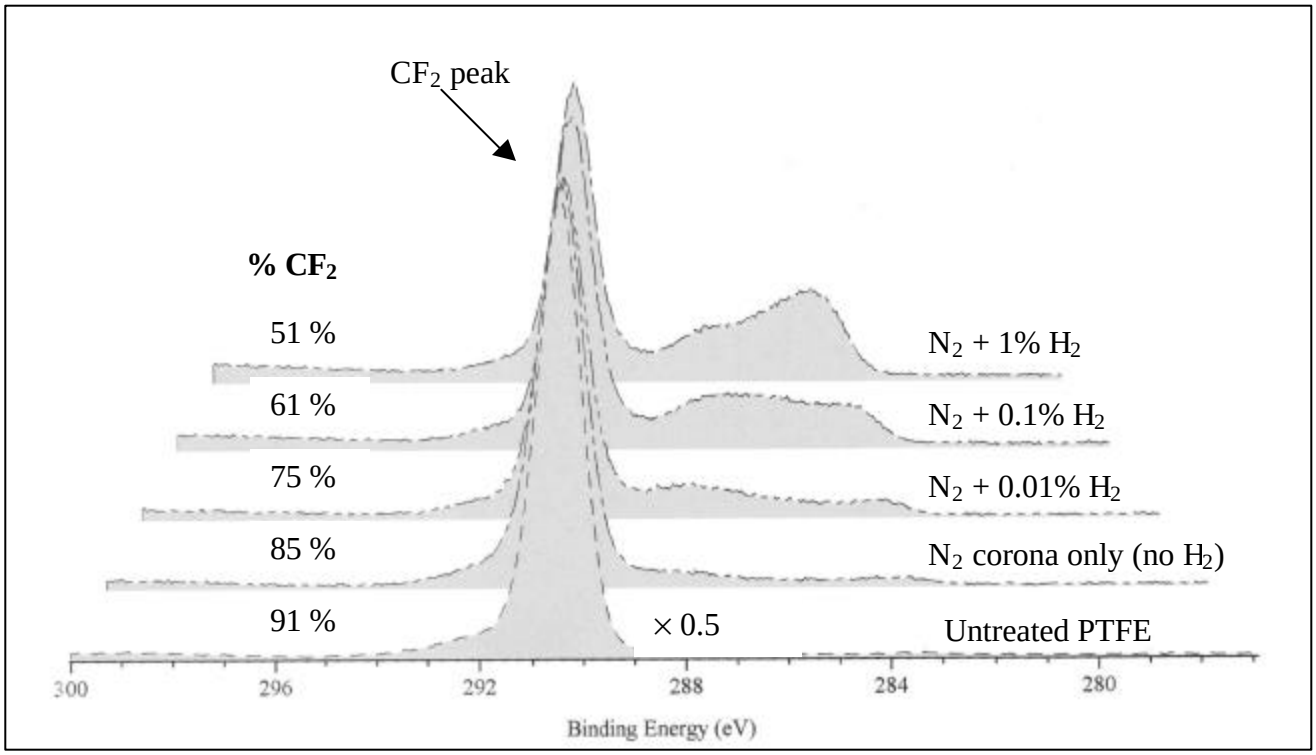

Figure 3. ESCA C1s spectra of PTFE treated with hydrogen/nitrogen coronas. Spectra not corrected for sample charging.

Corona-modified PTFE samples were further evaluated by measuring the advancing and receding contact angles of water in air, as shown in Figure 4. This analysis shows a decrease in the contact angles from treatment in the pure-nitrogen atmosphere and a continuing decrease in the contact angles with the addition of hydrogen to the discharge atmosphere. A more wettable, higher-energy surface develops with increasing additions of hydrogen to the nitrogen discharge.

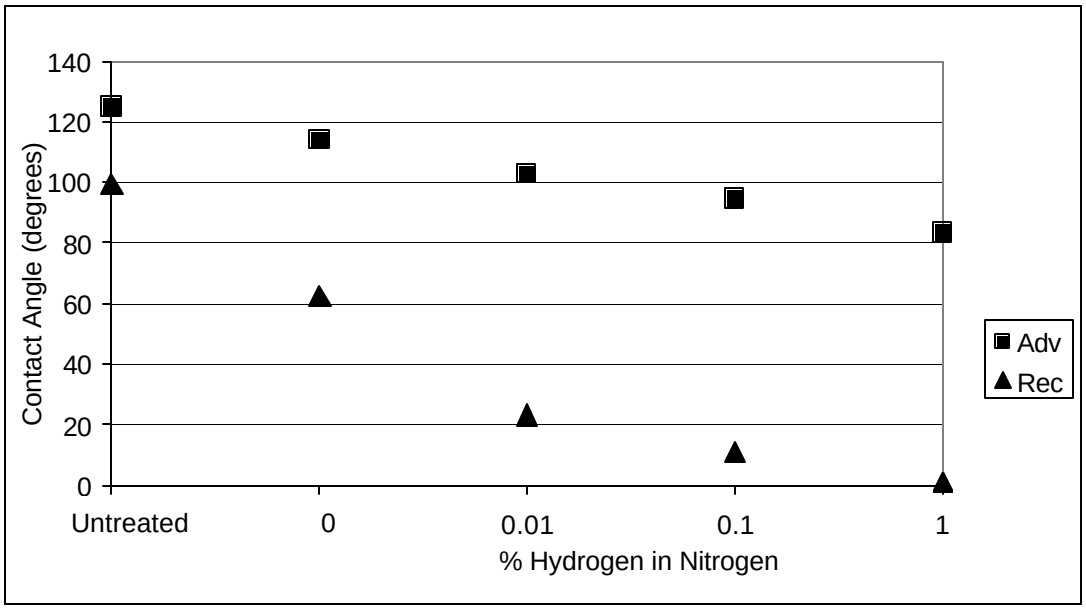

Figure 4. Advancing and receding water contact-angles in air of corona-treated PTFE

The same corona-modified PTFE samples were also evaluated by measuring the advancing and receding contact angles of hexadecane in air, as shown in Figure 5. This analysis also shows a decrease in contact angles from treatment in the pure-nitrogen atmosphere and a continuing decrease in contact angles with the

addition of hydrogen to the discharge atmosphere. The hexadecane contact angles respond strongly to the hydrocarbon functionalities on the modified PTFE surface and the 0º receding contact angles indicate the formation of hydrocarbon functionalities with hydrogen additions as low as 0.01%.

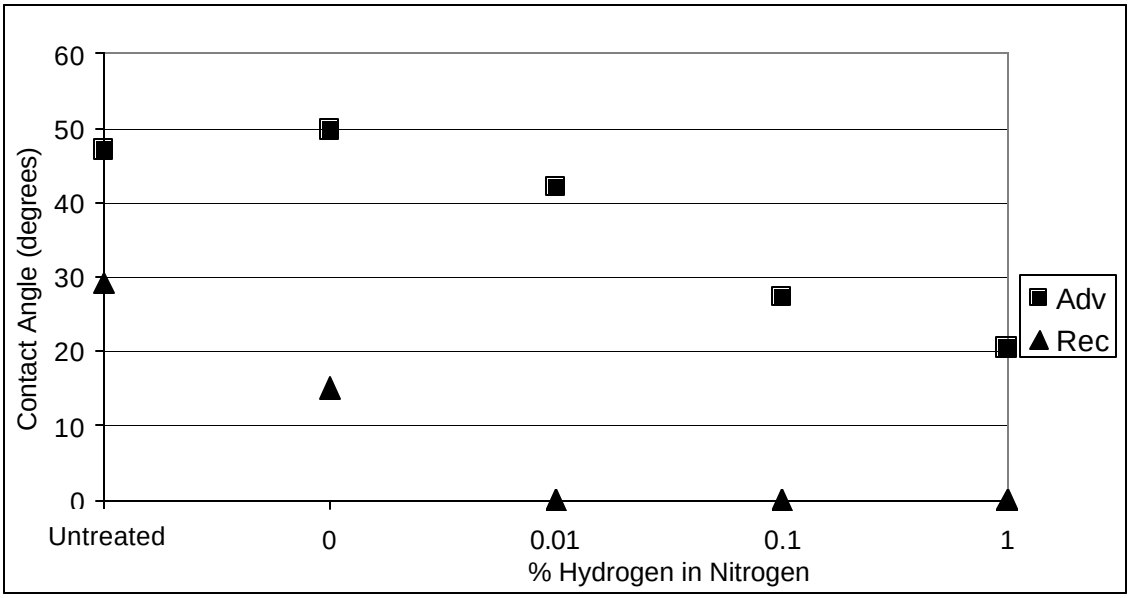

Figure 5. Advancing and receding hexadecane contact-angles in air of corona-treated PTFE

4. Discussion

The results presented here show that low concentrations of hydrogen in corona discharges can effectively defluorinate PTFE surfaces. Pure-nitrogen corona discharges have a minor effect on PTFE, indicating that the reactive species in these discharges cannot break significant numbers of C-F bonds. The addition of hydrogen to a nitrogen discharge allows the formation of hydrogen atoms that can break the C-F bonds on the surface of the PTFE. The decrease in surface fluorine resulting from increased hydrogen addition, combined with the limited role of ions and UV energy in the corona discharge, suggest that hydrogen atoms are primarily responsible for the removal of fluorine atoms from the surface of the treated polymer. The strongly bonded product species of this reaction, HF, removes surface fluorine and allows the other species in the discharge to react with the surface radicals formed by the abstraction of fluorine.

At low concentrations of hydrogen, the degree of surface modification is limited by the concentration of hydrogen introduced to the discharge atmosphere. As hydrogen is first introduced and increased, the increasing number of surface radicals formed from fluorine abstraction react with nitrogen and oxygen species in the discharge. As the hydrogen concentration continues to rise in the discharge atmosphere, surface defluorination increases, but the more abundant hydrogen atoms also compete with nitrogen and oxygen atoms for reaction with the surface radicals created by the fluorine abstraction. The result of this competition is seen in the ESCA results presented above, which show a point of maximum nitrogen and oxygen incorporation.

Selective Removal of Acetylene from Ethylene via RF Plasma Derived Pd Catalysts

Ai-Min Zhu, Kliff Pittman, Monyka Macias and Ben W.-L. Jang*
Chemistry Department, Texas A&M University-Commerce, Commerce, TX 75429-3011, USA

Abstract

Plasma treatment for supported Pd/SiO_2 catalysts has been studied using a custom-designed 360° rotating RF plasma system. The treatments using O_2 plasma, Ar plasma and H_2 plasma can enhance the selectivity to C_2H_4 of acetylene hydrogenation. The catalyst treated with H_2 plasma without thermal reduction exhibits higher C_2H_4 selectivity and C_2H_4 concentration than those with thermal reduction. H_2 plasma treatment is promising for reduction of metal catalysts at low temperatures to fine tune catalytic activity and selectivity.

Keywords: plasma, Pd catalyst, selective hydrogenation, acetylene, ethylene

1. Introduction

Selective hydrogenation has been widely used for chemical processing and environmental applications. For examples, the removal of highly unsaturated hydrocarbons from the C_2-C_4 alkene feeds is highly desirable for petrochemical industry and the selective reductions of halogen containing compounds, NO_x and SO_x are required to meet stringent environmental regulations [1]. This study focuses on the development of Pd catalyst via the radio frequency (RF) non-thermal plasma technology for selective hydrogenation of acetylene in the presence of ethylene because plasma based techniques for catalyst preparation have recently been reported to develop catalytic materials with unusual catalytic properties including high metal dispersion and better stability [2,3]. The selectivity and stability of catalysts for acetylene removal from ethylene has been an important research subject due to its slight improvement representing a large revenue for the industry.

2. Experimental

20-40 mesh silica particles with 144 m^2/g surface area are impregnated with a calculated palladium nitrate solution using the incipient wetness technique. The resulted material followed by drying at 120 °C for 12 hours in static air is designated as untreated $0.05\%Pd/SiO_2$ catalyst. The obtained materials are treated with O_2, Ar and H_2 plasmas are designated as $0.05\%Pd/SiO_2(O_2)$, $0.05\%Pd/SiO_2(Ar)$, $0.05\%Pd/SiO_2(H_2)$, respectively. Some portion of un-calcined $0.05\%Pd/SiO_2$ is further calcined at 300 °C in air for half an hour and is designated as calcined $0.05\%Pd/SiO_2$.

Plasma treatments for catalytic materials were carried out in the custom-designed 360° rotating RF plasma system. The detail of the system is described in the previous publication [4]. The schematic of the system is shown in Figure 1. System pressure of 400 mTorr was used for plasma treatments in this study. Typically, one gram of catalysts is loaded in the plasma chamber for plasma treatments. The time for plasma treatment is set at 30 minutes with a continuous or pulsed (10 ms on duty and 50 ms off duty) waveform.

All catalysts are tested for the selective hydrogenation of acetylene. If not otherwise specified, the Pd/SiO_2 catalysts were reduced in situ in hydrogen from 25 °C to 300 °C or 400 °C with a ramp rate of 5 °C/min and held at 300 °C or 400 °C for half an hour before cooling to desired temperatures for testing of activity and selectivity. Reaction study was carried out with a space velocity of 84,000 sccm/h-g catalyst over 30 mg of catalyst. 40 sccm of the premixed gas consisting of 98.8% C_2H_4 and 1.2% C_2H_2 was mixed with 2 sccm of UHP H_2 to introduce

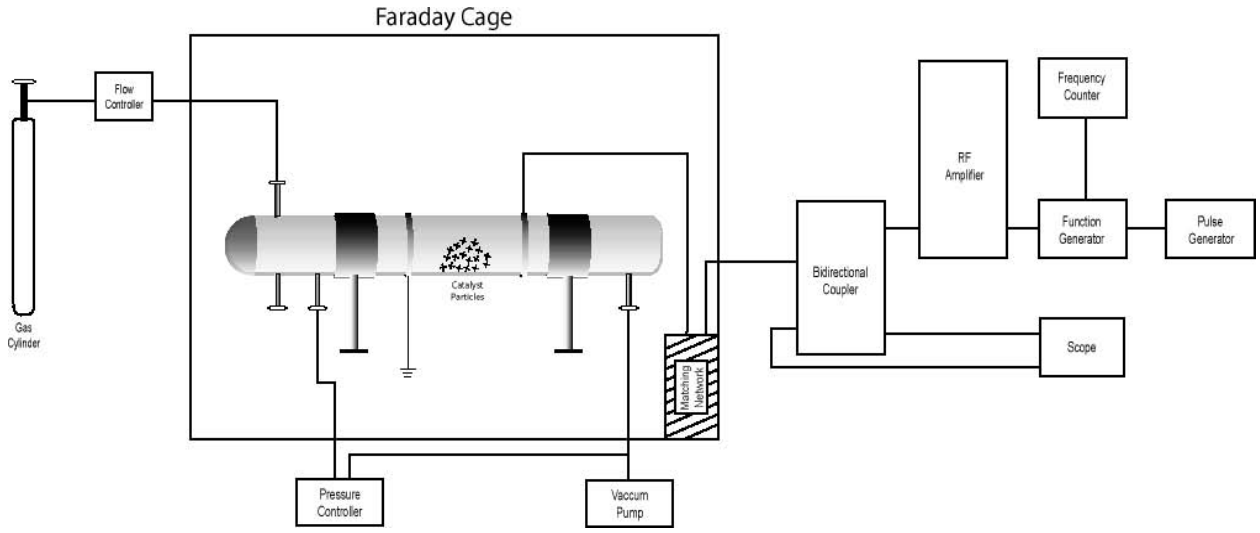

Fig.1 The schematic of the rotating RF plasma system for catalyst treatments

into the microreactor. All flows are delivered by mass flow controllers. The analysis of the gas components from the microreactor was performed by an on-line Shimadzu GC 17A equipped with a 30 m × 0.32mm (ID) ×1.50 μm GS-CARBONPLOT capillary column operating at 80 °C and a FID detector.

Possible products for acetylene hydrogenation are ethylene and ethane. The conversion of acetylene to ethylene is desirable. But, the conversion of acetylene to ethane or ethylene to ethane is not economical since they both reduce the net ethylene content, especially the hydrogenation of ethylene to ethane. The selectivity of acetylene hydrogenation to ethylene is defined as follows:

$$\%\ C_2H_4 \text{ selectivity} = (1 - \text{produced } C_2H_6 / \text{converted } C_2H_2) \times 100$$

Positive % C_2H_4 selectivity refers to a net gain of ethylene during the hydrogenation process and negative selectivity results in ethylene loss.

3 Results and Discussion

3.1 Effect of the Plasma Gas on Pd /SiO_2 Catalysts

Fig. 2a shows the activities of C_2H_2 conversion vs temperature on Pd /SiO_2 catalysts, including untreated and treated by O_2 plasma, Ar plasma, H_2 plasma and calcination. Compared to the untreated Pd /SiO_2 catalyst, the activity of Pd /SiO_2 treated with calcination is slightly improved. Yet, whether the plasma gas is O_2, Ar or H_2, plasma treated Pd /SiO_2 catalysts are less active than the untreated one. The activity order for the catalysts treated with plasma is O_2 plasma ~Ar plasma > H_2 plasma. As shown in Fig.2b, for any treated or untreated catalysts, the selectivity to C_2H_4 decreases with increasing temperature, which is in agreement with the literature [5]. The data also suggest that plasma treatment towards Pd/SiO_2 catalyst can lead to an improvement in C_2H_4 selectivity. However, the difference of C_2H_4 selectivity shown in Fig. 2b is affected by C_2H_2 conversion, which is also changing with different treatments on catalyst. To make this comparison meaningful, the selectivities of different catalysts should be compared at the same C_2H_2 conversion. As shown in Fig. 3, plotted as C_2H_4 selectivity vs C_2H_2 conversion, C_2H_4 selectivities of catalysts treated with O_2 plasma, Ar plasma, H_2 plasma and calcination appear to fall on one curve and are obviously higher than that of untreated catalyst. Results suggest that the plasma treatments towards Pd/SiO_2 catalyst using O_2 plasma, Ar plasma, H_2 plasma can enhance the selectivity to C_2H_4 of acetylene hydrogenation.

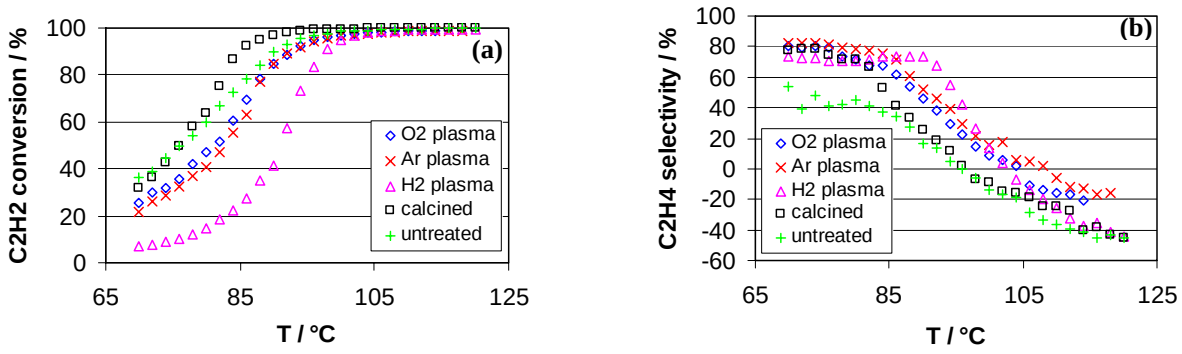

Fig.2 Curves of C_2H_2 conversion (a) and C_2H_4 selectivity (b) versus reaction temperature over untreated catalyst and catalysts treated by plasma or calcination. Plasma treatment conditions: pulsed waveform with 10 ms on duty and 50 ms off duty, 0.23 MHz of repetition frequency, 120 W, 400 mTorr, 0.5h. Calcination conditions: 300 °C, 0.5h

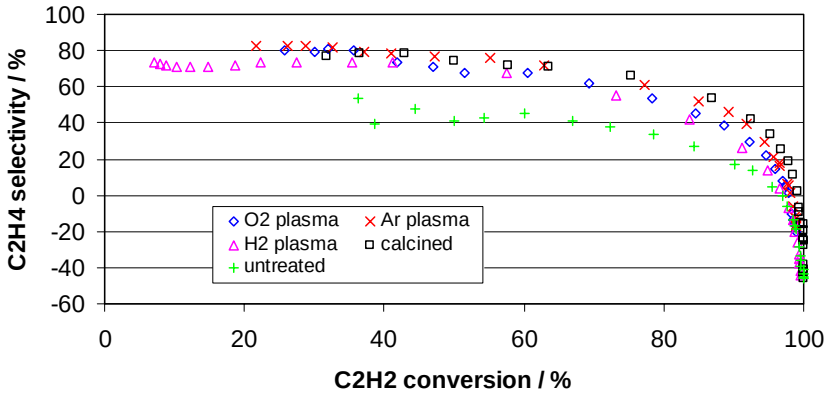

Fig. 3 C_2H_4 selectivity versus C_2H_2 conversion over plasma treated, calcined and untreated catalysts. The conditions are same as those in Fig. 2.

3.2 Effect of Reduction Temperature

The plasma employed to treat catalysts in this study belongs to a non-thermal equilibrium plasma (NTP) with much high electron temperature (>10^4 K) but rather low bulk gas temperature (R. T. ~ 400 K). Therefore, it is worthwhile to clarify whether high reduction temperature affects the catalytic performance of catalysts derived from plasma treatments or not. From this idea, untreated Pd/SiO_2 catalyst, calcined Pd/SiO_2 catalyst and $0.05\%Pd/SiO_2$ (O_2) catalyst were compared with 300 °C and 400 °C reduction temperatures. From Fig. 4a their activities with different reduction temperatures are comparable at same reaction temperatures. However, it can be seen from Fig 4b that the untreated Pd/SiO_2 catalyst reduced in H_2 at 400 °C shows higher C_2H_4 selectivity than that reduced at 300 °C at C_2H_2 conversion less than 80%. Reduction temperature, on the other hand, does not affect the C_2H_4 selectivity at C_2H_2 conversion higher than 80%.

For the calcined Pd/SiO_2 catalyst, it's found that the curves of C_2H_4 selectivity versus C_2H_2 conversion at 300 °C and 400 °C of reduction temperature appear to be similar as shown in Fig 5b, though the activity of catalyst reduced at 400°C is slightly lower (Fig 5a). In the case of the $0.05\%Pd/SiO_2(O_2)$ catalyst, activity and selectivity pattern is completely different from the calcined and untreated catalysts. As shown in Figure 6a, the selectivity of the catalyst reduced at 400°C decreases linearly with the increase in C_2H_2 conversion. These results in lower C_2H_4 selectivity of the catalyst reduced at 400°C at C_2H_2 conversion higher than 60% compared to the catalyst reduced at 300 °C. It indicates that catalysts derived from plasma treatments are quite different from those

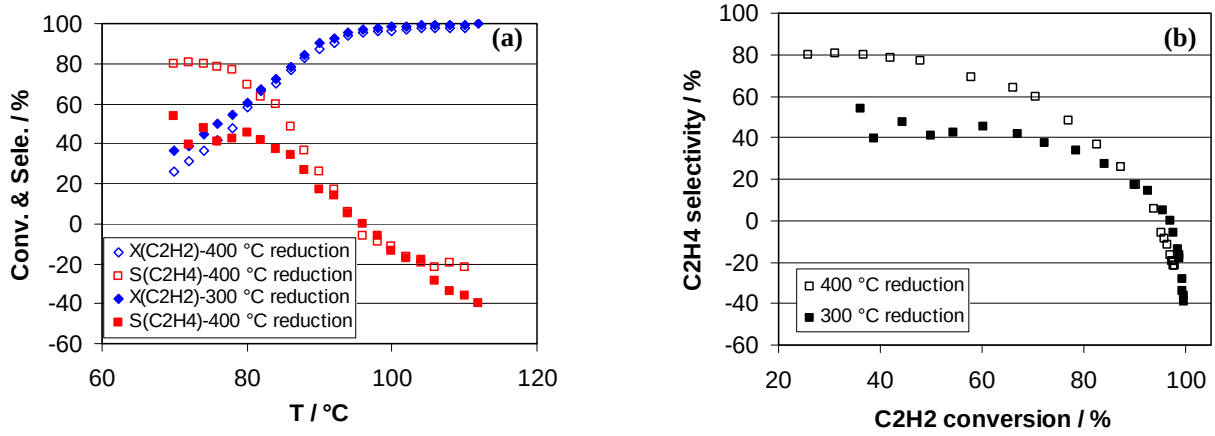

Fig. 4 Effect of reduction temperature over untreated Pd/SiO_2 catalyst. (a) conversion & selectivity vs temperature (b) C_2H_4 selectivity vs C_2H_2 conversion.

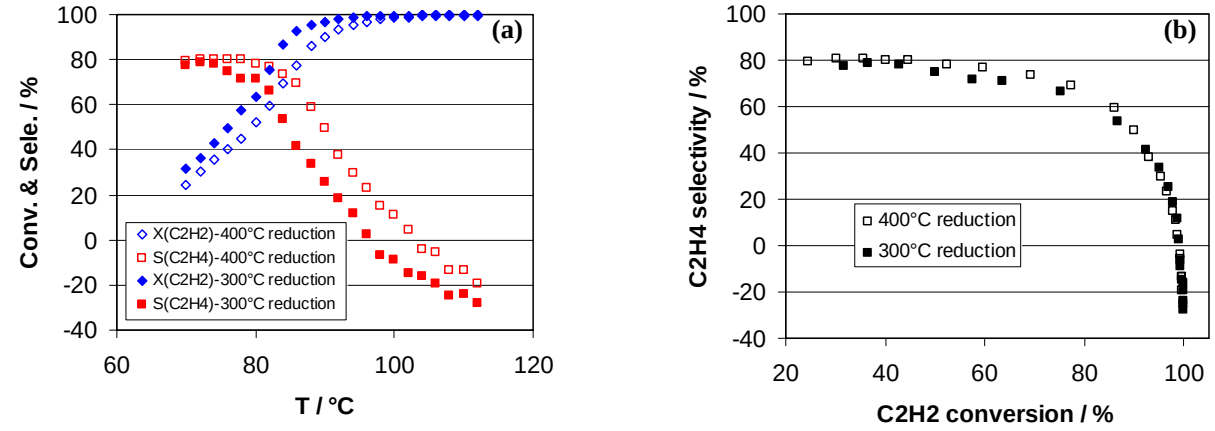

Fig. 5 Effect of reduction temperature over calcined Pd/SiO_2 catalyst (a) conversion & selectivity vs temperature (b) C_2H_4 selectivity vs C_2H_2 conversion.

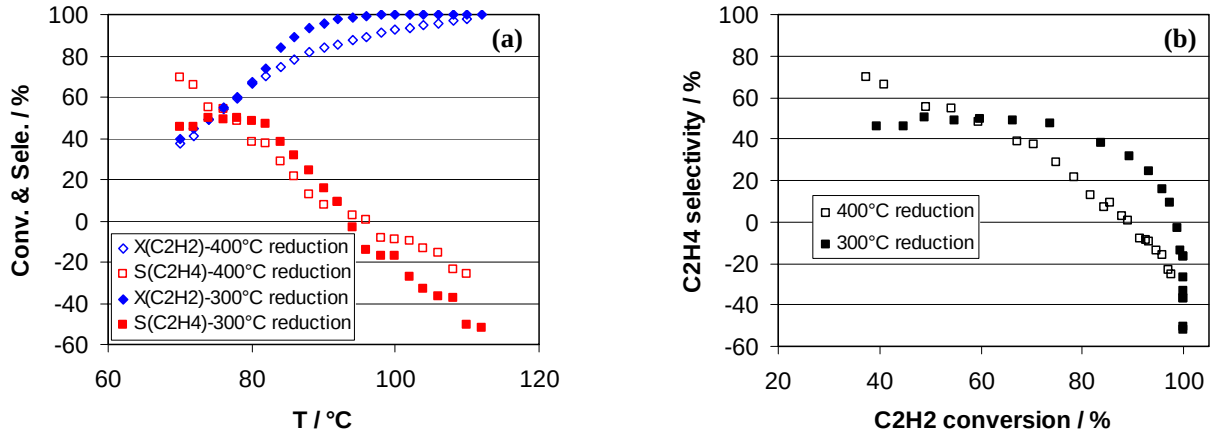

Fig. 6 Effect of reduction temperature over $0.05\%Pd/SiO_2(O_2)$ catalyst. (a) conversion & selectivity vs temperature (b) C_2H_4 selectivity vs C_2H_2 conversion. O_2 plasma treatment conditions: continuous waveform, 13.56 MHz, 160 W, 400 mTorr, 0.5h.

derived from conventional treatments and are more sensitive to reduction temperature than the latter. Catalysts treated by NTP may not be as stable as conventional catalysts in high temperature processes.

3.3 H_2 plasma reduction towards Pd/SiO_2 catalyst

As mentioned above, thermal reduction process may result in a decrease of catalytic selectivity and stability of catalysts treated with O_2 plasma. If H_2 is used as the plasma gas for plasma treatment of catalyst, can the thermal reduction process of Pd/SiO_2 catalyst be avoided? To answer this question, the catalytic materials treated by H_2 plasma with and without thermal reduction were compared. As shown in Fig.7a & b, the catalyst treated with H_2 plasma without thermal reduction exhibits higher C_2H_4 selectivity and C_2H_4 concentration (percentage of C_2H_4 in carbon-containing gaseous components) than those with thermal reduction either at 100°C or 300°C, though its activity is lower. It is suggested that the Pd precursor can be reduced by H_2 plasma to optimize the ethylene yield of acetylene hydrogenation. It is believed that H_2 plasma can likely reduce other metal catalysts at low temperatures and can be used to fine tune catalytic activity and selectivity.

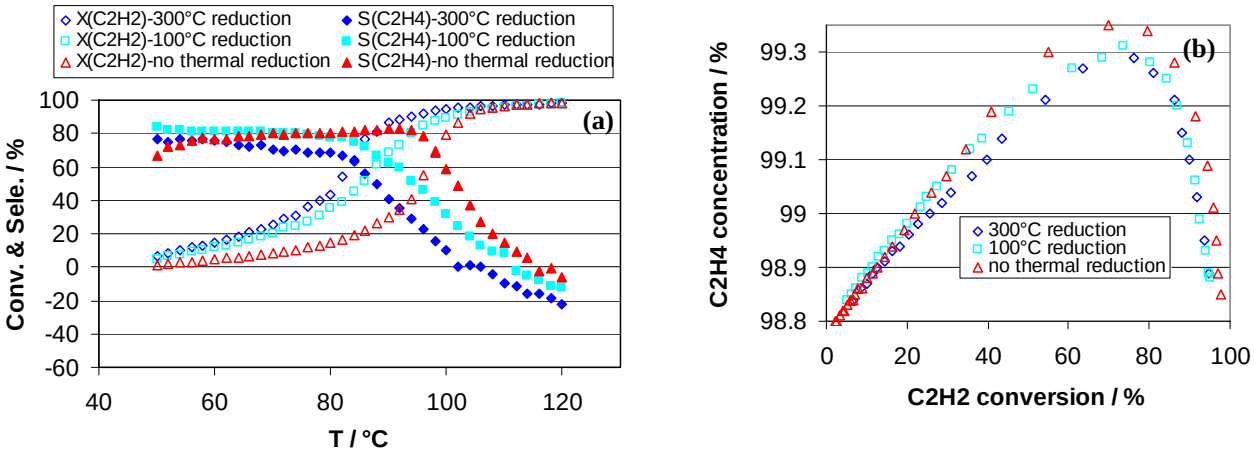

Fig.7 Effect of thermal reduction on (a) C_2H_2 conversion and C_2H_4 selectivity, (b) C_2H_4 concentration over catalysts treated by H_2 plasma. H_2 plasma treatment conditions: continuous waveform, 13.56 MHz, 160 W, 400 mTorr, 0.5h.

4. Conclusion

As compared to the untreated catalyst, the treatments towards $0.05\%Pd/SiO_2$ catalyst using O_2 plasma, Ar plasma, H_2 plasma can enhance the selectivity to C_2H_4 of acetylene hydrogenation and decrease their activity as the following order: O_2 plasma ~Ar plasma > H_2 plasma. The catalytic performance of catalysts derived from plasma treatments can be quite different from those derived from conventional treatments and is more sensitive to reduction temperature than the latter. Catalysts treated with plasma may not be as stable as catalysts obtained from conventional procedures for high temperature processes. The catalyst treated with H_2 plasma without thermal reduction exhibits higher C_2H_4 selectivity and C_2H_4 concentration than those with thermal reduction. It is suggested that the Pd precursor can be reduced by H_2 plasma to optimize the ethylene yield of acetylene hydrogenation. H_2 plasma treatment is promising for reduction of metal catalysts at low temperatures to fine tune catalytic activities and selectivities.

Abstract
The DFT/B3LYP and *ab initio* CASSCF methods were applied in order to calculate the relative energies for a few reactions of ozone with nitrogen oxide (NO) and nitrogen dioxide (NO_2). The electronic energies of substrates and products were corrected for the zero point energy (ZPE) vibrations. The energy ΔE released during the reaction, calculated as $\Delta E=E_{\text{products}}-E_{\text{substrates}}$, was then obtained. All reactions considered in this work turned out to be exothermic.

Keywords: oxygen, ozone, nitrogen oxides (NO_x), energetics, DFT, CASSCF

1. Introduction

Within the problem of limiting of nitrogen oxides pollutants (NO_x) even the widest applied methods of catalytic reduction cannot be considered to be universal. Methods based on the destruction of nitrogen monoxide (or its higher oxides) are usually quite efficient but very expensive because of the need to break the N–O bond. Although nitrogen monoxide is an endothermic compound its decomposition to nitrogen and oxygen in a molecular forms runs through the stage of dissociation into atoms which is a strongly endoenergetic process. For economical reasons substances of high oxidizing potential were not used to oxidize tail nitrogen oxides in the nitric acid production process. Recent years of intensive investigations of ozone synthesis process have resulted in significant reduction of ozone generation costs at simultaneous widening of the production scale [1,2]. First attempts of ozone application appeared to be quite efficient but the subsequent experiments on semi-technological scale revealed some disadvantages such as a tendency to produce hardly removable aerosols. Another disadvantage is that ozone is an expensive oxidizer and needs to be used in excess in order to obtain the nitrogen pentoxide.

The utilization of NO_x from the gas-phase based on the oxidation using ozone nowadays seems to be a very promising method for both economical and technological reasons [3]. The determination of the main factors affecting its efficiency requires the detailed knowledge of the mechanisms of individual reactions. In principle the method can be modeled by a couple of reactions involving different nitrogen oxides and ozone (O_3), which lead to the formation of the nitrous acid (HNO_3). We consider the following reactions:

$$NO + O_3 \rightarrow NO_2 + O_2 , \quad (1)$$
$$NO_2 + O_3 \rightarrow NO_3 + O_2 , \quad (2)$$
$$NO_2 + NO_3 \rightarrow N_2O_5 , \quad (3)$$
$$2NO_2 + O_3 \rightarrow N_2O_5 + O_2 , \quad (4)$$
$$N_2O_5 + H_2O \rightarrow 2HNO_3 . \quad (5)$$

However, their mechanisms are complicated and yet not well known. In addition obtaining such information only from experimental data seems to be very complicated, time-consuming and expensive. On the other hand the theoretical investigations of these reactions, as well as proposing the relevant model for the method may to be more economical. The theoretical (quantum chemical) methods may turn out to be very useful with that respect. The calculation of the energetics of each of these processes is of particular significance. The modern theoretical techniques, involving the density functional theory (DFT) and *ab initio* multiconfigurational approach (MCSCF), are well suited for this kind of calculations. In the following we present our theoretical investigations of structures of the oxygen molecule, the ozone molecule and a few nitrogen oxide molecules, as well as the energetics of the reactions (1) – (4).

2. Computational details

The primary goal of our theoretical investigations was the determination of the relative energies, defined as $\Delta E=E_{\text{products}}-E_{\text{substrates}}$, for the reactions (1) – (4). This can be accomplished by calculating the equilibrium geometries and electronic energies of substrates and products: the oxygen molecule, the ozone molecule and a few nitrogen oxide molecules NO_x, as well as their zero-point vibration energy (ZPE).

First the optimal structures of oxygen and ozone molecules and all nitrogen oxide molecules involved in the reactions (1) – (4) were calculated at DFT [4] level of theory. In particular the so-called B3LYP exchange-correlation potential [5,6] was used. This method, called DFT/B3LYP, is known to give accurate molecular geometries and (relative) electronic energies. Note, that in the case of the open-shell molecules (O_2, NO, NO_2, NO_3) the unrestricted DFT procedure has to be adopted. The DFT calculations were carried out using 6-311G(d,p) basis set [7].

Next the correlated *ab initio* calculations of the optimal structures were carried out. We have chosen the CASSCF [8–10] method, a special case of the more general MCSCF [11] approach. This method is known to account for the major part of the so-called static (or non-dynamic) correlation effects, the effects of particular importance in the description of systems containing the lone-pair electrons. However, it does not incorporate the very important dynamic correlation effects and therefore the final results may suffer from this deficiency. It should be emphasized that for the CASSCF calculations to be of reasonable quality the adequate choice of the so-called active space (the CAS space) is of particular importance. This is especially true with regard to the description of the phenomena involving a few different potential energy surfaces. The balanced and consistent (in a well defined way) inclusion of the configurations into the wave functions of all species of interest is essential in obtaining reasonable values of the relative energies. For example the active space adequate in the treatment of the static correlation in the case of ozone molecule should consist of at least all *p*-derived orbitals, i.e. 6 orbitals from the σ space and 3 orbitals from the π space [12]. This active space may be referred to as the (6/3) active space. The distribution of 12 electrons among 9 orbitals leads to the CI expansion of the CASSCF wave function into approximately 670 configuration state functions (CSF's). Note that the size of the CI expansion has been reduced not only by the spatial symmetry but also by the spin symmetry of the configurations. However, the choice of the active space on the same grounds for the biggest molecule considered in this paper, i.e. the N_2O_5 molecule, becomes impractical. We managed to carry out this kind of calculations, called CASSCF(σ- and π-derived), only for O_2, NO, O_3 and NO_3 molecules. This means, that the CASSCF(σ- and π-derived) relative energies only for the reactions (1) and (2) were computed. Thus we decided to reduce the CI expansion of the MCSCF wave functions by including the excitations only within the π space for all systems. However, it is known [12,13] that, at least for the ozone molecule, any restriction of the active space below that of the (6/3) quality leads to substantial worsening of some of the calculated properties. Indeed, the π-derived active space turned out to be too small (*vide infra*). The CASSCF calculations were carried out using smaller, 6-31G(d,p) basis set [14].

In both DFT and CASSCF calculations the type of the stationary point was determined by frequency calculations. All calculated frequencies turned out to be real indicating that structures corresponding to local minima were found. It is also important to realize that dissociation/association processes may lead to the change of the number of the vibrational degrees of freedom when going from substrates to products. Thus the harmonic frequencies were also used in the calculation of the zero-point energy (ZPE) correction for substrates and products.

All DFT calculations were carried out using the parallel version of the PQS [15] quantum chemistry software. All CASSCF calculations were carried out using the DALTON [16] quantum chemistry software.

3. Results and discussion

3.1. Equilibrium geometries and vibrational frequencies

The equilibrium geometries of the molecules considered in this work are presented in figure 1. Note that only a few selected parameters of the N_2O_5 molecule are reported. The total electronic energies as well as the harmonic frequencies are reported in table 1. These values were used in the subsequent determination of the relative energies for the reactions (1) – (4).

The equilibrium bond length of the ground state ($^3\Sigma_u^-$) oxygen molecule is in good agreement (within 1%) with the experimental value. Apparently the DFT method seems to slightly overestimate, and the CASSCF method – slightly underestimate the attractive forces between atoms, causing the bond length to be shorter/longer, respectively than that found experimentally. As a consequence the harmonic frequency (cf. table 1) of the stretching mode is higher (1640 cm^{-1}, DFT) and lower (1545 cm^{-1}, CASSCF) than the corresponding experimental value of 1580 cm^{-1} [17]. The same trends regarding the bond length are observed in the case of the NO molecule in its (open-shell, $^2\Pi$) ground state. However, the comparison of the theoretical frequency with experimental value cannot be done – only the fundamental experimental frequency was available [18].

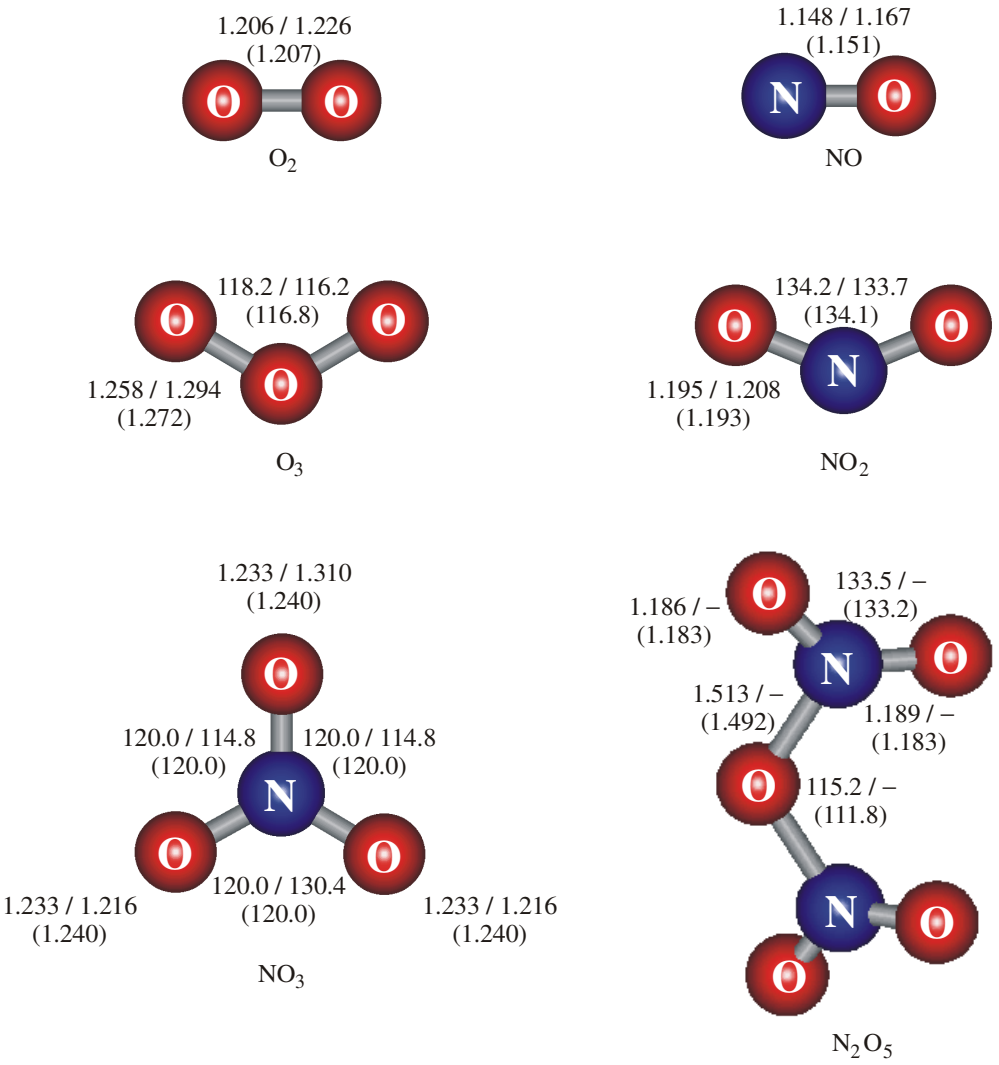

Figure 1. The geometrical parameters of the molecules considered in this work. The upper (separated by "/") are the theoretical values reported in the following order: DFT/B3LYP/6-311G(d,p) / CASSCF(σ- and π-derived)/6-31G(d,p). The experimental values (O_2: ref. [17], NO: ref. [18], O_3: [19], NO_2: [20], NO_3: [21], N_2O_5: [22]) are given in parentheses (bond lengths in Å, valence angles in deg).

In the case of the ozone molecule (in the $^1A_1$ ground state) the theoretically predicted bond lengths behave similarly – they are too short at the DFT level and too long at the CASSCF level. However, it should be noted, that much better agreement of the CASSCF results with experiment for both oxygen [23] and ozone [12] molecules was achieved using ANO-type basis set [24]. Consequently, the harmonic frequencies of two stretching modes (symmetric and antisymmetric) are higher at the DFT level of theory. They are 1249 cm^{-1} and 1191 cm^{-1} at the DFT level and 1078 cm^{-1} and 1015 cm^{-1} at the CASSCF level, respectively. These values are to be compared with experimental harmonic frequencies of 1135 cm^{-1} and 1089 cm^{-1} [25]. The theoretical (DFT and CASSCF) valence angle reproduces well the experimental value and the frequency of the symmetric bending mode is well accounted for. The theoretical geometry of the ground state ($^2A_1$) nitrogen dioxide molecule is also in good agreement with experiment, although the DFT method seems to perform slightly better than the CASSCF method. Somewhat worse performance of the CASSCF method may be due to the quality of the basis set – as was already pointed out the CASSCF calculations should be preferably carried out with a basis set of higher than 6-31G(d,p) quality. Again the comparison of the theoretical frequencies with experimental values cannot be done – only the fundamental experimental frequencies were available [20].

Table 1. The calculated at the DFT/B3LYP/6-311G(d,p) and the CASSCF(σ- and π-derived)/6-31G(d,p) levels of theory electronic energies and harmonic frequencies of oxygen, ozone and selected nitrogen oxide molecules used in the evaluation of the energy released during the reactions (1) – (4).

[a]Fundamental frequencies

The NO_3 molecule in its ground electronic state ($^2A_2$') is planar. The experimental investigations [21] clearly demonstrate that the molecule belongs to the D_{3v} symmetry point group. Thus all N–O bond lengths should be the same and the O–N–O valence angles should be equal to 120°. Apparently the DFT/B3LYP approach is capable of predicting the proper structure of the molecule, both with regard to the symmetry of the ground state and the lengths of the N–O bonds. Oddly enough CASSCF is not! The structure predicted by the CASSCF method has C_{2v} symmetry (cf. figure 1). In addition the N–O bonds are substantially shorter than these predicted experimentally. Although all the frequencies turned out to be real, indicating that the local minimum was found, the final result seems to be an artifact of the CASSCF approach.

As can be seen (cf. figure 1) only the DFT/B3LYP geometrical parameters for the N_2O_5 molecule are available. Actually the DFT is a very efficient correlated method, which is used nowadays to carry out the calculations on molecules containing hundreds of atoms. Molecules as small as these considered in the present work should not bring any kind of problem. Indeed, the DFT molecular geometry (note that only a few selected geometrical parameters for N_2O_5 are reported on figure 1) is in good agreement with experimental one. It should be noted that the N_2O_5 molecule is not planar – the torsion O–N–O–N angle predicted by the DFT/B3LYP approach is equal to (approximately) 30° (or 150°). Next the CASSCF calculations were carried out. However, the CASSCF calculations are more complicated than the DFT calculations on account of the rapid growth of the CI expansion of the MCSCF wave function with the increasing size of the active space. As was already pointed out the choice of the σ- and π-derived active space turned out to be impractical for this molecule. Thus we decided to reduce the size of the active space. The choice of π-derived (only) active space for all the molecules led, however, to (*i*) substantial worsening of the results for other molecules and (*ii*) arriving at the saddle point (one complex frequency) rather than at the

local minimum on the N_2O_5 potential energy surface. Many attempts to extend slightly the active space beyond that of the π-derived quality were made. A physically justifiable choice of the active space can be made on the basis of the MP2 natural orbital occupation numbers: (*i*) orbitals with occupation numbers above certain threshold remain inactive, (*ii*) orbitals with occupation numbers below certain threshold remain virtual and (*iii*) the remaining orbitals constitute the active space. However, we failed to find the local minimum of the CASSCF potential energy surface of N_2O_5 for all (chosen in this way) active spaces that could be handled in our laboratory.

3.2. Relative energies

The DFT/B3LYP/6-311G(d,p) and the CASSCF(σ- and π-derived)/6-31G(d,p) relative energies and the relative energies corrected for the zero point vibrational energy for the reactions (1) – (4) are presented in table 2. The data necessary to calculate these energies can be found in table 1.

Table 2. Calculated at the DFT/B3LYP/6-311G(d,p) and the CASSCF(σ- and π-derived)/6-31G(d,p) levels of theory relative energies ($\Delta E=E_{products}-E_{substrates}$) and relative energies corrected for the zero point vibrational energy for the reactions (1) – (4).

Reaction	Method	ΔE [kcal/mol]	$\Delta E^{(ZPE)}$ [kcal/mol]
$NO + O_3 \rightarrow NO_2 + O_2$	DFT/B3LYP	−62.78	−62.31
	CASSCF	−31.36	−30.54
$NO_2 + O_3 \rightarrow NO_3 + O_2$	DFT/B3LYP	−37.56	−38.59
	CASSCF	−15.63	−14.69
$NO_2 + NO_3 \rightarrow N_2O_5$	DFT/B3LYP	−21.62	−16.90
	CASSCF	–	–
$2NO_2 + O_3 \rightarrow N_2O_5 + O_2$	DFT/B3LYP	−59.18	−55.49
	CASSCF	–	–

For all reactions considered in the present work the DFT/B3LYP energy of products is lower than that of substrates. Apparently all reactions are exothermic. The relative energies are ΔE=−61.83 kcal/mol for reaction No (1), ΔE=−39.62 kcal/mol for reaction No (2), ΔE=−12.18 kcal/mol for reaction No (3) and ΔE=−51.80 kcal/mol for reaction No (4). Apparently the most exothermic is the reaction of nitrogen oxide with ozone (reaction 1), the least – the reaction of nitrogen dioxide with nitrogen trioxide (reaction 3). It should be noted that during the reaction (1) the number of vibrational degrees of freedom is the same for substrates and products. Obviously the ΔE and $\Delta E^{(ZPE)}$ are close (cf. table 2). Somewhat bigger difference between these quantities is observed in the case of the reaction 2, in which an extra vibrational degree of freedom appears for products. However, the two low-energy (degenerate, on account of symmetry) vibrational modes cause that the ZPE correction for products is smaller than for substrates and consequently $\Delta E^{(ZPE)} > \Delta E$. 6 and 7 additional vibrational degrees of freedom are gained in the course of the reactions (3) and (4), respectively. Thus the ΔE and $\Delta E^{(ZPE)}$ values for these reactions differ by as much as 4.5 – 5 kcal/mol.

Although all reactions considered in the present work turned out to be exothermic (the total energy of products is lower than the total energy of substrates) they may not be spontaneous. In order to calculate the activation energy of the reactions (1) – (4) the search for the transition states was also carried out. No transition state was found for any of these processes even though numerous initial geometries were used and a few low-energy modes were followed in the iterative procedure. This is a strong indication of the spontaneous character of each of these reactions.

The relative CASSCF energies of only the first two reactions (due to the lack of the reliable data for the N_2O_5 molecule, *vide supra*) were calculated. They are much (more than twice as much) lower than the corresponding DFT/B3LYP energies. However, we are inclined to trust more the DFT/B3LYP energies due to the lack of the dynamic correlation in the CASSCF wave function.

4. Conclusions

In this work the relative energies, defined as $\Delta E = E_{\text{products}} - E_{\text{substrates}}$, for a few reactions involving nitrogen oxides and ozone were calculated at DFT/B3LYP/6-311G(d,p) and CASSCF(σ- and π-derived)/6-31G(d,p) levels of theory. It was demonstrated that the DFT/B3LYP is superior to the *ab initio* CASSCF approach. The DFT method provides an efficient way of estimating the (static and dynamic) correlation energy for the (strongly multiconfigurational) species, like these considered in the present work. Good agreement between the DFT/B3LYP and the experimental geometries as well as harmonic frequencies (if available experimentally) was achieved. On the other hand in some cases the CASSCF approach either (*i*) gives the wrong structure of the molecule (like NO_3 molecule) or (*ii*) cannot be applied due to the computational problems (like in the case of N_2O_5 molecule). The (ZPE corrected) relative energies for *all* reactions, i.e. reactions (1) – (4), were computed at the DFT level only. The negative values of the $\Delta E^{(\text{ZPE})}$ (exothermicity) along with the lack of the transition states provides a strong indication that the spontaneous character of all reactions considered in the present work.

Abstract

The dynamic interaction between plasma and a semiconductor-based radio frequency (rf) power source at the initial start-up phase of induction plasma at atmospheric pressure is investigated experimentally. A strong deterioration of power efficiency of the rf source is observed during the dynamic *E-H* mode transition, thereby decreasing the effective plasma production efficiency. Having employ a constant current immittance conversion circuit shows successful improvement of the power efficiency in induction plasma generation.

Keywords

dynamic interaction, inductively coupled plasma, thermal plasma, static induction transistor, radio frequency, atmospheric pressure, and *E-H* mode transition.

1. Introduction

A radio frequency (rf) inductive discharge operated at atmospheric pressure range requires high voltage in the initial start-up phase and high power during the steady state sustainment phase. It is thus necessary to ensure that the maximum possible rf power is injected to the high-pressure plasma from the power source, especially where the rf power is limited to few kilowatts. To understand the insight of this feature, it is necessary to investigate the dynamic interaction between plasma and rf power source at the initial start-up phase of induction plasma especially during the *E-H* mode transition period. With those in mind, we have studied the dynamic behaviors of atmospheric pressure (101 kPa) argon inductive discharges at the ignition stage experimentally, at a radio frequency of 1.2 MHz and a moderate rf power of about 3.5 kW.

High-power semiconductor-based radio frequency inverter power source [1] has become popular in the last decade with their application to various kinds of induction heating and plasma generation [2, 3] due to their high-efficiency and high-power operation. Inherent problems [4-6] are faced during high-pressure induction plasma generation using a in a static induction transistor (SIT) inverter-based rf power source. Because, at high operating frequencies in the MHz range, rf system behaves transient and strongly non-linear due to the presence of switching devices and reactive components in the power source, and non-linear interaction between plasma and rf source [7, 8]. With those in mind, in this article we investigate the transient behaviors of radio frequency (rf) inductive discharges generated by inductively coupled plasma (ICP) technique at the initial startup phase at atmospheric pressure. These analyses enable us finding a way to generate high-pressure (near one atmosphere) induction thermal plasmas with moderate rf power of few kilowatts. In this article, we discuss a simple and robust method by having employ a constant-current high-power immittance circuit [9] to enhance the power efficiency of the rf source as well as the power coupling efficiency between plasma and rf source, thereby generating the efficient rf induction thermal plasmas at atmospheric pressure in argon.

2. Experiment

In the present experiment, plasmas are sustained in a cylindrical Pyrex glass chamber with an inner diameter of 7 cm and length of 20 cm by applying a static induction transistor (SIT) inverter power source [1]. The rating of frequency range and maximum output power of the SIT inverter is 0.5–1.5 MHz and 20 kW (pulse operation), respectively. An induction coil consisting of 7 turns of a copper tube of ¼ inch outer diameter is used as the loop antenna. Argon gas is injected both axially and spirally into the discharge tube with a total flow rate of 20 lpm.

The neutral gas pressure is measured with a total pressure gauge by using a mechanical rotary pump. The rf power level is modulated with a 100 ms square wave pulse without applying any cooling system. Repetitive spark discharge, using the spark discharge technique [3], with a repetition frequency of 500 Hz and duration of 20 ms (total 10-pulse), is applied simultaneously with the rf modulating pulse to initiate the discharge. This task is performed by using a typical automobile spark plug, placed at the center of the top flange of the discharge chamber with a high-voltage transformer circuit. An *LC* matching network is employed to optimize the power coupling efficiency. For details experimental set up with block diagram, the readers are referred to Ref.5.

3. Dynamic Behaviors

At the initial phase of rf breakdown, a streamerlike electrostatic discharge (*E* discharge) develops by the strong axial electrostatic field (100-200 kV/m) due to the high rf voltage on the induction coil for several hundred microseconds, and then a rapid transition from electrostatic to electromagnetic mode occurs developing the ring-shaped electromagnetic discharge (*H* discharge) to form the volumetric induction plasmas [4-6].

The temporal plasma loading resistance and reactance indicating a dynamic transition from one mode to another is shown in Fig. 1(a). A rapid increase of the temporal coil loading resistance and decrease of the effective coil inductance, obtained by the rf input voltage to current ratio, are observed during the dynamic change from *E* to *H* mode. The resistance in the *E* mode is very small due to a weak coupling of electrostatic discharge and becomes high in the *H* mode due to the growth of the inductive plasma. The reactance, on the other hand, is slightly positive in the *E* mode, and decreases and becomes negative with the development of the *H* mode as shown in Fig. 1(a) due to plasma reaction by the induction current flowing in the azimuthal direction but opposite to that of the rf coil current, which decreases the original axial magnetic flux thereby decreasing the effective coil loading reactance and thus the inductance. The rf coil current, therefore, drops abruptly, as shown in Fig. 1(b), when the load changes from the capacitive to inductive mode due to the impedance rise thereby decreasing the rf power absorbed by the plasma and thus the power coupling efficiency.

The temporal change of coil loading inductance is shown in Fig. 2(a). Due to decrease of effective coil inductance, the driving frequency and thus the phase between inverter output voltage and current are shifted from their resonance value as shown in Fig. 2(b). The temporal change of driving frequency and phase difference during the *H* mode deviate from the resonance value about 15 kHz and $+\pi/4$ radian, respectively with a resonance frequency of 1.09 MHz at atmospheric pressure as shown in Fig. 2(b). From Fig. 2(b) it is seen that the phase of inverter output current (with respect to inverter output voltage), which is zero before plasma ignition due to resonance tuning, becomes slightly negative during *E* mode due to electrostatic coupling and becomes positive during the *H* mode due to electromagnetic coupling. The total load, therefore, becomes slightly capacitive during the *H* mode thereby increasing the switching losses of the SIT inverter elements present in the rf system. As a result, the inverter output as well as the dc-rf power conversion efficiency (P_{dc}/P_{rf}) strongly deteriorates as shown in Fig. 2(c).

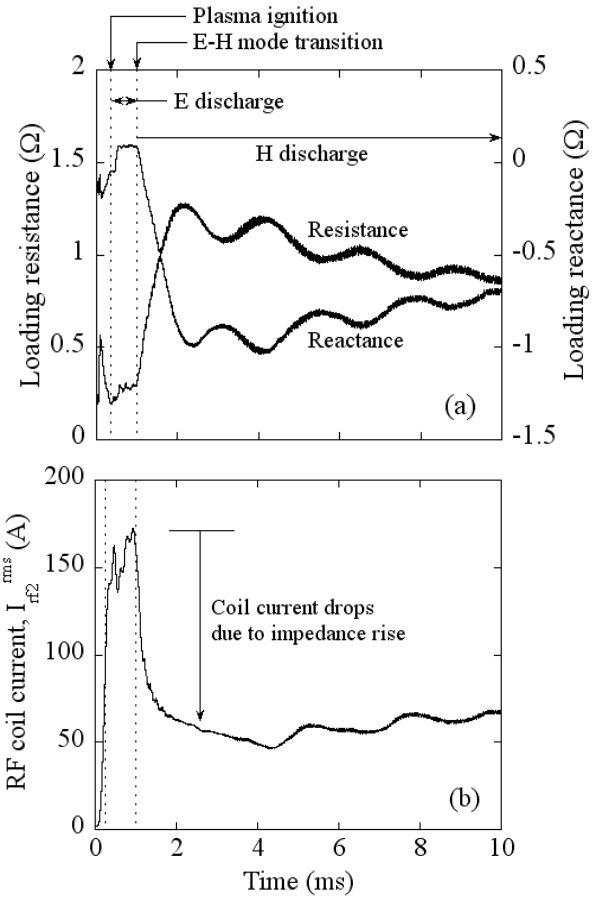

Fig. 1: (a) Temporal plasma loading impedance showing the different modes of operation; and (b) rf coil current waveform at the time of plasma ignition.

The dc-rf power conversion efficiency of the rf power source decreases from about 90% to a value of about 60% as shown in Fig. 2(c). This power conversion efficiency completely depends on the frequency and phase shift from their resonance value. Therefore, in some cases, the dc-rf conversion efficient drops to about 30% depending on the phase and frequency shift [7].

4. Enhancing the Power Efficiency

Having control gate driving frequency of SIT, the power efficiency of the rf source can be enhanced [4]. In this experiment, we use another simple and robust method by employing a high-power constant-current immittance circuit, which is shown in Fig.3, having other experimental conditions remain unchanged. Applying the resonance condition and assuming that the internal resistances of the inductors are negligible (r_{L1} = r_{L2} = 0), the voltage current relations can be obtained from Fig. 3 as

$$I_1 = V_1 Z_L / Z_0^2, \quad (1)$$

$$I_2 = V_1 / jZ_0, \quad (2)$$

where Z_L is the plasma loading impedance and $Z_0 = \sqrt{L_1/C_1}$ is the characteristic impedance determined by the primary inductance and capacitance.

From Eq.(2) it is seen that immittance circuit provides constant output current with a fixed voltage source since the characteristic impedance Z_0 is a constant. This confirms high output rf power thereby increasing the dc-rf power conversion efficiency of the rf source in induction plasma generation over the conventional series resonance circuit as shown in Fig.4. The time evolution of effective rf power using the immittance circuit with that of the series resonance circuit is compared in Fig. 4(a), from where the value of effective rf power, calculated from the rf power supply side, is found to be about 3 kW with immittance circuit, while about 1.2 kW with series resonance circuit after the plasma ignition under the same operating condition. Therefore, the effective rf power injected into the plasma is about three times larger in the case of immittance circuit than that of the series resonance circuit after the plasma ignition. Fig. 4 (b) shows the comparison of dc-rf power conversion efficiency (ratio of rf output power and dc input power) using immittance circuit with that of the conventional series resonance circuit, from where it is seen that the power conversion efficiency is about 90-92% using the immittance circuit, which is as much as three times than that of the conventional series resonance circuit (which is about 30%). Because, using the series resonance circuit, the total load behaves slightly capacitive due to the

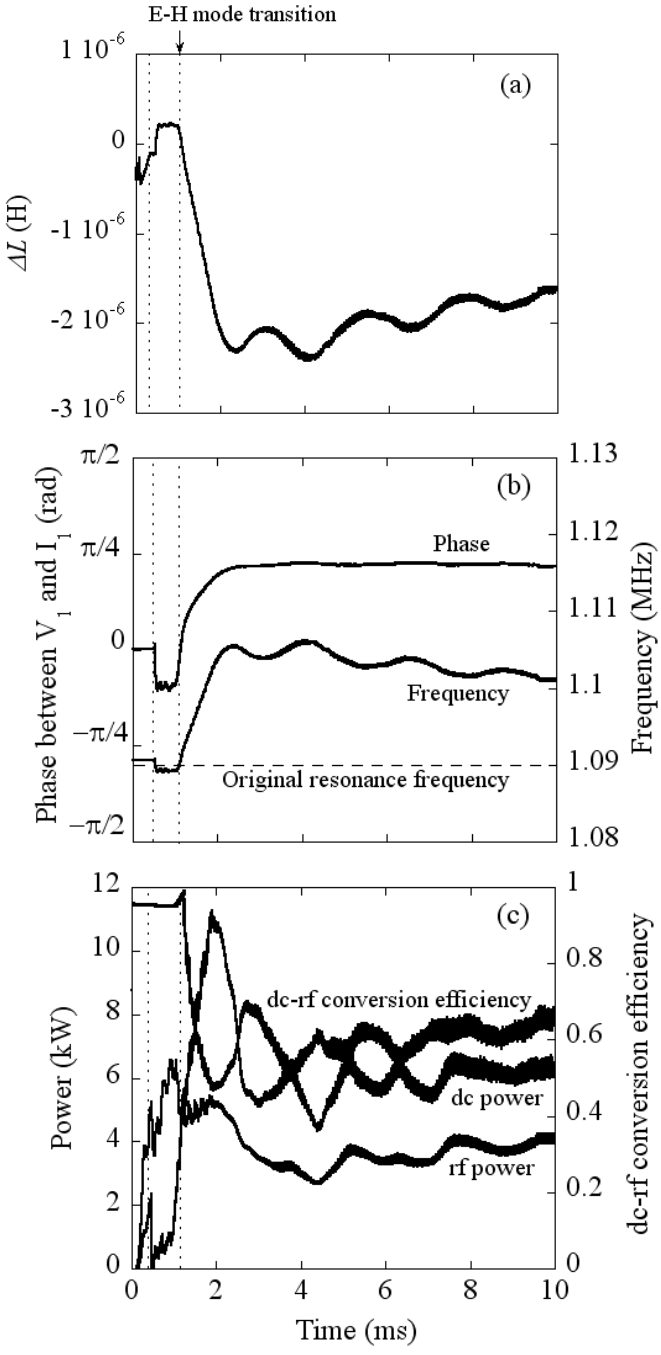

Fig. 2: (a) Temporal change of effective coil inductance; (b) Time evolution of frequency and phase; and (c) temporal rf output power and dc-rf conversion efficiency during *E-H* mode transition.

positive phase shift (about $+\pi/4$ radian) after the plasma generation, which increases the switching losses of the SIT inverter elements, thereby decreasing the rf output power and thus the dc-rf conversion efficiency. On the other hand, having the constant coil current properties as shown in Eq. (2), the immittance circuit helps to inject high rf power into the plasma thereby increasing the plasma heating efficiency as well as the plasma production efficiency.

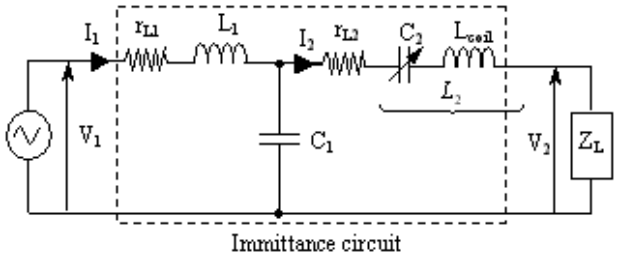

Fig. 3: Typical T-LCL immittance conversion circuit for constant current operation.

5. Conclusion

The dynamic interaction between plasma and a semiconductor-based radio frequency (rf) power source at the initial start-up phase of induction plasma at atmospheric pressure is investigated experimentally. A rapid increase of the plasma loading resistance and decrease of the effective loading inductance are observed during the dynamic change of plasma from electrostatic (*E*) to electromagnetic (*H*) mode, thereby deviating the output *RLC* circuit (including rf induction coil) from its ideal resonance condition. As a result, the power efficiency of the rf source strongly deteriorates from about 90% to 40%, thereby decreasing the effective plasma production efficiency. These analyses are very much helpful finding a way to generate of high-pressure (one atm or more) induction thermal plasmas especially where the rf power is limited to few kilowatts. In the present experiment, employing a constant-current high-power immittance conversion circuit shows successful improvement of the power efficiency in induction plasma generation (see Fig. 4).

Abstract

For the first time we applied THz-spectroscopy as diagnostics in reactive plasmas. A 20 fs TiSa laser was used to produce short, broadband THz pulses via a GaAs emitter. The measurements were performed in a dust particle forming Ar-C_2H_2 plasma. We observed rotational lines of different hydrocarbons including ions and radicals.

1. Introduction

The formation of dust particles is of great interest in the field of thin film deposition or dry etching. But still the growth process is not completely understood. Today there is the following scenario for the growth of dust particles in the case of hydrocarbon plasmas: starting with negative ions (C_2H^-) big negative charged molecules are built through reactions with the neutral gas. Those molecules collapse and grow further through accretion. Especially for the first phase of dust formation sophisticated diagnostics are required to understand the nucleation process and to identify experimentally the nature of growth precursors of the particles. As a new diagnostic tool we used THz time-domain spectroscopy in reactive plasmas.

2. Experiment

Figure 1 shows the experimental set up. The dust particles were grown in a capacitively-coupled GEC-cell, powered by 20 Watt at 13.56 MHz. C_2H_2 diluted with Ar was used as precursor gas. The gases were introduced through the showerhead-like upper electrode, controlled by mass-flow controllers. The chamber was placed directly into the beam path of the laser. The laser pulses were transmitted through the plasma via methylpentene copolymer (TPX) windows installed at two opposite flanges. TPX was used because of its high transparency in the far IR and in the visible region. A femtosecond TiSa-laser (2) (KMLabs Inc. [1]) was used as the pulse source, pumped by a 532 nm Verdi laser (1). The mode locked laser emits a 80 MHz pulse train of 20 fs pulse width and 500 mW overall optical output power. The infrared laser beam is split into two parts of similar intensity by a beam splitter (3), one part for the emission of THz-radiation, the other part for coherent detection of the THz-pulse. The two beams are focussed on emitter (7) and detector (12), respectively. Emitter and detector are made of low-temperature grown Gallium Arsenide doped with CrO as the photoconductive substrate. An Au:Ge:Ni alloy is used for ohmic contact. A detailed description of the photoconductive antenna substrate and geometry and its correlation to the emitted THz-field is given in [2,3]. The size of the used photoconductive gap is 5x5 μm^2 and the length between the transmission lines is 20 μm. For the emission process the

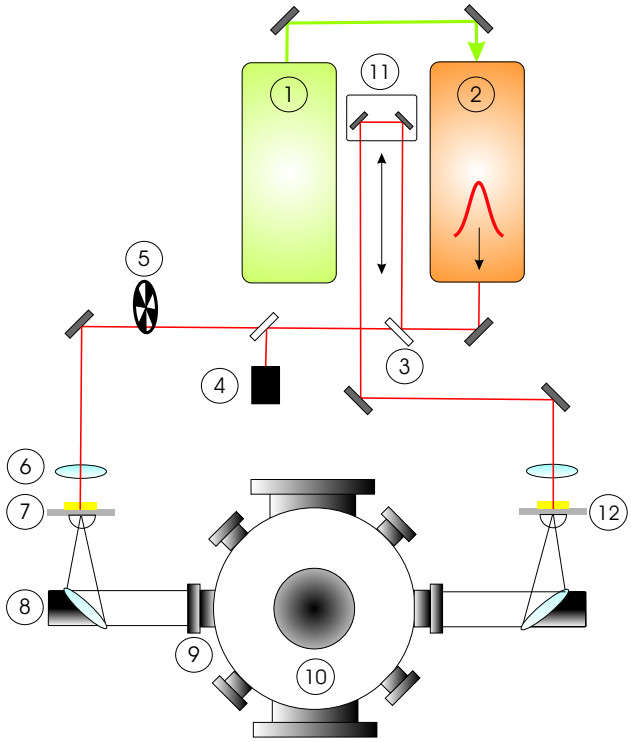

Figure 1: Experimental set up of the laser and the plasma chamber: (1) pump laser, (2) Ti:Sa femtosecond laser, (3) beam splitter, (4) Vis-IR spectrometer, (5) optical chopper, (6) microscope objective, (7) THz emitter (LTG-GaAs), (8) parabolic mirror, (9) methylpentene copolymer (TPX) window, (10) plasma chamber (GEC-cell), (11) delay line, (12) THz detector (LTG-GaAs).

photoconductive antenna of the emitter is contacted with 40 V DC bias. For coherent detection the induced photocurrent in the photoconductive antenna gap of the detector is measured using a lock-in amplifier. The emitted THz-pulse is collected and focussed using hemispherical high resistivity silicon lenses directly on the emitter. An off-axis parabolic mirror (8) focuses the beam through the TPX-windows and the plasma chamber. A second parabolic mirror and a silicon lens again focuses the THz-pulse on the detector, which is identical to the emitter. The transmitted THz-field is recorded by a variable delay between the first and second femtosecond pulse. The recorded electric field is transformed into the frequency domain using fast fourier transformation (FFT). For the measurements a pure argon plasma was ignited in the chamber as a reference (8 sccm Ar, 20 W rf power). The main measurements were performed in dusty plasmas, using 8 sccm Ar and 2 sccm C_2H_2 (20 W rf power, 10 Pa). After the ignition of the plasma the formation of dust particles starts immediately. After a while dust particles in the chamber between the electrodes could be detected by diffraction of HeNe laser light. Figure 2 shows dust particles collected in the chamber after the measurements. They consist mainly of carbon, are spherical and have a cauliflower-like

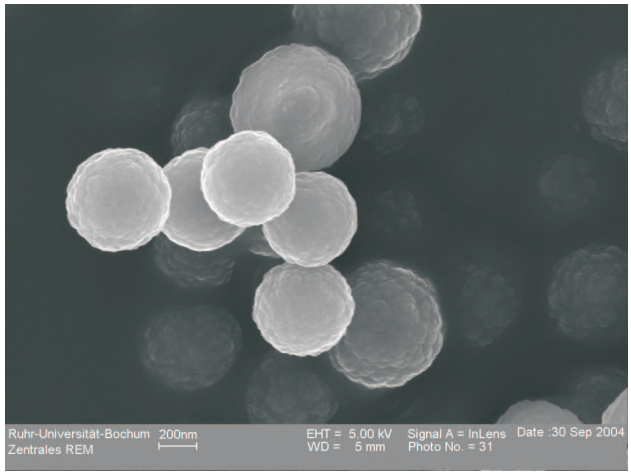

Figure 2: Dust particles collected from the chamber after the experiment

shape. Figure 3 shows a mass spectrum measured with a residual gas analyzer in the same set up. Besides C_2H_2 and its dissociation products also higher hydrocarbon molecules like C_4H_2 and C_6H_4 are observed. This gives evidence for the fact that dust particles are formed from chains of hydrocarbon molecules. C_2H^- ions are supposed to be a precursor for the dust formation [4]. They are built through dissociative electron attachment of C_2H_2. The C_2H^- molecules react with other gas molecules building larger molecules which collapse and grow further through accretion until macroscopic dust particles are generated [5]. Negative ions like C_2H^- are confined in the plasma and are therefore expected to have a long lifetime in the chamber.

The aim of the experiments is to monitor particles and molecules in the dusty plasma. The absorption and emission spectrum of the plasma was recorded and Fourier-transformed to obtain the THz spectrum between 3 and 35 cm^{-1}. The spectral resolution of the measurement was 0.05 cm^{-1}, scanning time was one hour. In order to eliminate background signals measurements with and without C_2H_2 were performed. The transmission function of the dusty plasma with respect to the pure argon discharge can be evaluated by comparing the squares of the electric fields or simply by dividing the two measured currents:

$$T(\nu) = \frac{I_{sample}}{I_{reference}}. \tag{1}$$

3. Results and Discussion

Figure 4 shows a measured spectrum in an Ar-C_2H_2 plasma. In this measurement we could assign several lines to the C_2H molecule, one to the CH^+ ion and one to the CH_2 molecule. In measurements with a different detector which could measure in a lower frequency region and with

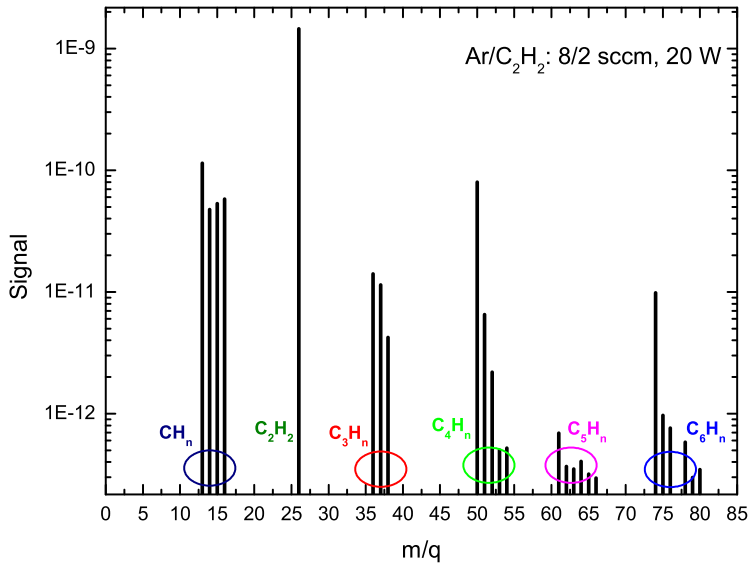

Figure 3: Mass spectrum of a discharge in an Ar-C_2H_2 discharge at 20 W rf power.

a higher resolution we were able to observe more lines of the above mentioned molecules and also lines of ArH^+ (41.3 cm−1) and of CH (18.3 cm^{-1} and 49.3 cm^{-1}). The origin of the observed lines are rotational transitions of molecules in the gas of the dusty plasma. Both emission and absorption are expected to be in the THz region. In the region from 3 to 35 cm^{-1} we observed emission, at higher wave numbers we saw absorption. Since only few data for rotational lines of hydrocarbon molecules in this frequency region are available, we were not able to assign the remaining lines. We assume the other lines also to be rotational lines of hydrocarbon molecules, including their ions.

4. Summary and Outlook

For the first time we performed THz spectroscopy in reactive plasmas. We observed several rotational lines of different hydrocarbons including positive ions and radicals. A whole set of lines in the region from 10 to 35 cm^{-1} could be attributed to C_2H (Fig. 4). Also other ions and radicals could be identified. We showed that THz spectroscopy is a powerful tool for the diagnostics of reactive plasmas. It is even possible to detect species like C_2H which are not easily detectable by mass spectrometry. With a higher resolution it is also possible to calculate the concentration and the temperature of the molecules and ions in the plasma.

In future we intend to detect possible eigenmodes of the nanoparticles which are assumed to lie in

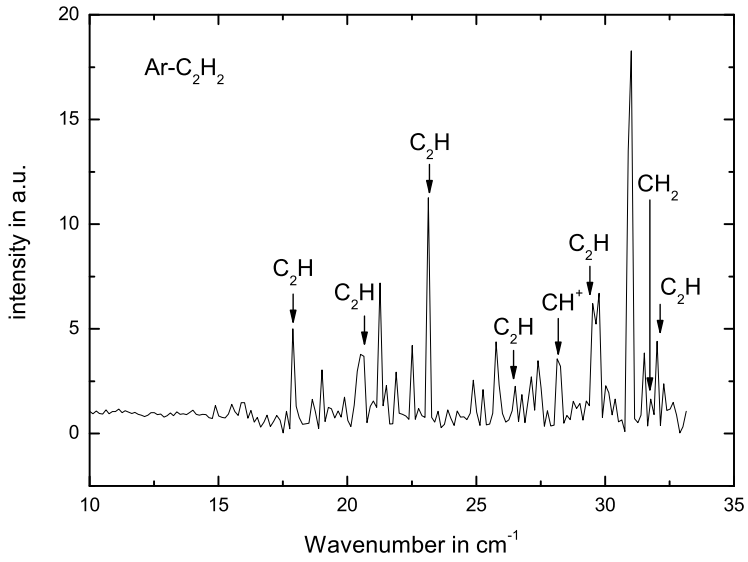

Figure 4: Measured spectrum in an Ar-C_2H_2 plasma. Several C_2H lines, one CH^+ line and one CH_2 line can be observed.

the THz frequency range in order to develop a diagnostic for very small dielectric particles which are not accessible by other optical methods (Mie-ellipsometry, laser light scattering). We think that THz spectroscopy offers a wide range of applications in the field of plasma diagnostics. It can close the gap between plasma ion mass spectrometry (up to 2000 amu) and Mie-ellipsometry (particles with diameter of 50 nm or bigger).

Abstract
Two different cold plasma sources capable of operation at atmospheric pressure were tested for continuous production of both carbon and iron nanoparticles. These experiments were successful with both sources.

Keywords: Cold plasma, atmospheric pressure, nanoparticles

Introduction

In cold or non-equilibrium plasma, free electrons gain sufficient energy from the applied electric field for ionisation and molecular dissociation, while ions and molecules remain at almost the initial gas temperature. When applied to nanoparticle production, these free electrons dissociate a volatile precursor, for instance a metal organic complex or a hydrocarbon. Thus a supersaturated metal or carbon vapour is formed in the cold plasma, which, due to the low overall gas temperature, condenses to form nanoparticles. Subsequently, the particles can be coated with a different compound in the same plasma system [1].

So far, cold plasmas used for nanoparticle production have been low-pressure (usually <40 mbar [1]) microwave and radio frequency plasmas. This requires complicated vacuum systems, severely limits particle production rates and makes analysis of the particles rather difficult. Cold plasma at atmospheric pressure would allow continuous operation and simplification of the process. Generating stable, cold atmospheric plasmas is not an easy task, however, because the plasma has the tendency to tranfer to a (hot) arc discharge.

In the research presented in this report, two different cold atmospheric pressure plasma sources were used to produce nanoparticles. We tested these sources by the production of carbon nanoparticles from acetylene (C_2H_2), and iron particles from ferrocene ($Fe(C_5H_5)_2$). Carbon nanoparticles of various forms have a myriad of industrial applications. Carbon black, indispensable to the rubber, paint, and chemical industries, is also commonly used in inks [2]. Iron nanoparticles have many uses, from enhancing catalysis with their increased relative surface area, to special magnetic applications in micro- and nano-electronics [3, 4]. In this size range, particles of all materials have unique and valuable properties, which make them particularly well suited for special technological applications.

Experimental

Helium and argon were used as carrier gasses. The precursors were introduced into the plasma by mass controlled flow (acetylene), or by passing the carrier gas over the sublimating solid (ferrocene). Hydrogen could also be added to the plasma.

Behind the plasma, a differential mobility analyser (DMA) [5] and an aerosol electrometer (AEM) [5] or a condensation particle counter (CPC) [5] were used to determine particle size distributions. The DMA size selects charged particles by deflecting them in an electric field, the AEM or CPC then counts the particles in a certain size range. In this way a size distribution is obtained. By reversing the direction of the electric field inside the DMA, both positively and negatively charged particles can be analysed. Particles can be charged either by the plasma or using a Kr-85 radioactive neutralizer. A typical setup for particle size distribution measurements is

shown in figure 1. Particles were also collected on grids placed in the effluent of the plasma for transmission or scanning electron microscopy (TEM or SEM) analysis. TEM analysis is combined with energy dispersive X-ray spectroscopy (EDX or EDS), which gives an idea of the elemental composition of a sample.

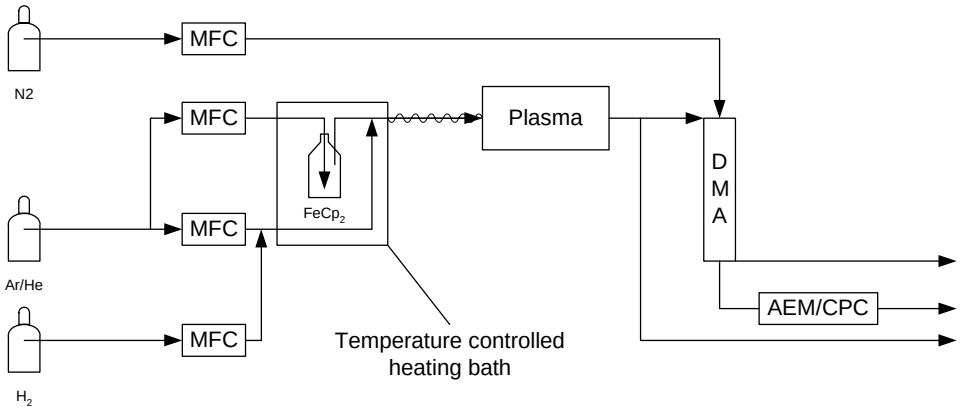

Figure 1: set-up for particle size distribution measurements for iron particles made from ferrocene

The two plasma sources that were used differ in the way the occurrence of unwanted arc discharges is prevented. The first source (for more details see [8]), in which the plasma is generated with a 13.56 MHz RF source [6], uses a high flow (> 20 L/min) to literally blow out the charged species before arcing can occur. This is a commercially available source and known as the Atmospheric Pressure Plasma Jet (APPJ). The RF power ranges up to 100 W at 13.56 MHz, and reflected power can be controlled on the source by a manually tuned matching network (set to minimal reflected power for each experiment). The plasma applicator has a diameter of 40 mm, and its exterior is electrically connected to the grounded electrode, as depicted in Figure 2 [7].

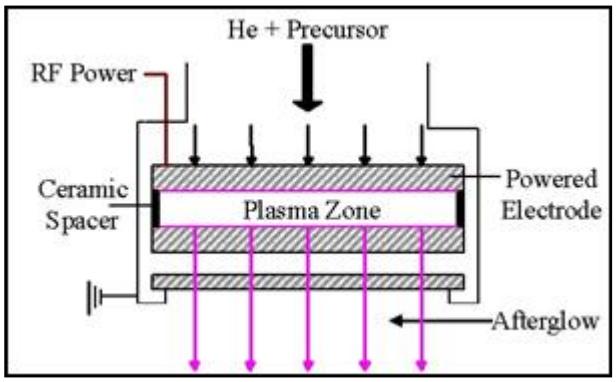

Figure 2: Electrode setup diagram of the APPJ.

In the second source, streamer-to-arc transition is prevented by dielectric barriers (DB) placed between the electrodes. The source used for iron particle generation consists of two concentric glass tubes (the dielectric barriers), between which there is a one-millimetre gap; through this gap the gas flows along the length of the tubes. The high voltage electrode is placed inside the inner tube, while the ground electrode is placed around the outer glass tube. Functionality for two plasma zones with intermediate coating precursor introduction was provided for. A 75 kHz high voltage AC power source is used to generate plasma. The source can be used with helium, argon and nitrogen as carrier gases, generally at a flow rate of 5 L/min. The discharge structure (homogeneous glow or filamentary streamer) depends strongly on gas composition. The structure of the plasma generated by this source was determined by analyzing the discharge current characteristics. A schematic of this plasma source is depicted in figure 3.

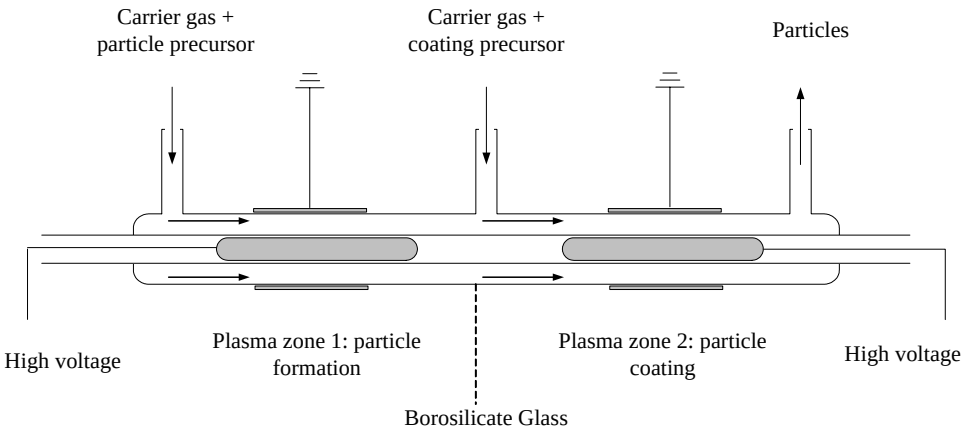

Figure 3: dielectric barrier plasma source used for iron particle production and coating

Results

Atmospheric Pressure Plasma Jet

Carbon nanoparticles sampled by plasma-enhanced deposition are depicted in Figure 4. The seven-minute deposition was made with 150 sscpm of Acetylene at 55 W applied power. The particles are highly agglomerated on deposition, and have primary diameters of ~15 – 30 nm. Closer imaging reveals no decipherable crystal structure, so it is presumed that the particles are amorphous in nature.

The effect of increasing Acetylene concentration has little effect on particle production. The mode of the distribution is decreased by only 1.5 nm, and total particle production is virtually unchanged. Nevertheless, a much finer distribution (smaller Full-Width Half-Maximum) is evidenced at the lower Acetylene flow. The effect of increased applied power is far more pronounced than that of precursor concentration. Overall nanoparticle production is drastically increased, with a slight decrease in average particle diameter. Finally, positively charged particle concentrations exceed those of negative ones in nearly every size range selected by the DMA. This is consistent with the excess of positive charge measured in the gas leaving a pure Helium plasma.

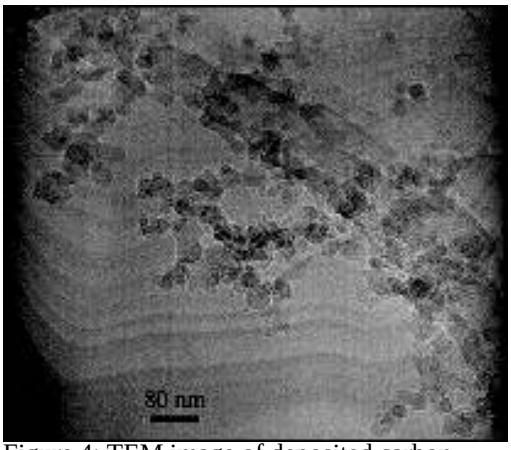

Figure 4: TEM image of deposited carbon nanoparticles made by APPJ

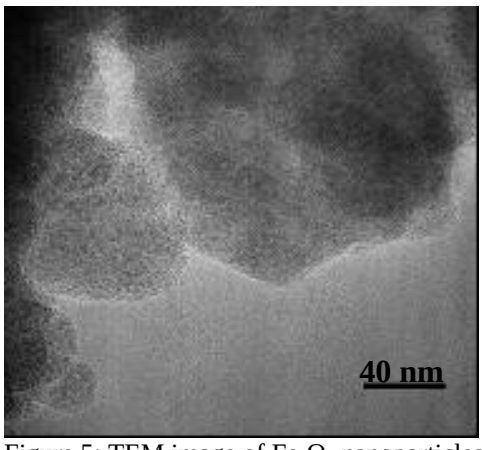

Figure 5: TEM image of Fe_2O_3 nanoparticles made by APPJ

Iron particles of approximately 20 nm were created from ferrocene. When the TEM grids on which the particles are collected are removed from the inert environment of the set-up, these iron nanoparticles are exposed to air and oxidize very rapidly. A pure amorphous iron particle converted fully to Fe_2O_3 will show a 29% increase in

diameter and a corresponding 115% growth in volume. This results in significant grain growth. Figure 5 depicts the resulting iron oxide nanoparticles; carrier gas flow rate through the ferrocene was set at 1.0 slpm He, and H_2 was fed at 400 sccpm for a 10 minute deposition. EDX analysis on samples not exposed to air indicates an extremely low presence of oxygen.

For iron, the generated particle size distribution (PSD) was observed as a function of ferrocene carrier gas flow, and H_2:He ratio. The experimental field is summarized in Table 1. Figure 6 indicates the resulting particle size distributions of produced iron nanoparticles. It is clear that an increasing relative hydrogen concentration causes a slight drop in average particle size and a drastic increase in the width of the distribution. The significant increase in overall charged particle production for increasing ferrocene concentrations is obvious. It is accompanied by an increase in particle diameter and a rise in the Full-Width at Half-Maximum (FWHM).

Table 1: Experimental field for Ferrocene.

Set	Settings		Results	
	Q_{Ferr} [slm]	H_2:He ratio [-]	d_p, at PSD maximum [nm]	FWHM [nm]
1	1.0	2:10	23.1	6.2
2	0.5	4:10	23.0	4.2
3	0.5	1:10	21.8	10.1

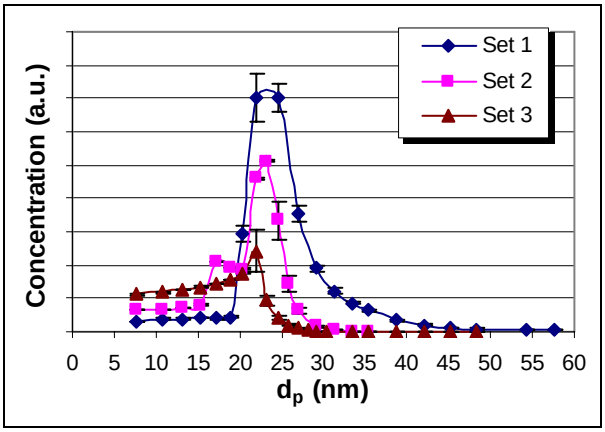

Figure 6: Iron distributions measured by AEM.

The particle charging properties of the ferrocene dosed plasma are similar to that of acetylene in so far as an excess of positively charged particles are produced. While the entire size range was not investigated, the concentration of the observed positively charged particles exceeds that of negatively charged particles at a nearly constant ratio of 2:1.

Dielectric Barrier Discharge

When helium is used as a carrier gas in conjunction with acetylene, the DMA/ CPC combination showed a large amount of particles, while none were seen with the scanning electron microscope. We speculate that the reaction only produces heavier hydrocarbons by acetylene oligomerization. These droplets are detected by the DMA/CPC but are invisible on SEM. When argon is used as a carrier gas, large amounts of amorphous carbon particles and agglomerates, with a primary particle size of 20-30 nm, were seen (Figure 7).

Nanoparticles were also produced successfully from ferrocene. TEM and EDX analysis proved these were iron-oxide particles. As for the APPJ, the original particles are assumed to be pure iron particles, the iron–oxide forming when the samples are removed from the set-up and exposed to air. Primary particle size of the iron oxide on TEM is generally between 6-11 nm, the original iron particles are therefore thought to be 5-9 nm in

size. On the TEM grid the particles form strange wire-like structures (figure 8). The reason for this kind of self-organization is not yet understood, but we believe that they originate from magnetic interaction between the superparamagnetic particles induced by an external magnetic field due to the Ni TEM grid applied.

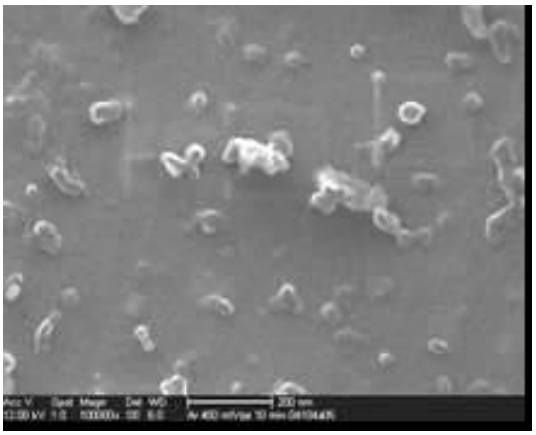

Figure 7: SEM image of carbon nanoparticles made with DBD

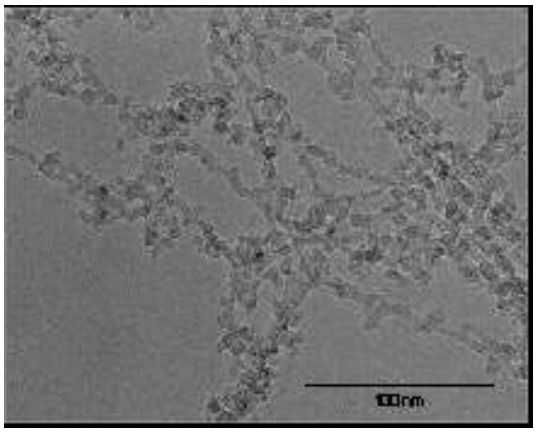

Figure 8: TEM image of iron (darker) and iron oxide (gray) particles

Although ferrocene is liable to form some carbon along with the iron, no carbon incorporation into the particles is detectable by EDX, and thus hydrogen is not needed to prevent this. Hydrogen does change the nature of the plasma and consequently the production rates, most noticeably for helium.

For a large number of different process adjustments, particle size distributions were recorded. Figure 9 gives representative PSDs for both argon and helium, both for positive and negative particles. Clearly, particle charge in an argon discharge is predominantly positive, while in helium the amounts of positive and negative particles are nearly equal. The larger positive space charge in the argon plasma is most likely the cause of this, although the exact mechanism of particle charging is not yet fully understood. Mean particle size for argon is generally lower than that for helium, even though the number concentration is much higher in the former case. We assume that the charge distribution in the plasma, which involves particles, ions and electrons, has a decisive influence on particle growth, but more experiments have to be carried out to to obtain results that are conclusive with respect to charge controlled growth mechanisms.

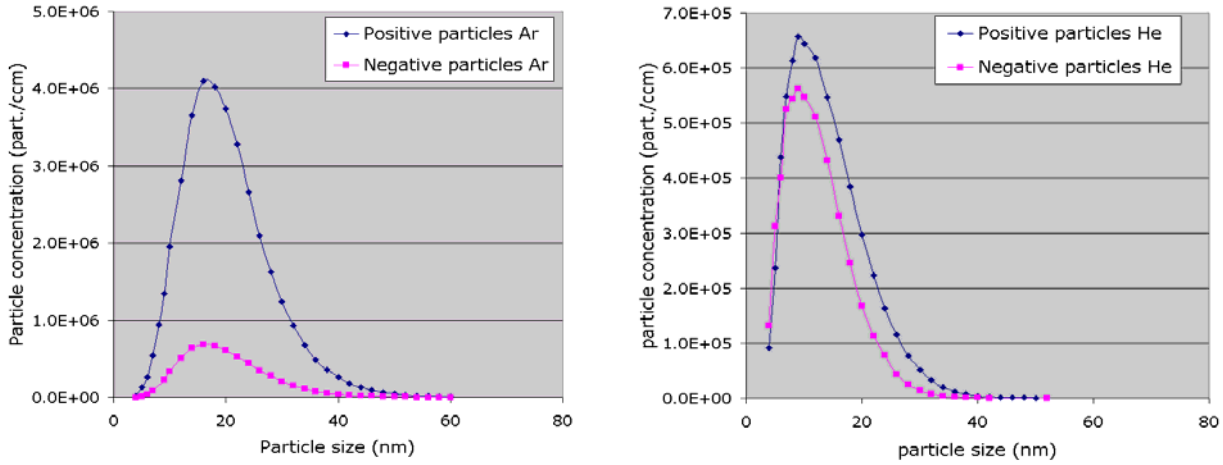

Figure 9: PSDs for both positive and negative particles in both argon (left) and helium (right). 4 ppm $FeCp_2$, no hydrogen, 4.8 kV applied voltage.

Mass production calculations were performed on the basis of the recorded size distributions; these seem to agree reasonably well with the amount of ferrocene that is introduced. The particle production rate is in the order of 10-100 μg/min. When argon is used as a carrier gas, the particle production rate is significantly higher than that for helium.

For both acetylene and ferrocene, a homogenous (glow) discharge was observed in helium. In argon, the plasma was an intermediate between glow and filamentary. In a filamentary plasma the actual plasma is localised in a large number of small micro-discharges about 100 μm in radius and a few nanoseconds in duration. A homogenous plasma, on the other hand, fills the entire volume between the electrodes. Given the fact that particle production was always higher for argon, even though the total power input into the helium plasma is higher, we believe that a filamentary discharge is more efficient in fully decomposing the precursor. This could have to do with the higher electron density and energy inside the filaments.

Conclusion

Cold atmospheric nanoparticle production is an interesting alternative for the production of nanoparticles. The possibility of carbon and iron nanoparticle production using cold atmospheric pressure plasma has been proven, and we expect that by choosing the right volatile precursors a large variety of nanoparticulate materials can be produced this way. Produced quantities are relatively high, and scale-up of the technology can be achieved by placing multiple plasma sources in parallel. Both the Atmospheric Pressure Plasma Jet as well as the Dielectric Barrier Discharge are relatively simple in design, construction and operation.

The higher flow of the APPJ leads to a higher particle production rate per unit plasma volume, but the high helium consumption would require recycling of the helium for the process to be economically feasible and sustainable. The dielectric barrier discharge can also operate with argon. In fact, the DBD operates even better using this more readily available and cheaper gas.

In the introduction of this article the possibility of directly coating produced nanoparticles was mentioned. In our experiments, particles were coated, first with polymethyl-methacrylate in the APPJ. This coating did not protect the particles from oxidation, as oxygen can diffuse through the small layer of polymer and oxidize the iron particles. This causes the iron particle to expand, breaking the polymer layer surrounding it. Therefore silicon/silicondioxide (from hexamethyldisiloxane, HMDSO) was tried as a coating. Although TEM indicated that some iron particles were covered, most of the silicon nucleated homogeneously. In future studies we will focus on a better mixing of iron particles and HMDSO vapour, which is expected to reduce homogeneous nucleation and moreuniform coating of nanoparticles.

Abstract

Thin films of Cu were thermal evaporated and sputter deposited on Teflon® PTFE, FEP and PFA surfaces and analyzed with XPS. In contrast to thermal evaporation, the high energy Cu atoms from sputter deposition produced substantial yields of copper fluorides which were studied as a function of sputter parameters. The formation of copper fluoride bonds correlated with good practical adhesion of sputtered Cu with FEP and PFA compared to PTFE which was the most resistant to the production of fluoride ions.
Keywords: copper; Teflon® PTFE, FEP and PFA; fluoropolymers; copper fluoride; adhesion

1. Introduction

Fluoropolymers, like Teflon® PTFE (polytetrafluoroethylene), FEP (fluorinated ethylene-propylene co-polymer) and PFA (polytetrafluoroethylene-co-perfluoropropyl vinyl ether), have been extensively used in space applications, protective coatings, biotechnology, and microelectronic packaging [1]. In the latter application, the low dielectric constant properties of fluoropolymers have the advantage of producing faster package transmission speeds and less electrical interference from neighboring circuit lines [2, 3]. However, their low surface energy properties present considerable challenges for adhesion and wettability when bonding to other materials, such as, the conductor copper.

During recent investigations to control Cu adhesion using surface modification of PTFE [4, 5], FEP [6, 7] and PFA [8] with vacuum UV radiation from plasma systems, untreated FEP and PFA were found to show good practical adhesion, using Scotch tape peel tests, compared to PTFE with sputter-deposited copper. Therefore, this study was conducted to investigate the reaction of copper, using the different energies of metallization from thermal evaporation and plasma sputter deposition, with the untreated fluoropolymer surfaces.

2. Experimental

Commercially available films, 50.8 μm thick, of Teflon® PTFE [–(CF_2-CF_2)$_n$–], and the random co-polymers FEP, [–(CF_2-CF_2)$_x$-CF_2-$CF(CF_3)$-]$_n$ where x≅7, and PFA, [–(CF_2-CF_2)$_n$-(CF_2-$CFOC_3F_7$)$_m$–] (n/m= 39), were obtained from Saint-Gobain Performance Plastics and American Durafilm, respectively. Before attempting deposition of Cu, the samples were treated in ultrasonic baths of first methanol and then acetone at room temperature for 5 min each followed with over-night drying in air at room temperature to help remove potential contamination from lubricants employed in the processes to form the polymer mass into commercial film [8, 9].

Vacuum deposited copper films were either evaporated or sputtered. Deposition rates and film thicknesses were measured with Inficon (Syracuse, NY) quartz crystal monitors that were calibrated with a Sloan Dektak (Santa Barbara, CA) surface profilometer. Residual gas pressures were less than ca. 3.0×10^{-3} Pa.

Evaporated films were deposited with deposition rates (0.05 – 0.2) nm/s in a thermal evaporator manufactured by CVC Corporation, Rochester, NY. The substrates were mounted on a glass slide (for mechanical stability) and then placed in a substrate holder at a distance of 40 cm above a tungsten boat used to melt the copper. The boat and substrate holder were enclosed in a 50 l. glass bell-jar.

Sputtered films were vacuum deposited using deposition rates (0.01 – 0.5) nm/s with a MAK 3" DC planar magnetron manufactured by US Inc, Campbell, CA. The samples were placed on a grounded substrate holder which was 20 cm in front of a 99.99% pure, 7.5 cm diameter copper target. The magnetron and substrate holder were enclosed in a vacuum chamber. Research grade argon (99.997% pure) was introduced through a mass flow controller. After the sputtering plasma was ignited, the target was pre-sputtered, while a shutter covered the substrate, for ca. 2 min to allow the plasma to reach steady state during the establishment of the pressure and deposition rate. To change the energy of the sputtered Cu interacting with the substrate, the following parameters were varied: discharge voltage (273 – 377 V), current (0.1 – 0.95 A), power (40 – 365 W) and pressure (0.27 – 2.1 Pa).

The samples were analyzed *ex-situ* after Cu deposition with X-ray photoelectron spectroscopy (XPS), a surface analysis technique that provides elemental, chemical state and quantitative analyses for the top 2 – 5 nm of a sample's surface. A Physical Electronics Model 5800 XPS system was employed for the characterization. A region about 800 μm in diameter was analyzed. The films were prepared by cutting sections from the sample and mounting them beneath a molybdenum sample mask for exposing to the x-ray beam. The atomic percentages reported for carbon are precise to within 5% for major constituents and 10% for minor components. The samples were irradiated with monochromatized Al Kα radiation (1486 eV), treated with minimum XPS scan times and charge neutralized with a flood of low energy electrons from a BaO field emission charge neutralizer. These methods were employed so as to not over expose the post-metallization samples since such exposures have been reported to produce copper fluorides for evaporated copper on PTFE [10] but not for FEP or PFA [11]. High-resolution XPS spectra in the C 1s, O 1s, F 1s and Cu 2p regions were used to determine the chemical environment changes. The analysis was performed at an angle of 45° between the sample and analyzer. The spectra were curve fitted using the software package provided by the instrument's supplier. The software utilizes commercial Matlab© routines for data processing.

3. Results

The XPS analysis for the thin films of copper produced by thermal evaporation (1.5 – 4.5 nm) and plasma sputter deposition (0.5 – 2 nm) on the fluoropolymers revealed the presence of carbon, fluorine, oxygen and copper with a trace amount of tungsten for the evaporation experiments. The chemical state determination showed evidence for fluoropolymer, some hydrocarbon contamination, oxidized hydrocarbon containing the O-C=O moiety and copper oxides.

For the evaporation experiments, the F 1s spectra were nearly identical to the cleaned fluoropolymer samples. Single strong peaks due to the CF_2 moiety are observed as shown in Fig. 1. The F 1s peak due to FEP showed some broadening at low binding energy that could indicate a very low concentration of copper fluoride, but, in general, none of the fluoropolymers produced significant yields of fluoride ion at about 684 eV. The quantitative XPS analyses for these samples are given in Table 1.

Table 1. Results of Quantitative XPS Analyses for Evaporated Copper on PTFE, FEP and PFA[1]

Sample	C (at%)	F (at%)	O (at%)	Cu (at%)	W (at%)
PTFE	30.2	29.2	24.5	14.8	1.3
FEP	29.0	24.2	30.3	14.6	1.8
PFA	30.9	36.4	20.7	10.6	1.5

[1]Evaporation Conditions: Pressure: 2.7 x 10^{-3} Pa.

In contrast to Cu deposited by thermal evaporation, sputter deposition, using the conditions reported in Table 2, formed substantial fluoride ions as shown in Fig. 2 which clearly demonstrates that PTFE does not react as readily with energetic Cu atoms as PFA and FEP.

Table 2. Results of Quantitative XPS Analyses for Sputtered Copper on PTFE, FEP and PFA[1]

Sample	C (at%)	F (at%)	O (at%)	Cu (at%)
PTFE	29.2	17.5	32.6	20.8
FEP	26.9	10.6	37.3	25.3
PFA	26.8	9.3	38.1	25.9

Pressure: 0.27 Pa.

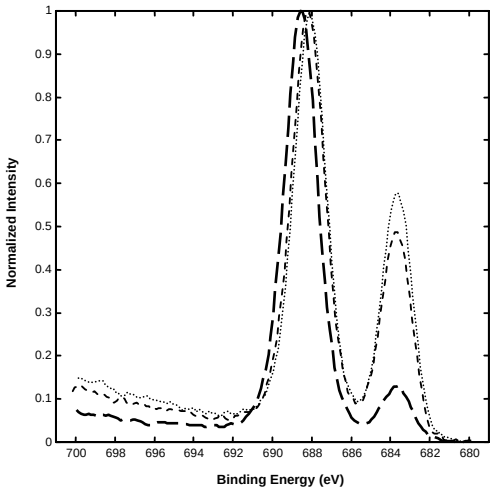

Figure 2. Overlapped F 1s Spectra for PTFE (_ _ _), FEP (- - -) and

PFA (…) Post-Plasma Sputter Deposition of Copper

Some experiments were conducted to investigate the effect of sputtering parameters on the production of fluoride ions. As an example, Table 3 and Figure 3 reports results for an experiment where the Ar pressure was mainly increased by a factor of about eight fold compared to the experimental conditions described in Table 2.

Table 3. Results of Quantitative XPS Analyses for "High Pressure" Sputtered Copper[1]

Post-Plasma Sputter Deposition of Copper Using "High Pressure" Conditions.

4. Discussion and Conclusions

The lack of significant fluoride formation, when evaporated Cu is deposited on the fluoropolymers, correlates well with the observed poor practical adhesion of Cu to PTFE [4, 10, 12], FEP [11, 12] and PFA [11-13]. Quantitative measurements of the adhesion strengths have shown stronger adhesion of evaporated copper to FEP and PFA than PTFE which was attributed to the larger group electronegativities of CF_3 in FEP, C_3F_7O in PFA compared to F in PTFE [12]. The low chemical reactivity of vapor deposited copper to PTFE has been explained on the basis of the strength of the C-F bond compared to the heat of condensation [10]. No reaction of Cu with PTFE has been observed with temperatures up to 703ºK [14] while Cr-coated Cu foil reacts with glass-fiber-filled Teflon PFA laminates at 653ºK to produce metal fluoride formation [15].

In the sputter deposition experiments, the energy of the copper atoms is substantially greater than the C-F bond dissociation energy (ca. 5 eV [16, 17]) and the F 1s XPS analysis detected the formation of fluoride ions either as CuF and/or CuF_2 moieties. Because of the presence of copper oxides during the sputtering of Cu, there was too much interference to adequately detect CuF_2 by the Cu 2p XPS spectrum at 935 eV [18, 19]. Within the range of parameters studied, the presence of copper fluorides decreased with a decrease in discharge voltage, which would decrease the energy of the Cu atoms, and an increase in pressure, that due to collisions would also shift the energy distribution of Cu atoms to lower energies. Polycrystalline PTFE was found to be the most resistant to the formation of fluoride ions, again, consistent with the findings that poorer practical adhesion of sputtered Cu was observed with PTFE [4, 5] compared to the more amorphous FEP [6] and PFA [8]. Previously, copper fluorides were detected for sputter-deposited Cu on fluoropolymer Teflon®AF1600 [20] but not FLARE™1.0 where the breakage of the C-F bond resulted in the loss of fluorine at the interface instead of the formation of copper fluoride [21].

Atmospheric Pressure DBD gun and Its Application in the ink Printability

Qiang Chen, Erli Han, Yuefei Zhang, Yuanjing Ge
Laboratory of Plasma Physics and Materials, Beijing Institute of Graphic Communication, Beijing 102600

Abstract: In this paper, a plasma source discharging at atmospheric pressure and its characterization diagnosed by a Langmuir probe, a digital camera and a computer processing are presented. As an application the dielectric barrier discharge (DBD) gun modifying an ultraviolet (UV) cured resin surface for ink printability is reported.

Keywords: plasma source, application, ink printability

Introduction

Modifying polymer surfaces using plasma techniques is of great and increasing industrial relevance [1]. Appropriate plasma treatments are widely employed to modify polymer surface properties such as adhesion, friction, penetrability, wettability, dyeability, printability and biocompatibility, so as to adapt them to specific applications [2, 3]. Depending on the treatment parameters, rapid, clean, environmentally friendly plasma-based processes are able to induce physical and chemical surface changes in polymers through several concurrent actions (etching, grafting, polymerization, cross-linking, etc.), usually without modifying their original bulk qualities [4,5].

Among these various plasma applications, dielectric barrier discharges (DBDs) in air (or in other gases or vapors) that run at or near atmospheric pressure are demonstrably convenient for the activation or modification of polymer surfaces. Such discharges provide chemically mild and mechanically nondestructive means of altering surface properties targeting improved and desirable surface characteristics. Moreover, they are obviously attractive to the industry in that they avoid the high engineering costs usually associated with vacuum-based plasmas [6, 7].

Even through DBD techniques are used widely for surface modification/polymerization: for the treatment of polymers, for plasma coating, for thin-film deposition, for the cleaning and activation of substrates, for the sterilization of surfaces and materials [8-13], however, the shape of the electrodes, especially the small gap between the electrodes, is a demonstrable limitation of the DBD technique

application.

Thus the plasma torches/jets were appeared and generated deep inside discharging between the column electrodes for other unique applications. The working gas flow from the nozzle stabilizes the plasma jet, and a well-defined plasma channel is created downstream from the gas flow and therefore plasma interacts with the substrate for modification/deposition. Thermal torches and arcs, for example, which are high-temperature sources ($>10000^0$C) that are used for a variety of applications of coatings, welding and cuttings is well known [14]. Recently for practical requirements a capacitively coupled rf plasma jet, a kind of low temperature one, was studied in relation to bio-compatible plasma source at 13.56MHz [15]. Beside that a dc micro-hollow cathode discharge gun served as an efficient source of vacuum UV radiation was explored [16], and an rf discharge needle developed and performed in a small area treatment was also emphasized [17].

Taking into account the above discussion, we here present a plasma source dependent on the use of DBD gun, which is quite different from the ones described above. Unlike an RF atmospheric pressure glow discharge [18], or a plasma jet/needle [17, 19, 20], the DBD gun including a dielectric material between the electrodes can generate a stable glow plasma. With a digital camera and computer processing the uniformity of the plasma out of the nozzle is diagnosed. The electron temperature near the nozzle is detected by Langmuir probe. Then the plasma generating from DBD discharge in 26kHz without any vacuum demands at atmospheric pressure, for instance, has been used for a number of plasma chemical technologies, in particular modifying the UV cured resin for ink printability, with surprisingly good results.

Experimental

Experiments to study the optical and uniform properties of the DBD gun were done in Ar flowing into ambient air at atmospheric pressure. The setup is schematically depicted in Fig. 1 (a), where the gun consists of an inner electrode, a quartz glass tube (0.1cm wall thickness), and a foil metal cylindrical tube around the glass as outer electrode. Normally the gap was 0.5 cm between the inner electrode and the quartz glass. And the discharges were operated in a high-frequency power supply (0-5 kV, 26kHz) with Ar fed into the annular space between the two electrodes as working gas. The gas stream was directed onto silicon wafers located at the downstream from the nozzle and the flow rate was adjusted using mass flow controllers.

The optical of discharging gun was characterized by digital camera. Light was collected from the side of the plasma gun as showed in Fig. 1(a) thereby sampling the radiation from the outflow region. And then spectra were acquired by a computer processing.

The plasma treatment of UV cured resin was performed at atmospheric pressure with DBD gun. The samples were prepared by curing the resin in UV light at power of 150W for 15s on Si substrate prior to placement blow the plasma gun. Discharges were struck and maintained a constant current and voltage during the modification. After processing the substrates were characterized by Fourier transform infrared (FTIR), contact angle measurement and ink printability. An illustration of the discharging gun is shown in Fig. 1(b).

Results

The effect of discharge voltage and diameter of inner electrode on the torch length is shown in Fig. 2. It obtains that the variation of torch lengths with the discharging voltages exhibits clearly the distinctions as Fig. 2(a) shows: below 70V discharging voltage the torch length at the exit of the nozzle is relatively short and dependent on the gas effluent. But in higher voltage the change of length is relatively small and trend to the similarity for the three kinds of flow rates. In contrast, the variation of torch lengths influenced from diameters of the inner electrode is in a reverse way: the larger diameter of the inner electrode, the shorter length of the plasma torch. It can be explained by the resistance causing from decreased gap between the inner electrode and dielectric glass due to the increase of inner electrode diameter, and the less Ar effluent from the nozzle.

Fig. 2 (b) also demonstrates the plasma power obviously determined the torch length. For instance as Fig. 2(b) shows in 3mm diameter of inner electrode the torch length was 4.3cm

corresponding to 3.5kV discharging voltage but the length was only ca. 2.2cm in 2.6kV discharging voltage.

Fig. 3 Distributions of the three-light intensities versus the radius of torch at (a) 0.5cm; (b) 1.4cm and (c) 2.5cm from the gun mouth, and (d) the axial position from gun mouth (red light 600-700nm, green light 500-600nm, and B-blue light 400-500nm)

It is known that the light intensity is relevant to the electron density and the electron temperature in plasma. By a digital camera and processing in a computer the characteristics of the plasma in DBD gun is revealed quantitatively. Figure 3 shows the relationship of the three-light intensities (red light 600-700nm, green light 500-600nm and blue light 400-500 nm) with the distances from the nozzle to the detected site, and the distributions of light intensities in the radial and axial directions. It indicates from Fig. 3(a, b, c) that in a large region of plasma zone the light peaks are relatively flat and homogenous, and the intensities are demonstrably strong and uniform in the central areas of torches. In the axial direction, furthermore, Fig. 3(d) shows that the light intensity decreases also slowly along the flow direction outside the nozzle. It results that the DBD gun can generate a torch with relatively homogenous and uniform distributions of electron, ion and radicals in radial and axial directions.

Langmuir probe measurement reveals that the electron temperatures at 0.5cm site downstream from the nozzle were 0.3eV to 1.4eV depending on the probe position in the radus. It is simalar to the electron temperature measured in the rf capillary discharge of 0.2-1.2eV [20].

As an application, the DBD gun is used to treat VU cured resin for ink printability. Normally the UV cured resin has a surface energy blow $28\times10^{-3}N/m^2$ where the ink on the surface even cured by UV light is still easily being erased from the surface because of the poor adhesion causing by the low surface energy. Increasing the surface energy is an efficient and conventional method to improve the printability.

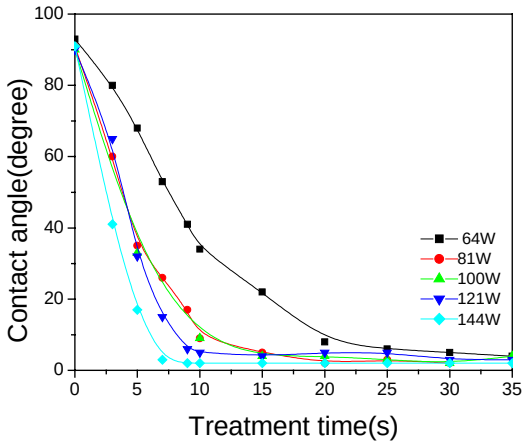

Fig. 4 Contact angles of the UV cured resin versus plasma powers (Ar flow rate 22.5L/min, 10mm between the substrates and the nozzle)

Fig.4 shows that the contact angles after Ar plasma treatment drastically decreased whereas the periods of plasma interaction were less than 5s for all incident powers. But after 20s exposure time, the contact angles

seem to be constant and negligible variation with the extension times.

The influence of Ar flow rates on contact angles in Fig.5 indicates that before ca. 5s exposure period the contact angle decreased greatly with the increase of flow rate. But after 5s the contact angle decreased relatively slow, similarity to the influence from plasma power. It derives that the surface modification of UV cured resin can be achieved in a short period, and means the DBD gun seems to be an effective tool to improve the surface energy. Moreover in this figure it notices that at flow rate 22.5 L/min a super hydrophilic surface can be obtain with the contact angle of 4^0.

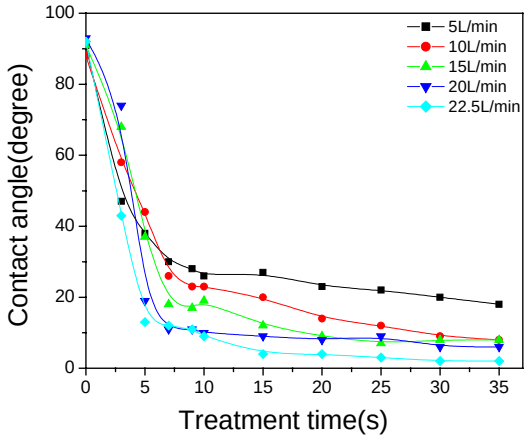

Fig. 5 Relationship of contact angles with Ar flow rates in DBD gun (conditions: 144W plasma power, 10mm between the substrate to the nozzle)

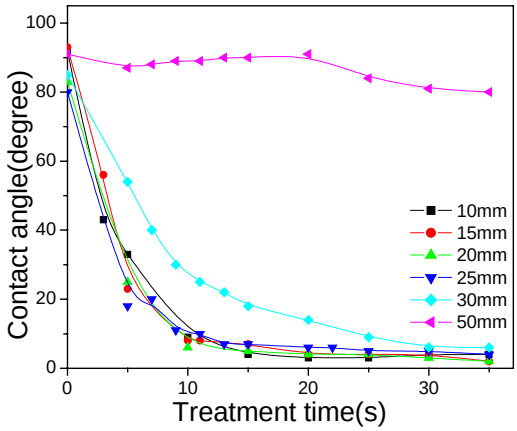

Fig. 6 Influence of the distance from substrates to the gun nozzle on the contact angles (plasma power 100W, flow rate 22.5L/min)

Due to the dependent of plasma densities on the distances from gun nozzle to substrate the

effect of distances on the contact angles is reasonable as Fig. 6 shows. When the substrates were placed less than 25mm form the nozzle in axis the efficiency of plasma modification were significantly strong by exponentially decreasing of the contact angles with the exposure times. But when the gap was beyond 30mm, the plasma interaction was relatively weak. Especially when the substrate was put 50mm under the nozzle, the contact angle shows a negligible variation after plasma treatment in Fig. 6.

The aging properties of UV cured resin after DBD plasma gun treatment are shown in Fig. 7. The recoveries of the contact angles were significant after DBD gun treatment. In particular at beginning when stored the sample the contact angles increased remarkably. After one day later the contact angles trended to stable and the recovery of contact angle was relatively slow. It can be explained by the polar groups in the surface turning into the body and stabilizing the surface [21], and the plasma generated from the gun occur the resin covalently grafted the polar groups on the surface and the dangling bonds remained on surfaces were much activity binding the species from the air to neutralize the polarity in the surface. Fig.7 also notes that the different exposure periods did not lead to any variable behaviors on the recovery of contact angles. The 15s period plasma treatment shows the same behavior as done in that 10s exposure period sample.

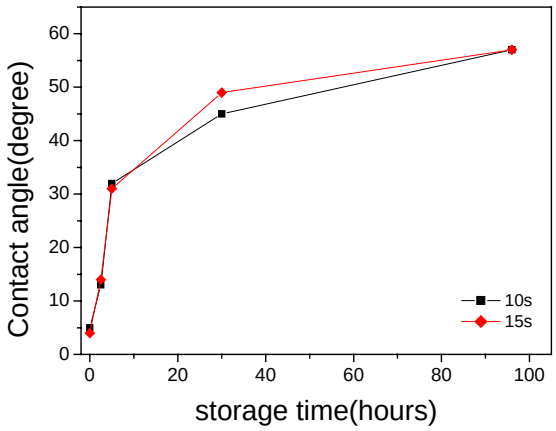

Fig. 7 Delay of contact angles after plasma treatment with the aging times (plasma power 144W, flow rate 22.5L/min, and distance was10mm between the substrate and the nozzle)

In Fig.8, Fourier transform infrared (FTIR) spectrum presents the comparison the structure change of UV cured resin before and after DBD gun treatment. The spectra exhibit a series of infrared

bands at 1060-1260 cm^{-1} which are due to O-H and C-H stretching, bending modes and hydrogen bond interaction [22]. That is indicative of the polar groups on the surface. In addition, infrared band seen at 3400cm^{-1} is assigned to the bending and stretching vibrations of hydroxyl groups. At peak 1450cm^{-1} C-O stretching, 1740cm^{-1} O=C rocking deformation clearly show the polar groups were grafted and significantly improved due to plasma interaction [23]. The very strong latter band can be attributed to polarized carboxyl and hydrogen bonding between neighboring hydroxyl and oxide groups.

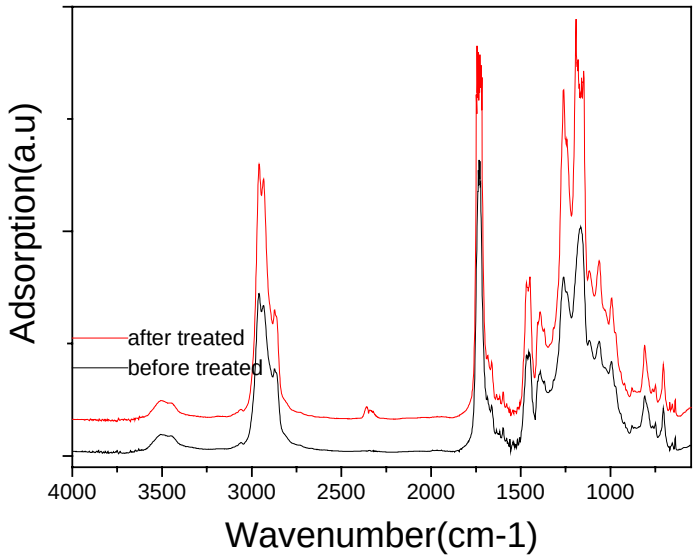

Fig. 8 FTIR spectra of UV cured resin before and after DBD gnu treatment

The surface energy measurement is established in Tensiometer K100, Germany. Table 1 shows the results in which testifying the features of FTIR spectrum. The grafted polar groups especially the carboxyl, hydroxyl and oxide groups increase the polar energy of UV cured resin and improve the ink printability.

Table 1 the surface energy of UV cured resin before and after DBD gun treatment

UV cured ink	surface tension（mN/m）	disperse part（mN/m）	polar part（mN/m）
untreated	27.2	24.3	2.9
treated	34.0	16.9	17.0

The ink printability was evaluated by printing the ink on surfaces and then measuring the ink

density. Fig. 9 shows that untreated substrate after ink printed visually appeared lots of blank sites on surface rather than the whole surface covered by ink in treated samples. The data in Table 2 indicates quantitatively the ink density on the treated surface increased ca. 27.3% after DBD gun treatment.

a **b**

Fig.9 Ink printability on UV cured resin a-before and b-after DBD gun treatment

after	2.541	2.378	2.511	2.430	2.497	2.471
increased rate(%)	30.6	30.4	23.4	24.4	28.0	27.3

Discussion

After characteristic of the plasma generated by DBD gun with a Langmuir probe, the digital camera and computer processing, and then the application of the DBD gun to treat UV cured resins for ink printability, it obtains that the DBD gun is a very convenient tool for the controlled surface activation and modification of various categories of surfaces, where remarkably uniform treatment and relatively stable modified surface properties result over the entire treated area of the test surfaces.

Langmuire probe detected the electron temperatures in the gun were 0.3 to 1.3 eV near the mouth. It means the DBD gun is capable and suitable for polymer modification especially with its convenient and handable for a small zone. The measurements of light intensity along the axis of flow direction outside the nozzle reveal that concentrations of electron, ion and radicals in the downstream are quite homogenous and uniform when the substrates are near the nozzle. Increasing the distance, however, the concentration of species remarkably decreased. It is consistent with the contact angle measurement, where in long distances, for example 50mm between the substrate and nozzle, the contact angle showed a negligible variation after DBD gun treatment.

In the radial direction the species: electron, ion and radicals are concentrated in the core and

dispersed with the radii of nozzle and the distance from gun nozzle to detected site, which is intrinsic characteristic of torch plasma. Fig. 10 the droplets of distilled water visually demonstrate no dispersion around plasma interacted area and clearly indicates the plasma uniform under the nozzle. The circled area by droplets is consistent with the diameter of plasma torch.

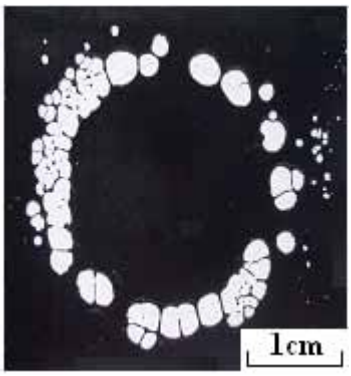

Fig. 10 Droplets of distilled water circling the plasma treatment zone

The FTIR spectrum reveal polar functional groups of carboxyl, hydroxyl and oxide grafted covalently on the surface contributed to resin printability and indicate even in a short exposure period and a relatively low power the DBD gun can achieve efficiently the surface modification in air at atmospheric pressure. The oxygen in the chemical structure of resin surface caused from the process carrying on the ambient environment whereas Ar as the working gas. The polar groups on the surface turning into body leaded to the modified resin aging, e.g. the contact angle increase very rapidly at beginning storage. Nevertheless, until now it is still to estimate of the species concentration in the atmospheric pressure DBD gun and cannot make any conclusions regarding the role of electrons, ions or radicals in the modification process.

Conclusion

The novel plasma source working at atmospheric pressure and its characteristic are presented. The high-frequency DBD gun and its applications as a unique instrument for interested works in printing are investigated. Langmuir probe detected the temperature of electrons near the nozzle is 0.3 to 1.3 eV. The digital camera and a computer processing reveals that the distribution of light intensity in the downstream of the nozzle is quite uniform and homogenous but depending on the distance from

the nozzle to detected site. The application of DBD gun treated UV cured resin for ink printability concludes that it can be utilized conveniently as a hand-operated tool to practically modify the micro-zone in printing industry such as a label on stamp surfaces.

ABSTRACT

Method of biochemical patterning which allows for micro and nano-scale resolution on non-planar substrates is presented. Utilizing this method, bio molecules (including DNA, proteins, and enzymes) can be delivered to charged locations on surfaces by charged water buffer droplets. Charging of water droplets is accomplished using either Dielectric Barrier Discharge (DBD) plasma or Corona discharge. DBD and Corona were effectively stabilized in the presence of high concentration of micron-size water droplets. Discussed in this paper are the concepts of the proposed method as well as first experimental results supporting the idea.

Keywords: non-thermal plasma, biomedical applications, xerography

I. INTRODUCTION

Patterning of different biochemical molecules on surfaces has many applications ranging from biosensors, used in genetic discovery and monitoring of dangerous toxins, to tissue engineering constructs where surfaces control tissue assembly or adhesion of cells. Most existing methods of biochemical patterning are suitable only for planar surfaces. In addition, micro and nano-scale patterning often relies on complex sequences of lithography-based process steps.

Many methods are available for printing today. The most common ones, that led us to our idea, are Inkjet printing and its derivative – electro-spray technology, and Laser printing technologies. Disadvantages of Inkjet printing technology are splashing caused by droplets accelerated to high speeds hitting target surface, low precision caused by droplet diffusion, and, in many of the variations of the technology, like electro-spray – high dependence on chemical composition of the ink, i.e. printer has to be heavily modified to be able to print a slightly different substance. Laser printers address many of the issues brought up by Inkjets but raise many of their own – for example, toner particles undergo high mechanical strains that biochemical molecules and DNA are likely not to survive. There also is a multitude of issues associated with heating.

(1) droplet atomizer,
(2) DBD plasma reactor, and
(3) charged droplet deposition substrate.

We are developing a method of biochemical substance patterning, or printing, which allows for micro and nano-scale resolution on planar and non-planar substrates. Our goal is to print droplets of buffer containing bio-molecules (including DNA), peptides, and cells. We accomplish this by creating droplets with the molecules or cells in their respective buffer solution, then charging the droplets in cold atmospheric pressure discharges, like Dielectric Barrier Discharge (DBD) and Corona discharge plasma, and finally delivering them onto substrate with charge

pre-written onto the substrate via well-known xerography (micron-resolution) or charge stamping (nanometer-resolution) (Fig. 1).

DBD was selected as the plasma source because of its lower volumetric power – we are able to charge droplets in a more "gentle" way than competing technologies and more powerful plasma sources [1,5,7]. DBD is also a non-thermal discharge able to function under room temperature and pressure conditions which are required for survival of most bio-chemicals. In addition, DBD design allows us to charge large volumes and throughput more liquid than most available technologies resulting in faster printing. Finally, we have precise control of the droplet flow speed (carrier gas flow speed) and are able to virtually eliminate splashing problems that occur with other methods like electro-spray [2-5]. Slower droplet speeds also allow for better control over printing precision and rate. However, DBD plasma at atmospheric pressure is highly non-uniform, unlike a less powerful Corona discharge – we are currently investigating both discharges to determine optimal conditions for droplet deposition without biochemical damage.

II. EXPERIMENTAL SETUP

Experimental setup and schematic illustrations of the Plasma BioPrinter are presented in Fig. 2.1-2.3. In the experiments with Corona discharge, "grounded mesh" in Fig. 2.2, 2.3 is replaced with thin powered wire and "high voltage electrode" is disconnected.

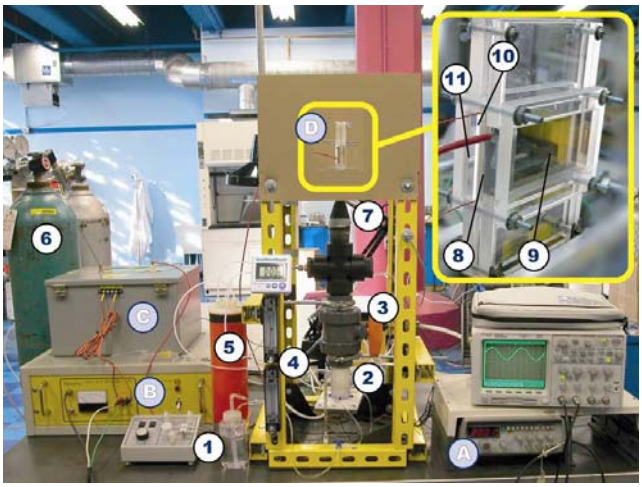

Fig. 2.1. Plasma BioPrinter Experimental Setup

Plasma BioPrinter Setup Schematic: (1) Liquid supply (bottle & variable flow pump); (2) Ultrasonic Nebulizer; (3) Droplet Flow control valve; (4) Gas Flow control; (5) Liquid Nitrogen cooler; (6) Carrier Gas Supply; (7) Flow conversion nozzle; (8) Quartz Dielectric Barrier; (9) High Voltage Electrode; (10) Grounded Mesh Electrode; (11) Target Substrate.

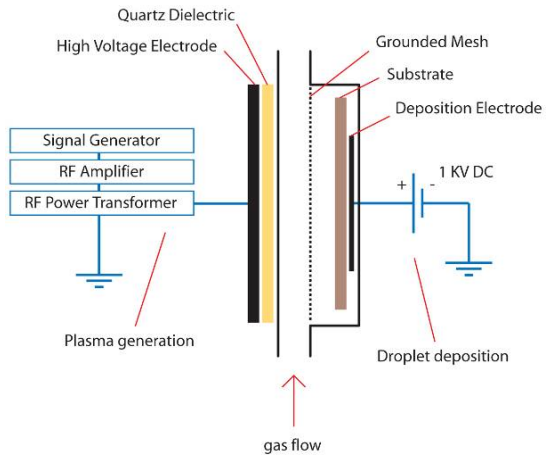

Fig. 2.3. Printer head setup schematic with DBD plasma.

Experimental process is as follows. Liquid is supplied by a variable flow mini-pump at 130 ml per hour (1). Piezoelectric Ultrasonic Nebulizer (atomizer) then produces 1-4 micrometer droplets (2). Aerosol flow into the system is controlled by the ball valve (3) and by supplying carrier gas into the Nebulizer (4). Carrier gas is supplied in two locations to allow control of the flow rate as well as droplet concentration via gas dilution (4). Air, Argon, or Helium can be used as carrier gases (6) which are cooled by liquid Nitrogen to ensure minimal water vaporization from droplets in the discharge (5). Our gas flow through plasma ranges from 1 to 2 liters per minute (4 to 8 cm per second flow speed through plasma gap), thus staying laminar with low Reynolds number; connection from Nebulizer to plasma is made in such a way as to ensure laminar flow (7). Plasma region consists of a 40x80 mm gap with 1 mm thick quartz dielectric (8). Gold was thermally evaporated onto quartz to act as one electrode (9). Second electrode is an open stainless steel mesh (10) which provides us with the ability to extract charged droplets from plasma onto target substrate (11) using an external electric field.

In plasma, droplets are charged to their "floating potential" – a potential at which flow of electrons onto a droplet is balanced by flow of positive ions. Bohm's sheath model [3,8] allows us to estimate floating potential as φ_{fl}:

$$\varphi_{fl} = -\frac{T_e}{2}\ln\left(\frac{M_i}{2\pi m_e}\right) = -4.7 \text{ V} \qquad \textbf{(1)}$$

where T_e – electron temperature, M_i – ion mass, m_e – electron mass. For droplet of radius r = 500nm we can estimate its charge to be:

$$q_{drop} = \varphi_{fl} c = \varphi_{fl} 4\pi\varepsilon_0 r \approx 1000 \text{ electrons} \qquad \textbf{(2)}$$

where c – droplet capacitance, ε_0 – permittivity of free space. In DBD discharge in Argon at room temperature and pressure, number of electrons $n_e \approx 10^{12}$ cm^{-3} and their velocity $v_e \approx 10^8$ cm/sec we can calculate electron flux [5,8]:

$$\Phi_e = 4\pi r^2 \frac{n_e v_e}{4} \approx 10^5 \ \frac{\text{electrons}}{\text{second}} \qquad \textbf{(3)}$$

Thus, a 500 nm radius droplet will gain 1000 electrons in $5\cdot10^{-3}$ seconds; and at the flow speed of 4 cm/sec through plasma we can estimate that the droplet will be charged after $2\cdot10^{-2}$ cm in plasma (more details on DBD plasma modeling and particle charging dynamics can be found in literature [4,5,8-12]). Even though plasma characteristics of a Corona discharge differ from DBD plasma, based on experimental evidence will assume that droplets gain similar charge [7].

Piezoelectric crystal in Ultrasonic Nebulizer vibrates at 2.4 MHz generating droplets of 1.7 micrometer diameter on average at room temperature and pressure [2]. Sonozap corp., makers of the crystal, measured droplet diameters to be in the 1 to 4 micrometer range (via light scattering). We plan to repeat those experiments at our lab in the near future. Nebulizer liquid throughput of 130 ml/hour and flow rate of 1 l/min yields droplet concentration of $7.8\cdot10^8$ droplets/cm^3 – droplet-carrier gas mixture is very dense and evaporates very slowly at the time scales relevant to our system [2,3,7].

Our droplets are too small to feel the effect of gravity during their residence in the system [3,7]. Neglecting the effect of gravity we notice that the only two forces are acting on the droplet: force exerted by the electric field pulling the droplet onto the substrate $F_{el} = Eq$ (E – applied electric field, q - charge) and drag force exerted by the gas on the droplet $F_{drag} = 6\pi\eta r v$ for low Reynolds number (η - dynamic viscosity, r – droplet radius, v – relative velocity) [2]. To find droplet's drift velocity let us equate the two forces:

$$Eq = 6\pi\eta rv \Rightarrow E\varphi_{fl} 4\pi\varepsilon_0 r = 6\pi\eta rv \Rightarrow$$

$$v = \frac{2}{3}\frac{\varphi_{fl}\varepsilon_0}{\eta} E \ \frac{\text{cm}}{\text{sec}} \qquad \textbf{(4)}$$

Thus we observe that charged droplet drift velocity under the influence of electric field will not depend on the size of the droplet. This allows us to control droplets motion more precisely as well as virtually eliminate splashing problems [2].

III. RESULTS

We have demonstrated our ability to ignite and sustain DBD discharge in Argon and Helium in the presence of water aerosol (Fig. 3.). The discharge operates at room temperature and pressure with power of 50-70 Watt in Argon and 15-25 Watt in Helium (Fig. 4.).

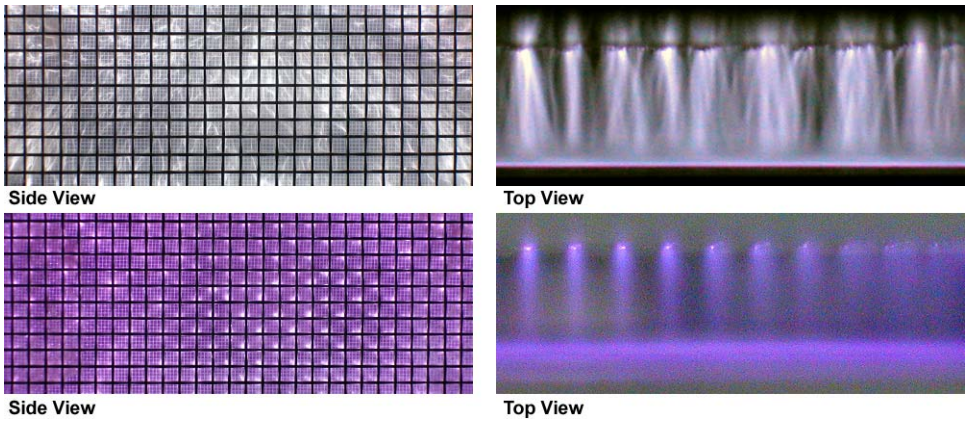

Fig. 3. DBD plasma with water aerosol at room conditions. Top: chilled Argon; bottom: chilled Helium.

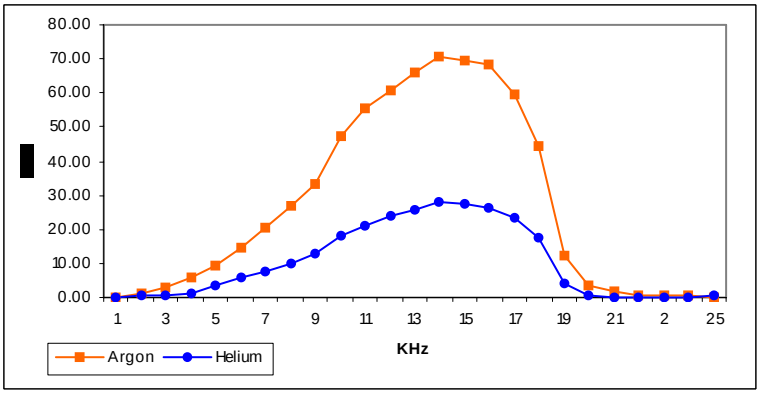

Fig. 4. Power of Argon and Helium discharges with water aerosol present.

We have demonstrated droplet deposition onto a 1 mm thick positively biased wire from DBD plasma and obtained similar results using a Corona discharge (Fig. 5.1, 5.2). This leads us to believe that our hypothesis of the droplets gaining a negative charge is, in fact, true; however, further testing is needed to ensure this fact. The obtained results did not differ between Argon to Helium.

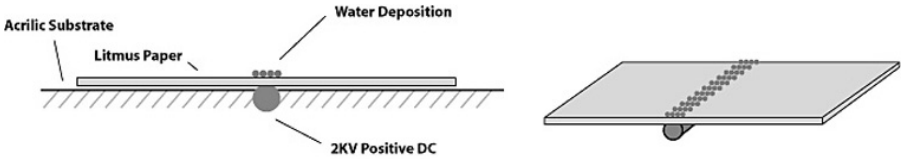

Fig. 5.1. Schematic of the substrate for deposition on positive electrode.

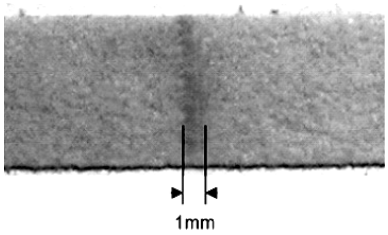

Fig. 5.2. Droplet deposition onto 1mm positively biased electrode.

Additionally we were able to demonstrate bio-active compound survival by printing Bovine serum albumin (BSA) onto a glass slide followed by fluorescein dye stain. BSA maintains its activity after passing through DBD plasma (Fig. 6.). However, more fragile molecules, like enzymes, rapidly loose their *activity* in DBD plasma (Fig. 7) – they still remain proteins but are no longer biologically active. This suggest that we need to keep residence time in plasma to a minimum to make sure bio-active molecules maintain their activity; however, this should not be a problem since our estimations show that droplet charging occurs in ~$5 \cdot 10^{-3}$ seconds which is significantly less time that required for Trypsin inactivation. Further testing of Enzyme inactivation rates in Corona discharge is pending.

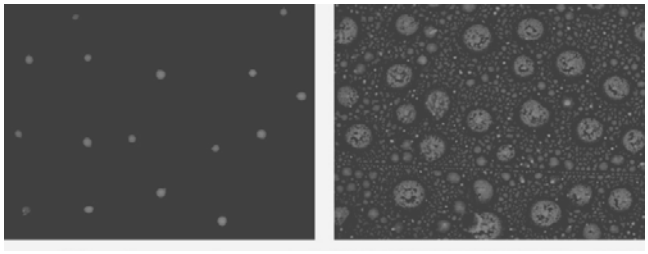

Fig. 6. Bovine Serum Albumin (BSA) fluorescein dye stain after deposition: (left) 15 second treatment; (right) 2 minute treatment.

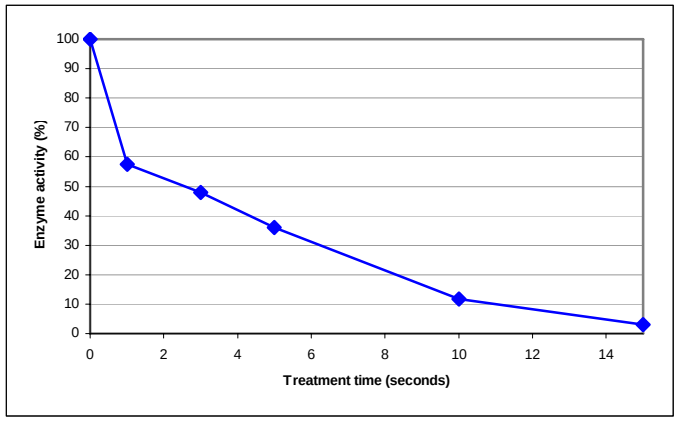

Fig. 7. Trypsin enzyme activity in plasma.

IV. CONCLUSION

Ignition of atmospheric pressure discharge in dense Argon and Helium atmospheres with dense liquid aerosol at atmospheric pressure and temperature was demonstrated. Droplet charging was demonstrated by droplet deposition controlled by electric field. Additionally it was demonstrated that DBD plasma in noble gases (under the discussed conditions) has little if any influence on bioactive compounds such as BSA (small protein). Detailed investigation of DBD plasma and Corona discharge inactivation of various protein and plasma influence on enzymatic activity of various bio-chemicals is being currently performed. Nano-precision is theoretically possible but was not yet demonstrated – our plans for near future include fabrication of charge-stamping setup – an existing and well-studied phenomenon that will provide us with nano-scale electrodes for charged droplet deposition.

ACKNOWLEDGMENTS

We would like to thank Ben Franklin Nanotechnology Institute for supporting this work, and Kurt Sieber of Eastman Kodak Company for his assistance with DBD plasma power supply construction.

Abstract

We demonstrate the ability of non-thermal plasma to promote blood coagulation and tissue sterilization in under 15 seconds of treatment. We demonstrate no gross (visible) or microscopic damage to tissue in as much as 5 minutes of plasma treatment. This procedure would be safe for patients since there are no exposed electrodes, discharge is cold, and current is low. Initial experimental results obtained using cadaver organs and donor blood support the fact that the DBD plasma can simultaneously sterilize skin and promote coagulation in bleeding tissue. This technique will decrease wound healing time and virtually eliminate wound infections with skin flora.

Keywords: non-thermal plasma, tissue sterilization, blood coagulation, wound healing

1. Introduction

In the last decade, advances in electrical discharge plasma systems allowed for many new applications. Such systems have been used for sterilization of surfaces, for biochemical surface functionalization, and for many other new applications [6-13]. Specifically, thermal plasma discharges are applied in the field of blood coagulation as a faster alternative to normal biochemical coagulation [7-9]. However, the use of thermal plasma is limited for two reasons: (a) the extremely high temperatures (2,000 K up to 10,000 K) cause severe tissue damage [7-9] (Fig. 1) and (b) the necessity of general anesthesia makes it inconvenient for wide-spread patient use, apart from the hospital setting [8,9].

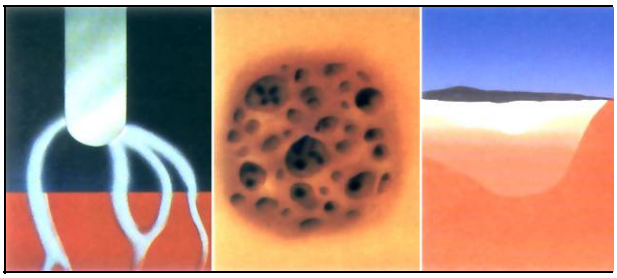

Fig. 1. Tissue damage by thermal plasma: tissue overheating, puncture and charring [7-9].

We have developed a Floating Electrode Dielectric Barrier Discharge (DBD) plasma (Fig. 2) system that promotes blood coagulation with simultaneous tissue sterilization for treatment of surface wounds. This treatment would be safe to patients because no exposed electrodes are involved and high frequency current is kept below a mili-ampere (see "Safety Considerations" below). Our initial experiments have shown that such plasma treatment hastens blood coagulation and causes simultaneous wound sterilization (probably via a large concentration of chemically active species in plasma [10-13] that are ions, radicals (O, OH, N) and electronically-excited atoms and molecules [1-6]). Fig. 3 and 6 display our prototype quartz-coated treatment electrodes for wound surface treatment by DBD plasma.

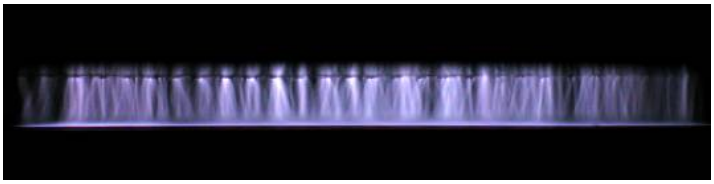

Fig. 2. Dielectric Barrier Discharge

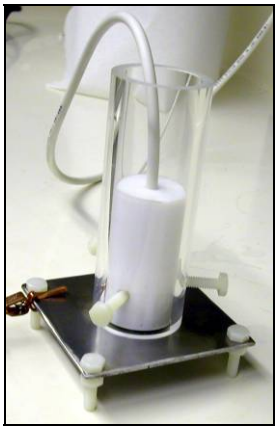

Fig. 3. Quartz-coated Treatment Electrode

This plasma technology can find many applications in the medical field. Within the hospital setting, this technology may prove useful in the operating room for patients suffering from bleeding not amenable to other methods of coagulation. Because of the potential for simultaneous sterilization, our device could also help prevent intra-operative infections. Sterilization effects of non-thermal plasma are well-known [10-13] and were confirmed, for example, in our research with NASA Jet Propulsion Lab [14]. In the future, we intend to develop a significantly smaller version of our power supply to create a portable, possibly battery-operated blood coagulator and wound sterilizer (Fig. 4). In addition, due to its ability to promote coagulation, the non-thermal plasma discharge device can be used for hemophiliac patients who have clotting difficulties or those who are on anti-coagulants.

2. Experimental Setup

Schematics of our experimental setup of the varying and fixed (Fig. 4) frequency, voltage, and power Floating Electrode DBD setups are presented. Power of both systems is approximately 1 W/cm^2 and the treatment surface varies from less than 1cm^2 to 10cm^2 depending on the attached electrode (Fig. 6). Utilizing the variable frequency, voltage, and power setup we are able to tune the setup for treatment dose appropriate for a specific application. I.e. for tissue sterilization we might want lower power with longer treatment time; while for blood coagulation we might want high power with low treatment time to stop "gushers" – large flow of blood; or lower power to coagulate blood in small cuts.

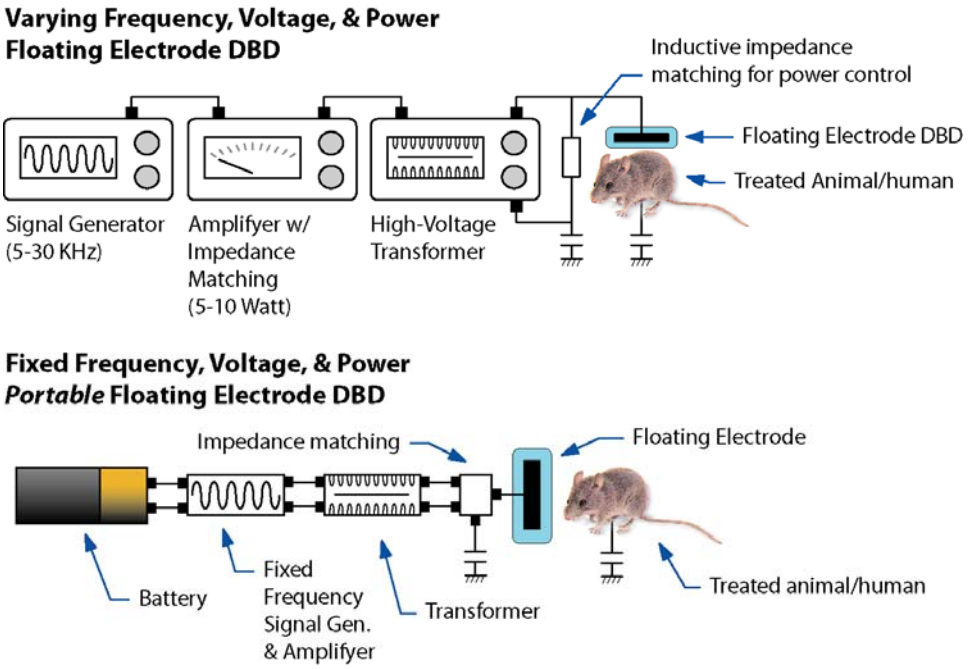

Fig. 4. Floating Electrode DBD schematic.

We started a fundamental study of mechanism of blood coagulation with the help of electrical discharge plasma. Fig. 5 presents our setup for treatment of small blood volumes – 500µl. While not wasting too much blood per test, this volume is a minimum required for standardized hematological tests we perform at the Drexel University Hahnemann Hospital hematology lab: PT (Prothrombin time), aPTT (activated partial thromboplastin time), and STA-Thrombin® (Diagnostica Stago proprietary Thrombin formation time test). In this setup we are able to precisely control the distance of Floating Electrode DBD to the treated blood sample for the purpose of

determining correct dose required for clot formation and to get reproducible results necessary for the fundamental study.

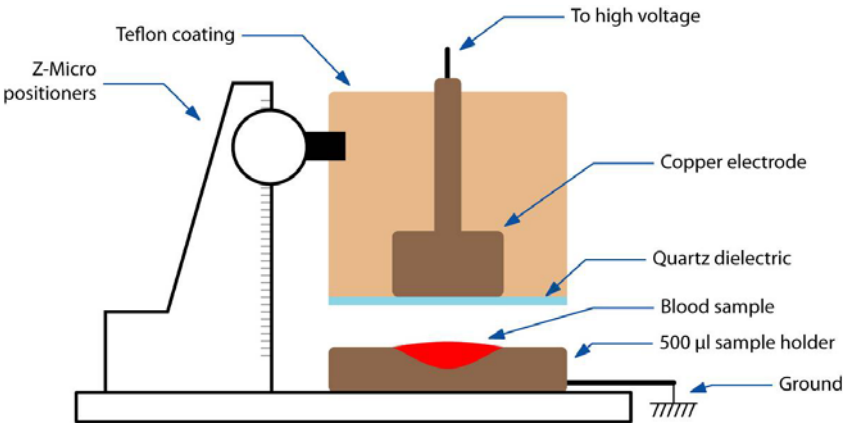

Fig. 5. Blood treatment experimental setup schematic.

Schematic representations of the three treatment electrode types used for this research are shown in Fig. 6. “Round” electrode is used for treatment of small areas and when distance between electrode and the treated surface is closely monitored (±0.1mm). “Wand” electrode is used in hand-held operation where distance and treated area are not precisely monitored. “Roller” is used for treatment of large flat areas.

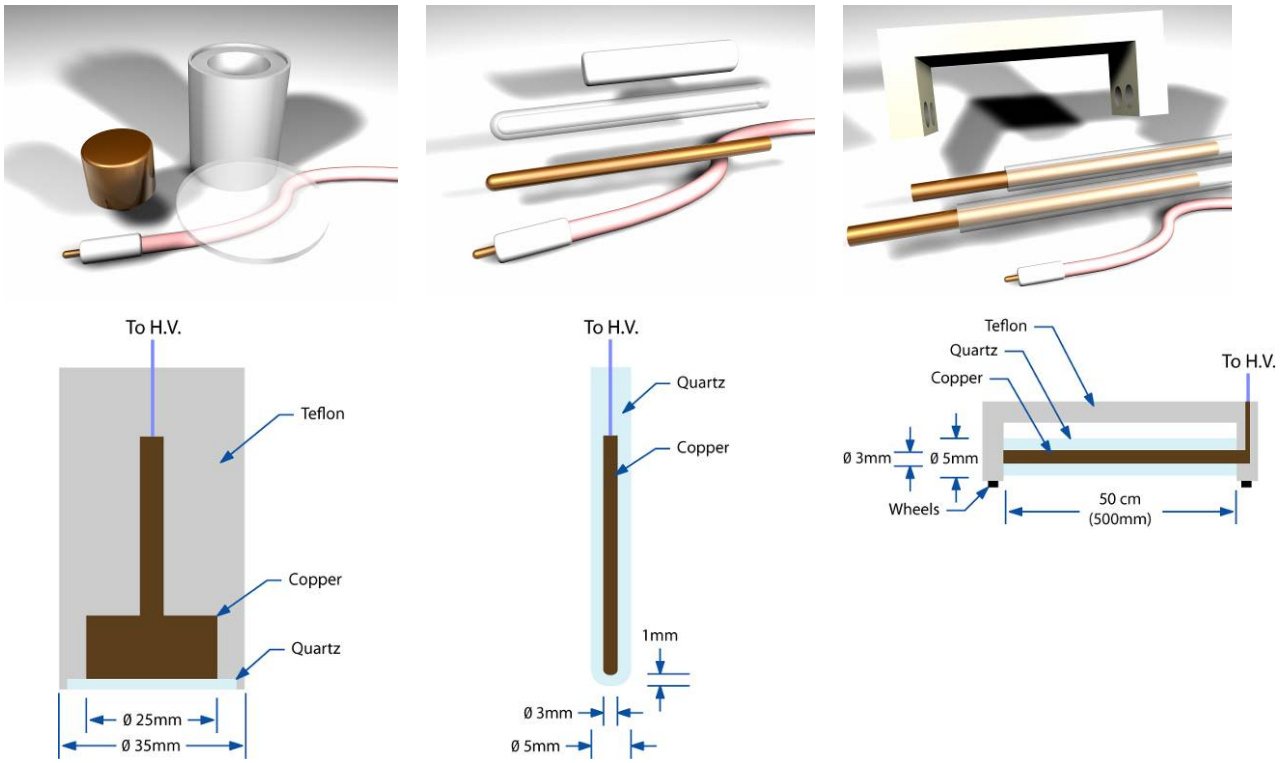

Fig. 6. Treatment electrodes. Top: 3D models; bottom: schematic representations;
left to right: “round”, “wand”, “roller”.

During treatment, tissue samples are placed directly on a grounded stainless steel plate. Blood samples are dispensed into 0.1 or 0.5 ml grounded stainless steel, aluminum, brass, or titanium containers (Fig. 5). For blood treatment we found titanium to be the best material where control blood sample coagulates the slowest.

3. Safety considerations

Safety of Floating Electrode DBD plasma electrode for humans needs to be considered for application in wound healing. Here we consider a simplified electric scheme to estimate conditions required for electrical safety. Once human approaches Floating Electrode, plasma ignites and at that point we can consider DBD plasma as capacitor and resistor in series and human as a resistor and capacitor in series (Fig. 7).

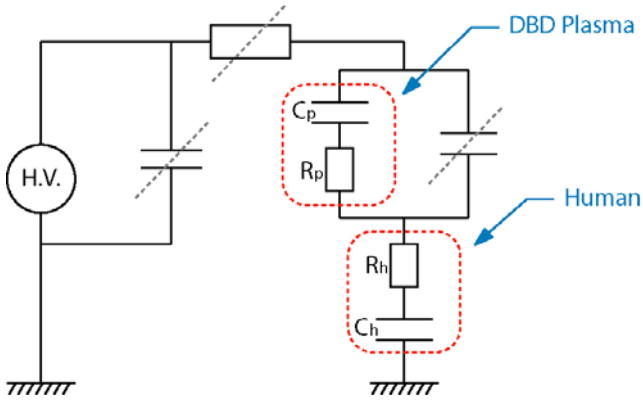

Fig. 7. Plasma/human interface principal schematic.

Total plasma resistance can then be estimated as a sum of capacitive and active resistances:

$$\overline{R}_p^{\Sigma} = \frac{i}{C_p\omega} + R_p$$

$$R_p^{\Sigma} = \sqrt{\left(\frac{1}{C_p\omega}\right)^2 + \left(R_p\right)^2}$$

Where R_p^{Σ} is total plasma resistance, C_p is plasma capacitance, R_p is plasma active resistance, and ω is the signal frequency. Similarly, total resistance of a human can be estimated as:

$$R_h^{\Sigma} = \sqrt{\left(\frac{1}{C_h\omega}\right)^2 + \left(R_h\right)^2}$$

Where R_h^{Σ} is total resistance of a human, C_h is human capacitance, and R_h is active resistance of a human. For the Floating Electrode DBD plasma device to be safe, total plasma resistance needs to be greater than total resistance of a human:

$$\sqrt{\left(\frac{1}{C_p\omega}\right)^2 + \left(R_p\right)^2} >> \sqrt{\left(\frac{1}{C_h\omega}\right)^2 + \left(R_h\right)^2}$$

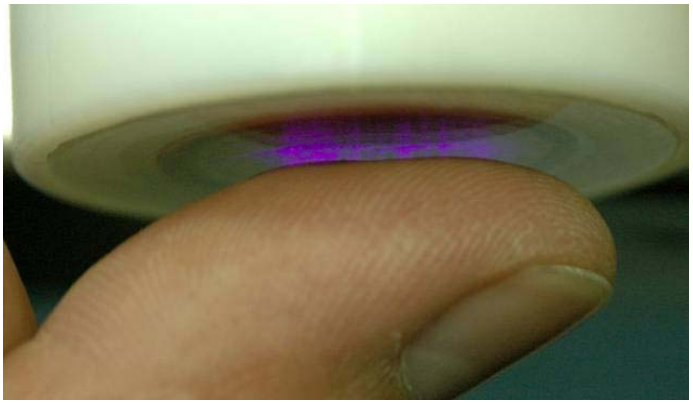

Fig. 8. Floating Electrode DBD: safe to touch.

Active resistance of a human is ~1 MOhm [15-17] and human capacitance is ~50 pF (though it ranges from 20 pF to 90 pF, depending on the surface human is standing on, thickness of his/her soles, and distance to nearest grounded object) [15,17]. For our frequency range, Floating Electrode DBD plasma active resistance can be estimated to 5 to 10 MOhm and its capacitance to ~50pF [18,19]. Thus at the operating frequency of 12 kHz we see that total resistance of a human (1.9 MOhm) is far smaller than total plasma resistance (5.3 MOhm), assuming C_h=50 pF, R_h=1 MOhm, C_p=50 pF, R_p=5 MOhm. Even in the case where human total resistance will increase for some reason, total current passing through the human will be very low because of a massive total resistance of the system. From this estimation we can conclude that even in the worst case where resistance of a human is approaching that of plasma, the overall system will still be completely safe from the electrical standpoint (Fig. 8).

4. Results

In our tests we have successfully accomplished the following:

- Designed and built a Dielectric Barrier Discharge (DBD) system capable of delivering 1 W/cm^2 of plasma power at operating frequencies of 10-30 KHz. While the system employs a power supply delivering voltage of up to 10 KV, it is perfectly safe as the high frequency plasma current is limited to below a milli-ampere.
- Developed treatment electrodes (Fig. 3-6) for treatment of blood and tissue samples.
- Performed blood coagulation tests on blood from cadaver organs (Fig. 9). The results consistently show faster coagulation when exposed to DBD plasma: for example, blood treated for 15 seconds completely coagulates in 2 minutes while untreated sample coagulates in 13 minutes.
- Performed blood coagulation tests on cadaver organs with subsequent gross and microscopic evaluation of tissue to test for damage. Our analysis demonstrates blood clotting within 15 seconds without gross or microscopic evidence of tissue damage (Fig. 10,11).
- Performed skin sterilization tests on cadaver skin with subsequent microbiologic culture. The results demonstrate complete sterilization of skin flora after 6 seconds of treatment by the plasma.
- Examined skin histology to find existence and/or extent of microscopic damage. No tissue damage was found after as much as 5 minutes of plasma treatment (Fig. 11).

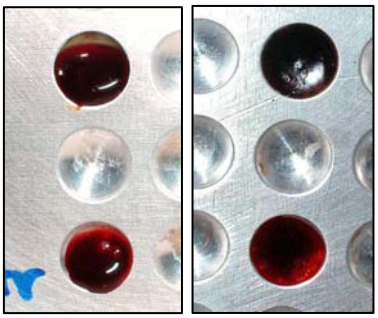

Fig. 9. Plasma-assisted blood coagulation with 15-second treatment (left) and 1-minute treatment (right); control drop on the bottom, treated drop on top.

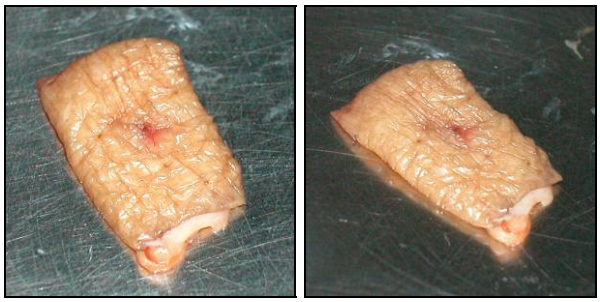

Fig. 10. 1-minute plasma treatment shows no visible tissue damage. Left: before treatment; right: after treatment.

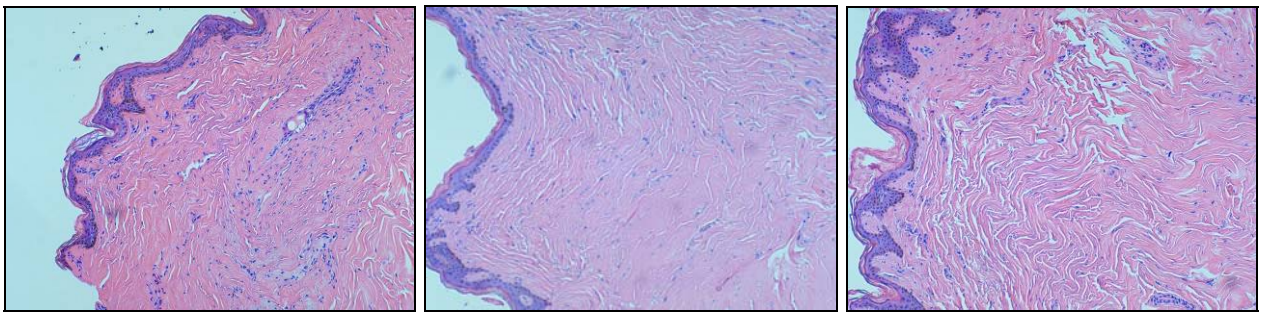

Fig. 11. Skin histology (left to right): control, 1 minute, and 5 minute treatment times show no detectable tissue damage.

5. Conclusion

This device can find many applications in the medical field, ranging from replacing high-power, high-temperature thermal plasma coagulators in the operating rooms to personal portable wound sterilizing and healing instruments. The scope of the presented research included only initial studies of plasma influence on blood coagulation and simultaneous tissue sterilization. However, these studies are essential in providing us with knowledge and expertise on the underlying processes.

At the present, we are actively working on developing a kinetic model of DBD plasma influence on Blood plasma coagulation cascade as well as DBD plasma role in the tissue sterilization process. We have interesting modeling results (that agree with experimental evidence) involving DBD plasma influence on Calcium ion

concentration and in turn on blood coagulation cascade. These results will be presented at the ISPC-17 conference.

Abstract

A 2.45GHz microwave excited microplasma at atmospheric air was produced using a SMMAP (stripline microwave micro atmospheric plasma) device based on microstrip technology. Plasmas were the self-ignition at a power of about 5W and were sustained at even under 1W. The rotational temperature of nitrogen molecules measured using optical emission spectroscopy (OES) was 480K with no flow of gas. A SMMAP device has been applied to polymer surface modification.

Keywords

microplasma, non-equilibrium plasma, atmospheric plasma, microwave excited plasma, wettability

1. Introduction

Atmospheric pressure microplasmas have offered many possibilities for the generation of new applications such as bio-MEM's sterilization, small-scale materials processing, propulsion of micro- and nanosatellites, and micro-chemical-analysis systems [1,2]. In addition, microplasmas can provide a large-scale non-equilibrium plasma the materials processing at atmospheric pressure using the array configuration. Recently, various microplasma sources have been developed including microwave excited microplasmas at atmospheric pressures based on microstrip technology [3-7]. Microwave excited microplasmas based on mictrostrip technology are with a long lifetime, stability, robustness, and simplicity, compared to other microplasma systems. Microstrip technology and a small semiconductor microwave source make it possible to achieve the low-power operation and the portability of the microplasma system. However, in these plasmas, He or Ar gases were used for the sustainment of stable plasmas at atmospheric pressure. Also, it is difficult to enlarge the plasma scale using the array configuration due to the configurations of their plasma systems used in these works.

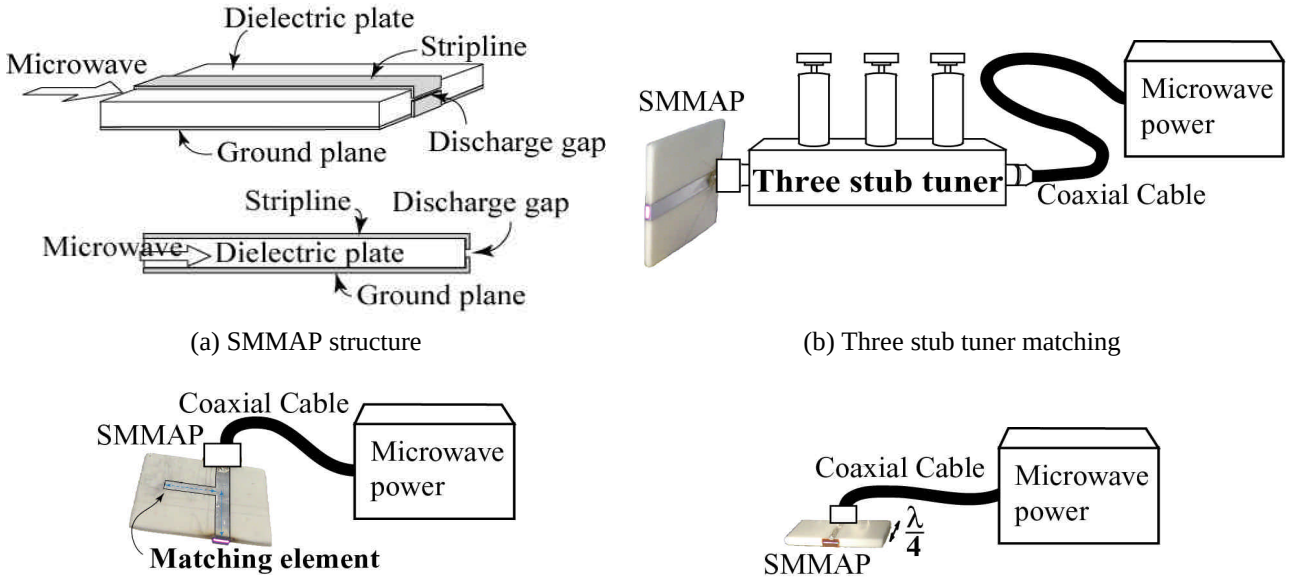
While, in previous our work [8, 9], a SMMAP (stripline microwave micro atmospheric plasma) device was reported. Microplasmas at atmospheric air using the SMMAP device were ignited at over microwave power of 15W and were sustained at a microwave power of about 1W. The experimentally measured gas temperature using OES was about 800K. The SMMAP device permits the array configuration for enlarging of the plasma scale.

In this work, the SMMAP system has been improved to reduce the operation microwave power and to provide the plasmas with a lower gas temperature. The SMMAP has been applied to the modification of material surface such as a polymer for wettability, adhesion, bonding, and printability. In this paper, we report the results experimentally obtained recently.

2. Experimental setups

The SMMAP device consists of a dielectric plate, a stripline, a ground plane, and a discharge gap. The discharge gap is placed on a transverse cross-section of the dielectric plate between the stripline and the ground plane, which play the role of electrodes for generating plasmas. Figure 1 (a) shows the structure of the SMMAP device.

2.45GHz microwave power is introduced to the SMMAP device through a coaxial cable and a SMA connector and propagates along the inside of the dielectric plate between the stripline and the ground plane approximately in TEM mode. Electric fields are strongly concentrated at the discharge gap with smaller width than the thickness of dielectric plate. Electric fields are going from the stripline electrode to the ground electrode, resulting in the low radiation of electric fields to external space. Electric fields at the discharge gap become stronger by increasing the characteristic impedance of the transmission line. For the impedance matching, a three stub tuner, a stub matching, or a quarter-wavelength transformer have been used as shown in figure 1 (b), (c), and (d).



(a) SMMAP structure

(b) Three stub tuner matching

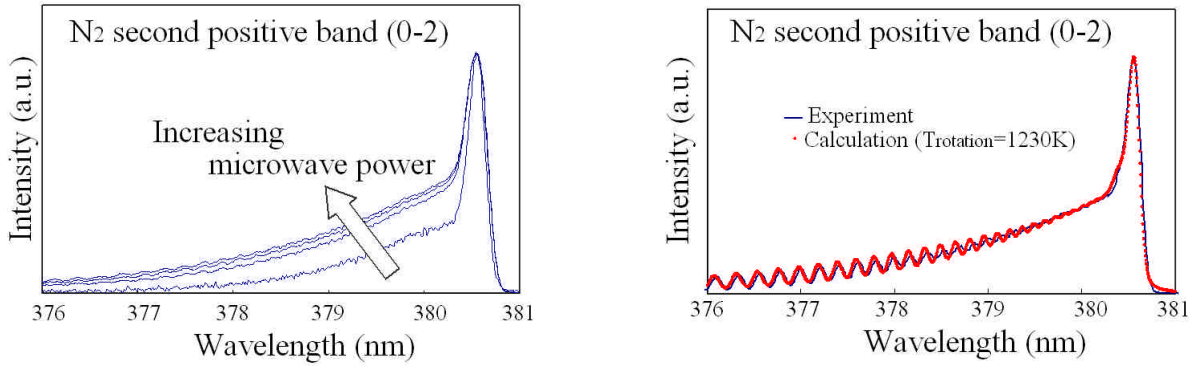
(c) Stub matching

(d) Quarter-wavelength transformer matching

Figure 1. SMMAP system.

Rotational temperatures of nitrogen molecules were measured to investigate gas temperatures in air plasmas by means of optical emission spectroscopy (OES). Rotational temperatures were obtained by fitting the experimentally observed spectrum of the second positive system with the numerically calculated one [10,11]. In this work, to obtain rotational temperatures in air plasmas, the second positive system of the nitrogen molecule was used. Rotational temperatures were investigated for the change in microwave powers at atmospheric pressure and the change in gas pressures at fixed microwave powers. Figure 2 (a) shows an experimentally observed spectrum. Figure 2 (b) shows a numerical fit and an experimentally observed spectrum.

A SMMAP device used in this work was modified from the previous structure [8,9]. The width of the stripline (1mm) was made smaller than that (5mm) in the previous structure, which provides stronger electric intensities at the discharge gap because a small width of a stripline increases the characteristic impedance.



(a) (b)

Figure 2. (a) Experimentally observed spectrum and (b) a typical numerical fit and an experimentally observed spectrum.

3. Results

In this work, filamentary-like discharges were observed. Figure 3 shows the observed filamentary-like discharges. Filament-like discharges were observed with uniform plasmas simultaneous or were observed alone. The positions where the filament-like discharges happened were varied with times. These filamentary-like discharges cause some problems of the non-uniformity and the instability of plasmas. The sputtering of electrodes by the filament-like discharges was observed with naked eyes.

In order to avoid these problems, a dielectric plate was installed between two electrodes as shown in figure 4 (a). Uniform plasmas with no filamentary-like discharges were successfully produced at atmospheric pressure as shown in figure 4 (b). The plasmas was ignited at a microwave power of about 5W and was stably sustained under a microwave power of 1W.

Figure 4. (a) SMMAP device with the dielectric plate between two electrodes and (b) a picture of the uniform plasma.

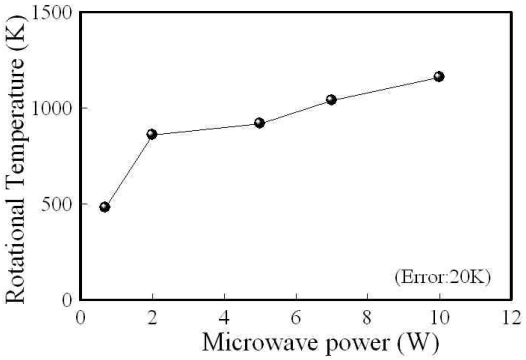

Figure 5. Rotational temperatures for the variation in microwave powers.

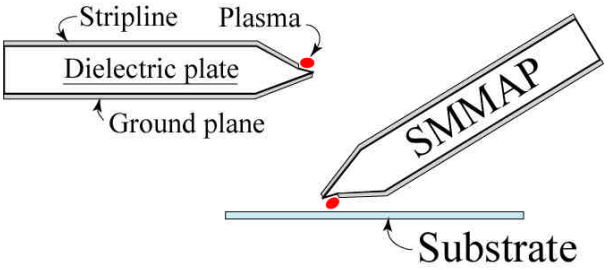

Figure 6. A modified SMMAP device by considering the processing of a substrate.

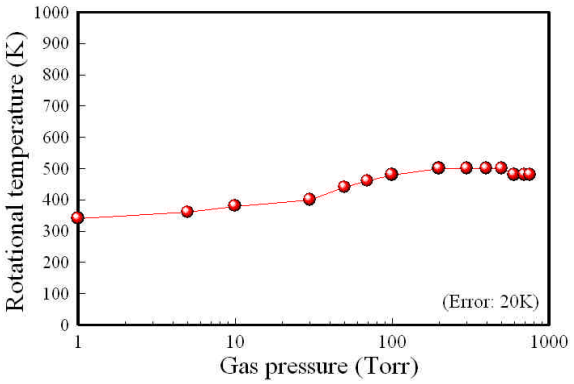

Figure 7. Rotational temperatures for the variation in gas pressure.

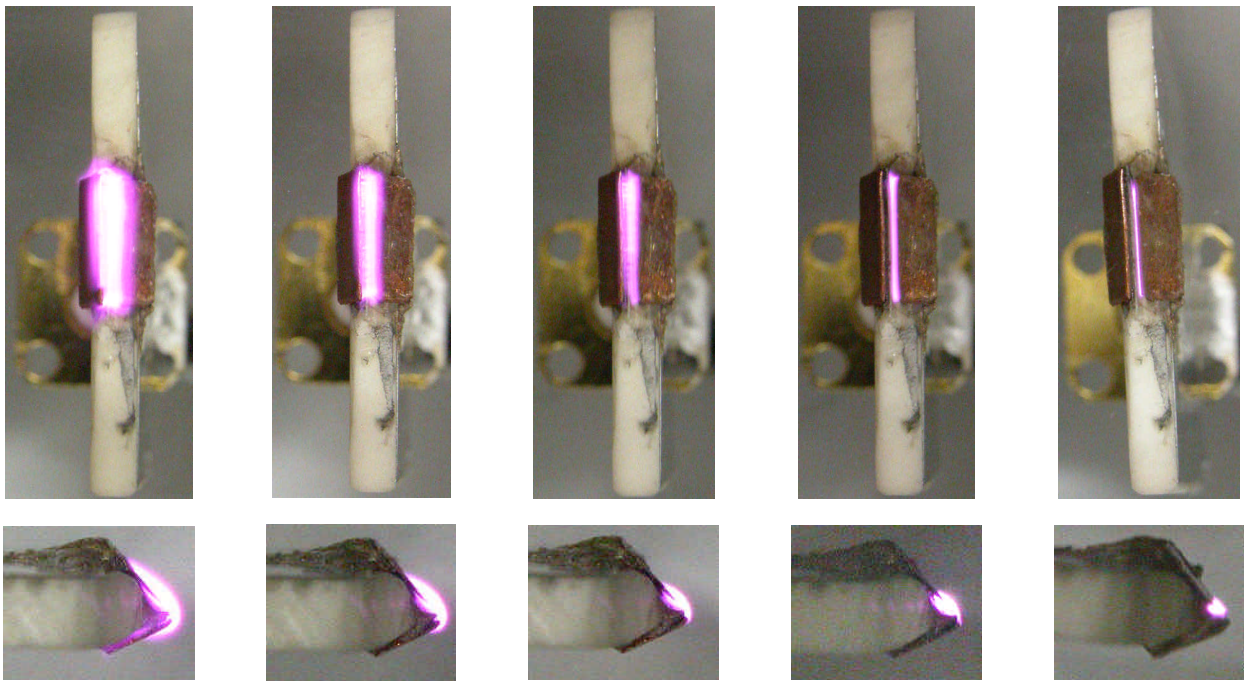

Figure 8. Pictures of plasma optical emission for the variation in gas pressure.

Figure 5 shows the changes in rotational temperatures of nitrogen molecules in air plasmas at atmospheric pressure as the changes in microwave powers. The rotational temperature of 1230K at microwave powers of 10W was reduced with the decrease of microwave powers. Under the microwave power of 1W, the temperature was 480K.

The SMMAP device shown in figure 4 was modified by considering the processing of a substrate as shown in figure 6. The modified SMMAP device was used to investigate the gas pressure dependence of plasma. Figure 7 shows the change of the rotational temperatures as the change of gas pressures from 760Torr to 1Torr. The microwave power was fixed at under 1W. As decreasing the gas pressure, the rotational temperature was decreased from 480K to 340K. Figure 8 shows the pictures of plasma optical emissions as changing gas pressures. The plasma region was diffused as the decrease in the gas pressure.

Moreover, a SMMAP device has been used for the of the polymer surface modification of wettability at the gas pressures of 10Torr to 760Torr. Figure 9 shows a typical photograph of water drops on a treated surface of a polymer film with air plasma treatment and on that without surface plasma treatment. It was found clearly that the surface wettability of a polymer film was improved by the treatment of air plasmas.

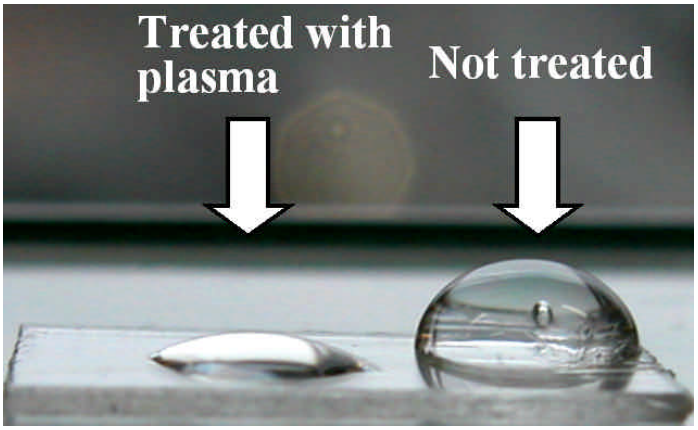

Figure 9. Water drops on a treated surface of a polymer film with plasmas and on a not treated surface.

4. Summary

A 2.45GHz microwave excited microplasma at atmospheric air was produced based on microstrip technology. Plasmas were the self-ignition at an input power of about 5W and were sustained at even under 1W. The rotational temperature of nitrogen molecules measured by using OES was 480K with no flow of gas. The wettability of a polymer film was improved by the treatment of air plasmas.

The optimization of the system is in progress for the ignition and the sustainment of plasmas with the lower microwave powers. The SMMAP device will provide a large-scale atmospheric non-equilibrium plasma using the array configuration and a potable plasma source.

Abstract

Cathode spots of a low-pressure arc can remove oxide layers and evaporate impurities on metal surfaces. Removal of the oxide layer using cathode spots is expected to solve recent obstacles to chemical and mechanical cleaning methods. Various phenomena of cathode spots have been investigated for pre-treatment of atmospheric pressure plasma spray (APPS). This study treated the surface shapes of oxide and non-oxide samples using a composite pre-treating method: cathode spots after grit blasting. In addition, the samples are compared with conventionally treated cathode spots and mechanical blasted surfaces. Results show that the roughness on the sample surfaces is higher concomitant with the initial oxide layer thickness. This fact reveals the factors that dominate bonding strength on the pre-treated surface using cathode spots of a low-pressure arc. Bonding strength is higher in relation to the arithmetical mean height of the surface roughness caused by the initial oxide layer thickness. Bonding strength is also higher when the mean spacing of profile irregularities is narrow. The bonding adhesive strength after treatment using cathode spots after the grit blasting is greater than 90 MPa, assuming over 100MPa.

Keywords : Low pressure arc, Plasma spray, Cathode spots, Oxide layer, Grit blasting, Pre-treatment

1. Introduction

Oxide layers accrete stably on steel material surfaces during manufacturing. Low-pressure arc cathode spots can remove oxide layers from metallic surfaces [1,2]. After removal of oxide layers, the surface is rough. For that reason, pre-treatment by thermal spray coating has been examined [3]. Grit blasting and chemical decontamination are widely used as pre-treatments, but these are environmentally unsound methods because they scatter sludge, create noise, and generate liquid waste. Application of a low-pressure arc creates neither noise nor sludge because pre-treatment is conducted in an enclosed space. Cathode spots are characterized [1,4] by: (1) numerous arc spots, (2) vapor emission of a cathode material because of the extremely intense arc power, (3) rapid movement of the spots on the cathode surface in a random manner [1,5], and (4) preferential formation on the oxides [1,6]. The oxides under the cathode spots are vaporized and removed instantaneously. Only a few reports have addressed the cleaning action of the cathode spots in the process of low-pressure plasma spray (LPPS)[3]. Removal characteristics of the oxide layer on stainless steel were reported recently [1]. In the present study, surface shapes of oxide and non-oxide samples of SS400 carbon steel were treated using cathode spots of a low-pressure arc with or without grit blasting. This study also compares the resultant surfaces with those of conventional and mechanically blasted surfaces [8].

2. EXPERIMENTAL ARRANGEMENT

2.1 Experimental set-up for removal of oxide layer by cathode spots

The experimental set-up comprises a vacuum chamber with electrodes inside, a water-cooled copper electrode as an anode, a DC power supply (open circuit voltage is 200 V) for the arc, and an evacuation system with a rotary pump, as shown in Fig. 1. The surface of the SS400 carbon steel sample has an oxide layer. It is connected with a negative pole of the power supply and serves as a cathode. The anode and cathode (steel) surfaces are maintained at 20 mm separation. The chamber with the specimen was evacuated to 30 Pa. Argon gas was introduced into the chamber to 0.1 MPa; it was evacuated again to 30 Pa. This operation was repeated. Adjusting the needle valve of the gas inlet controlled the chamber pressure. At this time, the pressure was adjusted to 100 Pa. A transferred-arc was ignited using an RF igniter. Then the arc-current was adjusted to 30 A in the constant current mode. Arc time was controlled by a timer at 0.1 s. For

measurement of the instantaneous removal rate, a sample was removed from and put back inside the chamber after each short arc duration. Areas of removed oxides are recognizable by their silver-metallic luster because the carbon steel oxide is black. The removal area was measured using a digital image scanner before, during, and after the removal process.

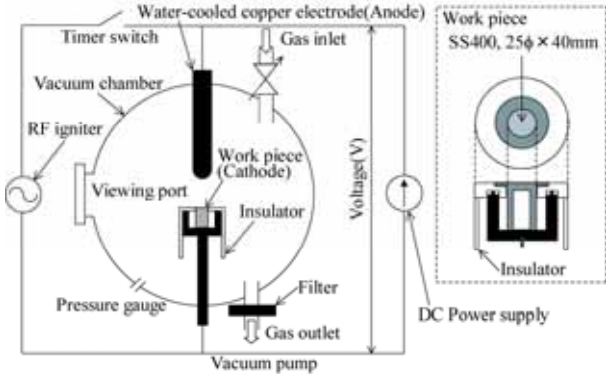

Fig. 1. Schematic illustration of experimental set-up

2.2 Oxide-layer covered samples

The chemical components of SS400 carbon steels were used as samples. Sample dimensions are 25 ϕ diameter and 40 mm height. The relationship of oxide thickness D_o with heating temperature T_h and component ratio of oxide layer on SS400 carbon steel are shown in below. First, the upper surface was polished using a buffing wheel; then ultrasonic cleaning with acetone was performed for several minutes. Finally, they were heated in an electrical furnace with heating temperatures T_h at 773, 873 and 973 K for 1 h. Thickness of oxides D_o was analyzed by glow discharge spectroscopy (GDS); its half value of the oxygen peak was adopted. The sample surfaces were covered uniformly with a black oxide. Oxide thickness was greater in geometric proportion to increased T_h. Furthermore the component ratio differed for each condition: main components were Fe_3O_4 or FeO for all temperatures.

The distribution of Fe and O elements in the depth direction along with a comparison of a sample and a real mill scale is measured by GDS. The oxide layer formed multi-layered iron oxides; it was Fe_2O_3, Fe_3O_4, FeO, in order from the surface on SS400 carbon steel. A real mill scale measurement of SS400 manufactured by hot rolling was carried out. Multi-layer components are similar.

3. ADHESIVE CHARACTERISTICS AND THE SURFACE FORM OF PLASMA SPRAY

3.1 Adhesive Strength for R_a Resulting From Surface Treatment

Figure 2 shows the adhesive strength for the average roughness, R_a, that is attributable to surface treatment using cathode spots and grit blasting. The current is 20 A, the distance between electrodes is 20 mm, and the oxide layer thickness is 6.7 μm. Arc times used here were 13–60 s. The R_a does not depend on the arc time. The surface temperature increases concomitant with the arc time. Consequently, the R_a changes only slightly. Furthermore, when the surface temperature becomes ca. 500 K [7], the cathode spot motion slows and the arc becomes constrictive. Adhesion between the sprayed film and the basic element increases with R_a for both treatments because of the anchor effect. Adhesion strength measurements have a margin of error for treatment with cathode spots from a low-pressure arc, but the values of R_a are almost equal. A margin of error also occurs in adhesive tests. The R_a that is obtained by treatment with grit blasting is sometimes greater than that by treatment with cathode spots. Therefore, the adhesive strength obtained through grit blasting is sometimes greater than that achieved using the low-pressure arc. Treatment of cathode spots after grit blasting is also shown in Fig. 2. The arc current is 20 A and arc times are 1–5 s. Adhesive strength is greater than 90 MPa because cement adhesion is dislodged by the combination of the cement and plasma spray. This is a limited combination. Therefore, this value should be greater than 90 MPa in most circumstances. The adhesive strength in the case of a composite of cathode spots after grit blasting is more than double that of conventional treatments by cathode spots or grit blasting.

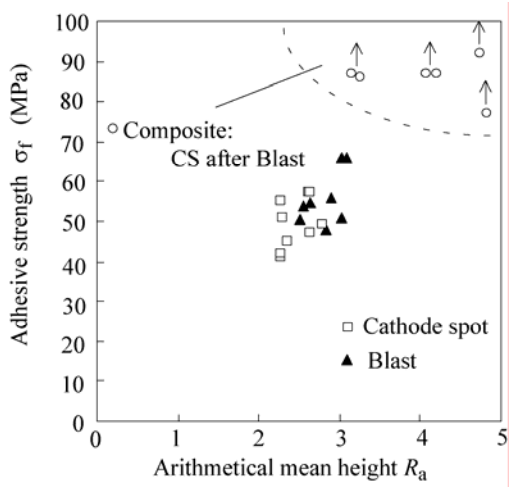

Fig. 2 Adhesion due to R_a attributing to surface treatment with cathode spots and grit blasting, and a composite.

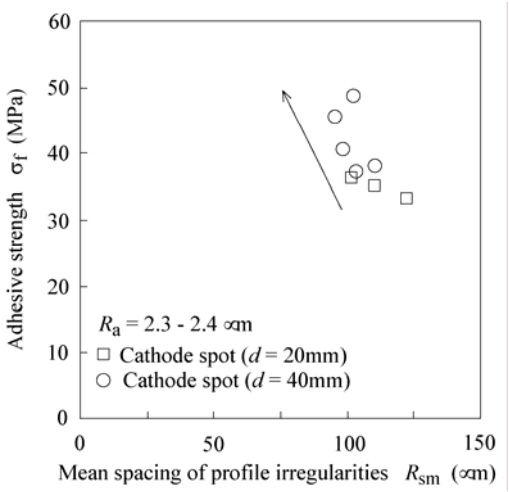

Fig. 3 Effect of R_{sm} on adhesive strength.

3.2 Effect of Adhesive Strength for R_{sm} in the case of equal R_a with Cathode Spots

Figure 2 shows that R_a has dispersion at 2.2–2.8 μm in the case of cathode spot treatment. Figure 3 shows the mean spacing of profile irregularities, R_{sm}, of the uneven surface. Figure 3 also shows effects of R_{sm} for adhesive strength σ for R_a of 2.3–2.4 μm. For equal R_a, the adhesive strength is greater when R_{sm} is smaller. In this example, when R_{sm} becomes less by 25 μm, increase of the adhesive strength is ca. 9.2 MPa. The adhesive strength is determined correctly here because of R_{sm} in the case of equal R_a. This relationship is influenced slightly by sample oxide thickness d. For lower d, σ_f is higher. Plasma spray particles are sprayed on the uneven areas, but also on the concave side. Thereby, a high adhesive strength is obtained for cases with large R_a and small R_{sm}. The maximum height of R_a and R_z changes greatly with R_{sm}, but the mean values of R_z are nearly equal: there is little dispersion of the mean R_z because of the constant standard deviation.

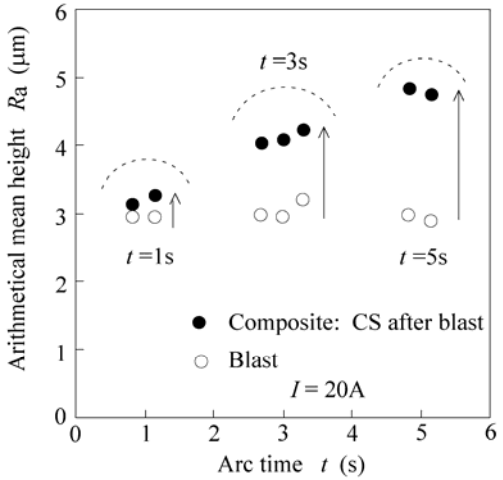

Fig. 4 R_a with composite treatment.

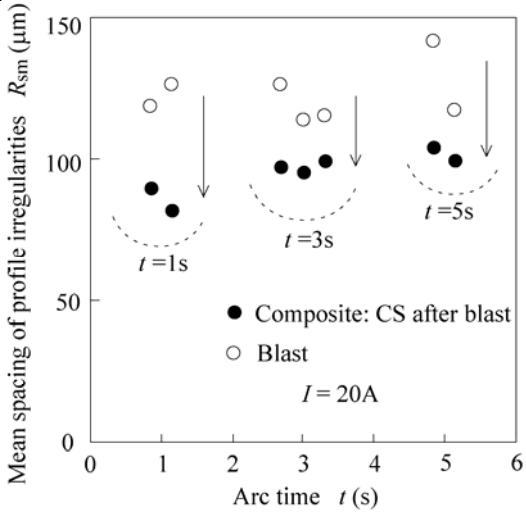

Fig. 5. R_{sm} with composite treatment.

Figure 4 and 5 shows the side and R_{sm} with cathode spots of low pressure arc after the grit blasting treatment. Although the mean R_a becomes around 3μm and the R_{sm} becomes around *120* μm with only the grit blasting treatment, the R_a increases with the arc time up to around 5 μm at 5s. The mean R_{sm} decreases to around 100 μm by 20% while the R_{sm} does not concern with arc time. Therefore the higher adhesive strength can be obtained with cathode spots of low pressure arc treatment after the blast to because the R_a increases and the R_{sm} decreases. The R_a and R_{sm} trend in change is the same in order to obtain the higher adhesive strength as shown in Fig.3.

4. SUMMARY

Surfaces samples with and without oxides were treated using cathode spots of a low-pressure arc after grit blasting. This study compared those surfaces with conventionally treated cathode spots and mechanical blasted surfaces. The main results are shown below.

(1) The roughness on the sample surfaces becomes greater for thicker oxide layers. The surface height has a maximum value at the final removal of the oxide layer. Bonding or adhesive strength of the sprayed surface is greatest in such a condition.

(2) Some factors dominate bonding strength on the surface pre-treated using the cathode spots of the low-pressure arc.

(3) Bonding strength increases with the mean value of surface roughness in a positive correlation to the initial oxide layer thickness.

(4) Bonding strength is greater when the mean spacing of profile irregularities becomes narrow when the arithmetical mean height of the surface pre-treated using the cathode spots is the same.

(5) The bonding adhesive strength of a sample treated by cathode spots after grit blasting is greater than 90 MPa, assuming over 100MPa, which is more than double that of previous treatments such as either cathode spot treatment or grit blasting.

Abstract

In this investigation, carbon black filled high density polyethylene (HDPE) samples (2%) having a melt flow index of 0.77 g/10min used for the transportation of natural gas were exposed to plasma in humid air for different exposure times. Decohesion stress of the assembled samples as measured according to NFT 54-034 standard was shown to improve as a function of exposure time. Mechanically etched samples showed a higher decohesion stress for small exposure times to plasma. Epoxy assembled polyethylene pipes showed that the burst pressure increased from 14 bar for untreated assembled material to 33 bar for the 90 sec treated sample. Thermal stability study of plasma treated samples showed that oxidation induction time diminishes from 38 min for untreated samples to 17 min for 150 sec treated samples.

Keywords: Non thermal plasma, humid air, HDEP

I) Introduction

The application of non-thermal atmospheric plasma of glidarc type to polymeric surfaces modifies their physicochemical properties through cross-linking and formation of functional groups, which could have interesting adherence as well as selective permeability applications where a barrier effect to diffusion phenomena may take place. Reactive species mainly produced by electron-molecule collisions in such non-thermal equilibrium plasma were identified by emission spectroscopy technique, and predominantly correspond to OH° neutral radicals [1]. The presence of NO radicals is observed but in less quantity which confers to such humid air plasma interesting oxidising properties due to the overwhelming OH° highly reactive species created.
Several processes resort to plasma techniques that are now used for solutions processing in environmental applications and surface treatment for barrier diffusion creation and corrosion prevention. Previous investigation concerned humid air plasma-surface interaction where pure iron [2] and 304L and 316L stainless steel samples [3] were exposed at different treatment time and flow rate. Electrochemical and X-rays analysis reveal the presence of iron hydroxide $Fe(OH)_3$ at different proportions where it is more abundant on pure iron than on stainless steel surfaces. The presence of other chemical elements (Cr, Si, Mg, and others) seems to influence the interaction of the reactive species-iron atoms on the surface.
Polyethylene constitutes presently a large group of products exhibiting various characteristics. It has a very good chemical stability at a processing temperature lower than 60 °C and is not attacked by non-oxidant acids. The setting up of gas distribution networks requires the application of rigorous techniques, especially on pipe assembling such as electrofusion welding.

II) Materials and methods

II. a) Samples preparation and characteristics

In order to study the impact of plasma in humid air on the adhesive properties of carbon black filled high density polyethylene samples (2%) having a melt flow index of 0.77 g/10min used for the transportation of natural gas, samples from this plastic were cut out according to NFT 54-034 standard and exposed to plasma

in humid air for different exposure times. Figure 1 shows the samples used for plasma exposure. Some of the samples were pre-etched mechanically. The saturated humid air flow rate entering the high voltage set-up was 700 cm^3/min through two diverging aluminium electrodes 2 mm apart. The target samples were placed at a distance of 15 mm from the electrodes end.

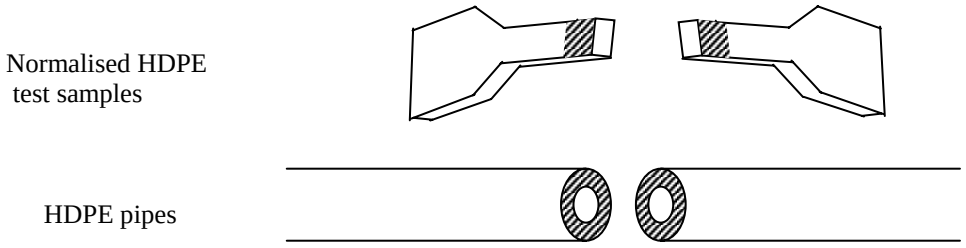

Fig. 1: HDPE samples exposed to plasma in humid air on the hatched area.

The commercial high density polyethylene was first characterised through the determination of carbon black content, melt flow index, tensile stress and Young's modulus (according to NFT 51-140, NFT 51-016, NFT 54-034 standards, respectively). Table 1 gives the experimental results obtained:

Table 1: Some HDPE characteristics.

Carbon black content (%)	Melt flow index (g/ 10 min)	Tensile stress (Mpa)	Young's modulus (Mpa)
2.05	0.77	18.46	125.20

According to these testing standard procedures, the values obtained for the HDPE samples are consistent with mean values.

II. b) Experimental methods

- **Decohesion tests:** The normalised samples were exposed to plasma in humid air as shown in Figure 2 for varying times ranging from zero to 100 seconds. They were subsequently assembled on the 15 mm^2 treated area with epoxy resin and let to settle down for 24 hours. Decohesion tests were performed using a Oroell Zwick machine according to NFT 54-034 standard.

- **Burst tests:**

Burst tests according to ISO 1167 standard were also performed at 20°C on plasma treated HDPE pipes (20 cm diameter) and assembled with the same epoxy resin.

- **Oxidation induction time**

Thermal stability tests were carried out on raw HDPE samples exposed to plasma, by differential scanning calorimetry according to NFT 58 – 003 standards.

III) Results and discussion

It can be noticed from Figure 2 that the decohesion stress improved as a function of exposure time passing from 3.02 MPa for untreated samples to 12.04 MPa for a plasma treatment time of 100 sec. In order to further assess the activating effect of such a plasma, similarly assembled samples were mechanically etched before plasma exposure and

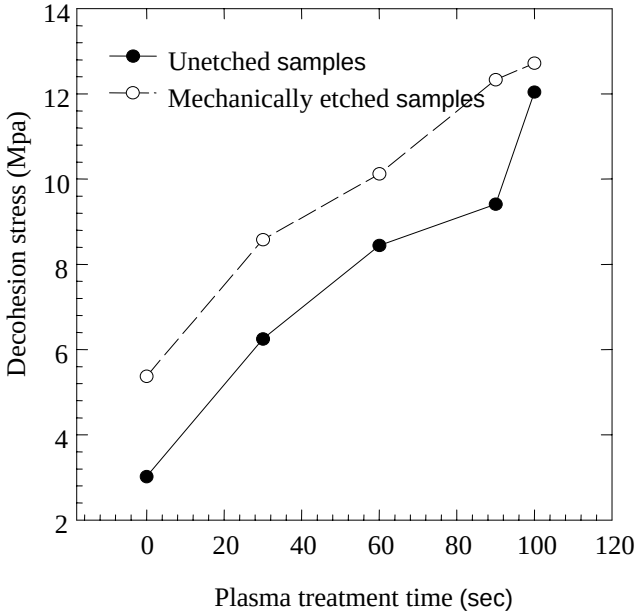

Fig. 2: Decohesion stress versus exposure time to plasma in humid air.

the results are also depicted in Figure 2. This mechanical treatment resulted in a higher decohesion stress for small plasma exposure times (5.01 MPa) but for 100 sec treatment time almost the same values were attained (12.4 MPa), highlighting the etching and activating effects of the plasma.

Burst tests (according to ISO 1167 standard) performed at 20°C on epoxy assembled polyethylene pipes 20 cm in diameter showed that the burst pressure increased from 14 bar for untreated assembled material to 33 bar for the 90 sec treated sample. For the pre-etched samples theses values varied from 15.33 to 37.50 bar as depicted in Figure 3. The burst pressure difference between unetched and pre-etched samples decreases versus plasma exposure times proving the activating efficiency of the plasma.

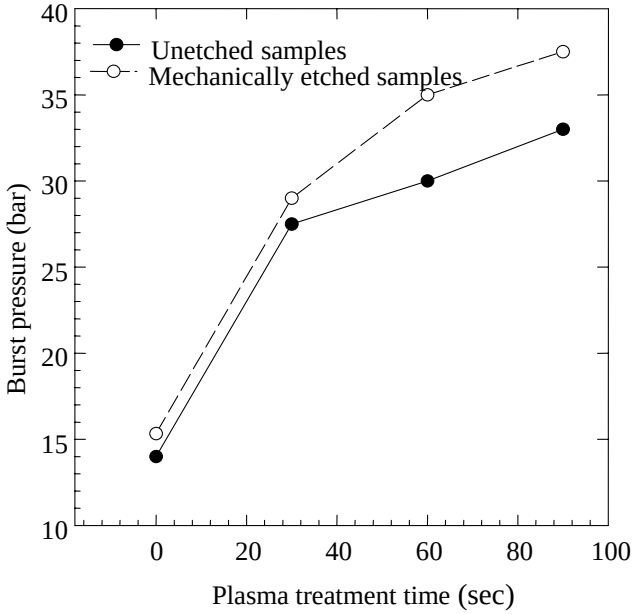

Fig. 3: Burst pressure versus exposure time to plasma in humid air.

On the other hand, thermal stability study (according to NFT 58-003 standard) using differential scanning calorimetry of plasma treated samples weighing 15 mg was performed under nitrogen flow rate of 50 cm^3/min at a heating rate of 20°C/min until a final temperature of 210°C was attained. After five minutes under nitrogen gas, thermograms were recorded under oxygen flowing at a rate of 60 cm^3/min until the exothermic peak attained its maximum. The results are presented in Table 2.

Table 2: Influence of plasma in humid air on the thermal stability of HDPE samples.

Plasma treatment time (sec)	0.00	90.00	120.00	150.00
Oxidation induction time (min)	38.00	24.00	19.00	17.00

It can be observed that oxidation induction time diminishes from 38 min for untreated samples to 17 min for 150 sec treated samples. The interaction of humid air plasma may create active radicals sites, chain scission resulting in new functional groups such as carbonyls and reaction of volatile products in the plasma. These results combined with earlier cited works confirm the interesting activating power of the plasma produced in these conditions, which can be profitably applied to activating polymers at an industrial scale. Their introduction to industrial scale is currently being developed as the production cost is constantly diminishing.

IV) Conclusion

The interaction of humid air plasma may create active radicals sites, chain scission resulting in new functional groups such as carbonyls and reaction of volatile products in the surface. In the case of polyethylene, the oxidised surface resulted in increased adhesive forces as shown through decohesion stress and burst pressure values. The oxidising power of such humid air plasma is also revealed through the oxidation induction time.

This work confirms the interesting activating power of the plasma produced in humid air and demonstrates the high oxidising ability of this kind of plasma, which can be profitably applied to activate polymers at an industrial scale.

chifen@mpip-mainz.mpg.de

Abstract
Deposition of gradient metal-oxide-like films with low carbon contents from HMDSO, TTIP and O_2 was carried out in a 13,56 MHz r.f. plasma. The aim was to structure the films to have specific chemical, optical and electrical properties. The chemistry and thermal stability of the films were investigated using FTIR and XPS. The surface roughness was examined using AFM. An interpretation of their electrical properties using EIS is presented.

Keywords: SiO_2, TiO_2, gradient metal-oxide films, electrical and optical properties

INTRODUCTION

Nano-structured gradient metal-oxide materials have new and often enhanced properties as compared to conventional TiO_2 and SiO_2. The properties of the tailored materials are related to their possible applications, e.g. leaf like structures in solar cell application [1], porous structures, consisting of nanoparticles used as gas sensors [2] and photocatalysts [3, 4].
Vacuum techniques such as co-sputtering, metalorganic chemical vapor deposition and plasma enhanced chemical vapor deposition (PECVD) have been used to fabricate gradient materials [5, 6, 7]. Titanium (IV) isopropoxide; $Ti(OC_3H_7)_4$, [TIPP] in combination with Ar, O_2 or N_2 as a carrier gas has previously been used as a precursor for the deposition of TiO_2 films in CVD processes and has high a refractive index *n* ($2 < n < 2.6$) [8].
Pure stoichiometric titanium dioxide (TiO_2) has numerous desirable properties e.g. low resistivity, high conductivity and refractive index, which can be correlated to the oxidation state of Ti and its crystal structure [9, 10]. SiO_2 films from HMDSO/O_2 have proven to be effective primer coatings for adhesion [11] and have a lower refractive index than TiO_2 ($1.4 < n < 1.6$).
Structuring the properties of thin gradient material would be of great importance in sectors such as adhesion, optical, microelectronic devices, biomaterials, protective coatings and thin film technology [12, 13].
In order to understand the interaction between the films, firstly, we study the depositions of each precursor, secondly the effect of the relative precursor ratio on the chemical composition, optical and electrical properties. Characterisation was done by Ellipsometry, Electrochemical Impedance Spectroscopy (EIS), X-ray Photoelectron Spectroscopy (XPS), Fourier transformed infrared (FT-IR) spectroscopy and Atomic Force Microscopy (AFM). The reasons for the thin gradient film structures are explained qualitatively.

EXPERIMENTAL

The precursors, TTIP and HMDSO were purchased from ACROS Organics (99,99 %). TTIP has been used for previous TiO_2 film deposition and it is less harmful in contrast to halides gases [4]. Simultaneous stirring and heating at 70 °C of TTIP outside the reactor assisted in the conveyance of the vapour into the reactor. The TTIP partial pressure was controlled by a needle valve (LV10K, EDWARDS) and a floating ball flow meter [Kobold Messring] was used to control the inlet concentration of HMDSO.
We therefore aimed at fabricating thin gradient films with definite refractive indices by varying the partial pressure of both monomers at constant input power (Ppeak). The reactor geometry is the same as earlier described [14], equipped with a temperature sensor [PT 100] built at the outlet. Depending on the characterisation technique, the films were deposited on evaporated gold

(BK7 glass) or Si-wafers. Figure 1 shows a schematic of the process step. The deposition of gradient films is divided into four steps; **1**) plasma pre-treatment process was used to clean and activate the substrate (30 sec. Ar:O_2 (10:1) and 40 W pPeak), **2**) TiO_2 like films were plasma polymerised (TTIP, 220 W, 300 sec, 0.07 mbar), **3)** SiO_2 like films were plasma polymerised (HMDSO:O_2 (1:10), 100 W, 10 sec, 0.02 mbar) to obtain an adherence layer for the gradient layers, **4**) co-deposition of HMDSO/O_2:TTIP: adding TTIP into the reactor, thus raising the total process pressure (0.07mbar, 220 W, ~ 260 °C). The partial pressure of the precursors in the reactor was varied between 0.025 and 0.07 mbar from step 3 to 4. Films between 25 and 70 nm thick, were deposited by varying the vapour flow of HMDSO and TTIP, while their total flow and other deposition parameters were kept constant.

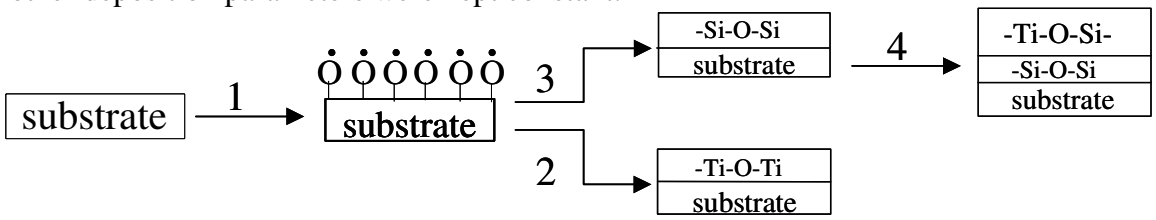

Figure 1: activation and deposition procedure of gradient films

Refractive index *n,* and thickness *d,* of the films were determined from the Ellipsometer ($\lambda = 450$, 630 nm) (Nanofilm Surface Analysis EP^3). The surface profiler (Tencor®) was used to approximate the thickness. To quantify our results, the thickness and refractive index determined were fitted using the surface analysis software based on the Cauchy model [15].

Chemical structure of the samples was analysed by X-ray photoelectron spectroscopy (XPS) using a ESCA 5600 (Physical Electronics GmbH) with a monochromated Mg Kα X radiation at 1253,6 eV beam operated at 300 W in a residual vacuum of $>5\times10^{-8}$ Pa with the analyzer in fixed transmission mode. Additional information was obtained by FTIR using a Nicolet Magna-IR spectrometer. The electrochemical impedance measurements were made in 0.1 M NaCl solution. The electrical properties of both the annealed and non-annealed deposited films were measured using Autolab PGSTAT 30 equipped with a Frequency Response Analyser (FRA) controlled by a PC with FRA software package (ecochemie). A Dimension 3100 Atomic Force Microscope was used to analyse the topology of the deposited annealed and non-annealed Ti-O-Si films. Contact angles for water (2µl/min) was measured using a Drop Shape Analyser (DSA 10-MK2, KRÜSS).

Results and Discussion

The results of refractive indices *n*, and thickness *d*, measured by ellipsometry are shown in Figure 2 and Figure 3 respectively. The film thickness was seen to increase with Ppeak (input power) for all pp films. The deposition rate of the Ti-O-Si (0.08nm/sec) film is lower than Si-O (0.5 nm/sec) film, which indicates that the mixture vapour requires longer interaction time (not shown here). The refractive indices of the Si-O and Ti-O film showed an increase with Ppeak in Figure 3. The isotropic arrangement of the molecules and structure is more decisive for the index of refraction rather than the thickness. This measurement was carried out at three different spots, which showed averaged error values less than 5% for both Si-O-Si and Si-O-Ti.

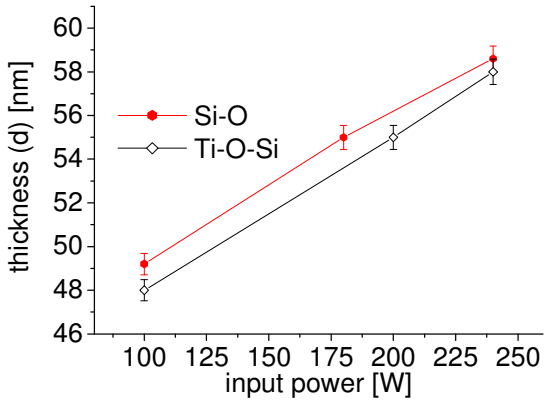

Figure 2: effect of power on the film thickness for Si-O-Si and Ti-O-Si thin films

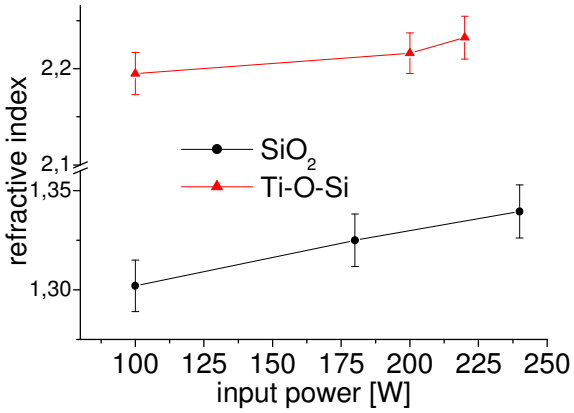

Figure 3: effect of refractive index of pp Si-O-Si and Si-O-Ti thin films

The chemical structures of the Si-O, Si-O-Ti films were analysed using detailed analysis of XPS and FTIR. Figures 4 and 5 show the data from XPS spectra of these films. Figure 4 shows that the concentration of Si atoms is increasing with plasma Ppeak. The oxygen atom ratio increases with Ppeak because the oxygen plasma promotes the loss of carbon, therefore creating more Si-O bonds. This increase in the oxygen ratio leads to the formation of cross-linked siloxane network. The ratios of Si:C and Si:O attained 6:1 and 1:2 respectively.

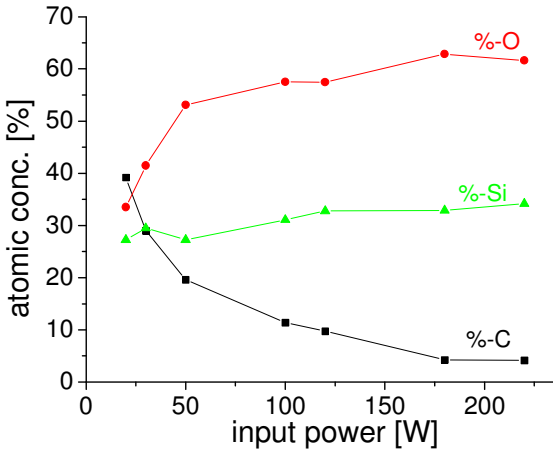

Figure 4: the effect of pPeak on atomic concentration for pp Si-O-Si film (50 nm)

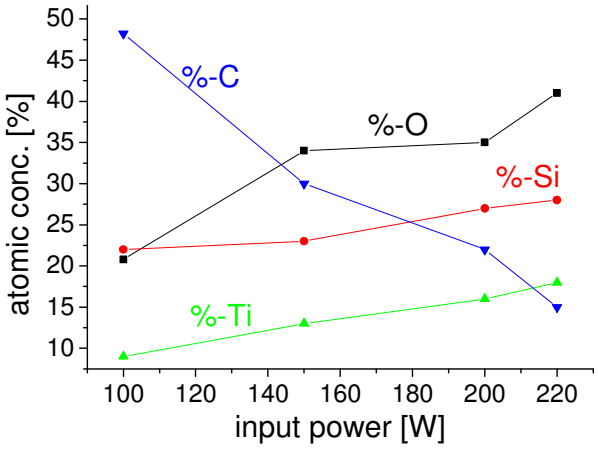

Figure 5: the effect of pPeak on atomic concentration for Ti-O-Si film (70 nm)

The data from XPS spectra of Ti-O-Si films in Figure 5 shows the relationship between Ppeak and atomic concentration. Increasing the pPeak was seen that the %-C decreases significantly but O, Si, and %-Ti increased because of the intensity of the oxygen plasma. The highest atomic concentration is oxygen, which suggest that a Ti-O-Si network is formed at the pp condition. The higher C-content in the Ti-O-Si film as compared to Si-O film may be related to the hydrocarbon components in the mixture and a higher temperature in the reactor, which is necessary for the fragmentation [9]. Furthermore, the elemental ratio for Ti-O-Si was $SiO_{1.4}C_{0.5}Ti_{0.6}$ compared to Si-O films with $SiO_{1.8}C_{0.12}$ showing lower %-C as a result of higher temperatures during the TTIP deposition. Figure 6 shows IR absorbance spectra of the pp SiO_2, TiO_2. The spectra interpretation of HMDSO film is based on well-known data [10]. The spectrum in Fig. 6(b) shows a shift of the Si-O peak to lower wavenumber and a new peak could be seen at 500 cm^{-1}.

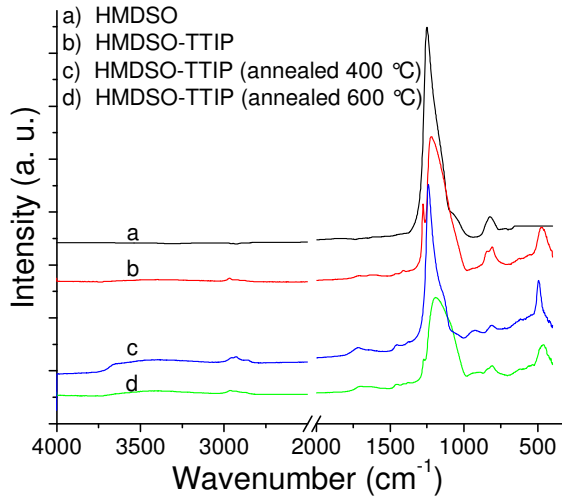

Figure 6: FT-IR spectra of pp-HMDSO+TTIP films

This shift and new peak can be attributed to Ti-O-Si bond formation, confirming a phase containing Ti, Si, and O [11]. Annealing at 400 and 600 °C, Fig. 6 (c & d) show that Ti-O-Si peak increased in intensity, indicating stability of Si and Ti network. This stability may be explained that Si and Ti atoms are randomly distributed in the network and bonded over an O-atom. Although the surface roughness (R_q) of Ti-O, Si-O and Ti-O-Si films analyzed were below 0.4 nm on polished silicon wafer, their surface morphology could not be distinguished using the AFM. The annealing effect showed relatively small changes with respect to surface analysis.

Electrical properties

Figure 7 shows the impedance spectra obtained for the deposited films as mentioned above having the same thickness. The ionic resistance of the Ti-O and Si-O is compared by the EIS. The spectra were numerically fitted using the equivalent circuit shown in Figure 7, with less than 5 % error for each component. The capacitance |Z| obtained from the fittings for a SiO_2 is lower than the TiO_2 film, which correlates the fact that TiO_2 has a higher dielectric constant than SiO_2. The fitted capacitance spectrum for the co-deposited film (Ti-O-Si) lies in between the Si-O and the Ti-O film spectra. The observed difference in the ionic resistance was related to the co-deposition of TTIP. A single RC time constant was observed for the Si-O-Ti film, suggested the ion penetration through the film consist of a single homogeneous material phase. The stability of the Si-O-Ti films was monitored over a period of time. For longer electrolyte (0.1M NaCl)-film (Ti-O-Si) exposure times, the film impedance measured was constant for over 25 hours, indicating that the Si-O film also served as an adhesion layer.

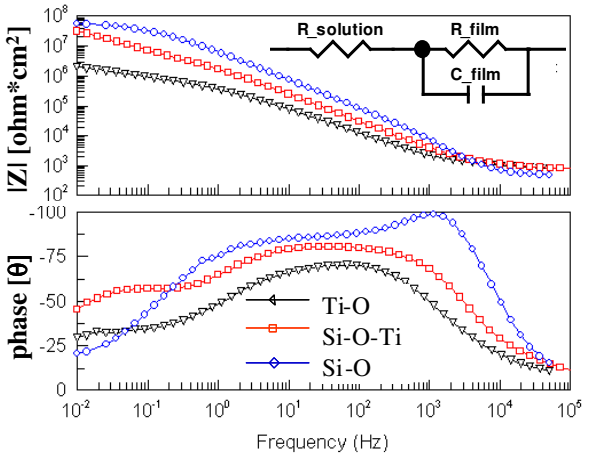

Figure 7: EIS spectra obtained from pp samples & equivalent circuit used for fitting

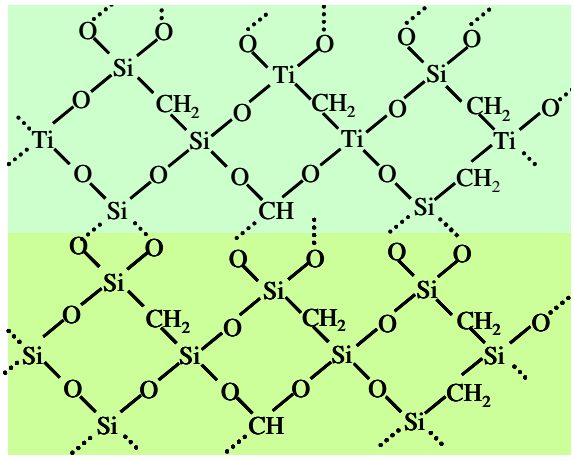

Figure 8: Theoretical model of Si-O-Si and Ti-O-Si films

CONCLUSIONS:

It should be therefore possible to polymerise films with desired index of refraction, if a relationship between the partial pressures of the precursors and the film composition and their effect on optical properties is well known. Valuable information regarding the surface morphology, chemical composition, optical and electrical properties, was achieved by the different method of analysis. Different refractive indices were attained due to input power increase or the monomer composition. From the electrical properties, the resistance of the co-deposited film (HMDSO/O_2 and TTIP) lies between the values of Ti-O and Si-O films. The phase angle spectra could be related to the homogeneity of the co-deposited films. A film network of Ti-O-Si could be concluded from the XPS and FT-IR analysis. No phase separation (stability) upon annealing from neither the FT-IR nor EIS spectra was noticed. The properties of Si-O-Ti films prepared by PECVD may be suitable for stable photo-optical and catalytic applications.

Acknowledgements

The authors wish to acknowledge the technical assistance of D. Moessner (IMTEK, Uni-Freiburg) for XPS measurement, Toda Masaya for fitting the ellipsometric data. We also thank Dr. J. Robertson for the helpful discussions about EIS.

Investigating the properties of plasma polymerised films (e.g. Polystyrene, Allylamine) on organosiloxane polymer films

A. N. Chifen, W. Knoll and R. Förch
Max-Planck Institute for Polymer Research, Ackermannweg 10, Mainz 55128, Germany
chifen@mpip-mainz.mpg.de

Abstract

This report presents the deposition of plasma polymerised allylamine and polystyrene films on SiO_2-like films (patterned gradient films in a two step process) at 13,56 MHz r.f. plasma. The properties of both layer films are investigated, aiming to tailor stable films with specific combined properties, e.g. barrier, hardness, biocompatibility and insulating properties. The chemistry of the layer films was investigated using FTIR and XPS. The surface morphology was examined using AFM. An interpretation of their electrical and layer interface properties using EIS is presented.

Keywords: SiO_2, allylamine, polystyrene, thin layer films

INTRODUCTION

Plasma deposited organic films can be used to modify the surface of biomedical and synthetic polymers in order to attain specific properties in various sectors (e.g. biotechnology). Plasma-based coatings like SiO_2 have been applied to polymers as scratch and corrosion resistant, barrier or hydrophilic coatings [1, 2, 3, 4]. Investigating the properties of patterned allylamine or polystyrene films on plasma polymerised (pp) hexamethyldisiloxane (HMDSO) at different process parameters will clarify certain properties of tailoring patterned gradient films. The amine group in allylamine (AA) offer promising characteristics for a variety of biomedical applications [5] and Polystyrene (PS) is a disposable ware in medical diagnostic, primarily due to its optical transparency, durability, low cost, and good mouldability [6].
Using micro- and nano-patterning techniques to produce surfaces with pre-determined morphology and defined structured chemical functionalities, are increasingly demanded in these sectors, e.g. for specific bonding of bioactive molecules or protein or enzyme immobilization [1, 7, 8, 9, 10].

EXPERIMENTAL

The precursors, AA and styrene were purchased from ACROS Organics (99,99 %). The plasma source used was capacitively coupled plasma source. The vapour concentration delivered into the chamber was controlled using a floating ball flow meter [Kobold Messring]. A RF power supply operating at 13.56 MHz provided the power for the plasma generation. This reactor has been earlier described in literature [11, 12]. The films were deposited onto Si-wafer and Gold substrates. HMDSO was pp at 140W at 0,2 mBar for 30 sec, yielding 15nm (also serves as an adhesion layer). Previous results showed that SiO_2-like films were obtained at these conditions (see conference presentation No. 702).

AA was pp at constant monomer pressure (0.1mBar), different input power conditions, 5, 45 and 90W. Styrene was pp at 0,052mBar, (40, 80 180 W) and a film thickness of 50 nm was obtained depending upon deposition time (max. 600 and 60 sec for AA and styrene respectively). Approximately, 50 nm of AA and PS was deposited 20nm SiO_2-like films.

	Allylamine	Styrene	HMDSO/O_2
preesure/mBar	0.1	0.052	0.2
max. dep. time [sec]	600	60	25
Ppeak W	5	40	140
	50	80	
	90	180	
thickness/nm	50	50	15

Table 1: deposition parameter of pp films

The chemical characterization of the deposited film(s) was with conventional surface analytical tools such as contact angle goniometry, X-ray Photoemission Spectroscopy (XPS) and Fourier Transform Infrared Spectroscopy (FTIR). Surface morphology was studied using atomic force microscopy (AFM). Electrochemical Impedance Spectroscopy (EIS) was used to explain the interface and electrical properties of the multilayer structures.

Results and Discussion

The deposition of both thin films AA and styrene on SiO_2 film (pp) could be detected with FTIR spectroscopy. Figure 1 shows the spectrum of ppAA on SiO_2 (pp). Referring to Figure1, the broad absorption band between 1000–1200 cm^{-1} indicates the presence of Si-O-Si and also Si=O bonds. The multiple peaks with relatively low intensities around 830 cm^{-1} is due to the Si-C or Si-CH_3 strectching deformations. The peak around 2200 cm-1 indicates the presence of nitrile groups, while the bands at 1600 cm-1 are assigned to the bending modes of amines, the stretching of imine groups and the stretching of amide groups. The band intensities of the amine, imine and amide groups reduce with increase in input power. This indicates that the fragmentation of the amino functional group. The intensity of the Si-O band tends to be broader due to this conversion, formation of Si-H groups (at 1100 cm^{-1}). These band assignments are based on literature data [13, 14, 15].

The spectra in Figure 2 show the effect of increasing input power of ppPS on SiO_2 films. The peaks around 770 cm^{-1} indicate the presence of a benzene ring. This peak seems to disappear with increasing input power. The intensities of Si-C, Si-H, Si-O-Si bands seen around 1000–1200 cm^{-1} decreases with increasing power. The Si-C and Si-H bonds seem to be dissociating to form Si-O-Si bonds. The band at 1700 cm^{-1} may be attributed to aryl derivatives (R-CO) and stretching vibrations of C=C double bonds. The bands of the functional groups of the precursors (HMDSO and allylamine or HMDSO and styrene) could be seen in the spectra, indicating the presence of both films. Additionally, the film thickness was scanned using a surface profiler (figure 3 and 4).

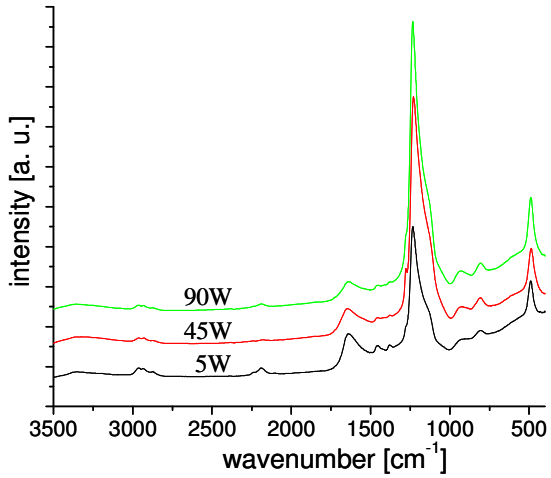

Figure 1: FTIR spectra of ppAA at different input power

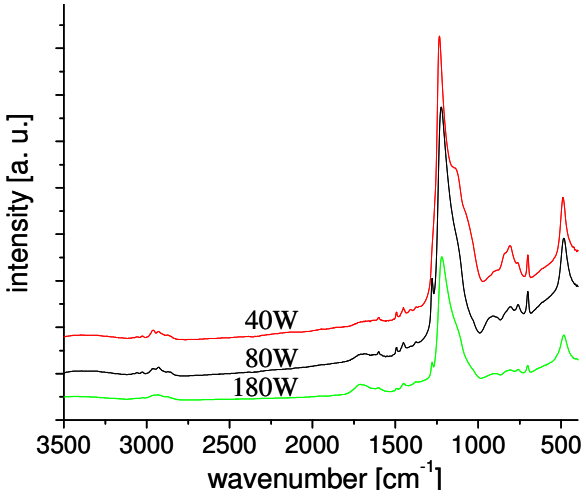

Figure 2: FTIR spectra of ppPS at different input power

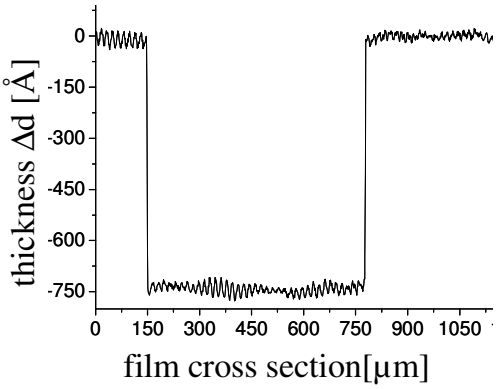

Figure 3: ppAA film thickness measured by the profiler

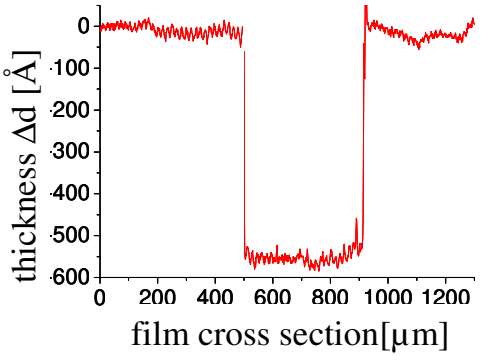

Figure 4: ppPS film thickness measured by the profiler

Figure 5 shows the impedance spectra obtained for the ppAA films on SiO_2. The impedance |Z| is relatively constant with increase in input power. A distinct trend of the ionic resistance plotted using the phase (θ) could not be distinguished with increasing power. A single RC time constant was observed for the films, the ion penetration through the film provides some information about the layer structure. Two "humps" could be distinguished on the phase spectra in Figure 5, indicating a heterogeneous material phase, low. The ppAA on SiO_2 films contact with the electrolyte (0.1M NaCl) seems to be considerably stable, because the impedance spectra are not distorted at low frequencies. This also indicates that the Si-O film also served as an adhesion layer.

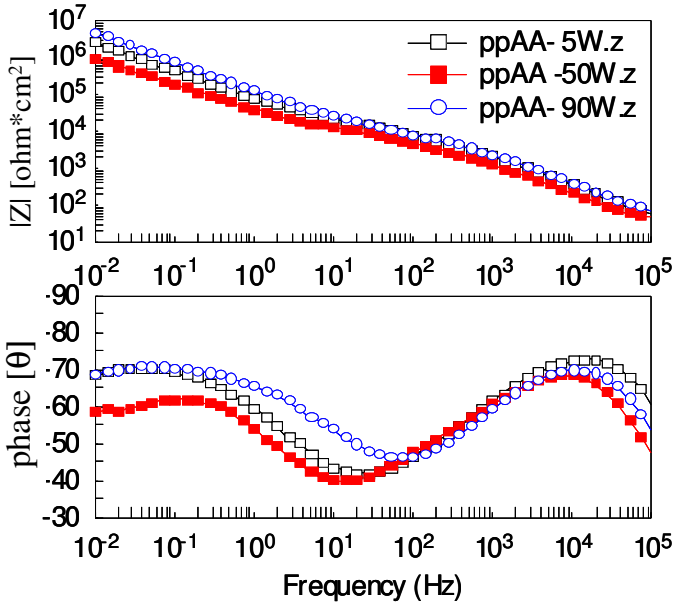

Figure 5: EIS spectra obtained from ppAA on SiO_2 film

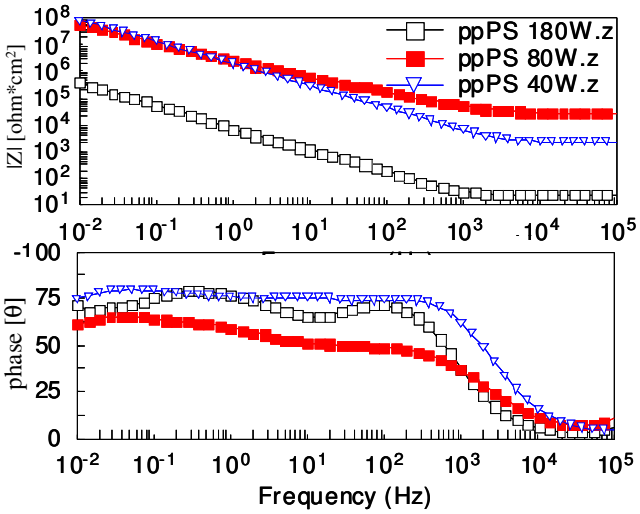

Figure 6: EIS spectra obtained from ppPS on SiO_2 film

Similar to Figure 5; Figure 6 illustrates the effect of input power on ppPS on SiO_2 films. At higher input power (180W), the impedance is lower than at 80 and 40W. This can be attributed to highly polymerised and closed network created during the plasma. Additionally, the scratch resistance of the films was measured using AFM cantilever tip (not shown here), showed that the films above 170W were harder to scratch than films below 100W. This maybe suggesting a higher degree of cross-linking causes lower impedance. The incorporation of the ppPS layer on the SiO_2 film was monitored with a single RC time constant, the ion penetration through the film provides some information about the layer structure. Two "humps" could be noticed for the films pp at 180W, whereas this cannot be seen at 40 and 80W. This cannot be explained here, but maybe films pp at lower input power is highly bonded to the SiO_2 films than the 180W pp film.

Figure 7 and 9 show images of the deposited ppAA and ppPS respectively at different input power. The results of AFM analysis show decreasing roughness with increasing input power (Table 2). This homogeneity may be due to plasma density because the more high plasma power can easily break monomer and cluster in the gas phase or on the surface. In summary, the contact angle of the thin films decreases with increasing input power, while the roughness decrease. This may be due to high cross-linking density with increasing input power.

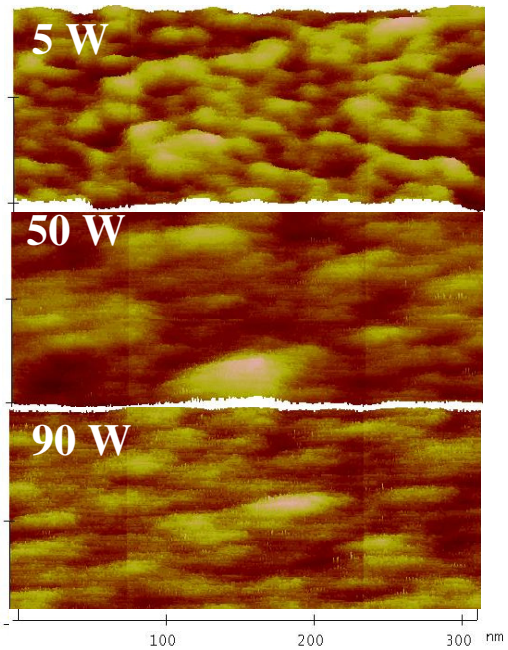

Figure 7: AFM images of ppAA on pp SiO2 deposited at different RF powers

ppAllylamine	
Power/W	Rz(500nm)
5	0.297
50	0.193
90	0.151

ppPolystyrene	
Power/W	Rz (500nm)
40	0.281
80	0.268
180	0.255

Table 2: surface roughness depicted from AFM images

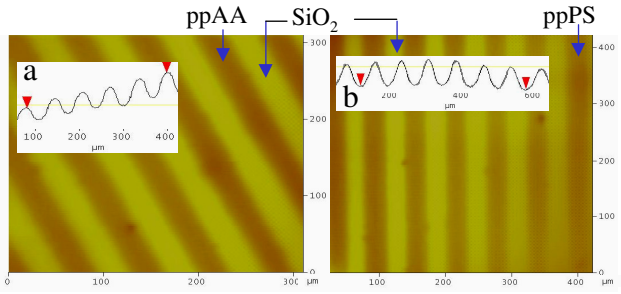

Figure 8: surface patterned with a grid a)ppAA, b)PS stripes

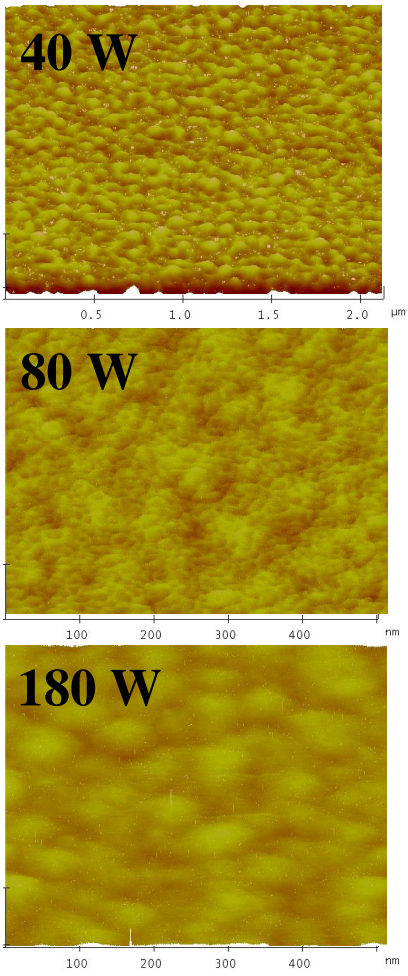

Figure 9: AFM images of ppPS on pp SiO2 deposited at different RF powers

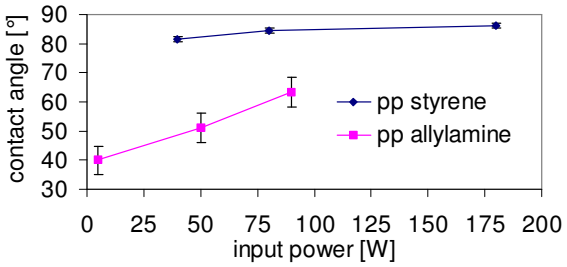

Figure 10: effect of input power on contact angle

Most notably in Figure 8 is the definite deposition of AA and styrene, which shows a constant profile obtained between the stripes. The contact angles between these stripes also showed that contact angle increases with decreasing surface roughness and oxygen content, existing C=O or C-O bond related species (see Figure 1 and 2).

Due the breakdown of the XPS equipment, the results will be belated. This will be presented on the poster.

CONCLUSIONS:

In this study, we especially compared two different films at various input power to determine their characteristics at different input power. This will deepen further studies to apply these films for adhesion or immobilization of protein. The FTIR spectra showed the plasma does not affect the SiO_2 film, but the spectra of the subsequent films (AA or styrene) were altered by the increasing input power, more evident were the amino and benzene bands. The EIS measurements showed that the impedance is relatively not affected by the input power, but analyzing the ion penetration depicted the interface layer information. The surface analysis (roughness and contact angle values) was correlated to the monomer fragmentation in the plasma and functional groups retention in the films. These surface characterisitics have a strong influence on the protein attachment. In the patterned surfaces, a definite deposition profile could was observed for both pp films, which also showed the properties determined for the non-patterned surface.

AN EXPERIMENTAL AND NUMERICAL STUDY OF SIO_2 NANOPARTICLES SYNTHESIS IN AN RF PLASMA REACTOR

B. M. Goortani[1], N. Mendoza[1], P. Proulx[1]

[1]*Department of Chemical Engineering, Université de Sherbrooke, Québec, Canada*

Abstract

Nanoparticles of SiO_2 were produced in an induction thermal plasma reactor. The resulting nanoparticles were characterized on the bases of their morphology and size distribution. Computational fluid dynamics (CFD) software Fluent™6.1 combined with a Fine Particle Model (FPM) developed by Chimera™, was used to simulate the whole synthesis process. The SiO_2 nanoparticles produced and collected at the exit lay in the size range of 20-150 nm, the predicted numerical results being in good agreement with the experimental revelations.

1. Introduction

Radio frequency (RF) thermal plasma processes may be used as a technique for the production of metallic and ceramic powder materials with particle sizes in the nanometric range [1]. To date, the control and understanding of such processes, which are of the vapor synthesis type, is still not well known and there is still a major challenge for achieving scale-up and subsequent industrial applications [2]. So far, a number of researchers in the field of nanoparticle production by aerosol methods have studied this kind of processes. Some examples are found in the literature [3,4], where the experimental work is combined with theoretical models. Such publications also present particle dynamics models implemented with Fluent™. Thus the synthesis of iron nanoparticles in a small scale RF reactor was studied by Girschick et. al. [1]. Ishigaki et al. [5] also experimentally studied the vaporization of Titanium Carbide in a much larger scale RF plasma reactor. In this present work, the study of SiO_2 nanoparticles synthesis in an RF induction plasma reactor is presented, followed by numerical simulation study of the process.

2. Experimental study

Figure 1 shows a schematic diagram of the complete experimental set up employed for the experiments. Micronised quartz particles (MIN-U-SIL 5™, US Silica Company) with an average diameter of 2 and maximum of 5 µm were used as the raw material in a methanol suspension of 50% solids.

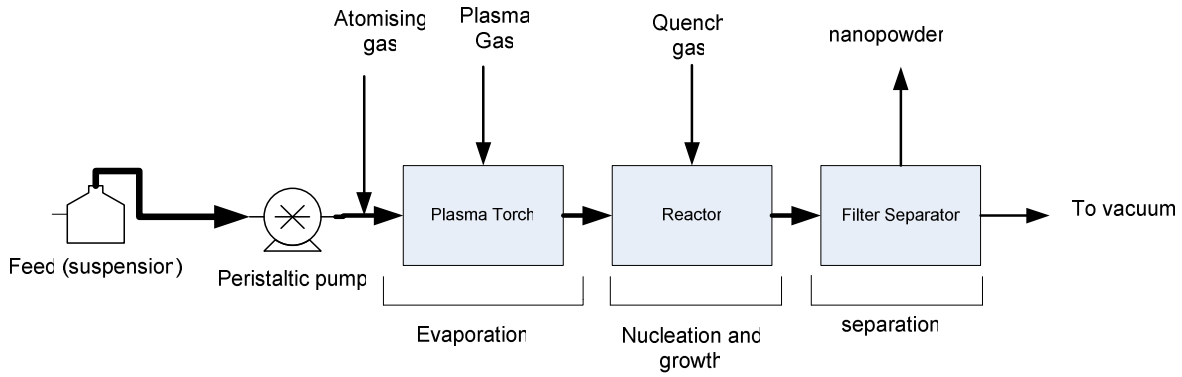

Figure 1. Schematic diagram of the experimental set-up for the production of SiO_2 nanoparticles.

The reactor set-up used here was a modification of that used by Jurewicz J. et al [6] (liquid circulation system were removed, demister was replaced by a Goretex^{TM} filter and the nozzle modified for quench gas injection). This was used with an induction plasma torch; model PL-50 (Tekna Plasma Systems, Sherbrooke, Qc, CA). The operating parameters of the reactor and the RF torch are summarized in table 1.

Table 1- Experimental conditions for the production of SiO_2 nanoparticles.

Process Parameter	*Value*
Plasma gas and Flow rate - Central Gas - Sheath gas	 Argon , 22.5 slpm Oxygen (75slpm), Ar (22.5 slpm)
Feeding rate and Mechanism	4.5 - 16 gpm SiO2 (a suspension of SiO2 in methanol)
Plasma Power Plate	40 kW
Reactor Pressure (absolute)	650 torr

Silica feed rates varied from 4.5 gpm (net SiO_2 injection) to about 16 gpm. Below 4.5 gpm it was difficult to achieve steady flow rates as a result of presence of higher pressures (related to atmospheric) in the induction zone of the torch. Oxygen, used as the "quench" gas, was injected counter-current into the reactor at its base. The nanoparticles produced were separated from gas suspension on the installed filter and the walls of the reactor.

- **Experimental Results**

Scanning electron Microscopy (SEM), Nitrogen adsorption (BET), X-ray diffraction and laser diffraction techniques were all used to characterize the resulting SiO_2 nanoparticles .

Figure 2 shows a typical product SiO_2 SEM image, for the case of 4.5 gpm quartz input feed rate. Product particles were sampled on the filter. In general, these particles are spherical and partially agglomerated (sintered). The average diameter of the primary particles lies in the range of 20-200 nanometers. By increasing the quartz feed rate, increased in sintering and agglomeration of product particles was observed.

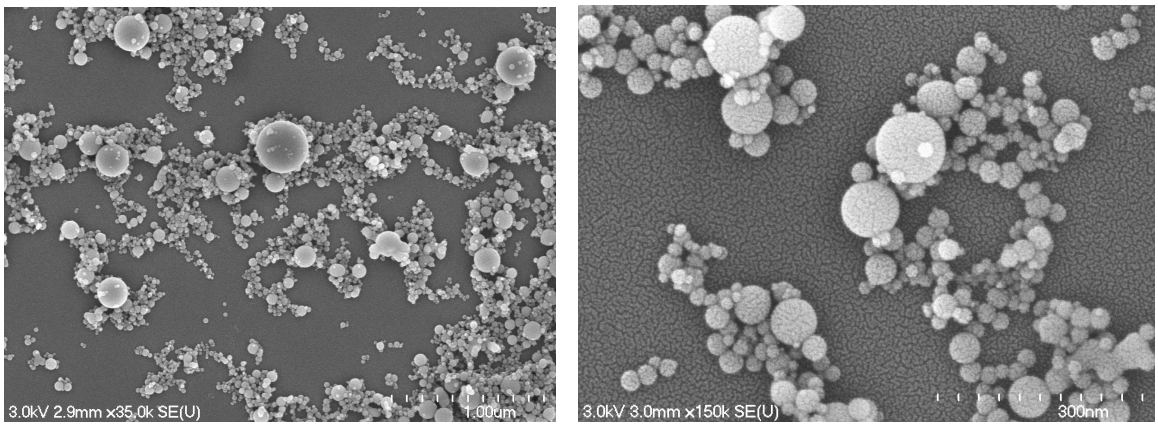

Figure 2. SEM image of the produced silica nanoparticles.

The results of X-ray diffraction studies show that the synthesized particles are completely amorphous in comparison the original input quartz particles that were fully crystalline. This

absence of original crystalline particles on the filter recovered product points to total process treatment of the input powder in the plasma zone. Nitrogen adsorption BET results later showed that, by increasing the quartz feed rate from 4.5 gpm to 16 gpm, the resulting specific surface area of the product powder decreases from 80 m^2/gr to 40 m^2/gr. Laser diffractometry also showed a similar behavior, i.e. by increasing the plasma process feed rate, the percentage of the produced nanoparticles (by volume) decreased.

3.Numerical study

The numerical model is applied to the torch and the reactor of the experimental set up, as described in figure 1. The synthesis process first initially consists of the evaporation of silica particles into the hot plasma formed from input oxygen and argon. In the following step, the mixture of plasma gas is transported to the second vessel (reactor in figure 1), in which condensation takes place and the product particles are produced.

The commercial CFD software Fluent™ 6.1, combined with a Fine Particle Model FPM developed by Chimera™, was used to simulate the overall synthesis process. The synthesis reactor is represented by a computational domain in figure 3, which is then split into discrete control volumes. The underlying computational grid consists of a total of 17598 cells, thereby assuring a high computational grid density. By integrating the governing equations on individual control volumes, algebraic finite difference equations result for the discrete unknown scalars. These discretized equations are solved with the Line Gauss-Seidel algorithm. Further details can be found in the software manuals (Fluent 6.1) or in the book by Bird et al. [7]. The whole model of SiO_2 nanoparticles synthesis involves the solution of fluid mechanics and particle dynamics equations.

The fluid mechanics part of the calculation concerns the solution of continuity, momentum, energy and species. In this approach, the model developed by S. Xue et al. [8] was used for the calculation of the electromagnetic fields, fluid mechanics, heat and mass transfer in the induction plasma generation zone. The evaporation of particles is considered with the model of discrete phase in a Lagrangian frame of reference, i.e. the Discrete Particle Model of Fluent™. The coupling between the phases and its impact on both the discrete phase trajectories and the continuous phase flow are included.

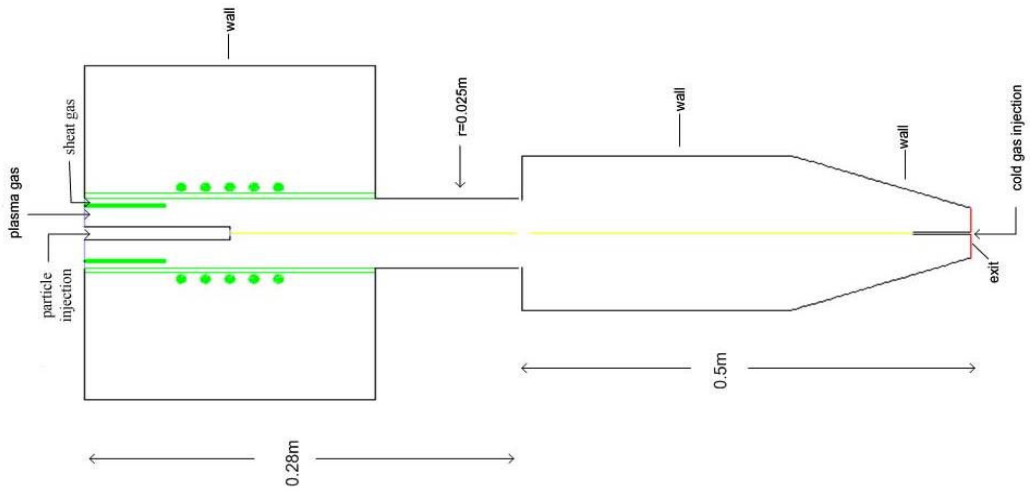

Figure 3. Calculation domain.

The particle dynamics part considers the effect of internal (nucleation, particle growth) and external (fluid convection particle diffusion and external forces) processes affecting particles within a homogeneous control volume. The FPM model for particles nucleation, growth and transport, based on the models of Whitby [9] and Wilck [10], is coupled also with the fluid mechanics.

The particles size distribution is represented using a modal approach. The evolution of particle distribution in space and time is governed by an equation known as the General Dynamics Equation for Aerosols (GDE) [11], which is transformed by applying the definitions for the integral moments of the modes into the Moment Dynamic Equation (MDE):

$$\frac{\partial \mathrm{M}_{j,k}}{\partial t} = conv_{j,k} + ext_{j,k} + diff_{j,k} + coag_{j,k} + cond_{j,k} + nuc_{j,k} + src_{j,k} \qquad (1)$$

This equation accounts for the changes of the size distribution moments $M_{j,k}$ due to external processes of convective transport (*conv*), transport by external forces (*ext*) and diffusion (*diff*), as well as the internal processes of coagulation (*coag*), condensation and evaporation (*cond*), homogeneous nucleation (*nuc*), and general source terms (*src*).

For the present simulation no source terms were involved. The coagulation coefficient is calculated with the transition regime provided by Dahneke [12]. The expression of Barret [13] is used to calculate the mass transfer rate for the condensation-evaporation mechanism. The expression of Girshick [14] for the homogenous nucleation rate is selected in this model. Finally, the equation provided by Talbot [15] is applied in this work for the thermophoresis velocity calculation.

- Assumptions

-Steady state.
-Axisymmetric flow.
-Laminar model for the induction zone and the k-ε turbulent model for the condensation zone.
-Particles are spherical.
-Particle temperature is uniform and equal to the fluid temperature.
-Particle velocity is the sum of convective and external-force velocities.
-Particle size distribution is represented using a lognormal distribution function.

- Boundary conditions

Pure argon is injected at the central entrance of the reactor with the solid particles. A mix of argon 25% and oxygen 75% is used for the sheath gas. Velocity profiles are given for each radial section at the entrance of the reactor: injection probe, plasma gas, sheath gas. The injected SiO_2 particles have a mean diameter of 2 μm. The induction zone is limited by water cooled walls (r=0.025 m). Gradients are assumed to be zero at the exit of the condensation tube. Radial gradients are assumed to be zero for all variables on the axis of symmetry. The condensation zone is limited by cooled walls (T=300K).

- Results of simulation

The results for a case with 4.5 gpm rate of SiO_2 particle injection without quench, are presented in this section. The temperature fields in the reactor are given in figure 4. The SiO_2 particles injected by the central probe are subjected to temperatures of more than 11000 K, which thereby assures complete melting and evaporation of the particles. The gas temperature decreases when the fluid reaches the condensation zone, thereby producing high temperature gradients. The mass

fraction of SiO_2 produced by evaporation of input raw material is decreased along the reactor length because of condensation, as shown in figure (5). Due to condensation, there is a "burst" of nucleation, thereby forming the new particles of SiO_2.

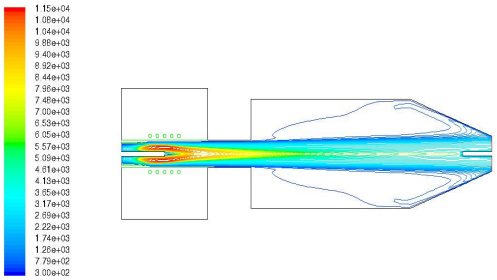

Figure 4. Contours of temperature (K)

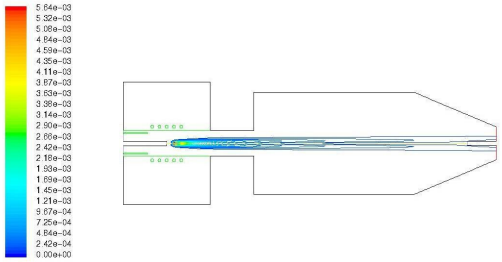

Figure 5. Contours of mass fraction of SiO_2

Particles start to grow and they attain sizes of up to 400 nm near to the reactor exit. This result is likely because the exit is the coolest zone of the reactor and the average residence time for particles is greatest here. Near the axis, slower cooling retards the onset of condensation. However the central cloud is gradually depleted by radial diffusion towards zones where the vapor is condensed. High particle concentrations are formed near the reactor walls. This is due to the presence of strong temperature gradients and thus the short time available to grow. Low temperature gradients at the axis lead to the formation of relatively large particles, even though the vapor concentration is reduced. In figure 6, the diameter isocontours of particles at any point of the reactor can be observed. An x-y plot for the final size of particles produced at the exit of the reactor is presented in figure 7, where the mean particle diameter is calculated as 160 nm. Further simulations, using higher particle feed rates shows similar tendencies, with larger SiO_2 particle sizes, but these results are not presented here.

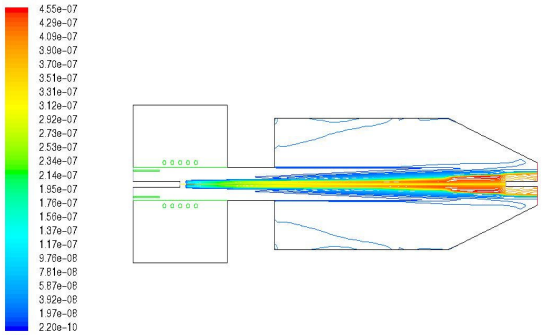

Figure 6. Contours of diameter (m)

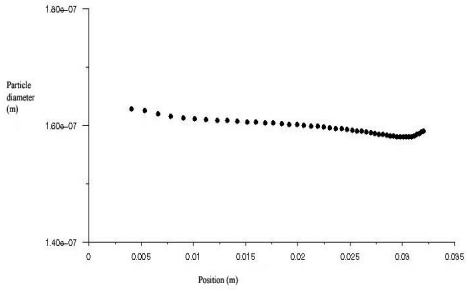

Figure 7. Particle size at the exit of the reactor

4. Conclusions

The overall process of nanoparticle synthesis has been studied both experimentally and numerically and the findings described. The experimental part accounted for the set up of the synthesis process reactor and several plasma conditions were examined. In respect of the numerical analysis part of the work, simulation was effected with low usage of computer time, easy access for parameters and geometry changes, and excellent visualization of the calculation results. This finding suggests that this model has distinct advantages in comparison with other classical models. Good agreement between the results of experimentation and simulation was observed. The final diameters of primary SiO_2 particles lie with the range of 20-200 nm for the cases studied. Finally, this work has helped to provide considerable insight into the phenomena occurring in the reactor and to point towards the appropriate direction for future work on this topic.

Optical emission diagnostic of an impinging supersonic induction plasma jet

Y. Lakaf[1], S. Mhim[1], D.V. Gravelle[1] and M. I. Boulos[1]
[1]Energy, Plasma and Electrochemistry Research Centre (CREPE)
Université de Sherbrooke, Sherbrooke, Québec, Canada

Abstract:

The objective of the present study is to determine the temperature and plasma composition profile, using the emission spectroscopy method, across the thin boundary layer formed over the surface of a flat plate on which a supersonic plasma jet is impinging. The complex structure of the supersonic jet near the region of impact, such as the structure of the standing shock wave formed over the plate, motivates use of this non-intrusive diagnostic method. The radial profile of temperature obtained is very interesting comparing with those described in literature.

1. Introduction:

Supersonic plasma jets are characterized by very high temperature, velocity and pressure gradients which get them many advantages in industrial applications. They have been widely used for re-entry simulation studies and in the plasma spraying of high density nanostructured thin and thick coatings. In most of these applications, a fundamental understanding of the conditions in the boundary layer over the substrate is of critical importance for achieving the right conditions for the surface treatment and/or coating quality.

The supersonic plasma jets are produced by means of simple adjustment of the convergent-divergent nozzle and chamber pressure reduction. Optically the supersonic jet is narrow and fast. Downstream from the exhaust nozzle, it consists of an alternation of expansions and compressions zones, generated by the fact that the static pressure of the jet tends to balance with the medium of evolution. On the flat plate, the supersonic jet impingement includes very complicated phenomena, with the presence of multiple shock system that consists of the barrel shock, the plate shock, and the reflected shock, as well as the instability of a stagnation point. [1-2]

Previous studies [3-4] that have been conducted on the impinging flows have reported that the pressure and the local heat flux profiles along the plate both should have maxima at the center of the plate. However, it has also been reported in the literature [2] that the surface pressure distribution has the peripheral maximum due to the presence of bubble and it's also affected by the nozzle-to-plate distance. Indeed, if the plate is located in inside of some cycles of reflexion, the plate shock is formed. The flow downstream from this wave becomes subsonic and is allowed like the zone of stagnation of the flow. The fluid thereafter accelerates radially along the surface of the plate and possibly passes by again in supersonic mode. If it is the case, the radial expansion of the fluid makes so that the flow becomes again sonic at some distance. The bubble formation is the consequence of the very high gradient of velocity which surrounds it, dragged on its top by the high radial velocity.

Although it emerges from these studies a good comprehension of the impinging under-expanded gas jet dynamical properties onto the plate, it remains about it less concerning the heat transfer across the thin boundary layer formed over the surface of a flat plate on which an induction supersonic plasma jet is impinging.

The aim of this paper is to determine the temperature and plasma composition profile of supersonic plasma RF jet impinging on flat plate by the atomic emission spectroscopy nearest of the impact region and in the

stagnation bubble. The zone of interest is located at a few millimetres upstream from the plate where a very luminous structure is observed. Since we are interested essentially in the impact region where the plate shock wave appears, we have fixed the distance between the plate and the exit nozzle according to a relevant study reported in literature relatively to bubble appearance. [5]

Because of the plasma doesn't emit sufficiently, all of measurements were performed with no light in the diagnostic room, in order to be able to position our plasma on the slit entry of the spectrometer. So, the thinner boundary layer where the plasma doesn't emit, was estimated around 2 to 3 mm upstream the plate.

Spectroscopic measurement of inductively coupled plasma of pure Argon is carried out, and several plasma properties are determined from data. The radial excitation temperature (T_{LTE}) profile following Local Thermodynamic Equilibrium (LTE) assumption is determined along jet axis, and the electronic temperature T_e and density N_e are also estimated using the Boltzmann graph and the continuum emission, and confronted after with those giving by LTE assumption.

2. Experiment:

The experimental apparatus is shown in Fig1. The plasma is generated by RF plasma torch (PL-35 Tekna Plasma System) equipped with a convergent-divergent nozzle designed for Mach number of 4. The power is fixed at 16.65 kW and the pressure in the chamber was about 1.84kPa. The reactor supported the plasma torch is cylindrical and is fitted with the collecting pipe of exhausts gases connected in its turn with the system of vacuum. The reactor is provided with quartz port-holes laid out on the optical axis of spectroscopic measurements. The luminous rays coming from plasma are forwarded to a Jobin-Yvon monochromator of focal length of 1m via a system of lenses and mirrors disposed front of the plasma. The monochromator fitted with a grating having 1200groves/mm, makes it possible to break up the rebuilt image of plasma, with a factor of contracting of 1/8, in its emission spectrum. The resulting light intensities are read by a CCD detector with 1024x256 pixels, the rows and columns of this CCD correspond to the spectrum and radial emission profile of the plasma respectively. We were interested in the emission given by the spectrum of line of argon to a wavelength of 415.9 nm, 430.01 nm and 727.3 nm. Depending on the spectral wavelength, integration time of the CCD varied from 0.03 to 1s. The entrance slit width was kept at 8 μm.

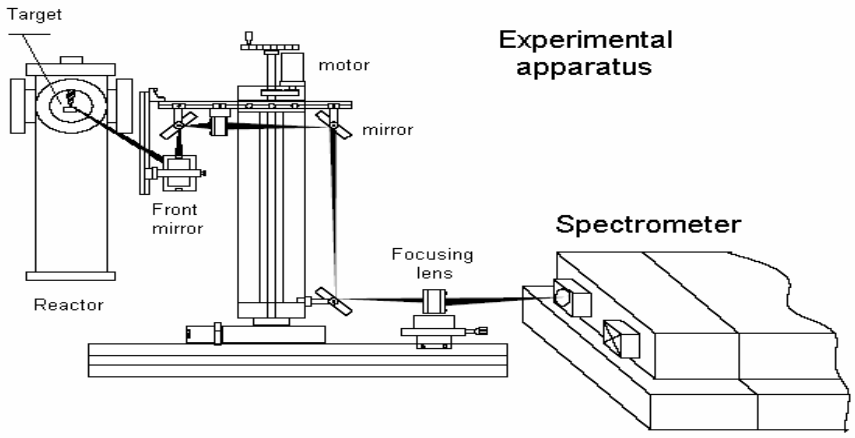

Figure 1: Schematic diagram of the reactor with the optical spectrometer instruments

In the vertical position, each diode recorded the signal corresponding to the light emitted by a cord of a slice of the plasma jet. The spectral width is equal to the product of the total height of the photodiodes

(0.027mm) and the linear dispersion of the monochromator (0.78 nm.mm^{-1}), i.e. 0.021mm. The absolute intensity of the line's radiation was obtained by calibration using a standard tungsten filament lamp.

3. Results and discussion:

Typical photographs of such chock waves formed for a Mach 4 supersonic plasma jet impinging on a flat plate located at a distances of 90 mm from the exit nozzle of the plasma jet are shown in Figure 2.

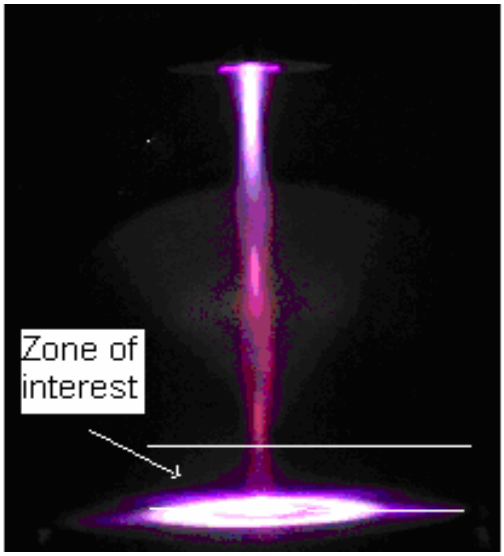

Figure 2: Mach 4 supersonic induction plasma jet impinging on flat plate placed at Z=90mm.

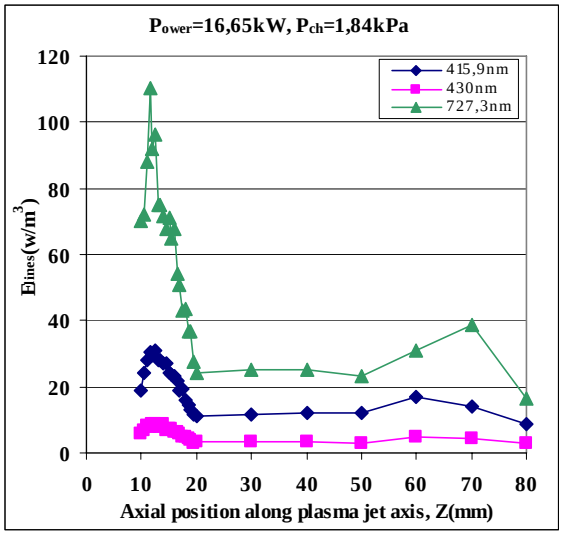

Figure 3: Emissivity lines of 415.9 nm, 430nm and 727.3nm vs. axial plasma jet position Z.

The figure 3 representing the emissivity lines of 415.9 nm, 430.nm and 727.3nm along the jet axis, shows the general structure of the impinging RF plasma jet, resulting in compression and expansion zones. The three profiles have shown the same phenomena. First plasma emission is observed at 10 mm away the from the plate, followed by a compression zone located at 12 mm , until a compression zone observed close to the nozzle exit at 70 mm from the plate. The emissivity increases to maximum, and then decreases till the 20 mm axial position, and then kept constant close to the first compression near the nozzle exit. The zone of interest is located within 20 mm from the plate surface where the measures were performed with axial displacement step of 0.5 mm, then the interval was increased to 10 mm between two measures, on the top region of interest.

The first attempt regarding the emissivity profile at 430.0nm line, after Abel inversion, as seen in Fig.4, shows interesting phenomenon occurring near the periphery of the plasma. The profile shows that the emissivity decreases with the radius, and then increases through the off axis maximum. This phenomenon has already been reported (Fig.5) through modeling and calorimetric measurements [6], showing an off axis maximum of heat exchange. This phenomenon results from lateral shock wave near the centre with peripheral off axis shocks, due to the radial plasma flow acceleration along the plate. [7]

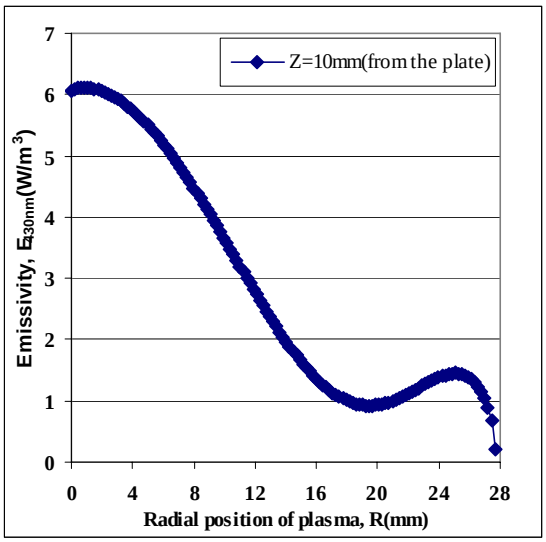

Figure 4: Emissivity of 430 nm lines from the centre of the impact zone. M=4.0, P_{ower} =16.65kW

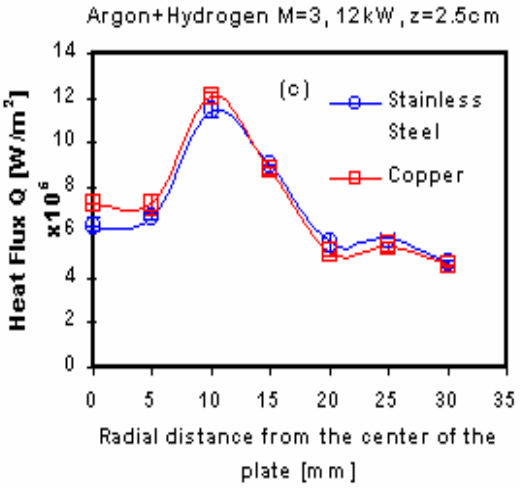

Figure 5: Heat flux calorimetric measurement along the radial distance from the centre of the plasma

The emissivity spectral lines of 415.9nm, 430nm and 727.3 nm are used to determine the temperature. Two methods were employed:

1- Atomic Boltzmann plot method
2- Absolute line intensity method, by solving a non linear system of equation given by Saha, Dalton and Boltzmann distribution, assuming LTE assumption.

For the first method, the plasma temperature can be obtained by plotting the equation:

$$y = \log \frac{N_m}{g_m} = \log\left(\frac{\varepsilon_{mi}\lambda_{mi}}{A_{mi}g_m}\right) = \ln A - \frac{E_m}{kT_e} \quad (1)$$

Where ε_{mi} are the absolute lines intensities (emissivity), and λ_{mi} are the wavelengths and E_m and g_m the excitation energy statistical weight of the upper atomic state respectively; K constant of Boltzmann.

The Boltzmann's diagram, while laborious, has the main advantage of not depending on the local pressure or composition in the measurement of plasma section. Then, the slope of the straight line obtained is inversely promotional to the temperature. We will call the temperature obtained, T_b, Boltzmann temperature. (See Figure5-6)

In the same time, are we getting the Boltzmann temperature, we can estimate the electronic density, by using the equation giving by the absolute continuum expressed as follow:

$$\varepsilon_{\lambda c} = C_1 \frac{N_e^2}{\lambda_u^2\sqrt{T}}\xi(\lambda_u, T_e) \quad (2)$$

Where $C_1 = 1.63.10^{-43}$ $Jm^4K^{1/2}s^{-1}st^{-1}$, and constant fro all Argon lines. λ_u is the continuum wavelength, and T_e the Boltzmann temperature.

These two properties (T and N_e) of plasma can be determined assuming LTE assumption near the central axis of plasma in the impact region. The plasma flow tends to stagnate in front of the plate, and the presence of the shock wave on the plate, resulting in the pressure increasing, allows to consider that the thermo dynamical non equilibrium plasma is approaching a temperature-equilibrium, one due to frequent energy transfer collisions among all particles species. The collision results by an increase from the temperature supporting by consequence of LTE assumption. [4]

The system of equation which allowed measuring excitation temperature, giving by the absolute line emission of 430nm, and the density of electron is given by equations (3, 4 and 5):

$$\varepsilon_{mn} = \frac{hc}{4\pi}\frac{N_0(T)}{Z(T)}\frac{A_{mn}\,g_m}{\lambda}\exp(-E_m/KT_{exc}) \quad (3)$$

$$\frac{N_e N_i}{N_0} = 2\frac{Z_i(T_{exc})}{Z_0(T_{exc})}\left(\frac{2\pi m_e K}{h^2}\right)^{3/2} T_{exc}^{3/2}\exp(-E_i/KT_{exc}) \quad (4)$$

$$\frac{P}{K} = N_e T_{exc}(N_i + N_0)T_{exc} \quad (5)$$

This system can be solved if the local pressure of the plasma is known. Because of the pressure in the stagnation pressure is unknown, and never reported in literature, we have used the pressure of the plasma environment which is the chamber pressure (1.84kPa), knowing well that is not represents the pressure of plasma.

The temperature of excitation and the density of electron are shown in the Figure (5-6)

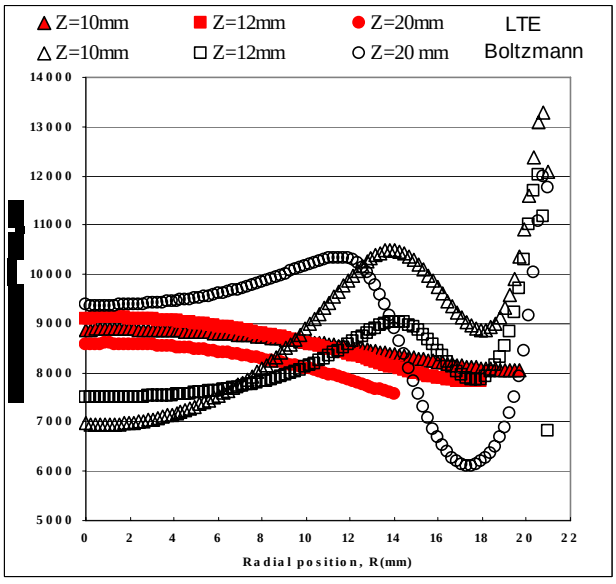

Figure5: Radial temperature profile at different axial position Z=2mm-4,5mm-12mm

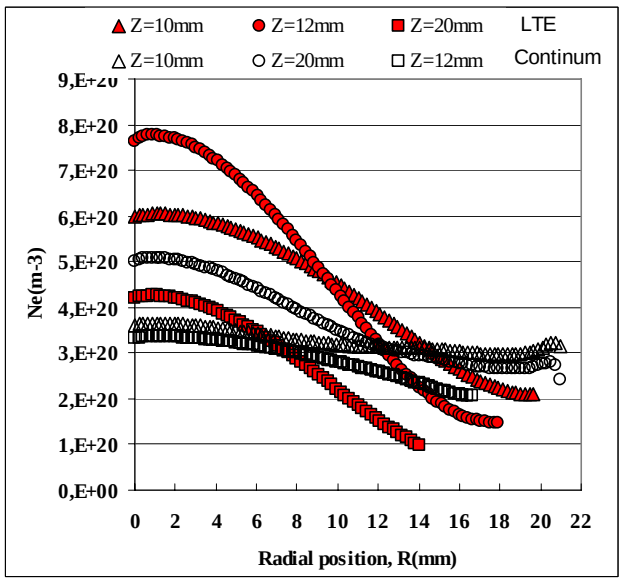

Figure6: Radial temperature profile at different axial position Z=2mm-4,5mm-12mm

In these graphics, three positions along plasma jet axis were chosen, relatively of expansion and compression zones apparition located at Z=10mm, 12mm and 20mm. The temperatures given by the two methods mentioned above were confronted. The Boltzmann temperature T_b (Fig.5), along the plasma jet centreline increases from 7000K to 9500K, due to shock plate formation, resulting by the formation of the stagnation bubble located upstream of the shock wave plate. Radially, the temperature profile also increases outward up to about 10500K at 12 mm in radius, for Z=10mm, over the plate. It is also valid for Z=10-12mm, where the same phenomena are observed, where the both temperature profiles passes from maxima to decrease then towards plasma periphery. This phenomenon has already been reported by the literature [2], due to the existence of cooled region near the jet periphery. Concerning the temperature given by solving the system of equation of Saha-Dalton-Emissivity distribution, following LTE assumption, this latter is shown in the Figure 5. Along the centreline plasma jet the T_{LTE} has a maxima at Z=12mm of about T=9100K before to decrease to T= 8600K at Z=20mm, according to the emissivity distribution along the centreline of plasma jet (Fig.4). Radially, the temperature profile T_{LTE} gradually decreases for all axial positions and have no great variation at these axial positions, compared with that given by T_b, until plasma periphery. However, towards the periphery of plasma profiles radial of temperature it's maximum in the direction of Z increasing.

The characteristics of the electron number densities shown in Fig.6, following LTE assumption, are almost similar to those of the temperatures. The electron densities distribution at the centreline of jet plasma for the three axial positions has peaks on the order of 4.10^{20} to 8.10^{20} m^3, and they gradually decrease radially outward to the order of 1.10^{20} to 2.10^{20} m^3. The profile at Z=20mm is greater that those at 10mm and 12 mm, because of the intensive collision transfer energy due to plasma jet compression.

Concerning the electron densities profile given by the Continuum equation, the same observation is observed, exception that the radial profile of the electron densities at Z=2mm almost equal to that at 12mm. radially all profiles decreases gradually and are much lower than those given by LTE.

4. Summary:

Optical emission spectroscopic measurements were performed to examine an impinging supersonic plasma induction jet over the flat plate. The complex phenomena characterising the impact region has motivated us to use this non-intrusive method of diagnostic. The spectral intensity response of the lines 415.9nm, 430nm and 727.3nm conducting throughout the thinner boundary layer at different axial position from the plate has permitted the temperature estimation at few millimetres upstream the plate. The radial profile of temperature has shown the existence of the shock wave at the periphery of the plasma nearest the plate due to radial acceleration of the plasma on the plate. The temperature pass from maxima at Z=12 mm due compression zone. Lastly, the electron number densities and temperature giving by the LTE do not give us entire satisfaction for their non conformity with those giving by the Bolztmann's temperature. This attempt to consider the LTE assumption is may be not applicable, and consist for further investigation.

Abstract
Ferromagnetic nanopowders (NP), created with magnetically decoupled cores, are interesting for their further utilization in bulk nanostructured magnetic materials in low and high-frequency applications. Capacitively coupled RF discharges, at P=100-250 Pa, were used for the synthesis of binary iron/carbon NP from argon diluted vapors of iron pentacarbonyl ($Fe(CO)_5$). Obtained NP were investigated by TEM, XRD, TGA, FTIR and magnetization measurements. Diamagnetic NP, with ≈4% iron content, were obtained at lower pressures (100-130 Pa); increasing the pressure to 250 Pa resulted in the synthesis of ≈40% iron content NP with ferromagnetic properties (M_S ≈50 emu/gr). The first NP type is formed of particles some 10-50 nm long and several nm wide, being carbon/iron rods, covered by graphitic layers and integrated into an amorphous carbon matrix. The second ferromagnetic NP consist of isolated hexagonal shaped 20-60 nm crystals of the Fe_7C_3 or Fe_2C_3 carbides, embedded in an amorphous carbon. Factors, favoring the carbide NP formation are the temperature decrease, the shifting of the chemical equilibrium from non-bound *Fe* and its oxides towards the state of carburization, and the deceleration in the rate of removal of the *Fe* oxidation products towards the reactor walls.
Keywords: nanopowder, plasma, iron carbonyl, iron carbides, ferromagnetic.

1. Introduction
Binary or multi-component nanopowders (NP) attract interest as starting materials for the synthesis of composites with improved properties, e.g. advanced ceramics and ferromagnetics. Numerous methods for the composite NP fabrication, such as deposition from colloidal solutions [1], annealing [2], electric arc [3] and low power RF plasma treatment [4] and acoustic decomposition [5] have been developed. The plasma synthesis of binary NP can be processed with a variety of material couples and integrated into serial technological process. Such applications, for example in binary ceramics, are known since several years [6]. Encapsulation of the magnetic NP in carbon can protect them from oxidation and reduce the magnetic coupling between individual particles [2]. Bulk materials with new magnetic properties can be fabricated from such NP by densification. At [7] a capacitively coupled (CC) RF discharge in hydrocarbon gases was used for the in-flight coating of SiO_2 nanopowders with an *a-C:H* nanolayer. In the present work, a modified CC RF plasma system, operating under similar conditions, is applied for the synthesis of ferromagnetic NP, using iron pentacarbonyl as a gaseous precursor. $Fe(CO)_5$ is used for the fabrication of nanostructured materials by various methods, such as e^--beam assisted CVD [10] or ultrasound decomposition of the precursor [5]. The iron group metals are known as active catalysts for reactions involving graphitization and *CO* conversion [2, 9]. Hence, the application of $Fe(CO)_5$ combines the synthesis of ferromagnetic NP and the individual NP encapsulation in a carbon/graphite matrix. The NP cores may contain non-bound iron and a variety of iron carbides. The used plasma setup enables the control of the product composition, its magnetic properties and morphology.

2. Experimental setup
The capacitively coupled (CC) RF discharge facility used in this work can operate in various gases at pressures of 1000-10000 Pa, flow rates of 0.01-0.1 slpm and applied powers from 500 to 1800 W (5-20 W/cm^3). Detailed description of the facility is given at [7]. For the present work, iron pentacarbonyl was employed as the powder precursor for the synthesis of ferromagnetic powders. Saturated vapours of $Fe(CO)_5$, at corresponding partial pressure P_p ≈4000 Pa, were diluted with the argon, and the resulting mixture, of 5% vol. *iron* carbonyl and 95% vol. *Ar*, was supplied to the plasma reactor at 0.015-0.020 slpm. The plasma was operated under *P*=100-200 Pa and power density of 4-6 W/cm^3. Synthesized powder product was collected by a filter, located at the exit of the HF discharge quartz

tube. The iron carbonyl concentrations and exiting gases compositions were monitored by a *Baltzers* QMS 200 mass spectrograph. The *JEOL 100CX* 120 kV microscope, was used for the TEM, *Perkin-Elmer TGS-2* thermo-gravimetric analyzer for the TGA, *Philips* X'Pert MPD powder X-ray diffraction system for the XRD and *Nicolet 5DXB* FTIR spectrometer ofr the IR. A Quantum Design Physical Property Measurement System (PPMS) was used to measure the DC and AC magnetization for the T=2-300 K, for field strengths up to 9 Tesla. The resolutions are 2×10^{-5} emu in DC fields, and 1×10^{-8} emu for the value of AC magnetization. The DC magnetization was measured by utilizing the extraction method.

3.Results

The most abundant product of the $Fe(CO)_5$ processing is a tube walls deposit, observed mostly at the tube upper part in front of the high voltage electrode. Its elemental material was found to be Fe_2O_3; (XRD) capturing more than 90% of the initially introduced iron. The processing also results in the synthesis of smaller quantities of dispersed powders collected on the filter. This NP inception takes place in the reactor quenching zone, appearing as a disruption of the uniform plasma, creating instabilities in the form of swiftly moving and abruptly ceasing streamers. Typically, about 50 mg of black, ultra-dispersed powders were collected on the 2 cm^2 paper filter after the 1-hour experiments. This powder bound about 2-4% of the totally fed iron. TEM images of these powders, obtained in $Ar/Fe(CO)_5$ plasmas, are shown at Figs.1,2. Depending on the plasma conditions employed, the product represents two kinds of NP:

1. dense cores or rods ("nanocigars"), 10 to 50 nm long and several nm wide, encapsulated into layered cells and clustering into transparent flakes (Fig.1). For different conditions such clusters may represent 10 - 80 % of the observed NP. These NP were obtained under a lower plasma pressure, P=110 Pa, gas flow rate of 0.015 slpm and a power of 450-550 W for the total plasma volume of 60-70 cm^3.

2. dense, hexagonal shaped crystals, 20-60 nm in diameter, either individually covered by a transparent coating or integrated into transparent matrices. The conditions are: P=250 Pa, gas flow rate 0.020 slpm and applied power = 550-600 W of (Fig.2).

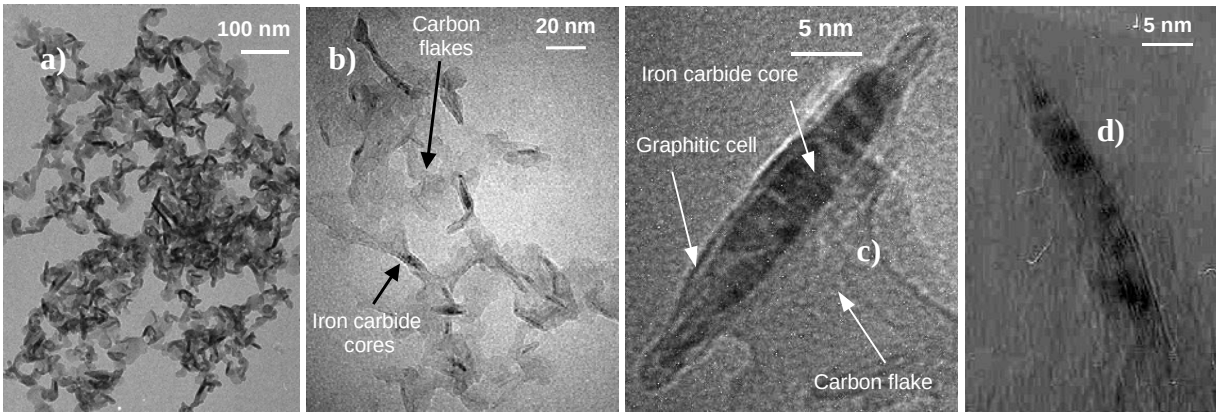

Fig 1. Powders synthesized at P = 110 Pa: iron containing "nanocigars" in graphitic cells integrated into the amorphous carbon matrix. a)-c) TEM; d) HRTEM .

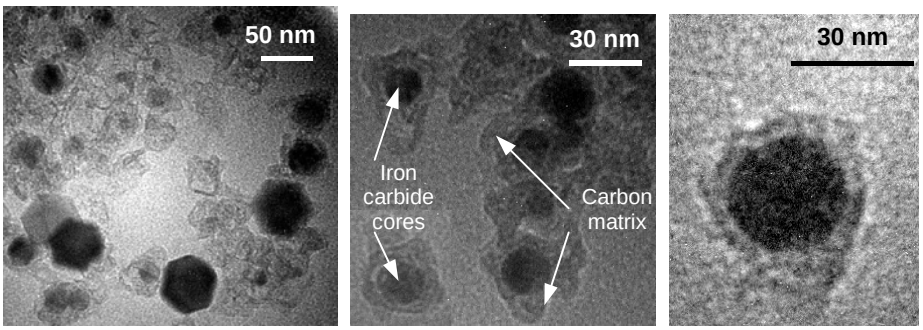

Fig. 2. Powders synthesized at P = 250 Pa; Fe_7C_3/Fe_2C crystals embedded in amorphous carbon.

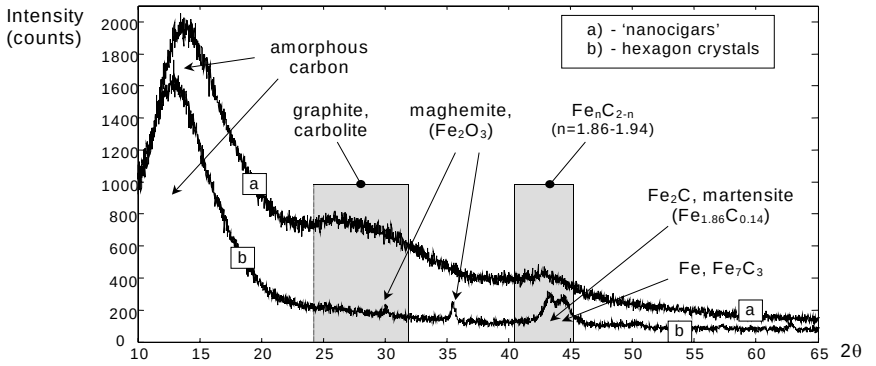

Fig. 3. XRD analysis. Typical NP synthesized at P=110 Pa (a-"nanocigars") and at P=250 Pa (b-hexagon crystals).

As detected by XRD (Fig.3b) and elementary analysis, for the first NP kind, the cores of "nanocigar" powder particles contain iron, either in the form of Fe_2C or as inter-phase surface *Fe* atoms, bound with carbon. The surrounding layered cells are graphite-like structures (detected by e^--diffraction), it correlates with the presence of graphitized carbon in NP (Fig. 3). Cell graphite planes have structural similarities with other metal carbide/graphite NP [13] or MWNT, with their graphite-like atomic bonding and hybridization. Core and cell layered structures are also observed by HRTEM (Fig. 1d). The surrounding flakes are amorphous, yielding to the intense diffuse XRD peak at 2θ =12-18° (Fig.3). Peaks at 22-28°, belong to graphitic structures. Both matrix carbon and iron carbides Fe_nC_{2-n} (n=1.86-1.94), contained in NP can contribute to the diffuse peak at 42-45°. The e^--diffraction pattern reveals as well the absence of structure, as is to be expected if the amorphous carbon forms the bulk of the matrix [14]. In the second kind of NP, the hexagonal shaped crystals consist of a mixture of iron carbides, the observed XRD peaks can be attributed: the 43.0-43.5° to Fe_2C or to martensite, $Fe_{1.86}C_{0.14}$; the 44.0-44.5° to iron, to Fe_7C_3 or to χ-Fe_5C_2 carbides [14]. Possible lattices for both Fe_2C and Fe_7C_3 (*bcc* pseudo-hexagonal) [15, 16] are consistent with the observed hexagons. The χ-Fe_5C_2 or Fe_7C_3 are the more stable phases among the mentioned carbides, they can also be final phases of Fe_2C transformation, presumably via $Fe_{2.2}C$ [8, 17]. Both ε-Fe_2C and ε'-$Fe_{2.2}C$ are thermally unstable hexagonal carbides [8]. Thus, the observed hexagon crystals are to be attributed to the Fe_7C_3, with a possible admixture of the Fe_2C phase. A similar composition of iron carbides' nanostructures has been obtained from $Fe(CO)_5$ by the e^--beam induced CVD [10]. The transparent matrices, embedding nanocrystals, should be associated with the amorphous carbon, yielding to the 2θ =12-17° peak (Fig.3). The traces of Fe_2O_3 /maghemite are also observed, with 30.2, 35.6, 63.0° peaks. This can result from the post-oxidation, suggesting that not all nanoparticles are completely coated by the carbon.

The Fig. 4 presents TGA of two kinds of synthesized NP. It is assumed that various carbon phases form volatile products of oxidation, while free and carbon bonded iron remain in the residuals. For the absolute mass loss data, in the case of hexagon crystals, the residual product constitutes ≈45% of the initial mass. Supposing this to be the Fe_7C_3 phase (XRD data), the iron mass fraction in the NP is ≈41%. In the case of "nanocigars", the residuals have only ≈4.1% (3.8% of iron mass fraction). A small 1% gain at T>700°C is related to the formation of non-volatile oxides and means that vulnerable to oxidation non-bonded iron is present in the "nanocigars". Differential gravimetry (Fig.4b) reveals at least one distinctive peak at 400-410°C common for both kinds of NP, and one extra peak at ≈500°C for "nanocigars". The 410°C peak should correspond to the combustion of amorphous carbon, the 500°C peak – to the combustion of graphite-like cells of "nanocigars" [12, 18]. This difference between the two kinds of NP is consistent with the TEM and XRD detection of a graphitic phase for the "nanocigars", and with the absence of this phase in the hexagonal crystal NP. Further separation of TGA peaks suggests that a third combustion peak exists at 280-320°C. This can be also attributed to the amorphous carbon phase [12,18].

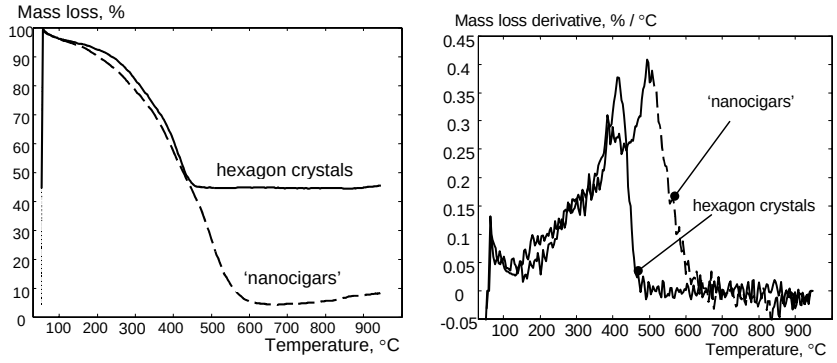

Fig. 4. TGA results for two kinds of powder a) mass loss b) differential mass loss. Two mass loss peaks at 410°C and 500°C correspond to the amorphous carbon matrix (both cases) and graphitic phase ("nanocigar" cells only).

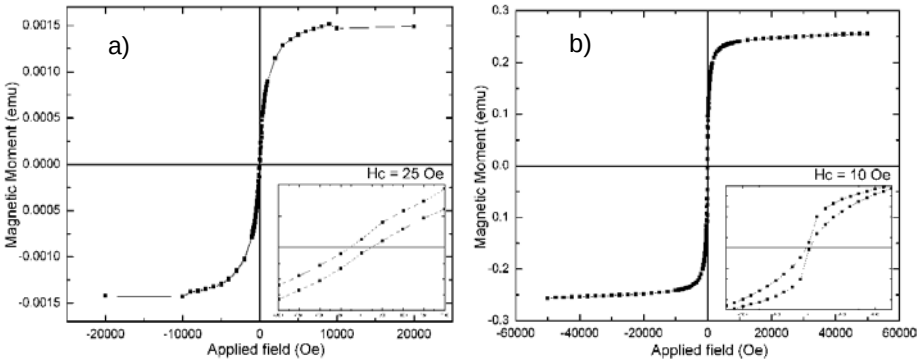

Fig. 9. Field dependence of the magnetization at 293 K for the two types of powder samples: a)"nanocigar" and b) hexagon. Mass of the sample m ≈ 6 mg.

The FTIR spectroscopy revealed two diffuse peaks of 1659 cm^{-1} and 1590 cm^{-1}, for all samples. They are associated with vibrational *C-O* bonds, arising from traces of oxygen. While the undisturbed CO_{vib} has apeak at 1659 cm^{-1}, the *Fe-CO* interaction results in its shift towards 1590 cm^{-1}, thus confirming the formation of carbon-iron chemical bonds [19]. The 1590 cm^{-1} peak relative intensity is higher than that of 1659 cm^{-1} for the hexagon crystals NP; therefore higher iron contents can be expected in this case, which corresponds to the higher iron content, as detected by TGA and XRD for this NP type.

Fig.9 presents results for induced magnetization of NPs as a function of the applied magnetic field. Powders synthesized at higher pressures have their magnetic moment saturation, M_S ≈50 emu/gr, typical for a variety of ferromagnetic NP [19, 20, 22]. The lower pressure synthesized "nanocigars" have a very low M_S value, ≈0.3 emu/gr and no ferromagnetic properties; the coercive forces H_C are 25 Oe and 10 Oe, respectively. The zero field cooling/field cooling (ZFC/FC) analysis of the hexagon crystal NP shows an intersection of the two curves, corresponding to a blocking temperature T_B, at ≈280 K. Thus the NP is ferromagnetic at $T<T_B$, and becomes superparamagnetic at $T>T_B$ when thermal fluctuations start to randomize the orientation of domains. The H_C is relatively high, meaning that each particle might contain several magnetic domains. The effective magnetic anisotropy constant (*K*) of the NPs can be estimated from T_B: $K=25kT_B/V$ (*V* is the particle volume). For the typical NP crystal sizes of 20-40nm a value for $K\approx 3000\text{-}5000\ erg/cm^3$ can be estimated, i.e. this powder has a relatively high magnetic anisotropy.

The mass-spectrography (MS) demonstrated complete $Fe(CO)_5$ decomposition; the iron supplied with the $Fe(CO)_5$ always remains bound within solid phases; the differences in the experimental conditions result in changes to the fractions of the exiting *CO* and CO_2 species. Increased pressure leads to the rise of the *CO* and CO_2 fractions, detected at the reactor exit, in comparison with that of *Ar*. Consequently, higher *Fe/C* ratios can be expected in those solid phases collected in the reactor under the higher pressure. It is consistent with the synthesis of ferromagnetic NP (hexagon crystals) exclusively from the higher pressure (250 Pa) plasma and is confirmed by the results of TGA and XRD measurements.

4. Discussion

The results obtained demonstrate that kinetics mechanisms for carbides and oxides formation in $Ar/Fe(CO)_5$ plasma may differ, and depend principally on the pressure conditions. Power input and gas flow rate in experiments are related with the pressure, to ensure the formation of the NP synthesis quenching zone. Experiments at the higher pressure (250 Pa) had, in comparison with these at 110 Pa, a 10% approximately higher power and a 30% higher gas flow rate and hence a 20% lower specific power value. Thus, higher pressure could result in lower gas temperatures. The gas temperatures for the present case are expected to be around 700-900 K (compare with the conditions of [7]), and electron temperatures $T_e \leq 1$ eV. For such a plasma, the part of the thermal conductivity λ, related to *CO* excitation and dissociation, can became pressure dependent [24], thus increasing the λ value for the higher pressure case. Hence, higher pressures can result in higher thermal losses and become a factor for the temperature decrease seen in the 250 Pa case. $Fe(CO)_5$ easily decomposes at temperatures >200°C, with *CO* decomposition following, via: 1) $CO^*+CO^* \rightarrow C+CO_2$; E_a=6eV, ΔH=5.5eV/mol and 2) $CO_2^* \rightarrow CO+1/2O_2$; E_{diss}=5.5 eV. Though the activation energies E_a of these reactions are quite high for the present non-thermal conditions (low T_{kin}), the reactions remain stimulated by the *Fe* nanoparticles, which are active graphitization catalysts, and through the vibrational excitation of the *CO* and CO_2. The latter factor is important because, from the results of [7], it can be presumed that for the plasma conditions of this present work: $T_e > 6000$ K >> $T_{gas} \approx$ 700-900 K.

Thus, the plasma chemistry considered represents competing processes for formation of iron carbides and oxides, in reactions involving *CO* and its reforming products. High rates of Fe_2O_3 deposition on the discharge tube walls mean an abundance of *Fe* oxidation products in the system. However, the formation of carbides (Fe_3C, Fe_2C, χ-Fe_5C_2 or Fe_7C_3), either directly from the gas phase or via transformation of iron particles, should remain a competing process at temperatures 700-1400 K [25]. For the range considered and up to 3000 K, the carbides' formation is endothermic, (e.g. for the Fe_3C $\Delta H^0_{solid} \approx$25 kJ/mol); while the formation of the presumed oxide species (FeO, Fe_2O_3, Fe_3O_4) is exothermic, with $\Delta H^0_{solid} \approx$-270, -820 and -1120 kJ/mol respectively [23, 26]. Hence, most of iron is bound within oxides, so forming the Fe_2O_3 wall deposit. Generally, temperature increase should decrease the carbides' fractions. Thus, the products of the reaction $3Fe + 2CO \rightarrow Fe_3C + CO_2$ are thermodynamically favored (ΔG<0) up to about T=1000K [27]; for higher T the equilibrium in the system is shifted towards free iron and its oxides. Formation of the higher carbides results, as a rule, in a greater decrease of entropy than formation of oxides, the latter process passes with lesser impact on the entropy [23, 27]. Reducing the entropy at higher T leads to greater impact on the rise of ΔG, therefore *Fe* carburization becomes less favored with rising temperature. The diffusive removal of the oxidation products, such as gaseous *FeO*, towards walls may also influence reactions chains. It is slowed by raising the pressure, thus shifting the equilibrium for oxidation reactions towards the initial species (free iron, *CO* and CO_2) [27, 28], thereby favouring the carbides formation. The estimation of mean free path χ for molecular *FeO* yields values of $\chi \approx 0.31$ and $\chi \approx 0.13$ mm for P=110 and P=250 Pa respectively. The turbulent mixing in the reactor tube (d=20 mm), can result in effective stirring. Then the mentioned change in the mean free path can drastically influence the removal of *Fe* oxides from the reaction zone, thus inhibiting further oxidation and favouring the carbide synthesis through the release of iron vapours.

We can conclude that the pressure rise changes the plasma kinetic processes in favor of volume formation of iron carbide solids. The NP properties change from the iron poor carbon clusters, with "nanocigars" (Fig.2), formed at 110 Pa pressure, to the synthesis of iron/iron carbide hexagon crystals (Fig.3) at 250 Pa. The appearance of less stable carbides instead of cementite (Fe_3C) in the ferromagnetic NP, can be favored by the carburizing environment containing up to 20 % vol of *CO*, shifting the phase balance of carbides from Fe_3C towards Fe_2C [25]. The presence of the less stable/intermediate carbides (Fe_7C_3, Fe_5C_2, Fe_2C) and the absence of cementite can also be related to the fast quenching of the plasma gas. For both kinds of NP, metal or carbide particles act as templates for the coating [25]. A possible formation mechanism for the graphitic cells of "nanocigars" is that of carbon dissolution in metal particles, followed by diffusion and precipitation of the graphitic phase on the surface. Oversaturation of the solution by carbon may also result in the formation of carbides, creating bulk particles or acting as a barrier against further penetration of carbon. The very low

saturation magnetization of "nanocigar" NP must be due to its very low *Fe* content and is probably due to the diamagnetic behaviour of the surrounding graphitic cells. A decrease in the M_S and a rise of the graphite fraction, for the temperatures over 1000°C, was observed for the CVD synthesis of nanostructures derived from $Fe(CO)_5$ [22].

5. Conclusions

A gas phase synthesis of nanosized powders, composed of iron/iron carbides embedded in carbon, was performed in RF CC plasma of $Ar/Fe(CO)_5$. Two kinds of nanopowders can be obtained: a) a high iron content NP (at over 40% mass of *Fe*), consisting of hexagonal carbide crystals (Fe_7C_3 or Fe_2C) embedded in amorphous carbon. This NP is produced under the P=250 Pa and demonstrates ferromagnetic properties; b) low iron content NP (less than 4% mass of *Fe*), formed from tiny nanorods of iron/iron carbides, surrounded by graphitic cells and integrated into the amorphous carbon matrix. This NP are produced under P ≈110 Pa and they are diamagnetic. The chemistry in the system is determined by the competing reactions of iron oxidation and carburization. Higher pressure conditions may: a) correspond to the lower gas temperatures, which favor the shift of the chemical equilibrium towards the formation of carbides; and b) slow the removal of *Fe* oxidation products to the reactor walls and thus shift the oxidation equilibrium towards non-bound iron and the formation of carbides. Adjusting the applied RF power, precursors' feed rates and the system pressure, provides control of the physical-chemical reaction kinetics and the powder product properties. The carbide particulates obtained at higher pressures are isolated and have no magnetic coupling. This NP can be applied as a precursor for the fabrication of bulk ferromagnetics with new magnetic permeability, hysteresis width or re-magnetization frequency. Using H_2 or CO admixtures in the plasma gas, and in scaling-up the processing facility, might reduce the co-fabrication of the amorphous carbon and increase the desirable NP output.

Abstract
A thermal and chemical non-equilibrium model, developed recently by the authors [1] of this paper, is applied to the modelling of multi-component supersonic induction Ar-H_2 plasma flows and to calculate the heat flux from the supersonic plasma flow to a copper substrate, which is put 45mm below the M4 supersonic nozzle exit. The model treats the subsonic discharge region above the supersonic nozzle and the supersonic region below the nozzle together. Three numerical schemes, provided by a commercial software, FLUENT, are used to the modelling of the supersonic plasma flow. It is found that FLUENT's coupled solver with second order upwind scheme, gives the best heat fluxes to the substrate, compared to the experimentally measured heat fluxes.

1. Introduction.

For the industrial and laboratory applications of induction plasma, such as, inductive plasma coatings, material processes, the formations of ultra-fine particles etc. a variety of mixtures of different gases are used as the working gas for the induction plasma torch and in some case the supersonic plasma flows, generated by the inductive plasma torch with a supersonic nozzle installed a few centimetre below the induction coil, are preferable for the applications [2]. The multi-component plasmas are normally neither in thermal equilibriums nor in chemical equilibrium, especially at low pressure. To predict the behaviours of these multi-component supersonic induction plasmas accurately a thermal and chemical non-equilibrium model is necessary.

In last a few decades, many publications [3-9] in the literature deals with the thermal no-equilibrium of the inductive plasma with pure argon as the working gas and some of the published papers in literature devoted to the modelling of supersonic plasma flow of pure argon under the thermal non-equilibrium without the treatment in the discharge region. A few publications reported the treatment of the multi-component Air[10-11]] and Ar-N_2[12] plasma under the thermal and chemical non-equilibrium state. In this paper, a thermal and chemical non-equilibrium model for multi-component argon-hydrogen[1] (Ar-H_2) plasma, developed recently, is applied to the modelling of argon-hydrogen supersonic plasma flow and to calculate the heat flux from the supersonic plasma flow to a copper substrate which is placed 45mm below the exit of M4 supersonic nozzle. The model for the inductive supersonic plasma flow modeling has been improved from the separate treatment[32] of discharge region and supersonic flow region to a united model, which treats the subsonic discharge region and the supersonic region below the nozzle together. The comparisons between the calculated heat fluxes from the model and the experimentally measured ones are made. Different numerical schemes are used to simulate the same supersonic flow and calculate the heat fluxes to the substrate it is found that FLUENT's coupled solver with second order upwind scheme, gives the best heat fluxes to the substrate, compared to the experimentally measured heat fluxes.

The thermal non-equilibrium model in the last half centuries remains almost the same, except for some improvements in transport properties used for non-LTE modelling. All the thermal non-equilibrium (two-temperature) models for pure argon plasma are similar to the first non-LTE model, proposed by M. Hoffert[13]. The only chemical reactions includes in the model for the pure argon plasma flow are the ionization of argon and the corresponding recombination. The rate coefficient of ionization is derived under the assumption that all bound electrons in the atom are thought to be ionized provided that they can reach the first excitation state and the recombination coefficient is derived through the condition that at Saha equilibrium electron density the net production rate of electrons equals to zero. The recombination coefficient thus derived become too big at low

temperature region near the quartz wall. At low temperature, Hoffert's recombination coefficients do not agree well with the experimental measurement[5]. For our present modelling, at high electron temperature region Hoffert's recombination coefficients are still used but in low temperature region the recombination coefficients from Biberman[14] for argon and from van de Sanden[15] for hydrogen, both are deduced from the experimental measurements and valid at low temperature, are used. In the modelling the smaller of the two recombination rate coefficients are used.

The accuracy of the model prediction depends on the accuracy of the transport properties. For thermal and chemical non-equilibrium multi-component plasma the transport properties are not only the function of electron and heavy species temperature but also the function of plasma compositions, electron density and pressure. Although the transport properties for many monatomic and diatomic gas plasmas, or their mixture, are available in the literature most of these data are obtained under that assumption of the plasmas being in LTE. Some authors calculated the transport properties by assuming two-temperature plasmas (non-LTE) but the Saha equilibrium electron density, calculated using the electron temperature, was still used. For induction plasma the electron density in discharge region is always different from the Saha equilibrium electron density at whatever pressure, otherwise there will be no electrons produced in the discharge region. And for supersonic plasma flow, the pressure change dramatically. Therefore, the available published transport properties data are not appropriate for non-equilibrium supersonic plasma modelling. That's a drawback in many of the published thermal non-equilibrium supersonic models. A proper way to get the transport properties for the supersonic plasma modelling is to calculate them directly from the collision cross-sections or the collision integrals between species in the mixture using the formulas, derived by Hirschfelder, Curtiss and Bird[16]. The transport properties thus obtained are used for our present thermal and chemical non-equilibrium model. The collision integral data are taken from publications[17-19] of Murphy, Devoto and Mason. The temperature in the data of collision integrals between two species is considered to be that of heavy species if no species in the two is electron, otherwise, the temperature is assumed to be the electron temperature because the collision integrals depends on the relative velocity between the two species. The binary mass diffusion coefficients between the species in the mixture are also calculated from these collision integral data. The effective mass diffusion coefficient of a species in the mixture is calculated using Stefan-Maxwell relations from the binary mass different coefficient and the Ambipolar electrical field is not included in the Stefan-Maxwell relations because it is difficult to get the effective mass diffusion coefficient from the full multi-component diffusion formulations[20] with the Ambipolar electrical field being included. Then the ambipolar effects of charged species are approximately taken into account by adding a factor of $(1+T_e/T_h)$ to their effective mass diffusion coefficient. Mass conservation equations are solved to obtain the mass fractions or mole fractions or the number densities of all the species except for electrons. The electron number density is determined by the condition of electrical neutrality, $N_e=N_{H+}+N_{Ar+}$. The electron electrical conductivity and thermal conductivity are calculated using Devoto's second order formulas [21]. The modelling of turbulence effect on the plasma flow is based on the Reynolds stress turbulence model[22-23] using standard wall function[24].

2. Description of the model

The multi-component plasmas includes six species: e, H, H+ H_2, Ar+ and Ar. It is assumed that all the species except for electron have the same temperature and all the species have the same convective velocity. The electron temperature is allowed to deviate from that of the heavy species. The plasma flow is assumed to be steady, axisymmetric and turbulent.

a. Model equations

Since the chemical reaction energies are treated as the source term, the energy conservation equations for electrons and heavy species take the following forms:

$$\nabla\cdot(\frac{5}{2}kn_e\vec{u}T_e)=\nabla\cdot((\lambda_e+\mu_t C_{pe}/\mathrm{Pr}_t)\nabla T_e)+P_{Ohmic}-P_{ir}-P_{eh}-P_{rad}+\vec{u}\cdot\nabla p_e \quad (1)$$

$$\nabla\cdot(\vec{u}\sum_j C_{pj}Y_jT_h)=\nabla\cdot\left\{(\lambda_h+\mu_t C_{ph}/\mathrm{Pr}_t)\nabla T_h-\sum_j C_{pj}Y_jT_h\vec{J}_j\right\}-P_{dr}+P_{eh}+\Phi_\mu+\vec{u}\cdot\nabla p_h \quad (2)$$

where the summation is over all the heavy species and n_e, T_h, p and λ are electron number density, heavy species temperatures, static pressure, and thermal conductivities, respectively. C_{pj} ,Y_j, J_j, μ_t and Pr_t are the specific heat, mass fraction and mass flux of species j, turbulent viscosity and Prandtl number, respectively. P_{eh} represents the energy exchange rate through elastic collision between electron and the heavy species, P_{ir}, the net ionization or three-body recombination energy exchange rate, P_{dr}, the energy exchange rate due to H_2 dissociation and the corresponding recombination, Φ_μ , the viscous dissipation, P_{rad}, the volumetric radiation losses and the last term in Eq.(1) and Eq.(2), the pressure work. The electron pressure work may be neglected because $\vec{u} \cdot \nabla p_e$ is related mainly to the energy transfer between the thermal energy and the mechanical energy of electrons. Even for supersonic flow, the mechanical energy of electrons is negligible due to their small mass.

The mass fraction Y_j of a species in the mixture are determined from the conservation equations of the species:

$$\nabla \cdot (\rho \vec{u} Y_j) = \nabla \cdot ((\rho D_{j,m} + \mu_t / Sc_t) \nabla Y_j) + R_j . \quad (3)$$

where $\rho = \sum_j \rho_j$ is the total mass density and $D_{j,m}$ is the effective mass diffusion coefficient of a species in the mixture. R_j is the net mass production rate of species j. Among the 6 species, only 4 mass fraction equations are solved. The principal species, argon, is determined by the condition that summation of mass fractions of all the species is unity and the electron number density is obtained by the condition of electrical neutrality. The mole fraction X_j of a species can be computed for the mass fractions:

$$X_j = (Y_j / M_j) \sum_j (Y_j / M_j)$$

And then the number density N_j of a species can be calculated by the following:

$$N_j = p \cdot X_j / (kT_h (1 - X_e) + kT_e X_e)$$

where $p=p_e + p_h$ is the total pressure and k is the Boltzmann constant.

$$p = kT_h \sum_{j \neq e} (N_j) + kN_e T_e$$

According to condition of electrical neutrality of charge:

$$N_e = N_{H+} + N_{Ar+}$$

The electromagnetic fields are obtained from solving the vector potential equation using the extended field model[25]. Momentum equations are same as these for pure argon plasma [26]. The Reynoids stress model equations used in the present modelling are described in Ref.[26].

b. Chemical reaction

Four chemical reactions are included in the modelling:

(1). The H_2 dissociation and the corresponding recombination induced by Ar:

$Ar+H_2 \leftrightarrow Ar+2H$

(2). The H_2 dissociation and the corresponding recombination induced by the H_2:

$H_2+H_2 \leftrightarrow H_2+2H$.

The forward and backward chemical reaction coefficients k_f and k_b for (1) and (2) can be found in Ref.[27].

(3) The argon ionization and the corresponding recombination

$Ar + e \leftrightarrow Ar^+ + 2e$

The forward reaction rate was given by Hoffert[13]. The backward reaction, the three-body recombination rate k_b coefficient is calculated based on the condition that at Saha equilibrium electron density, the net electron production rate is zero. In low temperature region, the backward coefficient thus obtained is too high and an experimentally deduced recombination coefficient[15], which is valid at T<5000K, is used

$k_b = 7*10^{-22} T^{-4.6}$ ($m^6 s^{-1}$)

In the modelling, the smaller of the two backward coefficients is used. The net electron production rate is:

(4) The hydrogen atom ionization and the corresponding recombination

$$H + e \leftrightarrow H^+ + 2e$$

For the ionization of hydrogen atom, the rate coefficient is calculated from the experimentally determined excitation cross-section of hydrogen atom[25]. It is assumed that the excitation rate coefficient from 1S to 2S and 2P equals to that of ionization. The way to calculate the backward coefficient is same as that to calculate backward coefficient of reaction (3). In the low temperature region [14]

$$k_b = 7*10^{-20}T^{-4.5}\ (m^6s^{-1})$$

In the same way, the smaller of the two backward coefficients is used in the modelling.

c. Transport properties

Since the published transport property data are obtained using either the condition of LTE or Saha equilibrium electron density or the both, the transport properties for our present modelling are computed directly from the collision integrals or the collision cross-section. The expressions, derived by Hirschfelder, Curtiss and Bird[16] and based on the first Chapman-Enskog approximation, are used to calculate the viscosity and translational thermal conductivity. The contributions of rotational and vibrational energies of hydrogen molecules to the thermal conductivity is calculated using Yos's mixing law[11,29]. The collision integral data are taken from publications[17-19] of Murphy, Devoto and Mason. The second approximation formulas [10, 21], given by Devoto in 1967 are used to calculate the electron thermal conductivities and electrical conductivity. The binary and effective mass diffusion coefficients (D_{ij} and D_j) are given by[20,30]

$$D_{ij} = \frac{3}{8}\left[\frac{(m_i + m_j)kT}{2\pi m_i m_j}\right]^{1/2} \frac{kT}{P\Omega_{ij}^{(1,1)}(T)} \qquad D_j = \frac{1 - X_j}{\sum_{i \neq j} X_i / D_{ij}})$$

If no species is electron, T is the heavy species temperature, otherwise T is the electron temperature. The effective mass diffusion coefficients D_j of a species in the mixture are computed from the binary mass diffusion coefficients using Stefan-Maxwell relation.

The ambipolar diffusion coefficient $\overline{D}_j$ of the charged heavy species may be written approximately as:

$$\overline{D}_j = D_j(1 + \frac{T_e}{T_h})$$

The boundary conditions are described on detail in Ref.[1, 22].

3. Computational results

The RF plasma torch, as used in this study, is the Tekna PL-35 with a M4 supersonic nozzle installed 25mm below the induction coil. The torch dimensions can be found in Ref.[31]. The working frequency of the power supply is 5.5MH_z. The gas flow rates used for the M4 supersonic plasma flow experiments (25.2kW plate power) are: the sheath gas flow rate, 50slpm Ar + 1slpm H_2. The swirling (75^0 relative to axis) central gas flow rate is 2.5slpm. The measured pressure from the working chamber is 13.5 torr (around 1800pascal).

The modelling results below are obtained from the FLUENT's coupled solver with second order upwind scheme. Under previously mentioned operation conditions the contours of stream function, pressure are shown in Fig.1. As can be seen from this figure, the pressure in the discharge region reaches 4.3 atmospheric pressures, while the minimum pressure (around 18mm above the substrate) in the working chamber is only 73 pascal. The pressure ratio reaches 5912. At such high pressure in discharge region, the electron and heavy species temperatures, shown in Fig.2 are almost the same. Fig.3 indicates the magnitude of velocity and Mach number. The maximum Mach number reaches 6.9. The mole fractions of H_2, H, H^+ and Ar^+ are shown in Fig.4 and Fig.5. As can be seen from Fig.4, almost all H_2 molecules are dissociated in discharged region. This is different from the case of low pressure[1], where only part of the H_2 molecules is dissociated even in high temperature region(T>6000K). The reason is simple, that is, at high pressure the H_2 molecules have enough time to dissociate before they are carried away to the downstream. Also in the case of high pressure (Fig.5), 28% charged particles are hydrogen ions. Fig. 6 shows the heat flux to the substrate from the supersonic plasma flow to the copper substrate. The heat fluxes

are obtained by using three different numerical schemes, the FLUENT's coupled solver with second order upwind scheme, the coupled solver with first order upwind scheme and the segregate solver with first order upwind scheme, for the modelling of the supersonic plasma flow. The measured heat fluxes are also shown in Fig.6. By the comparison with the measurement, FLUENT's coupled solver with second order upwind stream scheme gives the best heat fluxes.

Abstract
This paper discusses some aspects of n-hexane soot reactivity in a multi-pin to plate pulsed corona discharge working in the nanosecond regime. The soot-discharge interaction was quantified by measuring the densities of the resulting CO and CO_2. Results showed an enhancement of soot oxidation for $\%O_2$ greater than 10 and cathode temperatures above 150°C. A saturation effect in the treatment efficiency is observed at high power and $\%O_2$, which would indicate that the reactivity is kinetically limited by the de-sorption of CO and CO_2.

1. Introduction

The incomplete combustion of hydrocarbon fuels is known to produce carcinogenic compounds such as polycyclic aromatic hydrocarbons (PAH) and soot particles [1]. The emission regulation for these compounds are becoming more and more stringent, and new technological approaches for the removal of these pollutants from flue gas are needed to fulfil the emission limits expected in the near future.
Among these new technologies non-thermal plasmas techniques are certainly one of the most promising. Pulsed corona and dielectric barrier discharges have been indeed already used, sometimes as a part of a more complex process, to remove SO_x, NO_x and VOC compounds from flue gas [2-4]. Their use lies on their ability to produce a very active medium that contains highly reactive species, like O-atom and OH-radical, through electron-impact dissociation.
This work, is related to the investigation of n-hexane soot reactivity under atmospheric pressure pulsed corona discharges (APPCD). Its purpose is to assess the potentiality of APPCD process as a mean to remove soot particles from flue-gas.
The soot reactivity was investigated in term of the concentrations of CO and CO_2 that result from the interaction between the discharge streamers and the soot particles. The discharge parameters investigated was the oxygen percentages in the feed gas, the cathode plane temperature and the discharge frequency.
The paper is organized in 4 sections. In the next one the nanosecond pulsed corona discharge cell is described and its electrical characteristics are discussed. section 3 describes how n-hexane soot is synthesised and gives the main features of soot particles as derived from gas phase chromatography. section 4 reports a parametric study of soot gasification where the effect of oxygen in the feed gas, temperature and discharge frequency are investigated.
Results showed very weak soot reactivity for oxygen percentage below 10% in the feed gas. This reactivity becomes much more significant at higher O_2 percentage. Similarly, the soot reactivity strongly increases above 150 °C . The amount of CO_2 and CO produced from the interaction between the soot and the discharge increases linearly with the discharge frequency.

2. Main characteristics of the nanosecond pulsed corona discharge

The discharge investigated in this work is schematised in figure 1. It consists of a multi-pin anode, with up to 300 pins, and a plane electrode. The typical gap distance is around 0.7 cm and the plane-cathode on which soot particles are deposited may be heated up to 200 °C with the help of small cylindrical heating rod. The electrode system is placed in a 56 mm diameter cylindrical Pyrex cell. The feed gas enters the discharge cell from the bottom plane electrode and the flue gas resulting from the interaction between the discharge streamers and the soot exits from a second exit hole drilled in the cathode.
The pins are connected to a high voltage supply that may deliver up to 40 kV voltage steep front with a rise time of around 10 ns. To prevent transition to the arc regime a resistor is placed in parallel to the high voltage electrode, which enables to keep the discharge duration below 200 nsec. Figure 2 shows a typical voltage pulse used to produce the investigated discharge. The current corresponding to the voltage signal of figure 2 is shown in figure 3. The current pulse shows several oscillations with

maxima that reach 100 A. This value corresponds to an average current of 330 mA for each pin. The discharge current cancels after 200 ns duration. The energy absorbed by the discharge during a single pulse was evaluated by integrating the voltage-current product over the discharge duration. The values for the energy deposited in the discharge obtained for several oxygen percentages in the feed gas are shown in figure 4. They ranges between 45 and 60 mJ per pulse. For constant input voltage and electrode gap this energy decreases when increasing the oxygen percentage in the feed gas.

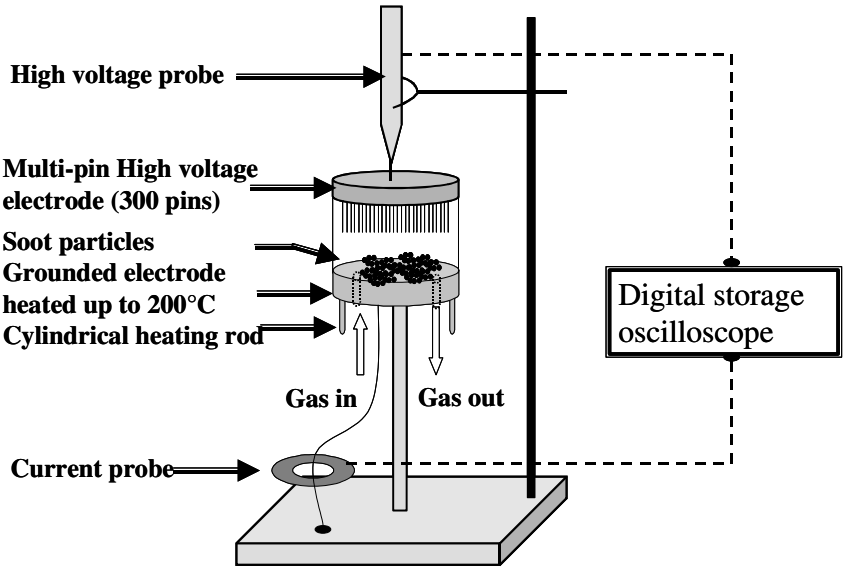

Figure 1. Schematic diagram of the experimental apparatus for the treatment of soot with a corona dicharge

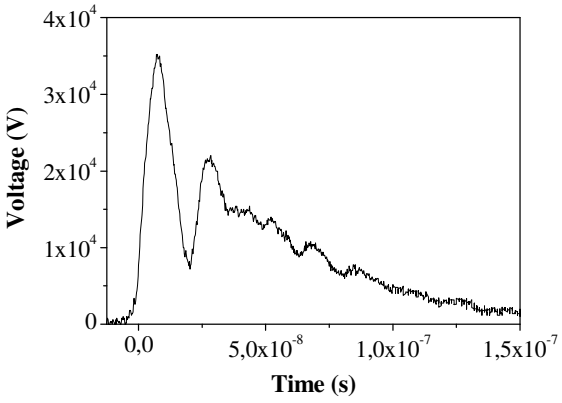

Figure 2. Voltage pulse as a function of time.

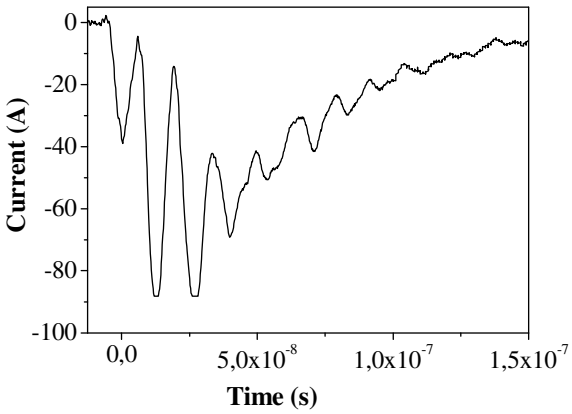

Figure 3. Current pulse as a function of time

3. n-hexane soot synthesis and characterization

Soot particles were synthesised from the combustion of liquid n-hexane. Figure 5 shows the FTIR spectrum of freshly produced soot. This spectrum exhibits several absorption bands associated to the aromatic C=C bonds (at 755 cm^{-1}, 840cm^{-1} et 880 cm^{-1}), the 1590 cm^{-1} which corresponds and the 3040 cm^{-1} and 1440 cm^{-1}bands that correspond to C-H bonds of aromatic compounds.

This first FTIR characterization would show that the soot is mainly composed of aromatic rings that may be substituted by radical groups and linked with anhydride bridges. This result is in quite good agreement with that of reference [4].

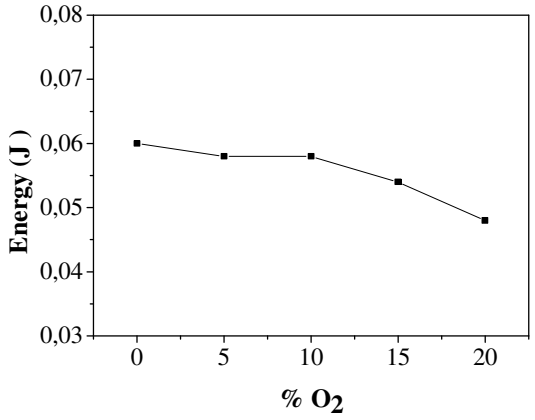

Figure 4: Energy deposited in the discharge as function of oxygen percentage

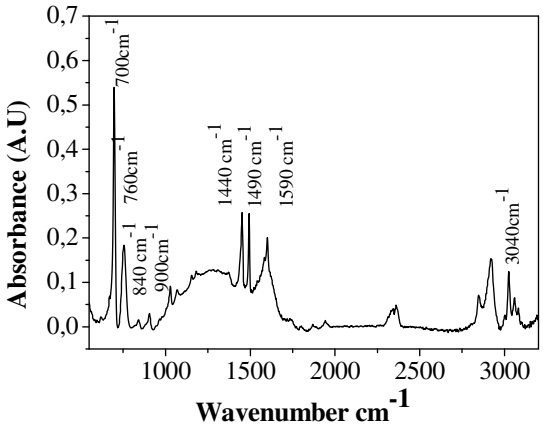

Figure 5 : FTIR spectrum of freshly produced n-hexane soot

4. A parametric study of soot particle reactivity in the pulsed corona discharge.

To investigate the reactivity of soot particles in the presence of the atmospheric pulsed corona, 40 mg of particles was introduced in the discharge vessel and placed on the cathode plane. They were subsequently treated by the discharge streamers produced in a N_2/O_2 mixture during several minutes. The total flow rate in the discharge vessel was set to 100 sccm and the cathode temperature was set at a constant value that was changed between 25°C and 200°C.

The soot reactivity was investigated in term of CO and CO_2 concentration in the flow exiting the discharge vessel. CO_2 concentration was measured by integrated infrared absorption spectroscopy while CO concentration was measured by a commercial electrochemical cell.

4. 1. Effect of oxygen amount in the feed gas

The variation of CO_2 concentration in the discharge cell outflow as a function of oxygen content in the feed gas for a plane cathode temperature of 200 °C and pulse frequency of 6 Hz is shown in figure 6. CO_2 concentration in the discharge cell outflow for pure N_2 discharge is around 30 ppm. This shows that there exists a small amount of CO_2 that desorbs from soot particles under interaction with streamer discharges. The increase of $\%O_2$ from 0 to 10 % leads to the increase of CO_2 concentration from 30 to 200 ppm. Further increase of $\%O_2$ between 10 and 20% leads to more than twofold variations of CO_2 concentration in the outflow.

The variation of CO concentration, x_{CO}, in in the discharge cell outflow is shown in figure 7. x_{CO} increases from 30 ppm to 140 ppm when $\%O_2$ varies between 0 and 20%. The soot oxidation leads therefore to much less CO than CO_2. It is also noteworthy to mention that the CO variation trends are somewhat different from CO_2 variation one. The variation of X_{CO} is indeed much smaller at high $\%O_2$, while CO_2 shows opposite behavior. This result could be expected since at high O_2 percentage the oxidation of soot is likely to result in a preferential formation of CO_2, which would consequently lead to the observed limited increase of CO concentration at high $O_2\%$.

4. 2. Effect of the discharge frequency

The discharge frequency ν_D was varied between 5 and 50 Hz. Figure 8 shows the variation of X_{CO} and X_{CO2} as function of ν_D at a cathode temperature of 140° C and 20% O_2 in the feed gas. Both CO and CO_2 concentrations increase quasi-linearly when ν_D is varied from 5 to 15 Hz and remain almost constant above this frequency. The maximum CO_2 and CO concentration achieved at this temperature of 140 °C are 250 and 400 ppm. This saturation effect would indicate that, for high oxygen content in the feed gas, the limiting step in the soot oxidation kinetics in pulsed corona discharge is not the production of oxidizing species which tends to keep increasing with power input in the discharge. This limitation may be well understood in the light of the surface chemistry model of reference [5]

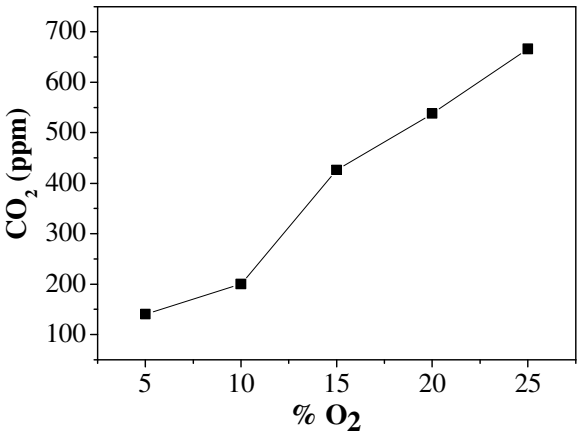

Figure 6: CO concentration in the discharge cell outflow as a function of oxygen at a cathode temperature of 200° C

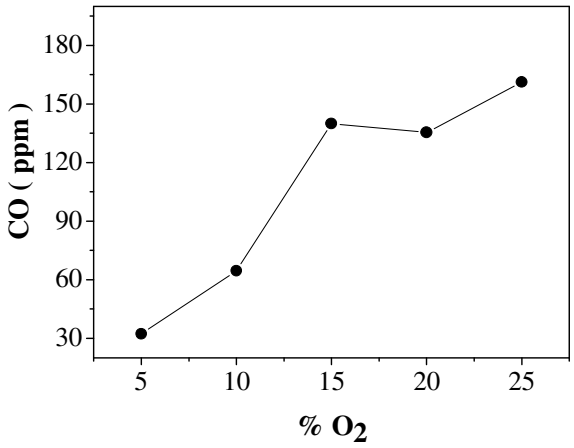

Figure 7: CO_2 concentration in the discharge cell outflow as a function of oxygen at a cathode temperature of 200° C

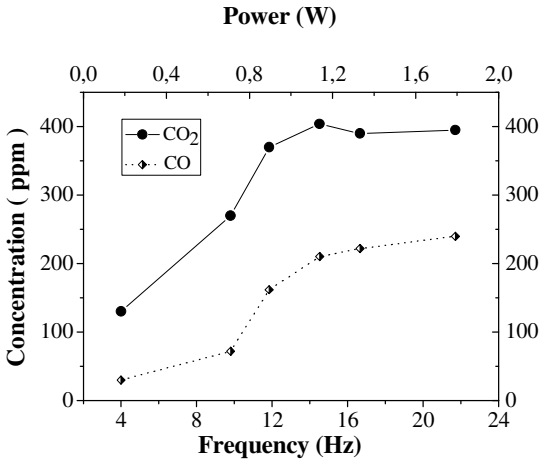

Figure 8: variation of X_{CO} and X_{CO2} as function of ν_D at a cathode temperature of 140°C and 20% O_2

5. Conclusion

The present study showed that soot particles may be oxidized at fairly low temperature by a pulsed corona discharge working in a nanosecond regime. The pulsed corona discharge used are characterized by a discharge pulse duration of 200 ns, a discharge frequency ranging between 4 and 60 Hz and a discharge current that may reach 100 A. The average current per streamer is around 300 mA. FTIR characterization showed that the n-hexane soot investigated in this wok was mainly composed of aromatic rings linked by anhydride functional groups. Results showed that the oxidation of soot mainly lead to the formation of CO_2. The amount of CO is also significant even though it remains below the obtained CO_2 concentration for all the investigated discharge conditions. This result is quite surprising since a preferential CO production was expected at low oxygen concentration in the feed gas. The increase of O_2 in the feed gas leads to a quasi-linear increase of CO and CO_2 in the flow exiting the discharge cell at low discharge frequency, i. e. average input energy. A saturation effect in the increase of CO and CO_2 is however observed in the high energy/high oxygen concentration regime. This would indicate that the soot oxidation kinetics is governed (or limited) by the de-sorption of the oxidation product and not by the production active species in the discharge. This means that further improvement of soot oxidation under discharge conditions would require to enhance the de-sorption kinetics. This may be obtained by increasing the temperature. This solution would however cancel the main benefit that motivates the use of APCCD : the low temperature discharge conditions.

Further effort is therefore needed to find the discharge conditions that would favour both the production of active species and the de-sorption of the products of the oxidation reactions at the soot surface.

Abstract

A new geometry of the powder port ring holder used in atmospheric plasma spraying has recently been designed to avoid lump formation, and successfully tested for a set of process parameters associated with Ni-5Al powder used in production to form bond coat [1]. But with ZrO_2 powder used to made top coat, improvements were not enough satisfactory. Here, we investigate numerically the cause of the remaining defects, and further improve the ring geometry to prevent lump from forming in any part of the coating.

Keywords

1. Introduction

During atmospheric plasma spraying (APS), powder is injected into a plasma jet, melted and deposited onto a substrate. Under standard operation conditions, a back-stream of powder may return to the spray gun, leading to clogging of the nozzle wall. Under certain operation conditions a dramatic increase of clogging frequency can be observed [2]. Typically, this occurs when the carrier gas flow rate is increased above some limit to built-up coatings with enhanced tensile bond strength. When clogging occurs during operation (see figure 1a), the powder clogged on the nozzle or on the end piece of the spray gun aggregates in larger droplets, which are liquid due to the high wall temperature. The droplets are pulled by gravity, get loose and are ejected into the plasma jet. They cause disturbances in the spraying process, resulting in blisters and lumps being generated in the coating (see figure 1b). As these coating defaults are unacceptable, the damaged work-piece must be stripped and re-coated.

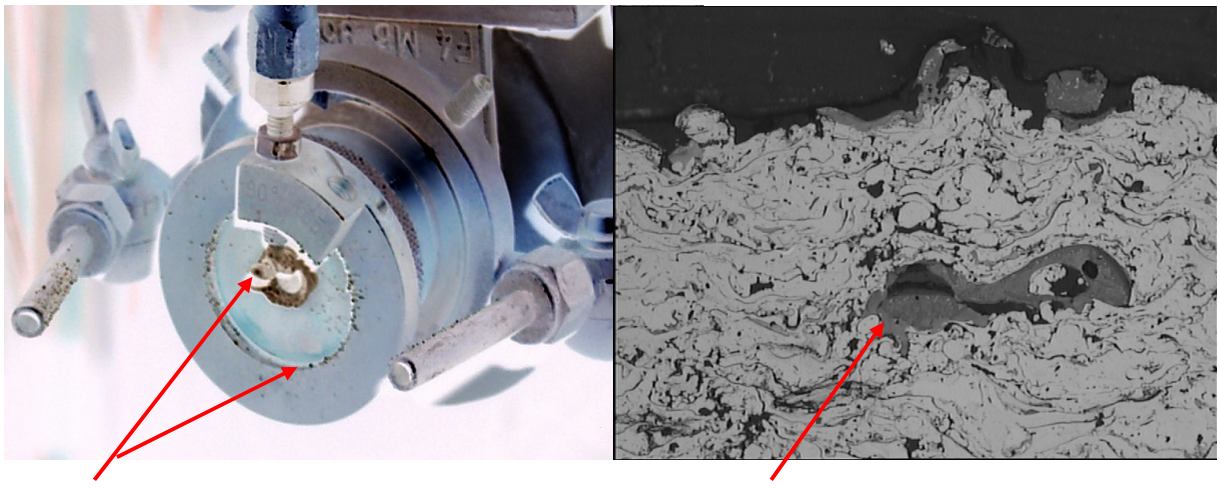

Fig. 1: a) Nozzle wall of a spray gun with traces of clogging that can be observed after operation. **b)** Optical microphotographs; 768x576 µm. Microstructure for a ZrO_2 top coat sprayed with 32 slpm of argon through the powder port ring holder.

A previous study was focused on the understanding of the cause of lump formation, and the development of a solution for avoiding it [1]. The coating baseline used in this investigation was a standard Ni-5Al one used in Volvo Aero production, operating with an F4 atmospheric plasma spray gun manufactured by Sulzer Metco Ag (Wholen Switzerland). This spray gun is equipped with a Sulzer Metco annular holder ring with

one or two threads for assembly of up to two powder injectors, figure 2a. The ring is fixed at the nozzle exit; the powder is thus injected downstream the nozzle.

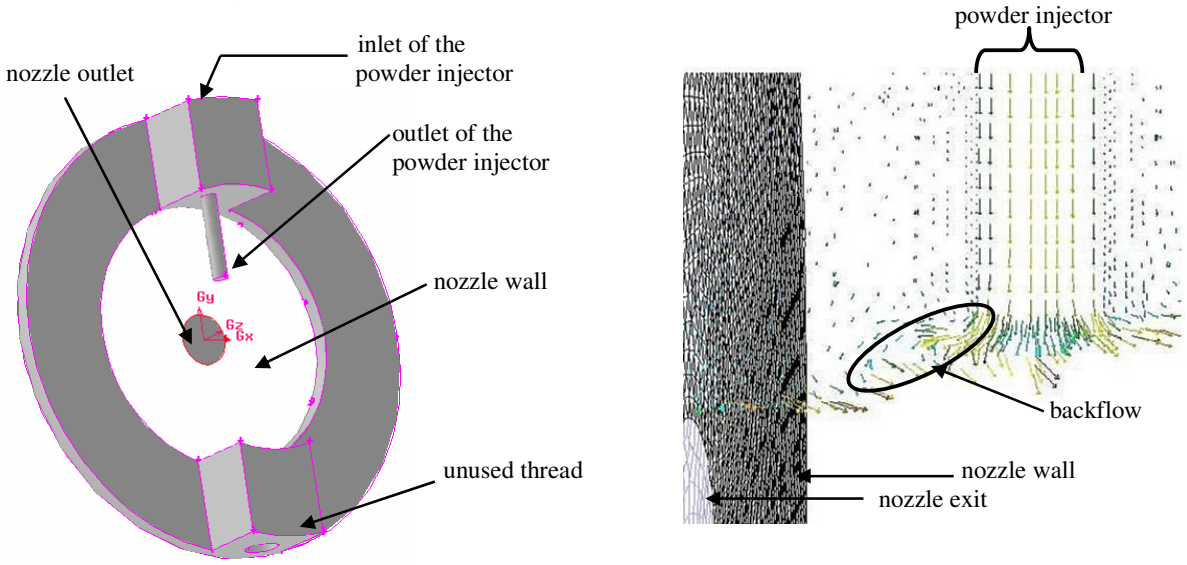

Fig. 2: **a)** CAD representation of a ring with two powder port holders, only one powder port injector, **b)** velocity vectors (calculated numerically with Fluent 6.1) showing the carrier gas backflow at the powder pipe outlet (the plasma flow is not plotted here).

Numerical simulations showed that beyond some critical value of the carrier gas rate, the carrier gas starts expanding towards the nozzle as it exits the injector, figure 2b, and entrains some powder particles. The solution proposed in [1] to prevent this backflow of powder from clogging the nozzle wall consisted in applying a screen between the nozzle wall and the powder pipe injector. The intention was to divert from their path the small fraction of powder flowing backwards, while keeping the coating quality. For this purpose, a new geometry of the powder port ring holder has been designed. It allows the injection of a gas through the ring to form a protective layer in the vicinity of the nozzle wall. When properly formed, this gas layer prevents the powder back-stream from reaching the nozzle wall and thus from initiating lump formation.

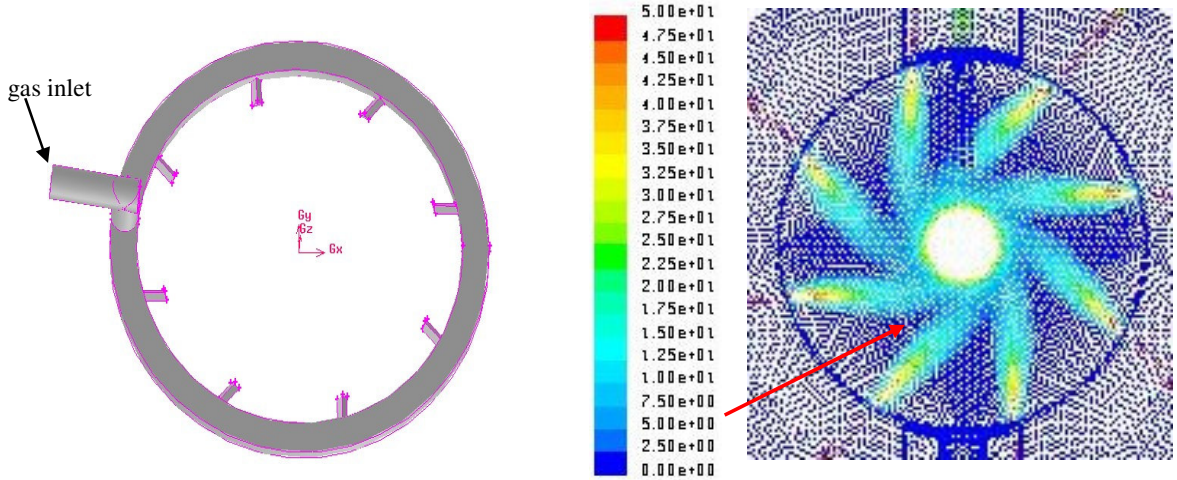

Fig. 3: **a)** CAD representation of the channels allowing to inject the protective gas layer through the powder port ring holder, **b)** velocity vectors of the protective gas layer formed at the nozzle wall (calculated numerically with Fluent 6.1) showing areas (red arrow) hat should be further protected (the plasma flow is not plotted here).

The new ring has been designed in [1] starting from a standard annular powder port ring holder. It has been made by milling grooves in a Sulzer Metco ring with two threads, figure 2a, to form a path for the gas layer

injection. When sealing the ring on the nozzle exit, the grooves result in channels, plotted figure 3a. They link the pressurized gas inlet, via a circular channel of rectangular section (1 mm x 3 mm), to eight gas channels of triangular section (right isosceles of base 1.8mm) opening on the inner radius of the ring. The eight inner gas injection channels are evenly angularly distributed along the circumference of the ring. They are oriented along a non-radial direction, such that the injected gas flows in the close vicinity of the outer periphery of the plasma jet, as illustrated by the velocity vectors of figure 3b. This orientation allows avoiding any direct interaction between the gas injected through the ring and the plasma jet. So the protective gas layer should: *i*) prevent from lump formation in the coating, *ii*) not modify the properties of the powder particles prior to impact on the substrate (velocity, temperature, oxidation, etc.) and thus *iii*) preserve the coating quality.

These properties have indeed been successfully verified experimentally when spraying a bond coat on Titanium coupons with the commercially available powder NiAl Amdry 956 from Sulzer Metco, [1]. No lump was observed when using the new ring with a gas rate of 32slpm to form the protective layer. No difference was noticed when using a protective gas layer of argon or air. The measured properties of the coating microstructure remained within the required quality range.

Other experimental tests have been carried out building the top coat with the commercially available powder ZrO_2 Amperit 827.873 from HC Starck. When sprayed with a standard ring, this powder leads to more severe clogging problems than NiAl Amdry 956. Using the new ring and the same gas flow rate as for the bond coat, a significant reduction of the number of lumps was reached. But this improvement was not sufficient since lumps could still be observed in some coupons, as illustrated figure 1b. ZrO_2 Amperit 827.873 is characterized by particles of smaller size than NiAl Amdry 956. Plotting the protective gas layer formed at the nozzle wall (such as the velocity vectors calculated numerically with Fluent 6.1, figure 3b) we can observe, in the vicinity of the plasma jet, areas of the nozzle wall that are poorly protected by the gas layer. So we assumed that the finest powder particles could still find a path through these weakly protected areas. The purpose of this study was thus to further optimize the geometry of the channels through the ring in order to prevent lump from forming in the coating when spraying powder lots containing very small particles. The two constraints we fixed are: to maintain the quality requirements for the coating and design a solution based on a standard annular powder port ring holder.

2. Simulation model

APS processes are composed of three separate sub-processes: the plasma generation by an arc discharge [3], the plasma/powder particle interaction, and the formation of the coating [4]. In this work the plasma generation was modeled by imposing profiles at the nozzle outlet, and the plasma/powder particle interaction was calculated up to the substrate location. The models used to simulate both the atmospheric plasma and the powder particles are summarized in [5]. They have been widely studied and validated by comparisons with experimental data; related references are also given in [5].

Three species were taken into account in the calculations: the plasma gas, the surrounding air and the carrier gas. The plasma gas was formed by the ionization of a mixture of argon and diatomic hydrogen (here 24.5% of H_2 in volume). The carrier gas was pure argon. The gas used to form the protective layer at the nozzle wall was either argon or air. Each of these gases was supposed to be in local thermal and chemical equilibrium.

The system of equations governing these fluids was the complete set of turbulent Navier-Stokes equations. The turbulence closure was a k-epsilon model in its RNG formulation, supplemented by a corrective term for the k-conservation equation [6]. Quantities such as the transport coefficients were derived from kinetic theory as in [7]. This system was solved using a finite volume method (Fluent 6.1, [8]) and numerical schemes of second order accuracy in space.

The computational domain was 3-dimensional and started from the wall at the exit of the plasma gun. It included the powder port ring holder fixed at the nozzle outlet. The geometrical dimensions were the same as in [1].

The boundary conditions at the nozzle exit were imposed profiles of temperature, velocity, turbulence kinetic energy and dissipation rate. Their expressions are detailed in [1]. The maximum temperature was $T_{max} = 12575$ K and the maximum velocity $U_{max} = 2167$ m/s. These quantities were derived from the

operating conditions of the arc generator, as explained by Nylén [5]. The boundary equations for the turbulent kinetic energy and the dissipation rate are also reported in [5].
Pure argon was injected through the inlet of the powder injector. This boundary condition was set assuming a constant temperature of 300 K and a parabolic velocity profile corresponding to an average velocity of 26.2 m/s for the figures presented here. Concerning the hole of the ring that was not occupied by a powder port, the boundary condition was, as for the surrounding, air at rest and 300 K. The wall of the nozzle was assumed to be at a constant temperature of 1000 K.
The powder feed rate was 54 g/min. The particles were modeled as described by Nylén [5]. However, the calculations did not account for all phenomena involved such as vaporization or oxidation of the particles. This powder feed rate is low enough to avoid any loading effect. A weak coupling between plasma and powder particles was thus retained: heat and momentum were transferred from the plasma to the particles, but the effect of the particles on the plasma was neglected.

5. Numerical results

The first change we did to obtain a more extended protective gas layer around the plasma jet at the nozzle wall was to increase the number of triangular channels (from 8 to 16), reduce their section area by two, and keep the same total inlet gas flow rate. As illustrated by the argon mass fraction, and the argon velocity vectors, figures 4a and b, the evenness of the protective gas layer gets worst than with only 8 triangular channels. Similar disappointing results are obtained with air rather than argon to make the gas layer.

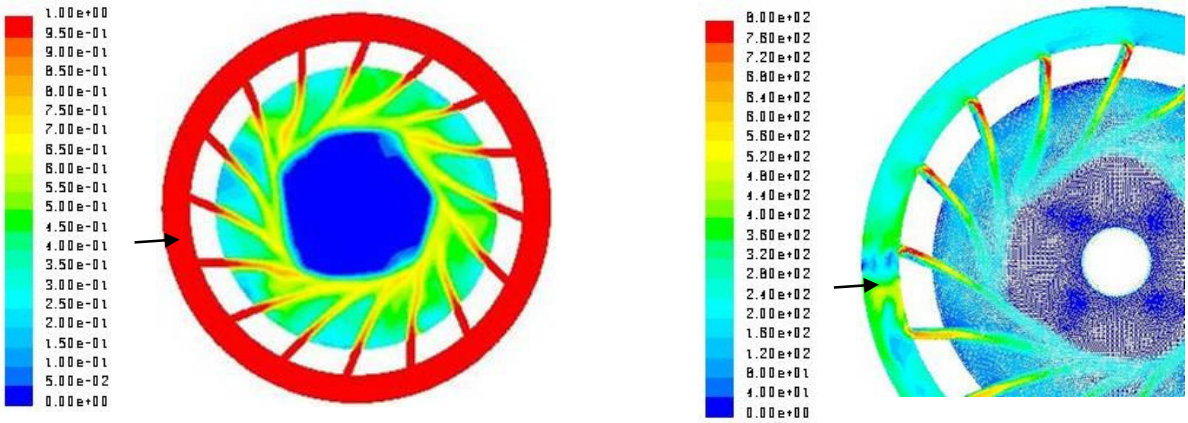

Fig. 4: Protective gas layer made of argon at the nozzle wall (calculated numerically with Fluent 6.1) with 16 triangular channels. The arrow indicates the location of the gas inlet. **a)** argon mass fraction, **b)** velocity vectors (zoom; the plasma flow is not plotted here).

We observe that the gas layer is far away from the plasma jet. The gas jets leaving the triangular channels vary significantly from one channel to the next. This non-uniformity is already important at the junction between the circular channel and the triangular ones.
So we did a second change: inject the gas through two inlets rather than only one. The gas inlets are located on the circular ring, symmetrically, each being equidistant from two neighboring triangular channels. This modification results in the gas flows at the exit of the triangular channels being more similar. Then, the central area (i.e. at the center of the nozzle wall) that is not covered by the protective gas layer becomes circular, as required. However its radius is twice larger than the nozzle exit, so the screen extension is not sufficient to prevent powder particles from reaching the nozzle wall.
A part of the kinetic energy given to the gas at the inlet is indeed lost on the way through the ring. This loss is here too large to form an efficient protective gas layer. The channels used here are short. Many changes occur along the gas path though the ring: in direction, in shape, and in size. The minor losses are thus more important than the major ones. But they can be reduced at various levels. For instance by changing the bending angle of the pipe for gas injection into the circular channel from 90 degrees to 45 degrees, and adjusting properly the distance from the bended edge to the circular channel, figures 5a and b. An additional way to reduce losses is to force the gas to flow mainly along the external radius of the circular channel (which is smooth), rather than the internal one (that contains all the triangular channels inlets). This can be achieved inserting a conical shape in the circular channel, on its internal side, and vertically aligned with the

injection pipe (see figure 6.a). In this way the turbulent flow is confined to the vicinity of the connection between the inlet channel and the circular channel, figure 6.b. Notice that the injection pipe bend angle, the distance from this bend to the circular channel, the size and location of the conical shape are dependent parameters.

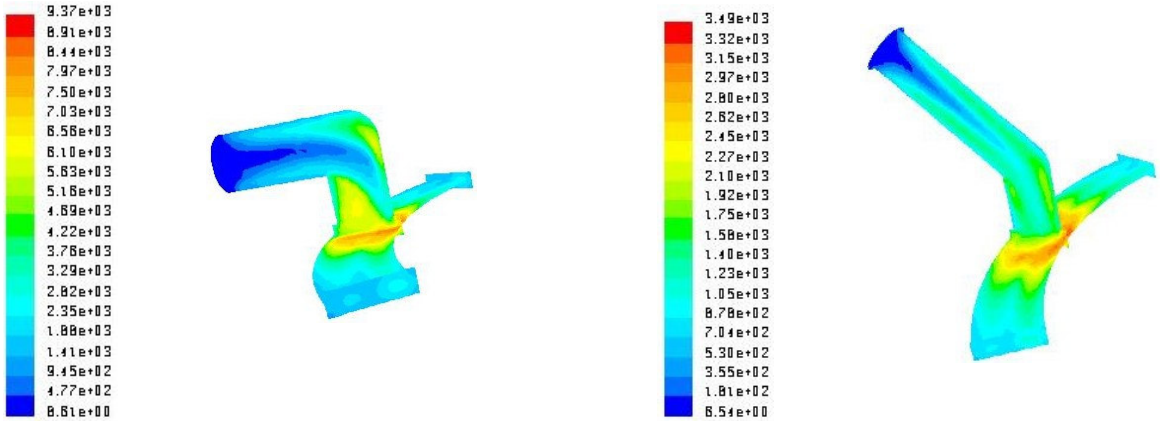

Fig. 5: Turbulence intensity in the pipe for gas injection and a section of the circular channel for a gas injection pipe bended at **a)** 90 degrees, **b)** 45 degrees.

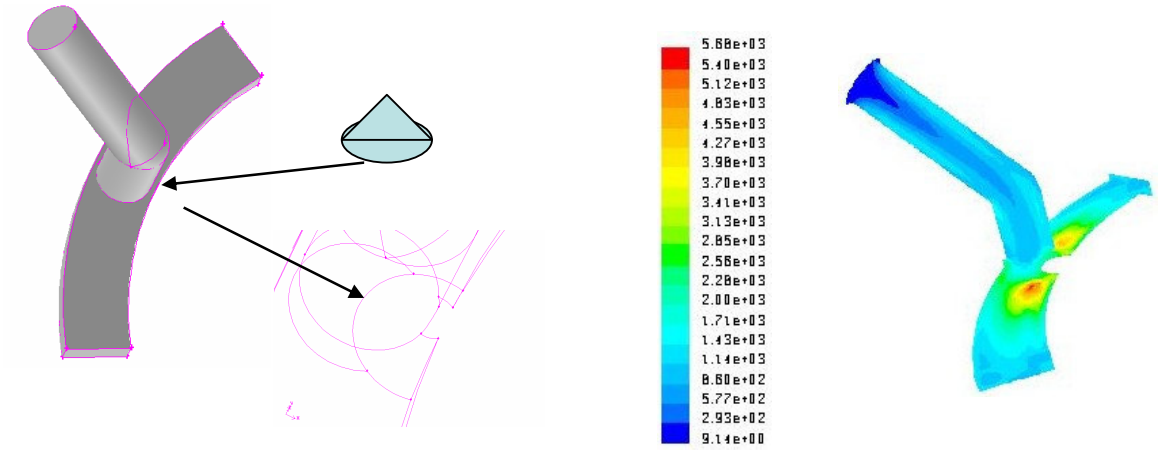

Fig. 6: **a)** Schematic representation of the conical shape inserted at the junction between injection channel and circular channel to redirect the flow, **b)** turbulence intensity in the pipe for gas injection and a section of the circular channel obtained with the channels geometry 6.a.

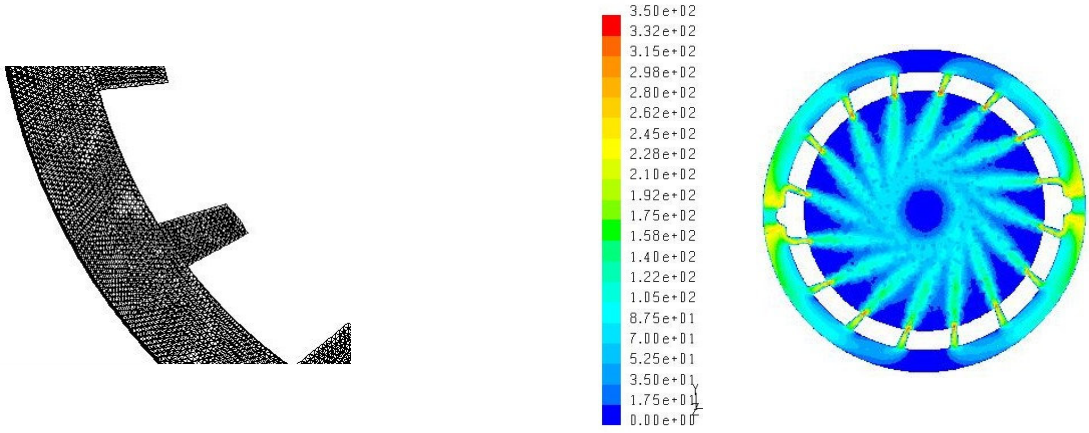

Fig. 7: **a)** A section of the circular channel and a triangular convergent channel, **b)** velocity vectors (zoom; the plasma flow is not plotted here) obtained with the modified geometry.

Unfortunately these changes are not enough to sufficiently reduce the losses. To go further we could also use more than two pipes for gas injection through the ring, but this does not seem to be very convenient. We could also change the section of the circular pipe, from a rectangle to a square, but this is not consistent with our whish to use a standard ring. A thicker ring would indeed be needed. Another source of loss is the large difference in sections between a triangular channel and the circular one. For this reason, the triangular channels are instead modified by increasing regularly their section in the direction of the circular ring. This last modification reduces losses, also accelerates the gas flow since the triangular channels now act as nozzles. As a result, the protective gas layer becomes sufficiently extended to cover the nozzle wall up to the vicinity of the plasma jet, figure 7.b.

These modifications result in a gas layer that better screens the nozzle wall between the powder injector outlet and the plasma jet. The non-radial orientation of the triangular channels is determined so that plasma jet and protective gas layer do not directly interact. The numerical results show that the properties of the powder particles (such as velocity, temperature) prior to impact with the substrate are kept unchanged (when using or not the protective gas layer). During preliminary experiments, no lump formation could be observed in top coats sprayed with the new system of 16 channels through the ring. Other experiments are in progress to further validate this numerical study.

6. Conclusion

The efficiency of the proposed solution to avoid lump formation in coatings built up using APS (with powder injection downstream the plasma nozzle) depends on the evenness of the protective gas layer. To completely eliminate lump formation, a minimum number of channels used to form the screen, and a minimum flow rate through these channels are needed. These minimum values depend on the distribution in size of the powder particles. The solution suited to Ni-5Al Amdry 956 powder from Sulzer Metco used to form bond coat [1] was not sufficient for the finer powder ZrO_2 Amperit 827.873 from HC Starck. The present numerical investigation indicates that a few modifications in the channels geometry designed in [1] are needed to sufficiently improve the screen quality to avoid lump formation with these finer powders. Preliminary experiments with ZrO_2 Amperit 827.873 support this numerical study.

A key issue is also to maintain the coating properties. It has been checked numerically that just prior to impact with the substrate, the average temperature and velocity of the powder particles are kept unchanged when using the new ring (with either argon or air) compared to a standard ring. So the coating quality should not be affected by the injection of gas through the ring. Experiments are in progress to confirm this last point.

Abstract

In our present study, two non-thermal plasma devices, dielectric barrier discharge and magnetically-rotated gliding arc, are being used to sterilize air containing high concentrations of viral and bacterial bioaerosols. A Pathogen Detection and Remediation Facility was designed for bioaerosol generation, containment, and sampling during plasma sterilization experiments.

Keywords: non-thermal plasma, sterilization; decontamination, airborne virus, bacteria, influenza

1. Introduction

The improvement of indoor air quality has been a challenge since the dawn of heating, ventilation, and air conditioning (HVAC) systems. Incidents like the infamous outbreak of Legionnaires disease in 1976 in Philadelphia and the recent increasing threat of bioterrorism have raised awareness of the dangers of airborne microorganisms in indoor environments. In recent years, non-thermal atmospheric pressure plasma has been the focus of research as an improved method for the sterilization of air from biological contaminates. Non-thermal plasma has been proven to inactivate many different types of microorganisms, such as viruses and bacteria, on surfaces of materials, but there have been few scientific studies of air sterilization using non-thermal plasma. Also, of the few researchers that have been able to use plasma to decontaminate a moving air stream, many rely on high efficiency particulate air (HEPA) filters to remove a large portion of microorganisms. HEPA filters are effective at trapping particles down to 0.5 microns in size; however, studies have shown that they are not as effective at capturing airborne viruses, which are among the smallest (20-300nm) known microorganisms [1]. HEPA filters also cause significant pressure losses in HVAC systems giving rise to higher energy and maintenance costs. There are several alternative methods for air cleaning, which include electrostatic precipitators, Ultraviolet Germicidal Irradiation (UVGI) devices, and some portable negative air ionizers, that are all capable of reducing particulates and even certain levels of microbial contamination in indoor environments. However, many of these methods are not proven as an efficient and cost effective means of eliminating airborne viruses. In this ongoing scientific study, we will examine the sterilization effect of two types of non-thermal plasma; dielectric barrier discharge (DBD) and magnetically-rotated gliding arc on air contaminated with high concentrations of aerosolized Influenza A virus. A non-pathogenic unicellular bacterium known as Synechococcus Elongatus, or Cyanobacteria, was also used in initial trials to demonstrate the decontamination ability of active chemical species generated from dielectric barrier discharge for bacteria in water and to provide benchmark data regarding bioaerosol sampling efficiency.

2. Non-thermal plasma for air sterilization

Although Dielectric Barrier Discharge (DBD) and magnetically-rotated Gliding Arc [2] are quite different in terms of current-voltage characteristics and operational power levels, both devices can provide a high concentration of active chemical species, which are a necessary component of the sterilization process. There are two main sterilization effects that bioaerosols are subjected to as they are passed through each plasma device: the direct interaction with the lethal environment of the discharge itself and the downstream interaction with active chemical species, such as ozone (O_3) and hydroxyl (OH), produced by the discharge. Figure 1 below shows a photo of the DBD device which consists of a thin plane of wires with equally spaced air gaps of 1.5 mm. The high voltage electrodes are coated with a quartz capillary dielectric that has an approximate wall

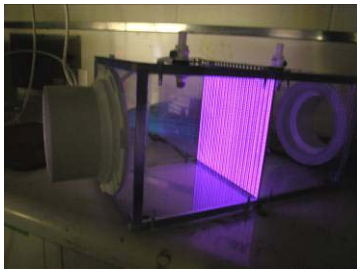

Figure 1. Dielectric Barrier Discharge for air sterilization

thickness of 0.5 mm and the device requires 14 kV for breakdown while consuming less than 200 watts of power. DBD is a low temperature discharge that is very efficient for the production of ozone, which is a strong oxidizer and proven microbial disinfectant [3-6]. The second discharge, magnetically-rotated Gliding Arc, generates a transitional non-thermal plasma and has a relatively low translational gas temperature with a high electron temperature. Gliding Arc uses a strong magnetic field to rotate and elongate an initial thermal arc resulting in rapid convective cooling, keeping the passing air flow near room temperature. This type of discharge has a large power density that can work at atmospheric pressure, but is still very efficient in providing active species. The Gliding Arc device is eight inches in diameter which keeps air velocity low allowing for greater uniformity of treatment. In figure 2, the arc is partially elongated at the center electrode. Additionally, both DBD and gliding arc devices have been designed to prevent an air pressure loss during operation and are capable of retrofit into existing HVAC systems.

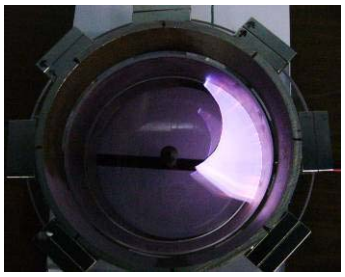

Figure 2. Magnetically Rotated Gliding Arc

3. Preliminary experiments with plasma-water decontamination

To understand the decontamination effectiveness of DBD, we designed a simple experiment to test the effect of active chemical species generated from this discharge on cyanobacteria suspended in liquid growth medium. Approximately 35 ml of liquid with cyanobacteria was placed in a Petri dish at a distance of 30 mm from the surface of the plasma discharge. A small fan forced air through the discharge at a direction normal to the surface of the liquid. Figure 3 shows a diagram of the experimental setup. The DBD discharge produces 0.11 mg of ozone per liter of air, most of which was directed toward the liquid-gas interface as the solution was stirred with a magnetic stir bar. After 3.9 minutes of treatment, we demonstrated more than a 2-log reduction (99.3%) of bacteria in the solution. We attribute ozone as the main active specie responsible for the inactivation of bacteria in this case because of its longer lifetime in comparison to hydroxyl. A similar experiment was performed by Moreau, et al. [7] to demonstrate the lethal effect of a gliding arc discharge on strain of a bacterial plant pathogen, Erwina, suspended in a liquid medium.

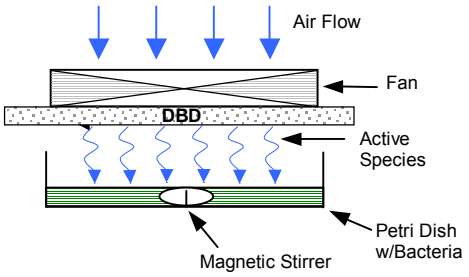

Figure 3. Water decontamination experiment using Dielectric Barrier Discharge (DBD).

4. Air Decontamination / Sterilization

In order to prove that non-thermal plasma is the main factor responsible for sterilization, one must first build a system that is capable of creating, handling, and analyzing dense concentrations of viable bioaerosols. Designing and building an air sterilization system is challenging because there are many factors that contribute to losses of aerosolized microorganisms in moving air streams. These factors include diffusion of aerosol to walls of the air flow system, desiccation stress on the microorganism due to evaporation of bioaerosol droplets in flight, and inertial and gravitational forces which can remove larger droplets from the air stream. The factors causing these losses must be carefully considered in order to avoid misinterpretation of sterilization data and may also be one reason why bioaerosol sterilization studies are limited in comparison to studies involving water or surface sterilization. Careful attention to these potential sources of error will yield greater accuracy and validity in distinguishing non-thermal plasma as the true sterilizing agent. Figure 4 below shows a scheme of the Pathogen Detection and Remediation Facility (PDRF) which is a plug flow reactor that was designed for

bioaerosol generation, containment, and sampling. It was designed to simulate conditions commonly found in an HVAC system: it has an overall volume of 250 liters, and can operate at flow rates up to 25 liters per second. The PDRF houses interchangeable non-thermal plasma devices, DBD and Magnetic Gliding Arc, which are connected to the system with four inch (10 cm) diameter flexible piping. At a flow rate of 25 L/s, the residence time, that is, the time for one droplet to make one revolution through the system, is approximately 10 seconds. An air sampling system is included in the PDRF and was designed to take as large volume air sample as possible (~ 1 liter) in a short period of time (~ 1 second) so that we do not disturb the flow inside the system and can evaluate the viability of the bioaerosol as a function of treatment time.

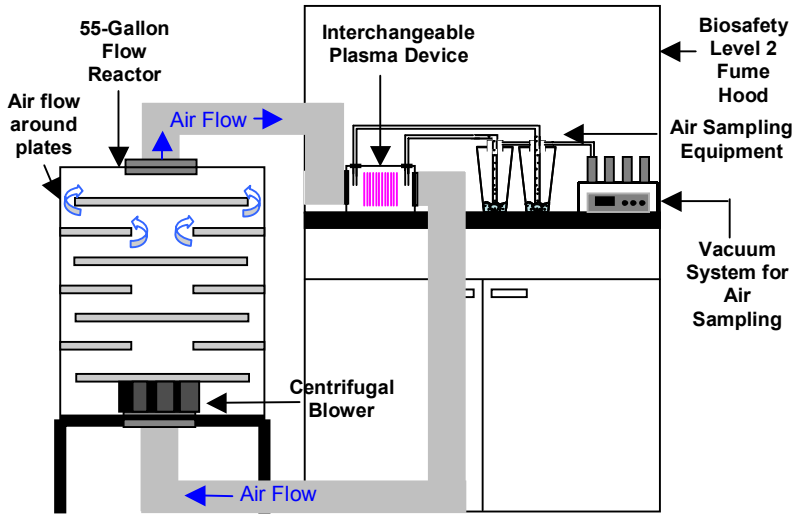

Figure 4. Pathogen Detection and Remediation Facility (PDRF)

Liquid impingement was chosen as the air sampling method for our system, as opposed to filtration or impaction, because it minimizes dessication stress and allows for the direct deposition of the microorganism into growth media. The AGI-30 liquid impinger is a commonly used bioaerosol sampler and it operates by drawing a sample of air through in inlet tube submerged in a solution, thereby causing the air stream to strike the liquid bed trapping aerosols in the solution through forces of inertia [8]. The AGI-30 impinger contains a critical orifice that contains one exit port and limits the maximum air sampling rate to 12.5 liters per minute [9]. To accommodate our desired sampling rate of 1 liter per second, we modified the AGI-30 by increasing its overall volume and replacing the standard critical orifice with a hollow spherical tip with several exit ports. Several calibration experiments performed with our modified AGI-30 impinger demonstrated reproducibility in terms of sampling efficiency. In these experiments, a Collison nebulizer was connected directly to the modified liquid impinger and after five minutes of continuous sampling in each trial, we obtained a stable sampling efficiency rating of 3.5%. Some may not consider this as an optimal efficiency rating, however, when sampling bioaerosols, reproducibility is often considered more important than the efficiency rating because the final conclusions are derived from internal comparisons between various data collected using the same samplers [9].

Several additional calibration experiments were performed in which cyanobacteria aerosol (droplet size: 1.5 micron) was injected into the Pathogen Detection and Remediation Facility (PDRF) not for the purpose of sterilization, but to identify all bioaerosol losses from diffusion, inertia, and evaporation, thereby establishing accurate controls before non-thermal plasma is introduced. In these experiments, a Collison nebulizer was used to generate the bioaerosol, the air flow rate was fixed at 25 liters per second, and the lifetime of droplets was measured by periodic air sampling with two modified liquid impingers. For all experiments described here, the system was prehumidified with sterile de-ionized water until the internal surface of the system walls were wet prior to input of the bioaerosol. Initial results showed a very poor recovery of cyanobacteria bioaerosol from the PDRF in comparison to air sampler calibration experiments. When examining the sources of loss: diffusion, inertia, and evaporation, we ruled out inertial forces because air velocity is relatively low and the aerosol droplets are small (1-2 microns). Also, our estimate of droplet diffusion time to the wall is approximately 40 minutes, well beyond the upper time limit of these trials. The effect of small droplet evaporation, however, can be prominent because the saturation pressure around a small droplet is high in comparison to the saturation pressure near the wet walls of the system. To test the effect of evaporation on the survivability of cyanobacteria, we performed two experiments: the first (Experiment A) in which additional humidity was applied continuously with the bioaerosol using an additional nebulizer with with sterile de-ionized water, and the

second (Experiment B) without additional humidification. Our results, which are described in figure 5 below, show that additional humidification reduces the rate of inactivation of aerosolized cyanobacteria, by dessication stress compared to the results of experiments without additional humidification.

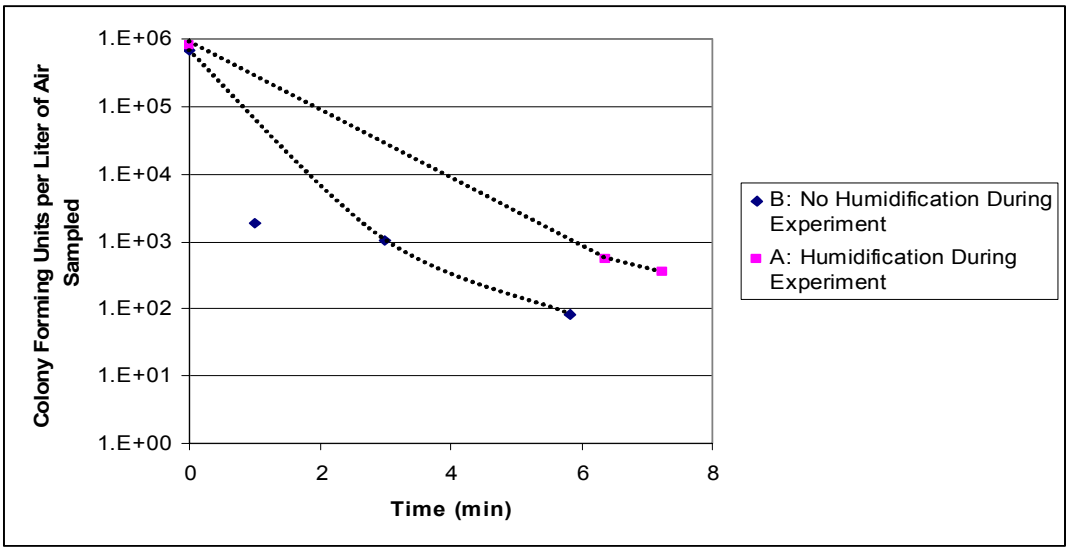

Figure 5. Evaluation of the effect of droplet evaporation on the survivability of aerosolized cyanobacteria. Experiment A minimizes evaporation by providing constant humidity.

The experimentally estimated maximum lifetime of aerosolized Cyanobacteria is 10 minutes, which is far below the estimated diffusion time of droplets to the walls of the system. We desire to have the ability to recover viable cyanobacteria over an extended period of time (tens of minutes) so that when we perform sterilization experiments with non-thermal plasma, we have enough time to take several air samples and thus acquire many data points to accurately describe the rate of inactivation. To determine if the droplets were indeed still present in the air flow after 10 minutes, we added a laser to the system to characterize the optical density of the bacterial aerosol over time. Figure 6 shows an image of the illuminated laser beam at the first minute of the experiment when the concentration of viable Cyanobacteria is high. Illumination from the laser beam slowly decayed over a period of nearly 2 hours indicating that aerosolized bacteria were still present in the flow, however, they were non-viable. Similar results were reported by Ehresmann & Hatch, who described the optical density of aerosolized unicellular bacteria lasting up to four hours at high humidity (92-94%) with viability lasting only minutes [10]. These calibration experiments with Cyanobacteria provided us with a basic understanding of the flow characteristics of the Pathogen Detection and Remediation Facility and efficiency of our air sampling system. This was a necessary step before working with viral bioaerosols because immunoassay detection methods used to quantify viruses are less accurate than the serial dilution methods used to quantify Cyanobacteria in these calibration experiments. Sterilization experiments with Cyanobacteria and Influenza A virus are in progress and we expect to have results in the summer of 2005.

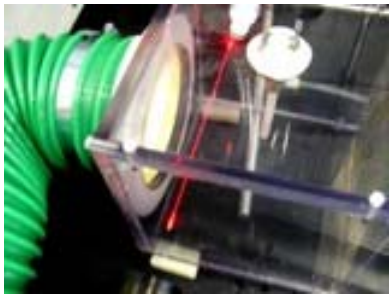

Figure 6. A laser beam illuminates the dense concentration of bioaerosol

5. Plasma chemistry sterilization modeling

The results from our experiments with the PDRF will be used to verify a model of plasma chemical sterilization [11]. We have composed a physiochemical model of the oxidizing effects of the active chemical species

generated by non-thermal plasma on many different types of microorganisms. We are investigating the individual sterilizing effects of hydroxyl radicals (OH), ozone (O_3), ultraviolet radiation (UV) as there is a large amount empirical data regarding the role of each of these components for the sterilization of various bacteria, viruses, and spores in various media. Our model combines this data with the chemical kinetics of non-thermal plasma to predict the rate of destruction of microorganisms under varying conditions.

This research is supported by Telemedicine and Advanced Technology Research Center of the US Department of Defense (TATRC of DoD) through Civilian Medical Response Center (CiMeRC).

Abstract

The spark that ignites the combustible mixtures is a glow discharge produced between the electrodes of a spark plug, connected to the secondary of a coil at the high voltage. A good combustion require a frank spark, in a volume as large is as possible and with a maximum of energy.

We propose a solution to increase the plasma volume and present electrical discharge parameters as function of inter-electrode distances, pressures in the test-reactor and the electrical pulses width of the power supply.

1. Introduction

To ignite an air-combustible mixture into the combustion room of an engine it is necessary to have an unshaken spark discharge between the electrodes of the spark plug that assure as higher energy as possible. This is a minimum condition to burn up and to increase the engine power.

The classic ignition uses a contact breaker and a coil boosting supplied at 12-13V that provide in secondary 15-20kV. This level of high voltage is required to breakdown the spark between electrodes. This could happen only if the high voltage exceeds a threshold value imposed by the dielectric constant of the mixture.

The ignition timing must be very precise. The optimum work could reduce the ignition consumption (power feed). Besides it is possible to replace the rich mixtures used so often with poor mixtures resulting an important diminution of the poluant emissions (HC, CO, NO_x) and a lower consumption [1]. However, for a good combustion is necessary to inject higher ignition energy that in the case of the classic spark plug [2].

The production of an economic and clean engine need a quick and efficient combustion of the poor mixtures at high pressure. The evolution of the combustion depends on the interactions between the flame and the plasma movement. However the used electric spark rest located ($\approx 1mm^3$) and could not assure the perfect (best) ignition for an air-hydrocarbure mixture to increase the engine performances.

Few solutions to improve these incovenients have already been proposed [3, 4, 5, 6, 7, 8, 9], but for many of them, it is difficult to believe that could become industrial applications. Nevertheless, the work of Nakamura [10] which analyze the influence of many ignition points with a device containing few classic spark plugs by cylinder has shown that the combustion cycle takes place more quickly, thereby is possible to increase the ratio. The use of poor mixtures reduces certain pollutants and the combustible efficiency was increased.

The purpose of this study concerns the conception and the realisation of a plasma ignition system for a combustion engine room, increasing the plasma volume and the electrical power injected into the discharge in order to have a quick and efficient combustion ignition. We have been interested to simultaneously produce two sparks at high pressure ($\leq$9atm), by a high voltage pulsed power supply. This power supply does not allow the transition of the spark to an electric arc. The preliminary experiments have been done in air.

2. Experimental arrangements

2.1. Schematic structure of the ignition spark plug with double spark

The experimental device [Cf. Figure 1] uses a third auxiliary electrode ③, not connected to the power supply, placed between the main electrodes ① - high voltage electrode and ② - ground electrode of a typical spark plug supplied by a pulsed high voltage power supply ⑨ through the medium of a coil ⑧. A such geometry assure the existence of two spark discharges ④ respectively between the electrodes ① and ③, called “first discharge” (referenced by *1*), and between the electrodes ③ and ②, called “second discharge” (referenced by *2*). The double spark is produced after an horizontally direction that could also help the combustion of air-combustible mixture [11].

The ceramics insulated passages ⑥ fixed by epoxy resin ⑤ assure the electric connections. The spark plug manufactured in this way is placed and fixed in a combustion room by a classic screwed ⑦.

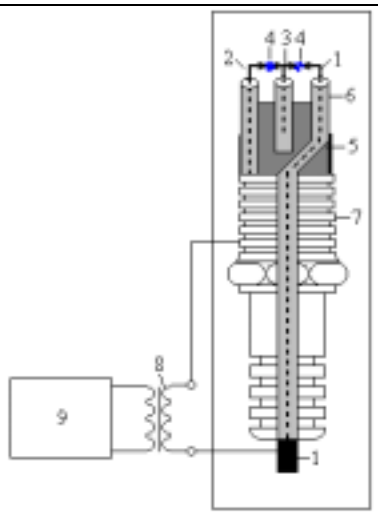

Figure 1 - New type of spark plug

① HV Electrode ; ② Ground Electrode ; ③ Auxiliary Electrode ; ④ Sparks ; ⑤ Epoxy Resin ; ⑥ Insulated passages ; ⑦ Fixative screwed ; ⑧ Coil ; ⑨ Pulsed high voltage power supply

The pulsed high voltage supply allow to provide in the secondary of the coil a high voltage up to U_d=50kV at the frequency of f_d=100Hz with an adjustable pulse width τ_d between 0.05 and 6 msec. Furthermore, to study the breakdown of each spark, the experimental device has used a time relay (opened t_{on}≈15ms and closed t_{off}≈10s). The measurements have been taken in this way in order to eliminate any luminescent post-discharge inffluence due to the metastable atoms persistance or any others species with important life time (typicaly few miliseconds [12]) into the milieu.

2.2. Experimental device for electric and optic measurements

The distance d_1 between the electrode at high voltage ① and the auxiliary one ③ is fixed by construction at 1.5 or 2mm and the distance d_2 between the auxiliary electrode ③ and the grounded one ② is adjustable between 0 and 4mm by a micrometric screw. The adjustment of the distance can modify the volume of one spark and it is possible to establish the best adapted distance under a given pressure corresponding to the necessary level of the high voltage delivered by the power supply.

The instantaneously values of spark voltage *u(t)* and discharge current *i(t)*, have been measured respectively using a differential high voltage probe [Max.: 100kV; Atenuation: 1/3300], and a shunt (RCH50 56Ω 5%MD). They were stored by a numerical oscilloscope TEKTRONIX TDS210 to get the evolution of the instantaneously power *P(t)* injected in the sparks, its average value and even the spark resistance *R(t)*.

The sparks have been studied optically using an adapted device and two fast photodiodes, whose signals were stored on a digital oscilloscope LECROY Waverunner-2 LT584L. Each of these optical signal records permit to determine simultaneously the total time T_1 of the first spark between the beginning of the positive front and the end of the negative one; the numbers N_1 and N_2 of breakdowns (discharges) corresponding to the first and second spark, resp.; the delay Δt between the first and the second discharge breakdown, but also their respective lifetimes, τ_1 and τ_2, measured between the end of the positive front and the beginning of the negative one; and eventually the lifetimes t_2', t_2'' of each discharge composing the second spark, and the past times Δt_1, Δt_2 between the negative front of one discharge and the positive front of the next discharge of each spark. Under certain conditions (only for pressures between 2 and 6atm) some anomalies of sparks behaviour have been observed.

The electrical and optical parameters have been simultaneously recorded on the computer, and the absolute pressure into the measurement chamber is controlled by a manometer sensitive from 1 to 10atm.

2.3. The structure of the power supply

The used pulsed power supply uses controller unit based on a special circuit (βAA145) or on AT89C2051 microcontroller. It allows modifying the number of pulses, the pulse width and the phase of the pulse by the microcontroller software. The last adjustment is very important for a good concordance between the pulses and the synchronization signal.

3. Experiment Results

3.1. Preliminary measurements and results

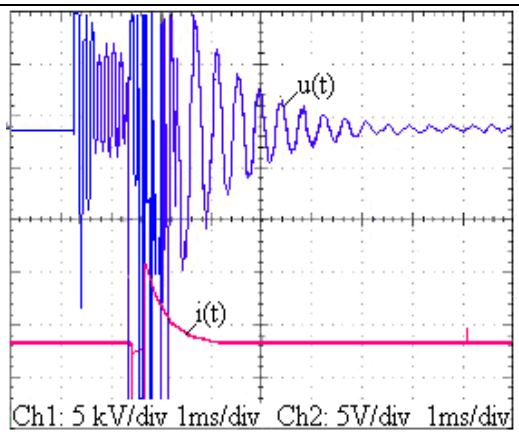
The records of electrical and optical parameters of the spark on computer allow observe the good time correlation between the electrical current and the optical spark signal.

The evolution of the all spark parameters depends on the total distance d between electrodes, and the air pressure p in the experimental device [CF. Figure 2]. The observed oscilations on the electrical parameters strongly depend on the using coil. Particularly, using a new one design by Volkswagen, they completely disapear.

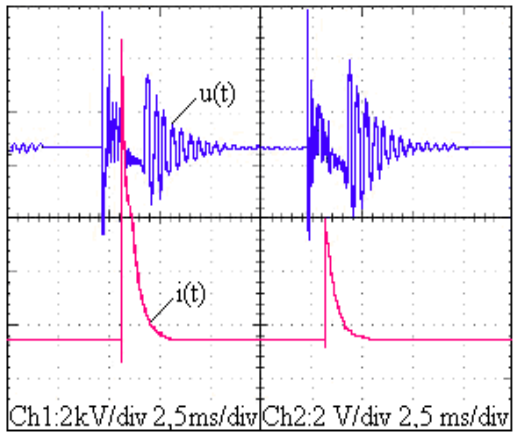
The breakdown minimum voltage U_d for a normal electrical discharge between two electrodes spaced of d, is given by the Paschen law [13, 14]. It depends on the $p.d$ and has one breakdown voltage minimum. It was already proved that the maximum distance between electrodes could be increased using different geometries of the electrodes [15, 16] that allow the breakdowns of the electrical discharges. These previous results have lead to the geometry of the spark plug proposed in this paper.

During the breakdown of the first spark between the electrodes ① and ③ all demanded conditions are achieved for producing the second spark breakdown between the electrodes ③ and ②. The spark aspect strongly depends on the experiment pressure.

For the next experiments, the distances between electrodes have been fixed to d_1=d_2=1.5mm and then we have obtained the breakdown for absolute pressures up to 9atm.



a/ d=3mm; p=3atm



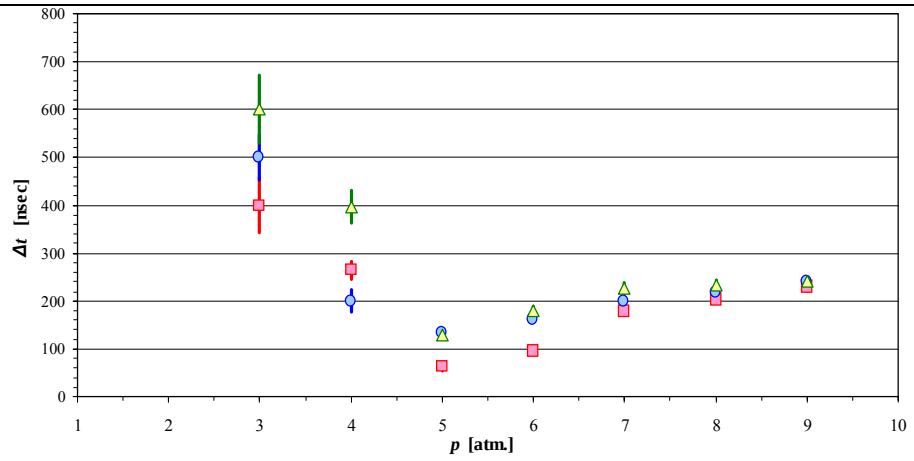
b/ d=3mm; p=1atm

Figure 2 – *u(t)* and *i(t)* for different air pressures

3.2. Breakdown delay between ①-③ and ③-② electrical discharges

For a good work of the experimental device, it is important to verify the breakdown delay between the two sparks: if the delay is too high the second spark could not influence the ignition, so the efficiency of the ignition system will not increase.

The measurements of the Δt breakdown delay between the sparks and their lifetime τ_1 and τ_2 have been done for a τ_d imposed and adjustable value of the pulse width given by the power supply.



[□ τ_d=3.0ms ; ○ τ_d=4.5ms ; △ τ_d=6ms]

Figure 3 - Breakdown spark delay Δt as a function of pressure p *[d_1=d_2=1.5 mm]*

Usually the sparks breakdowns are simultaneously ($\Delta t \approx 0$). However, if there is a delay, it is always between the first and the second spark. For different pulse width we have obtained almost the same results, but the delay depends on the pressure variation [Cf. Figure 3, where data are averaged on important number of acquisitions, and incertitudes are due to measurements and process repetability].

The measurements done at pressures nearby 1atm are relative dispersed and it is very difficult to have the accurate values of Δt. However if the pressure increase the delay Δt reach a minimum near p=5atm and trends to $\Delta t \approx 240$ns at maximum high pressure.

These results are extremily hopefully for the future of our ignition device because the ignition into the engine chamber takes always place at high pressure (p>7atm). Besides for an air-methane mixture [17] the combustion needs few millisecondes so the both sparks will interfere to the mixture ignition. It is oviously that the results obtained using the air could be not exactly the same like for an air-combustible mixtures that have a bigger dielectric constant. But our last tests with a double spark ignition system applied to an monocylinder engine have shown very encouraging results.

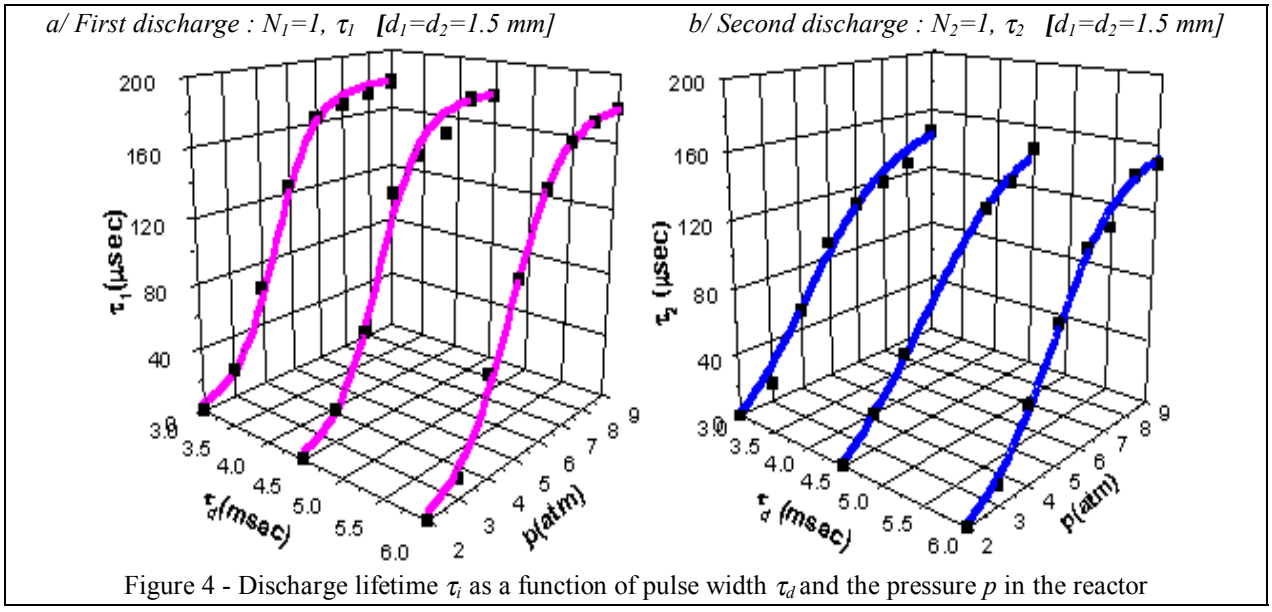


Figure 4 - Discharge lifetime τ_i as a function of pulse width τ_d and the pressure p in the reactor

3.3. Lifetime of ①-③ and ③-② sparks for one pulse

The evolutions of spark lifetimes $\tau_1(p, \tau_d)$ and $\tau_2(p, \tau_d)$ as a function of pressure p and pulse width τ_d, are given in Figure 4, where the experimental data have been fited with the same law of variation for all the family characteristics. One can observe the similar evolutions of each spark optic signal, with maximum spark lifetimes for the higher values of the air pressures.

It is obviously that the modification of pulse width τ_d does not strongly influence the work of the ignition system. The lifetime of the discharges varies from $\tau_1 \approx \tau_2 \approx 10$µs at normal pressure to $\tau_1 \approx 180$µs and $\tau_2 \approx 150$µs for 9 atm pressure. This evolution depends on the gaz type, the pressure, the distance between electrodes and the physical phenomenon inside the reactor. However, if the pulse width is too narrow, the breakdown of the sparks won't be produced. The time of the first spark breakdown, is linked to the negative front of the pulse width.

3.4. Average number and mean lifetimes of ①-③ and ③-② sparks for one electric pulse

For the most part of the experiments, we have obtained $N_1=N_2=1$. But it is possible to obtain multiple successiv sparks during the same electrical pulse (N_2, $N_1 > 1$), especially at intermediary pressure. Then, we have verified that the mean discharge time $<\tau_i>=\tau_i/N_i$ by spark is not significally modified; but on result, the total discharge time τ_i during one electrical pulse is increases compare to the case with only one spark.

The delays Δt_1 and Δt_2 between two consecutive breakdownss of each spark when $N_1,N_2>1$, have no clear dependance on the pressure: then, they seem quite independent on p, but increasing with the pulse width τ_d [Cf.Figure 5]. So, to profit of this situation, it could be necessary to adjust the τ_d value in order that the the second sparks (and the following ones) interfere with mixture ignition and not only with burned gases.

Nevertheless, we must noted that above p=6atm, it is to tell at necessary pressures for the ignition into an engine chamber, these multi-sparks effet doesn't take place.

τ_d [ms]	Δt_1 [µs]	Δt_2 [µs]
3.0	94 ± 34	70 ± 28
4.0	94 ± 41	89 ± 22
4.5	153 ± 32	157 ± 34
6.0	288 ± 34	263 ±50

[Mean values of Δt_1 and Δt_2 following pressure dependance, when N_1,N_2>1]

Figure 5 – Delay between consecutive breakdowns during one electric pulse

4. Discussion

Few conclusions of the first experiments realized at high pressure with dry air are the following:

- The order of the spark breakdowns is always the same: firstly it occurs the spark *1* and then the spark *2*.
- Once the sparks started the discharge voltage decreases and his tendency is to follow the minimum value to hold the discharges; it is possible to observe also that the discharge voltage oscillations increase with the value of the pressure into the experimental device so the instantaneous values of the electric field will increase with the pressure;
- At low pressures (p < 2atm) there are parasite discharges, D.B.D. type, produced around the ceramic insulation of the main high voltage electrode ①. These perturbations produce few difficulties for the electrical parameters measurements.
- For one pressure the sparks become instable and will stopped if the distance d_2 between the electrodes ② and ③ is constant increased.
- For one inter-electrodes distance, the sparks become instable to the variation of the pressure. The spark established between the electrodes ② and ③ is more sensitive to this variation than the other spark.
- The utilization of the auxiliary electrode ③ permits to increase the maximum breakdown distance between the electrodes, at atmospheric pressure from d_{max}=23 mm to $d_{max}=d_1+d_2$=28 mm. In this case the electrical power injected into the sparks is from (2÷10)W for energy up to 60mJ [18].
- The sparks breakdown has been done for a maximum absolute pressure of 9 atm at a maximum distance between electrodes $d_{max}\approx d_1+d_2$=2+2 mm=4 mm.
- The sparks have a red-violet color at atmospheric pressure, and becomes blue and more shining when the pressure increases.
- During the breakdown of the sparks all the energy accumulated in the magnetic field of the coil is consumed, after a transient process to the gas, the secondary coil resistance and the shunt.
- There are three successive frequencies on the records of discharge voltage [See Figure 2]: The first one at ≈8kHz is due to the breakdown and the power supply corresponding to an energy charge regime. The second corresponds to the physical behavior of the sparks. The third one, like a relaxation phenomenon at ≈2.5kHz is influenced by the coil and electrical circuit parameters. We have considered that the plasma is physically equivalent with a diode in series with a low (dissipation) resistance and the oscillations appear because of the energy transfer into the electromagnetic field [19] and the coil characteristics [20].

6. Conclusion

The presented double spark ignition system seems to be well adapted for the combustible mixtures ignition and it could assure a better combustion by its two simultaneously discharges, therefore a bigger plasma volume for ignition. We have observed that the first spark breakdowns always before the second and it is more stable and with a longer lifetime.

The total distance between the electrodes has been increased from 0.7 mm to about 2 mm. Furthermore, the duration of the two discharges is much lower than the electrical pulse widths τ_d: this phenomena allows to generate under intermediary pressures successiv ignitions in each electrodes gap.

Under certain conditions (intermediary pressures) it was observed more that one breakdown corresponding to the sparks for one pulse. All the observations have been found on both electrical and optical parameters

evolution. Then the maximum number of discharges N_{1max} and N_{2max} is limited to 1 for normal pressure and high pressure and could be 3-4 for pressures between 2 and 6 atm. The pulse width has no influence on this evolution (variation). The case with just one discharge for each spark was found much more often (90% of cases).

Our results were encouraging for the air pressure bigger than 7 atm. In this case, there is only one breakdown for each spark for one command pulse applied to the coil from the power supply. We intend to continue the study with the chemical results of the combustion and the sparks diagnostic obtained for modulated pulses train (2 or 3). The last experiments already done proved good results in real conditions with a BRIGGS & STRATON engine for upper breakdown pressure (breakdown at 7-8 atm pressure). Therefore, we have used a controller unit, based on AT89C2051 microcontroller, to ensure synchronisation of the ignition with the maximum pressure into the cylinder obtained during the compression time. In these conditions, we have verified that the purposed double sparks system provides bigger energy than with the classic system.

Abstract
This paper reports the study of the influence of two particle size distributions of powders (submicron and micron, respectively) on the microstructure of coatings produced by Suspension Plasma Spraying. It is shown that finely structured coatings are reached by carefully adjusting plasma spraying parameters for both powders.

1. Introduction

Since the beginning of the eighties, the plasma spraying process has increasingly been used in many manufacturing industries such as aeronautics, nuclear, chemistry, oil, textile, automotive[1,2]. Despite this large field of applications, the plasma sprayed coatings always contain a network of connected porosities and reach thicknesses between 100 µm and 1 mm. This is due to the coating growing which consists in a layering of splats resulting from melted particles with diameters ranging between 5 and 50 µm impacting the substrate. That is why, for a few years, research efforts have been devoted to develop the Suspension Plasma Spraying (SPS) process which aims at reaching thin (e.g., one order of magnitude smaller in thickness than in conventional plasma spraying) and finely structured coatings. The flexibility of this process should offer the possibility to adjust the porosity rate in coatings [3,4] as well as its chemical composition provided that the suspension injection is controlled.
This paper is devoted to show that finely structured coatings can be built by carefully choosing the plasma spraying parameters as function of particles sizes contained within suspensions.

2. Experimental facilities

In this section, first, the powder characteristics and their preparations are described as well as that of the corresponding suspensions. Second, the experimental set-up and the operating conditions are given.

2.1 Powders

Two different powders are used in this study to obtain finely structured coatings. The first one consists of submicron particles and the second one of micron particles. The former results from a sedimentation technique of a commercial Yttria Stabilized Zirconia (YSZ with 13.5wt% Yttria) powder provided by Tosoh Corp. (Japan). Figure 1-a shows a picture obtained by Scanning Electron Microscopy (SEM) of the submicron particles after sedimentation. It highlights particles with a few hundreds of nanometer in diameter.

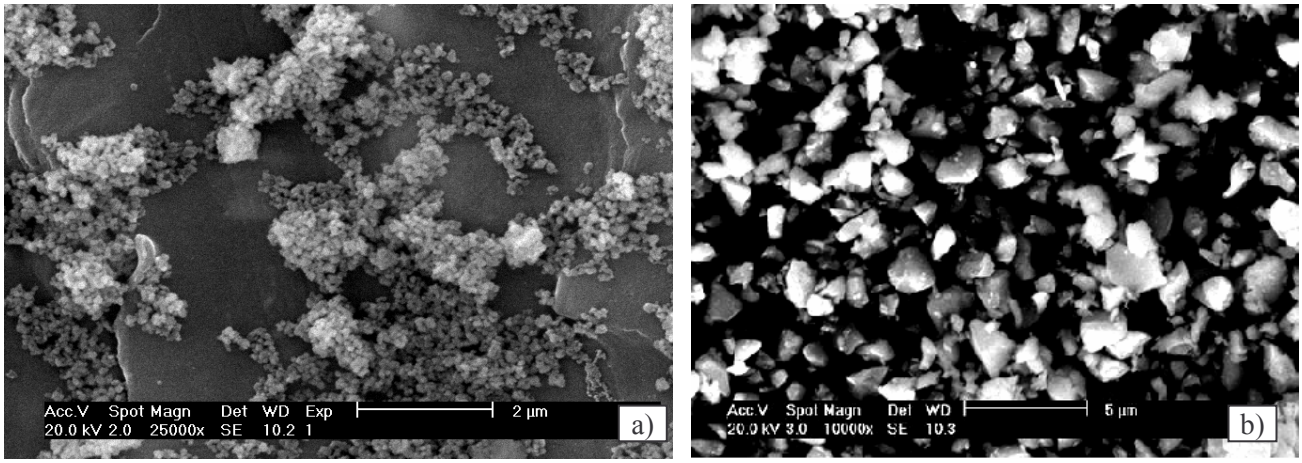

Figure 1: Pictures obtained by scanning electron microscopy of a) the submicron powder and b) the attrition milled powder

Figure 2 shows a volume particle size distribution of the submicron particles. This powder is mainly composed of particles with diameter smaller than 600 nm, with a large amount of particles with diameters ranging between 100 and 300 nm.
The second powder containing micron particles is obtained using an attrition milled technique. Fused and crushed particles are attrition milled to achieve a narrow particle size distribution centred on 3 µm. A -22+5µm YSZ powder was attrition milled during 13 hours (see the SEM picture in Figure 1-b). The Figure 2 shows that this powder is mainly composed of micron particles. Less than 10vol% particles have a diameter smaller than 1 µm, whereas the maximal diameter does not exceed 5 µm.

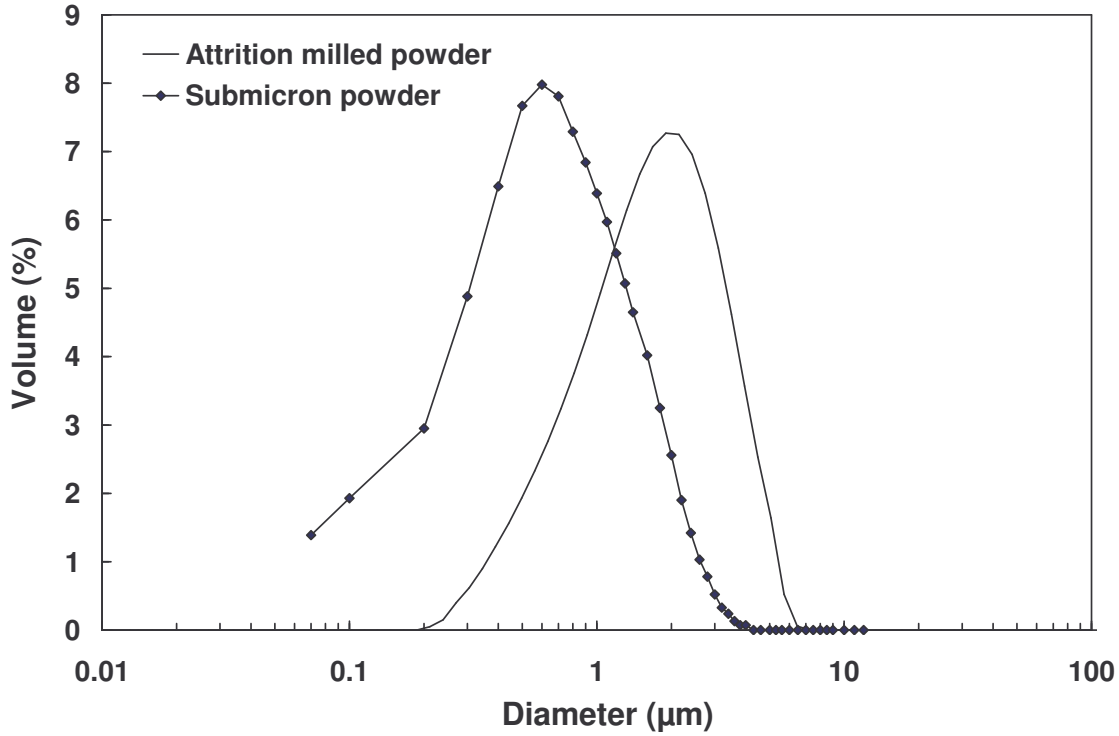

Figure 2 : Powder size volume distributions of the attrition milled powder and submicron powder.

The suspensions are produced according to the following criteria: they must be time-stable, maintaining good particle dispersion (without agglomeration), have the lowest viscosity, for a given particle loading, corresponding to an optimum dispersion and enabling an efficient injection, and, have a high particle loading to increase the deposition efficiency. Suspension of YSZ particles consist of a solvent, e.g. ethanol, in which solid particles are dispersed using a dispersant, e.g. an ester phosphate. The stabilization mechanism is based on an electrical charge balance produced at the surface of particles [5] and a stabilizing effect induced by the polymeric chains of the dispersant [6]. Chartier *et al.* [6] explains that the lowest viscosity of ceramic/dispersant/solvent systems corresponds to the best degree of deagglomeration and the highest stability. They show that the dispersant behaves as anionic dispersants by partially dissociating when immersing it within the solvent and liberating hydronium ions (H_3O^+). Ceramic particles initially presenting a negative charge on the surface, the hydronium ions adsorb to charge positively the surface of the particles. Then, ceramic particles attract the anionic dispersant molecules which present long polymeric chains. Consequently, the latters prevent the particles from falling into the van der Waals attraction potential at close distance of the particle surface (steric repulsion).
Suspensions of YSZ powders were prepared with a powder mass percentage of 7% of the ethanol and powder mass. The mass percentage of the phosphate ester selected for use is 2 % of the powder mass for both powders.

2.2 Experimental set-up

The plasma spraying set-up (Figure 3) consists of a PTF4 plasma torch, four suspension feeders and, either a splat collector or a deposition system. The internal diameter of the anode nozzle is 6 mm. The operating conditions are summarized in Table 1.

The pressure of the tank of the suspension feeders can be varied to modify the drop injection velocities. Three tanks are used to spray different suspension compositions only by switching tank valves. The fourth is filled only with solvent to clean the injection nozzle (150 µm in internal diameter) when the injection of a given suspension is finished.

The suspension is counter-flow injected, with a 15° angle with respect to a vertical axis. Moreover, in order to ensure the repeatability of experiments, the injector position is rigorously controlled by micro-positioning it with respect to the plasma torch.

In respect of the deposition system, a micro-controlled table carrying the substrate can be moved in the three space coordinates (x,y,z). Moreover, the plasma torch voltage V and current I as well as the thermal losses Q at the electrodes are controlled and measured on-line. The torch efficiency η can be deduced from the following equation: $\eta = 1 - Q/VI$, as well as the specific enthalpy $\bar{h}$ of the plasma jet from $\bar{h} = \eta VI/\dot{m}$ where $\dot{m}$ is the total plasma forming gas mass flow rate. The plasma voltage decreases with the deposition time due to the erosion of electrodes, resulting in a reduction of the available specific enthalpy inducing mainly a decrease of the plasma velocity and a lowering of the heat transfer to particles. This is compensated for by increasing the arc current to keep the specific enthalpy constant. For new electrodes without erosion, Table 1 gives the specific enthalpy of plasma jets used.

The local heat flux absorbed by the coating is measured. The measurement simply consists in measuring the total heat flux received from the plasma jet by a copper target rapidly crossing it. The temperature rise ΔT is measured by means of a thermocouple inserted within the copper target. It is assumed that the heat uptake is rapidly and homogeneously transferred within the target interior. Moreover, a pseudo-stationary temperature state is assumed to exist within the copper target after exposure to the plasma since its natural cooling period is much longer (3 to 4 orders of magnitude) than its heating one.

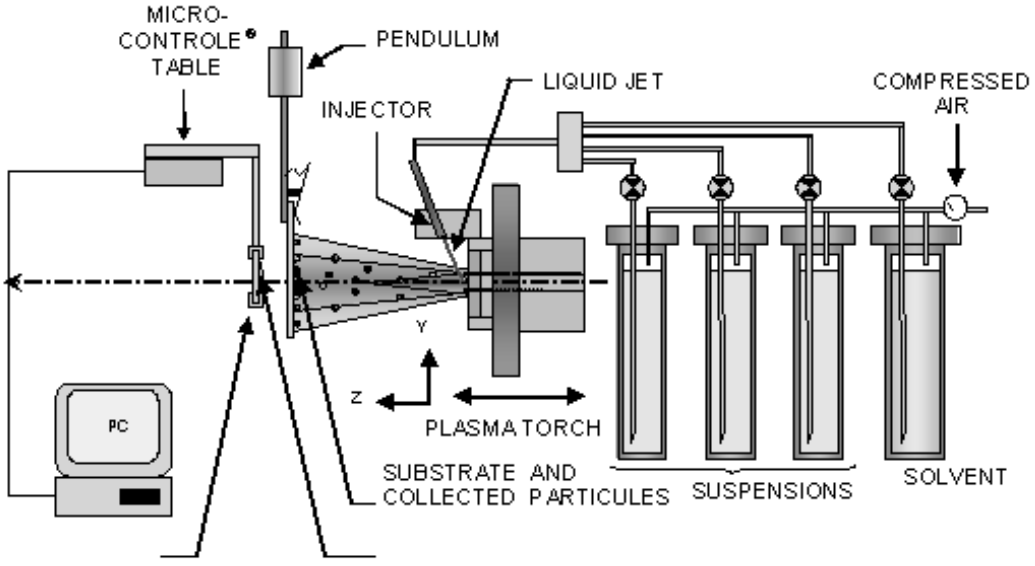

Figure 3: Experimental set-up

The copper target crosses the plasma jet without suspension injection at the same location as a normal coating. Crossing distances are respectively at 40, 50 and 60 mm from the nozzle exit. The heat, ΔQ, transferred to the copper target is calculated using the relation $\Delta Q = mc_p\Delta T$ where m (kg) and c_p ($J.kg^{-1}.K^{-1}$) are respectively the mass and the specific heat of the copper target. The exposure is time is 31.25 ms and the copper target exposed area is about 2.10^{-4} m^2. It has to be pointed out that this area is related to the plasma area intercepted by the target which is not precisely defined because it has been evaluated from the trace left by the plasma jet on the copper target.

Table 1: Spray parameters

Internal nozzle diameter (mm)	6	6
Stand-off distance (mm)	40	40
Plasma forming gas (slm)	Ar-He (40-80)	Ar-H_2-He (40-10-50)
Powders	Submicron	Attrition milled
I (A)	300	500
Power (kW)	18.6	37.5
Specific enthalpy (MJ/kg)	13	20.6

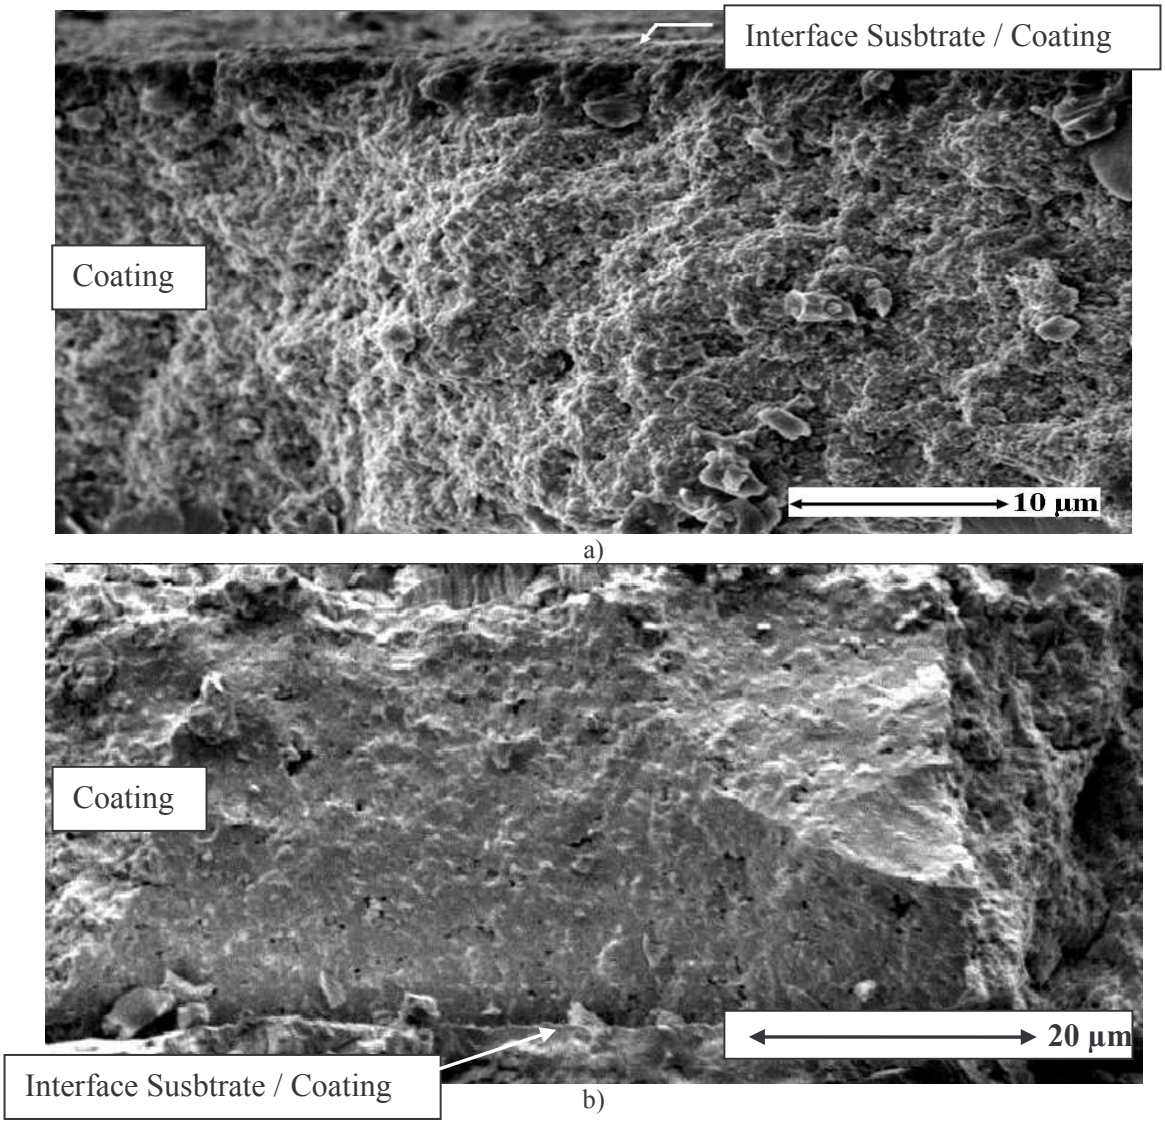

Figure 4: Fractured cross-section of coatings sprayed at 40 mm dowstream of the nozzle exit with a) the submicron powder and b) the attrition milled powder.

3. Results and discussion

3.1 Coatings

Coatings are produced following both operating conditions given in Table 1. The suspension containing submicron particles is sprayed onto a smooth (Ra=0.05 µm) and pre-heated (350 °C) stainless steel substrate. The suspension consisted of the attrition milled particles is sprayed onto a conventionally plasma sprayed YSZ substrate.

Figure 4 shows the fractured cross-section of coatings sprayed with the submicron powder and the attrition milled powder, respectively in Figure 4-a and 4-b. First, no layering of splats is observed in both coatings as obtained in conventional plasma spraying when using particles with a few tens of microns in diameter.

Both coatings exhibit a granular microstructure without interconnected porosities and micro-cracks. However, despite a different scale between both figures, Figure 4-a seems to highlight a more finely structured microstructure and less dense than in Figure 4-b

The choice of plasma parameters for the submicron powder is devoted to obtain a reduced available specific enthalpy within the plasma jet which allows treating submicron particles limiting their vaporization. That is why a higher specific enthalpy is used in the case of the attrition milled powder where particles are one order magnitude higher in diameter than within the submicron powder. Moreover, in order to homogeneously treat the particles, the helium plasma forming gas is used because it tends to limit the voltage fluctuations and to generate a more stable plasma jet as shown in Figure 5 [7]. It shows that the voltage amplitude relatively to the mean voltage is almost twice higher when using a plasma forming gas with hydrogen than when using helium alone. It has to be noted that the heat and momentum transfer characteristic times of particles is proportional the square of their diameter. Submicron and micron particles are therefore much more sensitive to changes in momentum and heat transfers than particles used in conventional plasma spraying.

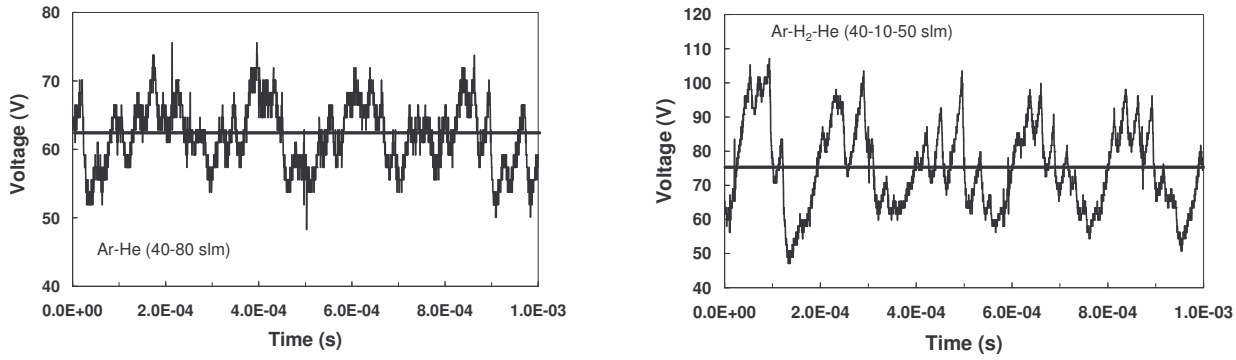

Figure 5: Torch voltage fluctuations as function of the plasma gas composition

3.2 Heat Fluxes

It is expected that the convective transfers between the plasma jet and the coating should be of great importance due to the short stand-off distance (40 mm downstream of the nozzle exit). That is why heat fluxes are measured as function of the stand-off distance for both plasma compositions, Ar-H_2-He (40/10/50 slm) and Ar-He (40/80 slm), as explained in section 2.2.

Figure 5 shows the heat flux transferred to growing coatings under the above mentioned experimental conditions. At 40 mm from the nozzle exit, for the Ar-H_2-He plasma, the heat flux to the copper target reaches 17 $MW.m^{-2}$, this flux level being some 10 times larger than that used in conventional plasma spraying where the coatings are generally deposited at a stand-off distance of 100-120 mm. These very strong heat fluxes probably involve drastic increases in the surface temperature of the deposited YSZ pass (of only about 0.8 µm thickness) which should either be higher than the sintering temperature of zirconia (about 1500 °C) or keep the sprayed pass melted resulting in a quite dense coating. The heat flux induced by the Ar-He plasma is less important than that of the ternary mixture permitting the conservation of the fine microstructure.

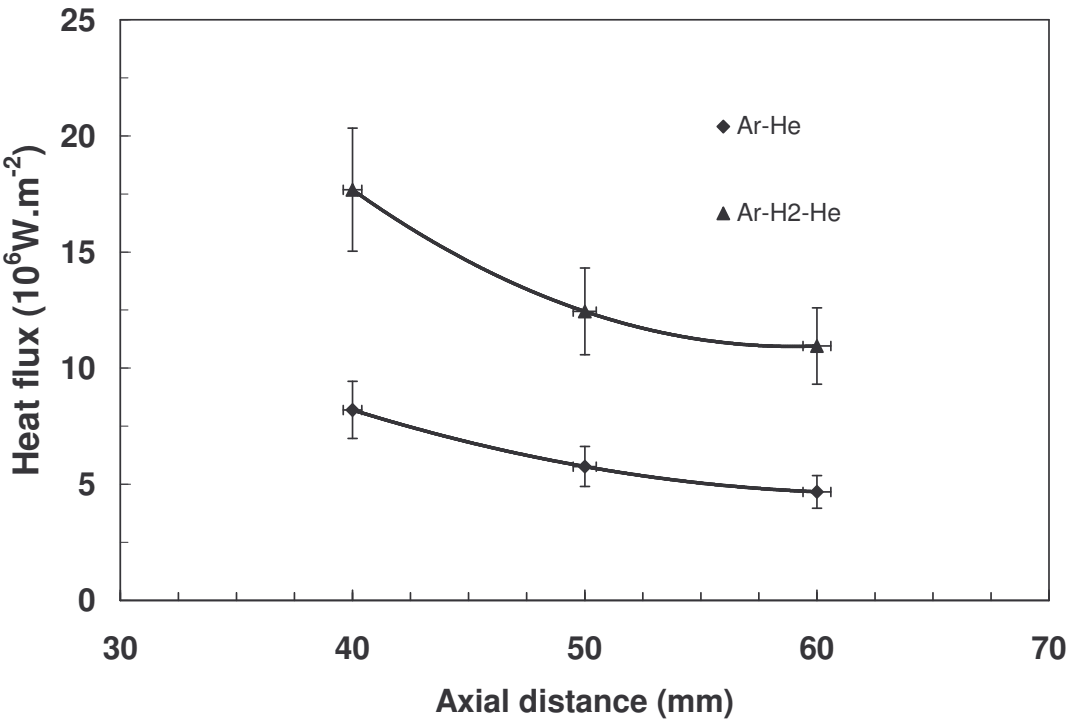

Figure 5: Evolution along the torch axis of the heat fluxes imposed to the substrate with three plasma forming gases: Ar-H_2, Ar-H_2-He and Ar-He.

4. Conclusion

Suspension Plasma Spraying (SPS) is a novel process which aims at producing coatings with intermediate thicknesses of a few micrometers up to a few tens of micrometers. Actually, it fills the gap between the Chemical/Physical Vapor Deposition processes and the thermal spraying processes. The main characteristic of SPS is the possibility to plasma treat submicron particles by a thermal plasma jet provided that the particles are injected within the core of the plasma. This paper shows that finely structured coatings are obtained using SPS by analyzing the microstructure of coatings. The latters are produced by injecting suspensions of powders with narrow micron and submicron particle size distributions. It is shown that finely structured coatings are obtained for both powders but, choosing a set of plasma spraying parameters adapted to the size of particles. For submicron particles, it has to be recommended a reduced specific enthalpy available within the plasma jet to limit particle vaporization as well as a more stable plasma source. However, for micron particles, even if the last condition should be maintained, an enhanced specific enthalpy must be used. Consequently, in this case, it is shown that the plasma jet should contribute to increase the density of coating during its growing due to the strong heat flux transferred from the plasma to the coating.

Abstract; performance of CH_4 conversion with pulsed corona, dielectric barrier discharge, microwave torch plasma, gliding arc, and micro-hollow cathode plasma are compared. After the comparison tests, O_2 is added into the reactor, which leads to 1) elevated temperature conditions through exothermic partial oxidation reactions and 2) higher CH_4 conversion rate and H_2 yield.

Introduction

A small-scale plasma reformer has great potential to apply in advanced combustors. Fig. 1 shows the effect of syngas (hydrogen and carbon monoxide) on the unstable flame. Here, the syngas is produced from CH_4 using the small-scale plasma reformer. The emitted gas compositions from the reformer are 66.9 % N_2, 15.1 % CH_4, 8.1 % O_2, 3.4 % H_2, 3.0 % CO, and C2, C3 chemicals. As shown in fig.1, even the small amount of syngas is effective to stabilize the unstable flame. Flame stabilization has been one of the most critical issues in combustion study, since flame stability problems frequently occur in developing low NOx combustors, high throughput combustors, low emission engines and gas turbine combustors, etc. Fig. 1 clearly shows that flame stabilization technique with plasma reformer could be an alternative approach to conventional flame stabilization techniques.

(a) (b)

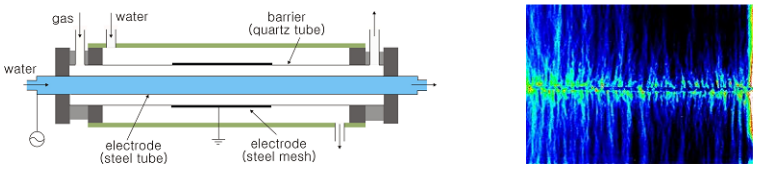
Fig. 1 modification of flame stability, (a) plasma reformer off, (b) plasma reformer on

Plasma reforming technique has inherent advantages in applications of syngas assisted

combustors for the capability of fast start-up and low cost of device. However, operating cost for producing syngas could be problems for practical applications. As reviewed by Cormier et al [1], operating cost of plasma reformer is higher than those of conventional catalytic steam reformer by several factors of magnitudes. The objective of the present study is to search for the approaches to reduce the operating cost, i.e. specific electrical power consumption for producing hydrogen. In the early stages of the study, numerous types of atmospheric pressure plasma have been tested and compared. The tested plasma generation techniques are pulsed corona, spark, DBD (Dielectric Barrier Discharge), microwave torch plasma, micro hollow cathode plasma, and gliding arc. In this comparison study, hydrogen is produced through methane direct decomposition, $CH_4 \rightarrow C + 2H_2$. Methane conversion rates, compositions of products, and specific power to produce hydrogen are varied depending on the types of plasma. After the comparison tests, syngas was obtained through partial oxidation process of methane, $CH_4 + 1/2\ O_2 \rightarrow 2H_2 + CO$. Here, modified gliding arc, i.e., rotating arc is adopted for generating plasma.

Comparison of plasma generation technique

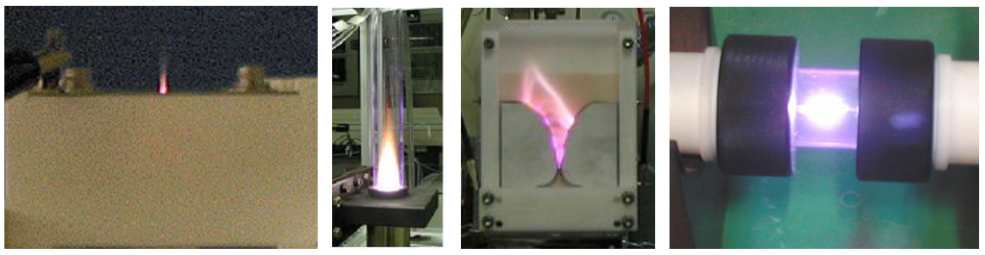
Fig. 2 (a) shows typical shapes of plasma reactor for generating DBD and pulsed corona. The length of the electrode is 10 cm, and the dia. of the quartz tube is 30 mm. For CH_4 decomposition tests, up to several hundred kJ/L of specific input power are needed, which used to cause break down of the quartz tube. In order to protect the quartz tube and to run the test for the long periods, cooling water is supplied into the inner and outer electrodes. When generating DBD, medium frequency (10 kHz) and high voltage (up to 10 kV) AC power supply is used. When generating positive pulsed corona, pulsed power supply is used to produce 20 kV peak voltages with 100 nsec pulse width. Fig. 2 (b) shows typical images of positive pulsed corona taken by ICCD. The gate time of the ICCD is 100 msec, which is long enough to superpose multiple images of corona. So-called non-thermal plasma, shown in fig. 2, can produce relatively high electron energy and low gas temperature. Detailed numerical and optical analysis showed that the mean electron energy of the streamer head is about 10 eV and the electron number density of streamer head is about $10^{13} - 10^{14}$ cm^{-3} [2]. These conditions of electrons are good enough for decomposing CH_4 that is relatively inert compared to other hydrocarbons. The calculation also predicts that the life-time of the single pulsed corona is about several tenth nano seconds. This means that the plasma zone in a fixed time is quite small, considering the actual volume of the reactor shown in the figure.



(a) (b)

Fig. 2 (a) Schematics of pulsed corona and DBD reactors, (b) images of positive pulsed corona taken by Intensified CCD (gate time: 100 msec)

Fig. 3 shows micro-hollow cathode plasma, microwave torch plasma, gliding arc and spark, respectively. These plasma reactors are fabricated in the lab for the present study. We expect that effective chemical reactions induced by plasma need 1) high electron energy, and 2) dense plasma zone in the reactors. Unfortunately, none of typical atmospheric pressure plasma produces such ideal conditions. Mean electron energy of non-thermal plasma is high, but the effective reaction volume occupied by such high electron energy inevitably small, as shown in fig. 2. On the other hand, even though the mean electron energy of the plasma shown in fig. 3 is relatively low, the pathways of the treated gas are filled with plasma. Since none of the previous studies compared the performance of the above types of plasma while producing syngas, we need a preliminary test for choosing an appropriate plasma sources for producing syngas.



(a) (b) (c) (d)

Fig.3 (a) micro hollow-cathode plasma; hole dia. 1 mm, 22 kV, 60 Hz AC power supply is used, (b) microwave torch plasma, (c) gliding arc, 10 kV, 60 Hz AC power supply is used, and (d) spark generated by a pulsed power supply.

Hydrogen produced from CH_4 can be obtained through several different chemical reaction pathways; direct CH_4 decomposition ($CH_4 \rightarrow C + 2H_2$), partial oxidation ($CH_4 + 1/2\ O_2 \rightarrow CO + 2H_2$), steam reforming ($CH_4 + H_2O \rightarrow CO + 3H_2$), etc.. Among these pathways, we tested direct CH_4 decomposition to determine which types of plasma could be appropriate for hydrogen production. Fig. 4 showed the CH_4 conversion rate and the specific input power, kJ/L. In the cases of the microwave torch plasma, gliding arc, and micro-hollow cathode

plasma, the inlet gases are diluted by 93 - 95 % of nitrogen. We observed that ignition and continuous operation of the present microwave torch is difficult when CH_4 concentration is higher than 10 %. Without dilution, continuous operation of gliding arc and micro-hollow cathode plasma was also difficult due to carbon deposition on the reactor wall. Some modifications of reactor configurations might be helpful to solve these problems, but such efforts were not tried in the present comparison tests.

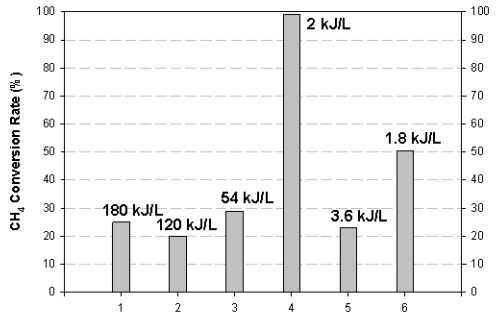


Fig. 4 CH_4 conversion rate and specific input power along with different types of plasma, (1): DBD, (2) Pulsed Corona, (3) Pulsed Spark, (4) microwave torch, (5) gliding arc, (6) micro-hollow cathode plasma

Several characteristics of direct CH_4 decomposition can be verified based on the fig. 4 result. Non-thermal plasma sources, which generate DBD and pulsed Corona, are not effective for producing H_2, since the input power of these plasma sources are higher than those of other types of plasma by orders of magnitudes. In addition, these plasma sources also produce unwanted by-products, i.e., C_2H_6, C_2H_4 and C_3H_8, which result in lower H_2 selectivity. On the other hands, plasma sources with relatively high gas temperatures, which are microwave torch, gliding arc, and micro-hollow cathode plasma, consume small electrical power. H_2 and C_2H_2 selectivity with these plasma sources is also high. In the case of the pulsed spark, the highest C_2H_2 selectivity is obtained among the tested plasma sources, and is about 50 %. An additional test shows that C_2H_2 selectivity tends to decrease and H_2 selectivity tends to increase when the gas residence time in the reactors increases. In conclusion, the plasma sources with relatively high gas temperature and longer gas residence time are desirable for hydrogen production process.

O2 addition test

Gas temperatures of the plasma sources can be significantly increased by addition of O_2, since partial and complete oxidation process of CH_4 with O_2 is exothermal reactions. A rotating arc

reactor shown in fig 5 was used in the present O_2 addition tests. The arc generated in the reactor is rotated by tangentially injected gas, as suggested by Hnatiuc et al [3]. The rotating arc can produce relatively high gas temperatures like gliding arc, and can be operated continuously without the problems of carbon deposition on the wall. Another advantage of the rotating arc is that the gas residence time can be longer than that of the two dimensional gliding arc reactor shown in fig. 3, since the area of the outlet section of the rotating arc reactor is larger than that of the two dimensional reactor. The power supply used in the present test operated with 10 kHz of high voltage (5 – 10 kV) AC power. Fig. 6 shows the schematics of the test apparatus. In order to measure the outlet gas compositions, quartz tube is located after the reactor. Gas sampling and temperature measurements are conducted through the quartz tube.

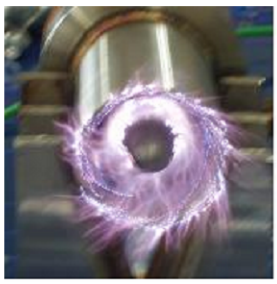

Fig. 5 rotating arc reactor (gas: Nitrogen)

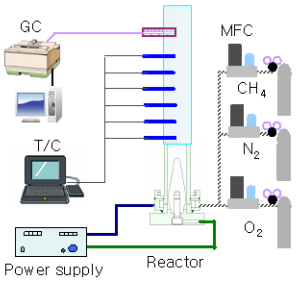

Fig. 6 Schematics of test apparatus

Temperatures measured at the outlet of the reactor are increased by the O_2 addition, as expected. The temperature measured at the closest port to the outlet of the reactor is 500 °C when O_2/C ratio is 0.5. The temperature increases up to 1,000 °C when O_2/C is 1.0. Here, O_2/C = 0.5 is the O_2/C ratio of the partial oxidation, $CH_4 + 1/2\ O_2 \rightarrow CO + 2H_2$, and O_2/C=2 is the O_2/C ratio of the complete combustion, $CH_4 + 2\ O_2 \rightarrow CO_2 + 2H_2O$. CH_4 conversion rate, H_2 yield, and CO yield also increase, as the O_2/C ratio increases, as shown in fig. 7. In the tests, total gas flow rates are 10 lpm. When O_2/C ratio is 0.5, the inlet gas consists of N_2: 70 %, CH_4: 20 %, O_2: 10 %. The input power is 200 W, which corresponds to 1.2 kJ/L of the specific input power. Considering CH_4 conversion rate, H_2 yield, and the specific input power, the performance of the O_2 addition test is much higher than the test results shown in fig. 4. Such enhanced performance could be attributed to the increased temperature caused by the heat released by the partial oxidation or combustion. A chemical equilibrium calculation also predicted that the CH_4 conversion rate and H_2 yield increase as the temperature increases. This simple explanation, however, might not be sufficient, since strong interactions between plasma and oxidation (combustion) are expected in the reactor. At present we do not have information of electron energy distributions and number densities at the elevated temperature conditions. In a further study, clarifying of such phenomena is expected.

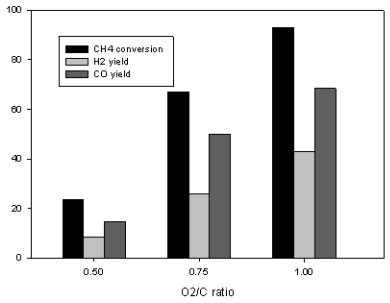

Fig. 7 CH_4 conversion, H_2 and CO yield at different O_2/C ratio

Conclusion

Numerous types of plasma generation techniques are investigated to search for appropriate plasma sources for hydrogen production. Comparison test results showed that so-called non-thermal plasma is not effective for CH_4 conversion and H_2 production. This could be attributed to the fact that 1) non-thermal plasma produces relatively low gas temperature and 2) effective reaction zone, e.g. streamer head, is small compared to the total reactor volume. Microwave torch plasma, gliding arc, and micro-hollow cathode plasma, which produce relatively high gas temperature, are effective for CH_4 conversion and higher H_2 yield, although these plasma sources generate relatively lower mean electron energy. After the comparison test, we performed O_2 addition tests that generated higher temperature conditions in the reactor. The increased temperature, which is caused by the heat released by partial oxidation and combustion, are effective to enhanced performance of CH_4 conversion and higher H_2 yield.

A Miniature RF Atmospheric Pressure Glow Discharge Torch (APGD-*t*)

S. Coulombe and V. Léveillé

Department of Chemical Engineering, McGill University, Montréal (QC), Canada

The interest in the development of atmospheric pressure glow discharge plasma sources has grown considerably over last few years [1,2]. Ideally, such sources would offer the principal benefits of the "classical" low-pressure glow discharges with additional advantages associated with the operation outside vacuum chambers (lower equipment and operation costs, compact size and portability, ease of sample handling). There is in fact an interest to develop such sources for the treatment of biological surfaces since those are particularly difficult to handle under low-pressure conditions, and/or require *in-situ* treatment. Some examples of actual (or potential) applications in this field are the sterilization of contaminated surfaces [3], the removal of cells and biofilms, the momentarily disruption of the cell adhesion properties [4], the surface functionalization of polymer surfaces for the microcontact printing of proteins, and the disruption/acceleration of biochemical processes. This paper reports recent research activities that led to the development of a miniature atmospheric pressure glow discharge torch (APGD-*t*) suitable for the precise treatment of biological surfaces.

Figure 1 shows a schematic of the atmospheric pressure glow discharge torch (APGD-*t*) and its electrical circuit. The torch consists of a quartz confinement tube which downstream end is shaped into a convergent nozzle (final I.D. = 500 μm). The central stainless steel tube serves two purposes: as powered electrode and for the injection of reactive gaseous species into the afterglow plasma jet. A silver epoxy painted on the external surface of the quartz tube serves as the ground electrode. Two zones with distinct functions are created with this geometry: a plasma-forming zone where electrons, excited neutral He and metastables are formed, and a recombination zone (the afterglow plasma jet) where the active species formed in the plasma-forming zone recombine and loose their energy to excite the reactive gaseous species injected through the capillary. From the electrical standpoint, the torch assembly forms a concentric electrodes capacitor having a theoretical capacitance value of ≈1.5 pF. A pulsed RF (13.56 MHz) excitation is used to sustain a stable glow discharge jet of various power levels in the flowing plasma-forming gas (He). A homemade series inductor is used in order to provide near-resonance circuit conditions. The power delivered to the torch is determined from the measurement of the torch voltage, circuit current and phase angle between both signals. Due to the extremely low electrical capacitance of the torch and the use of 13.56 MHz excitation, the voltage probe (Tektronix P3169A, 10X, 10 MΩ, 8 pF) has a drastic effect on the operating conditions and thus, has to be accounted for. Detailed circuit analyses and experimental investigations showed that an inductance value of 6.3 μH gives rise to reasonable operating conditions.

The measured breakdown voltage of the APGD-*t* operating with 1 SLM He fed in the quartz tube is ≈67 $V_{pk\text{-}to\text{-}0}$. This low value is attributed to the geometrical amplification of the electric field at the capillary electrode surface. In fact, the estimated value for the electric field at the breakdown voltage is ≈1.6×10^5 V/m thanks to a 4.4X geometrical amplification factor. This minimum electric field value compares well with the value of ≈2×10^5 V/m one obtains by extrapolation of the Paschen's curve data reported for the high-frequency breakdown of He [5]. At 10% pulse duty cycle, the measured RMS torch voltage, RMS circuit current (Tektronix CT-2 current transmitter, 1mV/1mA into 50Ω) and phase shift between both signals were 382 V_{rms}, 410 mA_{rms} ($|Z|$=910 Ω) and -86°, respectively ("ON" period only). The torch/voltage probe system thus represents a highly-capacitive complex impedance in the circuit. The torch's resistance (R_T) and capacitance (C_T), and resistive power dissipated in the torch (P_T) and voltage probe (P_P) were determined from the circuit analysis. Values of R_T ≈160 Ω, C_T ≈5.1 pF, P_T ≈ 450 mW and P_P ≈640 mW were obtained. The power density of the glow discharge is thus ≈6 W/cm^3.

Fig. 2 shows telemicroscopic images of the plasma jet for three sets of conditions: 1 SLPM He in the quartz tube (top); 1 SLPM He in the quartz tube with 1 SCCM O_2 injected through the capillary electrode (middle); and 1

SLPM He + 1 SCCM O_2 injected in the quartz tube (bottom). When no reactive gas is injected in the plasma-forming region, a bright plasma jet extending ≈2.5 mm downstream of the nozzle exit is observed. This jet appears symmetric and laminar. The presence of a structure similar to a bow shock requires further investigation since the flow is subsonic. Experiments carried out under similar conditions but using a metallic mesh as ground electrode instead of the silver epoxy paint showed that the glow discharge fills the entire inter-electrode volume (≈76 mm^3). The bluish appearance of the jet is attributed to the entrainment and excitation by He metastables of N_2 molecules from the ambient air. The injection of small quantities of O_2 through the capillary electrode does not lead to a significant alteration of the jet though atomic oxygen is detected further downstream (by OES). The injection of the same amount of O_2 to the plasma-forming gas causes a quench of the optical emission of the plasma jet. Thorough studies of the plasma jet characteristics by optical emission spectroscopy and laser-absorption spectroscopy and of the interaction of the jet with a biological surface are currently under progress.

Modeling zirconia melt droplet – substrate interaction

A.N. Cherepanov, V.N. Popov, O.P. Solonenko
Institute of Theoretical and Applied Mechanics, SB RAS, Novosibirsk, Russia

Abstract
Thermal and hydrodynamic processes that occur during impingement of the liquid metal and metal oxide droplets onto a multilayered substrate were numerically studied. The model developed is based on the Navier-Stokes equations for an incompressible liquid and on 'substrate–particle' heat transfer equations that take into account the surface tension forces and solidification of a melt. The simulation results are found to be in satisfactory agreement with experimental data.
Key words: micro-droplet, melt, substrate, collision, spreading, cooling, solidification, splat formation

1. Introduction

During the last one and half decades, increasingly growing interest was expressed to the problem of ultra-rapid quenching of melt micro-droplets of various materials upon their impingement on a surface [1-17]. This phenomenon is basic to many advanced technologies such as plasma, arc, detonation and flame spraying, powder micro-atomization, solder-drop-printing in microelectronics, production of microcrystalline and amorphous materials and high-temperature superconductors. Also, it is of great interest for heterogeneous plasma chemistry and materials science when it is necessary to study non-equilibrium state diagram of different alloys and composite materials under extreme exposures. It was recognized that further progress in improving both quality and structure of sprayed materials largely depends on our understanding of processes that occur during interaction of liquid particles, carried by a high – temperature jet, with substrates.

Characteristic features of this system are the fine particulates, the wide range of velocities and temperatures of droplets at their interaction with a surface and, as a consequence, the presence of many factors essentially complicating the analysis of the attendant phenomena. The interaction proceeds under extreme conditions like the high rate of droplet deformation, cooling, phase changes, and abnormal high local density of thermal fluxes and drastically variation of the physical properties of particle and substrate materials. Therefore, as the result of heating a particle in high-temperature jet and its subsequent quenching under impact with substrate, a spread out and solidified droplet, what is known as splat, can be in specific cases in metastable or amorphous state.

In this connection, it seems to be an urgent matter to further develop hydrodynamic and thermophysical concepts for the interaction between a liquid particle and a solid surface. Since a detailed experimental study of the majority of processes that occur in a melt particle and in the near – surface region of base (a substrate or already deposited layer) is extremely difficult, the only way to get a better insight into the phenomenon is to perform numerical experiments together with derivation of model analytical solutions [10,15,16].

The main goal of the paper presented is to develop and testing the physical and mathematical model and numerical method for unsteady conjugated conductive – convective heat transfer and phase transitions that occur during impingement of liquid micro-particles onto solid surfaces.

2. Physical and mathematical model

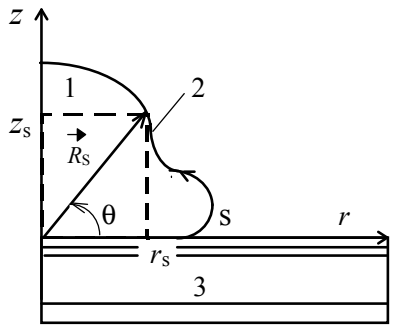

Fig. 1. Diagram of deforming droplet after collision with multi-layer substrate.

Let's assume that spherical droplet impinges onto a wet rigid substrate. The trajectory of the drop is normal to the substrate surface, and the initial substrate temperature is lower the melting point of the particles' material. After collision, a drop surface starts deforming, and an initial liquid flow develops in the drop (Fig. 1).

Viscous fluid dynamic equations. To numerical study the dynamic of a liquid drop after its impingement onto solid surface, we use the Navier-Stokes equations for a viscous incompressible fluid. We suppose the flow in the droplet to be laminar and the values of the thermophysical properties of the melt to be constant and equal to their mean values in the temperature range under consideration.

With allowance for the assumptions used, the equations of the fluid flow in the cylindrical coordinates shown in Fig. 1 have the following dimensionless form [18, 19]:

$$\frac{\partial U_z}{\partial \bar{z}}+\frac{1}{\bar{r}}\frac{\partial\left(\bar{r}U_r\right)}{\partial \bar{r}}=0,\quad \frac{1}{\bar{r}}\frac{\partial}{\partial \bar{r}}\left(\bar{r}\frac{\partial P}{\partial \bar{r}}\right)+\frac{\partial^2 P}{\partial \bar{z}^2}+\frac{1}{\bar{r}}\cdot\frac{\partial^2(\bar{r}U_r^2)}{\partial \bar{r}^2}+\frac{2}{\bar{r}}\frac{\partial^2(\bar{r}U_rU_z)}{\partial \bar{r}\partial \bar{z}}+\frac{\partial^2 U_z^2}{\partial \bar{z}^2}=0,$$

$$\frac{\partial U_z}{\partial \tau}+\frac{\partial U_z^2}{\partial \bar{z}}+\frac{1}{\bar{r}}\frac{\partial\left(\bar{r}U_rU_z\right)}{\partial \bar{r}}+\frac{\partial P}{\partial \bar{z}}-\frac{1}{\mathrm{Re}}\left[\frac{1}{\bar{r}}\frac{\partial}{\partial \bar{r}}\left(\bar{r}\frac{\partial U_z}{\partial \bar{r}}\right)+\frac{\partial^2 U_z}{\partial \bar{z}^2}\right]+\frac{1}{\mathrm{Fr}}=0, \tag{1}$$

$\tau=tu_{p0}/D_p, \bar{r}=r/D_p, \bar{z}=z/D_p, U_r=u_r/u_{p0}, U_z=u_z/u_{p0}, P=p/(\rho_{pm}^{(l)}u_{p0}^2)$. System (1) is solved with the dimensionless boundary conditions:

$$\begin{aligned}&U_r=0,\quad U_z=-1,\quad P=4/\mathrm{We}\ \text{ for }\tau=0,\\ &U_r=0,\quad \partial U_z/\partial \bar{r}=0,\quad \partial P/\partial \bar{r}=0\ \text{ for }\bar{r}=0,\\ &U_r=0,\quad U_z=0\ \text{ for }\ \bar{z}=\zeta(\bar{r},\tau),\quad \zeta(\bar{r},0)=0,\end{aligned} \tag{2}$$

$\bar{z}=\zeta(\bar{r},\tau)$ is the solidification front. The last relations are supplemented by the conditions at the free surface of liquid particle:

$$\left(P-\frac{2K}{\mathrm{We}}-\frac{2}{\mathrm{Re}}\frac{\partial U_r}{\partial \bar{r}}\right)n_r-\frac{1}{\mathrm{Re}}\left(\frac{\partial U_r}{\partial \bar{z}}+\frac{\partial U_z}{\partial \bar{r}}\right)n_z=0,\left(P-\frac{2K}{\mathrm{We}}-\frac{2}{\mathrm{Re}}\frac{\partial U_z}{\partial \bar{z}}\right)n_z-\frac{1}{\mathrm{Re}}\left(\frac{\partial U_r}{\partial \bar{z}}+\frac{\partial U_z}{\partial \bar{r}}\right)n_r=0. \tag{3}$$

Here n_r and n_z are the components of a unit vector normal to the free surface of the droplet, along the *r* and *z* axes, respectively, and the dimensionless curvature of drop surface is given by the relation [7]

$$K=\left\{x_s^2(x_s'y_s''-y_s'x_s'')+[(x_s')^2+(y_s')^2]x_sy_s'\right\}/\left(2x_s^2[(x_s')^2+(y_s')^2]^{3/2}\right),$$

where the prime denotes the derivative with respect to the dimensionless arc length $S=s/D_p$ and $x_s=r_s/D_p$, $y_s=z_s/D_p$ are dimensionless projections of the vector R_s/D_p onto the $\bar{r}$ and $\bar{z}$ axes, respectively (Fig.1).

Heat transfer equations. We determine the change in the temperature field in the droplet – substrate system from the solution of the conjugate heat transfer problem posed both in the liquid and solid phases of the particle, which undergoes solidification, and in the substrate. We take into account the liberation of the latent crystallization heat during the phase transition by introducing an effective heat capacity [20].

We write the heat transfer equations in the melt (*i*=1), in the layer that has already solidified (*i*=2), and in the substrate (*i*=3) in the following dimensionless form:

$$c_{eff}\left(\frac{\partial\vartheta_1}{\partial\tau}+U_r\frac{\partial\vartheta_1}{\partial \bar{r}}+U_z\frac{\partial\vartheta_1}{\partial \bar{z}}\right)=\frac{1}{\mathrm{Pe}_1}\left[\frac{1}{\bar{r}}\frac{\partial}{\partial \bar{r}}\left(\bar{r}\frac{\partial\vartheta_1}{\partial \bar{r}}\right)+\frac{\partial^2\vartheta_1}{\partial \bar{z}^2}\right],\ c_{eff}\frac{\partial\vartheta_i}{\partial\tau}=\frac{1}{\mathrm{Pe}_i}\left[\frac{1}{\bar{r}}\frac{\partial}{\partial \bar{r}}\left(\bar{r}\frac{\partial\vartheta_i}{\partial \bar{r}}\right)+\frac{\partial^2\vartheta_i}{\partial \bar{z}^2}\right], \tag{4}$$

where $\mathrm{Pe}_i=D_pu_{p0}/a_i$ is the Peclet number, $\vartheta_i=T_i/T_{pm}$ (*i*=2,3), and $\tau=u_{p0}t/D_p$ is the dimensionless time. The effective heat capacity c_{eff} is defined by the relations

$$c_{eff}=\begin{cases}1, & \vartheta>1+\Delta\vartheta/2,\\ 1+\mathrm{Ku}_p^{(l)}/\Delta\vartheta, & 1-\Delta\vartheta/2\le\vartheta\le1+\Delta\vartheta/2,\\ c_2/c_1, & \vartheta<1-\Delta\vartheta/2,\end{cases} \tag{5}$$

where $\Delta\vartheta=\Delta T/T_{pm}$ is dimensionless temperature interval over which the phase transition is "smeared" [20]. To describing crystallization of the droplet one may use the Stefan-problem approximation, assuming that the temperature at the solid-liquid interface coincides with the equilibrium solidification point, the crystallization front is macroscopically smooth, and the nucleation in the liquid metal may be ignored.

Equations (4) should be supplemented with the following boundary conditions.

1. Initial values of the droplet and substrate temperatures: $\vartheta_1|_{\tau=0}=\vartheta_{p0}$, $\vartheta_3|_{\tau=0}=\vartheta_{20}$. (6)

2. Adiabatic condition at the free surface of the drop: $\bar{\lambda}_i\left(\frac{\partial\vartheta_1}{\partial r}n_r+\frac{\partial\vartheta_1}{\partial z}n_z\right)=0.$ (7)

3. Condition of heat transfer between the drop and the substrate:

$$\bar{\lambda}_i \frac{\partial \vartheta_i}{\partial \bar{z}}\Big|_{\bar{z}=+0} = \lambda_3 \frac{\partial \vartheta_3}{\partial \bar{z}}\Big|_{\bar{z}=-0} = \mathrm{Bi}(\vartheta_i - \vartheta_3). \tag{8}$$

Hear $\bar{\lambda}_i = \lambda_i / \lambda_1$ (i=1 for $\vartheta \geq 1$, i=2 for $\vartheta < 1$), $\mathrm{Bi} = \alpha D_p / \lambda_1$ is the Biot number, $\alpha = 1/\sum_j \delta_{sj} / \lambda_{sj}$ is the coefficient substrate-to-particle heat transfer through the previously deposited layer(s), and δ_{sj}, λ_j are the thickness and thermal conductivity of the jth sub-layer, respectively.

4. Conditions of heat transfer at the lower, side and upper substrate surfaces, respectively:

$$\partial\vartheta / \partial\bar{z}|_{\bar{z}=-L} = \partial\vartheta / \partial r|_{\bar{r}=\bar{r}_3} = \partial\vartheta / \partial r|_{\bar{z}=0} = 0. \tag{9}$$

Here $\bar{L} = L / D_p$, $\bar{r}_3 = r_3 / D_p$ (L, r_3 are the thickness and radial dimension of the substrate; $r_3 >> D_p$).

5. Symmetry condition at the z axis in the droplet spreading and substrate:

$$\frac{\partial \vartheta_i}{\partial \bar{r}}\Big|_{\bar{r}=+0} = 0, \quad i = 1, 2, 3. \tag{10}$$

The heat-transfer equations (4) with boundary conditions (6)-(10), together with Navier-Stokes equations for the liquid part of the particle (1), govern the droplet cooling and solidification process.

3. Numerical method

The numerical algorithm for computing the problem formulated was describe in [18]. It is based on a finite-difference approximation of the Navier-Stockes and heat-transfer equations with an implicit scheme of order $O(\tau, h)$. The region occupied by the unsteady flow of melt is marked with successively enumerated particles-markers located along the droplet free surface and moving with the local fluid velocity. To satisfy the monotonicity conditions for the finite-difference scheme, the special derivatives in the inertial terms are approximated by using the "up-wind" scheme. The diffusion terms are approximated by their second-order difference analogs. In this approach, no limits are imposed by Reynolds numbers on the stability of the numerical calculations.

Having determined the velocity field, we calculate the temperature field in the drop and substrate in accordance with the Eqs. (4)–(10). The thermal problem is to be solved in two conjugated computational domains, in the drop and in the substrate. The match the temperature distributions in the two domains, no more than three iterations were sufficient. The new coordinated of the markers, $r_m^{(n+1)}$ and $z_m^{(n+1)}$, at the (n+1)-th time step are calculated by the relations

$$r_m^{(n+1)} = r_m^{(n)} + u_m^{(n)} \Delta\tau_{n+1}, \quad z_m^{(n+1)} = z_m^{(n)} + v_m^{(n)} \Delta\tau_{n+1}, \quad m=1,\ldots, M(t_n).$$

Here $u_m^{(n)}$ and $v_m^{(n)}$ are the particle velocities determined in accordance with the mean local velocities in a small vicinity of each of the markers and $M(t_n)$ is the number of markers at the time t_n. At each time step, we have to either remove or add some part of markers, in order to obtain their uniform distribution over the droplet contour, and re-enumerate them. Throughout the whole computational domain, a spatial grid h_z=h_r=0.01·D_p was used. At the time moment t_{n+1}, the time step $\Delta\tau_{n+1}$ was computed by the formula

$$\Delta\tau_{n+1} = \min\{h_z, h_r\} / K_0 \max\{|u_m^{(n)}|, |v_m^{(n)}|\}, \quad K_0=20.$$

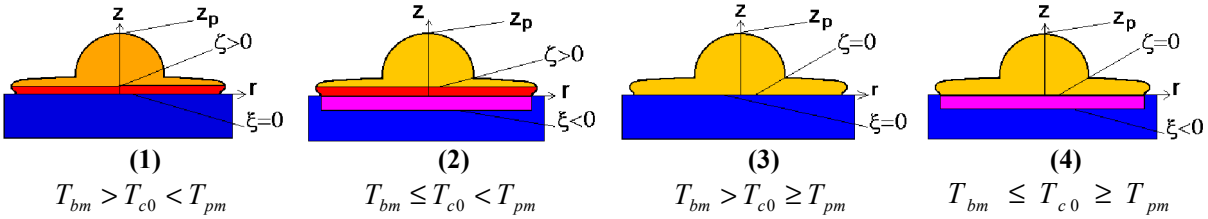
Following [20], we chose the region over which the boundary between the phases was "smeared" so that the region included two or three nodes of the spatial grid. This could be achieved through preliminary estimation of typical temperature gradient. In the computer program, the temperature interval ΔT was chosen automatically. It should be noted that, in the calculations, the mean value of this parameter was around 5°C.

At each time step, the system of algebraic equations is solved using an iterative procedure. The computations were terminated on reaching the relative error of 0.002.

The simulation results are found to be in satisfactory agreement with different experimental data (low and high Reynolds and Weber number). In particular, it is possible to simulate the droplet's oscillation during splat formation. The results of computational experiment allow to analyze the influence of the key physical parameters (KPPs) - and thermophysical properties of particle and substrate materials on morphology of splat, the time of its formation, the size of contact spot splat-substrate, etc. A typical CPU time of one running using conventional PC computer (f ~ 1-2 GHz) is 2-3 hours.

4. Results and discussion

In accordance with [21], the following four basic scenarios of splats formation are possible, depending on the temperature $T_{c0} = (T_{p0} + K_{\varepsilon}^{(b,p)} T_{b0})/(1 + K_{\varepsilon}^{(b,p)})$ of the particle/substrate interface and melting points of particle (T_{pm}) and substrate (T_{bm}) materials (Fig. 1):



(1) $T_{bm} > T_{c0} < T_{pm}$ (2) $T_{bm} \le T_{c0} < T_{pm}$ (3) $T_{bm} > T_{c0} \ge T_{pm}$ (4) $T_{bm} \le T_{c0} \ge T_{pm}$

Fig. 2. Possible scenarios of splat formation.

(1) – spreading of the droplet over the solid surface of the base and its simultaneous solidification;
(2) – spreading of the droplet over the surface, its simultaneous solidification, and partial sub-melting of the base at the base/particle contact spot;
(3) – spreading of the liquid particle over the solid surface, followed by cooling and solidification of the flattened drop with simultaneous recoiling of its edges;
(4) – spreading of the liquid droplet over the surface with simultaneous sub-melting of the base, followed by their cooling and solidification.

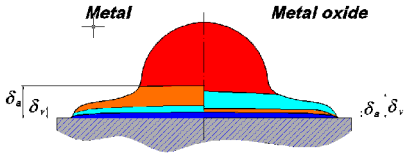


Fig. 3. Relative thickness of thermal (δ_a) and hydrodynamic (δ_v) boundary layers under metal (Pr<<1) and metal oxide (Pr>1) splats formation.

For each of the above-mentioned scenarios, two characteristic regimes of heat transfer between the melt and the solid wall (either the particle solidification front surface $\zeta(r,t)$ or the substrate z=0) are possible depending on the ratio between the thicknesses of the dynamic and thermal boundary layers in the melt flow (see Fig.3), whose value, in a first-order approximation, can be estimated as $\delta_v / \delta_a \approx \sqrt{\mathrm{Pr}}$.

4.1. Testing the model and numerical method

The proposed model was tested for adequacy by comparing the droplet shape computed for different times after its impingement onto copper substrate with the experimental data previously reported in [15].
It was carried out the additional model numerical experiments to study the deviation of experimentally measured and numerically predicted splats' diameter and morphology at reduced We and Pe numbers in order to study the influence the surface tension on splat formation on stainless steel substrate (see Figs. 4–7). It takes place a rather good agreement between experimental and numerical results. As evident from the results of comparison, the influence of a surface tension is negligible at We > 200 and Pe>250.

4.2. Modeling zirconia splats formation

The next series of computer simulation has been fulfilled regarding the zirconia splats' formation. The results of calculations presented in Figs. 8–10 establish a fact a rather satisfactory agreement between experimental and numerically predicted final diameter and morphology of splats.

5. Conclusions

Thermal and hydrodynamic processes that occur during impingement of the liquid metal and metal oxide droplets onto a multilayered substrate were numerically studied; the model developed is based on the Navier-Stokes equations for an incompressible liquid and on 'substrate–particle' heat transfer equations that take into account the surface tension forces and solidification of a melt. The model and numerical method developed were tested on example of tin droplets impacting with stainless steel substrates.

The simulation of the ZrO_2 splats formation on a nickel substrates were carried out using the mathematical model and numerical method developed. The results obtained are in a reasonable good agreement with the experimental data [22].

Analysis of Capability of the Polychromatic Pyrometry Method to Measure Temperature of Single Particle in High-Temperature Flow

E.V. Kartaev, A.A. Mikhalchenko, O.P. Solonenko
Institute of Theoretical and Applied Mechanics, SB RAS, Novosibirsk, RUSSIA

Abstract. The main goal of the paper presented is to model the procedure of measuring the temperature of alumina particles by implementing the 4-color pyrometry technique as well as to analyze the applicability of photo electronic multipliers (PEM-83) in comparison with that of Si-based avalanche photodiodes (APD S5344). The conducted numerical analysis regarded 4-color pyrometry technique as being promising for measuring the "non-gray" particle temperature, with APD S5344 being used as particle radiation detector.
Keywords: plasma, single particle, temperature, modeling, 4-color pyrometry, spectral emissivity.

1. Introduction

The reliable in-situ measurement of velocity, temperature and size of single in-flight particle in high-temperature flows, including plasma ones, is still of major interest since in a number of cases the information about an individual particle needed instead of statistical estimates of above parameters of the representative particle ensemble. In particular, this problem appears when the mechanisms of formation of splat as flattened and solidified melt droplet is studied as function of the key physical parameters (KPPs) of particle collision with a substrate [1].

Particle temperature in high-temperature dust-laden flows is measured by detecting the particle thermal radiation. Here, the radiation intensity is simultaneously recorded in two spectral bands and the ratio of spectral intensities is derived to determine particle color temperature. The latter is equal to a real particle temperature assuming the particle behaves as "gray" radiator. The error of the method is primarily affected by spectral dependence of particle emissivity, an essential temperature gradients within the particle (for instance, in semi-transparent particles of alumina or YSZ) and chosen band centers for two-color pyrometry as well. The mentioned spectral particle emissivity in measurement procedure is commonly considered to be indeterminate.

In order to reduce both an instrumental error and that of the method one should increase the number wavelength bands to detect. The recording of particle thermal radiation in three bands is regarded as giving the optional feature in particle temperature measurement. This is due to using of an expanded scope of operating spectral bands as well as implementing the two independent methods of signal processing [2]. Assuming particle as "gray" body these methods allow one to match three independent particle temperatures (two color temperatures and 3-color one) having differed instrumental errors and those of the methods.

In the present work by simulating the measurement procedure of particle temperature the analysis of the method of multicolor pyrometry taking into account the 4 wavelength bands is conducted, with spectral particle emissivity being as $\varepsilon(\lambda,T)=a_o+a_1\lambda$.

2. Modeling and comparative analysis

The comparative analysis of measuring the temperature and size of alumina particles (original powder being close to mono-disperse one) have revealed the three-color pyrometry as having the least instrumental error of particle temperature measurement. Here the alumina powder was chosen as its optical properties in wide spectral region for vast variety of temperatures are most accurate, for instance, the effective absorption cross-section [3]. Attempting to take into consideration a "non-gray" radiation of particle by applying the linear approximation of its emissivity ($\varepsilon(\lambda,T)=a_o+a_1\lambda$) have shown to be stipulated unsatisfactorily which is pronounced by several minima within noise "grass" [2]. It is dealt with the excess of number of unknown parameters (particle temperature and size, the coefficients of linear approximation of spectral emissivity) over the number spectral bands to detect the particle radiation (3 wavelengths).

Detecting the particle radiation in four spectral bands enables one to provide the comprehensive survey of particle thermal state owing to the both enhanced spectral scope and three independent methods of signal data processing. The total error in measuring the particle temperature is caused by following factors: addition of detector shot noise to the pyrometric signal, plasma background noise, the violation of "gray" behavior of the particle radiation.

In the present paper the 4-color pyrometry technique assuming a linear spectral dependence of particle emissivity $\varepsilon(\lambda,T)=a_o+a_1\lambda$ is used in order to test whether it is capable to estimate average temperature of

alumina particles' ensemble more precisely. The latter is urgent when detecting YSZ particle radiation for which corresponding optical properties in wide spectral region for vast variety of temperatures are rather scarce. Moreover, when traveling in plasma jet the temperature gradients inside the YSZ particles are likely valuable. This influences the YSZ particle emissivity [5].

To investigate a potential of diagnostic setup presented in [2] intended for detecting the particle parameters in plasma spraying, the photo electronic multiplier (PEM-83) used by this time and the avalanche photodiode (APD S5344 commercially available by Hamamatsu Inc.) were separately analyzed as detectors based on the multicolor pyrometry technique. The basic characteristics of both detectors are denoted in Table 1.

Table 1. The basic features of the detectors

Detector	Spectral response bandwidth, μm	Dark current, nA	Gain M	Cut-off frequency band Δf at 50 Ω load resistance, MHz	Photo sensitivity $S_{\lambda i}$, mA/Wt			
					λ_1= 0.5145 μm	λ_2= 0.6328 μm	λ_3= 0.7212 μm	λ_4= 0.8906 μm
PEM-83	0.4-1.2	500	$4 \cdot 10^5$	100	0.6	1.5	2.4	1.9
APD S5344	0.2-1.2	20-100	50	25	410	420	400	140

As the development of [2] the simulation of the measurement procedure of alumina particle temperature by detecting the signals with different noise levels for each of stated detectors has been executed. This was done to analyze an influence of noise level on the error of temperature estimate. The original particle parameters to be restored: size, velocity and temperature. Particle diameter and velocity, plasma background temperature were supposed to be constant (D_p= 50 μm, u_p= 100 and 200 mps, T_g= 2000 K), whereas particle temperature was varied within the range of T_p= 2400÷2800 K. The intensity P_{0i} of modeled signal per each spectral range was calculated in accordance with formula (1) below:

$$P_{0i} = f(D_p, u_p, t)\varepsilon(\lambda_i, T)\int_{\lambda_i-\Delta\lambda_i}^{\lambda_i+\Delta\lambda_i}\Phi_i(\lambda)\frac{C_1 d\lambda}{\lambda^5\left[\exp(C_2/\lambda T)-1\right]},\ i = 1 \div 4, \tag{1}$$

where $f(D_p,u_p,t)$ is the function that describes passing of the image of a spherical particle of diameter D_p in the plane of the intake diaphragm in time as a function of its velocity u_p, this function is proportional to the area of the particle image sequentially truncated by slits S_1 and S_2 (Fig.1) of the intake diaphragm; $\varepsilon(\lambda_i, T_p)$, ($i$=1÷4) – the emissivity of particle substance at the center of the spectral region of the i-th interference filter with measured transmission factor $\Phi_i(\lambda)$, $\lambda \in [\lambda_1 - \Delta\lambda_i/2;\ \lambda_i + \Delta\lambda_i/2]$.

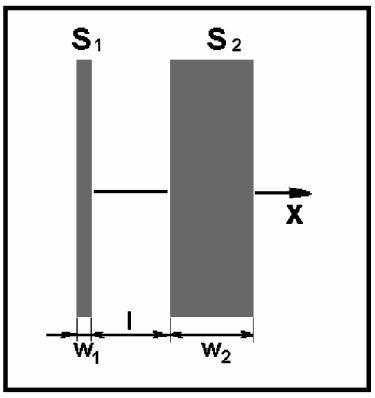

Fig.1. Geometry of the intake diaphragm. The S_1 slit width w_1= 100 μm, S_1 slit width w2= 800 μm, the inter-slit distance I= 800 μm, the diaphragm height – 3 mm.

The modeled signals are considered to be superimposed additively by a normally distributed noise with the relative mean-root-square error being expressed as following:

$$\sigma_{ni} / P_{0i} = P_{0i}^{-1} \sqrt{PkT_g \Delta f + 2e(P_{0i} + P)(1+B)\Delta f / S_{\lambda i}}\ , \qquad (2)$$

where P – average power irradiated by plasma background at i-th spectral region, i=1÷4; k = 1.38·10^{-23} J/K - Boltzmann constant; e = 1.6·10^{-19} A·sec - electron charge; (1+B)=2.5 - the coefficient including shot noise of PEM-83 dynodes; $S_{\lambda i}$, A/Wt - spectral sensitivity of PEM's photocathode; Δf = 20 MHz - the transmittance bandwidth of the electronic channel. In Fig.2(a) the typical profile of current signal of detected particle thermal radiation at λ_3= 0.7212 μm when using APD S5344 as the passive detector is drawn, in Fig.2(b) the corresponding current signal at PEM-83 photocathode is shown. In both cases the parameters of irradiating particle were following: D_p= 50 μm, u_p= 100 mps, T_p= 2400 K and ε(λ) =0.1.

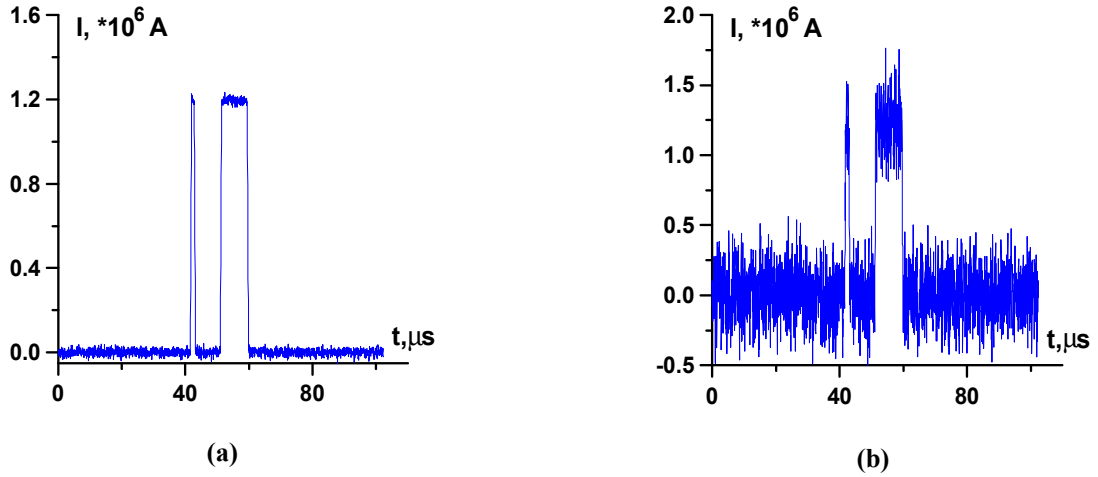

Fig.2. The typical signals of current for detecting the particle radiation at λ_3= 0.7212 μm when using APD S5344 as the passive detector – (a); the corresponding current signal at PEM-83 photocathode – (b). Parameters of irradiating particle: D_p= 50 μm, u_p= 100 mps, T_p= 2400 K and ε(λ) =0.1.

In the expression for relative noise mean-root-square error of APD S5344 the value allowing the APD magnification to be dependent on selected wavelength should replace (1+B) value in (2). It is physically caused by distinguished depth of penetration of light with different wavelengths in photosensitive area in silicon. In further modeling the particle thermal radiation this factor was neglected.

Within the restrictions of the model proposed by authors of [6,7] and described in detail in [8], the estimates of 3-color temperature T_{3c} using least square method for the same spectral regions λ_2=0.6328 μm, λ_3= 0.7212 μm, λ_4 = 0.8906 μm were obtained assuming particle as "gray" body. With the object of considering the real spectral dependence of emissivity of single Al_2O_3 particle, this model have been generalized for the case of $\varepsilon(\lambda)=a_0+a_1\lambda$ by means of complementary information on the base of the particle radiation intensity at λ_1=0.5145 μm. 4-color temperature T_{4c} is complied with minimum of the following discrepancy:

$$\Delta(r_p, \varepsilon, T) = \sum_{i=1}^{4} \left\{ \pi r_p^2 \varepsilon(\lambda_i, T) \int_{\lambda_i - \Delta\lambda_i/2}^{\lambda_i + \Delta\lambda_i/2} \Phi_i(\lambda) \frac{C_1 d\lambda}{\lambda^5 [\exp(C_2/\lambda T) - 1]} - \overline{P}_i \right\}^2 / \sum_{i=1}^{4} \overline{P}_i^2, \qquad (3)$$

where πr_p^2 - the area of irradiating particle, $\overline{P}_i$ - average power irradiated by the particle at i-th spectral region on the signal "plateau" corresponding to traveling the full particle image through wide slit S_2 (see Fig.1). Previously when calculating 3-color temperature the constancy of particle emissivity $\varepsilon(\lambda) = a_0 = const$ was postulated. The authors of [6] maintain yet the minimum of $\Delta(r_p,\varepsilon,T)$ to be determined in the best way when the linear approximation $\varepsilon(\lambda,T)=a_o+a_1\lambda$ is used.

Numerical algorithm of computing the minimum of (3) by analogy with that in [7] comprises the plotting 3D grid with nodes (q_i, p_j, T_k), i=1,…N_1, j=1,…N_2, k=1,…N_3 within the area of varying the quantities $q_i = a_{oi}\pi r_p^2$, $p_j = a_{1j}\lambda\pi r_p^2$ and T_k corresponding to some discrepancy Δ_{ijk}. The sought values of q^*, p^* $T_{4c} = T^*$ are supposed to be adequate the minimization of $\Delta^* = \min \Delta_{ijk}$ determining the instrumental error of the given model.

(d)

Fig. 3. Bar charts of particle temperature distributions of 10 μm alumina powder: *a*, *b* – color temperatures T_{c34} and T_{c24}; *c*, *d* – T_{3c} and T_{4c} calculated for 3 and 4 spectral regions respectively.

To estimate the potential limits of diagnostics of alumina particles using APD S5344 the modeling of 100 in-flight single particles with fixed parameters (D_p= 510 μm, u_p= 100 mps, T_p= 2350 K), with chosen spectral emissivity of alumina particle ε(λ) = 0.15-0.1λ (μm) being close to that in [3]. This has a descending slope of spectral emissivity for selected Al_2O_3 particle size and temperature. Here the modeled signals had following noise levels relative to useful ones in spectral regions of interest in the view of transmission bandwidths of filters: $\sigma_{n1} / \overline{P}_1 = 0.18$, $\sigma_{n2} / \overline{P}_2 = 0.11$, $\sigma_{n3} / \overline{P}_3 = 0.07$, $\sigma_{n4} / \overline{P}_4 = 0.08$.

The results of statistical data acquired for color temperatures T_{c34}, T_{c24}, 3-color temperature T_{3c} ("gray" body assumption) as well as 4-color temperature T_{4c} taking into consideration spectral dependence ε(λ) are depicted in Fig.3. The estimate of averaged velocity of particles' ensemble was 197 mps, with standard velocity deviation being about 6 mps.

As seen from the bar charts of the temperatures that averaged 4-color temperature T_{4c} is close to the real temperature of the particles modeled, nevertheless it has a relatively wide standard "3σ" data scattering of ±150 K. For given noise level the procedure permitted to restore certainly the negative slope of dependence $\varepsilon(\lambda)$. At the same time the absolute emissivities at each wavelength had been restored with averaged error of ~20-25%. The selected averages of as 3-color temperature as either color temperature are still biased from the real temperature. The error of estimation of T_{3c} is entirely specified by methodical error of the "gray" body approach. Though it had a very narrow data scattering (±15 K), conditioned by presence of shot noise of the detector. The errors of estimates of the color temperatures are much greater than that of T_{3c} in average and in data scattering too as already notified in [8].

The modeling for the same particle parameters assuming "gray" particle with emissivity of $\varepsilon(\lambda) = a_0 = 0.1$ demonstrated almost complete coincidence of all the temperatures. Here the sensibility of the 4-color technique seemed to be too weak on order to estimate accurately the quantity of particle emissivity. Data scattering for ε was about 20-30%. The corresponding modeling of particles' diagnostics with the help of PEM-83 shown clearly the diagnostic complex as being unable to detect these particles with given parameters.

The comparative modeling of the procedure of detecting 50 μm alumina particles at higher temperatures illustrated more evidently the preference of implementing the avalanche photodiodes in respect to the reduction of instrumental error for both 3- and 4-color pyrometry techniques. Further modeling investigation is required to analyze thoroughly 4-color technique sensibility to varying particle parameters. Although the above stated estimates are promising from the point of view of applying these techniques under real conditions of plasma spraying.

The small instrumental error and low threshold of determination of 3-color temperature T_{3c} when using APDs as detectors compared with those obtained for PEMs are primarily resulted from higher level of APD spectral sensitivity. For this reason APDs are preferable as detectors in diagnostics of particles to be sprayed. The basic APD shortcomings are an insufficient gain and some narrow cut-off frequency band Δf. These could be overcome by matching the conventional units of amplifying.

Abstract
A novel method based on thermionic vacuum arc plasma was developed to grow carbon films for MEMS applications. Carbon films deposited on mirror-polished Si and glass substrates were identified as DLC phase with sp^3 bonds up to of 89% and diamond crystallites size of 3-11 nm. Atomic force and electron transmission microscopes, Raman and X-ray photoelectron spectroscopes, were used to characterize the morphology and the phase composition of the samples after the growth stages.

1. Introduction

Microsystems domain represents a growing interest due multiple applications in health care, environment, automotive and aero-spatial industries, etc. being developed in the frame of many European programs.

MEMS (Micro-Electro-Mechanical-Systems) technology is about 80% based on Si. Even Si can be used in many applications its usage is limited due to the low mechanical and high wear resistances and high coefficient of friction between Si and SiO_2. These problems can be solved by using new materials with enhanced tribological properties [1-2] ensuring lubrication and hydrofobicity to prevent adhesion. High value of hardness and low coefficients of friction determine a longer liftime. Materials with high tribological properties are: diamond like carbon (DLC), diamond, cubic boron nitride, silicon carbide, carbon nitride, aluminum nitride. DLC is an extremely interesting prospective material for MEMS due to its superior wear-resistant qualities, hydrophobicity, resistance to stiction (i.e. a combination of stickiness and friction) and potential as a biocompatible material that could be used inside the human body for medical purposes without generating an allergic reaction. Thermionic vacuum arc (TVA) method [3-5] was adopted to prepare DLC films on Si and glass substrates

2. Experimental set-up

One of the most important characteristics of TVA method is the presence of energetic ions in the pure carbon vapor plasma. Moreover, the energy of ions can be fully controlled from outside of the discharge vessel via the control of the arc voltage drop value. It results that during film preparation, just during deposition, the growing thin film is bombarded by energetic ions with an in advance established value of the energy of ions. The bombarding ions are just the ions of the depositing material (carbon). A Whenelt cylinder is used to focus the electrons on the anode surface. A bright discharge is established in high vacuum conditions in the cathode-anode space. Due to the high energy dissipated in the unit volume plasma, the material is strongly dispersed and completely droplets free. The obtained thin film is very smooth and in some experimental conditions has a nanoscale structure.

Coatings on mirror-polished Si (size of 20 mm x 20 mm x 0.5 mm) and glass substrates (size of 8 mm x 60 mm x 0.5 mm) were performed. The main working parameters are presented below: Anode material; graphite rod of 10 mm diameter and 200 mm in length; Cathode material: W + 0.2% Th, 1.5 mm in diameter; Distance between cathode and anode (2 -10 mm); Angle between the electron beam and the horizontal line (30 – 45^o); Intensity of the heating current of the cathode filament (100 – 120 A); TVA applied voltage (1-6kV); TVA

discharge voltage (1.5 – 2kV); Intensity of the TVA current (0.1 – 1 A); Distance between anode and substrate holder (100-300 mm); Deposition rate (0.2 – 3 nm/s).

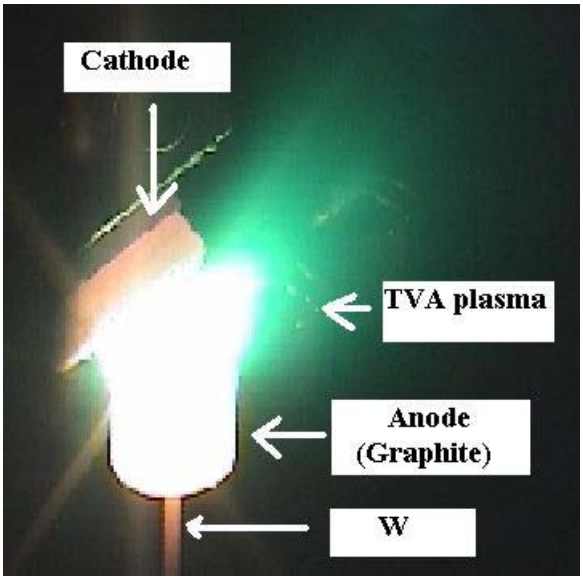

Fig.1 Photograph of TVA running in pure carbon atoms.

The obtained films were analyzed by Raman and X-ray photoelectron spectroscopy (XPS), transmission and atomic force microscopy (TEM and respectively AFM), microindentation and tribological tests.

3. Results and discussion

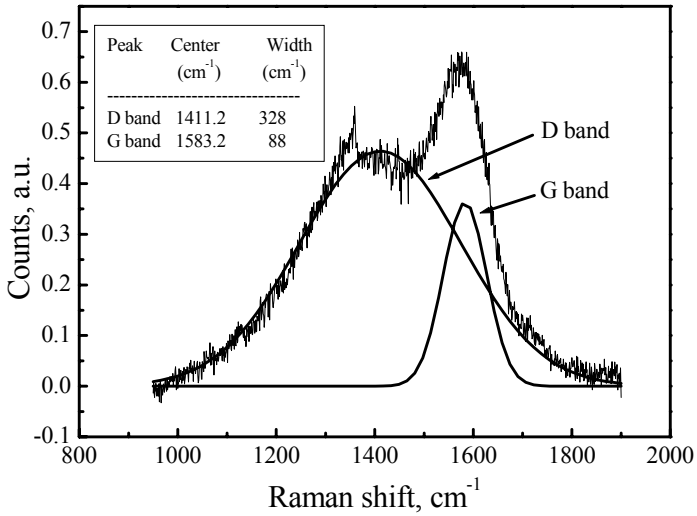

Fig. 2 Typical Raman spectrum of the DLC film

Raman spectroscopy was used to identify the C phase of the deposited films. Raman spectra were obtained in a back-scattering configuration using the 514.5 nm line of an Ar^+ laser with 5 mW power and 50 μm spot diameter. The signal was detected with a photomultiplier using a standard photon counting system with the acquisition time of 60 s. Carbon was identified as DLC phase, as defined recently by Ferrari and Robertson [6] with a large ratio of characteristic D-band/G-band intensities. Figure 2 shows a typical spectrum of the prepared

films and a Gaussian fit made in order to separate the D and G-bands. The D and G-bands are characteristic of the sp^2 sites of all disordered carbons at about 1411 and about 1583 cm^{-1}, respectively. Development of the D-band indicates disordering of graphite due to the formation of sp3 bonds between graphitic adjacent planes but ordering of an amorphous carbon structure; its intensity is proportional to the number and size of sp^2 clusters, while its width is more related to a narrower distribution of clusters with different order and dimensions. The G-band involves the in-plane bond-stretching motion of pairs of carbon sp^2 atom; this mode does not require the presence of sixfold rings and so it occurs at all sp^2 sites [6].

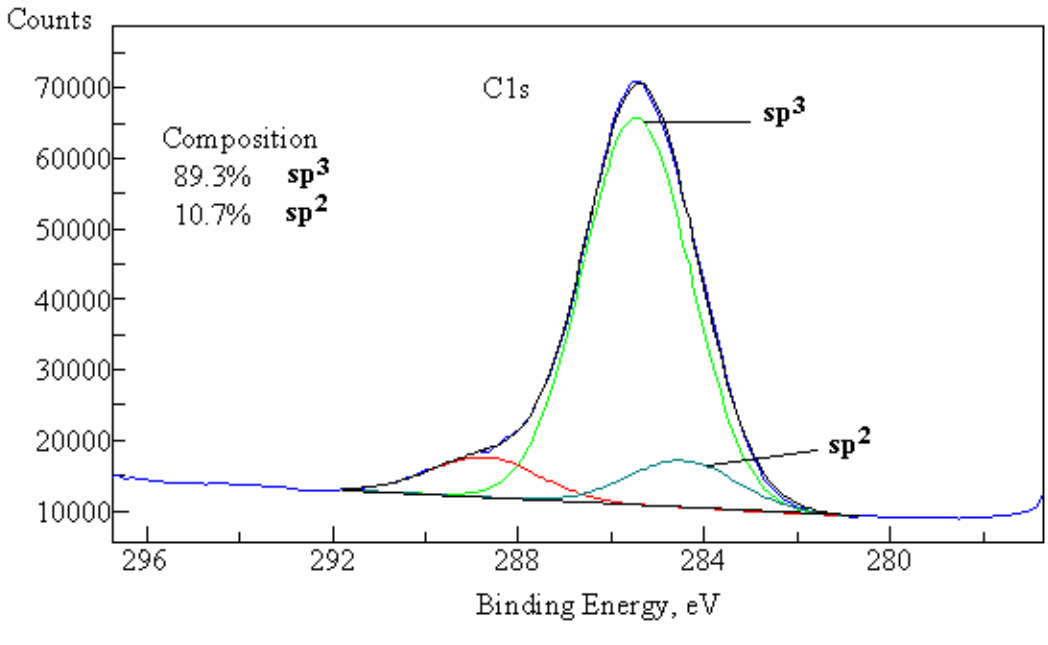

Fig.3 C1s peak deconvolution

The sp^3 bonds were found in the range of 89% compared with 11% of the sp^2 bonds after calibration and deconvolution of the C1s peak of the XPS spectrum of the prepared film as can be seen in Fig. 3.

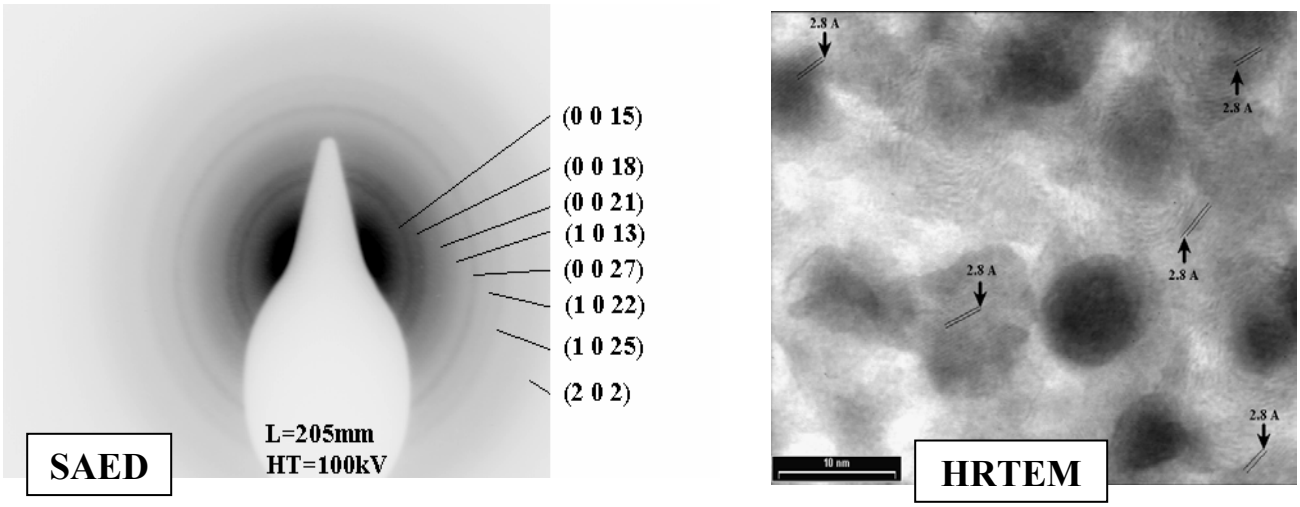

Fig. 4 Rhombohedra structures of the film with following parameters: a = 0.25221 nm, c = 4.3245nm (ASTM pattern: 79-1473) corresponding to diamond/carbon, determined by SAED (selected area electron diffraction) and HRTEM (high resolution transmission electron microscopy)

HRTEM images analysis shows the interference fringes given by the complex crystallites included into the amorphous carbon (Fig. 4). The arrows show the interplanar distances corresponding to the crystalline structure. The particles, 3-11 nm in diameter, were embedded into the film containing amorphous carbon. .

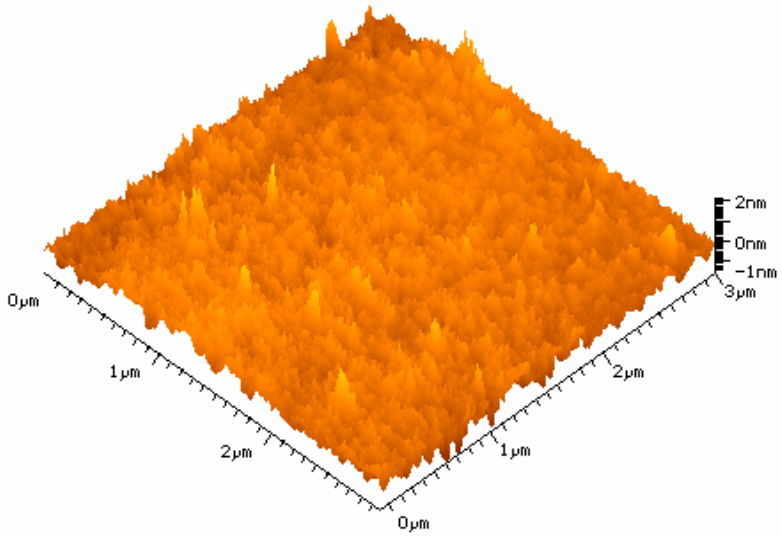

Fig. 5 AFM image of the analyzed film

The AFM image presented in Fig.5 shows the DLC film surface with a the peak-to-valley roughness in the 2-3 nm range.

The hardness of the deposited films was found in the range of 50-60 GPa, typically values for the DLC films.

The coefficient of friction of the deposited films tested by a flat to flat tribometer in dry conditions was in the range 0.05 -0.1. This suggests the predominant influence of the DLC acting as a solid lubricant in dry friction.

4. Conclusions

We can conclude that TVA method can be used successfully for preparation of DLC films for MEMS applications. High resolution TEM images of the deposited films using TVA reveals nanostructured particles with 3-11 nm diameter size, embedded in the amorphous carbon film. Super hard (50-60 GPa) nanostructured carbon films with low value of roughness and coefficient of friction can be obtained quite easily. Further developments will be related mainly to the improvement of the TVA stability at the transition from electron bombardment heating of carbon rod to the TVA arc plasma ignition and running.

MICROSTRUCTURAL STUDY OF SILICON NITRIDE WHISKERS PRODUCED BY NITRIDATION OF PLASMA-SPRAYED SILICON LAYERS

M.S.Alaee [1,2]
[1] *Department of Physics, Azad University, Karaj, Iran*
[2] *Department of Physics, University of Tehran, Tehran, Iran*

Abstract
plasma-sprayed silicon layers have been used to produce silicon nitride with fiberous microstructure which optimizes fracture toughness and strength. In order to study the oxygen contamination effect as well as other contaminants introduced during spraying and nitridation processes, surface sensitive analysis techniques like AES and XPS have been used to determine concentration of these contaminants. SEM examination of the specimens shows that the surface is covered by fine needles and whiskers of Si_3N_4.
Keywords: plasma spray, silicon nitride, whiskers, surface analysis, microstructure, contamination

1. Introduction

Silicon nitride whiskers offer the advantages of high melting point, low density and high moduli which makes it an important reinforcing material in composites [1]. Silicon nitride layers have been studied extensively in recent years on account of the potential uses as a material which has many desirable properties such as strength, light weight, low coefficient of friction and high wear resistance and fracture toughness, which make it one of the more promising candidates for high temperature structural materials. Silicon nitride is a hard material with low expansion coefficient and possesses high strength by comparison with other ceramic materials. The reaction-sintered form of silicon nitride which is known as the first engineering form of silicon nitride has some 15-30% porosity which limits the strength of the material. This problem may be overcome by taking advantage of the inherent capability of the plasma spraying technique to produce layers with low porosity. On the other hand, to some extent, low porosity hinders the nitridation. Plasma sprayed silicon subjected to nitridation has been shown to be promising technique for developing layers of silicon nitride of thickness in the micron to sub-micron range. Due to the low porosity of the plasma sprayed silicon layers, nitridation of the whole body seems impossible; however, this technique is suitable for applications where only a thin layer of silicon nitride is desired. Commercial production of silicon nitride by conventional methods takes place very slowly by the reaction of nitrogen gas and silicon in a nitridation furnace. The long time needed for this process to take place can provide a relatively impure product as well as an increase in the cost of silicon nitride. In this work we have shown that parameters effecting the development of silicon nitride are: temperature, positive pressure of nitrogen gas, particle size of the starting silicon powder and the firing time. The characterization of the layers has been carried out using: (I) X-ray diffraction (XRD) to determine the crystalline structure of the silicon nitride layers, (II) scanning electron microscope (SEM) to show the morphology and surface structure of the samples, (III) Auger electron spectroscopy (AES) to determine the elements in the ultra thin layers and (IV) electron spectroscopy for chemical analysis (ESCA) to determine the surface chemical composition of the specimens.

2. Experimental Procedure

Silicon powder was prepared from semiconductor grade billets with 99.9% purity .The billets are crushed into small ingots using a standard jaw crusher. To pulverize the smaller ingots a ceramic milling machine was used. The powder is then acid washed to remove the iron contamination introduced during pulverization process and then sieve separated into 75-105mm powder sizes.

The Metco type 3M plasma flame spray equipment is used in this work which is an integrated group of modular units consisting a type 3MB plasma gun, type 6MC plasma flame spray control unit and type MP powder feed unit. The plasma forming gases used are argon as the primary gas and the hydrogen as the secondary gas. The addition of about 10-20 % hydrogen gas has shown to act as a useful deoxidizing agent.

Layers of silicon, 0.5-2.0 mm thick are plasma sprayed onto an ultrasonically cleaned alumina substrates placed at some 10-15 cm away from the plasma gun. The alumina substrates are then heated in order to separate the silicon layer from the substrate.

The nitridation process is carried out in a gas tight Metal Research furnace type PC A10 with molybdenum heating element and inner alumina tube. The samples are placed in the alumina boat and are then introduced into the furnace. Before nitridation, the furnace is out-gassed in vacuum at 700^{o}C for five hours and then backfilled with nitrogen gas (99.999%) to a slightly positive pressure which continued all through the nitridation process. Nitridation was carried out for eight hours at 1150-1350°C. Too rapid an increase in temperature involves sample damaging, either from gross melting of silicon or torsion in the sample.
XPS (ESCA) & AES analysis of the samples which are well known methods of surface chemistry studies have been carried out using a VG ESCALAB 200 and MICROLAB 300. All measurements were performed at pressures lower than 10^{-8} Torr in the analysis chamber.

3. Results and discussion

AES microanalysis of the samples

Important chemical information can be obtained from Auger spectra. The chemical effect will appear either in the form of a simple peak shift or a change in peak shape and in many cases as both. Fig.1 shows the AES general spectra after the removal of about 50 nm of the surface layer, both KLL and LMM peaks show a shift in position between pure silicon and the silicon in the form of silicon nitride. For the LMM peak there is a shift of about 8 eV between pure silicon and silicon in the form of silicon nitride. There is also a change in the peak shape and width. In the case of silicon oxide, due to an electron beam induced effect, oxygen has been lost from the surface and Si LMM spectra from silicon oxide show distinct peaks in the elemental silicon position at 91 eV. In the case of silicon nitride it is somewhat different, because a distinct shift of about 4 eV in the Si LMM peak due to silicon and silicon nitride is clearly observed. The Si KLL data obtained is shown in fig.2. Careful curve fitting of the Si KLL line shows the silicon oxide peak at the kinetic energy of 1605.8 eV and silicon nitride at 1612.3 eV. The AES spectra clearly show that the nitrogen is depleted in the near-surface layer. This effect is more pronounced in the AES depth profile than in the ESCA due to a better depth resolution and signal to noise ratio in the AES spectra.

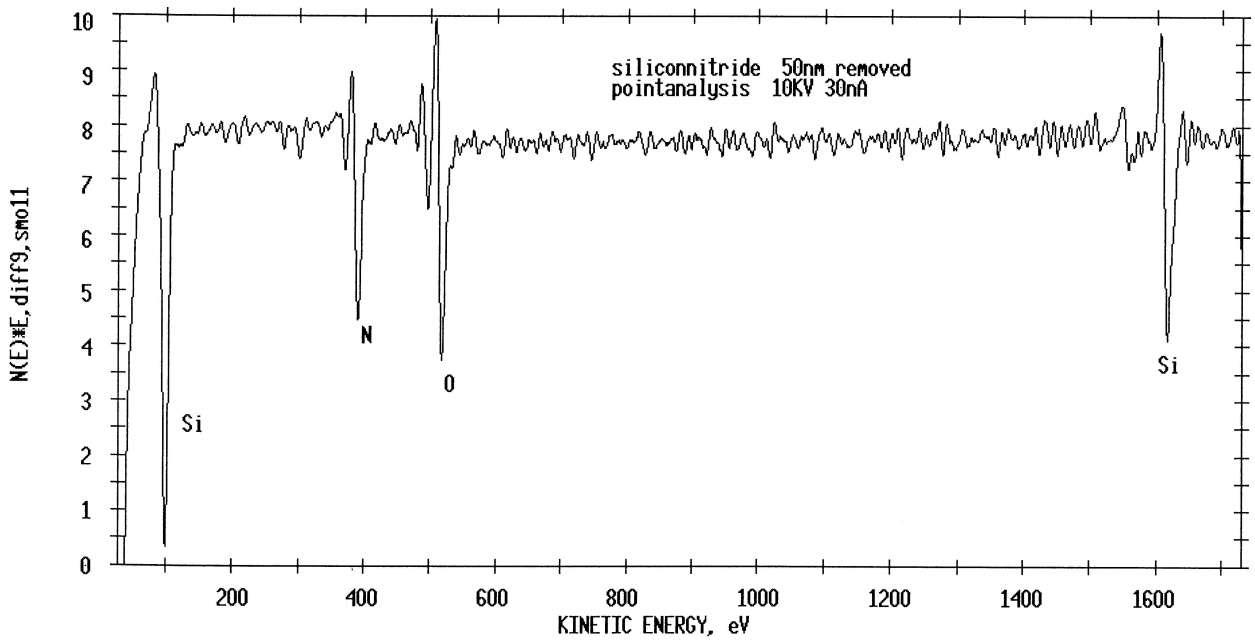

Figure 1. General AES spectra indicating the presence of Si KLL, N, O & Si LMM

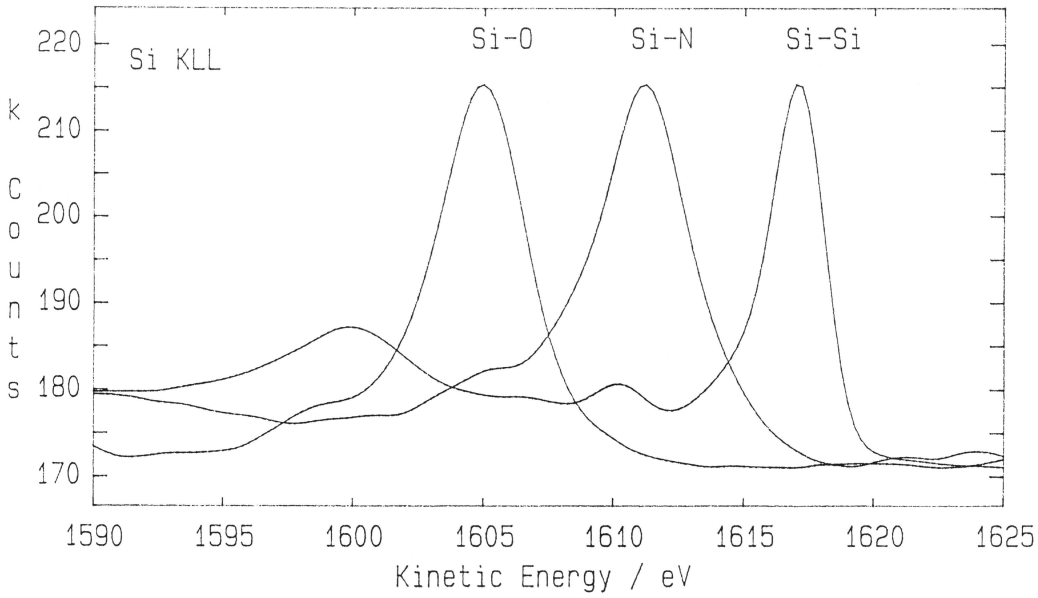

Figure 2. AES spectrum showing the chemical shift in the Si KLL peak for the nitride and oxide

ESCA analysis of the samples

The chemical state of Si in the nitrided sample was determined from the value of the Si binding energy after a 50 nm layer was removed from the surface. The formation of silicon nitride was explained by the binding energy of the Si $2p^{3/2}$ peak referred to ESCA handbooks and standard samples [2]. The binding energy of Si 2p was measured to be 104.5 eV compared with 99.3 eV for pure silicon. According to the binding energy of the Si 2p peak, the Si in the sample is thought to be silicon nitride with some mixed amount of silicon oxide and oxynitride. Due to the presence of Si, SiO_2 and Si_3N_4 the assignment of the peaks in the Si 2p spectrum cannot be easily accomplished. The difference in binding energy of the two peaks is only a few electron volts. The Si 2p peak shows the presence of silicon nitride at 105.6 eV. Computer curve fitting of the Si 2p spectra has been used to obtain the relative intensities of the Si 2p oxide and nitride components. Fig.3 is a XPS montage of sputtered depth profile analysis of the Si 2p peak which shows the shift in the binding energy from a higher value (106 eV) due to the Si-O bond, towards the lower binding energy (103 eV) being due to the Si-N bond.

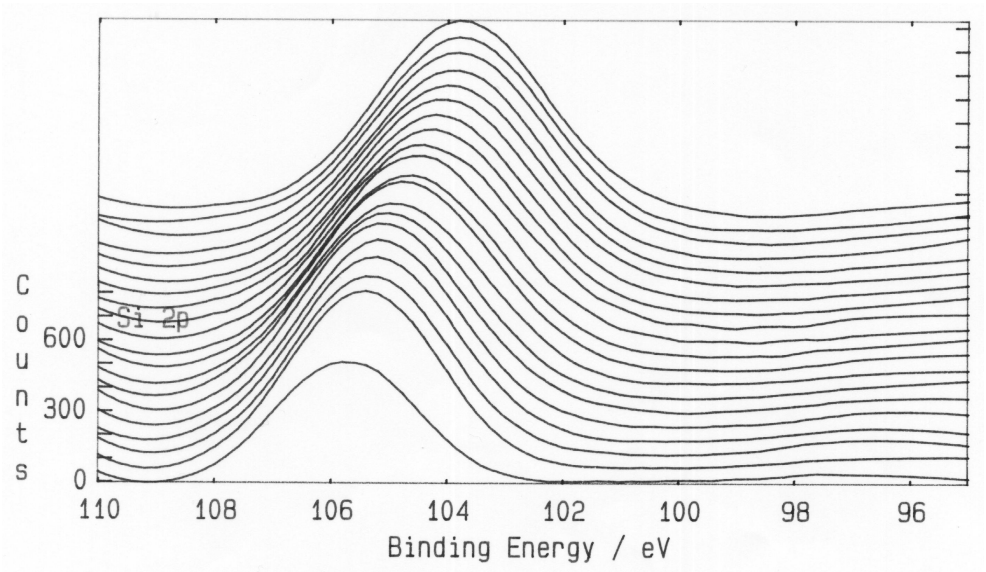

Figure 3. XPS montage of sputtered dept profile showing Si 2P peak shift

Surface structure of the samples

The surface morphology of the nitrided silicon has been investigated by SEM and shows that the orientation of the whiskers in the matrix is nearly three dimensionally random as shown in fig.4. The diameter of each whisker is about 300 nm having various lengths.

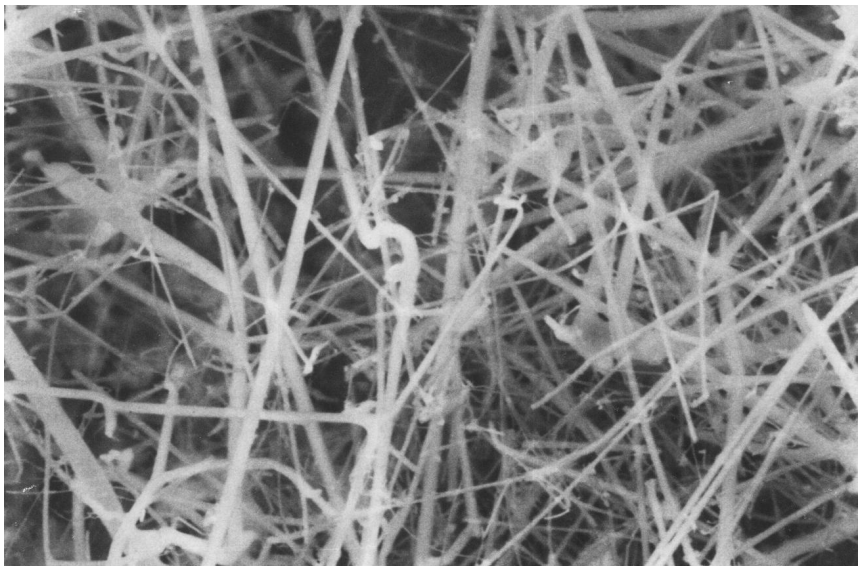

Figure 4. SEM micrograph of whiskers (Mag. 6 k)

It is well known that the reaction of SiO_x vapour with carbon and nitrogen always produces alpha and not beta silicon nitride [3]. In the absence of impurities in the reactants, formation of beta and oxynitride is completely suppressed. There are no liquid phases in the Si-O-N-C system in the temperature range used for the production of silicon-nitride layers, but small amounts of impurities have a pronounced effect on the melting temperature [4]. Iron is also known to influence both the phases formed as well as the rates of reaction. When the sample crucible is removed from the furnace after the reaction, the exposed inside surface of the graphite crucible as well as the top surface of the specimen pellet (containing excess carbon) are covered by fine white needles of alpha-silicon nitride.

This product provides clear evidence that the mechanism of formation of alpha Si_3N_4 is by a solid-gas mechanism. The crystal shapes produced within the sample pellet are twisted and faceted which is due to restricted growth within pores and cavities, but when grown on a free surface such as on the top of the pellet or on the crucible walls, perfect whiskers and needle growths are produced.

Silicon oxide film formed on the surface of the plasma sprayed silicon samples was analyzed prior to nitridation using AES and ESCA [5]. The results showed that silicon powder particles acquired oxygen in the plasma-spraying environment to form a thin layer of oxide on the periphery of each particle upon splat quenching on the substrate.

Beta-silicon nitride was the dominant phase [6]. The alpha silicon nitride whiskers are easily distinguished by the ribbon-like morphology with about one micron in width and less than 0.1 micron in thickness. The growth direction of the alpha silicon nitride whiskers is <211> as determined by XRD. Since single crystals usually include much less impurities than other forms; therefore, it can be concluded that the samples made contain whiskers of pure silicon nitride. The microstructure also contains many small globules, which appear to have been liquid during reaction and in some cases the globules are seen to be attached to the ends of needles. Scanning Auger Microanalysis (SAM) reveals that the globules are composed of Si, N, O and some iron (Fe) content [7]. Although the precise composition could not be obtained by microanalysis, it is suggested that the iron is present in the matrix in the form of a Fe-Si intermetallic phase. The iron-silicon phase diagram contains four eutectics at about 1250 degree centigrade and the formation of Fe-Si phases at the reaction temperature is therefore possible.

4. Conclusion

The main advantage of the present method is its potential to develop relatively thin layers of silicon nitride on complex shaped bodies which is otherwise impossible to form by other conventional methods i.e. powder compaction or hot pressing. Data obtained shows that this method is a promising one for producing submicron to a few micron thick fiberous films of silicon nitride.

The nitridation process should be carefully controlled, since it has been recognized for some time that the exothermic nature of the nitridation reaction plays a significant role in the process. This behavior may cause some spots to be melted once the temperature of the sample approaches the melting point of silicon. It is predicted that the critical defects in reaction-sintered silicon nitride were large pores that resulted from melting of particles of unreacted silicon when the temperature of the sample exceeded 1400 °C. It has been reported that a more complete nitridation and generally higher nitriding rate can be obtained by using the variable atmosphere in the nitrogen-demand nitriding runs by decreasing nitrogen partial pressure [8]. By using an isothermal nitriding run it was found that a more complete nitridation was obtained with reduced nitrogen partial pressure.

Plasma sprayed silicon for the purpose of producing layers of silicon nitride by nitridation has shown to be a promising technique for developing layers of silicon nitride from submicron to a few micron thick. Due to the low porosity of the plasma sprayed layers, nitridation of the whole body of the sample seems impossible. However, this technique is suitable for applications where only a thin layer of silicon nitride is desired.

The plasma spraying technique has enabled us to produce silicon nitride from plasma sprayed silicon bodies having various shapes and sizes. By analyzing various spots on the surface of the samples, it was found that the Si_3N_4 whiskers formed are relatively homogeneous in composition.

Abstract:

In this study, general-purpose finite element code ANSYS with coupled solution has been employed to analysis fracture in ceramic coating subjected to thermal loadings. Coatings with substrate material Tungsten, coating materials Diamond, Si_3N_4 and interlayer materials NiAl were modeled. The aim was to evaluate the stress intensity factors in different coating systems. The result showed that the shorter the crack length and the better material combinations the sounder is the coatings.
Keywords: Thermal loading, Fracture, finite element

Introduction

Plasma coating systems are used for many severe engineering applications. Most of these applications are in the form of thermal barrier coatings, which allow for higher engine temperatures and better efficiencies [1]. The strength of the bonded system is governed by a number of variables; the thermal and elastic mismatch, the plastic flow stress of the metal [2], the relative substrate/coating thickness[3], thickness of interlayers [4], elasticity of interlayers [5], the fracture resistance of the interface, and the flaw distributions in the ceramic and at the interface [6]. Most failures in the thermal barrier bond coatings system also depend on processing parameters, i.e. contact temperature, surface composition, solidification of sprayed particles [7]. A main problem of such coatings has been the failure in the form of debonding and spalling from the substrate [8-9]. In most cases the failure appears to be close to the interface between the ceramic and the metal. More recent experimental observations [5] suggest that the crack have strong tendency to extend into the substrate and propagate parallel to the interface. The fracture and crack propagation in homogenous elastic brittle materials is well understood , while that of bimaterials is still the subject of much debate. The general approach for the bimaterial fracture mechanics [10] is that increase the flow orientation in affects of crack propagation through the coating, interfaces and substrate. Evans [11] , investigated the fracture energy of bimaterial interfaces. They concluded that the fracture energy is influences on many problems of technological importance, particularly the mechanical properties of composites [2,11,12] and the decohesion of films and coating [10] as well as the strength of bonds [12]. In case of thermal stresses, it is well known that the thermal stresses are generated at the interfaces when dissimilar materials are bonded together. Most studies in this area have considered steady-state excursions. More recently, the thermal stresses in ceramic-metals bonds has been analysed by taking into account the transient nature of the heat transfer process [11,12]. Again the principlesof fracture mechanics is used to determine the effect of a transient thermal load on the interface [13].

Diamond and Si_3N_4 based ceramic coatings are most used as thermal barrier coatings because of their low thermal conductivity which reduces the detrimental interfacial stress [14]. In this investigation ANSYS finite element packet programme was employed to analyse the influence of interfacial crack length and material properties on fracture toughness of ceramic coatings. The results showed the significant influence of the thermal expansion coefficient, thermal conductivity and crack length on the stress intensity factors K_I and K_{II}.

Analysis

A general purpose finite element code ANSYS, is employed to obtain thermal/structure coupled solution. A half of a disc sample was modeled using 4-node, plane strain, quadratic elements see Figure 1a,b. The ends of the model were constrained and the loads were applied by cooling down the model from 600 °C to room temperature in very short time using an 30 W/m^2 °C heat transfer coefficient at the top end of the model. To avoid bending problems an coating to substrate materials thickness ration of geometries with 1/10 and three different crack lengths 1.2, 2.4 and 4.8 mm were modeled to evaluate the influence of the crack length. A transient coupled thermal/ structure finite element analysis was executed for the coating and for all different geometry models. The stress intensity factors K_I and K_{II} were obtained and compared. Table 1 present properties of the materials used in this investigation.

Results and Discussions

Figure 2 represents K_I and K_{II} stress intensity factor - time curves for reference coatings Diamond-W and Si_3N_4-W coating systems. This figure shows a 5% decrease in the K_I value for about a times 14 increase in thermal conductivity of the coating material. This effect is hardly noticeable in K_{II} value. This is explained as the thermal stresses are significantly effected by the thermal expansion at the end of homogeneous heating period.

Figure 3 shows the influence of coating thermal expansion coefficient value on the stress intensity factors K_I and K_{II} for models with 0.2 mm coating thickness, 1.2 mm crack length and α values of $3.5x10^{-6}$ and $1.75x10^{-6}$ /°C. It is clear from this figure that a times two decrease in thermal expansion coefficient value lead to 220% increase in K_I and K_{II} values. Because as mentioned before, thermal stress values are largely dependant on the thermal expansion mismatch in bimaterial systems.

Figure 4 represent the influence crack length on K_I and K_{II} stress intensity factor values for Si_3N_4 coating material of 0.2 mm coating thickness and 1.2, 2.4 and 4.8 mm crack length. This figure shows a 100% increase in K_I and a 75% increase in K_{II} values for a times 3 increase in crack length. It is clear that stress intensity factors are influenced by the crack length.

Conclusions:

1- Under thermal stress conditions, the stress intensity factors K_I and K_{II} decreases with the increase in thermal conductivity of the coating material.
2- The stress intensity factors K_I and K_{II} increases with the decrease in the thermal expansion coefficient of the coating material.
3- It is clear that stress intensity factors are influenced by the synergetic effect of crack length and material properties mismatch.

Abstract

C-Au-S film formed by cooperation process of plasma CVD and sputtering showed a large refractive index like as 3.5, which can be used for a photonic crystal at a visible light range because of transparency and process compatibility. 2D photonic crystal with C-Au-S-PMMA dielectrics processed by plasma processes can be used as an optical wave-guide and other optical devises at a visible light wavelength range. 2D photonic crystal pattern with beehive type at around 500 nm was successfully fabricated.

Key Words: Photonic Crystal, C-Au-S Film, Cooperative Process of Plasma CVD and Sputtering, Refractive Index

1. Introduction

Optical computing integrated circuit or optical integrated circuit is named as OIC. The OIC device size is limited by the light wavelength. However the computing speed is very fast composed to a silicon-computing device. The OIC technology is used for an optical inter-connection circuit between the silicon integrated circuits, an optical sensing system and so on. Therefore the OIC minimizing technology is important to realize new devices.

Photonic crystal introduced by E. Yablonovitch [1], S. John [2] etc. in 1987 is expected to be a new and important element for optical device. The crystal has a periodic refractive index distribution in 1-D, 2-D, 3-D structure and shows photonic band gap (PBG) property. By using the 2-D or 3-D photonic crystal, curved optical waveguide is fabricated by introducing linear crystal defects array. Therefore the circuit become very small compared to a thin film wave- guide. Additionally, The photonic crystal acts as photon traps and emitters depending on the defect size at the wavelength level if point defect is introduced near the wave-guide in the 2-D photonic crystal [3]. These photonic crystals can be utilized to the OIC.

For the photonic crystal, high refractive index material must be used. In this work, C-Au-S (carbon-gold-sulfur) film [4] was used because it is optically transparent in the visible light range, high refractive index and process compatibility for oxygen plasma etching. The C-Au-S film was fabricated by co-operative process of plasma chemical vapor deposition (CVD) with using CH_4, SF_6 and Ar mixture gas and sputtering Au plate discharge electrode. The optimized optical properties of film were a refractive index of 3.5 and transmittance of 51 % at a wavelength of around 500 nm.

Using the C-S-Au film, 2-D beehive photonic crystal was designed and fabricated by an electron beam lithography with using two-layer resist system of negative resist and evaporated Al film, which works as an oxygen plasma etching stopper. The 2-D beehive photonic crystal pattern has hexagonal structure, which is effective for both of TM and TE mode light propagation [5]. These theoretical and experimental

investigations on the photonic crystal structure are reported variously [5-8]. The 2-D beehive (hexagonal) structure for 500 nm light is shown in Fig. 2.

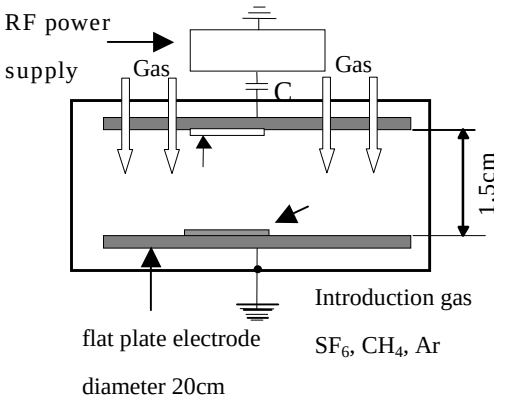

Fig. 1 Plasma CVD apparatus

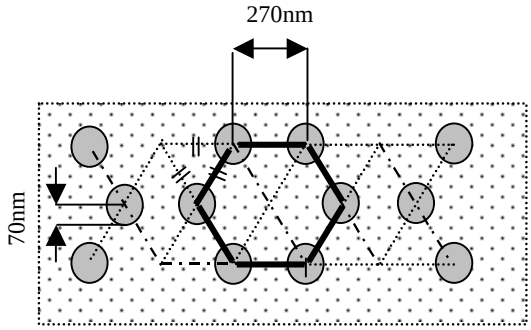

Fig. 2 The photonic crystal for 500 nm light

2. Structure and fabrication of beehive type photonic crystal

The C-Au-S film was formed by plasma CVD reactor (ULVAC CPD-1108). The plasma CVD reactor has a parallel plate electrode with 20 cm diameter and 1.5 cm gap distance between the two electrodes. A gold plate with area of 50×50 mm^2 was set on the upper electrode which was made of graphite and connected to the RF power source of 13.56 MHz. Substrates of Si wafer were located on the lower electrode grounded and electrically connected to the reactor vessel of stainless steel.

The C-Au-S film with a refractive index of 3.5 was fabricated as followings. The deposition condition was kept to be constant at a pressure of 0.1 Torr, a discharge power of 100 W, and a discharge duration of 30 min. The flow rate of CH_4 was 10 SCCM, the flow rate of Ar and SF_6 were 15 SCCM. The C-Au-S film was characterized by measuring the refractive index using an ellipsometer.

2-D photonic crystal was fabricated as followings. After Al film evaporated on the C-Au-S film, which works as etching stopper, negative resist (SHIPLEY SAL601) was spin coated on the Al film at 4000 rpm and pre-baked at 105°C for 60sec. Then electron beam patterning apparatus (JEOL JBX-6000SG) was used for patterning of 140 nmϕ poles at six apex of hexagonal with 270 nm sides as a single cell as shown in Fig. 3. The pattern delineation was performed at an acceleration voltage of 50 kV and a current of 100 pA. After the pattern delineation on the resist, it was post-baked at 115°C for 60sec. The pattern was developed by SHIPLEY MF CD-26 and rinsed by pure water to made the pattern clear. Al film was etched off through the resist pattern by etching liquid of HNO_3 5%, HF 3% and H_2O 92%. The C-S-Au film with around 500nm thickness was etched through the Al patterns by oxygen plasma with using RIE (SAMCO RIE-1C) at 13.56 MHz. The etching rate of this film was measured at oxygen flow rate of 10 SCCM and a pressure of 0.09 Torr as a function of discharge power.

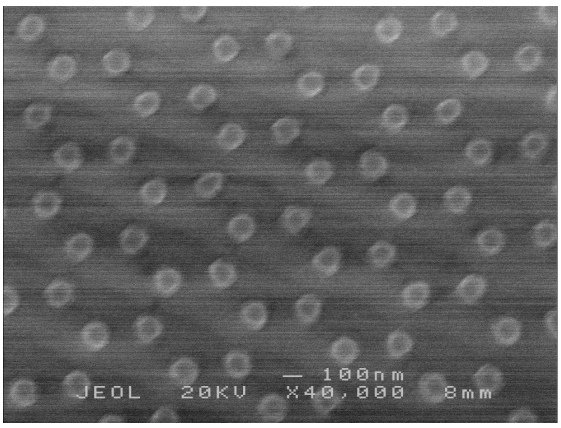

Fig. 3. The SEM photograph after negative resist etching

3. Integrated optical wave-guide with a light source

EL light source will be fabricated on the 2-D photonic crystal to fabricate the OIC. For the device, the beehive type C-Au-S structure surface must be flattened. For the filling substance, the refractive index must be lower then that of C-Au-S. Therefore, PMMA was selected as a low refractive index substance because the refractive index of PMMA is 1.5. Also, PMMA can be filled in the 2-D beehive C-Au-S photonic crystal structure by spin coating. EL element is formed on the flatted surface. Then a transparent wave-guide with a light source is formed on the crystal. The cross-section view of the device is expected as shown in Fig.4. Where the amorphous carbon layer was formed to separate the wave-guide from the substrate with large refractive index. The refractive index of amorphous carbon is about 1.5~1.6.

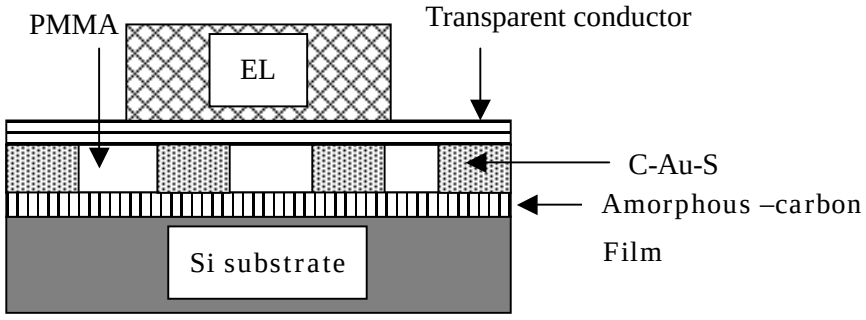

Fig.4 Basic structure of OIC with EL light source on the 2-D photonic crystal

4. Conclusion

The C-Au-S film was synthesized by co-operation process of plasma CVD and sputtering with using methane, SF_6 and Ar mixture gas and gold plate on the discharge electrode. We found that the C-Au-S film was etched by oxygen plasma RIE and has high refractive Index. The 2-D beehive type (hexagonal) photonic crystal was successfully fabricated for a visible light wavelength range at 500 nm. The photonic crystal of C-Au-S – PMMA with EL element will be proposed for the OIC element.

Acknoledgement

The lithography works were carried out at the center for Cooperation Research in Advanced Science and Technology, Nagoya University. We express our gratitude to all who contributed to this study.

Oscillations in the low-frequency Townsend mode of DBD

D. Nikandrov, L. Tsendin
St.Petersburg State Polytechnical University, Polytechnicheskaya 29, 195251, St.Petersburg, Russia

Abstract
The physical mechanism and scaling laws for the non-linear relaxation oscillations in the Townsend mode of DBD are presented. The fact that the space charge can be neglected with respect to the surface charge on the dielectric, allows to derive analytic dependences and to perform the comparison with the numerous experiments. The analysis is valid for an arbitrary time dependence of the applied voltage *U(t)*.
Keywords: Dielectric-barrier discharges; silent discharges, non-linear oscillations.

1. Introduction

Dielectric Barrier Discharges (DBD) are characterized by the presence of dielectric layer(s) between the gas and metal electrode. These discharges are widely used in industrial applications [1].
The Townsend mode DBDs are usually oscillatory. The oscillatory mode of traditional DC Townsend discharges results from the falling static Volt-Ampere Characteristic (VAC) [2-5]. These oscillations can be considered as a result of development of instability of the homogeneous stationary discharge mode; so their evolution can be continuously traced, starting from the small-signal linear stage up to the amplitude saturation.
The oscillations physical mechanism in the DBDs, in which the static VAC is altogether absent, is quite different. These oscillations exist only in the strongly non-linear form, and no continuous transition from the linear to the non-linear mode can be traced.

2. Simple model

The frequency restriction:

$$\tau = \frac{L}{E_{br} b_i} << \frac{2\pi}{\omega}. \qquad (1)$$

is considered here. E_{br} – the breakdown field; b_i - the ion mobility; ω - the applied voltage frequency; τ - the ion transit time at $E = E_{br}$.
The born in the discharge gap ions are collected on the dielectric surfaces (Fig. 1), resulting in the surface charges with densities.

$$\sigma_1(t) \approx -\sigma_2(t). \qquad (2)$$

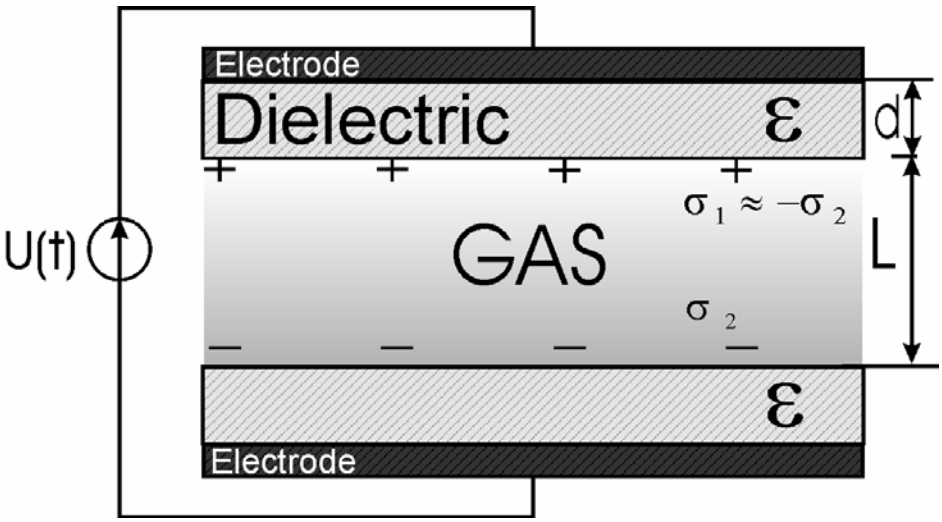

Fig. 1 Discharge cell

Due to (1), the electric field in the discharge gap is created mostly by the surface charges, and the space charge field can be neglected. So the field can be considered as spatially uniform: $E = E(t)$. From the Gauss' theorem the relation between the applied voltage $U(t)$, the electric field in the discharge gap E, and the surface charge follows:

$$E = U\frac{1}{L+\frac{2d}{\varepsilon}} + \sigma\frac{8\pi}{L+\frac{2d}{\varepsilon}}\frac{d}{\varepsilon}. \qquad (3)$$

At the time scale exceeding τ the conductivity current behaves as

$$j \propto \exp\left(\int^{t}\frac{M-1}{\tau}dt\right), \qquad (4)$$

where the multiplication factor M equals to the electrons number generated by one cathode-emitted electron during τ. If the standard local approximation for the ionization rate is valid,

$$M = \gamma\left(e^{\alpha(E)L}-1\right). \qquad (5)$$

As the Townsend's coefficient α itself depends exponentially on the field, the dependence (4), (5) is extremely steep, and the surface charges are piled up fast, which, according to the Le Chatelier principle, reduce the field back to the value E_{br}. So the crudest model corresponds to the assumption that

$$|E(t)| \le E_{br}. \qquad (6)$$

This crude discharge scenario for the sinusoidal $U(t)$ is sketched in Fig. 2, Fig. 3.

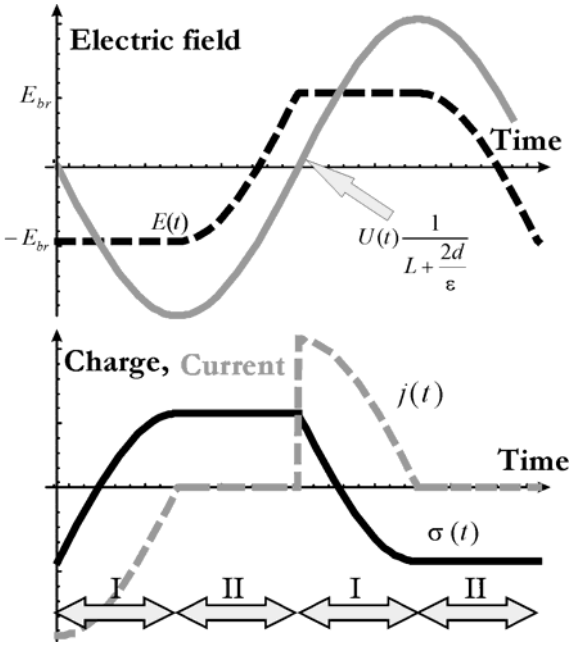

Fig. 2 Crude model of a discharge evolution

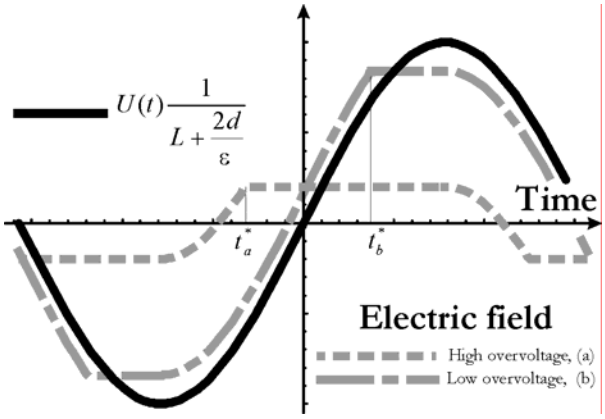

Fig. 3 Evolution dependence on overvoltage

The passive phase II corresponds to a low field; the ionization at this stage is absent, and the surface charge remains constant. During the active phase I the current which creates the surface charges and maintains $|E(t)| \approx E_{br}$, flows.

The moment t* (Fig. 3), when the breakdown starts, is defined by equation

$$U(t^*) = \left(2E_{br}\left(L+\frac{2d}{\varepsilon}\right) - U_{\max}\right). \qquad (7)$$

At low overvoltage, when

$$U_{\max} < 2L\left(1+\frac{2d}{L\varepsilon}\right)E_{br} \tag{8}$$

the moment t* is later, than the moment when $U(t)=0$; in the opposite case, the breakdown occurs when the gap field is opposite to the applied voltage.

For the description of the phase I this approach is oversimplified. Since the background electron density at t=t* is extremely low, it takes a rather long time, which considerably exceeds τ, for the current to rise enough to influence on the surface charge and to initiate the field reduction. According to (3), it means that during the time of the order of several τ after the exponential current rise starts, the surface charge remains practically unchanged, and the gap field $E(t)$ continues to rise. The storage of the surface charge starts to reduce the field, when $E(t) > E_{br}$. When the field reaches the value $E(t) = E_{br}$, a considerable current continues to flow; which is maximal at this moment. It takes some time (again of the order of several τ) for the current to fall off, and to start the following $E(t)$ rise process. As the current flow continuously reduces the field, this rise starts from the low value, $E(t) < E_{br}$. So during the active phase I the non-linear relaxation oscillations arise.

3. Oscillations characteristics

The conductivity current during the phase I, when the oscillations occur, is given by expression:

$$j(t) = \int_{-\infty}^{t} \frac{j_{ext}(t')}{\tau} \exp\left(\int_{t'}^{t} \frac{\ln M\left(E\left(t''\right)\right)}{\tau} dt''\right) dt' \tag{9}$$

where j_{ext} is the external (independent from the discharge) electron current from the cathode. Equation (9) is equivalent to

$$\tau \frac{dj}{dt} = -j \ln M(E) + j_{ext}. \tag{10}$$

By differentiating (3) we obtain

$$\frac{dE}{dt} = \frac{dU}{dt}\frac{1}{L+\frac{2d}{\varepsilon}} - j\frac{8\pi}{L+\frac{2d}{\varepsilon}}\frac{d}{\varepsilon}. \tag{11}$$

Introducing the dimensionless variables: time $\theta = \frac{t}{\tau}$, field $\mathrm{E} = \frac{E}{E_{br}}$, applied voltage $\Phi = \frac{U}{1+\frac{2d}{\varepsilon L}}\frac{1}{E_{br}L}$, external current $\imath = \frac{j_{ext}}{j\big|_{t=0}}$ and parameter:

$$\kappa = \frac{8\pi\, d}{\left(\varepsilon L + 2d\right)}\frac{j\big|_{t=0}}{E_{br}}\tau, \tag{12}$$

we obtain the equation for the oscillatory discharge phase I.

$$\begin{cases} \dfrac{d^2\mathrm{E}}{d\theta^2} - \dfrac{d^2\Phi}{d\theta^2} - \ln\left(M(\mathrm{E})\right)\left(\dfrac{d\mathrm{E}}{d\theta} - \dfrac{d\Phi}{d\theta}\right) = -\imath\,\kappa; \\ \mathrm{E}\big|_{\theta=0} = 1, \qquad \left.\dfrac{d\mathrm{E}}{d\theta}\right|_{\theta=0} = \left.\dfrac{d\Phi}{d\theta}\right|_{\theta=0} - \kappa \end{cases} \tag{13}$$

According to (1), the term $\frac{d^2\Phi}{d\theta^2}$ can be neglected, and the oscillations characteristics follow adiabatically value of $\frac{d\Phi}{d\theta}$. Since during the active phase I the external current is negligible, the right-hand side of (13) can be replaced by zero, and the undamping oscillations result. Their mechanical model corresponds to the particle motion with non-linear friction force, which changes its sign at $\mathrm{E}=1$. The expressions for the maximal and minimal electric field values, and the oscillations frequency can be derived.

In small oscillation case $M(\mathrm{E}) \approx 1 + M'(\mathrm{E}-1)$ simple expressions for the amplitude (in units E_{br}):

$$\mathrm{E}_{\max} = 1 + \sqrt{\frac{2\Phi'\left(\ln\frac{\Phi'}{\kappa} - 1\right)}{M'}}; \quad \mathrm{E}_{\min} = 1 - \sqrt{\frac{2\Phi'\left(\ln\frac{\Phi'}{\kappa} - 1\right)}{M'}} \tag{14}$$

and the oscillations period (in units τ):

$$\sqrt{\frac{8\ln\frac{\Phi'}{\kappa}}{\Phi' M'}} \tag{15}$$

follow.

On the other hand, if the dependence $U(t)$ is meander-like, the oscillations disappear.

4. Comparison with experiments

In experiments [6] with He at 730 Torr, frequency of the external voltage (for the triangular (a) and sinusoidal case (b)) was 1.5 kHz, L=0.2 cm, d=0.23 cm, ε=5. In Fig. 4 and Fig. 5 the experiment comparison with the calculations is presented.

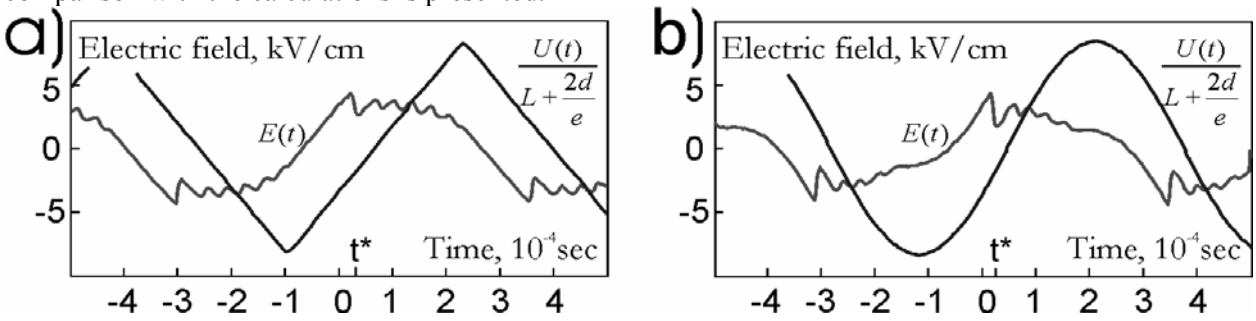

Fig. 4 The oscillations onset (7) is shown

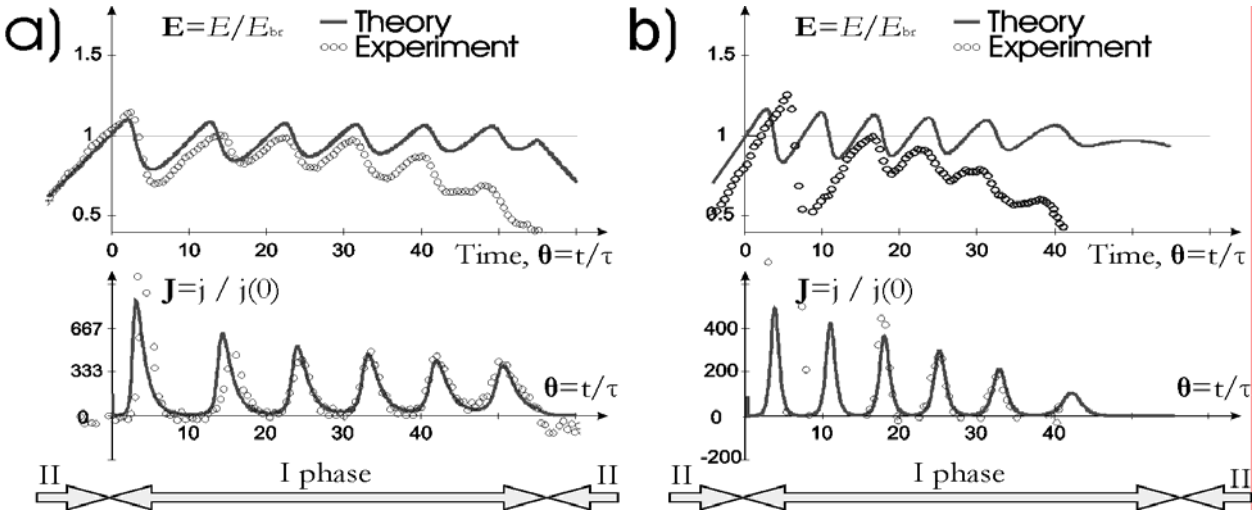

Fig. 5 Oscillations characteristics

In the experiments [7] DBD in methane at 0.75 Torr, L=0.5 cm, d=0.5 cm, f=1.4 kHz, was used. In Fig. 6, Fig. 7 the comparison of the experiment with the calculations is presented.

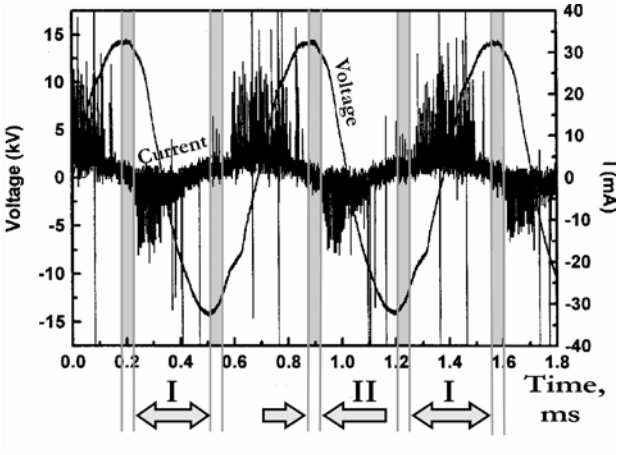

Fig. 6 Phase separation (on active I, and passive II)

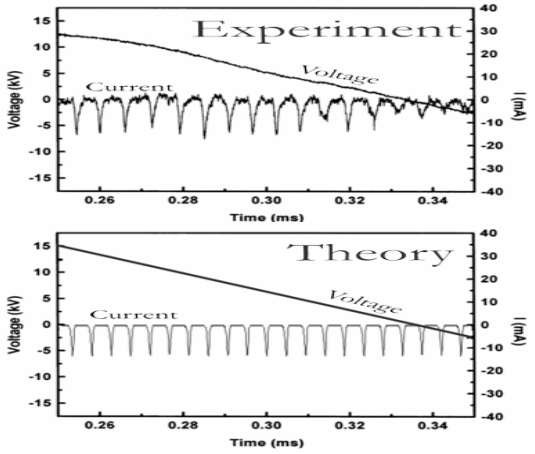

Fig. 7 Oscillation characteristics

In the experiments [8] the DBD in He at atmospheric pressure, L=0.3 cm, d=0.23 cm, ε=7.63, γ=0.01. For the voltage frequency of 100 Hz and 500 Hz in the Fig. 8 the comparison experiment and theory is presented. In the Fig. 9 the scaling for the pulses number during the phase I is shown for different discharge parameters. The agreement for the 3 mm gap looks reasonable, but for the 5 mm gap agreement is considerably worse. This fact can be attributed to the rise of the field distortion by the space charge with the gap length increase.

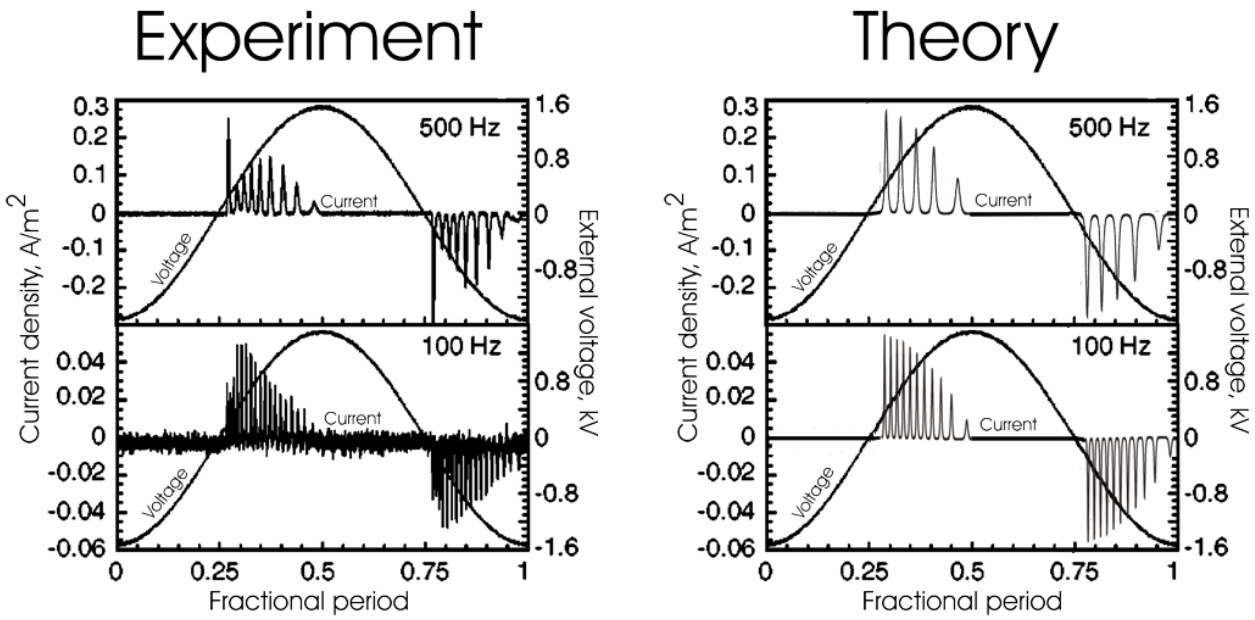

Fig. 8 Oscillation pattern

Since the calculation results depend on j_{ext} logarithmically, they are rather insensitive to its precise value. In all the calculations the values of j_{ext} in the range $10^{-4} \div 10^{-5} \frac{mA}{cm^2}$ was used.

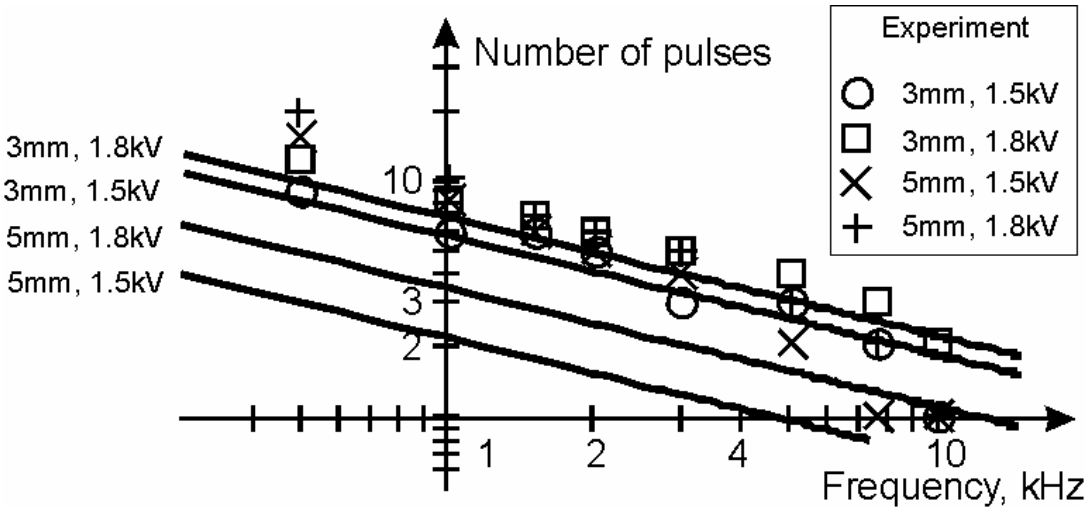

Fig. 9 Scaling for the pulses number

Plasma arc beam characteristics in hybrid plasma and laser deposition

Ying-ping Qian, Hai-ou Zhang, Gui-lan Wang
State Key Lab. of Plastic Forming Simulation and Die & Mould Technology,
Huazhong University of Science and Technology, Wuhan 430074, China

Abstract
In order to research the characteristics of plasma arc in the hybrid plasma and laser deposition manufacturing (PLDM) process of high temperature alloy, the high speed CCD camera was used to obtain the picture around the plasma arc. And then the clear sketch of picture was obtained through dealing with the plasma arc picture. The effect of laser parameters, such as average power, pulse width and pulse repetition frequency on the plasma arc appearance was studied experimentally. The results show that the modality of plasma arc is influenced markedly by laser beam.
Key words: Hybrid plasma and laser deposition manufacturing (PLDM), Characteristic, Modality

1. Introduction

In the late 1980s, the emerging of RP (Rapid Prototyping) technology provided a new idea for the rapid development of high-temperature components. Now the RMP (Rapid Metal Prototyping) has become the advanced manufacture in RP technological research [1-5]. In terms of RMP, there are various kinds of RMP, in which we can mainly gain LENS (Laser Engineering Net-Shaping), electron beam deposition technology, PDM (Plasma Deposition Manufacturing) and the other technologies that can fabricate components with high density [6-8]. The LENS technology adopts the high-power laser to melt the powdered metal that is sent to a substrate and then solidifies quickly and finally forms a work-piece by depositing layer by layer. The density of the work-piece is far higher than that in the SLS (Selective Laser Sintering) method, and the mechanics performance reaches formal casting standards. But because of the overheating power, the shaped work-piece is easy to fracture. Besides, there exist several problems such as non-full densification, low surface quality and too much investment in equipment. The electron beam deposition method adopts the electron beam with 4KW power to melt metal powder materials. According to the computer model, the control system exerts the electromagnetic field, controls the movement of the electron beam to scan layer by layer until the end of the whole component shaping. The porosity is about 0.5%. However, the process condition is required strictly. It has to move in vacuum to limit the prototype length, and the expense of the equipment is very high. The PDM adopts highly compressed and centralized plasma beam, to heat metal powder and melt the metal in a molten pool on the substrate, then the metal-prototype or component is deposited and formed layer by layer, which has such features as materials to be more widely used, higher shaping efficiency, fuller density and lower cost of equipment than those of LENS and electron beam deposition methods [9-10]. But this technology has some problems such as lack of forming energy, arc stability and centralization of the beam when using the micro-plasma arc to shape precision and thin walled component. Therefore, the PLDM (Hybrid Plasma and Laser Deposition Manufacturing) as a new direct metal prototyping technology is proposed in this paper. The characteristics of the PDM technology are applied, and the better collective laser beam as a supplemental energy resource is adopted to make the high temperature material prototype with high quality. The effects of laser beam parameters, such as average power, pulse width and repetition frequency on the performance characteristics of plasma arc in the process of hybrid plasma and laser deposition manufacturing are studied

experimentally.

2. The principle of PLDM

The principle of PLDM technology is shown in Fig.1. The conception model is gained by means of concept design first, and then work out a CAD model. According to the requirement of the component's dimensional accuracy, the CAD model is dealt with slices and transferred into an STL document. In accordance with the shape of every layer, the control system draws up route, generates the CNC code to control the movement of the NC machine. On the one side of the plasma arc, the laser beam is focused on the plasma arc into the molten pool through adjusting the optical path for light transmitting and focusing. The deposition and shaping are then carried out under the controlling of the parameters such as movement of worktable, plasma arc-stream, shielding gas flow, carrying powder gas flow, electric current according to the design in advance. The high-temperature alloy powder is sent to the molten pool to melt and solidify into a compact metal layer rapidly, then continue repeating the lamination until all the three-dimensional component's layers are formed.

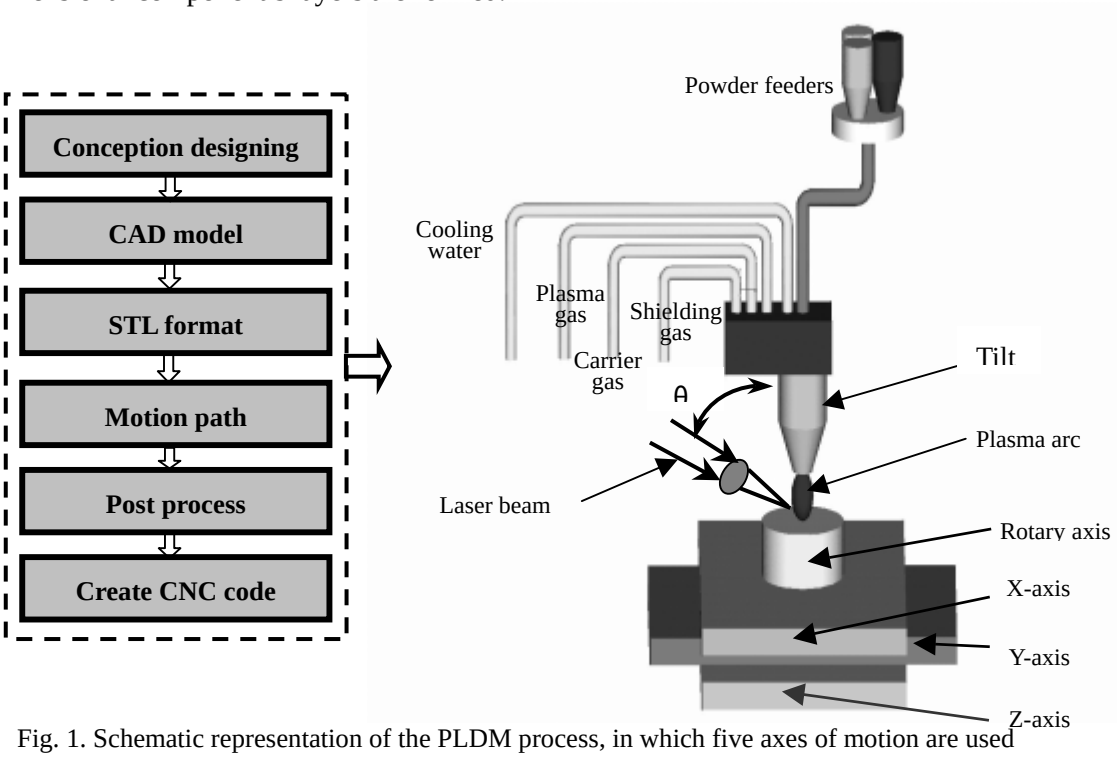

Fig. 1. Schematic representation of the PLDM process, in which five axes of motion are used

3. The condition and method of experiment

3.1. Experimental material

The experimental material was nickel-chromium-cobalt high-temperature alloy powder, with the characteristics of greatly high yield and creep strength under the lower 800℃, crack resistance while strain aging, satisfactory performance of fatigue when it was heated. And the main elements were shown in table 1.

Table 1.Chemical composition of nickel-chromium-cobalt alloy powder

Composition	Al	Co	Cr	Mo	Si	Mn	Mo
Wt (%)	0.59	20.56	19.79	5.88	<0.40	<0.60	5.88
Composition	W	Fe	Nb	Ti	Ti+Al	Ni	Ti
Wt (%)	<0.20	<0.7	<0.25	2.14	2.73	Bal.	2.14

3.2. Condition of experiment

The parameters of plasma arc deposition shaping process remained unchangeable during the experiment. The pressure ratio of ion air, protection air, argon as carrying-powder air was 1:1:1, electric current of transferred arc: 80-200A, moving speed of worktable: 200mm/min, feeding quantity of powder: 25g/min. A pulse YAG laser was adopted and the parameters values were shown in table 2.

Table 2. The laser parameters in the experiment

Average power (W)	4	39	91	160	254	-
Pulse width (ms)	0.3	2	4	6	8	-
Repetition frequency (Hz)	1	10	30	50	70	99

3.3. Method and device of experiment

The laser beam was focused on the molten pool, which remaining the parameters of the plasma; changing the laser average power, pulse width and repetition frequency. The high-speed CCD camera was used to obtain the picture around the plasma arc. And then the clear sketch of the picture was gotten after dealing with the plasma arc picture. By means of the obtained picture sketch, the diameter of plasma arc was measured and the influence of the laser parameters on the plasma arc shape was analyzed. The position using measure the diameter of the plasma arc was selected at the same distance below the nozzle of plasma gun.

The PLDM equipment with five-axis numerical controlling function as shown in the fig. 1 was used in the experiment. The range of the laser average power was from 4W to 280W, the transmission and focus of laser could be adjusted freely in the optical path system.

4. The result and discussion of experiment

4.1. The influence of the laser average power

Fig.2 (a) shows the relationship between plasma arc characteristics and laser average power. Fig.2 (b) is the plasma arc sketch dealt with by Gauss-Laplace method. The relationship between average power and plasma arc diameter is shown in fig.3. It is clear that the plasma arc is becoming small when the laser average power is increasing, which means that the laser has the compression effect on the plasma arc. The reason is that the increase of the laser average power makes the energy absorbed by the plasma arc increase, which improves ionization and magnetic effect compression, and then results in the reduction of the plasma arc diameter.

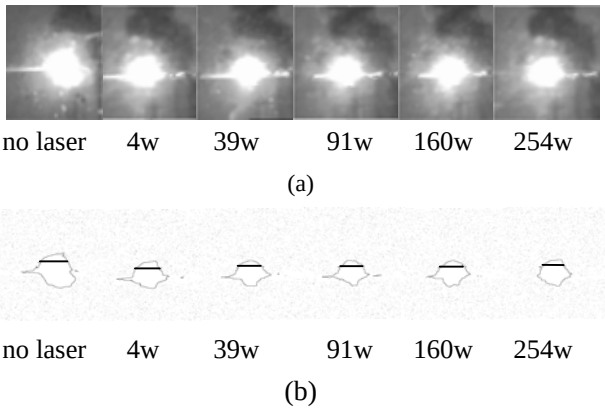

Fig. 2. The plasma arc pictures under the condition of different laser average power (a), and the plasma arc sketch dealt with by Gauss-Laplace (b).

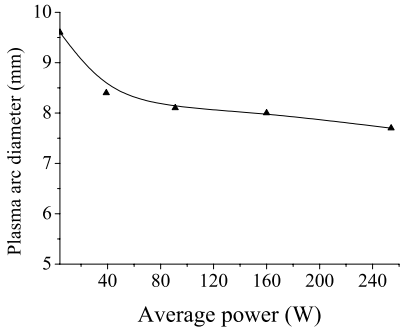

Fig. 3. The relationship between laser average power and plasma arc diameter

4. 2. The influence of the laser pulse width

Fig.4 (a) is the plasma arc under the different pulse width conditions and fig 4 (b) is plasma arc sketch dealt with by Gauss-Laplace method. The relationship between the different pulse width and plasma arc diameter is given in fig.5. As shown in the picture, the plasma arc diameter is reducing with the increasing of the laser pulse width, which means that the compression of plasma arc increases as the pulse width increases. The reason is that the increasing of the pulse width increases the energy of the single pulse, and the average power equals the single pulse energy multiplied by repetition frequency. Therefore when the pulse width increases, the energy absorbed by the plasma arc also increases. As a result, the plasma arc diameter reduces while the plasma arc has a further compression.

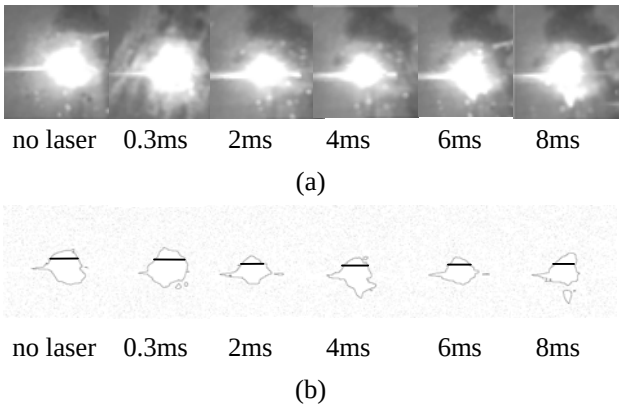

Fig. 4. The plasma arc picture under the condition of different laser pulse width (a), and the plasma arc sketch dealt with by Gauss-Laplace (b).

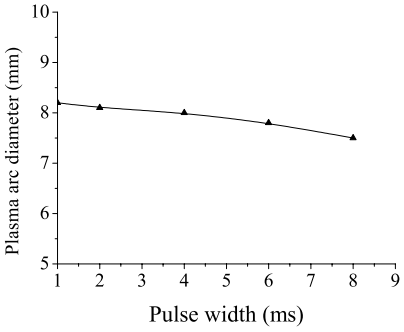

Fig. 5. The relationship between laser pulse width and plasma arc diameter

4. 3. The influence of the laser repetition frequency

Fig.6 (a) is the shape of plasma arc under the condition of the different laser repetition frequency and Fig.6 (b) is the plasma arc sketch dealt with by the Gauss-Laplace method. The relationship between the repetition frequency and the plasma arc diameter is shown in Fig.7. From the figure, the plasma arc diameter becomes reducing when

the laser repetition frequency increases. But with the increasing of the repetition frequency to a certain range (about 50Hz), the plasma arc diameter begins tending to increase. This means that the increasing of the laser repetition frequency makes the plasma arc compress at the beginning, but the compression effect gradually goes down. When it goes over a certain value, the plasma arc begins to extend reversal. The reason is that during the compounding of the laser and plasma, first the plasma arc absorbs laser energy through the inverse bremsstrahlung absorption mechanism, then the plasma arc ionization and magnetic compression effects increase, and the plasma arc compresses effect and arc diameter reduce. On the other hand, the plasma induced by the interaction of the laser and substance has a process of generating, extending and disappearing. Under the unchangeable condition of the electronic arc plasma, and under the condition of using low laser repetition frequency, the influence of laser repetition frequency on the plasma arc is not obvious. The magnet compression effect of electronic arc plasma plays an important role, thus the plasma arc diameter reduces. When the laser repetition frequency increases further to a valve value, the ionization of the electronic arc plasma will reach a maximum value, and the electron density and temperature will reach the valve value. The electron density and temperature no longer increase with the increasing of the repetition frequency. And then the magnetic compression effect no longer increase. However the interval between every laser pulse becomes smaller and the laser average power becomes greater with the repetition frequency increasing more, which makes the energy accumulated in the laser function area more and more and the temperature of the laser pulse function area higher and higher. At the same time, the plasma induced by laser extends towards outside at a rapidly increasing speed. So after counteracting the magnetic compression effect of the electronic arc plasma, the diameter of the plasma arc becomes greater.

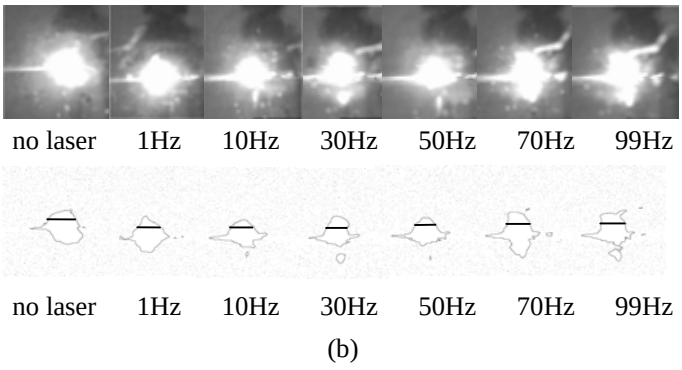

Fig. 6. The plasma arc picture under the condition of different laser repetition frequency (a), and the plasma arc sketch dealt with by Gauss-Laplace (b).

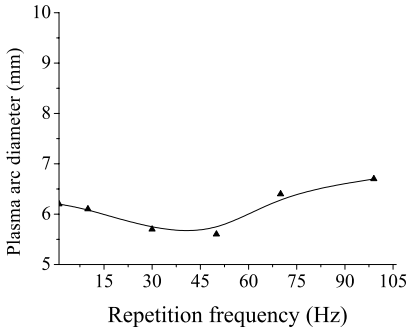

Fig. 7. The relationship between laser repetition frequency and plasma arc diameter

5. Conclusion

(1) Hybrid plasma and laser will bring about a plasma arc compression effect. This compression effect has related to the laser average power, pulse width and pulse frequency, and also has an important influence on the plasma arc beam shape.

(2) The compression of the plasma arc increases with the increasing of the laser average power, pulse width. The increasing of the laser repetition frequency causes the plasma arc compression effect to reduce. When the repetition frequency exceeds a certain value, the plasma arc will begin to extend contrarily. This effect and the inverse bremsstrahlung absorption effect of plasma has related to the ionization degree.

Quenching the Inductively Coupled Thermal Plasma for Nanoparticle Synthesis

St. Siegmann, M. Leparoux, C. Schreuders, J.-W. Shin, L. Rohr

EMPA - Swiss Federal Institute for Materials Research and Technology,
Feuerwerkerstrasse 39, CH-3602 Thun, Switzerland

Abstract
Temperature evolution during nanoparticle synthesis by thermal plasma has an enormous influence on the final size, size distribution, and phases of the generated products. The influence of several quenching parameters, like two gas jets or eight nozzles quench ring, different gas flow rates and chemical composition, quench jet positions on the resulting temperature profiles has been investigated. The modelling has been supported and validated with experiments, in-situ diagnostics, and ex-situ measurements.

Keywords: quenching, inductively coupled plasma, nanoparticles

1. Introduction

The worldwide activities in nanoparticles research increased dramatically during the last 5 to 10 years. Among the different routes for nanoparticle production, the main directions envisaged are mechanical milling, wet chemical reactions or gas phase processes. Each of these processes has its specific advantages and limitations. Mechanical milling and wet chemical reactions are typically time intensive and batch processes, whereas gas phase processes by flames or plasma can be carried out continuously and fast.
Materials of interest are mainly oxides, carbides, nitrides, and pure metals or alloys. Nano-ceramics are attractive candidates for application in coating technologies due to the expected higher coating toughness, better thermal shock and wear resistance. Inductively coupled plasma (ICP) facility provides a versatile tool for nanoparticle formation by controlling the heating, evaporation, quenching, and chemical composition of the atmosphere.

2. Experimental

The thermal plasma techniques, especially the inductively coupled plasma (ICP) process, offer many advantages compared to other gas phase techniques [1]. A high temperature and energy density enable the processing by vaporisation/condensation of high refractory materials and the use of inexpensive commercial available solid precursors [2]. Furthermore, the electrodeless operation of the ICP torch generates high purity products. The processability even under reduced pressure or reactive atmosphere offers some distinct advantages compared to other processes.
The induction plasma equipment consists of a plasma torch (PL-35, TEKNA Plasma System Inc., Canada) operated at a frequency of 13.56 MHz with an electrical input power of up to 35 kW. This torch is mounted on a modular vacuum synthesis chamber equipped with numerous view ports for in-situ monitoring. Finally the off gases are passing an on-line sampling filter or alternatively a large mass filtration unit [3] to retain the produced nanopowders. The detailed description of the experimental set-up is published elsewhere [2, 3].
A photograph of the setup is shown in *Figure 1*.

Figure 1: Photograph of the inductively coupled plasma (ICP) equipment for nanoparticle synthesis.

One important factor influencing the chemical and physical properties of the generated nanoparticles is quenching. Quenching can be carried out using different approaches e.g. using a cold surface [4], an expansion nozzle [5], or cold gas quenching [6] for nanoparticle condensation. The quench gas jets have some advantages like for instance easy positioning, variable quench gas flow rates, use of a reactive quench gas, etc. Only few references are available on this topic among them e.g. Hansen et al. [6] reporting on modelling of quench ring designs for a flame reactor or Soucy et al. [7] investigating the axial and radial mixing of two gas streams.

In this work two different quench nozzle designs are compared, i.e. a two jet nozzle and a ring type nozzle with eight holes. The influence of the different conditions on the plasma temperature and velocity field was measured by enthalpy probe technique [8]. The modelling of the temperature and velocity of the plasma flow field and quenching designs was carried out using the commercial CFD software Fluent 6.1.18. As quench gas Ar and N_2 have been investigated for the simple two jet nozzles as well as for the eight nozzles quench ring.
Commercially available tungsten carbide (WC) powder (d_{50} = 1.1µm) was used as precursor. The powder was injected into the plasma at the height of the first induction coil with a feed rate of approximately 300-350 g/min. The plasma conditions where the following (*Table 1*):

Table 1: Plasma parameters used for the study:

Parameters	**Values**
Central gas: Ar	27 slpm
Sheath gas (Ar / H_2)	80 slpm / 6 slpm
Electrical net power	15 kW
Chamber pressure	40 kPa
Powder carrier gas: Ar	5 slpm

3. Results:

The symmetric two jet nozzles positioned in opposite directions have shown good agreement between experimental observations *(Figure 2a)* and the 3D model exhibiting the splitting of the plasma jet (*Figure 2b)* at an Ar quench gas flow rate of 56 slpm. The asymmetry in *Figure 2a* is caused by a small deviation from the symmetry axis.

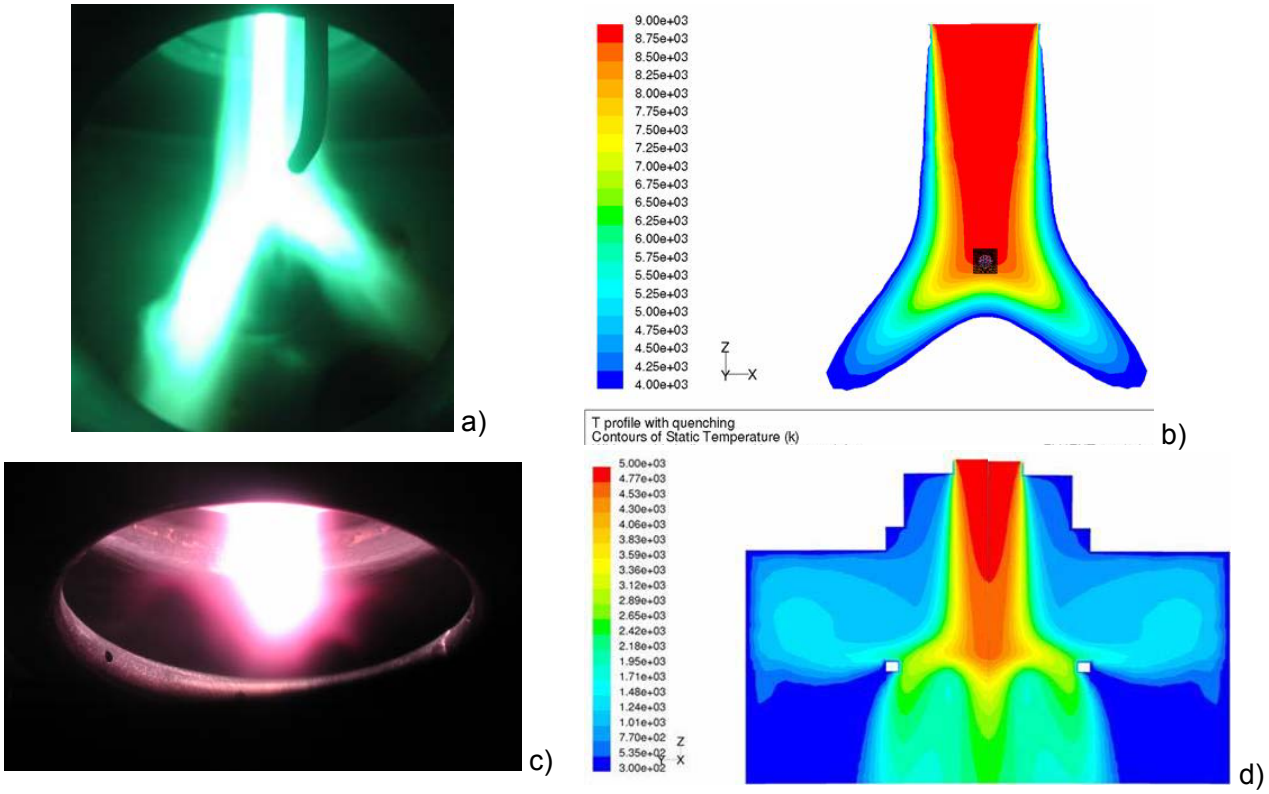

Figure 2: Comparison between a) photograph of two jet quenching and b) 3D temperature modelling and c) photograph of plasma jet quenched by an eight nozzles quench ring and its modelled trend in d).

The eight nozzles quench ring performed a more homogeneous and symmetrical quenching of the hot plasma. Figure 2c) shows a photograph of the plasma at the same quench gas flow rate level (56 slpm) like the two jets in Figure 2a). The two jets nozzle intersects the plasma in two parts giving rise to uncontrolled cooling and strongly variable and broad temperature and velocity profiles. In the case of the eight nozzles quench ring, the condensed particles are forced to flow through the ring. A better control of the nanoparticle size and size distribution is expected than for the 2 jets geometry.

The influence of quenching on the resulting size of the products is shown in *Figure 3*. Without quenching a particle growth is observed compared to the precursor. The non-quenched product also shows a smaller size distribution due to nucleation of the vapour on the non-vaporised, i.e. cold particles. A clear reduction of the particle size is visible when quenching has been used. The size distribution depends on the temperature and velocity profiles followed by the particles.

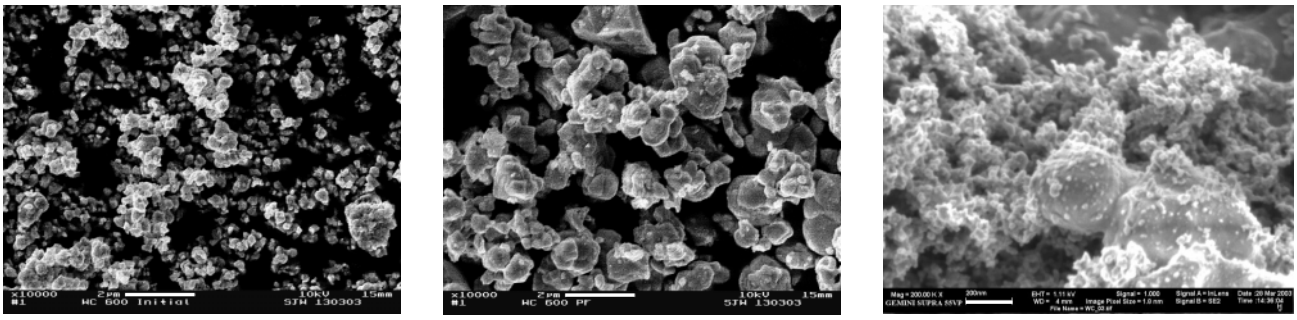

Figure 3: (left) SEM picture of WC precursor; (middle) plasma processed and grown WC without quench; (right) HR-SEM picture of plasma processed WC with 2 jets quench (white bars correspond to 2 μm in the SEM pictures and 200 nm in the HR-SEM picture).

As expected, quenching does not only influence the particle size and distribution, but also the chemistry. The XRD spectra in *Figure 4* show the phase composition of plasma processed WC as a function of the quenching gas flow rate and gas chemical composition.

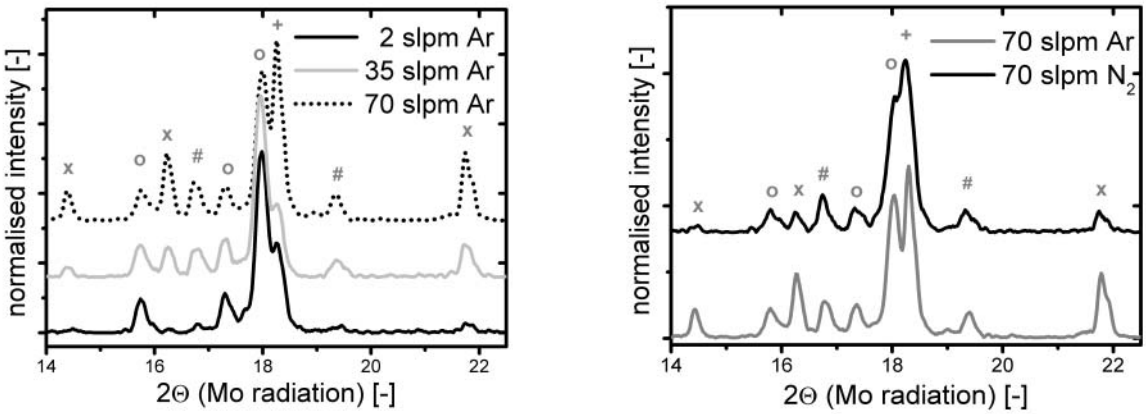

Figure 4: Phase composition determined by XRD of the synthesised WC powders for (left) different Ar quench gas flow rates and (right) comparison between 70 slpm of Ar and N_2 quench gas (X: WC, #: WC_{1-x}, O: W_2C, +: W).

4. Conclusions:

The optical observations, enthalpy probe measurements [9], and CFD modelling showed all good agreements between each other. The developed CFD model allows further optimizing the quenching of the plasma by adjusting the position, the geometry and the flow rates for controlled nanoparticle synthesis.

Abstract: At atmospheric pressure and room temperature, dielectric barrier discharge induced plasma driven surface reaction (PDSR) for the preparation of $TiO_2/\gamma–Al_2O_3$ photocatalyst has been investigated. $TiCl_4$ and O_2 were used as reagents in successive cycles. The adsorbed-state $TiCl_4$ may be oxidized by O_2 plasma to form Cl_2 and TiO_2, which exhibits high activity in the photocatalytic degradation reaction of formaldehyde. It has been found that there is an optimum cycle number to obtain the highest photocatalytic activity.

Keywords: dielectric barrier discharges, photocatalyst, TiO_2, plasma driven surface reaction

1. Introduction

Chemical vapor deposition (CVD) has been widely studied for depositing TiO_2 thin films on the supports with various geometric shapes[1-8]. In these studies, most TiO_2 films were prepared by thermally activated low-pressure (10^1-10^2 Pa) CVD at 573K followed by heat treatment or atmospheric pressure CVD (APCVD) at 773-923 K. Plasma enhanced CVD (PECVD) has been known to activate the deposition process more effectively than that of thermally driven CVD, because it makes use of low temperature, non-thermal equilibrium plasmas that provide energetic species to activate reactant molecules at temperature compatible with a wide range of substrate materials. However, PECVD have been studied in the preparation of TiO_2 films for photocatalyst mainly using radio frequency (RF) or microwave (MW) discharges at low pressure (10^2-10^3 Pa) [9,10]. Recently, a hybrid process of EFCM (electrostatic formation of ceramic membrane) and SPCP (surface corona discharge induced plasma chemical process) was proposed and successfully utilized to prepare TiO_2 photocatalytic membrane at atmospheric pressure[11]. In our previous paper, the supported $TiO_2/\gamma–Al_2O_3$ photocatalyst prepared by dielectric barrier discharges (DBD) induced PECVD at atmospheric pressure and room temperature has been explored, and exhibits high photocatalytic activity[12].

Generally, for the dominant TiO_2 deposition pathway in low-pressure CVD, it is believed that a Ti precursor molecule collides with another molecule in gas phase to form a more active intermediate species. They in turn react with the surface active site to produce deposited TiO_2 onto the surface of the support. But for atmospheric pressure CVD, in most case, another pathway is easy to take place that TiO_2 powders are generated in gas phase and settle down on the support surface. This pathway leads to very poor adhesion of TiO_2 to the support and should be avoided. For this purpose, in this work, DBD induced plasma driven surface reaction (PDSR) for the preparation of supported $TiO_2/\gamma–Al_2O_3$ photocatalyst at atmospheric pressure and room temperature has been investigated.

2. Experimental

The experimental setup designed for this work has been reported previously [12]. The discharge chamber consists of an outer quartz tube (*i*. *d*. 17 mm, *o*. *d*. 20 mm), a stainless steel tube (*i*. *d*. 4 mm, *o*. *d*. 6 mm) placed along the axis of the outer tube as the high-voltage electrode and 6 ml of γ–Al_2O_3 pellets (ϕ1 mm) filled between the two tubes. A copper wire mesh (height 30 mm) wound on the outside surface of the quartz tube was used as the ground electrode. The DBD power supply source is capable of supplying a bipolar sine wave output with 0–40 kV peak-to-peak voltage (U_p) at an a.c. frequency (f) of 5-20 kHz.

Titanium tetrachloride ($TiCl_4$) was chosen as the precursor. $TiCl_4$ was stored in a separate container and introduced into the PDSR reactor by bubbling 10ml/min of Ar carrier gas through. The temperature of $TiCl_4$ was kept at 340K using a water bath.

The preparation of TiO_2/γ–Al_2O_3 photocatalyst by DBD induced PDSR was performed at atmospheric pressure and room temperature. After the γ–Al_2O_3 pellets were loaded into the PDSR reactor, if not otherwise specified, $TiCl_4$ was first introduced and absorbed onto the supports for 30 min and then purged residual $TiCl_4$ vapor in the reactor by 18 ml/min of Ar for 15 min . Afterwards 20ml/min of O_2 together with 8ml/min of Ar was introduced into the PDSR reactor and the dischargestarted and lasted for 30 min (discharge conditions: f = 5 kHz, U_p=12kV).

This experiments for TiO_2/γ–Al_2O_3 preparation were carried out in a cyclic way. The above mentioned operation is just for1 cycle.

To determine the loading amount of titanium on the surface of γ –Al_2O_3, the coated γ –Al_2O_3 pellets were placed in warm $(NH_4)_2SO_4$-H_2SO_4 mixture solution, then the solution was heated up boiling for 2 h. The dissolved titanium was quantified by colorimetric method [13].

The photocatalytic activities of the TiO_2/γ–Al_2O_3 photocatalysts were evaluated by the photocatalytic degradation of formaldehyde solution. 10 ml of 3.0 mg/l formaldehyde solution, together with 1.3 g of TiO_2/γ–Al_2O_3 photocatalyst, were irradiated by a ultraviolet lamp (254 nm, 8 W) for 0.5 h. The concentrations of formaldehyde were determined by colorimetric method. It is worthwhile to point out that there is no need for heat treatment for the TiO_2/γ–Al_2O_3 photocatalyst prepared by the PDSR process at room temperature.

The optical emission spectrometer (Acton, SP-300i) was composed of an optical collection and a transmission system. The collection of the light was carried out with a lens (diameter ϕ 30 mm), by which the collected light was focused onto the input slit of the monochrometer through a group of supplement lens. After being amplified by a DC-amplifier, the out-put signal of the optoelectron multiplying tube (PMT) was sent to a computer. The wavelength scanning range of the monochrometer was 200-900 nm with highest resolution 0.1nm. The response scope of the PMT was 200-900 nm. The mass spectrometry (Balzers, Omistar^{TM} 422) was used to determine the products of PDSR.

3. Results and discussion

3.1 Comparison of two synthesis routes of PDSR process

Generally, in thermal CVD process[3], $TiCl_4$ was first introduced and absorbed onto the porous supports, then water vapor was brought through to start the hydrolysis of those absorbed $TiCl_4$ species. In the PDSR process, whether $TiCl_4$ is absorbed followed by discharge in O_2-containing gas (designated as Route A) or O_2 is absorbed

followed by discharge in $TiCl_4$-containing gas (designated as Route B), this should be first determined by a comparative experiment. As shown in Fig.1, formaldehyde conversions of $TiO_2/\gamma–Al_2O_3$ photocatalyst prepared by Route A and B are 83% and 4%, respectively. This result strongly supports that Route A is much more advantage than Route B for $TiO_2/\gamma–Al_2O_3$ photocatalyst preparation using PDSR process. Thereby, Route A was employed in all the following experiments.

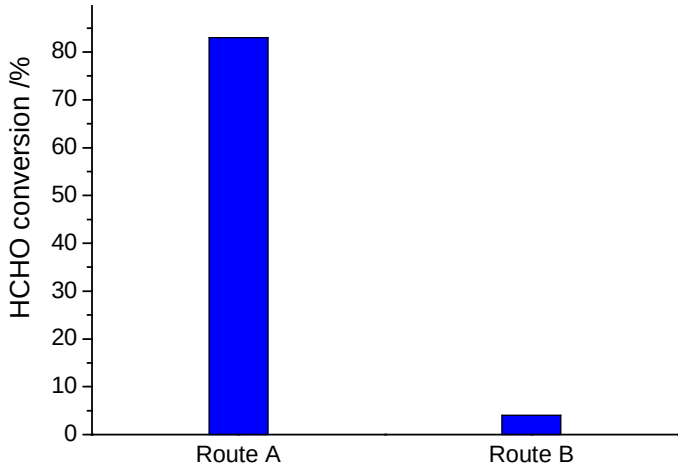

Fig. 1 Comparison on photocatalytic activity of $TiO_2/\gamma–Al_2O_3$ photocatalysts prepared by Route A and B (2 cycles of adsorption-PDSR)

3.2 Effect of the number of PDSR cycles

Fig.2 shows TiO_2 loading amount and formaldehyde conversion of $TiO_2/\gamma–Al_2O_3$ photocatalyst versus the number of adsorption-PDSR cycles. The TiO_2 loading amount increases with increasing the cycle number. This result differs from the work using the Chemical Surface Coating (CSC) method in literature [14], where it was reported that the uptake of Ti is linearly during the first 6 reaction cycles and afterwards no further uptake of Ti was found. In the CSC process, $TiCl_4$ and H_2O were used as reactants. But, $TiCl_4$ is too reactive with water to handle the reaction rate. In the PDSR process, O_2 was employed instead of H_2O and the reaction of adsorbed-state $TiCl_4$ and O_2 driven by plasma was easy to control.

It can be also seen that there is an optimum number of PDSR cycles to obtain the highest photocatalytic activity, which is around 6 cycles. When further increasing the cycle number, the TiO_2 loading layer becomes thicker and it is more difficult for UV light to penetrate and for formaldehyde molecules to diffuse through. Furthermore, with increasing the loading amount, the small TiO_2 crystals tend to agglomerate which also has an disadvantage effect on the performance of the catalyst.

3.3 Mechanisms of TiO_2 coating in the PDSR process

Generally, the overall oxidation reaction for $TiCl_4$ is

$$TiCl_4 + O_2 \rightarrow TiO_2 + 2Cl_2 \quad (1)$$

and can be carried out in the gas phase or on a solid surface. To shed light upon the reaction mechanism in the

PDSR process, the gas phase stable species were monitored in situ by mass spectrometry and optical emission from plasma of PDSR was measured.

In the process of PDSR, no peak related to $TiCl_4$ appears in the mass spectrum at *m*/*e* =190 ($TiCl_4^+$), *m*/*e* =153 ($TiCl_3^+$), *m*/*e* =118 ($TiCl_2^+$), *m*/*e* =83 ($TiCl^+$). Fig.3 shows the peaks of the gas effluent from PDSR reactor, these include: the peaks related to Ar appears at *m*/*e* =40 (Ar^+) and *m*/*e* =20 (Ar^{2+}); the peaks related to Cl_2 appears at *m*/*e* =70 (Cl_2^+), 72 (Cl_2^+), 35 (Cl^+); the peaks related to O_2 appears at *m*/*e* =32 (O_2^+) and *m*/*e* =16 (O^+).

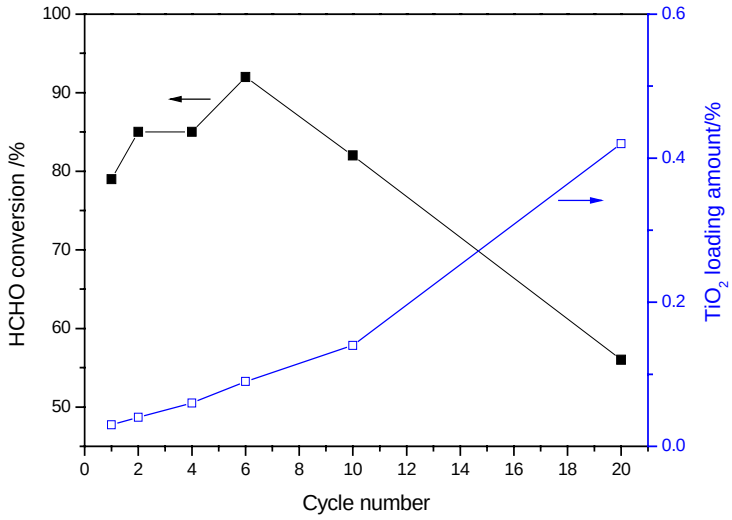

Fig.2 TiO_2 loading amount and formaldehyde conversion of $TiO_2/\gamma–Al_2O_3$ photocatalyst as functions of the number of adsorption-PDSR cycles.

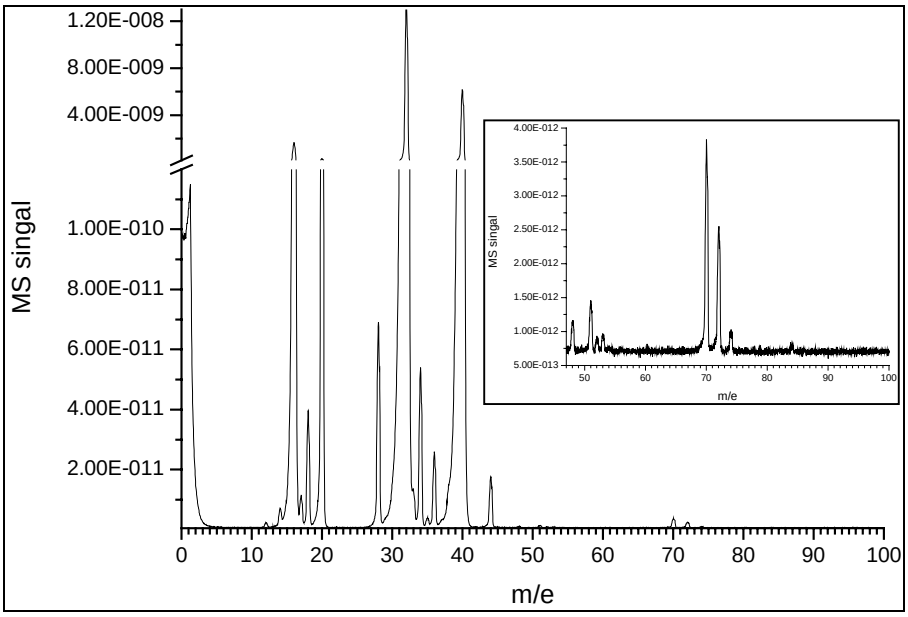

Fig.3 Typical mass spectrum of the gas effluent from PDSR reactor

Fig.4 exhibits peak intensity of Cl_2, the oxidation product of $TiCl_4$, changes with time. In a PDSR cycle, with the increase of discharge time, peak intensity of Cl_2 rises rapidly to the maximum and decreases slowly, which implies that $TiCl_4$ adsorbed onto the γ–Al_2O_3 surface was being consumed and getting less and less. As shown in Fig.5, the emission spectrum of O (778.0 nm) and Ar (772.8 nm, 795.4 nm) from the plasma of the PDSR process is observed.

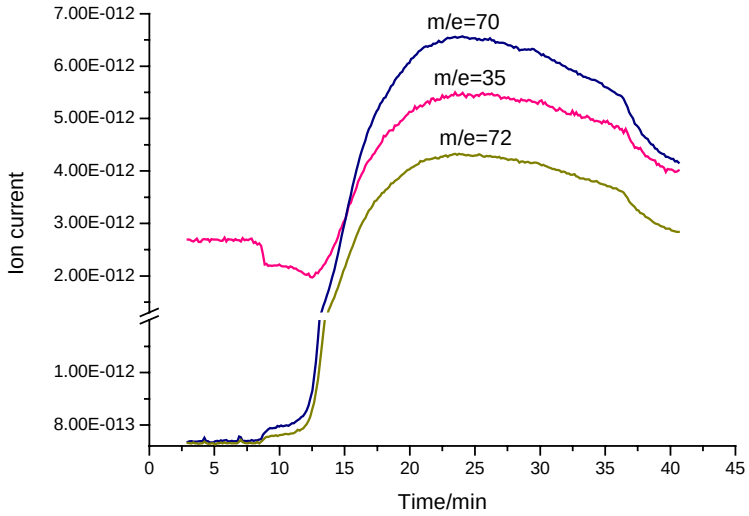

Fig.4 Intensity of peaks related to Cl_2 at *m*/*e* =70, 72 and 35 versus time

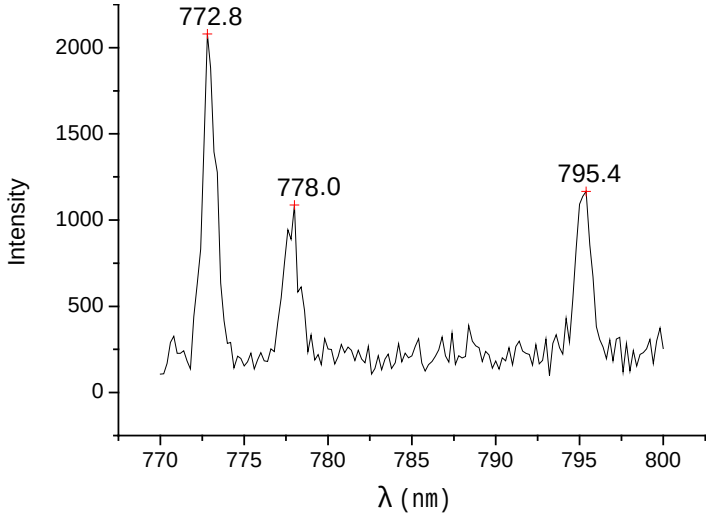

Fig.5 Optical emission spetra from the plasma of the PDSR process

Based upon the above experimental results, the mechanism for the adsorption and PDSR process can be explained as follows:

$TiCl_4$ first adsorbs on γ–Al_2O_3 surface

$$TiCl_4\ (g) \rightarrow TiCl_4\ (ad) \qquad (2)$$

Adsorbed-state $TiCl_4$ is oxidized by oxygen atom derived from the collision of O_2 molecule with energized

electron in the plasma

$$TiCl_4\ (ad) + O \rightarrow TiCl_2O\ (ad) + 2Cl \quad (3)$$

$$TiCl_2O\ (ad) + O \rightarrow TiO_2\ (s) + 2Cl \quad (4)$$

The recombination of Cl atom from reaction (3) and (4) forms Cl_2

$$2Cl \rightarrow Cl_2 \quad (5)$$

4. Conclusion

$TiO_2/\gamma-Al_2O_3$ photocatalyst was prepared by means of DBD induced plasma driven surface reaction at atmospheric pressure and room temperature. By plasma-driven reacting adsorbed-state $TiCl_4$ with O_2 in a cyclic way, a TiO_2 coating is formed which is chemically bound to the support and exhibits high activity in the photocatalytic degradation reaction of formaldehyde. It has been found that there is an optimum cycle number to obtain the highest photocatalytic activity. There is no need for heat treatment for the $TiO_2/\gamma-Al_2O_3$ photocatalyst prepared by the PDSR process at room temperature.

THEORETICAL STUDY OF AR/O_2 MIXTURES IN ECR PLASMAS: IS IT POSSIBLE TO USE OPTICAL EMISSION SPECTROSCOPY AS A QUANTITATIVE DIAGNOSIS TOOL?

Abstract

In this work a collisional-radiative model of Ar and O_2 is used to model low pressure microwave ECR discharges for these gases and their mixtures. The model is formed by two parts which are self-consistently solved, one global model of the discharge zone and a 2D model of the downstream region. The model is able to reproduce the trends experimentally observed for the different parameters of the discharge, but further refinements are needed in order to find a quantitative agreement with the Optical Emission Spectrocopy measurements carried out in the same reactor.

1. Introduction

Low pressure Ar/O_2 discharges are frequently used for applications such as etching or thin film deposition of different oxides. In our laboratory, in the past five years an ECR reactor in an SLAN configuration has been successfully used for such purposes[1,2]. One of the advantages of these devices is that the discharge is generated inside a quartz chamber that is connected to the metallic reactor in which the reactive process takes place (Fig. 1), so that Optical Emission Spectroscopy (OES) measurements can be easily made in the discharge region. However, in PECVD and etching processes it is interesting to get further information not only about the species that are present in the plasma, but also of the active species that are reaching either the substrate or the etched material.

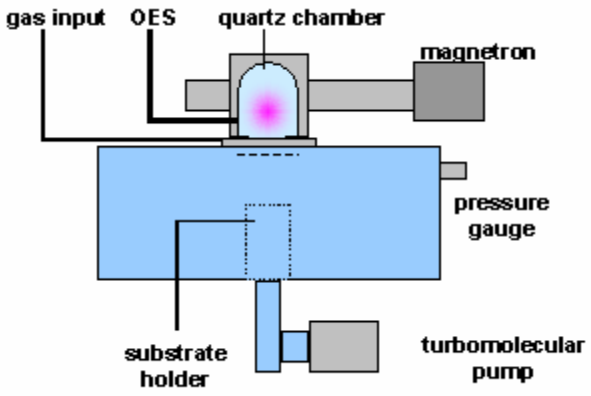

Figure 1: Scheme of the experimental set-up

Optical emission spectroscopy is a non-intrusive characterisation tool that has been used in many works to characterise the excited species that appear during the deposition process[2]. In oxygen discharges, quantitative information has been obtained from the optical emission spectroscopy by techniques such as actinometry. Other works have tried a different approach, using theoretical models of the main plasma kinetics in order to get information of some of the key parameters of the discharge (i. e., electron density or electron temperature) from experimentally measured emission intensities.

In this work we have followed this second approach, so that a collisional radiative model for Ar, O_2 and Ar/O_2 mixtures has been developed in order to get the populations of the different species as a function of the main experimental parameters, that is, microwave power, pressure and mixture composition. The model would serve as a starting point to identify Ar and O emission lines that could be used to check the theoretical results obtained with OES experimental measurements[3].

2. Theoretical model

The discharge zone is studied using a global model in which the electron energy distribution function and a collisional-radiative model taking into account the main species for discharges in Ar and O_2 are solved self-consistently. For the case of argon, the kinetic model includes 32 argon levels, so that the populations of the excited states responsible of the argon main emission lines are considered[4]. We have included a coherent cross-section set including the most recent experimental data available which has been previously tested and compared with other collisional-radiative models[5].

In the case of oxygen, seven species have been included in the model: O_2 (X), O_2 (a), O_2 (b), O_2^+, O, O^- and O_3. The oxygen kinetics has been modeled following the models presented by Capitelli et al[6] and the references cited therein. Ar and oxygen models have been linked through three main reactions[6,7]: charge transfer process between Ar^+ and O_2^+, metastable dissociation of O_2 molecule and O three-body recombination with Ar as the third body.

In order to study the evolution of the different species in the downstream region, the global model previously described is coupled to a 2D model of the deposition chamber. Populations of the different species are calculated in the difussion approximation with an effective diffusion coefficient D_e[8]. Milne boundary conditions have been used at the walls of the reation chamber. In the case of charged particles and metastable states of Ar and O_2, the wall recombination and de-excitation probability has been taken into account as in the work of Takechi and Lieberman[9].

The use of these two different approaches in the calculations is justified by the presence in the experimental reactor of a grounded grating between these two regions, so that the glow zone is confined in the quartz reactor. Both models are solved for the geometry and the conditions used in our laboratory as described in previous works. Averaged values of the electron density and temperatures as well as density profiles of some key species in the downstream are obtained using microwave power, pressure, gas temperature and Ar/O_2 ratio as input parameters.

3. Results

The model described above has been solved for different conditions. Pressure and power are the two parameters with greatest interest from the experimental point of view, along with the Ar/O_2 fraction when mixtures are studied. Gas temperature is also another parameter that may have an important influence on the discharge, especially due to the strong dependence of the wall recombination probability with the wall temperature. However, as can be seen in Fig. 2, measurements of the outer wall temperature of the quartz carried out in our reactor show that it is almost independent of the pressure and the electromagnetic power. Therefore, taking into account the high thermal conductivity of quartz, all results presented here correspond to a gas temperature of 300 K.

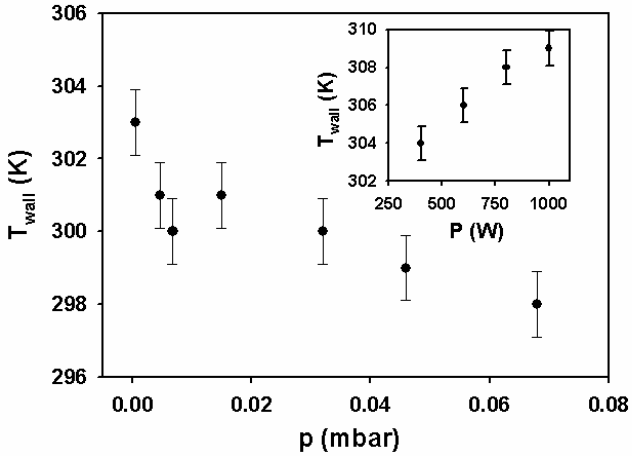

Figure 2: Wall temperature measurements

In Figure 3, the electron density ne and the population of atomic oxygen n_O are presented as a function of pressure and power for a pure oxygen discharge. Both depicts a characteristic behaviour reaching a maximum value for intermediate pressures, in contrast with the behaviour of the electron temperature, which decreases when increasing pressure.

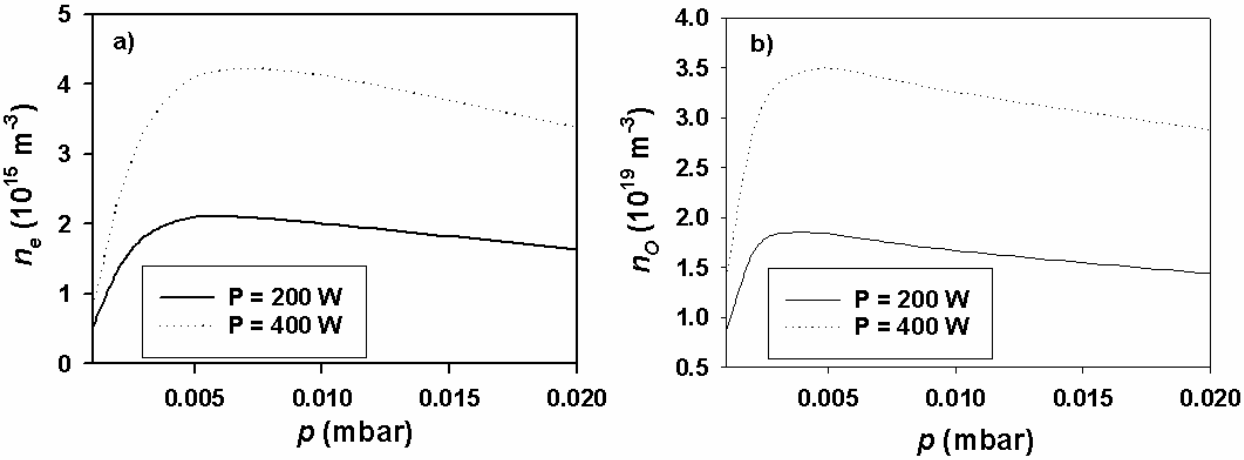

Figure 3: Electron density (a) and atomic oxygen population (b) as a function of pressure

The case for pure argon is presented in Figure 4. The electron density, in contrast with the behaviour of the oxygen discharge, increases with pressure and the values agree well in order of magnitude with the experimental measurements carried out by other autors for the SLAN plasma source. The electron temperatures presented follow the same trend as in the case of oxygen, but their values are lower than the obtained for O_2 discharges.

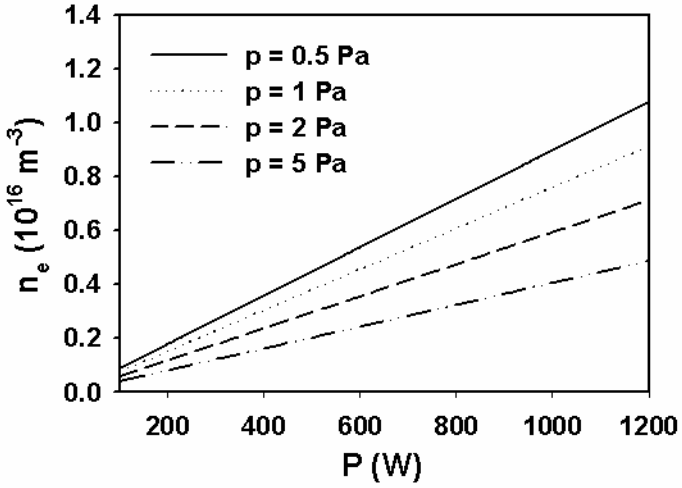

Figure 4: Electron density as a function of power for an Ar discharge

The presence of oxygen affects to both the electron temperature and the electron density of the discharge. In Ar/O_2 mixtures the charge transfer process between Ar^+ ions and O_2^+ is very effective, so that the population of O_2^+ ions in higher than that of Ar^+.

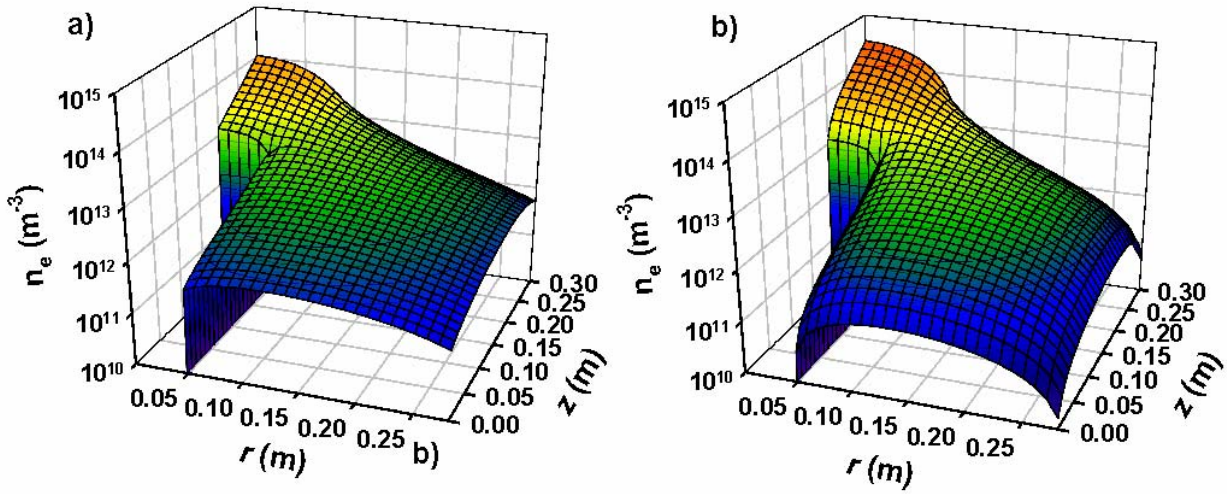

Figure 5: Downstream electron density profiles for two different pressures: (a) 10 mtorr; (b) 50 mtorr

Pressure is the main parameter affecting the evolution of the active species of the discharge in the downstream region. In Figure 5, the profiles for the electron density are presented for a pure argon discharge at two different pressures: tal and tal mbar. As a consequence of the increase on pressure the discharge is almost confined to the glow zone, and the flow of ionized particles onto the substrate-holder decreases significatively. Contrary to what happens with electron density, populations of metastable Ar are very important in the position of the substrate-holder. In this regard, in Figure 6 the joint flows of the Ar metastable levels of the 4s configuration, Ar 4s($^3P_0$) and Ar 4s($^3P_2$) is presented along the position of the substrate holder along with the flow of charged species for a pure argon discharge. The flow of Ar metastable states onto the substrate holder are almost an order of magnitude higher than the flow of charged

particles.

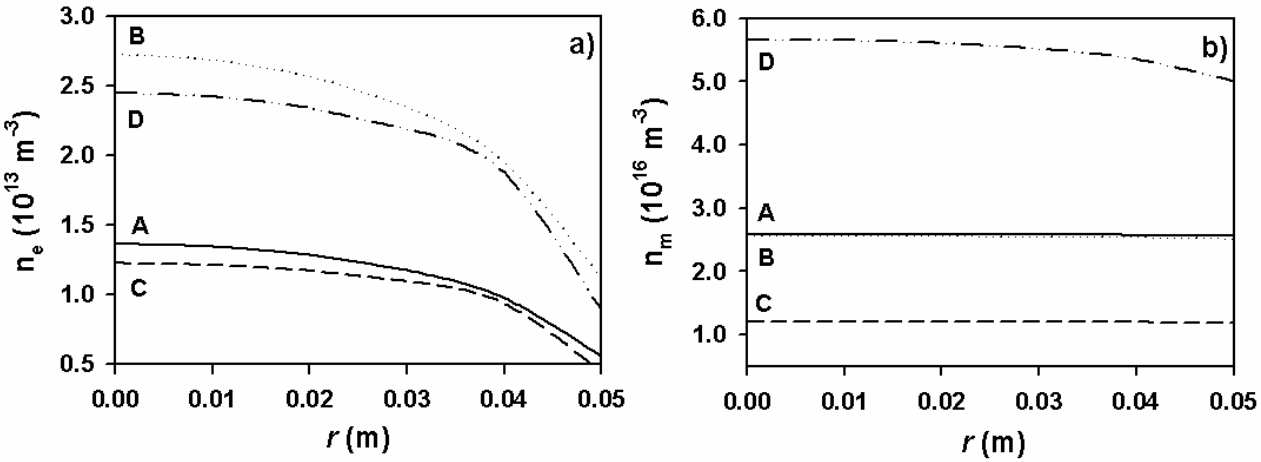

Figure 6: electron density and metastable population over the substrate holder: A 10 mTorr, 200 W; B 10 mTorr, 400 W; C 50 mTorr, 200 W; D 50 mTorr, 400 W

4. Discussion:

According to the model electron density behaves with pressure in a different way for argon or oxygen discharges. In this latter case, there are optimal conditions in which the electron density and the atomic oxygen reach their maximum value. In this regard, Optical Emission Spectroscopy measurements carried out in our SLAN reactor show that both the 777 nm and the 845 nm atomic lines of O present a similar behaviour with pressure, as well as the deposition rate in the case of SiO_2 thin films. In contrast, argon atomic lines do not exhibit such behaviour, in agreement with the monotonally increasing variation of the electron density with the pressure for argon plasmas.

Pressure is the main parameter that controls the evolution of the different species of the discharge in the afterglow. As the diffusion coefficients of Ar^+ and O_2^+ are similar, the variations in the populations of charged species in the afterglow are more influenced by total pressure than by the specific composition of the Ar/O_2 mixture. Due to their long mean lifes, these species are strongly affected by both the boundary conditions and the diffusion coefficients.

One of the limitations of the present model is that no detailed description of the kinetics of the excited states of the O_2 molecule has been included: in general, most of previous models found in literature either consider effective rate coefficient for the ionisation or neglect the contributions of the excited levels over the $O_2(b)$ excited state. In the case of argon, it has been found that the step-wise ionisation can be very effective, and when the full collisional-radiative model is considered, the electron temperatures theoretically calculated are lower and closer to the experimental data. Without having an accurate description for step-wise ionisation for the molecular oxygen the electron temperatures calculated are expected to be higher than the real ones. Although this is not very important when trying to reproduce the trends experimentally observed, this is an important issue if a quantitative agreement is desired.

A new Surface Tension Measurement Technique for High-Melting-Point Materials

A. Moradian[1], J. Mostaghimi[2]

[2] *Centre for Advanced Coating Technologies, University of Toronto, Toronto, Canada*

Abstract
A new experimental/numerical method is proposed to measure the surface tension coefficient of high-melting-point materials. In the proposed method, radio-frequency-Inductively Coupled Plasma (rf-ICP) is employed to melt materials. Dynamics of melting is photographed. The surface tension dominant phenomenon of melting is then numerically modeled. Interfacial tension, as the major parameters governing the dynamics of melting, is estimated by comparison between the theory and observation. The results for copper generally agree with those obtained in previous studies. Preliminary findings suggest promising application of the method for ceramics.
Keywords: Surface tension measurement, radio-frequency plasma, dynamics of melting

1. Introduction

Because of the relatively high temperatures involved and the reactivity with any container, measurement of the surface tension of high-melting-point materials poses special challenges. Therefore, only a few of the common methods can be implemented at high temperatures [1,2]. Metal manufacturing and fabrication industries are increasingly using computational based mathematical models to obtain a better understanding or control of their processes, or to predict defects in their final products. These models are highly developed in terms of the mathematical equations used, but they rely on the accuracy of the physical and physico-chemical property data of materials they are modelling. In many cases these data are not available, and this is particularly true in the case of surface tension and viscosity of high-melting-point materials. These properties are the critical factors in the modelling of the processes of interest. According to the limitation imposed because of melting temperature of materials, methods for the measurements at high temperatures should be container-less. Using atmospheric rf-ICP samples can be heated to high temperatures. Figure 1 shows the heating of a ceramic sample by a rf-ICP torch.

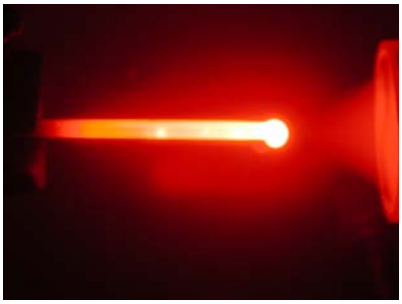

Fig. 1: Plasma heating of a ceramic sample

Details of the methods available for measuring surface tension of ordinary liquids have been reviewed [3,4] and will not be repeated here. Because of the relatively high temperatures involved and their reactivity with any container, surface tension of high-melting-point materials pose special challenges. Therefore, only a few of the common methods can be implemented at high temperatures. The maximum bubble pressure has frequently been employed in experimental determination of the surface tension of liquid metals and alloys. The maximum drop pressure method has been applied for determining the surface tension of highly reactive, low melting point metals, but it is limited to about 1000 K because of difficulties related to the design of equipment for high temperatures. The capillary rise method is not commonly used for metallic liquids; because the exact knowledge of contact angel is required. This angle is often more difficult to measure than surface tension [5]. The pendant drop method and the drop weight methods are applicable to most transition metals. The sessile drop method has

been extensively used for measuring surface tension of melts. In addition to the common methods many sophisticated techniques have been developed. For example, levitating drop method in which electro-magnetic levitators employ inhomogeneous radio frequency electro-magnetic field to heat and position samples. Such a field induces eddy currents within the material which due to Ohmic losses eventually heat up the samples (inductive heating). In addition, the field exerts a force on the sample and pushes it towards region of lower strength of the filed (Lorentz force). The latter effect produced by a strong magnetic field can be used to compensate for the 1 g gravitational force [6].

A brief review of the traditional methods manifests the drawbacks in using the methods for high temperature materials. Problems such as contamination, economic issues, equipment limitations and unexpected instabilities are the reasons that makes the levitation method deficient for high melting point materials.

Also, by using the theoretical relations for axisymmetric profile of pendant drops proposed by Young (1805) and Laplace (1805), surface tension of fluids can be measured. To this end, a comparison between the experimental drop profile and the theoretical profiles results in an appropriate capillary constant. Hence, having the density of the fluid interfacial tension will be calculated

The earliest efforts in the analysis of axisymmetric drops were those of Bashforth and Adams (1883) [7]. Hartland and Hartley (1976) [8] also investigated the interfacial tension measurement of axisymmetic fluid-fluid menisci. Based on their pioneering approach, Rotenberg et al. (1983) developed a technique called Axisymmetric Drop Shape Analysis-Profile (ADSA-P). The ADSA-P technique fits the measured profile of a drop to a Laplacian curve [9].

To quantify the equilibrium condition used in the drop weight method, Tate (1864) [10] proposed the following relationship.

$$m^* g = \pi d \sigma \qquad (1)$$

Where m^* is the mass of total pendant volume and d is the diameter of the wire at the melting point. However, this simple form does not allow for true determination of surface tension, which let Harkins (1919) to introduce a correction factor F, as “a fraction of the ideal drop separating from the rod” with using m (the mass of the collected drop) instead of m^*; therefore $F = \frac{m}{m^*}$ [11].

Harkins & Brown (1919) showed that the $f(R_0/a)$ is better correlated with a third-order polynomial. Their method led to the well-known “drop-weight” method to determine surface tension. Garandet et al. (1994) showed that the Harkins’ empirical correction factor F can be derived from a momentum balance written just before release [12].

Present study deals with the melting of copper samples by using the plasma torch, observation of the melting dynamics through high-speed imaging, extracting the profiles which are the result of full Navier-Stokes equations, and producing the analytical Young’s profiles. Figure 2 shows the digitally reproduced pendant drop based on image post processing and a numerically simulated pendant drop at the end of a horizontal rod.

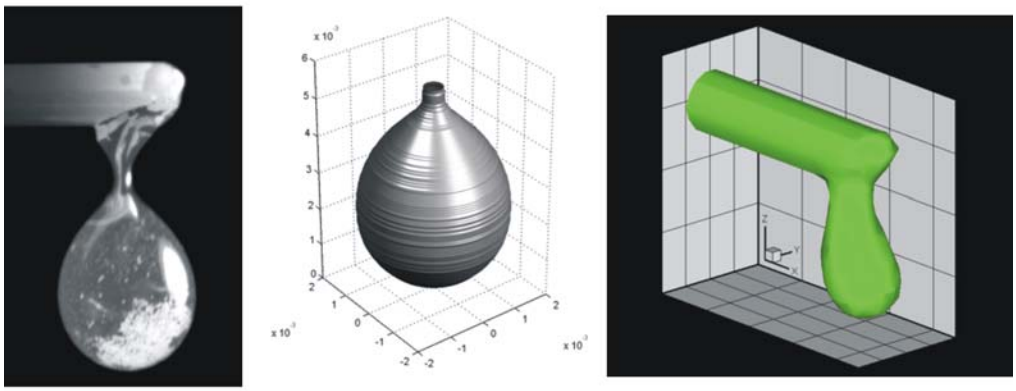

Fig.2: Schematic of the new container-less surface tension measurement method, left to right; copper drop, reproduced experimental profile in an image analysis process, and numerically simulated melting dynamics

2. Experimental setup

Atmospheric 40 MHz argon rf-ICP plasma with a maximum power of 1 kW is used to melt copper rods. Argon flows at 1.2 and 7.6 *slpm* as plasma and sheath gases, respectively. The rod is aligned with the axis of symmetry of the rf-ICP (see Figure 1). Initial studies were conducted on copper rods of 1.6 mm diameter with a melting point of 1370 K. The argon radio frequency plasma produces the required high temperatures for melting the rod. In addition, the flow of argon prevents the samples from oxidations. The rf quartz torch (Delta Scientific Laboratories, Mississauga) has a diameter of 18 mm. The rf power supply (Advanced Energy Industries, Inc., Co) generates up to 1 kW forward power at 40 MHz. A CCD video camera (Sensicam, Optikon Corporation Ltd., Kitchener, ON) equipped with a 90 mm macro lens with an intensified CCD chip capable of recording 30 frames per second and a resolution of 1280 by 1024 pixels is used to record the dynamics of the process. The camera was triggered by an external digital time delay generator (DG 535 Stanford Research Systems, Sunnyvale, CA) at 50 Hz frequency. Dynamics of melting phenomenon is also recorded by a high-speed camera (PHOTRON FASTCAM-ultima 1024, Corporation Ltd., Kitchener, ON) at rates of 500, 1000, and 2000 frames per second.

3. Governing Equations

3.1. Numerical simulation

An axisymmetric two fluid model based on finite volume method [13] is used to solve the full Navier stokes equations. The incompressible interfacial flows in such two immiscible fluids (melt and surrounding gas) are separated by an interface. The present numerical model uses a one-field volume of fluid tracking method based on the one fluid volume of fluid (VOF) method modified by Youngs. It is assumed that only one of the fluids governed the motion of the fluids which is a reasonable assumption in dealing with incompressible and immiscible fluids. The numerical code is based on RIPPLE with the modified volume tracking and surface tension implementing. Surface tension is applied by using the continuum surface force (CSF) method. This method applies the surface tension force as a body force on a limited region around the interfacial cells. In the one-field method, the concept of mixed properties is used to represent cells containing multiple fluids.

Process of melting is modeled by a continuous injection of liquid from a nozzle with a diameter equal to the diameter of the rod. The interface is continuously under oscillations during the growing period. The oscillations (capillary waves) are the result of interacting injected momentum and restoring surface tension force. Injecting flow rate is changed during the process to decrease the inertia forces acting on the motion of the pendant drop. In order to decrease the CPU time of the simulation and obtaining a quasi-equilibrium condition velocity is defined by a step function.

$$V_i = \begin{cases} V_{i1} & ;\ t < t_c \\ V_{i2} & ;\ t > t_c \end{cases} \qquad (2)$$

where; $V_{i2} < V_{i1}$.

Reducing the velocity after the time t_c improves the possibility of comparing the resulting profiles with the Young's profiles while the inertia forces became very small. This will also decrease the oscillations due to the momentum of the injected liquid and restoring force of interfacial tension. Therefore, the pendant drop will be closer to the equilibrium state presumed in the Young analytical profiles.

3.2. Theoretical pendant drop profile

Based on the Young-Laplace equation the profile of a pendant drop can be represented by a set of three simultaneous nonlinear, non-homogeneous, and first order ordinary equations [8] which can be solved simultaneously to calculate three unknowns, (φ, X, Z) while S is the independent variable measured from the apex (see figure 3); and B is the curvature at the apex.

$$\frac{d\varphi}{dS} = \frac{2}{B} - Z - \frac{\sin\varphi}{|X|} \tag{3}$$

$$\frac{dX}{dS} = \cos\varphi \tag{4}$$

$$\frac{dZ}{dS} = \sin\varphi \tag{5}$$

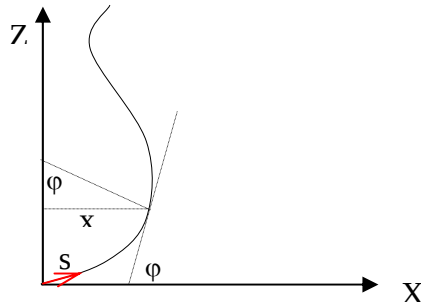

Fig. 3: Theoretical profile of a pendant drop

4. Results and discussions

An image analysis program is developed to obtain the evolving profile of the melting portion from the high-speed recorded movies [14]. Then the program fitted an optimized theoretical profile based on the Young-Laplace equation on each image. The curvature at the apex and an scaling factor are adjusted to improve the fitting process. Therefore, the scaling factor, $\sqrt{\frac{\Delta\rho g}{\sigma}}$, is used to measure the dynamic surface tension. Fitting the profiles is evaluated based on an error defined as:

$$e = \frac{1}{N}\sum_{i=1}^{N}\left|\frac{R_{\text{exp.}} - R_{young}}{R_{\text{exp.}}}\right| \times 100 \ \ \% \tag{6}$$

Figure 4 shows one images which is fitted by Young-Laplace profile. Accordingly, the surface tensions measured during the melting process is depicted in figure 5. Dots (red) in the figure are surface tension values based on the drop weight method using the detached drops which were quenched in water.

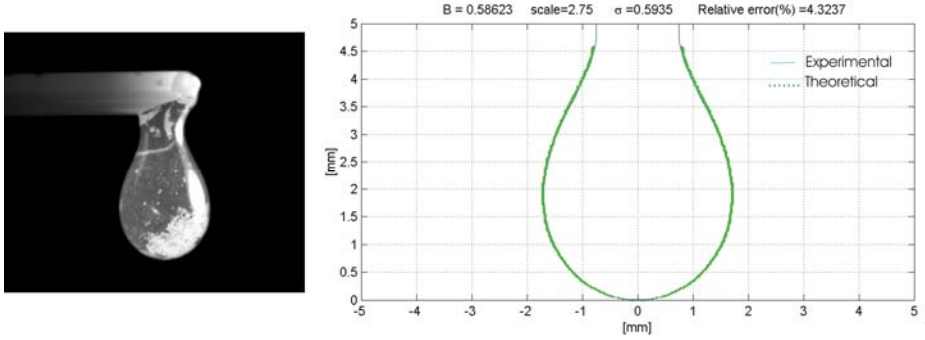

Fig. 4: Pendant drop of the copper sample (left), fitted analytical profile on the experimental profile (right)

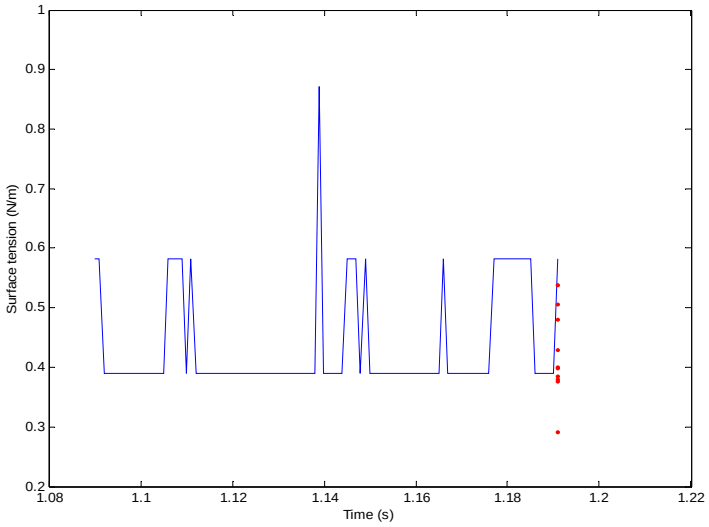

Fig. 5: Surface tension measured based on fitting theoretical profiles on the experimental profiles during the melting process (continues line), surface tension measured based on the weight of detached drops

The profiles are also produced by solving the flow field equations. Figure 6 shows a numerically generated profile at a specific time during the growth process by solving the axisymmetric Navier-Stokes equations. While the Young-Laplace equation ignores viscous and inertia effects it is expected that the numerical profiles do not match during the whole process of melting (injection).

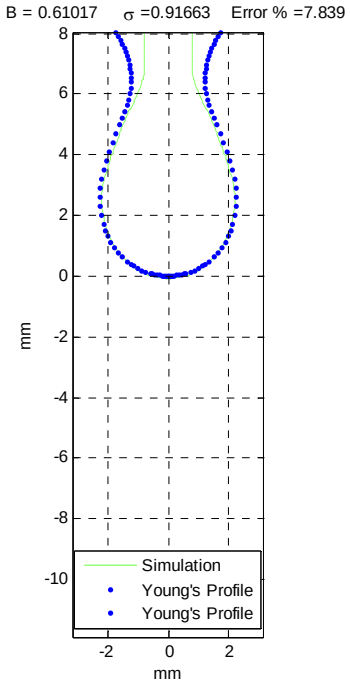

Fig. 6: Fitting the simulated and the theoretical profiles

5. Conclusion

The results show a good agreement in surface tension value measured for the sample by different methods. While the method is not influenced by the limitations imposed because of a container or lack of a high temperature source the method is applicable to very high melting point materials such as ceramics and alloys. However, more investigations are still needed to determine the effect of melting rate, surrounding gas, temperature, and effect of oxidation at the elevated temperature in both the experimental and numerical approaches.

Control of the stability of Plasma Polymerized Acrylic Acid coating deposited in a low frequency discharge on Polyethylene (PE) films

R. Jafari, M.Tatoulian, F. Arefi-Khonsari

Laboratoire de génie des procédés plasmas et traitement de surface, ENSCP, UPMC, 11 rue Pierre et Marie Curie, 75005 Paris, France

Abstract

Plasma polymerized acrylic acid (PPAA) coatings were deposited on PE films, in a 70 kHz low pressure plasma reactor with an asymmetrical configuration of electrodes, at various plasma powers. The COOH retention of PPAA coatings and its stability to washing in water were investigated by XPS, WCA (water contact angle), SEM analyses. The results have shown that the use of higher powers leads to an increase of the stability of the coating due to a high degree of cross-linking. Optical emission spectroscopy measurements (OES) have shown good correlation between the CO density in the gas phase and the carboxylic content of PPAA coating. Under optimized conditions, it is possible to obtain stable PPAA coatings which resist to washing with a COOH retention rate of 15 %, which is much higher than the coating deposited in a 13.56 MHz discharge.This high stability of the coatings is probably due to the ions which play an important role in such discharges.

Keywords: stability, selectivity, plasma polymerisation, acrylic acid, ions

Introduction

The plasma polymerization of acrylic acid to produce thin coating with carboxylic functions has been an active area of research for applications in biomedical and biosensors [1-5]. The objective of this work is therefore to produce a surface containing a high density of COOH functions on the polymer films (PE) for the covalent immobilisation of biomolecules. For such applications, there is a strong need to obtain stable plasma polymerised acrylic acid coating, resistant to washing with water. M.R. Alexander et al. have found stable crosslinked polymers formed by copolymerising a mixture of acrylic acid –and 1,7-octadiene under high plasma power [6]. They have obtained a percentage of COOH less than 6 % after rising in water. L. Detomaso at al. studied the increase of power and of duty cycle in a modulated plasma for the deposition of acrylic acid ; they obtained a surface containing 3-4 % of COOH groups after washing [7]. All the studies have been carried out at 13.56 MHz. At this high frequency, the ions cannot follow the fluctuation of the electrical field. In this work, we have used a low frequency discharge of 70 kHz with an asymmetrical configuration of electrodes in order to obtain coatings from acrylic acid precursor. Different physicochemical analyses have been used such as water contact angle measurements (WCA), XPS, OES and SEM analyses to characterize the PPAA coatings deposited under different experimental conditions. Special attention will be paid on the level of retention of the carboxylic acid functionality and on the stability of the coating upon washing.

Experimental

A bell-jar reactor with an asymmetric blade-type configuration of electrodes was used for the plasma polymerisation of acrylic acid. It has been described in details elsewhere [8]. The stainless steel blade is hollow and serves for the introduction of the gases. It faces a grounded stainless steel cylinder (length 22 cm and diameter 3.5 cm) onto which the polymer film to be covered is rolled on. The gaseous mixture was produced by bubbling Argon at a rate of 10 sccm in a 10 ml round bottom flask containing the acrylic acid monomer (Sigma Aldrich, 99% pure). The flow rate of the acrylic acid was around 0.06 sccm. The main chamber was evacuated by a TPH 170 (Balzers) turbo molecular pumping system and a base pressure of 10^{-3} Pa was obtained. The operating pressure was maintained at 0.1-0.2 mbar by a 2012 AC chemical pump.

Plasma emission was monitored through an optical fiber (diameter : 200 µm, Incident angle = 47°). The radiation transmitted was analysed by a spectrophotometer SpectraPro-500i (Acton Research

Corporation) equipped with a 3600 and 1200 grooves/mm holographic grating for the analysis of the 300-450 nm spectral domain.

Surface characterization

The XPS spectra were acquired on a Thermo VG ESCALAB 250 spectrometer. The XPS spectra were recorded with the monochromatized Al Ka X-ray source (1486.6 eV, size 650 µm) and a combination of electron and argon ion flood guns for charge compensation. Quantitative surface and interface analyses were performed using the peak areas of the high-resolution spectra and the Manufacturer's sensitivity factors. Sample charging was corrected by positioning the hydrocarbon peak component of the C_{1s} signal at 285.0 eV.

Contact angle measurements were performed with an image processing system using bi-distilled water liquid (liquid droplet: 2 µL). The reported values correspond to the average of four measurements of the static contact angle, on different parts of the samples rinsed in water and dried.

Results and Discussion

Plasma polymerised acrylic acid coating was produced on the PE films at different plasma powers and analysed by XPS. A peak-fitted spectrum for the C_{1s} core level is shown in Figure 1. The high-binding energy structure is indicative of the existence of carbon-oxygen bonds. The spectrum can be satisfactorily fitted by a combination of four distinct peaks: the peak at 285 eV (C_0) corresponds to C-C and C-H moieties, the peak at 286.5 eV (C_1) to C-OH and C-O-C functional groups, the peak at 287.8 eV (C_2) to C=O groups and the peak at 289.4 V (C_3) is due to COOH and/or COOR groups. Some authors have distinguished the contribution of the acid form from that of the ester by a derivatization experiments with trifluoro-ethanol [9,10]. Their investigations have shown that the contribution of the carboxylic acid form represented more than 90 % of the component at 289.4 eV. In our case, we have then assumed that the ester contribution in the C_3 component was absent or negligible.

The well resolved feature at 289.4 eV of an unwashed PPAA deposited at low power (13 W) (figure 1a) is indicative of a high carboxylic acid group retention : the COOH/C_{1s} ratio is around 28.0 % compared to a theoretical maximum of 33 % for a conventional poly acrylic acid. The latter corresponds to a COOH retention rate of around 80 %. Since the stability of the polymerized coating to solvents is essential for biotechnological applications, we have therefore investigated the resistance of the films to washing in water. Figure 1b showed a sharp decrease of the COOH content that passed from 28 % to 7-8% after washing.

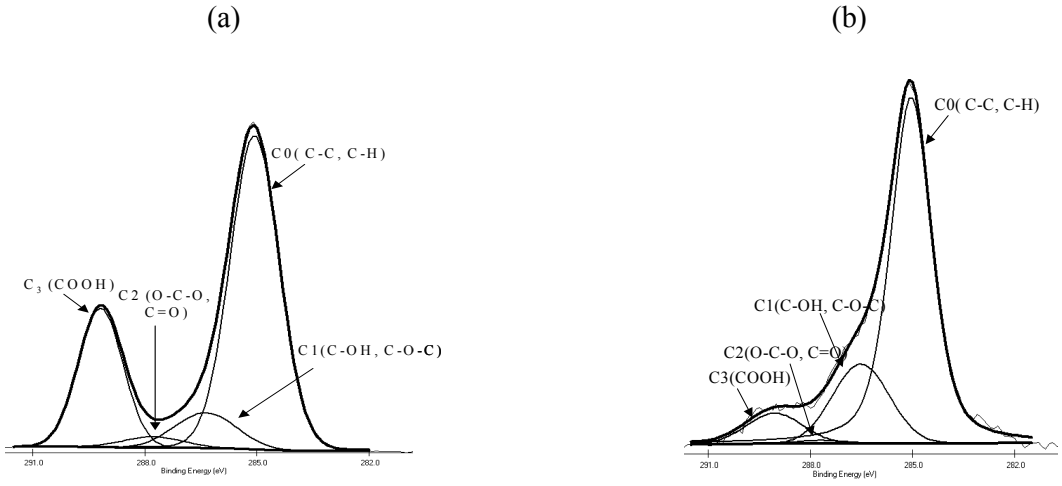

Figure 1: C1s spectra of PPAA deposited at 13 W before (**a**) and after (**b**) washing the samples with water (p = 0.4 mbar, t = 10 s, Q_{Ar} = 10 sccm, $Q_{\text{acrylic acid}}$ = 0.06 sccm)

The use of a plasma pretreatment of the PE films in Ar or N_2 before the plasma polymerization of acrylic acid has shown negligible effect on the COOH retention. This indicates that the instability of

the coating was not due to a weak adhesion between the PPAA coating and the PE film. At a low frequency of 70 kHz, the PE film at the first stage but also the growing polymer are constantly bombarded by energetic ions during the process. This first of all leads to an activation of the underlying PE film which favors the formation of covalent binding with the coating. Secondly the ion bombardment results in a more crosslinked and cohesive PPAA coating. In a previous study, we have clearly pointed out the role of the ions in the functionalization process of PP films in a NH_3 discharge by comparing the grafting process at two different frequencies [11]. This is why at 70kHz there is no need to have a pretreatment of the substrate in order to ensure a good stability of the PPAA coatings. On the contrary complementary results done in a 13.56 MHz reactor show the necessity of carrying out a pretreatment in order to have a good retention of carboxylic groups [12]. OES has been used to estimate the energetic character of our 70 kHz discharge as compared to a 13.56 MHz one, by calculating the ratio of the first negative system of N_2^+ (B) line at 391.4 nm and that of the second positive system of N_2 (C) at 394.3 nm. Figure 2 clearly shows that the N_2^+/N_2 ratio, which is an indicator of the mean electron temperature, is much higher in a low frequency system explaining the formation of a coating which is crosslinked and presents a good adhesion to the substrate as well.

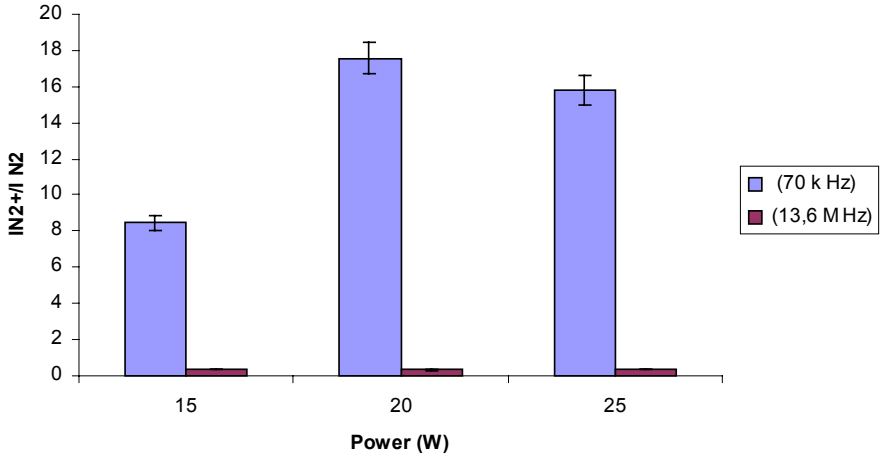

Figure 2 : N_2^+/N_2 ratio as a function of power at two frequency system

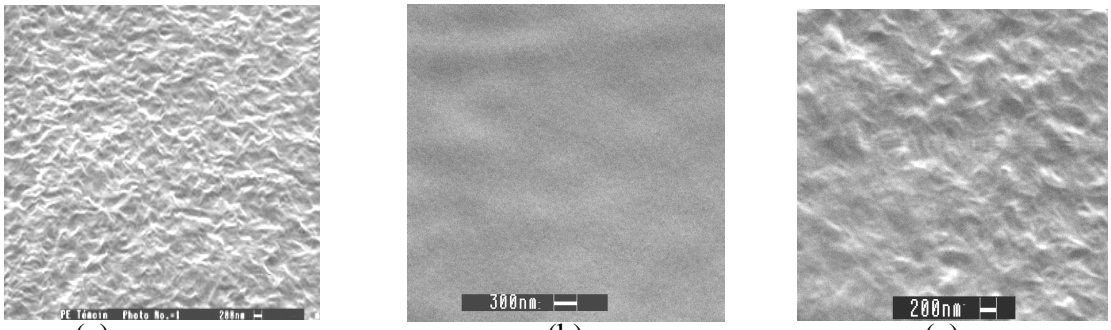
SEM analyses have been used in order to look at the change of morphology of the coatings upon washing due to a partial removal of the soluble deposits (figure 3). Figure 3b corresponds to an unwashed PPAA coating ; the film is thick, homogeneous and covers the porous zones of the untreated PE film (figure 3a). After rinsing the coating in water (figure 3c), porous zones of the underlying PE film appear, revealing a partial solubility of the coating in water ; this phenomenon may be due to the formation of low molecular oxidized fragments weakly bonded to the growing film.



(a) (b) (c)

Figure 3 : SEM analysis of a non treated PE (a), and PPAA deposited on PE films before (b) and after washing in water (c). (P= 13 Watts, Q_{argon}=10sccm, $Q_{acrylic\ acid}$ = 0.06 sccm, treatment time = 10 s, p=0.4 mbar)

In order to increase the cohesive strength of the coating, we have increased the input power of the discharge during the plasma polymerization of acrylic acid. The XPS analyses of unwashed and rinsed deposits presented in figure 4, illustrates that the increase of the input power renders the deposit less soluble ; the COOH content deposited at a power of 25 Watts, is around 15 % for both deposits, which is in agreement with a high stability of the coating.

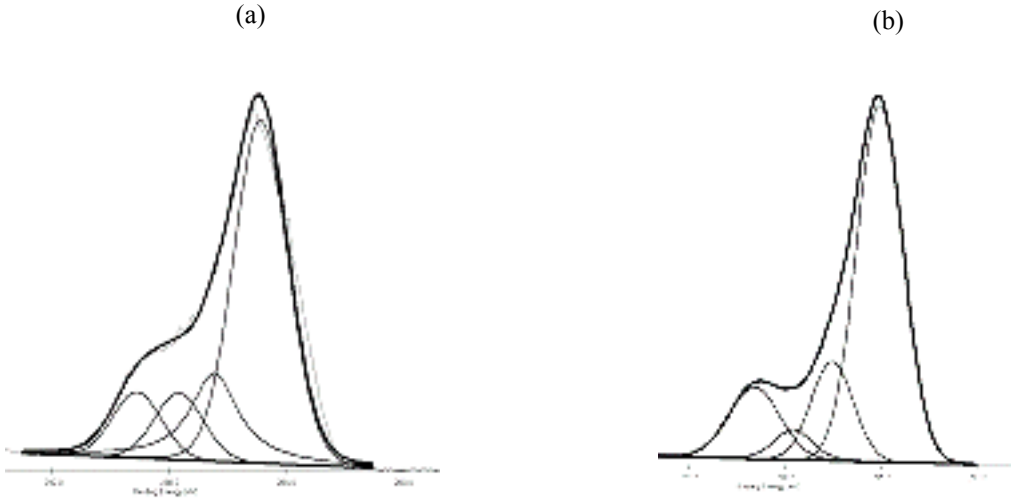


Figure 4 : C1s spectra of PPAA deposited at high power (25 W) before (**a**) and after (**b**) washing the samples with water (p = 0.4 mbar, t = 10 s, Q_{Ar} = 10 sccm, $Q_{\text{acrylic acid}}$ = 0.06 sccm)

Some authors [9,13] have explained that this phenomenon results from an increase of the degree of cross-linking in the film. SEM analysis of the rinsed deposit confirmed this hypothesis (figure 5) since the coating still remains on the substrate after rinsing. In our work, the increase of cross-links in the coating was confirmed by the formation of cracks in the PPAA film which is consistent with a more brittle coating.

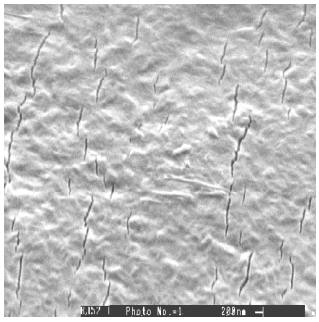

Figure 5 : SEM analysis of a washed PPAA deposited on PE at high power (P = 25 Watts, Q_{argon}= 10 sccm, $Q_{\text{acrylic acid}}$ = 0.06 sccm, t = 10 s, p = 0.4 mbar)

In order to have further information about the deposition process, Optical Emission Spectroscopy (OES) was used to study the fragmentation of acrylic acid in the plasma in function of the power. The OH ($A^2\Sigma^+$-$X^2\Pi$ at 306.6 nm), the CH ($A^2\Delta$-$X^2\Pi$ at 431.4 nm) and the CO ($B1\Sigma$-$A^1\ \Pi$ at 519.8 nm) lines were followed in order to link these results with the monomer functionality [9, 10]. Figure 6 shows that the acid fragmentation (CO and OH products) increases with the power injected in the plasma. The emission intensity of CO increases linearly with the applied power within the experimental range but the emission intensity of OH reaches a plateau at high power.

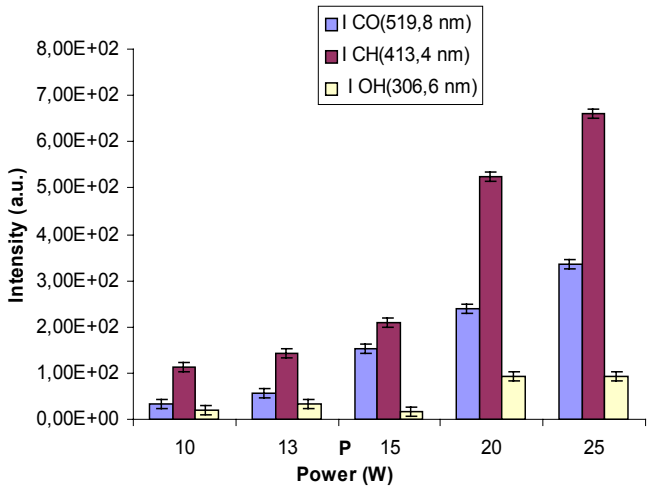

Figure 6 : Evolutions of CO, CH and OH emission intensities with plasma power (Q_{argon}=10sccm, $Q_{acrylic\ acid}$ = 0.06 sccm, p=0.4 mbar)

F. Palumbo et al [9] have shown that the I_{CO}/I_{Ar} ratio in a 13.56 MHz discharge could be advantageously used as a process control parameter to monitor the retention of the carboxylic groups in the film. We have also found that at 70kHz there exists a good correlation between this ratio which is proportional to the density of CO species in the fundamental state, and the carboxylic groups content in the PPAA coating (figure 7). An increase of the power leads to a decrease of the I_{CO}/I_{Ar} ratio (Fig.6), indicating a more fragmented AA monomer in the gas phase ; as a consequence, the carboxylic groups in the PPAA coating decreases since instead of being incorporated in the films, are fragmented in the discharge in the form of CO species which ate pumped out of the reactor.

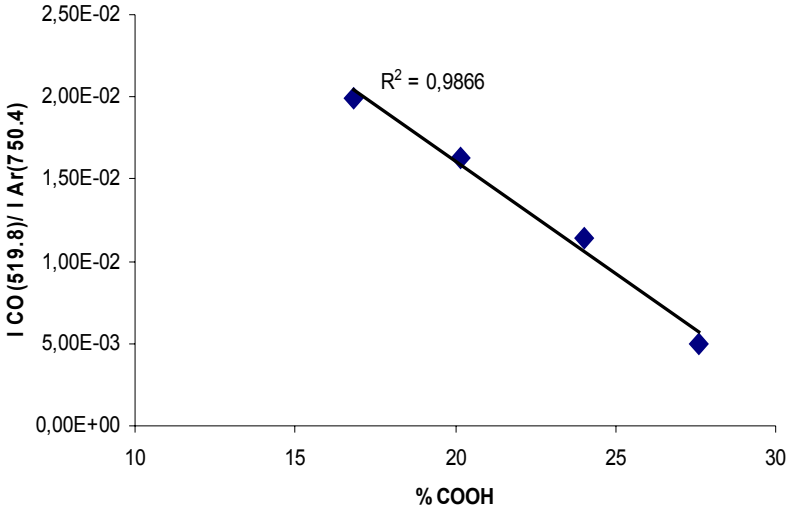

Figure 7: Correlation between the I_{CO}/I_{Ar} ratio and the carboxylic content in the PPAA coating, as measured by XPS. (Q_{argon}=10sccm, $Q_{acrylic\ acid}$ = 0.06 sccm, p=0.4 mbar)

Conclusion

Numerous studies on PPAA have been carried out for applications in the field of biotechnology and biomedical. However, the majority of the studies have been performed in 13.56 MHz pulsed or continuous discharges and which report on the fact show that their stability is highly affected by washing. In this work, the plasma polymerization of AA has

shown to be very efficient for the retention of carboxylic groups. Under optimized conditions, it is possible to obtain a stable PPAA coating upon washing with a COOH retention rate of 15 %. This high stability of the coatings is probably due to the ions which play an important role in such discharges.

Silicon nanocrystal formation on post-annealed substoichiometric SiO_x layers deposited in SiH_4-N_2O radiofrequency discharges

M. Bedjaoui, B. Despax

Laboratoire de Génie électrique (UMR 5003), Université Paul Sabatier, 118 Route de Narbonne, F-31062 Toulouse Cedex, France

Abstract
SiO_x films grown using Plasma Enhanced Chemical Vapor Deposition (PECVD) in SiH_4-N_2O-He discharges were thermally annealed at 1000°C for 1h. The chemical composition was dominated by silicon suboxide containing Si-N and Si-H bonds. Raman spectra and spectroscopy ellipsometry measurements showed that the SiO_x films exhibited the amorphous state in the as-deposited samples and a mixture of (i) amorphous materials (ii) silica (iii) silicon nanocrystals in the annealed samples.
Keywords
PECVD, SiO_x, Silicon nanocrystals, FTIR, Raman, Spectroscopic Ellipsometry.

1. Introduction

Recent developments of new forms of silicon have brought about renewed interest in the fabrication of integrated devices. The main goal of the new electronic technology is to integrate micro-structures showing appropriate electronic, chemical and structural properties and compatible with the well established silicon micro-electronics. Therefore, after the initial studies in porous silicon [1], growing attention has been paid to nano-structured silicon thin films with desired properties. This attention has been motivated mainly by their promising optical and electronic properties [2]. Indeed, these materials can be produced in a wide range of systems and involve various scientific communities. In the field of nanocrystalline materials, significant effort has been focused on the formation and characterization of silicon nanocrystals. Among the various Si nc fabrication techniques [3,4,5], a process that has been widely used for Si nanocrystal formation involves high temperature annealing of substoichiometric SiO_x thin films. Subsequently, an intensive research activity has been devoted to study the properties of silicon suboxide thin films, in particular the possibility of varying their composition with the operating process conditions which is of great interest for the control of Si nc formation. Recently, Iacona et al. [4] reported some detailed works on the structural and optical properties of silicon nanocrystals formed by high temperature annealing of substoichiometric silicon oxide produced by PECVD. In particular, they showed a good correlation between structural data, including crystal radius and width size distribution, and the optical properties of the films. In the same way, C. Bonafos et al. [5] using ion implantation of Si^+ in SiO_2 draw similar conclusions.
In this work, we report a detailed study of the physical, structural and optical properties of thin silicon rich SiO_x films within a large range composition. They were produced by PECVD using SiH_4 and N_2O as precursors. The formation of silicon clusters embedded in a dielectric silicon oxide matrix is investigated. The properties of as-deposited films and annealed films were studied by Fourier Transform Infrared (FTIR) spectroscopy, Raman spectroscopy, Transmission Electron Microscopy (TEM) and Spectroscopic Ellipsometry (SE). We have found that by varying the flow ratio of the gaseous precursors it is possible to change the properties of the film, therefore the size of the Si nc.

2. Experiments

Silicon-rich silicon oxide SiO_x thin films were prepared by PECVD at a low temperature in silane-N_2O-He discharges. The reactor shown in Fig. 1 [6] is a rectangular parallelepiped box placed under a vacuum bell jar ($1x10^{-7}$ Torr). An electrode driven by a 13.56 MHz signal splits the inside of the box into two symmetrical plasma zones since the rest of the box is grounded. In order to obtain homogenous gas flows on each side of the driven electrode, the gas first enters a buffer-zone, then flows through two small slits in the plasma zones and finally flows out through two other identical slits. The size of a single plasma zone is 25.6 cm x 25.6 cm with an electrode spacing of 3.9 cm. The silicon substrates were placed on the grounded walls. The electrode was capacitively coupled to a 13.56 MHz RF generator by means of a LC matching box. 200-350 nm thick SiO_x films were grown

on intrinsic silicon substrates and silica substrates. All deposition processes were performed at 380°C, under a pressure of 0.5 Torr and a RF power of 5 Watt. The source gases used were SiH_4, N_2O and He, the N_2O gas flow rate was kept constant at 40 sccm for all the samples. After deposition, the SiO_x films were annealed for 1 hour at 1000°C in nitrogen atmosphere.

The SiO_x film composition ($0<x<2$) was controlled by varying the SiH_4/N_2O flow rate ratio ($\gamma = Q_{SiH4}/[Q_{N2O}+ Q_{SiH4}]$). Physico-chemical, structural and optical absorption properties of SiO_x films, as-deposited and subjected to thermal annealing, were investigated by FTIR spectroscopy, Raman spectroscopy, TEM and SE. The infrared analyses were performed by means of a BIORAD QS 300 FTIR spectrometer. The IR absorbance spectra of the silicon oxide films were compared in the range of 400-4000 cm^{-1} (1.3-12.3μm) with a resolution of about 4 cm^{-1}. The Raman measurements were carried out with a Dilor UV spectrometer equipped with a charge-coupled device multichannel detection system and a microprobe focused on the sample with a spot surface of 1 μm^2. The incident beam at 363 nm line of argon laser was used for the excitation. Dark-field plan-view TEM analyses were carried out with a CM30 Philips microscope to determine the nanocrystals size distribution. The SE experiment is based on the measurement of the ratio "ρ" of the Fresnel reflection coefficients, $\rho=r_p/r_s=\tan(\Psi)\exp(i\Delta)$ where r_p and r_s are, respectively, the Fresnel reflection coefficients for a plane wave polarized parallel and perpendicular to the plane of incidence. The ellipsometric angles Δ and Ψ characterize the phase difference between the two polarizations and the amplitude ratio, respectively. Ellipsometric functions $\tan(\Psi)$ and $\cos(\Delta)$ were measured in the spectral range from 200 to 880 nm at 75° angle of incidence, using a rotating polarizer spectroscopic ellipsometer SOPRA GES-5 with tracking analyzer.

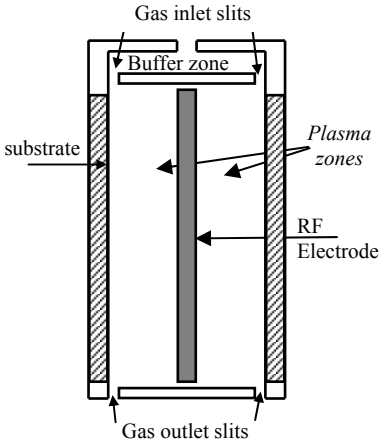

FIG.1. Schematic representation of the plasma reactor.

3. Results and discussion

3.1 Chemical and structural characterization

FTIR spectroscopy was used as a non destructive technique to obtain further information about the structural and compositional properties of films, and the types of chemical bond present. The spectral positions of the absorption bands correspond to the vibrational frequencies of the chemical groups present in the layer, their intensity to the concentration of such groups. As a matter of fact, a lot of works [7, 8] were carried out to ascribe the positions of the infrared bands present in amorphous SiO_x and SiO_xN_y. A particular attention was paid to the position of the stretching mode for the Si-O-Si, the SiH and SiN band which varies in relation to the O/Si ratio of SiO_x films. Figure 2 shows the IR spectrum of a $SiO_xN_yH_z$ film obtained under the same operating conditions but for different flow rate ratio, γ, as-deposited Fig. 2(a) and after annealing Fig. 2(b). The analysis of the spectrum of the as-deposited sample exhibits a dominant absorption band around 1020-1030 cm^{-1} which can be attributed to the Si-O-Si stretching mode [9]; a subsidiary band located between 810-820 cm^{-1} due to the Si-O-Si bending mode [9] and also the Si-O-Si rocking in the range 440-460 cm^{-1} [9]. Another band that should be mentioned is the Si-H bending in the range of 640-660 cm^{-1} correlated to the Si-H stretching between 2100-2260 cm^{-1} [10]. Besides, the IR spectrum shows the presence of nitrogen in the as-deposited films; indeed; the absorption region at about 860-880 cm^{-1} is due to the stretching vibration of the Si-N bonds [11], while a weak peak of the N-H stretching 3385 cm^{-1} [12] is observable only for the sample with $\gamma = 0.15$.

For the lowest values of γ ($\gamma = 0.15$), the Si-N band contribution (860-880 cm^{-1}) with respect to the Si-O stretching band in the spectra appears very low. Conversely as γ increases, the Si-N peak becomes significant and the IR spectrum of the as-deposited films also characterized by other relevant absorption bands at around 2100-2127 cm^{-1} and 640-660 cm^{-1} suggest the presence of H-Si≡Si3 groups

in the layers [7]. Hydrogen incorporation has been found to be more efficient in SiO_x films having the highest silicon content [4].

After annealing, the stretching absorption bands shift towards higher frequencies in the range of 1050–1075 cm^{-1}. This effect accounts for the evolution of the amorphous phase present in the as-deposited SiO_x films towards a Si/SiO_2 mixture. Another major effect is the disappearance of the Si-N bonds and the Si-H bonds. This behavior of the spectrum is due to the partial conversion of the Si-N and Si-O phases to a mixed Si-O-N phase and the effective elimination of hydrogen from the films after the annealing treatment. These last observations could explain the unusual broadening of the band at 1070 cm^{-1} after annealing due to a residual SiO_x network containing Si-O-N and Si-Si bonds.

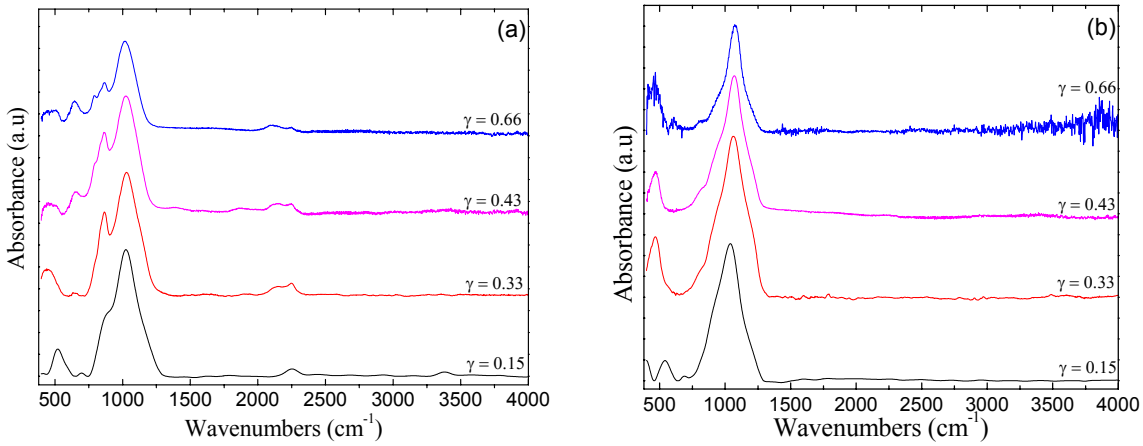

FIG.2. Transmission infrared spectra of SiO_x films obtained for different flow rate ratioγ, as-deposited (a) and annealed at 1000°C for 60 min in N_2 atmosphere (b).

Although Si-Si vibrations cannot be directly detected by IR spectroscopy, they can easily be detected by Raman spectroscopy. Raman scattering provides a fast and non destructive method for detecting the presence and studying the structure of silicon particles in the deposited layers [13]. Figure 3 shows typical Raman spectra of SiO_x films as-deposited and annealed at 1000°C during 60 min on silica substrate under a flow rate ratio, $\gamma = 0.43$. The Raman scattering shows essentially two components, a broad band at around 490 cm^{-1} for the as-deposited sample (Fig.3, dashed spectra), indicating that it is amorphous [13, 14], and a sharp peak at 513 cm^{-1} (Fig.3, solid spectra) after annealing, that we attributed to the incorporation of nanosilicon in the SiO_x films [13, 14]. The band shape modification of the Raman spectra has been used in the past for the evaluation of the average size of nc-Si. This can be achieved by using different theoretical models [15, 16]. Let us take the peak position in crystalline silicon at around 520 cm^{-1}. When the flow rate ratio decreased from $\gamma = 1$ (polysilicon) to $\gamma = 0.43$, the position of these nanocrystalline silicon peaks were shifted down by approximately 7 cm^{-1}. It suggested a decrease in the silicon nanocrystallite size by a few nanometers. According to the Zi's confinement model [15] and Viera's studies [16], the crystallite size is about 2 nm and about 3.6 nm, respectively. The Raman results indicate that the SiO_x films obtained by PECVD exhibit the amorphous state of the as-deposited samples and a mixture of two phases, an amorphous matrix and ordered silicon domains or nanocrystallites of the annealed samples.

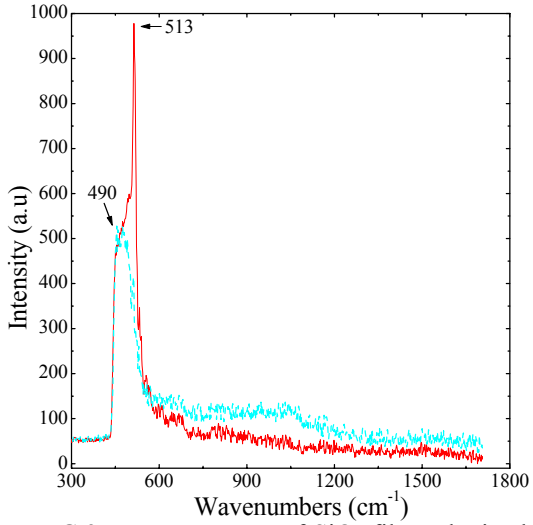

FIG.3. Raman spectra of SiO_x films obtained for a flow rate ratio $\gamma = 0.43$, as deposited (dashed spectra) and annealed at 1000°C for 60 min in N_2 atmosphere (solid spectra).

In order to map the presence of Si nanocrystals

embedded in the SiO_x layers after the annealing process and to exclude any crystallization induced by the laser in the Raman measurements, we used a High Resolution Transmission Electron Microscopy (HRTEM). Figure 4 reports the TEM image relative to SiO_x film obtained with a flow rate ratio, γ = 0.43, after annealing 1 hour at 1000°C. This sample was deposited under the same experimental conditions as the sample characterized by Raman spectroscopy (Fig. 3). The analysis of the TEM image showed clearly that the amorphous SiO_x contained a high density of small clusters which could be identified as Si nanocrystals. The statistical analysis of the crystal size distribution (histogram reported in Fig. 4) obtained from the TEM micrograph shows a distribution of crystal size that range from 3 to 6 nm, and a mean radius of 4 nm, in good agreement with the particle size calculated from the Raman measurements with the Viera's model [16]. The distribution had a standard deviation σ of 0.7 nm, accounting for all the different crystal sizes detected in the micrograph.

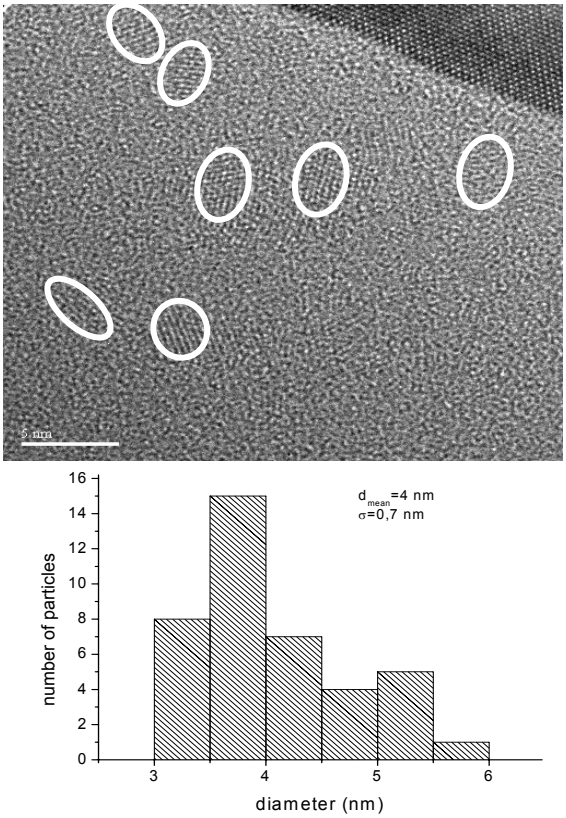

Fig. 4. HRTEM micrograph and relative Si-nc size distribution of a SiO_x film with a flow rate ratio γ=0.43 annealed at 1000°C for 1h in nitrogen atmosphere.

3.2 Optical analysis of thin films

The measurements of SiO_x optical properties allow an evaluation of the dielectric function in addition to the determination of the volume fraction of constituents, cristanallity of the layers and consequently, the effect of the incorporation of nc Si in an amorphous phase. Most of the studies aiming at determining the optical properties of nc-Si have been performed either by the use of a mixture of known materials [17] or by a direct inversion of the optical parameters of thin film [18], or else by a theoretical calculation [19]. Ellipsometry is a nondestructive, rapid and highly sensitive method often used for studying properties of silicon-based films. Therefore, it would be interesting to apply it to the analysis of nanocrystal silicon formation in thin SiO_xN_y films. Up to now, *Ex situ* spectroscopic ellipsometry measurements were performed in order to determine the thickness, composition and optical properties of the films. In this work, the complex optical index N is defined as $N = n - ik$ where n is the refractive index and k, the extinction coefficient. The optical constants of the as-deposited and post-annealed silicon compounds are obtained by fitting spectroscopic ellipsometry measurements with an appropriate model in the wavelength range from 200 to 880 nm. For the determination of N in $SiO_xN_yH_z$ films, the first step concerned the choice of a correct and suitable optical model for the dispersion law of layers. In agreement with our previous Raman spectra analysis, the as-deposited films consist of amorphous $SiO_xN_yH_z$ layers whereas the annealed films can be modeled as mixtures of poly-silicon crystals, amorphous silicon compounds, and SiO_2. In this part, two classes of models were selected and tested to describe the sample optical properties. One class uses the Forouhi dispersion model [20]. In this, we assumed that the films were homogenous and the as-deposited films can be based on this model. Another model uses Bruggeman Effective Medium Approximation (BEMA) [21] which can be utilized to describe the optical properties of the annealed films. In this case, the fit parameters are the layer thickness and the volume fraction of the different materials constituting the effective medium. Therefore, the complete physical model should take into account the surface roughness and possible surface oxidation. Thus, a two layer model plus a topmost layer with a void fraction are required to reproduce the optical data of the as-deposited and annealed films. The film thickness deduced from the fit compares very favorably with the value that we determined experimentally by measuring the height of the step by profilometry technique.

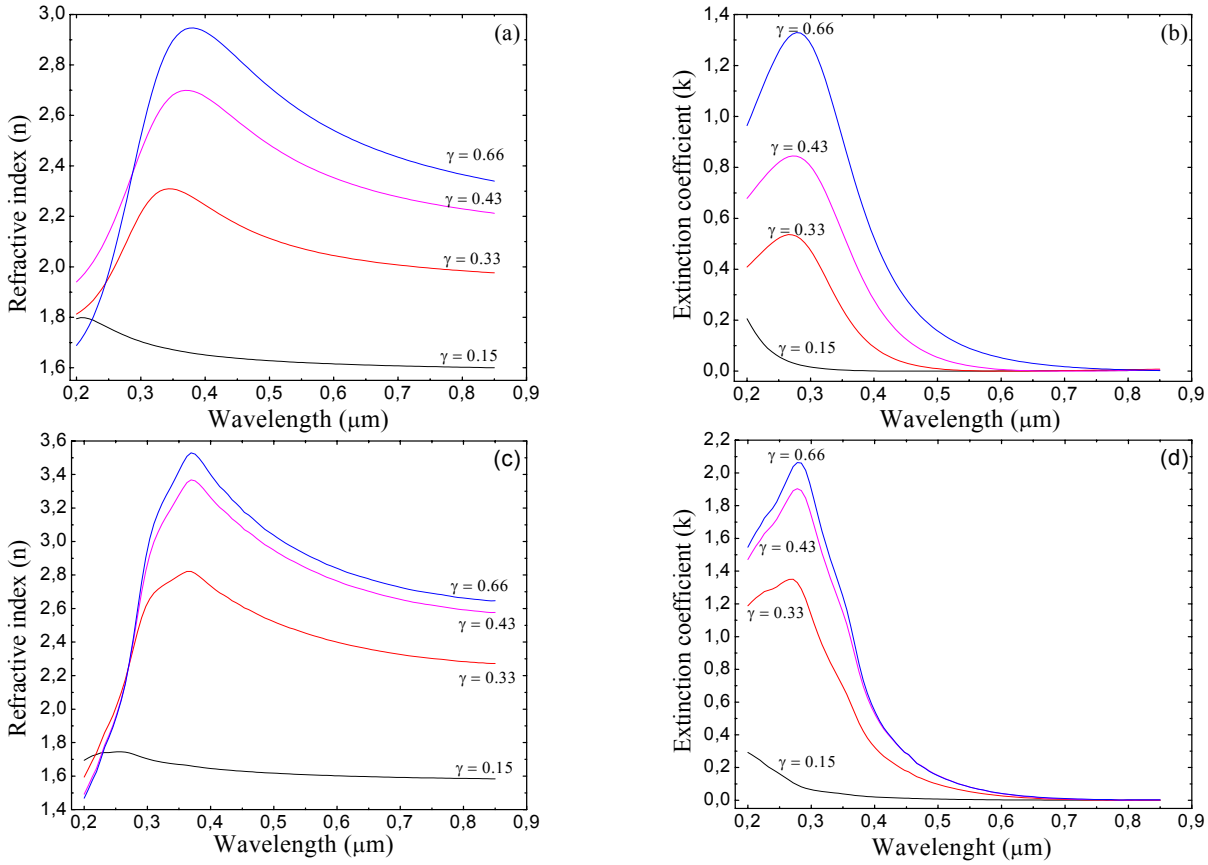

FIG.5. Refractive index (a, c) and extinction coefficient (b, d) as a function of wavelength for the SiO_x films obtained for different γ, flow rate ratio, as-deposited (top panel) and annealed at 1000°C for 60 min in N_2 atmosphere (bottom panel).

We present in Fig. 5 the optical constants n and k of samples obtained under the same operating conditions at different flow rate ratios, as-deposited (Fig. 5(a,b)) and annealed (Fig. 5(c,d)), derived from the BEMA and Fourouhi fits. At first above λ = 0.25 μm, a simple comparison of the spectra shows that the both n and k coefficients increase with increasing flow rate ratio. In fact, the increase of the n and k amplitudes is due to the layer compactness related to the silicon concentration increase (Fig. 5(a,b,c,d)). Besides, we also observe that the shapes of the optical spectra n and k of the annealed SiO_xN_y films are quite different from those of the as-deposited films. In agreement with our previous FTIR and Raman observations, this difference may be attributed to the phase separation between SiO_2 and silicon after thermal annealing process. On the other hand, we also observe that with increasing flow rate ratio the polycrystalline silicon volume fraction increases and the SiO_2 volume fraction decrease (see Table 1). However in each case, a small amount of residual amorphous phase (a-SiO_x) remains present.

Actually, in agreement with the very low standard deviation between Fourouhi modeling results and experimental results, the refractive index curves of as-deposited films are a smooth and structureless spectra bump [17], confirming an amorphous state. After the 1000°C annealing process of suboxide layers, we know that the silicon is crystallized [17, 22]. The n and k values of the annealed films with respect to the amorphous films are higher when the wavelength decreases from 0.7 μm to 0.3 μm [17]. The optical layer behavior is conveniently simulated by BEMA model involving appropriate mixtures of SiO_2, a-SiO_x and poly-Si. The BEMA modeling results shows an increasing contribution of poly-Si and a decreasing contribution of SiO_2 and a-SiO_x with increasing γ. These calculated optical constants from the annealed samples lead with respect to the amorphous optical constant to a shift of the spectral hump to low energies and, at the same time, to an increase in the absolute value of the refractive index and the extinction coefficient. According to the above observations, we can conclude that the annealed films converge from a structure dominated by the SiO_2 for the lowest γ, flow rate ratio, to a structure dominated by the polysilicon crystals for the highest γ.

TABLE.1. Fit values for the SiO_x films obtained for different flow rate ratios, γ, as-deposited and annealed at 1000°C for 60 min in N_2 atmosphere.

γ	sublayer thickness (nm)		layer thickness (nm)		optical gap E_g(ev)		Bruggeman mixture (%)		
	as-deposited	annealed	as-deposited	annealed	as-deposited	annealed	SiO_2	a-SiO_x	p-Si
0.15	2.3	4.3	265	249	2.58	1.67	91.3	2.6	6.1
0.33	2.4	7.1	331	282	2.02	1.56	57	17.2	25.8
0.43	4.6	15	280	226	1.84	1.5	44.1	17.6	38.3
0.66	3.6	11	247	217	1.78	1.48	29.1	17.4	52.5

It is known that the variations of the optical properties are due to the size reduction of nanocrystals [23]. In order to clarify this assumption, we have reported in Table 1 the optical band gap of several samples. The optical gap E_g is determined using the absorption coefficient α, and from an intercept on the energy axis of $\sqrt{\alpha \times E}$ versus E plot. Before annealing, the optical gap decreased as the γ, flow rate ratio, increased. This expected phenomenon could be explained by the change of size and distribution of the particles formed. Other studies [4, 19] attribute this behavior to the quantum confinement effect, e.g. the gap energy is conditioned on the size of the nanocrystals although, from the present result, it can be concluded that reducing the size of the silicon clusters induced a variation in the electronic band structure which is quite different from that of bulk silicon.

4. Conclusion

SiO_x layers were grown by PECVD technique by varying the flow rates of SiH_4 precursor gases and keeping N_2O constant at 40 sccm. Using Infrared and Raman spectroscopy, Transmission Electron Microscopy and Spectroscopic Ellipsometry the films were found to consist of an amorphous state in as-deposited and of very small crystals (3-6 nm) embedded in an amorphous SiO_2 matrix formed after a high-temperature annealing. In particular, it has been established that the value of γ, flow rate ratio, strongly affects both physico-chemical and optical properties of the SiO_x films. This effect is a serious drawback in determining the Si nc size.

Modeling of Chemical Reactions for Plasma Coating of Nanoparticles

B. Rovagnati[1], A. L. Yarin[2], and F. Mashayek[1]

[1]*Department of Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, IL, USA*
[2]*Faculty of Mechanical Engineering, Technion-Israel Institute of Technology, Haifa, Israel*

Abstract
A hybrid model of kinetic theory and continuum theory for predicting coating of nanoparticles by plasma enhanced chemical vapor deposition in low-pressure conditions is presented. The model is used to investigate the important phenomena occurring during the surface deposition on a single submicron particle immersed in non-equilibrium CH_4/H_2 plasma. Self-consistent electric field, chemical composition of the gas, species fluxes towards the particle, rate of deposition, and particle charging are calculated.
Keywords: nanoparticle, film deposition, chemical vapor deposition, plasma reactor.

1. Introduction

Plasma processing is nowadays considered as a critical technology for a large number of industries, which are attracted by its remarkable capability to modify matter at submicron or nanometer scales. Nanoparticles are the important constituents of many chemicals, ceramics and metal composites, pharmaceutical and food products, energy related products, and electronics related products, to name a few. Particle's surface modification may improve properties such as corrosion/oxidation resistance, adhesion, electrical properties, hydrophobicity, printability, etc. In particular, surfaces of particles can be coated with other materials allowing for example removal of metal ions from water when ZnO particles are coated with acrylic film [1], reinforcing of materials using SiC particles coated with metallic nickel and copper for aluminum-based metal matrix composites [2, 3], controlling pharmaceutical dosage by using microcapsule coated with composite latex membrane [4], or improving energetic properties of solid fuels for combustors if aluminum nanoparticles coated with carbon are used [5].

Among various techniques, plasma enhanced chemical vapor deposition (PECVD) is an attractive route for substrate coating. In PECVD, low-pressure (order of 100 mtorr) and low-temperature (300-600 K) conditions allow the achievement of a wide range of highly reactive chemical species capable of sticking onto surfaces, producing surface features in the nanometer range and maintaining excellent purity control. In particular, a low-pressure plasma process was applied for depositing films with thicknesses of the order of few to several hundred nanometers on micron and sub-micron particles [6, 7]. However, the ever-growing interest in dust particle surface deposition during industrial processing calls for further investigation. In order to improve the deposition process, plasma modelling can be of great use by predicting the composition of the plasma and by optimizing the plasma parameters, i.e. pressure, temperature, gas mixture, etc.

The present work aims to model the time-dependent deposition of amorphous carbon layers onto a sub-micron particle in a CH_4/H_2 low-pressure plasma. A detailed chemical kinetics scheme of the reactions occurring in plasma is considered [8] along with a "sticking model" that accounts for surface reactions and coating.

2. Description of the Model

A hybrid model of kinetic theory and continuum theory is proposed to evaluate effective fluxes of species towards the particle, since only a fraction of the species molecules reaching the proximity of the particle collides with it (Fig. 1). To a distance longer than the mean free path, λ, from the surface of the particle, the diffusion approximation is used,

$$\frac{\partial C_j}{\partial t} = -\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\Gamma_j\right) + \omega_j, \quad j = 1, 2, \cdots, 20, \;\; r \geq \lambda \tag{1}$$

where r and t are the radial coordinate and time, respectively. C_j is the concentration of species j in m^{-3}, [H, H_2, H_2^+, H_3^+, CH, CH_2, CH_3, CH_3^+, CH_4, CH_4^+, CH_5^+, C_2H_2, $C_2H_2^+$, C_2H_4, $C_2H_4^+$, C_2H_5, $C_2H_5^+$, C_2H_6, C_3H_8, e^-],

and the source terms ω_j correspond to the species reaction rates of reactions shown in Table 1. The fluxes Γ_j, in $\mathrm{m^{-2}s^{-1}}$, are defined as

$$\Gamma_j = -\mathcal{D}_j \frac{\partial C_j}{\partial r} \pm C_j \mu_j E_r, \quad j = 1, \cdots, 20, \tag{2}$$

where μ_j is the mobility coefficient, and E_r is the local radial electric field strength, plus is for ions and minus is for electrons. The electric field has no effect on neutral species for which μ_j=0. The diffusion coefficient, $\mathcal{D}_j$ in $\mathrm{m^2/s}$, is defined for species j in a mixture with all other species and is calculated by first determining the separate binary diffusion coefficient, as reported in [9],

$$D_{ij} = \frac{3k_B T_{gas}\sqrt{4\pi k_B T_{gas}/2\mu_{ij}}}{16 P_{tot}\pi\sigma_{ij}^2 \Omega_D(\Psi)}, \tag{3}$$

where k_B is the Boltzmann's constant, T_{gas} is the gas temperature in K, P_{tot} is the total pressure in Pa, $\mu_{ij} = \frac{m_i m_j}{m_i + m_j}$ is the reduced mass in amu, and $\sigma_{ij} = \frac{\sigma_i + \sigma_j}{2}$ are the reduced Lennard-Jones length scale parameters in Å. $\Psi = \frac{T_{gas}}{\epsilon_{ij}}$, with $\epsilon_{ij} = \sqrt{\epsilon_i \epsilon_j}$ and ϵ_i's denoting the Lennard-Jones energy parameter. The parameter Ω_D and various Lennard-Jones parameters are found and evaluated as described in [9]. The diffusion coefficient of a neutral species j in the whole mixture is given by

$$\frac{P_{tot}}{\mathcal{D}_j} = \sum_{i=\text{background}} \frac{P_i}{D_{ij}}, \tag{4}$$

where the summation is carried out over all the background gases i. The partial pressure P_i of species i is determined via concentrations C_i and the equation of state. The ion mobilities, μ_j in $\mathrm{m^2/V{\cdot}s}$, are calculated similarly to the diffusion coefficients of the neutrals,

$$\frac{P_{tot}}{\mu_j} = \sum_{i=\text{background}} \frac{P_i}{\mu_{i,j}}, \tag{5}$$

The binary mobility, $\mu_{i,j}$, of ion j in each of the background gases i is calculated as

$$\mu_{i,j} = 0.514 \frac{T_{gas}}{P_{tot}\sqrt{\mu_{ij}\alpha_i}}, \tag{6}$$

where α_i is the polarizability of neutral i in $\mathrm{Å}^3$. Diffusion coefficients of ions, $\mathcal{D}_j$, and of electrons, $\mathcal{D}_e$, are defined as

$$\mathcal{D}_j = \frac{k_B T_{ion}}{e}\mu_j, \quad \mathcal{D}_e = \frac{k_B T_e}{m_e \nu}, \tag{7}$$

where e is the electron charge, $T_{ion}(= T_{gas})$ and T_e are ion and electron temperatures, respectively, and m_e is the electron mass. The collision frequency, ν, is estimated as ([10], p. 352)

$$\nu = c_\nu 10^{-6} B T_e^{-3/2} \sum_{j=1}^{20} C_j, \tag{8}$$

where the dimensionless constant B is about 10 ([10], p. 181). In Eq. (8), T_e is in eV and C_j is in $\mathrm{cm^{-3}}$, while ν is obtained in $\mathrm{s^{-1}}$. The $\sum C_j$ term relates the dependence of electron collision frequency to the presence of various species. The dimensionless coefficient c_ν is introduced to obtain correct estimates of the electron diffusion coefficient as can be found in previous works [11]. Finally, integrating the Poisson equation, the total electric field strength E_r can be calculated as,

$$E_r = \frac{1}{4\pi\epsilon_0}\frac{Q_p}{r^2} - \frac{e}{\epsilon_0 r^2}\int_{r_p}^{r} \xi^2 \left[C_{elec} - \sum_{i=\text{ions}} C_i\right] d\xi, \tag{9}$$

where ξ is a dummy variable, r_p is the particle radius, and Q_p is the particle charge.

Inside the so-called vacuum sphere, $r_p < r < \lambda$, a molecular-kinetic approach is implemented. Accordingly, the species j at $r = \lambda$, moving towards the particle and absorbed at the particle surface, are characterized by the flux

$$\Gamma_{\lambda j} = -C_{\lambda j} \left(\frac{8 k_B T_j}{\pi m_j} \right)^{1/2} \left(\frac{r_p}{2\lambda} \right)^2 \gamma_j, \tag{10}$$

where m_j is the considered species, and it is assumed that $r_p/\lambda \ll 1$. The factor γ_j accounts for the possible interaction between charged species and charged particle, and is calculated following [12].

Inside the vacuum sphere it may be shown that charged species are represented by a spatially uniform effective concentration $C_{\lambda j}\gamma_j$. Thus, the modified electric field strength outside the vacuum sphere $r > \lambda$ can be calculated using Eq. (9) by replacing Q_p with the effective charge

$$Q_{\text{effective}} = Q_p - e\frac{4\pi\lambda^3}{3} \left[C_{\lambda \text{elec}} \gamma_{\text{elec}} - \sum_{j=\text{ions}} C_{\lambda j} \gamma_j \right]. \tag{11}$$

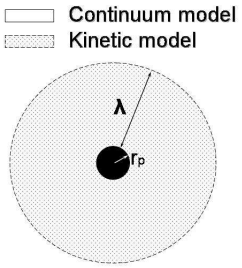

Figure 1: Kinetic and continuum models are implemented on the inside and outside of the vacuum sphere with radius λ, respectively.

Table 1: The reaction mechanism

Reaction	Rate constant (m^3/s)	Reaction	Rate constant (m^3/s)

$CH_5^+ + C_2H_6 \rightarrow C_2H_5^+ + CH_4 + H_2$	5.0×10^{-16}	$CH_2 + CH_2 \rightarrow C_2H_2 + H_2$	1.1×10^{-16}

* $f(\epsilon)$ expressed as the first term of Taylor series approximation of the mean electron energy.

The boundary conditions for different species are defined as follows. At an infinite distance from the particle at which electroneutrality is restored, species of H_2 and CH_4 are continually supplied so that their concentrations are constant at $r = \infty$. Also, since the ionization process has not been modeled in the present work, an electron concentration is assumed so that C_{elec} balances $\sum_{ions} C_j$ at $r = \infty$. For all other species, $\partial C_j/\partial r = 0$, which guarantees that none of these species are supplied to or from infinity.

At $r = \lambda$, for those species which are absorbed at the particle surface, the concentration $C_{\lambda j}$ is found via matching the diffusion, Eq. (2), and molecular-kinetic, Eq. (10), fluxes. At the particle surface, the species' flux is given by

$$\Gamma_{pj} = \Gamma_{\lambda j} \left(\frac{\lambda}{r_p} \right)^2. \tag{12}$$

For all other species j not absorbed at r_p, it is imposed $\Gamma_{\lambda j} = 0$. To calculate the growth rate of the coating, we make use of a "sticking model" [13]. Following Herrebout *et al.* [9], for radicals R assumed to be responsible for

film growth, i.e., CH_3, CH_2, and C_2H_5, the sticking coefficient s is 0.01, 0.025, and 0.01, respectively. Thus, the layer thickness h in m/s is calculated from

$$\frac{dh}{dt} = -\sum_R s_R \Gamma_R v_R, \tag{13}$$

where v_R's are radicals volumes in m^3, taken all to be equal to 10^{-24} m^3.

3. Results and Discussion

The species transport equations, valid where plasma is considered as a continuum, are integrated in a radial symmetric geometry by means of a splitting algorithm, accounting separately for the diffusion term and for the reaction source term. The discrete region has been taken into consideration through the appropriate matching boundary conditions, as described in section 2. Both species transport and Poisson equations have been solved on a nonuniform grid. Typical results of the present model are the concentrations of various species, the electric field generated by charge distribution, and electron density as a function of space and time. Moreover, information is obtained about the fluxes of the different species towards the nanoparticle, and the growth rate of the amorphous carbon layer at the particle surface and its composition.

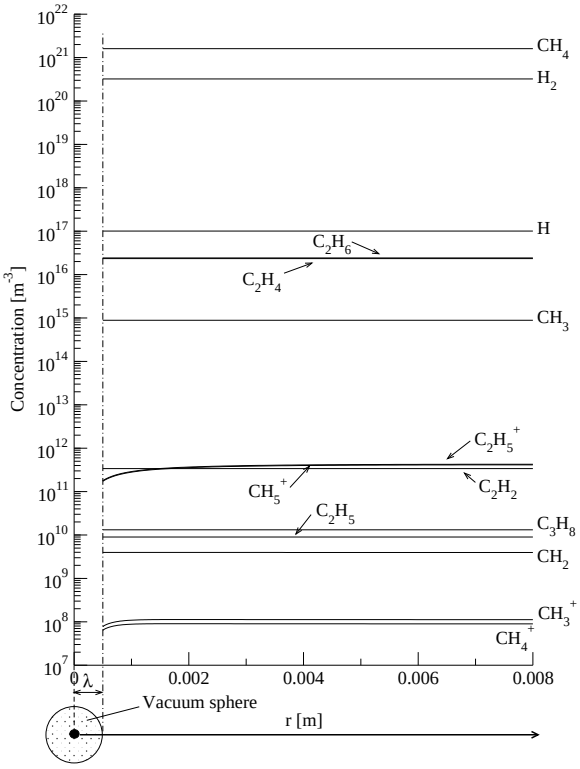

Figure 2: Concentrations of non-radical neutrals, radicals and ions as functions of distance from the dust particle.

Figure 2 illustrates the calculated concentration of the non-radical neutral molecules, the radicals and the ions for the particle radius r_p=100 nm, P_{tot}=100 mtorr, T_{gas}=T_{ion}=500 K, and the electron energy ϵ=1 eV (equivalent to the electron temperature T_e=11600 K). A constant ratio $[CH_4]/[H_2]|_\infty = 0.2$ was imposed so that together with equation of state, the concentration of CH_4 at infinity equal to 1.6×10^{21} m^{-3}. From Fig. 2, non-charged species are found to be almost homogeneously distributed within the domain. This is due to the low fluxes of such species from/towards the particle, which affects only their magnitudes. Similarly to Herrabout *et al.* [9], also for particle coating, the most important radical is found to be CH_3, with a concentration of 8.4×10^{14} m^{-3}. Smaller contributions to the film growth are given by CH_2 and C_2H_5, whose concentrations are 3.9×10^9 m^{-3} and 8.9×10^9 m^{-3}, respectively. Finally, in Fig. 2, only the most important ions are shown, for which $C_2H_5^+$ and CH_5^+ are the most dominant ones. In proximity of the particle, ions are characterized by a decreasing profile as they feel the effect of the generated electric field. In fact, due to the higher speed and mobility of electrons as compared to ions, the dust particle in a plasma acquires a negative charge and a negative potential with respect to the unperturbed plasma. However, the potential adjusts such that, by repelling the mobile electrons and attracting positive ions, the dust particle is being surrounded by an overall positive charge within the vacuum sphere. Outside this region, ion and electron concentrations are distributed as seen in Fig. 3a, and a positive electric field is generated in the continuum domain (Fig. 3b). In Fig. 3a, it is shown that as $r \to \infty$ ions and electrons balance each other, and electroneutrality is restored as expected. In the order of 6-8 mm the charged particle is completely screened by the ion-electron cloud, and no electric field is felt at these distances.

In this framework, the time-dependent charging of the particle can be calculated, as shown in Fig. 3c. After less than a second a steady-state value of -235.6e is reached. In a longer run, also growth-rate (dh/dt) approaches a value of approximately 0.49 nm/min (Fig. 3d). Thus, at long times the layer thickness vs. time (Fig. 3e) approaches a linear behavior, in accordance to [6], and after 200 sec, a layer of approximately 2.96 nm is deposited.

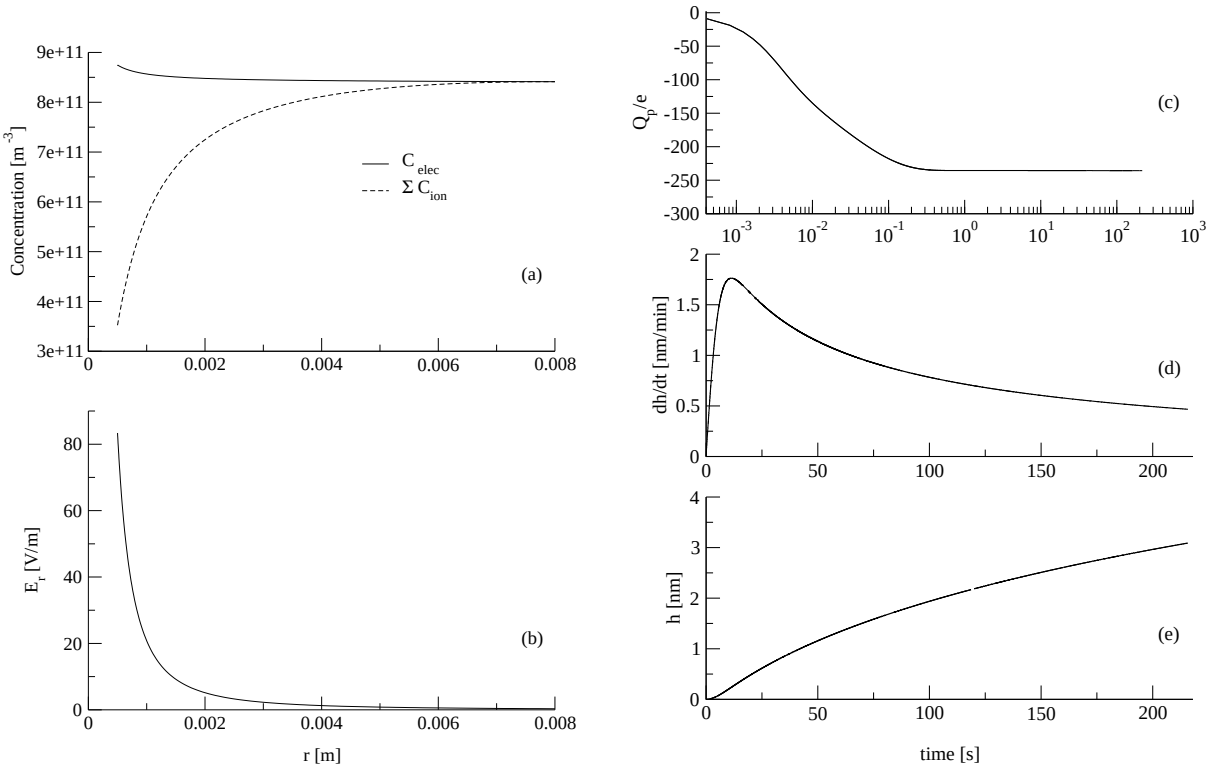

Figure 3: (a) Spatial variation of electron and total ion concentrations. (b) Spatial variation of electric field. (c) Temporal variation of particle charge. (d) Temporal variation of the coating growth rate. (e) Temporal variation of the coating thickness.

4. Conclusions

A kinetic/continuum theory model for predicting coating of nanoparticles by PECVD in low pressure conditions has been presented. Species transport phenomena were considered along with kinetics of chemical reactions consisting of 20 species. Electron-neutral, ion-neutral, and neutral-neutral reactions were counted in a total of 31 reactions, whereas vibration excitation electron-neutral reactions have been ignored to limit the number of species. Plasma-particle interaction of radicals was included by means of sticking coefficients and surface reactions. It was found that the thickness growth rate of the coating approaches a constant behavior as the system moves towards a constant at about 200 sec. For pressure P=100 mtorr, after 200 sec, a layer of approximately 2.96 nm was deposited, and a quasi constant growth rate deposition of $\simeq$0.49 nm/min was calculated.

Abstract

This paper describes the optical behaviour of TiO_2 thin films prepared by PECVD. The refraction indexes of these thin films generally decreases with thickness. Changes in microstructure and surface roughness are related with the scaling behaviour of these thin films. Differences are found depending on the plasma composition (O_2 or mixtures O_2/Ar) and interpreted within the concepts of the Dynamic Scaling Theory (DST).

1. Introduction

It is known that refraction index of oxide thin films may change with deposition time. Thus, thick films of a material may have distinct refraction index that another thin film made under identical conditions. Although there are some works in literature that have reported about the variations with thickness of the refraction index of evaporated films [1], the importance for practical purposes of this feature is not always recognised. Even less information is avalaible about the factors that influence such a behaviour. The present paper constitutes a first contribution trying to account for these observations and the causes that produce them in thin films prepared with Plasma Enhance Chemical Vapour Deposition.

Since roughness, along with porosity, is one of the factors that affects refraction index, in the present paper we have compared the evolution of this parameter for TiO_2 thin films grown by Plasma Enhanced Chemical Vapour Deposition (PECVD) for different periods of time with the evolution of the surface roughness. PECVD is a well established method for the preparation of TiO_2 thin films. With this technique different working parameters can be modified for an effective control of thin film compactness (and, therefore, refraction index). Here, besides deposition time, we have investigated the influence of using oxygen or argon/oxygen mixtures as plasma gas on the thin film properties. From Dynamic Scaling Theory (DST) [2] it is also known that the increase of the roughness with thickness until reaching a saturation value is a common behaviour in thin films growth.

The analysis of AFM images of the surface of samples grown for increasing periods of time under the concepts of DST has shown that no saturation of surface roughness is attained under our working conditions and that the surface morphology is mainly controlled by shadowing effects and not by surface diffusion. This agrees well with the SEM observation of the microstructure of the thin films.

2. Experimental

TiO_2 thin films were prepared by PECVD in a reactor with a downstream configuration. The plasma source is a SLAN type [3]. It was operated at a power of 400W with either pure O_2 or mixtures Ar/O_2 (90% Ar) as plasma gas. Titanium isopropoxide was used as titanium precursor [4]. Due to its low vapour pressure at room temperature, to dose this precursor into the chamber oxygen was bubbled though it while heated. Both the bubbling line and the shower-type dispenser used to dose the precursor were heated at 373K to avoid any condensation in the tube walls. Total pressure during deposition was $4x10^{-3}$Torr either with pure oxygen or Ar+O_2 mixtures as plasma gas. Films were deposited at room temperature simultaneously on quartz and silicon substrates.

The optical properties of the samples were determined by UV-Vis absorption spectroscopy (Perkin-Elmer Lambda 12 Spectrometer) and by spectroscopic ellipsometry (SOPRA). These two techniques yielded similar values of the refraction index except for differences of the order of 0.01 in some determinations. These differences will not be considered explicitely in the rest of this work. AFM images were collected in a Topometrix Explorer 3000 in non contact mode using high frequency levers. SEM cross section and normal images were measured for TiO_2 thin films grown on silicon.

3. Results

Fig. 1 shows the refraction index values measured for TiO_2 thin films prepared for increasing periods of time with different compositions of the plasma gas. It is apparent in this figure that the refraction index of the films decreases with deposition time and that this decrease is more pronounced for the samples prepared with mixtures $Ar+O_2$ as plasma gas. In relation with this behaviour it is interesting to note that the growing rates for the films grown in pure O_2 (5nm/min) were greater than in $Ar+O_2$ mixture (2.4 nm/min for 10% of O_2).

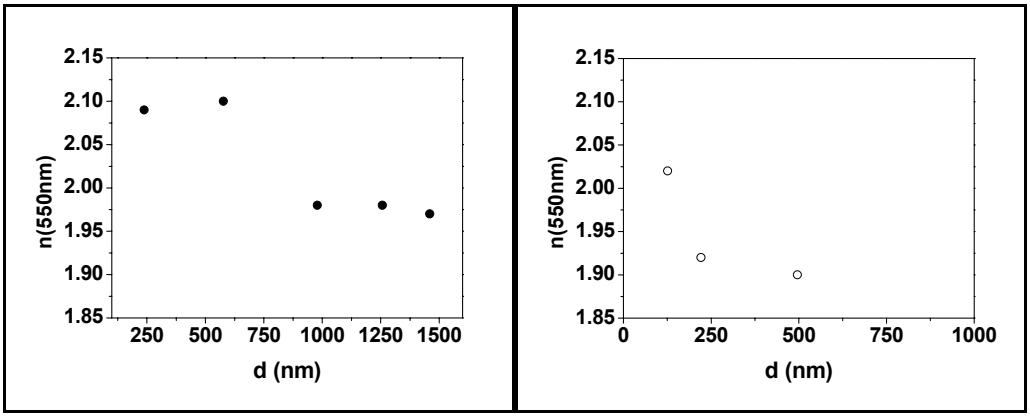

Figure 1: Variation of the refraction index with the film thickness for three experimental conditions: pure oxygen (left) and Ar/O_2 mixtures (right)

Another characteristic of the thin films that changed with deposition time was surface roughness. Fig. 2 shows a series of AFM images taken for TiO_2 thin films prepared with a Ar/O_2 mixture with 90% of Ar and for increasing periods of time. Meanwhile a comparison between the surface morphology of TiO_2 films grown with pure oxygen and Ar/O_2 mixtures is presented in Fig 3.

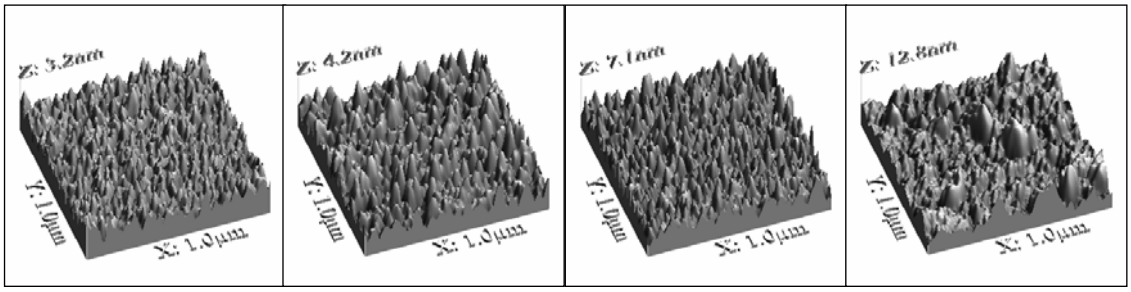

Figure 2: Increase of surface roughness with film thickness (Ar/O_2 mixture with 10% of oxygen): (a) 50 nm; (b) 126 nm; (c) 221 nm; (d) 496 nm

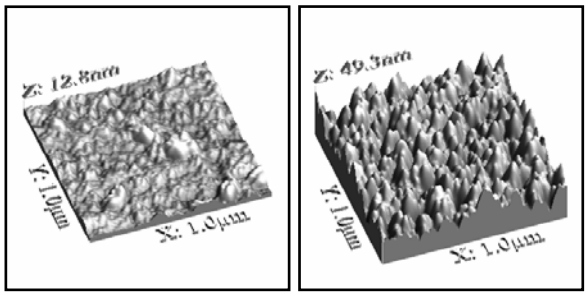

Figure 3: Comparison of the surface morphologies between TiO_2 films grown with Ar/O_2 mixtures (left, 10% O_2, 496 nm) and pure O_2 (right, 577 nm)

The average roughness was calculated from these images according to the expression:

$$w = \sqrt{\langle h_i^2 \rangle - \langle h_i \rangle^2}$$

where w is the roughness and h_i the height of each point of the surface [2]. The evolution of roughness with time is plotted in Fig. 4 in a logarithmic scale. The resulting plots define two straight lines whose maximum values do not saturate even after deposition for long periods of time.

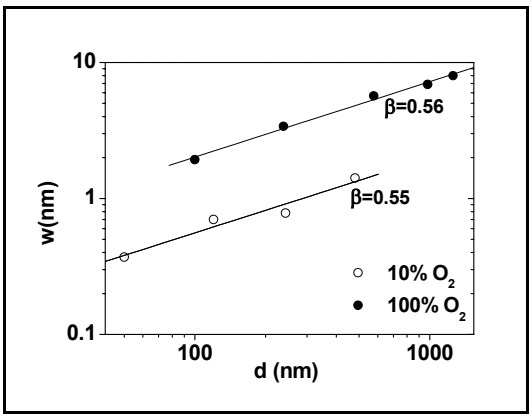

Figure 4: Roughness evolution with film thickness for 10% and 100% of oxygen

According to the DST, the slopes of this kind of plots define the value of the exponent β, the so called *growth exponent* [2], that serves to characterise the scaling behaviour of growing surfaces. In the present case, the values determined for the two series of samples were β =0.56± 0.03 for pure oxygen and β =0.55± 0.08 for the Ar/O_2 mixture.

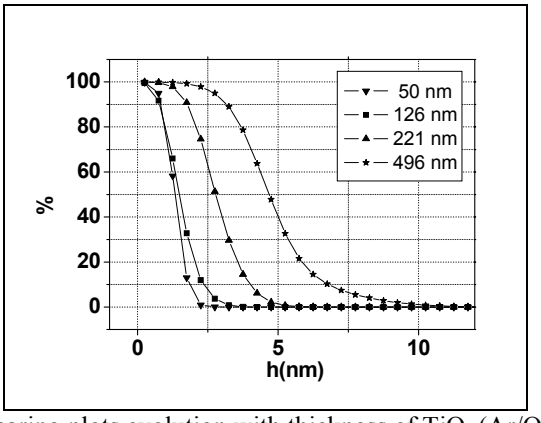

Figure 5: Bearing plots evolution with thickness of TiO_2 (Ar/O_2) samples.

Besides roughness, another interesting parameter that can be derived from AFM images is the particle size distribution. This is typically done by the so called Bearing plots as those represented in Fig. 5 for the series of samples prepared with this Ar/O_2 mixture. It is apparent from these series of diagrams that average particle size increases with the deposition time.

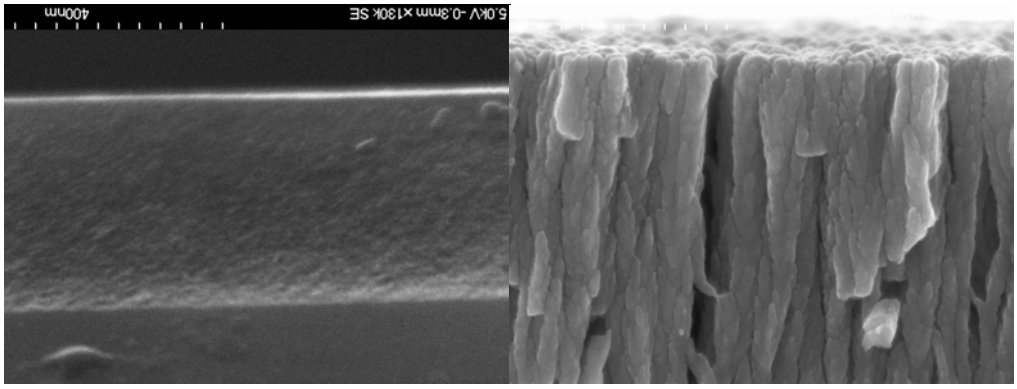

Figure 6: SEM cross sections of two TiO_2 films: 10% of O_2 (left) and 100% (right)

The behaviour depicted in Fig. 4 for the films grown with pure oxygen or with Ar/O_2 mixtures is congruent with the cross section SEM images presented in Fig. 6. This figure clearly shows that the TiO_2-O_2 films are characterised by a columnar microstructure with columns having a relatively big size. By contrast, TiO_2 - Ar/O_2 samples do not have a well defined columnar structure.

4. Discussion

The two sets of samples prepared in this work present different values of their refraction indexes and surface roughness, but also depict quite different microstructures. All these differences must be a consequences of the growth mechanism occuring in each case. However, a preliminary interpretation of the growth processes based on the application of the DST concepts does not reveal significant differences. The two sets of samples are characterised by a similar growth exponent $\beta \approx 0.55$ and a non-saturation behaviour of roughness. In previous reports in literature [5,6] these two features have been associated with growth processes characterised by very high sticking probabilities of the fragments/particles reaching the surface and the eventual development of a columnar microstructure. In this case, surface diffusion is restricted or supressed and the incoming particles remain in the same place where they have touched the surface. This is certainly the case for TiO_2-O_2 samples characterised by homogeneus columns that grow in height from practically the interface with the substrate up to the surface films. The slight decrease in n found in these samples when their thickness increase has probably to be associated with the continuous increase in surface roughness found for the samples. On the other hand, the high growing rate found in this case (i.e. 5 nm min^{-1}) points out to a high efficiency of the plasma to induce the fragmentation and oxidation of the titanium isopropoxide precursor in the gaseous phase.

Samples TiO_2-O_2/Ar show a globular microstucture and low values of n that sharply decrease with the thickness of samples. The presence of Ar in the plasma must be the reason for these differences as well as the most important factor for decreasing the growing rate of these samples (i.e. 2.4 nm min^{-1}). Characterization of the O_2 and O_2/Ar plasmas in our experimental set-up has shown that the electron density is greater in this latter case. It is therefore likely that the plasma particles arriving to the surface have a higher perpendicular component of velocity when the concentration of Ar in the plasma is important. Under these conditions the columnar growth is hindered even though the sticking coefficient of titanium fragments is high (columnar growth mechanisms are typically recognised as the result of a random distribution of the velocity direction of

the incoming particles). In addition, the high rate and momentum of the Argon particles may induce a certain sputtering of surface, a feature that is also reflected by the lower growing rate of these samples.

The considerable decrease in n found for the TiO_2-O_2/Ar films as they grow in thickness reveals an accumulation of voids and pores. Meanwhile, the much lower values of surface roughness found in these samples as compared with TiO_2-O_2 discard that roughness is a significant parameter for the control of n. We rather believe that the increase in the particle size that occurs as the thickness of samples increases (cf. Fig. 5) is the inmediate cause of this increase in porosity. The study of these and other sets of samples is still being carried out at present based on a more thorough characterisation of the scaling behaviour of the different families of thin films.

Abstract

An AC three-phase GlidArc discharge plasma generator and its characteristics are described. Some experimental results about the GlidArc discharge of the plasma generator were obtained. This type of GlidArc plasma generator is potentially used in air pollution treatment processes and treatment of medical waster.

1. Introduction

GlidArc discharge plasma is a type of non-equilibrium plasma near atmospheric pressures, and has many applications in chemical industry and environment engineering [1-3]. The non-equilibrium plasma near atmospheric pressure is the so-called non-thermal plasma in between the thermal plasma and cold plasma. In general, the GlidArc discharge was powered by a DC power source supply[3-6]. In this paper, a novel AC three-phase GlidArc plasma generator is presented. The principle of the plasma generator is analyzed. The main advantages of AC GlidArc discharge plasma are simplicity of the power supply system and its low cost.

This AC three-phase GlidArc plasma is potentially used in air pollution treatment processes and treatment of medical waster.

2. Electrical device and GlidArc plasma generator

The experimental set-up of the GlidArc plasma generator is shown in Fig.1. It consists of a GlidArc discharge plasma generator, an AC three-phase main power supply, a high voltage ignition power supply and a gas supply. The AC three-phase main power supply included a variable transformer, three transductors and a main transformer. The GlidArc discharge plasma generator included a water-cooling center electrode, three water-cooling outside electrodes, a gas injection device and an electric discharge chamber. The shortest distance between the center electrode and outside electrodes is 2-3 mm. When a high voltage ignition power supply of 10000 volts is attached to the center electrode and the outside electrodes, the arc will be ignited at the shortest distance and then driven towards the exit of the setup by the gas flow and electromagnetic force created by own arc current. The force on the electric arc by gas flow per unit length is

$$F_g = \frac{1}{2} c_d \rho (v_g - v_a)^2 d \qquad (1)$$

where c_d is the resistance coefficient of gas flow on the electric arc, ρ is the density of gas, v_g is the velocity of gas flow , v_a is the velocity of electric arc, d is the diameter of the electric arc.

This work is supported by National Nature Science Foundation of China №.90205026，№.10375082.

The electromagnetic force by own arc current per unit length is

$$F_e = IB_i \qquad (2)$$

Where I is the arc current, B_i is the magnetic field strength created by own arc current. When the arc current is low, the electromagnetic force is much lower than the force of gas flow.

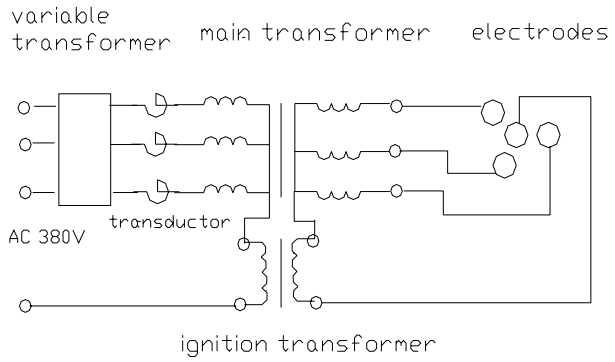

Fig.1 Experimental set-up of the AC three-phase GlidArc discharge plasma

Parameters of the AC three-phase power supply and the high voltage ignition power supply are given in Table 1. The gas flow-rate for the plasma generator is 8-10m^3/h, and the gas medium is air.

Table 1. Parameters of the AC three-phase power supply and the ignition power supply

	Voltage (V)	Current (A)
AC Three-phase power supply	1000	10
Ignition power supply	10000	0.1

The configuration of the AC three-phase GlidArc plasma generator is shown in Fig.2. The diameter of the plasma generator is 120mm, and length is 220mm. Six holes for gas injection with 2mm diameter are set on the top of the generator.

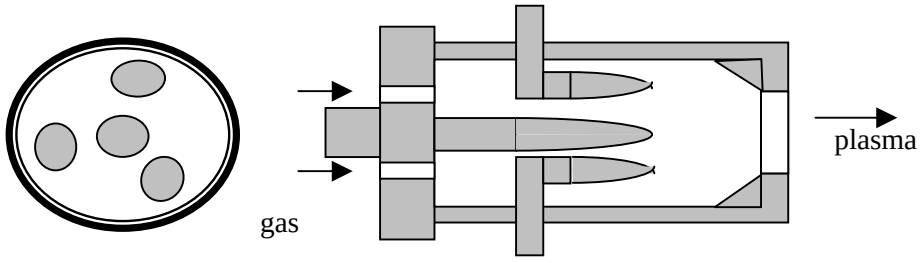

Fig.2 Schematic diagram of AC three-phase GlidArc discharge plasma generator

Fig.3 shows the photograph of the AC three-phase plasma generator. The average electric power of the plasma generator is 3-8kW.

Fig.3 Photograph of the AC three-phase GlidArc plasma generator in operation

3. Characteristics of discharge

Fig.4-5 show the current and voltage curve of the discharge recorded with a digital oscilloscope. Fig.4 shows that the discharge current has some oscillator when the instantaneous voltage is low. If the arc voltage is high enough, the oscillator of the arc current will decrease. Fig.5 shows that after arc current be ignited the voltage of the arc will be near a constant.

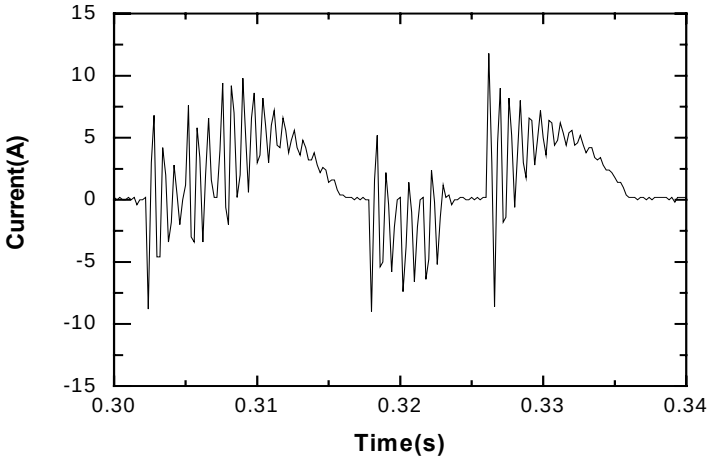

Fig.4 Current curve for the AC GlidArc discharge

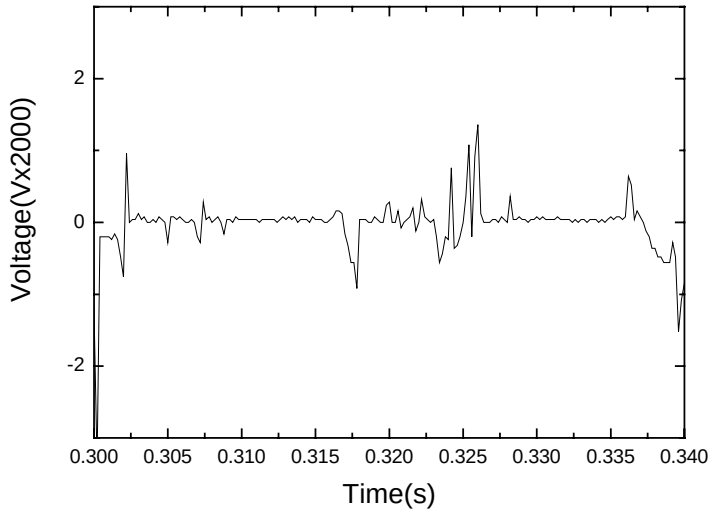

Fig.5 Voltage curve of the AC three-phase GlidArc plasma generator

4. Discussion

We report here an AC three-phase GlidArc plasma generator and some results of experiment for GlidArc discharge. This type of three-phase GlidArc discharge plasma generator has some advantages (for example, simplicity of the power supply system and its low cost, uniform temperature distribution of the plasma at the exit cross-section of the plasma generator.) and offer good application prospect in environment engineering.

Abstract
APGD was used for surface modification of polycarbonate (PC). The discharge was generated in pure nitrogen or in nitrogen–hydrogen mixture. The surface properties of treated and untreated samples were investigated by surface free energy measurements, X-ray photoelectron spectroscopy. The influence of the treatment time and the aging on the surface properties of PC was studied. The surface free energy of PC increased from 30 to 53 mJm^{-2}. The decrease in the surface free energy during the ageing was approximately 10%.

Introduction

Polycarbonate is widely used material in different branches of industry. This thermoplastics material is used everywhere high impact resistance and transparency is required. However, surface properties of polycarbonate (e.g. wettablity and adhesion with deposited metallic or dielectric films) are not suitable for every application. Plasma surface treatment is very promising technique for adhesion improvement. Most of reported works with plasma activation of different polymers [1] especially polycarbonates were made in different types of low-pressure plasma [2, 3]. The disadvantage of the low-pressure techniques is their demand of expensive vacuum pumping systems. Moreover, the difficulties in arranging the system for large area treatment have to be overcome. Recently, plasma activation of polymers at atmospheric pressure has become a promising technology due to its economical and ecological advantages.

Dielectric barrier discharges at atmospheric pressure are widely used in various applications such as depolution, ozone production, surface treatment and thin film deposition. Two modes of barrier discharge can occur: filamentary and glow. In the filamentary mode the treatment is not homogeneous so its application is limited for surface activation and plasma depositions. The atmospheric pressure glow discharge (APGD) allows homogenous treatment of the surface however this kind of discharge is possible to obtain only under certain specific conditions.

The main objective of this paper was to investigate the effect of the plasma surface treatment in APGD on the surface properties of polycarbonate. The influence of the treatment time and the aging on the surface properties of PC was studied. The surface free energy of PC increased from 30 to 53 mJm^{-2}. The decrease in the surface free energy during the ageing was approximately 10%.

Experimental

The atmospheric pressure glow discharge was generated in a reactor chamber between two brass electrodes. The upper electrode was covered by a dielectric (pyrex glass) 1 mm thick and the bottom one was covered with the polycarbonate sample. The discharge was generated in pure nitrogen or in pure nitrogen with small admixture of hydrogen (3%). The bottom electrode was periodically moving with sample during the treatment to achieve higher homogeneity and to increase the treated area. The distance between electrodes was 1 mm. The operating frequency was kept at 10 kHz and the input power density was kept at 0.8 $W.cm^{-2}$ in all cases. The treatment time varied from 4 to 100 s.

So called Acid Base Regression method [4] was used to calculate the total surface free energy γ and its components (Lifshitz-van der Walls γ^{LW}, acid-base γ^{AB}, acid part γ^{+} and base part γ^{-}) from contact angles measured by means of Surface Energy Evaluation System [5]. The topology of treated and untreated samples was studied by means of AFM and SEM and chemical changes were investigated by XPS.

The discharge properties were studied by means of the optical emission spectroscopy. The spectra emitted by the discharge were recorded with the Jobin-Yvon TRIAX 550 spectrometer with a CCD detector.

Results and discussion

Typical spectrum of the nitrogen discharge with 3 % hydrogen admixture is displayed in Fig. 1. The spectrum consists only of the molecular bands of the second positive system of nitrogen ($C\ ^3\Pi_u \rightarrow B\ ^3\Pi_g$). Neither hydrogen atomic lines nor hydrogen molecular lines were registered, although the integration time was exaggeratedly raised. This is probably due to the complex structure of nitrogen molecule excited states, which absorbs the most of the supplied energy.

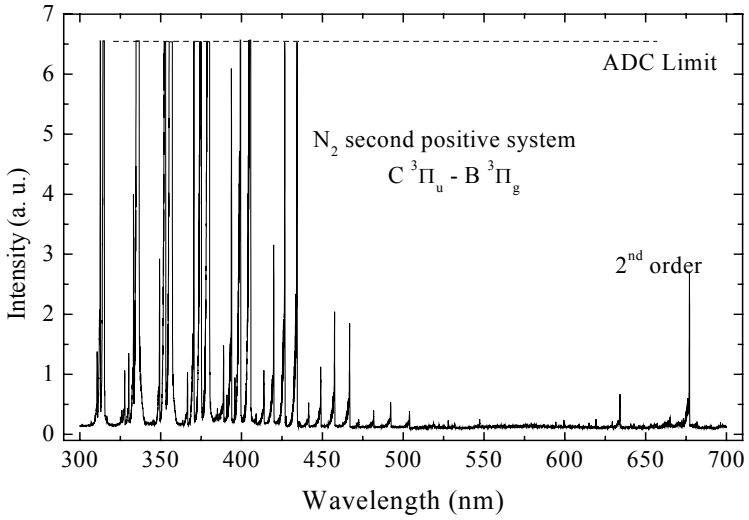

Figure 1. Overview spectrum of APG discharge in nitrogen with 3 % hydrogen admixture. Whatever the hydrogen admixture was, only nitrogen emission was observed.

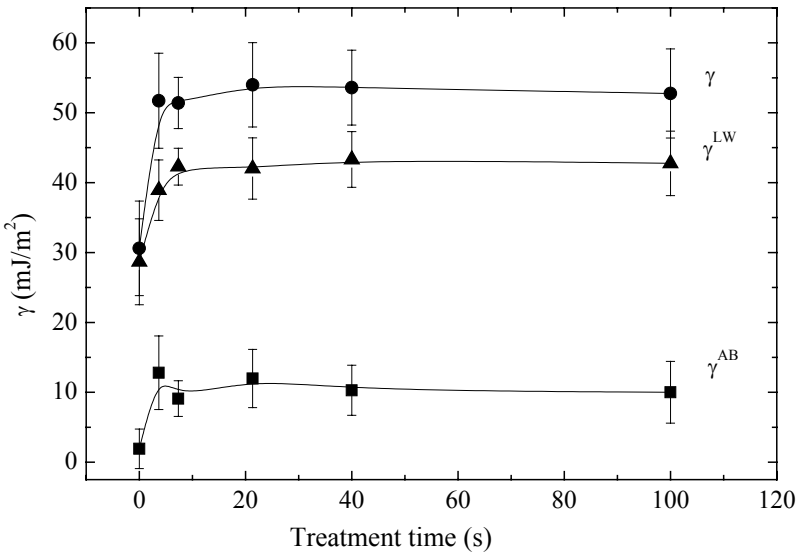

Figure 2. *SFE of sample versus treatment time. γ is total surface free energy, γ^{LW} is Lifshitz-van der Walls component and γ^{AB} is acid-base component.*

The surface free energy (SFE) of treated polycarbonate as a function of the plasma treatment time in nitrogen-hydrogen mixture is shown in Fig. 2. The total surface free energy γ and also its components (γ^{LW} Lifshitz-van der Walls and γ^{AB} acid-base component) rapidly increased during the first 7 s of treatment then reached saturation.

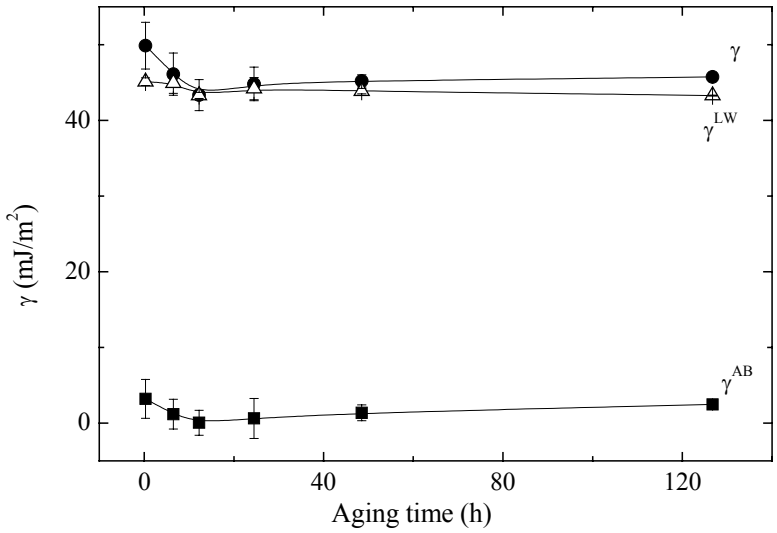

Figure 3. *SFE of sample versus aging time. γ is total surface free energy, γ^{LW} is Lifshitz-van der Walls component and γ^{AB} is acid-base component. Plasma treatment time of sample was 100 s.*

The time stability of treated samples was also investigated (see Fig. 3). The total surface free energy and its components slightly decreased during the first 12 hours of the aging and remained constant. The stable value of SFE of aged sample was considerably higher then the value of SFE of untreated sample. We suppose the good stability is caused due to croslinking effect.

The surface atomic concentration of samples was measured by X-ray Photoelectron Spectroscopy using Mg K_α photon beams. The results are in Tab.1.

Tab. 1: *Atomic concentration of virgin sample and treated samples. Plasma treatment time of samples was 100 s.*

Sample	**C**	**O**	**N**
	%	**%**	**%**
virgin PC	83.2	16.8	0.0
PC treated in N_2	72.1	17.9	10.0
PC treated in N_2+H_2	68.1	16.9	15.0

Conclusion

Polycarbonate samples were activated in the atmospheric pressure glow discharge. The surface free energy of treated samples increased from 30 to 53 $mJ.m^{-2}$. The treated samples showed out only low ageing effect. The saturated value of SFE of samples plasma treated in APGD was comparable with saturated value of

SFE of samples treated in low-pressure discharges. The benefit of the technique based on APGD is short-process time and low aging effect in contrast to low-pressure techniques.

A parametric study of carbon nanotubes produced from the thermal plasma dissociation of tetrachloroethylene

D. Harbec, J.-L. Meunier, L. Guo, J. Jureidini
CRTP / Department of Chemical Engineering, McGill University, Montreal, Quebec, Canada

Abstract
We produce carbon nanotubes (CNT) using a nominal 100 kW dc non-transferred plasma torch and tetrachloroethylene as carbon raw material. The erosion of the torch electrodes emits tungsten vapours that nucleate *in situ* into catalytic nanoparticles within the plasma jet. CNT mass yield values are based on thermogravimetry analysis correlated using electron microscopy and Raman spectroscopy. This led us to conduct a parametric study and determine the influence of the different operating parameters on the yields of carbon nanotubes. Formation of a supersonic jet, high vapour pressures of carbon and a control of the temperature profile within the torch nozzle enable the rapid growth of CNT.

1. Introduction

Carbon nanotubes (CNT) are long hollow tubes that contain hundreds of carbon atoms. Their nanometric diameter and their micron-size length give them a one-dimensional structure. Single-Walled Nanotube (SWNT) consists of the roll-up of a graphene sheet and closed on itself, whereas a Multi-Walled Nanotube (MWNT) constitutes an arrangement of concentric SWNT. Due to their 1-d hollow structure, CNT possess interesting properties. They feature mainly high modulus of elasticity, high tensile strain, superconductor and semiconductor behaviours, high thermal conductivity and storage capabilities. Novel applications are being developed in advanced materials [1-3], electronic components [4-5], and storage applications [6-7]. The availability and the high cost of CNT however limit the development and the commercialization of most applications. Our objective is to contribute in solving this problem through the development of a manufacturing process that can produce CNT on an industrial level based on thermal plasma torch technology.

In this paper, we present CNT catalytically produced using tetrachloroethylene (TCE) as carbon raw material injected in the nozzle of a dc plasma torch. Researchers widely use metallic nanoparticles to catalyze the formation of CNT. These metallic nanoparticles enhance the yields of CNT by anchoring the tip of the CNT structure. These mainly inhibit the formation of pentagonal rings preventing a premature closure of the CNT structure into by-products and allowing an efficient elongation and CNT growth [8-10]. Here, the erosion of a thermal plasma torch electrode emits metallic vapours that nucleate *in situ* into catalytic nanoparticles within the plasma jet [11-12]. In this simple scheme, the tungsten particles act as the metal catalyst within the graphitic deposit formed on the internal wall of the torch nozzle, thereafter called the "nozzle deposit". Here, we present results regarding the mechanism of formation of CNT within the torch nozzle using the particular tungsten/TCE precursors, and implementation of a method to quantify and characterize yields of CNT. This makes possible to conduct a parametric study and investigate the effect of the various operating parameters on the yields of CNT.

2. Experimental

As outlined in the introduction, we produce CNT from the thermal plasma dissociation of TCE. We inject TCE vapours using 20 slpm of carrying argon gas in the water-cooled nozzle of a dc non-transferred thermal plasma torch (*Pyrogenesis Inc.*, model RPT-2) operating with 100 slpm of plasma-forming argon and a torch power of 30 kW. Upstream of the torch nozzle, the arc plasma erodes both the anode and the cathode made of tungsten and supplies tungsten vapour as a source for catalyst nanoparticles for the growth of CNT. The arc current controls the supply of tungsten in the process [11-12]. We characterize CNT and the catalyst nanoparticles using electron microscopy (EM): Transmission Electronic Microscopy (TEM) and Field-Emission Scanning Electronic Microscopy (FE-SEM).

We quantify yields of CNT using thermogravimetric analysis (TGA; *Perkin Elmer* TGA 7) and characterize the diameter distribution of CNT using Raman spectroscopy (*Renishaw inVia*). Raman spectra are recorded on raw soot using the 514 nm wavelength of an Ar-ion laser. The results are then confirmed using a 785 nm wavelength

laser, this yielding a higher signal-to-noise ratio compared to the 514 nm Ar-ion laser. For the mass evaluation of CNT, 15-18 mg of raw soot is placed in the TGA crucible. A temperature ramp rate of 5°C/min from 50°C to 1000°C and an air flow rate of 60 cc/min are used. Weight loss in wt.% is recorded as a function of furnace temperature, thereafter called the TG curve. The derivative of the TG curve with respect to temperature yields the DTG curve. The DTG curve shows peaks associated to the weight-losses of each carbonaceous species contained in the raw soot, the peak temperature representing the burning temperature of the related carbonaceous species. CNT are identified using EM techniques on samples taken before and after a given TGA peak, and using a TGA analysis on purified samples having similar morphology.

3. Formation of CNT

We previously reported that the flow and the temperature conditions within the torch nozzle enable a good dispersion of tungsten and the synthesis of large concentrations of long MWNT, carbon onions and carbon nanoparticles within the nozzle deposit [11]. Using TEM, these MWNT are typically 50μm long and their internal and external diameters are respectively 2-3 nm and 10-20 nm. TEM micrographs (Figure 1a) show nanoparticles of tungsten carbide (C_xW_y) encapsulated at the tip of CNT. These particles likely play a role of catalyst in the growth of CNT. The mechanism of formation of the CNT occurs most probably in a similar fashion as Kataura *et al.* [8], Gavillet *et al.* [9] and Larouche *et al.* [10]. Upon cooling, the carbide nanoparticles segregate their excess of carbon to their surface at their eutectic temperature. The segregated carbon graphitizes and forms CNT at the surface of the carbide nanoparticles. The growing CNT continuously uses the segregated carbon and carbon in the gas phase as building blocks to elongate their structure and CNT grows from the surface of the carbide particles until the temperature become too low. Below a certain temperature level, the nanoparticles solidify and stops further growth of the CNT. On Figure 1b, an electron diffraction pattern of the nozzle deposit using TEM shows good resonance of the diffracted light. This reveals a highly graphitic arrangement of the carbon atoms and a negligible content of amorphous carbon in the nozzle deposit.

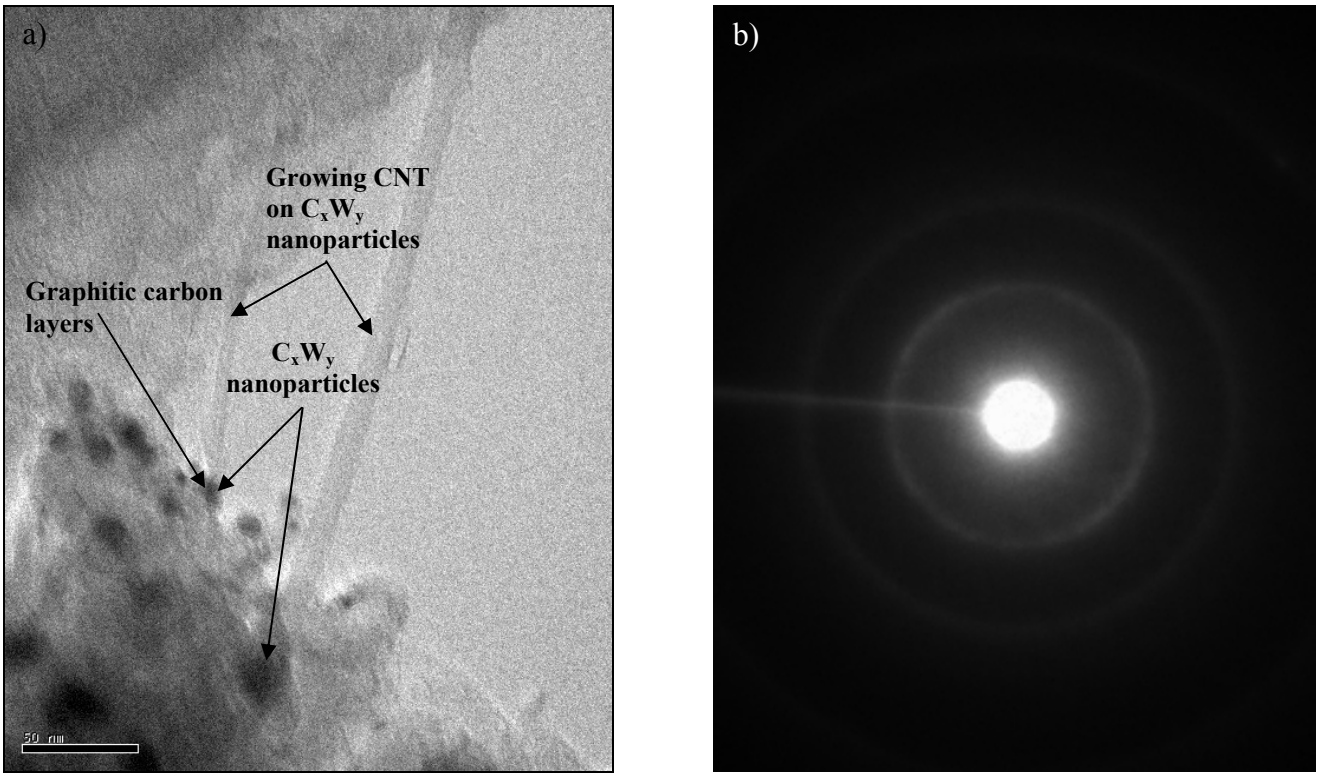

Figure 1 a: Nanoparticles of tungsten carbide at the tip of CNT promoting the growth and the elongation of CNT. **b:** Electron diffraction analysis demonstrates that the nozzle deposit contains carbon in graphitic and crystalline forms.

The Raman spectrum using the 514 nm and the 785 nm lasers of an as-produced nozzle deposit effectively confirms that this method of production promotes the growth of MWNT (Figure 2). The absence of peak in the RBM mode at both wavelengths indicates the absence of SWNT in the nozzle. The spectrum obtained with the 785 nm laser particularly consolidates this affirmation due to its higher signal-to-noise ratio. The G mode peaks (Raman shift @ 1582 cm^{-1}) inform about the relative content of graphitized carbon: MWNT, carbon nanoparticles and onions. Due to the small amount of amorphous carbon in the nozzle deposit, the D mode peak (Raman shift @ 1357 cm^{-1}) reflect most probably the relative content of the amount of pentagonal rings of carbon and defects in the sample. As indicated above, the as-produced MWNT show a defect-free morphology over lengths exceeding 50 µm [11], and are less likely the source material for the D peak intensity. The D mode rather indicates the relative amount of carbon nanoparticles and onions.

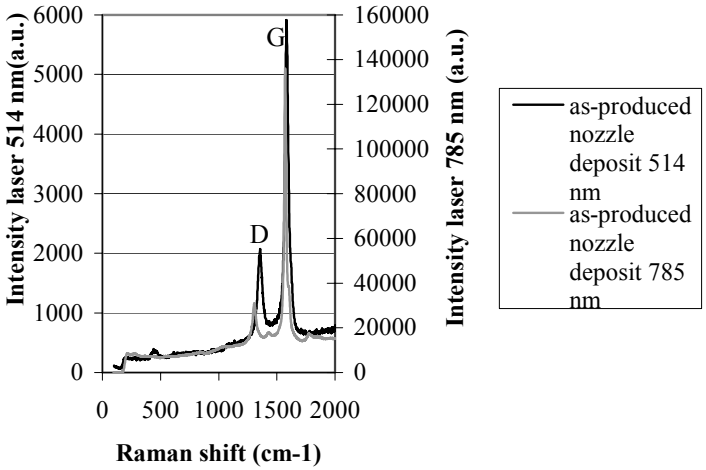

Figure 2: Raman spectra using the 514 nm laser and the 785 nm laser of an as-produced nozzle deposit.

On Figure 3, CFD modeling of the temperature profiles within the nozzle using *Fluent 6.1* demonstrates for two pressure conditions that a strong quench upstream of TCE injection ports is induced by a supersonic plasma jet expansion followed by two shock waves. According to the average velocity of the plasma jet, the upstream expansion cools the plasma at rate of ≈50x10^6 K/s, while rates of 2-4.5x10^6 K/s are calculated for the two subsequent shock waves (see related ISPC-17 paper [13]). Such quench rate values at or above 10^6 K/s were evaluated by Larouche *et al* [10] as a requirement for CNT synthesis. From these considerations, we stipulate the growth of MWNT in the nozzle occurs as the following. The plasma arc erodes the tungsten electrodes and generates tungsten vapours upstream of the nozzle within the plasma torch. Nanoparticles of tungsten nucleate in the quench zone generated by the supersonic expansion and in the cold areas along the nozzle walls. Most of the particles generated are transported to the nozzle walls by thermophoresis effect from the strong temperature gradients, and by the cold gas recirculation loops upstream in the nozzle. Meanwhile, the plasma jet atomizes the injected TCE and provides atomic carbon contamination to the tungsten particles. A fraction of the carbon vapours also nucleate in the cold wall areas into carbon nanoparticles and onions. The tungsten carbide (C_xW_y) particles having suitable temperature and size will be the site of CNT growth. These particles attached to the nozzle wall are characterized by very long residence times in a given high temperature window, together with a continuous supply of atomic carbon. This temperature window is presumably the eutectic temperature of C-W mixture being 2700K. Such a situation should lead to the observed CNT showing average lengths exceeding 50 µm and defect-free morphology because of the high temperature of this tungsten-based nucleation.

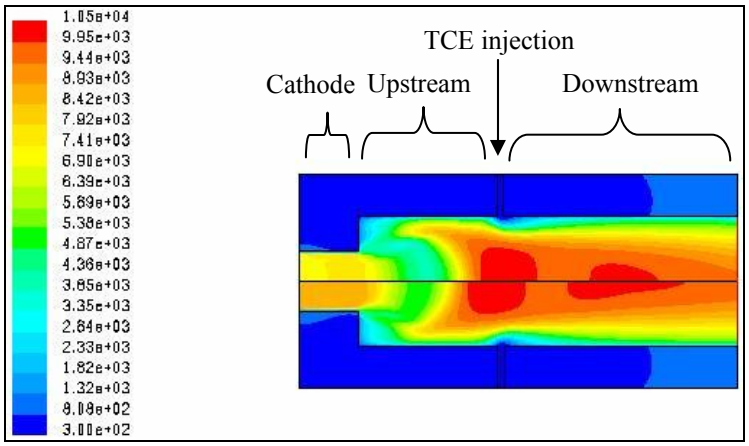

Figure 3: CFD modeling temperature profile inside the torch nozzle. Upper part: 200 torr, bottom part: 500 torr.

4. Quantification of CNT

Quantification of CNT still remains a challenge due to its insolubility in most solvent and difficulty to extract them. Here, we use a simple method to quantify these using TGA. TGA of the nozzle deposit as shown on

Figure 4 typically shows DTG curves with two steps weight loss between 50°C and 1000°C. The first one occurs at 575°C and the second, at 830°C. We are thus in presence of two specific types of carbonaceous species in the nozzle deposit. To identify the morphologies associated to these peaks, we performed TGA analysis of pure MWNT sample having similar size characteristics to those found in the nozzle deposit (*Nanostructured & Amorphous Materials Inc. #1228MNG*). The combustion of the pure MWNT sample occurs characteristically at 575°C. EM observations of the TGA samples taken above and below the peak temperature confirm the disappearance of MWNT at a temperatures of 690ºC (Figure 5). Only a few carbon fibers and particles remain in the sample. These evaluations allow associating the first weight-loss peak occurring at around 575°C to the combustion of the MWNT contained in the nozzle deposit, and the second to the combustion of the by-products such as the carbon nanoparticles and onions. We exploit in the following section the area under the weight-loss peak at 575ºC to quantify the concentration of MWNT in the nozzle deposit.

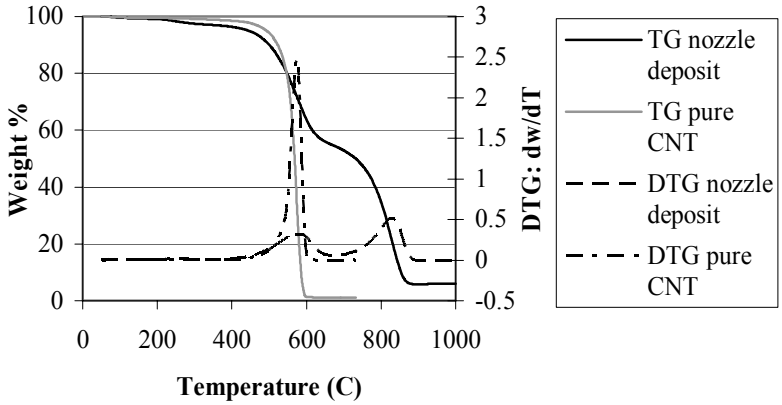

Figure 4: Typical TG and DTG curves of the nozzle deposit and the pure MWNT sample obtained after TGA.

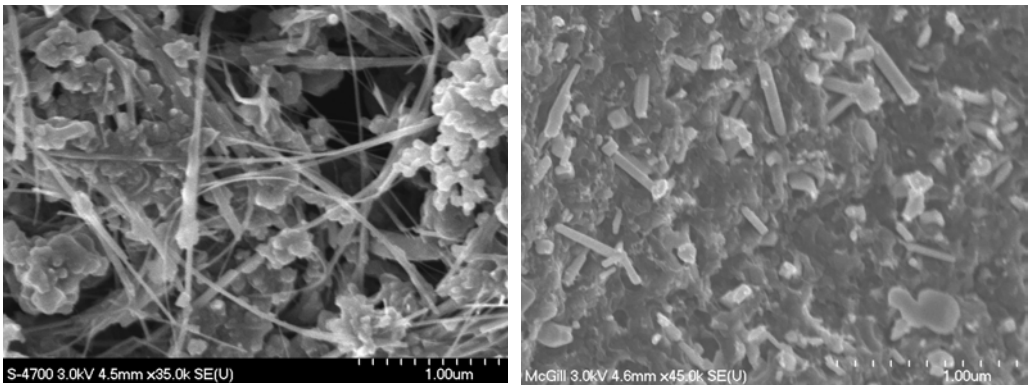

Figure 5 left: Fe-SEM micrograph of nozzle deposit prior TGA. **Right:** after TGA up to 690ºC

5. Parametric study

The influence of process parameters such as the reactor pressure, the TCE feed rate and time are evaluated using the MWNT yield from the TGA analysis. MWNT condense mainly on the internal wall of the torch nozzle. The mass of the soot collected following 5 minutes of TCE injection experiments remains relatively constant around 1 g. Table 1 summarizes the concentration of CNT obtained from TGA and the averaged I_D/I_G intensity ratio calculated from the Raman spectra for the different operating parameters investigated.

Table 1: Concentration of MWNT in the nozzle deposit and I_D/I_G as a function of the process parameters

Investigation	TCE feed rate (mol/min)	Pressure (Torr)	Time (min)	MWNT conc. from TGA (wt.%)	I_D/I_G from Raman spectra
Effect of pressure and TCE feed rate	0.15	200	5	49.8%	1.00
	0.15	500	5	43.9%	0.94
	0.05	200	5	38.6%	0.64
	0.29	200	5	51.3%	1.07
Effect of time of operation	0.15	200	1	1.9%	N/A
	0.15	200	2	0.1%	0.10
	0.15	200	3	0.1%	0.04
	0.15	200	4	8.16%	0.26

I_D/I_G rises as increasing the MWNT concentration. EM observations reveal that the concentration of carbon nanoparticles and onions increases with the MWNT concentration. These two by-products are synthesized in similar conditions as the CNT without the use of metal catalyst [14-15]. Their synthesis occurs due to the lack of metal catalyst in the plasma jet and the I_D/I_G becomes a tool for the appreciation of the experimental conditions for the growth of MWNT.

- *5.1 Effect of the reactor pressure*

We perform experiments using two different reactor pressures, 200 torr and 500 torr. We compare the yields of CNT in the nozzle deposit synthesized at these two pressure levels and at a constant TCE feed rate of 0.15 mol/min. Calculations of the area under the weight-loss peak at 575°C indicate that the reduction of the reactor pressure tends to increase the yield of MWNT. For the experiment performed at 500 torr, we evaluate the yield at 43.9% and for the experiment performed at 200 torr, 49.8%. The I_D/I_G for both experiments are respectively 0.94 and 1.00. From Figure 3, the quench produced by the supersonic expansion at the nozzle entrance cools the plasma jet to a lower temperature at 200 torr. This quench reduces the temperature of the plasma jet from ≈7000K to ≈3350K at 200 torr, respectively from ≈8000K to ≈4890K for 500 torr. The stronger quenching effect at 200 torr enables a more efficient nucleation of tungsten particles from the tungsten vapours provided by the arc erosion. A larger amount of metal catalyst nanoparticles is expected to be available at this pressure for the growth of CNT [13].

- *5.2 Effect of the TCE feed rate*

In order to investigate the TCE feed rate on the MWNT concentration in the nozzle deposit, we conducted three experiments at three different levels of TCE feed rate: 0.05, 0.15 and 0.29 mol/min. We performed these at constant pressure (200 torr), flow of plasma-forming argon (100 slpm) and torch power (30 kW). The concentration of MWNT in the nozzle deposit increases with the increase of the TCE feed rate. On table 1, the TGA of the nozzle deposits synthesized at TCE feed rate of 0.05, 0.15 and 0.29 mol/min respectively indicate a concentration of 38.6%, 49.5% and 51.3%. The Raman spectra respectively indicate an I_D/I_G of 0.64, 1.00 and 1.07. The increase of the yield of MWNT with the increase of the TCE feed rate means that the vapour pressure of carbon is a parameter to consider in the growth of MWNT here. At a high TCE feed rate, a high vapour pressure of carbon presumably favours higher carbon concentration in the tungsten nanoparticles for the initial nucleation stage, and a better supply of carbon to feed the growing tube. The present method of production of CNT uses a relatively small amount of metal catalyst compared to the carbon feed. According to the erosion rates outlined previously [11], the quantity of tungsten vapour in the system varies from 0.01% to 0.2% of the carbon fed. This is much smaller than the range suggested by Pacheco [16] for the graphite arc process giving percentages of metal catalyst over the carbon fed between 0.4% and 13% for an efficient CNT synthesis. The lack of available metal catalyst particles is most probably the reason behind what seems to be a levelling of the curve of CNT production when moving to the highest carbon feed at 0.29 mol TCE/min.

5.3 Effect of time of operation

We investigated the effect of time on the concentration of MWNT grown in the nozzle deposit in performing experiments at constant flow rate of plasma-forming argon (100 slpm), torch power (30 kW), TCE feed rate (0.15 mol/min) and pressure (200 Torr). We stopped the experiments at interval of 1 minute after TCE injection and perform these tests up to 5 minutes. Table 1 shows the evolution of the concentration of MWNT and of the I_D/I_G as a function of time of operation. Small concentrations of MWNT are observed during the first 3 minutes of TCE injection, and then an increase is observed during the 4^{th} minute of operation followed by a drastic increase in the 5^{th} minute of operation. The thickness of the nozzle deposit also gradually increases with the time of operation. We collected 0.02g of soot after the 1^{st} minute of operation and 1g after the 5^{th} minute. The small quantity of soot produced after only 1 minute of operation does not allow the measurement of a Raman spectrum. One may thus estimate that the quantity of CNT reported in Table 1 for experiments lasting 5 minutes are in fact produced over a 1-2 minutes timescale achieved after a temperature ramp up period. Although the present operating conditions and metal/carbon precursors are exploratory and not optimized particularly with

respect to the availability of metal catalyst, this corresponds roughly to a generation rate between 24-30 g/h of CNT in continuous operation.

CFD modeling as shown on Figure 3 indicates that the temperature of the plasma jet is in the order of 2400K near the internal wall of the torch nozzle. This temperature is actually colder than the eutectic temperature of the tungsten-carbon alloy (C-W) varying around 2700K. During the first minutes of operation, thin layers of graphitized carbon condense in the nozzle due to the relatively cold temperature near the internal wall of the nozzle. The nozzle deposit thickens during operation and accumulates condensed nanoparticles of tungsten carbide. This wall deposit acts as an additional thermal resistance between the water-cooled nozzle wall and the hot plasma, and will tend to increase in temperature as the layer grows in thickness. The temperature of the nozzle deposit eventually reaches the eutectic temperature of the C-W mixture and enables the growth of MWNT at the surface of the nanoparticles of tungsten carbide. According to the TGA, this moment occurs during the 4^{th} and the 5^{th} minute of operation due to the drastic increase of the MWNT concentration in the nozzle deposit. The long MWNT synthesized showing lengths in the 50μm scale [11] indicates that the catalyst nanoparticles of tungsten carbide are available for growth over a long period within their eutectic temperature window.

6. Conclusion

In summary, our process based on the thermal plasma torch technology uses the supersonic expansion of the plasma to generate *in situ* the metal catalyst particles and simultaneously treat large amounts of carbon containing gas for conversion into CNT. This process can operate under a continuous operation regime and has the potential for scale increase, thermal plasma torch technologies currently operating at the megawatt level. The supersonic expansion of the plasma realizes quenching rates up to $50x10^6$ K/s that lead to the nucleation of the metal catalyst nanoparticles. We implemented a quantification method for the CNT mass based on TGA calibration with purifies samples, electron microscopy and Raman spectroscopy. This method enabled a parametric study to determine the effect of some operating parameters on the yields of CNT. Optimal conditions in argon are achieved at 200 torr pressure and TCE feed rate of 0.29 mol/min. An important time evolution in the 5 minute experiments is observed on the yield of CNT. In the present conditions, we believe that this time evolution results from a temperature increase of the carbon deposit reaching the eutectic temperature of the tungsten catalyst.

Improvement of Gas Barrier Properties of Polymers by Microwave Plasma CVD

A. Ogino, T. Tanaka, T. Matsuda, M. Nagatsu

Department of Electrical and Electronics Engineering, Shizuoka University, 3-5-1 Hamamatsu, 432-8561 Japan

Abstract

We have carried out the experiments of the gas barrier coating by hydrogenated amorphous carbon (a-C:H) thin films prepared with surface-wave plasma (SWP). The SWP allows to perform the large-area film deposition at low temperature. According to the gas permeation experiments, it was found that the gas barrier properties of polyethylene terephthalate (PET) sheets were improved by a-C:H thin film coating by a factor of 150~200 compared with one of uncoated PET sheets.

Keywords: Microwave plasma chemical vapor deposition; Amorphous carbon; Gas barrier film; Polymer

1. Introduction

Recently, the replacement of glass to transparent plastics, e.g. polymetylmethacrylate (PMMA), polycarbonate (PC) and polyethylene terephthalate (PET), are demanded due to their properties, such as low weight, good impact resistance and forming with ease in medical or industrial fields. However, these polymer materials have a weakness for the impermeability of oxygen or carbon dioxide gases. Polymers with high gas barrier properties are required for packaging of foods or drinks, protecting the environmental pollution of cars, organic light emitting display (OLED) and so on. For example, a water vapor transmission rate (WVRT) of 10-50 g/m^2·day is enough for the dampproof packaging sheet for the products to contain fats and oil [1], on the other hand, in order for the transparent panels of OLED to have reliable performance and practical lifetime, an oxygen transmission rate (OTR) of below 10^{-5} cm^3/m^2·day and WVTR of approximately 10^{-6} g/m^2·day at 39 ºC and 95% RH are required [2]. It is well known that organic light emitting device structures and other active display materials degrade in the presence of oxygen and moisture.

In order to improve the gas barrier properties, various coating techniques, such as plasma-enhanced chemical vapor deposition (PECVD) [3-6], ion implantation or ion-assisted deposition [7-9], DC or RF magnetron sputtering [10, 11], and so on, have been studied. And also, various type of thin films grown on polymer substrates, such as diamond like carbon (DLC) or tetrahedral amorphous carbon (ta-C) [12,13], hydrogenated amorphous carbon (a-C:H) [3-5,14,15], and aluminum or silicon oxide (AlO_x or SiO_x) films [16-19], and so on, have been investigated. Among these techniques, surface wave plasma chemical vapor deposition (SWP-CVD) is one of the most suitable techniques for low temperature not to deform polymer substrate with low heat resistance, and allows large area thin film deposition. Therefore, we have carried out making the gas barrier coating by a-C:H films which can be prepared by SWP-CVD of helium and methane mixture gas at low pressure. In this paper, we have reported on the deposition and the gas barrier properties of a-C:H film coated on high density polyethylene (HDPE) and PET sheets.

2. Experimental set up

In this study, we have employed the SWP-CVD system for the deposition of a-C:H films at low temperature. A schematic drawing of the experimental setup is shown in Fig. 1. The SWP was produced in a 400 mm diameter, cylindrical vacuum chamber by introducing a 2.45 GHz microwave through a quartz window via slot antennae [20]. A rectangular quartz window with inner dimension of 109 mm x 380 mm is used as vacuum sealing on the top metal plate. Five transverse slots are cut vertically to the waveguide axis with a spacing of one-half of the waveguide wavelength, and four pair of longitudinal slots are also cut

between the transverse slots. The length and width of each slot are 61 mm and 10 mm, respectively. The vacuum chamber was evacuated to ~10^{-6} Torr using a turbo molecular pump.

In the SWP, the microwave introduced through the slot antennae damps exponentially below the quartz window where the electron density exceeds the cutoff density [21]. The high density plasma with uniform electron density more than 10^{11} cm^{-3} was formed in the vacuum chamber and broadened in the downstream region due to the particle diffusion.

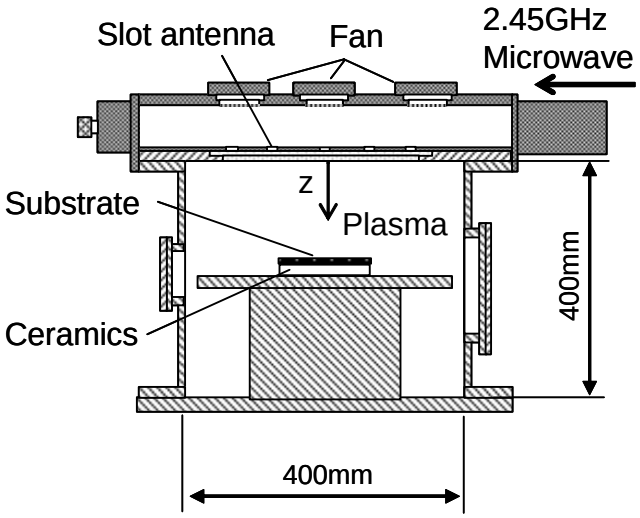

Fig.1. Schematic drawing of the experimental setup.

Film deposition was carried out on HDPE and PET substrates with a thickness of 1.0 mm placed on the substrate stage at 185 mm below the quartz window. The launched microwave power was typically 650 W and the total gas pressure was 2.0 Torr, where the gas flow rates were 280 sccm for helium and 6 sccm for methane.

To investigate the characteristics of the deposited films, we carried out the measurements of Fourier-transform infrared spectroscopy (FT-IR), the atomic force microscope (AFM) and gas permeation. FT-IR spectra of the deposited films were obtained with a JASCO FT/IR-550 spectrometer used in transmission mode in the spectral wave number form 1000 to 4000 cm^{-1}. In the FT-IR measurements, samples deposited on silicon substrate were used. The absorbency of the silicon substrate was subtracted from the measured spectral absorption curves. The morphologies of deposited films were characterized by AFM (SEIKO SPI3700). The gas transmission rate (GTR) was measured as an index of the gas barrier effectiveness of polymer sheet by manometer method. The measured polymer sheet was installed to vacuum chamber for the measurement of GTR and sealed using a vacuum rubber ring. The vacuum chamber sealed with the polymer sheet was pumped to 1×10^{-6} Torr, and it was closed by a valve. After then, the increase in pressure of the vacuum chamber was monitored with a pressure gauge. The measurements were curried out for polymer sheets and SUS plate without gas permeation. The increase in pressure in the case of SUS plate is considered that the effect of gas release from the plate surface and the inner wall surface of the chamber appeared significantly. The GTR of polymer sheets can be estimated by subtracting the outgas effect of chamber wall from the results of polymers.

3. Results and discussion

In the CVD experiments, a small amount of methane gas was added into helium gas at a pressure of approximately 2.0 Torr. Polymer sheets used in the coating were cut in a size of 70 mm x 70 mm. The special uniformity of amorphous carbon film thickness is less than ±5% over a diameter of 100 mm. The deposition rate is approximately 11~13 nm/min.

The polymer sheet is easily influence by heating, and the glass transition temperature and softening temperature of polymers are considerably lower than the melting of them. The glass transition temperature of PET and the softening temperature of PE are around 77 ºC and 130 ºC, respectively. Therefore, it is necessary to make a coating of polymer sheets at the low temperature of 75 ºC or less to avoid the change of physical properties and the transformation of shape by heat. Figure 2 shows the temperature measured by thermal labels attached to a glass plate on substrate stage. The temperature of substrate and the deposition rate depend on the position of substrate and the microwave power. In the condition of z=185 mm and the microwave of 650 W, the temperature changed from 20 ºC at room temperature to 75 ºC with the 15 minutes

of plasma irradiation as shown in Fig. 2. In addition, polymer sheet was warped at higher than 75 ºC, the height of swelled rule in PET sheet was from 2.0 mm to 2.7 mm after the deposition of 20 minutes. The measured maximum temperature in the deposition of 20 minutes was 80 ºC. On the other hand, the change of swelled rule in PE sheets was not so large after CVD, i.e. less than 0.1 mm.

In order to investigate the bonding structures of the carbon film, FT-IR measurement was carried out. Figure 3 shows the FT-IR transmittance spectrum of the deposited films. The prominent absorption bands are observed between 2800 and 3000 cm^{-1} corresponding to sp^3 C-H bond, which indicate a bond in diamond with tetrahedral geometry. The absorptions at 2870, 2930 and 2960 cm^{-1} are corresponding to sp^3-CH_3 symmetric, sp^3-CH_2 asymmetric and sp^3-CH_3 asymmetric C-H stretching [5,14], respectively. Also, the absorption band ranged from 3000 to 3100 cm^{-1} is typical for sp^2-bonded carbon [22]. A weak absorption corresponding to sp^2 C-H asymmetric C-H stretching appears in the 3050 cm^{-1} region [23]. In the region between 1000 and 1800 cm^{-1}, broad asymmetric peaks are observed, which are typical characteristics of amorphous carbon films [24]. The absorption at 1580 cm^{-1} is assigned to C=C double-bond stretching vibration [25], which indicates non-graphite bonding of carbon [26]. The distinct absorption bands ranged from 1640 to 1900 cm^{-1} are assigned to be due to C=O. [27] The absorption centered around 2357 and 2140 cm^{-1} can be ignored because they result from background noise, corresponding to the CO stretching vibration. The result of FT-IR spectrum shows that the film structure is composed of hydrogen linked to carbon mainly in sp^3-CH_x bonding, which is consistent with the polymer like amorphous carbon [25]. According to NMR analysis of a-C:H films under a gas flow rate of 280 sccm in helium and 6 sccm in methane, a fraction of sp^2-carbon bonding was approximately 25% and that of sp^3-carbon bonding was approximately 75%, respectively [28].

Figure 4 shows AFM image of the surface morphology of a-C:H film deposited on silicon substrate with film thickness of 0.43 μm when the

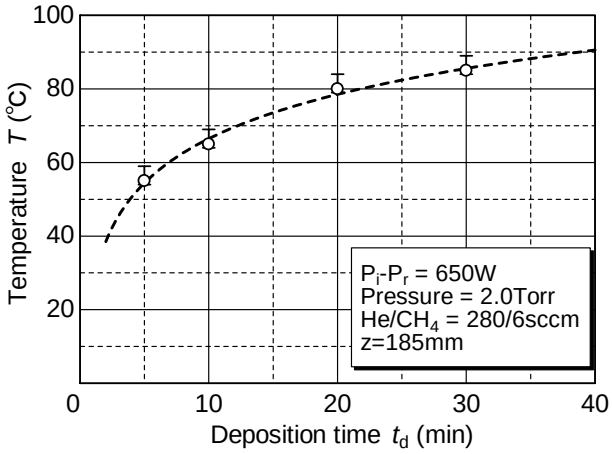

Fig.2. The relation between stage temperature and the deposition time.

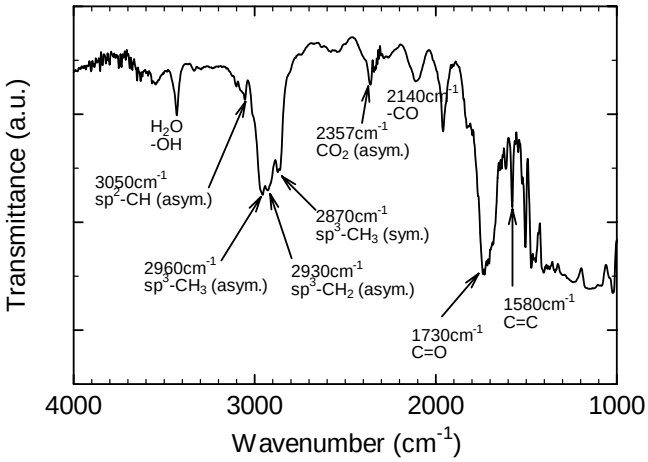

Fig.3. FT-IR transmittance spectrum of a-C:H film deposited at the microwave of 650 W, He/CH_4= 280/6 sccm, pressure of 2. 0 Torr, z=185 mm and film thickness of 620 nm.

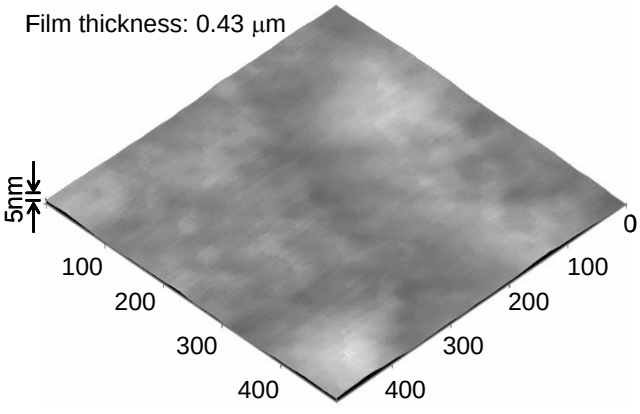

Fig.4. AFM image of a-C:H film deposited on silicon substrate with film thickness of 0.43 μm.

gas flow rates were He/CH_4 =280/6 sccm. The surface morphology of a-C film is considerably flat and smooth with the surface roughness of a few nm.

The downstream pressure p_g changes due to the permeation of air through (a) HDPE and (b) PET sheets covered with different thickness of a-C:H film are plotted as a function of time after closing the valve in Fig.5, where the increase in the extra pressure due to the outgas from chamber wall was subtracted. In the present experimental conditions, though air was used for the gas permeation measurement, the permeating gas particles could be considered to be mainly oxygen molecules considering the composition ratio of air and the gas species dependency of permeability, diffusivity and solubility [29]. The GTR is obtained from the gradient dp_g/dt of these curves which are proportional to it. In all cases the film deposition of a-C:H results in a reduction of gas permeation. It was found that the GTR had decreased from 135 to 5.8 $cm^3/m^2 \cdot day \cdot atm$ when HDPE sheet surface was covered with the a-C:H film thickness of 620 nm. From the results, it was found that the gas barrier properties of the HDPE sheet had been 2~23 times better than uncoated one depending on film thickness. Furthermore, the a-C:H coating on PET sheet shows better barrier property about 0.27 $cm^3/m^2 \cdot day \cdot atm$ at film thickness of 207 nm. The gas barrier performance of coated polymers depends on coating film thickness and substrate roughness. Rougher surfaces require thicker coating for maintained barrier properties. However, thicker coating tends to result in cracking. When the film thickness becomes 310nm and 620nm, it seems that the effect of cracking decreases in adhesion of a-C:H films or thermal stress during plasma irradiation appears sensitively.

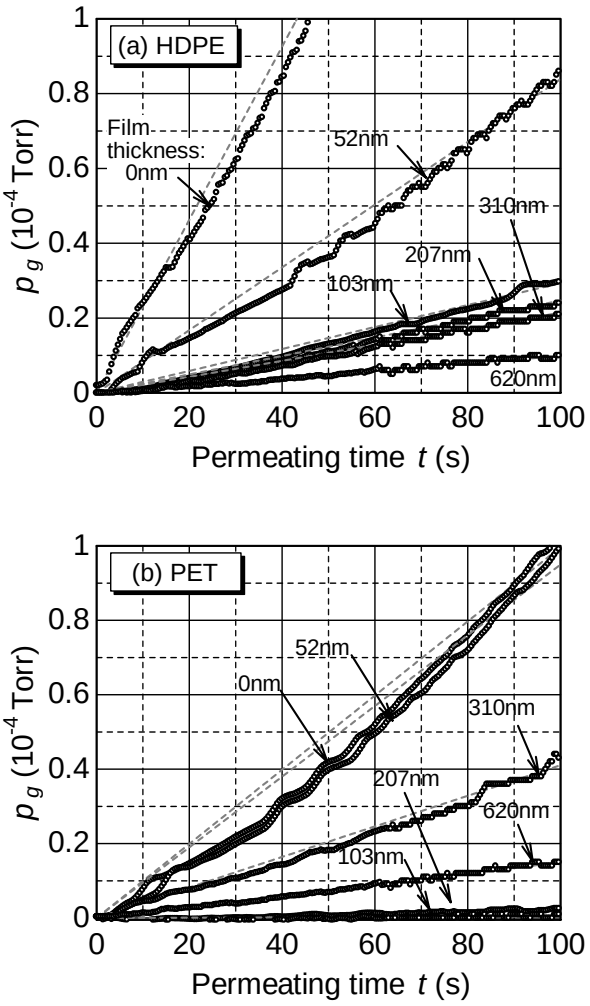

Fig.5. The downstream pressure p_g changes due to the permeation of air through (a) HDPE and (b) PET sheets covered with different thickness of a-C:H film under the conditions of 15~18 ºC and ~40%RH.

4. Conclusion

In this study, we carried out making the gas barrier coating by a-C:H thin films which can be prepared by SWP-CVD of helium and methane mixture at low temperature. The launched microwave power was typically 650 W and the total gas pressure was 2.0 Torr, where the gas flow rates were 280 sccm for helium and 6 sccm for methane. The temperature of substrate stage at 185 mm below the quartz window changed from 20 ºC at room temperature to 75 ºC with the 15 minutes of plasma irradiation. According to FT-IR measurements, the a-C:H film structure is composed of hydrogen linked to carbon mainly in sp^3-CH_x bonding. The a-C:H film possesses polymer-like structure. Gas permeation measurements show that the GTR of polymers covered with a-C:H film has been improved compared with uncoated one. It was found that the GTR of HDPE had decreased from 135 to 5.8 $cm^3/m^2 \cdot day \cdot atm$ with the a-C:H film thickness of 620 nm. The gas barrier properties of the HDPE sheet had been 23 times better than uncoated one. The GTR of PET

sheet with 207 nm a-C:H film was about 0.27 $cm^3/m^2 \cdot day \cdot atm$. However, the present GTR is far away from 10^{-5} $cm^3/m^2 \cdot day$ for the enough lifetimes of flexible and lightweight OLEDs.

Preparation of solution containing luminescent nanocrystalline silicon particles for medical application

K.Shinoda, S.Yanagisawa, K.Sato, and K.Hirakuri

Department of Electronic & Computer Engineering, Tokyo Denki University
Ishizaka, Hatoyama, Saitama 350-0394, Japan

Introduction

Semiconductor nanoparticles have attractive characteristics for a luminescent phenomenon, i.e., size-depended luminescence. Especially, nanocrystalline silicon (nc-Si) particles are useful candidate materials for medical applications such as cancer cells observation and drag delivery system because they have good biocompatibility. The nc-Si particles, however, are inexpedient for medical applications to exist in the thin film under the general synthesis methods. Therefore, the condition of nc-Si should be changed from thin film form to particle structure owing to supply in the medical fields.

In this study, we report a synthesis technique for the particle shape of nc-Si using plasma processing and wet process. Moreover, the shape and photoluminescence (PL) property of the nc-Si particles will be discussed.

Experiments

The solution containing the nc-Si particles was fabricated by manufacturing process as shown in Fig. 1. Samples were deposited on a p-type Si (100) substrate using a radio frequency (RF) sputtering method which is one of dry process [1]. A sputtering target used 36 pieces of p-type Si (100) chips with 5 mm × 5 mm placed on a SiO_2 with purity of 99.99 % and 100 mm diameter. The Si chips/SiO_2 target was sputtered in argon (Ar) atmosphere at a gas pressure of 1.33 Pa and a RF power of 200 W for 240 min. To form the nc-Si particles the sample, subsequently, was annealed at 970 ℃ in Ar atmosphere for 60 min. The nc-Si particles were prepared in a SiO_2 layer with thickness of 3 μm (Fig. 1(a)). The thick SiO_2 layer, then, was etched by hydrofluoric (HF) acid steam (wet process) for 5 min to uniformly extract the nc-Si particles on substrate surface (Fig. 1(b)) [2]. After the HF treatment, the nc-Si particles were shaken off from the substrate into the solution by supersonic wave treatment and thereby they were dispersed in the solution (Fig. 1 (c)).

The size and shape of nc-Si particles was confirmed by using high-resolution transmission electron microscopy (HRTEM). The PL spectra of nc-Si particles in the solution were detected by using a photonic multichannel analyzer. The light source was utilized a Xenon lamp with an optical band-pass filter of 313 nm.

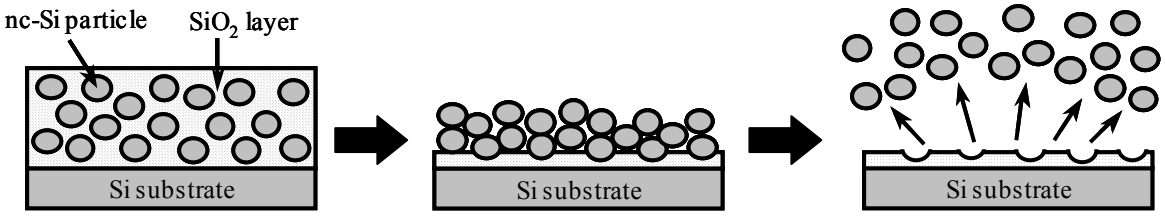

Fig. 1 Schematic illustrations of manufacturing process for the solution with nc-Si particles form: (a) annealing at 970 ℃ ; (b) HF treatment; (c) supersonic wave treatment.

Results and discussion

The existence of the nc-Si particles was confirmed by the presence of regular lattice fringes by the HRTEM observation. The lattice fringes were corresponded to (111) plane of cubic Si (diamond structure) with correct atomic spacing of 0.314 nm. The nc-Si was uniformly dispersed with a spherical form. Moreover, the average size of nc-Si particles was approximately 2.5 nm.

Figure 2 shows the PL spectra for the solution containing the nc-Si particles. The solution exhibited the strong and stable red PL with a peak of 670 nm. The PL peak wavelength of the solution was as same as that of the thin film form with the nc-Si. This result indicates that the PL spectra of both particle form and thin film form is originated from same radiative recombination process between electron and hole.

From the above results, the condition of nc-Si could freely change from the thin film form to the particle form by using the processes of dry and wet. And the nc-Si particle was stably existed without the transform of shape in the solution. This leads to stable and strong red luminescence. Consequently, the nc-Si particles fabricated in this study would be sufficiently adapted to apply for medical fields.

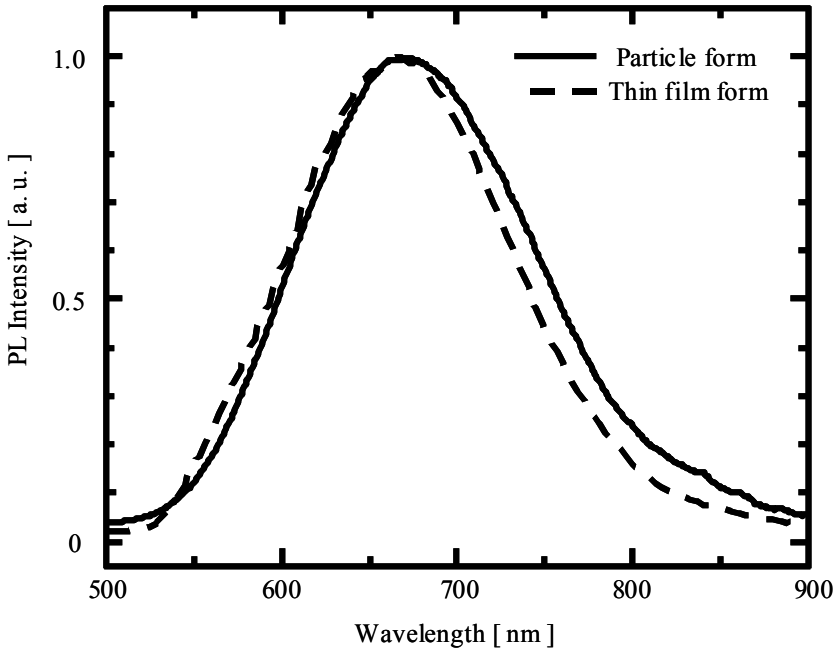

Fig. 2 PL spectra of the thin film form and the particle form.

Conclusions

We have investigated the formation condition and PL property of the solution containing the luminescent nc-Si. The nc-Si particles with size of 2.5 nm were uniformly formed with the spherical form. The solution with the nc-Si particles strongly and stably emitted the red light.

Investigations into the vibrational populations of the N_2 A-state ($^3\Sigma_u^+$) and the N_2^+ ground state ($^2\Sigma_g^+$)

L. Thornton[1], G. Hancock[1], R. Peverall[1] and G.A.D. Ritchie[1]

[1]*Physical and Theoretical Chemistry Laboratory, Oxford University, Oxford, United Kingdom*

Session Topic 2: Gas Phase Plasma Diagnostics

The populations of the $v = 0$, 1, 3 and 6 levels of the $^3\Sigma_u^+$ state (the A-state) of N_2 have been studied as a function of plasma power and pressure in an inductively coupled plasma (ICP) chamber. This was achieved using tunable diode lasers to probe the $^3\Pi_g \leftarrow {}^3\Sigma_u^+$ (B ← A) transition at the wavenumbers listed in table 1. The low concentrations of these species required the use of cavity enhanced absorption techniques to enhance the effective pathlength through the plasma chamber.

In Cavity Enhanced Absorption Spectroscopy (CEAS), laser radiation is injected into the back of one of a pair of AR-coated high reflectivity mirrors (typically R = 99.94) and the cavity is then intentionally mis-aligned to produce a highly congested mode structure. Leakage of the light out of the second mirror is incident upon a PMT. Rapid scanning of the laser radiation across the transition and subsequent averaging produces the absorption feature. The laser radiation background, I_0, and the optical emission from the plasma, γ, must both be removed from the raw data to enable analysis to be undertaken using equation 1.

Table 1: Transitions frequencies of the vibrational bands

Line	Band Centre (cm^{-1})
$v = 3 \leftarrow 0$	14580.7
$v = 3 \leftarrow 1$	13147.9
$v = 6 \leftarrow 3$	15133.0
$v = 7 \leftarrow 6$	12699.1

$$\text{CEAS Signal} = \frac{I_0 - I(v)}{I(v) - \gamma} = \frac{\alpha L}{1 - R} \qquad (1)$$

Conversion of the resultant signal into an absorption coefficient α is achieved with a knowledge of the physical length of the cavity (L) and the reflectivity of the mirrors (R). The latter is obtained using Cavity Ring-Down Spectroscopy (CRDS) where, upon mode excitation, an Acousto Optic Modulator (AOM) is used as a fast switch to cut-off the laser radiation being fed into the cavity. This allows the decay of the light intensity from the cavity to be recorded as a function of time using a PMT, an example trace of which is shown in figure 1. The spectra of the bands are assigned using a simulation program [1] and spectroscopic constants [2], [3] taken from the literature. Figure 2 shows a section of the (3, 1) band.

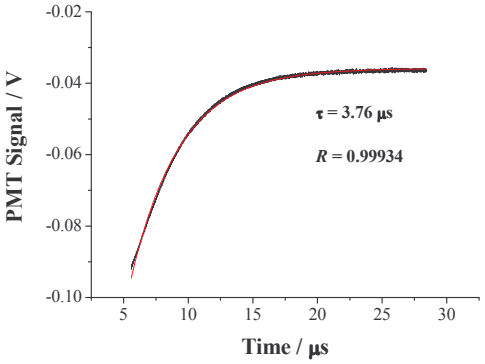

Figure 1: CRDS trace taken at 13149 cm^{-1} to obtain the mirror reflectivity (R).

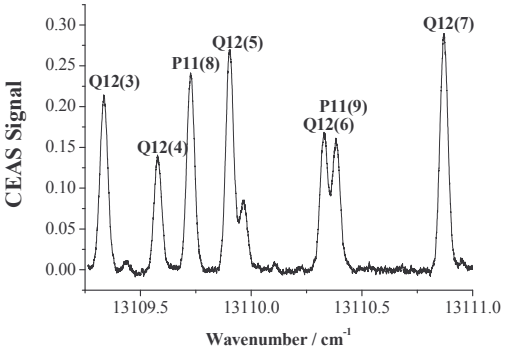

Figure 2: A section of the (3, 1) band taken at 300 W and 10 mTorr plasma power and pressure.

The absorption coefficients are converted into absolute concentrations of the ro-vibrational levels using cross-sections taken from the literature [4], [5], [6]. Conversion of these into the total concentrations of the various vibrational levels was achieved assuming a Boltmann distribution over rotational levels, weighting for the nuclear spin and inputing the rotational temperature which is obtained from comparing the intensities of two different rotational lines. This temperature was found to be independent of plasma pressure (~ 350 K for 100 W) but increased with plasma power (from ~300 K at 50 W to ~ 500 K at 500 W). The translational temperature is calculated from analysing the Doppler Widths of the absorption profiles and is found to be in agreement with the rotational temperature. Figures 3 and 4 show how the concentrations of these vibrational levels vary with plasma parameters.

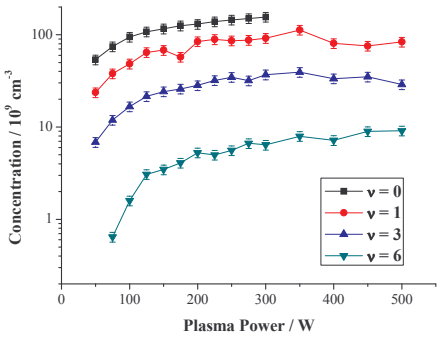

Figure 3: Vibrational populations measured at 25 mTorr plasma pressure.

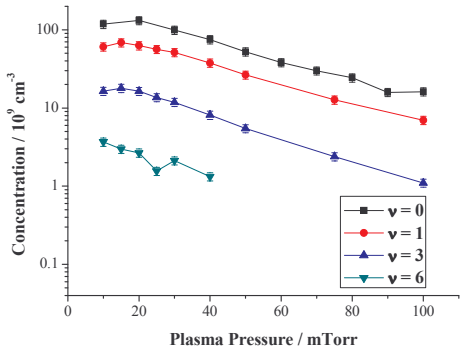

Figure 4: Vibrational populations measured at 100 W plasma power.

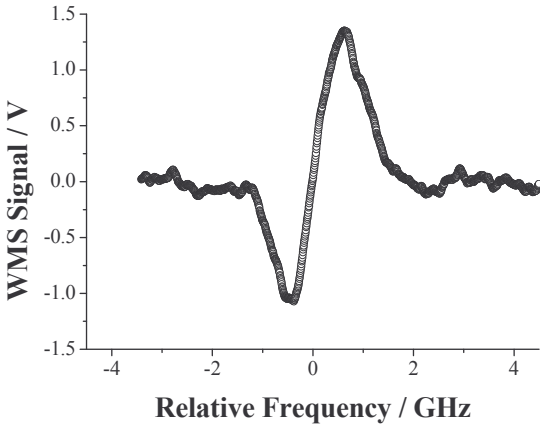

Figure 5: CEAS/WMS 1st harmonic trace taken at 10 mTorr and 400 W plasma pressure and power.

The technique of CEAS is combined with wavelength modulation spectroscopy (WMS) in an observation of the $v = 0$ level of the ground state ($^2\Sigma_g^+$) of N_2^+, utilising a diode laser at 12677 cm^{-1} corresponding to the (2, 0) band of the $^2\Pi_u \leftarrow {}^2\Sigma_g^+$ (A ← X) transition. The use of WMS is expected to improve the sensitivity as the noise in the system is dominated by plasma emission, and the detectivity increased from $\alpha_{min} = 3.49 \times 10^{-8}$ cm^{-1} $Hz^{-1/2}$ for homodyne CEAS to $\alpha_{min} = 3.91 \times 10^{-9}$ cm^{-1} $Hz^{-1/2}$ for CEAS combined with WMS. A typical trace is shown in figure 5. The spectra can be assigned to N_2^+ using [7] and a cross-section calculated using constants found in the literature [5], [6] to extract a total N_2^+ concentration of $(2.68 \pm 0.32) \times 10^9$, which shows a weak increase with plasma power and a weak decrease with plasma pressure. Electron density measurements taken previously with a Langmuir probe suggest a value for $[e^-]$ of $\sim 5 \times 10^9$ cm^{-3}, which may present evidence for the existence of other charged species inside the plasma.

Abstract

Magnesium and aluminum are very important in technology but are characterized by very low hardness and wear resistance. By using microarc discharges in different ecologically safe electrolytes the properties of magnesium and aluminum surfaces were improved by growing thick oxides films. Results about the properties of microarc discharges and on the properties of treated surfaces obtained under different experimental conditions are reported.

Keywords: Magnesium; Aluminum; Microarc discharge; Electrolyte

1. Introduction

The micro arc discharge oxidation of materials is gaining increased attention as a new and innovative technique for depositing thick, dense and hard ceramics on metals from valve family (Al, Mg, Ti, V) and a wide range of their alloys. This process combines an electrochemical process (anodic oxidation) with a plasma process (micro arc discharge) and the resulted coating exhibit superior mechanical properties and superior adhesion on the substrate as compared with the classic anodic oxide coating. The ceramic coatings obtained by using the above technique are characterized by many useful properties as controllable thickness, high hardness and wear resistance, low friction coefficient, improved corrosion resistance and high resistivity at high temperature [1]. All these properties recommend this process as being of real interest to different industries and many applications can be developed for chemical, mechanical, thermal, electrical, food processing, aerospace, environment protection and electronics industries.

By applying a positive voltage to a sample made from metal of the valve family, immersed in a low concentration alkaline electrolyte, the oxidation of surface occurs and forms an oxide layer at the anode-electrolyte interface. When the applied voltage exceeds a threshold value and, on a local area of the anode, the electric field is greater than the dielectric breakdown field for the oxide, micro arcs develop as a result of dielectric breakdown of the growth oxide film. This process is accompanied by visible light emission and by a high frequency noise. The voltage threshold value is dependent on electrolyte concentration and on the nature of treated material. These micro arc discharges are short-lived, move randomly on the treated surface and promote plasma-chemical reactions on the surface of anode. The high locally electric field determines that OH^- anions to be drawn into discharge micro channel. Positive metal ions from the substrate and negative OH^- ions from the electrolyte react and form oxides in the places where micro arcs develop. The growth oxide film is formed mainly by conversion of the substrate material and by deposition of electrolyte components. The material in the channel is heated by locally high density plasma up to temperatures higher as 10^4 K [2]. Locally developed transient high temperatures melt the anode material, enter the micro channel and get oxidized, growing the oxide layer into the substrate and improving the adherence. The low temperature electrolyte in contact with the melted material determines a very high cooling rate and different nano crystalline phase are promoted in the growth film together with amorphous material. The reaction products are deposited onto the walls of micro channels. The location of the micro discharge moves randomly on the all anode surface and promotes the increase in the coating thickness. Oxygen and steam gases, anodically produced, determine the growth oxide layer to be porous with porosity dependent on the discharge parameters.

2. Experimental details

The treatments were performed by using an electrochemical cell (1) with treated surface as anode (3) and a stainless steel plate (4) with a much higher area as cathode (Fig.1). The temperature of electrochemical cell was kept at low temperature (approximately 10°C) by a stainless steel coil with circulating cooling fluid (6).

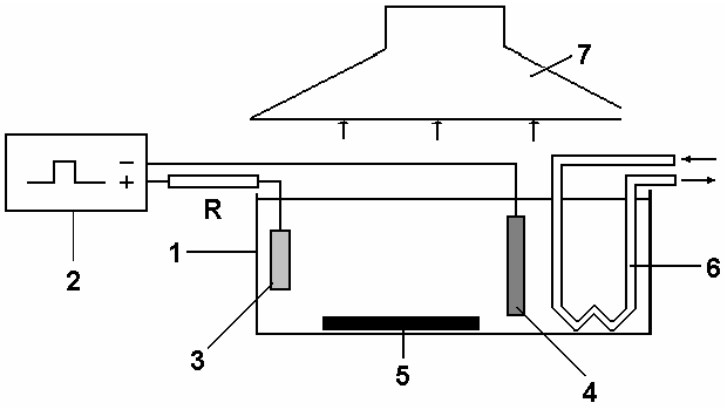

Fig.1. Experimental set-up for micro arc discharge treatment of aluminum and magnesium surfaces
1- electrolytic cell; 2 –pulsed power supply; 3 – Al or Mg treated substrate as anode; 4 - high area stainless steel cathode; 5 – magnetic stirrer, 6 – cooling coil; 7 – ventilation system

In order to homogenize the electrolyte composition and temperature, an external propelled magnetic stirrer was utilized (5). A variable frequency, pulsed power supply in constant current, voltage or constant power modes was utilized in the time of process (2). Low concentration of sodium hydroxide and tri-sodium phosphate in distilled water were utilized as electrolytes. The pH of solutions was controlled in the time of process and kept at high values between 8 and 12. The properties of microarc discharge were characterized by measuring current – voltage characteristics. A high speed digital camera was utilized to obtain information about the evolution of microarcs onto the surface of the anode. The properties of treated surfaces were analyzed by different techniques: Field Emission Scanning Electron Microscopy interfaced with Energy Dispersive X-ray analyzing system (FESEM - EDX, JEOL JSM- 6330F), X-ray difractometry (Rigaku X-ray Difractometer) and nanoindentation (TriboScope ^{TM} Nanomechanical Test Instrument).

3. Experimental results and discussion

Current-voltage characteristics revealed three regions in the operation of the treatment process (Fig.2). In the first region, for low input voltages, the current intensity was low and only oxygen evolution on the anode and hydrogen evolution on the cathode surfaces were observed. This first region is characterized by a low slope of current-voltage characteristic. In the second region, by increasing the applied voltage, the current intensity and the quantity of evolved gasses increases rapidly and also the slope of current voltage characteristic has a high value. When the applied voltage exceeds a threshold value, dependent on the anode material, electrolyte and electrolyte concentration, microarcs begin to develop on the surface of the anode. This process is accompanied by visible light emission and by a high frequency noise. At the end of second region all the surface of the anode was covered by micro arcs. By increasing the applied voltage the slope of current intensity variation changed to a lower value in the third region and the intensities of light and sound emitted by micro arcs developed on the treated surface increased. The behavior of current-voltage characteristics do not changes with the increase of electrolyte concentration, only the thresholds values of voltages between regions change to lower values, while the maximum current intensity increases. In the second and third regions the process is accompanied by intense heat generation, determined by the high temperature micro arcs developed on the anode, by ohmic lost in the electrolyte, from condensation of water steam generated in the vicinity of micro arcs and in the cooling time of melted oxide.

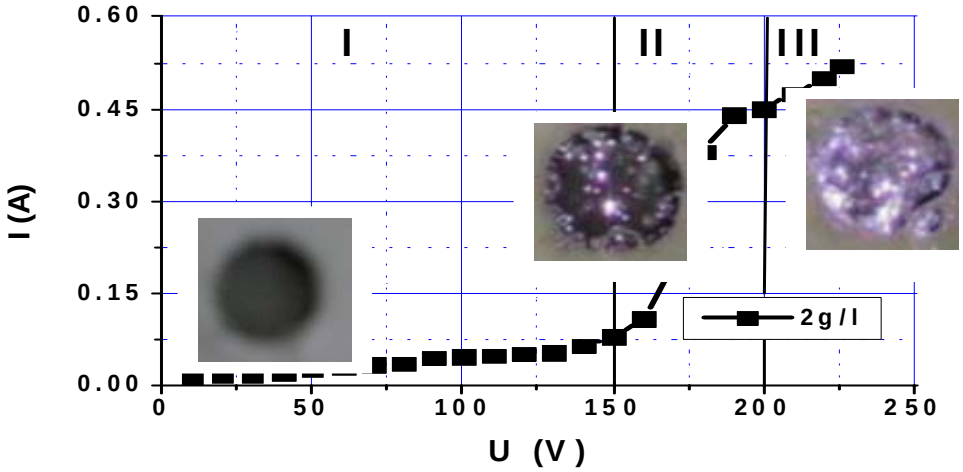

Fig.2. Current – voltage characteristic of microarc discharge (Al anode, NaOH electrolyte)

The amount of produced heat increased in the second region of current - voltage characteristics and attended maximum value in the third region. Electron microscopy images revealed that a porous oxide layer was formed onto the samples surface after the microarc plasma treatment of both materials (Fig.3 – FESEM images of surface and cross section of treated Mg substrate).

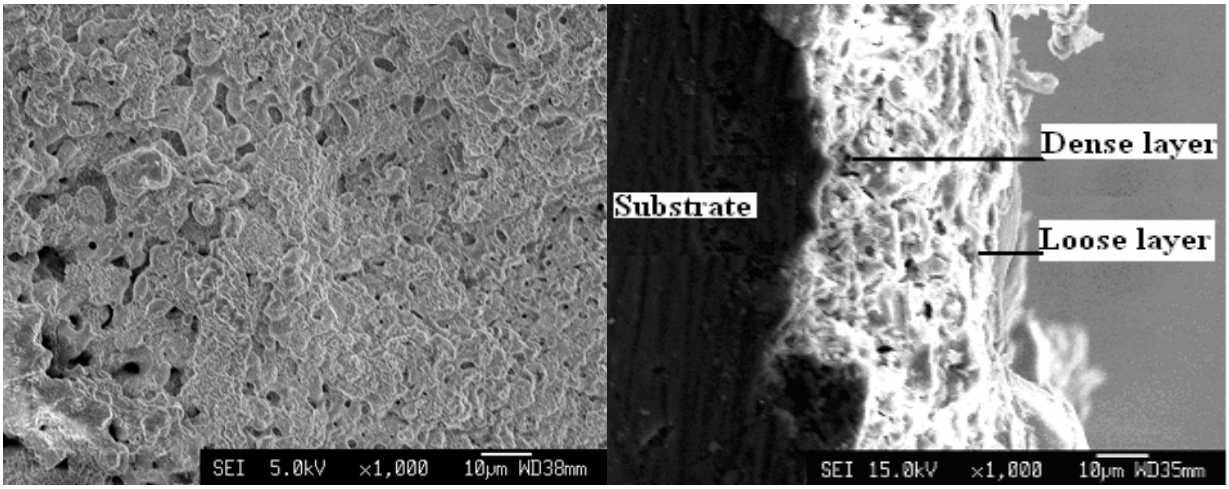

Fig.3. FESEM image of surface and cross section of treated magnesium sample

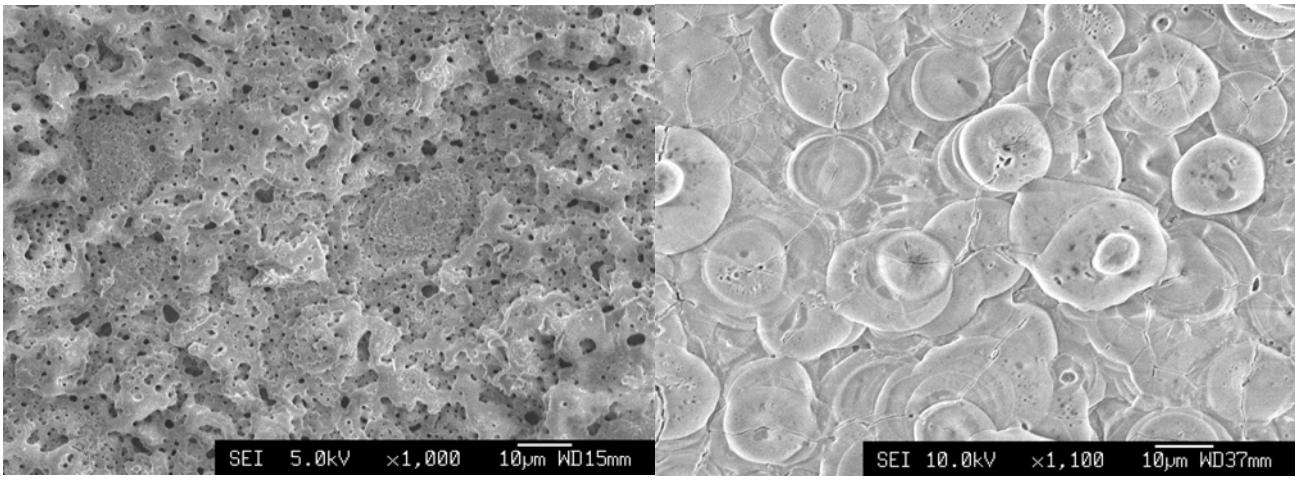
The morphology of surfaces was also dependent on the current density during the treatment (Fig.4, Al substrate). For low discharge current the porosity is high (Fig.4.a) and by increasing the discharge current the porosity decreases as a consequence of melting of produced oxide under the influence of high temperatures developed in the place of micro discharges (Fig.4.b). Two kinds of pores were observed: one in micrometer scale and

another one in nanometer scale. The pore diameter decreased with the increase of current intensity and, for a constant applied current, the thickness of the oxide film increased almost linearly with the time of treatment.



(a) (b)

Fig.4. FESEM images of treated aluminum sample

Higher growing rates as 1.5 μm/min was obtained for both substrates. XRD measurements of treated aluminum substrates indicated the presence of $\alpha - Al_2O_3$ and $\gamma - Al_2O_3$. The peak intensity of $\alpha - Al_2O_3$ was higher, indicating a high content of this phase and confirmed the high temperature developed in microarc discharge. This higher content of alpha phase in aluminum oxide film could explain the high value of hardness obtained from nanoindentation measurements (approximately 30 GPa) because alpha form of aluminum oxide is characterized by a high hardness. XRD measurements of treated magnesium substrates indicated the presence of MgO, the peak intensity increasing with the treatment time. EDX mapping indicated the presence of oxides on treated surfaces and a small amount of cations from utilized electrolytes.

Conclusion

The micro arc discharge in different electrolytes was utilized to treat the surfaces of aluminum and magnesium. The current – voltage characteristics indicated three region of the process. In the first region a normally anodization occurs. The micro arc discharge develops in the second and third regions of the process and is accompanied by intense heat generation. The growth rate of both aluminum and magnesium oxides was high and higher values as 1.5 μm/min were obtained. Deposited thin films presented a layered and porous structure. The external layer was with low strength and with high porosity. The internal layer was harder and well adherent to the substrate because the micro arc melts the growing film in the substrate. Different textured surfaces were obtained by controlling the growth condition of oxides. The measurements indicated that surface properties of light metals as magnesium and aluminum were improved by micro arc plasma treatment in different electrolytes, demonstrating a big potential for the treatment of complex configuration components as those utilized by aero spatial, ship and car industries.

Abstract
The properties of diamond like carbon thin films obtained with a hybrid method by combining the hollow cathode discharge and plasma enhanced chemical vapor deposition are presented. Methane and pyrrole were utilized as precursors for DLC thin films synthesis. The conductivity of deposited films increases in the low impedance state of discharge as a consequence of higher nitrogen content in deposited films resulted from the decomposition of pyrrole precursor.

Keywords: Diamond like carbon; Hybrid process; Hollow cathode; Plasma enhanced chemical vapor deposition; Mechanical and electrical properties;

1. Introduction

One of the main problems in the case of deposition of diamond like carbon (DLC) thin films by the most utilized capacitively coupled plasma enhanced chemical vapor deposition methods is the low deposition rate. In this case DLC thin films are deposited on powered electrode and this geometry determines a big connection between deposition rate and the properties of deposited thin films. This connection is determined by the importance of ion energies on the content of sp^3 bonded carbon atoms in deposited films. To increase the deposition rate it is necessary to increase the input power and the self bias voltage, responsible for ion energies, increases also. Optimum carbon ion energies, approximately 100 eV, were suggested by much experimental work in order to obtain high sp^3 content in thin films [1]. In a capacitively coupled RF powered CVD the self generated bias voltage is a measure of ion energies and, as an example, - 150 V bias voltage is obtained for only 50 W input power. For this input power the deposition rate is very low (8 nm/min) [2]. A possibility to overcome this problem is to use a hollow cathode discharge, characterized by high decomposition and ionization rates of precursor gases. In this case the reactive gases enter in the reaction chamber passing through high density plasma established inside of the hollow cathode and radicals and ionized reactive species forms DLC thin films on a separate biased substrate. In this way the substrate bias can be independently controlled in the view to obtain DLC thin films with desired properties.

2. Experimental set-up

The utilized experimental set-up is presented in Fig.1. A graphite tube with 8 mm external diameter, 5.5 mm internal diameter and 35 mm in length was utilized as cathode. This hollow cathode was capacitive coupled to a 13.56 MHz frequency and a variable power supply (0 - 400 W) or to a DC power supply. Thin films were deposited at different distances in the front of the cathode on a water cooled substrate holder. Methane (CH_4) and pyrrole (C_4H_5N), one of the most known monomer for conductive polypyrrole polymer processing, were utilized as precursors. Nitrogen was utilized as supplementary doping element in order to influence the conductivity of deposited DLC films. The properties of obtained thin films were compared with those prepared only with capacitively coupled plasma chemical vapor deposition system without hollow plasma enhancement. The substrates holder was biased by the same RF power supply and the measured bias voltages were utilized as indicator of ions energies involved in the growth of thin films. Thin films were deposited onto silicon and Al_2O_3 substrates in different experimental conditions: maximum 100 sccm mass flow rate of reactive gases, 10 to 400

W variable applied RF power on hollow cathode and variable negative substrate bias voltage between - 10 and - 800 V.

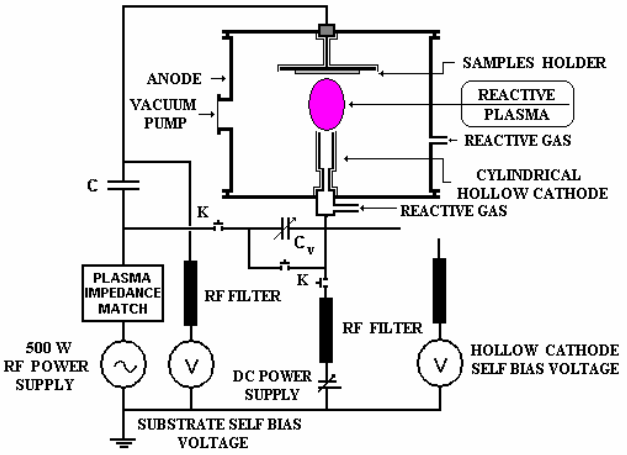

Fig.1. Experimental set-up

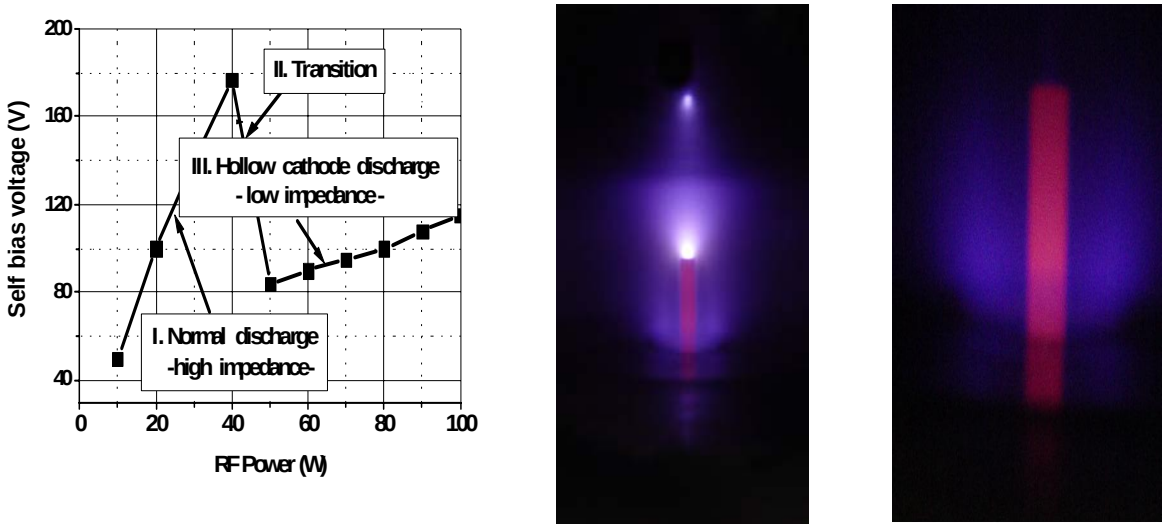
The surface morphology of DLC thin films was observed with an atomic force microscope (AFM; JSPM – 5200 T, JEOL). The deposition rate was estimated by measuring the thickness of deposited thin films using a surface profilometer (Surfatest SV-600, Mitutoyo). The infrared spectra of the films were analyzed in order to characterize carbon - hydrogen bonding in thin films (FTS 175 C, Bio- Rad). Raman spectra were recorded using a Jobin Yvon spectrometer with 514.5 nm laser excitation line and 10 mW output power. The spectra were fitted with curve fitting software, based on two Gaussian curve shapes, to identify the G and D peaks positions, to measure and compare the intensities (GRAMS/AI^{TM} from ThermoGalactic). The hardness and Young's modulus of the DLC films were determined from loading-unloading curves on a nanoindentation instrument (TriboScope, Hysitron). Ten indentations were made for each sample and the hardness and Young's modulus were calculated by averaging the measurements.

2. Experimental results and discussion

The hollow discharge presented two stable regimes: one with high impedance and another one with low impedance. The evolution of self bias voltage developed on the hollow cathode evidences very clearly this particularity: for a given pressure the self bias voltage increases with the increase of input power and then, at a specific power, suddenly decreases to a lower value. The bias voltage increases again with the increase of input power, as indicated in Fig.2.a. The reactive gas pressure influences the threshold values of input power for transition from normal plasma with high impedance (external to the cathode) to low impedance plasma (mainly inside of the cathode). This value increases with decreasing internal diameter of hollow cathode and by increasing the pressure of reactive gas. The low impedance state of discharge is explained by the increased plasma density induced by the multiple reflections of secondary electrons inside of hollow cathode. The transition in the low impedance state is accompanied by an increase of cathode temperature to very high values, as indicated in Fig.2.b, by the red color of graphite cathode. This behavior is determined by the increase of dissipated power inside the cathode. In the high impedance state the discharge is outside of the hollow cathode, as indicated in Fig.2.c (image obtained after the transition from low impedance state). As a characteristic of this geometry is the non uniformity of thin films. The highest thickness is obtained on the axis of hollow cathode with a radially decreasing tendency. Deposition rate increases after the transition in the low impedance state, being determined by the increased decomposition of precursors in high density plasma developed inside the hollow cathode. The nature of reactive gas precursor influences the deposition rate and the biggest value of 294 nm/min was obtained from pyrrole. This behavior can be explained by the content of five carbon atoms in

pyrrole molecule as compared with only one carbon atom in the methane molecule. Also the ionizing potential is different: 8.8 eV in the case of pyrrole and 12.2 eV in the case of methane. This difference influences the plasma density obtained for the same input power, the biggest value being obtained in the case of pyrrole precursor.



(a) (b) (c)

Fig.2. a - Transition modes of hollow cathode discharge;
b - Image of the discharge in low impedance state;
c – Image of the discharge after the transition from low to high impedance state

The deposition rate increases with the increase of input power on hollow cathode and the bias voltage applied on the substrate. The deconvolution of Raman spectra presented in Fig.3 reveals the presence of graphitic and disordered graphitic components in thin films (G band, I_G - 1580 cm^{-1} and D band, I_D - 1370 cm^{-1}). The integrated intensities ratio I_D/I_G increases with the increase in the input power suggesting a decrease in the sp^3 fraction and the increase of disordered sp^2 fraction in deposited DLC thin films.

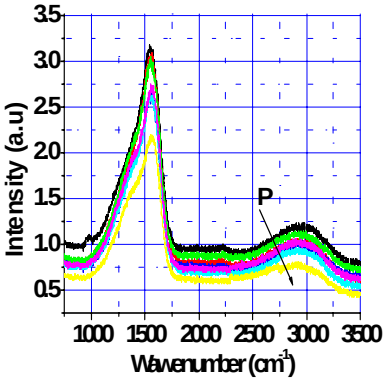


Fig.3. Raman spectra of DLC thin films obtained from pyrrole for increased input power

The infrared transmission spectra at wave numbers from 700 to 4000 cm^{-1} were analyzed in order to characterize the bonding of hydrogen and nitrogen with carbon in thin films. The deposited films were transparent in the infrared range. The spectra are characterized by absorption peaks centered at 1400 cm^{-1}, 2189 cm^{-1}, 2955 cm^{-1} and 3368 cm^{-1}. The high intensity and large absorption peak at 1400 cm^{-1} is a superposition of unsolved bands situated in this region, determined mainly by N-H bending and C=C stretching. The intensity of this peak increases with the increase of input power, suggesting the increase of nitrogen content in thin films. The peak registered at 2189 cm^{-1} was assigned to CN triple bonds stretching. The intensity of this peak increases with the increase of the input power or by adding nitrogen in the discharge, indicating the increase of nitrogen content in thin films. The peak at 2925 cm^{-1} was associated with the C-H stretching of sp^3 - CH_3 (2885 cm^{-1}), with sp^3 - CH_2 (2920 cm^{-1}) and sp^3 - CH_3 (2955 cm^{-1}) group. The peak at 3368 cm^{-1} was associated with the pyrrole monomer not decomposed in the plasma and included in thin films. The intensity of this peak decreases at higher input powers, indicating the decrease of residual pyrrole in thin film. Also, the adding of nitrogen in the discharge induces the decrease of the intensity of the peak situated at 3368 cm^{-1}, indicating a more efficient decomposition of pyrrole monomer. AFM measurements reveal a very smooth surface of thin films obtained from both precursors without important change with the increase of input power and bias voltage. RMS roughness of deposited thin films decreases with the increase of bias voltage (from 4.5 nm at - 50 V bias voltage to 0.8 nm at - 400 V bias voltage). From nanoindentation measurements resulted the increase of hardness with the increase of bias voltage with a maximum value of 16 GPa obtained at - 150 V bias voltage. The main advantage of hollow cathode plasma enhanced chemical vapor deposition geometry, high deposition rate, is diminished by the nonuniformity of thin films deposited in static mode, without the movement of substrate in the front of the cathode. To overcome this disadvantage, a twin hollow structure with parallel connected hollow cathodes was designed and tested. The influence of the distance between cathodes on the uniformity of deposited films was investigated. A distance of 10 mm between the axes of hollow cathodes was found as optimum for a nonuniformity less than 10% in the thickness of deposited thin films. To obtain larger uniform thin films by utilizing this geometry it is necessary to move the substrate in the front of a multi hollow structure, the number of parallel connected hollow cathodes being determined by the dimensions of substrates. Electric measurements of DLC films deposited onto aluminum oxide substrates showed that the resistivity was very high for low values of bias voltages ($\rho > 10^7$ k Ω·cm at -100 V) in the case of DLC films obtained from both precursors and decreased for higher values of input power, the bigger decrease being obtained in the case of pyrrole ($\rho \approx 55$ kΩ·cm at – 700 V). Nitrogen addition in the pyrrole discharge induces a further decrease of the resistivity, 3.5 kΩ·cm being obtained for 20 sccm mass flow, suggesting that nitrogen acts as a weak donor element.

3. Conclusion

By using a hollow cathode plasma enhanced chemical vapor system and a plane cathode plasma enhanced chemical vapor deposition system, DLC thin films were deposited from methane and pyrrole. DLC with similarly mechanical and electrical properties were obtained by using both geometries. DLC films were transparent in IR spectrum, with absorption peaks characteristic for carbon bonding with hydrogen and nitrogen. The deposited films were nonuniform as a consequence of axially symmetric geometry of generated plasma, with the maximum thickness on the axis of the hollow cathode. To obtain larger uniform thin films by utilizing this geometry it is necessary a multi hollow structure with the movement of the substrate, the number of parallel connected hollow cathodes being determined by the dimensions of the substrate. From the experiments made with a twin structure with parallel connected hollow cathodes, a distance of 10 mm between the axes of hollow cathodes was found as optimum for nonuniformity less than 10% in the thickness of deposited thin films.

Abstract

Results about mechanical, electrical and electrochemical properties of diamond – like carbon thin films obtained by plasma enhanced chemical vapor deposition (PE-CVD) method are presented. The overpotential for hydrogen and oxygen evolution is larger than that of graphite electrode. The electrochemical window of DLC (approximately -1.0 to + 2.5 V vs. Ag/AgCl electrode) is lower than that of diamond electrode (about -1.25 to + 2.30 V) and is higher as electrochemical window of graphite electrode (- 0.40 to + 1.60 V).

Keywords: Diamond like carbon; Plasma enhanced chemical vapor deposition; Mechanical, electrical and electrochemical properties;

1. Introduction

Diamond like carbon (DLC) is a promising material for application in different fields as mechanics, electronics, optics, tribology and chemistry. DLC thin films are characterized by many properties similarly with diamond: high hardness, high elastic modulus, transparency in infrared region of electromagnetic spectrum and chemically inertness [1, 2]. The deposition rate of diamond thin films is very low and the production cost is high and this particularity restricts the area of applications. On the contrary, DLC thin films are widely utilized in various fields since the deposition rate is much higher than that of diamond and the production cost is much lower. The high chemical stability of DLC recommends this material for electrochemical applications: DLC is not destroyed by acids (or mixed acids as acid etch), alkalis solutions at high temperature and also by organic solvents. As a result of their chemical resistance DLC thin films can be utilized as corrosion resistant coatings. Generally, DLC is characterized by high resistivity. The electrical property can be controlled by changing the ratio between sp^2 and sp^3 bonded carbons, by controlling the concentration of bonded hydrogen and by doping with nitrogen or different metallic elements. By using different doping elements as nitrogen, boron, transition metals and metals from platinum group, the resistivity can be decreased and DLC thin films can be successfully utilized for electrochemical applications in aqueous solutions.

2. Experimental details

The DLC thin films for this investigation were fabricated onto low resistivity Si (111) substrates through the radio frequency capacitively coupled plasma chemical vapor deposition method. A RF variable power generator (50 – 400 W) and fixed frequency (13.56 MHz) was utilized as power supply (Fig.1). The power supply was connected to the cathode of discharge by using a manually matching box in the view to adapt the variable plasma impedance to the fixed 50 Ohm output impedance of the generator. A fixed value capacitor was utilized between matching box and the cathode in the view to permit the measurement of self developed bias voltage. The measured bias voltage was utilized as indicator of ions energies involved in thin films growth. Methane, acetone and toluene were utilized as precursors and the pressure of reactive gases was kept at 25 Pa in the time of process. The pressure was monitored by using a capacitance manometer. Nitrogen was utilized supplementary as a doping element in the view to increase the conductivity of thin films. The film

thickness was adjusted to approximately 1μm by controlling the input power and the deposition time.

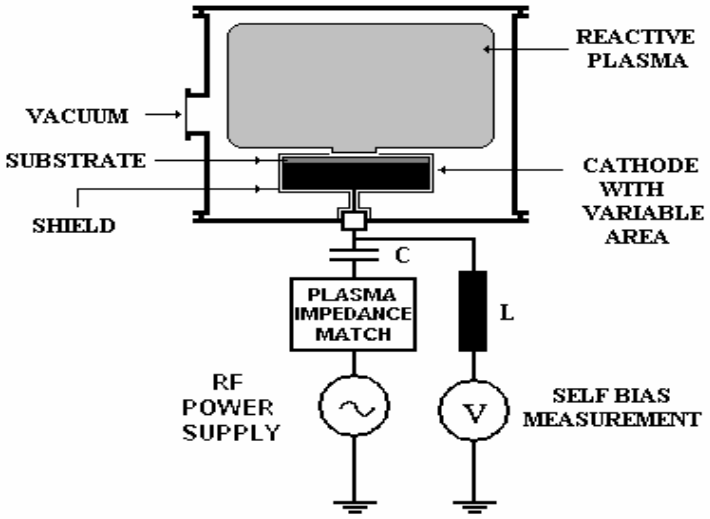

Fig.1. PE-CVD reactor for DLC thin films deposition

The electrical properties of deposited thin films onto high resistivity aluminum oxide substrates were evaluated by a two point method by applying a constant current between silver electrodes deposited by magnetron sputtering and by measuring the developed voltage. The surface morphology, structure and bonding states of DLC thin films deposited under various RF input power were analyzed using atomic force microscope (AFM; JSPM – 5200 T, JEOL), Field Emission Scanning Electron Microscopy (FESEM; JSM- 6330F; JEOL), Fourier Transform Infrared Spectroscopy (FTIR, FTS 175 C, Bio-Rad) and visible Raman spectroscopy (Nanofinder®,TOKYO INSTRUMENTS INC., with 488 nm argon ion laser line and 10 mW output power). The hardness and Young's modulus of the DLC films were determined from loading-unloading curves on a nanoindentation instrument (TriboScope, Hysitron) using a Berkovich diamond tip. The hardness and Young's modulus were calculated by averaging the measurements of ten indentations on different area for each sample. Electrochemical properties were investigated by cyclic voltammetry. The voltammograms were obtained with the electrodes immersed within a conventional electrochemical cell with three electrodes. Cyclic voltammetry were carried out in 0.1M H_2SO_4 solution by using a computer controlled potentiostat and function generator (Solartron 1280Z). In advance, the back sides of substrates were etched in HF solution and aluminum was deposited in the view to improve electric contact. DLC thin film was sealed with an open area surface of 5 mm in diameter. The potential of working electrode was varied over a certain range with respect to a reference Ag/AgCl electrode and a platinum mesh was utilized as counter electrode. I - V characteristics were obtained at a scan rate of 20 mV/sec.

3. Experimental results and discussion

The deposition rate increases with the increase of input power up to values as higher as 45 nm/min in the case of CH_4 precursor. The highest deposition rate was obtained in the case of toluene (350 nm/min) and acetone (70 nm/min) at 400 W input power. By adding nitrogen in the time of deposition the deposition rate increased (50 nm/min in the case of $CH_4 - N_2$ mixture) and this behavior was associated with an enhancement of the plasma density and in more active plasma.

The hardness of DLC thin films increases with the input power, attains maximum and then decreases. At about 150 W input power the hardness of DLC thin films deposited from methane reach maximum values (13 GPa). In the case of toluene the maximum hardness (17.5 GPa) was obtained at 400 W and in the case of acetone the maximum hardness (12.5 GPa) was obtained at 100 W input power. The nitrogen adding in the time of process decreases the values of hardness and elastic modulus.

The infrared transmission and absorbance of DLC thin films at wave numbers from 400 to 4000 cm^{-1} were analyzed in order to characterize the strength bonding of hydrogen with carbon. For DLC films obtained from all precursors the peak of absorption spectra are centered at approximately 2920 cm^{-1} which is associated with the majority presence of hydrogen in the form of $sp^3 - CH_3$ and $sp^3 - CH_2$ group. The peak intensity decreases with the increase of input power for films obtained from all precursors. For the same input power the peak intensity was different for films obtained from different precursors, decreasing from toluene to acetone and methane. By adding nitrogen in the time of process the intensities of this peak decreased, suggesting an induced dehydrogenation by the nitrogen included in thin films.

Raman measurements revealed a large luminescence background of thin films obtained at low input power and the high slope of this luminescence background suggests a high content of hydrogen. The ratio of disordered graphite component and graphite component intensities in thin films obtained from both precursors decreases with the input power suggesting the decrease in sp^3 and the increase in sp^2 components.

Electrical measurements of DLC thin films deposited on high resistivity aluminum oxide substrates showed that films obtained in methane, acetone and toluene plasma has very high resistivity ($\rho \approx 16x10^6\ \Omega.cm$). Addition of nitrogen decreases the resistivity of thin films to lower values ($12.5\ x10^3\ \Omega.cm$ for 10 sccm of nitrogen mixed in 100 sccm methane). In the case of acetone precursor the smallest value of resistivity was only $55\ x\ 10^3\ \Omega.cm$ at 40 sccm nitrogen added in methane precursor and no significant variation of resistivity was registered in the case of toluene plasma. These results suggest the necessity to increase the input power in order to increase the graphite component in thin films in order to obtain a lower resistivity. The decrease of thin film resistivity obtained from methane and acetone with the increase of nitrogen mass flow suggests that N acts as a weak donor and improve the conductivity.

No visible grain features could be observed under FE-SEM measurements. AFM measurements revealed a very smooth surface of DLC films, without big modification with increased input power. As generally characteristics, RMS roughness decreases with input power (Fig.2). In the case of methane plasma RMS decreased from 0.47 nm at 50 W to 0.30 nm at 400 W and in the case of toluene plasma RMS decreased from 1.23 nm at 50 W to 0.75 nm at 400 W input power.

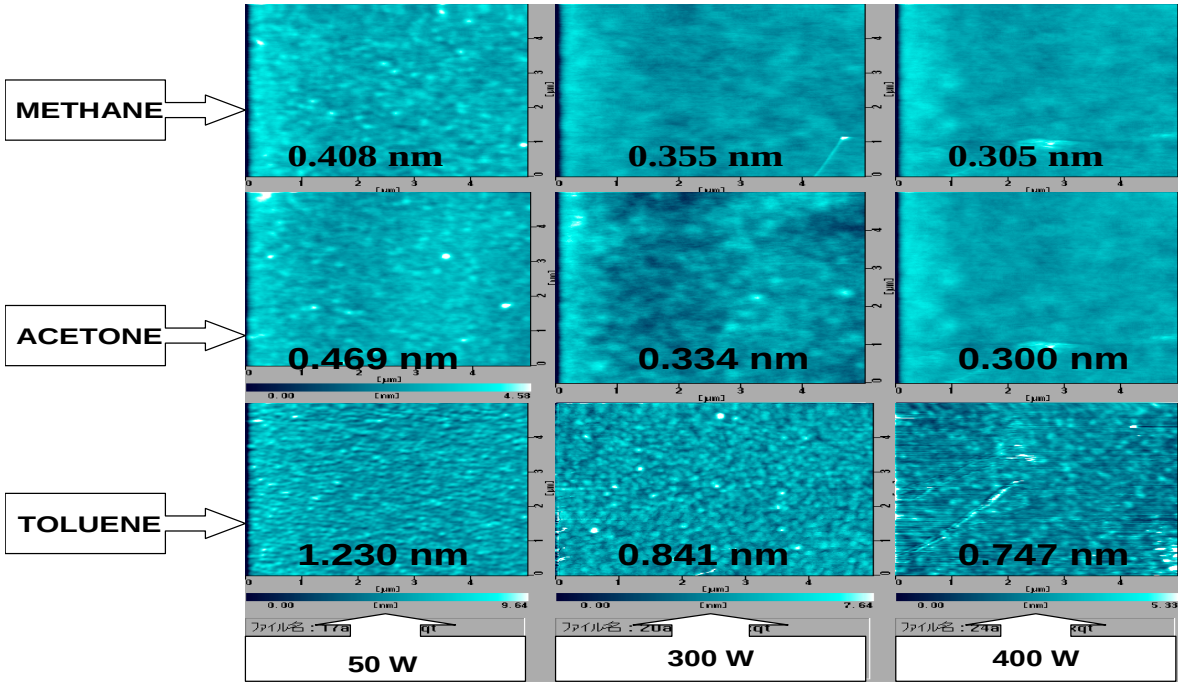

Fig.3. RMS roughness values for DLC thin films obtained from different precursors

A characteristic cyclic voltammogram of DLC film in 0.1M H_2SO_4 solution is presented in Fig.3.

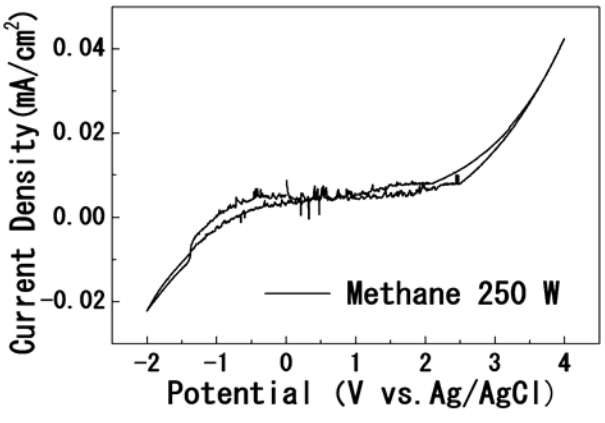

Fig.2. Cyclic voltammograms of DLC electrode

The overpotential for hydrogen and oxygen evolution on DLC thin films is larger than that of graphite electrode. The typical average potential limit corresponds to a current density of $20\mu A/cm^2$. For a DLC electrode, a broad potential range (approximately -1.0 to + 2.5 V vs. Ag/AgCl electrode) is observed over which no significant water decomposition occurs. The wide electrochemical window of DLC is lower than that of diamond electrode (about -1.25 to + 2.30 V) and is higher as electrochemical window of graphite electrode (- 0.40 to + 1.60 V). As evidenced by measurements, DLC electrodes present catalytic activity for Cl^2/Cl^- evolution and also high sensibility for Pb^{2+}/Pb^0 in the trace lead solutions. High hardness, good adherence on silicon substrates and large electrochemical window in aqueous solution recommends DLC thin films as environmental-friendly disposable electrochemical electrodes. Another important feature of DLC electrochemical electrode is the possibility to reuse the substrate or to repair the destroyed thin films by re - depositing the active film.

4. Conclusion

By using plasma enhanced chemical vapor deposition, hard and very smooth DLC thin films were deposited on different substrates. Mechanical, electrical and electrochemical properties were investigated and correlated with the plasma properties. Hardness and elastic modulus were dependent on the value of radio frequency input power. The maximum values were different for different precursor, the highest values of hardness being obtained in the case of toluene, H = 17.5 GPa. FTIR measurements indicated the decrease of hydrogen content in deposited films as a consequence of intense ion bombardment at high input power. Raman measurements indicated high hydrogen content in thin films obtained at low input power and an increase of disordered graphite component with the increase of input power. The adding of nitrogen in the time of process decreased the hardness and elastic modulus and increased the conductivity of thin films. Electrochemical measurements revealed that the overpotential for hydrogen and oxygen evolution on DLC electrode is larger than that of graphite electrode. The electrochemical window of DLC electrode is lower than that of diamond electrode and is higher as electrochemical window of graphite electrode.

THERMAL BEHAVIOR AT IMPACT OF MICROMETRE AND MILLIMETRE SIZED PARTICLES, INFLUENCE OF SUBSTRATE ROUGHNESS AND SKEWNESS

J.Cedelle[1], M.Vardelle[1], P.Fauchais[1], M. Fukumoto[2]

[1]S.P.C.T.S Laboratory, University of Limoges, France
[2]Advanced Joining Process Laboratory, University ot Toyohashi, Japan

Abstract :

Two different techniques have been developed in order to study plasma sprayed particle behavior at impact. The first one (SPCTS lab.) allows direct studying under dc plasma spray conditions, while the latter one, based on the millimeter sized free falling drop, enables the visualization of flattening phenomena, but at larger scale (time and dimensions about 3 order of magnitude larger). These two techniques bring complementary approaches and results.

Introduction :

The increasing request for more and more plasma sprayed coatings with improved service properties, requires a better understanding of phenomena at impact [1]. Although the experimental data are difficult to obtain on micrometer sized droplets impacting at velocities in the hundreds of m/s range, they are absolutely necessary for a better understanding of impact phenomena. Leading in parallel a study on millimetre sized particle enables to observe phenomenon at a larger scale. That's why a collaboration between the SPCTS Laboratory in France and the Advanced Joining Process Laboratory in Japan was realized. SPCTS Laboratory developed a new experimental set-up for the investigation of the splashing processes under direct current (dc) plasma conditions using an imaging technique composed of two fast shutter cameras and two long distance microscopes. The study of millimetre sized drop at impact using a free falling drop experiment was realized in Advanced Joining Process Laboratory in Japan.
The impact splashing is exclusively observed with the first technique when the particle impacts with high velocities (>100 m/s) [1,2]. The second technique presents other advantages, like comparing nickel drop cooling rates for different substrate characteristics. Results show that the quenching rate seems to be equivalent on a hot (673 K) or on room temperature substrate once preheated to 673K and higher than that measured on a room temperature substrate. The formation of peaks of oxide (positive skewness) resulting from the preheating seems to improve the contact with the droplet resulting to a disk shaped splat. The recalescence phenomenon can also be observed in few cases.

Experimental procedure :

- **Description of the experimental set up developed at SPCTS Laboratory (Limoges, France):**

This study is focused on the impact of a single droplet in plasma spraying. The research is carried out using an imaging technique with fast CCD cameras (PCO Sensicam) aimed both parallel to the substrate or almost orthogonal to it, in order to visualize all phenomena generated at impact. The correlation of the images with the results of a set of measurements allowing determining in-flight a single particle parameters just prior to its impact allow a better understanding of the splashing and flattening processes. All the difficulties of such investigations are linked to the fact that the impact of a single droplet in plasma conditions is not a reproducible event (in conventional spray condition between 10^6 and 10^8 particle/s, depending on their positions within the sprayed spot). A change in the particle mass causes a variation in the temperature and velocity of the droplet and can modify the morphology of the resulting splat. That's why a significant number of experiments should be realized to draw general tendencies.
Plasma spraying is carried out using a direct current plasma torch (PTF4 type) with a 7 mm internal diameter nozzle. The plasma torch is operated between 300A and 600A, and the inlet plasma gas flow consists of a mixture of 45 L/min Ar and 10 L/min H_2. An yttria partially stabilized zirconia's powder (8 wt % Y_2O_3) with

fused and crushed particle sizes ranging between 22 µm and 45 µm is used in this study. These spray conditions result in fully melted particle with velocities at impact ranging between 100 and 300 m/s [2].
The powder is injected 2 mm upstream from the nozzle exit and the argon carrier gas flow rate is adjusted to the torch working parameters in order to achieve a mean trajectory making an angle of about 3,5° with the torch axis (optimum value). The internal diameter of the injector tube is 1.8 mm. Besides, to limit the number of impacting particles, the powder flow rate is only 10 g/h (instead of a few kg/h in spraying conditions !).

Splats are collected on a substrate at a distance of 85 mm. Only particles following the trajectory close to the plasma jet axis are selected thanks to a moving water cooled shield positioned at 70mm downstream the torch nozzle exit and a another one positioned 11 mm upstream of the substrate with a 1.5 mm hole.
The experimental set-up for a single particle is two fold : in flight characterization by an optical sensor head and a fast (50ns) two-color pyrometer and flattening characterization by a two color pyrometer and two imaging systems, i.e fast CCD cameras triggered by the velocity signal

Measurement techniques :
The parameters of a single molten droplet are measured prior to its impact, with the experimental set-up already described in previous paper [3].

Synchronisation – Triggering of cameras :
Camera triggerings are generated by external TTL signals (5 V) in order to catch images at the impact moment. The latter are produced by a LabVIEW® program which creates TTL pulses from the velocity signal described in figure 2b. This procedure allows being sure that images come from the same particle, which velocity has been calculated.
It is necessary that cameras are activated as the particle impacts on the substrate. Knowing the particle velocity and the position of the substrate, it would then be possible to calculate the delay to be allocated to one pulse TTL for the release of both movie cameras. All this work is made possible thanks to a LabVIEW® program which allows, after the acquisition of the velocity signal, calculating the speed of the particle and thanks to a simple calculation the delay necessary in the release of movie cameras. All this is performed takes about 20 µs with a precision of the order of 0,1 microseconds.

- **Description of the experimental set up developed at Advanced Joining Process Laboratory (Toyohashi, Japan):**

The experiment has been described in details in previous paper [4]. Commercially available pure Ni and Cu wires (diameter 2 mm, > 99,99% purity) are used in this study. These wires are heated and melted by a radio frequency heating equipment. The mirror polished substrate (using 0,3 µm Al_2O_3) AISI 304 stainless steel substrate can be heated and its temperature is measured by a K-type thermocouple. The experiment is performed in a nitrogen atmosphere to eliminate oxidation. The impact velocity is calculated from the falling distance. It can be varied between 2 and 5 m/s. In order to maintain fluid and thermal similarity with the thermal spray process, i.e. analogy of Reynolds and Peclet numbers, the droplet velocity and diameter are adjusted.
Temperature measurements are obtained using the same fast two color pyrometer technique as that used with the thermal spray process : the temperature of the droplet just prior to its impact and that of the resulting splat are calculated from the ratio of the two signals obtained thanks to the optical head focused on the substrate surface. The main cooling rate of the splat is estimated from the time-temperature evolution of the lamella. For the observation of the flattening process, a sequence of images is recorded with a high speed camera (4500 frame/s).

Results

- **Plasma-sprayed particles**

Spraying a single particle on a preheated smooth stainless steel substrate using the experimental conditions summarized in table 1 allows understanding impact phenomena thanks to events chronology :

Table 1: Experimental conditions

Plasma gas	Ar /H_2 36/12
Arc Current	500 A
Voltage	55 V
Substrate	Smooth stainless steel
Ceramic powder	Zirconia
Powder granulometry	50-63 µm

Lamella formation on a preheated substrate :
In this first case, lamella formation with a disk shape is expected by preheating the substrate to 673 K which is higher than the transition temperature T_t (550 K) [5] To determine exactly when the cameras are triggered ,only pyrometer signal (fig 1a) and the TTL pulse (fig 1b) need to be recorded. The intrinsic delay of cameras must be taken into account in order to determine precisely when the image acquisitions start. This delay is 4,98 µs for a fast shutter camera PCO Sensicam. Dotted line on the left side corresponds to cameras acquisition beginning. In this experimentation the time exposure of cameras was 2 µs, so the second dotted line corresponds to the end of exposure

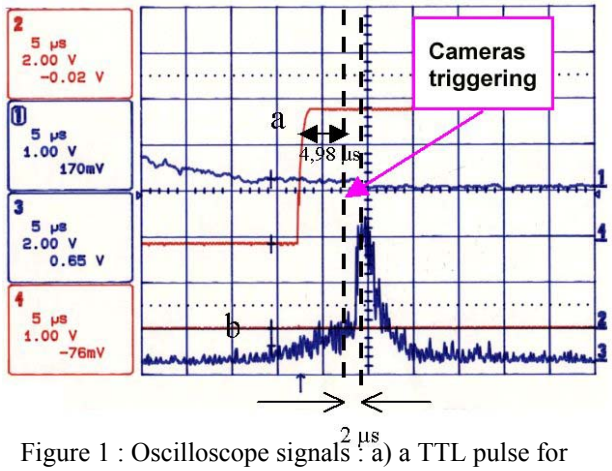

Figure 1 : Oscilloscope signals : a) a TTL pulse for cameras triggering, b) pyrometer signal

A correlation between the oscilloscope signals and the image makes it possible to see the very short period of the lamella formation. The disk shape of the flattening particle is already perfectly drawn (see figure 2a) and different as the acquisition of the photo ends, i.e., at the end of the flattening period (see figure 2b). The resulting splat of the selected droplet is immediately located on the substrate in order to be analysed. If this image is compared with that of the same lamella observed after impact with an exposure time of 1 ms, it can be noticed that the diameters are identical. It seems to mean that the complete spreading of the droplet is achieved in 2 µs and that the maximum diameter is 200 µm. During the spreading, the nuances of luminosity between the centre and the peripheral crown testify of a difference of temperature and allow saying that the cooling seems to begin during the phase of spreading. The resulting splat which is observed by optical microscopy presents microcraks in the central zone of about equal thickness and a rim in its periphery .This observation shows that a homogeneous and fast cooling took place in the central part while the warm and liquid material was still present (see fig 2a) at the outside crown 2 µs after impact (curling of the splat inducing a poor contact of its rim with the substrate).
Flattening velocity of the droplet after impact can be estimated thank to this imaging technique : within 2 µs after impact, droplet has spread on a distance of 100µm from the centre, which corresponds to a mean velocity of 50 m/s for the flattening stage.

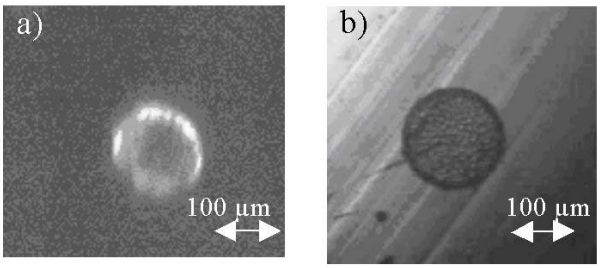

Figure 2: Disk shape obtained on a hot substrate. a/ Image of the spreading droplet (camera 1,time exposure 2 µs) velocity prior impact : 97 m/s, size range :50 – 60 µm. b/Resulting splat

Splashing on a room temperature substrate :
With the same experimental conditions, spraying a particle on a room temperature (300 K) substrate doesn't result in a regular disk shape splat but in impact and flattening splashing. The oscilloscope

signals presented in figure 3 show that cameras were triggered at the impact moment and that acquisition of each image had a 3 µs duration.
Both obtained images (fig 4, parallel and orthogonal to the substrate) show splashing phenomena. The resulting splat is extensively fingered and present a poor adhesion to the substrate. In order to have a better understanding of the splashing, a more precise study has been realized using longer time exposures for image acquisition.

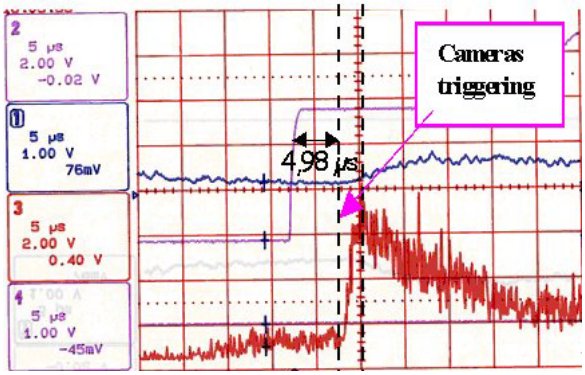

Figure 3 : Oscilloscope signals

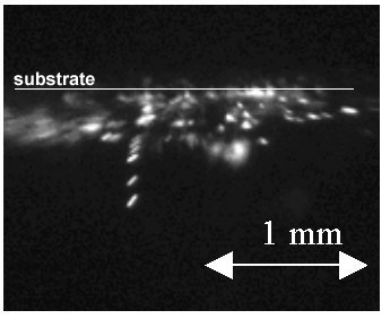
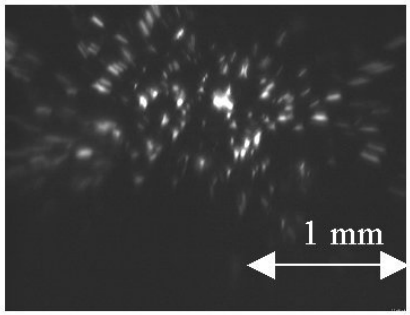
Camera 2, parallel to y substrate axis makes it possible to visualize ejected matter generated just after collision. This kind of splashing called "impact splashing" [5] in the following, is associated with tiny droplets ejection (d~1µm). Results obtained with zirconia (22 – 45 µm) particles in conjunction with room temperature stainless steel substrate (flat surface Ra< 0,05 µm) confirms C. Escure ones with alumina particles [5]. These ejections seem not only to be in the impact direction (fig 4) but also in a direction with a 45 ° angle with substrate surface.





Figures 4a and 4b: Splashing observation : time exposure 3 µs, velocity prior impact : 102 m/s, size range : 50-60 µm

In order to materialize these matter emission, photographs were taken with a multiple exposure operation (10 shots exposure : 5 µs , delay 5 µs) (fig 5). The latter allows estimating the mean velocity of these ejections. It appears that they are a ten factor less than droplet impact velocity ($v_{ejection}$ = 15-20 m/s). These tiny droplets are ejected up to one millimetre over the substrate. The origin of this phenomenon is probably due to wave propagation at impact which velocity is estimated to be 3000 m/s for a liquid droplet. These observations confirm Armster et al. collision theory [6] which introduced expansion waves notion which can result in the formation of appreciable tensions within the liquid in the first phase of impact.

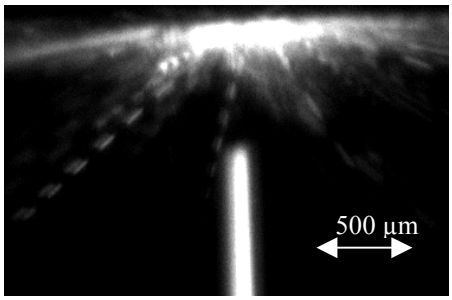


Figure 5 : Multiple exposure operation to materialize matter ejection

Substrate temperature seems to affect flattening splashing but not impact splashing. Wave regime is probably little or none dependent of substrate properties whereas the latter may govern flattening splashing [3].
To have a better understanding of the disk shape formation which presents a good contact with the preheated smooth stainless substrate, work with bigger drops was undertaken measuring in parallel their temperature and shape evolution.

- **Millimetre-sized drops**

The following results were obtained with the free-falling drop apparatus. The advantage of such an experimental study of flattening process is to work with millimetre sized droplets impacting with velocities about a few m/s. The time ranges are one thousand more important than in plasma spraying conditions, allowing following the flattening process with a camera speed of 4500 frame/s.
Using the high speed camera aimed parallel to the substrate surface makes it possible to realize a more precise study of directions of matter ejections in case of a splashing process.
Results obtained show that these ejections are mainly parallel to the substrate surface. Instabilities responsible of such ejections appear at the very early stage after impact (about 0,5 ms) but first secondary droplets are ejected only 2,2 ms after impact, i.e., more than 1 ms after the end of flattening stage. If these results are compared with those obtained under plasma conditions, it can be seen that using a falling-drop experiment does not allow the impact splashing visualisation, but only flattening splashing. These observations confirm the wave propagation theory for impact splashing in case of a particle impact with high velocities (150- 300 m/s).
The following results present pyrometric signals and temperature calculations, for millimetre sized nickel droplets impacting on a mirror polished substrate. Three different conditions were studied: impact of a 1,5 mm sized drop on a preheated substrate (673 K), on a room temperature substrate and a room temperature substrate once preheated at 673 K (fig 6).
Cooling rates can be calculated thanks to the temperature evolution of the resulting lamellae.(See table 2)
Results obtained thanks to the two colour pyrometer technique show that cooling rates measured for the resulting splats after flattening seem to be equivalent for a preheated substrate and for that once preheated at 673 K. The latters are more important than those obtained with a room temperature substrate. These results confirm Fukumoto et al [4] last ones concerning the link between splat morphologies and substrate surface roughness. They recently showed the effect of the physical change of the substrate surface due to its preheating (see fig 7).

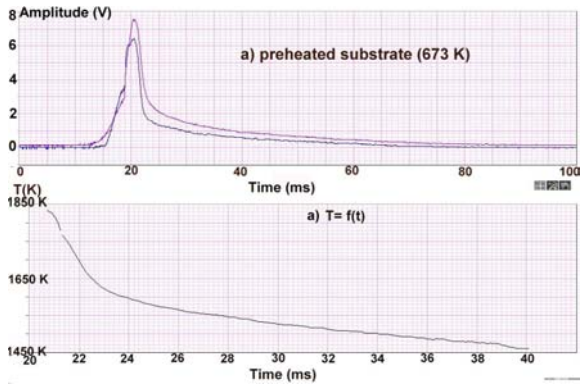

Figure 6: Pyrometric signals obtained with a millimetre-sized Nickel droplet impacting on a mirror-polished stainless steel substrate

Table 2 : Quenching rate calculation

Substrat Temperature	**R.T (room temperature)**	**Preheated at 673 K**	**R.T Once preheated at 673 K**
Lamella temperature after flattening stage	1770 K < T < 1880 K		
Quenching rate calculation	6-16.10^3 K/s	50-75.10^3 K/s	35-50.10^3 K/s
Resulting splat morphology	Fingered shape	Disk shape	Disk shape

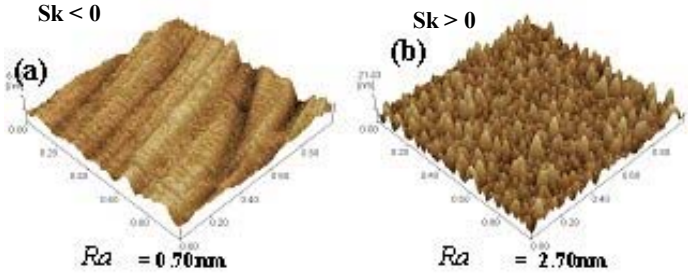

Figure 7 : Measurements of surface roughness on AISI 304 substrate by AFM. ***Fukumoto et al. [4]*** (a) as polished with 0.3µm Al2O3, (b) once heated to 673K after polishing with 0.3µm Al2O3

As it can be seen in figure 7, many oxide peaks were formed on once heated substrate. If the results for the corresponding splat cooling are compared, it can be imagined that these more numerous peaks with less undercuts induce more contact points between the splat and the substrate which enable a better quenching phenomenon. The transition temperature effect seems to improve the contact by surface modification in nm scale.

Fukumoto et al [4] showed that the skewness S_k value modification by preheating the substrate corresponds well to the splat shape for each substrate. Increasing the quantity of contact points between the substrate and the flattening droplet enables a rapid cooling and results in a columnar growth. As for the spraying case, in the free falling drop experiment, flattening splashing does not occur for a substrate temperature $T_s > T_t$.

Using the free falling drop experimental set up, recalescence phenomenon was also observed in some cases. For example, the results obtained with a millimetre-sized copper droplet exhibits a less conventional shape in case of impact on a room temperature substrate. Figure 8 presents the pyrometric signals and the calculated temperature evolution after the end of the flattening stage for a 2 mm diameter sized droplet impacting at 4m/s. Thanks to these time temperature evolution calculations, it can be seen that the second dump which appears after the droplet was in the supercooling stage (temperature reached 1280K) corresponds to a small increase of temperature which can be associated to the release of the latent heat of solidification of the material at the end of its undercooling. A dump is also observed in the case of a nickel droplet impacting on a glass substrate. This recalescence phenomenon seems to be linked to a bad wettability of the drop corresponding to a high thermal contact resistance between it and substrate.

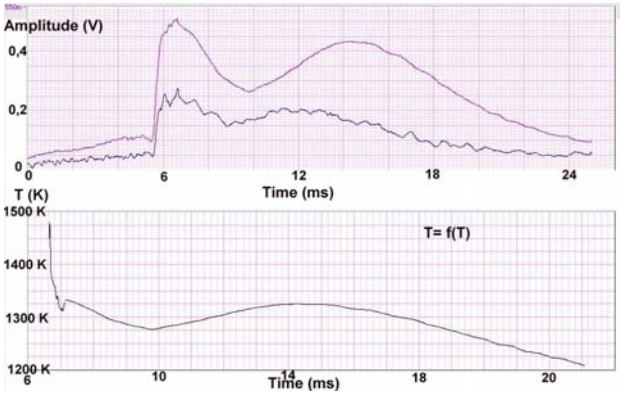

Figure 8 : Pyrometric signals obtained with a millimetre sized copper droplet and time-temperature evolution of the resulting splat.

Conclusion

The impact splashing is exclusively observed with the plasma spraying impact technique when the particle impact with high velocities (>100 m/s). The millimetre-sized drop impact technique presents other advantages, like comparing nickel drop cooling rates for different substrate characteristics. Results show that the quenching rate seems to be equivalent on a hot (673 K) or on room temperature substrate once preheated to 673K and higher than that measured on a room temperature substrate. The formation of peaks of oxide resulting from the preheating seems to improve the contact with the droplet resulting to a disk shaped splat. The recalescence phenomenon can also be observed in few cases. Future experiments will study the latter under d.c. plasma conditions with micrometer sized droplets. However, depending on the kinetic of these phenomena, it is not sure that they could be observed on the pyrometric signals.

Abstract

We performed the generation of micrometer-scale discharge plasma in high pressure H_2O and Xe up to a supercritical condition. Compared with conventional Paschen's curves, there exist two peculiar features in breakdown voltages. The first one is the shift from the right-hand branch of Paschen's curve and the second one is the drastic decrease near the critical point. We discussed these features by employing gaseous breakdown theory and the density fluctuations, which are caused by the clustering of the particles.
Keywords: micrometer-scale discharge, **s**upercritical fluid (SCF), H_2O, Xe, and density fluctuation

1. Introduction

Supercritical fluid (SCF), the intermediate state between gas and liquid, has received great attention because of its unique characteristics, such as a drastic change of thermal conductivity and high dissolving power near the critical point. From the microscopic viewpoint, SCF consists of the clusters of various-size particles and it produces large density fluctuations, which contribute the above-mentioned characteristics. Due to these characteristics, the applications of SCF have widely spread in many fields, especially in environmental science, nanotechnology, and chemical engineering. For instance, supercritical fluid extraction using supercritical carbon dioxide ($scCO_2$) as the solvent, substitutes for the conventional extraction process [1].

We have succeeded in generating discharge plasma in high-pressure CO_2 (critical point: 7.38 MPa and 304.2 K) up to a $scCO_2$ condition with a micrometer-scale gap electrode, and discovered that, near the critical point, its breakdown voltage was about 1/4 at the lowest of the value expected from conventional Paschen's curve [2, 3]. In addition, we have succeeded in fabricating carbon nanotubes and some other carbon nanostructured materials without any catalysts by discharge plasma in $scCO_2$ [4]. Although there had been few reports about discharge plasma in SCF yet, some groups have recently started reporting their interesting studies on this topic, which indicates that the unique features of SCF-plasma have recently been recognized in various fields [5, 6].

In this study, we performed the generation of micrometer-scale discharge plasma in high pressure H_2O (critical point: 22.12 MPa and 647.3 K) and Xe (critical point: 5.84 MPa and 289.8 K) up to supercritical conditions to compare the results with our previous work, which focused on CO_2 [2]. The main purpose of this study is to clarify that the unique phenomena of SCF-plasma, which were observed in the $scCO_2$ experiment, are general and analyze the differences among H_2O, Xe, and CO_2.

2. Experimental

Fig. 1 shows a schematic illustration of the apparatus for the discharge in high-pressure H_2O. The apparatus consists of a hastelloy cell with approximately 10 ml inner volume, heaters, thermocouples, pressure sensor, direct current (dc) generator and coplanar film electrodes (CFE), whose gap distance, thickness, and width are 1 μm, 1μm, and 50μm, respectively. CFE is produced with platinum on a sapphire substrate by lithography technique [7]. The procedure of the experiment is as follows. Ultra pure H_2O is injected into the cell and heated by four heaters. The pressure and temperature in the cell are controlled within the accuracy of ±0.07 MPa and ±2.5 K, respectively. The dc voltage applied to CFE generates the micrometer-scale discharge plasma. The radiation of the plasma is observed through a sapphire window, which is attached to the cell.

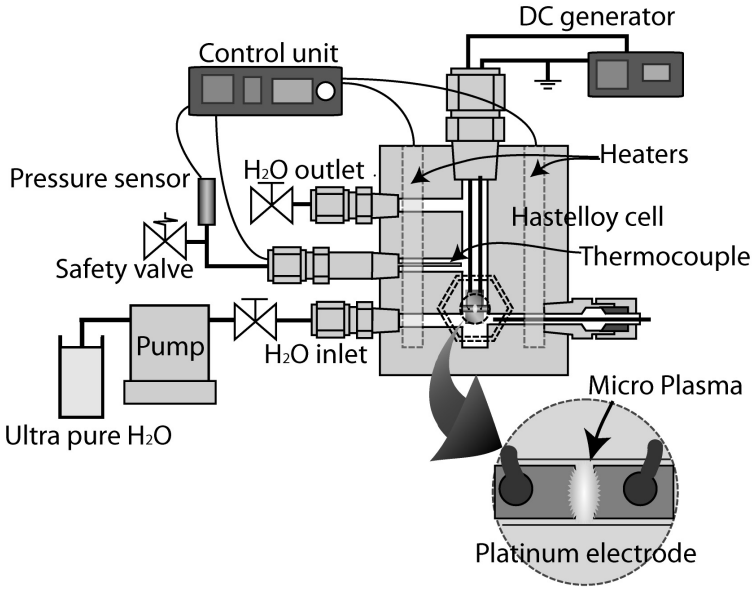

Fig. 1 A schematic illustration of the apparatus for the discharge in high pressure H_2O

Fig. 2 is a schematic illustration of the apparatus for the discharge in high-pressure Xe. The experimental setup is basically the same as that of H_2O except that we employ tungsten CFE on a quartz substrate for Xe experiment and Xe gas is once liquefied by liquid N_2 before injecting into the cell. The pressure and temperature of the environment are controlled within the accuracy of ± 0.07 MPa and ±1.0 K, by cooling the cell, which is surrounded by the ice and water. These parameters are also monitored all the time by using a pressure sensor and thermocouples.

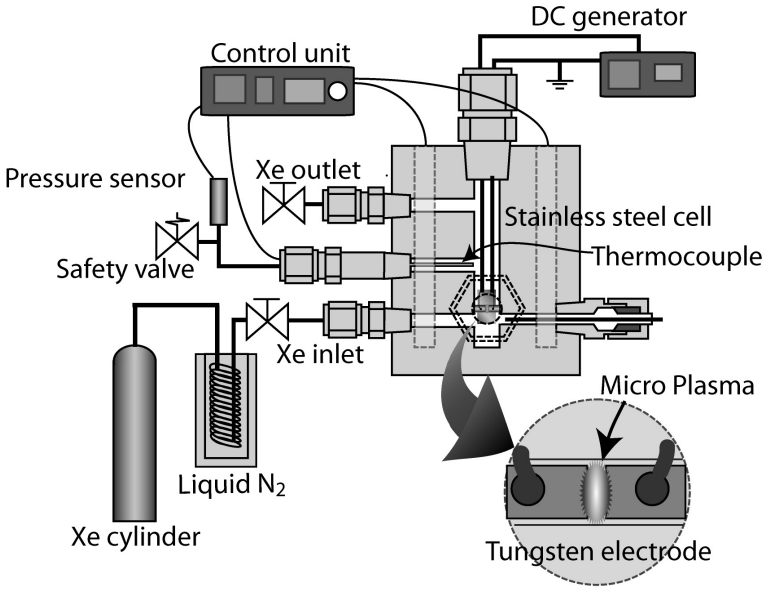

Fig. 2 A schematic illustration of the apparatus for the discharge in high pressure Xe

3. Results

Fig. 3 (a) and (b) show the breakdown voltages as the functions of environmental pressures for (a) H_2O, and (b) Xe, respectively. Fig. 3 (c) is from our previous report for CO_2 [3]. These three experiments were performed at 650.65 K ($T/T_c = 1.005$) for (a) H_2O, 292.15 K ($T/T_c = 1.008$) for (b) Xe, and 305.65 K ($T/T_c = 1.005$) for (c) CO_2, respectively, which were close to the critical temperature of each gas. The insets show the density fluctuations of each gas at the above-mentioned temperature. According to the results, there exist two peculiar features in not only CO_2 but also in H_2O and Xe. The first one is the shift from Paschen's curve above around 3MPa. The second one is the drastic decrease of the breakdown voltages in the vicinity of the critical pressure. Accordingly, these two unique features probably are general phenomena for the micrometer-scale discharge plasma under high-pressure gases up to supercritical conditions.

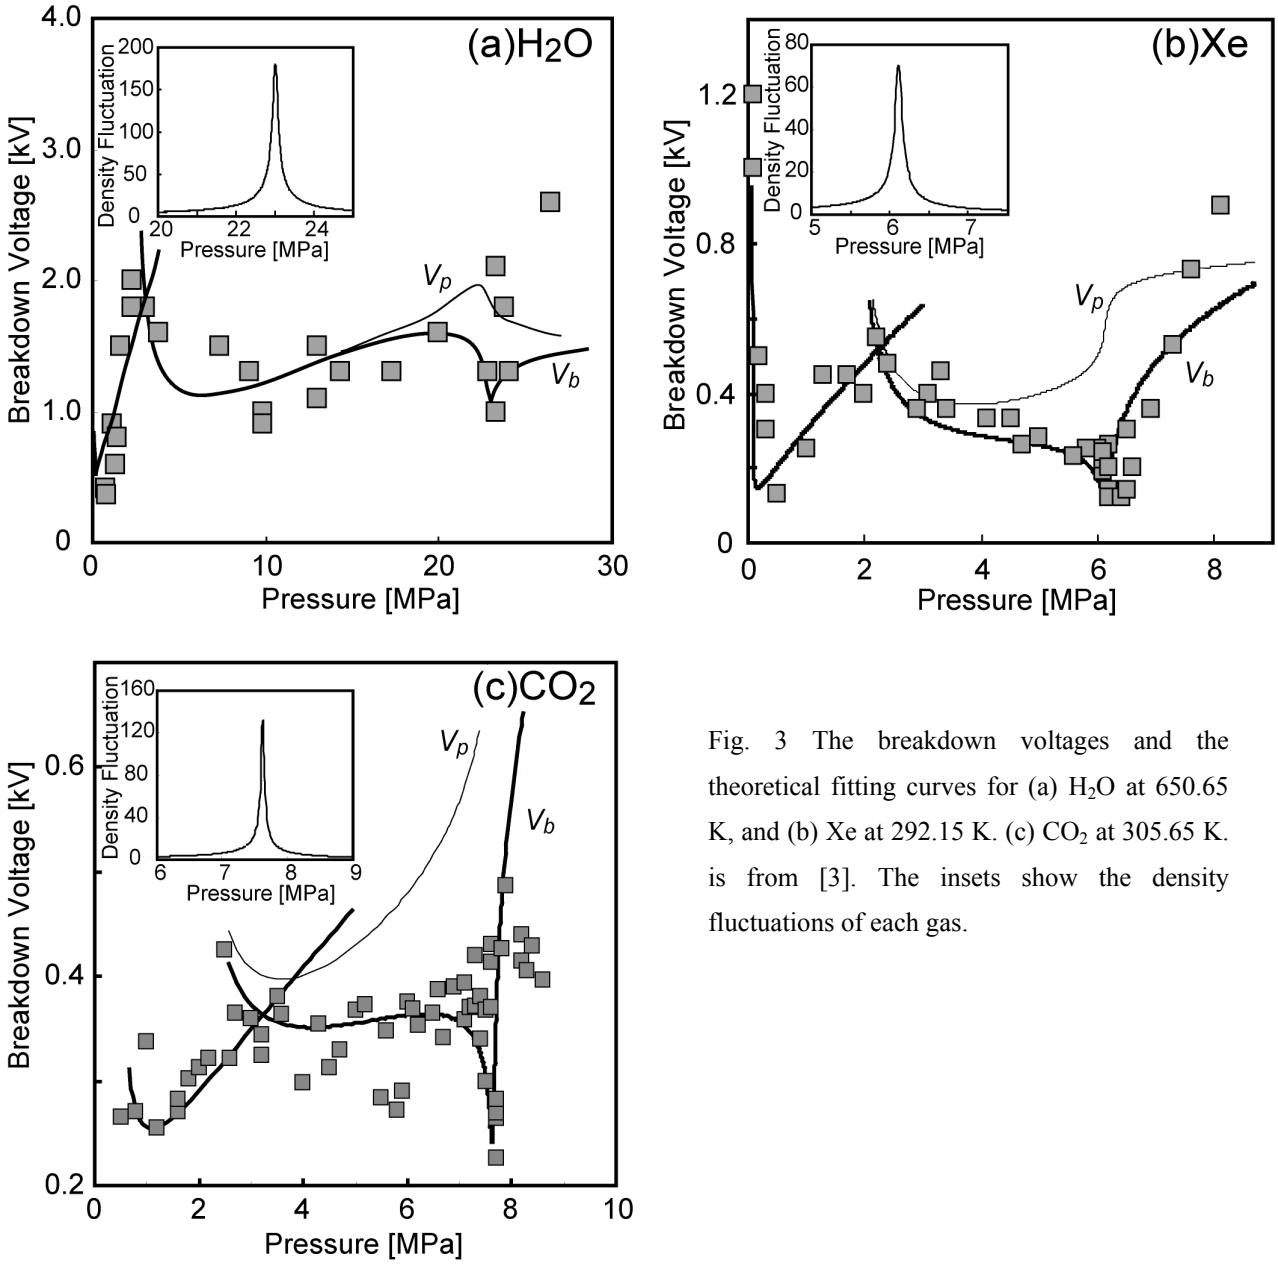

Fig. 3 The breakdown voltages and the theoretical fitting curves for (a) H_2O at 650.65 K, and (b) Xe at 292.15 K. (c) CO_2 at 305.65 K. is from [3]. The insets show the density fluctuations of each gas.

According to the gaseous breakdown theory (Townsend's theory), the breakdown voltage V_p is generally described as [8]

$$V_p = \frac{dn\sigma\psi_i}{AB}\left\{\frac{1}{\ln(dn\sigma) - \ln\left(\ln\left(1/\gamma' + 1\right)\right)}\right\}, \tag{1}$$

where d is the gap distance of the electrode, n is the number density, σ is the electron-to-particle cross section, φ_i is the ionization potential, γ' is the secondary Townsend coefficient, A is the effective coefficient related to the electrode sharpness, and B is the coefficient associated with the dielectric constant.

The trough locations of the breakdown voltages in Fig. 3 are fairly close to the pressures, at which the density fluctuations take the maximum. In our previous report, which was about CO_2, the drastic decrease of the breakdown voltages near the critical point was analyzed systematically by employing Townsend's theory and the density fluctuations due to the clustering of the molecules [3]. The density fluctuation F_D is calculated from the equation [9]

$$F_D = \left\langle (\Delta N)^2 \right\rangle \Big/ N = (N/V)\kappa_T k_B T = \kappa_T / \kappa_T^0, \tag{2}$$

and the isothermal compressibility κ_T is calculated from the equation [10]

$$\kappa_T = (-1/V)(\partial V/\partial P)_T, \tag{3}$$

where N is the number of molecules, V is the volume, k_B is Boltzmann's constant, T is the temperature, κ_T^0 is the compressibility of a ideal gas, and P is the pressure. To explain the drastic decrease near the critical point, we proposed the correlation between the conventional breakdown theory and the density fluctuations as

$$V_b = \alpha V_p F_D^{\beta}, \tag{4}$$

where α and β are individual coefficients [3]. Also in this study, we employ this equation (4) to analyze the unique phenomena of the breakdown voltages near the critical point.

The lines in Fig.3 (a) show the theoretical fitting curves for H_2O at 650.65 K. The fitting curves V_p and V_b are calculated from the equations above. In the region higher than around 3 MPa, σ of 1.5×10^{-20} m^2, and γ' of 1.0×10^{-18} are assumed for agreement with the experimental results, while σ of 1.9×10^{-19} m^2, and γ' of 8.0×10^{-8} are employed under the lower pressure. The dielectric constant is calculated from [11]. φ_i of 12.62 eV, A of 1.2, α of 1, and β of –0.15 are employed for all estimations. The location of the inflection in Fig.3 (a) agrees with the pressure, at which the electron mobility decreases because of the electron attachment to the clusters [12]. We discussed this inflection at 3 MPa, taking into consideration of the possibility of the electron attachment as were done in our previous report [3].

On the other hand, the lines in Fig.3 (b) show the theoretical fitting curves for Xe at 292.15 K. The fitting curves V_p and V_b are calculated from the equations above as H_2O. In the region higher than around 2 MPa, σ of 3.0×10^{-20} m^2, and γ' of 1.0×10^{-6} are employed for agreement with the results, while σ of 3.3×10^{-19} m^2, and γ' of 4.5×10^{-3} are employed in the region lower than around 2 MPa. The dielectric constant is calculated from the Clausius - Mossotti function [13]. φ_i of 12.1 eV, A of 1.2, α of 1, and β of –0.25 are employed for all estimations. We discussed the inflection of the breakdown voltages at 2 MPa,

taking into consideration of the possibility of the electron attachment to the clusters as we did for CO_2 and H_2O.

4. Discussion

We discussed two unique behaviors (the inflection at around 2~3 MPa and the drastic decrease near the critical point) of the micrometer-scale discharge with the electron attachment to the clusters and the change of the discharge space, respectively.

Firstly, as the shift from the conventional breakdown theory above 2~3MPa, according to the results, there must be some environmental changes at this pressure. V. Giraud, et al. reported that the density-normalized mobilities of these gases rapidly decrease at the pressure above 2~3 MPa [12, 14, 15]. This is believed to result from the electron attachment to the clusters. Therefore, at the pressure above 2~3MPa, some clusters in the discharge space have negative charges and it makes the electron to difficult to collide to the clusters. Consequently, the electron could acquire sufficient energy for ionization because the actual cross section becomes smaller and the mean free path extends enough. The attached electron might be emitted mainly from the cathode edge. Therefore, the emitted electrons may work more effectively as we employ the smaller electrode because the ratio of the number of the electron to the molecules in the discharge space becomes higher. In fact, the shift from the conventional Paschen's curve has not been observed when the gap distance was longer than several μm [3]. Therefore it indicates that our micrometer-scale discharge plasma may be the peculiar and different from the conventional one.

As the drastic decrease of the breakdown voltages near the critical point for these three gases, there is the possibility that the discharge space changes by the density fluctuations. In other words, the discharge space becomes sufficiently large for electrons to be accelerated in SCF, compared to the space estimated from the average density. Hamaguchi, et al. also reported, according to the simple calculations, that the discharge space might become sufficient and the discharge plasma could be generated with low voltages near the critical point [16]. Table 1 shows the individual coefficients α and β for H_2O, Xe, and CO_2, respectively. The values of β are different from one another. As shown in equation (4), $F_D{}^{\beta}$ expresses the ratio of V_b to V_p. In these three gases, Xe is the closest to the ideal gas, while H_2O and CO_2 have the polarities and the internal bonding angles. Therefore, Xe is reflected by the density fluctuations directly, compared to the other two gases. As the value –0.35 (~-1/3) of β for Xe, it might be explained by the dimension of the density fluctuation and the electric field. Though the density fluctuations express the deviation of the number of molecules per unit volume, it affects only to the direction of the electric field. Hence, the influence of the density fluctuations to the breakdown voltage might become approximately 1/3. As the differences in the value of β among these gases, there are two reasonable possibilities. The first one is that CO_2 and H_2O have the polarities and accordingly, the actual voltages, which accelerate the electrons, might become smaller than the displayed voltages applied to the electrode because the molecules or clusters which have polarities, changes the electric field slightly. Therefore, it prevents the electrons from being accelerated enough for ionization. The second one may be the differences in the packing structure due to the shapes of the molecules. Xe molecules, which have

Table 1 The individual coefficients for H_2O, Xe, and CO_2

	H_2O	Xe	CO_2
α	1	1	1
β	-0.15	-0.35	-0.25

spherical shapes, make a neat and tight structured cluster. On the other hand, CO_2 and H_2O molecules make less efficient clustering because these molecules have the limitations for gathering.

5. Summary

In this study, we succeeded in generating dc discharge plasma under H_2O and Xe environments from the atmospheric pressure up to supercritical pressure with a micrometer-scale gap electrode, and confirmed that there were the shifts from the conventional Paschen's curve at the pressure above 2~3 MPa, and near the critical point, the breakdown voltages were extraordinary low. We proposed the possibility of the electron attachment to the clusters and the changes of the discharge space for understanding of these unique features of micrometer-scale discharge plasma in a high-pressure environment up to a supercritical condition.

ABSTRACT

Gas to particle conversion refers to production of particles from individual atoms or molecules in the gas phase. In the current work, a transferred arc is used to produce nanometric particles from the condensation of metallic vapours obtained by controlling the evaporation of the anode material of a d.c. transferred arc. The synthesis of desired particles requires both the control of the heat transfer and more precisely the heat flux to the anode and its stability, which depend on properties of the cold boundary layer close to the anode surface. That's why a new and original experimental set-up was built in order to control cold boundary layer properties close to the anode surface, and so the vapour production and its thermal history.

I-Introduction

Ultra fine powders are used in many fields. For example, catalysts, sensors, sintered parts and electric insulators under high temperature would perform better if ultra fine particles (UFP) were used as materials. Several processes can be used for producing ultra fine particle, such as sol-gel process [1], ball- milling [2], and gas phase synthesis [3-4]. Gas to particle conversion refers to production of condensed particles from individual atoms or molecules in the gas phase. Particle formation is driven by the cooling of a supersatured vapour or by the generation of atoms and molecules by chemical reaction of gaseous precursors. Once particles form in the gas phase, further growth depend of the properties of the flow into which they are imbedded. Thermal plasma based vapour condensation methods which utilize a transferred arc, have not been successful up to now to generate fine or ultra fine powder of materials such as metals, alloys, ceramics or composites on a commercial scale because of rudimentary control of powder properties such as particles size and distribution, shape and cristallinity [5-6]. As the synthesis of ultra fine particles with desired size and composition requires reactive species production control, a good understanding of the heat transfer mechanisms to the anode, which depends of properties of the cold boundary layer and arc roots dynamic is of prime importance. In plasma transferred arc devices, it is well known that there are two distinct types of anode attachment modes, namely the diffuse and the constricted mode. It appears that the cold boundary layer properties and particularly its thickness govern both the dynamic and geometry of the arc root attachment. In previous works [7-9], the cold boundary layer modifications were obtained by several ways such as the addition of diatomic gases, the variation of the electrode gap and the internal diameter of the exit nozzle, or the use of constrictor tube [8] or with a superimposed cross flow [9]. In this work, its modification is performed by the inclination of the torch assembly to the normal of the anode surface. By increasing the angle, for given arc working conditions, the normal velocity of the plasma flow close to the anode surface decreases as well as the fraction of the convective heat transfer, thus modifying the arc root attachment, from the diffuse one to the constricted one. Beyond the modification of the heat transfer mechanisms and so vapour production, this inclination allows controlling the jet orientation of the metallic vapours towards a pressure and temperature controlled zone. Hence, the synthesis of particles with controlled characteristics may become possible, by controlling their thermal history.

II-Experimental set-up

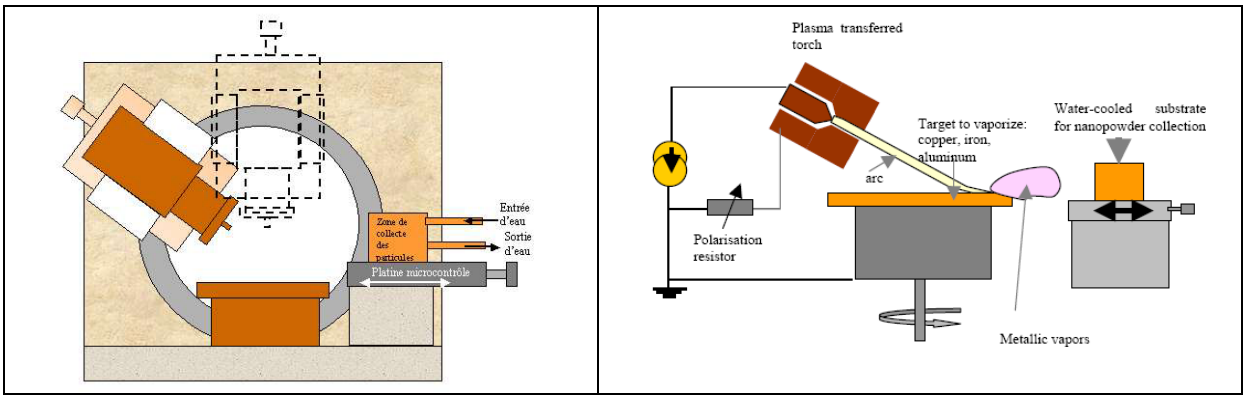

Figure 1: experimental set up developed

A transferred arc reactor (see fig 1) was designed to generate a stable arc jet, less than 3mm in diameter, using pure argon, argon-hydrogen mixture or nitrogen as plasma forming gases (4-10 slm) and power supplied by a current regulated source (I = 15-40A). The arc, stabilized by a superimposed plasma jet, is transferred between the cathode made of thoriated tungsten and the main anode precursor, made of the material to be eventually proceeded and situated perpendicular to its axis. According to the nozzle internal diameter (1.6mm or 2.5mm) used to constrict the arc, the jet velocity is over 1000 $m.s^{-1}$.The pilot arc offers several advantages, such as arc ignition and arc column stability. The pilot arc, first started, feeds the gap between the exit nozzle and the anode precursor with hot gases. Hence, it becomes easier to transfer low current intensity to the anode precursor. The heat flux density transferred to the anode can also be regulated by mean of the electrical resistor R, distributing the current between the stabilization anode-nozzle and the main anode. Furthermore, the arc pilot allows rising the plasma jet momentum, allowing its inclination. As the torch assembly is mounted on "ball bearings", the angle between the jet axis and the normal to the anode surface can be changed continuously from $\theta = 0°$ to 85°, whereas the electrode gap can vary from 1 mm to 25 mm. Thus, for given working conditions, the normal velocity varies between V_p and $V_p.\cos\theta$, where V_p corresponds to the plasma jet velocity. Beyond the orientation of the metallic vapors towards a pressure and temperature controlled zone, the inclination allows controlling cold boundary layer thickness and so the heat transfer at the anode. Hence, the control of vapours production and their thermal history becomes possible [10]. Besides the target is rotating, permitting the temperature control at the arc attachment, and thus, the vaporization flux. The particles are collected onto a water-cooled substrate, mounted on micrometric displacement in order to modify the residence time of particles imbedded in the flow. Ultra fine particles synthesized must be characterized. This requires control of size and size distribution, as well as composition. Micro structural features of the particles were studied using the scanning electron microscopy (Philips XL 30). If the particles synthesized were too small to be visualized on SEM microscopy, the collected powder was dispersed ultrasonically in alcohol and then allowed to settle on carbon coated copper grids for investigation by transmission electron microscopy (TEM JEOL 2010). The chemical composition of the particles was obtained by XRD diagrams. The diffraction pattern of the powder was recorded at a speed of $0.04°.s^{-1}$ using Cu Kα radiation.

III- Experimental results

Thermal vapour history could be achieved either by blowing the arc root by a superimposed cross flow or by tilting the angle between the jet issued from the cathode and the normal to the anode surface. As the plasma jet is stabilized by a superimposed plasma jet, it can be tilted. This inclination allows the orientation of the metallic vapours toward a pressure and temperature controlled zone. Hence, the control of vapours thermal history becomes possible.

.

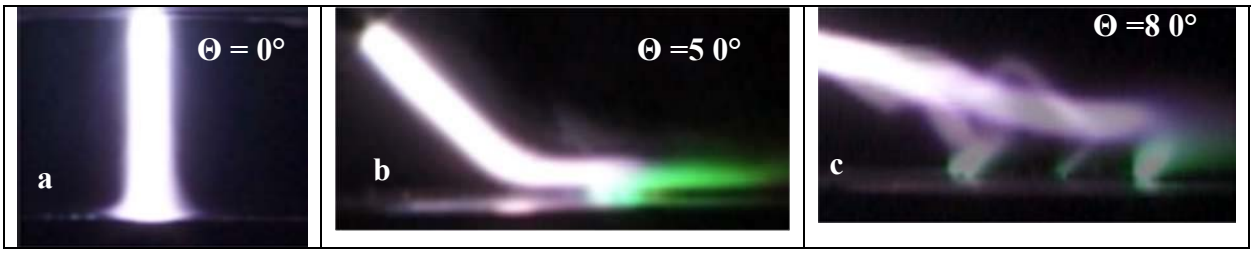

Figure2: different arc root attachment mode: (a) diffuse stable, (b) constricted stable, (c), constricted unstable, Ar plasma, I=20A, arc length L=15mm.

It is then suggested by pictures of figure 2 that it is possible to go continuously from a steady mode, for normal or low inclination, to a transient mode, where the arc root jumps from place to place, as soon as the arc length overcomes a critical value. As already discussed in former work [8-9], arc root dynamic and geometry are strongly dependent on the cold boundary layer properties (flow affected zone) close to the anode precursor. For angle $\theta < 30°$, the diffuse attachment is observed and no vapour production can be noticed in that case. The plasma forms symmetrically beneath the nozzle exit and a diffuse and stable arc root attachment is observed. For angle between 30° and 65°, the diffuse attachment changes to a constricted and stable one. The constriction, which appears as soon as the cold boundary layer becomes visible, leads to an enhanced heat flux and the anode material evaporates, as testified by green copper vapours It must be understood that the cold boundary layer disappears for normal incidence and increases in thickness as the normal component of the plasma jet velocity decreases. This clearly demonstrates that cold boundary layer thickness is governed by thermal effects for low values of θ.

Nevertheless, when the angle overcomes a critical value, appreciatively 65° for the actual plasma parameters, plasma flow acts tangentially onto arc root attachment and normal impact jet velocity tends to zero. Hence, cold boundary layer thickness is mainly governed by thermal effects and no more by mechanical effect. The arc root is still constricted but becomes unstable. In such configuration, the electrical connexion is submitted to the drag force induced by the plasma flow and also to the Laplace interaction of the magnetic field induced by the column and the current density at the wall, giving rise to a backward force. The cold flow pushes the arc root, and in the same time, the arc voltage increases together with the electric field in the cold boundary. When the field overcomes a given value, the breakdown in the sheath initiates a new path for the arc and the attachment jumps to another place. The arc root is still constricted but becomes unstable. It is then believed that the same phenomena occur inside the nozzle of a plasma torch, because the recorded time resolved voltage shows the same waveform. This unsteady mode, termed “restrike” mode, is accompanied by a saw tooth shaped voltage, showing linear increasing ramps followed by sudden negative jumps, this scheme being repeated in a few kilohertz range. It can be seen, following that example that phenomena inside the sheath participate to the arc column instability. Finally, three arc root attachment behaviours can be distinguished, as shown on figure 3, depending of the cold boundary layer thickness close to the anode: diffuse or constricted and stable ones, or stable or unstable constricted once.

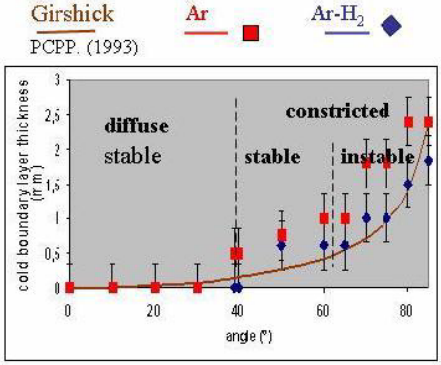

Figure 3: evolution of the “cold boundary layer thickness as a function of the inclination for Ar or Ar-H_2 plasma forming gas

Figure 3 shows the evolution of the arc root dynamic and geometry as a function of the cold boundary layer thickness, for argon and argon-hydrogen mixture as plasma forming gas. As the arc current intensity and plasma forming gas could be imposed by the nature of the particles to be produced, it could be interesting, for given working parameters, to visualise their effects on arc root attachment properties. The main result is that adding hydrogen delays the shifting from one mode to another. That must be explained by the fact that shifting from argon to argon-hydrogen as plasma forming gas result into a better heat transfer and a higher plasma jet velocity of the superimposed plasma jet. Hence, cold boundary layer is governed longer by mechanical effect and higher angles are needed for reducing the normal impact jet velocity at the anode and then shifting from one mode to another. Same results are obtained both by increasing arc current intensity or decreasing exit nozzle internal diameter. The role which is played by the sheath may be completely different following the kind of confinement of the arc column as it is the case either for a free burning arc or for a wall stabilized arc. In the last case, the electric field in the cold boundary layer may be high enough to give rise to the breakdown of the gas, which initiates another pass for the electric current.
As the key-point of this process consists in keeping the heat flux at a critical value for which anode erosion is only due to its vaporization, minimizing droplet ejection, the angle is set-up in order to obtain a constricted and stable arc root for powder synthesis. Stable arc root allows both the reproducibility and vapour phase production whereas constricted arc root enhances by one order of magnitude the heat flux transferred to the anode precursor.

III-2 Alumina particles synthesised

Synthesis of particles with controlled sizes and compositions requires the control of the vapour flux and its thermal history. Nevertheless, as experiments presented here were performed at atmospheric pressure, in air; control of chemical composition is not possible. The experimental parameters are summarized in table1.With such parameters, the arc root is constricted and stable. Due to the high power level transferred to the anode precursor, vaporisation of anode precursor occurs. The vapours are naturally canalised by the plasma flow towards the collecting substrate.

Plasma gas	Intensity transferred (A)	Total voltage (V)	Gas flow rate (L/min)
Ar	15 A	50V	4 L/min
Nozzle internal diameter (mm)	Collection distance	Rotating speed ($cm.s^{-1}$)	Angle
2.5 mm	20 mm	$0.5cm.s^{-1}$.	45

Table 1 : working parameters for alumina synthesis

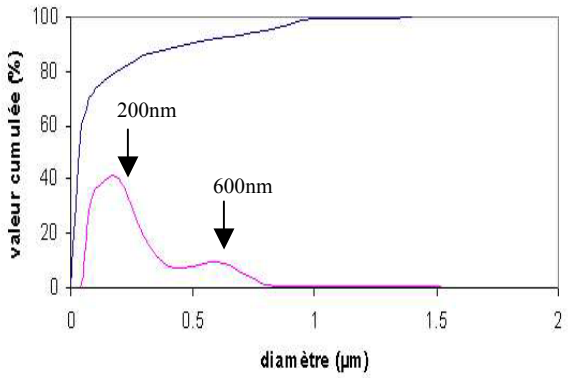

Figure 4 : Particles size distribution

Particle size distribution of the processed powder is shown in figure 4. It comes that vapour phase production and orientation allow decreasing the mean averaged size of the particles and their granulometric distribution. It is obvious from figure 4 that all the particles are in the submicrometer range. That must be explained by the very good control of the vaporization step, avoiding droplet ejection, and by the dissociation of the vaporization and nucleation/growth event. By the way, it must be said that the reproducibility of the experiments is achieved. Two main peaks can be distinguished, centred respectively at 200 nm and 600 nm.

Ultra fine particles have an inherent tendency to form agglomerates and aggregates, and very often, the results of particle size distribution studies by laser scattering mostly gives the size distribution of these agglomerates. The actual size of the individual particles in the clusters can be determined by electron microscopy (figure5).

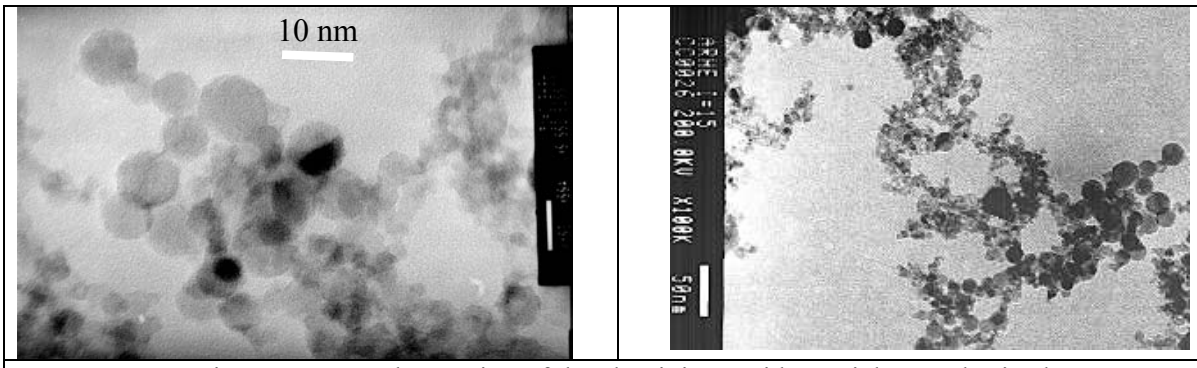

Figure 5: TEM observation of the aluminium oxide particles synthesized

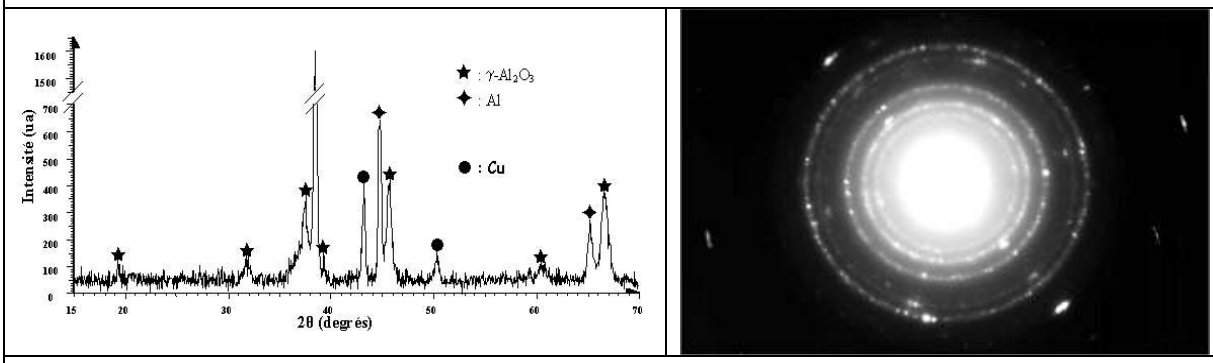

Figure 6 : XRD of powder synthesized

Particles synthesized are clearly nanoparticle chain aggregates, whose compactness depends on ramifications orientation, composed of primary particles that are approximately 10 nm, even if particles with diameters reaching 40 nm can be observed. The spherical or near spherical morphology of the powder is evident. X ray diagram (figure 6) proved that particles are well crystallized, even if some of them are not. The presence of discontinuous rings, as well as broadened peaks from normal X ray patterns, proves that the particles are crystallized and in nanometric range (below 40nm). X-rays diffraction results of the powder indicate that they are heterogeneous. The presence of copper can be explained by the fact that the aluminium precursor is an alloy with 4% of copper (AU 4G). The analysis of diagrams tends to prove the existence of the gamma alumina phase. As no oxygen has been introduced in the plasma plume during the experiments, formation of aluminium oxide can be explained as follow. For appropriate working parameters, vaporization of aluminium precursor occurs. These vapours are naturally orientated by the plasma flow towards the water cooled substrate for collection. Nevertheless, due to viscous strength, air penetrates in the fringes of the plasma and diffuses inside the core, where it is dissociated. Hence, atomic oxygen can react with atomic aluminium vapour to form aluminium oxide. The formation of gamma phase is consistent with the highly non equilibrium nature of the process. Vapours of aluminium react with oxygen to form aluminium oxide, which crystallizes in the metastable γ phase due to of the rapid quenching associated with the process. The formation of the metastable γ phase, in preference to the thermodynamically stable α phase has also been observed in fine alumina powder prepared by other high temperature techniques, such as plasma spraying, arc discharge and electrodynamic atomization.

IV- Conclusion

Ultra fine powder has been synthesized and the product has been characterized. As synthesis of powder with controlled size and composition requires the dissociation of the vaporization and

nucleation events, a new experimental set up has been developed. The process developed consists in keeping the local heat flux at a critical value for which anode erosion is only due to its vaporization. Orientation and so dissociation of nucleation event is achieved by tilting the angle between the jet issued from the cathode and the anode. Experiments showed that it was possible to control arc root attachment geometry and stability close to the anode surface by modifying cold boundary layer thickness at the anode. It becomes then possible to generate diffuse or constricted stable arc root attachment, and so vapour production. Nevertheless, when the angle overcomes a critical value, approximatively 65° for the actual plasma parameters, plasma flow acts tangentially onto arc root attachment and normal impact jet velocity tends to zero. Hence, cold boundary layer thickness is mainly governed by thermal effects and no more by mechanical effect.
The vapours produced are naturally canalised and orientated towards a temperature controlled zone, where they are collected onto water cooled substrate. The powder synthesized is heterogeneous, because oxygen is the limiting reactive specie. Results of X-ray powder diffraction studies show that the particles are nano-sized and are mainly crystallized under the gamma phase. Particles synthesized are clearly nano-particle chain aggregates initially about few hundred nm long, composed of primary particles that are approximately 10 nm, even if particles with diameter reaching 40 nm can be observed. In some applications, such as catalysis, agglomerates with an open structure like those are desired. However, in many potential applications non-agglomerated spherical nano-particles of uniform size are needed. More experimental studies are needed using a wider range of materials and operating conditions. Nevertheless the most important result may be the fact that reproducibility of the experiments is achieved.

Abstract

Plasma treated E-glass fibre to improve the mechanical properties of acrylic resin denture base material, polymethylmethacrlyate was studied. Three different types of monomers 2-hydroxyethyl methacrylate, triethyleneglycoldimethyl-ether, and ethylenediamine were used in the plasma polymerisation modification of glass fibres. Results revealed that treatments had significant effect ($p<0.001$) on the flexural strength. SEM was used to examine the microstructure and XPS was used for chemical analysis of surface.

Keywords: Plasma polymerisation; Glow discharge; E-glass fibres; Ethylendiamine, 2-hydroxyethyl methacrylate, triethyleneglycoldimethyl-ether

Introduction

The addition of glass fibre reinforcement is known to improve the stiffness, strength, and the high temperature performance of polymeric materials [1,2]. In general, the advantages of glass fibres compared with other competing fibres are high tensile and compressive strengths and, especially, low cost. Glass fibres are also effective in improving the mechanical properties of polymethylmethacrlyate (PMMA). PMMA is the most commonly used material in the construction of dentures. The reinforcement of PMMA through the addition of glass fibres has been shown to be effective in enhancing the mechanical properties of the assembly [3,4]. One of the drawbacks observed in the composites is poor compatibility between glass fiber and polymeric matrix, and difficulty to distribute glass fiber uniformly**.** The interfacial adhesion between the glass fiber and polymer is not strong enough, which affects the mechanical properties of the composites. A strong interface generally leads to the best composite properties, and many effective interfacial coupling agents that are capable of forming strong interface have been identified for single component polymer matrices. The need for techniques to bond glass fibers to polymer matrices is recognized since glass fibers were first used as reinforcement. Silane coupling agents are widely used for this purpose [5]. The enhancement of the adhesion between a polymer matrix and a plasma-treated fiber is caused by both physical and chemical modifications. The physical modification is the surface roughening of the fiber by the sputtering effect, producing an enlargement of contact area that increases the friction between fiber and the polymer matrix. The chemical modification is the implantation of active polar groups on the fiber surface, reducing the surface energy and promoting chemical bonding between the fiber and the polymer matrix. This difficulty can be avoided by emloying the plasma polymerization technique, which has advantages of being cost-effective and environmentally friendly. The main purpose of plasma surface treatment of fibres or whiskers used as reinforcements in composite materials is to modify the chemical and physical properties of their surface with tailoring fibre-matrix bonding strength, yet without affecting their bulk mechanical properties. Oxygen or argon plasma gas treatment has been most commonly used to introduce hydroxyl functional groups in the surface of materials. Wettability can also affect considerably the interfacial adhesion between the fiber and the matrix [6,7]. Radio frequency (RF) glow discharge plasma is one of the most widely used sources for surface modification. In our previous study, two different agents 2-hydroxyethyl methacrylate (HEMA) and air were used for the modification of glass fibres by RF glow discharge treatment [8]. The deposition of plasma polymers by hexamethyldisiloxane and vinyltriethoxysilane plasmas was also studied [9,10].

In this study, three different types of monomers, 2-hydroxyethyl methacrylate (HEMA), triethyleneglycoldimethylether (TEGDME) and ethylenediamine (EDA) were used for the plasma polymerisation modification of glass fibres. The plain and surface modified glass fibres were incorporated into the PMMA structure and the effect of modification was tested in terms of mechanical properties, surface chemical composition change and microstructure.

Material and Method

The Modification of glass fibers

In the study, glass fibers were treated in a glow discharge reactor by plasma polymerisation technique to change the surface properties. The reactor was a glass tube with two external cupper electrodes. A 13.6 MHz radio frequency generator was used to sustain plasma in the reactor. Power losses were minimized by means of a matching network. The reactor was evacuated to $2x10^{-3}$ mbar and monomer vapor allowed to fill the reactor until the pressure in the reactor to reach a level of $8x10^{-3}$ mbar. Then, RF power was adjusted to 25 W and the glass fibers were exposed to glow discharge for 30 min. The preliminary studies of our group to optimize the plasma polymerisation conditions for reinforcement of the PMMA based denture materials were reported elsewhere [4]. At the end of process the RF generator was turned off and the system was fed with Argon gas for 20 min. to deactivate free radicals. Monomers: HEMA, TEGDME and EDA were used for surface modification of reinforcement material glass fibers.

The testing of mechanical properties of plasma modified glass fibers

For testing mechanical properties, fibers were incorporated in the PMMA with %1 (w/w) loading. Specimens were prepared using standard gypsum moulds of 3x0.5x0.8 cm in dimension. Glass fibers were wetted with 1 ml of methyl methacrylate monomer and mixed with 2,4 g of polymer. The mixture was allowed to reach the dough stage and loaded in to the mould in a dental flask. The upper portion of the flask was placed over the lover and two portions were pressed in a hydraulic press. The flask was placed in a heated water bath during the polymerisation. The polymerized specimens were removed from the gypsum and their dimensions were checked. Each group consisted of 8 specimens. Control group contained no fibers. Specimens were stored dry at room temperature the mechanical testing. In order to test record the load of the fracture, each specimen subjected to three-point-bending test in an universal testing system Machine (AGS-J, Shimadzu Co., Kyoto, Japan) of 10 KN capacities with bending apparatus at a crosshead speed of 5mm/min. The ultimate flexural strength σ (MPA) of each specimen was determined with the formula (Philips Science of dental materials).The results were compared statistically by one way analysis of ANOVA (SPS Inc., Chicago, Illinois, USA). The Duncan post hoc test was used to analyze the statistically significant differences between the flexural strenght values (α=.05).

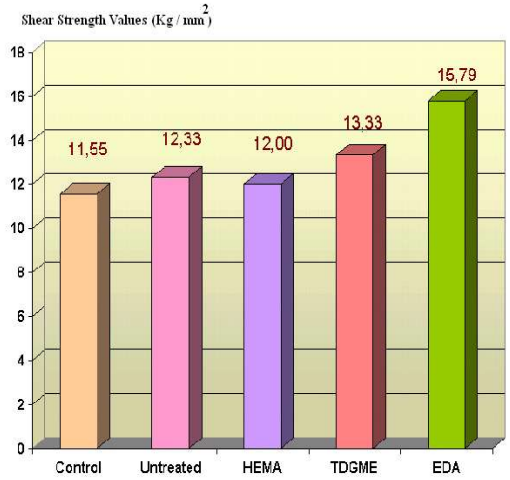
The Surface characterisation of plasma modified glass fibers

An X-ray photoelectron spectrometer ADES-400 ADES-400, by Mg Ka and Al Ka excitation sources and a hemispherical energy analyzer was used to obtain information about the composition and the chemical bonding of elements found in a surface region of unmodified and plasma treated samples. The thickness of a surface region from which information can be obtained depends on kinetic energy of photoelectrons in question and on the material analyzed. For carbon-based polymers the thickness can reach ~10 nm. Photoelectrons in the present work were excited by Mg Ka radiation (1253.6 eV, 200 W), the incidence and the emission angles were set at 70∞ and 0∞, respectively, both measured from the surface normal. Photoelectron spectra were recorded with the analyzer operated with constant pass energy of 100 eV or 20 eV. The atomic concentrations of unmodified and plasma treated glass fiber surfaces were determined from background-subtracted Si 2p, O 1s, C 1s and N 1s peak areas [11] corrected for the photoelectric cross-sections and the photo emission asymmetry [12]. The electron inelastic mean free paths [13] and for the measured transmission function of the spectrometer which comprises all instrumental factors influencing the measured quantity [14].

The surface morphology of modified glass fiber was investigated by using scanning electron microscope (SEM) (JSM-820, JEOL Ltd, Tokyo, Japan). Fibers were coated with a thin layer of gold by using sputter coater (VG Microtech Polaron SC500, USA) and photographed in the electron microscope with x4000 magnification. Beside this, the unmodified and modified with EDA glass fibers, which inserted in the PMMA was used for the imaging with SEM.

Results

The mechanical tests results given in Figure 1 show that the tensile strength of the denture texture reinforced with EDA plasma treated glass fibres was improved by 36%. Also, the surface treatment using TEGDME plasma improved the reinforcement properties of glass fibres by 15%.



Group	Treatment	Shear strength values (kg/mm2)	% Change
1	Control	11.55±2.09	0.00 %
2	Untreated	12.33±1.87	6,75%
3	HEMA	12.00±2.14	3,89%
4	TGME	13.33±2.15	15,41%
5	EDA	15.79±2.63	36,71%

Fig1 Mechanical Test Results of Glass Fibres

The results of XPS quantitative analysis for untreated and plasma modified glass fibres are summarised in Table 1. The high resolution C 1s, O 1s and N 1s spectra are obtained. The C 1s spectra are asymmetric indicating carbon-oxygen (C-O, C=O) and carbon-nitrogen bonding environments. The O 1s lines are rather wide including different types of oxygen bonding, such as O-C, O=C, -OH. The N 1s peak position is corresponding to the N-C bonding [8]. A slight decrease of silicon and oxygen concentrations and a slight increase of carbon concentration indicate a development of thin plasma polymer film on the glass fibre surface. The most pronounced changes in composition were found for EDA plasma treated glass fibre. In this case, very weak Si 2p signal was recorded. In addition, nitrogen concentration was calculated as high as 15.5 at. %. Therefore, the EDA plasma treatment of the glass fibre surface appears to be more efficient, also in accordance with the improvement of mechanical properties already mentioned.

Table 1 Chemical Composition of Surface

Sample	%C	%O	%N	%Si
Untreated	44.1	39.9	0.0	16.0
EDA	63.7	16.1	15.5	4.7
TEGDME	47.8	37.4	0.0	14.7
HEMA	44.4	39.5	0.0	16.1

Besides the changes of the chemical structure of the surface, the physical changes have been visualized by using SEM analysis. Figure 2, 3, 4 and 5 showed the change in the surface characteristic of glass fibers by changing the monomer used in plasma polymerisation respectively. In the case of monomer EDA surface roughness of the glass fiber was increased much more than in the case of the other monomers.

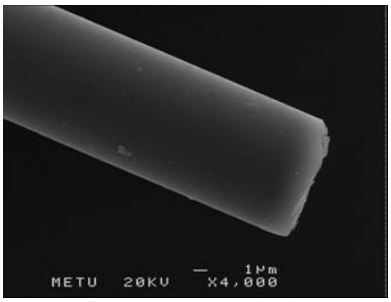


Fig2. Unmodified Glass Fibre

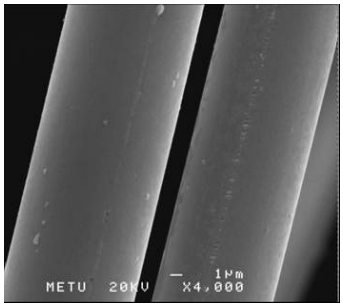

Fig3. Modified glass fiber with HEMA

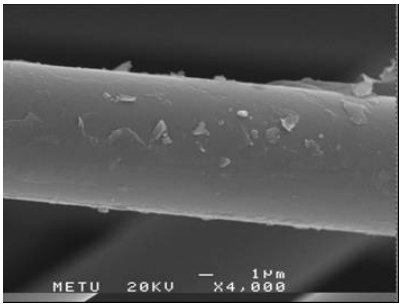

Fig4. Modified glass fiber with TEGDME

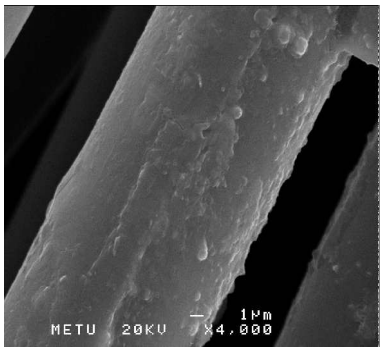

Fig5. Modified Glass Fibre with EDA

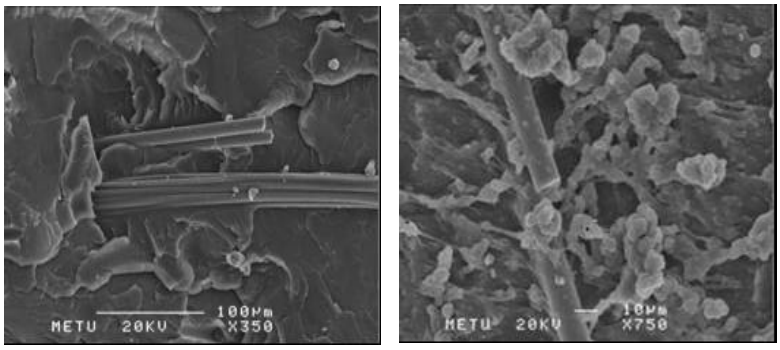

Fig6. Glass fibers in PMMA structure; i.)unmodified ii.)modified withEDA

Glass fibers that were modified with EDA showed uniform distribution in PMMA structure while not modified glass fibers suffered from aggregation in the PMMA matrix (Fig6).

Mechanical tests results showed that the tensile strength of the denture texture reinforced with monomer EDA treated glass fibers were improved by 36%. Also, the surface treatment using monomer TEGDME improved reinforcement properties of glass fibers by 15%. In XPS results the most significant change occurred by EDA treatment. The composition of untreated glass fiber surfaces corresponds to an air-exposed SiO_2, as expected. The glass fiber surfaces modified by HEMA showed no difference in the composition with respect to the reference sample. It indicates that the modified surface layer is very thin or that the surface modification process was, in this specific case, less efficient. The plasma surface treatment using TEGDME monomer resulted in slight changes in the surface composition with respect to the reference sample surface. A slight decrease of silicon and oxygen concentrations and a slight increase of carbon concentration indicate a thin modified film on the glass fiber surfaces. The most pronounced changes in composition were found for EDA plasma treated glass fiber surfaces. In this case, very weak Si 2p signal was recorded. In addition, nitrogen concentration was calculated as high as 15.5 %. Therefore, the EDA plasma treatment of the glass fiber surface appears to be more efficient, also in accordance with the mechanical properties already mentioned. Also the SEM results show that all plasma treatment cause the change of the physical topology on the surfaces. And also, most significant change occurs on EDA treated surfaces. EDA has been found to be the most effective monomer from those here investigated for the increase of mechanical properties of the PMMA based denture material. So, for the increasing bonding properties of the glass fibers to the PMMA denture materials, the physical changes could be effective factor. The researchers of this study are planning further studies focusing on EDA and EDA like amine group containing monomers with different plasma polymerisation parameters, such as discharge power, pressure and exposure time.

Conclusion

In this study, mechanical tests show that shear strength of PMMA can be improved by coating of glass fibers in a glow-discharge system. We also showed that, the treatment of glass fibers with an amino group containing monomer such as EDA is an alternative method to maintain a higher strength dental material. The chemical structure of the surface especially increasing the amount of -N could give an idea that for the amine film deposition which facilitates the improvement of mechanical properties.

Plasma Processing Prior To Wire Bonding and Underfill

A. Dr. Jack Zhao, B. Dr. James D. Getty
March Plasma Systems, 2470-A Bates Avenue, Concord, CA 94520 USA
www.marchplasma.com

Abstract
The market demand for smaller and faster IC devices drives the microelectronic packages smaller and more complicated, resulting in more substantial challenges in the advanced packaging process. To ensure high device reliability and minimize manufacturing costs, it is important to ensure a well prepared surface for increasing bond strengths in wire bonding or enhancing the underfill performance in flip chip package. In this paper, how plasma improved the wire bonding and underfill processes in advanced packaging has been demonstrated.

Key words: Plasma, wire bonding, underfill, and reliability

Introduction
Integrated circuits continue to shrink in size, and the associated decrease in size of the wire bond pad on both the die and substrate presents substantial challenges in the manufacturing process. To ensure high device reliability and minimize manufacturing costs, it is important to optimize the wire bonding process to ensure good bond strengths and yields. Poor bond strengths and low yields are often due to the selection of materials in advanced packaging or upstream contamination sources.

In the flip-chip packaging process, capillary underfill is traditionally used to ensure the highest reliability. However, the underfill dispensing process presents challenges, particularly with advanced chip designs including die size, gap, bump density, and differing die passivation materials. Specific challenges include wicking speed, fillet height and balance, and underfill adhesion to various materials. All of these challenges are related to the properties of the substrate, underfill fluid, and flip chip device [1].

Plasma is a partially ionized gas that has an electrically neutral mixture of physically and chemically active gas phase species. These reactive radical species are capable of chemical work, whereas the ionized atom and molecular species are capable of physical work through sputtering. As a result, plasma can perform numerous surface modification processes including surface activation; contamination removal; cross-linking; etch by chemical reaction; and physical bombardment [2].

Plasma is widely used for applications such as surface cleaning, activation and modification for enhancing surface adhesion, improving surface bondability, and tailoring surface energy. Plasma has proven to improve the pull strength and uniformity of wire bonds; increase fillet height and uniformity; increase underfill adhesion for flip chip devices; and alter surfaces for better adhesion in mold and encapsulation processes.

Two plasma modes, downstream and direct plasma, can be chosen in actual application. In direct plasma mode, the substrate is directly exposed in the glow discharge zone. Since both ions and free radicals are involved in the process, the direct plasma process is an aggressive, faster and effective plasma process. However, it may not be suitable for certain devices that are sensitive to ultraviolet (UV) light and ion bombardment.

In downstream plasma mode, including ion free plasma (IFP), the substrate is placed outside the plasma glow discharge zone, normally downstream of the gas flow. Downstream plasma is a mild plasma process since most ions and UV light are filtered before the activated species reach the substrate surface. This process is safe for some devices which are very sensitive to UV light and ion bombardment.

Plasma Prior To Wire Bonding

Generally, poor wire bond strength and bonding yield are attributed to surface contamination on the bond pad. Bond pad contamination is mainly from epoxy bleed-out from the die attach step. This organic resin bleed can be removed with oxygen-based plasma. The oxygen radicals generated in the plasma oxidize the organic resin, producing gas phase carbon dioxide and water. Typical results of pull strength improvement for a quad flat no-lead (QFN) package is displayed in Figure 1. The die was attached with conductive epoxy; oven cured; direct plasma treated; and wire bonded with 25-micron wire. A statistically valid set of samples yielded a mean pull strength of 10.00 grams with a CpK of 2.07 with plasma, compared to a mean pull strength of 3.89 and CpK of 0.03 without plasma.

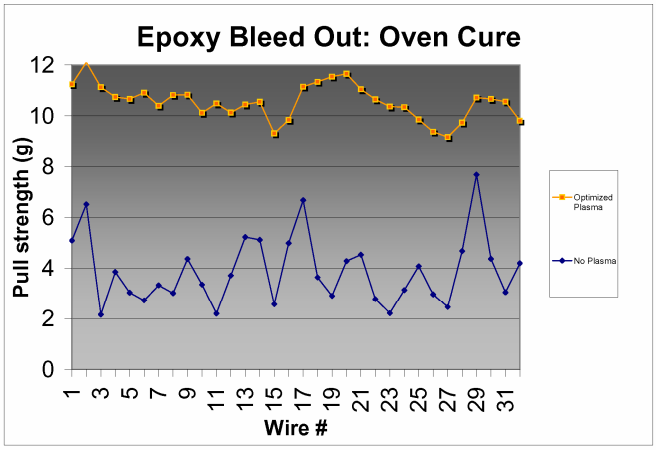

Figure 1

When an identical QFN package was attached with conductive adhesive, the package was snap-cured and wire bonded with 25-micron wire. The pull strengths for this package with and without plasma are displayed in Figure 2. Comparing Figures 1 and 2, both the oven-cured and snap-cured samples yield similar mean pull strengths and CpK after plasma treatment. However, the relative increases when compared to the no-plasma condition are dramatically different. The snap curing process has less epoxy bleed-out than the oven curing process, resulting in less surface contamination on the bond pad and higher mean pull strength in the wire bond process. These results highlight the importance of understanding the upstream processes and how significant the plasma treatment can be in overall wire bond yield improvement.

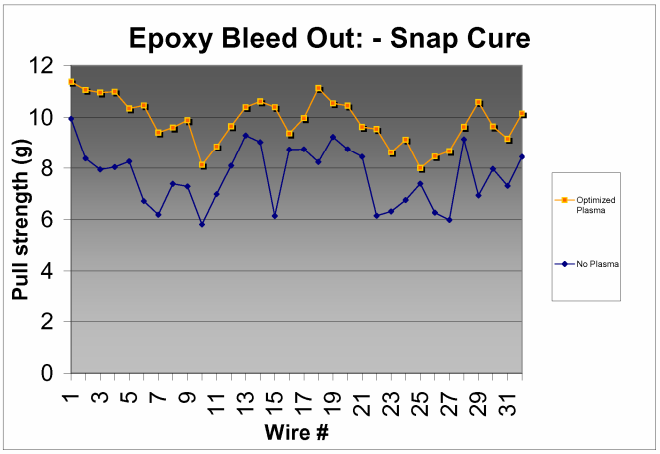

Figure 2

Wire bonding pull strength is sensitive to the substrate's bond pad metallization. Precise control of the plasma treatment process is necessary to achieve the best wire-bonding strength (see Table 1). The samples used for this evaluation were identical QFN packages with wire bond pads consisting of 25 nanometers of gold on palladium. The package was die attached with conductive adhesive; oven cured; treated or not treated with direct plasma; and wire bonded with 25 micron wire.

Table 1

Sample Conditions	Mean Pull Strength (grams)	CpK
No Plasma	3.72 g	0.07
Under Treated	4.67 g	0.35
Optimized	8.52 g	2.15
Over Treated	4.82 g	0.45

The pull strength data in Table 1 was collected with a constant plasma power, pressure and argon source gas while varying the plasma process time. The "Under Treated" sample showed some improvement over the "No Plasma" sample, but did not remove all of the epoxy bleed when compared to the "Optimized" conditions. The "Over Treated" sample yielded poor pull strengths due to the removal of the thin gold film on the palladium bond pad.

It is necessary to precisely control the direct plasma condition. If the sample is over-treated, the thin film gold on palladium will be removed, resulting in decreased wire bonding strength. In ion-free plasma, the QFN will only be exposed to the chemically active radicals, thus limiting the effect of sputtering the gold.

Figure 3 displays pull strengths for these QFN packages under the following conditions: no plasma; optimized direct oxygen plasma; and IFP oxygen plasma. In both plasma cases, the wire bond pull strength and CpK improve dramatically when compared to the no-plasma condition. However, the direct plasma condition is slightly better in this case, possibly because bond pull strength not only depends upon the removal of the organic resin bleed, but also relates to the other surface characteristics such as surface roughness.

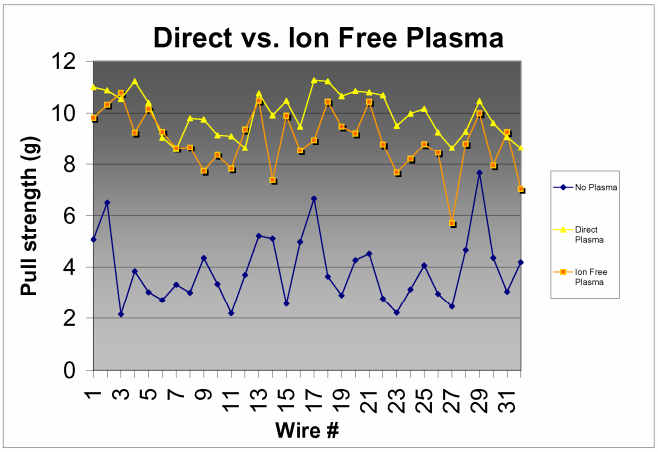

Figure 3

When applying plasma for pre-wire bonding applications, the sensitivity of the semiconductor device to all the active components contained in a direct plasma must be taken into consideration. In very specialized applications, the semiconductor device may be sensitive to either UV light exposure or ion exposure. In this case, IFP plasma technology can be employed to improve pull strengths for applications with epoxy bleed-out. Figure 4 compares the pull strength distribution of no plasma and IFP plasma-treated samples. In this study, a low temperature co-fired ceramic (LTCC) multi-chip module was populated with seven different active die; the

conductive epoxy was oven cured; no plasma or IFP plasma treated; and wire bonded with 25-micron wire. A sensitive pre-programmed EEPROM device was monitored for device erasure. In all IFP plasma processes, the EEPROM device was not erased, and with optimum plasma conditions an improvement of pull strengths was observed (Figure 4).

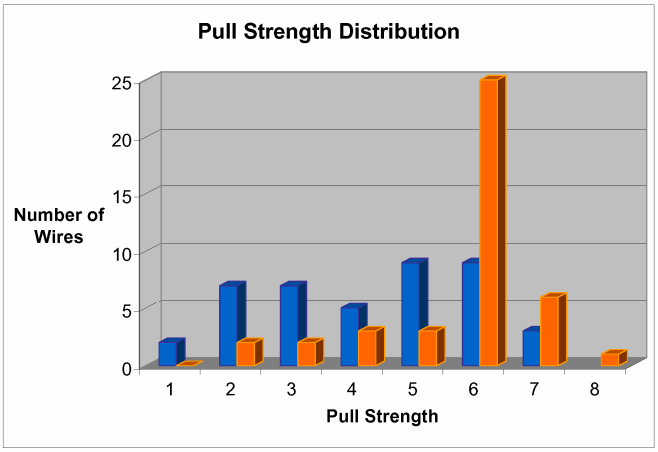

Figure 4

Plasma Prior to Underfill

The underfill process is very important for successful flip chip packaging since it can increase the mechanical and thermal reliability and improve the quality of the package itself. However, the flip chip process also meets challenges related to the surface properties of the die and substrate such as low wicking speed, lower and unbalanced fillet height, and possible delamination.

It has been proven that plasma can increase the surface energy, improve bondability, and enhance the interface adhesion. However, the gap between the die and substrate in the flip chip package is very small. Answers to the following questions are required: "Can plasma modify the surface properties beneath the die in the flip chip package?" and "Does a plasma-modified surface promote the underfill process?"

The surface wettability under the flip chip die depends on the geometry of the flip chip, materials, and plasma chemistry. Figure 5 displays contact angle data for plasma conditions of pure argon, pure oxygen, and pure nitrogen with two different die sizes. The die surface has a polyimide passivation layer with solder balls, and the substrate is FR-4 material. It is clear that chip size affects the surface cleaning effectiveness in flip chip packaging. With the increase of die size, the surface contact angle on the center of both the die and substrate increases, meaning that the plasma cleaning effectiveness decreases with increased die size. The activated species have more difficulty reaching the center of the flip chip due to the larger physical barrier of the large die.

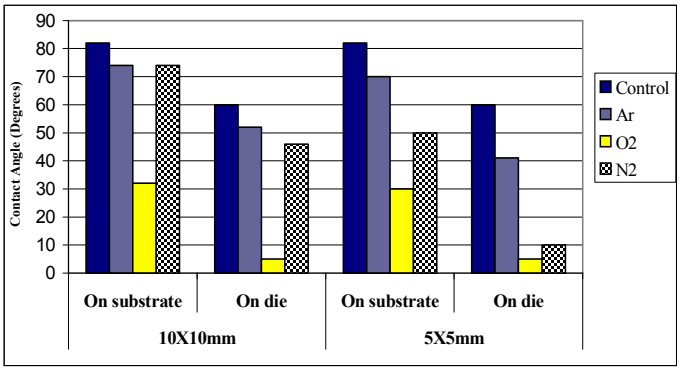

Figure 5

Contact angle vs. die size, substrate materials and plasma chemistry

The surface material also affects the surface contact angle after plasma treatment. Under the same plasma condition, the surface contact angle on the die is lower than that on the substrate surface. It is also clear that the surface contact angle at the center of the die and on the substrate beneath the flip chip is impacted by the plasma source gas. In general, the oxygen-based plasma has a greater impact on the contact angle than either nitrogen or argon. The contact angle trend is: O_2 plasma > N_2 plasma > Ar plasma.

The plasma processes can be characterized by two key surface mechanisms: physical bombardment and chemical reaction. An argon plasma process is a pure physical process where the argon ions generated in the plasma perform surface changes through ion bombardment. The Ar ions must penetrate beneath the die and still have sufficient energy to be effective. This process is inefficient as very few activated species penetrate into the gap between the die and substrate. As a result, the treatment performance of Ar plasma under the flip chip is not effective.

When oxygen is used for the process, both physical bombardment and chemical reaction work on the surface, but the chemical process plays a more important role. Oxygen-free radicals can diffuse and move in all directions since the free radicals are uncharged particles and not confined by an electric field. This random movement results in many activated species penetrating into the gap between the die and substrate, producing better surface contact angles than those achieved with argon plasma.

The treatment performance of nitrogen plasma is between the oxygen plasma and argon plasma. It is likely that the free radicals generated in the nitrogen plasma are less effective in chemically changing the surface. As a result, the surface contact angle beneath the die is different with differing gas chemistry. The cleaning performance trend is O_2 plasma > N_2 plasma > Ar plasma when considering treatment under a flip chip package.

The data shown in Figure 5 indicates that plasma can modify the surface beneath the die in flip chip packages. The specific challenges from the underfill process include wicking speed, fillet height, fillet uniformity and underfill adhesion between the underfill and die passivation.

Wicking speed is inversely proportional to the flow-out time, which is proportional to the contact angle. The relationship between the flow-out time and flip chip condition can be expressed by the following formula:

$$T = 3\mu L^2/h\gamma\cos\theta \quad (1)$$

T is flow-out time in seconds; μ is fluid viscosity; L is flow distance; h is gap or bump height; γ is surface tension of liquid vapor interface, and θ is the contact and wetting angle.

For certain flip chip packages, the lower the contact angle the faster the wicking speed, and therefore, the higher the production line throughput.

Plasma-induced surface energy changes are employed to increase wicking speed. In Case Study 1, 20x20-mm die with silicon nitride passivation were plasma treated with oxygen for both chemical cleaning and surface activation. The contact angle on the center of the die under the flip chip package was 40 degrees before plasma, and 20 degrees after plasma treatment. The reduction in contact angle translated into a reduction in flow-out time from 60 to 22 seconds, a 270-percent improvement (Table 2). This flow-out time enhancement will have a dramatic impact on the production line throughput.

Table 2

Case Study 1		
Experimental conditions		
Equipment	Batch plasma treatment system	
Plasma	Oxygen plasma (Chemical cleaning and surface activation)	
Conditions	AP-1000*, 500 Watts, 13.56 MHz, 50 CFM pump	
Loading	6 magazines of 10 Auer boats each (four flip chip per boat)	
Flip Chip Package	20 X 20 mm die	
	Silicon nitride die passivation	
	Bump height: 80 μm, Bump pitch: 200 μm, No. bumps: 2400	
Results		
Item	**No plasma**	**Plasma treated**
Contact angle on center of die surface	40°	20°
Flow out time	60 seconds	22 seconds
Voids?	Yes	No
Fillet height and uniformity	Poor	>40% fillet height with ± 4% uniformity

**The AP-1000 is a batch plasma system from March Plasma Systems.*

Although plasma treatment improves the flow-out time, the effect of other parameters, such as material types and bump density, can impact the magnitude of improvement as shown in Table 3. In Case Study 2, the substrate material and die passivation layer differed, as did the pitch pattern. There was a significant reduction in contact angle from 90 degrees on the untreated sample to 28 degrees on the plasma-treated flip chip. However, the improvement in flow-out time was only 14 percent, indicating that material sets are very important when considering flow-out time.

Typically, a more uniform fillet results in a more reliable packaged device. Non-uniform fillet heights often result in uneven stresses on the chip, which could cause fillet cracking and package failure. The low surface energy of both the substrate and die impacts both fillet height and uniformity. Table 3 shows both fillet height and uniformity with and without plasma treatment. The fillet height and imbalance were defined by the following equations:

$$\underline{\text{Fillet Height}}: \quad \text{Dispensing Side: } H_d = (H_{disp}/H_c) \times 100\% \qquad \text{Opposite Side: } H_o = (H_{opp}/H_c) \times 100\% \tag{2}$$

$$\underline{\text{Imbalance}}: \text{ Fillet height of dispensing side} - \text{Fillet height of opposite side} = H_d - H_o \tag{3}$$

where H_c is the thickness of the die, H_{disp} is the fillet height on the dispensing side and H_{opp} is the fillet height on the opposite side.

For these experiments, a single-line dispense was performed. With single-line dispense, the fillet on the opposite side of the die will often be lower than the dispensed side. The objective is to provide not only sufficient fillet height (> 20-percent of the height of the die) but also an imbalance lower than 30 percent.

As shown in Table 3 with plasma versus no plasma, there was a 220-percent improvement in fillet height on the opposite side and significant improvement in imbalance.

Table 3

Case Study 2

Adhesion and Voiding

Delamination of a flip chip package is often seen between the underfill and die passivation, typically around the edges of the die. There are numerous factors that impact underfill adhesion, including surface contamination and passivation layer material type. However, plasma can treat these surfaces to both remove contamination and chemically modify the surface to enhance adhesion. CSAM analysis indicated that the O_2 plasma-treated sample did not show any delamination after 3000 temperature cycling testing. The temperature cycling range is 0 to 100 °C.

Table 4 illustrates the difference between the control set and the oxygen plasma-treated polyimide passivation layer on the flip chip. Plasma treatment changes the surface composition through modification of the surface chemical functional groups. After oxygen treatment, the oxygen composition on the substrate surface increased approximately 36 percent. The surface functional group analysis indicates that the total oxy-functional group increased by 19 percent. The increase in these chemical functional groups is likely responsible for the improved adhesion of the underfill fluid to the polyimide passivation.

Table 4

	Surface composition			Surface functional group			
	C	N	O	OC=O	OCO, C=O	C-O-	C-C
Control	79.5 %	5.9 %	14.6 %	2.2 %	11.7 %	25.9 %	60.2 %
Treated*	74.8 %	5.4 %	19.9 %	0.9 %	17.4 %	29.1 %	52.6 %

*Sample treated in XTRAK-IFP system with oxygen plasma condition, 45 sccm, 200 W, 60 seconds.

Generally, oxy-functional groups on the surface interact and chemically bond the underfill materials during the underfill process. Therefore, the greater the concentration of oxy-functional groups, the less likely it is for delamination to occur. Removing contaminants on the interfaces and chemically activating the surface minimize delamination. Additionally, this process improves wettability under the die resulting in a reduction in the incidence of voiding as shown in Table 2.

Conclusion

Plasma treatment can be successfully applied to the wire bonding and capillary underfill processes. Plasma improves the bond strength and increases the CpK in wire bonding. It has also been demonstrated that various plasma chemistries improve the fillet height and uniformity, but oxygen chemistry is the most effective at lowering the contact angle under the die. The use of oxygen chemistry for improved wicking speed and enhanced adhesion performance has been demonstrated.

Chemical reactivity of atmospheric pressure water plasma as a function of temperature monitored by emission spectroscopy

I. G. Koo, M. S. Lee, J. M. Lee and W. M. Lee

Department of Molecular Science and Technology, Ajou University, Suwon, Korea,443-749

Abstract

Chemical reactivity of water in an electrical discharge was studied by allowing hot water vapor to pass through micro hollow cathode (MHC) array. Atmospheric pressure water vapor heated up to 700^{o}C, often mixed with sulfur dioxide SO_2, was introduced to the electrode assembly and the resulting plasma flame was studied using emission spectroscopy. The experimental results in this study include the current-voltage profile as a function of the medium temperature and emission spectra of the species such as OH, H, O and SO also as a function of the temperature.

Keywords: atmospheric pressure discharge, micro hollow cathode, emission spectra, water dissociation.

1. Introduction

Chemical reactivity of water vapor heated to high temperature, often near 800^{o}C, is an interesting subject particularly when the heating is coupled with electrical discharge from the standpoint of utilization of nuclear heat as a means of dissociating water [1]. The excitation of water molecules by thermal as well as electrical means could provide an alternate reaction path for their dissociation. Plasma-chemical reactions of water molecules in electrical discharge have been encountered in applications such as hydrogen isotope exchange reaction [2,3], non-thermal removal of NOx in presence of water [4] and water-stabilized plasma generators [5]. When thermal excitation of water molecules is coupled with electrical excitation it is not difficult to foresee that such combined effect can first result in improved sustainability of the MHC discharge and can also bring in enhanced reactivity of the molecules. First, the discharge can be sustained using less power as the medium temperature goes up due to an increase in the rate of thermal ionization and the ion flux. Second, the population distribution at vibrational energy levels of water molecules should shift somewhat to higher states with increase of temperature and particularly, the existence of non-thermal electrons in MHC discharge should help bring in further excitation of their quantum states of the involved molecules. Third, the net charge accumulated at the electrode surface for the MHC discharge helps a certain orientation of water molecules residing at the electrode surface. With such regularity in the alignment of water molecules adsorbed at the surface the added molecules to the system such as SO_2 would also orient themselves in a regular fashion configuration wise in reference to the water molecules. Consequently the whole reacting system consisting of metal-water-SO_2 would have drastically modified potential energy surface so that the temperature effect of the system on the reactivity would be more clearly manifested.

2. Experimental

The electrode design for generating large-area atmospheric pressure plasma was based on micro-hollow electrodes assembly[6]. The assembly consisted of two stainless steel disks, 100 μm thick and 1 cm^2 surface area, separated by a mica sheet of 200 μm thickness. Holes of 300 μm diameter, the spacing between them to be about 1 mm, were bored through the assembly for the gas passage. A DC power supply was connected to the electrodes and the voltage and current during the sustained discharge were measured at various temperature. The hot water vapor in temperature range of 100-700^oC was introduced into the electrode assembly, at the flow rate of 400 ml min^{-1}, after passing through ceramic tubing placed in a furnace. In some experiments the water vapor was mixed with SO_2. The resulting plasma flame generated out of the electrode assembly was guided into a chamber at which optical probe was attached. The emitted light from the reactor was collected and transmitted through an optical fiber to Monochromator with the resolution of 0.01-0.05 nm attached to CCD camera. The whole experimental design is schematically depicted in Fig. 1.

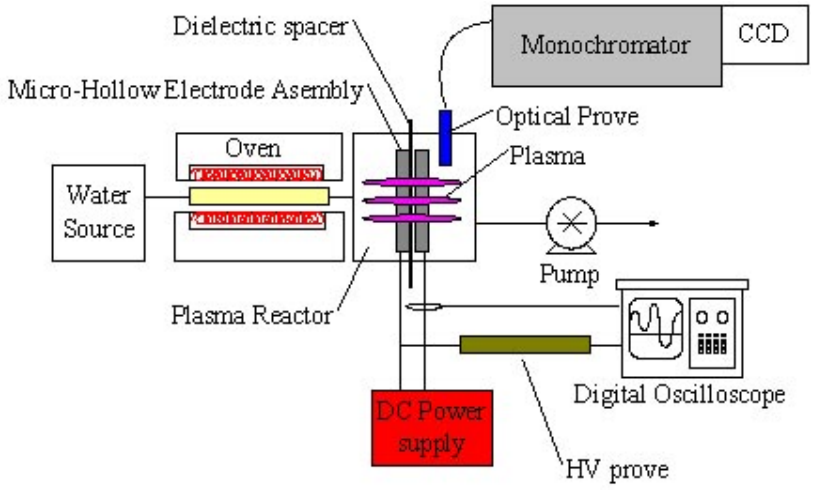

Fig.1 Schematic experimental setup

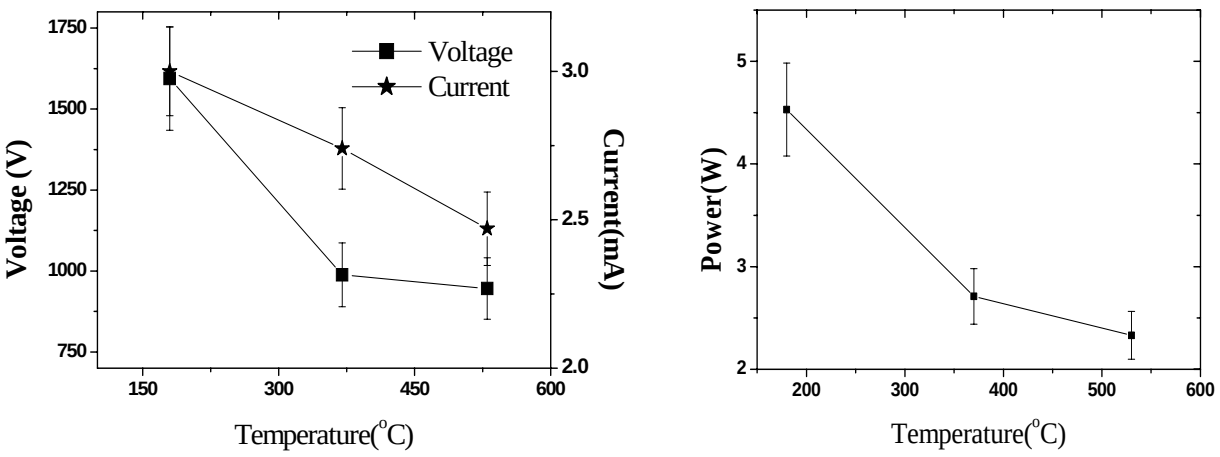
3. Results and discussion

The current and the voltage between the electrodes during the sustained discharge were measured as a function of the water vapor temperature as shown in Fig. 2. As the temperature went up from 200^oC to 530 ^oC, the power decreased from 4.5 to 2.5 W, accompanying more than 40% reduction. As explained before the discharge requires less power as the medium temperature goes up due to an increase in the rate of thermal ionization and the ion flux. The power of 2.5 W is equivalent to 9 kJ of the electrical energy if the discharge is continued for one hour, a time span during which about 0.3 moles of water, as the flow rate is fixed at 400 ml min^{-1}, is electrically excited. Since electrolyzing 0.3 mol of water requires about 80 kJ of electrical energy, the power consumption exhibited in MHC discharge is rather encouraging if most of the excited water molecules can undergo dissociation.



(a) (b)

Fig.2 Power consumption for MHC discharge as a function of the medium temperature: (a) I-V characteristics (b) Power.

In our experimental setup the vapor is introduced into the micro hole of the gas-in electrode, generating the glowing plasma microjet while it leaves the hole of the gas-out electrode. The emission measurement of this glowing region showed that the intensity of various peaks depends on the polarity of the gas-out electrode. For example, Fig. 3 shows that the intensity ratio of oxygen(777.1nm) to hydrogen(486nm) peak, I_o/I_H, varies from 2.4 to 1.0 as the polarity of the gas-out electrode switches from anode to cathode, respectively. With the reversal of the polarity no such change of the relative intensity was observed when He was used as the working gas. Thus, tentatively we came to a conclusion that the chemical reaction of the water plasma depends on the polarity of the gas outlet[7].

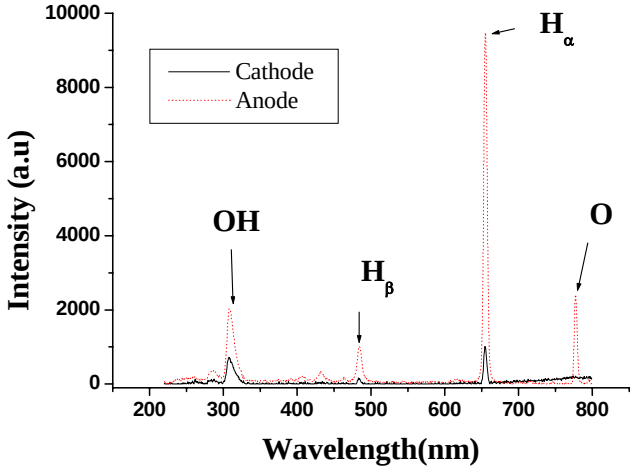


Fig.3 Dependency of the emission spectra intensity on the polarity of the gas-out electrode (T= 150°C).

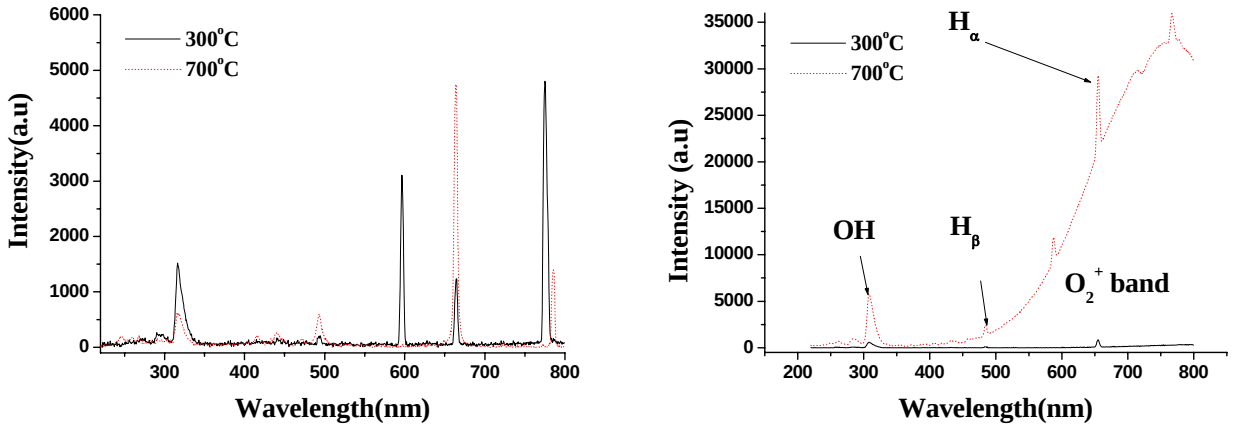
With the polarity of the gas-out electrode set as the anode the electron density of the plasma microjet was determined by measuring "the half width half maximum (HWHM)" of the gauss-fitted H beta line(486.13nm). The electron density, 1.14×10^{14} cm^{-3}, was obtained from its relationship to the HWHM [8]. It turned out that the density changed very little as the medium temperature was raised from 300 to 700°C.

Fig. 4 shows the dependency of the relative intensity of different lines of the emission spectra on the medium temperature. With the polarity of the gas-out electrode set as anode the spectra shows that the intensity of OH lines at 306 and 600 nm and O line at 771 nm decreases with increase of the temperature whereas the intensity of H lines at 486 and 656 nm increases [9]. This trend is attributed to increase of the rate of the $OH + O \rightarrow O_2 + H$ reaction with the increase in temperature (the thermodynamic prediction does not support the shift of the reaction to the forward direction.) With the polarity reversed the spectra shows the appearance of O_2^+ band as the temperature is over 500 [10]. Formation of the O_2^+ band with polarity reversal clearly indicates that the chemical reactions in the plasma region is sensitive to the polarity of the nearby electrode, which in turns could dictate the electric field contour of the region, and possibly the electron density profile.



(a) (b)

Fig. 4 The emission spectra at different medium temperature with polarity of the gas-out electrode set as (a) anode or as (b) cathode.

When SO_2 was added to the water vapor some changes were observed in the emission spectra, as shown in Fig. 5. With the addition of SO_2 the OH lines almost completely disappeared, indicating that OH species could have reacted with the added species [7,9,10].

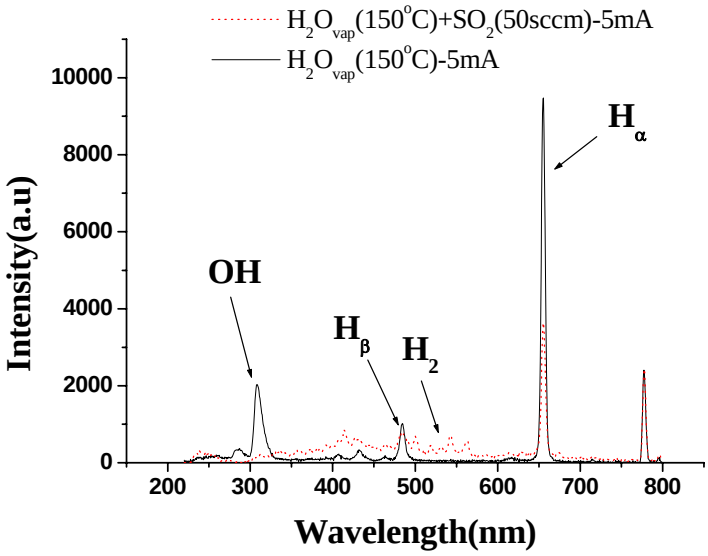


Fig. 5 Disappearance of OH line with SO_2 to the water vapor. The gas-out electrode is set as the anode.

Atmospheric pressure plasma-chemical preparation of Pt nanoparticles in liquid phase

I. G. Koo, J. H. Shim, M. S. Lee, K. W. Joung, Y. J. Kim and W. M. Lee

Department of Molecular Science and Technology, Ajou University, Suwon, Korea.443-749

Abstract

We have developed a novel method for preparing nano-sized Pt catalysts based on a plasma-chemical method. Pt nanoparticles were prepared in H_2PtCl_6 solution when electrical discharge powered by 60Hz AC was sustained between two electrodes, one outside the solution and the other placed in the solution, using atmospheric pressure H_2/He gas mixture as the working gas. The average particle size was in the range of 2.2 and 3.5 nm with the solution temperature maintained between 10^oC and 40^oC.

Keywords : platinum nanoparticles, atmospheric pressure plasma, plasma-chemical reduction, liquid phase discharge.

1. Introduction

Metal nanoparticles, particularly noble metals, have drawn increasing interest due to their potential use in preparation of high surface area electrodes and to some unique properties different from those of bulk materials [1]. The use of Pt as an electrocatalyst requires that the active area remains stable with time of operation and that the utilization of expensive Pt metal is most efficient. It is well-known that the catalytic activity of the metal is strongly dependent on the particle size, shape, and size distribution. Thus, numerous methods to produce and utilize Pt nanoparticles have been developed [2]. We are proposing a novel method for preparing nano-sized Pt catalysts based on a plasma-chemical method. Our work was motivated for a search of a method that warrants simple and fast preparation of Pt nanoparticles without using stabilizers and reducing agents, which could be toxic, so that the whole process would involve simplest possible chemical system. The critical step in preparation of its colloidal solution is the reduction of the metal by various reducing agents under the protection of stabilizers. Our group recently showed that $PdCl_2$ can be reduced to metallic Pd when the chloride reacts with hydrogen plasma. The plasma-chemical conversion of 3 μm thick $PdCl_2$ film coated on alumina substrate into Pd film took only 30 seconds without heating the reacting system; atmospheric pressure hydrogen plasma was generated by RF discharge through H_2/He working gas in contact with the film [3]. We extended this technique to plasma reactions at liquid-vapor interface so that hydrogen plasma in contact with aqueous Pt salt solution can possibly reduce the metal complex ions. We used the ionic compound, hexachloroplatinic acid (H_2PtCl_6), as the precursor. The novelty of the approach is manifested in fast kinetics, low temperature reaction, and no use of stabilizing agents. In this note we present the outline of the approach and some evidence of the nanoparticles produced under the circumstances described.

2. Experimental

Fig. 1 shows the experimental setup used in our work. A similar discharge system has been reported by other groups to generate non-thermal air plasma [4]. Pt nanoparticles were prepared in H_2PtCl_6 solution when electrical discharge powered by 60Hz AC was sustained between two electrodes, one outside the solution and the other placed in the solution, using atmospheric pressure H_2/He gas mixture as the working fluid. The total power consumption needed to sustain the discharge was less than 10 W. The gap between the upper electrode and the surface of the solution was maintained to be 5 mm. The inside of the tubular upper electrode (2mm OD, 1.5 mm ID) shielded by alumina provided the path through which the mixture of He and H_2 flew at the rate of 500 and 100 ml/min, respectively, with their total pressure approaching the atmospheric value. The surface of the metal salt solution acted as the water electrode while a stainless disk placed at the bottom of the solution completed the electrical connection to the power source. The temperature of the solution under constant stirring with a magnetic bar was set at 10 ± 0.1 ^oC or 40 ± 0.1 ^oC using a water bath (JEM-2010). The voltage and current were measured by a Tektronix 400Mhz digital oscilloscope with current prove.

The Pt colloidal formation in the solution and the plasma reaction were monitored using UV-Vis spectrometer (Scinco UV-2100). Pt colloids collected on carbon grids were examined using TEM (JEOL JEM-2010) and EDX.

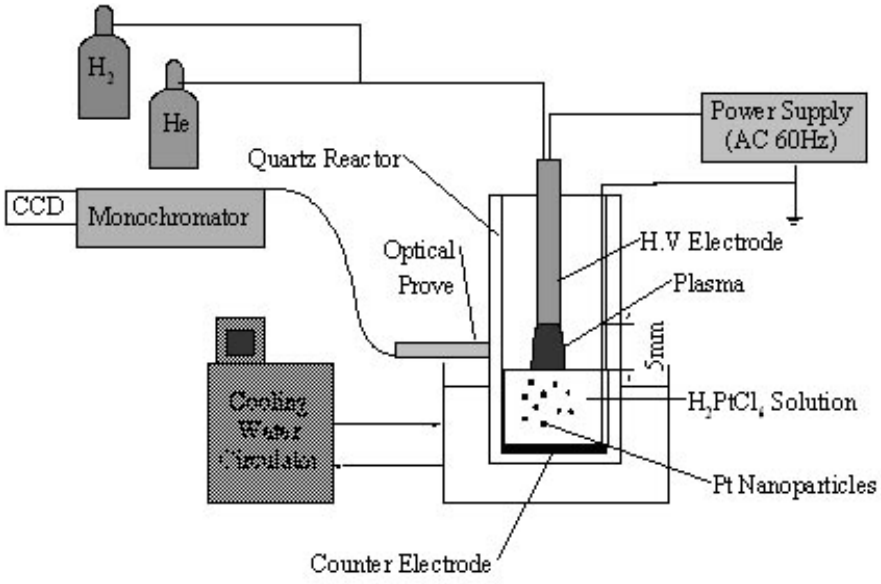

Fig.1 Schematic experimental setup

3. Results and discussion

The plasma-chemical generation of Pt nanoparticles, apparently at the interface region of the plasma and the solution as shown in Fig. 2, was achieved within 10 seconds during which most of the platinum chlorides in the solution was converted into Pt particles, evidenced by color change of the solution. The clear yellow aqueous H_2PtCl_6 solution changed to dark gray upon hydrogen plasma-chemical reaction. Fig. 3 shows that the

characteristic absorption peak of $PtCl_6^{2-}$ at around 260 nm disappeared 5 minutes after the onset of the discharge. The reduction rate of the metal salt was estimated to be about 1.2 x 10^{-5} mol/min from the change of UV/Vis absorbency. The black particle formation took place at the interface where the plasma touched the solution and the spread of the particles to other regions of the solution was clearly observable. The plasma formed with He gas alone without H_2 did not engage any reaction with the metal salt solution. As a plausible reaction mechanism it is proposed that the excited hydrogen species existing in the plasma helped, even at ambient temperature, fast dissociation of Pt-Cl bonds in $[PtCl_6]^{2-}$ ions producing Pt nanoclusters and HCl.

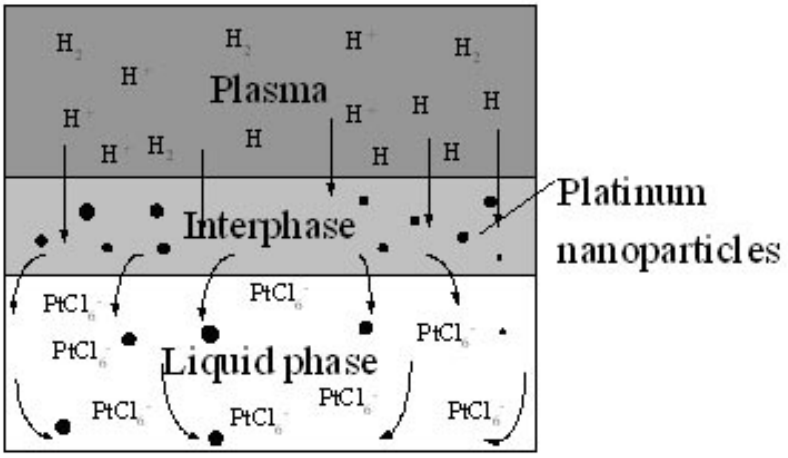

Fig.2 Plasma-chemical reaction

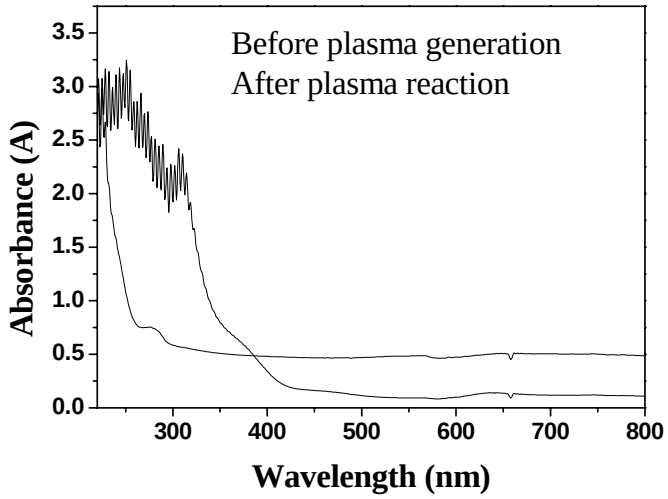

Fig. 3 UV-vis absorption spectra of solution containing H_2PtCl_6 before and after plasma-chemical reduction.

The formation of pure Pt particles was confirmed first by EDX profile taken on the Pt sample collected on

carbon conductive tab. The profile showed the peaks of only carbon and Pt, confirming that the chloride was completely converted to pure metallic phase as shown in Fig. 4. Fig. 5 shows the TEM images of the Pt particles. The TEM image discloses that the particles are not completely separated from one another since no stabilizer was used, but they are not coalesced into tight agglomerates, allowing size measurements of each particulate to be still possible. The particle size distribution determined from the image of Fig. 5 clearly indicates that it decreases as the solution temperature is lowered; the average size was around 2.2 and 3.5 nm at 10^{o} C and 40^{o} C, respectively.

Spectroscopic Analysis of Capillary Underwater Discharges

F. De Baerdemaeker[1], C. Leys[1] and M. Šimek[2]

[1] *Department of Applied Physics, Ghent University, Rozier 44, B-9000 Ghent, Belgium, Christophe.Leys@UGent.Be*
[2] *Laboratory of Pulse Plasma Systems, Institute of Plasma Physics, Za Slovankou 3, 18221 Prague, Czech Republic simek@ipp.cas.cz*

Abstract
A capillary underwater discharge in solutions of distilled water and $NaH_2PO_4.2H_2O$ (conductivity: 50 ÷ 1000 $\mu S.cm^{-1}$), sustained with AC (50 Hz) voltages up to 15 kV, was investigated by time-resolved ICCD spectroscopy. Preliminary measurements indicate that this discharge concept might be an efficient source of OH, H^I and O^I radicals. For the negative pulsed microsecond discharge regime, most radicals are generated during the first few hundreds of nanoseconds after the breakdown event. The average plasma duration is of the order of a few microseconds. For the glow-like discharge regime the rotational distribution of $OH(A^2\Sigma^+, v=0)$ state deviates from a single Boltzmann distribution.
Keywords: water, capillary, AC discharge, OH emission

1. Introduction
The past few years witnessed an increasing interest in underwater plasmas, but compared to the broad knowledge on discharges in the gas phase, the physics of underwater discharges is still largely unknown. Electrical discharges above water surface or underwater can be generated in several ways [1-6], e.g. excited with either short or slow rising voltage pulses and by using various electrode geometries. Envisaged application areas include water purification and shock wave generation.
An approach that allows generating underwater plasmas with DC or low frequency AC voltages at atmospheric pressure is the 'diaphragm' discharge. The principle relies on forcing the electrical current to flow through a narrow bore in a dielectric material between two submerged electrodes. When the current density is sufficiently high, local boiling and subsequent vapour breakdown results in the formation of a plasma within this pin-hole. A variant is the 'capillary' discharge, generated in a bore with large length-to-diameter ratio.

2. Experimental set-up
In this study an AC capillary underwater discharge was investigated in solutions of distilled water and $NaH_2PO_4.2H_2O$. The applied high voltage (up to 15 kV rms) is obtained by stepping up the 220 V (50 Hz) mains, and is varied using an autotransformer. In series with the capillary a 50 Ω resistor is placed which allows measuring the electrical current flowing through the capillary. Dimensions of the Macor glass ceramic capillary are 0.5 mm inner diameter and 5 mm length. The electrodes are aluminium bars, and both water vessels are cooled to room temperature (see figure 1). Two different discharge regimes occur, depending on the conductivity and the excitation voltage, ranging from repetitive microsecond discharge pulses at a frequency of 100 Hz to a quasi-continuous discharge with a glow-like voltage-current characteristic [7]. Electrical conductivity was varied in the range 50 ÷ 1000 $\mu S.cm^{-1}$ and the excitation voltage was varied in the range 5 ÷ 15 kV.

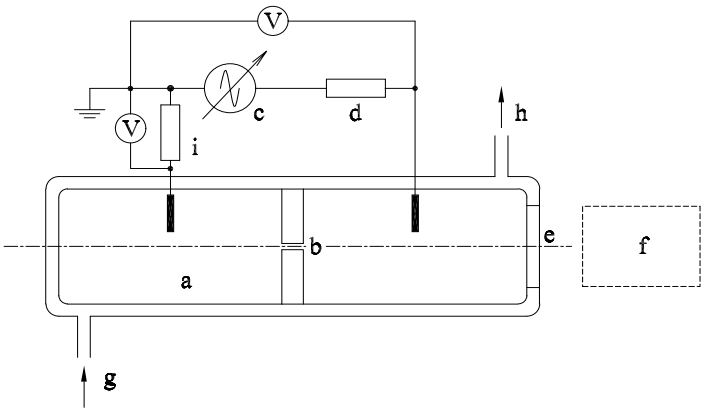

Fig. 1. Experimental set-up: (a) cooled water vessels, (b) dielectric capillary, (c) high voltage source (*U*: 0-15 kV rms, 50 Hz), (d) 100 kΩ resistor, (e) quartz window, (f) ICCD spectrometer, (g) cooling water inlet, (h) cooling water outlet, (i) 50 Ω resistor.

Optical characterization of plasma induced emission for the negative pulsed microsecond discharge regime was carried out for varying conductivity and excitation voltage by time-resolved ICCD spectroscopy. Furthermore, time-averaged measurements were performed to evaluate rotational temperature by analyzing emission of OH radical. The CHROMEX-500i imaging spectrometer equipped with an intensified TE/CCD-1024 TKB/UVAR/1 two-dimensional charge-coupled device detector (gated through a PI PG-200 gate pulse generator) monitored the emission coming out along the symmetry axis of the discharge through quartz optics and color-glass filters. Spectra acquisition was performed through a PI ST-138 controller and WinSpec software. Spectra were corrected for the detection sensitivity by means of a tungsten ribbon lamp (OSRAM Wi 17/G).

3. Results and discussion

3.1. Basic emission features

Spectroscopic measurements of the plasma induced emission performed without time-resolution indicate that this kind of 'underwater' plasma might be an efficient source of OH, H^I and O^I radicals (see figure 2). Clear evidence is given by observing radiation produced in 280-900 nm spectral range. The most intense emissions are produced by OH, H^I and O^I electronically excited species (see figure 2).

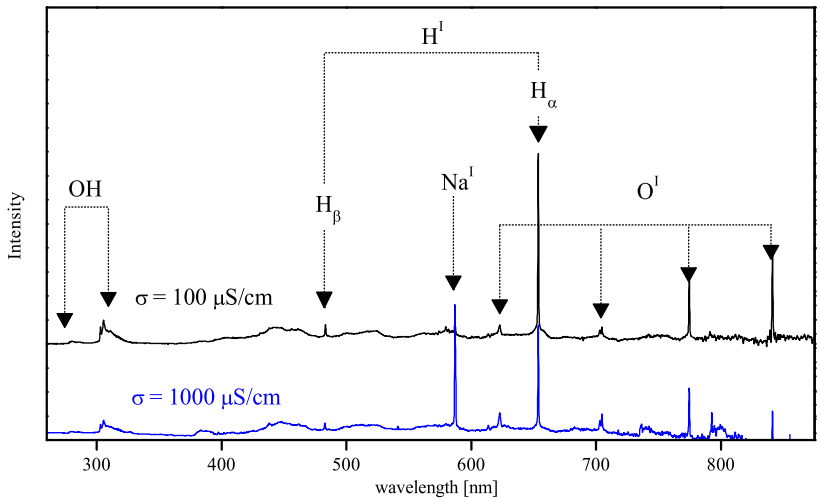

Fig. 2. Time-averaged ICCD spectrum of the glow-like capillary discharge regime;
a) σ =100 μS.cm^{-1} (upper trace; U = 8.5 kV (50 Hz)) and b) σ =1000 μS.cm^{-1} (lower trace; U = 5.5 kV (50 Hz)).

3.2. Time evolution of OH and H_α emission

Characterization of the evolution of the plasma induced emission intensity and the average plasma duration for the negative pulsed microsecond discharge regime was performed using time-resolution which was defined by the opening gate of an ICCD intensifier. A time-resolution was selected as a compromise between necessity to acquire spectra with both high time-resolution and sufficient S/N ratio during reasonably long accumulation period (typically 2-10 min/spectrum). Figure 3 shows typical evolutions of OH and H_α emissions for the negative pulsed microsecond discharge regime at two different conductivities (100 and 200 μS.cm^{-1}) and at an applied AC voltage of 8 kV rms. Time evolution of the applied AC voltage and current signal for this pulsed microsecond discharge regime is shown in figure 4. All time evolutions shown in figure 3 were normalized to 1 for the first point of each curve. The measurements indicate that radiative species are mostly generated during the first few hundreds of nanoseconds of plasma generation. All acquired emission intensities clearly show a two slope decay characteristic with characteristic time-constant of initial fast part τ = 0.2-0.4 μs. Due to internal delays and jitters of the used diagnostic instrumentation, the plasma induced emission could not be explored with sufficient time-resolution for discharge onset delays lower than ~200-400 ns, consequently we are missing the initial development of emission intensities. The average duration of plasma emission induced by the breakdown event for the negative pulsed microsecond discharge regime is however clearly of the order of a few microseconds.

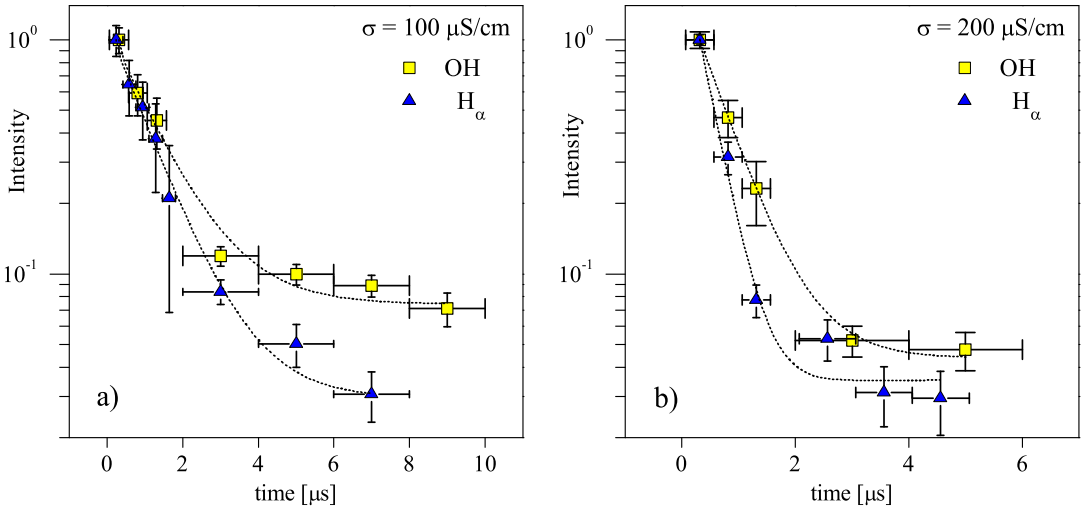

Fig. 3. Characteristic evolutions of OH and H_α emission intensities acquired for the negative pulsed microsecond discharge regime at an applied AC voltage of 8 kV for water solution conductivities of a) 100 and b) 200 µS.cm^{-1}.

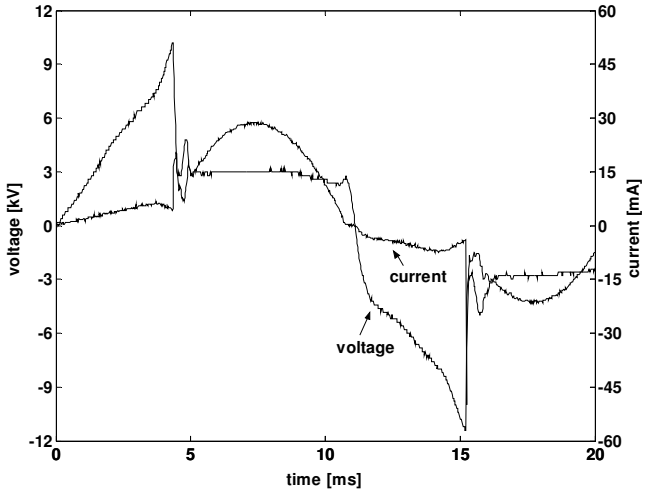

Fig. 4. Voltage and current signal for the pulsed microsecond discharge regime for water solution conductivity of 100 µS.cm^{-1} at an applied AC voltage of 8 kV rms.

3.3. Rotational distribution of OH($A^2\Sigma^+$, v=0) state

Partially resolved profile of OH($A^2\Sigma^+$,v=0 → $X^2\Pi$,v=0) band is often being used to evaluate rotational temperature T_{rot} in order to estimate, especially in high-pressure discharges, the gas temperature T_g. We attempted to evaluate T_{rot} by means of a synthetic model [8]. However, we found it impossible to reproduce well the overall (0,0) band-profile using a single Boltzmann rotational temperature T_{rot} as a fitting parameter. As the resolution of the 0.5 m spectrometer is not sufficient to resolve fully most intense rotational lines arranged in R_{11}, R_{22}, Q_{11} and Q_{22} branches, we had to resort to a set of very weak $^SR_{21}$ satellite lines occurring, quite well isolated, in 302-306 nm spectral region, just in front of the first band head at 306.26 nm (figure 5).

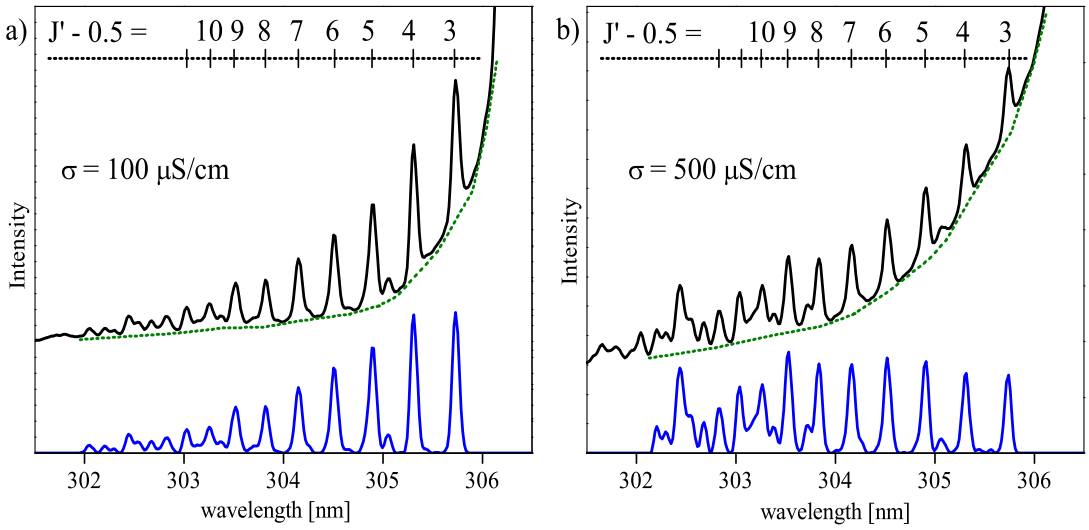

Fig. 5. Characteristic, partially-resolved OH emission through the $^{S}R_{21}$ branch of the OH($A^2\Sigma^+$,v=0 → $X^2\Pi$,v=0) band. Spectra acquired for the glow-like discharge regime for water solution conductivity of a) σ= 100 μS.cm^{-1} (U = 8.5 kV (50 Hz)) and b) = 500 μS.cm^{-1} (U = 8 kV (50 Hz)).

The rotational distributions plotted as a function of the roto-vibronic energy of $A^2\Sigma^+$ state levels are shown in figure 6. They were derived from spectra shown in figure 5. The distribution shown for water solution conductivity σ= 100 μS.cm^{-1} can be quite well fitted with a straight line (least-square fitting procedure applied to $^{S}R_{21}$(J'=3.5, 4.5, 5.5, 6.5, 7.5, 8.5) corresponding to a Boltzmann rotational temperature T_{rot} = 1530 K (figure 5a). Higher levels (J'= 9.5 - 12.5) show deviations from a single Boltzmann slope. A qualitatively very different distribution, obtained for water solution conductivity σ= 500 μS.cm^{-1}, is shown in figure 5b. It is apparently a highly non-Boltzmann distribution with the initial slope (evaluated from $^{S}R_{21}$(J'=3.5) and $^{S}R_{21}$(J'=4.5) line intensities) corresponding to T_{rot} = 2660 K. Here we have to note that the two distributions shown in figure 6 have been selected among many others as the two extreme cases (with all other distributions in between those two extremes). Furthermore, source spectra were acquired as time and space (along the capillary axis) averaged data; therefore they cannot be identified, at the moment, with any local discharge parameter.

4. Concluding remarks

Discharge generation in a thin dielectric capillary filled with liquid water solution driven by an AC high-voltage power supply presumably involves a breakdown of a water vapour bubble. The bubble is formed inside the capillary as a consequence of local heating of water solution due to increased current density. During the breakdown, various species may be formed through electron impact dissociation processes. Except of H_2O molecules, we have to consider other species as, e.g., NaH_2PO_4, N_2/O_2 (dissolved air molecules) and fragments of dielectric Macor glass ceramic (borosilicate glass + fluorophlogopite mica).
We investigated the discharge sustained with AC (50 Hz) voltages up to 15 kV rms by employing ICCD spectroscopy. Our measurements performed for water solution conductivity in the range 50-1000 μS.cm^{-1} indicate that this discharge concept might be an efficient source of OH, H^I and O^I radicals. The rotational distribution of OH($A^2\Sigma^+$, v=0) state for the glow-like discharge regime deviates from a single Boltzmann distribution. The rotational temperatures we have derived from the beginning of OH($A^2\Sigma^+$, v=0) rotational distribution indicate that quite high gas temperatures might be achieved during the breakdown event. This is consistent with observing a progressive erosion of Macor capillary profile after several hours of discharge operation. For the negative pulsed microsecond discharge regime, most emitting species are generated during the first few hundreds of nanoseconds after the breakdown event. The average plasma duration for the negative pulsed microsecond discharge regime is of the order of a few microseconds.

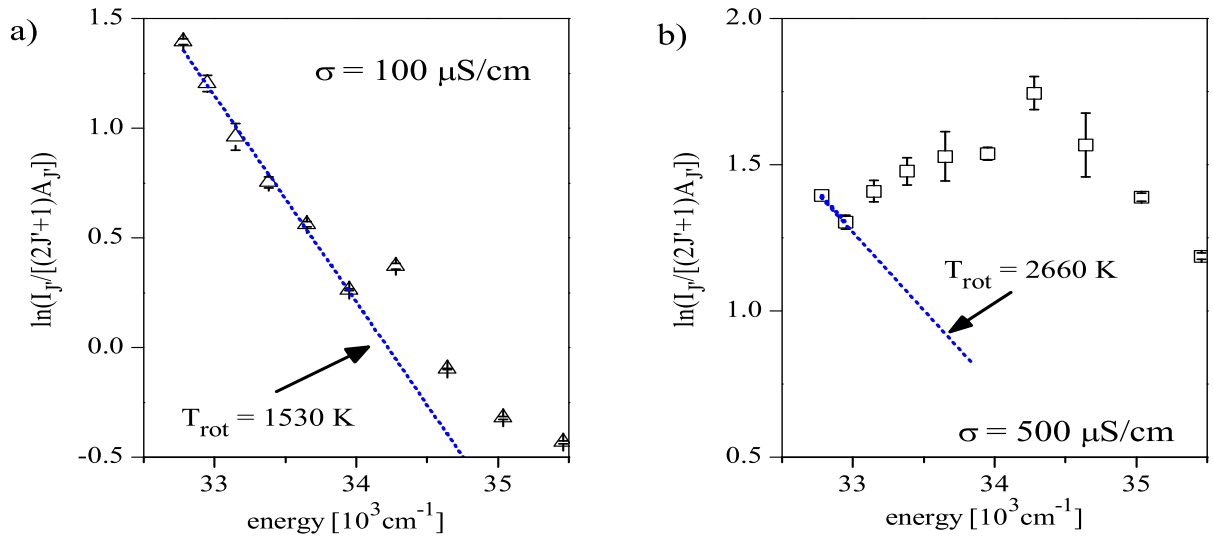

Fig. 6. Rotational distribution of OH($A^2\Sigma$,v=0) electronic state as derived from isolated lines belonging to $^{S}R_{21}$ branch of the OH($A^2\Sigma^+$,v=0 → $X^2\Pi$,v=0) band in the case of a) σ= 100 μS.cm^{-1} (U = 8.5 kV (50 Hz)) and b) σ= 500 μS.cm^{-1} (U = 8 kV (50 Hz)).

Modeling nanoparticle effects on a low-pressure plasma

S. J. Warthesen and S. L. Girshick

Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN.

Abstract

The interactions between a plasma and nanoparticles are discussed here in the context of plasma-enhanced chemical vapor deposition. Results are obtained from a 1-D plasma model coupled to an aerosol transport model. The influence of nanoparticles on plasma properties is reviewed, and the charge distribution for 2-5 nm diameter particles is presented. A significant fraction of particles are found to be positively charged in a region of the sheath, close to the electrode.

1. Introduction

Nanoparticle-plasma systems are of interest for various processes, such as hypersonic plasma particle deposition, plasma etching, and plasma-enhanced chemical vapor deposition. Particles may be detrimental to plasma processes, causing contamination problems, or may be desired for the production of nanostructured materials and devices. In either case, the industrial goal is to control the nanoparticles in the plasma. Ultimately, this requires the study of formation, growth, and transport of nanoparticles, and their influence on the plasma parameters driving the process of interest. The focus of this research is to model the interactions between nanoparticles and plasma in the context of plasma-enhanced chemical vapor deposition (PECVD). During PECVD of silicon thin films using a silane or diluted silane plasma, nanoparticle formation can occur in the gas-phase. The mechanisms of nanoparticle nucleation, growth, and transport, as well as the interaction between nanoparticles and the plasma, form a complex system resulting in several interesting phenomena. These include the formation of trapped particle layers within the plasma and a drastic increase in electron temperature in the presence of particles (α-γ' transition) [1]. Several research groups have investigated the nanoparticle-silane plasma system, including many numerical studies. Akdim *et al.* developed a one-dimensional plasma model describing the influence of 2-μm-radius particles on the plasma characteristics [2]. De Bleecker *et al.* extended this model to include silane plasma chemistry predicting particle nucleation [3]. They equated nuclei formation with particles in the 10-100 nm size range and discussed the development of particle trapping layers for various particle sizes. Bhandarkar *et al.* predicted nucleation of particles using an extensive chemical clustering mechanism, and coupled this to an aerosol growth model in 0-D [4]. Both modules are solved consistently with bulk plasma parameters, predicting the temporal evolution of particle concentration and size and charge distributions. The focus of this research is the extension of this 0-D model to 1-D to describe spatial variations of the plasma and particle properties during particle nucleation, growth, transport, and charging. Preliminary results of this development are discussed here, focusing on the interaction between the plasma and nanoparticles in the 2-5-nm-diameter range in a parallel plate PECVD reactor.

2. Model Description, Plasma Module

Our model describes a radio frequency, capacitively-coupled plasma in a parallel plate reactor. The reactor is assumed to have large electrode diameters compared to the electrode separation distance. Thus, the analysis is reduced to solving the governing equations in the axial direction between electrodes, as the system varies in time. Time-varying profiles of electron and ion concentrations, electron energy, and electric field are computed in the plasma module by solving the continuity equation for each species at each location in the discretized computational domain (for example, refer to [2, 5, 9]). The species flux terms are estimated by the drift-diffusion approximation. Ions, large compared to electrons, cannot follow the instantaneous electric field due to inertial effects. Thus, an effective electric field, described by Richards *et al.* is used in the drift-diffusion approximation in place of the local instantaneous electric field [5]. The loss of ions and electrons to particles is accounted for as a sink in each continuity equation, and is calculated according to collision frequencies discussed below. The electron energy balance is solved to calculate the electron temperature, and includes the energy absorbed by

electrons when intercepted by particles (to overcome the particle potential). Poisson's equation is solved to determine the electric field from the space charge, and accounts for charges residing on particles as well as free electrons and ions.

3. Particle Module

The change in size distribution and concentration of aerosols in space and time is described by the aerosol general dynamic equation. Mechanisms accounted for in the transport of neutral particles include diffusion, convection, and thermophoresis. Additional transport mechanisms are incorporated in the model to account for particle interaction with the plasma, including ion drag and electrostatic effects. Coagulation and surface growth are not included in these preliminary results. For computational ease, the complex chemistry mechanism is not included here. Instead, nucleation occurs at a prescribed rate.

The charge distribution of particles at a given location in space is calculated by assuming spherical particles and applying orbital-motion-limited (OML) theory to calculate ion and electron interception rates by the nanoparticles [6]. The collision frequency of electrons with a nanoparticle of radius r_p and potential V_p depends on electron concentration N_e and electron temperature T_e.

$$\nu_e = \pi r_p^{\,2} N_e \left(\frac{8 k_B T_e}{\pi m_e} \right)^{1/2} \alpha \qquad (1)$$

$$\alpha = \exp\left(\frac{eV_p}{k_B T_e} \right) \text{ for } k < 0 \qquad \alpha = \left(1 + \frac{eV_p}{k_B T_e} \right) \text{ for } k > 0 \qquad (2)$$

In the above equations, ν_e is the electron-particle collision frequency, m_e is the electron mass, k_B is Boltzmann's constant, and α is an enhancement or retardation factor, depending on the sign of the particle charge, k. For ions, the collision frequency equation is similar. However, the energy acquired by positive ions in the plasma sheath is taken into account by calculating the ion energy, E_o, based on the ion drift velocity, v_D, and using it in the collision frequency calculation below, where ν_i is the ion-particle collision frequency, m_i is the ion mass, T_i is the ion temperature (assumed to be the same as the gas temperature), N_i is the ion concentration, and β is the charge dependent enhancement or retardation factor.

$$E_o = \left(\frac{8 k_B T_i}{\pi m_i} \right) + \frac{1}{2} m_i v_D^{\,2} \qquad (3)$$

$$\nu_i = \pi r_p^{\,2} N_i \left(\frac{2 E_o}{m_i} \right)^{1/2} \beta \qquad (4)$$

$$\beta = \left(1 + \frac{eV_p}{E_o} \right) \text{ for } k < 0 \qquad \beta = \exp\left(\frac{-eV_p}{E_o} \right) \text{ for } k > 0 \qquad (5)$$

By assuming that the particle charging process is in equilibrium with the local plasma properties, a recursive relationship is defined for the distribution of charges on particles of a given size, equation (6), where $\nu^k_{e\,(i)}$ is the collision frequency of electrons (ions) with a particle that has k unit charges. Subsequently normalized, F_k, represents the fraction of particles with k unit charges, providing a discrete charge distribution function [7]. The effect of secondary electron emission is not currently accounted for in this calculation, but may slightly shift the charge distribution toward positive charge values, depending on the reactor conditions [8].

$$F_{k+1} = \frac{\nu_i^k}{\nu_e^{k-1}} F_k \qquad (6)$$

The ion and electron continuity and electron energy equations are solved using the Scharfetter-Gummel scheme [9, 10]. These equations, as well as Poisson's equation for potential, are discretized and solved in a tridiagonal matrix solver. As suggested by Akdim and Goedheer, a time stepping procedure is implemented in two stages [2]. One time step is applied to the plasma balance equations, and a second, larger time step is applied to the nanoparticle module. Plasma parameters, such as the electric field, ion and electron concentrations, and electron temperature are time-averaged over the nanoparticle time step. The time-averaged profiles are applied to nanoparticle transport and charging calculations, since particles are too slow due to inertial effects to follow the high frequency oscillations of the plasma.

4. Results

Results presented here correspond to a typical PECVD reactor under conditions of particle formation. The electrode separation is 3 cm. The upper electrode (x = 3 cm) is the RF-powered electrode, while the lower, representing the film substrate, is grounded (x = 0). The RF voltage and frequency are 200 V and 13.56 MHz, respectively. The reactor pressure is ~13 Pa (100 mTorr), with a uniform gas temperature of 300 K. The plasma is modeled as an argon plasma in a static gas (excluding convection effects). The ion drag force has been shown to have a negligible influence on the transport of particles in this size range under these conditions [3], thus it is excluded from the present calculations for computational simplicity. Initially, the plasma is established by running the simulation without particles for several cycles. Once a periodic steady state for the non-contaminated plasma is obtained, particles are introduced at low concentrations (less than that of the electron concentration). An initial population of particles is placed in a region approximating the bulk plasma (indicated in Figure 1), and subsequent nucleation is assumed to occur only in this region. This assumption is consistent with the simulation results of De Bleecker *et al*, who showed that nucleation in a diluted silane plasma, for similar conditions, mainly occurs in the plasma bulk [11]. The nucleation rate applied to the system is estimated from results of quasi-1-D simulations coupling the chemical clustering mechanism to aerosol and plasma modules [4].

In Figure 1, the period-averaged ion and electron concentrations are compared to the particle concentration at 0, 10^{-3}, and 10^{-1} seconds after nucleation began. N_+ represents the ion concentration (Ar^+), N_e is the electron concentration, and N_p represents the concentration of particles within the reactor. Particles here are 2 nm in diameter, with a constant production rate (~ nucleation) of 10^{11} $cm^{-3}s^{-1}$. As time proceeds, an increase in particle

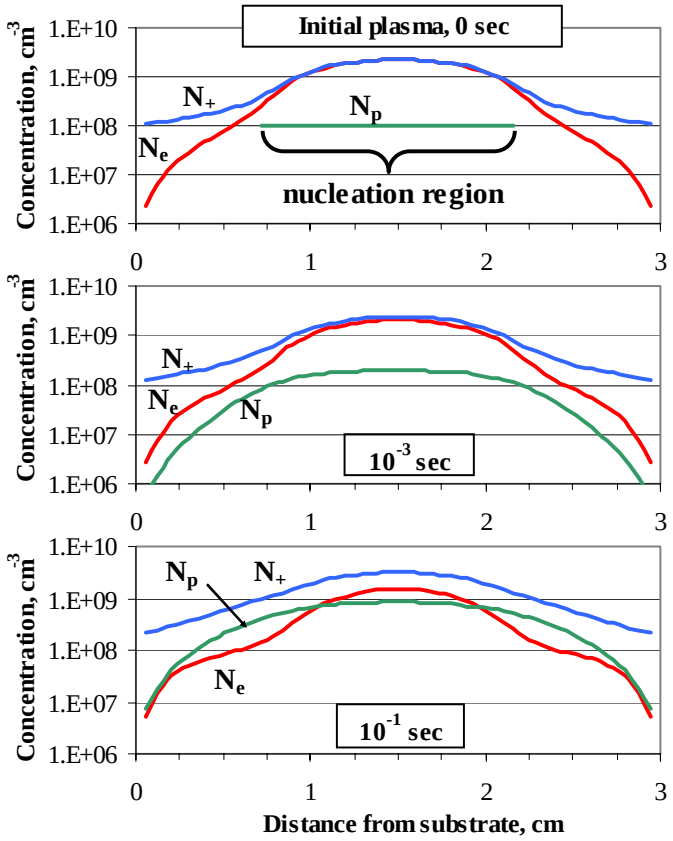

Figure 1. 2-nm-diameter particle concentration (N_p) in the reactor at various times. Initially $N_p = 10^8$ cm^{-3}, with a nucleation rate of 10^{11} $cm^{-3}s^{-1}$. Concentration is compared to ion and electron concentration (N_+, N_e) in the plasma. The electron concentration drops slowly in time, while the ion concentration increases.

concentration occurs throughout the reactor as particles nucleated in the center region are transported due to diffusion and electrostatic force. The period-averaged electron temperature, T_e, and ionization rate corresponding to profiles in Figure 1 are displayed in Figure 2. When particles are present, electrons are lost to particles and they become negatively charged. Ions are also lost to particles, but to a much lesser degree than electrons because of the electron:ion mobility ratio. In the center of the plasma, where the electron concentration is highest, electron loss results in a slight increase in T_e. In this region, T_e, increases slowly from 2.1 to 2.6 eV over 0.1 seconds, as seen in Figure 2a. Contrastingly, in the sheath region, T_e quickly increases from 2 to 4 eV. Since the electron concentration in the sheath is significantly lower than in the plasma center, the electron temperature is more sensitive to particle charging effects. The increase in T_e causes an increase in ionization rate, which is maximum in the plasma center where the electron concentration is highest (Figure 2b). The ion concentration increases with ionization rate (a factor of 1.5 – 2 over 0.1 seconds), as does the power absorption in the plasma (the RF voltage is maintained, allowing absorbed power to change).

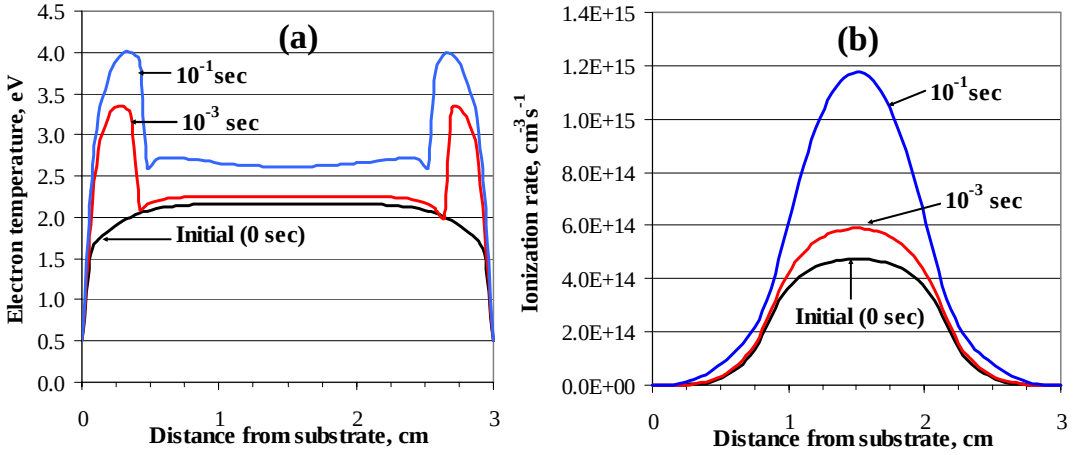

Figure 2. Variation of plasma properties as particle concentration increases. (a) Electron temperature increases quickly in sheath, and slowly in the plasma bulk. (b) Ionization rate increases in time.

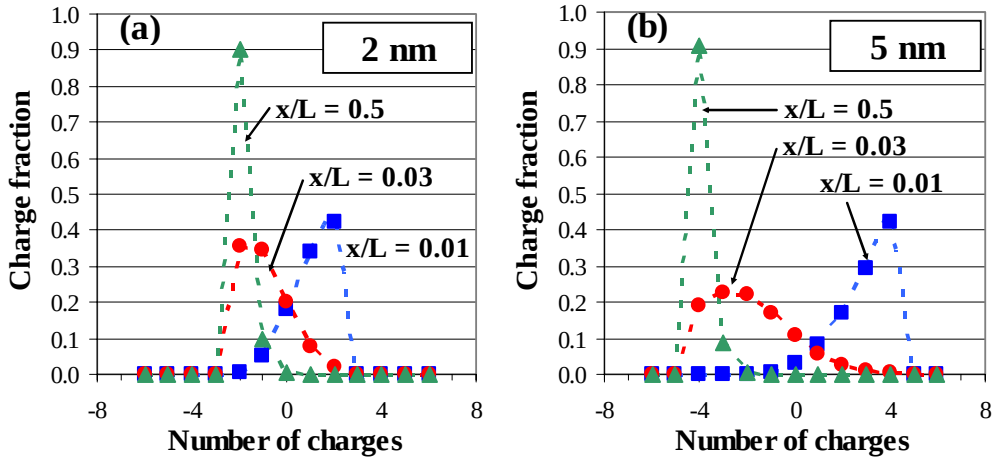

Figure 3. Charge distributions, at 0.1 s, for particles at three locations within the reactor (for position x relative to electrode separation L); near the electrode, within the sheath, and in the plasma center. Particles have a diameter of (a) 2 nm and (b) 5 nm. Near the electrode, particles may acquire a positive charge due to the increased energy of ions and small electron concentration in the sheath. Lines are added to the discrete charge distributions for visual clarity.

The charge distribution of 2-nm-diameter particles is shown for various locations (close to electrode, mid-sheath, and plasma center) in Figure 3a, where *x/L* indicates the position in the reactor *x* relative to the electrode separation *L*. The charge distribution is shown at 0.1 seconds, and changes little over the time simulated here. It is interesting to note that due to low electron concentrations and high ion velocity in the sheath, particles are likely to become positively charged. The contribution of ions to charging is mostly due to their energy acquired in the sheath (equation 3). If only the thermal energy of ions is considered, the calculated charge distribution remains almost completely negative. Figure 3b shows the charge distribution for nanoparticles with a diameter of 5 nm. The charge distribution was taken after 0.1 seconds under conditions similar to those described for the 2-nm simulation. The same three locations are shown in Figures 3a and 3b. It is assumed that 2-nm particles are limited to a maximum of 2 charges, while 5-nm particles are allowed to hold up to 4 charges [12]. Both sizes show similar charge distribution characteristics. In the plasma center, the electron supply is sufficient such that most particles are charged to their negative charge limit. As particles move into the sheath, however, the competition for electrons among particles shifts the distribution to a less negative charge. As particles continue to move toward the electrode, the contribution of ions becomes significant, and both negatively and positively charged particles are likely to exist (*x/L* = 0.03, Figure 3). Very close to the electrode, the particle charge distribution is almost completely positive. Particles are present in low concentrations here, thus there is little or no competition among particles for charges. In both the 2- and 5-nm case, most particles attain their maximum allowed charge, now positive as opposed to the negative charge in the center of the plasma. Thus, a region of one or two millimeters extends from both electrodes into the plasma where positive particles are likely. These positive particles will be quickly rejected from the plasma due to the electric field. This mechanism of particle loss will influence the growth of particles in the reactor as well; small particles are likely to diffuse to the sheath region and can be expelled before growing to larger sizes. For example, compare the *x/L* = 0.03 charge distribution for 2 and 5-nm diameter particles. If a 2-nm particle grows to 5 nm near this location, it is more likely to acquire a negative charge and be transported toward the center of the plasma for further growth. In addition to the effect on growth mechanisms, the existence of a positive charge region near the electrode has significant implications for plasma processing of materials. Even if the number concentration of particles is low in the sheath, a high percentage of them may have high velocities upon deposition or impaction on the substrate.

5. Summary

This research attempts to simulate nanoparticle behavior during PECVD of silicon films. In development of a more complete model, we have presented preliminary results using a one-dimensional plasma model coupled with an aerosol transport and charging model. Using this model, simulations have been presented and the interaction between nanoparticles and a plasma have been explored. It is found that ionization rate increases as particles become more populous, and the electron temperature increases drastically in the sheath. In the bulk plasma, the electron temperature is also increasing, but more slowly and to a lesser magnitude than the sheath electron temperature. Finally, charge distributions have been presented, discussing the existence of positively charged particles in the sheath. Positively charged particles are likely to escape and reduce the overall growth rate of particles in the reactor. Also, positive particles can significantly affect the quality of the film being deposited due to the high energy acquired by positively charged species over the large electric field of the sheath.

This research is supported by NSF under IGERT grant DGE-0114372 and MRSEC grant DMR-0212302, by DOE under grant DE-FG02-00ER54583, and by the Minnesota Supercomputing Institute.

Numerical Study of the Transition from Filamentary Dielectric Barrier Discharges to Uniform Glows in Helium at Atmospheric Pressure

Peng Zhang, Uwe Kortshagen

Department of Mechanical Engineering, University of Minnesota, Minneapolis, USA

Abstract

The transition from filamentary dielectric barrier discharges to uniform glow discharges in atmospheric helium has been studied by a two–dimensional fluid model. Influences of different operating parameters have been investigated. The results show that for a filamentary discharge the number of filaments increases with the frequency and the voltage. The overlap of the filaments favors the formation of a uniform glow. For dielectric barriers with lower permittivity, the number of filaments decreases, resulting in a uniform Townsend discharge.

Keywords

Dielectric barrier discharge, atmospheric pressure glow, two-dimensional fluid model

1. Introduction

The dielectric barrier discharge (DBD) is a non-equilibrium discharge in which one or both electrodes are covered with an insulating layer [1]. At atmospheric pressure, DBDs typically have a filamentary structure, characterized by a large number of short-lived microdischarges. This behavior is highly transient and non-uniform over the electrode surface; hence high-pressure DBDs are of limited use for applications that require high plasma uniformity [2, 3]. Operated in similar reactor set-ups as DBDs, atmospheric pressure glow (APG) discharges have attracted great attention [4-7]. Typical APGs have a structure similar to low-pressure glow discharges. Being transversely homogeneous, they have a unique advantage over the filamentary DBDs for applications that require uniform plasma treatment such as thin film deposition [8], VLSI processing [9, 10], biological sterilization or decontamination [11].

Dielectric barrier discharges have been studied for many years [3, 12-15]. Under certain conditions, self-organized filaments can be formed. Brauer *et al* simulated the formation of self-organized filaments and demonstrated that for large *pd* values the discharge had a natural tendency to become filamentary [14]. An increasing number of filaments were reported for increasing voltage by T. Shirafuji *et al* [15]. However, so far no comprehensive numerical study of transition from filamentary to glow discharge has been reported.

The two-dimensional modeling of APGs is still in an early stage. Highly disparate time-scales have to be satisfied for capturing both the instantaneous and long-term behaviors of the discharge. A first successful effort was made by Schweigert and Kortshagen [16]. In this work, the time-dependent two-dimensional distribution of electrons and ions was obtained for the first time. However, with only electrons and atomic helium ions considered, the kinetic model was too simple to represent the real experimental situation, where experimental results have revealed the existence of strong nitrogen emission in otherwise high purity helium atmospheres. More sophisticated kinetic models were developed in later works by other groups [17-19]. With those the breakdown process of the APG in helium [17] and in nitrogen [19] has been reproduced. However, limited information was given on the discharge evolution up to reaching a periodic steady state, which typically takes several ac cycles.

In the current paper, based on a two-dimensional fluid model, the transition between a filamentary DBD and a uniform APG is investigated. Influences of operating parameters such as the driving frequency, the amplitude of the applied voltage, and the dielectric constant of the dielectric barrier material are studied. The paper is organized as follows: Section 2 describes the model and elementary processes, section 3 presents the numerical results and their interpretations, and section 4 summarizes the main conclusions.

2. Model and Elementary Processes

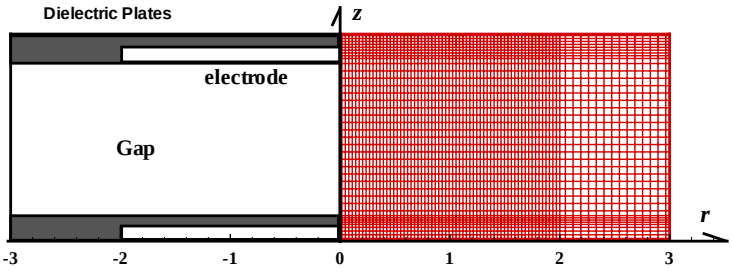

Fig. 1. Numerical simulation domain.

A two-dimensional fluid model has been developed for the simulation of APGs. Based on the experimental setup (see ref. [20] for details), the numerical simulation domain is selected, which includes two 1mm-thick dielectric barriers and a 5mm discharge gap as shown in Fig. 1. The electrodes are embedded in the dielectrics. The radius of the electrodes and the dielectrics are 2cm and 3cm, respectively. The gap is filled with atmospheric-pressure helium. Assuming azimuthal symmetry, cylindrical coordinates *(r-z)* are used. A non-uniform mesh of 81x121 nodes is used with the minimum node spacing being 62 μm.

For a pure helium discharge, due to the small leak rate of the experimental system, the known effects of nitrogen impurities must be considered in the simulation. The following species are used for the model: electrons (e^-), atomic and molecular helium ions (He^+, He_2^+), helium metastables (He^*), and molecular nitrogen ions (N_2^+). Here helium excited states of 2^3S and 2^1S are lumped into one single state for simplicity (denoted He^*). The model involves the self-consistent solution of the Poisson equation for the electric field and the continuity and momentum equation for all the species. The momentum equations are simplified by using the drift-diffusion flux approximation. The governing equations are:

$$\nabla^2\phi = -\frac{e(n_i - n_e)}{\varepsilon_0} \tag{1}$$

$$\frac{\partial n_e}{\partial t} = G_e - L_e + \nabla\cdot(-\mu_e n_e \nabla\phi - D_e \nabla n_e) \tag{2}$$

$$\frac{\partial n_i}{\partial t} = G_i - L_i + \nabla\cdot(\mu_i n_i \nabla\phi - D_i \nabla n_i) \tag{3}$$

$$\frac{\partial n_m}{\partial t} = G_m - L_m + \nabla\cdot(-D_m \nabla n_m) \tag{4}$$

Here ϕ is the electric potential, n is the number density, μ is the mobility, and D is the diffusion coefficient. The subscript *e*, *i*, and *m* represent the electrons, ions, and metastables in the discharge, respectively. The generation term $\boldsymbol{G}$ and loss term $\boldsymbol{L}$ are determined by the elementary processes inside the discharge. The reactions and the corresponding rate coefficients are the same as in ref. [20].

The secondary electron emission at the dielectric surface due to ion bombardment is regarded as a main source of electrons sustaining the glow discharge. The space charge deposited on the plates is obtained from the drift-diffusion flux to the dielectrics. The surface sticking coefficients of the electron and ions is set to 1 for simplicity.

The simulation was started with one electron avalanche located at cathode, with a maximum electron density equal to 10^6 cm^{-3}. For all the cases, a sinusoidal alternating current (ac) voltage was applied. The nitrogen concentration was assumed to be 20ppm. The simulations were stopped once a periodic solution was reached, usually occurring after 8-10 ac cycles.

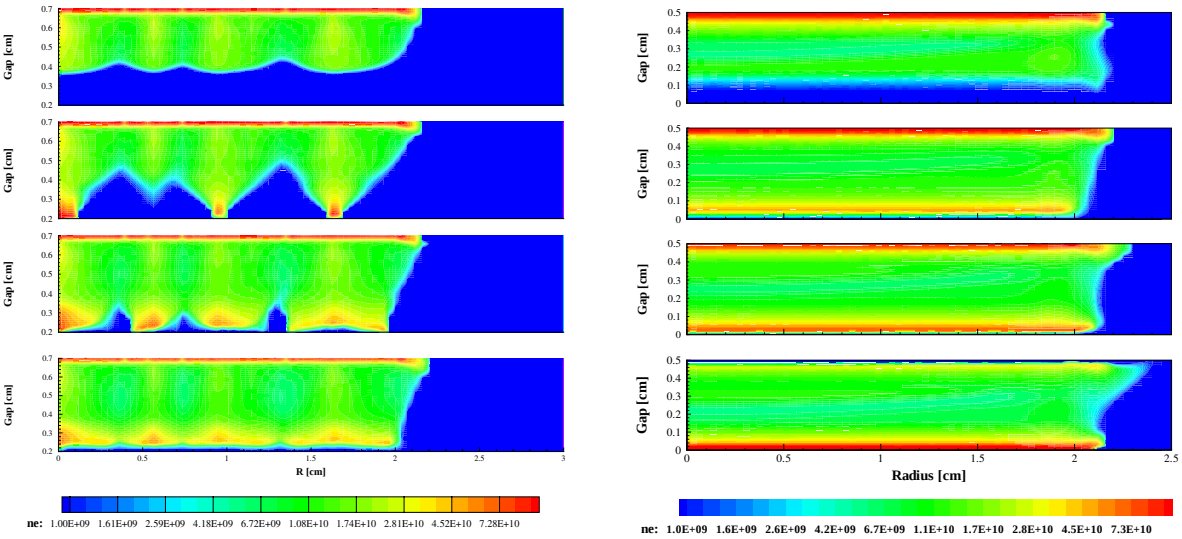
The transport terms in the continuity equations are discretized using the Scharfetter-Gummel exponential scheme [21] on a non-uniform mesh. To increase the time-stepping efficiency, an adaptive time step and a semi-implicit

time integration scheme [22] are adopted. All the numerical simulations were implemented on an IBM Power4 supercomputer at the University of Minnesota Supercomputing Institute.

3. Results and discussion

In the following, we study the influence of frequency, voltage amplitude, and dielectric material, which are all important parameters that can affect the discharge behavior.

3.1 *Driving frequency*



(a) (b)

Fig. 2 Electron density profiles at different times for f =15kHz (a) and f =30kHz (b).

To study the influence of the driving frequency, the applied voltage amplitude is fixed at 1.8kV. Alumina dielectrics are used with a relative permittivity equal to 9. Fig. 2(a) shows the electron density profile at different times for a 15kHz frequency. Four self-organized filaments are observed in the discharge gap. The location of the filaments is balanced by the repulsive force between the filaments and the confining potential as stated in [15]. The number of filaments increases as f increases to 18kHz, 20kHz, 23kHz (Fig. 3). Eventually, when the frequency reaches 30kHz, numerous filaments are formed. The coalescence of these filaments finally leads to the uniform appearance as shown in Fig.2 (b).

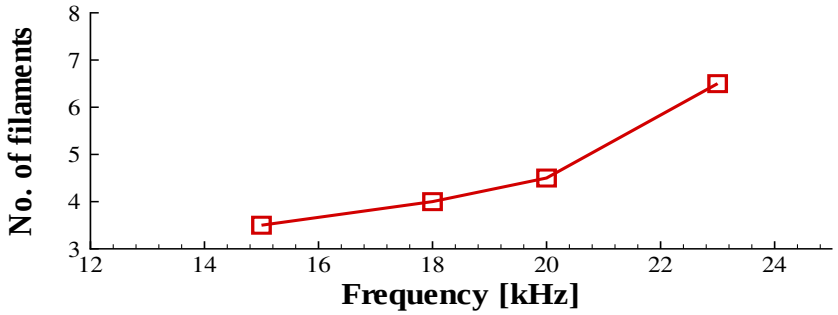


Fig. 3 Number of filaments as a function of frequency.

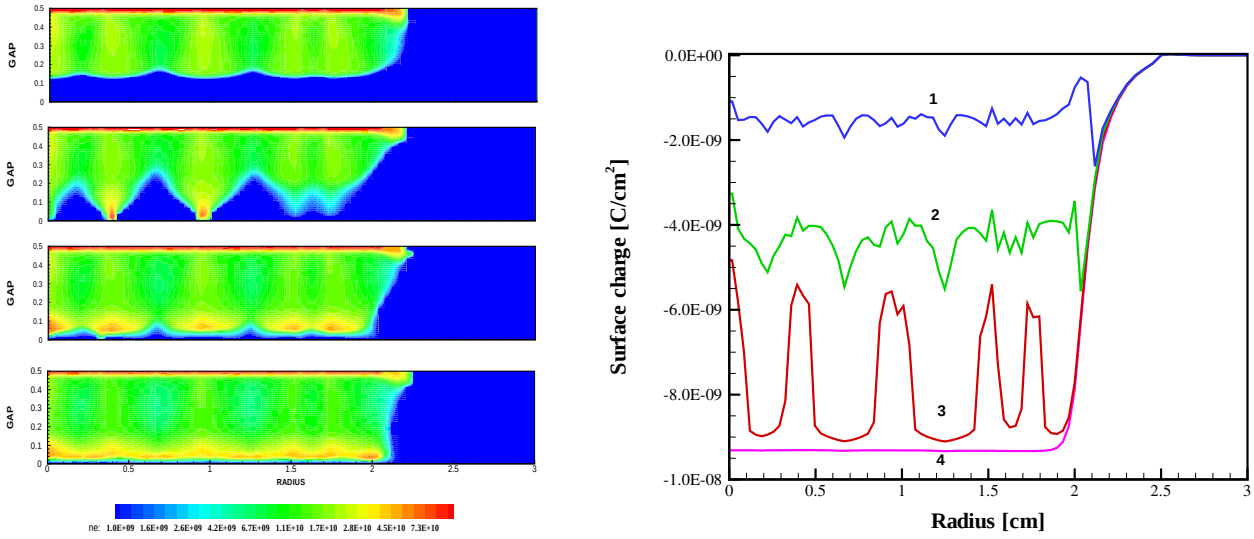
It should be pointed out that the trend we observe here, namely, the number of filaments increasing with driving frequency, is consistent with the results obtained by other researchers [14, 16]. The observed trend is based on two mechanisms: The first is the increasing pre-ionization with frequency since at higher frequency there is less time between discharge pulses for the density to decay through recombination. The second is related to the ion

transport and diffusion, which are limited at a higher frequency, resulting in a smaller separation between filaments and an increasing number of filaments.

3.2 Amplitude of the applied voltage

For the formation of a glow discharge at atmospheric pressure, a Townsend breakdown is required instead of a filamentary breakdown. For this purpose, the applied voltage has to be only slightly larger than the breakdown voltage. Too large an overvoltage will result in a filamentary breakdown and thus an inhomogeneous filamentary discharge.



(a) (b)

Fig. 4. Electron density (a) and surface charge density on the powered dielectric (b) at different times for a 2.5kV voltage.

For a self-organized filamentary discharge, the discharge appearance also changes with the voltage amplitude. If the voltage for the case in Fig. 2 is elevated to 2.5 kV, the number of filaments increases from 4 to 5 along the electrode radius as shown in Fig. 4(a). This effect may be explained by the limited capacitance for a unit area of the dielectric. Because the gap breakdown voltage remains approximately constant, a higher voltage drop occurs across the dielectrics with increasing voltage amplitude leading to an increase in the total surface charge on the dielectrics. As a consequence, the number of surface charge spots increases. These results are consistent with [15, 23]. Fig.4 (b) shows the surface charge density on the powered dielectric. Five localized negative surface charge spots are observed. The non-uniformity of the surface charge is one important reason for the non-uniformity of the discharge, as it reinforces the inhomogeneity of the electric field in the discharge gap.

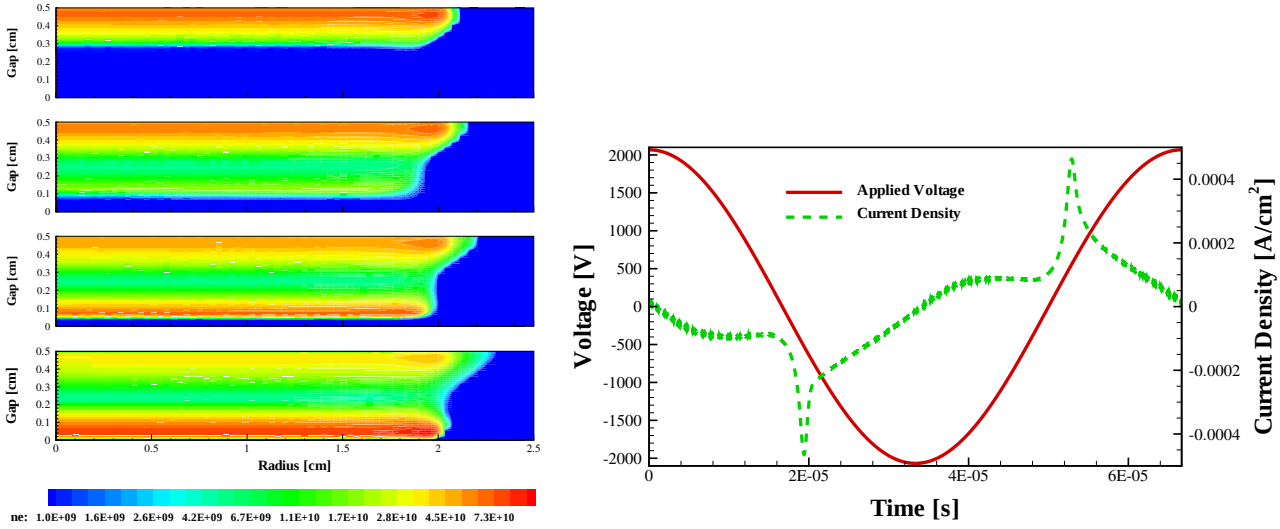
3.3 Relative permittivity of the dielectric

As discussed before, we expect the surface charge pattern on the dielectrics to affect the electric field distribution. If the non-uniformity of the surface charge is smoothed out the discharge is more likely to become uniform. Starting from the case in Fig. 2, fewer filaments are formed when the relative permittivity ε_r is decreased. A uniform glow appears when ε_r equals 2.0 (see Fig. 5(a)). Fig. 5(b) shows the current density–voltage waveform with one current pulse per half cycle, the typical V-I profile for an APG.

The reduced number of filaments with decreasing relative permittivity can be explained by the increased impedance of the dielectrics. This leads to an overall slower increase of the gap voltage and a slower evolution of the breakdown compared to a dielectric with larger ε_r. This slower evolution of the breakdown allows for more time for the inhomogeneity in the gap and on the surface to be smoothed out. The reduced inhomogeneity

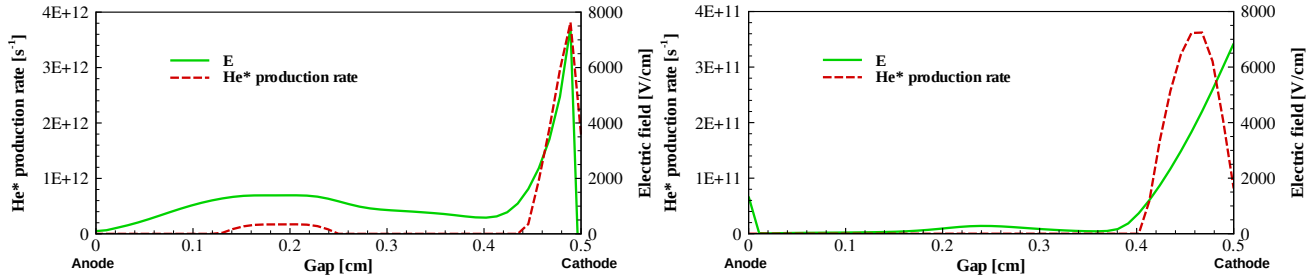
is accompanied by weaker gradients in the plasma density which otherwise may give rise to strong space charge fields, which again non-linearly enhance the inhomogeneity through increased ionization.

Even when starting from a filamentary discharge (15kHz, 1mm thick alumina dielectrics), a uniform discharge can be obtained either by increasing the driving frequency or replacing the dielectrics with a material that has a lower permittivity. However, the mechanisms leading to this transition are different. In the former case the uniform discharge is related to the overlapping of the numerous filaments. In the latter case it is due to the reduction of the number of filaments. These two uniform discharges actually belong to different regimes. Fig. 6 shows the axial profile of the electric field and helium metastable production rate for these two uniform discharges. The 30 kHz case shows a typical dc glow discharge structure, with a high electric field in a narrow cathode layer and a relatively low electric field in the positive column. The helium metastable production rate has a similar structure (Fig. 6(a)) following the behavior of the electric field. However, for the case with ε_r equal to 2.0, a much broader cathode layer is formed and the positive column is missing as shown in Fig. 6(b). Correspondingly, the helium metastable production has only one peak, which is located inside the cathode layer. This structure is similar to a Townsend discharge, although it has the same V-I characteristic as an APG in the glow mode.



(a) (b)

Fig. 5 Electron density profile at different times (a) and voltage-current wave form (b) for the case with ε_r=2.0



(a) (b)

Fig. 6 Electric field and helium metastable production rate at current maximum for glow discharge (a) and Townsend discharge (b). In (a), f=30kHz, ε_r=9.0; in (b), f =15kHz, ε_r=2.0.

4. Conclusion

A two-dimensional fluid model was used for the study of the transition between filamentary dielectric barrier discharges and uniform atmospheric pressure glows in a helium atmosphere. The influences of the driving frequency, voltage amplitude and the dielectric material were investigated. For self-organized filaments, the number of filaments was found to increase with increasing frequency. This is due to the less pronounced drop of the pre-ionization level and the limited ion diffusion and transport at higher frequency. Once a large enough number of filaments was formed, the overlapping of the filaments gave a uniform appearance of the discharge. The influence of the voltage amplitude manifests in a decreasing number of filaments at lower voltage amplitude. The dielectric material also influences the discharge appearance. Fewer filaments were formed for materials with lower permittivity, as the slower increase of the gap electric field tends to smooth out the non-uniformity of the surface charge and of the gap plasma density. The localized surface charge is believed to be one important reason for the formation of the non-uniform filamentary discharge.

Although increasing frequency and decreasing permittivity of the material both favor a uniform plasma, the resulting discharges fall into different regimes. A glow discharge was formed on increasing the driving frequency, while a Townsend-like discharge appeared for a lower permittivity material.

Other than the above operating parameters, intrinsic properties of the background gas also have a large influence on the discharge behavior. A study in this direction is now in progress.

High-Yield Synthesis of Luminescent Silicon Quantum Dots in a Continuous Flow Non-thermal Plasma Reactor

L. Mangolini, E. Thimsen and U. Kortshagen

Department of Mechanical Engineering, High Temperature and Plasma Laboratory
University of Minnesota, Minneapolis, MN 55455

Abstract

Light-emission from nanostructured silicon has sparked intense research ever since its discovery about 15 years ago. The lack of a simple high-yield synthesis approach for luminescent silicon nanocrystals has so far hampered their widespread application in such diverse areas as opto-electronics, solid-state lighting for general illumination, and fluorescent agents for biological applications. In this paper we discuss a non-thermal plasma process for the synthesis of luminescent silicon nanocrystals.

Introduction

Silicon is a material with rather poor optical emission and absorption properties due to its indirect band gap, which requires that photon emission and absorption involve a momentum balancing phonon. This fact has so far prevented the development of silicon-based opto-electronic devices, which would have the potential to enable a new level of integration of silicon electronics with optical devices on one chip. Hence first reports of room temperature light-emission from quantum confined silicon structures were met with great enthusiasm. Initial processes for the production of luminescent silicon nanostructures used magnetron sputtering of silicon in a hydrogen atmosphere [1] and the production of porous silicon [2, 3]. Other reports of luminescence from quantum confined silicon nanostructures such as surface oxidized nanocrystals [4, 5] and silicon/insulator superlattices [6] soon followed. Since then the proof of concept of the silicon based light emitting diode was given [7], and the observation of optical gain from silicon nanocrystals was reported [8]. While initially light emission from silicon was studied mostly with regards to the role of quantum confinement, more recently increased attention has been paid to the important influence of the surface conditions of silicon nanocrystals [9].
A wide range of synthesis approaches has been proposed for silicon nanocrystals both in the liquid and in the gas phase. Liquid phase approaches range from the synthesis in inverse micelles [10], to the synthesis in high temperature supercritical solutions [11], to the oxidation of metal silicide [12], to the reduction of silicon tetrahalides and other alkylsilicon halides [13]. However, liquid phase approaches are often time-consuming and sometimes have a low yield of crystalline material. Gas phase approaches range from the pyrolysis of silane in furnace flow reactors [4, 14], to the decomposition of silane or disilane through laser light irradiation (photolysis) [15], to the laser pyrolysis using high power infrared lasers [16, 17]. These approaches often have faster processing times, but particle agglomeration in the gas phase may annihilate the desired quantum confinement properties. A high rate laser pyrolysis process was proposed in ref. [17] with yields of up to 200 mg/h., however, particles required post-process etching to reduce the particle size. The resulting effective yield of luminescent material was significantly lower than the original synthesis yield.
Here we report an approach based on a non-thermal plasma. This approach benefits from the unipolar negative charge distribution acquired by the particles immersed in the plasma [18]. The negative charge is required to ensure a steady state balance between electron and ion fluxes to the particle surface, and the subsequent unipolar distribution significantly decreases the agglomeration rate and reduces particle growth through coalescence. Moreover, the recombination of electrons and ions at the particle surface and the weak convective cooling in the low pressure environment leads to a significant heating of the nanoparticles, whose temperatures can be several hundreds of Kelvin above the surrounding gas temperature [19]. The intense particle heating leads to the synthesis of nanometer-sized silicon crystals between 2-8 nm on timescales of a few milliseconds.

Experimental set-up

The schematic of the plasma reactor is shown in figure 1. An argon-silane gas mixture is passed through a reactor which consists of a 3/8" O.D. quartz tube with an inner diameter of 1/4". Two copper rings with an intermediate gap of 1/4" serve as electrodes. The plasma exhibits an intense emission between the electrodes and downstream of the electrode pair. Weaker emission is also observed upstream of the ring electrodes. The residence time of the gas is estimated based on the distance between the grounded ring electrode and the fitting of the quartz tube to the vacuum chamber. This distance is kept constant at 1". The plasma is typically generated at a pressure of 1.4 Torr. The total gas flow rate is adjusted between 12 and 60 sccm, changing the residence between ~7 and ~1.2 ms. The discharge is operated in a SiH_4-Ar mixture and the silane partial pressure is adjusted between 10 and 60 mTorr. The RF power is delivered to the discharge through a T-type matching network, and the discharge is excited at a frequency of 27.12 MHz. The power consumption, read from the power meter of the matching network, is 200 W, with <5 W of reflected power. However, this power reading does not correctly reflect the power absorbed by the discharge, since it does not account for the power reflected from the discharge back into the matching network, and for the power losses through heat dissipation and radiation. Measurements of the RF current and voltage indicate that the power consumption in the plasma is of the order of only a few W. Given the very small discharge volume (<1 cm^3), a considerable power density is achieved in the plasma region. The particles produced in the plasma are collected on a fine stainless steel mesh placed about 1" downstream of the discharge. After a few minutes of deposition, the mesh is completely coated with particles. After deposition, the mesh is extracted from the system and the particles are rinsed into vials with methanol or ethanol. For transmission electron microscopy (TEM) studies, TEM grids can be placed onto the filter. Grids are exposed to the aerosol flow typically for 2-6 seconds which results in a coverage sufficient to obtain a reasonable statistic for particle size distribution measurements using a TEM image analysis software.

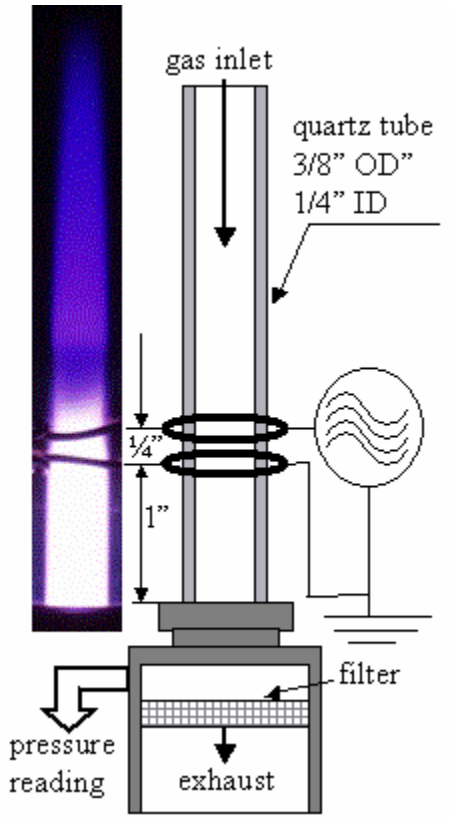

Figure 1: Schematic of experimental apparatus with digital picture of the argon-silane discharge during operation

Results and discussion

Particles produced in our system do not immediately show photoluminescence. When particles are collected on the filter or on a piece of glass and exposed to the air, luminescence sets in after a few minutes of exposure. When particles are collected on the filter and rinsed into vials with methanol, luminescence sets in later typically after several minutes to a few hours. We interpret this delay in the onset of luminescence as being caused by the formation of a native silicon oxide that passivates surface states that otherwise quench photoluminescence. The photoluminescence emission spectra for different experimental conditions are shown in figure 2.

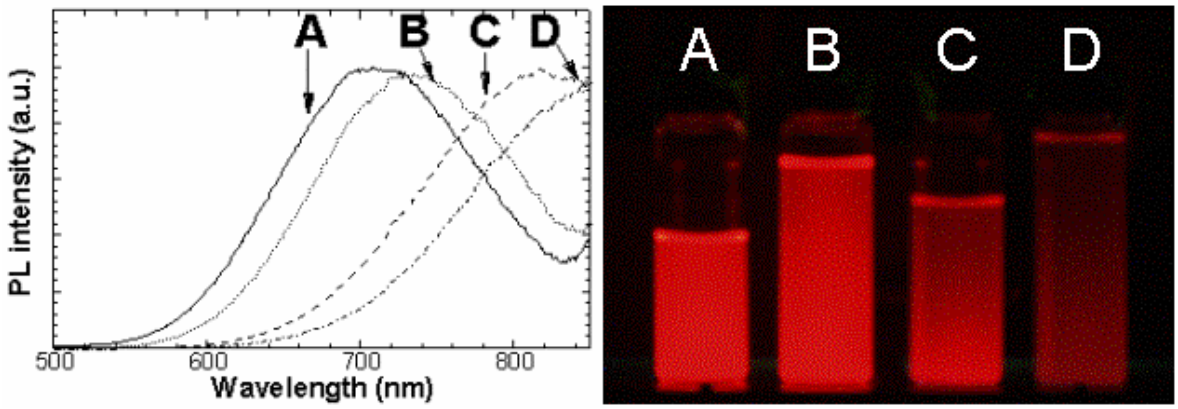

Figure 2: Photoluminescence of silicon particles produced for: (A) 50 sccm Ar, 10 sccm Ar-SiH4 (95:5); (B) 40 sccm Ar, 8 sccm Ar-SiH4 (95:5); (C) 30 sccm Ar, 30 sccm Ar-SiH4 (95:5); (D) 24 sccm Ar, 24 sccm Ar-SiH4 (95:5); pressure= 1.4 Torr, 200 W RF power.

The particles luminesce in the red-orange range, as it is expected for silicon particles with a native oxide layer on the surface [9]. The influence of oxygen on the quantum dot electronic structure has been extensively studied since the luminescence from porous silicon was first observed. Oxygen is known to introduce a large Stokes shift between the absorption band gap edge of the particles and the energy at which the particles emit. Oxygen terminated quantum dots are not expected to shown luminescence at wavelength shorter than that corresponding to orange emission [9]. The change in the peak emission wavelength with the experimental conditions is consistent with the change of the silicon nanoparticle size. Sample A and B were produced at the same SiH_4 partial pressure (11 mTorr), with a residence time of 1.48 ms for A and 1.85 ms for B. For C and D the partial pressure was increased to 35 mTorr which leads to larger particles, shifting the peak emission to longer wavelengths. Our result is consistent with the current understanding of the optical properties of silicon quantum dots.

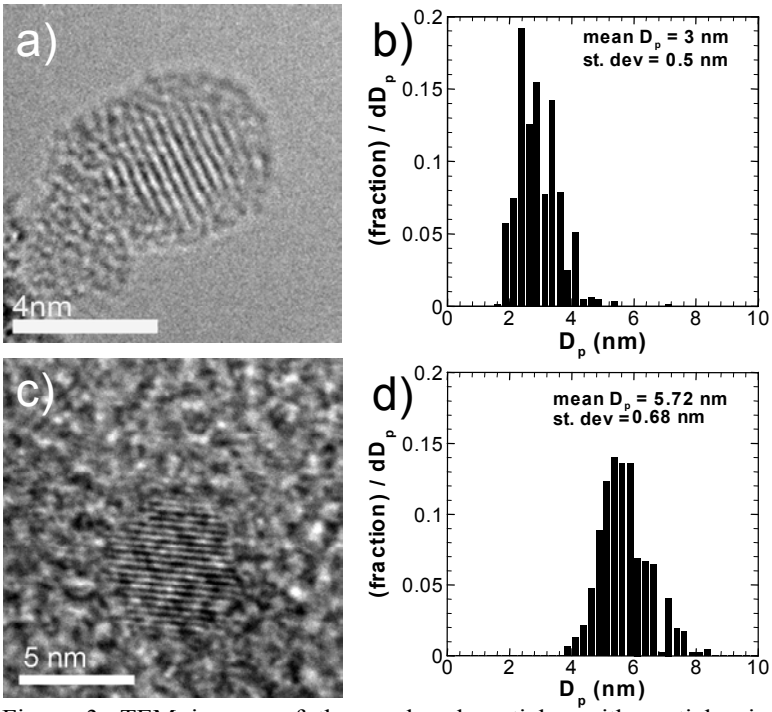

Figure 3. TEM images of the produced particles with particle size distribution as obtained from micrograph analysis. a) and b) were obtained for 40 sccm Ar, 8 sccm Ar:SiH4 (95:5); c) and d) for 10 sccm Ar, 2 sccm Ar:SiH4 (95:5). (Image b) courtesy of Dr. C. Perrey taken on a 300 kV Tecnai F30).

The particle size distribution and the particle crystallinity were studied by TEM analysis. Figure 3 shows high magnification micrographs as well as the particle size distributions for both a short and a long residence time case. For figure 3 a) and b) the Ar flow rate is 40 sccm and the Ar-SiH_4 (95:5) flow rate is 8 sccm. Under these conditions the residence time is 1.85 ms. For figure 3 c) and d) the Ar flow rate is 10 sccm and the Ar-SiH_4 (95:5) flow rate is 2 sccm, the residence time is 6.8 ms. The partial pressure of silane is the same for these two cases and equals 11 mTorr.

It can be seen that reducing the residence time leads to a decrease of the particle size from an average of 5.7 nm to 3 nm. The size distribution is relatively monodispersed, with a standard deviation of 0.5 nm for the short residence time case, and 0.68 nm for the long residence time case. Particles observed for these two

cases are almost exclusively crystalline. Figure 3 c) shows fringes from the (111) plane of a 5-nm silicon particle deposited on a regular carbon film grid. The particle in figure 3 a) has a crystalline core of around 2 nm in diameter and an amorphous layer of about 1 nm in thickness which is likely a native oxide. This result shows that the non-thermal plasma process can produce sub-5 nm silicon crystallites. A crystalline fraction of ~100% is observed for the long residence time case. At the shorter residence time less than 100% of the particles are crystalline. Decreasing the residence time of the particles in the plasma leads to the production of smaller particles, however, these particles are less likely to be crystalline.

Mass spectroscopy and direct mass measurements have been performed to determine the process yield. Measurements with a mass spectrometer show that the plasma dissociates virtually 100% of the fed silane precursor. A flow rate of 40 sccm of Argon and 8 sccm of Ar-SiH_4 (95:5) corresponds to a mass flow rate of silicon of 30 mg/hour. The deposition rate on the filter was measured to be 14.4 mg/h. At the same time, a silicon film was deposited in the reactor tube at a rate of 14.7 mg/h. This result indicates that slightly less than 50% of the silane is converted into silicon nanocrystals, while another 50% are deposited as a silicon film on the reactor walls. For slightly larger nanocrystals with emission wavelength peaking at 800 nm we achieve a net yield of ~40 mg/h.

While it is still not clear which processes lead to the formation of crystalline silicon particles at relatively low gas temperatures, we have recently pointed out that the heating of the particles by electron-ion recombination at the particle surface can be a significant heating process [19, 20]. The time dependent energy balance for a particle immersed in a plasma is given by:

$$\rho c V_p \frac{d(T_p - T_{gas})}{dt} = J_i A_p E_{ion} + G_m A_p E_{bind} - \frac{1}{4} n_g v_g A_p \frac{3}{2} k_B (T_p - T_{gas}) \qquad [1]$$

ρ and c are the material density and specific heat, V_p is the particle volume, T_p the particle temperature, T_{gas} the background gas temperature. The first term on the right hand side describes the particle heating due to electron-ion recombination at the particle surface, where J_i is the ion flux to the particle, A_p the particle surface area and E_{ion} the ionization potential (15.76 eV in the case of Argon). The second term on the right hand side describes the heat of condensation released during the particle growth. G_m is the flux of monomers to the particle surface, for the case of silicon each monomer releases an energy of 4.07 eV when it binds to the particle. The last term describes the gas cooling, n_g and v_g are respectively the background gas density and its thermal velocity.

In order to estimate the particle heating rate a good estimate of the plasma density is needed. The plasma density was measured with the help of a capacitive electrostatic probe. This technique is described in details in ref [21], and in contrast to other probe diagnostic methods is not perturbed by the silicon film which is inevitably deposited on the probe. A 5 mm long 0.4-mm diameter wire was placed in the plasma and connected to an external test capacitor. By coupling an RF signal to the probe, the probe is charged negatively with respect to the plasma in a process similar to that of RF biasing of silicon wafers in microelectronics processing. The negative potential on the probe also charges the test capacitor. After the turn-off of the RF signal, the free positive ions in the plasma discharge the capacitive probe and the test capacitor. From the rate of discharge of the capacitor, the plasma density can be determined. For typical conditions that yield luminescent nanocrystals a plasma density of $\sim 5 \cdot 10^{10}$ cm^{-3} was found.

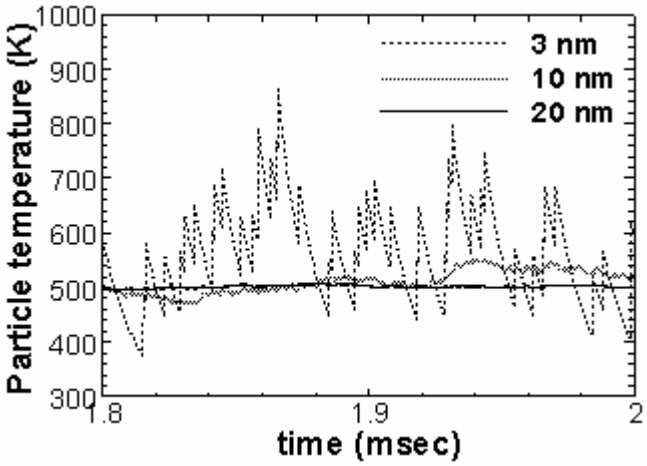

Figure 4: Simulation results of the temperature history of nanoparticles of different size in an argon-silane plasma. Gas pressure is 1.4 Torr, the gas temperature is assumed to be 300 K, the plasma density is $5 \cdot 10^{10}$ cm^{-3}.

Using this plasma density and assuming a gas temperature of 300 K and pressure of 1.4 Torr, the particle energy balance was solved. Results of this simulation are presented in Figure 4. The time-

dependent simulation was performed assuming that the ion flux to the particle is well described by the orbital motion limit (OML) theory, from which the average frequency of recombination events ν_+ is calculated. The electron-ion recombination occurs in stochastic time-intervals at the particle surface such that the average recombination frequency is equal to the calculated ν_+. The calculated temperature history shows that small particles of 3 nm diameter undergo significant temperature fluctuations while immersed in the plasma. Small particles never reach a steady temperature and their instantaneous temperature can be much larger than the gas temperature. This heating of the particles is likely responsible for the efficient synthesis of crystalline particles.

Conclusions

A continuous flow, non-thermal plasma reactor has been developed for the production of silicon nanocrystals. Nanoparticles are synthesized in a simple, single-step flow-through reactor on the time-scale of a few milliseconds. The low pressure plasma environment serves to prevent particle agglomeration and leads to an efficient heating of the particles through electron-ion recombination at the surface. Production yields on the order of several tens of milligrams per hour can be achieved.

Abstract

Semiconductor nanoparticles are candidates of interest in a range of applications in the fields of nano-electronics and nano-optoelectronics. This paper describes a constricted-mode capacitive plasma synthesis process for making single-crystal cubic silicon nanoparticles. Single-nanoparticle field-effect transistors are fabricated using these nanoparticles. Operation and electrical characterization of these devices are also described.

Keywords

Nanoelectronics, Nanoparticles, Plasma synthesis, Transistor.

Introduction

Semiconductor nanoparticles are attracting research interest due to a wide range of potential applications [1-3]. Silicon especially is important due to its low toxicity and maximum compatibility with current semiconductor manufacturing processes. A number of gas-phase methods such as laser ablation of a silicon target, thermal pyrolysis and laser pyrolysis of silane have been tried for the synthesis of silicon nanoparticles [3-7]. Formation of amorphous particles and particle agglomeration are reported to be the main problems.

Non-equilibrium silane plasmas have been widely used in the semiconductor industry. They were primarily studied to prevent gas phase particle nucleation [8-10]. Nanoparticle synthesis using such non-equilibrium plasma based methods, however, can overcome issues associated with other methods because plasmas tend to unipolarly charge suspended nanoparticles and prevent agglomeration. Plasmas can also heat the particles to high temperatures leading to particle crystallization. Plasmas processing is widely used in the semiconductor industry, making it easier to for it to adopt a plasma-based process.

We have developed a novel non-thermal plasma process for silicon nanocrystal synthesis that can produce freestanding, defect-free, cubic silicon nanoparticles in a size range from 20nm-80nm. Such freestanding, defect-free, silicon nanoparticles are good candidates for new methods for fabricating microelectronic devices, such as vertical transistors and LEDs. These particles are synthesized separately and could potentially be intermixed with other materials to form novel nanocomposite heterostructures and devices.

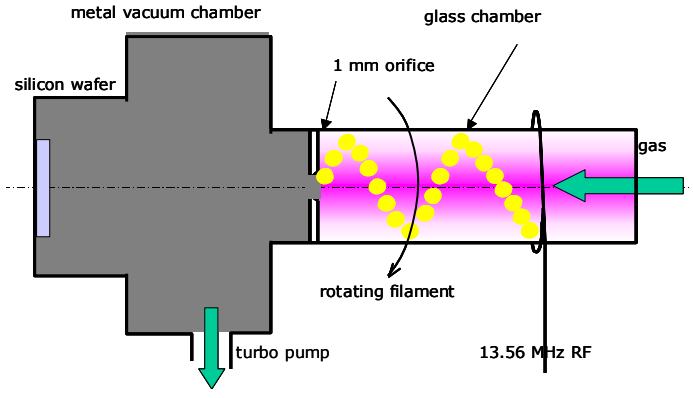

Fig.1 Sketch of constricted plasma setup used for nanoparticle deposition on silicon wafers

In this paper we describe the synthesis process for producing single crystal nanoparticles and the current understanding of the particle heating and crystallization mechanism. A prototype vertical Schottky-barrier field effect

transistor (FET) is fabricated using these nanoparticles. The paper describes the fabrication process and the electrical characteristics of the fabricated devices.

Particle Synthesis

The nanoparticle synthesis process employed here has been described in detail elsewhere [11]. To explain in brief, silicon nanoparticle synthesis is done using a 13.56 MHz constricted-mode RF capacitive discharge in 5% silane diluted in helium. Argon is used as a carrier gas. A 2 sccm flow of silane-helium and 3 sccm flow of argon are used to produce a pressure of 1.5 Torr in the discharge chamber. The substrate is kept in the downstream chamber that is evacuated to a much lower pressure of 10^{-3} torr. A 1mm diameter orifice separates these two chambers. The plasma is formed between a powered electrode shaped in form of a ring and a metal flange as ground as shown in Figure 1. The discharge runs at around 100-200W RF power to form a single luminous filament, which consists of ten to twenty individual plasma globules. The discharge may be a high-density plasma thermal instability as described by Raizer [12]. The filament is unsteady and oscillates at frequencies of up to 150 Hz.

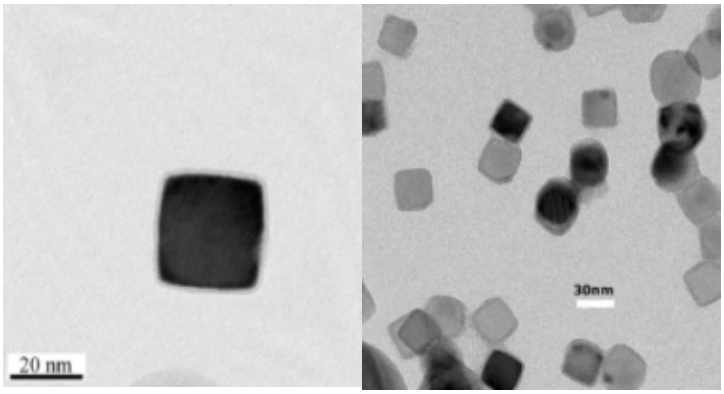

Fig.2 TEM images of cubic nanoparticles.

Silane undergoes dissociation and subsequent nucleation reactions in the plasma to form a nanoaerosol of silicon particles. This aerosol accelerates through the orifice to form a high-speed beam of particles in the substrate chamber. Particles are then collected by inertial impaction. For characterization, particles are collected on electron microscope grids, whereas for device fabrication particles are deposited on to patterned silicon substrates. The discharge is run for up to 2 minutes to achieve requisite particle density on the silicon substrate.

Varying process parameters such as residence time of particles in the discharge and the plasma chamber tube diameter can control the particle size and morphology to a certain extent.

Particle characterization and analysis

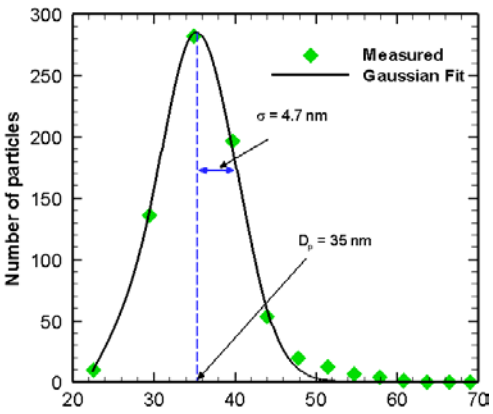

Fig.3 Particle size distribution centered at 35 nm with a standard deviation of 4.7 nm.

Nanoparticle characterization is primarily done using e*x-situ* transmission electron microscopy (TEM). Particles are deposited on TEM grids (01822-F ultra-thin carbon type–A from *Ted Pella Inc.*) TEM analysis is carried out using a JEOL 1210 (120kV accelerating voltage) and an FEI Tecnai T12 (LaB_6 filament, 120 kV)

Fig. 2 shows electron micrographs with cube shaped particles. It is seen that particles are monodisperse and single crystal. Fig.3 shows a plot of a typical size distribution obtained from a TEM image analysis using NIH ImageJ [13] The nanoparticles are diamond-cubic silicon with (100)-plane faces. Particles are highly oriented with no line or planar defects. Defect-free particles are necessary for electrical devices because the nanoparticle acts as the channel of the device, and any defects would create trap states, affecting device performance. Selected area electron diffraction and high resolution TEM are used to characterize the crystal structure and defects, if any.

The constricted-mode discharge is a non-equilibrium plasma where the electron temperature is greater than the gas temperature. Thermometrically measured gas temperature in the discharge is around 450K, which is substantially lower than the melting point of silicon of 1783K. This indicates that a unique heating mechanism is at play. Particle heating most probably occurs via argon ion-electron recombination on the particle surface. Each recombination event heats a particle with an energy equivalent to the ionization energy of argon (15.75eV). The primary cooling mechanisms on the other hand are conduction heat loss to the gas, and radiative heat transfer to the surroundings. A simple energy balance calculation using eqn.1 for a single particle yields particle temperatures that are 500-1000K higher than the gas temperatures. The left hand side term accounts for the heating of the particle due to the release of argon ionization energy E_{ion} during each recombination event. The first term on the right hand side is for conduction heat loss, whereas the second term is radiative heat loss. A detailed analysis of this process is described elsewhere [11].

$$n_i v_b A_p E_{ion} = \frac{1}{4} n_g v_g A_p \cdot \frac{3}{2} k_B (T_p - T_g) + \sigma (T_p^4 - T_g^4) \quad (1)$$

Transistor Fabrication

As shown in Fig.5, a vertical transistor using platinum silicide (PtSi) as a Schottky barrier for source and drain electrodes is fabricated using these nanoparticles. Freestanding, monodisperse, cubic particles are synthesized with the constricted mode plasma and deposited on to an oxide (SiO_2) patterned, Pt-coated silicon wafer. The pattern essentially is a window in the covering SiO_2 layer, where the bottom Pt layer is exposed. These windows serve as sites for fabricating clusters of silicon nanoparticle based transistors. The nanoparticles from the reactor get deposited either on the Pt or on the CVD oxide as shown in Figure 6(a). The substrate then is heat treated at 165ºC for 30 minutes during which the nanoparticles deposited on the Pt react with the metal to form a few nanometer thick layer of PtSi The particles deposited on the oxide are unchanged. The next step is removal of the unwanted particles deposited on the oxide. For that, the whole substrate is coated with SiO_2. (Figure 6(b)) The surface is then planarized using chemical mechanical polishing (CMP). CMP is carried out until the thickness of covering SiO_2 layer is equal to or less than the original thickness before nanoparticle deposition, as illustrated in Figure 6(c).

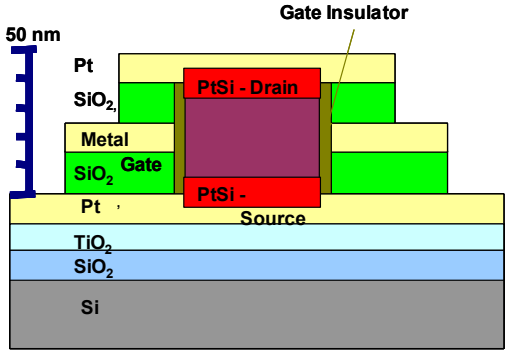

Fig.5 Cross-section schematic of the vertical PtSi Schottky source/drain SiNP-MOSFET

The number of nanoparticles in a window depends on its area and the time of particle deposition. The area of the windows is defined in a series from 5x5 μm^2 up to 20x20 μm^2. An average density of about 160 nanoparticles/100μm^2 is obtained after a one-minute deposition. That means, even for 5x5 μm^2 window, there are about 40 silicon nanoparticles. For ease of electrical contact and characterization of the nanoparticle device, all the nanoparticles in the same window are developed into nanoparticle transistors that are connected in parallel.

After the CMP planarizing, a dry etch process with high SiO_2/Si selectivity is performed to etch back the SiO_2 uniformly, and is stopped at point where the thickness of remaining thin SiO_2 layer is 10 to 15 nm, which is about a third the height of the 45 nm side cubic nanoparticles. Two-thirds of the

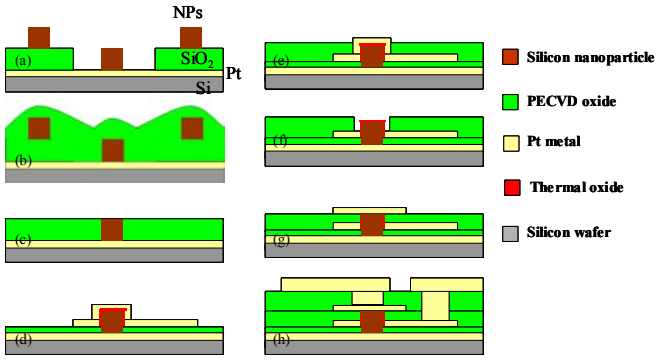

Fig. 6. Schematics of the process flow of the fabrication

height of the nanoparticle is now exposed. This SiO_2 serves as an insulating layer between the Pt layer *source* at the bottom and the metal *gate* electrode which is not yet deposited. The control of the thickness of the CVD oxide by dry etching is a challenging step, especially considering the additional requirement of a very small surface roughness. AFM characterization is employed to monitor this step. It is found that the height of exposed silicon nanoparticles is around 26 nm and the mean roughness (R_q) of the fresh SiO_2 surface after etching is ~1.5 nm or less. A higher R_q value might lead to short-circuiting of the source and gate.

The next step is to build the surround gate structure. But before that, a layer of gate insulator is necessary between the gate and the nanoparticle channel. The gate insulating layer is formed on the exposed nanoparticles by first immersing the substrate into boiling H_2O_2 for 30 minutes and then heat treating it at temperature of 500^0C under an oxygen atmosphere for another 30 minutes. The same oxidation process, done on a Si monitor wafer reveals nearly a 2 nm thick thermal silicon oxide on surface. This oxide has a leakage current of 1.8 x 10^{-5} A/cm^2 at a bias voltage of 0.5 V. This electrical performance satisfies the requirement of gate insulator of the proposed transistor. After that, surrounding the thermal oxide coated nanoparticles, a 15 nm thick metal layer is deposited to serve as the gate, as shown in Figure 6(d). Both Pt and Cr have been used as gate electrodes. The metal workfunction significantly affects the turn-on voltage of the device.

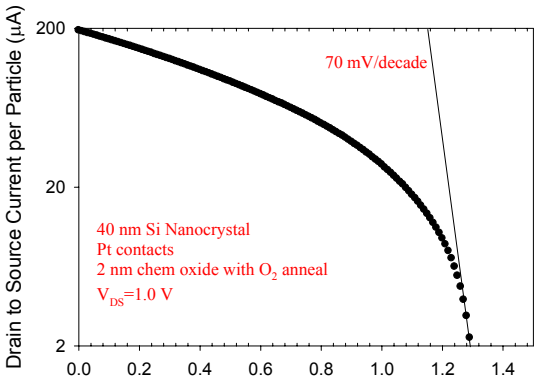

Fig.7 Single SiNP transistor's I-V characteristics showing turn off characteristic of p-channel device.

It is necessary to note that before this deposition, the substrate is patterned with photoresist. The pattern is nearly the same as the windows mentioned above, but with an extension for electrical contact pads. A lift-off process is employed at this step to remove the extra Pt. A second CVD oxide is then deposited to isolate the gate and drain electrodes. CMP is performed to planarize the oxide surface. A second etch back of the planarized surface is done to expose the top of the metal-coated nanoparticles. See Figure 6(e). Subsequently, wet etching in diluted aqua regia is done to remove the metal coating on the top of the nanoparticles first and later along the side of the nanoparticles. A result for this step is as shown in Figure 6(f) where the gate metal is in close contact with nanoparticles, but no longer covers the particles on the top and side. These steps are particularly important to avoid a short circuit between the gate and the drain electrodes.

Insufficient etching and over-etching of the metal gate will both result in a failure of the transistor either through short circuit or due to loss of field effect control by the gate.

During this wet etching a recess might be introduced in the gate insulator oxide, but a subsequent SiO_2 CVD is used to fill it up. CMP is used a third time over to expose the tip of nanoparticles prior to laying down the top Pt electrode. Finally, this top Pt layer slightly reacts with the tip of the silicon nanoparticle to form Schottky junction for the drain electrode, as shown in Figure 6(g).

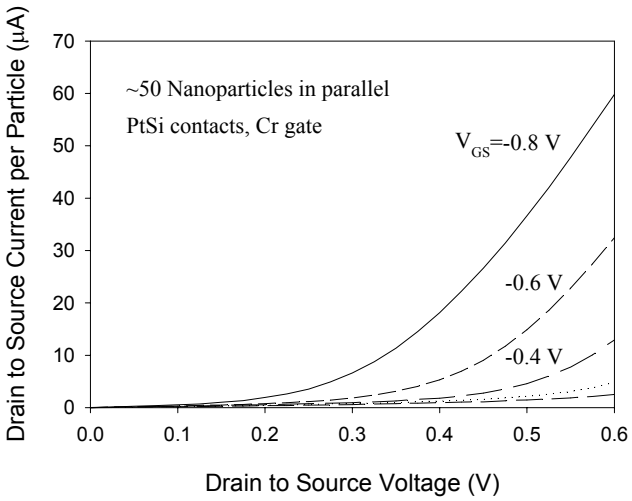

Fig.8 Family of curves for a single SiNP transistor using a Cr gate. The nonlinear behavior at low voltage is believed to be due to the Schottky contacts.

Transistor Characterization

Microprobes are used for electrical characterization of the nanoparticle devices. In order to get reliable test results under microprobes, a test structure is built for the devices, by which a direct

contact of the microprobes onto the drain or gate is avoided. A passive layer of 500 nm thick CVD SiO_2 is deposited, patterned and etched to realize the gate and drain contact via. Pt/Al bi-layers are deposited both as via and as test pads, as shown in Figure 6(h).

Typical transistor behavior of drain/source current I_d controlled by the gate-source voltage V_{gs} has been successfully demonstrated (Fig.7). The I_d-V_{gs} characteristic shown is for a single device, after accounting for the multiple devices fabricated in a single window. Electrical measurements show turn off characteristics of a p-channel device. Reasonable turn-off behavior is observed although leakage occurs, particularly through the chemical gate oxide. The device transconductance is roughly 80 μA/V per 40 nm particle or $5x10^6$ amp/V-cm^2. To the best of our knowledge, this is the first time that such a transistor has been reported that is built using a plasma synthesized single crystal Si nanoparticle.

Conclusion

In conclusion, a reliable plasma process has been established to synthesize high quality cube shaped, single crystal, nanoparticles. The particles have been used to successfully fabricate a prototype single particle vertical surround gate nanoelectronic FET. The p-channel device shows gate controlled drain-source current characteristics. This demonstrates the ability of non-equilibrium plasmas to synthesize high quality, high throughput nanomaterials, having a wide range of potential applications.

Short-time plasma surface modified polymer powders – Improved bonding and wettability

C. Arpagaus, Ph. Rudolf von Rohr

ETH Swiss Federal Institute of Technology Zurich, Institute of Process Engineering, ETH Zentrum, Sonneggstrasse 3, CH-8092 Zürich, Switzerland

Abstract
Hot-melt adhesive HDPE and CoPA polymer powders were short-time plasma surface modified (0.1s) to improve wettability and adhesive bonding strength of polymer glued textile laminates and aluminum plates simultaneously. Peel strength of polymer glued textile laminates increased up to 25% for CoPA powder. Aluminum adhesive bonding strength increased up to 85% for HDPE after plasma exposure. Increased interfacial bonding is attributed to stronger chemical bonds of plasma formed polar groups on the powder and cross-linking.

Keywords: plasma surface modification, polymer powder, XPS, wettability, bonding, adhesion, viscosity

1. Introduction

Recently, a Plasma Downer Reactor (PDR) has been developed to allow the study of powder-plasma interaction in short-timescale (0.1sec) processing [1]. HDPE (high density polyethylene) and CoPA (co-polyamide) polymer powders were examined, which are used as thermoplastic hot-melt adhesives in paste dot coating applications in textile interlining industry. The feasibility to increase water wettability of the polymer powders was shown. XPS studies confirmed the formation of polar functional groups on the particle surface after O_2/Ar plasma exposure (Fig. 1). O/C-ratio on HDPE powder increased from 0.0 (no oxygen on untreated HDPE) up to 0.15 and from 0.1 up to 0.27 for Co-PA [2]. Ageing (hydrophobic recovery) occurred for treated HDPE powder mainly in the first 7days of storage due to a diffusion-like process of oxygen into the bulk of the polymer [3]. However, powder was still water wettable after 40days of storage.

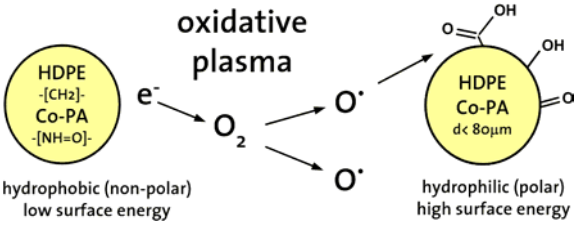

Figure 1: Incorporated hydrophilic groups on polymer particles (HDPE, CoPA) by plasma-assisted surface modification.

Besides conditioning of water-based pastes out of polymer powders, beneficial improvement of their adhesive strength is expected. Results of flat polymers showed that wettability has often been used as an estimate of bonding quality for adhesives. Lap-shear bonding strength of flat polymer-polymer bonds using epoxy adhesives improved significantly after various plasma treatments e.g. HDPE from 2.2 to 21.6N/mm^2, Nylon from 5.9 to 27.6N/mm^2 [4] or PP from 0.2 to 1.4N/mm^2 [5]. Moreover, plasma oxidation is known to enhance metal-polymer adhesion [4, 5, 6]. Reaction of adhesives with surface species during curing leads to covalent metal-oxygen-carbon (M-O-C) bonds. Fourfold improvement of epoxy bonding peel strength of PE or PP to aluminum was measured [4].
In this study, the objective was to treat hot-melt adhesive polymer powder by reactive plasma (mixtures of N_2, O_2 and Ar) in the PDR, thereby enhancing interfacial compatibility to materials like aluminum and textile fabrics (cotton). Wettability was quantified by water contact angle measurements. Lap-shear aluminum bonding tests and textile peel tests were used to study the adhesion strength of glued adhesive powder. Rheological tests of molten powder were performed to investigate possible changes in viscosity. XPS measurements were applied to determine the chemical elements of the modified surfaces.

2. Experimental

2.1 Materials and plasma treatment

HDPE (Schätti Fix 1820) and CoPA (Schätti Fix 5000) powder were used as model substances supplied by Schätti AG (Wallisellen, CH). Particle sizes were smaller than 80µm with a mean of 50µm. Manufacturers melt flow rates were 20g/10min (HDPE, 2.16kg, 190°C) and 15g/10min (CoPA, 2.16kg, 160°C) with a melting point between 120°C and 130°C. Plasma treatment of the powders was conducted in the PDR. Powder is fed into a vertical glass-tube reactor and simply moves downwards by gravity and gas acceleration forces through the plasma treatment zone. Efficient contact between reactive plasma species and particle surfaces is provided by nozzle-dispersion into the reactor. Plug-like flow regime ensures a narrow residence time distribution in the plasma zone. More details on the reactor setup can be found elsewhere [1]. Main operating parameters for this study were 100W RF power, 5kg/h powder throughput, 1.7mbar pressure, 500sccm gas flow rate and O_2, Ar, N_2, (technical purity) process gas.

2.2 Methods

Wettability was quantified by water contact angle measurements on a tensiometer (K100, Krüss GmbH, D) according to the liquid penetration method into a porous media [7]. Contact angles were measured at 25°C using hexane as perfect wetting liquid to determine the geometric constant. Reported water contact angles are average values of two measurements. The errors were calculated by proper error propagation of the modified Washburn equation [7]. The method procedure was described in detail previously [3].

Bonding strength of the adhesive powders was examined by **single overlap shear tests** on **aluminum plates** (Anticorodal 110, AlMgSi1, 1.5x25x100mm). Joint preparation, geometry and testing were in agreement with ISO 4587 [8]. Prior to bonding, aluminum plates were sandblasted (quartz sand 100µm) to provide better mechanical interlocking and washed with acetone. To ensure a constant bond thickness a 0.2mm thick wire was placed in the glued joint in direction of the load. A fixing device provided a parallel 12.5x25mm shear plane overlap of the samples. The joints were glued in a laboratory hot-press (THB400, Fontijne, NL) at 170°C under 5kg/cm^2 pressure for 20min. After cooling to room temperature, lap-shear strength of the joints was tested on a material-testing machine (Zwick 1474, Zwick GmbH, D) at constant test speed (2mm/min.) until sample failure. Maximum load was determined for each powder from an average of five specimens. Commercial epoxy adhesive (Araldite 2011, Ciba SC, Basel, CH) was used to compare the bonding strength of plasma treated adhesive powder. Araldite manufacturers lap shear strength on aluminum at 23°C was given to be 19N/mm^2 (at 1h cure cycle and 60°C).

Hot-melt adhesives strength on **textile bonding** was examined by **peel tests**. Cotton-cretonne fabric (black, 150g/m^2, 16x5cm) was used as textile model. In the case of CoPA, cotton tapes were equally sprinkled with powder dots out of a perforated sieve. HDPE powder was uniformly strewed in plane on the cotton tapes through a metal sieve. Total weight of the powder coating on the tapes was 15g/cm^2 for both powders. After sintering at 140°C two tapes were fixed one upon the other and were fused in a fusing press (PR1, Gygli AG, CH) for 15s at 150°C and 0.5bar overpressure. Reported textile peel test data are average values of 3 samples.

Rheological behavior was investigated using melt mass-flow rate (MFR) (Meltflixer LT, Haake, D) and shear-viscosity measurements (MCR300 rheometer, Anton Paar Physica, D). MFR is expressed in grams per 10min. at 190°C (HDPE) and 160°C (CoPA) with 2.16kg piston load according to ISO 1133 [9]. MFR data are means of two values. Cone-plate arrangement was adopted for shear-viscosity measurements with a cone angle of 4°. Testing specimens (pills) were prepared by melting cold pressed tablets in a hot press (THB400, Fontijne, NL) under vacuum conditions (<5x10^{-2}mbar) for 15min. at 150°C and 5MPa. The rheometer chamber was purged with dry nitrogen during measurement to avoid oxygen degradation. Strain controlled angular frequency sweep tests of 0.1 to 400rad/s at 10% strain amplitude were performed. The measuring temperature was 150°C and polymer densities were 0.78g/cm^3 (HDPE) and 1.05g/cm^3 (CoPA). Reported shear-viscosity data are average values of at least two measurements with the same powder.

XPS analysis was performed using a PHI Quantera SXM photoelectron spectrometer (Scanning X-ray Microprobe, ULVAC-PHI, Inc.). The residual pressure in the spectrometer during data acquisition was $<10^{-7}$ Pa. The X-ray source was monochromatic AlKα (1486.6eV), run at 25W and 15kV. The spectrometer was operated with 280eV pass energy for survey spectra. The electron take-off angle was 45°. For analysis, polymer powder was fixed on indium foil. X-ray spot size was 100µm in diameter. Charging of polymer surface during X-ray exposure was controlled using a flood gun and ions. Spectra were referenced to aliphatic carbon C1s signal at 285.0eV.

3. Results and Discussion

3.1 Wettability results

Figure 2 shows the effect of RF power on water contact angle after 1hour (fresh) and 45days of treatment. HDPE data show a decrease in contact angle from >90° (untreated powder was not-wettable) down to 70° indicating more hydrophilic surface. At higher power both mean electron energy and density increase in the plasma and more energetic chemically reactive species are formed through dissociation reactions of oxygen, suggesting higher incorporation of oxygen functionalities and better wettability [10, 11]. Increase of oxygen atom concentration is therefore a key factor to increase the modification rate. CoPA data show no significant dependency on power. Water contact angle remained stable between 77° and 80°. A low power is sufficient to activate the surface since CoPA possess inherently polar amide groups. After 45days of storage HDPE water contact angles reverse back to 80°. Hydrophobic-recovery (ageing) is attributed to mobility of plasma introduced polar species in the surface, which was confirmed by XPS in a previous work [3].

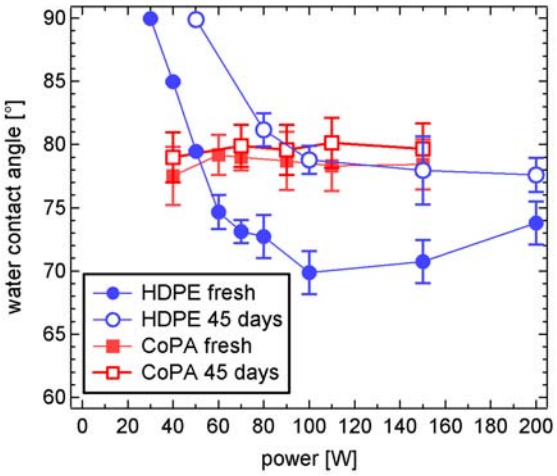

Figure 2: Water contact angles of HDPE and CoPA powder vs. RF power in the plasma after 1 hour (fresh) and 45 days of treatment (experimental conditions: 1.7mbar, 500sccm, HDPE 90%O_2/10%Ar, CoPA 30%O_2/70%Ar)

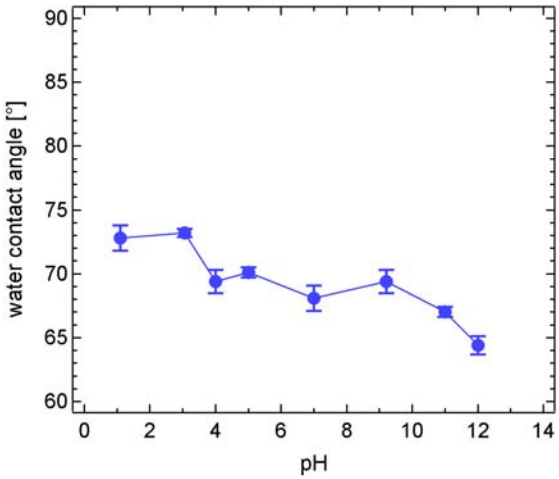

Figure 3: Water contact angles of fresh (within 1hour) O_2-plasma treated HDPE power vs. pH of buffer aqueous solutions (DURACAL buffers, Hamilton, CH).

In order to determine the existence of new functions on plasma modified HDPE powder a series of contact angles with buffered aqueous solution and different pH was measured (Figure 3). After O_2 plasma treatment a tendency of lower contact angle at higher pH was detected suggesting an acidic character to the surface. At higher pH functional groups (carboxylic acid) on the HDPE surface may dissociate and are capable of undergoing liquid solid acid-base interactions leading to a contact angle decrease. This information is at least qualitatively for HDPE powders in agreement with acid-base studies at interfaces between water and surface-functionalized PE-films as a function of pH of buffered water drops [12, 13].

Table 1 reports wettability results derived after O_2/Ar, N_2/O_2, N_2 and Ar plasma treatment of the powders. The best wettability conditions were found with O_2/Ar treatment for HDPE and N_2/O_2 for CoPA. Those powders were examined further for bonding and rheological tests.

Gas composition	HDPE	CoPA
untreated	>90° (no water penetration)	
O_2/Ar	90%/10%	30%/70%
	69.9° ± 2.0°	78.5° ± 1.4°
90%N_2/10%O_2	86.1° ± 1.1°	70.1° ± 0.8°
100%N_2	> 90°	84.6° ± 0.8°
100%Ar	> 90°	> 90°

Table 1: Water contact angle data of plasma treated HDPE and CoPA powder vs. different process gases.

3.2 Bonding results

Figure 4 shows the variation of mean lap shear bond strength of aluminum/powder/aluminum joints (12.5x25mm overlap) with different plasma gases (from Table 2) compared to untreated powder and araldite. After treatment mean shear strength increased for HDPE from 6.8 to 12.5MPa (+85%) and 12% improvement was observed for CoPA. However, strength was almost constant regardless of the treatment gas and lower than araldite joints. Improved adhesion is attributed to formation of hydrogen and chemical bonds between polar functional groups at the polymer surface and the aluminum oxide layer. Microscope analysis of failed bonds suggested the locus of failure for treated HDPE and CoPA within the polymer (cohesive failure) rather than in the bond line of the interface polymer/aluminum. Untreated HDPE did not adhere properly to sandblasted aluminum and failure was more like adhesive, due to its non-polar character. Untreated CoPA showed cohesive failure.

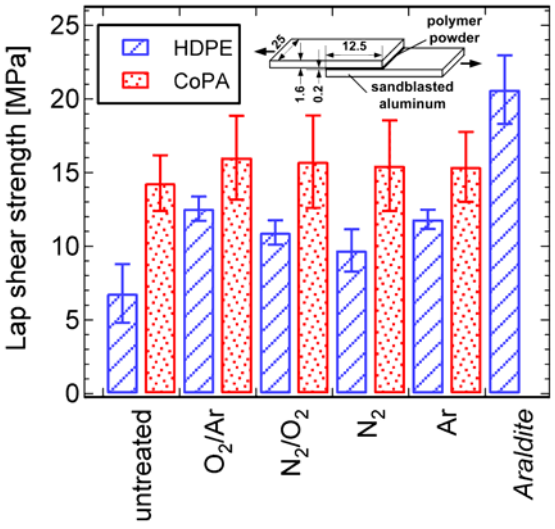

Figure 4: Influence of plasma gas composition on aluminum/adhesive powder/aluminum lap-shear force for HDPE and CoPA powder

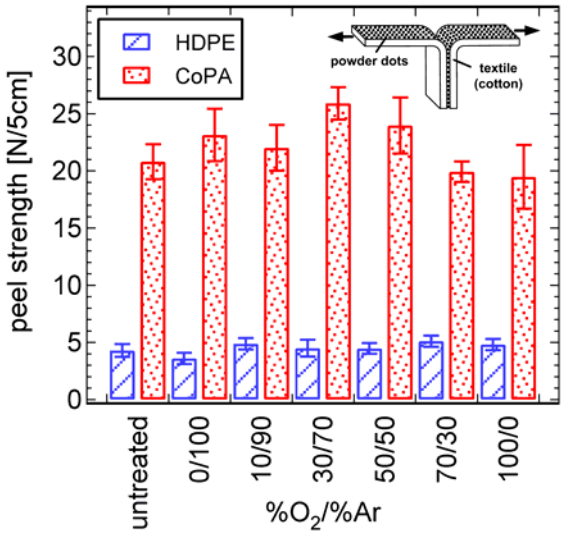

Figure 5: Peel strengths of bonded cotton tapes with HDPE and CoPA powder adhesive vs. O_2/Ar plasma gas composition. (15s fusing time, 0.5bar pressure, 150°C (HDPE), 140°C (CoPA))

Ar and N_2 plasma data revealed that good bonding was possible to obtain even with poor water wetting. A general correlation between improved wettability and bonding-strength could not be established.

Figure 5 shows the influence of O_2/Ar gas composition on the powders as a function of peel strength of powder glued cotton tapes compared to untreated powder. Data indicate a slight improvement of bonding strength after treatment (HDPE: from 4.3 to 5.1N/5cm, +19% and CoPA: from 20.8 to 25.9N/5cm, +25%). However, the improvement was not as high as for aluminum bonding. Failure locus was identified between powder dots and cotton fabric suggesting adhesive bond failure in the bond line. During short-time plasma treatment only a very thin particle surface layer is modified, the inner part remains untreated. A low volumetric ratio of surface modified shell to bulk (in the order of 1% for a spherical 50µm particle and a modification depth of 100nm) is a sign that a dilution effect of surface functional groups occurs in the molten state of the powder.

3.3 Viscosity results

Figure 6 and Figure 7 present typical shear-viscosity results $\eta^*(\omega)$ (with included MFR values) for a set of HDPE and CoPA powder as a function of different plasma gas treatment. HDPE viscosity did not appear to be significantly affected by the treatment. Except for pure Ar a slight increase (+8%) compared to the untreated was detected but the effect was barely above the limits of measurement accuracy. The change in MFR was in the same range. CoPA shear-viscosity raised significantly from 1279 to 1646Pas (+25%) due to plasma exposition. MFR decreased from 16.4 to 12.3g/10min. Since polymer zero shear viscosity η_0 depends on average molecular mass M_W according to $\eta_0 \sim M_W^{3.4}$ [14] (exponent 3.4 is an empirical factor), treated CoPA suggests a 7% increase in the average molecular weight caused by plasma treatment.

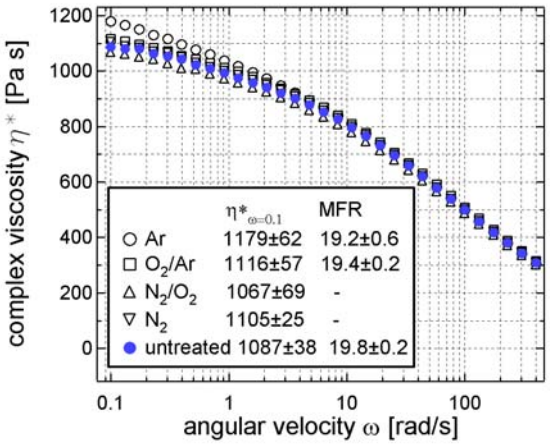

Figure 6: Influence of process gas composition on the viscosity function of HDPE powder (at 150°C)

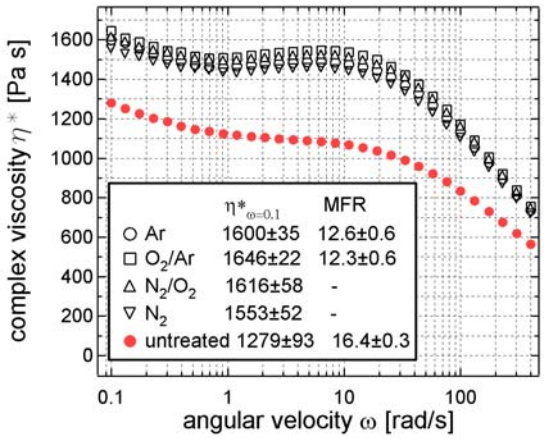

Figure 7: Influence of process gas composition on the viscosity function of CoPA powder (at 150°C)

There is evidence for vacuum-UV-radiation (VUV λ<200nm) in plasmas [15], whereby VUV emission spectra overlap with VUV absorption spectra of polymers [16]. VUV photons are responsible for change in the depth of a polymer. C-C or C-H bonds undergo scission reactions leading to free radical sites. These can in turn react with plasma gas species or crosslink, e.g. to form C=C bonds, which work as chromophores [17]. Powder exposed to reactive gas plasma (O_2, N_2/O_2, N_2) showed clear discolouration (dark-yellow colour) after melting. The yellowing effect is stronger at higher RF powder and is attributed to the presence of new chromophores, such as C=O and C=C, caused by photo degradation and ageing at elevated temperatures in the melted state.

3.4 XPS results

Figure 8 shows XPS survey spectra of HDPE powders plasma treated with 90%N_2/10%O_2 and 100%N_2 process gas composition. Untreated HDPE showed no oxygen or nitrogen indicating a pure polymer. After plasma treatment the properties of the powder surface changed with process gas composition. Oxygen and nitrogen were detected in the polymer surface.

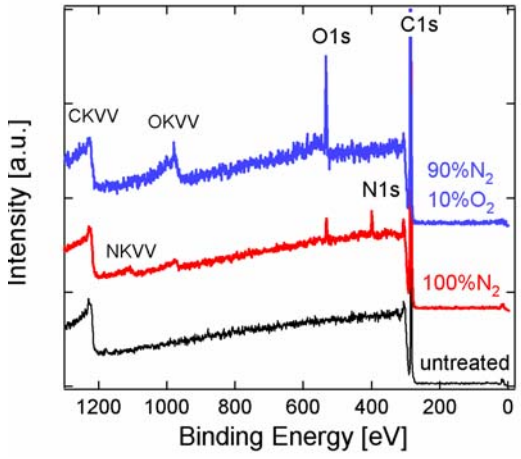

Figure 8: XPS survey spectrum of HDPE powder after different plasma gas treatments.

4. Conclusions

In a novel short-time plasma modification system for polymer powders (hot-melt adhesive HDPE and CoPA) it was shown that wettability and adhesive bonding strength could be improved simultaneously. Water contact angles reduced from >90° down to 70° (HDPE) and 78° (CoPA). Peel strength of polymer glued textile laminates (cotton tapes) increased slightly up to 25% for CoPA. Adhesive bonding strength increased up to 85% for HDPE based on aluminum lap shear tests. Failure mode analysis indicated changes from separation of polymer/aluminum interfacial bond (adhesive failure for untreated HDPE powder) to cohesive failure after plasma treatment. Increased shear-viscosity of melted CoPA (+25% compared to raw material), lower MFR (-25%) and yellowing effect provided evidence to plasma induced crosslinking reactions in the material due to plasma VUV radiation. Higher interfacial bonding is attributed to stronger chemical bonds based on incorporation of oxygen and nitrogen into the powder surface.

Aknowledgements

This work was supported by the Claude & Giuliana foundation. We would like to thank Prof. Antonella Rossi for the XPS measurements, Dr. Thomas Schweizer for the use of the rheometer, Dr. Gerhard Kuhn for lap-shear test analysis and our material supplier Schätti AG.

Abstract

This work presents experimental and calculated results of the concentrations of N and C atoms in a flowing N_2-CH_4 afterglow of a microwave discharge. Two situations are investigated: methane is added to N_2 in the downstream afterglow; methane is added to the discharge. There is a very good agreement with the predictions of our model for [N] in situation 1, as well as in situation 2 for very small values of CH_4. However, our model fails to predict the efficient production of carbon atoms in these two situations.

1.Introduction

The study of a N_2-CH_4 afterglow has an actual interest due to the large number of applications in different fields, such as in the study of the atmospheric chemistry of Titan [1], detoxification of gases [2], and metal surface nitrocarburizing [3]. The afterglow resulting from a methane-nitrogen flowing microwave discharge can be very efficient in metal nitrocarburizing, since this treatment can be improved with the presence of carbon and hydrogen atoms [3,4]. Recently, various papers have reported experimental values for these active species when small concentrations of CH_4 are added to N_2, either in the discharge or in the afterglow [4,6]. In this work, we present theoretical and experimental results for the concentrations of N and C atoms in a N_2-CH_4 flowing afterglow, due to the importance of these two species in the formation of carbonitrides ε-Fe_{2-3} (C,N) and γ′-Fe_4(C,N) in metal nitrocarburizing processes. We consider two different situations: methane is added to N_2 in the downstream afterglow (set-up I); methane is added to the discharge (set-up II).

2.Experiment

The experimental device is presented in Figure 1. The originality of this set-up is the possibility of heating the post-discharge in order to reach the temperatures of nitriding and nitrocarburizing treatment. The gas mixture is introduced into a 5 mm inner diameter quartz tube. The gases (N_2 and CH_4) are considered to be pure (99.995%) and the flow rates are controlled by mass flow meters. The discharge is produced using a surfatron device connected to a microwave generator (2.45 GHz). The post-discharge is analysed at about 200 mm downstream from the discharge in a quartz tube (26 mm internal diameter and 600 mm length). The methane can either be mixed with nitrogen before the discharge cavity or introduced in the post-discharge. The central part of the afterglow can be heated up to a temperature within the range 300 - 850 K using a cylindrical furnace. The gas temperature corresponding with the furnace temperature has been measured by means of a thermocouple with the discharge off. Several holes in the furnace allow the collection of the light emitted in the heated post-discharge. Optical Emission Spectroscopy (OES) is carried out in the post-discharge using a HR640 Jobin Yvon spectrometer with a CCD detector. Our observations take place mainly in the quartz tube of 26 mm diameter that constitutes the post-discharge reactor, at a distance of 540 mm from the discharge gap. The total pressure is 2670 Pa and the N_2 flow rate is 1000 sccm. The microwave power is kept constant equal to 150 W.

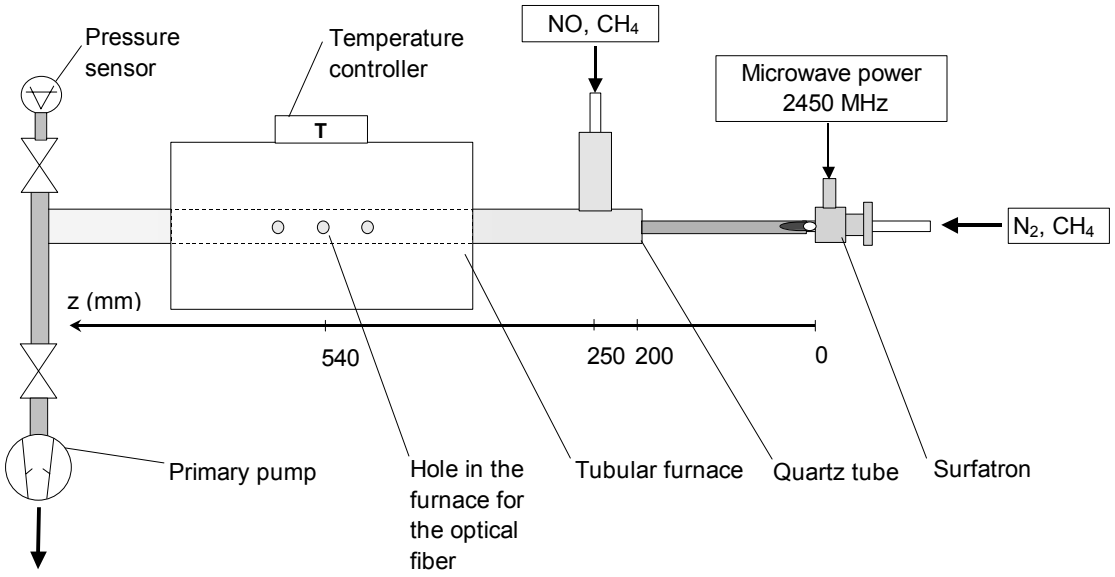

Figure 1: Experimental set-up.

The densities of carbon and nitrogen atoms in late post-discharge can be inferred from OES measurements of the first positive system of N_2 for different wall temperatures [4]. Briefly, the nitrogen atoms density is obtained from the emission of the $N_2(B^3\Pi_g,11) \rightarrow N_2(A^3\Sigma_u^+,7)$ transition at 580.4 nm, by assuming that $N_2(B^3\Pi_g,11)$ is exclusively populated by three-body re-association of N atoms. On the other hand, by means of a simple kinetic model, the carbon atoms density is deduced from the intensity of the CN violet band $CN(B^2\Sigma,7) \rightarrow CN(X^2\Sigma,7)$ at 384.7 nm, by assuming that the $CN(B^2\Sigma,7)$ state is populated via the three-body reaction $C+N+N_2 \rightarrow CN(B^2\Sigma,7)+N_2$ for low CH_4 content (< 5 vol.%). These relative measurements are then calibrated by an absolute measurement of N atoms density using NO titration. It is possible to obtain the evolution of the densities of nitrogen and carbon atoms under different reactive conditions. Uncertainties on the determination of the atomic densities by this method are approximately 20% for N atoms density and 40% for C atoms density.

3. Kinetic Model

Since we consider two different situations, in which the methane is introduced either in the afterglow or in the discharge (set-up I and II, respectively), we have developed two different models. In the first case, we considered the self-consistent determination of the active species concentrations in the discharge for pure N_2, by solving the Boltzmann's equation for the electrons coupled to a set of rate balance equations for the various molecular and atomic species produced in the discharge, including the different ions produced and the vibrational distribution of $N_2(X^1\Sigma_g^+,v)$ molecules. The sustaining electric field in the discharge is self-consistently determined as well. The electron density in the discharge is assumed to be equal to the critical value for surface wave mode propagation in a quartz tube, which is equal to 3.74×10^{11} cm^{-3} at $\omega/2\pi=2.45$ GHz. Once the concentrations of the various neutral and ionic species at the end of the discharge are obtained, the relaxation of the most populated heavy species is studied in the afterglow by considering a system of coupled time-varying kinetic master equations, in which the electron impact processes are neglected [7]. This has been done in two parts: first we determine the heavy species concentrations in the discharge and analyze their relaxation in the near afterglow in which only N_2 exists; then we consider the introduction of a small methane percentage into the post-discharge, at 250 mm downstream from the end

of the discharge (see figure 1). At this point we replace the former system of time-varying kinetic rate balance equations for pure N_2 with another for a N_2-CH_4 mixture, in which methane dissociation occurs in the presence of nitrogen together with several other reactions leading to formation of HCN, $CN(X^2\Sigma)$, $CN(B^2\Sigma)$, etc [8]. In order to describe the dissociation of CH_4 in the nitrogen afterglow and to interpret the measured values of carbon atoms, we need to consider among other reactions, the following processes:

$$N_2(A)+CH_4 \rightarrow N_2(X)+CH_3+H$$

$$N_2(A)+CH_4 \rightarrow N_2(X)+CH_2+H_2$$

$$N_2(a')+CH_4 \rightarrow N_2(X)+C+2H_2 \quad .$$

The first two processes are responsible for the production of the active species CH_3 and CH_2 in the afterglow [8], whereas the third process, as suggested in [5, 6], can be an important reaction leading to C atoms formation. In our calculations we assume that the introduction of methane occurs at $t=10^{-3}$ s downstream from the end of the discharge, which is a value obtained from the molecular flow rate used in the experiment. The gas temperature has been assumed equal to 620 K and 320 K in discharge and post-discharges zones, respectively.

In what concerns now the set-up II, in which a flowing microwave discharge is conducted in a N_2-CH_4 mixture, since we are dealing with very small relative concentrations of methane introduced in the discharge ($[CH_4]_0/N_g<0.5\%$, with $[CH_4]_0$ and N_g denoting the initial methane concentration and the gas number density), we assume that the electron energy distribution function (EEDF) in the mixture is the same as in pure N_2 for identical discharge parameters. Thus, once the EEDF is obtained in the discharge, we determine the electron impact rate coefficients for excitation of N_2 and CH_4 states, dissociation and ionization. These electron rate coefficients are then considered in a system of time-dependent rate balance equations used to describe the evolution of the most important heavy species produced in a nitrogen-methane discharge [8]. This is done by solving this time-dependent kinetic model between the times t=0 and t=0.1 s, with the initial conditions $[N_2(X,v=0)]=[N_2]$ and $[CH_4]=[CH_4]_0$. The correctness of the present approach has been confirmed by checking that steady-state solutions are obtained for $t<0.1$ s. Finally, the afterglow kinetics in N_2-CH_4 is described by considering the relaxation of the same time-varying system of rate balance equations used in the mixture, neglecting electron impact processes.

4. Results and Discussion

Figure 2 shows the concentrations of nitrogen and carbon atoms 540 mm away from the end of the discharge, as different values of methane concentration are introduced at 250 mm from the end of the discharge, which is in the near afterglow (see figure 1). The marked points correspond to experimental values, whereas the plotted curves are our calculated values obtained at the equivalent flowing time of $3x10^{-2}$ s with its origin taken at the end of the discharge. We note that this equivalence between post-discharge distances and afterglow times is an estimation since the flow velocity is not kept constant along the post-discharge. This figure shows a slightly decrease of the nitrogen atom concentration when small CH_4 concentrations are added to the afterglow. This effect mainly results from collisions between N atoms and active species resulting from methane dissociation.
With respect to carbon atoms, their observed concentration increases with added CH_4. Although our model shows a very good agreement between the experimental values for nitrogen, our calculations for carbon atoms concentration are several orders of magnitude lower than the respective measured values. We obtain typically $[C] \sim 10^8$-10^9 cm^{-3}, whereas the experimental values are $\sim 10^{12}$ cm^{-3}. Hence, we decided to represent in this figure only the measured values.

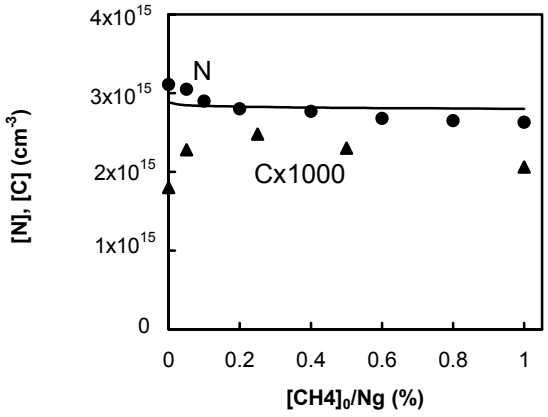

Figure 2: Concentration of nitrogen and carbon atoms 540 mm away from the end of the discharge as a function of the percentage of CH_4 introduced in the near afterglow of a pure N_2 discharge with p=2670 Pa and $\omega/2\pi$=2.45 GHz. The points represent experimental values, [N] (●) [C] (▲), and the curve is the calculated values for [N] .

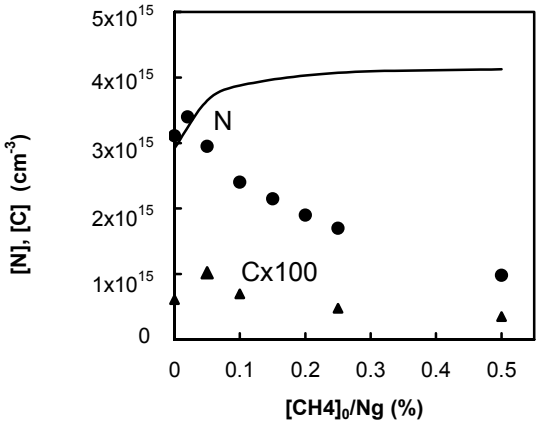

Figure 3: Concentration of N and C atoms 540 mm away from the end of a N_2-CH_4 microwave discharge, as a function of CH_4 concentration introduced in the discharge with p=2670 Pa and $\omega/2\pi$=2.45 GHz. The points represent experimental data, [N] (●), [C] (▲) , whereas the curve is the calculated value for [N].

Figure 3 shows the concentration of N and C atoms in the post-discharge 540 mm away from the end of a N_2-CH_4 discharge (set-up II), for different values of methane concentration added to the discharge. The points represent experimental values, while the curve corresponds to calculated values for [N]. The measurements show to exist a maximum in both the nitrogen and carbon atoms concentrations for added methane percentages equal to 0.02% and 0.05%, respectively. As the CH_4 percentage increases beyond these values, it is observed a smooth decrease in the concentrations of both these species. Our model predicts the magnitude of the measured N atoms concentration, but it fails to reproduce the maximum occurring at very small concentrations of CH_4, although the initial increase is also observed. As in figure 2 the calculated concentrations of C atoms are considerably smaller than those measured here.

The rapid increase of the measured N concentration for $[CH_4]_0/N_g \sim 0.02\%$, as observed in figure 3, is predicted by the model and it results from an increase of the dissociation rate by direct electron impact on $N_2(X)$ molecules, when CH_4 is added to the discharge. In fact, the methane addition leads to a reduction of the contribution from associative ionization, since the excited states $N_2(A)$ and $N_2(a')$ that are able to participate in such a process are strongly quenched by the species resulting from methane decomposition, in particular by collisions with H_2 molecules. Consequently, the electric field needs to increase in order to maintain the discharge, which leads to an increase of the electron impact dissociation rate. However, this effect cannot explain the measured decrease observed in figure 3 for the N-atoms concentration at $[CH_4]_0/N_g > 0.02\%$. This behaviour is probably a consequence of the increase of the probability for wall re-association of nitrogen atoms, γ_N, as small concentrations of CH_4 are added to the discharge. In our model, we do not take into account the complex surface kinetics and the probability γ_N is assumed to be constant.

The concentration of N and C atoms in the flowing afterglow of a N_2-0.05%CH_4 microwave discharge is presented in figure 4.

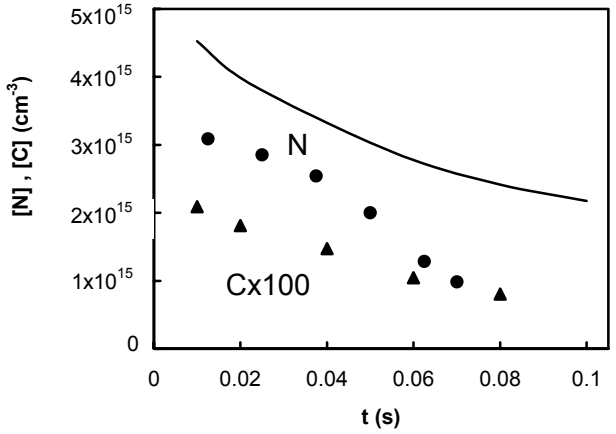

Figure 4: Concentration of N and C atoms in the flowing afterglow of a N_2-0.05%CH_4 microwave discharge, with p=2670 Pa and $\omega/2\pi$=2.45 GHz. The points and curves represent our experimental ([N] (●), [C] (▲)) and calculated data, respectively.

This figure shows a decrease in the measured concentrations of both species during the afterglow, which is in qualitative agreement with the predictions from the model for the N-atoms concentrations. However, the model predictions for the concentrations of C atoms are clearly underestimated by some orders of magnitude, so that they are not shown here. Although the production of C atoms through the reactions $CN(X)+N_2 \rightarrow C+N+N_2$ and $N_2(a')+CH_4 \rightarrow N_2(X)+C+2H_2$ have been both included in the model, we found a strong decomposition of CH4 in parallel with a depopulation of CN(X), which avoid that the C atoms may be produced. Hence, explanations are still lacking to explain the important creation of C atoms measured in both situations 1 and 2. This discrepancy can also result from a still little rigorous evaluation of the map of flow velocities in the reactor. The work is in progress to improve this point.

Abstract

The radial structure of a chlorine high-density plasma sustained by electromagnetic surface waves was investigated using various plasma diagnostics. While the radial distribution of Cl^+ and Cl_2^+ are relatively similar in magnetized plasmas sustained at low pressure (~0.5 mTorr), the radial profile of Cl_2^+ significantly differs from that of Cl^+ at higher pressure (~5 mTorr). On the other hand, in the absence of magnetic field, the radial structure of Cl^+ and Cl_2^+ remains similar over the whole range of pressures investigated. This behavior is found to result from the changes in the driving kinetics of the positive ion species that depends on both pressure and magnetic field intensity.

Introduction

The last two decades have seen the development and characterization of high-density plasma sources aimed at improving the performance of etching in the high technology industry, particularly for the replication of deep sub-micron features in microelectronics. However, experimental plasma characterization and modeling remains quite limited even though they are crucial for the development and optimization of advanced plasma etching tools.

In this context, over the last few years, we have carried out exhaustive experimental investigations of the concentration of neutral and charged species in a magnetized high-density plasma sustained by electromagnetic surface waves. In this work, we specifically investigate the influence of the gas pressure and magnetic field intensity on the radial structure of the plasma, having in mind to provide a comprehensive picture of the kinetics driving the various charged species. This work is performed for pure chlorine plasmas that we have recently modeled.[1]

Experimental setup and diagnostics

The high-density plasma under investigation is produced at 190 MHz by an electromagnetic surface wave excited in a 15 cm diameter fused silica tube opening in a 28 cm stainless steel chamber (see Fig. 1). Both in the source region and the downstream chamber, the plasma can be confined by the action of an axial magnetic field, whose strength B_0 can be varied continuously from 0 to about 1 kG. In the present work, the absorbed RF power is kept constant at 250 Watts (yielding a power density of about 2.5 mW/cm^3). The gas pressure can be varied from 0.1 to about 10 mTorr by adjusting either the chlorine flow rate (between 5 and 10 sccm), or a throttle valve located at the entrance of the pumping system.

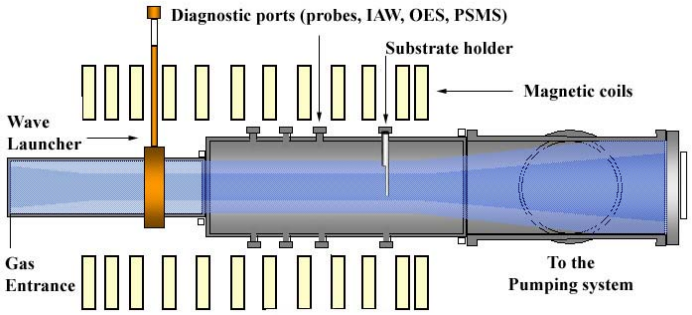

Fig 1 : Schematic drawing of the high-density plasma reactor.

The diagnostics used for plasma characterization are the following: *(i)* ion mass spectrometry using a plasma sampling mass spectrometer (PSMS) to obtain the relative density of Cl_2^+ and Cl^+ and *(ii)* electrostatic probe for the total positive ion density. More details on the use of such diagnostics in our experimental conditions can be found elsewhere.[1,2]

Results and discussion

Figure 2 shows the radial structure of the Cl^+ and Cl_2^+ density at two gas pressures: 0.5 mTorr (Fig. 2a) and 5.0 mTorr (Fig. 2b). These results have been obtained by using PSMS and Langmuir probes as in refs. [1,2]. At 0.5 mTorr (Fig. 2a), the density of both species slowly decreases between 0 and 6 cm, exhibits a peak at about 6-8 cm, and rapidly decreases beyond. The presence of the peaks in the density profiles of positive ion species was reported and modeled in ref. [3] for argon and SF_6 plasmas. It was attributed to a combination of two factors: (*i*) the fact that ionization is essentially peripheral (i.e., the ionization frequency is maximum at the edge of the fused silica tube in which the wave is launched, a common feature in surface-wave plasmas produced in large diameter tubes), and (*ii*) the anisotropy of the diffusion process in the presence of a magnetic field. This phenomenon can be either enhanced or smoothed out when further considering the volume losses for molecular gases. Finally, even though the radial distributions of Cl^+ and Cl_2^+ do not significantly differ from each other, Cl^+ remains however the main positive charge carrier between 0 and 8 cm while Cl_2^+ becomes slightly larger than Cl^+ from 8 cm.

In contrast, at 5 mTorr (Fig. 2b), the Cl^+ and Cl_2^+ density profiles are similar up to about 6 cm, while Cl^+ falls much more rapidly than Cl_2^+ beyond this position. In addition, Cl_2^+ dominates the positive ion composition for any radial position.

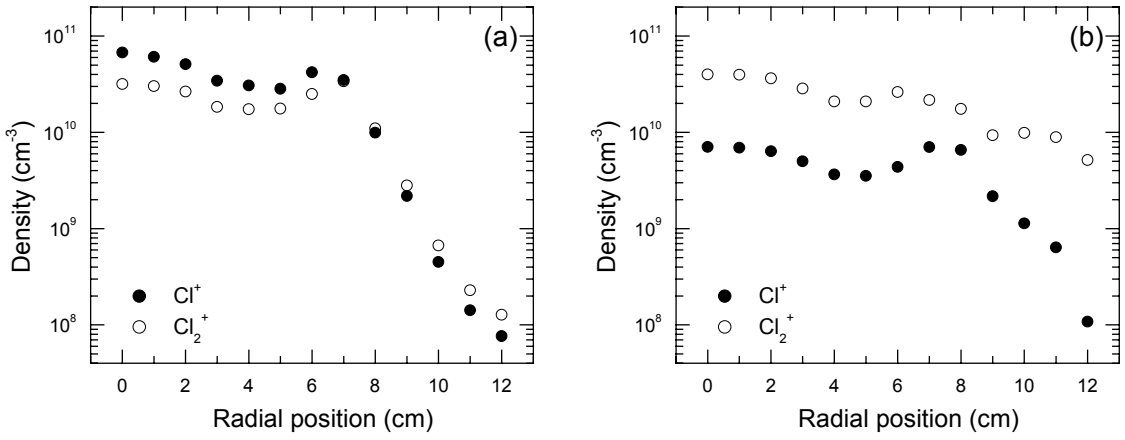

Fig. 2 : Radial distribution of the Cl^+ and Cl_2^+ density for B_0=600 G at two gas pressures: 0.5 mTorr (Fig. 2a) and 5 mTorr (Fig. 2b).

In order to more precisely examine how the gas pressure influences the radial profiles of the positive ions, we show in Fig. 3 the radial distribution of the ratio n_{Cl+}/n_{Cl2+} in the region 6-14 cm where the differences in the profiles are the most significant. Clearly, when moving to the wall, n_{Cl+}/n_{Cl2+} monotonously decreases by typically a factor of 5-7 for pressures up to about 1 mTorr. At 5 and 10 mTorr, the ratio is drastically different. Not only it shows a maximum (~ 8 cm), but it also decreases very rapidly when moving to the wall.

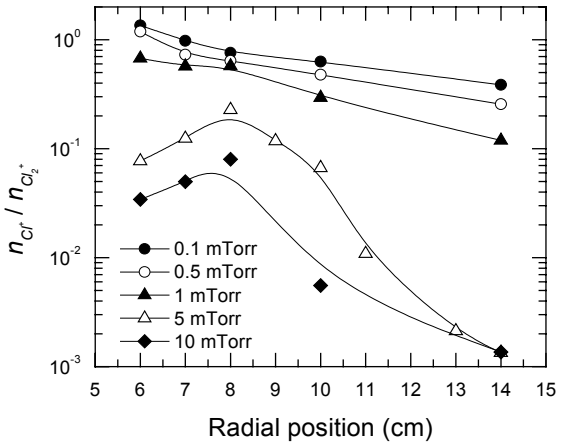

Fig. 3 : Radial distribution of n_{Cl+}/n_{Cl2+} at various gas pressures for B_0=600 G.

In order to gain insights into the meaning of the results presented in Figs. 2 and 3, we resume here the predictions of a simple fluid model recently developed for describing magnetized Cl_2 high-density plasmas. The reader is referred to previous works for details.[1] This model allows to determine the dependence of the density of electrons, Cl, Cl_2, Cl^+, Cl_2^+ and Cl^- on the experimental conditions (e.g. gas pressure, magnetic field intensity, and absorbed power). The reaction set used in the model is presented in Table 1 (from refs.1,2,4).

#	Mechanism	Reaction	Rate (cm^3/s)
1	Electron-impact ionization of Cl_2	$Cl_2 + e^- \rightarrow Cl_2^+ + 2e^-$	$\beta_1 = 9.214\times10^{-8}\exp(-12.9/T_e)$
2	Electron-impact ionization of Cl	$Cl + e^- \rightarrow Cl^+ + 2e^-$	$\beta_2 = \sqrt{T_e/12.96}\exp(-12.96/T_e)\sum_{i=0}^{5} a_i\left[\log\left(12.96/T_e\right)\right]^i$ $a_0 = 1.419\times10^{-7}$; $a_1 = -1.864\times10^{-8}$; $a_3 = 3.306\times10^{-8}$ $a_4 = -3.54\times10^{-9}$; $a_5 = -2.915\times10^{-8}$
3	Dissociative ionization of Cl_2	$Cl_2 + e^- \rightarrow Cl^+ + Cl + 2e^-$	$\beta_3 = 3.881\times10^{-8}\exp(-15.5/T_e)$
4	Electron-impact detachment	$Cl^- + e^- \rightarrow Cl + 2e^-$	$\beta_4 = 2.627\times10^{-8}\exp(-5.375/T_e)$
5	Dissociative recombination	$Cl_2^+ + e^- \rightarrow 2Cl$	$\beta_5 = 5.1\times10^{-7}(0.025/T_e)^{0.43}$
6	Dissociative attachment	$Cl_2 + e^- \rightarrow Cl^- + Cl$	$\beta_6 = 3.69\times10^{-10}\exp\left(\sum_{i=1}^{5} a_i/T_e^i\right)$ $a_1 = -1.68$; $a_2 = 1.457$; $a_3 = -0.44$; $a_4 = 0.0572$; $a_5 = -0.0026$
7	Ion-ion recombination	$Cl_2^+ + Cl^- \rightarrow Cl_2 + Cl$	$\beta_7 = 5\times10^{-8}$
8	Ion-ion recombination	$Cl^+ + Cl^- \rightarrow 2Cl$	$\beta_8 = 5\times10^{-8}$
9	Polar dissociation	$Cl_2 + e^- \rightarrow Cl^- + Cl^+ + e^-$	$\beta_9 = 8.549\times10^{-10}\exp(-12.65/T_e)$

11	Electron-impact dissociation	$Cl_2 + e^- \rightarrow 2Cl + e^-$	$\beta_{11} = 3.80\times10^{-8}\exp(-3.824/T_e)$
12	Surface recombination	$Cl + Wall \rightarrow 1/2\ Cl_2$	

Table 1 : Chlorine reaction set involved in the model presented in ref. [1].

In the magnetized plasma conditions examined in Figs. 2 and 3, the model predicts that the creation of Cl^+ is governed by electron-impact ionization. On the other hand, the creation of Cl_2^+ results only from electron-impact ionization of Cl_2 at very low pressure (~0.5 mTorr) and from both electron-impact ionization and charge transfer at higher pressure (~5 mTorr). In addition, even though diffusion dominates the losses for both Cl^+ and Cl_2^+ at low pressure, it can be ignored above about 1 mTorr. In these conditions, Cl^+ and Cl_2^+ are lost by charge transfer and recombination (ion-ion and dissociative), respectively.[1]

Based on the predictions of the model, the charged particle balance equation for Cl^+ and Cl_2^+ can be considerably simplified. At 0.5 mTorr (low-pressure regime), assuming that Cl^+ and Cl_2^+ diffuse at a similar rate, the Cl^+-to-Cl_2^+ density ratio can be approximated by

$$\frac{n_{Cl^+}}{n_{Cl_2^+}} = \frac{\beta_2 n_{Cl}}{\beta_1 n_{Cl_2}}. \qquad (1)$$

Since n_{Cl} and n_{Cl2} are independent of the radial position, the radial distribution of n_{Cl+}/n_{Cl2+} is uniquely determined by the radial variation of β_2/β_1.This ratio depends on the electron temperature distribution through the individual dependence of the rate coefficients on T_e (see Table 1).

We have calculated β_2/β_1 as a function of the electron temperature. The results of Fig. 4 show that β_2/β_1 increases with T_e. In our experiments, we found that T_e decreases with increasing radial position in the 6-12 cm region as shown in Fig. 5 for a gas pressure of 0.5 mTorr. Therefore, β_2/β_1 also decreases when moving from 6 to 14 cm. As a consequence, for low-pressure conditions, the ratio n_{Cl+}/n_{Cl2+} must correspondingly decrease, as observed experimentally in Fig. 3. Note that according to Eq. (1), the absolute value of n_{Cl+}/n_{Cl2+} also depends on n_{Cl}/n_{Cl2}, which is an increasing function of pressure.[1,2] Thus, at any radial position, n_{Cl+}/n_{Cl2+} must increase with pressure, in agreement with the experimental data presented in Fig. 3. These results are a clear indication that Eq. (1) adequately describes the plasma kinetics of positive ion species in the low-pressure regime.

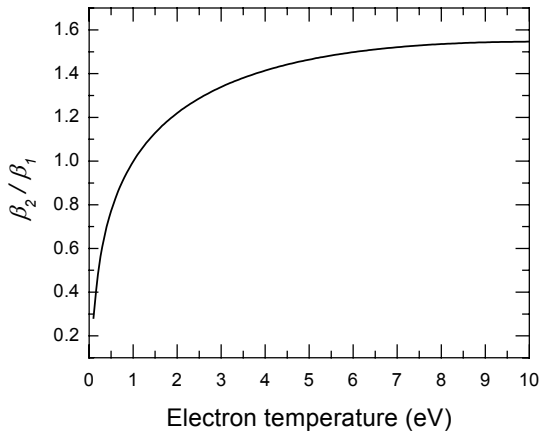

Fig. 4 : β_2/β_1 as a function of T_e

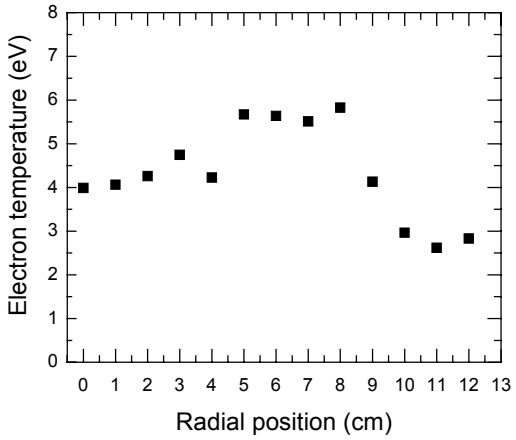

Fig. 5 : Radial distribution of T_e for B_0=600 G and a gas pressure of 0.5 mTorr.

On the other hand, at 5 mTorr, the Cl^+-to-Cl_2^+ density ratio is given by

$$\frac{n_{Cl^+}}{n_{Cl_2^+}} = \left(\frac{\beta_2 n_e n_{Cl}}{\beta_{10} n_{Cl_2}}\right)\left(\frac{\beta_5 n_e + \beta_7 n_{Cl^-}}{\beta_1 n_e n_{Cl_2} + \beta_{10} n_{Cl_2} n_{Cl^+}}\right). \qquad (2)$$

Clearly, Eq. (2) cannot be reduced to a simple form as Eq. (1). Therefore, it is not possible to identify the specific reactions responsible for the difference between the Cl^+ and Cl_2^+ profiles. However, the weakest dependence of the Cl_2^+ profile on the radial position as compared to that of Cl^+ underlines the importance of reactions independent of the electron temperature, i.e. charge transfer, ion-ion and dissociative recombination.

Finally, Fig. 6 shows the radial distribution of n_{Cl+}/n_{Cl2+} in unmagnetized plasma conditions. Clearly, n_{Cl+}/n_{Cl2+} monotonously decreases over the whole range of pressures investigated. This indicates that Eq. (1) correctly describes the positive ion kinetics even at pressures up to 10 mTorr. As shown in ref. [1], this is because for B_0=0 G, the creation of positive ion species remain governed by electron-impact ionization and the losses by diffusion up to about 10 mTorr in comparison to about 1 mTorr for B_0=600 G.

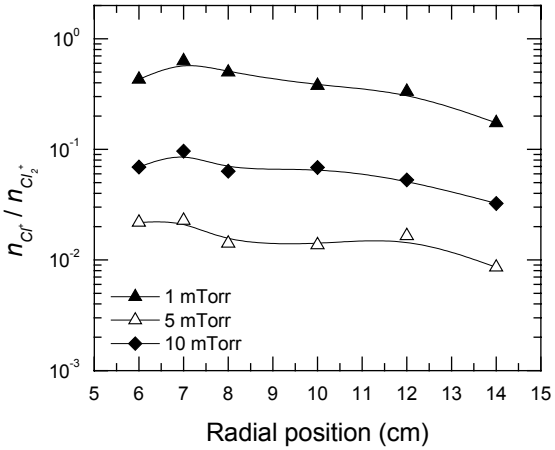

Fig. 6 : Radial distribution of n_{Cl+}/n_{Cl2+} at various gas pressures for B_0=0 G.

Conclusion

In summary, we have shown that in chlorine plasmas, the radial distribution of Cl^+ and Cl_2^+ strongly depends on the gas pressure and the magnetic field intensity due to changes in the driving kinetics of charged species with the experimental conditions. To further understand the radial structure of such plasmas, this work needs to be extended to the characterization of the negatively charged carriers. Preliminary results obtained from ion acoustic waves measurements [1,5] seem to indicate that at low pressure, the radial distribution of all positive and negative species are similar. At higher pressure, Cl^- and Cl_2^+ are closely correlated, whereas the electron and Cl^+ radial profiles are similar. This investigation is in progress.

Abstract
Multicrystalline silicon (mc-Si) samples were submitted to hydrogen plasma under various conditions. The role of exposure time, and gas composition on photovoltaic properties were determined. Impedance spectroscopy, SIMS, hydrogen effusion and EBIC techniques showed the presence of optimal conditions to improve the quality of mc-Si by exposing to hydrogen. Soft hydrogenation improves the electrical conductivity and the diffusion length, while severe hydrogenation decreases the properties by creation of acceptors defects. Hydrogen effusion spectra showed the presence of 2 peaks confirming the formation of 2 kinds of Si-H bonds. Deuterium depth profile measured by SIMS SHOWED D concentration on the surface reaches 7×10^{19} atoms/cm^3 and 2×10^{17} atoms/cm^3 at 4000 nm depth.
Keywords
Silicon**,** hydrogen, plasma, impedance spectroscopy, SIMS, minority carrier diffusion length.

1. Introduction

It is well admitted that hydrogen plays an important role in improving the electrical properties of silicon for photovoltaic devices [1-4]. Incorporation of hydrogen into the silicon bulk can be achieved commonly by direct hydrogen plasma processes [5-8]. Atomic hydrogen diffuses from plasma into silicon and interacts with a variety of defects in the bulk, especially with grains boundaries. The exact mechanism of passivation is not well understood for many defects, but reaction of hydrogen with defects can be roughly classed as passivation of unsatisfied bonds (or dangling bonds). The passivation of these defects can reduce their recombination activity and increase the minority carrier diffusion lengths [9-11].
The objective of this work is to review, in relation to photovoltaic properties, the effects of the hydrogenated plasma treatment on mc-Si. The samples were treated by an inductive RF hydrogen plasma. The influence of exposure time and gas composition were studied.
In order to determine the electrical properties of the silicon's surface, we choose Electrochemical Impedance Spectroscopy technique that has widely been used for electrochemical measurements specially to determine the electrical characteristics of solid oxide fuel cells [12].
The hydrogen diffusion was studied by Secondary Ion Mass Spectrometry (SIMS). SIMS profiles show that the hydrogen concentration at the surface reach to 10^{20} atoms/cm^3 and diffuses in depth more than 4 µm. Hydrogen effusion permits to identify the silicon-hydrogen bonds. The combination of these two techniques gives information's about the hydrogen concentration into silicon samples.
The Electron Beam Induced Current (EBIC) is a powerful technique to extract the minority carrier diffusion length from the collection efficiency versus the applied voltage of electron beam.

2. Experiments

The investigations were carried out on multicrystalline silicon mc-silicon (so-called polix) made by Photowatt International S.A. that were p-type, boron doped to 3×10^{16} cm^{-3} and whose mean grain size was about 5 mm, and the thickness of the wafer was 300 µm.
The set-up consisted of an inductive radiofrequency (40MHz) plasma source with typical power between 100-500 Watts and a glass tube with 50 mm in diameter. A substrate-holder equipped with an electrical heater and a temperature sensor (type K) were placed in the center of reactor at 5 cm below the RF coils. The pressure was ranged between 0.7 and 1.3 mbar by the mean of a vacuum pump and a MKS pressure gauge (figure 1). Prior to measurements, the surface of a polycrystalline boron-doped silicon samples was cleaned during 6 min by a mixture of (HNO_3+2%HF) to eliminate the native oxide layer. The impedance spectroscopy was used as a new method to determine the electrical properties of mc-Si surface. The device consisted of a potentiostat Solartron SI 1287 coupled with a frequency analyzer Solartron 1250. An alternative voltage of 100 mV between 2 platinum electrodes applied on surface of the samples using silver

glue. In turn, the current is measured while the frequency swiped from 1 Hz to 65 kHz. Data are presented in the form of imaginary impedance, Z", versus real impedance, Z'. The electrical resistance values are given from the intercepts of the curves with the Z' axis at low frequency [13].
During the tests we observed that the measurements were very sensitive to light, temperature and atmosphere. So we carried out measurements in dark under nitrogen atmosphere at constant temperature.
The deuterium profiles were obtained by SIMS, using a CAMECA IFS4f apparatus, the primary ions was Cs^+. For this analysis, deuterium was used as a readily identifiable isotope which can duplicate the chemistry of hydrogen. Effusion spectra were obtained either through linear (13.5°C/min) or isothermal heating of the deuterated samples. EBIC was performed using JOEL JSM 840 scanning electron microscope. The collections junctions were obtained by vacuum evaporation of a 100 nm thick aluminium layer to perform the EBIC measurements. The excitation electron beam current was less than 10^{-10} A. The minority carrier diffusion lengths at the junction were deduced by fitting the variation of the collection efficiency as a function of beam voltage.

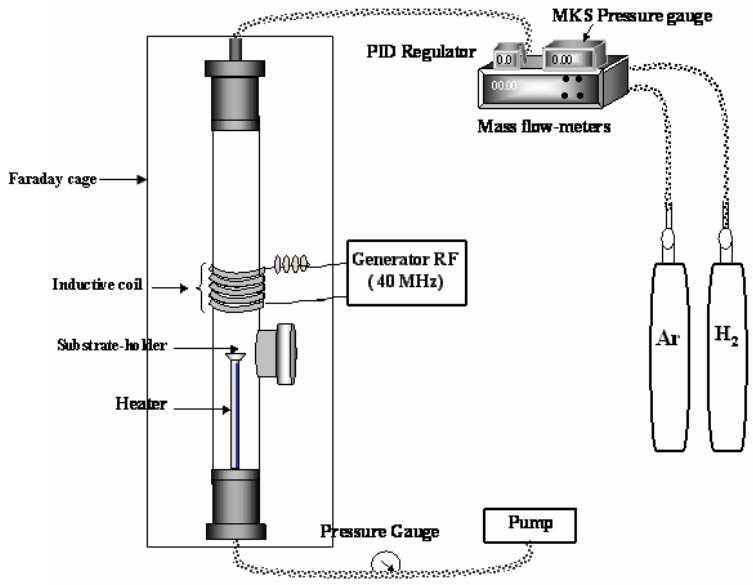

Figure 1 : Experimental set-up for treatment of silicon wafer by a low pressure plasma

3. Results and discussion

Figure 2 shows the impedance data for a silicon sample before and after exposure to pure hydrogen plasma. The electrical resistance is obtained by the intersection of the curve and Z' axis. Before hydrogenation, the electrical resistance of the silicon sample is 22000 ohm. After 1 minute exposure to hydrogen plasma at 85°C, the electrical resistance decrease to 9000 ohm.

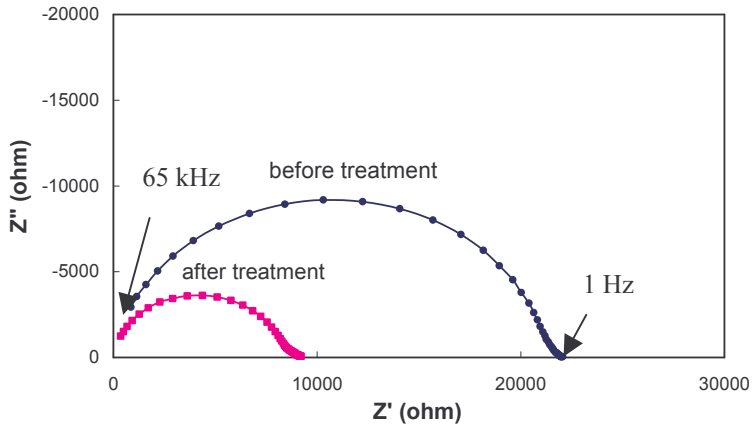

Figure 2 : Impedance data for a mc-Si sample treated 1 minute by hydrogen plasma (P=1.25 mbar, 120 W, 85°C).

In order to elucidate the role of the hydrogenation time, silicon samples were exposed to hydrogen plasma and the electrical resistance was measured as a function of exposure time. Typical reduced electrical conductivity (σ/σ_0) curve is shown in figure 3 at 180°C, σ_0 represents the conductivity of the untreated sample. We observed the same behavior at various temperatures from 150 to 400°C.

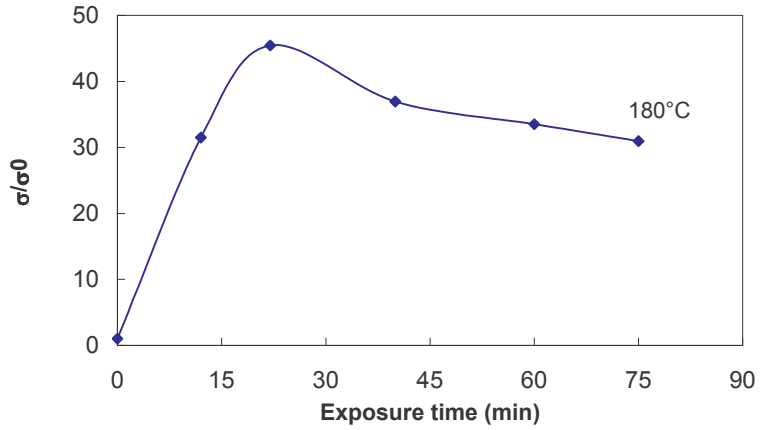

Figure 3 : The reduced electrical conductivity of poly-Si during various exposure times under pure hydrogen plasma at 180°C (1.25 mbar, 120W)

The reduced conductivity exhibits a steep increase after 12 minutes exposure to hydrogen plasma. With increasing hydrogenation time, σ/σ_0 reaches a maximum (about 22 minutes) and decays on a longer time. The observed conductivity enhancement is due to migration hydrogen atoms in the silicon host. Moreover, since the treated samples are boron-doped, hydrogen introduces from the plasma diffuses in the positive charge state, H^+, donating electrons according to the reaction $H \longrightarrow H^+ + e^-$, that indicates the passivation of grains boundaries causes an increase of the electrical conductivity [14,15].
Whereas, after a longer hydrogenation time, the reduced electrical conductivity decays exponentially. This effect, also observed by Nickel et al. [16], could be explained by a generation of new acceptors defects due to the excess of hydrogen concentration in the bulk.
In order to elucidate the effect of hydrogenation exposure time, we carried out SIMS measurements on silicon samples exposed to deuterium at 250°C. The data in figure 4 reveal that with increasing the exposure time from 15 min to 60 min, the deuterium concentration increases at the near-surface by an order of magnitude (from 2×10^{18} to 2×10^{19} atoms/cm^3). This effect is also visible until 4000 nm.

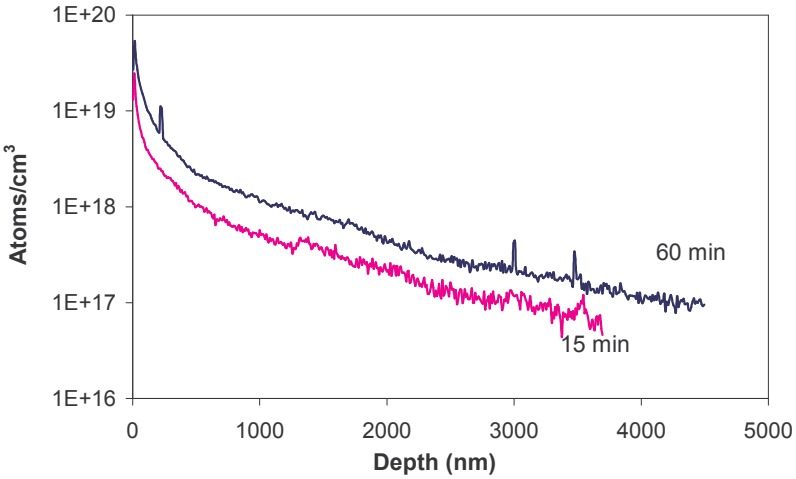

Figure 4 : Time dependence of deuterium depth profile. The samples were deuterated by plasma (50%Argon-50%Deuterium) : P = 120 W, P = 1.25 mbar, T = 250°C at indicated times.

Deuterium effusion spectra obtained for these samples were shown in figure 5. Two peaks were observed at 400°C and 550°C. In a quite similar case reported for p-type hydrogenated amorphous silicon by Stutzmann and Brandt [17]. These authors attribute the first peak (at 400°C) to clustered Si-H bonds, and the second peak to stable Si-H bonds. Accordingly, as a prelude to the desorption process, the formation of H_2 molecules from neighbouring Si-H bonds occurs at low temperature and is responsible for the 400°C peak. The hydrogen concentration in the sample calculated from Effusion spectra after 15 minutes is 1×6.10^{17} atoms/cm^3 while the sample treated 60 minutes contains 3×10^{17} atoms/cm^3.

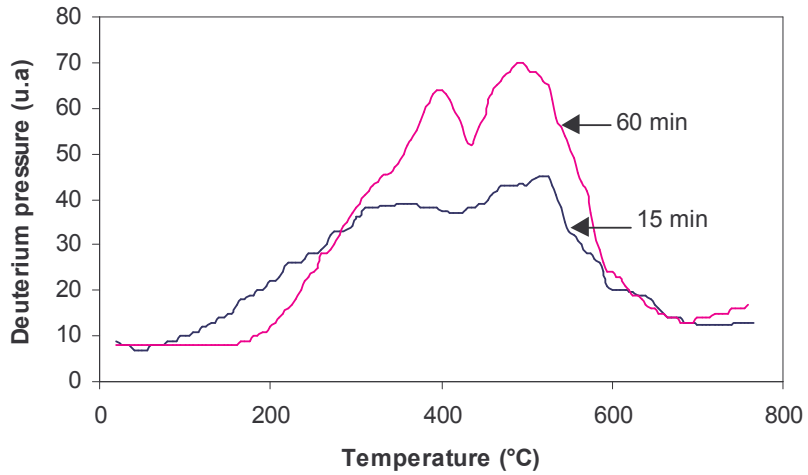

Figure 5: Deuterium effusion spectra.The samples was deuterated at 1.25 mbar, 120 Watts and 250°C at indicated times

Then, EBIC technique was used in order to control the photovoltaic properties of material. The diffusion length was measured before and after 15 and 30 minutes hydrogenation. The experimental curves of the EBIC collection efficiency as a function of accelerating voltage measured in the center of a grain are reported in figure 6. The strong increase of collection efficiency after hydrogenation treatment was characteristic of an improvement in the minority carrier diffusion length at the junction. The mean diffusion length was improved up from 72 µm (curve a) to 110 µm for 15 minutes hydrogenation time (curve b) and seems to decrease for longer times (curve c).

In order to explain this phenomena, we compared this results to those obtained by Impedance Spectroscopy in figure 3. We can conclude that, at 180°C, for a short hydrogenation time (15 minutes), the hydrogen leads to decrease the recombinant activity of grains boundaries which improve the mean diffusion length. However, for a longer time, the amount of hydrogen into silicon exceeds the density of defects and leads to a generation of new defects, that results in a decrease of mean diffusion length.

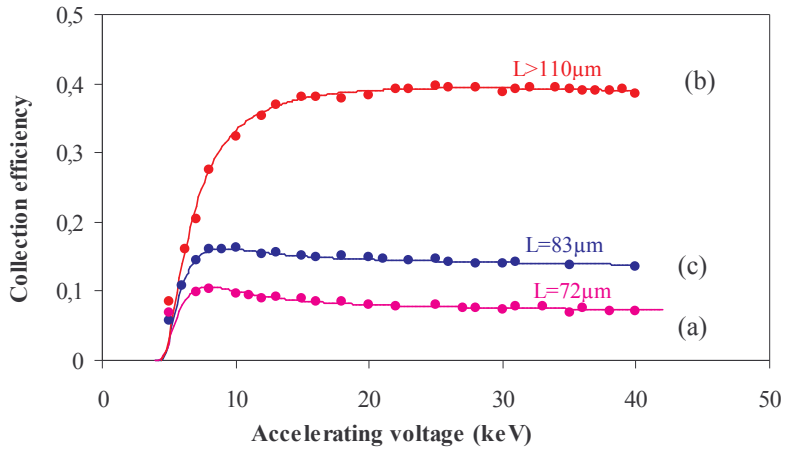

Figure 6 : Collection efficiency vs. accelerating voltage before and after treatment at different times. (a) untreated sample, (b) mc-silicon treated by pure hydrogen plasma (P = 1.25 mbar, P = 120 W, T = 200°C, t=15minutes), (c) mc-silicon treated by pure hydrogen plasma (P = 1,25 mbar, P = 120 W, T = 200°C, t=30minutes).

Experiments were carried out to study the influence of deuterium molar fraction in plasma gas on the profiles of D concentration in silicon samples. A comparison of depth profiles of deuterium is shown in figure 7. In this figure, we observed a higher concentration of deuterium on the surface of Si specimen after treatment by 100% D plasma, especially at depth below 3000 nm than that sample exposed to plasma containing 50%D. It decreases from 1.6×10^{21} to 1.1×10^{19} atoms/cm^3 with the reduction of D molar fraction in the plasma by factor 2.

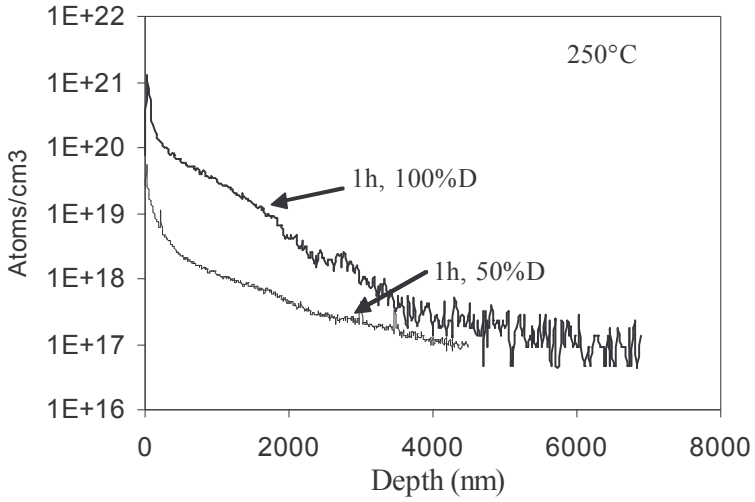

Figure 7 : Depth profiles of deuterium in mc-Silicon. The samples were exposed to deuterium non-equilibrium plasma (at various D rate), for 1hour at 250°C

EBIC measurements was used in order to elucidate the effect of plasma composition on the electronic properties of mc-silicon (figure 8). Results show that, after a treatment by pure hydrogen plasma, the mean diffusion length was smaller than this obtained after a treatment by a plasma (Ar-50%H_2). This effect is probably related to the hydrogen concentration in plasma. When the molar fraction of hydrogen in plasma is large, the hydrogen diffusion into silicon is more important, and its amount exceed that of the defects. In this case, the hydrogen can generate a new defects or reduce the diffusion length.

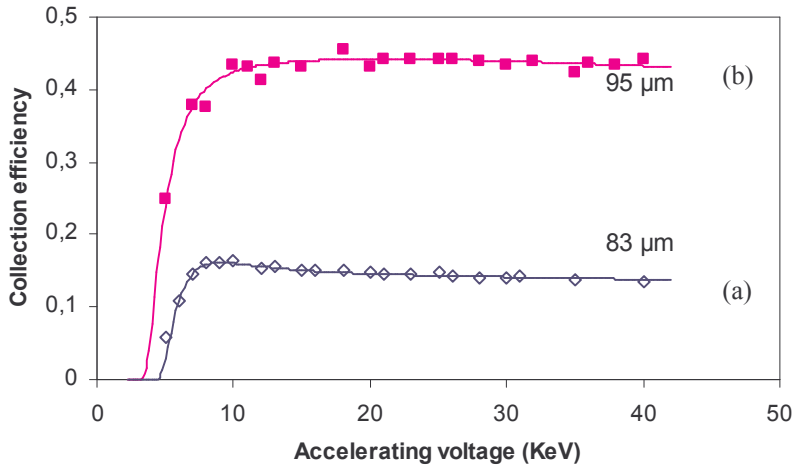

Figure 8 : Collection efficiency vs. accelerating voltage before and after treatment for different plasma composition (a) mc-silicon treated by pure hydrogen plasma (P = 1,25 mbar, P = 120 W, T = 200°C, t=30minutes), (b) mc-silicon treated by plasma (50%Ar+50%H_2) (P = 1,25 mbar, P = 120 W, T = 200°C, t=30 minutes)

4. Conclusion

In summary, we have presented an investigation of the effects of hydrogen plasma on the properties of silicon surface. Impedance spectroscopy was used as a new method to determine the electrical properties. The electrical conductivity of silicon surface depends strongly on the hydrogenation time. SIMS measurements were also carried out in order to confirm the impedance data. We observed a strong influence of the experimental parameters (exposure time, Deuterium rate) on deuterium concentration at the surface. Hydrogen effusion exhibit the presence of two kinds of silicon-hydrogen bonds. The electron beam induced current have been applied to control the electronic properties of our material. The collection efficiency as deduced from EBIC analysis allowed us to extract the minority carrier diffusion length. We have shown that the effective diffusion length can be strongly improved by plasma hydrogenation. Results obtained by these techniques show that there exists an optimum time for hydrogen incorporation and minimum defect generation.

Abstract
The paper is devoted to study of the growth of the aligned CNT in the anode sheath of the glow DC discharge on silicon substrate and in the MW discharge using porous Al_2O_3 template. Numerical simulation of transport processes in the anode sheath for conditions of CNT growth is carried out. It was found that the alignment of CNT was induced by the electric field in the near anode sheath region under plasma enhanced chemical vapor deposition (PA CVD) process.
Keywords
Carbon nanotube, DC glow discharge, anode sheath, chemical vapour deposition, microwave discharge

1. Introduction

Considerable interest to highly-aligned carbon nanotubes (CNT) is due to the possibility of using them in the field electron emission [1], micro- and nanoelectronics [2], filter mediums [3], electrical super-capacitors as well as for super-hydrophobic surfaces [4]. At present different synthesis methods are developed for production of CNT. These methods basically use different plasma sources (see review [5]), such as direct current (DC), radio-frequency (RF) and microwave (MW) discharges, inductively-coupled RF discharges. It is widely believed that electric field plays key role in aligning CNT by PA CVD. But possible mechanisms for the influence of the electric field upon aligned CNT growth do not understand yet. We have studied the properties of anode sheath region of DC discaharge and the possibility of aligned CNT growth in MW discharge.

2. Aligned CNT synthesis in the DC glow discharge

The scheme of the experimental setup is presented in fig.1. In the DC glow discharge the electrodes were made from molybdenum. The anode of 2.7 cm in diameter was grounded; the 2.4 cm diameter cathode cooled by water was fed with the negative voltage from the DC source. The deposition time was varied from 1 up to 15 minutes. The working pressure in the chamber was within 100-140 Torr and the substrate temperature was within 960-1080°C.

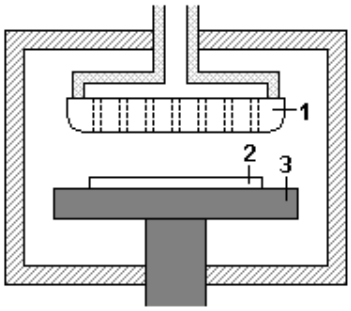

Figure 1. The scheme of the setup: 1 is the water-cooled cathode containing holes for loading the working gases; 2 is the substrate; 3 is the anode.

Before the deposition of CNT the Si substrates were successively coated by magnetron sputtering with layers of titanium (as a barrier layer and for a better adhesion) and nickel (the latter is one of the best catalysts for CNT growth). After that the substrate was placed into the chamber of a DC discharge, and the annealing process was performed in pure hydrogen for 10-15 minutes under the pressure of 120 Torr and the temperature of $T \sim 980$°C. This procedure resulted in the modification of solid nickel film to nanoparticles of 20-30 nm in size.

Then methane was added to the working gas and deposition of CNTs was performed. In Fig.2 there are SEM image of the chip of the film grown by this procedure and consisting of the oriented CNT. Deposition was performed for 15 minutes, the discharge current was 1.35 A, the discharge gap voltage was 720 V, flow rate of hydrogen was 30 l/hour, that of methane was 2.7 l/hour. The deposited nanocarbon films were also studied with the transmission electron microscopy (TEM) and Raman spectroscopy.

3. Numerical simulation of the DC discharge anode sheath

The gas density in our experiments under the conditions of growing nanotubes was about 10^{18} cm^{-3}, so in the $10\%CH_4+90\%H_2$ mixture the free path length of electrons was equal to $l_e \approx 8$ μm , and that of ions to

$l_i \approx 20$ μm. Therefore, the hydrodynamic approximation can be used to describe transport processes of charged particles in the anode sheath. To determine the distribution of the potential and the electrical field strength as well as of the density of electrons and ions in the anode sheath the following self-consistent system of equations was used:

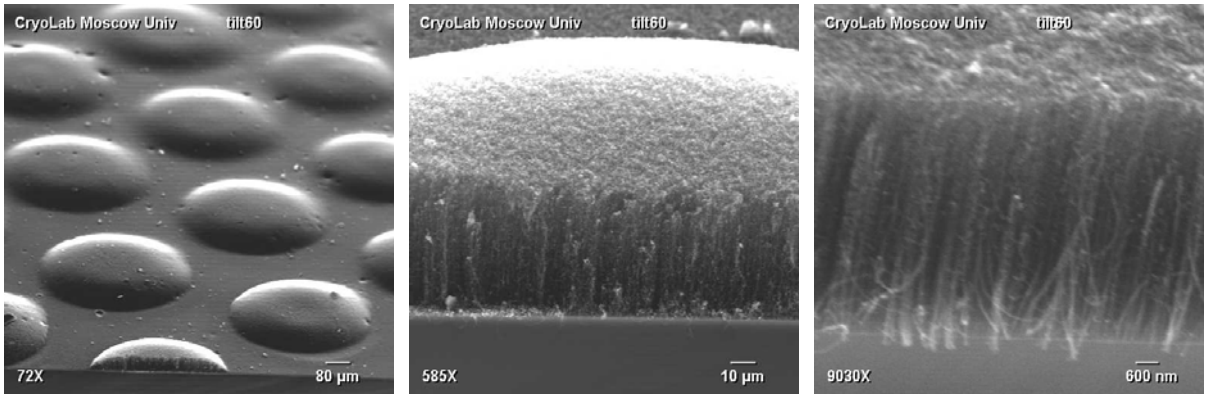
$$\frac{\partial n_e}{\partial t} = \frac{\partial^2 \left(D_e n_e\right)}{\partial z^2} + \frac{\partial \left(k_e n_e E\right)}{\partial z} + \nu_{ion} n_e - \beta_{ei} n_e n_i \,, \tag{1}$$

$$\frac{\partial n_i}{\partial t} = -k_i \frac{\partial \left(n_i E\right)}{\partial z} + D_i \frac{\partial^2 n_i}{\partial z^2} + \nu_{ion} n_e - \beta_{ei} n_e n_i \,, \tag{2}$$

$$\frac{\partial \left(n_e \varepsilon_e\right)}{\partial t} = \frac{\partial^2 \left(G n_e\right)}{\partial z^2} + \frac{\partial \left(\beta n_e E\right)}{\partial z} - e j_e E - n_e W_S \,, \tag{3}$$

$$\frac{\partial E}{\partial z} = 4\pi e \left(n_i - n_e\right), \tag{4}$$

where n_e, n_i, k_e, k_i, D_e, D_i are the densities, the mobilities and the diffusion coefficients of electrons and ions respectively, ν_{ion} is the frequency of gas ionization, β_{ei} is the coefficient of electron-ion recombination, ε_e is the mean energy of electrons, β is the thermal electricity coefficient, W_S is the rate of energy loss in elastic and inelastic collisions, E is the electrical field strength, e is the absolute value of the electron charge.



(a) *(b)* *(c)*

Fig.3. SEM images of grown nanotubes.

System of equations (1)-(4) was completed with the following boundary conditions:

$$\left[n_e - \gamma_e l_e \frac{\partial n_e}{\partial z}\right]_{|z=z_0} = 0 \,, \left[n_i - \gamma_i l_i \frac{\partial n_i}{\partial z}\right]_{z=z_0} = 0 \,, \left[p_e - \gamma_\varepsilon l_e \frac{\partial p_e}{\partial z}\right]_{|z=z_0} = 0 \,; \tag{5}$$

$$n_{e|z=z_\infty} = n_{e\infty}, \quad n_{i|z=z_\infty} = n_{i\infty}, \quad \varepsilon_{e\,|z=z_\infty} = \varepsilon_{e\infty}, \; E_{|z=z_\infty} = E_\infty \,; \tag{6}$$

where $p_e = n_e T_e$ is the pressure of the electron gas; T_e is the electron temperature defined by $T_e = 2\varepsilon_e/3$, γ_e, γ_i, γ_ε are the coefficients which, for the case of the plane geometry, are equal to the Hopf constant

$$\gamma_{e(i)} = \left(2D_{e(i)} / l_{e(i)} \upsilon_{T,e(i)}\right)\Big|_{z=z_0} \approx 0.7104 \,; \; \gamma_\varepsilon = \left(G_e / l_e \upsilon_{T,e} T_e\right)\Big|_{z=z_0} \,; \tag{7}$$

$\upsilon_{T,e(i)}$ is the thermal velocity of electrons (ions), z_0 is the anode coordinate, z_∞ is the coordinate of the point after which the influence of the electrode (anode) upon the positive arc column can be neglected. The values with the subscript "infinity" are the positive column values.

During this stage we do not consider negative ions, because it is conventional view at present that the methane-hydrogen mixture that is being studied is an electropositive gas [1,3-5]. In principle the system can be easily supplemented by the balance equation for negative ions. Usually the ion diffusion in transport processes in the DC glow discharge does not play any role; therefore, to increase the calculation rate and to avoid numerical instabilities (those of Gibbs type), for ions we solved the first-order balance

equation with the boundary condition in the anode. It is supposed that the basic positive ion is $C_2H_5^+$ with the dissociative recombination coefficient

$$\beta_{ei} = 7.4\times10^{-7}\left(T_e/300\right)^{-1/2}\ \text{cm}^3/\text{s}$$

(the temperature of electrons is in K). The mobility of ions was calculated from the equation:

$$k_i = \left(\chi_{\text{H}_2}/k_{i,\text{H}_2} + \chi_{\text{CH}_4}/k_{i,\text{CH}_4}\right)^{-1},$$

where the numerators contain the fractions of the corresponding molecules in the mixture, and the ion mobilities reduced to normal conditions for pure gases was derived from the Langevin relationship:

$$k_i = 36/\sqrt{\alpha\mu}\ \text{cm}^2/\text{V s},$$

where α is the polarizability of hydrogen (α_{H2}=0.819) or methane (α_{CH4}=2.6) molecules in atomic units, μ is the reduced mass of the ion and the selected molecule.

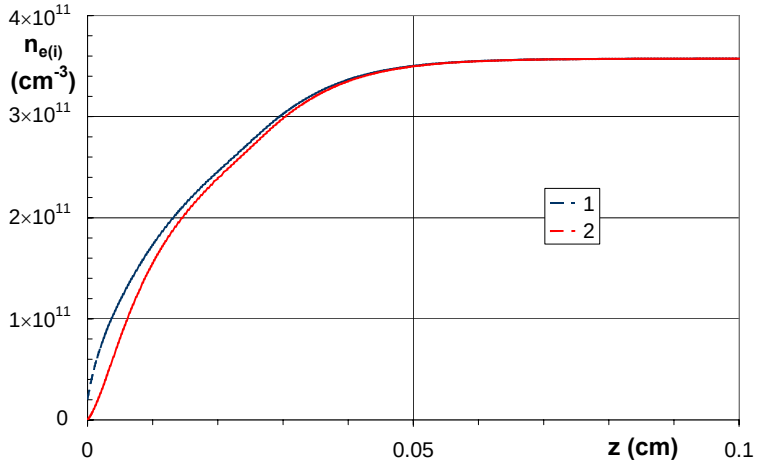


Fig.3. Distributions of electron (1) and ion (2) densities in the anode sheath of the glow discharge in the 10%CH_4+H_2 mixture.

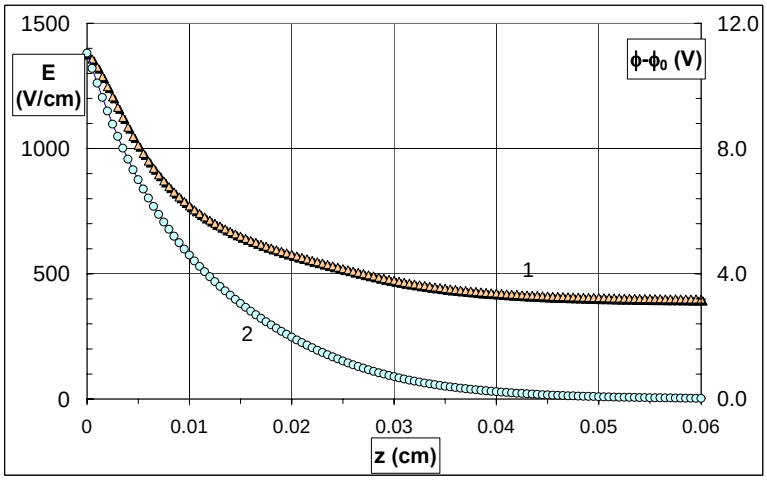

Fig.4. Distributions of electric field strength (1) and potential (2) in the anode sheath of the glow discharge in the 10%CH_4+H_2 mixture. The ϕ is the total potential, the ϕ_0 is the potential of the homogeneous external field without considering the net charges

In figures 3-5 there are results of numerical calculations in the H_2:CH_4=1:9 mixture under the following input parameters: the pressure was p = 120 Torr, the gas density $N = 9.474\times10^{17}$ cm^{-3}, the gas temperature T_{gas} = 1250 K, the discharge current density in the positive column j_d = 670 mA/cm^2. Such parameters were maintained in experiments in growing oriented nanotubes. Then these parameters were used in

numerical calculations to determine the reduced electrical field strength, the electron density and temperature in a positive column, which were equal to the following:

E_{pc} = 404.5 V/cm, $E_{pc}/N = 4.27\times10^{16}$ V cm^2, $T_{e,pc}$ = 1.444 eV, $n_{e,pc} = n_{i,pc} = 7.91\times10^{11}$ cm^{-3},.

It is clearly seen from the presented figures that the size of the anode sheath in the mixture is about several hundreds of microns, which is considerably larger than the height of highly oriented nanotubes.

According to the present literature data there is opinion (for example, [2]), that the electrical field considerably influences upon the growth of nanotubes, but there is no recognized mechanism for this influence. It was shown in [2] that the growth of the oriented nanotubes only occurred under the electrical field strength of 0.1-0.15 V/μm, and no nanotubes grew under the electrical field of 0.07 V/μm.

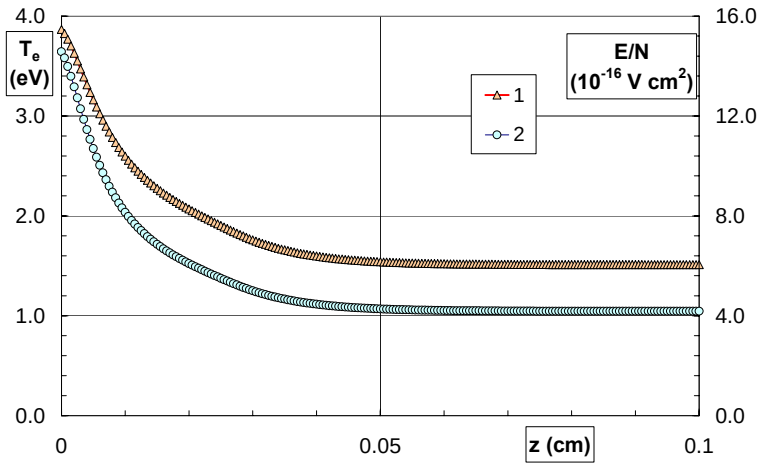

Fig.5. Distributions of electron temperatures (1) and reduced electric field strength (2) in the anode sheath of the glow discharge in the 10%CH_4+H_2 mixture.

According our simulations aligned CNTs in the anode sheath grow in the electric field with the strength of about 1.4 kV/cm (fig.4). The interaction energy of a nanotube with such a field is negligible, about 10^{-5} eV, therefore the ponderomotive force cannot be the reason for the aligned growth of nanotubes. Consideration of possible mechanisms of electric field effect on the oriented CNT growth showed that the ordered alignment of the nanotube array could result in our conditions from the collective Coulomb interaction of charges induced by the electric field on nanotube heads. It was found that aligned CNTs could only grow within the rather narrow temperature range of 960-1000^{o}C. Termination of the aligned CNT growth could be due to the fact that the increase of CNTs height is accompanied by enhanced heating of nanotubes by the electrons and the hot gas from plasma.

4. Aligned CNT synthesis in the MW discharge

The basic advantage of MW discharge is the plasma purity due to absence of electrodes, which is important in using deposited film in microelectronics. Among the basic features of the MW discharge the following ones stand out: high ionization and dissociation degree under relatively low gas temperature, which is caused by a considerable difference in gas and electron temperatures. For typical deposition processes under the gas pressure of 50 Torr those are 2000 K and 18,000 K respectively. In comparison with other types of discharges this results in great dissociation degree of hydrogen, which is a strong etching agent for sp^2 carbon phase. The influence of these conditions is particularly negative for CNT formation process. In the same way, relatively high energy acquired by electrons influences the composition of the gas phase, where low molecular compounds are dominating, owing to which the formation of complex structures such as, for example, fullerene complexes, is complicated.

As a result, the basic difficulty to grow CNT in the MW discharge is the necessity to decrease the rate of etching CNT by atomic hydrogen, which is formed in the dissociation process of both hydrogen molecules and carbon containing gas (for example, methane). The etching effect is increased with the rise in the working pressure, which results in the impossibility of producing CNT under high pressures (about

100 Torr) in the gas mixture of hydrogen-methane. It should be noted that the concentration of etching components in plasma should be sufficient to provide appropriate purification of the deposited film surface from growth sites of unsuitable phases, which decrease the quality of the CNT structure.
The following three methods can be used to decrease the concentration of atomic hydrogen near the substrate under high pressures: (a) growing CNT under the graphite grid, (b) adding the gas substituting hydrogen into the working mixture and (c) using the pulsed mode (PM) for gas excitation.
The first method consists in placing a graphite grid with holes of about 1 mm in diameter and a step of 2 mm within 1-2 mm above the substrate surface (see the fig.6). The grid supplies additional amount of carbon into the growth region and at the same time screens atomic hydrogen within the graphite surface. The mechanism of the grid action has not yet been studied completely.

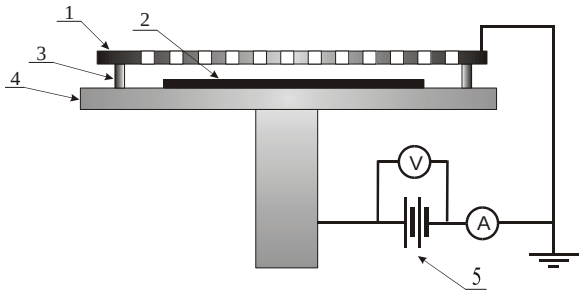

Fig.6. Arrangement of sample holder . 1 – graphite grid; 2 – Si sample; 3 – spacer; 4 – Mo plate; 5 – DC power supply.

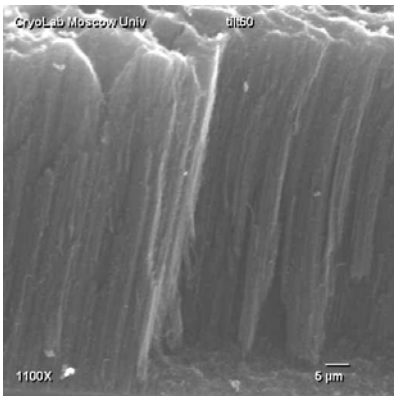

Fig.7. Aligned nanotubes produced with graphite grid.

The grid can also provide an electrical shift for the oriented growth of CNT. Fig.7 shows SEM image of produced CNT film. The Si substrates were the same as used in DC CVD. It was found that growth of aligned CNT are only possible when the Si resistivity is no more than 10 kΩ.
Lately the second method is rather widely used. The hydrogen in a standard methane-hydrogen mixture can be substituted partially or completely by nitrogen, oxygen containing gas or rare gases (usually Ar is used). The use of mixture of methane and carbon dioxide shows good results. Oxygen binds atomic hydrogen forming OH, and, in addition, results in enrichment of the mixture with carbon. In such a mixture growing CNT occurs within a wide range of deposition parameters, also under low temperatures of a substrate.
The third method is based on the difference in time dependence of formation and recombination rates for radicals and ions in plasma. By varying the duration of pulses and the interval between them it is possible to influence considerably the radical composition of discharge, and hence, the structure of the film formed. The pulse mode (PM) MW CVD provides also a possibility of low-temperature nanomaterials growth. This is especially urgent for the case of glass substrate, which could be easily built into present-day electronic technology. In continuous mode decrease in the substrate temperatures is connected with MW energy decrease, which leads to decreasing plasma volume and essential change in plasmochemistry. Using PM it is possible to eliminate both of these factors: increasing on-off ratio one can decrease average MW power and, hence, substrate temperature, keeping pulse power constant and, thus, preserving plasmochemistry and discharge volume. In such a way we successfully perform the CNT growth at a substrate temperature of 370-400^0 C.
When CNTs arrays are used as emitters of electrons, there occurs mutual electric shielding of separate nanotubes. Deposition of a solid layer of nanotubes leads to considerably weakening the effect of the electric field increase on nanotube tips and to the higher emission threshold for the specimen coated with such a film. Besides, there is the natural fluctuation in the length of grown CNTs, as a result the emission homogeneity also becomes worse. This problem can be solved by separating individual emitters. One of the effective approaches to solve this problem is growing nanotubes through the pores of the anodic Al_2O_3

(porous anodic alumina – PAA). In our experiments PAA substrate 30-40 μm thick was covered with Mo film 20 μm thick to form an electrode. The Co catalyst was cathodically deposited into the nanopores of PAA.

The growth of CNTs was performed by MW CVD in continuous mode with graphite grid or pulse mode. In the first method the deposition conditions were the following: CH_4:H_2 gas mixture with methane concentration of about 16%, total pressure of 80 Torr. Substrate temperature was equal to 780°C. The deposition time was about 10 min. The negative bias applied to the substrate holder relative to the grounded grid electrode was about 100 V. The bias current reached 5 mA.

The pulse mode of plasma excitation makes it possible to change the C_2/CH radicals concentration, that allows the optimization of the CNT deposition conditions. Using the optical emission spectroscopy we found out that changing of the modulation frequency made it possible to manipulate the [C_2]/[CH] ratio within 15% range (fig.8). The CNT were grown in CH_4:CO_2 gas mixture (1:1) under the following conditions: total gas pressure was 30-40 Torr, average MW power 100 W, modulation frequency 1.5 kHz, on-off ratio of 4, the substrate temperature was 500°C. Fig.9-11 show SEM images of the chips of the films grown and Raman spectrum of CNT.

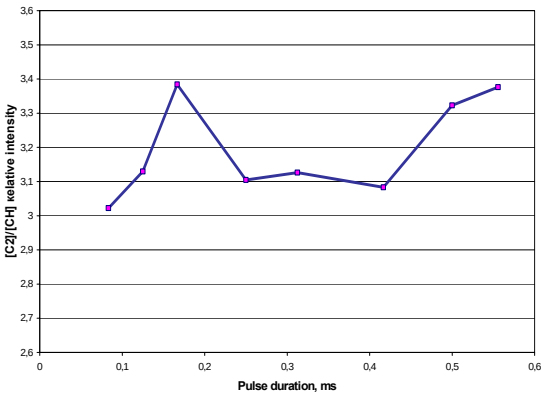

Fig.8. Dependence of [C_2]/[CH] from MW pulse duration in CH_4:H_2 plasma.

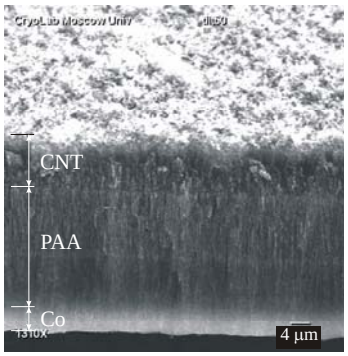

Fig.9. CNT grown in the continuous mode.

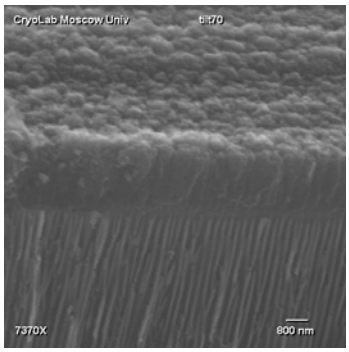

Fig.10. CNT grown in the pulse mode.

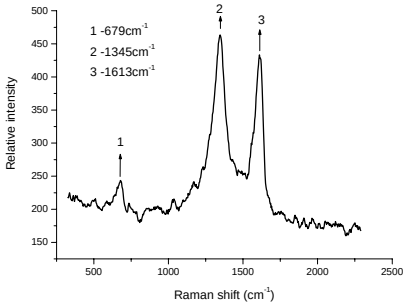

Fig.11. Raman spectrum of CNT film grown in the pulse mode.

Practically through each pore of the PAA an individual nanotube grows about 10 μm height over the template (fig.9).

Water treatment by radical injection with atmospheric micro plasma generated in fast oxygen flow

Atsushi Yamatake, Jeremy Fletcher, Koichi Yasuoka and Shozo Ishii

Department of electric and electronic engineering, Tokyo Institute of Technology, Tokyo, Japan

Abstract

In this study, a new water treatment method by O radical injection with DC driven micro plasma was examined. This method can realize stronger oxidation than an ozone process because of O and OH radicals. The effect of radical injection was measured by using a water solution of acetic acid (CH_3COOH). This was examined with various parameters (discharge current, gas flow rate, hole diameter), and the results indicated that high gas flow velocity was important to inject short-lived radicals into water effectively.

1. Introduction

Atmospheric plasma is used for various fields such as decomposition of toxic substances. In the plasma, molecules are dissociated by high energy electrons and radicals. One of the methods for decomposition of toxic substances is using ozone which is produced by oxygen discharge. Oxygen atoms (O radicals) and ozone molecules are generated by following equations.

$$e + O_2 \rightarrow O + O + e \quad (1)$$

$$O + O_2 + M \rightarrow O_3 + M \quad (2)$$

Ozone is useful for oxidation processes such as water purification because it is stronger than chlorine and harmless to the environment. However, ozone cannot perfectly decompose organic substances, so it is impossible to decompose persistent substances such as dioxin. Therefore stronger oxidants than ozone are needed for advanced oxidation process, such as O and OH radicals.

We have studied radical sources with atmospheric micro plasma such as micro hollow cathode discharge [1]. Oxygen molecules are decomposed in the plasma and ozone molecules are generated at the downstream of the plasma when feeding oxygen into the plasma at high speeds [2][3]. In this case, O radicals, whose life is very short, can be directly used within several millimeters from the electrode. In this study, direct water treatment with O radical was achieved. It is considered that OH radicals are also generated in water by Eq. (3).

$$O + H_2O \rightarrow OH + OH \quad (3)$$

2. Experimental setup

Fig. 1 shows the structure of the discharge electrode. The upper electrode (cathode) is molybdenum with a thickness of 200 μm, and there is a small hole at the center. The lower electrode (anode) is separated from the upper electrode with alumina of 500 μm thickness. Plasma is generated in the hole when DC high voltage is applied. Oxygen gas is injected into the discharge and radicals are emitted from the hole.

The experimental setup is shown in Fig. 2. DC high voltage was applied to the electrode with a DC high voltage source through a ballast resistor. Oxygen was supplied with a mass flow controller. Water was on the electrode and treated directly by radical injection.

The treated water was a solution of acetic acid (CH_3COOH) as a persistent substance. To detect the decomposition of the acetic acid, TOC (Total Organic Carbon) concentration in the water was measured by a TOC analyzer (Sievers 810) because a decrease of TOC means decomposition of acetic acid.

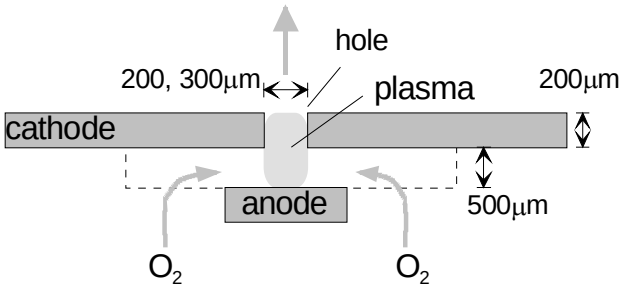

Fig. 1 Schematic of electrode

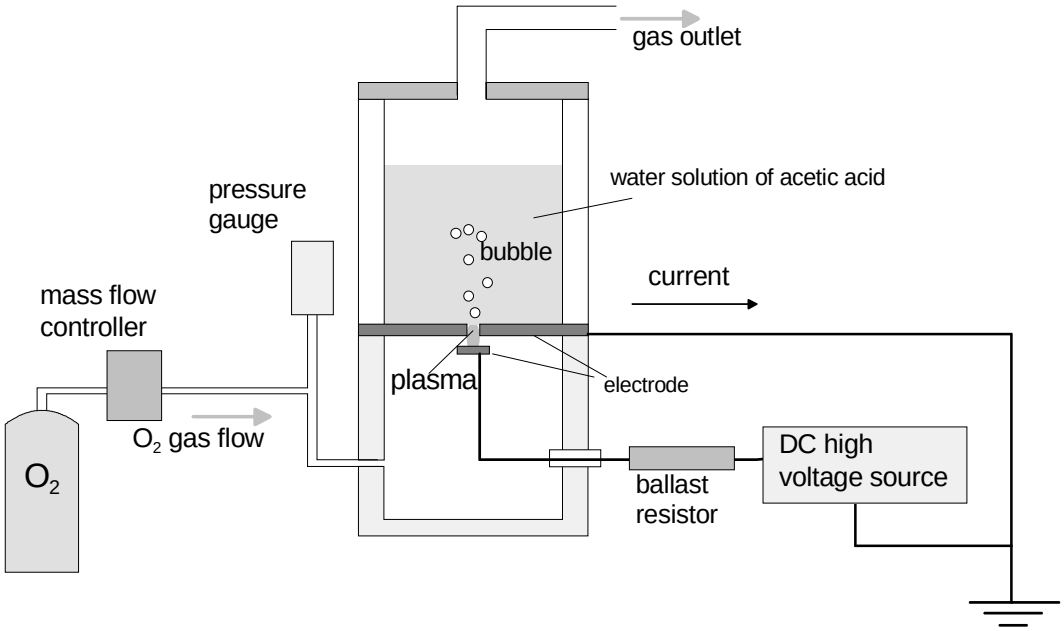

Fig. 2 Experimental setup

3. Results and discussion

First, sustaining voltage was measured by oscilloscope at various currents with water and oxygen gas flowing through the hole. The results are shown in Fig. 3. A stable plasma was generated even when the electrode was in contact with water. The plasma was not in direct contact with the water because of the high gas flow rate and surface tension of the small hole. But the stability was less than that of plasma generated in the atmosphere.

Fig. 4 shows the result of decomposition of TOC. Initial TOC concentration was 10 ppm, and the water volume was 10 mL. In this case, oxygen gas flow rate was 500 sccm. When gas flowed without discharge, TOC didn't decrease because acetic acid isn't decomposed by only bubbling. The symbol of "O_2 + O_3" means injecting ozone which was generated in another place, and TOC didn't decrease because ozone can't decompose acetic acid. When plasma was made at the electrode and oxygen was fed through, the effect of decomposition was measured. It was found that this system has the ability to inject radicals into water. The decomposition rate became higher after increasing the discharge current. That can be explained that the amount of O radicals generated at the plasma being larger because the electron density was higher.

In order to compare various results, the energy efficiency of decomposition was calculated by the results and below equation [4]:

$$\eta = \frac{w\Delta C / m}{IV\Delta t} \tag{4}$$

where η[mol/J] is energy efficiency for decomposing acetic acid, w[g] is the weight of sample water, ΔC is the variation of TOC concentration, m[g/mol] is the weight of carbon in 1 mol (m=24 in case of CH_3COOH), I[A] is discharge current, V[V] is sustaining voltage and Δt[s] is processing time.

Fig. 5 shows the energy efficiency calculated by the results of Fig. 4. The efficiencies were not largely changed with various discharge currents.

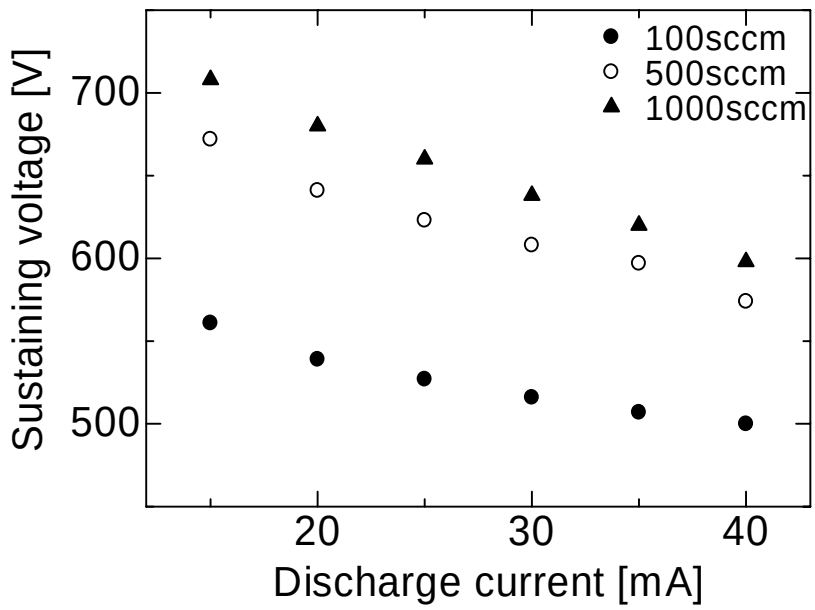

Fig. 3 *V-I* characteristics

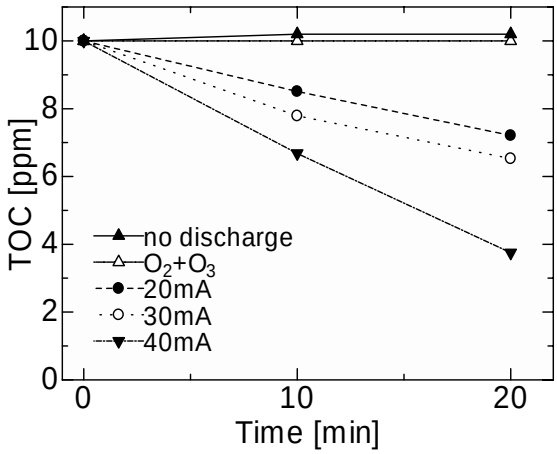

Fig. 4 Time dependences of changing of TOC (hole diameter is 200 μm, gas flow rate is 500 sccm)

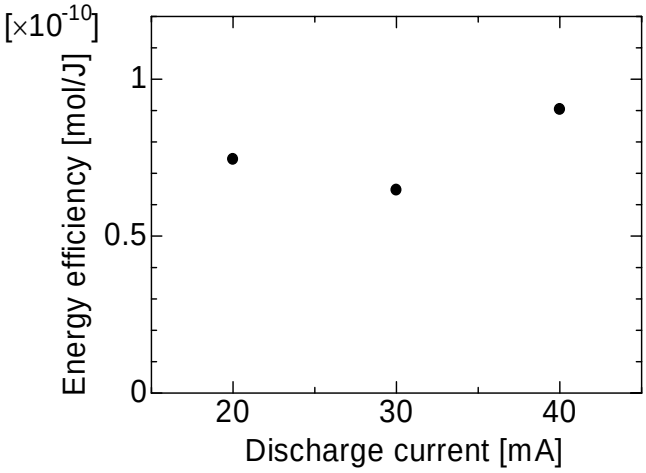

Fig. 5 Energy efficiency of decomposition with various currents

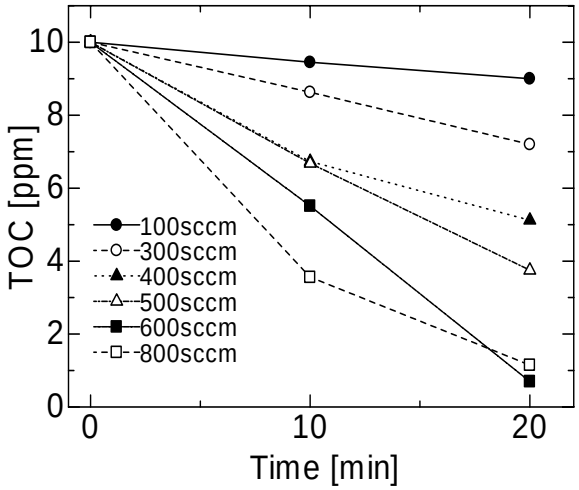
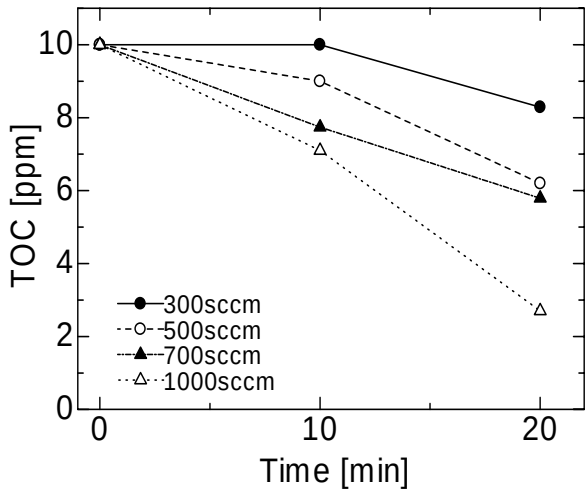


(a)ϕ200 μm



(b)ϕ300 μm

Fig. 6 Decomposition of TOC with various gas flow rate when the hole diameters were (a)200 μm, and (b)300 μm.

Fig. 6 shows the results of the process with various gas flow rates and fixed discharge current (=40mA), and hole diameters are (a)200 μm and (b)300 μm respectively. Fig. 7 shows the energy efficiency which was calculated by the same method as Fig. 5. From Fig. 7, it is found that the energy efficiency became higher with increased gas flow rate. It can be assumed that this was caused by the injection of more gas. But considering that the efficiencies of ϕ300 μm were lower than those of ϕ200 μm, the gas flow rate is not a critical parameter.

The lifetime of O radicals, which were generated in the plasma, was very short, so it is important to inject radicals into water within the lifetime of O radical. The gas flow velocity at the hole was calculated with the gas flow rate, the hole diameter and the gas pressure. However, accurate values couldn't be calculated and the converted gas flow velocities were unrealistic values. Fig. 8 shows the results when x-axis has been converted to gas flow velocity from Fig. 7. It is found that the efficiency largely depended on the gas flow

velocity. O radicals seem to exist only within very short distance from the electrode because they disappear within several millimeters if the lifetime is several tens microseconds and the gas flow velocity is 100 m/s. That indicates that quick injection of radical was important.

It can be also considered that the effect was caused by the difference of the size of bubbles. In any case, the gas flow velocity is important parameter because the size of bubbles is affected with gas flow velocity.

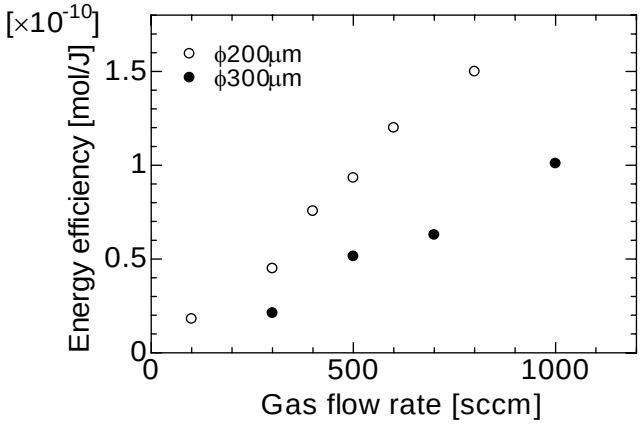


Fig. 7 Energy efficiency of decomposition with various gas flow rate.

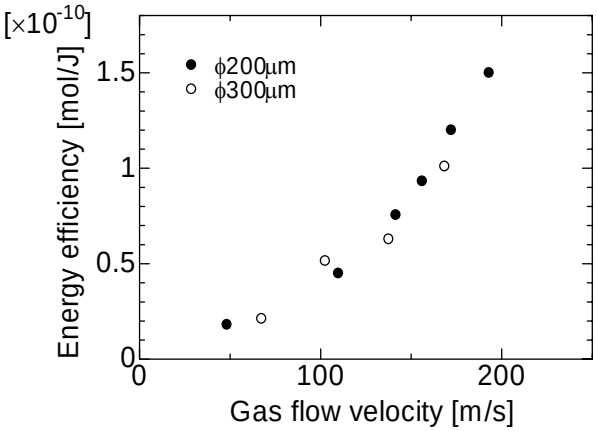

Fig. 8 Energy efficiency of decomposition with gas flow velocity converted from gas flow rate and so on.

4. Conclusion

Direct water treatment by radical injection with DC driven micro plasma and oxygen was achieved, and decomposition of acetic acid in water was measured by analyzing TOC concentration.

- Acetic acid couldn't be decomposed by injecting ozone and oxygen bubbles.
- Decomposition rate became high when increasing the discharge current.
- Energy efficiency of decomposition became high with increasing the gas flow rate.
- Energy efficiency in the case of the hole diameter of 300 μm was lower than that in case of 200 μm. The most important parameter was the gas flow velocity, and not the gas flow rate.

Pulsed Corona Discharge in Supercritical Carbon Dioxide

E.H. Lock[1], A.V. Saveliev[1], L.A. Kennedy[1]

[1]*Department of Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, USA*

Abstract
The initiation of a pulsed corona discharge in supercritical CO_2 is studied experimentally. The corona discharge was successfully generated using wire-to-cylinder and point-to-plane configurations. In the wire-to-cylinder configuration plasma was produced in the vicinity of the critical point. In the point-to-plane geometry plasma was observed in a wide range of temperatures and pressures. Possible applications of plasmas generated in supercritical CO_2 are discussed.
Keywords: pulsed corona, supercritical fluid, breakdown

1. Introduction

Although the ability of the supercritical fluids (SCFs) to dissolve non-volatile solids has been well known for more than a century, interest in their commercial applications has risen dramatically in the past twenty years. Supercritical fluid extraction for the decaffeination of coffee with supercritical CO_2 and the ROSE process for separating the components of heavy fraction of petroleum using supercritical pentane are well established large scale applications. Recent developments in supercritical CO_2 research include several different areas such as polymerization and polymer processing, cleaning and degreasing of parts in microelectronics, metal and low-k film deposition, organic and inorganic chemistry, fine particles formation, bacteria inactivation and drug delivery. Such intensive research is driven by the unique physical and chemical properties of supercritical fluids, which are in an intermediate between the gas and liquid states.

In SCFs, the large effective mass transfer is realized by their low viscosity and high diffusivity while the high heat transfer is achieved by large thermal conductivity. The solvent properties of the SCF can be tuned by simply varying their pressure and temperature. SCFs are often referred to as "cluster fluids" [1], which means that regions of strong density inhomogeneities are observed. This provides a unique chemical reaction medium. Molecular association via intermolecular interactions or the formation of solvation structure of solute molecules is local and short-lived, and does not inhibit the transport of the reactants and products as in the case of liquid phase. Concurrently, the molecular clusters formed in SCF are responsible for reaction mechanisms typical for liquids. In these conditions reactants are usually surrounded by a number of supercritical molecules, which accelerates the reaction rates relative to the gas phase.

In this study we chose supercritical CO_2 as a medium for plasma generation because it is nontoxic, not corrosive, inflammable and not explosive. Its critical temperature of 304 K is close to the ambient temperature. Supercritical CO_2 solvent properties such as diffusivity, viscosity, and thermal conductivity can be tuned by simply varying the pressure and temperature. The solvation power of the SC CO_2 is directly proportional to its density [2]. Another important property of SC CO_2 is its zero surface tension, which allows the carbon dioxide to penetrate into small cracks, cavities, and cell walls. This is very important for medical waste treatment and for microelectronic industry, where size reduction of chips and other components is a critical issue. Furthermore, supercritical CO_2 is characterized by solvent-free reactions, which means that by simply reducing the pressure gaseous carbon dioxide leaves the system due to phase transformation.

Supercritical plasma is a new emerging area in plasma research. In 2002, Terashima and co-workers demonstrated the generation of plasma in 1 and 2 μm gaps between planar electrodes [3]. The further efforts of several research groups were directed toward pulsed discharges with large interelectrode distances. Non-thermal pulsed corona discharge under supercritical fluid conditions was generated in two discharge configurations: wire-to-cylinder and point-to-plane [4-6]. In the present work we studied development of corona discharges in a wide range of supercritical pressures and temperatures. The basic feature of non-thermal plasma technologies involves the generation of plasma where the majority of the electrical energy goes into the production of energetic electrons. These energetic electrons produce excited species (free radicals and ions), which under supercritical fluid conditions are expected to increase the rate of cluster formation while supercritical fluid will provide a chemical environment for their effective chemical

utilization. The unique combination of gas phase discharge and heterogeneous chemistry defines several potential applications of supercritical plasmas. This includes material synthesis and processing, plasma chemical reactions and pollution control. Several developed applications of supercritical fluids include extraction and removal of toxic components, e.g. in medical and pharmaceutical fields and in chip manufacturing. The application of SCF discharge plasmas is an innovative approach to the development of pollution control technologies.

2. Experimental Setup

The experimental setup is presented in Fig. 1. Liquid carbon dioxide is compressed to the desired pressure by high-pressure pump (Thar Technology, P-50) and supplied in the supercritical fluid cell, which is 10 ml cylindrical stainless steel optical chamber. The high-pressure windows (Pressure Products, Co.) are made from quartz. A thyratron-based variable-voltage, variable-frequency power source is used for plasma generation. The delivered power can be varied from 0.2 to 12 W by controlling the high voltage pulse amplitude and the pulse repetition rate. Pulses of about 100 ns duration and 10 ns rise time are transmitted to the corona electrode inside the supercritical cell by means of the electrical high-pressure high voltage feedthrough (Conax, Inc.). The thickness of the used wire was 80 μm. Additional breakdown experiments were conducted using point-to-plane geometry. The radius of the curvature at the top of the needle electrode was 90 μm and the interelectrode distance 84 μm.

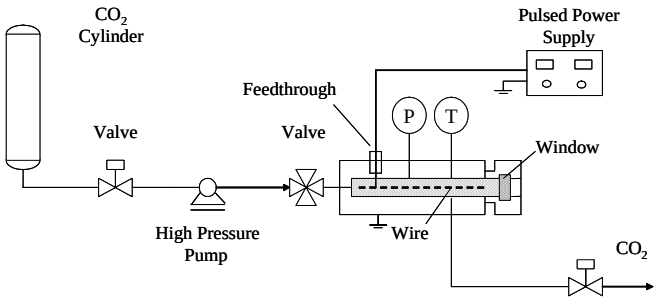

Fig. 1. Experimental setup for generation of pulsed corona discharge in supercritical CO_2.

3. Results and Discussion

The experiments on plasma generation in supercritical fluids were first performed using the wire-to-cylinder configuration. Picture of the resulted discharge is shown in Fig. 2. The experimental conditions were close to the critical point with temperature of 310 K and pressure of 80 bar and the required voltage was only 6 kV. This voltage was much lower than the one predicted by the Paschen's law [4]. The generation of non-thermal plasma at elevated pressures usually requires high voltages or small interelectrode distances. In gases, the Paschen's law is usually applied to estimate breakdown voltage required to initiate discharge between coplanar electrodes. This law states that the breakdown is a function of the product Pd, where P is the pressure and d is the interelectrode distance. This defines the breakdown region with the boundary usually referred to as a Paschen curve. The region of high pressure corresponds to the linear right-hand branch of the Paschen curve where the breakdown voltage increases linearly with Pd. This suggests that extremely high voltage will be required for breakdown of supercritical CO_2 at pressures approximately 74 times higher than atmospheric. Even more challenging will be a plasma generation in supercritical water due to the much higher critical point temperature and pressure equal to 647 K and 221 bar, respectively.

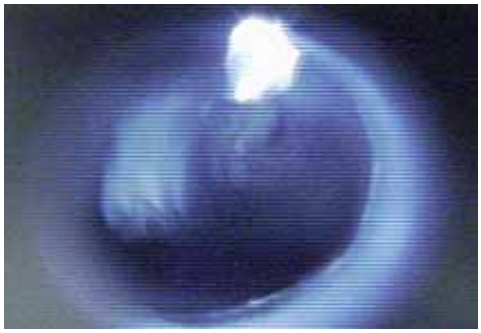

Fig. 2. Pulsed corona discharge in supercritical CO_2, wire-in-cylinder configuration.

Due to the extensive cluster formation in supercritical fluids, the breakdown mechanism significantly differs from the known mechanisms for gas and liquid phase. The clusters affect all elementary processes involving electrons. These include ionization, collisional energy losses, and loss of electrons via recombination and attachment. The clusters in supercritical fluids typically have low ionization potentials, which, in turn, reduce required breakdown voltages. Concurrently, the losses due to recombination and attachment can be increased by the cluster presence. Additionally, a high heat capacity of the fluid near the critical point affects development of the streamer channels and slows the development of thermal instabilities.

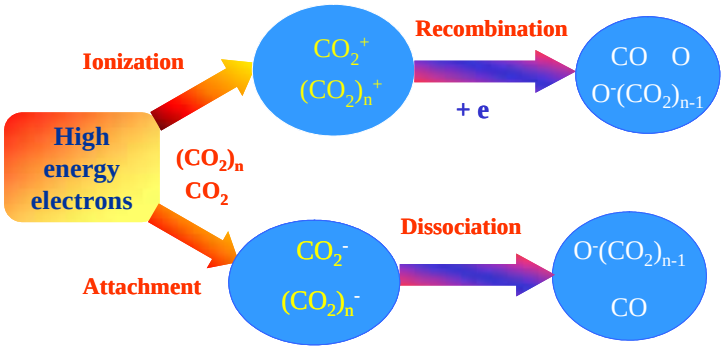

Fig. 3. Electron kinetics in supercritical CO_2.

Possible explanation of the electrical discharge initiation in supercritical CO_2 with sufficiently low voltage involves the presence of clusters and density inhomogeneities. The energetic electrons are formed in the regions of supercritical fluid, where the density is low. These electrons ionize clusters in the high density regions additionally forming ion and radical clusters. The important aspect of supercritical plasma studies is to understand the effect of the neutral SCF clusters and plasma-generated radicals and ions on discharge characteristics. As shown in Fig. 3, the high energy electrons ionize the CO_2 molecules and clusters to produce CO_2^+. The electron losses occur via recombination (charge neutralization) and electron attachment. The electron attachment reactions are important for the electrical breakdown and can occur either dissociative via the reactions

$$e + (CO_2)_n \rightarrow O^-(CO_2)_{n-1} + CO \quad (1)$$

$$O^-(CO_2)_{n-1} \rightarrow CO_3^-(CO_2)_{n-2}^* \quad (2)$$

or nondissociative depending on the electron energy [7]. Other important reactions that need to be considered involve electron transfer between the clusters. As some studies suggest this process could be caused either by their reorganization or by core switching [8]. Further research is needed for development of electron kinetic mechanisms governing the breakdown in supercritical fluids.

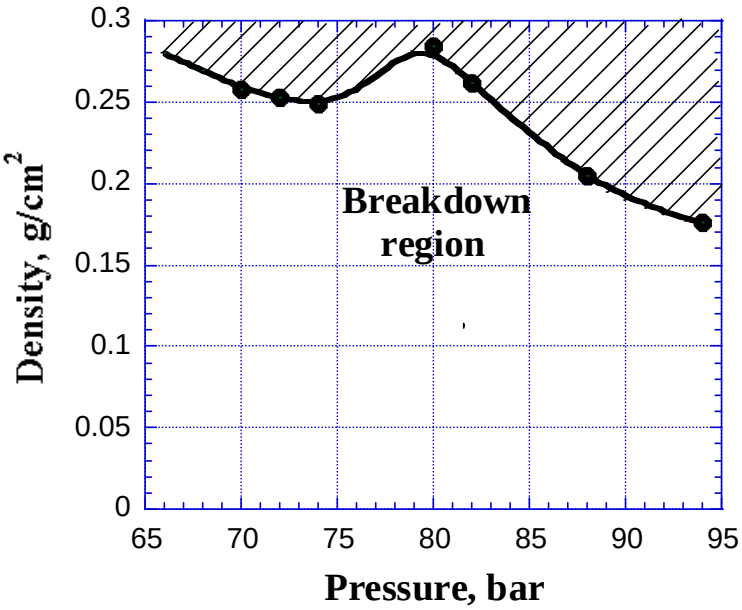

Fig. 4. Pressure-density diagram depicting the breakdown region in supercritical CO_2: point-to-plane configuration, breakdown voltage 10 kV.

The results for point-to plane-configuration (Fig. 4) suggest that another critical parameter affecting the electrical breakdown is the density of the supercritical CO_2. The breakdown was initiated using peak pulse voltage of 10 kV. Electrical breakdown was observed even at pressures as high as 100 bar and temperature as high as 373 K due to the relatively low density. However, in the vicinity of the critical point plasma was not produced due to the high critical density of the SC CO_2. The Pashen's law would represent constant density line in Fig. 4. In the supercritical state, the non-linear dependence of breakdown voltage from the density is observed with pronounced maximum effect in the region close to the critical point. Further research is needed for complete understanding of the breakdown in supercritical conditions.

As mentioned in the introduction, supercritical plasmas offer a novel approach for effective cleaning and waste treatment technologies. This original method also provides opportunity for material synthesis and surface modification. Supercritical plasma can be used as a unique process combining the advantages of supercritical fluids such as penetration in small cracks, liquid free processing, and low operational cost with the advantages of plasma treatment. Supercritical plasma cleaning will be compatible with most metals, ceramics and plastics, because supercritical CO_2 does not corrode their surfaces. The pressures and temperatures sufficient for effective processing are easily attainable with the modern pressure pumps. By-product vapors will not require scrubbing and can be vented into the atmosphere. Application of supercritical CO_2 plasma will be beneficial when there is a need for CO_2 cleaning so that the solvent can be reused. If in some applications chlorofluorocarbons still have to be employed, and the supercritical plasma offers a solution for cleaning the residues of these processes.

Non-thermal supercritical fluid plasma will allow environmentally friendly synthesis of novel materials eliminating the problem of recycling and reuse of residue solvents. Plasma polymerization under supercritical conditions may not result in a crosslinked polymer, which is typically produced by plasma. This would extend the variety of polymers that can be produced by plasma treatment. Plasma produced thin film are extensively used in chip manufacturing industry. Chemical fluid deposition (CFD) as alternative to chemical vapor deposition (CVD) was recently implemented in thin film production. Including plasma in the CFD process may increase its efficiency in analogy with the well-known plasma enhanced chemical vapor deposition (PECVD).

5. Conclusions

In this paper generation and possible applications of supercritical CO_2 plasma are discussed. The initiation of pulsed corona discharge is studied using wire-to-plane and point-to-plane configurations. It is found that a relatively large area exists where plasma generation is possible with relatively low breakdown voltages.

Pressure, temperature, and density in the SCF region are the important parameters controlling abnormal behavior of breakdown voltages in this region. From practical point of view supercritical plasma offers interesting potential applications that include waste treatment, polymer synthesis, and surface processing.

Comparison of the Efficiency of Nanosecond Gas Discharge and Laser Flash-Photolysis in Initiation of Combustion

I.N. Kosarev[1] , E.N. Kukaev[1] , S.M. Starikovskaia[1] , A.Yu. Starikovskii[1]

[1] *Physics of Nonequilibrium Systems Laboratory, Moscow Institute of Physics and Technology, Institutskii lane,9, Dolgoprudny 141700 Russia*

Abstract

Measurements of ignition delay time for combustible gas mixtures with N_2O as an oxidant in a case of autoignition, ignition by high-voltage nanosecond gas discharge and ignition by excimer laser flash-photolysis have been performed. Experimental data for temperature range 1100-1700 K and pressure range 0.3–0.9 atm are represented and analyzed.

1 Introduction

The problem of the uniform fast ignition of combustible mixtures is of great importance. The question of the efficiency of using nonequilibrium plasmas for initiation of combustion still remains open. In a case when high-voltage nanosecond discharge us used for artificial initiation of ignition, it is possible to excite gas mixture homogeneously in a large volume and to produce ionized, dissociated and excited species practically instantly in comparison with typical time of ignition. The relative role of different species in initiation of combustion is under discussion now. To check the role of excited and dissociated species we organized special set of experiments with excitation by laser flash-photolysis with dissociation of molecules of the mixture at wavelength of 193 nm.

2 Experiment

The diagnostic system used for ignition by the discharge, described in details elsewhere ([1], [2]) was modified to control ignition by laser flash-photolysis. A scheme of experimental setup is represented in Fig. 1. gas mixture was heated by the shock wave. A flash of UV-radiation of ArF excimer laser ("Center of Physical Devices" production, Troitsk, $\lambda = 193$ nm) was organized behind the reflected shock wave. The laser radiation was supplied to the dielectric section of the shock tube through the MgF_2 optical window perpendicularly to the shock tube axis in the same cross-section were we performed measurements in a case of the ignition by nanosecond discharge. Laser spot had approximately rectangular shape with 5×21 mm dimensions and was controlled by special sensible paper. The synchropulse to trigger the laser was produced at the instant the reflected shock wave arrived at measurement cross-section. The time delay between the synchropulse and laser flash was a few μs. The schlieren system consisted of three He-Ne lasers mounted at different points along the shock tube and three photodiodes (PD). The gas density (ρ_5), pressure (P_5), and temperature (T_5) behind the reflected shock wave were determined from the known initial gas mixture composition, the initial pressure, and the velocity of the incident shock wave, using conservation laws and assuming that relaxation was complete and chemical reactions frozen. Thermodynamic data were taken from [3].

A piroelectric detector (PEM21) with 21 mm diameter of receiving site was used to determine energy input from laser radiation into the gas. Signal from PEM21 was controlled every time before the experiment, when the system was pumped up to 10^{-2} Torr and then during the experiment. Knowing spectral transmission of MgF_2 windows in this spectral range (were controlled by Varian Cary50 Spectrophotometer) we calculated energy input into a gas. We organized experiment so, that energy input in the discharge and energy input from a laser were within one order of magnitude. We controlled initial

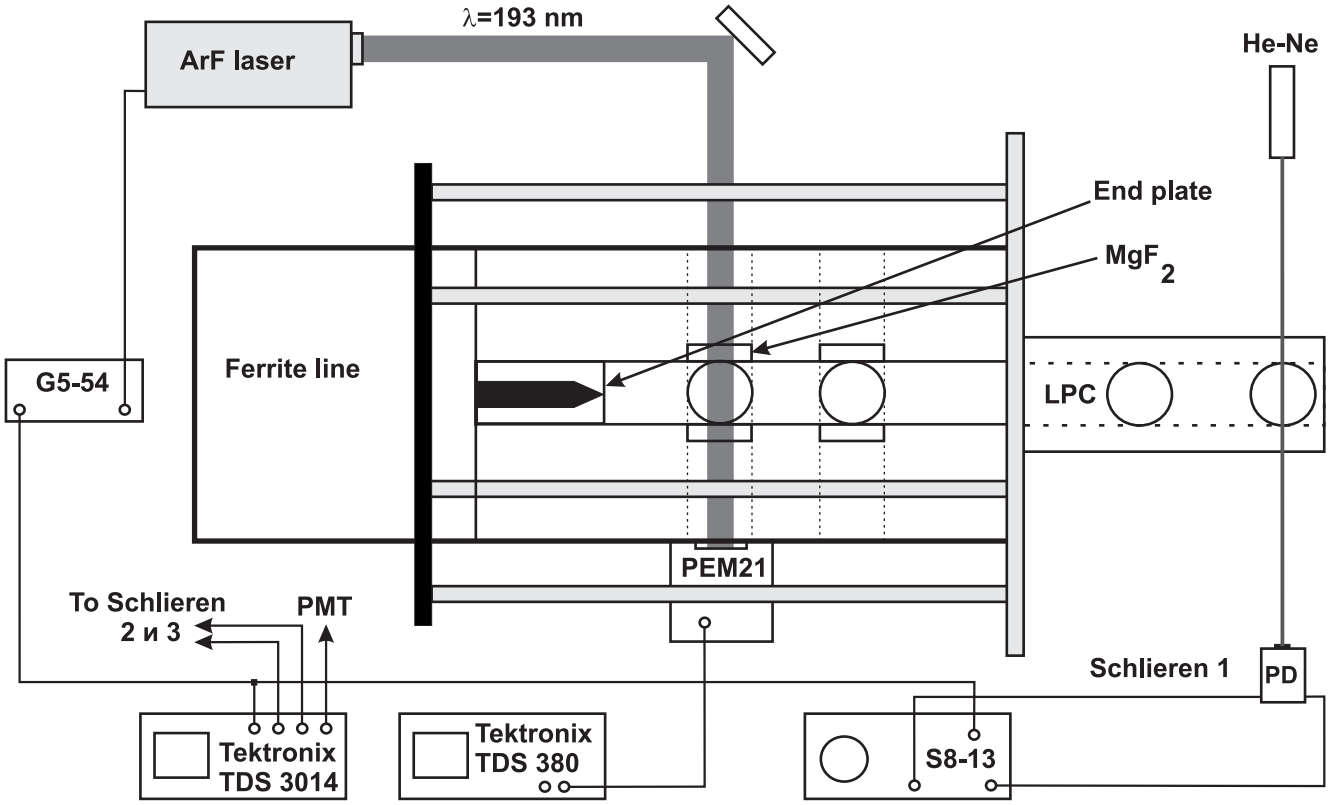

Figure 1: Scheme of the experimental setup: LPC - low pressure cell of a shock tube; PM - photomultiplier; PEM21 - energy meter; G5-54 - pulse generator.

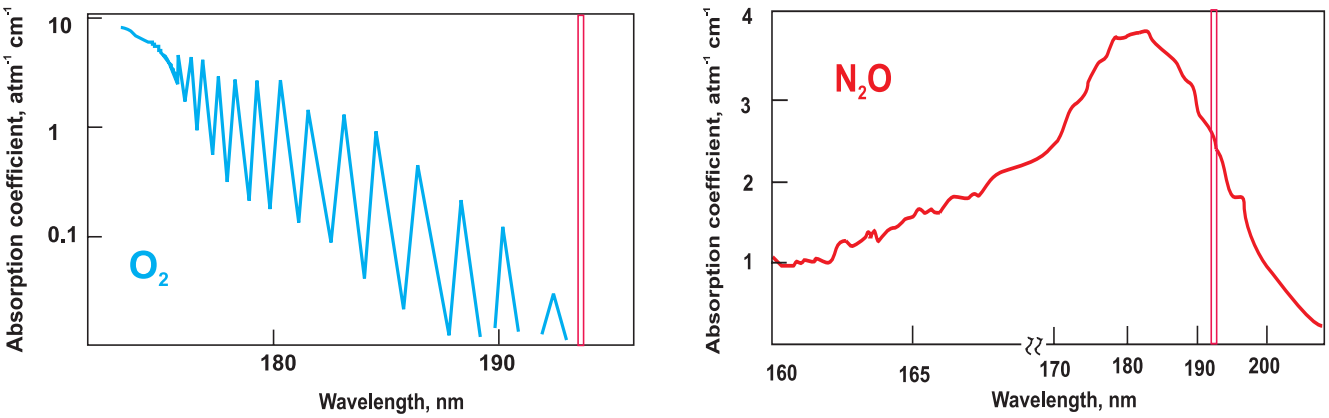

Figure 2: Cross-sections of absorption for oxygen and N_2O in UV-range of spectrum [4].

gas pressure and shock wave velocity, and parameters behind the reflected shock wave were calculated as in the previous case. Ignition delay time was calculated from the OH emission at 306 nm.

The combustion process was investigated using emission spectroscopy. Emission generated in the course of combustion was monitored in the direction perpendicular to the shock tube's axis at a distance of 55 mm from the end plate with the help of an MDR-23 monochromator (1.2 nm/mm, 1.2-m focal length, 1200 groove/mm, manufactured by LOMO), an FEU-100 photomultiplier (PMT) manufactured by MELZ, and a Tektronix TDS 3014 oscilloscope. Ignition time delay was determined from OH emission at 306.4 nm.

To compare action of the discharge and of flash-photolysis, we have repeated discharge experiments for investigated mixture. Simultaneously with OH emission in nanosecond time scale, we controlled nanosecond discharge parameters. The system for monitoring the electric parameters of the nanosecond discharge included a magnetic current gauge measuring the discharge current and capacitance gauges, located at two different points along the discharge section, and measuring the shape and amplitude of

the high-voltage pulse. The gauges were calibrated with a high-voltage signal of known amplitude and duration. The power deposited in the discharge was determined from the simultaneous measurements of the discharge current and voltage.

The experiments were repeated with the same mixture for autoignition, nanosecond discharge initiation of ignition and ArF flash-photolysis. Ignition delay times were compared for all cases. To make these experiments, we chosen N_2O as a main absorbing component. Really, N_2O is known to be very efficient as an oxidant. On the other hand, it absorbs radiation at 193 nm better than molecular oxygen. To demonstrate this, cross-sections of molecular oxygen and N_2O molecule at gas temperature 300 K are represented in the Fig. 2. With temperature increase, cross-section of molecular oxygen increases significantly, while cross-section of N_2O remains practically constant [5]. Nevertheless, at 1300 K cross-section of N_2O (approximately $3 \cdot 10^{-19}$ cm^2) is still by an order of magnitude higher than cross-section of O_2. So, the experiments were performed in gas mixtures N_2O:H_2:Ar = 1:1:8 and N_2O:H_2:Ar = 1:4:5. In part of our experiments 1% of CO_2 was added to a gas mixture for control of a gas temperature using emission in IR range of spectrum.

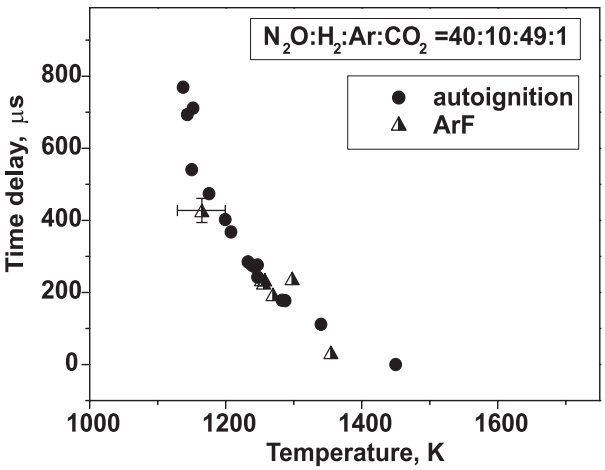

Figure 6: Ignition time delay dependence upon gas temperature for gas mixture with additive of carbon dioxide. 40% N_2O in the mixture; gas pressure is 0.7-0.9 atm

3 Results and Discussion

Typical energy input in a gas in experiments with flash-photolysis is demonstrated by Fig. 3. To obtain energy input per cubic centimeter, the energy value obtained by piroelectric gauge was divided by volume 5x20x25 mm^3, where 25 mm is a transverse size of a shock tube channel.

It is known that N_2O photolysis takes place via the reactions:

$$N_2O + h\nu = N_2 + O(^1D), \tag{1}$$

$$N_2O + h\nu = N_2 + O(^4S), \tag{2}$$

at the weight of reaction (1) is 99%. $O(^1D)$ is a metastable atom, its life time is 150 s, and usually it loses excitation in collisions with other species. It may destruct N_2O via the reactions

$$N_2O + O(^1D) = N_2 + O_2, \tag{3}$$

$$N_2O + O(^1D) = NO + NO. \tag{4}$$

On the other hand, $O(^1D)$ has to be active in chain initiation:

$$H_2 + O(^1D) = OH + H. \tag{5}$$

Reaction rates for reactions (3) and (4) are $4.9 \cdot 10^{-11}$ cm^{-3} and $6.7 \cdot 10^{-11}$ cm^{-3}, respectively [3]. Reaction rate for process (5) is $1.1 \cdot 10^{-10}$ cm^{-3}, that is for gas mixture were N_2O:H_2= 1:4, $O(^1D)$ losses due to reactions with N_2O may be significant. In gas mixture N_2O:H_2:Ar = 1:1:8 without CO_2 additives we were able to obtain a few distinct points, which is represented in the Fig. 4. Unfortunately, we were not able to reproduce these points systematically. The nanosecond discharge shifts the threshold by hundreds of K, which is typical for this discharge in different gas mixtures. Behavior of mixture with 1% CO_2 additive is illustrated by Fig. 5. Energy input into a gas under the action of nanosecond gas discharge in these experiments was within a range of $(3-5) \cdot 10^{-3}$ J/cm^3, which is in a good correlation with energy input in experiments with laser flash-photolysis. We performed experiments with gas mixture N_2O:H_2:Ar = 1:4:5 (also with 1% CO_2) to enhance N_2O fraction (Fig. 6) and focused laser radiation, but we obtained zero shift in the ignition delay under the action of flash-photolysis.

Preliminary calculations made by N.A.Popov [7] demonstrate that autoignition correlates quite well with our experimental data, while significant shift of ignition delay time can be reached only when $O(^1D)$ exceeds 10^{15} cm^{-3}. Estimations of possible density of $O(^1D)$ atoms based on energy input (Fig.3) give values in a range $(1-3) \cdot 10^{15}$ cm^{-3}, that exceeds a little bit the boundary of possible effect. We believe that it is possible to obtain delay time shift by ArF flash-photolysis analyzing gas mixture composition and relative role of reactions (3) and (4), which are responsible for $O(^1D)$ quenching.

4 Conclusion

So, autoignition, ignition by nanosecond discharge and ignition by laser flash-photolysis were investigated for N_2O-containing mixture. Shift of the ignition by nanosecond discharge has been obtained. Absence of shift for a case of laser flash-photolysis can be explained by reactions of excited atomic oxygen with N_2O molecule.

VUV Wavelength-Dependent Surface Modification of Polyolefins

F. Truica-Marasescu, M. R. Wertheimer

Groupe de Couches Minces (GCM), Department of Engineering Physics,
Ecole Polytechnique, Montreal, QC, H3C 3A7, Canada

Abstract

We report λ-dependent VUV photolysis of polyolefins under high vacuum and in a low-pressure ammonia gas. LDPE and BOPP samples have been exposed to the radiation generated by four different VUV sources. We use in-situ quartz crystal microbalance (QCM) measurements to monitor material ablation, while the near-surface chemical composition and the formation of unsaturation during photolysis is characterized by attenuated total reflectance infrared spectroscopy (ATR-FTIR) and X-ray photoelectron spectroscopy (XPS).

1. Introduction

The surface treatment of organic polymers for adhesion enhancement, for example, is now routinely performed with the help of electrical discharges [1]. Plasmas comprise a wide variety of different components like energetic particles, both charged (electrons, ions) and neutral (excited molecules, radicals, metastables), which react with a polymer in the outermost molecular layers, and photons that can penetrate much deeper into the material. Due to its complex nature, an understanding of interactions between the plasma and the surface can only be achieved by appropriately separating the contributions of each component type to the overall observed modification. Since the pioneering work of Hudis [2], it is known that vacuum ultraviolet (VUV) photons can give rise to an important photochemical contribution during plasma treatments of polymers. Hydrocarbon polymers display a very strong absorption band below 160 nm that originates from electronic excitation of carbon-carbon and carbon-hydrogen σ bonds [3]. The absorption of radiation with $\lambda < 200$ nm leads to homolytic scission of C-C, and C-H bonds, followed by the formation of radicals [4] on the polymer surface that can evidently undergo further reactions. In the outermost surface region (a few nm) these can react with other free radicals, including ones in the neighbouring gas phase, thereby incorporating new functional groups which are chemically bonded to the polymer. In the region where gas molecules have little or no access, for example in the "subsurface" (typically a few tens of nm), radicals can recombine among one another to form a linkage, or a radical can split a hydrogen atom from a neighbouring carbon atom to form a double bond (C=C) [4]. The present work is intended to investigate the interaction mechanisms of VUV radiation with polymer surfaces. For this purpose, samples of low-density polyethylene, LDPE and biaxially oriented polypropylene, BOPP have been exposed to the radiation generated by four different VUV sources, and the wavelength-dependent effects of the VUV radiation on their physico-chemical properties have been investigated under two different circumstances: (i) for the case of exposure in vacuum, and (ii) when specimens were irradiated in a reactive low-pressure ammonia atmosphere.

2. Experimental Methodology

The experimental set-up used for the VUV treatments is presented in detail elsewhere [5]. Briefly, it consists of a stainless steel "cross" chamber evacuated to a base pressure of about 5×10^{-6} torr ($\sim 7 \times 10^{-4}$ Pa), and then filled (when necessary) with pure ammonia, NH_3 at low pressure (p = 300 mtorr, or 40 Pa). The VUV sources used for this study are commercial resonant or excimer lamps with MgF_2 windows (cut-off wavelength, $\lambda_c = 112$ nm, all from Resonance Ltd., Barrie ON, Canada), based on radiofrequency (r.f.) discharges in noble gases. Their main characteristics are shown in Figure 1.

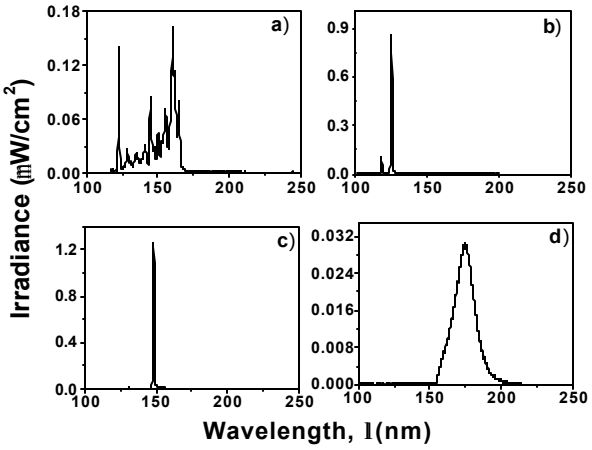

Figure 1 Intensities, I and spectral distributions of the VUV radiation emitted by the a) D_2Ar (I_{tot} = 1.8 mW/cm^2); b) resonant Kr, KrL (I_{tot} = 1.2 mW/cm^2) ; c) resonant Xe, XeL (I_{tot} = 1.8 mW/cm^2) ; and d) Xe excimer, XeE (I_{tot} = 0.6 mW/cm^2) lamps, measured at d = 4.0 cm.

For the case of treatment (i), in-situ mass change measurements during irradiations were carried out using a QCM (Phelps Electronics Inc.) placed perpendicularly to the impinging photon flux, at a frontal distance of d = 4.0 cm. Real mass changes result in frequency shifts which are recorded using a Philips PM 6669 universal frequency counter connected to a personal computer through a GPIB interface. Thin polymer films were prepared on quartz crystals (Xinix, 5 MHz, with gold electrodes from Phelps Electronics Inc.) by dip coating using solutions of LDPE (Chevron Phillips Company, 2% w/w in xylene, 80°C), and BOPP (3M Company, 2% w/w in xylene, 100°C). The irradiation dose, D, has been calculated using the following formula:

$$D = \Phi \times t \qquad (ph/cm^2) \qquad (1)$$

where Φ is the photon flux impinging on the polymer surface (ph/cm^2/s), and t is the treatment duration (up to 4200 seconds).

For the case of treatment (ii), the polymer samples (4x4 cm squares of commercial films) were mounted on a stainless steel sample holder, which can move axially within the treatment chamber, over a maximal distance of 10 cm. This allowed us to vary the sample distance, d, with respect to the lamp window, and thereby also the VUV power density arriving at the polymer surface, according to the Beer-Lambert law:

$$I_s = \int_{\lambda} \frac{I_0(\lambda)}{d^2} \exp\left(-\alpha(\lambda) \cdot p \cdot d\right) d\lambda \qquad (W/cm^2) \qquad (2)$$

where I_0 and I_s are the intensities at the MgF_2 window and at the polymer surface, respectively; α is the absorption coefficient of ammonia (NH_3) [6] (in cm^{-1}atm^{-1}); p (atm) is the NH_3 pressure, and d (cm) is the distance between sample and the MgF_2 window.

Following the same protocol presented in ref. 5 and 6, we investigated the physico-chemical effects produced by the treatments using a combination of surface analytical techniques. These methods included X-ray Photoelectron Spectroscopy (XPS), and Fourier Transform Infrared Spectroscopy in the Attenuated Total Reflectance configuration (ATR-FTIR), using a germanium prism.

3. Results and Discussion

3.1 VUV Irradiation in Vacuum

The mass variations, Δm for LDPE and BOPP during irradiation in vacuum with all four VUV sources are presented in Fig. 2, as a function of irradiation dose, D.

Values of the etch rate, R_0 (ng/photon), defined as the initial slope of the Δm versus D curve, are summarized in Table 1.

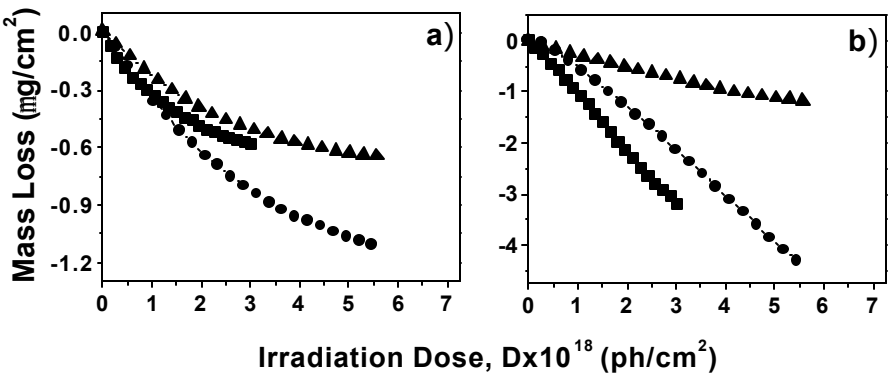

Figure 2 Mass losses for a) LDPE; and b) BOPP during irradiation with the KrL ( ), XeL ( ), and D_2Ar ( ) VUV sources as a function of the irradiation dose, D.

Table 1: Initial etch rate, R_0 for the investigated polymers.

Polymer	Lamp	R_0 x 10^{-15} (ng/ph)
LDPE	KrL	0.42±0.02
	XeL	0.34±0.02
	D_2 Ar	0.24±0.01
	XeE	Very small
BOPP	KrL	0.98±0.03
	XeL	0.50±0.07
	D_2 Ar	0.29±0.04
	XeE	Very small

Since the absorption coefficient, α of both polyolefins increases with decreasing λ, α (KrL) > α (XeL) > α (D_2Ar) > α (XeE) [3], it is not surprising to observe the same trend for R_0 values: R_0 (KrL) > R_0 (XeL) > R_0 (D_2Ar) (see Table 1). Note that R_0 was immeasurably small under irradiation with the XeE lamp, most probably due to the fact that very little VUV radiation with λ > 160 nm is absorbed by both LDPE and BOPP samples [3, 6]. However, we observed that the etch rates, R(D), continuously decreased with increasing D values (see Fig. 2). The explanation resides in structural changes (formation of double bonds and crosslinking) within the polymer near-surface layer [2, 4, 7]. Since C=C bonds absorb at λ = 180-190 nm [4], a region where our VUV sources emit very little, the formation of unsaturation tends to lower α, and hence also the value of R(D). We investigated this hypothesis by means of ATR-FTIR. Figures 3 a) and b) show the difference spectra of LDPE and BOPP, respectively, following 60 min of KrL irradiation. Regardless of λ of the source, VUV irradiation of LDPE gives rise to three new absorption bands at 965, 909, and 888 cm^{-1}, which can be assigned to *trans* vinylene -CH=CH-, vinyl -CH=CH_2, and vinylidene >C=CH_2 groups, respectively, and to a shoulder at 3050 cm^{-1} assigned to =CH_x (x = 1,2) stretch vibrations in unsaturated hydrocarbons (see Figure 3 a). VUV irradiation of BOPP with the KrL, XeL and D_2Ar lamps produces only chain-end double bonds, as proven by the two new IR bands at 909 and 888 cm^{-1}, and the shoulder near 3000 cm^{-1}. Although the type of alkene groups seems to be a function only of the nature of the polymer, their concentrations was found to depend strongly on λ used for irradiation [5]. In agreement with the previously presented QCM results, irradiation with XeE lamp produced no measurable structural changes at the surface of both polyolefins.

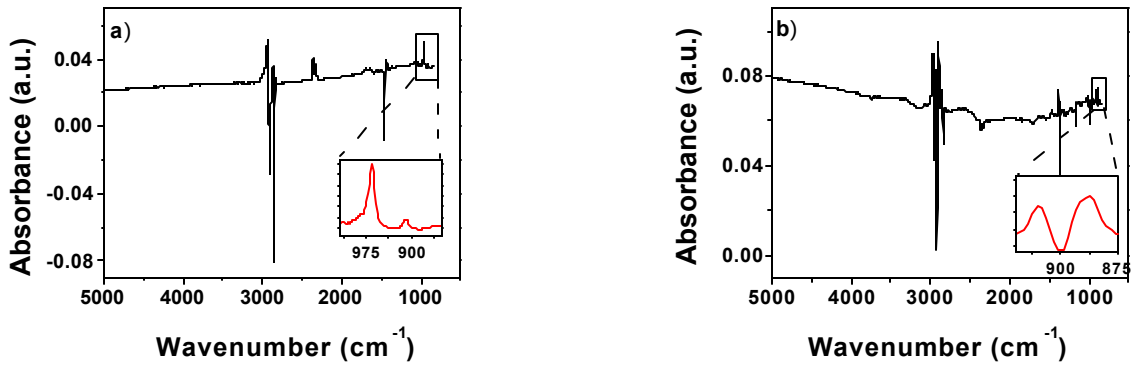

Figure 3 FTIR-ATR difference spectra between irradiated and pristine a) LDPE and b) BOPP; irradiated samples were treated for 60 min with a) KrL (D = 2.88 x10^{18} ph/cm^2). The inserts show the newly- formed bands; in all cases 200 spectra were accumulated, resolution 4 cm^{-1}.

3.2 VUV Irradiation in Low Pressure Ammonia

The results presented in section 3.1 suggest that KrL and D_2Ar lamps efficiently activated the polyolefins' surfaces, while the XeE lamp was found to produce no measurable effect. Gaseous ammonia absorbs in the 112-220 nm spectral range; since its bond energy is approximately D_0 (H-NH_2) = 4.4 eV, the absorption of energetic VUV photons ($h\nu$ > 6.2 eV) will lead to photo-dissociation of the NH_3 molecule, to produce amino ($NH_2^{\bullet}$) and imino ($NH^{\bullet}$) radicals in various excited states [6]. Using emissions from the three above-mentioned sources for polymer irradiation in low-pressure NH_3 gas, three types of irradiation experiments have been carried out:
(1) Kr (resonant), radiation which efficiently activates both ammonia molecules and the polymer surface, (2) D_2Ar, radiation which efficiently activates the polymer surface, but not the gas phase; and finally(3) Xe (excimer), radiation which is absorbed only by NH_3 molecules, producing NH and NH_2 radicals that may possibly react with the unactivated polymer surface.
Therefore, it is possible to investigate the relative importance of surface and/or gas phase activation to the overall reaction using this set of experiments. In Figures 4 a) and b) the evolutions of nitrogen, [N], and oxygen, [O], surface concentrations (determined by XPS) are plotted versus I_s for VUV treated LDPE using the Kr and the D_2Ar lamps, respectively, both for total durations of 60 min. Using the KrL lamp (Fig. 4 a) we can obtain high [N] values (up to 25%), roughly proportional to I_s, until saturation is reached near 3 mW/cm^2. The presence of some oxygen ([O] ≤ 5%) can be attributed to reactions between long-lived radicals or unstable functional groups created during the VUV irradiation with molecular oxygen or water vapor when the samples are subsequently exposed to ambient atmosphere [5, 7]. Regarding Fig. 4 b, corresponding to D_2Ar irradiation, the situation is seen to be very different: while only 1.5 % [N] is incorporated into the LDPE surface, [O] is seen to rise to nearly 8%. This can be attributed to the relatively high degree of surface activation of the polymer, accompanied by inefficient photo-dissociation of NH_3 in the gas phase [6]. Finally, regarding treatment (3), XeE radiation, no measurable nitrogen incorporation was detected by XPS on LDPE. Based on these results, we believe that although simultaneous activation of gas and solid phase might not always be necessary, it can greatly enhance the degree of surface modification for engineering the physico-chemical properties of polymers.

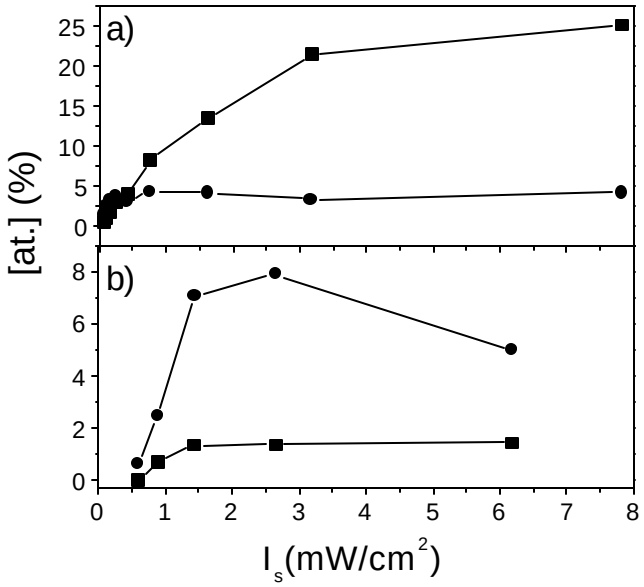

Figure 4 Surface concentrations (in at. %) of nitrogen, [N] ( ), and oxygen, [O] ( ), incorporated during irradiation of LDPE for 60 min in flowing NH_3 (p = 300 mtorr) with the Kr lamp a), and the D2Ar lamp b), as a function of I_s.

4. Conclusions

We show that during the initial stages of photolysis in vacuum, the etch rate, R (in ng/ph), of the investigated polyolefins rises with decreasing λ, which correlates very well with their λ-dependence of VUV absorption coefficients, α. However, with increasing irradiation dose, D, R tends to gradually decrease, due to near-surface structural changes, namely the creation of C=C bonds and crosslinks. For irradiation in low-pressure NH_3 gas, XPS measurements of nitrogen up-take at the surface have proven that the mechanism involves simultaneous, synergetic activation (formation of free radicals) of both the solid and gas phases, followed by heterogeneous reaction of these chemically activated species.
The data presented here, based on complementary experimental techniques, provide a coherent, self-consistent picture of the VUV photolysis of polyolefins both in vacuum and in a reactive gas, along with valuable new information about the mechanisms in the photochemical/plasma surface modification of polymers.

Microstructural investigation of YSZ thermal barrier coatings fabricated by hybrid plasma spraying

J.Q. Li, H. Huang, M. Kambara, K. Eguchi, T. Yoshida

Department of Materials Engineering, The University of Tokyo, Tokyo, Japan

Abstract

Zirconia-yttria thermal barrier coatings fabricated by hybrid plasma spraying have fine and sophisticated microstructure. For a comprehensive analysis on the microstructure over the whole coatings, chemical etching method using HF acid was attempted. After being etched, the splat structure and columnar grains within splats were observed clearly in thermal plasma sprayed coatings. The etching procedure further revealed a nano-sized structure of twin variant of t' phase in the spraying PVD coatings. These results clearly show an effectiveness of this technique for an investigation of the microstructures of both the sprayed and PVD coatings.

Keywords: TBCs, Microstructure, Etching, Plasma spraying

Introduction

Yttria-stabilized Zirconia (YSZ) is the top candidate material for thermal barrier coating due to its high melting temperature, low thermal conductivity, relative high thermal expansion coefficient matching with that of metallic substrates and other superior physical properties. Plasma spraying (PS) and Electron beam-physical vapor deposition (EB-PVD) are well-developed techniques to fabricate YSZ coatings with characteristic structures [1]. In plasma spraying, molten droplets of a desired materials impact on substrate and undergo rapid spreading and solidification. The solidified droplets called splats, are the basic building units of PS coatings. Splats are usually composed of columnar grains with the width often less than 100 nanometers due to high cooling rate [2]. EB-PVD coating, on the other hand, is characterized by its structure in which feather-like columns with diameter at a micron scale, intercolumnar pores, subcolumns, and nanopores were present [3,4]. In contrast, Hybrid Plasma Spraying (HYPS) is a novel and promising technique which enables deposition of the coatings with plasma powder sprayed and/or spraying PVD columnar structures [5,6]. Such HYPS coatings exhibit in general more sophisticated microstructure compared to that produced by PS and EB-PVD.

Structural knowledge such as grain size, growth direction on YSZ coatings is obtained by TEM and SEM. Such structural information is important to understand the coating formation and the resultant high temperature performance. However, it is practically difficult to evaluate the variations of the microstructure over a wide area of the coating [7]. Chemical etching may be the one of the effective techniques to facilitate this.

Only a few papers were reported on the chemical etching of YSZ coatings [8]. This is probably because zirconia is chemically inert against most of the corrosive chemicals. In the present paper, therefore, the etching with HF acid at ambient condition was attempted to show the characteristic structures of the HYPS processed YSZ coatings.

Experimental

The YSZ coatings were deposited by a novel Twin Hybrid Plasma Spraying System, which is equipped

with two hybrid plasma torches and is capable of the combination of plasma PVD, CVD and/or spraying techniques. The splat, columnar, and their composite structures have been achieved through precise control of powder size, powder feeding rate, RF input power, etc. The detail of processing conditions can be found elsewhere [5,6].

Table 1 The processing conditions of HYPS

Parameters	**Powder spraying**	**Spraying PVD**
Powder size	63-88μm	5-15μm
Substrate holder	Rotated	Stationary, water cooled
DC/RF power	8/100 KW	8/70 KW
Plasma gas (slm)	DC: 10Ar RF: 170Ar, 30H_2	DC: 10Ar RF: 85Ar, 15H_2
Powder carrier gas	4 slm, Ar	4 slm, Ar
Feeding rate	15 g/min	2 g/min
Deposition time	7min	3.5min
Coating thickness	870μm	550μm

In the present study, two typical specimens were prepared. One is plasma sprayed coating and the other is spraying PVD coating. The general processing conditions are listed in Table 1. The coatings were deposited on the graphite block so that only the top coat was removed easily from the substrate for observation. The removed coating segments were embedded in resin, sliced and polished up to 0.1μm in surface roughness. The whole specimens were dipped into HF acid (mass 50%) for various durations, and rinsed in water with supersonic facility and dried afterwards.

The microstructure of the coatings was analyzed using a laser microscope (KEYENCE, VK-8510) and a field-emission scanning electron microscope (FE-SEM, JEOL, JSM-6340F). The phase was identified by X-ray diffraction (XRD, MAC Science Co. Ltd., MXP18XHF).

Results and Discussion

I. Microstructure of plasma sprayed coating

Figure. 1 shows the optical micrographs of the cross-section of the plasma sprayed coating which was etched in HF acid for different soaking durations. From the un-etched sample (Fig. 1a), we can not observe clear boundaries between splats except some macro cracks and pores. In contrast, after being etched for 5min (Fig. 1b), splat form appeared clearly and exhibited well-flattened, wavy structure with a thickness of about 2-3 μm. It also indicates that the splat boundary was etched more easily than the splat body due to its higher reaction rate with HF acid. Figure 1 (d) shows the morphology of the specimen etched for 15min. The splats boundary was etched heavily and exhibited the huge gaps between the splats with a width up to 1μm. Some big holes were also observed within the splat body, indicating the over-etching by HF acid. As a result, 5-10 min etching are found to be an appropriate condition for etching the plasma powder sprayed coatings.

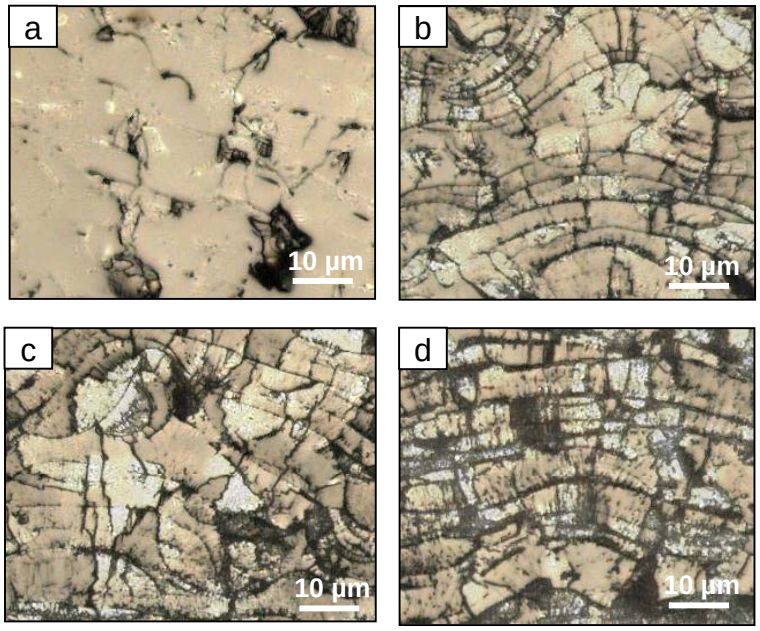

Fig.1 Optical micrographs of a sprayed coating etched for (a) 0min (b) 5min (c) 10min (d) 15min.

Figure 2 is a magnified SEM micrograph of the etched section. Not only splat boundaries (arrow A) but also columnar grain boundaries (arrow B) within the splats were observed clearly. The columns in a single

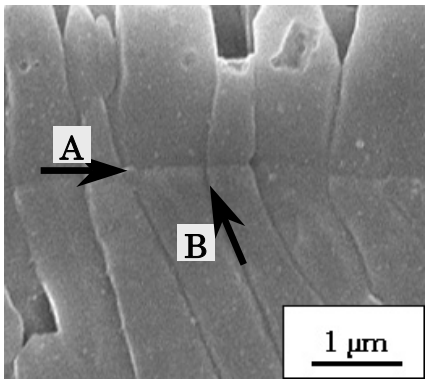

Fig. 2 SEM micrograph of cross-section of plasma sprayed coating after etching for 10min

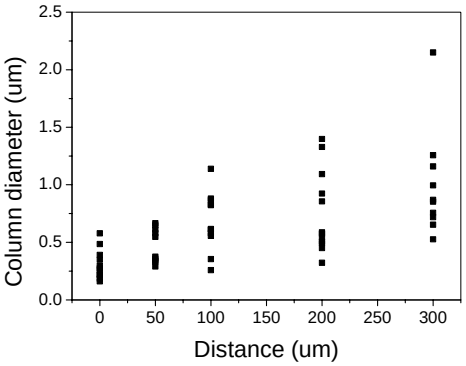

Fig. 3 Average column diameters of splats with different distances from the bottom of the coating

splat are approximately parallel each other. Grain size has a large distribution within a splat from 100 nm to 1μm. Furthermore, the width of each column is not uniform from its bottom to top. The columnar crystals above and below the splat boundary contact well and have the approximately same diameter and grain shape. It is similar to the columnar grains grown continuously within two splats reported by others [9].

The above results show that the nano structures appeared by an etching with HF acid. As a result, the structural information over the whole coating, such as the flattening degree of molten droplet, columnar grain size, can be evaluated. The variation of average column diameter of splats through the coating thickness is analyzed in Fig. 3, as a function of distance from the bottom of the coating. The distance ranges from 0 to 300 μm. Although the rather scatters, at least the average column diameters increase with the distance. This tendency is an indication that the grains growth rate reduced during deposition as a result of thermal insulting effect of the underlying grains.

II. Microstructure of plasma spraying PVD coating

PVD coatings normally have finer structure than plasma powder sprayed coatings. No structural information was obtained from the un-etched cross-section of the spraying PVD coating, as shown in Fig. 4a. However, after etched for 3min, fine cross-bracing columnar grains became visible and showed wider column width compared to that of the columns in EB-PVD coating, as observed in Fig. 4b. The width of the cross-bracing structure is less than 1.5 μm on average. Figure 4c demonstrates the morphology of the coating cross-section etched for 10min. In this case, finer cross-bracing grains were destroyed by HF acid. In PVD case, therefore, an appropriate etching time was considered to be 3 min.

Figure 5a shows the TEM morphology of the same specimen shown in Fig. 4. Large PVD grains were observed clearly and cross-bracing structure was also found inside the grains. In comparison Fig. 5a with SEM image shown in Fig. 5b, it was found that both TEM and SEM images showed the nearly identical microstructure. That is, the size and shape of the fine cross-bracing grains were preserved after the etching. This result, therefore, confirms that the etching is a powerful technique to observe the fine and complicated structure of YSZ coatings produced by HYPS.

Only the *t'* phase was identified in the sprayed PVD coating by X-ray diffraction. In addition, the TEM diffraction pattern (shown in the inset of Fig. 5a) confirmed that no *m*- and *c*- phases in the coating. Also, the TEM structural analysis revealed that the twin variant in *t'* phase grain and antiphase domain boundaries were present in the variant. Therefore, it is possible that such complicated microstructure was formed through the *c*-*t'* phase transformation during rapid cooling after deposition [10]. It is notified that there is no report on the finding of such a cross-bracing structure in PVD YSZ coating. Therefore, more detailed analysis is

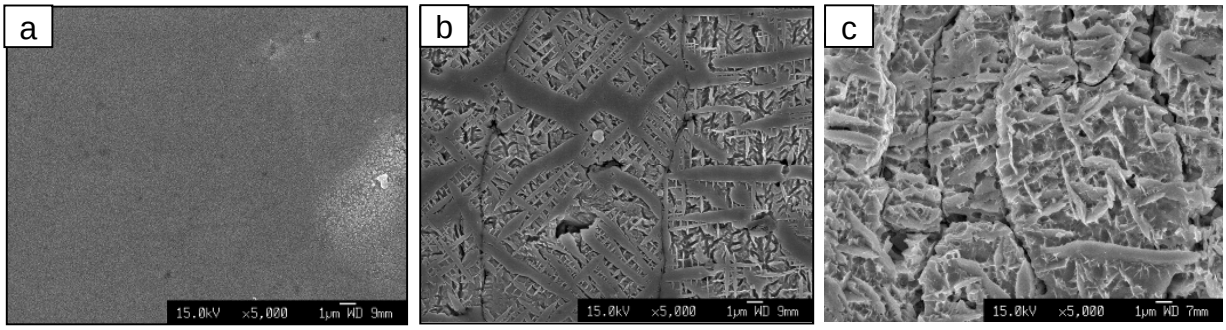

Fig. 4 SEM micrographs of plasma PVD coating etched for (a) 0min (b) 3min (c) 10min.

required to identify the formation of such a structure. Nevertheless, this structure has shown an enhanced reflectance for light in the infrared wavelength [11]. A real novel coating as TBC is expected to control this *t'* phase formation.

Conclusion

The chemical etching by HF acid was found effective to investigate the microstructure of YSZ thermal barrier coatings. After etching, the structural characteristics of plasma sprayed coating were observed at micron and nanometer scales by optical microscopy and SEM. A novel twin variant structure of *t'* phase was demonstrated in spraying PVD coating by HF etching, which was confirmed by TEM characterization.

Abstract

In previous modeling studies for non-equilibrium thermal plasmas, different forms of energy conservation equations for electrons and heavy particles were employed by different authors. In this paper, the energy equations for electron and heavy-particle subsystems, which can be used for the modeling of kinetic and/or chemical non-equilibrium plasma systems, are derived in detail. For the LTE case, the energy conservation equations presented here can be reduced to the form being extensively employed for LTE plasma modeling.

Keywords Thermal plasmas, Non-equilibrium, Energy conservation equation, Theoretical derivation

1. Introduction

Non-Equilibrium phenomena often exist in thermal plasma systems, such as in the plasma regions near the arc electrodes, near a cold wall, near the outer edge of a plasma jet, etc. (e.g., [1, 2]). Since the electron mass is much less than the heavy-particle (atom or ion) mass, the energy coupling between electrons and heavy particles is rather weak, and thus at lower electron number densities, electrons might not transfer promptly their excess energy gained from an external electric field to heavy particles. The electron temperature may thus be different appreciably from the heavy-particle temperature and the plasma deviates from local thermodynamic equilibrium (LTE) state for many cases. Two-temperature (2-T), local chemical equilibrium (LCE) or non-LCE models are often employed to study the non-equilibrium plasma characteristics [3-20]. Numerous 2-T modeling results have been reported in past decades, such as those for arc plasmas [3-7, 10-13, 16-19], for plasma jets [8, 9, 15, 20], for radio-frequency (RF) and microwave (MW) plasmas, etc. However, so far there still exists some confusion in the available 2-T plasma modeling approaches, mainly in the formulations of the energy equations for the electron subsystem and for the heavy-particle subsystem. In the papers previously published [3-20], different forms of the energy conservation equations for electrons and heavy-particles were employed by different authors. And most of the employed equations even cannot be reduced to that for the LTE model if the plasma is assumed to be in the LTE state. Hence, it is worthy to re-examine the formulation of the energy equations suitable for the 2-T plasma modeling. In this paper, a theoretical derivation on the energy conservation equations of electrons and heavy particles used for modeling of kinetic and/or chemical non-equilibrium plasmas is presented with 2-T argon plasma as an example. The forms of the derived energy conservation equations are also examined for the limiting case of LTE plasmas.

2. Theoretical derivations

2.1. Assumptions

For simplicity, an argon plasma is considered in this study for deriving the energy conservation equations of electrons and heavy-particles with the following assumptions:

(1) The argon plasma system consists of four species, i.e., electrons *e*, atoms *Ar*, singly-ionized ions Ar^{+}, and doubly-ionized ions Ar^{++}.
(2) The argon plasma system is divided into two subsystems, i.e., electron subsystem, including free electrons and electrons in the excited energy levels of atoms and ions, and heavy-particle subsystem, including all of the translational degrees of freedom of atoms and ions. The electron and heavy-particle subsystems are characterized by electron temperature T_e and heavy-particle temperature T_h, respectively, and separate Maxwellian distributions of electrons and heavy particles are satisfied, respectively, with T_e and T_h as the characteristic temperatures.
(3) The species number densities have been calculated. For the 2-T LCE case, the four particle number densities can be calculated from the state equation, the quasi-neutrality condition and two 2-T Saha equations [21], respectively, for single and double ionizations. For the 2-T non-LCE case, two species conservation equations (e.g., for atoms and for doubly-ionized ions) are used to replace the two 2-T Saha equations, but for this case the related kinetic constants must be known.
(4) The forms of the continuity equation, mass-averaged momentum equation and electromagnetic field equations are the same as those used for LTE plasmas.
(5) The plasma flow is quasi-steady and in laminar regime.
(6) The thermodynamic and transport properties of argon plasmas are functions of the species number densities (n_j) and the temperatures (T_e and T_h).

2.2. Theoretical derivations

Based on the foregoing assumptions, the energy conservation equations for electron subsystem and for heavy-particle subsystem can be derived in a finite control volume by using energy balance, i.e., under steady state, the energy leaving the control volume should be balanced by the energy entering the control volume and the energy produced inside the control volume for each of the subsystems. Due to the paper space limit, only the final forms of the energy equations are presented in this paper as follows.

Electron energy conservation equation:

$$\nabla\cdot\left(\frac{5}{2}n_e k_B T_e \vec{v}\right)=\nabla\cdot\left(k_e\nabla T_e\right)-\nabla\cdot\left(\frac{5}{2}k_B T_e\vec{\psi}_e\right)+\vec{j}\cdot\vec{E}+\vec{v}\cdot\left(\nabla p_e\right)-U_{r,e}+\frac{5}{2}\frac{k_B}{e}\left(\vec{j}\cdot\nabla T_e\right)-\dot{E}_{el}-\dot{E}_{ex}-\dot{E}_{ion\text{-}rec} \tag{1}$$

Heavy-particle energy conservation equation:

$$\begin{aligned}\nabla\cdot\left\{\left[\frac{5}{2}\left(n_a+n_i+n_d\right)k_B T_h+\left(n_i E_{i,i}+n_d E_{i,d}\right)\right]\vec{v}\right\}=&\nabla\cdot\left[\left(k_a+k_i+k_d\right)\nabla T_h\right]-\nabla\cdot\left[\frac{5}{2}k_B T_h\left(\vec{\psi}_a+\vec{\psi}_i+\vec{\psi}_d\right)\right]-\nabla\cdot\left(\vec{\psi}_a E_{ex,a}\right)\\&-\nabla\cdot\left[\vec{\psi}_i\left(E_{ex,i}+E_{i,i}\right)\right]-\nabla\cdot\left[\vec{\psi}_d\left(E_{ex,d}+E_{i,d}\right)\right]+\vec{v}\cdot\nabla p_h+\vec{\tau}:\nabla\vec{v}-U_{r,h}+\dot{E}_{el}+\dot{E}_{ex}+\dot{E}_{ion\text{-}rec}\end{aligned} \tag{2}$$

In Equations (1) and (2), the subscripts *h*, *e*, *a*, *i* and *d* express heavy-particle, electron, atom, singly-ionized ion and doubly-ionized ion, respectively. *p*, *n* and *T* are pressure, particle number density and temperature; $\vec{\tau}$ viscous stress tensor; *e* and k_B elementary charge and Boltzmann's constant; *k* and U_r thermal conductivity and radiation power per unit volume; E_{ex} and E_i internal excitation energy and ionization energy; and $\vec{v}$, $\vec{\psi}$, $\vec{j}$

and $\vec{E}$ are velocity, particle diffusion flux, electric current density and electric-field intensity vectors, respectively.

The terms on the left-hand side of Equations (1) and (2) represent the convective energy transfer, while the first terms on the right-hand side of these two equations express the conductive heat transfer. $\dot{E}_{el}$ is the energy transferred in elastic collisions between electrons and heavy particles. $\dot{E}_{ex}$ is the energy loss (or gain, if negative) of the electron subsystem in excitation collisions between electrons and heavy-particles, whereas $\dot{E}_{ion-rec}$ is the energy loss (or gain, if negative) of the electron subsystem in ionization-recombination collisions between electrons and heavy-particles. The radiation energy loss for electrons and atoms can be calculated from experimental data or using a three-level collision-radiation model [22].

The terms related with diffusion flux of species *j* (*j*=*a*, *i*, *d* and *e*) on the right-hand side of Equations (1) and (2) represent the energy transfer due to diffusion process in the argon plasma system. Here there are two points should be emphasized for the calculation of the diffusion flux of species *j*: (i) The number flux of species *j* can be calculated by using Equation (19) in Ref. [23] without including the term related with externally applied electric field. The influence of the external electric filed on the energy transfer due to diffusion process is represented by the electron enthalpy transport term appearing on the right-hand side of Equation (1). (ii) In Equations (1) and (2), only two particle diffusion fluxes have to be calculated from pertinent concentration and temperature gradients, since the other two diffusion fluxes can be obtained using the relations $\vec{\psi}_e = \vec{\psi}_i + 2\vec{\psi}_d$ and $\vec{\psi}_a = -(\vec{\psi}_i + \vec{\psi}_d)$ [24].

2.3. Simplification of the energy conservation equations

In many previous studies (e.g., [5-7, 17-19]), the following additional assumptions were used:

(1) Double ionization can be neglected (i.e., argon plasma temperatures are lower).
(2) There is no change in excitation energy of atoms or ions.
(3) Only electron impact ionization and three-body collision recombination with electron as the third body are treated as the ionization-recombination mechanism.
(4) Pertinent Mach number is small so that the pressure work and viscous dissipation in the energy equations can be ignored.

Based on those additional assumptions, Equations (1) and (2) reduce to the following forms:

$$\nabla\cdot\left(\frac{5}{2}n_e k_B T_e \vec{v}\right) = \nabla\cdot\left(k_e \nabla T_e\right) - \nabla\cdot\left(\frac{5}{2}k_B T_e \vec{\psi}_e\right) + \vec{j}\cdot\vec{E} + \frac{5}{2}\frac{k_B}{e}\left(\vec{j}\cdot\nabla T_e\right) - U_{r,e} - \dot{E}_{el} - \dot{E}_{ion-rec} \tag{3}$$

$$\nabla\cdot\left\{\left[\frac{5}{2}\left(n_a + n_i\right)k_B T_h + n_i E_{i,i}\right]\vec{v}\right\} = \nabla\cdot\left[\left(k_a + k_i\right)\nabla T_h\right] - \nabla\cdot\left[\frac{5}{2}k_B T_h\left(\vec{\psi}_a + \vec{\psi}_i\right)\right] - \nabla\cdot\left(\vec{\psi}_i E_{i,i}\right) - U_{r,h} + \dot{E}_{el} + \dot{E}_{ion-rec} \tag{4}$$

In Equations (3) and (4), the energy loss related with ionization-recombination process can be expressed as

$$\dot{E}_{ion-rec} = k_{ion} n_e n_a E_{i,i} - \alpha k_{rec}\, n_e^2 n_i E_{i,i} \tag{5}$$

in which α is a factor introduced to account for such a fact that a part of the atoms formed in the recombination processes are initially in their excited state (*p*-level instead of *s*-level), and thus, the energy carried away by the third body (electron) will be less than $E_{i,i}$. The energy released in the transition from the excited level (*p*-level) to the ground level (*s*-level) has been included in the radiation power loss $U_{r,h}$. The energy exchange between electrons and heavy particles due to elastic collisions can be expressed as

$$\dot{E}_{el} = (2m_e / m_h)(\bar{\nu}_{ea} + \bar{\nu}_{ei}) n_e [(3/2) k_B (T_e - T_h)] \tag{6}$$

where $\bar{\nu}_{ei}$ and $\bar{\nu}_{ea}$ are the average collision frequency between electrons and ions [25], and between electrons and atoms [26], respectively.

Equations (3) and (4) can be used for non-equilibrium modeling of DC arc plasmas in subsonic, laminar regime. It can be seen that Equations (3) and (4) are somewhat different from their counterparts used in previous modeling studies for non-LCE case (e.g., [3, 7-11, 15, 17-20]), and even for the LCE case with $k_{ion} n_e n_a = k_{rec}\, n_e^2 n_i$ (e.g., [4-6, 16]) if α is not equal to 1.

In addition, for the case of RF and MW thermal plasmas, the term $(5/2)(k_B / e)(\vec{j} \cdot \nabla T)$ in Equations (1) and (3) will disappear since the electric current is alternative. For the plasma jets, all the terms containing the current density $\vec{j}$ will disappear.

2.4. Energy conservation equation for LTE plasmas

Although different forms of energy conservation equations of electrons and heavy particles for non-equilibrium modeling of thermal plasmas have been employed in previous references, not all of these energy equations can be reduced to the commonly used form of the energy equation for the limiting case of LTE plasmas. In our opinion, as one of the necessary conditions, the correct, self-consistent energy conservation equations of electrons and heavy particles, after combined, should be reduced to the energy equation extensively used for modeling of LTE plasmas if the plasma system is in kinetic and chemical equilibrium state.

For the limiting case of LTE plasmas, the electron temperature is equal to heavy particle temperature, and no net production of electrons occurs, i.e., $T_e = T_h = T$ and $k_{ion} n_e n_a = k_{rec}\, n_e^2 n_i$. By combining Equations (1) and (2) together, one can obtain

$$\begin{aligned} \nabla \cdot \left\{ \left[\frac{5}{2} (n_e + n_a + n_i + n_d) k_B T + (n_i E_{i,i} + n_d E_{i,d}) \right] \vec{v} \right\} &= \nabla \cdot [(k_e + k_a + k_i + k_d) \nabla T] + \vec{v} \cdot \nabla (p_e + p_h) + \vec{\tau} : \nabla \vec{v} - (U_{r,e} + U_{r,h}) \\ &- \nabla \cdot \left[\frac{5}{2} k_B T (\bar{\psi}_e + \bar{\psi}_a + \bar{\psi}_i + \bar{\psi}_d) + \bar{\psi}_a E_{ex,a} + \bar{\psi}_i (E_{ex,i} + E_{i,i}) + \bar{\psi}_d (E_{ex,d} + E_{i,d}) \right] + \vec{j} \cdot \vec{E} + \frac{5}{2} \frac{k_B}{e} (\vec{j} \cdot \nabla T) \end{aligned} \tag{7}$$

The total specific enthalpy of argon plasmas (h) is defined as

$$\rho h \approx \frac{5}{2}\left(n_e + n_a + n_i + n_d\right)k_B T + \left(n_i E_{i,i} + n_d E_{i,d}\right) \tag{8}$$

in which ρ is the mass density of argon plasmas.

According to the definition of reactive thermal conductivity for reacting gas mixtures in chemical equilibrium [24, 27], the term containing diffusion flux of species j (j = e, a, i, d) on the right-hand side of Equation (7) can be expressed as

$$-\nabla\cdot\left[\frac{5}{2}k_B T\left(\vec{\psi}_e + \vec{\psi}_a + \vec{\psi}_i + \vec{\psi}_d\right) + \vec{\psi}_a E_{ex,a} + \vec{\psi}_i\left(E_{ex,i} + E_{i,i}\right) + \vec{\psi}_d\left(E_{ex,d} + E_{i,d}\right)\right] = \nabla\cdot\left(k_r \nabla T\right) \tag{9}$$

where k_r is the so-called reactive thermal conductivity of argon plasmas [27].

In addition, the total pressure and radiation loss per unit volume of plasmas can be expressed as

$$p = p_e + p_h;\ \ U_r = U_{r,e} + U_{r,h} \tag{10}$$

Thus, the final form of Equation (7) can be written as

$$\nabla\cdot\left(\rho\vec{v}h\right) = \nabla\cdot\left(k\nabla T\right) + \vec{v}\cdot\nabla p + \vec{\tau}:\nabla\vec{v} - U_r + \vec{j}\cdot\vec{E} + \frac{5}{2}\frac{k_B}{e}\left(\vec{j}\cdot\nabla T\right) \tag{11}$$

where $k = k_e + k_a + k_i + k_d + k_r$ is the total thermal conductivity of argon plasmas. Equation (11) is the energy equation used extensively for the modeling studies of LTE plasmas. Particularly for the subsonic flow simulations, the pressure work and viscous dissipation in the energy equation can be ignored, i.e.,

$$\nabla\cdot\left(\rho\vec{v}h\right) = \nabla\cdot\left(k\nabla T\right) + \vec{j}\cdot\vec{E} + \frac{5}{2}\frac{k_B}{e}\left(\vec{j}\cdot\nabla T\right) - U_r \tag{12}$$

3. Conclusions

In this paper, the energy conservation equations for electron subsystem and heavy-particle subsystem used for non-equilibrium (including kinetic and/or chemical non-equilibrium) modeling of thermal plasmas are derived based on the energy balance in a finite control volume. The physical meanings of the terms appearing in the energy equations for electron subsystem and heavy-particle subsystem are discussed. The simplified form of the energy equation for the limiting case of LTE plasmas is consistent with that extensively employed in the literature. For investigating the characteristics of non-equilibrium plasmas, the following research work need to be conducted based on this primary study:

(1) The influences of the source terms related with elastic/inelastic collision processes and radiation processes on the non-equilibrium characteristics of plasmas should be clarified.

(2) The correct calculation of the thermodynamic and transport properties of non-equilibrium plasmas is one of the prerequisites for non-equilibrium modeling of thermal plasmas.

(3) The energy equations for electrons and heavy particles derived here can be extended for simulating the non-equilibrium characteristics of other gases, such as helium, nitrogen, oxygen, etc., with the similar derivation method. Perhaps, the source terms in the energy conservation equations need to be modified.

(4) For simulating the non-equilibrium plasma flow patterns in turbulent regime, the turbulent kinetic energy and its dissipation rate equations should be solved simultaneously with the continuity, momentum, energy and species conservation equations modified for the turbulent case.

Atmospheric-pressure SiO_2 deposition using remote plasma source of integrated microdischarges

O. Sakai and K. Tachibana

Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan

Abstract

A new plasma-enhanced chemical vapor deposition (PE-CVD) scheme working at the atmospheric pressure was presented with experimental and numerical results. Dielectric barrier microdischarges were integrated on one plane by low driving voltage (~ 2 kV) in N_2 and O_2 mixture with their hollow structures leading to activation of O_2. Created O and O_3 coalesced with N_2 flow including tetraethoxysilane and gave rise to precursors. Deposition rate of SiO_2 significantly depended on the laminar flow rate due to change of diffusion flux to a substrate.

1. Introduction

One of the conventional schemes of thin-film deposition of high-quality semiconductor and dielectric layers has been plasma-enhanced chemical vapor deposition (PE-CVD) under low pressure less than 1 kPa in a vacuum chamber [1]. If the working gas pressure is shifted up to the atmospheric pressure, vacuum equipment can be removed, which leads to simple and low-cost reactor system for semiconductor and flat-panel-display industry.

Several methods of non-thermal plasma production at atmospheric pressure have been proposed so far, such as plasma jets, microwave discharges, radiofrequency discharges, and dielectric barrier discharges (DBDs) [2]. If we aim at replacing low-pressure PE-CVD with atmospheric-pressure PE-CVD, a stable discharge which is uniform over large area (or at least a stable line discharge with one-dimensional uniformity) is required, hopefully using low-cost gases like N_2. However, almost every method contains some problems against this goal. Most of the problems are attributed to high pd condition, where p is the discharge gas pressure and d is the discharge gap. The plasma source we used here is integrated microdischarges to reduce the value of pd by decreasing d by one or two orders of magnitude and to realize a stable palsma source for N_2 and O_2 by low discharge voltage.

In terms of application of these schemes to PE-CVD, there have been several reports on thin-film deposition using atmospheric-pressure glow discharges (APGDs) so far [3-6], and such studies are now limited to phenomenological understanding of the gas phase at the atmospheric pressure. Sawada *et al.* [3] set substrates in an APGD of a parallel-plate DBD, and gas mixture of tetraethoxysilane (TEOS), O_2, and He was introduced into the discharge region to deposit SiO_2 films. That is, He plays a role of both reducing discharge voltage and sustaining discharge uniformity. Babayan *et al.* [4] and Nowling *et al.* [5] used APGD sources driven by radio-frequency power supply to deposit SiO_2 and silicon nitride films using TEOS and SiH_4. Their plasma source was remote type, but they also used He for plasma production at atmospheric pressure. Yuasa [6] utilized N_2 and O_2 gases without He, but the operation voltage for plasma production would be so high since their APGD was produced in a parallel-plate DBD.

Here we propose a new scheme for thin-film deposition at the atmospheric pressure using the integrated microdischarges [7] without He gas, which is widely used as an APGD working gas but is quite expensive. In our scheme, the microdischarges take place in small holes penetrating through two electrode platescovered with dielectric layers, and enable the gas flowing in the holes dissolve into reactive species. These reactive species coalesce N_2 including TEOS and produce precursors of deposition of SiO_2 films. These combined gas flow gets into deposition space which is separated from the plasma source. That is, the deposition process is affected by several key parameters in the gas phase. The goals of this study are realization of lower driving voltage for an atmospheric-pressure plasma source despite of no use of He, optimization of thickness and flow rate of the laminar flow in the deposition space, and understanding of the gas-phase reactions and the transports of reactive gases.

We show first the experimental setup in Section 2, and demonstrate the experimental results in both terms of

discharge properties and deposition film features in Section 3. In Section 4, the gas flow regime in the reactor is numerically analyzed and it is compared with the experimental results of deposition rate dependence on the gas flow rate. Finally we summarize this study in Section 5.

2. Experimental Setup

Integration of microdischarges for atmospheric-pressure plasma processes has realized a sheet-like plasma source with 50 mm diameter and perpendicular gas-flow structure [7]. A coaxial microhollow electrode structure was covered with dielectric layer, and the opening of the unit hole became 200 μm x 1700 μm. A dielectric barrier discharge generated in this small hole between the stacked electrodes, and such microdischarges were assembled on one plane. Inlet gases flew through the holes where discharges took place. The equivalent discharge path *d* between the two electrodes was several hundred μm in length, and relatively low discharge voltage is possible in such a low *pd* condition even at the atmospheric pressure.

Using this plasma source, we developed a remote-plasma-enhanced chemical vapor deposition reactor, shown in Fig. 1 (a). TEOS was vaporized at 170 ℃ in a liquid delivery system (PD-0-1, Japan Pionics), and its laminar flow carried by N_2 was combined with the gas flow dissociated by the plasma source. The predominant dissociation of TEOS is by electrons, O atoms, and O_3 molecules [1, 8]. The main deposition area, which was located under the combined gas flow with the thickness of 2 mm, was separated from the plasma source region. Gas flow rate was not so high (less than 10 litter per minutes (SLM)), leading to condition of the atmospheric pressure along all gas-flow paths including the plasma source region and the deposition area. In the cases of film deposition, the typical gas flowing through the microdischarges was O_2, and the gas of the laminar flow carrying TEOS was N_2. The applied voltage on the powered electrode was 2.1 kV_{0p} with 1-20 kHz bipolar square pulses, and discharge current was 2.2 A as a peak value. Used substrates for deposition rate estimation by thin-film step-height standard method (XP-2, Ambious Technology) were plates of Fe and Ni alloy, and Si wafers were used for film bonding analysis by Fourier transform infrared (FT-IR) spectroscopy (WINSPEC100, JEOL). The substrate temperature was set to be 150 ℃.

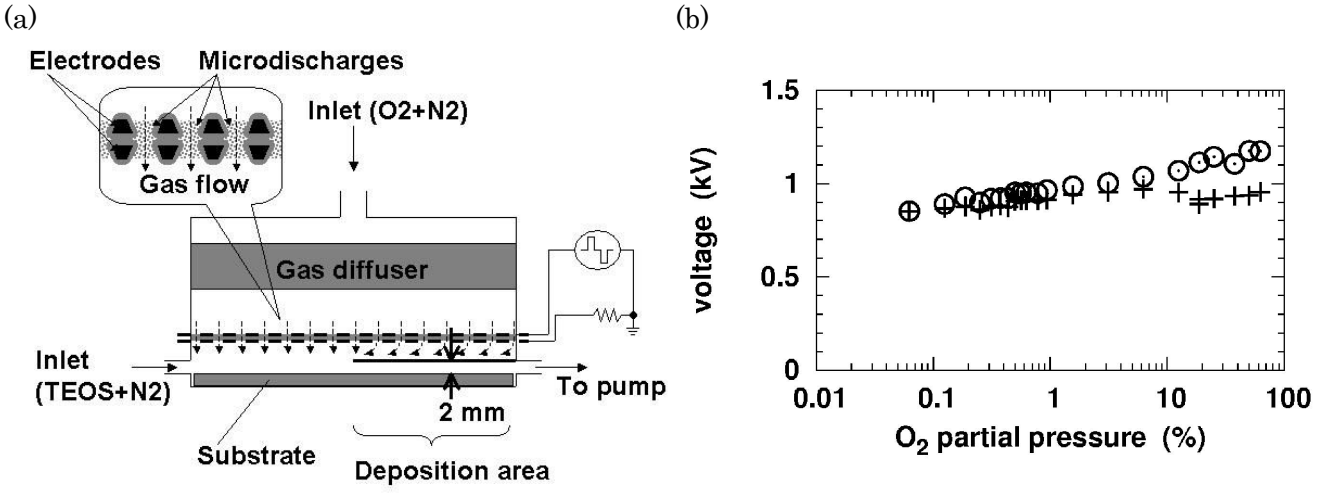

FIG. 1. (a) Schematic view of deposition reactor using remote plasma source of integrated microdischarges. (b) Firing voltage as a function of O_2 partial pressure in N_2 and O_2 mixture gas. Crosses and open circles indicate the partial ignition and the whole-area ignition voltages, respectively.

3. Experimental results

Mixture gas of N_2 and O_2 flew through the plasma source region, and homogeneous discharge emission was observed in the aperture of a square of 50 x 50 mm. Figure 1 (b) shows firing voltage as a function of O_2 partial pressure. Although the voltage increases up to 40 % as the O_2 partial pressure is raised, the discharge voltage is

quite low in comparison with that in usual dielectric barrier discharges [9].

In the measurement of the FT-IR spectroscopy, the deposited films showed the usual properties of SiO_2 films without C-H peaks. To characterize precursor's transport in the gas phase, the total gas flow rate was varied with the same fraction of N_2, O_2, and TEOS flow rates. Simultaneously, the frequency of the power supply was also changed linearly to the total flow rate, which means that power dissipation density in a unit mass flow is kept constant. The standard condition was as follows: the N_2 gas flow rate was 3.0 SLM with TEOS flow rate 0.25 g/min, and the O_2 gas flow rate was 3.6 SLM, and the power supply frequency was 14 kHz. Since the TEOS flow was by 2 orders lower than the N_2 and O_2 flows, the total flow rate of this standard condition was 6.6 SLM.

Figure 2 shows the film deposition rate as a function of the total flow rate. As the total gas flow rate was increased with the same partial flow rate of each gas, the deposition rate decreased significantly. Figure 2 also shows estimated gas residence time in the deposition area. The tendency is similar to the deposition rate, which indicates that diffusion of the precursors across the combined laminar flow is important for the deposition process. If we keep the similar residence time to that in a low pressure case, the gas flow rate should be raised in a high pressure case. However, diffusion flux toward the substrate, which decreases as the pressure increases due to reduction of diffusion coefficient, becomes smaller in comparison with convective flux in the laminar flow. One solution to overcome this discrepancy about the gas flow rate is to decrease thickness of the laminar flow, which enhances the diffusion flux by increasing gradient of precursor density near the substrate. In our experimental setup, the laminar flow thickness was 2 mm, which is by one order smaller than the electrode-to-substrate gap in a conventional parallel plate PE-CVD used in low pressure operation.The relation between the flow rate and the deposition rate in our experiment will be reexamined in Section 4 by fluid dynamics analysis.

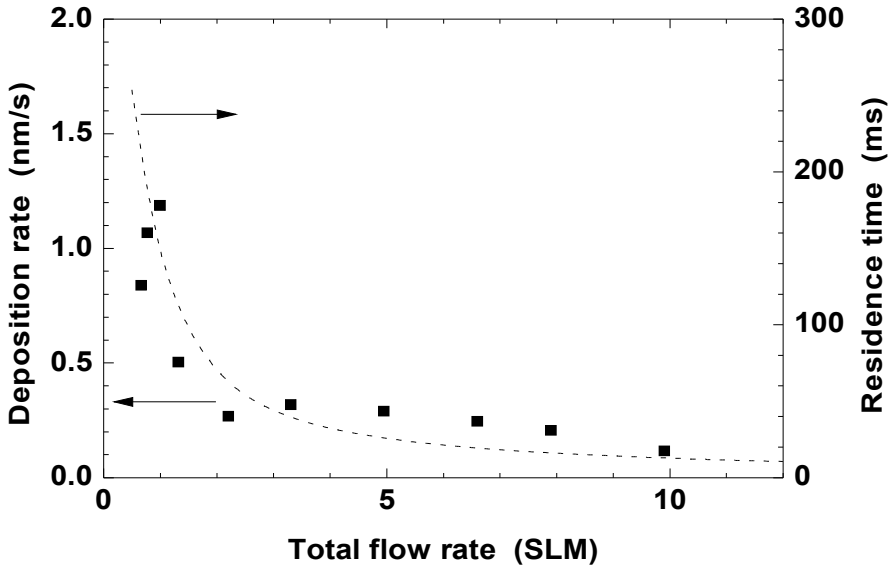

FIG. 2. Deposition rate (closed squares) as a function of total gas flow rate. The film thickness for the deposition rate estimation is measured 7 mm inside from the outlet point. The inset dashed line indicates estimated residence time of gases in the deposition area.

When the total gas flow rate was decreased down to 1 SLM, the deposition rate reached its maximum value. As the total flow rate was decreased further, the deposition rate became lower. This is due to the powder formation resulting from gas-phase polymerization of deposition precursors, since white particles were attached on the surface of the substrate after the deposition process in the case of the lowest total flow rate (0.66 SLM). In general, shorter residence time enhances both precursor diffusion flux to the substrate and particle growth in

the gas phase. If the collision rate is so high and the precursor particles encounter each other so frequently, they will get together before they arrive on the substrate surface and cannot contribute to form the film. The low substrate temperature (150 ℃) is another enhancement factor for powder growth. The other mechanism of enhancement of the powder formation will be mentioned in Section 4.

4. Discussion

Numerical analysis of gas flow distribution was performed by a solver for computational fluid dynamics (PHOENICS version 3.5.1, Concentration Heat & Momentum Limited) [10]. In brief, the general conservation equations of mass, momentum and energy are numerically solved using the finite volume method. It is capable of analyzing three dimensional gas flows, although we calculated two dimensional distribution in a cross section from the gas inlets to the outlet shown in Fig. 1 (a). Figure 3 displays the model configuration used for numerical analysis which will be compared to the experimental results. From the inlet on the left wall, N_2 gas at 170 ℃ flows into the analysis space, and O_2 at 27 ℃ flows down from the inlet on the upper wall. Rigorously, N_2 flux carries TEOS particles, and O_2 flux includes O and O_3 fractions, but they are simplified into pure N_2 and pure O_2 flows, respectively. They are combined in the left part in Fig. 3, which we can denote "mixing region" here, and the mixture flows through the deposition area under the insert plate and goes out from the outlet on the right wall. To distinguish a fraction of O_2 from N_2, each continuum equation is written as, using the total mass density as ρ and the average velocity as $\boldsymbol{u}$,

$$\frac{\partial (C_\alpha \rho)}{\partial t} + \nabla \cdot (C_\alpha \rho \boldsymbol{u}_\alpha - D_\alpha \rho \nabla C_\alpha) = 0, \qquad (1)$$

where C_α represents a fraction of α species in the mixture at each position, and $\alpha = N_2$ or O_2 with $C_{N2} + C_{O2} = 1$. Each D_a represents diffusion coefficient of α species at 27 ℃. In the specific calculation, Eq. (1) for O_2 species is solved and N_2 concentration is determined from the rest part of ρ. The lower wall can be considered as a substrate. Gas flow is assumed to be laminar one, and the boundary condition on the walls is no-slip wall boundaries. The unit calculation cell is 1.0 mm x 0.25 mm, and the fluid dynamics parameters in each cell depends on the local composition of the gas species.

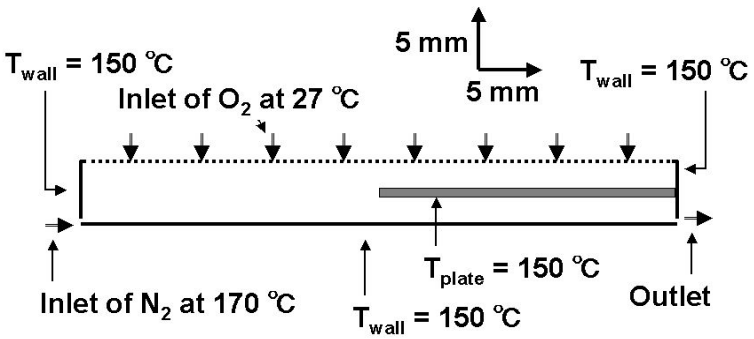

FIG. 3. Model configuration of the reactor. The experimental parameters are adapted to the boundary condition of the numerical analysis.

Figures 4 and 5 show the typical numerical results obtained using this model, where the flow rates are adjusted to the experimental values shown in Fig. 2. When the total gas flow rate is high, shown in Fig. 4, the N_2 flux from the left inlet expands in a limited region on the substrate and goes almost directly to the deposition area, and so no contact of N_2 including TEOS with the microdischarges occurs. The O_2 flux cannot diffuse in the N_2 flux layer so much, and so the mixing rate is very small. When the fluxes get into the deposition area, the large vertical gradient of the O_2 concentration is kept throughout this region, which indicates that dissociation above the substrate cannot be expected so much. On the other hand, when the total gas flow rate is low, as

shown in Fig. 5, the N_2 flow expands the mixing region up to the upper inlet where the microdischarges take place. The O_2 flow, including O_3 in the experiments, also expands downward in the mixing region, and so the well-mixed flux is formed before it enters the deposition area. In the deposition area, the flux is almost homogeneous vertically and the flux with high O_2 concentration gets contact with the whole substrate surface.

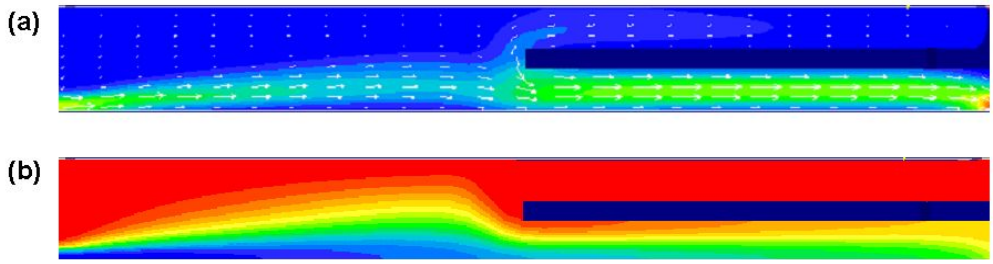

FIG. 4. (a) Velocity distribution calculated in the cross section shown in Fig. 3 in the case with the total gas flow 6.6 SLM. The contours and the white arrows indicate the velocity values and its vectors, respectively In the region in bright red the velocity becomes maximum (3.2 m/s), and the dark blue represents the minimum velocity region (~0.0 m/s). (b) O_2 concentration distribution calculated in the similar condition to (a). The bright red region is the area where only O_2 is present, whereas there is no O_2 in the dark blue area.

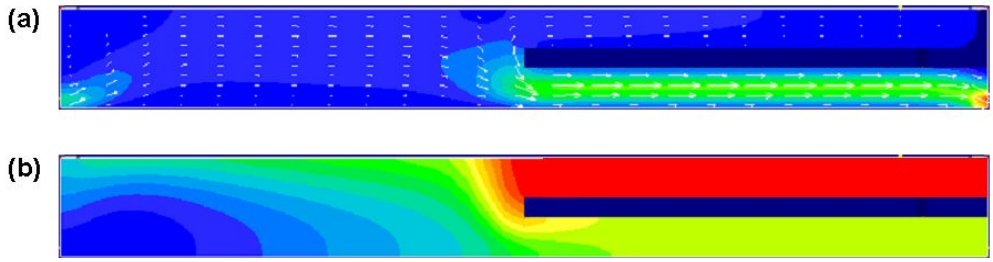

FIG. 5. (a) Velocity distribution in the cross section shown in Fig. 3 in the case with the total gas flow 0.66 SLM. The maximum velocity is 0.35 m/s on the outlet. (b) O_2 concentration distribution in the case similar to (a). The contours and the arrows are used in the similar way as in Fig. 4.

Figure 6 shows the O_2 concentration on the surface of the substrate. As indicated in Figs. 4 and 5, the O_2 concentration is low on the substrate surface when the total flow rate is high. As the total flow rate decreases, the O_2 concentration increases, which would enhance precursor production near the substrate and oxidation of the grown film surface. This tendency coincides the change of the deposition rate for the total flow rate more than 2 SLM in Fig. 2, but this result cannot explain the deposition rate increase as the total flow rate is decreased in the range less than 2 SLM.

As mentioned in Section 3, the diffusion flux of the precursors towards the substrate would be enhanced when the gas flow rate is decreased. That is, the decrease of the total gas flow rate affects two important factors in the deposition process; one is the increase of precursor production in the collisions between O_3 and TEOS, and another is the precursor transport to the substrate surface. These two factors would create a larger effect than that expressed by a simple consideration of residence time of the gas species, and could be related to the drastic change of the deposition rate in the range less than 2 SLM. Another possibility for this drastic change can be attributed to the direct dissociation of TEOS by the microdischarges in the low-flow-rate region. In the case of Fig. 5 (b), the TEOS molecules have a chance to encounter the microdischarges which play a major role in dissociation of O_2 throughout the whole flow-rate range. The attachment with the microdischarges might also enhance powder formation in the gas phase due to excessive decomposition of TEOS. Further clarification of this complicated feature of this deposition process is beyond the scope of this study, but the aspects revealed in

this study on the combined laminar flows and the diffusion flux across them can be lead to more understanding and development of atmospheric-pressure plasma processes.

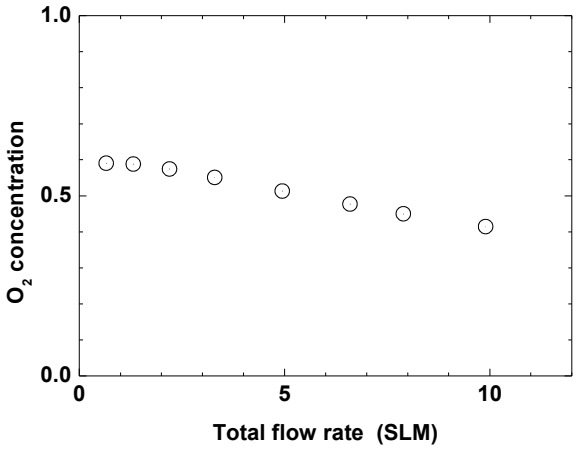

FIG. 6. Calculated result of O_2 concentration on the surface of the substrate 7 mm apart from the outlet, as a function of the total gas flow rate.

5. Conclusion

A new plasma-enhanced chemical vapor deposition (PE-CVD) scheme working at atmospheric pressure was presented, and the deposition process was investigated as a dependence of the total gas flow rate experimentally and numerically. Dielectric barrier microdischarges were integrated on one plane with their hollow structures leading to activation of gases O_2 flowing through them. Created O atoms (and O_3 molecules) coalesced with N_2 flow including TEOS and gave rise to precursors. Deposition rate strongly depended on their laminar flow rate, and gas-phase transports of active species were examined using the computational fluid dynamics solver. The gas flow rate affects the mixture rate of the O_2 and the N_2 fluxes, the precursor diffusion fluxes, and the direct dissociation rate of TEOS. The revealed experimental and numerical results in this study indicated quite different features from the cases of low-pressure PE-CVD.

Abstract

Through an experimental design method, we have investigated the influence of working pressure, of organic precursor flow and of r.f. power on plasma polymer films properties synthesized through PECVD. The organic precursor is the methyl 2-methyl propanoic ester, a saturated counterpart of the widely studied methyl methacrylate. Surface stoechiometry and chemical functions are determined by means of XPS measurements and the deposition rates are evaluated through height step profilometry.

Keywords: Aluminum, Corrosion, Experimental Design, PECVD, Plasma Polymer, Ester, XPS.

1. Introduction

New European environmental protection laws require industries to eliminate as much as possible potentially dangerous treatments, reagents or by-products from their industrial processes. To date, the corrosion protection of aluminium alloys has been extensively based on chromate conversion treatments. Unfortunately, these processes use dangerous reactants and produce toxic waste. Moreover, the chromium VI, a capital element for the conversion coating properties, is proved to be carcinogenic. Its release into the ground waters by lixiviation or because of industrial bath cleanings must be avoided [1, 2, 3]. Among the numerous alternatives, the deposition of a functionalized plasma polymer through PECVD is an attractive approach to solve the problem. From a mechanical point of view, the plasma polymers are dense, quite hard material, highly cross-linked and free of structural defects like pinholes [4, 5]. Moreover, good adhesion of the plasma layer on the substrate could also be achieved through plasma processes. For example, the substrate pre-treatment can be performed by plasma cleaning using the same reactor [6, 7]. Finally, the adhesion of a topcoat could be highly enhanced by grafting specific chemical organic functions at the plasma polymer surface.
In the present work, we synthesize a plasma polymer from the methyl 2-methyl propanoic ester, a saturated counterpart of the widely studied methyl methacrylate. Any possible implementation problems because of using unsaturated compounds are avoided. Indeed, drastic conditions of temperature, pressure, purity or light must be kept to prevent uncontrolled polymerization of such unsaturated monomers in the precursor source or vacuum system. The influence of discharge parameters on adhesion and on protective properties of functionalized plasma polymers has to be studied. The adhesion with aluminium and with subsequent primer layer can be enhanced by the presence of carboxylic functions. Therefore, equilibrium between preserving the carboxylic functions at the film surface and synthesizing a truly highly cross-linked plasma polymer is to be found. The fragmentation rate of monomer in the r.f. inductive plasma must be controlled.

2. Experimental

The plasma polymers are deposited by inductively coupled r.f. plasma in a PECVD vacuum chamber. The precursor is methyl 2-methyl propanoic ester. The chamber is a cylinder of 300 mm diameter and of 450 mm length. High vacuum is maintained through a mechanical and turbo molecular system (Pfeiffer TPU 621) with a total pumping speed of 440 l/s. A throttle valve (MKS 653 B) placed upstream the pumping system is regulating the pressure in the chamber. A load and lock system allows transferring the substrate inside the

reactor without any venting of the main chamber. Eventually, a Baratron gauge and a Pfeiffer Full range Gauge measure the pressure in the PECVD reactor. A water-cooled coil placed inside the reactor produces the r.f. (13.56 MHz) induction field by which the plasma is powered. The r.f. generator is a Restler Caesar with a maximal delivering power of 1000 W. The copper coil has a diameter of 150 mm and is placed in front of the substrate at a distance of 50 mm. No copper pollution has been detected on polymer film because of capacitive discharges appearance. We assumed that the plasma polymer quickly covers the r.f. coil as all the plasma-exposed surfaces. The different substrates are aluminium "2024" foils of 360 mm^2 for ageing tests, floated glass for contact angle measurements and thickness determination, and silicon wafers of about 10 mm^2 for XPS measurements. The substrate holder could be earthed, kept at floating potential or independently biased up to 600 volts by an r.f. generator (ATX 600 Advanced Energy). The samples are strongly clamped to provide good electrical contact. The substrate holder is entirely mounted on the linear drive of the load and lock system. The distance between the coil and the sample can be varied from 50 mm to 300 mm. The organic precursor is introduced into the chamber through a needle valve. The boiling point of methyl 2-methyl propanoic ester is quite low (57 °C). Therefore, evaporation is simply performed under low vacuum to feed the reactor; no carrier gas is used. Measuring the pressure inside the chamber allows controlling and calibrating the precursor flow. The deposition rates are determined by step height profilometry (Dektak).

The surface chemical composition of the polymer films is obtained by means of XPS measurements (VG-ESCALAB 220iXL spectrometer). The pressure inside XPS analysis chamber is about 1.3×10^{-10} mbar. The excitation radiation is an Al Kα mono chromatised x-ray beam and the irradiated surface is about 1 mm^2. As the plasma polymers are insulating, an electrical compensation is always applied through an electron flood gun. The carbon and oxygen atomic compositions are deduced from the photoelectron peak areas corrected by photo ionization cross-sections calculated by Scofield. The escape depth dependence on the kinetic energy of the electrons (assumed to have the form $\lambda = KE_{kin}^{\ 0.6}$) and the analyser transmission function are taken into account. An evaluation of the organic functions present at the film surface is deduced by means of envelope fitting of the C1s photoelectron peaks. The samples are exposed to air for one day before being transferred to the XPS load and lock system. Contamination of the surface is expected during this period.

3. Results and discussions

The surface chemical composition has been studied in function of working pressure (mbar), of organic precursor flow (ml/min) and of r.f. power (W). To outline our domain of investigation, we use an experimental design program called Design-Expert from Stat-ease. The software sets the studied discharges parameters (factors) through a Box-Bhenken type design. In this experimental design, two parameters vary simultaneously to investigate possible factor interactions. Moreover, the central domain experiment is duplicated five times to evaluate experimental errors. Finally, a response surface is calculated as a function of the three previously selected discharge parameters. The responses are constituted of the film surface oxygen contents determined through XPS, of deposition rate evaluations and of water contact angle measurements. The response surface adequacy is checked by means of different statistical diagnosis. Eventually, the so-called experimental design is an efficient and complete method of process diagnosis and results treatment. However, a full explanation is beyond the scope of the article [8,9].

The experimental domain boundaries results from technical limitations or experimental observations. The applied r.f. power range lies between 50 W and 120 W. Below 50 W there is no film deposition. The working pressure varies from 2×10^{-2} mbar to 8×10^{-2} mbar and the monomer flow from 0.04 ml/min to 0.08 ml/min. For each experiment, the deposition duration is 15 minutes and the substrate coil distance is set to 50 mm. Seventeen films were deposited according to the established experimental design. Eight additional samples were prepared to confirm (or not) predicted values. Determination of film deposition rate, measurements of water contact angles, MEB photography and XPS surface characterization were performed. Here we will discuss XPS results obtained with the experimental design program.

Substrates are cleaned in capacitive coupled argon oxygen plasma. The r.f. power (50 W) is applied on the substrate holder and the resulting bias is about – 650 V. A pre treatment of 10 minutes is realized and less than 1 carbon at% of residual organic pollution is detected through further XPS measurements. The film

thickness varies from 20 nm up to 1000 nm depending on the studied discharge parameters. The deposition rate is about 1 nm/min at 50 W r.f. power and rises up to 60 nm/min at 120 W r.f. power values. Water contact angle changes from 75° down to 55° while the applied r.f. power rises from 50 W to 120 W. The working pressure is of 4 x 10^{-4} mbar and the monomer flow is set at 0.06 ml/min.

3.1 Dependence of the surface chemical composition on applied r.f. power, precursor flow and working pressure

The carbon/oxygen surface ratio is determined through XPS on plasma polymer coated silicon wafers substrates. The influence of the discharge parameters on the surface composition is studied by means of the experimental design response surfaces. Afterwards, the C1s photoelectron peak is fitted to identify the grafted organic functions at the film surface. To avoid over or under estimation of the surface oxygen responses due to the program fitting, Y'"logit" values of the oxygen at% are introduced as responses into the experimental design [9, 10].

$$y' = \ln\left(\frac{y - \text{lower}}{\text{upper} - y}\right)$$

This mathematical transformation allows outlining the predicted values. As the organic precursor is the methyl 2-methyl propanoic ester ($C_5H_{10}O_2$) and hydrogen atoms are not detected through XPS measurements, the oxygen maximal value is set up to 30 at% and the minimal oxygen content is of course set to 0 at%. The response equation is expressed in coded factors to reflect the statistical weight of the studied parameters. The equation of oxygen content response surface is expressed as follows:

$$Ln\left(\frac{O-0}{(30-O)}\right) = -0.11 + 0.017P - 0.48W - 0.09P^2 + 0.13W^2 \quad (a)$$

Where O is the oxygen at%, F the monomer flow, P the pressure and W the applied r.f. power.

Equation (a) indicates that the pressure has a lower influence on the film oxygen content compared to r.f. power. Moreover, the monomer flow is not taken into consideration. It has probably no influence on the oxygen content within our experimental limits. The lack of interaction between the discharges parameters is expressed by the absence of mixed term in equation (a). The standard deviation error is about 6 % and there are no outliers in the predicted values. Finally, the model adequacy is verified through residuals analysis on a normal probability plot.

Increasing the applied r.f. power reduces the surface oxygen content from 18 at% (50W) to approximately 10 at% (120W). At higher r.f. power (120 W), the plasma probably produces more volatile non-reactive species (like CO_2 as detected with MS measurements) since the collision cross section increases [9]. These oxygen-containing fragments do not polymerize at the substrate and are evacuated by the pumping system. Moreover, it is assumed that the monomer fragmentation is already significant at 50 W. Indeed, the oxygen content reaches a maximum of 18 at% while the organic precursor contains 28 at%.

Each surface response graph presented below is expressed in actual values and illustrates the general behavior of the equation (a).

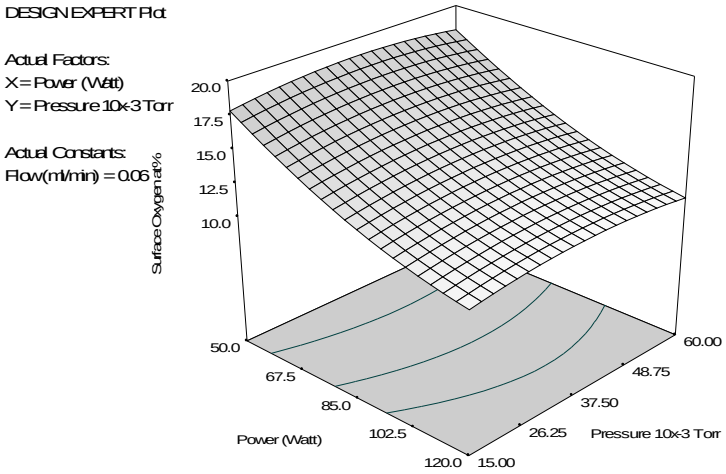

Figure 1: O at% in function of pressure (torr) and r.f. power (W)

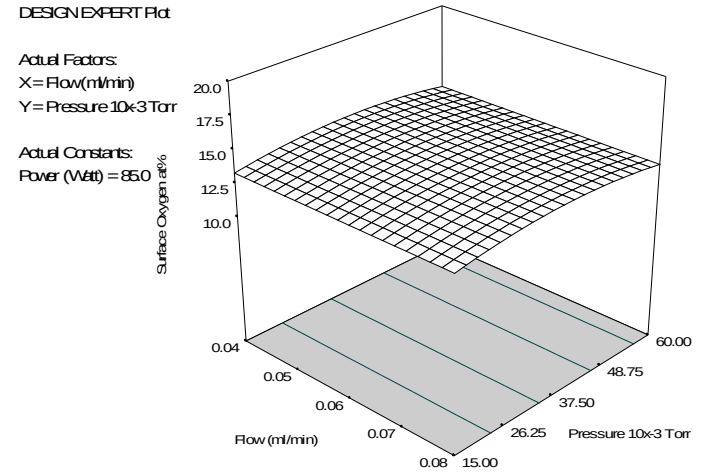

Figure 2: O at% in function of pressure (Torr) and monomer flow (ml/min)

As already noted on equation (a), the figure 1 illustrates perfectly the expected r.f. power influence on film surface oxygen contents. Regardless of any pressure variation, the oxygen rate decreases by a factor two when the applied r.f. power doubles. Figure 2 shows the lack of influence of monomer flow and of pressure on the surface oxygen content the plasma polymer. According to literature [11, 12], this behavior was not truly expected but could be explained owing to our very low working pressure and monomer flow.

3.2 Determination of the plasma polymer surface chemical functions deduced from the C1s XPS peak fitting.

The plasma polymers exhibit quite complex C1s peaks that allow fitting. The discriminated components give us information about the chemical surface composition of the films. Indeed, prior to any polymerization, the organic precursors are first decomposed by the plasma into various reactive fragments. Only a part of the primary monomer chemical functions is remaining at the polymer surface but new ones may appear. Moreover, the samples are exposed to air before XPS analyses and chemical surface reactions like oxidation may occur during the delay.

Eventually, six components are discriminated in the C1s peak that depends on the carbons atoms chemical environment. An example of a C1s peak fitting spectra is presented in figure 4. Some fitting constraints were

applied to avoid impracticable ratio intensities, abnormal peak widths and binding energy inconsistencies. The peaks binding energies of the ^{2}C,^{3}C,^{4}C,^{5}C,^{6}C carbons are imposed regards to ^{1}C carbon position and to the hypothetical surface functions. The fitting peak width (FWHM) is set to 1.5±0.1 eV. Finally, α carbon peak areas (^{2}C and ^{3}C) are linked to peak areas of their corresponding functions (^{6}C and ^{5}C respectively). Four components are directly resulting from the organic precursor structure: carbon-carbon bond -C-^{1}C (285 eV), α carbon of carboxyl ^{2}C-COO (285.5 eV), methyl carbon of ester -O-^{4}C (286.5 eV), and carboxylic carbon O-^{6}C=O(289 eV). Two additional components are resulting from the plasma processing: α carbon of carbonyl ^{3}C-C=O, and carbonyl carbon ^{5}C=O. Accordingly, the films surface compositions are supposed mainly formed of carboxyl, carbonyls, ether and hydroxyl organic functions. This assumption has to be confirmed by future FT-IR measurements. The carbon peak ^{4}C is related to the ester monomer function but also to plasma born ether and hydroxyl functions. However, chemical shifts are too close for allowing peak discrimination. The peaks assignments and component ratios are summarized in table 1 for two different powers (50 W and 120 W, p = 4 x 10^{-2} mbar, monomer flow = 0.06 ml/min).

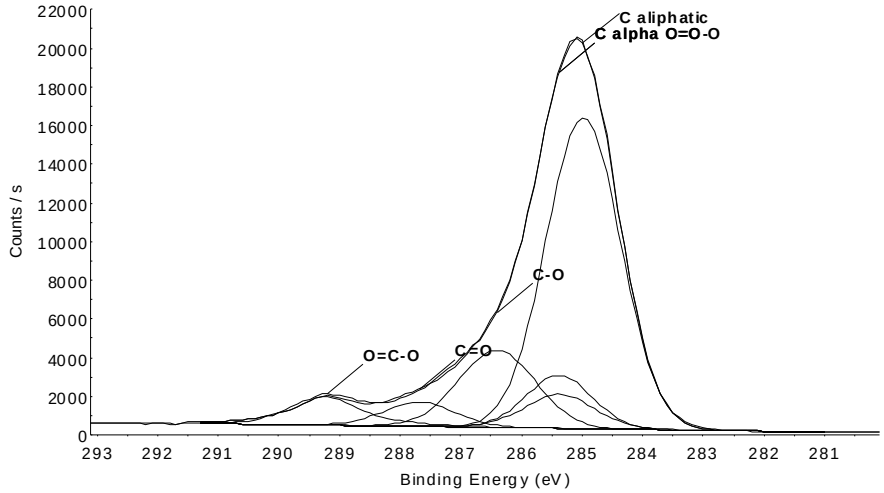

Figure 3: C1s peak fitting spectra example (85 W, 0.06 ml/min and 5x10^{-2} mbar)

Table 1.Plasma polymers atomic ratios measured through XPS by fitting the carbon peak Area

Bonding energy (eV)	%at ratio r.f. 120W	%at r.f. 50W
285 (^{1}C-C)	} 84	} 71
285.5 (^{2}C-COO)		
285.5 (^{3}C-C=O)		
286.5 (^{4}C-O)	9.7	18.1
288 (^{5}C=O)	2.4	5.2
289 (^{6}COO)	4.1	5.7

Table 1: C1s peak fitting assignments and ratios

According to table 1, the surface functions are mainly composed of ester/ether/hydroxyl (^{4}C), and to a lesser extend of carbonyl (^{5}C) and of carboxyl (^{6}C). Concerning the origin of these organic functions, one may notice that the plasma generates the majority. First, the carbonyl functions are entirely generated by the plasma as it does not appeared in the initial monomer. Secondly, the ester contribution to the ^{4}C component is linked to the carboxyl function and may not exceed it. As the esters represent less than 50% of the ^{4}C component intensity, it is mainly composed by plasma-born hydroxyl and ether functions. This behavior has

to be related to the significant fragmentation rate occurring since 50 W and that is resulting in a low-content carboxyl plasma layer. Another important feature is the seemingly lack of power influence on the ^{6}C peak intensity that could be explained through monomer adsorption occurring at the very end of the process. As mentioned earlier, total oxygen content decreases with a rising of the applied r.f. power. This oxygen ratio evolution seems mainly related to the variation of the ^{4}C and ^{5}C plasma-born components intensities. This observation is in agreement with the assumption that more volatiles oxygenated species are produced while the applied r.f. is increased.

4. Conclusions

Plasma polymer films have been synthesized from methyl 2-methyl propanoic ester through PECVD process. Experimental design technique has been used to study the influence of discharge parameters on film formation. More particularly, surface atomic and chemical composition of the films were deduced from XPS spectra. The most significant discharge parameter is the r.f. power applied at the coil. An increase of the r.f. power decreased the surface oxygen content. This behavior was explained through the production of non-reactive volatile oxygenated compounds in the plasma. Finally, the plasma polymer surface is mainly composed of plasma born carbonyl and ether/hydroxyl functions.

Abstract

Plasma-polymerized hexafluoropropene (PPHFP) film had adhesive strength that was low enough for use as a release coating, but the bond strength between PPHFP film and a poly (ethylene terephthalate) (PET) base substrate film was slightly weak. The insertion of a soft and elastic polymer, polyethylene glycol, between the two films hindered the peeling off of PPHFP from PET. The results also suggested that the polymerization degree of PPHFP was low and that this caused the weak bond strength.

1. Introduction

Pressure-sensitive adhesive (PSA) tapes are kept in rolls until use. To peel them out smoothly when we use them, PSA tape surfaces, which are in contact with their own glue, are generally coated with some low adhesiveness matter (*the release coating*). Some silicone polymers have frequently been used as a release coating because of their quite low surface energy. However, since those silicone polymers can become a serious impurity especially for the semiconductor industry, the development of a silicon-free PSA is strongly desired.

Generally, the adhesive strength between PSA tapes and solids strongly depends on the surface morphology and the surface energy of the solid: an extra smooth or a moderately rough solid surface and a lower surface energy will make the adhesive strength weaker [1]. Thus, it is clear that any material with sufficiently low surface energy is suitable for depositing release coatings. According to references 1 and 2, some fluorinated polymers such as polytetrafluoroethylene (PTFE) and polyhexafluoropropene have lower critical surface tensions, from which the surface energies can be estimated, than the values of some silicone polymers. However, they are rarely used as release coatings since there is currently no solvent suitable for applying the fluorinated polymers onto PSA tape films.

We have already reported that atmospheric pressure glow (APG) plasma can polymerize some fluorinated plasma-polymers [3-5]. In those studies, we found that a plasma-polymerized hexafluoropropene (PPHFP) film deposited using a dielectric barrier discharge (DBD) reactor had adhesive strength low enough for use as the release coating. These studies also showed that the adhesiveness of PPHFP film was lower than that of plasma-polymerized trifluoroethylene (CF_2CFH) film; this result agreed with the general propensity that a fluorinated polymer with a trifluoromethyl functional group (CF_3) has a lower critical surface tension (surface energy) than one without CF_3 [1, 6].

However, a small amount of PPHFP did peel from the PET film during the peel force measurement. This phenomenon could not be solved completely only by making the bond between PPHFP and PET stronger; for example, by insertion of some intermediate plasma-polymer layers between them or by introduction of radical sites on the PET surface. We supposed that this phenomenon occurred due to the high hardness and low elasticity of PPHFP. Thus, in this study, we examined the effect of the insertion of a soft and elastic polymer, polyethylene glycol (PEG), between PPHFP and PET as a solution of the problem.

2. Experimental

The DBD reactor shown in figure 1 was used for the PPHFP deposition. The reactor body was made of a Pyrex glass tube whose inner diameter was 46 mm. The inner stainless tube whose diameter was 44 mm was the ground electrode and the copper mesh electrode, whose height was 110 mm, wrapped around the Pyrex tube was the high voltage electrode. A PEG-coated PET film whose height was 130 mm was wrapped around the inner stainless electrode. Another (non-PEG-coated) PET film was used for preventing PPHFP deposition on the inner surface of the reactor.

First, the pressure in the reactor was lowered with a rotary pump to 3 Pa to remove any impurity gas. Then He gas was introduced into the reactor and the reactor pressure was restored to atmospheric

pressure. Finally, the PET film was treated with He plasma for 30 s to introduce some radical sites on the PET or PEG surface. Continuously (while we maintained the discharge), hexafluoropropene (HFP, C_3F_6) was added into the He gas to deposit PPHFP. The PPHFP deposition conditions are shown in table 1.

PEG coating was performed as follows: 1 wt% PEG - 33 wt% H_2O - 66 wt% ethanol solution was dropped on a PET film and was spread with a Mayer bar, which is a grooved rod. Then this film was dried in the atmosphere at 100 ºC for 1 min. The PEG thickness could be varied, if one used a Mayer bar with a different groove depth. In this study, the PEG thickness was fixed at about 200 nm.

The peel force was measured with a 180º peel test: No.31B PSA tape (Nitto Denko Co., Ltd) of 20 mm width was pressed onto the deposited film and then peeled off at a speed of 300 or 30 mm·min^{-1}. Although peel force was formerly presented in units of grams (force) per 20mm, the SI unit, Nm^{-1}, is used in this article, the relationship between these units is 1.0 gf(20mm)$^{-1}$ ≈ 4.9×10^{-1} Nm^{-1}. The chemical state of the deposited films was determined by XPS (ULVAC-Phi Co., Ltd., ESCA-5800ci). The XPS spectrum binding energy was corrected by shifting the hydrocarbon component (CHx, x=0 to 3) peak in the C_{1s} spectrum to 284.6 eV in most cases. Then we carried out curve fitting with the XPS program of ULVAC-Phi by reference to the interval energies between each chemical group observed from references 7 and 8. If the CHx peak in the C_{1s} spectrum was not identified clearly, for example in the PPHFP film, we set the peak position of F_{1s} spectrum at 689 eV; this value is the F_{1s} peak energy of an ordinary Teflon sample [9]. Then, the same process as mentioned above was followed.

3. Results and Discussion

Figure 2 shows peel forces of PET substrate, Teflon sheet as a control and PPHFP on PET without or with PEG coating. And Figure 3 shows atomic ratios F/C obtained from XPS measurements of adhesive tape glue side surfaces, which were used for the peel force measurement of the same samples as in Figure 2. If we compare among the white bars in Figure 2, the peel force of the PPHFP on the PET without PEG coating (#3) was low enough, but the F/C ratio was quite high. This result indicated that some PPHFP flakes had moved to the adhesive tape glue side. On the other hand, the peel force of the PPHFP deposited on PEG coated PET (#4) became slightly bigger than those of the #3 sample and the Teflon sheet (#2), but was low enough to use for the release coating. However, the F/C of #4 showed a much lower value than that of #3: it was almost the same as the value of the Teflon sheet; since the fluorine atoms on the Teflon surface are easily transcribed to a contacted surface, the F/C of the Teflon sheet was not zero. These result indicated that a soft and elastic polymer such as PEG inhibited the peeling off the PPHFP from the PET film by decreasing the stress on the PPHFP.

Since the F/C of #3 was slightly bigger than that of Teflon, we tried to use several times thicker PEG coats. However, there was no dependence between the PEG thickness and the inhibitory effect. We supposed that the PPHFP was essentially fragile: in other words, the polymerization degree of the PPHFP was quite low. Then, we measured the peel force of those samples with low peel speed, 30 mm·min^{-1} again.

The peel force obtained from the 180º peel test generally becomes smaller with slower peel speed because the adhesive glue of a test PSA tape becomes extended like a rubber band: the

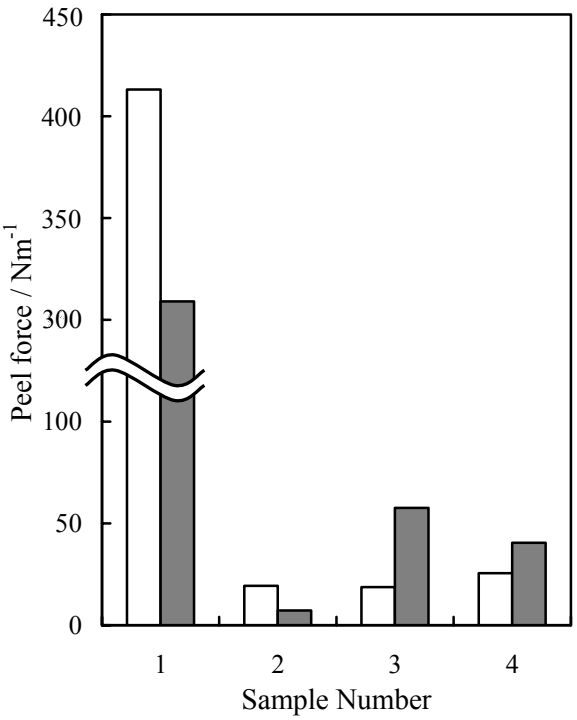

Fig. 2 Peel forces of 1) PET film, 2) Teflon sheet, 3) PPHFP on PET without PEG coating and 4) PPHFP on PEG-coated PET. The peel speeds of white and gray bars were 300 and 30 mm·min^{-1}, respectively.

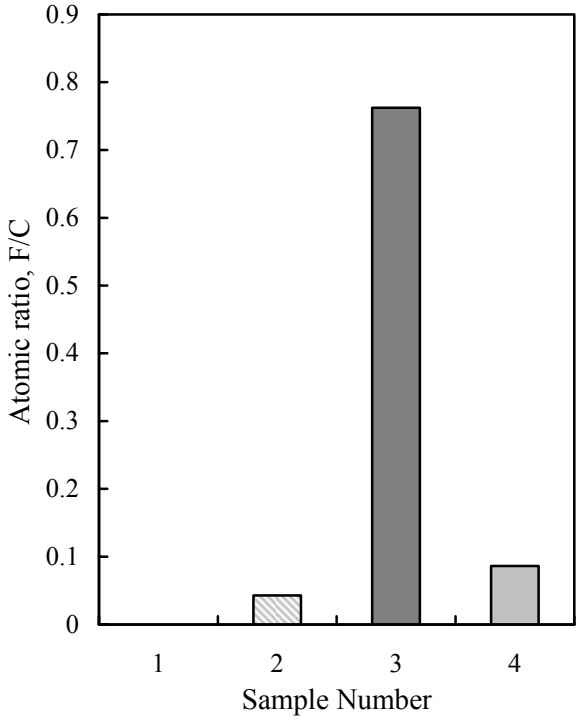

Fig. 3 Atomic ratios, F/C of adhesive tape glue side surfaces which were used for peel force measurement of the same samples as those in Fig. 2.

stress on a sample surface will decrease as a result of this phenomenon.

While the peel force of the PET film (#1) and the Teflon sheet (#2) shown with gray bars in figure 2 became smaller as mentioned above, those of PPHFPs (#3 and 4) became bigger. Moreover the PPHFPs (#3 and 4) were not peeled off from the PET film with slow peel speed. This result suggested that the peel forces under high peel speed condition indicated seemingly low values, since some PPHFP flakes peeled off, and that the peel forces of the PPHFPs under slow peel speed condition were the true values. If this assumption was true, the peel forces of PPHFPs (#3 and 4) were not as low as that of Teflon.

One well-known fact is that the cross-linking in a plasma polymerized polymer becomes less as one decreases the discharge frequency. Thus, we supposed that the polymerization degree of PPHFP would be made higher with a low frequency discharge, so we tried to deposit a PPHFP with 3 kHz power generator.

Figure 4 show the peel forces of PET substrate, Teflon sheet and PPHFP deposited on PEG coated PET under conditions of 100 and 3 kHz discharge frequency. And Figure 5 shows atomic ratios F/C of adhesive tape glue side surfaces, which were used for the peel force measurement of the same samples as in Figure 4. The deposition time of the PPHFP deposited with 3 kHz generator (#5) was 60 min. The #5 sample showed almost the same peel force as #4: according to their C_{1s} XPS spectra shown in Figure 6, the reason of this peel force result was considered that their chemical compositions and structures were not so different. On the other hand, the fact that the F/C of #5 was lower than that of #4 suggested that our assumption was probably true. And the slightly sharper C_{1s} spectrum of #5 shown in Figure 6-(b) than that of #4 suggested that the PPHFP deposited with 3 kHz generator had a more homogeneous chemical structure. We thought that this result also supported our assumption. However, the #5 peel force of slow peel speed shown with gray bar was even bigger than that of high peel speed. This indicates that the PPHFP was peeled off from the PET substrate.

4. Conclusion

The insertion of the soft and elastic polymer, polyethylene glycol (PEG), between PPHFP and PET inhibited the PPHFP peeling off from the PET substrate. However, since the PPHFP was essentially fragile, we considered that the peeling off problem would be not solved only by improvement the bond strength

between PPHFP and PET. One of the solutions was that one would use a low frequency generator or pulse-controlled high frequency generator with low duty ratio.

Acknowledgments

The authors wish to express their gratitude to Professor Frank Scott Howell S. J. for his valuable comments.

Abstract

Fe ion doped TiO_2 particles for coametics were atained by means of atmospheric pressure glow discharge using IAA and TEOS. The ion doped particles were coated by a silica protection layer. To examine the UV catalytic ability of ion doped TiO_2, a squalene that contained the powders after being irradiated by a Xe lamp for one hour, were measured by GCMS for the gas products. Using of silica coated ion doped TiO_2, we have no signal assigned as harmful organic oxides in the GC-MS spectra of the UV irradiated squalene.

1. Introduction

Some kinds of pigments that are used for cosmetics give rise to a skin irritation problem when they contact the skin directly. TiO_2 is an UV reflective white pigment powder for cosmetics. But naked TiO_2 is a kind of photosensitive catalyst, so the powder easily attacks a human skin surface and oxidizes oil in the sweat as a squalene. Oxidized squalene molecules will produce many kinds of peroxy-organic compounds that may cause an allergy or cancer. So we need to avoid such effects caused by the catalytic ability of TiO_2 particles.

Some previous studies reported the possibility of powder handling with atmospheric pressure glow discharge [1-5]. Then, at the first stage in this experiment, we will try to develop some SiO_2 coating on the TiO_2 powder pigments by means of atmospheric pressure glow discharge using TEOS adsorbing and plasma oxidation to prevent the oxidation of squalene oil in the UV irradiation.

On the other hand the SiO_2-coated TiO_2 powders will not have only a very high refractive index for the UV region but also high transparency for visible and IR regions. For such reasons, silica-treated powders will have too white a tint to use for the cosmetics and cannot prevent IR penetration through the powder, which is also a cause of human skin irritation. We can expect that some metal ion doping can achieve wide band light absorption in TiO_2. At the second stage, we will try to obtain a thin deposition layer of iron between the TiO_2 surface and the silica layer to eliminate the photo-catalytic ability and to suppress the wide band light transparency of bulk TiO_2.

Finally, we measure the catalytic effect and light absorption of the new material iron doped silica- coated TiO_2.

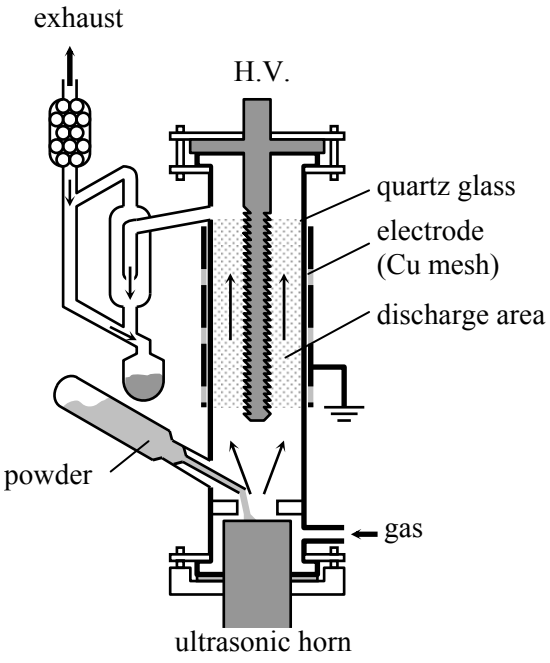

Fig. 1 Schematic of discharge apparatus.

2. Experimental

The mean diameter of TiO_2 particles is two hundred nm; they contain 80% of anatase and 20% of rutile (Toho Titanium Corporation, HT-170R). For iron doping, we used tris (2, 4-pentanedionato) iron (IAA). In this study, we employed the Adsorb and Dry method to achieve the coated surface [5]. The schematics of the discharge reactor is shown in Figure 1. The discharge conditions are as follows: discharge frequency, 13.56 MHz; power, 1.5 - 2.5 kW; O_2/He gas flow rate, 100 ml min^{-1}/10 l min^{-1}. Treating rate is about 2 g min^{-1} for the powder.

To examine the photo catalyst ability of the powders, we irradiated the squalene oil
(2, 6, 10, 15, 19, 23-hexamethyl-2, 6, 10, 14, 18, 22-tetracosahexaene) that contained the powder samples by UV in a Pyrex glass bottle. After 1 hour UV-irradiation by Xe lamp, the gas products were measured by GC-MS (Shimazu QP5050).

Process 1) Silica coating on TiO_2

At first we tried to make sure of the possibility of the Adsorb and Dry method with TEOS to coat SiO_2 on the bulk TiO_2. In this treatment, adsorbed TEOS is partly reacted with naturally adsorbed water on the TiO_2 surfaces to deposit SiO_2. The percentages of SiO_2 on the sample TiO_2 powders are calculated using the next equation:

$$Y=Xa/100\times W/M \qquad (1)$$

Y, SiO_2 wt% on TiO_2 powders
X, sample powder weight/g
a, wt % of SiO_2 on the sample powder
W, Molecular weight of SiO_2 (60)
M, Molecular weight of TEOS (208)

Weighed TEOS is diluted in ethanol (lower than 10%); then the powder is dried in air ambience. Adsorbed powder is treated in the atmospheric pressure glow plasma in He-O_2 system to eliminate the organic part from the adsorbed TEOS molecules.

Process 2) Iron ion doping

TiO_2 powders were pre-treated with IAA-ethanol mixture to adsorb organic metal molecules on the surfaces of the particles. The amount of IAA in ethanol are calculated using same equation(1) as in TEOS adsorption. After the evaporation of the ethanol, the IAA adsorbed powders are treated to have iron ion doped TiO_2 using atmospheric pressure glow plasma in He-O_2 system to eliminate the organic part from the adsorbed IAA molecules.

Process 3) Silica-Iron-TiO_2 multi coating.

After process 2, the iron-doped TiO_2 powders were pre-treated with TEOS (tetraethoxysilane) - ethanol mixture aero - sol to adsorb TEOS on the surfaces of the particles. After the ethanol evaporation, the powders are oxidized in atmospheric pressure glow plasma. Using the plasma treatment, SiO_2 was deposited on the iron-doped TiO_2 surface as an inorganic fine layer. The thickness of SiO_2 deposited can be controlled by the concentration of TEOS in the solvent ethanol during the adsorbing process.

3. Results and discussion

Process 1)

From the XPS analysis, we found Si2p and Ti2p spectra for TiO_2 that adsorbed TEOS (b), and for TiO_2 that adsorbed TEOS and then was oxidized in the He-O_2 plasma (c), as shown in figure 2. After plasma oxidation (c), Si atomic concentration is increased because the naked TiO_2 surfaces are completely covered by an inorganic SiO_2 thin layer.

In figure 3, sharp peaks of O_{1s} were obtained in the spectra of (a), (b) and (c). In the spectrum of (a) only one

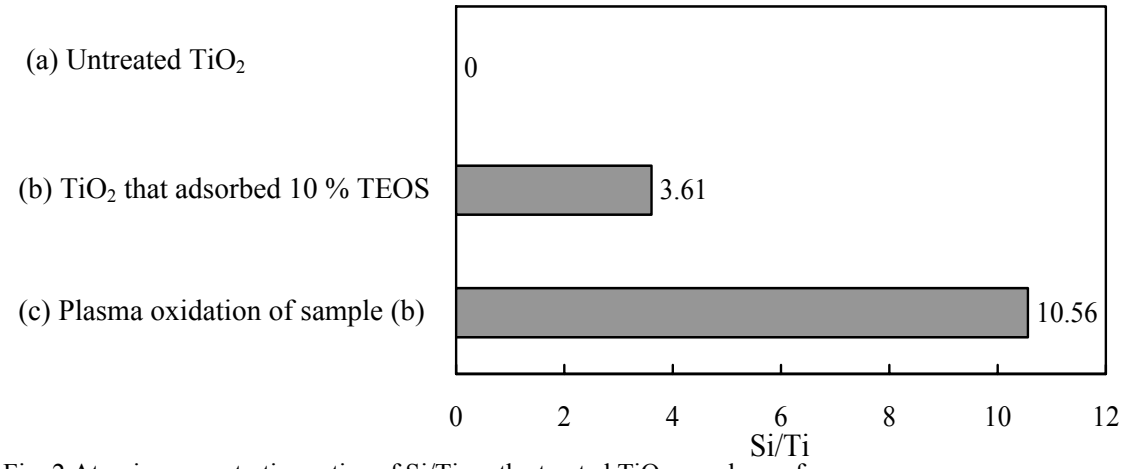

Fig. 2 Atomic concentration ratios of Si/Ti on the treated TiO_2 powder surfaces.

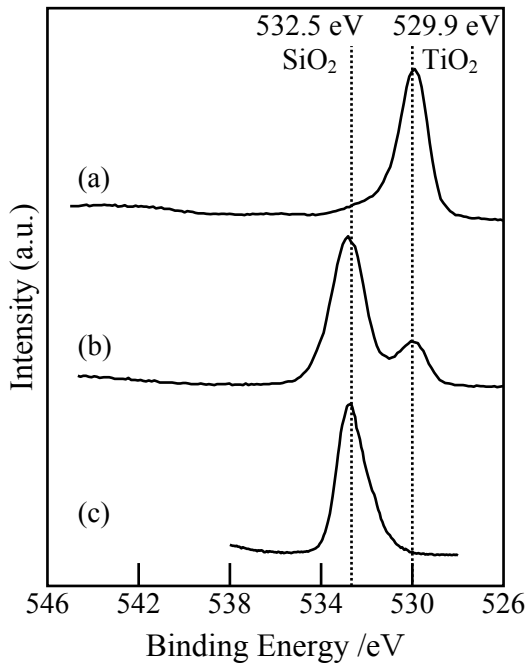

Fig. 3 O_{1s} spectra of XPS: a) untreated TiO_2,b) TiO_2 that adsorbed 10wt%TEOS c) Plasma oxidation of TiO_2 that adsorbed 10wt%TEOS.

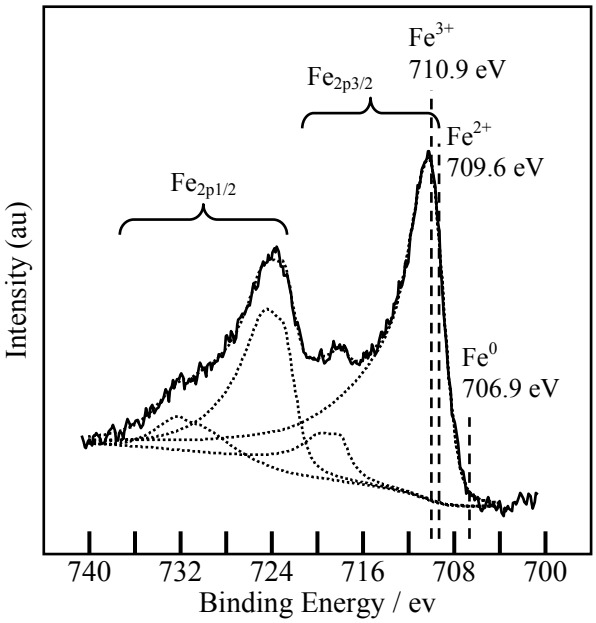

Fig. 4 XPS Fe_{2p} spectra of IAA-treated TiO_2 particles oxidized in the O_2/He plasma.

peak (529.9 eV) assigned to TiO_2 existed. On the other hand, in the spectrum of (b) the peak (532.5 eV) assigned to SiO_2 newly appeared while the peak assigned to TiO_2 decreased. Therefore, we concluded that the surface of (b) was coated with SiO_2 but the coating was not enough. The surface of TiO2 is still partly covered by half-dissociated TEOS molecules that are reacted with adsorbed water on the surface of TiO_2. In the spectrum of (c), the peak assigned to TiO_2 has almost disappeared and the shape of the peak looked like that of pure SiO_2. So, we could confirm that the surface of (c) was almost completly coated with an inorganic SiO_2 layer without any organic contamination.

A TEM photo of silica-coated TiO_2 particles is shown in photo 1. In the photo, homogineous SiO_2 thin layer(1-2nm in thickness) is found on the particles. So we attained a very homogeneous SiO_2 layer with the TEOS Adsorb and Dry method.

Process 2)

Figure 4 shows the XPS Fe_{2p} spectra of IAA-treated TiO_2 particles oxidized in the O_2/He plasma. In the figure, we can find $Fe_{2p1/2}$ and $Fe_{2p3/2}$ peaks assigned as Fe ion, but the binding energies of Fe^{2+} and Fe^{3+} ions are very close to each other. So it is difficult to define which ion is on the TiO_2. The amount of deposited Fe ion can be controlled by the concentration of IAA in the solvent ethanol at the adsorbing process. Figure 5 show the UV-VIS reflection spectra of naked TiO_2, IAA 1% adsorbed TiO_2; adsorbed, then plasma -treated TiO_2; and pure IAA powder. Naked TiO_2 show a high and flat reflectivity from near IR region to UV region. Light incident to the surface partly penetrates into the bulk and is absorbed in the solid, then it reflects to the surface boundary, so the reflection spectra contain the absorption characteristics. IAA-adsorbed TiO_2 shows small peaks attributed to adsorbed IAA on the TiO_2 but such a peak is lost in the plasma-irradiated IAA itself. It

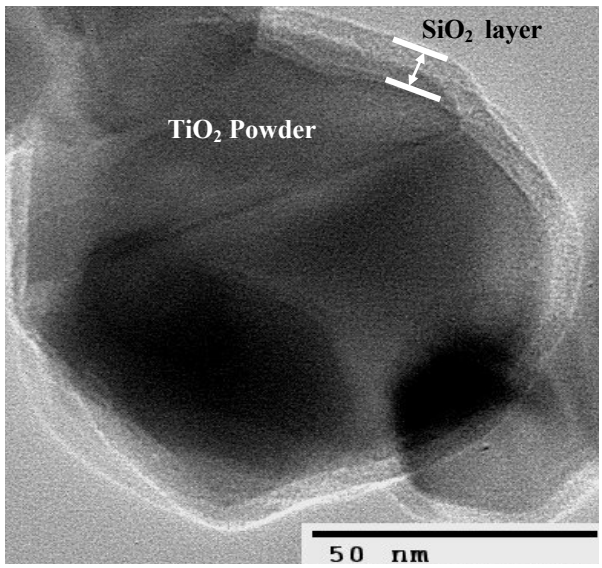

Photo 1 TEM photography of TiO_2 treated by SiO_2 in plasma oxidation

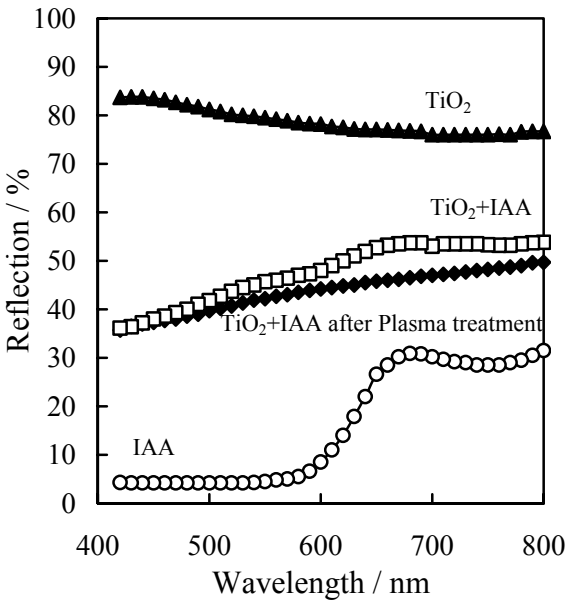

Fig. 5 Reflection spectra of TiO_2; IAA adsorbed TiO_2; adsorbed, then plasma-treated TiO_2; and pure IAA powder.

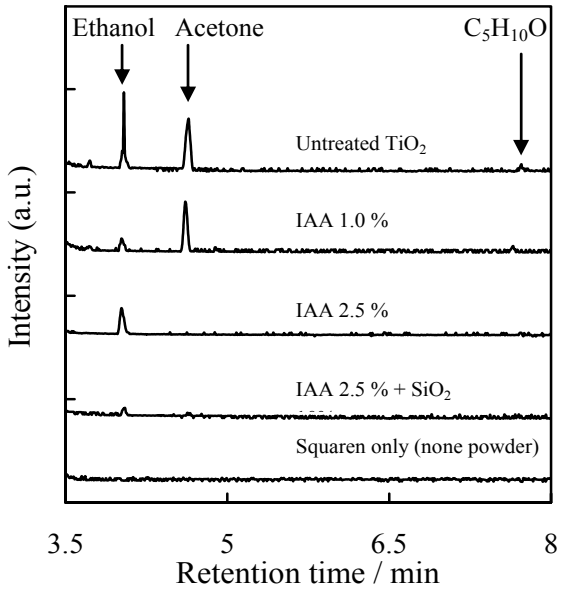

Fig. 6 GCMS spectra of gas products in squalene which contained the powders after one hour irradiated by Xe lamp.

seemed that plasma-treated IAA on the TiO_2 were completely oxidized to inorganic Fe ion.

Figure 6 show the GCMS spectra of gas products in squalene which contained the powders after being irradiated by an Xe lamp for one hour.

Untreated TiO_2 produces many kinds of organic oxides such as ethanol, acetone and long chain oxidant compounds that should be harmful materials for human skin. Also, the oil emits a foul odor. The product concentrations decreased with increasing of the concentration of the doped iron. However even for 2.5% iron-doped TiO_2, we still have a small amount of alcohol in the spectrum. But using silica-coated iron-doped TiO_2 which is produced in process 3), we have almost no signal assigned as an organic oxide in the GC-MS spectra of the UV irradiated squalene, except for a very small amount of ethanol signal. Normally the anatase-type TiO_2 crystals have small rectangular open spaces, such a few angstroms in size, in the structure. It seemed that the iron ions are partly inserted into the open spaces of the TiO_2 latice. However, the crystal lattice of iron-doped TiO_2 is the same as that of untreated one measured by XRD. So we could not infer whether the iron ion is in solid solution in TiO_2.

The treated powder shows fine and flesh colour with pearl-like glowing, that should be caused from a multi-reflection effect from the thin layer boundaries of silica-iron-TiO_2. Especially, the powder can cover the skin furrows and prevent easy drop-off of the powder from the skin surface by sweat, because of the high reflection for the incident light in the skin furrow and the strong absorbing ability of the nano powder to absorb the skin oil.

4.Conclusion

We attained Fe ion doped TiO_2 particles by means of atmospheric pressure glow discharge using IAA, TEOS adsorbing and plasma oxidation method. The particles were coated by a silica protection layer to avoid the UV catalytic ability of TiO_2. The plasma -treated TiO_2 powders will provide many functional contributions for the future cosmetics.

Modeling of Plasma Chemistry and Particle Growth Mechanisms in Dusty Plasmas

Kathleen De Bleecker[1], Annemie Bogaerts[1], and Wim Goedheer[2]

[1]*PLASMANT, Department of Chemistry, University of Antwerp (UA), Wilrijk, Belgium*

Abstract
The initial mechanisms of dust formation in radiofrequency acetylene (C_2H_2) plasmas are investigated by means of a self-consistent 1D fluid model. Possible routes for particle growth are discussed and a comparison with particle formation in silane (SiH_4) discharges is made. The model considers a set of 39 species, including neutrals, radicals, ions and electrons, describing hydrocarbons (C_nH_m) containing up to 12 carbon atoms. Both successive anion/cation – molecule reactions seem to lead to a fast build up of the carbon skeleton.

1. Introduction

Dust particles, from a few nanometers up to several micrometers, have been observed in many processing plasmas used for etching, sputtering or deposition of thin surface films. Until recently, the presence of dust was solely considered as a potential hazard, especially in the microelectronic and other surface processing technologies, as particles provide a significant source of film defects redeeming them as 'killer' particles. Therefore, early investigations mainly attempted at suppressing the particle growth or tried to avoid interference with the wafer surface. Currently, it seems that small particles can also have very interesting and useful properties, mainly due to their very small sizes (e.g. nanometer range), chemical composition or uniform size distribution [1,2]. In the photovoltaic cell production, for example, the creation and inclusion of nanocrystalline silicon particles in the intrinsic layer of amorphous hydrogenated silicon (a-Si:H), can result in a significant increase of the product quality [3]. The newly formed material shows improved transport properties and stability against the light induced effect, also known as the Staebler-Wronski effect. In order to obtain a controlled growth and deposition of these particles on the substrate material, we obviously must understand the mechanisms behind their origin and their behavior, including their transport, in the plasma. Comprehension of these aspects will help to advance the existent and future technological applications.

In chemically active plasmas, such as silane (SiH_4) and acetylene (C_2H_2), it is generally believed that particle formation proceeds through a series of chemical reactions in the gas phase, better known as gas phase polymerization, whereby parent gas monomers are gradually transformed to macromolecules. Although the behavior of particles in the micrometer-sized regime is relatively well understood, the transition of gas species to particles remains a complex process, which is still open for investigation. These earlier stages, known as nucleation and coagulation, are of specific interest in current research. Besides investigations of the plasma chemistry, the dust particles will also acquire a negative charge due to the collection of plasma ions and electrons. The magnitude of the charge on a particle will greatly depend on the particle size and the plasma conditions. This negative charge will also be responsible for the confinement and consequently longer lifetimes of such particles in the plasma. Once the particles reach a certain size (i.e. several nanometers), other forces, besides the electric force and diffusion, will dominate their transport (e.g. the ion drag, the thermophoretic, and the neutral drag force). The competition between these different forces ultimately leads to the confinement of the particles in well-defined regions of the discharge [4,5]. In the end, particles will continue to grow until gravity drags them out of the discharge.

In this paper we will mainly discuss the chemical processes through which larger particles can be formed in a capacitively coupled acetylene (C_2H_2) RF discharge and try to identify the precursors of the dust formation with the use of a self-consistent one-dimensional (1D) fluid model. The gas phase discharge chemistry is investigated and the similarities and differences with particle formation in silane discharges are discussed.

2. Plasma chemical kinetics

Particles in chemically active plasmas emerge as a result of numerous chemical processes in the ionized gas phase. In silane plasmas, anion-induced chain reactions are considered to be the main pathway leading to powder

formation. Negative ions are generally believed to play a very important role in the dust formation, as they are confined by the sheath electric fields in the plasma bulk [6]. The long residence time of the anions in the plasma favors their further growth and makes them good candidates to trigger particle formation. Previously we have developed a detailed chemical kinetics model for gas phase nucleation of hydrogenated silicon particles [7,8]. In that model dust is primarily formed by successive reactions of anions with silane molecules,

$$Si_nH^-_{2n+1} + SiH_4^{(*)} \rightarrow Si_{n+1}H^-_{2n+3} + H_2 \quad (1a)$$

$$Si_nH^-_{2n} + SiH_4^{(*)} \rightarrow Si_{n+1}H^-_{2n+2} + H_2\,. \quad (1b)$$

In addition to ground state SiH_4 molecules, reactions with vibrationally excited SiH_4 ($SiH_4^{(1\text{-}3)}$ and $SiH_4^{(2\text{-}4)}$) are also taken into account, as these species have sufficient internal energy to overcome probable energy barriers in some of the endothermic chain reactions [9]. The mechanism starts primarily from SiH_3^- and SiH_2^- anions, and includes silicon hydrides containing up to twelve silicon atoms. Other pathways involving e.g. positive ions can be excluded as a kinetic bottleneck is already formed at particles having relatively low numbers of silicon atoms, preventing the formation of positive ions having more than five or six silicon atoms [10].

Discharges in hydrocarbon mixtures also tend to produce dust, especially when a sufficient amount of acetylene is present [11]. In contrast to silane plasmas, the dust formation mechanisms in hydrocarbon discharges are much less understood and only a limited amount of data for hydrocarbon molecules is available. Therefore, various mechanisms have been proposed. Presumably both positive and negative ions play a role in the initial phase of the dust forming process, as mass spectrometry measurements reveal the same features in both the anion and cation mass spectra [12, 13].

In this paper acetylene is considered as an example of the hydrocarbon discharge chemistry, as it yields more highly polymerized ions than methane (CH_4) and also has a much stronger and faster tendency to form dust. Table 1 gives an overview of the 39 different species considered in the acetylene model, besides the electrons. Starting from C_2H_2 a series of chemical reactions has been gradually incorporated in the 1D fluid model that leads to the formation of larger hydrocarbons (C_nH_m) containing up to a maximum of 12 carbon atoms. The absence of hydrocarbon molecules with an odd number of carbon atoms is a distinct feature of acetylene discharges. The typical spectral pattern in mass spectrometric measurements shows clear sequences of ions with even numbers of carbon atoms indicating that the strong carbon bond structure ($H-C \equiv C-H$) of the initial acetylene molecule persists upon successive insertion of acetylene in the hydrocarbon species.

Table 1. Different species taken into account in the hydrocarbon model, besides the electrons

Molecules	Ions	Radicals
C_2H_2	$C_2H_2^+$, C_2H^+, CH^+, C_2^+, C^+	CH, CH_2
C_4H_2, C_6H_2, C_8H_2	$C_4H_2^+$, $C_6H_2^+$, $C_6H_4^+$, $C_8H_6^+$	
$C_{10}H_2$, $C_{12}H_2$	$C_{10}H_6^+$, $C_{12}H_6^+$	
		C_2H_3, C_4H_3, C_6H_3
	C_2H^-, C_4H^-, C_6H^-, C_8H^-	C_2H, C_4H, C_6H, C_8H
	$C_{10}H^-$, $C_{12}H^-$	$C_{10}H$, $C_{12}H$
H_2	H_2^+, H^+	H

While in our model for silane plasmas the positive ions could be limited to three different species, i.e. SiH_3^+, $Si_2H_4^+$ and H_2^+ [8], both the positive and negative ions in the acetylene model are extended up to hydrocarbons containing 12 carbon atoms, as the role of both pathways in the first step of particle formation can not be excluded. In the model we account for a total of 78 volume reactions comprising 22 electron impact reactions with acetylene and hydrogen, 35 ion-neutral reactions (anion or cation – acetylene reactions and mutual anion-cation neutralization reactions) and 21 neutral-neutral reactions (hydrogen abstraction, C_2H insertion). Since detailed data on many processes in an acetylene discharge is still lacking, some assumptions have to be made which are tested against the data known from the experimentally obtained mass spectra. Below a comprehensive summary is given of the most important part of the reaction mechanism.

2.1 Reactions involving anions

Usually negative ions are not considered in the modeling of 'standard' acetylene discharges, i.e. without the inclusion of dust formation [14,15]. However, the primary C_2H^- ion, formed through the dissociative attachment of C_2H_2, can be incorporated in neutral species, thereby creating larger negative ions which can eventually grow to nanometer and micrometer sized particles that remain trapped in the plasma due to their large negative charge. In spite of the difficulty of adding an electron to the filled valence shell of acetylene, the electron affinity of the C_2H radical seems to be sufficiently large to produce a stable C_2H^- anion,

$$e^- + C_2H_2 \rightarrow C_2H^- + H\,. \tag{2}$$

This dominant anion is the first species of the particle formation and can in turn undergo the following anion-molecule chain reactions:

$$C_2H^- + C_2H_2 \rightarrow C_4H^- + H_2 \tag{3a}$$

$$C_4H^- + C_2H_2 \rightarrow C_6H^- + H_2 \tag{3b}$$

$$\cdots$$

$$C_{2n}H^- + C_2H_2 \rightarrow C_{2n+2}H^- + H_2\,. \tag{3c}$$

High resolution mass spectra [12] show that the majority of the anions in C_2H_2 plasmas are nearly pure carbon anions, hence, in accordance with the analogous path in silane discharges, molecular hydrogen is lost in every polymerization reaction. Only anions with an even carbon atom number are included in the model, as the triple carbon bond of acetylene is preserved.

No precise rate coefficients for anion chain reactions can be found in literature, but a theoretical upper limit for ion-molecule reactions can be predicted by the Langevin collision rate constant k_L [16]:

$$k_L = e\left(\frac{\pi}{\varepsilon_0}\right)^{1/2}\left(\frac{\alpha}{m_r}\right)^{1/2} \tag{4}$$

where α is the neutral atom or molecule polarizability (in $Å^3$) and m_r is the reduced mass (in amu) of the two reacting species. Inserting the polarizability of 3.49 $Å^3$ for acetylene [17] results in a Langevin rate of the order of 10^{-15} m^3 s^{-1}. However, since these rate constants represent an upper bound for the actual reaction rates, we have used, according to experimental data in [18], Langevin rate constants reduced by three orders of magnitude in our modeling study, i.e. values of the order of 10^{-18} m^3 s^{-1}. Taking larger reaction rates would result in an increase in concentration with rising carbon atom number, which is not in agreement with the observed high resolution mass spectra [12].

2.2 Cation-molecule reactions

In contrast to silane plasmas, the hydrocarbon positive ions polymerize to the same extent as the negative ions and, hence, can not be excluded as a possible route of powder formation. Positive ions are formed from acetylene by electron impact ionization, creating mostly $C_2H_2^+$. Starting from $C_2H_2^+$ rapid condensation reactions with acetylene yield the production of higher mass hydrocarbon cations with or without subsequent loss of molecular or atomic hydrogen. The principal reaction sequence can be summarized by:

$$C_2H_2^+ \xrightarrow{C_2H_2} \underset{(+H_2)}{C_4H_2^+} \xrightarrow{C_2H_2} C_6H_4^+ \xrightarrow{C_2H_2} C_8H_6^+ \xrightarrow{C_2H_2} \underset{(+H_2)}{C_{10}H_6^+} \xrightarrow{C_2H_2} etc. \tag{5}$$

The specific ionic product obtained from any given ion-acetylene reaction, and thus the degree of hydrogenation, depends upon the extent of stabilization achieved by the chemical intermediate [19, 20]. The primary reaction between $C_2H_2^+$ and C_2H_2 can for example lead to $C_4H_2^+$ and $C_4H_3^+$ production. $C_4H_3^+$ is not considered as a separate species in the model; however its production is intrinsically incorporated in $C_4H_2^+$ by using the overall reaction rate constant of both reaction channels, i.e. 1.2 x 10^{-15} m^3 s^{-1} [21]. Another fragment ion generated from acetylene ionization, i.e. C_2H^+, also reacts with C_2H_2 to give $C_4H_2^+$,

$$C_2H^+ + C_2H_2 \rightarrow C_4H_2^+ + H \tag{6}$$

with the fast rate constant of 1.7 x 10^{-15} m^3 s^{-1} [20]. C^+, C_2^+ and CH^+ ions are also formed through dissociative ionization of acetylene, and can in principle react with C_2H_2 via condensation with loss of H or H_2. Although all

these reactions are rapid with rate constants close to the collision limit, these reactions are not taken into account in the model, since the initial formation of these species is too low to make these reactions efficient.
Besides fast polymerization reactions, mutual ion-ion neutralization represents another loss process for both the anion and cation molecules. The rate constant for neutralization is taken from [22] and is only weakly dependent on the nature of the molecule, resulting in our case in a reaction rate constant of 8.7 x 10^{-14} m^3 s^{-1}.

2.3 Neutral chemistry

Breakage of a C-H bond in acetylene by electron impact dissociation produces the C_2H radical that can in turn be inserted into hydrocarbons to produce larger $C_{2n}H_2$ molecules,

$$C_2H + C_{2n}H_2 \rightarrow C_{2n+2}H_2 + H\ . \qquad (7)$$

The reaction chain is initiated by the insertion of C_2H into acetylene leading to the formation of diacetylene (C_4H_2) and atomic hydrogen. A corresponding $C_{2n}H$ radical can be formed by electron induced dissociation of the $C_{2n}H_2$ molecule and can play a role in the deposited layer. The deposition process itself is described by a sticking model that ensures that the loss of species due to plasma-wall interactions is taken into account.

3. Results and discussion

A typical parallel-plate PECVD reactor has been modeled with an inter-electrode spacing of 3 cm at a discharge frequency of 13.56 MHz. The capacitively coupled RF plasma is operated at a total gas pressure of 40 Pa, a power of 5 W and a gas temperature of 400 K, with a gas flow of 20 sccm of pure acetylene or silane. Figure 1 presents the calculated densities of the electrons and the most abundant positive and negative ions in a pure acetylene (a) and a pure silane discharge (b) as a function of position in the plasma. Near the sheaths a slight time variation of the ion profiles can occur, hence, time-averaged electron and ion densities have been plotted.

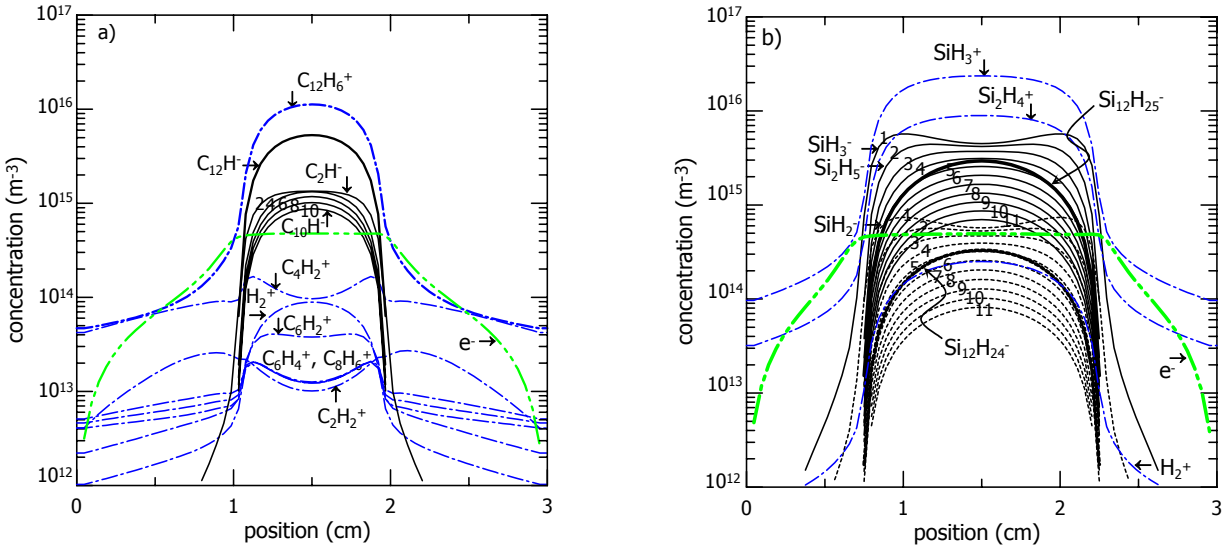

Fig. 1. Density profiles of ions in an acetylene (C_2H_2) discharge (a); and a silane (SiH_4) discharge (b); at a pressure of 40 Pa, a power of 5 W and 13.56 MHz.

In the acetylene plasma (Fig. 1a) two different pathways involving positive or negative ions, respectively, can be distinguished. The number indicated on every anion plot specifies the number of carbon atoms. In each pathway a gradually decreasing trend can be observed with increasing number of carbon atoms. This is in good agreement with the observed mass spectra in [12] where the same trend can be detected. In the model both chains are stopped at hydrocarbon ions containing 12 carbon atoms. Therefore, $C_{12}H_6^+$ and $C_{12}H^-$ appear to be the most prominent species formed in the plasma which represent the final accumulating stage and thus symbolize the sum of all larger cations or anions, respectively. Since most cation-acetylene reactions proceed at a rate close to the collision limit (see above) lower concentrations of the intermediate hydrocarbon positive ions are produced in comparison to the intermediates in the anion chain, where the reactions proceed at a rate constant close to

10^{-18} m^3 s^{-1}. The cation density profiles exhibit a lower density in the plasma bulk which is probably a direct consequence of the fast loss processes, i.e. association reactions with C_2H_2, which can not be entirely compensated by the slow movement of the positive ions towards the plasma center. In the figure only the most dominant positive hydrocarbons are shown. Other positive ions formed through the dissociative ionization of acetylene, i.e. C^+, C_2^+ and CH^+, reach a concentration of approximately 10^{10} m^{-3} (not shown). $C_4H_2^+$ appears to be the most abundant positive ion followed by $C_6H_2^+$ and $C_6H_4^+$. This is also seen in mass spectra which peak at ions containing 4 and 6 carbon atoms.

For comparison the electron and ion profiles in a silane plasma are shown in Fig. 1(b). The major positive ion appears to be SiH_3^+ with a density of about 2 x 10^{16} m^{-3} in the center of the discharge. In experimental data no cation powder route can be observed, hence, only two other positive ions are considered in the model, i.e. $Si_2H_4^+$ and H_2^+. For the anions, however, two different routes can be discerned, starting from either SiH_3^- or SiH_2^- [see Eqs. 1(a) and 1(b) above]. Similar to the acetylene plasma, the anions are mostly confined to the bulk of the discharge since they are repelled by the high electric fields in the plasma sheaths, and they show a general decreasing trend towards larger numbers of silicon atoms (apart from the final $Si_{12}H_{25}^-$ and $Si_{12}H_{24}^-$ stages which represent the sum of all larger anions). The rate coefficient for the anion reactions (~10^{-18} m^3 s^{-1}) is similar to the one used in the acetylene anion chemistry. It is clear from Fig. 1(b) that mainly the SiH_3^- pathway, represented by solid lines, will create higher mass silicon hydrides and less than 10% of the particle formation proceeds through the SiH_2^- pathway, depicted by dashed lines.

In Fig. 2 the calculated concentrations of the various hydrocarbon molecules (a) and radicals (b) in the acetylene discharge are shown at the same conditions as discussed above. The densities of the background neutrals are homogeneously distributed over the entire reactor and are produced in larger amounts compared to their corresponding radicals. Similar to the ion density profiles higher mass hydrocarbon molecules show a decreasing trend with increasing number of carbon atoms.

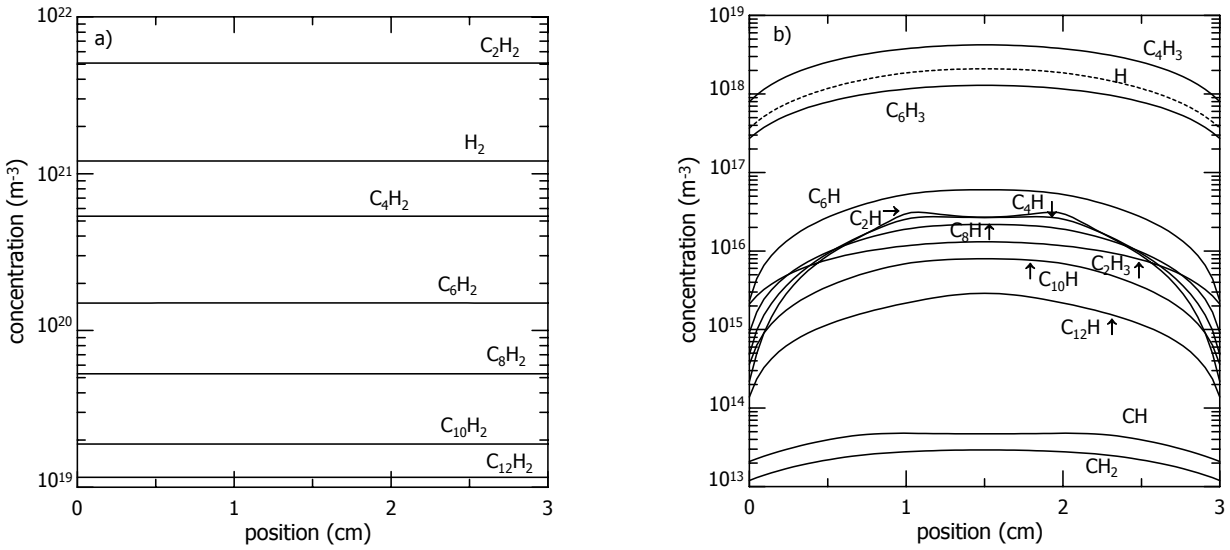

Fig. 2. Density profiles of the various hydrocarbon molecules (a); and radicals (b) in an acetylene discharge; at a pressure of 40 Pa, 5 W and 13.56 MHz.

The acetylene background gas is present at the highest density and takes a value of 4 x 10^{21} m^{-3}. Other non-ionic gaseous products that can be found at high concentrations in the acetylene discharge are diacetylene (C_4H_2) and molecular hydrogen. The high H_2 concentration comes from the many chemical reactions that produce molecular hydrogen as a side product (see above).

All twelve radicals are depicted in Fig. 2(b) and mostly encompass carbon rich species C_nH_m (with n > m). The radicals are typically characterized by their decreasing density towards the electrodes, representing their reactivity at the walls. A large amount of atomic hydrogen is present with a density of ~ 1 x 10^{18} m^{-3}.

From our results we can conclude that more pathways towards dust formation exist for acetylene plasmas. Indeed, both positive ions, starting from $C_2H_2^+$, and negative ions, starting from C_2H^-, derived from acetylene may participate as precursors to dust formation, while in silane processing discharges the anions, and more specifically SiH_3^-, are the likely precursors of powder formation. Once the particles reach the nanometer size the negative ions will however probably again persist as the most important dust precursors, since they remain trapped in the discharge due to their large negative charge, while the positive ions will likely be extracted from the discharge before they can grow any further.

Abstract
The work is focused on investigation of chemical processes occurring during the diaphragm discharge in water solutions, especially on production of various chemical active species (hydrogen peroxide, hydroxyl radicals) and on degradation of organic compounds (dyes) dissolved in water. All processes are investigated for various discharge conditions (applied voltage, initial conductivity of the solution, used electrolyte, diaphragm parameters, electrode material etc.). Chemical analyses are complemented with electrical measurements.

Keywords: discharge in water, degradation of organic compounds, hydrogen peroxide

1. Introduction

Discharges generated in liquids have a special position among the plasma sources. Various active chemical species such as hydroxyl radicals, hydrogen and oxygen atoms, hydrogen peroxide etc. are produced by this kind of discharge [1]. These active species initiate many further chemical reactions. Therefore the processes taking place in such discharges can be applied in fields of water treatment, surface treatment etc. Especially the destruction of various organic pollutants or organic dyes dissolved in water and specific reactions in liquid phase are currently the main research fields of discharges in liquids [1, 2].

The most common discharge configurations used for the discharge creation in previous works of many authors are point-to-plane [1] and coaxial [3], several experiments were done in diaphragm (electrode-less) configuration [4, 5]. During almost all of these experiments, a pulsed high voltage in range from about 10 to 20 kV was used to create the discharge.

This work focuses on the diaphragm discharge created using the non-pulsed DC high voltage with the tension of about 2 kV only. Such discharge is also called "electrode-less" [4] because it is created in a small pinhole in the centre of the dielectric diaphragm in a relatively great distance from the high voltage electrodes (2 cm). The dielectric diaphragm is placed between two plane electrodes [6]. When the DC voltage is used, different plasma channels (so-called streamers) are created in both parts of the reactor (Fig. 1). These streamers have converse polarity and differ in their structure, shape, velocity of propagation and energy of electrons [4].

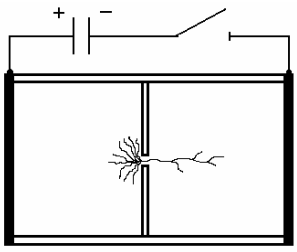

Fig. 1: Scheme of the diaphragm discharge principle with different plasma channels in the parts of the reactor.

2. Experimental setup

A special batch discharge reactor was used in experiments. Its simplified scheme is shown in Fig. 2 and it was described in details in [7]. It consisted of two chambers divided by a dielectric diaphragm (PET). A small pinhole (initially with the diameter of 0.25 mm) was localised in the centre of this diaphragm. During the discharge the pinhole slightly enlarged its diameter and the edges became corroded. In the case of some tested diaphragm materials, the increase in the diameter was too rapid, therefore it was not convenient to create the discharge. Each chamber contained a planar electrode (stainless steel or platinum), a cooling box with a mixture of ice and water, a defined volume of electrolyte (1500 ml) and a mixing system that ensured homogenous conditions. The electrodes were arranged in the distance of 4 cm symmetrically with respect to the dielectric diaphragm. To generate high voltage and to create the discharge, a non-pulsed DC high voltage source (1-3 kV) was applied.

In experiments where production of hydrogen peroxide by the discharge was studied, it was important to ensure the liquid temperature of about 15°C in the whole volume because in the case of the temperature close to 30°C and higher, hydrogen peroxide was thermally decomposed to hydroxyl radicals.

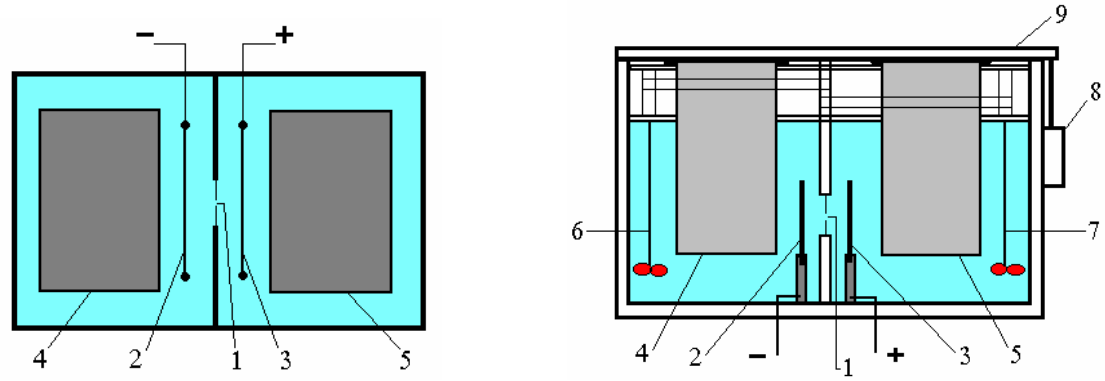

Fig. 2: A simplified scheme of the discharge reactor – a platform (left) and a side view (right): 1 – diaphragm with pinhole, 2 – cathode, 3 – anode, 4, 5 – cooling boxes, 6, 7 – stirrers, 8 – security pin, 9 – security top.

Demineralised water containing electrolyte of defined concentration (NaCl, Na_2HPO_4) was used to obtain the solution of defined initial conductivity (optimum 300-700 $\mu S \cdot cm^{-1}$). Various organic dyes dissolved in water and of various structure, colour, origin and purpose of use were used in experiments. The concentration of the used dyes varied from 1 to 20 $mg \cdot l^{-1}$. As most of the organic dyes were not electrolytes, it was necessary to add extra electrolyte of a defined amount to the solution.
Concentration of hydrogen peroxide produced by the discharge was determined by colorimetric method using a specific reaction between H_2O_2 and titanium reagent [8]:

$$Ti^{4+} + H_2O_2 + 2H_2O \rightarrow TiO_2 \cdot H_2O_2 + 4H^+ \qquad (1)$$

The yellow-coloured peroxotitanyl complex was determined by UV-VIS spectroscopy at 407 nm, hydrogen peroxide concentration in this complex was directly proportional to its absorption intensity. Concentration of organic dyes in the solution was also determined by photometry. Generation of hydroxyl radicals was observed by the optical emission spectroscopy. Electric measurements using the oscilloscope were carried out to ascertain the character of the discharge.

3. Results and Discussion

A series of electric investigations, done by two probes installed in the circuit and measured a discharge current, had ascertained the real discharge character. Figure 3 shows the real evaluation of the discharge current, voltage and resistance in time. Although the continuous DC high voltage was used to create the discharge, the evaluation of electric characteristics is not completely non-pulsed and we have estimated it as quasi-pulsed. This phenomenon is probably caused by the mechanism of creation of the diaphragm discharge (i.e. creation in the pinhole) and it can be explained by the thermal (bubbles) theory [8]. This theory is based on the fact that liquid in the region of a high electric field (it means in the pinhole) is heated and starts to boil, the bubbles appear and the breakdown is created in these bubbles of evaporated liquid. So the discharge is in fact generated in the gas phase. A very important phenomenon is that the bubble is expanding and in quite a short time it is disappearing along with the discharge. But immediately, a new bubble is created and a new breakdown appears. When the bubble (with the discharge) exists, the discharge current is high and resistance very low. But if the bubble vanishes and the discharge is switched off, the discharge current decreases and, on the other hand, the resistance rapidly increases, all with high repetition. Therefore the discharge character is quasi-pulsed.

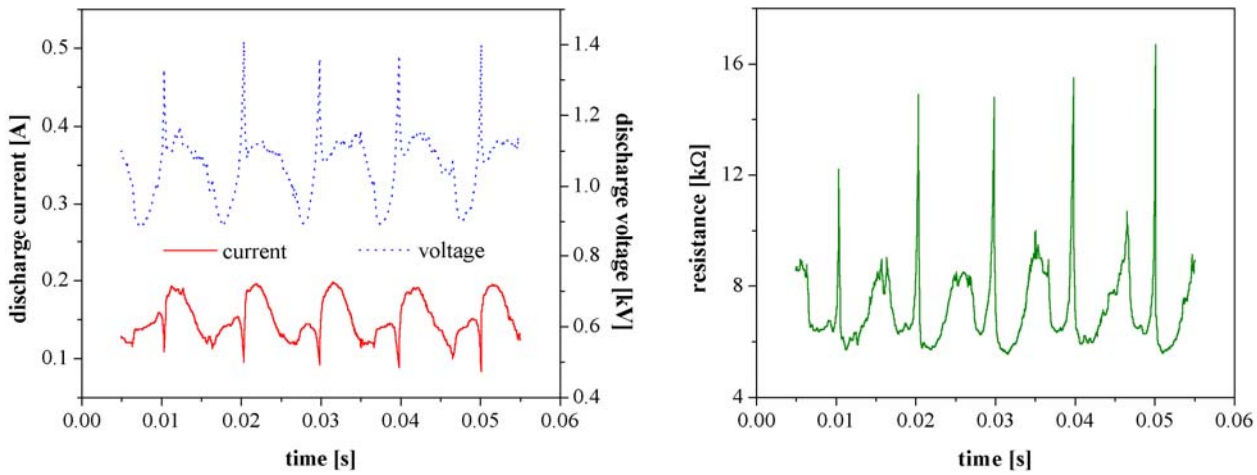

Fig. 3: Evaluation of the discharge current and voltage (left) and discharge resistance (right) in time (3,7 mM Na_2HPO_4, the initial conductivity of 700 $\mu S \cdot cm^{-1}$).

The investigation of hydrogen peroxide generation by the DC diaphragm discharge in water solutions has already been an object of our study in some previous works [6, 7]. This contribution extends the dependencies of hydrogen peroxide concentration on the initial discharge conditions. A special view is focused on the material of the dielectric diaphragm. Several kinds of materials were used in experiments, varied in their chemical structure and thickness. The rate constants of H_2O_2 creation were calculated as a quantitative parameter characterising each process. They are compared in Table 1. The most convenient material for the hydrogen peroxide generation was PET or PES with the thickness about 0.20 mm. For example PTFE (Teflon®) was not suitable, because this material became very soon mechanically degraded by the discharge and it was not possible to create the discharge.

Table 1: Rate constants of hydrogen peroxide production for various types of the dielectric diaphragm (1.75 kV, 5 mM NaCl, the initial conductivity of 500 $\mu S \cdot cm^{-1}$).

Material	Thickness [mm]	Rate constant [$mol \cdot l^{-1} \cdot s^{-1}$]
PET	0.25	$3.750 \cdot 10^{-7}$
PES	0.05	$1.167 \cdot 10^{-7}$
PES	0.19	$3.600 \cdot 10^{-7}$
PTFE	0.50	unmeasurable
PTFE	1.00	unmeasurable
POM-C	1.00	$4.667 \cdot 10^{-8}$

Generally, production of hydrogen peroxide by the discharge in water solution was almost linear in time as it can be seen in Figure 4 (right). The generation of H_2O_2 was also highly dependent on the discharge polarity. In the case of the one-hour positive discharge treatment (i.e. in the part of the reactor with the cathode!), the final concentration of H_2O_2 was approximately 1.8 $mmol \cdot l^{-1}$ (about 60 $g \cdot l^{-1}$), in the opposite polarity, the amount of hydrogen peroxide was only about 0.3 $mmol \cdot l^{-1}$ (about 10 $g \cdot l^{-1}$), i.e. six times lower. The comparison with another process, a degradation of organic compounds by the discharge, is described below.

At present, our work is focused on the investigation of the degradation force of the electric discharge in water, which is caused mainly by the active species (especially hydroxyl radicals and hydrogen peroxide). One of these processes is decolorisation and degradation of organic dyes dissolved in water [9]. This process is, of course, dependent on initial discharge conditions, for example on the discharge polarity, applied high voltage etc.

Several organic dyes differed in chemical structure, colour and purpose of used (for textile dying, in food industry etc.) were used. Water solutions of each dye (the initial concentration from 6 to 20 $mg \cdot l^{-1}$) were carried out with a defined amount of electrolyte (NaCl, Na_2HPO_4) to obtain the required solution conductivity. A typical evaluation of the dye concentration during the discharge treatment is shown in Figure 4 (left). This figure shows the relative concentration decrease of the dye Evans Blue. The degradation was dependent on the discharge polarity because the decolorisation process was more significant in the negative discharge treatment than in the positive one. The concentration of Evans Blue became less than 10% after 30 minutes in the negative discharge. In the positive discharge, the concentration was about 30% after 100 minutes.
The comparison with hydrogen peroxide generation (Fig. 4 right) gives very interesting results. In the case of the positive discharge treatment, the production of H_2O_2 was higher than in the negative one and therefore we had expected more significant decolorisation in the positive discharge. But the experiments gave opposite results! This phenomenon is an object of our contemporary study and we hope it will be solved soon.

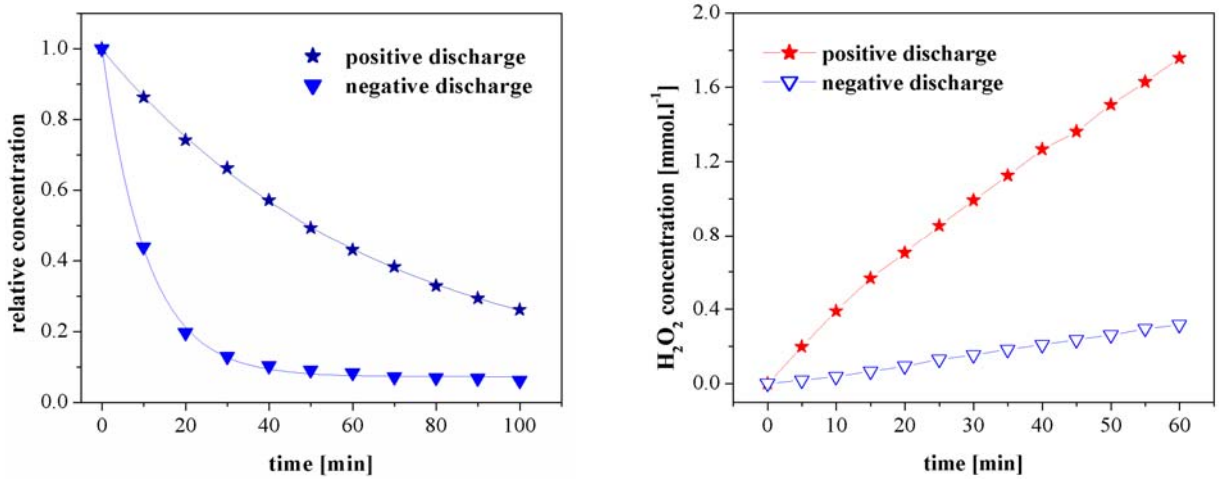

Fig. 4: Evans Blue dye decolorisation (left) and hydrogen peroxide generation (right) in time as a function of applied voltage polarity (2.45 kV, 5 mM NaCl, 500 $\mu S \cdot cm^{-1}$).

The process of organic dye degradation was investigated as a function of various parameters. One of them was a chemical structure of used dyes. Five different compounds were treated by the discharge and their concentration decreases during the discharge treatment are shown in Figure 5.

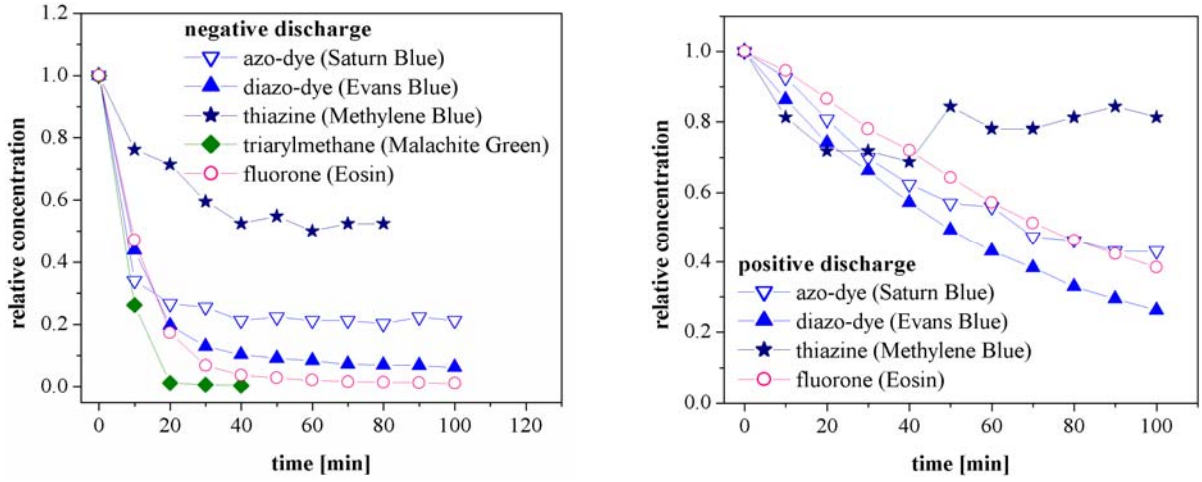

Fig. 5: Comparison of the concentration decrease for various organic dyes solutions treated by the negative (left) and positive (right) discharge (2.45 kV, 5 mM NaCl, 500 $\mu S \cdot cm^{-1}$).

The comparison is given for both negative (left) and positive (right) discharge polarity. The fastest decrease of concentration was observed in the case of Malachite Green that was ranked among triarylmethane dyes. Its concentration became nearly zero in the first twenty minutes of the discharge. All investigated dyes except Methylene Blue had more or less similar evaluation of the degradation process. Generally, it started with a quite fast decolorisation in the negative discharge but after twenty minutes of the experiment, the concentration decrease was not very significant. The final concentration of the studied dyes became lower than 20% of the initial dye concentration after 100 minutes of the experiment. In the case of Methylene Blue, a thiazine, the process of decolorisation was much slower and the final concentration did not even reach 50%.

Another parameter investigated in our experiments was the applied high voltage. The dependence of the processes in the discharge on the voltage polarity is discussed above, the influence of the voltage magnitude on investigated processes is given in Figure 6. The dependence of hydrogen peroxide concentration after one-hour discharge treatment (Fig. 6a) was increasing with the increasing applied voltage and it was also almost linear. The production of hydroxyl radicals by the discharge was proportional to the high voltage (Fig. 6b). The OH emission intensity was also dependt on the electrolyte and on the initial solution conductivity. The most significant dependence was observed in the case of NaCl solution with the initial conductivity of 400 $\mu S \cdot cm^{-1}$.

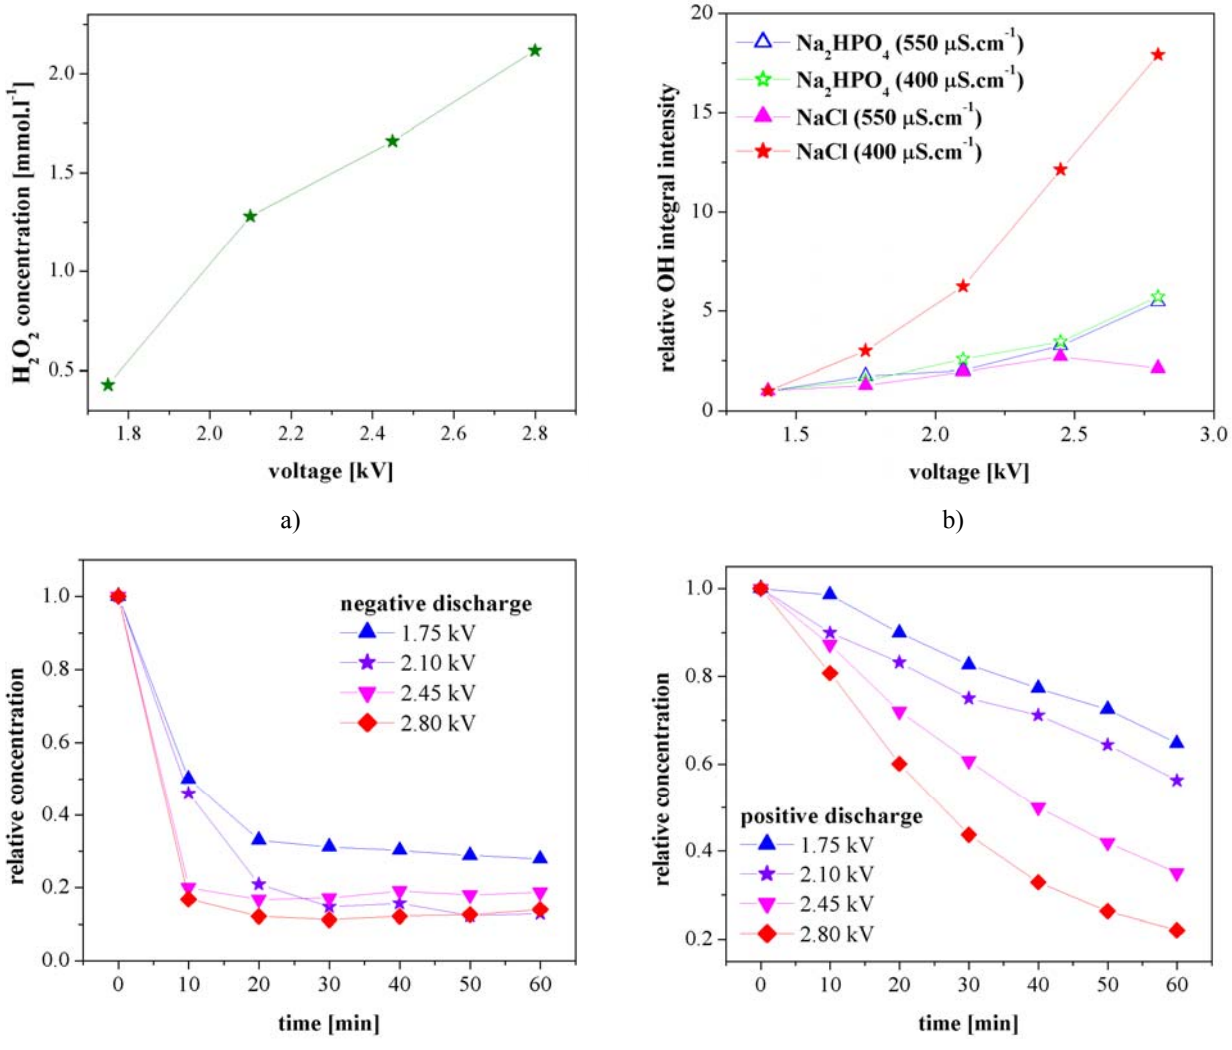

Fig. 6: Influence of the applied high voltage on the production of a) hydrogen peroxide, b) hydroxyl radicals and c) on degradation of the organic dye Saturn Red (5 mM NaCl, the initial conductivity of 500 $\mu S \cdot cm^{-1}$).

The time evaluation of the relative dyes concentration as a function of the applied voltage is shown in Figure 6c. The comparison is given for both negative (left) and positive (right) discharge treatment of the water solution of Saturn Red dye. While in the case of the lower applied positive voltage (1.75 kV) the dye was decomposed to only 65% of the initial concentration, in the case of the higher positive voltage magnitude (2.80 kV), the concentration became about 25% of the initial concentration. The voltage dependence did not cause a significant difference in the negative discharge polarity. Generally, the investigated processes, such as production of reactive species (hydrogen peroxide, hydroxyl radicals) and degradation of organic compounds (organic dyes) in the diaphragm discharge were highly dependent on the applied voltage.

4. Conclusion

This contribution has described selected chemical processes occurring during the diaphragm discharge in water solutions, namely the production of chemical active species (hydrogen peroxide, hydroxyl radicals) and the degradation of organic compounds (dyes) dissolved in water. The processes were investigated for various discharge conditions (applied voltage, initial conductivity of the solution, used electrolyte, diaphragm parameters). Chemical analyses were completed with electric and optical measurements.

The series of electric measurements ascertained the real character of the diaphragm discharge. It was estimated as quasi-pulsed. This character was probably caused by the discharge creation mechanism in the pinhole.

Hydrogen peroxide was produced by the diaphragm discharge in water solutions. Its concentration increase in time was almost linear and was influenced by the applied voltage and by parameters of the dielectric diaphragm (its material and thickness). The most suitable diaphragm was made of PET or PES with the thickness of about 0.2 mm. The production of hydrogen peroxide was more significant in the positive discharge polarity, its concentration became about 60 $g \cdot l^{-1}$ after one-hour experiment. The dependence on the voltage magnitude was proportional and almost linear. A similar evaluation of the dependence of the process on the high voltage was also observed in the production of hydroxyl radicals. The OH emission intensity increased with the increasing voltage and it was influenced by the used electrolyte and also by the initial conductivity of the solution.

The degradation of organic compounds by the diaphragm discharge was studied in water solutions of selected organic dyes. The decrease of the dye concentration was observed in the both discharge polarities but in the negative discharge the decolorisation was more evident. This was the opposite phenomenon than in the production of hydrogen peroxide. In most of the experiments, the dye decomposition had decreased to the final concentration of less than 20% of initial dyes concentration after 100 minutes of the discharge treatment. Five organic dyes differing in their chemical structure, colour and its purpose of use were compared. A fast decomposition was observed in the solution of Malachite Green. The influence of the magnitude of the applied high voltage was studied, too. The degradation increased with the increasing applied voltage in both discharge polarities.

Abstract
Three new practical exercises oriented on the application of plasma chemical processes are presented. Two exercises for the special practical course are focused on the study of processes in the DC diaphragm discharge in a water solution. The first measurement is the hydrogen peroxide generation, the second part of the task studies destruction of the chosen organic dyes. The third exercise is focused on the plasma treatment of polymers by the surface discharge. The treated and untreated samples are characterised by the surface energy evaluation from the contact angles of 3 different testing liquids with the measured sample. Each of these works can be completed within a relatively short period of 150 minutes.

Keywords: discharge in liquids, diaphragm discharge, practical exercises, surface discharge, plasma treatment, surface energy, contact angle.

1. Introduction

Plasma chemistry is a comparatively new scientific discipline that has became a part of university curricula relatively recently. The discipline can be studied from two rather different points of view. The plasmachemistry courses for physicists are naturally focused on the basic phenomena in plasmas, the courses for chemists focus more on the use of plasma as an instrument for demonstrating various processes. In both of these conceptions, the problem of modern plasmachemical technologies plays only a minor role, although a huge increase of plasmachemical technologies has been observed during the last years. Practical exercises complementing the lectures at universities are normally focused on the basic processes and basic phenomena (studies of DC glow discharge etc.) and on some plasma diagnostic methods. At technical universities, practical exercises are usually in the form of plasma technology demonstrations without an active participation of students.
The curricula at our university include a course in applied low temperature plasma physics and chemistry, where students can obtain the basic information about a theoretical description of plasmas and later about some plasmachemical technologies. Four years ago we prepared a special practical course focused on the applications of low temperature plasma processes [1]. This contribution presents two new practical exercises. Both of them share the main characteristics of the other exercises, the expenses connected with them are reasonable and the degree of their safety gives students a possibility to carry them on. Finally, the experimental plasma devices used in the practical course are simultaneously used also during the work on the students' master and doctoral theses. This in return makes possible the continual enlargement and improvement of the exercises.

2. Diaphragm discharge in liquids

Experimental

A special batch discharge reactor is used in the experiments [2]. It consists of two chambers with one planar electrode in each part. Electrodes are arranged in the distance of 2 cm from the diaphragm. A small pinhole (initially of 0.25 mm) is located in the centre of the dielectric diaphragm. Processes investigated in this discharge are influenced by the material of the dielectric diaphragm and the high voltage electrodes, too. The most convenient material for the diaphragm is PET with the thickness of about 0.2 mm, stainless steel electrodes are suitable for the experiments [3]. The DC non-pulsed voltage source (from 1.3 kV to 1.6 kV) is used to create the discharge [2]. To ensure the homogeneous conditions in the whole volume of liquid, a mixing system is placed in the reactor. Due to the considerable heating of the reactor by the discharge and to prevent the hydrogen peroxide from destruction, two cooling boxes with ice are installed in both parts of the reactor. In the case of organic dyes, the cooling system is not necessary.

Results and Discussion

The experimental studies showed that hydrogen peroxide molecules are one of the main active species for the other processes in the liquid phase [4]. Therefore they are measured also in this practical exercise as a quantitative parameter of the discharge.

The demineralised water containing suitable electrolyte (NaCl, Na_2HPO_4) was used to obtain the defined initial conductivity of the solution (optimal 300-700 $\mu S \cdot cm^{-1}$).

The mechanism of hydrogen peroxide generation by the electric discharge in water is not simple, because the process is a series of subsequent chemical reactions. Partially it was described in [3]. The active species (especially radicals) are produced by the discharge, they can react together to create molecules or they can react with other compounds present in the liquid medium and cause their decomposition. However, we can express the overall reaction of hydrogen peroxide creation by the following equation [5]:

$$2\ H_2O \xrightarrow{disch.} H_2O_2 + H_2. \quad (1)$$

The rate constant of this reaction is $k_{per.}$. Due to the constant water concentration, the reaction is regarded as a zero-order reaction. Thus the final expression for the peroxide concentration is:

$$c_{per.,\,t} = k_{per.} \cdot t, \quad (2)$$

so it increases linearly in time.

The colorimetrical method was used for the hydrogen peroxide determination. The selective titanium reagent in sulphuric acid reacted with H_2O_2 and gave a yellow complex with the maximum absorbance at 407 nm. The hydrogen peroxide concentration in the sample was directly proportional to the absorbance value. This exercise was more suitable for students of chemistry due to the special chemical reagent used in experiments.

The second exercise focused on the organic dyes decomposition by the discharge could be more suitable for students of physics. Different organic dyes in solid phase, varied in colour and structure, and of the defined quantity were solved in demineralised water. The list of suitable dyes with their absorbance maximum is shown in Table 1. These dyes were quite fast decomposed by the discharge and thus this effect was also clearly seen visually. For example, the dye Methylene Blue was not convenient for this experiment because its degradation took more time and its decolorisation was not visible without a photometer.

Table 1: List of organic dyes suitable for the experiment.

Organic dye	**Type**	**Colour**	**Absorbance maximum**
Fluorescein	fluorone	yellow	484 nm
Saturn Red L4B	azo-dye	red	506 nm
Azorubin	azo-dye	red	516 nm
Evans Blue	disazo-dye	blue	592 nm
Malachite Green	triarylmethane	green	621 nm

Chemical active species (especially radicals) produced by the discharge caused the decomposition of organic dyes dissolved in water. This process was visible directly through the decolourisation of the dye [6]. Therefore the degradation can be clearly and simply observed by photometry. The main absorption peaks of these dyes are relatively broad and no significant peaks of the discharge products were observed around the absorbance maxima listed in the Table 1. Due to this fact, the photometer can be replaced by a simple photodiode detector equipped with an interference filter transparent around the absorbance maximum of the selected dye.

Figure 1 shows the H_2O_2 concentration increase during the discharge in water. The production of hydrogen peroxide had almost a linear character in time and it was highly dependent on the discharge polarity. The generation was more significant in the positive discharge. The hydrogen peroxide amount became about 1 $mmol \cdot l^{-1}$, i.e. approximately 34 $g \cdot l^{-1}$. The second process, degradation of organic dye dissolved in water, is presented in Fig. 2. Water solution of the dye Azorubin was treated for 100 minutes by the discharge. The concentration decrease was more significant in the negative polarity, when the concentration became nearly zero already after 40 minutes of the experiment. Therefore the experimental time for the practical exercises can be

shorter, e.g. about only half an hour. The evaluation of the dye decrease was approximately exponential in both discharge polarities. In the case of positive discharge, the final concentration became about 30 % after 100 minutes.

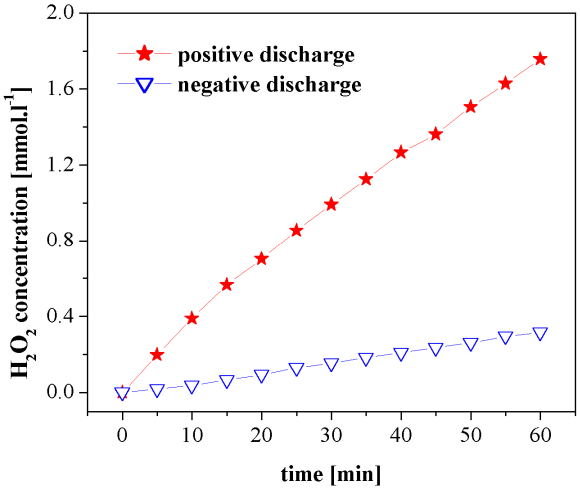

Fig. 1: Production of hydrogen peroxide by the diaphragm discharge in a water solution (146 W, 5 mM NaCl, 500 μS·cm^{-1}).

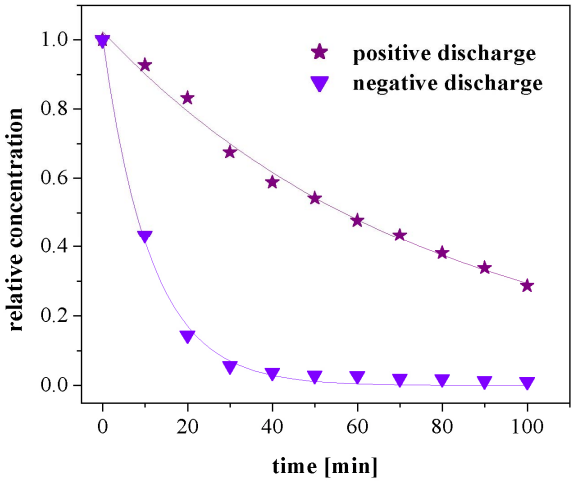

Fig. 2: Concentration decrease of the dye Azorubin during the discharge treatment (146 W, 5 mM NaCl, 500 μS·cm^{-1}).

During the experiments, the changes in both conductivity and pH were observed. Results of these measurements are given in Figs. 3 and 4. The solution conductivity increased in both discharge polarities (Fig. 3). A higher enhancement was observed in the negative discharge (i.e. in the part of the reactor with the anode). This effect can be explained by the production of chemical species by the discharge and by metallic traces involved NEROZUMÍM from electrodes by the electrolysis. Fig. 3 also compares two water solutions – electrolyte NaCl (left) and Saturn Red dye with NaCl (right). The relative increase in conductivity was higher in the pure electrolyte and the difference between the two polarities was also more significant in this solution.

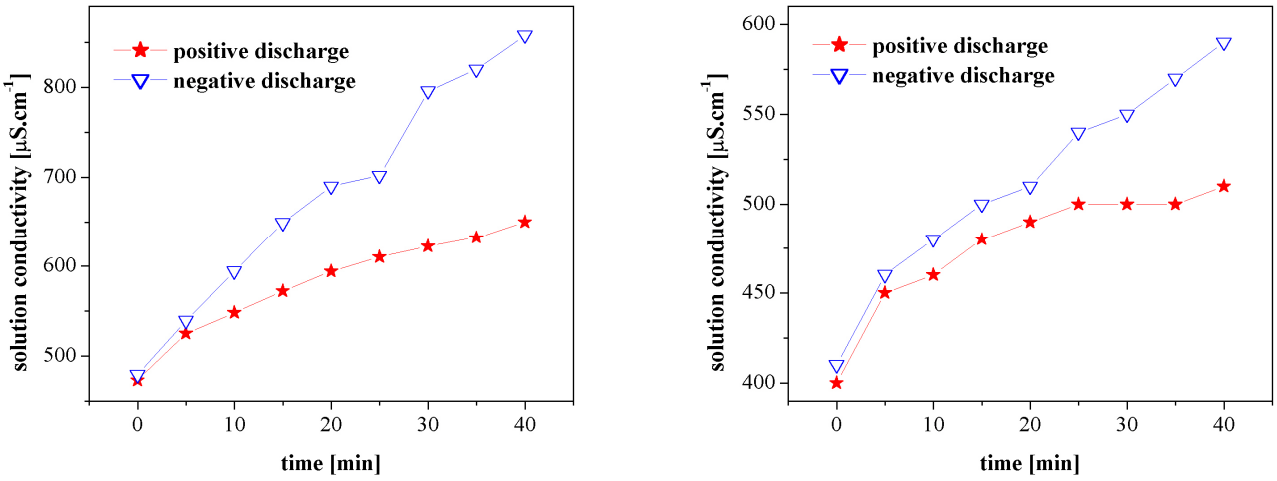

Fig. 3: Change in conductivity during the discharge treatment in a water solution of the electrolyte NaCl (left) and in a water solution of the same electrolyte with the dissolved organic dye (right); 117 W, 4 mM NaCl, Saturn Red dye (12 mg l^{-1}).

Fig. 4 demonstrates the obtained results of pH measurements in both solutions, pure electrolyte (left) and Saturn Red dye with NaCl (right). The time evaluation had similar character in both experiments. While in the positive discharge the pH increased from approximately 6 to almost 10, in the opposite polarity, it had a decreasing tendency (from 6 to less than 4). In the solution with the dissolved dye, the difference in pH was more significant.

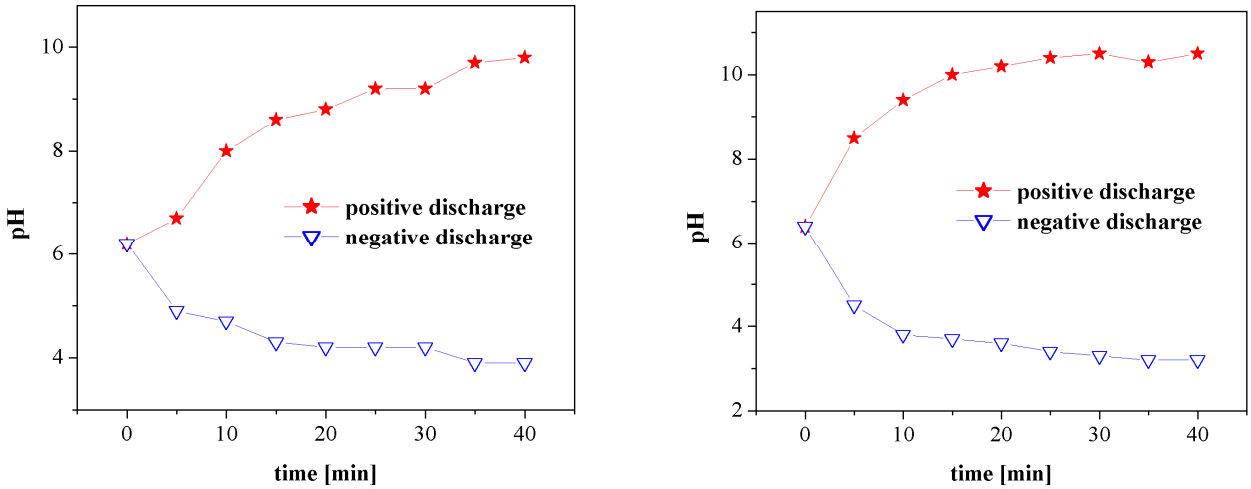

Fig. 4: Change in pH during the discharge treatment in a water solution of the electrolyte NaCl (left) and in a water solution of the same electrolyte with the dissolved organic dye (right); 117 W, 4 mM NaCl, Saturn Red dye (12 mg l^{-1}).

3. Treatment of polymers by the surface discharge

Experimental

The surface modification of the polymers is at present one of the most emerging plasma technologies. Industrial applications prefer the treatment in low temperature plasma at an atmospheric pressure. The surface barrier discharge and diffuse coplanar discharge are very suitable for this purpose.

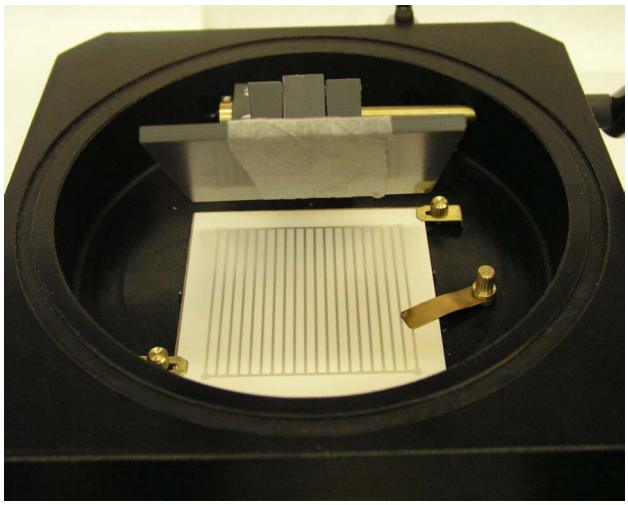

Fig. 5: a) An universal plasma reactor UPS100W. *b) A detail of the discharge electrode.*

A special plasma reactor based on the surface barrier discharge [7] was developed for this application (see Fig. 5). The surface discharge is the non-equilibrium plasma supplied by the high DC voltage with the operation frequency of 7 kHz. The reactor was constructed in order to prevent students from being injured by the high

voltage, therefore the plasma chamber is mounted with a power supply and the electrode is placed under a glass cylinder. Moreover, the device is portable (30x30x35cm). The discharge chamber can be evacuated before the plasma treatment and then filled with pure gases or various gas mixtures. The reactor is constructed only for laboratory tests therefore the treated samples are restricted to the maximal dimensions of 10x10cm. In the real industrial application it is possible to shape the treating unit for a continuous treatment of materials with the width of even more than 1 m. The treatment time can vary from a few seconds up to 20 min, but the electrode and power supply need cooling. The treatment time longer than one minute is not necessary during the exercises (see below) therefore the supplementary cooling is not integrated in the reactor.
Students investigate the effect of treatment time on the surface properties of samples (polyethylene and polyester plates). Smooth materials are used for easier characterisation of the surface energy. The discharge is burning in separate rows parallel with the electrodes and thus the treatment is not homogeneous over the whole sample, if the sample is not moved through the reactor. The width of the treated rows is about 3 mm and it is sufficient for the treatment characterisation. The treatment time of both used materials is up to 60 s, a longer treatment is not recommended due to a thermal deformation of the samples that significantly decreases the treatment homogeneity.
The treated and untreated samples are characterised by the surface energy evaluation from the contact angles of 3 different testing liquids with measured sample. Surface energy evaluation is provided by the means of Surface Energy Evaluation System (SEE System) [8]. Inexpensive and fully computer-controlled setup allows to measure contact angles of various testing liquids with the sample surface and to calculate the surface energy using different models. The acid-base model was applied in our case [9, 10]. The setup is also equipped with a complete analysis of errors.

Results and discussion

The experimental results are shown in Fig. 7. It can be seen that the contact angles of the selected liquids decrease with the increase of the plasma treatment time. This effect is most remarkable in the case of distilled water, i.e. the hydrophylity of both materials increases. The main changes can be observed during the first 30 seconds, later the changes are not so high. Both figures clearly demonstrate also the problem with the surface energy estimation. The contact angles at longer treatment times are similar for the used liquids. The contact angles also have significant experimental errors that result from the inhomogeneity of the static plasma treatment. This causes the high errors in the calculated surface energies (see Table 2 below).

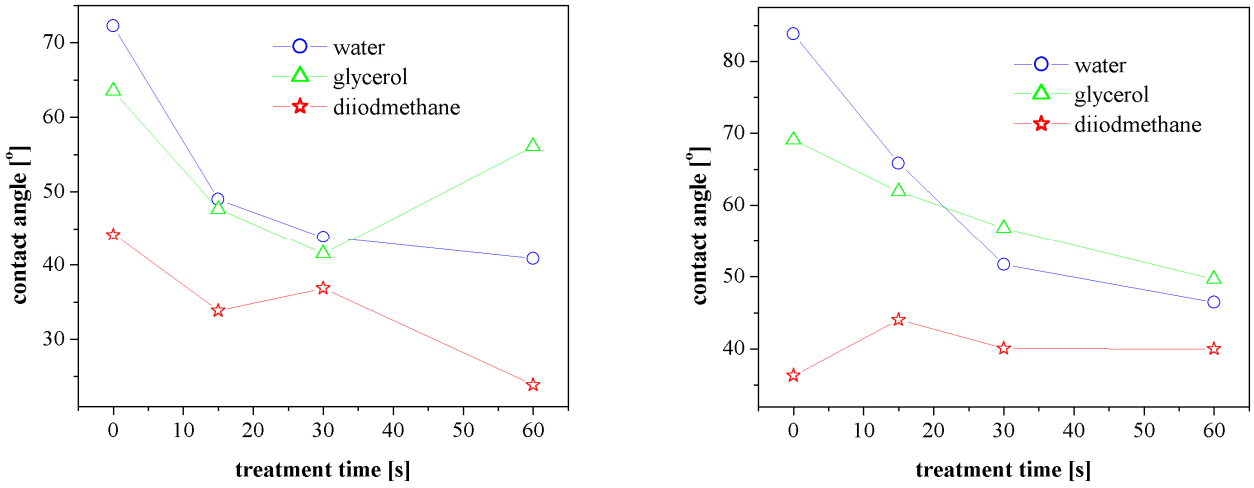

Fig. 7: Dependencies of the contact angle for various liquids as a function of the treatment time; left – polyethylene, right – polyester.

Table 2: Calculated surface energies of plasma treated polyethylene and polyester samples.

Material	treatment time [s]	Total surf. energy [mJ·m^{-2}]	Disperse component [mJ·m^{-2}]	Polar component [mJ·m^{-2}]	Acid component [mJ·m^{-2}]	Basic component [mJ·m^{-2}]

4. Conclusions

The practical exercises described in this contribution are a part of a special practical course focused on applied low temperature plasma-physical and plasma-chemical processes. The first exercise consists of two parts investigating the processes in the DC diaphragm discharge – hydrogen peroxide generation and organic dyes degradation. The experimental basis of this exercise is mostly very cheap, and thus the device can easily be installed anywhere. The diagnostic methods presented above are based on the apparatus available to us and they can be replaced by other methods as it was proposed.

The second exercise is focused on the treatment of polyethylene and polyester by the surface discharge. The contact angles of the selected liquids are measured as a function of treatment time up to one minute. On this basis the changes of the polymer surface energy are calculated. The whole experimental equipment is inexpensive and as safe as possible, and thus it can easily be used anywhere.

Each of the presented practical exercises can be completed within 150 minutes without any significant problems. These practical exercises show students new directions in the plasma-chemical processes and technologies. They are fully interdisciplinary, a good knowledge of both physic and chemistry is necessary. A further extension of our course is planed in the near future.

THERMAL PROPERTIES OF GRAVITY-FREE ARC DISCHARGE AND ITS APPLICATION TO PRODUCTION OF CARBON CLUSTERS

T. Mieno, D. Kato, A. Yamashiro

Department of Physics, Shizuoka University, 836 Ooya, Shizuoka-shi, 422-8529, Japan

Abstract

Diffusion properties and gas temperature around a DC arc discharge are analyzed related with the carbon-cluster production. By means of parabolic flight of a jet plane, the gravity-free arc discharge is carried out. The point symmetric temperature distribution and slow diffusion of carbon clusters are clearly observed under the gravity-free condition.

Keywords: gravity-free arc discharge, production of carbon clusters, thermal property, nanotubes, fullerenes, heat convection, cooling process

1. Introduction

Carbon clusters are produced by the arc discharge method, where strong heat convection flows up sublimated carbon atoms immediately, and the reaction time is restricted. The cooling and cohesion process of carbon clusters is important for the production of fullerenes and carbon nanotubes. In order to examine the effect of gravity and heat convection for the arc production, a 12-m-high vertical-swing-tower was constructed, and endohedral metallo-fullerenes and single walled carbon nanotubes (SWNTs) [1, 2] were produced under repetitive gravity-free condition. From this experiment dramatic increase of production efficiencies of metallo-fullerenes and SWNTs was obtained.

In order to make clear this gravity effect [3], gas temperature distribution under the gravity-free condition is investigated by use of parabolic flight of a jet plane, and the result is compared with that of the normal gravity condition [4]. Production place and diffusion characteristics of carbon clusters around the arc are measured by the Mie scattering method.

2. Theory

When carbon particles are produced at the center of the spherical coordinate and they diffuse isotropically without reaction with diffusion coefficient D_C, the equation of continuity is written as,

$$\frac{\partial n_c}{\partial t} = D_c \frac{1}{r}\frac{\partial}{\partial r}\left(r \frac{\partial n_c}{\partial r}\right) \quad , \tag{1}$$

where n_C is density of carbon molecules. In the steady state condition, the density profile and the particle flux J_C are written as

$$n_c = C_1 \ln(r) + C_2 \quad , \tag{2}$$

$$J_c = -\frac{C_3 D_c}{r} \quad , \tag{3}$$

where C_i shows some constant value. When the carbon clusters diffuse in He gas, their diffusion coefficient D_{cHe} is written as,

$$D_{cHe} = C_4 \frac{T^{3/2}}{\sqrt{m_c}\, d_c^2\, p_{He}} \quad , \tag{4}$$

where T is the gas temperature, m_C is the averaged cluster mass, d_C is the averaged cluster diameter and

p_{He} is He pressure. From this equation, radial diffusion velocity of carbon clusters can be estimated. Figure 1 shows the calculation results of diffusion velocities of C_2 and C_{60} molecules versus He pressure (where T_{He}= 5000 k and r= 3 cm and the chamber size is same as the experimental chamber). The natural convection velocity of He, by which all the carbon clusters are brought up, is calculated by the fluid simulation program (SMAC method) using a UNIX computer and the result is shown in the same graph. From these calculations it can be predicted that heavier and larger carbon clusters much more slowly diffuse under the gravity-free condition. As the gas temperature monotonically decreases at the edge of the plasma flame, big carbon clusters cool down much more slowly under the gravity-free condition.

From the fluid simulation, time evolution of temperature contour of He gas around the arc flame can be calculated. Figure 2(a) shows the temperature contour under the gravity-free condition at t= 1.0 s after the arc start, where p= 40 kPa and the region of T=500-5000 k is shown. Under this gravity condition the hot gas reagion monotonical expands isotropically, and it takes much time to be a steady state. Meanwhile, under the normal gavity condition, temperature contour is calculated as Fig. 2(b), where t= 0.6 s, p= 40 kPa and the region of T=500-5000 k is shown. Under this gravity condition, the temperature contour immediately becomes a steady state, and thereafter there is almost no change. The particles and the thermal energy are continuously brought to the upper- end boundary.

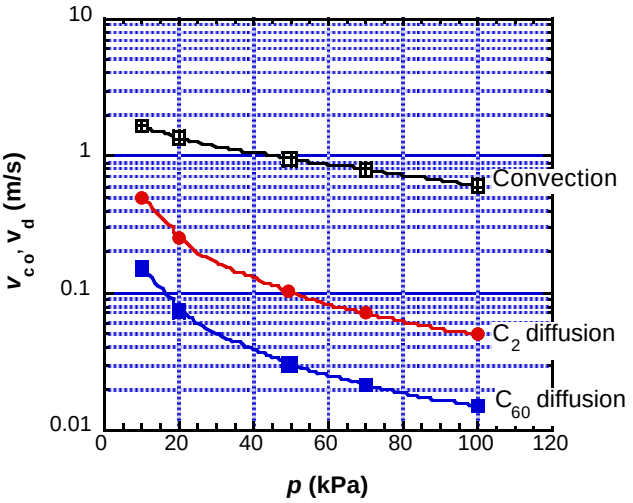

Fig. 1 He pressure dependence of thermal difusion velocities and heat convectino velocity. Calculation for T= 5000 k and r= 3 cm.

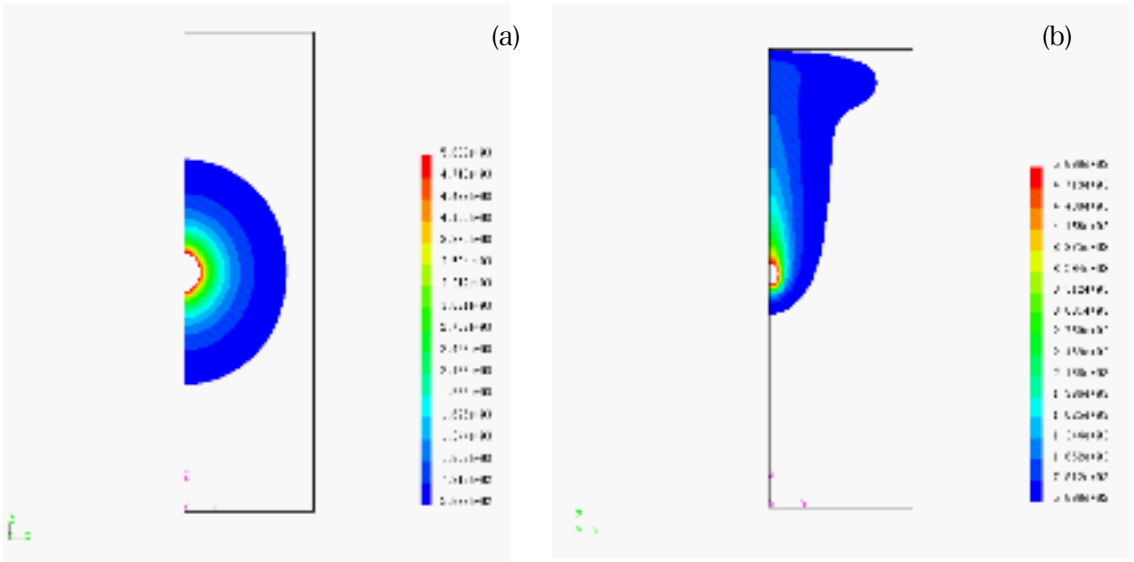

Fig.2. Simulation results of temperature contours (T= 500-5000 k) for the two gravity conditions. (a) G= 0, t= 1.0 s, p(He)= 40kPa. (b) G= 1g_0, t= 0.6 s, p(He)= 40 kPa.

3. Experimental setup and method

All the experimental setup is installed in one aluminum rack as shown in Fig. 3, which is specially prepared for a jet plane (Grumman G-II operated by Diamond Air Service, Japan). A pumping system, a gas-feeding system, a DC power supply, a video camera, an array of thermocouples and a recording system are installed. In a cylinder-type arc reactor of 11.5 cm***f***, 19.4 cm high, two carbon electrodes are set. After evacuation, He gas is introduced and the reactor is closed.

When the jet plane starts parabolic flight and the gravity becomes zero, the arc is turned on by an operator and kept for about 40 s (20 s of the gravity-free time, $G = 0$, and 20 s of $G = 1.5\ g_0$), where time dependence of the vertical distribution of gas temperature over and under the arc is measured by 11 thermocouples. The analog data are digitized by a special AD converter and stored in a computer. At the right upper side of Fig. 3, a typical arc flame (side view) is shown.

In order to make clear the production place of carbon clusters and their diffusion speed, the passive-type Mie scattering method is utilized. By using a metal-obstacle plate, the direct light from the arc flame is cut and scattered light from the produced carbon clusters is recorded by a video camera, by which a vertical profile of the produced carbon clusters and their diffusion can be observed.

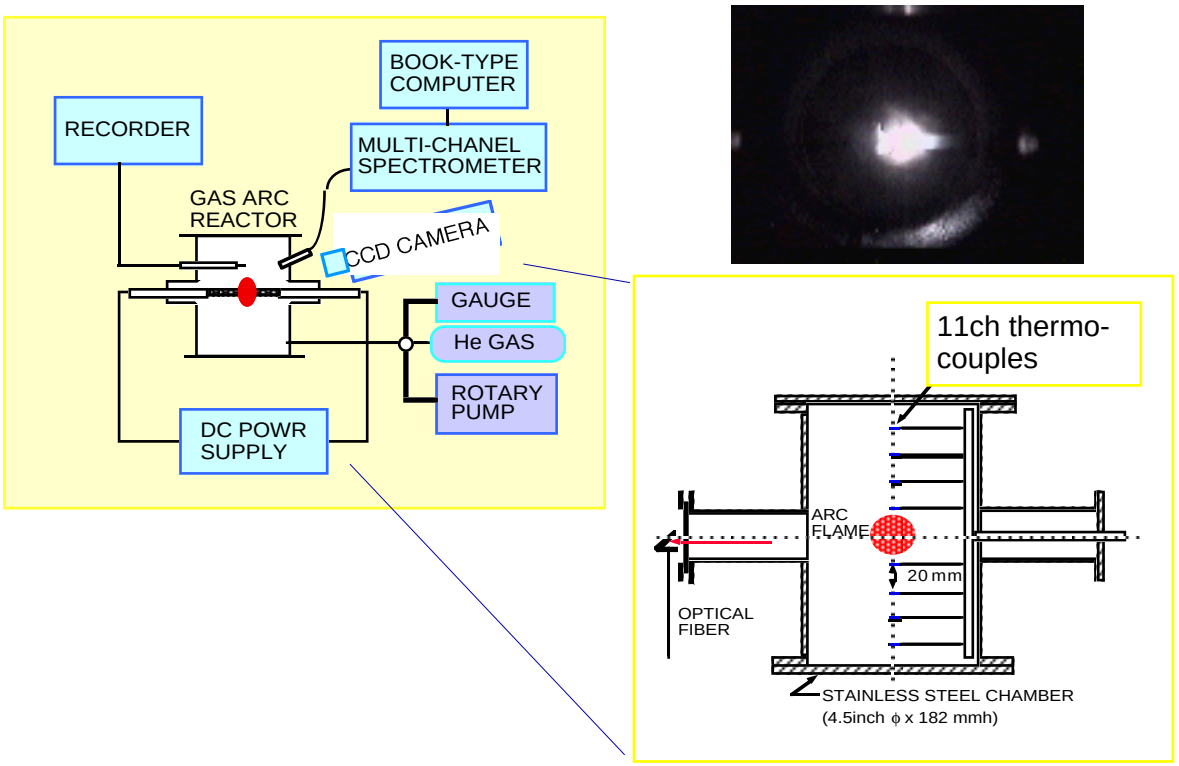

Fig. 3 Schematic of experimental setup set in a jet plane. A typical photo of the arc is shown at the upper right side.

4. Experimental results and discussion

Typical time variation of gas temperatures over and under the arc are shown in Fig. 4, where $p = 40$ kPa, and $I_d = 40$ A. When the gravity becomes zero from 2 g_0, the arc is turned on. After about 45 s, the arc is turned off (20 s of 0 g_0 and 25 s of 2 g_0). The clear gravity effect is recorded.

Figure 5 shows gas temperature distributions under the gravities $G = 0\ g_0$ and $1.5\ g_0$, where He pressure $p = 40$ kPa and discharge current $I_d = 40$A. When the gravity becomes 0, the arc is turned on, and hot gas region monotonically and symmetrically expands with the arc time Dt. It is conjectured that the heat flow is suppressed under the convection-free condition and the generated ohmic heat tends

to be accumulated, which makes spherical large-volume hot-gas region. The model of the temperature contours is shown on an upper inset, which is consistent with the simulation result. It is confirmed that the steady-state, spherical hot-gas region with large volume can be generated under the longer gravity-free condition, which can be realized by longer gravity-free time than 20 s. Figure 6 shows typical expansion speed of temperature contour of T= 500 k as a function of He pressure. The expansion speed is very slow and it does not become zero within 20 s. Under the normal gravity condition, the steady-state convection flow is immediately formed and the thermal energy continuously diffuse to the upper region. Therefore, the hot gas region is not symmetrical and has small volume, which is also consistent with the simulation result.

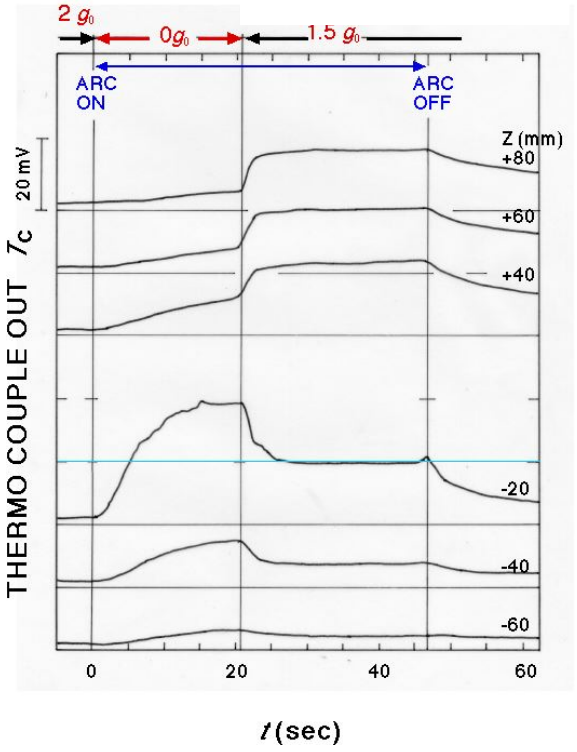

Fig. 4 Typical time variation of thermo-couple outputs at 6 postion over and under the arc. p(He)= 84 kPa and I_d= 40 A.

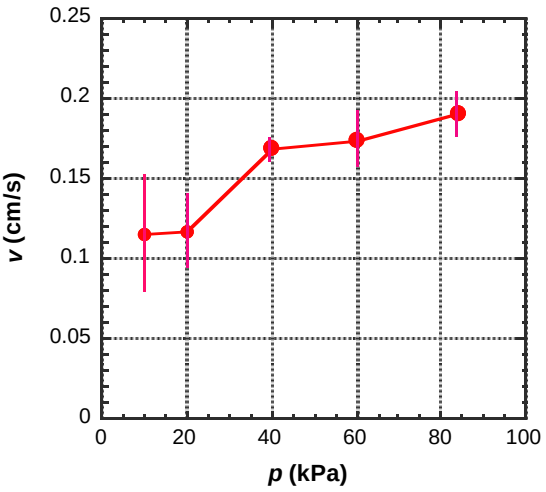
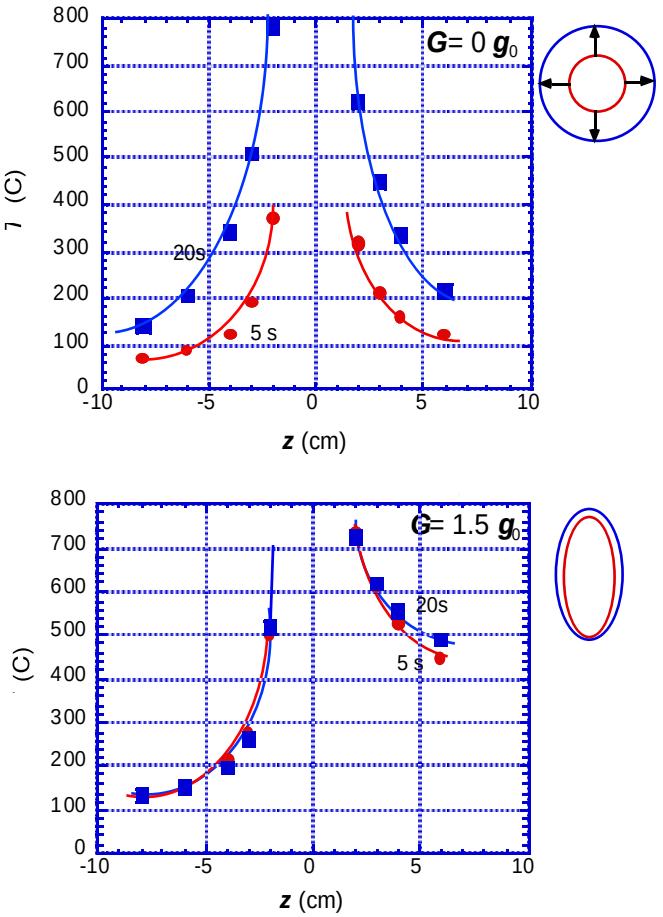


(a)



(b)

Fig. 5 Vertical temperature distributions over and under the arc at Δt= 5 s and 20 s after gravity becomes 0 (a) and after gravity becomes 1.5 g_0 (b). p(He)= 40 kPa and I_d= 40 A.

Fig. 6 Typical expansion speed of temperature contour of T= 500 k versus He pressure, when the gravity-free arc is turned on. I_d= 40 A.

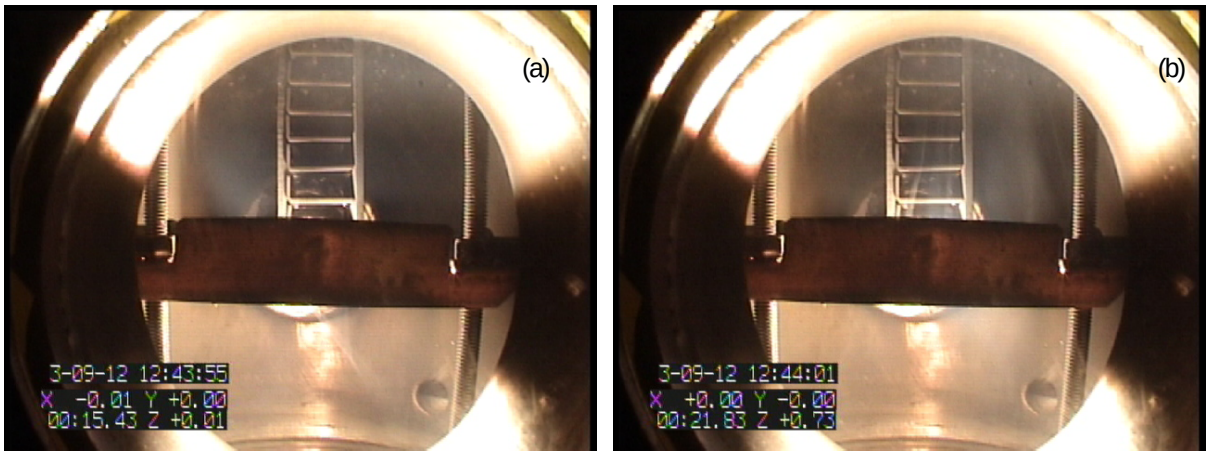


Fig. 7 Photos of scattered light by the Mie scattering taken from a side port. SWNTs are synthesized around the arc flame. p(He)= 40 kPa, I_d~ 50 A. (a) under 0 g_0 and (b) under 1.5 g_0.

By using an obstacle plate, the passive style Mie scattering from the carbon clusters is measured. Two shots of the video images under the two gravity conditions are shown in Fig. 7. Under the gravity-free condition, the carbon clusters diffuse isotropically and its speed is very slow (less than 1 cm/s with random motion). The carbon clouds move very slowly and randomly and their density is rather homogeneous. When the scattering is measured under the normal gravity condition (1 g_0), strong heat convection (about 1 m/s) is measured. The continuous particle flow to upward direction is clearly observed. From these measurements, the production place of the clusters is regarded as the narrow region around the arc flame for the both gravity conditions, where the gas temperature drops from 10000 k to less than 1000k. Only in the narrow region around the arc flame, carbon clusters are synthesized.

SWNTs are produced by using a catalyst-mixture carbon anode under the two gravity conditions. Produced samples are observed by a TEM and analyzed by a Raman spectrometer. It is confirmed that fatter bundles of SWNTs tend to be efficiently produced under the gravity-free condition.

5. Summary

The thermal properties of the arc discharge are measured by use of a jet plane and the clear expansion of the hot gas region is observed under the gravity-free condition, where the lower temperature gradient and the slow expansion of the hot gas region are expected. From the Mie scattering method, the production place and the diffusion properties of carbon clusters are observed, which is consistent with the theoretical prediction.

Abstract
A dielectric barrier discharge (DBD), in a cylindrical geometry, has been used for acetaldehyde removal in air at atmospheric pressure. Efficiency of the DBD for the VOC molecule decomposition has been measured, by chromatographic and electrical measurements, for different types of applied voltage (AC and pulsed) to the DBD reactor and for various values of the initial concentration of acetaldehyde. It has been shown that the AC energized DBD is much less efficient than the pulsed one.
Keywords - Dielectric barrier discharge - VOC abatement - Acetaldehyde

1. Introduction

A large interest is still growing for Dielectric Barrier Discharges (DBDs) due to their large area of applications like pollutant destruction, ozone generation, surface treatment, excimer UV lamps, CO_2 lasers and plasma display panels. The DBD generates a non-equilibrium plasma at atmospheric pressure following application of a high voltage, of AC or pulsed type, to special system of electrodes [1, 2]. Quickly described, the DBD consists of plasma microfilaments which are established following the propagation of ionization fronts, usually called streamers, in multiple places in the gas volume. These filaments have a very short lifetime, of the order of a few tens of nanoseconds. Each one is a narrow cylindrical channel (radius of the order of 100 μm). The exchange of energy between electrons and molecules takes place mainly during the phase of discharge development, namely during the propagation of the streamers. Electrons (average energy of some eV) excite the molecules and then transform a share of their kinetic energy into energy stored by excited species and free radicals (by dissociation of molecules). Therefore, like other type of transient discharges, non-thermal plasmas of DBDs have the advantage of decreasing the energy necessary for the elimination of the pollutants in air compared to more traditional techniques like thermal decomposition.
The capacities of a DBD to break up Volatile Organic Compounds (VOCs) were already shown [3-5], but much of work remains to be made to achieve a full understanding of the physico-chemical mechanisms responsible for this decomposition. For some VOCs like aliphatic hydrocarbons, alcohols, or aldehydes, it seems clear that production of oxygen atoms and hydroxyl radicals in the plasma leads to the removal of the undesirable molecule through oxidation processes. The higher the specific electrical energy deposited in the gas mixture (in Joule/litre), the higher radical productions and removal efficiency of those molecules. However, following recently published investigations on the removal of NO in air [6], one can expect that the removal efficiency of the above mentioned VOCs should not only depend upon the specific energy value, but also should depend upon other discharge parameters such as the number of streamers per unit volume and the energy deposited in each micro-discharges. In other words, the electrical excitation type of the DBD, AC mode or pulsed mode, as well as the discharge geometrical characteristics (which perhaps could have an influence on the reduced electric field value in the streamer head), should play a role. As a first step to study this problem in our laboratories, the aim of this paper is to determine the effect of the electrical excitation on the elimination of acetaldehyde, and to understand the implied kinetic mechanisms.

2. Experimental set-up and experimental conditions

The whole experimental set-up (Fig.1), which was constructed for evaluating the removal of acetaldehyde from air, is composed of three different parts: (i) a continuous gas flow generating system, (ii) a DBD reactor, and (iii) a gas sampling analysis and detection system.
The gaseous acetaldehyde was generated by passing part of the air (2.5 sccm) above liquid acetaldehyde, kept at a constant temperature (-35°C±0,5°C) in a cooled alcohol - liquid nitrogen mixture. The gas flow rates of each component, in air with acetaldehyde and air with or without water vapour, were kept constant

using mass flow controllers. The value of the total gas flow rate was 602.5 sccm and the residence time in the DBD was 0.97 s. All experiments were performed at atmospheric pressure and room temperature.
The DBD reactor was made of a pyrex tube (relative permittivity ε_r=4.6). The inner diameter of this tube was 11 mm and the wall thickness was 1.6 mm. The high voltage electrode was the central electrode, which was made of stainless steel screw rod with 3 mm diameter. The grounded outer electrode was made of stainless steel wire mesh and covered up the outside of the dielectric. This electrode was 10.7 cm long, while the inner one and the pyrex tube were 40 cm long.

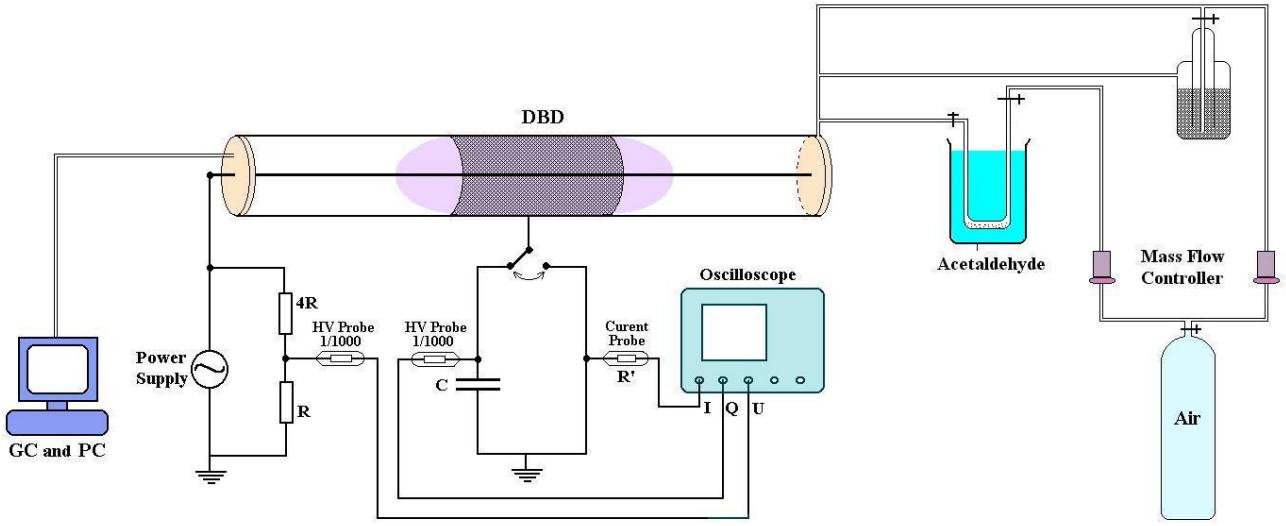

Fig. 1 - Experimental set-up

The electrical energy was supplied either by a high voltage AC generator (peak voltage value up to 30 kV, working at a frequency of 50 Hz), or by a pulsed high voltage generator (peak voltage value up to 30 kV, voltage pulse duration 2 µs, working at a frequency between 10 Hz and 10 kHz). Electrical characterization was made by measurements of the applied voltage across the electrodes (Ua), the electrical charge (Q) flowing through the system or the discharge current (I_d). The applied voltage was measured using a resistance divider and a high voltage 1:1000 probe (Tektronix P6015A) coupled to a 200 MHz digital oscilloscope (LeCroy 9304AM) (Fig.1). The electrical charge was determined using another high voltage 1:1000 probe (LeCroy PHV-1308) in order to measure the voltage across a capacitance C. The current intensity was measured via a current probe as in Fig. 1. Typical waveforms of the applied voltage, electrical charge flowing through the system and electrical current for the AC DBD discharge and the pulsed DBD discharge are displayed in figures 1 and 3.

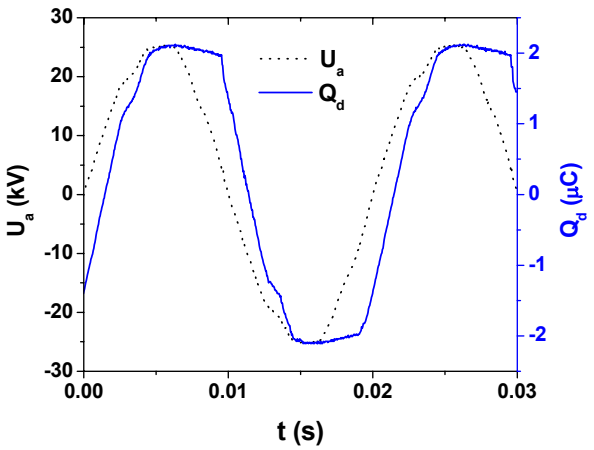

Fig. 2 - Example of electrical discharge characteristics in case of the AC excitation.

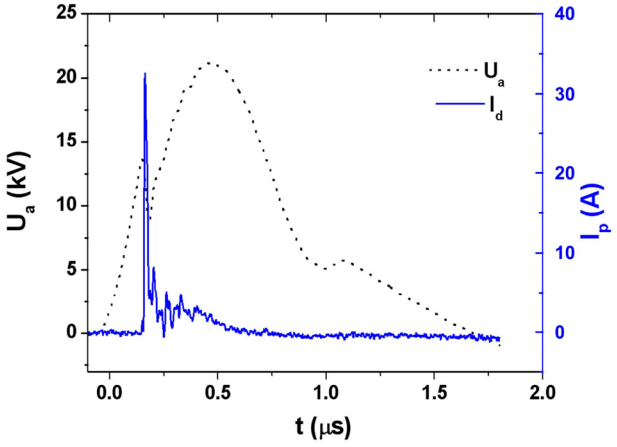

Fig. 3 - Example of electrical discharge characteristics in case of the pulsed excitation.

For the AC DBD discharge, the electrical power was determined using the well-known Manley's method of Lissajous figures [7]. The maximum value is 600 J/l at 30 kV peak voltage. As shown in figure 4, the specific energy increases linearly when the peak voltage value increases from 14 kV up to 30 kV. For the pulsed high voltage generator, the electrical energy per pulse is almost constant for a frequency varying between 20 Hz and 200 Hz. Therefore the energy increases linearly when the frequency increases, as shown in figure 5.

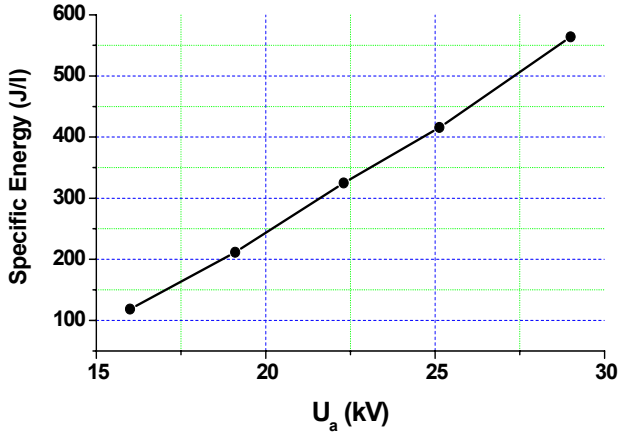

Fig. 4 - Specific energy versus applied voltage, for AC generator, in dry air and humid air.

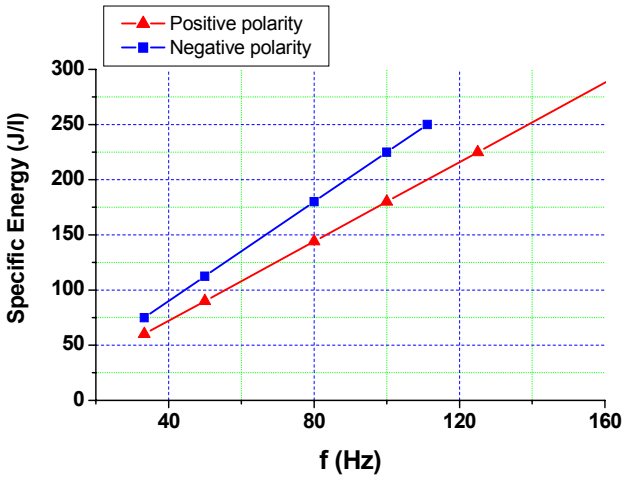

Fig. 5 - Specific energy versus frequency, for pulsed generator, in dry air.

The treated gas mixture was flowing from the DBD reactor to the gas analysis apparatus (Micro Gas Cromatography CP-4900) equipped with a thermal conductivity detector. The Micro GC has three columns. Two of them are identical, molsieve, but with different carrier gases (He and N_2 respectively). The third chromatographic column is a CP-PoraPLOT Q and the carrier gas is He. Using the Micro GC, by-products such as CO, CO_2, H_2O, and HCHO have benn identified. Concentrations of carbon oxides have been measured after appropriate calibration of the apparatus. Three compounds have not been yet identified, at retention times equal to 72.7, 72.8 and 157 seconds.

3. Results and discussions

The acetaldehyde removal has been studied as a function of the specific energy and of the initial acetaldehyde concentration, $[CH_3CHO]_{initial}$. These results are plotted in figure 6.

Acetaldehyde removal efficiency was calculated as follows,

$$\mathrm{CH_3CHO\ Removal}\,(\%) = \frac{[CH_3CHO]_{initial} - [CH_3CHO]_{afterDBD}}{[CH_3CHO]_{initial}} * 100 \qquad (1)$$

where $[CH_3CHO]_{aftef\,DBD}$ is the acetaldehyde concentration at the exit of the reactor.

It was found that the CH_3CHO removal increases with the increase of the specific energy, both for AC and pulsed voltages. The CH_3CHO removal decreases slightly with increasing initial concentration of acetaldehyde, for the case of pulsed voltage, but for AC voltage this effect is more accentuated. For the same value of specific energy (such as, 200 J/l) and the same value of initial acetaldehyde concentration (such as, 195 ppm), it was observed that the removal of acetaldehyde is more efficient when the DBD is energized using a negative or positive pulsed generator by comparison with the case of an AC power supply.

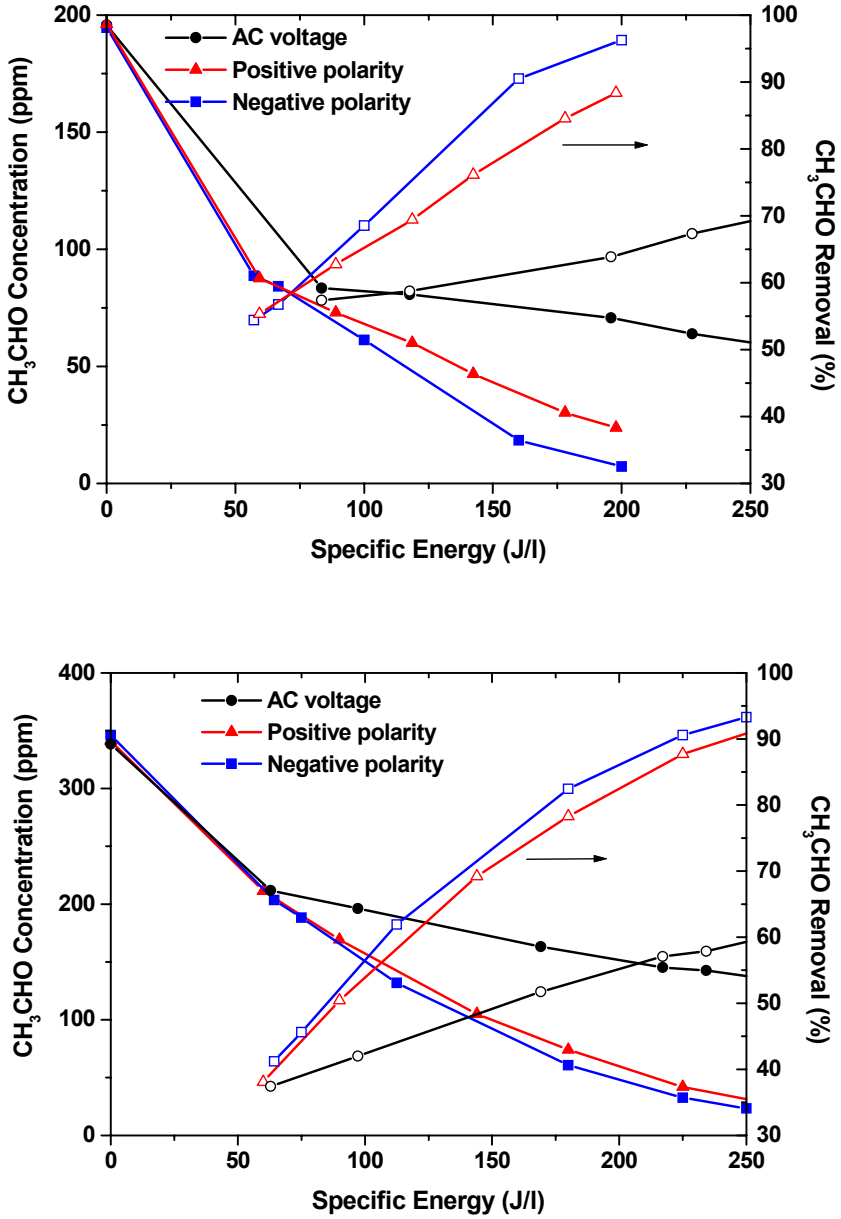

Fig. 6 - CH_3CHO concentration and CH_3CHO removal at the exit of the DBD reactor in dry air, energized by different type of generators, for various values of initial concentration of CH_3CHO: 195 ppm (upper diagram) and 343 ppm (lower diagram).

Figure 6 clearly emphasizes that the removal of acetaldehyde is more efficient when the DBD is energized with the pulsed generator by comparison with the case of the AC power supply. This should be related to the fact that the discharge current pulses are very different, i.e. one very short intense current in the pulsed case, and a great number of much less intense current pulses in the AC case. Streamers are probably more intense in the pulsed case, or more numerous per unit volume, leading to a higher production of oxygen atoms which leads to a higher oxidation rate of acetaldehyde for a given value of the specific deposited electrical energy. This result is similar with those obtained for other VOCs [8, 9].

Amongst by-products following the VOC oxidation, only concentrations of CO_2 and CO are significant, see figures 7 and 8.

For same values of the specific energy and of the initial acetaldehyde concentration, it was observed that the concentrations of carbon oxides are doubled, or even tripled, when the DBD is energized with a negative or positive pulsed generator as compared to the AC one.

The ratio between CO_2 and CO concentrations is approximately 1:1 for the pulsed excitation, whereas it is 1.5: 1 in the AC case (see Table 1). Therefore the overall oxidation of the CH_3CHO molecule is more important in the pulsed DBD than in the AC DBD.

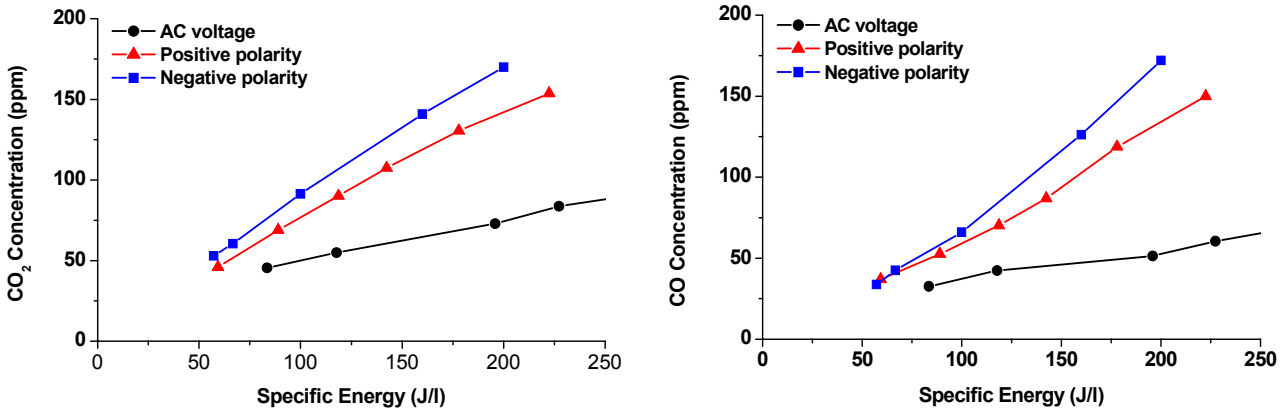

Fig. 7 - CO_2 and CO concentrations at the exit of the DBD reactor, for an initial CH_3CHO concentration of 195 ppm

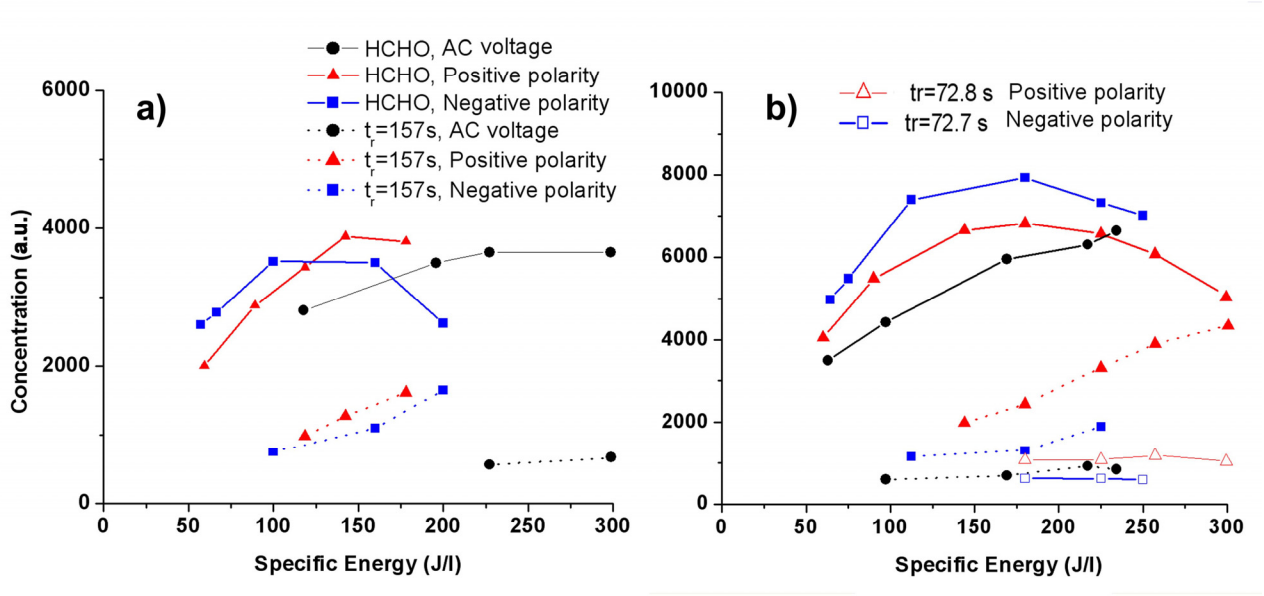

Fig. 8 - Concentration of other by-products at the exit of the DBD reactor, for an initial concentration of : a) 195 ppm and b) 343 ppm. Unidentified products are refereed by their respective retention time values.

Between 70 % to 92 % carbons of acetaldehyde are going to CO_2 and CO, for an initial acetaldehyde concentration value of 195 ppm. This percentage decreases slightly with an increase of the initial acetaldehyde concentration. In Table 1 are given the CO and CO_2 concentration values and carbon balance at the exit of the DBD reactor for the two initial concentration of acetaldehyde studied and for three types of electrical excitation at a fixed deposited electrical energy of 200 J/l : (i) AC, (ii) pulsed with a positive polarity and (iii) pulsed with a negative polarity. The carbon balance is determined as follows,

$$\%C = \frac{[CO_2] + [CO] + 2*[CH_3CHO]_{afterDBD}}{2*[CH_3CHO]_{initial}} * 100 \qquad (2)$$

Table 1- Typical CO and CO_2 concentrations and C balance at the exit of the DBD reactor.

Type of excitation, (E_S=200 J/l=const.)	$[CH_3CHO]_{initial}$ **(ppm)**	$[CO_2]$ **(ppm)**	$[CO]$ **(ppm)**	$CO_2 : CO$	$[CH_3CHO]_{afterDBD}$ **(ppm)**	$\%C$	**Removal (%)**
AC generator	195	75	53	1.41 :1	70	68.5	**64**
Positive polarity		144	132	1.08 :1	23	82.5	**88**
Negative Polarity		170	173	0.98 :1	**8**	**92.2**	**96**
AC generator	343	105	66	1.6 :1	151	69.1	**56**
Positive polarity		191	170	1.13:1	60	70.0	**83**
Negative Polarity		212	170	1.25 :1	**48**	69.7	**86**

5. Conclusions

The removal of acetaldehyde by a DBD reactor, in dry air at atmospheric pressure, has been investigated for two different types of electrical excitations, an AC voltage waveform or a pulsed voltage waveform. It has been found that the removal of acetaldehyde is more efficient when the DBD is energized with the pulsed generator by comparison with the case of the AC power supply. Studies on the spatial distribution of the electrical energy deposition (number of micro-discharges per unit volume and energy deposited in each micro-discharge) are probably necessary to explain these results.

[1] *Instituto Nacional de Investigaciones Nucleares, México*
[2] *Instituto Tecnológico de Toluca, México.*

Abstract
This study provides a simple technique to treat automotive toxic gases, particularly nitrogen and sulfur oxides, by using an inexpensive and small sized reactor. The reactor proposed combines a dielectric discharge barrier (DBD) with a corona discharge. Theoretical results obtained from kinetics of different species present in the plasma reinforce and explain experimental results effectuated. Spectroscopic analysis giving information about some species in plasma was also reported.
Keywords: NO_x removal, SO_x removal, non-thermal plasma.

1. Introduction

Air pollutants like nitrogen and sulfur oxides (SOx, NOx), carbon monoxide (CO), unburned hydrocarbons (HC) and particulate matter (PM) have been released into the atmosphere over the last decades. These pollutants are the main cause of acid rain, urban smog, and respiratory organ disease. Mexico City is an alarming example of these huge emanations; mobile sources are responsible for the generation of more than 80% of atmospheric contaminants. In relation with an inventory of 1998, for year 2010 an increase of air pollutants is expected (i.e. 48% in SO_2, 37% in NO_x and 30% in CO emissions) [1].

The exhausts of gasoline engines are cleaned efficiently with the three-way-catalyst, but for diesel and lean burn engines, these technique does not operate because the high oxygen content in these exhaust gases prevents the reduction of NO [2]. Non thermal plasma technologies can solve such problems [3].

The plasma process, here proposed, is particularly attractive for this purpose, because it can be operated stably at atmospheric pressure, besides, the reactor dimensions are small. Particular conditions of the plasma induce the formation of active chemical radicals which lead to the destruction of gaseous pollutants.

This paper is focused in a dielectric barrier discharge technique (DBD) combined with the Corona effect, and their consecutive application in treatment of flue gases, particularly SO_x and NO_x. A theoretical and experimental analysis of removal of these gases will be presented.

2. Plasma Model

In a DBD-Corona process energetic electrons can interact with molecules, like O_2, H_2O, N_2, to produce active chemical radicals which contribute to the subsequent chemical reactions responsible of the De-NOx/SOx process. These radicals could be OH, N, O, H, $O(^1D)$. Another way to produce radicals as OH and O is by rapid quenching of excited oxygen atoms ($O(^1D)$) .

We consider a uniform electric field for uniform plasma. The proposed model consists in two main steps:

1) Electrons generation by discharge and formation of radicals by direct electron dissociation impact and quenching of $O(^1D)$
2) NO_X and SO_X removal by radicals formed in 1)

In order to simulate the streamer head (high field) we start with 1 electron/cm^3 in a uniform field corresponding to an E/N of 100Td. For the streamer channel the E/N was 40Td.

A total of 18 species were taken into account in the model for de-SOx process (e-, O, OH, $O(^1D)$, O_2, O_2^-, O^-, H^-, H, $O_2(a^1\Delta g)$, O_2^+, O_3, H_2O, N_2, SO_3, SO_2, H_2SO_4, HSO_3). For de-NOx process 23 species were used (e-, O_2, O_2^-, O^-, $O_2(a^1\Delta g)$, O, O_2^+, H_2O, H^-, OH, H, O_3, NO, NO_2, NO_3, N_2O_5, N, N_2O, O('D), N_2, $N_2(A_3\Sigma_u^+)$, HNO_3, HNO_2). Rate coefficients as well as the main reactions most likely responsibly for NOx and SOx removal were taken from [4-6].

3. Experimental

The non-thermal plasma reactor uses a barrier discharge, which prevents large current intensities because of the use of glass as a dielectric, quenching the current and distributing the discharge over the whole surface.
A pyrex glass tube of 27 mm of diameter and 175 mm of length is used as reactor; outside the glass tube, a grounded mesh electrode is wrapped. A stainless steel central electrode of 2.1mm of diameter is used to establish a radial discharge homogenously distributed along the reactor (figure 1).

This reactor is connected to different voltage sources and different operating frequencies (60 Hz to 70 kHz) and atmospheric pressure. The voltage required to produce a high frequency discharge was supplied by a series-parallel resonant converter described in [7].

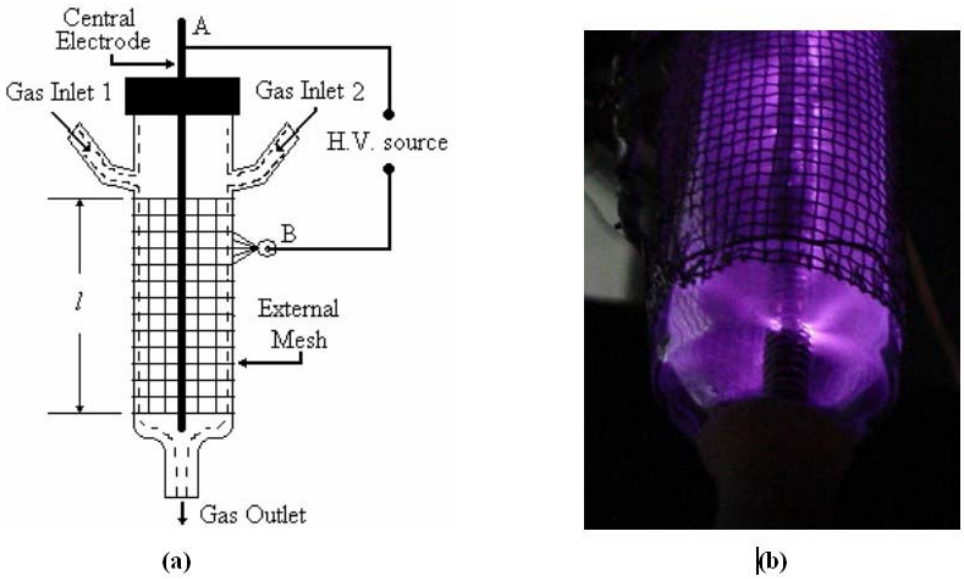

Figure 1. DBD-Corona reactor. (a) Reactor scheme. (b) Plasma discharge with an air-He-NOx mixture.

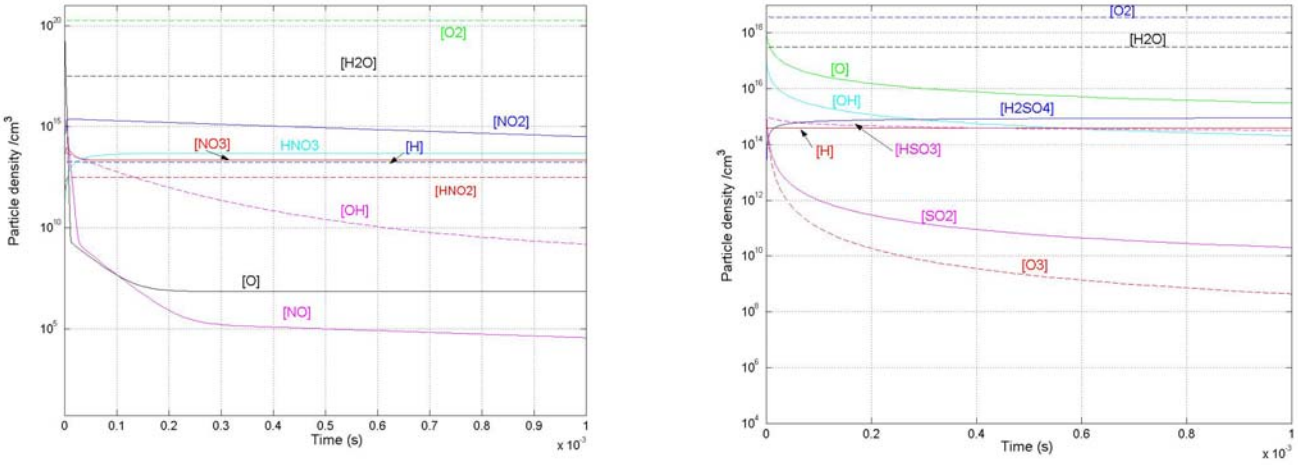
During each test, exhaust gases are characterized by gas chromatography (Varian Star 3400CX) and a gas analyzer (SENSONIC 2000) to obtain the degree of pollution abatement.
The plasma reactor was also provided with a special port for OES measures. The radiation emitted by the plasma discharge was focused by a convergent lens towards the entry slit of the monochromator, endowed with a 1800 grooves/mm holographic grating, and a CCD detector (122 x 1024 pixels) with a spatial resolution of 0.6nm. The optical signal of the plasma discharge was guided by an optic fiber mounted in a XY electromechanical system so to achieve a vertical and horizontal scanning of the plasma discharge with very precise incremental steps (0.1mm).

4. Results

- **Plasma model.**

Preliminary results obtained shown the importance of different radical in de-SOx process. In general the O radical have a major role in the oxidation of SO_2 to SO_3. The excited oxygen atoms ($O(^1D)$) formed have a significant effect in producing OH radicals. These radicals are the most important in removing SO_2 contributing to acid formation

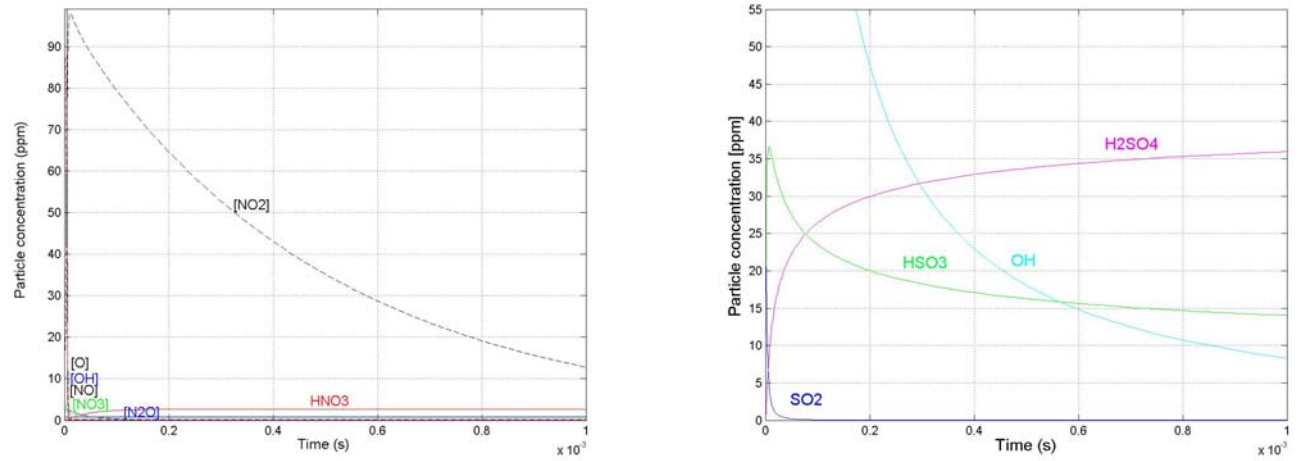
In figure 2 we observe particle densities per cubic centimeter taking into account mixtures of 50 ppm of NOx-air and SOx-air respectively considering 1.5% of water vapor. From figure 2a a rapid diminution of NO and its conversion to NO_2 is observed; for the SOx-air mixture, SO_2 and radicals [OH] diminishes rapidly generating acids.



a)NOx-air b)SOx-air

Figure 2. Calculated species concentrations

In figure 3 we appreciate the de-NOx and de-SOx in parts per million (ppm). We observe NO_x ($NO+NO_2$) removal being slower than SO_2 removal (figure 3a); OH radicals play a more important role in de-SOx process than de-NOx process, turning SO_2 in H_2SO_4 almost immediately (figure 3b).



a)NOx-air b)SOx-air

Figure 3. Calculated species concentrations in ppm.

From results of our calculations, considering mixture of NO_x-air, we observe that the principal channel for the removal of NO_x is through reduction by N atoms. Some reverse reactions oxidize the nitrogen atoms and produce NO, however the effect of these oxidation reactions is small compared with the reduction reactions.

For de-SO_x and de-NO_x processes, the radical OH has the major role in removing SO_2 and a minor effect in removing NO_x.

OH radicals are mainly produced from the dissociative attachment of electrons to water vapor and from the reaction of $O(^1D)$ atoms with water vapor. Therefore several tests, with different concentrations of vapor water, were done in order to observe the influence of OH radicals in the de-NOx and de-SOx processes.
In table 1, NO, NO_2 and SO_2 concentrations obtained at 1ms in function of water percentage added are summarized.

Products (ppm)	**H_2O % added**					
Air-NO_x	**0**	**1**	**5**	**10**	**50**	**80**
NO	0	0	0	0	0	0
NO_2	12.5	12.5	5	1	0	1
Air-SO_x						
SO_2	50	0	0	0	0	15

Table 1. NO_x and SO_2 concentrations obtained in function of water vapor concentration.

For de-NOx process a conversion of NO to NO_2 is observed with no addition of water; when a percentage of water is added, OH radicals lead to reactions which produce nitric acid (figure 3a).
Influence of OH radicals in SO_2 removal is more marked than in NO_x removal. From the table we can appreciate that small amounts of water vapor are sufficient to remove SO_X.

However if percentage of water vapor is about 80% we observe an incomplete SOx and NOx removal, it could be explained by a disappearance of OH radicals. O. Motret et al [8] explain this effect in argon-water plasma following three main mechanisms: two collisional processes with argon atoms and with water molecules and the radiative de-excitation.

The collisional de-excitation with water molecules becomes dominant at higher water vapor concentrations. For example, at water vapor saturation the decay term of OH by water molecules collisions is about 100 times larger than those observed through the two other ways. Consequently the increase of the water vapour ratio strongly accelerates the decay kinetic of OH.

- **Experimental results**

To identify the various chemical species present in the discharge, OES is applied. OES allows the analysis of the radiation emitted by the atoms, ions, molecules, and radicals when they are excited by the field or by collisions with other particles. Figure 4 shows the emission bands from the He-air discharge in the wavelength range of 300–700 nm. The spectra are dominated by N_2, OII and HeI transitions. Note that the emission bands above 600 nm are due to second-order light (no filters were used in front of the entrance slit of the monochromator).
When NO_x or SO_x are introduced (without vapor water, therefore no OH bands are present) same spectral lines appear but with a lower intensity.

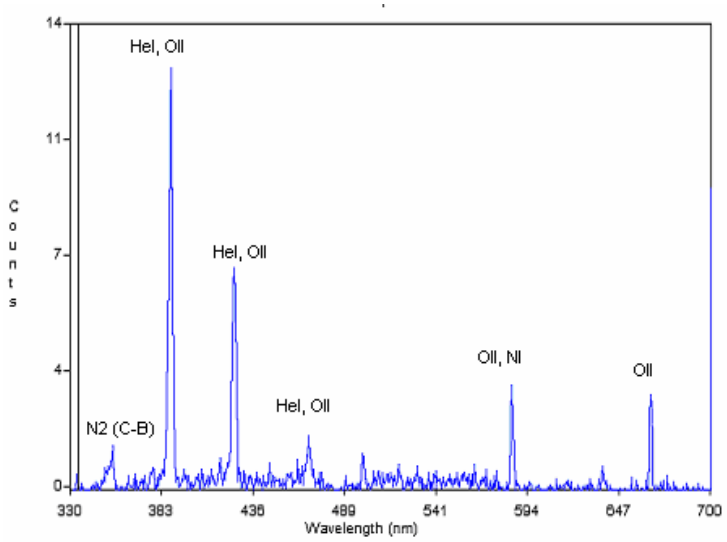


Figure 4. Emission spectra in the 300-700 range of a He-air plasma

Removal experiments were only done with a He-SO_2-air mixture with 50ppm of SO_2, 67kHz, and 150mA peak to peak. From figure 2 we observe a slow removal of this gas arriving approximately to 98% in 40 seconds. In this case no water vapor was added. If we compare with theoretical results it seems to be a contradiction, however we thought that a small amount of humid air penetrates the reactor during the discharge. More experiments must be done in order to verify the presence of OH radicals.

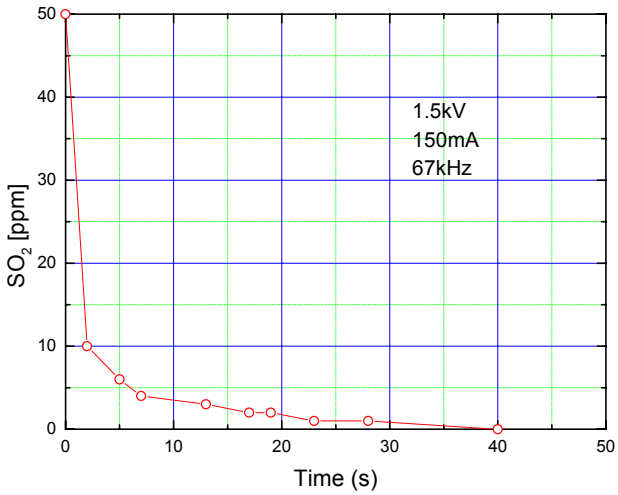

Figure 5. SO_2 removal.

5.Conclusions

Experimental results obtained shown a 98% of SO_2 removal in 40 seconds, OH radicals necessary to its removal were probably generated by humid air.

Results obtained shown the major role of OH radical in removing SO_2, whereas radicals N remove NO_x. The importance of including vapor water is also discussed.

Removal of SO_2 in dry air is zero; then, it will be absolutely necessary to add water vapor (production OH by the dissociative attachment of electrons to water) for its removal, as we will see in our theoretical results. More experiments will be done in order to study the influence of OH radicals in the de-NOx-SOx processes.

Fluid Model for dc Glidarc Discharge Plasma[1]

WU Bin, LIN Lie, YANG Chi, WU Cheng-Kang

Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, China

Abstract

A fluid model for dc gliding arc plasma is presented to describe the arc and to understand the arc property in detail. It can give the velocity and temperature field of the plasma reactor. This model is based on steady-state analysis and some experimental data. The numerical results at ignition stage show that the arc boundary is sharp on the upstream side, whereas it is relatively blurred on the down stream side at this stage.

Key words: Glidarc, Fluid Model, Plasma

1. Introduction

Interest in Glidarc plasma reactor has been continuing in recent ten years for its simplicity, easy operation and high efficiency [1], [2].

Some models have been proposed to describe the arc [3]-[5]. Most of them assume the arc as string or column. However, the arc boundary properties on the upstream side and the downstream side are different. The nature of the velocity and temperature in the reactor and the flow downstream of the arc is also important. The objective of the present paper is to give a fluid model of gliding arc plasma generator. It can describe the arc property of the arc to understand the arc in detail. Special attention is given to the arc shape described by the model.

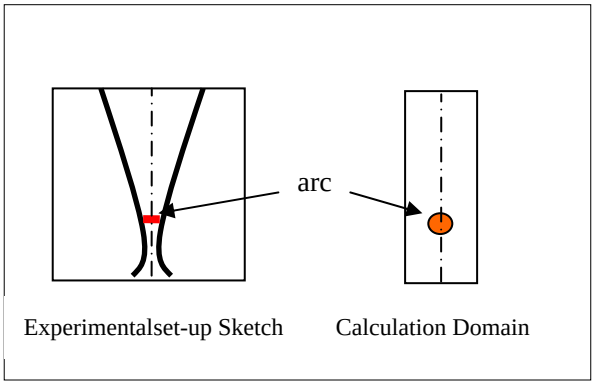

Fig 1 Experimental set-up sketch and calculation domain

2. Gliding arc plasma generator

Figure 1 gives the experimental set-up sketch and corresponding calculation domain.

The experimental set-up consists of two electrodes and two dc power supply. Two copper rod electrodes are formed into a horn-like shape with 30^0 included angle and 1mm minimum electrode separation distance. The power source combines a main supply (600V, 20A) with one for ignition (10000V, 0.1A).

The modeled air plasma is generated by a dc gliding arc working at one atmosphere. The gas flow was inlet from the down side. The arc was ignited at the narrowest position and then moves to the upward by the gas flow.

[1]This work is supported by National Natural Science Foundation of China projects 10375083, 90205026.

Figure 2 showed the voltage and current measured during eight consecutive ignition and extinction cycles. The current and the voltage are all saw tooth-like signals. From the result, we can know that the current and voltage of the arc at different time.

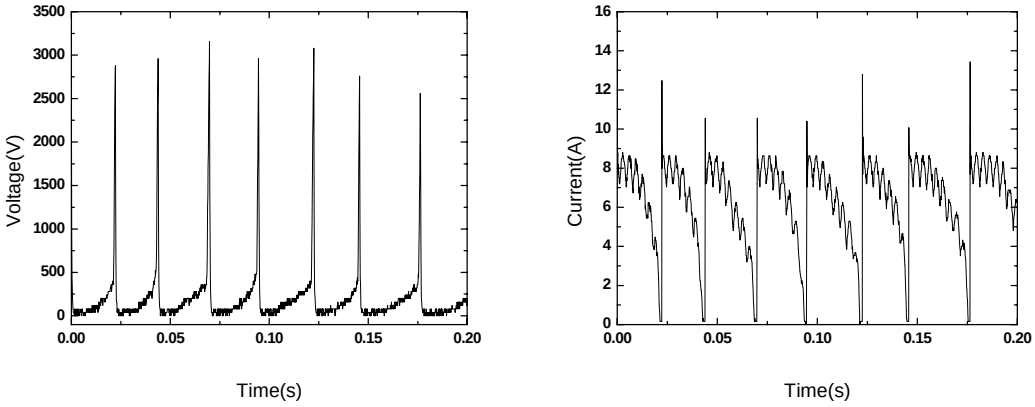

Fig.2 Voltage and current as functions of time

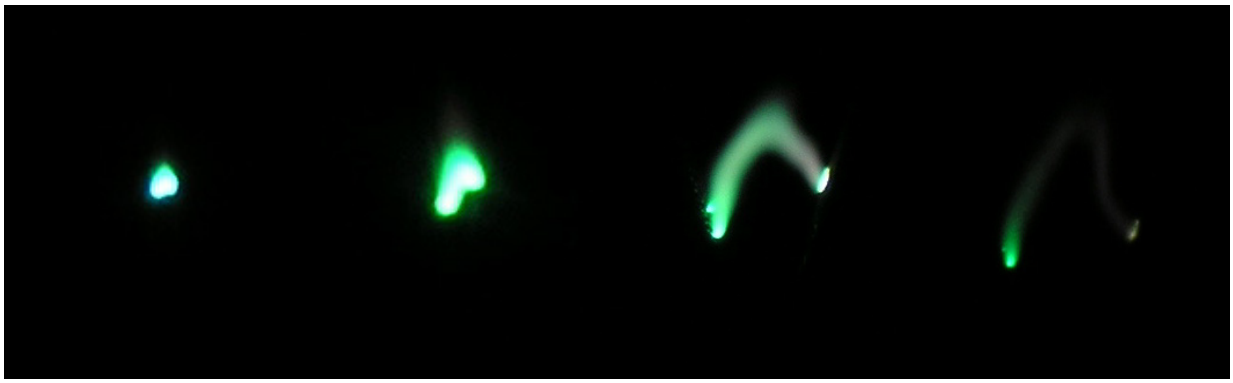
The four stages of the gliding arc from arc ignition to break are shown in figure 3. It includes four stages. Figure 4(a) is the ignition stage, in which the arc just starts. The arc becomes bigger, pushed by the gas flow in Fig 4(b). Then the arc is the longest in Fig 4(c). Finally, the arc breaks in Figure 4(d). From the sequence of the photo and the time interval, we can decide the arc velocity.



(a) ignition (b)bigness (c)elongation (d) break

Fig.3 Four stages of the gliding arc from arc ignition to break

3. Theoretical model

The model is based on steady-state analysis and some experimental data. We focus on the temperature and flow field at specific time. The arc root and the arc itself are complex physical phenomena. To form a simplified model for use in flow field analysis, the arc position and arc velocity are recorded by a CCD camera in the experiment. The arc properties are measured by oscillograph, and the measured parameters are used as known conditions in this model.

3.1 General governing equation

The mathematical model is based on the k-ε two-equation turbulence model. In order to introduce the

governing equations, the following assumptions are made.

(1) The plasma is an optically thin.

(2) The displacement current, viscous dissipation and pressure work in the energy equation are negligible.

(3)The magnetic effect of the arc is not considered.

Under this given assumptions, the governing equations of a turbulent arc and its surrounding flow are presented as follows.

$$\nabla \cdot (\rho \vec{V}) = 0 \tag{1}$$

$$\nabla \cdot (\rho \vec{V} \phi) = \nabla \cdot (\Gamma_\phi \nabla \phi) + S_\phi \tag{2}$$

ϕ represents *u, v, w, k, ε,* T_i, T_e respectively. $\vec{V}$ is the velocity of the gas. The meaning of ϕ, Γ_ϕ and S_ϕ are shown in Table 1, where μ is the laminar viscosity, μ_t is the turbulent viscosity, $\lambda_{eff\text{-}i}$ and $\lambda_{eff\text{-}e}$ are the effective thermal conductivity for i and e, respectively.

Table 1. Definitions of parameter in governing equations

equations	ϕ	Γ_ϕ	S_ϕ
continuity	1	0	0
X-momentum	u	$\mu+\mu_t$	S_u
Y-momentum	v	$\mu+\mu_t$	S_v
Y-momentum	w	$\mu+\mu_t$	S_w
Turbulent kinetic	k	$(\mu+\mu_t)/\sigma_k$	S_k
Turbulent dissipation	ε	$(\mu+\mu_t)/\sigma_\varepsilon$	S_ε
Energy for i	T_i	$\lambda_{eff\text{-}i}$	S_i
Energy for e	T_e	$\lambda_{eff\text{-}e}$	S_e

Where ρ is the gas density, σ_k and σ_ε are the constant in turbulent model.

3.2 The governing equation for the ignition stage

At ignition stage of the gliding arc generator shown in figure 2(a), the general governing equation can be simplified into two-dimension. We set the 2-D domain vertically to the arc length direction, as shown on the right of Fig 1.

The two dimensional governing equations should be as the following:

$$\frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v)}{\partial y} = 0 \tag{3}$$

$$\frac{\partial(\rho u \phi)}{\partial x} + \frac{\partial(\rho v \phi)}{\partial y} = \frac{\partial}{\partial x}\left(\Gamma_\phi \frac{\partial \phi}{\partial x}\right) + \frac{\partial}{\partial y}\left(\Gamma_\phi \frac{\partial \phi}{\partial y}\right) + S_\phi \tag{4}$$

ϕ represent u, v, k, ε, T respectively. At the ignition stage the plasma is in the equilibrium state [6]. Then, we have $T_i=T_e=T$.

3.3 Calculation procedure

To obtain flow and temperature field at a given time instant during the cycle, Equations (3) and (4) were solved using an iterative finite difference scheme with appropriate boundary conditions. The numerical procedure used is based on vorticity and stream function equations [10].

The boundary conditions are as follows. On the walls, the non-slip condition was assumed and the temperature was given as 350K. On the axis of symmetry, symmetrical conditions were imposed. At the inlet, base on the given flow rates, uniform velocity profiles were assumed. At the exit, axial gradients were set equal to zero. The thermal conductivity, electrical conductivity, total radiation and velocity of air were obtained from ref. [8] and [9].

The calculation was performed for a 30×100 grid system in the x and y direction, respectively. As a general rule, more grid points were introduced in areas where a steep temperature of vorticity gradient existed. Parameter relaxation was also applied to stabilize the solutions. The relaxation factors varied between 0.5 and 0.7. The auxiliary relations and the transport properties were evaluated in every iteration cycle.

4. Numerical results and discussion

Calculations were made for air plasma at atmospheric pressure. The plasma operating conditions were as follows:

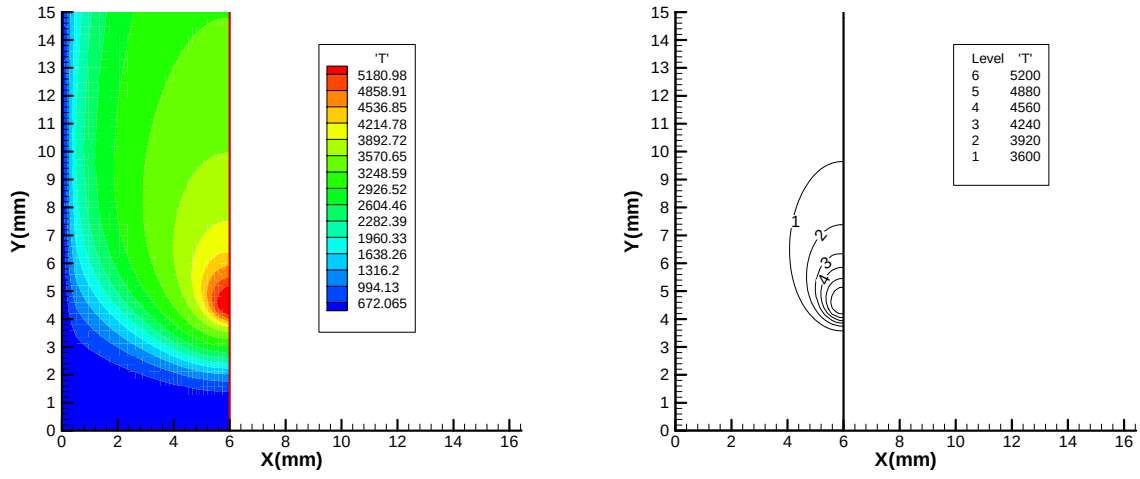
A total plasma gas flow rate of Q=140Scm^3/s.

The current was 8A, as shown in figure 2.

The Joule heat

$$Q=I^2R \qquad (5)$$

Where, R is resistance of the arc, determined by the electrical conductivity corresponding to the temperature.



(a) Whole zone (the temperature in K) (b) Arc zone (the temperature in K)

Fig. 4 Temperature field of Glidarc at ignition

Typical results are shown in Fig. 4. This temperature field is vertical to the arc and only half of the field was shown. The red circle corresponds to the half arc area. The gas was inlet from the down edge. The

left side was the solid and the right side is the axis of symmetry of the field. The upper side is the outlet of the generator. Figure 4(a) gives the temperature field in the whole area. The 4(b) shows the temperature field near the arc. From the result, we can see that the temperature near the arc is not as a perfect column, but an egg-like shape. The gradient of temperature up stream side is much greater than down stream side. The figure 2(a) has shown the similar shape in experiment.

5. Conclusion

In order to understand the arc in the gliding-arc plasma generator in detail, we simulated the arc in a fluid model. The results are summarized as follows:

1) The fluid model is helpful for the description of arc in detail.
2) The simplified 2-D numerical results show that the arc in the ignition stage of glidarc is not exactly column. The arc boundary is sharp on the up stream side, whereas it is relatively blurred on the down stream side at this stage.
3) In order for it to be more useful, the model needs to be further developed, especially in the arc root behavior.

Abstract
Silicon nitride-like films have been deposited at low temperature in radiofrequency inductively coupled plasmas fed with bis(dimethylamino)dimethylsilane (BisDMADMS)-Ar mixtures. The effect of input power and of BisDMADMS-to-Ar ratio on the chemical composition of the coating has been investigated by means of FT-IR and XPS analysis. The results indicate that at high input power and low monomer-to-Ar ratio stable silicon nitride-like films, with a refractive index as high as 1.87, can be obtained.

Keywords: PECVD, silicon nitride-like, organosilicon, FT-IR, XPS.
