
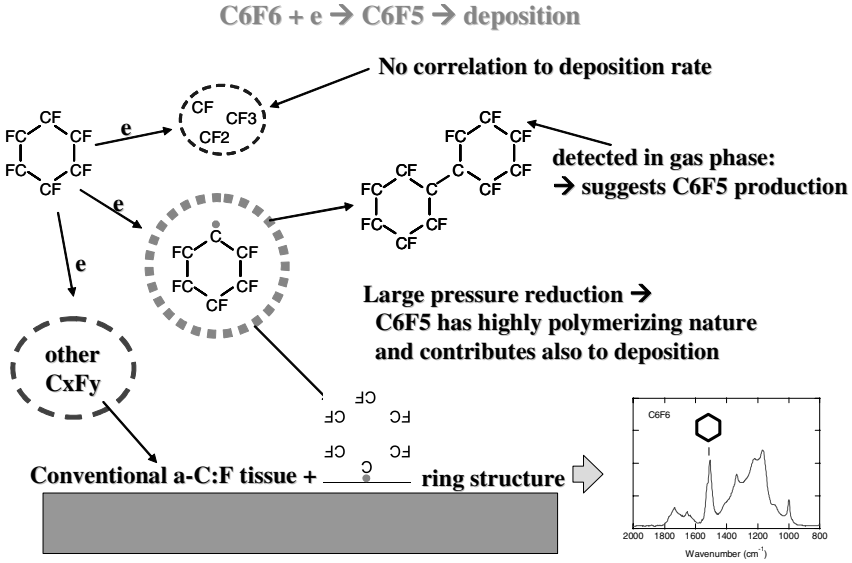

Fig.9 Proposed deposition model for C_6F_6 plasma.

4. Summary

Amorphous fluorinated carbon films with C-ring structures have been prepared by plasma enhanced chemical vapor deposition method using C_6F_6 at substrate temperature of 400°C. Deposition rate reduction due to higher substrate temperature can be suppressed by highly polymerizing nature of C_6F_6. Film availability at 400°C, which is not achieved by the other monomers such as C_4F_8 and C_5F_8, has realized thermal stability up to 400°C. Dielectric constant of the films is 2 even for F/C ratio of almost unity, which may be due to symmetric structure of C-F ring structure. Infrared absorption spectra of the films have indicated that the films contain the benzene rings in their amorphous tissue. In situ FTIR observation has suggested that C_6F_5 and C_xF_y (not fragmented CF_x) are contributing to the film deposition for preparing C-ring structure and amorphous a-C:F structure, respectively.

Abstract
Plasma polymerization of DVS-BCB has been performed for preparation of low-*k* SiOC films. Films have shown dielectric constant of ~2.3, but it increased to 3.3 for higher RF power. The causes of the increase in dielectric constant are discussed on the basis of the data of *in situ* gas phase FT-IR diagnostics of the plasma and characterization of the films.
Keywords plasma polymerization, low-k, in situ FTIR

1. Introduction

In ultra-large-scale integrated circuits, it is necessary that the dielectric constant k of inter-metal dielectric should be low for decreasing resistance-capacitance time delay. Many materials and process techniques have been proposed for the low-*k* applications. Due to this frequent change of materials and processing methods, low-*k* engineering is always under construction. In order to fulfill up-coming requirements smoothly, "scaling rule" should be applied also to low-*k* materials, where processing method is fixed, and only minor changes in monomers are required [1]. This kind of approach can be realized only for polymerization and/or co-polymerization methods using monomers with suitable functional groups, and a plasma polymerization method has been proposed by Kikkawa *et al* [2], in which divinyl siloxane-bis-benzocyclobutene (DVS-BCB) shown in **Fig.1** has been used as the first attempt.

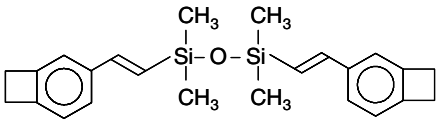

Fig.1 Structure of DVS-BCB monomer.

However, this monomer was not used for plasma polymerization before, and nobody knew its reaction mechanisms in the gas phase and/or surface. Therefore, in order to clarify decomposition scheme and deposition mechanisms, and also its correlation to film properties, we must perform *in situ* diagnostics of plasma polymerization of DVS-BCB.

In our previous work, we have investigated effects of plasma exposure on DVS-BCB monomer coated on substrate surface using *in situ* FTIR reflection spectroscopy, in which UV irradiation has been revealed to work for bond breaking [2]. In this work, we have performed gas-phase diagnostics of DVS-BCB plasma together with structural and electrical characterization of the deposited films.

2. Experimental

Experimental setup is shown in **Fig.2**. As the DVS-BCB was liquid source and had quite low vapor pressure, liquid mass flow controller and vaporizer were used, and all the reactor walls (except windows) were heated up to 200°C. Although configuration of plasma source was ICP (13.56MHz), it seemed to be operated under CCP mode due to quite high operation pressure. Vaporizer temperature was 180°C, where Ar gas was used as a carrier gas with 500 sccm, and flow rate of DVS-BCB was 0.102 g/min. Under this condition, DVS-BCB/Ar was fed into reactor until total pressure reached 3 Torr. Film deposition experiments were performed under this condition as a function of RF

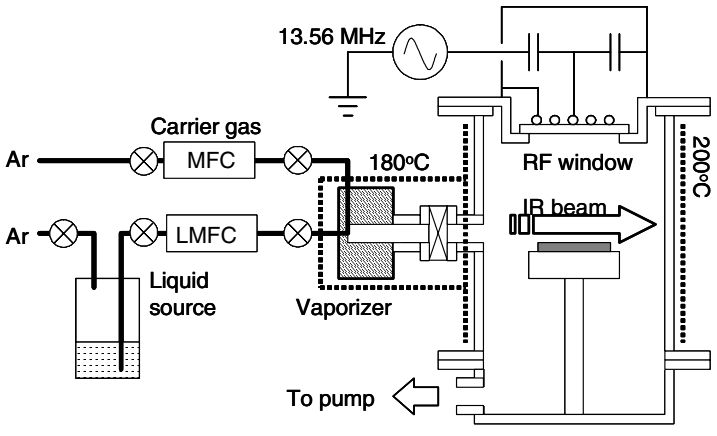

Fig.2 Schematic illustration of experimental apparatus.

power. In order to investigate decomposition scheme of the monomer as a function of discharge time, gas-phase diagnostics were performed on closed reactor without gas flow and pumping. Chemical structure of the deposited films was investigated with FT-IR and XPS. Relative dielectric constant was obtained from capacitance of the films by constructing MIS structure with Al, film and p^+ c-Si substrate. Measurement frequency was 1 MHz.

3. Results and Discussion

3.1 Deposition rate

Figure 3 shows deposition rate of the films as a function of RF power. With increasing RF power from 50 to 100 W, deposition rate increases from 5 to 23 nm/min, and saturates for higher RF power. This means that rate determining step is decomposition of the monomers for 50-100 W. For higher RF power, on the other hand, it turns out to be supply of the monomers, and excess decomposition of the monomers may occur in this condition. Therefore, by characterizing properties of the films deposited under these conditions, it is expected that effects of excess decomposition of the monomers on the structure and dielectric properties of the films.

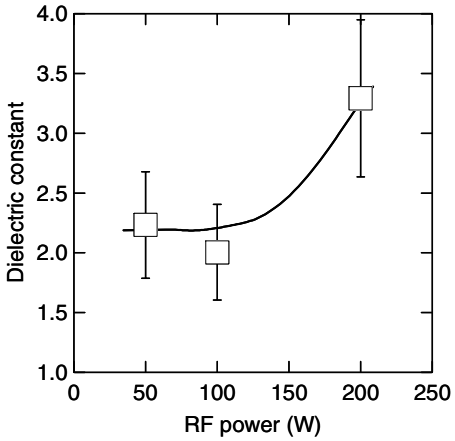

Fig.4 Relative dielectric constant of the films as a function of RF power.

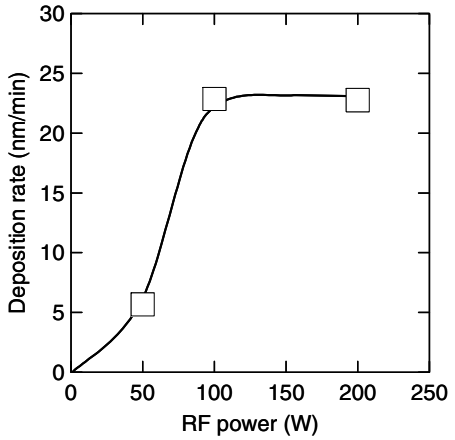

Fig.3 Deposition rate of the films as a function of RF power.

3.2 Relative dielectric constant

Figure 4 shows relative dielectric constant of the films as a function of RF power. As expected from variation of deposition rate as a function of RF power, dielectric constant of the films deposited at lower RF power shows lower value. As the spatial uniformity of the film thickness was quite poor for our present experimental setup (namely, source monomer was fed from a side of the reactor), thickness of the film where the MIS structure is prepared is not obtained. Therefore, the film thickness was obtained by averaging the thickness around the area of MIS structure. The error bar in **Fig.4** is due to this thickness uncertainty. Although there remain several technical issues, the data in Fig.4 show that relative dielectric constant of 2~2.5 can be obtained. For practical use of these films as a low-k film, mechanical strength and thermal stability must be examined. This will be carried out in future. Before going to practical issues, we have investigated deposition mechanisms of the films by characterizing film structure and gas phase of the plasma.

3.3 Chemical structure of the films

Figure 5 shows infrared absorption spectra of the films deposited at 50, 100 and 200 W. The vertical axis in the figure is absorption coefficient calculated from absorbance and thickness of the films, and peak intensity (or area) is proportional to density of these chemical bonds in the films. As shown in the figure, chemical bonds detected by IR spectroscopy are Si-O-Si, Si-CH_3, CH_x, C-ring and Si-H_x, in which most of the components comes from structure of the monomer except Si-H_x bonds. Cyclobutene and vinyl group are not detected in the spectra, which means these bonds are used for polymerization, and mainly affected (or attacked) by electron impact in the plasma.

The film deposited at low RF power of 50 W, highly amount of carbon-containing groups are detected in the spectrum, which suggests that deposition condition is not closer to CVD condition characterized by high fragmentation of monomers, but polymerization in which only limited parts of a monomer is decomposed by electron impact. In this condition, lower dielectric constant is expected. With increasing RF power, density of carbon-containing group decreases, and film structure becomes closer to amorphous SiO_x, which may lead

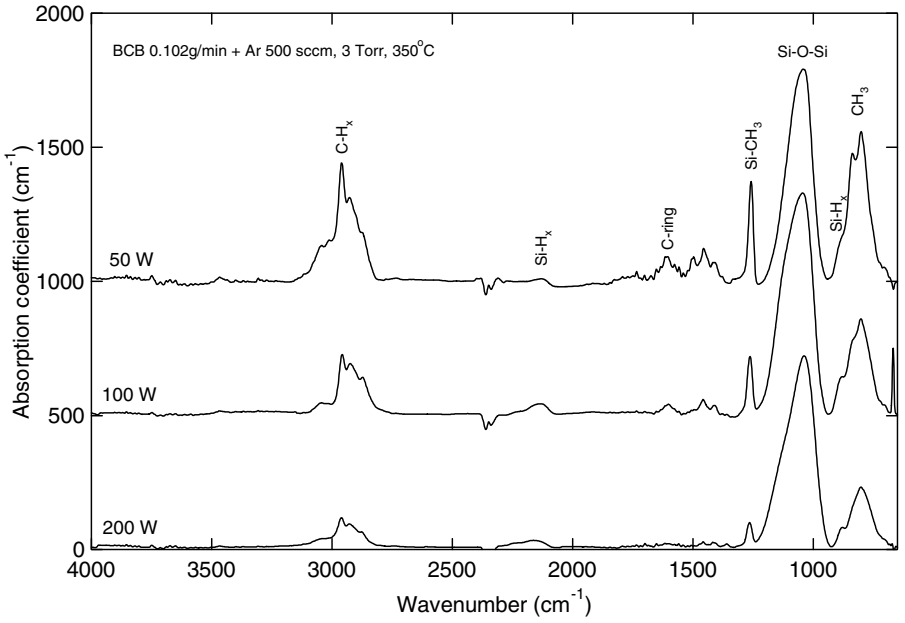

Fig.5 IR absorption coefficient of the films deposited with BCB/Ar plasma as a function of RF power.

increase of dielectric constant. At the same time, density of Si-H_x bonds increases. In order to generate Si-H bonds in the films, H atoms must be removed from C-H_x groups attached on the monomers in the gas phase, which also means that this condition is highly fragmenting condition for the monomers.

Figure 6 shows relative composition of Si, O and C in the films. Density of hydrogen is not represented in the figure because the H atoms cannot be detected by XPS. However, most of H atoms are regarded to be attached as C-H_x group as can be understood from IR absorption spectra of the films. Regarding density of C atoms relative to Si or O atoms, it is 4 or 8 even for the condition with the highest C density. These value is quite smaller than the ratio of C/Si or C/O in a monomer structure (12 or 24). This result suggests that some parts in monomer structure are detached by electron impact, and becomes stable species to be exhausted out of deposition zone. As the vinyl groups are weak bridge in the monomer and benzene ring is stable structure, vinyl groups in the monomer are considered not to be simply opened, but also decomposed. The ratio of Si/O is always 2 even for higher RF power of 200 W, this means that Si-O-Si in the monomer is tough structure in comparison to the other groups in the monomer.

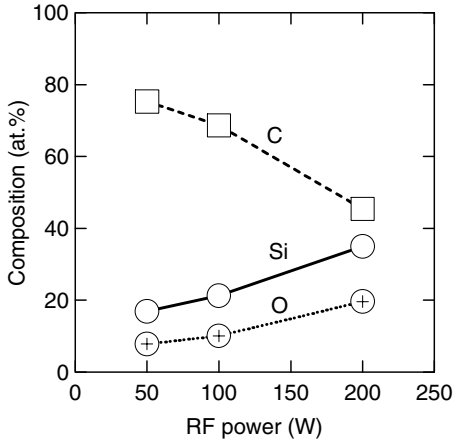

Fig.6 Composition of the films as a function of RF power, which was calculated from relative intensity of XPS spectra of the films (instrument function is also considered).

3.4 Gas-phase diagnostics

Figure 7 shows *in situ* IR absorbance of the gas phase of reactor after discharge for 0, 2, 6 and 10 seconds. As seen in the figure, intensity of the IR absorption peak decreases with increasing discharge duration except for the peak at ~2000 and 900 cm^{-1}. The structure of a BCB molecule consists of Si-CH_3, Si-O-Si and benzene ring with cyclo-butene group, and vinyl group as shown in **Fig.1**. IR absorption peaks for these structures are indicated on the **Fig.7**. As can be understood from the figure, decrease rate of the peak intensity is not the same for each other. For better understanding of this behavior, variation of intensity for these peaks has been plotted as a function of discharge duration, which is shown in **Fig.8**.

Vinyl and cyclo-butene show the fastest decomposition rate. In

the

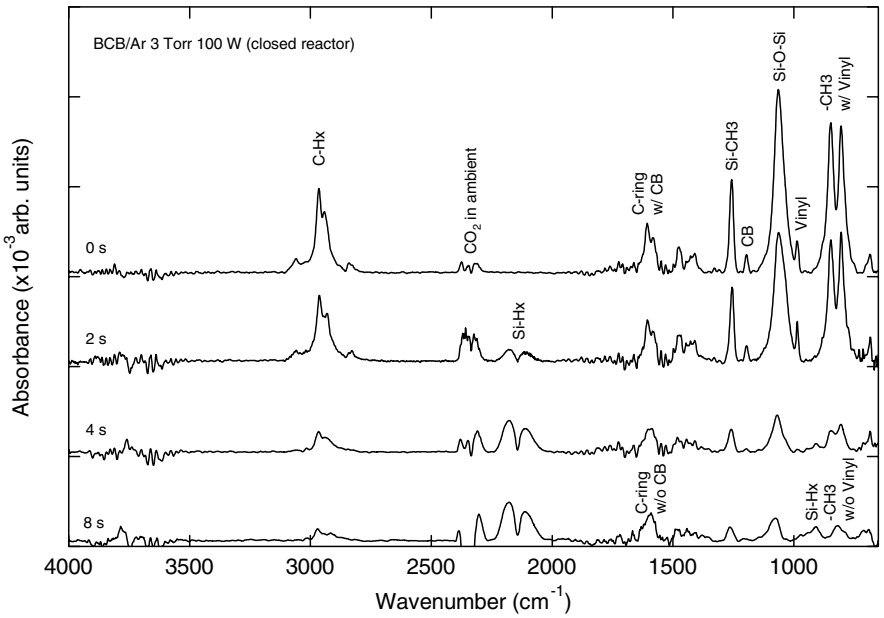

Fig.7 In situ gas-phase IR spectra of BCB/Ar plasma in closed reactor as a function of discharge time.

spectrum after 10-second discharge, these peaks disappear completely. This can be explained by chemical instability of these chemical bonds, because they contain double bonds which easily open by electron impact with smaller energy, which supports speculation deduced from film structure analysis.

On the other hand, the peaks for benzene ring, Si-O-Si and Si-CH_3 still exist even after 10-second discharge. Therefore, these chemical structures can be incorporated in the films. This is consistent to the results of chemical structure analysis of the films.

With increasing discharge duration, several peaks change their peak shape. For example, the benzene ring at 1600 cm^{-1} has two peaks before discharge, and its peak shape turns into one peak after 8-second discharge. This must be due to that cyclo-butene ring associated with benzene ring has been opened by electron impact, and a vibration mode due to association of cyclo-butene has disappeared. Similar trend is seen at around 800 cm^{-1}, where C-H_x mode exists. In this region, all the C-H_x bonds are contained. Before discharge, BCB contains CH_3, CH_2 in vinyl. As the vinyl structure rapidly disappear within the first 8 seconds, the peak profile with two peaks

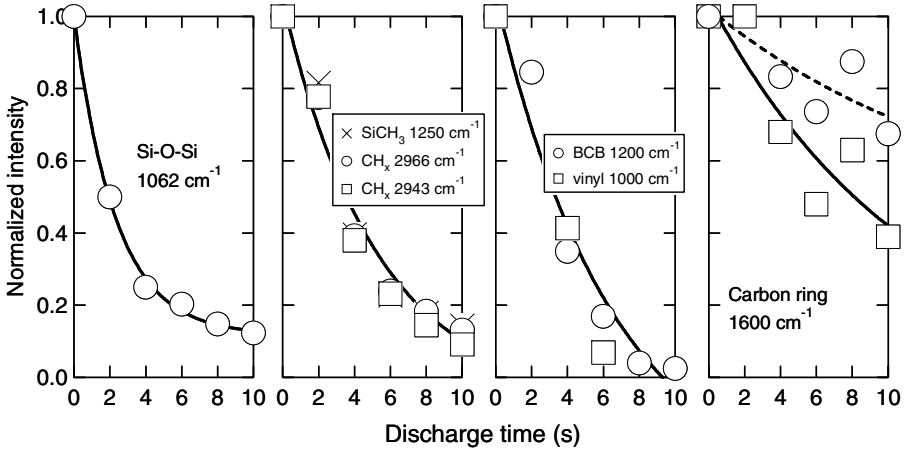

Fig.8 IR peak intensity of several chemical bonds detected in the gas phase as a function of discharge time.

disappear and becomes one peak after 10-second discharge. Except for the fact that benzene ring at 1600 cm^{-1} still exists and a new peak appears at 900 cm^{-1}, entire peak profile in the range of 1800-650 cm^{-1} is quite similar to that for HMDSO molecule, because chemical structures contained in the HMDSO are only Si-O-Si and $Si-CH_3$.

As shown in **Fig.7**, two peaks at 2100 cm^{-1} are generated with increasing discharge duration. Although these peaks are similar to R and P branch of SiH_4, Q branch was not observed. Although CO has absorption peak at the similar region, variation of CO_2 is not consistent to this peak. Therefore, this result suggests that Si-H containing species are created in the gas phase. As the films contain Si-H bonds, especially for higher RF power, bond breaking of Si-C-H is considered to occur at higher RF power, and H atoms attach to Si.

4. Summary

Plasma polymerization of DVS-BCB has been performed for preparation of low-k SiOC films. Films showed dielectric constant of ~2.3 for lower RF power of 50 W, but increased to 3.3 with increasing RF power to 200 W. Structural analysis of the films suggested that C-containing parts were reduced in the case of higher RF power. Gas phase diagnostics results suggested that, as a possible reason for the reduction of C-containing species, higher RF power brings about higher decomposition of C-containing bonds and/or detachment of C-containing groups from the monomer, which was faster than those for Si-O-Si and benzene rings. Furthermore, much higher RF power leaded also Si-C-H bond breaking and production of Si-H containing species, which were incorporated in the films.

Experimental Investigations of Spatial and Temporal Distributions of Oscillations in a Thermal Plasma Jet

J. Hlina, J. Gruber and J. Sonsky

Institute of Electrical Engineering, Academy of Sciences of the Czech Republic, Prague, Czech Republic

Abstract
Series of images from a high-speed CCD camera were used for evaluations of spatial distributions of hydrodynamic fluctuations and their temporal evolution in a thermal plasma jet. The evaluation procedure was based on the fast Fourier transform and wavelet analysis of time series reflecting the evolution of the plasma jet optical radiation in each pixel of the camera record. The results have shown the existence of various types of oscillations differing in both the locations of maximal amplitudes and their temporal stability.

Keywords
Thermal plasma jet, hydrodynamic fluctuations, CCD camera, fast Fourier transform, wavelet analysis.

1. Introduction

Thermal plasma jets are being used in a growing number of applications where the thermal transport in the jet or between the jet and an inserted body is important for the efficiency of technological processes. The energy transfer is influenced significantly by turbulent phenomena [1,2] which manifest themselves also as a modulation of the plasma jet optical radiation and can be thus recorded and analysed [3]. The effects of vortex structures on the characteristics of a plasma jet are stressed by the resulting entrainment of external air [4]. Experimental investigations of these processes are important because the theoretical models of thermal plasma jets still do not include realistic involvement of turbulence [5] and more experimental results concerning plasma instabilities are needed [6]. In this work we describe the results of investigations of oscillations detected in a thermal plasma jet based on analysis of their spatio-temporal characteristics mainly by means of wavelet analysis of CCD camera records. These investigations build on a previous work dealing with mapping of spatial distribution of the oscillations [7] by means of the fast Fourier transform (FFT).

2. Experimental arrangement and results

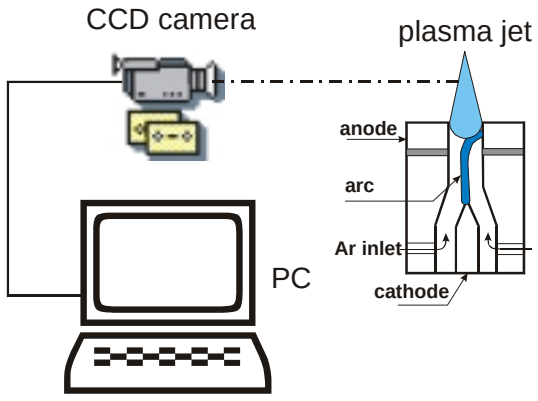

Fig.1. Experimental arrangement.

The experiments were carried out (Fig.1) using a vertically oriented cascaded d.c. fed arc torch working with argon with a typical arc length about 30 mm. The torch design was of a common type with a conical cathode and cylindrical anode working also as an output nozzle. The arc current was 100 A and the arc voltage 30-60 V depending on the gas flow rate which was varied in the range 10-80 slm. The gas heated by the arc discharge exited the plasma torch through the orifice with the diameter 8 mm. Records of the plasma jet radiation (examples are in Fig.2, colours represent the total optical radiation intensity) contained 4096 shots of the plasma jet acquired by a high-speed, black/white, 8 bit CCD camera with the frame frequency 33 kHz and resolution 72 x 96 pixels.

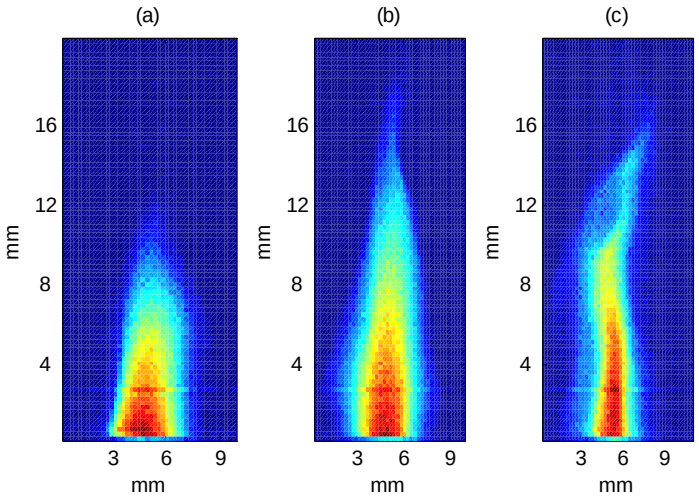

Fig.2. Examples of plasma jet images taken at 10 (a), 20 (b) and 60 slm (c).

The evaluation of the acquired data is possible using the FFT of data series reflecting time evolution of the signal recorded in each pixel of the CCD camera chip. The FFT yields frequency spectra with peaks showing significant oscillations in the plasma jet. The examples of frequency spectra in Fig.3 for the gas flow rates 10, 20 and 60 slm are the summations of FFT amplitudes in the whole plasma jet and show except the distinct peak at 300 Hz (which is caused by the modulation of the arc current) several peaks reflecting oscillations of a hydrodynamic origin. The spatial distribution of FFT

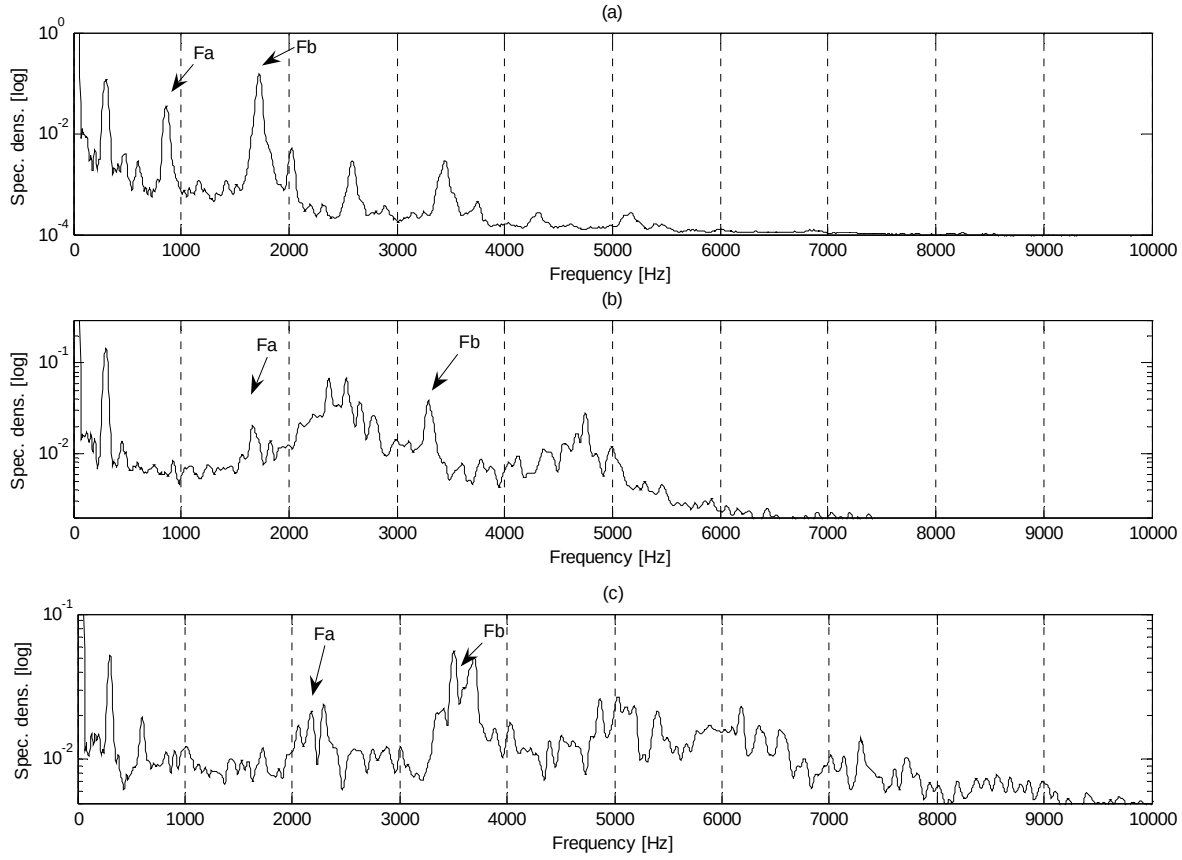

Fig.3. Frequency spectra at 10 (a), 20 (b) and 60 slm (c) with labels showing frequencies used for wavelet analysis.

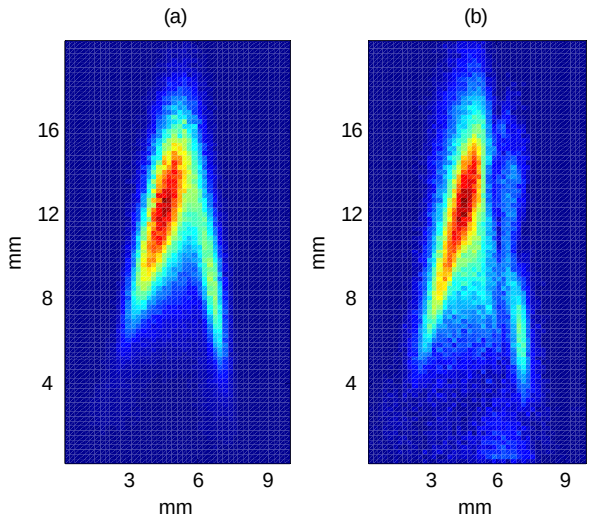

Fig.4. Comparison of spatial distribution of oscillations acquired by means of FFT in range 2300-2600 Hz (a) and wavelet analysis, scale 13 (b), at 20 slm.

amplitudes may be used to see the spatial distribution of oscillations on an arbitrary frequency in the spectrum.

The same data series have been used in this work mainly for the wavelet analysis on some chosen frequencies indicated in Fig. 3. The wavelet analysis was carried out using the complex Morlet wavelet. In the case of this wavelet type the relation between the wavelet pseudofrequency f and wavelet scale is $f=f_s/a$, where f_s is the sampling frequency (Hz) and a the wavelet scale given in number of samples. Using the complex wavelets, it is possible to study separately the behaviour of the real and imaginary components which reflect the coincidence of amplitudes or phases of the wavelet with the analysed signal. In our case we can so reveal the regions of significant occurrence of the studied oscillations and shifts of their location in time. The evolution of correlations on wavelet scales corresponding to

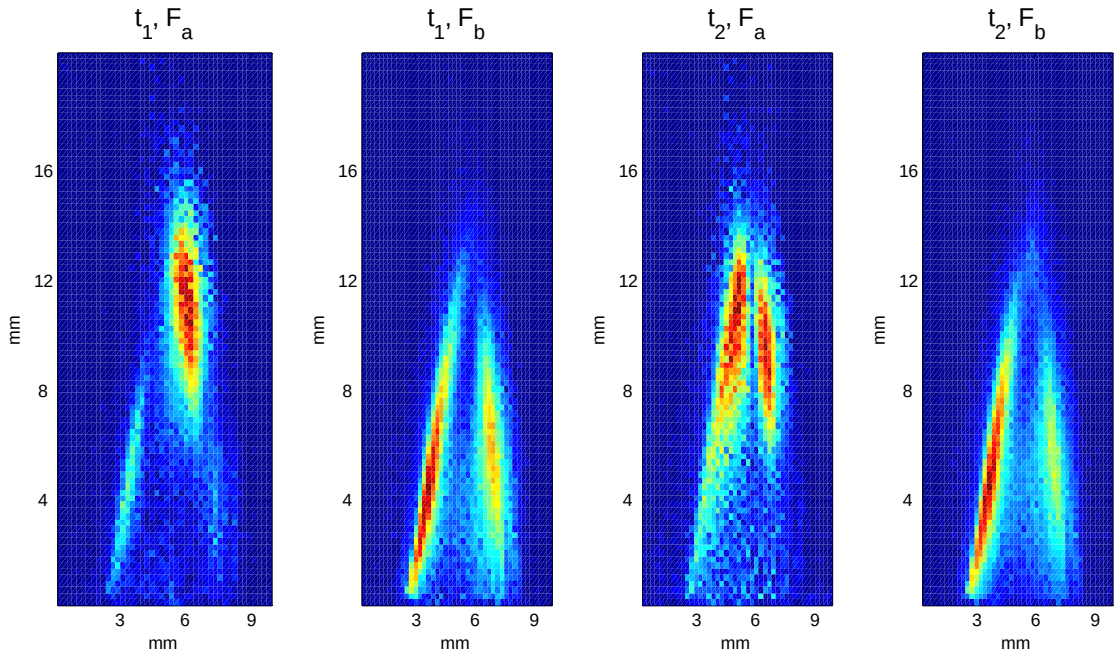

Fig.5. Distributions of oscillations for wavelet scales 38 and 19, corresponding to frequencies F_a, F_b, respectively, indicated in frequency spectra on Fig. 3a and at instants of time t_1, t_2. Gas flow rate 10 slm.

the chosen frequencies show then the temporal evolution of oscillation amplitudes on these frequencies. The summation of the wavelet correlation coefficients in the time series should result in the same spatial distribution of oscillation amplitudes as that acquired by the FFT and may be thus used e.g for checking

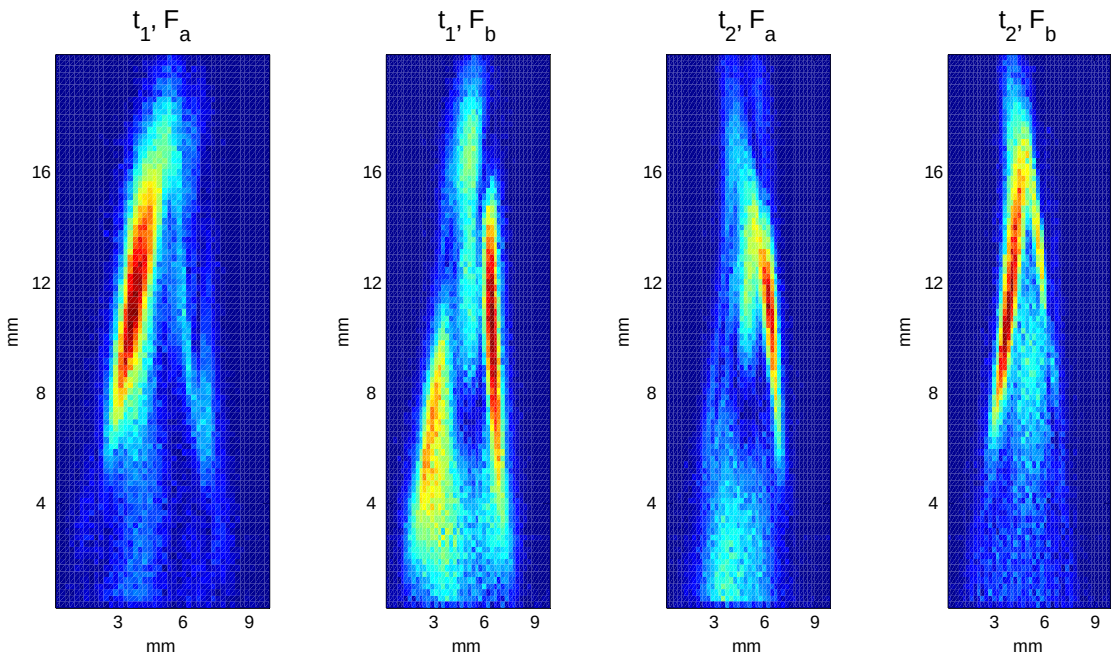

Fig.6. Distributions of oscillations for wavelet scales 20 and 10, corresponding to frequencies F_a, F_b, respectively, indicated in frequency spectra on Fig. 3b at two instants of time t_1, t_2. Gas flow rate 20 slm.

the correctness of the wavelet scale selection (an example of this comparison for the gas flow rate 20 slm and frequency Fb=2540 Hz in Fig.4 - corresponding to the wavelet scale 13).

Some examples of spatial distributions and their temporal changes for significant oscillations are in Figs.5–7. Each of the figures shows distributions of oscillations for two frequencies (F_a, F_b) indicated in frequency spectra on Fig. 3 and two instants of time for the gas flow rates 10, 20 and 60 slm.

3. Conclusion

Previous results [7] achieved by the FFT analysis of the images taken with a CCD camera have shown that most of oscillations occurring in thermal plasma jets are generated mainly on the jet boundaries or tail and their relative intensities may be sometimes distributed strongly asymmetrically, while the amplitudes corresponding to the plasma jet modulation introduced by the ripple of the arc current at 300 Hz show distributions with several maxima at distinct plasma jet regions or a distribution similar to the plasma jet total radiation intensities. The wavelet analysis is able to complete these findings with the information concerning the temporal stability or instability of the spatial distributions. The investigations of wavelet amplitudes derived by the application of the Morlet complex wavelets have shown that while the spatial distribution of some hydrodynamic oscillations at low gas flow rates may be relatively stable (scale 38 - frequency 870 Hz at 10 slm), the spatial location of all oscillations at higher gas flow rates (exceeding 20 slm) changes irregularly in time. Further increase of the flow rate (60 slm) leads to frequent localization of oscillations in the plasma jet core alternatively with splitting into many regions throughout the whole jet area characterising the transition to global plasma jet oscillations and strong turbulence. This work does not contain results dealing with investigations of the imaginary component of the complex wavelet analysis that yield phases of the oscillations and enable to study the velocity of their propagation in the jet which will be dealt with in another paper. The results have shown that the application of the wavelet analysis to records of a plasma jet optical radiation using high-speed CCD cameras may present a powerful tool in investigations of turbulent phenomena in plasma jets especially in studies of temporal instabilities of oscillations and relating heat transport phenomena.

ELECTRON DRIFT AND IONISATION IN Ne-Xe GAS MIXTURES

Abstract

We have measured the electron drift velocity v_e, the density-normalised longitudinal diffusion coefficient ND_L and the density-normalised ionisation coefficients α/N in the Xe-Ne mixtures over a wide range of the density-reduced electric field strength E/N from 1.4 to 200 Td. The values of v_e and α/N are in general in good agreement with the calculated values with the Bolsig code. In contrast, the experimental ND_L values disagree strongly with the calculated ones.

1. Introduction

The mixtures of noble gases with Xe are nowadays used in the Plasma Display Panel industry as a means to generate UV light from microdischarges in which the Xe atoms play an important role. Also, this kind of mixtures with Xe are used for building detectors like wire chambers and proportional counters in the high energy physics experiments, where data such as the drift velocity are essential. There is at present a great deal of activity related to the simulation and modelling of such discharges in order to improve their efficiency [1]. Among the many swarm data and cross sections needed for a meaningful and comprehensive model, a thorough knowledge of the electron drift velocity v_e and diffusion coefficients, as well as the density-normalised ionisation coefficients α/N in these mixtures is essential. We report on the measurement of these swarm coefficients over a wide range of the density-normalised electric field intensity E/N from 2 to 200 Td (1 Townsend = 10^{-17} V cm^2).

2. Apparatus and measurement technique

The electron drift velocities and the density-normalised ionisation coefficients were derived from the analysis of pre-breakdown electron avalanches observed from a Pulsed Townsend Experiment (PTE) [1-3]. The apparatus and the analytical techniques have been described previously in detail [1,2]. Briefly, the PTE is based on the measurement of the displacement current due to electrons and ions drifting in a parallel-plate discharge gap. The initial current is initiated by the release of photoelectrons from the cathode by a UV light pulse from a nitrogen laser (1 ns, λ=337 nm, 1.4 mJ). These photoelectrons and their progeny brought about by ionising collisions drift to their corresponding electrodes. Provided that the electrons are much more mobile than the ions, and that no electron detachment takes place (as in the present case, since no negative ions are formed) then the measured current can be separated into two components, namely fast and slow, corresponding to electrons and ions, respectively. Thus, we have used the electron component to derive the electron drift velocity from the measurement of the transit time of the electrons, and the ionisation coefficient from the exponential growth of the avalanche. The longitudinal diffusion coefficient was obtained from a curve fitting procedure to the electronic transients to the formula [5]

$$i_e(t) = \frac{n_0 q_o}{2T_e} \exp(\alpha v_e t)\left\{\left[1-\phi\left(\frac{(v_e+\alpha D_L)t-d}{\sqrt{4D_L t}}\right)\right]+\exp\left(\frac{v_e+\alpha\ D_L}{D_L}d\right)\left[\phi\left(\frac{(v_e+\alpha\ D_L)t+d}{\sqrt{4D_L t}}\right)-1\right]\right\} \qquad (1)$$

where n_o is the initial photoelectron number, q_o is the electron charge, d is gap spacing, T_e=d/v_e is the electron transit time, and

$$\phi(x) = \frac{2}{\sqrt{\pi}} \int_0^x exp(-u^2)\, du \qquad (2)$$

is the error function

The purity of Ne Xe was 99.999%. The total gas mixture pressure range used was 0.5-40 torr. The measurements were performed at room temperatures over the range 293-300 K. The gap distance was kept fixed at 3 cm to within an accuracy of 0.001 cm.

3. Results

To our knowledge, no previous data of the drift velocity, the density normalized longitudinal diffusion coefficient or the density normalized ionisation coefficient have been published in the literature. It appears that, whenever the knowledge of these coefficients is needed, resort is made of the simulation codes to derive them. The overall precision of our measurements is $\approx$1.5% for v_e, $\approx$ 6-10% for ND_L and $\approx$6% for α/N.

3.1 Electron drift velocities

The drift velocity of electrons in the Ne-Xe mixtures is shown in Fig. 1 for Xe concentrations of 2%, 5%, 20%, 30%, 50% and 100% covering a wide range of E/N from 1.4 to 200 Td. It seems that there exists a well defined dependence of the drift velocity with the Xe concentration, since v_e increases with an increase of the Ne content for fixed E/N.

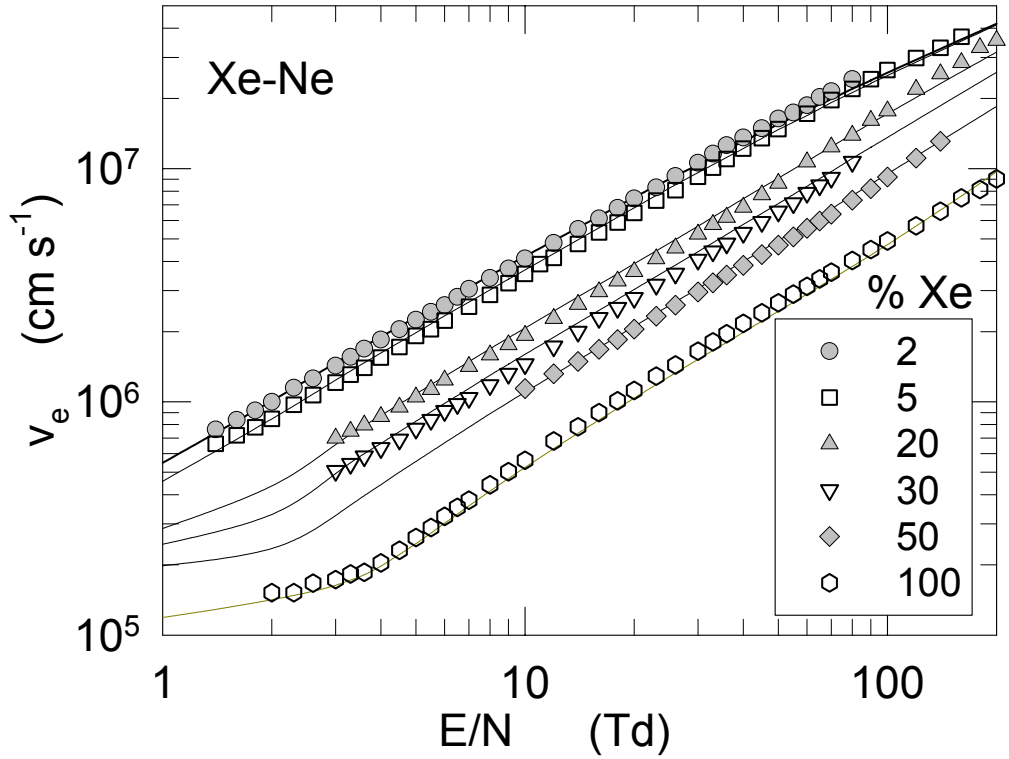

Figure 1. The electron drift velocity in the Xe-Ne mixtures as a function of E/N. Symbols, experimental data; lines, Bolsig calculations, with the exception of that for 100% Xe, which belongs to a Monte Carlo calculation [4]. For the sake of clarity, the Bolsig calculations for the mixtures with 2% and 10% Xe are not shown.

In the absence of previous data for comparison, we have resorted to use the Bolsig Code [6] to calculate these coefficients for the mixtures and to a recent Monte Carlo calculation for pure Xe [7]. The results are also plotted in the same figure, and are indicated by the solid lines. In general, the agreement between our data for the drift

velocity in the mixtures and the Bolsig calculations is very good over most of the ranges, within quoted uncertainties. On the other hand, even though the agreement with the Bolsig calculations for pure Xe was good, this code is only able to provide v_e data for Xe for E>9 Td. Thus we have compared our data with the Monte Carlo calculations [7], as shown in Fig. 1, in which the agreement seems to be excellent over the whole E/N range.

3.2 Longitudinal diffusion coefficients

The density-normalized longitudinal diffusion coefficients ND_L are shown in Fig. 2 for only two mixtures, since we have noticed a great discrepancy between our measurements and the Bolsig calculations, as it becomes apparent in this figure. Firstly, it appears that over the region of E/N being investigated, the ND_L values increase slightly with E/N, for E/N>10 Td. As with the electron drift velocities, for fixed E/N, ND_L increases steadily as the amount of Xe in the mixture is decreased. The Bolsig calculations depart strongly from our data in magnitude by factors between two and three, and the trend of the curves at low E/N contradicts that of the experimental values.

We are of the opinion that new calculations, with more powerful and accurate codes than Bolsig, which is a two-term code, could help resolve this discrepancy. It is also worth stressing the fact that the agreement between our data and the Bolsig calculations was very good, since it is known that the two-term codes are accurate for the calculation of this transport coefficient.

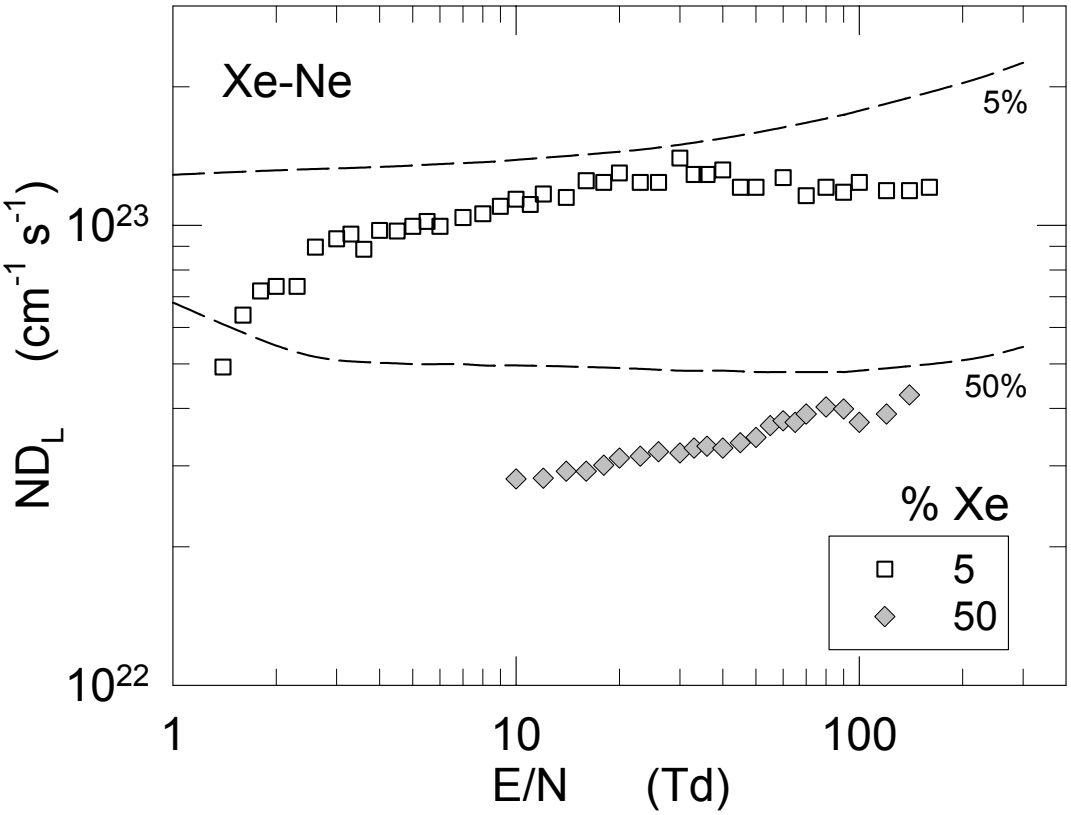

Figure 2. The present density-normalized longitudinal diffusion coefficient ND_L of electrons in the Xe-Ne mixtures (5% and 50% Xe only) (symbols). The solid lines represent the Bolsig calculations for this coefficient.

3.3 Ionisation coefficients

The density-normalised ionisation coefficients are shown in Fig. 3 as a function of E/N. Again, a well defined dependence with the Xe content is observed. For fixed E/N, the α/N values increase as the Xe content in the mixture decreases. The solid lines through the points correspond to the Bolsig calculation. Thus, with the

exception of the data for 2% Xe for E/N<40 Td and 30% Xe for E/N>20 Td, the agreement between measurements and calculations is very good. As regards comparison with other data, to the best of our knowledge there are no α/N values for the Xe-Ne mixture with which to compare.

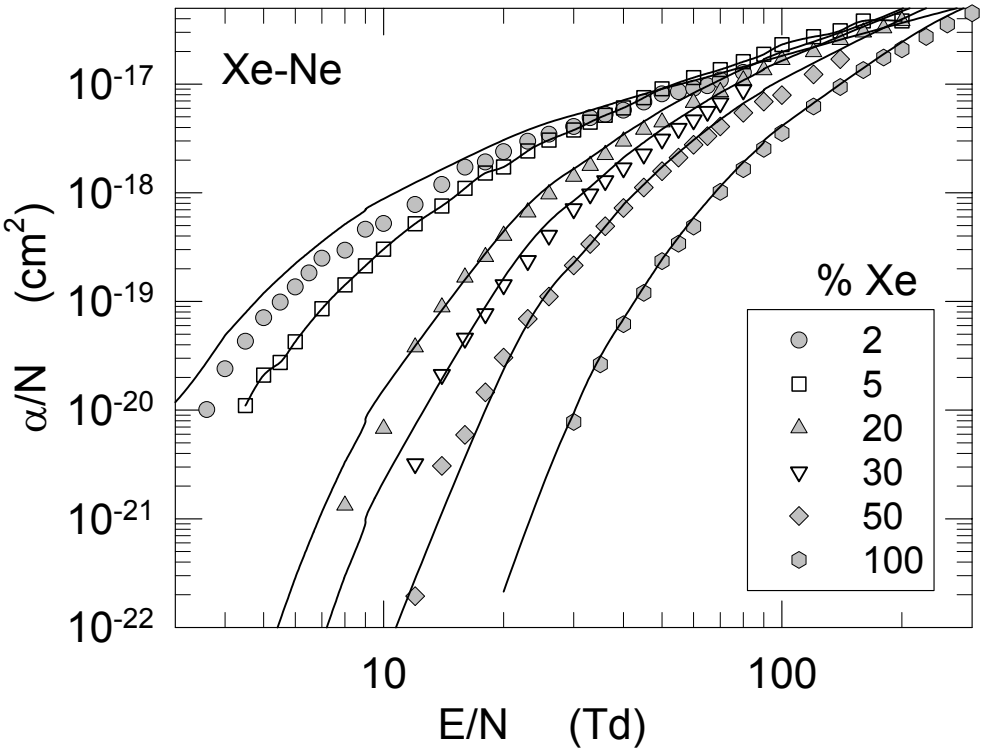

Figure 3. The density-normalised ionisation coefficient in the Xe-Ne mixtures as a function of E/N. The solid lines correspond to the Bolsig calculations.

4. Conclusion

We have measured the electron drift velocity, ionisation coefficients and longitudinal diffusion coefficients for the Xe-Ne mixture over a wide range of E/N. In general, we have found good agreement with the Bolsig calculations for v_e and α/N, but strong disagreement with the longitudinal diffusion coefficients. More comprehensive and accurate calculations are needed to resolve this matter.

Abstract

High frequency discharges and respective post-discharges are investigated by means of emission spectroscopy and NO - titration. In the present conditions a strong pink afterglow is formed in the post-discharge region, this extended field free region is rich in active species such has nitrogen atoms, vibrationally and electronically excited nitrogen molecules and ions. The experimental results are interpreted using a kinetic model [1].

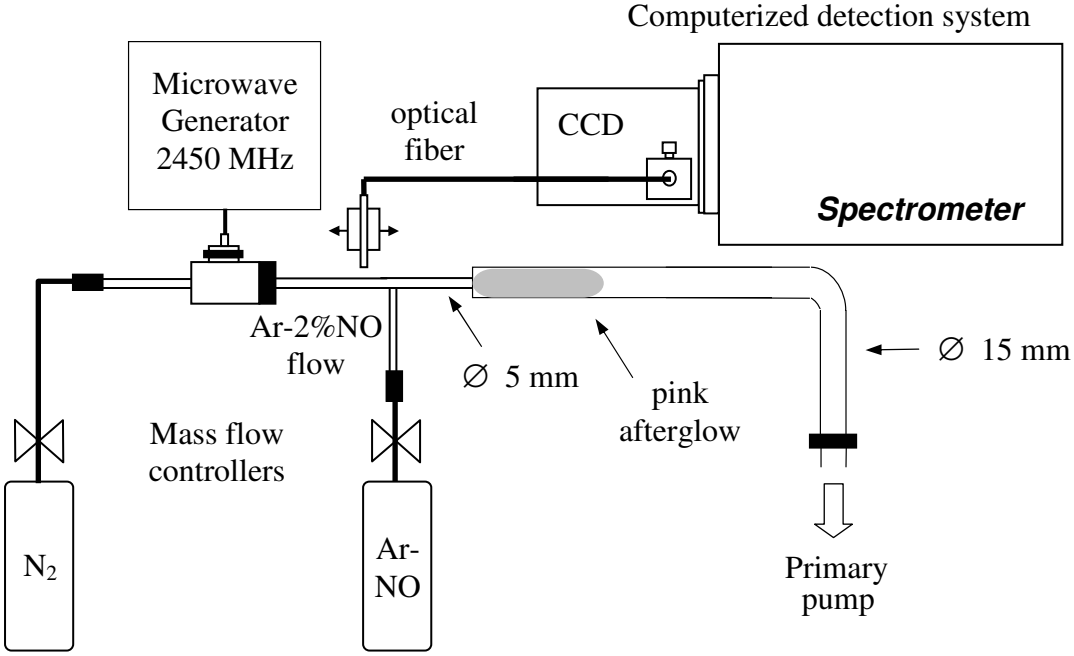

Figure 1. Experimental setup showing the discharge and post-discharge reactor.

Experimental setup

The experimental arrangement is reproduced in Fig. 1. High frequency discharges are produced using a Surfatron (at $\omega/2\pi$ = 2.45 GHz) in a quartz tube with 5 mm of internal diameter (i.d.) sealed to a bent quartz tube of i.d. 15 mm. The high frequency power transmitted to the plasma can vary between 30 to 150 watts, with a negligible reflected power. The total gas flow can be adjusted from 0.1 to 10 $L_n\,min^{-1}$ and the gas pressure in the chamber can be adjusted from 0.1 to 50 Torr. An Ar-2%NO gas mixture can be injected in the 5 mm i.d. quartz tube after the end of the discharge. The plasma and afterglow lights are collected by a quartz optical fiber connected to a Jobin-Yvon 270M spectrometer (1200 grooves mm^{-1} grating), equipped with a CCD detector.

Experimental Measurements

Emissions from the N_2 1st positive system (1st pos.) at 775.3 nm (see Fig. 2), 2nd positive system with the 367 – 380 nm sequence and 1st negative system at 391.4 nm (see Fig. 3) and vibrational spectra of the 1st pos.

N_2(B,v'=7 – 12) in the range between 570 – 610 nm (see Fig. 4), are studied as a function of the axial position in the discharge and post-discharge regions.

The rotational spectra of the N_2, 1st pos. at 775.3 nm allows us to determine the rotational temperature of N_2 as indicated in reference [2], measuring the intensity ratio of the P1/P2 rotational branches. In these measurements we have assumed that the N_2, 1st pos. rotational temperature is near the plasma gas temperature. The atomic nitrogen density at the end of the plasma column is measured by using the N_2 580nm band intensity which is calibrated by NO titration.

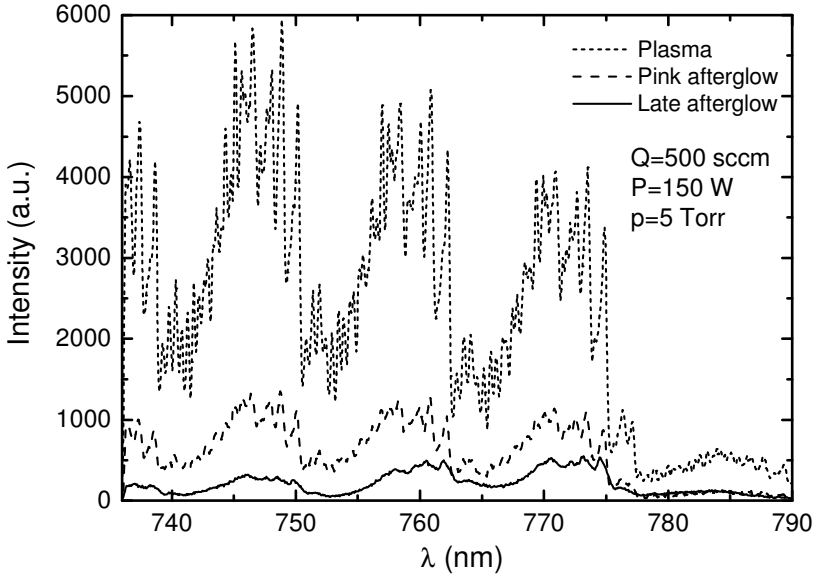

Figure 2. Emission spectra between 730 and 790 nm measured in the plasma at the gap (short dash line), in the beginning of the pink afterglow (dash line) and in the late afterglow (solid line).

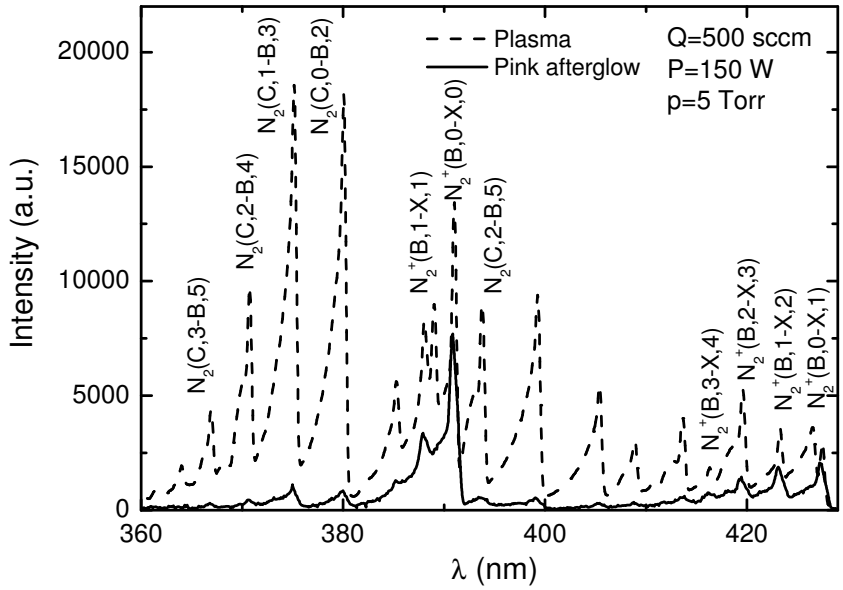

Figure 3. Emission spectra between 360 and 430 nm measured in the plasma at the gap (dash line) and in the beginning of the pink afterglow (solid line).

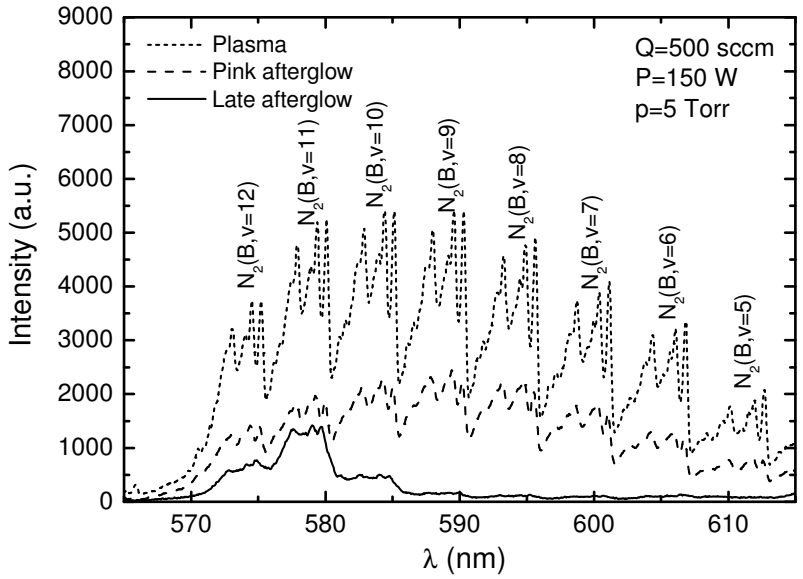

Figure 4. Emission spectra between 560 and 620 nm measured in the plasma at the gap (short dash line), in the beginning of the pink afterglow (dash line) and in the late afterglow (solid line).

Results

The ratio between the emission intensity lines of the transitions N_2^+(B,0–X,0) and N_2(C,0–B,2) increases 15 times from the gap to the beginning of the afterglow (see Fig. 3 and 5). The strong emission of the transition N_2^+(B,0–X,0) after the discharge end is the signature of the pink afterglow.

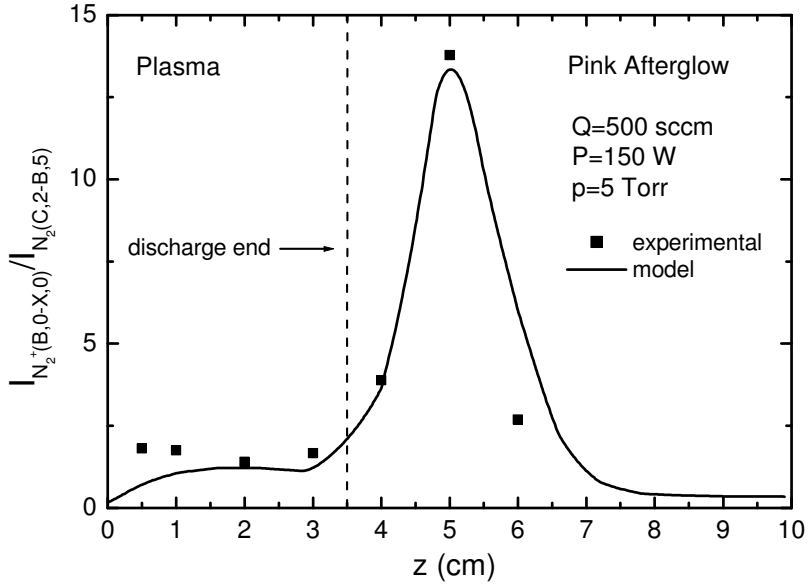

Figure 5. Axial distribution of the measured (black square) and theoretical (solid line, see ref. [1]) intensity ratios of N_2^+(B,0-X,0) over N_2(C,2-B,5) in the plasma and in the pink afterglow.

The gas temperature as determined from the rotational structure of the N_2 (1st pos.) increases from 500 K close to the gap to 950 K in the middle of the discharge column, remaining almost constant until his end. After the discharge end the temperature decreases slightly, attaining 650 K at 6 cm from the gap (see Fig. 6).

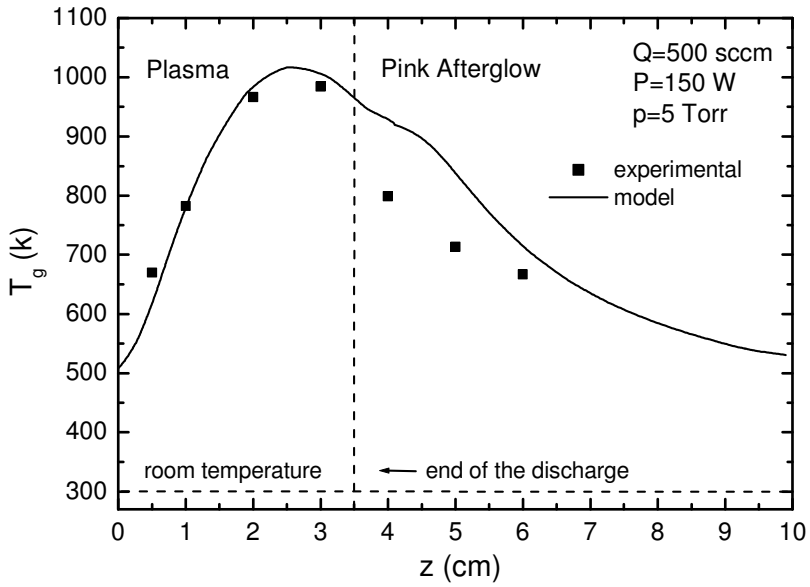

Figure 6. Axial distribution of the measured (black square) and theoretical (solid line, see ref. [1]) gas temperatures in the plasma and in the pink afterglow.

The vibrational distributions of $N_2(B,v'=7–12)$ in the discharge and in the pink afterglow remain almost unchanged. In the late afterglow an overpopulation of the $N_2(B,v'=11)$ is observed (see Fig. 7). The N – atom density measured by NO titration at the end of the pink afterglow is of 8.3×10^{14} cm^{-3} (uncertainty of 20 %).

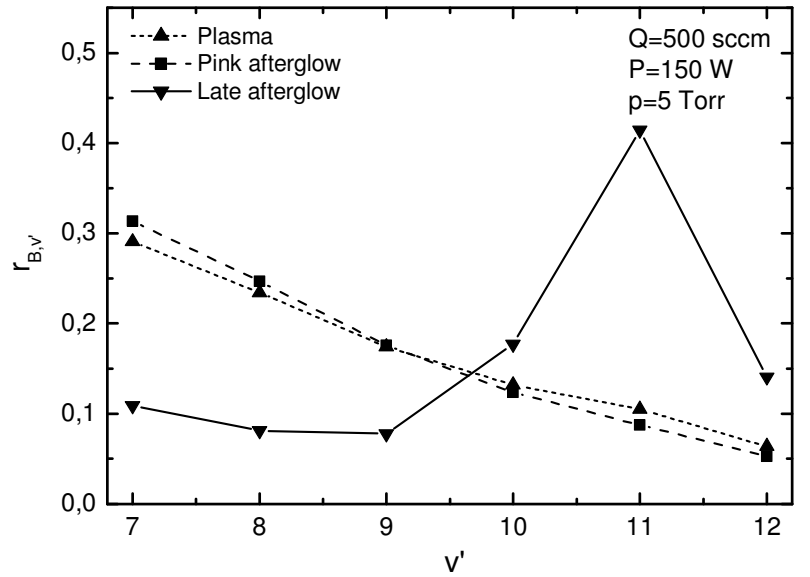

Figure 7. Normalized vibrational distributions $r_{B,v'}$ of $N_2(B,v')$ for v' = 7 – 12 in the plasma and afterglows.

Interpretation of the results

The sharp increase between the intensity ratio of the transitions $N_2^+(B,0\text{-}X,0)$ and $N_2(C,2\text{-}B,5)$ is directly related to the relaxation after the discharge end (field free region) of the vibrational distribution function (VDF) and of the electronic energy distribution function (EEDF). $N_2(C)$ is produced mainly by electronic impact in the plasma (more than 60%) with a small contribution of the pooling reaction $N_2(A) + N_2(A) \rightarrow N_2 + N_2(C)$ [3] (more than

30%). Due to the decrease of the electric field towards the end of the plasma, the electronic energy decreases and the productivity of these two reactions is equalized. After the plasma end the productivity of the pooling reaction between the flowing $N_2(A)$ metastable molecules grows in importance (see Fig. 8) together with the collisions between $N_2(B)$ and the growing vibrationally excited $N_2(X,v>12)$ states : $N_2(B) + N_2(X,v>12) \rightarrow N_2(C) + N_2(X,v=0)$ [4].

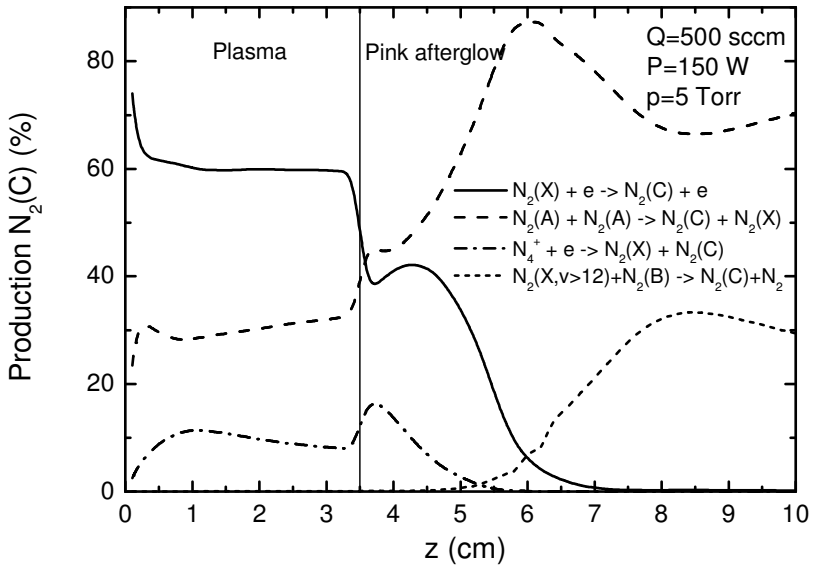

Figure 8. Calculated axial distribution of the $N_2(C)$ production channels in the plasma and in the pink afterglow.

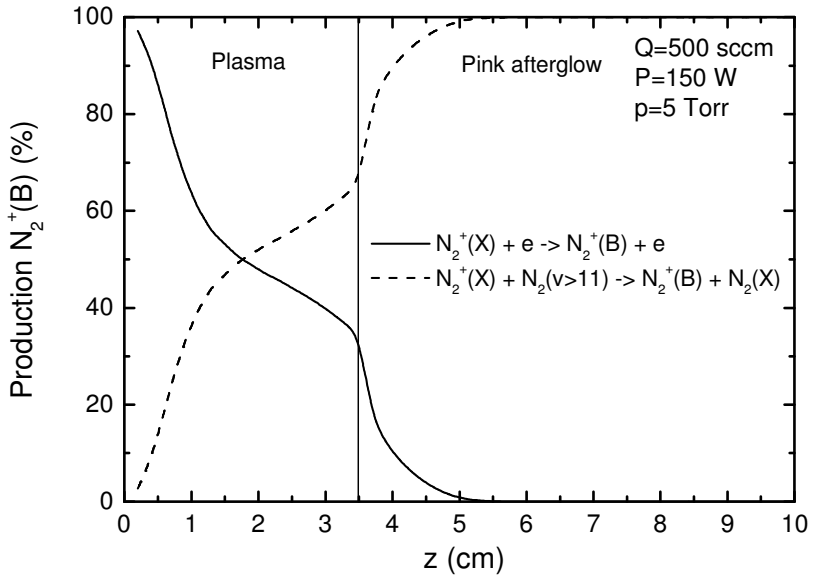

Figure 9. Axial distribution of the $N_2^+(B)$ production channels in the plasma and in the pink afterglow.

$N_2^+(B)$ is produced mainly by electronic impact in the discharge close to the gap, by the reaction $N_2^+(X) + e \rightarrow N_2^+(B) + e$. With the approach of the end of the discharge this reaction becomes less important and his productivity is equalized in the middle of the discharge (z = 2 cm) to the one of the reaction $N_2^+(X) + N_2(X,v>11) \rightarrow N_2^+(B) + N_2(X,v=0)$ [5]. After the end of the discharge the production of $N_2^+(B)$ is made almost entirely by collisions between $N_2^+(X)$ and the growing vibrationally excited $N_2(X,v>11)$ states (see Fig. 9). The

production of $N_2^+(B)$ is made mostly via $N_2^+(X)$. In the discharge $N_2^+(X)$ is produced mainly by the Penning ionization reaction $N_2(a') + N_2(a') \rightarrow e + N_2^+(X) + N_2(X)$ [6] (> 60%), by electronic impact reactions $N_2(X,A,B,a') + e \rightarrow N_2^+(X) + e$ and also by the penning ionization reaction $N_2(A) + N_2(a') \rightarrow e + N_2^+(X) + N_2(X)$ [6]. In the strong pink afterglow region (between 3.5 and 7 cm), $N_2^+(X)$ is produced mainly by penning ionization involving the flowing molecular nitrogen metastables $N_2(A,a')$. After that $N_2^+(X)$ is produced by the charge transfer reaction $N_4^+ + N_2 \rightarrow N_2^+(X) + N_2 + N_2$ [1,5] and N_4^+ is produced by the $N_2(a')$ flowing metastable and the growing vibrationally excited $N_2(X,v>12)$ states (see Fig. 9): reaction $N_2(X,v>24) + N_2(a') \rightarrow N_4^+ + e$ [7].

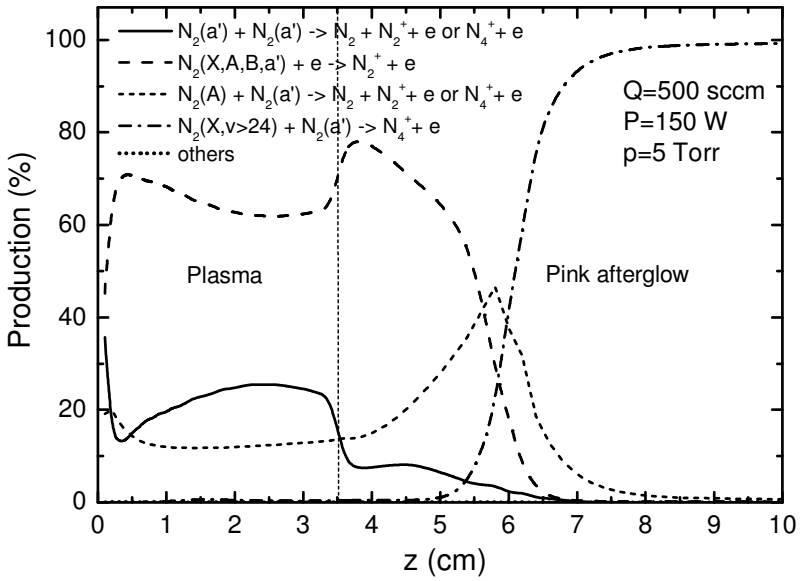

Figure 9. Axial distribution of the charge (N_2^+ and N_4^+) production channels in the plasma and in the pink afterglow.

Conclusion

A nitrogen glow and pink afterglow were produced and experimentally investigated by means of optical spectroscopy and NO - titration. The experimental results were interpreted using a kinetic model. An increase of 15 times in the emission intensity ratio of $N_2^+(B,0–X,0)$ over $N_2(C,0–B,2)$ were observed from the gap to the beginning of the afterglow. This effect is the consequence of the strong production of $N_2^+(X)$ in the pink afterglow by the Penning ionization reactions $N_2(A,a') + N_2(a') \rightarrow e + N_2^+(X) + N_2(X)$ followed by the reaction $N_2^+(X) + N_2(X,v>11) \rightarrow N_2^+(B) + N_2(X,v)$. A good agreement was obtained between the experimental and theoretical results.

Two-dimensional Modeling on Filamentary Mode of Dielectric Barrier Discharge in Nitrogen at Atmospheric Pressure

J. I. Kim, J. M. Park, D. Lee, S. I. Choi, and S. H. Hong

Department of Nuclear Engineering, Seoul National University, Seoul, 151-742 Korea

Abstract

Filamentary mode characteristics of dielectric barrier discharge (DBD) in atmospheric-pressure nitrogen are studied numerically by a fully two-dimensional simulation, in which the dynamics of a single streamer in the parallel-disk DBD are analyzed by the spatio-temporal plasma characteristics with an axi-symmetry. Simulation results describe not only the formation and propagation process of a streamer in the filamentary mode of the DBD but also the distinctive discharge phases of avalanche, streamer, and decay. It is revealed that the filamentary discharge is extinguished due to the surface charges accumulated on the dielectric barriers.

Keywords

Dielectric barrier discharges, Filamentary discharges, Streamer, Numerical modeling

1. Introduction

Dielectric barrier discharges (DBDs) as typical sources of atmospheric non-equilibrium plasmas are generated by applying high voltage to the electrodes, one or both of which are covered with the dielectric barriers. Since DBDs are simply operated without expensive vacuum equipment and make abundant chemically active species, they are widely used in numerous industrial applications such as ozone production, decomposition of gaseous pollutants, surface treatment of polymers, excimer lamps, and plasma display panels [1]. For their more effective applications, however, it is essential to fully understand the inherent discharge characteristics of DBDs. The filamentary and homogeneous (or diffusive) modes of the discharges are known to exist in DBDs according to their operating conditions. Each discharge mode of the DBD has its own formation mechanism and discharge characteristics, and especially the filamentary discharges, which are caused by the evolution of a streamer, play an important role in the plasma chemistry.

Extensive numerical studies on a streamer as a kind of an ionizing wave have been conducted because the streamer has such properties of a fast velocity and highly localized dynamics that the experimental research has been limited to some extent. To overcome the weakness of 1.5-dimensional modeling assuming a constant radius of the streamer channel [2], two-dimensional modeling on a single streamer was attempted for a discharge without dielectric barriers [3]. Especially in the DBD, it is of importance to take effects of surface charges due to their essential role in preventing the filamentary discharge from transferring to an arc discharge. In the present numerical work, the filamentary mode of DBD in nitrogen at atmospheric condition is studied by a fully two-dimensional modeling for a single streamer channel with different radii, in which an azimuthally symmetry about its propagation axis is assumed in cylindrical coordinates.

2. Theoretical model

2.1. Governing equations

A hydrodynamic drift model is employed for the numerical simulation on the filamentary mode of DBD. The fluid approach used broadly in a streamer modeling is not only simple to deal with but also productive with sufficiently reasonable results. Since the response time which takes electrons to reach an equilibrium state at atmospheric pressure is shorter than the time constant for electric field **E** to change due to the effects of space charges, it is assumed that the average velocity and momentum of electrons are instantly in equilibrium with

electric field [4]. In other words, the relaxation time and distance of the electron momentum and energy are so short that it is possible to take advantage of the 0th-order moment equations to describe electron and ion motions macroscopically. The governing equations are then given for electrons (e) and ions (i) as follows:

$$\frac{\partial n_e}{\partial t} + \nabla \cdot (n_e \mathbf{v_e}) = S_e \tag{1}$$

$$\frac{\partial n_i}{\partial t} + \nabla \cdot (n_i \mathbf{v_i}) = S_i \tag{2}$$

$$\mathbf{v_e} = \mu_e \mathbf{E}, \quad \mathbf{v_i} = \mu_i \mathbf{E} \tag{3}$$

where n is the number density, $\mathbf{v}$ is the drift velocity, S is the particle source term, and μ is the mobility.

Diffusion of charged particles is neglected and only electron impact ionization is considered in the source term for the sake of simplicity. Townsend's ionization coefficient α is dependent on a reduced electric field E/P due to a local field approximation. Then, α = 5.7 P exp(-260P/E) (cm^{-1}), $\mu_e = 2.9\times10^5$/P (cm^2/V·s), and $\mu_i = 2.6\times10^3$/P (cm^2/V·s) for nitrogen gas where P is the pressure in Torr [3] and set to be 760 here. The electric field is found from the following Poisson equation,

$$\nabla \cdot (\varepsilon \nabla \phi) = -e(n_i - n_e), \quad \mathbf{E} = -\nabla \phi \tag{4}$$

The governing equations are discretized based on a finite difference method (FDM). The continuity equations are solved by an upwind method and a fine grid is used to minimize numerical diffusions. A fast direct method is applied to the Poisson equation by using a sparse matrix solver, UMFPACK library, [5].

2.2. Initial and boundary conditions

A computational domain for describing the single streamer characteristics in a filamentary mode is a discharge gap of 0.2 cm between two parallel dielectric barrier disks, each of which covering a cathode or anode surface has a thickness of 0.1 cm. The origin of the axi-symmetric cylindrical coordinates (r, z) is placed at the center of the cathode barrier disk. A quasi-neutral plasma of a Gaussian profile is assumed to be initially exist in front of the cathode barrier surface as an initial condition for electron and ion densities: $n_e(r,z) = n_i(r,z) = n_0\ exp[-\{r^2+(z-d)^2\}/\delta^2]$ where $n_0 = 10^3$ cm^{-3}, d = 0.03 cm, and δ = 0.02 cm. The electron density at the cathode barrier surface is determined from the flux of secondary electrons emitted by ion bombardments.

Assuming that all of the charges moving toward the dielectric barriers are accumulated on the dielectric surfaces without dissipation, the equation for the surface charges on the dielectric barriers are given as

$$\frac{\partial \sigma_e}{\partial t} = n_e \mathbf{v_e} \cdot \hat{\mathbf{n}}_z, \quad \frac{\partial \sigma_i}{\partial t} = n_i \mathbf{v}_i \cdot \hat{\mathbf{n}}_z \tag{5}$$

where σ is the surface charge density and $\hat{\mathbf{n}}_z$ is the unit vector from plasma toward the dielectric barrier.

The electrostatic potential at the anode is set to 11 kV, the cathode potential to zero, and the derivatives of the potential vanish at the radial boundary of the cylindrical discharge chamber. The boundary condition for the potential at the interface between plasma and dielectric barrier is expressed as

$$\frac{\partial \phi}{\partial z} - \varepsilon_r \frac{\partial \phi_D}{\partial z} = \frac{e}{\varepsilon_0}(\sigma_i - \sigma_e) \tag{6}$$

where ε_r is the relative permittivity of dielectric material, and ϕ and ϕ_D are the electric potentials on the plasma and dielectric barrier sides, respectively.

3. Results and discussion

Temporal evolution of electron density at an early phase of discharge is shown in Fig. 1. The electron density grows exponentially with time as electrons move toward the anode barrier until 7.0 ns. It represents a Townsend discharge phase, in which electron multiplication dominates by electron impact ionizations due to frequent collisions between electrons and neutral atoms. There is little distortion of electric field during this avalanche stage since the effect of space charges is negligible. This stage could be omitted when the initial plasma density is high enough to affect the applied electric field. In that case, positive and negative streamers immediately propagate toward both of the dielectric barriers.

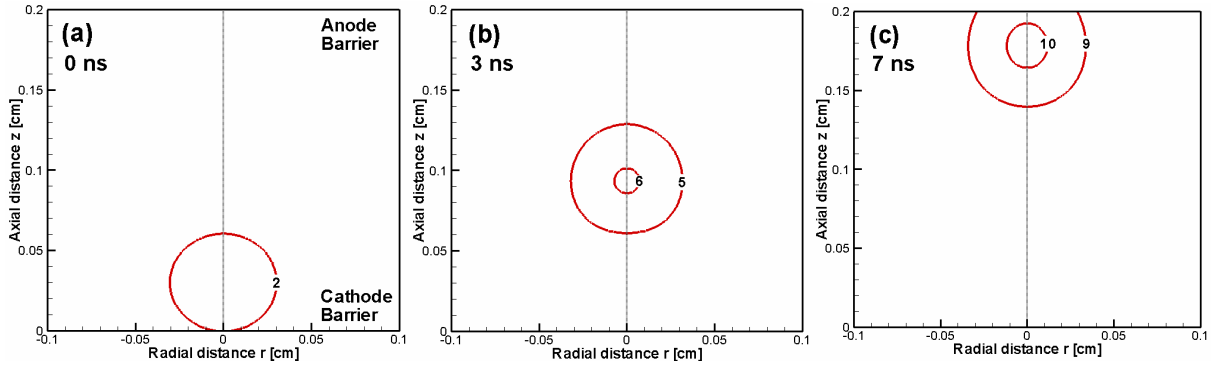

Fig. 1. Contour plots of electron density in a logarithmic scale at (a) 0 ns, (b) 3 ns, and (c) 7 ns during an avalanche phase in a parallel-disk DBD. The cathode and anode barrier disks are placed at z = 0 and at z = 0.2, respectively. Numbers typed on the contour lines are the power of 10, i.e., 2 stands for 10^2 cm^{-3} of electron density.

After the avalanche phase, the electric field near the anode dielectric barrier begins to decrease. Figure 2 shows the time change of highly distorted electric field during the propagation of a cathode-directed streamer. It takes several tens of *ns* for the streamer to be formed before the electron density is built up above about 10^{11} cm^{-3}.

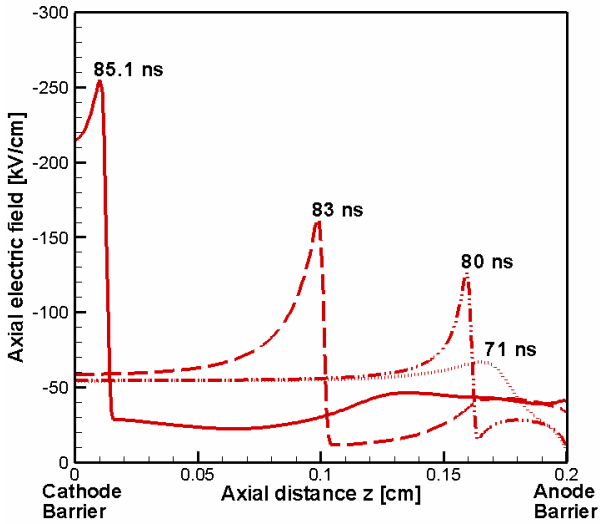

Fig. 2. Time variation of axial electric field along the axis (r = 0) during the streamer propagation from the anode barrier (z = 0.2) to the anode barrier (z = 0).

From the spatio-temporal profiles of electron density in Fig. 3(a), the velocity of the streamer propagation approximates to 10^7 cm/s and the radius of the streamer is about 400 μm. Since these results are similar to those obtained from the discharge case with no dielectric barriers [6], the dielectric barriers appear not to have much influence on the streamer propagation stage. As seen in Fig. 3(b), horseshoe-like distributions of space charges

are built up near the streamer head, but the net space charge density is low inside the streamer channel. This results in strong electric fields near the streamer head of net positive charges, while near-zero fields inside the streamer channel of a quasineutral plasma region. However, shielding of the electric field inside the streamer is not perfect because of a finite dielectric relaxation time of plasma [3]. The time evolution of detailed electric field distributions is plotted in Fig. 3(c). The steep gradients of electric fields appear at the streamer head due to large displacements between electrons and ions. The energetic electrons, which will generate abundant chemically active species in the filamentary mode of DBDs, are produced in this region.

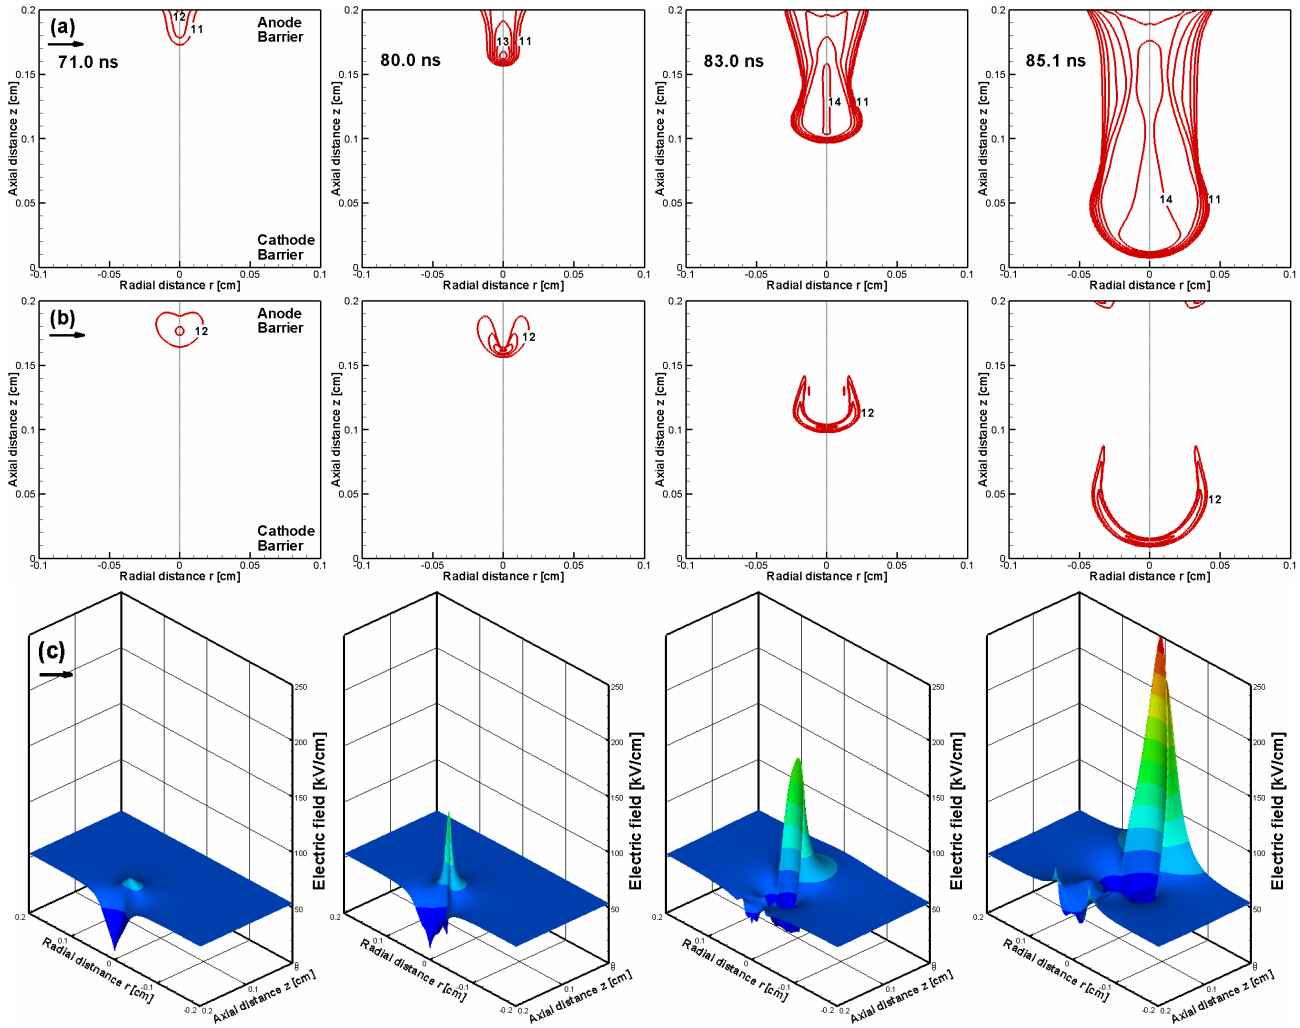

Fig. 3. Contour plots of (a) electron density, (b) net space charge density, and (c) electric field strength during the streamer propagation from the anode (z = 0.2) to cathode (z = 0) barriers in a parallel-disk DBD at 71.0 ns, 80.0 ns, 83.0 ns, and 85.1 ns from left to right column, respectively. Numbers typed near the contour lines in (a) and (b) are the power of 10, i.e., 11 stands for 10^{11} cm^{-3} of particle density.

Figure 4 shows a decay phase of the streamer discharge, in which the electric field vanishes with time and the electron density practically sustains a stationary state. The electrons on the cathode barrier are radially extended with time as seen in Fig. 4(a), and the electric fields at the streamer head decay with time reaching the cathode dielectric barrier in Fig. 4(b). A high electric field strength of over 900 kV/cm decreases rapidly within only a few 10 μm in front of the cathode barrier surface. This locally intensive cathode fall moves outward radial direction and disappears quickly. After the streamer arrives at the dielectric barrier surface at t = 85.2 ns, a single

filament channel is formed between two dielectric barriers and the discharge current records its maximum value of 1.8 A. Figure 5 shows an evolution of the discharge current density which demonstrates the filamentary mode of DBD – formation of the streamer channel and quenching of the discharge. As discussed above, one cycle of the filamentary discharge consists of the distinct discharge phases: avalanche, streamer propagation, cathode fall formation, and decay. After formation of a single filament channel, the discharge current a bit slowly decreases owing to the weakened motion of free charges, and then the filamentary discharge is finally extinguished.

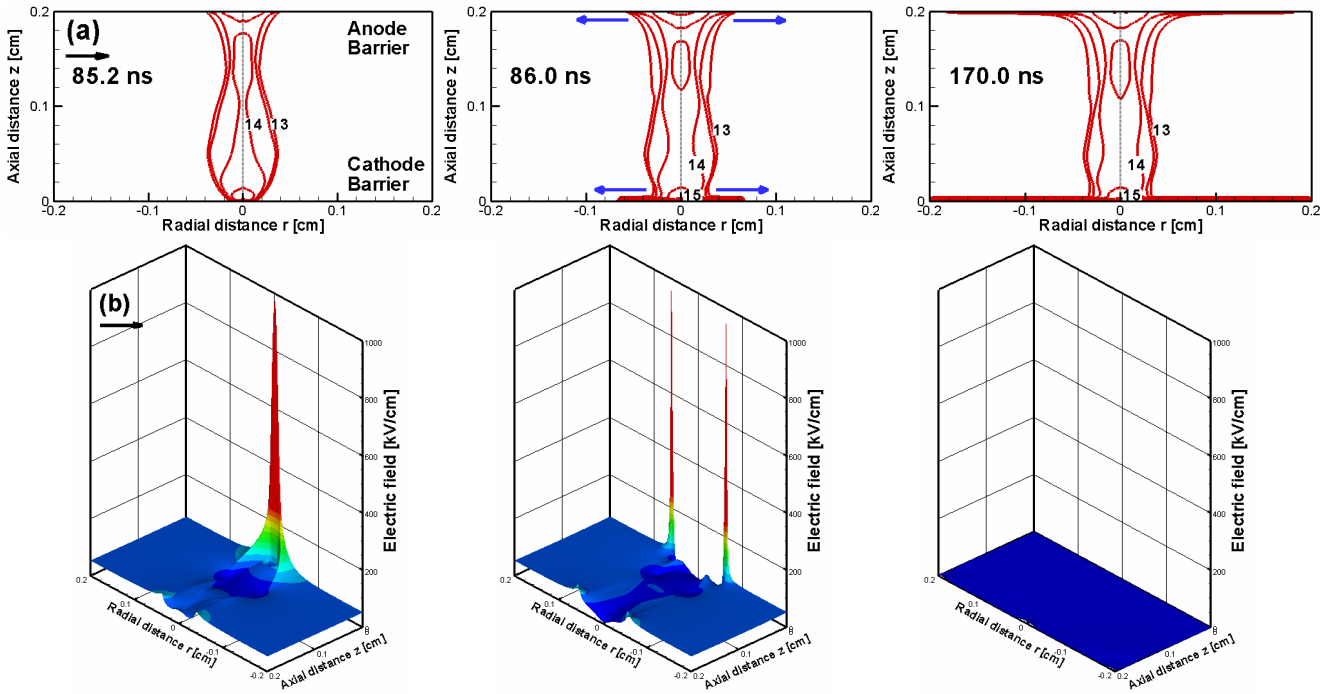

Fig. 4. Contour plots of (a) electron density and (b) electric field strength during a decay phase between the cathode (z = 0) and anode (z = 0.2) barriers in a parallel-disk DBD at 85.2 ns, 86.0 ns, and 170.0 ns from left to right column, respectively. Numbers typed near the contour lines in (a) are the power of 10, i.e., 13 stands for 10^{13} cm^{-3} of electron density.

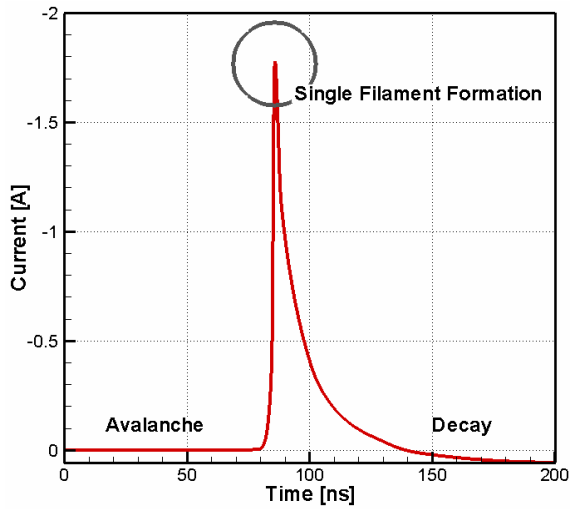

Fig. 5. Time evolution of discharge current during a filamentary discharge in a parallel-disk DBD with an initial uniform electric field of 54 kV/cm.

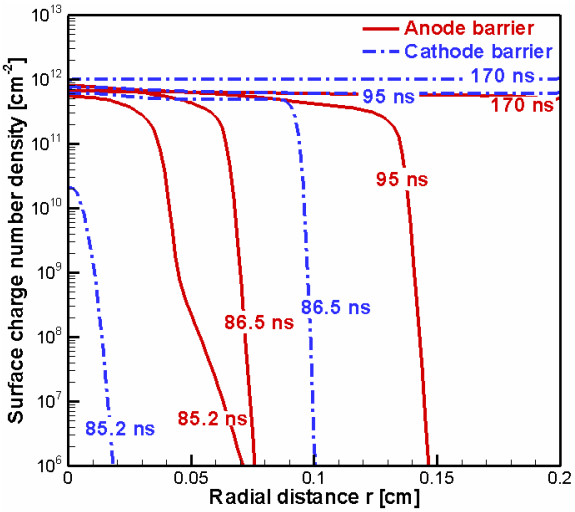

Fig. 6. Time variations of radial distributions of surface charges on both the dielectric barrier surfaces in a parallel-disk DBD.

The surface charges deposited on the dielectric barriers play an important role in shielding the applied electric field and in preventing the filamentary discharge from changing to an arc discharge. Time-varying surface charges accumulated on the dielectric barrier disks are drawn in Fig. 6. The surface charges deposited on the barrier surfaces rapidly increase after the streamer arrives at the cathode barrier, and then they become to spread radially outward direction on the surfaces. As the surface charges are distributed uniformly on the barrier surfaces, they make the applied electric field shielded in the discharge gap. The single filamentary discharge is thus quenched because of the net surface charges of opposite polarities accumulated on the surfaces of a pair of the dielectric barriers.

4. Conclusion

A two-dimensional modeling on parallel-plate type DBD in atmospheric-pressure nitrogen is carried out in order to study the filamentary discharge characteristics and the streamer dynamics. The simulation results show that the space charges in the DBD manly affect the formation and propagation of the streamer, and that a very steep electric field appears in front of the cathode barrier surface as the streamer head approaches to it. As a thin filament channel connects the dielectric barriers to each other, the discharge current reaches its maximum value, and subsequently, the discharge is quenched due to the accumulation of the surface charges. For a more realistic modeling of the filamentary mode of DBD, it is suggested that the detailed loss mechanism and radial behavior of the surface charges accumulated on the dielectric barrier should be taken into account in the future work.

Theoretical Analysis of Factors Affecting NOx Removal Performance by Barrier Discharge

T. Shoyama[1], S. Senda[1], Y. Yoshioka[1]

[1] *Department of Electrical Engineering, Kanazawa Institute of Technology, Ishikawa, Japan*

Abstract

NOx removal process was analyzed using a simplified micro-discharge model and by solving the rate equations and diffusion equation simultaneously. As the results, it became evident that (1) the temperature rise in the discharge channel had a negative effect on NO removal performance, (2) the existence of N_2 metastable state influences the NO removal performance if the quenching reaction of the metastable state N_2 is small and (3) wave form of the applied voltage has smaller effect on NO removal performance except the case that pulse discharges concentrate in a short period.

1. Introduction

NOx removal from diesel exhaust gas is difficult by conventional technologies. Thus, NOx removal techniques using non-thermal plasmas like silent discharge and corona discharge have been investigated actively so far. The principal mechanism of NOx removal by non-thermal plasmas is the oxidization of NO to NO_2 by O radical and O_3. However, it became apparent that the energy efficiency of this process is not enough for industrialization. In order to find ways to improve the energy efficiency, it is necessary to investigate the NO removal paths more in detail [1]. We developed a simulation model, which calculates the various chemical reactions induced by discharge, and also reactions induced by the diffused radicals to the outside of the discharge channel [2]. In this paper, we investigated the effects of three factors affecting NO removal performance, such as temperature rise of the inside of a discharge channel, the existence of N_2 metastable state $N_2(A^3\Sigma_u^+)$ and voltage waveform.

12. Analytical Method

2.1 Model of a micro discharge and calculating conditions

Here, we describe a model of a micro discharge and calculation conditions which were used in the analysis. In the silent discharge device, many micro discharges occur in the air gap between electrodes covered with a dielectric plate by applying AC high voltage. Fig.1 shows the electric equivalent circuit of silent discharge. We focused to a one micro discharge, and the micro discharge in the gap is assumed as a discharge of a small capacitor C_1. Fig. 2 is a model of one micro discharge structure.

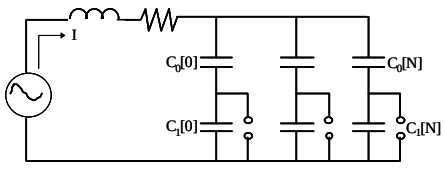

Fig.1 Equivalent circuit of silent discharge

micro-discharges in the electrode area *S* becomes *m*, which is calculated by Eq. (2).

Followings are the calculation conditions. When AC voltage is applied to the discharge device, pulse micro discharges occur only when the gap voltage exceeds the breakdown voltage of the gap. Many radicals are generated by collision of molecules with the energetic electrons, and at the same time they react with the gas molecules during the discharge period. However, there are no radical generations during the non-discharge period. Thus, the non-discharge period is the period, when the residual radicals diffuse from the discharge channel and react with pollutants. The ratio *Rd* defined as Eq.(8) is the ratio of discharge period in a half cycle, and it varies with the wave form of the applied voltage. Usually, *Rd*=50%. So in the case that the frequency *h*=250Hz, the micro discharges occur for 1ms, and they don't occur for another 1ms, namely the discharge period comes at 1ms intervals. The discharge period continues for 40ms, and after 40ms, the chemical reactions are induced by residual reactive species and finally all the reaction products reach the equilibrium state. Location of pulse micro discharge was assumed to be at the same place all time.

The electron density in the micro discharge channel n_e was calculated by Eq.(9). A reduced electric field *E*/*n* in the gap was assumed as constant value of 100Td. An electron consumption rate κ of 0.55 was used from the literature [3]. *P*(1)~(3) in Table.2 are very important physical parameters, and the typical physical values that reported by Dr. Kogelschatz were used as shown in Table 1 [4], *P*(4) is a calculation condition, and *P*(5)～(6) are the dimension of our discharge device, and *P*(11)~(18) are values of the physical

parameters, and they are calculated from the typical physical values of $P(1)$~$P(3)$ by Eq.(1)~(8).

2.2 Calculating method of chemical reactions and diffusion

Diffusions of various species from a micro-discharge channel are governed by Eq.(10) in a micro-discharge model which is illustrated in Fig.3.

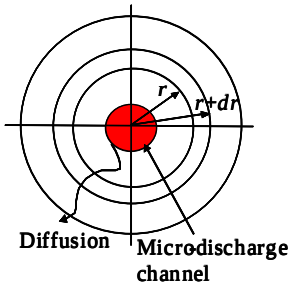

Fig.3 micro-discharge model

$$\frac{\partial c}{\partial t} = D \cdot \left(\frac{\partial^2 c}{\partial r^2} \right) + \frac{D}{r} \cdot \frac{\partial c}{\partial r} + \Gamma \quad \text{.....(10)}$$

$$\Gamma = k_1 \cdot [A] \cdot [B] + k_2 \cdot [A] \cdot [E] + \cdots \quad \text{.....(11)}$$

Where, $[X]$: density of substance X(cm^{-3})

Boundary condition at an edge of analyzing area is $dc/dr=0$. D (cm^2/s) means a diffusion coefficient, and as a D value, $0.41 cm^2/s$ was used. Γ in Eq.(11) is an amount of chemical reaction, which is calculated by the multiplication of the reaction rate k(cm^3/s-2body reaction, cm^6/s-3body reaction) and the density of gas molecules(cm^{-3}). The calculation took 161 reactions and 24 species into consideration, and the reaction rates were taken from NIST database [5] and Ikebe's report [6].

3. Results and discussion

3.1 Influence of local elevation of temperature on NO removal performance

When the many successive micro-discharges occur in the same channel, a portion of discharge energy is deposited in the volume of the micro-discharge channel. Gas temperature in the volume will increase by the deposited energy. On the other hand, since the reaction rates depend on the gas temperature, we investigated the effect of local elevation of gas temperature on NO removal performance. The elevation of gas temperature was calculated by solving the heat conduction equation and the NO removal performance was calculated by solving Eq. (10), considering the change of the reaction rate at high temperature.

At first, we estimated the temperature rise per single micro-discharge. In Eq. (9) of Table 1, the electron consumption rate κ was used, and κ means the rate of discharge energy used for radical reactions. According to the literature [3], κ was estimated as 0.55. If we think it from the other side, it is understood that the rest of the energy, namely (1-κ), is used for vibrational / rotational excitation and for ionization. So we assumed a half of the residual energy, namely R_T=0.225, was used for the temperature rise. On this assumption, the temperature increase $d\theta$ per single micro-discharge was calculated as 10.4K by using Eq.(12). Here, gas in the discharge device is air. Eq.(13) shows the heat conduction equation applied to our micro-discharge model.

$$d\theta = \frac{Q \cdot R_T}{c \cdot w} = \frac{C \left(V_g^{\,2} - V_b^{\,2} \right) \cdot R_T}{2 \cdot c \cdot w} \quad \text{.....(12)}$$

$$\rho \cdot c \cdot \frac{\partial T}{\partial t} = \frac{\lambda}{r} \left\{ \frac{\partial}{\partial r} \left(r \cdot \frac{\partial T}{\partial r} \right) \right\} \quad \text{.....(13)}$$

Where, c: specific heat (J/kg K), w: weight of micro discharge channel volume, ρ: mass density (kg/m^3), λ: thermal conductivity (W/m K).

Fig.4 shows gas temperature distribution of radial direction in the micro-discharge model. When t=39ms, gas temperature T at the center of micro-discharge reached the maximum value of 510K. After this time,

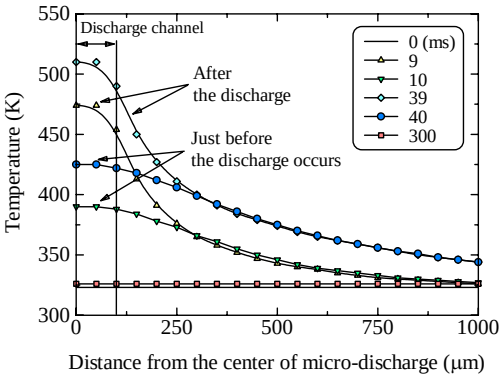

Fig.4 Temperature distribution

Table.3 NO removal/formation reactions and each reaction rate [5]

No.	Reaction	Reaction Rate $k(T)$
$k(1)$	$NO+O_3 \rightarrow NO_2+O_3$	$1.5*10^{-12}\exp(-1300/T)$
$k(2)$	$O+NO+O_2 \rightarrow NO_2+O_2$	$8.6*10^{-32}(T/300)^{-1.8}$
$k(3)$	$O+NO+N_2 \rightarrow NO_2+N_2$	$1.0*10^{-31}(T/300)^{-1.8}$
$k(4)$	$NO_2+O \rightarrow NO+O_2$	$1.7*10^{-11}\exp(-300/T)$
$k(5)$	$N+O_2 \rightarrow NO+O$	$1.5*10^{-11}\exp(-3601/T)$
$k(6)$	$N+O+N_2 \rightarrow NO+N_2$	$2.6*10^{-31}T^{-0.5}$

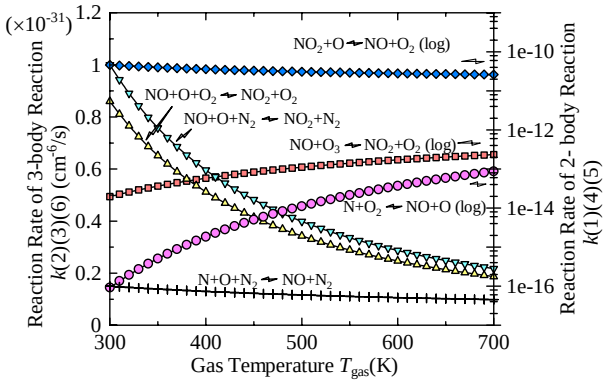

Fig.6 Dependence of reaction rate on temperature

decrease of the gradient of temperature distribution continued and finally, the gas temperature reached the equilibrium state of 326K.

Fig.5 shows the time variation of the concentrations of NO, NO_2 and O_3. At first, let's consider the case of NO. When the elevation of gas temperature was taken into consideration, NO concentration (solid line) was 150ppm at 150ms. On the other hand, when T is constant, NO concentration was 70ppm at same time. It was calculated that the NO removal efficiency was 40.9g/kWh at constant T and 15.9g/kWh at elevated temperature respectively. It is evident that NO removal rate decreases when the temperature rise is considered. The reason why is explained as follows.

The first reason is in the difference of O_3 concentration. O_3 is an important substance for the oxidation of NO to NO_2. But, it is well known that O_3 dissociates at high temperature. In fact, as it is seen in Fig. 5, in the case that temperature rise is considered, O_3 concentration (solid line) is smaller than the one in the case that T is constant (dot line). Therefore, the amount of oxidization of NO by O_3 decreased.

The second reason is the activation of NO formation reaction by N and O radicals. Table.3 shows typical NO removal and formation reactions and also their reaction rates. Fig.6 shows the dependence of reaction rate on temperature. Reaction rates which increase with temperature rise are $k(1)$: $NO+O_3 \rightarrow NO_2+O_2$ and $k(5)$: $N+O_2 \rightarrow NO+O$, and the other reaction rates are all declined. If the reaction rate $k(1)$ became large at higher temperature, the oxidization of NO by O_3 did not increase. Because, the O_3 concentration decreases with the temperature. But, NO formation reaction rate $k(5)$ at 500 K increases about 10^2 times as high as the rate at 323K. And the amount of generated N radical is not varied by the temperature elevation. Thus, NO formation reaction by N radical becomes very effective. In summary, the reasons that NO removal

Table.4 Typical reactions and reaction rates relating $N_2(A)$

No.	Reaction	Reaction Rate	Ref.
$k(7)$	$N_2+e \rightarrow N_2(A)+e$	$3.37*10^{-10}$	[7]
$k(8)$	$N_2(A)+O_2 \rightarrow N_2+2O$	$2.0*10^{-12}$	[8]
$k(9)$	$N_2(A)+N_2 \rightarrow N_2+N_2$	$2.7*10^{-11}$	[8]
		$1.9*10^{-13}$	[9]
		$<3.0*10^{-18}$	[10]

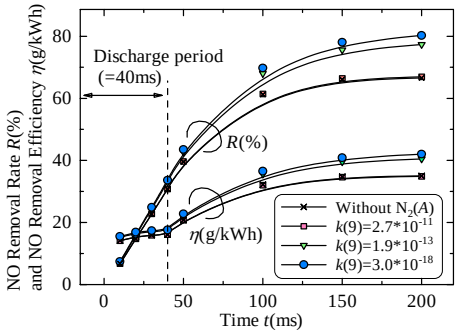

Fig.7 Influence of $N_2(A)$ on NO removal

performance becomes worse are concluded as the degradation of NO oxidization by O_3 and the activation of NO formation reaction by N radical.

3.2 Influence of the N_2 metastable state $N_2(A^3\Sigma_u^+)$

It is known that when electron energy is low, O_2 is dissociated into O radicals by N_2 excited in a metastable state in addition to the direct collision with electron. Previous model did not consider the metastable state of the N_2. Since the exhaust gases include high concentration of N_2, this reaction is very important. Here, we considered 15 reactions associated with $N_2(A^3\Sigma_u^+)$ (hereinafter $N_2(A)$). Table.4 shows a $N_2(A)$ generation reaction and typical $N_2(A)$ quenching reactions. Reaction rate $k(7)$ is the value when E/n=150Td[7]. Regarding the reaction rate $k(9)$ of $N_2(A)$ quenching reaction, there are a couple of data, but they are extended in a wide range (10^{-11}~10^{-18}). As the result of calculations, it was found that the reaction rate $k(9)$ ($N_2(A)+N_2 \rightarrow N_2+N_2$) is a very important value, because it almost determines the influence of $N_2(A)$. In this study, various values of $k(9)$ were used and investigated their effect on NO removal.

Fig.7 shows the influence of $N_2(A)$ on NO removal rate R(%) and also on NO removal efficiency η(g/kWh). When $k(9)$ is 10^{-11}, R and η have no difference with the previous result (without $N_2(A)$). Because, if $k(9)$ reaction is active, almost all of $N_2(A)$ which generated by electron collision, is quenched by N_2. However, when $k(9)$ of 10^{-13} and 10^{-18} were used, R and η became large. Especially, the difference of NO removal performance is quite apparent at the time after discharge has stopped. Namely, NO removal rate R at t=200ms is 78% for $k(9)=1.9*10^{-13}$ and 67% for case of the previous work, respectively. This comes from difference of O_3 concentration in the time after-discharge period. Because the lifetime of O and N radicals are very short, NO removal reaction in the after-discharge period is done by the residual substance, especially by O_3. Thus, O radicals generated by $N_2(A)$ are mainly used for O_3 generation reaction, and not for the direct oxidation of NO to NO_2. When $k(9)$ is 10^{-18}, O_3 concentration increases as much as 30% in comparison with the case without $N_2(A)$.

The effects of $N_2(A)$ on NO removal performance are summarized as follows. (1) If $N_2(A)$ quenching reaction rate $k(9)$ is low, the oxidization of NO by O_3 will increase. (2) If the reaction rate $k(9)$ is high, since almost all of $N_2(A)$ are consumed by N_2, the effect of $N_2(A)$ on NO removal performance is not so large. (3)Although $N_2(A)$ is able to produce O radicals, NO oxidation is mainly done by O_3, because O radicals soon changes to O_3.

3.3 Influence of voltage waveform

The barrier discharge usually occurs intermittently in a half cycle and the time period that discharge occurs is a period that dV/dt of the applied voltage is large. So the discharge period can be controlled by the voltage

waveform of applied voltage. Here, we introduce a parameter *Rd* which is defined as the ratio of discharge period to total period, and investigated the effect *Rd* on NO removal performance. If *Rd* is small, it means that the discharge concentrates in a short period and there are relatively long period of time without discharge. As for the wave form of applied voltage, trapezoid wave form corresponds to small *Rd*, and sinusoidal wave form gives larger *Rd*. In this study, *Rd* was changed in keeping with the constant input energy. In the practical calculation, the interval between the successive pulse discharges was changed in accordance with Eq.(7) without changing the number of micro-discharges.

Fig.8 shows relation between the discharge ratio *Rd* and NO removal performance (*R* and η). It is evident that both *R* and η deteriorate at smaller *Rd* than about 30%. It comes from a difference of the amount of O_3 destruction. When the time interval t_{int} between successive pulse discharges is large, namely when *Rd* is large, O_3 generated around discharge channel can diffuse to the surroundings without destruction by discharge, which leads to the improvement of NO removal performance. But the improvement is not so large.

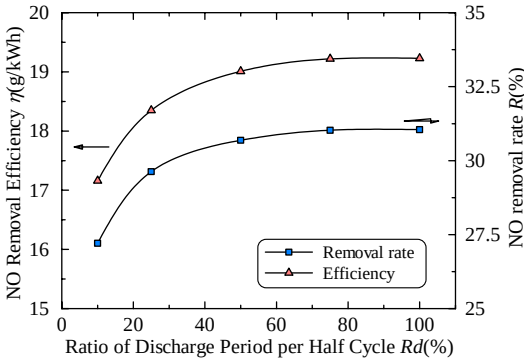

Fig.8 *Rd* vs. NO removal performance

4. Conclusion

Three factors affecting NO removal performance were investigated using a micro-discharge model, which takes the chemical reactions and diffusion of species into consideration. Principal results obtained in this work are summarized as follows.

(1) Temperature elevation in micro discharge volume makes the NO removal performance worse. It is because that NO formation reaction by N radical is activated at higher temperature. (2) Influence of N_2 metastable state depends on the reaction rate of $N_2(A)$ quenching reaction, namely the reaction $N_2(A)+N_2 \rightarrow N_2+N_2$. (3) When the ratio of the discharge period *Rd* is large, namely when *dV*/*dt* of applied voltage is small, η and *R* improve a little better. But, this factor is not so effective for the improvement of NO removal performance.

Abstract

The good properties of polymer nanocomposites are due to the good dispersion of the filler in the polymeric blend. The dispersion of clay particles is achieved with the use of plasma technique as an alternative route to alter the hydrophilic character of the clay. The plasma-polymer coated onto silicon wafer was characterized as composed of aliphatic groups and its growth was correlated to the fragmentation of acetylene in the electrical discharge and the issued reactive species detected by optical emission spectroscopy.

Keywords : acetylene, plasma, OES, hydrophobic coating

1. Introduction

In the field of polymer composites, a new class of materials with better mechanical, electrical or permeability properties has emerged in the past decade: the nanocomposites. They are composed of a polymer matrix and filler whose dispersion in the polymeric blend will grant the better final properties. Their dispersion is controlled by the interaction energy between the filler particle and the polymer chains [1]. The dispersion of clay particles can not be achieved without a pre-treatment of each individual layer of the clay since both products are incompatible. Therefore, the cohesion of the blend is obtained when an organic molecule, i.e. tensio-active molecule [2,3] is absorbed onto the clay surface. To alter the hydrophilic behavior of the clay, the dry plasma technique can be proposed as an alternative route to the synthesis of the organo-clay usually run in wet organic or aqueous medium with all the difficulties for the environmental protection with such synthesis route [3].Clays such as Wyoming montmorillonite and Laponite RD are treated in acetylene plasma to modify their surface properties and to improve their compatibility towards the polyethylene. The acetylene fragments will precipitate as hydrocarbonated coating onto the clay layer and will give an apolar – organophilic character to the clay surface.

Acetylene plasmas are nowadays mostly used in the deposition of the diamond –CH like film. Stoykov and al [4] proposed a model that analyses the clusterisation kinetics in a low pressure acetylene rf discharge in order to predict the temporal evolution of all different reactive gaseoues species and the mechanism of clusterisation. This model takes into account the neutrals species, hydrocarbonates cycles, positif and negative ions and electrons. Gordillo-Vasquez and Albella [5-6] studied the effect of different plasma parameters, the pressure and the rf power influence, on the $C_2H_2(1\%)/H_2/Ar$ rf discharge chemistry in the diamond nanofilm synthesis. The argon proportion was also varied. Benedikt [7-8] used the Cavity Ring Down Spectroscopy (CRDS) to characterize the species in an Ar/ C_2H_2 arc plasma. The detected C_2, C_2H, CH radicals seem to play an important role in the deposited layer growth mechanism.

The aim of this study is to analyse the acetylene plasma chemistry in order to optimize the plasma parameters to obtain a deposited layer with the lowest polar energy. The plasma-polymer layer is also fully characterized by different surface analyses such contact angle measurements, X-ray photospectroscopoy and FTIR spectroscopy.

2. Dependence of the plasma- polymer properties versus the plasma parameters

In the attempt to determine the optimum conditions for obtaining the most hydrophobic layer, different plasma parameters were tested: the duration (t, 1-7 mn), the discharge power (P, 10-40 W), and the gas flow (Q, 10-30 sccm). Depending on these parameters, the plasma polymer shows a hydrophobic character with a surface energy around 45 $mJ.m^{-2}$ and its FTIR spectrum is mostly composed of the C-H stretching and bending respectively at 2925, 2856 and 1387, 657 cm^{-1} suggesting the presence of CH_2 and CH_3, the C=C stretching vibration band at 1645 cm^{-1} and the C-C stretching vibration band at 1008 cm^{-1}. No bands at 2200 cm^{-1} and 2100 cm^{-1} corresponded to C≡C stretching bands, are found suggested that the acetylene molecule is fragmented into C=C, C-C and C-H. Some stretching bands of carbonyl, ketone and hydroxyl functions respectively at 1855, 1695 and 3446 cm^{-1} are noticed. Similar attribution reported by other authors [9-12] and assigned to a post-oxidation of the plasma-polymer with air rather than the plasma phase contamination, since no oxygen was

detected by OES. By XPS spectroscopy, the plasma-polymer was also prooved to be essentially composed of hydrocarbon functions (around 90 %). The examination of the C1s high-resolution peak shows the existence of three components corresponding to different nature of carbon bonds. The main component fixed at 285 eV is related the polymer hydrocarbon structure and represents the C-C and C-H bonds. The second component located at 286.5 eV indicates the presence of species containing C-O bonds such as alcohol, ether. The component at 287.6 eV reveals the presence of C=O bonds assigned to aldehyde and ketone. The percentage of chemical bonds determined by the ratio (total C1s peak area/bond C peak area), corresponds to 78.9 % C-C and C-H bonds, 18.1 % of C-O bonds and 3 % of C=O bonds, with these plasma parameters.

The effect of the gas flow (Fig. 1a) was determined with constant power of 20 W and duration of 1 mn. With a small addition of acetylene in the reactor (10 sccm), the surface energy of the substrate and its polar component decrease rapidly respectively of 27 % and of 80 %. Its apolar componant increases of 78 %. Then, with higher flow, the surface energy slowly decreases and reaches a plateau equal to 48 $mJ.m^{-2}$, while the apolar energy tends to 42 $mJ.m^{-2}$. With a fixed 30 sccm flow and power of 10 W and duration equal to 1 mn (Fig 1b), the total surface energy diminishes of 35 % and reach a plateau value of 47 $mJ.m^{-2}$. The apolar surface energy increases of 81 % and remains constant (43 $mJ.m^{-2}$) for longer duration. The polar surface energy is minimal, i.e. 6.8 $mJ.m^{-2}$, at 1 mn. Varying the power input with duration equal to 1 mn and flow of 30 sccm shows that the decrease of total surface energy and the increase of its polar componant reach at 20 W a plateau value, respectectively of 47 $mJ.m^{-2}$ and around 40 $mJ.m^{-2}$ (Fig 1c). Therefore, the optimum conditions to the obtention of the hydrophobic layer whose polar surface energy is equal to 3.9 $mJ.m^{-2}$ correspond to 20W of power input, 30 sccm of gas flow and 1 minute of duration.

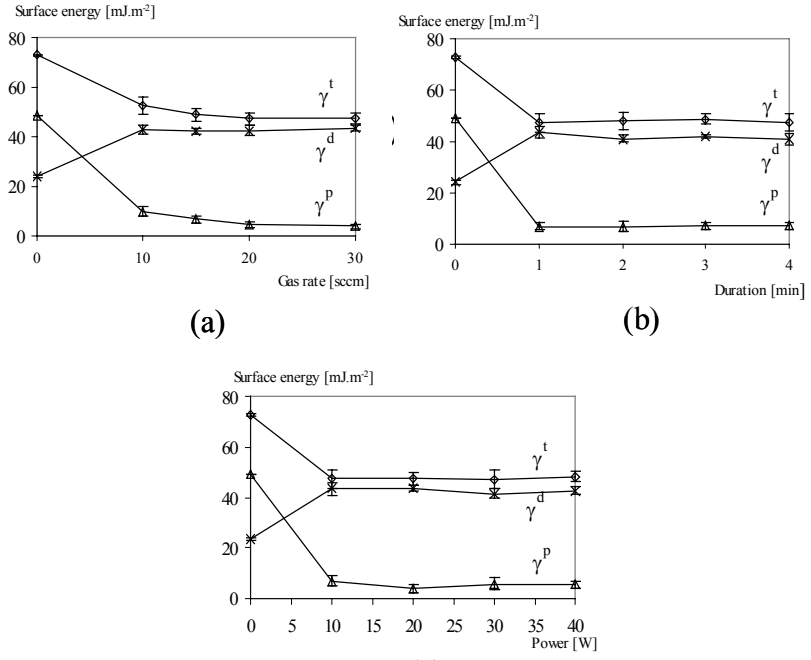

Fig. 1. Surface energy of plasma-polyacetylene versus (a) the gas flow (P=20 W, t=1 minute), (b) the duration (P=10 W, $F(C_2H_2)$=30 sccm), (c) the power input ($F(C_2H_2)$=30 sccm, t=1 mn).

3. Chemical composition of the acetylene plasma phase analysed by optical emission spectrocopy

This study deals with the detection of emissive species in the 300-800 nm range. The global spectrum (Fig. 2) consists of the different lines of the species in the plasma such as CH, C_2, CH^+, H_β et H_2. The highest line is the signature of CH at 431.4 nm. This radiation is the Q–branch of the (0,0) transition in the $A^2\Delta$ -$X^2\Pi$ system. CH is also representated at 388.9 nm due to the Q-branch radiative transition (0,0) of $B^2\Sigma$ -$X^2\Pi$ system. However this line can also be the C^+ signature : according to the spectrocopic tables, C^+ emits in this wavelenght area at 386.8 and 387.1 nm. C_2 is also shown at 453.6 nm for the transition (2,3) of the Swan system and at 404.6 nm for the transition (2,3) of Deslandres system. The lines at 546.1 and 506.8 nm are assigned to the emissive radiation at 545.9 and 505.5 nm of H_2. Unfortunately, both signatures of C_2 and H_2 overlap and it is difficult to assign some lines to C_2 or H_2 precisely, or a C_2/H_2 contribution. The dual lines are : the 468.1 nm line which can be either C_2 at 468.4 nm from Swan system (transition 4,3) or H_2 at 468.3 nm. The 471.1 nm line may be assign to C_2 at 471.5 nm from Swan system (transition 2,1) or H_2 at 486.1 nm; and the

542.1 nm line can correspond to C_2 transition (6,7) at 541.3 nm from Swan system or to H_2 at 545.9 nm. H is detected by its H_β signature at 486.1 nm. CH^+ appears in the emission spectrum at 374.8 nm and 379.8 nm assigned to (2,0) and (4,1) radiative transitions from the $A^1\Pi$ system of CH^+. Moreover, a continuum between 420 and 600 nm is shown : ones could be tend to attribute it to the hot carbonate particule incandescence produced in the discharge [11]. Indeed, such continua were observed on carbonated particles producted in graphite laser assisted evaporation. In our case, this assumption would suppose particule temperature of 5000 K which is impossible at this rf power and this gas pressure.Benedikt and al [8] assumed that it is known that excited C_2H emits a continuum band light in the visible region and similar continuum band emission was also observed using optical emission spectroscopy (OES).

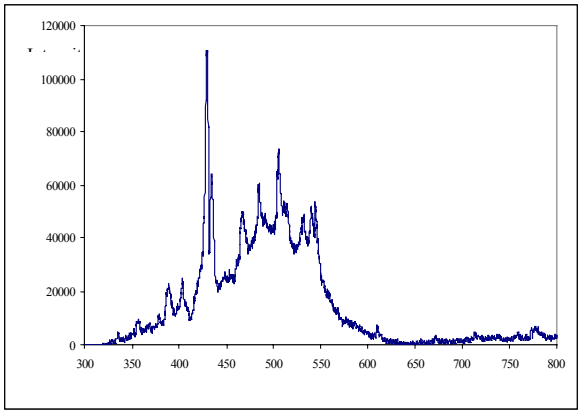

Fig. 2: Optical emission spectrum of the rf acetylene plasma in the 300-800nm range (Q_{C2H2}=10 sccm, P=10W)

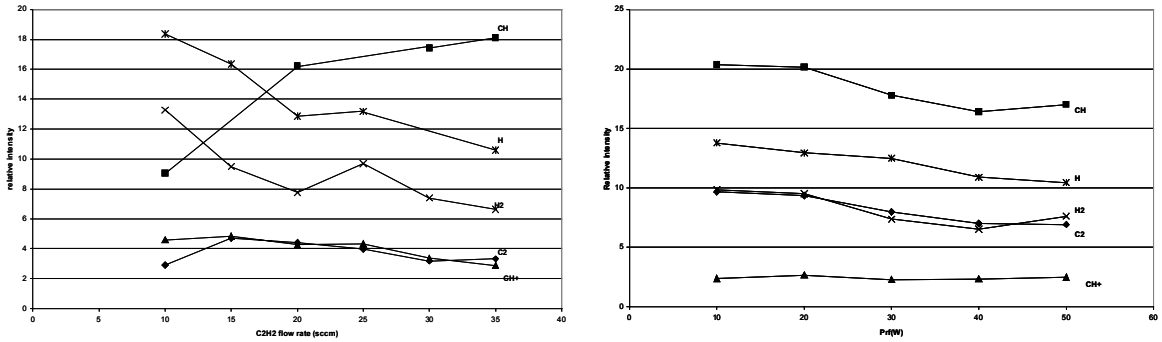
By actinometry, a quantitave analysis of the discharge parameters (rf power and pressure) was carried out over the principal plasma species by following the CH^+ line at 374.8 nm, CH at 431.4 nm, C_2 at 435.3 nm, H_β at 486.1 nm, and H_2 at 545.5 nm. Argon was chosen as actinometer in so far as it does not interfere with acetylene.

The study of the gas flow influence (Fig. 3a) on the plasma composition was carried out at constant rf power (20W) and the acetylene flow was varied from 10 to 35 sccm. At a constant acetylene flow of 10 sccm, the concentration of H is the highest in the plasma phase. Then it continuously falls down by nearly 50%: the H consummation is then higher than its production. Indeed, the H production is due to the dissociation of acetylene and CH who both increase, to the deshydrogenation reactions to form C_xH_y compounds. The reactions between CH, CH_2, and C_XH_Y then consume it [5-8,13]. Between 10 and 35 sccm, H_2 decreases. It can be due to the dissociation of H_2 to form H whose rate is more important or to the association with CH to form CH_3 or CH_2. CH always rises as the acetylene flow rises. From 10 to 20 sccm, the raise is important whereas from 20 sccm this raise slows down. At 20 sccm, CH becomes majoritar behind H and H_2. CH is producted by the C_2H_2 dissociation and the $C_2H_2^+$ electronic recombinaison and consumed during the collisions between two CH molecules, with other molecules CH_x or with H_2 [5-8,13]. When the acetylene flow goes up, the CH line also rises up : the CH production is due to the likely acetylene dissociation. C_2, CH^+ appear in less quantity than H, H_2 and CH. Their concentrations smoothly vary with the acetylene flow. CH^+ slightly falls down. When the inlet gas rate increases, the amount of C_2H_2 increases. In our reactor, gas flow and pressure are linked : When the pressure increases, the mean path free decreases and the collision probability increases.The $C_2H_2^+$ electronic dissociation and and the CH ionisation product CH^+. It is then used in the collisional reactions with C_2H_2 [5-8,13]. As the collisions increase, $CH^+$is more used by collision reactions, and the CH^+ line intensity decreases in spite of the augmentation of C_2H_2 and CH. C_2 rate smoothly varies with C_2H_2 inlet gas. To conclude, the influence of the inlet flow is not negligable on the plasma phase composition. The C_2H_2 dissociation increases to produce CH which will recombine with other molecules when acetylene flow and the pressure increase in the reactor. Those results agree with Stoykov and al [4], Gordillo-Vazquez and al [5-6] : the pressure has a drastic effect on the amount of neutrals and more especially on CH whose production is more important when the inlet gas flow and the pressure increase. Morover, whatever the acetylene gas flow is, CH and H are more important than CH^+, C_2 and H_2. This leads to think that the most reactive species are CH and H, one or both of them are the plasma precursor of the hydrophobic caracteristic of the deposit.

The line intensities were measured for the different rf power and then plotted in Fig. 3b. This figure shows that in the plasma phase CH is the main specie. When the rf power increases, the chemical composition

of the plasma phase smoothly varies : CH decreases as the power increases up to 30W. For upper power values, CH reaches a plateau. CH^+ stays still :CH^+ and CH are mainly producted by the C_2H_2 dissociation . The CH^+ spectra line intensity is slightly affected by the augmentation of the rf power. H_2,C_2 and H slightly decrease. To conclude, the rf power has a weak influence on the chemical composition of the plasma phase. These results agree with Gordillo and al [5-6] who assumed that the rf power influence is weak.



(a) (b)

Fig. 3: Evolution of the major spectra line (a) versus C_2H_2 inlet flow rate (P= 20 W) and power (Q_{C2H2} = p = 4,2.10^{-2} mbar)

4. Plasma species responsible of the growth of the plasma-polymer

From the optical emission spectroscopy technique, we know that CH and H are the main species in the plasma phase. The correlation between the CH and H densities in the plasma phase and the polar energy on the surface of the deposited layer is linear (Fig. 4). The polar energy of the deposit surface decreases when the CH density increases whereas it increases when the H density in the plasma phase increases. To obtain a hydrophobic deposit, the formation of CH must be enhanced, the plasma parameters (pressure, inlet gas rate and RF power) must improve the acetylene dissociation. The experiments shows that for a flow rate of 20 sccm and a rf power of 20 W the maximum rate of CH is detected in the plasma phase.

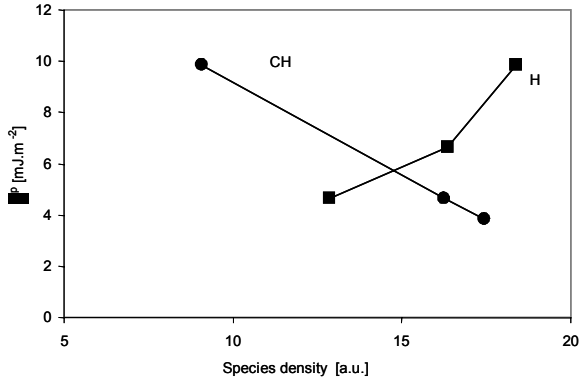


Fig. 4: correlation between the CH and H densities in the plasma phase versus the polar energy of the coated surface

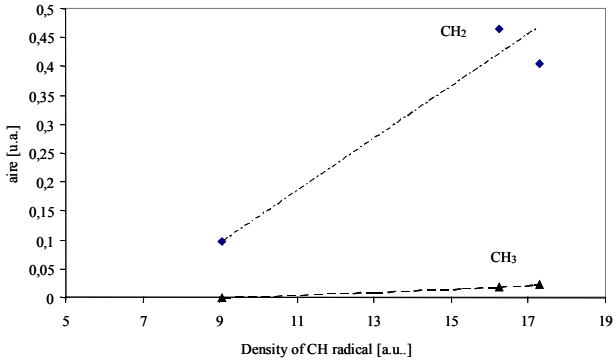

Fig. 5 : Correlation between the CH density in the plasma phase and CH_2 ,CH_3 concentrations in th eplasma polymer (P=20W)

Fig. 5 represents the evolutions of the CH_2 and the CH_3 groups analysed by FTIR spectroscopy versus the variation of CH density. When the CH density increases in the plasma phase, both amounts of methylene and methyle groups on the surface analysed by IR spectroscopy increase. The amount of CH_3 is less influenced by the CH density in the plasma phase

4. Conclusion

The most reactive species are CH and H detected by optical emission spectroscopy, one or both of them are the plasma precursor of the hydrophobic caracteristic of the deposit. The plasma-polymer, coated onto silicon wafer was characterized with different surface analyses. Its structure is composed of CH, CH_2, CH_3 groups, double carbon-carbon bonds and few oxygen-carbon bonds. The different plasma parameters were chosen to lead to the most hydrophobic coating with surface energy lower than 3.9 $mJ.m^{-2}$. The correlation between the CH and H densities in the plasma phase and the polar energy on the surface of the deposite is linear. The polar energy of the deposit surface decreases when the CH density increases whereas it increases when the H density in the plasma phase increases. To obtain a hydrophobic deposit, the formation of CH must be enhanced , and therefore the acetylene dissociation too. CH seems to be the plasma precursor for the surface functionalisation. The CH density increases in the plasma phase, both amounts of methylene and methyle groups in the plasma polymer increases. The rf power does not influence a lot the chemical composition of the plasma phase.

Plasma polymerized polyaniline used as sensitive layer for gas sensors

Dominique Nicolas-Debarnot, Fabienne Poncin-Epaillard

Laboratoire Polymères-Colloïdes-Interfaces (UMR CNRS 6120), Université du Maine, Avenue Olivier Messiaen, 72085 Le Mans, France

Abstract
Polyaniline has been synthesized using plasma technique. Different plasma conditions have been studied in order to minimize the surface degradation and to obtain the polyaniline layer which can be used for gas detection.

Keywords: Plasma, deposition, polyaniline.

1. Introduction

Most of gas sensors available on the market are semiconducting ones, measuring a conductivity alteration under gas adsorption. These sensors, based on tin dioxide, operate at high temperature to ensure sensor sensitivity and selectivity. However, their performances, specially selectivity, have to be improved. To improve gas sensors characteristics, novel sensitive organic layers, electronic conducting polymers, were developed. The interest of these materials has been recognized by the awarding of the Nobel prize in Chemistry in 2000 to A.J. Heeger, A.G. MacDiarmid and H. Shirakawa [1,2], who synthesized the first conducting polymers and proved their potentialities in a large number of applications. Besides, some commercial electronic noses are based on electronic conducting polymers organized in an array [3]. The advantages of conducting polymers compared to inorganic materials used until now are their diversity, their easy synthesis and particularly, their sensitivity at room temperature. Polypyrrole has been one of the first polymers used in gas sensors. However, it shows a low sensitivity, a high response time and an incomplete desorption of gas molecules, *i.e.* an incomplete reversibility of the sensor response. So, the research were extended to polyaniline (PANi) [4].

Common routes to synthesis polyaniline are chemical and electrochemical routes. In this study, PANi is elaborated using an original, clean method: the plasma technique. As the sensitive sites for gas molecules are NH^+ groups, the aim is to obtain the highest concentration of N-containing groups, i.e. the highest electrical conductivity of the PANi layer by varying the parameters of the plasma. The plasma parameters studied are the discharge power, the polymerisation time and the use of a dilution gas (argon or nitrogen).

2. Materials and methods

Polyaniline thin films were deposited onto silicon substrates oxidized in order to obtain a 100 nm silica layer. The cleaned substrate was placed into the plasma reactor where the plasma is induced thanks to a radio-frequency generator. The pressure into the reactor during the polymerization was maintained at 0.02 torr for all the experiments whereas the discharge power, the polymerization time and the reactive gases (aniline, aniline + 1 sccm argon or aniline + 1 sccm nitrogen) varied.

The obtained polyaniline films were then characterized by thickness and wettability measurements, FTIR and XPS analyses.

3. Characterization of plasma polymerised polyaniline

3.1. Thickness measurements

The polyaniline layer grows linearly with time as shown in figure 1(a). Figure 1(b) presents the influence of the discharge power and the use of a dilution gas such as nitrogen or argon in the gas phase, on the thickness of the layer. Whatever the discharge power is, the thickness is more important without the presence of a dilution gas. Nitrogen or argon seems to act more like dilution agent than etching one. Moreover, after 20 W and whatever the reactive gases used, the thickness decreases proving that after this discharge power, the plasma phase may contain in majority ions which degrade the surface. Then, after a discharge power of 20 W, degradation becomes predominant compared to deposition.

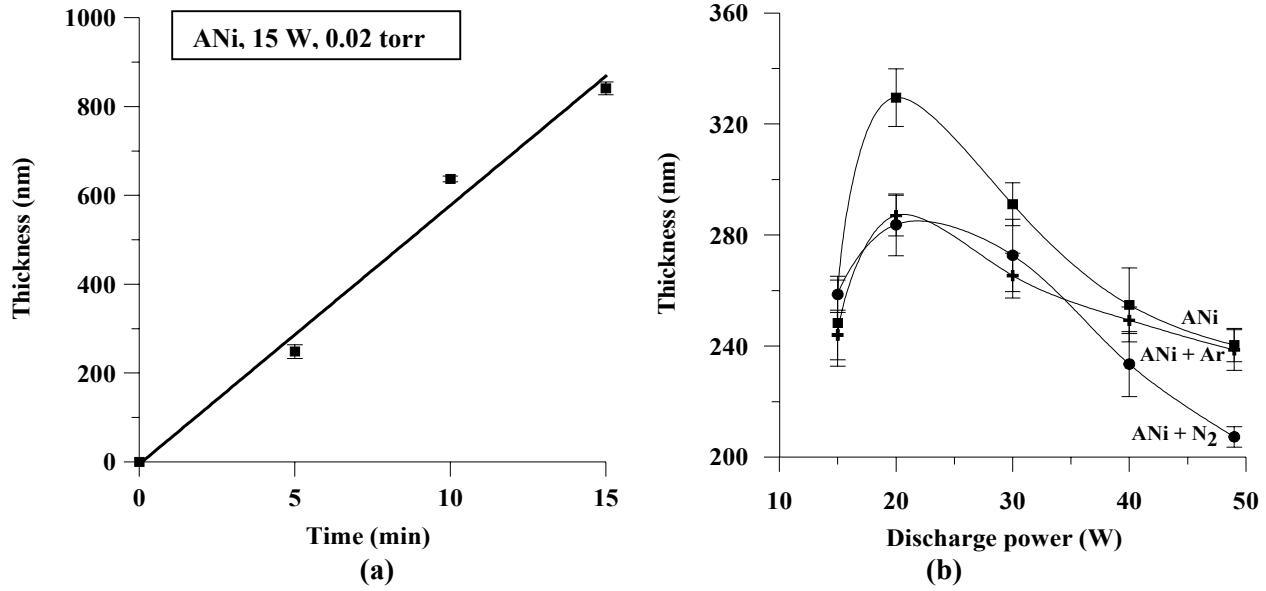

Fig. 1. Evolution of the thickness of plasma polymerized polyaniline versus (a) time and (b) discharge power.

In conclusion, it is better to use a discharge power lower than 20 W to avoid degradation and to favour deposition. Moreover, a longer polymerization time is preferable to obtain a thicker layer and then a more conductive one.

3.2. Surface energy determination

The polar component of the surface energy increases with discharge power and more when the reactive gas is just composed of aniline without a dilution gas. When the discharge power increases, the number of polar groups, i.e. N-containing functionalities (amine, imine, nitrile) increases. The increase of the polar component occurs almost totally between 15 and 20 W. Note that the total surface energy of the plasma polyaniline is comprised between 50 to 55 $mJ.m^{-2}$.

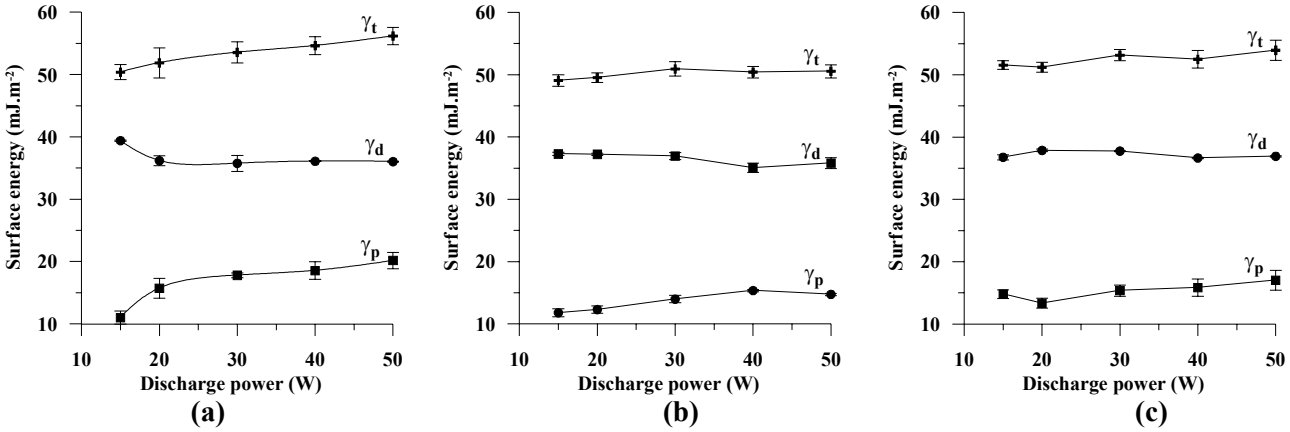

Fig. 2. Surface energy of plasma-polymerized polyaniline according to the precursor gas: (a) aniline or (b) aniline + 1 sccm N_2 or (c) aniline + 1 sccm Ar. (pressure=0.02 torr, polymerization time=5 min)

However, after deposition of a drop (water or diiodomethane) to measure the contact angle and then determine surface energy, we observe the formation of cracks accross the polyaniline films, only when the precursor gas is just composed of aniline and the discharge power is 20 W (pressure=0.02 torr). We attribute this phenomenon to excessive tensile stresses. Stress in thin films results in a thermal component and an intrinsic one [5]. The thermal stress is due to the difference in thermal expansion coefficients between the

substrate and the film. Then, after film deposition, differential contractions occur on cooling. The intrinsic stress is a function of the microstructure and stoechiometry of the film which strongly depend on the deposition method and then, process parameters [6]. The intrinsic stress is also function of the thickness of the film [5]. It has been found that the intrinsic stress is influenced by incorporated impurities [7] and ambient humidity after deposition [8]. In our experiments, intrinsic stress due to a too high deposition rate seems to be responsible for the formation of these cracks.

In conclusion, with aniline as precursor, the discharge power must be 15 W to avoid cracks across the film.

3.3. FTIR spectra

The FTIR spectrum of aniline is shown in figure 3. The two bands at around 3350 and 3450 cm^{-1} are attributed to primary aromatic amine N-H stretch. The bands between 3000 and 3100 cm^{-1} are due to aromatic C-H stretch. The two dominant peaks at 1500 and 1600 cm^{-1} are due to benzene ring C=C stretch; at around 1600 cm^{-1}, there is also the deformation of primary aromatic N-H. At 1300 cm^{-1}, the absorption of C-N bond stretch occurs. Finally, the peaks at 700 and 750 cm^{-1} correspond to C-H out-of-plane deformation of a mono-substituted benzene ring.

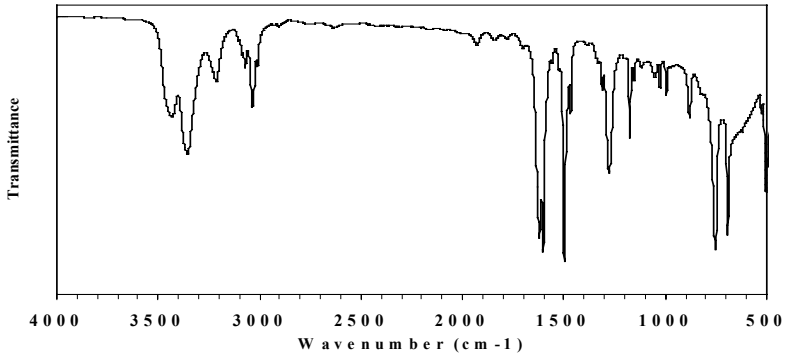

Fig. 3. FTIR spectrum of the aniline monomer

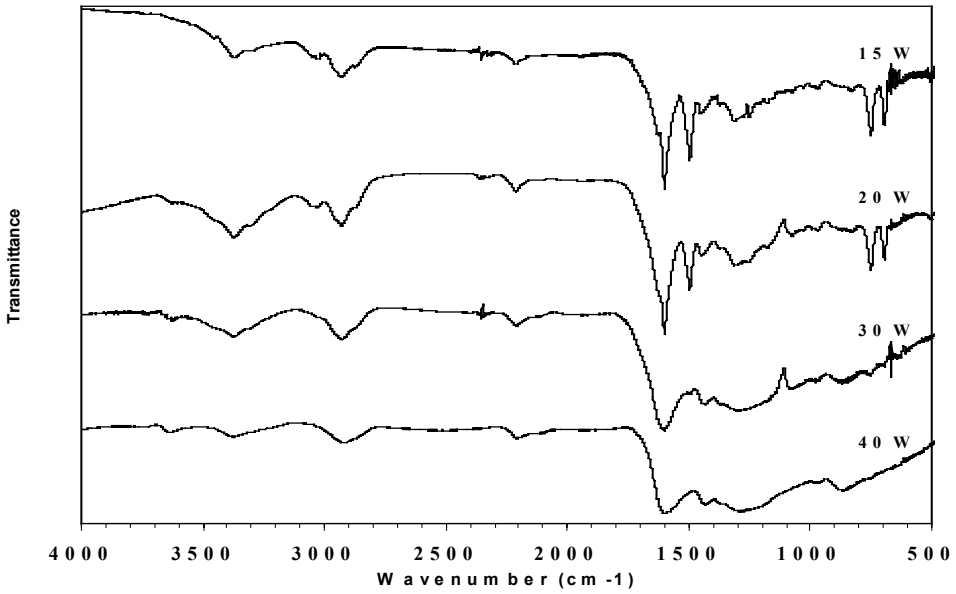

Fig. 4. FTIR spectra of plasma-polymerized polyaniline obtained at different discharge powers. (Aniline, pressure=0.02 torr, polymerization time=15 min)

Figure 4 presents FTIR spectra of plasma polymerized polyaniline at different discharge powers. At 30 and 40 W, the bands become broader which is typical of a highly disordered polymer. This result is in agreement with the evolution of the thickness with the discharge power (Figure 1(b)), showing the degradation of the film at 30 and 40 W. Compared to the monomer, the plasma-polyaniline elaborated at 15 and 20 W shows absorption at around 2900 cm^{-1} due to saturated C-H stretch, proving then the breakage of the benzene ring during plasma deposition. Moreover, we observe a peak at 2200 cm^{-1}, which can be assigned to aromatic nitrile stretch. We can attribute the peaks at 700 and 760 cm^{-1} to the C-H out-of-plane deformation of meta and ortho di-substituted benzene ring, respectively. The weak peak at 830 cm^{-1} may correspond to para di-substituted benzene ring. According to Wang et al., the weak intensity of this last peak compared to the meta and ortho substitution is the sign of a branched structure in the polymer [9].
The polymerization time does not influence the structure of the polymer as proved by figure 5. The same bands are observed on all the spectra. Therefore, a higher polymerization time is preferable to increase the electrical conductivity of the layer.

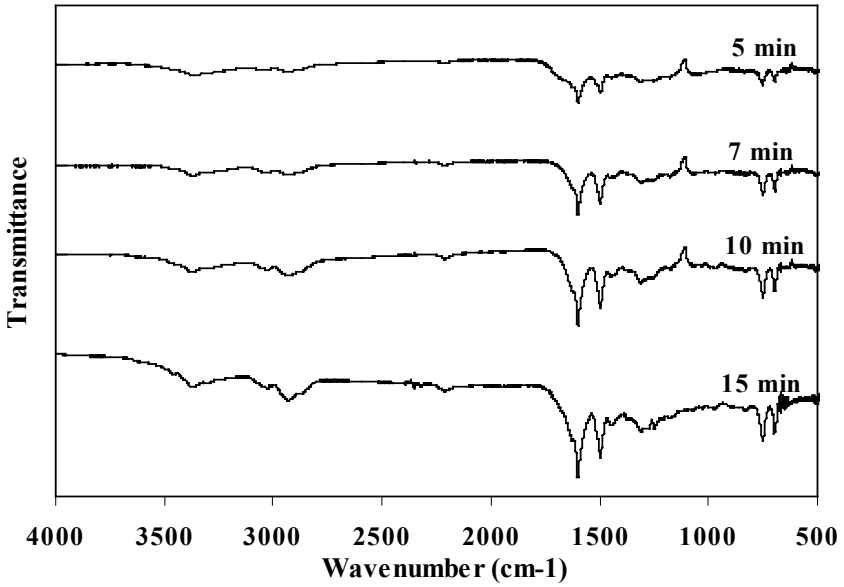

Fig. 5. FTIR spectra of plasma-polymerized polyaniline obtained at different polymerization times. (Aniline, discharge power=15 W, pressure=0.02 torr)

3.4. XPS analysis

The C 1s and N 1s XPS core-level spectra of plasma polymerized polyaniline are presented in figure 6. The C 1s spectrum can be decomposed into three components at 284.9, 286.2 and 287.3 eV, attributed to aliphatic and aromatic C-H and C-C, C-N and C-O groups, respectively. The N 1s spectrum is composed of a single peak at 399.5 eV corresponding to -NH- groups. According to literature, the N 1s XPS spectrum of polyaniline synthesized by chemical way shows two components of almost similar intensities, attributed to -NH- and -N= groups [10]. This result could be the sign of the formation, by plasma, of oligomers which contain a higher quantity of -NH- groups. Whatever the discharge power and the precursor gas are, the same decomposition of C 1s and N 1s XPS spectra can be made.

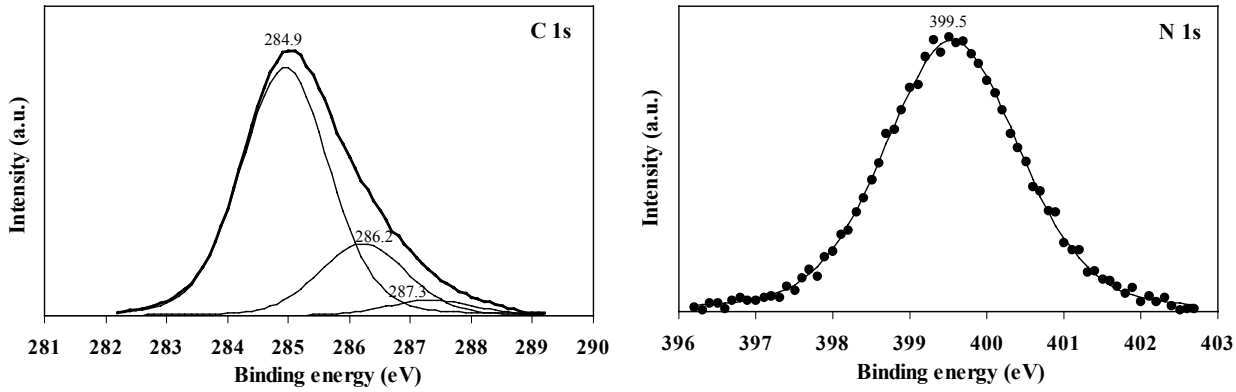

Fig. 6. Typical C 1s and N 1s XPS core-level spectra of plasma-polymerized polyaniline. (Aniline, discharge power =15 W, pressure=0.02 torr, polymerization time=5 min)

The C/N ratios (Table 1) remain almost the same whatever the discharge power is, when the used precursor gas is aniline. If the precursor gas is aniline with 1 sccm N_2, the C/N ratio decreases when the discharge power increases, showing then a higher incorporation of N-containing groups. If the precursor gas is aniline with 1 sccm Ar, the C/N ratio increases with the discharge power. So, a high power favours the breakage of the C-N bonds, this hypothesis is confirmed by the C-C/C-N ratio (table 2) which increases with the discharge power. So, we can conclude that the addition of argon in aniline gas phase is not interesting for gas sensor application since argon leads to a decrease in N-containing groups which are the gas absorption sites.
At 30 and 40 W, the C/N ratio is lower when the reactive gases are aniline with 1 sccm N_2 than when it is only aniline. It would the sign of a higher incorporation of N-containing functions if N_2 is added to aniline gas phase but as the C-C/C-N ratio is almost the same for the two kind of reactive gases, the additional N-containing functions would not link to carbon.
At 15 and 20 W, C/N and C-C/C-N ratios are almost the same for aniline or aniline + 1 sccm N_2 reactive gases. To increase N-containing groups, the nitrogen flow have certainly to be increased.

Table 1- C/N ratio of plasma polymerized polyaniline according to the discharge power and precursor gas

	ANi	**ANi + 1 sccm N_2**	**ANi + 1 sccm Ar**
15 W	10	10.4	10.4
20W	10.5	10.2	11.2
30 W	10.2	9.2	11.5
40 W	10.6	9.5	12.2

(pressure=0.02 torr, polymerization time=5 min)

Table 2- C-C/C-N ratio of plasma polymerized polyaniline according to the discharge power and precursor gas

	ANi	**ANi + 1 sccm N_2**	**ANi + 1 sccm Ar**
15 W	3.45	3.4	3.6
20W	3.8	3.9	3.8
30 W	3.9	3.5	3.9
40 W	3.3	3.3	4.1

(pressure=0.02 torr, polymerization time=5 min)

Conclusion

This work shows that to be used for gas detection, the polyaniline layer must be prepared at low discharge power for the deposition rate to be low and for the layer to be not degraded. Moreover, the polymerization time must be important to increase the film thickness and then the electrical conductivity since time doesn't influence the polymer structure. Finally, the addition of nitrogen to aniline in the gas phase seems to be promising as the N-containing groups increase.

Abstract

The elaboration of multilayers onto oxidized silicon wafer using a self-assembled octadecyltrichlorosilane (OTS) monolayer treated by CO_2-plasma is presented. The plasma effect onto the surface of the SAM was characterized by wettability measurements and X-ray spectroscopy. The structural properties of modified monolayers were investigated by X-ray reflectivity and AFM microscopy. The formation of multilayers was then demonstrated by grafting a second layer of OTS.

Keywords

SAMs, multilayers, plasma functionalization, X-ray reflectivity, atomic force microscopy

1. Introduction

Self-assembled monolayers (SAMs) have attracted increasing interests over the past 20 years due to their ability to form spontaneously highly organized organic structures on different substrates. A long linear hydrocarbon chain favoring upright monolayer ordering on the surface and a terminal functional group defining the surface functionality [1-6]. Alkylsiloxane SAMs have emerged as one of the most widely studied SAMs [7] due to its convenient attachment to hydroxyled and/or oxided surfaces and to its applications in microfluidic [8,9] protein adsorption [10] chromatography [11] and molecular electronic [12].

The surface modification of SAMs was little studied [13-17]. In most of the cases such an exposure results in either partial or total damage. One of the perspectives of modification of alkylsiloxane SAMs is the plasma processing. Whereas this method is widely applied in microelectronics or chemical modification of polymeric surfaces, there are only few examples for plasma treatment on SAMs [13-14]. In this study, we used silicon wafers that were functionalized with octadecyltrichlorosilane (OTS) to demonstrate the ability to prepare a layer-to layer self assembly system after surface modification by a CO_2 plasma treatment. OTS was selected as a model of higly-packed organic monolayer. The thickness and the density of the monolayer were controlled by X-ray reflectivity measurements whereas the surface homogeneity was studied by atomic force microscopy (AFM).

2. Formation of the OTS precursor monolayer

Quality of the OTS monolayer was preliminary demonstrated by the high water contact angle (110°±2), and by the analysis of X-ray reflectivity curves. In Fig. 1, we show the Fresnel normalized XR curve of silicon wafer functionalized by OTS-SAM and the best reflectivity fit as the solid line which describes the two well-defined Kiessig fringes. The fringes spacing of 0.240 $Å^{-1}$ which is inversely proportional to the total film thickness and the Q_z value of the first minimum at 0.125 $Å^{-1}$ (denoted Q_{zmin}) are good indicators of the quality of the SAM yielding to an approximate total film thickness of 25 (±1) Å. The full analysis of the XR curve gives a fully description of both orientation and density packing of the OTS monolayer. All the parameters found in this analysis were obtained from a four-layer model: a silicon substrate, a silicon oxide layer, a transition layer and the OTS monolayer. Structure of OTS monolayers have been studied by such various means as FTIR-ATR spectroscopy, X-ray diffraction and X-ray reflectivity, evidencing that OTS monolayers were composed of close packed, generally vertical chains *all trans* extended. As the total film thickness calculated from the Q_{zmin} is in agreement with a highly dense OTS monolayer with alkyl chains in *all-trans* conformation , we have performed constrained fits in which the length and the electron density of the hydrocarbon chain was fixed to it expected nominal values i.e. 0,316 $e^-.Å^{-1}$. The parameters which are allowed to vary during the fit are therefore the thickness of the OTS layer, the thickness of the silicon oxide layer, the roughness of each interface and the transition oxide parameters.

The fit yields roughness lower to 4 Å indicating the presence of atomic-level smooth interfaces. The thickness of the silicon oxide layer was found to be 12.9 Å which was in good agreement with the value proposed by Brzoska et al. for the typical thickness of the native silicon oxide layer on silicon substrate (10-15 Å). The parameters obtained for the transition layer (i.e. electron density and thickness) can be attributed to a

complex interface between the silicon oxide layer and the alkyl chains of the OTS monolayer. Therefore, the fitting analysis of the X-ray reflectivity curve provides a reliable measure of the thickness of the layers, the electron density and interface roughness consistent with a highly ordered OTS-SAM with fully extended hydrocarbon in all-trans conformation.

	ρ [$e^-.Å^{-3}$]	roughness [Å]	thickness [Å]
Substrate	0.710(*)	0.7	-
Oxide layer	0.682(*)	0.2	12.9
Transition layer	0.601	3.1	3.5
OTS layer	0.316(*)	2.8	23.0

Fig. 1. Calculated, measured X-ray reflectivity curves and data of OTS film grafted on silicon substrate.

The coverage of the monolayer surface was studied by AFM (Fig. 2). RMS roughness determined from the AFM image (180nm×180nm) is found to be 0.15 nm indicating that, at this scale, surface is smooth. The lack of default in a wider scale (1μm×1μm) confirms the high degree of homogeneity of the OTS-SAM. Thus, this observation is consistent with the structural studies which clearly indicated the formation of a dense and oriented perpendicularly OTS monolayer.

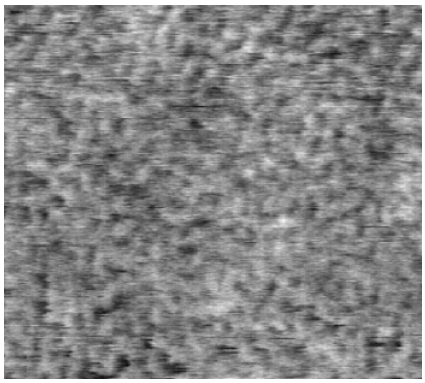

Fig. 2. AFM image of the OTS monolayer (tapping mode – Image size = 180 nm × 180 nm).

Methyl-terminated monolayers such as OTS, are known to be chemically resistant because of their poor reactivity. Thus, in order to elaborate a multilayer system on such monolayer, modification of the surface chemistry is needed.

3. CO_2-plasma surface modification of the OTS monolayer

In order to modify chemically the surface of the OTS monolayer, CO_2-plasma was preferred to O_2 plasma because the degradation processes are less efficient. Four parameters can be monitored with the plasma reactor used in this study : *P* the power, *F* the gas flow, *t* the treatment duration and *d* the distance between the bottom of the excitator and the sample. Parameters *P* and *F* were chosen to be the most effective to introduce hydroxyl (C-OH) and carboxyl groups (-COOH) onto organic surface. The distance *d* was kept to be maximal (~70 cm). We expected that this positioning will enable to expose OTS monolayer predominantly to only radicals which are responsible of the functionalization since electrons and ions responsible of the degradation do not exist in the post-discharge.

The effect of the plasma treatment onto the OTS monolayer was evaluated by following the evolution of the water contact angle as function of the plasma treatment duration (Fig. 3). A decrease of the water contact angle is observed since the first seconds of the plasma treatment until treatment

duration of 150 s, and then a plateau is observed. Such variation could be assigned to the progressive introduction of polar functions onto the monolayer surface leading, for the plasma duration of 150 s, to a surface saturation with polar functions.

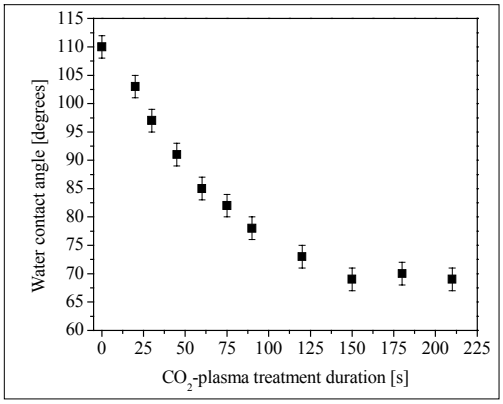

Fig. 3. Evolution of the water contact angle as function of the CO_2-plasma treatment duration.

To confirm these results, surface chemical composition was determined by X-ray photoelectron spectroscopy (XPS). After decomposition of the XPS signal of the plasma treated monolayer, it can be seen the appearance of three components at 286.1, 287.4, and 288.7 eV corresponding to C-O, C=O, and COO groups, respectively. Thus, XPS analysis confirms that CO_2-plasma introduces reactive polar groups onto the surface of the OTS film. Table 1 shows a progressive increase of the polar groups proportions (C-O, C=O, and COO) with the treatment duration until 210 s. As the immersing time was further prolonged, the decrease of the proportions of polar functions can be associated to the degradation of the monolayer surface caused by fragmentation of chains containing polar groups.

time [s]	C/O	% C-C	% C-O	% C=O	% COO
0	-	100	0	0	0
20	2.7	85	10	3	2
45	2.2	81	12	5	2
60	1.9	70	19	7	4
120	2.0	68	20	8	4
210	1.8	71	18	8	3

Table 1. Effect of CO_2-plasma treatment time on the surface chemical composition of the OTS film determined by XPS

In order to evaluate the effect of the degradation processes onto the structure of the monolayer, we performed X-ray reflectivity measurements as a function of the plasma treatment duration. In Fig. 4, we observed that above a treatment time of 120 s, the position and the height of the first minimum don't change. Such a result indicates that under these treatment conditions, electron density and thickness of the plasma treated monolayer remain the same that the non treated one. This result clearly indicates that until the treatment duration of 120 s, the degradation of the monolayer may be negligible.

On the contrary, for the duration of 210 s alterations of both height and position of the first minimum of the reflectivity curve are observed indicating the decrease of the plasma treated monolayer density. The shift of the first minimum towards low Qz wave vector transfers and the decrease of the contrast are likely due to the decrease of the initial OTS monolayer density and the polymerization of removed molecular chains on the top-most surface. Consistently, the decrease of the densities of polar groups observed by XPS measurements was interpreted as the result of the degradation of the monolayer

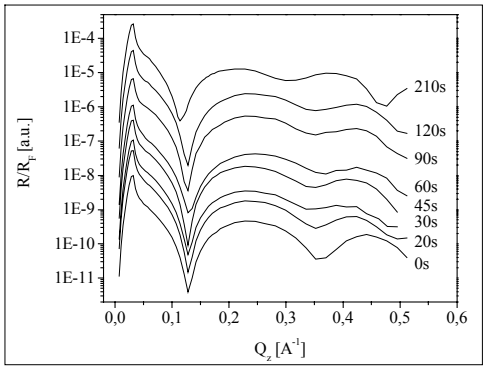

Fig. 4. Evolution of the reflectivity curves as function of the CO_2-plasma treatment duration.

Surface structure of the plasma treated monolayer was monitored using AFM. topography images (Fig. 5) indicate that the plasma treatment of 120 s doesn't modify the surface structure of the monolayer. Furthermore RMS rugosities were comparable between plasma treated monolayer (RMS = 0.28 nm) and the initial OTS monolayer (RMS = 0.23 nm); under these conditions, the monolayer is not degraded by the plasma treatment. On the contrary, AFM image of the 210 s plasma treated monolayer shows the structural modification of the surface with the appearance of hills and holes. The observed increase of the RMS roughness to 0.49 nm indicates a modification of the surface morphology associated to the degradation of the monolayer.

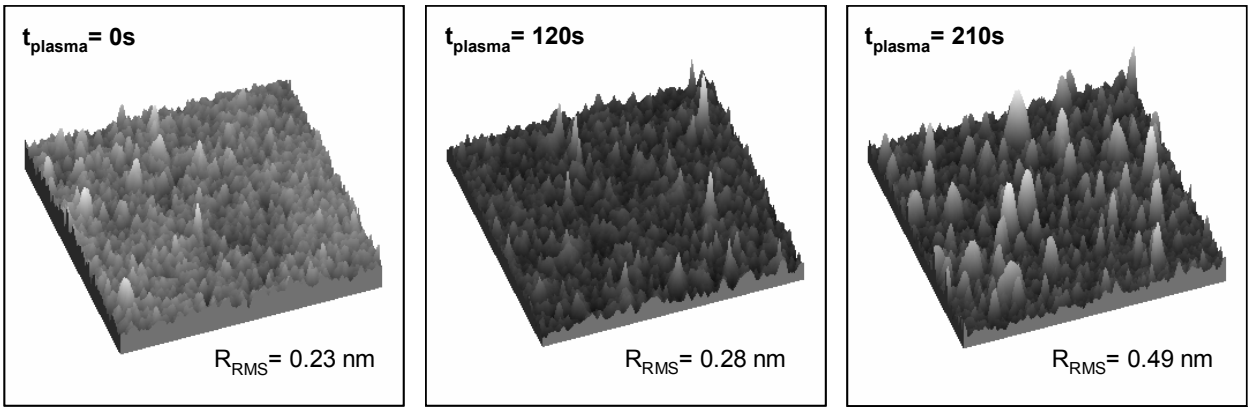

Fig. 5. AFM topography and RMS rugosity of monolayers treated by CO_2-plasma (Image size = 400×400 nm).

In order to optimize the grafting of a second layer onto the modified SAM surface one first needs to choose plasma conditions for which the functionalization is maximum and the degradation minimum. The chemical composition and structural studies of the treated OTS monolayer allow us to conclude that the plasma treatment duration of 120 s was very efficient. Indeed, for these conditions the surface modification of the OTS monolayer is maximum and proceeds without degradation.

4. Formation of the bilayer

In order to demonstrate the ability of grafting a second layer onto the plasma functionalized OTS monolayer, we have chosen to use similar OTS molecules. Indeed, the presence of C-OH and COOH groups introduced by the plasma treatment onto the surface should allow the grafting of a second layer of alkyltrichlorosilane molecules.

The efficiency of the grafting reaction was followed by measuring the water contact angle (Table 2). As shown before, the water contact angle decreases from 110°(±2) for the OTS monolayer to 72°(±2) for the 120 s plasma treated monolayer because of the introduction of polar groups by plasma onto the surface. After the deposition of a second layer of OTS molecules, the water contact angle increases to a value of 103°(±2) indicating the formation of a new hydrophobic layer without reaching the value obtained with the first OTS

monolayer. Such a result can be explained by le lack of presence of homogeneous second OTS layer due to the presence of non reactive groups such as –C=O and residual $–CH_3$ of the first layer which don't allow the grafting of OTS molecules leading to a second OTS layer less organized than the OTS monolayer (Fig. 6).

Sample	Water contact angle
OTS monolayer	110° (±2)
CO_2-plasma treatment (t = 120s)	72° (±2)
Grafting of a second OTS layer	103° (±2)

Table 2. Evolution of the water contact angle during the formation of a second OTS layer.

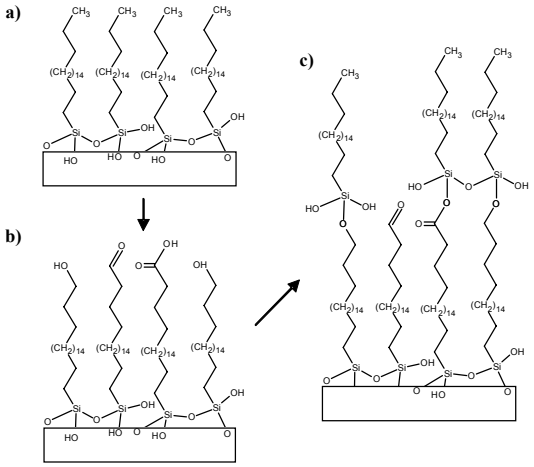

Fig. 6. Representation of the structure of a) OTS monolayer, b) CO_2-plasma treated monolayer, and c) after the grafting of the second OTS layer.

X-ray reflectivity measurements were performed in order to characterize the structure of the new OTS layer. Figure 8 indicates that the position of the first minimum was shifted from 0.128 $Å^{-1}$ for the plasma treated monolayer to 0.065 $Å^{-1}$ after the deposition of the second OTS layer. This shift corresponds to an increase of the total thickness from 24.5 to 48.3 Å indicating that the formation of a second layer of OTS molecules was achieved. However, although the position of the first minimum is consistent with the calculated data in a model taking into account two similar layers, we were not able to find a realistic model explaining the XR curve. The explanation is probably the complexity of the different interfaces and layers composing our system.

Abstract

The fundamental experiments were carried to examine the tracking phenomenon that was one of the main causes of fire breaking. AC high voltage was applied to one of the electrode. As the electrode, the following samples were prepared: the mesh plate, the flat ribbon cable and the ignition plug. The current, voltage waveforms of partial discharge and the sound signal detected by the condenser microphone were stored in the memory Hi-coder. In this scheme, Short Time Fourier Transformation (STFT) and Continuous Wavelet Transform (CWT) were applied to discriminate the acoustic sound of the partial discharge and the dominant frequency components were studied. It was found that the estimates provided by CWT have better accuracy and precision than those obtained with STFT on the data sets of sound signal.

Keywords STFT, Continuous Wavelet Transform, micro discharge, mesh type electrode, dielectric barrier discharge

1. Introduction

The fires caused by arc tracking phenomenon are about 700/year in Japan. The dust accumulated in the plug for the power supply of household utensils is main reason for the arc tracking phenomena. Electrical current will flow through dusts only when the dusts contain water. If the moisture is continuously replenished, the currents will be sustained. It is thought that small leakage currents through such contamination cause degradation of the plug material leading to the partial discharge, charring or igniting combustible materials around the discharge. The combined effects of surface moisture and pollutants cause leakage currents across the surface of the insulator, which can lead to formation of carbonized tracks [1]. A more energetic arc through the carbonized dusts might cause a fire under the right conditions. The similar phenomenon occurs on the electronic circuit board of computer and household electric appliance. The deposited dust carbonizes with a long time, and it becomes a cause of the arc tracking phenomenon [2]. We proposed the procedure to detect the tracking phenomenon using the acoustic signal due to the partial discharge. The fundamental experiments to examine the characteristics of the discharge were performed. AC high voltage was applied to one of the electrode. The partial discharge was generated by the applying high voltage and initiated the acoustic sound. In this scheme, the STFT and the CWT were applied to discriminate the acoustic sound of the partial discharge and the dominant frequency components were studied.

2. Experimental procedures

The fundamental experiments were carried to examine the tracking phenomenon that was one of the main causes of fire breaking. The schematic diagram of experimental equipment is shown in Fig.1.

The following three type of electrode were used to simulate the arc tracking phenomenon: the mesh type electrode, the flat ribbon cable and the ignition plug. The structure of the mesh type electrode is shown in Fig.2. In the mesh type electrode, the microscopic hole of 200μm diameters has been opened in great numbers. The cover glass(22mm x 24mm,Thickness: 0.12～0.17mm) is held between mesh electrode (30mm x 50mm) of the 2 sheets, and the gap length of mesh type electrode is 0.5～1.0mm. The flat ribbon cable (ϕ:1.1mm, length:100mm) is used in order to connect the mother boards of personal computer. The ignition plug (gap: 1.5mm) is used for automobile engine.

We generated the partial discharges using the electrode in order to understand the fundamental relationship between the partial discharge and the acoustic sound properties. One of the electrode was connected to the high voltage terminal through the resistance 200kΩ. Other terminal was grounded. The sound signal was generated by the partial discharge of the electrode. The high voltage (2∼15kV, 60Hz) produced by the neon transformer was applied to the electric wire. The current, voltage waveforms of partial discharge and the sound signal detected by the condenser microphone were stored in the memory Hi-coder 8855(Hioki). The sampling frequency was 1 MHz and the measurement time was 1 second. Data analysis was performed using MATLAB with the Signal Processing toolbox and Wavelet toolbox. (The Mathworks, Inc.)

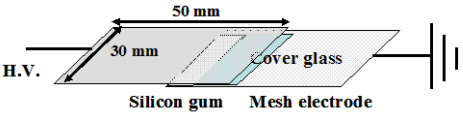

Fig.2. Mesh type electrode

3. Time-frequency analysis of sound signals

3.1 Short Time Fourier Transform (STFT)

The Fourier transformation mainly used in frequency analysis is not suitable for the analysis of the unsteady signal. The basis of Fourier transformation infinitely spreads in the time domain. Gabor extended the applicability of Fourier transform method dividing the input signal into segments. The signal in each window can be assumed to be stationary. The STFT for a given signal $f(t)dt$ can be expressed as

$$\hat{f}(\omega,b)=\int_{-\infty}^{\infty}\frac{1}{2\sqrt{\pi}\sigma}e^{-\frac{(t-b)^2}{\sigma^2}}e^{-i\omega t}f(t)dt \qquad (1)$$

σ is the window width of the window function, b is the time shift parameter[3]. Equation (1) shows that $\hat{f}(\omega,b)$ is the function of ω, b. Therefore, the time-frequency analysis became possible by Eq. (1). The squared magnitude of the STFT, $\left|\hat{f}(\omega,b)\right|^2$ is called spectrogram. It can be used to obtain the energy distribution of the signal along the frequency direction at a given time.

3.2 Continuous Wavelet Transform (CWT)

The wavelet transform converts a signal from time domain to the time-scale domain. Wavelet analysis involves the breaking up of a single prototype function called the mother wavelet. $\psi^{(a,b)}(t)$ is obtained by scaling the mother wavelet $\psi(t)$ at time b and scale a

$$\psi^{(a,b)}(t)=\frac{1}{\sqrt{a}}\psi\left(\frac{t-b}{a}\right) . \qquad (2)$$

When a becomes large, the basis function $\psi^{(a,b)}$ becomes a stretched version of the prototype, which can be useful for analysis of the low-frequency components of the signal. On the other hand, when the scale parameter is small, the basis function $\psi^{(a,b)}$ will be contracted, which is useful for the analysis of the high-frequency components of the signal [3].

As a mother wavelet, the gabor wavelet is used.

$$\psi(t) = \frac{1}{2\sqrt{\pi}\sigma} e^{-\frac{t^2}{\sigma^2}} e^{-it} \qquad (3)$$

Equation (3) is similar to the STFT which is used the Gaussian function in window function. So it is easy to compare with the analytical results of the STFT and the CWT. In this paper, real part of gabor function is used as a mother wavelet (σ =8).

$$\psi(t) = \frac{1}{2\sqrt{\pi}\sigma} e^{-\frac{t^2}{\sigma^2}} \cos(t) \qquad (4)$$

Therefore the wavelet transform of a continuous signal is defined as:

$$\hat{f}(a,b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} \frac{1}{2\sqrt{\pi}\sigma} e^{-\frac{(t-b)^2}{\sigma^2 a^2}} \cos\left(\frac{t-b}{a}\right) f(t)dt \qquad (5)$$

where the signal $f(t)$ is transformed by the mother wavelet (Eq. (3)). Similar to the spectrogram, the squared magnitude of the CWT, $\left|\hat{f}(a,b)\right|^2$ is called scalogram and can be used to obtained the energy distribution of the signal over the entire time-scale plane.

4. Results and Discussion

4.1 Mesh type electrode

There was no partial discharge at the applied voltage of 2kV in the mesh type electrode. The partial discharge appeared at the applied voltage of 2.5kV. Figure 3 shows the voltage and the current waveforms with applied voltage of 2.5kV. The discharge current appears within 1/4 half-cycles which increase or decrease from 0V at the voltage value. The discharge current flows during 1.7ms～2.8ms, 9.9ms～11.3ms and 18.7～19ms. The current value is 2.7mA even in the maximum. The current waveform is pulse-like, and it seems to generate the dielectric barrier discharge, because the cover glass has been inserted between the electrodes.

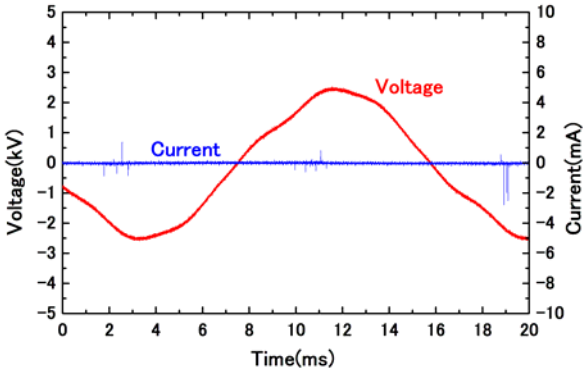

Fig.3. Voltage and current waveforms with applied voltage of 2.5kV.

When AC 2.5kV voltage is applied in the electrode, the measurement result of sound and current waveforms are shown in Fig.4. The acoustic signal is observed in the form superimposed on the drift signal, and the maximum value of the amplitude is 2.6mV.

When AC 2.5kV is applied to the mesh type electrode, the time-frequency spectrum of sound signal with dielectric barrier discharge is shown in Fig.5. The frequency characteristics of the sound signal are studied by STFT. The sound signal steadily contains the high frequency components. The frequency components of 20kHz or less are almost contained over all time. The spectrum at the

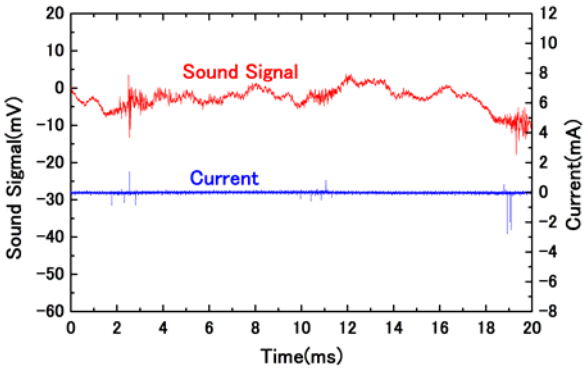

Fig.4. Sound signal and Current waveforms with applied voltage of 2.5kV.

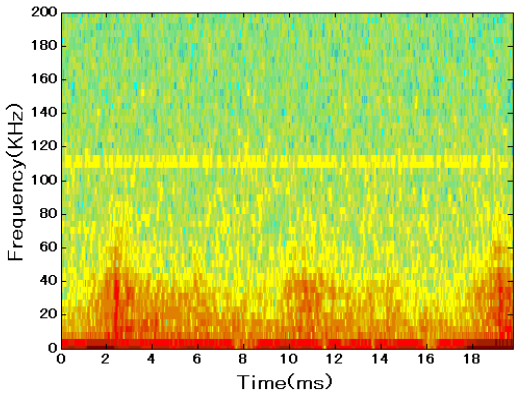

Fig.5. STFT spectrogram of sound signal with applied voltage of 2.5kV.

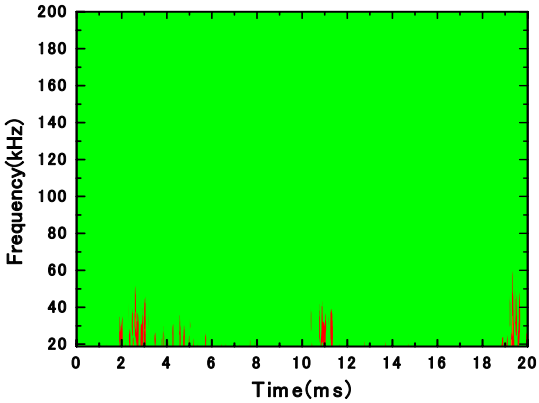

Fig.6. CWT scalogram of sound signal with applied voltage of 2.5kV.

applied voltage of 2.5kV with partial discharge has the dominant frequency components. The frequency components over 40kHz appear during 2ms～3ms, 10ms～12ms and 18～20ms. These results show that the partial discharge can be detected by observing the sound signal. They are almost same with the time in which the pulse-like current is generated.

When AC 2.5kV is applied to the mesh type electrode, CWT scalogram of sound signal with dielectric barrier discharge is shown in Fig.6. The frequency components over 40kHz appear during 2.1ms～3.3ms, 10.9～11.3ms and 19.2～19.7ms. These results of the CWT are good agreement with the time period of acoustic signal with the dielectric barrier discharge.

4.2 Flat ribbon cable

The flat ribbon cable is used as an electrode. Figure 7 shows the voltage and the current waveforms with applied voltage of 15kV. The pulse-like discharge current flows during 0.3ms～4ms, 8.6ms～12.6ms and 16.6～19.7ms. The current value is 32.9mA even in the maximum. The discharge current appears within 1/4 half-cycles which increase or decrease from 0V at the voltage value. The flat ribbon cable is covered with vinyl chloride and the pulse-like waveforms of the discharge current indicate dielectric barrier discharge.

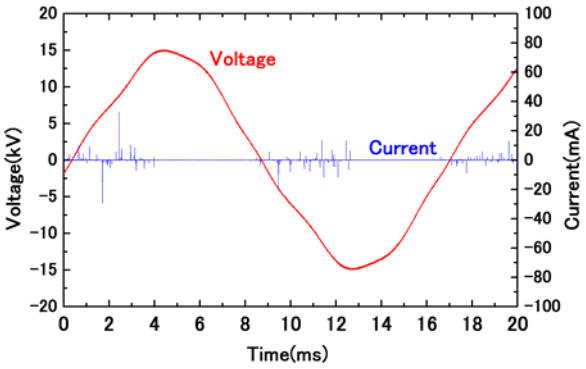

Fig.7. Voltage and current waveforms with applied voltage of 15kV.

Figure 8 shows the sound signal and the current waveforms with applied voltage of 15kV. The acoustic signal is observed in the form superimposed on the 8ms period (125Hz) signal, and the maximum value of the amplitude is 8.3mV.

When AC 15kV is applied to the flat ribbon cable, the time-frequency spectrum of sound signal with dielectric barrier discharge is shown in Fig.9. The sound signal steadily contains the high frequency components. The frequency characteristics of the sound signal are studied by STFT and wavelet. The spectrum at the applied voltage of 15kV with partial discharge has the dominant frequency components. The frequency components over 80kHz appear during 0.5ms～4.5ms, 9ms～13ms and 18～20ms. This results show that the

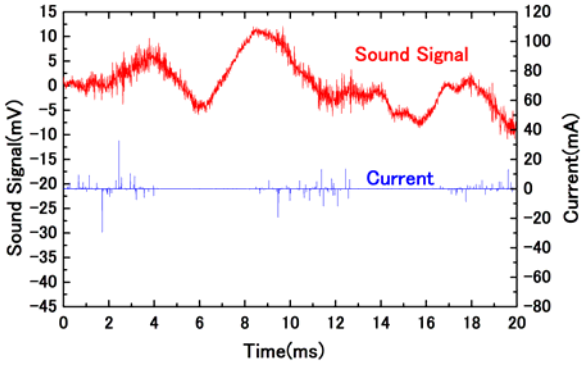

Fig.8. Sound signal and Current waveforms with applied voltage of 15kV.

partial discharge can be detected by observing the sound signal. It is almost same with the time in which the pulse-like current is generated.

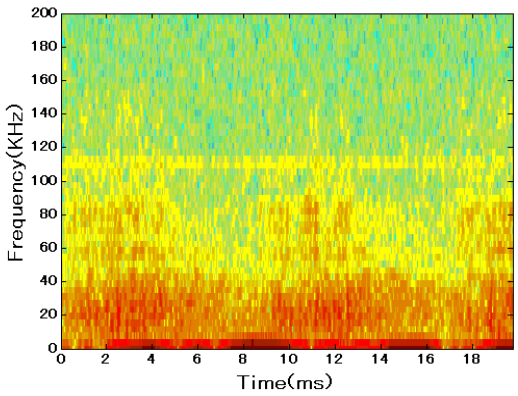

Fig.9. STFT spectrogram of sound signal with applied voltage of 15kV.

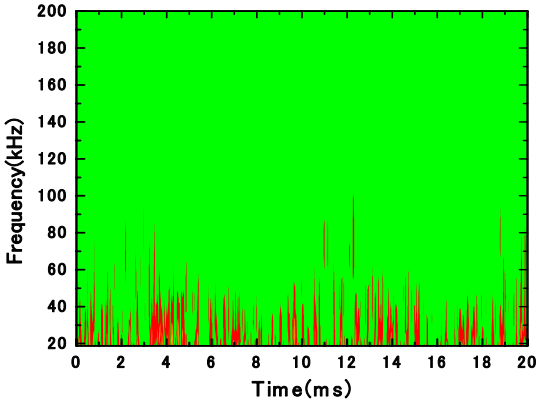

Fig.10. CWT scalogram of sound signal with applied voltage of 15kV.

When AC 15kV is applied to the flat ribbon cable, the CWT scalogram of sound signal with dielectric barrier discharge is shown in Fig.10. The frequency components over 80kHz appear during 1.1ms～3.5ms, 11.0ms～12.3ms and 18.7～20.0ms. These values by CWT are comparatively well agreement with the time of acoustic signal by the dielectric barrier discharge.

4.3 Ignition plug

When AC 7kV voltage is applied in the ignition plug, the measurement result of sound and current waveforms are shown in Fig. 11. As well as electrode using the mesh type electrode or the flat ribbon cable, the pulse-like current with the electric discharge is generated. The electric discharge has been generated at 11.6ms, 12.7ms and 18.8ms. The current maximum value is 270mA. This value is large compared with the electrode using meshed electrode or the flat ribbon cable. In addition, the acoustic signal also shows 1.8V in the maximum. This result shows that the arc discharge has been generated.

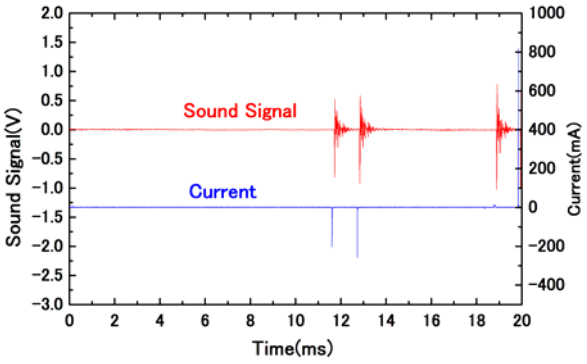

Fig.11. Sound signal and Current waveforms with applied voltage of 7kV.

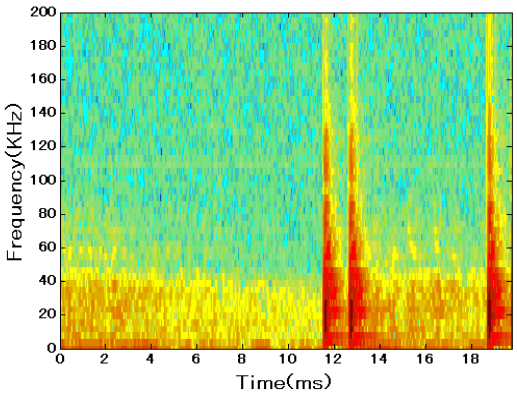

Fig.12. STFT spectrogram of sound signal with applied voltage of 7kV.

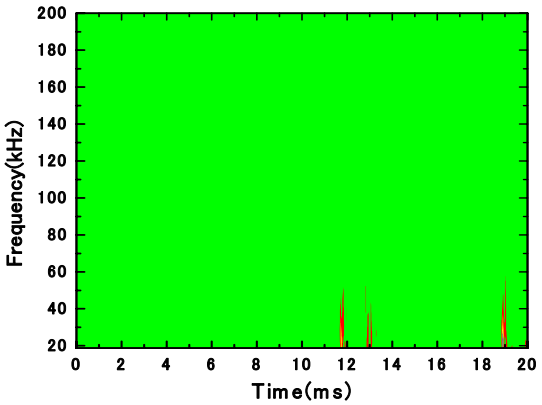

Fig.13. CWT scalogram of sound signal with applied voltage of 7kV.

The acoustic signal has been retarded from arc discharge at 0.1ms. It propagates at 3cm in 0.1ms, as the temperature in the laboratory is made to be 30℃, and The propagation distance is almost same with the distance of the microphone and the ignition plug.

Figure 12 shows the analyzing result of the acoustic signal by STFT with applied voltage of 7kV. The sound signal steadily contains the frequency components of 40kHz or less over all time. The signals with the frequency components over 100kHz are detected at 11.7ms, 12.8ms and 18.8ms. This value is almost same with the time of acoustic signal by the arc discharge.

When AC 7kV is applied to the ignition plug, the CWT scalogram of sound signal is shown in Fig.13. The frequency components over 45kHz appear at 11.7ms, 12.8ms and 18.9ms. These values by CWT are fairly good agreement with the time of acoustic signal by the arc discharge.

4. Conclusions

The fundamental experiments to examine the tracking phenomenon were carried. The high voltage of alternating current was applied to the electrode such as the mesh type electrode, the flat ribbon cable and the ignition plug. STFT and CWT were applied to discriminate the acoustic sound of the partial discharge and the dominant frequency components were studied. The following results are obtained:

1. When AC 2.5kV is applied to the mesh type electrode, the discharge current flows during 1.7ms～2.8ms, 9.9ms～11.3ms and 18.7～19ms. The current waveform is pulse-like, and it seemed to generate the dielectric barrier discharge. CWT scalogram of sound signal shows that the frequency components over 40kHz appear during 2.1ms～3.3ms, 10.9～11.3ms and 19.2～19.7ms.
2. The pulse-like discharge current flows during 0.3ms～4ms, 8.6ms～12.6ms and 16.6～19.7ms, when AC 15kV is applied to the electrode of flat ribbon cable. The CWT scalogram of sound signal with dielectric barrier discharge shows that the frequency components over 80kHz appear during 1.1ms～3.5ms, 11.0ms～12.3ms and 18.7～20.0ms.
3. When AC 7kV voltage is applied in the ignition plug, the electric discharge has been generated at 11.6ms, 12.7ms and 18.8ms. The CWT scalogram of sound signal shows that the frequency components over 45kHz appear at 11.7ms, 12.8ms and 18.9ms.
4. The calculation results by the CWT are more accurate compared with the STFT results.

1. Abstract

Commonly atmospheric glow plasma can be straightforwardly generated only in He or very pure nitrogen and at relatively low power density. In this paper it is shown that through electronic suppression of the unstable plasma modes the atmospheric glow can be generated at high power density and in a variety of gases. It is argued that not the pre-ionization but the plasma stabilization is the key factor in atmospheric glow generation.

2. Introduction

Due their huge potential for cost efficient industrial applications uniform atmospheric plasmas (atmospheric glow) attracted a lot of interest in the recent years. Most of the atmospheric plasmas are generated in filamentary unstable form and the existence of atmospheric glow is a quite intriguing exception. It is widely believed that atmospheric glow generation is related to a large pre-breakdown pre-ionization [1-5]. This theory is based on the reasoning that pre-ionization would suppress the avalanches space charge and will eliminate the possibility of a filamentary streamer breakdown [1]. Nevertheless the link between pre-ionization and atmospheric glow generation it is still under debate. They are several experimental evidences that atmospheric glow can be generated with a negligible pre-ionization [6,7]. Moreover at the relatively low electric fields and gaps conditions under which atmospheric glow is commonly generated, the space charge of the avalanches is negligible. Thus the streamer breakdown is impossible and the pre-ionization is not necessary [6]. To our opinion not pre-ionization is the key factor in atmospheric glow generation but plasma stability. There is no plasma physics law forbidding the generation of an atmospheric glow *if the streamer breakdown does not occur.* There are however several reasons for which the generation of a *stable and uniform glow* at atmospheric pressure is rather improbable. Due to the large pressure a fast growth of instabilities due to large collision rates will occur. These instabilities will be slow damped (due to the slow diffusion) so a local perturbation will growth very fast and will remain localized generating a tendency of plasma to filamentate .As it will be argued in this paper the straightforward generation of atmospheric glow in He is the result of ionization cross-section peculiarities that makes plasma in He very stable to perturbations. Atmospheric plasma generation in other gases requires the suppression of the unstable plasma modes. Only in this atmospheric glow can be generated at high power density and for a variety of gases.

3. Experimental

The plasma was generated in He, Ar, N2 , Ar/O_2 , N_2/O_2 and air (gas flow speed 0.5-1 m/s), between two parallel electrodes (electrode gap 1 mm, plasma surface 60 cm^2). The discharge was operated in air surroundings or in a controlled environment. In the case of discharge in air surroundings it was estimated that at the standard flow conditions of 1 m/s there are hundreds of ppm of air due to the leaks in the reactor from the surroundings. In another set-up the purity of environment was strictly controlled by vacuuming the system up to $8*10^{-2}$ mbar and

filling it afterwards with gas up to atmospheric pressure. In this case the impurities are estimated to be of few ppm. No significant differences were noted in the plasma I-V characteristics or plasma uniformity and stability between the two set-ups. Glow generation was investigated using as surfaces in contact with plasma polyethylene naphthalene (PEN) , polyethylene teraphtalate (PET) , polyethtlene (PE) of 100-200 μm thickness , and alumina coated on metal (~500μm thick) .The high voltage (0.2-8 kV, 5-450 kHz) was applied to the electrodes using a system consisting of a computer controlled pulse generator and a power amplifier. The current and voltage waveforms were recorded through a computer controlled TDS 3034 B TEKTRONIX oscilloscope (sampling resolution 1 ns, bandwidth 350 MHz). The current flowing through the APG reactor was measured using (Tektronix CT-1 and TCP 202) current probes. In order to monitor the plasma uniformity the spatial distribution of the light emitted by the plasma was recorded using a DALSA Eclipse fast CCD camera (integration time 13μs).

4. Plasma instability

Plasmas at atmospheric pressure tend to be extremely unstable due to a critical combination of fast growth of perturbations and slow perturbation damping. As it will be argued below the fast growth of perturbation is due to the plasma generation at pd values (pressure *gap) much larger than the optimum pd value where the plasma stability to perturbations is optimal. The relatively large value of the **pd** product of order of 100 mbar*cm is determined by the high pressure and the practical need of having a gap of the order of at least one millimeter.
The slow damping of perturbation is mainly due to the small diffusion coefficient at atmospheric pressure and thus of a slow diffusion of ions, vibrationally excited molecules and metastables. The diffusion is so slow that a perturbation in the charge or excited species density will need milliseconds to diffuse over a millimeter. The tendency of a fast growth of instabilities can be demonstrated by evaluating plasma stability to the common thermal/ionization instability [8,9]. This instability is common because all local perturbations of ionization are also changing the temperature and are likely to trigger a thermal instability. For example if the temperature increase locally due to some perturbation the particle density **n** will decrease because the pressure remains constant in the neighborhood of the perturbed area. Then **E/n** (E is the electric field) will increase. Consequently the ionization rate will increase which in turn will increase again the temperature. At the atmospheric pressure due to high collision rate the temperature will follow in very short time (10-100 ps) the changes in the current density . Note that this instability occurs after the breakdown and it can not be suppressed by a pre-breakdown pre-ionization. The ionization is already large enough when the thermal/ionization instability occurs.
If one neglects the perturbation damping the speed of variation of the current density will be given by :

$$\frac{d\ln j_{plasma}}{dt} = S_0 + \frac{d\ln j_{plasma}}{d\ln(E/n)}\frac{d\ln(E/n)}{d\ln T}\frac{d\ln T}{dt} = \frac{1}{1-\beta\left(\frac{d\ln j_{plasma}}{d\ln(E/n)}\right)}\Phi_0 \qquad (1)$$

where : j_{plasma} is the plasma current density, $\Phi o = \delta j_{plasma}/dt j_{plasma}$ is the initial perturbation in current density ,T is the absolute temperature and β is the feedback coefficient of the plasma temperature to the perturbation reflecting the increase of absolute temperature in percents when the plasma current increase with one percent. To have a stable plasma β must be as small as possible and the plasma current density must not change to much with the electric field i.e :

$$\beta\left(\frac{d\ln j_{plasma}}{d\ln(E/n)}\right) << 1 \qquad (2)$$

If the condition given by eq.2 is not fulfilled than the denominator of eq.1 will tend to zero and the amplification of perturbation can occur explosively.

The feedback coefficient β will be larger if the plasma power is larger or if the gas is molecular one (due to the storing of energy in the vibrational levels). This may be the why reason atmospheric glow generation at large power densities or in molecular gases is very difficult. Using the general formula for the current density of glow plasma given in [8] one can see that at low current density (below the normal glow current density) the derivative of the current density on the electric field has a sharp minimum at the Stoletov point where the breakdown voltage is minimum as function of **pd**. The pd value of this minimum is determined by the ionization cross section and mean free path of electrons. For most of the gases the pd value is much larger than optimum pd. Incidentally for He plasma the pd of minimum breakdown voltage is large (~100 mbar*cm) which makes this plasma more stable to ionizations perturbations at atmospheric pressure. The low breakdown voltage of He is also a reflection of the fact that at millimetric gaps He is very close to the minimum value of the breakdown voltage. A numerical simulation of Boeuf et al. [10] indicated also that at breakdown He plasma is extremely stable to voltage perturbations.

The equation (2) may be rewritten as :

$$\beta\left(\frac{d\ln j_{plasma}}{d\ln(E/n)}\right)=\beta\frac{\frac{dI}{I}}{\frac{dV_{plasma}}{V_{plasma}}}=\frac{\frac{dI}{dV_{plasma}}}{\frac{I}{V_{plasma}}}=\beta\frac{R}{r}<<1 \qquad (3)$$

where I is the plasma current, V_{plasma} is the voltage drop on plasma , r is the dynamic resistance of the plasma (dI/dV_{plasma}) and R is the plasma resistance (I/V_{plasma}). The ionization instability will growth very fast if :

$$\beta\frac{R}{r}<=1\Rightarrow\frac{r}{R}>=\beta \qquad (4)$$

The ratio of dynamic to static resistance *must be of order of unity or larger in order to have a stable plasma*. Thus if the thermal/ionization instability is indeed a risk at atmospheric pressure one will expect that the IV characteristics of plasma will have a low ratio of the dynamic to static resistance. This is indeed the case. In all our experiments we observed that the filamentary plasmas or the unstable plasmas have a low ratio of dynamic to static resistance *r/R*. For example in Fig. of filamentary plasma in Ar1 it is presented the IV characteristic. In Fig. 2a one can note that even the He plasma has at the end of the discharge a low dynamic resistance. Due to this instability the plasma will switch in another mode of lower dynamic resistance, which is giving the current peak observed in Figs.2. Note that it is clear that the instability observed in Figs.2 cannot be linked with a deficit of pre-ionization. It is developing at a moment when the current and the pre-ionization are large enough. Also it is not an instability developed due to a over-voltage at the breakdown as assumed in [10]. The probable source of perturbation is the surface of material in contact with the plasma.

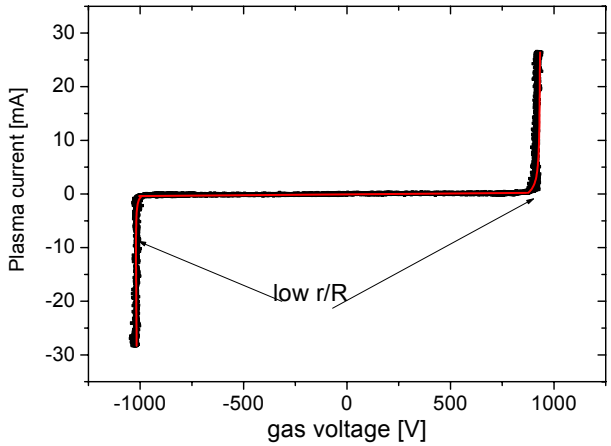

Fig.1 Filamentary plasma
Ar d=1 mm, f=12 kHz, PEN dielectric

Impurities or a local pin-like shape of the surface topography can trigger changes in secondary ionization and field electron emission. In [4-6] it was demonstrated that the nature of cathode material affects significantly the plasma stability.

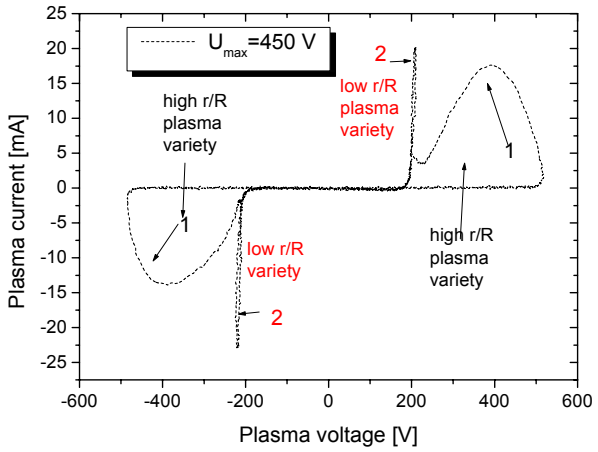

Fig.2a Plasma I-V characteristics for f=10.8 kHz, d=1 mm, U_{max}=450 V

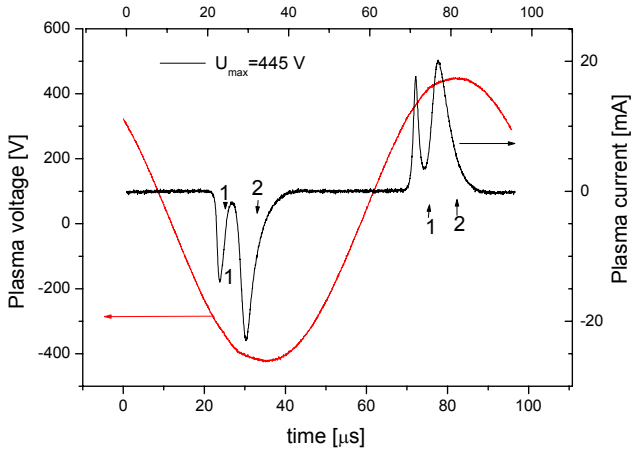

Fig.2b Multiple discharge pulses in He triggered by the plasma instability
f=10.8 kHz, d=1 mm, U_{max}=420-450 V

5. Plasma stabilization

The development of instabilities and of filamentation must be prevented in order to generate the stable glow variety. The peculiar low *r/R* ratio of the unstable plasmas can be exploited in order to suppress electronically this plasma variety. In Fig.3 the IV characteristics of a electronically stabilized Ar plasma are presented and in Fig.4 a those of a Ar+10% O_2 plasma. One can note that to the contrary of the case presented in Fig.1 for most of the current pulse duration the electronically stabilized plasmas have a *r/R* ratio of a stable plasma of order of unity. Moreover the spatial distribution of the light emitted by the plasma is not anymore filamentary but uniform (see Fig.5).

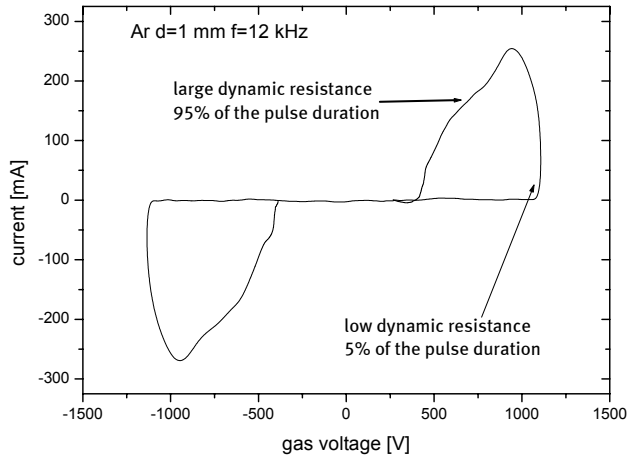

Fig.3 I-V characteristic of a stabilized Ar plasma d=1 mm, f=12 khZ, PEN dielectric

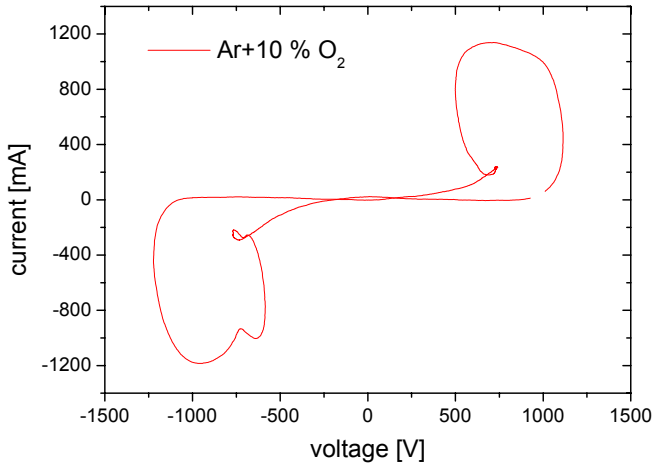

Fig.4 I-V characteristic of a stabilized Ar/O_2 plasma d=1 mm, PEN dielectric

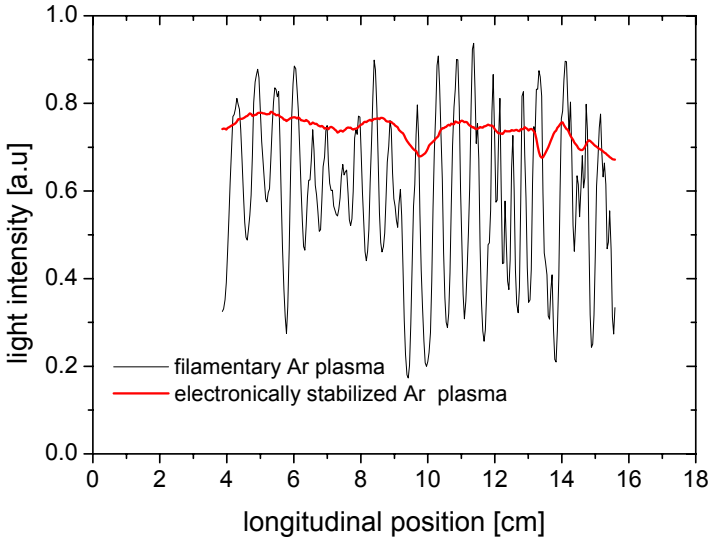

Fig.5 Spatial distribution of a filamentary and electronically stabilized Ar plasma

In Figs 6 are presented the IV characteristic of nitrogen plasma before and after electronic stabilization. The common form of atmospheric glow in nitrogen can be generated only at low power density below (1 W/cm^3) and is extremely unstable switching in a filamentary form when the voltage is increasing with 10-20% above the breakdown voltage or more than 0.01 % of oxygen is added to the discharge.

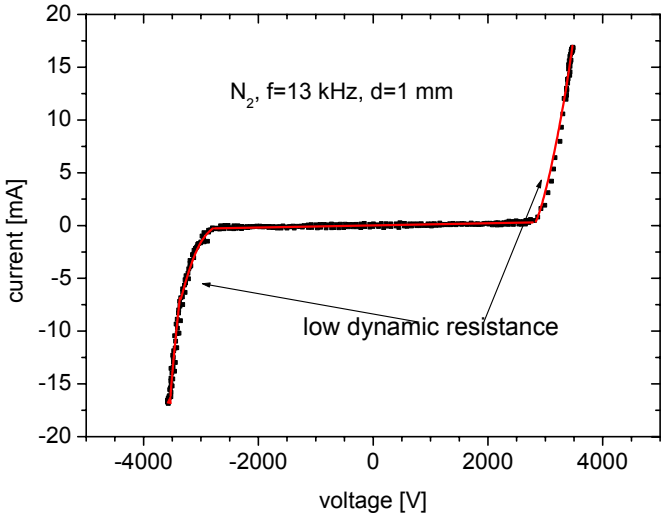

Fig.4a I-V characteristic of N_2 Townsend discharge d=1mm f=12 kHz, PEN dielectric

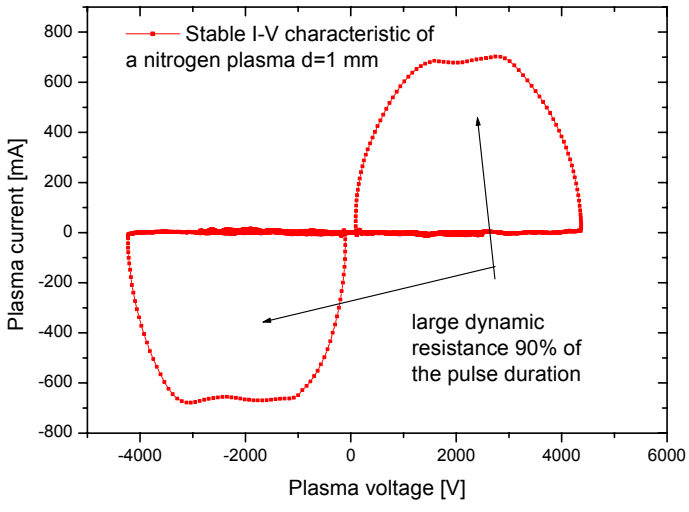

Fig.4b I-V characteristic of a stabilized N2 discharge

Again as one can see in Fig.6a the reason of this instability is the low *r/R* ratio of the IV characteristics. In this case the low *r/R* ratio is due to the fact that the common form of atmospheric glow in nitrogen is a Townsend discharge. For such discharges the current is extremely sensitive to any change in voltage [8]. After the electronic stabilization a discharge variety of larger dynamic resistance is generated (see Fig.5b). This electronic stabilized discharge is stable up to several percents of oxygen added to the discharge. Also it can be generated at large power density. In this way the surface energy of PP a notorious hydrophobic polymer can be increased to 66 mJ/m after a exposure of only 0.5 s in a nitrogen atmospheric glow [12].

A method of plasma stabilization is the limitation of the speed of the current growth *dI/dt* during the plasma breakdown. During the breakdown plasma has a negative dynamic resistance in order to limit the *dI/dt* the voltage applied to the plasma should not decrease during this phase of plasma generation. This is done by inserting in series with the AGP reactor a choke coil that operates in the saturation regime during the plasma generation [11].

6. Conclusions

Thermal/ionization instability is the key factor, which is preventing the atmospheric glow generation. Excepting He atmospheric plasma generation requires the suppression of the unstable plasma modes. Several dedicated electronic circuits were developed for this purpose. Only in this way we succeeded to generate the atmospheric glow at high power density and for a large variety of gases.

Abstract

In this paper we present results from the synthesis and deposition of Si-Ti-N nanostructured coatings using hypersonic plasma particle deposition. Focused particle beam deposition of micropatterns using aerodynamic lenses demonstrates promise in the synthesis of structures constructed from SiC nanoparticles. This study analyzes individual nanoparticles, nanostructured coatings and micropatterns, with particular emphasis on phase composition, morphology and particle/grain size distributions.

1. Introduction

Nanostructured materials are attractive candidates for advanced friction and wear-resistant coatings due to their potentially enhanced mechanical properties. Furthermore, generation of patterned ceramic microstructures made of nanoparticles has potential applications in microelectromechanical systems (MEMS). We have developed a one-step method called hypersonic plasma particle deposition (HPPD) to produce and deposit nanoparticles using a thermal plasma reactor [1]. In the HPPD process, particles are deposited on a substrate by hypersonic impaction to form a coating, or are deposited as micropatterns using focused particle beam deposition [2]. This paper analyses Si-Ti-N nanostructured coatings synthesized and deposited with the HPPD process. Micropatterns consisting of Si and SiC nanoparticles deposited at room temperature using the focused particle beam are also examined. Patterns were also deposited into gear molds using the coating deposition stage at elevated temperatures. Additionally, in-situ particle size distribution measurements were performed using a sampling probe interfaced to an extraction/dilution system in series with a scanning mobility particle sizer (SMPS) [3]. These data were compared to measurements obtained from X-ray diffraction peak broadening using the Warren-Averbach method [4].

2. Experimental Setup

HPPD involves a one-step process in which nanoparticles are both synthesized and deposited. The details of the experimental apparatus and operating conditions have been described previously [1] and are briefly explained here. In the HPPD process, vapor phase reactants are injected into a thermal plasma where high temperatures at the injection location dissociate the reactants into their elemental constituents. The gaseous mixture is expanded through a cooled ceramic nozzle driving the nucleation of nanoparticles, which are then accelerated in a hypersonic jet. The particles are deposited on a substrate by hypersonic impaction to form a coating, or are deposited as micropatterns after passing through an aerodynamic lens assembly. The experimental setup is shown schematically in Figure 1.

In the film deposition stage a molybdenum substrate (Module A in Fig. 1) is positioned normal to the flow, and particles as small as a few nanometers in diameter impact the substrate at high velocity to form a dense, nanostructured coating. The position of the substrate is 2 cm away from the exit of the ceramic nozzle.

In the focused particle beam deposition process, nanoparticles from the nozzle are collimated into a tight beam using an aerodynamic lens assembly consisting of a set of thin-plate orifices mounted inside a cylinder (Module B in Fig. 1) [5,6]. The entire unit is made of stainless steel, with the lenses spaced 47 mm apart. The gas inside the lens assembly contracts and expands as it passes through each of the lenses. Sufficiently small particles follow the gas, whereas large particles are lost to the walls. Particles of intermediate sizes are pushed closer to the centerline. Our lens assembly focuses 10-100 nm particles into a collimated beam with a diameter of a few tens of microns. An accelerating nozzle is placed at the end of the barrel, beyond which the flow undergoes another expansion to pressures around 1 Pa. The focused nanoparticles are then deposited onto a motion-controlled substrate to form micropatterns or onto TEM grids for off-line analysis.

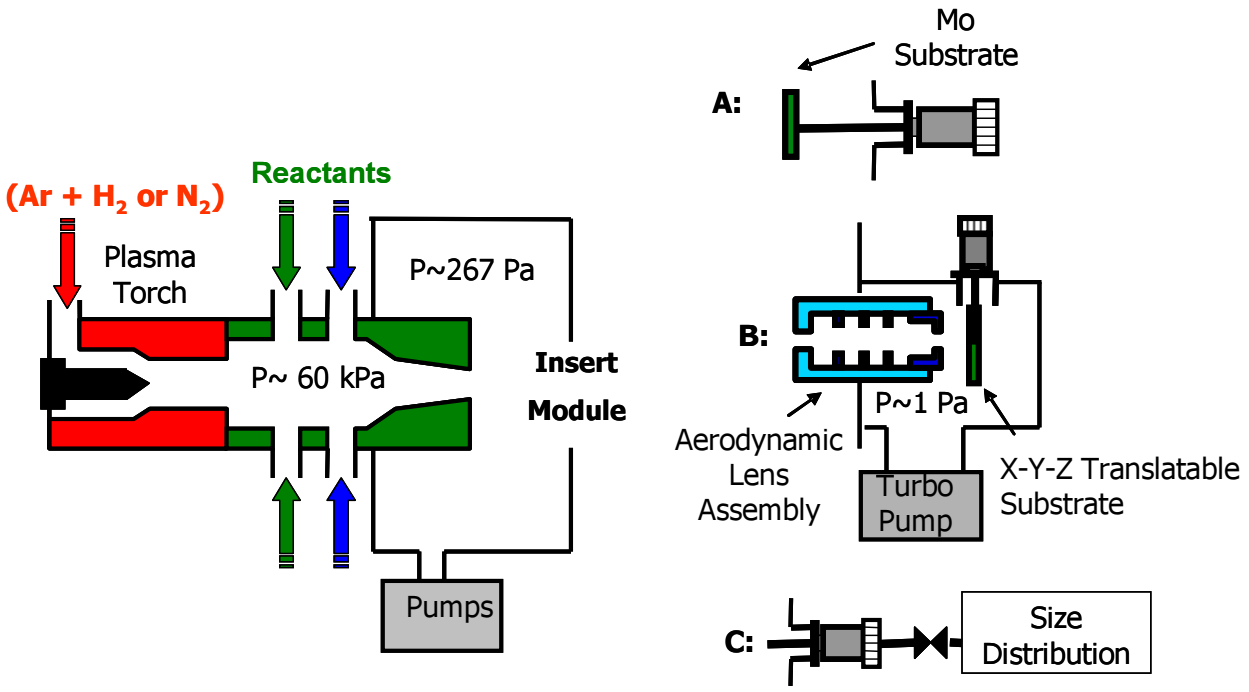

Figure 1: Schematic of the HPPD system

The HPPD process has been used to deposit nanostructured films composed of elements from among the following: silicon, titanium, carbon and nitrogen. The reactants include silicon tetrachloride and/or titanium tetrachloride, with methane additionally injected to produce the carbides, and nitrogen or ammonia to produce the nitrides.

Several techniques have been employed to investigate properties of nanoparticles prior to deposition, and structures constructed from these nanoparticles. A sampling probe interfaced with a scanning mobility particle sizing (SMPS) system allows in-situ access to particles in the hot gas jet for measurement of size and charge distributions (Module C in Fig. 1). During measurements, the sampling probe was placed 2 cm away from the nozzle, corresponding to the substrate standoff distance for film deposition. X-ray diffraction (XRD) spectra were obtained with a Bruker AXS microdiffractometer (CuKα) as well as a Siemens 5005 diffractometer. Scanning electron microscopy (SEM) was performed with a JEOL 6500 field emission gun (FEG) microscope equipped with an energy dispersive spectrometer. Transmission electron microscopy (TEM) was performed using a JEOL 2010 FEG TEM.

3. Results and Discussion

3.1. Si-Ti-N Coating Deposition

Si-Ti-N nanostructured films have shown good promise as potential candidates for high hardness and friction resistance applications [7]. We have synthesized Si-Ti-N coatings of 10-50 μm thickness on molybdenum substrates at deposition rates of 2-30 μm/min, depending on reactant flow rates, at substrate temperatures ranging from 400-1000°C. (All substrate temperatures quoted refer to the deposition surface.) Our previous study has shown the coatings to consist of TiN nanocrystals surrounded by an amorphous Si_3N_4 matrix [8].

To determine the effect of plasma gases on coating properties, we synthesized coatings with a plasma gas mixture of either Ar + N_2 (30 slm + 2.5 slm) or Ar + H_2 (30 slm + 2.5 slm) at substrate temperatures of 940 °C. For both cases the reactant flow rates were identical. X-ray diffraction spectra of films synthesized with a plasma gas mixture of Ar + H_2 show the presence of crystalline TiN, $TiSi_2$, and Ti_5Si_3, while films synthesized

with an Ar + N_2 mixture show only crystalline TiN (Fig. 2). The difference in crystalline phases present in the coatings can be attributed to the effect of extra nitrogen available during the synthesis process. Studies on the phase stability of Si-Ti-N have indicated that nitrogen activity plays a key role in changing phase components [9]. When the partial pressure of N is sufficiently high, Si does not form a stable titanium silicide phase. In our system, the partial pressure of nitrogen is increased significantly by adding extra N_2 as one of the plasma gases, resulting in the formation of only TiN with Si existing in an amorphous phase. These results indicate that we can switch crystalline phases in our coatings by changing the plasma gases.

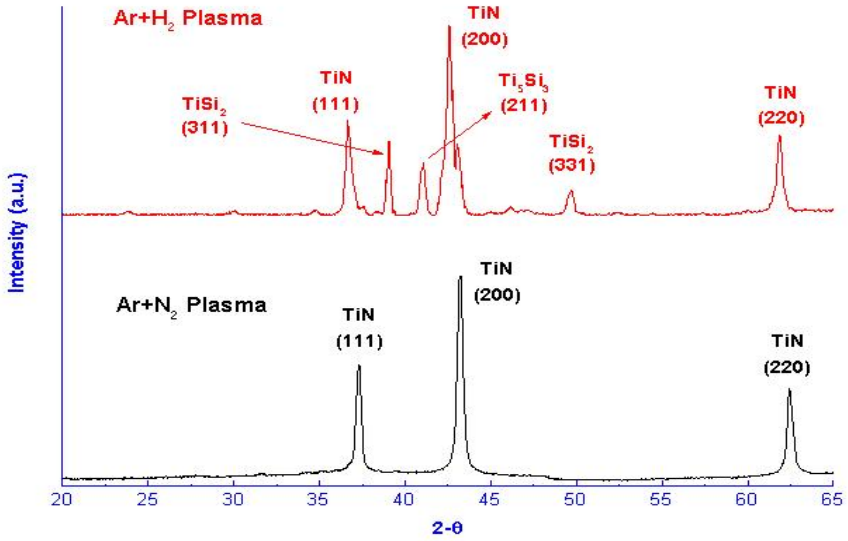

Figure 2: X-ray diffraction spectra of Si-Ti-N coatings deposited with an Ar + H_2 plasma gas mixture (top) and an Ar + N_2 mixture (bottom). The flow rates are: $SiCl_4$ 20 sccm, $TiCl_4$ 120 sccm and NH_3 500 sccm.

However, particle size distribution measurements performed for the same flow rates using either an Ar + H_2 or a Ar + N_2 gas mixture showed only a small difference (Fig. 3). The modes of the distributions for both cases are approximately 14 nm. It may be concluded that even though changing the plasma gas mixture results in different

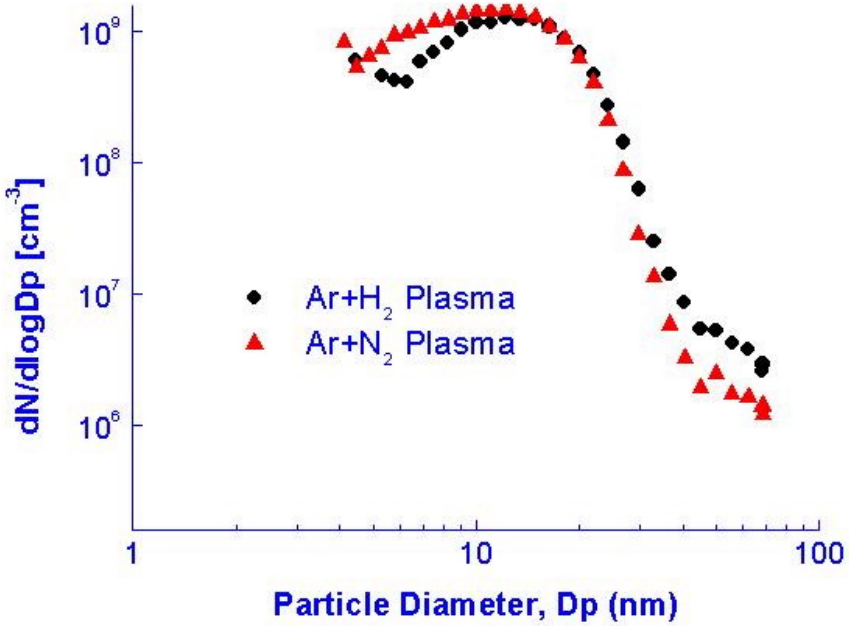

Figure 3: In-situ size distributions of particles synthesized with different plasma gas mixtures

crystalline phases, it does not significantly affect the size of the impacting particles forming the coatings.

In addition to the near real-time SMPS measurements, crystallite size was also determined from broadening of the Bragg reflections obtained from XRD measurements of the coatings. The Warren-Averbach (WA) method was utilized for this analysis, as researchers have found it to be more accurate than other methods when dealing with grain sizes in the nanometer range [10]. However, size determination could only be performed for coatings synthesized using the Ar + N_2 gas mixture. A disadvantage of WA analysis is that it requires multiple non-overlapping peaks of a phase for accurate size determination. As coatings synthesized using an Ar + H_2 mixture did not contain more than one distinct peak for any phase, accurate size analysis could not be performed. Crystallite size determined from the broadening of TiN reflections for the Ar + N_2 case showed the mean size to be 14.9 nm, corresponding well with the SMPS measurements. It is interesting to note that the mode of the distribution from the SMPS data and the mean size from XRD peak broadening were similar, even though the SMPS measures all synthesized particles, whereas the WA analysis provided information only concerning crystalline TiN. The results indicate that for the deposition conditions examined, the size of the TiN crystallites may be representative of the overall grain size distribution in the film.

3.2. Focused Beam Deposition

In concert with standard microfabrication techniques, focused nanoparticle beams can be used to deposit lines or patterns, or to build three-dimensional objects, made out of nanoparticles. We are currently pursuing micromolding of MEMS devices by filling micromachined silicon molds with focused nanoparticles. Molds were fabricated by standard photolithography tools and dry etched using deep reactive ion etching (DRIE). Figure 4a shows a microgear-shaped mold fabricated using DRIE. This mold was filled using SiC nanoparticles collimated by the aerodynamic lens system. The gear mold was rastered across the nanoparticle beam at a velocity of 50 μm/s. The time required for the deposit to cover three microgear molds (250 μm diameter separated by 100 μm) was on the order of 15 min. Cross-sectional SEM of a completely filled gear mold with a depth of ~8 μm is shown in Figure 4b. It should be noted that micropattern deposition on the Si substrate is carried out at room temperature, although the possibility of substrate heating exists for additional control of deposit properties.

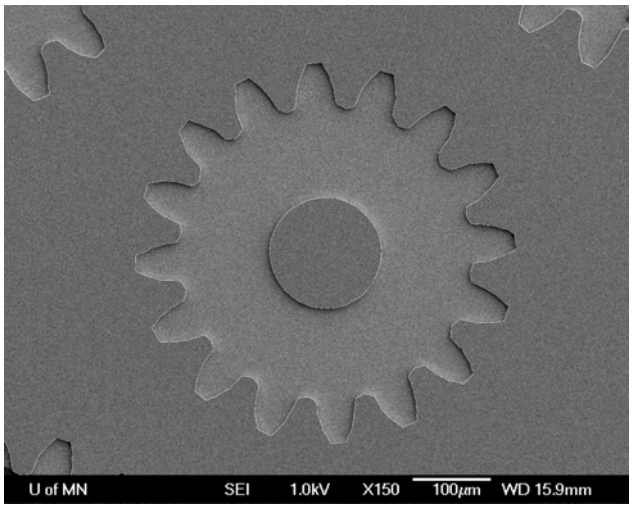

Figure 4a: Micromachined silicon gear mold.

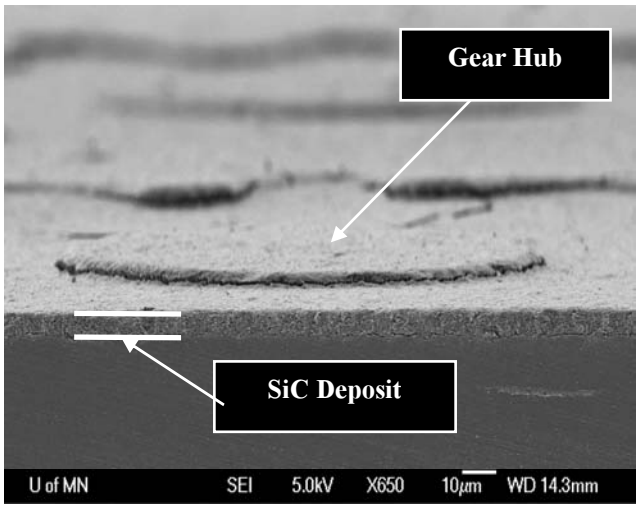

Figure 4b: Cross-section of mold filled by a layer of SiC nanoparticles from the focused beam.

We have conducted a number of experiments to characterize nanoparticles passing through the lens assembly. Studies of individual particles allow us to relate properties of the micropatterns to their nanostructure. These experiments were performed by removing the Si substrate and replacing it with a substrate containing TEM girds for off-line analysis of individual particle properties. Figure 5 shows a high-resolution TEM image highlighting

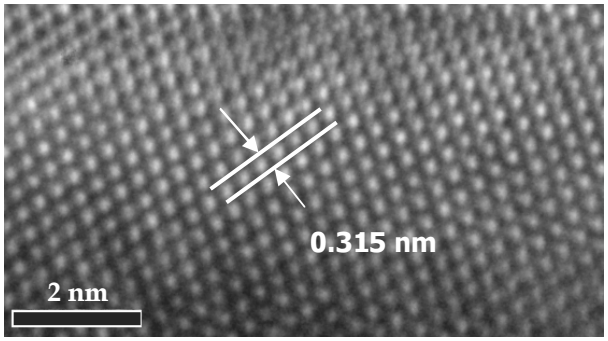

Figure 5: High-resolution TEM image of a crystalline Si nanoparticle collected using aerodynamic focusing.

the crystalline nature of a 100-nm-diameter Si particle collected on a copper grid. The calculated fringe spacing of the particles is 0.315 nm, corresponding to the Si (111) phase, which has a lattice spacing of 0.314 nm. The highly crystalline nature of the Si particle is typical of particles collected after the lens assembly.

In additional experiments, we also filled gear molds by replacing the molybdenum substrate used in the film deposition setup. This was done to utilize the high rate deposition capabilities and higher substrate temperatures attainable in the hypersonic impaction stage. Preliminary results (Fig. 6) illustrate a cross section image of a gear partially filled with a film of Si-Ti-N nanoparticles.

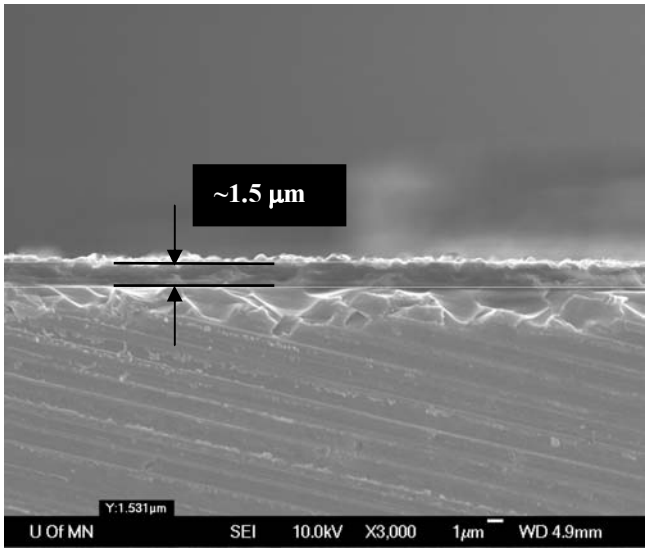

Figure 6: Cross-section of Si-Ti-N nanoparticle film deposited in "valley" of a gear mold using the film deposition stage. Substrate temperature ~650-800°C, 1-minute deposition.

4. Conclusions

The work reported here presents results using the HPPD process to deposit nanocomposite coatings and nanostructured micropatterns. The phase distribution in the Si-Ti-N coatings was studied as a function of plasma gases. When the plasma gases contained Ar + H_2, crystalline phases in the coatings consisted of TiN, $TiSi_2$, and Ti_5Si_3. When the system was switched to a plasma gas mixture of Ar + N_2, the only crystalline phase was TiN. However, there were only small differences in particle size distributions between the two cases. Size distribution measurements indicate the mode of the impacting particles to be ~14 nm in diameter. This corresponded well with the average size of the TiN crystallites in the films obtained from Warren-Averbach analysis.

Focused beam deposition presents a new and promising approach for fabricating hard microparts for MEMS systems. Results show that particles being focused through the lens system are primarily crystalline in nature. Preliminary experiments illustrate the capability of the deposition process to completely fill 8-μm-deep microgear molds with SiC nanoparticles. This approach has the potential for high-rate coating applications as well as for micromolding and free-form fabrication of nanostructured materials.

Abstract
The complete process of plasma oxidation of metals in oxygen plasma consists of several stages: activation of oxygen in discharge, transport of charged species from undisturbed plasma to metal substrate immersed into the plasma, processes on the surface and the growth of oxide layers including the ion transport through growing oxide film. In the contribution the plasma oxidation of aluminium and tin in pure oxygen and in oxygen/argon mixtures is analysed, the methods of study being both the direct measurement and computer simulation.
Keywords: plasma oxidation, plasma volume processes, sheath, computer simulation, AFM.

1. Introduction

Thin dielectric films are very important in many material engineering disciplines. There exist various techniques for preparation of dielectric films, the oxidation being one of the most important of them. The high-temperature processes as thermal oxidation or chemical vapour deposition often give rise to defect formation; therefore the low-temperature processes are popular. The plasma oxidation, utilizing highly activated oxygen plasma, is one of the low temperature techniques used to grow dielectric films on metal surfaces [1]. Substrates immersed into plasma are held on various biases relative to plasma. Typical procedure is the plasma anodisation, when the positive external bias is applied in order to enhance the diffusion of oxygen ions through the growing oxide layer, however the oxidation without external bias or even with negative biases is sometimes used too.

For the study of plasma oxidation there exist several reasons: to understand the mechanisms of plasma oxidation of metal thin films, to find basic factors playing the dominant role in studied process, and to find factors determining the properties of created oxide films. During our previous studies [2]- [3] it was found that the combination of two approaches – experimental and computational – is very efficient method for the analysis of physical and chemical processes taking place in the plasma oxidation of metals.

2. Bulk processes – Experimental study

The first part of our computer experiment, i.e. activation of oxygen in the discharge and transport of obtained charged species to the substrate, is based on experimental data obtained by measurements performed in our two laboratories. In the laboratory of J. E. Purkyně University the experiments were carried out in the system for the plasma chemical surface modifications of thin films [4]. Two types of discharges were applied: DC glow discharge and 13.56 MHz RF discharge in pure oxygen and in oxygen/argon mixtures. The DC flowing discharge was produced in the Pyrex tube at typical parameters: total gas pressure 50 Pa, flow rate 2.5×10^{-4} $l \cdot s^{-1}$, discharge current 25 mA. In the same ranges of gas pressures and flow rates an RF discharge was produced, too. For the diagnostics of the discharge process, a movable cylindrical Langmuir probe and optical emission spectroscopy system consisting of quartz fiber, spectrometer and CCD camera were used. Beside these measurements the visualization of the field of intensities emitted by plasma was performed by CCD camera with combination of various filters. The main experimental results were electron temperatures and densities and their radial profiles in the discharge tube, the spatial distribution of discharge and above all the plasma emission spectra enabling to analyse various atomic transitions in argon and oxygen.

In the laboratories of Charles University the measurements were made mostly in the positive column of DC glow discharge in the mixtures of rare gases containing oxygen (combinations: pure oxygen, oxygen/argon, oxygen/neon and oxygen/helium) in the pressure range 67 to 800 Pa and for discharge currents in limits 5 to 30 mA [5]. For the study of plasma properties various diagnostics were used – optical, microwave and probe

diagnostic method. The main studied plasma parameters were the axial electric field in the discharge, the electron density and electron temperature for the basic experimental parameters: composition of gas mixture, its pressure and discharge parameters.

As examples of obtained results some characteristics are presented in Figs. 1 and 2. These results can be used both as input data for the following modelling and for testing of results derived by our computer experiments.

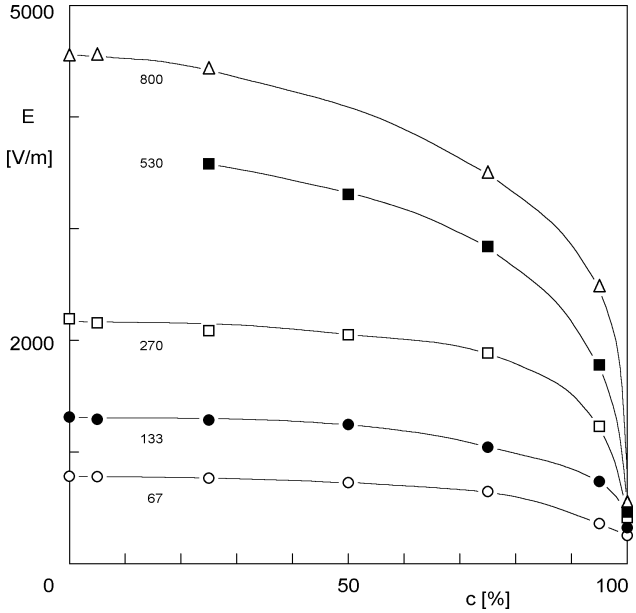

Fig. 1: Measured intensity of axial electric field *E* in the oxygen/argon plasma in the dependence on the concentration *c* of argon in the mixture. Discharge current 20 mA. Parameter: pressure of the mixture in limits 67-800 Pa [5].

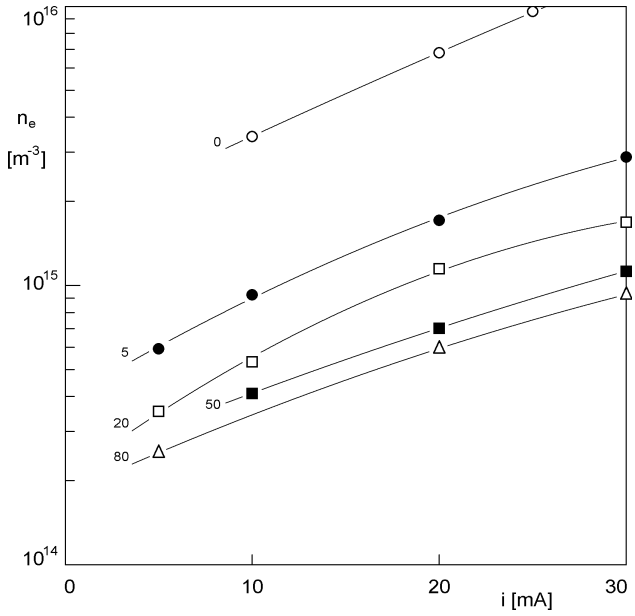

Fig. 2: Measured electron density n_e in the oxygen/neon plasma in the dependence on the discharge current *i*. Pressure 800 Pa. Parameter: concentration of neon in the mixture (0-80 %) [5].

3. Bulk processes – Computational study

As a second method for the study volume processes in plasma, a computer experiment was prepared. The numerical simulation of the plasma composition is based on a macroscopic kinetic approach (e.g. [6]). In reality there exist several similar models – for pure oxygen discharge and for mixtures of oxygen with various rare gases. The model of the oxygen/argon plasma consists of nearly two hundred reactions between 15 kinds of neutral, charged and excited particles (electrons; O, O_2, O_3, O^-, O^+, O_2^-, O_2^+, O_3^-, $O(^1D)$, $O_2(^1\Delta_g)$, $O_2(^1\Sigma_g^+)$; Ar, Ar^+, Ar^*). This set of reactions includes the basic physical processes in O_2/Ar plasma – ionisation, recombination, dissociative attachment, dissociative recombination, radiative attachment, direct dissociation, three-body collisions and excitation. The reaction set consists of three parts – reactions between oxygen particles, reactions in argon and mixed reactions oxygen-argon. The attention is paid to evaluation of the influence of individual chemical reactions on the resulting products, especially on those important from the point of view of plasma oxidation of metals (i.e. electrons and negative oxygen ions).

In the macroscopic kinetic approach, it is necessary to analyse the reactions in the model and to prepare the large set of partial differential equations describing the concentrations of individual species in plasma. The complete model is too complicated and very difficult to solve. However, if both the drift and diffusion terms can be neglected, the set of ordinary differential equations is obtained in the form

$$dn_i / dt = A_i(n_1,\ldots,n_m) - B_i(n_1,\ldots,n_m), \quad i = 1, 2,\ldots, m,$$

where n_i is the concentration of the i-th specie and m is the total number of species in the suggested mechanism – e.g. 15 in our oxygen/argon model. The creation and loss processes A_i and B_i consist of the terms $\pm k_p \cdot n_a$; $\pm k_p \cdot n_a \cdot n_b$ or $\pm k_p \cdot n_a \cdot n_b \cdot n_c$, where rate constants k_p may depend on gas temperature T_g or electron temperature T_e. The correspondence with experimental conditions can be obtained through these rate constants as well as through the input concentrations of basic species in the discharge. The resulting set of stiff equations was integrated with the help of a semi-implicit extrapolation Bader-Deuflhard method [7].

As a result, the time dependencies of neutral, excited and ionised products were obtained for various discharge parameters. For our experimental conditions, the concentrations found for O_2 glow discharge at E/N = 60 Td [2] were used for further simulation (all concentrations are given in relative scale – compared to concentration of molecular oxygen):

- neutral and excited species:
  O_2: 1.00 O: 7.53×10^{-1} $O_2(^1\Delta_g)$: 1.48×10^{-1} $O_2(^1\Sigma_g^+)$: 4.34×10^{-3} O_3: 7.70×10^{-5}
- positive charged species:
  O_2^+: 1.60×10^{-6} O^+: 5.17×10^{-10} O_4^+: 3.00×10^{-10} ...
- negative charged species:
  electrons: 1.33×10^{-6} O^-: 2.62×10^{-7} O_2^-: 8.60×10^{-9} O_3^-: 4.64×10^{-10} ...

The corresponding concentrations of particles for oxygen/argon plasma are modified by the presence of argon atoms, the most important positive charged specie being the Ar^+ ion. The relations between oxygen and argon particles depend on the concentration of oxygen in the mixture.

The model of physical and chemical processes in the bulk of oxygen plasma results in the steady-state concentrations of most important stable products. For further simulation as well as for the whole process of plasma oxidation of metals the relative concentrations of two basic negatively charged species – electrons and atomic oxygen ions – is very important. This ratio depends on discharge parameters alike on the concentration of oxygen in the mixture. The sheath properties depend in large extent on the masses of main charged species and

while for positive ions (Ar^+, O_2^+ and O^+) these masses are comparable, for negative species the situation is quite different.

3. Transport through the sheath

The following part of our computer experiment analyses the transport of charged particles through the region of disturbed plasma near the substrate. The model of charge transport through both the sheath and presheath is based on a hybrid particle simulation technique, i.e. on the combination of molecular dynamics and Monte Carlo methods (e.g. [8]). In our contribution the self-consistent approach of modelling was used; it is extremely time-consuming. Taking into account the planar form of the most of oxidized substrates and in order to simplify the simulations, the planar geometry of the model was used, too. This assumption enables to use the spatially one-dimensional approximation for the simulation. It increases the performance of the simulation, however slightly decreases the accuracy of obtained results [9].

The model consists of the following standard parts:

- Source of particles:
  Undisturbed plasma consisting of electrons, positive ions and negative ions with the total concentration of particles of one sign of the order of 10^{15} m^{-3} with Maxwell velocity distributions. The numbers of species and their relative concentrations are taken from the study of volume processes, either experimental or computational. If only qualitative estimations of processes in the sheath are sufficient, only the main species containing the majority of the charge (positive: Ar^+ and either O_2^+ or O^+, negative: electrons and O^-) are included. For detailed calculation it is possible to include much larger number of charged species.
- Equations of motion:
  Newton´s equations of motion were solved by the second order Verlet algorithm.
- Force calculation:
  The movement of particles is influenced by self-consistent electric field created by other particles and by substrate bias. For its determination the standard PIC technique was used [8]. By this technique the interactions between charged species are handled.
- Interactions:
  A minimal set of basic interactions between charged and neutral species in the sheath was used. This set consists of elastic collisions, excitation, ionisation and charge transfer interactions with mean free paths given by experimental data [10]. The interactions are treated by the Monte Carlo method, so the resulting code is of the type PIC-MC.

In this part of our computer experiment, we calculated the changes of concentrations and energy distributions of both electrons and ions originating in the bulk plasma during their transfer through self-consistent electric field in the transient region between plasma and metal electrode. As a result of this simulation the sheath properties (its thickness and potential distribution) were obtained together with basic characteristics of charged particles and their changes during the transport from undisturbed plasma to the surface of immersed substrates (the fluxes of different types of charged species, their energy and angular distributions both in the sheath and in the close vicinity of the substrate). Some examples of obtained results can be found in our second contribution [11].

4. Processes on the surfaces of immersed substrates

The last part of the computer experiment is the simulation of basic processes on the substrate – impingement of charged particles, their reflection, secondary emission, etc. This simulation is supported again by experimental data obtained by various techniques – the composition and depth profiles of oxide films were studied by Secondary Ion Mass Spectrometry, the morphology of oxide surfaces and surface roughness were performed by Atomic Force Microscopy. The experiments were carried out in the system for the plasma chemical surface modification of thin films. In these experiments two types of discharges were applied. Besides the DC discharge, the experimental characteristics of which were used as inputs for our modelling, the RF discharge at 13.56 MHz in both pure oxygen and oxygen/argon mixture was used, too. In order to compare our computer experiment even with these data, the dynamical processes were included into the model of the transport of charged particles

through the sheath region. The combination of all above-mentioned diagnostics and computational techniques enables us to analyse the plasma oxidation process in detail and to discuss the role of most important plasma parameters in this process. It has been proven that the method of plasma oxidation is a possible applicable alternative method for preparing thin oxide films.

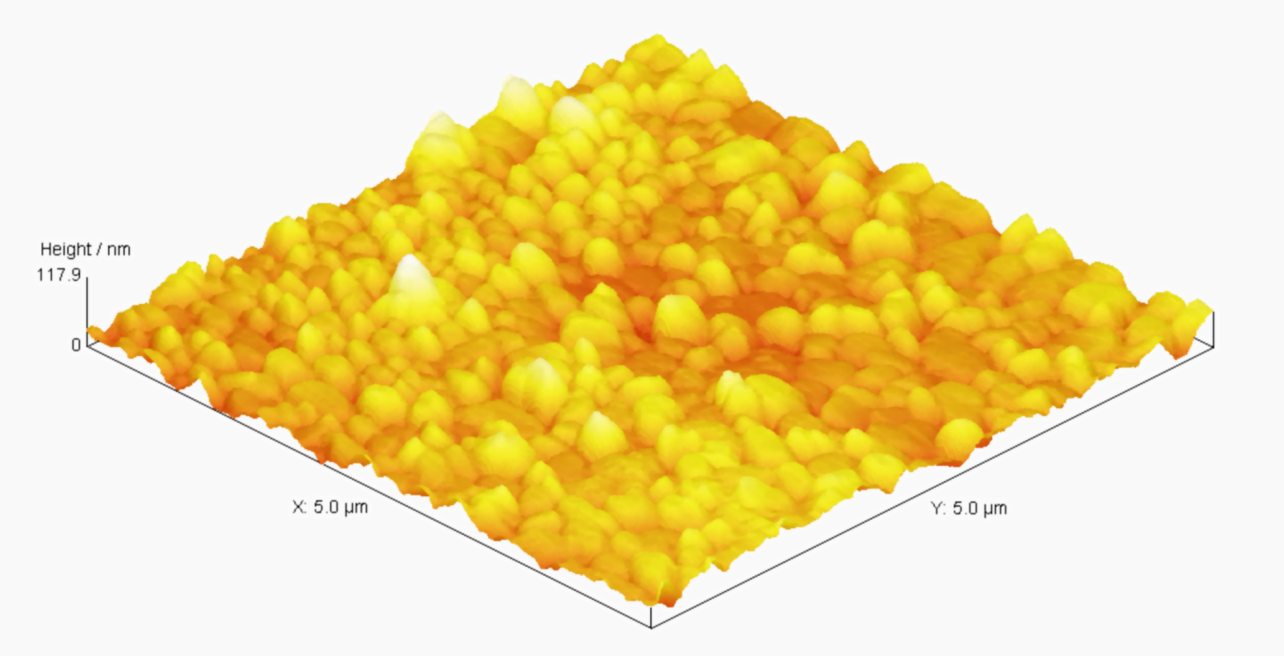

Fig. 3: AFM three-dimensional image of surface of thin SnO_2 film prepared by plasma oxidation of thin tin film.

5. Discussion

The main experimental results in bulk processes were electron temperatures and densities and their radial profiles in the discharge tube, the spatial distribution of discharge and above all the plasma emission spectra enabling to analyse various atomic transitions in argon and oxygen. These results can be used both as input data for the following modelling and for testing of results derived by our computer experiments. Computational studies showed that the relative concentration of electrons and atomic oxygen ions is very important. This ratio depends on discharge parameters alike on the concentration of oxygen in the mixture. The sheath properties depend in large extent on the masses of main charged species and while for positive ions these masses are comparable, for negative species the situation is quite different. As a result of simulations the sheath properties were obtained together with basic characteristics of charged particles and their changes during the transport from undisturbed plasma to the surface of immersed substrates. We can say it has been proven that the method of plasma oxidation is a possible applicable alternative method for preparing thin oxide films.

Abstract
Concentration measurements of the methyl radical rely on the data availability of spectroscopic properties such as the line strength. New measurements of line strengths of several transitions of the ν_2 fundamental band have been carried out. In the present work the temperature dependencies of the line strength from cryogenic temperatures up to moderate plasma temperature has been calculated.

Keywords:
methyl radical, infrared spectroscopy, line strength, transition dipole moment,

1. Introduction

The key role of the methyl radical in plasma kinetics, combustion, diamond deposition and semiconductor technologies has been demonstrated in numerous studies. The presence of the methyl radical in space has also been confirmed. Concentration measurements of the methyl radical (CH_3) in laboratory plasmas and in interstellar space are commonly made by IR spectroscopy of the ν_2 band. It has been demonstrated that detection of CH_3 in plasma processing reactors [1] and in the atmospheres of planets in our solar system [2] is most appropriately carried out by detection of the ν_2 band. The accuracy of concentration measurements depends on spectroscopic data such as the transition dipole moment or the line strength. New experimental values of the transition dipole moment and the line strengths have been published [3]. Here the temperature dependencies of the line strengths in the range of diamond plasma processing down to cryogenic temperatures will be presented.

2. Theoretical aspects

One of the physical quantities that can be measured by absorption spectroscopy is the integral value of the absorption coefficient (K_ν). The relationship between the total concentration (N) of the particles and K_ν is given by the following equation:

$$K_\nu = S(T)N \qquad (1)$$

where *S(T)* is the line strength of the specific absorption line at the equilibrium temperature *(T)* of the medium. The relationship between the line strength and the transition dipole moment is given by (2):

$$S(T) = \frac{8\pi^3}{3hc}\nu_{mn}\frac{g_m \exp\left(-\frac{E_m}{kT}\right)}{Q(T)}|\mu|^2 H_{KJ}\left[1-\exp\left(-\frac{hc\nu_{mn}}{kT}\right)\right] \qquad (2)$$

where ν_{mn} is the transition frequency, μ is the transition dipole moment, H_{KJ} is the Hönl-London factor, Q(T) is the total partition function, g_m is the degeneracy and E_m the energy of the lower level. Some comments can be made about equations (1) and (2). First if the concentration of CH_3 can be independently measured by another method or technique then the line strength can be obtained. In order to calculate μ we have to calculate the temperature dependent factors namely: the Boltzmann energy factor, the partition function and the stimulated emission factor. In this work the determination of the CH_3 concentration was made using decay measurements of the absorption coefficient during the off phase of the discharge. The principle of the method is described in detail in reference [3]. The transition dipole moment was found to be 0.215(0.025) D. Using the new value of μ the line strengths can be calculated for a wide temperature range and for several transitions.

Equation (2) relating the line strength and the transition dipole moment contains the total partition function $Q(T)$ and the total statistical weight, g_m, where $Q(T) = Q_E Q_V Q_R Q_{NS}$ and $g_m = g_e g_v g_J g_K g_{ns}$

(*E, e* – electronic; *V, v* – vibrational; *R, J,K* – rotational; *NS, ns* – nuclear spin; components). Special attention was given to the calculations of the total partition function, particularly the vibrational partition function at higher temperature and the rotational partition function at very low temperatures. Under the experimental conditions used here it can be safely assumed that only the ground electronic state is populated. The first excited state lies at 46305 cm^{-1}. Hence Q_E = 1 and, provided the spin-rotation splitting is not resolved, g_e = 1 also. The vibrational partition function is a product of the partition functions of all four normal modes,

$$Q_v = \prod_1^i \left[1 - \exp\left(-hc\nu_i / kT\right)\right]^{-g_V} \qquad (3)$$

where g_v is the vibrational mode degeneracy. The wavenumbers and degeneracies of the fundamental modes of CH_3 used to calculate Q_V are: ν_1=3004.8 cm^{-1} (g_v=1), ν_2=606.453 cm^{-1} (g_v=1), ν_3=3160.821 cm^{-1} (g_v=2) and ν_4=1396 cm^{-1} (g_v=2). In earlier works the vibrational partition function has been calculated using only the ν_2 and ν_4 modes. Figure 1 shows that above 1000 K this assumption begins to seriously underestimate the vibrational partition function.

The ν_2 band is a parallel band ($\Delta K = 0$) and non-degenerated, hence g_v = 1. Each rotational level for a symmetric top molecule also has a rotational degeneracy g_J and g_K: $g_J = 2J+1$, g_K = 1, for levels with K = 0 and g_K = 2 for levels with K = 1,2,3…. Because CH_3 is a planar molecule of the D_{3h} symmetric group, the reflection of the nuclei in the centre of mass produces a configuration that can be obtained by simple rotations of the molecule. The inversion doubling of the levels does not occur with the result that g_k = 1 for all K.

The rotational partition function, Q_R, for a planar symmetric top (D_{3h} symmetry) in which nuclear spin effects are ignored is given by,

$$Q_R = \sum_{J=0}^{\infty}\sum_{K=0}^{J}(2J+1)\exp(-\left[BJ(J+1)+(C-B)K^2\right]\frac{hc}{kT}). \qquad (4)$$

At sufficiently high rotational temperatures this expression approximates to

$$Q_R = \sqrt{\frac{\pi}{B^2C}\left(\frac{kT}{hc}\right)^3}, \qquad (5)$$

where B and C are the rotational constants. At high temperature the nuclear spin effects can be included through the nuclear spin partition function Q_{NS}:

$$Q_{SUM} = Q_{NS}Q_R = (2I+1)^3\frac{1}{\sigma}\sqrt{\frac{\pi}{B^2C}\left(\frac{kT}{hc}\right)^3} \qquad (6)$$

where we have assumed three equivalent nuclei with non-zero spin (I = 1/2) i.e. CH_3. σ is the symmetry number which is 6 for D_{3h} symmetry. Q_{NS} represents the number of the arrangements of the H nuclear spins of the CH_3 molecule. Specifically then for CH_3,

$$Q_{sum} = \frac{8}{6}\sqrt{\frac{\pi}{B^2C}\left(\frac{kT}{hc}\right)^3}. \qquad (7)$$

The nuclear spin degeneracy, g_{ns}, associated with each rotational level is included implicitly in the approximate equation (7). At low temperatures this equation is no longer valid and must be replaced by the exact sum, equation (4), modified to include the specific g_{ns} for each level. For a symmetric top molecule (D_{3h}) the value of g_{ns} depends on the quantum number K of the rotational level.

The statistical weights due to nuclear spin for K > 0 are:

$$g_{ns} = \frac{1}{3}(2I+1)(4I^2+4I+3) \text{ for } K = 3n\,;\ I = 1/2 \qquad 8(a)$$

$$g_{ns} = \frac{1}{3}(2I+1)(4I^2+4I) \text{ for } K \neq 3n\,;\ I = 1/2 \qquad 8(b)$$

Since CH_3 is a planar molecule, it consequently belongs to the D_{3h} point group. In this case, with three identical nuclei of spin *I*, the weight factors due to the nuclear spin for the levels with K = 0 are:

$$g_{ns} = \frac{1}{3}(2I+1)(2I+3)(I+1) \quad \text{for J even} \qquad 9(a)$$

$$g_{ns} = \frac{1}{3}(2I+1)(2I-1)I \quad \text{for J odd} \qquad 9(b)$$

Thus, the K = 0 and J odd lines are missing.

We have g_{ns}=4 for K=3n, g_{ns}=2 for K≠3n, n=1,2,3,… and g_{ns}=4 for K=0 and J even. The transitions which take place from the levels with K = 3, 6, 12… have double weight in comparison with the others. As a result, largerer absorption coefficients will be obtained. Since A_2 rotational levels are not allowed then K=0 and J odd levels are missing [4] (the H nuclei follow Fermi statistics, i.e. I = 1/2). Experimental proof is given in the work of Yamada et al. [5] were no transitions were observed for K=0 and J odd in the 2_0^1 band, J even in the 2_1^2 band and J odd in the 2_2^3 band. At low temperature then

$$Q_{SUM} = \sum_{J=0}^{\infty}\sum_{K=0}^{J} g_{ns}(2J+1)\exp(-\left[BJ(J+1)+(C-B)K^2\right]\frac{hc}{kT}) \qquad (10)$$

The rotational partition functions for CH_3 (actually Q_{SUM}) calculated from equations (7) and (10) are indistinguishable over a wide temperature range (< 1 % divergence) but deviate below 100 K (Figure 2). The Q_{SUM} from (10) was calculated considering up to 200 levels, more levels do not change the total sum. As expected equation (7) tends to zero as T → 0 while (10) tends to 4, the nuclear statistical weight of the lowest rotational level.

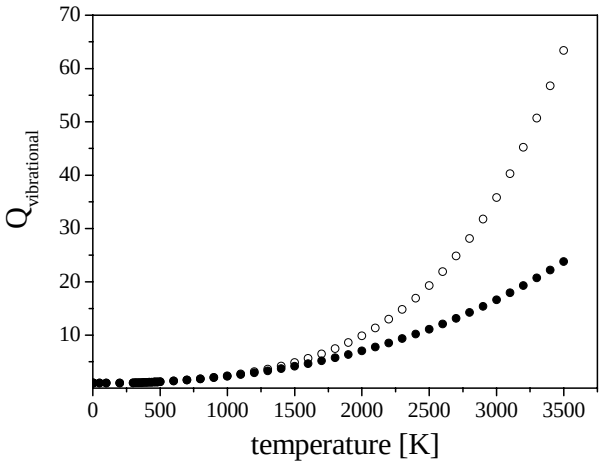

Figure 1. Temperature dependencies of $Q_{vibrational}$, considering vibrational modes: ν_2, ν_4 (•); ν_1, ν_2, ν_3, ν_4 (o).

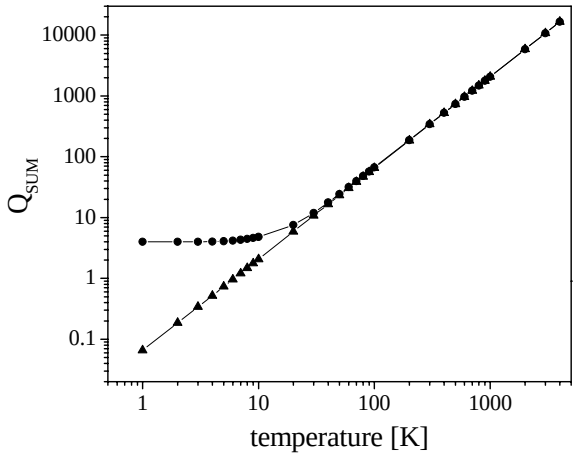

Figure 2. Q_{SUM} as a function of temperature: (▲), approximation given by equation (7); (●), exact summation given by equation (10).

3. Line strengths temperature dependence

The choice of the vibration rotation line to optimise the sensitivity of infrared absorption spectroscopy for detecting the methyl radical is an important issue in practical applications. The temperature dependence of the line strength is given for Q(3,3), Q(6,6) and Q(12,12) in figure 3. These lines were chosen because the levels involved in these transitions have high statistical weights (K = 3, 6, 12) and thus the measured absorption coefficients are large. A useful aspect, which can be obtained from figure 3., is the choice of the temperature regions where one of the line strengths becomes dominant. The plot can be separated into three regions. The first region is for temperatures below 300 K. In this domain Q(3,3) has the highest line strength and therefore this line is recommended for use in this region. In the work of Bezard et al. [2] the methyl radical was observed in the atmosphere of Neptune. The temperature of the upper atmosphere of Neptune is estimated to be about 170 K. In their recorded spectra the measured intensity of Q(3,3) is shown to be higher in comparison with Q(6,6). This agrees with the present calculations. The second temperature region which is considered is between 300 K and 1000 K where Q(6,6) is the strongest line. The third region is higher than

1000 K where the Q(12,12) line strength becomes stronger. This line was used in the experimental work of Lombardi et al. [1] where the temperature in their diamond deposition reactor was above 2000 K.

Detection of methyl in the interstellar medium at temperature of 17 K has recently been reported by Feuchtgruber et al. [6]. Absorption features of the Q-branch and the R(0,0) transition were detected. The temperature was obtained from the absorbance ratio of these features. The R(0,0) transition occurs from the lowest energy level of the methyl radical and is expected to have the largest line strength for very low temperature. Thus, it is of interest to see the behaviour of the line strengths of the transitions which occur between the lower energy levels. Figure 4 shows the temperature dependence of the line strengths of several transitions from the lower energy levels. The line strengths have been calculated using formula (2). It can be seen that all line strengths tend to zero as $T \rightarrow 0$ except for the transition R(0,0) which is the only transition from the lowest level (v = 0, J = 0, K = 0, $E_m = 0$ *J*). Above 10 K, Q(1,1) and R(1,1) are the first lines which can be detected with substantial line strengths. Over 25 K several transitions such as Q(3,3), R(2,0) and so on have greater line strengths and should be detectable at such temperatures.

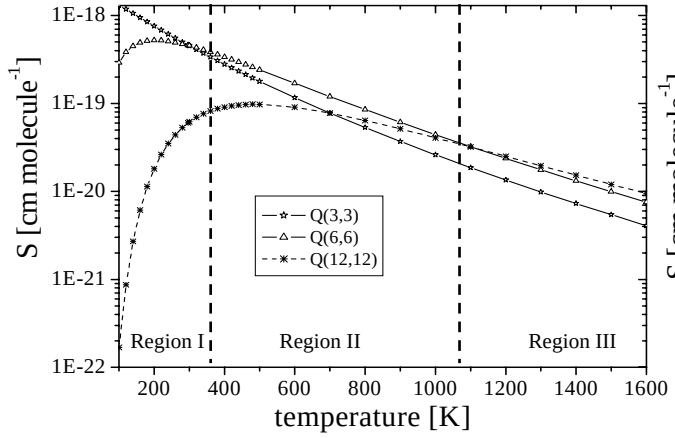

Figure 3. Temperature dependencies of the line strength of the transitions Q(3,3), Q(6,6) and Q(12,12).

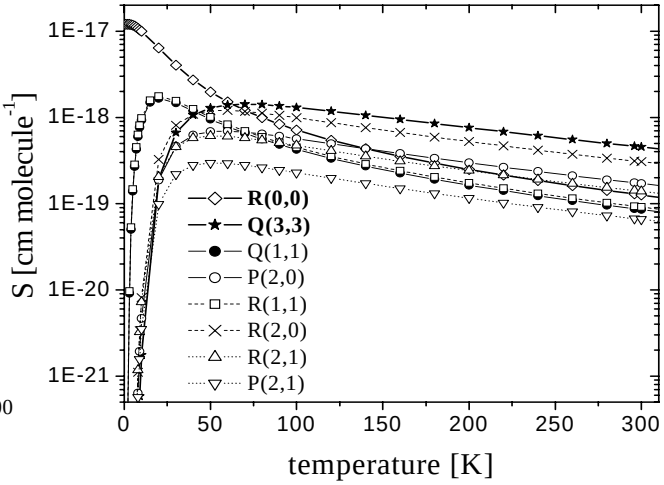

Figure 4. Q(3,3) has the highest line strength over 50 K R(0,0) is the strongest transition below 50 K

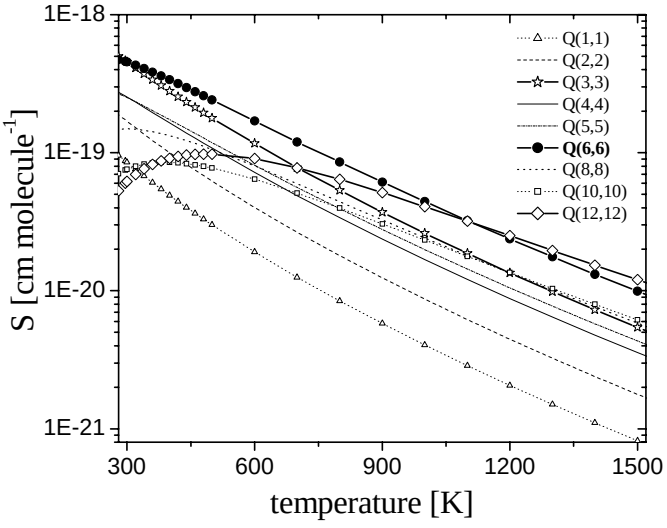

Figure 5. Temperature dependencies of line strengths in the range 300 – 1500 K. Q(6,6) is the most sensitive transition for this temperatures range.

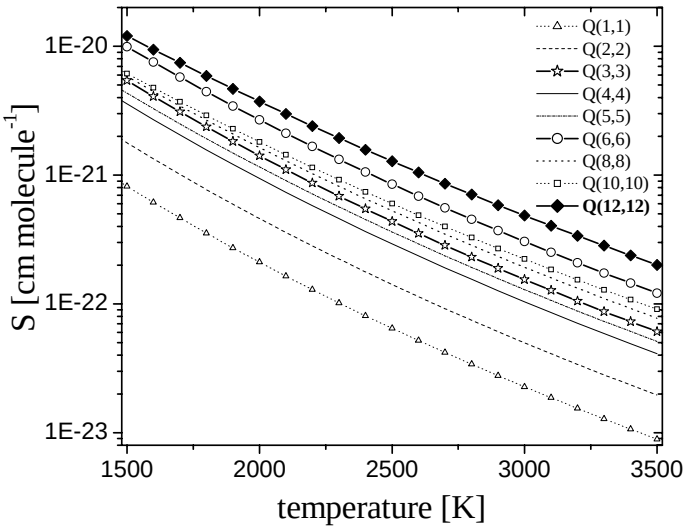

Figure 6. Temperature dependencies of line strengths in the range of 1500 – 3500 K. $Q_{(12,12)}$ (largest S) is recommended for this temperatures range.

The line strength dependence can be used to determine concentrations as well as the gas temperature if at least two absorption coefficients are measured. Based on formula (1), measuring the ratio of two absorption coefficients is the same as the ratio of their line strengths. Taking a measured absorption coefficients ratio, the temperature for which their line strength ratio is the same will determine the rotational temperature. In recent measurements which were done in a hot filament diamond deposition reactor [7] the gas temperature was determined from the ratio of Q(6,6) to Q(12,12). The gas temperature was found to be about 800 K near the deposition substrate, which is essentially the same as the temperature measured by a thermocouple probe. Figures 5 and 6 contain line strength temperature dependencies for some of the most intense transitions of the CH_3 ν_2 fundamental band, for laboratory plasma applications.

Abstract
In this paper, we have studied surface properties of SnO_2 thin films produced by thermal evaporation of Sn films followed by in situ plasma oxidation with additional substrate heating. The oxide layer properties were studied by Atomic Force Microscopy (AFM) and Secondary Ion Mass Spectrometry (SIMS). The plasma oxidation with additional substrate heating is a possible alternative method for preparing stochiometric SnO_2 layers.
Keywords: plasma oxidation, SnO_2 thin films, AFM, SIMS.

1. Introduction

The phenomenon that the adsorption of some gases on the surface of oxide semiconductors can results in a significant change in the electrical resistance of the material was discovered several decades ago [1]. The SnO_2 thin films are widely used for gas sensor application. The gas sensing properties of the films are strongly dependent on the morphological properties, like as surface roughness, grain size, grain geometry, and chemical composition. The material properties depend on the preparation procedure [2], [3], [4] and [5]. In this work we have studied the properties of tin oxide films prepared by plasma oxidation of thin tin films [6].

2. Experimental conditions

The experiments were carried out in the system for plasma-chemical surface modification of thin films, see Fig. 1.

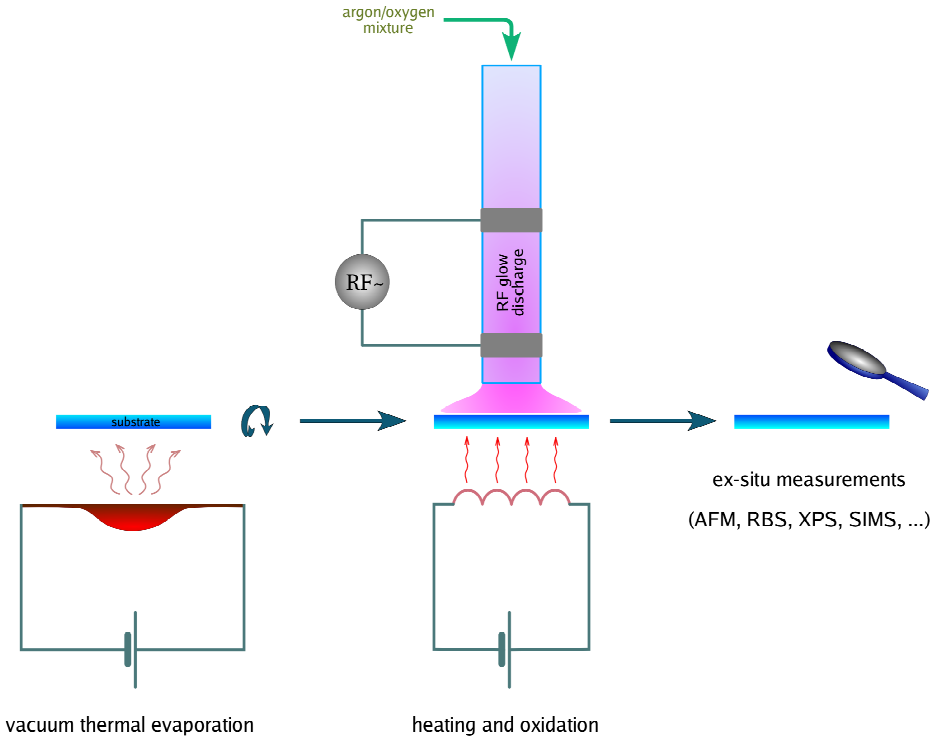

Fig. 1: . The schematic view of the experimental set-up for plasma oxidation of thin metal films

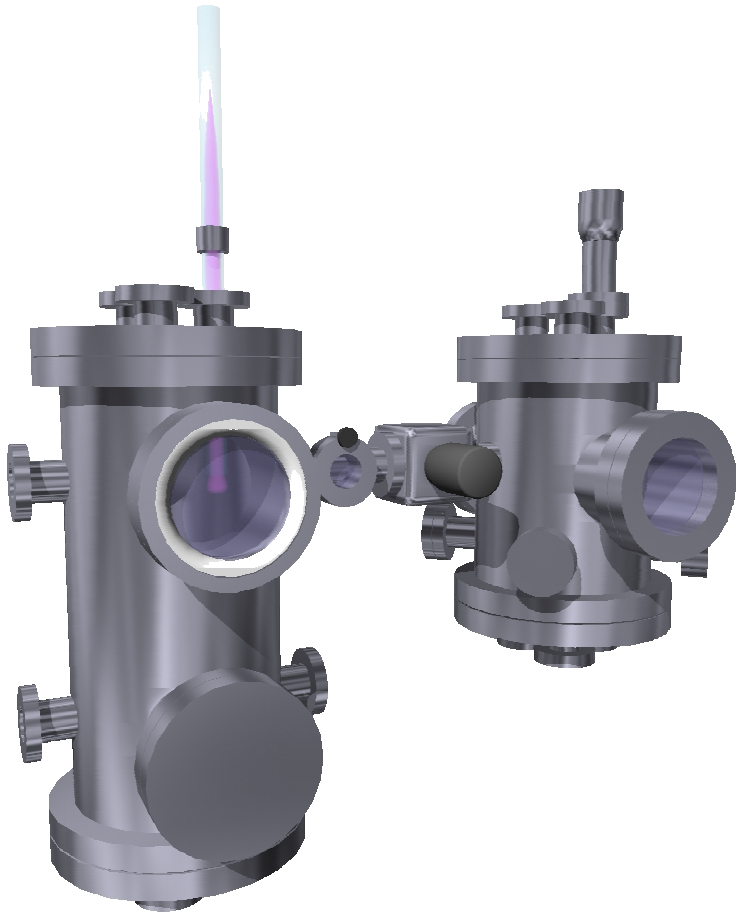

Fig. 2: Experimental system for plasma oxidation with RF discharge

Tin metal films were evaporated in an UHV chamber from Mo boat. The SiO_2 substrates were used. The tin oxide films were then obtained by in situ plasma oxidation in the flowing post-discharge. The RF discharge (13.56 MHz) was applied in oxygen or oxygen/argon mixture (purity: argon 99.9999 %, oxygen 99:995 %). Flow rates were adjusted in order to obtain a total mixture pressure of 50 – 100 Pa which was found to be the optimum pressure for the plasma ignition (RF power 35 W). The substrate was held on the plasma floating potential during plasma oxidation (oxidation time 30 – 120 min). The experimental system has an incorporated heater (the quartz lamp 20 W mounted in a polished stainless steel reflector) which allows an indirect heating of the substrate holder by radiation to temperatures within the range of 100 - 250 °C. The substrate holder temperature was determined directly by an attached resistance temperature detector Pt 100.

3. Characterization techniques

The surface topography and roughness were measured by the Atomic Force Microscopy (AFM - Metris – 2001A – NC, Burleigh Instruments Inc.). A commercially available pyramidal probe of silicon nitride (Si_3N_4) was used. All AFM measurements were carried out in the contact mode at the ambient atmosphere and at room temperature. The scan area varied from 1.2 μm x 1.2 μm to 25 μm x 25 μm.

The depth profiles were measured by the Secondary Ion Mass Spectrometry (ATOMIKA 3000 SIMS system). The SIMS analysis was made using a Cs^+ ion gun, 3.3 keV. The primary beam current was 80 nA and the scan area was 0.5 mm x 0.5 mm.

4. Experimental results

The morphology of the tin films prepared by thermal evaporation on SiO_2 substrates, is a near flat-grain structure (roughness R_q ~ 12 nm). The typical grain size of the film deposited by thermal evaporation was about 0.5 μm. The thickness of Sn films was derived from the AFM images of surfaces with a mechanical scratch and was changed from 10 nm to 80 nm.

The morphology of the tin oxide surface after plasma oxidation is characterized by a sharper grain structure with a higher roughness [6].

Our previous measurements [7] indicate that the ratio of oxygen concentration to the tin concentration varies from 1.5 to 1.8, thus the thin oxide films (thicker than 20 nm) prepared by plasma oxidation contain a mixture of SnO, and SnO_2 oxides. Therefore we prepared a set of samples oxidized at different substrate temperatures (100 °C, 150 °C, 200 °C and 250 °C). The AFM measurements indicate that the increase of the substrate temperature during plasma oxidation causes a higher surface roughness (R_q ~ 25 nm), see Fig. 3. The electrical properties of SnO_2 thin films depend on the distribution and nature of the grain boundaries. The grain dimension does not change appreciably with recpect to substrate temperature.

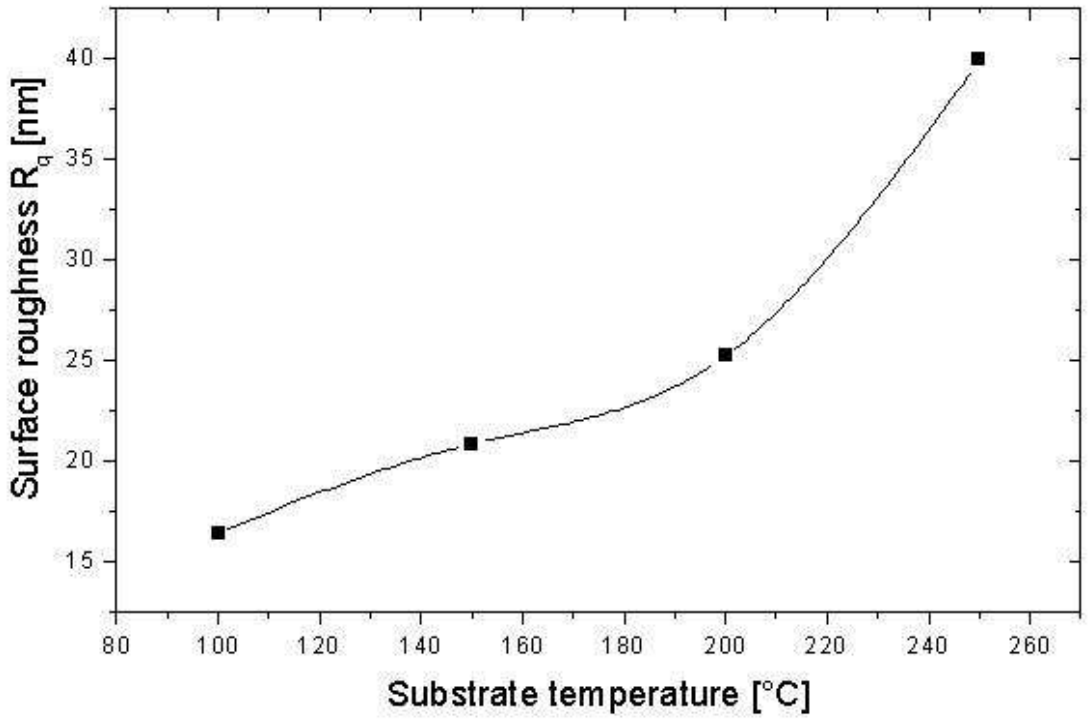

Fig. 3: The dependence of root mean square roughness R_q on substrate temperature

The SIMS measurements indicate that the stoichiometry is better at higher substrate temperatures. The oxide stoichiometry seems not to be influenced by film thickness up to 180 nm at higher substrate temperature (about 250°C), see Fig. 6.

The plasma oxidation without an additional substrate heating produces only thin oxide layers, no matter how long the oxidation time is.

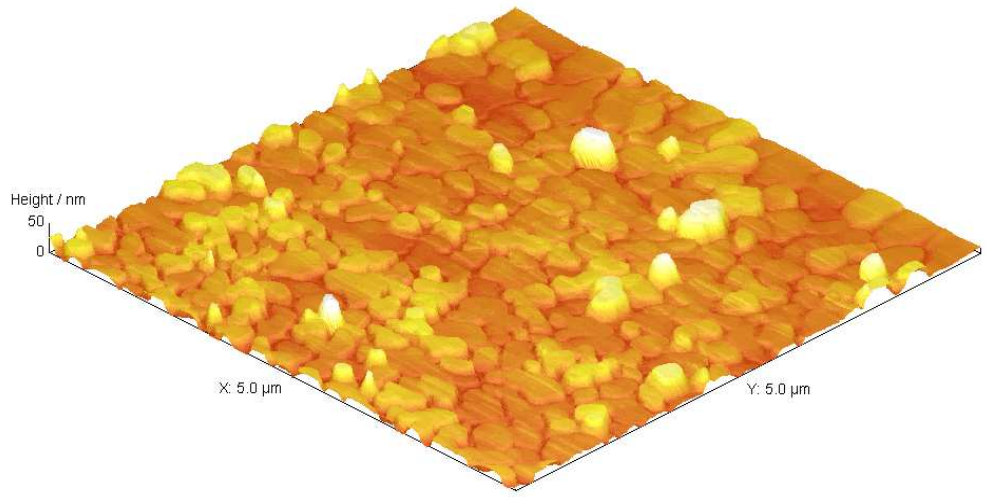

Fig. 4. AFM 3D image of oxidized tin layer prepared without additional substrate heating - mixture of SnO_2, SnO and Sn when thicker than approx. 20nm.

.

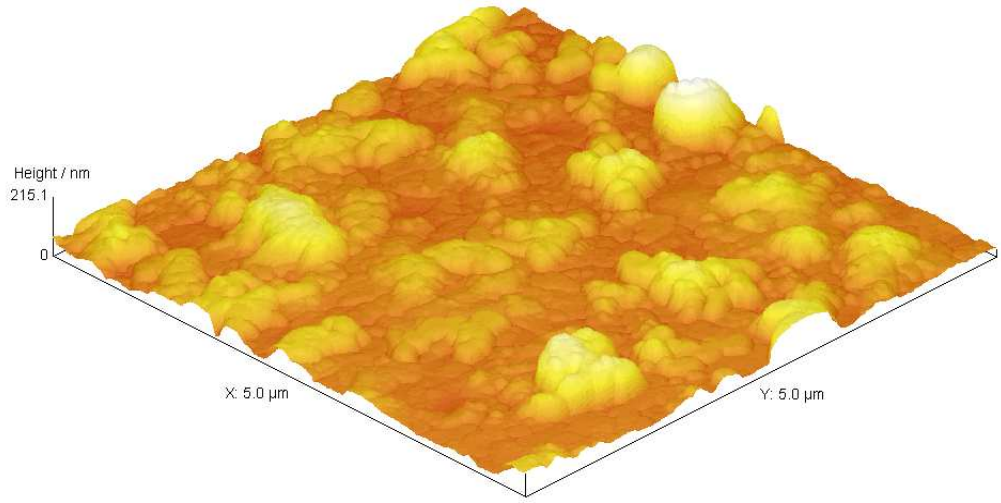

Fig. 5: AFM 3D image of oxidized tin layer prepared with additional substrate heating (~250 ^{o}C) – better stoichiometry in case of thick layers, higher surface roughness.

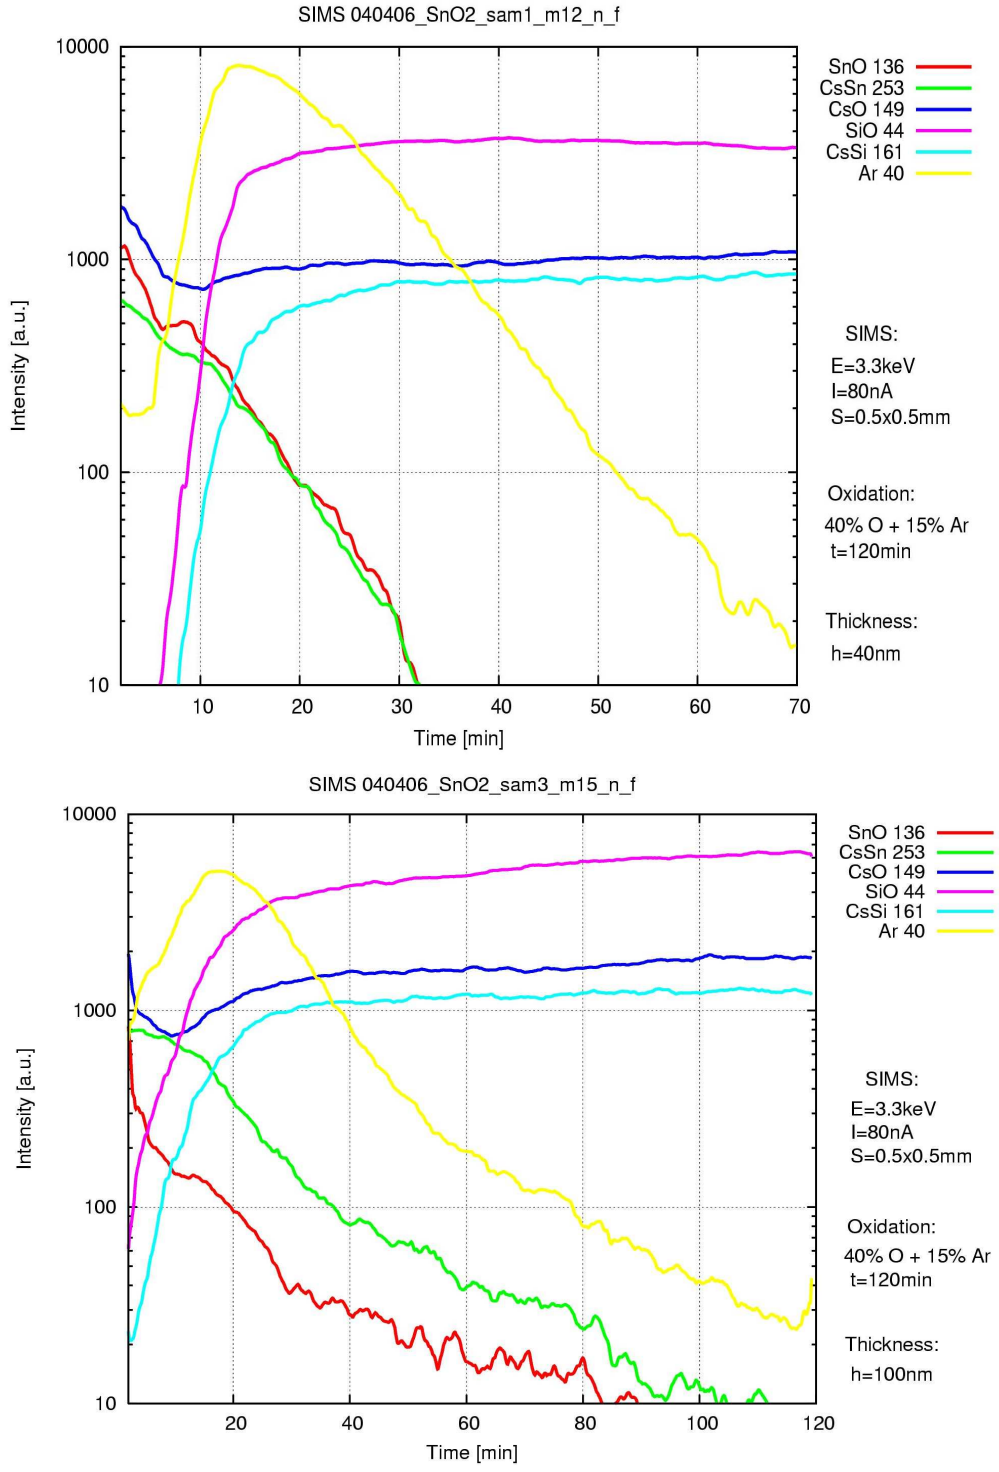

Fig. 6: The depth profiles obtained from SIMS measurements of two samples prepared by plasma oxidation of thin tin films (thickness 40 nm and 100 nm) at higher substrate temperature during oxidation (about 250°C). The cesium ion source has been used.

5. Conclusion

It has been proven that the method of plasma oxidation is a applicable alternative method for preparing thin SnO_2 films. We can prepare pure samples with surface topography different from samples prepared by other techniques. Our experimental results indicate dependence of SnO_2 surface morphology on substrate properties, evaporation conditions and parameters of plasma oxidation. Plasma oxidation without additional substrate heating produce only thin stochiometric oxide layers. On the other hand the plasma oxidation with additional substrate heating seems to be able to produce oxide layers whose stoichiometry seems not to be influenced by film thickness up to 180 nm at higher substrate temperature.

Abstract
Transient response of the induction coil loading impedance and the RF inverter power supply in the initial startup of RF induction thermal plasmas and the power flow in the steady state condition were studied experimentally. This dynamic transition of the discharge can be seen both from the fast camera observation and the RF coupling between induction coil and generated plasma. The plasma coupling characteristics of the induction coil was analyzed using a simple equivalent circuit model.

1. Introduction

Radio frequency induction thermal plasmas(RF ITPs) around atmospheric pressure range have been widely used for plasma metallugy, material processing, hazardous waste treatment and so on[1, 2]. In these engineering applications efficient generation and controllability of functional thermal plasmas are very important engineering issues. So far, studies on fundamental properties of RF ITPs have not been done deeply in contrast to intensive studies on their engineering applications. Efficient production of atmospheric RF ITPs has already done by using semiconductor inverter for RF generator[3, 4]. RF inverters using MOSFETs and static induction transistors(SIT) have a very high DC-RF power conversion efficiency of about 0.9 at several hundreds kHz and 0.8~0.9 below 2 MHz, respectively. An easy power control of RF inverters has been also demonstrated in pulse amplitude modulation experiments[4]

In the present study the electrostatic and electromagnetic coupling between induction coil and generated plasma is analyzed by simple equivalent electric circuits of the induction coil-plasma system. A dynamic mode change from electrostatic discharges to electromagnetic discharges can be seen clearly in the coil loading impedance. In addition to the circuit analysis calorimetric measurements of the RF ITP system are carried out to study the power flow from the RF generator to the plasma, and the heat and particle loss mechanisms of generated plasmas.

2. Experimental Setup

The SIT RF circuit which comprises of an RF inverter, an impedance matching transformer, a tuning capacitor bank and an induction coil is shown in Figs. 1(a) and (b). The loading impedance of the induction coil including the impedance transformer and tuning capacitors is calculated from the inverter output voltage v_1 and current i_1 shown in Fig. 1(b). The DC-RF conversion efficiency η is calculated by

$$\eta = \frac{1}{T}\int_0^T v_1(t) i_1(t) dt \,/\, P_{DC}, \qquad (1)$$

The power losses from the plasma are measured by calorimetry in the plasma torch and the reaction chamber. Heat loads to the plasma torch and the reaction chamber are separately measured by temperature and flow meters in each water cooling section.

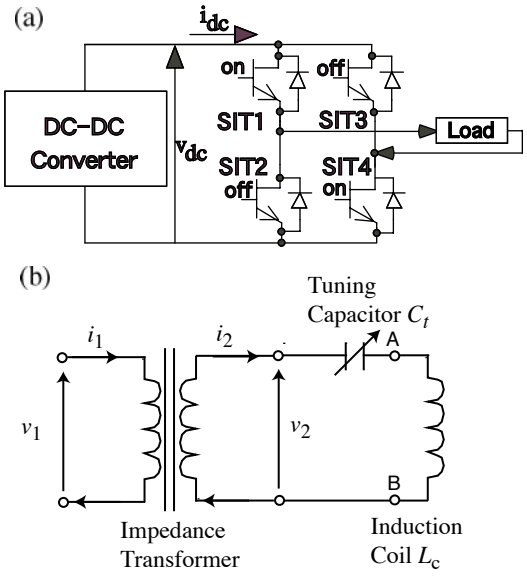

Fig. 1 SIT inverter(a) and induction coil circuit(b)

3. Initial Breakdown and Growth of Argon ITP

3.1 Discharge Mode and Coil Loading

Fast camera pictures of the initial startup of ITP discharges are shown in Fig. 2, where streamer-like electrostatic discharges are generated near the coil conductor inside a quartz glass tube and a ring-shape electromagnetic discharges start to grow at the inner surface of the glass tube. This mode transition from the electrostatic to electromagnetic discharges can be seen clearly in the coil loading impedance shown in Fig. 3. For a few milliseconds after breakdown the discharge is capacitive and the resultant LCR series impedance becomes slightly inductive, which is shown in Fig. 3(d). The discharge current is limited by the dielectric quartz tube, which leads a weak power coupling between the induction coil and the generated plasma. After enough growth of the streamer-like electrostatic discharges the discharge mode transition occurs and the loading resistance rises abruptly, which means the plasma absorbed power increases. The growth of the inductive discharge also changes the LCR series impedance capacitive. The positive feedback mechanism of the induction coil-plasma coupling brings these dynamic plasma response. In the present experiments the inverter output voltage is saturated just after the mode transition since the DC voltage fed to the inverter is limited to 400 V in the present SIT inverter system , and the inverter output power is strongly reduced after voltage saturation. This power reduction comes from the large detuning of the LCR series circuit and the increase of the inverter loss by capacitive inverter load. Preliminary frequency tracking experiments have shown to improve the power coupling efficiency successfully.

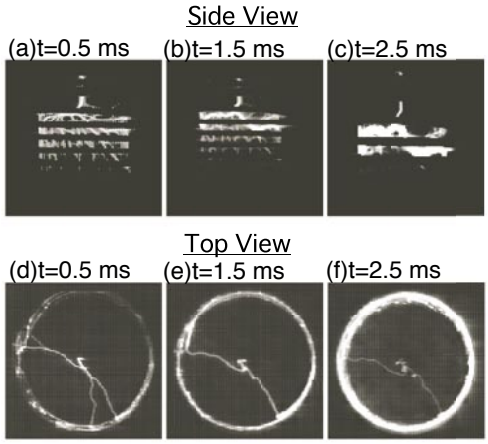

Fig. 2 Fast camera picture of the initial startup of argon ITP. Discharge tube diameter is 70 mm and argon gas pressure is 30 kPa.

3.2 Equivalent Circuit Analysis of Induction Coil Loading Impedance

The dynamic behavior of the induction coil loading impedance is analyzed using simple equivalent circuits of the induction coil both in the electrostatic and electromagnetic discharges discussed previously. Equivalent circuits of the induction coil are shown in Fig. 4. In the electrostatic discharge phase the discharge current is driven by the electrostatic field between coil conductor through the dielectric glass discharge tube. This barrier type electrostatic discharge gives a parallel capacitance in the coil equivalent circuit shown in Fig. 4(a). In the electrostatic discharge phase the primary coil impedance given by $Z_1=V_1/I_1$ in Fig. 1(b) becomes slightly inductive between the ignition and E-H discharge transition as shown in Fig. 3. The coil reactance in Fig. 4(a) is given by

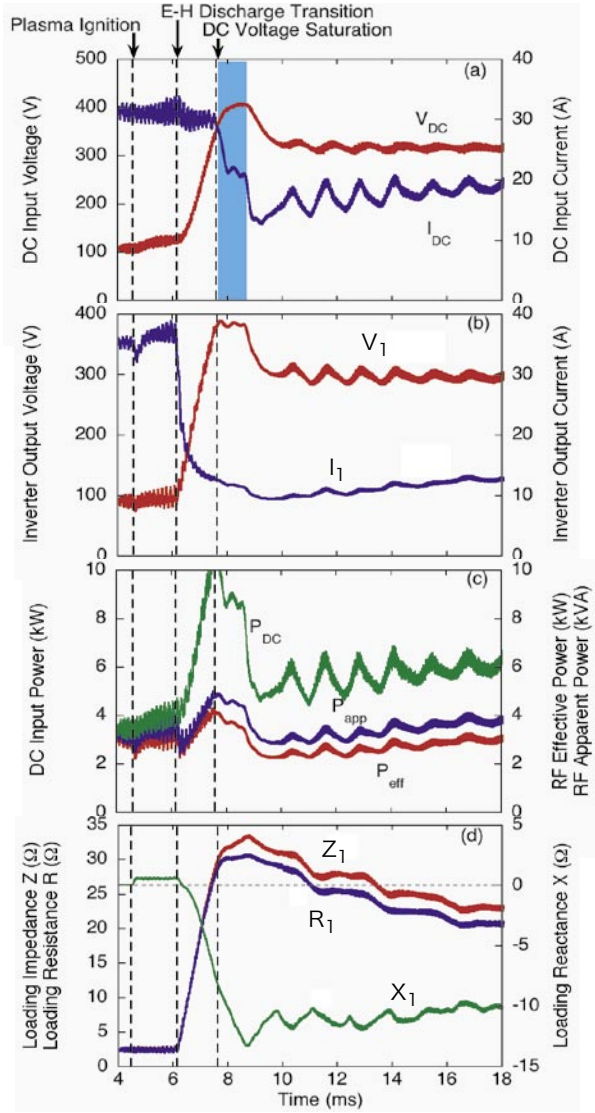

Fig. 3 Inverter response and coil loading impedance in the initial startup phase of argon ITP. (a)Inverter DC voltage and current, (b)Inverter RF voltage and current, (c)Inverter DC input power, apparent RF power and effective RF power and (d)coil loading impedance. The discharge is different from that of Fig. 2.

$$\mathrm{Im}[Z_L] = \frac{1-\omega^2 L_c C_p^{es} + (\omega C_p^{es} R_p^{es})^2}{(1-\omega^2 L_c C_p^{es})^2 + (\omega C_p^{es} R_p^{es})^2}\omega L_c \ , \qquad (2)$$

When $\omega^2 L_c C_p^{es} < 1$, the coil reactance becomes more inductive than the vacuum reactance ωL_c. Rough estimation gives R_p^{es}=3~8 kΩ and C_p^{es}=20~40 pF in the typical argon discharge shown in Fig. 3.

In the electromagnetic discharge a ring shape discharge plasma works as a ring conductor, which has a mutual inductance M. Then the coil impedance is given by

$$Z_L = (R_C + \frac{\omega^2 M^2 R_p^{em}}{(R_p^{em})^2 + \omega^2 (L_p^{em})^2}) + j\omega(L_C - \frac{\omega^2 M^2 L_p^{em}}{(R_p^{em})^2 + \omega^2 (L_p^{em})^2}) \ . \qquad (3)$$

The effective coil inductance decreases and the primary coil impedance Z_1 becomes capacitive as shown in Fig. 3. The effective coil inductance decreases by

$$\frac{\omega^2 M^2 L_p^{em}}{(R_p^{em})^2 + \omega^2 (L_p^{em})^2}, \qquad (4)$$

and the Z_1 becomes more capacitive as shown in Fig. 4.

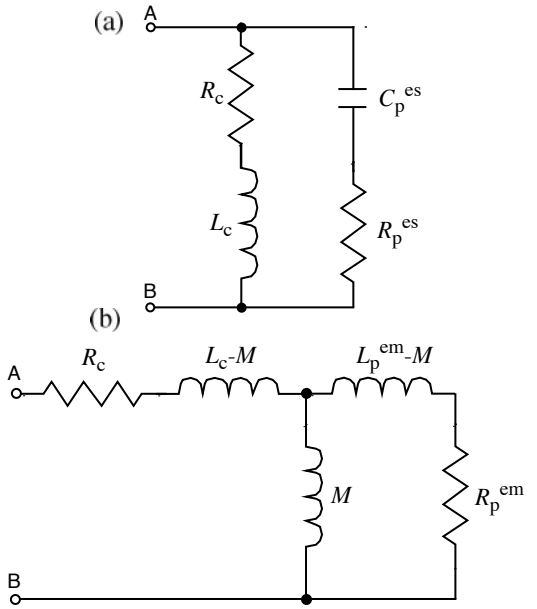

Fig. 4 Equivalent circuits of the induction coil in the electrostatic (a) and electromagnetic discharges(b).

4. Heat Load Measurement and Power Flow Analysis

Heat load to various components of the RF plasma torch is measured by calorimetric method in 450 kHz ITP powered by MOSFET inverter[5]. Preliminary heat load measurements are summarized in Table 1. The inverter output power P_1 and the effective power fed to the induction coil were calculated from measured RF voltage and current. Heat Loads to the torch separately measured are also summarized in Table 2. The coil loading resistance is an effective resistance which indicates the electromagnetic coupling between the induction coil and the generated thermal plasma. In the present experiments shown in Table 1 ~85 % of the fed power to the induction coil is effectively coupled to

Table 1 RF power, induction coil impedance and measured total heat load in 450 kHz RF torch.

generate the thermal plasmas. The total power coupling efficiency of the present MOSFET ITP system, which is shown in Fig. 5 is about 60 %. Conversion loss in Fig. 5 means RF conversion efficiency of the MOSFET inverter. The total RF circuit loss is about 30~35 % in the present system. The coil loading resistance is very sensitive to the gas pressure. In the pressure range where the argon thermal plasmas are generated, the coil loading resistance decreases significantly with increasing the gas pressure as shown in Fig. 6.

The preliminary calorimetric measurements shown in Table 2 give that roughly 50 % of the absorbed RF power is carried to the downstream reaction chamber through the convective flow of the argon gas and 25 % of the absorbed power goes to the quartz tube through the convective, conductive and radiative heat flow in the pure argon ITP. When the gas flow rate is increases to improve the heat transfer between hot thermal plasma and cold gas, however, the fraction of the power flow from the hot thermal plasma does not change significantly. Further experimental studies are necessary to clarify the power flow mechanism in the RF ITPs.

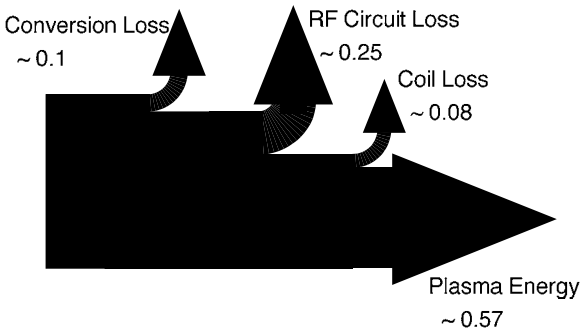

Fig. 5 RF power flow of the 450 kHz MOSFET ITP system. AC input power is about 15 kW. Argon plasma, P=20 ~ 230 Torr.

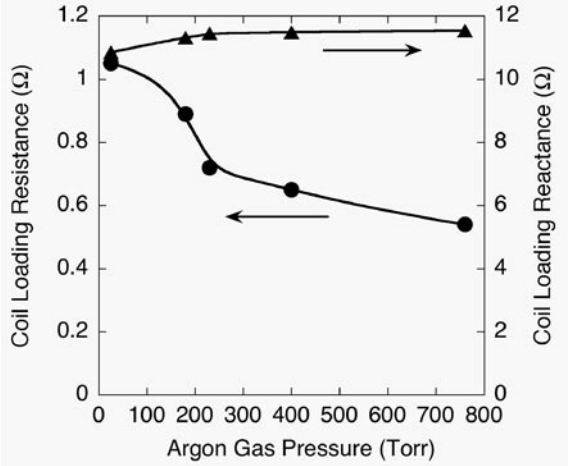

Fig. 6 Induction coil loading resistance and reactance as a function of the gas pressure. AC input power is about 15 kW.

5. Summary

Dynamic startup characteristics of RF ITP were studied by fast camera observations and the equivalent circuit analysis of the induction coil. The initial mode transition from the electrostatic to electromagnetic discharges can be clearly seen both in the visible light observation and the coil loading impedance. The equivalent circuit analysis of the induction coil can clearly explain the transient impedance change of the induction coil during electrostatic to electromagnetic discharge mode change. Initial results of calorimetric measurements of the heat load to the torch and reaction chamber show that the coupling efficiency of the MOSFET ITP system calculated by the electric measurements of the RF voltage and current agrees well with that estimated by plasma heat load measurements.

Calorimetric measurements is done to study the thermal plasma energy transfer to the torch wall through the conductive, convective and radiative heat transfer. About 25~30 % of the thermal energy is delivered to the quartz tube near the plasma production area and about 55~60 % is carried to the down stream reaction chamber mainly through the convective heat transfer. The experimental result that the portion of the delivered heat load of the argon RF ITP does not depend strongly on the gas flow rate is still an open question. Further experiments will be done in near future to study the heat transfer mechanism of the RF thermal plasmas and to improve their performance.

Abstract

Thin films preparation which an organ-metal solution was used for has very long history, but there is a little use to that new device materials. We used the solution for the catalyst, and carried out the preparation of carbon nano-tubes or (CNTs). In this paper, we investigated intensively about PLA/CVD hybrid system for CNTs growth. Those were deposited in the temperature range from R.T. to 1100 °C. The deposited CNTs were characterized by a 3D-FE-SEM and a Raman spectrophotometer.

Keywords

carbon nanotubes, pulsed laser ablation, organ-metal solution

1. Introduction

Ever since the discovery of carbon nanotubes (CNTs), a lot of efforts have been given to utilizing their unique electric and structural properties [1]. That is to say, CNTs have been focus of considerable attention because of many possible applications in nanostructure, super strong materials, semiconductor, electron emitting device and hydrogen storage [2]. Several process methods such as arc discharge, chemical vapor deposition (CVD) and pulsed laser ablation (PLA) have been used to produce CNTs. However, as for which methods as well, it isn't easy to apply it the catalyst metal which is necessary for the CNTs growth. In this study, the way that we applied a catalysis organ-metal solution to a substrate and then it was burned out was used [3]. This method is very unique, especially it has almost never used as the catalyst for the nanotubes. Nano size dots of catalytic metal such as platinum (Pt), Nickel (Ni), mixture of Pt/Gold (Au) and mixture of Ni/Au, on Silicon or quartz glass substrate preparation technique by burning of catalysis organ-metal solution had already been developed. Also two apparatus were used for the growth of CNT by this study. One was a traditional thermal CVD system, the other hand was a PLA and CVD hybrid system. When a catalysis organ-metal solution was used, the thermal CVD could obtain the CNTs very easily but high process temperature (less than 1000 °C.) was necessary. On the other hand, when the PLA/CVD hybrid system was used, we obtained CNTs in low temperature relatively.

In this paper, we investigated intensively about PLA/CVD hybrid system for CNTs growth; those were the wavelength of laser (Nd-YAG: λ = 1064nm and 532 nm, pulse duration of 3.5 ns and ArF

excimer laser: λ = 193 nm, pulse duration of 20 ns), the influence of laser fluence and substrate temperature on crystallization and characteristics of the CNTs. The CNTs were deposited in the temperature range from room temperature (R.T.) to 1100 ℃ and laser fluences ranging from 2 to 30 J/cm^2. The deposited CNTs were characterized by an electron probe surface roughness analyzer (3D-SEM: Elionix model ERA 8900FE and ERA 8800) and a field-emission scanning secondary electron microscope (FE-SEM: JEOL model JSM-6301F) and a Raman spectrophotometer (JASCO model NRS-3300).

2. Experiments

Fig. 1 shows a schematic diagram of the PLA/CVD hybrid system used in this study. After the chamber (ϕ = 300 mm) was exhausted by a turbo-molecular pump to a base pressure of 1.3x10^{-4} Pa. In the chamber a sintered pure graphite target (purity 99.99%) of 30 mm in diameter and 5 mm thickness was mounted on the rocking holder. Three kinds of pulsed laser beam was introduced into the chamber through lenses and a quartz window. The laser beam impinges on the target at an incident angle of 0° or 45°. In order to prepare CNTs, n-type Si(100) wafers or quartz glass substrates, which an organ-metal solution was spread, were positioned 30 mm apart from the graphite target. The substrates were heated with a block heater or an electric furnace or an IR lamp, which was mounted on the exterior of the vacuum chamber, from room temperature to 1100 °C. Substrate temperature (Ts) was measured by using a thermocouple. The gas pressure was varied from the base pressure to 1 Torr with 100sccm flow rate by feeding pure methane (CH_4) gas (in case of Nd-YAG laser use) or 500 Torr with 750 sccm flow rate by feeding pure Ar gas (in case of ArF Excimer laser use) into the reaction chamber.

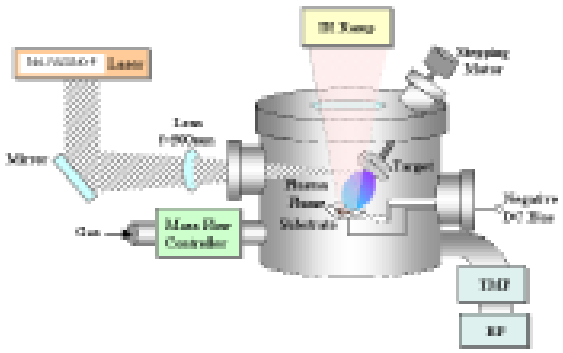

Fig. 1 Schematic diagram of experimental apparatus.

3. Results and discussions

The surface morphology of Pt catalytic metal dots on the Si substrate which should be used for the CNTs growth was examined by 3D-SEM, as shown in Fig. 2(a) and (b). When the burning temperature was 300 °C, it was a very smooth morphology with a silver mirror condition. When temperature rises up to 900 °C, Pt makes an dot type island-shape structure. Moreover dot can be classified in three kinds of diameter, such as about 30 nm, 100nm and 200 nm. Now we consider that these dots have a different

surface direction from the observation of XRD measurement (it is not listed), such as (220), (200) and (111) respectively.

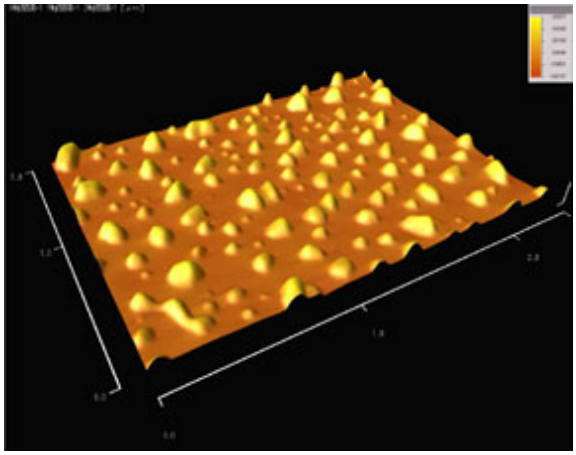

Fig.2 (b)

Fig2(a) burning temperature 300°C at atmospheric ambient condition. Roughness: 0.5 nm.
Fig2(b) burning temperature 900°C at atmospheric ambient condition. height of dots: about 30nm.
Fig.2 3D-SEM images of Surface morphology of Pt nano dot on Si substrate (2.2 μm*1.8μm)

Fig. 3(a) and (b) show FE-SEM images of the CNTs prepared by simple CVD using Pt and Ni catalyst, substrate at 1000 °C, CH_4 ambient gas condition. CNTs growth can be confirmed both catalyst. Tube diameters were 60 nm and 80 nm respectively. Although CNTs grows very long and flexibly with a Ni catalyst, it seems to be hard to grow with a Pt catalyst. This is based on the difference in effect on the catalyst, but in case of Pt, improvement of flexible growth should be possible for that by control of reaction temperature and ambient gas kinds and flow rates.

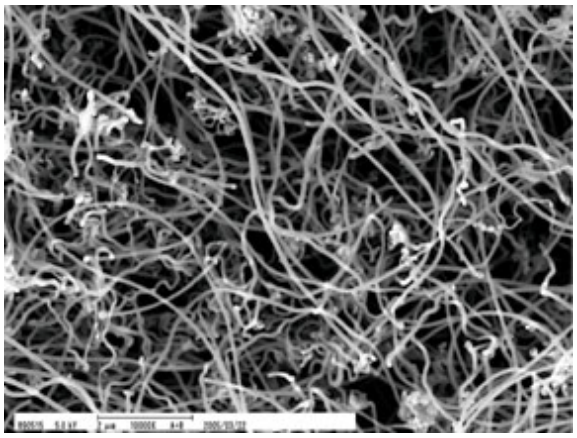

Fig. 3 (a) CNTs on Ni catalyst

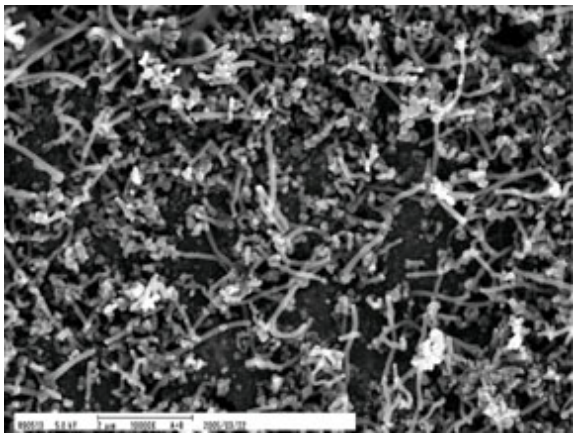

Fig. 3(b) CNTs on Pt catalyst

Fig.3 FE-SEM images of CNTs
(CH_4 ambient gas condition with Ts = 1000 °C)

Fig. 4 shows FE-SEM image of the CNTs prepared at laser fluence of 5 J/cm^2 (λ = 1064 nm), Ts = 650 °C, and 1 Torr CH_4 ambient condition by PLA/CVD hybrid system using Ni catalyst substrate. Though very few CNTs were confirmed, an aspect ratio of tube is large and doesn't curve. Tube

diameter was about 120 nm. However the growth of the CNTs could not be confirmed with this PLA/PLD hybrid system with Pt catalyst.

Accordingly we carried out completely another condition of PLA/CVD hybrid system. Extremely high Ar gas pressure of 500 Torr was given on PLA target ablation. The condition that CNTs were composed of the gaseous phase was considered. Because Ar pressure is very high, plasma plume hardly to spread out. On this condition, ejected carbon atoms and particles were slowed down suddenly. Fig.5 shows EF-SEM images of CNTs on Pt catalyst (pre-burning substrate temperature of 900 °C). (a) and (b) are same images but resolution is different. Average tube diameter was 80 nm.

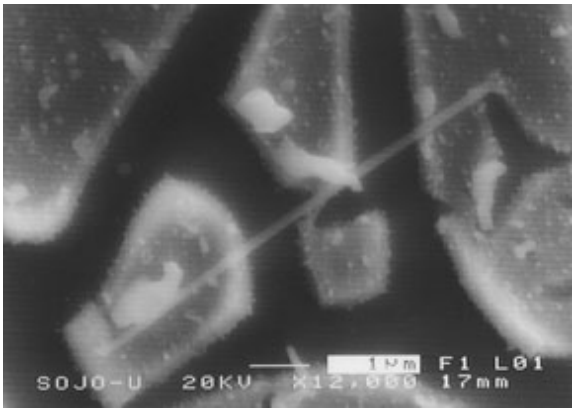

Fig. 4 FE-SEM image of CNTs by PLA/CVD hybrid system
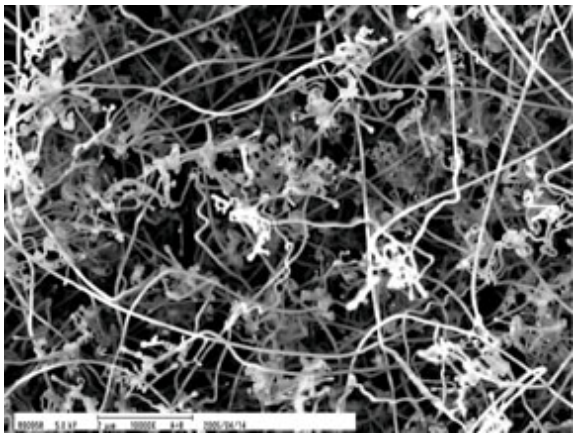
CNTs prepared by PLA/CVD with Nd-YAG laser (λ = 1064 nm) on organ-metal-Ni solution.



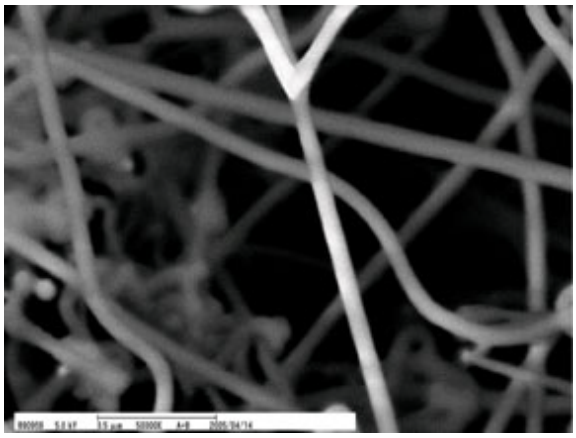


Fig. 5 (a) CNTs on Pt catalyst Fig. 5(b) CNTs on Pt catalyst
Fig. 5 FE-SEM image of CNTs by high Ar pressure PLA/CVD hybrid system
CNTs prepared by PLA/CVD with ArF excimer laser (λ = 193 nm)

Also we carried out the experiment of the selective growth of the CNTs. Because it doesn't have a effect of catalyst with Au, the substrate that the solution on which mixed a little (about 2 weight %) Ni or Pt to Au organ-metal solution was used for was burned out at 900 °C on 100 Torr Ar ambient condition.

Fig.6 shows selective growth of the CNTs by using high Ar pressure PLA/CVD hybrid system on Ni/Au and Pt/Au substrate. CNTs grows around the Ni and Pi island-shape particles. Therefore selective CNTs growth was confirmed in both Ni/Au and Pt/Au substrate. In case of high pressure PLA/CVD Hybrid system, there is no difference

with the appearance of the CNTs between Ni and Pt catalyst. Both average tube diameter was 60 nm.

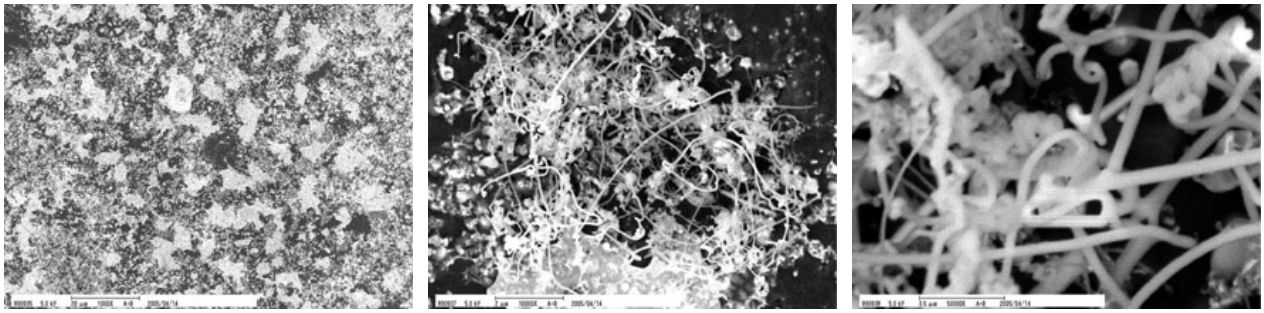

Fig.6(a)CNTs on Ni/Au catalyst

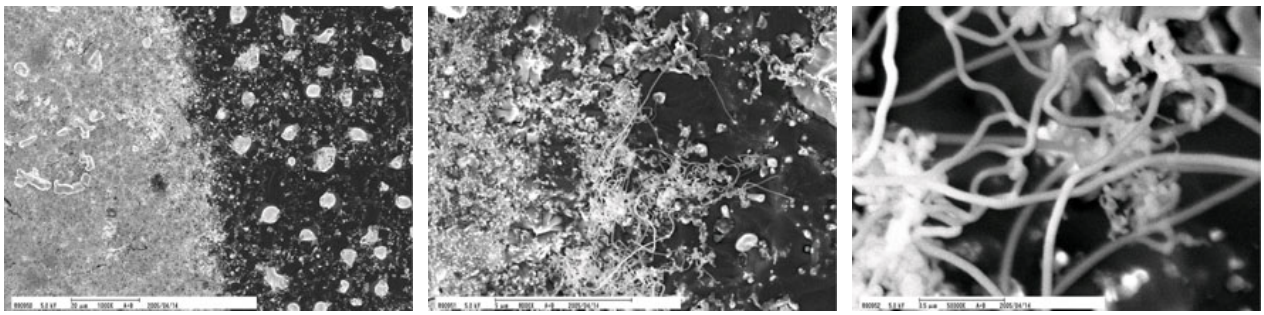

Fig.6(b)CNTs on Pt/Au catalyst

Fig. 6 FE-SEM image of CNTs by high Ar pressure PLA/CVD hybrid system
CNTs prepared by PLA/CVD with ArF excimer laser (λ = 193 nm)

We also measured G band and D band peak ratio of all CNTs by using Raman spectrophotometer. A G/D ratio was almost close to 1, it confirmed that the element which was close to DLC existed in the substrate surface. Therefore it has a possibility to be the mixture of the CNTs and carbon nano fiber.

4. Conclusions

In this study, CNTs were prepared using very new technique which makes an organ-metal solution departure catalytic material. This technique is very simple therefore, it has a possibility of large-scale composition with lower cost. Also it has the possibility to have process temperature reduced by using PLA/CVD hybrid system. Moreover we carried out high pressure PLA/CVD hybrid system. This system had high yield rate of CNTs growth. Also we confirmed selective growth of CNTs.

Abstract
Experimental investigations have been conducted to study the simultaneous removal of NO_x and diesel soot particulate matter (DSPM) from the exhaust of a diesel engine power generator using a electrostatic precipitator (ESP) and magneto-trench barrier discharge reactor (MT-BDR) placed upstream of Na-Y catalyst. The ESP prevented fouling of MTBDR by removing over 99.9% of DSPM. However, results showed that presence of DSPM in MTBD reactor may assist in NO_2 and NO_x removals which were 35-70% and 6-45%, respectively.
Keywords Plasma Catalyst, NO_x Removal, Diesel Exhaust, Power Generator, Particulate Removal

1. Introduction

Increased use of diesel engines (diesel cars, diesel generators, tracks, and marine ships) motivated the development of various technologies for lowering gaseous pollutant emissions especially for NO_x emissions [1]. The major pollutants in diesel exhaust emissions are a direct result of the diesel combustion process itself. The most toxic gases present in diesel exhaust include carbon monoxide (CO), sulfur dioxide (SO_2) and nitrogen oxides (NO_X). The CO concentration is a function of the air excess ratio, combustion temperature and air/fuel mixture while SO_2 is a function of fuel oil sulphur content. Hydrocarbons (HC) are very engine dependant but a function of the amount of fuel and lubrication oil left unburned during combustion due to insufficient temperature or air supply. Diesel soot particulate matter (DSPM) originates from unburned fuel, ash content in fuel and lub-oil. While the type of fuel used and combustion strategy play a major part in determining the composition of the emissions, other important factor that determines the amount of NO_x is engine speed and load.

There are a number of methods for reducing the NO_x concentrations in exhaust gases that can be divided into three basic categories namely: pre-treatment, internal measures, and after-treatment. Pre-treatment methods are focusing on lowering the combustion temperature by denitration of fuel, use of alternative fuels or adding water to the fuel. Internal measures include changes to the combustion process, such as modification of combustion, the scavenge/charging air or water injection or exhaust gas recirculation. After-treatment methods are applied directly to the combustion gases and can be categorized as re-burning, selective catalytic reductions and plasma assisted reduction methods. In the later case, of interest here, oxidation reaction dominate during the plasma discharges so that the plasma alone is ineffective in reducing NO_x. A combined strategy with a plasma and a catalysis system can enhance the catalyst NO_x removal efficiency by oxidizing NO to NO_2 that are more easily reduced by downstream catalyst. Recently, Szanyi et al [2] have showed that Na- and Ba-Y based catalyst in conjunction with a non-thermal plasma results in a high level of NO_x reduction at relatively low temperatures (~200°C). In this work, NO_x and dust particle removals by combined electrostatic precipitator and trench type barrier dischartge-Na-Y catalyst system were investigated for real diesel engine power generator exhaust gases.

2. Experimental set-up

The experimental test facility, as shown in Fig. 1, consists of diesel engine, electrostatic precipitator (ESP) for DSPM treatment, plasma-catalyst reactor system for gas treatment, flow control devices, and gas sampling system. The diesel exhaust, generated by a 5W single-cylinder diesel generator, was carried to the hybrid

reactors, consisting of magneto-trench barrier discharge [3], schematically shown in Fig. 2, and Na-Y catalyst, approx. 1m downstream of the generator via Ø35 mm tube. The discharge characteristics of MT-BDR and ESP shown in Figs.3 and 4 were conducted for the engine load from 0 to 2.4kW, exhaust gas flow rates from 2 to 5kg/h and applied voltages from 0 to 22kV at fixed magnetic field of 0.5kG. Removal performance of pollutant gases and DSPM by ESP-plasma-catalyst reactors has been evaluated for ESP dc applied voltage of -20kV, reactors flow rate of 2kg/h and trench reactor ac operating voltages with peak to peak values from 5 to 15 kV.

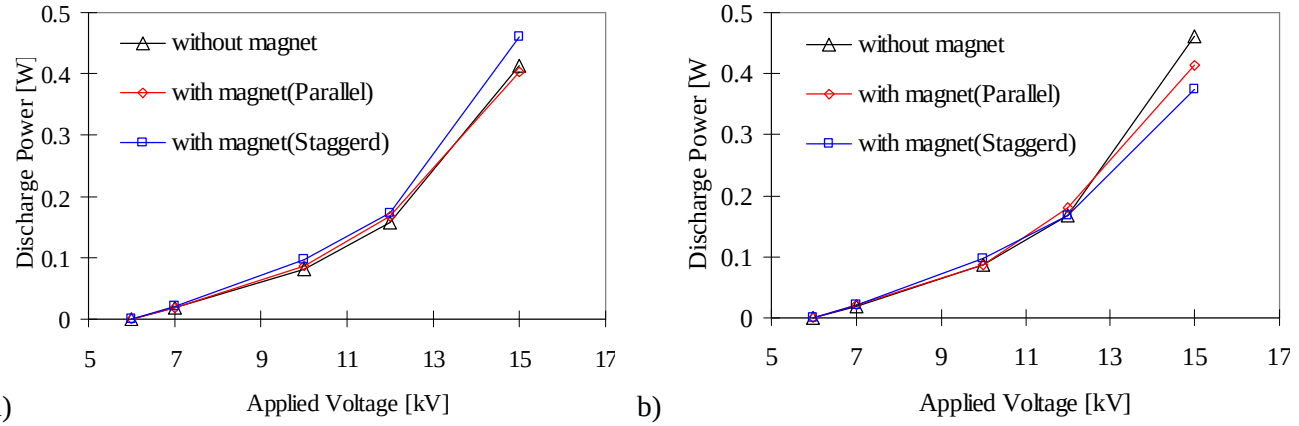

Figure 3. MT-BDR Discharge power versus peak to peak applied voltage with and without permanent magnets for the air flow rates of : (a) 28 l/min, and (b) 56 l/min.

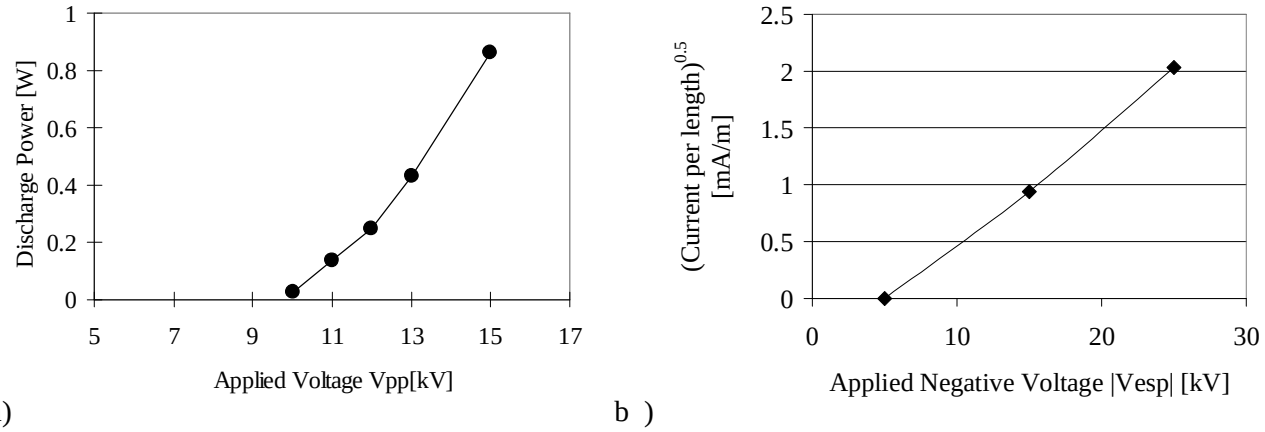

Figure 4. a) MT-BDR discharge power versus peak to peak applied voltage (Vpp), and (b) current-voltage characteristic of ESP for the exhaust flow rate of 2kg/h and engine load of 1.5kW.

3. Results

Figure 5 shows the removal efficiency of DSPM by ESP that was operated at voltage magnitudes lower than 20kV in order to avoid spark discharge. For ESP operating voltage of -15kV more than 99.99% of DSPM was removed. Figure 6 shows the removal of pollutant gases by MT-BDR for cases of : (a) clean and (b) soot-deposited trench reactor. The results show that the NO_x, (NO and NO_2) decreases immediately after non-thermal plasma treatment. However, by increasing the discharge power of trench reactor, the removal rate of NO_x and NO_2 were slightly decreasing.

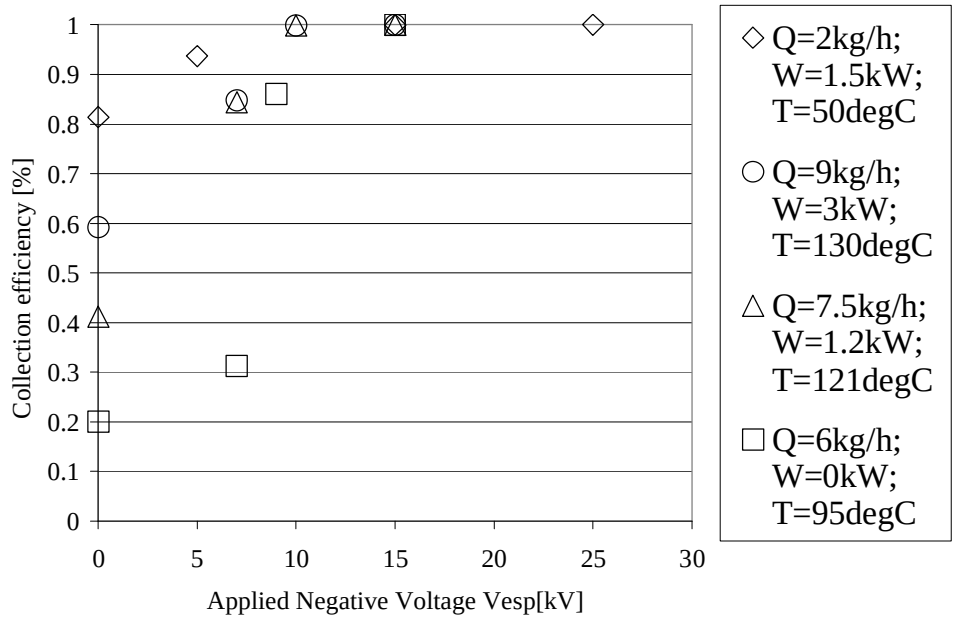

Figure 5. DSPM collection efficiency by ESP for exhaust flow rates (Q) from 2 to 9kg/h and the engine loads (W) from 0 to 3kW (T…average ESP temperature).

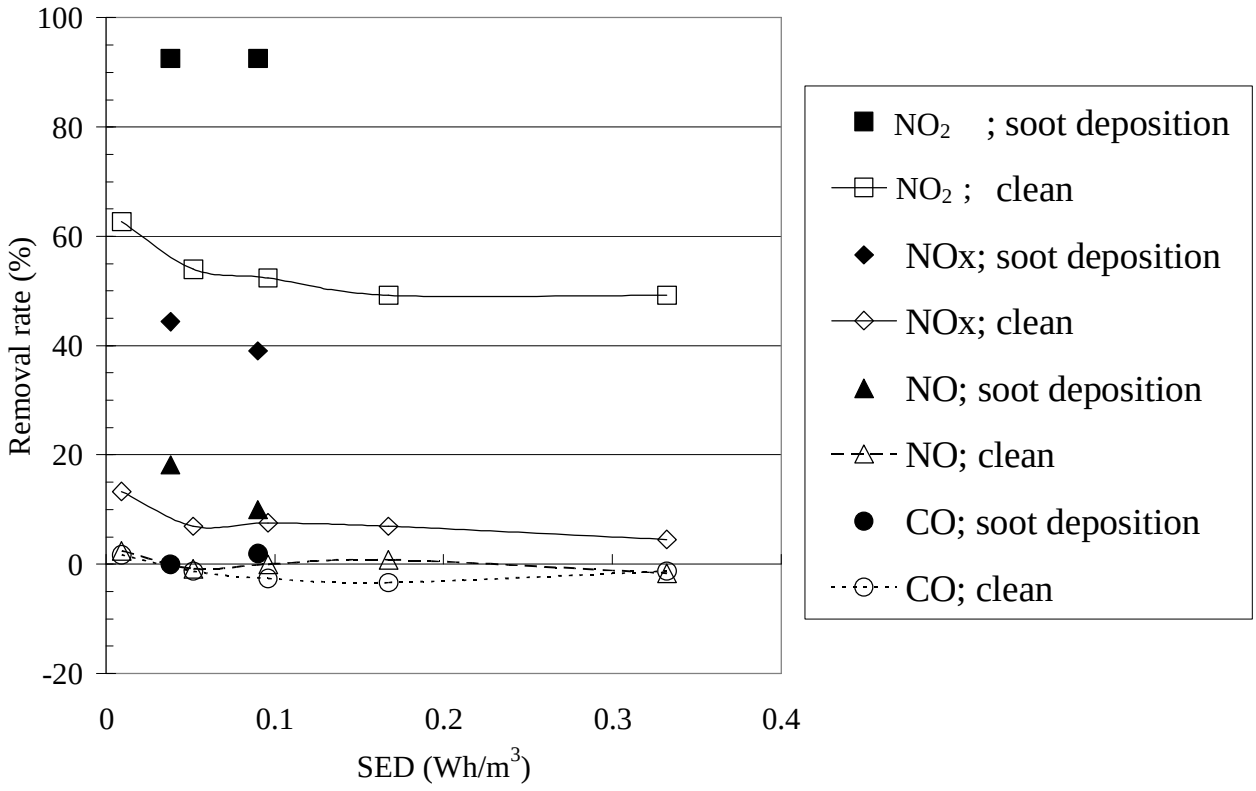

Figure 6. Pollutant gas removal efficiencies as a function of specific energy density for clean and soot deposited trench reactor.

4. Conclusions

Experimental investigations have been conducted to study the simultaneous removal of NO_x and diesel soot particulate matter and the results show that: a) Staggered magnet arrangements can increase the discharge power from 10 to 17% and the improvement is highest at the lowest applied discharge voltage; b) The power improvement decreases with increasing flow rate; c) The NO_2 and NO_x removal rates were 35-70% and 6-45%, respectively. It seems that soot deposition in plasma-catalyst reactors assist in NO_x removals; d) The ESP successfully removed over 99.9% of DSPM from exhaust.

ELECTRON-BEAM PLASMA IN THE PRODUCTION OF BIOACTIVE AGENTS AND DRUGS

M. Vasiliev[1], T. Vasilieva[2]

1 Moscow Institute of Physics and Technology, Moscow region, Russia
2 Hematological Scientific Center, Moscow, Russia

Abstract
The modification of some biopolymers and amino-acids by the Electron-Beam Plasma was studied experimentally. The plasma was generated by injecting the continuous electron beam in gaseous or vapor media. Due to the treatment the powders of the substances under consideration were found to change their physical-chemical and biological properties. In particular, the modified synthetic derivative of 2-aminopropanoic acid was proved to acquire the anti-aggregation activity for platelets of human blood.
Keywords. Electron-beam plasma. Plasma treatment. Plasma modification of biomaterials.

1. Introduction

The Electron-Beam Plasma (EBP) is generated by injecting an electron beam (EB) into a gaseous medium. Under typical conditions of the EBP generation (the medium pressure $0{,}1 < P_m < 10$ kPa and moderate EB power $N_b < 1$ kW) the plasma is strongly non-equilibrium and cold. Being injected into the gas the EB ionizes the gas, excites the gas molecules and is able to cause the molecule dissociation. As a result, the EBP composition is complicated and there are a lot of chemically active particles that don't exist under equilibrium conditions. With respect to non-equilibrium plasmas generated in conventional ways (for instance, the plasma of gas discharges) the EBP has the following advantages:

- the EB can be injected into any gases, vapors and gas-vapor mixtures; the EBP bulk doesn't contract even at very high gas pressures ($P_m \sim 10$ kPa and higher).
- the solid powders and liquid droplets injected into the gas don't prevent the EBP generation; large-size bodies can be inserted into the plasma bulk.

The EBP was proved to effectively modify properties of materials thanks to the plasma chemical activity, complicated organic and polymer molecules being the most modifiable even at low temperature.

2. The Electron-Beam Plasmachemical reactor and the treatment procedure

Fig. 1 illustrates a typical way of the EBP generation. The focused EB 3 generated by the electron-beam gun 1 located in the high vacuum chamber 2 is injected into the working chamber 6 filled with the molecular gas through the injection window (IW) 4. In passing through the gas the EB is scattered in elastic collisions and the energy of fast electrons gradually diminishes during various inelastic interactions with the medium (ionization, excitation, dissociation). Eventually the EB power transforms into the heat increasing the temperature of the medium and heating the unit elements. It may also cause the phase transformations or is radiated. As a result the plasma cloud 5 is generated, all plasma parameters being functions of *z*- and *r*-coordinates.

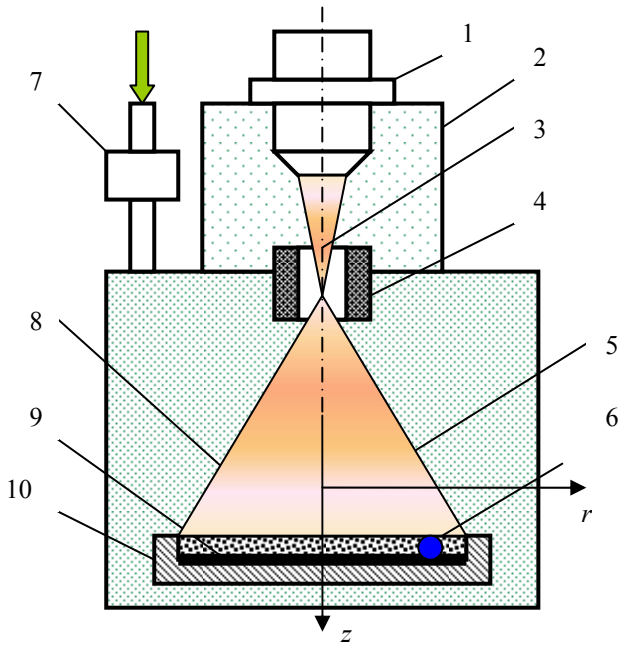

Fig.1.

The working chamber is preliminary evacuated to pressure $\sim 10^{-3}$ kPa and then filled with the plasma generating gas through the feeder 7. The pressure P_m varied within the range 1-10 kPa depending on the gas composition and treatment conditions required. The following gases were used to

generate the EBP: air, nitrogen, oxygen, noble gases (He and Ar), gaseous hydrocarbons, CO_2, water vapor and vapors of some organic liquids. Gaseous and vapor-gas mixtures were used as well.
A specially designed double-stage gas-dynamic window is used to transport the EB of energy E_b = 20-40 keV from high vacuum ~1 Pa (that is a typical pressure required for the operation of electron guns with thermionic cathodes) into the working chamber filled with the gas.

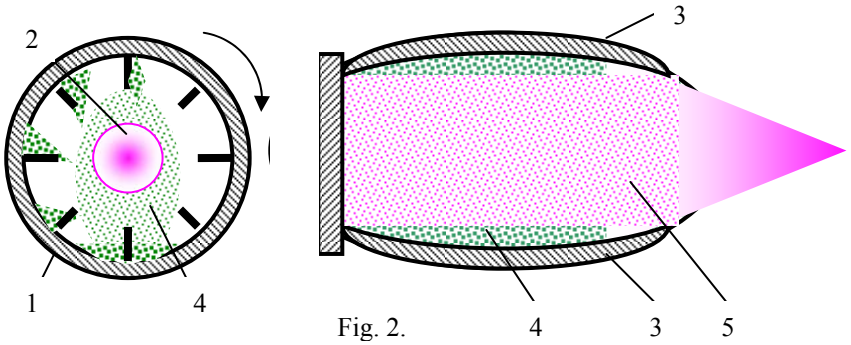

Fig. 2.

The powder of the substance to be treated is filled in the glass container 10. Thin plate 9 made of piezoelectric ceramics is placed on the container bottom. Being fed with AC voltage the plate vibrates, throws up the powder particles and forms the mixing layer 8 of the treated material. The miniature thermo-sensor 9 is inserted into the container to monitor the material temperature T_s during the treatment. Adjusting the EB power the temperature T_s could be varied within the range 300-450 K, no additional heaters or coolers being used to maintain the constant T_s-value. Note that the power is heated by the EB more effectively than the gas and usually $T_s > T_m$, where T_m is the plasma generating medium temperature.
Another version of the reactor developed to treat larger amounts of the biomaterials is illustrated by in fig. 2. The general axis of this reactor (and the axis of the EB injection) is horizontal, the reaction chamber being a cylindrical or barrel-shape vessel 1 equipped with internal ribs 3. The EBP cloud is formed in the vessel hollow by the EB 2 injected throught the open end of the chamber. The powder 4 of material to be treated is mixed by means of the vessel rotation; as a result the aerosol reaction zone 5 is formed inside the chamber. Note, the reaction chamber 1 is placed inside the working chamber (that isn't shown in fig. 2) filled with the plasma generating gas at required pressure P_m.

3. The biopolymers treatment in the Electron-Beam Plasma

The plasmachemical modifications of cellulose materials (pure cellulose, wooden sawdust and crushed paper), peat and chitosan in EBP of O_2, He, H_2O, NH_3, CO_2, SF_6 are studied in detail. The yield (S, %) and the average molecular mass (M, amu) of water-soluble products extracted from the solution were taken to be the quantitative criteria for the modification. Note, typical content of water-soluble substances in untreated cellulose materials does not exceed 1-2%. The molecular mass of the cellulose may reach several million.

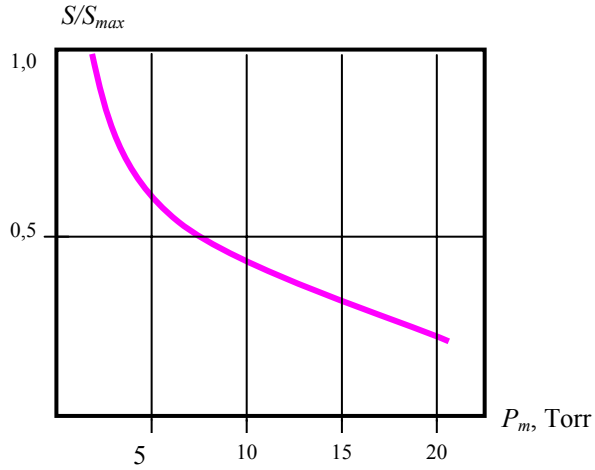

Fig. 3.

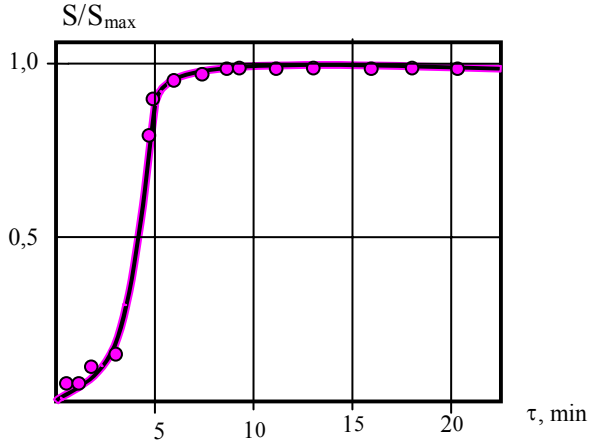

Fig. 4.

The water-soluble products yield depends upon the processing conditions and has a maximum value S_{max} for each plasma-generating gas: for O_2 plasma $S_{max} \approx 45$ %, for H_2O-plasma $S_{max} \approx 56$ %, for (H_2O + NH_3) plasma $S_{max} \approx 70$ % which are reached during certain time periods of the treatment τ_0. At first the dependence $S(\tau)$ increases smoothly, then – steeply close to τ_0 after which the yield of the water-soluble products does

not change whatever the time of the treatment could be (fig. 3). The dependence between S and the pressure of O_2 - plasma is shown in fig. 4. The NMR- and IR-spectroscopy analyses showed the final water-soluble products of the cellulose modification to be β-($C_1 \rightarrow C_4$)-tetrasaccharide, the molecule structure and chemical bonds of the products being identified [1].
The products of the EBP modification of all substances mentioned above turned out to be bioactive. For instance, modified cellulose and peat are effective substrates for microorganisms and fungi: the yield of the yeastrel on the plasmachemically treated peat attained 0,14 kg per 1 kg of the peat, whereas productivity of the untreated substrate was only 0,053 kg. The yield of water-soluble products from plasmachemically modified chitosan achieves 75-80% whereas the efficiency of conventional technologies doesn't exceed 35-40%. Preliminary tests showed the water-soluble products of the chitosan modification to be promising for skin therapy.

4. The amino-acids treatment in the Electron-Beam Plasma

Plasmachemically modified organic substances were supposed to be active agents for drug production. Some natural α-amino acids with artificially inserted pirozolidine cycles into their structures were used as original substances and the products of their modification in the EBP of helium and water vapor were tested as inhibitors of the human platelet aggregation. Preliminary analysis showed the substances of this class to be promising as active agents for medical therapy of acute coronary events, and cardiovascular diseases that remain the leading cause of the mortality. Their advantages are due to selectivity of the pharmacology action and limited side effects.
Biological effect appearing due to plasmachemical modification can be detected by means of the standard techniques *in vitro*, the aggregation degree being chosen as the quantitative characteristics of the biological effect. The platelet aggregation A (%) were measured by the turbodimetric method and A was defined as the ratio of the light transparency of the platelet suspension after ceasing the aggregation process to the initial value of the light transparency [2]. The aggregation was monitored by the aggregometer *Biola* (Russia), ADP (final concentration 1×10^{-5} M; *Boechringer Mannheim*, Germany) being used as an aggregation agent.
The experimental data were statistically analyzed by Student′s test, P-values smaller than 0,05 were considered as reliable. Table presents the results of the statistical analysis.
The powder samples (≈ 50 mg in mass) of the original substance were treated in the EBP of water vapor at pressure $P_m \approx 2$ kPa for variable time duration τ = 45-300 s. The monolayer of the powder to be treated was filled on the glass substrate and placed into the reaction chamber of the electron beam plasmachemical reactor. The typical EB power was $N_b \approx 0{,}1$ kW, the sample temperature T_s under the treatment could be varied within the range 30-110 °C.

Table. The effect of the plasma modification in the EBP of water vapor on the antiaggregation activity of the tested α-amino acid (*in vitro*): the aggregation degree A as a function of the treatment duration τ and temperature of the substance T_s under the treatment procedure.

ADP	ADP + untreated amino acid	ADP + treated amino acid				
		τ = 45 s, T_s = 38 °C	τ = 90 s, T_s = 38 °C	τ = 180 s, T_s = 38 °C	τ = 180 s, T_s = 55 °C	τ = 300 s, T_s = 55 °C
56±2%	46±2%	41±3%	41±3%	34±3%	32±3%	31±3%

The treated substance became partially water-soluble at room temperature and the solution at maximum concentration was added to the platelet suspension to measure the aggregation degree. The main results are:

- The untreated derivative of the α-amino acid decreased human platelet aggregation *in vitro* from 55,82±2,53% (control experiments) to 45,97±3,51%. The untreated compound wasn't dissolvable in distilled water at room temperature and the water heating up to 90 °C followed by cooling to 25 °C was required to carry out the control experiments.
- The water-soluble products of plasma treatment reduced the aggregation degree up to ≈ 30 %, i.e. being treated by the EBP for 5 min the studied substance reduced the platelet aggregation activity by approximately 45 %.
- The effect of the treatment duration on their anti-aggregation activity increased as the treatment prolonged, the anti-aggregation activity rising sharply at $90 < \tau < 180$ s. Our previous experiments

with cellulose, starch, chitosane show that the yield of the plasmachemically modified products began to rise abruptly at some duration τ_0. At shorter durations $\tau < \tau_0$ the plasma didn't modify the original substance and the longer treatment $\tau > \tau_0$ resulted in insignificant additional effect (see fig. 4 and [1]).

- Moderate sample heating amplified the treatment effect slightly, i.e. plasmachemical processes are responsible for the modification. Cellulose and chitosane modification was found to occur due to plasmachemical processes, whereas the substance heating was a minor factor only.

5. Mechanisms of the plasmachemical modification of biomaterials

The properties modification of biomaterials and, in particular, the higher anti-aggregation activity of the α-amino acid after EBP-treatment is assumed to be due to the following reasons:

- Plasma treatment increases the solubility of the studied substance. Regarding the anti-aggregation activity, it means that the concentration of the active agents in platelet suspension during the aggregation degree measurements was inherently higher in comparison with the non-soluble original substance.
- Possible chemical transformations of substances are also supported by the observed changes of the original color due to the plasma treatment. Fig. 5 illustrates the color transformations in the powder of studied amino acid due to the treatment in the EBP of helium and water vapor, the solutions of the treated products and products in solid phase being of the same color.
- Changes of the compound conformation could occur without alteration of its structure. This could improve the affinity of the substance under consideration to the platelet GPIIb/IIIa-receptors.
- Some new chemical groups might be included into the molecule structure during the treatment in the EBP. For instance, the EBP of the water vapor is enriched with H, OH and H_2O_2 radicals that can react with the amino acid molecules.

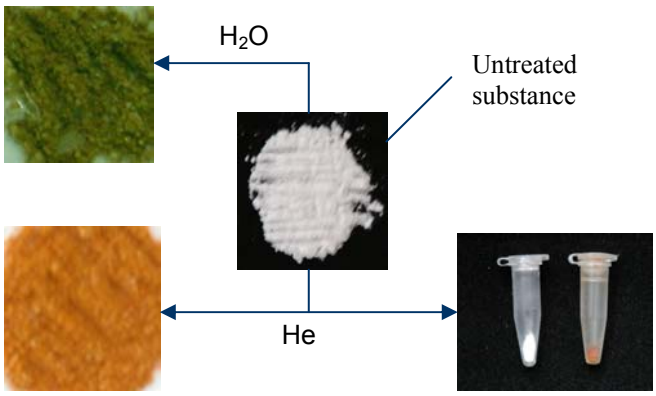

Fig. 5.

These explanations seem to be reasonable and qualitatively correspond to the data of our previous experiments on biopolymers modification by the EBP. Undoubtedly, the higher effect of the plasma modification can be attained by optimizing the treatment regimes and adjusting the design of the plasmachemical reactor.

Conclusions.

- The plasmachemical treatment of natural organic materials and substances is very promising for bioactive agents production and electron beam plasmachemical reactors are able to change the product properties controllably. For instance, the technique involved is likely to be useful for the platelet aggregation antagonists development since inhibitors that can reduce the aggregation activity by fifty percent are considered to be effective.
- The modification of the natural α-amino acid derivatives in the EBP of the water vapor can be explained by the same plasmachemical mechanisms that were found and confirmed in the experiments with cellulose, peat and chitosane.

GENERATION AND APPLICATIONS OF THE ELECTRON-BEAM PLASMA OF AEROSOLS

A. Mahir, M. Vasiliev

Moscow Institute of Physics and Technology, Moscow region, Russia

Abstract
The plasma generation by means of the electron beam injection in aerosols was studied, both dispersed liquids and solid powders being used to produce the aerosol medium. Stable and unstable aerosol clouds and aerosol flows (both sub- and super-sonic) were obtained in the electron beam plasma. The plasma-assisted ignition and combustion of dispersed liquid propellants were realized in trans-sonic air flows. The electron beam plasma was found to influence the ordered dust-plasma structures remotely.
Keywords. Electron-beam plasma; plasmachemical reactors; dusty plasma; plasma-assisted combustion.

1. Introduction

Usually the Electron-Beam Plasma (EBP) is generated by injecting an electron beam (EB) into a gaseous medium, the typical range of gas pressure being ~ 0,1–10^3 Torr. In general, the properties of the generated EBP and the geometry of the plasma bulk are due to the parameters of the EB being injected (electron energy E_b, beam current I_b and current density j_b) and the gas properties (composition, pressure P_m and temperature T_m). Many industrial and aerospace applications of the EBP, which will be further considered, result from the following peculiarities of the EBP generation procedure:

- The EB can be injected into any gases and vapors or gas-vapor mixtures. There are no physical restrictions as to the density of the gaseous medium since the EBP bulk doesn't contract even at very high gas pressures (P_m ~ 10^2 Torr and higher).
- Being added to the plasma-generating gas the solid powders and liquid droplets don't prevent the EBP generation. Large-size bodies can be inserted into the plasma bulk. Liquid jets can be injected into the EBP as well.
- The EB can be injected in both still gas and gas streams; the EBP flows appear to be stable.
- When the EB is injected into preliminary generated plasmas, so called Hybrid Plasma (HP) is produced. Experiments showed the EB to be compatible with gas discharges. The HP of aerosols and the HP flows can be generated as well.

To describe the EBP of the aerosol two interrelated problems should be considered: the propagation of the EB through the aerosol cloud (scattering and absorption of the EB) and the behavior of the aerosol irradiated by the EB (electrostatic charging, particle motion, heating, and phase transitions). Plasmachemical reactions both on the particle surface and in the gaseous phase can occur. In developing the EBP plasmachemical reactors, aircraft on-board units and other applications all these problems have to be considered as well.

2. Experimental unit

The experimental complex specially developed to study the aerosol EBP and its applications is shown in fig. 1 and described in detail in [1]. The complex consists of the generator of the EBP, which is the main part of the complex, and accessory systems such as a vacuum system, a gas feeding system, radiation protection and others. The EBP generator characteristics are as follows: E_b = 20-30 keV, I_b = 1-100 mA, j_b = $5\cdot10^3$-$5\cdot10^5$ A/m^2, P_m = 0,1-50 Torr, T_m = 260-600 K.

The focused EB 3 (j_b ~ $5\cdot10^3$-$5\cdot10^5$ A/m^2) was generated by the electron gun 1 inside the high-vacuum chamber 2. The EB was injected into the working chamber 5 through the gas-dynamic Injection Window (IW) 4. Compact and reliable one-, two- and three-stage windows were developed for various ranges of the P_m-value. The EBP cloud 6 was generated due to the interaction of the EB and the gas the working chamber was filled with.

The high-voltage power source fed the three-electrode electron gun. It produced the accelerating voltage (U = 25-60 kV) and the additional negative potential (U_{contr} = 0 ÷ –5 kV) that was supplied to the controlling electrode of the gun to change the EB current within the range I_b = 1-50 mA. The controlling module #1 controlled the power source operation and changed the I_b and E_b values (E_b = U).

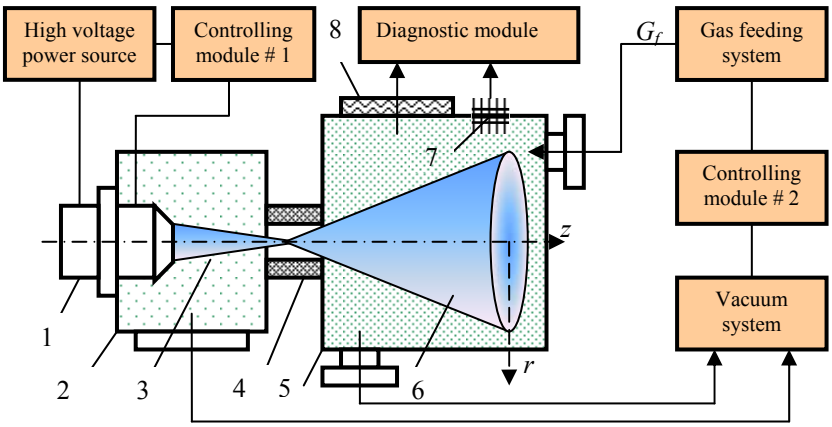

Fig. 1. The scheme of the experimental complex

The large volume working chamber ($V \sim 0{,}5$ m^3) was used to study free EBP clouds that didn't contact the chamber wall. To study localized plasma bulks special reaction chambers (cylinders 30-300 mm in diameter) were placed inside the working chamber, the EB being injected along the cylinder. The cylinder was made of both metallic and dielectric materials. The working chamber was equipped with holders to insert the large-size models in the EBP flow (aerodynamic experiments) or to place a sample of materials to be treated (industrial technologies development). The glass window 8 was used for optical plasma diagnostics. The sensors placed inside the working chamber were connected with the external devices through the hermetic plug and socket units 7. The controlling module #2 was responsible for the operation of the vacuum and gas feeding systems. Operating together they kept the pressure in the high vacuum chamber $\leq 10^{-4}$ Torr and varied the gas pressure in the working chamber within the range $P_m = 1\text{-}10^2$ Torr. EB jets were generated by means of nozzles of different kinds. Usually EB was injected through the choking section of the nozzle along the jet axis. Cylindrical (subsonic), Laval (supersonic) shortened (non-adapted supersonic) and center-body (both sub- and supersonic) nozzles were used. EBP generation by means of the shortened maladapted nozzles is illustrated by fig. 2. The EB 5 was injected through the throat of the nozzle 4 combined with the IW 6 along the gas flow 3. As a result the EBP jet 2 was formed.

The dispersed particles were injected into the working chamber of the experimental unit to produce the aerosol clouds or aerosol flows. The mechanical sprayers were used to introduce powders; liquids were injected by means of centrifugal sprayers or sprayed pneumatically as shown in fig. 2. The liquid jet 7 was injected in the EBP flow 2 which was generated in the supersonic gas flow 3 by the center- body nozzle 4 combined with the IW. The zone 1 is the flow of the aerosol EBP.

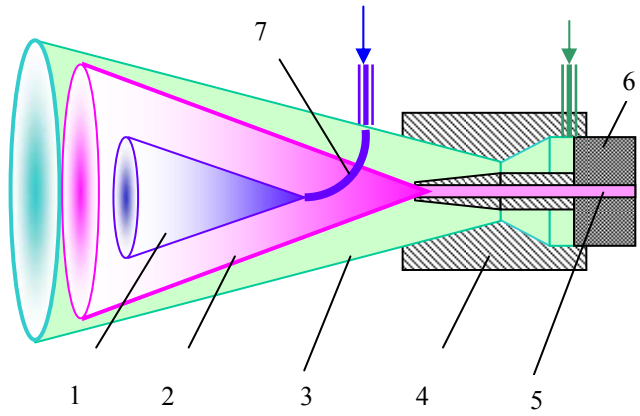

Fig. 2. A supersonic EBP plasma jet generation and pneumatic spraying of the liquid jet in the supersonic EBP flow

The dust layers were formed upon a vibrating membrane, piezoceramic plates and metallic foils equipped with electromagnetic shockers were used as the membrane. The dust clouds were formed in the large-size working chamber by spilling the powder from a vibrating sieve or inside the small-size spinning reaction chamber like a concrete mixer. To produce the aerosol of droplets either liquid jets or liquid films were injected into the gas flow. The centrifugal nozzles were used to generate still aerosol clouds as well.

The working chamber was equipped with the electrode that generated the electrostatic or RF-electromagnetic field in the working chamber. The electrodes of various designs were used:

- to generate HP of aerosol (both still plasma clouds and HP flows);
- to ignite the aerosol of liquid fuels;
- to form ordered dust-plasma structures in the RF-electromagnetic field.

The ordered dust plasma structures (fig. 4) were found to appear above the RF-electrode of a special design [2]. By injecting the EB over the structure the properties of the HP and spatial distribution of the field near the electrode can be changed (see section 4).

3. Stability of the aerosol cloud irradiated by the EB

The stability of the aerosol clouds irradiated by the EB was investigated experimentally to develop the electron beam plasmachemical reactor for the powders treatment. The aerosol particles motion in the EBP of various gases was studied, the gas pressure being varied as well. The aerosol particles were found to begin to fly apart at some the P_m-value due to the EB action i.e. being injected the EB destroyed the aerosol cloud and scattered the solid particles toward the working chamber walls (fig.3). The particle acceleration reduced as the gas pressure rose. The aerosol cloud dispersion was supposed to be explained by electrostatic charging of the powder particles and special experiments were carried out to measure the particle charge as a function of the pressure P_m. A spherical probe, imitative a single aerosol particle, was inserted into the plasma cloud and the potential difference ΔU_p between the probe and the ground was measured. The ΔU_p-value was found to be very small at higher pressures (P_m > 5 Torr) but it began to increase rapidly at $P_m \approx$ 1-2 Torr (see fig. 4). At P_m < 0,5 Torr the potential could reach 100 V and higher. The typical values of the gas pressure at which the $\Delta U_p(P_m)$-function changed its behavior were in agreement with the P_m-values at which the character of the aerosol particles motion changed. Therefore, the electrostatic charging of the aerosol particles irradiated by the EB was responsible for the aerosol flight and scattering.

Fig. 3. The solid aerosol fly apart, P_m = 0,3 Torr

The radial distribution $\Delta U_p(r)$ in the EBP cloud at various distances z from the IW was studied and fig. 5 illustrates the results of these measurements. The figure shows that the points of the plasma cloud located far from the axis z acquire a sufficiently high negative potential.

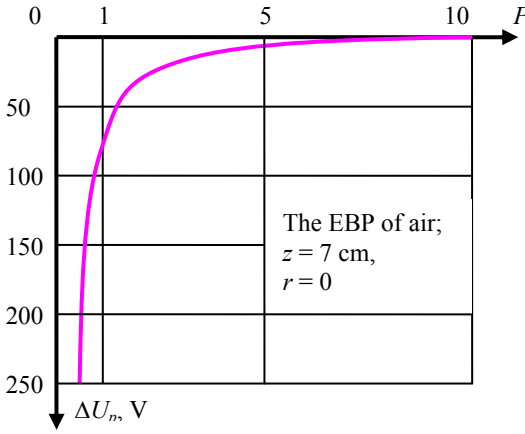

Fig. 4. The potential of the point z = 7 cm on the EBP axis as function of the gas pressure.

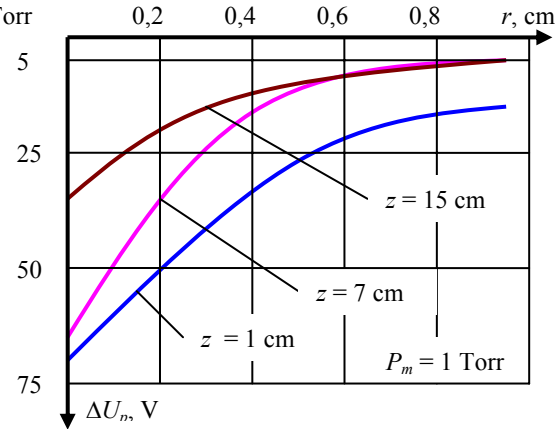

Fig. 5. The potential of various points of the air-EBP at pressure P_m = 1 Torr.

4. The formation of the dust-plasma structures and the remote control of the structures by the EBP

The ordered dust plasma structures are known to be formed in the RF gas discharge [2]. When a small amount of the powder was filled on the active electrode of the RF-discharge system the particles could levitate over the electrode as shown in fig. 7. Certainly, appropriate power of the RF-generator and the gas pressure value should be found and the powder must be introduced carefully. Vibrating membranes or sieves are usually used to introduce various powders: ceramics, glass, polymers and others. Note that the dust plasma structures were proved to exist at sufficiently low pressures P_m < 2-5 Torr only.

The ordered dust structure formation by means of condensation of the evaporated materials was observed as well (see fig. 6). The powerful EB pulse evaporated a target of a solid material in the working chamber filled with the noble gas to create the dense gas + vapor mixture. The vapor condensation resulted in the formation of the ordered dust structures above the RF-electrode. When polymer targets were used the stable dust-plasma crystals were formed during ~15 s after the EB cutoff. In comparison with the dust structures formed by directly introduced powders, the condensed dust-plasma structures were denser and the particle size didn't exceed 5 μm, whereas typical sizes of available solid powders were ~10-20 μm (compare fig. 6 and 7; the

figures present the ordered dust structures of the polymer material in the helium plasma that were formed by vapor condensation and direct introduction of the powder respectively).

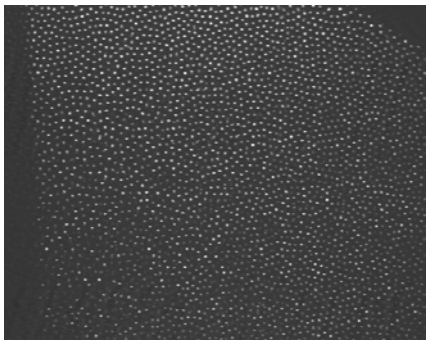

Fig.6. The ordered dust structure formed by condensation of the polymer vapor in the EBP of helium, P_m = 1 Torr.

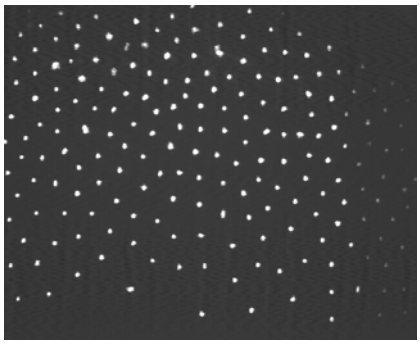

Fig. 7. The ordered dust structure of the polymer powder formed by means of the vibrating sieve in the HP of helium, P_m = 1 Torr.

Though our experiments showed that no ordered dust plasma structures are formed in the pure EBP (in the plasma without gas discharge component), the EBP is able to control the dust-plasma structures. The following phenomena were observed when the EB was injected above the structure but didn't touch it:
- the particles density was changed and the uniformity of the powder layer was violated;
- the structure, as a solid crystal, followed the EB when the beam scanned over the structure slowly.
Thus, the EBP controlled the dust plasma structures remotely and the observed phenomena can be attributed to the electrostatic potential that occurs on the periphery of the EBP bulk (see section 3 and fig. 5).

5. Ignition and combustion of the aerosol in the EBP

The ignition and combustion of liquid aerosols stimulated by the EBP were studied experimentally within the range of the air pressure $10 < P_m < 30$ Torr. The automobile gas and aircraft kerosene were sprayed into the subsonic and supersonic airflow to produce flammable mixture. The aerosol flow of the dispersed liquid propellants was formed as shown in fig. 2 and the EB was injected along the airflow axis. Being preliminary excited by the EB the aerosol flow was ignited by a high voltage RF-electrode introduced in the flow. The kerosene-air mixture was found to combust only if the EB was switched on (fig. 8). When the EB was cut off the flame was extinguished, i.e. the EB really assisted the combustion. Fig. 9 illustrates the luminescence of the kerosene aerosol excited by the EB before ignition. In this experiment the fuel jet was injected toward the airflow and the ignition electrode wasn't fed.

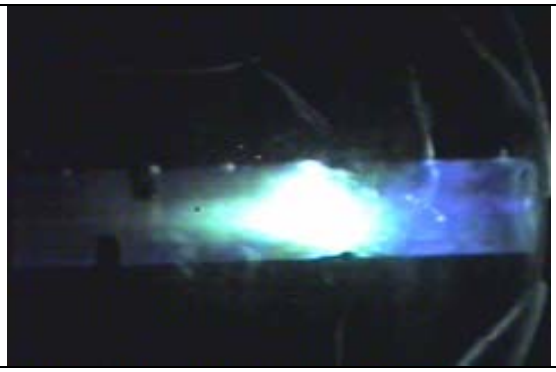

Fig. 8. The EBP-assisted combustion of kerosene in trans-sonic airflow.

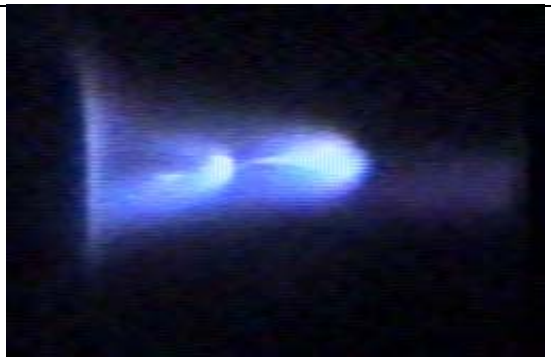

Fig. 9. The luminescence of dispersed kerosene in the trans-sonic air-EBP flow; the mixture isn't ignited.

ITC-IRST, Divisione Fisica Chimica delle Superfici e Interfacce, via Sommarive 18, Povo, Trento, Italy

Abstract

In the attempt to produce thin carbon films with attractive mechanical properties we found out that combining different materials in a multilayered structure can result in a significant improvement of the properties of the whole system (low stress for example). In order to relate the film macroscopic properties to its chemical composition and architecture an optimization of the in-depth Auger analysis conditions were studied. An optimal resolution of the 7 nm half-period layered structure has been obtained.

Keywords: AES; Depth profiling; Depth resolution; Sputtering and PACVD deposition, Carbon multilayer

1. Introduction

Recent development of the in-depth distribution and chemical composition analysis along the third dimension perpendicular to the surface has been significantly stimulated by the progress in thin films technology as well as in the opto-electronic and semiconductor materials. A great number of material properties and macroscopic phenomena depend on the atomic scale properties of materials interfaces [1]. For example, friction, wear, hardness and elastic modulus are governed by the structure and composition of inner interfaces. In multi-layered structures, mechanical, thermal and chemical stability of interfaces between different materials (hetero-interfaces) are fundamental for the functioning reliability of technological products such as sensors, microelectronic devices, tools and medical prosthesis, and protective coatings [2]. Although the correlation between macroscopic behavior and structure, properties and composition represents a difficult and a not completely well understood task, it is commonly accepted that the chemical and structural characterization has to be considered as a close link with the preparation and synthesis of a structured sample [1,3]. A number of techniques have been developed for this purpose. Surface and interface analysis methods (ESCA, AES, XPS, etc.) combined with ion sputtering are the most commonly used since they can be easily applicable to nearly all kind of materials.

In multi-structured samples a detailed compositional characterization of the single layer and interface is more than ever crucial if a correlation between film mechanical properties and its chemical composition is required. In depth profiling analysis of thin film or multilayer samples an important figure of merit that defines the accuracy and precision of the in-depth distribution of elements concentration is the depth resolution (Δz) that could be definitely considered as the key parameter for the quality of a depth profile measurement.

The commonly definition of the depth resolution, recommended by the International Union of Pure and Applied Chemistry (IUPAC) and by committee E 42 of The American Society of Testing and materials (ASTM-E42) is given by the distance over which the difference between 84% and 16% of the maximum intensity of the profile at the interface is measured [4-6]. The relative depth resolution is defined by $\Delta z/z$ where z is the depth value measured at interface.

In the case of a more structured sample multilayer of constant ½ period thickness (d) an evaluation of the depth resolution may also be derived by the normalized amplitude of I_m/I_0 [5,6] where I_m represents the difference between the maximum (I_0) end the minimum (I_s) of the signal on both sides of an interface profile.

It has been experimentally demonstrated that in Auger depth profiling (Δz and I_m/I_0) is affected by a large number of factors (instrumental, sample characteristics, beam interaction with a specific sample, etc.) [1,5,7,9].

These effects may lead to a distortion of the shape of the profile, broadening of interface and consequently a degradation of the depth resolution. The primary ion beam nature [8], the ion beam energy [1,5,7] and the ion beam incident angle [1,5,8,10] are the most important experimental aspects which should be taken into account to avoid detrimental contributions to the achievement of an appropriate depth resolution.
In order to find out the more appropriate experimental conditions to optimize the depth resolution in the AES depth profiling of multilayered films both film/substrate and single layers interfaces have been considered.

2. Experimental

Sputtering and PACVD (Plasma Assisted Chemical Vapor Deposition) processes were used in alternate order to deposit, on a n-doped silicon substrate, nanometer-thick carbon films. Samples structured in 2, 4, 8, 16, 32 layers, with single layer thickness varying from 100 to 7 nm ½ period, have been characterized. The two kinds of carbon materials differ by their structural properties. The carbon layers (hereafter indicated as C layers) obtained by graphite sputtering in Ar-H_2 (16%) discharge was hard (hardness ~ 8 GPa), while those prepared by PACVD exhibited polymer-like properties (hardness ~ 1 GPa). During the PACVD process nitrogen was introduced in the hydrocarbon-hydrogen gas process as a marker element, therefore these layers are named C:N. Nitrogen is switched off during the subsequent sputtering deposition process, but some remnant amount is detected in the hard C films and for this reason N concentration varies in an oscillating way along the film depth. The thickness of the single layers of the structure has been reduced when increasing the number of layers in order to approximately maintain the same total thickness of the films (Table 1).
Both kind of films contain hydrogen and would be better described as C:H and C:H:N, however for simplicity we omit it in their nomenclature.

Sample	Total number of layers	Measured film thickness (nm)	Theoretical single layer thickness (nm)
A	2	257	128
B	4	249	62
C	8	254	32
D	16	205	13
E	32	225	7

Table 1
Film thickness, interface width and depth resolution for C/C:N multilayer sample deposited on Si using sputtering and PACVD process.

AES (Auger Electron Spectroscopy) depth profiling is one of the most important and extensively used sectioning methods used for the tree-dimensional analysis of thin films. The technique combines a focused ion beam that is scanned over a sample surface and the measurement of the secondary Auger electron that can be done either discontinuously after the sputtering process or simultaneously with it..
Measurements presented here were performed in a PHI model 4200 system, equipped with a variable resolution cylindrical mirror analyzer (CMA) and a W electron emitter coaxial electron gun. The system base pressure was in the low 10^{-8} Pa. Auger spectra was excited by a 3 keV, 8.75 10^{-4} Acm^{-2} current density electron beam that was scanned over an area of 400 μm^2. A differentially pumped ion gun, model 04-300, was used for the sputtering process. Ion gun gas pressure has been fixed at 20 mPa and positive Ar^+ ions were accelerated to different energies (2, 3 and 4 keV). The 800 μm diameter ion beam has been rastered over an area of 1x1 mm enabling a better uniformity of the beam intensity leading to a more flat bottom of the sputtering crater which is necessary for improving the depth resolution [1] The incidence angle of the ion beam to the surface sample, θ, has been varied with respect to the sample surface from 28 to 68 degrees. C_{KLL}, N_{KLL}, Si_{LMM} and O_{KLL} Auger lines has been acquired and an elemental quantification applying the Physical Electronics manufacturer's relative sensitivity

factors has been obtained. The depth distribution of the elements was recorded as a function of the depth, assessed on the basis of the erosion time and the film thickness.
Films thickness was obtained using a KLA-Tencor P-15 stylus profilometer and an atomic force microscopy (AFM) was applied in the contact mode to investigate the surface roughness.

3. Results and Discussion

As a first step, a carbon film (121 nm thick) material with similar chemical and compositional characteristics to the samples has been used as a reference in the attempt to find out the appropriate experimental ion gun setting giving the best Δz at the Si/film interface and $\Delta z/z$ value. These etching parameters were subsequently applied to the in-depth measurements of the multi-layered samples. With this purpose a thin a:C film has been deposited on Silicon by graphite sputtering.
A number of AES depth profiles obtained by varying both ion beam incidence angle θ with respect to the sample surface and ion beam energy have been acquired. The latter parameter has shown better results at low energy value (2 keV) as largely reported in the literature [1,5,8,10,11].
In Table 2 the Δz and $\Delta z/z$ values measured from the Auger depth concentration profiles of the reference sample are reported as a function of the ion beam incidence angle.

Ion beam incidence angle (°)	Depth resolution Δz (nm)	Relative depth resolution $\Delta z/z$ (%)
68	7	5,8
53	8	6,4
38	6	4,8
28	5	4,1

Table 2.
Dependence of the depth resolution (Δz) at film/Si interface and the relative depthresolution ($\Delta z/z$) for a 121 nm Carbon film on different ion beam incident angle.

A number of phenomena and in particular sputtering-induced effects and escape depth of Auger electrons as well as the experimental ion gun set-up may be the primary causes of a broadened depth profile interface and of a degradation of the depth resolution. The initial surface roughness can greatly influence the depth from which the analytical information is obtained and the AES elemental signal intensities as well. Shadowing effect due to a rough surface may prevent the secondary electrons from reaching the analyzer and they may be recaptured after leaving such a surface. For an initially smooth surface the etching-induced roughness is certainly the prevailing factor for the degradation of the depth resolution and it generally appears as the result of different local etching rates which depend on the crystallographic grain orientation whenever and ion incidence angle [1,9,12]
An increasing trend of depth resolution and relative depth resolution is observed when decreasing the incidence angle down to 28 degrees. The best values of Δz and $\Delta z/z$ obtained at the smallest angle (28°) of Ar^+ ions incidence can be explained taking into consideration the above phenomena. It has been experimentally demonstrated that surface roughness induced by sputtering process, atomic mixing and shadowing that have detrimental effects for the depth resolution and the relative depth resolution can be minimized using a low ion beam incident angle if the sample surface is relatively rough [1].
An Atomic Force Microscope (AFM) has been used to attain information about surface roughness of the samples. Before etching, preliminary results show, for all the samples, a relatively smooth surface (< 10 nm) that is in agreement with the previously statement. For the following reasons a thorough examination of surface roughness and sputtering-induced effects is though required since they are considered one of the most important causes of degradation of the depth resolution [1,9].

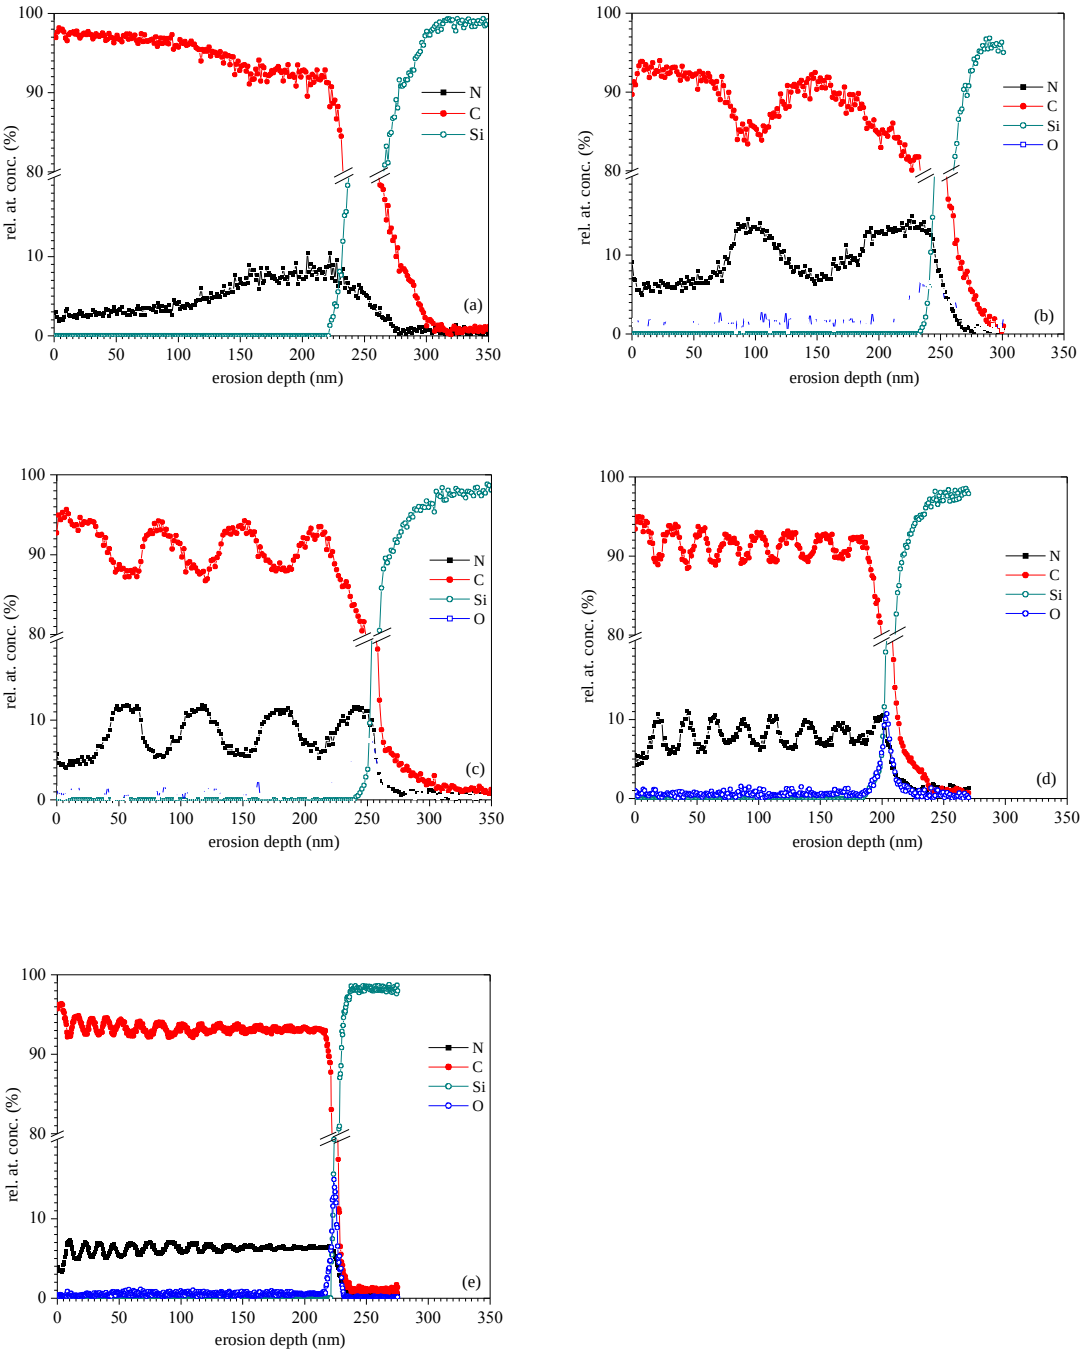

Fig. 3 AES depth profiles of the C/C:N multilayer samples on silicon: (a) 2 layers, (b) 4 layers, (c) 8 layers, (d) 16 layers, (e) 32 layers. All measurements were acquired using a 3 keV, 8.75 10^{-4} Acm^{-2} current density electron beam. Alternating mode sputtering was performed with a 2 KeV, 800µm diameter ion beam which rastered over a 1x1 mm^2 area and the samples were tilted to obtain a 28° ion beam glancing angle respect to the surface sample.

Experimental ion gun set-up which have been adjusted in order to achieve an optimization of Δz and Δz/z parameters on the reference material, low ion beam energy (2 keV) and 28° argon ions incidence angle with respect to the sample surface, have been consequently used to perform the Auger depth profiles on the multilayered structured C/C:N samples.In order to obtain a satisfactory number of C/C:N profile data points, the etching time between two acquisitions during the depth profile has been also reduced from 0.5 to 1.0 min when analyzing the more structured samples (16 and 32 layers).The Auger depth profile raw data expressed as elemental intensity signal as a function of the sputtering time has to be converted to a more universally used in-depth quantification image: elemental composition versus erosion depth. Figure 3 shows the Auger depth profiles through the 2, 4, 8, 16 and 32 C/C:N multilayer samples after conversion of the sputtering time to eroded depth. The Y axis has been expanded in order to emphasize the elements signals trend and to get a better visualization of the layers definition.

In first approximation we have assumed a constant sputtering rate through the depth profile but obviously this estimation may be liable to systematic errors due to both the accuracy of total film thickness measurement using the mechanical stylus ()and the different sputtering yield when analyzing not uniform matrix [1].

In all depth profiles the alternating layers are satisfactorily well defined and this is also confirmed by the normalized amplitudes of I_m/I_0, calculated for every single layer of the structure which shows values that are in agreement with the definition of good in-depth multilayer resolution given in literature [1,4]. In a structured sample with constant single layers thickness the depth resolution in fact may be evaluate by the decreasing of I_m defined as the difference between the maximum and the minimum signal on the both side of an interface, compared to I_0, which is the maximum intensity of the signal (fig. 4a). I_0 has been here defined as the average value calculated on the first carbon layer since t Nitrogen is present, in an oscillatory trend, all through the depth profile. The more reasonable explanation of this effect could be given by the presence of N_2 residual gas in the deposition chamber and the diffusion and mixing phenomena during the layer deposition process.

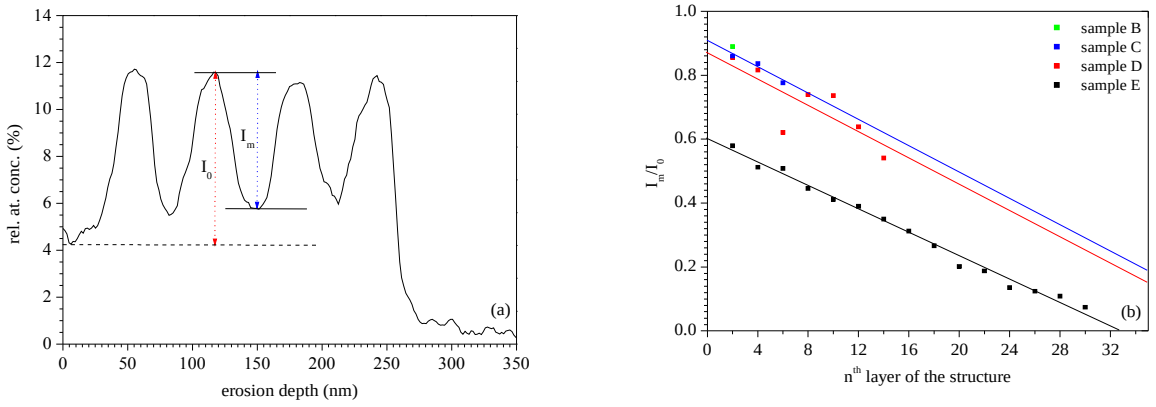

Fig. 4 Schematic picture of the determination of the resolution in a multilayer structure as I_m/I_0 ratio calculated on the Nitrogen profile (a) and evolution of the I_m/I_0 ratio through the multi-layer samples.
B, C, D, E: refer to the samples described in Table 1.

Regarding the analyzed I_0 and I_m may be obviously evaluated only when the number of layers is more than 2. A I_m/I_0 decreasing trend is observed (fig. 4a) when increasing the number of layers and this is an indication that the depth resolution deteriorates with the number of layers. This trend could be better observed in figure 5b where the I_m/I_0 final and the initial ratio has been represented for each

sample as a function of the total number of layers. Up to 16 layers this value is remarkable larger than 0.5 and this is a good indication of well defined adjacent layers. For sample DE (7nm half-period), the resolution is still maintained ($I_m/I_0 > 0.5$) up to 6^{th} layer of the structure, after which it falls drastically.

4. Conclusion

In this work we have optimized the Auger analysis depth resolution parameters (Δz and I_m/I_0) on a number of multilayer structured samples consisting of a sequence of hard and soft thin carbon films on a silicon substrate. Incident ion beam angle and ion beam energy used for the film in-situ erosion during the analysis have been appropriately chosen in order to achieve a good in-depth film-substrate (< 10 nm) and interlayer resolution. Even in the 16-layers structured sample good results have been obtained and every single layer (12 nm thick) could be easily defined with a good degree of accuracy. Measurements have been also performed on a more structured system (7 nm half-period). The depth profile shows satisfactory results as to the Δz but further experiments have to be done in order to improve the I_m/I_0 ratio and the interlayer resolution. Data are not presented in this work as a more detailed evaluation of the factors and experimental conditions which influence the resolution parameters have to be considered.

Abstract
Hydrogen enriched premixed methane combustion was investigated using a compact burner set-up with an integrated plasma reforming unit. A part of the fuel is transformed to syngas by a gas discharge in a fuel rich mixture and then added to the very lean methane air mixture before combustion. The hydrogen enrichment has a strong influence on the combustion behavior with regard to flame stability and flame offgas composition. The blow-off limit could be extended from an air number of 1.67 without plasma application to 2.01 with plasma.

Keywords
methane combustion, hydrogen enrichment, plasma reforming, flame stability, emissions

1. Introduction

Natural gas plays an important role as a fuel in combustion processes for power generation, e.g. in gas turbines, and for other industrial applications. Due to the increasing restrictions regarding the emission of noxious pollutants, huge investments are made in order to improve current combustion technology and fulfill those requirements.

Characteristic properties of hydrocarbon combustion such as efficiency, flame stability, emission of unburnt fuel and pollutants, which are formed in the flame, depend strongly on the relative air-to-fuel ratio, which is also referred to as air number. But there is a trade-off between some of these properties. For example, increasing the air-to-fuel-ratio can reduce pollutant emissions, but at the same time reduces the flame stability.

Various approaches to increase flame stabilization at high air-to-fuel ratio have been made by fluidic means with a co-axial jet flame burner for highly turbulent premix flames [1], by application of electric fields [2,3] and by generating electrical discharges in the flame [4,5]. The difference between the two latter methods is whether the electric field strength is kept below the breakdown value or not. In the first case, the electromagnetic forces act only on the radicals formed in the flame by chemoionization, whereas in the second case charged particles are generated additionally by gas discharges and the effect on the combustion characteristics is much stronger in general.

Hydrogen combustion differs considerably from methane combustion due to a much broader flammability range and a higher flame speed. Even the addition of a few percent hydrogen to methane fuel can improve the combustion characteristics significantly [6]. Hydrogen can be generated from methane and oxygen or water vapor in a catalytic reaction or by plasma treatment. Several plasma techniques have been studied for hydrogen generation from hydrocarbons ranging from dielectric barrier discharges, spark discharges, electron beam, gliding arc and microplasmatron discharges [7-9]. It has been shown that among plasma methods the most efficient are those with high power density and a certain gas heating capability.

The aim of this work was to combine a methane premix burner with a plasma methane reformer to improve the combustion by in situ hydrogen generation, with special regard to blow-off limits and pollutant emissions. The work was divided into two parts. The first one consisted of designing and testing a plasma reactor producing a gas discharge of the gliding arc type in a coaxial configuration, with the intention of finding the most appropriate operating condition. The second part of the work consisted of the integration of the plasma reforming unit in a gas burner and testing by measuring the blow-off limits, pollutant emission and evaluation of the plasma input power in comparison to the thermal input power of the combustion process.

2. Experimental

The heart of the experimental set-up was a burner with an integrated plasma reforming reactor assembled in a coaxial configuration which is sketched in Fig. 1. The plasma unit was removable in a way that a separate characterization and optimization of the reformer could be done. The advantages of this integrated configuration of the reforming unit inside the burner are on the one hand the compact structure of the set-up and on the other hand the fact that the heat energy which is released from the plasma reformer and which would otherwise be lost can be recovered by the lean gas mixture passing the reformer unit.

The plasma reformer consisted of a tubular housing with 10 mm o.d., 8 mm i.d. and a lateral gas inlet for the rich methane air mixture to be treated in the plasma. A section at the downstream end of the housing had a narrower inner diameter of 2.2 mm with a diverging axial gas outlet. A stainless steel wire electrode with 1.5 mm diameter insulated by a ceramic tube was placed in the center of the housing with one end protruding into the narrower section forming the beginning of the discharge zone between the electrode tip and the grounded housing with a gap of 0.35 mm. The high voltage power supply was connected to the back end of the electrode outside the housing. A baffle plate in front of the reformer outlet facilitated the slowing of the plasma flow by diverting it to a radial direction. This way, the treated gas gets mixed with the lean mixture flowing up from the bottom of the burner.

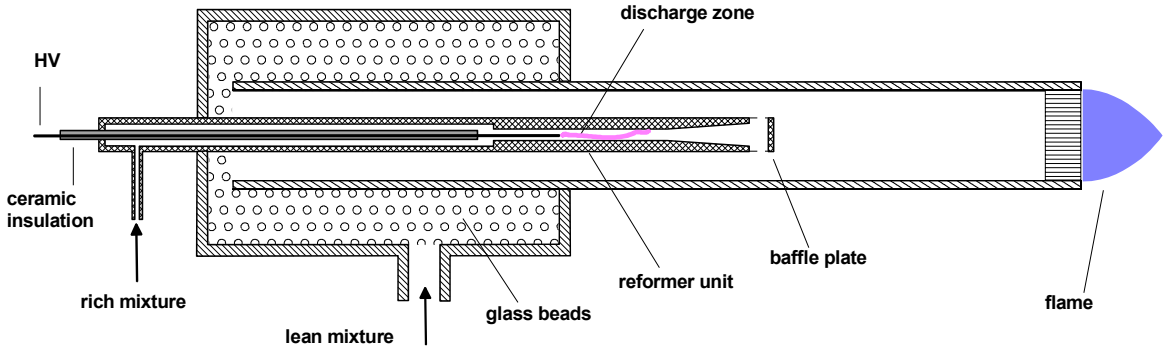

Fig. 1: Burner with integrated plasma reforming unit

The burner was made of a stainless steel tube with 240 mm length and 22 and 25 mm inner and outer diameter, respectively. A perforated plate is located at the outlet of the burner in order to stabilize the flame. The open back end of the burner tube is inserted into a container which has an inlet opening for the lean methane air mixture. The container is filled with glass beads in order to achieve a homogeneous gas distribution all over the cross section of the burner.

A dc power supply (9000-6K-2000 from EA-Elektro-Automatik) was used in the experiments with maximum voltage and current output of 6 kV and 350 mA respectively. It is equipped with an internal electronic system which allows limiting the current and thus the electrical power applied to the gas stream. Voltage and current measurement were performed by means of an 11 kΩ shunt resistor between the power supply and the reactor and two HV probes (LeCroy) connected to a digital storage oscilloscope (LeCroy Waverunner 6030, 2.5 GS/s).

Methane (99.995 %) from gas cylinders as well as O_2 and N_2 from the in-house pressurized-gas network was used for the experiments. The gas flows were adjusted using mass flow controllers (MKS). Samples of the off gas were drawn for analysis, in the case of the open burner flame from a point about 20 cm above the burner head, and piped through heated tubes to the analytical instruments without removing water or other condensable compounds. An FTIR spectrometer (Bruker Tensor 27) with a heated long way gas cell was used to measure the concentrations of CH_4, CO, CO_2, NH_3 and HCN. During plasma reformer characterization a Shimadzu GC-14B gas chromatograph was used to measure the concentrations of H_2, N_2, O_2, CH_4, C_2H_2, C_2H_4, C_2H_6, CO and CO_2. The concentration of NO_x in the burner off gas was measured with a flue gas analyzer based on electrochemical sensors (Testo 300 XL).

3. Results and Discussion

Three different gas mixtures (λ=0.4, 0.5 and 0.6) were tested under different gas flow rate in the range between 2 and 4 l/min (STP) and mean discharge current values between 50 and 100 mA corresponding to electrical power values of 45-75 W. With these air number values of the feed gas, the stoichiometry is between that of partial oxidation to syngas and complete combustion, so a mixture of carbon monoxide, carbon dioxide, hydrogen and water could be expected as reaction products. In fact, only CO, H_2 and H_2O were formed to a major extent, whereat the latter could not be quantified reliably. However, carbon dioxide appeared only in traces, as well as C_2 hydrocarbons (< 0.5 %), ammonia and hydrogen cyanide (< 100 ppm each).

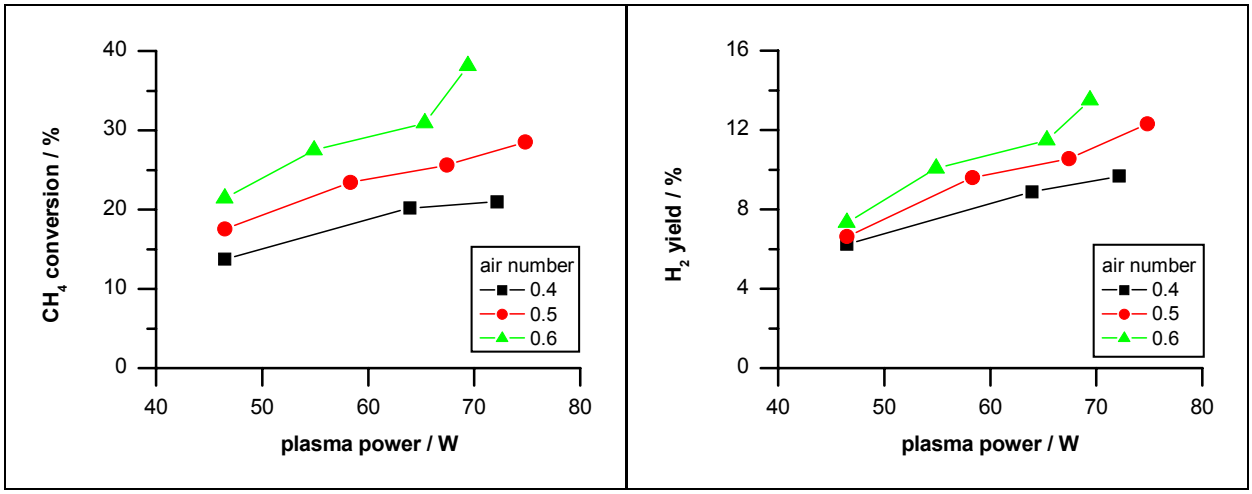

Fig. 2: Influence of plasma power and air number on methane conversion and hydrogen yield

Fig. 2 (left) shows the influence of plasma power and air number λ on the methane conversion at a total gas flow of 3.4 l/min. Methane conversion shows a growing tendency with rising electrical power. The results can be explained in terms of a higher amount of energy transferred to the gas flow, which allows the reaction of a larger amount of methane. Also an increasing air number leads to increasing methane conversion, not only in relative terms as displayed in the diagram but also in absolute terms, i.e. the decreasing methane concentration cannot explain this increase. It is rather due to a higher reaction enthalpy of the leaner mixture, which results in a higher gas temperature in the reaction zone.

The corresponding hydrogen yields are shown in Fig. 2 (right). With regard to the air number, the results show that the yield improves when excess air is supplied. It must be taken into account that since the composition was varied while the gas flow was maintained constant, methane concentration in the gas feed varied from experiment to experiment. Therefore, the influence of the air number on the hydrogen yield is not as strong as shown in Fig. 2 (left). While H_2 selectivity is about 50 % for λ=0.4, it decreases to below 40 % with λ=0.6. However, with regard to the generated hydrogen amount, it can be affirmed that the yield increases with growing air number.

Compared to the H_2 yield, the CO yield was almost twice as high over the whole range of reaction conditions; in other words, the carbon selectivity of CO reached almost 100 %.

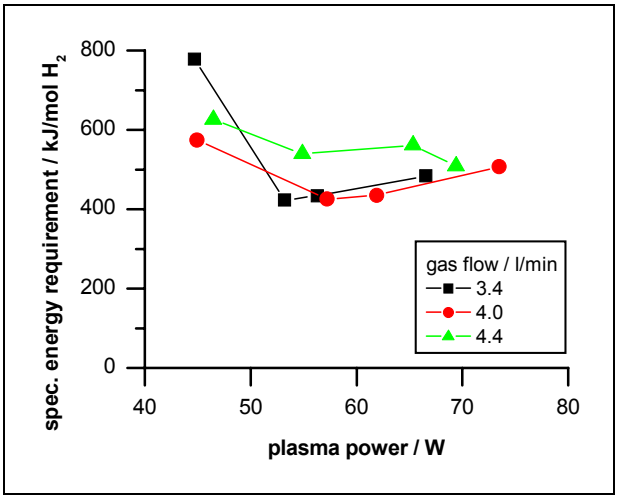

Fig. 3: Specific energy requirement for H_2 formation depending on plasma power and gas flow (λ=0.6)

The energy requirement for the hydrogen generation has been also studied, the influence of plasma power and gas flow are shown in Fig. 3. A decreasing tendency with increasing electrical input power is observed, but above 50 W the three studied gas flow values seem to reach a plateau between 400 and 600 kJ/mol, being somewhat higher at the highest gas flow. At electrical input power below 50 W the energy requirement is also higher. This is attributed to the fact that methane conversion (between 20 and 30 %) and hydrogen yield (between 6 and 9 %) do not reach very high values. This led us to work subsequently at higher electrical power values (current limited to 70 and 90 mA) in order to minimize the energy requirement.

It can be concluded that it is reasonable to work under the conditions which permit the highest hydrogen yield and methane conversion with the lowest possible energy requirement. These requirements are fulfilled under operating conditions with an air number of 0.6, a gas flow of 3.4 l/min and an electrical input power of about 55 W. The electrical input power was subsequently varied to study its effect on the blow-off limits of the combustion process, the above-mentioned conditions are the most adequate to continue the work.

A series of experiments has been carried out with lean methane-air flames in the presence and absence of a plasma in order to establish a comparison between both states, with special regard to blow-off limits, unburnt methane as well as CO and NO_x emissions. Since the methane flow rate was kept constant, the air number increase from experiment to experiment was made by raising the air flow rate and thus increasing the flow velocity. The experimental set-up permitted the air entrainment, which caused a dilution of the exhaust gas. The values of the offgas concentrations have been corrected by individual factors obtained from calculating the carbon balance.

Various series of experiments were carried out to study the influence of the electrical input power on the extension of the flammability limits. The procedure was the following: the flame was ignited at $\lambda = 1.2$ and subsequently – except in the first series – the power supply system was connected in order to ignite the discharge and then the air flow was continuously increased until the extinction of the flame. The overall air number is calculated for fuel and air of both, inner (plasma) and outer flow together.

The highest achievable air number (blow-off limit) without plasma reforming reaches 1.67 under the given experimental conditions. When a gas discharge was applied the blow-off limit increased linearly with increasing plasma power up to an air number of 2.01 with 56 W. This corresponds to 8.5 % of the thermal power of the flame, which was calculated to be 663 W, based on the higher heat value.

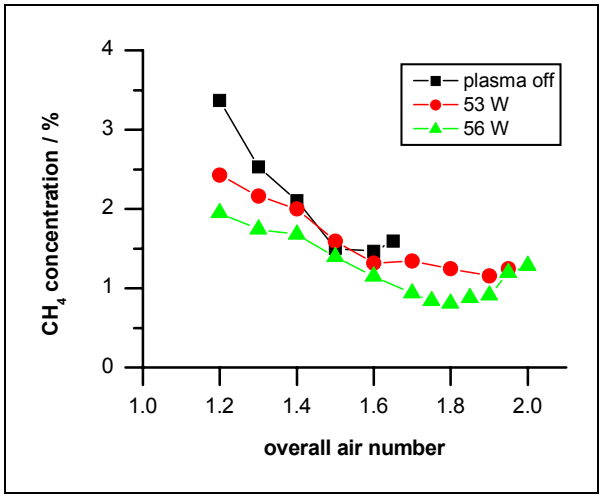

Fig. 4: Concentration of unburnt methane in the flame

The concentration of residual methane, which is measured in the offgas, is displayed in Fig. 4. It is observed that the methane concentration decreases in general with increasing plasma power. This is on the one hand due to the fact that a part of the methane from the inner flow reacts in the reforming unit; on the other hand, the increase in burning velocity in the presence of plasma causes better methane utilization and thus lowers its concentration in the exhaust gas.

With increasing air number the concentration of unburnt methane decreases corresponding to a lower methane concentration of the starting mixture. However, just below the blow-off limit, it rises again forming a minimum in the curve, which lies at $\lambda = 1.8$ at a plasma power of 56 W.

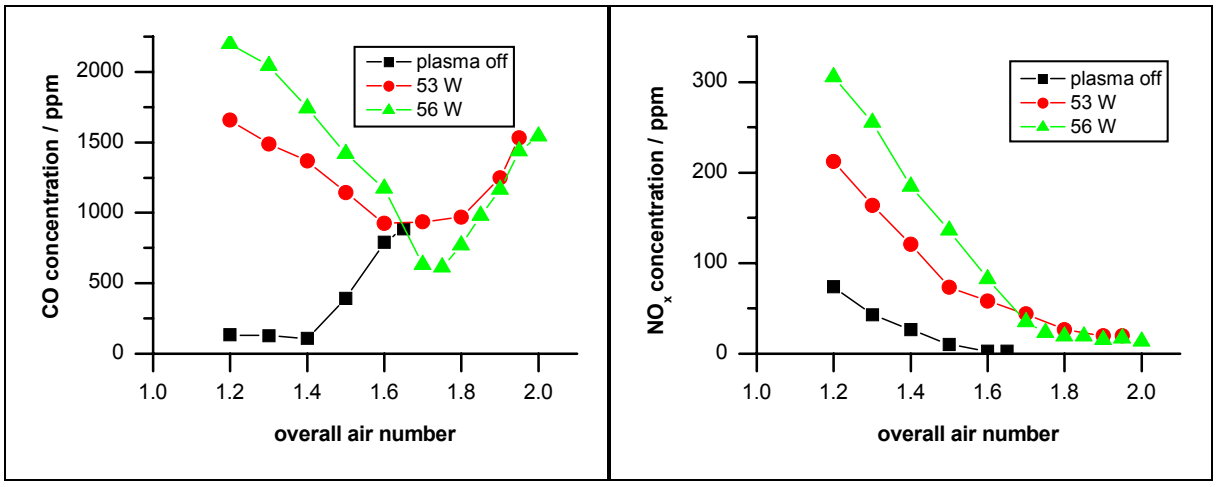

Fig. 5: Concentration of carbon monoxide and nitrogen oxides in the flame

The concentration of carbon monoxide and nitrogen oxides in the flame offgas is represented in Fig. 5 in dependence on the overall air number and plasma power. Without plasma operation the CO concentration remains at a constant and low level of about 100 ppm as long as $\lambda < 1.4$. Nevertheless, at higher air numbers the CO concentration rises rapidly. The reason can be sought in the increasing dilution with air, which reduces the flame temperature and therefore the reaction speed, so that CO cannot be oxidized completely.

In the presence of plasma, the CO concentration is very high at low air numbers, the higher the plasma power the higher the residual CO concentration. This is obviously an effect of the high amount of CO formed in the plasma. However, at $\lambda = 1.6$ approximately, the three curves intersect and the 56 W curve decreases further to

reach a minimum value at about $\lambda = 1.7$. Here the increase of the reaction velocity due to hydrogen combustion could compensate the high feed flow of CO due to plasma reforming.

NO_x emissions show the same tendency without plasma and with varying plasma power applied: a continuous decrease at rising air numbers. This is due to a dilution effect caused by the increase of air flows with growing air number. Moreover, since a higher air flow reduces the combustion velocity and thus also the heat release, the flame temperature decreases. Since the most important NO formation mechanism is that the thermal NO, which, as mentioned, takes only place at very high temperatures, a great part of the emissions could be eliminated by lowering the combustion temperature.

Although the blow-off limits are extended in the presence of plasma, a comparison between the two cases shows that NO_x emissions are always higher than without plasma. This can be mostly attributed to an increase in the burning temperature caused by the additional electrical energy input of the gas discharge and the higher total methane conversion. On the other hand, NO can be generated by the oxidation of ammonia and hydrocyanic acid formed in the plasma reforming step (prompt NO_x).

4. Conclusion

Hydrogen enrichment of lean methane premix flames is a powerful instrument to influence and control the combustion behavior. By integrating a plasma reformer into the burner, the hydrogen enrichment can be done in a compact and flexible way and allows the control of the flame properties with a very low response time. Furthermore the heat loss in the reforming step can be immediately recovered by the lean air mixture.

Blow-off limits can be extended proportionally to the applied discharge power up to values higher than 2, which gives a high flexibility in the choice of operating conditions for the combustion process. The electric power necessary for plasma generation amounts to a maximum of 8.5 % of the chemical input power which is determined by the heat value of the fuel. The emission of unburnt methane can be reduced by nearly a factor of 2, whereas CO and NO_x emissions are higher, at least in the low air number range. An optimum operating point with regard to fuel utilization and reduction of noxious emissions is at an air number 1.8.

Abstract
A newly approach to the hydrogen recovery from methane by a cusp plasma device is presented. The cusp magnetic geometry is attractive because its high stability on plasma confinement. The paper comments the preliminary results regarding the CH_4 conversion and H_2 selectivity rates (up to 98% and 49% respectively) for different gas mixtures (90-10% to 10-90% of Ar-CH_4) at different fluxes (from 10 to 30 cm^3/min). A study of the influence of the magnetic field is presented too. Future improvements regard the application of an rf signal to increase the hydrogen selectivity, besides the use of a membrane in the plasma phase to recovery the converted H_2 is proposed.
Keywords: methane conversion, hydrogen production, plasma, cusp confinement.

1. Introduction

Hydrogen is supposed to have an important role in the future worldwide energy vector supply and environmentally safe technologies. In the last years plasma has becoming a great alternative for hydrogen production [1]. The addition of a static magnetic field increases the particle confinement time and, consequently, the hydrogen production rate. In this view a plasma device with a cusp magnetic field configuration has been built to investigate the cracking of methane in a plasma environment.
The cusp magnetic configuration approach is very attractive for the purpose of cracking of methane; it has a very simple geometry and the high magnetohydrodynamic stability of the plasma allows to obtain high plasma concentrations with a high dissociation of the CH_4 molecules, besides technique for plasma processing (e.g. radiofrequency ion plugging [2] or hydrogen recovery by permeation membranes [3]) can be easily combined in order to increase the confinement time and allow the recovery of the converted H_2 , they are proposed as improvements of the device.

Here the preliminary results concerning the dissociation of methane in the cusp plasma, measured by quadrupole mass spectrometers and an optical spectrometer, are presented. A large fraction of the converted methane has been deposited along the line cusp vacuum wall as amorphous carbon (a-C) film. The surface morphology of the film has been observed and the results indicate that the film has a prevalently amorphous structure with a significant presence of crystalline clusters.

2. Experiment layout

The experiments have been carried out on the cusp plasma device, developed at the Institute of Plasma Physics in Milan. The cusp magnetic field configuration is obtained by two identical bundles of coaxial solenoids where each bundle carries the same electric current intensity but with opposite directions. The static magnetic field can reach a maximum intensity of 0.5 T at the point cusp and 0.3 T at the line cusp. The experimental apparatus with the vacuum system is shown in Figure 1 (the electromagnets are depicted in dash lines).

The plasma source (labeled PS in the figure) is located at one point of the cusp and is fed with gas (a mixture of Ar and CH_4) through a mass flow controller (FC, model MKS M-200) that maintains a discharge pressure between 10^{-3} and 10^{-2} mbar under a flow rate spanning from 2 to 40 cm^3/min (NTP). The plasma source is a cylindrical rf capacitor composed by an inner tube with 10 mm diameter, 460 mm length, and an outer electrode (ground) represented by the vacuum chamber tube (internal diameter of 60 mm). The plasma source is powered by a commercial 13.56 MHz rf generator with a maximum power of 300 W (Huttinger mod. PFG 300 RF) connected to an automatic impedance matching network. Additional rf power can be coupled to the plasma by means of two ring-shaped electrodes (RSE) which enclose the thin plasma located at the line cusp.

At the second point cusp, opposite to the plasma source, is situated a permeation membrane holder (PR), which is placed at a proper distance from the cusp centre, to allow the plasma, enriched in hydrogen atoms, to strike on the membrane itself. The holder is arranged to mount a 60 mm diameter membrane and is provided with heaters and a thermocouple to monitor the membrane temperature. The permeation membrane is supposed to have a selectivity for hydrogen only (see section 6).

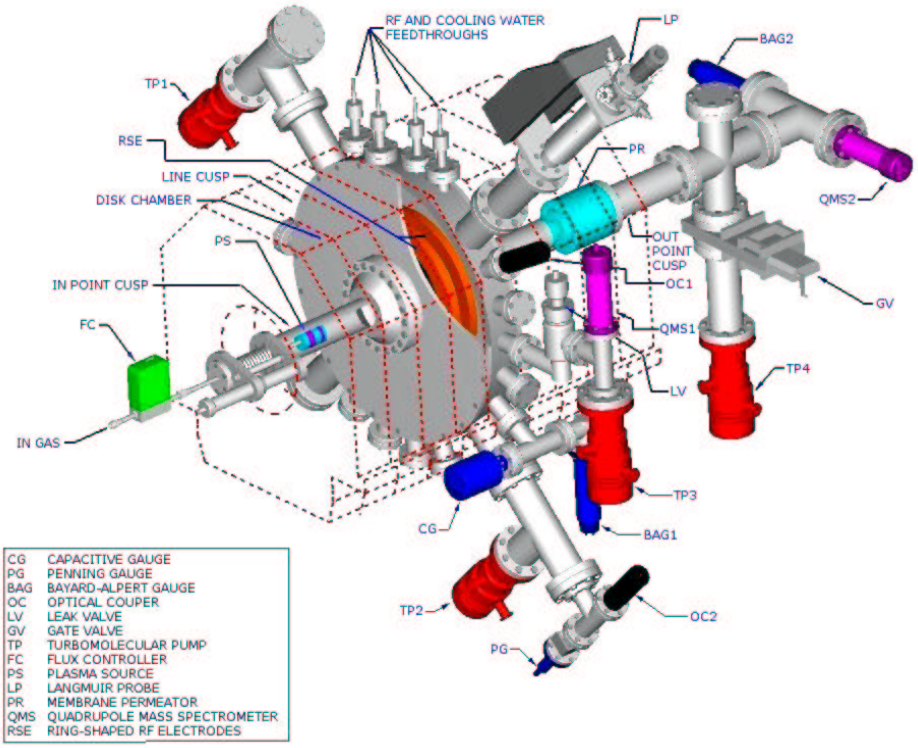

Figure 1 3D layout of the apparatus.

The total pressure in the line cusp chamber is determined by a hot cathode gauge (BAG1) type Bayard-Alpert and by a capacitive manometer (CG) with measuring ranges from 10^{-7} to 10^{-3} mbar and 10^{-3} to 10 mbar respectively. A Langmuir probe (LP), located near the rf ring plates, provides plasma parameters as the electron temperature and the plasma density.
Spectral lines intensities, emitted from the plasma, are provided by a VIS-NUV optical spectroscopy (OC1), model Triax 320 – Jobin Yvon. In particular, the optical collimator OC1 collects the light radially emitted from the centre of the cusp.
The gas composition at the exits of the line cusp chamber and at the second point cusp can be determined by two quadrupole mass spectrometers (QMS1, QMS2) type Balzers QMA 125 adequately screened against the magnetic field [4]. Here gas samples from the cusp chamber are admitted by means of leak valves to the quadrupole volumes; additional turbomolecular pumps provide the gas pumping in these volumes.
Films of the deposited hydrocarbon are obtained from a specimen holder located along the line cusp.

The device is taken under vacuum by two 60 L/s and one 230 L/s single rotor turbopumps. The two 60 L/s (TP1 and TP2) are located at the line cusp and the other pump (TP4) at the second (exit) point cusp.

3. Experimental procedure

The quadrupole mass spectrometers (QMS1, QMS2) are here used for a quantitative analysis of the conversion of methane to hydrogen by measuring the gas partial pressures in the cusp chamber volume (CV). The quadrupoles have been calibrated (determination of the characteristic spectra) for the gases of main concern: hydrogen, argon and methane; while the characteristics spectra of other gases have been taken from literature data. The acquired mass spectra have been analyzed by a multiple linear regression

algorithm that at first automatically detects the gases present in the volume, successively it calculates the gas partial pressures [5].

Before the experiment the CV was pumped at a base pressure of nearly 10^{-7} mbar, the quadrupoles measurements indicate a residual gas composition mainly of water and smaller amounts of CO, CO_2 and hydrogen. Next a known gas mixture of argon and methane is injected inside the source region of the CV volume at a constant flow rate. Quadrupole measurements in these conditions give the reference composition of the introduced gas before the plasma conversion of methane.
Since the methane cracking phenomena is influenced by several parameters (characteristics of the inlet gas mixture, generated plasma and cusp magnetic configuration), some introductory experiments have been performed to maintain nearly constant the influence of the applied static magnetic field (SMF) against the variation of the other parameters. The results are showed in Figure 2 where QMS1 detected ion currents are given respect to the SMF intensity at the point cusp. The detected H_2 signal increases with the SMF intensity and reaches a nearly constant value for SMF larger than 0.1 T; this behavior agrees with the similar decreases of the CH_4 signal. In the following duties, the SMF has been fixed to 0.2 T at the point cusp.

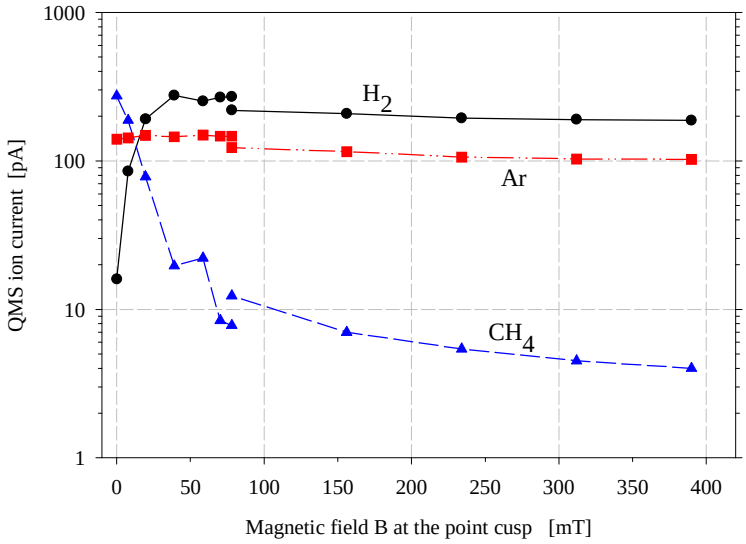

Figure 2 QMS1 detected ion current versus the SMF applied for a mixture of 50% Ar and 50% CH_4. The gas flux is 2 cm^3/min with an rf plasma source power of 100 W.

4. Results and discussion

Plasma parameters have been calculated from Langmuir probe data. The traditional analysis of the voltage-current characteristic has been revised to include the influence of the static magnetic field.
Reliable results have been obtained with argon plasma, since the presence of methane determines a contamination of the probe by carbon deposition. The computed electron temperature is comprised between 5-10 *e*V and the plasma density is within 10^8 - 10^9 cm^{-3}.

The conversion of methane to other compounds is defined as:

$$CH_4 \text{ conversion } (\%) = (\text{moles of } CH_4 \text{ decomposed / moles of } CH_4 \text{ injected}) \times 100. \quad (1)$$

Assuming small differences between the gas temperature with and without the plasma and assuming the hypothesis of perfect gas, the above relationship can be written again in terms of methane partial pressures P_{CH4}:

$$CH_4 \text{ conversion } (\%) = (1 - P_{CH4}/P^0_{CH4}) \times 100 \quad (2)$$

where P^0_{CH4} is the methane partial pressure calculated in absence of plasma.
The conversion of methane to hydrogen is expressed by the hydrogen selectivity according to:

$$H_2 \text{ selectivity} = (\text{moles of } H_2 \text{ produced} / (2 \times \text{moles of } CH_4 \text{ decomposed})) \times 100. \quad (3)$$

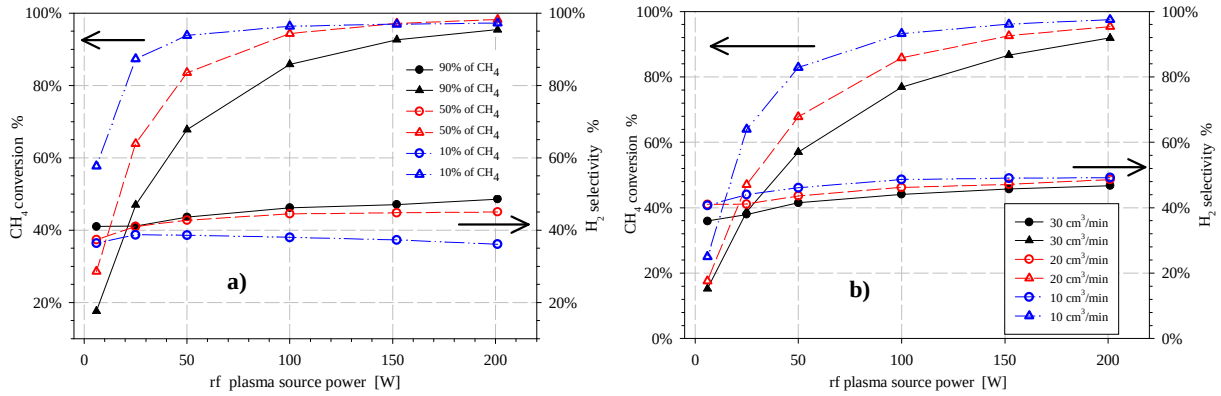

Figure 3 CH_4 conversion (left axes) and H_2 selectivity (right axes) for: a) different inlet gas mixtures at a constant flux of 20 cm^3/min; b) different fluxes of inlet gas mixture at a constant concentration of 10% Ar and 90% CH_4.

The CH_4 conversion and H_2 selectivity are shown in Figure 3a as function of the applied rf power for a constant inlet flux of 20 cm^3/min. At constant rf power discharge, the methane conversion increases with the concentration of argon of the introduced gas mixture. Qualitatively this occurrence can be ascribed to a high concentration of argon atoms in a metastable state [6]. These atoms are characterized by a lifetime comparable or longer respect to the gas or ions collision times. The quenching of the metastable atoms occurs mainly by collisions with methane molecules, with the dissociation of methane in hydrogen atoms and molecules plus methane radicals. Argon metastable states are generated by electron impact excitation.
All these reactions have rates proportional to the electron and argon densities. Besides the SMF configuration of the plasma contributes to increase the overall hydrogen production by expanding the reaction volume (plasma volume) and the confinement time of ions and electrons.
The results in Figure 3a show that above 150 W the methane conversion approaches to 85% while the hydrogen selectivity is less dependent on the rf power and it is comprised between 35-45%. Besides mass spectrometers results have indicated that acetylene and other alkenes compounds are formed, only at high methane flow rate, with concentrations less than 1%.
Figure 3b reports the data relative to an initial 90% CH_4 – 10% Ar gas mixture at different inlet mass flow rates. The methane conversion increases as the gas flow is diminished, that can be supported by a longer residence time of the gas mixture in the plasma volume at lower mass flow rates.

The results from optical spectroscopy are shown in Figure 4 relative to the same set of measurements of Figure 3. The hydrogen emission line at 656.2 nm (H_α of Balmer series) increases with the applied rf power and with the methane concentration in the inlet gas mixture, besides it remains always higher respect to the molecular hydrogen emission line (463.4 nm) which exhibits a less dependence on the applied rf power. Although, from these data, it is not possible to discern the content of atomic hydrogen respect to molecular hydrogen; the results suggest that the applied rf power (in addition to enhance the reactivity in the plasma with a consequent increase of the methane conversion), enriches more and more the concentration of atomic hydrogen of the plasma which is favorable for the foreseen upgrade of the experimental device with permeation membranes working in the plasma phase (see section 6).

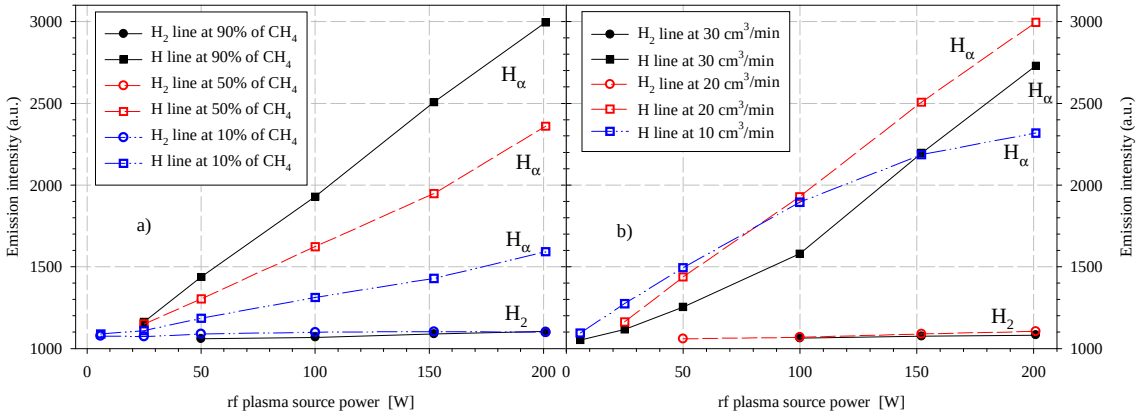

Figure 4 H_α (656.2 nm) and H_2 (463.4 nm) emission lines for: a) different inlet gas mixtures at a constant flux of 20 cm^3/min; b) different fluxes of inlet gas mixture at a constant concentration of 10% Ar and 90% CH_4.

5. Film deposition

A large flux of energetic neutral particles, ions, and thermal radicals is produced and escape from the magnetic field along the line cusp. A portion of such flux has been deposited, as a thin film, on the target/sample mounted along the line cusp.

Observations on the films, by a Fourier Transform Infrared Spectroscopy (FTIR) analysis, showed that a fraction of the converted methane was deposited on the samples as amorphous carbon (a-C) film. In order to investigate the films characteristics and the deposition proprieties, the surface morphology of the films have been examined by scanning electron microscopy (SEM), see Figure 5, while the transmission electron microscopy (TEM) has been used to determine the structure of the films. The results indicate that the films have a significant presence of crystalline clusters embedded in the amorphous structure.

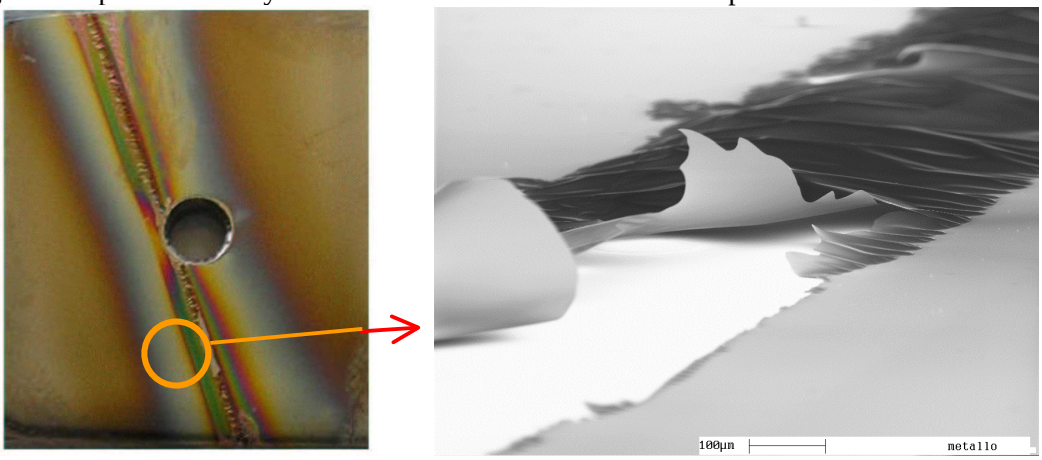

Figure 5 Film deposited on the sample (left) and the enlargement of the rounded particular (right) obtained by SEM.

6. Future improvements

After the preliminary tests on the plasma device here presented, some improvements are under way. They regards: increase of the hydrogen ions confinement time by rf coupling to the plasma and the recovery of hydrogen by means of permeation membranes.

An additional rf signal can be applied to the plasma by the ring-shaped rf electrodes (RSE in Figure 1) which are powered by a broad band rf generator at a frequency close to the ion cyclotron frequency of hydrogen. The rf field generated by the electrodes will be perpendicular to the plasma disk of the line cusp and, according to the theory [7], a repulsive ponderomotive force (directed from the line cusp to the cusp

centre) acts on the plasma species depending on their mass to charge ratio. It will be possible increase the concentration of hydrogen ions against other ions species.
A niobium superpermeable membrane can be mounted inside the permeation holder (PR) at the exit point cusp. This kind of membrane, that can be heated at a temperature around 400 °C, has a high permeation coefficient for *atomic* hydrogen (almost the whole flux pass through the membrane) and negligible for the other species. Moreover, a partial poisoned surface (e.g. with monolayer of deposited carbon atoms) has a beneficial effect to increase the hydrogen atoms permeation [3,8]. The membrane in touch with the plasma is a great way to separate the hydrogen atoms from other particles before their recombination outside the plasma phase.
The increase of the plasma characteristics, density and degree of ionisation, will be achieved by a new plasma source antenna powered at a higher rf frequency (40.68 MHz). The source will allow to operate at higher gas flow rates respect to the values here investigated, in this conditions it is expected a further increase in the methane conversion efficiency.
Besides more advanced diagnostics (e.g. ion mass spectrometer with ion energy analyser, and gas chromatograph) will allow a more comprehensive analysis of the methane cracking phenomena.

7. Conclusions

The plasma device, here proposed, for the decomposition of methane and the hydrogen production presents many advantages:

- a high reaction rate which is enhanced by the cusp magnetic confinement;
- the presence of water and oxygen in the system in negligible quantities exclude the formation of greenhouse gas (like CO_2) by methane steam reforming reactions;
- since the device is based on a physical principle, the possibility to operate with other gases; e.g. hydrogen formation from water vapor.

The results, here presented, may be considered preliminary since they are limited to a low methane flow rate regime. The most significant achievements are: methane decomposition higher than 90% and hydrogen selectivity close to 50%

Some upgrades of the experimental device are in realization, they will allow: to operate with higher plasma densities (and with higher inlet gas flow rates) and to increase the selectivity and production of hydrogen. One improvement employs rf coupling to the plasma to increase the confinement time of hydrogen ions. Another improvement takes advantage of the composition of hydrogen plasmas that present a high content of hydrogen in atomic form. In this case the use of superpermeable membranes will increase the selectivity of hydrogen thanks to their high permeation rate for atomic hydrogen, and no-permeability respect to other gases.

Abstract
It is reported about the results of studying the stationary non-self-sustained discharge controlled by a fast electron beam in atomic and molecular gases containing dusty particles of microns in size. It was predicted and experimentally found that there occurred the formation of stable dusty structures in this plasma. Modelling of the non-self-sustained gas discharge has been performed according to the non-local transport model of plasma charged particles with electron diffusion taken into account.
Keywords: dusty plasma, e-beam ionization, non-self-sustained discharge, cathode sheath.

1. Introduction

At present, small-sized 1 – 10 kW autonomous sources of electric energy with an operating lifetime of the order of several years are in demand. Such sources are needed for electric power supply of spacecraft, automatic weather stations, antisubmarine buoys, and for other similar users [1]. At present, such sources are provided by photoelectric converters of solar energy, thermoelectric sources with fuel elements of Sr^{90}, Pu^{238}, or Po^{210}, and thermionic converters with a U^{235} reactor used as a heat source. All of these sources suffer from a number of disadvantages; in particular, they have a very low efficiency. In addition, a nuclear reactor is very complex in fabrication.

Given in this paper are the results of investigations aimed at developing the physical principles of a current source for nuclear-to-electric energy conversion. It is suggested to accomplish this conversion owing to the photovoltaic effect in wide band-gap semiconductors based on CVD of diamond and boron nitride. The operating principle of the novel atomic battery is as follows [2]. High-energy particles, which are formed during decay of radioactive materials in the form of dust grains, ionize an inert gas such as xenon at a pressure of about an atmosphere or higher. The dissociative recombination of formed diatomic xenon ions results in an effective excitation of xenon excimers which emit vacuum ultraviolet (VUV) photons with a wavelength of about 172 nm. These photons fall on a wide band-gap diamond-based photoconverter and generate electron-hole pairs which are separated and develop an electromotive force. Estimates indicate that the total efficiency of a battery utilizing this principle may be as high as 25 – 35%.

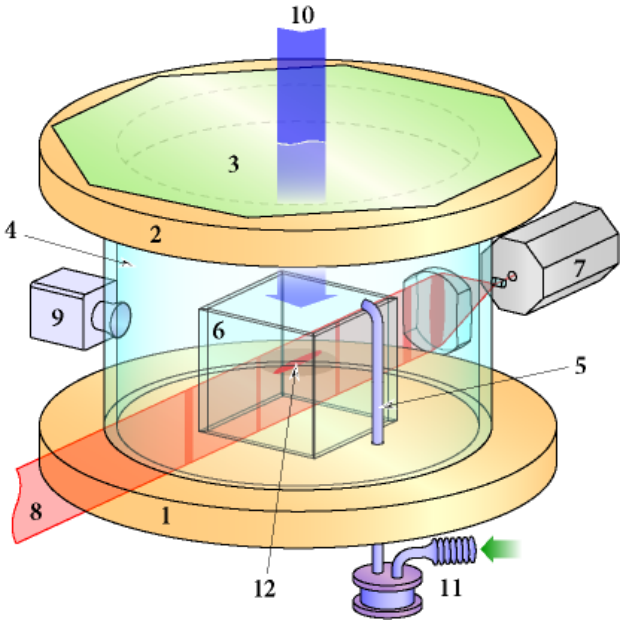

Fig.1. The picture of the experimental setup. (1) the Cu electrode, usually cathode; (2) the top electrode; (3) the Al foil; (4) the cylindrical chamber; (5) the dust particle injection tube; (6) the glass cubic; (7) the He-Ne laser; (8) the laser "knife"; (9) the digital video camera; (10) the e-beam; (11) the dust particles injection system; (12) the dust particles.

One of the key problems in developing such an energy source is creating homogeneous gas dusty mixture with the suppressed sedimentation and/or the hindered deposition of dusty particles on the walls. To solve this problem as well as to decrease the loss of ultraviolet quanta formed under the action of high energetic radionuclide decay particles in the noble gas medium when these quanta are transported to the photoelectric converter it is necessary to create an ordered structure of dusty particles. The present work is devoted to studying the dusty plasma created by the injection of dusty particles into the gas ionized by an electron beam under atmospheric pressure.

2. Experiments

The scheme of the experimental setup is presented in the fig.1. The electron beam (10) with energy varied within 85-115 kV was formed by the vacuum gun with the heated cathode and was then directed through the aluminum foil (3) of 14 μm in thickness into the cylindrical chamber of 7 cm in diameter and 3 cm in height. To suppress the convection, in the central area of the chamber there was a glass cube (5) that was top (from the direction of the electron beam) and bottom (above the bottom electrode) open, the cube's edge being about 1.5 cm. The massive bottom Cu electrode (1) was under the constant negative voltage of 200-4000 V. The anode was a grounded grid on the top of the glass cube. The beam current density in experiments was varied within 0.1-1.0 μA/cm^2. The electron gun operated in the stationary regime. The injection of dusty particles from the storage was performed by the gas flow. The behavior of dusty particles lighted by a laser "knife" (8) was observed with a digital video camera (9).

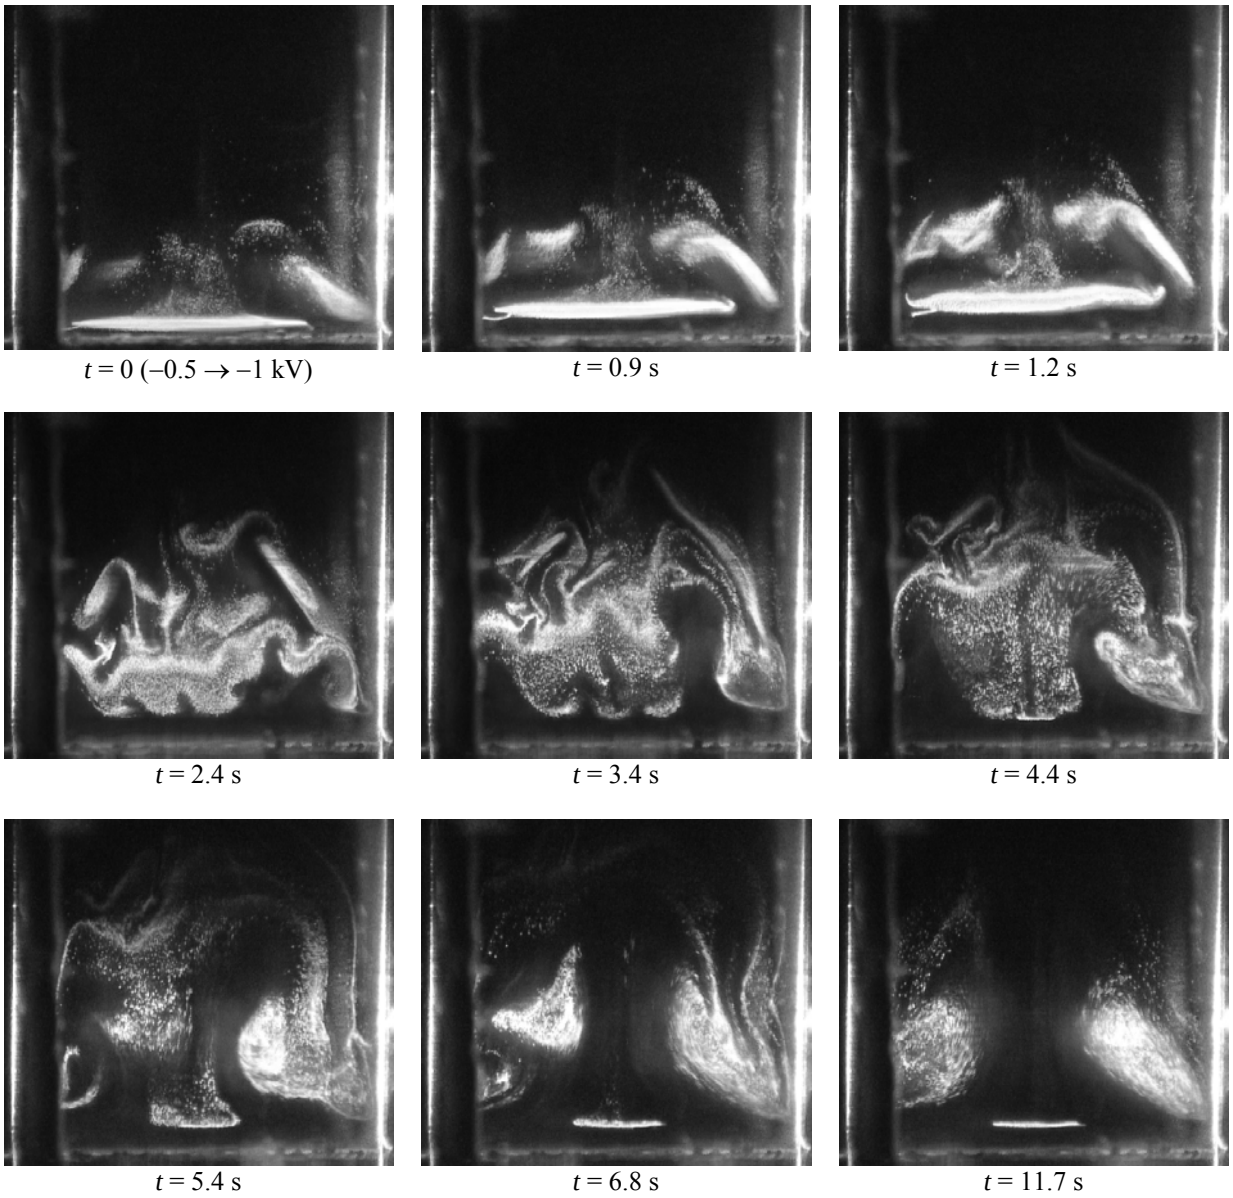

Fig.2. Video frames of the dusty structure evolution in the non-self-sustained discharge in nitrogen when the voltage in the discharge gap is changed from 500 V to 1000 V ($p = 10^5$ Pa, the beam current at the output window of the electron gun is j_b=22 μA/cm^2).

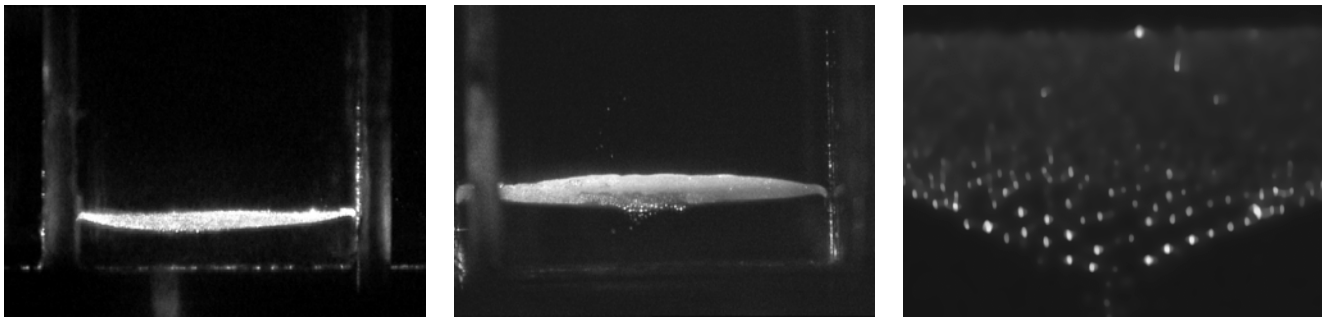
In fig.2 there are frames from a video-film which was made under the accelerating voltage of the electron gun of 115 kV, the beam current density of 100 μA in nitrogen under the pressure of 10^5 Pa with polydisperse CeO_2 dusty particles with the mean size of 1 μm. The first frame in fig.1 shows a stable plate-like structure of dusty particles. The following frames show the evolution of the plate under the step change in the voltage in the discharge gap. The voltage on the bottom electrode, –500 V, was changed to –1000 V under $t = 0$ that resulted in the explosion of the dusty cloud, which 12 seconds later ended in the formation of a plate with a clear-cut side boundary at another height. Above the plate near the side walls of the cube there formed stable vortices whose bottom boundary practically coincided with the location of the plate.

When the bottom electrode was grounded, all dusty particles were deposited on it in about 0.1 s, and when the grounding was removed and the initial voltage supplied there occurred a throwing of dusty particles upward. In this case the plate was not restored, but vortices appeared at the former sites. After the injection of a new portion of dusty particles there formed a more developed plate and vortices at the same sites. It should also be noted that no dusty particles penetrated into the cube area lower than the plate either after the injection or in the course of the following movement. However, in the discharge chamber outside the cube where the vortex motion of dusty particles is more accelerated due to the convective flux the particles could be observed near the bottom electrode. For unchanged parameters the picture described above about dusty particles moving in the discharge gap in the cube also remained unchanged.

Replacing nitrogen by argon in the experiments caused the formation of more stable dusty structures without auxiliary vortical motion of dust particles that more adequately simulated the working regime necessary in the atomic battery. In fig.3 there are dust particle structures which form in argon. In fig.3a there is a CeO_2 particle structure, and in fig.3b there is a structure from polydisperse spherical carbonglass particles whose average radius is 3 μm. Fig.3c shows the image of the low central area of fig.3b dust plate with a five-fold magnification. It is seen that there formed a structure similar to the crystal one with the average inter-particle distance of 150-250 μm.



(*a*) (*b*) (*c*)

Fig. 3. Video images of dusty structures in the non-self-sustained discharge in argon under the pressure of $p = 10^5$ Pa, the voltage at the low electrode of U_d=–0.5 kV. and of 22 μA/cm^2. (*a*) CeO_2 particles, j_b=22 μA/cm^2; (*b*) carbon glass spherical particles, j_b=15 μA/cm^2 and (c) the magnified central bottom part of dusty plate from (b).

It was shown in [3] that it was at low gas ionization rates of about 10^{14} cm^{-3}s^{-1} that the formation of ordered plasma-dusty structures was possible. In order to determine the fulfillment of a condition for the levitation of dusty particles in the non-self-sustained discharge in nitrogen the numerical simulation of the cathode sheath was performed according to the non-local model for transport processes, we had developed this model to study the charging of dusty particles [4]. The non-local model of the non-self-sustained discharge consisted of electron and ion number balance equations, the balance equation for electron temperature and the Poisson equation. The numerical simulation offers a clearer view of formation mechanism of dusty trap in the non-self-sustained discharge and verification of fulfillment of a condition for the levitation of dusty particles.

3. Discussion

In the experiments the typical transverse size of the discharge area was 5 times as large as the size of the cathode layer, and the gas ionization according to the calculation by the Monte-Carlo method and by the analytical theory developed by us was quite homogeneous along the radius, therefore, the modelling was performed within one-dimension plane geometry. Fig.4 shows the distribution calculated within the analytical theory for the gas ionization rate in nitrogen and argon under the pressure of 10^5 Pa along the discharge symmetry axis.

Fig.5 shows the distribution of electrical field strength and potential in the cathode layer. The produced pictures are in good agreement with the results of the analytical consideration [5]. It is seen that the field is weak in the positive column, and in the cathode area the field sharply grows. In the anode area in argon there forms a region with the negative electrical field strength, which is due to the diffusion component of the electron flow to the anode when the field in the positive column is weak. When the discharge voltage is increased the non-self-sustained discharge transfers into the normal regime with the self-sustained ionization in the cathode layer and the region with a negative field near the anode disappears. In nitrogen this region also forms, but the absolute values of the field there are much lower than those in argon.

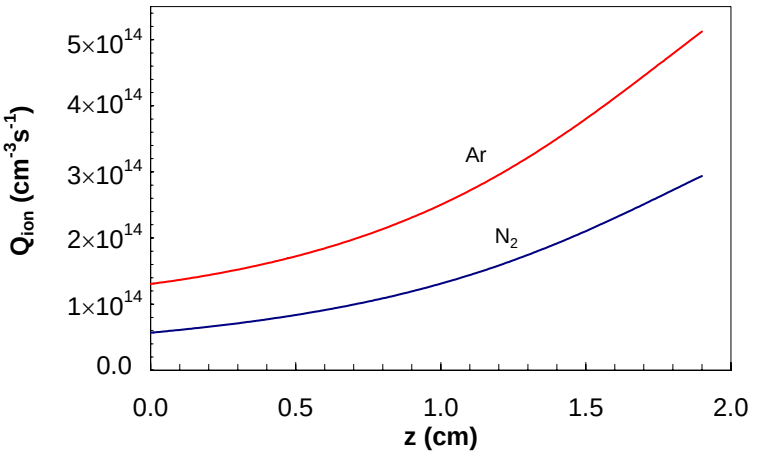


Fig. 4. Distribution of the gas ionization rate under the electron beam current density of 22 μA/cm^2 at the output window of the electron gun and the accelerating voltage 120 kV at the pressure of 10^5 Pa.

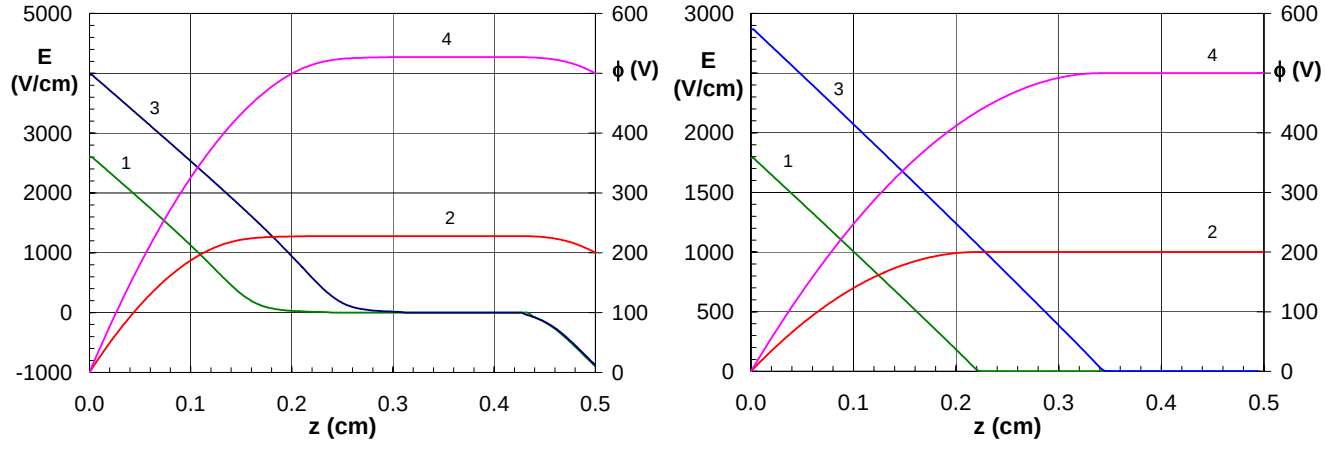

Fig. 5. Distribution of the electrical field strength (1,3) and potential (2,4) in the cathode layer under different voltages at the cathode in Ar (**a**) and N_2 (**b**) for $p = 10^5$ Pa, $L = 0.5$ cm, $j_b = 22$ μA/cm^2. 1, 2 – $U_d = 200$ V, 3, 4 – $U_d = 500$ V.

Let's estimate the electrical force acting upon dust particles in the cathode layer. As it was shown in [2], when the gas ionization rate is low the electron distribution in the vicinity of a dust particle is well described by the Boltzmann distribution, and the flow of ions to the dust particle rather well coincides with the Langevin one. For this case we have the following transcendental equation to estimate the charge of dust particles with taking into account the difference between the density of electrons and ions in the cathode layer

$$j_e = 4\pi r_0^2 \cdot \tfrac{1}{4} n_e \mathrm{v}_{T,e} = \pi r_0^2 n_{e0} \mathrm{v}_{T,e} \exp\left(e\phi/T_e\right) \equiv j_i = -4\pi e k_i q n_{i0}$$

where r_0 is the radius of dust particles, n_{e0}, n_{i0} is the density of electrons and ions in the considered point of the cathode layer far from the dust particle, $v_{T,e}$ is the thermal velocity of electrons, ϕ is the potential of a dust particle, T_e is the temperature of electrons, k_i is the mobility of ions, q is the charge of a dusty particle in elementary charges. On the assumption of vacuum-type relation between the charge and the potential $\phi = eq/r_0$ this equation can be easily numerically solved. The calculations showed that near the cathode where there were practically no electrons the charge of dusty particles became positive. In fig.6 there is dependence of forces acting on CeO_2 dust particles of r_0=1 μm in nitrogen and carbonglass dust particles of r_0=3 μm in argon in the cathode layer upon the distance from the cathode. It is seen that in the cathode layer there considerably increases the force making dusty particles move upwards. The points where curves 1,3 intersect curve 5 and curves 2,4 intersect curve 6 determine the equilibrium position of dusty particles in the cathode layer. The dust particle equilibrium positions determined from the video images and from the calculation data are given in the table.

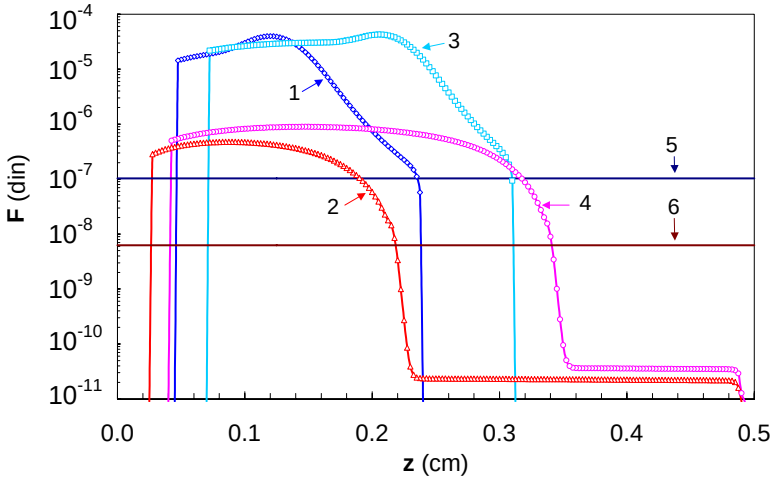

Fig. 6. Forces, acting upon dusty particles in the cathode layer, as a function of the distance from the cathode under different voltages at the discharge gap in Ar (1,3) and N_2 (2,4) for p = 1 atm. 1,2 – the Coulomb force for U_d = 200 V and 3,4 – that for U_d = 500 V; 5,6 – the gravity force for carbonglass dust particles of r_0=3 μm and for CeO_2 dust particles of r_0=1 μm respectively.

It is seen that in argon there is a satisfactory agreement of the experiment with the calculation, and that in nitrogen the disc forms at a much lower level than in the calculation. Neither the addition of oxygen to the plasma model (up to 1%), nor the change in the electron recombination coefficient by an order of the magnitude, nor the consideration of the additional gas ionization by a fast electron beam reflected from the cathode resulted in the better agreement of the calculation with the experiment in nitrogen. The reason for the divergence can be due to the fact that the gas in the near cathode region is highly heated that is most clearly seen in nitrogen.

Table. Experimental and calculation values for the equilibrium height of the dust plate structure in the cathode layer.

Gas	U_d	–200 V	–500 V
Argon	Experiment	0.12	0.18
	Theory	0.23	0.31
Nitrogen	Experiment	–	0.06
	Theory	0.22	0.34

Let's carry out estimations of the non-ideality parameter of the dusty component in the structure given in fig.3c. The non-ideality parameter of the Debye plasma is determined by the following expression [3]

$$\Gamma_s = \frac{e^2 q^2}{a T_d} \exp\left(-a / R_{sh}\right),$$

where $a = \left(n_d\right)^{-1/3}$ is the mean inter-particle distance, n_d is the dust particle density, T_d is the temperature of the dust component in energetic units, R_{sh} is the shielding radius. It was shown in paper [6] that the shielding radius in non-isothermal plasma with the external ionization source for the condition $\beta_L > \beta_{ei}$ was determined by the expression

$$R_{sh} = R_{De}\sqrt{\frac{\beta_L}{2\beta_{ei}}} = \sqrt{\frac{k_i T_e}{2\beta_{ei} e n_{e0}}},$$

where β_{ei} is the coefficient of electron-ion recombination, $\beta_L = 4\pi e k_i$ is the coefficient of Langevin recombination of ions. The calculations showed that in the area of the structure levitation given in fig.3c the electron temperature changes within the range of 0.1-1.0 eV, decreasing with the increase in the distance from the cathode. In argon under atmospheric pressure the basic ion in plasma is Ar_2^+, whose dissociative recombination coefficient is [6]

$$\beta_{ei} = 0.85\times10^{-6}\ (0.025/T_e)^{0.67}\ \mathrm{cm^3/s}$$

(T_e is in eV) and whose mobility under atmospheric pressure is $k_i = 2.1\ \mathrm{cm^2/V\cdot s}$ [6]. Thus we obtain that $\beta_L = 3.8\times10^{-6}\ \mathrm{cm^3/s}$, and the shielding radius

$$R_{sh} \approx 200\ T_e^{0.67}\ \mu\mathrm{m}$$

(T_e is in eV) changes from 200 μm in the low part of the structure down to 40 μm in the top part. It should be noted that the electron Debye radius for our plasma parameters changes as

$$R_{De} \approx 38.5\ T_e^{0.33}\ \mu\mathrm{m}$$

(T_e is in eV) and varies from 38.5 to 18 μm in the high ordered dust structure. Taking into consideration that the charge of dust particles is directly proportional to the electron temperature and is equal to $q \approx -3000T_e$ (T_e is in eV) for carbonglass particles, we obtain that the non-ideality parameter decreases from 1000 down to 2 with the increase in the distance from the cathode, and the critical value of the non-ideality parameter [3] changes from 54 down to 15. Therefore, we can come to the conclusion that the observed structure is similar to the crystal one in the low area and turns to liquid and then gas at the increase in the distance from the cathode.

Abstract
This work presents a study on the processes of copolymerization by plasma of polypyrrole and polythiophene with chloroform. The main objective was to study the interaction of halogens with heteroaromatic polymers from the point of view of the transport of electric charges along the material. This kind of polymerization can be seen as a hybrid combination of fragmentation, polymerization and doping processes, because some of the fragments resulted from the decomposition of chloroform by plasma can be considered as dopants in the chemical reactions.

Introduction
The polymerization by plasma usually involves particles with energy that can go beyond the level of most of the chemical bonds found in organic compounds (3-6 eV). The amount of collisions with high energy particles break bonds and promotes the creation of new ones in such a way that the polymerization occurs in a sea of fragments of molecules, free radicals and ions. In those conditions, the chemical reactions have to be directed to obtain a reasonable proportion of the expected results, and they can only be manipulated by controlling the electric and the thermodynamic variables. In the same scheme, the doping of polymers occurs by the inclusion of different atoms, molecules or excited species and, depending on the electronic configuration of the dopants, they modify the electronic balance in the material. In a traditional doping, the dopants release the polymers along time or under strong conditions; however, if sufficient energy is applied to a dopant-polymer system, as in a plasma environment, chemical bonds could appear between them, transforming the doped material in different chemical compounds, making the function of the dopants far more complex [1].
In this work we studied the possibility of using chloroform and their fragments, resulted from the high energy collisions with the plasma particles, to form copolymers doped in-situ to modify the electronic configuration in pyrrole and thiophene polymerized by plasma in order to enhance the electric conductivity of the final material. Chlorine in these polymers can be seen in the same way as the traditional solid state dopants, whose fundamental function is to modify the clouds of charges through the entire polymeric network in order to facilitate the electric conduction. The chlorinated polypyrrole (PPy-Cl) and polythiophene (PTh-Cl) were synthesized in this way with resistive glow discharges at 12 W and $7x10^{-2}$ Torr.

Results

Elemental composition
The elemental analysis is discussed in this work to evaluate the participation of the chloroform in the polymers. The atomic carbon/nitrogen (C/N) ratio in PPy and the sulphur/carbon (C/S) ratio in PTh should have the same proportion as in the respective monomers, 4. However, considering the additional C atoms from the chloroform in the polymerization, those ratios should be slightly greater than 4. Table 1 presents the elemental composition of PPy-Cl and PTh-Cl synthesized by plasma. The atomic proportion in the polymers shows that the C/N ratio in PPy-Cl is 4.44, whereas the C/S ratio in PTh is 4.12.

Polymer	C	N	O	S	Cl	C/N	C/S
PPy-Cl	70.8	15.9	9.3	----	4.0	4.4	---
PTh-Cl	70.2	----	9.4	17.1	3.3	---	4.1

Table 1. Elemental composition of PPy-Cl and PTh-Cl.

The oxygen atoms can be attributed to the reaction of the residual radicals in the polymers, which survive at the end of the reactions, with the atmospheric oxygen. As the conditions at the end of the syntheses in both polymers are approximately the same, the oxygen percentages in both polymers are also approximately the same.

Structure

The IR and XPS spectra of both polymers suggest that some chlorine atoms are chemically linked to the pyrrole or to the thiophene rings. The absorption at 613 cm^{-1} in the spectra of Fig. 1 belongs to C-Cl bonds in both polymers. This absorption is part of a wide band involving also the C-S bonds in PTh-Cl and the substitutions of C-H bonds in the heteroaromatic rings.

The C-H aliphatic bonds can be found between 2927 and 2969 cm^{-1}. These groups can be originated from the fragments of chloroform, pyrrole and thiophene due to the high energy discharges. The absorption around 3037 cm^{-1} indicates the presence of C-H aromatic bonds. In both polymers, the aliphatic and aromatic absorption of C-H groups have approximately the same magnitude, indicating, by analogy, that the polymers could be composed with the same proportion of aliphatic and aromatic fragments of chloroform and their respective polymers.

The peaks at 1654 and 1685 cm^{-1} belong to the C=C bonds of PPy-Cl and PTh-Cl, respectively. Both absorptions are partially overlapped by the C-N and C-S groups.

The absorption at 1041 cm^{-1} can be attributed to the oxidation resulted from the interaction of the last free radicals, at the end of the polymerization, with the atmospheric oxygen. The oxygen groups can recombine with hydrogen atoms to form alcohols, C-O-H. This possibility appears also in the XPS analysis. The N-H and/or O-H groups are located in the wide band involving the 3353 cm^{-1} and 3216 cm^{-1} region.

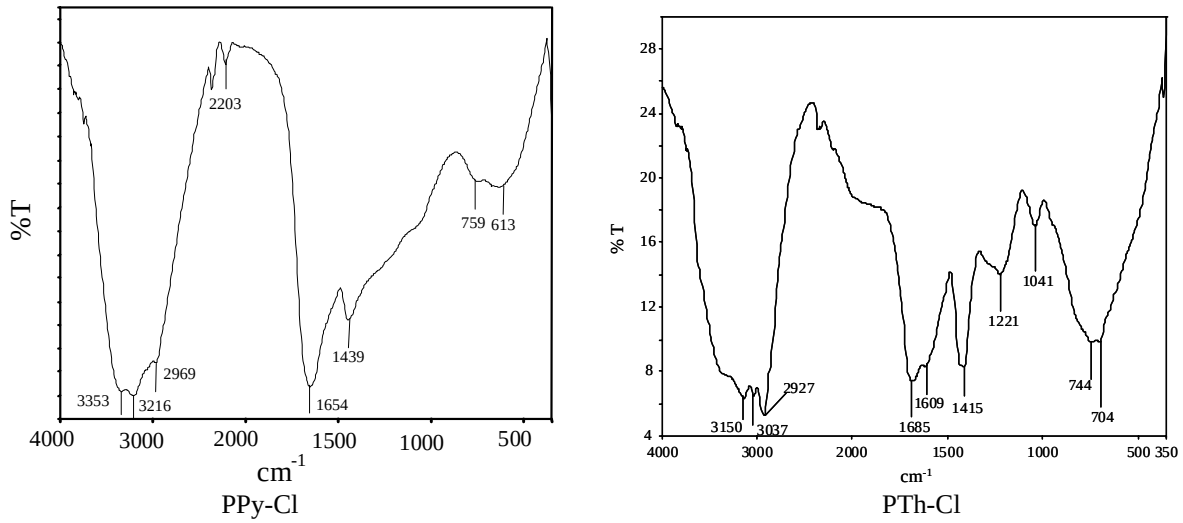

Figure 1 - FT-IR transmission spectra of PPy-Cl and PTh-Cl.

Figure 2 shows the binding energy of the C 1s, N 1s, O 1s and Cl 2p peaks of PPy-Cl and PTh-Cl. Each contribution was deconvoluted with the most probable groups in the polymers. The C1s spectrum of PPy-Cl can be resolved in five peaks. The energy at 284.4 eV can be assigned to the C=C bonds in the pyrrole rings. The peak at 285.0 eV belongs to the C-C and C-H groups; they include the aliphatic carbon bonds. The peak at 286.4 eV implies contributions of C=N and C-O bonds, most probably as a consequence of the polymer oxidation at the end of the reactions. It includes also the contributions of the chlorine atoms as C-Cl bonds. The fourth peak, at 287.7 eV, can be assigned to the C=O groups. The last peak at 288.6 eV can be assigned to C-O and C-N groups.

There are two contributions in the adjustment for the N 1s spectrum. The first one is centered at 399.2 eV and corresponds to both N-C and N-H bonds. The second peak is found at 400.5 eV and is related to the contributions from amine groups. The S 2p signal was adjusted with two contributions. The first one in 163.5 eV represents the S-C groups [2], and at 165.0 eV, the vibration of the sulfur into of the thiophene rings is found [3].

The O 1s signal can include two contributions: the main signal is found at 531.8 eV which belongs to C-O and

C=O groups, whereas the other contribution at 533.6 eV represents the C-O bonds. The C12p signal can be resolved into two doublets, the first one at 197 eV corresponding to chlorine anions, while the other at ~200 eV corresponding to covalent chlorine [4].
Both, XPS and IR analysis suggest that the energy of the plasma is sufficient to break the chloroform molecules and that the fragments combine with the polymers to form chains with aliphatic fragments bonded to them. The fragments come from the chloroform and from some pyrrole and thiophene rings that break during the polymerization. Both techniques suggest the presence of oxygen in the polymers which could be as alcohol groups.

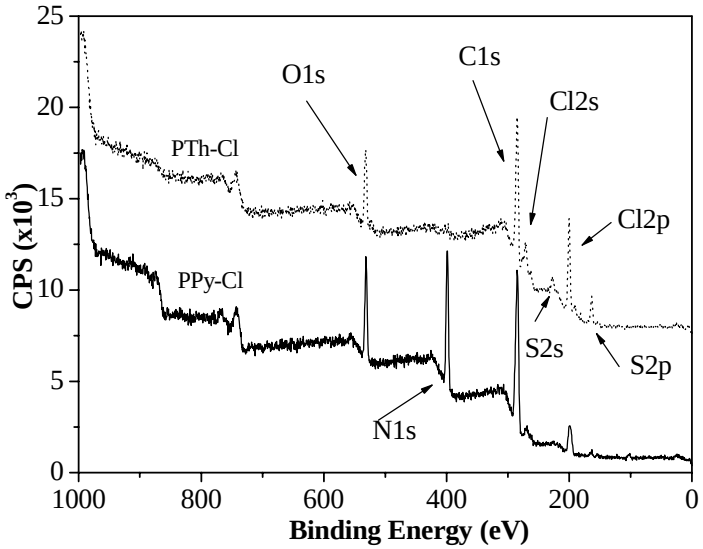

Figure 2 - XPS spectrum of PPy-Cl and PTh-Cl.

Conductivity
The conductivity of PTh-Cl and PPy-Cl is presented in Figure 3 as a function of the relative humidity (RH). The results indicate that PTh-Cl has higher electric conductivity than PPy-Cl in the 30-95% RH range studied. PTh-Cl shows approximately 10^{-5} S/cm conductivity at 40% RH and reaches up to 10^{-3} S/cm at 75% RH. Although it has only an increase of 2 orders of magnitude as a consequence of humidity, its tendency suggests only one mechanism of conduction. PTh without doping has conductivity of approximately 10^{-10} S/cm at 40% RH.

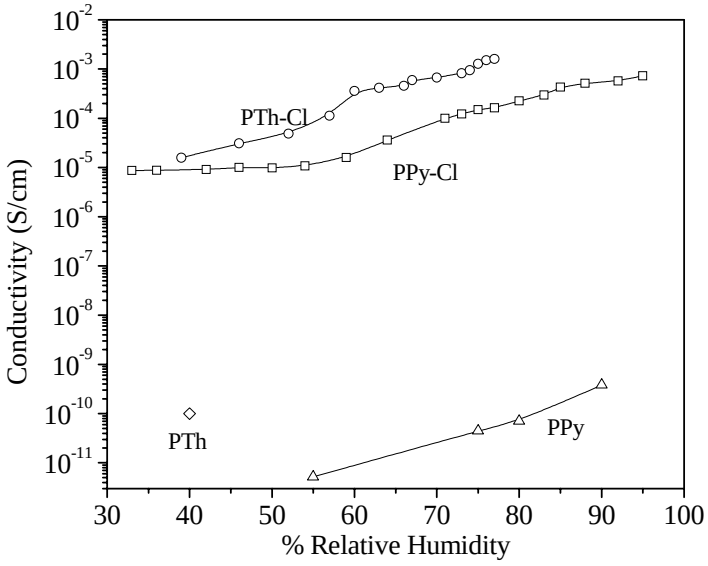

Figure 3 - Conductivity of PTh-Cl and PPy-Cl.

PPy-Cl presents an approximately constant electric conductivity of 10^{-5} S/cm from 35% to 50% RH and after that, increases continuously up to 10^{-3} S/cm at 95% RH. This behavior suggests two conduction mechanisms, the first one at low humidity that could be predominantly electronic and the second, at high humidity, which could be a combination of electronic and ionic transference of charges. Plasma PPy without doping has low conductivity and has been studied, among other reasons, because of its dielectric properties [5]. However, other studies have shown that iodine doped PPy exhibits an exponential response in conductivity with respect to the water content in the structure that makes PPy, or its derivatives, suitable to be used in wet conditions [6].
Chlorine and iodine atoms, combined with water, give better conditions for the transport of electric charges in polypyrroles. The interaction of water in the structure of some semiconductor plasma polymers is important because these polymers can be used as biosensors or in biocompatible materials and, inside the body fluids; the polymers are immersed in an aqueous medium [7]. Figure 3 contains also the conductivity of PPy and PTh without doping. The difference resides in the level of conductivity, 10^{-10}-10^{-11} S/cm for PPy and PTh.

Discussion

PTh-Cl and PPy-Cl were synthesized by plasma in simultaneous copolymerization and doping processes that involves chloroform molecules and its chlorined derivatives which are incorporated to the polymers in formation. The structural analyses indicate that some Cl atoms are chemically bonded to the structure of both polymers and other Cl atoms behave as anions. The chlorine content increases the conductivity of PTh and PPy in approximately 5 or 6 magnitude orders compared with the same polymers without doping. The mechanism of transference of charges has two tendencies in PPy-Cl, one that predominates up to 55% RH and another that rules above that point. The transference of charges in PTh-Cl has a unique tendency along the RH interval studied.

Abstracts

The soil sterilization was studied by using ozone which is generated by the coaxial dielectric barrier discharge. We developed here the ozonizer with water-cooled screw type electrode and generated the high ozone concentration of 80g/m^3 at 0.3liter/min. Time evolution of injected ozone in the soil and the sterilization of the agricultural soil under various ozone dosages and treatment intervals were investigated. The ozone treated volume and the sterilization rate were clarified from several analytical method such as pH and electrical conductivity measurement.

Keywords: ozone, soil sterilization, dielectric barrier discharge

Introduction

The pressing need to develop environmentally benign alternatives to methyl bromide for soil sterilization requires new technologies for the agricultural and horticultural fumigation. The objective of soil sterilization is to destroy/eliminate microbial cells without significantly altering the chemical and physical characteristics of the soil. Numerous methods including autoclaving (moist heat), dry heat and microwaves have been used to sterilize soil or inhibit microbial activities in soil.[1-3] Ozone has oxidative and germicidal.

Ozone also has many benefits based on on-site generation, minimum human toxicity, low persistent chemicals in the soil. Ozone has been generated by many processing technologies such as dielectric barrier discharge, pulsed discharge, corona discharge and surface discharge. We have developed the ozone generation system suitable to soil sterilization which provides wide range of ozone concentration till 40gO_3/m^3 by varying applied voltage. The coaxial dielectric barrier discharge using the pyramid type electrode or the screw type electrode produced the ozone with high concentration at high efficiency. [4-6] Injection of the on- site generated ozone gas into the soil resulted in decreasing soil pathogen and changing chemical properties of the soil.[6-8]

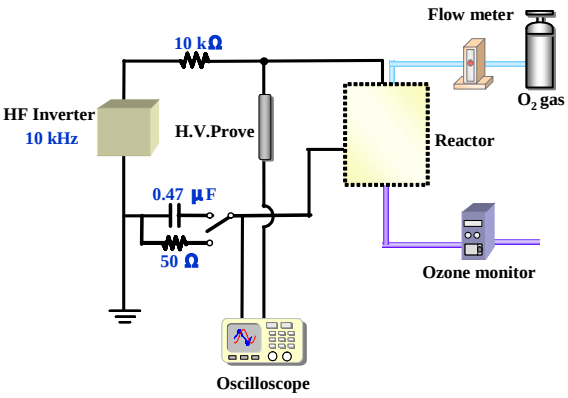

Fig.1 Ozone generation system.

We report here ozone diffusion and sterilization of agricultural soil when it is treated by varying ozone dosages and process duration. The temporal and spatial properties of the soil were investigated using the pH

and electrical conductivity. The bacteria populations , pathogen and soil-borne fungi after ozone treatment were determined and correlated with the processing conditions.

Experimental

Fig.1 shows the outline of the ozone generation system. An electric power of high frequency inverter (10kHz) was applied to the electrodes in the range of applied voltage (1.7 kV-5.5 kV). Material gas (oxygen 99.9 %) was supplied to the reactor of the dielectric quartz glass tube (ϕ 8 mm) with an inner electrode. The inner electrode is the structure of a water-cooled screw type electrode (in Fig.2) and a pyramid type electrode of stainless steel rod (ϕ 6 mm) . The ground electrode is cupper foil wrapped around the quartz tube. The gap separation between the inner electrode and the insulator tube was kept at 1 mm.

Fig.3 shows the ozone concentration as a function of applied voltage. The ozone concentration for the water–cooled electrode changed gradually from 4 g/m^3 to 38g/ m^3 by increasing the applied voltage.

Fig.4 shows the relationship between the ozone generation efficiency and ozone concentration when oxygen flow rate was changed. The high ozone concentration around 80g/ m^3 is generated at a low gas flow rate of 0.3 liter/min. This level of ozone is enough to sterilize bacteria and fungi in the soil. The high value of ozone generation efficiency of 220g/kWh was obtained at 1-2 liter/min where a low ozone concentration of 10g/m^2 was generated.

Fig.5 shows the ozone injection system into the agricultural soil (Audisols: Kumamoto soil). Ozone was introduced into the soil through the drip tube of 1/4 inch Teflon pipe. Two sets of the pH sensor and the electrical conductivity (EC) probe were placed at appropriate separation. The treatment container was arranged in an incubator of which temperature and light illumination can be automatically controlled. These measured data can be transmitted to the PC through the wireless network system.

Results

Fig.6 shows time evolution of pH and EC when the soil was treated by the ozone of 100gO_3/m^3 in 2 liter/min O_2 during 60min (a commercialized ozonizer was used). Decrease of the pH value and increase of EC are clearly shown during the ozone treatment. Agricultural soil consists of mud, sand, organic matter, minerals and water. Electrical conduction in the soil is mostly due to cation (Ca^{2+},Mg^{2+}, K^+, Na^+) and anion (Cl^-, NO_3^-, SO_4^{2-}) originated from mineral components in the

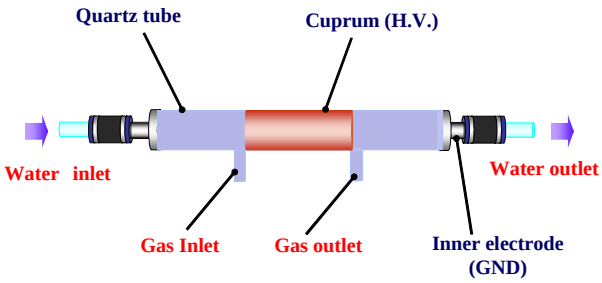

Fig.2 Water cooled screw type electrode

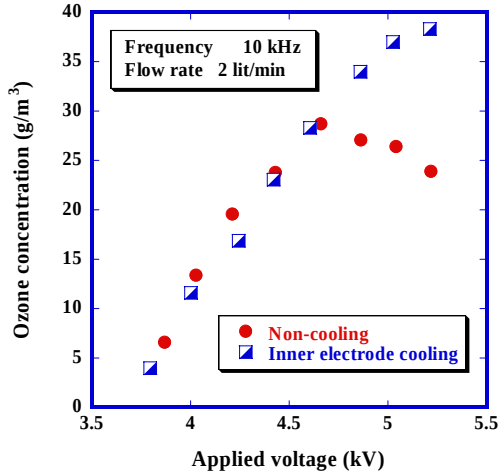

Fig.3 Ozone concentration as a function of applied voltage

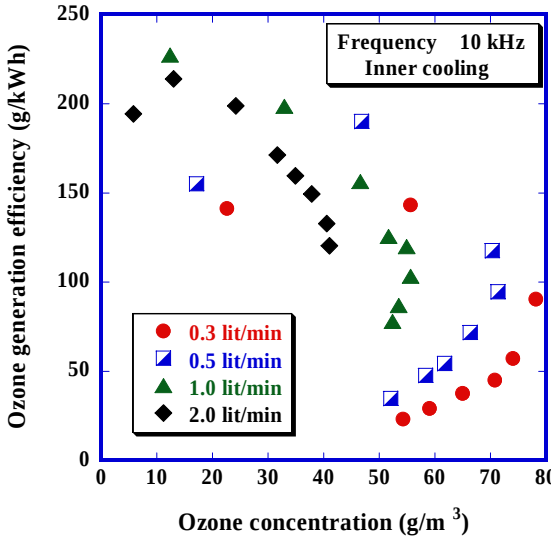

Fig.4 Ozone generation efficiency as a function of ozone concentration

soil. Gradual increase of the EC after treatment is attributed by complicated chemical reaction with ozone. We confirmed that the sterilization terminated in initial 30 minutes by referring the diagnostic results of microbial cells. The behavior of the EC and the pH is expected to be one of indexes for estimation of the sterilization level.

Fig.6 indicates that ozone can diffuse near 30mm away from the gas outlet embedded in the agricultural soil.

In order to apply the proposed system to large area of agricultural land, the ozone supply system with many gas tubes is required. Fig.7 is the double injection system to study the diffusion length between two gas outlets(separation:100mm) in the soil. Time development of EC is shown in Fig.8. The value of EC measured at the center of two sensors shows abrupt increase during ozone injection.

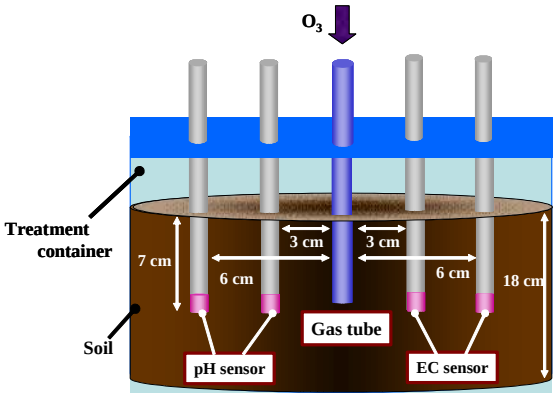

Fig.5 pH sensor and EC probe arrangement

Fig.9 shows the ozone sterilization results when the agricultural soil (50g) was treated varying the ozone dosages (0-40gO_3/m^3) and the duration (1-60min). In this experiment the agricultural soil was filled in an chamber(ϕ 70mm) and ozone gas was supplied from the top of the chamber and evacuated from the bottom exit.[6-7] The soil samples subjected to the sterilization process were sterile. Fasarium oxysporum of 10^6 conidal/mL was inoculated into the soil. The CFU(colony forming unit) counting was used to evaluate the number survivors after 72 hours. The total ozone amount (g) is calculated from the product of ozone concentration, gas flow rate, and treatment duration. For example, the test soil of $7.2x10^6$ CFU shows $1.7x10^2$ CFU after the treatment of ozone dosage of 6.39g where ozone concentration of 38.5 g/m^3 at gas flow rate of 3 liter/min and treating time of 60min were used. The resulting sterilization rate is 100% as shown in Fig.9 (left end data).

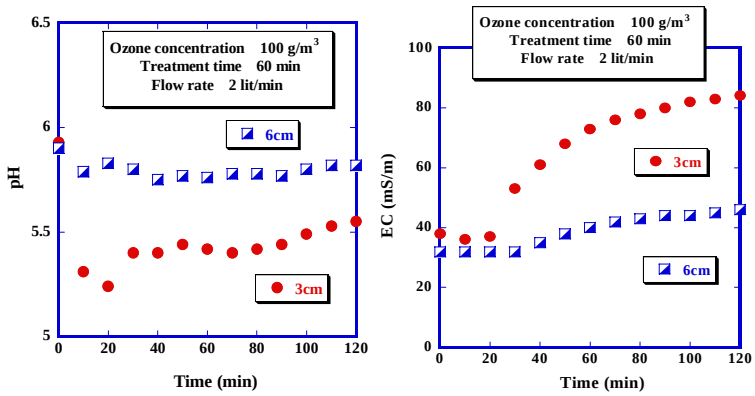

Fig.6 Soil properties during and after ozone treatment at different positions (3,6cm from the gas outlet).

It is shown that the sterilization by ozone injection is effective when the ozone dosage becomes over 0.3g for the 50g soil.

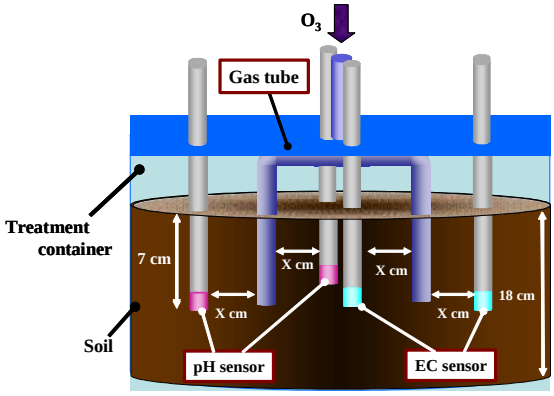

Fig.7 Two ways gas pipe system for ozone supply

Conclusions

We have studied the soil sterilization by using ozone which is generated by the coaxial dielectric barrier discharge. We developed here the ozonizer

with water-cooled screw type electrode and generated the high ozone concentration of 80g/m^3 at 0.3liter/min. Ozone diffusion and the sterilization of the agricultural soil were investigated using ozone injection into the soil. The ozone treated volume and the sterilization rate were clarified from several analytical method.

Abstract
Different kinds of hard masks have been evaluated to pattern oxide lines for 90 nm and 65 nm technology nodes application. The materials studied as hard mask and ARC have been TiN and SiON, as well as a Bi-layer and an AHM (Ashable Hard Mask) approach. The main focus of this work has been the characterization of the interaction between the RIE plasma and the mask material surface, in order to understand the weak and the strength points of every architecture choice.
Keywords: RIE, Hard mask, plasma

Introduction

Technological nodes evolution in semiconductor devices requests to both litho and etch to pattern pitches which become more aggressive from time to time. Lithography is forced to use materials (such as 193 nm photoresist) with low resistance to etch, whose thicknesses are to be thinner than they were for previous technological node. This means that the resist mask itself is not enough to make possible an etching process. In addiction to that, very often BARC is not enough to avoid interference effects due to light reflection from the underlying layers, so making necessary the use of thicker BARC or additional anti-reflecting layers.
These layers can be chosen and characterized to be able to work both to drop the interference effects and to act as a hard mask to make the etching process feasible. Hard masks are used for many applications.[1,2]
In this work, inorganic and organic hard masks have been evaluated to pattern oxide lines with pitches for 90 nm and 65 nm technology nodes application. The materials used as inorganic hard mask and ARC have been TiN and SiON. For the organic hard masks, a Bi-layer and an AHM (Ashable Hard Mask) approach have been studied. The main focus of this work has been the characterization of the interaction between the plasma and the mask material surface, in order to understand the weakness and the strength points of every architecture choice.

Experimental

Hard masks under characterization have been studied analyzing their response while used to pattern lines in a single damascene approach. The etched pattern has been an array for 90 nm technology for TiN, SiON and Bi-layer, its shrink to further node (65 nm) for SiON and AHM. Pitches were ranging from 210 nm to 140 nm.
The film to be etched was made of PECVD FSG 4%. A chemistry based on $Ar/C_4F_8/O_2/CO$ was used to etch such a film, selectively landing on Si_3N_4.
The samples have been etched in a DFC (Dual Frequencies Coupled) RIE (27MHz and 2 MHz).
The Hard mask opening for TiN has been performed in a Inductively Coupled Plasma reactor (Cl_2-based chemistry), while the same RIE used for FSG has been used for he others.

Inorganic Hard Masks

Inorganic materials are a very common choice when a hard mask is needed. These materials are usually already present in device's process flow, so neither new tools nor new precursor gases are needed for their deposition. So, as far as they are able to support technological shrink, they are the easiest and less expensive choice. Among them, PVD TiN and PECVD SiON are the most common choices.
PVD TiN is well known for its anti-reflective properties; in addiction to that, from the selectivity point of view, a metallic material is the best mask when a dielectric film is to be patterned. This means that a thin hard mask could be enough to transfer the pattern, so no dramatic increases of final aspect ratio are caused by it.
The first trials done to pattern a TiN-masked FSG showed a very hard etch stop issue to deal with. This was probably due the Ti presence in the polymer. In order to make the Ti-based by-products more volatile and to avoid them to enter the polymer, wafer temperature have been increased. Figure1 shows how an increase of

35°C moved the process latitude from a severe etch stop region (etch stop occurred after 150A of FSG were etched) to an etch stop-free region.

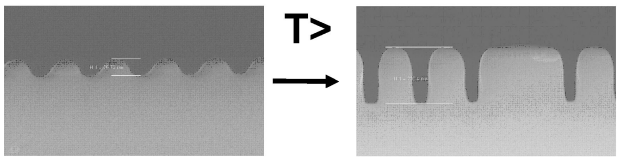

Figure 1: temperature effect on etch stop process window

The need of heating up the wafer during the etching process means that the RIE is to be dedicated for such a process, so making it more expensive from the manufacturing point of view. In addiction to that, if a bipolar ESC is used, it requires an optimization for chucking and dechucking voltages and time, in order to take into account ESC resistance increase with temperature (ESC capacitance does not change), which make narrower the window against wafer re-clamp.
After the first wafer was etched, Ti contamination in the reactor has been evaluated; a bare Si wafer has been exposed to an Ar plasma, then measure by TXRF. The dose revealed on its surface is assumed to be directly correlated to the Ti content in the chamber's hardware.

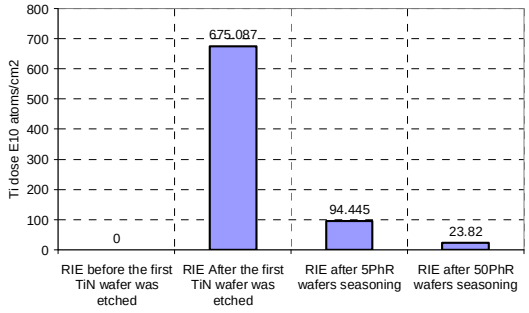

Figure 2: Ti dose monitored by TXRF

Ti presence in the tool can be partially recovered by a standard seasoning, but no complete recovering was possible.Figure2 shows the dose measured on bare Si test chips and its evolution after seasoning; Ti contamination can be decreased of several orders of magnitude, but never completely recovered once a TiN wafer have been processed. In order to estimate Ti effect, a baseline process, not using hard mask but instead a standard resist, has been ran before and after RIE contamination. Results are shown in figure3.

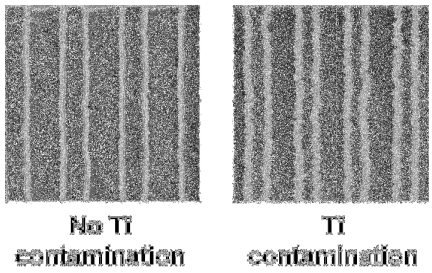

Figure 3: Ti contamination effect evaluated on baseline process.

This result demonstrated that a Ti presence modifies the performances of an etching process. Having observed the effect of Ti on the baseline process, a marathon has been done in order to evaluate the self-contamination risk for the etching process on TiN hard mask. Test chips have been processed by Ar plasma along the TiN marathon to monitor the Ti content of the RIE. Bare Si wafers are supposed to efficiently simulate the top electrode behaviour with respect to Ti contamination (Top electrode is made of Silicon). A ToF-SIMS analysis has been carried on for Si surface and Ti profile (Fig4).

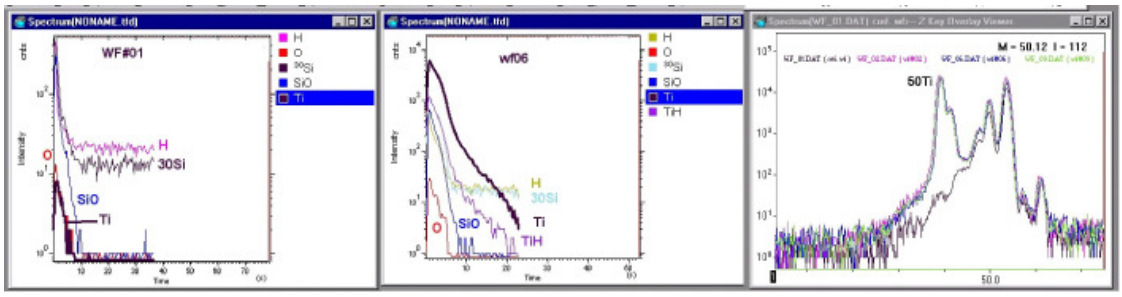

Figure 4: ToF-SIMS analysis of bare Si wafers processed during the marathon

According to ToF-SIMS results, after the first wafer of TiN is processed the Ti content directly goes to its saturation value. The surface spectrum shows that the ^{50}Ti peak, absent before the RIE is contaminated, starts appearing after the first TiN wafer is etched. Its intensity does not change while processing other TiN wafers. Independent XRF measurements carried on the same Si chips, confirm that the saturation level is reached after the first wafer. Ti profile measurement shows that, accordingly to the small diffusion coefficient of Ti in Si bulk, Ti contamination in Si is only at its surface. Considering bare Si behavior as descriptive for top electrode, it can be argued that a thin Ti film is growing on it. So, ESC contamination could take place during WAC (Waferless Auto Clean, a cleaning plasma ran after the process of each wafer to clean the reactor from etch by-product deposited on RIE walls).

No self-contamination in TiN hard mask-based etching process has been revealed from both morphological and electrical data.

As a conclusion for studies on TiN, it seems clear that a TiN hard mask choice would lead to several manufacturing problem. Although the process is not affected by self-contamination, the RIE cannot be shared with other applications for contamination issues. Dedicated ESC temperature is required in order to let the process work.

PECVD SiON has been in parallel evaluated as an alternative to the TiN hard mask. Such a material is known for the extreme tunability of its physical and chemical-physical properties: tuning its stoichiometry, in fact, it is possible to change its optical properties (allowing good performances as ARC) and its response to the etching process.

A first trial have been done to transfer the pattern using the dielectric hard mask; the material chosen as starting point showed a very bad etch resistance (Fig 5). So, a study has been carried on to understand whether it was possible or not to use such a material to pattern lines for 90 nm node. PECVD precursor gases have been tuned, so tuning Si-Si, Si-N and Si-O content in the film, in order to determine the best working range.

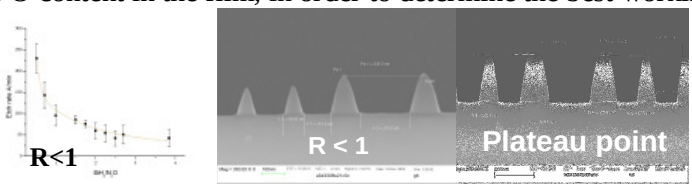

Figure 5: Etch rate for the main etch step on blanket SiON wafers (stoichiometry tuning) and correlated result on patterned wafer

Figure 5 shows the results in term of etch rate for the main etch step on the "tuned" SiON blanket wafers. Increasing the SiH_4/N_2O ratio in deposition step, the etch rate for the correspondent material decreases until it reaches a plateau. Within this plateau, it is still possible to tune optical properties for the film, so its performances as anti reflective coating. Figure 5 also shows results on patterned wafer; the sample with R<1 was the starting point, with a SiON coming from the zone in which SiH_4/N_2O ratio is lower than one. Moving closer to the plateau, the selectivity becomes high enough to allow an efficient pattern transfer. A μ-Auger analysis has been carried on in order to understand which is the microscopic parameter impacting such an etching response. If $Si_xO_yN_z$ is the generic material stoichiometry, it has been found that selectivity FSG-to-SiON increases with x/y ratio, keeping z constant. According to this trend, it is reasonable that, increasing Si/O

ratio keeping constant N, part of Si-O bonds are converted in Si-Si bond. It can be inferred that moving into the plateau means to move far from an “oxide-like” chemical structure. As a consequence, a chemistry to etch oxide becomes more selective to it, so improving the material performances while used as a mask.
Etching data also showed that not always is necessary to move in the plateau zone. Once feasibility is observed for a point out of the plateau, fine tuning on SiON stoichiometry can be used, as shown on fig 6, to tune CD bias; if a CD shrink is necessary and an issue on polymerization process window is present, the desired morphological result can be obtained by a fine tuning for the hard mask material.

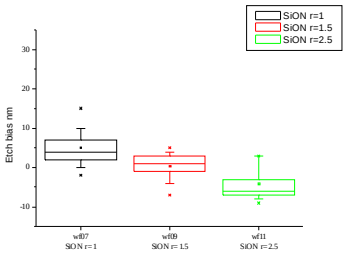

Figure 6: CD bias response to SiON modification

This is a very important strength point for such an approach: hard mask can be tuned as a further degree of freedom in order to reach the right dimensional result without losing in process window width from the etching process point of view.
After the right SiON modification has been found, very good results have been obtained for line patterning in term of profile, dimension, striations and process window. Standard temperature set up allows the definition of a good working point, and no issues have been revealed from marathon test. This demonstrates a strength point of SiON with respect to TiN: while its more expensive in term of characterization work (the stoichiometry is to be tuned to find the best material for each application), it becomes then less expensive in terms of manufacturing, allowing to share the tool with other applications.
Data from the etching characterization showed another issue hard mask-related: selectivity FSG-to-SiON of the main etch depends on pitch. As far as the pitch is shrunk, in fact, the mask faceting effect becomes an additional part of its etch rate during line patterning, so causing a higher mask loss in dense zones. In order to evaluate whether SiON can support a technological shrink or not, a comparative feasibility has been evaluated for 65 nm technology node.

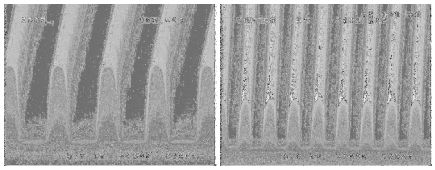

Figure 7: morphological result for the 90 nm and 65 nm technological node

Figure 7 shows the morphological result of the comparative study: once a material is tuned to be enough etch resistant, it is able to support a shrink for at least the next technological node.

Organic Hard mask

Organic hard masks are an alternative to inorganic material for advanced patterning transfer. The main advantage in an organic choice is that the mask can be stripped after the pattern is transferred to FSG. A simple and standard stripping step completely removes the mask. This is not possible if an inorganic material is used, so its presence is to be taken into account making more complicated the integration schemes.
Bi-layer resist for 193 nm lithography has been evaluated for array patterning in 90 nm node. A Bi-layer approach consists of a thick anti-reflective organic coating, called underlayer, and a thin photo resist Si-rich (called Imaging Layer). Silicon presence in the imaging layer allows the etching process to reach a good selectivity imaging-to-under layer, so the pattern can be transferred from the first one to the second one, which acts as the real hard mask to pattern the FSG. A dry development for the underlayer followed by an FSG etch

step has been used for the analysis. Having a Si-rich imaging layer film, it has been observed since the beginning an issue profile-related. In order to have CD control and a vertical profile in the hard mask, H_2 is needed in the mask opening step. Hydrogen in the plasma can react with Si present in the underlayer to generate volatile Si-H compounds, then re-deposited on large areas as Si-based compound, whose composition depends on the overall chemistry of the step. This re-deposition leads to a micromasking effect while etching the oxide by a step selective to Si_3N_4. To avoid this process marginality, a H_2-free chemistry has been chosen. As a consequence, a CD bias always positive and a bowed mask profile are to be accepted.

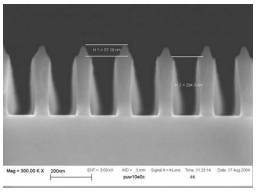

Figure 8: underlayer profile after mask dry development

Figure 8 shows the profile in the underlayer after the dry development step was applied. An average CD bias of 10 nm has been measured for this wafer.

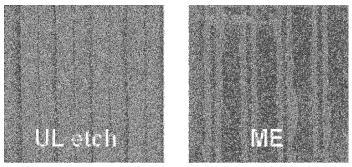

Figure 9: Top view after underlayer etch and after Main Etch followed by O_2 strip

Figure 9 shows the result after a full etch trial: after main etch and strip, strange "shadows" appeared at line bottom. Further analysis demonstrated they are made of oxide. The hypothesis done to explain such an issue is a hard mask reflow mechanism or a chemical modification in the film structure taking place during ME, probably driven by Ar sputter. To support this explanation, it has been observed that strip is not able to remove the underlayer after etch from large unpatterned zones, while the stripping is effective when applied on the same material directly after deposition (Figure 10).

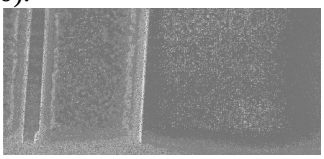

Figure 10: hard mask residuals after strip on large oxide stripes

As a consequence, while no concerns have been found for selectivity and pattern transfer, stronger defectivity problems and questions about post etch strip are open for this organic material. An Ashable Hard Mask (AHM) has been evaluated as well. AHM approach consists of a triple step: a thick α-C layer, a thin Inorganic anti-reflective layer (usually a SiON), called DARC, and then a resist mask. The sequence is: the pattern is transferred from the resist mask to the inorganic layer, which is then the mask to transfer the pattern to α-C. This film is the real hard mask for the etching process; the inorganic layer is thin enough to be completely consumed during FSG etch, so the hard mask can be removed by ashing after the full process is terminated. The evaluation for this approach has been directly done for 65 nm technology application. Again, a H_2-based chemistry would give re-deposition issue in large zone, so a bowed profile has been accepted. While for Bi-layer approach a positive CD bias was to be accepted, the AHM approach allows a CD tuning by modulating both BARC etch step and DARC opening. In general, inorganic material, such s TiN or SiON, are able to allow very high selectivity to oxide, while selectivity is always lower with an organic hard mask. As a consequence, organic hard mask are always thicker. Dealing with very dense arrays, it is important to characterize the process windows against hard mask collapse during main etch, which would give severe electrical failure. CD tunability for AHM approach allowed such a characterization

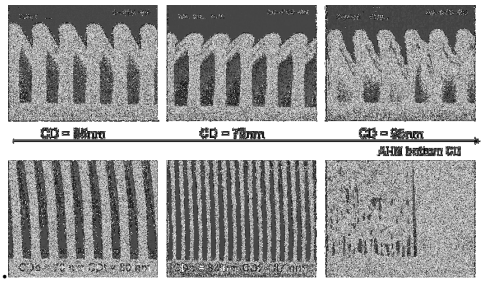

Figure 11: Line collapsed evaluation versus CD bias during mask opening

Figure 11 shows the results for this characterization. The bowed profile has probably a role in making narrower the process window, but it seems very hard to make the profile vertical without generating problem on large areas. As a consequence, depending on pitch and CD target, hard mask thickness is not a degree of freedom but its highest allowed thickness depends on collapse process window. Depending on dimensional requirement, this upper limit can cause selectivity issues, so leading to the need of a high polymerization process, with a consequent issue of narrower process window with respect to etch stop.
When a "collapse-free" condition was realized (in term of CD and carbon thickness) and the pattern was transferred to oxide, no issue related to strip has been observed.

Conclusions

In this work organic and inorganic hard masks have been studied for advanced microelectronic technology node (90 and 65 nm). In particular four layers have been characterized (TiN, SiON, bi-layer and Ashable Hard Mask) and the advantages and disadvantages of each one have been discussed.
For inorganic hard mask it has been showed how PVD TiN is the one able to guarantee the best selectivity (almost no consumption during dielectric etch, no pitch dependence on final oxide line height) but several constraint related to process manufacturability are present. PECVD SiON, on the other side, requires a fine optimization for each application, so it costs more in term of process development time; nevertheless, the final optimized process is a standard one from the RIE point of view, so it's easier to manufacture. Final oxide stripe height depends on pitch, so denser areas are expected to undergo higher consumption than isolated lines, but it has been demonstrated this approach can support at least the 65 nm-node shrink.
Organic hard masks are the easiest choice from integration point of view. After a standard strip, they are supposed to be completely removed, so no particular process flows are needed to manage the residual hard mask. Poor dimensional tuning window has been observed for Bi-layer approach, coupled with severe defectivity and stripping problems. AHM tri-layer guarantees a CD tuning feasibility, but, moving along the technological roadmap, it has been demonstrated its thickness has to decrease with pitch, in order to be free from line collapse problem. Feasibility is proven for 65 nm technological nodes, but its extension to further shrink could be affected by this limit.

Diagnostics of pulsed mercury free low pressure fluorescent lamps

E. Robert, C. Cachoncinlle, R. Viladrosa, S. Dozias, S. Point and J.M. Pouvesle

GREMI, CNRS-Polytech'Orléans, 14 rue d'Issoudun, BP 6744, 45067 Orléans Cedex 2, France

Abstract This work deals with the development of mercury free low pressure glow discharges likely to be used for publicity lighting. The experiments are performed in neon xenon mixtures powered by a pulsed electronic driver delivering electrical pulses of microsecond duration at repetition rate of a few kHz. Time resolved spectroscopic and electrical measurements are presented during the pulse application and in the afterglow phase of the discharge. The population of NeI, XeI and XeII representative lines is described in correlation with the current pulse development across the sign.

Keywords: mercury-free lamp, fluorescent lamp, glow discharge, UV-VUV, pulsed discharge, plasma kinetics

1. Motivation

This work presents a time resolved spectroscopic and electrical study of new rare gas based fluorescent signs, likely to be used in publicity lighting, powered by a pulsed electronic driver.
The search for efficient and environmentally friendly substitutes for mercury is today a key issue in many light source technologies, such as automotive lamps and fluorescent lighting systems [1].
In a first research and development program, the use of neon-xenon based low pressure discharges appeared as the best solution for the excitation of phosphors [2,3]. A strong trade off between the luminous flux and the setup lifetime was also measured [4,5] and shown to be the result of a very efficient removal of the xenon from the gas mixtures during the sign operation [5]. Furthermore, the increase of the mean current leads to a saturation of the luminous flux extracted from rare gas based signs for injected powers higher than about ten watts when using conventional ballasts on the contrary to the linear behaviour of mercury based devices.
The development of a pulsed electronic driver delivering high repetition rate current pulses in the microsecond time range allow to achieve a three to four times enhancement of both the luminous flux and efficiency of mercury free signs [5]. Besides this significant improvement, the use of pulsed excitation also indicates that high luminous fluxes can be obtained for higher mixture pressures and/ or higher xenon concentrations than those necessary for the AC excited signs, which could be a key factor for the long lifetime operation. Finally, the study of the plasma kinetics induced through pulsed excitation of low pressure rare gases mixtures appears as a crucial issue for the development of efficient and long-living mercury free fluorescent lamps. A first approach for the description and optimization of the pulsed binary rare gas mixtures properties is obtained through time resolved emission spectroscopy by measuring the population of the excited levels of both neon and xenon neutral and ionic states during the current pulse and in the afterglow.

2. Experimental results

The search for the better operating conditions (mixture composition and pressure, pulse amplitude, duration and repetition rate, etc.) of pulsed rare gas based signs is investigated in this work through time resolved spectroscopic diagnostics of the near by electrode and positive column plasmas in relation with electric probe measurements. The spectroscopic measurements have been performed with a 13 mm inside diameter neon xenon sealed sign which radiation is dispersed through a spectrometer equipped with either a photomultiplier tube or a fast ICCD camera. Two probes record the voltage across the sign, with typical amplitudes of a few kV, and the voltage pulse across a resistive shunt providing the current flowing through the cold hollow cathode pulsed discharge. The lab-developed electronic driver allows the selection of the voltage pulse amplitude, duration and repetition rate and as

a consequence the current pulse properties. Each cycle of the driver consists in one positive polarity pulse and one negative polarity pulse to allow a symmetrical operation of the two hollowed electrodes.

2.1. Neon - xenon emission during the electrical pulse

As an illustration of the parametric study, the figure 1 presents the voltage and current waveforms together with the temporal evolution of three emission lines representative of the neon xenon plasma species. The spectroscopic measurement was performed with the spectrometer entrance slit aligned with the close vicinity of the hollow electrode. About 0.4 µs after the onset of the voltage pulse across the sign, a short current spike is observed in relation with the strong emission of neon lines. While this current spike is measured with the same amplitude but a reverse polarity through a complete cycle, following the mode of operation of the electronic driver, it appears that the neon line emission spike exhibits a large and very reproducible amplitude modulation with the pulse polarity. This peculiar relationship, between the current and the plasma emission during the very first stage of the pulsed discharge, also evolves in close correlation with the moderate heating of the electrodes during a few minutes after the sign ignition. These observations are supposed to be correlated with the electron emission processes at the electrodes, essentially monitored by the ion fluxes which also induce the electrode heating and sputtering.
During the time gate spanning from about 0.5 to 2 µs, the neon lines are largely quenched at the benefit of neutral xenon emission radiation. The third phase of the pulsed discharge results in the quenching of the neutral xenon radiative states, the repopulation of neon transitions, and the production of high energy xenon ionic levels. Simultaneously with this plasma kinetics, a strong and nearly linear increase of the current amplitude is measured during the third phase of the pulsed discharge.

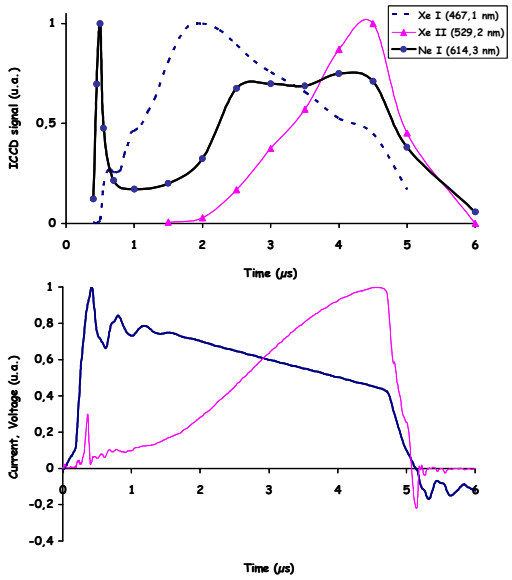

Figure 1 Temporal evolutions of the NeI ($3s[1^1/_2]°$ - $3p[1^1/_2]$, 16,62-18,63 eV, bold line), XeI ($6s[1^1/_2]°$ - $7p[2^1/_2]$, 8,31-10,97 eV, dotted line) and XeII ($6s^4P$ -$6p^4P°$, 23,67-26,02 eV, thin line) emission lines. The spectroscopic diagnostics is performed in a 10 mbar sign powered by a pulse driver delivering the voltage (bold line) and current (thin line) waveforms presented in the bottom diagram. Each data point is measured by averaging over a few thousands of current pulses, the light collected by the ICCD detector set with a 50 ns width intensifying gate.

The figure 2 presents the temporal evolution of the same NeI, XeI and XeII lines for a 4 microseconds pulse delivered at 500 Hz and 1 kHz. On the contrary to the experiment described in figure 1, the spectroscopic diagnostics is performed in the middle part of the sign positive column. It was observed that when the pulse repetition rate is high enough to measure an early current spike, the NeI and Xe I

lines exhibit such a temporal spike only in the electrode zone. This radiative spike rapidly decreases with the distance from the electrode so that it is no more observed in the positive column region for high repetition rate conditions. On the other hand, for the lower repetition rate operation, the current waveform does not exhibit the early spike described in figure 1 while both the XeI and NeI emissions present such a short spike at 500 Hz even at long distance (a few tens of centimetres) from the electrodes. These observations tend to indicate that the spikes observed for the Ne and Xe lines reveals the existence of strong electric field gradients in the electrode region, so called electrode fall, which amplitude and spatial extension is strongly dependent on the pulse repetition rate and also probably pulse duration in our experimental conditions. For the higher pulse repetition rate the field gradient are probably strong enough to result essentially in the production of ionic species in the electrode region and the appearance of the strong current spike. The temporal evolution of the XeII line exhibits a small spike for the 1 kHz measurement. It was also measured that the spike amplitude observed for the NeI lines is correlated with the upper level of the radiative transition. In figure 2, the XeI line maximum is measured at shorter time during the current pulse in correlation with the earlier appearance of the XeII lines and the faster rise of the current pulse. The population of the XeII lines can process through various processes such as electronic excitation from the neutral xenon, from the excited levels of xenon or through collisions between xenon ion and excited states of the neon. The fast production of the XeII lines, on microsecond timescale, indicates that the two first processes seem to be more relevant for the population of the ionic xenon states. Work is in progress to study the effect of the mixture partial pressures on the production of XeII lines and the current increase during the pulse application.

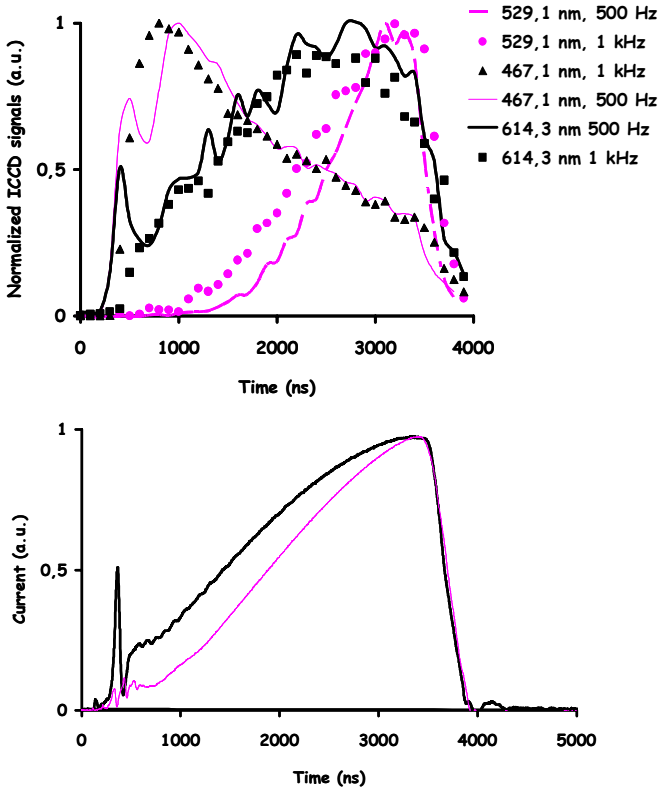

Figure 2 Temporal evolutions of the NeI, XeI, and XeII lines (labelled in fig.1) at 614,3 nm (squares for 1 kHz, bold line for 500 Hz), 467,1 nm (triangles for 1 kHz, thin line for 500 Hz) and 529,1 nm (dots for 1 kHz, dashed line for 500 Hz). The spectroscopic diagnostics is performed in a 10 mbar sign powered by a pulse driver delivering the current (bold line for 1 kHz, thin line for 500 Hz) waveforms presented in the bottom diagram.

2.2 Neon-xenon afterglow

The figure 3 presents the temporal evolutions of the XeI (467,1 nm) and XeII (529,1 nm) lines over 22 microseconds measured in the 10 mbar sign powered by the current pulse shown in fig.2 at 500 Hz.

The line intensities are sampled on one microsecond intensifying gate and averaged over a few thousand pulses. The XeI and the NeI (not shown in fig. 3) lines are populated during the afterglow while the XeII does not exhibit such a behaviour. After the current pulse extinction, in the time window between 5 to 8 microsecond, no signal is measured and the peak of the afterglow signal is observed around 16 microsecond both for XeI and NeI lines for 500 Hz and other pulse repetition rates. The afterglow contribution is about three times larger than the radiation emitted during the pulse application. This features explain in a large extend the considerable improvement in sign performance (output flux and efficiency) when using pulsed excitation in comparison with conventional AC excitation. The zero signal window (5-8 microsecond) is usually explained by the electron cooling, after the current pulse application, necessary for the recombination processes to be efficient. The recombination of molecular ions is known to be one the main processes likely to induce a strong population of the atomic excited states during the afterglow. The recombination for the neon lines has been measured to be at least five times smaller than that of the xenon lines. Work is in progress to study the afterglow to pulse signals ratio versus the mixture partial pressures, the formation of molecular ions in low pressure conditions being strongly dependent on the gas mixture pressure.

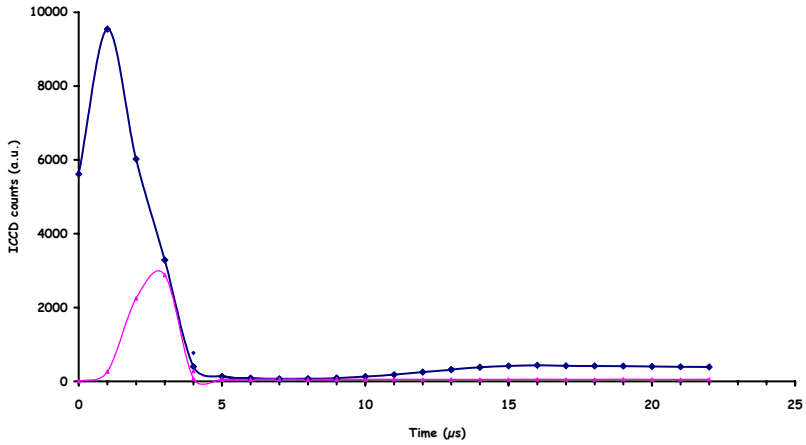

Figure 3 Temporal evolutions of the XeI (467,1 nm) line (bold line) and the XeII (529,1 nm) line (thin line) for a 10 mbar sign powered by 4 microsecond pulses delivered at 500 Hz.

Finally, in the later stage of the afterglow phase, time window ranging from 20 to 500 microseconds, a quasi exponential decay of both NeI and XeI lines is measured. While the XeI lines decay curves are almost similar whatever the radiative states considered in this work (spectral domain ranging from 400 to 600 nm) and for different pulse repetition rate operation modes, the NeI lines decay curves are faster for the lower lying levels (in the range 18,96 to 18,55 eV) and present a strong dependence on the pulse repetition rate.

Conclusion

The pulsed excitation of neon xenon mixtures allowed a three to four times enhancement of the optical flux and efficiency issued from low pressure signs in comparison with the conventional AC excitation scheme. This feature is essentially obtained by the strong emission occurring in the afterglow phase of the discharge. During the pulse application, fast kinetic processes, evolving on microsecond time scale, lead to the population of NeI, XeI and XeII radiative states. The appearance of the XeII lines occurs in correlation with the decay of XeI states and the quasi linear rise of the current amplitude. After the application of the electrical pulse, the plasma cooling allow recombination reactions to occur leading to the efficient population of XeI levels and in a much smaller extend of the NeI lines. The decay of the radiative levels during the afterglow appeared to be sensitive to the pulse repetition rate for neon transition while being quite independent on the radiative states and electronic driver operation mode for the xenon transition. The understanding of all the cross correlated spectroscopic and electrical observations reported in this work are thought to be a key issue for the development of

efficient and long living mercury free signs presenting both high illuminance and controlled photometric (chromatic coordinates) characteristics.

Abstract
The aim of this work is to show preliminary results from the characterization of cotton fabric samples chemically and physically modified by Atmospheric Pressure Plasma (APP). The surface properties of cotton fibres were characterized by capillarity test, Attenuated Total Reflectance – Fourier Transform Infrared (ATR-FTIR), X-ray Photoelectron Spectroscopy (XPS), and Atomic Force Microscopy (AFM). The results provide a strong evidence that all APP treatments enhance capillarity diffusion of dye liquid and chemical oxidative process on the surface of cotton fibres.

1. Introduction
The general reactions to be achieved by plasma treatment of cotton fibres are the surface oxidation, the generation of radicals and the edging of surface. Both the surface chemistry (confinement of functional groups to the surface) and the surface topography may be influenced to result in improved hydrophilization, wettability and wickability properties of cotton fabrics, as well as printability and dye uptake [14-15].
Instead of traditional low-pressure plasma treatments, APP is a very promising technique to treat cotton fabrics because it doesn't require a vacuum equipment and it can be applied directly on-line in a textile industrial process. The realization of an industrial APP prototype able to treat cotton fabric two-meters in width is the main result reported in the present work.

2. Experimental
A roll-to-roll system has been mounted around the APP system, in order to make the homogeneous plasma treatment on cotton fabrics. The roll-to roll system moves the cotton fabrics in a speed ranging from 1 to 10 m/min and can simulate the industrial process. This type of simulation is useful to show off how several plasma treatments could be used for many on-line applications, such as dyeing phase or mercerization or any kind of finishing treatment on cotton.
Textile fabrics run under the treatment zone, represented by a short gap (1-5mm) between a high voltage powered electrode, commonly called cathode, and a grounded electrode, anode. As shown in Fig. 1, in this configuration called Dielectric Barrier Discharge (DBD), the cathode is fixed while the anode is a free rotating cylinder, dragged by the fabrics.
Before the treatment, textile fabrics are opportunely dehumidified thanks to three big steel cylinders heated by an internal steam flow at a pressure of 5 bars. Humidity absorbed by cotton fabrics must be as low as possible, in order to avoid discharge instabilities and filamentary discharge appearance.
A gas manifold with two manual flow meters, with a full range scale of 6 m^3/h, has been used to control the inlet of many gases and their mixtures: N_2, CO_2, He, Ar, N_2O_2, dry air. The gas inlet is an integral part of the cathode, and the more diffuse is the gas distribution, the more effective is the plasma treatment.
The equipment for high voltage signal generation is constituted by a low-medium frequency signal generator and a high voltage transformer, both exactly designed for DBD applications by Grinp s.r.l. Common AC 220-380 V at 50 Hz signals are properly processed by the generator and sent to the transformer, which amplifies them up to 20 kV peak voltages. The generator provides the maximum of electrical power to the load electrode when the system resonance frequency is reached.

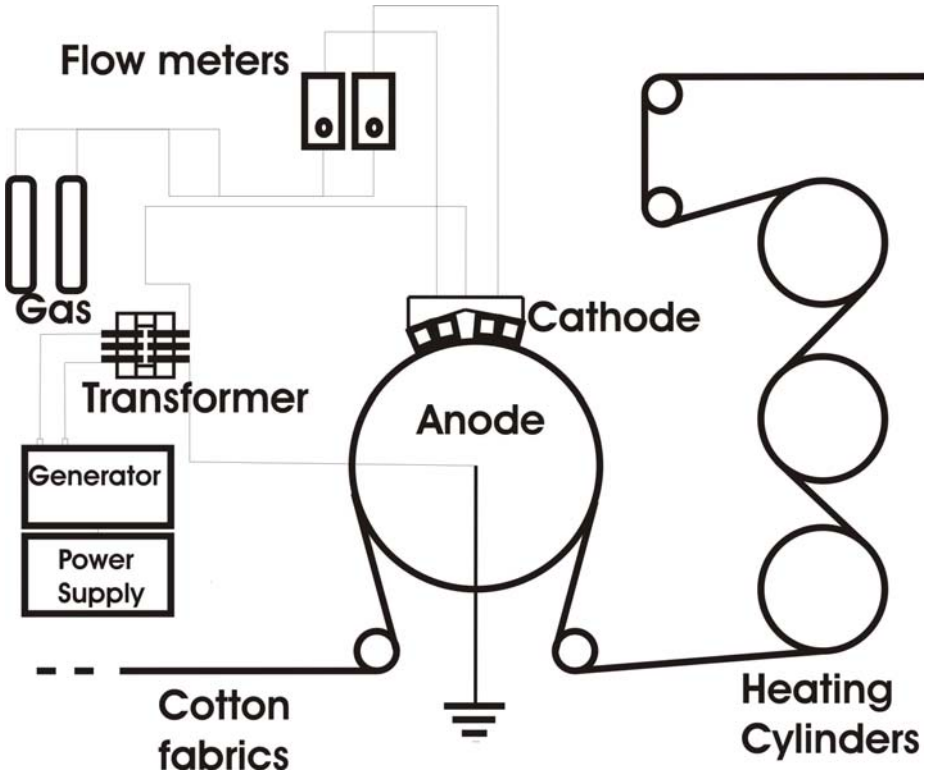

Fig. 1: Experimental arrangement for fabric plasma treatment

Capillarity test has been used to evaluate the diffusion coefficient D of a dyeing liquid into the cotton fabrics. This is a quantitative measurement of wickability, i.e. the bulk absorptivity of cotton fabrics.
The results were treated on the basis of the general wettability relationships [1-4], according to Washburn's equation, the squared rate of liquid capillary rise in porous media is given by:

$$h^2 = \frac{r\gamma\cos\vartheta}{2\eta}t \tag{1}$$

where h is the height by the liquid at the time t, $r = \frac{R_D^2}{R_S}$ is the ratio between R_D the mean hydrodynamic radius of pores and R_S the mean static radius of pores, η the viscosity of the liquid, θ the advancing contact angle of the liquid on the solid and γ is the surface tension of the liquid. The static radius is equal to the geometrical radius of pores, whereas the hydrodynamic radius depends also on the tortuosity of these pores.
Hence, h^2- values must vary linearly with time:

$$h^2 = Dt \tag{2}$$

where the slope D is a capillary diffusion coefficient related to the size of the capillaries r and to the physicochemical characteristics of the liquid. Therefore, a surface treatment of a fabric that modifies r and contact angle causes some variation of this diffusion coefficient D and a set of height adsorption values vs time allows qualitative characterization of fabric sample wettability and wickability. The dye liquid is represented by a chemical inert blue pigment that does not react with the surface of the fibres. This allows to appraise the distribution of the dye liquid along the height of the analyzed samples.
A SensIR Technologies Attenuated Total Reflection – Fourier Transform Infrared (ATR-FTIR) spectrometry was used to provide valuable information related to the chemical structure of sample surface [4,5]. The IR radiation actually penetrates a short distance (~0,5 μm).
X-ray Photoelectron Spectroscopy (XPS) were carried out using a XPS spectrometer equipped with a monochromatised Al K X-ray source (1486.6eV) at 15kV and 10mA.

Physical surface changes on the samples were detected with a SPM DualScope Scanner DS -200Digital Atomic Force Microscopy (AFM). Since cotton fibre surface is very jagged measurements were carried out in non-contact mode.

3. Results and Discussion

Within the limits of consequential variability (due to small electrical instabilities at very high voltages on a two-meters-wide DBD system), the same electric parameters have been maintained (Table 1), mainly in order to study the effects of the type of gas and flows on plasma treatments. In some cases, a treatment has been repeated several times to appraise the effects on the fabrics caused by the plasma exposure time.

Voltage (kV)	**Frequency** (kHz)	**Power** (W/cm^2)
11	30	11

Table 1: electrical parameters

Table 2 provides a summary of the capillarity test results; for each sample the discharge evidence mainly drawn from electrical data is reported. In some cases a specific treatment was repeated to establish a relation between D and the time of plasma exposure and to verify the existence of a saturation exposure time.

In general, an increase of D is appreciable for all plasma treatments compared to an untreated sample. But D is obviously influenced by the gas used for the discharge and the homogeneity of the discharge, and by the gas flow. In each situation considered N_2 plasma gives an homogeneous (diffuse) discharge at atmospheric pressure, commonly called Atmospheric Pressure Glow Discharge (APGD); this plasma regime is related to a high D values. A similar discharge behaviour can be observed when He is added to the gas mixture because He metastable species help obtaining a diffuse discharge characteristic by Penning ionization effect.

It has been shown that presence of CO_2 in the gas mixture drastically influences D because all the Oxygen containing species such as molecular oxygen, ozone or water vapour lead to a filamentary discharge mode because of production of ozone, nitrogen metastable species loss, due to an increased dielectric barrier surface conductivity.

Under the same electrical conditions, an identical small amounts of N_2 and CO_2 (0,2 m^3/h) corresponds to a D = 10,91 mm^2/s and D = 1,41 mm^2/s respectively. The diffuse characteristic of a N_2 discharge progressively disappears when CO_2 flow increases in a mixture of the two gases; D decreases simply by adding CO_2, in agreement with previous deductions.

Nevertheless, D doesn't increase with nitrogen flow values as it could be expected. Enriching the atmosphere with N_2, most of the atmospheric oxygen (existing as impurity in the unevacuated reactor and brought by the cotton fabrics movement) doesn't reach the process zone.

Oxygen is the source of highly chemical reactive species, and, provided that it doesn't exceed certain concentrations to induce discharge instabilities, it is very important in surface oxidation treatment and in surface ablation (etching).

The last evidence can be verified by comparing samples #74 – #77 (table 2). He makes the diffused characteristic of the Townsend discharge to strongly increase with a concentration of only 4,5% in a nitrogen/helium mixture (sample #74 and #75), but at the same He concentration in the mixture (sample #76 and #77), the capillarity effect is more evident when the N_2 concentration is lower.

In fig. 2 there is an overlapping of four spectra concerning four different samples. The spectral region involves typical vibrational activities due to cellulose chemical bonds. In fig. 2a it can be noticed that the use of CO_2, as seen in samples #31 #71, increase the superficial oxidation of the cotton fibres. That activity is bound to the peak at 984 cm^{-1} of vibrational stretching of C=O carbonyl bond. Sample #5 (fig. 2b), obtained by a nitrogen plasma treatment, shows a weak variation of the same peak if compared to the untreated sample [6]. Thus, the surface oxidation is related to the presence of oxygen precursor, such as CO_2 gas or other Oxygen containing mixtures.

However, even if the carbonyl peak is the most evident vibrational activity, it has a very weak intensity, and this is in accordance with the fact that the plasma treatment doesn't penetrate deeply into the bulk fibre [5].

Table 3 sums up measurement data of XPS analysis on some samples. Untreated and plasma treated samples are compared with a "test" sample obtained with wet chemical treatment in highly concentrated NaOH solution (mercerization).

Sample	Velocity	N treat	Discharge	N_2	CO_2	He	D

(a) (b)

Fig.2: ATR-FTIR analysis. Comparison of different samples

Conc. at %	C	O	N
Untreated	83.4	14.2	0.9
Test	70.4	27.7	0.3
Sample 74	74.4	20.2	4.0
Sample 75	77.9	18.3	2.8

Table 3: percentage concentration of chemical elements on cotton fibres

The XPS data show that the treatment in plasma increases the superficial concentration of nitrogen and oxygen [8,7]. N_2 plasma treatment increases the nitrogen surface concentration, maybe in the form of $–NH_2$ group or similar (primary or secondary amino groups). Nitrogen content doesn't seem to exceed a saturation value after four times treatment duration as in sample #74.
Oxygen content on the surface of cotton fibres comes from impurities in the processing atmosphere, due to the bad isolation of the plasma reactor. However, also a small O_2 amount in the gas feed leads to an increase of oxygen signal [7]. Many studies on the role of gas composition [10-13] in the DBD treatment of polymers show that O_2, even when present in small quantities, can significally affect the surface chemistry and hence the level of surface transformation.
The fittings of the carbon peak C1s have been carried out for sample #74 and sample #75. It is possible to isolate three components of the carbon peak: the first two are typical of the cellulose (286.7 eV and 288.1 eV), while the third one belongs to a carbossyl or carbonyl groups (290 eV).

	-C-**C**H_2-OH	-O-**C**-O-	HO-**C**=O
Test	69 %	22 %	9 %
Sample 74	63 %	26 %	11 %
Sample 75	62 %	29 %	9 %

Table 4: percentage concentration of the chemical bonded carbon

Table 4 shows the fractions percentages of the three components for the single analyzed samples.
From the point of view of superficial carbon compounds the two samples treated with plasma are quite similar. This is the evidence that N_2 or N_2/He plasma treatments do not strongly affect surface chemistry over a certain limit. The contribution of the 290 eV signal doesn't exceed 11% even after a high time exposure to the plasma. The plasma action is strictly closed to the surface region [5].
Atomic force Microscopy (AFM) provides information about the topography of to the cotton fibres. AFM analyses are carried out comparing topographical images of plasma treatment with untreated samples. AFM measurements of treated samples generally show some changes in surface roughness: it increases if compared to untreated samples. Fig. 3 shows the comparison between sample #74 and an untreated sample. Samples #74 was treated four times with a nitrogen plasma, gradually caused more wrinkled surface. Such superficial wrinkleness can be correlated to the capillarity increase and to the diffusion coefficient D of the sample #74.

Fig. 3: comparison between sample #74 treated by nitrogen plasma (a), and untreated sample (b)

4. Conclusions

APP industrial prototype system has been assembled in order to treat textile fabrics in movement.
The morphology of cotton fibres is affected by Plasma treatment. AFM measurements show a notably change in surface roughness and a characteristic wrinkled surface on N_2 plasma treated fibre. Improvement of roughness and wrinkled characteristic can be related to higher D coefficient.
Plasma treatments generally increase wickability properties of cotton fabrics, but wickability is strictly correlated to homogeneity of discharge rather than to surface chemical changes. On the other hand wettability (fig. 1) is related both to homogeneity of discharge and surface chemical changes due to different precursors.
The aim of this work was to demonstrate how the plasma can be an interesting industrial application for textile processes. In the future new plasma processes will be investigated, in order to find the best processes for each type of dyeing substance, to find new kind of surface functionalization for different textile application by plasma grafting or plasma polymerization, and to optimize plasma pre-treatment processes.

5. Aknowledgments

The authors would like to thanks Prof. F. Geobaldo, Dott. G. Ieluzzi, and J. Rocci of Polytechnic of Turin in Italy for ATR-FTIR and AFM measurements, Dott. L. Meda of Polimeri Europa – Istituto Donegani of Novara in Italy for XPS measurements, Dott. C. Ricciardi of Polytechnic of Turin in Italy for his valuable discussion and advice.

Abstract

TiN, TiAlN, TiAlSiN and nanostructured TiN films were deposited on samples and on prostheses components by DC-ARC-DC LARC™ with a growth rate of 2.5-3 μm/hr, while a-SiO_x coatings of about 6 μm thickness were grown by RF-PECVD on dental materials with a growth speed of about 1.4 μm/hr; the films were characterized respect to their surface properties by means of Electron Scanning Microscopy and high resolution Surface Profilometry.

Keywords: Dental prostheses; plasma assisted deposition; thin films

1. Introduction

Thin-film coatings are extremely important as enabling technology for the fabrication of prostheses to be implanted in the human body [1, 2]. Nanocomposite thin films support several organism functionalities and allow significant enhancement of prostheses performance in different ways. First of all, ceramic and amorphous coatings have excellent barrier properties and they can substantially improve the bio-compatibility of the prosthesis that are directly in contact with the living tissues, avoiding the contact with potentially dangerous materials and blocking the diffusion in the human body of poisonous or allergenic elements coming from the massive material such as Chromium, Nickel and Cobalt, which are present in 95% of alloys (i.e. stellite) for dental prostheses and implants applications. Ceramics coatings also exhibited very good osteogenic properties when applied on artoplastic implants [3]. Ceramic coatings considerably extend also the overall reliability and longer components life cycle, since they can avoid the deterioration of the prosthesis, that is responsible for the formation of particles that can diffuse in the body, with potentially harmful effect on the human health. In the case of dental applications deposition of amorphous or ceramic bio-compatible thin films can also protect the prosthesis from the corrosive action of the saliva and some by-products of food mastication. Durability of ceramic and amorphous coatings functional properties constitutes a major source of reliability for the medical implants and movable prostheses. TiN and ZrN ceramics coatings deposited on OT58 substrate were proven [4] to provide excellent chemical barrier against very aggressive acid agents such as HF, HCl, H_2SO_4 as well as against strong bases such as NaOH. Salt test spray guaranteed resistance of such coatings in extreme environmental conditions [4]. This provides a good reliability of such materials when exposed to less extreme pH and salty environments such as the oral one. Another aspect in which thin film coatings can be helpful is the one of aesthetic features of the prostheses, regarding their colour and brightness selection and preservation in time against ageing. Thin-film coatings can greatly improve the aesthetic features of the prostheses by changing their chromatic properties and light reflection in a controllable way, thus achieving the proper colour and increasing the surface brightness. Typical colour accepted for these applications are within the gold chromatic range. For this reasons TiN and ZrN-containing coatings were developed. For the above

mentioned reasons nanotechnological coatings determine an innovative enabling solution to cure patients allergic to heavy metals contained in prostheses bulk material as well as for providing long life materials preserving the same good looking characteristics. Along with chemical inertness, ceramic coatings were also considered for other functional enhanced properties such as high hardness (up to 3500 micro-HV), fatigue resistance, flexibility, toughness, and good adhesion properties over a large number of materials.

The amorphous silicon-oxygen alloys (a-SiO_x) are also among the most suitable materials for achieving this tasks due to their physical properties such as chemical inertness, high hardness, transparency and good adhesion properties over a large number of materials, together with good properties against diffusion. This kind of materials can be deposited by means of various growth techniques, such as Physical Vapor Deposition (PVD), Chemical Vapor Deposition (CVD), Plasma Enhanced Chemical Vapor Deposition (PECVD). The most suitable techniques for the deposition of thin films on dental prostheses are plasma assisted techniques, since they allow the material growth at a very low temperature. This is particularly important because the materials of which the prostheses are made cannot usually stand high temperatures without a sensible degradation of their properties. Among plasma assisted techniques, PECVD offers the advantages of simplicity, relatively low cost, versatility and allows the deposition of composite materials (such as a-SiO_x), varying the ratio of the different components in a wide range, while deposition of PVD coatings proves to be the best process for attaining highly dense and packed coatings with minimal content of micro-particles, flexible nano- and micro-structure design.
Films of a-SiO_x where grown in a Radio Frequency (13.56 MHz) PECVD (RF-PECVD) reactor using SiH_4 and N_2O as precursor gases at temperatures lower than 100°C on substrates of different materials used for the fabrication of dental prostheses; the films were characterized respect to their surface morphology by Scanning Electron Microscopy (SEM) and profilometry. Moreover, binary, ternary and quaternary Nitrides where grown by PVD on metal alloy substrates for dental frames and implants: the fluxes of reactive gases, arc currents and bias voltages were changed in order to test the properties of the coatings characterised by different chemical compositions.

2. A-SiO_x films

Films of a-SiO_x where grown on two different dental materials by a RF-PECVD reactor using silane (SiH_4) and nitrous oxide (N_2O) as silicon and oxygen precursors respectively. The deposition system was a standard capacitively coupled PECVD system, composed by two electrodes of 144 cm^2 area each, located at a relative distance of 20 mm. A RF potential at a fixed frequency of 13.56 MHz was applied between the electrodes in order to light the plasma discharge. The gas precursors were injected in the space between the electrodes by a Mass Flow Controller (MFC) driven injection system, ensuring a controlled gas flux inside the reactor. The reaction byproducts and exhausted gases were pumped away by a pumping system consisting of a turbo-molecular and a downstream mechanical base pump.

The substrates, having the shape of small square pieces of dimensions 10 mm x10 mm x 2 mm, were cleaned before the growth process rinsing them in a acetone ultrasonic bath for 5 min; two types of microcomposite dental materials were used as substrates for the film deposition: Gradia from GC and Signum from Haeraeus-Kulzer. All the samples were put together in the deposition chamber; each substrate was partially covered with a mask in order to obtain a step between the film and substrate surfaces (see fig. 1).

The gas flow ratio and total gas flow were kept fixed to the following values: $[N_2O]/[SiH_4] = 40$; $[N_2O+SiH_4] = 61.5$ sccm. The total pressure inside the reactor was 400 mTorr, the power density applied to the plasma discharge was 20.8 mW cm^{-2}, while the substrate temperature was about 70 °C in order to avoid the risk of degradation of the substrate material.

A Tencor PL-10 mechanical profilometer was used to evaluate the film thickness by measuring the height of the step between the film surface and the uncovered substrate surface: the deposition rate, obtained by dividing the measured film thickness by the deposition time, was found to be about 1.4 μm/hr. The same instrument was also used for the evaluation of the roughness of the samples surfaces before and after the film deposition. A Scanning Electron Microscope was used to get images of the surface morphology of the film and substrate

surfaces; before the microscope analysis the samples were covered by a thin metal film in order to improve the detection signal, as shown in fig 1.

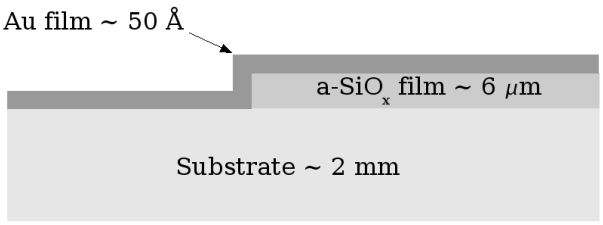

Fig.1. Structure used for the investigation by SEM of a-SiO_x films deposited on dental materials

Tab.1 shows the results of roughness measurements, performed on two different types of dental materials (Gradia and Signum Heraeus) before and after the deposition of a a-SiO_x film. The measurement was performed by acquiring the surface profiles along five different paths for each sample; the paths lengths were kept in range 4-5 mm and were taken in the central part of the sample. The measured surface profiles were filtered in order to separate the long-wave component (waviness) from the short-wave one (roughness); the separation was performed by a software filter provided by the data acquisition software of the profiler. The roughness was evaluated for each path as the RMS of the surface profile and the mean value of the five paths is reported in last table row. It is clear from the measured data, that the surface roughness was not significantly modified by the presence of the film; this fact is due to the high roughness value of the given substrates, that cannot be reduced by a film of this thickness.

Fig. 2 shows two SEM images, taken in the area surrounding the step between the film and the uncovered substrate surface; the darkest area on the right is covered by the a-SiO_x film, while the lighter area is uncovered. As can be seen, the surfaces of the samples present several kind of structures, such as stripes and holes, that are probably due to the mechanical surface polishing procedure. The same structure are still present after the film coverage, confirming that the film thickness is not sufficient to reduce the substrate roughness, as shown by profilometry.

3. Ceramic films

Binary, ternary and quaternary nano-composite ceramics coatings of the family TiN, TiAlN and TiAlSiN were deposited on samples and on prostheses components defining a new class of thin films applicable to bio-medical metal alloy substrates. In particular, nano-structure and composition in which nano-cristals of TiN (n-TiN) are dispersed in a amorphous matrix of Si_2N_3 (a-Si_2N_3) determined enhanced wear resistance and hardness; multilayered and graded microstructure and composition allow for maximum barrier efficiency against migration of undesirable chemical compounds and elements. Stoichiometry determining chromatic characteristics has been devised in such a way to fulfil the aesthetic requirements (colours were limited in the 'gold range') also for coatings naturally not displaying such chromatic variety . The final layer of the developed coatings has been heavily loaded by either TiN or by ZrN non-stoichiometric compounds.

Fig.3. Images of different typical dental materials prostheses with complex geometry coated with TIN

Among different technical solutions (sputtering, evaporation, etc.) the PVD ARC-DC LARC™ process was chosen in order to grow complex, dense-packed, microparticle-free ceramics thin films. LARC™ is a innovative evolution of the existing standard PVD ARC-DC deposition techniques in that it allows dramatically decreasing the output of micro-particles, although preserving efficient growth rates (about 2,5-3,0 microns/hour). Indeed the LARC™ technology provided by the Clean NT Lab Platit-PL55 unit with rotating cathodes proved to be an efficient solution to deposit thin ceramic films on stellite three dimensional complex substrates. The innovative cathode geometry increases the cathode surface and assures uniform and controlled

target consumption. Cathode surface may be kept at low temperatures (15-30°C) through an efficient closed loop cooling system, spot trajectory is controlled by adjustable magnetic fields which minimize the spot residence time on the target surfaces, determining uniform evaporation and decreased microparticles yield.

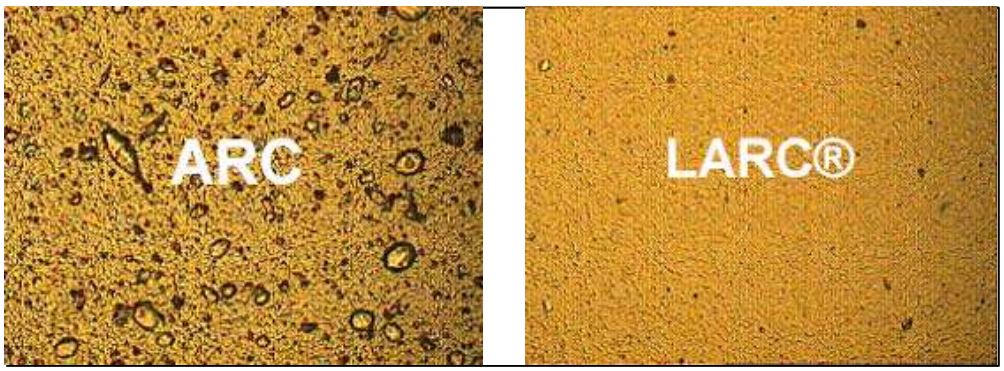

Fig.4. Comparative optical microscope Images in the 10 microns range of two TiN coated substrates showing dramatic decrease of microparticle content in LARC® deposited ceramics coatings

The coating quality in terms of low macro-particles content is quite important for avoiding stress concentration at discrete positions on the coated surface, which may determine an adhesion fault or substantial depletion of barrier property, as well as for aesthetic requirements, especially for what pertaining surface gloss. The process was run in the 200-450°C temperature range at pressures in the order of 10^{-5} mbar, thus assuring the growth of high quality and dense-packed layers columnar- free micro and nano-structures

One or two cathodes were used according to the required stoichiometry. For binary and ternary coatings one Ti or Zr target was employed with Nitrogen as process gas (for binary coatings), Nitrogen and Acetylene as process gases for ternary ones were employed. For quaternary coatings deposited Stoichiometric and non-stoichiometric compounds were realized by employing two cathodes in the same process. For specified process parameters it was possible to deposit nano-structured and nano-composite ceramic thin films. These films were realized by exploiting the spinoidal decomposition occurring in the specified temperature and pressure range. Nano-structured coatings were realized by growing a Si_2N_3 amorphous matrix in which nanocrystals of the metal employed (i.e. Titanium) are dispersed. These films belong the family of super-hard coatings, displaying hardness values exceeding 3500 micro-Vickers, deriving from the grain boundary interactions with the amorphous matrix.

Particular attention was devoted to find the optimal bias voltage in order to avoid excessive energetic impacts of ions on the substrates, characterised by geometries in which at least one of the typical substrate scale lengths was much smaller than the others. This allowed avoiding the possibility of damaging such components by overheating them or by performing a too energetic etching of the surface and bulk material.

Testing and characterization to bio-compatibility requirements of the developed coatings are in progress.

Abstract
This work is focused on the developing and validation of materials grown by plasma techniques, processed for the realization of micro and nano-structures for advanced devices and sensors for genomics, post-genomics and proteomics analyses. Carbon, silicon and titanium based alloys - deposited by means of Physical Vapor Deposition (PVD) - were implemented in miniaturized cantilever microbalances produced with a 2-masks bulk micromachining process.
Keywords: cantilever, micromachining, PVD, genomics

1. Introduction

The recent scientific and technological advances in micro- and nano-technologies, in material and surface science (particularly concerning the interaction between synthetic materials and biologic molecules) in connection with the exceptional developments in the area of genomics and proteomics pave the way to the development of highly innovative methods for DNA, RNA, protein, other biologic molecules and cell analysis, and open new perspectives for the application of molecular diagnostics methods into bio-medical, pharmaceutical and agro-food areas [1]. However, in these areas, the technology is still requiring the availability of fundamental research on materials in order to realize devices which are able to carry out quickly thousands of complex biochemical assays at high resolution down to the femtogram level [2]. Present knowledge and technologies meet clear limitations in satisfying this demand, limitations that also hamper some of the potential application of molecular diagnostics into still unexplored and unexploited fields.
Aim of the research activity is to develop microgravimetric technologies employing cantilevers in order to build MEMS/NEMS-based arrays of microbalances ("cantarray") by means of different plasma processes that allow reaching the sensitivity sufficient to detect and identify nucleic acid molecules. This sensor technology, to be developed as nano-balances with integrated readout, holds great promises as a fast and cheap 'point of care' device (avoiding polymerase chain reaction - PCR [3]), as well as a powerful research tool. This promising technique proves to be quite efficient since does not involve labelling of the molecules by fluorescent, magnetic or radioactive markers and bulky detection schemes are avoided, with consequent relevant time and cost saving. The possibility of realising parallel operation [4] through hybridisation, detection and analysis of different nucleic acid sequences allows a dramatic speed-up in basic and applied research of identified carcinogenic mechanisms and specific genetic pathologies.
This work proposes the optimisation of physical- and chemical-plasma processes for suface and bulk microbalances functionalisation in order to develop arrays of cantilevers (so named cantarrays) to be employed as nanobalances on which cDNA or oligonucleotides will be spotted, to hybridise with complex molecular probes and to characterize the abundance of single cDNA by "weighting" the cantilever after hybridisation. This technology is potentially more sensitive and faster than classical micro-array, and thus it offers the opportunity to analyse rare transcripts or transcripts obtained from a few cells. The analysis of very small quantities of materials [4] and the enhanced reliability deriving by the direct measurement process determine several expectations on plasma processes as enabling technology in new application fields. Moreover, in spite of traditional microarrays, this method allows the precise quantification of cellular transcription, thus opening the way to a number of new applications.

2. Cantilever process, simulation and characterization

Arrays of cantilever structures have been realized through MEMS techniques by using a reactive ion etching on the front of the wafer, for the definition of the cantilever shape, and a back-side bulk micromachining technique for the release of the cantilever structure (2-masks process). The advantage of an array of cantilever, instead of a single device, is the possibility to perform contemporarly different measurements with increased speed in collection of data and complexity of elaboration, but also the opportunity to neglect noise effects due to the environment, by subtracting the output signal of a functionalised cantilever from a non-functionalised one. The process is illustrated in fig. 1. (100)-oriented silicon wafers with a thermally grown 500 nm thick SiO_2 layer on both sides were used as starting substrates (fig. 1a). RIE of SiO_2 and silicon was used on the front of the wafer to define the cantilever array (fig. 1b and c). A thermal oxidation was performed to produce a 500 nm thick SiO_2 etch-stop layer on the lateral sides and on the bottom of the square window hosting the cantilever array (fig. 1d). Then, access to the back-side silicon was obtained through BHF wet etching of the back SiO_2 masking layer (fig. 1e). A time controlled TMAH anisotropic wet etching, assisted by the front SiO_2 etch-stop layer, was used to produce a thin diaphragm made by SiO_2 and the same silicon array of cantilever (fig. 1f). The array was finally released by BHF dipping (fig. 1g).

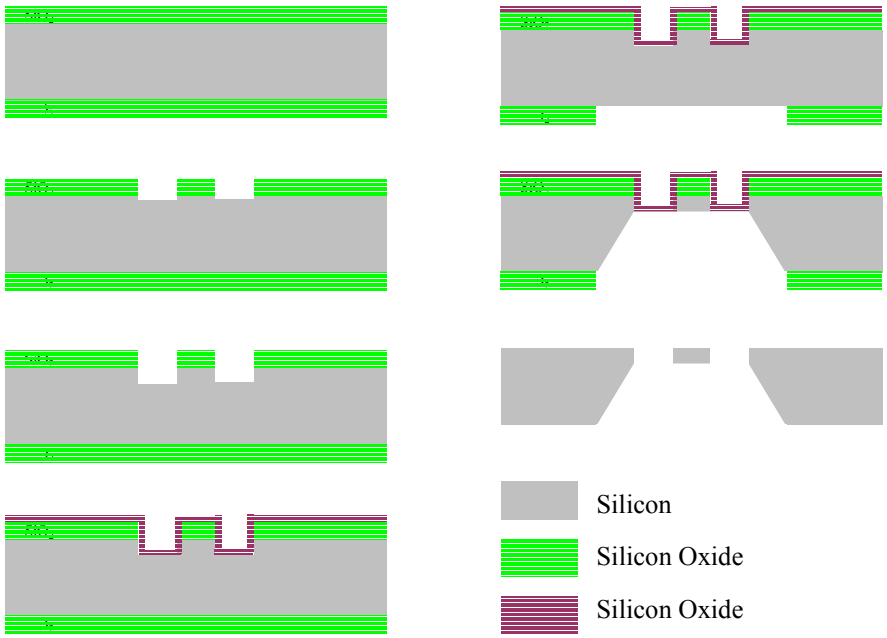

Fig. 1 - Process steps for the fabrication of the cantilevers.

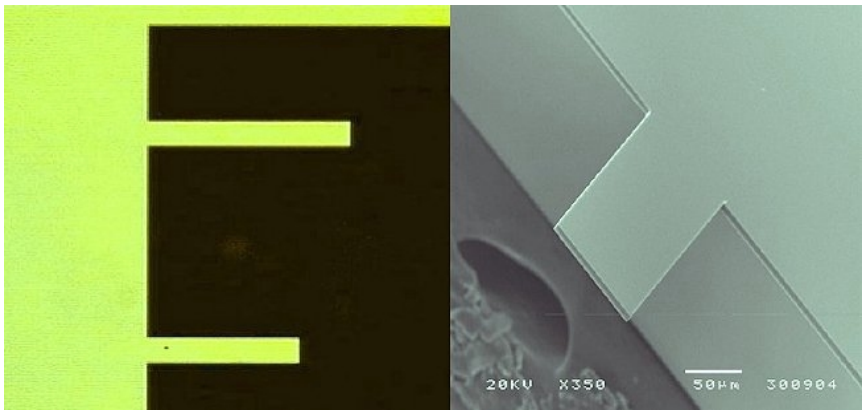

Fig. 2 - Optical and SEM micrographs of the cantilevers.

This solution allows the realization of cantilevers deriving from the same bulk silicon, with a good control on their thickness (defined by RIE etching), and most of all, avoiding stress due to structural films deposition. Cantilevers of different dimensions in a quite broad range were produced (width = 5 ÷ 100 μm; length = 30 ÷ 800 μm; thickness = 5 ÷ 20 μm) to investigate different vibrational properties such as stiffness and oscillation eigenmodes as well as static mode bending for free cantilevers. Actually a SOI wafer solution is under study as an alternative to the described process, to obtain thinner and better controlled cantilevers. In fact thickness is a key point to increase the sensitivity of the cantilevers to be used as functionalised microbalances.
Also simulations of structures behaviour have been carried out by means of finite difference analysis for design purpose. We use the Finite Element Method to develop cantilever suitable surface functionalisation in order to maximize the sensibility of the resonant DNA-microbalance. Dynamic model of such a system provided relevant indications in order to select few among the most efficient nanostructured LARC PVD ceramic thin films (mono and gradient nanostructured layers) capable to increase the resonance frequency of the beam-sensor to be employed as a mass-sensor.
We used the FEA Coventorware™[1] software to build (Process editor), discretize (Pre-processor) and simulate (MemMech) the undamped mechanical modal frequencies and mode shapes of the single-crystalline silicon (SCS) rectangular single clamped cantilever-beams: the mechanical properties used are listed in table 1 with the properties of the PVD coatings.

Material	**Density**	**Young modulus**	**Poisson ratio**
	[g·cm^{-3}]	[MPa]	
Si (SCS)	2,331	1,30E+05	0,278
Ti	4,5063	1,10E+05	0,333
TiN	5,21	5,90E+05	0,232
Cr	7,1	1,62E+05	0,21
CrN	6,4	6,40E+05	0,28

Table 1 - Material properties of silicon and other PVD materials.

Thanks to the flexibility of the Coventorware™ package we were able to design our model from the common bulk process from chip on a silicon <100> wafer: i.e the bulk with the negative sidewall angles obtained from a TMAH backside wet etch up to the thickness of cantilever and ideal simple rectangular base cantilever beams with 5 μm thickness, as from an etch of the residual silicon oxide membrane.

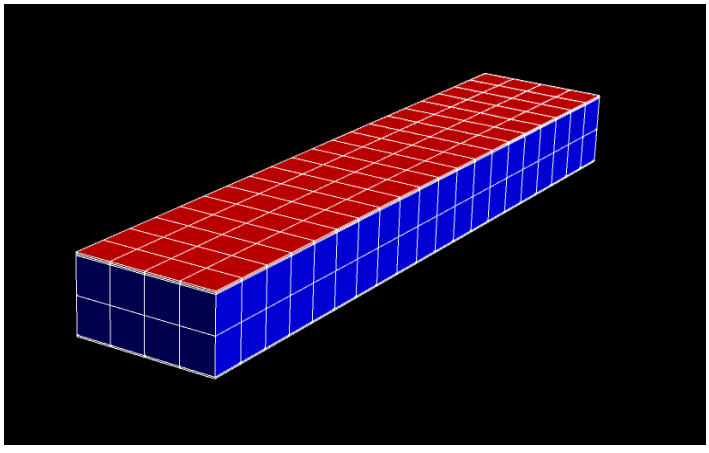

Fig. 3 - 50x10x5 μm cantilever discretized model.

[1] Coventor, Inc., 4000 CentreGreen Way, Suite 190, Cary, NC 27513

In our simulation we used 20-node parabolic brick elements to discretize our system and the mesh optimal density was obtained from convergence studies.
Modal equilibrium undamped mechanical simulations provided the first ten modal frequencies and mode shapes that characterised the silicon cantilever beams.

Mode	Frequency [Hz]	Generalized Mass [kg]

Table 2 - First 10 modal natural frequencies of the 50x10x5 μm cantilever beam (l-w-t).

Comparative analysis between uncoated cantilevers and coated cantilevers where done considering:

- double and single side uniformally metal/LARC PVD (i.e Ti/TiN) coated models;
- lower side metal PVD-coated and upper uniformly metal-coated with a micrometric PVD coating near the cantilever free end.

Comparative analysis have showed as the most sensible cantilevers are the LARC-PVD coated silicon with ceramics geometrical structures[2] at the cantilever free end. The subsequent simulation and experimental steps will be to evaluate the cantilever damping and energy loss in the DNA biological solution in order to extract their Q factor and their mass sensitivity.

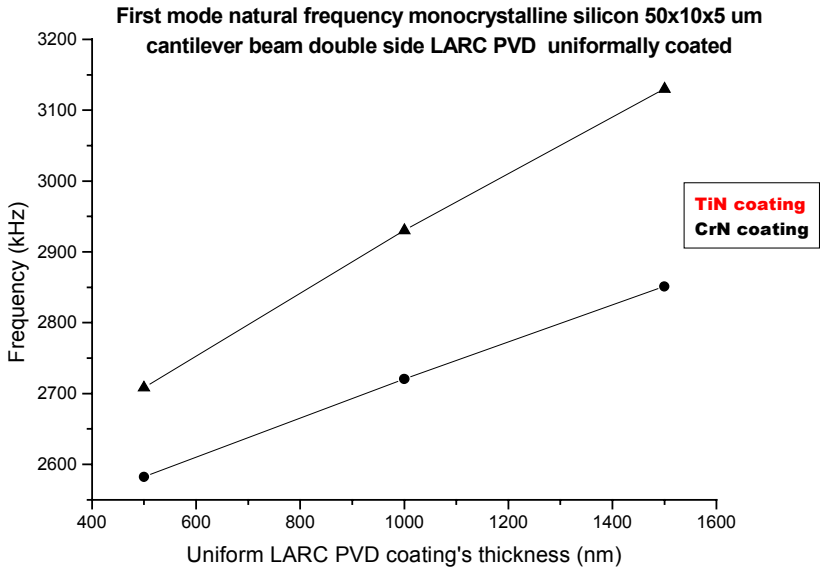

Fig. 4 – First mode natural frequency of uniform LARC PVD coated double side cantilever beams as function of film thickness and material properties.

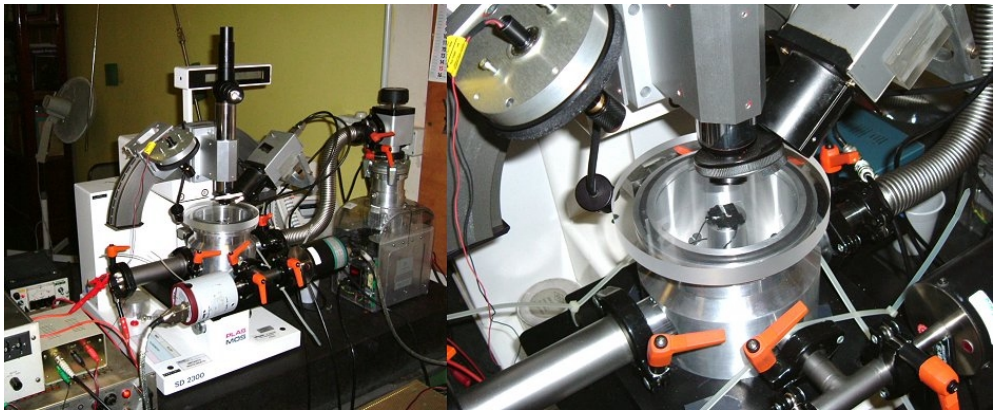

Fig. 5 – Photographs of the measurement setup and a close view of the holding cell with a cantilever die.

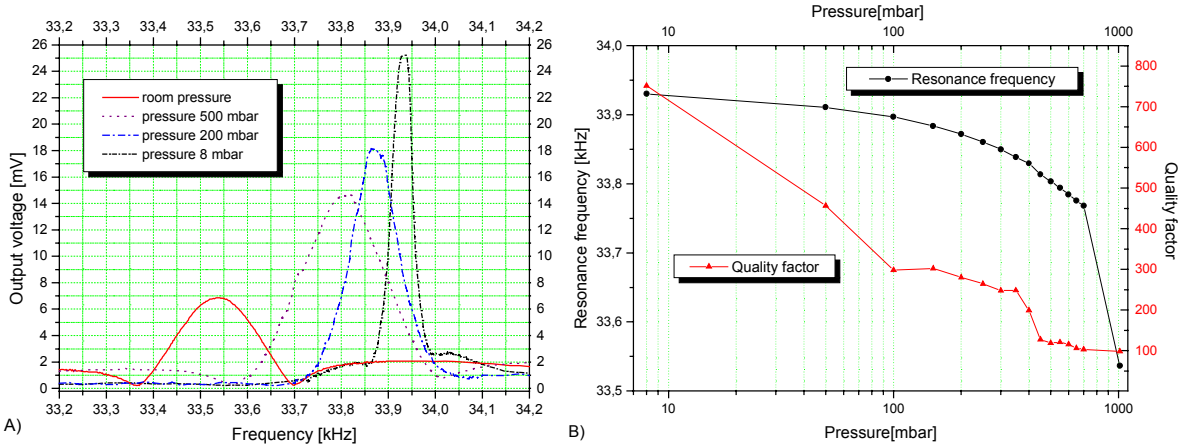

Fig. 6 - (A) Measured resonance spectra at different pressure levels for the 400x100x5 µm cantilever and (B) its corresponding resonance frequency and quality factor vs applied pressure.

The air damping mechanism, and consequently the quality factor of the cantilever, are functions of both the surrounding environment pressure and the internal friction in the cantilever material. Therefore, a systematic investigation of the cantilever resonance behaviour as a function of pressure was performed to develop a deep insight into the response of a cantilever used as a sensor. For the excitation of the microstructures, a small piezoelectric disc was used. A function generator (HP 33120A) produced a sinusoidal signal that first was amplified and then sent to the piezoelectric actuator. The actuator was linked to a holding cell, the test die with the array of cantilevers was attached to the actuator with double-sided tape and the cell was evacuated by a series of a membrane and turbomolecular pump (fig. 5). A needle valve with incorporated micropositioner was used to maintain a precise level of pressure, ranging from 10^{-8} bar to atmospheric pressure. Cantilever vibrational characteristics are measured with the 'optical lever' technique. The position of a focused laser beam reflected off the top side of the cantilever onto a position sensitive detector (PSD) is monitored. The current output of the PSD was amplified and converted into a voltage output, sent to a lock-in amplifier (EG&G 7260) for signal extraction and filtering and stored to a PC, together with the stimulus signal for the function generator. The procedure is controlled in a Labview® environment. The resonant frequency of each cantilever was measured by sweeping through frequencies with the function generator, observing the amplitude of the waveform at the output of the lock-in amplifier, and recording the frequency at which the first peak occurred. Calculation of the quality factor is performed by the Labview code. A vacuum level of 1 mbar implies an increase of the quality factor from less than 100 to about 1000 (fig. 6). Quality factors in excess of 40000 can be obtained in high vacuum conditions. Relative resonance frequency variations are of the order of 1÷1.5 % when shifting from room pressure to 1 mbar (under 1 mbar a saturation behaviour occurs and no more shift in the resonance frequency can be registered).

3. Thin functional film deposition by PVD processes

One of the major issues in the development of advanced cantilever systems for achieving high resolution assays down to the femtogram level is to realise cantilevers with high resonance frequencies. Two different (non mutually exclusive) approaches may be pursued to achieve this goal: improving geometric and/or physical parameters. The 'geometric' solution considers reducing the length of cantilever structures in order to get stiffer beams. The 'physical' approach considers attaining enhanced mass detection resolution by increasing the beam rigidity while keeping the beam inertia to convenient limited values, such that the resonant fundamental harmonic frequency may increase by some orders of magnitude. To tackle this issue, we applied thin ceramic films deposition processes on silicon via Physical Vapour Deposition (PVD). Development of binary, ternary and quaternary ceramics thin films with variable chemistry, stoichiometry and microstructure allows attaining cantilever stiffness enhancement of some orders of magnitude. Specific geometry and mass localisation was indicated by numerical simulations. Materials to be deposited where chosen according to the values of their Young modulus and on the basis of the numerical simulations results. Different types of microstructures were considered: single layered, gradient, multilayered thin films and combination of them. Various film thickness were grown in order to exploit to the maximum extent the cantilever stiffness possible increase. Single (upper) side PVD coated crystalline silicon cantilevers as well as double side coated cantilevers were realised in order to assess possible exploitable benefits from symmetric or asymmetric micro-structural configurations.

Among different technical solutions (sputtering, evaporation, etc.) the PVD ARC-DC LARC^{TM} process was chosen in order to grow complex, dense-packed, microparticle-free ceramics thin films. LARC^{TM} is an innovative evolution of the existing standard PVD ARC-DC deposition techniques in that it allows dramatically decreasing the output of micro-particles, although preserving efficient growth rates (about 2,5-3,0 μm/hour). Indeed the LARC^{TM} technology provided by the Clean NT Lab Platit-PL55 unit with rotating cathodes increases the cathode surface and assures uniform and controlled target consumption. The process was run in the 200-450°C temperature range at pressures of the order of 10^{-5} mbar. The silicon substrates where electrically connected to the substrate bias by a conductor frame, in which the samples have been allocated. This allowed to bypass the hampering question of ARC-DC deposition on non conducting material. The PVD process is run in high vacuum assuring the growth of high quality, dense-packed layers without columnar micro-nano-structures.

One or two cathodes were used according to the required stoichiometry. For binary and ternary coatings one target of Ti, Zr or Cr was employed with nitrogen as process gas (for binary coatings), nitrogen and acetylene as process gases for ternary ones. For quaternary coatings deposited stoichiometric and non-stoichiometric compounds were realised by employing two cathodes in the same process. Different bias voltages and deposition pressures were tested in order to decrease the residual thin film stress. Surface prefunctionalisation etching phases were run with Ar/H_2 mixture for assessing better silicon surface passivation.

For specified process parameters it was possible to deposit nano-structured and nano-composite ceramic thin films. These films were realised by exploiting the spinoidal decomposition occurring in a specified temperature and pressure range. Nanostructured coatings were realised by growing a Si_2N_3 amorphous matrix in which nanocrystals of the metal employed (i.e. titanium) are dispersed. These films belong to the family of super-hard coatings, displaying hardness values exceeding 3400 micro-Vickers deriving from the grain boundary interactions with the amorphous matrix.

Deposition uniformity and process reliability was analysed in order to comply with the stringent quality parameters for these applications. Overall characterisation and analysis of thin film adhesion properties, relevance to the resonance frequency increase, film compliance to the dynamic regime (presence of critical frequencies compromising film adhesion or stiffness, resistance to cyclic loading) are still in progress. Some of the first test results shown good agreement with simulations predicting convenient frequencies up-shifts

Abstract. The optical behavior of yttria-stabilized zirconia (YSZ) plasma-sprayed coatings made under various plasma operating conditions has been investigated over the 0.25-20 µm wavelength range. The oxygen loss in the sprayed material during the deposition process has a strong effect on the reflectivity level as it brings about an increase of absorption. Annealing the coatings at 500 °C for 1h results in an increase in reflectivity over the 1.0-5.0 µm wavelength range. More investigations are required to point out the influence of the microstructural features.
Keywords. Optical properties; Plasma spraying; Microstructure; Stoichiometry; Yttria-stabilized zirconia.

1. Introduction

An extensive effort has been carried out to engineer yttria stabilized zirconia (YSZ) plasma-sprayed deposits as thermal-barrier coatings (TBCs) [1]. Most of studies are about the correlation of the spraying parameters to coating microstructure and macrostructural properties such as thermal conductivity and mechanical resistance [1, 2]. Since the major heat transfer process at high temperature is radiation, the development of high performance TBCs requires a better knowledge of the infrared (IR) properties of thermal-sprayed YSZ coatings. However, only a few studies have dealt with this topic. Eldridge and al. [3] investigated the optical behavior of plasma sprayed YSZ coatings over the 0.25-15 µm range: although YSZ does not provide intrinsic barrier to radiation at wavelengths shorter than 5µm, it is possible to engineer high reflecting TBCs with high volume scattering due to microstructural defects such as porosity and microcracks.
Indeed, thermally-sprayed coatings exhibit a lamellar microstructure resulting from impinging, flattening and solidification of semi or fully molten particles on the substrate. This build-up mechanism induces a large variety of different length-scale defects [2]: rapid solidification and curling up of lamellae result in interlamellar pores; high cooling rates (10^5-10^7 K/s) provide interlamellar microcraks due to stress relaxation; unmelted or partially melted particles included in the coating and poor inter-splat contact lead to spherical pores. Moreover, plasma-sprayed deposits can present bulk chemical modifications as the sprayed particles are exposed in flight to high temperatures and reducing gases. Since the microstructure of thermal-sprayed coatings is process-dependent, it is essential to establish correlations between microstructure and optical properties and determine the heterogeneities that may interact.
Optical properties of homogeneous materials can be described by the complex refractive index $\tilde{\mathbf{n}}$ with a real part **n** and imaginary part **k** related to the phase velocity and attenuation of waves in the matter, respectively. In the case of heterogeneous materials, the scattering of the incident light modifies the optical properties. When an incident ray strikes an interface between heterogeneities and material matrix, some of the light radiation is transmitted; some is reflected due to backward scattering; some is absorbed. The total reflectance **R** and transmittance **T** can be defined as the sum of two contributions: diffuse and spectral. Besides, it is necessary to distinguish the surface scattering from the volume one: the former is due to surface imperfections (mainly roughness), the latter to defects in matter volume (heterogeneities).
The volume scattering process depends on the nature, size, shape and distribution of scattering elements. A general approach of scattering is formulated in the Mie theory for powder beds or spherical dispersions included in materials. A dimensionless quantity **Q,** called scattering efficiency, can be introduced to quantify scattering. It can be regarded as the ratio of two cross sections: the *scattering cross section* defined as the total energy flux abstracted from incident light by scattering versus the incident irradiance (energy flux per unit area) and the *geometrical cross-section* of scattering elements. Q depends on two important factors [4]:

- the relative refractive index **m** between the scattering particles and medium which is equal, for pores ($n_{pore}=1$) embedded in YSZ matter ($n_{YSZ}=2.16$), to $\mathbf{m=n_{pore}/n_{YSZ}}=1/2.16=\mathbf{0.46}$,
- the relative size **x** between the radius **r** of particles and the wavelength of incident light with $\mathbf{x=2\pi r/\lambda}$.

For plasma-sprayed coatings, the scattering centres exhibit flattened shape due to the built-up mechanism. Only assumptions can be made on the role of scattering centres for such a microstructure. Inter and intra-lamellar pores should play a key role because of an important refractive index gap with that of the medium. Their size and distribution have to be managed to improve the radiative properties. At first glance, the contribution of splat boundaries appears to be quite limited insofar as there are no impurities or second phases in these sites. Nevertheless, the characteristics of lamellae should be addressed as they act as separation between inter-lamellar pores. Consequently, porosity was chosen in first approach as an arbitrary criterion in order to engineer coatings with different optical properties.
The purposes of the present study are the following: investigate the effect of process parameters on microstructure characteristics and establish relationships between deposit microstructure, chemistry, reflectance and transmittance measurements. The first section of the paper describes the plasma-spraying experimental set-up and the tools used to characterize the microstructure and optical properties of coatings. The second section presents the experimental results and discusses the determination of the effect of stoichiometry, translucent thickness and microstructure on optical properties.

2. Experimental set-up

2.1. *Plasma spraying*

Plasma spraying has been carried out with a F4-VB Sulzer Metco torch. Agglomerated-and-sintered 7 wt.% Y_2O_3-stabilized ZrO_2 powder (Table 1) has been sprayed on stainless steel substrates located at 120 mm downstream of the nozzle exit. Particles were injected through a 1.5-mm internal diameter injector perpendicular to the plasma torch axis and located at 6 mm from the nozzle exit. The powder injection conditions was fixed according to particle size range and torch operating conditions in such a way that the median particle trajectory was nearly the same whatever were the spraying conditions. During spraying, the substrate temperature maintained around 200-250 °C was monitored using a pyrometer and controlled by an argon cryogenic system.
The particle temperature and velocity at the substrate stand-off distance were measured using a DPV-2000 equipment (Tecnar Automation Ltd, Canada). For each combination of spray parameters, the data from a total of about 5000 individual particles in the highest-flow particle density were acquired and averaged. Velocity and temperature measurement errors are 5% and 20%, respectively [5].
The operating conditions were selected in order to have a large range of particle velocities and temperatures at impact. The following operating parameters were been varied: torch nozzle internal diameter (6 and 8 mm), arc current (320 to 600 A), gas mixture (binary or ternary mixtures of argon, hydrogen and helium) and flow rates. About 25 sets of spraying conditions were investigated. Only two spraying conditions resulting in significant differences in coating microstructure are reported in this paper (Table 2).

Table 1: Feedstock characteristics – ZrO_2-7%wtY_2O_3

Powder reference	Manufacturer	Powder type	Manufacturing Process	Particle size distribution (µm)
827.054	H.C Stack GmbH & Co	Agglomerated and sintered (A&S)	Spray-dried and sintered	10-45

Table 2: Spraying conditions, in-flight particle parameters and coating porosity

Spraying parameter set number	Plasma gas flow rates (slm)	Arc current (A)	Arc Voltage (V)	Nozzle diameter (mm)	Particle in-flight parameters		Coating open porosity
					T (°C)	V ($m.s^{-1}$)	
I	Ar: 45 H_2: 15	600	75	6	3014±185	224±62	10±2%
II	Ar: 12 H_2: 3 He: 45	450	52	6	2598±130	126±30	23±1%

2.2. *Porosity measurement*

Deposit cross-section observations were performed by optical microscopy and digital image analysis was used to estimate the amount of pore in a 3.5-mm^2 cross section. The coating porosity was analyzed by using two volume methods: Archimedes and mercury intrusion porosimetry. The latter provides both open porosity level and pore size distribution. Acidic dissolution was used to remove the coating from the stainless steel substrate.

2.3. *Annealing treatment*

In order to evaluate the effect of oxygen content on optical properties, the samples were annealed in air at 500 °C for 1h. To dismiss any phase and microstructural transformation, the porosity measurements and X-ray diffraction were carried out before and after annealing. The annealing time was evaluated by performing thermogravimetric recordings. It was defined as the time from which no more change in coating weight was measured.

2.4. *Optical characterization tools*

The coating hemispherical reflectance and transmittance were measured over the 0.25-20 µm wavelength range by using two spectrometers. For the 0.25-2.5 µm range, measurements were performed with a Varian Cary 5000 spectrometer equipped with a 11-cm diameter integrating sphere. The inner wall is covered with a white diffuse, homogenous Teflon paint in order to allow multiple reflections.

For the 1.5-20 µm range, a Mid-IR Bruker IF66v/S spectrometer was used. It includes a Fourier Transform IR (FTIR) double-beam spectrometer with a globar source, KBr beam splitter and mercury-cadmium-telluride MCT nitrogen-cooled detector. A 7.6-mm diameter integrating sphere with a gold inner coating (Fig. 1) has been mounted in order to collect hemispherical radiation. A "diffuse" gold sample was used as calibration reference. To acquire the reflectance data, the incident radiation was alternatively directed toward the gold reference and plasma-sprayed sample by switching a mirror. The sample room was maintained under secondary vacuum (P<2000Pa) to avoid the absorption bands of atmospheric gases, mainly CO_2 and H_2O.

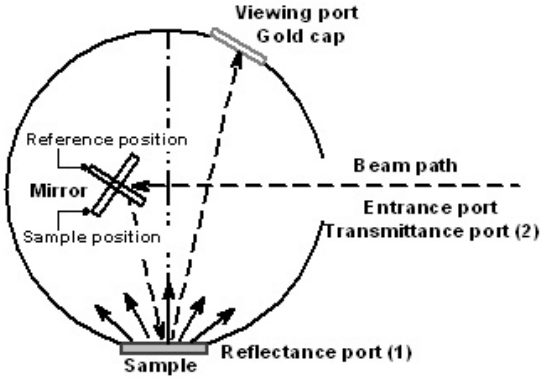

Fig 1: Diagram of IR integrating sphere reflectance (1) and transmittance (2) positions

To examine the optical properties over the entire wavelength range, the Bruker data were adjusted and merged with the Varian data between 1.5 to 2.5µm, using the OPUS software (Bruker Optik GmbH).

3. Results and discussion

3.1. *Darkening of plasma-sprayed zirconia*

The as-sprayed YSZ coatings exhibited various colors depending on the operating conditions. Indeed, the sprayed particles undergo severe reducing conditions i.e. high temperatures and reducing atmosphere (H_2). Chemical modifications may take place and induce a darkening of the YSZ plasma-sprayed coatings. Although the darkening of YSZ materials is commonly noticed under such reducing conditions, controversial causes have been proposed. Few authors attribute the black color to the migration and reduction of impurities (Fe, Li, Ti…) within grain boundaries [6], but most of them assume that the depletion of oxygen induces a modification of the neighbourhood of Zr^{4+} and change in the electronic state to Zr^{3+} [7].

The difference in YSZ deposit color can be regarded as oxygen stoichiometry variation. The spray type I condition led to dark coatings while type II condition resulted in bright yellow coatings. This discrepancy arises from the difference in particle temperature and dwelling time and plasma chemistry i.e. hydrogen content. Figure 2 shows the reflectance spectra of these two as-sprayed coatings. Low reflectivity is observed for sample I over the 1-8µm wavelength range contrary to sample II. However, this significant difference in optical features can be linked to coating stoichiometry as well as microstructural features.

To distinguish these two contributions, the annealing of coatings was performed coupled with thermal gravimetric (TG) experiments at 400°C and 500°C, under air with a 10°C/min rise in temperature. The water evaporation induced a weight loss of 0.04% from the ambient temperature to 330°C. Beyond, a slight weight gain of 0.03% was measured; it could be attributed to an oxygen gain during reoxidization. After one hour at 400°C, no weight variation was observed and the reoxidization process was considered to be completed. Only half hour was required at 500°C to observe the same evolution. In order to allow the diffusion of oxygen in material, the oxidation time was doubled: one hour at 500°C, two hours at 400°C. No microstructural modification was observed under these annealing conditions. So, all coatings were annealed at 500°C during one hour. After annealing, the dark specimens became pale-gray and not white as expected. Some substantial variation in oxygen stoichiometry may remain even after annealing. The re-oxidation ability seems to depend both on initial under-stoichiometry condition and microstructure.

3.2. *Effect of annealing on optical properties*

The reflectance of coatings before and after annealing is shown in Fig. 2. The annealing process had a marked effect on high under-stoichiometric materials (sample I) with a substantial increase in reflectance level over the 1-5µm range. Nearly no variation was observed for initially white coatings (sample II). The different behaviors of reflectance with annealing treatment can be explained by the competition between K, the absorption coefficient and S, the scattering coefficient. Assuming a diffuse incidence of radiation, even though it is not the case in the commonly-used spectrometers, the Kubelka-Munk's theory [8] can be used in first approximation to evaluate the ratio of these two coefficients as a function of the reflectance R :

$$\frac{K}{S} = \frac{(1-R)^2}{2R} \quad (1)$$

For semi-transparent medium, reflectance values (R) lower than 27% (K/S>1) indicate that absorption is dominant; beyond scattering becomes important. Thus, the absorption is predominant for as-sprayed sample I. After annealing, the reflectance increases, K/S ratio decreases and scattering plays a major role.

In the UV-visible range, the radiation absorption results in electronic polarization. In dielectrics, electronic absorption occurs for photons with energies higher than the band gap: in zirconia, the gap energy is estimated around 5.2 eV [9] namely in the near UV (250 nm). Different optical behaviors must be contemplated as a modification of the electronic environment in the matter. Under reducing atmosphere, using the Kröger-Vink notation, the oxygen incorporation equilibrium can be described as follows:

$$O_o^x \Leftrightarrow V_o^{\bullet\bullet} + 2e' + \frac{1}{2}O_{2(g)} \quad (2)$$

where O_o^x is an oxygen atom in normal oxygen site, e' is an electron and $V_o^{\cdot\cdot}$ is a doubly ionized oxygen vacancy. No-stoichiometric coatings exhibit high content of oxygen vacancies which can capture one or two electrons to form neutral or single ionized vacancies. The vacancy creation induces changes in the electronic band structure of materials by acting as donor levels. Zirconia containing oxygen vacancies show additional bands between the valence and conduction bands [10]. Such bands called "vacancy energy bands" are located at a depth around 2.5 eV below the conduction gap which corresponds to absorption around 600nm. The thermoreduction during plasma spraying increases drastically the oxygen deficits and leads to a filling by the electrons of the empty vacancy energy levels. Transitions between this additional band and conduction band may occur. Such a transition requires low energy photons and absorption can take place in the near IR wavelength range (1-5µm) as observed for as-sprayed type I coatings (Fig. 2).

3.3. *Determination of translucent thickness*

The translucent thickness can be defined as the thickness for which the optical transmission falls below 1% [11]. A preliminary study was carried out on freestanding deposits (type I coatings) 300, 500, 800 and 1100-µm thick. For coatings thicker than 500 µm, the transmittance was equal to zero. For thinner coatings, the transmittance values varied between 2% and 5% in the 1-5 µm wavelength range. Thus, all the optical measurements (Fig. 2) were performed with 500-µm thick coatings since it seems to be enough to insure the opaqueness of YSZ coatings.

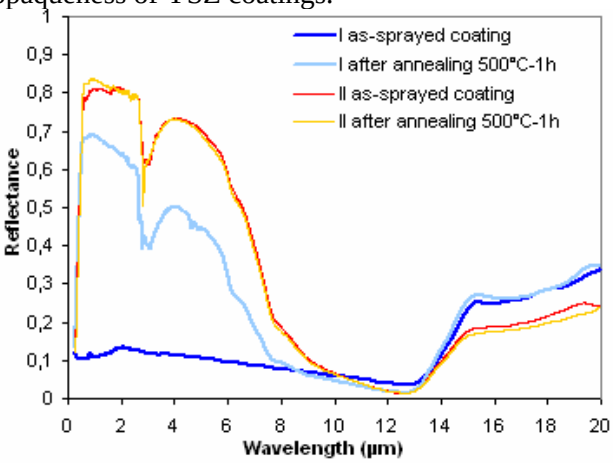

Fig 2: Reflectance spectra for as-sprayed and annealed coatings (sample I and II).

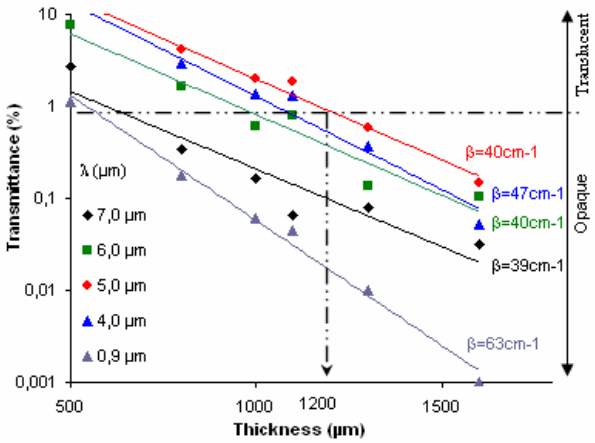

Fig 3: Effect of thickness on transmittance at given wavelength. Sample I annealed at 500°C for 1h.

Nevertheless, the type I coating exhibits oxygen-deficient. Therefore, the absorption contribution might be predominant and scattering restricted according to the Kubelka-Munk's model. As the translucent thickness is sensitive to stoichiometric effects; new investigations were made on type I coatings after annealing. These results are compiled in Fig. 3 where the transmittance *T* is plotted versus coating thickness x in µm at given wavelength values. As expected, the light attenuation takes place according to the Beer-Lambert law:

$$T=\exp(-\beta x) \quad (3)$$

where β is the extinction coefficient. As the extinction coefficient is a measure of the decrease in intensity of the incident beam due to matter absorption and scattering of the light, it can be defined as the sum of the absorption coefficient ($K=4\pi k/\lambda$) and scattering coefficient S. The translucent thickness of annealed type I coating can be evaluated around 1200µm (see Fig. 3).

The translucent thickness is also microstructure-dependent and the evolution of extinction coefficient can be regarded as microstructure effects. Indeed, a slight increase in absorption coefficient K has been reported by Makino and al. [12] for zirconia in the 1-5µm range: $K=0.1cm^{-1}$ at 1.0µm; $K=0.5cm^{-1}$ at 5µm. Conversely, in this wavelength range, YSZ coatings exhibit a decrease of the extinction coefficient β (Fig. 3) which implies a decline in the scattering contribution. This feature can be understood through the evolution of the size of heterogeneities *d* relative to wavelength λ: the increase in wavelength leads to a decrease in the parameter size $x=\pi d/\lambda$. Consequently, the scattering efficiency Q may be reduced around 5µm for lack of suitable size of heterogeneities compared to the wavelength.

3.4. *YSZ optical behavior*

A typical reflectance spectrum of annealed YSZ coating is shown in Fig. 4. The optical behavior can be divided into three radiative regions.

In region **I** ($\lambda<5$ µm), the refraction index n is higher than 1 and the extinction index k is very low (<<1); volume scattering is predominant. The hemispherical reflectance is mainly composed of the diffuse reflectance due to scattering centres like pores or other discontinuities in the matter. Around 3 µm, the absorbed water causes absorption bands and a consistent drop in reflectivity. In region **II** ($6<\lambda<12.5$ µm), the increase in light wavelength brings about a drop in reflectance caused by the decrease in the relative size of the scattering centers compared to λ. Besides, n decreases and k begins to increase due to lattice vibration.

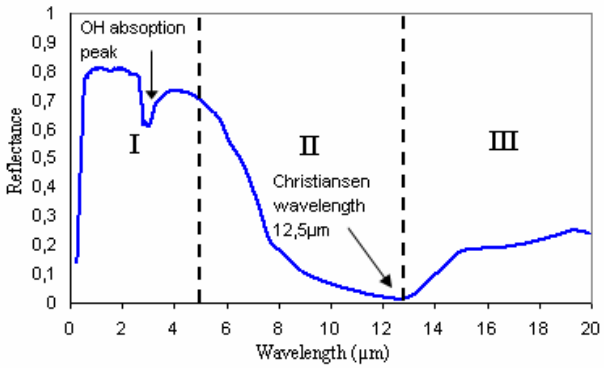

Fig 4: Typical reflectance spectrum of YSZ plasma-sprayed coatings

When n is equal to the refractive index of air (n=1), no scattering occurs and the radiation spreads freely in the material with little absorption due to k value. This phenomenon is a remarkable property of dielectric materials and is called the Christiansen feature. It results in a minimum of transmittance T and reflectance R and a maximum of emissivity ε (Kirchhoff's law: ε=1-R-T). This feature is nearly independent of temperature and texture; its value is fixed by lattice vibration. Christiansen point of YSZ is around 12.5 µm. In region **III** ($\lambda>12.5$ µm), k is large (>0.1) and the resonant lattice vibrations play a key role in such a way that the incident radiations can not enter further than the first surface layers. The scattering process must originate from coating surface.

3.5. *Microstructural effects*

While keeping in mind the preponderant effect of stoichiometry, part of the observed differences after annealing might be indicative of a microstructural dependence of the optical spectra. Figure 2 shows the spectra after annealing for two different microstructures. The type II coating exhibits high reflectivity in the 1-6µm wavelength range except around 3µm where a sharp drop is observed owing to OH absorption. According to the Kubelka-Munk ratio (K/S), scattering is predominant for these two kinds of coatings after annealing. High reflectivity values can be related to an increase in diffuse backward reflection around scattering centres. Compared with type I spectrum, higher reflectivity seems to come along with higher porosity values (see Table 2). Although the deposit porosity seems to be the main cause of diffuse reflection, it could be inadequate to consider only porosity levels. A global description of the optical

properties of porous media needs also the knowledge of scattering centres characteristics: pore size, distribution and shape. The measurement of porosity by mercury intrusion and microscopic observations are in progress to evaluate the mean size of pores and their distribution.
The effect of microstructure can be illustrated in an indirect way by the reoxidation process and also water absorption. The latter can be related to the specific area of open porosity. OH bondings cause absorption around 3 µm which is still present after annealing with a narrower and sharper peak (Fig. 3). Some OH bondings may survive the water desorption or some water could be absorbed again [3].

4. Conclusions

Under-stoichiometry inherent to YSZ plasma-sprayed coatings has a major effect on the optical behaviour of resulting coatings. Dark coatings (i.e. deficient in oxygen) exhibit low reflectivity below 12.5µm due to two kinds of electronic absorption: in the UV-Visible range, a transition occurs between the valence and conduction bands; in the near IR range, the absorption may be due to transition from the vacancy energy and conduction bands. The latter depends on oxygen deficiency. It can be removed by annealing the coatings at 500°C for 1 h. However, such annealing can not guarantee the stoichiometry of coating and, therefore, the intrinsic optical properties of the media (n and k values). The study of the diffusion of oxygen into YSZ coatings is in progress to investigate the reoxidation mechanisms.
The OH bondings cause strong absorption near 3µm and may be reduced by high-temperature annealing.
Annealed coatings exhibit substantial volume scattering that induces a high reflectivity below 5µm. The reflective discrepancy between the two types of coatings used in this study is of particular interest as it can be contemplated as microstructural effects. Further studies of scattering centre characteristics are necessary to understand the scattering phenomena and resulting optical behaviour. The size, distribution and shape of pores must be investigated to engineer highly reflective thermal barrier plasma sprayed coatings.

Pulsed Corona Plasma Pilot Plant for VOC Abatement in Industrial Streams as Mobile and Educational Laboratory

Giyoung Tak, Alexander Gutsol, and Alexander Fridman

Department of Mechanical Engineering, Drexel University, Philadelphia, USA

Abstract

High –volume pulsed corona discharge system, which is able to treat up to 750 m^3/h of gas, has been developed at the Drexel Plasma Institute as a core of the mobile Pilot Plant to demonstrate promising technology in paper and wood industry for treatment of high volume – low concentration (HVLC) industrial ventilation streams contaminated by Volatile Organic Compounds (VOC). In this paper, the experimental results for the removal efficiency are presented with respect to several parameters.

Keywords: VOC control, pulsed corona, air cleaning, methanol, dimethylsulfide, alpha-pinene.

1. Introduction

Since Volatile Organic Compounds are the major causes of many environmental problems due to their toxicity and their contribution to the global warming mechanism, many researchers have put their efforts into cleaning of gaseous streams containing VOCs in various ways. Many different industrial processes produce VOCs. In the paper industry, VOCs are mainly contained in solvents, chemical binders, bleaching chemicals for paper production; they are also contained in the wood itself and they released into the exhaust gases during the processing of the wood paste. These emissions are classified as high volume – low concentration (HVLC) gas streams.

Major traditional techniques for VOC removal include biological filters, two stage absorbers and, most important, regenerative thermal incineration or regenerative thermal oxidation (RTO). These methods for the treatment of the dilute off-gases require relatively high energy consumption and result in high treatment costs [1]. Gas phase hazardous organic wastes can be destroyed by oxidation to non-hazardous compounds, such as carbon dioxide and water. The most effective way of oxidizing organics is to use highly reactive species, i.e. reactants with a high oxidizing potential, such as ·OH, ·O, ·H, O_3, and H_2O_2. The hydroxyl radical is especially known to play an important role in oxidative purification and degradation of organic compounds [2]. In a combustion process, efficiency of production and concentration of these free radicals and active species depend on the process temperature. In order to attain the required temperature, a considerable amount of energy must be spent for direct heating of the gas (e.g., by incineration or thermal plasma). To perform incineration of HVLC gas streams, some quantity of fuel must be added to promote effective combustion, since the concentration of organic material is not sufficient to sustain combustion by itself. To uniformly heat the whole gas stream by thermal arc, a high amount of electric energy must be spent. Both these methods are inefficient in terms of production of active species [3].

Low-temperature non-equilibrium (non-thermal) plasma discharges represent an alternative technology for gas phase de-pollution. Here most of the energy (up to 99.9%) is directed in the production of high-energy electrons [3], rather than in heating the gas. Radicals, ions and other active species, which oxidize, reduce or decompose the pollutant molecules, are efficiently produced mainly via electron-impact dissociation, excitation and ionization of the background gas. Non-equilibrium discharges have been tested for the removal of a number of different toxic or environmentally hazardous compounds, such as SO_x, H_2S, VOCs, PAHs (Polycyclic Aromatic Hydrocarbons), heavy metals, and others, like chemical warfare gases such as nerve gas [3].

The feasibility of non-thermal plasmas for VOC control application in the paper and forest products industry was studied by Harkness and Fridman [3]. In that work, published data from all non-thermal processes being currently developed were reviewed to estimate the applicability of the process to contaminants and conditions typical for forest products applications. Four non-thermal plasma technologies appeared to promise both lower capital costs and operating costs than the incineration-type process currently available. They are: 1) dielectric packed bed corona discharge; 2) electron beam discharge; 3) non-thermal gliding arc discharge; and 4) heterogeneous pulsed corona discharge. After investigation sponsored by Department of Energy (DOE), the heterogeneous pulsed corona discharge was chosen as the best non-equilibrium plasma technology for control of the vent emissions from HVLC Brownstock Washers. While the research was conducted, laboratory experiments were carried out using installation with the average power up to 20 W. For the compounds of interest in the DOE project (methanol, acetone, dimethylsulfide and α -pinene), high removal efficiencies were obtained with power levels competitive with the present technologies for the VOCs removal [4]. As continuation of the DOE project, trailored pilot plant as shown in Figure 1, which can treat up to 750 m^3/h of gas stream, was built for testing in industrial conditions [5]. Experiments with the pilot plant were performed with average plasma power up to 3.5 kW. Different design of the laboratory and pilot plant pulsed coronas, as well as different analytical methods revealed many new peculiarities of the VOC abatement process. The work reported herein describes the experimental results for the VOCs removal efficiency with respect to energy consumption, residence time, water effect and initial concentration. In addition, generation of organic byproducts which are hardly removable by plasma is discussed.

Fig. 1. Photograph of the Mobile Plasma Pilot Plant

2. Experimental Setup

Figure 2 illustrates the schematic diagram of the pilot plant including sampling, measuring and calibration equipment. Basically the pilot plant process consists of three stages of gas treatment:

1. Preliminary washing of the exhaust gas stream by a water shower for removing particulates and soluble VOCs such as methanol and acetone.
2. Exhaust stream treatment by dry or wet pulsed corona discharge for VOC oxidation.
3. Removal of the balance of ozone and VOC by self-cleaning adsorbent.

The first stage is similar to scrubbing. For maximum removal of soluble VOCs, the direction of the water flow is opposite to that of the gas stream. System and water flow rate were optimized to reach highest scrubbing efficiency of the soluble VOCs with expected gas flow rates and to prevent water droplets from being carried over by the gas stream. It was presented in the previous laboratory experiments and modeling that it was

possible to remove nearly all the soluble VOCs using this technique [4, 5]. The scrubber volume is about 1 m^3 and is filled with special low density-high surface packed bed material.

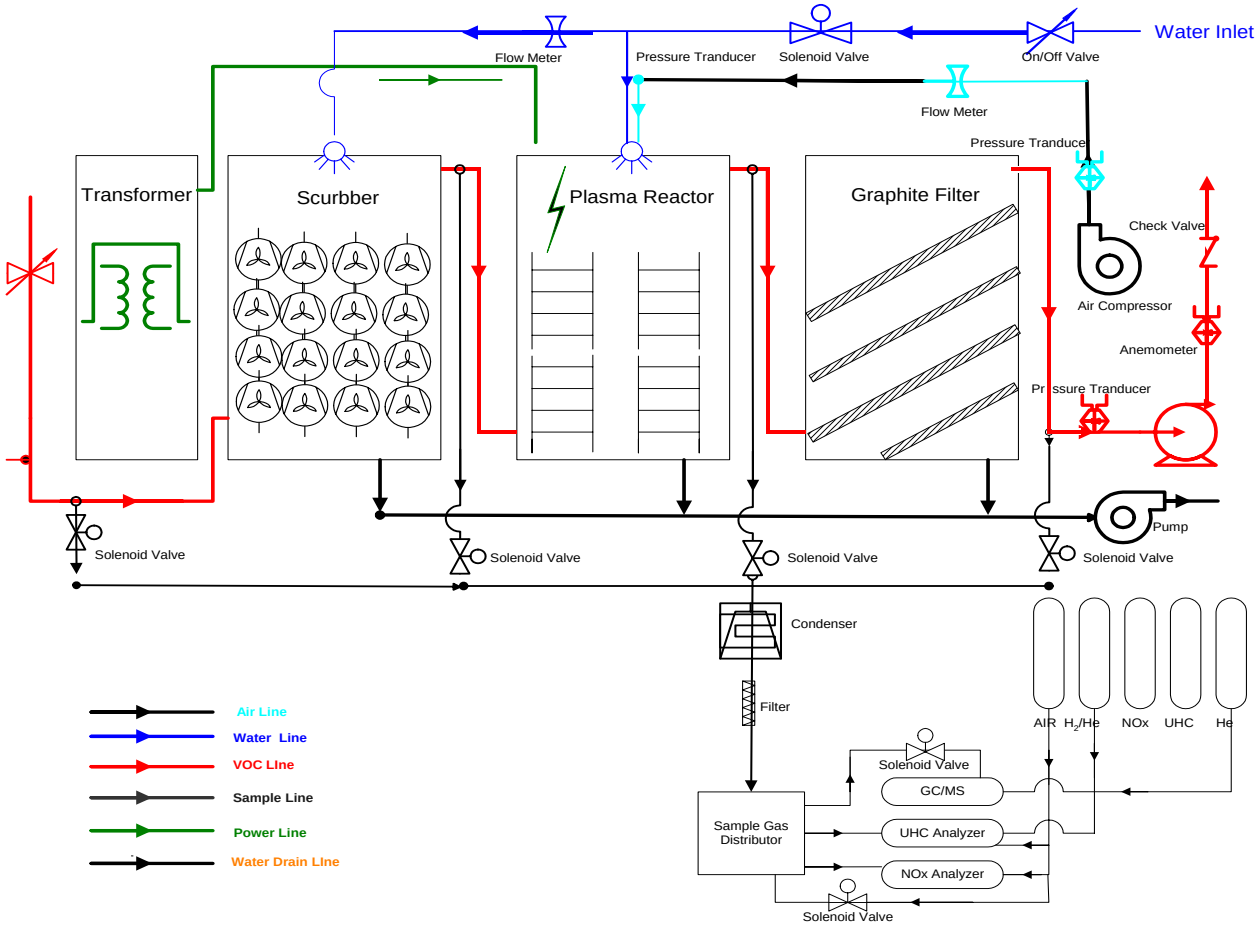

Figure 2. Process Schematic Diagram of the Pilot Plant

In the second stage, the gas stream is treated in the pulsed corona discharge plasma reactor, which includes an option of supplying a water spray flow into the discharge volume. Compressed-air atomizers are used for spray formation. The pulse corona discharge unit consists of 12 units (channels), and each of them includes high-frequency converter with an intermediate frequency of 25 kHz on the base of field (IGBT) transistors, pulse high-voltage transformers, work capacitance and special high-voltage self-firing discharge gap for high voltage pulse formation on the corona electrodes. Discharge power is regulated by stepwise changing of the pulse repetition frequency in the range 20-100% (20%, 40%, 60%, 80%, and 100%). The main parameters of the corona discharge are the followings: peak voltage is about 40 kV, pulse repetition frequency is up to 1 kHz, and pulse duration is of 200-250 ns. The structure of the pulsed corona discharge blocks (Fig. 3) consists of alternate rows of grounded and high-voltage electrodes. Such a structure provides transparency of the discharge volume for the water spray. Plasma discharge zone is formed by 12 corona blocks installed in three layers. Total discharge volume is about 3.6 m^3.

Figure 3. Corona Block

The last cleaning stage includes adsorption and oxidation of any remaining VOCs with filter. The filter is formed by activated charcoal particles of 3 mm size in layers of 2 cm thickness. Total area of the layers is about 2 m^2. This filter contributes to enhance complete removal of any remaining VOCs, ozone and nitrogen oxides.

The pilot plant has three sampling ports after the three cleaning stages for precise analysis of the removal efficiency. Soluble VOC and products of the plasma-chemical destruction may be removed by industrial wastewater. Additionally clean water flow is necessary for cooling electronic equipment.

3. Results and Discussion

Fig. 4 shows overall combination effect of scrubber and plasma on removal of methanol. Temperature of the plasma reactor is kept constant (room temperature). It is possible to reach desirable level of Destruction and Removal Efficiency (DRE) (for example 98%, according to the new U.S. regulations for paper and wood industry) by two ways: just by plasma power increase, or by combination of small plasma power level with scrubbing. If scrubbing and following water treatment is acceptable (as in paper mills), the second approach looks much more promising. If water discharge is not permitted (as in U.S. wood industry), plasma treatment should be applied without preliminary scrubbing, or additional water treatment system should be built. Plasma treatment of methanol is relatively expensive process, even for low concentrations, because as it was shown earlier [4, 5] energy cost of one VOC molecule oxidation by plasma rises enormously with VOC concentration decrease. Our results are a little better but comparable to that obtained with small 20 W system [4, 5]: energy cost is about 300 eV per methanol molecule for 12 ppm initial concentration.

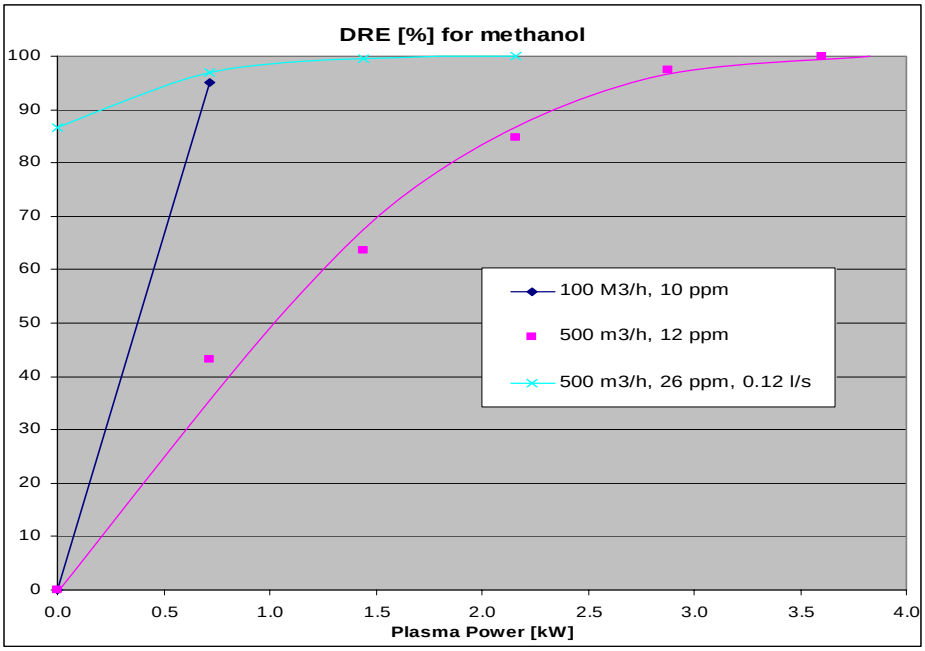

Figure 4. Methanol destruction and removal efficiency depending on plasma power without and with water scrubbing under 0.12 l/s of water flow rate in scrubber (upper blue curve).

The main analytical tool at the pilot plant is a California Analytical Model 300HFID/MHFID Heated Hydrocarbon Analyzer, in contrast to a gas chromatograph used in lab experiments [4, 5]. Thus, instead of direct measurement of concentration for particular VOC we measured cumulative concentration of the initial VOC and all hydrocarbon byproducts. Methanol oxidation (Fig. 4) in plasma is going without formation of any byproducts [4, 5], so interpretation of these results is very simple. As it was demonstrated earlier [4, 5] oxidation of dimethilsulfide (DMS, Fig. 5) in plasma is going faster than oxidation of methanol, but is accompanied by

formation of byproducts – methanol and acetone. It is possible to distinguish two parts on concentration curves in Fig. 5: initially concentration of total hydrocarbons going down relatively fast (mostly DMS oxidation with energy cost about 200 eV per DMS molecule for 10 ppm initial concentration), and then much weaker dependence on power (compare with Fig. 4) that corresponds to oxidation of byproducts. It was shown earlier [4, 5] that elimination of DMS in plasma is going considerably easier than elimination of methanol and much easier than acetone. Addition of NaOH solution spray (0.13 l/s, pH =11.5 and 12.1) into pulsed corona reactor does not change DMS oxidation process considerably.

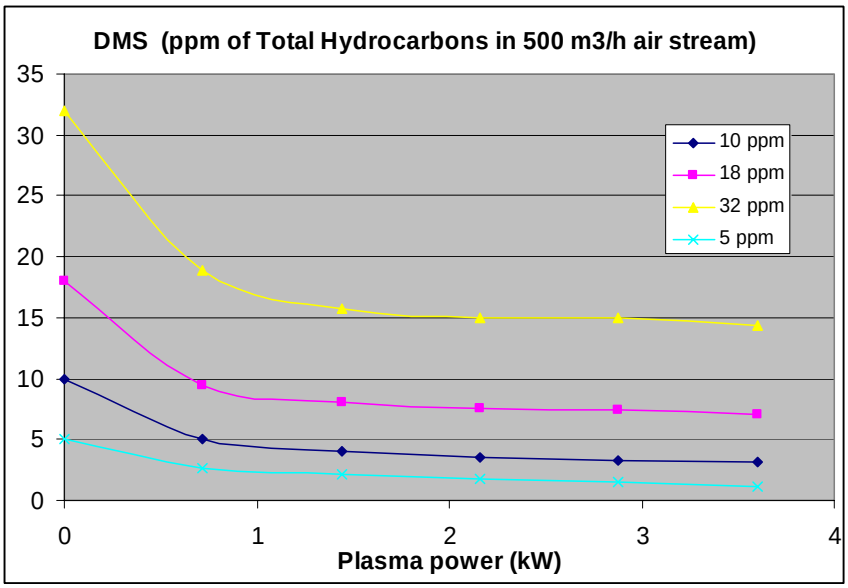

Figure 5. Dimethylsulfide oxidation in plasma: concentration of total hydrocarbons depending on plasma power.

When we considered alpha pinene ($C_{10}H_{16}$) destruction, influence of by-products formation was not so obvious (Fig. 6) while we used relatively high concentration of alpha-pinene (note that 1 ppm of $C_{10}H_{16}$ corresponds approximately to 10 ppm of total hydrocarbons). Nevertheless, control of by-products using GS-MS (HP5890A gas chromatograph with HP5970 Mass Selective detector) revealed high-molecular byproducts (like $C_{25}H_{46}$) than contained cyclopentane rings in molecular structure, which seems hardly to decompose, as these molecules can be considered as soot precursors. Strong influence of these by-products was found in experiments with low concentration of alpha-pinene (Fig. 7). This very specific picture hints us to suggest that there are two very different mechanisms of alpha-pinene interaction with plasma products: chain oxidation that starts by some radical and goes without formation of stable by-products; and decomposition by plasma particles (electrons, first of all) with following formation of soot precursors. We are going to test this suggestion, and if confirmed this leads to reconsideration of the optimal process organization scheme. Water spray in the corona reactor reduces efficiency of the alpha-pinene elimination process (Fig. 6). Energy cost is about 300 eV per alpha-pinene molecule for 2 and 7 ppm initial concentration (probably the most correct figure is for 2 ppm, see Fig. 7) and 40 eV per molecule for 64 ppm initial concentration. The last figure is in a good agreement with the data obtained using 20 W pulsed corona [4, 5].

As it was mentioned earlier, energy price is strongly related to the initial concentration. For relatively low VOC levels, high energy price is required. This is due to the fact that not all the active species produced in the gas discharge can actually target VOC molecules, i.e. not all the electric energy to create active species is consumed for oxidation of organic compounds; some of these species undergo reactions with each other or lose their energy on walls. Reactions with VOC molecules are statistically more frequent if the concentration of VOC is relatively high; in this case, the fraction of energy spent for the purpose of removing the molecules is higher and the energy spent for the elimination of each single molecule decreases.

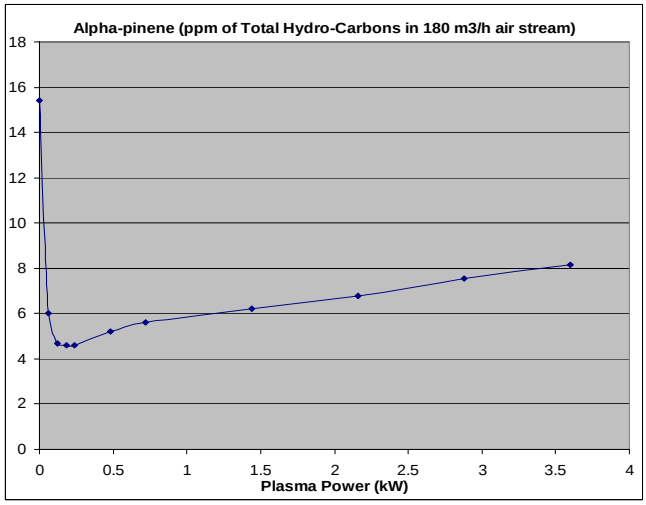

Figure 7. Alpha-pinene oxidation process accompanied by production of stable by-products.

4. Application

The Pilot Plant or Mobile Environmental Plasma Laboratory (Fig. 1) was built to demonstrate this promising plasma technology for VOC emissions control on paper mills. This work was supported by U.S. Department of Energy (project DE-FC07-00ID13868). Later it was decided to use the same Pilot Plant for the test on wood product plant to treat the Oriental Strandboard (OSB) press ventilation stream (US DOE project DE-FC36-04GO14052/A000). Meanwhile the Mobile Laboratory is used for educational purposes at Drexel University, Goodwin College of Professional Studies, as laboratory equipment in the special course AET 380: "Plasma Environmental Laboratory". This laboratory introduces students to the engineering principles of non-thermal plasma application to air cleaning from VOCs and other methods of VOC control and measurements, by combining hands-on laboratory experience with lectures. Specifically, the students learn the engineering and physical principles of non-equilibrium plasma systems operation using the unique pulsed corona system and carry out experiments on plasma cleaning of VOC contaminated air, measure dependence of DRE of particular VOC on plasma power and other system parameters, calculate the energy cost of VOC removal compare to other methods. The work in the laboratory enhances the fundamentals taught in the classroom sessions

Okishin 1-1, Sasebo, Nagasaki 857-1193, Japan

Abstract

Carbon nanomaterials have been prepared using a simple production method of pulsed arc discharge and pulsed laser ablation in liquid. Field emission scanning electron microscopic observation revealed that most of nanomaterials produced by arc discharge were sphere shape nanoparticles. On the other hand, small amount of products like nanofiber can be produced using pulsed laser ablation method. The ratio of the products like nanofiber produced in the deionised water with SDS is high compared with those produced in the deionized water. The size of the particles produced by pulsed laser ablation was slightly small, and the density of the particles produced by pulsed laser ablation is high compared with those of produced by arc discharge.

1.Introduction

Recently, several kinds of arc in liquid method have been developed as a cost-effective technique to fabricate various kinds of nanomaterials [1–6]. The method has some advantages in the mass production of carbon nanomaterials compared with any other well-known conventional methods, such as vacuum arc, laser ablation and plasma enhanced chemical vapor deposition. In the past few years, carbon nano-onions, multi-wall carbon nanotubes, single-wall carbon nanotubes (SWNTs), single-wall carbon nanohorns (SWNHs), and their metal included forms, have been successfully synthesized by the arc in liquid method using water and liquid nitrogen to host arc discharge. However, the high-quality single-walled structures such as SWNTs and SWNHs have been produced only when liquid nitrogen was used in the simple arc in liquid method, and the value of those nano materials was small. On the other hand, pulsed laser ablation in liquid method has been also developed for fabricating high quality nano materials [6-8]. Sugiyama et. al. prepared oxo(phtalocyaninato)vanadium(IV) (VOP) nanoparticles dispersed in water by using femtosecond laser ablation of its bulk crystals. They found that the mean size of the VOP nanoparticles was 17 nm, estimated by a scanning electron microscope (SEM) analysis. Furthermore, they suggest that nanoparticle formation process can be controlled precisely by pulsed width, wavelength, repetition rate and fluence using this laser ablation method.

In this paper, carbon nanomaterials have been prepared using arc discharge and pulsed laser ablation methods in the same liquid condition. Morphology, size and density of the particles are observed by field emission scanning electron microscopy (FESEM), and analyzed using computer software. Measurements of optical emission spectra were performed to estimate the processing plasma state in liquid using high speed photonic multichannel spectral analyzer.

2.Experimental

A schematic of the pulsed arc discharge equipment is shown in Fig. 1. In our arc discharge method in liquid, a direct current (DC) arc discharge was generated between two high purity carbon rod electrodes (purchased from Nilaco Corp., Japan; 99.99% purity). Our apparatus consisted of two electrodes (anode 5mmϕ × 50mm, and cathode 20mmϕ × 30mm) in a vertical alignment submerged in 500 ml of deionized water (0.2 mS/m conductivity) or ethanol in a Pyrex beaker. These carbon electrodes were connected to a DC power supply. Arc discharge was

generated by touch and release of these carbon electrodes. The gap distance between the two cylindrical carbon electrodes was initially set to 3 mm, but eventually changed by arc-induced erosion. The discharge current and voltage were set at about 40 A and 5–15 V, respectively. The repetition rate of the pulsed arc discharge was about 0.5 Hz. Nanomaterials formed in the arc plasma region are collected on the water surface and in the water bottom.

A schematic of the pulsed laser ablation system is shown in Fig. 2. High purity carbon target (purchased from Nilaco Corp., Japan; 99.99% purity, 30mmϕ × 5mm) are suspended in 30 ml of a deionized water, ethanol and deionized water (30cc) with sodium dodecyl sulfate ($CH_3(CH_2)_{11}OSO_3Na$; SDS: 3mg) as anionic surface active agent. In the present work, we demonstrate the formation of carbon nanoparticles by using a pulsed Nd:YAG laser (Continuum SureliteIII; wavelength of 532 nm, pulse duration of 3.5 ns, maximum output energy of 340 mJ). The laser beam was focused on the center of the target with a lens, and the spot size was about 3 mm^2. Repitition rate of the pulsed laser was 10 Hz, and nanomaterials were produced at 6000 shots.

Morphology, size and density of those nanomaterials were observed by FESEM (Joel JSM-6800, 3kV, 8μA). Optical emission spectra in the arc plasma were observed by high speed photonic multichannel spectral analyzer (PMA-11: Hamamatsu Photonics) with ICCD detector (C8808-01: Hamamatsu Photonics). Simultaneous measurement wavelength range of this system was from 200nm to 860nm. Effective light-receiving area of optical fiber was 1mmϕ and A/D resolution was 16bits.

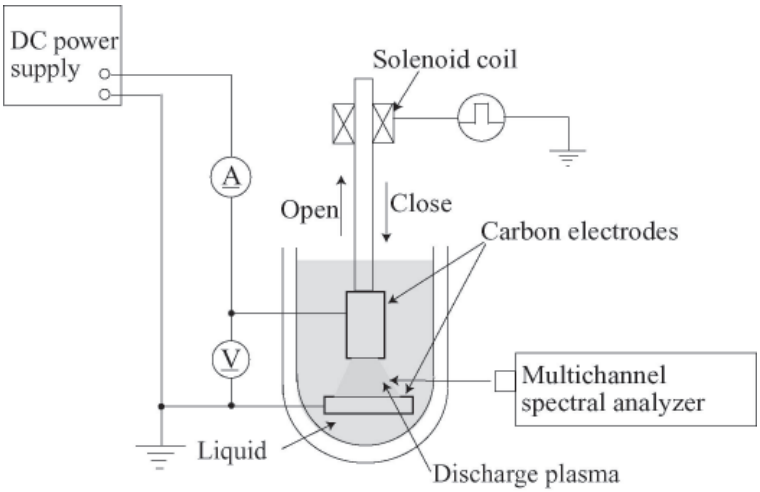

Fig. 1 A schematic of the pulsed arc discharge equipment.

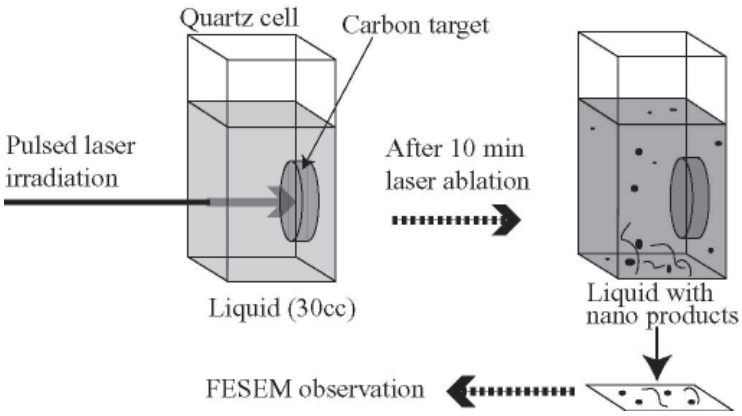

Fig. 2 A schematic of the pulsed laser ablation system.

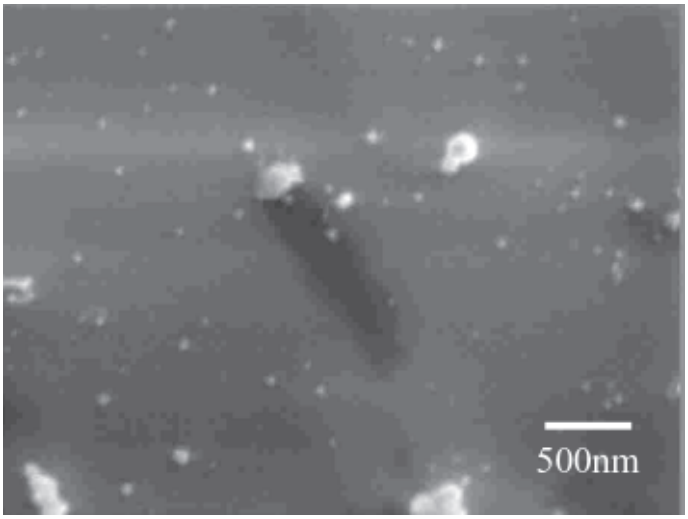

Fig. 3 FESEM image of the nano material products using arc discharge in deionized water.

3.Results and discussion

Figure 3 shows the FESEM images of the nanomaterial products using arc discharge in

deionized water. After the arc discharge experiments, there are two kinds of nano products can be obtained. One of them is powdery products floating on the water surface, and another one is bulky deposits sank down in the water bottom. This result is agree with our previous experiment measured by high resolution transmission electron microscopy (HRTEM; Hitachi H-9000 operated at 300 kV) [9]. In this obserbation, most of the products are the sphere shape particles and some of them are coagurated each other. The FESEM images were further analyzed using computer software (Mitani Syoji ; Winroof) to obtain the diameter distribution of individual nanofibers. The diameter of the nanofiber was distributed from 5 nm to 300 nm. Mean diameter of the particles was approximately 100 nm, and the value is slightly larger than that of our previous results. FESEM images of the nanomaterial products produced in ethanol and deionized water with SDS, not shown here, have almost same images of those produced in pure deionized water. These results suggest that the nanomaterials produced by arc discharge method are independent on the liquid.

Figure 4 shows the FESEM images of the nanomaterial products using pulsed laser ablation in pure deionized water. As shown in Fig. 4, two kinds of nanomaterial products can be observed in the liquid. One of them is sphere shape nanoparticles, and another one is products like nanofiber. In the pure deionized water, many nanometer size sphere shape particles were frequently observed, and some of them were aggregates. The size of the particles produced by pulsed laser ablation was small, and the density of the particles produced by pulsed laser ablation is high compared with those produced by arc discharge. In addition, small amount of nanofibers are observed. The FESEM images were further analyzed using Winroof to obtain the diameter distribution of the particles. The diameter of the particles was distributed from 10 nm to 200 nm. Mean diameter of the particles was approximately 70 nm. FESEM images of the nanomaterial products in ethanol, not shown here, have almost same images.

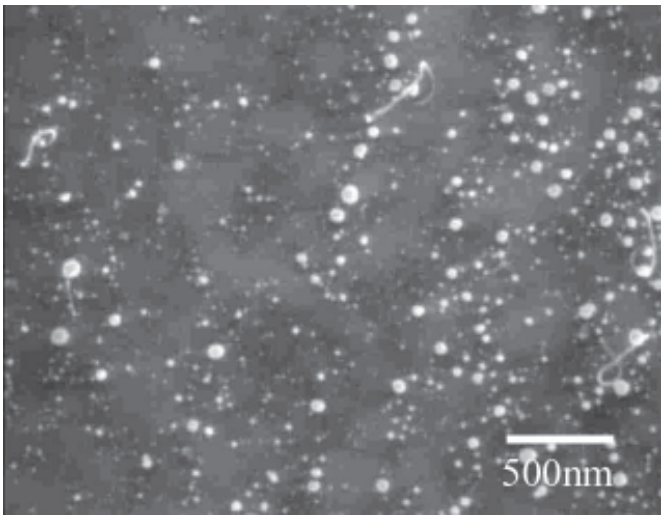

Fig. 4 FESEM image of the nanomaterial products using pulsed laser ablation in pure deionized water.

Figure 5 shows the FESEM images of the nano material products in deionized water with SDS. The shape of the particle is not always spherical compared with that in the pure deionized water and ethanol, and the ratio of the nanofibers increased. The reason of this tendency is not clear yet, but it is considered as follows. SDS molecules with a negatively charge encloses the nano particles which are positive charge. Therefore, products like micell are produced at some part of the particles, and the growth of the particles may be changed as compared with the other liquids.

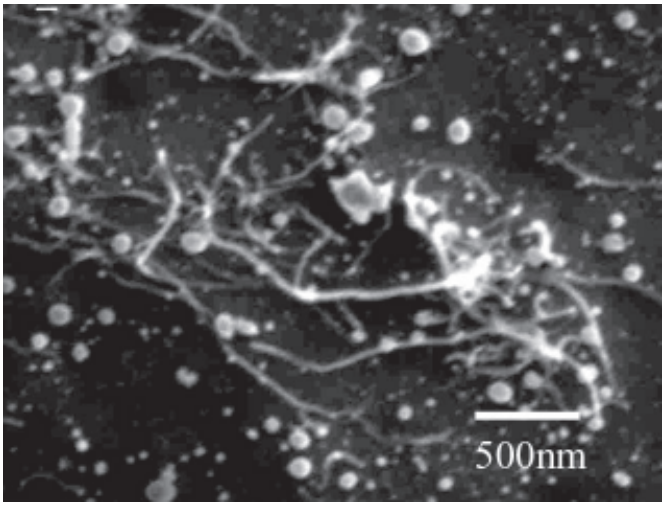

Fig. 5 FESEM images of the nano material products in deionized water with SDS.

Figure 6 shows the emission spectroscopy of the arc discharge plasma in the deionized water with SDS. As the results, C^+(426.7nm), H_β(486.1nm), H_γ(434.0nm) and C_2 swan bands can be observed. Strong peak of H_α(656.3nm) can be also observed, not shown here. Emission spectroscopy from the arc plasma is almost same compared with that in the deionized water described elsewhere [9].

Figure 7 shows the FESEM images of the nano material products by pulsed laser ablation using carbon with metal catalyst (Ni/Co; 1.2at.%) target in deionized water. There are a lot of nanofibers and nano particles, and they are bundled. The reason of the phenomenon is also not clear yet, but it may be due to the metal catalyst.

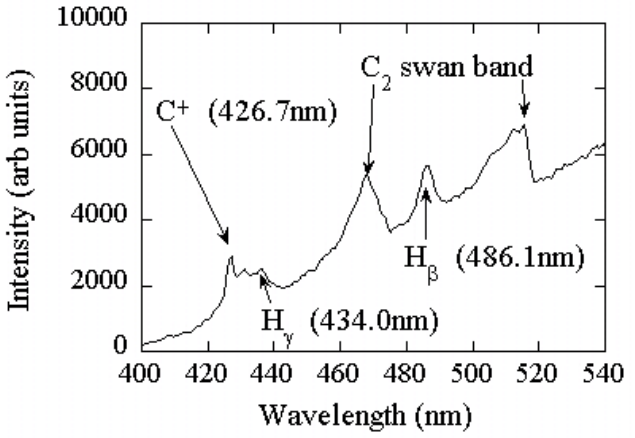

Fig. 6 Emission spectroscopy of the arc discharge plasma in the deionized water with SDS.

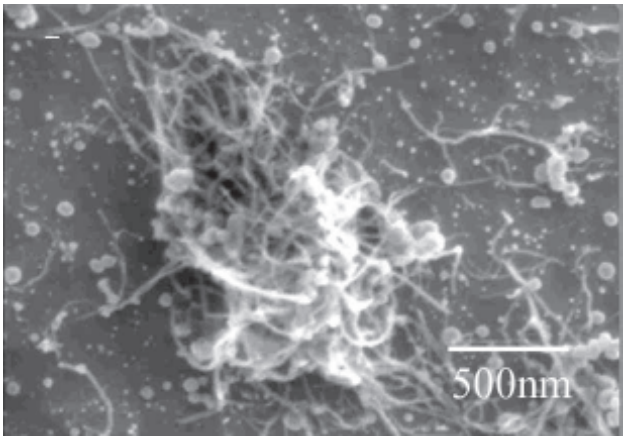

Fig. 7 FESEM images of the nano material products by pulsed laser ablation using carbon with metal catalyst (Ni/Co 1.2at.%) target in deionized water.

4.Conclusion

Carbon nanomaterials have been prepared using pulsed arc discharge in liquid and pulsed laser ablation. FESEM observation revealed that most of nanomaterials produced by arc discharge were sphere shape nanoparticles. On the other hand, small amount of products like nanofiber can be produced using pulsed laser ablation method. The ratio of the products like nanofiber produced in the deionized water with SDS is high compared with those produced in the deionized water and ethanol. The size of the particles produced by pulsed laser ablation was small, and the density of the particles produced by pulsed laser ablation is high compared with those produced by arc discharge.

Abstract

Highly Ionized Sputter Deposition Process is a new technique of magnetron sputtering working in high power pulsed regime. The high current densities obtained with this process ensure a high ionization ratio of the sputtered vapour. This work deals with the study of the transport of titanium ions and neutrals in such a discharge. Current measurements were completed by time and space resolved absorption spectroscopy and by a simple diffusion model.

Keywords: pulsed magnetron sputtering, absorption spectroscopy, titanium diffusion

1. Introduction

In magnetron discharges, the cathode mainly emits sputtered species as neutral particles. Due to gas phase collisions, these particles have relatively low energy when hitting the substrate and lead to deposited films with poor qualities. To improve the film quality as well to deposit materials on complex surfaces for industrial applications [1] (tools, connectors, vias and trenches for highly integrated microelectronics …), works were developed on Ionized Physical Vapor Deposition (IPVD). Classical magnetron devices were then equipped with additional source of vapor ionization using RF loops [2] or microwave antennas [3] in the region between the target and the substrate.

More recently, an alternative technique was explored using magnetron discharges working in high power pulsed regimes [4]. Typical pulsed current density values of the order of 3 A/cm^2 were achieved (two orders of magnitude higher than in continuous DC magnetrons). These high current densities ensure a high ionization ratio of the sputtered vapour.

2. Experimental set-up

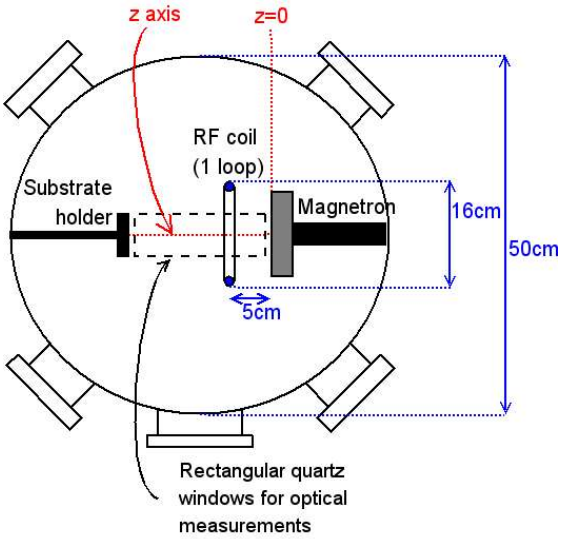

Fig. 1: Diagram of the reactor

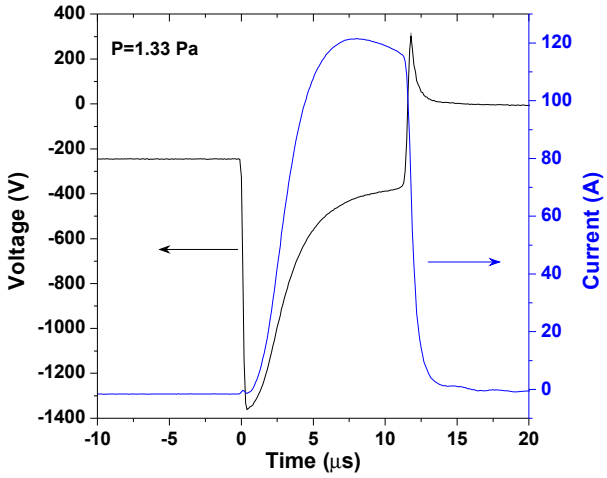

Fig. 2: Typical current and voltage shape during the pulse

The reactor is presented on Figure 1. It is a 50 cm diameter and 45 cm height cylinder. It contains a 10 cm diameter planar circular magnetron cathode and a 16 cm diameter radio-frequency coil with one loop. The "z axis" is the magnetron-substrate holder axis. The "z=0" position corresponds to the target surface. Buffer gas

was argon and the materials of the target was titanium. Working pressure values were 1.33 Pa and 4 Pa. The distance between the titanium target and the substrate-holder was z=14 cm. The quartz windows on top and bottom of the reactor allow spatially resolved optical measurements.

The magnetron cathode was supplied by a high power adapted pulsed generator [5,6]. Typical pulse shapes of the applied magnetron voltage and current are presented on figure 2. The pulse has the following characteristics: the time duration can vary between 5 and 50 µs, the frequency between 20 Hz and 1 kHz, the cathode voltage can reach -1400V and the current 120A. The radio-frequency coil was supplied with a 13,56 MHz – 1600 W generator.

In order to investigate the transport of ions during and after a high power pulse, the ion current on the substrate holder was measured. In order to avoid a great negative current on the substrate holder, a negative bias of -60V was applied.

Spatially resolved absorption measurements were carried out using a titanium hollow cathode lamp. The light emitted by the lamp entered the reactor through the top quartz window and the absorption signal was collected through the bottom quartz window. This lamp was operated in pulsed regime (100µs duration, 100Hz frequency) using a generator developed in our laboratory. In pulsed regime, the absorption signal is clearly separated from the plasma emission and the enhancement of the ionic line emission in the pulse allows the determination of Ti^+ densities by absorption. The method involves the use of the three titanium neutral ground state sub-levels. This allows the determination of titanium densities if thermalisation is achieved [7]. However, the temperature value is needed to deduce absolute densities. In the present study, the density was not determined because we were unable to precisely measure the titanium temperature. We will only discuss the evolution of the absorption coefficient. This coefficient is calculated with the following formula: $A=1-I_t/I_0$, where I_0 is the lamp intensity and I_t is the transmitted intensity through the plasma.

3. Transport of species to the substrate

Time resolved current measurements at 1,33 Pa and 4 Pa are presented on Figures 3 and 4. Two majors contributions to the ion current can be observed and explained.

The first peak is attributed to Ar^+ which are created during the pulse by the electron avalanche near the substrate-holder. They are collected during the pulse and at the beginning of the post-discharge. In this first contribution, the fast Ti^+ (a few $km.s^{-1}$) reaching the substrate-holder without collisions also have to be taken into account (ballistic regime).

The last maximum of each curve is attributed to ions slowed down and thermalized through collisions with argon atoms (classical diffusion regime).

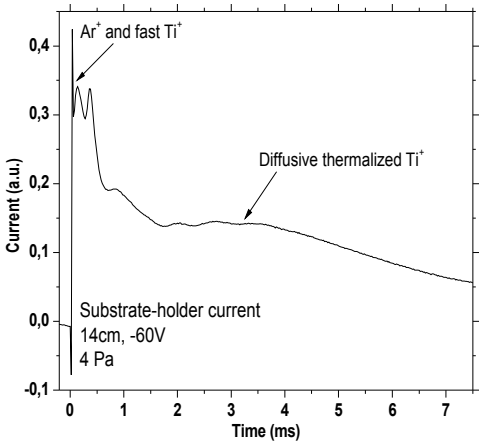

Fig. 3: Current measured on the substrate holder at 4 Pa

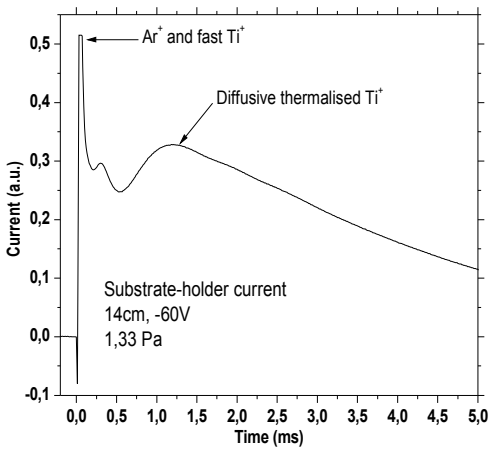

Fig. 4: Current measured on the substrate holder at 1,33 Pa

In order to investigate the first contribution of Ti^+, we made time-resolved current measurements while moving the substrate-holder along the "z" axis. This measurement was only made at 1,33 Pa because the signal was too noisy at 4 Pa to make a correct analysis. We observed that the time delay between the pulse and the arrival of the first peak on the substrate-holder was strongly dependant to the distance between the magnetron and the substrate-holder. We present on Figure 5 a plot of this delay versus the distance. This plot is linear and we can deduce a speed of 6,7 $km.s^{-1}$ which is consistent with magnetron ejection speed reported in [1].

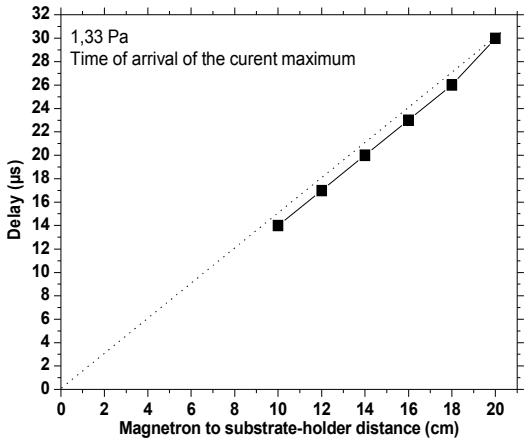

Fig. 5: Delay of the current maximum versus the magnetron to substrate holder distance

We then made time resolved optical absorption measurements at 14 cm to determine the absorption coefficient of titanium species (neutral ground state and ion ground state). On Figures 6 and 7, we compared the absorption coefficient for ionized titanium to the current measurement. It appears that at both pressures, the last maximum of the substrate-holder current effectively corresponds to the maximum of absorption.

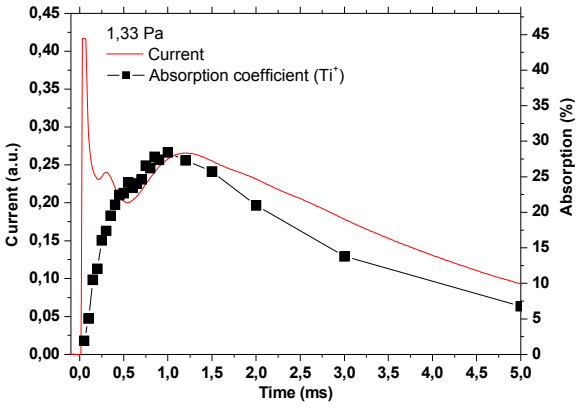

Fig. 6: Comparison between current measurement and absorption measurement at 14cm for 1,33Pa

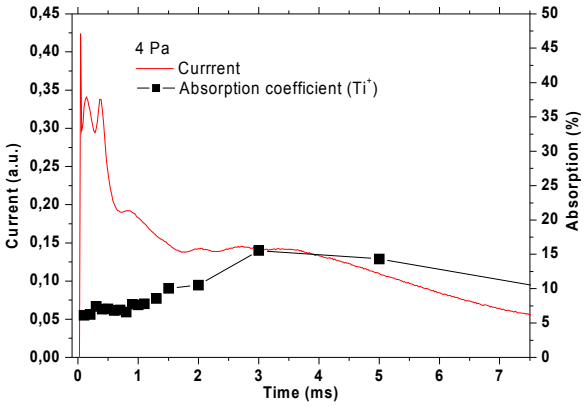

Fig. 7: Comparison between current measurement and absorption measurement at 14cm for 4Pa

In order to have a better understanding of the transport of Ti species, we have made absorption measurements at other distances from the magnetron (6, 8 and 10 cm). The results of these measurements are presented on Figure 8 for 4 Pa. The first interesting result is the translation of the maximum of the absorption

coefficient with the distance. As awaited, the maximum is seen later for longer distances from the magnetron. Furthermore, the peak is widening with an increasing distance. It suggests that for this time scale of several ms, Ti and Ti^+ are transported to the substrate -holder by diffusion.

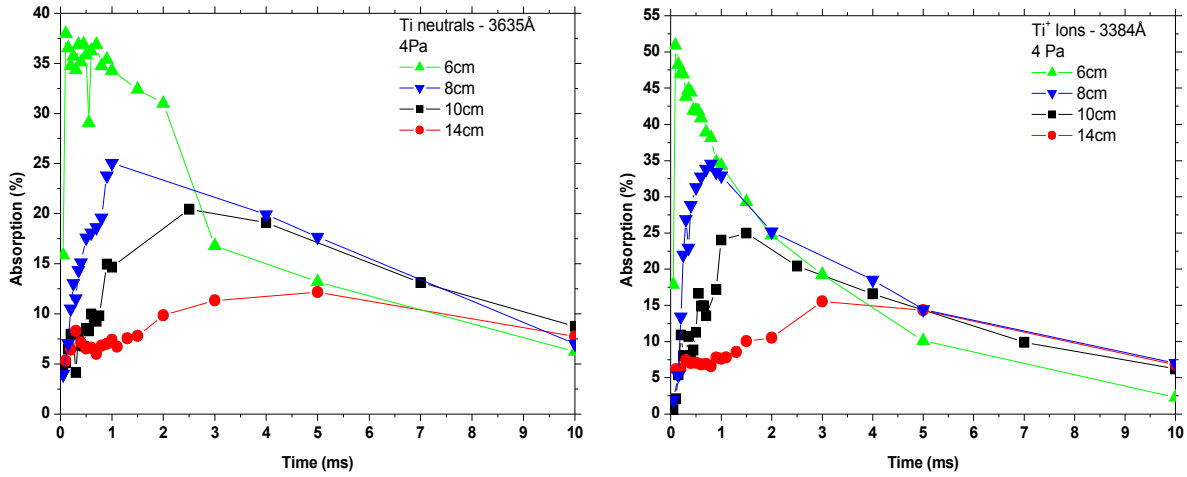

Fig. 8: Absorption measurements on a neutral (3635Å) and an ionic (3384Å) titanium line at 4 Pa for various distances

To investigate this diffusion regime, we have made a very simple 1D simulation of particle diffusion in the reactor. Only diffusion in the *z* direction was taken into account. We neglected the losses in radial direction because the distance between the magnetron and the substrate is lower than the radius of the reactor. The equation is the following:

$$\frac{\partial n}{\partial t} = D \frac{\partial^2 n}{\partial z^2}$$

The calculation of the diffusion coefficient is made using the formula: $D=D_0.k.T/P$. The value of D_0 is given in [8] at 300K: $D_0(300K)=3,1.10^{20}$ atoms.cm^{-1}.s^{-1}. Since D_0 dependence against the temperature is a square root function ([8]), we can easily convert this given value to the wanted temperature. The limit conditions are: n=0 cm^{-3} at z=0cm and z=15cm because the titanium atoms are stuck on the wall without reflection. The initial conditions are:

- the density profile is a Gaussian centred at 4cm with a half-width of 1 cm (see Figure 9) because we estimate that at this distance, the majority of the titanium population is thermalised, and the initial maximum density value is estimated at 1.10^{12} cm^{-3} from the absorption values at 6 cm,
- the initial temperature profile is presented on Figure 9. The simulation was made with this profile for the first 100 µs. After t=100 µs, the temperature is taken constant T=350 K. This is a very simple way to render the duration of the pulse and the temperature decrease with time.

The calculation was only made at 4 Pa because the thermalisation distance at this pressure is low enough to consider that the diffusion model is valid on the length of the reactor (approximately 15cm). In other words we consider that the distance between two collisions is lower than the z-stepping in the model (0,1 mm).

The results are shown on Figure 10. The times found for the maximum at each distance are really close to the times observed previously (neutrals on Figure 8). This very simple model confirms that the last maximum on the current measurement is consistent with a diffusive transport.

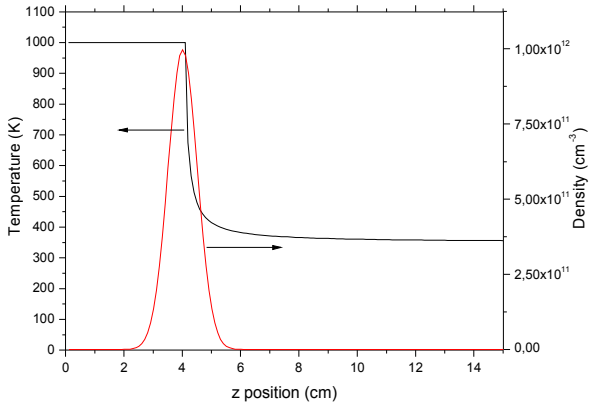

Fig. 9: Initial temperature and density profiles used for the diffusion model

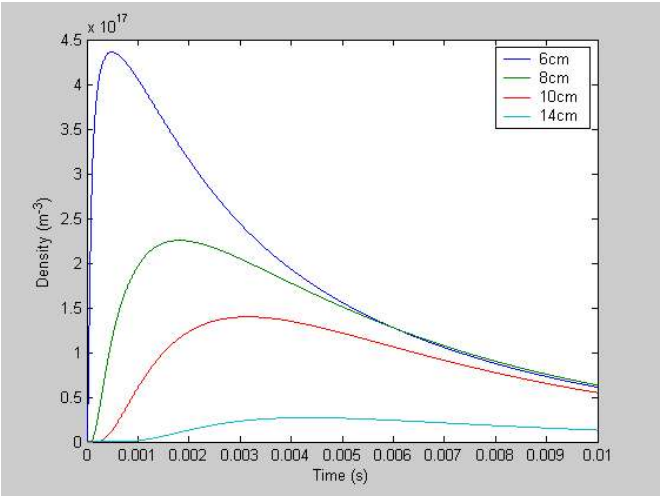

Fig. 10: Density results given by the diffusion model at a pressure of 4 Pa for titanium neutrals

4. Conclusion

Highly Ionized Sputter Deposition Process is a recent alternative technique ensuring a high ionization ratio of the sputtered species. However, the transportation of species in such a discharge is not commonly studied. We were able to make various time and space resolved measurements on our experiment. Current measurements showed two distinct contributions of ions: fast Ti ions and diffused ions.

The first population was investigated with current measurements and the ballistic regime of these ions was confirmed by a measured velocity similar to the ejection speed. The supposed diffused regime (second population) was investigated using resonant absorption spectroscopy. We showed that the behaviour of the measured absorption coefficient was consistent with a diffusion regime. Moreover, the use of a simple diffusion model confirmed this assumption.

Future works will imply the study of the effect of an additional ionization device (the radio-frequency coil) on the transport of species. Preliminary results are presented on Figure 11: when increasing the RF power, the maximum of the current is arriving sooner after the magnetron pulse. This can be due to the creation of a conductive region with an effect similar to an unbalanced magnetron. The potential distribution has to be determined and time resolved Langmuir probe measurements are going to be undertaken.

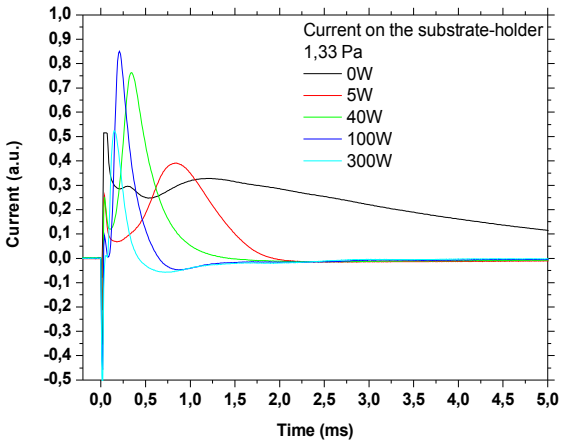

Fig. 11: Current measurements at 1.33 Pa for an increasing additional RF power

An improvement of the model, taking into account the temperature diffusion, as well as a precise measurement of the initial profiles (density as well as temperature) is also to be undertaken.

[2]Department of Electrical and Electronic Engineering, Nagasaki University, Japan

Abstract

For the inner surface coating of narrow tubes, we have investigated pulsed coaxial sputtering process with the 2nd harmonic electron cyclotron resonance (ECR) plasmas. As a result of detailed investigation of temporal evolutions of the target ions current and the pulse voltage, we found that the selection of pulse bias voltage and gap length was very important. As a result, we have succeeded in coating Ag films onto the inner surface of an insulated narrow tube with 1.75mm inner diameter.

Keywords: Sputtering, Micro plasma, ECR, Inner coating, Narrow tube

1. Introduction

Materials with properly modified surface can be used under severe environment. The surfaces modification technique should be used to prolong the lifetime of narrow tubes, which are used in engineering plants and medical instruments such as the catheter. In recent years, there are few examples of researches on tube inner coating [1-8].

The coaxial electron cyclotron resonance (ECR) plasmas and 2nd harmonic ECR plasmas are high-density in spite of generation in low-pressure and narrow gap condition. We have already reported the generation of Xe micro plasmas with the minimum gap length of 500μm at the pressure of 0.01 Torr under the 2nd harmonic ECR condition. Recently, we have succeeded in coating Ag films onto the inner surface of an insulated tube of 1.75mm inner diameter using pulsed coaxial sputtering with the 2nd harmonic electron cyclotron resonance (ECR) plasmas. Pulsed target biasing was indispensable for this process. In this paper, we report the experimental results of temporal behaviors of the target ion current against the pulsed target biasing.

2. Experimental details

Figure.1 shows the experimental setup used in this research. Microwave source of 2.45GHz has been used. The three-stub tuner was used to control microwave transmission. In the present experiments, Ar gas and small coaxial tube as electrodes has been used. Inner electrode was transmitted TEM mode microwave and applied pulse bias voltage. Outer electrode is grounded. Plasma was generated in narrow area between outer electrode and inner electrode.

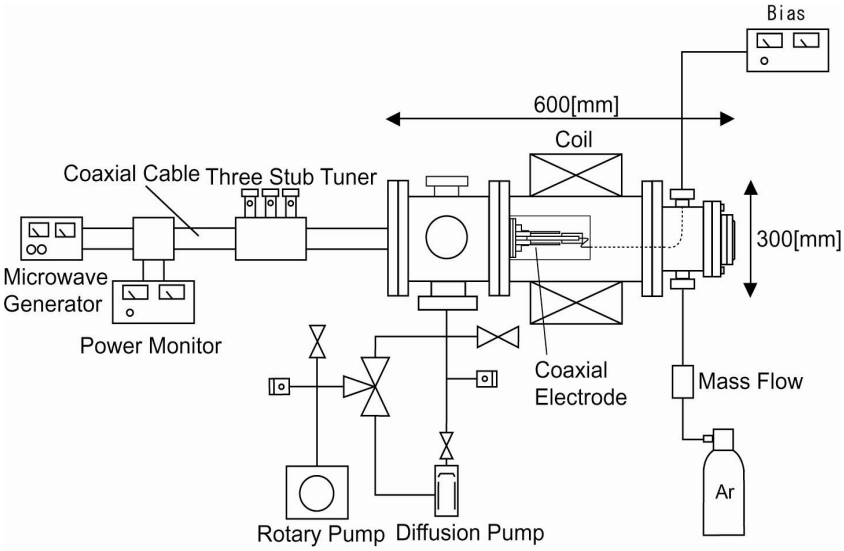

Fig.1 Schematic of Experimental setup

Figure. 2 shows a cross section view of the coaxial sputtering system used in this study. Inner electrode is impressed with TEM mode microwave and pulse bias voltage. Outer electrode is grounded. Plasma is generated between the inner and outer electrodes. In this system, a narrow insulator tube (equal to a substrate) was inserted in the outer electrode and films were deposited on the inner surface of the narrow tube by sputtering. In addition, in order to coat substrates with smaller diameters, a wire target with a smaller diameter was used. However, since the wire target was bent by heat and gravity, the spring was used to always apply a tension to a wire. As a result, the wire was maintained at the center axis of the tube.

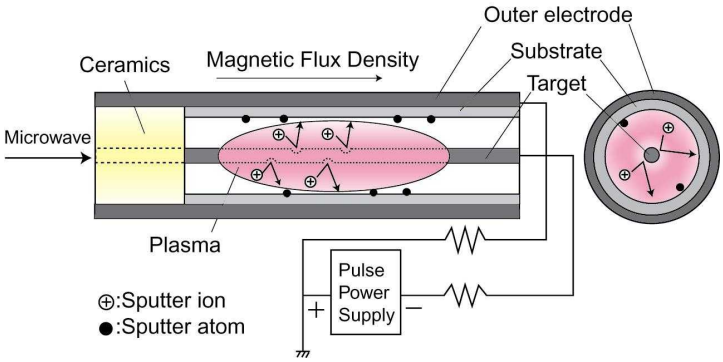

Fig. 2 Coaxial sputtering system

3. Results and discussion

A current probe measured temporal evolution of the target ion current. The target ion current vs. pulse bias

voltage was shown in Fig.3. In this figure, the ion current is decreased with increasing the target bias voltage. Expansion of a sheath can be considered as this cause. When the magnitude of target pulse voltage is increased, sheath width expands, resulting in the decrease in the ions current flowing into a target.

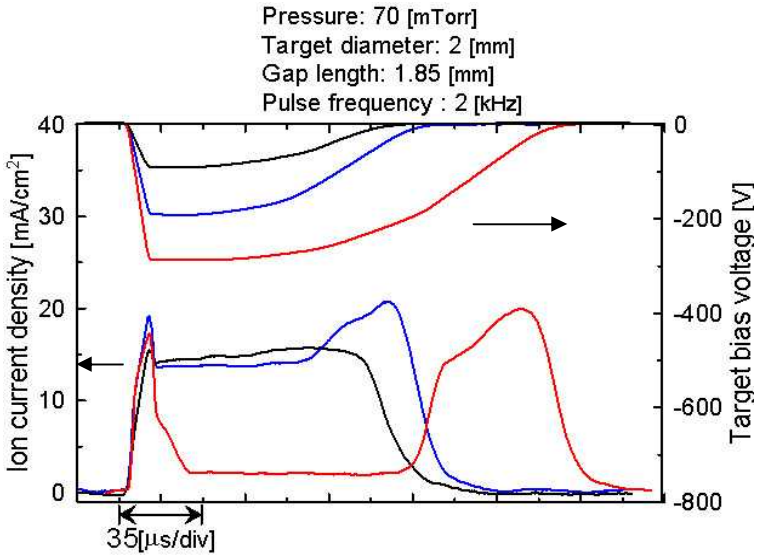

Fig.3 Target ion current vs. pulse bias voltage
(Gap length 1.85mm)

Fig.4 shows the temporal behaviors of the target ion current and the target bias voltage for different gap lengths of 1.85mm and 3.5mm. The ion current is decreased with decreasing the gap length. From this result, it is understood that the gap length has a large influence on plasmas. When the gap length becomes short, the influence of the sheath width is enhanced. In addition, it is noted that the target ion current is increased again at the falling time of the pulse bias voltage, indicating a restoration of plasma density.

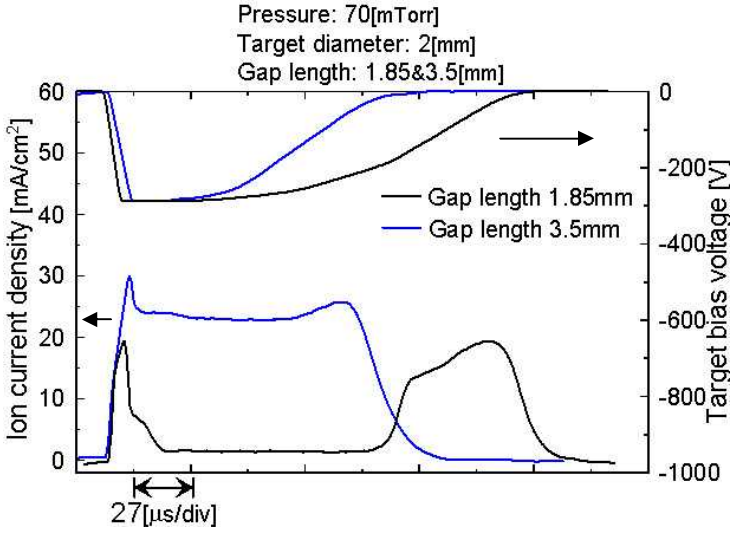

Fig.4 Compared target ion current of gap length 1.85mm with 3.5mm

Based on the above-mentioned experimental results, we have tried to coat Ag thin films onto the inner surfaces of insulated narrow tubes using pulsed coaxial sputtering with the 2nd harmonic electron cyclotron resonance (ECR) plasmas. As a result, we have succeeded in coating Ag films onto the inner surface of an insulated narrow tube with 1.75mm inner diameter. However, in order to keep the reproducibility of the sputter-deposition process for the narrow tubes, geometrical alignment of the center target is indispensable. Further improvements of a mechanical setting of both the target and substrate are necessary.

4. Conclusion

For the inner surface coating of narrow tubes, we have investigated pulsed coaxial sputtering process with the 2nd harmonic electron cyclotron resonance (ECR) plasmas. When the magnitude of target pulse voltage is increased, sheath width expands, resulting in the decrease in the ions current flowing into a target. When the gap length becomes short, the influence of the sheath width is enhanced, resulting in the decrease in the ions current. The target ion current is increased again at the falling time of the pulse bias voltage, indicating a restoration of plasma density. Based on these experimental results, we have succeeded in coating Ag films onto the inner surface of an insulated narrow tube with 1.75mm inner diameter.

[2]Department of Electrical and Electronic Engineering, Nagasaki University, Japan

Abstract

Plasma generation has been succeeded for the pressure of 0.01Torr and gap length of 500μm in xenon gas for the 2nd harmonic Electron Cyclotron Resonance (ECR). Resonant confinement of electrons at the 2nd harmonic ECR leads to interesting micro plasma characteristics: the higher electron density, the lower plasma potential, the lower electron temperature and the effective power absorption. PIC-MC simulation of low pressure micro plasma supported such plasma characteristics obtained by the experiments.

Keywords: Micro plasma, 2nd Harmonic ECR, Low-Pressure, Narrow Tube Inner Coating

1. Introduction

Recently, much attention has been paid to microscale science and technology in various fields.

We are developing the low-pressure microplasma to realize the inner coating of narrow tube by the sputter processing and/or EUV source with less self absorption [1].

By our past researches, it was found that the 2nd harmonic ECR micro plasma could be generated for low pressure condition [2].

In the present paper, we will report on the results of measurement of the plasma parameter for the low-pressure micro plasma developed previously. In addition, the experimental results have been estimated by PIC-MC simulation.

2. Experiment

2.1 Experimental Setup

Figure 1 shows the experimental setup. Microwave with frequency of 2.45GHz was emitted by the coaxial TEM mode, which had no cut-off, so that the microwave can propagate through metallic tube of any size. Figure 2 shows the electrode structure. The diameter of an inner electrode was 5mm, and the gap length was adjusted by changing the diameter of an outer electrode. Plasma generation point was located at about 25mm from the edge of electrodes. It is located in the center of the magnetic coil.

2.2 Results and Discussion

As a result of our previous experiment, we have succeeded the low-pressure microplasma generation. The plasma has been mainly generated for the condition of the 2nd harmonic ECR ($\omega_c/\omega=0.5$).

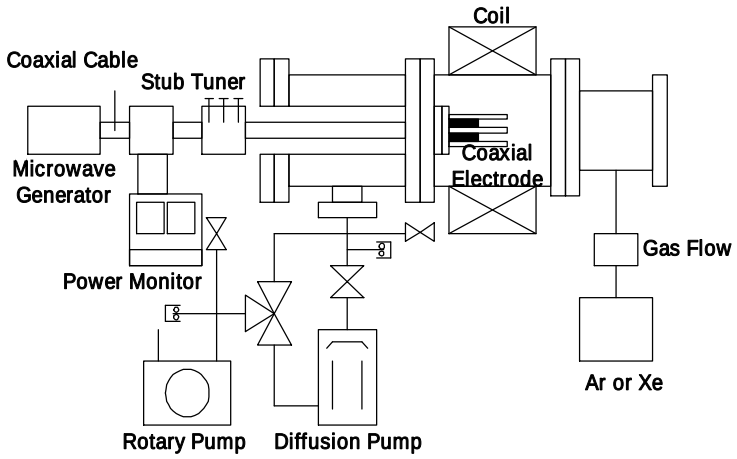

Fig. 1 Experimental setup.

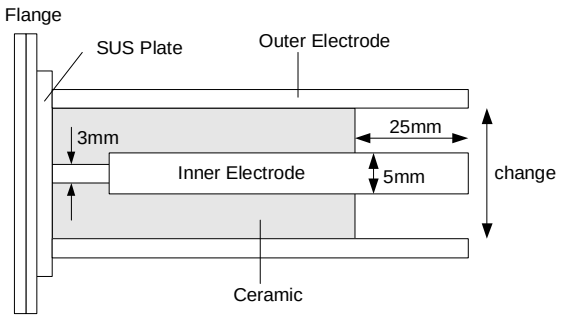

Fig. 2 Electrode structure

Probe measurement has been performed for the conditions of Are pressure 0.03Torr, gap length 3.5mm and incident microwave power 30W. Figure 3 shows the probe system. The cylindrical tungsten rod (diameter 0.3mm) has been used as a Langmuir probe in the plasma, which was generated between the coaxial electrodes. (From the edge of the electrodes to 12.5mm) The top surface of the probe has been insulated to prevent the charged particles flowing to the direction perpendicular to the magnetic field.

Figures 4 and 5 show that the magnetic field dependence of electron density and electron temperature measured by the probe. From these experimental results, the higher electron density and the lower electron temperature has been confirmed at the 2^{nd} harmonic ECR condition. In our previous calculation [2], it was suggested that the electron orbit was very small (<20μm) at the 2^{nd} harmonic ECR condition. Therefore it may be considered that highly efficient ionization by trapped electron collision can be performed at the 2^{nd} harmonic ECR condition because of the "resonant confinement".

In micro plasma world, ECR has rather disadvantage for plasma generation because of the fast electron loss to wall by the resonant acceleration.

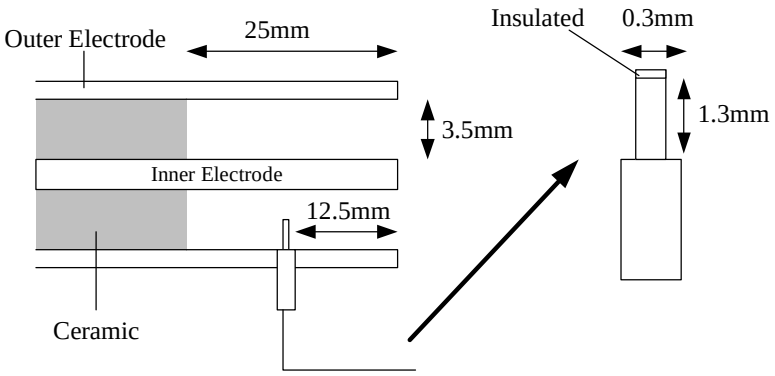

Fig. 3 Probe system

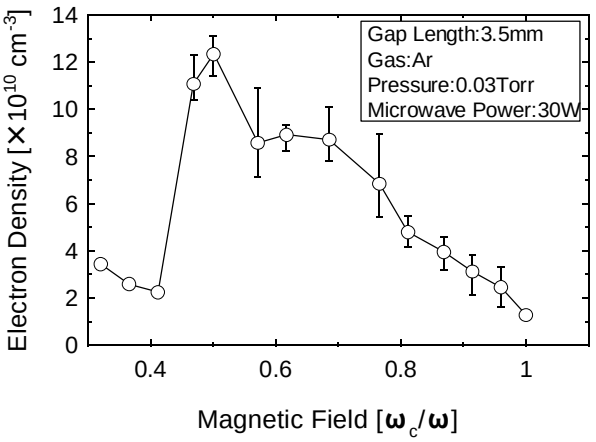

Fig. 4 Magnetic field dependence of the electron density

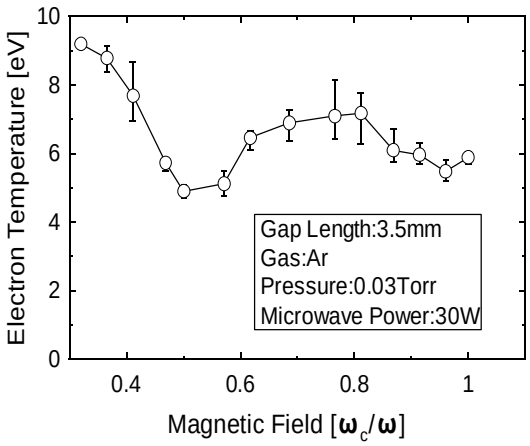

Fig.5 Magnetic field dependence of electron temperature

3. PIC-MC Simulation

3.1 Calculation model

By using the xpdp1 and xpdc1 codes developed at the PTSG, it has been investigated the characteristics of the ECR and the 2nd harmonic ECR micro plasmas. At the xpdc1 code, electrode is Coaxial Tube. Plasma generation region is between inner electrode and outer electrode. Inner electrode radius r_0 is 2.5mm which is connected with 2.45 GHz microwave generator. Outer electrode radius r_1 is 4.5mm that is connected to ground. So that means gap length is 2mm. Source is 2.45GHz microwave power supply ($A \cdot \sin\omega t$, A=30V). Gas is Ar and the pressure is 0.05 Torr.

3.2 Results and Discussion

The simulation result clearly shows that the electron density at the 2nd harmonic ECR become higher than that at ECR condition, as shown in Figure 6. It was also found that the total absorbed power for 2nd harmonic ECR condition was over 10 times higher than the ECR condition.

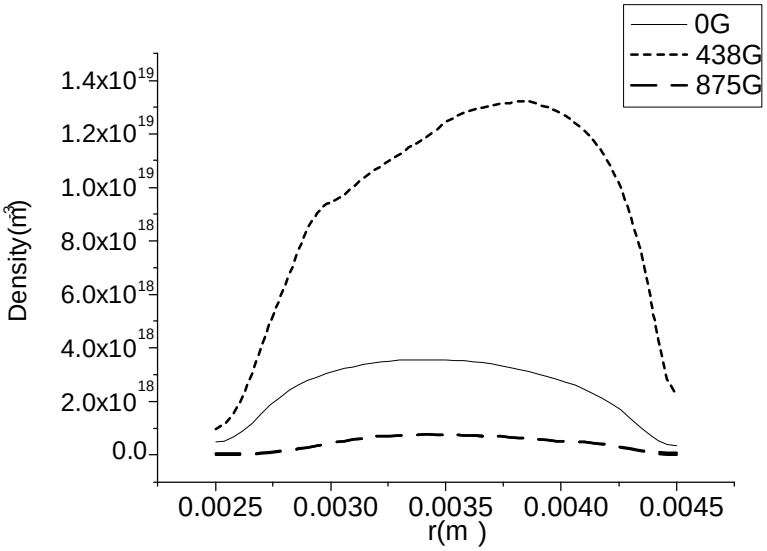

Fig. 6 Simulation results using xpdc1:Electron density

4. Conclusion

Low-pressure micro plasmas generated at the 2nd harmonic ECR have been characterized by the probe measurement and PIC-MC simulation. In spite of the measurement in the gap length of 3.5mm to decrease the probe disturbance, it has been confirmed that the 2nd harmonic ECR plasma has the higher electron density and lower electron temperature compared with the ECR plasma.

Abstract

Plasma-surface interactions play an important role in the production of molecules in plasmas. We investigated the plasma-activated catalytic formation of ammonia in N_2-H_2 plasmas. Using different diagnostic techniques, we measured the N, H, NH, NH_2 and NH_3 densities under varying plasma conditions. From the results obtained, we conclude that NH and NH_2 radicals are formed by reactions of the formed NH3 and N+ ions and H atoms emitted by our plasma source.

Plasma-surface interactions, NH, NH_2, expansion

1. Introduction

In applications in which plasma is used for chemical conversion, but also for surface treatment or deposition newly formed molecules are often detected in the background gas. It has been acknowledge for quite some time that plasma-surface interactions are of great importance in the production of these molecules. To gain a better understanding of the plasma-surface interactions, we have investigated this formation of molecules from atomic sources in more detail. Previously, we showed that ammonia can be formed efficiently in plasmas generated from mixtures of hydrogen and nitrogen, i.e. 11% of the total background pressure became ammonia [1]. The ammonia density as a function of the relative hydrogen flow rate was also measured in a low pressure N_2–H_2 flowing discharge [2] and was predicted fairly well from a self-consistent model assuming that NH_3 is mainly produced at the vessel wall [3].

The formation of ammonia is generally ascribed to stepwise addition reactions from absorbed nitrogen and hydrogen radicals at the surface. NH_3 is formed by subsequently hydrogenation of absorbed nitrogen atoms and the intermediates NH and NH_2 at the surface [4]. To obtain further insight in the ammonia formation mechanism, the plasma chemistry was studied in more detail. More specifically, the densities of the atomic radicals (N, H), and the molecular radicals (NH, NH_2) as well as the NH_3 density were determined using various diagnostic techniques. Results on the N and H radical fluxes emitted by the source as measured using two-photon absorption laser induced fluorescence (TALIF) will be presented. The role of the NH_x radicals in the N_2–H_2 plasma was studied by measuring their densities on various positions from the nozzle using cavity ring down spectroscopy. These nitrogen and hydrogen containing plasmas are also of interest in other fields of research, e.g. the deposition of amorphous silicon nitride (a-SiN_x:H) films and the plasma assisted atomic layer deposition of TaN thin films [5].

2. Experimental setup

In the experiments, a high pressure cascaded arc is used as a plasma source to generate N_2-H_2 containing plasmas (Figure 1). This plasma expands supersonically into a low pressure vessel, leading to high fluxes of hydrogen and nitrogen radicals. Via an injection ring monomers can be injected into the background. These monomers undergo charge transfer, and subsequently dissociative recombination reactions with ions (Ar^+, N^+) emanating from the source, leading to atomic and/or molecular radicals. Most of the radicals will arrive at the surface at which they will adsorb. At the surface, new molecules can be generated which subsequently desorb. This process is called plasma-activated catalysis, because a plasma is used to produce the radicals for the molecule production and the almost fully covered (metallic) wall is used as a catalyst [6]. In this so-called remote source approach,

the dissociation and ionization in the plasma source are geometrically separated from the plasma chemistry in the vessel. In this way the plasma conditions can be controlled independently from the downstream plasma chemistry. The plasma is produced with both nitrogen and hydrogen applied through the cascaded arc with a total flow of 1 standard liter per minute. The arc pressure is typically at 0.1-0.2 bar and the current is 55 A and the plasma vessel is kept at 20 Pa.

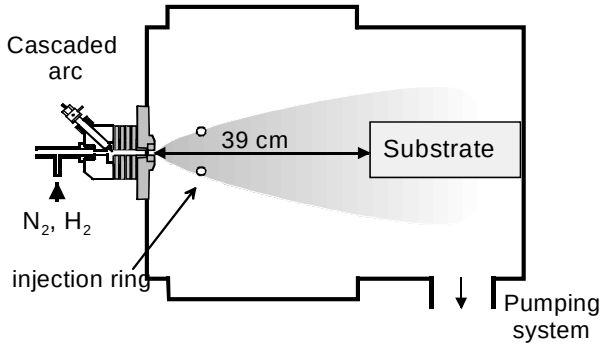

Figure 1: Sketch of the setup in which the thermal plasma expansions are created.

Cavity ring down spectroscopy was used to measure the density of NH and NH_2 radicals on various positions from the nozzle (z = 10, 21, 35 cm). CRDS is an absolute absorption technique based on the measurement of the decay rate of a light pulse confined in a high-finesse optical cavity rather than the magnitude of the absorption. The optical cavity is formed by two highly reflective plano-concave mirrors. The mirrors were directly flanged onto the stainless steel vessel, in which the plasma expands. The light leaking out of the cavity was detected by a photo multiplier tube. When there is an absorbing medium present in the cavity, the intensity of the light pulse will decay faster. From the difference in decay time, (ring-down times) between an empty cavity and a cavity with absorbing species can be related to the density of the absorbing species in the cavity, when information on the cross section and the partition function (state sum) of the absorbing species is known.

The NH radical density was determined using the isolated $A^3\Pi(v'=0) \leftarrow X^3\Sigma^-(v''=0)$ $P_{3,3}(9)$ transition at 339.52 nm. The NH_2 radical was detected at the isolated $\tilde{A}^2A_1 \leftarrow \tilde{X}^2B_1$ $(0,9,0) \leftarrow (0,0,0)$ $\Sigma^P Q_{1,7}$ absorption line at 597.21 nm. The density information is determined by scanning the laser over the absorption line and using the integrated absorption cross-section, which is deduced from the oscillator strengths reported in literature. The Doppler broadening was used to determine the kinetic gas temperature of the radicals by deconvoluting the experimental absorption lines into a Lorentzian laser-line-width and Gaussian Doppler contribution. The laser line-width was 0.11 ± 0.01 cm^{-1} at 339.52 nm and 0.054 ± 0.01 cm^{-1} at 597.21 nm. The temperature was determined for two reasons. Firstly, in order to determine the total density one has to take into account the density distribution in all possible states (determined by the temperature). Secondly, the temperature gives an indication of the possible reaction mechanisms leading to NH and NH_2 radicals.

The densities and fluxes of the atomic radicals (N, H) emitted by the source were measured using two-photon absorption laser induced fluorescence (TALIF). In the case of hydrogen atoms, 205 nm photons are used to excite the H atoms from the $1s^2S$ ground state to the $3d^2D$ and $3s^2S$ states. The resulting non-resonant fluorescence on the Balmer-α transition at 656 nm is detected by a photo multiplier tube. From a spectral scan over the two-photon transition, the H atom density, temperature and velocity along the laser beam are obtained. In all of the measurement the dye laser wavelength is calibrated by the simultaneous recording of the well-known absorption spectrum of molecular iodine. The densities are calibrated using a two-photon transition in a known amount of krypton.

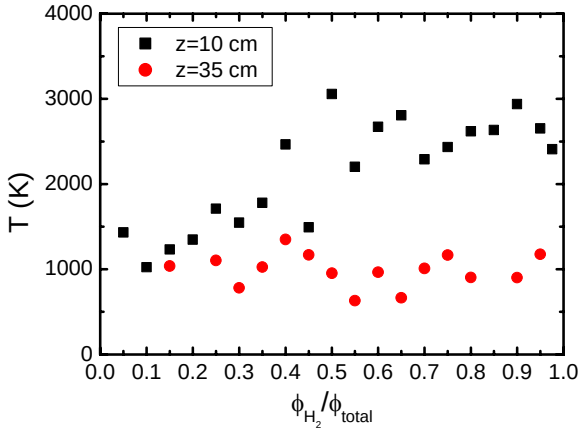

Figure 2: The temperature of the NH_2 radicals at two different positions from the nozzle, i.e. z = 10 and 35

3. Results

The temperature of the NH radicals as determined for z = 10 and 21 cm, is the same as the plasma temperature, i.e. about 1500 K. The temperature of the NH_2 radicals as measured at z = 10 and 35 cm are plotted in Figure 2 as

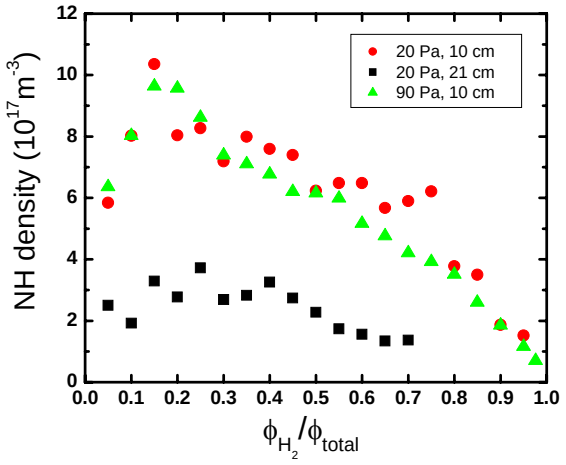

Figure 3: NH density as function of the relative hydrogen flow at two different z-positions and pressures.

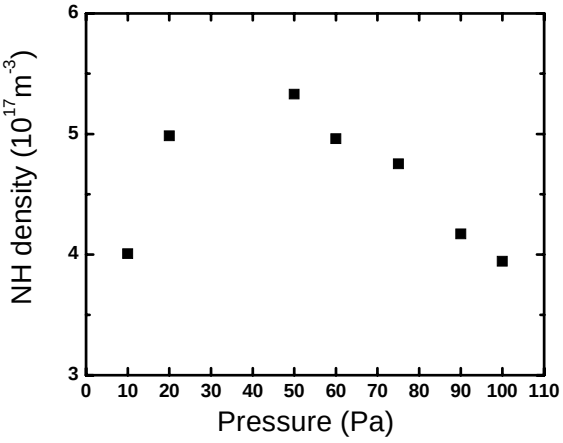

Figure 4: NH density as function of the background pressure. Both nitrogen (5 sccs) and hydrogen (11.67 scs) are applied through the arc.

function of the relative hydrogen flow. The temperature at z = 10 cm increases from 1400 K at almost full nitrogen plasmas to 2500 K for plasmas containing more than 50% hydrogen. The temperature behaviour of NH_2 as function of the relative hydrogen flow, is due to a different plasma temperature at z = 10 cm for different relative hydrogen flows. At low relative hydrogen flows, the plasma is dominated by N atoms and N_2 molecules. Therefore, the formed NH_2 undergoes enough collisions with heavy particles to be thermalized, i.e. the NH_2 radicals have the same temperature as the other particles in the plasma, which is around 1500 K. At high relative hydrogen flows, the temperature of the H atoms is higher than at low relative hydrogen flows and the formed NH_2 radicals undergo mainly collisions with H atoms. Due to the fact that H atoms have a small mass, it takes more collisions and thus time before the plasma is thermalized. At z = 10 cm, the NH_2 radicals didn't undergo enough collisions to be thermalized, i.e. have a temperature around 1500 K. At z = 35 cm, the temperature is 1000 K, independently of the relative hydrogen flow. At z = 35 cm the plasma is completely thermalized, so no dependence on the relative hydrogen flow is expected. Furthermore, a temperature of 1000 K is expected, since z = 35 cm is 2.5 cm in front of the substrate, and a temperature drop takes place from 1500 K in the plasma a few centimetres before the substrate to 600 K at the substrate.

The density of NH shows a maximum at a 80%/20% N_2/H_2 flow, which decreases with increasing distance from the nozzle (Figure 2), in contrast to the NH_3 density which shows a maximum at 30%/70% N_2/H_2 flow. In Figure 3, also the NH density at z = 10 cm is depicted for two different pressures, i.e. 20 and 90 Pa. For the condition, which shows the most NH_3 production in the background, also the pressure dependence of the NH density was measured (Figure 3). The maximum of the NH_2 density occurs at around 15%/85% N_2/H_2 flow. We note that the NH and NH_2 densities (both in the order of a few times 10^{17} m^{-3}) are only about 1% of the maximum ammonia density.

As already mentioned, the temperature of the NH_x (x=1,2) radicals indicates that the NH_x radicals are produced in the plasma expansion. From a comparison of the rate coefficients of neutral-neutral reactions and charge exchange (CE) reactions in the N_2-H_2 plasma expansion, we conclude that charge exchange reactions are dominant in the production of the NH_x radicals at low hydrogen flows. We note that under optimal conditions a significant amount of background gas in our vessel is ammonia, which can diffuse into the plasma beam. The NH_3 originates from surface reactions of plasma produced N and H radicals [6]. A possible reaction path for the formation of NH_x radicals is a CE reaction between ammonia and N^+ from the source. To underpin this idea, the formation of NH_x radicals was studied in Ar-NH_3 plasma expansions in which a CE reaction with Ar^+ is the most important source for NH_x formation [7]. With the outcome of this study, we can explain the NH_x trends we observed.

The charge exchange reaction of N+ with NH_3 produces mainly NH_3^+:

$$N^+ + NH_3 \rightarrow N + NH_3^+. \quad (1)$$

Subsequently, the ammonia ions recombine dissociatively with electrons leading to the formation of NH and NH_2:

$$NH_3^+ + e \rightarrow NH_2 + H \quad (2)$$
$$\rightarrow NH + pH_2 + (2\text{-}2p)H \ (p=0,1),$$

with a 50%-50% branching ratio.

At low hydrogen flows, the decrease of the NH density with increasing hydrogen flow rate can be explained by the decrease in N^+ flux emanating from the source with increasing hydrogen flow rate. The fact that the trend of the NH density as a function of the hydrogen flow rate is independent of the pressure (Figure 3) indicates that indeed N^+ is reacting with ammonia. The N^+ flow emanating from the arc is independent of the background pressure, and thus reaction (1) is the limiting step in the production of NH. However, at high hydrogen flows, the produced N^+ ions are immediately consumed due to reactions with H_2, thus no N^+ ions are left at z = 10 cm. Still, NH is observed at high hydrogen flows. This indicates that a second mechanism has to be taken into account, especially at high hydrogen flows. The mechanism responsible for NH at high hydrogen flows is the reaction between H and NH_3 leading to NH_2 and subsequently the reaction between H and NH_2 leading to NH. This is underlined by the behaviour of the NH_2 density. The NH_2 density has a maximum around 15%/85% N_2/H_2 flow. This is the regime in which no N^+ ions are available and NH_2 can only be formed by:

$$H + NH_3 \rightarrow NH_2 + H. \quad (3)$$

That NH and NH_2 are formed out of ammonia is illustrated in Fig. 4, in which the NH density is shown as a function of pressure (10-100 Pa). The pressure dependence can be explained by recognising that the ammonia density increases with increasing background pressure, leading to a higher NH density. However, when the pressure is even higher, the diffusion of ammonia into the plasma beam becomes more difficult, which counteracts the effect of a higher NH_3 density and leads to a decreasing trend in the NH density as a function of pressure.

4. Conclusions

We have shown that the NH and NH_2 radical densities in N_2-H_2 plasma are in the order of a few times 10^{17} m^{-3}. This is only about 1% of the maximum ammonia density. This indicates that NH and NH_2 play only a minor role in N_2-H_2 plasma in which ammonia is formed. From our results, we conclude that at low relative hydrogen flows the NH_x radicals are mainly formed by charge exchange reactions between N^+ and NH_3 with subsequently dissociatively recombination of NH_3^+ with electrons. At high relative hydrogen flows, the reactions between NH_x (x=2,3) and H lead to the production of NH and NH_2 radicals.

Abstract
Mass spectrometry studies on (Ar–)N_2–O_2 and Ar–NO plasmas revealed the tendency of the systems to produce the most thermodynamically favorable molecules in wall association processes. This means that in these plasmas mainly O_2 and N_2 are formed. Still, in plasmas containing mixtures of nitrogen and oxygen a significant amount of nitric oxide (NO) is formed, i.e. up to 4% of the O_2 and N_2 are converted in nitric oxide, as also measured by means of Tunable Diode Laser Absorption Spectroscopy (TDLAS).
Plasma-surface interactions, nitric oxide

1. Introduction

In applications in which plasma is used for chemical conversion, but also for surface treatment or deposition, newly formed stable molecules are often detected in the background gas. It has been acknowledged for quite some time that plasma-surface interactions play a key role in the production of these new stable molecules. To gain a better understanding of the plasma-surface interactions that take place during the formation of stable molecules, we have chosen to investigate the formation of molecules from atomic sources in more detail. We studied the molecule formation processes in plasma containing nitrogen and hydrogen, in which ammonia is formed in large amounts [1], and plasma containing nitrogen and oxygen, in which NO is formed. To better understand the dynamics leading to the production of NO, also the dissociation of NO has been investigated in Ar–NO plasma.

Here, the formation of molecules in plasmas containing nitrogen and oxygen will be discussed. These kind of plasmas are nowadays extensively studied, because of their relevance in various fields of research, e.g. understanding of atmospheric and ionospheric physics, in re-entry studies of orbital space vehicles [2] and as sources of active species for applications in plasma chemistry. Examples of the latter include such as air pollution cleaning by atmospheric pressure discharge treatment [3], sterilization [4], and surface treatment of materials, like etching [5]. From various studies, it was concluded that NO molecules are formed in these kind of plasmas [6]. Furthermore, the results showed that the densities of e.g. NO are strongly influenced by plasma-surface processes [7].

In this paper, we report on the study of the formation of molecules in recombining plasmas generated from mixtures containing N_2 and O_2 using the expanding thermal plasma (ETP) technique. A main advantage of the Expanding Thermal Plasma (ETP) technique is the fact that the plasma is a recombining plasma in which the energy is contained in the ions in the expansion; the electron temperature T_e is too low for electronic collisions to play a role in dissociation or excitation processes. Furthermore, due to the remote nature of the technique, the plasma production, plasma transport and plasma-surface interactions are separated, which allows independent studies of the different aspects of the process. This in contradiction to almost all previous studies on N_2-O_2 plasmas which were performed in non-equilibrium systems, which are driven by electron collisional excitation, and in which the knowledge of electron and ion densities and energy distributions, as well as of the density and internal state distributions of reactants and products, is necessary to generate a kinetic model explaining the plasma behavior. Moreover, the large number of processes that has to be taken into account leads to the development of complex kinetic models.

The density of the molecules generated, were determined with Tunable Diode Laser Absorption Spectroscopy (TDLAS) and mass spectrometry. We detected molecules like NO, N_2O, N_2 and O_2, formed in expanding plasmas generated from: (a) Ar plasma to which mixtures of N_2 and O_2 are admixed; (b) N_2 plasma to which O_2 is added in the background of the vessel. Our measurements revealed the tendency of the systems to

produce the most thermodynamically favorable molecules in wall association processes. This means that in these plasmas mainly O_2 and N_2 are formed. Still, in plasmas containing mixtures of nitrogen and oxygen a significant amount of nitric oxide (NO) is formed, i.e. 4% of the O_2 and N_2 are converted in nitric oxide. Moreover, in N_2–O_2 mixtures, the interaction of the plasma with a substrate leads to an orange glow around the substrate. Emission spectroscopy has revealed that the emission is ascribed to the formation of molecules in an excited state by association of N and/or O atoms at the substrate.

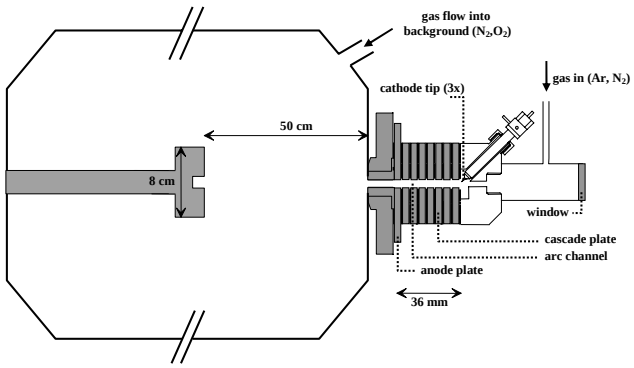

Figure 1: Sketch of the setup in which the thermal plasma expansions are created.

2. Experimental setup

The setup consists of a thermal plasma source in which a high-density argon or nitrogen plasma is created (Figure 1). This plasma expands supersonically into a low-pressure vessel. The pressure gradient between source and the process chamber (0.1-1 mbar) causes, after a supersonic expansion and a stationary shock, a subsonic expansion towards the substrate. Monomers, like oxygen and/or nitrogen are injected into the background. In this way the dissociation and ionization in the plasma source are geometrically separated from the plasma chemistry in the vessel. In this way, the plasma conditions can be controlled independently from the downstream plasma chemistry. Charge transfer reactions between plasma created ions (Ar^+, N^+) or radicals (N) and the monomers, and subsequent dissociative recombination reactions, lead to the production of atomic radicals. Most of the atomic radicals will arrive at the surface at which they will adsorb. At the surface new molecules can be generated which subsequently may desorb. Since the plasma is used to produce the radicals for the molecule production and the almost fully covered (metallic) wall is used as a catalyst, the process is called plasma-activated catalysis [8].

In typical experimental conditions, the cascaded arc source is operated on Ar flows of typically 50 sccs (standard cubic centimeters per second). In argon, a typically ionization degree of 10% is reached with an arc current of 45 A , equivalent to 10^{20} ions/s (and electrons) emanating from the source. The current of the arc can be set to 30-90 A and the voltage over the arc ranges from 100 to 300 V. We studied the formation of molecules like NO, N_2O, N_2 and O_2, in expanding plasmas generated from: (a) Ar plasma to which mixtures of N_2 and O_2 are admixed; (b) N_2 plasma to which O_2 is added in the background of the vessel.

The density of the molecules generated, like NO, N_2O, N_2 and O_2, were determined with Tunable Diode Laser Absorption Spectroscopy (TDLAS) and mass spectrometry. For the Tunable Diode Laser Absorption Spectroscopy (TDLAS) measurements, the so-called infrared multi-component acquisition (IRMA) system based on infrared absorption spectroscopy was used [9]. The IRMA system consists of four independent tunable diode lasers, which can be temporally multiplexed. Rapid scan software measures the mole fractions of several molecules simultaneously with millisecond time resolution. The setup was equipped with a quadrupole mass spectrometer (Balzers QMS 421C) on top of the reactor to analyze the stable species present in the background. The mass spectrometer was calibrated (absolute) by injecting a controlled NO mass flow rate into the N_2-O_2 flow while the plasma is off.

3. Results

Results of TDLAS measurements on NO, formed when an Ar plasma expands in the low-pressure vessel and mixtures of N_2 and O_2 (total flow of 1800 standard cubic centimeters per minute (sccm)) are injected in the background, are depicted in Figure 2. The plasma source is operated at 75 A and a flow of 3000 sccm Ar is applied. The NO mole fraction is defined as: $n[NO]/(n[O_2] + n[N_2])$ (closed symbols) and the efficiency of use of N_2 and O_2 as: $n[NO]/n[N_2]$ (cross) resp. $n[NO]/n[O_2]$ (open circle). In this way 100% means maximal conversion to nitric oxide of the nitrogen (cross) and oxygen molecules (open circle). The results show that a significant

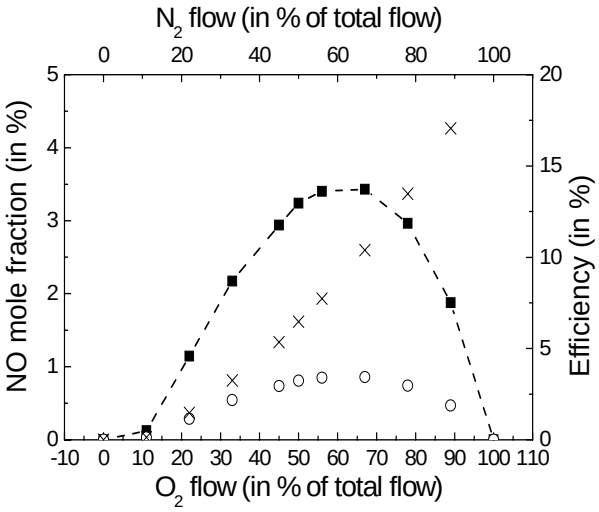

Figure 2: NO mole fraction produced in an Ar plasma expansion to which mixtures of N_2 and O_2 are added. The background pressure in the vessel was 20 Pa (see text for details).

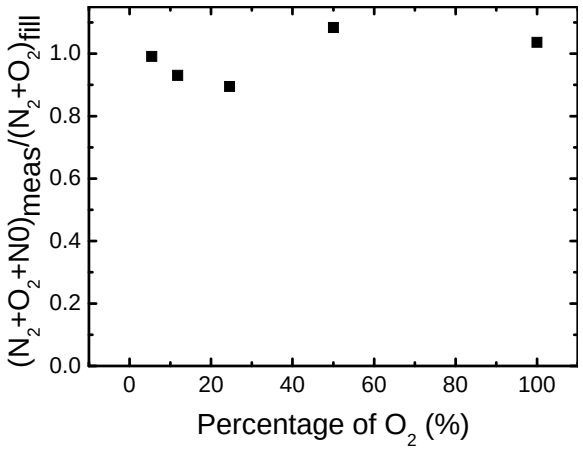

Figure 3: Ratio of the measured densities over the input gas densities for the three main molecules N_2, O_2 and NO.

amount of nitric oxide (NO) is formed, i.e. up to 4% of the O_2 and N_2 was converted in nitric oxide Under our conditions NO is mainly formed by wall association of N and O atoms to NO. The main loss mechanism of NO is:

$$N + NO \rightarrow N_2(X, \nu\sim3) + O. \quad (1)$$

This loss mechanism is responsible for the asymmetry in Figure 2, as it is more effective for higher nitrogen flows. The threshold observed for low oxygen flows is also attributed to this reaction, but also the following reaction could play a role:

$$N + NO_{ads} \rightarrow N_2O. \quad (2)$$

Mass spectrometry data measured under the same conditions show that the ratio of the measured densities over the input gas densities for the three main molecules N_2, O_2 and NO is around one (Figure 3). This indicates that atomic and molecular radicals present in the plasma are converted back into molecules. This is even stronger shown in the case NO is injected in the background, mass spectrometry measurements showed that when the Ar ion flow is larger than the NO flow, 90 % of the NO is converted to N_2 and O_2, which are thermodynamically more favorable than NO. This result clearly shows that the system has the tendency to produce the most thermodynamically favorable molecules in wall association processes. Under the same experimental conditions during which the data of Figure 2 were obtained, no nitrous oxide (N_2O) was detected by means of TDLAS.

Next N_2 plasmas with O_2 injected in the background were studied. In a nitrogen expanding plasma, N^+ and N are emitted by the cascaded arc source. The charge exchange reaction of N^+ with N_2 leads to N_2^+, which partially dissociatively recombines to N atoms. When oxygen is injected in the background, the O_2 undergoes charge exchange reactions with N^+ and N_2^+, which leads to O atoms.

In this case, when after NO measurements the O_2 flow was stopped, N_2O was observed with a time behavior as shown in Figure 4. The two time traces shown in Figure 4 are recorded after 1 minute (black line) and after 5 minutes (gray line) of N and O exposure of the vessel. After exposure times longer than 5 minutes, no change in the trend of the

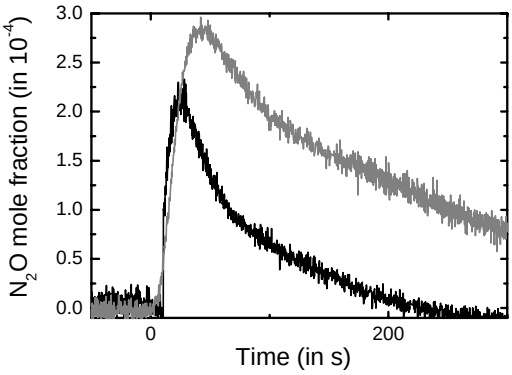

Figure 4: Time behavior of the N_2O mole fraction after switching off the O_2 flow (see text for details).

N_2O mole fraction is observed. Both time traces show a maximum of which the height depends on the time the vessel was exposed to N and O fluxes. Once the maximum is reached, it takes minutes before the density of N_2O is below the detection limit. Since the residence time of the gasses in the vessel is in the order of a second, N_2O is most probably produced in a surface association process of N radicals from the plasma and NO at the surface.

Furthermore, emission spectroscopy and imaging studies on the light emission of N_2–O_2 plasma revealed an intensification of the light around the substrate (Figure 5). The plasma brightness on the right side of Figure 5, (source side) decayed due to dissociative recombination of molecular ions and by mutual recombination of negative and positive ions.

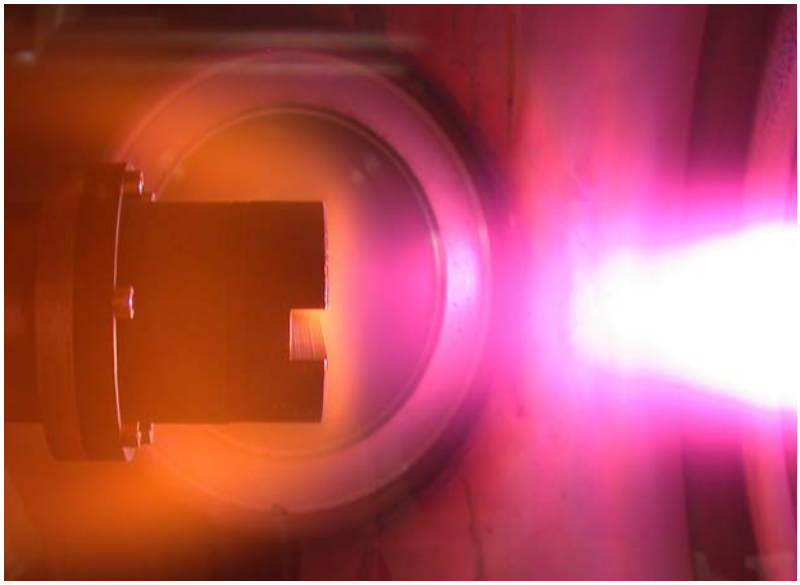

Figure 5: Enhanced emission around a substrate exposed to an N_2/O_2 plasma expansion.

A second clear result is the appearance of an orange glow at and around the substrate. The thickness of the light layer indicates a transition with a lower transition probability, which would be consistent with a broadband feature observed in spectral analysis of the emission. Under certain conditions this light has a remarkable resemblance with the emission observed during the reentry of space vehicles. This light is tentatively attributed to the formation of excited NO_2 in an association reaction of O radicals from the atmosphere and NO adsorbed at the surface of the space vehicle [10]:

$$O(^3P)_{atm} + NO_{ads} \rightarrow NO_2\{^2B_1\} \rightarrow NO_2\{^2A_1\} + h\nu \quad (3)$$

In our plasma vessel the substrate is exposed to high fluxes of oxygen and nitrogen atomic radicals. As shown before, NO can become adsorbed at the surface during N/O exposure, and thus a similar process as in the space vehicle experiments can lead to NO^*_2 emission. However, recombination of N and O atoms to a high vibrational excited B state of NO can also contribute to the radiation.

4. Conclusions

The densities of NO, N_2O, N_2 and O_2 were determined using Tunable Diode Laser Absorption Spectroscopy (TDLAS) and mass spectrometry in on the (Ar–)N_2–O_2 and Ar–NO plasmas. From our results, we conclude that the plasmas reveal the tendency of the systems to produce the most thermodynamically favorable molecules in wall association processes. This means that in these plasmas mainly O_2 and N_2 are formed. Still, in plasmas containing mixtures of nitrogen and oxygen a significant amount of nitric oxide (NO) is formed, i.e. 4% of the O_2 and N_2 are converted in nitric oxide.

This contribution deals with the etching of amorphous hydrogenated carbon films by thermal nitrogen atoms. The flow rate of nitrogen atoms which is a crucial parameter for any quantitative analysis of the etching process (i.e.for the determination of the erosion yield) is determined by means of Threshold Ionization Mass Spectroscopy (TIMS). The etch rate of the amorphous hydrogenated carbon films is determined by means of a multi-wavelength-ellipsometer which allows the measurement of film thickness and refractive index.

Introduction

Amorphous hydrocarbon films (a-C:H films) have found an increasing number of applications. They are used as protective coatings for optical devices, as wear or corrosion resistant coatings and for biomedical applications (coating of stents, hip and knee joints for example). Depending on the deposition conditions (as gas composition and ion energy) the properties of a-C:H-films can vary from soft polymer-like to hard diamond-like carbon (DLC) [1].

A newer development concerns the incorporation of nitrogen atoms in the carbon network. Stimulated by the work of Liu and Cohen [2] a lot of work has been done to produce and study the properties of such carbon nitride materials [3,4].

In this paper we investigate the interaction of (soft) a-C:H films with a flowing afterglow of a nitrogen plasma. The etching capability of N-atoms is studied for different substrate temperatures by means of ex-situ- ellipsometry. The flux of nitrogen atoms that is impinging on the film is determined quantitatively by means of modulated beam mass spectroscopy. The knowledge of etching rate and N-atom flux allows to determine the erosion yield of the nitrogen atoms. The diffusion of nitrogen atoms into the carbon network-during the etch process- is investigated by means of sputter-XPS-measurements.

Experimental set up

In this contribution we are using the flowing afterglow of a nitrogen discharge to study the etching of amorphous hydrocarbon films. Figure 1 shows a sketch of the experimental set up which consists mainly of two parts: the discharge, where the N-atoms are created, and a differentially pumped process chamber. The discharge is created in a quartz tube (inner diameter 10 mm) by a travelling surface wave at 2,45 GHz, which is excited by a Waveguide-Surfatron structure [5]. The total gas throughput does not exceed 500 sccm, resulting in an upstream pressure in the glass cylinder between 1 and 10 mbar. A 1500 liter/sec turbomolecular pump ensures a downstream pressure of about 10^{-3} mbar in the process chamber. The flow rate of nitrogen atoms which is a crucial parameter for any quantitative analysis of the etching process is determined by means of Threshold Ionization Mass Spectroscopy (TIMS). Losses of N atoms at the inner wall of the mass spectrometer are taken into account by a modulation technique (Modulated Beam Mass Spectroscopy MBMS [6]). The mass spectrometer (Hiden HAL PSM 300) can be moved axially and the substrate holder is mounted on an edge welded bellow which allows radial translation with respect to the axis of the tube. The latter is provided with a Nickel Chromium 80/20 heating wire (Thermocoax 1Nc type) pressed between two copper plates in order to ensure a reasonable heat transfer to the sample.

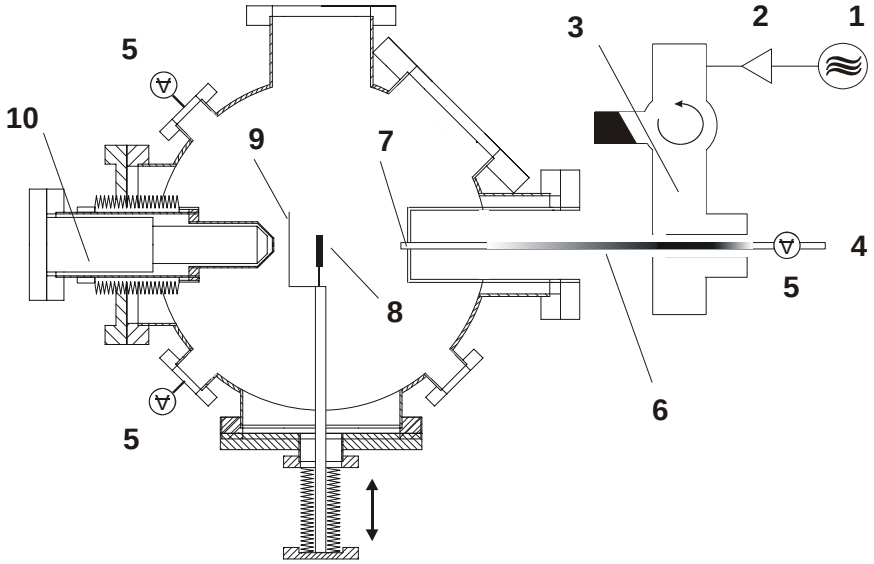

Figure 1 : Experimental arrangement: 1. Microwave Generator, 2. Klystron and Pre-amplifier (+70 dB), 3. Waveguide-Surfatron, 4. Gas inlet, 5. Baratron. 6.Quartz tube (d_{in}=10 mm, d_{out} = 12 mm), 7. Post-discharge 8. Temperature-controlled substrate holder, 9. steel plate, 10. Mass Spectrometer.

The sample which is to be treated (a-C:H films deposited on a Si-substrate, dimensions : 20 mm x 25 mm) by the N radicals is placed on the substrate holder. Both the temperature of the substrate and of the substrate holder are measured by a thermocouple, ensuring good thermal transfer from the sample to the thermocouple. The samples can be heated to a temperature of 600° C. The proximity of the mass spectrometer makes it necessary to enclose the substrate holder with steel plates for thermal shielding.

Experimental results

The thickness d and the refractive index n of the films are measured by ex-situ- ellipsometry before ($d_{initial}$) and after (d_{final}) the treatment in the remote plasma. The deposited films are polymer-like films, with an averaged refractive index of about 1,7 in the spectral range 300-800 nm and are typically 100 nm thick. At temperatures above 300°C (which was measured directly at the surface of the films), they become thermally unstable. At 350 °C, significant thermal desorption of the films occurs under the absence of atmosphere, leading to a diminution of the film thickness with a rate of 0,1 nm/min. After an exposure time Δt to the remote N_2 plasma, the etch rate is determined from the measurement of the thickness d_{final} of the treated film .

$$R = \frac{d_{initial} - d_{final}}{\Delta t} \qquad (1)$$

The thermal activation of the etch reaction was studied by controlling the temperature of the substrate The results are shown on figure 2. The exposure time of the films to the remote plasma was varied between 1 hour at 300°C and 5 hours at 130°C. As can be seen, the etch rate depends strongly on the substrate temperature and varies between 0,14 ± 0,03 nm/min. at 130°C and 1,04 ± 0,25 nm/min. at 300°C. The N flux was approximately 5.10^{16} cm^{-2}/s in all cases.

The etch rate R can be described by an Arrhenius behaviour :

$$R = R_0 \exp\left(-\frac{E}{k_B T}\right) \quad (2)$$

where the pre-factor R_0 depends on the N atom flux, k_B is the Boltzmann constant and T is the substrate temperature. The activation energy E of the etching reaction is deduced from the best fit of equation (2). The value is E = 0,25 ± 0,06 eV.

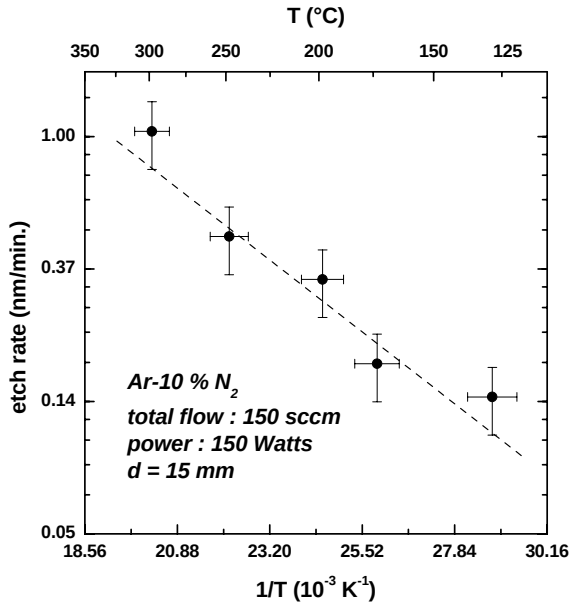

Figure 2 : Arrhenius plot of the temperature dependent etch rate.

Since the C atom density in the film is known from previous Rutherford Backscattering measurements [7], (revealing [C] = 4.10^{22} cm^{-3}) the above etch rates and atomic nitrogen fluxes allow to determine quantitatively an erosion yield (defined as the yield of C atoms removed per impinging N atom). The obtained values are varying between $1{,}9.10^{-4}$ C/N^0 at 130°C and $1{,}4.10^{-3}$ C/N^0 at 300°C. These values are similar to those reported in [8] for carbon erosion by thermal hydrogen atoms on graphite (about 10^{-3} to $5.\ 10^{-3}$ C/H^0).

The nitrogen content of the films is determined by means of Sputter X-ray photoelectron spectroscopy. For the typical kinetic energy of the ejected electrons, the escape depth is about 2 nm in the present case. The films are sputtered by an energetic Ar^+ beam (1 keV). When the film has been sputtered away, the Si substrate is exposed to X-ray radiation, and the spectrum exhibits two signatures at 99 and 151 eV, typical for Si. Thus, given the initial film thickness and the sputtering time, the sputter rate was approximately 2 nm/min. With this method, the depth profile of the relative concentration of the constituents in the films was obtained.

The results show that the surface nitrogen content represents up to 15 % of the carbon content. After 30 sec. sputtering, the N(1s) peak is observed at 398,5 eV, the standard value of N in carbon networks, leading to [N[/[C] = 5 %. Even after 10 minutes of sputtering N atoms are present in the film with a relative concentration of about [N[/[C] = 1 %.Thus, under the experimental conditions (60 min. exposure time, J_N = 5.10^{17} cm^{-2}/s, $T_{substrate}$ = 250°C), the N atoms are diffusing into the carbon network. The presence of N atoms in the film results from a competition between etching and diffusion processes, making it difficult to achieve high values of the [N]/[C] ratio in the bulk of the film

Abstract
When dealing with thin film deposition, contamination of the material is an important parameter. In this paper, we present results concerning contamination of the deposited material in an RF-IPVD reactor by the internal coil. We have worked in argon and the sputtered material was titanium. The film contamination is explained by comparing the flux of deposited titanium to the flux of titanium sputtered by argon and titanium ions on the RF coil.
Keywords: IPVD, radio-frequency, contamination, thin film deposition

1. Introduction

Ionised Physical Vapour Deposition (IPVD) has been developed since the 1990s to obtain deposited film coatings that are more conformal and of better quality than those obtained with conventional sputtering technique [1]. The main goal of IPVD is to ionize a significant fraction of the neutral species sputtered from the magnetron target. The ionized sputtered particles can then be collimated by applying an electric bias on the substrate. IPVD reactors consist of a magnetron discharge assisted by an additional plasma source which ionises the sputtered vapour flowing from the magnetron. Reactors using helicon [2] or ECR coupled discharge [3] have already been studied but most of the IPVD reactors use radio-frequency coils to create the additional ionisation [4].

One of the main constraints when working with the deposition of materials, is the control of the purity of the deposited layer. The goal of this work is to point out the problem of contamination by the internal coil in an RF-IPVD reactor and to propose an explanation of the phenomenon.

2. Experimental set-up

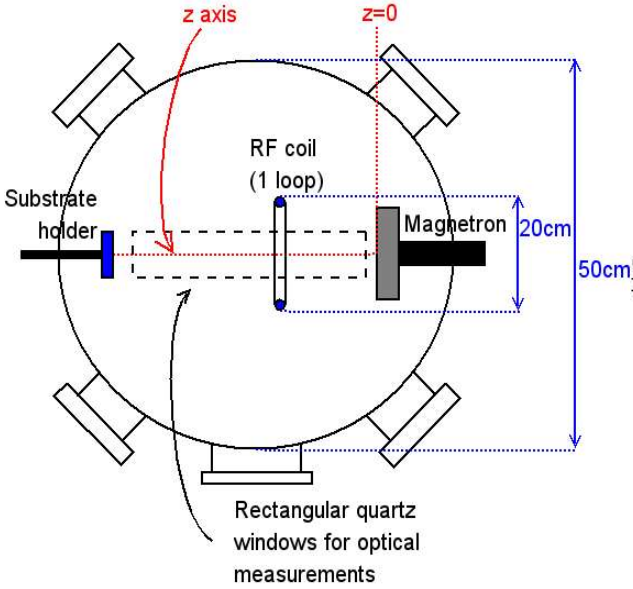

Fig. 1: Diagram of the RF assisted magnetron reactor

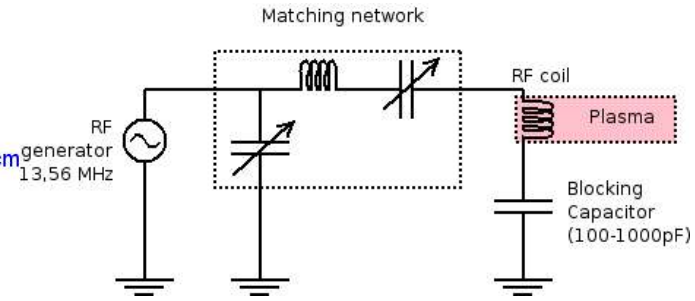

Fig. 2: Electric connection of the coil

The reactor is presented on Figure 1. It is a 50 cm diameter and 45 cm height cylinder, and contains a 10 cm diameter planar circular magnetron cathode. The “z axis” is the magnetron-substrate holder axis. The “z=0” position corresponds to the target surface. Buffer gas is argon and the materials of the target is titanium. The

distance between the titanium target and the substrate-holder is z=14 cm. The quartz windows on top and bottom of the reactor allow spatially resolved optical measurements.

The magnetron cathode is powered by a DC 500V-3A generator. The reactor is flexible enough to allow the use of different RF coils, with 1 or 3 loops, with different coupling to the ground (either grounded or capacitively coupled). The coils are supplied with a 13.56 MHz - 1600W radio-frequency generator. In the present study, we used a 1-loop coil capacitively coupled to the ground. The electric set-up used in this case is presented on Figure 2.

An RF compensated Langmuir probe (manufactured by Scientific Systems) was used to determine the plasma potential, the electron density and the electron temperature. The probe was inserted in place of the substrate holder and it was possible to translate it along the z-axis to make spatially resolved probe measurements.

Various optical diagnostics are possible with this experiment. Spatially resolved optical emission spectroscopy was performed using a collimator, taking light through the bottom quartz window. The emitted light was collected by an optical fibre and analysed through a photomultiplier tube by a Jobin-Yvon HR1000 spectrometer (1200 grooves.mm^{-1} grating, 1000mm focal length). Spatially resolved absorption measurements were carried out using a titanium hollow cathode lamp. The light emitted by the lamp entered the reactor through the top quartz window and the absorption signal was collected through the bottom quartz window. This lamp worked in pulsed regime (100µs duration, 100Hz frequency) using a generator developed in our laboratory. In pulsed regime, the absorption signal is clearly separated from the plasma emission and the enhancement of the ionic line emission in the pulse allows the determination of Ti^+ densities by absorption. The complete method and algorithm used for the determination of densities are described in [6].

Rutherford Backscattering Spectroscopy (RBS) was used to determine the composition of our thin films.

3. Contamination by the RF coil

One problem with the RF-IPVD method when the coil is grounded is the high value of the plasma potential. In our case, in standard deposition conditions (2A magnetron and 450W_{RF}), the plasma potential was measured to be 130V. In these conditions, the potential difference between the plasma and the grounded chamber walls is high enough to allow sputtering of the material deposited on the walls.

A solution to this problem is to use a capacitor to modify the coupling between the coil and the ground [5]. This method gives a much lower plasma potential: in the same conditions as before, we measured a plasma potential of 20V. We therefore have no more sputtering of the walls. However, even if the plasma potential has been lowered, the coil potential still remains high with a mean value of -130V for 450W_{RF}. The phenomenon of sputtering can now happen on the coil.

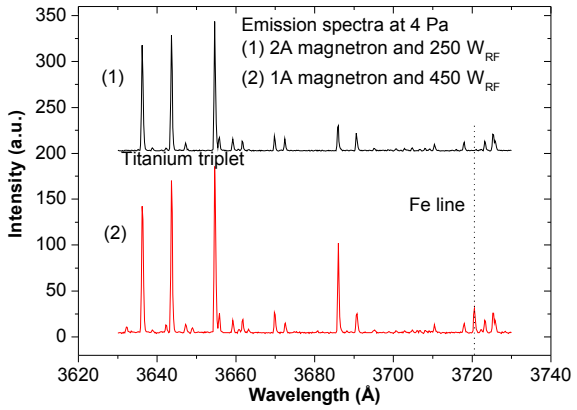

Fig. 3: Emission measurements in the plasma

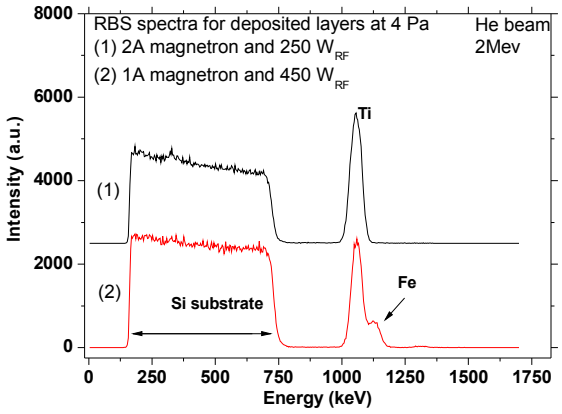

Fig. 4: RBS measurements on a deposited layer

We present, on Figure 3, results obtained by optical emission spectroscopy in two different conditions

of deposition. In the first condition, the Fe emission line was not visible. But when increasing the RF power while decreasing the magnetron current, this emission line became visible. Same observations can be made with surface analysis.

We present, on Figure 4, results obtained by RBS measurements on two deposited layers in the two previous conditions. With 2A on the magnetron and 250W on the RF coil, the RBS spectrum shows only a large band corresponding to the silicon substrate and a single peak corresponding to the Ti deposited thin film. On the other hand, with 1A on the magnetron and 450W on the RF coil, a third peak, indicating the presence of iron in the film, is visible. What does it mean?

In the first case, the lack of iron in the layer means that the flux of titanium depositing on the coil is higher than the flux of material leaving the coil (either titanium or iron), there is enough titanium deposited on the coil to mask the stainless steel of the coil. In the second case, the magnetron current is lower, inducing a lower flux of titanium toward the coil, while the RF power is higher, inducing more sputtering and a higher flux of species leaving the coil, the titanium layer deposited on the coil is progressively removed and the stainless steel can be sputtered.

4. Calculation of the fluxes and correlation with contamination

In order to confirm these assumptions, we have to precisely determine the fluxes reaching and leaving the coil. We suppose an isotropic direction distribution for titanium species around the coil. The absolute densities of Ti species were measured using optical absorption spectroscopy. The magnetron was used without RF power on the coil prior to every absorption measurement in order to avoid the sputtering of the material of the loop. The procedure described in [6] allows to determine a titanium temperature by assuming that the three fundamental sublevels of titanium are in equilibrium. With the RF additional ionization, we found that this assumption was clearly not possible because of a too high electron density, so we had to use another way to measure the titanium temperature. Laser absorption measurements were performed on Ti (λ = 8435,68 Å) metastable and a titanium temperature was deduced using Doppler broadening. The experimental set-up used for the laser measurements is presented on Figure 5. We used a dual passage in order to have a high enough signal, the Fabry-Pérot was used to have a frequency reference.

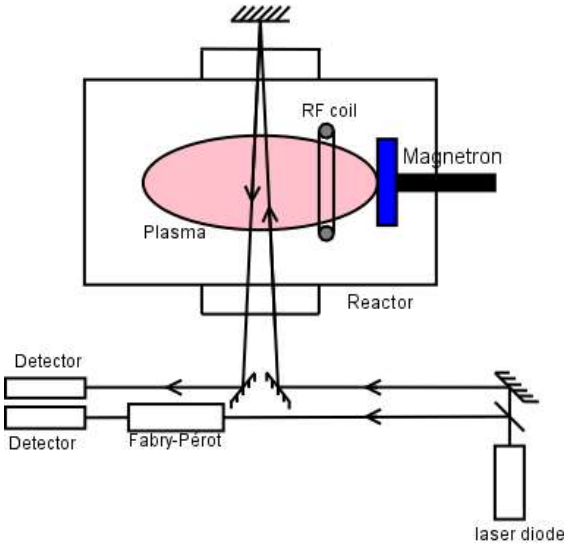

Fig. 6: Diagram of the laser measurement set-up

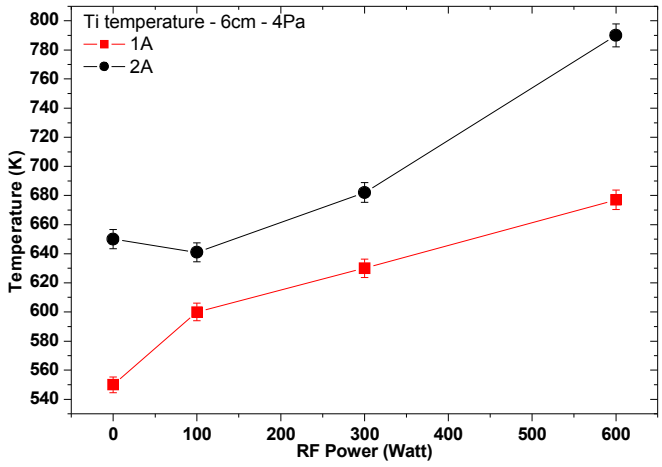

Fig. 5: Temperature determined by laser absorption versus RF power near the RF coil

We present results obtained with this laser measurements on Figure 6 for both 1A and 2A magnetron. We see that the increase of the RF power leads to an increase of the titanium temperature. Combining these temperatures and optical absorption results, we can calculate the absolute densities of species. These densities are reported on Figure 7 and show a decrease of the total titanium density with an increasing RF power. This decrease in density is due to a combination of a decrease of the sputtering yield (coupling between the RF and

the magnetron plasma) and the increase of the temperature (rarefaction of titanium) [8].

We now have all measurements needed to calculate the fluxes. We first consider the flux of atoms depositing on the coil. For neutral titanium atoms depositing on the coil, we consider that their velocity is the mean thermal velocity. Concerning the titanium ions, we consider that they are accelerated in the pre-sheath and reach the Bohm velocity when entering the sheath. Since the flux of species entering the pre-sheath and the flux of species arriving on the coil are equal, the flux of deposited titanium can then be calculated with:

$$\Phi_d = \frac{[Ti]+[Ti^m]}{4}\sqrt{\frac{8\,kT_{Ti}}{\pi\, m_{Ti}}} + [Ti^+]\,e^{-1/2}\sqrt{\frac{kT_e}{m_{Ti}}}$$

where [Ti] is the titanium neutral ground state density, [Ti^m] is the titanium neutral metastable state density and [Ti^+] is the titanium ion density.

Second, we consider the sputtering of the coil. Argon and titanium ions must be taken into account for the sputtering. The titanium ion density is given by absorption spectroscopy, and we consider the argon ion density to be equal to the electron density minus the titanium ion density. The final parameter needed to calculate the flux of species leaving the coil is the sputtering yield. This parameter is calculated using the formula given in [7]. The flux of titanium sputtered from the coil can now be calculated using:

$$\Phi_s = Y_{s,Ti^+}[Ti^+]\,e^{-1/2}\sqrt{\frac{kT_e}{m_{Ti}}} + Y_{s,Ar^+}[Ar^+]\,e^{-1/2}\sqrt{\frac{kT_e}{m_{Ar}}}$$

The parameters needed for the flux calculation are reported in table 1.

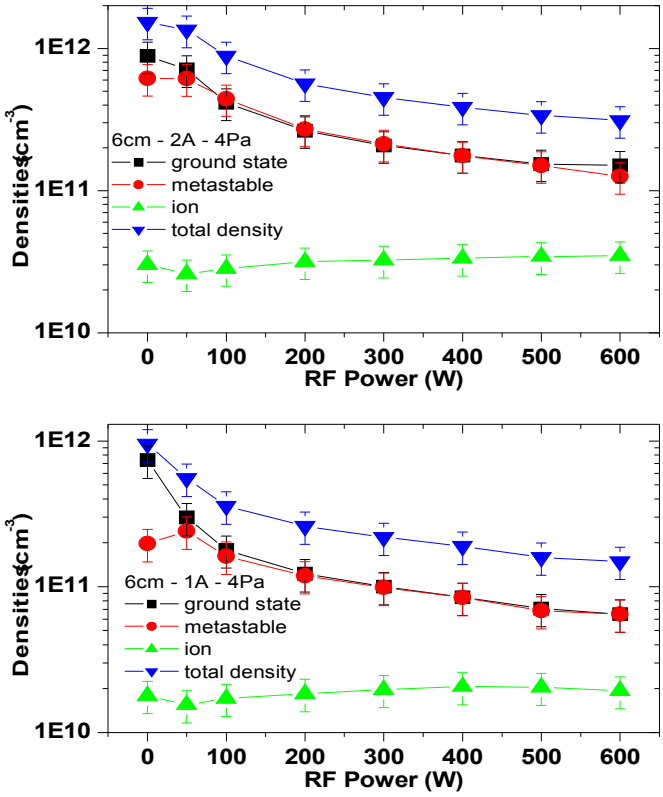

Fig. 7: Densities (titanium ground state, metastable state and ions) evolution versus RF power near the RF coil

With 2A magnetron and 250 W of RF power, the total flux of deposited species is: Φ_d=9,4.10^{22} $cm^{-2}.s^{-1}$ while the total flux of ejected species is Φ_s=1,1.10^{23} $cm^{-2}.s^{-1}$. On the other hand, the same calculation in the case

of an applied magnetron current of 1A and an applied RF power of 450W gives: $\Phi_d=5{,}8.10^{22}$ $cm^{-2}.s^{-1}$ and $\Phi_s=3{,}1.10^{23}$ $cm^{-2}.s^{-1}$.

We clearly see that in the case of a high RF power and a low magnetron current, the flux of species leaving the coil is five times higher than the flux of species deposited on the coil. This result corresponds to the RBS analysis of the deposited layer showing contamination of the film (see Figure 4). On the other hand, in the case of a low RF power and a high magnetron current, the fluxes are similar and iron should not be seen in the deposited layer. This is consistent with the RBS results.

	1A - 450W	2A - 250W
n_e	$5{,}6.10^{11}$ cm^{-3}	$2{,}8.10^{11}$ cm^{-3}
T_e	1,7 eV	1,66 eV
T_{Ti}	653 K	622 K
$[Ti^n]+[Ti^m]$	$2{,}2\pm0{,}6.10^{11}$ cm^{-3}	$4{,}8\pm1{,}2.10^{11}$ cm^{-3}
$[Ti^+]$	$2{,}1\pm0{,}5.10^{10}$ cm^{-3}	$3{,}2\pm0{,}8.10^{10}$ cm^{-3}
$[Ar^+]$	$5{,}4.10^{11}$ cm^{-3}	$2{,}5.10^{11}$ cm^{-3}
V_p	15,4 V	15,3 V
V_{RF}	-161 V	-141 V
$Y_{s,Ti+}$	0,16	0,13
$Y_{s,Ar+}$	0,18	0,15
Φ_d	$5{,}8\pm1{,}5.10^{22}$ $cm^{-2}.s^{-1}$	$9{,}4.10^{22}\pm2{,}4$ $cm^{-2}.s^{-1}$
Φ_s	$3{,}1\pm0{,}8.10^{23}$ $cm^{-2}.s^{-1}$	$1{,}1.10^{23}\pm0{,}3$ $cm^{-2}.s^{-1}$

Table 1: Parameters used for flux calculation

5. Conclusion

Purity of the deposited layers is a parameter of great importance when dealing with material deposition. We have found with layer analysis that this contamination is occurring when the power applied on the radio-frequency coil is rather high while the magnetron power is quite low. In order to quantify this “high” and “low” powers, we determined the flux of species deposited on the coil and the flux of species sputtered from the coil. This calculation has required different experimental studies (Langmuir probe, optical absorption spectroscopy and laser absorption) to measure all the parameters needed. We showed that the contamination can be explained by the comparison of the two fluxes: if the flux of sputtered species is higher than the flux of depositing species, then contamination occurs. At the studied pressure of 4 Pa, the isotropic distribution assumption seems correct.

Further work will consist in other deposited layers analysis at different pressures to check the validity range of the methods presented in this paper especially concerning the isotropic assumption at lower pressure.

6. Acknowledgements

The authors would like to thank N. Sadeghi for his decisive help for the laser absorption measurements and the interpretations of the results.

Abstract:

In this paper, nanopowders of perovskite cathode materials ($La_{0.8}Sr_{0.2}MnO_{3-\delta}$, $La_{0.8}Sr_{0.2}FeO_{3-\delta}$ and $La_{0.8}Sr_{0.2}CoO_{3-\delta}$), for use in solid oxide fuel cells (SOFCs), were successfully synthesized using induction plasma techniques. Their compositions, structures, morphology, particle size distributions, and BET specific surface areas were determined for comparison with their counterparts which were prepared by the Pechini method and by the glycine-nitrate combustion (GNC) technique. The particle sizes of the plasma-synthesized powders are mostly around 63 nm. These plasma-synthesized powders are generally globular, their BET specific surface areas being about 26 m^2/g, approximately twice those of powders prepared by the glycine-nitrate combustion and Pechini methods. These plasma-synthesized powders are readily reproducible. Their individual particle sizes and distributions are independent of their composition.

Keywords

Induction plasma synthesis, nanoparticles, ceramic powders, SOFC, perovskite cathode materials

1. Introduction

Recently, nanotechnology has become one of the most important and exciting fields in the forefront of many sciences and technologies. It is widely felt that nanotechnology will be at the “leading edge” of the next industrial revolution [1]. Ceramic nanopowders demonstrate improved or unique characteristics in comparison with conventional ceramic materials. The method of synthesis for nanoscale particles has received considerable attention because of the potential for the fabrication of new materials possessing unique properties. These novel properties and the numerous applications for nanophase materials, especially with respect to ceramic nanopowders, have attracted many scientists and engineers to invent and explore the applications of the now many ceramic nanoparticle preparation methods. Plasma synthesis is one of them.

Being based on oxide-ion conducting electrolytes, solid oxide fuel cells (SOFCs) offer a clean and low-pollution level technology to electrochemically generate electricity at high efficiencies, and are thus very promising energy conversion systems. The fabrication of SOFC components and cells have, to the present, been conducted through a series of sintering processes that are both time consuming and costly. To solve these problems, many efforts are being made to develop a number of new techniques. Among them, as an effective and relatively inexpensive process (no intermediate sintering process or post-treatment, and easy scale-up to mass production) for fabrication of porous and dense thin metal oxides films, thermal plasma technology is a promising and innovative technology, capable of being applied to the development of novel SOFCs [2].

In this paper, nanopowders of SOFC cathode materials ($La_{0.8}Sr_{0.2}MnO_{3-\delta}$, $La_{0.8}Sr_{0.2}FeO_{3-\delta}$ and $La_{0.8}Sr_{0.2}CoO_{3-\delta}$) synthesized by induction plasma technique is described. For comparison purposes, their structure, morphology, and particle size distributions were determined and compared with their counterparts, as prepared by the previously mentioned Pechini [3] or glycine-nitrate combustion (GNC) techniques [4-6].

2. Experimental

2.1. Powder synthesis methods of various cathode materials

2.1.1. Induction plasma technique

Powders of the perovskites $La_{0.8}Sr_{0.2}MnO_{3-\delta}$, $La_{0.8}Sr_{0.2}FeO_{3-\delta}$ and $La_{0.8}Sr_{0.2}CoO_{3-\delta}$, were synthesized by the induction plasma technique from corresponding metal nitrate solutions.
The stoichiometric ratio metal nitrates of $La_{0.8}Sr_{0.2}MO_{3-\delta}$ (M= Mn, Fe or Co) were dissolved to obtain a concentration of 1.1 M solution. Glycine was added to the solution at a concentration of 1.45 M.

The induction plasma synthesis technique was used for production of the $La_{0.8}Sr_{0.2}MnO_3$, $La_{0.8}Sr_{0.2}CoO_3$ and $La_{0.8}Sr_{0.2}FeO_3$ powders. Figure 1 shows a scheme of the induction plasma system. The atomization probe was used to inject the atomization gas (Ar) and the nitrate metal solution. In this system, the plasma was generated by means of a copper induction coil included in the torch body, as shown in Figure 2. The plasma torch was a TEKNA PL50 unit, the coil of which was connected to a LEPEL HF power generator. The plasma jet was formed inside the torch by ionization of input Ar and O_2. Argon, as the central gas and oxygen, as the sheath gas are supplied via the upper part of the torch body and they are initially separated by a concentric quartz tube.
The induction plasma synthesis was performed under conditions of low pressure (75 Torr), input power of 35 kW, and an argon flow rate of 20 l/min as the central gas. In addition, there was a 90 l/min flow rate of oxygen as the sheath gas and 35 l/min of argon as the probe gas. Metal nitrate solution was pumped into the torch at a rate of 15 ml/min. At the end of a synthesis run, the plasma was shut down and the generated powders were recovered from the surfaces of the double walled reactor and the heat exchanger.

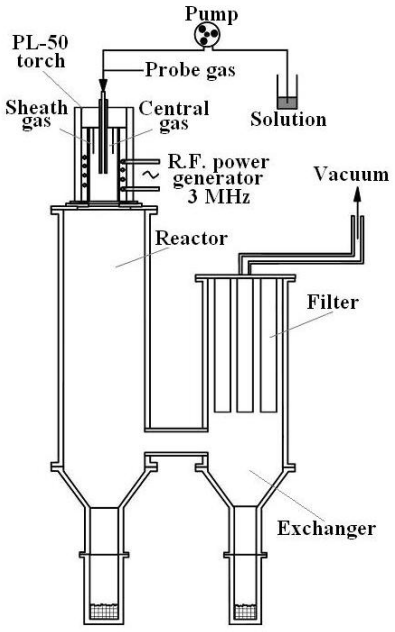

Figure 1: Schematic of nanopowder plasma synthesis system

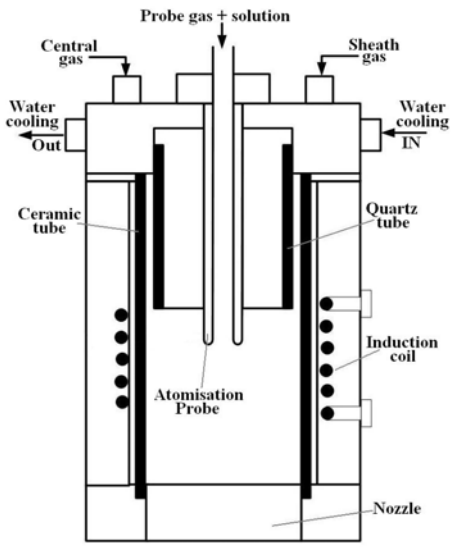

Figure 2: Schematic details of the plasma torch and the atomization probe

2.1.2. Pechini and glycine-nitrate combustion methods

In order to compare the structure, morphology and particle size distribution of plasma-synthesized cathode materials, the Pechini and glycine-nitrate combustion methods have been used to prepare the counterparts of the cathode powders.

A glycine-nitrate combustion technique [4-6] was employed for synthesis of the $La_{0.8}Sr_{0.2}FeO_{3-\delta}$ and $La_{0.9}Sr_{0.1}MnO_{3-\delta}$ powders. The desired molar ratio of La, Sr, Mn or Fe nitrates (as the nitrate salts) were dissolved in water to provide one mole of the final perovskite. 2 moles of glycine were added to this mixture as a chelating agent and aid combustion. Water was subsequently evaporated from the resulting solution using a hot plate maintained at 95 °C until the 'onset of combustion' was achieved. Powders so synthesized were subsequently calcinated at 800ºC for 4 hours.

The Pechini method [7] was employed for the synthesis of the $La_{0.9}Sr_{0.1}MnO_{3-\delta}$ and $La_{0.9}Sr_{0.1}Mn_{0.7}Fe_{0.3}O_{3-\delta}$ powders. Nitrate salts of La, Sr, Fe and/or Mn were dissolved in water in the required molar ratios, equimolar amounts of ethylene glycol and citric acid were then added to the metal ion solutions. These were then heated at 80 ^{o}C to 100 °C for 2 to 3 hours to induce polymerization. After this step, the residue was "charred" at 300 °C for 2 hours and calcinated at 800 °C for 4 hours.

3. Results and discussion

3.1. Morphologies of the synthesized powders

Figure 3 shows high resolution SEM micrographs of powders ($La_{0.8}Sr_{0.2}MnO_{3-\delta}$,) synthesized by the plasma process. All particles shown in this micrograph are close to being globular in shape. Figure 4 is a SEM micrograph of $La_{0.8}Sr_{0.2}FeO_{3-\delta}$ powders, as formed by the glycine-nitrate combustion technique, in which the powder's skeletal structure is illustrated. These powders are very porous, due to the nature of the combustion process. The powders, as formed by the Pechini method also have a porous structure.

Figure 3: SEM micrographs of the plasma synthesized powders: ($La_{0.8}Sr_{0.2}MnO_{3-\delta}$)

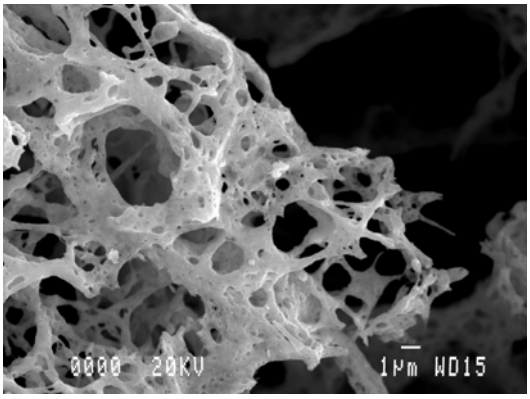

Figure 4: SEM micrographs of powders synthesized by glycine-nitrate combustion technique ($La_{0.8}Sr_{0.2}FeO_{3-\delta}$)

3.2. Particle size distributions and specific surface areas

Figure 5 shows a typical particle sizes distribution of the plasma-synthesized powders. The distribution of particle sizes is independent of their composition. Most of the particles of these plasma-synthesized powders have sizes of 63 nm in average. The distribution of particle size of chemically synthesized powders is shown in Figure 6. The particle sizes of the chemically synthesized powders are bigger than the plasma-synthesized powders (120 nm).

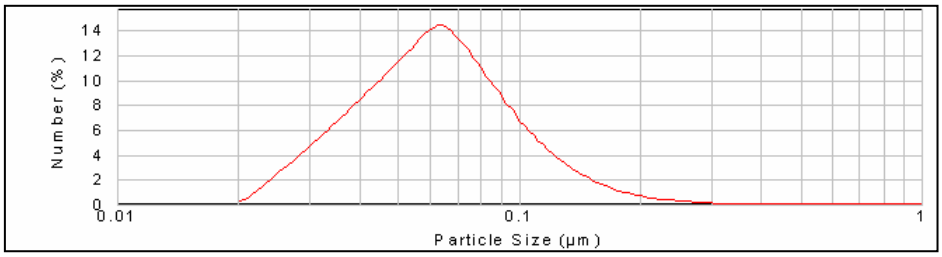

Figure 5: Distribution of particle size of powders formed by plasma synthesis

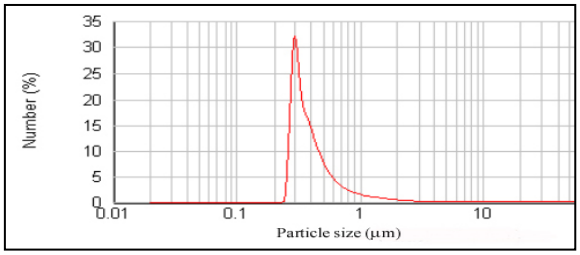

Figure 6: Distribution of particle size of powders formed by glycine-nitrate combustion technique

Table 2 lists the BET specific surface areas of some cathode powders, as synthesized by the three methods. BET specific surface areas of plasma synthesized $La_{0.8}Sr_{0.2}MnO_{3-\delta}$, $La_{0.8}Sr_{0.2}FeO_{3-\delta}$ and $La_{0.8}Sr_{0.2}CoO_{3-\delta}$ nanopowders are the same, about 26 m^2/g. This is approx. twice that of $La_{0.8}Sr_{0.2}FeO_{3-\delta}$ powders, prepared by the glycine-nitrate combustion method and $La_{0.9}Sr_{0.1}MnO_{3-\delta}$ powders, synthesized by the Pechini method. As a result, plasma-synthesized powders have the smallest particle size and the largest BET specific surface area values found in this paper.

Table 2. BET specific surface areas for some cathode powders.

Synthesis methods	Compositions	BET specific surface area (m^2/g)
Plasma synthesis	$La_{0.8}Sr_{0.2}MnO_{3-\delta}$	27
	$La_{0.8}Sr_{0.2}FeO_{3-\delta}$	25
	$La_{0.8}Sr_{0.2}CoO_{3-\delta}$	26
Glycine-nitrate combustion	$La_{0.8}Sr_{0.2}FeO_{3-\delta}$	14
Pechini method	$La_{0.9}Sr_{0.1}MnO_{3-\delta}$	13

3.3. Structures of the synthesized powders

Figure 7 shows a typical X-ray diffraction pattern of ceramic powders formed by plasma synthesis or chemical synthesis technique. All peaks in this figure are labeled by the Miller index of the perovskite The X-ray diffraction patterns of the synthesized perovskite powders have been compared to standards and the crystal systems obtained are orthorhombic for $La_{0.8}Sr_{0.2}FeO_3$, monoclinic for $La_{0.8}Sr_{0.2}MnO_{3-\delta}$, and rhombohedric for $La_{0.8}Sr_{0.2}CoO_{3-x}$ and $La_{0.9}Sr_{0.1}MnO_3$. However, plasma-synthesized $La_{0.8}Sr_{0.2}CoO_{3-\delta}$ powders are a pure perovskite phase, indicating that it is possible to directly synthesize pure perovskite cathode composition materials, as nanosized particles by the induction plasma synthesis technique. Both GNC and Pechini methods can also produce perovskite cathode materials without significant content of impurities.

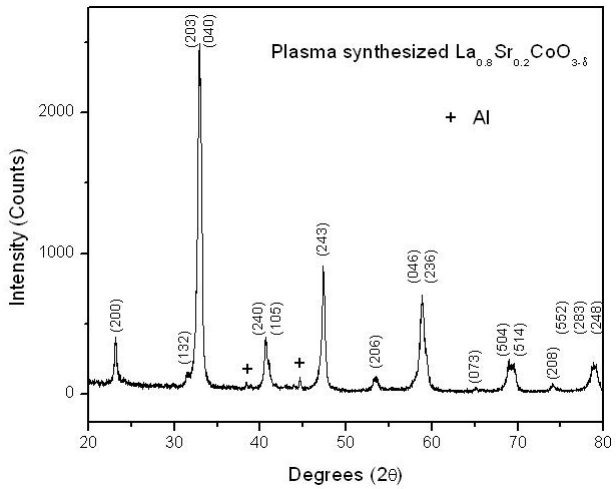

Figure 7: Typical X-ray diffraction patterns of plasma and chemically synthesized powders ($La_{0.8}Sr_{0.2}CoO_{3-\delta}$)

4. Conclusions

Through the use of three different synthesis methods (induction plasma technique, Pechini method, and Glycine-nitrate combustion technique), the nanopowders of target SOFC perovskite cathode materials ($La_{0.8}Sr_{0.2}MnO_{3-\delta}$**,** $La_{0.8}Sr_{0.2}FeO_{3-\delta}$ and $La_{0.8}Sr_{0.2}CoO_{3-\delta}$) were successfully produced with accurate stoichiometry. Most particles of the plasma-synthesized powders are around 63 nm in size. The plasma-synthesized powders are almost globular in shape and their BET specific surface areas are about 26 m^2/g, i.e. about 2 twice that of powders prepared by the glycine-nitrate combustion and Pechini methods. The plasma-synthesized powders are fully reproducible in composition and sizing and are not agglomerated. Particle size and size distribution are independent of particle composition. The next step in this project will be the combination synthesis and the spray projection of these powders onto an electrolyte substrate to form a good electronic and ionic conducting interface between the electrolyte and the cathode. The plasma projection of ceramic nanopowders is a time efficient process. The most immediate practical application lies in the fabrication of SOFC fuel cells, to be performed by the plasma spray projection technique.

Non-Catalytic Direct Amination of Carbon Double Bond Using Atmospheric Non-Thermal Plasma

H.Ito, Y.Suga and H.Sekiguchi
Department of Chemical Engineering, Tokyo Institute of Technology, Tokyo, Japan

Abstract

This study investigated the non-catalytic amination of 1-decene using atmospheric pressure glow discharge (APGD). The reaction was carried out by exposing ammonia plasma jet to the substrate of 1-decene. The experimental results indicated that the productions of 1-decylamine and 2-decylamine were identified. This study suggested the APGD was attractive for the amination of organic compounds having carbon double bond under atmospheric pressure without catalysts.

Key words,

Atmospheric non-thermal plasma, Amination, Ammonia, 1-decene

1. Introduction

Plasma has been widely used in processing technique such as welding, etching, thin film formation as well as in the field of energy and environment issues. However, in chemical synthesis, most of them have not been put into practical use except ozone synthesis which has been done for a long time. One of the reasons is that consecutive reactions take place because the products formed in the plasma are also activated by the plasma, resulting in low selectivities of the products.

The development of atmospheric pressure glow discharge (APGD) in recent years has made it possible to generate plasma including electron, ion and radical at room temperature under atmospheric pressure. The APGD can be formed with a simple equipment and has outstanding characteristics, for example, reactor material is hardly restricted by lower pressure and higher temperature, and it can be exposed directly on the surface of liquid and solid having temperature-sensitive properties. Heterogeneous reactions of the plasma with liquid surfaces are expected to have higher selectivity than in gas phase homogeneous reactions because rapid quenching of hot primary products is achieved and consecutive reactions are suppressed due to continuous elimination of them from the surface layer. These characteristics of APGD lead to the creation of new chemical synthesis tool. We have already achieved the epoxidation of carbon double bond by exposing oxygen plasma directly on liquid olefin without catalysts [1]. The study expected a possibility on different reactions using other plasma gas or liquid. Therefore, in this research, mixture of argon and ammonia was used as a plasma gas for direct production of amine with olefin. Some researches on plasma amination have been reported using silence discharge [2-5]. Being different from these researches, our technique seems to have an advantage in no decomposition and no fragmentation of the substrate since the high energy electron does not impact the substrate.

There are a lot of ways to produce amine and currently main methods are (1) hydrogenation of nitrile for alkylamine having carbon number below 5 (R-CN $\rightarrow$ RCH_2NH_2), and (2) amination of alcohol for alkylamine with carbon number over 5 (R-OH $\rightarrow$ RNH_2). The proposed amination technique dose not require catalysts and other additives, therefore, it is expected to be a simple method as compared with the general ways mentioned above.

2. Experimental

The experimental apparatus shown in Fig.1 is almost the same as reported in [1]. The plasma gas was a mixture of argon (Ar) and ammonia (NH_3). The discharge was generated between a tungsten rod at center of quartz tube (high voltage) and aluminum foil on outer wall (ground) by applying rf power (770kHz, 20W). Quartz tube was used as a dielectric material. The electrode configuration is shown in Fig.2 with its dimension. 1-decene ($C_{10}H_{20}$) was chosen as a model of olefin having a straight carbon chain with relatively high boiling point. The batch operation was performed in which the plasma was irradiated to 1-decene as illustrated in Fig.1. The reactant was stirred and its temperature was kept constant with a thermostat. The products in gas and liquid phases were analyzed by gas chromatography (GC) and gas chromatography mass spectroscopy (GCMS). The products including 1-decylamine, 2-decylamine and decane were observed in both exhaust gas and liquid remaining in the reactor in the experiment. Hence conversion, products yield and selectivity are defined as followed:

$$Conversion = \frac{C_{g,i} \times F \times t + C_{l,i} \times V}{n_{init,decene}} \quad , i=1\text{-}decene \tag{1}$$

$$Yield = \frac{C_{g,i} \times F \times t + C_{l,i} \times V}{n_{init,decene}} \quad , i=1\text{-}decylamine,\ 2\text{-}decylamine,\ decane \tag{2}$$

$$Selectivity = \frac{Yield}{Conversion} \tag{3}$$

where $C_{g,i}$ and $C_{l,i}$ respectively indicate the concentrations of species i in the exhaust gas and liquid remaining in the reactor, F represents the volume feed rate, V means the volume of the samples after the experiments, and $n_{init.\ decene}$ is the amount of initial 1-decene. The experiments were performed with changing reaction time, distance between the tip of the tube and the liquid surface and flow rates of NH_3 and Ar as summarized in Table 1.

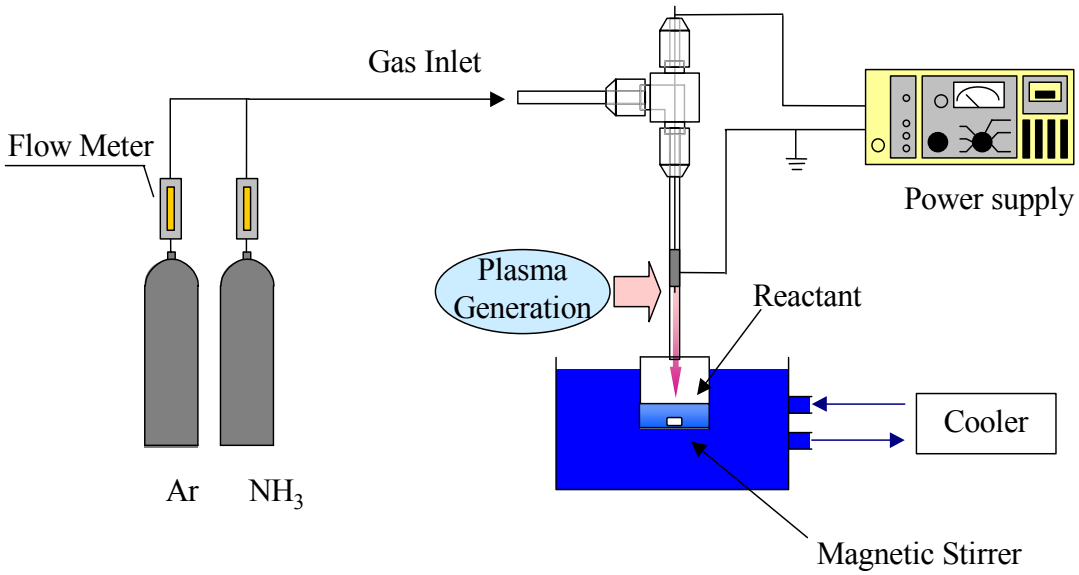

Fig.1 Experimental apparatus

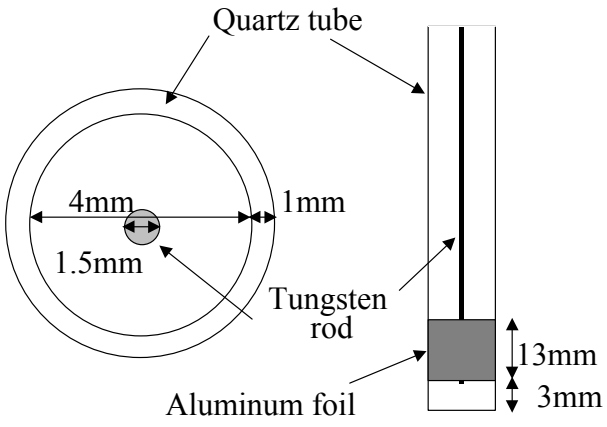

Fig.2 Detail of plasma jet

Table1 Experimental conditions

Sample Volume	2ml
Discharge Power	20 W
Discharge Frequency	770kHz
Thermostat Temperture	-6℃
Reaction Time	0 – 130 min
Ar Flow Rate	3.0 – 4.5 l/min
NH_3 Flow Rate	10 – 90 ml/min
Exposing Distance	1 – 11 mm

3. Results and Discussion

The productions of 1-decylamine, 2-decylamine and decane were clearly observed in all the experimental conditions. Therefore we carried out quantitative analysis on these three products. Many slight peaks were also detected, one of which was assigned to dimerization of 1-decene, however, we couldn't identify them clearly.

3.1 Dependence of reaction time

Figures 3 and 4 show the time dependence of 1-decene conversion and the products yield, respectively. The conversion and products yield increased with reaction time and these increases drew slack curves. This was because the evaporation of liquid 1-decene lengthened the distance between the plasma and reactant surface, resulting in the reduction of the reactivity. As shown in Fig.4, decane was most produced. The production of 2-decylamine was dominant as compared with 1-decylamine. Figure 5 shows the time dependence of the selectivity. The selectivities of decane and 2-decylamine were about 50% and 20% respectively, and they hardly changed with the reaction time elapsed.

3.2 Dependence of distance between the tip of the tube and liquid surface

Figure 6 shows the effect of the distance between the tip of the tube and the liquid surface on the products yield. All the yields decreased gradually as distance became longer. It was expected that active species generated in the plasma were diminished by collision each other and irradiation itself when it was distant from discharge area. This phenomenon was also observed in Figs.3 and 4 as mentioned above.

3.3 Dependence of Ar flow rate

The effects of Ar flow rate on the products yield are shown in Fig.7. The products yield increased with Ar flow rate. The increase in Ar flow rate extended the plasma jet, which increased the flux of active species to the liquid surface. The dilution by Ar might also promote the dissociation of NH_3.

3.4 Dependence of NH_3 flow rate

The effects of NH_3 flow rate on the products yield are shown in Fig.8. The products yield decreased with increasing NH_3 flow rate. The plasma jet became shorter as ammonia flow rate increased. These results suggested that the flux of active species might be reduced even if ammonia flow rate increased.

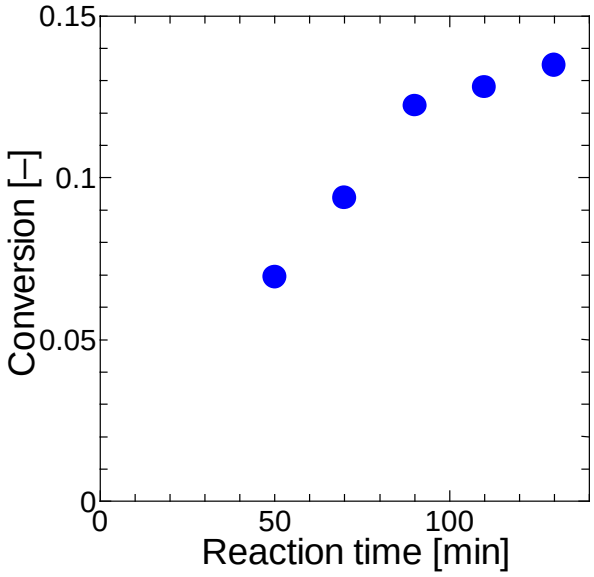

Fig.3 The effect of reaction time on the conversion;
Ar = 3.0l/min, NH_3 = 30ml/min, distance = 5mm.

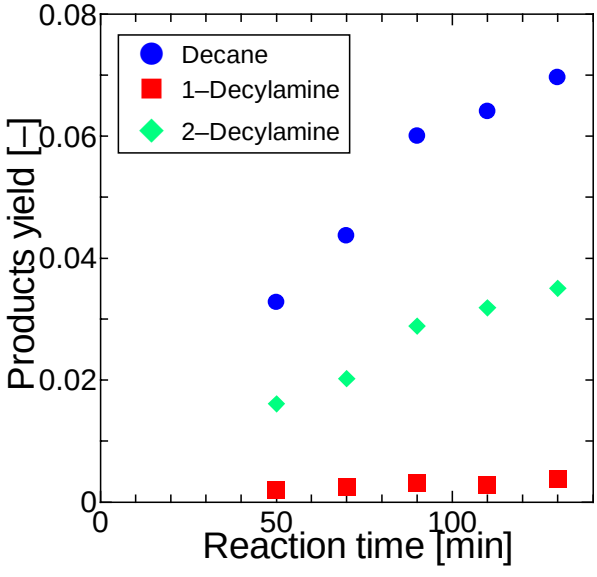

Fig.4 Effects of reaction time on the products;
Ar = 3.0l/min, NH_3 = 30ml/min, distance = 5mm.

Ar = 3.0l/min, NH_3 = 30ml/min, distance = 5mm.

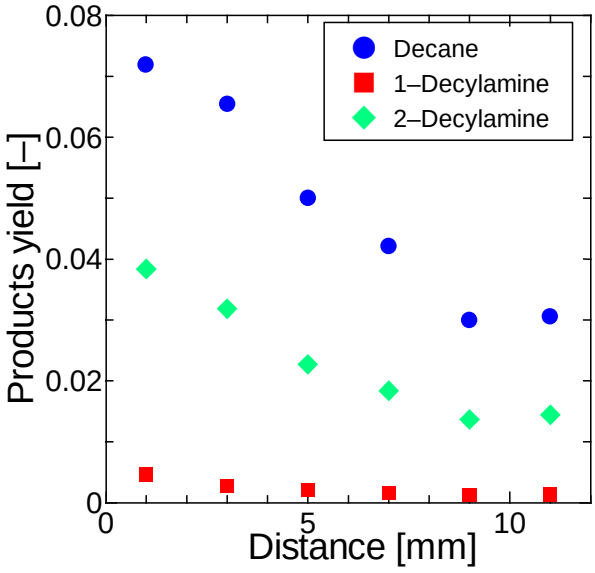

Fig.6 Effects of distance on the products yield;
Ar = 3.5l/min, NH_3 = 30ml/min, reaction time = 70min.

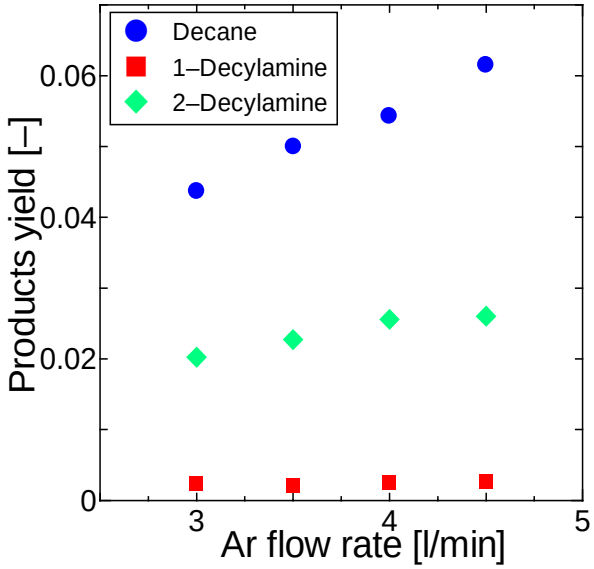

Fig.7 Effects of Ar flow rate on the products yield;
NH_3 = 30ml/min, reaction time = 70min, distance = 5mm.

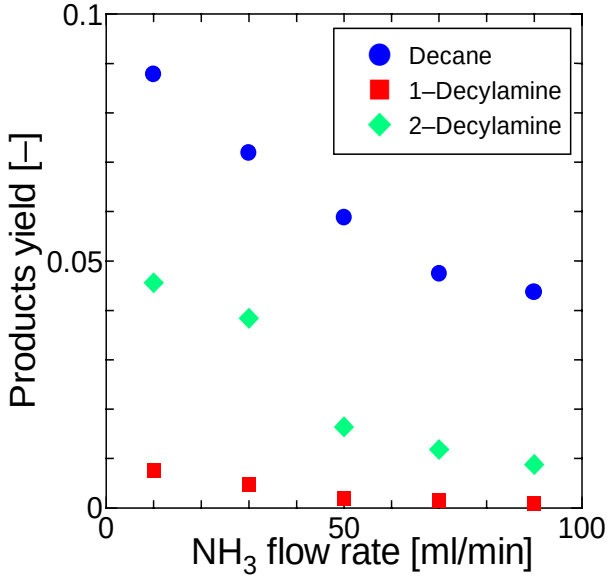

Fig.8 Effects of NH_3 flow rate on the products yield;
Ar = 3.5l/min, reaction time = 70min, distance = 1mm.

3.5 Reaction mechanism

It is expected that the reactions at least occur by two steps because two substituents of carbon double bond would be added to form the amine. The following reaction scheme in Fig.9(a)(b) is proposed to explain the plasma amination where the key radicals are both H and NH_2 generated by APGD:

(a) Hydrogen addition followed by NH_2 attachment

In the case of the addition reaction of H radical to the carbon double bond at the first step, H can be added to the secondary or terminal carbon of the olefin, resulting in forming the primary and secondary radical intermediates, respectively. However, since the secondary radical intermediate is more stable than primary one, the secondary intermediate is produced dominantly. Consecutive addition reactions with H and NH_2 give decane and 2-decylamine, respectively.

(b) NH_2 addition followed by H attachment

When NH_2 radical is added at the first step, similarly to the above case, the secondary radical intermediate is more produced than the primary one. The reaction of the intermediate with H produces 1- decylamine dominantly, hence, 1-decylamine is likely formed in this case. If NH_2 reacts with the intermediate, 1,2-didecylamine will be produced. However, we did not detect its production in the experiment.

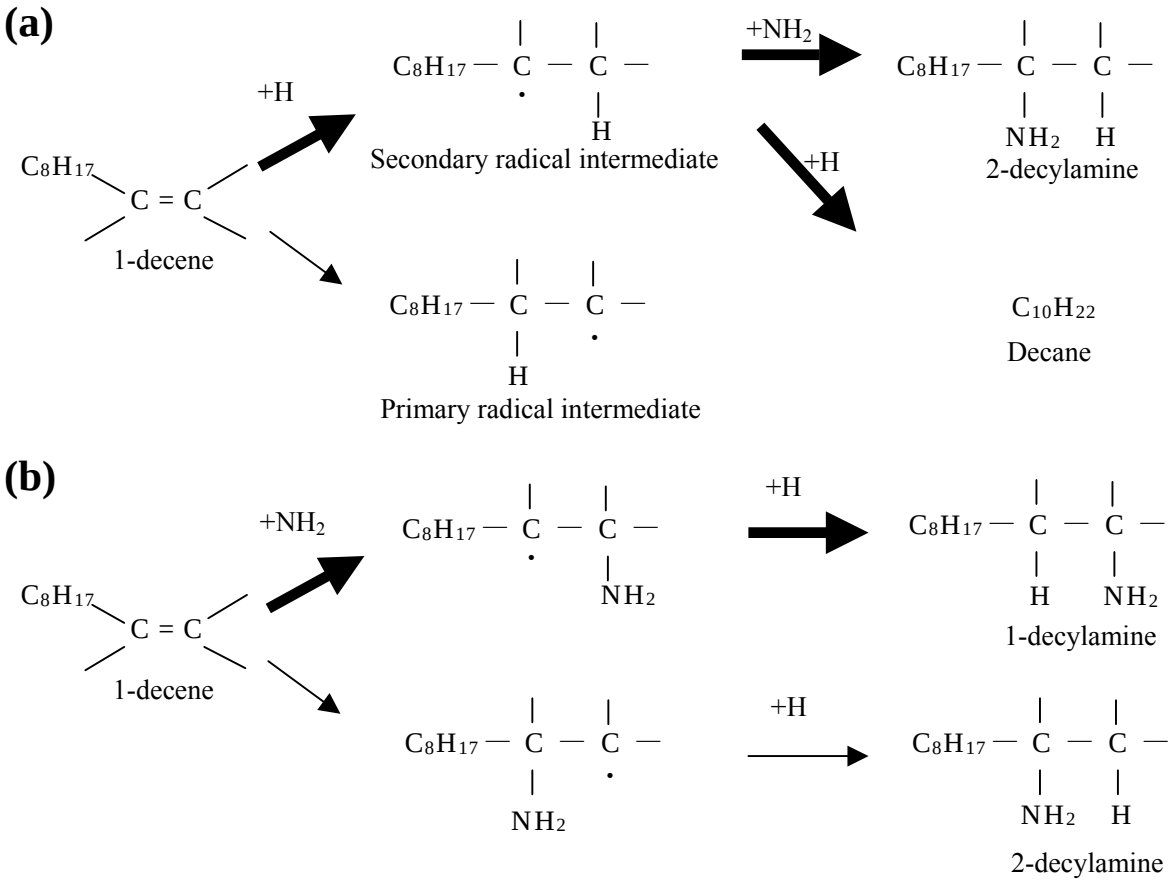

Fig.9 Reaction mechanism proposed;
(a) Hydrogen addition followed by NH_2 attachment,
(b) NH_2 addition followed by H attachment.

Considering the yields of the three products explained above, the concentration of H was higher than that of NH_2 in the plasma. Furthermore, the reactivity of H might be higher as well. Since other radicals such as NH and N would exist in the plasma, further discussion on the mechanism should be done with precious investigations of the plasma and by-products.

From the results of the present study as well as the previous one, the APGD could carry out the addition reactions to carbon double bond without catalyst in two different gases of O_2 and NH_3. Therefore the APGD would be a powerful tool for organic synthesis.

4. Conclusion

The APGD was applied to the non-catalytic amination of 1-decene. The results showed that the amination was successful. The simple reaction mechanism was proposed with the experimental data. This study suggested the possibility of a new organic synthesis technique using APGD.

DIRECT SYNTHESIS OF METHANOL FROM WATER VAPOR AND METHANE THROUGH DIELECTRIC-BARRIER DISCHARGE

Baowei WANG*, Hua SONG, Genhui XU

Key Laboratory of Green Chemical Technology of State Education Ministry, School of Chemical and Technology, Tianjin University, Tianjin 300072, People's Republic of China

Abstract: The direct synthesis of methanol from methane and water vapor mixtures in a continuous flow reactor through dielectric-barrier discharge of non-equilibrium plasma reaction was studied. Technology conditions including flow rate of reactants, diameter of inner electrode, temperature of water, discharge voltage, dilution ratio and length of outer electrode were investigated through orthogonal experiment. The results showed the selectivity to methanol is as high as 50% and the methanol yield is more than 10% under optimal conditions.
Keywords: plasma; methane; water; methanol; dielectric-barrier discharge.

1 Introduction

Direct synthesis of methanol from methane and water vapor mixture has a high possibility to realize a highly sophisticated energy utilization system with energy regeneration. Nevertheless, this process can never occur by conversional thermo-chemical methods due to the large increase of Gibbs free energy [1]. Direct conversion of water and methane into useful chemicals and clean energy remains to be a big challenge in catalysis in the 21st century [2-5]. Although a large number of studies have contributed to the direct decomposition of conversion of methane in the past decade and many new methods and catalysts have been developed for the direct activation and conversion of methane, there is still no direct process with commercial viability at this moment [6].

In this investigation, direct synthesis methanol from methane and water vapor mixture has been successfully realized via a clean, low power, low-temperature and non-equilibrium plasma trans-normal chemical reaction developed a novel plasma reactor with dielectric-barrier discharge at room temperature and under atmospheric pressure. The effects of flow rate of reactants, the diameter of inner electrode, the temperature of water, the peak voltage, the length of outer electrode and the ratio of methane with water vapor and dilution gas on the methanol formation characteristics has been investigated.

2 Experimental

2.1 Experimental apparatus

Fig.1 shows a reactor and schematic of experimental apparatus. The plasma reactor is a concentric cylinder with an inner stainless steel electrode and an outer electrode of copper foil around a quartz glass thin glass. The length of reactor is 300mm, and its diameter 19.4mm; the wall of reactor is 2.3mm. A high-voltage triangular wave is applied between the inner stainless steel electrode and an outer electrode of copper foil. Power consumption by the plasma reactor is between 5 and 40W; the Ljssajous figure method is used for measurement. A Tektronix TDS 210 digital real-time oscilloscope（Tektronix 2440,500M）with a Tektronix P6015A high voltage probe monitors is used to measure the discharge voltages. The flow rates of methane and dilution gas argon/hydrogen were regulated by mass flow controllers (Jianzhong Instrument, Model D07). The water was heated up through electrical power. The temperature of water was controlled with WMZK-01 temperature display and controller. The feed gases were mixed and then downward introduced a reactor for all experiments.

The exhaust gases were cooled with ice and then analyzed by gas chromatograph (HP Agilent 4890D) on-line. A thermal conductivity detector (TCD) with H_2 carrier gas was used. The liquid products were detected with GC-MS (HP5971A). MSC200 quadrupole mass spectrograph (Switzerland Balzers Quadstar^{TM}) is used for the qualitative detection of hydrocarbon and hydrocarbons produced on line. The analytical condition is EI source, measuring range 0~200amu, electron multiple detector, vacuum chamber press 1.2×10^{-5}Pa, ion-current

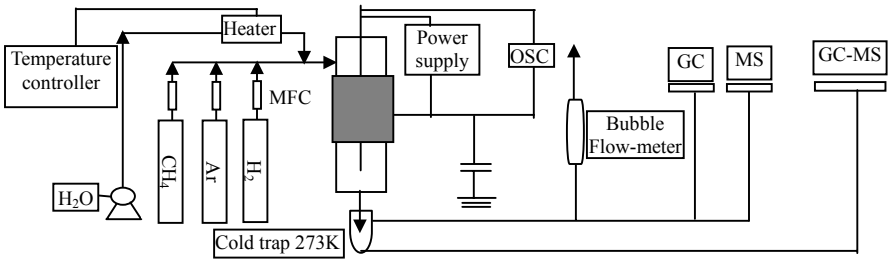

Fig.1 Plasma reactor and measurement apparatus

2.2 Experimental method

A one-pass yield is described as products generated without recycling and separation of initial feedstock. The reaction lasts out one hour at every data points. The exhausted gases were analyzed every six minutes. Thus, every data point was analyzed ten times. The average values were used calculated. The liquid products were analyzed every one-hour. Methane conversion, product selectivity, yield, and ratio of dilution are defined as follows.

%conversion of CH_4=[1- $M_{CH4}\mid_{outlet}$/($M_{CH4}\mid_{outlet}$+$M_{CH3OH}\mid_{outlet}$+2$M_{C2H4}\mid_{outlet}$+$M_{C2H6}\mid_{outlet}$+$M_{C2H2}\mid_{outlet}$)]

%selectivity of methanol=$M_{CH3OH}\mid_{outlet}$/($M_{CH3OH}\mid_{outlet}$+2$M_{C2H4}\mid_{outlet}$+$M_{C2H6}\mid_{outlet}$+$M_{C2H2}\mid_{outlet}$)

%yield of methanol =selectivity×%conversion of methane

DR(ratio of dilution)= $F_{total}\mid_{inlet}/F_{CH4}\mid_{inlet}$

Those results were compared to the total weight of liquid products and changes in total gas flow for consistency. The carbon balance was consistent with 9% error throughout the experiment.

This experimental factor is rather more, such as flow rate of reactants (F), ratio of dilution gas (DR), discharge voltage (U), temperature of water (T), inner electrode diameter (d), length of outer electrode (L). The distributing of data point will be equality if the whole arrange in pairs method was used. However, suppose that the experimental factor have six and three levels of every factor, the needed experimental times will be reach 2187 times. The orthogonal experiment method was selected in order reduce the experimental times. The main purpose of this experiment is that the technology parameters were optimized and the selectivity/yield of methanol can be improved.

The factors and levels used in this experiment are shown in table 2-1. First, the interaction of all factors was not taken into account. Thus, the orthogonal table $L_{16}(4^4\times2^3)$ can be used. Its table head designed is shown in 2-2.

Table 2-1 Experimental factors and level

Factor Symbol	Flow/ml/min F	Ratio of dilution DR	Voltage/kV U	Inner diameter s /mm d	Outer length/mm L	H_2O temp./℃ T

Table 2-2 $L_{16}(4^4\times2^3)$ table head designed

Number column	1	2	3	4	5	6	7
Symbol	F	DR	U	d	L	Empty column	T

3 Results and discussion

The experimental results are listed in table 3-1, which were obtained from the orthogonal table $L_{16}(4^4\times2^3)$.

Table 2-3 tells us that the less of selectivity and yield of methanol, the more of total feedstock flow rate. That is to say, the selectivity and yield of methanol is better when the residence time is longer. The reason is that it entrains water vapor increases when total feedstock flow rate increases and other conditions are constant. Water is a type elimination ionization reagent, the energies of absorbed by water vapor increases for its absorb

electrons character; these lead the amount of dissociative water vapor to reduce and the selectivity of methanol decreases if the input energy is not enhanced. Meanwhile, the residence time decreases, the conversion of methane also decreases, so the yield of methanol decreases.

We can see from table 3-1, the selectivity of methanol increases when the ratio of dilution is increasing. The probably reason is that the concentration of argon gas in feedstock gases increases when the ratio is increasing and other conditions are constant. This indicates argon can promote water and methane to dissociate.

Table 3-1 also indicates that the selectivity and yield of methanol increases when the discharge voltage is increasing. It suggests that the OH* and O* produced from water are propitious to synthesis methanol when the degree of dissociation of water remarkably increases after the discharge voltage is more than 50kV.

We can see from table 3-1, for the inner electrodes, the thickest hollow stainless steel tube is best, the filamentary inner electrode is better, the solid stainless steel tube with the diameter 2mm and 5mm, respectively, are last of all. This indicates the inner electrode surface have no effect on the yield and selectivity of methanol.

Table 3-1 suggests that the selectivity of methanol and yield increases with the length of outer electrode extending. Therefore, the levels of outer electrode should be increase and ulteriorly studied. The reason is that the effective plasma zone extends when the length of outer electrode is extending and other condition are constant.

Table 3-1 also suggests that the selectivity and yield of methanol is better under the temperature 80℃ than that under 95℃. The reason is that it entrains water vapor increases when the temperature of water increases. It also indicated the levels of the water temperature should be increase.

The experimental data listed in table 3-1 were obtained without taking into account the interaction of all factors. Therefore, in the next experimental process, the interactions of some factors have to be considered. For interaction of the diameter of inner electrode with total feedstock flow rate, they each can influence the residence time. In addition, the levels of the temperature of water and the length of outer ought to be increased. Thus, the orthogonal table $L_{27}(3^{13})$ was selected to used. The factors and levels are shown in table 3-2. Its table head designed is shown in 3-3.

Table 3-4 tells us that the conversion of methane decreases; the selectivity and yield of methanol first increase and then decrease when the total feedstock flow rate is increasing and other conditions are constant.

Table 3-4 also tells us that that the conversion of methane first increases and then decreases, the selectivity and yield of methanol first decrease and then increase when the diameter of inner electrode is increasing and other conditions are constant.

From table 3-4, we can see that the conversion of methane decreases with the temperature of water increase. The selectivity and yield of methanol hardly increase when the temperature of water changes from 40℃ to 60℃, however, they suddenly move up when the temperature of water changes from 60℃ to 80℃ and other conditions are constant.

From table 3-4, we can see that firstly the conversion of methane linearly rises with the discharge voltage increasing; however, it changes little after the discharge voltage is more than 35kV. The change of the yield of C_2 hydrocarbons (mainly ethane) is not too. The selectivity and yield of methanol firstly linearly rise with the discharge voltage increases, they reach their maximum when the discharge voltage is more than 45k, and then gradually decreases.

Table 3-4 indicates that the conversion of methane linearly rises with the ratio of dilution gas increasing. The reason is that the concentration of methane reduces and argon can promote methane and water activation. Firstly, the selectivity of yield of methanol slowly increases, and then they quickly go up when the ratio of dilution is more than three.

We can see that it is not significant for the conversion of methane when the significance level a=0.25. It suggests that the length of outer electrode has no obviously effect on the conversion of methane. However, when the length of outer electrode changes from to 34.5mm to 87mm, the selectivity and yield of methanol each have a maximum. It suggests that the yield of methanol is mainly controlled by the selectivity of methanol. It also suggests that most methanol can be decomposed if the length of outer electrode is too long.

The significance test was calculated according to the data in table 3-4. The significance test results are shown in table 3-5.

Table 3-5 significance of every factor

Symbol	F	d	F×d	T	U	DR	T×d	L
Significance	4	4	2	3	4	4	2	0
	0.01	0.01	0.10	0.05	0.01	0.01	0.10	0.25

Table 3-5 indicates that it is significant for the total feedstock flow rate, the diameter of inner electrode, the discharge voltage and the ratio of dilution when the significance level is a=0.01. It is significant for the temperature of water when the significance level is a= 0.05. It is significant for the interaction of the total feedstock flow rate with the diameter of inner electrode (F×d) and the interaction of the temperature of water with the diameter of inner electrode (T×d) when the significance level is a= 0.10. However, it is not significant for the length of outer electrode when the significance level is a=0.25.

According to the orthogonal experimental analyses after taking into account the interaction of some factors, the appropriate technology parameters are listed in table 3-6.

Table 3-6 the appropriate technology parameters

Symbol	F	d	T	U	DR	L
unit	ml/min	mm	℃	kV		mm
Optimal parameters	17.256[a] 28.76[b]	12.0	80	45	4	69.0

[a] Feedstock flow rate is 17.256ml/min, the selectivity and yield of methanol are the biggest.

[b] Feedstock flow rate is 28.760ml/min, the output of methanol in the same time is the biggest.

4 Reaction mechanisms

In general, a unique feature of low temperature plasma is that at least four different types of radicals from

methane and three different types of radicals from water vapor are shown to be produced simultaneously by electron swarm, which is a group of electrons having a wide distribution of energies: the impact of high-energy electrons produces excited methane and water vapor for which the internal excited energy (9~13eV and 12.6eV, respectively) is much higher than the methane and water vapor dissociative threshold (4.51eV and 5.0eV, respectively).

$H_2O+e \rightarrow H_2+O^*$ (1)

$H_2O+e \rightarrow H^*+HO^*$ (2)

$CH_4+e \rightarrow H^*+CH_3^*+e \rightarrow CH_2^*+H_2+e \rightarrow CH^*+H^*+H_2+e \rightarrow C+2H_2$ (3)

Methanol can be produced through HO* and CH_3* reaction or CH_4 and O* reaction after methane was dissociated into CH_3* and water vapor was dissociated into H* and HO* or H_2 and O*. Methanol can be produced through reaction (4) and (5). C_2 hydrocarbons and hydrogen are by-products. The detail reaction mechanism of C_2 hydrocarbons synthesis from methane through plasma reaction was expatiated in the papers [7-8].

$HO^*+CH_3^* \rightarrow CH_3OH$ (4)

$CH_4+O^* \rightarrow CH_3OH$ (5)

5 Conclusions

1. The direct synthesis of methanol from methane and water vapor is doable with continuous flow reactor through dielectric-barrier discharge non-equilibrium plasma under atmosphere press.
2. The selectivity and yield of methanol decrease with the total feedstock flow rate increasing. The selectivity and yield of methanol first decrease, and then increase with the radius of inner electrode increasing. The selectivity and yield of methanol decrease with the water temperature increasing. The selectivity and yield of methanol increase with the discharge voltage increasing, the ratio of dilution increasing, or the length of outer electrode increasing.
3. The appropriate technology condition is d=12.0mm, T=80℃, U=55kV, DR=4, L=69.0mm. When the total feedstock flow rate is 17.256ml/min, the selectivity and yield of methanol is as high as 50% and 10%, respectively. When the total feedstock flow rate is 28.760ml/min, the output of methanol in the same time is the biggest.

Abstract
In this work synthesis of nanosized zinc ferrites was studied under thermal plasma conditions. Mixture of oxide powders and ethanol solution of corresponding salts were used as precursors. The products were characterized by ICP-OES and XRD methods. Morphology was studied by SEM and TEM. Magnetic properties were characterized by saturation magnetization. Nanosized zinc ferrite particles having ferromagnetic properties were produced which refers to the formation of zinc ferrites of inverse spinel structure in particular conditions.

Keywords: Zinc ferrite; $ZnFe_2O_4$; Thermal plasma; XRD; SEM; TEM; Saturation magnetization

1. Introduction

Ferrite spinels crystallize in face centered cubic lattice. In the normal zinc ferrite structure, Zn^{2+} ions are in tetrahedral, while Fe^{3+} ions are in octahedral positions. Zinc ferrites having normal spinel structure exhibit paramagnetic properties. They are used as pigments, catalysts and adsorbents for desulphurization [1].
Under extreme conditions, such as mechanochemical activation or rapid quenching, position of Zn^{2+} and Fe^{3+} cations in the crystal structure can be partially or even completely reversed [2]. The resulted structure, referred as inverse spinel one, is ferromagnetic with a high saturation magnetization. Thus, inverse zinc ferrites can be used as electrical and magnetic materials. Zinc-ferroferrites ($Zn_xFe_{3-x}O_4$, where $x \leq 0.5$), in which the Fe^{2+} ions are partially substituted by Zn^{2+} ions, have the highest saturation magnetization among spinel ferrites.
Inverse zinc ferrite spinels of ultrafine particle size can be produced in RF thermal plasma conditions due to high processing temperature and the rapid quenching of the formed, meta-stable phases [3-4]. In addition, thermal plasma synthesis makes production of ferrite devices from powders simpler.
In this report, results of the thermal plasma synthesis of zinc ferrites from different precursors are presented. Research was aimed to reveal correlations among properties of products and parameters of processing and to optimize conditions of zinc ferrite production.

2. Experimental

The experiments were performed in an RF thermal plasma reactor operating at a maximum plate power of 30kW (3÷5 MHz). Experimental set-up is shown in Fig. 1. Argon was used as plasma gas with a flow rate of 20 $l \cdot min^{-1}$. The sheath gas was a mixture of Ar and O_2 with flow rate of 23 $l \cdot min^{-1}$ and 20 $l \cdot min^{-1}$, respectively. The oxide precursors were fed using PRAXAIR powder feeder, while the ethanol solutions were injected by a TEKNA suspension feeder. Both mixture of solid oxides and ethanol solution were atomized by argon with flow rate of 3 $l \cdot min^{-1}$. Injection probe was positioned as shown in Fig. 2.
Precursors were prepared by two methods:

- Analytical grade Fe_2O_3 and ZnO powders were thoroughly mixed in a Fritsch laboratory agate mortar grinder
- Analytical grade $Fe(NO_3)_3 \cdot 9H_2O$ and $Zn(NO_3)_2 \cdot 6H_2O$ were dissolved in technical grade ethanol using a magnetic stirrer.

The Fe to Zn molar ratio was set to 2:1 in all cases. In the tests the following parameters were varied:

- Type of precursor
- Plate power
- Position of injection probe
- Concentration of salts in the ethanol solution.

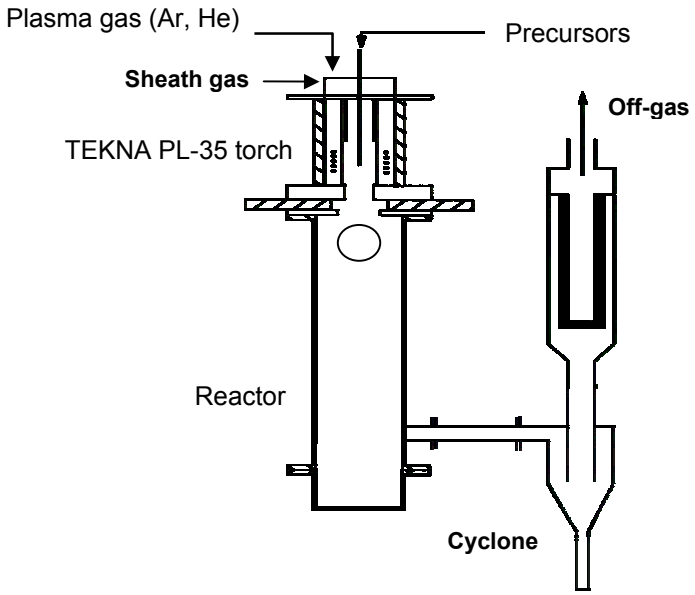

Figure 1 Scheme of the experimental set-up

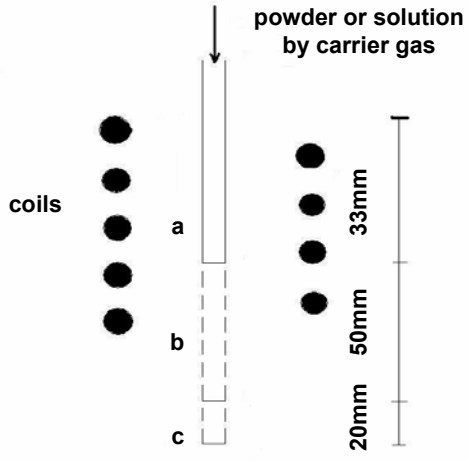

Figure 2 Positions of the injection probe

The experimental conditions are summarized in Table 1.

Table 1 Experimental conditions

Sample No.	Plate power (kW)	Probe position	Molar concentration (M)	Feed rate
Powder				
1	15	a		0.460 g/min
2	25	a		0.360 g/min
Solution				
3	15	b	1.3	0.010 l/min
4	15	c	1.3	0.014 l/min
5	25	c	1.3	0.014 l/min
6	25	c	0.65	0.021 l/min
7	15	b	0.65	0.019 l/min
8	25	b	0.65	0.019 l/min

The reaction products were collected from the reactor wall. Their chemical composition was analyzed by ICP-OES (Thermo Jarrell Ash Atomscan 25). A Philips Xpert XRD apparatus operating with Cu K_α radiation was used to analyze the phase composition. The lattice parameters (a) of the crystalline phases were determined from the positions of the particular diffraction peaks. The mean particle size was calculated from the peak broadening. Product morphology was studied by SEM (Philips XL30 ESEM) and TEM (Philips CM20). Magnetization measurements were performed at room temperature by means of a vibrating-sample (Foner-type) magnetometer varying the external magnetic field up to 2 Tesla. The saturation magnetization was determined by extrapolating the linear high-field part of the magnetization curve to zero fields.

3. Results and discussion

The experimental results are summarized in Table 2. Plasma treatment resulted in extensive spinel formation from both precursors (Figs. 3 and 4). However, in most of the cases, the spinel phase contained magnetite (Fe_3O_4), as well. XR diffractograms indicated some ZnO (zincite) and Fe_2O_3 (hematite) phases in the products. In order to compare results of different experiments, the most intense reflections of the by-products were related to the $ZnFe_2O_4$ 311 reflection. Ratio of Fe_3O_4 to $ZnFe_2O_4$ was calculated by deconvoluting the 731 spinel reflection.

Table 2 Properties of zinc ferrite powders

Sample no.	Zinc ferrite phase				Other phases				Fe : Zn ratio	Saturation magnetization ($emu \cdot g^{-1}$)
					Magnetite		Zincite	Hematite		
	a (Å)	Composition	D (nm)	RI	D (nm)	RI	RI	RI

7	8.438	$ZnFe_2O_4$	80	100	39	31	10	1	2.0 : 1.0	28
8	8.441	$ZnFe_2O_4$	70	100	16	128	7	2	2.24 : 0.76	32

RI – relative intensity

Starting from solid precursors, the product contained relatively high amount of un-reacted oxides. At plate power of 15 kW, the product consisted of spinel phase ($ZnFe_2O_4$) only. However, at plate power of 25 kW a remarkable amount of magnetite could be detected in the product, as well. In both runs, practically same concentrations of un-reacted precursors were detected. Increase of the plate power, and hence, the specific energy (kWh/g, applied energy related to the mass unit of precursor) seems to be unfavorable regarding formation of single spinel phase. For the pure $ZnFe_2O_4$ spinel (Sample 1) a saturation magnetization of 19 $emu \cdot g^{-1}$ was measured. This refers to inverse spinel structure.

The mixture of nitrates, as precursor was transformed into spinel with a good efficiency (Fig. 4.). The low relative intensity of ZnO and Fe_2O_3 phases, respectively, refers to more complete formation of ferrites as compared to solid precursor. However, intensity of magnetite reflection is very close to (Sample 6), or even higher (Sample 8) than that of zinc ferrite. This means that the spinel structure contains less zinc than required. A plate power of 25 kW and diluted solution may favor the zinc loss. The highest $ZnFe_2O_4$ formation was observed in Sample 5. This material was produced from a 1.30 M nitrate solution that was fed at a probe position of "b" at plate power of 25 kW.

Crystallites in $ZnFe_2O_4$ had sizes in the range of 50-80 nm for all cases. Size of magnetite particles was smaller. It should be emphasized that these data refer to particles below 1 μm, because particles being greater than 1 μm do not exhibit line broadening of XRD peaks.

SEM and TEM micrographs confirmed calculations of mean particle size based on XRD data. Products from ethanol solutions consist of slightly agglomerated grains having particle size below 200 nm (Fig. 5(a)). In the TEM micrographs (Fig. 5(b)) particles can be classified into three groups, namely those having smallest (5-10 nm), medium (~50 nm) and largest (100-300 nm) sizes.

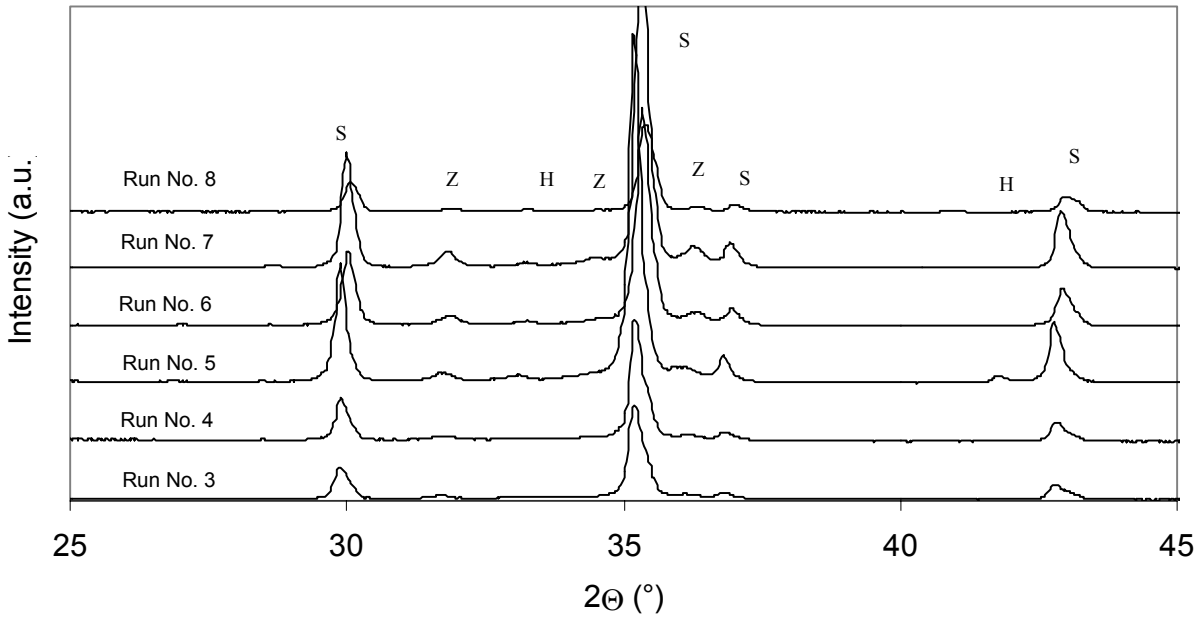

Figure 4 XRD patterns of products from ethanol solutions (S: Spinel, H: Hematite, Z: Zincite)

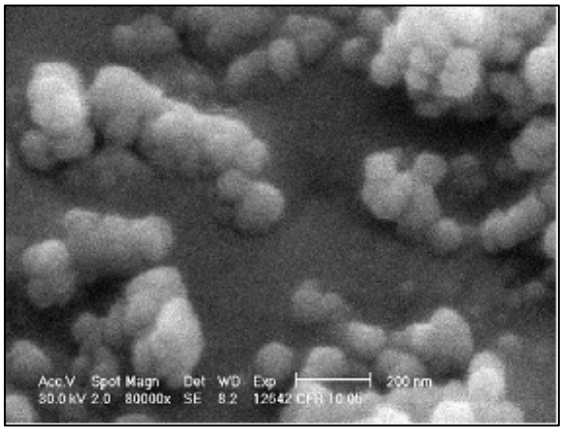

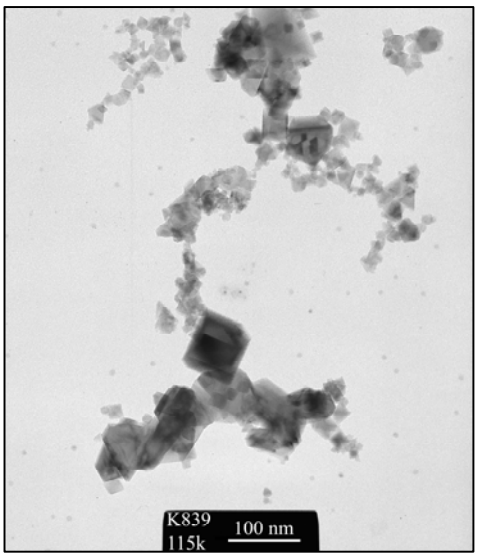

(a) (b)

Figure 5 SEM and Tem microphotograph of a typical product from ethanol solution of metal salts

4. Conclusions

RF plasma treatment of the mixture of Fe_2O_3 and ZnO, and also the ethanol solution of the metal nitrates resulted in an extensive spinel formation. The main reaction product was $ZnFe_2O_4$. However, different amounts of magnetite (Fe_3O_4) were formed, as well. Starting from solid precursors, considerable amount of oxides did not react in particular conditions. Using ethanol solution of metal nitrates, transformation of precursors to spines was much more complete. Thus, for the synthesis of ferrite spinels of well defined composition, use of solutions of metal salts as precursors is recommended. Small particles in the size range of 5-300 nm were produced in this case at specific energies of 0.05-0.1 $kWh \cdot g^{-1}$. Particular energies are less of one order of magnitude as compared to the solid precursors (0.6-1.1 $kWh \cdot g^{-1}$). Saturation magnetization exhibited rather poor correlation with the $Fe_3O_4/ZnFe_2O_4$ intensity ratio. It suggests formation of inverse $ZnFe_2O_4$ spinel with ferromagnetic properties.

Rotating Non-Equilibrium Gliding Arc Plasma Disc for Enhancement in Ignition and Combustion of Hydrocarbon Fuels

Shailesh Gangoli, Alexander Gutsol, Alexander Fridman
Department of Mechanical Engineering & Mechanics, Drexel University, Philadelphia, PA

Abstract

The best plasma discharge system for combustion applications should generate non-equilibrium plasma with high concentration of active species and intermediate temperatures, high enough to support chain in propagation reaction. The non-equilibrium Gliding Arc (GA) aptly suits this application. A novel, non-equilibrium gliding arc plasma disc reactor has been developed to study possibility of flame speed increase, flammability limit extension for hydrocarbon fuel and oxidizer mixture.

Introduction

The motivation for this work has come from analyzing the two major sources of problems in supersonic combustion: ignition and flame stabilization in supersonic flow. From the viewpoint of chemical kinetics, combustion is a chain process with two limiting reactions: chain-initiation and chain-continuation. Plasma as a source of free radicals and ions can significantly reduce the chain initiation time. Plasma enhanced combustion devices developed in the past have ranged from using plasma torches [1] to nanosecond high voltage discharges. [2, 3] These devices enhance combustion characteristics in supersonic flow significantly, but at the cost of high power consumption.

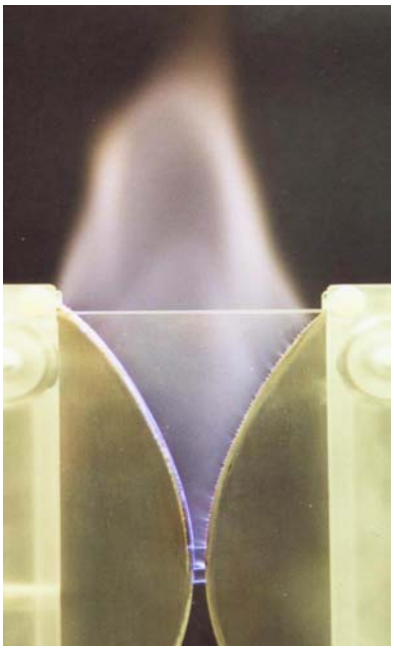

Figure 1: Conventional Gliding Arc discharge in flat geometry.

At low temperatures, equilibrium concentration of radicals reduces very fast and to ignite the combustible mixture within reasonable time, it is necessary to provide some heat to the mixture, in addition to radicals. So, the best discharge system should generate non-equilibrium plasma with high radical concentration and intermediate (better adjustable) temperature, high enough to support chain continuation reaction. The discharge that aptly suits these requirements is the non-equilibrium Gliding Arc (GA). In conventional GA system, as shown in figure 1, the arc starts at the smallest gap between two diverging electrodes under an electric field of approximately 3kV/mm in air and elongates as it is pushed by air. During this elongation period, the thermal arc changes its ionization mechanism into a non-thermal one. Hence it is also known as a transitional discharge.

Non-thermal plasma generated by this unique discharge has relatively high plasma density, power and operating pressure in comparison with other non-equilibrium discharges; high electron temperature (about 1.5eV), relatively low gas temperature (<3000K) and good chemical selectivity in comparison with thermal discharges. High temperature electrons are more efficient in producing ions, radicals, excited and dissociated molecules than those in equilibrium plasma (<1eV). The discharge can be divided into various regions qualitatively, shown in figure 2.

Evolution of conventional flat GA

The evolution of GA can be best explained in the following manner. The arc ignites at the shortest gap and is

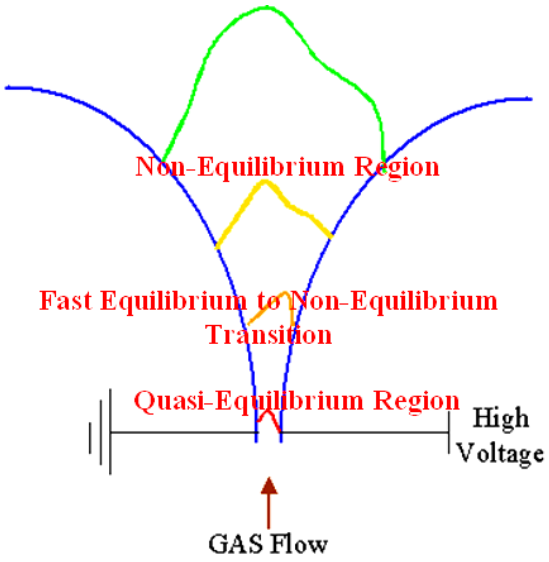

Figure 2: (top) Qualitative classification of regions in the flat GA discharge.

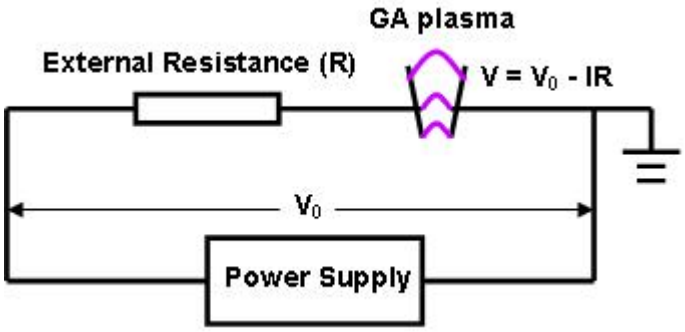

Figure 3: (top right) Electrical scheme for conventional flat GA.

elongated by air flow. Within a short time (microseconds), the arc current *I,* reaches its maximum value $I_{max} \leq V_0/R$, while the voltage drops to almost zero. As the gas flow pushes the arc, its voltage increases and current starts to decrease. The elongating arc demands more power to sustain itself, until it reaches a maximum that the power supply can provide. For the electrical configuration shown in figure 3, by Ohm's law, the power dissipation in plasma reaches its maximum $W_{max} = (¼)\ V_0^2/R$ when the plasma resistance equals the external resistance *R*. The length of arc continues to grow, but the power supplied by the source is insufficient to balance the energy losses to the surrounding gas. If the electric field is sufficiently high (meaning the power supply can provide sufficiently high voltage), the arc changes its ionization mechanism to a non-thermal one. Due to instability the arc cools down and finally extinguishes marking the end of one cycle. The next cycle of arc evolution begins as voltage in the gap reaches its breakdown value. Transition from thermal to non-thermal can be verified from figure 4 [10], wherein the electric field increases i.e. slope of dV/dL increases, after a certain arc length elongation, which in turn explains the increase in electron energy as the arc propagates. The non-thermal zone of the discharge can be considered to be in the normal glow discharge [11], as we can make a visual comparison between snapshots of atmospheric pressure flat GA and atmospheric pressure glow discharge as shown in figure 5.

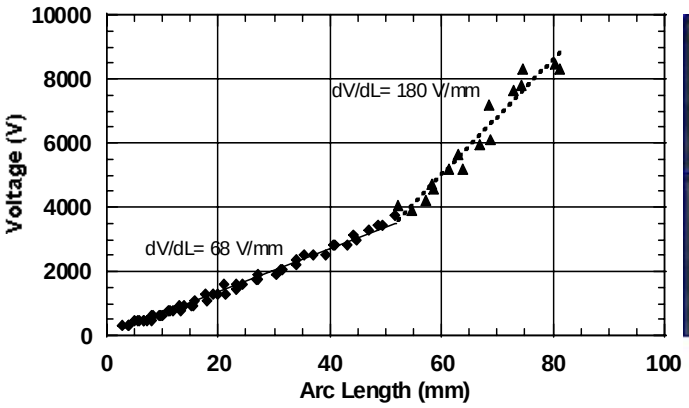

Figure 4: Arc voltage vs length during evolution of GA [10]

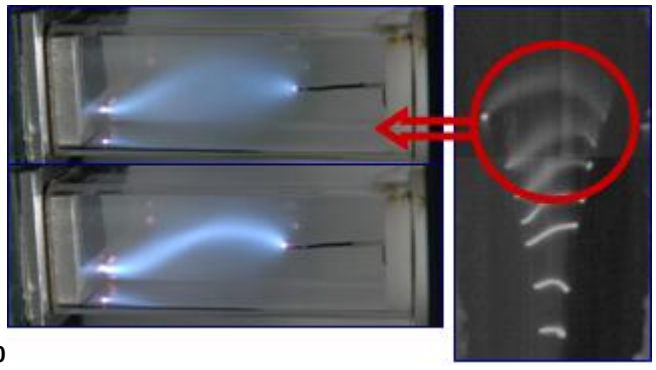

Figure 5: Visual comparison of atm. pressure glow discharge (left) and atm. pressure GA (right)

However, it was recently found that after the GA reaches maximum power and before it quenches, it is still stable in the most non-equilibrium regime [4]. This "overshooting" regime is observed at sufficiently low arc currents. It is possible to extend "life" of the extremely elongated non-equilibrium GA infinitely if we can stop its elongation just before extinguishing. One of the technical solutions to achieve this "infinite life" of the non-equilibrium GA is to rotate it in a magnetic field inside the gas flow.

Principle & Design of Magnetic Gliding Arc (MGA)

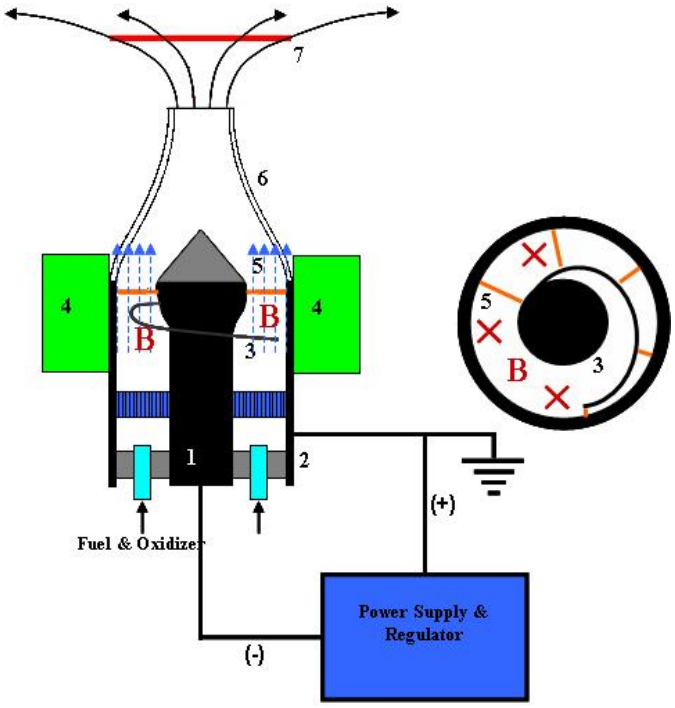

Figure 6: Diagram of newly developed non-equilibrium plasma enhanced counter flow burner: 1. Anode, 2. Cathode, 3. Wire for gliding arc initiation, 4. Circular magnet, 5. GA plasma discharge, 6. Nozzle

The MGA is based on the principle of Ampere force, which is experienced by a current carrying conductor in a magnetic field. The Ampere force is given as $F = IL \times B$, where, F – Ampere Force, I – Current through the conductor, L – Length of the conductor and B – Strength of magnetic field.

The schematic of the MGA setup is as shown in figure 6. Just as in the conventional GA, the arc is initiated at the shortest gap between the spiral wire (connected to the central cathode) and the anodic cylinder. The arc is then rotated by the magnetic field to cause it to move (rotate) upwards along the spiral wire, until it stabilizes on top of the cathode. The arc then rotates in the cross-section of the flow. The stabilized non-equilibrium plasma arc is still just one arc between the electrodes in the plasma device, but depending upon the strength of the magnetic field, the arc is rotated at a high enough rate to pass through a significant portion of the fuel mixture and provide quasi-uniform activation of the flow. The stabilized non-equilibrium plasma arc constantly produces some amount of heat and high density of electrons that produce radicals and active species for maximum flame enhancement.

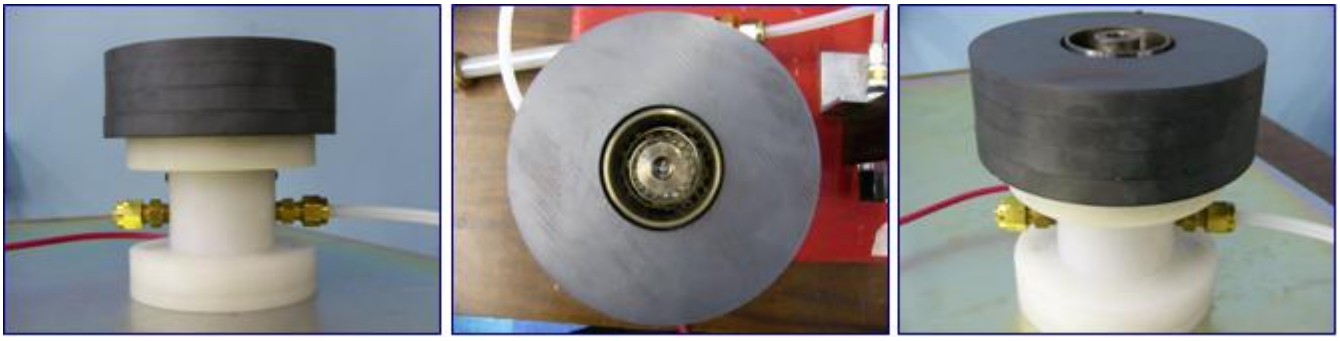

Figure 7: Photographs of the MGA from (left to right) front, top and isometric views, respectively.

Uniformity of Treatment

The frequency of rotation of arc depends on the arc current and magnetic field within the reactor. A simple model can be formulated to predict the flow rate of gas passing through the plasma that can be 'uniformly' treated by it.

For the current MGA configuration: Outer diameter of central electrode Di= 1cm; Inner diameter of anodic cylinder Do= 5cm; Hence, Arc Length ≈ (Di-Do)/2 ≈ 2cm

For a particular case of operation: Current = 130 mA; Magnetic Field = 0.15 T

We make an assumption that the arc is "*not transparent*" to the surrounding air i.e. it experiences a drag force as it rotates. Hence, the plasma arc behaves like a current carrying cylinder (wire) which experiences two sets of forces namely, Ampere Force per unit length = IB = F_a and Drag Force per unit length = $C_d \rho d V^2 = F_d$. Under equilibrium conditions; $F_a = F_d$.

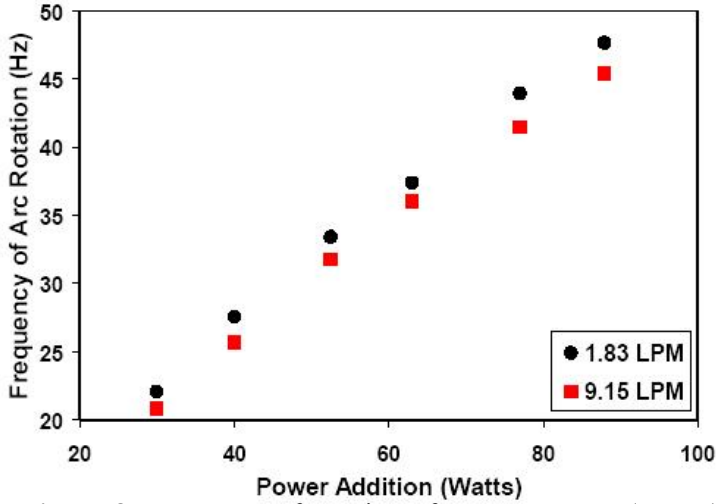

Figure 8: Frequency of rotation of arc vs. Power (current) addition at varied flow rates.

Figure 9: Reactive Capacitive Resistance based power supply, specially developed for GA's

Using this relation we can approximate the velocity of propagation of the arc ~ 4.5 m/s. Hence, the frequency of arc rotation would be ~ 60 Hz. The arc, which is at least 2mm in diameter, appears at the same position 60 times in one second; thus, the velocity of gas that would be treated 'uniformly' is < 12 cm/s. This gives in turn gives us the flow rate of gas that would be treated uniformly < 903 cm^3/s. Figure 8 shows the experimentally measured frequency of arc rotation at different power (current) levels, which conforms to our simplistic model for frequency of arc rotation [9].

Power Supply

As discussed earlier, maximum power is supplied to the GA when the plasma resistance equals the external resistance in the circuit. Even in this case the conventional power supply with the serial resistor (fig. 3) can use only 1/2 of available energy to support the Gliding Arc. All other energy is dissipated in the serial resistor. A new power supply has been developed, which incorporates a reactive capacitive resistance circuit that imitates active resistance, but does not consume significant power. This ensures that it operates more or less in the non-thermal regime of operation. Also, during operation the current can be reduced manually (causing corresponding increase in voltage), to as low value as possible before it extinguishes and restarts again. Figure 9 shows the power supply that specially constructed for this purpose.

MGA Snapshots

Snapshots of the MGA were taken at different shutter speeds to obtain the images (RGB and Grayscale) as shown below. At $1/1000^{th}$ sec, we see a discharge column with a cathode glow.

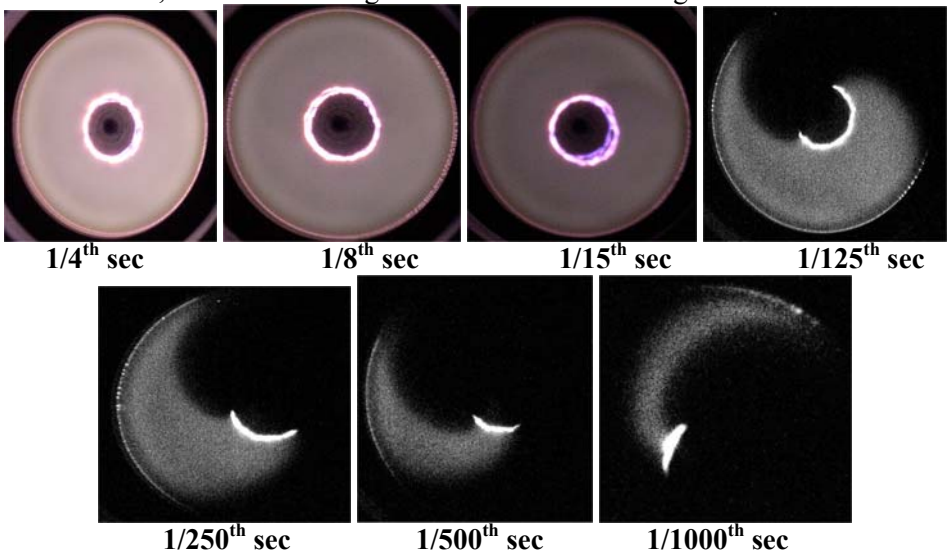

Figure 10: Snapshots of the MGA

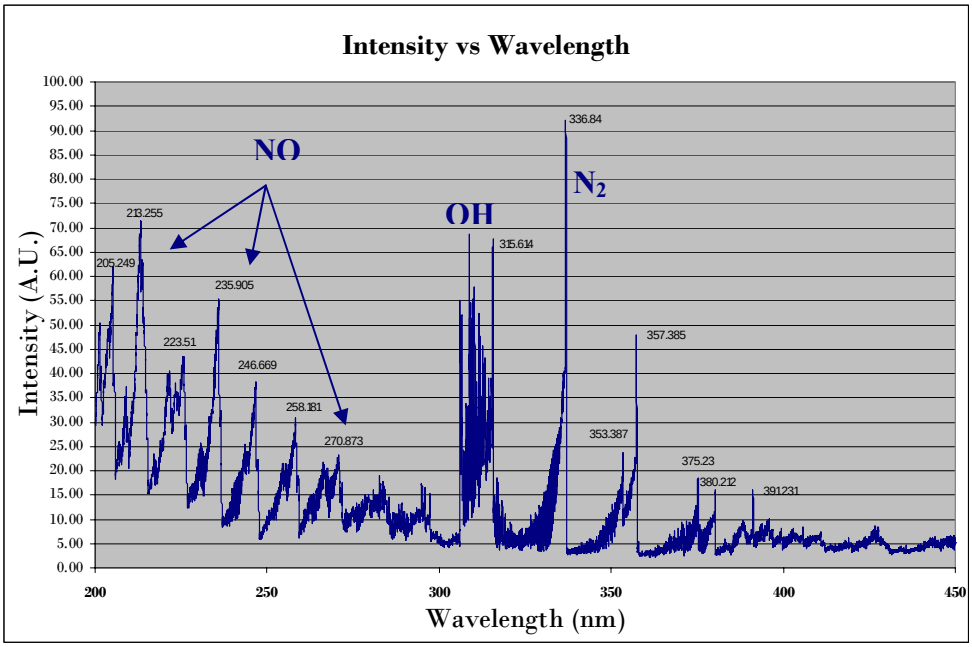
Gliding Arc Discharge Diagnostics

Figure 11. Spectra obtained for MGA in 200-450 nm wavelength range



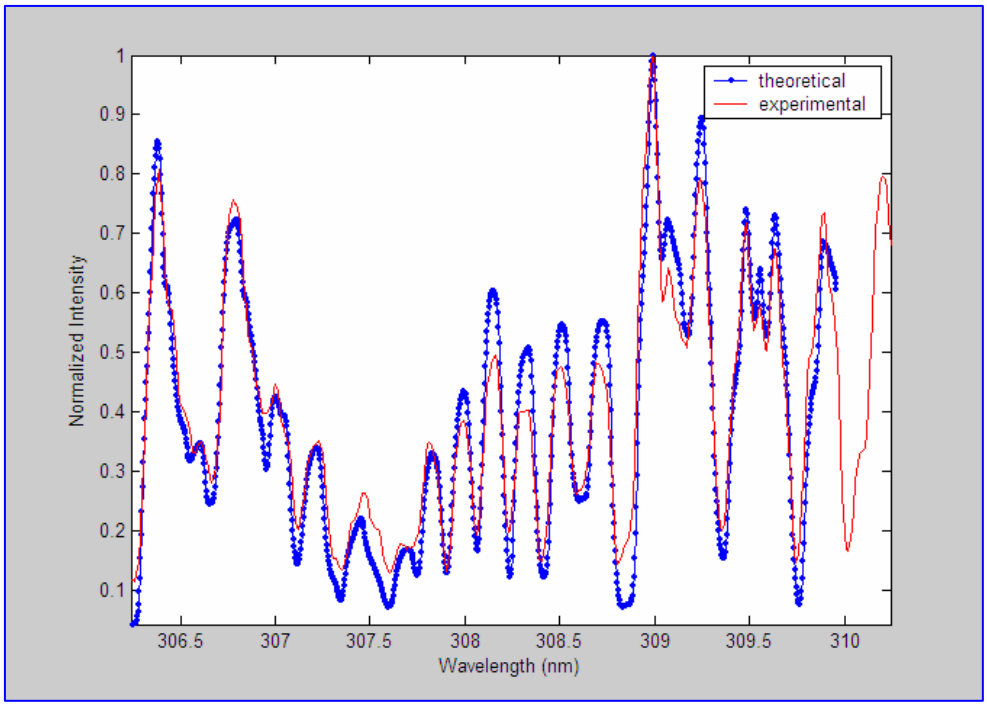


Figure 12: Comparison between experimental and theoretical OH spectra generated for temperature T= 2300K

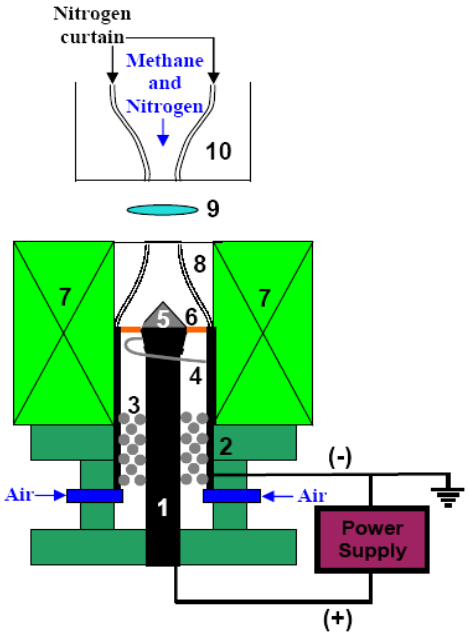
In our earlier work, we had conducted microwave diagnostics conventional flat GA, and the results for electron density obtained were in the range, $\mathbf{n_e = (1\text{-}3).10^{11}\ cm^{-3}}$ [5]. Figure 11 shows the experimental spectral diagnostic results obtained for the MGA. A theoretical OH spectrum was developed based on data obtained from [6] and methodologies suggested in [7, 8]. Figure 12 shows the comparison between experimental spectrum and a simulated one for the temperature 2300K (theoretical spectra were generated for the temperature range 1000K - 8000K), and then a best fit procedure was applied to find MGA temperature).

Using the data rotational gas temperature ≈ **2300K**, and using BOLSIG, Boltzmann equation solver (Kinema Research) we obtain the average electron energy in the MGA to be ~ **1.56 eV**. This high electron energy is conducive to efficient dissociation and ionization of species that cause 'plasma enhancement effect.'

Experimental Result



Experiments with opposite diffusion flame were conducted [9] using the MGA. The schematic of the setup is as shown in figure 13. The results obtained are shown in figure 14. We see that the air flow rate, required to cause blow-out of the diffusion flame increases with increase in plasma power.

Abstract

The transient heat flux to an asymmetric graphite anode in a Hot Refractory Anode Vacuum Arc (HRAVA) was determined using three-dimensional numerical simulation of a thermal anode model and the experimentally measured anode temperature distribution. The HRAVA anode is initially heated by the plasma flux from cathode plasma jets (t<30 s), and then from the dense anode plasma plume in the developed arc stage (t>1min). It was shown that asymmetry parameter of the heat flux increases with anode asymmetry.

Keywords: vacuum arc, hot asymmetric anode, anode plasma plume, heat flux, anode temperature.

1. Introduction

The Hot Refractory Anode Vacuum Arc (HRAVA) is a high current electrical discharge between a consumable cathode and a non-consumable refractory anode, and may be used to deposit coatings of the cathode material with low macroparticle contamination on substrates facing the anode [1,2]. The mechanism of plasma generation in the HRAVA is different from that in the well know hot evaporated anode vacuum arc [3,4]. The plasma configuration would be similar to that which occurs in an arc with non-condensable gas such as argon [5]. Initially (about 1min after ignition), the cathode spot plasma jets heat the refractory anode and then later, in the developed stage of the arc, a dense anode plasma plume is formed [6]. Simultaneously, cathode material is deposited on the refractory anode surface during the initial stage, and then, during the developed stage, the deposited material is re-evaporated from the heated anode. The anode plasma plume appears as a result of cathode material re-evaporation from the anode surface and its ionization by cathode jets dissipated in the plasma plume [6]. Previously, a one-dimensional (1-D) [7] model of the HRAVA anode was considered and the heat flux to a symmetric graphite anode was determined using the 1-D model and measured anode temperatures. The radial distribution of temperature on the symmetric anode surface was taken into account using a 2-D mode for graphite and molybdenum anodes [8]. Anode plasma plume propagation may be directed [9] using anodes with inclined facing surface. However, heretofore, a 3-D model considering asymmetric HRAVA anodes was not developed.

This work presents a 3-D thermal model of asymmetric graphite anodes. The time-dependent heat flux was determined numerically using the measured anode temperature distribution.

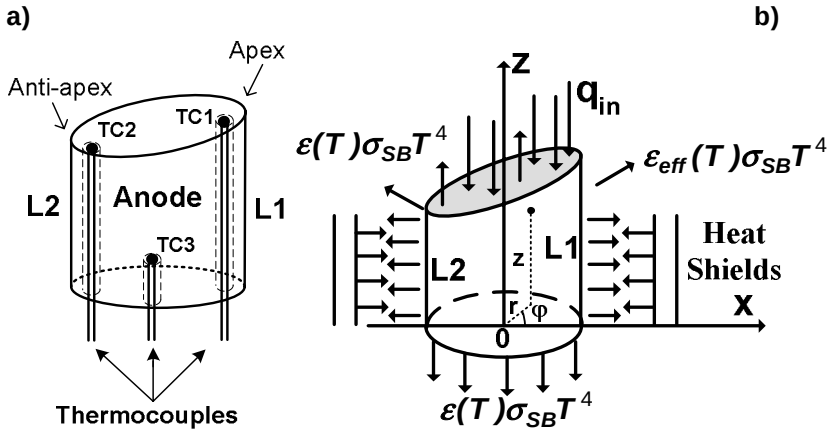

Fig 1. Schematic diagram of anode: a) thermocouple locations; b) heat flux.

2. Experimental Setup

The anode geometry and its heating are presented in Fig. 1. Cylindrical graphite anodes with radius R_a=16 mm and arc currents I=175 and 225 A were considered. The front surface of the anodes was inclined so that the maximal (apex) and minimal (anti-apex) anode

lengths (L1, L2) were: (1) (30, 25), and (2) (30, 20) mm, whereas the length of the symmetric anode was 30 mm (Fig.1a).

The anode temperature was measured using three high-temperature thermocouple probes (W/Re 26%, W/Re 5%) placed in cylindrical cavities with diameter 4 mm in the anode body: TC1 and TC2 - 2mm inside from the front anode surface near the apex and anti-apex, and TC3 – 7 mm from the back anode surface as shown on Fig. 1a, so that thermocouples TC1 and TC2 measured the temperature at two points near to the front anode surface (T_1 near the anode apex and T_2 near the anti-apex, see Fig. 1a) and TC3 at a point near the rear anode surface (T_3). Boron Nitride tubes were used to electrically insulate the thermocouples.

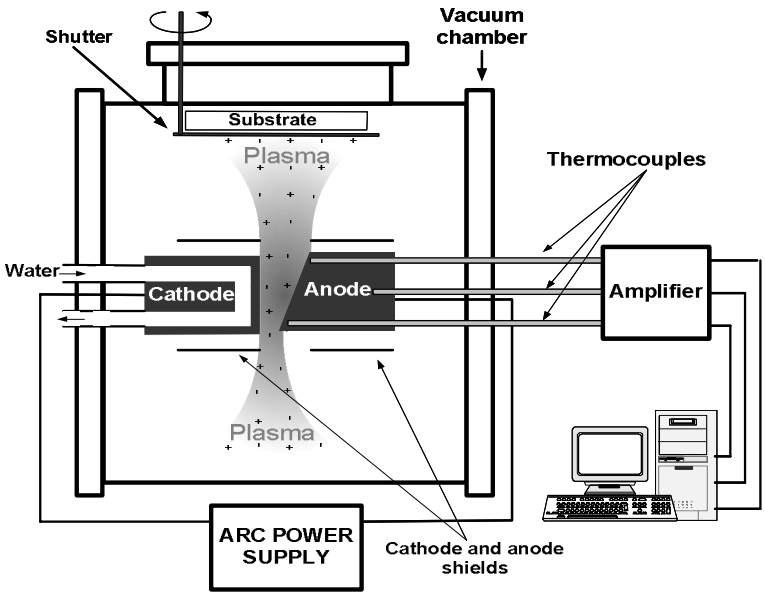

Fig 2. Schematic diagram of the HRAVA experimental setup, plasma expansion and temperature measurement.

Experiments were conducted in a cylindrical vacuum chamber (400 mm length, 160 mm diameter), as shown schematically in Fig.2. The chamber was pumped by a diffusion pump to 2.6×10^{-3} Pa. During the arc, the pressure in the chamber was 2.6×10^{-2} Pa. The discharge was ignited between a water-cooled copper cathode and a co-axial anode. The anode was produced from graphite (POCO DFP-1). The electrodes were surrounded by shields as shown in Fig. 1b and Fig. 2: the cathode by a boron nitride shield and the anode by two cylindrical Mo radiation shields with diameters 60 and 70 mm. The distance between the cathode surface and the anode apex was 18 mm. The arc duration was ≤150 s.

3. Calculation model

The heat flux from the interelectrode plasma to the anode surface was determined using a numerical solution of the heat conduction equation for anode body and the experimentally measured anode temperature distribution.

3.1 Anode temperature calculation

A thermal model of the asymmetric anode considered the 3-D time dependant heat conduction equation in cylindrical coordinates (z,r,φ, Fig.1b) taking into account the temperature T dependence of the thermophysical coefficients of the anode material and the Stefan-Boltzmann radiation from the front, rear and lateral surfaces (Fig.1b):

$$\rho(T)c(T)\frac{\partial T}{\partial t} = \frac{\partial}{\partial r}(\lambda(T)\frac{\partial T}{\partial r}) + \frac{1}{r}\lambda(T)\frac{\partial T}{\partial r} + \frac{\partial}{\partial z}(\lambda(T)\frac{\partial T}{\partial z}) + \frac{1}{r^2}\frac{\partial}{\partial \varphi}(\lambda(T)\frac{\partial T}{\partial \varphi}) + \rho_e(T)J^2 \qquad (1)$$

with the following initial conditions:

$$T(z,r,\varphi,t=0) = T_0 = 300K\ ;$$

and boundary conditions:

$$\lambda(T)\frac{\partial T}{\partial z} = q_{in}(r,z,\varphi,t) - \varepsilon(T)\sigma_{SB}T^4 \qquad \text{at the front anode surface;}$$

$$\lambda(T)\frac{\partial T}{\partial z} = \varepsilon(T)\sigma_{SB}T^4 \qquad \text{at z=0;}$$

$$-\lambda(T)\frac{\partial T}{\partial r} = \varepsilon_{eff}(T)\sigma_{SB}T^4 \qquad \text{at } r = R_a \qquad (2)$$

where ρ, c, λ, ρ_e, ε are the mass density, heat capacity, thermal conductivity, electrical resistivity and emissivity of the anode material, $J = \frac{I}{\pi R_a^2}$ is the current density and $q_{in}(r,z,\varphi,t)$ is the unknown incoming heat flux from the plasma to the front anode surface. The effective emissivity ε_{eff} used in the boundary condition at $r=R_a$ takes into account the heat flux returning from the heat shields to the lateral anode surface [7].

3.2 Anode heat flux model

The observed plasma plume was largely concentrated at the anode apex as shown in Fig. 3.

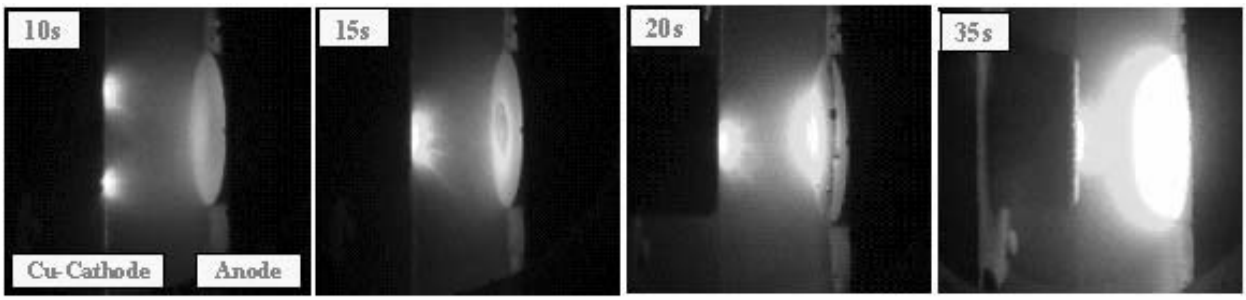

Fig 3. Selected frames demonstrating HRAVA discharge development for I=175A, h=18mm, L2=25mm.

It was assumed that the heat flux incident to the asymmetric anode surface is asymmetric. A simple linear approximation of heat flux was assumed $q_{in}^{asym}(r,\varphi,t) = q_{in}^{sym}(t)\cdot\left[1 + k_{as}^{flux}\frac{r\cos\varphi}{R_a}\right]$ where k_{as}^{flux} is a coefficient of asymmetry for the heat flux, $q_{in}^{sym}(t)$ is the previously defined incoming heat flux for the symmetric anode [7], in the form $q_{in}^{sym}(t) = q_{ss} + q_0 e^{-t/\tau}$, where q_{ss} is the steady state heat flux, ($q_{ss} + q_0$) is the initial heat flux (i.e. at t=0), and τ is the characteristic time for the anode plume to reach the cathode and is obtained from visual observation. The expression of $q_{in}^{asym}(t)$ is obtained assuming that the total net heat fluxes (Q_{in}) for symmetric and asymmetric anodes are equal: $Q_{in}(t) = Q_{in}^{asym}(t) = Q_{in}^{sym}(t) = q_{in}^{sym}(t)\pi R_a^2$. The heat flux may be characterized by an effective anode potential $U_{eff}(t) = \frac{Q_{in}(t)}{I}$ where $Q_{in}(t)$ is the net input power to the anode surface and I is the arc current. Thus heat flux could be expressed finally as:

$$q_{in}^{asym}(r,\varphi,t) = \frac{\left(U_{eff}^{ss} + U_{eff}^{0}e^{-t/\tau}\right)I}{\pi R_a^2}\cdot\left[1 + k_{as}^{flux}\frac{r\cos\varphi}{R_a}\right] \qquad (3)$$

where $U_{eff}^{0} + U_{eff}^{ss}, U_{eff}^{ss}$ are the initial and steady state effective anode potentials, respectively.

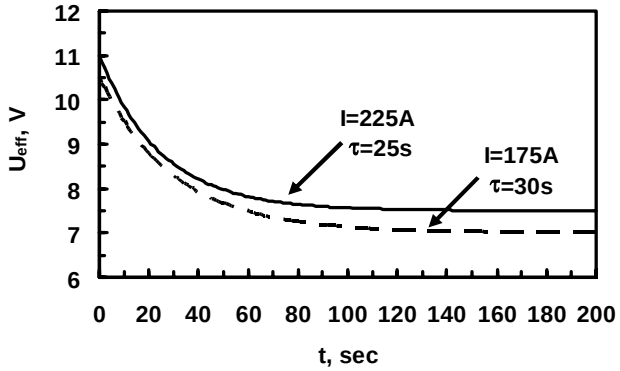

Fig 4. Effective anode potential vs. time

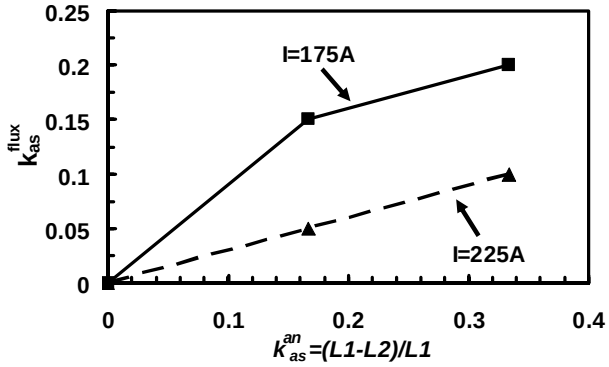

Fig 5. Incoming heat flux asymmetry vs. anode body asymmetry

$U_{eff}^{0} + U_{eff}^{ss}, U_{eff}^{ss}$ were determined from symmetrical anode simulations (with $k_{as}^{flux} = 0$) using the temperature measurements. These values were used for the asymmetric anode simulations. The parameter k_{as}^{flux} was determined by fitting the calculated temperatures (solving the system of equation (1)-(3)) at the thermocouple locations to the measurements.

Eq. (1) was numerically simulated with initial and boundary conditions (2) using a finite-difference method.

4. Results

The dependence of U_{eff} on time is shown in Fig. 4. It is seen that U_{eff} decreased from 10.5 V at t=0 to 7 V in steady-state for I=175A. U_{eff} slightly increased with arc current (up to 11 V at t=0 and 7.5V at steady state for I=225A). k_{as}^{flux} is presented in Fig. 5 as a function of the anode body asymmetry coefficient defined as $k_{as}^{an} = \frac{L1 - L2}{L1}$. It can be seen that heat flux asymmetry increased for more asymmetric anodes.

The time dependent anode temperature T_1 (apex) and T_3 (rear surface) are shown in Fig. 6 for *I=175 A* and *L2=20 mm*. The apex temperature increased with time reaching saturation of about 2000 K at t~80 s after arc ignition. The radial temperature distributions on the front and rear anode surfaces (along the *x-line* as shown in Fig. 1b) are shown in Fig. 7 for symmetric and asymmetric anodes with L2=20 mm. In the case of the symmetric

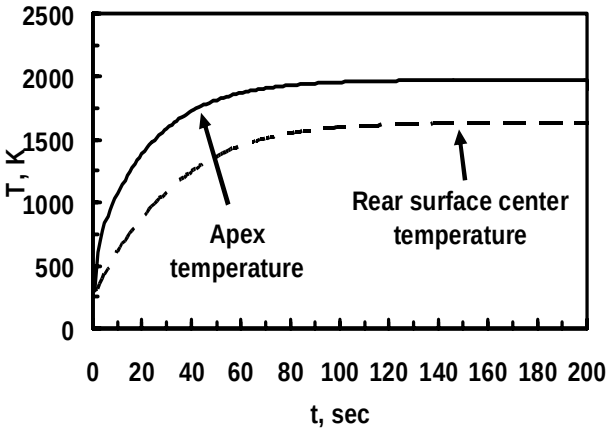

Fig. 6. Asymmetric anode temperature evolution (L2=20mm, I=175A)

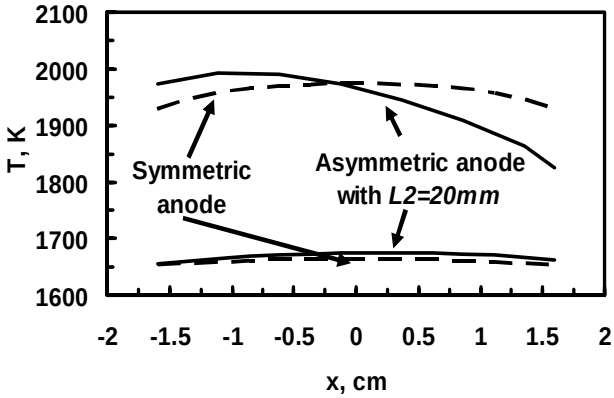

Fig 7. Radial anode temperature distribution. Upper and lower curves - front and rear surfaces, respectively. Solid and dashed curves - asymmetric and symmetric anodes, respectively (*I=175A* and *L2=20mm)*

anode, the maximum surface temperature was at the anode axis ($T_{max}^{sym} = 1975K$), and the temperature decreased slightly in the radial direction.

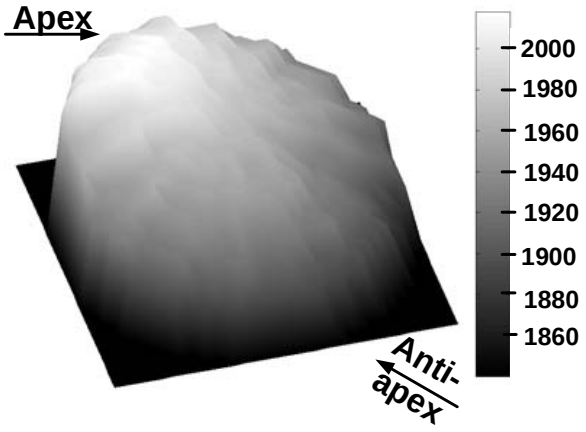

Fig 8. An illustration of face anode surface temperature distribution (*I=175A* and *L2=20mm)*.

The temperature distribution for the asymmetric anode was asymmetric, with the maximum ($T_{\max}^{asym} = 2000K$) shifted from the anode axis in the apex direction (Fig.7). The temperature at the anode boundary near the apex was lower than $T_{\max}^{asym}$. The difference between the maximal and minimal surface temperatures increased from 50 K for the symmetric anode up to 150 K for an asymmetric anode with L2=20 mm for I=175 A. The rear surface temperatures for both anode geometries were close.

A typical front anode surface temperature distribution obtained from 3D calculation is shown in Fig. 8 for *I=175 A* and *L2=20 mm* shows the asymmetry of the anode temperature distribution.

4. Discussions

According to the time dependence of $U_{eff}(t)$, the heat flux to the anode decreases with time. This dependence is a characteristic of a transition from the conventional arc mode to the HRAVA mode. During the transition, the plasma plume developed in the interelectrode gap, expanding and increasing its density. The cathode plasma jets are dissipated in the anode plasma plume [6]. As a result, the radial energy loss from the gap increases while the cathode jet energy impinging on the anode decreases during the transition. Slight increasing of U_{eff} with I may be associated with the previously observed increasing of the plasma temperature with I [6].

The obtained 20% increasing of heat flux from anode center to the apex may be caused by change of the interelectrode distance and therefore the plasma distribution change due to the gap geometry. Slight decreasing of k_{as}^{flux} with I indicates that the plasma distribution in gap was more uniform for higher I.

The sharply increasing anode temperature with time during the initial stage is due to linear heat conduction in the anode body during this stage of arcing when the incoming heat flux was much higher than the energy losses by the radiation. During non-linear heat conduction (anode radiation is important), the rate of temperature rise decreases with time and then the anode temperature reached the saturation determined by the balance of incoming and radiated heat fluxes.

The asymmetric heat flux distribution for the asymmetric anode produced an asymmetric anode temperature distribution. Heat flux was maximal at the anode apex and therefore the maximal temperature was shifted from the anode axis (for the symmetric anode) in direction to the apex (for the asymmetric anode). However, the calculated anode surface temperature located at the anode boundary (see Fig. 7 at x=-1.6) was lower than the maximal apex temperature due to the lateral anode surface radiation.

As the anode body asymmetry reduced with distance from the asymmetric anode face to rear surfaces then the radial temperature distribution is more symmetric in direction to the rear surface and it is close to that at the rear surface for symmetric anode.

Abstract

Polypropylene (PP) foils were coated with thin SiO_x layer elaborated in DECR plasma reactor from a mixture of hexamethyldisiloxane and oxygen. According to contact angle measurements, the surfaces of PP become hydrophilic after the deposition of ultra thin SiO_x film. AFM analysis revealed the formation of irregular structures, which disappear with increasing film thickness. XPS showed that the films composition transforms into more oxidized state as the deposited film thickness increases.
Keywords: Polypropylene; SiO_x films; Contact angle; XPS; AFM

1-Introduction

Polypropylene (PP) is one of the common polymers with very wide field of applications due to their low density, flexibility, chemical inertness and cost-effectiveness. However, PP has very low surface energy which has limited the widespread use of this material. Therefore, the surface modification techniques that can transform these inexpensive materials into highly valuable products have become an important part of the polymers industry. Various surface treatment techniques have been developed to improve the wettability and adhesion properties of PP surfaces without affecting their excellent bulk properties. Some of the common used surface treatment techniques include: plasma, corona discharge, ion beam and microwave irradiation [1-4]. In many cases, surface treatment tends to create an increased surface tension, which is often explained by the formation of new functional groups on the surface of the polymer such as hydroxyl (OH) and carbonyl (C=O) groups [5]. However, it is well established that these surface modifications are degraded in time (aging effects), when exposed to the atmospheric conditions [6]. Hence, new surface modification technique is required to get the polymer surfaces free of damage and having good wettability with a long lifetime. A coating of polymer surface was found to be relatively successful in enhancing the wettability of polymers yielding a more stable hydrophilic treatment.

In this study, surface modification of PP films was carried out via the deposition of thin SiO_x film using plasma enhanced chemical vapor deposition (PECVD). Such films find great potential in biomaterial application and in microelectronics industry [7-8]. The films were elaborated in a microwave DECR plasma reactor from a mixture of hexamethyldisiloxane (HMDSO) and oxygen.

2. Experimental details

PP films of 100 µm thickness were used in all plasma deposition experiments. The polymer was cut into square shaped samples (20 x 20 mm^2) and they were washed with acetone in an ultrasonic washer and dried in an ambient air prior to plasma deposition. The precursor used for PECVD deposits was the hexamethyldisiloxane (HMDSO) which chemical formula is $(CH_3)_3$-Si-O-Si-$(CH_3)_3$.

The PECVD coating experiments were performed in a DECR reactor (2.45 GHz) illustrated in figure 1. The apparatus and its main features have been fully described in more detail in ref [9]. During deposition, the PP substrates were located 18 cm below the glow discharge zone. The deposition was carried out from a mixture of HMDSO and O_2 in the 1:9 proportions. The microwave power and the gas pressure were kept constant at 400 W and 2 mTorr respectively. According to these discharge parameters, the deposition rate was estimated to be 0.047 nm/s [10]. Deposition time was varied in order to observe different stages of the film growth on the polymer substrate.

Films deposited on PP substrates were characterized by contact angle measurements in order to investigate direct effects of the plasma treatment on their wetting property. The measurements were

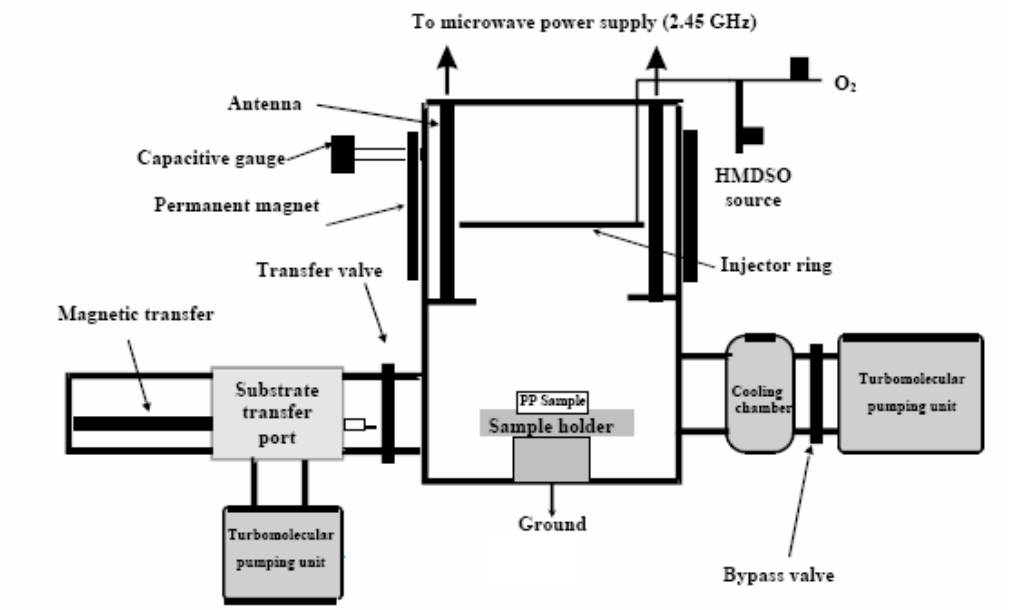

Figure 1: Schematic view of the DECR reactor.

performed using Digitrop contact angle meter made by GBX scientific. Mean value of all contact angles data were averaged from three to five replicates. The measurements were carried out immediately after plasma deposition, at room temperature and atmospheric pressure. For surface energy estimation, different test liquids with different surface free energy values have been used (de-ionized water, formamide, and diiodomethane). The surface energy and its related components were calculated using Owens and Wendt model [11].

The morphology of the deposited film surfaces was studied by atomic force microscopy (AFM) technique. The AFM images were recorded by an Autoprobe CP from Park Scientific Instruments using tapping^{TM} mode and scan rate of 1Hz/line. All scans were characterized by measuring the root-mean-square roughness (R_{rms}) and the arithmetic average of the absolutes values of the surface height (R_{av}) [12]. In order to obtain representative information, different areas were studied on each sample.

Atomic composition was determined by X-ray photoelectron spectroscopy (XPS). The measurements were performed on a VG Scientific photoelectron spectrometer using the monochromatic AlKα X-ray source ($h\upsilon$=1486.6 eV) at normal photoelectron emission angle. The XPS spectra were referenced with respect to the carbon C1s core level at binding energy of 284.4 eV to eliminate charging effects. A constant value of full width at half maximum (FWHM) was used for spectral deconvolution, using a Gaussian type of fitting. The Si 2p peaks were resolved into three components according to the method described by Alexander et al [13].

3. Results and discussion

The extent of surface modification of PP films achieved because of plasma coating has been evaluated by using the contact angle measurement. Surface free energy and its related components for untreated and coated PP films were calculated by measuring the contact angles for three testing liquids (water, formamide and diiodomethane). Figure 2 shows the variation of the contact angle as a function of the deposited film thickness. The values of contact angle decreased rapidly with increasing deposited film thickness for all testing liquids and then reached a constant minimum level. For untreated PP film, the water contact angle was in the order of 99° then decreased significantly to only 27° after the deposition of about 6.6 nm thick SiO_x film on PP substrate. Increasing film thickness to about 28 nm did not improve the hydrophilicity much further. The obtained values of water contact angle were in the range of that found for glass substrate [14]. Figure 3 shows the variation of the surface free energy and its related components as function of deposited film thickness. The results derived from the calculations using the Owens and Wendt model [11], showed that the surface tension of untreated PP was about 27 mJ/m^2. Especially the polar part is near 0.5 mJ/m^2 only. After the deposition of ultra thin SiO_x layer of about 3 nm, there is a considerable increase in the total surface energy and the polar part, which reached a maximum value of about 35 mJ/m^2

and 64 mJ/m^2 respectively. The dispersion component remains practically unchanged, which indicates that the polar component is responsible for the wettability of the material. Increasing film thickness did not improve the hydrophilicity much further. The loss of PP surface hydrophobicity during DECR plasma deposition is believed to arise from the formation of polar SiO_x layers.

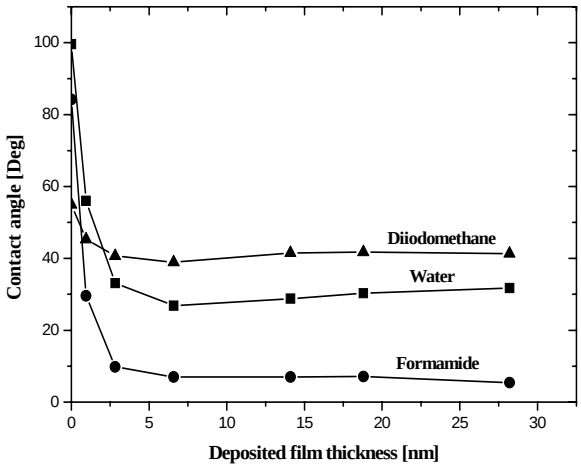

Figure 2: Measured contact angle of untreated and SiO_x coated PP as a function of deposited film thickness.

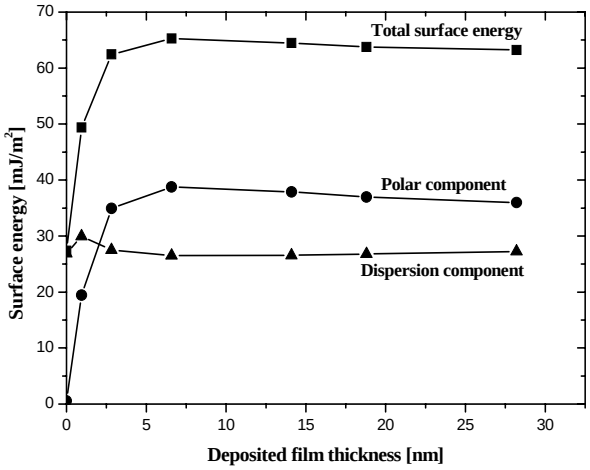

Figure 3: Computed surface energy and its related components.

AFM images of PP surface before and after plasma coating are presented in figure 4. The analyzed area was 2x2 μm^2. The topography shown in Figure 4a is typical of that found for untreated PP samples [15]. The surface roughness (R_{rms}) was in the order of 4.8 nm. For PP coated with 6.6 nm thick SiO_x layer, AFM image showed the formation of irregular structure on PP surface (Figure 4b). This AFM image also shows the presence of microvoids of considerable depth. The surface roughness (R_{rms}) was slightly increased from 4.8 to 6.2 nm. This kind of topography structure has also been observed by Segundo et al [16] for SiO_x films grown by microwave method. The topographical modification induced by plasma deposition is attributed to the ablation effect (etching effect) operating during the early phase of the deposition process in presence of oxygen active species. The ablation process is also supported by the VUV radiation. For thicker coating (28 nm), the irregular surface topography structure has vanished and replaced by the growth of nearly regular ripple structure as can be seen in Figure 4c. The roughness of the surface is however, not changed (R_{rms} = 6.5 nm).

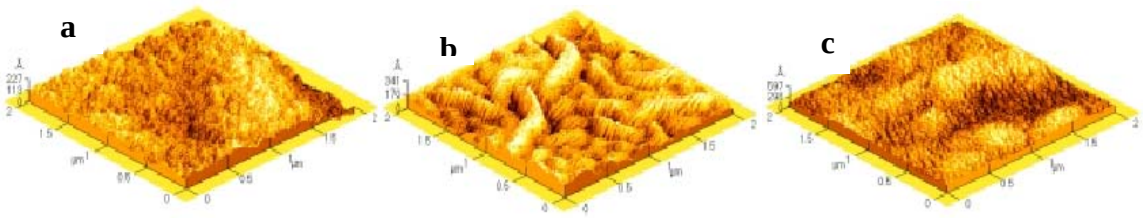

Figure 4: Surface roughness of: (a) untreated PP (R_{rms} = 4.8 nm), (b) PP coated by a 6.6 nm thick SiO_x film (R_{rms} = 6.2 nm) and (c) 28 nm thick SiO_x film (R_{rms} = 6.5 nm).

Table 1 summarizes the Si, O and C content in at.%, obtained from XPS data, of SiO_x films with various film thicknesses. For ultra thin layers, the detected signal of carbon may include also the carbon of the PP substrate. The deposited films were characterized by high proportions of C, which decrease with increasing film thickness. The significant carbon content may be attributed to the existence of an interlayer

between the organic substrate and the PECVD coating. This interlayer has been revealed by many workers [17]. The origin of this interphase was found to be ablation/redoposition process involving volatile organic fragments from the polymer substrate during the first instants of the deposition process. This region was found to consist of cross-linked layer with varying chemical composition. The ablation (etching) of the polymer may be resulted from the action of oxygen active species and VUV photons.

SiO_x film thickness (nm)	Si 2p (%)	O 1s (%)	C 1s (%)	Si 2p peaks components (%)		
				102.1 eV	102.8 eV	103.4 eV
2.8	16	32	52	33	44	23
6.6	21	38	41	22	58	20
28	27	50	23	34	30	36

Table1: Atomic composition and results of the curve fitting of Si 2p peak for SiO_x coated PP.

High resolution of the Si 2p peaks has been performed in order to quantify the silicon environments of the deposited layers. A constant value of full width at half maximum (FWHM) was used for spectral deconvolution, using a Gaussian type of fitting. The Si 2p peaks were resolved into three components (Figure 5) at different binding energies according to a method described by Alexander et al [13]. The 102.1 eV peak was associated with Si bound to two oxygen atoms (unoxidized environment $Si(O-)_2$), the 102.8 eV peak was associated with Si bound to three oxygen atoms (partly oxidized environment $Si(-O)_3$) and the 103.4 eV peak was associated with Si bound to four oxygen atoms (silicon dioxide $Si(-O)_4$). The remaining bonding requirements of the silicon are fulfilled by a various combination of carbon and hydrogen atoms [18]. Figures 5a, 5b and 5c show the effect of film thickness on the distribution of the Si 2p peak amongst the three Si environments. The deconvolution results show that the Si 2p peak shifts toward the high binding energy values as the film thickness increases. For 2.8 nm thick SiO_x films, the partly oxidized environment ($Si(-O)_3$ binding energy 102.8 eV) is the major component (Table 1). When the films thickness is increased, the proportion of unoxidized Si environment ($Si(-O)_2$ binding energy 102.1eV) decreases in favor of the partly oxidized Si environment. At the thickness of about 28 nm, the proportion of partly oxidized Si environment decreases in favor of the oxidized Si environment ($Si(-O)_4$ binding energy 103.4 eV). The deconvolution of the Si 2p peak indicates that the deposited film transforms into more oxidized state when the film thickness increases.

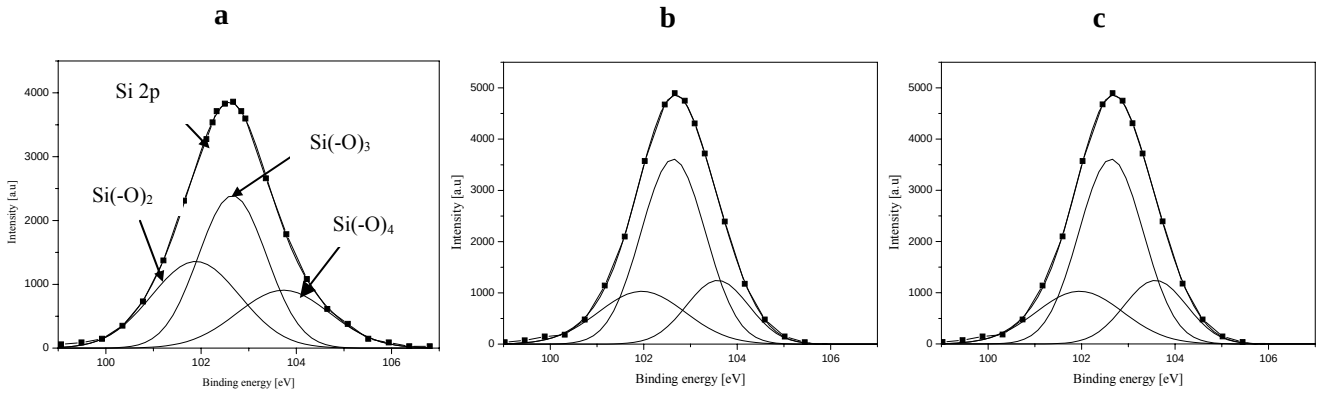

Figure 5: Distribution of the Si 2p signal among the three silicon environments for: 2.8 nm thick SiO_x film (a), 6.6 nm thick SiO_x film (b) and 28 nm thick SiO_x film (c).

4. Conclusions

DECR plasma deposition of thin SiO_x films elaborated from mixture of hexamethyldisiloxane and oxygen on highly hydrophobic PP surface, induces the formation of polar layers. According to the contact angle measurements, the polar component of the surface energy showed a considerable increase from about 0.5 to 35 mJ/m^2 after the deposition of ultra thin SiO_x layer and then stayed nearly at the same level still for

thicker coating. For ultra thin SiO_x layer, AFM images showed the formation of irregular in shape and size structure, due to substrate ablation effect which operates during the very first instants of the film growth. Increasing film thickness, the irregular structure was replaced by the growth of regular ripple structure. The surface roughness was increased from 4.8 nm to 6.2 nm. XPS results show that the deposited films are characterized by high proportions of carbon which decrease with increasing film thickness indicating the presence of an interlayer between the SiO_x film and the polymer substrates. High resolution of the Si 2p peak indicated that as the deposited film thickness increases, the films composition transforms into more oxidized state. The observed improvement in PP wettability may result from the combination of topology modifications (revealed by AFM images) and the chemical composition of the SiO_x deposited layer.

Photographing Impact of Plasma-Sprayed Zirconia and Amorphous Steel Particles on Hot and Cold Glass Substrates

A. McDonald[1], M. Lamontagne[2], S. Chandra[1], C. Moreau[2]

[1]*Department of Mechanical Engineering, University of Toronto, Toronto, Ontario, Canada*

Abstract

Plasma-sprayed molten yttria-stabilized zirconia and armorphous steel (38 – 55 μm diameter) were photographed during impact (velocity 135 – 220 m/s) and spreading on a smooth glass surface that was maintained at either room temperature or 400°C. As a droplet approached the surface, it was sensed by a photodetector and after a known delay, a laser was triggered to illuminate the spreading splat. The splat was photographed with a CCD camera. A rapid two-color pyrometer was used to collect the thermal radiation from the impacting and spreading particles to follow the evolution of their temperature and size. The molten particles that impacted a surface at room temperature ruptured and splashed after impact leaving only a small central core adhering to the substrate. On a surface held at 400°C, there was no splashing and a circular splat remained on the surface. Splats on a glass surface held at room temperature had a large maximum spread diameter, almost three times that on a hot surface. The cooling rate on a cold surface was significantly lower than that on a hot surface, suggesting that thermal contact resistance was much greater.

1. Introduction

Plasma spraying is used to deposit coatings that protect against material degradation processes such as wear, erosion, or corrosion. A high-temperature ionized gas jet is used to melt and accelerate metal or ceramic particles to coat a substrate. The molten or partially molten particles impact the substrate, spread while cooling down, and solidify on the substrate or on previously deposited layers. The quality and strength of the coating depends on the size and degree of splashing of the particles after impact. Many experimental studies have been conducted to identify the parameters that influence the size and morphology of the droplets after impact. Aziz and Chandra [1] have presented photographs of tin droplets spreading on cold and heated stainless steel surfaces in intervals of a few milli-seconds after impact. They found that as the droplet impact velocity increased, the maximum diameter of the splat increased and significant splashing occurred. Bhola and Chandra [2] also found that large impact velocities caused impacting droplets to fragment. They used the Rayleigh-Taylor instability to determine the number of satellite droplets formed after impact.

Fukumoto, et al. [3] found that, for nickel and copper droplets in a thermal spray simulated experiment, increasing the substrate temperature reduced the occurrence of splashing and produced disk-like splats. They defined a "transition temperature" as the temperature of the substrate at which 50% of the splats changed from a splash morphology to a disk-like morphology. Since it was shown that impact on cold substrates enhance splashing and fragmentation [3], Jiang, et al. [4] have shown that removal of condensates and/or adsorbates from a cold stainless steel substrate may eliminate splashing and splat fragmentation of impacting molten ZrO_2 and produce contiguous, disk-like splats. The formation of the disk-like splats were attributed to improved contact between the splat and substrate, in the absence of the condensates and adsorbates. It was also shown that the same contiguous, disk-like morphology occurred for splats on a substrate held at 500°C.

Many images have been presented of the impact and spread of low velocity (1 - 10 m/s) droplets on flat surfaces. However, it is difficult to capture images of the spreading particles in the actual plasma-spray process (100 – 250 m/s). Mehdizadeh, et al. [5] and McDonald, et al. [6] have photographed plasma-sprayed molybdenum droplets impacting cold and hot glass by using a CCD camera and long-range microscope. A rapid two-color pyrometer was also used to obtain the size and temperature evolution during spreading. The two-color pyrometric method, as described by Vardelle, et. al [7], calculates the splat size and temperature from the ratio of the intensities of radiation collected at two different wavelengths. The two-color pyrometric method was used by Moreau, et al. [8] to show that there is a period of rapid decrease of the size of the splat after reaching the maximum extent. This was attributed to contraction and fragmentation of the splat due to surface tension forces.

Studies of the microstructure of splats and coatings have shown that the cooling rates of splats on cold substrates differ significantly from those on heated substrates. Fukumoto, et al. [3] found that the

microstructure of the splat on the hot substrate was fine, columnar, flat, and non-porous, while on the cold substrate it was composed of isotropic coarse grains. The transitional change of grain size and quality with increasing substrate temperature indicated that the cooling rate of the splat on the hot substrate was larger than that on the cold substrate. However, actual temperatures during the cooling of the splat were not measured. McDonald, et al. [6] measured the cooling rates of molybdenum splats on cold and heated glass from the temperature evolution obtained from two-color pyrometry. It was found that the cooling rate on hot glass was an order-of-magnitude larger than that on glass held at room temperature.

This study extends the work of McDonald, et al. [6] by photographing the impact and spread of zirconia and steel droplets on glass held at room temperature and at 400 ^{o}C. The steel used in this study is an amorphous iron-chromium based alloy with chemical composition, 44% Cr, 48% Fe, 6% B, 2% Si, and traces of C and S and melting point at ~1550 ^{o}C. A CCD camera was used to capture images of the splat at several instances during spreading. The maximum spread diameter was measured from the images. The temperature evolution of the splat during spreading was used to calculate the cooling rate. A high speed two-color pyrometer was used to measure the temperature of the particles after collision and during spreading on a flat, smooth glass surface.

2. Experimental Method

The experimental assembly and method have been described in detail by Mehdizadeh, et al. [5] and McDonald, et al. [6]. A schematic diagram of the experimental setup is shown in Figure 1.

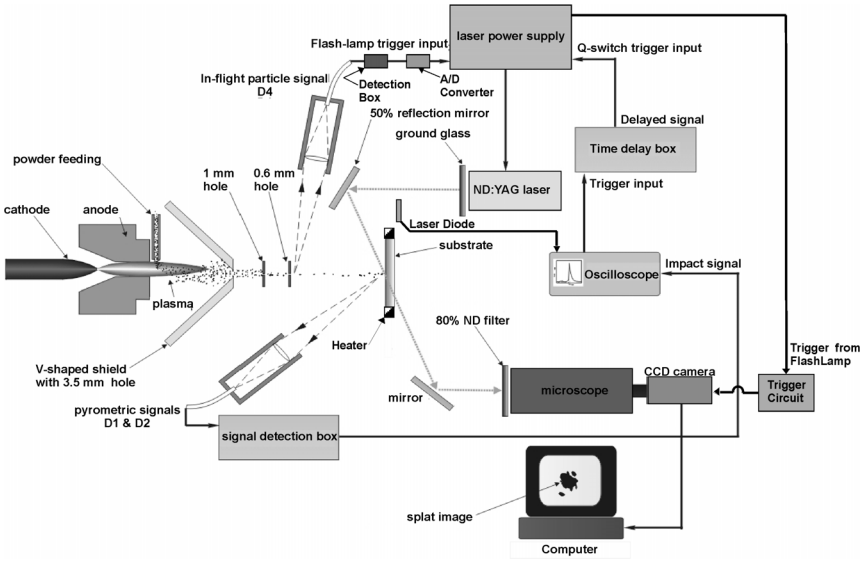

Figure 1. Schematic of the experimental assembly.

A SG100 torch (Praxair Surface Technologies, Indianapolis, IN) was used to melt and accelerate the dense, amorphous steel (LMC-M, Liquidmetal Technologies, USA) and zirconia (#825, Amperit, USA) powder particles, seived to +38 –55 µm. The powder feed rate was less than 1 g/min. The substrate was a glass microscope slide (Fisher Scientific, Pittsburgh, PA) that was washed with water and ethanol and dried in an oven at 140°C for 30 minutes.

The plasma torch was passed rapidly across the glass substrate. In order to protect the substrate from an excess of particles and heat, a V-shaped barrier was placed in front of the torch.

The thermal radiation of the particle was measured with a rapid two-color pyrometric system.This system included an optical sensor head that consisted of a custom-made lens, which focused the collected radiation, with a 0.21 magnification, on an optical fiber with an 800 µm core [5,6]. This optical fiber was covered with an optical mask that was opaque to near infrared radiation, except for three slits. The two smaller slits, with dimensions of 30 µm by 150 µm and 30 µm by 300 µm, were used to detect the thermal radiation of the particles in flight. The radiation was used to calculate the temperature, velocity, and diameter of the in-flight particle [9]. The largest slit, measuring 150 µm by 300 µm, was used to collect thermal radiation of the particle as it impacted and spread on the substrate. With the thermal radiation from this slit, the splat temperature, diameter, and cooling rate were calculated at 100 ns intervals after impact.

The collected thermal radiation was transmitted through the optical fiber to a detection unit that contained optical filters and two photodetectors. The radiation beam was divided into two equal parts by a beam splitter. Each signal was transmitted through a bandpass filter with wavelength of either 785 nm or 995 nm and then detected using an avalanche silicon photodetector. The ratio of the radiation intensity at these wavelengths (referred to as D_1 and D_2, respectively) was used to calculate the particle temperatures with an accuracy of ± 100°C [9].

The thermal emission signals captured by the photodetectors showed the temporal positions of the particle as it passed through the field of view of each of the optical slits. When the particle was not in an optical field of view, the signal voltage was zero. Two small peaks were produced by thermal emissions from the particle as it passed through the first two small slits. The droplet average in-flight velocity was calculated by dividing the known distance between the centers of the two slits by the measured time of flight. A plateau on the thermal emission signal corresponded to the presence of the in-flight particle in the field of view of the third and largest optical slit before impact. Upon impact, the signal increased as the particle spread and eventually decreased as the particle cooled down and/or splashed out of the field of view.

To illuminate the impacting particle, a 5±2 ns duration pulse of light from a Nd:YAG laser (Continuum Minilite, Santa Clara, CA) was used. Since the flashlamp of the laser had to be triggered at least 150 μs before it was pulsed, an optical sensor (labelled D_4 in Fig. 1) was positioned to detect thermal radiation from a particle immediately after it exited the 0.6 mm hole in the third shielding plate (Fig. 1). When the particle entered the third slit field of view of the optical fiber, a signal was sent to trigger the laser after a controlled time delay. This permitted illumination of the substrate at different time intervals after impact and during spreading of the droplet.

A 12-bit CCD camera (QImaging, Burnaby, BC) was used to capture images of the spreading particles. The electronic shutter of the camera was triggered to open by a signal from the flashlamp of the laser. The camera was connected to a long-range microscope (Astro-optics Division, Montpelier, MD) that had an 80% neutral density (ND) filter to attenuate the intensity of the laser beam. The images captured by the camera were digitized by a frame grabber and recorded on a personal computer. Since the images were not photographed directly, but rather, their reflection in a mirror that was at an angle relative to the substrate, the digitized images were rotated and shortened on both dimensions.

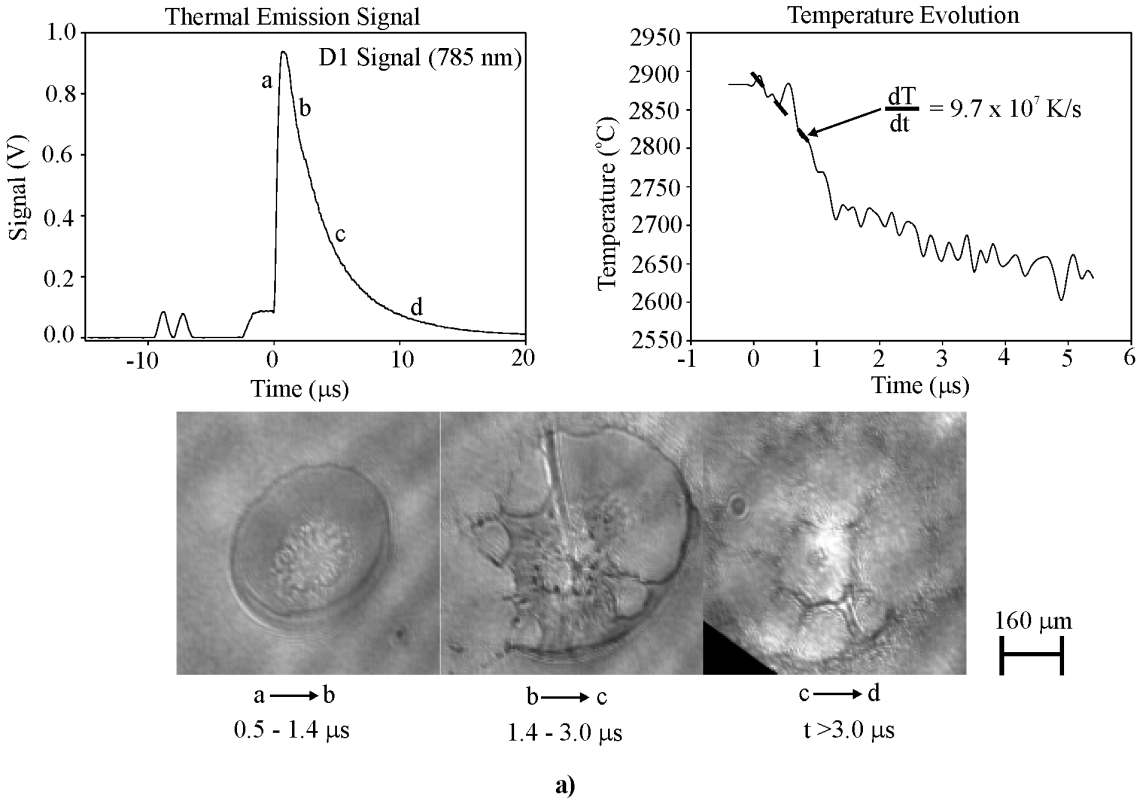
3. Results and Discussion

Impact on glass at room temperature

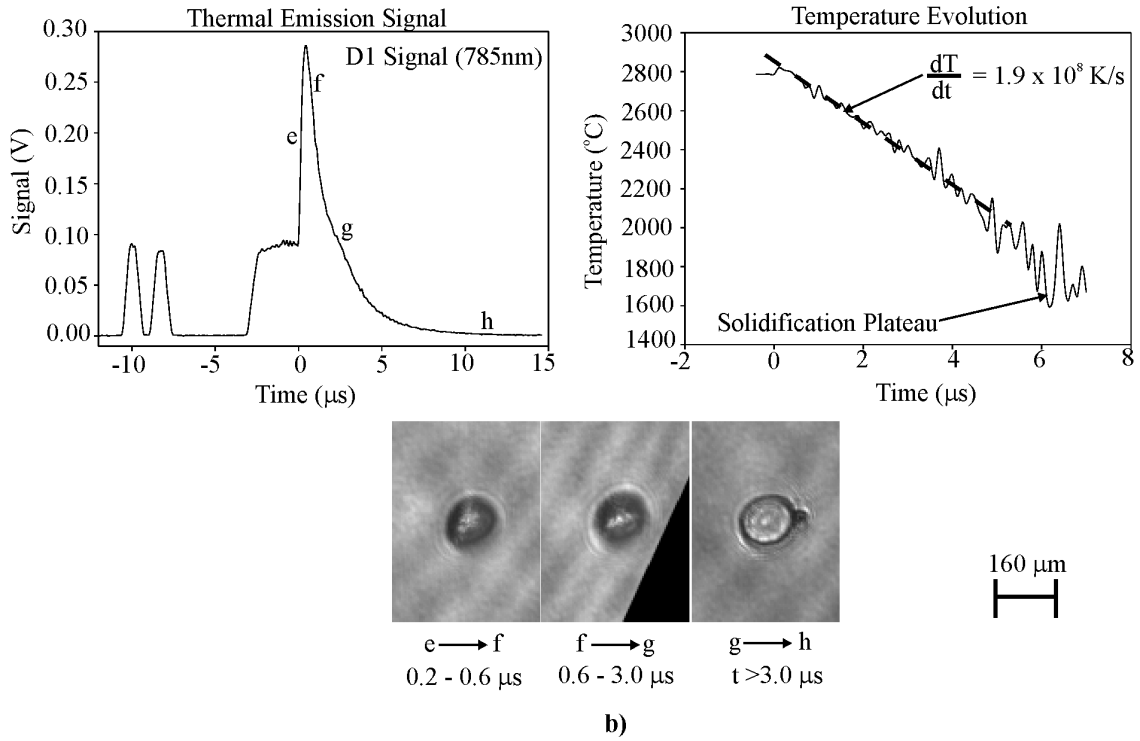
Typical thermal emission signals and images showing the evolution of the splat size and morphology after impact on cold glass are shown in figures 2a and 3a, respectively for zirconia and steel. The average impact velocities of the zirconia and steel particles were 200 m/s and 175 m/s, respectively. The average in-flight temperatures were 2750 ^{o}C and 2910 ^{o}C for zirconia (melting point: 2700 ^{o}C) and steel (melting point: 1550 ^{o}C), respectively. According to the signals, between points *a* and *b*, the splat reaches the maximum spread diameter within 2 μs after impact. As determined from the images collected with the CCD camera and the thermal emission signals, the average maximum diameter of the zirconia splats on cold glass is approximately 450 μm and that of steel is approximately 400 μm. The images show that as the particles on cold glass spread to the maximum extent, they become thin film liquid splats that begin to disintegrate, approximately 1.5 μs after impact (Fig.2a and 3a). The splat material eventually splashes out of the fields of view of the camera and the thermal emission detectors, leaving a central solidified core on the glass surface.

Impact on glass at 400 ^{o}C

Figures 2b and 3b show that on glass held at 400 ^{o}C, there was almost no splashing or break-up. The splats, for both materials, spread to a maximum diameter of approximately 200 μm. Beyond the maximum extent, the splats receded to a diameter smaller than the maximum diameter. In figure 3b, it is evident that the diameter of the steel splats decrease significantly, possibly due to surface tension forces that pull back the liquid film before significant solidification occurs. Some investigators have found that the splat does not begin to solidify until after reaching the maximum splat diameter [10], enabling the liquid to recoil due to



a)



b)

Figure 2. Photodetector signals and images of zirconia at different times after impact on glass at a) room temperature and b) 400 °C

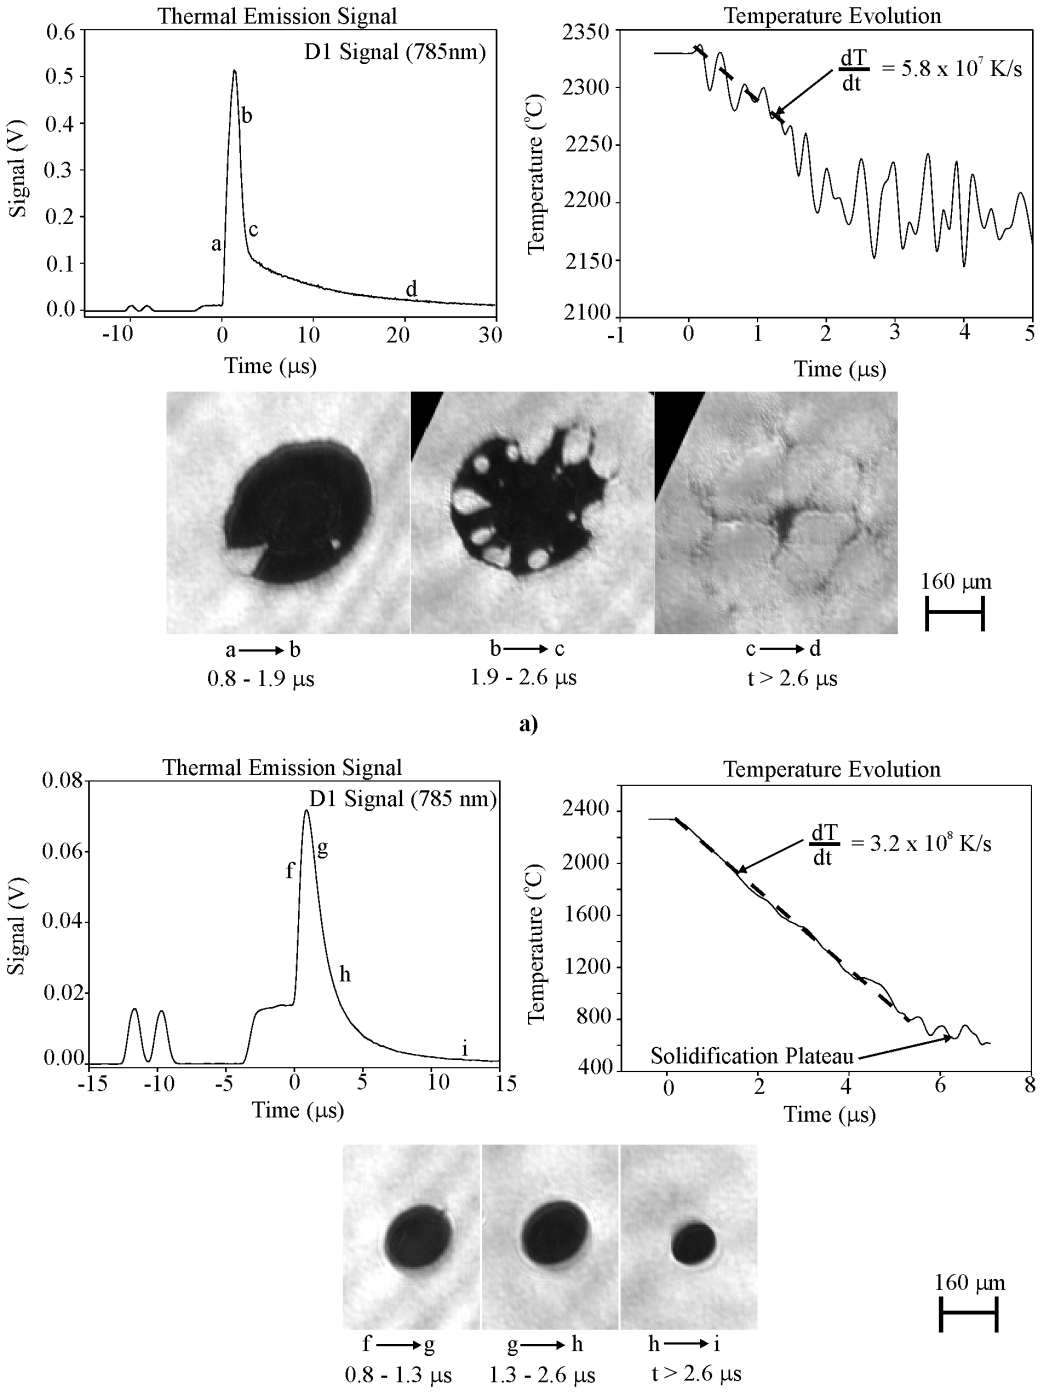


Figure 3. Photodetector signals and images of armacor at different times after impact on glass at a) room temperature and b) 400 °C.

surface tension forces after reaching the maximum spread extent. The thermal emission signals show that the maximum extent occurs within 0.5 μs after impact for both materials. Comparison of the images and thermal emission signals for the splats on cold and hot glass, shows that the maximum spread diameter on cold glass is almost three times larger than that on hot glass. McDonald, et al. [6] and Moreau, et al. [8] have found similar results for molybdenum impact on hot and cold glass.

Splat Temperature Evolution

The splat temperature evolution and the average liquid cooling rates are shown in figures 2 and 3. The cooling rates on the hot glass (order of 10^8 K/s) were much larger than that on the cold glass (order of 10^7 K/s), suggesting that there is lower thermal contact resistance between the splat and the hot glass. The contact resistance between the cold glass and splat may be due to a gas barrier composed of vaporized adsorbates/condensates [4] and entraped air [11].

On the cold glass, the splat liquid cooling rates were calculated from temperatures at the point of impact to the maximum spread extent and before splashing, to ensure that the temperature decrease was not due to loss of material out of the pyrometric fields of view. Since significant splashing did not occur on hot glass, the cooling rate was calculated from temperatures at the point of impact to the solidification plateau (Fig. 2 and 3). The solidification plateau for zirconia occurred at a temperature that was approximately 10% lower than the melting point. For the amorphous steel, the plateau occurred at a temperature that was about 65% lower than the melting point. This, coupled with the large cooling rates, indicates that there was undercooling of the splats on hot glass [12].

4. Conclusion

The influence of substrate temperature on the splat morphology, the maximum spread diameter, and the cooling rate of plasma-sprayed zirconia and steel particles was studied. The flattening of the droplet was monitored by a rapid two-color pyrometer and the thermal emission signals were used to calculate the splat temperatures and cooling rate.The splat was photographed after impact with a CCD camera.

Molten particles that impacted a surface at room temperature disintegrated and splashed after impact leaving only a small central portion adhering to the substrate. On a surface held at 400°C, there was no splashing and a circular splat remained on the surface. Splats on a glass surface held at room temperature had a large maximum spread diameter, approximately three times that on a hot surface. The cooling rate on a cold surface was much lower than that on a hot surface, suggesting that thermal contact resistance was much lower on the hot surface.

Abstract
We present optical emission spectroscopy studies of atmospheric pressure glow discharges in flowing pure helium (He), and He/nitrogen (N_2) mixtures. Two different metallic high-voltage electrode geometries have been examined, namely planar and cylindrical, the grounded dielectric-covered electrode being planar. The gap distributions of gas temperature have been evaluated from rotational spectra of molecular nitrogen ion emissions.

Keywords: Atmospheric pressure**,** dielectric barrier, glow discharge, non-thermal plasma, helium, rotational temperature, optical emission spectroscopy

1. Introduction

Dielectric barrier discharges (DBD) at atmospheric pressure are steadily gaining importance since they obviate the need for expensive vacuum systems and can thereby reduce production costs [1]. The gas temperature, T, in the discharge is evidently of great importance, because an excessively high T value can damage thermally-sensitive materials, for example polymers. The purpose of this research has therefore been to measure T in DBDs using optical emission spectroscopy (OES), which has the great advantage of being non-intrusive and non-perturbing. This is accomplished by analyzing high-resolution rotational bands in the emission spectra of suitable electronically-excited molecular species in the discharge. Several molecules have been used in the past for this purpose, but the most frequently studied are nitrogen bands from the Second Positive System (SPS) of N_2 and the First Negative System (FNS) of N_2^+. The latter has the advantage that rotational structure can be fully resolved even with a spectrograph of average performance, and that the rotational temperature, T_{rot}, can be determined from a conventional Boltzmann plot [2].

2. Experimental arrangement

Using the glass-walled DBD apparatus (Fig. 1) described by Radu et al. [3], we have studied atmospheric pressure discharges in flowing He and He/N_2 mixtures, these being excited by audio-frequency (1 to 10 kHz) high voltage (HV). Two different metallic HV electrode geometries have been examined, namely a planar, polished stainless steel electrode with rounded edges, 2.54 cm in diameter, and a cylindrical steel electrode with a radius of 3.15 mm and a length of 26.3 mm. The grounded dielectric-covered electrode is a 1.6 mm thick Al_2O_3 ceramic plate, metallized on its bottom surface.

Optical emission spectroscopy (OES) was studied using a 0.5 m focal length spectrometer (Acton Research SpectraPro 500i), coupled to an ICCD array detector (Roper Scientific PI-MAX 512RB). The spectrometer has a resolution of 0.05 nm at 435.8 nm using a 1200 g/mm grating and a 10-μm slit. Light from the discharge was directed to the spectrometer slit by a mobile optical system, which can provide a (one-dimensional) spatial resolution down to 100 μm. However, to achieve an acceptable signal-to-noise ratio, most of the experiments had a spatial resolution of 250 μm. The rotational band spectra were recorded using an entrance slit width of 10 μm.

Using the R branch of FNS $N_2^+(B^2\Sigma_u^+, v'=0 \rightarrow X^2\Sigma_g^+, v''=0)$ bands near 391 nm, we have measured spatial distributions of T_{rot} for different electrode geometries, gap spacings and gas mixture compositions.

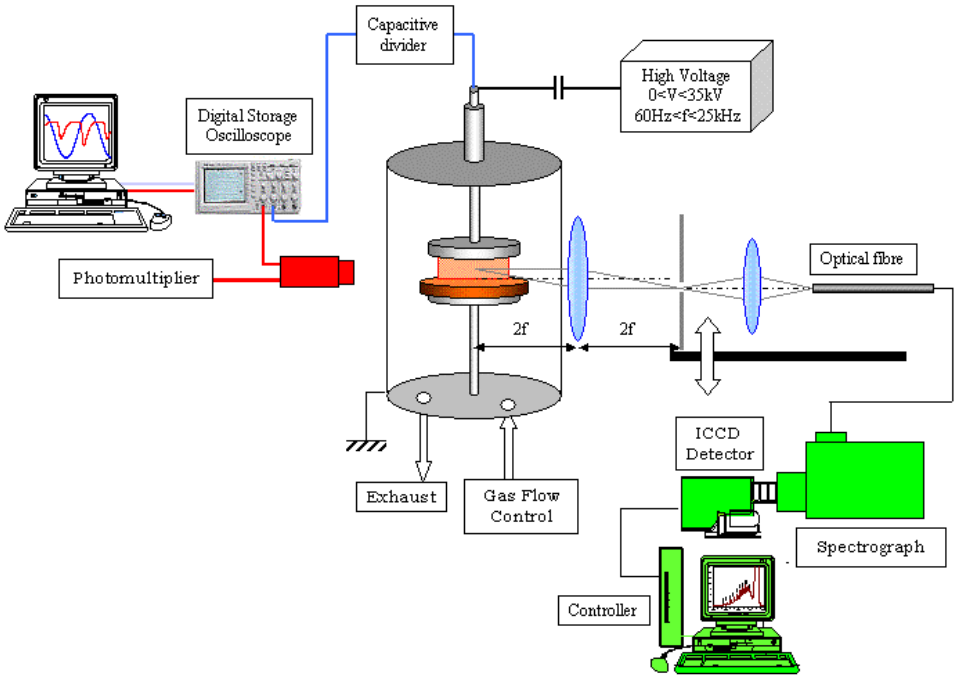

Figure 1. Experimental set-up.

3. Results and Discussion

The optical emission spectrum (Fig. 2) taken between 350 nm and 860 nm of an atmospheric pressure glow discharge (APGD) in high purity helium is very similar to that reported in the literature [4]. This spectrum was obtained in the plane-plane configuration, but it differed little from that obtained in the other configuration. The only differences between the two configurations or between two different axial positions are the relative intensities of the various emission lines. The frequency and amplitude of the voltage applied to the upper electrode and the gap length were also found to influence emission line intensities. However, in each of the discharges emission lines from SPS $N_2(C^3\Pi_u - B^3\Pi_g)$ and FNS $N_2^+(B^2\Sigma_u^+ - X^2\Sigma_g^+)$ bands, triplet oxygen at 777 nm ($3^5P \rightarrow 3^5S$), and the $3^3S \rightarrow 2^3P$ transition at 706.5 nm from helium could be clearly identified.

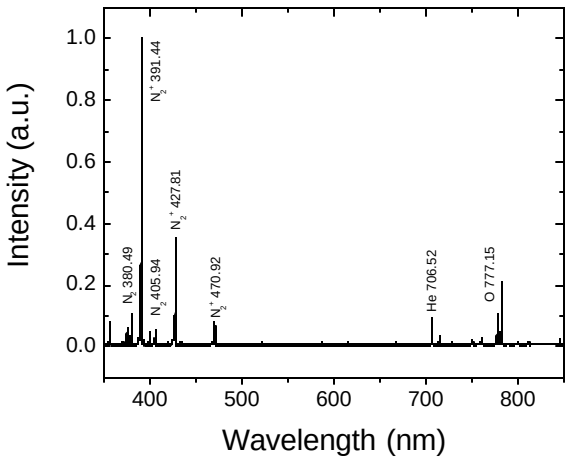

Fig. 2 A typical emission spectrum from high purity helium APGD.

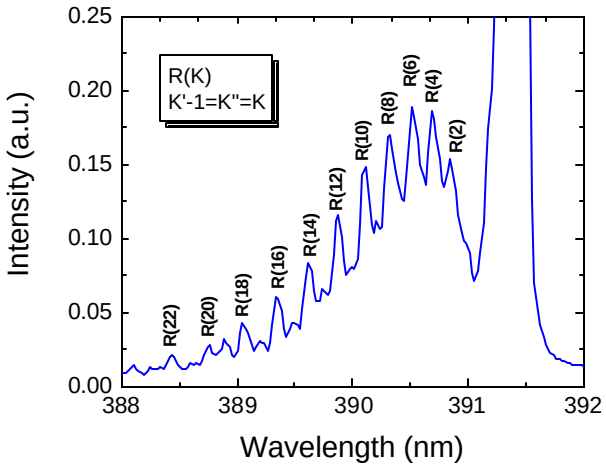

Fig. 3 A typical $N_2^+(B^2\Sigma_u^+, v'=0 \rightarrow X^2\Sigma_g^+, v''=0)$ spectrum from helium APGD.

The most intense emission is the headband of P branch from the $N_2^+(B^2\Sigma_u^+, v'=0 \rightarrow X^2\Sigma_g^+, v''=0)$ transition at 931.44 nm, while helium lines were observed at 667.8 nm ($3^1D \rightarrow 2^1P$), 587.6 nm ($3^3D \rightarrow 2^3P$), or 388.8 nm ($3^3P \rightarrow 2^3S$). The latter is positioned between the R(19) and R(20) lines of the rotational emission spectrum from FNS of N_2^+ (0,0).

Clearly, even in a flow of nominally very pure He, N_2 impurity at the ppm level is sufficient to yield high enough spectral intensity for accurate T_{rot} measurements (Fig. 3). This temperature was determined from the R branch of $N_2^+(B^2\Sigma_u^+, v'=0 \rightarrow X^2\Sigma_g^+, v''=0)$ using the Boltzmann plot method (Fig. 4). The intensities of emission lines from the rotational spectrum are given by the equation

$$\ln\left(\frac{I_{K'K''}}{n\,\nu^4_{K'K''}S_{K'}}\right) = A - \frac{B_{v'}K'(K'+1)hc}{kT_{rot}} \qquad (1)$$

where A is a constant for all lines in a same band (v', v'') for a given rotational temperature, v' and v'' are the vibrational quantum numbers of the upper and lower vibrational states, K' and K'' are the rotational quantum numbers of the upper and lower rotational states, $I_{K'K''}$ is the intensity of a line originating from the same electronic and vibrational level, $\nu_{K'K''}$ is the corresponding wave number, $S_{K'}$ is the line strength, $B_{v'}$ is the molecular rotational constant of the upper vibrational state, h is Planck's constant, c is the velocity of light, and k is Boltzmann's constant. Therefore, by plotting $ln(I_{K'K''}/\nu^4_{K'K''}\,S_{K'})$ against $B_{v'}K'(K'+1)$, a straight line of slope hc/kT_{rot} is obtained [2]; knowing the line intensities and the rotational constants, one can readily determine T_{rot}.

However, some precautions have to be taken to reduce the error in evaluating T_{rot}. Each line of the R branches is overlapped by rotational lines of the folded-back portion of the P branches, that is, R(K) and P(K+27). As a result, at high gas temperatures the P branch lines begin to have an appreciable influence on the measured intensity of low quantum number R branch lines, resulting in lower apparent T_{rot}. Occasionally, between the R(19) and R(20) lines, the emission from the $3^3P \rightarrow 2^3S$ helium transition at 388.865 nm is quite strong; this may artificially increase the intensity of R(20) and result in a higher apparent T_{rot} value.

Each value of T_{rot} has been determined by plotting the average intensities obtained from 25 recorded emission spectra. The standard deviation of the emission line intensities from the R branch is usually between 2 and 5%. We have found that a standard deviation of 5% results in an uncertainty of less than 5% in T_{rot} and we assume that this is close to the average gas temperature, like other authors [5, 6].

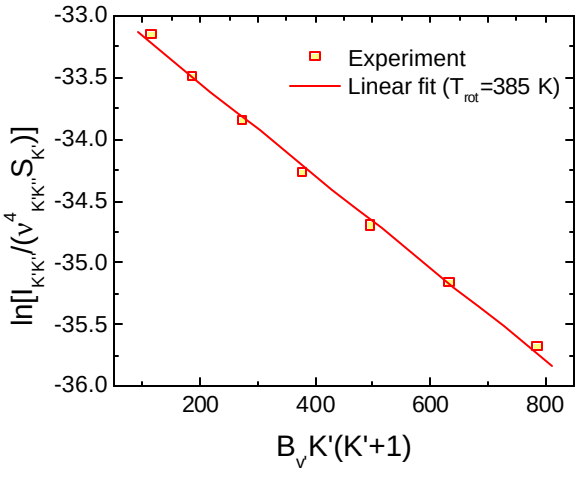

Fig. 4 A typical Boltzmann plot of R(6)-R(14) line intensities from the R branch of $N_2^+(B^2\Sigma_u^+, v'=0 \rightarrow X^2\Sigma_g^+, v''=0)$ versus the energy of the upper rotational levels.

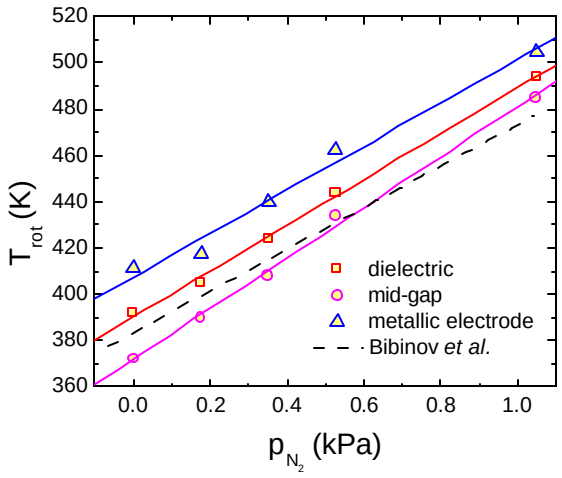

Fig. 5 T_{rot} versus partial pressure of N_2 in He/N_2 mixture obtained in 1.5 mm gap length plane-plane discharges.

Presumably, the presence and types of impurities in the discharge-cell can influence temperature values and their distribution. Because N_2 (from air) appears to be the dominant impurity in our experiments, we increased its concentration in order to evaluate its influence on T_{rot} values. In Fig. 5 we present the evolution of T_{rot} at three different gap positions, namely at the metallic electrode, at mid-gap, and at the dielectric, as a function of N_2 concentration in the He, along with comparable data reported in the literature [5, 6]. Both our and Bibinov's experiments relate to 1.5 mm plane-plane gaps, 1.5 ÷2 kV/19.7 kHz and 2 kV/10 kHz in Bibinov's and our case, respectively. In their case, both electrodes were covered with dielectric (glass) plates.

Figure 5 shows that T_{rot} increases linearly with rising N_2 concentration (up to ~ 1 vol%), and the T_{rot} distribution in the 1.5 mm gap. Mid-gap T_{rot} values are seen to agree well with literature data [5, 6], while those at the two electrode surfaces appear to be appreciably higher, the highest being at the metallic electrode. During sustained discharge the two electrodes heat up, and because they have a higher heat capacity than the gas, their temperature increases with time to a steady-state value that depends on the experimental conditions. With increasing N_2 concentration, the specific heat of the gas, the discharge propagation time and the spatiotemporal distributions of charge carriers and metastable species all are altered. It is interesting to note that the temperature differences between the three locations (at the two electrodes and in the mid-gap) gradually decrease with rising N_2 concentration.

Figure 6, for the case of the cylinder-plane discharge configuration, also shows a linear increase of T_{rot} with rising N_2 concentration (up to ~ 1.4 vol%); here, the APGD was produced in a 1 mm gap, but the temperature was found to be nearly constant throughout the gap, i.e. independent of axial position.

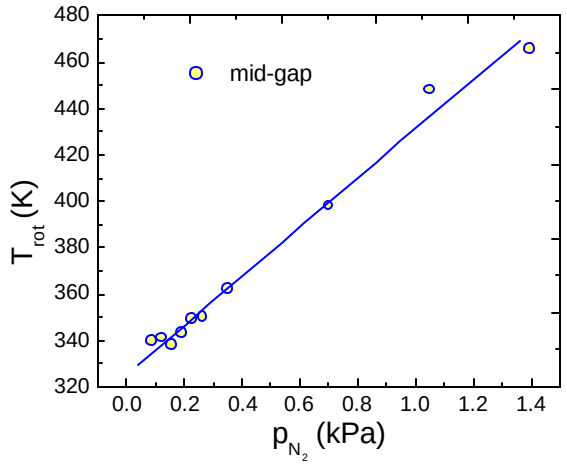

Fig. 6 T_{rot} versus partial pressure of N_2 in He/N_2 mixture discharges in the cylinder-plane electrode configuration.

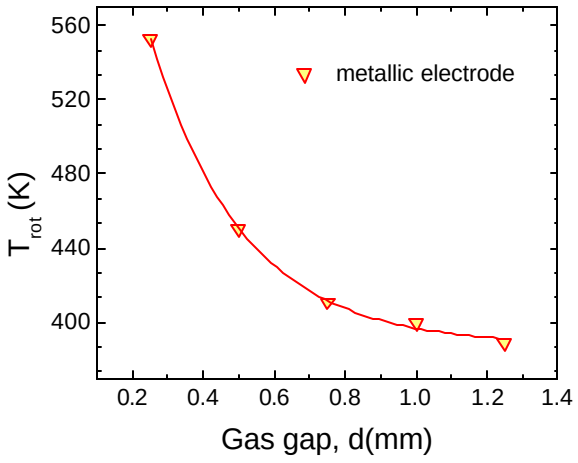

Fig. 7 T_{rot} near the metal electrode in a pure He DBD, versus gap width in the plane-plane configuration.

Finally, if the plane-plane interelectrode gap is narrowed, T_{rot} in a pure He discharge is seen to rise substantially (Fig. 7); this is to be expected, on account of reduced heat transfer. We present the temperature near the upper (metal) electrode, but T_{rot} is almost constant in the gap for gap widths less than 1 mm.

4. Conclusions

In this paper we present systematic investigations of gas temperature in different electrode configurations in short-gap helium APGD under uniform and non-uniform field conditions. The gas temperature is assumed to be equal to the rotational temperature, T_{rot}, which was determined from conventional Boltzmann plots using the R branch of FNS $N_2^+(B^2\Sigma_u^+, v'=0 \rightarrow X^2\Sigma_g^+, v''=0)$ bands near 391 nm. The influence of the N_2 partial pressure in He on T_{rot} in plane-plane and cylinder-plane discharge geometries has been examined, and T_{rot} was found to increase linearly with rising N_2 concentration (up to ~ 1 vol%).

Keywords: Søderberg electrodes, FeSi production, Thermal stresses, Plasma arc

Abstract

The purpose of this paper is to analyze the thermal effects of an electric arc on the surface of a carbon based electrode.The thermal conditions are then used to examine stress conditions in the vicinity of an arc.

Results show that the electrode surface is heated quickly up to a maximum temperature and for a specific test case, the surface can only withstand the load for about $10\,\mathrm{s}$. Also, the thermal stresses on the surface are very high which will increase erosion on the surface in addition to normal evaporation.

1 Introduction

Ferro Silicon is most frequently produced in submerged arc furnaces with Søderberg electrodes, see [1]. The metal is produced in a chemical process which receives energy from an electric arc. Carbon based electrodes are needed for that purpose. The uniqueness of the Søderberg process originates from the fact that these electrodes are manufactured during and in connection with the production itself.

In order to understand better the part of the process that has to do with the energy flow into the metal, fairly accurate mathematical models have been derived. The focus in most of these models has been the electrode, see e.g. [2], as well as the arc, see [3],since most of the production problems are located in these areas. An one-dimensional model was presented in [4] with the main purpose of describing the phase transition at the arc surface. A more complex two dimensonal model was furthermore used in [5] where the focus is on conditions that prevail in the initiation phase of a cathode spot. The results of this work indicates an overheating area of the spot, inside the surface itself, due to ohmic heating and heat losses at the surface.

The purpose of this paper is to focus on the electrode near the spot where the electric current leaves the electrode and forms an electric arc. This can be done with a relatively simple heat transfer model, similar to the model in [4], where a solid with alternating current flowing through it is modelled. The solid is semi-infinite and therefore only one surface (or boundary) is included in the analysis. The current flows out of the solid at the surface at one single area, which is circular with a given radius. Therefore it is assumed that the current density in the whole solid is pointed at this single area, which simplifies the problem.

The problem is furthermore analyzed by using an axi-symmetric finite element model in two dimensions. This is done primarily in order to verify the one dimensional model, and also to compute structural stresses in the arc vicinity.

This particular problem definition corresponds to a conductor with a single electric arc burning from the circular area as shown in figure 1. The figure also shows the model domain near the arc.

The paper is organized as follows. In section 2 a mathematical model is posed, which describes the problem. This is followed by some general results in section 3 and the by a real case study in section 4. Finally, conclusions are drawn in section 5.

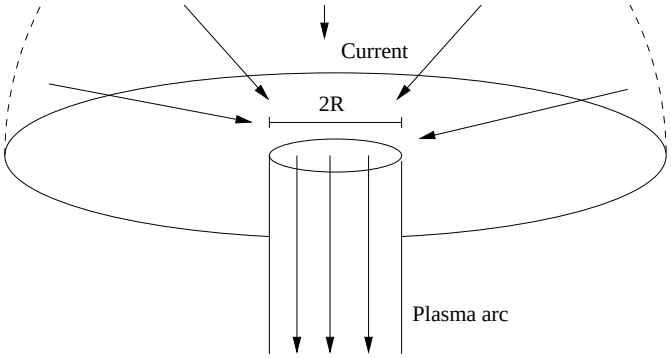

Figure 1: Semi-infinite solid with an electric arc on the surface

2 Mathematical models

2.1 The one dimensional case

A dynamic representation of the temperatures in the solid is described mathematically as an initial value problem. A general formulation of this problem is

$$\rho c_p \frac{\partial T}{\partial t} = k\nabla^2 T + \frac{J^2}{\sigma} \tag{1}$$

where ρ is density, c_p is specific heat, k is thermal conductivity, J is current density, σ is electric conductivity and T is the temperature.

The general problem can be simplified considerably by assuming spherical symmetry in the problem. This implies the following:

- All variables and parameters are constant at a given distance from the center of the arc area.
- It is assumed that a total current I flows directly towards the center and is uniform at a fixed distance.
- A spherical hole is assumed to be present at the arc center, so the solid is bounded by a half-sphere with radius R_s.
- The surface is insulated if the distance from the center is greater than R_s.

These assumptions allow for a model in spherical coordinates where the radius r is the only spatial variable. If the total current is given as I, then the current density becomes $J = \frac{I}{2\pi r^2}$ as it goes through a half-sphere. The initial value problem for the heat equation, (1), then becomes

$$\rho c_p \frac{\partial T}{\partial t} = \frac{k}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial T}{\partial r}\right) + \frac{I^2}{4\pi^2 \sigma r^4} \tag{2}$$

2.2 Dimensionless form of the heat equation

It is convenient to use dimensionless variables in (2) where it is possible. Consequently the following dimensionless variables are defined

$$\theta = \frac{T - T_\infty}{T_0 - T_\infty} \qquad \eta = \frac{R_s}{r} \qquad \tau = \frac{k}{\rho c_p R_s^2} t$$

where T_0 is a reference temperature at the boundary and T_∞ is the temperature far away from the center (when $r \to \infty$).

The spatial differential operator is transformed into the dimensionless variable η and the time variable becomes t. Therefore the differential operators become

$$\frac{d}{dr} = \frac{d\eta}{dr}\frac{d}{d\eta} = -\frac{R_s}{r^2}\frac{d}{d\eta} = -\frac{\eta^2}{R_s}\frac{d}{d\eta} \qquad \text{and} \qquad \frac{d}{dt} = \frac{d\tau}{dt}\frac{d}{d\tau} = \frac{k}{\rho c_p R_s^2}\frac{d}{d\tau}$$

When θ and η are inserted into (2) the result is

$$\frac{\rho c_p k(T_0 - T_\infty)}{\rho c_p R_s^2}\frac{\partial\theta}{\partial\tau} = \frac{k(T_0 - T_\infty)R_s}{r^4}\frac{\partial}{\partial\eta}\left(R_s\frac{\partial\theta}{\partial\eta}\right) + \frac{I^2}{4\pi^2\sigma r^4}$$

$$\Rightarrow \quad \left(\frac{r}{R_s}\right)^4 k(T_0 - T_\infty)\frac{\partial\theta}{\partial\tau} = k(T_0 - T_\infty)\frac{\partial^2\theta}{\partial\eta^2} + \frac{I^2}{4\pi^2\sigma R_s^2} \quad \Rightarrow \quad \eta^{-4}\frac{\partial\theta}{\partial\tau} = \frac{\partial^2\theta}{\partial\eta^2} + 2\beta \quad (3)$$

where

$$\beta = \frac{I^2}{8\pi^2\sigma k(T_0 - T_\infty)R_s^2} \quad (4)$$

It is clear from (3) and (4) that all the physical properties of the problem can be gathered into a single parameter, β. This simplifies further analysis of the problem, since the solution to the partial differential equation in (3) can be developed as a single parameter function, which includes all the characteristics of the physical problem.

2.3 Finite element modeling

In order to compare the one dimensional model to a more realistic case, a finite element representations of an electrode has been built.

A two dimensional axi-symmetric model is considered, where it is assumed that the current flows from the electrode bottom. The accuracy of this model can be increased by using a very dense mesh, and it is appleciable for both static and dynamic analysis.

3 One dimensional analytical results

3.1 A steady state solution

An extreme case of an arc flowing out from a surface is where the arc does not move, and thus all time changing conditions converge to a steady state solution. This corresponds to setting $\frac{\partial\theta}{\partial\tau} = 0$ and thus the equation to be solved is

$$\frac{\partial^2\theta}{\partial\eta^2} + 2\beta = 0$$

By assuming the boundary conditions $\theta(1) = 1$ ($T(R_s) = T_0$) and $\theta(0) = 0$ ($T(\infty) = T_\infty$), the solution becomes

$$\theta(\eta) = \eta(1 + \beta(1 - \eta))$$

Some interesting values can be derived from the solution. The first one is the maximum value of θ and the position of that value. Differentiation gives

$$\eta_{max} = \frac{1}{2} + \frac{1}{2\beta} \qquad \theta_{max} = \frac{(1+\beta)^2}{4\beta}$$

Another interesting value is the maximum value of η, where $\theta \leq 1$. This corresponds to the minimum radius r where $T \leq T_0$. The solution to this problem is

$$\eta < \frac{1}{\beta} \quad (5)$$

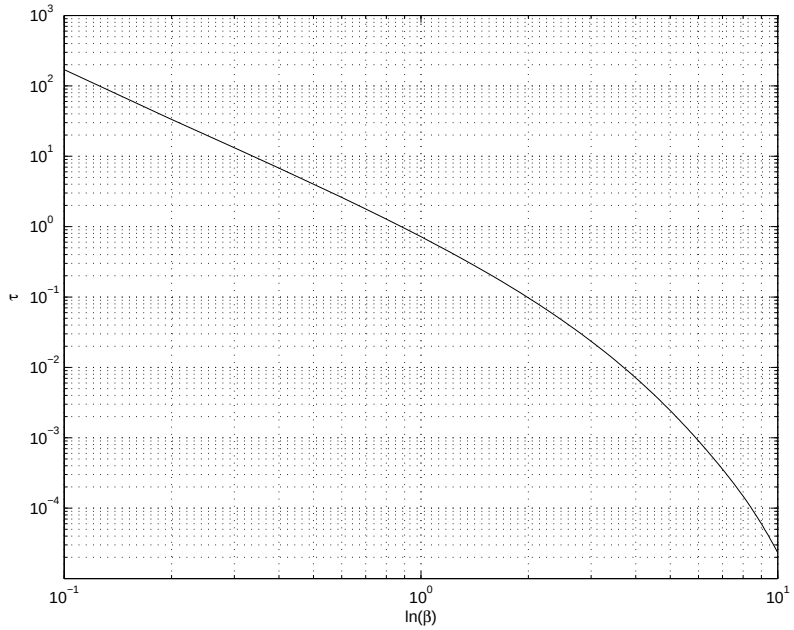

Figure 2: Dimensionless time until temperature penetration occurs as a function of $\ln(\beta)$.

which corresponds to the intrusion of temperatures higher than T_0 in to the solid. The assumption of $\theta \leq 1$ is justified by realizing that the maximum temperature of the material is $\theta = 1$, since it will sublimed into gas at higher temperature. Values of $\theta > 1$ are therefore outside the physical frame of the problem.

3.2 A time dependent solution

It is clear that the steady state solution can only be used as a reference, since it is clear that a realistic case study would not have an arc flow out from the same spot forever. Therefore it is necessary to solve the time dependent problem and thus solve (3) with appropriate boundary conditions.

It turns out that (3) is hard (or impossible) to solve analytically, and numerical methods must be used. This is done by discretizing the space derivative with finite differences and then integrating the result as a system of ordinary differential equations.

The discretization is performed by dividing the interval $0 \leq \eta \leq 1$ into N spaces, such that θ_j is an approximation of θ for $j = 0 \ldots N$. The result is a set of equations

$$\frac{\partial \theta_j}{\partial \tau} = \eta^4 N^2 (\theta_{j-1} + \theta_{j+1} - 2\theta_j) + 2\eta^4 \beta \tag{6}$$

which are mutually dependent. This is then integrated by using a numerical method, in this case a Runge-Kutta method for stiff systems.

The solution of (6) is dependent on β and therefore there is not much point in plotting it as a general solution. But there are some derived quantities that are of special interest and can be shown as a single graph with respect to β.

The first study involves a problem where the initial condition $\theta(\eta, 0) = 0$ is applied, as well as the boundary conditions $\theta(0, \tau) = 0$ and $\theta(1, \tau) = 1$. Thus the temperature at the boundary is raised suddenly to T_0, which is what happens if an arc is suddenly started at the surface. It is of interest to find out how long time passes until this surface temperature starts penetrating the surface (and thus generating abnormally high temperatures inside the solid). Figure 2 show this relationship for a wide range of β.

Result	$R = 5\,\mathrm{cm}$	$R = 3.54\,\mathrm{cm}$
Static R_{max} (based on η_{max})	$9.5\,\mathrm{cm}$	$9.7\,\mathrm{cm}$
Static T_{max} (based on θ_{max})	$16500\,^{\circ}\mathrm{C}$	$30400\,^{\circ}\mathrm{C}$
Static penetration of T_0 (based on (5))	$0.93\,\mathrm{m}$	$1.86\,\mathrm{m}$
Time until penetration starts	$10.5\,\mathrm{s}$	$2.2\,\mathrm{s}$

Table 1: Results for an one dimensional model

It can finally be concluded that figure 2 shows that the time until penetration occurs decreases with increasing arc current I and with decreasing electric conductivity of the electrode material.

4 A real world case study

A realistic case study is analysed in this section, where a baked carbon paste of a Søderberg electrode is considered. Real material parameters are used and the applied current is assumed to be $I = 115\,\mathrm{kA}$. It is further assumed that $T_0 = 4000\,^{\circ}\mathrm{C}$ and $T_\infty = 1000\,^{\circ}\mathrm{C}$. For a discussion of material parameters in Søderberg electrodes see e.g. [7] and [8].

4.1 The one dimensional model

It is assumed that the arc has a radius of $R = 5\,\mathrm{cm}$ and therefore a natural choice would be to set $R_s = R$. But it should be noted that the surface area of the half-sphere bounded by R_s is not the same as the surface are of an arc flowing from the bottom. Therefore, a correction is also considered which results in $R_s = \frac{R}{\sqrt{2}} = 3.54\,\mathrm{cm}$. Both these cases are examined and the results are shown in table 1.

Apparently there is a considerable difference between the two chosen values of the radius, so a comparison to a more complete finite element model should indicate which method should be used.

4.2 Time dependent results from an axi-symmetric finite element model

A model was constructed with the purpose of focusin on the electrode bottom and compare time dependent simulation to the results from the one dimensional model.It is assumed here that the current flows from the bottom in a circular pattern with radius $5\,\mathrm{cm}$.

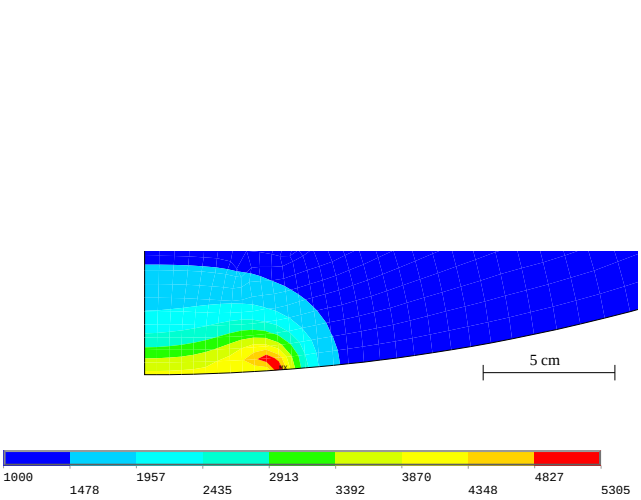
Figure 3(a) shows the temperature near the arc after $10\,\mathrm{s}$ of simulation time. Here it is clear that the temperature is in some points larger than T_0, but this can be analysed further by choosing two points near the arc and plotting the temperature as a function of time. This is shown in figure 3(b) where the maximum temperature is reached at time from about $9\,\mathrm{s}$ to $20\,\mathrm{s}$. This is close to the result found with the one dimensional model where $R_s = 5\,\mathrm{cm}$.

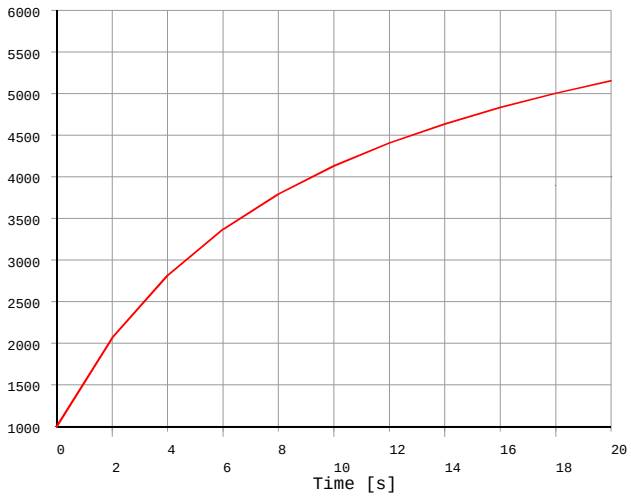
It should be noted that the edge of the arc (the outer surface for a circular arc) is a problematic spot for the finite element solution because of the fact that the current is forced to flow out perpendicularly to the surface. Nevertheless, this only affects the solution near the problem spot.

4.3 Structural stresses in an axi-symmetric model

The final study here is to look at structural stresses which are the result of temperature changes in the electrode. As before, it is assumed that this effect mostly occurs near the arc, and the results support this fact.

Figure 4(a) shows the stresses at the electrode bottom at a given time points. This time is the same as in figure 3(a), which is $10\,\mathrm{s}$ after the start of the arc at the bottom. It is clear that the stresses are closely related to the temperatures, and appear to be very high, several magnetudes higher than the stress that the electrode is supposed to withstand. This is the case in the contour region, but only penetrated about $2\,\mathrm{cm}$ into the electrode.

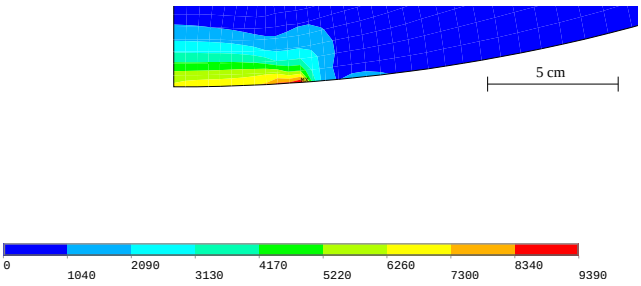


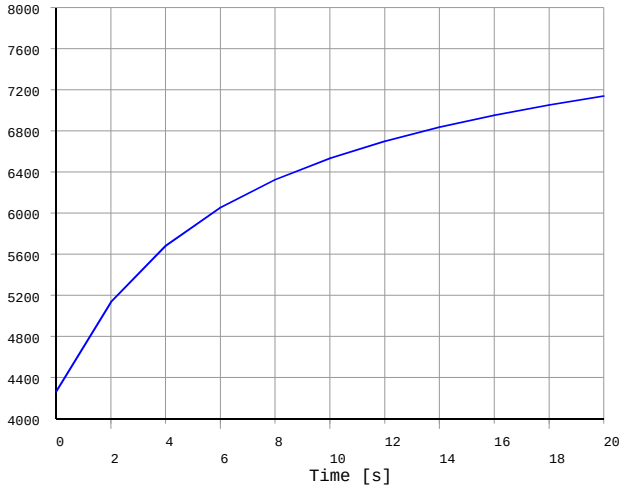


(a) Distribution after 10s

(b) As a function of time

Figure 3: Temperature in an axi-symmetric model [°C].





(a) Distribution after 10s

(b) As a function of time

Figure 4: Equvalent stresses near the arc outlet in an axi-symmetric electrode [MPa].

Finally, figure 4(b) shows the changes in stresses with respect to time. This follows the change in temperatures very well, as expected.

5 Conclusions

A spherical model of thermal conditions in a semi-infinite solid has been developed in this paper. This model is in reality one dimensional since changes are only considered in the radial direction. Furthermore, more complex finite element models have been built and compared to the one dimensional model.

The model seems to agree with the more complex two and three dimensional models, and is applicable in the vicinity of an electric arc. This indicates that the results found in figure 2 can be used to analyze the time dependent effect of an arc, burning at the bottom of an electrode. The key parameter here is β, which was defined in (4).

The results indicate that when an arc is formed with a relatively high current, then it affects the surface of the electrode greatly, both with respect to temperatures and structural stresses. Particularly, it is apparent that an electric arc with a current over $100\,\mathrm{kA}$ flowing from a Søderberg electrode would burn at the same point for only up to $10\,\mathrm{s}$, since the material cannot withstand higher temperatures than $4000\,^{\circ}\mathrm{C}$. It is then likely that the arc is moving around within such a time frame, or that more than one arc are present at once.

Furthermore, analysis of the thermal stresses due to the arc heating near the surface show very high stresses, which indicates that the erosion at the surface would considerably support erosion of the electrode.

The combined findings of this paper are an important addition to research on arc movement and electrode consumption. Further work could focus on the somewhat complex plastic behaviour of the electrode material.

Finally, the authors would like to thank for the financial support of this research, which was funded jointly by The Research Council of Norway , The Norwegian Ferroalloy Producers Research Association, and The Icelandic Centre for Research.

Analysis of initial layer growth process for CVD plasma polymerization

Prof. Dr.-Ing. E. Schmachtenberg[1], Dipl.-Ing. D. Binkowski[1], Dipl.-Ing. S. Göbel[1]

1 Institute of Plastics Processing at Aachen University, Aachen, Germany

Abstract
Films for barrier improvement of polymers (e.g. PET-bottles) deposited by Plasma enhanced CVD at low pressure are being investigated. For the microwave assisted plasma polymerization of C_2H_2 the correlation of morphology, barrier properties and process parameters is being studied on PET-substrates as well as on Si-Wafers. The AFM analysis shows structures which suggest island growth. ESCA measurements indicate that a high amount of C-C bonds is essential for barrier improvement.

Keywords
Plasma enhanced CVD, layer growth, morphology, barrier properties, acetylene

Introduction

Plasma assisted coating of polymers is a well know process e.g. for barrier improvement of polymers. The initial growth processes are determining the morphology and the further layer growth of thin films. Mechanical and physical properties depend highly on the film morphology. To optimize film properties such as permeation barrier a good understanding of the initial layer growth process is necessary. Previous studies show that the barrier quality of films deposited by Chemical Vapor Deposition (CVD) depends on the film morphology [1, 2]. Defects in the film are one reason for a higher gas permeation. Aim of the presented studies is to identify reasons for the occurrence of defects and to identify a correlation between process parameters, film morphology and barrier properties.

For the deposition of thin films using Physical Vapor Deposition (PVD) processes a broad base and wide variety of research work and papers are existent [3, 4, 5, 6]. However, for Chemical Vapor Deposition this is not the case, even though the industrial use of CVD processes is increasing at a high rate. To optimize the functionalities of the deposited thin films (e.g. anti scratch, anti fog or barrier coatings) a deeper understanding of the processes during layer growth is necessary. This is also essential to improve manufacturing methods.

Thin film deposition

The deposition of thin films can be divided into three different phases. In a first step the particles which will be forming the film are being transported to the surface. In a second step those particles are being absorbed on the substrate respectively on the growing film. The particles diffuse over the substrate and are either being implemented in the film or being removed from the surface by vaporization or sputtering. In a third step the particles migrate to their final position in the film [7].

For the creation of thin films three different models are being found in the literature (fig. 1). These models can also be used to describe growth of plasma polymerized films. These can be a growth in layers as described by Frank-van der Merwe [9], an island growth known as Volmer-Weber [8] growth or a combination of both, described by Stranski-Krastanov [10]. Bauer describes a thermodynamic approach [11, 12] and defines surface energy of the substrate (γ_s), absorbed particles (γ_a) and an energy for the intermediate layer (γ_i). He indicates that island growth occurs when $\gamma_s - \gamma_i < \gamma_a$. If not, layer growth occurs. Stranski-Krastanov growth is described by variation of γ_i with growing film thickness. This approach may not be feasible for low pressure CVD processes due to the lack of a thermodynamically balance.

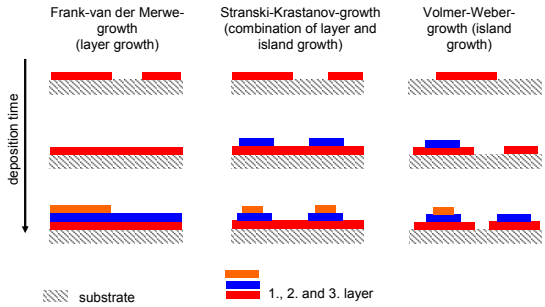

Figure 1: Different models of thin film creation

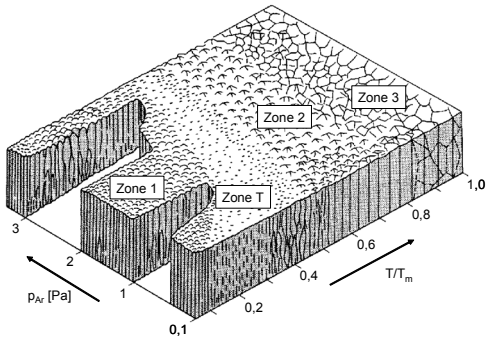

Figure 2: Structural zone model according to [13]

Movchan and Demchishin [5] observe that the morphology of evaporated films can be described by a function of the ratio of substrate temperature T to the melting point of the coating T_m. They describe three different zones in this structural zone model. Zone 1 ($T/T_m < 0{,}3$) is described as zone consisting of tapered crystallites with domed tops. Zone 2 can be observed for $0{,}3 < T/T_m < 0{,}45$ and describes columnar grains. Zone 3 consists of equiaxed grains for $T/T_m > 0{,}45$. [13] observes in addition to that a transition zone T of tightly packed fibrous grain (fig. 2). [6] extends the model with the interdependence on the energy of the deposited particles. Increasing energy leads to a shift of the zones to lower T/T_m values. Thus the two components of the adatom mobility are taken into account. Those components are the thermally induced mobility and the mobility induced by the bombardment with particles of high energy.

Results and Discussion

For microwave assisted plasma polymerization of C_2H_2 at low pressure there are few papers found, which discuss the different produced microstructures during the process, excluding the deposition of diamond like carbons (DLC). Studies on how a variation of the process parameters influences the morphology of the deposited films and how this has an effect on the barrier properties are being made at the Institute of Plastics Processing at Aachen University.

The coatings using acetylene (C_2H_2) as process gas and argon (Ar) as carrier gas are being deposited on two different substrates. For industrial use (especially barrier coatings) the polymer polyethylene terephthalate (PET) is an interesting substrate to investigate. To differentiate the plasma polymerized C_2H_2 from the substrate during ESCA (Electron Spectroscopy for Chemical Analysis) and to have an ideal surface without almost any defects Si-Wafers are being used as second substrate to be coated. The thin films are being deposited using a microwave CVD laboratory plant for barrier coating. The process parameters which are being varied are microwave power, gas flow and composition as well as coating time. To increase the quality of the results and to reduce the number of trials the methodology for design of experiments is being used. This also allows to display the effects of the different parameters in a Pareto chart of effects, which shows also a vertical line to indicate the minimum magnitude of statistically significant parameter estimates. All effects beyond this limit are statistically significant according to the chosen 95% confidence interval.

To have a good bases for correlating barrier, morphology and process parameters with each other barrier measurements of coated PET-bottles against CO_2 are being made in a first step. Secondly the morphological and chemical analysis is being conducted.

The barrier measurements spread for the used parameter range between barrier improvement factor (BIF) 1 and 3,6. This factor represents the ratio of the permeation coefficients of a reference material to the barrier material. Main effects on barrier of deposited C_2H_2/Ar coatings have pressure, gas flow and gas flow ratio as well as process time (fig. 3). Interactions of those can also be observed.

To see whether there is a correlation between barrier and morphology or not Atomic Force Microscopy (AFM) is being used. The AFM analysis shows no significant influence of surface properties to barrier quality. In addition to that could no Frank-van der Merwe growth be observed at any time. The AFM scans rather show structures, which suggest island growth. Figure 4 shows height pictures of coated samples compared to the uncoated Si-Wafer. Also the phase contrast analysis underlines that. A growth as described by Stranski-Krastanov may occur, but this observation could not be exactly determined by the AFM scans. An analysis of a cross section will eventually provide more information. To examine the correlation between barrier and morphology the surface structures of samples with high BIF values are being compared to those with low values for BIF. No significant correlation was found, even though samples with a good BIF seemed to have a more flat and smooth surface.

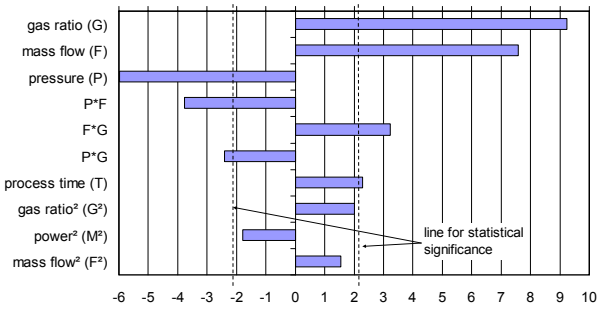

Figure 3: Pareto chart of standardized effects on BIF (R^2=0,90)

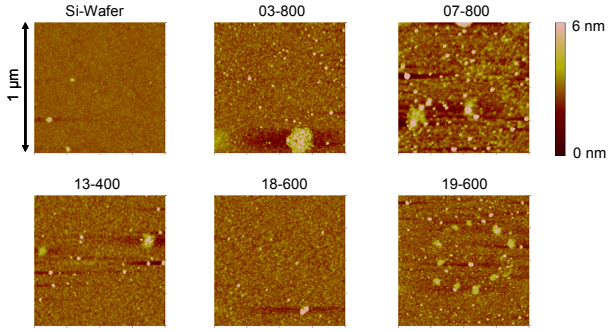

Figure 4: 1µm AFM scans of different samples (height pictures)

The analysis of coating thickness gives a more clearly picture of the effects (fig. 5). As expected the process time has the biggest effect on the thickness of the film. Also the distinct effect of gas ratio and mass flow is accountable, because C_2H_2 is being implemented very fast in plasma when there is sufficient energy to stimulate the gas particles. Of interest is the derived value called layer growth rate (growth rate = d(layer thickness) / dt). A time dependency of the layer growth rate could be observed. The shorter the process time is, the higher the growth rate. Also gas flow and gas ratio have a statistical significant influence on layer growth rate (fig. 6). One reason for this observation may be that not enough monomer gas is present during the whole process, so that after the initial surplus of gas is being used the growth rate decreases.

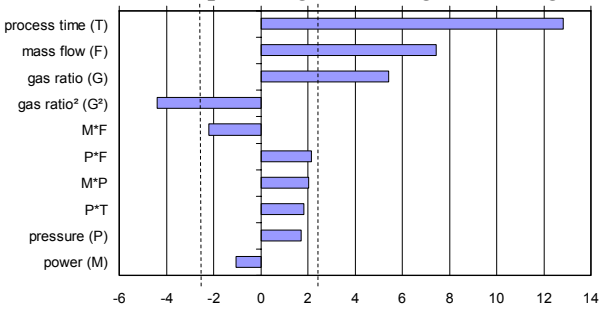

Figure 5: Pareto chart of standardized effects on film thickness (R^2=0,99)

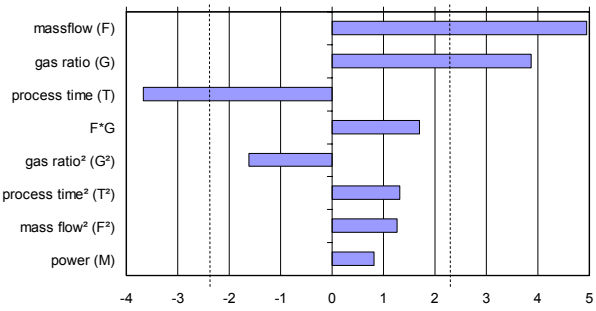

Figure 6: Pareto chart of standardized effects on growth rate (R^2=0,96)

ESCA measurements show that the chemical composition of the thin films is almost identical for all deposited coatings for the conducted design of experiments. Table 1 shows the average elemental composition of the deposited films using acetylene in combination with argon on Si-Wafers. The presence of fluorine may be due to the gas inlet of the coating plant, which is made of PTFE. The nitrogen is either being implemented at the beginning of the process due to some residual nitrogen, which has not been properly removed from the process or it has been implemented after the deposition due to the share of radicals on the film surface. Furthermore ESCA analysis did not verify the existence of covalent Si-C bonds, which suggests a sudden change from Si-Wafer to the film without any transition. Also no change in the film composition could be observed with

increasing film thickness. The wide range of measured barriers with a variation up to factor 3,6 indicates that barrier properties depend solely on the morphology of the films. In addition to that the existence of C-C bonds seems to be a necessary but not sufficient criteria to get a good barrier (fig. 7). Significant influences of process parameters on the occurrence of C-C bonds were found for the gas ratio, the mass flow and the pressure at which the coatings were deposited.

element	C	O	Si	N	F
average [atomic-%]	78,1	14,9	4,8	1,6	0,7
standard deviation	6,3	2,4	4,5	1,6	1,3

Table 1: Average elemental composition of the DOE

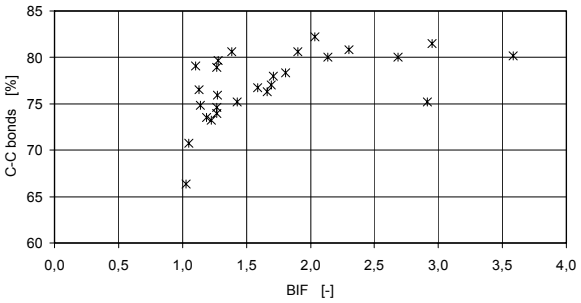

Figure 7: Share of C-C bonds vs. measured BIF

Perspective

AFM analysis shows for C_2H_2/Ar-films on Si-Wafers island growth. If the film growth as described by Volmer-Weber (island growth) or has a growth mechanism based on Stranski-Krastanov (combination of layer and island growth) can not be decided. If Stranski-Krastanov growth occurs, the transition layer is rather thin. Frank-van der Merwe growth could not be observed. To get a better understanding and a more detailed picture additional analysis of a cross-section should be taken into account.

The chemical composition of the deposited films is for all investigated films almost identical, yet the barrier improvement factor varies from 1 – 3,6. This indicates that a good BIF depends solely on the morphology of the deposited films. As described by the structural zone models a higher ion bombardment may lead to a film with lesser defects, thus a better barrier against permeation.

Abstract

We report a mass spectrometry study of volatile fragments emanating from the surfaces of several types of hydrocarbon and heteroatom-containing polymers under direct exposure to (i) low-pressure glow discharge plasma, and to (ii) VUV radiation. Depending on the polymer composition and structure, in some cases types (i) and (ii) spectra show substantial differences. In others, the same mass peaks appear, but with different intensity ratios.

Keywords: Polymers, Glow discharge plasma, Vacuum ultraviolet radiation, Mass spectrometry.

1. Introduction

Surface modification of polymers, for example for enhanced adhesion, is now indispensable [1]. One of the main methods involves their exposure to glow discharges, but these are also strong emitters of ultraviolet (UV) and even vacuum ultraviolet (VUV) radiation [2]. In view of this fact, it is of scientific and technological interest to distinguish a possible VUV-induced contribution to the overall interaction between the plasma and a polymer surface. An important effect resulting from this interaction is the scission of macromolecular bonds and the ensuing liberation of volatile organic fragments. These can readily be detected and identified with the help of mass spectrometry, as we have shown in the past [3]. The purpose of the present work has been to compare mass spectra of volatile fragments emanating from the surfaces of several types of polymers under two different conditions, namely (i) direct exposure to low-pressure glow discharge plasma, and (ii) exposure to VUV radiation generated by a low-pressure radiofrequency (r.f.) discharge, but shielding the polymer surface from the active particles of that discharge.

2. Experimental Methodology

In order to accomplish tasks (i) and (ii), we use a specially-designed plasma reactor, coupled to a quadrupole mass spectrometer (QMS) via a small (100 μm) orifice [3]. By means of differential pumping of the reactor and the QMS, one enables the extraction of volatile species from the former to the latter. For all experiments the pressure in the reactor was adjusted within the 50-150 mTorr range, for example by controlling the gas flows. The pressure in the QMS was always kept to about 10^{-7} Torr (Fig. 1).

In the case of type (i) experiments, perforated polymer foil specimens were placed directly onto the orifice plate of the QMS, where they were exposed to active particles (electrons, ions, excited metastables) and photons from the 13.56 MHz r.f. He or Ar plasma, generated with the help of a concentric, powered electrode at 150 W of r.f. power.

Regarding type (ii) experiments, a commercial VUV lamp (Resonance Ltd, Barrie ON, Canada) with a flow of Ar or He + 1% H_2 generated strong, near-monochromatic VUV Lyman α radiation from atomic hydrogen (λ=121.5 nm) [4]. The lamp was placed a short distance from the polymer surface (see the inset of Fig. 1), but the activated gas stream was deviated towards the pumps by a MgF_2 window. In this way, the volatile species detected by the QMS were practically only attributable to VUV-induced bond scissions in the polymer surface region [5]. Figure 2 shows the emission spectrum of the Ar + 1% H_2 flow-lamp at 150 mTorr pressure, as an example. The flows of argon and hydrogen were 99 sccm and 1 sccm, respectively.

We have examined the mass spectra of hydrocarbon polymers (polyethylene, PE; polypropylene, PP; polystyrene, PS), and of others containing heteroatoms (polyethylene-terephthalate, PET; polyethylene-naphthalate, PEN; polycarbonate, PC; and nylon-6 polyamide, PA).

3. Results and Discussion

3.1 Plasma experiments

Figure 3 depicts the mass spectra recorded in the mass range 0-150 amu during He plasma exposure without any sample, and with samples of PE or PP. The intensities were normalized to that of the highest intensity peak, He^+. The recorded background spectrum (plasma ignited without any sample) shows mass lines that are characteristic for He plasma, i.e. He^+ (m/e=4 amu) and He^{2+} (m/e=2 amu), and of some contaminants. The latter include desorbed water vapour (H_2O^+, m/e=18 amu; OH^+, m/e=17 amu; O^+, m/e=16 amu; and H_2^+, m/e=2 amu), carbon dioxide (CO_2^+, m/e=44 amu; CO^+, m/e=28 amu), molecular oxygen (O_2^+, m/e=32 amu; O^+, m/e=16 amu) and

some hydrocarbons, of which $C_2H_3^+$ (m/e=27) dominates. However, even though the filament of the QMS ionization source was cleaned by repeated heating cycles, it is not excluded that it may have contributed some of these detected species.

When aliphatic hydrocarbons, in our case PE and PP, were exposed to the He (or Ar) plasma, many C_xH_y hydrocarbon peaks were observed in the mass spectra. They include light species, like carbon (C^+, m/e=12), methylene, (CH_2^+, m/e=14), methyl (CH_3^+, m/e=15) and methane (CH_4^+, m/e=16). One can observe that mass spectral lines appeared as groups (bands) between 38-46, 50-60, 64-73, 77-85 and 95-99 amu, respectively, with diminished intensity for heavier species. Among the most intense mass lines we note 27, 28, 29, 41, 42, 43, 55, 56, 57, 69, 70, 71, 83, 84 and 85. These are recurrent values of ions of alkenyl carbenium ($C_nH^+_{2n-1}$), alkene C_nH_{2n}, (n≥2) and alkyl carbenium ($C_nH^+_{2n+1}$), when a methylene group (mass 14) is eliminated from the polymer backbone. Similar hydrocarbon fragments were reported as by-products for Ar plasma-exposed polyolefins [3]. However, compared with Ar plasma, for PE there are differences of relative intensities within the groups of spectral lines. Moreover, in the case of PP, the mass spectral lines are more numerous and have a greater intensity in the He plasma than their Ar plasma counterparts. These findings suggest that more fragments of heavier masses are formed when polyolefin samples are exposed to the He plasma. As helium has an ionization potential ($1s\ ^2S_{1/2}$, 24.48 eV) higher than that of argon ($3p^5\ ^2P_{3/2}$, 15.76 eV), a higher efficiency of excitation and ionization is expected in the helium plasma leading to the formation of more energetic metastable species that bombard the polymer surface [6].

.

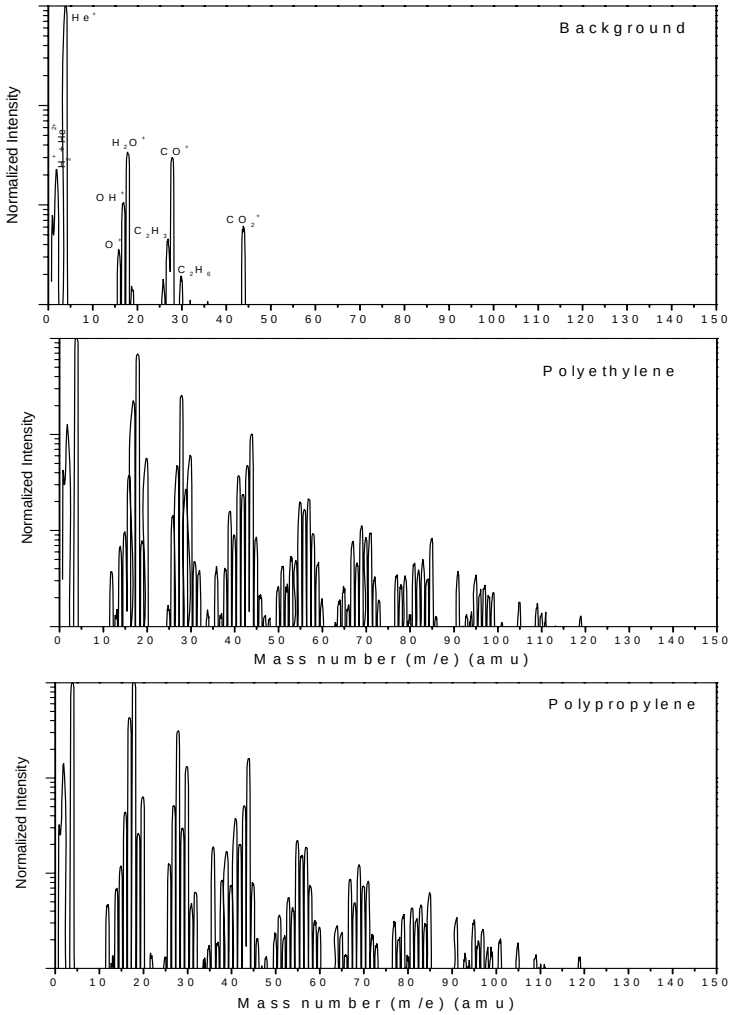

Figure 3. Mass spectra recorded during a He plasma treatment without (a) and with samples of polyethylene (b) and polypropylene (c). Intensities are normalized to the highest intensity peak, He^+.

For aliphatic hydrocarbons the main fragmentation mechanism is the elimination of H_2 and the creation of mid-chain and/or end-chain double bonds (the so-called molecular path); they are easily identifiable in the mass spectrum as alkene species (Fig. 3). Note that in the configuration we used, no measurable signals were detected for masses exceeding 150 amu.

3.2 VUV versus Plasma

In the case of exposure to VUV from the flow lamp, the mass spectra of a given polymer manifested peaks in the same positions as those observed under exposure to inert gas plasma. However, there were systematic differences in the peak intensities, as we now show.
Figure 4 represents the ratio of mass spectral intensities under types (i) and (ii) experimental regimes (I_{plasma}/I_{VUV}) versus the mass number of H_2 and of hydrocarbon fragments liberated from (a) PE, and (b) PP.

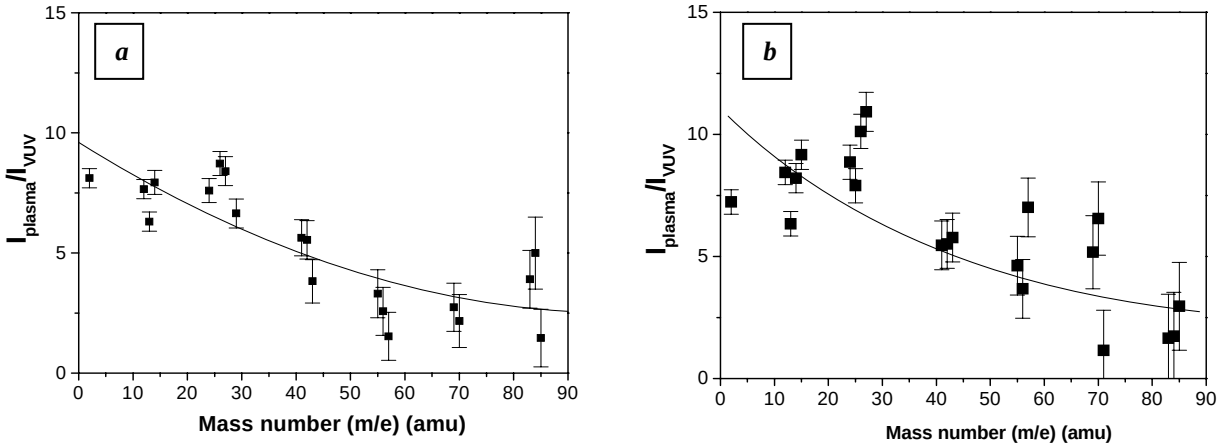

Figure 4. Ratio of mass spectral intensities under types (i) and (ii) experimental regimes vs the mass number of H_2 and of hydrocarbon fragments liberated from (a) PE, and (b) PP

A rather different picture emerged in the case of polymers with aromatic structure and those containing heteroatoms, namely PS, PET, PEN, PC and PA. Here, the signals of the lighter species were found to have lower intensity when exposed to the VUV radiation (regime (ii). In order to examine systematic differences of mass intensities between the two exposure regimes, we present the I_{VUV}/I_{plasma} ratios; Figure 5 shows the evolutions for PC, PS and PA.

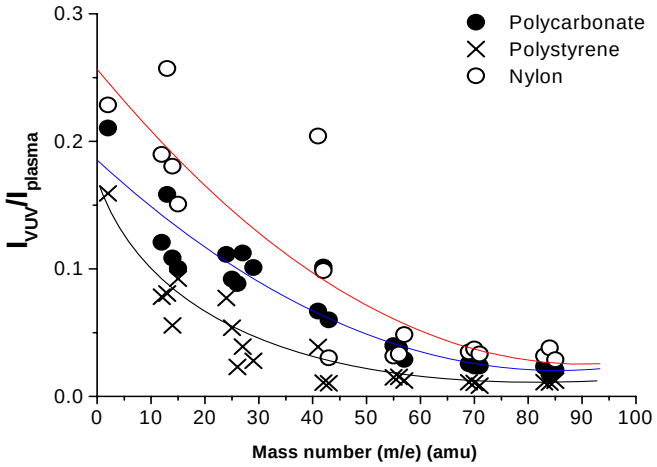

Figure 5. Ratio of mass spectral intensities under types (ii) and (i) experimental regimes vs the mass number of H_2 and of hydrocarbon fragments liberated from polycarbonate, polystyrene and nylon-6 polyamide

4. General Discussion and Conclusions

Figure 4 clearly shows that for the case of polyolefins, PE and PP, exposure to inert gas plasma (type (i) treatment) favours the formation of "lighter" fragments, compared with type (ii), VUV irradiation. In the case of polymers containing aromatic structure (PS, PC), however, Fig. 5 suggests that the opposite appears to apply. While these data must still be considered preliminary, they nevertheless illustrate that bond-breaking events at a given polymer surface are quite different in types (i) and (ii) excitations.

All polymers strongly absorb VUV photons below 160 nm, for example the present Lyman α radiation at 121.5 nm, on account of C-C and C-H σ bond scissions [5]. However, aromatic polymers like PS are far less susceptible to VUV-induced ablation than their aliphatic counterparts. The reason for this is that aromatic structures can dissipate the excitation energy through fluorescence [5]. In the cases of PE and PP, on the other hand, plasma (type (i)) and VUV (type (ii)) excitations both give rise to much bond scission in surface-near layers of the polymers, hence to many volatile fragments. In the case of type (i), however, these are further fragmented in the plasma before entering the QMS, and this explains the trends illustrated by Figs. 4(a) and (b). The reverse behaviour, Fig. 5, is currently the object of further investigations.

Abstract
By plasma spraying of titanium carbide and diboride using water stabilized plasma torch and CVD deposition of titanium nitride, followed by their surface oxidation, compact photoactive ceramic parts of chemical reactors can be produced. Photocatalytic efficiency of TiC, TiN and TiB_2 and the products of their oxidation at 450°C and 1000°C in air and at 450°C in oxygen plasma was determined and compared with plasma treated TiO_2 and Ti_2O_3.

Photocatalytic activity, titania precursors, water stabilized plasma, oxygen plasma, titanium diboride, titanium carbide, titanium nitride, titanium oxide

1. Introduction

In recent years, a lot of attention is paid to photocatalytic reactions taking place on catalysts based on titania, especially its anatase modification [1,2]. During photocatalysis, intense degradation of organic substances and bacteria takes place on the photocatalyst surface under UV radiation. In study [3] we found that rutile modification also possesses photocatalytic properties, when processed by thermal plasma to obtain oxygen deficiency or defective crystal structure. It was also found that ilmenite, reduced in a hydrogen plasma (in a C/RF reactor under experimental conditions P_{H2} = 350 - 1010 Pa, P_{Ar} = 50 - 100 Pa, T_n = 600-720 K, T_e ~ 11 000K) to metallic iron and TiO_2 with highly disordered structure, exhibits measurable photoactivity [4].
Fabrication of large, strong free-standing parts (FSP) or free flight particles (FFP) from photoactive anatase by plasma spraying is not feasible, due to the low temperature of its transformation to rutile. This is in the 460-600°C range, depending on pressure.

The objective of this study is to produce free-standing parts from such titanium compounds that can be plasma sprayed and then transformed, either in bulk or superficially, to a photocatalytic base. For example, titanium boride, carbide and nitride are such compounds. The working hypothesis assumed that mechanically strong catalytic components of chemical reactors can be prepared using surface oxidation of such compounds under the anatase-rutile transformation temperature.

2. Experimental

Thick, compact coatings of TiB_2 and TiC [5] and TiO_2 were produces by plasma spraying onto graphite substrates using water stabilized plasma generator WSP®. TiN coating was produced by a CVD method. From these coatings, powder samples were prepared by milling after the graphite removal; these were sieved to <50 μm. Further, commercial Ti_2O_3 powder (HiChem Ltd. Praha, CZ) with <50 μm size was used. These powders were subjected to thermal gravimetry analysis in ambient air. It was found that oxidation starts already at 600°C, spontaneous oxidation occurred between 900-1000°C. To obtain information of the process kinetics, they were then oxidized isothermally in ambient air at 450°C and 1000°C and, for comparison, in a barrel rotating plasma chemical reactor in an oxygen plasma, generated by capacitively or inductively driven RF generator [6]. The RF generator (Fig. 1) operated at a frequency of 27 MHz with a power output of 1-4 kW. Total flow rate of oxygen controlled by mass flowmeters was 100 sccm, which corresponds to a pressure of 150 Pa. For plasma-assisted oxidation or reduction in plasmachemical reactors, the kinetic and energy conditions can be varied to obtain the same yield at lower temperatures (up to hundreds of degrees), which is particularly advantageous for low temperature phase transitions.

Fig.1. RF barrel reactor with capacitive coupling.

Variations in morphology, surface state, structural defect concentration of the reactants and products were characterized by SEM, XRD, BET and IR spectrometry. Photocatalytic activity of the materials was determined by colorimetry, based on the measurements of changes of optical parameters L*, a*, b* and DE* of an indicator (3,3´,5,5´-Tetrabromophenolsulfonphthalein (Bromophenol Blue) and 2-nitroso-1-naphtol) mixed with a powder sample, under UV radiation with a dominant wavelength of 360 nm. A Color Quest XE (Hunter Lab USA) instrument was used at D65 (daylight) and 10° viewing angle. The DE* values were obtained as

$$DE^* = [(DL^*)^2 + (Da^*)^2 + (Db^*)^2]^{½}.$$

The yellowness index, characterizing the degradation processes, was calculated according to the ASTM E313-98 standard. The products of titanium carbide and nitride oxidation were measured as received. However, oxidation of titanium diboride produced – besides TiO_2 – also boron oxide, causing surface sintering of the powder. Thus, boron oxide was removed by water leaching prior to photoactivity measurement.

3. Results and discussion

X-ray diffraction on powders and deposits oxidized in air showed that all samples oxidized at 1000°C for 1 hour transformed, in agreement with theory, to the high-temperature titania modification, rutile. Depending on the exposure time, the oxidation products at 450°C were mixtures of the reactants with a varying amount of rutile and anatase. When the oxidation time was extended to 4 h, all remainders of anatase transformed to rutile. Informative data on the oxidation kinetics are presented in Table 1.

Table 1 - DE* values in dependence on time and temperature of oxidation in air.

	oxidation temperature 450°C				oxidation temperature 1000°C			
sample	0,5 h	1 h	2 h	4 h	0,5 h	1 h	2 h	4 h
Ti_2O_3	15	17	18	18	4	9	10	10
TiC	8	12	12	-	3	4	4,5	-
TiB_2	14	15	15	-	4	5	5.5	5.5

The results of photoactivity measurements of the original and treated samples are shown on Figs. 2-4. The measurements were performed on samples oxidized for a constant time of 1 hour.

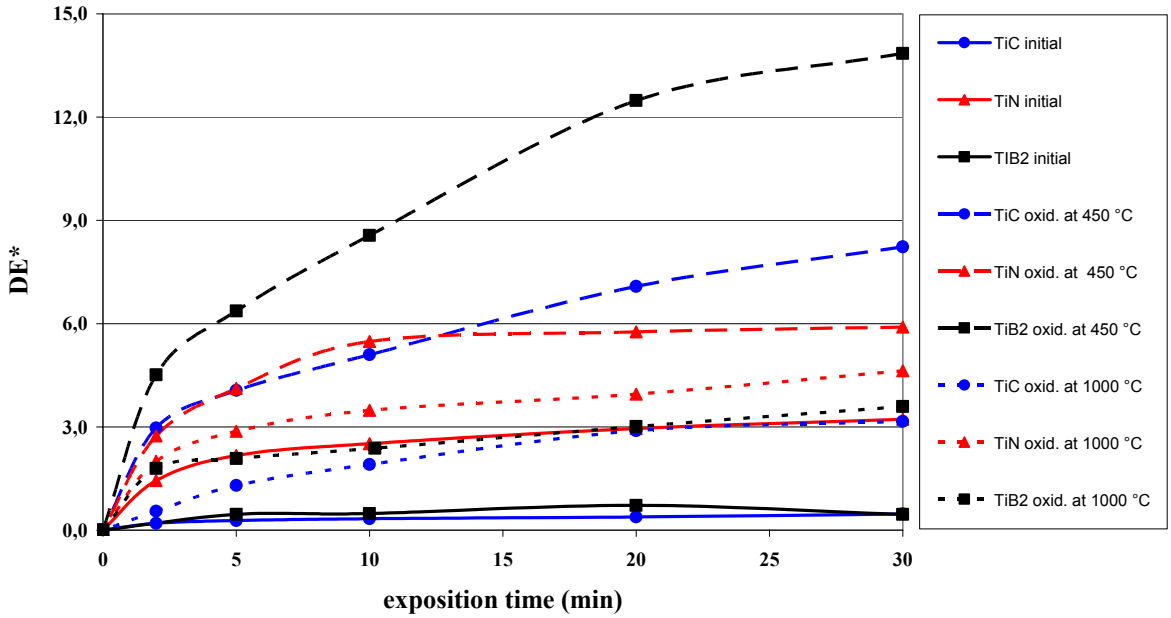

Fig.2 Dependence of a color change DE* of TiC, TiN a TiB_2 coatings colored by 2-nitroso-1-naphtol on the time of exposure by UV light (360 nm) in contact with atmospheric oxygen.

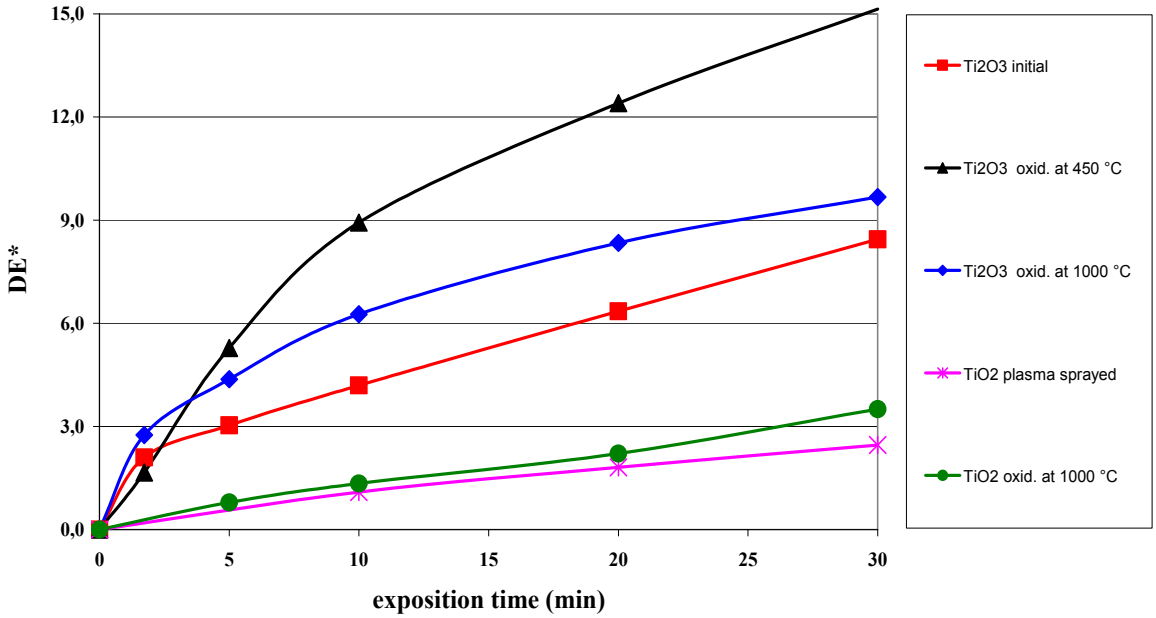

Fig.3. Dependence of a color change DE* of TiO_2 and Ti_2O_3 coatings colored by 2-nitroso-1-naphtol on the time of exposure by UV light (360 nm) in contact with atmospheric oxygen.

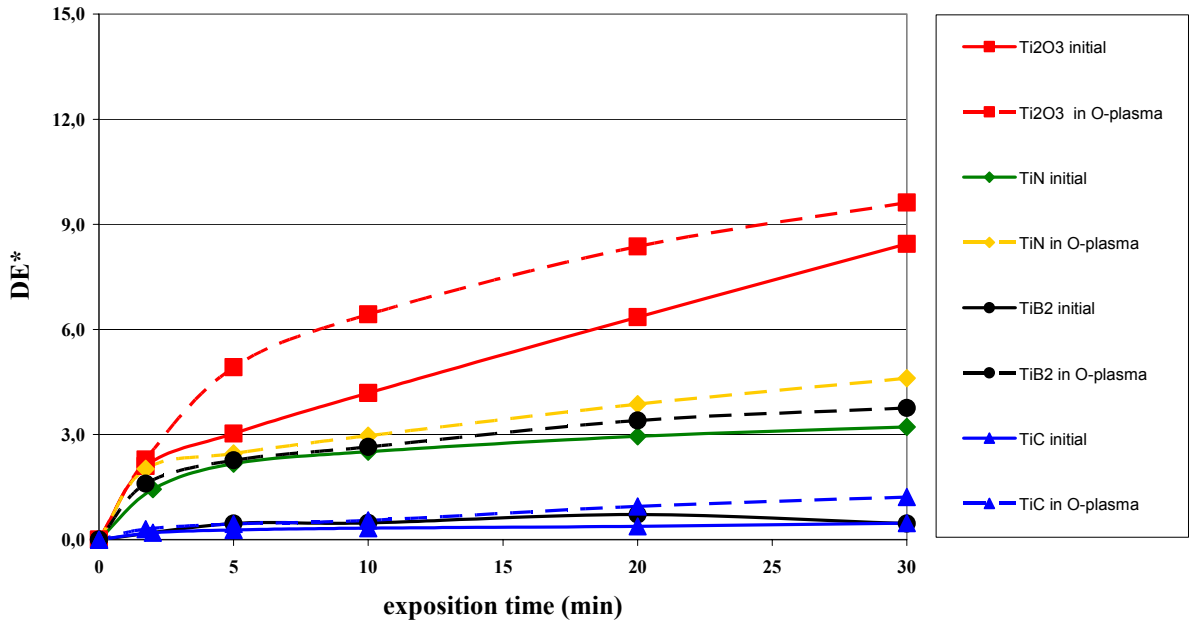

Fig.4 Dependence of a color change DE* of samples oxidized in oxygen plasma, colored by 2-nitroso-1-naphtol, on the time of exposure by UV light (360 nm) in contact with atmospheric oxygen.

From the measured DE* values and YI E313-98 curves, one can see that from the untreated compounds, only Ti_2O_3 (DE* 9/30 min) and TiN (DE* 3/30 min) exhibited moderate photoactivity. T his is probably a result of the TiN production, yielding TiN with 0.04 % oxygen. Plasma sprayed TiC and TiB_2 did not exhibit a distinct photoactivity; the measured values of DE* = 1–3 (see Fig.2) could not be unambiguously attributed to the effect of these non-activated substances.

Oxidation at both 450°C and 1000°C increased photoactivity in all studied substances. The photoactivity of all samples oxidized at 450°C was significantly higher than of corresponding samples oxidized at 1000°C. This corresponds to the presence of highly photoactive anatase in the 450°C oxidation products and presumed higher concentration of lattice defects and surface roughness, caused by lower processing temperature. Analysis of the surface layer of the 450°C samples showed anatase as the major phase and rutile as a minor phase. This influenced the DE* parameter. Maximum photocatalytic effect was observed in oxidized TiB_2 (DE* 15/30). Minimal effect was found in TiN (DE* 6/30), where, due to its high thermal resistance, only minute surface oxidation took place. In its diffractogram, only rutile was weakly identified. Photoactivity of TiC is characterized by DE* = 8/30 min.

Oxidation in the oxygen plasma at an outer wall temperature of 450°C confirmed the order of activity, but with a higher efficiency. The increase was up to fifteen-fold for TiB_2 and TiC and two-fold for TiN, after a 5-10 min exposure. Comparison with a photoactivity of titanium(III) oxide was not possible in this case, because of its intense black color.

SEM images of the deposit surfaces indicated a relationship between photoactivity, thermal treatment and powder morphology. Oxidation leads to increased surface roughness – for example, in TiN oxidized at 450°C, particles with needle-like protrusions 0,1–1 μm were observed. Higher oxidation temperature increases the rutile content in the surface layer and rounds the powder particles. This reduces the specific surface and the number of surface defects, leading to a further decrease in photoactivity. The defects and changes in oxidation state are currently studied also by EPR [7].

4. Conclusions

To obtain compact photocatalytically active materials, we verified the preparation of new titanium oxide forms by oxidation of various titanium compounds (precursors) with different crystal structures and titanium oxidation degree. Four model substances were chosen – titanium boride, carbinde, nitride

and titanium(III) oxide. These compounds can be prepared either as powders with high specific surface, or in the form of large area compact parts, using CVD, PVD and especially plasma spraying (except Ti_2O_3). After the treatment at high temperatures, reached by the water stabilized plasma generator WSP®, measurable photoactivity appears, which can be further controlled by a post-treatment under 450°C. Oxidation in an RF generated oxygen plasma initially seemed more efficient, especially regarding shorter reaction time. However, experiments have shown that although the outer wall temperature was controlled (450°C), uncontrolled temperature increase inside the reactor occurred during the reaction of oxygen plasma with the titanium compounds, leading to the formation of the less active rutile phase. Further process optimization is foreseen especially in the capacitively driven plasmachemical reactor, where the oxygen plasma concentration can be varied, but it is currently difficult to maintain a constant temperature and a stable discharge, due to the electrical conductivity of some precursors.

Abstract
Control of blood platelet adhesion on biomaterials requires high-quality equipment of surfaces with signal molecules. Here, these requirements are investigated for the case of the development of a new blood platelet assay in microtitre plates made from polystyrene (PS). PS surfaces modified in ammonia plasma were found to improve the adsorption and enable the covalent coupling of collagen I (Coll I), which causes high and reproducible platelet adhesion.

Keywords
Polymer, biomaterial, ammonia plasma, microwave plasma, surface modification, blood platelet

Motivation
Gas-discharge plasmas are widely spread applied for the mass production of surface modified polystyrene (PS) disposables. The products are called "tissue-culture treated" PS (TCPS) [1] and they possess different oxygen-containing surface groups, and in some cases additional nitrogen-containing groups. In certain applications including the one presented here this is not sufficient and surface modifications become necessary, which are aimed at increased densities of selected chemical functional groups and controlled biomolecule coupling.
In the present case blood platelet adhesion has to be quantified in a multi-well plate. Such a quantification is important to detect enhanced risk of vascular disorders caused by increased platelet adhesiveness, or by a reduced platelet adhesion compromising the haemostatic process. Platelet adhesion can be measured with perfusion chambers [2, 3], but this method is technically complex, very time-consuming and demands a lot of material and man power. In addition, although a number of platelet adhesion assays have been established, most of them need high amounts of expensive extracellular matrix biomolecules, still. Furthermore, instability of the adsorbed layer due to "unspecific" coating procedure was observed during platelet adhesion measurements.
To avoid these problems, here a new platelet adhesion assay was developed utilizing plasma-induced surface modifications, which improve specific adsorptive or covalent immobilization of extracellular matrix proteins.

Experimental
Polystyrene microtitre plates for fluorescence experiments (96 well flat bottom, high binding, black, non-pyrogenic, DNase and RNase free) were purchased from Greiner Bio one (Frickenhausen, Germany). The plates were treated in ammonia plasma generated in a microwave reactor V55G (Plasma Finish, Schwedt, Germany) using 500 W power, 40 ml NH_3 per minute gas flow at a constant pressure of 0.2 mbar for 30 s. This special experimental setup was found to possess enhanced selectivity concerning the formation of amino-functional groups on polymer surfaces [4]. Following this treatment, Collagen I (Coll I) was deposited to account for the needs of specific, selective adhesion. Here, Coll I served as model biomolecule for assay development, only. More specific and more expensive platelet adhesion stimulating substances could be applied in a high-throughput assay. Two different coupling methods (see Fig.1) were tested since it is well known, that functionality of biomolecules can be strongly impaired by immobilization and a prognosis of functionality for a certain method is difficult due to the complexity of polymer surfaces and biomolecules. Here, amino groups of the proteins were linked to polymer surface bound amines. The first route investigated is the reaction of glutardialdehyde (GDA, 2 % in water, Sigma, Taufkirchen, Germany) with amines to form Schiff bases. The second route utilizes a water soluble

carbodiimide (CDI, EDC, 0.12 mol/l, Sigma, Taufkirchen, Germany) as a catalyst for the coupling of acid groups of the spacer polyethylene glycol diacid (PEG-DA) with the amines. The methods mainly differ in the functionality of spacer molecule. While GDA is a short-chain molecule prone to ring formation and protein cross-linking by intermolecular condensation reactions, PEG-DA is a long-chain substance with self-organizing capability according to the repeating ethylene oxide groups. This means, GDA links the protein more rigid than PEG-DA, which additionally enables a higher disposability of the acidic head groups.

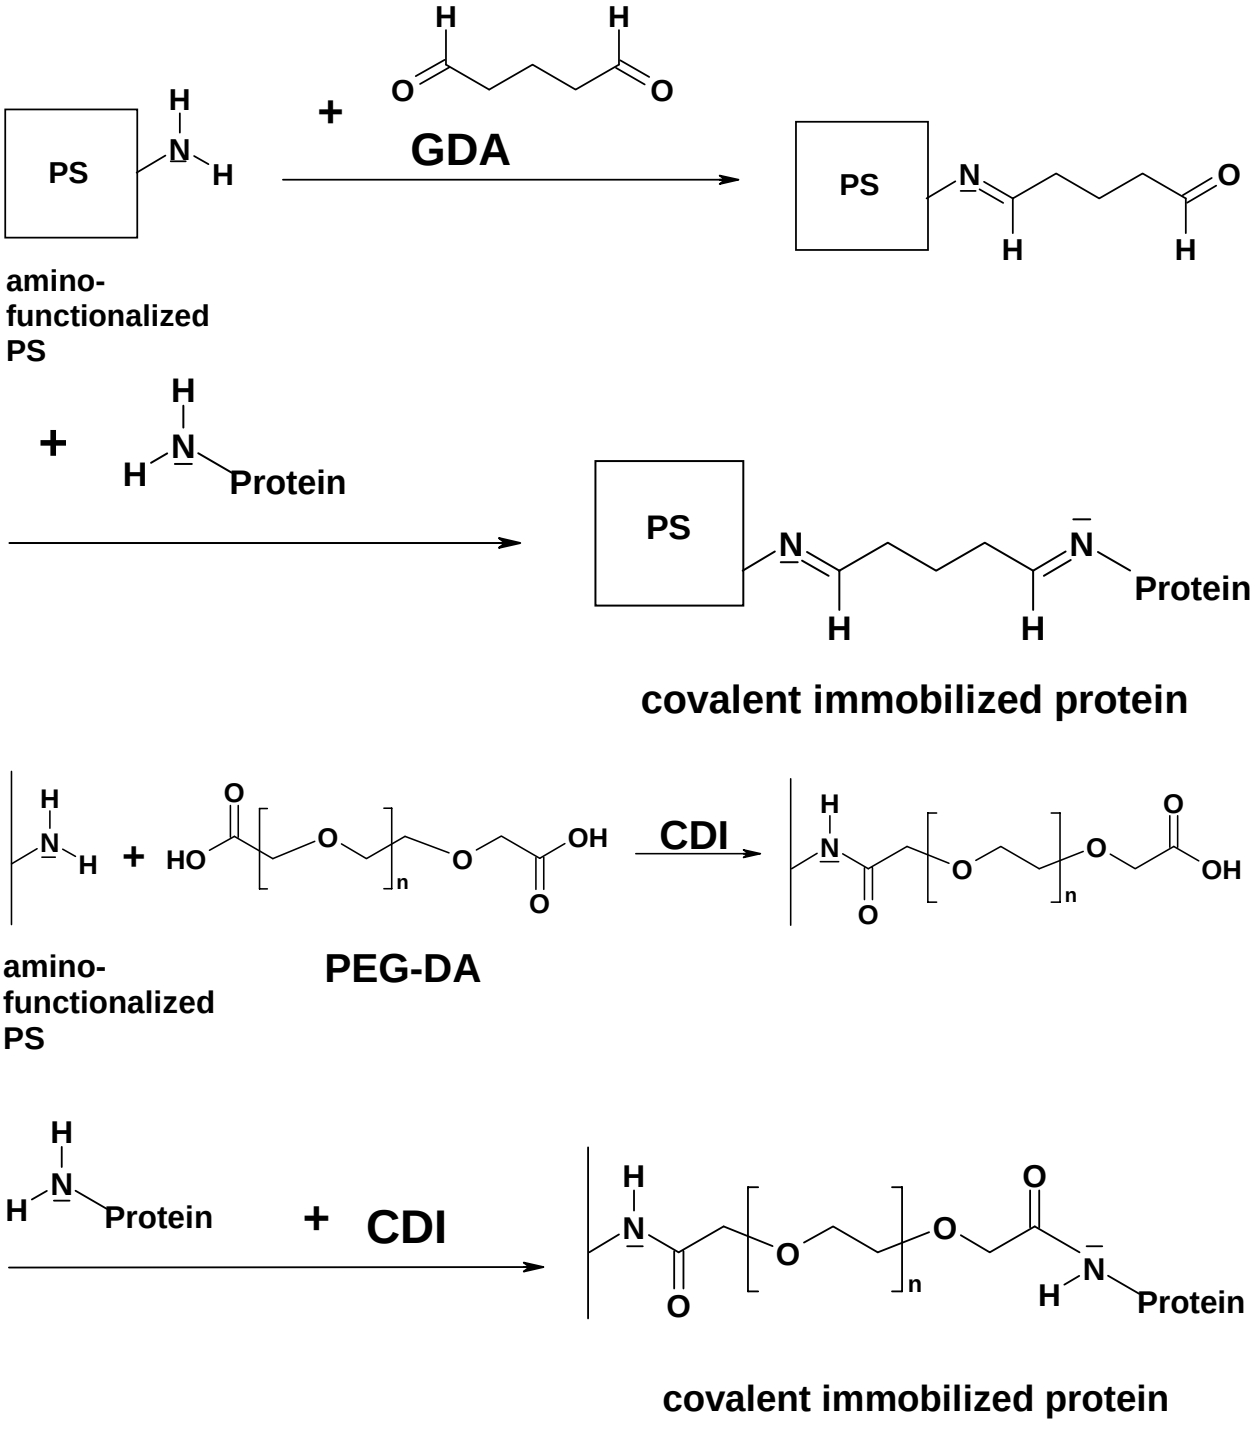

Fig.1: Schematic description of covalent protein-coupling to amino-functionalized PS surfaces by use of glutardialdehyde-method (GDA) and carbodiimide-method (CDI) with polyethylene glycol diacid (PEG-DA), respectively.

For XPS measurements, plane pieces of the bottoms of the wells with a diameter of about 5 mm were cut out. XP spectra were taken with an Axis Ultra (Kratos, Manchester, UK) with monochromatic Al K_α irradiation, charge neutralization and a spot size of about 700 µm diameter.
Human platelets were isolated from whole blood, which was obtained from healthy volunteer donors. Briefly, platelets were harvested from blood by centrifugation and platelet rich plasma (PRP) was transferred into the same volume washing buffer composed of NaCl, KCl , citric acid, $MgCl_2$, $CaCl_2$, glucose (pH 6.5). The PRP was incubated for 15 min at 37°C and centrifuged afterwards. The platelets were gently resuspended in 2 ml washing buffer containing PGE1 and apyrase. Again, washing buffer was added, incubated and centrifugated.

For the adhesion tests, 100 µl of fluorescence labelled platelets (calcein labelling, 100.000/µl) were incubated per well in the dark at 37 °C for 30 min. The number of adherent platelets was determined fluorometrically (Microplate-Reader, FLX 800, BIO-Tek, Winooski, Vermont, U.S.) after three washings.

Results and Discussion
The availability of surfaces with enhanced amino-functionalization is a useful starting point for coupling of biomolecules [5]. The effects of coupling can be approximately characterized by XPS-measurements. In Fig.2 results of such measurements are summarized which are relevant for the present investigations.

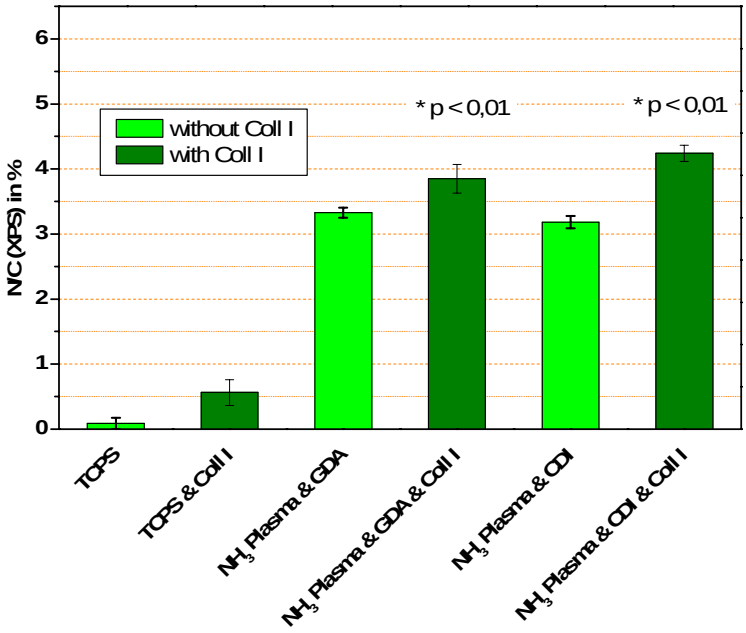

Fig. 2: XPS measurements for comparison of covalent bonding of Coll I from a highly diluted solution (0.01 µg/ml) on ammonia plasma treated surfaces via GDA- and CDI-PEG-DA-method with TCPS surfaces.

Here, the amount of nitrogen on the surface is taken as an indication for the presence of positively charged nitrogen-functional groups in general. Clear differences can be seen between the starting material TCPS (0.1±0.1 % N/C), and the ammonia plasma treated samples (> 3 % N/C). The nitrogen detected on the surfaces coupled with Coll I and the nitrogen detected on surfaces covered with GDA or PEG-DA may stem from different sources. In the latter case it is an indication of nitrogen functional groups generated by the ammonia plasma treatment since both GDA and PEG-DA do not contain any nitrogen. For the Coll I coated surfaces the nitrogen signal may originate from the Coll I, likewise. At least the surplus of nitrogen in comparison to the respective uncoated samples should arise from it. This assumption is supported by the results of additional coupling experiments which used different concentrations of collagen in the coating solution. A high concentration of collagen of 5 µg/ml resulted in surface nitrogen content as high as 17 % for GDA coupling and 13 % for carbodiimide polyethylene glycol diacid (CDI-PEG-DA) coupling. A strong reduction of the concentration to 0.1 µg/ml resulted in a substantial reduction of this signal to about 5 % in both cases with a difference of 1 % to the uncoated

materials (NH_3-plasma + GDA or PEG-DA, respectively). This difference did not change anymore for a further strong reduction of the concentration to 0.01 µg/ml, as can be seen from Fig. 2. Hence, it seems reasonable to assume that for these very low concentrations a certain similar amount of Coll I is deposited on the surfaces for the cases of pure adsorptive coating on TCPS and for both routes of covalent coupling.
In Fig. 3, the results of the respective platelet adhesion investigations are presented. Obviously, Coll I coating on TCPS is much less effective than the other coating methods. That means Coll I possibly adsorbed to TCPS in these small amounts is not active or washed during platelet adhesion assay.
The tenfold platelet adhesion on Coll I immobilized by the PEG-CDI method demonstrates significant advantages of covalent coupling. Also, covalent coupling by the GDA-method shows advantages. But it is not as efficient as the PEG-method. This can be interpreted as an effect of the more rigid coupling of the collagen to the surface which can influence its conformation in a way limiting its activity. Interestingly, a high platelet adhesion is also achieved, if Coll I is applied directly to ammonia plasma treated microtitre plates. The adhesion is similar to the PEG-method. This suggests the conclusion that Coll I is only adsorbed to the surface since otherwise its activity would be limited due to close and rigid surface contact. Vice versa, the similar activities suggest, that covalent coupling by the PEG-method results in optimum conformation of Coll I for platelet adhesion.

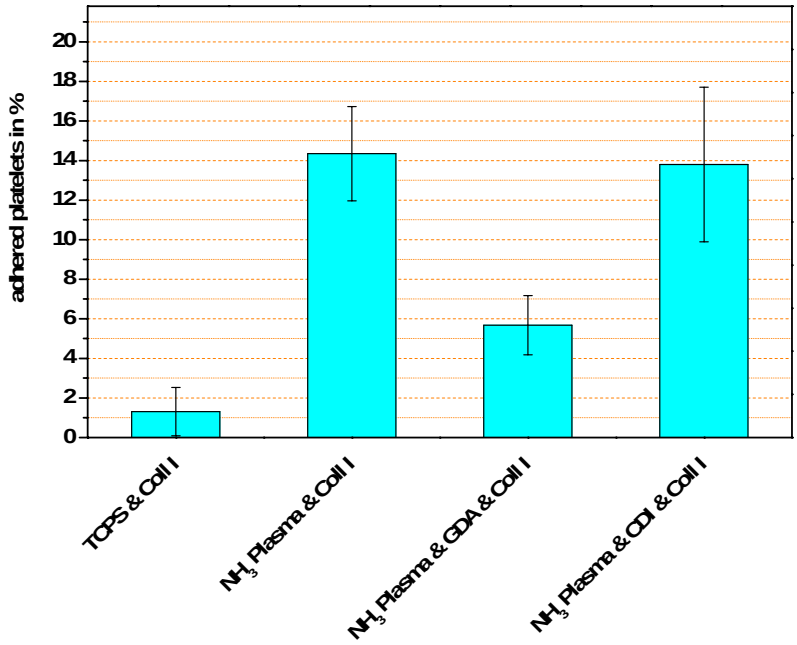

Fig. 3: Coll I coating from diluted solution (0.01 µg/ml): Analysis of platelet adhesion.

For the purpose of assay development, such a combination of low consumption of platelet adhesion stimulating substances and high platelet adhesion is highly desired. It would be of interest to know whether improvements are possible or not. One possibility to test this is to change the concentration of the Coll I solution. In Fig. 4 the results of adhesion tests are given for much more concentrated solutions (5 µg/ml) compared to Fig. 3. With the exception of Coll I on TCPS, only small improvements of adhesion are obtained. This means, that collagen bonding by PEG-DA and high quality ammonia plasma surface treatment may result in an enormous potential to save expensive signal molecules.

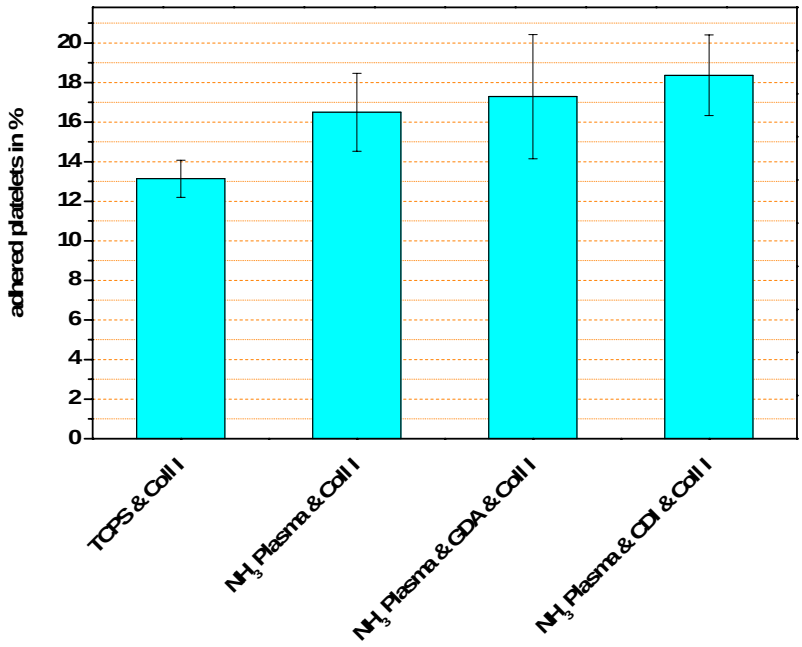

Fig.4: Coll I coating from concentrated solution (5 µg/ml): Analysis of platelet adhesion.

The here observed effects follow the predictions of a very general concept of understanding of the biological responses at non-physiological interfaces, which is known for a long time. According to this understanding, cationic electrostatic forces exhibit a low complement activation and coagulation, but very high platelet adhesion [6]. Also platelet adhesion on plasma polymers agree with it, as e.g. earlier investigation using plasma polymerized allylamine deposits on polyethylene (PE) [7] and polyethyleneterephthalate (PET) [8] demonstrated. These polymeric deposits were found to be more thrombogenic, i.e. adherent for platelets, than the untreated polyethylene, acrylic acid plasma polymers or PET and polyurethane. Similar effects were obtained in an investigation of hydrogels for the improvement of interfacial biocompatibility of polymers. Once more, a positively charged surface (introduced via dimethylaminoethyl DMAEMA copolymers) increased platelet adhesion compared to the nonionic hydrogel polyacrylamide (PAAm) [9]. Mostly, in the literature the increased adhesion is believed to be a consequence of fibrinogen adsorption due to ionic interactions between the positively charged amino groups on the surface and the fibrinogen molecule [8]. More recently, a comparison of the effects of pure fibrinogen, fibronectin, vitronectin and von Willebrand's factor preadsorbed on polystyrene substrates demonstrated that all of these biomolecules are able to support platelet adhesion. Except for fibrinogen, a dependence on the substrate surface pretreatment, whether untreated, fluorinated or positively charged, was found. Also it was reported, that very low amounts of fibrinogen were sufficient to support full-scale platelet adhesion [10].
The here reported results seem to extend the validity of all of these findings for the case of surfaces equipped with covalently bound biomolecules.

Abstract: Applications of atmospheric pressure non-equilibrium plasmas, now exclusively produced in the form of filamentary barrier discharges, atmospheric pressure glow discharges, and microplasmas, is spreading out into various engineering fields of not only material processing, but also energy and environment due to its special advantages of forming highly reactive plasmas at atmospheric pressure using simple reactor system. Our research group has been focusing on not only the development of new applications of those plasma sources, but also the establishment of appropriate modeling that enable us to characterize and optimize given plasma processes. This paper overviews our recent projects that range from nano-fabrication in materials processing to fuel upgrade in mega-industries.

1. Introduction

Atmospheric pressure non-equilibrium plasma has been exclusively produced in dielectric barrier discharges (DBDs), and historically used in ozone industry since 1857 [1]. DBD is now recognized as viable processing plasma for chemical conversion processes and applications are spreading out into many fields such as gas cleaning and fuel reforming with growing concern of global environment. In the late 80s, S. Okazaki and co-workers has explored atmospheric pressure glow discharge known as APG that gives spatially diffuse non-equilibrium plasma at high pressure [2]. Research activities and applications in this new field of plasma science and technology have been expanding into not only gas treatments, but also surface modifications, coatings, and PECVDs. The primarily interest of APGs is emphasized in practical applications since it minimizes vacuum system and allows to handle bulky materials in continuous process. It even enables us to use liquid precursors to deposit functional films [3]. From fundamental viewpoint, broad range of operating pressures from 10^{-1} Pa to 10^{5} Pa bring us to the comprehensive understanding of fundamental processes in both gas phase and boundary phenomena in plasma materials processing: it is believed to create greater value-added plasma processing in various industries where processing plasma is currently too expensive to introduce. Atmospheric pressure non-equilibrium plasmas have made a recent remarkable progress in formation techniques in the filed of microplasma. Efficient generation method and diagnostics of microplasma and the development of new applications including light sources of ultra-short wavelengths, three-dimensional micromachining tools, and other plasma devices are now being investigated [4].

This paper overviews materials processing in atmospheric pressure non-equilibrium plasmas based on our recent work. In section 2 and 3, authors devote ourselves to introduce fundamental character of both filamentary and diffuse barrier discharges known as dielectric barrier discharge (DBD) and atmospheric pressure glow discharge (APG), respectively. Optical emission spectroscopy, 1-D simulation of streamer formation, energy balance analysis, and gas chromatographic analysis are provided in order to distinguish DBD and APG from the viewpoint of “thermalization of non-equilibrium plasma”. Novel applications using DBD, APG, and microplasma are briefly introduced in section 4: (1) Low-temperature fuel reforming due to radical injection, (2) Non-equilibrium chemical reaction control in micro-scale reactor, (3) Deposition of carbon nanotubes in atmospheric pressure glow discharge, and (4) Microplasmas and application to nanoparticle formation. Concluding remark is presented in section 5.

2. Atmospheric pressure non-equilibrium plasmas

Generation methods of atmospheric pressure non-equilibrium plasma can be classified into several ways. Filamentary discharges: (I) Barrier discharge type: At least one of two metallic electrodes must be covered by insulating material in order to limit discharge currents and extinguish them within 1-10 ns. An insulating barrier also enables to disperse filamentary discharges over the gap. (II) Corona discharge type: Non-uniform electric

field such as point-to-plane geometry creates sufficiently large electric field that locally breaks down the gap and produces weakly ionized discharge at atmospheric pressure. Corona discharge does not transform into spark discharge as long as voltage and current relationship maintains positive differential characteristics (i.e. $dV/dI > 0$). (III) Pulsed discharge type: Fast response switching device or pulse forming network is applied in order to limit power input to the discharge channel. The pulse duration is generally of the order of 100 ns to avoid arcing, but optimum pulse duration depends on voltage polarity, ignition delay, and streamer propagation period. Homogeneous discharges: (IV) Penning ionization type: If Penning ionization or cumulative ionization becomes a major source of secondary electrons, avalanche-to-streamer transition would be suppressed and Townsend-like break down takes place. This type of plasma is exclusively produced in He, Ar, and N_2. High frequency operation (RF~MW) increases plasma density and helps this mechanism. (V) Microplasma type: As reactor dimension gets smaller than effective $(pd)_{min}$ at given pressure, operating pressure must inevitably increases in order to sustain self-maintaining discharge. Here, $(pd)_{min}$ expresses Paschen minimum and typical value is given by $(pd)_{min} \sim 1$ mmHg cm in ordinary gases [5]. Unlike transient discharges such as DBD and APG, microplasma could be characterized by effective dc approximation when operating frequency exceeds 100 MHz at atmospheric pressure.

It does not necessarily mean that each type of discharge appears in a single reactor. Two or more of them are need to be appropriately combined in a single plasma reactor for desired purpose. The next section exclusively describes fundamental properties of dielectric barrier discharges in both filamentary and diffuse modes which are customary recognized as DBD (dielectric barrier discharge) and APG (atmospheric pressure glow discharge). These two types of discharge are clearly distinguished by not only current waveforms and emission distribution, but also heat transfer characteristics and thermal structures.

2.1. Dielectric Barrier Discharge

A peculiarity of DBD is the presence of a dielectric insulator on one or both metallic electrodes, which leads to a formation of large number of filamentary microdischarges of nanosecond duration. Figure 1 shows typical voltage and current waveforms observed in DBD. It also shows a photograph of streamers taken with high-speed intensified CCD camera (i-Star DH712; Andor Technology). A large number of nanosecond current pulses are observed at every half cycle of applied voltage. The immediate termination of developing discharge due to charge built up on dielectric barrier creates a highly reactive non-equilibrium condition at atmospheric pressure. Due to the charge accumulation on the barrier, streamers are randomly dispersed between electrodes. The gas breaks down based on streamer breakdown mechanism. The velocity of propagating streamer is ten times higher than the drift velocity of electrons at given reduces electric field (10^8~10^9 cm/s). Each filament corresponds to a nanosecond current pulse appearing in the current waveform. DBD has been extensively studied in ozone production and detailed characteristics of individual filamentary discharge have been investigated by many researchers [6-8]. It is not too much to say that electrical and chemical properties of DBD reactor are determined by those of an individual filamentary discharge. Unfortunately, principle parameters such as electron density and electron energy in individual filament are hardly controlled by external parameters because streamer propagation time is too short to establish electrical coupling with external driving circuit. Operating conditions such as frequency and voltage amplitude simply change the number of filaments per unit time and unit area. This kind of robustness, however, may propose some advantages: DBD reactor is operated with variety of power source from commercial frequency to several hundreds kHz without having matching problem. Once reactor is optimized in a laboratory, it is easily scaled up to large scale industry installation.

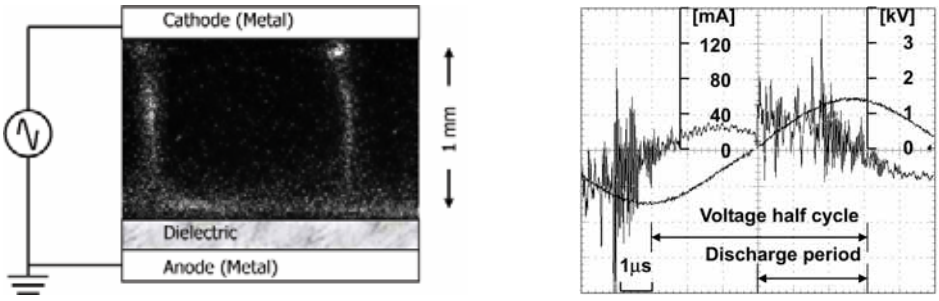

Fig. 1 Voltage and current waveforms in DBD (AC-80 kHz) and Photograph of a single streamer produced in pure methane (10 ns exposure time).

2.2. Atmospheric pressure glow discharge

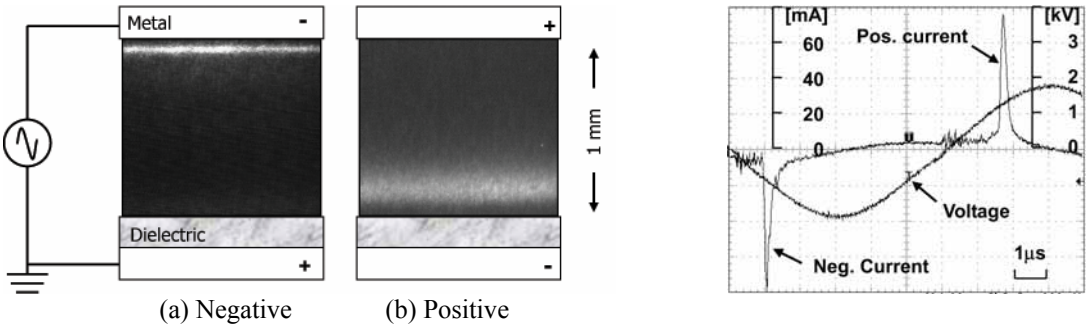
The discovery of atmospheric pressure "glow" discharge dates back to the early 30s and its history is well described by Kogelschatz [9]. This paper focuses on recent development of atmospheric pressure "diffuse" barrier discharge, in which S. Okazaki and co-workers called atmospheric pressure glow discharge (APG) [2]. Recent progress in formation technique and applications has been published in the journal [10]. Figure 2 shows AC-80 kHz high voltage and current waveforms obtained in APG (CH_4:He=2:98). APG in Fig. 2 was produced in identical barrier discharge reactor using the same power supply shown in Fig. 1. Only difference is that feed gas is diluted by helium. With minimum over voltage, a single current pulse with 500 ns duration appeared at every half cycle of the voltage. A single current pulse became multiple pulses with increasing over voltage [1]. Corresponding emission distributions in the visible spectrum are described in Fig. 2 (a) - (b). Figure 2 (a) shows a superposition of 100 discharge events synchronized with negative discharge current with 1 μs exposure time (metallic cathode - dielectric anode). Figure 2 (b) was recorded during positive discharge current. Light distribution is not localized in the radial direction, but intense emission layer is created near the temporal cathode in both pictures. The emission distribution of APG has the structure similar to that of low pressure glow discharge [12]. Faraday dark space, positive column, and cathode glow are established at the time when a single current pulse reaches its maximum. At this moment, electron density in the temporal cathode region reaches $10^{11}cc^{-1}$ [12,13]. Production of metastable state helium by electron impact and associated Penning ionization becomes important source of secondary electrons. Electron avalanche does not transform into streamer since operating voltage is sufficiently lowered in helium, and Townsend-like breakdown takes place. N_2-based APG attracts broad attention from practical point of view. Formation mechanism also relies on Penning ionization; however, the presence of gaseous admixture is limited below 0.1%, and electron density (10^8cm^{-3}) doesn't reach high enough to produce cathode region. Increasing frequency improves stability of APG, but radio frequency may not be suitable for large scale plasma reactor which extends over 1 m.

3. Thermal structure of atmospheric pressure non-equilibrium plasmas

As briefly described above, DBD and APG are characterized as weakly ionized plasma with properties resembling transient high-pressure glow discharge. The immediate termination of developing plasma due to charge built up on dielectric material realizes highly reactive non-equilibrium conditions at atmospheric pressure. On the other hand, the electrical energy put into atmospheric pressure plasma easily transforms into thermal energy via large number of particle collisions that may lead to serious gas heating. The energy efficiency of material conversion in those plasma process is normally less than 10%. From this point, we paid special attention to the analysis of energy distribution mechanisms in methane-fed DBD and APG by focusing on energy balance analysis, emission spectroscopy of the rotational band of CH ((0,0) $A^2\Delta \rightarrow X^2\Pi$), and gas chromatographic analysis [14,15]. For the best understanding of microscopic energy deposition characteristics and improving energy efficiency by molecular scale optimization, we also analyzed thermal structure of methane-fed DBD and APG by focusing on time averaged gas temperature profiles across discharge gap.

3.1. Relationship between rotational temperature and gas temperature

As shown in current waveforms in Fig. 1 and Fig. 2, feed gas repeatedly breaks down at regular intervals. Therefore, the following relation can express net gas temperature increase between gas gap.



(a) Negative (b) Positive

Fig. 2 Voltage and current waveforms in APG (AC-80 kHz) and photographs of APG synchronized with (a) negative discharge current, (b) positive discharge current with 1 μs exposure time.

$$\Delta T_{net} \approx (T_{rot} - T_0) \approx \Delta T_{ave} + \Delta T_{plasma} \quad [\mathrm{K}] \qquad (1)$$

Here, T_{net} represents net temperature increase between gap, T_{rot} refers to rotational temperature, T_0 is initial gas temperature, ΔT_{ave} represents average temperature increase of feed gas, and ΔT_{plasma} is local temperature increase due to microdischarge or glow discharge formation. The rotational temperature was derived by the Boltzmann plot of rotational band of CH emission [14,16]. Average temperature increase (ΔT_{ave}) depends on not only plasma properties, but also various engineering factors such as flow field, external cooling conditions, and total input power, whereas ΔT_{plasma} is closely related to local energy deposition into transient discharges. In order to characterize thermal structure of DBD and APG, we need to separate ΔT_{ave} and ΔT_{plasma} from net temperature increase (ΔT_{net}).

Rotational temperature versus initial gas temperature (see Eq.1) in methane-fed DBD is shown in Fig. 3 [15]. Rotational temperature is 100-150 K higher than initial gas temperature because microdischarges are localized in narrow filamentary region, but it showed enough sensitivity to the variation of initial gas temperature. The results shown here is much higher than those provided by Luque et al. [17]. They concluded that temperature increase in a streamer is close to 10 K in CH_4/CO_2 barrier discharges operated by 14 kHz pulsed voltage (FWHM: ~2μs). Comparison between these two conclusions suggests important aspect. High frequency operation conducted in our experiment (80 kHz) induces microdischarges that excessively heats up discharge channels. High frequency operation is desirable to design compact reactor and increase throughput, but it might work more like heat source than radical source. It was further investigated in DBD and APG by focusing on energy balance and heat transfer analysis [15,18]. Excess temperature increase in DBD (i.e. ≈100 K) was also observed with respect to input power and gas velocity as shown in Fig. 4 and Fig. 5, while rotational temperature in APG is fairly close to average gas temperature since diffused discharge decreases power density. From Fig. 3 to Fig. 5, ΔT_{plasma} is nearly constant regardless of initial gas temperature (300-400 K), input power (0.5-3.8 Wcm^{-2}), and gas velocity (1-6 ms^{-1}) as long as gas gap (0.5 mm), dielectrics (0.5 mm Pyrex), and pressure were unchanged. Raising the input power for a given configuration generates increasing number of microdischarges per unit of electrode surface, whereas energy spent in an individual microdischarge, on average, does not change significantly. On the other hand, ΔT_{ave} depends mostly on input power and external cooling conditions.

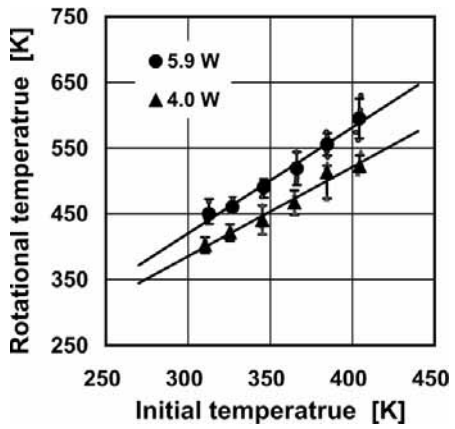


Fig. 3 Rotational temperature vs. initial gas temperature in DBD. Discharge area; 10×80 mm^2, gap; 0.5 mm, dielectric; 0.5 mm Pyrex, gas velocity, 1.0 ms^{-1}, and AC-80 kHz.

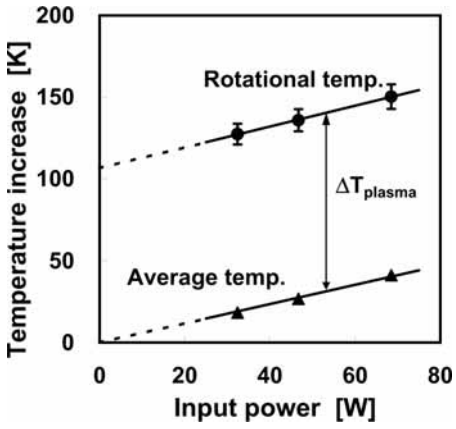

Fig. 4 Comparison between average gas temperature and rotational temperature in DBD. Discharge conditions: see Fig. 3.

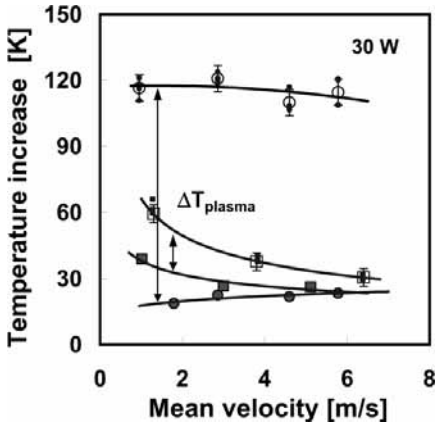

Fig. 5 Average temperature for (●) DBD and (■) APG. Rotational temperature for (○) DBD and (□) APG. Discharge conditions: see Fig. 3.

3.2. Net temperature distribution across discharge gap ($\Delta T_{ave}+\Delta T_{plasma}$)

In the practical interest, net temperature increase ($\Delta T_{ave}+\Delta T_{plasma}$) also poses important issues. Figure 6 (a) shows net temperature increase in DBD obtained by using AC-80 kHz high voltage. When increasing input power, net temperature (ΔT_{net}) in the middle of the gap remarkably increases because of poor cooling condition. Net gas temperature does not approach electrode temperature (20°C) even when decreasing input power to zero since energy spent in individual microdischarge does not continuously approach zero with decreasing input power. This means that gas temperatures increase on both electrodes should correspond to $\Delta T_{plasmae}$. In fact, $\Delta T_{plasmae}$ (~100 K) shown in Fig. 4 corresponds to the temperature increase on both electrodes. In addition, these temperatures are uniquely independent of input power. ΔT_{ave} could be minimized by improving external cooling condition of the reactor. However, memory effect due to high frequency operation induces significant gas heating which reached 100-150 K higher than initial gas temperature. In APG, net temperature increases near metallic electrode was remarkable as shown in Fig. 6 (b), and significantly increase with increasing input power. Temperature distribution is broadened by heat conduction through gas media (main component is helium). Local temperature increase near dielectric barrier becomes clear with input power even though magnitude is still moderate.

4. Applications

4.1. Fuel upgrade using filamentary barrier discharges

4.1.1. Streamer formation and related chemistry in methane

We performed numerical simulation on streamer propagation in pure methane for the best understanding of elementary electronic and chemical processes [19,20]. The model consists of two different stages: streamer propagation and related chemistry where ionization, excitation, and dissociation of methane by electron impact are evaluated along with time evolution of field strength and electron density. We adopted complete set of cross sections of methane compiled by Davies et al [21] as recommended by Morgan [22]. During streamer development, electric energy input and radical formation efficiency were analyzed in detail. After the termination of streamer development, the second stage, ionic and free radical chemistry that would last for 10 ms was performed with the reaction scheme proposed by Tachibana et al [23]. The model includes 16 neutral species, 4 positive ions, and 2 vibrationally excited species. Temperature and pressure were 300 K and 760 Torr, respectively. We simulated Anode Directed Streamer (ADS) [24] ignited from tiny plasma spot which is initially located in front of the cathode. We assumed streamer was one-dimensional cylinder with 100 μm diameter. Basic equations were continuity equations for electron, ions, and neutral species, and Poisson's equation. 38 elementary reactions including 8 inelastic collisions were simultaneously solved. Physical modeling and mathematical procedure are presented by many researchers [25-27].

Figure 7 shows temporal development of radical species and products. All radical species including electron are rapidly increases with streamer propagation. Electron density reaches $10^{14}cc^{-1}$ when stream hits the anode. C, CH, CH_2, and H are quickly consumed after streamer termination to form C_2H_2, C_2H_4, and H_2. CH_3 remains relatively high population since hydrogen subtraction from CH_4 by CH_4^+ ($CH_4+CH_4^+=CH_3+CH_5^+$) makes

radical chain, which eventually produces C_2H_6. From this point, formation of streamer is considered as radical injection phase. The most abundant species are vibrationally excited methane that reached 100 times higher than electron density. However, it can not participate further reactions because of low reactivity. Therefore, production of vibrationally excited methane leads to remarkable energy loss. Approximate radical density and energy distribution are summarized in Table 1 along with excitation threshold. Excitation threshold for vibrational excitation is of the order of 0.1-0.3 eV, however, nearly 40% of input electric energy was consumed since rate constants are 10 times larger than other reactions. From this point, decomposition of vibrationally excited methane during reforming reaction may significantly increase energy efficiency of the process.

4.1.2. Low-temperature fuel reforming due to radical injection

Although industrial applications of C_1 chemistry depend mostly on catalytic conversion processes, plasma catalysis are highlighted as unique technique for energy saving and environment safe purposes with increasing demand of hydrogen and synthesis gas [28-30]. More recently, atmospheric pressure non-thermal plasmas such as Plasmatron [31] and Glidarc [32,33] are recognized as economically competitive plasma fuel converters. Electrical energy consumption of those plasma reactors is normally less than 10% of heating value of the initial fuel when combined with partial oxidation. Driving force of reforming reaction essentially depends on heat released by partial oxidation, while the plasma preliminary enhances the combustion process of initial fuel/air mixtures.

We have developed a barrier discharge and catalyst hybrid reactor for the low temperature reforming of methane [19,20]. This technique allows utilizing low temperature thermal energy wasted from industries, which eventually provides variety of energy utility options. The idea behind the project is that low-calorie fuels such as biogas can be upgraded in the temperature range of 300°C to 400°C, which corresponds to the exhaust gas from internal combustion engine, by the help of non-equilibrium plasma. The resulting hydrogen enriched gas is then available to improve the ignition stability of poor fuels and drives a megawatt internal combustion engine. Figure 8 illustrates the configuration of barrier discharge and catalyst hybrid reactor. The basic idea of hybrid reactor was first developed by Mizuno and Yamamoto [34,35]. The rod-to-tube (ϕ_r 3 mm × ϕ_i 20 mm) reactor was packed with catalyst pellets of 12wt%/γ-Al_2O_3 (3 mm) in the volume of ϕ_i 20 mm × 50 mm. Bipolar pulsed voltage (+/-20 kV at 1-5 kpps with FWHM:~2μs) was applied between center and external ground electrode. The discharge is ignited at pellet contacts, and then propagates covering pellet surface, providing best interaction between plasma

and catalyst. We used simulated biogas which includes 60% methane and 40% nitrogen (CH_4:N_2 = 6:4). Steam and methane ratio (S/C) was set to one (S/C = H_2O/CH_4 = 1). The plasma hybrid process needs to convert 20% of initial methane that enriches hydrogen in output gas by 32% (dry base). It remarkably enhances combustibility of "poor" biogas and is able to drive internal combustion engine.

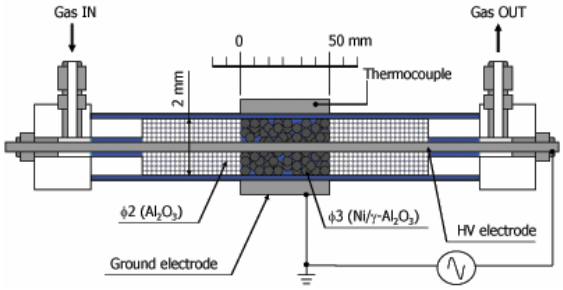

Fig. 8 DBD/Catalyst hybrid reactor

Figure 9 compares methane conversion obtained by three different conditions. The results clearly show that methane is hardly decomposed by barrier discharge since discharge power was limited in order to avoid excess gas heating, i.e. input power was carefully adjusted so as not to exceed endothermic enthalpy of the reaction. Input power density with respect to methane flow rate was smaller than 120 kJ/mol$_{CH4}$ (~13% of HHV of CH_4). According to Fig. 9, Ni/γ-Al_2O_3 catalyst is more effective than barrier discharge, but result does not reach equilibrium because the space velocity is high (SV = 10000 hr^{-1}). On the other hand, combined result reached equilibrium all the way through the temperature tested. Figure 10 schematically presents potential curve for methane molecule, showing tentative reaction mechanisms [18]. Thermal dissociation of methane to H and CH_3, for example, follows the ground state potential curve. This process requires high temperature heat source (> 800°C) and consumed 4.26 eV dissociation energy. Methane dissociation by electron impact must follow upper electronic state that is expressed as dissociation curve. The great benefit of electronic process is that methane decomposition proceeds independently of temperature and pressure, but main drawback is that electrons have to lose twice as much energy as dissociation energy by single collision (9-12 eV >> 4.26 eV). Excess energy fed into methane molecule increases kinetic energy of H and CH_3. Based on our numerical simulation (see 4.1.1), 50% of electric energy can be utilized for dissociation collision to form CH_i (i = 0,1,2,3) and H radicals. However, 60% of those excited energy must be released for gas heating as an excess input energy. This is the main reason that energy cost of plasma fuel conversion is much higher than that for thermal processes. Plasma enhanced catalytic reaction is explained by two-step process as shown in Fig. 10. Two vibrational states of methane are produced by inelastic electron collision. Dissociative chemisorption of vibrational methane takes place at low temperature (400°C ~ 600°C) [36]. This kind of electronic process does not accompany excess energy input since a series of reaction takes place within a ground state potential curve. In addition, number density of vibrational species is 100 times higher than electrons. The utilization of vibrationally excited methane in plasma catalysis potentially increases the efficiency on chemical conversion process in large degree.

4.1.3. Non-equilibrium chemical reaction control in micro-scale reactor

The great benefit of partial oxidation of methane, particularly direct synthesis of methanol, has attracted

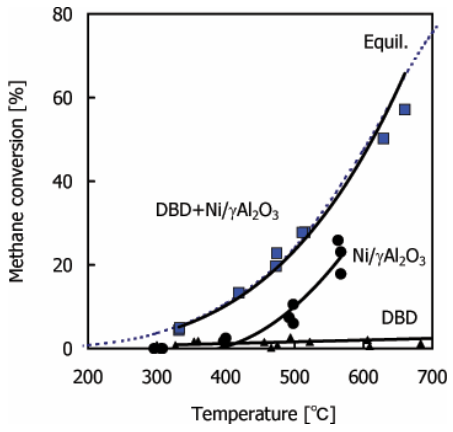

Fig. 9 Methane conversion vs catalyst bed temperature which is measure by infrared camera.. SV = 10000 hr^{-1}, $CH_4/N_2/H_2O$ = 1100/733/2200 sccm (S/C = 1). Power = 25-120 kJ/mol $_{CH4}$.

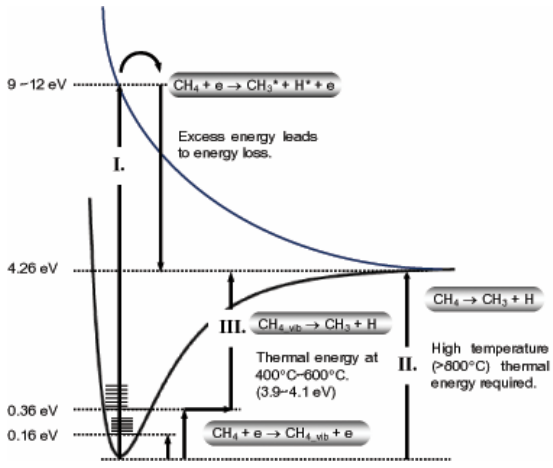

Fig. 10 Methane activation by thermal energy, electron impact, and their combined effect

substantial effort over the past decade because increasing demands for energy and environmental protection are incompatible with a modern two-step liquefaction process, which includes energy intensive syngas ($CO+H_2$) manufacturing. Nevertheless, one-pass yields of organic oxygenates in thermal reaction are generally no more than 5% [37]. More promising results that have claimed a 10% yield have proved difficult to reproduce [38]. One promising solution to achieve a higher yield of useful oxygenates such as methanol is to provide extreme quenching conditions within a single reactor even at elevated temperature and pressure (450~500°C and 3~6 MPa) to avoid successive destruction of highly reactive oxygenates [37,39]. The great benefit of barrier discharge is its simplicity: filamentary discharges can go through sub-micron gap or even liquid phase without particular matching device. Taking advantage of this point, a microscale barrier discharge reactor was developed for low temperature partial oxidation of methane ($CH_4 + O_2 \rightarrow H_2$, CO, CH_3OH, etc). The reactor is designed so that discharge gap becomes larger than Paschen minimum [5], but smaller than quenching distance of CH_4/O_2 flame [40]: i.e., 10 μm < d <1000 μm. Plasma does not have to be used as energy source. Plasma only needs to stimulate chemical conversion process at low temperature with minimum power consumption. A wide range of oxygen and methane mixtures was directly processed without dilution or explosion at ambient temperature because the microscale plasma reactor efficiently removes excess heat generated by partial oxidation, thereby maintaining a reaction field at temperatures near room temperature. Consequently, the least reactive methane was excited by high-energy electrons, whereas successive destruction of reactive oxygenates was minimized simultaneously within the extremely confined environment. A highly reactive and quenching environment is thereby obtained within a single reactor: these are paradoxical conditions in conventional thermochemical processes.

Figure 11 illustrates microplasma reactor used in this experiment [41,42]. A major product among liquid oxygenates was methanol, whose selectivity reached 34% at 30% of methane conversion (Fig. 12 [41]). Selectivity of oxygenates depends on the fragmentation pattern of methane dissociation by electron impact. Selectivity of methanol would reach 60% when the applied electric field corresponds to the breakdown field of methane (~80 Td) [43]. Active ionic oxygen species such as O^-, O_2^-, and O_2^{2-} are also believed to initiate dissociation of alkanes' C-H bonds [37,44]. In addition, atomic oxygen radicals such as O(3p) and O(1D) are recognized as important radical species in discharge chemistry. Along with dissociative excitation of methane by electron impact, production of ionic and atomic oxygen species must play an important role in moderate oxidation of methane in low-temperature plasma catalysis. Detailed mechanistic studies that involve labeled molecules with isotopic atoms are now being conducted in our laboratory for further understanding of reaction mechanisms.

4.2. Nano-fabrication in materials processing using atmospheric pressure homogeneous discharge

4.2.1. Deposition of carbon nanotubes in atmospheric pressure glow discharge

Atmospheric pressure enhanced chemical vapor deposition has great benefits in practical applications since it minimizes vacuum system and allows to handle bulky materials in continuous process. Our group has developed atmospheric pressure plasma enhanced CVD for nanotube deposition [45]. In the previous study, authors pointed out that the existence of energetic cathode region is important to grow nanotubes.

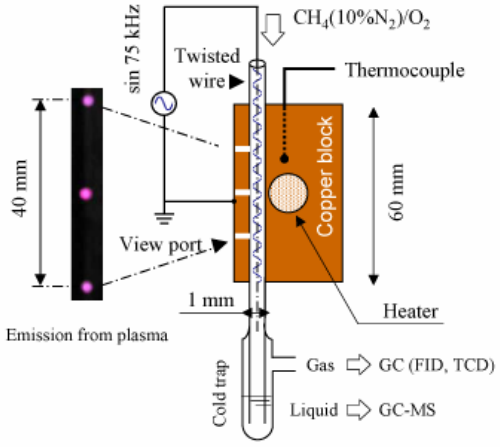

Fig. 11 Micro-plasma reactor setup and emission from view ports

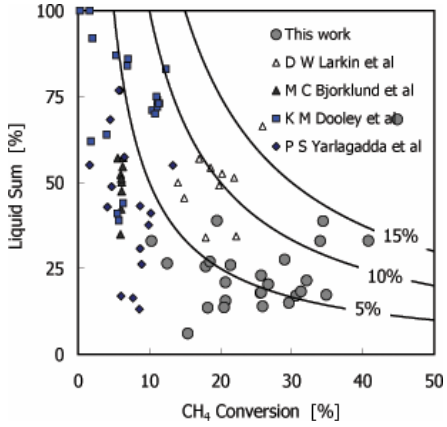

Fig. 12 Methane conversion vs. methanol (+formaldehyde) selectivity. Discharge power: 5 W. Glass inner diameter: 1 and 2 mm. Total gas flow rate: 5-20 sccm. CH_4/O_2 ratio: 1.0-5.0. Temp.: 25-120°C. (●, Δ); barrier discharges, (▲, ■, ♦); thermal reaction.

However, quality of nanotubes such as diameter, number density, and orientation was hard to control with ordinary APG which is operated with 10 kHz - 130 kHz frequency [46]. Main drawback is that APG is temporarily generated with much lower duty cycle. In our experiment effective deposition occurred when the bottom electrode was temporal cathode where discharge current flows for 500 ns (see Fig. 2). High frequency (e.g. RF) operation has several advantages [47,48]. It generates continuous plasma in atmospheric pressure which is probably the minimum requirement for the growth of vertically oriented nanotubes. In addition, operating voltage is significantly reduced due to electron and ion trapping in the discharge gap which minimizes the formation of filamentary discharges. In fact, a stable glow discharge is sustained between two metallic electrodes without dielectric barrier, thus it enables to apply external DC bias to the substrate. This technique especially becomes important in the deposition of nanotubes since high electric field near substrate is necessary to align growing nanotubes [49-51]. However, the role of highly collisional cathodic sheath for the alignment is not fully understood: not only electric field, but also the directionality of ion movement as well as ion energy may also become important parameters in the atmospheric pressure PECVD.

Figure 13 shows atmospheric pressure radio frequency discharge reactor (APRFD) for carbon nanotubes deposition. RF power source was connected to the upper electrode, while DC power supply is to the bottom electrode. Figure 13 (a) and (b) show carbon nanofibers deposited on silicon substrate at 700°C. The substrate was initially coated with Cr underlayer (20 nm) and Ni catalyst layer (20 nm). He, H_2, and CH_4 mixture was fed at constant flow rate of 1000, 4, 2 sccm, respectively. A sample shown in Fig. 13 (a) was obtained in normal APRFD, while (b) was deposited in APRFD with DC-50 V. The result clearly shows that alignment of nanofibers is improved by applying negative DC potential to the substrate. Negative potential attracts positive ions to the substrate, creating cathodic dark space near the substrate. Although actual bias potential is not known since plasma potential has not been identified yet, external DC bias seems to impose sufficient electric field on cathodic sheath. Well-oriented nanofibers also seem to grow in highly collisional cathodic sheath as long as strong electric field is imposed on substrate. Further investigation is being performed.

4.2.2. Microplasmas and application to nanoparticle formation [4]

In this paper, we specifically define microplasma as a non-filamentary, continuous, high-density ($N_e >> 10^{11} cc^{-1}$), reactive non-equilibrium plasma. As reactor dimension gets smaller than effective $(pd)_{min}$ at given pressure, operating pressure must inevitably increases in order to sustain self-maintaining discharge. Here, $(pd)_{min}$ expresses Paschen minimum and typical value is given by $(pd)_{min} \sim 1$ mmHg cm in ordinary gases [5]. Unlike transient discharges such as DBD and APG, effective dc approximation could be assumed when operating frequency exceeds 100 MHz at atmospheric pressure. We explore the new applications into the field of nanoparticle synthesis using such unique plasma source.

Figure 14 shows schematic diagram of microplasma reactor equipped with water-jacket in down stream where reactive microplasma is rapidly quenched. The process starts with the creation of supersaturated radical

condition (I) followed by homogeneous nucleation (II), cluster formation and/or particle growth (III), and annealing including aggregation of particles (IV). The proposed microplasma reactor has several advantages over these processes: (1) Microplasma under high frequency operation easily provides supersaturated environment, and also increases throughput of the process, (2) Micrometer scale reactor equalizes radical density and temperature, realizing uniform nucleation, (3) Charged particles prevent aggregation [52], (4) Particle synthesis due to consecutive reaction is easily optimized with short-residence time reactor (~μs). We have developed capacitively coupled VHF (144 MHz) microplasma shown in Fig. 15. At the moment, production and characterization of the microplasma has been carried out. Reynolds number, electron density, and rotational temperature increased with decreasing internal diameter of capillary tube: e.g. Re: 1200 [-], N_e: 4×10^{15} [cc^{-1}], and T_{rot}: 1800 [K] at 290 μm inner diameter. This process is now being developed for diamond and silicon nanoparticle synthesis.

5. Concluding remark

Authors discussed fundamental processes of atmospheric pressure non-equilibrium plasmas, and various applications based on our recent work were briefly overviewed. Industrial application of atmospheric pressure non-equilibrium plasmas will continue to grow into various engineering fields. At the same time, a number of technical challenges are being emerged. The major challenge that authors would like to emphasize is to suppress the thermalization of non-equilibrium plasmas [53]. Although atmospheric pressure non-equilibrium plasma is recognized as weakly ionized low-temperature plasma from the fact that electron temperature is much higher than gas temperature, electrons are likely to lose their energy through rotational, vibrational, and even momentum transfer collisions. Radical species produced by energetic electrons is the main driving force of chemical conversion process; however, heat generated by non-equilibrium plasma also accelerates thermal reactions as discussed in section 4.1.2. Modern plasma reactors become compact and operated at higher frequency (500-500 kHz). Specifically in filamentary barrier discharges, increasing power density simply increases the generation rate of heat, while electron energy and electron density in each filamentary discharge seems to remain unchanged: input power is preferably distributed to thermal energy rather than radicals. Non-equilibrium plasma may lose non-equilibrium nature and may become more like heat source. On the other hand, microplasma developed in our lab reaches the gas temperature of 1000-2000 K, while plasma density gets highly supersaturated at given temperature and pressure (see 4.2.2). Although temperature reaches much higher than room temperature, it is able to provide highly chemical non-equilibrium status. Scientific understanding of thermodynamic non-equilibrium nature of those plasma sources is strongly needed for further development of new field of plasma science and technology.

Research on Gliding Arc Discharge Driven by Magnetism

Yuhan Zhao, Qiang Ma, Weidong Xia[1]

Department of Thermal Science and Energy Engineering, University of Science and Technology of China, China, HeFei

[1] *Email: xiawd@ustc.edu.cn*

Abstract: The diameter of non-thermal arc plasma is one of the main parameters that determine the current density of arc, so as to the temperature and the density of electrons. The imagines of gliding arc discharge driven by magnetism at atmosphere are captured observed and its dimension is measured by commercial CCD. The diameter projecting in the direction of motion of the arc (diameter in positive direction) is attained. And the relationship between diameter and current, magnetic field is analyzed, too.

Keywords: Magnetically driving gliding arc, Non-thermal arc, Arc diameter

1. Introduction

Non-equilibrium plasma at atmosphere is a kind of non-thermal plasma which is between thermal and cold plasma. Compared with the thermal plasma, non-equilibrium plasma produced by gliding arc, which needs relatively less power input and has higher energy efficiency, can operate without vacuum system and is suitable to work under atmospheric or higher pressure. Non-equilibrium plasma has extensive application potential in the chemical industry, material preparation, surface modifying and environmental engineering, and etc. [1-3]. Gliding arc discharge is one of the main methods to produce non-equilibrium plasma at atmosphere [4-7].

Electron density n_e and non-equilibrium degree $K_{NE}=(T_e-T_h)/T_e$ (T_e and T_h are electron temperature and heavy particle temperature, respectively.) of non-thermal plasma are important parameters which determine the chemical reaction rate and energy efficiency [8]. In the case of magnetically driving gliding arc which moves fast with little diameter as a kind of non-thermal arc plasma at atmosphere, it's hard to measure the electron temperature and density directly. Electron temperature and density can be calculated by using the parameters as current density, electric field value, and heavy particle temperature [9-11]. And arc diameter is important for calculating current density. Therefore, there are many literatures about non-thermal arc diameter. The measuring methods of arc diameter mainly include hi-speed camera shoot [12,13], CCD imaging, and utilizing electron-multiplier phototube. Leland M. Nicolai chose a certain optical density as representing the edge of the arc, and determined the characteristic arc dimensions from densitometer scans of the arc photographs [12]. At the present time, researches on non-thermal arc diameter mostly focus on the arc diameter in side direction which is observed and measured from the side the electrodes plane. Reports about arc diameter in positive direction which is observed and measured from the end of motion of the arc is not seen now [14].

The magnetically driving gliding arc is observed by commercial CCD camera and arc diameter in positive direction is obtained. And also the dependences of diameter and current, magnetic flux density are analyzed here.

2. Experimental

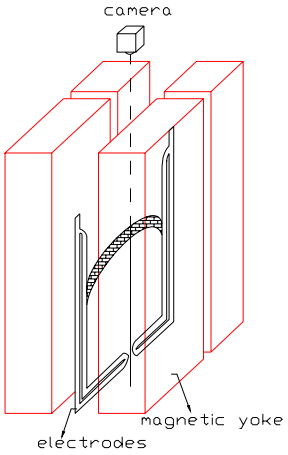

Fig. 1. Arc diameter measurement setting

Fig. 2a. Colorized arc photo (arc current 0.7A, magnetic field 0.8T)

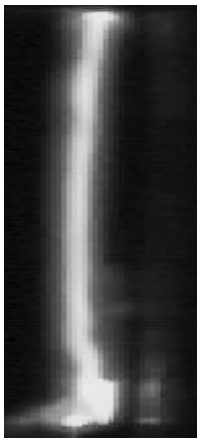

Fig. 2b. Arc grey-scale photo (arc current 0.7A, magnetic field 0.8T)

The arc diameter is investigated by using the experiment device of magnetically driving gliding arc presented by Li lei, Xia weidong et al. [4]. The set-up contains a adjustably constant current source and a magnet providing uniform magnetic field. The sketch of arc diameter measurement is shown in Fig.1. The space between the parallel parts of the electrodes made of copper is 30 mm. The gap between electrodes is 2 mm. The arc moves upward along electrodes. The plane containing electrodes is vertical to the magnetic field. The camera (Samsung VP-D99i , time of exposure is 0.1 ms, F2.0, 12 times optical zoom, 25 fps) is placed in the symmetry axes of electrodes, lens facing the arc. The typical photographs of the arc in the positive direction of arc are shown in Fig. 2a, and Fig. 2b shows the picture converted from Fig. 2a.

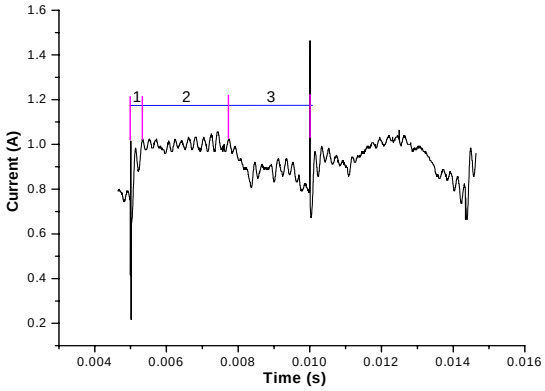

Fig. 3. Arc current waveform

There are three stages in the periodic arc evolution (arc current waveform is shown in Fig. 3): 1. Arc starting stage, before moving into the parallel parts of electrodes; 2. Arc moving along parallel electrodes stage; 3. Arc shifting out of parallel electrodes stage. The arc current ripple ratio is less than 1% in stage (2), thus it is able to determine the relation between arc current and arc diameter without synchronous electric signal and shooting signal.

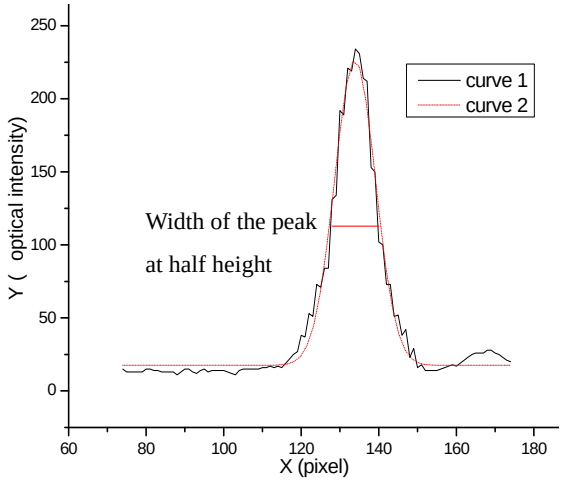

Fig. 4. Radial distribution of sensitization intensity

There was no specific diameter on gliding arc, because of the gradient radial distribution of temperature, current density, optic intensity and etc. Here, we determine arc diameter according to the distribution of absolute value of optic intensity (grey-scale value). First, convert the colorized photo (JPEG file) to BMP file (Fig. 2a), then switch to grey-scale one (Fig. 2b) through applying formula: **gray = 0.2990 * r + 0.5870 * g + 0.1140 * b**. And then by reading out the grey-scale value of every pixel point arraying along the axis of electrodes, one can attain the radial distribution of sensitization intensity

integral of all kinds of beam projected on CCD by arc column, as the curve 1 shown in Fig. 4.

Gauss Function:
$$y = y_0 + (A/(\omega \bullet \sqrt{\pi/2}))e^{\frac{2(x-x_0)^2}{\omega^2}} \quad (1)$$

where y_0: baseline offset , A: total area under the curve from the baseline, x_0= center of the peak, w= approximately 0.849 the width of the peak at half height, is applied to fit curve 1 to Gauss Fit Curve(Curve 2). Two times of the width of the peak at half height is defined as the diameter projecting to CCD of the arc column. Thus, after conversion of length picketage corresponding arc diameter is obtained.

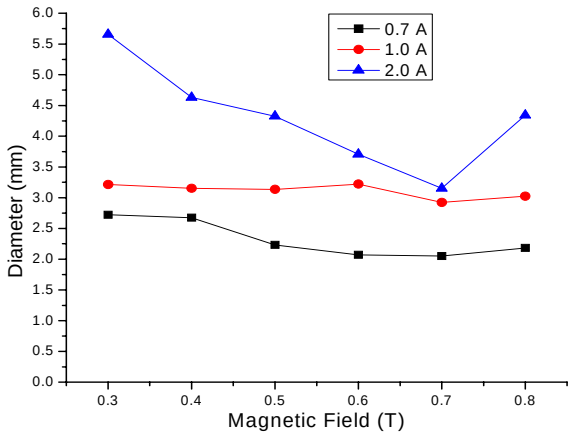

Fig. 5. Diameter-magnetism characteristics of a gliding arc

3. Results and Discussion

The effect of magnetic field and arc current is analyzed and results are given in Fig. 5. For the figure, arc current switch among 0.7A, 1.0A and 2.0A; the range of magnetic flux density is 0.3~0.8 T. One can see that arc diameter in positive direction increases with arc current increasing under constant magnetic field. And when arc current is invariable, arc diameter tends to decrease with the magnetic field value increasing.

4. Conclusions

The figuration and dimension of gliding arc discharge driven by magnetism at atmosphere are observed and measured. The effect of magnetic field and arc current on arc diameter in positive direction is analyzed, too. The following conclusions are reached:

Diameter in positive direction of arc increases due to increases in arc current when magnetic field is constant. And when arc current is invariable, diameter tends to decrease with the increasing magnetic field.

Double Arcs Phenomena of Rotating Arc Driven by Magnetism

Weidong Xia[1], Baihe Du, Lincun Li, Qiang Ma, Quan Chen

Department of Thermal Science & Energy Engineering, University of Science & Technology of China, Hefei, Anhui, China
[1]Email: xiawd@ustc.edu.cn

Abstract:

Large scale arc plasma generator has been developed to processing carbon black and nano-particle [1-3]. To get large-scale homogeneous plasma by arc discharge, an experiment equipment is designed for researching the probability of arc diffused [4]. The plasma generator is of coaxial inner cathode (15mm diameter) and outer anode (80mm diameter), both of them are made of graphite. Currents through the coil wrapping on the anode produce axial magnetic field, which drives the arc fast rotating. The plasma gas is Argon. Hi-speed CCD camera (4000fps, 0.1msec exposure time) is opposite to the spout of the generator, by which continuous end-on imagines of arcs and arc movements are captured.

Fig.1 and Fig.2 are consecutive end-on images of moving arcs. The experiment conditions are as follow: arc current 195A, gas flux 8SNL/min, lengthways magnetic induction 72 Gauss, CCD camera 1000 frames per second with 0.1ms exposure time.

Fig.1 shows the production and alteration progress double arc roots. On frame 1 of Fig.1 one anode arc root is situated on "r1". The greatest curvature of arc is at "c1", from here arc expands fast towards the wall of the anode along radial direction at the greatest curvature, so as that new anode arc root appears (r2, image 2). Double arc roots r1, r2 coexist on frame 2. The central angle between two arc roots is about 60 degree. Frame 3, 4 show the same results. But the double arc roots could not been proved to be steady. Two arc roots coexist less than 1 millisecond-the interval of two frames. In general, the phenomenon of double arc roots was considered as the alternating progress of arc root flopping[5] called as "arc shunting" and the current alternating progress from one root to another is less than 1ms[6].

Differing from Fig.1, Fig.2 shows the parallel double arcs coexist between the cathode and the anode. In the Fig.1 arc column from the cathode to root "r2", "r1" (Fig.1, image 2) on the anode is like in series. The double arcs in parallel astonishingly coexist about 4~5 milliseconds stably, known from frame 2 to frame 6 in Fig.2. Being digressive V-I characteristics and many factors of plasma instability, one arc of parallel two arcs always quickly extinguishes and current transfers to another arc column, or double arcs with common root prestissimo join from the common root [7] (at the cathode). To our knowledge, it is the first time that one reports the stable parallel arcs in large-scale arc plasma generator with rotating arc driven by magnetism.

Waves of arc voltage and arc currents have been measured. The both descending and of single arc and parallel double arcs appear. The ascending V-I characteristics always goes with steady double arcs. The great fluctuation of arc voltage arises from the large scale break of arc column to anode wall and result in breaking of parallel double arcs.

How to be generated the parallel double arcs? Why is the arc V-I characteristics some time ascending and some time descending? And why dose ascending V-I maintain more than 5ms during which without great fluctuation? They will be researched further.

Abstract

A new method combines catalyst and plasma to produce ozone is provided with lower energy consumption and higher ozone production efficiency. Factors which can affect the ozone production efficiency and concentration were studied, such as power, frequency, gas flow rate and catalysts. The ozone concentration and production increases as discharge power increasing，and decrease as gas flow rate increasing. The correlation between power and energy consumption is significant, and the energy consumption increases as increase of the discharge power. Spherical γ-Al_2O_3 is a nicer catalyst because it is likely to participate in surface discharge as a sort of dielectric.

1. Introduction

Ozone has been harnessed for beneficial purposes such as water treatment, odor and color control because of its strong oxidations. In these applications, ozone is almost always produced at high rates in dielectric barrier discharges in pure oxygen[2]. It is also known that broad application of ozone is hindered primarily because of its low efficiency of generation. The value of 1200g/kWh is the theoretical ozone generation efficiency calculated by thermochemical theory. In a practical ozonizer, the discharge energy is dissipated not only in producing ozone but also in heating the electrodes of the ozonizer and gas. In order to improve the efficiency, a lot of attempts have been made[1-8]. In this paper, a new kind of ozonizer combined hybrid discharge with catalysis is proposed to improve the ozone generation efficiency. The hybrid discharge includes corolla discharge, surface discharge and DBD discharge.

2. Experimental apparatus

The laboratory-scale reactor was made of a quartz tube with an inner diameter of 12mm and wall thickness of 1.0 mm. The inside electrode (hi-voltage electrode), made of a molybdenum wire with a diameter of 0.1 mm, was aligned horizontally along the centerline of the reactor. The outside of the quartz tube is surrounded by water inserted copper wire, which served as the outside electrode (ground electrode). The packing materials were filled in the quartz tube. The packing length was the same as the length of the outside electrode, 15 cm. To hold the packing materials in the tube, glass wool is placed at the front and rear of

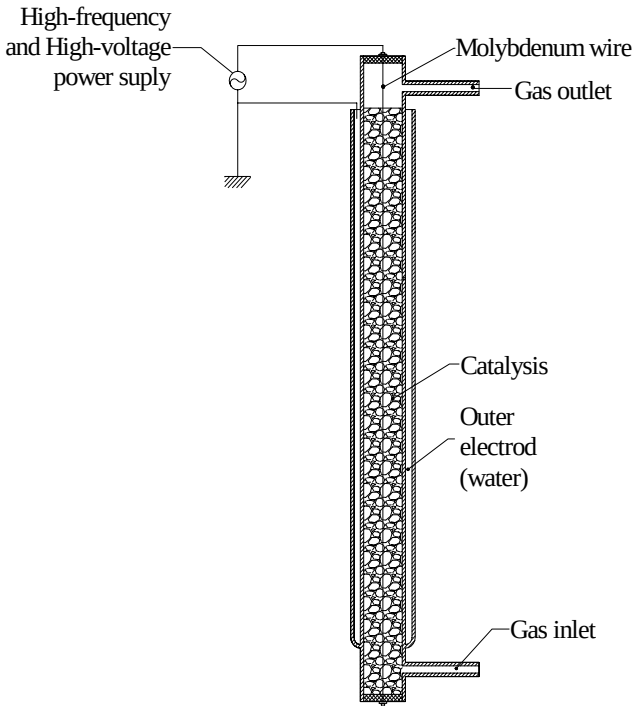

Fig .1. structure of ozone generator

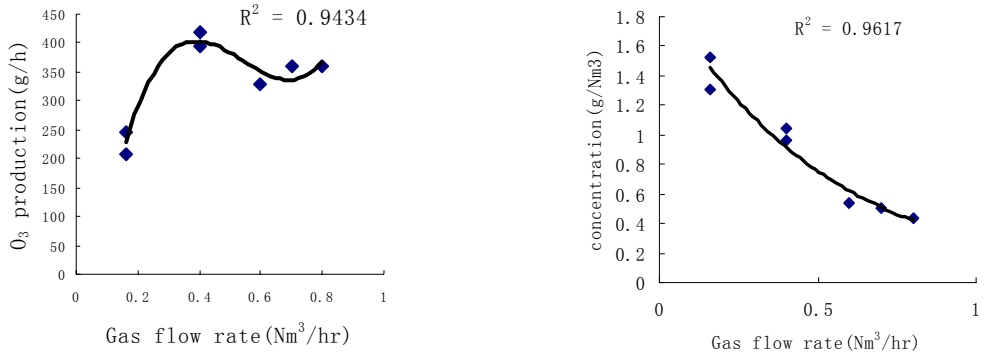
packing material. Power for the non-thermal plasma generating system was supplied by a variable voltage with the range of 0–20 kV (rms value) and the frequency of 10–50 kHz. The plasma reactor was packed with the spherical palletized γ-Al_2O_3 as catalysts in 3–4 mm diameter and 200m^2/g surface proportion. The bed porosity was about 0.4. The packing volume was 17 cm^3 in the reactor with a 15 cm length.

Power supply voltage, discharge currents and charges are measured by a digital oscilloscope (Tektronix TDS2014). The discharge power is calculated according to Lissajous Figure of voltage-charges. The ozone concentration was determined according to CJ/T3028.2-94 (Chinese Standard). The flux of air is determined with flowmeter.

3. Results and discussion

A. Effect of the Gas Flow Rate on the Ozone Concentration and production

The effect of the gas flow rate on the ozone concentration is shown in Fig. 2. The gas flow rate has a great effect on the ozone concentration, which decreases with increase of the gas flow rate. When the gas flow rate is 0.16Nm3/hr, the ozone concentration reaches the value of 1.5g/Nm^3 and production is 0.53g/h. When the gas flow rate is 0.4Nm^3/hr, the ozone production reaches the value of 0.4g/h and concentration is 1.0g/Nm^3.With the rising of the gas flow rate, the reduced trend of ozone concentration becomes generally slow because of the gas cooling.



a b

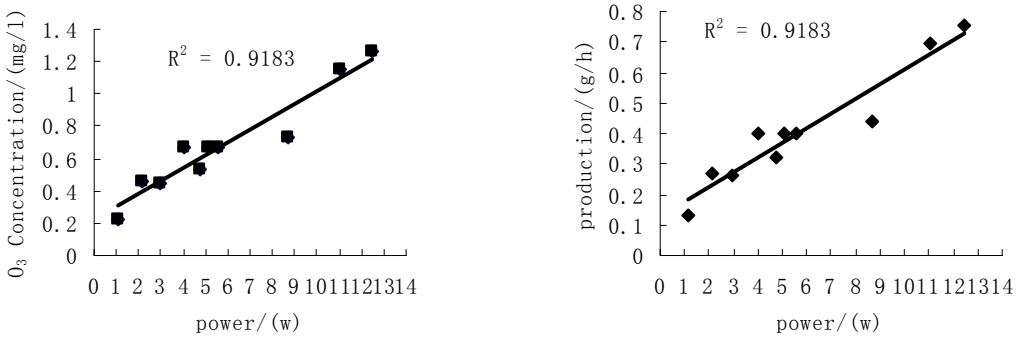
Fig. 2. Gas flow rate vs. (a)ozone concentration,(b)production with gas pressure is 0.12MPa, temperature of inlet air gas is 298K, power is 4w and frequency is 40kHz.

B. Effect of the power on the Ozone Concentration and production

The effect of the power on the ozone concentration is shown in Fig. 3. The power has a great effect on the ozone concentration and production, which increases with increase of the power. When the power is 1.1w, the ozone concentration reaches the value of 0.2g/Nm^3 and production is 0.13g/h. When the power is 12.5w, the ozone production reaches the value of 0.76g/h and concentration is 1.3g/Nm^3.

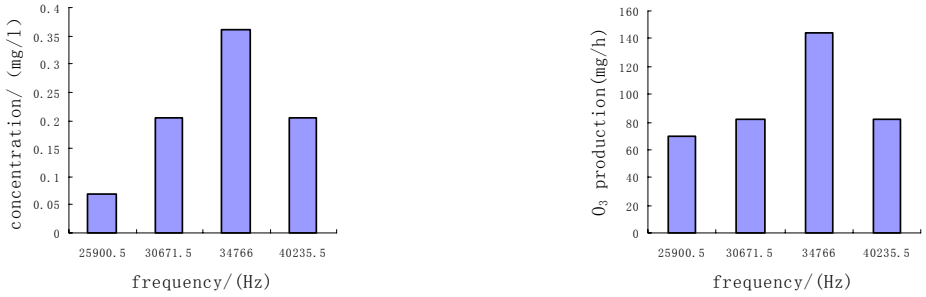
C. Effect of the frequency on the Ozone Concentration and production

The effect of the frequency on the ozone concentration is shown in Fig. 4. Ozone concentration and production increases with increase of the frequency when the frequency value is between 25kHz and 35kHz.But when the frequency value reaches 40kHz, the rule is changed.



a b

Fig. 3, power vs. (a)ozone concentration ,(b)production with gas pressure is 0.12 MPa, temperature of inlet air gas is 298 K, Gas flow rate is 0.6Nm^3/hr and frequency is 40kHz.



a b

Fig. 4, frequency vs.(a) ozone concentration, (b) production with gas pressure is 0.12 MPa, temperature of inlet air gas is 298 K, Gas flow rate is 0.4Nm^3/hr and power is 2.5w.

4. Energy Efficiency of Ozone Production

Currently, the energy consumption (kWh/kgO_3) is used to exhibit the ozone production efficiency. The effect of the ozone concentration on the energy consumption is shown in Fig.5.

Both power and frequency can affect ozone production efficiency.The effect of power and frequency on the energy consumption is shown in Fig.6. The experimental conditions are as follows: gas pressure, 0.12 MPa; temperature of inlet air gas, 298 K; Gas flow rate, 0.6Nm^3/hr.The correlation of power and frequency with energy consumption has been analyzed and shown in Table.1. The Pearson Correlation is 0.838 between power and energy consumption,and it is -0.242 between frequency and energy consumption.Therefore the correlate between power and energy consumption is significant.

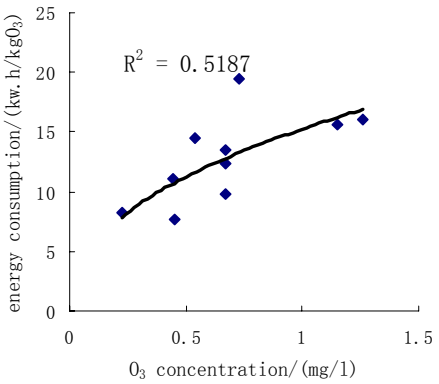


Fig. 5, Ozone concentration vs. energy consumption with gas pressure is 0.12 MPa, temperature of inlet air gas is 298 K, Gas flow rate is 0.6Nm^3/hr and Frequency is 40kHz.

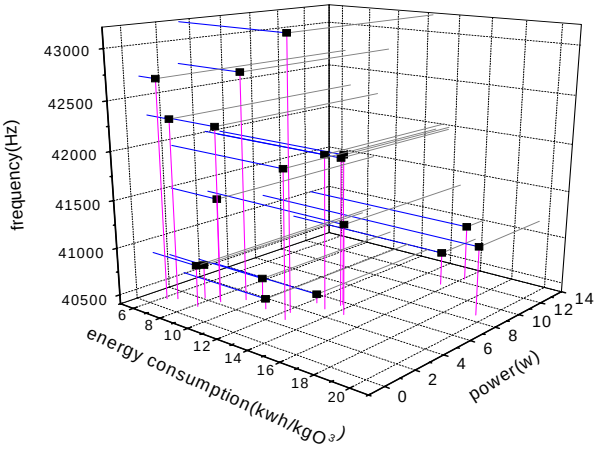

Fig. 6,power and frequency vs. energy consumption with gas pressure is 0.12 MPa, temperature of inlet air gas is 298 K and Gas flow rate is 0.6Nm^3/hr.

Table.1 Analysis of correlations

		power	frequency	energy consumption
power	Pearson Correlation	1.000	-.347	.838**
	Sig. (2-tailed)	.000	.146	.000
	N	19	19	19
frequency	Pearson Correlation	-.347	1.000	-.242
	Sig. (2-tailed)	.146	.	.318
	N	19	19	19
energy consumption	Pearson Correlation	.838**	-.242	1.000
	Sig. (2-tailed)	.000	.318	.
	N	19	19	19

**. Correlation is significant at the 0.01 level (2-tailed).

The effect of the power on the energy consumption is shown in Fig.7. The experimental conditions are as follows: gas pressure, 0.12 MPa; temperature of inlet air gas, 298 K; Gas flow rate, 0.6Nm^3/hr; Frequency,40kHz. The energy consumption increases with increase of the power. When the power is 1.1w, the energy consumption reaches a quite finer value of 8.2kwh/kgO_3. When the power is 12.5w, the energy consumption reaches the value of 16.1kwh/kgO_3.

The effect of the gas flow rate on the energy consumption is shown in Fig.8. The experimental conditions are as follows: gas pressure, 0.12 MPa; temperature of inlet air gas, 298 K; power, 4.5w;

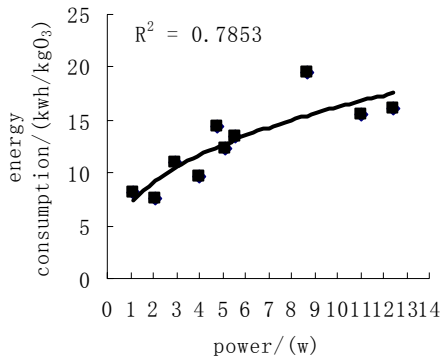

Fig. 7, power vs. energy consumption with gas pressure is 0.12 MPa, temperature of inlet air gas is 298 K, Gas flow rate is 0.6Nm^3/hr and Frequency is 40kHz

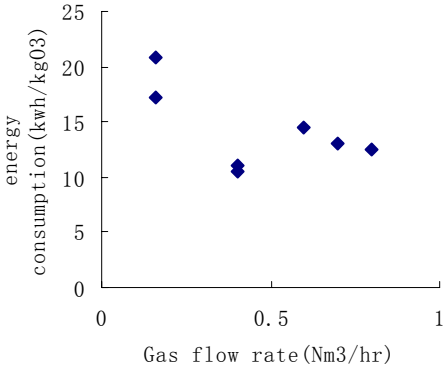

Fig.8,gas flow rate vs. energy consumption with gas pressure is 0.12 MPa, temperature of inlet air gas, is 298 K, power is 4.5w and Frequency is 40kHz

Frequency,40kHz.Between the gas flow rate and the energy consumption,we haven't found a overt correlation.

Efficiency of Ozone Production on other different parameters is shown in Table.2. When the gas flow rate is 0.6Nm^3/h,the power is 0.9w and the frequency is 45kHz, the energy consumption and the production efficiency reaches the best value of 6.2 kWh/kg and 160.9 g/kWh. Therefore the ozone production efficiency is higher than the commercial ozone generator.

Table.2 Efficiency of Ozone Production on the different parameters

frequency（kHz）	power(w)	energy consumption(kwh/kgO3)	O3 production efficiency(g/kwh)	gas flow rate(Nm3/hr)
41	1.1	8.2	121.5	0.6
41	2.1	7.6	131.4	0.6
44	1.2	6.6	150.6	0.6
45	0.9	6.2	160.9	0.6
40	2.7	8. 1	124. 2	0.4

5. Experiment of different catalysts

The plasma reactor was packed with the spherical palletized γ-Al_2O_3 as catalysts. Because of the high surface proportion of the spherical γ-Al_2O_3 in 200m^2/g, catalysts may adsorb large number of oxygen molecules, which will react with oxygen atom produced by discharge to form ozone. Moreover, spherical γ-Al_2O_3 is one sort of dielectric in the plasma besides the function of adsorption and catalysts, that means, other function may exist such as affect the property of plasma formed by the discharge.

Spherical molecular sieves,as a substitute of spherical γ-Al_2O_3, packed in the plasma reactor is studied.The different effect of the two kinds of catalysts is shown in Table.2. When The plasma reactor was packed with the spherical palletized γ-Al_2O_3 as catalysts in 3–4 mm diameter， the ozone concentration is 0.96g/Nm^3,the production is 0.38g/hr and the energy consumption is 9.8kwh/kgO_3; when The plasma reactor

was packed with the spherical molecular sieves type 5A as catalysts in 3–5 mm diameter，the ozone concentration is 0.78g/Nm^3,the production is 0.31g/hr and the energy consumption is 12.1kwh/kgO_3.Therefore spherical γ-Al_2O_3 is better than the spherical molecular sieves because spherical γ-Al_2O_3 is likely to participate in surface discharge as a sort of dielectric.

Table.3 Characteristic of Ozone Production on the different catalysts

Catalysts	ozone concentration (g/Nm^3)	Production （g/h）	production efficiency （g/kwh）	energy consumption （kwh/kgO_3）
. γ-Al_2O_3	0.96	0.38	103.1	9.80
molecular sieves	0.78	0.31	82.4	12.14

The experimental conditions are as follows: gas pressure, 0.12MPa; temperature of inlet air gas, 298K;power，3.8w. Gas flow rate, 0.4Nm^3/hr; Frequency ,40kHz.

The diameter of catalysts can affect the characteristic of ozonizer.We currently use the spherical palletized γ-Al_2O_3 as catalysts in 3–4 mm diameter.**W**hen The plasma reactor was packed with the spherical palletized γ-Al_2O_3 in 0.5–1mm diameter，there are hardly any ozone produced.

6．Conclusions

Ozone generation of combined surface discharging and catalysis is a new method,which is provided with lower energy consumption and higher ozone production efficiency in comparison with the technology of present commercial ozone generator. The plasma reactor was packed with the spherical palletized γ-Al_2O_3 as catalysts.Because of the high surface proportion of the spherical γ-Al_2O_3, catalysts can adsorb oxygen molecule,which will react with oxygen atom to form ozone.At the same time, spherical γ-Al_2O_3 can participate in surface discharge as a sort of dielectric.As a result, the ozone production efficiency are significantly improved in comparison with a ozone generator without catalysts, which the energy consumption and the production efficiency reaches the highest value of 6.2 kWh/kg and 160.9 g/kWh.

EFFECT OF OXYGEN RATIO ON FABRICATION OF DIAMOND NANO-WHISKERS IN RADIO FREQUENCY PLASMAS

C.Y. Li and A. Hatta

Department of Electronic and Photonic Systems Engineering, Kochi University of Technology, Japan

Abstract
Diamond nano-whiskers were fabricated by means of reactive ion etching in O_2 or Ar/O_2 radio frequency plasmas. Metal particles were coated onto diamond films to serve as micro-masks before etching. The results showed that the population densities and the distributions of diamond whiskers were dependent on the volumetric ratio of O_2 to Ar. The whiskers were still diamond after etching. Field emission characteristics of the whiskers were also inspected.
Keywords: Diamond, Etching, Radio frequency plasma, Micro-mask, Whisker.

I. Introduction

Diamond has drawn a great deal of attentions because of its outstanding properties such as extremely high mechanical hardness, high thermal conductivity, chemical inertness, the smallest coefficient of thermal expansion, and negative electron affinity characteristics [1]. All these properties are advantageous to various applications [2]. Recently, the negative electron affinity characteristics of diamond films are considered to be highly promising for applications in electron field emission devices [3]. However, the key point remains how to achieve an efficient electron field emission [4]. It has been reported that the electron field emission will be enhanced at the micro-tips of diamond [5]. Therefore, fabrication of sharper field emission tips is still a challenging issue. Among the various approaches, reactive ion etching (RIE) is considered as an efficient method to sharpen diamond into micro-rods or nano-whiskers [6]. In this paper, a novel method for fabrication of nano-whiskers using reactive ion etching in Ar/O_2 or O_2 plasmas was reported. Metals coated on diamond surfaces served as masks during the etching process. Furthermore, a comparison of the morphologies of diamond surfaces before and after etchings demonstrated that the properties of whiskers were dependent on the reacting gas. Field emission characteristics of the whiskers were also examined and a low turn-on field was obtained.

2. Experimental details

N-type Si (100) substrates were abraded with 5-12 μm diamond grits in a ultrasonic agitator for 30 min in order to enhance diamond nucleation before deposition. Polycrystalline diamond films were deposited onto Si substrates using a microwave plasma chemical vapor deposition (CVD) reactor system ASTeX (AX-6350). The deposition process was carried out under pressure of 124 torr, microwave power of 5 kW, and flow rates of 25 and 475 sccm for CH_4 and H_2, respectively. During the deposition, the substrate temperature was kept at 900–950 ℃, monitored by a spot thermometer.

After the diamond films grew to 3 μm in thickness, Al particles were coated on them for 10 min using a DC sputtering device (SANYUDENSHI, SC701HMC Quick Coater).

The etching process was performed for 60 min in a self-assembled radio frequency (RF) plasma reactor with frequency of 13.56 MHz. The chamber pressure was maintained at 22 Pa. Reacting gases were introduced through mass flow controllers. In this study, the gas compositions examined were O_2 (10 sccm)/Ar (90 sccm), O_2

(20 sccm)/Ar (35 sccm), O_2 (100 sccm), and Ar (100 sccm). The RF power was 100 W, corresponding to a DC self-bias voltage of -510 V for each sample. The substrate temperature was kept below 200 ℃ using a water cooling system.

Raman spectroscopy was carried out in a spectroscopic system (JASCO, NR-1800), with a 514.5 nm Ar ion laser (Coherent, K-70) in order to examine the changes in the properties of the diamond films. The samples were also inspected using an S-3000N scanning electron microscope (SEM). Energy Dispersive X-ray Spectroscopy (EDS) was used to analyze the surface composition after etching.

3. Results and discuss

Figures 1-3 present the SEM images of the diamond surfaces after 60 min of etching. From the top views, whiskers were found in each sample. An interesting phenomenon was that the distribution of whiskers was not random. Fig. 1(a) illustrates the result for etching in Ar/O_2 plasma with 10% O_2 (vol/vol). Whiskers with diameter of 150 nm and height of 200 nm were formed only at the grain boundaries, suggesting that the whiskers may form preferentially at the grain boundaries between diamond crystals. This can be explained, most probably, by the presence of non-diamond sp^2 inclusions (e.g., graphite) [7]. However, with increasing O_2 concentration (O_2: 36%), the roots of the whiskers extended gradually into the diamond grains, as shown in Fig. 2(a). It could be noticed that the height of the whiskers remarkably increased to 900 nm. The population density of whiskers increased with the concentration of O_2. When O_2 ratio approached to 100%, the whiskers had the highest population density (about 40 μm^{-2}), as shown in Fig. 3(a). The average diameter of the whiskers reduced to 100 nm with a height of 1 μm. In inert gas Ar (100 sccm), whiskers could not be formed on the surfaces after etching.

In general, there were two processes during the RF plasma etching [8]. Pure Ar plasma only caused physical bombardment etching which could explain why whiskers could not be obtained in pure Ar. The diamond surface would be polished completely if the RF power was higher enough. However, the etching process was different in the Ar and O_2 mixture plasmas. Whiskers obtained in this kind of plasma could be ascribed to the processes of ion-enhanced chemical etching and physical bombardment etching. O_2 would dissociate into O radicals accompanied by the formation of volatile products of CO and CO_2 [9], while Ar would contribute to bombarding the diamond surfaces. In the case of pure O_2 plasma, although O_2 contributed to both physical and RIE etchings, the effect of RIE was apparently predominant [10-11].

The above results suggested that the density and height of the whiskers increased with the flow ratio of O_2 to Ar. However, the diameters of the whiskers were quite different. It is conceivable that the formations of whiskers could be controlled by changing the concentration of O_2 in the reacting gas.

After etching, the EDS measurements were carried out to examine the composition of the etched diamond surfaces. The EDS spot measurements showed that Al remained on the top of the whiskers, as shown in Fig. 4. Because Al was used as coating material on the diamond surfaces before etching, it would react with O_2 to form Al_2O_3 islands on the tops of the whiskers, inhibiting the etching underneath. Some other metals, such as Pt and Au, although could not react with O_2, but could attach to the diamond surfaces and serve as masks due to their incomparably lower etching rate, comparing to that of the carbon substrate [12]. In addition to the whiskers, the bottom areas between the whiskers were also measured using the same method. It was found that there was no presence of Al particles because the diamond film was over etched without the protection of the Al coating.

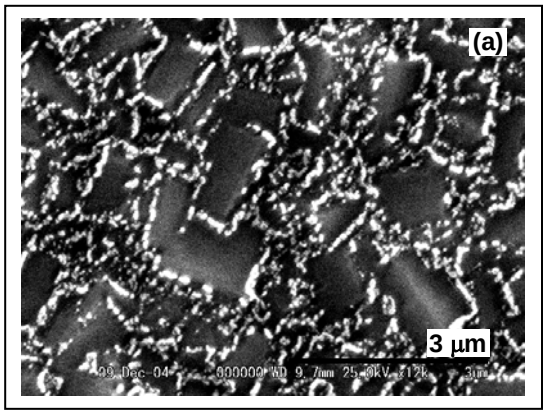

Fig. 1 SEM images of diamond whiskers obtained from etching in O_2 (10 sccm)/Ar (90 sccm). (a) top view, and (b) perspective view.

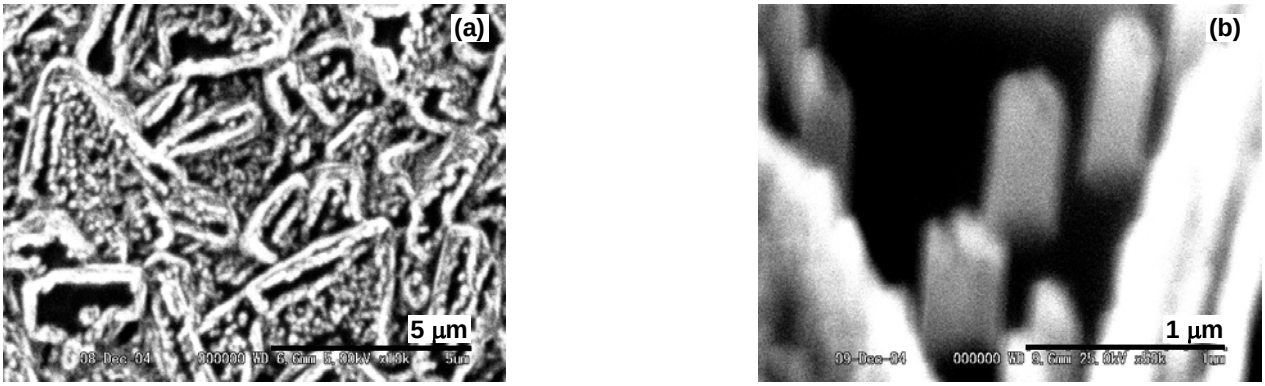

Fig. 2 SEM images of diamond whiskers obtained from etching in O_2 (20 sccm)/Ar (35 sccm). (a) top view, and (b) perspective view.

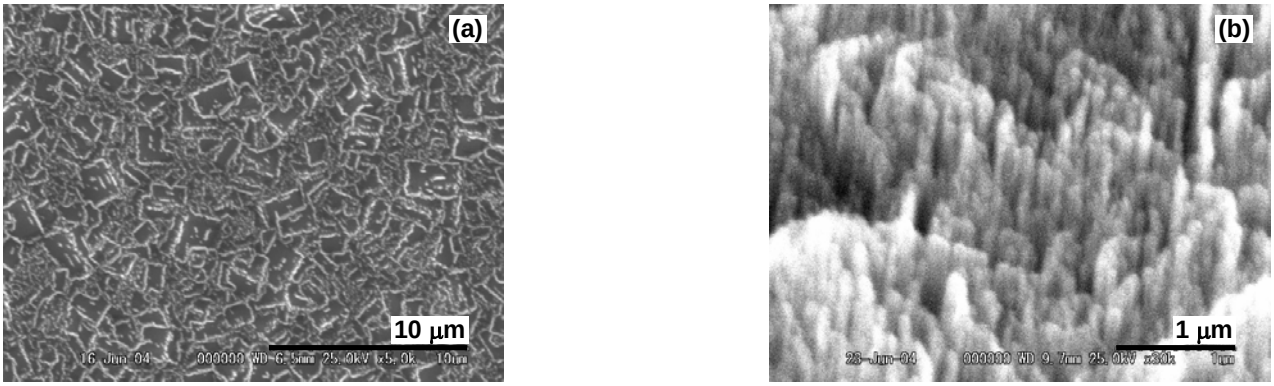

Fig. 3 SEM images of diamond whiskers obtained from etching in O_2 (100 sccm). (a) top view, and (b) perspective view.

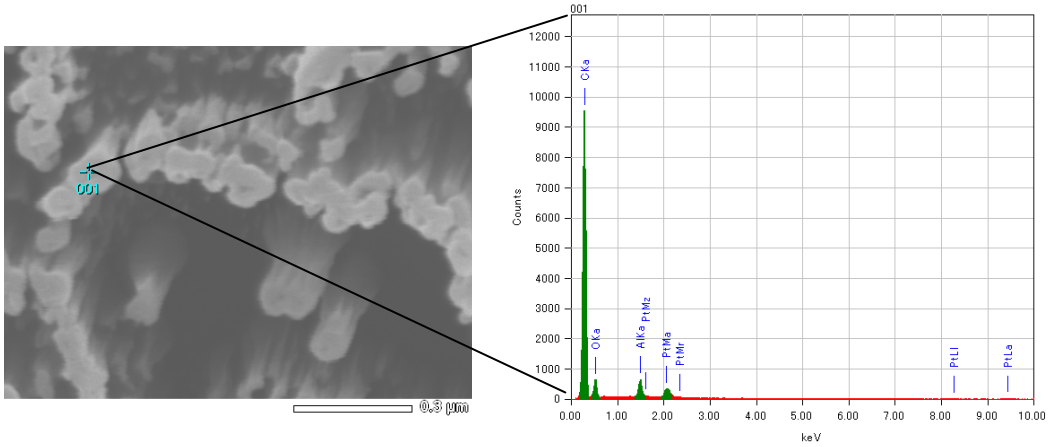

Fig.4. EDS spot measurement showed Al particles remaining on the top of diamond whiskers

It was necessary to inspect the graphitic transformation of diamond after etching. In order to determine the structures of whiskers, Raman spectroscopy was performed for the samples before and after etching. The whiskers were scraped off the substrate and collected on a piece of transparent glass. Scanning electron microscope was used to examine if there were diamond particles mixed with the whiskers in the collected diamond powders, and no diamond particles were found. In Fig.5, the Raman spectra showed a typical diamond (sp^3 bonding) peak at 1332 cm^{-1} along with a low broad non-diamond (sp^2 bonding) peak at 1580 cm^{-1}.

Theoretically, the Raman scattering cross-sections of the graphite should be 50 times higher than that of the diamond. If there were same quantity of sp^2 graphitic carbons, their peaks should be much stronger than that of the diamond. Obviously, for our samples, the diamond peak was much strong than the non-diamond peaks, suggesting that the whiskers had not changed their bonding structures after etching. The presence of a weak graphite peak could be attributed to a small amount of local transformation from sp^3 to sp^2. Most of the bonding structures were kept on sp^3 diamond structures during the etching process. Therefore, we could conclude that the whiskers were still diamond after etching.

Field emission characteristics of the whiskers etched in the pure O_2 plasma were shown in Fig. 6. The samples after etching were treated in hydrogen plasma for 8 min before the field emission measurement in order to get conductive surface. The field emission measurement system was installed in an SEM observation chamber with a gap size of 10 μm. A turn-on field of 10 V/μm was obtained for the whiskers. It was much lower than the original diamond film of 40-50 V/μm which we measured in other experiments.

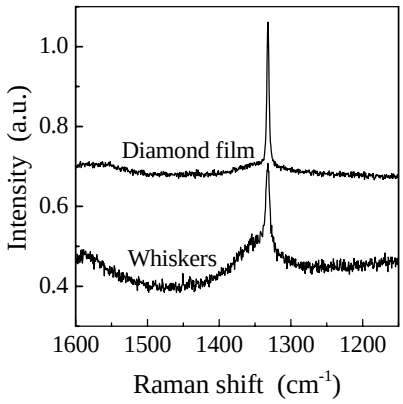

Fig. 5 Raman spectra for the diamond film and the whiskers (Al coated, O_2 100 sccm, etched 60 min).

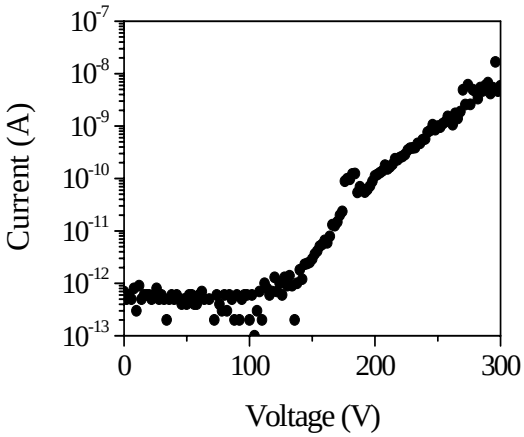

Fig. 6. Current-voltage curve from Al masked diamond whiskers (Al coated, O_2 100 sccm, etched 60 min).

4. Conclusion

Reactive ion etching in RF plasmas is an effective method to obtain diamond whiskers. The population densities and the distributions of whiskers could be controlled by adjusting the volumetric ratio of O_2 to Ar. The bonding structures of the whiskers were not affected by etching process. The turn-on field of the whiskers was as low as 10 V/μm. Therefore, it is possible to use diamond nano-whiskers as cathode emission devices.

Abstract

Nanocrystalline silicon (nc-Si) was deposited by plasma-enhanced chemical vapor deposition (PECVD) on transparent polymers in order to qualify these for possible use as electronic substrates. Thermally induced failure of the nc-Si/polymer composite was avoided within a range of deposition conditions, permitting structural and electrical characterization of the deposits. Good quality nc-Si films could be deposited on all substrates under appropriate conditions.

Keywords

PECVD, nanocrystalline silicon, flexible electronics, high T_g plastics, OLED

1 Introduction

The advantages of using polymer substrates instead of glass for electronic applications include light weight, flexibility and conformability, and low cost with the possibility of roll-to-roll processing. So far, the adoption of polymers for electronic applications has been slow due to their limited compatibility with semiconductor fabrication processes. In particular, the relatively high linear expansion coefficient, α, and low glass transition temperature, T_g, of most polymers restrict the process window to "low" substrate temperatures ($T_s < 300^{\circ}C$). Plasma-enhanced chemical vapor deposition (PECVD) is an attractive process in the present context since the crystalline volume fraction of deposited Si films can be varied within the said range of "low" temperatures [1-3]. Several high-T_g polymers ($220^{\circ}C < T_g < 330^{\circ}C$) with optical transparency, good chemical resistance and barrier properties have recently been developed for use in organic (OLED) display technology [4], and these have motivated the present research. Our goals have, therefore, been to deposit nc-Si films at the lowest possible T_s values, and to characterize their structural and electrical properties.

2 Experimental Methodology

2.1 Etching and Deposition

The substrate materials used in this work and some of their essential properties (α and T_g) are presented in Table 1. Since nc-Si films must not be contaminated by unwanted impurities, the polymer substrates must be resistant towards ablation (etching) in the H_2-rich plasma during the PECVD process. It was, therefore, deemed necessary to investigate possible etching of the polymer substrates as a preliminary step. Both etching and deposition experiments were performed in a "Reinberg-type" parallel-plate RF-PECVD reactor, operating at 13.56 MHz.

Table 1 Properties of the substrates investigated

Substrate	Symbol	T_g (°C)	α (ppm/°C)*
APPEAR® (cyclic polyolefin)	PO	330	60 + T/4
ARYLITE® (polyarylate)	PA	325	50 + T/15
SUMILITE® (polyethersulfone)	PS	223	50 + T/14
KAPTON® (polyimide)	PI	360	20
Glass (Corning 2947)	G	-	9.5
* T-dependent α values are linear approximations of data from ref. [4].			

Etch rates were determined by partially masking the substrates with 50 nm Au layers before exposing them to H_2 plasma at various RF power densities (25 mW/cm^2 < P < 350 mW/cm^2), and then profiling the etched areas by Atomic Force Microscopy (AFM). Such experiments were carried out with the substrates on the grounded or powered electrodes. In the case of depositions, P was 30 mW/cm^2, with substrates on the grounded electrode only. The SiH_4 and H_2 partial pressures were 8 mTorr and 120 mTorr, respectively (SiH_4 concentration, C_{SiH4} = $[SiH_4]/([SiH_4] + [H_2])$ = 6.25%). The chamber pressure was p = 150 mTorr (20 Pa), while the substrate temperature, T_s, was varied between 25°C and 250°C. Typical deposition durations were 200 minutes, and film thicknesses, d_f, measured by ellipsometry, were 120 $\pm$ 15 nm.

2.2 Characterization of nc-Si Films

Thin Si films deposited by PECVD were then subjected to structural and electrical characterizations, by micro-Raman spectroscopy (MRS) and DC conductivity measurements, respectively. MRS was used to estimate the films' crystalline volume fraction, I_c, by comparing the crystalline (c) and amorphous (a) transverse optical lattice vibrations (c-TO and a-TO) [2, 5]. We used an argon-ion laser, λ=514 nm, in Stokes configuration, calibrated with a c-Si sample displaying a c-TO peak centered at 520.5 cm^{-1} with a FWHM of 3.886 cm^{-1}. Data analysis (spectral deconvolution and area integration) was done using BOMEM GRAMS software. DC conductivity was measured by the four-point-probe method, with samples mounted on a temperature-controlled substrate holder and using computer-automation. This system allowed us to measure sheet conductivity during repeated thermal cycling. Other components of this system include a Keithly 220A current source, an Agilent 33101 Multimeter, and a Temptronic temperature controller. For the case of very low conductivity samples (σ < 10^{-6} S/cm), planar aluminum electrodes (with a 100 μm gap) were evaporated on the Si films, and measurements were carried out under vacuum.

3 Results

3.1 Etching and Deposition Rates

Figure 2 presents etch rates of three polymers in pure H_2 plasma, for samples placed either on the grounded or powered electrodes: Higher etch rates are seen to occur on the latter electrode (P < 0, in Fig. 2). Etch rates were negligibly small for low power densities (|P| < 50 mW/cm^2), especially in the absence of ion bombardment, that is, on the grounded electrode. When SiH_4 was added to the H_2 flow (C_{SiH4} = 6.25%, see Section 2.1), nc-Si films were grown on the grounded electrode only, at typical rates of 0.6 nm·min^{-1}.

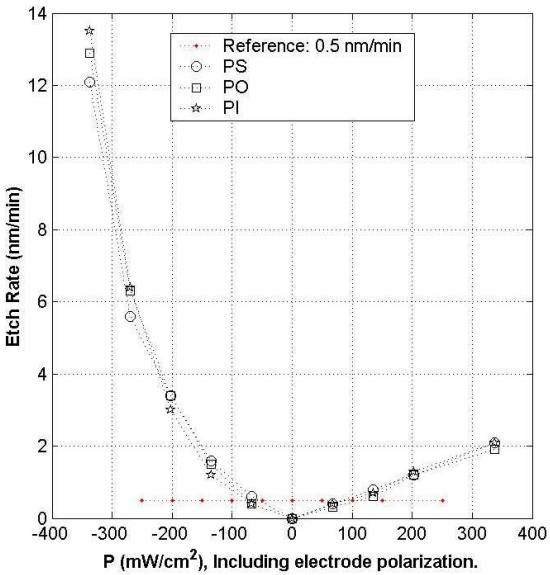

Figure 2 Etch rates for three polymers

3.2 Raman Spectroscopy

The TO spectral feature in our a-Si (a-TO) was Gaussian, centered at ~480 cm^{-1} with a FWHM of ~40 cm^{-1}. The c-TO feature was Lorentzian, centered at ~520 cm^{-1} with a FWHM ~12 cm^{-1}. Intermediate peaks centered at ~505 cm^{-1} with FWHM ~30 cm^{-1} were also detected. The crystalline volume fraction, I_c, can be been estimated using the formula [2]

$$I_c = \frac{A_{520}}{A_{520} + A_{480}} \tag{1}$$

where A signifies the areas under the respective peaks. Figure 3 plots I_c vs. T_s: Films are seen to be amorphous ($I_c \approx 0$) for $T_s < 100°C$, but I_c then rises near-linearly with increasing T_s values. The deviation of TO peak centers (see Fig. 4) is attributed to residual stresses [5].

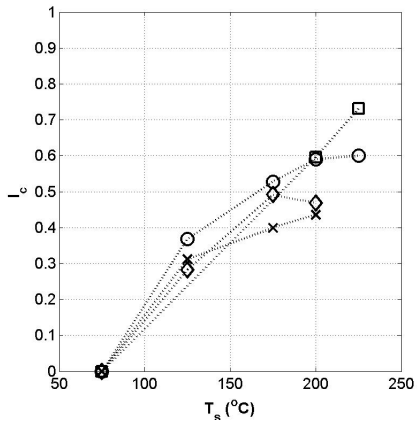

Figure 3 : I_c vs. T_s

: PI

: PO

: PA

Figure 4 : Raman peak-centers (cm^{-1}) vs. T_s

3.3 DC Conductivity

The electrical conductivity of semiconductors like nc-Si, $\sigma(T)$, is thermally activated and therefore obeys the Arrhenius relation [3]

$$\sigma(T) = \sigma_0 \exp\left(\frac{-E_a}{kT}\right) \tag{2}$$

where σ_o is the pre-factor, E_a is the activation energy and k is Boltzmann's constant.

Values of σ and E_a for nc-Si films grown at fixed conditions were very similar, whether deposited on polymers or on glass. "Arrhenius-like" behavior in the range $40^{\circ}C < T < 140^{\circ}C$ was observed for all films deposited at $T_s \leq 175^{\circ}C$, except for those grown on the PO material (see below).

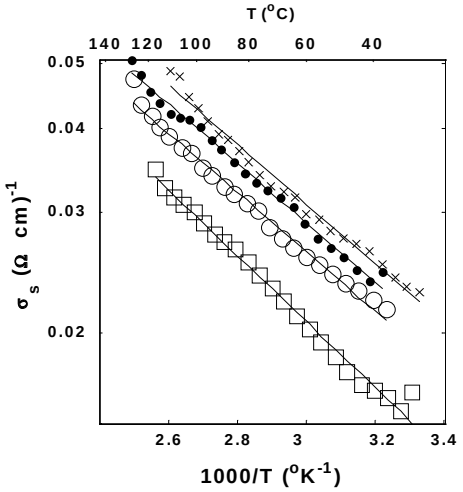

Figure 5

$T_s = 175\ ^{\circ}C$: x = PI; • = PS; ○ = Glass; □ = PA.

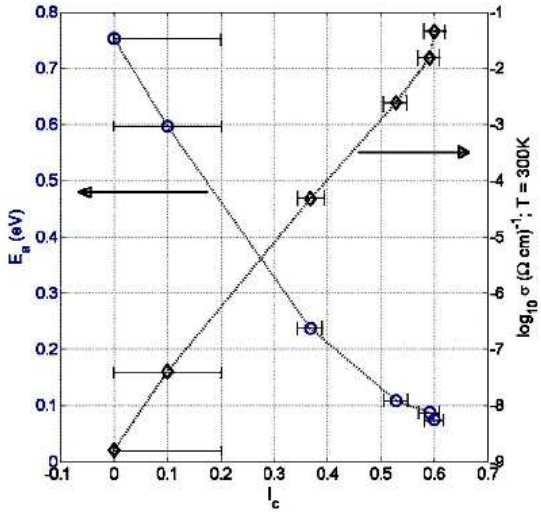

Figure 6 : (nc-Si on glass)

Activation energies and room-temperature dark conductivities for nc-Si films grown on Corning 2947 Ca-lime glass.

The present measurements correlate well with published results for nc-Si films on glass, if we take into account some doping by oxygen. This is known to occur on account of trace quantities of O_2 and H_2O in the reactor, and its extent depends on I_c since oxygen is reported to migrate preferentially within the grain boundaries [6].

3.4 Differential Thermal Expansion

The substrates were in thermal equilibrium at T_s during the nc-Si deposition, but they shrank upon return to ambient conditions. The differential thermal contraction between the substrates and the films can be approximated by

$$\delta = (\alpha_s - \alpha_f)\Delta T \tag{3}$$

where α_s and α_f are the respective coefficients of thermal expansion. Since the thickness of our nc-Si deposits was 10^3-fold less than that of the substrates, stress relaxation of the composite structure gave rise to curvature, which may be expected to follow the Stoney formula up to $Y_f/Y_s \approx 100$, where Y is Young's modulus [7]. This

condition is met, since $Y_f \approx 150$ GPa [8] and $1.9 < Y_s < 5$ GPa [4]. Since $d_s Y_s / d_f Y_f > 10$, we can use the following expression to estimate the interfacial stress in the film due to differential thermal contraction [9]

$$s_f = \frac{Y_f (\alpha_s - \alpha_f) \Delta T}{(1 - \nu_f)} \tag{4}$$

where ν_f is Poisson's ratio of the film. Films deposited on PO, the material with by far the highest value of α_s (see Table 1), at $T_s \geq 200\ ^\circ$C were observed to delaminate; using eq. (4), the compressive strain $\alpha_s \Delta T \approx 1.7\%$ resulted in a stress value $s_f \approx 3.6\, GPa$ that clearly exceeded the f-s adhesion strength. These may, therefore, be considered the limiting conditions for successful film deposition. The PO material undergoes a structural transition at $T \approx 65^\circ$C that was observed to result in anomalous (hysteretic, non-Arrhenius) behavior of nc-Si deposited at $T_s \geq 150^\circ$C.

4 Discussion

Previous research had elucidated the micro-structural evolution of thin Si films, deposited by PECVD, using highly diluted SiH_4 mixtures in H_2. With a suitable choice of C_{SiH4} (5%-9%, 6.25% in the present case) the microstructure of deposited films can be effectively controlled by varying a single parameter, T_s [1-3]. Our results (micro-structural and electrical) demonstrate that a wide range of material properties can be obtained by varying T_s within a range tolerated by the substrates we used. Thermal expansion, α, of these substrates is clearly the greatest challenge for the development of high-stability f-s structures. The nc-Si films nevertheless showed resilience against delamination, as evidenced by the stability of their electrical behavior during thermal cycling, when repeatedly subjected to ~ GPa stresses both in tension and compression. The limiting T_s value above which films delaminate from the substrate of highest α, suggests that the f-s structure can tolerate compressive stresses up to about $s_f \approx 3\, GPa$.

Contamination of the nc-Si by trace amounts of O_2 and H_2O resulted in n-doped behavior of our films, particularly for those deposited at $T_s \geq 150^\circ$C.

The low deposition rate of our process also calls for improvement. This situation was necessitated by minimal ablation of polymers through low power, and by the high dilution of SiH_4 required to produce "good" nc-Si. A feed-gas other than SiH_4 (for example, Si_2H_6) could help overcome this problem.

5 Conclusions

The polymers we have used as substrates fulfill the requirements of electronic applications, for example in OLED technology. Their high T_g values and resistance to ablation have allowed us to deposit satisfactory nc-Si films by RF-PECVD, subject to deposition parameters. The high α of some polymers remains the main obstacle for reliable devices, yet the resilience of nc-Si films is encouraging. Relationships between deposition conditions and structural and transport properties show similarity between nc-Si films grown on glass and on polymer substrates.

Carbon Nanotubes/Nanofibers by Plasma Enhanced Chemical Vapour Deposition

K. B. K. Teo[1], D. B. Hash[2], M. S. Bell[1], M. Chhowalla[3], B. A. Cruden[2], G. A. J. Amaratunga[1], M. Meyyappan[2] and W. I. Milne[1]

3 Department of Ceramics and Materials Engineering, Rutgers University, Piscataway, New Jersey, USA

Plasma enhanced chemical vapour deposition (PECVD) has been recently used for the production of vertically aligned carbon nanotubes/fibers (CN) directly on substrates. These structures are potentially important technologically as electron field emitters (e.g. microguns, microwave amplifiers, displays), nanoelectrodes for sensors, filter media, superhydrophobic surfaces and thermal interface materials for microelectronics. A parametric study on the growth of CN grown by glow discharge dc-PECVD is presented. In this technique, a substrate containing thin film Ni catalyst is exposed to C_2H_2 and NH_3 gases at 700°C. Without plasma, this process is essentially thermal CVD which produces curly spaghetti-like CN as seen in Fig. 1(a). With the plasma generated by biasing the substrate at –600V, we observed that the CN align vertically during growth as shown in Fig. 1(b), and that the magnitude of the applied substrate bias affects the degree of alignment. The thickness of the thin film Ni catalyst was found to determine the average diameter and inversely the length of the CN. The yield and density of the CN were controlled by the use of different diffusion barrier materials under the Ni catalyst. Patterned CN growth [Fig. 1(c)], with 1σ variation in CN diameter of 4.1% and 6.3% respectively, is achieved by lithographically defining the Ni thin film prior to growth. The shape of the structures could be varied from very straight nanotube-like to conical tip-like nanofibers by increasing the ratio of C_2H_2 in the gas flow. Due to the plasma decomposition of C_2H_2, amorphous carbon (a-C) is an undesirable byproduct which could coat the substrate during CN growth. Using a combination of depth profiled Auger electron spectroscopy to study the substrate and in-situ mass spectroscopy to examine gas phase neutrals and ions, the optimal conditions for a-C free growth of CN is determined.

The role of the plasma in a dc plasma enhanced chemical vapor deposition system for carbon nanofiber growth is investigated with a 1-D radially averaged computational model [1]. Equations for the conservation of species mass, ion momentum, and ion, electron, and neutral gas thermal energy are solved axially between the anode and cathode. The model includes 28 species and 200 reactions. The plasma decomposes the ammonia and acetylene feedstock through electron impact dissociation and ionization along with the endothermic ion-molecule sheath reactions of dissociative proton abstraction and collision-induced dissociation. These plasma reactions generate radicals that further contribute to decomposing the feedstock by way of radical exchange reactions (e.g. $NH_3 + H \rightarrow NH_2 + H_2$ and $C_2H_2 + N \rightarrow CH + HCN$). The result is the conversion of the feedstock to the more stable species of H_2, N_2, and HCN. The dramatic impact of this plasma-sponsored conversion on carbon nanofiber growth has been previously demonstrated [2], whereby, at the same substrate temperature, higher plasma power conditions result in much shorter nanofibers relative to lower power growth conditions. This is attributed to acetylene decomposing more readily on Ni catalyst than HCN given that the C-N triple bond strength [3] is 748 kJ/mol and the H-CCH bond strength is only 556 kJ/mol. In-situ mass spectrometry was used to confirm the simulation findings/model as shown in Fig. 2, which displays the mole fraction trends with plasma power for the three main plasma products. The trends are reproduced well where hydrogen and hydrogen cyanide increase with increasing power and nitrogen remains relatively flat. Furthermore, the simulation model has been used to predict the surface temperature at the PECVD cathode for various plasma powers, and this has been experimentally verified.

Two-dimensional self-consistent modeling of Ar microwave-surface-wave plasma at atmospheric pressure

Y. Kabouzi†, D. B. Graves†, E. Castaños Martinez‡, K. Makasheva‡ and M. Moisan‡

†Department of Chemical Engineering, University of California, Berkeley, California 94720
‡Groupe de Physique des Plasmas, Université de Montréal, Montréal, Québec H3C 3J7

Abstract

A self-consistent two-dimensional argon fluid-model coupled with Maxwell's equations is presented. The atmospheric-pressure argon discharge is sustained by the propagation of an electromagnetic surface wave. In addition to the plasma equations, the model takes into account the gas flow and temperature by solving the mass, momentum and energy balance equations for neutral particles. It is found that the gas temperature is a key parameter in modeling surface-wave discharges sustained at atmospheric pressure because it determines both wave propagation characteristics and radial contraction of the plasma column.

1. Introduction

Surface-wave discharges (SWDs) sustained at atmospheric pressure have recently began to be systematically investigated [1,2] because of their potential and current use in industrial applications. However, the properties of atmospheric-pressure SWDs are much less well understood than those of low-pressure surface-wave discharges. This is mainly due to complex phenomena involved in the modeling of SWDs at high pressure such as radial contraction and filamentation. In a recent study [2], we have shown that radial contraction is due to the influence of nonuniform gas heating on the kinetic of molecular ions and, therefore, on the radial distribution of the electron density [2]. To adequately describe the phenomena of radial contraction, one needs to couple Ar atom kinetic processes to Ar molecular ion (MIs) kinetic processes through dissociative recombination. The later recombination process not only controls charged-particules losses but also charged-particles creation, since one of the resulting atoms of the dissociative recombination is in an excited state (a metastable or radiative state), therefore, enhancing step ionization. In this study, a self-consistent two dimensional argon fluid-model coupled with Maxwell's equations is presented. The atmospheric-pressure argon discharge is sustained by the propagation of an electromagnetic surface wave at the frequency of 915 MHz. The tow dimensional plasma model is solved numerically using the commercial code FEMLAB®[3].

Results and conclusion

Figure 1 shows the calculated two-dimensional distributions of plasma and surface wave parameters, for an argon discharge sustained at atmospheric pressure at 915 MHz in a fused silica tube of 3 mm radius and 80 cm length. The total absorbed microwave power is 400 W. In this modeling, the wave-field distribution is obtained using the dielectric description of the plasma. The plasma is then represented by its dielectric permittivity, which is self-consistently calculated from the plasma density and the total elastic collision frequency (dependent on gas and electron temperatures). Figure 1(a) clearly shows that the plasma column is radially contracted: the electron density decreases exponentially, by more than an order of magnitude, form the axis towards the tube wall. In the axial direction, the electron density is almost constant except at the very end of the plasma column where its value decreases rapidly because the decrease of the wave power flux (not shown). The electron temperature is also constant over the whole length of the plasma column, while it decreases very rapidly at the edges of the plasma column (see Fig. 1(c)). Figure 1(b) shows that the gas is heated to

approximately 2500 K at the center of the plasma column where the electron density is the highest. The gas temperature axial and radial distributions follow those of the electron density, since the heating of the gas occurs through elastic collisions. Figure 1(d) shows the two-dimensional distribution of the total electric filed intensity. We observe that the field intensity presents strong inhomogeneities in both directions. While the radial inhomogeneity is related to the skin effect the axial inhomogeneity is due to fact that the electron density approaches the critical density when going towards the plasma column ends.

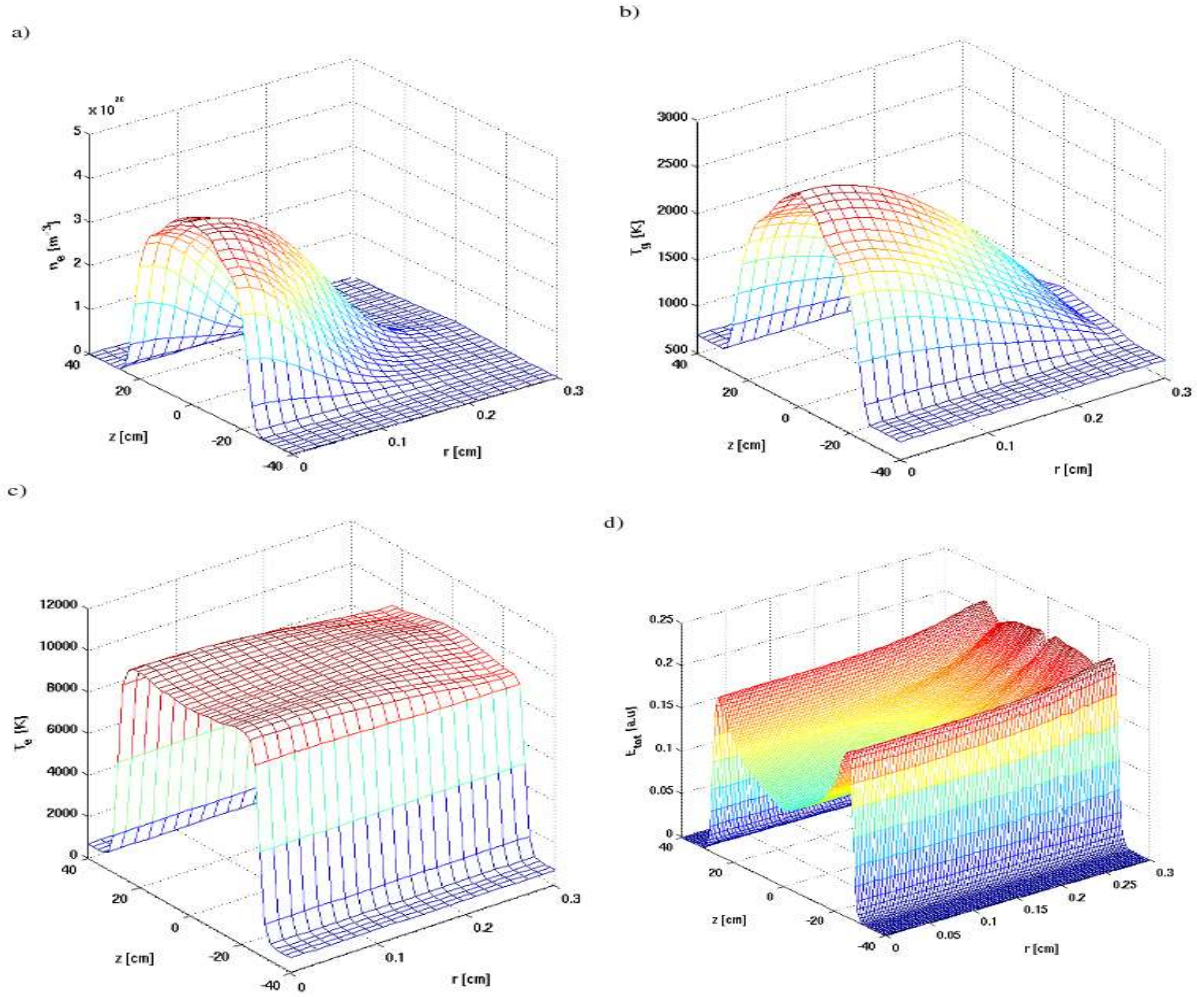

Fig. 1: Calculated two-dimensional distributions of plasma and surface wave parameters. Electron density (a), gas temperature (b), electron temperature (c) and total electric field intensity (d). The argon surface-wave discharge is sustained at 915 MHz in a silica tube of 3 mm radius and 80 cm length. The absorbed microwave power is 400 W.

Loss mechanisms of atomic hydrogen identification in the afterglow of pulsed microwave discharge thanks of gas temperature LIF measurements

T. Lamara , R. Hugon, J. Bougdira, G. Henrion, M. Belmahi and M. Rémy

Lab. Physique des Milieux Ionisés et Applications – CNRS UMR 7040
Université Henri Poincaré – BP 239

Abstract

The present work deals with studying the loss kinetics of atomic hydrogen in a H_2/CH_4 pulsed MPACVD reactor. Time resolved LIF measurements of H-atoms relative density being in the ground state and observed by H_α transition have been established. The decay of H-atoms density in the afterglow was investigated to clarify the involved loss mechanisms. The effect of the diffusion coefficient on the local H-atoms density was studied thanks of time resolved gas temperature LIF measurements, deduced from Doppler broadening.

Keywords

Pulsed MPACVD reactor, LIF, Atomic Hydrogen, Diffusion, Gas temperature.

A) Introduction

There is a particular interest of using H_2/CH_4 gas mixture for diamond growth purpose. It's well known in such plasma that several hydrocarbon spices (C_xH_y) and atomic hydrogen (H-atoms) have an important influence on film quality and deposition rate [1-7]. Atomic hydrogen has a special significance as a major etcher of non-diamond phases, and hence its production and loss mechanisms should be well understood. It has been also shown that operating in pulsed regime increases the enhancement of gas molecules dissociation [10-16]. The kinetic of diamond growth process is very rich under this functional mode, due to the time variations of gas temperature and species density. That is why, the efforts aiming to better understanding these phenomena have been undertaken.

Previous studies on hydrogen pulsed microwave or radio-frequency discharges [5-9], have pointed out the main mechanisms leading to H-atoms loss and creation, which is very important for diamond film growth. Two-photon Laser Induced Fluorescence (LIF) is the best appropriate method to curry out such study, as we can have access to the density of hydrogen atoms being in the ground state. This technique, due to its high spatial and temporal resolution, makes also possible the measurement of radicals flow at the close vicinity of the walls. Moreover, LIF measurements give additional information on the gas temperature as can be deduced from Doppler broadening. The temperature determination in such a plasma can give a helpful information about complex hydrogen loss processes.

B) Experimental arrangement

B.1. Plasma reactor

A big part of the experimental arrangement has been described previously [15-16], it was used mainly for diamond films growth. For more precision, the plasma reactor is a cylindrical stainless steel vessel, home-built MPACVD reactor, of which the configuration is close to the AsTex system §Fig 1. The 2.45 GHz microwave power (600 W - 6 kW), operating in either continuous or pulsed mode, is injected into the cavity by means of a water cooled antenna and a cylindrical wave guide through a upper quartz window. The plasma is, then, generated and adjusted to be localised in the centre of the reaction chamber, closely above the molybdenum substrate holder §Fig 1. The feed gas used for these experiments is either H_2 only or a H_2/CH_4 mixture, it's driven by mass flow-meters, controlled by a host computer in order to maintain both gas

flow ratios and the total pressure. In the whole cases the pressure was maintained at 120 Torr, and the total flow rate at 325 sccm. The pulsed power is controlled by means of wave form generator thus allowing the adjustment of the output peak power, the pulse duration and the pulse repetition rate. The pulsed discharge is ignited by injecting a high peak power (3.5 kW) which lasts 28 ms, followed by an afterglow of 12 ms duration.

B.2. Diagnostic LIF

The plasma characterisation is carried out by means of time-resolved laser induced fluorescence (LIF). The laser source is a tunable pulsed YAG-pumped dye laser, working at 615 nm, providing the photoexcitation. The required 205 nm beam is obtained by tripling the frequency of the dye laser, with an output energy of 1.2 mJ/pulse [16].

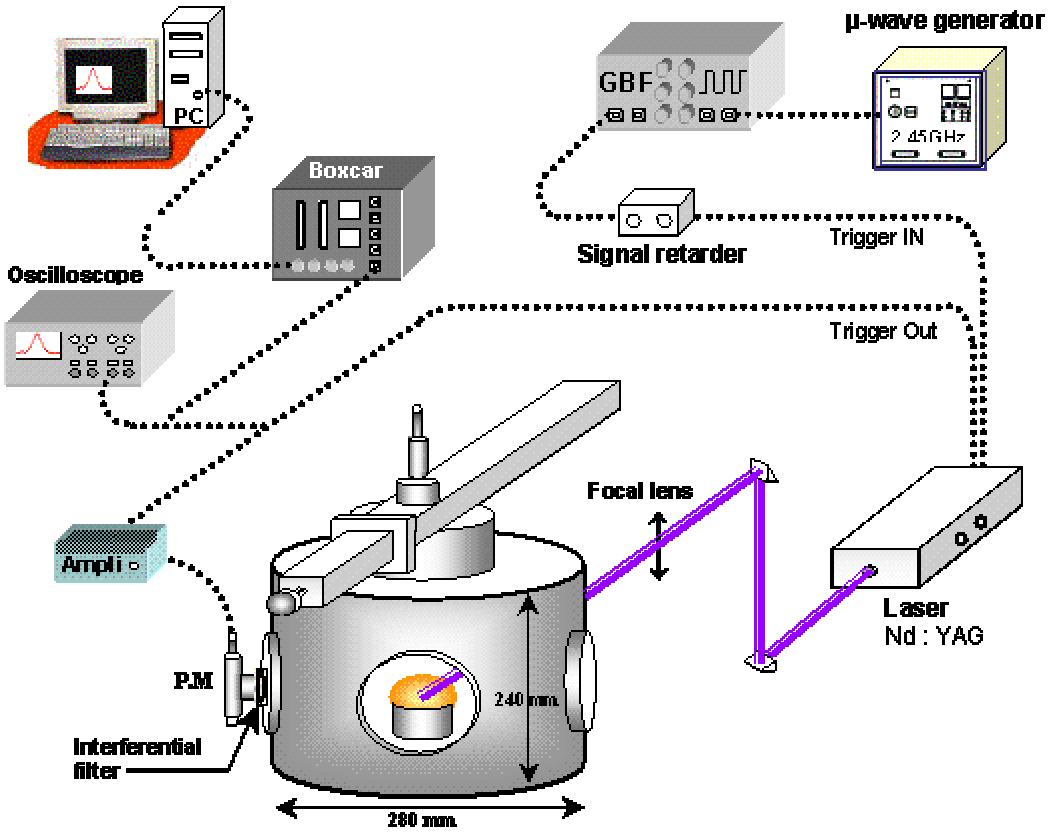

Figure 1: Experimental arrangement

The laser beam is guided to the bottom of the plasma by means of an optical system consisting of prisms and focusing lenses. The laser beam travels across the plasma in parallel to the substrate surface at a position of 4 mm above it. The spatial resolution is determined by the beam width at the focal point (0.5 mm). As we observe only the atomic hydrogen emission represented by H_α line at 656.28 nm, the monochromator was replaced by an interferential filter centred around 656 nm fixed at the entrance of photomultiplier tube (PM). The emitted light is filtered through this filter, and then, the selected H_α beam hurts the PM photocells. The output of the PM is connected to both devices of acquisition: an oscilloscope and a boxcar averager through a current amplifier (SRS 570) as shown in the figure 1.

C) Density and gas temperature measurements

Thanks to its high space and time resolution, we studied by LIF the evolution of the relative density of H-atoms in the center of plasma and the close vicinity of the substrate. A first study was curried out for different parameters, such as the pressure, the power and the gas composition.
The LIF technique, was extremely useful, firstly, for the quantitative study of H-atoms behaviour in the afterglow by measuring the relative density of H-atoms being at the ground state, from the profile observed by H_α transition ($n=3 \rightarrow n=2$) according to the reaction :

$$H\ (n=1)\ +\ 2h\nu_L\ \rightarrow\ H\ (n=3)\ \rightarrow\ H\ (n=2)\ +\ h\nu_f \qquad (1)$$

- ν_L et ν_f are, respectively, the laser excitation and the fluorescence (emission) frequencies

then for the gas temperature measurement, from Doppler broadening of LIF signal around the central wavelength λ_0 :

$$\Delta\lambda_{DH} = 7.167\times10^{-7}\,\lambda_0\sqrt{\frac{T_H}{M_H}} \qquad (2)$$

- T_H is the gas temperature and M_H is the atomic mass of hydrogen.

The temperature measurement was rather difficult because the effective bandwidth ($\Delta\lambda_m$) from the measured LIF profile is often a convolution of two principal contributions. The Broadening caused by Doppler effect and the laser apparatus function ($\Delta\lambda_L$) (convolution product of 2 gaussian profiles).

$$\Delta\lambda_m^2 = \Delta\lambda_{DH}^2 + 2\Delta\lambda_L^2 \qquad (3)$$

The laser contribution is counted two times because we have two-photons laser excitation.
In reality, we have not enough precision on the laser apparatus function, even if we know the spectral width. Because of the instabilities of the excited laser properties over multi-pulses, and the experimental consequences of these power and frequency fluctuations on the two-photon absorption LIF measurement of H-atoms is now being observed [17]. It is found that the averaging over a few tens of laser pulses to calculate the effective bandwidth of two-photon absorption LIF of H-atoms at 205 nm could underestimate the real contribution from the spectral line width of the fundamental laser radiation.

The method proposed to overcome this difficulty is based on measuring the spectral response of the atomic hydrogen and deuterium in H_2 + D_2 microwave discharge by scanning the excited laser frequency [16-17]. The hydrogen and deuterium atoms are supposed to be in thermal equilibrium ($T_H = T_D$) and their excitation frequencies are very close. The excitation wavelengths of hydrogen and deuterium are respectively 102.5722 nm and 102.5443 nm . The advantage of these very close values is that we can obtain two LIF profiles in a narrow frequency range [Fig. 2]. Combining the equations (2) and (3) one can deduce the laser apparatus function $\Delta\lambda_L$.

$$\Delta\lambda_L = \sqrt{\frac{2\cdot(\Delta\lambda_{mD})^2 - (\Delta\lambda_{mH})^2}{2}} \qquad (4)$$

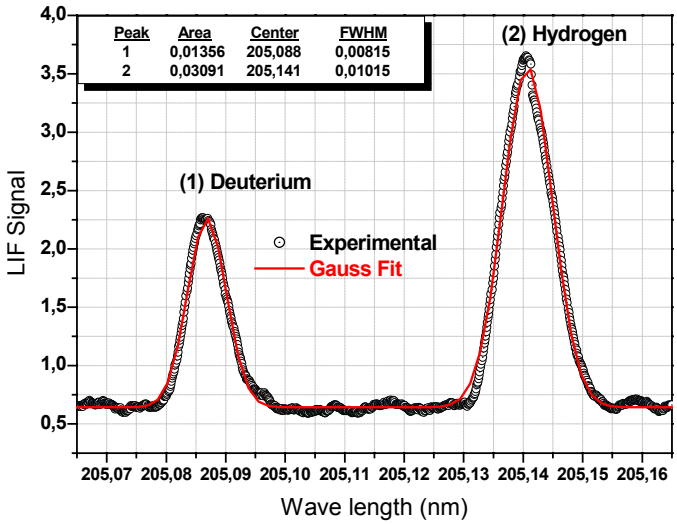

Figure 2: LIF Spectral profile of H_α and D_α lines, plasma H_2-D_2 37.5 % D_2 ; 200 sccm, 2500 W, 120 Torr.

D) Results and discussion

D.1. experimental results

The H-atoms relative concentration was evaluated by calculating the area under curve of LIF signal which has a gaussian profile. The relative density evolution in the afterglow was studied for two positions, at the close vicinity of the substrate (4 mm above the surface) and at the plasma centre (15 mm above the substrate surface), as we can see on the figure 32-a. We must keep in mind that all values are normalised to the value measured at the end of the discharge. One can notices the same evolution in the early afterglow till 2 ms, then a slight difference in benefit of the density near the surface. The most important point lies on the figure 3-b where the evolution is presented in logarithmic scale. At the first sight, we can assume that the decay of H-atoms density in the afterglow happens following tow distinguished regimes. Firstly, a fast loss regime till 2 ms, followed by a slow decay. This behaviour was already observed by several authors that sometimes interpreted by two different phenomena as a double exponential decay. While the classical kinetic theory forecasts only one slope (exponential decay), the existence of two slopes became a serious question to be answered.

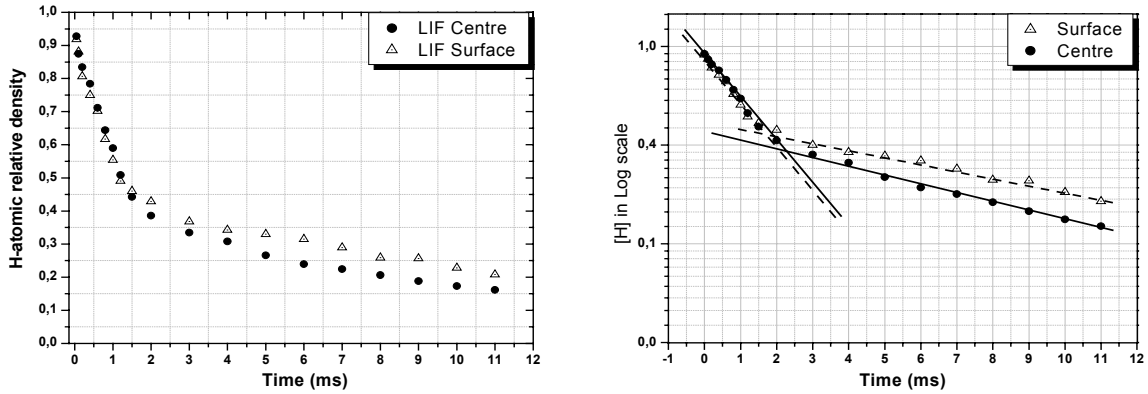

Figure 3: a) Evolution of H-atoms relative density in the afterglow.
b) the same evolution represented in logarithmic scale.

D.2. Kinetic of H-atoms evolution in the afterglow

The equation describing the temporal evolution of H-atoms local density is written:

$$\frac{\partial[H]}{\partial t} + \vec{\nabla}([H]\times\vec{v}) = Sources - Losses \qquad (1)$$

In the afterglow there is no creation process of atomic hydrogen, so no sources. In the probed volume, only volume recombination can contribute to the H-atoms consumption. This kind of recombination needs a third particle:

$$H + H + M \longrightarrow M + H_2 \qquad (2)$$

The local volume recombination rate of atomic hydrogen is given by term of losses : $2k_r[H]^2[H_2]$. with a reaction constant k_r, given by Baulch, $kr = 19.3\times10^{-31}T^{-1}$ ($m^6mol^{-2}s^{-1}$) [18].

To summarise other loss processes under our experimental conditions, which are surface recombinations, we should consider the diffusion term. This phenomenon is generated by the presence of gradient of density and is characterised by a flow of hydrogen atoms to the walls intended to homogenise this concentration. The relative term to this process can be written:

$$div([H]\times\vec{v}) = \frac{D}{\Lambda^2}[H]. \qquad (3)$$

where D is the diffusion coefficient (cm^2s^{-1}), which is considered constant in first approximation to simplify the analytical resolution of the kinetic equation, and Λ the characteristic length of diffusion.

The kinetic equation takes the following form:

$$\frac{\partial[H]}{\partial t} = -\frac{D}{\Lambda^2}[H] - 2k_r[H_2][H]^2 \tag{4}$$

The characteristic length of diffusion is calculated not only considering the reactor dimensions and geometry, but also from the different values of sticking coefficient given in the literature [19]. The reactor walls are made mainly from stainless steel, cooper and quartz windows with a sticking coefficients $\gamma \approx 10^{-4}$ - 10^{-1} at the room temperature [2-3,20]. The sticking coefficient can vary strongly with the surface conditions and for carbon substrate we take a typical value at 900°C $\gamma \approx 0.15$ [21].

Taking in account the reactor dimensions and the sticking coefficient values, we can conclude that the reactor walls loss contribution is too weak because of their big diffusion characteristic length. The carbon substrate situated in the close vicinity of the plasma with a high sticking coefficient has a strong contribution in H-atoms surface recombination, which is very useful for diamond film purity.

This term associated to the volume recombinations is proportional to the square of H-atoms density [H] and also depends on the local density of molecular hydrogen [H_2]. Under our working conditions, we assume that the volume recombinations are at least 100 times lower than surface losses, and hence they can be neglected.

The kinetic equation is reduced to :

$$\frac{\partial[H]}{\partial t} = -\frac{D}{\Lambda^2}[H] \tag{5}$$

where the solution, according to the classical kinetic theory, is an exponential decay if we consider the diffusion coefficient constant. This is not in agreement with the experimental curve of H-atoms density decay in the afterglow, as it can be observed on the figure 3. This evolution was usually interpreted by a double exponential decay.

Thanks of time resolved gas temperature LIF measurements, we studied the evolution of the diffusion coefficient (D) in the afterglow (Figure 4-a) according to the formula used by Lede [22] :

$$D = 1.25\times10^{-4}\frac{T_{gaz}^{1,72}}{P(atm)} \quad (\mathrm{cm}^2 s^{-1}) \tag{6}$$

As-estimated H-atoms density decay, taking into account the variations of diffusion coefficient, was compared to direct measured values from LIF profile as shown on the figure (4-b), where we can observe a good agreement.

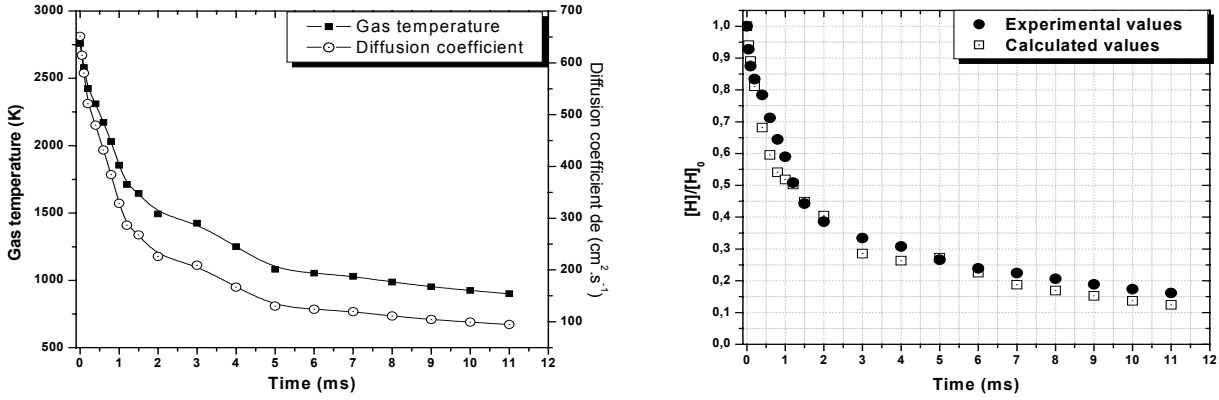

Figure 4: (a) Evolution of the gas temperature and the diffusion coefficient in the afterglow.
(b) The decay of H-atoms density in the afterglow, calculated and experimental evolutions.

Conclusion

In this study we have presented some new results based on the LIF technique which is a powerful diagnostic method for studying pulsed microwave discharge. We have explained, in the case of CH_4/H_2 plasma, the existence of only one loss mechanism of atomic hydrogen, governed by diffusion and recombination on the substrate surface.
The gas temperature and, then, the diffusion coefficient variations are of big interest for studying loss mechanisms at any discharge conditions.
This study shows also the importance of neutral dynamics study, especially gas heating and cooling phenomena for a better understanding of creation and loss processes.

Simultaneous determination of heavy metals in airborne particulate matter by ICP-AES following co-precipitation pre-concentration with sodium diethyldithiocarbamat

S. M. Talebi and M. Abedi
Department of Chemistry, Isfahan University, Isfahan 81744, Iran

Abstract

The concentrations of heavy metals in airborne particulate matter in the atmosphere of the city of Isfahan were determined by ICP-AES. Two different digestion procedures were investigated for decomposition of airborne particulate matter. A pre-concentration procedure was developed for the sensitive determination of heavy metals in samples collected with at lower sampling period and also for the samples collected from rural arrears. A comparison was made between the concentrations of heavy metals were determined by FAAS and ICP-AES.and an excellent agreement was found between them. ICP-AES was found to be a quite suitable technique for air pollution studies where a huge number of samples should be analyzed in a short period of time.

Keywords

Inductively coupled plasma atomic emission spectrometry, air pollution, heavy metals, pre-concentration of heavy metals, simultaneous determination of heavy metals.

Introduction

Heavy metals occur in the urban atmosphere mainly in particulate form originating from the mixing of finely divided materials from various sources[1]. Although both natural and anthropogenic sources contribute to distribution of heavy metals into urban atmosphere, the role of human activities is more important [2]. The major sources responsible for releasing heavy metals into urban atmosphere include; metallurgical processes, power plants, garbage incineration, consumption of fossil fuels in automobiles engines [3]. The determination of heavy metals associated with airborne particulate matter is very important in air pollution studies. During the last decades, an extensive database has been published providing different techniques for the determination of heavy metals in environmental samples [4-6]. Among the different techniques, atomic absorption spectrometry is the most popular one, but the single-element analytical methods are time-consuming and tedious. In air pollution studies that a large number of samples should be analyzed in a short period of time, the multi-elemental techniques of analysis are preferred. Because of low concentration some heavy metals and the complexity of the airborne particulate matrix, using a sensitive and accurate method for analysis is of greaty importance.

In this paper, ICP-AES as a popular multi-elemental technique method has been used for the determination of heavy metal concentrations in atmospheric total suspended particles (TSP).

Experimental

Sample collection

Airborne particulate matter from the atmosphere of the city of Isfahan was collected on quartz fiber filter (Whatman QM-A) using a conventional high-volume air sampler. Samples were collected from both urban and rural areas. Samples were collected from a height of 1.5 m above the ground level. Sampling flow rate and sampling period were 1 m^3 min^{-1} and 12 hours respectively. A continuous sampling was also performed for a couple of weeks in order to investigate the day to day variation in concentrations of heavy metals.

Reagents

All chemicals were analytical grade or better

Standard stock solutions (1000 mg/L) of Pb, Cd, Cr, Cu, Ni, Zn and Fe for atomic absorption spectrometry (Varian Company) were used.

Standard solutions in the working range were prepared from the stock standard solution by proper diluting with 5% v/v nitric acid.

The 0.1M solution of sodium diethyldithiocarbamate was prepared by dissolving 2.253 g of the reagent in 100 ml doubly distilled water.

Distilled de-ionized water was used for preparation of standard solutions and washing the dishes.

Standard reference material of airborne particulate matter, NIST, SRM-1648 was used for evaluation of the recovery of digestion procedures and capability of analytical methods.

Sample preparation

The exposed filters were with two different leaching procedures including; 1) digestion with a mixture of nitric acid and hydrogen peroxide as a proposed method , and 2) digestion with a mixture of nitric acid and hydrofluoric acid as a recommended method for releasing of heavy metals from airborne particulate matrix.

Digestion with a mixture of HNO_3 and H_2O_2

The exposed filter was folded and placed in a 100 ml conical flask. 15 ml nitric acid 1:1 (v/v) was added and the flask was then placed on a hot plate for digestion at a temperature below the boiling point of the mixture. When the volume of the solution was reduced to a half, a further 10 ml (v/v) nitric acid and 5

ml of 30% hydrogen peroxide were added to oxidize any organic compounds, and the mixture was heated again at sub-boiling temperature to reduce the volume down to about half. The solution was finally filtered into a 25 ml volumetric flask and made to the volime with de-ionized distilled water with rinsing. From the conocal flask.

Digestion with a mixture of HNO_3 and HF

The exposed filter was folded several times and placed in a PTFE beaker and moisturized with a few ml of de-ionized distilled water, and then 15 ml of Aristar nitric acid was added. The lid of the beaker was screwed and the beaker was heated on a hot plate and refluxed for 8 hours until all organic material be oxidized. The PTFE lid was then unscrewed and the beaker heated at 90 ^{0}C. When the volume was reduced to a half, 8 ml of nitric acid and 5 ml of hydrofluoric acid were added and the mixture was refluxed again to dissolve the material completely. The lid was then removed and the mixture evaporated to near dryness. After removing the remainder of HF (by adding HNO3 and heating) the digest was extracted in nitric acid 1:1 (v/v), transferred into a 100 ml volumetric flask and made to the volume by de-ionized distilled water

Pre-concentration of heavy metals

100 ml of the digest was transferred into a pyrex beaker and the its pH was adjusted to 5 and 50 ml. of the sodium diethyldithicarbamate solution was added on that and the solution was allowed to stand for 30 min. Then 1 ml 1% H_2O_2 was added and allowed to stand for 5 hours. The precipitate was filtered on a narrow pore filter paper and finally dissolved in concentrated nitric acid. The solution was transferred into a 10 ml volumetric flask and diluted to the volume with doubly distilled water.

Instrumentation

ICP-AES determinations were carried out on a Maxim system (Applied Research, Fisons Instruments) fitted with an axial viewing of torch. Axial viewing of the torch gives more light, better ability, and allows determination of easily ionized elements with high sensitivity and precision. Control of the Maxim ICP-AES spectrometer was affected from a suite of software program called Plasma Vision. The system was linked to a DECP 450, D2LP computer and an IBM 238 printer. The ignition, shut down, and sample uptake rate were computer-controlled. The wavelengths used for the determination of heavy metals include; 220.35 nm for lead, 228.80 nm for cadmium, 213.86 for zinc, 267.72 nm for chromium, and 324.75 nm for copper. The background correction was performed using two different positions. Position No. 1 in negative offset and position No. 2 in a positive offset from the analytical wavelength of the element of interest. The instrumental conditions are summarized in Table1.

Table 1: ICP-AES Scanning measurement parameters

Starting mirror	-60
Ending mirror	+60
Step size	4
Pre-integration time	0 (s)
Integration time	1 (s)
Plasma flow	0.8 (L/min)
Forward power	1100 (W)
Carrier flow	0.4 (L/min)
Analysing pump speed	2.0 (L/min)
Transport pump speed	20.0 L/min)
Transport time	30 (s)
Sample type	aqueous

The following analytical lines were used for analysis

Pb 220.35 nm, Cd 228.80 nm, Cr 267.72 nm, Cu 324.75 nm, Ni 231.60 nm, Zn 213.86 nm, and Fe 259.94 nm

Results and discussion

In order to evaluate the efficiencies of the digestion procedures, a standard sample (NIST, SRM-1648) was digested with both of the digestion procedures. The results were compared with certified value and showed that for complet decomposition using a mixture of nitric and hydrofluoric acid was necessary (Table 2).

In order to investigate the variation in concentrations of heavy metals in day and night times, we had to to reduce the sampling tine from 24 hours to 12 hours and in such a circumstance pre-concentration was necessary for sensitive determination. The pre-concentration was performed using co-precipitation of interest cations with sodium diethldithiocarbamate at optimized condition (pH, amount of sodium diethyldithicarbamate, standing time). The precipitate was then decomposed in concentrated nitric acid and analyzed by ICP-AES system. The recovery of heavy metals after pre-concentration was more than 96% at pH=5.

Table 2: The efficiencies of two decomposition methods for releasing heavy metals (µg/g) from NIST-SRM 1648

	HNO_3, H_2O_2 procedure		HNO_3, HF procedure		
Element	Mean	SD	Mean	SD	Certified value
Pb	5430	51.2	6530	62.5	6550
Cd	70	1.9	71	1.9	75
Cr	115	4.1	185	4.9	403
Cu	589	19.5	605	18.4	609
Ni	76	3.3	82	2.5	82
Zn	4711	31.3	4752	30.1	4760
Fe	32289	500	38700	589	39100

Several samples were digested and analyzed by FAAS and ICP-AES. The results were in excellent agreement. Although FAAS is known as a popular method for determination of heavy metals, it is time-consuming and tedious. ICP-AES with the same sensitivity especially after pre-concentration offers the same results at the shorter time. Comparison of the capabilities of FAAS and ICP-AES and the regression equation for the results obtained by the two techniques are summarized in Table 3.

Table 3: Comparison of FAAS and ICP-AES by a linear regression analysis

Element	Regression equation	X,Y pairs
Pb	Y = 1.221 + 0.981 X	26
Cd	Y = 0.132 + 1. 054 X	26
Cr	Y = 0.021 + 1.004 X	26
Cu	Y = 0.387 + 0.991 X	26
Ni	Y = 0.042 + 1.014 X	26
Zn	Y = -0.110 + 1.002 X	26
Fe	Y = 0.021 + 0.998 X	26

The pre-concentration procedure made it possible to reduce the sampling period from 24 hours and investigate the variation in concentration of atmospheric pollutants. Figure 1 shows the variation in concentrations of heavy metals in days with two rush hours and at night times.

Abstract
Modulated RF glow discharges fed with C_2F_4 were used to deposit nanostructured "teflon-like" coatings characterized by ribbon-shaped structures on a less fluorinated background. In continuous regime smooth samples were obtained. The coatings were analysed by means of X-rays Photoelectron Spectroscopy (XPS) and Atomic Force Microscopy (AFM). Nanostructured and smooth coatings were used in cell growth experiments with 3T3 fibroblast. The density of adhering cells depends on the roughness of the coatings.

1. Introduction

Non equilibrium, low-temperature plasma deposition (Plasma Enhanced-Chemical Vapour Deposition, PE-CVD), treatment and etching processes are nowadays extremely popular in Materials Science Technology for their ability to adapt surface chemistry and properties of materials in a wide range of applications at room temperature, in a controlled way, without changing their bulk [1], at negligible impact for the environment.
PE-CVD, in particular, allows to vary continuously the composition of treated surfaces and, consequently, their physical and chemical properties in a very broad range, by depositing thin (10-1000 nm) coatings of tuneable composition and properties, ranging from those with high retention degree of the monomer structure to those with a fully "scrambled" atomic distribution. PE-CVD allows to tune many surface properties of biomedical interest; Radiofrequency (RF, 13.56 MHz) driven Glow Discharges are the most utilized plasma sources for biomedical applications.
Thin coatings deposited in glow discharges fed with fluorocarbon gases have been investigated since years as source of thin films characterized by surface properties such as low surface energy and wettability, high hydro-phobic and oleo-phobic (stain resistance) character, low friction coefficient, high chemical inertness, low (k) dielectric constant and interesting interactions with biological systems [2]. Such coatings can be plasma-deposited in RF Glow Discharges both in continuous wave (CW) and modulated discharge (MD) regimes to obtain films with different surface properties.
Fluorocarbon films obtained in CW conditions are characterized by a variable fluorination degree and cross-linking character, depending on the experimental parameters, and by low roughness. In recent years PECVD processes have been also investigated in MD conditions; modulating the discharge (pulsing the discharge on/off at defined time intervals) [2-6], it is possible to improve the process control for both the plasma phase [7] and the deposited films [8, 9]. Previous papers [10-12] have shown that MD films, deposited from tetrafluoroethylene (C_2F_4), exhibit very rough surfaces and high fluorination degree. More specifically, low duty cycles in modulated plasma processes results in progressively less branched films and in an increased retention of the monomer structure in the coating including crystalline poly-tetrafluoroethylene (PTFE) nanostructures randomly distributed on an amorphous fluorocarbon background.
In this contribution we present results on the behaviour of cells cultured on fluorocarbon surfaces produced through RF (13.56 MHz) glow discharges fed with fluorine-carbon gases in CW and MD regimes, characterized by identical chemical surface composition, and different roughness determined by peculiar surface topographical features. It has been found, in fact, that the presence of random/oriented morphological features on biomedical materials can drive the behaviour of cells.
3T3 murine fibroblasts were cultured on two kinds of samples, flat and nanostructured, with different topographical features in order to study how the adhesion and growth of cell lines was influenced by topographical parameters. It is known, in fact, that cells adhering at the surface of biomedical materials are sensible to surface topography [13-15].

Data relative to X-ray Photoelectron Spectroscopy (XPS), Water Contact Angle (WCA) and Atomic Force Microscopy (AFM) measurement are presented. The correlation between cells adhesion, spreading and growth and the topography of the processed substrates is discussed.

2. Materials and Methods

RF Glow Discharges fed with C_2F_4 were conducted in CW and MD regimes to deposit flat and rough nano-structured ribbon-like fluorocarbon coatings [13] on 10 mm diameter PET (Goodfellow) circular substrates. Depositions were carried out in a parallel plate stainless steel reactor. The reactor is described in detail in previous papers [10-12]. The upper electrode (12 cm circular dia, stainless steel, shielded) and the lower one (19 cm circular dia, stainless steel, substrate holder, grounded) were 5 cm far. Discharges were ignited in the interelectrode gap with a 13.56 MHz generator (RF Power Products model RF5) connected to the upper electrode through an impedance matching network. A pulse generator was used in MD regimes.
Smooth fluorocarbon coatings were deposited in CW regime, in the following experimental condition: 6 sccm C_2F_4 flow rate, 100 W RF power, 200 mTorr pressure and 5 min of deposition time; this kind of substrates were called as FLAT.
Fluorocarbon coatings with controlled roughness and density of nano-structures were deposited on PET in the following MD experimental condition: 10 sccm C_2F_4 flow rate, 100 W RF power, 5% duty cycle (16 ms time on; 304 ms time off; total period 320 ms), 200 mTorr pressure and 60 min deposition time. These conditions result in ribbon-like nano-structured fluorocarbon coatings called as ROUGH surfaces. Figure 1 shows AFM images of the two different fluorocarbon coatings; smooth surfaces obtained in CW regime and nanostructured ones produced in MD at low duty cycle.

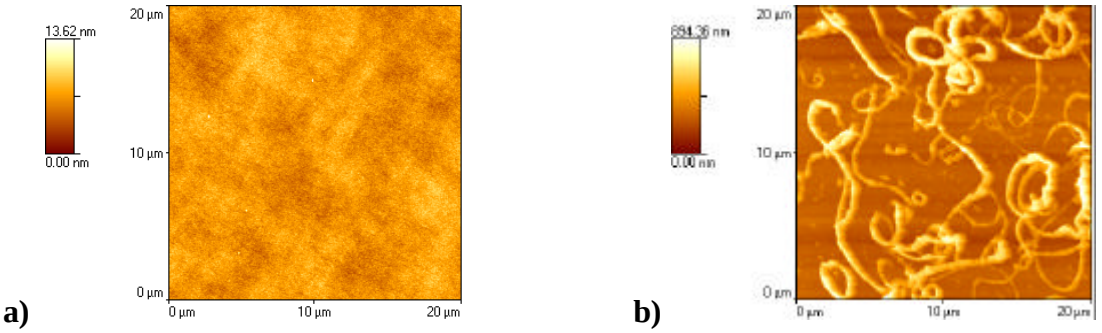

Fig1. AFM images of fluorocarbon coating deposited from C_2F_4 in CW **a)** and MD **b)** conditions showing the pronounced topographical difference between FLAT and ROUGH coatings.

Since a slightly different surface chemical composition was found between ROUGH and FLAT coatings, as known from previous publications [10-13], after the MD deposition process, the substrates were coated in the CW conditions described above for 50 s, in order to deposit a thin conformal (60 nm) CW coating on the nanostructured surface. The resulting substrates were characterized by a defined roughness value and by the same FLAT chemical composition. FLAT and ROUGH substrates were utilized in the same cell-culture experiments to compare in detail cell-surface interactions on fluorinated nanostructured coatings without and with nanostructures at their surface.
Surface chemical analysis of substrates were obtained by X-ray Photoelectron Spectroscopy (XPS). A PHI 5300 instrument (non-monochromatic MgKα X-rays, 1253.6 eV) was used. Only Carbon and Fluorine were detected. The surface chemical composition of FLAT and ROUGH coatings was expressed as F/C ratio; a deeper description of surface chemistry and properties of such coatings is reported in refs.10-12.
Static Water Contact Angle (WCA, 2 µl drops, double-distilled water) measurements were performed with a Ramé-Hart A-100 goniometer, to probe the hydrophobic character of the surfaces used in cell-culture experiments. AFM measurements (SPM - Autoprobe CP Research, Veeco, Sunnydale, CA) were run in non contact mode on 20µm x 20µm sample areas to better evaluate the roughness of the substrates. An a-step (KLA Tencor) instrument was utilized to measure the thickness of the coatings.
3T3 fibroblasts were used for cell culture experiments. Cells were obtained from stocks routinely grown in Dulbecco Modified Eagles Medium (DMEM, Sigma, UK), supplied with 10% fetal bovine serum and 200

mM glutamine, under 5% CO_2/95% air atmosphere at 37°C. ROUGH and FLAT samples were placed, modified side up, in 24 well (Iwaki) culture plates. Cells were obtained after trypsinization of confluent or near-confluent culture, then seeded at 1 x 10^4 cells/well in suspension on all materials. After incubation, cells were fixed with a 4% formaldehyde/PBS solution (15 min) and stained (3 min, Coomassie blue in methanol/acetic acid/water) at different time (3h, 24h, 48h, 96h), to carefully evaluate by means of optical microscopy, the percentage of substrate area covered by cells on different samples. Automated detection of cell outline was used to calculate individual and total cell areas. The Image J (National Institute of Health, US) image analysis software was used; 50÷100 cells were counted for single cell area analysis.
The unpaired Student's t-test was used to evaluate statistical significant differences among tests performed on at least four replicated samples. Differences were considered significant for $p<0.01$.

3. Results and Discussion

PE-CVD of FLAT and ROUGH fluorocarbon coatings

The surface chemistry of FLAT and ROUGH fluorocarbon coatings deposited on PET substrates, as defined in the previous section, are analyzed by XPS, WCA and AFM to detect their surface chemical composition, wettability and roughness, respectively.
An F/C ratio of 1.62±0.03 is detected by XPS on FLAT substrates, and WCA values of 105°±3°. From AFM analysis a root-mean-square roughness value (RMS) of 2.0 ± 0.2 nm is measured on FLAT coatings, confirming a very smooth surface, and a thickness of 300±15 nm of the deposited film.
MD plasma coated PET substrates resulted in a XPS F/C ratio of 1.89±0.03 and WCA values of 155°±5°. The very high WCA value is explained with the presence on the surface, at the same time, of a high fluorination F/C degree, and of the nanostructures; this combined effect of chemistry and roughness on the hydrophobic character of a surface is quite common and well known, and has been reported also in previous papers [11-14] on plasma-deposited MD fluorocarbon coatings. Due to the presence of the ribbon-like structures a RMS roughness value of 130±15 nm is measured by AFM on top of such coatings, which are characterized by a thickness, excluding nanostructures, of 160±15 nm.
In order to obtain surfaces with very similar F/C surface chemistry and different roughness, nanostructured surfaces are conformally coated in the same CW conditions used for FLAT coatings. In this way ROUGH surfaces obtained, have an F/C ratio of 1.61±0.03 measured very similar to FLAT samples.
XPS analysis demonstrate that the C1s spectra of ROUGH (MD) and FLAT (CW) films, before the conformal coating, are quite different. Nanostructured ROUGH films show a sharper C1s band with a predominant contribute of the CF_2 moieties. The smooth FLAT surface, instead, present a broader C1s band with comparable contribution of all CF_x components (Figure 2a). After the homogeneous CW deposition on nanostructured surfaces (MD+CW), the C1s bands of ROUGH and FLAT coatings overlap perfectly (Figure 2b).

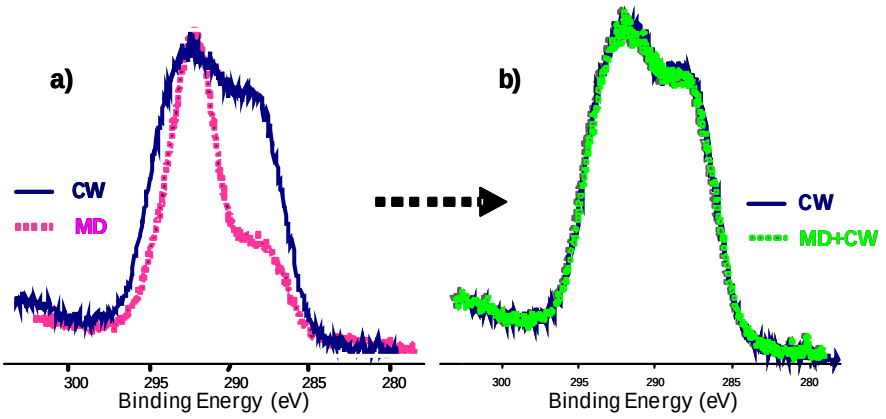

Fig.2 XPS C1s signal of FLAT (CW) and ROUGH (MD) samples before **a)** and after **b)** the conformal CW coating.

After the conformal coating a RMS roughness value of 120±15 nm is found on ROUGH surfaces, with WCA values of 140±5° and a thickness of 220±20 nm, excluding nanostructures. Respect to MD plasma coated

surfaces RMS roughness values and WCA values of ROUGH substrates are reduced due to the conformal deposited fluorocarbon layer.
These results attest that FLAT and ROUGH fluorocarbon surfaces exhibit the same chemistry but different density of nano-structures, so they can be used in cell-culture experiments for investigating in detail the effect of roughness on cell surface interactions.
FLAT and ROUGH fluorocarbon substrates are utilized in cell growth experiment in order to detect different behaviors as a function of the roughness of the substrates underneath.
3T3 fibroblast cells are seeded on FLAT and nanostructured ROUGH samples and the area of samples covered by cells is evaluated by optical microscopy analysis at different time of cell culture (3h, 24h, 48h, and 96h). As it's shown in Figure 3, after 48 hours of cell culture the area covered by cells on ROUGH surface becomes larger than on FLAT fluorinated substrates.
The effect is much more pronounced after 96 hours of culture, since 3T3 cells are almost confluent on nanostructured ROUGH samples, while on FLAT samples there are still large areas of the substrate where cells are not adhered.

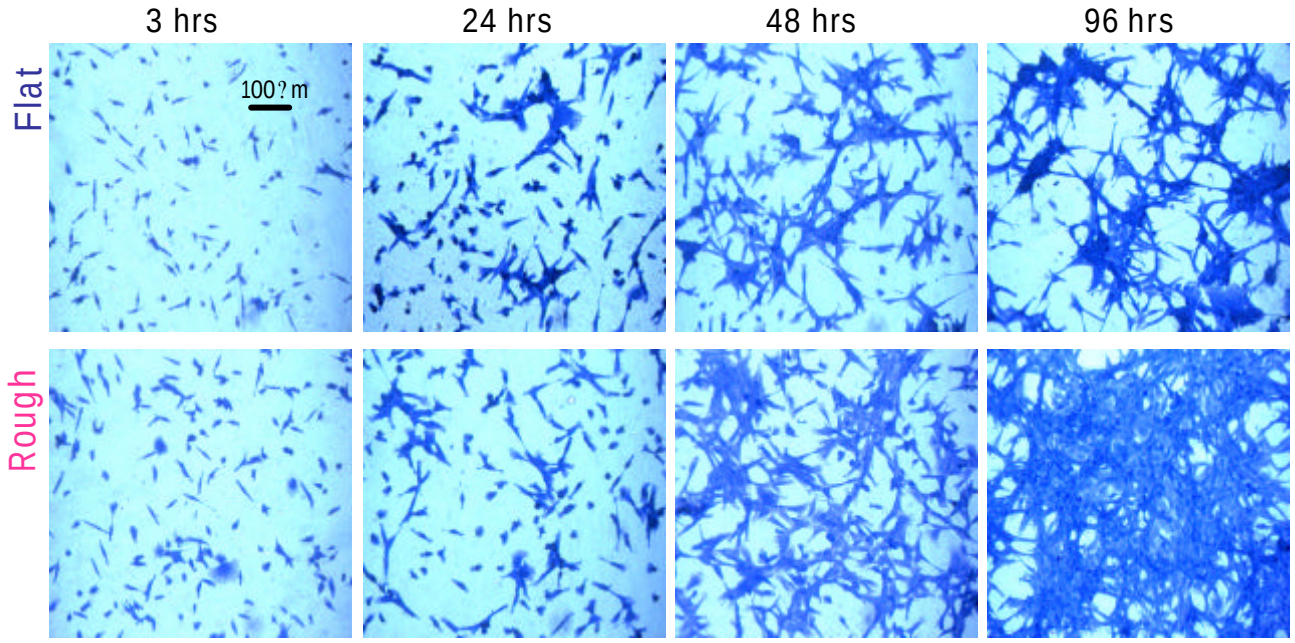

Fig. 3 Optical microscopy pictures showing differential adhesion of 3T3 Fibroblast cells on FLAT and ROUGH surfaces after different period of cell culture (3 h, 24h, 48h, 96h).

The mean values (± SD) of the sample surfaces covered by cells at different time points, shown in Figure 4, confirm the better attitude of cells to adhere on nanostructured ROUGH samples respect to the FLAT ones.

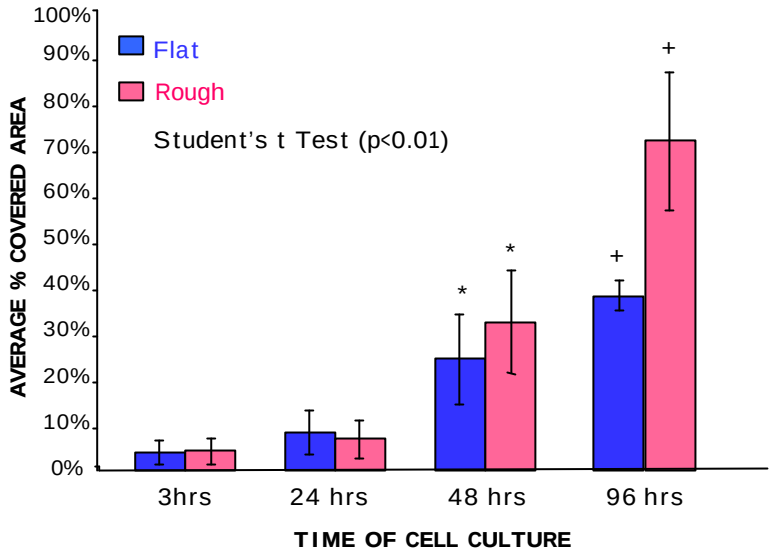

Fig.4 Graph showing % of area covered by 3T3 fibroblast/area 2.8mm^2 (n>10) on FLAT and ROUGH samples at different time of cell culture.

4. Conclusion

Adhesion and morphology of 3T3 murine fibroblasts appeared to be influenced by the topography present at the surface of the plasma deposited coatings. The used cell lines adhered in different way to nanostructured ROUGH samples and to FLAT samples. These results suggest that fluorinated smooth surfaces (FLAT) are not the best substrate for cells thus the increase surface roughness (ROUGH) result in improving the adhesion and growth of cells. Nanostructured coatings with different roughness surface can be modified by the plasma deposition of a thin film with different chemistry in order to observe the behaviour of cells adhered at their surface both to different chemistry and topography.

Abstract
Rate constants and product branching ratios for the reaction of $PO_xCl_y^-$ and $SO_xF_y^-$ ions with H atoms were measured in a selected ion flow tube (SIFT) from 298-500 K. The reactive ions underwent halogen abstraction to form HX (X=Cl, F) as the major reaction pathway, having rate constants of around 2×10^{-10} cm^3 s^{-1} from 298-500 K. Preliminary results show that the $PO_xCl_y^-$ ions did not react with N, N_2 or NO. Associative detachment of H atoms did not occur except for F^-, SO_2^- and PO^- ions.

1. Introduction

Phosphorus-containing compounds are potential contaminants in the plasmas of coal-fired magnetohydrodynamic (MHD) electric generators.[1] Anions produced by these compounds such as PO_3^- have also been observed in the mass spectra of numerous pesticides.[2] In addition, flames doped with $POCl_3$ have been observed to produce PO_3^- and PO_2^- as the major terminal ions,[3] and oxyphosphorus compounds have also been used as fuel additives in flame tests for hydrogen-fueled scramjet combustors, demonstrating a measurable increase in thrust by enhancing H, O, and OH recombination kinetics.[4] Nevertheless, the detailed chemistry involved in reaching the PO_2^- and PO_3^- terminal species has not been explained and the reactions of oxyphosphorus ions with atoms have not been extensively studied. This anion chemistry is equally useful for models of plasma-assisted combustion, where the role of negative ion chemistry is not well understood.[5]

An analogous situation concerns discharges where SF_6, O_2 and H_2O are present, leading to $SO_xF_y^-$ anions such as SOF_2^-, $SO_2F_2^-$ and SO_2F^-.[6, 7] The available kinetics for the formation and reactivity of these species are also sparse, despite some recent studies from our laboratory to begin understanding the plasma chemistry.[8, 9] Data on the reactions of the sulfur oxyfluoride anions with atoms is similarly lacking.

To address the dearth of information on the plasma chemistry of these anions, rate constants and branching ratios for $PO_xCl_y^-$ and $SO_xF_y^-$ anions reacting with relevant atomic species were measured in a selected ion flow tube (SIFT) from 298-500 K. Reactions between H atoms and $PO_xCl_y^-$ and $SO_xF_y^-$ ions are discussed as are preliminary results on reactions with O and N atoms.

2. Experimental

The selected ion flow tube (SIFT) has been described in detail elsewhere.[10] Therefore, only a brief description will be provided. $PO_xCl_y^-$ anions were generated in a remote ion source chamber by electron impact on $POCl_3$ and the subsequent ion-molecule reactions of these ions with remaining $POCl_3$.[11-13] All of the $SO_xF_y^-$ ions were similary generated by electron impact; however, various combinations of source gases were used to achieve the requisite source chemistry as follows. SF_6^- and SF_5^- were created from SF_6. SO_2^- was generated from SO_2 while $SO_2F_2^-$ and SO_2F^- were generated from a mixture of SF_6 and SO_2. A mixture of SF_6 and H_2O introduced into a source block cooled to 262 K was used to produce SOF_4^- and SOF_3^-.[8]

Once generated, the desired reactant ion was mass selected with a quadrupole mass filter and injected into a fast flow of helium buffer gas introduced into the temperature-controlled flow tube through a Venturi inlet. After thermal equilibration, atoms created using a microwave discharge on a gas mixture passing through a Pyrex tube were introduced into the reaction region of the SIFT. For H atoms, a mixture of H_2 in He was used in the discharge. For the initial O atom experiments, a microwave discharge on N_2 produced N atoms that were titrated with NO to produce O atoms.[14] Consequently, the reactions with the H_2, N_2 and NO gases used with the

microwave discharge atom source were studied first. After the reaction occurs over a known distance for a previously measured reaction time, a blunt nose cone aperture samples the remaining reactant ions and any product ions. These ions are analyzed with a second quadrupole mass filter and detected with an electron multiplier.

As the neutral reactant concentrations were in excess of the reactant ions, the decay of the reactant ion could be followed using pseudo-first order kinetics, giving the reaction rate constant with a relative uncertainty of $\pm$20% and absolute uncertainty of $\pm$30% for the atom reactions.[15] The product branching ratios as a function of reactant concentration were extrapolated to zero concentration to account for any secondary chemistry that might have occurred at higher concentrations. The branching ratios have uncertainties of $\pm$10%.

To address the issue of possible direct routes to PO_2^- and PO_3^- formation, the secondary reactions of $POCl^-$ product ions with O_2 and O_3 were also studied. $POCl^-$ ions were first created by the $POCl_2^-$ + H reaction and then pure O_2 and, subsequently, a 3% O_3 in O_2 mixture was introduced at an inlet upstream of the initial H atom reaction to react with $POCl^-$. Corrections were made to the branching ratios to account for the product contributions from the O_3 reaction with $POCl_2^-$ ions that could not be completely reacted away at the H atom concentrations achieved here. The operating conditions for this experiment also precluded the determination of whether Cl^- products came from the reactions of $POCl^-$ with O_2 and O_3.[15]

3. Results and Discussion

a. $PO_xCl_y^-$ Reactions with H atoms

The kinetics results for the reactions of $PO_xCl_y^-$ ions with H atoms are summarized in Table 1. All of the $PO_xCl_y^-$ ions in Table 1 were unreactive with H_2, giving a limit to the rate constant of $<5\times10^{-12}$ cm^3 s^{-1}. The rate constants for the reactions of these ions with H atoms were not dependent on temperature from 298-500 K, having rate constants of roughly 2×10^{-10} cm^3 s^{-1}, which are <20% of the capture collision rate constants, k_c, shown in brackets in Table 1.[16, 17]

As seen in Table 1, halogen abstraction from $PO_xCl_y^-$ producing HCl was the primary reaction pathway, resulting in a more energetically stable, less reactive anionic species. The enthalpies of reaction at 298 K in Table 1 were determined from *ab initio* geometry optimizations[15, 18] at the G3 level of theory[19, 20]determined using Gaussian 03W.[21] None of the primary $PO_xCl_y^-$ reactant ions underwent associative detachment with H atoms, which would have produced a neutral molecule and electrons, even though this reaction pathway is slightly exothermic for $POCl_2^-$ for either of the two $HPOCl_2$ isomers shown in Table 1. Associative detachment was observed for H atoms reacting with PO^- ions that were formed by the secondary reaction of H with the $POCl^-$ ions from the $POCl_2^-$ + H reaction. However, the PO^- channel was only observed at high H atom concentrations. A similar detachment channel for $POCl^-$ + H giving HPOCl with the H atom bound to the phosphorus was 48 kJ mol^{-1} exothermic, but the presence of PO^- ions in the flow tube precluded a definitive observation of this process with $POCl^-$. The lowest energy structures for HPO_xCl_y neutral molecules, determined using G3 theory, show the H atom bound to the O, with an O-H bond distance of ~0.98 Å for all of the molecules. The only exception is HP=O, which is ca. 1.5 eV lower in energy than POH.[15]

b. Routes to PO_2^- and PO_3^-

To further probe for reactive channels that directly produce PO_2^- and PO_3^-, the secondary reactions of $POCl^-$ product ions with O_2 and O_3 were studied. The results for this secondary chemistry are also shown in Table 1, where the final branching ratios given were corrected as described in the Experimental section above. Both O_2 and O_3 reacted with $POCl^-$ to directly produce PO_3^- and PO_2^-, respectively, with rate constants of $8.9\pm1.1\times10^{-11}$ and $5.2\pm3.3\times10^{-10}$ cm^3 s^{-1}.[15] These products were only minor channels with $POCl_2^-$ and $POCl_3^-$ reacting with O_3.[18]

c. $SO_xF_y^-$ Reactions with H atoms

The kinetics results for the reactions of $SO_xF_y^-$ ions with H atoms are summarized in Table 2. All of the $SO_xF_y^-$ ions in Table 2 were unreactive with H_2, with an upper limit to the rate constant of $<5\times10^{-12}$ cm^3 s^{-1}. The rate constants for the reactions of these ions with H atoms were weakly dependent on temperature from 298-500 K, with a slightly negative trend with increasing temperature. The rate constants for the reactive ions were roughly 2.5×10^{-10} cm^3 s^{-1}, which was also <20% of the capture collision rate constant.[16, 17] The F^- reaction with H was the exception, reacting at almost 90% of the collision rate at 500 K. This measurement at 500 K was the first for the F^- + H reaction above room temperature.

As seen in Table 2, halogen abstraction from $SO_xF_y^-$ producing HF was the primary reaction pathway, resulting in an unreactive anionic species, analogous to the $PO_xCl_y^-$ reactions. The enthalpies of reaction at 298 K in Table 2 were determined from the experimental literature values where available[22] and extensive G2 theoretical calculations of the thermochemistry.[8, 23, 24] The reactivity trends of $SO_xF_y^-$ ions with H atoms

were identical to those observed in the reactions of these ions with O_3 in the SIFT.[8, 9] In the O_3 reactions, the reactivity of the anion correlated with the bond order of the S atom in the ion, *n*, defined as the sum of the total number of S-F bonds and twice the total number of S-O bonds. Species with an even-numbered *n* such as $SO_2F_2^-$ (*n*=6) and SO_2^- (*n*=4) were reactive and species with an odd-numbered *n* such as SF_5^- and SO_2F^- (*n*=5) were unreactive. While a number of unreactive ions had exothermic reaction pathways with O_3, they were often spin forbidden. This partially explained the observations, e.g. the lack of a reaction for $SO_2F^- + O_3$.[8, 9] Spin did not completely explain the reactivity and it appeared that a kinetic bottleneck also existed. As seen in Table 2, the reactive sulfur oxyfluoride anions have highly exothermic product channels for producing HF. However, as discussed above, the rate constants are <20% of the theoretical limit.[16, 17] The unreactive $SO_xF_y^-$ species had exothermic pathways as well and all of these reaction channels were spin-allowed with H atoms. Therefore, a similar kinetic bottleneck must have contributed to the reactivity trends observed with the H atom reactions as well.

Table 2. Kinetics Results for the Reaction of $SO_xF_y^-$ + H

			Rate Constant, [k_c] ($\times 10^{-9}$ cm^3 s^{-1})

The only ions that underwent associative detachment with were F^- and SO_2^-. Associative detachment of H with SO_2^- produced HSO_2. The different isomers of HSO_2 were observed in both gas phase mass spectrometry experiments[25, 26] and matrix-isolated experiments[27, 28] and were also characterized by extensive theoretical calculations of the HSO_2 doublet potential energy surface.[23-29] Two main isomers were observed, a non-planar HSO_2 with H bound to the S atom and a planar *cis*-HOSO with H bound to the O atom. The *cis*-HOSO isomer is the global minimum on the potential surface and a *trans*-HOSO isomer was shown to be a first-order transition state on the surface. A large barrier exists for isomerization from *cis*-HOSO to HSO_2 and for dissociation from *cis*-HOSO to SO_2 + H. However, it is essentially barrierless to form HSO_2 from H + SO_2. RRKM calculations showed that the rate constant for isomerization from HSO_2 to *cis*-HOSO was much larger than the rate constant for the reverse process.[24, 25] Consequently, HSO_2 would preferentially be formed at

temperatures below ca. 700 K, above which *cis*-HOSO could increasingly be produced.[24, 25] These considerations are important as new preliminary G2 theoretical calculations[30] using Gaussian 03W[21] on the structures of HSO_2^- isomers show that it is 188 kJ mol^{-1} exothermic to form HSO_2^- and 168 kJ mol^{-1} exothermic to form non-planar $HOSO^-$ from SO_2^- + H. The structures of SO_2^-, HSO_2^- and HSO_2 are very similar. At the G2 level of theory, the electron affinity (EA) of HSO_2 is 2.41 eV, which is close to the vertical detachment energy (VDE) of 2.68 eV for forming HSO_2 with the HSO_2^- structure.

Based on our new G2 calculations and the known HSO_2 potential surface, a preliminary mechanism for the SO_2^- + H reaction can be given. The structural similarity of SO_2^-, HSO_2^- and HSO_2 indicate that barriers to forming HSO_2^- with subsequent electron loss should be minimal and that this pathway would require the least amount of structural rearrangement, consistent with the close values of the EA and VDE. However, the reaction to form HSO_2 from SO_2^- + H is 38 kJ mol^{-1} endothermic as shown in Table 2. At 298 K, the thermal energy in HSO_2^- is approximately equal to the endothermicity, making this reaction pathway energetically accessible. This analysis of the energetics is consistent with the observed rate constant being only ~12% of the collision rate constant. While the overall reaction to form *cis*-HOSO is 62 kJ mol^{-1} exothermic, considerably more rearrangement would be necessary to form $HOSO^-$ from SO_2^- + H. This rearrangement would be followed by further rearrangements either before or after electron detachment to form the planar *cis*-HOSO structure. Further calculations are being conducted to search for transition states that could connect the ionic and neutral HSO_2 structures.

c. O atom reactions – Preliminary Results

Oxygen atoms may also react with $PO_xCl_y^-$ ions to generate PO_2^- and PO_3^- directly. To examine this possibility, experiments were begun using the titration of N atoms with NO to produce O atoms for studying these reactions as discussed in the Experimental section. The reaction of $PO_xCl_y^-$ ions with N_2 and NO must be studied first to see if any background reactions must be accounted for in the N and O atom experiments. However, none of the $PO_xCl_y^-$ primary reactant ions shown in Table 1 reacted with either N_2 or NO, nor did PO_2^- and PO_3^- react with N_2 or NO, again giving a limit to the rate constant for these reactions of $<5\times10^{-12}$ cm^3 s^{-1}. In addition, none of the ions just mentioned reacted with N atoms either. The lack of reactivity with N, NO and N_2 meant that any products that would arise during the titration must come from O atom reactions. Initial attempts at reacting O atoms with $PO_xCl_y^-$ ions were hindered by issues surrounding the effect of O atoms on the ion sampling as well as O atom loss processes that need to be minimized.

4. Conclusions

The rate constants and branching ratios for the reactions of $SO_xF_y^-$ and $PO_xCl_y^-$ ions with H atoms were measured in a SIFT from 298-500 K. The rate constants for these reactions were in general about 2×10^{-10} cm^3 s^{-1}, which was <20% of the capture collision rate constant and displayed little or no temperature dependence over the limited range studied. Halogen abstraction from $SO_xF_y^-$ and $PO_xCl_y^-$ producing HF and HCl, respectively, was the primary reaction pathway, resulting in a more energetically stable, less reactive anionic species. Associative detachment of H to produce electrons was only observed with F^-, SO_2^- and PO^-. The structures and thermochemical properties of the relevant molecules were determined using *ab initio* geometry optimization calculations that aided in understanding the experimental results, particularly for the mechanism of the associative detachment reaction of SO_2^- + H. $POCl^-$ product ions reacting with O_2 and O_3 showed that these reactions produce the important PO_2^- and PO_3^- flame ions directly. Preliminary results for the reactions of these anions with O atoms generated via titration of N atoms with NO showed that N_2, NO and N atoms do not react with $PO_xCl_y^-$. However, further work is needed to perfect the experimental method for measuring the O atom reactions themselves.

Behaviors of Fluorocarbon Radicals in 60 MHz Capacitively Coupled Plasma

M. Nagai, M. Hori, and T. Goto,

[1] *Department of Quantum Engineering, Graduate School of Engineering, Nagoya University, Japan*

Abstract

Optical emission spectroscopy and infrared diode laser absorption spectroscopy were applied to measure rotational temperatures of CF radical in 60 MHz capacitively coupled $Ar/C_4F_8/N_2$ plasmas. The rotational constant Y of $^2\Delta$state of CF radical was evaluated to be 0.58 from the emission intensities using the line strength of Kovacs. The addition of N_2 gas to the Ar/C_4F_8 gases increased CF rotational temperatures. It was found that the rotational temperatures in the excited state were equilibrium with those in the ground state.

I. Introduction

Fluorocarbon gas chemistry is essential in a lot of fields of plasma processing, that is an etching of silicon dioxide (SiO_2) films, decomposition of polymers, and chamber wall cleaning. Generally, the SiO_2 etching is performed with Ar, C_4F_8, and O_2 gas mixtures for the purpose of realizing the vertical etch profile without eching stop. The etchings have been developed in high-density capacitively coupled plasma (CCP) in order to get the etching rate uniformly over 300 mm wafer. Recently, low dielectric (low-k) films such as organosilicate, SiOCH, and SiLK^{TM} are used for the solution of the resistance-capacitance (RC) delay in ULSI. The low-k films etching have been developed with N_2 addition to Ar/C_4F_8 plasma [1]. One of the most serious problems of low-k films etching is a line edge roughness of resists [2], which is considered to be closely related with the behaviour of the radical in $Ar/C_4F_8/N_2$ plasmas.

Plasma parameters such as the density of ion, radical, and electron are strongly influenced on the etch properties. Behaviours of radical have not investigated enough in $Ar/C_4F_8/N_2$ plasmas. Diagnostics of the fluorocarbon plasma is necessary to clarify the correlations between material processings and fluorocarbon gas chemistries.

Recently, several techniques have been employed to measure fluorocarbon plasma. For example, fuorocarbon radicals with plasma have been detected by infrared diode laser absorption spectroscopy (IRLAS) [3], and broadband absorption spectroscopy (BAS) [4,5] and so on. Some of these methods were applied to measure the radical temperatures. Optical emission spectroscopy (OES) is a powerful tool to measure the radical temperatures because it does not require complicated system such as a laser.

The rotational temperatures of CF radical were measured from the optical emissions by other studies [6-8]. In this study, the line strengths expressed by Kovacs were adapted to the calculation of the emission spectra $B^2\Delta$ - $X^2\Pi$ (0-1) and (1-2) band [9]. The line strengths could be used for the coupling of the intermediate case of both the excited state and the ground state. The rotational constant Y of CF $B^2\Delta$ state was evaluated to be 0.58 from the emission intensities in this work. The measurement was performed in $Ar/N_2/C_4F_8$ plasma. Furthermore, it was found that the rotational temperature in the excited state using OES was equilibrium with the temperature in the ground state.

II. Experiment

A. Experimental setup

60 MHz capacitively coupled plasma (CCP) was employed in this study. The power of 60 MHz was applied to the upper electrode. Ar, N_2, and C_4F_8 gases were introduced through the shower head on the upper electrode. The electrode was 30 cm in diameter. The gap distance between upper electrode and lower electrode was 3.5 cm. The electrode was cooled and kept at a temperature of 20 ℃.

Optical emission spectroscopy (OES) measurements were performed using an intensified charge-coupled device (ICCD) spectrometer (model PI-MAX1300RB-25-FG, focal length 750 mm, grating 1200 lines/mm, Rober) for measuring a rotational temperature in the excited state of CF radical and N_2 molecular. Generally, the rotational temperature in the excited state was known to equilibrate with the rotational temperature in the ground state. However, the temperature in both the excited state and ground state has never been measured simultaneously. In this study, the relation of the excited state with the ground state was investigated on the basis of measurement of radicals.

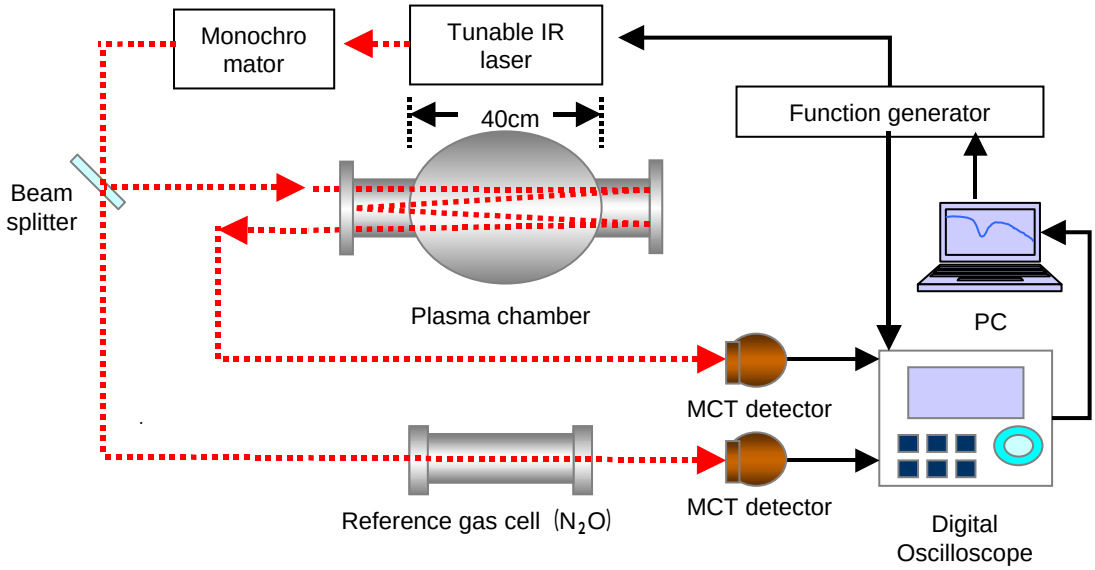

Fig. 1. Shematic diagram of IRLAS measurement in this study.

Infrared laser diode absorption spectroscopy (IRLAS) was performed for measuring the rotational temperature and density of CF radical in the ground state. Figure 1 shows shematic diagram of IRLAS measurement in this study. The infrared diode laser was introduced through NaCl windows into the White-type multiple reflection cell. The laser passed 32 times for the measurement of CF radical through the plasma. Absorption signals were detected by a mercury-cadmium-telluride (MCT) detector and collected by digital oscilloscope. Function generator was used for the tunable laser. The tunable laser and absorption signal were controlled by personal computer (PC) in order to get a high S/N with the accumulation, average, and filtering of the noise. N_2O gas was used for the reference of wavelengths.

B. Method of calculating the rotational temperature in emission

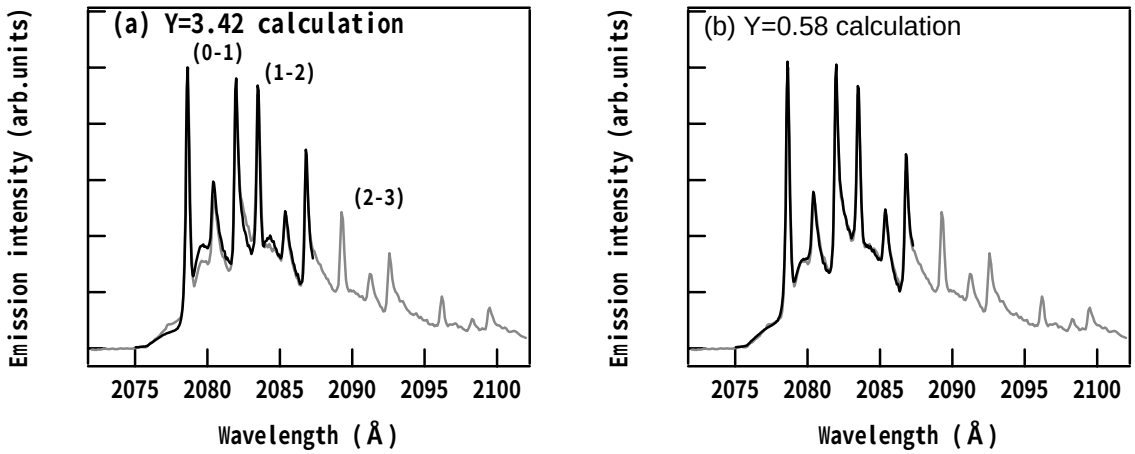

Fig. 2. The measured spectral (gray line) and calculated spectra (black line) of CF $B^2\Delta - X^2\Pi$ electric transition at a reported different coupling constant of (a) Y = 3.42 and (b) 0.58.

The rotational temperatures of CF radical were determined by simulating optical emission spectra of $B^2\Delta$ - $X^2\Pi$ electronic transition. The procedure was as following. (1) Calculation of the energy levels for the $B^2\Delta$ state and the $X^2\Pi$ [10]. (2) Calculation of the transition wavelengths for each branch using the selection rules. (3) Calculation of the line strengths for each transition wavelengths. (4) Simulation of the spectrum line shape and the population distribution as functions of the spectrum width and the rotational temperature [11].

In this study, the line strengths expressed by Kovacs were adapted to the calculation of the emission spectra of CF $B^2\Delta$ - $X^2\Pi$ (0-1) and (1-2) band. The line strengths were used for the coupling of the intermediate case of both the excited state and the ground state. Though the line strength was a function of the rotational constant Y, the rotational constant of CF $B^2\Delta$ state was not determined. The two coupling constants Y of $B^2\Delta$ state of (0-1) band were reported as 3.42 or 0.58 by Carroll and Grennan observing the spin splitting in high resolution emission spectra [12]. In this study, the rotational constant Y of $B^2\Delta$ state was investigated from the emission intensities. The simulation fitted with measured spectra of (0-1) and (1-2) band was executed between 2075 Å and 2087 Å. Figure 2 shows the measured spectra and calculated spectra in Ar/C_4F_8 plasma of CF $B^2\Delta - X^2\Pi$ (0-1) and (1-2) electric transition at a different coupling constant (a) Y=3.42 or (b) Y=0.58. The constant value Y of $B^2\Delta$ state of the (1-2) band was estimated as the same value with the (0-1) band. In the case of Y=3.42 calculation, the rotational temperature was evaluated to be 270 K for the (0-1) band and 230 K for the (1-2) band. In the case of Y=0.58 calculation, the rotational temperature was evaluated to be 290 K for both the (0-1) band and the (1-2) band. The calculated spectra of Y=0.58 was a good fit with the measured spectra as compared with the calculated spectra of Y=3.42. Therefore, the value of the coupling constant Y was 0.58 from emission intensities.

The calculating of CF emission spectra was applied to (0-0) band around 2027 Å as well as (0-1) band. It was found that the coupling constant Y of 0.58 was adapted to (0-0) band.

The rotational temperatures of N_2 were evaluated by simulating the optical emission spectra of $C^3\Pi_u$ - $B^3\Pi_g$ electronic transition. The rotational temperature was used well for neutral gas temperature in plasma [11,13,14]. The rotational constant used was found as a reference [15]. In this event, Honl-London factors were used as the intensity distribution, and Hund's case (a) was assumed.

C. Theory of infrared diode laser absorption spectroscopy (IRLAS)

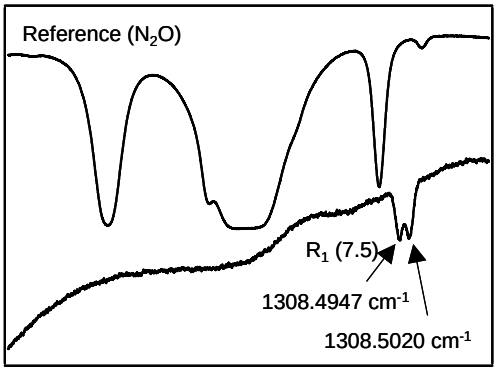

Fig. 3. The absorption spectral of the CF radical and N_2O molecule.

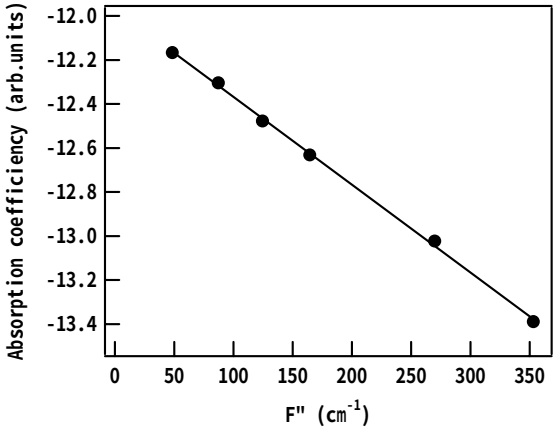

Fig. 4. Boltzmann diagram of CF radical in $X^2\Pi$ state in $Ar/C_4F_8/N_2$ plasma. The slope gives $-hc/k_BTr$ = -0.00399, which corresponds to Tr=360 K.

The rotational temperature and density of CF radical in the ground state were measured by Infrared laser absorption spectroscopy (IRLAS). Detailed observation of vibration-rotation bands of CF radical in the $X^2\Pi$ state have been carried out by Kawaguchi *et al* [16]. Figure 3 shows the absorption spectral of the CF radical of $R_1(7.5)$. The integrated absorption coefficient is related to the radical density n and the line strength S for the measured transition by

$$\int_{-\infty}^{\infty} k(v)dv = S \cdot n \tag{1}$$

The Honl-London factor for the line strength was given by other study [17]. The formula of the line strengths [18] is rewritten approximately as

$$\int_{-\infty}^{\infty} k(v)dv = Cv_c Ag'' exp\left(-\frac{F'' hc}{k_B T_r}\right) \tag{2}$$

where C is constant, v_c is the wavenumber at the center of the absorption line profile, A is the Honl-London factor, g'' is the statistical weight for the lower state of transitions, F'' is the rotational term value for the lower state of transitions, h is Planck constant, c is the light velocity, k_B is Boltzmann constant, and T_r is the rotational temperature. Eq. (2) is transformed into

$$ln\left[\frac{1}{v_c A g''}\int_{-\infty}^{\infty} k(v)dv\right] = -\frac{hc}{k_B T_r}F'' + C' \quad (3)$$

If the distribution of radical density over the rotational levels follows the Boltzmann distribution, a plot of the left-hand side of Eq. (3) against the rotational term value F'' for several transitions becomes a straight line and T_r can be derived from the slope of the plot.

The transition lines of $R_1(5.5)$, $R_2(5.5)$, $R_1(7.5)$, $R_2(7.5)$, $R_1(13.5)$, and $R_2(13.5)$ were measured in the condition at a pressure of 10 Pa, a gas flow rate of $Ar/N_2/C_4F_8$ = 900/100/6 sccm, a 60 MHz power of 1200 W. Figure 4 shows Boltzmann diagram of CF radical in $C^2\Pi$ state. The slope gives $-hc/k_BT_r$ = -0.00399, which corresponds to T_r=360 K.

The CF radical density was measured using the value of the band strength of 1.0 X 10^{-17} cm/molecule.

3. Results and Discussions

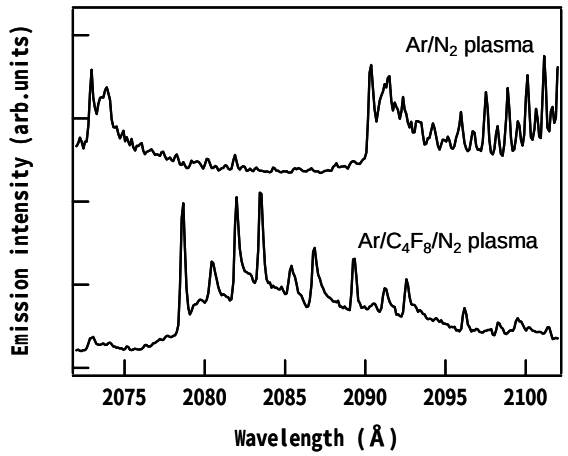

Fig. 5. Emission spectra of Ar/N_2 plasma and $Ar/N_2/C_4F_8$ plasma. N_2 spectra was not covered with CF (0–1) and (1-2) band spectra for calculating the CF rotational temperature.

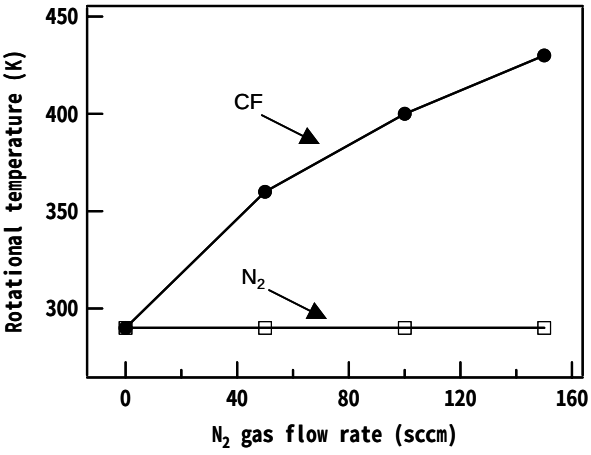

Fig. 6. Rotational temperatures of CF radical and N_2 molecular as a function of N_2 gas flow rate.

Fluorocarbon radical temperatures in $Ar/C_4F_8/N_2$ plasma were investigated using OES and IRLAS measurement. Figure 5 the emission spectra of Ar/N_2 plasma and $Ar/N_2/C_4F_8$ plasma in the condition at a pressure of 10 Pa, a gas flow rate of $Ar/N_2/C_4F_8$ = 900/100/6 sccm, a 60 MHz power of 1200 W. As compared with the emission spectra of Ar/C_4F_8 plasma in Fig. 3, the spectra due to the N_2 plasma were covered with the emission spectra of CF $B^2\Delta - X^2\Pi$. Though some peaks were reported around the (0-1) and (1-2) band of CF $B^2\Delta - X^2\Pi$ [19,20], the peaks seemed to be weak peaks in this plasma. Therefore, it was possible to calculate the emission spectra of the (0-1) and (1-2) band of CF $B^2\Delta - X^2\Pi$. The rotational temperature of CF radical was 360 K for the both the (0-1) and (1-2) band. The temperature was equilibrium with the temperature in Fig. 4. It was found that the rotational temperatures in the excited state were equilibrium with the rotational temperatures in the ground state.

Figure 6 shows the CF rotational temperature and N_2 rotational temperature as a function of N_2 gas flow rate in the condition of a in the condition at a pressure of 10 Pa, a gas flow rate of $Ar/N_2/C_4F_8$ = 1000-x/x/6 sccm, a 60 MHz power of 1200 W. The N_2 rotational temperature was used for the neutral gas temperature in plasma. The gas temperature was constant at 290 K, and the CF rotational temperature was increased from 290 K to 430 K with increasing N_2 flow rate. It was found that the CF rotational temperature was not equilibrium with the gas temperature. Radicals are mainly produced with collisions between molecular and energetic electron, and as a result the radicals are heated by Franck-Condon heating [21]. The radicals were dissociated with the energy of the difference between the excited energy and the electron

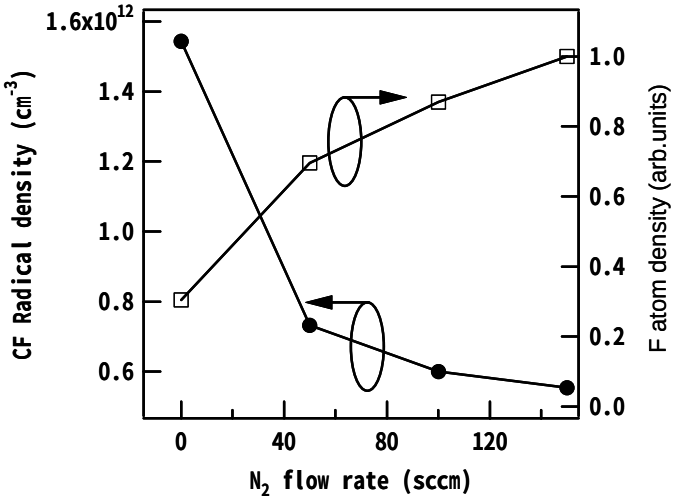

Fig. 7. CF radical and F atom densities as a function of N_2 gas flow rate.

dissociation energy of the neutral molecule. Therefore, it is considered that radical temperatures are related to electron energy distributions. The addition of N_2 was known to influence the electron energy distribution function (EEDF) in Ar plasma due to the vibrational rotational structure of the molecules [22,23]. N_2 leads to increase the electron temperature in the high energy region. One of the mechanisms of the incresion of the CF rotational temperature was the incresion of Franck-Condon effect due to the incresion of the electron temperature with N_2 addition.

It was considered that the difference between CF redical temperature and gas temperature was due to the excess energy of CF radicals from Franck-Condon heating.

The CF radical and gas temperatures in this 60 MHz capacitively coupled plasma (CCP) was much less than the temperatures in inductively coupled plasma (ICP) [6,7]. The cooling mechanism of species is due to losing the kinetic energy by the elastic collision with parent molecule gases, and the heat transfer by the diffusion to the cold wall. The cooling efficiency is dependent on the electrode temperature, the kinds of electrode materials, and the structure of chamber walls. In this 60MHz CCP, plasma was generated between the top electrode and the bottom electrode. The energetic species seemed to be cooled due to the abundant collisions with the electrodes with the mean free pass about 1 cm at a pressure of 10 Pa. It was considered that the difference of CF rotational temperature between CCP and ICP derived from the cooling efficiency and EEDF.

Figure 7 shows CF radical and F atom densities as a function of N_2 gas flow rate. CF radical density was decreased from 1.5 X 10^{12} cm^{-3} to 0.6 X 10^{12} cm^{-3}, and F atom density was increased with increasing N_2 gas flow rate. The decrease of the CF radical density was due to the recombination with CF radical and N atom. The generation of CNF molecule in plasma was reported [24]. The recombination and the excess dissociation due to the high electron temperature with N_2 addition were one of the mechanisms of increasing F atom density in $Ar/N_2/C_4F_8$ plasma.

4. Conclusions

Optical emission spectroscopy and infrared diode laser absorption spectroscopy were applied to measure CF rotational temperatures in both the excited state and the ground state at 60 MHz capacitively coupled $Ar/C_4F_8/N_2$ plasma. The CF rotational temperature was determined in the optical emission spectra by fitting the calculated spectra with the measured spectra. The rotational constant Y of $^2\Delta$state, which was estimated to be 0.58 or 3.42 by Carroll, was determined to be 0.58 from the emission intensities using the line strength of Kovacs. It was found that the rotational temperatures in the excited state were equilibrium with those in the ground state. The CF rotational temperatures in $Ar/C_4F_8/N_2$ plasma were increased from 290 K to 430 K with increasing N_2 flow rate.

Abstract

Pulse modulated RF plasma jet system was used for deposition of $Ba_xSr_{1-x}TiO_3$ (BSTO) and $SrTiO_3$ (STO) thin films on Si and on multi-layer $Si/SiO_2/TiO_2/Pt$ substrates. Time resolved Langmuir probe measurements were done for determination of plasma parameters at substrate position. Plasma emission spectroscopy was used for control of concentration of particles sputtered from the hollow cathode. Deposited thin films were analyzed by X-ray diffraction, which confirmed presence of BSTO and STO perovskite phase in the films.

Keywords: hollow cathode sputtering, Langmuir probe, emission spectroscopy, ferroelectric thin films.

1. Introduction

The low-pressure RF plasma jet sputtering system was already used for many PVD thin films depositions as for example TiN [1], TiO_2 [2], Cu_3N [3], CN_x [4], ZnO [5], and $LiCoO_x$ [6] thin films. Usually a metallic or single component hollow cathode was reactively sputtered in a suitable working gas in these applications. In the work presented in this paper, the RF hollow cathode was made of $SrTiO_3$ (STO) and $BaTiO_3$ (BTO) composed nozzle and reactively sputtered in Ar and O_2 gas mixture, in order to form $SrTiO_3$, or $Ba_xSr_{1-x}TiO_3$ films on Si and multi-layer $Si/SiO_2/TiO_2/Pt$ substrates.

BSTO thin films have wide range of application. They have, for example, potential use for capacitors due to their high dielectric constant. BSTO material is also very promising for microwave components as for example microwave varactors, phase shifters, or tunable filters. Many methods were used up to now for BSTO films deposition as presented for example in [7], [8], [9], [10], [11], [12], [13], and other works. BSTO thin films are usually prepared by CVD, MOCVD [10], sol-gel, or magnetron sputtering [7], [8]. Usual methods use elevated substrate temperatures above 600–900 °C or thermal post-deposition treatment for proper crystallization and oxidation of BSTO films. This paper describes preliminary results of deposition of BSTO and STO thin films by pulsed RF hollow cathode plasma jet sputtering system without post-deposition annealing and with substrate temperature below 600 °C during deposition.

For better control and reproducibility of the deposition process, plasma parameters at the substrate position should be measured. Langmuir probe measurements are suitable for determination of plasma parameters, which have influence on deposited thin films, as for example plasma potential, electron density, electron distribution function, or electron temperature. Time resolved Langmuir probe measurements are required in pulsed discharges in order to know these parameters in active part of the duty cycle (the pulse) and also their change in the non-active part of the duty cycle (between pulses). Further, plasma emission spectroscopy could be used for determination of concentration of sputtered particles from the hollow cathode.

Properties of the deposited thin films should also be studied and compared with plasma parameters measured at deposition conditions. Chemical composition of deposited thin films was investigated by electron microprobe and compared with plasma emission spectra in this work. Crystalline structure of the films was studied by X-ray diffraction (XRD) in grazing incidence geometry to find out if the desired perovskite phase of BSTO was deposited.

2. Experimental

The low-pressure plasma jet configuration for BSTO thin films deposition can be seen in Fig. 1. The reactor chamber was continuously pumped by combination of Roots and rotary vane pumps. The composed cylindrical nozzle acted as RF hollow cathode, which was reactively sputtered. The internal diameter of the nozzle was 3 mm. The length of the nozzle was 30 mm. In order to deposit $SrTiO_3$ thin films the nozzle was homogeneous; made of pure $SrTiO_3$ ceramic. In order to deposit $Ba_xSr_{1-x}TiO_3$ thin films one part of the nozzle was made of $SrTiO_3$ and one part from $BaTiO_3$, as it can be seen in Fig 1. Since it was known that STO ceramics has lower sputtering rate than BTO ceramics, the STO part was placed at the nozzle outlet, where the hollow cathode plasma has the highest density. The STO part was also made longer than the BTO part. The length of the STO part was 25 mm and the length of the BTO part was 5 mm. An intensive RF hollow cathode discharge [4] was generated inside the nozzle, on the background of the primary capacitive RF discharge excited in the volume of the reactor. Incoming working gas forced this RF hollow cathode discharge out of the nozzle into the reactor chamber and this plasma jet interacted with the substrate. The substrate was placed perpendicularly to the plasma jet axis in the distance of 20 mm from the hollow cathode outlet. The thin films were deposited simultaneously on Si wafers and on the Pt top layer of multi-layer $Si/SiO_2/TiO_2/Pt$ substrate. Five samples prepared at different deposition conditions are presented in the paper (see Table 1).

Pulse modulated mode was used for plasma jet excitation for all STO and BSTO samples. The length of the active part of the duty cycle was T_w = 1.4 ms. The length of the non-active part was T_0 = 4 ms. Power P_{RF} = 150–300 W was applied on the hollow nozzle electrode during the active part, and P_{RF} = 0 W appeared on the electrode during the non-active part of the duty cycle. The advantage of pulse-modulated mode was enhancement of plasma density and hence the sputtering process by virtually higher applied RF power during the active part. On the other hand, the average applied RF power was low enough to avoid hollow cathode overheating and destruction of ceramic nozzle.

A fraction of pulse-modulated RF power was fed through a tunable capacitance on the substrate (see Fig. 1) in order to generate a controllable pulsed DC bias around the substrate. Current and voltage probes with calibrated RF amplitude response and phase shift up to 100 MHz in combination with digital oscillograph Agilent Infinium 600 MHz 4 GS were capable to measure RF power, RF current and RF voltage on the nozzle, and DC self-bias on the substrate.

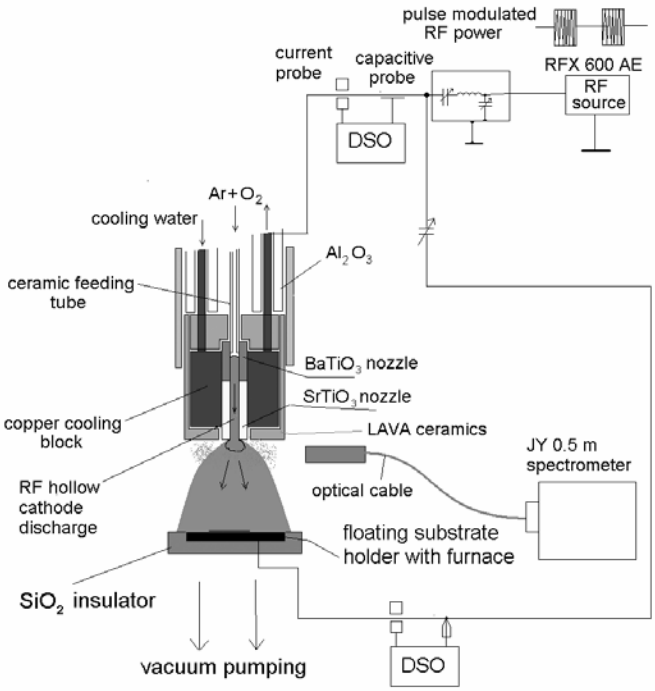

Figure 1. Experimental set up for the plasma jet deposition of STO and BSTO thin films.

Table 1. Deposition conditions for different deposited thin films. Q_{Ar} and Q_{O2} are Ar and O_2 flow rates through the nozzle. P_{RF} is RF power absorbed in the plasma. I_{RF} and U_{RF} are amplitudes of RF current and RF voltage on the nozzle.

Sample no.	Q_{Ar} [sccm]	Q_{O2} [sccm]	P_{RF} [W]	Used nozzle	I_{RFm} [A]	U_{RFm} [V]
1	85	64	178	STO	3.6	259
2	85	64	219	STO, BTO	4.11	232
3	42	32	—	STO, BTO	—	—
4	42	13	180	STO, BTO	4.0	217
5	42	64	—	STO, BTO	—	—

The DC self-bias on the substrate was set to $U_{DC} = -50$ V relative to the grounded reactor. The substrate was held on temperature 500–550 °C. Total gas pressure in the reactor was held at $p = 6$ Pa. These conditions were identical for all presented samples. Deposition conditions, which were different for the five presented samples are in Table 1. Power P_{RF} absorbed in the plasma was calculated from RF current and voltage waveforms taking into account their relative phase shift. RF power P_{RF}, amplitude of RF current I_{RFm}, and amplitude of RF voltage U_{RFm} on the nozzle electrode presented in Table 1 were recorded approximately at the time corresponding to the middle of the active part of the discharge cycle.

Time resolved Langmuir probe was used for determination of plasma parameters during the whole cycle. Probe characteristic at the time t within the cycle was obtained by averaging measurements taken at time t from the start of the pulse in several consequent duty cycles. The Langmuir probe measurements were done at the deposition conditions, but with the substrate holder not present in the reactor. Platinum cylindrical Langmuir probe with diameter $d_p = 200$ μm and length $l_p = 2$ mm was used. The probe was placed at the substrate position. High impedance filters and a metallic hollow cylindrical compensation electrode, connected with the probe through a capacitor, were used as a passive compensation of RF oscillations of probe current. The grounded metallic reactor worked as a voltage reference for the Langmuir probe. The probe surface was cleaned from deposited films by applying high negative voltage on the probe between probe characteristic measurements. This high negative voltage on the probe caused ion bombardment and sputtering of material deposited on the probe surface. Plasma emission spectroscopy was used for control of sputtered particles contained in the plasma jet channel during deposition. For this purpose, Jobin Yvon spectrometer with CCD detector and optical cable were used. Experimental set up can be seen in Fig 1.

Chemical composition of deposited films was measured by electron microprobe JXA 733 of JEOL. Energy of primary electrons in the beam was set to 10 keV. Electron microprobe method provides information about average composition over the whole profile of the analyzed films. Accuracy of this method for thin film atomic concentration analysis is not better than 5%. Therefore, electron microprobe measurements were always done on several points on the surface of the film. The analysis of films structure was performed by XRD in grazing incidence geometry using CuK_α radiation.

3. Results and discussion

Plasma parameters were measured in the position of the substrate by Langmuir probe. Electron energy probability functions (EEPFs) determined from the Langmuir probe measurements for different times can be seen in Fig. 2. The EEPFs were calculated from the second derivative of the electron probe current, according to the Druyvesteyn formula:

$$F(E) = \frac{2\sqrt{2em_e}}{e^3 A_p}\left|\frac{d^2 I_e}{dU_p^2}\right|, \qquad (1)$$

where $E = -eU_p$ is the kinetic electron energy, e is the elementary charge, m_e is the electron mass, A_p is the probe area, I_e is the electron probe current and U_p is the probe voltage relative to the plasma potential. Plasma potential was determined as zero crossing of the second derivative of the probe current. Plasma potential was approximately $V_{pl} = 45$ V in the active part and approximately $V_{pl} = 2$ V in the non-active part of the duty cycle. The EEPF is normalized on the electron density n_e according to the equation

$$n_e = \int_0^\infty F(E)\sqrt{E}\,dE\,. \qquad (2)$$

The EEPFs are depicted in semi-logarithmic scale in Fig. 2, because in this scale an ideal Maxwellian EEPF is linear. It can be seen that in both active and non-active part of the discharge cycle the electron distribution was not Maxwellian. In the active part of the on-off cycle, the EEPFs differed just slightly from Maxwellian; they were a bit rounded. On the other hand, in the non-active part of the discharge on-off cycle, the EEPFs were strongly non-Maxwellian. There was some excess of electrons with the energy around 3 eV in the latter case. The process behind forming of this electron group is not quite clear to us now and would be subject of further investigation.

The time dependence of electron density n_e determined from Langmuir probe measurements is depicted in Fig. 3. Electron density was calculated from the EEPF according to equation (2). This method of electron density evaluation is not very precise because of some disturbance of the second derivative of electron probe current near the plasma potential. However, this error in determination of the second derivative in equation (1) is partly compensated by multiplication by the factor $\sqrt{E}$ in equation (2), because this factor is low near the plasma potential, which corresponds to $E = 0$ eV. The big advantage of this method of electron density evaluation is that it does not require Maxwellian electron energy distribution. Therefore it is suitable for our case. For verification of results obtained by this method, the electron density in the active part of the discharge on-off cycle was also calculated from the electron current in plasma potential I_{e0}, according to the equation

$$n_e = \frac{4I_{e0}}{A_p e v_e}, \qquad (3)$$

where v_e is the mean electron velocity. The mean electron velocity was calculated for Maxwellian distribution. Effective electron temperature was determined from the slope of linear Maxwellian approximation of the second derivative of electron probe current in the semi-logarithmic scale. The effective electron temperature was approximately 4 eV in the active part of the discharge on-off cycle. Electron density in the substrate position during the active part of the cycle determined by both methods was quite similar (see Fig. 3) and its value was relatively high $n_e \approx 2.5\times10^{10}$ m^{-3}. In the non-active part of the duty cycle only first method was used, because electrons had strongly non-Maxwellian distribution there. The electron density decayed approximately exponentially after the end of active pulse (linear decay in semi-logarithmic scale – see Fig. 3).

It was possible to deposit $SrTiO_3$ and $Ba_xSr_{1-x}TiO_3$ thin films on Si and Pt surfaces. Maximum growth rate achieved was 250-300 nm/hour. Electron microprobe measurements showed that chemical composition was close to $SrTiO_3$ for sample no.1 and to $Ba_xSr_{1-x}TiO_3$ for samples no. 2-5 (see Table 2), with some excess of Ti and O atomic concentrations in both cases.

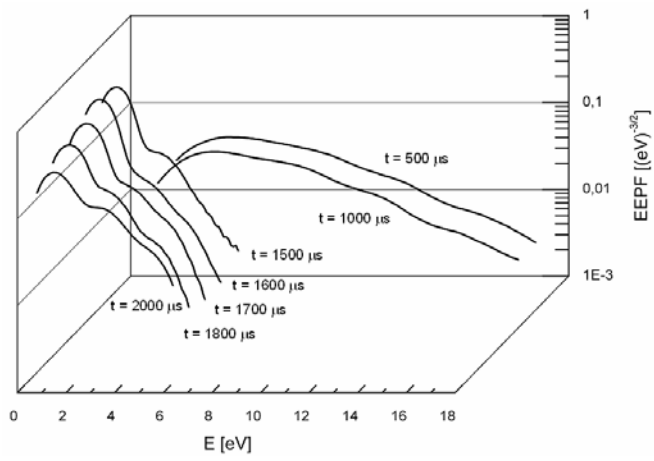

Figure 2. Electron energy probability function (EEPF) in the active part (in t = 500 μs, t = 1000 μs), and in the non-active part of the duty cycle (in t = 1500 μs, t = 1600 μs, t = 1700 μs, t = 1800 μs, t = 2000 μs). The active pulse starts at t = 0 s and ends at t = 1400 μs.

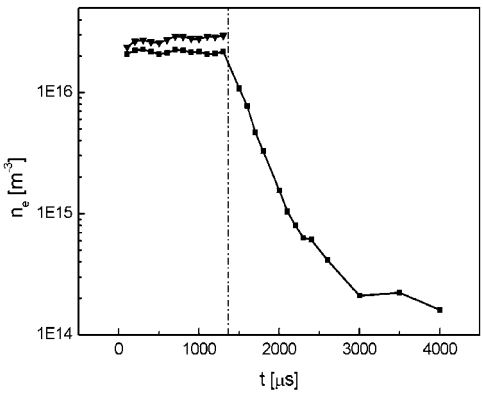

Figure 3. Time dependence of electron density n_e at the position of substrate. The active pulse starts at t = 0 s and ends at t = 1400 μs (indicated by a vertical dash dot line). -■- electron density computed from the integral of the EEPF [equation (2)]. -▼- electron density computed from the plasma potential [equation (3)].

Table 2. Thickness and chemical composition of deposited samples. STO and BSTO are desired values according to the respective chemical formulae: $SrTiO_3$ and $Ba_xSr_{1-x}TiO_3$.

Sample no.	Thickness [nm]	Atomic %(O)	Atomic %(Ti)	Atomic %(Sr)	Atomic %(Ba)
STO	—	60	20	20	0
1	644	60.1	20.2	19.7	0
BSTO	—	60	20	x	20 – x
2	823	61	22	7.4	9.1
3	286	61	22	7.6	9.25
4	232	60	21.5	9.2	8.3
5	215	61	22	9.2	7.3

XRD pattern of sample no. 2 obtained from measurement in grazing incidence geometry can be seen in Fig. 4. Several diffraction peaks belonging to BSTO perovskite phase were found. The BSTO peaks are located in the middle between STO and BTO standard peaks (see Fig. 4). It means that BSTO mixture contained approximately similar amount of Ba and Sr. This result was in agreement with electron microprobe measurement of elemental composition (see Table 2). From the accurate position of detected BSTO diffraction peaks, it was possible to calculate lattice parameter a = 3.980 Å. Furthermore, it was possible to estimate the grain size of crystallites from the width of the diffraction peaks. The estimated grain size was 30 *nm*. However, this estimation is valid only in case that we can neglect the internal stress in the films, which cannot be done with certainty in our case.

It was possible to identify spectral lines belonging to sputtered excited particles Ba, Sr, Ba^+, and Sr^+ in emission spectra taken during deposition. Intensities of these lines were roughly proportional to the deposition rate. The dependence of ratio of emission spectral line intensity of Ba and Sr excited atoms and ions on atomic concentration of Ba and Sr in the deposited films is depicted in Fig. 5. The ratio of emission spectral line intensities and the ratio of thin film concentrations were approximately proportional. This result means that it was possible to control the stoichiometry in deposited thin films by controlling conditions in the plasma for constant geometry of the system. This is important for future possibility of deposition of compositional gradient BSTO films.

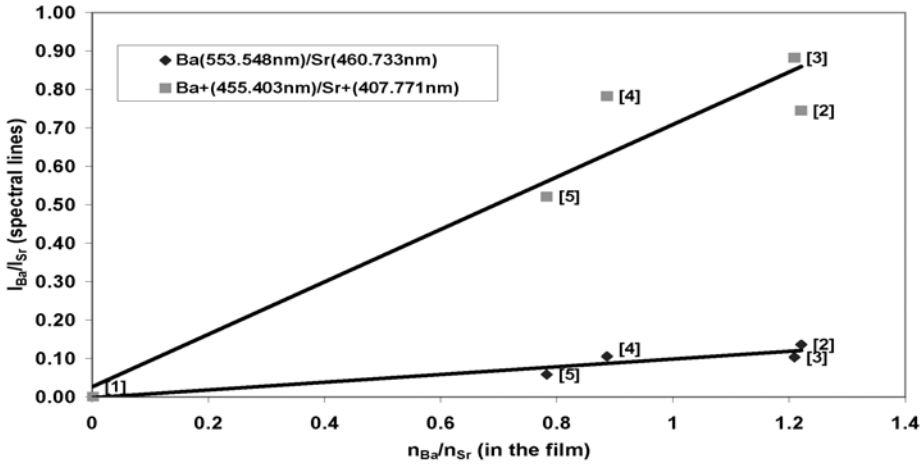

Figure 5. Dependence of the ratio of intensity of Ba and Sr (neutrals and ions) emission spectral lines taken during deposition on the ratio of Ba and Sr atomic concentrations in the deposited films. In the brackets there are numbers of the samples.

4. Conclusion

Low-pressure plasma jet system was investigated during the $SrTiO_3$ and $Ba_xSr_{1-x}TiO_3$ thin films deposition. Time resolved plasma parameters were determined by Langmuir probe measurement at the substrate position during the whole discharge on-off cycle. Electron energy distribution was non-Maxwellian during the whole cycle, with a strong deviation from Maxwellian in the afterglow plasma of the non-active part of the cycle.

$SrTiO_3$ and $Ba_xSr_{1-x}TiO_3$ thin films were successfully deposited. Electron microprobe measurements showed that chemical composition of deposited films was relatively close to desired one in all cases. X-ray diffraction revealed crystalline perovskite structure in all deposited samples.

Plasma Emission spectra measurements showed that the deposition rate of the thin films growth and the thin films stoichiometry can be better controlled by observing the atomic and ion spectral lines. Especially by setting the ratio of intensity of Ba and Sr or Ba^+ and Sr^+ spectral lines we can approximately set the ratio of Ba and Sr concentration in the deposited films. This is very promising for deposition of compositional gradient BSTO layers.

Abstract
Plasma is often used to assist deposition of thin layers of different types and properties. Magnetron sputtering deposition is one of the methods used for this purpose. Our work is focused on diagnostics of DC planar magnetron plasma creating by ionisation of working gas. Mixture of Ar (carrier gas) and N_2 or O_2 (reactive gas) was used in our case. Plasma was investigated by means of Langmuir probe and basic plasma parameters (plasma potential V_{pl}, mean electron energy E_m, electron density n_e, density of negative ions n_n) were determined.
Keywords
planar magnetron, Langmuir probe, plasma parameters, negative ion density, TiO_x and TiN_x layers

1. Introduction

Magnetrons are known for a long time in two basic configurations: as a cylindrical [1] or planar [2] magnetron, used in our case. Planar magnetrons can be operated in two modes – balanced and unbalanced mode [3]. The balanced mode is characterised by a conventional configuration of magnetic field. The field lines are well confined around the cathode and electron loss is reduced to a minimum. The basic principle of the unbalanced magnetron is to allow electron release from the magnetic trap (which is typical for balanced magnetron) in order to create plasma also further away from the magnetron cathode and close to the substrate. Elementary processes as electron and ion transport, energetic electron transport, sputtering processes and effects caused by electric and magnetic fields were studied and modeled in Monte Carlo several times [4]. The properties of thin solid films produced by plasma activated deposition are strongly influenced by the ions behaviour. Some works where ion interactions were studied and simulated were published in [5].

The fundamental aspects of magnetron discharges were studied e.g. in [6]. For practical applications, i.e. the layer deposition, mixtures of working gases and specific target materials are mostly used. Composition of gas mixture (carrier gas with reactive gases) determines most properties of deposited layer. Very often nitride layers (N_2 is added) or oxide layers (O_2 is added) are deposited because of their wide utilization range. Rare gases, e.g. Ar, are mostly used as carrier gases. Discharges in Ar+N_2 mixtures were experimentally investigated by optical emission spectroscopy in [7] and by Langmuir probe in [8]. The Ar+O_2 plasma discharges were investigated also by optical emission spectroscopy e.g. in [9] or by Langmuir probes in [10]. Langmiur probe diagnostic of plasmas, where O_2 is added, is not so easy. Problems arise mostly by deposition of non-conducting layers on the probe surface, which causes deformation of probe VA characteristics. Also possible presence of negative ions, when part of the mixture is electronegative gas, complicates interpretation of Langmuir probe data. In our case we carried out the complex diagnostics of pure Ar discharges and mixtures Ar+N_2, Ar+O_2 plasmas. The basic plasma parameters - plasma potential (V_{pl}), mean electron energy (E_e), electron density (n_e) - were determined by standard ways typical for probe measurements. Density of negative ions (n_n), in case of Ar+O_2 discharges, was revealed by simple method based on comparison of two probe characteristics – the one measured in electropositive and the second measured in slightly electronegative plasma [11,12].

2. Experimental setup and experiments

Our experiments were carried out in spherically-shaped stainless-steel vacuum chamber, see Fig.1. Magnetron of the type Vtech 75 by Genco-A was situated in the lower part of the chamber. The magnetron can be operated either in balanced or in unbalanced mode by mechanically changing permanent magnet configuration. This change of modes can be done when discharge is on by the external micrometer screw. Target made of Ti (Ti 99.9 % purity grade, diameter 3") directly connected with the cathode is used for deposition of TiX layers. Water cooling protects the cathode from overheating and consequent destruction. During the Langmuir probe measurements the probe was situated in the substrate plane. The vacuum chamber is pumped by a turbomolecular pump backed by rotary vacuum pump down to ultimate pressure 10^{-8} Pa. Pressure can be adjusted by a throttle valve installed between the chamber and the turbomolecular pump. The flow rate of working gas or mixture of carrier and reactive gases is controlled by MKS mass flow controllers. For our experiments the flow rate of carrier gas (Ar) was 19.3 sccm and rate of reactive gases (N_2, O_2) was kept at 1.5 sccm. The total pressure in the chamber during the experiment was p = 0.7 Pa. Ar gas injection line is fitted to the magnetron cathode. This allows directing the argon gas over the target surface. Pipe for reactive gases is inserted into the chamber with its nozzle end situated close to the target. The mass flow controllers, the throttle valve and magnetron were PC-controlled via their control units.

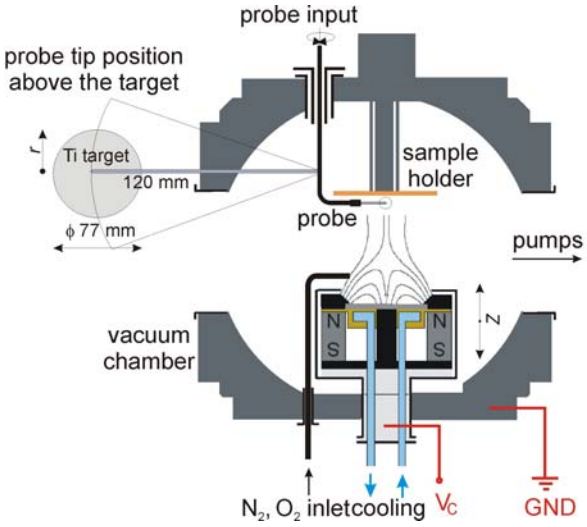

Fig.1. Schematic view of experimental setup. Magnetron is situated in lower part of the chamber, probe is in the position of substrate.

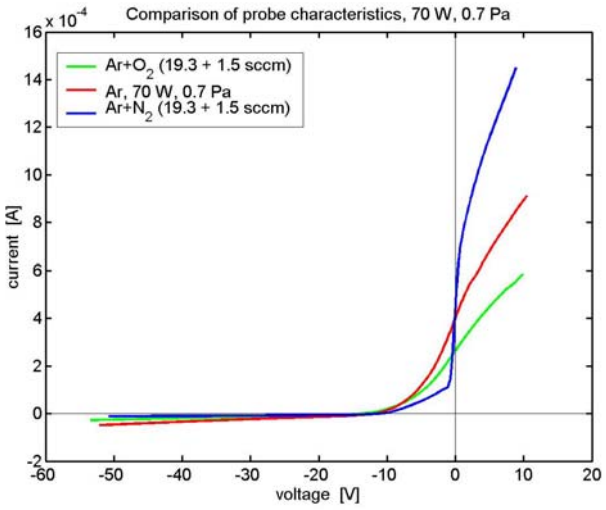

Fig.2. Comparison of three different VA characteristics in Ar, Ar+O_2, Ar+N_2 at the same total pressure and discharge power. The characteristics are shifted along the voltage axis so as $V_s = 0$.

Cylindrical Langmuir probe made of tungsten wire, diameter 50 μm and active length 6 mm was used for the plasma diagnostic. The probe wire was sleeved by a double capillary glass tube. The outer capillary was longer than the inner one. This arrangement prevented the probe from short-circuiting to the sleeve by the metal sputtered during the deposition process. The probe was situated near the plane of the substrate. The probe tip was positioned perpendicular to the magnetic field lines. This arrangement minimizes the effects of magnetic field on the probe measurements. In addition the magnetic field in the plane of measurement is relatively weak - in the order of 1 mT - in both operating modes. The mean gyroradius (r_{Le}) for electrons is in such case much larger than the radius of probe wire (r_p): we can write $r_{Le} >> r_p$. Probe measurement in magnetron discharges can be affected by E×B drift too [13]. This effect was also minimised by using configuration where the probe tip was parallel with E×B drift. For measurement of power dependences in the presented experimental study the probe was kept at the axis of the target and vertical coordinate (distance from magnetron cathode) was z = 65 mm. Probe diagnostics became more difficult when reactive gas was added into carrier gas. Then the probe was covered by deposited layer and the measured data were influenced. Because of this reason the probe was

cleaned by positive ion bombardment; high negative voltage was applied on the probe. In the case of Ar+N_2 discharge the layer (TiN_x) on the probe was electrically conductive and the cleaning process had not to be so aggressive. The powerful cleaning process had to be used when Ar+O_2 discharge was investigated because of non-conductivity TiO_x layer; negative voltage bias about – 190 V for 7 second was applied. Cleaning process minimized the influence of the layer being deposited on the collected experimental data but somewhat reduced life time of the probe. The measuring probe bias voltage was generated by Source Meter Keithley 2400 over the range from – 50 V to + 10 V with step 0.1 V. The acquired data were processed by program code written in Matlab. No noise reducing methods were applied.

3. Determination of plasma parameters

For understanding of elementary processes in the discharge as well as interaction of active particles with substrate knowledge of plasma parameters is necessary. Basic plasma parameters in electropositive discharges – Ar and mixture Ar+N_2 - were revealed by standard ways: the plasma potential (V_{pl}) was determined from the abscissa of the zero-cross of probe characteristics second derivative with respect to probe voltage. The mean electron energy (E_e) was calculated by numerical integration of measured second derivative and the electron density (n_e) was estimated from I_e^2 vs. V plot in electron acceleration regime of the probe characteristic.

Former plasma monitor measurements confirmed the presence of negative oxygen ions in Ar+O_2 discharge. However, direct estimation of negative ion density from Langmuir probe data is difficult. In slightly electronegative plasma, it is almost impossible to determine the n_n directly from measured data since the negative ions (n_n) density is low and the effect on the probe characteristic is almost not discernible. In other words it seems that estimation of charged particle density from characteristics taken in the discharge in pure argon and in the slightly electronegative mixture would yield very similar results. However, under certain (at low pressure fairly acceptable) assumptions it is possible to determine negative ion density by comparing probe characteristics measured in pure electropositive (Ar) plasma and in slightly electronegative (Ar+O_2) plasma at otherwise same conditions. Comparison of three different VA characteristics measured in pure Ar, Ar+N_2 and Ar+O_2 can be seen in Fig.2. The different shape of the curves is caused by different composition of gas mixture; not by presence of negative ions. Comparison of measured and modeled characteristics showed us that all VA characteristics obtained from experiments are similar to modeled characteristics computed based on the "double Maxwell" electron energy distribution, which was observed experimentally in *pure Ar* discharge.

4. Estimation of negative ion density

One possible way to estimate the negative-ion density is based on the charge neutrality condition $n_p = n_e + n_n$, where the subscripts *p, e* and *n* indicate quantities concerning positive ions, electrons and negative ions, respectively. To avoid difficulties concerning correct interpretation of positive-ion current we have taken into consideration two characteristics. The characteristic measured in electronegative mixture of Ar with trace of O_2 was evaluated with the aid of the reference characteristics measured in the pure electropositive Ar plasma [11, 12].

The total current normalized to the unit probe area consists of the electron and positive-ion part, $j = j_e - j_p$. The presence of negative ions, e.g. O^- disclosed by plasma monitor measurements, does not require taking into account their contribution to the total current in the electronic part of the probe characteristics. Indeed, the thermal current of negative ions is comparable to the electronic thermal current only for large n_n densities satisfying relation

$$\frac{n_n}{n_e} \sim \sqrt{\frac{T_e}{T_n}\frac{m_n}{m_e}}\,. \qquad (1)$$

For ratios $T_e / T_n \sim 10^2$ and $m_n / m_e \sim 10^3$ (typical discharge plasma) relation (1) gives the negative-ion density by approximately two orders of magnitude higher than the electron one. Such highly electronegative plasmas were not met in our measurements. Assuming Maxwellian electron energy distribution and the cylindrical probe, the electron current density in electron retarding region can be described by equation

$$j_e(V, n_e, T_e) = e n_e \cdot \sqrt{\frac{eT_e}{2\pi m_e}} \cdot \exp\left(\frac{V}{T_e}\right), \quad V < 0\,, \qquad (2)$$

where m_e and e are the electron mass and elementary charge, respectively, and T_e is the electron temperature measured in volts ($=kT_e^{Kelvin}/e$, T_e^{Kelvin} measured in Kelvins). In the above equation we denoted $V = V_p - V_s$, where V_p and V_s are the probe and the space (plasma) potential, respectively. Quite a few theories have been proposed for the description of the positive-ion probe current. We assume here the approximate formula of the general form [14]

$$j_p(V, n_p, T_e) = en_p \sqrt{\frac{eT_e}{M_p}} \cdot \left(\frac{|V|}{T_e} \right)^{\kappa} f(V), \quad V < 0 \tag{3}$$

with multiplicative factor f that is either constant or depends only on the voltage V. The parameters f and κ can be chosen on the basis of theoretical consideration or determined empirically. The simplest collision-less orbital motion model [15,16] suggests $\kappa = 0.5$, $f = 1$. The factor $\sqrt{eT_e / M_p}$ expresses the Bohm velocity v_B of positive ions at the sheath – presheath edge for the collision-less plasma sheath.

The key assumption of the proposed method is that the positive-ion current is for both electropositive and electronegative plasma expressed by the formula (3) with the same factors f, κ. Assuming that we can write for the ratio of positive-ion currents in electropositive and slightly electronegative plasma (at otherwise similar experimental conditions) the expression

$$\frac{j'_p(V)}{j_p(V)} = \frac{n'_p}{n_p} \sqrt{\frac{M_p}{M'_p}} \cdot \left(\frac{T_e}{T'_e} \right)^{\kappa - 1/2} . \tag{4}$$

Here the dashed quantities are related to the electronegative plasma. The formula (4) together with the quasineutrality conditions $n_p = n_e$, $n'_p = n'_e + n'_n$ results in expression for negative ion density in slightly electronegative plasma:

$$n'_n = \sqrt{\frac{M'_p}{M_p}} \cdot \left(\frac{T'_e}{T_e} \right)^{\kappa - 1/2} \left\langle \frac{j'_p(V)}{j_p(V)} \right\rangle n_e - n'_e . \tag{5}$$

The brackets $\langle\ \rangle$ denote averaging over a suitable chosen interval in the region $V < 0$, where the ratio of ion currents is approximately constant. The electron temperatures and densities are determined from the electronic parts of characteristics. With formula (5) there are associated two error sources. One error arises due to the uncertainty of the effective positive-ion mass M'_p in the electronegative plasma. The second error is connected with accuracy of the positive-ion current model (3). Nevertheless, the computation error was estimated about 35 % from systematic measurements.

5. Experimental results and discussion

In this part of the paper there are presented results of probe measurements in DC planar magnetron discharge. Mainly power dependences of basic plasma parameters are depicted in the plots. In each plot one can compare dependences measured in balanced (BLM, solid lines and full symbols) with dependences measured in unbalanced (UNB, dashed lines and open symbols) mode at the same experimental conditions (pressure, mixture of working gas). At the beginning pure Ar discharge was investigated. Then reactive admixtures N_2 and O_2 were subsequently added. The pressure in the chamber was kept constant at p = 0.7 Pa. Ratio of flow rates of the gas mixture components was kept constant as follows: 19.3 sccm of Ar and 1.5 sccm of N_2 or O_2. All represented results were performed at the axis of the discharge in substrate plane distanced from the target by about 65 mm.

One of the most important physical quantities is energy contained in the discharge. In our case we determined mean electron energy E_m; the dependence of E_m on power can be seen in Fig. 3. It is seen that all dependences have pronounced local maximum at 70 W especially in BLM mode. This fact probably corresponds with geometry of magnetic trap. Decrease of electron energy with incoming power higher at 70 W can be caused by geometry of the system; higher power more confines plasma to cathode. Another effect which can cause fall of

E_m with high incoming power is ionization of Ti particles. Plasma monitor measurements indicated that density of Ti^+ and Ti^{++} increased exponentially with discharge power. Presence of oxygen in the discharge increases E_m; the highest E_m was determined in Ar+O_2 discharge. From previous plasma monitor results we could deduce that negative ions were created by dissociative electron attachment to O_2. The energy equal to electron affinity of particular specie is released at the time of negative ion creation process. For O_2 it has resonance at electron energy around 6.5 eV. Most of the electrons with such energy spend therefore their energy on the dissociative electron attachment of O_2. At the same time the low energy electrons can efficiently transfer their energy to O_2 vibrations, i.e. they heat the oxygen gas. Lower E_m of Ar+N_2 discharge is probably caused by lower ionization potential of N particles and consequent higher ionization rate. In Ar+N_2 discharge the n_e was highest, see Fig.5.
Plasma potential V_{pl} is important plasma parameter especially for understanding plasma - wall interaction processes. Precise discussion of V_{pl} power dependences is difficult in our case. One of the reasons is the fact that voltage applied on the cathode was not constant when the discharge power was varied. Incoming power ($P = U.I$) was held constant (this was advantageous during layer deposition experiments) and cathode voltage as well as discharge current changed with discharge power. The second reason was connected with unwanted deposition of the substrate holder near to the probe. This effect also somewhat influenced measured values of plasma potential. By minimizing these undesirable effects we obtained dependences of V_{pl} on the power deposited in the discharge, which are depicted in the Fig.4. One can see qualitatively similar shapes of V_{pl} curves and E_m courses with distinct maxima around 70 W DC absorbed power. In all three cases we can clearly distinguish between UNB and BLM mode; V_{pl} (UNB) > V_{pl} (BLM) roughly by about 70 %. Neither quantitative nor qualitative differences between V_{pl} in pure Ar and in Ar+O_2 discharge were observed. On the other hand the V_{pl} of Ar+N_2 discharge was lower for both modes compared to that in pure Ar discharge.

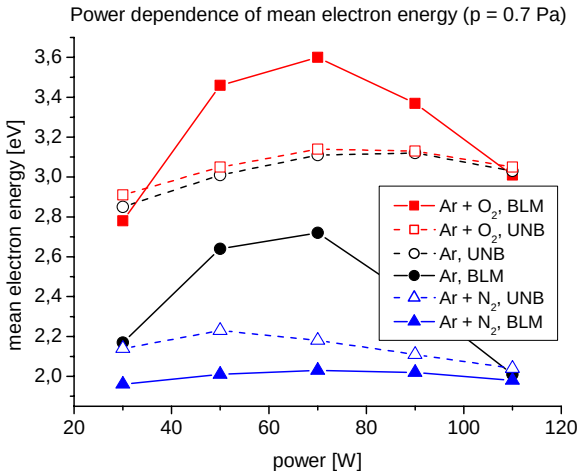

Fig.3. Power dependence of mean electron energy. Conditions: p = 0.7 Pa, Ar – 19.3 sccm, N_2, O_2 – 1.5 sccm

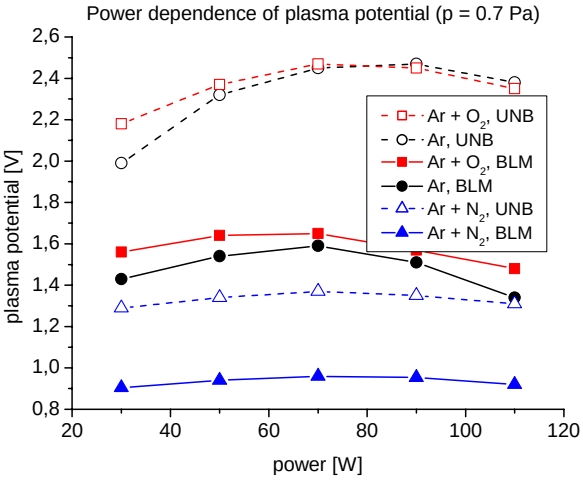

Fig.4. Power dependence of plasma potential. Conditions: p = 0.7 Pa, Ar – 19.3 sccm, N_2, O_2 – 1.5 sccm

Knowledge of charged particle density in the discharge is necessary for keeping reproducible technological properties of created layers (homogeneity of layers, deposition rate etc.). We determined electron density n_e in pure Ar discharge as well as in the mixture of Ar with oxygen. In electronegative Ar+O_2 plasma the negative ion density n_n has been determined by the method described in previous section.
Power dependences of electron density in semi-logarithmic scale are depicted in Fig.5. Generally, the n_e is higher in UNB than in BLM mode and increases almost exponentially with power dissipated in the discharge. This fact probably corresponds with shape of magnetic field which influences the free path of particles necessary for ionization. The highest $n_e \approx 10^{16}$ m^{-3} was estimated in Ar+N_2 discharge which could be caused by enhanced ionization of nitrogen particles via argon metastables. On the contrary the lowest $n_e \approx 10^{14\text{-}15}$ m^{-3} was revealed in Ar+O_2 discharges. This fact is connected with electron losses due to creation of negative ions by

electron attachment. The presence of negative ions, important for deposition of TiO_x layers, was confirmed by plasma monitor measurements. The density of negative ions $n_n \approx 10^{14}$ m^{-3} is lower by one or two orders of magnitude when compared to electron density in discharges in electropositive gases (Ar, Ar+N_2), see Fig.6. The n_n is higher in UNB mode and increases almost linearly. The computational error was estimated to about 30%.

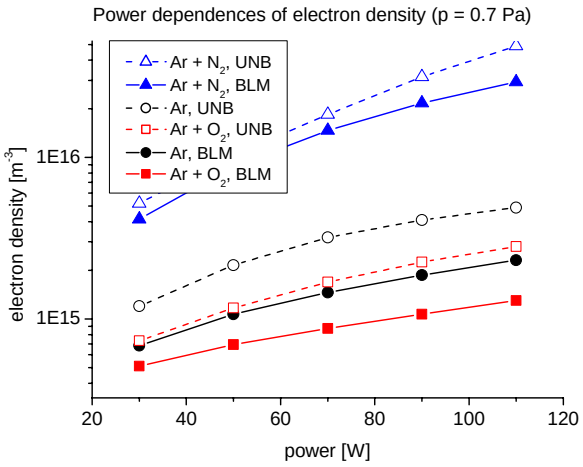

Fig.5. Power dependence of mean electron energy. Conditions: p = 0.7 Pa, Ar – 19.3 sccm, N_2, O_2 – 1.5 sccm

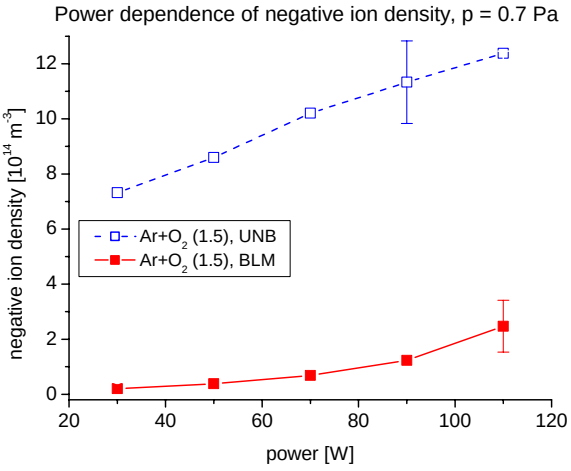

Fig.6. Power dependence of negative ion density. Conditions: p = 0.7 Pa, Ar+O_2 (19.3 + 1.5 sccm).

6. Conclusion

Ar plasma generated by DC planar magnetron with reactive admixtures N_2 and O_2 was investigated by Langmuir probe technique. Dependences of mean electron energy ($E_m \approx 3$ eV), plasma potential ($V_{pl} \approx 1.5$ V) and electron density ($n_e \approx 10^{15\text{-}16}$ m^{-3}) on discharge power were determined. Novel method for determination of negative ion density from probe measurement in slightly electronegative plasma was suggested and applied. In that manner estimated negative ion density was substantially lower ($n_n \approx 10^{14}$ m^{-3}) than electron density.

Abstract
Cylindrical dc magnetron discharges in argon in post-cathode (direct) and hollow-cathode (inverted) configurations are studied experimentally and theoretically. The electron component is modelled basing on a non-hydrodynamic solution to the Boltzmann kinetic equation in the radially inhomogeneous electric and axially directed uniform magnetic fields. The absolute values and radial profiles of the EDF and various macroscopic parameters are obtained and compared for the direct and inverted magnetron configurations.
Keywords cylindrical magnetron discharge, Boltzmann equation, non-hydrodynamic model

1. Introduction

The DC cylindrical magnetron discharge (CMD) considered in the present paper consists of two co-axial metallic cylinders serving as electrodes, with radii usually not exceeding several centimeters. The typical working pressures are units of Pa or fewer. The applied voltage has a typical magnitude of hundreds of volts and causes the radially directed electric field. The uniform magnetic field parallel with the discharge vessel axis is created by coils with current. The magnetic field strength in the range from 10 to 40 mT is strong enough to magnetize the electron plasma component, leaving ion motion almost unaffected. The CMD is called post-cathode, or direct magnetron discharge, if the inner electrode is the cathode and the outer one is the anode. In the swapped electrode arrangement, the discharge is called the hollow-cathode, or inverted CMD. Their difference can be attributed to the opposite directions of charged particle fluxes and the different areas of corresponding electrode surfaces. In this paper both configurations will be examined and compared.

The CMDs in inverted configuration are less studied theoretically, while they have been successfully used in technological applications. There are good reasons to believe that the radial courses of collision rates and other characteristics in the inverted CMD will differ from those in the post-cathode discharge.

The planar and cylindrical magnetrons have been simulated by various fluid [1,2], PIC-MCC [3] and non-hydrodynamic models [4,5], based on the Boltzmann kinetic equation for electrons.

In the present paper the cylindrical magnetron discharges in the post- and hollow-cathode configurations are studied, with particular emphasis on the less explored inverted CMD. The analysis of the physical processes and comparison between the two CMD types are performed in terms of the electron distribution functions and relevant macroscopic parameters. Electron plasma component is modelled basing on the spatially inhomogeneous Boltzmann kinetic equation in crossed electric and magnetic fields.

The experimental and simulation results presented here are obtained for the both direct and inverted CMDs of length L=12 cm and radii of the inner and outer electrodes r_0=0.5 cm and R=3 cm, respectively. The working gas was argon, at pressure $p\approx$3 Pa, discharge current $i\approx$100 mA and magnetic field strength B=20 mT.

2. Experimental set-up

The cylindrical magnetron apparatus in the inverted configuration is presented in Fig. 1. The same apparatus was used earlier to study experimentally the discharge in the direct design [6]. Electrodes are arranged co-axially, the anode is placed at the axis of the grounded stainless-steel cylindrical vacuum chamber, which serves as a cathode. The limiters (shields) at both ends of the chamber are connected to the anode. Two magnetic coils are placed symmetrically with the centre of the system to provide the axially directed homogeneous magnetic field. The magnetic coils are energized by a power supply in current-stabilized mode. Each coil has more than 5,000 turns, which results in magnetic field of up to 40 mT at the vessel axis at the winding current around 1 A. Cores of the coils as well as the cathode are water-cooled to avoid overheating at higher currents.

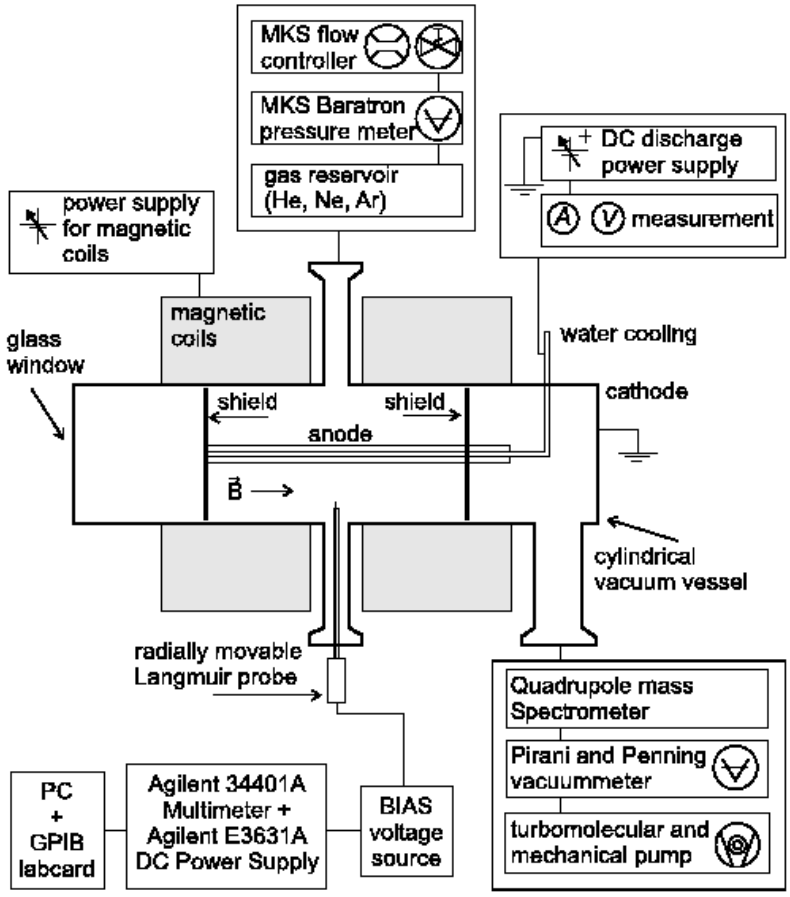

Fig. 1. Schematic diagram of the experimental set-up with the cylindrical magnetron in inverted configuration

The fact that the magnetic field is provided by two coils enables accommodation of several vacuum ports in-between of the coils in the middle of the vacuum chamber. They are used for measurements with radially movable Langmuir probe as well as for pressure measurement and gas inlet. Ports at the ends of the vacuum chamber serve for pumping and electrical feed-through to the anode, accommodation of Pirani and Penning manometers and axially movable Langmuir probe. As the discharge power supply the Advanced Energy MDX 500 unit is used in current-stabilized mode.

The vacuum system is pumped by means of the piston pump Leybold EcoDry M15 and the turbomolecular pump Leybold-Heraeus Turbovac 150. The mechanical piston pump pre-evacuates system down to several Pa and with the turbomolecular pump back-ground pressure of the order of 10^{-3} Pa can be achieved. Research-grade argon (5.6 purity) is introduced into the apparatus via MKS flow controller. Typical gas flow rate is less than 0.5 sccm at working gas pressure of units Pa.

Radially movable Langmuir probe is used to measure parameters of the discharge plasma. Probe holder is made of two Degusit pipes inserted tightly into each other and has special construction to prevent to highest degree the unwanted effect of the sputtered cathode material (short-circuiting of the deposited conducting layer on the ceramic probe holder with the probe wire). Probe measurement circuit consists of computer-controlled DC power supply (Agilent E3631A), which serves as probe bias voltage ramp generator and multimeter (Agilent 34401A), which measures the probe current. Probe bias can be further amplified by high-voltage operational amplifier to a range needed. PC equipped by the GPIB interface card controls the measurement circuit. It has to be noted that the probe bias voltage ramp requires additional dc bias in series to bring the range of the probe voltage up to approximately anode voltage. Most of the discharge voltage (in our case around 300 volts) falls in the cathode region and hence the plasma potential in most part of the positive column keeps close to the anode voltage. The entire probe data acquisition system is driven by control program written in the Agilent VEE Pro iconic programming environment. With this system it is possible to get one probe characteristics consisting of 300 experimental points in about one minute.

3. Theoretical model

The spatially inhomogeneous steady-state Boltzmann equation for the electron distribution function (EDF) $F(\mathbf{v},\mathbf{r})$ states

$$\mathbf{v}\cdot\nabla_{\mathbf{r}}F(\mathbf{v},\mathbf{r})-\frac{e}{m}(\mathbf{E}+[\mathbf{v}\times\mathbf{B}])\cdot\nabla_{\mathbf{v}}F(\mathbf{v},\mathbf{r})=C(F(\mathbf{v},\mathbf{r})).$$

Here m and $-e$ are the electron mass and charge, $\mathbf{E}$ and $\mathbf{B}$ are the electric and magnetic field strengths. $C(F)$ is the collision integral.

Under assumption of weak anisotropy the EDF can be represented in the form $F(\mathbf{v},\mathbf{r})=F_0(v,\mathbf{r})+\mathbf{F}_1(v,\mathbf{r})\cdot\mathbf{v}/v$, where only two first terms of the spherical harmonic expansion are retained. We consider cylindrically

symmetrical and axially uniform CMD plasma with the crossed configuration of the radial electric and axial magnetic fields. Application of the Boltzmann equation to the specified geometry yields the following set of equations, written in variables of the kinetic energy $U=mv^2/2$ and the radial coordinate r

$$\frac{U}{3}\frac{1}{r}\frac{\partial}{\partial r}rf_{1r}(U,r)-\frac{eE(r)}{3}\frac{\partial}{\partial U}Uf_{1r}(U,r)=S(f_0) \tag{1}$$

$$\begin{aligned} f_{1r}(U,r)&=\frac{UNQ_\Sigma(U)}{(NQ_\Sigma(U))^2U+m\omega_{eB}{}^2/2}\left[-\frac{\partial f_0}{\partial r}+eE(r)\frac{\partial f_0}{\partial U}\right] \\ f_{1\theta}(U,r)&=\frac{\sqrt{m/2}\cdot\omega_{eB}}{NQ_\Sigma(U)\sqrt{U}}f_{1r}(U,r); \qquad f_{1z}(U,r)=0 \end{aligned} \tag{2}$$

with $Q_\Sigma(U)$ being the total cross section of all collision types and $\omega_{eB}=eB/m$ denoting the cyclotron frequency. The functions f_0 and $\mathbf{f}_1$ differ from the corresponding functions F_0 and $\mathbf{F}_1$ by the factor $2\pi(2/m)^{3/2}$. The term $S(f_0)$ denotes the sum of the elastic, excitation and ionization collision operators $S(f_0)=S_{el}(f_0)+S_{ex}(f_0)+S_{ion}(f_0)$.

The elastic and excitation collision operators are taken in a customary form. If $Q^{el}(U)$ is the momentum transfer cross section for elastic collisions of electron with heavy neutral particles of mass M and density N, the corresponding operator is

$$S_{el}(f_0)=2\frac{m}{M}\frac{\partial}{\partial U}\left[U^2NQ^{el}(U)f_0(U,r)\right]$$

The excitation collision operator is

$$S_{ex}(f_0)=-UNQ^{ex}(U)f_0(U,r)+(U+U_{ex})NQ^{ex}(U+U_{ex})f_0(U+U_{ex},r),$$

with $Q^{ex}(U)$ denoting the excitation cross section with the threshold U_{ex}.

Integral representation [7] of the ionization operator employs the differential cross section $\sigma(U'',U')$ that defines a continuous spectrum of energies U' of the secondary electrons appearing in ionizing collisions produced by an electron with the incident energy U''

$$\begin{aligned} S_{ion}(f_0(U,r))=&-Uf_0(U,r)\int_0^{(U-U_i)/2}N\sigma(U,U')dU'+\int_{2U+U_i}^{\infty}U'N\sigma(U',U)f_0(U',U)dU' \\ &+\int_{U+U_i}^{2U+U_i}U'N\sigma(U',U'-U_i-U)f_0(U',U)dU', \end{aligned}$$

where U_i is the ionization potential.

The system of equations (1) and (2) can be considerably simplified by introducing a new variable ε being the total energy $\varepsilon = U-e\varphi(r)$, $e\varphi(r)$ is the potential energy. To solve the resulting system numerically it was discretized using implicit finite difference scheme on the two-dimensional non-equidistant grid in variables (ε,r). The resulting EDFs were normalized to the current density at the anode, depending on the discharge current. The discharge current i in the CMD is related to the total current density $ej_0(r)$ according to $i=2\pi Lrej_0(r)$.

The electron density n_e, radial flux j_{er}, excitation W and ionization I rates can be evaluated from the EDF according to

$$\begin{aligned} n_e(r)&=\int_0^{\infty}U^{1/2}f_0(U,r)dU \\ j_{er}(r)&=\frac{1}{3}\sqrt{\frac{2}{m}}\int_0^{\infty}f_{1r}(U,r)UdU \\ W(r)&=\sqrt{\frac{2}{m}}\int_{U_{ex}}^{\infty}UNQ^{ex}f_0(U,r)dU \\ I(r)&=\sqrt{\frac{2}{m}}\int_{U_{ex}}^{\infty}UNQ^{ion}f_0(U,r)dU \end{aligned} \tag{3}$$

Here $Q^{ion}(U)$ is the total ionization cross section $Q^{ion}(U)=\int_0^{(U-U_i)/2}\sigma(U,U')dU'$.

4. Results and discussions

The radial profiles of the electric field $E(r)$ and potential $e\varphi(r)$ used in the present kinetic analysis are reproduced in Fig. 2 for the direct and inverted configurations of the magnetron discharge. The profiles were chosen so, that the simulated electron densities fit the experimentally measured curves and the discharge voltages agree with the experimental values. Thus, a significant difference in the radial field distributions is observed for the direct and inverted CMDs, that influences essentially the formation of the EDF and macroscopic characteristic.

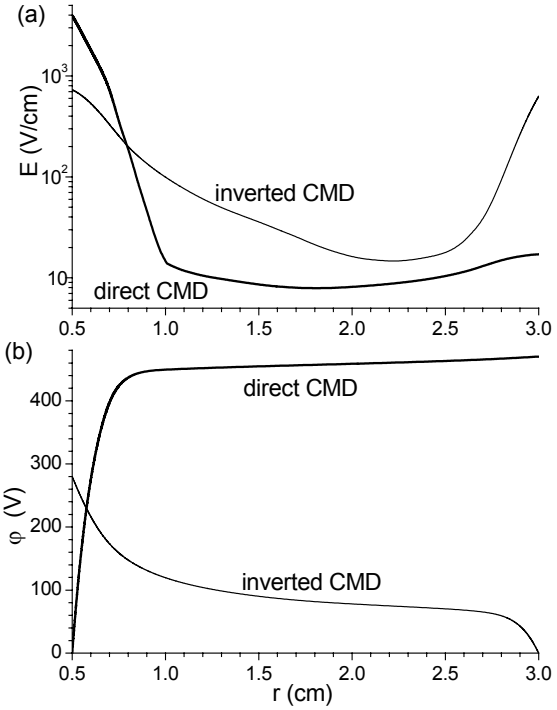

Fig. 2.Radial profiles of the electric field strength (a) and potential (b) in the direct and inverted CMDs used in calculations of the EDFs and macroscopic quantities.

The electron distribution functions calculated from the system of equations (1) and (2) are shown in Fig. 3 for both cylindrical magnetron configurations.

A beam of high-energy electrons accelerated by the cathode fall of the potential is formed in the cathode region. The EDF's tail extends to the energies of the order of the cathode fall, which is considerably larger in the direct CMD. In the positive column these fast electrons loose their energy in inelastic collisions mainly, and the EDF relaxation leads to depletion of the high-energy part.

Distinctions of the EDFs in the anode regions of the post- and hollow-cathode designs are connected with the different magnitudes of the anode fall. In the direct CMD the anode fall is small (≈1 V) and the EDF decreases smoothly to the anode due to electron sinking on the absorbing electrode. The simulations performed for the inverted CMD reveal a large value of the anode fall (≈100 V). In this case electrons, before having escaped to the anode, are accelerated by the action of a strong field in the anode region and populate the EDF in high energies. The EDF extends to the energies corresponding to the anode fall.

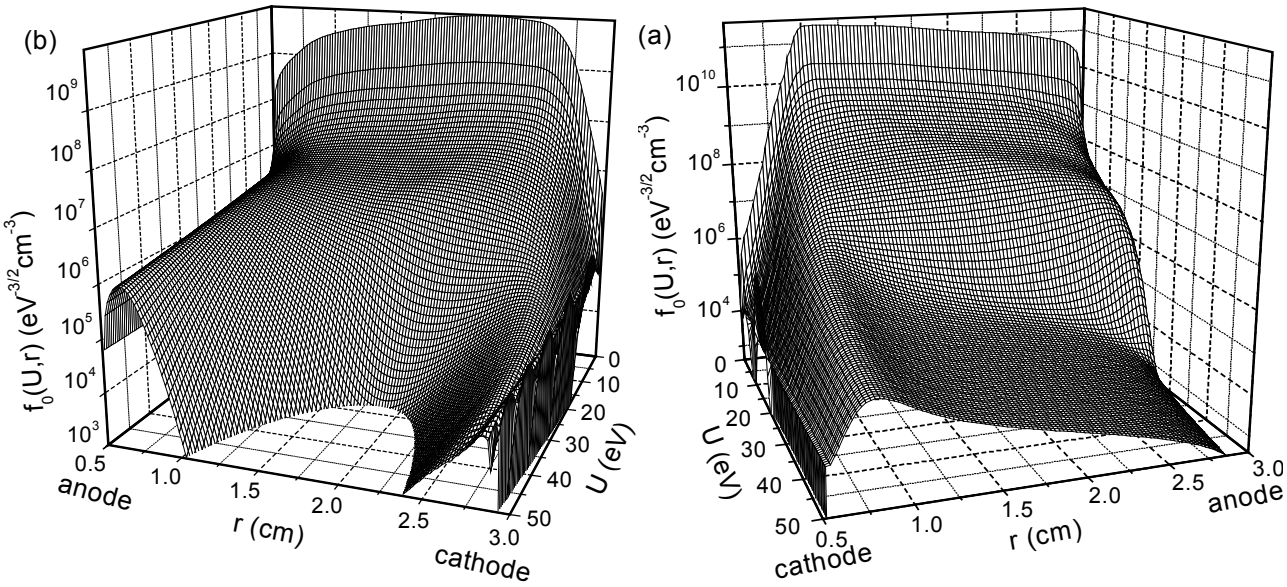

Fig. 3. The EDFs in the direct (a) and inverted (b) CMDs calculated in the corresponding fields shown in Fig. 2. Discharge conditions: (a) B=20 mT, p=3 Pa, i=90 mA and (b) B=2 mT, p=3.3 Pa, i=100 mA.

The general feature of the radial courses of electron density is the maximum located at almost equal distances from the cathode for both CMD configurations. At these distances the electric field strength has a minimum and large electron density values are required to sustain the discharge current in the quasi-neutral plasma. The radial course of the electron density in the direct and inverted CMDs resembles mirror-like pictures. The absolute value of the electron density in the inverted CMD is, however, smaller compared to that in the direct configuration under comparable experimental conditions.

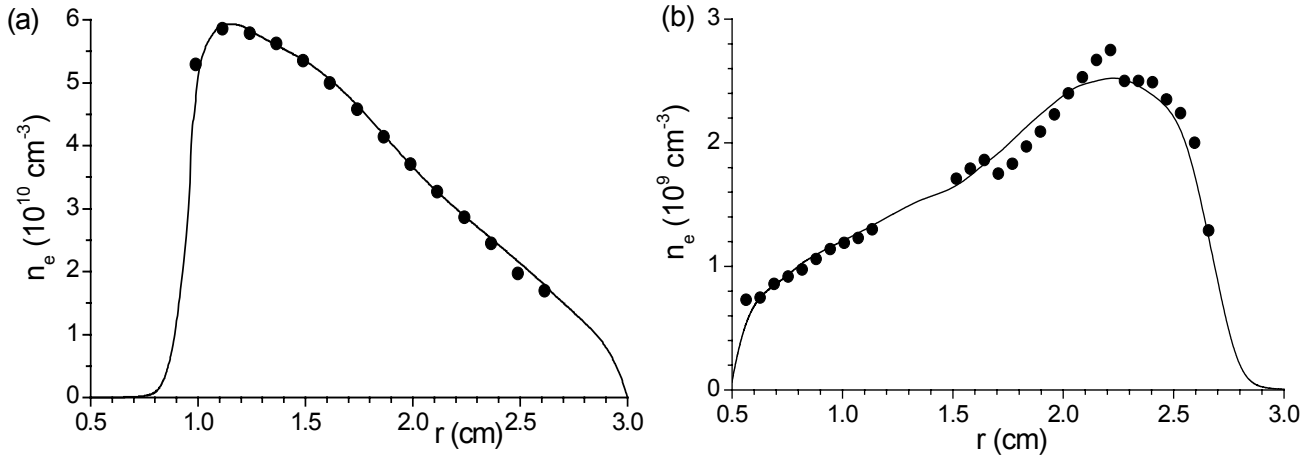

Fig. 4. The radial profiles of the electron density experimentally measured (circles) and calculated (solid lines) in the direct (a) and inverted (b) CMDs.

Along with the electron density $n_e(r)$, the excitation $W(r)$ and ionization $I(r)$ rates as well as the fluxes of charged particles $j_{er}(r)$ and $j_{ir}(r)$ have been calculated in both investigated types of the magnetron discharge.

The radial profiles of the excitation and ionization rates in the direct and inverted magnetrons are compared in Fig. 5. It should be noted, that the maxima of ionization and excitation and, consequently, those of spectral line emission, are formed in the vicinity of the inner electrode for the both CMDs. The electron density maximum is positioned, though, in the cathode vicinity. This can be attributed to the fact, that ionization and excitation rates are governed by the fast electrons concentrated mainly near the inner electrode in both configurations, as indicated in Fig. 3. The electron density is determined by the bulk of the distribution function and by slow electrons concentrated in the positive column. This phenomenon apparently illustrates the non-hydrodynamic regime of the plasma electron component formation.

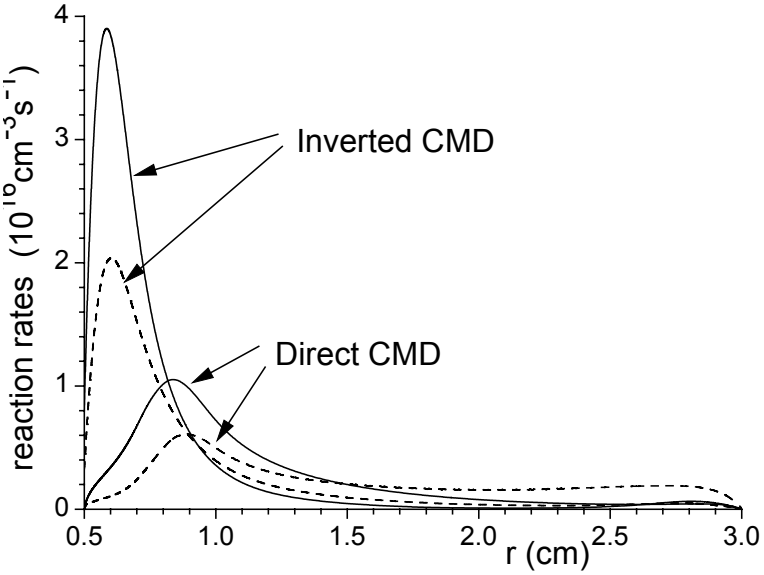

Fig. 5. The radial profiles of the direct ionization rate (solid lines) and the excitation rate (broken lines) in the direct and inverted CMDs.

In spite of the observed discrepances in the absolute values and radial distributions of the ionization rates, the total number of ionization events in the volume per unit time, written in terms of the discharge current $2\pi L\int_{r_0}^{R} I(r)rdr = i/\left[e(1+\gamma)\right]$ is the same in the direct and inverted configurations at equal currents.

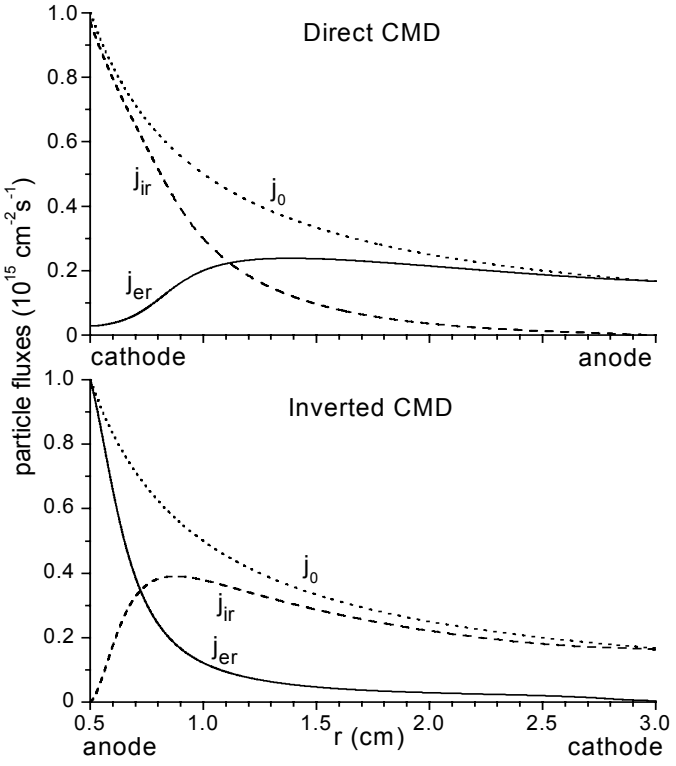

Fig. 6.The radial profiles of the electron $j_{er}(r)$, ion $j_{ir}(r)$ and total $j_0(r)$ current densities in the direct (a) and inverted (b) CMDs normalized by the total current density on the inner electrode: (a) $j_0(r_0)=1.49\cdot10^{16}$cm^{-2}s^{-1}, (b) $j_0(r_0)= 1.66\cdot10^{16}$cm^{-2}s^{-1}.

The transport of the discharge current in both magnetron configurations is demonstrated in Fig. 6, where the radial dependences of the electron $j_{er}(r)$, ion $j_{ir}(r)$ and total j_0 fluxes are reproduced. Electrons are the dominant current carriers in the direct magnetron, as opposed to the inverted CMD where the ion current is the main part of the discharge current. This ratio is valid for the whole discharge gap except for the regions adjacent to the inner electrode in both magnetrons, where intensive ion production takes place. The ions move to the cathode and their flux gives largest contribution to the total current density. For the inverted CMD the ion current dominates both in the cathode region and the positive column.

5. Conclusion

The present study addressed the issues of the plasma electron component formation in the direct (post-cathode) and inverted (hollow-cathode) CMDs. The calculations of the electron distribution functions, absolute values and radial distributions of the electron density, excitation and ionization rates and charged particle fluxes are carried out. The maxima in the electron density radial distribution are shown to be formed in the cathode vicinity in both CMD configurations, whereas the maxima of the ionization rates are situated in the vicinity of the inner electrode independently of its polarity. This fact is indicative of the non-hydrodynamic character of electron kinetics. The role of the electron and ion current densities in discharge current transport is analysed for both configurations.

Abstract

In this study, to deposit diamond-like carbon (DLC) films on a polycarbonate-inner wall using radio frequency (r.f.) plasma chemical vapour deposition (CVD) techniques, we have developed the cylindrical electrode plasma process. The plasma state was stably generated inside the polycarbonate tube. The thickness of the deposited-DLC film was 300 ~ 350 nm, and the structure was uniform. The cylindrical electrode process is expected to apply to 3-dimensional insulator structures such as polymeric tubes.

Keywords: inner wall surface of polymeric-tube, cylindrical electrode process, r.f. plasma CVD, diamond-like carbon film

Introduction

Radio frequency (r.f.) plasma chemical vapor deposition (CVD) technique can be used on most substrates at low temperatures, and it is possible to control characteristic of deposited films [1]. In common r.f. plasma CVD system, it consists of two planar electrodes. These planar electrodes have advantage of uniformly depositing films over large area [2]. In spite of these extensive advantages, application of r.f. plasma CVD technique has been limited to flat substrates, such as silicon or glass wafers, etc. Therefore, to achieve uniform deposition of thin films is impossible since it is difficult to generate the uniform plasma around complicated (3-dimensional) structure surfaces. For this reason, industrial acceptances of r.f. plasma CVD technology have been restricted. In this study, we have developed cylindrical electrode to deposit diamond-like carbon (DLC) film on inner wall of commercial polycarbonate-tube, using r.f. plasma CVD process. Since characteristics of DLC films depend strongly on plasma conditions, success of uniform DLC films deposition to 3-dimensional structures indicates that this deposition process is applicable to other thin film deposition techniques.

Plasma measurements

The schematic diagram of cylindrical electrode process is shown in Fig. 1. This process consists of an aluminum cylindrical electrode that is put on a cathode side electrode, an anode side electrode, an r.f. generator (model SS-301AAE, Fuji Electronic Industrial Co., Ltd.), a matching box (model HC-2000, Tokyo Hy-power Labs., Inc.), and a vacuum pump (model 1397, Sargent-Welch Scientific Co.). The cylindrical electrode, which is electrically conducted to the cathode side electrode and the power generator, holds the outside of polycarbonate-tube (internal diameter: 11 mm, length: 100 mm, thickness: 1 mm) completely. In this way, it is possible to impress the cylindrical electrode r.f. power to the polycarbonate-tube and to generate glow discharge plasma on the inside of the polycarbonate-tube.

The plasma states (the distributions of electron temperature T_e and electron number of density N_e) of the tube length direction at the central axis were measured using the double-probe data analysis system (Fig. 1). The position at the tips of two probes was kept at the central axis of the tube. The double-probe data analysis system consists of two Langmuir probes (platinum wires with 400 μm in diameter) and the power supply of the probes (model R6243, ADVANTEST CORPORATION). The two probes were positioned parallel to each other at a distance of 10 mm, and the probes outsides were shielded with glass. The experiments were performed with helium (He) plasma, an r.f. power of 13.56 MHz at 30 W. In order to keep the polycarbonate-tube inner wall clean and the Langmuir probe tip without any contamination, He gas was used for estimating the plasma states. The gas pressures were 50, 100, and 150 Pa. These experimental conditions were possible to keep plasma generation inside the polycarbonate-tube.

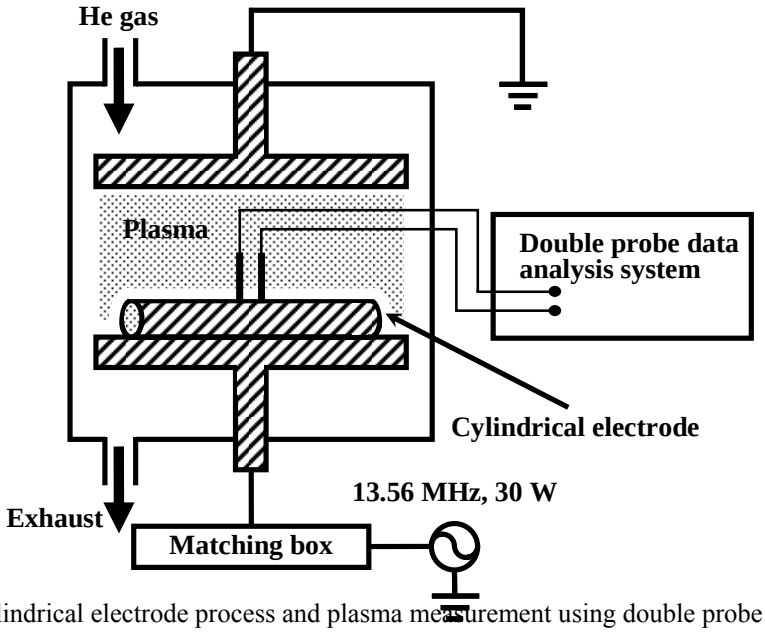

Fig. 1 Schematic of cylindrical electrode process and plasma measurement using double probe method.

Figure 2 shows the distributions of T_e and N_e, which were measured along the length direction at central axis of the polycarbonate-tube. Although the central axis profiles of T_e were higher at the edges part than at the center of the polycarbonate-tube with cylindrical electrode, under the all gas pressure conditions, the profiles of T_e were almost uniform inside the whole tube (Fig. 2-a). Moreover, the profiles of N_e were also measured. The profiles of N_e observed the same tendencies as well as the profile of T_e (Fig. 2-b). That is, both profiles of T_e and N_e were higher at the edges part than at the center of the polycarbonate-tube with the cylindrical electrode. From these results, it is considered that the plasma inside, which was in the hollow cathode discharge at the inner wall surface of the polycarbonate-tube, was generated from the both edges of the tube. Although the plasma inside was defused in the states of T_e and N_e which is show in Fig. 2, it was stably generated inside the whole tube.

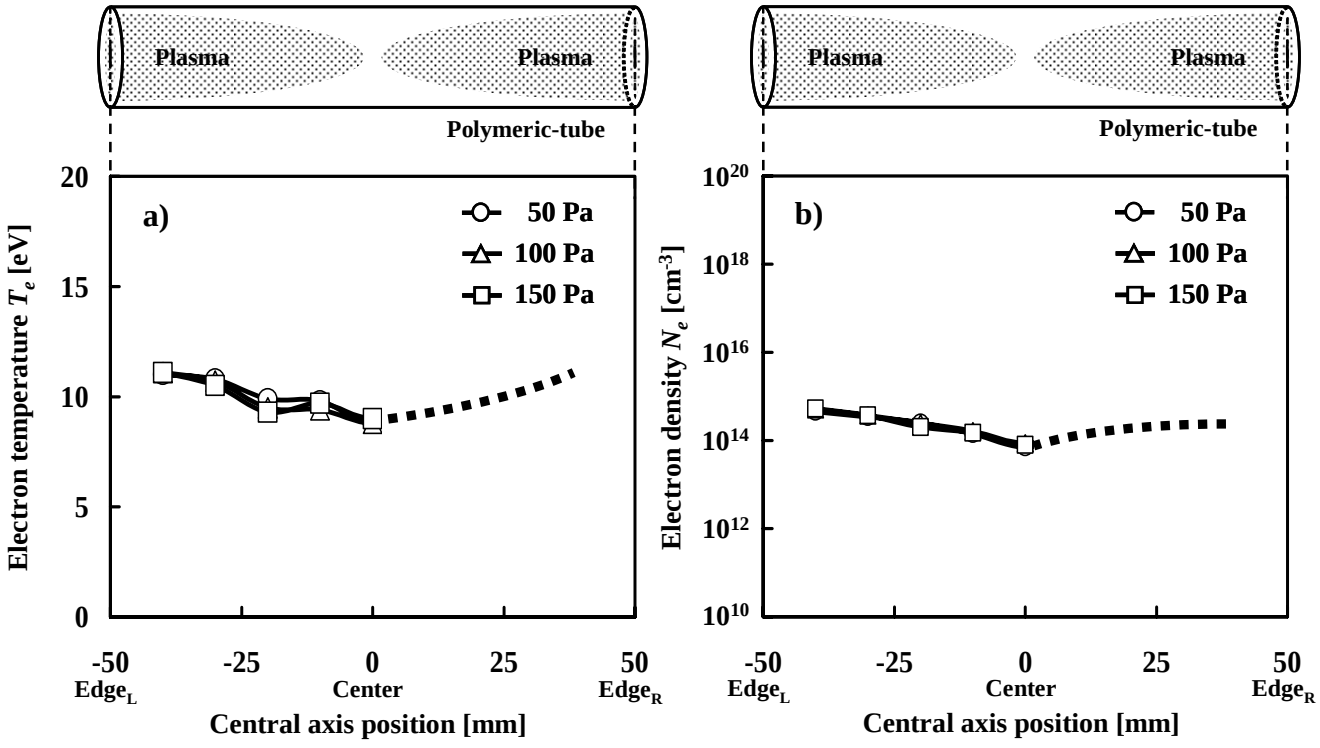

Fig. 2 Distribution of electron temperature T_e and density N_e, which were measured using double probe method.

DLC film deposition on polycarbonate-tube inner wall

The cylindrical electrode process with r.f. plasma CVD technique deposited DLC films on the polycarbonate-tube inner wall. The 13.56 MHz plasma of the electrical power was held constant at 30 W this decomposed the hydrocarbon gas (CH_4), and deposited DLC film on polycarbonate-tube inner wall under the following condition: CH_4 gas pressure at 10 Pa with a deposition time of 10 minutes.

The distribution of the film thickness was measured using the cross section of scanning electron microscope (SEM: JEOL, JSM-5310LVB) images. Additionally, the structure of the DLC film was investigated using infrared spectroscopy (IR: JASCO, FT/IR-620), and Ar-laser Raman spectrophotometer (Raman: JASCO, NRS-2100). Moreover, the chemical composition and bonding states of the DLC films were measured with X-ray photoelectron spectrometer (XPS: JEOL, JPS-9000MC). The monochrometer was used with *Al* K_α. DLC films contain a mixture of sp^3-bonds (tetrahedral or aliphatic), sp^2-bonds (trigonal or aromatic), and sometimes sp^1-bonds (linear or acetylenic) coordinated carbon atoms in a disordered network [2-4]. The properties of DLC films are determined by measuring bonding hybridization of the carbon atoms and relative concentration of the different bonds. Due to the importance of ratio of the sp^3/sp^2 hybridized carbon and hydrogen content in determining the properties of DLC films; it is of primary interest to characterize these two properties. IR, Raman, and XPS spectroscopy are most often used for study of DLC film structures [2]. In order to estimate the structure of DLC film satisfactorily, in this experiment, DLC film was deposited on silicon {100} substrates that were put on at the center and both edges (three different positions) of the polycarbonate-tube inner wall.

The DLC film thickness was decreased at the center of the polycarbonate-tube, it was kept at approximately 300 ~ 350 nm. The structure of the DLC film was investigated using IR, Raman, and XPS analysis. The IR spectra are shown in Fig. 3-a. These spectra were compared to the structure of the DLC film deposited at each different position (the $edge_L$ position, the center position, and the $edge_R$ position) on the inner wall surface. The main peak of all the spectra was the waveform of around 2920 cm^{-1}, and the sp^3 and sp^2 bonding spectra peak was observed at 2855 ~ 3000 cm^{-1} [2,4-7]. All the IR spectra at 3 different positions were similar; moreover, the ratios of sp^3/sp^2 were approximately at 2.4 ± 0.1. In this IR analysis, it is expected that the cylindrical electrode process produced uniformity of the DLC film deposition. The Raman spectra are shown in Fig. 3-b. As for the Raman spectra of all the positions on the inner wall surface of the polycarbonate-tube, each spectrum was of the same form. It is observed that all the spectra of the DLC film on the polycarbonate-tube inner wall were similar. The ratios of I_D/I_G that are ratio of intensities of *G*-peak and *D*-peak were approximately at 0.47. As well as the IR analysis, the cylindrical electrode process is expected to deposit the DLC films uniformly on the polymeric tube inner wall.

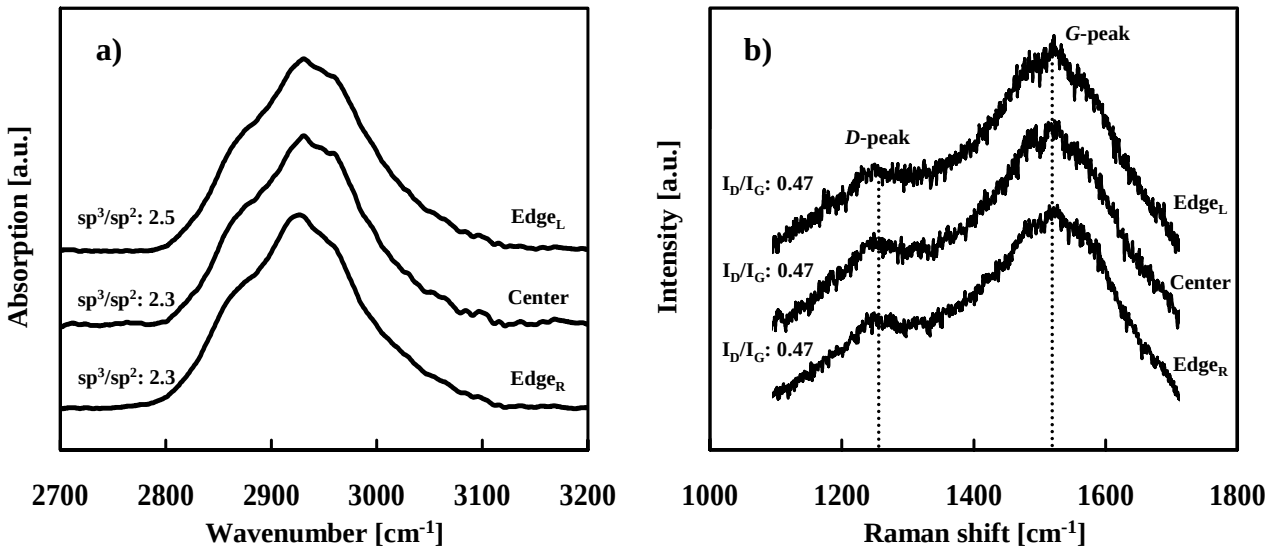

Fig. 3 IR and Raman spectra of the DLC film on the polycarbonate-tube inner wall.

In XPS analysis for the DLC film, carbon (C_{1s}) spectra have peak at 284.4 eV, and these asymmetric spectra were caused from π-bonding. XPS spectra of DLC films are decomposed into two types of peaks, sp^3-bonds (C-C bonds) and sp^2-bonds (C=C) [8,9]. All the FWHM for XPS spectrum of the DLC film were approximately at 1.55, there is no clear difference in these spectra including main peak positions. In this XPS analysis, it was revealed that the deposited DLC film on the polycarbonate-tube inner wall was uniform in structural characterization.

Conclusions

In this study, the DLC films were deposited on the polycarbonate-tube inner wall using the cylindrical electrode process. With the cylindrical electrode it is possible to generate hollow cathode discharge plasma inside the polycarbonate-tube. Based on the double-probe measurements of the plasma, it was expected that the plasma existed stably inside the tube. Additionally, the deposited DLC film on the polycarbonate-tube inner wall was uniformity. Due to the uniform film deposition, it is possible to guess that the plasma states were stable, during deposition, too.

The success of uniform DLC film deposition indicates that the cylindrical electrode process is applicable to other thin film deposition techniques and 3-dimensional structures such as polymeric tubes. Moreover, the cylindrical electrode process is expected to be adapted to slenderer and longer objects such as tubular medical devices. In that case, this process would be widely applied in industries.

Acknowledgment

We would like to thank Mr. Junya SHIROTO and Mr. Tsuneo TOYA for the discussion of the plasma measurements and analysis for DLC film structures. This work was supported by the Frontier Research and Development Center, Tokyo Denki University.

Abstract

The paper is covering part of our systematic experimental study of recombination of D_3^+ and D_5^+ ions with electrons in a He-Ar-D_2 afterglow plasma at temperatures T = 130–300 K. The data were obtained using Flowing afterglow (FALP) and stationary afterglow experiments. The experimental data are covering a large extend of buffer gas pressures and a large range of reactant partial number densities: $[D_2] = 10^{12}$-$3\cdot10^{15}$ cm^{-3}. Preliminary data on NIR-CRDS absorption spectroscopy of $D_3^+(v=0)$ are also reported.

Keywords: deuterium, **D_3^+ ions** recombination, rate coefficient, afterglow

1. Introduction

The ions H_3^+ and D_3^+ play important roles in the kinetics of media of astrophysical interest (interstellar molecular clouds [1, 2], and planetary atmospheres [2]) and also in laboratory produced plasmas (discharges, fusion plasmas at walls [3], etc.). The recent discovery of H_3^+ in diffuse interstellar molecular clouds has confirmed the presence of H_3^+ in space and has opened a problem of the observed high column density, which critically depends upon the recombination rate for H_3^+ with electrons at low energies [1, 4]. This problem was again discussed in the connection with very recent new experimental results [5]. The problem gets more complicated by taking into account the H_3^+ deuteration processes [2]. Recently several multiply deuterated species have been detected in interstellar medium, including some triply deuterated molecules e.g. ND_3. Deuterated species in some regions have been observed to have abundance >10% of their un-deuterated analogues, this is very high if we realise that abundance of D is ~10^{-5} with respect to H. Such large enhancement in the abundance of deuterated molecules and ions can be connected with gas-phase fractionation. The kinetics of the formation of H_3^+ and D_3^+ ions in hydrogen and deuterium containing plasmas is well understood (see e.g. [6]). Equally important for hydrogen and deuterium containing plasmas is to understand the processes of destruction of these ions in collisions with electrons. Differences in rates and products branching ratios of dissociative recombination of deuterium and hydrogen containing ions can be also partly responsible for enhancement of population of deuterium in some regions (for details see [7],[8]). Stimulation for present study is coming also from recent very successful theoretical studies of dissociative recombination of H_3^+ and D_3^+ made by V. Kokoouline and Ch. Greene [9].

However, despite enormous efforts, the results of experimental studies determining the rate of recombination of H_3^+ and D_3^+ ions with electrons have been found to yield values that vary by at least one order of magnitude from 1×10^{-8} to 3×10^{-7} cm^{3}s^{-1} for H_3^+ [10, 11, 12, 13] and 2×10^{-8} to 2×10^{-7} cm^{3}s^{-1} for D_3^+ [14, 15, 16, 17]. Moreover H_3^+ and D_3^+ as the simplest triatomic ions, are important examples for testing new quantum-theoretical calculations, but the agreement between theory, experiment and astronomical observations over a large range of energies has not yet been confirmed [9, 18, 19, 20, 21].

In our previous studies of recombination of D_3^+ ions with electrons in deuterium containing plasmas we observed the dependence of recombination rate coefficients on partial pressure of deuterium in the buffer gas. The dependencies were similar to one observed for rate coefficients of ternary ion molecule association reactions. In analogy with other ternary processes we expected strong temperature dependence of observed process, study of this dependence was the main goal of the presented experiment. The results of similar studies carried out in hydrogen plasma are reported in our previous paper [22, 23]. As follows from previous studies rate

coefficient of recombination of D_3^+ ions with electrons is at thermal energies of order of ~1-10x10^{-8} cm^3s^{-1} [25]. Because these values are too small to be measured in standard Flow Tube experiment (FALP), we have built a new version of the FALP with possibility to control temperature of the flow tube (FALP-VT). In the built FALP-VT high pressure and slow velocity of the buffer gas are used in order to be able to measure reliably rate coefficients of the order of ~10^{-8} cm^3s^{-1}. Previous measurements of recombination of D_3^+ with the Advanced Integrated Stationary Afterglow (AISA) apparatus [25] were supplemented and extended to lower temperatures (T=130–300K) and higher pressures of He buffer gas (6–8 Torr). A large range of reactant partial number densities was covered: $[D_2] = 10^{12}$ - $3 \cdot 10^{15}$ cm^{-3}.

The paper is covering part of our systematic study of recombination in low temperature deuterium containing plasmas. Reported is recombination of D_3^+ and D_5^+ ions with electrons in a He-Ar-D_2 afterglow plasma at temperatures T=130–300 K. These studies, [6, 24, 25] are complementary to recent very intensive experimental studies using large storage ring facilities [26, 27, 28]. Very recent experiments with rotationally cold ions indicate (in agreement with theory) that rotational excitation of H_3^+ can have influence on rate of recombination of these ions [20, 29]. In order to contribute to these studies we build near infrared cavity ring-down absorption spectrometer (NIR-CRDS) to monitor decay of H_3^+(v=0) and D_3^+(v=0) in decaying plasma [30] Preliminary data on NIR-CRDS absorption spectroscopy of D_3^+(v=0) are also reported.

2. Experiments

2.1. FALP – Flowing Afterglow

The *Flowing Afterglow Langmuir Probe (FALP)* technique is based on the so-called chemical reactor principle: The buffer gas flowing along the flow tube carries the plasma created upstream in the plasma source. We have built a high-pressure version of this apparatus – *VT-FALP*. The output nozzle at the end of the flow tube allows the working pressure to be increased up to 20 Torr. For ion identification and ion formation studies, we use a mass spectrometer placed statically down stream of the flow tube behind differential pumping. The electron and ion concentrations decay along the tube through diffusion and recombination losses. A *Langmuir Probe* (tungsten wire 18 μm in diameter and 7 mm long) movable along the axis of the flow tube is used for electron concentration measurements. Saturated electron current region of the probe characteristic is used to determine the electron number densities. Considering the constant velocity of the flowing gas (or plasma respectively) one can convert the position of the probe to the duration of the plasma decay. The well-understood recombination reaction of O_2^+ with electrons is used to validate *Langmuir probe* data (calibration procedure) at given temperature, pressure and gas flow rate. In order to minimize losses of ions under study in reactions

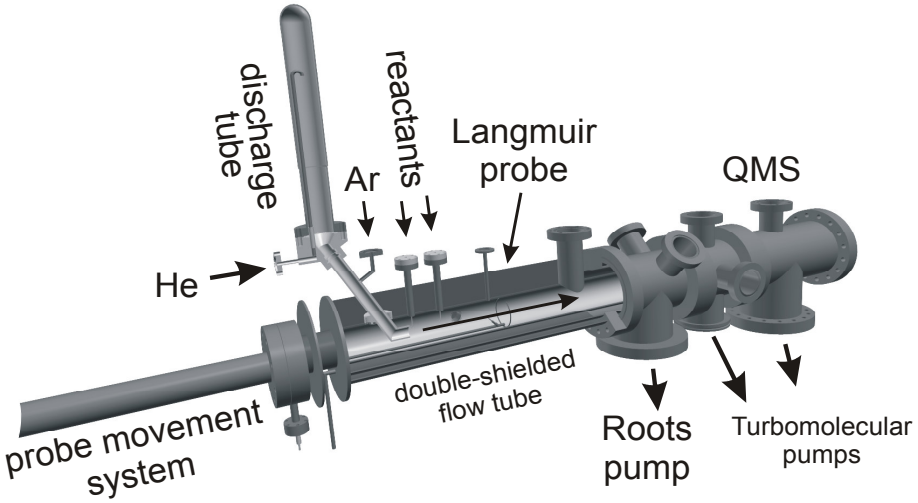

Figure 1. 3D design of the new *Flowing Afterglow Langmuir Probe – Variable Temperature (VT-FALP)* apparatus body. Discharge tube and flow tube is opened to show the internal arrangement. Total displayed length is approximately 1.5 m.

with impurities the gas handling system and the flow tube are using UHV technology and a buffer gas is cleaned by passing through the liquid nitrogen zeolite traps. The schematic 3D picture in Fig. 1. outlines the essential parts of present version of *VT-FALP*. The actual flow tube is embedded in cooling liquid (ethanol or liquid nitrogen) and thermally insulated by double shielding.

2.2. CRDS – absorption spectroscopy

As it was already mentioned possible differences between storage ring and afterglow data are due to differences in rotational excitation of recombining ions in different experiments. The identification of internal state of recombining ions can solve the problem. To study recombination of H_3^+ and D_3^+ ions we have built recently NIR Cavity Ring-Down Absorption spectrometer (NIR-CRDS). To measure recombination rate coefficient one has to determine absolute values of ion number densities. The transitions for D_3^+ were calculated [31], but there are not too many measurements in NIR of $D_3^+(v=0)$ ions. Short description of CRDS together with a configuration of "Test discharge tube" used in these measurements is given in Fig. 2. For more details see our recent papers [30, 32].

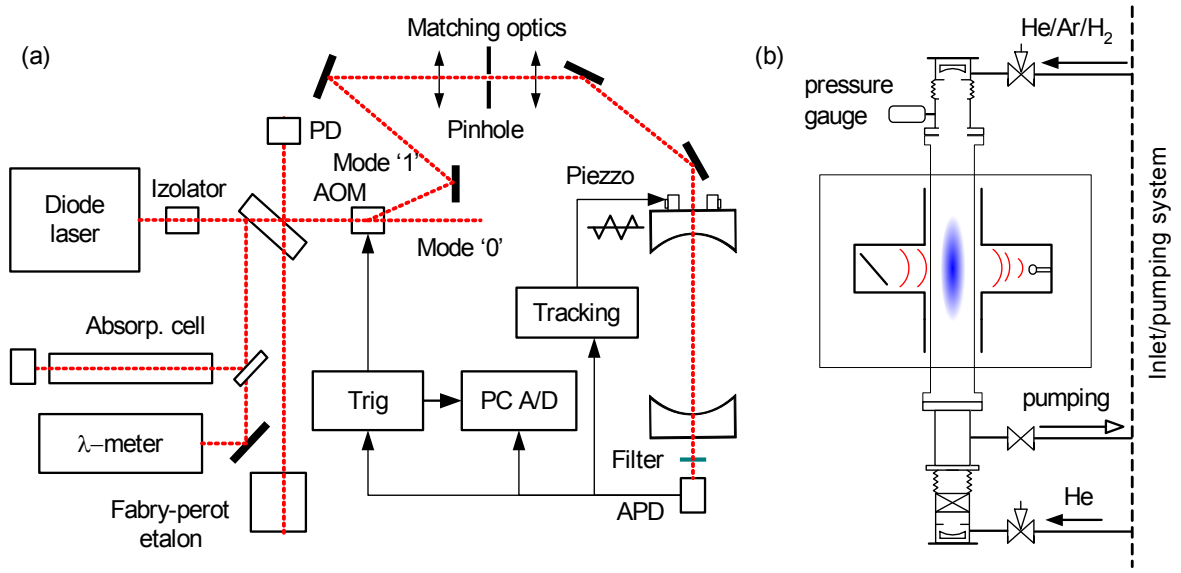

Figure 2. The schematics of the absorption experiment. a) The optical setup of NIR-CRDS spectrometer. The principle and details have been described elsewhere [33]. Light from a near IR diode laser (used in 1450 – 1470 nm region) was coupled into the high finesse optical cavity composed of spherical mirrors. The intensity decay of the light leaking from the cavity after interrupting the feeding beam by acousto-optic modulator (AOM) is recorded. b) Test discharge tube with microwave cavity (2.45 GHz, 30 W), optical cavity and gas handling system. The optical cavity is inside a pyrex tube (d = 4 cm, 72 cm long). The plasma column (5 cm long) is created in He (7 mbar) with small admixtures of D_2 and Ar in typical flow ratio 1100:3:1 (in sccm).

3. Results and discussion

In the present afterglow experiment (FALP-VT) a decay of the electron number density during recombination controlled afterglow is monitored and an effective rate coefficient, α_{eff} is calculated. In these calculations we are considering the deionisation process:

$$D_3^+ + e^- \xrightarrow{\alpha_{eff}} products\,, \qquad (1)$$

The rate coefficient α_{eff} was measured as a function of $[D_2]$ at several temperatures and pressures of the buffer gas. The obtained data together with previous data [6, 25] obtained in stationary afterglow (AISA) experiment are plotted in Fig. 3. Note significant dependence of the effective recombination rate coefficient on $[D_2]$ at all temperatures. We assume here that at very high $[D_2]$ and low temperatures α_{eff} is influenced by enhanced formation of D_5^+ ions and their consequent recombination (with rate coefficient α_5). At low $[D_2]$ and higher

temperatures formation of D_5^+ ions is not so effective and plasma is decaying mainly due to binary recombination of D_3^+ ions (with rate coefficient α_3). In intermediate region recombination of both D_3^+ and D_5^+ with electrons take place and simultaneously (if plasma is close to thermodynamic equilibrium) the number densities of both ions are coupled by van't Hoff equation. The overall dependence of the measured α_{eff} on He pressure, $[D_2]$ and temperature is given by three processes (corresponding rate coefficients are indicated):

$$D_3^+ + D_2 + He \underset{k_{-3}}{\overset{k_3}{\leftrightarrow}} D_5^+ + He\,, \tag{2}$$

$$D_3^+ + e^- \xrightarrow{\alpha_3} products\,, \tag{3}$$

$$D_5^+ + e^- \xrightarrow{\alpha_5} products\,. \tag{4}$$

where k_3 is the rate coefficient for three-body association and k_{-3} the rate coefficient for clusters destruction by collision-induced dissociation (CID) in collisions with He atoms. When considering processes (1) – (4) and diffusion losses (ambipolar diffusion with characteristic diffusion time τ_D), the balance equation for electrons is:

$$\frac{dn_e}{dt} = -\alpha_3 n_e [D_3^+] - \alpha_5 n_e [D_5^+] - ([D_3^+] + [D_5^+])/\tau_D\,, \tag{5}$$

Let us introduce the ratio $R=[D_5^+]/[D_3^+]$ and realize that $n_e = [D_5^+] + [D_3^+]$. Equation (5) can then be rewritten:

$$\frac{dn_e}{dt} = -(\alpha_3 + R\alpha_5)\frac{n_e^2}{1+R} - n_e/\tau_D = \alpha_{eff} n_e^2 - n_e/\tau_D\,, \tag{6}$$

If we consider: $R = \dfrac{[D_3^+]}{[D_5^+]} = \dfrac{k_3[D_2]}{k_{-3}} = K_C[D_2]$ the effective recombination rate coefficient can be written as

$$\alpha_{eff} = \left(\alpha_3 + \alpha_5 K_C [D_2]\right)\frac{1}{1+K_C[D_2]}\,. \tag{7}$$

where $K_C=k_3/k_{-3}$ is the equilibrium constant given by van't Hoff equation. The equilibrium constant has exponential dependence on temperature that is why dependence of α_{eff} on T is so strong. By fitting measured data values of α_3, α_5 and K_C corresponding to particular temperature can be obtained, see e.g. curve through data obtained at 190K in Fig. 4.

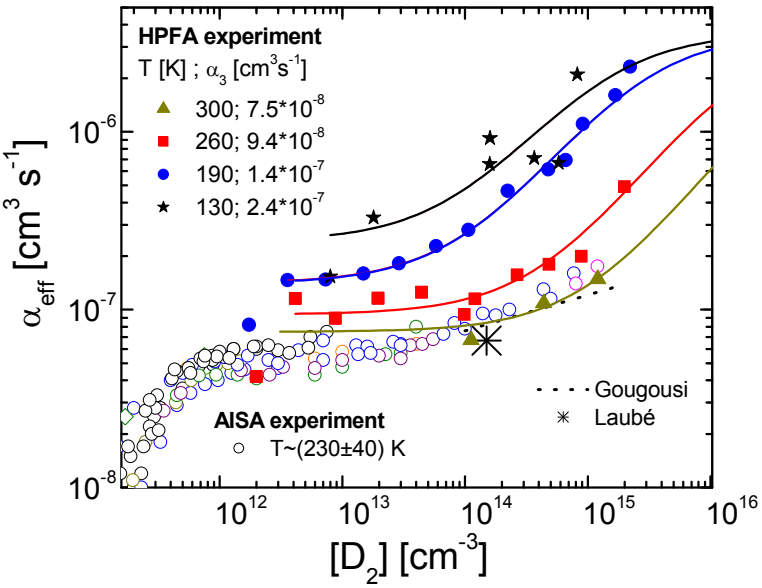

Figure 4. The effective recombination rate coefficients α_{eff} measured over a very broad range of hydrogen number densities on *AISA* (open symbols) and on *VT-FALP* (closed symbols) in a He-Ar-D_2 plasma mixture. The measurements on *AISA* were carried out at the temperature (230±40) *K*.

The obtained results are very similar to one obtained in previous measurements in the He-Ar-H_2 afterglow plasma [22]. Both hydrogen and deuterium plasma were successfully studied at similar conditions using Cavity Ring-Down Spectroscopy (CRDS) and preliminary results will be presented and compared with FALP and AISA studies. As was already mentioned spectra of D_3^+ ions were calculated [31] but not measured in frequency range covered by our diode laser. We have made first preliminary measurements of IR absorption spectra of $D_3^+(v=0)$ using continuous microwave discharge (see Fig. 2) and NIR-CRDS. Obtained spectra are plotted in Fig. 5. Using parallel absorption cell corresponding absorption spectra of H_2O molecule were also measured to increase accuracy of estimation of transition frequencies of $D_3^+(v=0)$.

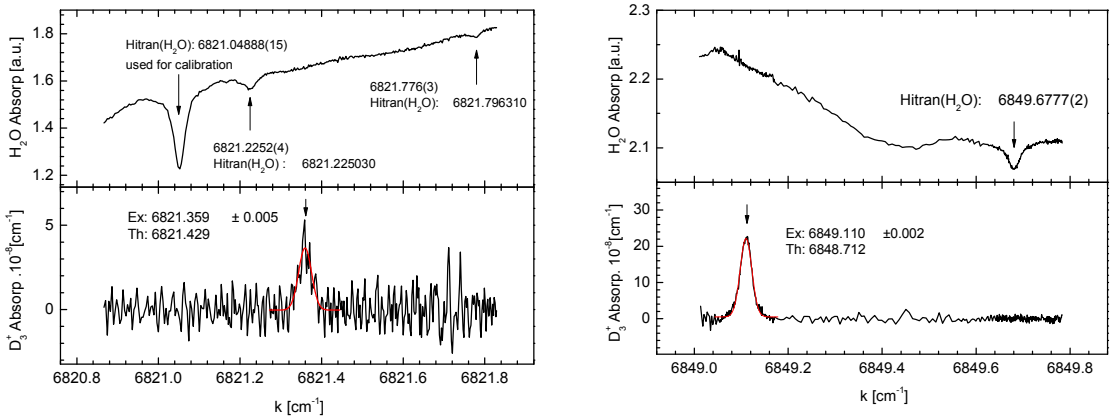

Figure 5. IR absorption spectra of $D_3^+(v=0)$ measured by NIR-CRDS. Ions were generated in continuous microwave discharge (see Fig. 2). In upper panels are plotted measured absorption spectra of H_2O molecule. Hitran tables, λ-meter and Fabry-perot etalon were used to measure frequency of transition.

Table 1. Notations of measured transitions together with theoretical [31] and experimental frequencies.

Re	J2	J1	E1	Th. Freq	Exp. Freq		
A1	1	1	43.609	6821.429	6821.359	±	0.005
E	3	2	85.627	6848.712	6849.05	±	0.050

Note excellent agreement of measured and calculated data. Agreement is far better as was agreement obtained in $H_3^+(v=0)$ studies, see CRDS study in ref. [32] and laser induced reaction study in ref. [34]. Obtained spectroscopic data will be used to measure recombination rate coefficient of $D_3^+(v=0)$.

Abstract
Plasma etching of PMMA (poly-methyl methacrylate) for microfluidic channel production has been performed by implementing either a hard-metallic mask or a polymeric *in situ* mask. Through this technique, an 80 μm-depth channel has been formed on PMMA, for application to rapid DNA-based analysis of genetically modified organisms. Plasma etch rate (ER) measurements are presented as function of the process parameters and they are correlated to plasma gas phase parameters. Relatively high ER was achieved (~1.5μm/min) with low voltage bias (-100V) at low pressures (0.53Pa).

1. Introduction

The fabrication of microfluidic devices with features of 10-1000μm size are of great importance in many fields of analytical science, where a small quantity of sample is available, enhanced resolution and sensitivity in separation is needed and increased functional integration is desired (medical, chemical and biochemical analysis, microchemistry etc) [1]. Even though the first microfluidic devices were fabricated on silicon and glass, the need for easy fabrication, low cost and disposability has recently shifted the attention on polymeric materials.

Microfabrication of polymers can be attained through many techniques such as hot-embossing, micro-casting etc [1]. The implementation of these methods entails the need for a mold fabrication, using standard microelectronic processes. Recently, deep plasma etching of polymers [2]-[4] has been proposed for the fabrication of polymeric microfluidic channels, thus introducing, a mold-free method. The implementation of plasma treatment presents some unique merits in that (i) plasma etching is an inherently mass production technique, (ii) the polymer is treated while being in its solid state, (iii) channel formation is performed in rather low temperatures (cold-plasma), and (iv) within the same plasma reactor several surface physicochemical and mechanical properties (wettability, hardness etc) may be modified, towards the requirements of the specific application. Moreover, plasma treatment is already proposed and in fact it is already widely used for the sealing of PDMS trenches with another PDMS or a glass-plate (providing the fourth wall), through what is referred to as 'plasma activation of PDMS'.

Plasma etching employs a patterned layer (above the plastic that will host the trench) which acts as a mask, enabling the plasma to engrave the plastic substrate only where it is required. This patterned layer should provide sufficient etch resistance throughout the plasma treatment. Hitherto, metallic-hard masks have been utilized, that provide outmost plasma resistance, but on the other hand, impose difficulties and complexity (wrinkles, curvatures etc), while sputtering of their surface contributes to channel roughness.

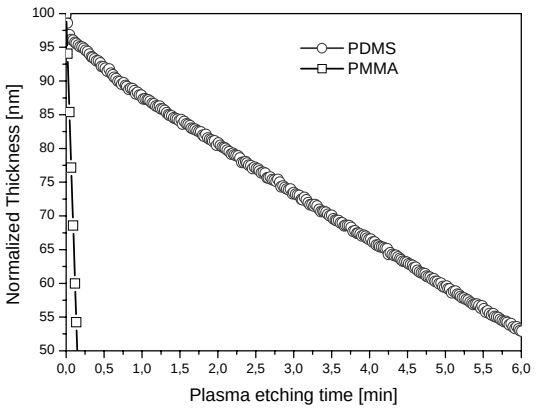

Fig. 1 Differential plasma ER of PMMA and PDMS during oxygen plasma treatment. High selectivity is obtained. Metals are virtually un-etchable in O_2-discharges.

In this work we present a method for fabrication of microfluidic devices based on the O_2 plasma etching of polymers -PMMA in particular- using a photosensitive silicon-containing polymeric mask (poly-dimethylsiloxane-PDMS). Our method relies on (i) the ability to lithographically pattern a thin PDMS layer and (ii) the differential plasma ER of the PDMS (top layer) and the underlying PMMA plate, as illustrated in Fig. 1. The etch resistivity of PDMS is attributed to the surface oxide layer formation, during the first seconds of the oxygen plasma treatment [5]. We also carried out plasma etching of PMMA following the conventional procedure; through a metallic -namely Al- mask.

The aim is to fabricate a plastic micro-device for DNA-based analysis of genetically modified organisms (GMOs) *via* capillary electrophoresis (CE) for separation and laser-induced fluorescence (LIF) for detection of GMO-specific sequences [6]. The rapid progress of recombinant DNA technology and its applications to agriculture has resulted in the development of genetically modified plants with herbicide or insect tolerance. In order to allow consumers an informed choice, various countries, including European Union and Japan, have set threshold values above which raw materials and food products must be labeled accordingly. A threshold value of 0.9% GMO content was set for EU. Although GMO testing may be accomplished by detecting either the novel protein synthesized by the transgenic plant or the foreign DNA introduced into the plant's genome, DNA is the preferred analyte due to its greater stability during food processing. Detection of GMO-specific DNA requires amplification of the sequences by using the polymerase chain reaction (PCR) and subsequent analysis of the products. Separation of the amplified fragments by agarose gel electrophoresis and ethidium bromide staining is currently the most widely used method of analysis. However this procedure requires at least 1 hour. We anticipate that by using microchip-based capillary electrophoresis of the amplified fragments we will achieve separation times of less than 1 min. Moreover, plastic chips have low cost and are disposable.

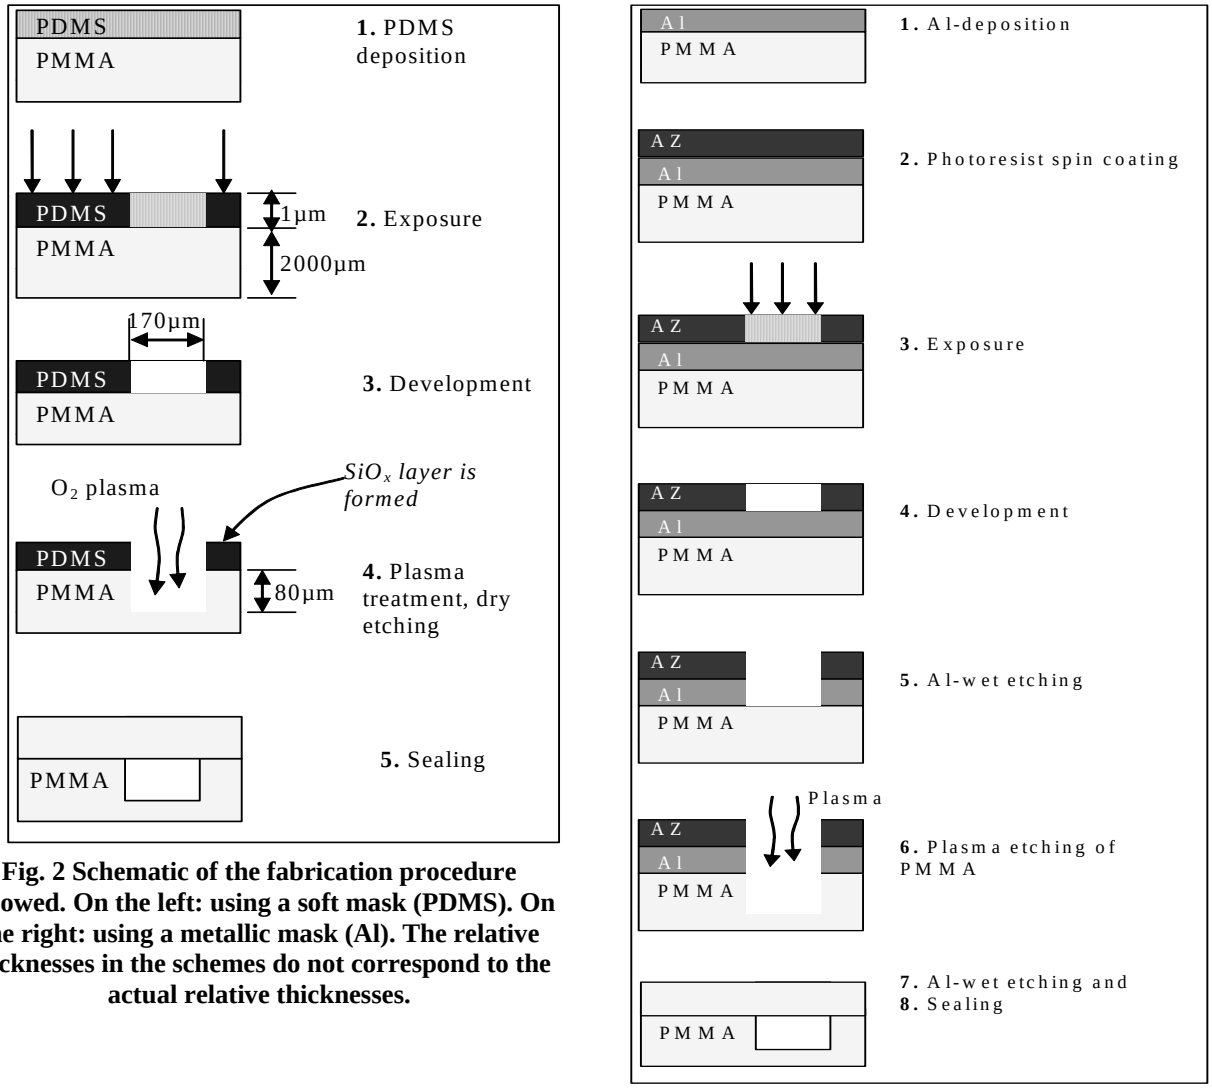

Fig. 2 Schematic of the fabrication procedure followed. On the left: using a soft mask (PDMS). On the right: using a metallic mask (Al). The relative thicknesses in the schemes do not correspond to the actual relative thicknesses.

2. Experimental

All devices are made of PMMA (2mm-thickness) by IRPEN. Two different methods were carried out, for lithographically defined masks that are summarized in Fig. 2. The first employs PDMS as a mask during plasma etching, while the second employs aluminum mask.

2.1 Lithography

With respect to the first one, photosensitive-PDMS solution (PS264, M_w=993k, 5-6% Diphenyl, 0.1-0.3% Methylvinylsiloxane copolymer, Gum from United Chemical Technologies, Inc), was spin coated on the PMMA-sheet. The PDMS layer (~1μm) was exposed through a photo-mask using broadband DUV radiation of an Hg-Xe arc lamp. The soluble part of PDMS was removed (developed) by means MIBK (methyl-isobutyl ketone) and IPA (iso-propyl- alcohol).

With regard to the second one, a thin (200nm) Al-layer was deposited on the PMMA-plate, using an electron gun evaporator. Then a typical photolithography procedure was followed; a commercial photoresist (AZ5214 from Clariant) was spin coated, and exposed through the same photomask as before. After the development of AZ the unprotected aluminum surface was wet-etched, within a thermally controlled tank.

2.2 Plasma etching

Pattern transfer was accomplished by oxygen plasma etching in an inductively coupled (ICP) etcher (MET) from Alcatel. Crucial for our experiments turned out to be the electrode temperature control. In our facilities this is ensured *via* He-backside cooling, which provide adequate temperature stability of the under-treatment specimen. The process variables of this plasma reactor are: plasma source power, bias voltage, gas flow, reactor pressure, and electrode temperature. These variables were properly tuned in order to achieve optimal results (see below in Results and Discussion).

The fourth wall of the channel was provided by another PMMA-sheet, that was thermally bonded to the plasma treated PMMA-plate.

ER was monitored *via in situ* spectroscopic ellipsometry, by J.A. Woollam (M2000), through appropriate procedure that has been described in detail elsewhere [7].

After the plasma etching the channels were sealed by thermal bonding with another PMMA-sheet (providing the fourth wall).

2.3 Gas phase characterization

Gas phase monitoring was performed by means of:

(i) Optical emission spectroscopy, by utilizing an Acton Research SP-500 monochromator with an SBIG CCD detector ST-6i. The subsequent optical actinometry performed by using Ar (actinometric gas) at 5% admixture in oxygen. Oxygen emission lines at 777nm and at 844nm and Argon emission line at 750nm were recorded during the tuning of the process parameters.

(ii) Ion flux measurements, by using an ion-flux probe by Scientific Instruments for determining ion fluxes.

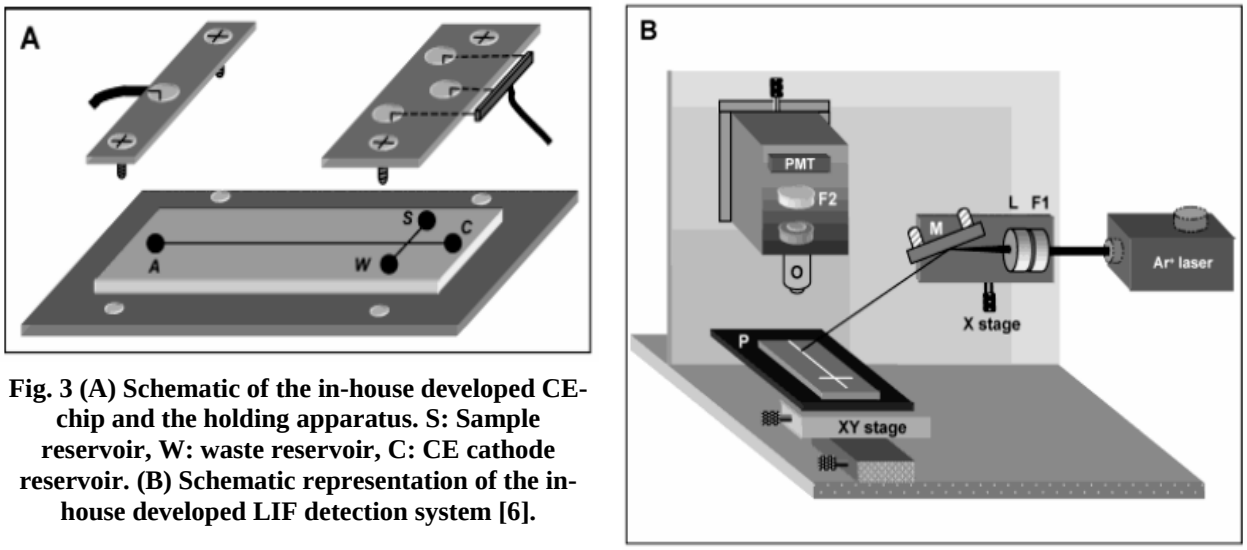

Fig. 3 (A) Schematic of the in-house developed CE-chip and the holding apparatus. S: Sample reservoir, W: waste reservoir, C: CE cathode reservoir. (B) Schematic representation of the in-house developed LIF detection system [6].

2.4 System setup for CE

The assembly of the chip is demonstrated in Fig. 3. In Fig. 3A the installation of the access holes and electrodes is illustrated. The overall analytic device and the detection setup is represented in Fig. 3B.

3. Results and Discussion

3.1 ER dependence on process parameters

In Fig. 4A and Fig. 4B the etch rate (ER) measurements of PMMA in oxygen plasma are presented as a function of the plasma source power and the pressure of the reactor. The aim is to find an optimum process condition set, with regard to the maximization of the ER; the higher the ER the shorter the total time needed for the process. As illustrated in Fig. 4A and Fig. 4B the ER increases vs. plasma source power and exhibits a maximum vs. reactor pressure. The higher achieved ER is ~1.5μm/min, which occurred at 1800W and at 0.53Pa. According to this result, the required time to engrave an 80μm trench would be 53min.

The ER strongly depends on the bias voltage (not shown here), indicating the ion-enhanced nature of the process. Gas phase characterization was performed to explain the above-mentioned variations of ER.

Actinometry was carried out to monitor the [O] variations during plasma treatment. Walkup et al [8] set out that the 844nm emission line must be selected rather than the 777nm emission line in order to follow the [O] profile. In Fig. 4C and in Fig. 4D we provide the information obtained through appropriate analysis of the optical emission data, namely the actinometric ratio $I_{O(844nm)}/I_{Ar(750nm)}$ vs. plasma source power and reactor pressure, respectively.

With respect to the effect of plasma source power, it can be seen that the actinometric ratio increases as the plasma power increases (Fig. 4C), in agreement with the measured ER. On the other hand actinometric ratio presents monotony throughout the measured pressures (Fig. 4D), while ER realizes a maximum. This behavior of the actinometric ratio is in accordance with previous published relevant studies [9], in a low-pressure distributed electron cyclotron resonance (DECR) plasma. This contradiction is solved through resonance absorption measurements in [9] indicating a local maximum of ground-state oxygen atom concentration at about 0.4Pa. The implementation of actinometry that hinges on the fact that only electron impact excitation of [O] occurs, seems to be questionable under these experimental conditions; the dominant mechanism for the production of the 844nm emission line under these conditions is dissociative excitation.

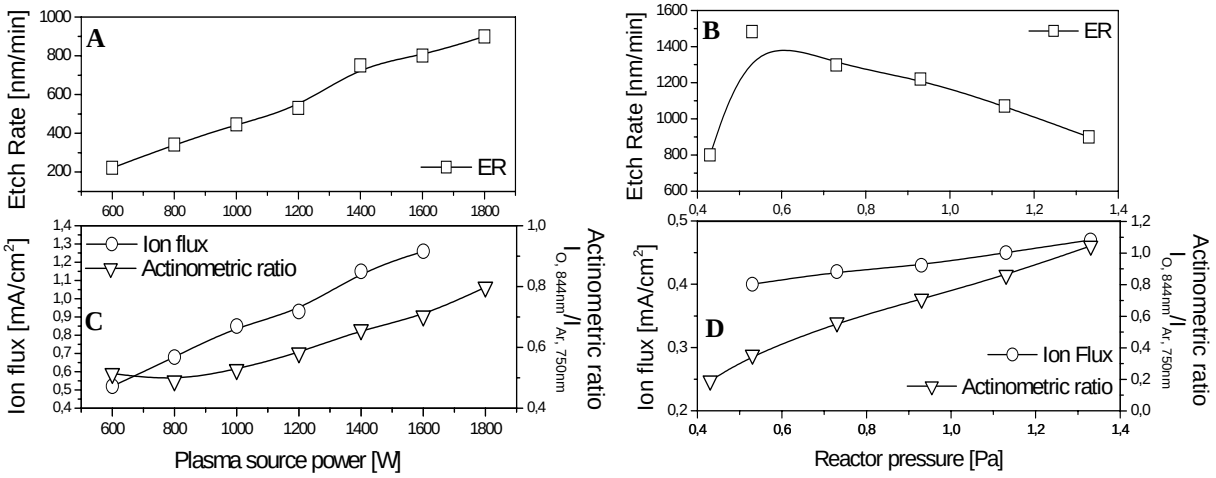

Fig. 4 (A) O_2-plasma etch rate measurements of PMMA vs. plasma source power [Electrode temperature: 15°C, Bias Voltage: -100V, O_2 flow: 100sccm, reactor pressure: 1.33Pa]. (B) O_2-plasma etch rate measurements of PMMA vs. reactor pressure [Electrode temperature: 15°C, Bias Voltage: -100V, O_2 flow: 100sccm, plasma source power: 1800W]. (C) Actinometric ratio $I_{O(844nm)}/I_{Ar(750nm)}$ and ion flux measurements of the oxygen-ICP vs. plasma source power and (D) vs. reactor pressure. The actinometric ratio in (D) has been appropriately treated to include the pressure dependence. In all cases lines are only to guide the eye.

Ion flux measurements designate an increment of J_+ with plasma power (Fig. 4C), which is in correlation with the ER measurements. Increase of plasma source power results in higher electron density and subsequent larger degree of dissociation and ionization. On the other hand J_+ remains practically constant (small increase) with pressure (Fig. 4D), while ER presents a maximum. We suspect that the collisions (mainly charge exchange collisions) in the sheath decrease as the pressure drops resulting in higher energy of the ions and so higher ER. This trend is limited by the decrease of the concentration of the oxygen species (Fig. 4D) as the pressure drops. This trade-off is found to realise a maximum at 0.53Pa.

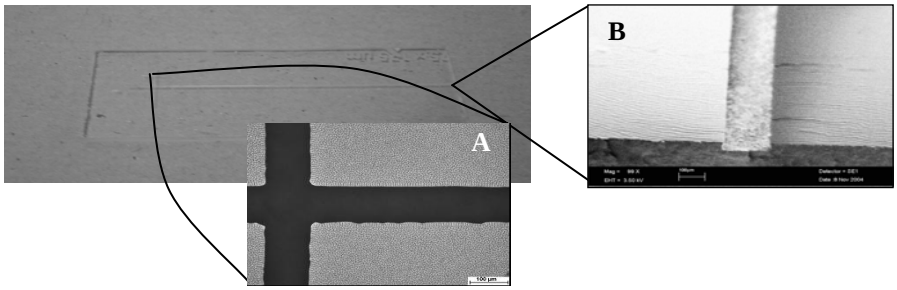

Fig. 5 The microfluidic channel before the sealing. The transparency of PMMA remains intact. (A) Detail of the cross by optical microscopy and (B) cross section of the trench by SEM.

3.2 Surface characterization

The plasma treatment induced manifold changes to the PMMA-plate. First of all PMMA has been patterned according the lithographically defined prototype. Fig. 5 demonstrates the PMMA-plate right after the plasma treatment (before the sealing). Optical microscopy photos (Fig. 5A) reveal the precise pattern transfer (fluctuations at one edge are due to the low quality of the photomask). Secondly, plasma treatment has modified the PMMA surface with regard to its wettability; the initially weakly hydrophilic surface (water contact angle=60^o) became highly hydrophilic (water contact angle=5^o) after the treatment. Finally, plasma treatment caused development of surface roughness (see Fig. 5B). This latter, plasma-induced effect, can be primarily attributed to micro-masking due to Si/Al sputtered material. The highly anisotropic character of plasma etching, due to the ion-enhanced chemical nature of the process, further amplifies/enhance the magnitude of the roughness. This of course is a drawback, imposing difficulties and worries for the subsequent optical detection, if the laser beam goes through the plasma treated plate instead through the non-treated channel cover plate. We are currently working to reduce the surface roughness, by appropriate tuning of the process parameters and/or by a post-etching procedure of the treated surface.

4. Conclusions

A PMMA microfluidic chip was fabricated by means of plasma etching. Thus, patterning and wettability control was accomplished simultaneously. This chip will be evaluated through capillary electrophoresis analysis of DNA (study under way).

Toluene destruction by DBD at atmospheric pressure: Identification of reaction pathways by isotopic labeling and use of the plasma DBD as a pretreatment for adsorption

S. Ognier, L. Martin, J. Amouroux
Laboratoire de Génie des Procédés Plasmas et Traitement de Surfaces, 11 rue Pierre et Marie Curie, 75231 Paris Cedex France

Abstract:
An hybrid process combining a plasma DBD discharge and an adsorbent bed was used for the removal of toluene, a mono-aromatic molecule that simulates volatile aromatic pollutant (VOCs). The first objective of the study was to understand the role of active oxygenate species produced by streamers in oxidation and polymerisation mechanisms of aromatic and polyaromatic compounds. The potentiality of plasma pretreatment for optimising the use of adsorbant for the treatment of polluted gaesous effluent was then demonstrated.
Key words:
Dielectric Barrier Discharge, isotopic labeling, toluene, VOC, adsorption

Introduction

Air pollution control is focused by European Union these last years. Two techniques are investigated for treating gaseous effluents containing VOCs at ppm and sub-ppm levels: adsorption [1] and non-thermal plasma [2,3] processes. However, severe limitations still exist in the use of these two techniques. On one hand, plasma processes that are developped with the objective to completely oxidise pollutants in COx encounter two severe limitations: high energetic cost and incomplete oxidation leading to by-products release. On the other hand, adsorption processes are limited by the regeneration costs and the life duration of the adsorbent.

In view of these considerations, a new process coupling a plasma pretreatment followed by an adsorption step is proposed in this study. In a first step, the plasma discharge is used to chemically modify the initial pollutant, to decompose it into smaller molecules or to polymerise it into larger molecules: these reactions contribute to enlarge the distribution of the species. As a result, in the following step, the adsorption process is favored by the large distribution of chemical species : the number of available adsorption sites is increased and therefore the life of adsorbent is enhanced.

In the first part of the study, isotopic labeling experiments were carried out to identify reactional pathways, in particular the role of oxygen in polymerisation and oxidation reactions. The reactor used was a multipoint-to-plane dielectric barrier discharge reactor already used for NOx destruction [4,5]. In the second part, the combination of plasma pretreatment by DBD discharge and adsorption was investigated in a system coupling a wire-cylinder plasma reactor and a fluidized bed of zeolithes.

Experimental

A general view of the experimental setup is presented Figure 1. Gas used to simulate the polluted effluent is a mixture of oxygen (10%), H_2O (1.8%) and toluene in nitrogen. Gas mixture is introduced in the reactor with a flowrate of 3 or 3.5 NL/min heated at 373K (figure 3). Bubbling method was used to set toluene and water concentrations in the gas stream. The concentrations were set by controlling either the flow rate of nitrogen or the temperature of water bath.

In isotopic labelling experiments, a multipoint-to-plane corona discharge reactor was used. Two mixtures were studied: one containing non labeled molecules, with a toluene concentration of 700 ppmv and the other one containing $^{18}O_2$ and toluene three times deutered on methyl group, with a concentration of 200 ppmv. The total mixture flow was 3 l/min.

The second set of experiments consisted of combining a plasma reactor followed by an adsorbant bed. Therefore, the gaseous mixture undergoes first a plasma discharge pretreatment, then it flows through a fluidised adsorbant bed so that the residual toluene as well as the by-products formed from toluene in the plasma discharge are removed by adsorption. The plasma reactor was a wire cylinder reactor. The adsorbant bed is a glass tube of 40 mm diameter filled of 18 g of zeolithes (Mordenite, Si/Al ratio : 60, specific area :

300 m^2/g, density : 0,5 g/cm^3, average diameter : 240 µm). The gaseous flow allows the bed of zeolithes to be at the minimum fluidisation velocity. Gaseous mixtures at toluene concentrations of 100, 400 and 700 ppmv toluene were treated at atmospheric pressure. The total mixture flow was 3.5 l/min.

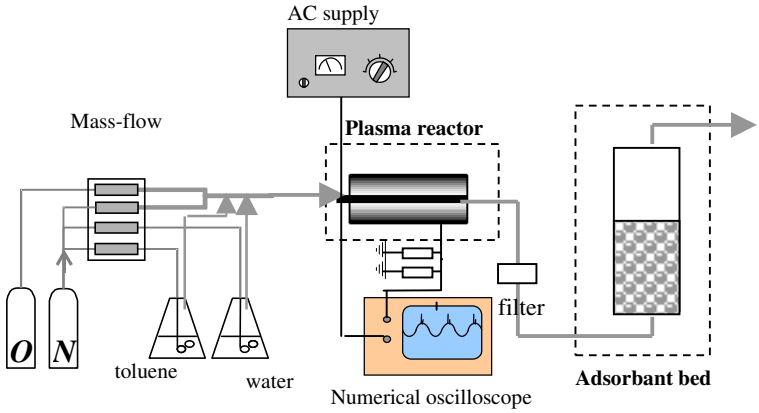

Figure 1: Experimental process and electrical setup

DBD discharge reactors :

The multipoint-to-plane corona discharge reactor is presented figure 2. The stainless steel high voltage electrode is a 4 mm wide and 22 mm diameter disc where thirteen tips are fixed. Each one is 5 mm long, 1 mm diameter and has a 100 µm curving radius. Twelve holes permit gas flowing across the high voltage electrode disc to the inter-electrode zone. The space between tip extremities and dielectric material is fixed at 2 mm. Dielectric used is stumatite, a natural alumino-silicate covering the grounded electrode. It is a 31 mm diameter disc, 4 mm thick; flaps covering the electrode on 4 mm high to center it. The grounded electrode is a stainless steel disc (25 mm diameter, 6 mm thick). Figure 3 presents the wire-cylinder plasma reactor. It consisted of an emitting stainless steal rod (length of 35 mm, diameter of 7 mm) held in the center of a cylinder (internal diameter of 11 mm) made of two layers of dielectric materials (7 mm thick stumatite and 3 mm thick glass) and covered by a copper cylinder. The space between tip extremities of the rod and dielectric material is 2 mm.

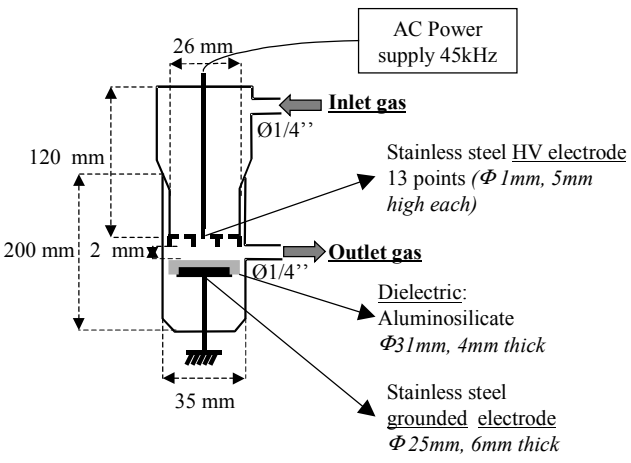

Figure 2: Depollution multipoint-to-plane reactor

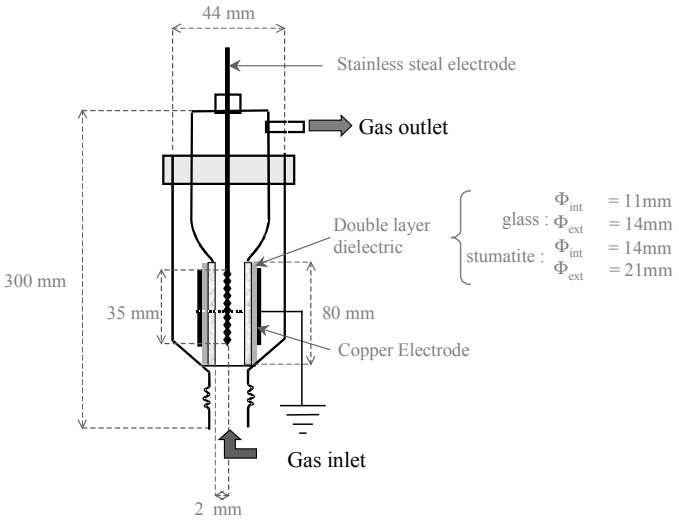

Figure 3 : Wire-cylinder Plasma reactor

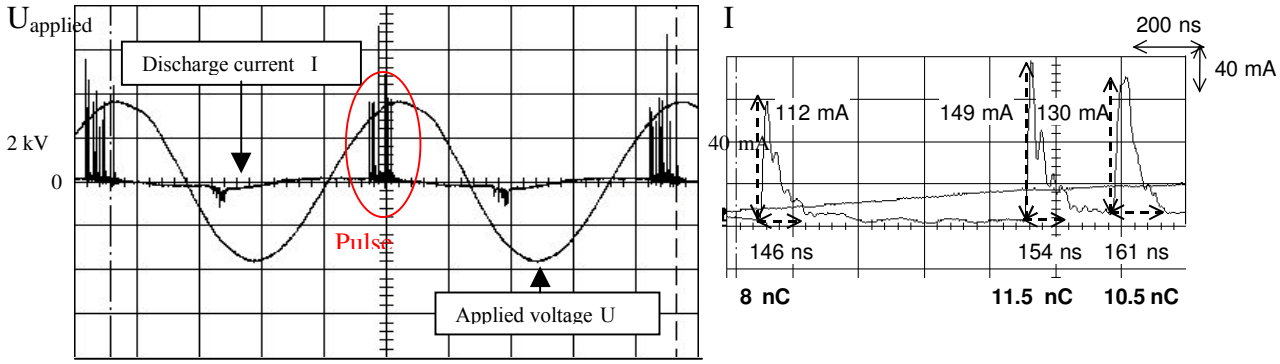
Products analyzing:
Toluene and toluene decomposition by-products characterised by a carbon number higher than one were analysed by Gas Chromatography coupled with a Mass Spectrometer (GCtop/Automass II, Porabond Q, carrier gas He,Thermoelectron). CO and CO_2 were quantified with a GC equipped with a TCD detector (IGC, Carboxen, carrier gas He, Intersmat). Gaseous samples were taken at the outlet of the plasma reactor and before the inlet of the adsorbant bed to determine the toluene conversion rate induced by the plasma pretreatment and the nature of the by-products formed. To estimate the performance of the adsorbant bed for trapping toluene and plasma by-products, gaseous samples were as well taken at the outlet of the adsorbant bed. Heavy decomposition by-products were trapped on filters (Teflon ® glass, Pall Gelman DOP 0.3 µm) located at the exit of the plasma discharge zone then extracted into liquid phase (CH_2Cl_2 ¾, acetone ¼) with a soxhlet during 24 hours before being analysed by GC-MS. Labeled and non-labeled molecules are determined by mass spectroscopy analysis, thanks to the ion fragment mass difference.

Electrical setup and pulses characterization:
A high voltage generator supplies from 5 to 30kV peak to peak (U_{pkpk}) alternative voltage while a LeCroy LT 342, 500 MHz digital oscilloscope acquires the electrical characteristics of the corona discharge. A typical oscilloscope screen is presented on figure 4. The pulse currents are responsible of chemical activity.



(a) (b)

Figure 4: Oscilloscope screen showing applied tension and reactor electrical response (a) and enlarged oscilloscope screen (b) showing elementary pulses (*multipoint-to-plane reactor, P = 18.15 W, P = 10^5 Pa, D = 3L/min at 373K, [Toluene] = 200 ppm, O_2 10 %, H_2O 1.8 %, N_2 balance*

The discharge power P was computed by the integration on two entire periods of instant applied voltage. Medium tensions of 3.4 kV and 4.85 kV were chosen for the multipoint-to-plane and the wire-cylinder reactors, corresponding to energy densities of 360 J/L and 220 J/L respectively.
Pulse characteristics (duration, current, pulses frequency and number of pulses during one period…) are determined thanks to enlarged oscilloscope screen (figure 4b). Each pulse is the electrical signature of electronic activity in the reactor. The characteristics of the impulsionnal component of the discharge for the multipoint-to-plane reactor are summarized in table 1.

Effective applied tension U_{eff} (kV)	3.40	Average pulse duration (ns)	109
Active power (W)	18.15	Average pulse max current (mA)	123
Energy density (J/L)	360	Average pulse charge (nQ)	6.7
Number of pulses on one period	8	Charge on one period (nC)	50

Table 1: Electrical discharge parameters and pulses characteristics for the labeled test

During one period, the electrical charge collected is 50 nC, what corresponds to $0.5.10^{-12}$ moles of electrons. This quantity is low compared to the quantity of oxygen flowing through the reactor during one period : $3.8.10^{-9}$ moles. That means that electrons are in the minority and that only a small ratio of oxygen could excited if there is accordance between electronic energy distribution function and oxygen excitation cross section. The same procedure allows to obtain an electrical charge collected of 50 nC for the wire-cylinder reactor at an energy density of 220 nC.

Results and discussion

Performance of DBD reactors for toluene decomposition

The performance of the two plasma reactors for toluene destruction was first investigated. Table 2 shows the toluene conversion rates and the quantity of toluene destroyed (ppm) according to the pollutant input concentration for both reactors. The results show that the toluene conversion rate decreases when the toluene input concentration increases. For example, the toluene conversion rate decreases from 85% to 15% when the toluene input concentration increases from 100 to 700 ppm in the wire-cylinder plasma reactor. On the contrary, the quantity of toluene destroyed in the plasma discharge remains almost unchanged whatever the toluene input concentration, about 100 ppm in the wire-cylinder reactor and 150 ppm in the multipoint-to-plane reactor respectively. Therefore, in these experimental conditions, the kinetic of toluene removal does not depend on toluene concentration.The limiting step could be the production of active species by the discharge. The results show as well that for a given energy density, the quantity of toluene destroyed is 50% higher in the MPP reactor compared to the Wire-Cylinder reactor. This result could be explained by the fact that the impulsionnal charge is higher in the MPP reactor (50 nC) than in the Wire-Cylinder reactor (20 nC).

Toluene input concentration	*Toluene conversion rate*	*Quantity of toluene destroyed*
Wire-cylinder reactor (Q = 3.5 l/mn, DE = 220 J/l)		
100 ppm	85 %	85
400 ppm	25 %	100
700 ppm	15 %	105
Multipoint-to-plane reactor (Q = 3 l/mn, DE = 360 J/L)		
700 ppm	20 %	140
200 ppm	80 %	160

Table 2 : Results obtained for toluene conversion in DBD plasma reactor
(P = 13 W, Q = 3.5 l/min)

Figure 7 shows the carbon balance–sheet for treatment of 400 ppm of toluene in the wire-cylinder plasma reactor. Light hydrocarbons CO, CO_2 and heavy by-products condensed on the filter at the exit of the plasma reactor represented respectively less than 20 % and 10 % of the toluene by-products. Among these compounds, monoaromatic compounds with oxygen and/or nitrogen containing groups (benzilic alcohol, benzaldehyde….) were the main by-products of the plasma pretreatment. Lee et al. [6] obtained a similar result using a DBD plasma to treat 100 ppmv of benzene at atmospheric pressure. At a specific energy density of 680 J/L, the benzene conversion rate was 80% but the benzene was not completely but partially oxidised in secondary products such as phenol, benzenediol and more oxidised form of benzaldehyde and benzoic acid.

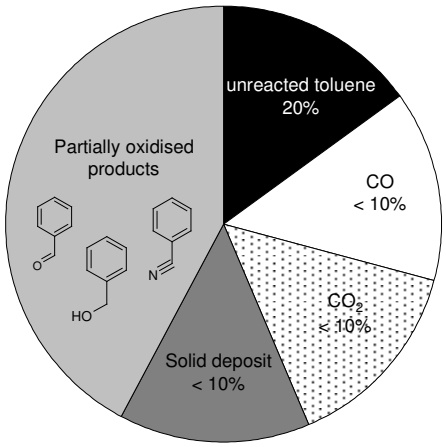


Figure 7: Carbon balance-sheet for treatment of a mixture (O_2 (10 % vol) and H_2O (1.8 % vol) in N_2) with 400 ppm toluene at a Specific Energy Density of 200 J/L in the wire-cylinder reactor

Identification of reaction pathways by isotopic labeling

Isotopic labeling was then used to identify reaction pathways and to understand the role of the different species in the chemical reactivity of the plasma discharge.The by-products identified by GC-MS analysis at the outlet of plasma reactor are presented figure 8. When they are present in a molecule, labeled atoms are pointed out according to : ^{2}H for deuterium and $^{18}0$ for oxygen.

The results show first that there is a large distribution of by-products. The volatile by-products can be classified in linear hydrocarbon compounds (propane, propyne), linear hydrocarbon compounds with oxygen or nitrogen containing groups (acetaldehyde, isocyanomethane), aromatic compounds (benzene, ethylbenzene) and aromatic compounds with oxygen or nitrogen containing groups (benzaldehyde, benzonitrile). Among the condensed by-products, alkans and alkens (linear or ramified, containing from 3 to 22 carbons), polyaromatic compounds and polyaromatics compounds with oxygen containing groups can be distinguished. The presence of oxidized light or heavy molecules confirms oxidation by –OH or –O radical as frequently shown in non thermal plasma discharges.The heavy molecules highlight that polymerization phenomena can take place during plasma treatment. Most of heavy molecules have an aromatic core. Therefore, polymerization is done rather by fragment attachment than by cycle opening.

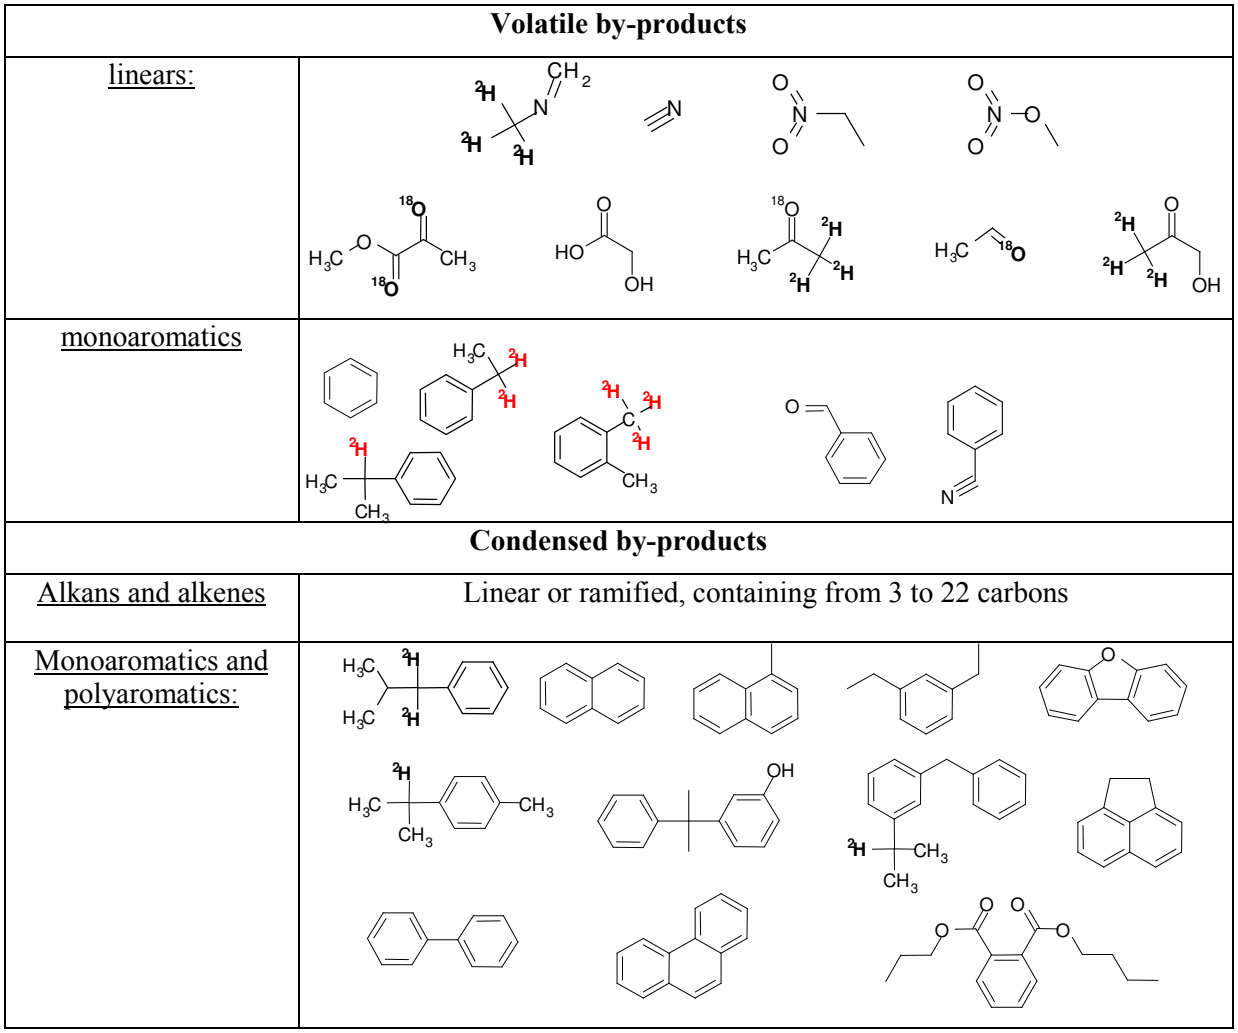

Figure 8: By-products detected by GC-MS analysis

According to these results, the following assumptions can be made about the reaction pathways characterizing the plasma reactivity: First step is the formation of radicals from the toluene compound by direct breaking by the excited species of the DBD reactor (electrons and/or heavy species). Then, radicals formed in the first step are undergoing oxidation and/or recombination reactions. Recombination reactions lead to long carbon chains (alkanes and alkenes) and poly-aromatic compounds. Concerning oxidation reactions, two types of oxidants can be distinguished : oxidants coming from molecular oxygen and oxidants coming from H_2O. The isotopic labeling shows that the nature of the products is highly depending on the

oxygen source. If the distribution of oxygen atoms is investigated, it can be observed that labeled oxygen atoms coming from molecular oxygen are only contained in small-oxidised molecules as ketonic functions. On the contrary, aromatic oxidised compounds contain only unlabeled oxygen atoms coming from H_2O. This result indicates that the active species coming from oxygen lead rather to oxidation reactions with carbon chain cleavage whereas oxidants coming from H_2O (for example hydroxyl radical OH°), less energetic, lead rather to addition reactions. The N-excited atoms react to produce essentially small molecules. Therefore, N-atoms are not involved in macromolecules formation but react only with small molecules and/or radicals. For example, nitrate oxides are formed by reaction of active oxygenate species coming from water with nitrogen and nitrate molecules are formed by reaction of carbon radicals (as $\cdot CH_3$) with ·N radicals. These reactions are usual in plasma medium [7]. Main reactions occuring in the DBD reactor are summarized in Figure 9.

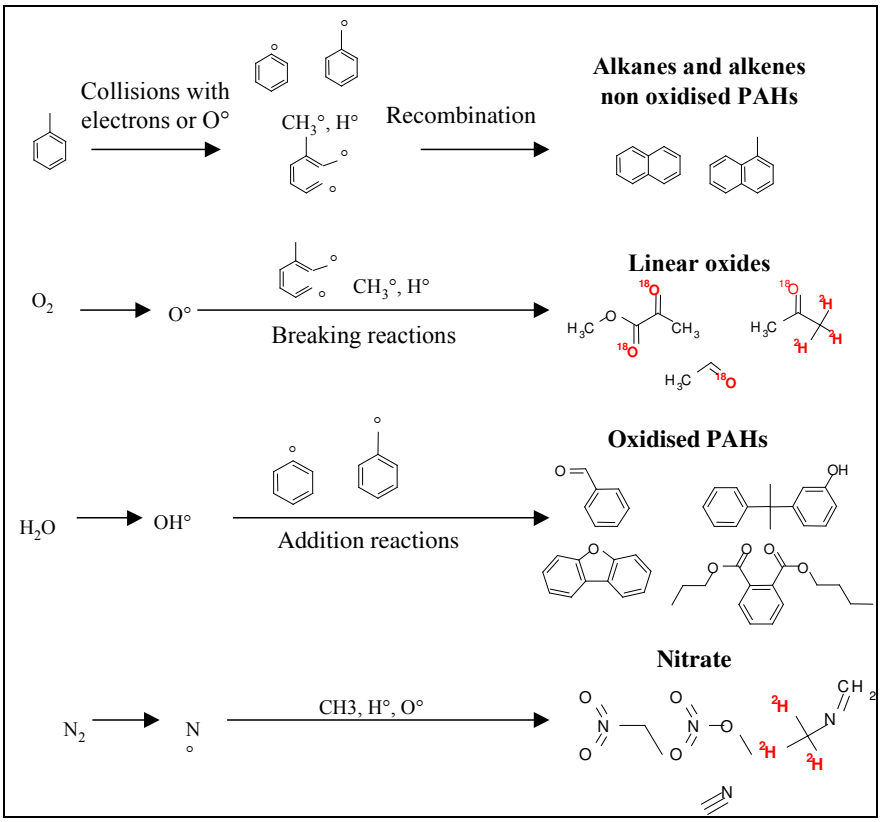

Figure 9 : Reactional pathways

Toluene and toluene by-products adsorption study

To determine wether the plasma discharge can enhance the use of an adsorbant in the treatment of polluted gaesous effluent, the adsorption of toluene and toluene by-products in a fluidized bed of zeolithe located at the exit of the plasma reactor was studied. For 400 ppm toluene concentration at the inlet of the process combining a plasma reactor (wire-cylinder) followed by an adsorbant bed of zeolithes, figure 10 shows the toluene concentrations at the outlet of the plasma discharge and the time evolution of toluene concentration at the outlet of the fluidized bed. The results show that the adsorbant bed is saturated in toluene after about 2 hours.

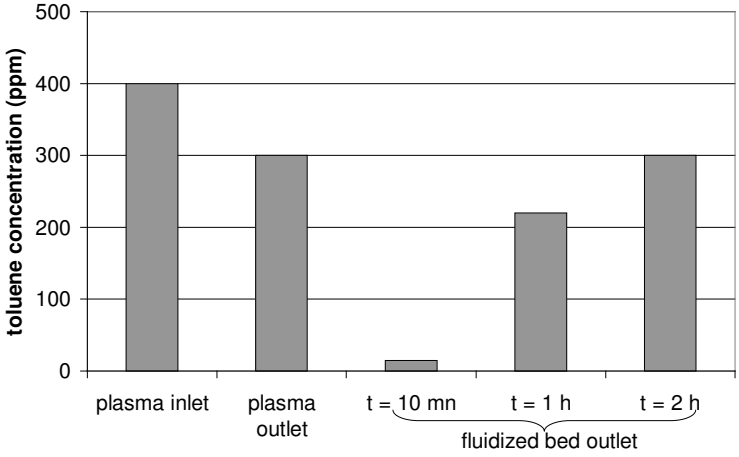

Figure 10 : toluene concentrations at the inlet (a) and at the outlet (b) of plasma reactor and time evolution (c) of toluene concentration at the exit of fluidized bed (Wire-cylinder reactor, Q = 3.5 l/mn, 400 ppm toluene)

The evolution of the relative concentrations of benzene, ethylbenzene, propyne, acetaldehyde, benzaldehyde and benzonitrile for 400 ppm toluene inlet concentration are presented figure 11. The relative concentration is defined as:

$$C_{relative} = \frac{C_{outlet\ of\ adsorbent\ bed}}{C_{inlet\ of\ adsorbent\ bed}}$$

The results show that after 2 hours, benzene and ethylbenzene concentrations at the inlet and at the outlet of the adsorbent bed are equal. This means that there are no more free adsorption sites available for these two compounds. On the contrary, the relative concentrations of linear hydrocarbons and aromatic coumpounds with oxygen or nitrogen containing groups are still lower than 1.0 after two hours of experiment.

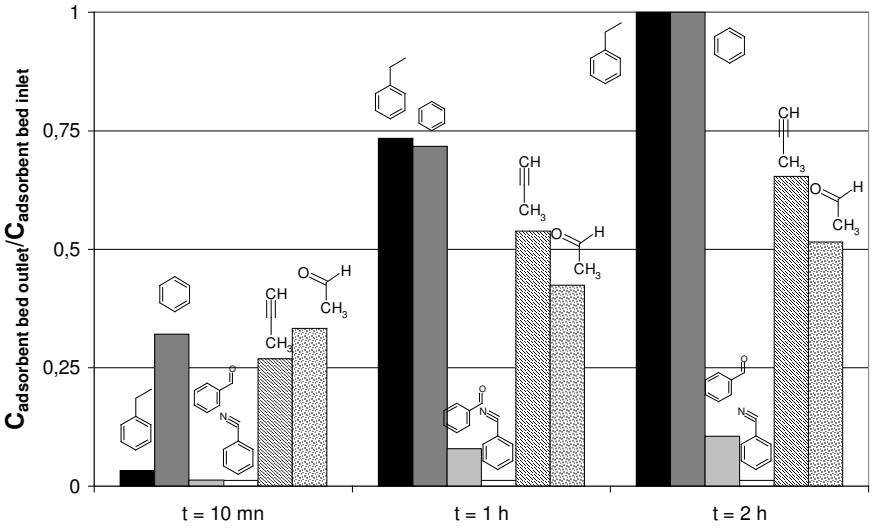

Figure 11: Evolution of relative concentrations of plasma by-products at the outlet of adsorbent bed (gas mixture: 10 % O_2, 1.8 % H_2O, 400 ppm toluene in N_2, Q = 3.5 l/min, Pplasma = 13 W, $m_{adsorbant}$ = 20 g)

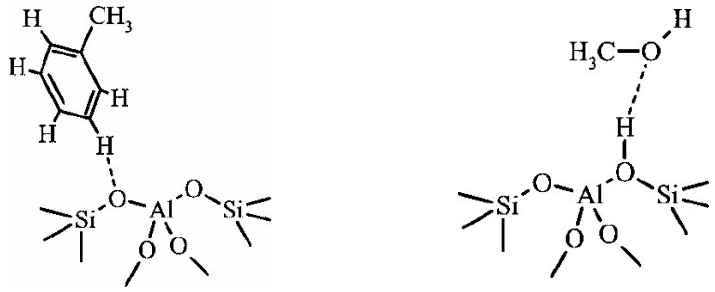
These results show that among the different species formed in the plasma, some are trapped on adsorption sites different from those used for toluene adsorption. Aromatic compounds containing oxygen and nitrogen groups such as benzaldehyde and benzonitrile are trapped on adsorption sites different from those used by toluene, benzene or ethylbenzene because of their electrophilic nature. In fact, Vos et al. [8] showed that the adsorption sites are different for hydrophobic and hydrophilic molecules (figure 12). Considering the linear molecules, they can adsorb on adsorption sites which were unavailable for toluene due to steric hindrance.



a) b)

figure 13: Interactions between hydrophobic (toluene, a)) and hydrophilic (methanol, b)) molecules and mordenite leading to the trapping of species [9]

Conclusion

In this work, a dielectric barrier discharge reactor was developed to identify depollution mechanisms in a gas mixture air + toluene. A mass balance on by-product was computed in order to underline the importance of oxidation and polymerisation in the process. Toluene and oxygene were labeled by deuterium on methyl group and ^{18}O in order to understand reactional pathways for toluene destruction in the DBD reactor. The oxygen active species lead to the breakage of carbon chains to form light oxidised compounds (C <5) and are also unfavourable in terms of polymerisation reactions. The oxygen atoms contained in heavy (C > 5) oxidised compounds came from H_2O molecules, underlining the role of OH radicals in the formation of these compounds.

The potentiality of plasma pretreatment for optimising the use of adsorbant for the treatment of polluted gaesous effluent was as well demonstrated in this preliminary study. The results showed that the secondary products formed from toluene by the plasma pretreatment were adsorbed on adsorption sites different from those used by toluene due to the chemical and sterical modifications induced in the plasma. As a result, with a plasma pretreatment step, the number of usable adsorption sites is increased compared to the sole adsorption process. Additional experiments are in progress to improve the step of the plasma treatment.

Optimization of transfer arc torch operating at low Reynolds number

O.P. Solonenko, K. Takeda(*), A.V. Smirnov
Institute of Theoretical and Applied Mechanics, SB RAS, Novosibirsk, Russia

Abstract
Transfer arc torch operating at relatively low mass flow rate of a working gas (low Reynolds number) has been developed and optimized in respect to provide a stable arc burning at distance between a nozzle exit and anode surface about 0.1 m. The effect of geometry of the outlet forming nozzle on transfer arc stability has been studied. The torch developed is rather attractive for surface engineering (modification, hard surfacing, etc.) when it necessary to apply a high density surface heat source.
Key words: transfer arc, torch, Reynolds number, stable arcing, optimization

1. Introduction

The plasma guns with a transfer arc are the effective means of surface treatment (cutting, welding, surfacing, surface modification, etc.) since the density of heat flux in the arc spot could reach the value of 10^9 W/m^2 and more. Depending on the functionality the requirements stated to such plasma guns are specified in different ways. For instance, when applying transfer arc for cutting the metals and alloys the continuous evacuation of the material occurred in a resulting molten pool is required. This could be provided only in the case of sufficiently high dynamic pressure of the impinging plasma flow. On the contrary, for welding, surfacing or surface modification one should guarantee a low level of the dynamic pressure at the arc spot providing high level of thermal flux power density. This is to prevent a destruction of fused surface layer.
A similar problem takes place when plasma jet is used to process the surface. Here, the application of the gun with turbulent plasma jet at small stand-off distances (~ 5 gauges between nozzle exit and a surface to be treated) would lead to destruction of the fused surface layer because of high dynamic pressure of plasma jet. If the stand-off distance is increased one is not able to heat the surface up to the given temperature and aggregate state of a surface layer as the length of high-temperature zone of the plasma jet is small owing to high turbulence extent of the jet. Latter results in the reduction of the thermal flux density. In Fig. 1 there are presented experimental data obtained [1] when changing the mass flow rate G of nitrogen and the dimensionless distance $\bar{z} = z / D_n$ between the outlet of nozzle with inner diameter D_n and a flat surface (curve 1 – $\bar{z}$=6, 2 – $\bar{z}$=8, 3 – $\bar{z}$=10; $N=\eta \cdot I \cdot U$ is a thermal power of the torch, and η is its efficiency) at the arc current I=240 A. Value of the Reynolds number $\mathrm{Re} = \bar{u}_{f0} D_n / \bar{\nu}_{f0}$ calculated in the cross section of the nozzle exit varied from 540 to 890. It was calculated at mean–mass plasma velocity and temperature defined by the calorimetric method. As it can be seen from Fig. 1, when G increases from 0.4 g/s to 0.8 g/s (Re number increases from 340 to 580 correspondingly), the linear growth of the integral heat flux into barrier is observed, and it depends on two factors. Firstly, with the increase of G the plasma torch power P increases. Thus, the mean–mass specific enthalpy of plasma at the nozzle exit and consequently the temperature increase and, secondly, the increase of the mass flow rate of the working gas leads to the increase of the heat flux from jet to the surface.

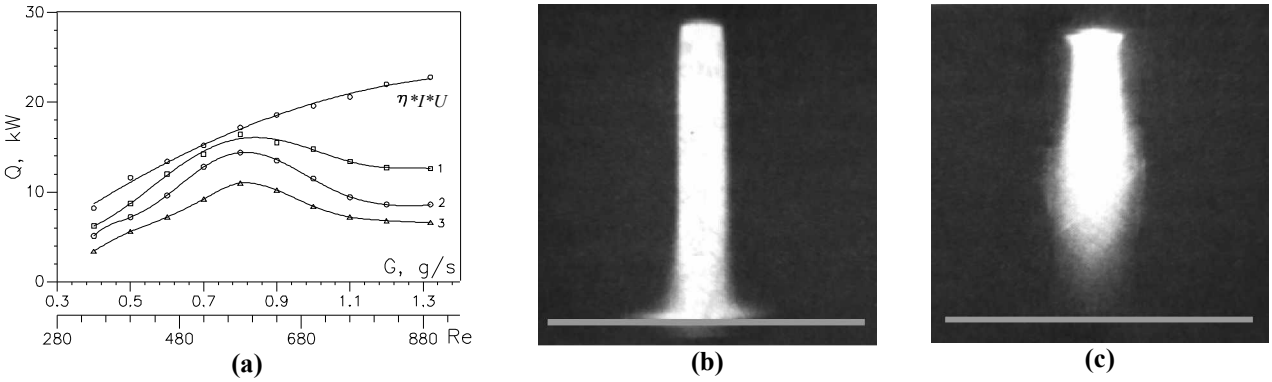

Fig. 1. The integral heat flux from nitrogen plasma jet into obstacle vs. mass flow rate of working gas (Reynolds number) – (a): $\bar{z}$=6 (1), 8 (2), 10 (3). Plasma jet impinging on flat obstacle at $\bar{z}$=8: (b) – Re=580, (c) – Re=820.

With a further increase of G, in spite of the growth of the useful plasma torch power, the decrease of the heat flux into the obstacle begins. The cause of this decrease is the transition of the plasma jet flow from laminar to turbulent regime at Re=580. Consequently, this increases the heat and momentum losses because of more intensive mixing with surrounding atmosphere.

The effect of geometry of the outlet forming nozzle on the stability of plasma jet outflow at reduced Reynolds numbers has been studied in [1, 2]. The following configurations of the outlet nozzle have been tested: cylinder, diffuser and the backward-facing step. The last design has been revealed to show the best result, when the ratio $L/\Delta r$ being ≤ 5 (L is the length of step, and Δr is its height). Here, the flowing out jet does not interact with the wall of the backward-facing step. Besides, within the internal region of a stepped part of the nozzle the additional ambient gas is leaked-in, thus stabilizing the jet. For this design the maximal axial temperatures have been attained in other conditions been equal.

Thereupon, the problem of designing the plasma guns providing a long transfer arc stable operation as well as stable outflow of plasma jet at low Reynolds numbers is to be solved.

The purpose of the paper presented is to study the possibility to develop a transfer arc DC torch providing soft argon arcing at as low as possible Reynolds number when the distance between the outlet of the forming nozzle and water cooled anode is about 100 mm. The Reynolds number is defined by formula $\mathrm{Re} = 4G_{\mathrm{Ar}} / \pi D_{n,i} \mu_{f0}$, where G_{Ar} is the mass flow rate of working argon, $D_{n,i}$ is the inner diameter at inlet of the forming nozzle, and μ_{f0} is the dynamic viscosity of plasma gas at mean-mass temperature at inlet of the forming nozzle. The diapason of arc current is 150–400 A, and flow rate of argon is 5-15 liter/min (0.15–0.4 g/s).

2. Experimental conditions

The plasma gun cathode of 4 mm diameter is made of lanthanum tungsten and is soldered into copper water-cooled holder. Plasma gun forming nozzle (see Fig.3) is made from M1 grade electrical copper. Both the cathode and the nozzle have external water cooling. Positive polarity electrode (anode) was the water-cooled copper disk being simultaneously a sensor of heat flux from an anode arc spot as well as from flowing plasma jet. The schematic of the water-cooled anode is depicted in Figs. 4 and 5. Temperature of anode cooling water at both inflow and outflow points were measured using thermocouples. This allowed one to determine integral heat fluxes into the anode. Concurrently inflow and outflow cooling water temperatures of negative polarity electrode (cathode unit) of the plasma gun were measured. The latter made it possible to estimate total heat losses in the cathode unit and plasma gun forming nozzle as well. Cooling water pressure at plasma gun inflow and anode was 10^6 Pa. In addition, water mass flow rate through the plasma gun was $320 \cdot 10^{-3}$ kg/sec, whereas that value through anode was equal to $733 \cdot 10^{-3}$ kg/sec. Total heat losses in the cathode unit was 5.8 kW. The data of thermocouples were digitized by analog-digital converter (ADC) and acquired for PC processing.

The following study has been carried out for the stable operation of a long soft arc under the above conditions:

1) effects of swirling motion of plasma gas; a cathode tip is fixed by a swirling screw nut; in this case arc stability has been examined by changing the levels of swirling intensity (without swirling, with a soft swirling and with a strong swirling); for this purpose few types of screw nuts were designed and made to produce a various level of swirling intensity (see Fig. 1 and 2),

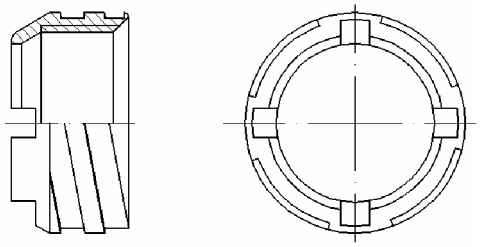

Fig.1. General view of the swirling nut geometry used in the experiments.

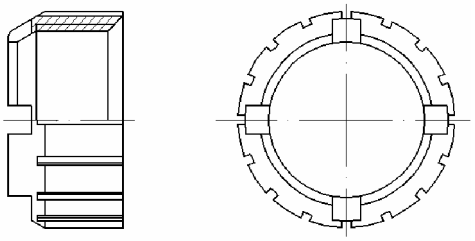

Fig.2. The scheme of the assemblage of the axial working gas supply.

2) effect of the forming nozzle shape; there were tested two types of the cylindrical nozzle with different inlet diameters (4 mm and 6 mm); not only the effect of the orifice diameter but also those of the orifice length and shape (backward-facing step) have been studied (see Fig. 3).
For the practical operation of the plasma torch, data on the life time of the consumable parts such as cathode tip and forming nozzle-anode are required, especially under high current operation. Weight losses and deformation of the parts were measured with time under 400 A operation.
The aim of this experimental course was to investigate an ability of improving the transfer arc stability for minimally possible mass flow rates of working gas (argon) at 100 mm stand-off distance between the forming nozzle exit and the water cooled anode surface. Operating arc current was chosen to be equal 400 A as being maximal current provided by "Plasma-4" power-supply source. The optimization was performed also for variety of the conditions of working gas injection into cathode zone. Here operating gas flow rate was fixed at 0.3 g/sec (different rates of gas swirling, Fig.1, as well as axial gas blowing, see Fig.2), with the forming nozzle geometry being varied (various forms of the backward-facing step, see Fig.3).

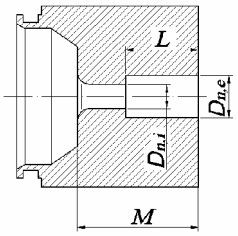

Fig.3. General view of the backward-facing step forming nozzle used in the experiments.

The following legends are used in Fig.3: $D_{n,i}$ is the inlet diameter of the forming nozzle, $D_{n,e}$ is the outlet diameter of the forming nozzle, $\Delta r=(D_{n,e}-D_{n,i})/2$, L is the length of its stepped part, M is the total length of the nozzle–anode.

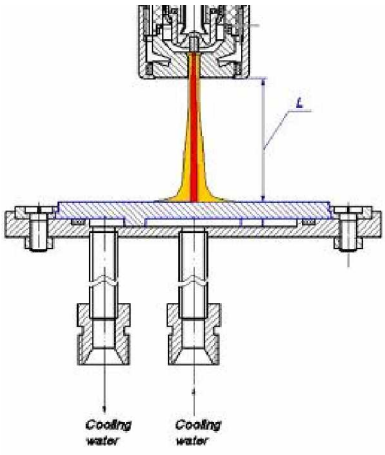

Fig.4. The principal schematic of the plasma gun with transfer arc and water-cooled anode.

3. Results

3.1. Integral characteristics of torch

It is of special interest to investigate the integral characteristics of transfer arc gun depending on the channel diameter of the cathode assembly, the plasma forming gas mass flow rate, the stand-off distance from the forming nozzle outlet section to water-cooled anode surface and its diameter as well. While carrying out the investigation the two sorts of water-cooled anodes were implemented. The diameter of heat transfer surface of the first sort of anode was chosen 100 mm (Figs.4, 5), that of the second one was 200 mm.
The integral characteristics of the transfer arc plasma guns to be compared are plotted in Fig.6, with channel diameter being 4 mm (curve #3) and 6 mm (curve #2).

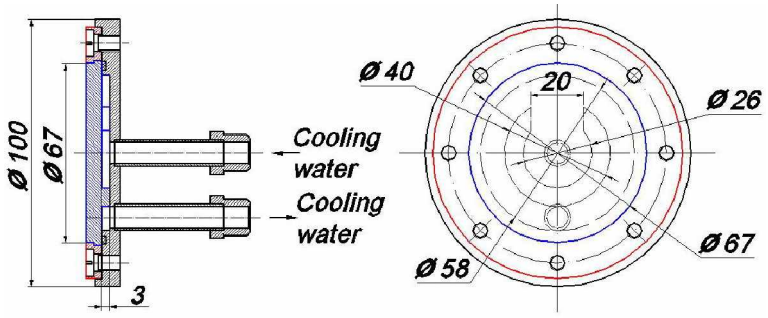

Fig. 5. The principal diagram of the water cooled anode. Blue part corresponds to cooper cooled anode, grey part is stainless steel holder isolated from cooper part by ribbon ring.

It is clearly seen, when reducing the channel diameter from 6 to 4 mm, the electric field intensity of the arc is valuably increased (~50%), other parameters being equal. Still, as arc current is increased (I>250 A) the heat

fluxes into anode are nearly the same. When current I<250 A the heat loss in the cathode assemblage is the smallest for 4 mm channel diameter. On the contrary, for I>250 A and 6 mm channel diameter the situation changes qualitatively. Nevertheless, the value of heat losses in the cathode assembly is small enough and doesn't exceed 6 kW for both cases when the electric arc power is ~60 kW ($D_{n,i}$=4 mm) and ~40 kW ($D_{n,i}$=6 mm). As the arc current is increased the efficiency of the heat transfer into the anode rises and, for instance, at I=300 A is about 40% ($D_{n,i}$=4 mm) and 60% ($D_{n,i}$=6 mm).

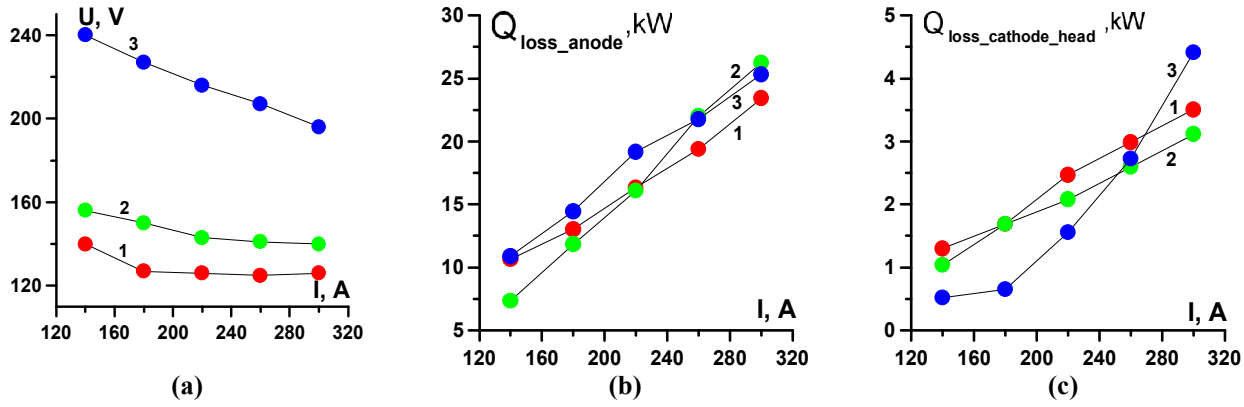

Fig. 6. Volt-amps characteristics – (a), heat flux into water cooled copper anode – (b), and heat losses into cathode assembly – (c) of transfer arc plasma torch. 1 – $D_{n,i}$=6 mm (G_{Ar} =0.3 g/s), 2 – $D_{n,i}$=6 mm (G_{Ar} =0.5 g/s), 3 – $D_{n,i}$=4 mm (G_{Ar}=0.5 g/s). The distance from the nozzle outlet to the anode surface was equal to 100 mm. Diameter of water-cooled anode is D_a=200 mm.

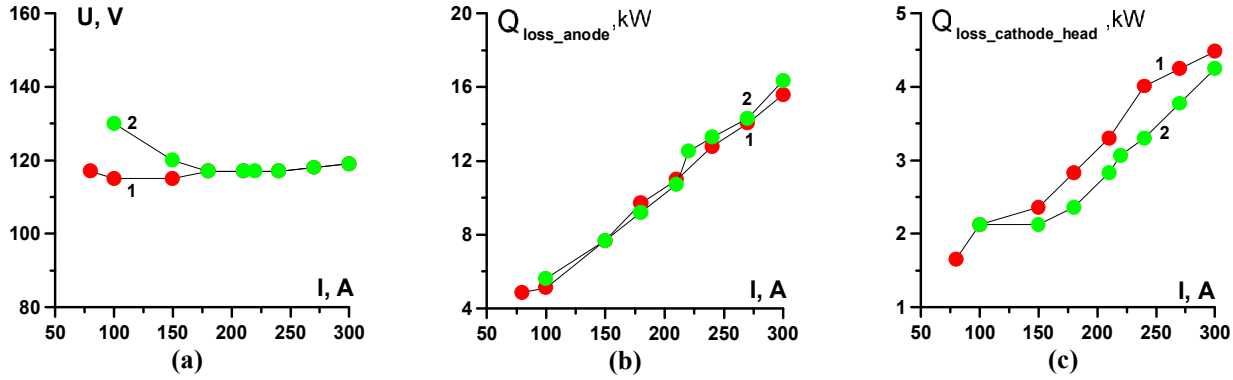

Fig. 7. Volt-amps characteristics – (a), heat flux into water cooled copper plate anode – (b), and heat losses into cathode assembly – (c). The curves (1) and (2) correspond to argon mass flow rate of 0.1 and 0.2 g/sec, accordingly. The distance from the nozzle outlet to the anode surface was equal to 100 mm. Diameter of water-cooled anode is D_a=100 mm.

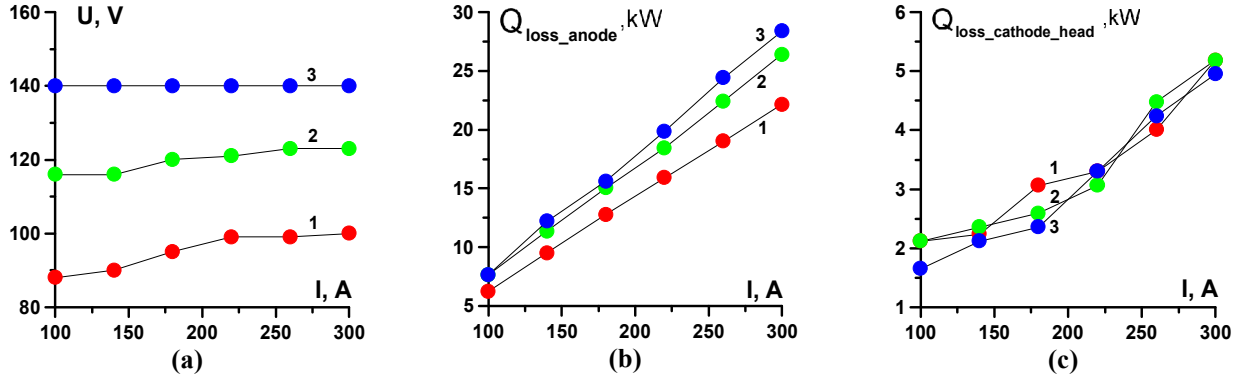

Fig. 8. Volt-amps characteristics – (a), heat flux into water cooled copper anode – (b), and heat losses into cathode assembly. The curves (1), (2) and (3) correspond to the distance from the nozzle outlet to the anode surface of 50, 75 and 100 mm, accordingly. The mass flow rate of argon was equal to 0.3 g/sec. Diameter of water-cooled anode was D_a=200 mm.

In Figs.6, 7 the integral characteristics (curves 1 and 2) of the plasma gun with fixed 6 mm channel diameter are indicated. As seen from Fig.6, increasing the plasma forming gas flow rate as much as almost double resulted in 15-20% increase of the heat transfer into the anode with diameter D_a=200 mm for arc current I>180 A. For lower argon flow rates the difference of thermal fluxes in anode with diameter D_a=100 mm is negligible virtually in the whole range of arc current variation (Fig7, *a,b*) whereas at I>180 A the volt-amps diagrams are coincided.

In Fig. 8 an influence of the distance between outlet cross-section of the cathode assembly and anode surface on the parameters of the transfer arc plasma gun to be studied is illustrated. As the distance becomes larger the increasing volt-amp curve turned to a steady one. When increasing the above distance from 50 to 75 mm the change in anode thermal flux is more noticeable than the change for increasing the distance from 75 up to 100 mm. The subsequent increase of the distance causes the thermal flux to be stabilized to the point of arc break.

The data depicted in Figs.6-8 indirectly point to an influence of the diameter of water-cooled anode on the value of thermal flux being taken. The feature of the transfer arc plasma gun is an air entrainment into plasma jet, and we have a conductive plasma jet flowing onto the wall. It is evidently, the value of the heat flux being taken depends on heat exchange area (i.e. anode diameter). The effectiveness of surface treatment is determined by the power density of the thermal flux in the arc spot where the major power flux is observed. Therefore, it is required to minimize arc spot diameter upon the surface being treated as much as possible. The extreme case is the laminar arc, for which the size of spot of attachment to the surface to be treated is larger a little than the channel diameter of the cathode assemblage. Thereupon, it is interesting to explore the methods of stabilizing the transfer arc at low Reynolds numbers (low mass flow rates of the plasma forming gas).

3.2. Experiments on plasma torch optimization

In these experiments argon flow rate G_{Ar}= 0.3 g/sec, arc current дуги I=400 A. Plasma gun was ignited at 25 mm stand-off distance between nozzle exit section and the water-cooled anode (see Fig.4). Having ignited the plasma gun one increased the stand-off distance to 100 mm.

During plasma gun operating period, along with measuring the heat flux into the water-cooled anode (Fig. 4), the arc root current and voltage were being displayed for each set of investigated operating conditions. This was done in order to analyze their spectral components. The attention was mainly focused on spectra of the voltage fluctuations. The latter can indirectly characterize arc root stability (its length). When valuing the spectral characteristics Blackman-Harris filter was applied. Here spectral amplitude is square root of the sum of squares of real and imaginary parts. Size of the window in which Fast Fourier Transform (FFT) was executed is 16384 counts, total number of counts – 65536, the measuring frequency is 10 kHz. Hence, for FFT upper frequency the resolution is equal to 5 kHz (2 counts per period), for lower one – 0.3 Hz (namely, 100 μsec x 65536 = 6.5 sec, i.e. period is 3 sec).

In Table 1 there are presented the initial parameters of the backward-facing stepped forming nozzles used in the experiments. In each series of the experiments, corresponding to fixed values of $D_{n,i}$ and $D_{n,e}$, the length of step L was varied in the following sequence $L/\Delta r$=6; 5; 4; 3; 2. It was found that for both inlet diameters $D_{n,i}$=4 and 6 mm of the forming nozzle the most stable arcing have taken place at Δr=2.5 mm, $L/\Delta r$=2.4. In other cases, including the forming nozzle without the backward-facing step, erosion of the inner edge at outlet of the nozzle occurred. This erosion is related with intensive micro-shunting of the arc.

Table 1. The geometry of the backward-facing steps investigated

$f_{initial}=L/\Delta r$	$D_{n,i}$	$D_{n,e}$	L	M
6	4	6	6	14
6	4	7	9	17
6	4	8	12	20
6	6	8	6	14
6	6	9	9	17
6	6	10	12	20

The experiments on optimizing the forming nozzle characteristics have shown that this ratio is most appropriate also for mass flow rate of argon of 0.1 and 0.2 g/sec. It is cited from references devoted to plasma jet stabilization using backward-facing step at low Reynolds numbers that above mentioned ratio

should not exceed 5. However in the case under consideration there is an intensive Joule heat release in the limit of nozzle step that would result in an increase of thickness of thermal and velocity boundary layers inside the stepped channel. Therefore the relative length of step has to be shorter in order to avoid a reattachment of the dynamic boundary layer to a wall within the step.
Using the optimal geometry of the forming nozzle the additional experiments have been carried out to study the influence of working gas supply into cathode zone (with and without gas swirling). It was established that axial supply of argon (V_φ=0) provides more stable arcing at L=100 mm. At the same time, the aforesaid micro-shunting was not observed.

3.3. Plasma gun life test

The 10 hour life test of the transfer arc plasma gun optimized have been conducted at arc current I=400 A, with argon mass flow rate being 0.1 g/sec. Taking into consideration the results of cathode unit optimization, in above life tests the axial supply of plasma forming gas in the cathode zone was implemented.
The internal nozzle channel utilized in the life test was the backward-facing steps with channel expansion from $D_{n,i}$=6 mm to $D_{n,e}$=11 mm across diameter. The length of step was 6 mm, this provided the ratio of its length to the height being equal to 2.4. As mentioned above, the experiments for optimizing the forming nozzle have shown that this ratio is most appropriate.
During 10 hours period of plasma gun operating mode the stand-off distance from nozzle cross-section to anode was set of $50 \cdot 10^{-3}$ m. Here the operating voltage was within 80÷85 V, while thermal flux registered by the sensor was about 14.7 kW.
Totally during the life test there were 5 plasma gun runs (4 times plasma gun was switched off). After 10 hour of life test there were no any noticeable erosion of the forming nozzle, the erosion of tungsten cathode was $3 \cdot 10^{-13}$ kg/Coulomb. Such a value of cathode erosion provides its continuous service (up to complete ablation of $1.5 \cdot 10^{-3}$ m length tungsten rod of $4 \cdot 10^{-3}$ m diameter) during more than 500 hours.

Conclusions

As a consequence of the experiments on optimizing soft transfer arc plasma torch it is possible to do the following conclusions:
1) the forming nozzle with inlet diameter of 6 mm, having a backward-facing step with length of 6 mm and diameter of 11 mm provides a maximal stable transfer arc burning at current of 400 A in a diapason of argon mass flow rate 0.1-0.5 g/sec and distance from nozzle exit and anode surface of 100 mm,
2) the axial supply (V_φ=0) of working gas (argon) in the cathode area in comparison with vortex one (V_φ>0) provides the increasing the stability of an arcing in the other conditions been equal,
3) at the optimal conditions found the time life of the cathode continuous operation is not less than 500 hours and time life of the forming nozzle is not worth than cathode.

Abstract

Polymeric polypyrrole-like nanocrystallines were fast synthesized through oriented plasma polymerization at atmospheric pressure and room temperature. The effects of discharge conditions such as discharge time and power on the nanocrystalline morphology and crystallinity were investigated. It was found the nanocrystallines could exhibit various shape such as powders, rods, wires etc at different polymerization conditions. The crystal phase could also change from amorphous to single-crystalline structure. The chemical structure of the nanocrystalline have been studied through FTIR, EDX etc. This novel polymerization method could have great applications in fabricating functional polymeric nanocrystallines.

Keywords

atmospheric oriented plasma polymerization, polypyrrole, nanocrysllines

1. Instruction

It is well known that the properties of materials depend not only on their chemical structures, but also on their morphologies. For example, nanoscale materials possess unique properties on account of their finite small size and have wide-ranging applications to a variety of areas. Especially carbon nanotubes exhibit excellent performance of importance for microelectronic devices and attracted people's great interest in the past 10 years[1,2]. On the other hand, one dimension conjugated conductive polymers are also of great interest[5]. Among these conducting polymers, polypyrrole (PPy) stands out because of its high conductivity, stability in air and array of potential applications [3]. Recently, nano/microwires were synthesized by a chemical and electrochemical method.[4] CNTs/PPY nanocomposites were obtained by in-situ polymerization in the carbon nanotube template.[6]Template-synthesized PPy monodisperse nanowires and tubules were prepared by using an anionic surfactante (diamyl sulfosuccinate) as the dispersing agent[7].

In this paper, PPy-like nanocrystallines were synthesized through oriented plasma polymerization at atmospheric pressure and room temperature. The effects of discharge conditions such as discharge time and power on the nanocrystalline morphology and crystallinity were investigated. The chemical structure of the nanostructures have been studied through FTIR, EDX etc.

2. Experiment

PPy-like thin films were grown on ordinary glass slides, using an oriented plasma polymerization system, which consist of a monomer supply system, an evacuable cylinder reactor (the bottom/top side was 9.0cm is diameter and the height was 20.0cm), housing wire-dielectric-plate geometric electrode that produced a gradient electric field, an argon flow system and a tunable power supply with a high voltage of 10-50 kV and a frequency of 10-100 kHz. The depositions were carried out with atmospheric pressure and ambient temperature by a water cooling system. Pyrrole was used and fed into the reactor through an argon carrier gas at a fixed ratio. After only a few seconds to several minutes, a thin brown film was deposited on the entire substrate, within which a large quantity of nanowires/powders were identified.

A SEM (JSM-5600LV) was used to measure the morphologies of the PPy-like film. Structures and compositions of the samples were investigated on a CM200FEG high-resolution transmission electron microscope (HRTEM) equipped energy dispersive X-ray spectroscopy (EDX) system operated at 200 kV. To obtain electron diffraction patterns from individual nanocrystallines, a nanobeam diffraction mode was used. FTIR (NEXUS-674) was used to characterize the chemical structure of the film.

3. Results and discussion

3.1 Mophorlogy

3.1.1 Effects of discharge time

(a) (b) (c)

Figure 1. SEM photographs of PPy-like thin films prepared by oriented plasma polymerization at atmospheric pressure: (a)t=1min; (b) t=2min; (c) t=3min.

Figure 1 shows SEM photographs of PPy-like thin films deposited during different time. The powders whose diameter was roughly 500nm lay on the surface of a loosely packed nanoparticulate layer. As shown in figure 1(b) and 1(c), the powders would like to link to each other and grow up into wires by molecular force with the elapse of time.

3.2 Effects of discharge power

(a) (b) (c)

Fig. 2 SEM photographs of polypyrrole-like crystals prepared by oriented plasma polymerization at atmospheric pressure: （a）3kV，0.4A，（b）6.5kV，0.7A，（c）8kV，0.8A.

Figure 2 shows SEM photographs of PPy-like thin films deposited at different powers. The length of the nanoswires increases with the increase of discharge power. Fig 2(c) also indicates that the growth rate of the nanowire was considerably high, and it took only 3 minutes to synthesize wires. It is relatively fast process compared to some other meothds[4].

As figure 3 shows, the length/width ratio increase with the discharge power. Since the powders connected and wires formed, there is a sharp increase between 4.5 and 6.5 kW. These photos (Fig. 2, Fig. 5(a)) strongly suggested that 3 min is enough long time to synthesize a single crystalline nanopowder/microwire.

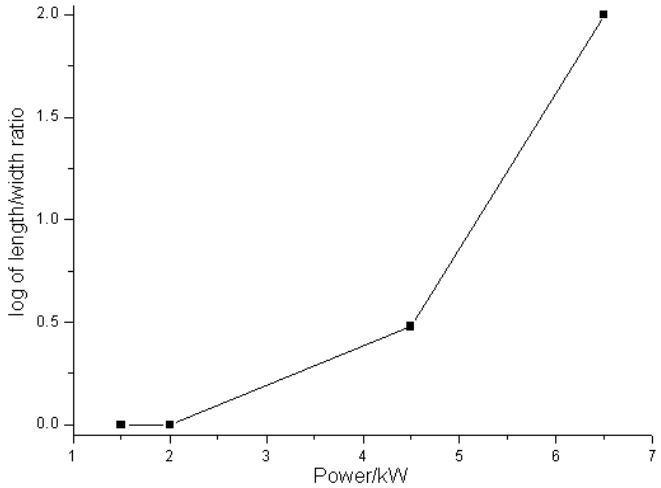

Fig. 3 The effect of the discharge power on the length/width ratio of polyporrole-like crystal wires.

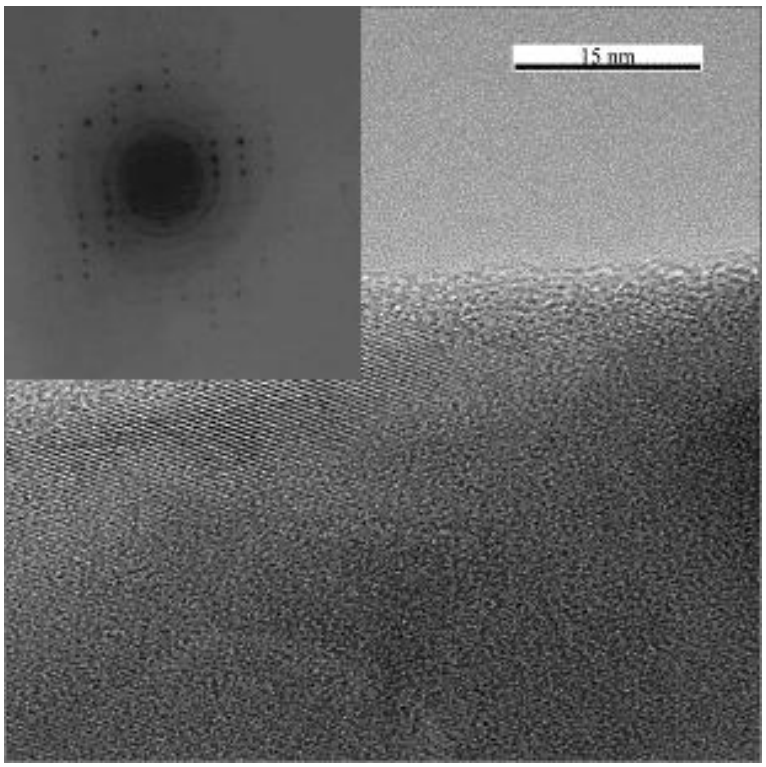
The substrate and its film were immersed into 10mL of absolute ethanol and ultrasonicated for 20 min to completely separate the nanopowders/wires from the substrate. A drop the liquid was placed onto a copper transmission electron microscopy grid, and the solvent was allowed to evaporate. The TEM image obtained after evaporation of the solvent shows that the desired monodisperse nanoweirs were prepared by our method. An anionic surfactant had been used to prevent the aggregation of nanoparticales [7], but our method is fast, simple and immediately.

PPy micro/nanowires with diameters of 50-2000 nm were synthesized by a chemical and electrochemical method[4]. CNTs/PPY nanocomposites with diameters of 80-100nm were obtained by in-situ polymerization in the carbon nanotube template[6]. PPy films were prepared by using a SAMCO plasma polymerizer[11]. It needs to be pointed out that the method proposed by us only needs 3 min, whereas the other method need several hours or even several days. Figure 4 indicates HRTEM photographs of PPy-like nanowire single crystals shown in Fig. 3 (c). Lattice fringes can be seen continuously through the whole particle. The inset in the extended picture is the electron diffraction pattern, which enabled us to confirm that the nanopowder/wire materials were single crystals. The results of EDX shows that the N/C ratio (0.05) of the nanocrystalline is smaller than that of ideal PPy (0.25). From the FTIR and EDX results, it is obvious that the pyrrole rings have been decomposed to some extent in the plasma polymerization precess.



(a)

(b)

Fig. 4 (a) HRTEM image of PPy-like nanowire single crystals shown in Fig. 2(c), the inset is its electron diffraction pattern, (b) EDX spectrum.

3.3 structural characterization

FTIR spectra of pyrrole liquid film and PPy-like film are given in figure 5. The spectra show that the structure of PPy-like film is similar to that of the pyrrole film. In the both spectra, two strong absorptions are observed at 3300-3440 and 745 cm^{-1}. The appearance of broad peak at 3300-3400 cm^{-1} suggests the presence of N-H stretching[9,10]. The other peak at 745 cm^{-1} is due to CH=CH out-of-plane deformation vibration. These suggest

PPy-like film synthesized by our method maintained more C-H, N-H and CH=CH bonds, compared with PPy synthesized by other method[4,11]. On the other hand, in the polymer spectra, peaks around 2900 and 1100 cm^{-1} corresponding C-H stretching vibration and C-H in-plane bending, respectively, are weaker than that of the pyrrole sample. Perhaps related to polymer's high crosslinked structure, C-H bond concentration in PPy-like film is lower than that of the pyrrole molecule. The other peak observed at 1635-1700 cm^{-1} is due to C=N and/or C=C stretching and N-H bending[12,13]. In PPy-like films sample, this peak shifts to high wave number compared with that of the pyrrole sample. The peak shift observed in the PPy-like film is probably due to the formation of C=O by the invasion of the oxygen into the PPy-like film[11]. It is supported by the EDX spectra, which shows an oxygen peak. The absorption peak of C=C in-plane vibration mode at 1384 is more intensive compared to the pyrrole sample. This may result from the structure change, for example, the long conjugation length of the polymer long chain in the PPy-like film. The peak observed at 483 cm^{-1} corresponding to pyrrole ring deformation vibration.

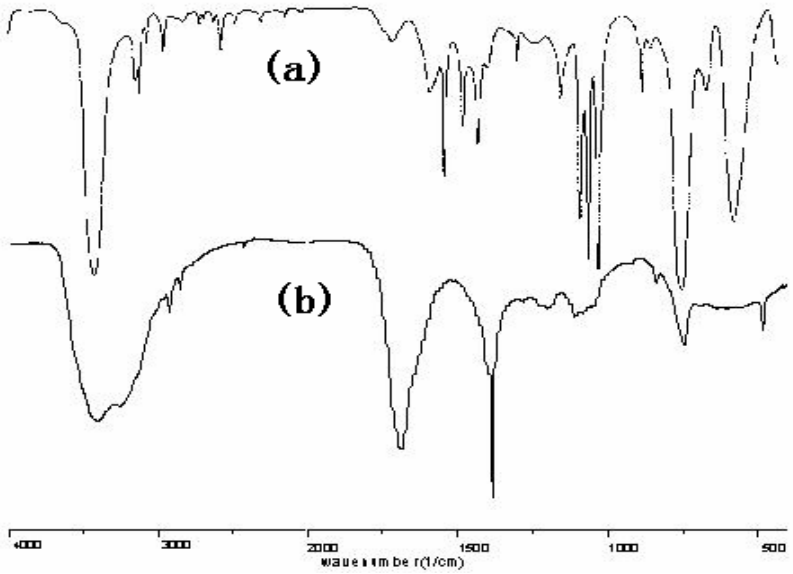


Fig. 5 FTIR spectra of (a) pyrrole liquid film, (b) PPy-like film synthesized by oriented plasma polymerization.

4. Conclusion

PPy-like film with nanostructures was synthesized using the oriented plasma polymerization at atmospheric pressure and room temperature, which was a fast one-step process and could be applied for many different monomers. By controlling the discharge power, the monomer and carrier gas ratio, the flux, etc., the configuration of the naonwires can be closely controlled so that single crystalline and large length/width ratio nanowires can be produced.

Abstract
In this research, it was aimed to modify the structure of Κ-carrageenan by means of air glow discharge to develop smart gel materials. The samples were exposed to 13.56 MHz RF air plasma at a residual pressure of 0.75 Torr. The air plasma produced oxidation and ablation, allowing a decrease in pH values. A noticeably decrease in the viscosity of κ-carrageenan, indicating a depolymerisation.

Keywords: smart gel, Κ-carrageenan, glow discharge, IR-ATR spectroscopy, XPS

1. Introduction

Stimulus-responsive or 'smart' polymers undergo strong conformational changes when only small changes in the environment (e.g. pH, temperature, ionic strength) occur. These changes result in phase separation from aqueous solution or order-of-magnitude changes in hydrogel size. Smart polymers are used in bioseperation and drug delivery, for the development of new biocatalysts, as biomimetic actuators, and as surfaces with switchable hydrophobic-hydrophilic properties. Several types of materials such as carrageenan, sodium alginate, xanthane and chitosan have been reported on literature to prepare smart gels[1]. Most of them had been used in their natural forms.

Low-pressure glow plasma is assumed to provide a waste-less dextrinization of polysaccharides. The destruction of these high molecular weight compounds as a consequence of depolymerisation caused by the reactive electrons, ions and radicals, local temperature increase, as well as oxidation by ozone and/or nitrogen oxides formed in the course of experiments, can be inhibited in some extent [2,3]. Those chemical changes on the bulk structure of the materials produced by plasma treatment encouraged us to check the possible positive changes in the performance of these materials as smart materials.

κ-carrageenan, which is selected as the model macromolecule for this research, consists of linear-sulfated polysaccharide of D-galactose and 3,6-anhydro D-galactose. In this research, it was aimed to investigate the changes in the κ-carrageenan structure by means of glow discharge. The chemical and physical characteristics of the κ-carrageenan prior to and after air plasma modification are reported.

2. Experimental

κ-carrageenan was obtained from Aldrich (Milkwaukee WI 53233, USA).

Exposure of samples to air plasma: A March Plasmod RF plasma Instrument (Concord, CA, USA) with a pyrex glass chamber of 19 cm length and 14 cm diameter was used in the experiments. Synthetic dry air (99.999 % purity) was introduced into the chamber with a flow rate of 16 ml/min. 20 minutes after the air was introduced into the chamber, a uniform air plasma was reached by using a residual pressure of 0.75 Torr. The glow discharge power and the exposure time were 75, 125

Watts and 20, 30 and 40 min, respectively. After plasma treatment, the reactor was placed up to 0.15 Torr for 30 minutes by means of a rotary vacuum pump.

ATR-IR spectroscopy, X-ray Photoelectron Spectroscopy (XPS), Scanning Electron Microscopy (SEM), Energy Dispersive X-Ray Spectroscopy (EDX), Differential Scanning Calorimetry (DSC) techniques, pH and viscosity measurements were used in order to determine the effect of air glow discharge treatment on the κ-carrageenan.

3. Results And Discussion

The effect of the glow discharge technique on the chemical and physical characteristics of the κ-carrageenan were investigated.

χ-carrageenan	**Assignment**
3436	ν(OH)
2963	ν(CH)
2907	ν(CH)
1648	δ(OH)
1379	$\delta(CH_2)$
1266	ν(S=O)Ester sulfate
1069	ν(C-O-C) Glycosidic linkage
1042	ν(C-O-C) Glycosidic linkage
929	ν(C-O)3.6-anhydro-D-galactose
847	ν(C-O-S)D-galactose-4-sulfate

Table 1. Assignment of IR bands (in cm^{-1}) of the as-received κ-carrageenan.

Table 1 shows the assignment of the IR-ATR spectra of the as-received κ-carrageenan (Figure 2). Bands due to OH, CH_2, C-O, S=O and C-O-C can be identified. Furthermore, the broad bands at 1630 and 2160 cm^{-1} in the IR spectrum of Figure 2 are due to inorganic calcium chloride, likely a contaminant in the κ-carrageenan. The air plasma treatment increases the ratio of the intensities of δ (OH)/ν(CH) bands at 1648 and 2907 cm^{-1} in the ATR-IR spectra in a greater extent by increasing the length of treatment up to 30 minutes. The increase is somewhat less important when the air plasma is carried out for 40 minutes. In addition, the intensity of the C-O-C stretching band at 1069 cm^{-1} due to the glycosidic linkage in the air plasma treated κ-carrageenan decreases with respect to the intensity of the OH bands at 1648 cm^{-1} compared to those in the IR spectrum of the as-received κ-carrageenan. These results might indicate that air plasma partially oxidized the κ-carrageenan and some depolymerisation is also produced. In fact, the lower intensity ratios of the C-O-C stretching (at 1069 cm^{-1} and 1049 cm^{-1}) and the OH stretching bands, which are almost similar in the ATR-IR spectra of all air plasma treated samples (Figure 2b) at different exposure time (20, 30, 40 min) and power of the discharge, also confirm the depolymerization of the κ-carrageenan.

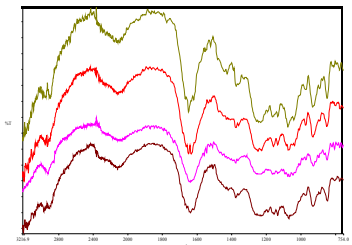

Figure 2a. ATR-IR spectra of a) as-received κ-carrageenan, and plasma treated κ-carrageenan for b) 20 min, c) 30 min, d) 40 min. Power = 75W.

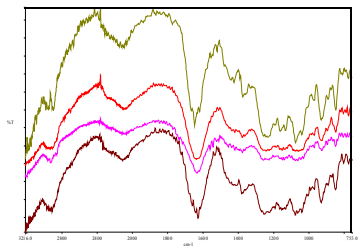

Figure 2b. ATR-IR spectra of a) as-received κ-carrageenan, and plasma treated κ-carrageenan for b) 20 min, c) 30 min, d) 40 min. Power = 125W.

Element	Binding energy (eV)	As-received	Treatment

Table 2a. Atomic percentages (at%) of elements on the as-received and air plasma treated κ-carrageenan.

Element	Binding energy (eV)	As-received	Treatment			
			75W-20min	75W-40min	125W-20min	125W-40min
$(C^*H_2\text{-}CH_2)_n$	283.3	16.9	17.9	20.9	24.6	19.5
C-H, C-C	285.0	65.8	58.1	59.0	46.7	53.8
C-OH, $(CH_3\text{-}C^*H_2)_2\text{-}O$	286.6	17.3	24.0	20.1	28.7	26.7

Table 2b. Percentages of species (at%) obtained from C 1s curve fitting on the as-received and plasma treated κ-carrageenan.

XPS analyses in more details the variation in the surface chemistry of the κ-carrageenan after air plasma treatment. The as-received κ-carrageenan mainly contains carbon and oxygen (Table 2a), although noticeable amounts of chlorine and potassium are also found; furthermore, a small at % of sulphur as expected in the chemical structure and sodium, calcium anions are detected. According to the binding energies, KCl, NaCl and $CaCl_2$ are present on the as-received κ-carrageenan. It has been reported that cations bind to carrageenan's blocking sulfate groups and

affect the balance of attractive and repulsive forces between the molecules so that the optimum gel strength will occur depending on cations such as K, Ca, and Na[4]. Table 2b shows that carbon in the as-received κ-carrageenan is due to –(C^*H_2-CH_2), C-O-C and C-OH. The air plasma treatment decreases the carbon content and slightly increases the oxygen content on the κ-carrageenan, due to surface oxidation. In fact, the amounts of C-OH and C-O-C species (Table 2a) increase after air plasma treatment. The air plasma treatment also changes the amounts of the different carbon species, increasing the –(C^*H_2-CH_2) moieties which is an indication of depolymerisation of the κ-carrageenan. On the other hand, the amounts of Cl, K, Na and Ca increases, indicating the removal of organic material in the κ-carrageenan by treatment with air plasma. The above mentioned modifications produced by air plasma treatment in the κ-carrageenan are more marked by increasing the length of plasma treatment and the power of the discharge.

The air plasma treatment also changes the morphology of the κ-carrageenan. SEM micrographs before and after air plasma treatment (Figures 3a and 3b, respectively) show a noticeable deterioration of the fibre bundles that becomes thinner after air plasma treatment.

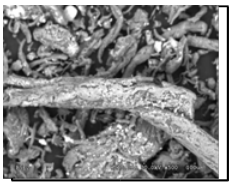

Figure 3a. As-received κ-carrageenan (X500)

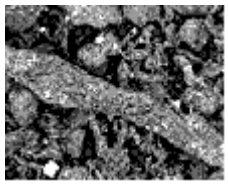

Figure3b. Air plasma treated κ-carrageenan at 125W for 20 min (X500)

pH measurements were carried out to further confirm the oxidation of the air plasma treated κ-carrageenan. Figure 4 shows a decrease in the pH of the κ-carrageenan after air plasma treatment in a greater extent by increasing the power and the length of treatment, supporting the oxidation produced[2].

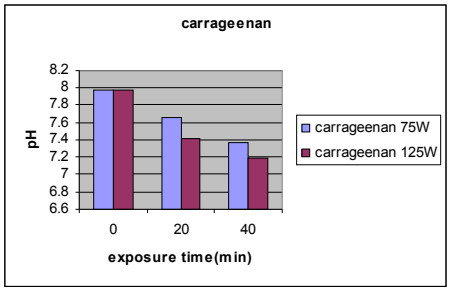

Figure 4**.** pH of aqueous solutions of κ-carrageenan prior to and after air plasma treatment

The air plasma treatment also modifies the viscosity of the aqueous solutions of the κ-carrageenan likely due to the depolymerisation produced (Figure 5). Extended air plasma length of treatment increased the viscosity due to the cross linking of κ-carrageenan fibres.

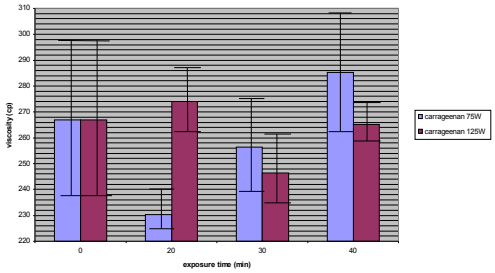

Figure 5. Brookfield viscosity of κ-carrageenan prior to and after air plasma treatment

4. Conclusions

The air plasma affected the structure of the κ-carrageenan by producing oxidation and depolymerization, affecting its pH and viscosity.

The jellification, water adsorption, and swelling behaviour of the air plasma treated polysaccharides for the preparation of temperature and/or pH sensitive smart gels are still under investigation. Further to stagnant modification of polysaccharides by glow discharge method, a rotary glow discharge reactor will also be employed for such powder treatments.

Dust Particle Dynamics in Plasma Sheath with an Oblique Magnetic Field

M. Davoudabadi and F. Mashayek

Department of Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, IL 60607, USA

Abstract
In the presence of a strong oblique magnetic field and under low-pressure limit, a weakly collisional, steady-state, two-fluid model is extended to examine the effect of the bulk plasma density on the structure of the plasma sheath. Conditions under which a single nano-sized dust particle can be trapped in the sheath are considered. While varying the particle density, the ion and electron densities at the particle steady state position and the charge on the particle are calculated for different magnetic field intensities.
Keywords magnetized plasma sheath, dust particle dynamics, fluid simulation

1. Introduction

Dusty plasma is a unique multi-component system composed of dispersed macroscopic charged dust particles that form a colloidal-type suspension in the parent plasma background [1]. It represents the most common configuration in astrophysical, laboratory, and industrial plasmas. The plasma-wall transition, existing for example as a sheath around the surface of a small astronomical body or near the walls of plasma processing reactors, has attracted the interest of the plasma community for many years [2, 3, 4, 5]. The dust charging mechanism and dynamics of dust particles in plasma sheaths have also been topics of many studies [1, 6, 7, 8, 9].

Well-established existing models can provide detailed information on the mechanism of plasma-wall interaction and formation of an electrostatic sheath in an unmagnetized plasma. These models are also being used for simulating the boundary region of *strongly* magnetized plasmas without any modification [10]. However, the extent of such studies involving a magnetic field is very limited and subject to some restrictive assumptions. In this work, we relax some of these assumptions to provide a more comprehensive investigation. In order to simulate the sheath structure, we extend an existing comprehensive model originally developed by Resendes *et al.* [6, 11] for modeling the *unmagnetized* plasma sheath. The model remains valid for a broad range of Larmor radii. After solving for the sheath variables, a single dust particle is considered and it is assumed that the particle does not contribute to the total space charge and, thus, does not modify the sheath structure. For a nano-sized particle with radius R, we consider moderate magnetic field intensities for which the condition $\rho_{e,i} > R$ is satisfied, where $\rho_{e,i}$ are the electron and ion gyroradii. Under these circumstances, following Tsytovich *et al.* [12] and Salimullah *et al.* [13], the orbit motion limited (OML) theory remains intact and is thus utilized to obtain the electric potential difference between the dust particle and the plasma and, consequently, the charge quantity on the dust due to the ions and electrons currents. A complete set of forces acting on the dust particle originating from the electric field in the sheath, the static magnetic field, gravity, and ion and neutral drags is taken into account.

This work is motivated by our ongoing effort in modeling of nanoparticle coating in low-pressure plasma reactors. In our recent paper [14], we fully discussed the effect of presence of a static oblique magnetic field in the plasma sheath and several other parameters on both the sheath structure and dust dynamics. In the present work, we turn our attention specifically towards the effect of bulk plasma number density on the sheath structure and also towards the amount of charge populated on the particle at steady state for various materials with different mass densities under different magnetic field intensities. The particle density ranges from 5,000 Kg m^{-3} to 20,000 Kg m^{-3} representing materials such as steel, copper, silver and gold.

2. Sheath model and dust particle equations

Since the hot electrons are repelled away from the negatively charged wall, their fluid directed velocity v_e is negligible compared to their thermal velocity v_{the}. Therefore, the use of Boltzmann relation as a solution of the electron equations is well justified even in presence of a magnetic field $\vec{B}$ with the intensity B,

$$n_e = n_0 \exp\left(\frac{e\phi}{k_B T_e}\right). \tag{1}$$

Here n_e is the electrons number density, n_0 is the bulk plasma particles number density, e is the elementary electron charge, ϕ is the electric potential in the sheath, T_e is the electron temperature, and k_B is the Boltzmann constant.

To simulate the cold ions concentration and velocity, however, we implement continuity and momentum equations, and include the pressure gradient and drag force due to the collision with neutrals as well as electric and magnetic forces on the ions [6, 15]. In low pressure ranges, ionization in the sheath can be neglected, owing to the low neutral density, n_n, and consequently, an ion mean free path much larger than the sheath thickness, D. Thus, in the present analysis a source-free model is used. We consider the physical parameters changing only along the z (normal to the wall) direction in the sheath region ($\nabla \equiv \hat{k}\frac{\partial}{\partial z}$). The magnetic field is embedded in the x-z plane intersecting the wall (at $z = D$) with an angle θ (see figure 1). We introduce the following normalized variables:

$$\eta = -\frac{e\phi}{k_B T_e}, \qquad \vec{u}_i = \frac{\vec{v}_i}{v_{thi}}, \qquad \xi = \frac{z}{\lambda_{Di0}},$$

where $v_{thi} = \sqrt{8k_BT_i/\pi m_i}$ is the mean ion thermal velocity, and $\lambda_{Di0} = \sqrt{\epsilon_0 k_B T_i/e^2 n_{i0}}$ is the ion Debye length with ϵ_0 denoting permittivity of free space. The steady state fluid equations for the three-dimensional adiabatic ion flow with mass m_i, temperature T_i, and number density n_i, after applying the continuity equation, are described as

$$u_{iz}\frac{\partial u_{ix}}{\partial \xi} = -\alpha u_i u_{ix} + \beta u_{iy}\cos\theta, \tag{2}$$

$$u_{iz}\frac{\partial u_{iy}}{\partial \xi} = -\alpha u_i u_{iy} + \beta(-u_{ix}\cos\theta + u_{iz}\sin\theta), \tag{3}$$

$$u_{iz}\frac{\partial u_{iz}}{\partial \xi}\left(1 - \frac{5\pi}{24}\frac{u_{0z}^{\frac{2}{3}}}{u_{iz}^{\frac{8}{3}}}\right) = \frac{\pi}{8}\frac{T_e}{T_i}\frac{\partial \eta}{\partial \xi} - \alpha u_i u_{iz} - \beta u_{iy}\sin\theta, \tag{4}$$

where $\alpha = n_n\sigma_s\lambda_{Di0}$ is the degree of collisionality and expresses the number of collisions within a Debye length, and the nondimensional parameter $\beta = \sqrt{\pi/8}\lambda_{Di0}/\lambda_{mi}$ is proportional to the magnetic field intensity ($\lambda_{mi} = \sqrt{k_BT_i m_i/e^2B^2}$ is the thermal Larmor radius). Finally, using equation (1) and assuming ions having a single positive charge, the nondimensional Poisson equation can be written as

$$\frac{\partial^2 \eta}{\partial \xi^2} = \frac{T_i}{T_e}\left[\frac{u_{0z}}{u_{iz}} - \exp(-\eta)\right]. \tag{5}$$

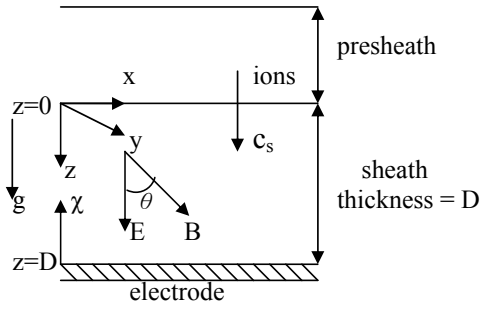

Figure 1: Magnetized plasma sheath configuration.

Chodura [16] proposed that the ions velocity entering the so-called "magnetic pre-sheath" is constrained to be along the magnetic field and to be equal or greater than sonic; while the ion drift velocity at the sheath edge is perpendicular to the solid surface and equal or greater than ion sound speed, $c_s = \sqrt{5k_BT_i/3m_i + k_BT_e/m_i}$. Franklin [17] later proved that in a simplistic fluid model the plasma equations are singular where the Bohm criterion is satisfied. This is regardless of the collision model for the ions and the generation mechanism for the charged particles; therefore, there cannot be a collisionally modified Bohm criterion. (For a detailed discussion on the validity of Bohm criterion at the plasma sheath edge in presence of a magnetic field we refer to [16, 4, 18, 19, 17].) As boundary conditions for the Poisson equation, we take the electric potential at the sheath edge to be zero, where the ion acceleration is also zero, thus giving rise to the other required boundary condition for the potential through the ions z momentum equation (4) [7]. The sheath thickness D is determined by the requirement that the potential takes a given value at the electrode, $\phi(z = D) = \phi_w$. The normalized boundary conditions are summarized as follows:

$$\xi = 0: \qquad u_{ix} = 0, \quad u_{iy} = 0, \quad u_{iz} = u_{0z} = \frac{c_s}{v_{thi}}, \tag{6}$$

$$\xi = 0: \qquad \eta = 0, \quad \frac{\partial \eta}{\partial \xi} = \frac{8}{\pi}\frac{T_i}{T_e}\alpha\left(\frac{c_s}{v_{thi}}\right)^2. \tag{7}$$

Equations (2) – (5) with boundary conditions (6) and (7) are solved using a fourth-order Runge-Kutta method. Starting from the sheath edge at $z = 0$, we march in space until the requirement $\phi = \phi_w$ is fulfilled.

We consider an isolated spherical dust particle of radius $R \ll \lambda_D$ and $R < \rho_{i,e}$, where $\rho_{i,e} = \sqrt{K_B T_{i,e} m_{i,e}/e^2 B^2}$. The latter inequality is satisfied for magnetic field intensities less than a critical value, found in practical units from [12]

$$B^e_{cr}(T)R(nm) > 4137\sqrt{\frac{T_e(eV)}{3(eV)}}.$$

With the above considerations, in the process of tracking the particle in space and time, orbit motion limited (OML) theory [20] can still be utilized to obtain the charge quantity on the dust due to the ion and electron currents and to find the electric force on the particle. Depending on the sign of the normalized potential difference between the particle and the plasma, $y(z, v_p) \equiv e(\phi_p - \phi)/k_B T_e$, in which ϕ_p denotes the particle potential and ϕ the sheath potential at the particle location, the electron and ion currents to the dust particle are given by

$$I_e = -\pi r^2 e \left(\frac{8K_B T_e}{\pi m_e}\right)^{\frac{1}{2}} n_e \exp(y), \qquad I_i = \pi r^2 e n_i v_i \left(1 - \frac{2K_B T_e y}{m_i v_i^2}\right), \tag{8}$$

for $y < 0$, and

$$I_e = -\pi r^2 e \left(\frac{8K_B T_e}{\pi m_e}\right)^{\frac{1}{2}} n_e (1 + y), \qquad I_i = \pi r^2 e n_i v_i \exp\left(\frac{2K_B T_e y}{m_i v_i^2}\right), \tag{9}$$

for $y \geq 0$.

For the ion current, we replace the thermal velocity and energy terms in the OML expression by the mean speed $v_s = \sqrt{v_{thi}^2 + \overline{v}_i^2}$ with which ions approach a dust particle. Here, $\vec{v}_i = (\vec{v}_i - \vec{v}_p)$ is the directed ion speed relative to a stationary dust particle while $\vec{v}_p$ is the particle velocity [21]. By equating the sum of the electron and ion currents to zero, we obtain an implicit equation for $y(z, v_p)$ (see [6, 11]), which depends on the position of the dust particle in the plasma sheath. Assuming a conducting dust particle, the particle charge can be calculated from

$$Q(z, v_p) = \frac{k_B T_e}{e} R y(z, v_p). \tag{10}$$

The main forces on a dust particle in a magnetized sheath are the electric, gravitational, ion drag, neutral drag and magnetic forces. Once the electric field $\overrightarrow{E}$ is calculated from the sheath equations and the charge Q on a dust particle is determined from equation (10), the electric force is simply obtained from

$$\vec{F}_e(z, v_p) = Q(z, v_p)\vec{E}(z). \tag{11}$$

The magnetic force acting on a moving dust particle is obtained via

$$\vec{F}_B = Q\vec{v}_p \times \vec{B}. \tag{12}$$

The ion drag force is given by [21]

$$\vec{F}_{id} = 4\pi n_i v_{thi} \widetilde{v}_s m_i \vec{\overline{v}}_i b^2_{\frac{\pi}{2}} \ln\Gamma, \tag{13}$$

where $b^2_{\frac{\pi}{2}} = e^2 Q^4/m_i^2 \overline{v}_i^4$ and $\ln\Gamma = \frac{1}{2}\ln(1 + b^2_{max}/b^2_{min})$. The maximum and minimum impact parameters, corresponding to maximum and minimum deflection angles, are $b_{max} = \overline{\lambda} = (2n_e\lambda_{De} + n_i\lambda_{Di})/(n_e + n_i)$ and $b_{min} = R$, respectively. Here, ion Debye length and local electron Debye length are defined as $\lambda_{De} = \sqrt{\epsilon_0 k_B T_e/e^2 n_e}$, and $\lambda_{Di} = \left[\epsilon_0(\frac{1}{2}m_i\overline{v}_i^2 + k_B T_i)/e^2 n_i\right]^{1/2}$, respectively.

Neglecting any gas flow, the relative velocity will be v_p, and the drag force due to neutral collisional coupling is given by the Epstein expression [22]

$$\vec{F}_{nd} = -\frac{8}{3}\sqrt{2\pi} R^2 n_n k_B T_n \left(\frac{\vec{v}_p}{v_{thn}}\right), \tag{14}$$

since the typical ratio $v_p/v_{thn} \ll 1$, where v_{thn} is the neutral thermal velocity defined as $v_{thn} = \sqrt{k_B T_n/m_n}$.

The total force acting on a dust particle is $\vec{F}_t = \vec{F}_e + \vec{F}_B + \vec{F}_g + \vec{F}_{id} + \vec{F}_{nd}$, where $\vec{F}_g$ is the gravity force on the particle with magnitude $F_g = m_p g$, where m_p is the dust particle mass and g is the gravitational constant. Having specified the forces, the dust particle Lagrangian equations are described as [11]

$$\frac{d\vec{x}_p}{dt} = \vec{v}_p, \qquad \frac{d\vec{v}_p}{dt} = \frac{\tau_0}{m_p v_{thi}}\vec{F}_t, \tag{15}$$

for particle position and velocity, respectively. Here $\vec{x}_p$ is the displacement normalized by the ion Debye radius λ_{Di} in the plasma, the time is normalized by $\tau_0 = \lambda_{Di}/v_{thi}$, and the velocity by v_{thi}. Initial conditions are provided for each equation having three components in three directions x, y and z.

3. Results and discussion

We consider argon to be the background gas, and the electrode to be held at a constant electric potential $\phi_w = -6V$. Other parameters are $T_e = 1$ eV, $T_i = 0.05$ eV, angle of incidence for the magnetic field $\theta = 20^o$, $P = 10$ mtorr, dust particle radius $R = 620$ nm. With the above parameters, B^e_{cr} is calculated to be 3.8524 T, hence, in the particle dynamics section we consider typical magnetic field intensities of 1.5 and 3 T and the OML theory remains valid. For B=3 T, ρ_i=47,499 nm and ρ_e=794.8 nm, and thus the inequality $R < \rho_{i,e}$ holds.

Figure 2(a), (b), (c) shows the ion velocity normalized by the mean ion thermal velocity, ion density normalized by bulk plasma density, and the normalized electric field as functions of distance from the electrode for different bulk plasma number densities and magnetic field intensities. As the plasma density n_0 increases, ion Debye length decreases; therefore, the degree of collisionality, α, also decreases. Hence, there will be less decelerating ion-neutral drag force but (see figure 2(c)) larger accelerating electric force through the influence of α on the boundary condition for electric potential at the sheath edge (equation (7)). The effect of the latter is dominant especially in the region starting from the sheath edge to near the electrode. This means that in higher n_0 case, ions will be accelerated more effectively and have larger velocity, and because of the continuity a smaller number density for the same distance from the electrode. Thus, the plasma shields the electrode potential more effectively leading to a thinner sheath.

In the present model, there is no restriction on the magnetic field intensity value in modeling the sheath structure. Therefore, to clearly show the effect of the magnetic field on the sheath, typical feasible magnetic field intensities as strong as up to even 4 T have been chosen for the results in this part. The presence of magnetic field induces fluctuations in the ion density. As the ions enter the sheath, they are decelerated by the Lorentz force in the z direction (see the momentum equations (2) – (4)) and thus, the ion density increases. As can be seen from figure 2(a) and (b), higher intensities of the magnetic field (e.g. B=4 T) can cause the ion flow to gyrate; the Lorentz force accelerates and decelerates the ions so the ion density experiences fluctuations. The reason that these fluctuations are more intense for lower plasma number densities can be attributed to the effect of ion Debye length on β which is responsible for the gyration-inducing terms in the momentum equations. For example, β is around 0.9244 for n_0=10^9 cm^{-3} while it is about 2.9233 in the n_0=10^8 cm^{-3} case. Furthermore, from the same figure it can be realized that the plasma sheath is thicker without magnetic field. This trend has been elaborated in details in [14]. Moreover, the indirect influence of magnetic field on the electron number density distribution in the sheath is obvious in figure 2(d).

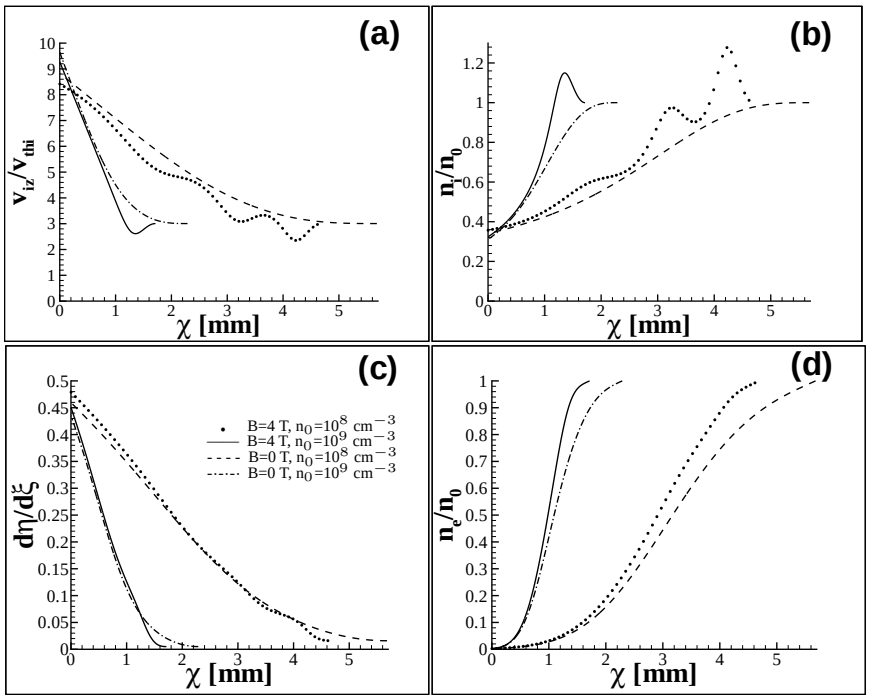

Figure 2: Comparison of plasma variables for different bulk plasma number densities and magnetic field intensities. (a) Normalized ion z-component velocity, (b) normalized ion number density, (c) normalized electric field, and (d) normalized electron number density.

Equations (15) for particle motion have been directly integrated in three directions with zero initial velocity for the dust particle initially released at the sheath edge. At steady state, position and charge of the particle, ion and electron number densities around the particle final position, and the potential difference between the particle and plasma as functions of the particle density are presented in figure 3 for three different magnetic field intensities B=0, 1.5, and 3 T. Since the gravity force on the particle increases with its density, the particle steady state z position, around which the particle oscillates in its transition phase, approaches the electrode. Hence, the number densities of both ions and electrons around the particle decrease (see figure 2(b) and

(d)). In the absence of the magnetic field in the sheath, the difference between these two number densities increases smoothly with the increase of the particle density. From the Poisson equation, this results in a larger negative value of the plasma electric potential ϕ at particle position. Because $(\phi_p - \phi)$ is negative in value and ϕ is also negative throughout the sheath, $(\phi_p - \phi)$ will decrease in magnitude (figure 3(d)). Consequently, according to equation (10), the amount of negative charge collected on the particle at steady state will also decrease in magnitude with the increase of the particle density which is evident in figure 3(a).

In the presence of the magnetic field, however, due to the induced fluctuations in number density of ions (see figure 2(b)), $(n_i - n_e)$ around the particle fluctuates with the increase of the particle density. Let us consider two particles with densities of 6.7×10^3 and 1.4×10^4 Kg m^{-3} both trapped in the sheath with an applied magnetic field intensity of B=3 T. Comparing the corresponding points A and B in figure 3(c), one realizes that ions are more concentrated around the lighter rather than the heavier particle equilibrium point, and thus,

$$(n_i - n_e)|_{z_{p_A}} > (n_i - n_e)|_{z_{p_B}}.$$

Intuitively, more net positive charge exists around particle A, hence less negative charge is expected to be populated on particle A. Furthermore, under the present conditions, it is found that for the case without magnetic field, nanoparticles with radius $R = 620$ nm and densities higher than 17,200 Kg m^{-3} might not be trapped in the sheath, while with the presence of a typical magnetic field intensity of 1.5 T or 3 T and with an angle of incidence of 20^o they can easily be trapped within the sheath.

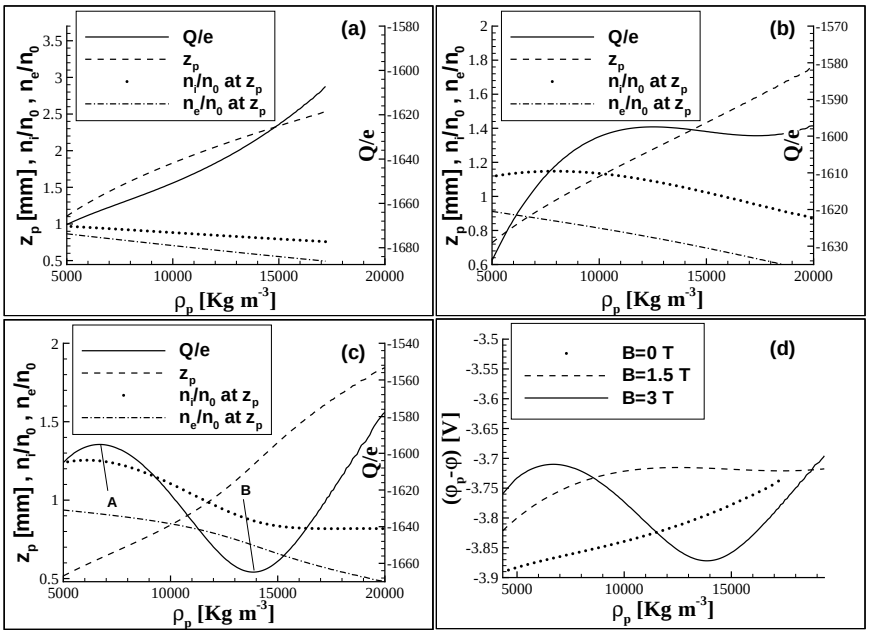

Figure 3: Steady state position and charge of the particle, ion and electron number densities around the particle final position as functions of the particle density for (a) B=0, (b) B=1.5 T, (c) B=3 T. (d) Potential difference between the particle and plasma as a function of the particle density for different magnetic field intensities.

4. Conclusions

The effect of the bulk plasma number density on the structure of a plasma sheath in presence of an oblique magnetic field has been studied by implementing a two-fluid model that adequately accounts for the forces acting on ions in the low pressure range. The primary effect of the magnetic field is to induce oscillations in the spatial variation of ions velocity and density. These oscillations become more pronounced as the magnetic field strength is increased. For varying bulk plasma density, different plasma parameters including the electron and ion densities, ion flow velocity, and electric potential are presented.

The dynamics of a dust particle located within the sheath subject to a moderate oblique magnetic field is examined through implementation of a comprehensive model taking various forces acting on the dust particle into consideration. The influence of the particle density and the magnetic field intensity on the amount of the charge collected on the particle has been discussed. Future studies are recommended to expand the parameter space in order to determine the ranges of various parameters for which particles can be effectively trapped in the sheath. As a practically important result, it is found that without magnetic field present in the sheath, heavier particles with the same size gather less negative charge; while in presence of magnetic field this trend can be violated depending on the field intensity and particle density. In addition, introduction of magnetic field to plasma can help trap heavier particles which could not be trapped in the unmagnetized sheath under the same conditions.

Kinetic Rate of Carbon Production in Cold, Vibrationally Excited CO Plasmas

Katherine Essenhigh and J. William Rich

Nonequilibrium Thermodynamics Laboratories, Dept. of Mechanical Engineering, The Ohio State University

The specific rate for the production of carbon by gas-phase Boudouard disproportionation of vibrationally excited carbon monoxide has been measured. The Boudouard disproportionation reaction is

$$CO\ (v) + CO\ (w) \rightarrow CO_2 + C.$$

Here, CO (v) and CO (w) represent carbon monoxide molecules in excited vibrational states v and w, respectively. This reaction has long been observed in various weakly-ionized molecular plasmas containing CO, and has been seen in optically pumped plasmas in which CO is vibrationally excited using a high power laser [1]. In other experiments, the reaction enters plays a role in synthesis of single-walled-carbon nanotubes using optically pumped, non-thermal plasma reactors [2]. Most importantly, the reaction has been known to occur on various metal catalytic surfaces; on iron, for example the reaction causes the carbon particle "pitting" of metal flues containing hydrocarbon/air combustion products. The reaction is not typically studied in the gas phase, however. From various plasma experiments, the activation energy for the gas phase reaction is estimated to be near 6 eV, requiring preparing reactants at a very high temperature for any measurable CO_2 yield by this process.

The experimental setup for the present experiments is shown in the schematic of Fig. 1. In these experiments, cold CO is mixed with an Ar carrier and flows through a reaction cell. The CO is vibrationally excited by the resonance absorption of the radiation from a c.w. CO laser, operating on the CO fundamental infrared bands from 4.7 to 5.3 microns wavelength. The CO rotation/translation modes remain in equilibrium at relatively low gas kinetic temperatures (~ 1,000 K) after vibrational excitation; the translational modes of the Ar carrier are also equilibrated to this temperature. The level of vibrational mode excitation in the CO reactant is measured by IR emission spectroscopy using the first overtone CO band emission. The distribution of energy among the CO vibrational quantum states (the vibrational distribution function, or "VDF") is inferred from these emission spectra. Fig. 2 shows typical VDF's , measured for such reactant preparation, for mixtures of CO in Ar, and for CO/Ar with various amounts of added He diluent. The gas translational/rotational mode temperature is also inferred by emission spectroscopy, from the rotational fine structure of the R-branch emission from the v = 1 – 0 CO fundamental band. It can be seen from Fig. 2 that a very non-Boltzmann distribution of vibrational populations is maintained in steady state; the high populations of vibrational levels near v =25, which are at energies near 6 eV, for example, would only be attained in thermally equilibrated environments at temperatures well above 10,000 K. Critical to the experiment is the ability to control the level of vibrational excitation. As seen in the figure, adding increasing amounts of He results in depopulating upper vibrational levels. This can rapidly decrease the reaction rate. The reaction rate is inferred by passing the mixture from the flow reactor through an FTIR, and inferring the concentration of the CO_2 product by absorption spectroscopy on the V_3 fundamental band. Fig. 3 shows the specific reaction rate inferred for the reaction, as a function of the amount of He added. The decrease in the reaction with the depopulation of higher levels is

easily inferred. It appears that significant reaction occurs only if the total energy in the reactants exceeds ~ 6 eV.

At the 1,000 K translational/rotational temperatures of the present environment, there would be ***no*** gas phase Boudouard reaction if the gas were thermally equilibrated. Indeed, the gas phase Boudouard reaction has only been observed previously by preparation of CO reactant in low-lying excited electronic states (notably, in CO($a^3\Pi$)) in photolytic or electric discharge reactors [3]. The only exception to this has been the measurements reported as CO "dissociation" reaction in very high temperature, shock-tube-generated, thermal environments from 5000 to 15,000 K [4]. No reaction is seen below 5,000 K, much less at the 1,000 K temperature of the present non-equilibrium rate measurements.

Table 1 gives a quantitative summary of the rate data. These data show that the reaction rate falls by an order of magnitude as the populations of vibrational levels above v ~ 25 are reduced by He addition. This reduction occurs although the total energy in vibration is not significantly reduced (see column 4 of Table I). It can be inferred that the effective activation energy of this reaction is approximately the energy of v~25, or, as indicated on the table, E_{act} ~ 5.8 eV. It may not be coincidental that this energy is very close to the ground energy level of the first electronically-excited state in CO, the $a^3\Pi$ state. It is possible that energy transfer from v ~ 25 into the $a^3\Pi$ mediates the reaction whose rate is reported in Fig. 3 and Table I. As we have noted, preparation of CO ($a^3\Pi$) results in a rapid disproportionation reaction. This possible channel is currently being investigated in our group. It is clear, however, why no *thermal* disproportionation is seen unless the gas temperature is above 5,000 K.

Abstract

An experimental investigation was performed to characterize the soot removal from the internal surface of a tube using a corona radical shower non-thermal plasma system. The corona radical shower non-thermal plasma removed soot from extended regions in the tube, but the removal was more effective near the tube entrance. The soot removal was also more effective for the case when the soot was dry. The emissions of unwanted gaseous by-products were monitored during these tests and found to be small.

Introduction

There has been considerable interest in using non-thermal devices to treat the flue gas in a range of applications [1-3]. Non-thermal plasmas can simultaneously remove the NO_x, particulate matter, and the volatile organic compounds present in the flue gas by promoting the oxidation reactions in the flue gas. Recently, there has been increased interest in using non-thermal plasma systems to oxide particulate matter deposited on surfaces, particularly in diesel exhaust gas pollution control systems. For example, Ohkubo et al. [4,5] considered the regeneration of diesel particulate filters using non-thermal plasmas. They were able to achieve a 85% removal efficiency using a needle-plate electrode configuration.

This investigation focused on developing a non-thermal plasma system to remove the diesel soot deposited in a wire-tube electrostatic precipitator (ESP) system that has been proposed as a possible low-pressure drop alternative for particulate filters[6]. The soot in the proposed system must be periodically removed and rapping can not be used because of concerns of soot reentrainment. There are a number of different designs for non-thermal plasma systems that can be operated in pulsed, flow-stabilized DC corona, dielectric-barrier, or pellet-bed discharge modes[1]. The latter two modes act to promote surface reactions in the reactor after the soot is deposited on the surface so they are not practical in the current application. Thus, it was decided to consider a flow-stabilized corona system with gas injected through the central electrode of the reactor. The flow-stabilized corona non-thermal plasma generates O and OH radicals that act to oxidize the carbon. The O radicals can also oxidize NO in a flue gas passing through the reactor to create NO_2 that could, in turn, oxidize the carbon. The soot oxidization will also result in the production of CO that is an undesired byproduct so that it is useful to characterize this during operation.

In practical applications, the corona radial injection system would have to be designed to optimize the interaction between radicals and the soot on the wall. The objective here was to assess whether the flow-stabilized corona system would be effective in oxidizing the soot so tests were preformed using a small diameter tube to ensure there was interaction between the radicals and the soot on the wall. The optimization for larger diameter tubes would be considered in later investigations. The flow-stabilized corona radical shower system and the experimental facilities used in this investigation are outlined in the next section. The results of the investigation are then presented and discussed.

Experimental Facility

The investigation was performed for a small diameter tube with a length of 200 mm that contained diesel soot deposited from the exhaust gas from a diesel generator described in [7]. After the soot was deposited in the tube, the tube was sectioned by cutting through most of the tube wall and then breaking the remainder of the wall manually. The thickness of the soot in the tube before the tests was

measured using an optical microscope. The sections of the tube were then inserted into a larger diameter tube that held them in place during the tests with the non-thermal plasma system.

The tube was inserted downstream of the non-thermal plasma reactor as shown in Figure 1. The non-thermal plasma reactor consisted of a grounded body tube and a discharge electrode made from a small diameter tube positioned in the center of this reactor. The flow in this system consisted of a main flow through the reactor and an auxillary air flow added through the hollow discharge electrode. The main air flow through the plasma reactor and the auxiliary flow through the electrode were measured using two flowmeters. The auxiliary flow was set so the nominal velocity ranged from 1 to 10m/s.

The discharge electrode was connected to a high-voltage pulsed-type power supply that generated a streamer-type corona discharge from the hollow electrode to the grounded electrode. The reactor was designed so the discharge should be approximately perpendicular to the main gas flow. The pulsed power supply was charged using a low voltage DC power supply. The frequency of the pulsed power supply was controlled using a frequency generator and a triggering circuit. The discharge voltage and current were monitored on a Textronic oscilloscope usaing a high voltage probe connected to the discharge electrode and a current transformer connected to the grounded side.

The experiments to characterize the soot removal were performed by exposing the sooted tube to the flow exiting the reactor for 6 to 11 hours. The gaseous by-products exiting the sooted tube were monitored using a combustion gas analyzer (Eurotron, Greenline 6000). The detection limit for CO, NO and NO_2 was 1 ppm.

Results

The flow stabilized corona system was operated using a pulse high voltage signal generated using an ignition coil, driven by low voltage DC power supply. The typical discharge waveforms of the voltage, the current and the power of the plasma reactor for a pulsing frequency of 200 Hz are shown in Fig.2. In this case, the discharge voltage and current oscillate for approximately 20% of the duty cycle, but the

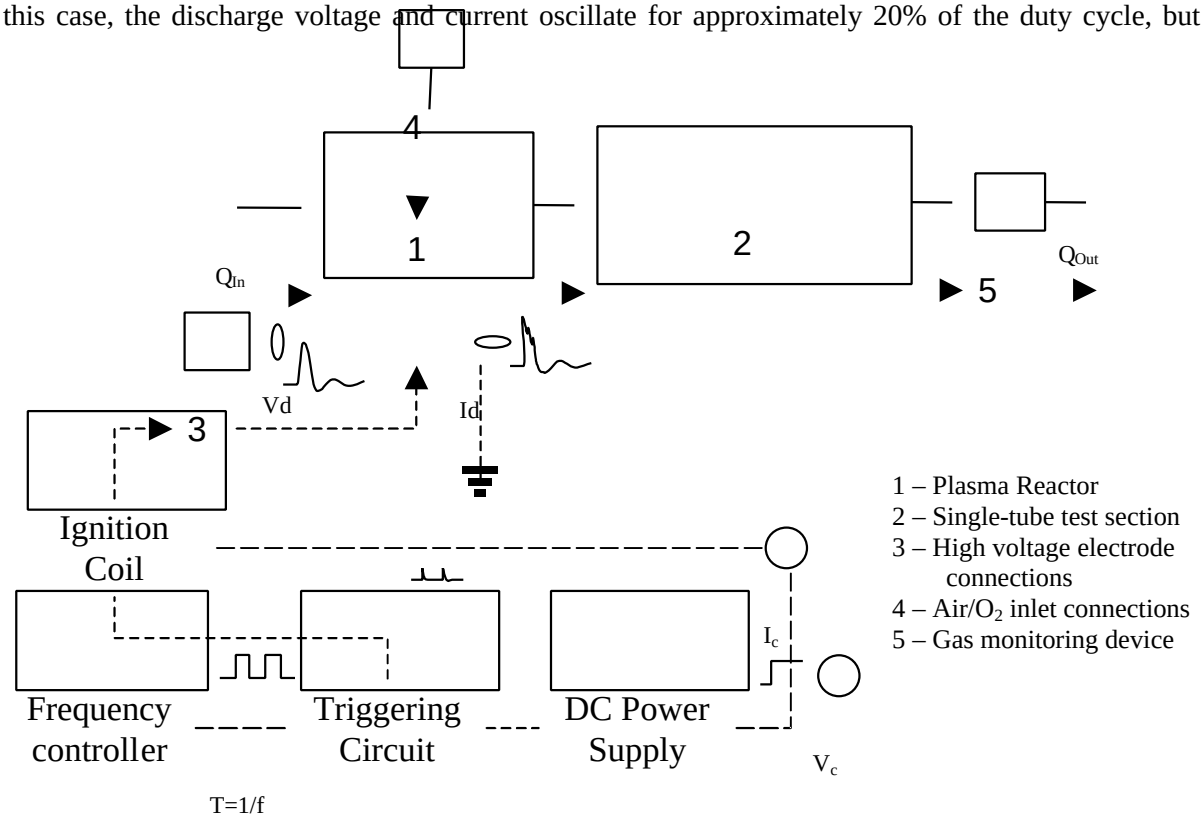

Figure 1 Schematic of experimental set-up of plasma reactor and power supply

discharge power is small after approximately 10% of this cycle. The change in the maximum discharge current and voltage with charging power for the different pulsing frequencies is shown in Fig. 3. The maximum discharge voltage increased rapidly with charging power to a maximum of approximately 15 kV. The charging power required to achieve this discharge voltage increased with frequency, as expected. The maximum charging current that could be achieved with the power supply decreased significantly for frequencies greater than 100 Hz.

The change in the average discharge power with charging power for different pulsing frequencies and air flow rates are shown in Fig. 4. The average discharge power increases with frequencies to 100 Hz before decreasing again as the frequency was increased, particular for frequencies above 200 Hz. The discharge power was relatively independent of the air flow rate for the range of flow rates considered here (Fig 4b), but the spark-over voltage was higher at the higher auxiliary flow rates. The efficiency of the power supply was low in part because no effort was made to impedance match the power supply and load to optimize the performance of the device.

The performance of the non-thermal plasma for soot removal was tested for two cases using

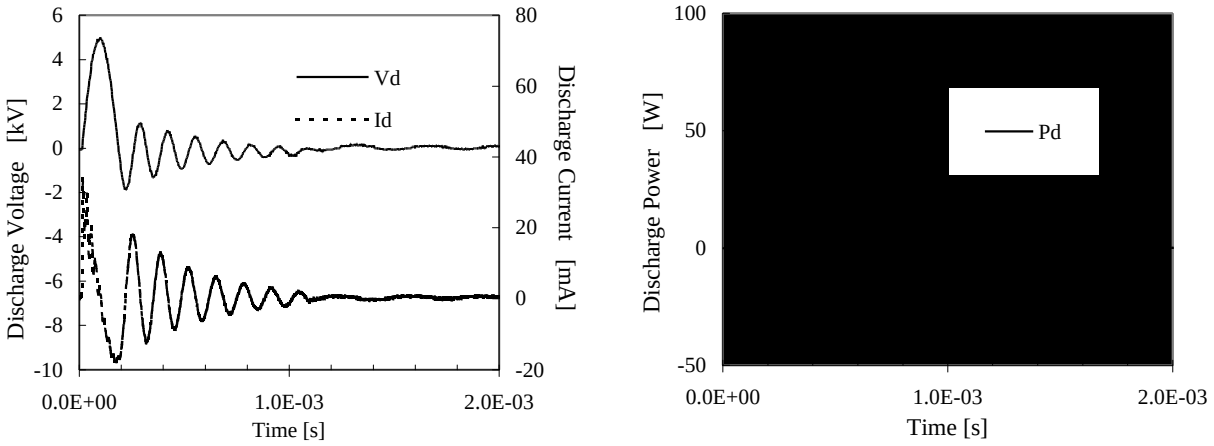

Figure 2. Typical discharge (a) voltage and current waveforms and (b) power waveforms for a charging voltage and current of 2 V and 0.4 A, respectively, a pulsing frequency of 200 Hz , and an air flow of 8 l/min.

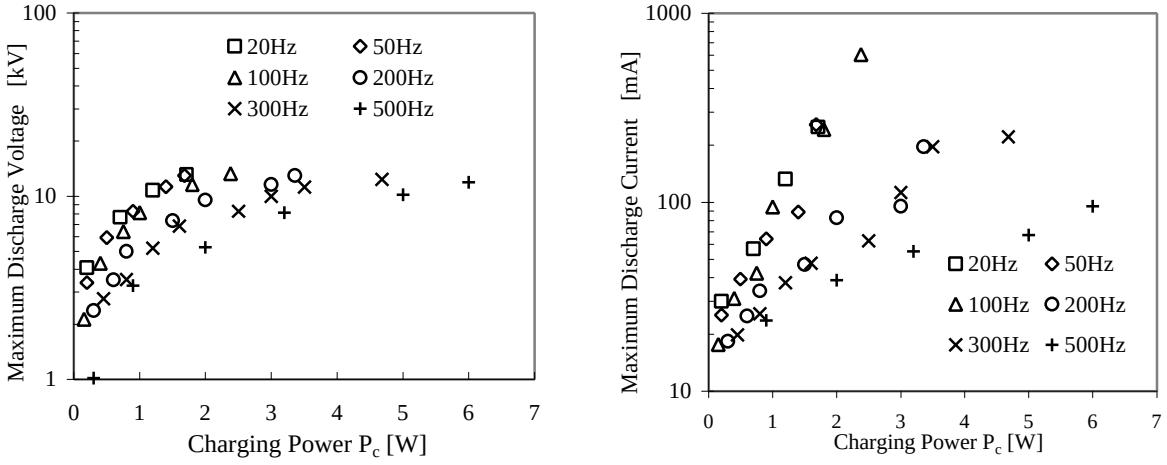

Figure 3. Change in the (a) maximum discharge voltage and (b) maximum discharge current with charging power for different pulsing frequencies.

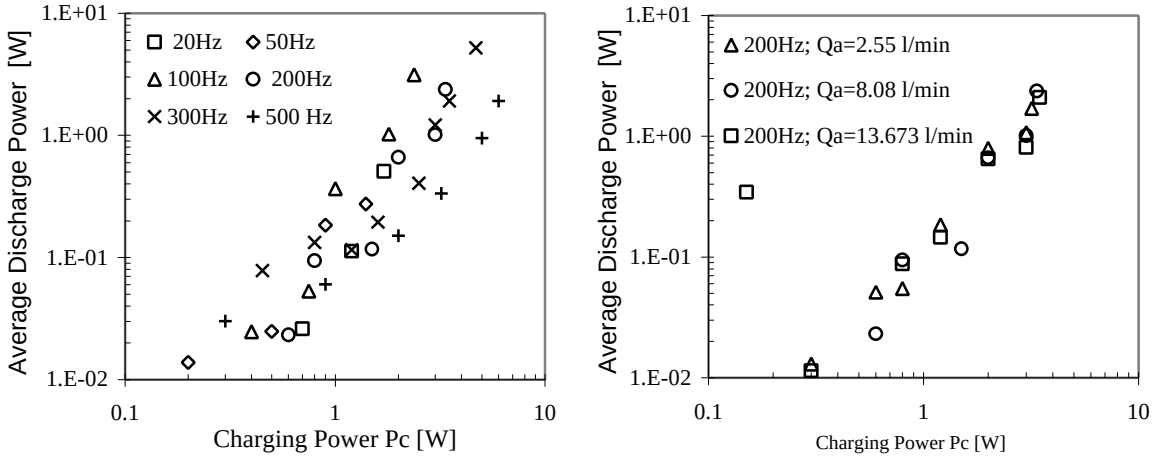

Figure 4. Change in the average discharge power with charging power for different (a) pulsing frequencies and (b) air flow rates.

tubes that had been exposed to diesel exhaust flow for approximately 1 hour of operation. In the first test, the deposited soot layer was treated soon after it was deposited (wet soot condition) for a total time of 11hrs with periodic measurement intervals to weigh the individual tube sections. The plasma reactor was operated at the frequency of 200 Hz, discharge power of 4.5 W. The main and auxiliary air flow rates were 13.7 l/min and 8 l/min, respectively and both were at a temperature of 23^{o}C. The activation of the soot oxidation was monitored by measuring the concentration of the CO in the exhaust gas. It was found that the soot oxidation started 20 to 40 minutes after the non-thermal plasma treatment was initiated. After that, only trace amounts (< 15 ppm) of CO and NOx were observed during the oxidation process.

The removal of the soot layer by the non-thermal plasma treatment was characterized by measuring the soot layer in the tube before and after the test. The deposited soot layer measured at 30 mm and 180 mm downstream of the tube entrance before and after the non-thermal plasma treatment are shown in Figs. 5 and 6. In both cases, the thickness of the soot layer was highly non-uniform around the circumference of the tube before the non-thermal plasma was applied, which was in agreement with the Neutron Radiography 3-D soot deposition thickness measurements in larger diameter tubes reported by Ismail et al. [7]. The thickness of the layer was also significantly thicker near the tube inlet that was also the flow inlet when the tube was in the diesel facility, similar to in Ismail et al. [7]. The application of the non-thermal plasma device reduced the soot layer at both locations near the inlet and the outlet indicating the non-thermal plasma was affecting the soot layer throughout the tube.

The removal of the soot layer throughout the tube was characterized using the circumferentially averaged soot layer thickness determined at the different downstream locations before and after the treatment shown in Fig. 7. The measurements showed that the non-thermal plasma treatment caused a significant reduction in the soot thickness throughout the tube. The soot removal was somewhat larger at the entrance of the tube, but there was significant removal of the soot throughout the tube. It was estimated that approximately 37% of deposited soot was removed after 11 hrs of operation.

In the second test, the soot layer was left undisturbed for more than 24 hours before the tube was treated (dry soot condition). This should remove much of the water and unburnt hydrocarbons absorbed in the layer. In this case, the soot layer was removed more rapidly than for the wet test. The soot layer deposited on the tube in this dry test was not accurately measured so that it was not possible to definitively determine the soot removal rate. It appeared though that over 50% of the soot was removed in 6 hours of continuous plasma treatment. This suggests that the presence of the unburnt hydrocarbons and water vapor in the soot layer had an effect on the oxidation of the soot layer. This difference could be due their presence affecting the diffusion of oxygen into the layer or because in the first experiment

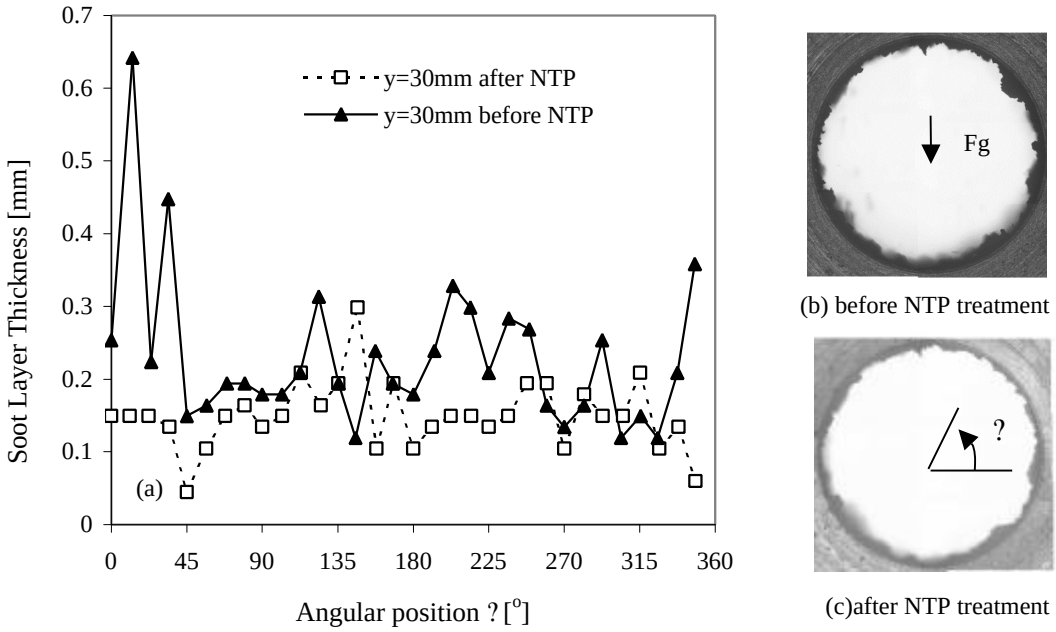

Figure 5. Comparison of the circumferential soot thickness profiles and images of the soot layer thickness at 30 mm downstream of the non-thermal plasma reactor before and after the treatment.

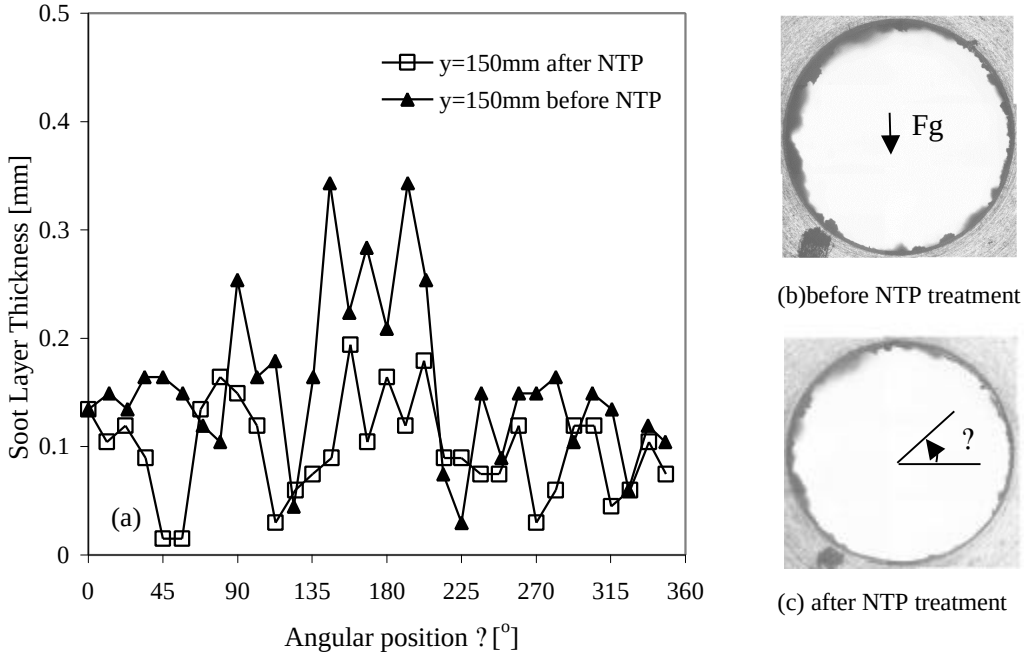

Figure 6. Comparison of the circumferential soot thickness profiles and images of the soot layer thickness at 180 mm downstream of the non-thermal plasma reactor before and after the treatment.

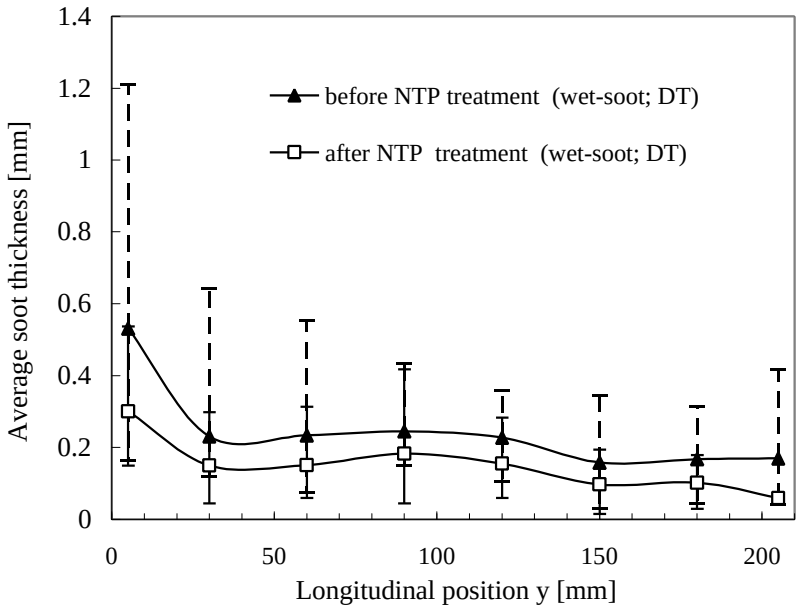

Figure 7. Comparison of the circumferentially averaged soot thickness along the pipe length before and after the 11 hour non-thermal plasma treatment applied immediately after the soot deposition. (The range of thickness at each point is indicated with the bars.)

the unburnt hydrocarbons is oxidized in addition to the carbon soot. In this test, the removal of the soot layer was more non-uniform with a much larger soot removal near the entrance.

Conclusions

Experiments were performed to characterize the removal of diesel soot from a tube using a corona radical shower non-thermal plasma operated using a pulsed-type power supply. The soot could be removed over the entire length of the tube but the soot removal was somewhat larger at the entrance near the corona shower. The measurements of the CO in the exiting flow indicated that the soot oxidation required 20 to 40 minutes to initiate. The tests also indicated that the soot removal rate was larger when the diesel soot had dried for approximately 24 hours.

Non-Thermal Plasma Processing for Dilute Trichloroethylene Decomposition

T.Oda, S.B.Han and R.Ono

Department of Electrical Engineering, the University of Tokyo, Tokyo, Japan

Abstract

Non-thermal plasma process for decomposition of dilute (mostly 250 ppm) trichloroethylene in atmospheric pressure air is experimentally studied. Various kinds of catalysts are tested to improve the decomposition efficiency and the manganese oxide is very effective in decomposing TCE with little energy consumption. The optimal plasma reactor design is also discussed related with the gas flow rate, humidity and oxygen content. Argon gas is also mixed with TCE contaminated air to understand discharge mode effect

Keywords: non-thermal plasma, catalyst, trichloroethylene, manganese oxide

1. Introduction

The atmospheric pressure non-thermal plasma has very strong chemical reactivity and many researchers have been applied that non-thermal plasma to remove environmental pollutants from air or combustion flue gas. Late Masuda developed ultra short pulse generator for the electrostatic precipitator. Florida group or Tokyo group applied that pulse technology to reduce NOx in the combustion flue gas[1,2]. RTI group also reported the VOCs (including CFC113) decomposition[3] by the barrier discharge or the pulse discharge. The authors also reported the CFC113[4] decomposition (maximum is more than 99%) by the surface discharge reactor which was designed as the ceramic reactor ozonizer for high concentration ozone generator. The authors are also engaged in developing the atmospheric pressure nonthermal plasma technology to decompose the dilute volatile organic compounds (VOCs), such as trichloroethylene, acetone and ethylalcohol[5]. The authors investigated the non-thermal plasma reactor not only for VOCs decomposition but also NOx removal from the combustion flue gas[6]. Already many other researchers have also studied on those VOCs decomposition technologies by using the non-thermal plasma[7-9]. Recent interest of those researchers is how to improve the VOCs or NOx decomposition energy efficiency which is very important for the practical usage of the non-thermal plasma. In order to estimate those parameters in the same table, target decomposition material is focused on the trichloro-ethylene ($CHCCl_2$) decomposition which concentration is from 50 to 1,000 ppm. To improve the TCE decomposition efficiency, several experiments have been done and a bolt type reactor (barrier discharge mode and the discharge electrode has sharp edge to generate uniform streamer discharge) and the authors would like to improve their performance more[10]. Many researchers investigated the new type plasma reactor combined with the catalyst[11-13]. The authors also tested the barrier discharge plasma reactor combined with various catalysts[14]. During those researches, the separation of adsorption effect by the catalysts and plasma decomposition effect was very difficult. Moreover, the decomposition efficiency of TCE was affected by the byproduct analysis method. That is; GCMS analysis suggested better decomposition results, compared with normal GC analysis or FTIR. That result suggested the ozone decomposition enhances the TCE decomposition[15]. Einaga et al suggested the usage of manganese oxide[16] and the authors also recognized that effect[15]. The manganese effect to the non-thermal plasma process has been investigated[17] and recent results will be described in this paper.

2. Experimental

There are several ways to realize the non-thermal plasma for the gas decomposition. As the power con-

sumption of DC high voltage discharge is too large, the discharge plasma should be generated by AC or pulse high voltage. Past experiments of the authors suggested that the pulse with ultra short rising time discharge is the best to decompose stable materials. However, the commercial frequency (50 or 60 Hz) high voltage discharge plasma can also decompose VOC (volatile organic compound) with good energy efficiency in most cases. Therefore, the authors usually use 50 Hz discharge because of the simple and economic power supply system.

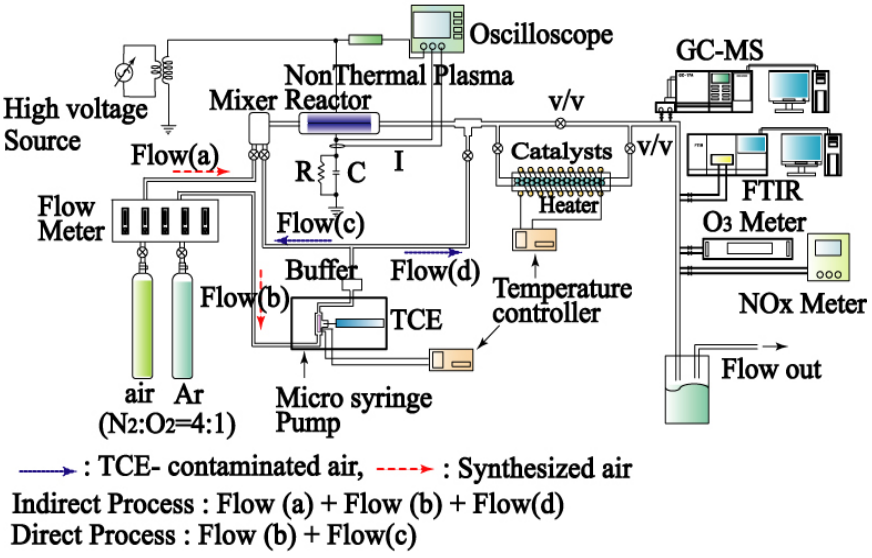

Fig. 1 Experimental setup including the gas flow.

The experimental system including the gas flow is shown in Fig. 1. A calculated amount of TCE is injected into a synthesized air by the micro syringe pump to adjust the TCE concentration. TCE contaminated air passes through non-thermal plasma reactor (Direct method) and passes through catalysts area in need. In another mode (Indirect Method), only pure synthesized air passes through the plasma reactor and is mixed with TCE-contaminated air at the downstream. Other processes are the same as the Direct method. Some times, the catalyst is filled in the plasma reactor. The following experiments are done by that method for Direct Process.

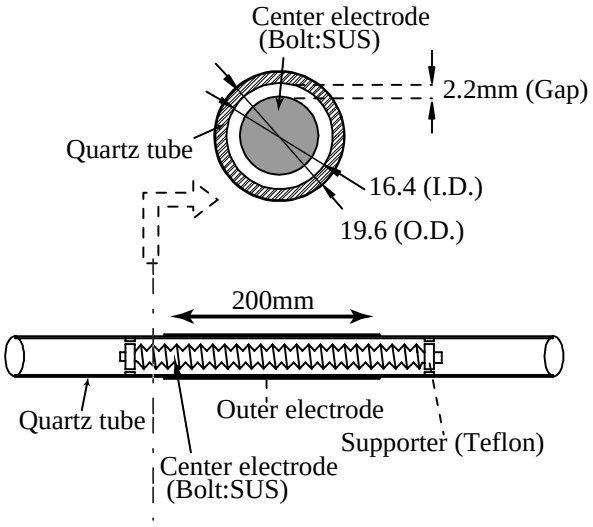

Fig.2 Nonthermal plasma reactor driven by 50 Hz high voltage.

There are many kinds of plasma reactors were fabricated and tested. The surface discharge reactor can generate high density ozone and be injected so much energy to decompose the stable CFC and so on, if the applying voltage frequency increases. As the energy efficiency is very good for the barrier discharge compared with the surface discharge, recent experiments use the barrier type plasma reactor. Typical example reactor is shown in Fig. 2. Various discharge electrode configurations have been tested and the bolt type discharge electrode is the best still now because that generates stable and many streamers from the edge of the plate. Figure 2 shows that example. In that case, the quartz tube (outer diameter 19.6mm and the inner diameter is 16.4 mm (that is; the glass thickness is 1.6 mm. At the center of the tube, 12 mm (in diameter) size stainless steel bolt is located. Ground electrode (Copper film) wounded the tube with 20 cm width. In this paper, the catalyst is filled in that plasma region, if the catalyst is used. As the catalysts, titania (TiO_2), vanadium oxide (V_2O_5), tungsten oxide (W_3O_4), zeolite (Na- or Cu-doped) and manganese oxide (MnO_2) were tested. Typical gas flow rate is 2L/min (1 or 2 L/min) and balance gas is synthesized air (80% nitrogen and

20 % oxygen) The zeolite sintered at low temperature has very large surface area and gas adsorption by the zeolite is too large to separate the adsorption effect and plasma decomposition effect. Finally, the authors decide to use manganese oxide as the ozone decomposition catalyst which also decomposes VOC, maybe by the atomic oxygen effect. That manganese oxide effect to decompose VOC is not yet understood. It is not still unclear whether atomic oxygen radical effect in the gas phase either manganese oxide surface chemical reaction with the ozone and VOC molecule is dominant to decompose VOC.

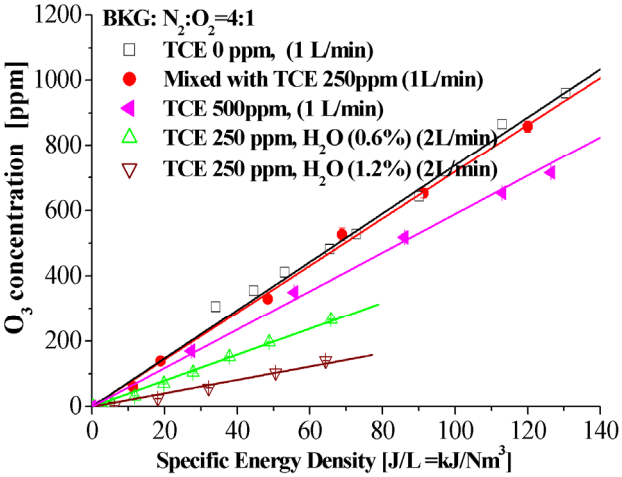

Fig.3 ozone concentration versus the specific energy density for water vapor pressure.

3. Results and Discussions

For ozone generation, humidity is very important. One example is shown in Fig. 3 where dry air without TCE can generate the largest amount of ozone. When the TCE concentration is 250 ppm, the ozone generation is not affected by the existing of TCE but 500 ppm TCE contaminants suppress the ozone generation of about 200 ppm. It is easily recognized that the ozone generation is smaller for artificial addition of water to the air (0.6% or 1.2 %) with 250 ppm TCE than that for dry condition. In that case, atomic oxygen radicals may be consumed to generate OH radicals. If the OH radical is very effective in decomposing TCE, high water content can assist TCE decomposition. At the same condition (without the catalyst), TCE decomposition efficiency is shown in Fig.4 suggesting that water vapor suppresses

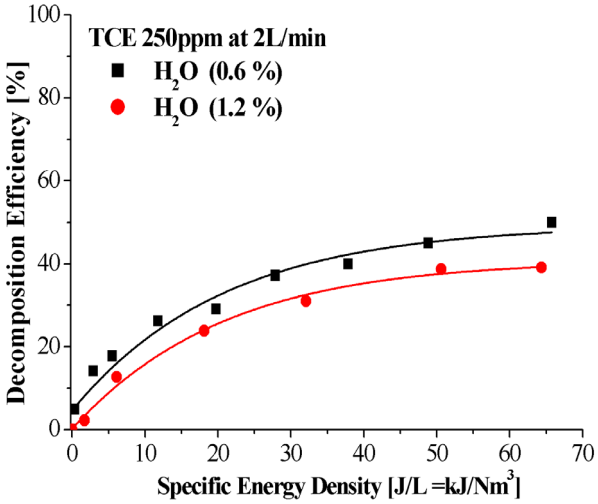

Fig. 4 TCE decomposition efficiency versus the specific energy density(humidity effect)

the TCE decomposition. OH radical is not so strong to oxidize TCE compared with the ozone. However, the decomposition efficiency difference is not so high as estimated from Fig. 3 (ozone suppression). Maybe some part of TCE can be decomposed by OH radicals but real chemical reaction is not yet clear. As byproducts, NO_2 concentration in the processed gas is observed where NO_2 for low water (0.6% H_2O) is rather higher (30 ~40%) than that for 1.2 % water, but total concentration is very low (2~ 4 ppm at high specific energy density; the specific energy density, SED is calculated as electric power consumption(W) / flow rate (L/min) X 60 seconds) observed by chemical luminescence method). Other byproducts

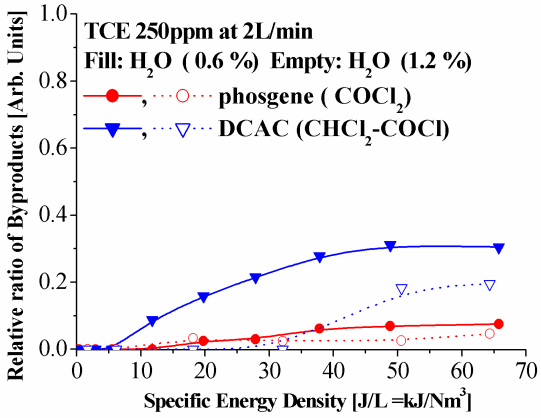

Fig. 5 Byproducts versus specific energy density fro 0.6% and 1.2 % water concentration.

are also measured by a GCMS (gas-chromate-graph mass-spectrometer: Shimadzu GCMS-5000A). Amounts of byproducts; such as DCAC (dichloro-acetylchloride: $CHCl_2$-COCl) and phos-gene ($COCl_2$) are observed for the different spe-cific energy density as shown in Fig. 5. When the specific energy density is less than 30 J/L, DCAC product is negligibly small for 1.2% water in the air, although DCAC for low water concen-tration (0.6%) is pretty high. Increasing the spe-cific energy density from 30 J/L, DCAC byprod-ucts also increases rapidly which does not agree with the Fig.4 where the decomposition efficiency is roughly proportional for both cases. On the other hand, phosgene production is proportional with the TCE decomposition efficiency. This mechanism is not yet clear but the specific energy of 30 J/L should be important. If the processed gas passes through the manganese oxide, the effi-ciency increases more than 98%. Concerning with the byproducts, generation of NO_2 is about 2 ppm for wet condition and 4 ppm for dry condition, at the specific energy of 60 J/L. The oxidation by the ozone with manganese oxide produces lot of TCAA (trichloro-acetaldehyde: CCl_3-CHO) and very little DCAC. Water addition effect should be explained by those results but the energy den-sity is not yet explained. The decomposition mechanism of the ozone on the manganese surface is not yet clear. Maybe some part of the ozone must be trapped on the manganese surface and atomic oxygen will be generated. The behavior of that atomic oxygen radical is not clear. That may stay on the man-ganese oxide surface or that may leave into the con-taminated-air from the surface of the catalyst and attack to VOC molecule to oxidize VOC to water and carbon oxide. Another possibility is that. VOCs themselves also may be trapped on the manganese oxide surface. Those trapped VOCs may be easily oxidized by the ozone with the aid of the manganese oxide catalyst effect. In that model, powder-like zeorite can adsorb VOCs very much but the decomposition of VOCs is not so

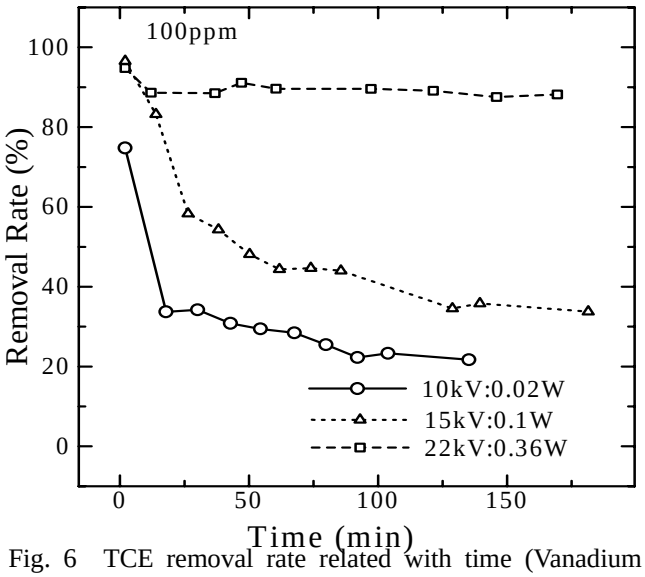

Fig. 6 TCE removal rate related with time (Vanadium Oxide on/in titanium oxide)

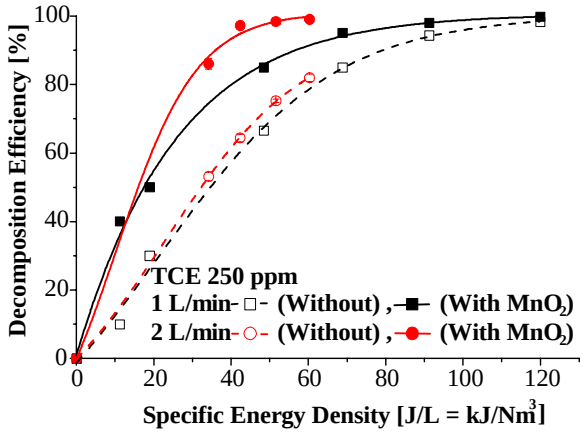

Fig. 7 TCE decomposition efficiency versus SED with/without manganese oxide.

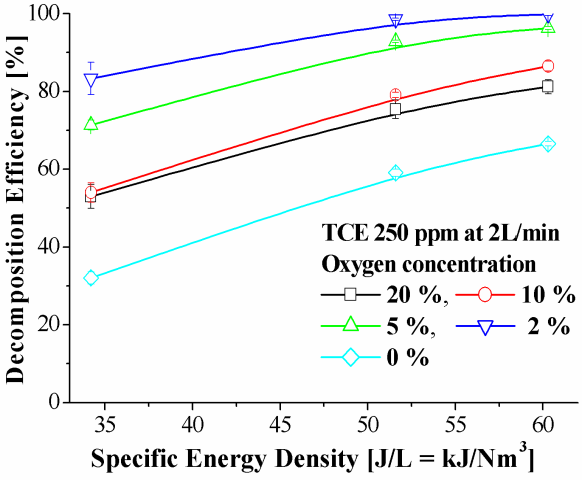

Fig. 8 TCE decomposition efficiency versus SED (oxygen concentration effect)

clear. In previous experiment, VOCs decomposition by the vanadium oxide surface is not clear as seen in Fig. 6 where the flow rate is 0.4 L/min. In this case, adsorption effect continues more than two or three hours except 22 kV plasma where the temperature increases very slowly becouse of the small discharge power and desorption of TCE from the catalyst still increases wit h time.

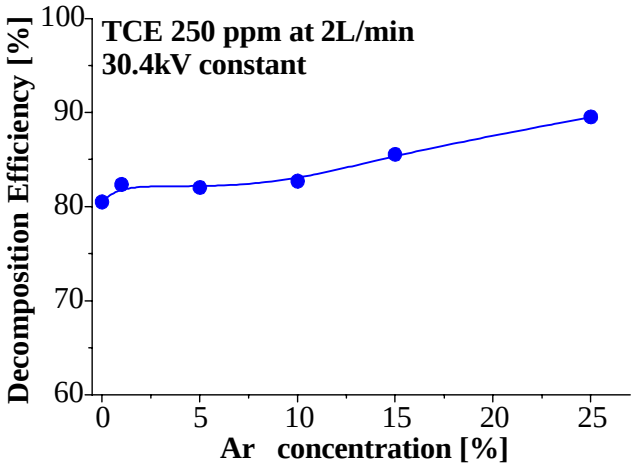

Fig.9 TCE decomposition efficiency (argon partial pressure effect)

Usually the background gas is the air and the oxygen concentration is roughly 20 % and nitrogen is about 80 %. Previous experimental results suggest the importance of the oxygen concentration for the TCE decomposition. However, the optimal oxygen concentration is not yet examined and the authors observe that as shown in Fig.8 where the process is Direct Process without the catalyst. Apparently for the nitrogen ~100% gas (0 % oxygen in Fig. 8), the TCE decomposition efficiency is the worst among all data. That decomposition may be caused by the electron impaction and nitrogen radical effect to disconnect some bondings without oxidation of VOCs. The optimal oxygen concentration is only 2 % which is much smaller value as formerly estimated. This result is in good agreement with atomic oxygen generation observed by TALIF (tow photon absorption laser induced fluorescence) method. Smaller oxygen concentration of less than 2% is not yet tested and this value is not yet optimal value. There is no apparent difference for 10 % and 20 % oxygen concentration. At the SED of 45 J/L, the TCE decomposition efficiency for 20 % oxygen is only 60 % but that for 2 % oxygen is 90 % which value is very useful and practical without manganese oxide. Maybe for further oxidation of VOCs, that oxidation needs much oxygen atom and the performance (for example, most carbon should be oxidized to carbon mono-oxide and carbon dioxide) will be improved for higher oxygen concentrated gas.

For further investigation of gas component effects, pure noble argon gas is added to TCE-contaminated air. That test results is shown in Fig. 9. As the argon gas concentration increases, TCE decomposition efficiency increases a little bit but not so apparent compared with oxygen. (From 80 % to about 90 %,) only 10 % change of TCE decomposition efficiency is recognized, although the decomposition efficiency change is about 20 % from zero to 20 % oxygen. The TCE decomposition efficiency difference is too large of 40 % only for 2 % oxygen concentration change. Since the argon gas is much easily ionized, the discharge energy increases with the increase of the argon concentration, the increase of TCE decomposition efficiency is understood but that value is rather small. If SED is the same, TCE decomposition efficiency will rather decrease. Moreover, the byproduct of phosgene increases with the argon gas concentration. In total, the argon gas addition is not effective in improving the plasma process efficiency, in practice.

4. Conclusions

In order to improve the non-thermal plasma process concerning with the VOCs decomposition efficiency, various parameters are examined. Especially, the balance gas conditions are changed. They are the humidity, the oxygen concentration and the argon gas addition.

4.1 Concerning with the humidity, the dry condition is better than the wet condition although OH radical for-

mation is enhanced by adding the water. Maybe the ozone or the atomic oxygen radical can oxidize the VOCs more than OH radicals. Further investigation must be done for better understanding of the humid plasma process.

4.2 A few percents oxygen contamination to nitrogen is very effective in decomposing TCE compared with normal air (20 % oxygen). That mechanism and the effect to the final oxidation to carbon oxide are not yet recognized.

4.3 Contamination of the argon gas to the air is not so effective in TCE decomposition.

Nonequilibrium Effects in Atmospheric Pressure Electric Arcs

V.A.Zhovtyansky

Plasma Technology Department, National Academy of Sciences of Ukraine the Gas Institute, Kyiv, 03113, Ukraine

Abstract

The nature of nonequilibrium state of plasma in atmospheric pressure electric arcs is investigated by experimental, analytical and numerical methods. The objects of study where a pulse electric arc in argon or helium and a free burning electric arc between evaporating copper electrodes. The state equations of plasma are proposed in the cases if the reason of deviation from local thermal equilibrium (LTE) were radiative transfer or radiation loss in plasma of high degree of ionisation.

1. Introduction

This paper is concerned with study of atmospheric pressure electric arc plasmas being a basis of modern numerous technological applications. The thermal equilibrium model of plasma was accepted in early stage of electric arc quantitative experimental investigation in the 1950s [1].

From the end of 60th some deviations from equilibrium as a result of radiative loss and diffusion processes influence [2 - 4] as well as radiation transfer [5, 6] in various type of arcs were fixed. Yet they were not investigated systematically. So the prior guess that equilibrium occurs in electric arc plasmas in all cases remains dominant. Really, these plasmas are of high density enough to support LTE at the central part of plasma volume as a rule. Nevertheless the bulk plasma is finite with space as any other plasmas in all practical applications. Appearing gradient effects consist in the energy and particles flux to the boundaries and outside of plasma volume.

Four important factors, determining conditions of plasma application, are connected with this.

First, these effects determine electric energy loss in their own transport in discharge channel and, correspondingly, the efficiency of plasma generation. (Really, this channel may be considered as an electric current conductor).

Second, the intensity of energy and particles flux through boundary of plasma determines the efficiency of their influence as a processing agent in technological applications.

Third, diagnostic of plasma is realized through their boundary layer, which influences as a filter on the primary observation results. Therefore to obtain results, adequate to state of plasma, it is necessary to take into consideration this influence correctly.

And finally, fourth, the most important from the viewpoint of physical investigation. Noncompensated energy and particle flux cause detailed balancing violation with respect to some elementary processes and, as a result, to non-equilibrium state of plasma.

2. Experiment

We have studied plasma obtained both in free-burning electric arc between melted cooper electrodes in air atmosphere and in pulse electric arc in discharge section of device type of electric shock tube (EST). The results of the experiments in the wall-stabilized arcs [7 - 9] based on the methods of plasma emission spectroscopy were taken into account to adequately determine the properties of cooper plasma in arc column.

Most complicated were investigations of near channel region of electric arc where the plasma turns into ambient gas gradually in radial direction and medium to be studied is weakly or non-radiating. Moreover, an arc in the absent of stabilization, is spatially unstable. It complicates its diagnostic by alternative methods of absorption spectroscopy. The problem in this case is recording both own spectral radiation of plasma and external source of plasma irradiation as it needs to perform simultaneously by the same image sensor [10].

The arc in cooper vapor was initiated between two noncooled copper electrodes of 6 mm in diameter each (the electrode gap of 2-8 mm). A pulse mode was used to avoid droplet formation. The current pulse of amplitude up to 100 A and duration 30 ms was applied to a pilot (“keep-alive”) low current (3 A) discharge. Investigations were performed in the quasi-stationary stage of the pulse process [11].

In the absence of stabilizing wall this free-burning arc could move chaotically across the working surfaces of electrodes (Fig. 1). That is why the fast scanning tomographic spectrometer was used to study electric arc plasma [12].

A coefficient of recombination of charge particles might be found if near-wall layer of plasma is studying quantitatively. Pulse regime only allows separating with time the specific effects in plasma including mentioned coefficient. Because of this, the relaxing plasma in pulse electric arc has been observed.

In this connection a technique of EST may be used (Fig. 2). They were developed as early as 60th to study plasma extension, including shock and heat waves [13, 14]. The EST was completed of a glass tube (R_t = 0.8 cm) with Kovar ring electrodes E_1 and E_2 1.5 cm wide each spaced at 5 – 7 cm and filled by argon or helium at initial pressure from 65 up to 1330 Pa (Fig. 2). The plasma was produced by a pulse current generator with amplitude up to 20 kA and time duration up to 5 μs. The discharge between electrodes E_1 and E_2 is practically wall-stabilized electric arc. The discharge section E_1 - E_2 was around with symmetrical system of conductors SC (up to 6 ones) to exclude breaks the symmetry of plasma in this section due to own magnetic field action.

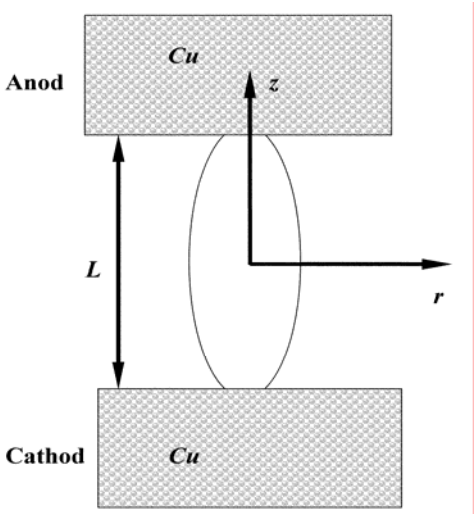

Fig.1. The scheme of free-burning electric arc and system of coordinates

The plasma in discharge section could be bounded by steel pistons every confined in a glass jacked. In this case it was convenient object to study decay of motionless plasma and the influence of near-wall sheath in this decay [15].

Due to sharp increase of plasma temperature up to 1 – 3 eV during pulse discharge, the pressure between electrodes E_1 – E_2 came nearer to atmospheric. If the obtained plasma could extend in enclosing space, there was an additional possibility to study influence of plasma expansion on its equilibrium properties.

The adequate diagnostic of non-stationary plasma was fulfilled by fast scanning emissive and absorb-

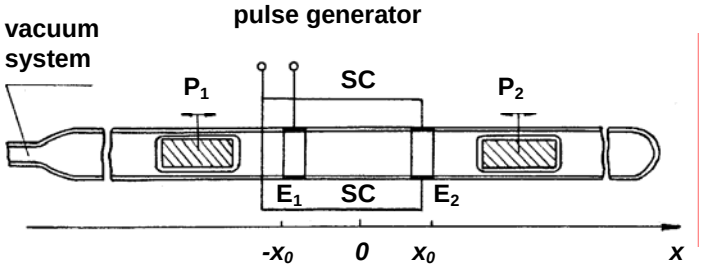

Fig. 2. EST to study plasma decay and system of coordinates:
E_1, E_2 – ring electrodes; SC – symmetrized conductors; P_1, P_2 – steel pistons every confined in a glass jacked

ing tomographic spectrometry. These methods are based on the spatial modulation of radiation of plasma across the section to be studied in combine with using of bifocal optical systems [10, 12]. The spectrometer proposed is suitable for study of short pulse processes, including single one.

Two problems are typical in the research of free-burning electric arc plasma in cooper vapor. First, one of the convenient in diagnostic spectral line 510.5 nm is subject to self-absorption. Second, as will be shown later, just the self-absorption of resonance spectral lines in its turn is the reason of deviation from LTE in plasma in the outer region of electric arc channel. To determine adequately the parameters of plasma in this case the so-called procedure of computational-adaptive spectroscopy was used [16]. In this procedure the initial data of spectroscopic measurements are correcting in the iterative process in accordance with the assumed collisional-radiative model [17] of the arc under study.

The spectroscopic measurements have shown, that N_e changes in a range of $2\cdot10^{16}$–10^{15} cm^{-3} over initial period of plasma decay in EST. The temperature of argon plasma insignificantly changes in a range of 1.3–1.1 eV during this period. In helium plasma the temperature decreases appreciably from 3.5–3 up to 2.5 eV due to electron's high thermal conductivity coefficient $\kappa(T) \sim T^{5/2}$. In all cases a relationship $\gamma = N_e/N_a < 1$ takes a place.

3. Violation of LTE in electric arc plasma due to radiative loss

The LTE-model allows describing the plasma by the same parameters as in complete equilibrium one, except radiation. This model is valid for the real finite plasma of high density where collision-induced proc-

esses of excited states population dominate over radiative ones, which are the factor of non-equilibrium. The population density of the exited states is Boltsmannian, and the distribution of the atoms and their ionization products obeys well-known Saha equation [1, 17]:

$$\omega^{(z)0} = N^{(z+1)} / N^{(z)} = S^{(z)}(T)/N_e. \quad (1)$$

Here $\omega^{(z)0}$ – relative particles density of specified element in sequential charge states (upper index "0" denotes equilibrium state); N - number density of particles in charge state, marked by index in brackets: (0) – for atoms, (1) – for single charged ions and so on; $S^{(z)}$ – depending on temperature function.

Griem [18] and Drawin [19] stated the most common requirements imposed on spatial and temporal non-uniformity of electron density N_e to plasma be in LTE. Biberman *et al*. [17] presented the criteria of various type of non-equilibrium occurrence on the basis of detail consideration of kinetic processes in plasma, including radiative and diffusion loss of charge particles. The restriction on N_e non-uniformity is one of this criterion, with this non-uniformity is some outside factor. Yet in practice most often the radial profile of electric arc itself is a function of plasma state and self-consistent influence of their parameters (first of all temperature and pressure gradients) and processes (diffusion, thermal conductivity, ionization-recombination processes etc). The special role in this context near-wall effects play, and for plasma with free boundary – fluid dynamic effects, determining the dynamic of plasma spatial-temporal structure. It is actually in relaxing plasmas since the specific time of the last ones usually is comparable with the specific time of plasma decay. As a result, the paradox takes a place: criteria of non-equilibrium have sufficiently general character from the one hand and from the other one – owing to these reasons are little acceptable for analysis of concrete processes in real laboratory plasma.

That is why the studying of non-equilibrium factors role in plasmas and determining of their hierarchy are problems of great importance.

Radiative processes begin dominating in the population of individual excited states of atom with decreasing of N_e in LTE-plasma. Thus the plasma changes its state to partial LTE (PLTE) wherein the ground and one or more low-lying exited states are underpopulated toward to equilibrium values for given particles kinetic temperature. The Boltsmann equation is correct only for upper exited states, which are in equilibrium with continuum, in this state of plasma.

The generalized Saha equation, as it is called, can be used as a basis for the state equation in PLTE [17]. This equation includes the additional coefficient $Y^{(z)}(T,N_e)$. It characterizes the deviation of the true value of ionization coefficient $\omega^{(z)}$ for particle of charge number z in PLTE plasma from its LTE-value $\omega^{(z)0}$:

$$\omega^{(z)} = \omega^{(z)0}/Y^{(z)}. \quad (2)$$

The ratio η between rates of collision processes of ground state population from the first exited state and competitive resonance radiation processes is at the hertz of quantitative Greem's criterion of deviation from LTE [18]:

$$\eta = (dN_1/dt)_{\text{рад}}/(dN_1/dt)_{\text{ст}}. \quad (3)$$

It is necessary that this ratio will be $\eta = 0.1$ in order to LTE would be correct with 10% accuracy. Such method corresponds to two-level atom model with two energy levels – ground and exited.

The non-equilibrium factor is $Y > 1$ in a case of radiative loss from plasma and thus decreasing of the ionization degree ω occurs as defined by (2).

The criteria of equilibrium state were refined by Biberman *et al.* [17] within the method of modified diffusion approximation (MDA). In so doing transitions between neighbour states are accounted exactly, and transitions into further states – approximately.

Self-absorption of resonance radiation reduces both the roles of radiative loss and threshold N_e at the same time. It must be emphasized that this effect is typical for electric arc plasmas. Really, the radiation free path is about 10^{-4} – 10^{-2} cm for plasmas of widespread gases at atmospheric pressure. It is substantially smaller than typical arc radius $R \sim 10^{-1}$ – 1 cm. The same parameters range occurs for plasma in vapor of most widespread metals at partial pressure of $0.01 \cdot p_a$, where p_a is pressure of ambient atmosphere. The partial pressure mentioned above just corresponds to their content in free-burning arcs between metal electrodes and also to typical conditions in various experiments [7 – 9, 11].

The problem is that the usual idealization of LTE is applicable only to one degree of ionization of plasma-forming particles. That is why the atom particles are in LTE and ions – in PLTE, as a rule, in high-ionized arc plasmas.

An example is the results of papers [20, 21]. Here the ratio of spectral lines HeII 468.6 and HeI 471.3 *nm* intensities where calculated as a function of T and N_e in plasma with specified characteristic dimensions (radius) in wide parameters range. As it follows from the results presented in Fig. 3, the ratio of mentioned

above intensities doesn't depend practically on N_e in wide parameter range, where $N_e < N_e^{**}$ [22]. This range corresponds to deviation from LTE in helium plasma. Since the densities of radiating particles are connected by generalized Saha equation (2), it follows with account of eq. (1):

$$Y^{(1)} N_e \approx N_e^{**} = \text{const}, \tag{4}$$

where N_e^{**} characterizes the electron density such that the deviations from LTE state become considerable. It allows obtaining simplified state equation for this range of plasma parameters.

If to introduce into the consideration the ionization degree of plasma

$$\omega = N_e/\Sigma N^{(i)} = N_e/N, \tag{5}$$

where N – heavy component densities, so Saha equation can be presented as

$$\omega^2/(1-\omega) = S/N. \tag{6}$$

The only one Saha equation for first ionization degree was used here; therefore (6) is correct only for values $\omega < 1$.

Using of the mass and charge conservation conditions

$$N = N^{(0)} + N^{(1)} + N^{(2)} = N^{(0)} + N^{(1)} (1 + S^{(1)}/N_e^{**}), \tag{7}$$

$$N_e = N^{(1)} + 2N^{(2)} = N^{(1)} (1 + 2S^{(1)}/N_e^{**}), \tag{8}$$

allows generalizing Saha equation into both charge states of particles:

$$\omega^2/[(2-\omega)(1 + S^{(1)}/N_e^{**}) - 1] = S^{(0)}/N. \tag{9}$$

The calculated results [20, 21] are extended by similarity method into other species of plasma forming particle [22]. In doing so the degree of ionization non-equilibrium for helium Y and for any other rare gas Y^* are to be equal if ratios η of collision and radiative resonance processes rates are equal too (see eq. (3)):

$$\eta = \eta^*. \tag{10}$$

The following ratio is the coefficient of similarity on temperature:

$$T^*/T = E_r^*/E_r, \tag{11}$$

where E_r characterize resonance state's excitation energy. Differences in structure of ions of rare gases were taken into account by MDA method [17]. Other coefficients of similarity are determined by concretize of expression (10) [22]. This method allows to find parameter N_e^{**} for other plasma forming gases too.

4. Transfer of radiation and in free-burning electric arc

As was noticed the model of LTE for the dense electric arc plasma was accepted [1]. The natural is tendency to present the object of investigation as is in equilibrium. Really, it allows describing the plasma properties by simple way based on equation (1), (7) and (8).

Nevertheless a lot of experimentors are familiar with the fact that the attempt to determine the pressure in free burning electric arc from experimentally obtained values of T and N_e are accompanied with the mistake by the factor of tens. We have studied gas dynamic process of copper vapor propagation in and out from arc channel to revise the feasible influence of the surplus pressure due to the product of the erosion of electrodes [23]. The result is a weak vary of atmosphere pressure in free burning electric arc channel up to discharge current of 100 A.

The deviation from LTE due to radiation transfer is the reason of this phenomenon. The direct experiment have shown that the area, where the essential absorption of resonance radiation occurs in free burning electric arc copper plasma, and so the excited into the state E_1=1.39 eV cooper atoms exist, is more extended, than the radius of electric arc plasma volume. Over a range of electric arc currents 3.5-30 A and electrode gap 2-8 mm the radius of absorption zone was some times as much than the arc channel radius in all cases. Thus, the resonance irradiation from plasma is screened by external layer of exited atoms with the optical path length

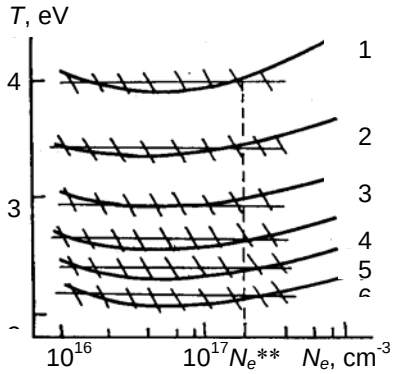

Fig. 3. Lines of the equal ratios $I^{(1)}/I^{(0)} = const$ of the spectral lines HeII 468.6 and HeI 471.3 nm intensities in a plane temperature T – electron density N_e for helium plasma with characteristic dimension (radius) δ = 1 cm: $I^{(1)}/I^{(0)}$ = 10 (1); $I^{(1)}/I^{(0)}$ = 1 (2); $I^{(1)}/I^{(0)}$ = 0,1 (3); $I^{(1)}/I^{(0)} = 10^{-2}$ (4); $I^{(1)}/I^{(0)} = 10^{-3}$ (5); $I^{(1)}/I^{(0)} = 10^{-4}$ (6).

Regions of introduced errors ± 2.5 percent in temperature measurements shown by hatching correspond to approximation of calculated curves 1-6 by straight lines in the range of N_e, where violation of LTE become essential

$\tau \geq 1$. This volume of plasma may be identified as non-equilibrium. Really, the radiation from the hot arc core is able to overpopulate the resonance level of Cu atom at the arc periphery, where temperature is relatively small. It was specified quantitatively too [18].

Two examples of energy levels population distribution in Cu atom in an axis of electric arc channel and in its peripheral area are presented as illustration in Fig. 4. It follows, that the resulting effect from the discussed mechanism of nonequilibrium can be presented through the reduction of effective potential of atom ionization outside of the electric arc axis. Really, as follow from consideration of Fig. 4.b, the ground level of Cu atom would be displaced on a certain potential $\Delta\varphi$ to achiev the same value of population N_0^a of this level in the case of uniform temperature of excited levels equal to local kinetic temperature T_a of plasma particles. This displacement may be treated as the reduction of ionization potential of Cu atom. It is possible to show from geometrical relations in Fig. 4.b or on the basis of Boltsmann equation, that

$$\Delta\varphi_{Cu}(r) = (\varphi_{res} - \varphi_{met})(1 - T(r)/T_0). \quad (12)$$

Here φ_{res} and φ_{met} - exitation potentials of resonance and metastable levels, respectively, of Cu atom.

The simple model of electric arc in copper vapor is proposed in papers [24, 25]. It allows to analyze the character of diffusion processes and heat transfer in plasma both within the limits of the arc channel, and outside of it. However the papers mentioned are developed in LTE assumption.

This part of present paper is devoted to study of the influence on physical properties of free burning electric of plasma non equilibrium arising due to transfer of resonance radiation. The account of this influence is founded in terms of ionization potential reduction according to (12).

At low temperatures the density of electrons in a copper-nitrogen mixture is fully defined by atoms of copper and according to the Saha equation it is proportional to

$$N_e \sim \exp[-\varphi_{Cu}/(2T)]. \quad (13)$$

Using this relationship, electron density N_e' which will take place at effective reduction of ionization potential may be presented in such kind:

$$N_e' = N_e \exp[\Delta\varphi_{Cu}/(2T)]. \quad (14)$$

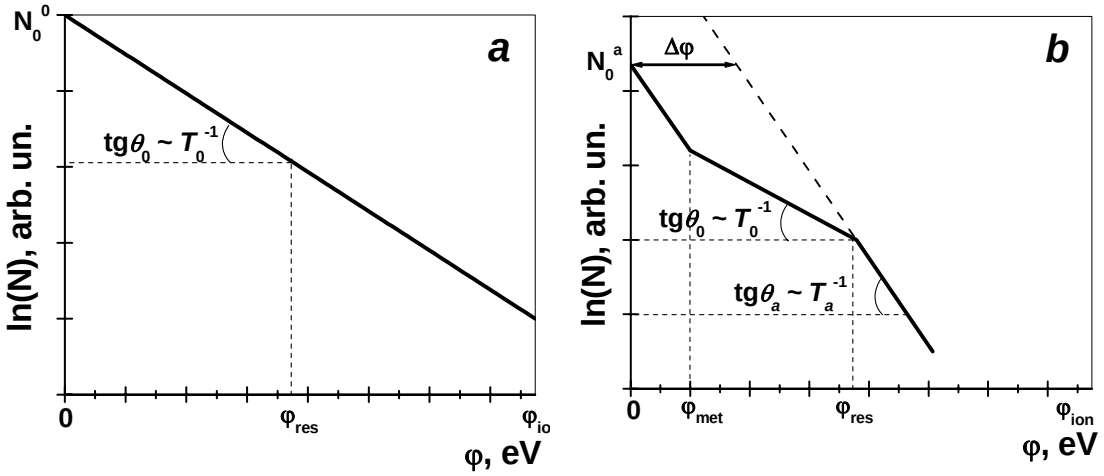

Fig. 4. Distribution of levels population in atom of copper in the electric arc axis (a) and in periphery area (b)

The conductivity of mixture σ' will be presented similarly as $\sigma \sim N_e$:

$$\sigma' = \sigma \exp[\Delta\varphi_{Cu}/(2T)]. \quad (15)$$

The relationships (12) – (15) may be introduced into channel model of electric arc between copper melted electrodes, presented in papers [24 - 27].

Steady existence of a long electric arc assumes, generally speaking, presence of some enclosing wall to heat energy removal. The question of a heat-conducting path in a short arc is solved mainly cooling on electrodes and due to the geometrical factor [28]; nevertheless, it is possible to enter into consideration some effective wall to simplify problem in this case too [26].

The electric current I, temperature T_w and radius r_w of the wall is counted set $I = 30\ A$, $r_w = 3\ mm$, $T_w = 1000\ K$, and distribution of temperature $T(r)$ and an electric field E may be found from the channel model of electric arc. The results of calculation in a case of radiation transfer absence or $\Delta\varphi_{Cu} = 0$ (see Eq.

(12)) are: axis temperature $T_0 = 6843\ K$, radius of electric arc cannel $r_a = 2{,}3\ mm$.

The choice of effective reduction of ionization potential of copper atom $\Delta\varphi_{Cu}$ demands of special remarks. Generally speaking, it can be chosen according to a ratio (12) in all area of existence of electric arc, using experimental data and modeling calculations [11]. The resulting effective reduction of ionization potential is equivalent to significant increase of temperature in the arc channel, taking into account, that the potentials of excitation of resonance levels φ_{res} are 3,71 and 3,82 eV, and metastable one φ_{met} - 1,39 and 1,64 eV for Cu atom. Thus within the framework of chosen channel model to system it is favorable "to establish" very small radius of the channel of an arch which is able to pass all discharge current due to high conductivity in according to exponential relation (15). Such calculation gives, in particular, values $r_a = 0{,}004\ mm$ and $T_0 = 5100\ K$. Nevertheless, it was beyond the channel model.

That is why the calculation with effective value $\Delta\varphi^* = \Delta\varphi_{Cu}/2$ were carried out to establish the tendency of influence of considered effect. The results are $T_0 = 6530\ K$, $r_a = 2{,}2\ mm$. In so doing the power $P = E{\cdot}I$, dissipated in electric arc channel, lowered by a factor 1.3 in comparison with a case without taking into account of radiation transfer.

From this results follows, that a finally the influence of radiation transfer in an electric arc is in the form of additional reduction of power loss on the transport of electric current in its channel. The obtained results open a basic opportunity for the adequate description of power dissipation in free-burning electric arc between melted electrodes (see, for example, [28]).

The Optimization of Thermochemical Processing of Materials

I.M.Karp, V.G. Nazarenko, O.G.Didyk, V.O. Khomych, V.A.Zhovtyansky

Plasma Technology Department, National Academy of Sciences of Ukraine the Gas Institute, Kyiv, Ukraine

Abstract

The results of study of the volume arc discharge with a plasma source of electrons are presented. The source of electrons is fulfilled as the hollow cathode with gas magnetron heating. The gas discharge plasma is generated in a working gas at pressure 0.1 ÷ 1 Pa and discharge power up to 1300 Wt. The plasma is uniformly enough distributed in the volume of 0.1 m^3; its density is $10^{10} – 10^{11}$ cm^3. Volt-ampere characteristic and distribution of density of an ionic current in working volume depend on discharge conditions are presented, too. Generator of plasma is adapted for joint operation with other sources of the charged particles and plasmas. It may be used in processes of oxidation and nitriding in hydrogen-free atmospheres as well as in energy saving technologies of the combined ionic-plasma processing of constructional materials.

Introduction

The modification of solid materials' surfaces allows obtaining principally new properties of materials and economy of resources. The rather perspective both on ecological cleanness of process, and on energy saving parameters is using of low-temperature discharge plasma for these purposes. The development of the reliable plasma equipment with large operation resource is actual problem in this connection.

The main tendency today is to combine some ionic-plasma processing of constructional materials in single equipment. A number of successive technologies allow obtaining a combination of properties that is impossible in using of these technologies separately [1].

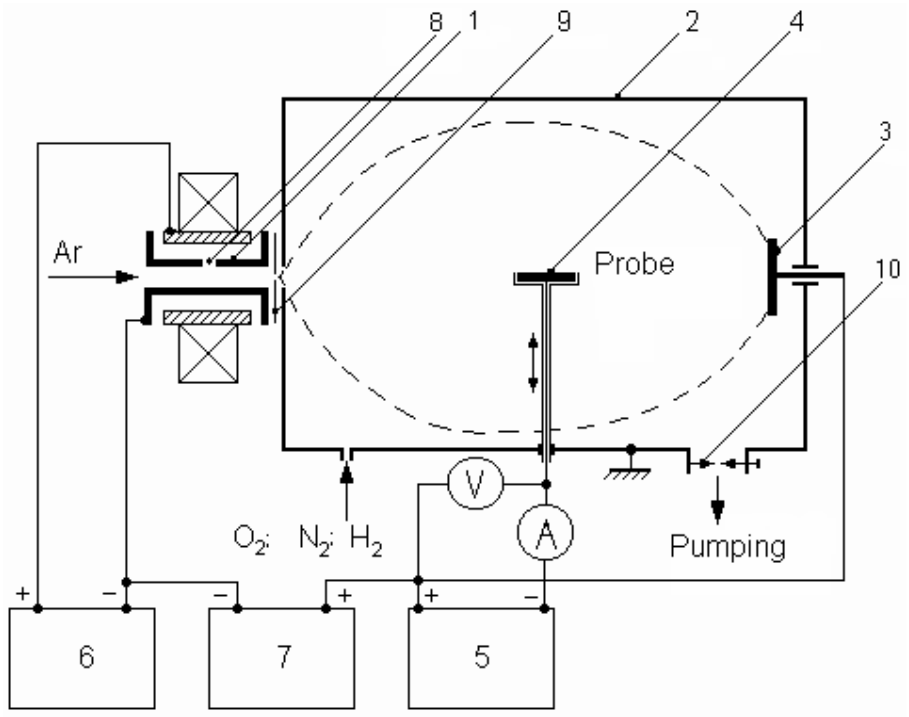

Fig.1

The cleaning and heating of surface is one of the controlling factors in ionic-plasma processing. The rate of cleaning and heating of constructional materials to be processed are defined by plasma parameters. In any case the energy input must all appear as 1 – 3 Wt/cm^2. These conditions are achieved with bias voltage on the material ~1 kV and plasma density $10^{10} ÷ 10^{11}$ cm^{-3}.

Plasma Cathode

The volumetric low pressure arc discharge with a plasma source of electrons may be considered as the most energy efficient device to ionic-plasma processing as estimations implies. In particular, a cathode unit of discharge plasma sources is one of the important elements of plasma devices, defining reliability and the operation resource. The requirements imposed on this unit will increase, if the active gases (N_2, O_2, CH_4 etc.) are applied during plasma processing. Plasma devices with heating tungsten cathode, placed usually in the separate camera and communicated with working volume through the diaphragm have a number of deficiency: the heating of the cathode up to thermoionic emission requires high value filament's currents; the high voltage (1 - 3 kV) is necessary for ignition of the main discharge; small resource due to self-sputtering. The last one is especially critical in a case of operation with large discharge currents (tens of amperes). The use of the hollow cathode allows increasing operation resource of a cathode unit considerably in a mode of an arc discharge. However, the preliminary heating of the hollow cathode is necessary for ignition and maintenance of stable operation of an arc discharge. The gas-magnetron method, on our sight, has the best characteristics in this relation. It is used ordinary in magnetron and ionic sources.

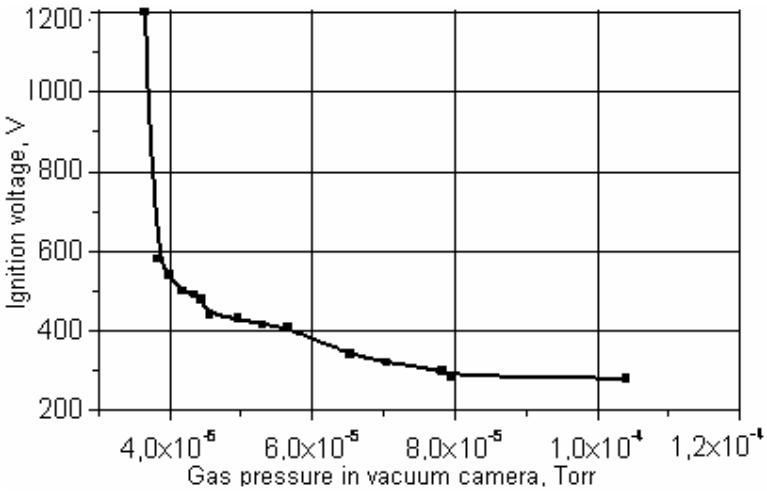

Fig. 2

The arrangement of a cathode unit permitting operation with large currents (tens of amperes) in conditions of significant gas emission from a surface to be processing and the presence of reactive gases (N_2, O_2, H_2 etc.) is presented below. It has additionally a large operation resource.

In plasma device, which scheme is shown in a Fig. 1, the cathode unit 1 is fulfilled as the autonomous system jointed through a ceramic insulator with the vacuum camera 2. Volume of the camera is 100 liters. The processing (reactive) gases are carried immediately into the vacuum camera.

The main discharge gap forms the hollow cathode 1 and main anode 3, located in the vacuum camera. The discharge between these electrodes is initiated by gas magnetron, which cathode is the external surface of the hollow cathode 1 with cathode reflectors in its sides, and anode - the water-cooling outer cylinder [2].

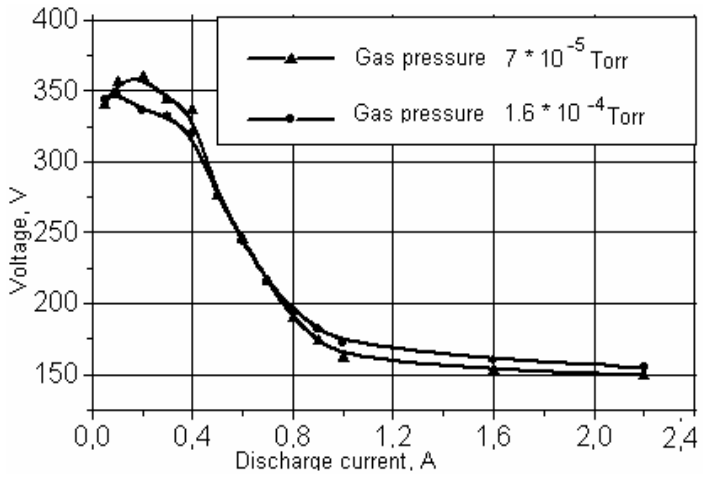

Fig. 3

The electrode system is placed inside a ring permanent magnet with strength of a magnetic field in a working clearance (the hollow cathode - cylindrical anode) ~ 0.1 T. The cathode concavity is connected with discharge gap of auxiliary (gas magnetron) discharge with hole 8. The hollow cathode is communicated with the vacuum camera through the diaphragm 9.

The ignition of the gas-magnetron discharge and transition of a cathode unit to an operating regime is carried out as follows.

With the supply of voltage on an electrode system (the hollow cathode - cylindrical anode) and allow a ballast gas (Ar) to bleed into the hollow cathode, the electrons begin to make rotary movement round the cathode under the influence of crossed electrical and magnetic fields. The length of a free path of electrons therewith is increased, that results in increase of probability of collisions them with atoms. In an outcome fast will increase rates of excitation and ionization of gas that results in ignition of the gas-magnetron

discharge. In a Fig. 2 the dependence of the gas-magnetron ignition voltage discharge on pressure of argon in the vacuum camera is indicated.

The ignition voltage of the discharge decreases with growth of a chamber pressure, achieving acceptable significance smaller than 500 V with the pressure of ballast gas ~ $4.5.10^{-5}$ Torr.

The volt-ampere characteristics of the discharge for various pressure of argon are indicated in a Fig. 3.

In accordance with magnification of a discharge current of the magnetron discharge the temperature of the hollow cathode up to significance of origin of thermionic emission will increase. From discharge gap the plasma of the gas-magnetron discharge will penetrate into the hollow cathode through the holes, thereby considerably improving conditions of ignition of the main discharge.

Ability of the developed cathode unit to work in atmosphere of active gases (N_2, O_2, CH_4 etc.) long time allows to use it in technological processes of nitriding and oxidation as well as in assisting of vacuum - arc processes of coatings deposition.

Arc Discharge

The plasma device is energized with power supplies 5-7 (Fig. 1). The gas discharge plasma is generated in a processing gas at the pressure 0.1 ÷ 1 Pa. The vacuum camera 2 is pumping through the diaphragm 10. The one-sided probe 4 was located in the plasma volume to estimate the distribution of plasma parameters in camera and its effect on a constructional material. The bias voltage was applied between the probe and anode 10.

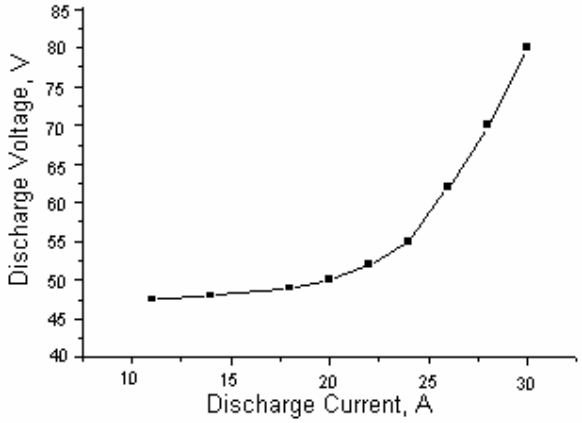

Fig. 4

The plasma generated in magnetron discharge, is penetrating in hollow cathode through the aperture 8. Electrons, emitted from plasma of the hollow cathode, are accelerated under action of the electric field enclosed between the hollow cathode and anode 3 and ionized a working gas in the vacuum chamber. In result the arc discharge in volume mode is initiated. The power delivered into the discharge, is adjusted by reactive impedance of a power unit 7. The density of plasma varies within the $10^{10} \div 10^{11}$ cm^{-3} in a range of working currents 5 ÷ 30 A.

The properties of the volume arc discharge with a plasma source of electrons were investigated experimentally and theoretically. Studies of the basic characteristics of the volumetric discharge were carried out in the following conditions. Electrodes of discharge system - hollow cathode of electrons source 1 and the anode 3 (Fig. 1) - were under the floating potential concerning the working chamber. Ballast gas was argon and reactive gas - nitrogen. Pressure of reactive gas in the working chamber was adjusted within the limits of 0.1 ÷ 1 Pa. The consumption of the ballast gas submitted in hollow cathode was adjusted within the 0.1 - 0.6 cm^3/s.

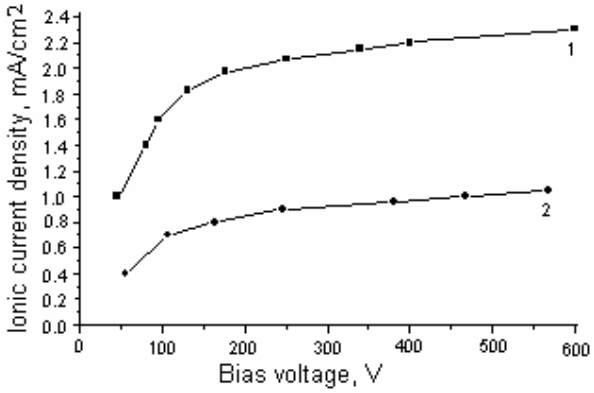

Fig. 5

The operating mode of the volumetric discharge, after its ignition, practically does not depend on parameters of the gas-magnetron discharge to the point of its deenergizing. The consumption of ballast gas had the greatest influence on the characteristics of volumetric discharge. The volt-ampere characteristic of the discharge in argon is indicated in a Fig. 4. The argon consumption was 0.15 cm^3/s in this case.

The working voltage increases with increasing of working current of the volumetric discharge at the constant consumption of ballast gas. This is resulted in instability of the discharge. Stability of the volumetric discharge burning with increase in working currents (from above 30 A) demands increasing of the consumption of ballast gas in

this connection.

An ionic current of saturation on a probe in the center of the chamber is plotted versus voltage bias in Fig. 5. The curves are obtained for the difference plasma-forming gases and pressure at the identical active power delivered into the discharge (1300 Wt). The specific power delivered into the processing constructional material is over 1 Wt/cm^2 (a curve 1) at a voltage bias ~500 V. It allows to make its clearing and heating to working temperature within 450-500^O C effectively. Specific power of heating can be raised and at rather low voltage bias <500 V (to exclude breakdowns) with increase of power delivered into the volumetric discharge. An ionic current of saturation on a probe is plotted versus discharge power in Fig. 6.

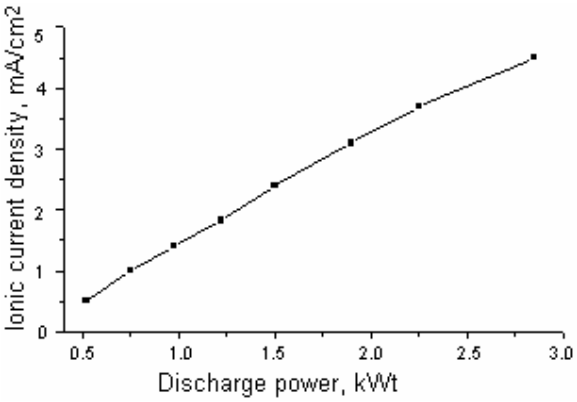

Fig. 6

As may be concluded from the external view of the volt-ampere characteristic in a Fig. 2, the volume recombination processes in plasma are essential to analyze efficiency of this technology. The procedure of thermochemical processing optimization in the device included determination of the base relationship between the plasma parameters and the constructive and technologies characteristics of the apparatus.

The balances of particles and energies in electric discharge plasma were included in treatment. In this case the specific diffusive length Λ for cylindrical camera is defined by

$$1/\Lambda^2 = (2{,}405/R)^2 + (\pi/L^2),$$

where R is radius and L - its length.

It is necessary to take into account also contracting processes in electric discharge plasma. It may be concluded from the distribution of ionic current density on the probe along a radius of camera (Fig. 7). These distributions are obtained for argon as plasma forming gas at the consumption 0.15 cm^3/s and a constant voltage bias 240 V. The power delivered into the discharge was 1300 Wt. The curves of ionic current density distributions in the working chamber at the pressure 0.2, 0.4 and 1.1 Pa are obtained at the fixed consumption of argon by change of diaphragm 10 throughput (Fig. 1).

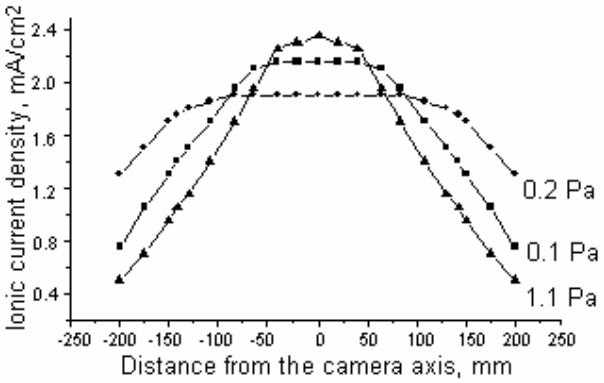

Fig. 7

Conclusion

Generator of plasma adapted for joint operation with other sources of the charged particles and plasmas is proposed. Ability of the developed cathode unit to work long time in atmosphere of active gases (N_2, O_2, CH_4 etc.) allows it using in technological processes of nitriding and oxidation as well as in assisting of vacuum - arc energy saving processes of coatings deposition.

Control of the quality of the discharge of low-pressure plasma RF. Application on the synthesis and homogeneity of $LaMnO_3$ Sr-doped layers for SOFC

F. ROUSSEAU[1], M. NIKRAVECH[1], D. MORVAN[1], J. AMOUROUX[1]

[1]Laboratoire de Génie des Procédés Plasmas et Traitements de Surface, ENSCP-Pierre et Marie Curie university, Paris, France

Abstract :
Plasma is a medium with a very high purity, which allows the synthesis of very pure product needed for electrochemical applications such as Solid Oxide Fuel Cell (SOFC). The chemistry in the plasma is very reactive, because of the formation of many reactive species. It can permit to synthesise and to deposit a layer on a substrate without undesirable phase formation, contrary to classical ways of ceramic synthesis which take time and energy. A low pressure plasma process has been developed in the laboratory in order to produce SOFC cathode. In recent works, properties of deposited layer were investigated in order to optimise plasma parameters. But it seemed to be possible to involve the efficiency of the plasma discharge. Plasma generator was equipped with six capacitors. Effects of the generator's modification on the synthesis and on the properties of the layers were studied. The efficiency of the generator was investigated by using calorimetric measurements. Species in the plasma have been characterised by Optical Emission Spectroscopy (OES). The conversion rate of the synthesis has been quantified by IR spectroscopy. Scanning Electron Microscopy and necked observations have been used to see the micro and the macro changes of layer's structure with and without generator's modification.
Keywords : efficiency, plasma discharge, reactive species, SOFC cathode

1. Introduction

Because of the need of respecting environment and decreasing pollutant's concentration in the atmosphere, fuel cells have known a major development. Solid Oxide Fuel Cell (SOFC) exhibits great efficiency for the electrical and thermal power production, as compared to the classical devices. That could permit a better use of fossil fuels like methane. SOFC are going to be essential for the conversion of chemical energy contained in H_2 and O_2 bonds into electrical power for mobile application and power plants [1].
SOFC continue to be investigated for the resolution of many problems, but for the need of material cost reduction too [2, 3]. Usually, process that synthesise ceramic layers needed for SOFC electrodes require two important steps. First, the slurry composed of mixture of commercial powders is screen printed on the electrolyte. Then, the electrode-electrolyte stack is co-fired under high temperature conditions (1200-1300°C during 3h) [4]. High temperatures often lead to undesirable phases formation due to the diffusion of species from each part of the electrode-electrolyte interface. In the case of low-pressure plasma process, reactive species used for the chemical transformation appear at very low temperature as compared to the classical chemistry. Moreover, precursors are injected directly in the plasma reactor with a high velocity, leading to a very strong adherence of the electrode into the electrolyte. A low-pressure plasma process have been developed in order to produce SOFC cathode in one step. The process consists in the synthesis and the deposit of $LaMnO_3$ or $LaCoO_3$ Sr-doped layers on Yttria Stabilised Zirconia [5, 6].
In this paper, results showed the role of induced RF energy on the properties of deposits. It was found that efficiency of plasma coupling was an important factor. In order to enhance the energetic efficiency, inductive coils were equipped with extra capacitors. The aim of this work was to present the behaviour of the plasma process due to these modifications.

2. Experimental set-up

The experimental set-up developed in the laboratory is described in the figure 1. A quartz tube equipped with a convergent nozzle was used as the plasma reactor. A vacuum pump allowed to obtain pressure in the reactor less than 1 mbar. Gas flow-meters controlled the composition and the quantity of gas used in the process. La, Sr, Mn or Co nitrates dissolved in water were used as precursors of the synthesis (ICP-DCP standard solution). An ultrasonic sprayer led to the production of few micrometers droplets containing water and nitrates. A difference in pressure from each part of a pulsed valve permitted the injection of droplets in the plasma reactor. A 40 mHz RF generator was responsible for the plasma discharge by the way of

inductive coils located on the reactor. When nitrates droplets passed through the plasma, nitrates were decomposed into NOx (detected by mass spectroscopy), and La, Sr, Mn or Co ions were oxidised in order to form MnO, SrO, LaO or CoO bonds. Finally, after their flight in the plasma reactor, particles deposited on YSZ.

In order to enhance the efficiency of the plasma discharge, we proceeded in electrical modification on the plasma generator by equipping the inductive coils with five capacitors of 80µF and one of 63 µF as shown on the figure 2.

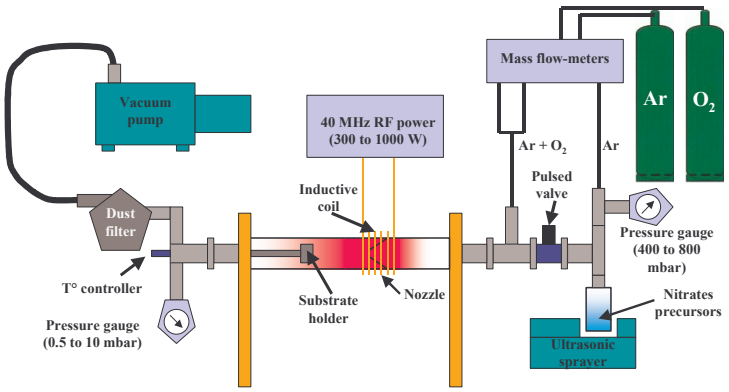

Figure 1 : plasma process experimental set-up

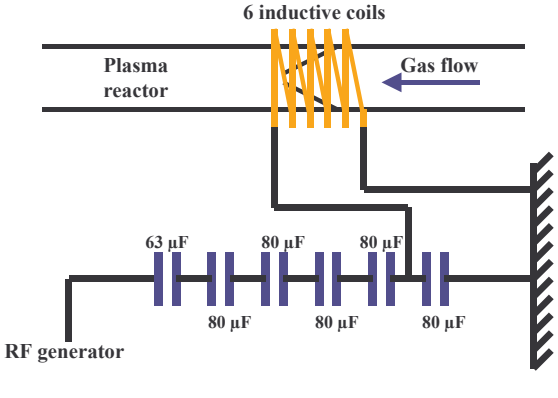

Figure 2 : capacitors add-on on RF generator

3. Effect of generator's modification on the efficiency of the discharge

In order to determine the energetic efficiency of the discharge, a liquid solution was used to simulate the plasma. This method consisted in measuring the electrical current of the generator as a function of the voltage for several electrolyte solutions by applying the inductive RF. Then, it was possible to measure the heat absorbed by the solution representing the same conductivity of plasma. That could be considered as the energy absorbed by the plasma.

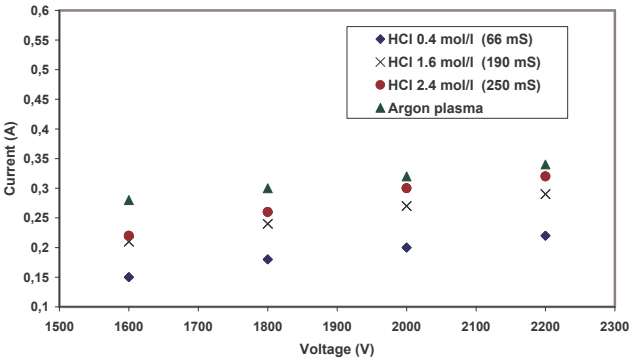

Figure 3 : Current as a function of voltage for different solution containing HCl

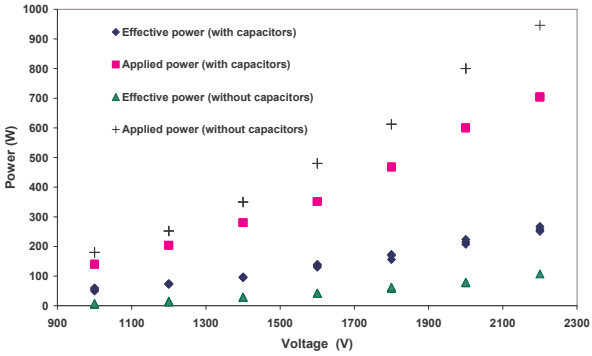

Figure 4 : Power versus plasma generator voltage

Solutions of HCl at different concentrations were elaborated. The conductivity of solutions was measured, showing an increase with the concentration of HCl (maximum for 2.4 mol.l^{-1} HCl). Each solution was placed among inductive coils equipped with capacitors, and the current was measured as a function of voltage on the generator (figure 3). The solution containing 2.4 mol.l^{-1} HCl exhibited almost the same current and voltage values as the plasma at high power. This solution (σ = 250 mS) was the best one which simulated our argon plasma conductivity.

This solution, with almost the same electrical conductivity as our plasma, was chosen to perform measurements of the effective power available in the plasma discharge. The increase of temperature due to the current circulating in coils was measured as a function of voltage. It was performed with and without capacitors on inductive coils. By knowing the heat capacity of the solution, it was possible to determine the

energy transferred into the solution during the working of the generator. The figure 4 represents the evolution of applied power and effective power as a function of the voltage. The results showed that the efficiency of the generator increased with capacitors add-on. Mean efficiency increased from 13 % (without capacitors) to 35 % (with capacitors). Results underlined the fact that quality of plasma discharge strongly depend on electrical characteristics of the generator.
The improvement of plasma coupling by the means of capacitors on inductive coils, resulted in increasing the energetic efficiency of the process. This was checked by comparing the conversion rate of nitrates precursors into $La_{0.7}Sr_{0.3}MnO_3$ in the plasma reactor. For an applied power (3600 W) the conversion rate was measured to be around 70 %. By equipping the inductive coils with capacitors, the conversion rate increased to more than 88 % for an applied power of 800 W [6, 7, 8].

4. Optical emission spectroscopy (OES)

The electrical modification probably had impact on the apparition and the evolution of species in the plasma. It was essential to study the evolution of reactive species like Ar and O as a function of injections in order to understand their role on the synthesis.
OES investigations were carried out on the plasma by equipping the reactor with observation windows of spectrosyl quartz. Spectra acquisitions were performed by using a JOBIN YVON device linked to the reactor with optical fibres.
OES measurements were performed at the exit of the nozzle. Evolution of Ar and O intensities was study as a function of time. Acquisitions were performed with and without capacitors for the same applied power. Figures 5 and 6 show the evolution of intensities for injections of nitrates precursors in an Ar + O_2 plasma (50cc. min^{-1} Ar and 50cc. min^{-1} O_2). Injection of droplets in the reactor resulted in an increase of the light intensity well visible during experiments. Results reported on figures 5 and 6 confirmed the enhancement of energetic efficiency of plasma generator due to capacitors. The light intensity increased highly in the case of inductive coils with capacitors. The higher intensity reached for atomic oxygen underlined the important chemical reactivity of plasma.

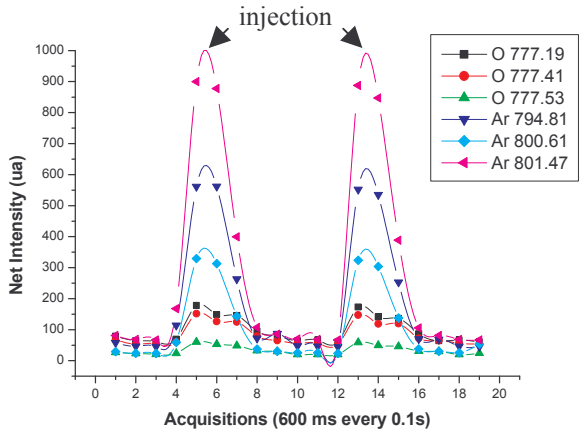

Figure 5 : evolution of intensities as a function of acquisition time (capacitors on inductive coils)

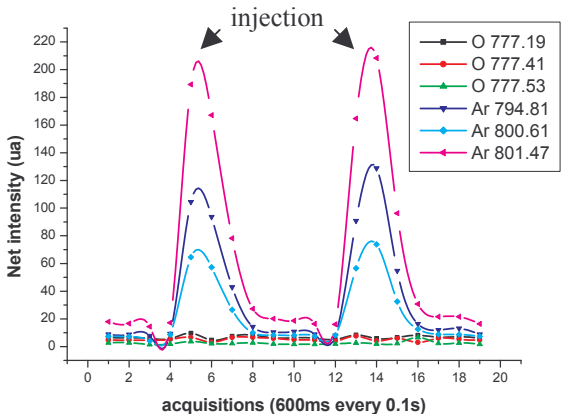

Figure 6 : evolution of intensities as a function of acquisition time (no capacitors)

The ratio of I (Ar 801,47 nm) / I (O 777.19 nm) were calculated in the case of Ar + O_2 + H_2O and Ar + O_2 + H_2O + nitrates as shown on the figure 7. In the case of nitrates precursors injections, it was clear that O intensities decreased as compared to the water injections. Because of respecting pressure, power, and gas composition of plasma for water and water containing nitrates injections, the difference of intensity could be considered as proportional to the concentration of O in the plasma [9]. More investigations on the evolution of O should be done to conclude that the decrease of O intensity was essentially due to the formation of MnO, LaO, SrO or CoO bonds.

Concerning OH radicals from the decomposition of water in the plasma discharge, OH° bands were investigated with and without capacitors on inductive coils. In the case of capacitors add-on, intensity of

OH° bands was more intense. Investigations are currently performed to determine the effect of capacitors on the OH° rotational temperature.

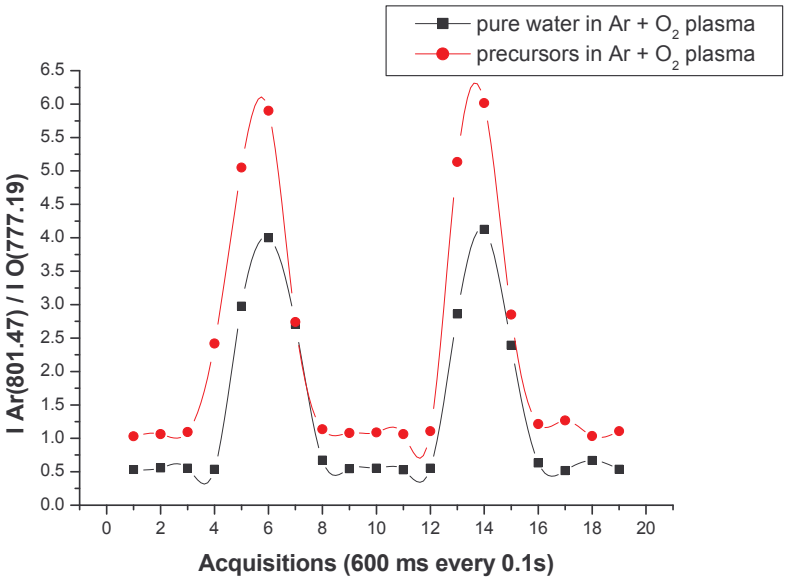

Figure 7 : I (Ar 801,47 nm) / I (O 777.19 nm)
as a function of acquisition time

5. Effect of electrical modification on the deposit

$LaMnO_3$ and $La_{0.7}Sr_{0.3}MnO_3$ layers were deposited with and without capacitors respecting same current and voltage values on the plasma generator. Infrared spectroscopy, neck observations and Scanning Electron Microscopy were used to control the structure of layers and the conversion rate of nitrates precursors into $La_{0.7}Sr_{0.3}MnO_3$.

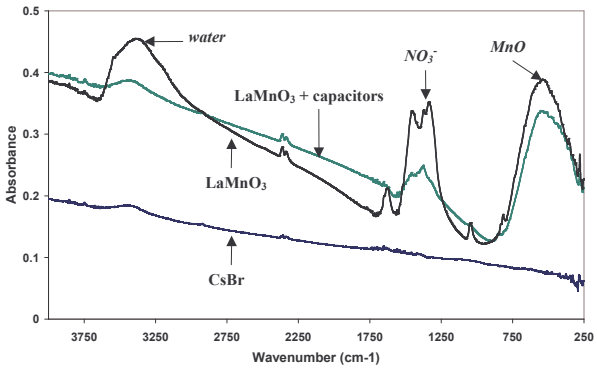

Figure 8 : IR spectra of $LaMnO_3$ deposited with and without capacitors

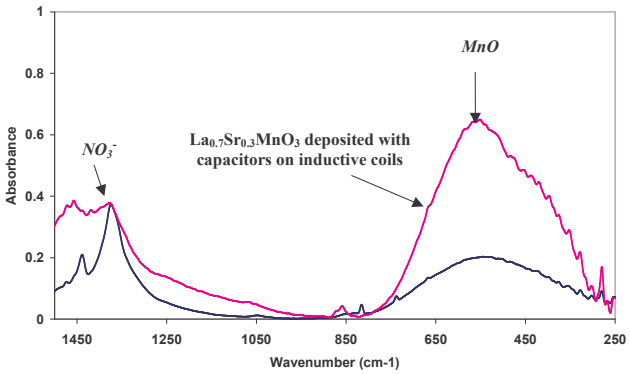

Figure 9 : IR spectra of $La_{0.7}Sr_{0.3}MnO_3$ deposited with and without capacitors

IR spectrum of $LaMnO_3$ deposited with and without capacitors were compared as shown on the figure 8. For same current and voltage values, capacitors add-on increased the efficiency and the power available in the plasma discharge. The effect of power enhancement was clearly visible on IR spectra. In the case of capacitors add-on, NO_3 bond and water intensity was lower and MnO bond intensity were higher, confirming a good oxidisation of nitrates precursors in the plasma. In previous works, IR spectroscopy was used to quantify the conversion rate of nitrates into $La_{0.7}Sr_{0.3}MnO_3$[7,8]. By comparing NO_3^- and MnO bonds intensities, and by using a calibration curve, it was possible to determine the conversion rate. Deposits of $La_{0.7}Sr_{0.3}MnO_3$ were performed in order to study the effect of capacitors on the conversion rate (figure 9).

For a same nitrates intensity, MnO bond intensity was higher for $La_{0.7}Sr_{0.3}MnO_3$ deposited with capacitors on generators. With the capacitors add-on, the conversion rate increased from 52 % to 84%, confirming a better efficiency of the plasma discharge.
Neck observations were used to study the structure of the deposited layer. With or without capacitors, the deposit had the same aspect after the synthesis. But after few days, the layers deposited without capacitors exhibited cracks well visible on the figure 10. This phenomena was probably due to the nitrates present in the deposit. Because of the low conversion rate in the case of no capacitors add-on, a quantity of nitrates were not transformed into NOx and stayed in the deposit. Atmospheric water adsorbed by remaining nitrates caused a swelling of the layer. This phenomena was not visible for layers deposited with capacitors.

$LaMnO_3$ deposited on YSZ. No capacitors on inductive coils

Figure 10 : photos of two $LaMnO_3$ samples deposited with and without capacitors

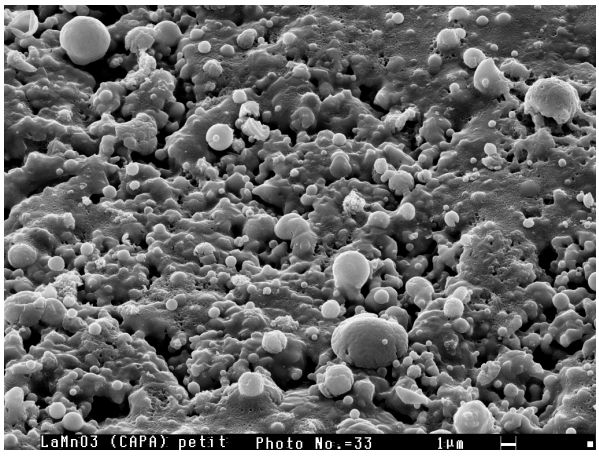

Figure 11 : $LaMnO_3$ layers deposited with capacitors

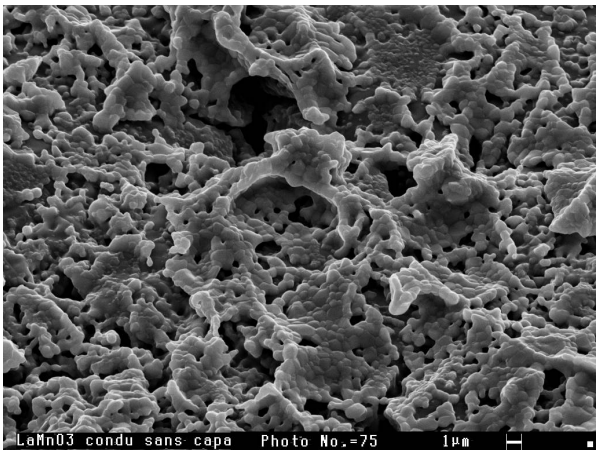

Figure 12 : $LaMnO_3$ layers deposited without capacitors, annealing at 1200°C during 1 hour

Scanning Electron Microscopy was used to study the microstructure of the deposit. The electrical modification of the generator had no visible impact on the aspect of the layers. Layers deposited with or without capacitors were amorphous and had the same structure (figure 11). But after an annealing of 1 hour at 1200°C, the two different layers exhibited an another microstructure (figure 12), probably due to a change of crystalline structure.

6. Conclusion

Electrical modifications on the generator power increased the power available in the plasma discharge. By using solutions of HCl to simulate the plasma, that permitted to determine the yield of RF energy transferred

to the plasma by the inductive coils. Effects of capacitors add-on were well visible on the plasma process. The OES proved that the intensity of activated species were more important in the case of capacitors add-on, probably due to a higher concentration of reactive species in the discharge. Infrared spectroscopy underlined the fact that the conversion rate of nitrates into lanthanum manganite Sr-doped increased with capacitors add-on. Layers deposited without capacitors contained nitrates which caused cracks apparition (due to the adsorption of water into the layers). A microstructure change was not visible by TEM on the layers deposited by using the two electrical configurations, and an annealing led to the apparition of crystalline structure in the two cases. Next studies will consist in a comparison of electronic and gas temperature for the two electrical configurations.

Abstract :
Solid Oxide Fuel Cell's (SOFC) development is of high energetic interest. Because of progress toward hydrogen storage and the need of reducing greenhouse gases into the atmosphere, it is clear that SOFC will play a great role in hydrogen-based transports and energy systems. A low-pressure plasma reactor equipped with a convergent nozzle has been developed in the laboratory in order to produce thin perovskite layers that could be used as the cathode for SOFC. Raw materials of La, Sr, Mn or CoO nitrates dissolved in water were introduced into the plasma in order to produce $LaMnO_3$, $LaCoO_3$ or Sr-doped layers on Yttria Stabilised Zirconia (YSZ) substrate. Properties of the layers strongly depend on the chemical reactions and physical phenomena which take place in the plasma reactor. The pressure and the velocity of gases in the reactor played major roles on the porosity and the adherence of the layer on the substrate. It was essential to investigate about the hydrodynamics of the reactor. The study has consisted in two steps : step one was the development of an hydrodynamic model in order to measure gases and particles velocities. The second was the quantification of velocity, concentration and diameter of injected particles by using in-situ measurement technique. Hydrodynamics of the process has been characterised, and the behaviour of particles in the reactor has been described. Model and experimental measurements have underlined the fact that particles were efficiently accelerated due to the depression in the nozzle (from 12 m. s^{-1} to 80 m. s^{-1}. Particles diameters was reduced along the reactor (22 µm to 10 µm from each part of the nozzle).
Keywords : nozzle, hydrodynamic model, Laser Doppler Anemometry, Laser Doppler Granulometry

1. Introduction

Solid Oxide Fuel Cell (SOFC) are promising electrical generator in a near future [1]. Recently, many SOFC prototypes were developed for automotive or power plant applications. But SOFC materials continue to be investigated, in order to solve problems which appear during the synthesis and the working of the cell. Classical ways of ceramic synthesis use the screen printing of a powder on the substrate [2]. But the adherence of the product layers on the substrate is often weak, and lead to bad electrochemical contacts at the interface. A very good adherence is absolutely required for electrochemical applications, such as SOFC.
A plasma process has been developed in order to obtain SOFC cathode materials on YSZ substrate in one step. The principle of this process consisted to a spray of precursors particles injected by a pulsed valve in the plasma. Accumulation of particles on the substrate permitted the growth of the deposited layer. In the case of spray, velocity of particles is a very important parameter, that condition the porosity of the deposited layer and the adherence [3].
In previous works, we observed that nozzle equipping a reactor creates hydrodynamics perturbations. Because of the convergent nozzle, over-pressure waves are created, leading to the acceleration of gases and particles circulating in the reactor. The effect of nozzle was well visible during experiments. For each injection, it was possible to observe shock-wave formation at the exit of the nozzle. The role of the nozzle and the pulsed valve on the gases and particles velocities, was investigated in order to characterise the hydrodynamics of the process.
A numerical model has been developed to determine the velocity and the temperature of gases along the reactor. In the first time, plasma parameters were not considered for the numerical model.
A non-intrusive technique based on the Doppler effect was performed on the reactor to investigate the velocity, the concentration and the diameter of particles along the reactor (Laser Doppler Anemometry LDA – Laser Doppler Granulometry LDG).
The knowledge obtained from these investigations could be used to understand the properties of hydrodynamics on the layer's growth (thickness, porosity and so on…).

2. Experimental set-up

The low-pressure plasma process is described on the figure 1. The plasma reactor consisted in a quartz tube (50 mm in diameter, 600 mm in length) equipped with a convergent nozzle (5 or 3 mm in diameter). A 40 mHz RF generator allowed the plasma discharge by the way of inductive coils (Plasma Ar + O_2 in various composition). Mass flow-meters permitted to control the composition and the flow of plasma and vector gases. The low pressure in the plasma reactor was obtained with a vacuum pump (0.7 – 6 mbar).

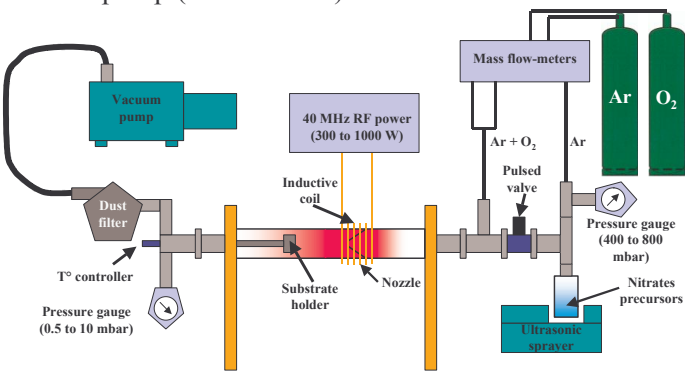

Figure 1 : Experimental set-up

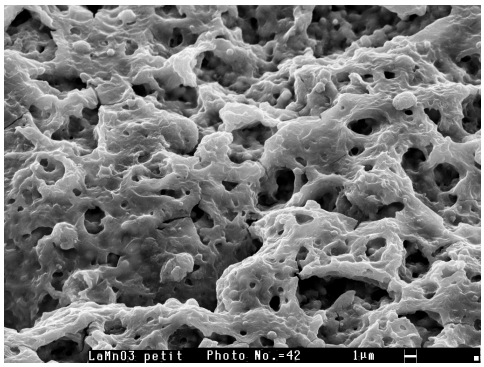

Figure 2 : $LaMnO_3$ deposit on YSZ substrate

The precursors used for the synthesis and the deposit of $LaMnO_3$ and $LaCoO_3$ Sr-doped layers were nitrates of La, Mn, Sr or Co dissolved in water (3 % HNO_3). The solutions were available as commercial product (ICP-DCP standard solution). Few micrometers droplets were formed due to the presence of an ultrasonic sprayer. Particles of water containing nitrates were injected in the plasma reactor by the way of a difference in pressure from each part of a pulsed valve (300 – 600 mbar difference in pressure).

For each injection, argon vector gas and droplets went through the plasma. Reactive species of the plasma (Ar*, O, OH radical from the decomposition of water) permitted the oxidisation of La, Mn, Sr or Co ions in order to form LaO, MnO, SrO or CoO bonds. After their flight through the plasma, particles deposited on YSZ in order to form $LaMnO_3$ and $LaCoO_3$ Sr-doped amorphous layers (figure 2). Between two injections, particles on YSZ continued to be treated by the plasma.

Many investigations had been performed on the plasma process in order to determine the effect of plasma parameters such as power and oxygen quantity in plasma gas on the deposit. Moreover, ex-situ techniques were used to characterise the structure and the electrochemical properties of the layer. Studies of the process and investigations about the deposit were used to optimise the process and to enhance the properties of thin films deposited [4].

3. Hydrodynamic model of the process

A numerical model using FLUENT® [5] software has been developed. By the way of this software, it is possible to calculate velocity, pressure and temperature of gases. Moreover, it is possible to model the evaporation and the trajectory of particles along the reactor.

In order to take into account dimensions and geometry of the reactor and the pulsed valve, different kind of meshes divided in thousands of cells were created, as shown on the figure 3. Meshes were used for the spatial resolution of Navier Stokes equations from the pulsed valve to the exit of nozzle.

The resolution of hydrodynamic equation required boundary conditions. Evolution of pressure from each part of the nozzle was measured in various conditions. By using two pressure gauges connected with a computer interface, it was possible to measure the evolution of pressure as a function of time (injection's pressure equal to 400 mbar) and pulsed valve opening time (figure 3 et 4). Figure 3 shows the evolution of the pressure on front and behind the nozzle. At the beginning of the injection, the curves exhibited a step increase in pressure during nearly 0.3s followed by an exponential decrease during more than 1s. Pressure values showed a maximal ΔP = 8 mbar on both side of the nozzle, probably responsible of shock waves formation. Figure 4 shows the effect of pulsed valve opening

time on the maximal pressure from each part of the nozzle. For opening time less than 0.25 s, max pressures from each part of the nozzle increased. But for opening time more than 0.25s, max pressures decreased. The pulsed valve continued to be open after the sprayer containing water and argon gas was injected. During a short time, the volume before the nozzle increased due to the pulsed valve that connected injection's system with the reactor. The increase of the volume led to a decrease of the pressure.

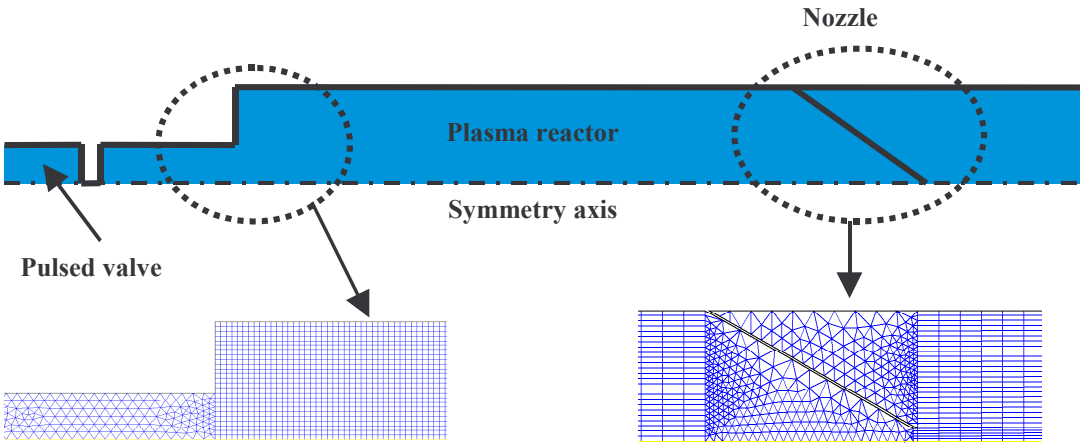

Figure 3 : mesh reactor used for Navier Stokes equation resolution

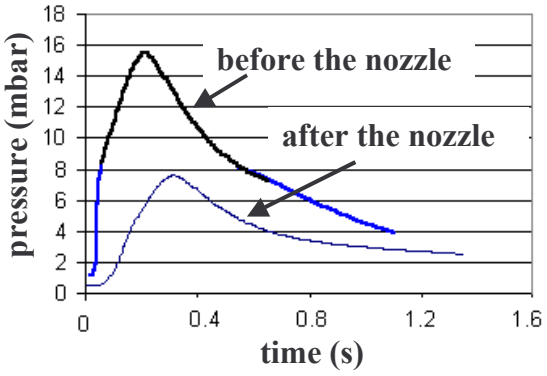

Figure 3 : pressure from each part of the nozzle as a function of time (for one injection)

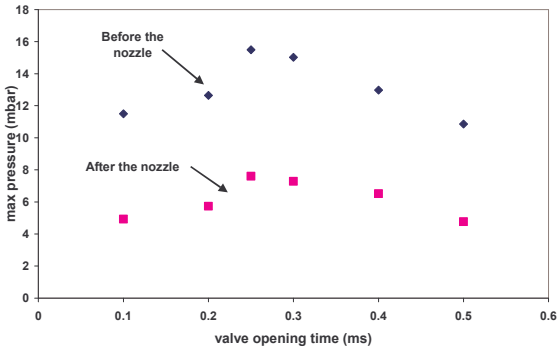

Figure 4 : Maximal pressure from each part of the nozzle as a function of valve opening time

By using pressure measurements as boundary conditions for the resolution of Navier Stokes equation, it was possible to calculate the evolution of velocity and pressure as a function of time (figure 5). The increase of pressure before the nozzle involved the formation of over-pressures waves that reflected against the nozzle. The calculated velocity of these over-pressure waves are shown in the figure 5 (maximal velocity = 380 m. s^{-1}). The over-pressure waves reached supersonic velocities, resulting in shock waves formation. Their velocity and intensity decreased during the different reflection processes. Finally, after a short time (25 ms after the beginning of the injection), the over-pressure waves seemed to disappear.

Concerning the velocity of gases at the exit of the nozzle, the maximal velocity was equal to 710 m. s^{-1} (t = 31 ms after the beginning of injection). High velocity at the exit of the nozzle resulted from the apparition of over-pressure waves before the nozzle. The velocity decreased as a function of time (400 m. s^{-1} at t = 0.2 s after the beginning of injection), due to the disappear of over-pressure waves before the nozzle.

Particles trajectory in the reactor have been modelled using the same boundary conditions. Even if the droplets were dispersed before, a particles jet centred on the reactor's axis was formed at the exit of the nozzle. There was no dispersion effect, so that most of the particles deposited on the substrate.

The evaporation of particles is currently under study using the same computer code The aim is the characterisation of the effect of pressure and gas flow on the vaporisation of injected droplets.

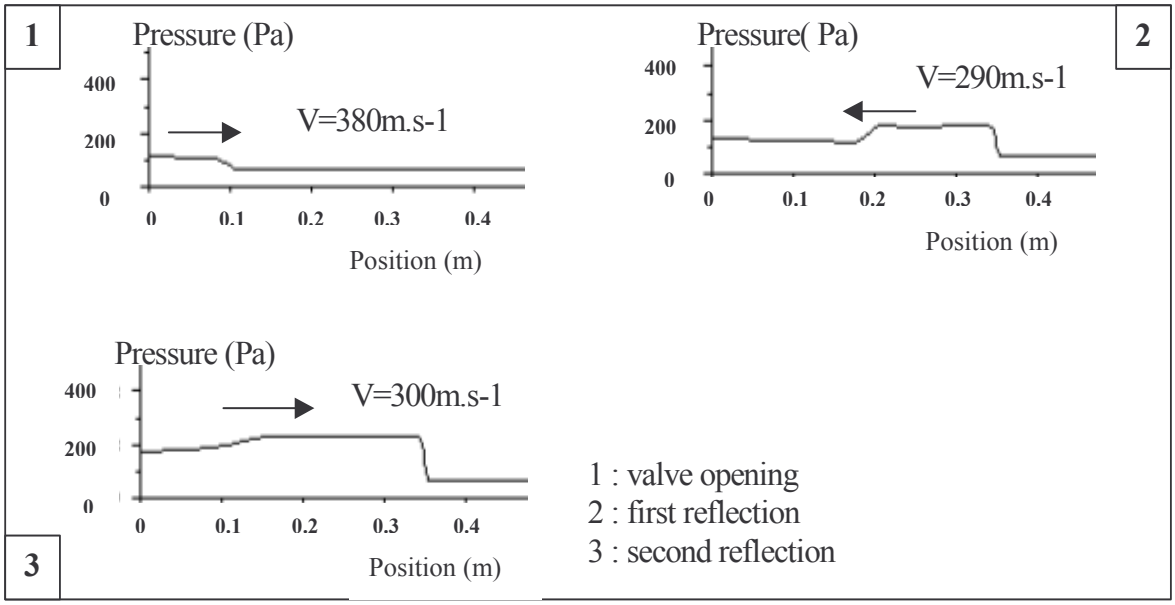

Figure 5 : Profile of pressure along the reactor

4. Laser Doppler Anemometry (LDA) – Laser Doppler Granulometry (LDG) measurements

LDA-LDG technique permitted to measure the velocity, the concentration and the diameter of particles directly on the plasma reactor. For this study, an analytical apparatus manufactured by DANTEC Dynamics corporation was used [6].

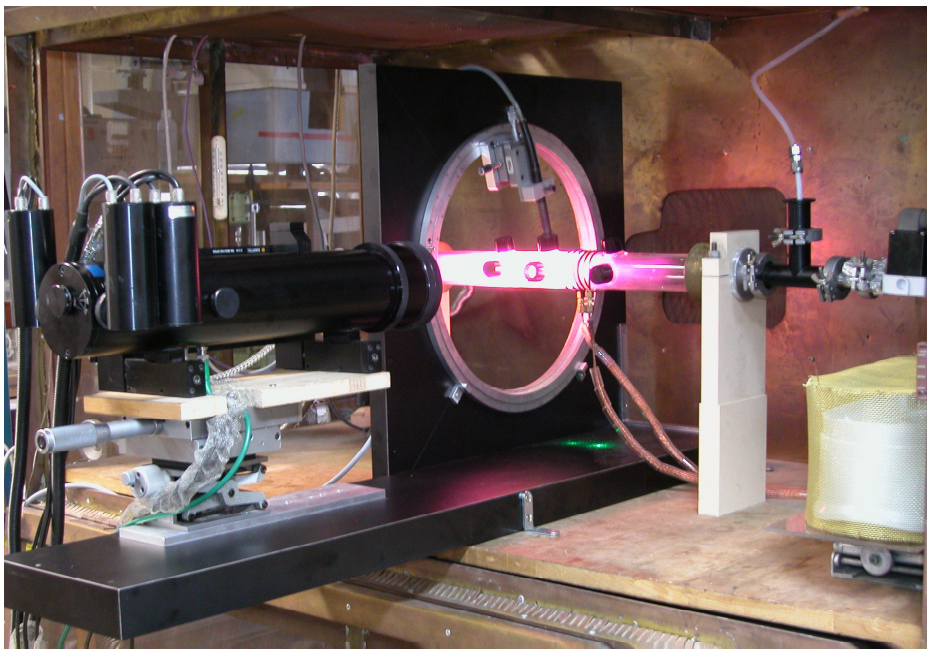

Figure 6 : LDA-LDG experimental set-up

A laser with a well known frequency was split in two beams. The two incident laser beams converged and created a small analytical volume. Each time a particle passed through this volume, it perturbed the frequency of the laser and his perturbation was directly proportional to the velocity of particles. In the case of LDG measurements, the phase difference of three detectors permitted to determine the diameter of particles. A reactor equipped with optical access (quartz spectrosyl) as shown on the figure 6, was specially developed for the measurements, in order to have an accurate detection.

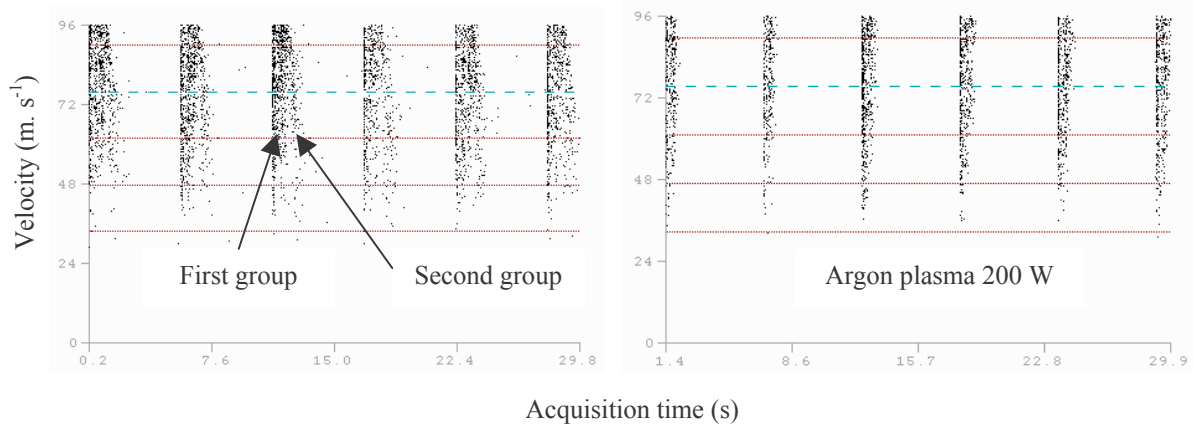

Figure 7 : Velocity of particles as a function of time (right : without plasma, left : with argon plasma 200 W)

Figure 7 shows the particles velocity as a function of time (injection's pressure = 400 mbar), 1 cm downstream of the nozzle exit without and with plasma. In the case of no plasma discharge, particles went through the nozzle in two groups, one following the other, because of shock waves. The second group seemed to be more dispersed than the first one. When the valve opened, the first group quickly was injected in the reactor and underwent the influence of the first over-pressure. Droplets passed through the nozzle with a high swiftness and were detected first. The second group underwent the influence of the pressure waves that were reflected in nozzle, resulting in a more important residence time before the nozzle. Because of re-circulation phenomena (confirmed by positive and negative velocities detected by the LDA before the nozzle), droplets of the second group were detected later.
In the case of plasma discharge application, only one group was detected. The detection of just one group means that the other group underwent a strong vaporisation due to the plasma. Particles of the second group lowered in diameter smaller than one micrometer (limit of detection by LDA). This phenomena, due to the high residence time, resulted from the re-circulation phenomena of particles before the nozzle.

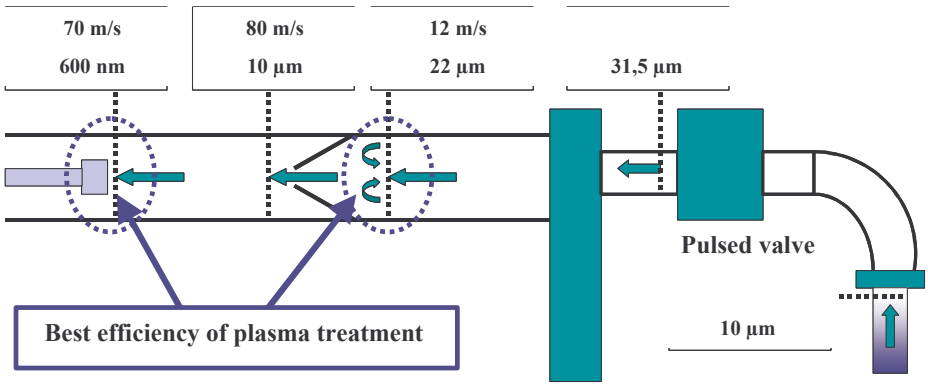

Figure 8 : Mean velocity and mean diameter values at different steps in the plasma reactor

Velocity values obtained at different places on the reactor are summarised on the figure 8. At the exit of the nozzle, the mean velocity was equal to 80 $m.s^{-1}$. Velocities of particles ranged from 20 to 130 $m.s^{-1}$. By comparing the velocities of droplets detected by LDA before the nozzle (12 $m. s^{-1}$) and after the nozzle, it can be assumed that the particles were efficiently accelerated by the gas flow. Particles had a great velocity (70 $m. s^{-1}$) just before they deposited, leading to a great adherence on the substrate.

The diameters of particles were determined by the LDG at different places of the reactor. The figure 9 shows typical velocity and diameter diagrams obtained at the exit of the nozzle (in the case of argon plasma discharge 400W). Diameter of particles was investigated with and without plasma in order to determine the effect of the discharge on the evaporation of droplets. In the two different cases, diameters acquired were the same, confirming that the vaporisation of droplet during the flight in the reactor was essentially due to the vacuum. The evolution of diameters is summarised on the figure 8. The mean diameter before the pulsed valve was equal to 10 µm. The increase of diameter at the exit of the pulsed valve (31.5 µm) was due to the agglomeration of particles. The mean diameter reduced from 22 µm to 10 µm, due to the depression at the exit of the nozzle. That resulted in an evaporation of more than 90 % in volume. Once deposited on the substrate, the mean diameter of particles was equal to 600 nm (determined by Scanning Electron Microscopy).

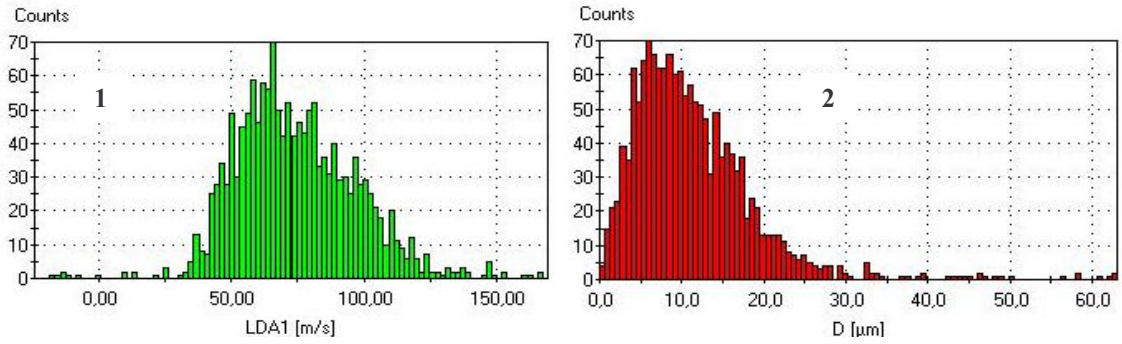

Figure 9 : Velocity (1) and diameter (2) measurements acquired after the nozzle (argon plasma, 400 W)

5. Conclusion

Aerodynamic phenomena taking place into the reactor have been modelled. In order to do that, experimental pressure values were measured and simplifying hypotheses were defined. Velocity and pressure calculations proved shock waves formation in the reactor. Considering some ignored phenomena such as chemical reactions and plasma physics could result in the building of more complex model. Concerning LDA and LDG measurements, it was demonstrated that particles were efficiently accelerated by the gas flow due to the presence of nozzle. Velocity measurements with the LDA were lower than velocity of gases calculated from the model, maybe due to the vacuum present in the reactor. LDA permitted to determine a re-circulation area, that involved the residence time of particles. LDA and LDG results confirmed that particles were strongly submitted to the effect of plasma and vacuum in the reactor.

Effects of Silent Electrical Discharge Plasma Excitation on the Combustion of Methane, Propane, and Butane

Louis A. Rosocha and Yongho Kim

Plasma Physics Group, Los Alamos National Laboratory, USA

Abstract
We have shown that silent electrical discharge (dielectric barrier discharge – DBD) excitation of methane, propane, and butane can significantly influence their combustion characteristics. In this paper, we compare DBD excitation of the three test fuel gases (in terms of post-plasma, air-mixed-burner combustion and excitation products without combustion). Flame images and mass-spectrometer measurements of decomposition products are presented for representative experiments with the three hydrocarbon test gases.
Keywords: plasma-assisted combustion, silent discharge excitation, flame speed.

1. Introduction

Combustion processes pervade modern life, providing propulsion (automobiles, aircraft, watercraft); generating electricity; and providing heat (homes, water, commercial buildings, industrial processes). Improvements in combustion processes are highly desirable because of the need to achieve better fuel utilization and to reduce pollution.

Over the past five decades, improvements in combustion have been attempted using electric fields, which can affect flame stability, flame propagation speed, and combustion chemistry [1, 2]. Electric-field generated thermal plasmas (usually not efficient and selective in directing electrical energy into the promotion of chemical reactions), have been applied to combustion during the past three or more decades with some success [3], particularly in the conversion of fuel-air mixtures into syngas (H_2 and CO) for use in increasing internal combustion engine efficiency and reducing NO_x emissions [4]. Non-thermal plasmas are potentially more useful tools for promoting combustion. For NTPs, the electrons are energetic ("hot"), whereas ions and neutral gases are near ambient temperature ("cool"), which results in little waste enthalpy (heat) being deposited in a process gas. Typical electron temperatures in such plasmas are of order a few electron volts, which is sufficient to decompose the fuel and to produce free radicals [5]. We consider the silent electrical discharge to be a very promising candidate for combustion enhancement. Two decades ago, Inomata *et al*. [6] demonstrated increases in flames speed when applying a DBD upstream of a methane-air flame. Work performed by Cha, *et al*. [7] during the past few years, showed that applying a DBD to the flame region results in a decrease in flame length and reduced soot formation.

Since 2002, we have carried out research on using DBD plasmas to pre-treat fuels (not fuel-air mixtures) before they are combusted [9-11]. In our technique, fuels are decomposed (cracked) into smaller molecular fragments, boosted into reactive excited states, or made into "free-radicals". The 'plasma-activated' fuel is then mixed with air and combusted. This has shown to stabilize flames, increase flame speed, and allows very lean-burn modes of combustion, highly desirable for the reduction of NO_x. Proof of principle has been demonstrated in experiments using propane as the fuel in a Bunsen-like burner. We have investigated the effects of the plasma on combustion by examining combustion stability under lean-burn conditions, observing increases in flame propagation speed by photography, and by sampling and analyzing the gas residues from combustion [9-11].

In our experiments, combustion is initiated at a place distant (6 cm) from the plasma region. Most previous plasma-assisted combustion works have not separated physical electric field effects (ionic wind) and chemical effects (radicals and fuel fragments) [12, 13]. In contrast to these other works, by having

combustion occur relatively far away from the plasma fuel-excitation region, electric field effects can be greatly reduced, thus providing more insight into the role of plasma chemistry.

In this paper, we report on comparing the effects of DBD excitation on the fuel gases methane, propane, and butane in terms of two characteristics: 1) Flame images indicating changes in flame propagation speed, after the activated gas is mixed with air and combusted in an air-flame burner; 2) Decomposition products resulting from activating the fuel gas, but not combusting it, as measured by mass spectrometry.

2. Experimental Setup

Figure 1 shows the experimental setup for a coaxial DBD fuel-activation reactor and associated burner. In this DBD reactor [10], air flows up through an inner grounded stainless steel tube (outer diameter 0.95 cm) and the fuel gas flows up through the annular region between the quartz dielectric tube (inner diameter 1.25 cm) and the inner metal electrode. This configuration, where the fuel flow encircles the air flow, is known as an inverse flame. The fuel gas and air flows are adjusted to a desired equivalence ration by adjusting gas flowmeters. For example, for a rich-burn equivalence ratio of $\phi = 2$ for propane (C_3H_8), the propane and air flow rates are 0.3 std lit/min and 4.6 std lit/min, respectively. The transparent quartz dielectric tube allows for visual observations of the plasma and flames. A copper mesh electrode, 12 cm in length, surrounds part of the quartz dielectric tube. This outer mesh electrode is powered by a HV AC transformer (Eurocom BHD1530) with a frequency tuned to about 450 Hz.

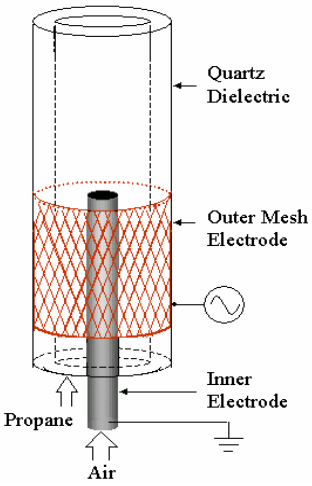

Fig. 1: Schematic diagram of the DBD apparatus.

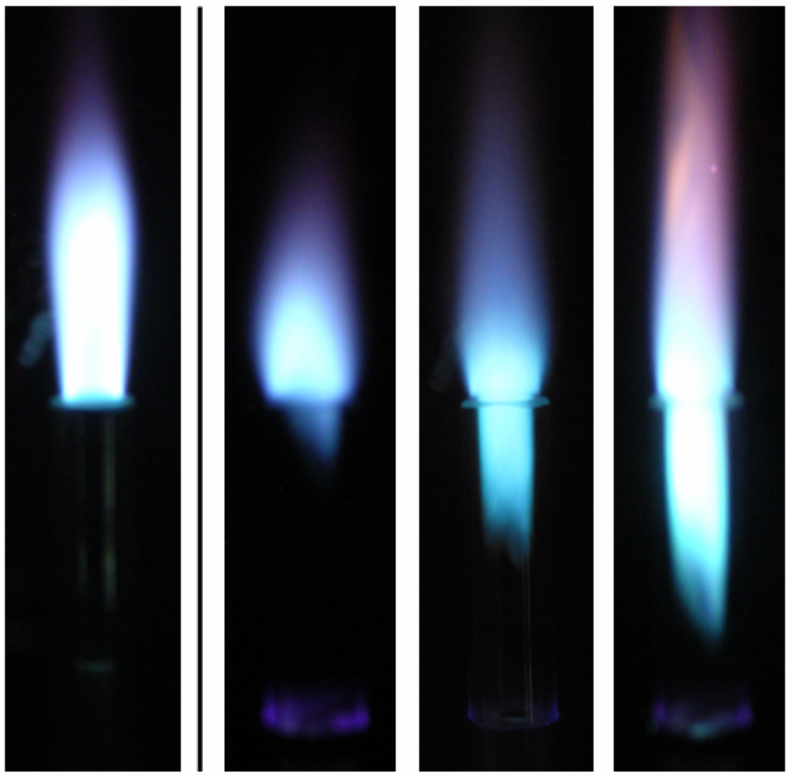
After a fuel gas is treated with the plasma, it is mixed with the air flow from the inner electrode as it moves to the end of the quartz dielectric. Upon leaving the reactor, the activated fuel-gas-air mixture is used in two types of experiments: 1) it is combusted, with a sample of exhaust being sent to a mass spectrometer (MS), MKS Instruments Model PPT Quadrupole Residual Gas Analyzer; or 2) a sample of activated-fuel mixed with air being directly sent to the MS, without being combusted. We measured the power deposited into the plasma, through the use of well-known Lissajous-diagram techniques (charge-voltage plot) [14]. Flame images were recorded with a digital camera (Nikon CoolPix 3100) to inspect flame quality and stability. The MS was used to identify combustion products (when fuel was combusted) and to correlate them with flame images, or fuel-gas-fragments (when the fuel gas was activated and not combusted). In both cases, the MS was used as a tool to determine if we were indeed decomposing the fuel gas molecules into smaller fragments.

3. Results and Discussion

Initial investigations carried out with the test gases examined how the plasma discharge power affected combustion stability. Previously, we have reported that, in experiments with plasma-activated propane burned in air, flame stability is improved, flame blowout limits are improved (i.e., a leaner burn can be sustained using the plasma), and flame propagation speed is increased [10, 11]. In the previous experiments, an increase in flame speed was determined by observing that the distance a plasma-excited propane/air flame would propagate back toward the plasma region (against the flow of propane and air) increased with plasma power.

In the results reported here, on comparing such an effect for the three different gases, we used a similar technique, namely using flame images to observe the "burnback' phenomenon. Figue 2 shows flame images, taken using the apparatus in Fig. 1, for methane propane, and butane. In this case, the fuel gas flow rate was fixed at 0.3 std lit/min (equivalence ratio set at $\phi = 2$ for each gas by changing the air flow rate) and the plasma power was adjusted to a nominal operating value around 10 W. Methane (CH_4) shows a very slight "burnback" at 10 W (increasing the power further only slightly changes this effect for the methane case. Propane (C_3H_8) shows a substantial effect at 10 W, while butane (C_4H_{10}) shows a dramatic effect at the lower power level of 7 W. For a tube with a 6 cm length above the plasma, as shown in Fig. 1, increasing the power above 7 W causes the flame to reach completely back to the ground center-tube electrode (causing electrical instability in the apparatus). At the beginning of our plasma-assisted combustion investigations, we intuited that more complex hydrocarbons might provide more fragments under plasma excitation, thus showing a larger plasma-assisted combustion effect. For the three test gases examined here, such an assumption seems to be confirmed by the Fig. 2 data.



(a) (b) (c) (d)

Fig. 2: Flame images of (a) propane-air without plasma excitation; hydrocarbon-air with plasma excitation, (b) methane, (c) propane, (d) butane; all 10 W, except for butane case of 7 W. "Burnback" is quite significant for propane and butane.

To understand the mechanisms of our observed plasma-enhanced combustion, attempts were made to identify the activated fuel species. In the absence of a flame, and with the air flow through the inner electrode adjusted to give $\phi = 2$ for a flow of 0.3 std lit/min for each test gas, plasma-treated effluent gas was collected at the top of the quartz tube and analyzed with the MS. Figure 3 shows the mass spectra obtained for the three test gases under the flow conditions mentioned above and a plasma power of 10 W for all three plots (plasma specific energy density of 10 W/0.3 std lit/min = 2 kJ/std lit). The plots are created by normalizing the MS signal

values to the total MS pressure and subtracting the spectrum of a normalized air-only background (because air is a co-flow gas for all cases). For both propane and butane, there is a substantial increase in the normalized MS signal for the lower mass peaks M = 15, 26, 27, and 29; but only M = 15 and 16 show a significant increase in the methane case. For all three gases, there is a slight increase in M = 2 (assumed to be hydrogen H_2), which reinforces our notion that the silent discharge behaves like a fuel-molecule decomposer, rather than a fuel converter.

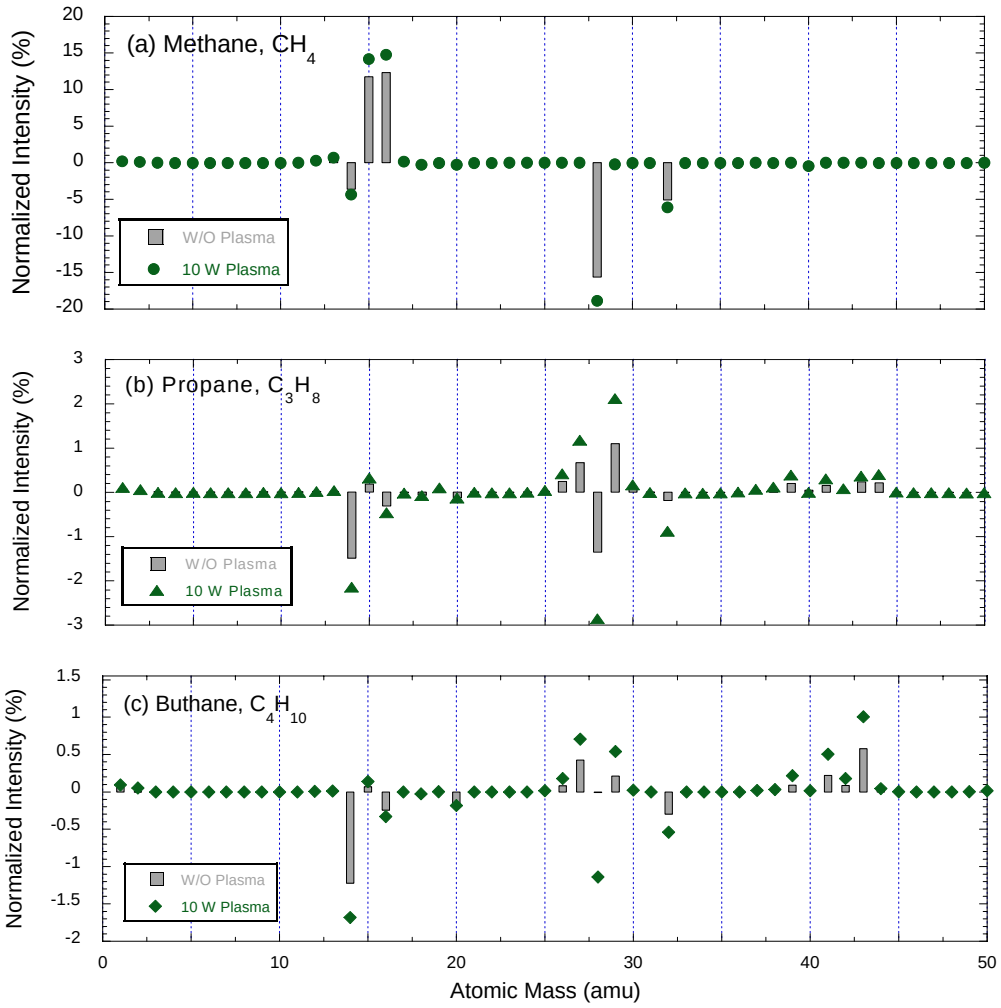


Fig. 3. Normalized mass spectra of (a) methane, (b) propane, and (c) butane under DBD plasma excitation at 10 W (2 kJ/std lit) and $\phi = 2$.

We believe that the fuel gas is decomposed ("cracked) by plasma electron-impact collisions that produce smaller, more easily-combusted fragments and, possibly, free radicals that can propagate combustion reactions. The data presented here in Fig. 3 appears to support that assumption.

In summary, when the hydrocarbons methane, propane, and butane are excited by a silent electrical discharge, mixed with air and combusted, their flame propagation speed increases (butane > propane > methane). In these experiments, the equivalence ratio was set at $\phi = 2$ and the plasma specific energy was relatively modest (2 kJ/std lit for methane and propane, and 1.4 kJ/std lit for butane). We propose that plasma-enhanced

combustion by silent discharges can be explained as an effective increase in the rate of combustion reactions, caused by breaking down fuel molecules and producing radical species in the plasma. In the future, more experiments will be performed to identify reactive species and fuel fragments, and correlate their concentrations with the enhancement of combustion reactions. Silent discharge fuel excitation appears to be a promising technique for enhancing combustion, although more research is needed for practical applications.

ABSTRACT

We tried direct reforming of ethanol-water mixture using LEP discharge with a novel liquid fuel reforming process. We succeeded to produce hydrogen in high energy efficiency using a diaphragm. So in liquid phase discharge, the most important factor was the diameter of the pinhole on the diaphragm. So, it was important to focus electrons at the pinhole. Moreover, energy efficiency in this discharge reached up to 92 % by HHV based calculations.

INTRODUCTION

Recently, demand of hydrogen is increasing as hydrogen-energy-apparatuses (Fuel-cell) are becoming widely used. It is required to establish hydrogen production process of high efficiency. Some catalytic processes have been considered already, but these had many problems (requirement of high temperature, deactivation of catalyst and coking).

Low energy pulsed (LEP) discharge can solve these problems. This novel technique has noteworthy feature. LEP discharge do not requires high temperature or pressure, thus if reforming using LEP discharge is possible, the reaction takes place at room temperature and atmospheric pressure. This process has many advantages compared to conventional process. We have already succeeded in reforming of hydrocarbon using this LEP discharge [1]-[9].

Additionally, ethanol has a potential for being an alternative fuel replacing fossil fuels because ethanol can be produced from various renewable sources (biomass etc.). And it has many advantages like as transportation, storage and friendly to environment compared to methanol [10]-[11]. Last year, we succeeded to develop a new reforming process from ethanol-water mixture into synthesis gas in vapor phase using electrode of carbon fibers [12]-[13]. So we tried direct reforming of ethanol-water mixture using LEP discharge and purposed to suggest novel liquid fuel reforming process.

EXPERIMENTAL

Diaphragm discharge is a kind of new liquid phase discharge at ambient temperature and atmospheric pressure [14]-[15]. An outline image of the reactor and experimental apparatus are shown in Fig.1. As shown in Fig.1, this reactor consists of two pyrex tubes (inner diameter: 100 mm, outer diameter: 110 mm, total length: 300 mm) and a pair of electrodes is set in the liquid fuel. The insulated teflon-membrane (diaphragm membrane) having single pinhole (diameter: 0.25-2.0 mm) is placed between the two tubes.

This membrane seems to have very important role in this discharge. The pinhole centralized the charge, and by that a discharge in liquid phase was generated, and liquid phase reforming was advanced. We chose ethanol-water mixture as a reforming fuel. The gap distance of electrodes was maintained at 6.0 mm in this study. This novel process is so attractive, because it doesn't require any heaters and pumps. Additionally, the process does not include unreacted ethanol-water mixture in outlet gases.

All products in outlet gases were analyzed by a gas chromatography equipped with FID and TCD (Shimadzu; GC14-B). The liquid fuel after the reaction was analyzed by GC-MS (Shimadzu; GCMS-QP2010). The non-equilibrium pulsed discharge was generated by a DC power supply. Waveforms of current and voltage were observed by a high voltage probe (Textronix), a current prove (Textronix) and a digital phosphor oscilloscope (Textronix).

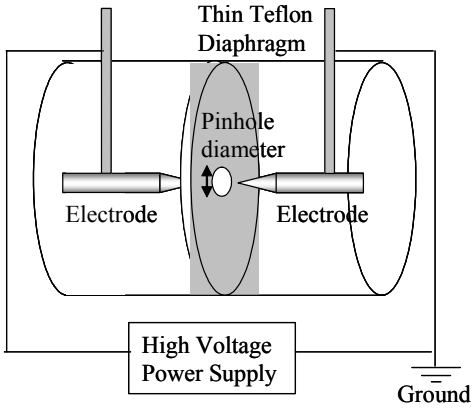

Figure 1. Outline for diaphragm discharge apparatus.

RESULTS AND DISCUSSION

1) Effect of a diaphragm membrane

We examined the diaphragm role in this discharge. So we compared results with and without the diaphragm. After the reaction without the diaphragm, the electrode was corroded and the discharge was not generated. It was considered that the pinhole on the diaphragm allowed electrons to move from high voltage side to ground side while ions and molecules were not allowed. Thereby, it controlled mass transfer and ionic reaction due to electrolysis. On the other hand, in the result with the diaphragm, it turned out that the electrode did not corrode and the discharge could be continued stably for a long time.

2) Shapes of electrodes

We investigated the correlation between shapes of electrodes and formation rates of products. Two types of electrodes which was a needle type (SUS304, outer diameter: 5.0 mm) or a flat-plate type (aluminum, outer diameter: 50.0 mm, thickness: 3.0 mm) were applied for this system. The result is shown in Fig.2, shapes of electrodes had a significant influence on gaseous formation rate in this reaction. In the reaction, hydrogen was generated predominately. In addition to hydrogen, CO, CH_4, C2 compounds (mainly C_2H_2) and small amount of CO_2 were produced. When using a couple of coaxial needle type of electrodes (Type A), the discharge showed the highest value of the formation rate of gaseous products. It was considered that the input power for dielectric breakdown was very low in Type A. It was very similar to the trend of selectivity in vapor phase reaction. On the other hand, diaphragm discharge with a couple of flat-plate electrodes was very difficult to control and the discharge was not generate.

Additionally, energy efficiency calculation based on LHV (lower heating value) is shown in Table 1. Energy efficiency (E_{eff}) based on LHV is defined as Eqn. 1.

$$\text{Energy efficiency} = (\Sigma E_{outoput} / \Sigma E_{input}) \times 100 \qquad (1)$$

Then, energy efficiency based on HHV (higher heating value) is defined as Eqn. 2.

$$\text{Energy efficiency} = ((\Sigma E_{output} + E_{lh}) / (\Sigma E_{input} + E_{lh})) \times 100 \qquad (2)$$

(E_{lh}: the value of latent heat of C_2H_5OH)

Energy efficiency was calculated by Eqn.(1) and Eqn. (2) in the following section. Input power and energy efficiency in this section are shown in Fig.3. Input power in Fig.3 is not the energy consumption of the discharge-gap but the presented value on the high voltage power supply. As the result of that, the energy efficiency was totally low, but type A showed the highest efficiency (LHV: 30.2 %, HHV: 30.8 %) in Fig.3.

Therefore the couple of coaxial needle type of electrodes was selected in the following experiments.

Conditions : discharge gap : 6.0 mm, C_2H_5OH Concentration : 50 mol%, Pinhole diameter : 1.0 mm, Input Current : 15.0 mA, Diaphragm Thickness : 1.0 mm.

4) Effect of input power

In this section, we investigated the effect of input power on gaseous formation rates and on carbon-selectivity. In Fig.4, the amount of product increased as the input power increased. The selectivity to carbon monoxide and C2 hydrocarbon were constant despite of the change of the input power. These results showed the same trend like as the gas phase reaction using LEP discharge. So it was proved that the number of electrons in the gap of electrodes serves as an important factor in this liquid phase discharge. In addition, the input power and energy efficiency are shown in Fig.5. The value of input power in Fig.6 was the presented value on high voltage power supply. As the same as Fig.4, energy efficiency increased as input power increased.

■: Input Power, ●: H_2 formation rate,

Conditions : discharge gap : 6.0 mm, C_2H_5OH Concentration : 50 mol%, Pinhole diameter : 0.5 mm, diaphragm Thickness : 1.0 mm.

5) Effect of the diameter of pinhole on the diaphragm

The influence of the diameter of the diaphragm pinhole was discussed. The correlation between input power for dielectric breakdown and the pinhole diameter (0.25~2.0 mm) was examined. Results are shown in Fig.6. The power was very high when the pinhole diameter was large. It gave suggestion that focusing electrons on the pinhole was very important. Consequently, we examined the effect of the diameter of pinhole on gaseous formation rates and on energy efficiency. The trend is shown in Fig.7. Even if the diameter of pinhole on the diaphragm was small, gaseous formation rates were not affected because the electron focusing energy was too high. So, the diaphragm membrane was damaged. Therefore, the optimal pinhole diameter was between 0.5 and 1.0 mm. On the other hand, energy efficiency in this range showed very high. When the pinhole was 0.25 mm, the energy efficiency showed as high as 92 % (HHV based).

Conditions : discharge gap : 6.0 mm, C_2H_5OH Concentration : 50 mol%, Diaphragm Thickness : 1.0 mm.

6) Influence of diaphragm thickness

As previously noted, in this liquid phase discharge, focusing electrons on the pinhole was very important. In this section, we investigated the influence of diaphragm thickness (the length of focusing electron's pass) on this discharge. Fig.8 shows the correlation between diaphragm thickness and input power for dielectric breakdown. In Fig.8, we could not observe a remarkable trend. Then, the effect of diaphragm thickness on gaseous formation rate and energy efficiency is shown in Fig.9. As the same as Fig.8, we could not get noteworthy trends. Whereby, the important element in this discharge was not the focused electrons volume, but the focused electrons density.

CONCLUSIONS

Using diaphragm membrane, liquid phase discharge was succeeded at ambient temperature and atmospheric pressure. The main gas in products obtained was H_2. In addition to H_2, CO, CH_4, C2 compounds (mainly C_2H_2) and small amounts of CO_2 were produced. First, as a consequence of the effect of shapes of the electrode, a couple of coaxial needle type of electrodes showed the highest yield and stable discharge. Next, we examined the effect of input power on the discharge. The gaseous formation rates showed the trend of increase as increase of input power. This results was as same as the vapor phase discharge (the reforming of C_2H_5OH using the electrode of carbon fibers). Additionally, we investigated the effect of diaphragm pinhole on the discharge. It showed that input power for dielectric breakdown could be very low when diaphragm pinhole was small. Therefore, in this discharge, the most important factor was diameter of diaphragm pinhole, in other words, it was important to focus electrons on the microscopic pinhole. On the other side, diaphragm thickness was not very important in the discharge. Finally, we examined energy efficiency at all conditions. As the consequence of that, energy efficiency in the discharge reached up to 92 % (LHV and HHV based calculations). The ability to generate hydrogen in this condition showed 96 MJ kgH_2^{-1}. And in order to increase energy efficiency, the electrode of coaxial needle type should be selected, and the input power should be increased and the diameter of diaphragm pinhole should be small. It was prospective to use this reformer in the future for hydrogen manufacturing process, because the reformer was very simple and small.

Atmospheric Pressure Normal Glow DC Microplasma in Air

D. Staack, B. Farouk, A. Gutsol, A. Fridman
Department of Mechanical Engineering and Mechanics, Drexel University, Philadelphia, PA, USA

Abstract

DC glow discharges were generated between a thin cylindrical electrode and a flat surface in atmospheric pressure air. Voltage-current characteristics and visualization of the discharge indicate operation in the normal glow regime. N_2 emission spectroscopy indicates a non-equilibrium plasma with T_{rot}= 750K to 1550K and T_{vib}= 4500K. Inter-electrode spacing ranged from 20 μm to 1.3 cm. The radius of the positive column is about 100 μm. This size is important in preventing thermal instabilities and the transition to an arc.

DC Glow Discharge, Microplasma

1. Introduction

The formation of spatially uniform, non-equilibrium atmospheric pressure plasma discharges[1] are desirable due to their potential industrial applications [2]. The non-equilibrium translational (T_{trans}), rotational (T_{rot}), vibrational (T_{vib}), and electron (T_e) temperatures ($T_{trans} = T_{rot} < T_{vib} < T_e$) allows them to be used for materials processing applications such as deposition and etching used in the semiconductor manufacturing industry without the need for expensive vacuum systems. One of the most studied non-equilibrium plasma discharge at vacuum pressures is the normal glow discharge [3]. Glow discharges at higher pressures are generally unattainable due to instabilities which lead to a glow-to-arc transition (GAT) [1]. As the pressure is increased the current density increases until reaching the threshold for the development of instabilities leading to a transition to the arc phase and an equilibrium plasma. Generally the thermal instability is suppressed in low pressure discharges by cooling at the walls.

For over 50 years methods to create DC glow discharges at up to atmospheric pressures have been known. Fan [4] used water cooling of the electrodes and stable discharges were achievable in hydrogen and nitrogen at up to 2A. In air, though appearing as a stable glow, even at the lowest currents tested (~100mA) high frequency transitions between glow and arc were noted. Gambling and Edels [5], created glow discharges in air for currents between 10mA and 0.5A noting a stable arc above 0.5A. Several methods have been tried to stabilize the glow discharge and prevent glow to arc transition (GAT). In DC glow discharges at atmospheric pressure, high speed gas flows have been used to provide sufficient cooling of discharges at high pressures [6]. DC microhollow cathode discharges (MHCD) have been reported by Sankaran et al.[7-10] and Stark and Schoenbach [11-13]. The MHCD of Sankaran and Giapis is flow stabilized and operates at up to 20 mA. Stark and Schoenbach operated the MHCD in atmospheric pressure air for current up to 22 mA. Stark and Schoenbach report the discharge being stabilized because the microhollow cathode supplies electrons to the positive column of the discharge rather than the instability-prone cathode region as in a traditional glow discharge.

In this paper, we report recent investigations showing the operation of glow discharges in atmospheric pressure air at lower currents than reported by Gambling and Edels [5]. At lower currents no fluctuating glow-to-arc transitions are seen, and a glow discharge is observable without any surrounding diffuse glow as seen by Gambling and Edels [5]. At these currents the discharge is shown to be stable with diameters of about 100 μm. Current-voltage measurements, visualization and parametric studies of the discharge show it to be a normal glow discharge. Analysis for low pressure normal glow discharges applied to this discharge agree well with experimentally measured values further indicating a normal DC glow discharge. Optical emission spectroscopy shows the discharge to be non-thermal although translational temperatures are between 750K and 1550K. Estimations of the heating and diffusion time show the non-thermal discharge is stable due to its small radius. High pressure discharges stabilized by operating with small characteristic dimension have been termed microplasmas [14].

2. Experimental Setup

The circuit used to generate the glow discharge is similar to that used in low pressure glow discharges. Figure 1 is a schematic of the setup used for creating and analyzing the discharge. A DC power supply is connected in series to a ballast resistor a shunt resistor and the discharge. Various values of shunt resistor, ballast

resistor, power supply polarity, and applied voltage were used depending on the regime of study. For studies in the normal glow discharge regime in air the shunt voltage was 1 kΩ and the ballast was 100 kΩ. The shunt resistor is connected to a voltmeter or an oscilloscope for DC or time dependant current measurements respectively. Typically the power supply voltage was set and the discharge voltage was calculated from the measured current on the shunt and known resistance values. The lower electrode is made from stainless steel. The upper electrode is a steel wire positioning stage which controls the spacing between the wire tip and the lower electrode.

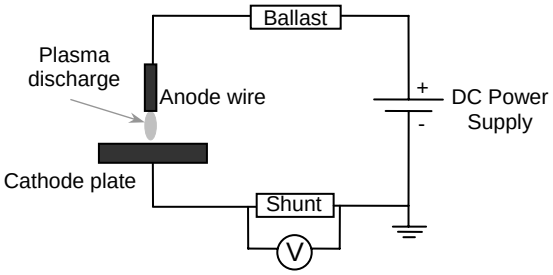

Figure 1: Electrical circuit used to generate and analyze the glow discharge.

For visualizing the discharge a 640x480 resolution Sony CCD-iris color video camera was mounted to a microscope focused on the discharge. The microscope-camera setup provided a variable magnification allowing between a 2mm x 1.5mm and a 20mm x 15mm field of view. For spectroscopy an Acton Research SpectraPro 500i scanning monochromator was used. The entrance slit to the monochromator was placed ~1" from the discharge. Optical emission spectra (OES) of the discharge were taken in a range of 200-450 nm averaging emission from the entire discharge. A roper scientific model 7430 CCD camera was mounted to the exit slit to digitally acquire the spectra at approximately 0.6 nm resolution. Typical acquisition times for the CCD image were 1-5secs. Background images with the discharge off were subtracted and a low pressure mercury lamp was used to determine the slit (apparatus) function and calibrate the spectrometer.

3. Experimental Results and Discussion

Figure 2 shows a series of images of the glow discharge at increasing electrode spacing. The anode is the wire coming from the top of the image and the cathode is the surface along the bottom edge of the image. For electrode spacings of 0.1, 0.5, 1 ,3 and 13 mm the voltages across the plasma required to sustain the discharge were 385, 430, 505, 780, 1450 Volts respectively. Images (a), (b) and (c) were taken at the same magnification; image (d) and (e) were taken at a decreased magnification. Similar to a vacuum glow discharge near the cathode we see the 'Negative Glow' region which maintains approximately the same length as the electrode spacing is increased. Moving up from the 'negative glow' we have the 'Faraday dark space' followed by the 'positive column'. The discharge does not completely cover the electrodes or fill the region between the electrodes. For the same discharge current and same gap spacing with differing electrode sizes the shape and size of the discharge are identical. These general visualizations of our glow discharge match those of a low pressure normal glow. From these images at atmospheric pressure the cathode sheath is unresolved and less than 10 μm in thickness. The occurrence of luminous and non-luminous regions is a major indication that the discharge is a non-thermal discharge. These images are similar to those of Gambling and Edels [5] except that at these low current no diffuse glow surrounding the primary column is seen.

From Figure 2 we see that at increasing electrode spacing the length of the negative glow remains constant while the length of the positive column changes. This is consistent with the discharge being a glow discharge and the electric field in the primary column can be attained by measuring the change in discharge voltage as a function of electrode spacing while maintaining the discharge current constant. For discharge currents of 1.0, 2.1, 5.1 and 10.2 the corresponding electric fields in the positive column were 4.5, 3.8, 2.3 and 1.4 kV/cm. Discharges with large *d* (>1.5mm) as shown in Figures 2 could be created in two ways. If a power supply with sufficient high voltage capability was used the discharge could be directly initiated. An alternative method was to initiate the discharge at smaller *d* and then extend the discharge by moving the upper electrode.

Since the required breakdown voltage was not available in these cases the discharge was only marginally stable. A large disturbance, for example a significant gas flow, could extinguish the discharge. Larger discharge currents were more stable than smaller discharge current.

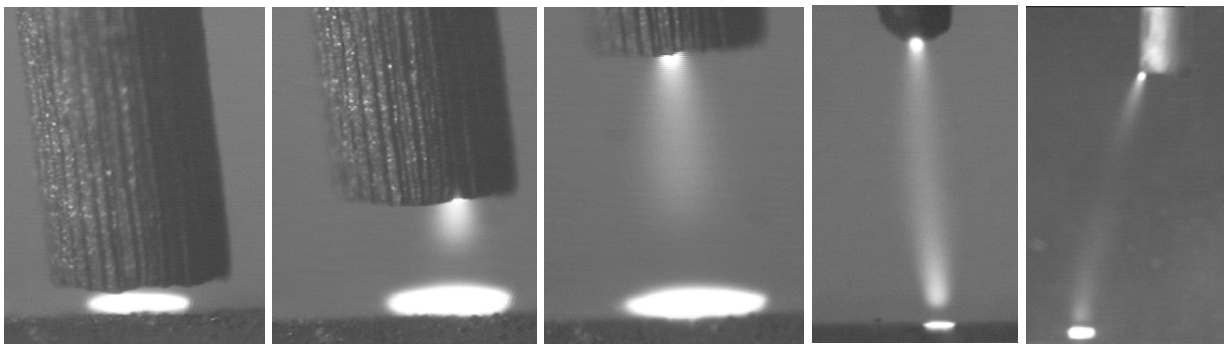

Figure 2: Images of glow discharge in atmospheric pressure air at (a) 0.1 mm, (b) 0.5 mm, (c) 1 mm, (d) 3 mm and (e) 13 mm electrode spacings.

The dimensions of the positive column, and negative glow were estimated from images such as those shown in Figure 2. The cross sectional area of the discharge was then calculated assuming that the negative glow and positive column were cylindrical in shape. Using the measured area and discharge current the current density in the negative glow and positive column regions was calculated. Figure 3a is a plot of the current density in the negative glow and the positive column as a function of current for several different electrode spacings. Figure 5b is a plot of the width of the negative flow and positive. As can be seen from figure 5a the current density in the negative glow region is nearly constant at a value of 5.95 A/cm^2. The occurrence of a constant or normal current density in the cathode region is another hallmark indicating that the discharge is a normal glow discharge. The positive column has increasing current density with increasing current and a nearly constant size of the positive column.

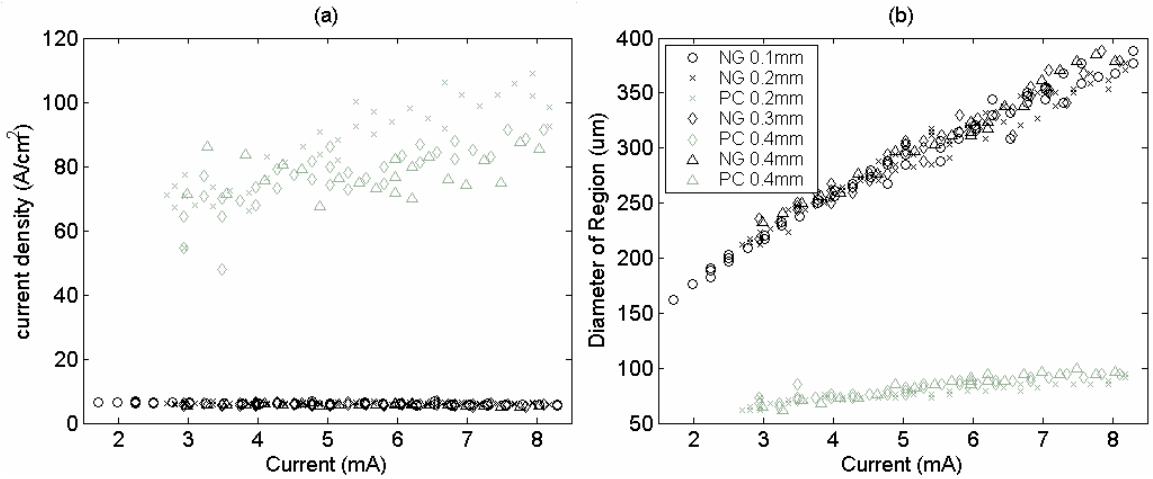

Figure 3: Plot of current density in (a), and diameter of (b) the negative glow (NG) and positive column (PC) regions of the discharge as a function of discharge current for electrode spacings between 0.1 and 0.4 mm. Discharge is in air and conditions correspond to those in Figure 3.

Figure 4 is a plot of discharge voltage vs. discharge current for electrode spacings between 20 μm and 3 mm. Errors in the electrode spacing of +/- 5 μm are due to thermal expansion of the wire and shortening of the gap at higher currents. Errors in current are +/- 20μA and errors in voltage are less than 10V. These plots are for a stainless steel anode and cathode, and with the upper wire electrode 0.8 mm in diameter as anode. The current was varied by changing the DC power supply voltage with a constant ballast resistor. Oscilloscope traces and Fourier power spectrums of the discharge current showed the current to be constant with no significant AC components. Over the range of currents shown all of the discharges were similar in structure to those of figure 2.

Shown in Figure 4 are discharges corresponding to powers between 50 mW to 5W. For the small spacing of electrodes the V-I characteristic is relatively flat. This is consistent with the idea of this being a normal glow discharge and with past measurement in atmospheric pressure glows [4, 5, 12] and MHCDs operating in normal glow mode [12]. For a normal glow discharge in air the normal cathode sheath potential drop is around 270V, the discharge voltage above that occurs mostly in the positive column. For the larger electrode spacing the V-I characteristic the positive concavity and negative slope is more indicative of a subnormal regime. The breakdown voltage to initiate the glow discharge followed the general trends of a Paschen curve. The equation $V_{br} = 940ln(d)+5750$, where d is the electrode spacing in cm and V_{br} is the breakdown voltage, fit our data to within 2% for d between 40μm and 1.5 mm.

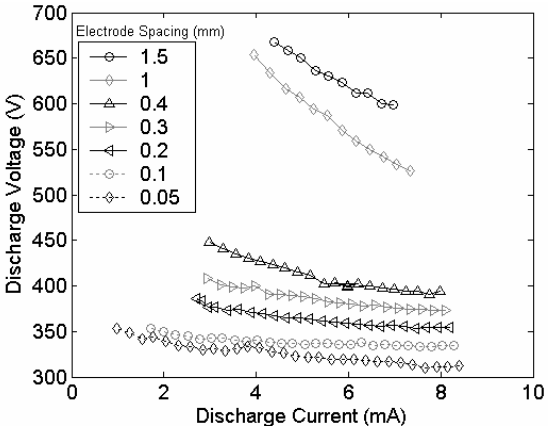

Figure 4: Voltage current characteristics for plasma discharge in air at several electrode spacings.

Figure 5a is the OES from the glow discharge in air between 200 and 450 nm. The brightest lines between 300 and 450 nm are due to the nitrogen 2nd positive electronic transition $N_2(C^3\Pi_u\text{-}B^3\Pi_g)$ and its family of vibrational and rotational level subtransitions. In the ultra violet region between 200 and 300 nm there are weaker NO lines from the $NO(A^2\Sigma^+, v'\text{-}X, v'')$ electronic transition. No OH line which exceeded the height of the tail of the N_2 2nd positive transitions was visible at 308 nm. Some significant N_2+ first negative $N_2^+(B_2\Sigma^+_u\text{-}X^2\Sigma^+_g)$ transitions were also visible in the violet range.

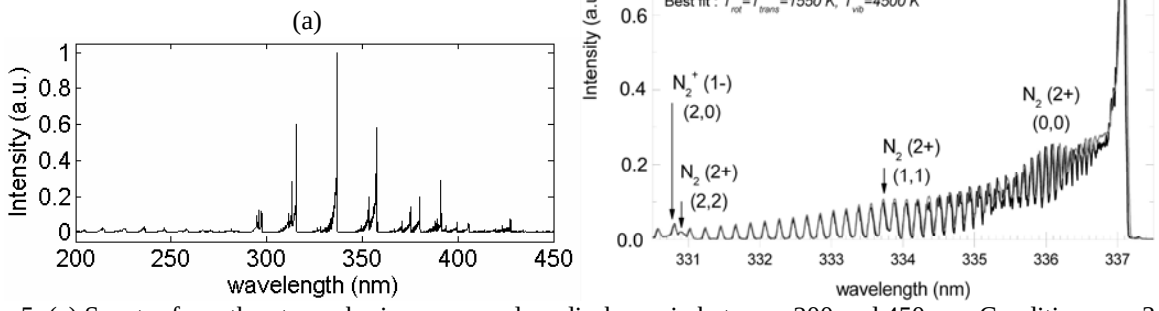

Figure 5: (a) Spectra from the atmospheric pressure glow discharge in between 200 and 450 nm. Conditions are 3.8mA discharge in air with 150 μm electrode spacing. (b) Measured OES and curvefit using SPECAIR for 10mA glow discharge in atmospheric pressure air.

Figure 5b is the measured spectra and a curvefit using SPECAIR at 10mA discharge current. The strongest line is the N_2 2nd+ (0-0) at 337 nm and it overlaps with other lines in the 330 to 337 nm range as listed on the figure. The comb like peaks to the left of 337nm correspond to the rotational sublevels of the transition. The relative heights of these rotational transitions are related to the rotational temperature, T_{rot}. The relative

heights of transitions with different initial vibrational energies are related to the vibrational temperature T_{vib}. SPECAIR[15] a spectroscopic modeling code developed at Stanford was used to model the spectra from these transitions[16]. A least squares curvefit between the modeled spectra and the experimental spectra was using T_{rot} and T_{vib} as fitting parameters. The determined temperatures were 1550K and 4500K for rotation and vibration respectively. These temperatures indicate the non-equilibrium nature of the discharge and are similar to the 1700K-2000K rotational temperature measured in a MHCD [17]. At 0.1mA discharge current similar spectral measurements indicate T_{rot}=750K and T_{vib}=5000K. A decrease in temperature with discharge power is to be expected. At 10mA thermocouples placed 5 mm from the discharge measured an increase from room temperature of about 50K. This indicates temperature gradients on the order of or greater than 2400K/cm.

4. Analysis

Based upon the various measurements detailed above the discharge may be considered a normal glow discharge. Significant formulations are available to describe the parameters of a low pressure normal glow discharge and can be compared to our experimental results. Many of these formulations assume a room temperature gas typical of low pressure glow discharges. Also many of the heuristic invariants are listed in terms of pressure when in fact they are functions of number density. For variable temperatures as high as 1500K in the glow discharge this effect needs to be taken into account. The replacement of p in the relations by an effective pressure $p*T_n/T$ is sufficient in most cases, where p is the pressure in torr, T_n is the normal gas temperature (~293K) and T is the actual gas temperature.

The low pressure normal glow current density for Air and an iron electrode at room temperature from the literature is approximately 300 $\mu A/cm^2\text{-}torr^2$. Using the effective pressure: $j=j_n p^2(T_n/T)^2$ where j_n is the normal current density at room temperature (300 $\mu A/cm^2\text{-}torr^2$). For our conditions of p=760 torr and T=1500K the calculated normal glow current density in the cathode regions is 6.6 A/cm^2. The experimentally measured current density was 6 A/cm^2. The correspondence between the experimentally measured current density and the normal glow current density is further evidence that the discharge is a normal glow discharge at atmospheric pressure. The normal cathode layer thickness and normal cathode potential drop are also consistent with our experimental results as discussed earlier. The electric field can also be estimated. E/p for low pressure glow discharges is typically in the range of 10 to 30 V/cm-torr. Again using an effective pressure, electric fields at 760 Torr and 1500K should be in the range of 1.5 to 4.5 kV/cm. These values are consistent with those measured. E/n can also be determined from the discharge regime. If the discharge is controlled by electron attachment the frequencies of ionization and electron attachment which are both function of E/n will be equal. In air this occurs at $E/n = 13\text{x}10^{-16}$ V/cm^{-2} [18]. At 1550K this corresponds to an electric field of 6.1 kV/cm about a factor four higher than measured at 10mA. If the discharge is controlled by particle diffusion out of the discharge the Engel-Steenbeck relation holds [18]. Taking into account the gas temperature of 1550K and discharge radius of 50μm the electron temperature should be around 1.4eV which corresponds with an E/n of $6\text{x}10^{-16}$ V/cm^{-2} and an electric field of 2.8 kV/cm closer to the experimental value.

These estimations further indicate that the discharge is a normal glow discharge. Building on these estimations we can explain the stability of the discharge. We can show that the discharge is stable due to its small size; a neutral is able to leave the volume of the discharge before it gets too hot. To estimate this consider the diffusion time of a neutral out of a cylindrical volume and the heating time of a neutral in that volume. The time for a neutral to diffuse out of the discharge is the cooling time, τ_c, and is related to the diffusion coefficient, D, and the radius of the cylindrical volume, R. $\tau_c \approx R^2/4D$. D is proportional to the mean free path and the molecular speed and thus has a $T^{3/2}/p$ dependence. D is 0.147 cm^2/sec for N_2 in room temperature atmospheric pressure air.

The heating time for a single neutral is the inverse of the electron density n_e times the rate constant for vibrational excitation of the neutral, k_{ven}. For molecular gases like air the vibrational excitation of the molecule is the fastest mode of energy transfer between the electrons and the neutrals. For nitrogen and 1 eV electrons k_{ven} is $4\text{x}10^{-9}$ cm^3/s. n_e, can be estimated from the current density, j, and the electron drift velocity v_d. The drift velocity corresponding to our E/n is $6\text{x}10^6$ cm/s. The current density, j, calculated before was for the negative glow. In the positive column the current density may be controlled by other mechanisms, the measured current density of

about 80 A/cm^2 corresponds to a n_e of 8x10^{13}cm^{-3}. The heating time for the discharge is thus calculated to be 3 μs. Equating the heating and cooling time gives an estimate for the size of a stable discharge at 45μm. The calculated radius of a stable discharge (45μm) and the experimentally measured discharge radius (30-50μm) are of the same order. This indicates that the discharge can be thermally stable due to its size.

5. Conclusions

We have generated atmospheric pressure microplasma discharges in our laboratories. Several experimentally observed facts lead us to believe this is an atmospheric pressure normal glow discharge. 1) Visualization of the discharge show distinct bright and dark regions corresponding to the 'negative glow', 'Faraday dark space' and 'positive column' of a glow discharge. 2) Voltage-current characteristics of these discharges are relatively flat and are in the regime of a normal glow discharge. 3) Current density measurements indicate a constant current density with increasing discharge current in the 'negative glow' region. Additionally, low pressure normal glow discharge heuristics accurately apply to our atmospheric pressure discharge. Correspondence is seen with experimentally measured values of the current density and electric field. The accurate application of normal glow discharge physics further indicates that the atmospheric pressure discharge is a normal glow discharge. Spectroscopic temperature measurements indicate that the discharge is a non-thermal, non-equilibrium discharge, T_{vib} = 5000K > T_{trans} = 750 to 1550 K. Low pressure normal glow discharges are also non-thermal; however, gas temperatures are lower and typically near room temperature. Estimations also show that the non-thermal glow discharge is stable because of its size. For ~100μm diameter discharges the diffusion time out of the discharge volume is approximately the same as the heating time within the volume.

For low currents and small gap length the discharge the discharge behaves as a normal glow discharge. The breakdown characteristics are also similar to low pressure discharges. However, explorations at high current (greater than approximately 10mA) and large electrode spacing (greater than approximately 1 mm) indicate that the discharge can appear less like a normal glow discharge without transitioning to an arc. At large electrode spacing the discharge begins to bend and is only sustained with higher currents. At larger current the primary column also appears as a diffuse glow.

A modified method of synthesis has been used to prepare highly luminescent crystalline silicon nanopaticles (Si-NP).These particles, which are coated by an oxide layer, are prepared by combustion of silane (SiH_4) [1]. Photoluminescence (PL) situated in the red to yellow spectral range 650-850 nm has been activated by etching the Si-NP in two phase cyclohexane /propanol-2 solutions mixed with hydrofluoric acid. A thin homogeneous layer (about 20 nm) of these Si-NP, sized about 2nm and having PL maximum at ~650nm was used to prepared light emitting p-i-n diodes (LED) operated at room temperature. Their cross section is shown in Fig. 1(a). The current-voltage curves show basic properties of good rectifying diodes with rectification factor of about 10^5. Electroluminescence (EL) images and spectra are studied by a microscope connected to an imaging spectrograph with an intensified CCD camera. EL spectra are broad, covering almost all visible range with peak around 600 nm. The decay of EL excited by current pulses is shown to be comparable to photoluminescence decay, i.e. it has stretch exponential form with dominant decay time of tens of microseconds (depending on wavelength). The unique properties of our Si-NC based LED will be compared to other types of Si-NC LEDs.

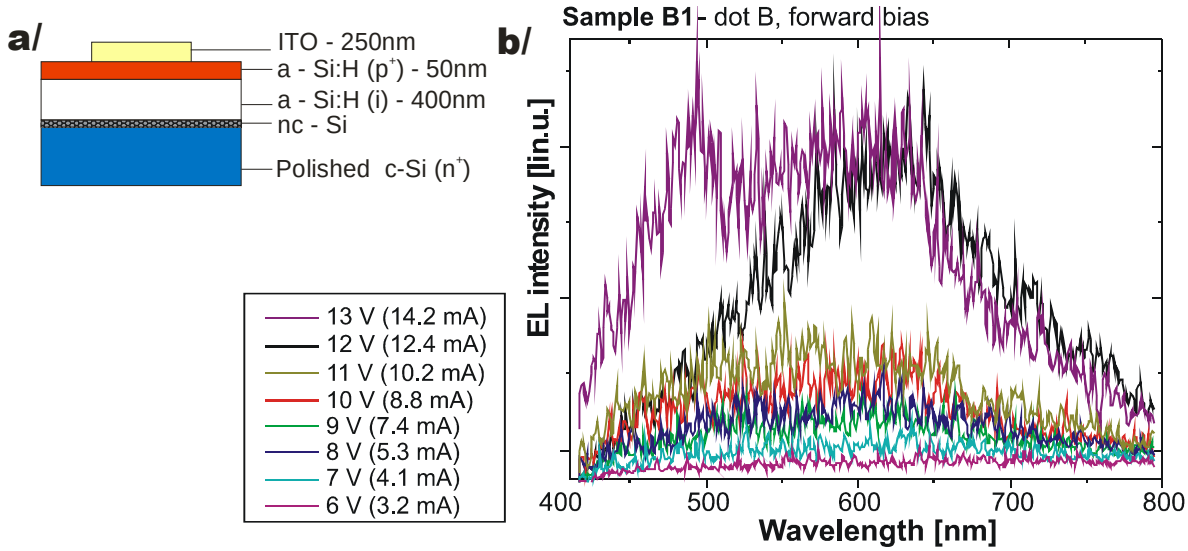

Fig. 1: (a) A schematics of the LED structure. (b) The EL spectra of one emitting spot under various forward bias voltages from 6 to 13 V (indicated in the inserted label).

Abstract

The influence of treatment of middle-fiber cotton seeds of C6540 and C6524 sorts (G.hirsutum L.) in ozone-air mixture on germination and energy of germination in dependence of exposition dose and time delay after seed's treatment have been studied. For this purpose the ozonizing installation of productivity 100 g ozone per hour and the technology of seeds treatment by ozone-air mixture have been elaborated. It has been shown that the treatment of cotton seeds by ozone results in enhancing both of germination and energy of germination up to 15-20%.

Introduction

Existing methods of pre-sowing treatment of seeds are based on desinfection of seed material by various toxic reagents, such as: vitavaks, raksil etc.[1]. Providing positive results, these methods have a number of the negative sides connected with the danger of poisoning of operating personnel and environment pollution. Proceeding from this, during the last years in many countries the investigations on search, development and usage of new technologies of pre-sowing treatment of seeds of different agricultural cultures have been carried out. The analysis of different alternate technologies of stimulation of processes of seeds germination has shown, that one of the most effective ways of an activation of seeds material is its treatment in gas atmosphere with some concentration of ozone (ozone treatment) [2]. It is stipulated by that the ozone shows complex influence on seeds, as the actuating and deodorizing agent, and the technologies of ozone application are enough simple, ecological clean and safe. The ozone is received directly at the place of it usage, and after treatment ozone decays up to oxygen, which does not pollute environment.

In the given work our investigations on influence of treatment of middle-fiber cotton seeds of new variety C-6540 and widely cultivated on territory of Central Asia variety C-6524 (G.hirsutum L.), in ozone-air mixture are presented. Investigations at various concentration of ozone depending on exposure time and time of seeds storage after treatment ("binning") have been carried out. The purpose of performed investigations was creation of special ozonizing installations and developing an optimum regime of treatment of cotton seeds that provides energization of process of germination of the seed material, and development on this basis of a new non-polluting technology of pre-sowing treatment and disinfection of cotton seeds with ozone and replacement of the old methods based on chemicals usage.

Technique of investigations

Treatment of seeds by ozone was carried out with help of the compact ozonizing installation "Ozone-Uzb-100" by productivity 100 g ozone per hour that was developed for this aim in NSC «Kharkov Institute of Physics and Technology». This installation is the generator of ozone synthesis of a new generation, which is based on use of the high pressure discharge in oxygen-containing gas, e.g. in air at atmosphere pressure Discharge is ignited in a coaxial system between the tubular cathode and sectioned many needle anode and is supplied by a high-voltage source of direct current. Discharge gap does not contain a dielectric barrier. It favorably distinguishes the developed non-barrier ozonizer from conventional barrier ozonizers as it does not suffer at all of accidental spark breakdowns in discharge gap and is considerably more technological at manufacturing. The main constituents of the generator of ozone "Ozone-Uzb-100" are the block of ozone synthesis, system of high-voltage direct-current feed (voltage up to 18 κV, current up to 65 mA), system of pumping of working gas of efficiency 100 m^3/hour, the monitoring system of electrical and gas

performances, and cooling system.

Treated seeds were loaded into hermetic container by volume of 10 liters, in bottom part of which the ozone-air mixture was fed with the help of oilless compressor. Depending on speed of air flow and a charge current in ozonizers it was possible to receive in working volume the concentration of ozone in a range 0.2 – 9.0 g/m^3. Lots of 600 tomentous seeds were exposed to treatment by ozone. They were settled down in working volume in mesh containers motionlessly. After treatment the seeds were stored required time ("binning") in linen bags at temperature 20-25^{0}C and then were sowed by sets of 150 seeds in standard baths made from the zinced iron of the size 130mm x 260mm x 40mm., filled with sand. Preliminary sand was sifted through special sieves so that to select grains of sand in the size 0.5-1.0mm., then the selected grains of sand were carefully washed out by flowing water after that it was gotten tempered at temperature 400^{0}C during several hours. Treatment of seeds was made at humidity of an environment of 50-60% and temperature 20-25^{0}C. Sprouting was made at average daily temperature 25-28^{0}C and humidity of 65%. Watering of sprouting seeds was carried out in the same time of day by boiled water cooled up to 25^{0}C. Energy of germination was determined on the fifth day, and germination of seeds on the seventh day after their sowing. By results of three measurements average value of germination and energy of germination of seeds for each concentration, exposure time, and time of seeds storage after treatment ("binning") were determined.

It is necessary to note, that in experiments cotton seeds of superstrain of variety C-6540 and C-6524 were used. The seed material is shaped at the collecting of cotton from 2 to 8 simpodial branch. In total for the season of vegetation on a cotton bush can form 16 and more simpodial branches. In our investigations cotton seeds collected from all bush, which did not subjected to any presort and treatment, were used.

Results and discussion

X-ray analysis (fig.1), performed for control untreated seeds of both varieties, selected randomly, has shown, that "fullness" of seeds was equal 97-98 %. This value displayed the maximal possible quantity of viable seeds. Despite of a so high index of vitality the germination of control untreated seeds (average value) was 64 % for variety C-6540 and 72 % for variety C-6524, i.e. about 25-35 % of seeds did not give plantlets.

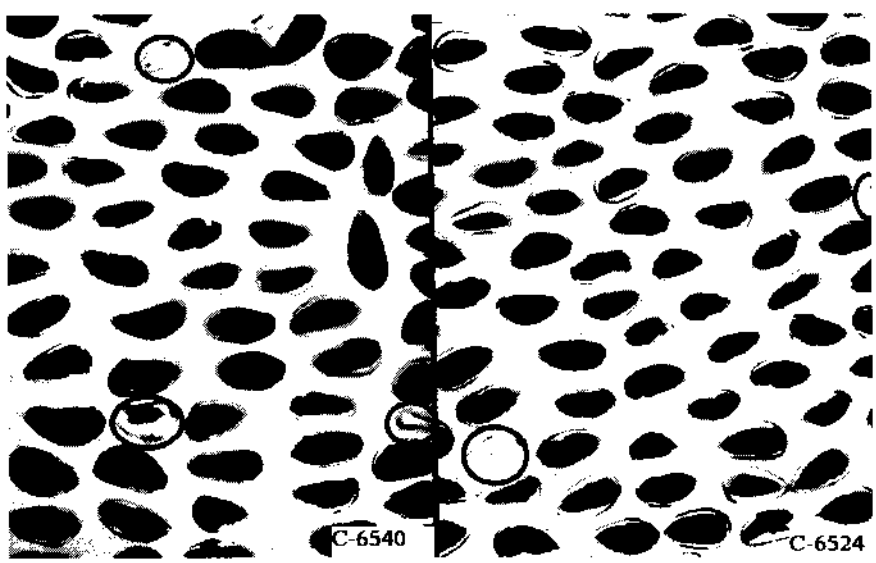

Fig.1. X-ray images of cotton seeds. Empty seeds are marked by a circle.

After treatment of similar seeds in ozone-air mixture the parameters of growth varied. At small concentration of ozone (0.2-2.0 g/m^3) depending on exposure time germination of seeds of variety C-6524 grew approximately by 10-15 % and for variety C-6540 by 5-10% in comparison with the control untreated seeds. The most essential change of germination was obtained not at once, but only after some time delay ("binning" time) after treatment. In that time treated seeds were stored in linen bags at a stationary temperature ~20^{0}C. The most favorable day occurred 5th day and 10th day after treatment for variety C-6524

and for variety C-6540, accordingly. At that energy of germination of seeds of variety C-6540 increased by ~10 %, and seeds of variety C-6524 it was even lower, than for control untreated seeds.

Increase of ozone concentration up to average values (3.0-5.0 g/m^3) resulted in increase seeds germination by value of 15-20% at exposure time 40 minutes. So at treatment of cotton seeds of variety C-6540 by ozone-air mixture with ozone concentration of 5 g/m^3 at exposure time of 40 minutes germination of seeds grew from 64% for the control untreated seeds up to 80 % at time of "binning" 10 days. At the same parameters energy of germination of the above-mentioned seeds increased from 21 % up to 51 % at time of "binning" 7 days and from 21% up to 30% at time of "binning" 10 days. For cotton seeds of variety C-6524 similar results have been obtained: at 7 day of "binning" germination grew from 72% up to 88%, and energy of germination grew from 28 % up to 70%. The increase in exposure time in an ozone-air mixture above 50 minutes and increase in terms of seeds "binning" after treatment more than 10 days, as a rule, resulted in reduction of considered parameters.

In Fig. 2 dependences of germination and energy of germination of cotton seeds treated in ozone-air mixture at ozone concentration of 5 g/m^3 are presented. It is seen that in considered regime of treatment of cotton seeds simultaneous increase of germination and energy of germination was observed.

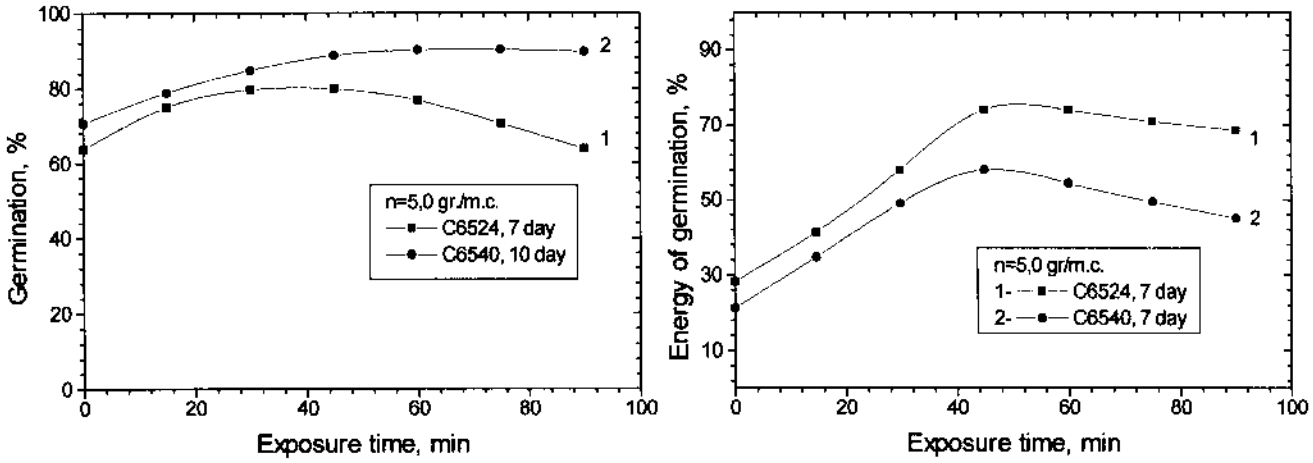

Fig.2. Dependence of germination and energy of germination of cotton seeds subjected to treatment in ozone-air mixture at ozone concentration of 5 g/m^3 on exposure time.

In Fig. 3 the dependences of germination and energy of germination of cotton seeds of both varieties for various terms of "binning" are presented. As it is seen, for cotton seeds of variety C-6524 a maximum of germination and energy of germination were observed at "binning" of 7 day, while for cotton seeds of variety C-6540 a maximum of germination was observed at "binning" of 10 day, and maximum of energy of germination was observed at "binning" of 7 day. The difference in value of germination at "binning" in 7 and 10 day for seeds of variety C-6540 made a value ~2-3 %, but energy of germination for this period varied up to 20%. From our point of view, the peak of seeds activity came for 7 day.

The further increase in concentration of ozone in working volume up to 7,0-9,0 g/m^3 result in more higher germination than for untreated control seeds, but it begins to be reduced in comparison with similar values for medium concentrations of ozone.

General result of the carried out investigations is that fact, that the treatment of cotton seeds in ozone-air mixture results in activation of seeds and enhancement of their growth – energy of germination and germination of cotton seeds.

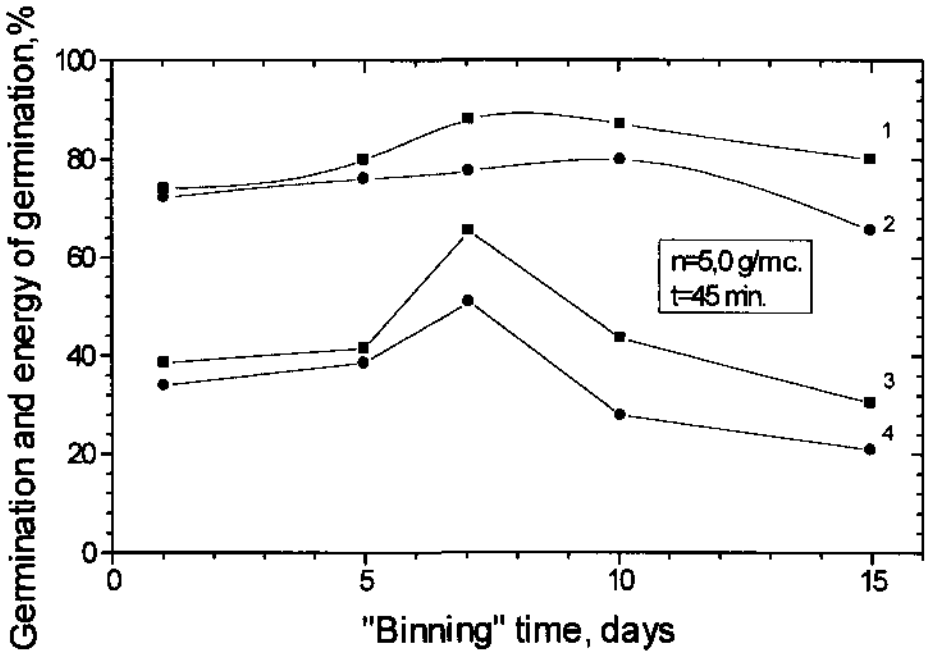

Fig.3. Dependence of growth parameters of cotton seeds from time of "binning": 1- germination of seeds C-6524, 2- germination of seeds C-6540, 3- energy of germination C-6524, 4- energy of germination C-6540

After determination of an optimum regime of cotton seeds treatment the additional experiment on influence of treatment time on germination and energy of germination of cotton seeds was carried out. As it was already noted, increasing in exposure time more than ~50 minutes or increasing of ozone concentration up to 7,0-9,0 g/m^3 results in decreasing of germination of cotton seeds, i.e. the process of depressing of an energy of germination and germination of seeds begins. In the experiment cotton seeds subjected to long-time treatment (2,5-15 hours) in ozone-air mixture at ozone concentration n=5,0 g/m^3. The results on determination of germination of cotton seeds on 7th, 10th and 13th day after their sowing are shown in the Table 1.

Table 1. Germination of cotton seeds treated in ozone-air mixture

№	Variety	Concentration of ozone, g/m^3	Treatment time, hours	Germination, %		
				on 7th day	on 10th day	on 13th day
1	C-6540	0	0	64	70	78
2	C-6540	5	0,6	83	87	88
3	C-6540	5	2,5	57	83	84
4	C-6540	5	5,0	0	78	80
5	C-6540	5	8,0	0	50	76
6	C-6540	5	15,0	0	40	74
7	C-6524	0	0	71	85	93
8	C-6524	5	0,6	95	96	98
9	C-6524	5	2,5	65	81	84
10	C-6524	5	5,0	64	70	72
11	C-6524	5	8,0	0	59	70
12	C-6524	5	15,0	0	52	85

As it is seen from Table 1, the long-time treatment of cotton seeds in ozone-air mixture of medium concentration of ozone, has not resulted in full depressing of seeds growth, and has led only to decreasing of percent of germination and delay in seeds growth. So, if at treatment during 0,6 hours the germination of seeds of varieties C-6540 and C-6524 already on 7th day after sowing was 83% and 95%, accordingly, after treatment during 2,5 hours the germination is reduced up to 57% and 65%. The further increasing in

exposure time reduces the percent of germination even more, down to zero value at 8-15 hour of treatment. But on 10^{th} day even these seeds have sprouted and percent of germination was 40% and 52%, accordingly.

From the table 1 it is seen, that the maximum of germination of control untreated seeds was observed on 13^{th} day after sowing. At the same time after treatment of cotton seeds in ozone-air mixture, already on 7^{th} day the germination was equal 83% and 95%, and in subsequent days this parameter increased some more. It indicated that seeds were more «active» and we saved time of about 6^{th} days. The presence of such "reserve" in time can promote strengthening of sprouted seeds, which subsequently will have an effect on force of the cotton plant.

Thus, the correctly chosen regime of treatment of seed material, can activate the process of seeds growth and increase their germination and energy of germination.

Conclusion

The carried out investigations on influence of treatment of cotton seeds in a ozone-air mixture have shown, that the similar treatment results in activation of process of seeds growth. There is a varietal difference of response of cotton seeds on effect of ozone for different varieties of seeds. It is necessary to take into account at choice of treatment regimes. From the performed investigations optimum regime of treatment of cotton seeds of varieties C-6540 and C-6524 has been determined.

The present work was supported STCU project Uzb-55J.

Comprehensive spectroscopic study of argon glow discharge

A.A. Garamoon[1], A. Samir[1], F.F. Elakshar[1], A.Nosair[1] and E.F. Kotp[2]
[1]Center of Plasma Technology, Faculty of Science, Azhar University, Nasr City, Cairo, Egypt
[2]Physics Department, Faculty of Science, Alazhar University, Assuit Branch, Assuit, Egypt

Emission spectra of both positive column and negative glow regions of the DC glow discharge have been measured at different pressures and currents. The intensity of the lines in the negative glow is in the order of five times of that corresponding lines intensity in the positive column region. It is found that the line intensity increases linearly with the discharge current, while it increases as P^{α} with the gas pressure. The electron temperature has been estimated using the line-to-line intensity ratio technique. It is found that the electron temperature in negative glow region is about 3/2 of that in the positive column.

Introduction

The objective of plasma diagnostics is to obtain information about the state of the plasma by means of different experimental techniques. Knowledge of plasma characteristics is required to understand fully the effects of the different physical processes taking place in the plasma and to deduce from them its properties. These diagnostics includes electric probes and optical emission spectroscopy .

Usually, only probes are used routinely for measuring the temperature and density of electrons and ions. However, in magnetized or depositing plasmas in particular, the interpretation of probe characteristics is difficult and can lead to erroneous results **[1]**. Optical methods such as emission, absorption, , laser scattering or fluorescence spectrometry are proven techniques for probing various parts of the plasma without disturbing its state and composition **[2]**.

Among these techniques there is the optical emission spectroscopy **[3]**. This technique is based on the measurement of the optical radiation emitted from the plasma as it reflects the properties of the plasma in the immediate environment of atomic , molecular and ionic radiators **[4]**. The radiation is the result of electron or ion interaction with other particles in the plasma. Because of their high velocity, electron interactions tend to dominate the collisional excitation and ionization processes. Three electron transitions may occur during these interactions:- bound-bound transitions, bound-free transitions, and free-free transitions. The light emitted as a result of these transitions forms line, band, or continuous spectra.

Atoms and ions of the working gas and trace impurities emit radiation when transitions of electrons occur between the various energy levels of the atomic system. The radiation is in the form of narrow spectral lines, unlike the continua of free-electron radiation such as bremsstrahlung **[5]**. Four plasma models, were suggested by **McWhirter** [6], which are dependent on the mechanism of electron interaction. These are The local thermal equilibrium (LTE) model, The steady state corona model , The time dependent corona model and The collisional radiative (CR) model.

The methods used to measure the plasma parameters depend on the plasma model. Three methods are available for electron temperature measurement, these are:-

i- The ratio of two lines intensity.

ii- The ratio of a line to continuum intensity.

iii- The ratio of two parts of continuum intensities.

The first method will be used in the present work for the estimation of the mean electron temperature in the discharge .

Experimental setup

In this experiment a typical DC glow discharge between two parallel copper plates has taken place in a dynamic flow of argon gas the full description of it can be seen in Garamoon **[7].** McPherson scanning monochromator [model 270] with 35 cm focal length has been used, having a diffraction grating of 1200 grooves/mm has been used to scan the spectral lines. The resolution of this monochromator is less than 0.2 Å. The intensity of the light has been measured using a photomultiplier tube (type 9558QB). The output of the photomultiplier was recorded using a digital multimeter (type GDM-8145).

Results and discussion

Figures (1) and (2) show the emission spectrum of argon gas in positive column and negative glow regions respectively.

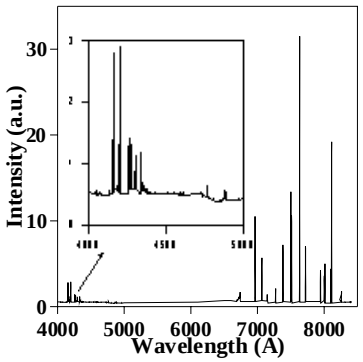

Fig. (1) emission spectrum of positive column at p= 2.25 torr and I= 10mA.

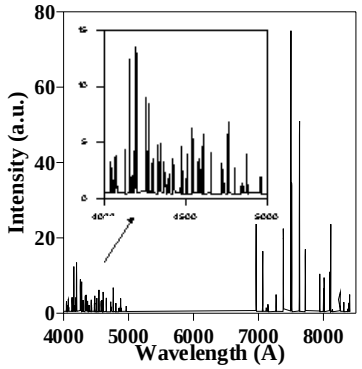

Fig. (2) emission spectrum of negative glow at p= 2.25 torr and I= 10mA.

All lines appeared in the spectrum have been identified as Ar and Ar^+ spectra.

Comparison between Fig (1) and Fig (2) shows that:

i) Intensity of lines in negative glow region is much higher than that in positive column region.

ii) Intensity of the lines in the long wavelength range (7000 - 8000 Å) in negative glow region is in the order two times of that corresponding intensity of lines in the positive column region. At shorter wavelengths (4000 - 5000 Å), however, the intensity of lines in the negative glow region is in the order of five times of the corresponding intensity of the lines in the positive column region.

iii) Lines of Ar^+ appear clearly in the negative glow, while they hardly appear in the positive column region.

The general increase of the intensity of the lines in the negative glow region can be attributed to the increase in the rate of exciting collisions due to both of the higher electron temperature and higher electron density in negative glow region rather than those in positive column. This discussion can explain why the ratio of the intensities of the lines in negative glow to that in positive column is much higher at short wavelengths than those at long wavelengths.

A comparison between the intensities of the two lines of neutral atom Ar and that of the singly ionized ion Ar^+, in positive column and negative glow regions has been represented in Fig. (3).

The intensity of the lines in positive column has been multiplied by a factor of 4, in order to be comparable with that in the negative glow. In negative glow region, the intensity of the line 4348Å is higher than that of the line 4334Å. In positive column region however, the line 4348Å hardly appears and its intensity is much lower than the intensity of the line 4334Å. Since ion density and the mean electron energy in negative glow is much higher than that in positive column region. the intensity of the lines in positive column has been multiplied by a factor of 4, in order to be comparable with that in the negative glow. In negative glow region, the intensity of the line 4348Å is higher than that of the line 4334Å. In positive column region however, the line 4348Å hardly appears and its intensity is much lower than the intensity of the line 4334Å . The intensity of the lines in positive column has been multiplied by a factor of 4, in order to be comparable with that in the negative glow. In negative glow region, the intensity of the line 4348Å is higher than that of the line 4334Å. In positive column region however, the line 4348Å hardly appears and its intensity is much lower than the intensity of the line 4334Å. Since ion density and the mean electron energy in negative glow is much higher than that in positive column, therefore the probability of exciting collisions of electrons with Ar^+ in negative glow region is higher than that in positive column. Consequently most of Ar^+ lines appear clearly in negative glow region and hardly appear in positive column region.

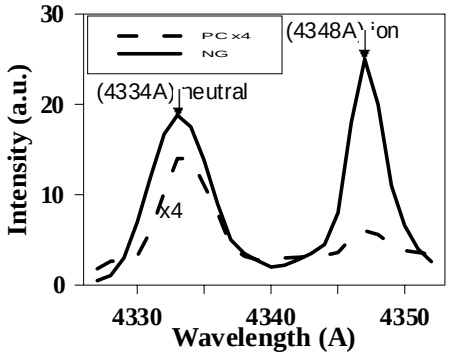

Fig. (3) emission spectrum from PC and NG of two lins; (4334A) neutral atom and (4348A) single Ion.

Figures (4) and (5) represent the line intensity of some lines as a function of the gas pressure in positive column and negative glow where intensity increases by increasing the gas pressure (*p*).

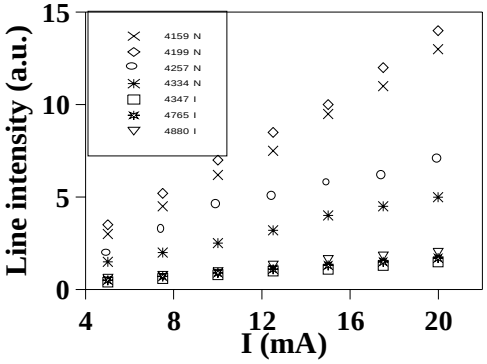

Fig. (4) line intensity, of 4 lines from neutral atom and 3 lines from ion, as a function of discharge current in positive column region P= 0.75 torr.

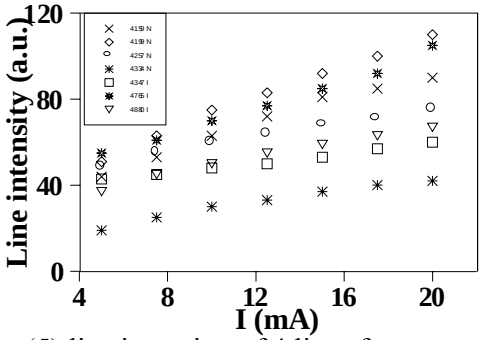

Fig. (5) line intensity, of 4 lines from neutral atom and 3 lines from ion, as a function of discharge current in negative glow region P= 0.75 torr.

The line intensity I_{pq} can be expressed in the form [8]:

$$I_{pq} = N_e N < Q_{pq}(v_e) v_e > \qquad (1)$$

where v_e is the electron velocity $\{v_e=(2kT_e/m_e)^{1/2}\}$, $Q_{pq}(v_e)$ is the excitation cross-section for the p-q transition, N_e is the electron density, and N is the density Ar atoms or the density of Ar^+ ions. As the gas pressure increases;

a) N_e and N increase, consequently the lines intensity increases.
b) T_e decreases and hence the rate coefficient of electron exciting collision $<Q_{pq}(v_e)\ v_e>$ decreases, consequently the intensity of the lines decreases whereas $v_e \sim T_e^{1/2}$.

In the range of p of 0.75 - 12 torr that has been used, the first factor is more effective than the second one. Therefore the intensity of the lines increases by increasing the gas pressure, where the intensity of the lines has been found to be proportional to p^{α}, where α is constant which varies between 0.2 - 0.5, and depends on the wavelength. Figures (6) and (7) show the variations of the line intensities as a function of the discharge current, I.

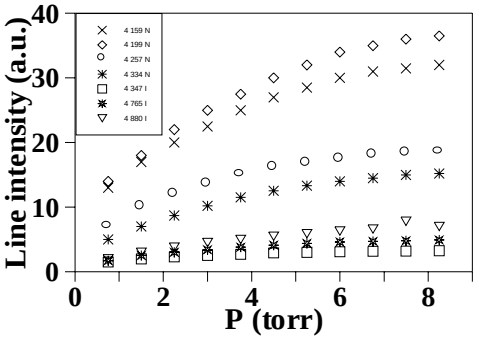

Fig. (6) line intensity, of 4 lines from neutral atom and 3 lines from ion, as a function of gas pressure in positive column region I= 20 mA.

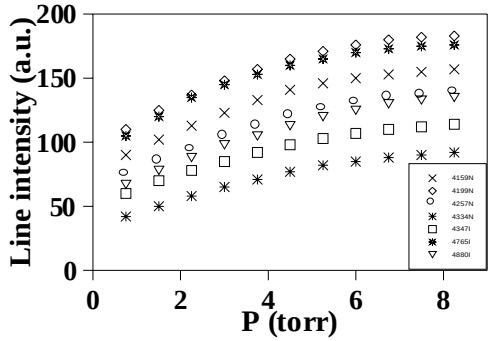

Fig. (7) line intensity, of 4 lines from neutral atom and 3 lines from ion, as a function of gas pressure in negative glow region I= 20 mA.

It can be noticed that, the lines intensity increases linearly by increasing the discharge current, i.e. $I_{pq} \sim I$, in general. This can be attributed to the increase in the electron density N_e which is a linear function of the current where, $I_{pq}=cI$ (mA), c is a constant which found to vary between 0.07 to 0.7 in positive column and 1.2 to 3.8 in negative glow and depends on the wave length.

Electron Temperature by Optical Emission Spectroscopy Technique.

Determination of T_e using optical emission spectroscopy technique the ratio of the intensity of two lines has been adopted here in the present work. For high accuracy it's desirable to choose two spectral lines whereas the ratio of the relative intensity of the two lines is a strong function of T_e; this will be the case if the difference between the transition energy levels of the two lines is large enough. However for neutral atoms, the greatest attainable energy difference yields a minimum uncertainty in temperature of 70 % for argon gas in the range of 0.5 to 1.5 eV **[9]**. The accuracy may

be improved somewhat by measuring several pairs of spectral lines and averaging the resulting temperatures. However this rather time-consuming technique is only partially successful in reducing the experimental uncertainty. A larger energy difference can be obtained if one of the transitions occurs in singly ionized atom, and the other occurs in a neutral atom. Therefore the relative intensity of argon neutral atom (4159 and 4259 Å) and argon singly ionized atom Ar^+ (4348, 4765, and 4880 Å) have been measured at different pressures and discharge currents in both NG and PC regions.

In the first trials if the present work , T_e has been determined assuming LTE model. Using the ratio of two lines intensity T_e can be expressed in the form:-

$$kT_e = \frac{E'-E}{\ln(I\lambda^3 g' f' / I' \lambda'^3 gf)} \qquad (2)$$

where I, λ, g, and f are the total intensity, wavelength, statistical weight, and absorption oscillator strength, respectively, of one line and E its excitation energy. The corresponding quantities for the other line are I', λ', g', f', and E'. The values of the above parameters have been taken from **[10]**.

T_e values obtained by this method, were in the range of 0.3 - 0.9 eV. These results are much smaller than the measurements of the electruc single and double probes. This may be attributed to the fact that the plasma density is so low that the criterion of LTE model is not valid i.e. that:

$$N_e \geq 1.6\times10^{12} T_e^{1/2} X(p,q)^3 \qquad cm^{-3} \qquad (3)$$

One the other hand the criterion of the steady state corona model i.e. that

$$N_e < 5.6\times10^{8} (z+1)^6 T_e^{1/2} \exp(\frac{1.16\times10^3 (z+1)^2}{T_e}) \qquad (4)$$

is valid in the present work. Consequently, steady state corona model has been assumed to estimate T_e. The ratio of two lines intensity T_e is expressed in the form :

$$\frac{I'}{I} = \frac{f' g' \lambda^3}{fg\lambda'^3} \exp(\frac{E'_\infty - E' - E_\infty + E}{kT_e}) \frac{S}{\alpha} \qquad (5)$$

where ; $$\frac{\alpha}{S} = (7.87\times10^{-9}) E'^2_\infty (\frac{E'_\infty}{kT_e})^{3/4} \exp(\frac{E'_\infty}{kT_e}) \qquad (6)$$

Eliminating S/α from equation (5) , therefore ;

$$kT_e = [(7.87\times10^{-9}) E'^{\,7/4}_\infty \frac{fgI'\lambda'^3}{f' g' I\lambda'^3} \exp(\frac{E'+E_\infty - E}{kT_e})]^{4/3} \qquad (7)$$

Values of the parameters used in equation (7) have been taken from **[10],** as tabulated in the following table.

λ (Å)	Transition	E (eV)	**J - J'**	f
4158.6	$1S_3 - 3P_6$	14.47	2 – 2	0.0017
4259.4	$1S_2 - 3P_1$	14.67	1 – 0	0.0022
4348.1	$3P^4 4S - 3P^4(3P)4P$ $[^4P - ^4D^o]$	19.41	5/2 – 7/2	0.43
4764.9	$3P^4 4S - 3P^4(3P)4P$ $[^2P - ^2D^o]$	19.78	1/2 - 3/2	0.37
4879.9	$3P^4 4S - 3P^4(3P)4P$ $[^2P - ^2P^o]$	19.6	3/2 – 5/2	0.35

The ratios of two lines intensities I'/I, one from single ionized atom and the other from neutral atom, have been estimated for six pairs of lines (4159/4348, 4159/4765, 4159/4880, 4259/4348, 4259/4765, and 4259/4880 Å).

Equation (7) shows that, T_e can not be written as an explicit function of the ratio of lines intensity [i.e. $T_e \neq f(I'/I)$]. The implicit function [$T_e = f(I'/I, T_e)$] can be solved numerically. Successive iteration has been curried out to solve equation (7). The guess point has been chosen using single and double probe measurements to accelerate the iteration process.

Figures (8) and (9) show values of T_e as a function of the gas pressure, using the six pairs of lines, in PC and NG respectively.

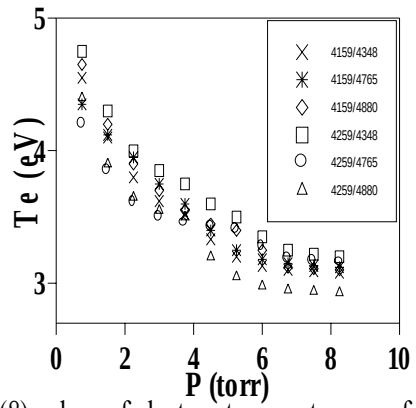

Fig. (8) values of electron temperature as a function of gas pressure in the positive column, using emission spectroscopy technique with different lines ratios.

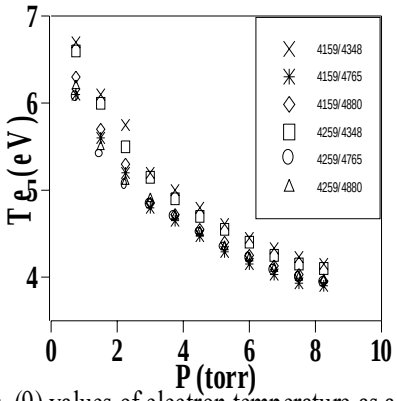

Fig. (9) values of electron temperature as a function of gas pressure in the negative glow, using emission spectroscopy technique with different lines ratios.

Figures (8) and (9) indicate a reasonable agreement of the estimated values of T_e and also that T_e has the same trend of behaviour with pressure using the different pairs of lines, i.e. , T_e decreases by increasing the gas pressure (p). Since the kinetic energy of an electron can be expressed as $mv^2/2 = eE\lambda_e$, where λ_e is the electron mean free path, so T_e is proportional to λ_e and hence inversely proportional to p. Also It can be noticed that the electron temperature in the negative glow region is about 3/2 of that in the positive column.

5-2-4 Comparison between the three techniques used to measure T_e

Figures (10) and (11) represent values of T_e as a function of the gas pressure in positive column and negative glow regions, respectively, using the average values measured by the three techniques i.e. single probe, double probe (the results of which to be published later separate) , and optical emission spectroscopy.

A good agreement between the three techniques is observed.[11} have confirmed a rough agreement between measurements of T_e by optical emission spectroscopy and single probe in Ar positive column. Figures (5-25) and (5-26) prove that, the agreement between optical emission spectroscopy and the probes techniques in the positive column region is much more closer than that in the negative glow region. This may be attributed to the fact that the distribution of electrons in the negative glow region is non-Maxwellian.

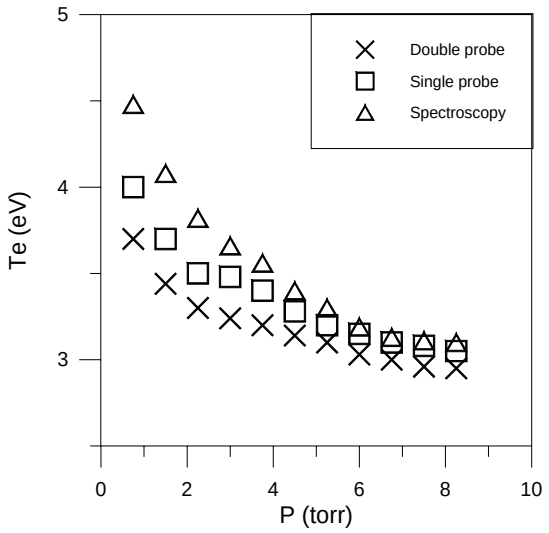

Fig. (10) values of electron temperature as a function of gas pressure measured by different techniques in positive column.

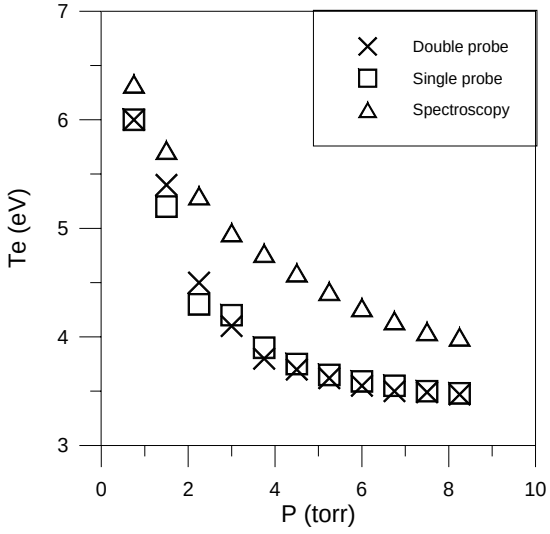

Fig. (11) values of electron temperature as a function of gas pressure measured by different techniques in negative glow.

Plasma Assisted Combustion of Non-Premixed Hydrocarbon Fuel in High-Speed Airflow

Klimov A., Bityurin V., Moralev I., Tolkunov B., Vystavkin N.
Institute of High Temperature RAS, Moscow, Russia

Abstract

Plasma-assisted combustion (PAC) in high-speed airflow was studied in our previous works [1-6]. Present work is devoted to continuation of internal PAC study. Experiments are carried out in the hot wind tunnel HWT-1. Supersonic airflow (M<2, P_{st}<1 Bar, T_{st}<1000K) is created in test section of this experimental set up. Combined electric discharge (DC+ pulse repetitive discharge, mean power ~1kW) is used for airflow pre-heating and fuel- airflow radical generation. Optical spectroscopy, IR spectroscopy and chromatographic method are used to study plasma and radical generation in PAC zone. Experimental and theoretical results on internal PAC are considered and discussed in this work.

Keywords: combustion, plasma, airflow, radicals, optical spectra

Introduction

It well knows that there are some difficulties connected with ignition, mixing and combustion of hydrocarbon fuel in high-speed airflow. These difficulties are connected with large characteristic ignition time τ_i and combustion time τ_c of hydrocarbon fuel in high-speed airflow at the parameters closed to scramjet ones. Active radical and exited molecule generation in combustion region can decrease these characteristic times considerably [1-6]. The active radicals O, H, CH, OH, NO, CN, CH2 and vibration exited molecules play important role in combustion process. Recently it was revealed that three radicals CN, C2, CH2 play most important role in plasma-assisted combustion namely [1-6]. Non-equilibrium electric discharge can generate these radicals effectively. It was revealed that characteristic propane ignition time τ_I and propane characteristic combustion time τ_c in supersonic airflow M~2 are decreased up to factor 2-3 by non-equilibrium plasma formation (in comparison with the ones at plasma off), [1].

The PAC of *non-premixed* hydrocarbon fuel in high-speed airflow (M<2) was studied in our previous works [1-6]. According obtained experimental background there are two main problems (tasks) in PAC physics, namely

- Fuel PAC completeness in high-speed airflow,
- Fuel mixing in high-speed airflow.

It is revealed that non-premixed PAC is non-homogeneous and non-stationary one as a rule. There is strong plasma-fuel combustion interference in high-speed airflow. Modulation of the discharge and plasma parameters by PAC disturbances and soot particles (carbon clusters) is measured in experiment.

Important role of charged and excited carbon clusters (soot particles) in PAC kinetics and dynamics is considered in the works [1-6]. These particles can accelerate and decelerate the PAC in airflow by its local electric field considerably.

Main experimental results.

1. Internal PAC is studied in experimental set up HWT-1, fig. 1. Hot wind tunnel HWT-1 is designed and manufactured to study PAC in high-speed airflow. Main technical characteristics of HWT-1 are the followings:

- Airflow parameters M<2, P_{st}< 1 Bar
- Airflow mass flux < 100 g/s

- Propane mass flux < 10 g/s
- Gas temperature in arc heater T_o< 1000K
- HF power of the igniter N_d< 2 kW
- Mean power of PG-jet N_d< 3 kW

HWT-1 is consisted of two quartz tubes. This duct design helps us to use optical diagnostic instrumentation in PAC experiment.

Two types of the plasma generators (PGs) are designed, manufactured and tested in PAC experiment, namely:

- Tesla's coil HF plasma generator for HF streamer discharge generation in high-speed airflow,
- PG- Comb for combined electric discharge generation (DC current discharge + high voltage pulses).

Mean power of each PG is about 2-3 kW.

2. Stable internal PAC stimulated by streamer HF discharge and combined discharge (DC discharge + pulse repetitive discharge) is created in a high-speed airflow (M< 2, P_{st}< 1 Bar), fig.2.

   Characteristic plasma parameters of a single HF streamer are the followings:

- Electron concentration N_e<10^{15} cm^3
- Electron temperature T_e=1-2 eV
- Gas temperature T_g=1000-2500K,
- Vibration temperature T_V~2500-7000K
- Specific energy storage ~1-10 J/cm^3
- HF streamer characteristic lifetime T_{str}~50-100 mcs.

   This plasma formation is non-equilibrium one. It has high specific energy storage. So, this plasma formation can stimulate plasma chemical reactions and radical generation in a fuel-airflow mixture.

3. It is revealed that HF streamer discharge has a number of important positive properties (peculiarities) in PAC experiment comparing with other types of electric discharges, namely:

- HF discharge is ignited and burned near a mixing contact surface with high gas density gradient (or near chemical flame front) as a rule, but it never burns inside chemical flame,
- Modulated HF streamer discharge can disturb mixing contact surface considerably and stimulate propane- air mixing (advanced mixing).
- Fuel penetrates through a HF streamer in external airflow deeply. Mean velocity of fuel transportation inside a streamer channel is about V_{fl}~ 10^3 m/s, and more. So, study of this fuel transportation by single HF streamer is very important for advanced fuel mixing.

4. Very small characteristic ignition time τ_1 and combustion time τ_2 are measured in PAC experiment (M< 1,2 , P_{st}< 1Bar, T_o~300K), namely: τ_1~ 30-50 mcs, τ_2~ 100-150 mcs. These experimental values $\tau_{1,2}$ are more than 100-1000 times smaller than traditional chemical ones at plasma off (at the same other conditions).
5. Radical creation by electric discharge is measured in PAC experiment, such as: CH, CH_2, O, O_3, CN, and others. Maximal relative concentration of radicals in PAC experiment is about N*~10^{-2} (our estimations).
6. Final products of PAC are H_2O and CO_2 only in near stoichiometric fuel-airflow mixtures (no toxic impurities and propane).
7. Additional small water vapour injection (propane: water ~ 100: 1) can intensify PAC (increase a mixing rate and combustion rate).
8. It is revealed that small HF power (about ~100W) is needed for the propane-air ignition and PAC. Total chemical power was about N_{ch}~16-17 kW, (it corresponds to propane mass flux M_p~0,4 g/s). So, ratio η= (N_d /N_{ch}) 100%= 0,1-1%.

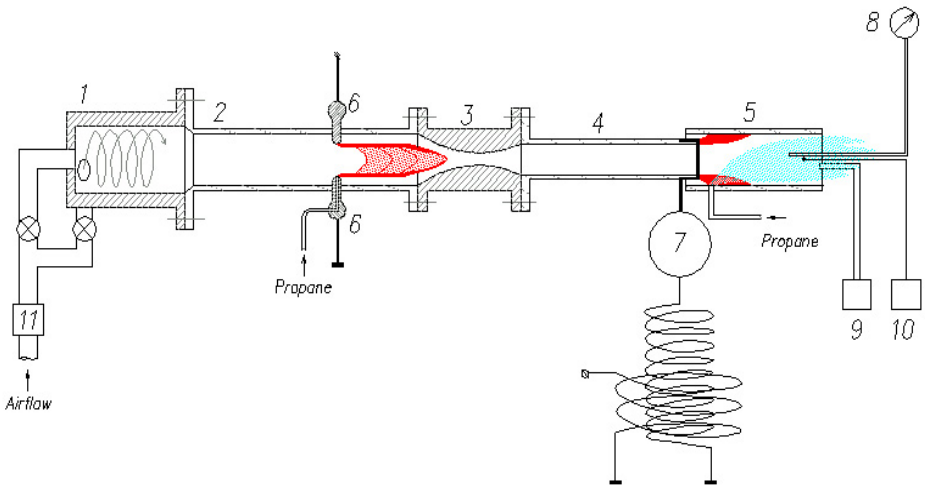

Fig.1. 1,2- fore-chamber with electric arc pre-heater, 3- nozzle, 4, 5- test section, 6-arc electrodes, 7- HF electrode, 8- pressure sensor, 9-chemical probe, 10- thermocouple, 11- mass airflow

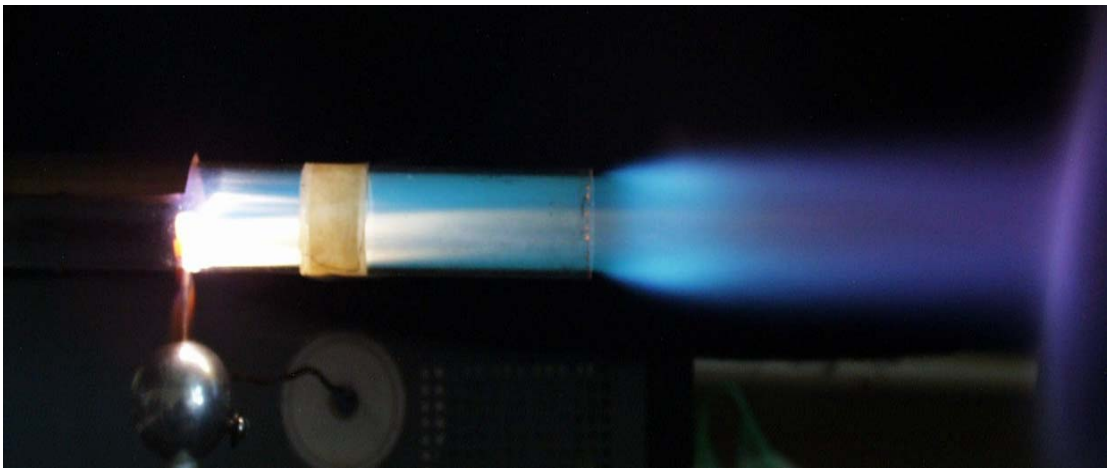

Fig. 2. Stable plasma-assisted combustion in the set up HWT-1 in high-speed airflow (M=0,6; P_{st}=1 Bar), HF discharge (F_{HF}=13,6 MHz), modulation frequency F_i~ 100Hz

9. Extension of fuel combustion concentration limit for rich and lean mixtures up is about 2-4 times at plasma assistance.
10. Combustion temperature limit is decreased up to 2-3 times at plasma assistance.
11. The final PAC specie composition is obtained by IR absorption method and chromatographic method. Partial pressures and concentrations of these species are measured, fig.3.
12. Effective H2, CO, C2H2, CH4…. generation is obtained in rich propane-airflow mixtures at plasma assistance
13. It is revealed that there is high fuel PAC completeness (80-100%) in lean fuel mixture only, fig. 3,4.
14. It is revealed that radical concentration in PAC zone is increased up to 2-3 times at non-intensive external UV radiation created by KrF laser.

PAC optical spectra

Analysis of optical spectra in PAC region is very important to study of plasma-chemical kinetics and PAC dynamics of hydrocarbon fuel in high-speed airflow. Detail optical spectra have been recorded by spectrometer MS-257 in different cross sections of PAC zone at different operation modes of the plasma generator.

The typical optical PAC spectra are shown in fig.5. These spectra are recorded in the PAC zone created by transverse DC discharge at electric current I_d=1 Amp and voltage U=500-1000 V. These spectra are obtained in stoichiometric, rich, and lean C_3H_8/C_4H_{10}-airflow mixtures (static pressure P_{st}=1Bar, M= 0,1). The following molecular bands are observed and processed:

- CN "violet" system. Sequences Δv= 0 (380-389 nm), Δv= -1 (415-430 nm), and Δ= -2 (455-461nm);
- C_2 Swan system. Sequences Δv=0 (510-517 nm), Δv=1 (467-474 nm), and Δv=-1 (558-564 nm);
- OH $^2\Sigma$-$^2\Pi$ system. Sequences Δv=0 (306-318 nm) and Δv=-1 (280-295 nm);
- NH $^3\Pi$-$^3\Sigma$ system in the 330-345 nm region;
- weak CH $^2\Delta$-$^2\Pi$ (0-0) band.

In some combustion regimes (closed to the stoichiometric one), there are well-pronounced electronic-vibration bands are appeared in the wave range of 597-620 nm (see Fig.5). Their nature is not clarified finally today. However it seems that the following consideration may be of relevant interest. Some of the optical lines in these spectrum are identified as the CH2 ones. Remember that this radical plays very important in PAC kinetics namely [x].

Among atomic lines, most pronounced are WI lines (coming from evaporation of the electrode material) in the regions of 280-305, 320-365, and 407-430 nm. The NI and OI lines in the near IR region.

The rotational T_r temperature and vibration T_v temperature in different regions of a non-uniform combustion zone are determined by performing a global fit of the above-mentioned spectral regions using the line-by-line numerical simulation of the rotational structure of the electronic transitions allowing for the experimentally derived apparatus function, fig.6.

It is revealed that there is the following ration:

$$T_e \geq T_v > T_r \approx 4000\text{-}5000\ K$$

in the cathode plasma filament region. There is the absolutely different relation in the intermediate zone between plasma filaments:

$$T_e \sim T_v \sim T_r \approx 4000\text{-}5000\ K$$

Note that average gas temperature T_g in PAC zone measured by optical pyrometer and thermocouple is about $T_g \sim 2000K$. The same value is obtained by processing of the continuous domain of the optic spectra, fig.x. One can suppose that there is non-homogeneous and non-stationary PAC in the combustor. The analysis of the high-speed video frames recorded in PAC zone proves this conclusion, fig. X.

Anomalous PAC kinetics in some operation mode of plasma generator

Anomalous plasma-chemical kinetics was revealed in lean mixture at some operation modes of plasma generator [x]. Traditional final combustion species (OH, CO, CO2…) were absent behind PAC zone in this regime.

Anomalous soot composition and final gas composition are obtained in rich mixture combustion at plasma assistance, fig.x. There are many carbon and silicon nana-tubes inside soot particles. Remember that high concentrations of the C2H2, C6H6 and other heavy species C7+ are created in this regime also.

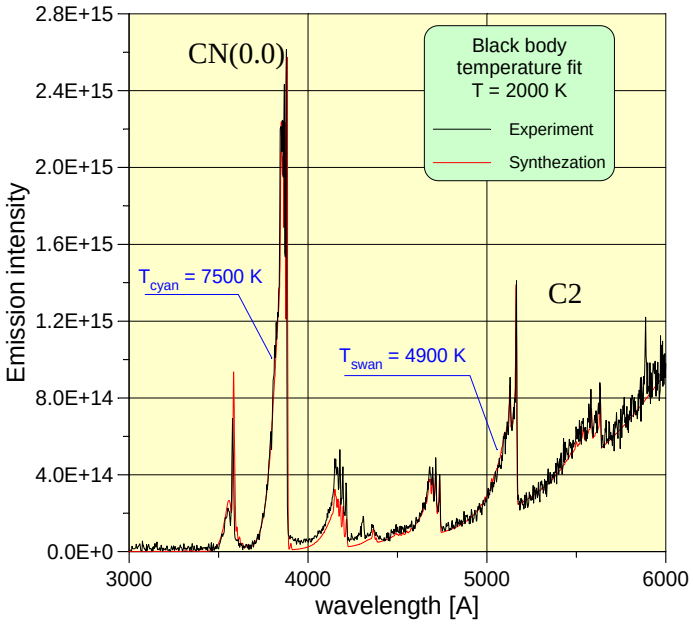
High-energy release is measured in propane-argon mixture at plasma assistance. Thermal power of heated final gas flow behind PAC zone is about 6-10 times higher than initial chemical power of propane (its combustion energy in air). Note that this "combustion" is associated with active soot particle generation (high concentration) in PAC zone.

Chemical composition of the soot particles obtained in PAC region is studied by ion mass spectrometer and micro X-ray spectrometer. A number of new elements, such as Na, Al, Si, Cl, P, S, K, Ca, Cr, La and others, are recorded by diagnostic instrumentation inside these particles, fig.7,8. Note that these elements are absent in initial fuel, airflow and electrodes. Molecular ions NAr+, CAr+ , HAr+ and others are recorded inside tested soot particles by ion mass

spectrometer also (in fuel-argon-airflow mixture). There is a question: - how these *unstable ions* conserved inside of these soot particles during *long time period*? It is possible to suppose that different heterogeneous plasma-chemical reactions are realised on the soot particle surface.

It was revealed that charged and excited soot particles play important role in PAC kinetics, PAC completeness, electric discharge stability and flame stability [1-5]. The high local electric potential (up to φ~ 200-1000V) and high local electric field are measured on the surface of these particles (E_S~ E_{br}, where – critical electric breakdown field in gas flow). These particles can accelerate and decelerate fuel PAC in airflow by local electric field considerably.

These experimental results prove the conclusion about possibility of non-traditional anomalous plasma-chemical kinetics in non-premixed hydrocarbon fuel combustion in airflow at plasma assistance. This question will be studied in our future experiment in detail.



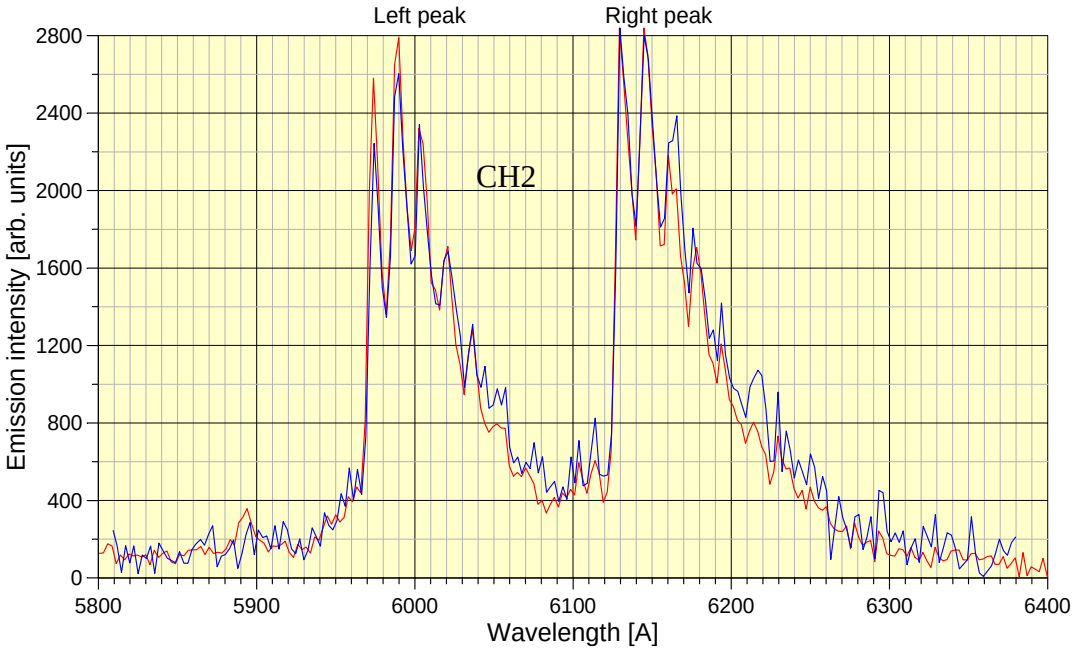


Fig.5. Experimental optical spectra obtained in PAC zone.

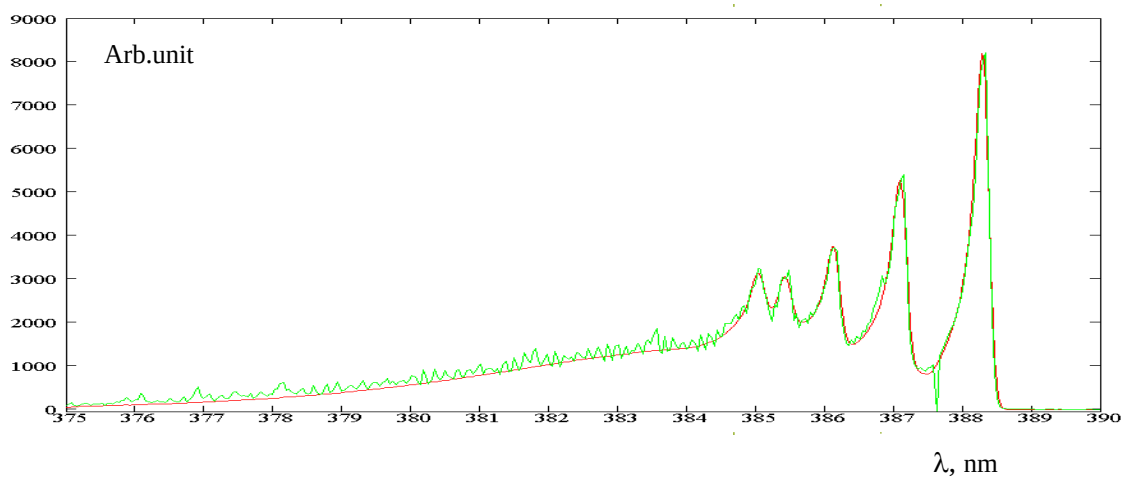

Fig.6. Experimental CN (0,0)- optical spectra (green) and simulated one (red), T_r=5000 T_v=6700K

Conclusions

1. Stable internal PAC regimes are studied in high-speed airflow.
2. Final PAC species are studied by IR absorption method and chromatograph method. Partial pressures and concentrations of these species are measured.
3. It is revealed that that the fuel PAC completeness of the lean propane-airflow mixtures is about η= 90-100%.
4. Optical spectra are obtained in PAC region in airflow and analyzed.

Abstract

Measurements of electron density decay in high pressure, room temperature pulsed e-beam generated air plasmas demonstrate that vibrational excitation, to T_v ~2,000 K, results in nearly complete mitigation of electron loss by O_2 attachment. Kinetic modeling suggests that two mechanisms may be playing a role simultaneously: i), detachment enhancement by collision of O_2^- (or other negative) ions with vibrationally excited neutrals, and ii), attachment inhibition due to electron heating by superelastic collisions with vibrationally excited neutrals.

1. Introduction and Experimental Results

Recently there has been renewed interest in a variety of potential aerodynamic applications of high pressure air plasmas. In general, such applications require stable, large volume (~1 m^3) non-equilibrium plasmas, with electron density of order 10^{12} - 10^{13} cm^{-3}, which must be sustainable for time periods of order seconds, or more. In addition, practical considerations dictate a total power budget of the order 1-10 MW/m^3. In pursuit of these extremely challenging goals, we have initiated [1] a program to study the influence of vibrational excitation on low temperature electron attachment / detachment / dissociative recombination kinetics in diatomic gases. The essential elements of the experimental apparatus, described in more detail in [1], are shown in Fig. 1. An electron gun is used to generate a pulsed (~ 5-40 microsecond, 80 keV, ~1-2 mamp) electron beam which is introduced through a foil window into a four-armed cross cell containing a variety of room temperature $N_2/O_2/CO$ mixtures, with total pressure between 200 and 760 torr. Perpendicular to the e-beam axis a 10-15 Watt continuous wave (cw) crossed CO laser beam vibrationally excites all diatomic species contained within the laser beam path to vibrational "temperatures" of ~ 2000-3000 K, as confirmed by vibrational (Q-branch) Raman spectroscopy [2]. Time-resolved relative electron density is measured by microwave attenuation, using a 40 GHz oscillator and a pair of 1 cm (length) x 0.20 cm (width) rectangular wave guides, which for clarity are omitted from the figure. The wave guides are located in front and behind the plane of the figure, separated by a gap of 1 cm. The long axis of the wave guide is oriented parallel to the CO laser beam propagation direction in order to maximize the overlap of the vibrationally excited volume with the volume within the gap of the wave guides. In addition, spectrally filtered pure rotational Raman scattering, using a narrow linewidth titanium:sapphire laser in combination with a rubidium vapor filter, [3] is used to obtain accurate (+/- ~10K) spatially resolved heavy species rotational/translational temperature.

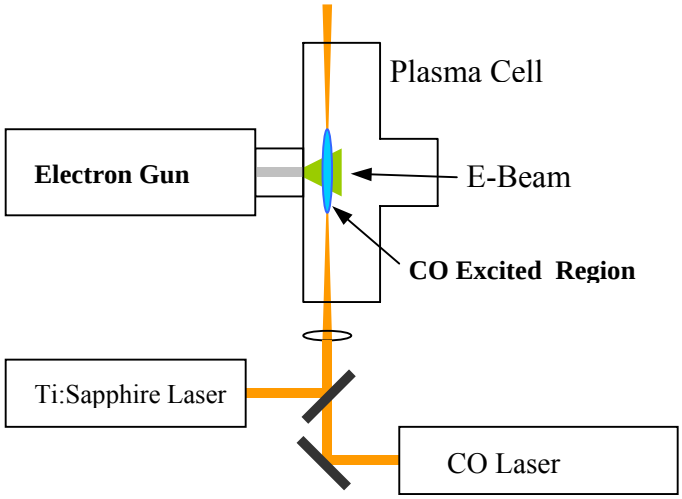

Figure 1: Schematic diagram of nonequilibrium, e-beam sustained plasma apparatus. Microwave waveguides, not shown, are located in front and behind plane of paper.

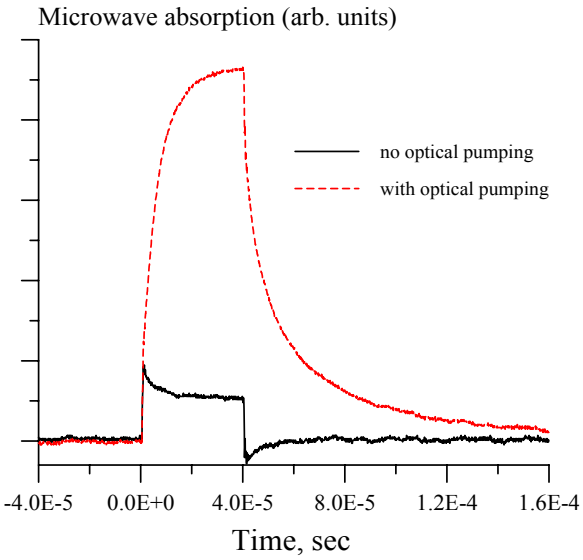

Figure 2. Microwave absorption measurements in e-beam sustained CO/air plasma at P=250 torr, with and without CO laser vibrational pumping. E-beam current and energy are 1 mA and 80 keV.

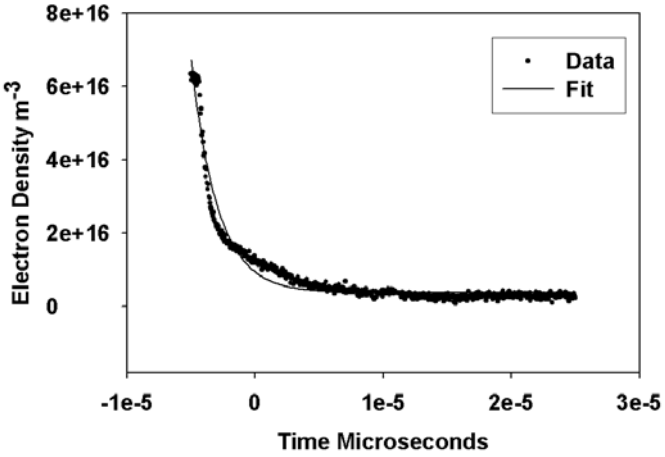

Figure 3. Experimental (dotted) electron density decay and least squares fit (solid) to Eq.(3) for cold gas mixture of 1% O_2 in N_2 at P=300torr. Electron beam current and energy are ~1 mA and 80 keV.

Figure 2 shows a pair of electron density traces obtained from a 7% CO – 93% synthetic air mixture at P=250 torr, with (dashed curve) and without (solid curve) vibrational excitation by the CO laser. It can be seen that when the gas mixture is CO laser pumped, both the plasma rise and decay times increase considerably, from ~0.5 μsec to ~20 μsec, which is similar to the rise/decay time observed in a pure 250 torr nitrogen (attachment-free) plasma [1].

These results can be understood by considering that under equilibrium conditions the electron density in low temperature air plasmas is primarily controlled by rapid three-body electron attachment to oxygen,

$$e + O_2 + M \rightarrow O_2^- + M \qquad (1)$$

In such an attachment-controlled plasma, the time-dependent electron density is described by the simple first order equation

$$\frac{dn_e}{dt} = S - k_a^{(eff)} n_{O_2} N n_e = S - \nu_a n_e \qquad (2)$$

with solution

$$\frac{n_e(t)}{n_\infty} = 1 - \exp\left[-\nu_a t\right] \quad \textbf{(generation)}$$

$$\frac{n_e(t)}{n_\infty} = \exp\left[-\nu_a t\right] \quad \textbf{(decay)} \qquad (3)$$

$$n_\infty = S/\nu_a$$

The attachment frequency, ν_a, is given by $\nu_a = k_a^{(1)} n_{O_2}^2 + k_a^{(2)} n_{O_2} n_{N_2} = k_a^{(eff)} n_{O_2} N$, where $k_a^{(eff)}=6.4\cdot10^{-31}$ cm^6/sec is the effective attachment coefficient for air, defined as 20% O_2 and 80% N_2, and N is the total heavy species number density with rate coefficients $k_a^{(1)}=2.5\cdot10^{-30}$ cm^6/sec for M=O_2 and $k_a^{(2)}=0.14\cdot10^{-30}$ cm^6/sec for M=N_2 [4]. For the conditions of Fig. 2, $\nu_a \sim 10^7$ sec^{-1}, which exceeds the bandwidth of our existing microwave detector. As an alternative the oxygen fraction was reduced in order to yield an attachment rate such that the free electron

decay could be temporally resolved. Figure 3 shows a least squares fit of the experimental electron density decay along with a least squares fit to Eqs. (3) for a 1% O2/N2 mixture at 300 torr and a beam current of 1 mamp. The best fit value of ν_a is 4.8 x 10^5 sec^{-1}, as compared to a prediction of 2 x 10^5, using the oxygen attachment rates from Ref. [4]. While the cause of this discrepancy is not completely understood, it can be seen that the decay curve in Fig. 3 appears to deviate somewhat from a single exponential, an effect which we believe to be a measurement artifact related to small change in wave guide coupling of the microwave signal during the duration of the primary beam current pulse.

Nonetheless, the results illustrated in Figs. 2 and 3 strongly suggest that the O_2 attachment rate in the vibrationally excited, non-equilibrium air plasma is greatly reduced, by two orders of magnitude or more. However, it is well established that the detachment rate of O_2^-, ie, the reverse of (1), is strongly temperature dependent, increasing by a factor of approximately 1,000 when the temperature is increased from 300 K to 600 K [5]. It is essential, therefore, to perform more accurate temperature measurements than were previously possible using low resolution vibrational Raman spectroscopy [2].

Figure 4 (left/right) show the Stokes portion of rubidium vapor filtered pure rotational Raman spectra obtained in the e-beam apparatus corresponding to the lower/upper traces in Fig. 2, respectively, along with least squares fits to a simple sum of Lorentzians spectral model. For the cold gas, the best fit rotational temperature is 308 ± 10 K (2σ) where as for the vibrationally excited gas, the temperature is found to increase slightly, to 350 ± 10 K (2σ).

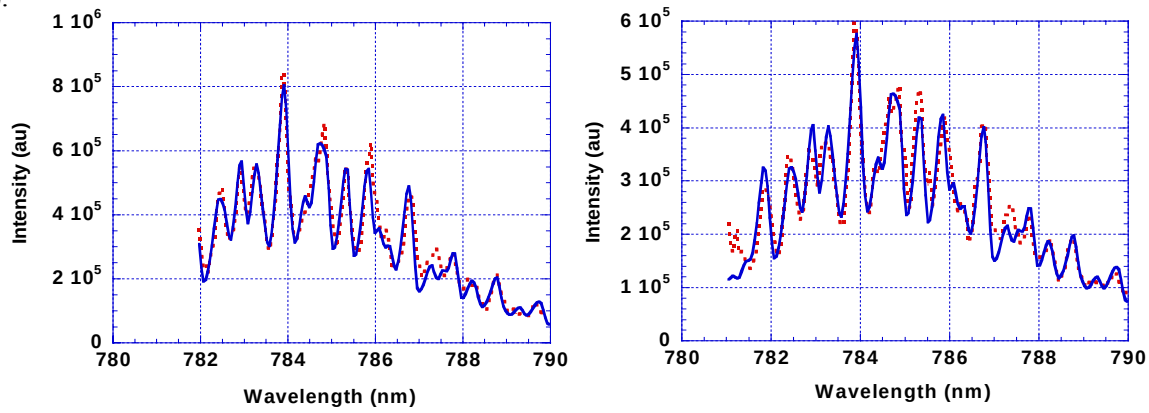

Figure 4: Filtered rotational Raman scattering spectrum obtained from cold (left) and optically pumped (right) gas

In order to determine the extent of the optically pumped region and to verify that the heavy species temperature has been probed at the centerline of the CO laser excitation, a series of filtered rotational Raman spectra were obtained as a function of radial position. This was accomplished by translation of the CO laser beam, while maintaining the alignment of the titanium:sapphire probe laser beam with respect to the image of the exit slit of the spectrometer used to resolve the spectrum. The CO laser was translated in two orthogonal directions, parallel and normal to the plane of the paper in Fig. 1. It was determined that the volume vibrationally excited by the CO laser has a diameter of ~ 0.1 cm, defined as the region in which the rotational temperature exceeds the cold gas value by ~ 10 K or more (the measurement precision). Also note that, unlike previous work performed with a 10 GHz microwave system [6], the diameter of the CO laser excited volume (~0.10 cm) is a significant fraction of the span-wise dimension of the wave guide antennae (0.2 cm).

We conclude, therefore, that although the detachment rate of O_2^- ions is extremely temperature dependent, the attachment mitigation observed previously and confirmed by the data of Fig. 2 is definitively due to a non-thermal mechanism, ie, to vibrational excitation.

2 Kinetic Modeling and Discussion

In order to explore the influence of vibrational excitation on air plasma lifetime more quantitatively we have performed kinetic modeling for two limiting cases, attachment mitigation by i), accelerated detachment and ii), inhibited attachment. First, however, it must be noted that at these conditions the microwave absorption signal is gathered from both the optically pumped and vibrationally non-excited regions of the plasma (See Fig. 1). Since the ambipolar diffusion time at these conditions is $\tau_{diff} \sim R^2/D_a \sim$ 500 μsec, the signal from the optically pumped plasma region can be isolated by a simple subtraction of the microwave signals measured with and without optical pumping. This assumption is justified by the relatively low steady-state electron density in the cold gas region as well as the fact that the optically pumped region fills only a small (~4%) fraction of the total volume between the microwave wave guides.

Limiting case (i), accelerated detachment, is motivated by the fact that the electron affinity of O_2 is only ~0.4 eV. It is reasonable, therefore, that electron detachment from O_2^- (or other negative ions such as O_4^-) is enhanced by collisions with vibrationally excited CO, O_2, and/or N_2 molecules, such as

$$\mathbf{O_2^- + O_2(v \geq 2) \rightarrow e + O_2 + O_2} \tag{4}$$

If it is assumed that the detachment rate for processes such as that described by Eq. (4) are nearly gas kinetic, $k_d \sim 10^{-10}$ cm^3/sec, so that attachment is balanced by rapid detachment, ie $\nu_a << k_d n_d$, one can estimate the required number density, n_d, of "fast detachers", i.e. molecules with vibrational energy sufficient for detachment. To see this more quantitatively, we note that according to this assumption nearly all negative ions formed by attachment are rapidly removed by detachment. In this case ion-ion and electron-ion recombination processes must be included so that the time-dependent electron density is described by

$$\begin{aligned} \frac{dn_e}{dt} &= S - \beta_{ei} n_e n_+ - k_a n_{O_2} N n_e + k_d n_- N \\ \frac{dn_-}{dt} &= k_a n_{O_2} N n_e - k_d n_- N - \beta_{ii} n_- n_+ \end{aligned} \tag{5}$$

where n_- and n_+ correspond to the total number density of negative and positive ions, respectively, and $\beta_{ii}=2\cdot10^{-6}$ cm^3/sec is the ion-ion neutralization rate coefficient [4]. The assumption of rapid detachment implies that the steady-state approximation can be invoked for the time dependence of n_-. The result is

$$[n_-]_{ss} = \left(\frac{\nu_a}{\nu_d + \beta_{ii} n_+}\right) n_e \approx \left(\frac{\nu_a}{\nu_d}\right) n_e \tag{6}$$

where we have assumed that $\nu_d >> \beta_{ii}\, n_+$ and that detachment is dominated by "rapid" detachers. Manipulation and substitution of (6) into (5), assuming that the electron number density is equal to the total positive ion number density, gives

$$\begin{aligned} \frac{dn_e}{dt} &= S - \beta_{ei}^{(eff)} n_e^2 \\ \beta_{ei}^{(eff)} &= \beta_{ei} + \beta_{ii}\frac{\nu_a}{\nu_d} = \beta_{ei} + \beta_{ii}\frac{k_a^{(eff)} n_{O_2} N}{k_d n_d} \end{aligned} \tag{7}$$

with solution

$$\frac{n_e(t)}{n_\infty} = \tanh\left[n_\infty \beta_{ei}^{(eff)} t\right] \quad \textbf{(generation)} \qquad \frac{n_e(t)}{n_\infty} = \frac{1}{1 + n_\infty \beta_{ei}^{(eff)} t} \quad \textbf{(decay)} \tag{8}$$

$$n_\infty = \sqrt{S/\beta_{ei}^{(eff)}}$$

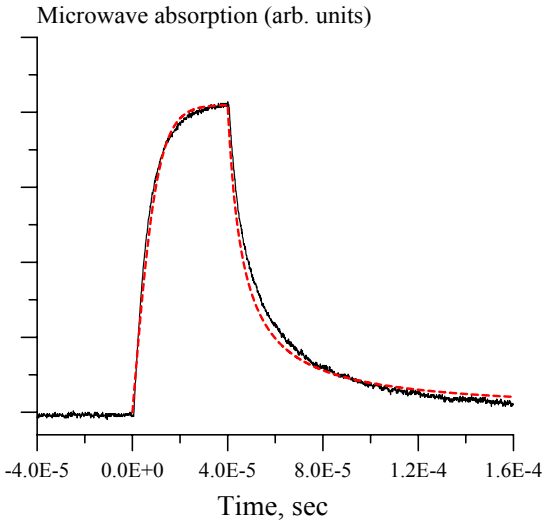

Figure 5. Experimental microwave absorption measurement from Fig. 2 – pumped case (solid line), overlayed with theoretical, rapid attachment model (dashed line) of time-dependent electron

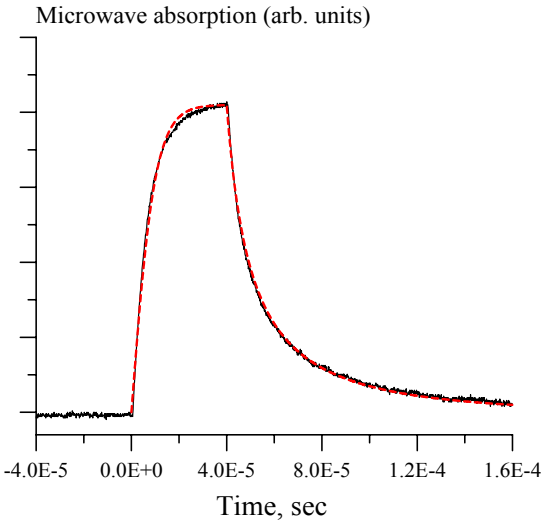

Figure 6. Microwave absorption measurements (solid line) and theoretical time-dependent electron density of Eqs. (10) (dashed line) in e-beam sustained CO/air plasma at P=250 torr (with optical pumping). E-beam current and energy are 1 mA and 80 keV.

Fig. 5 shows the results of fitting the difference between the pumped and non-pumped microwave signals from Fig. 2 to Eqs. (8) (i.e. completely mitigated attachment), assuming an ionization rate of $S=0.3\cdot10^{17}$ cm^{-3}/sec [4]. The best fit to the experimental data is obtained for $\beta_{ei}^{(eff,1)}=3.0\cdot10^{-7}$ cm^3/sec (generation) and $\beta_{ei}^{(eff,2)}=5.0\cdot10^{-7}$ cm^3/sec (decay), which are quite close to the inferred recombination rates in the nitrogen plasma at similar conditions [1]. Clearly to provide such a fit, $\beta_{ii}\,\nu_a/\nu_d$ must be of the same order as $\beta^{(eff)}_{ei}$, or less. Assuming that $\beta_{ii}\,\nu_a/\nu_d = \beta^{(eff)}_{ei} \sim 4\cdot10^{-7}$ cm^3/sec, we find that $n_d/N\sim0.05$. In other words, if only a few percent of all molecules in the plasma are excited to vibrational level v=2 and above, and if such molecules induce detachment with a near gas kinetic rate coefficient, attachment would be completely mitigated. In air this level of vibrational excitation is realized at vibrational temperatures, T_{vob}, of ~2000 K and above, which we have previously measured in optically pumped CO-air mixtures at these conditions [2].

It can be seen, however, that the fit of the plasma decay using Eqs. (8), while very good, is not perfect. This suggests the alternative possibility that electron attachment may remain unbalanced, i.e. a significant fraction of negative ions disappear not by detachment but by ion-ion neutralization. To estimate the effect of the remaining electron attachment, we model the opposite limit to that implied by eqns (5)-(8) and assume that detachment of electrons from O_2^- (or other negative ion) never occurs and that all negative ions eventually neutralize with positive ions. Under this limit, the kinetic equation for electron density is

$$\frac{dn_e}{dt} = S - \beta_{ei} n_e^2 - \nu_a n_e \qquad (9)$$

with analytical solution

$$\frac{n_e(t)}{n_\infty} = \frac{\frac{\Delta}{\nu_a}\tanh\left[\frac{\Delta}{2}t + \tanh^{-1}\left(\frac{\nu_a}{\Delta}\right)\right] - 1}{\frac{\Delta}{\nu_a} - 1} \quad \textbf{(generation)} \qquad \frac{n_e(t)}{n_\infty} = \frac{\exp(-\nu_a t)}{1 + \frac{1}{2}\left(\frac{\Delta}{\nu_a} - 1\right)\left(1 - \exp(-\nu_a t)\right)} \quad \textbf{(decay)}$$

$$\Delta = \sqrt{4S\beta_{ei} + \nu_a^2}$$

$$n_\infty = \frac{\Delta - \nu_a}{2} \qquad (10)$$

Figure 6 shows the best fit of Eqs. (10) to the microwave absorption data for $\beta_{ei}^{(1)} = \beta_{ei}^{(2)} = 3.0 \cdot 10^{-7}$ cm^3/sec and $k_a^{(eff)} = 1.3 \cdot 10^{-33}$ cm^6/sec, which is about 500 times lower then the attachment rate coefficient in room temperature air without optical pumping. It can be seen that taking into account electron removal by both recombination and attachment (although greatly reduced) substantially improves agreement with the experiment. This suggests that the observed increase of the plasma lifetime after the e-beam is turned off may be due not only to fast detachment, but also to slower attachment. Since in the optically pumped plasma the majority of oxygen molecules and third body collision partners participating in the attachment process of Eq. (1) are not vibrationally excited, and the gas temperature remains close to room temperature, slower attachment is most likely due to electron heating in superelastic processes such as

$$\mathbf{e(\varepsilon) + CO(v) \rightarrow e(\varepsilon + \Delta\varepsilon) + CO(v - \Delta v)} \qquad (11)$$

Indeed, experimental measurements [4,7] show considerable reduction of the attachment coefficient as the electron temperature is increased, by about a factor of 10 for $T_e \sim 0.3$ eV.

3 Conclusions

Measurements of the temporal evolution of electron density have been performed in pulsed e-beam generated, high pressure molecular plasmas. Measurements in nonequilibrium air mixtures, vibrationally excited to T_{vib} of order 2,000 – 3000 K by means of CO laser optical pumping, show nearly complete mitigation of the O_2 attachment mechanism, which dominates electron loss in equilibrium systems at these temperatures. Spatially and temporally resolved pure rotational temperature measurements, indicate heavy species rotational/translational temperature is only slightly increased as a result of CO laser pumping, to approximately 350 K. The combination of these two results demonstrates conclusively that the mitigation of electron attachment is due to vibrational excitation, and is not a thermal effect. Kinetic modeling of two limiting cases, accelerated detachment and inhibited attachment, suggests that two mechanisms may be playing a role simultaneously: i), detachment enhancement by collision of O_2^- (or other negative) ions with vibrationally excited neutrals, and ii), attachment inhibition due to electron heating by superelastic collisions with vibrationally excited neutrals.

Production of N-atoms in N2 microwave post-discharge jets for sterilization purposes

S.Cousty, J.Henriques, S.Villeger, J.P Sarrette, A.Ricard

CPAT, Univ. Paul Sabatier, 31062 Toulouse, France

Abstract
The afterglows of N_2 flowing post-discharges have been studied by emission spectroscopy. For post-discharge times of more than 10^{-3} sec., it is observed a late afterglow which is produced by the N+N recombination with enhanced emission of the N_2, 1st pos.band at 580 nm.
At low gas pressure, it is observed a homogenous afterglow in the whole post-discharge reactor.
At high gas pressures, up to 20 Torr, it appeared a post-discharge jet with a N-atom density higher than in the surrounded diffuse afterglow.
The N-atom density has been determined in the post-discharge from the vibrational distribution of N_2, 1^{st} pos. band intensities after calibration by NO titration.
Keywords: Plasma spectroscopy, NO titration, hydrodynamics and kinetics modelling.

1-Introduction

A large interest in flowing microwave N_2-O_2 post-discharge at low gas pressures (1-10 Torr) appeared for sterilization processes of microorganisms [1-4]. In these studies, it was fully destroyed 10^6 spores [1,2] and up to 10^{12} oral bacteria [3,4] after treatment times of 30 minutes in N_2-5%O_2 post-discharges. It was verified that a pure N_2 post-discharge was also effective to sterilize bacteria when N-atoms are reacting on bacteria support heated between 60 and 120°C [5].
In the present paper, it is reported experimental results obtained by emission spectroscopy to characterize a flowing post-discharge with a homogenous afterglow at low pressure (less than 5 Torr) and with a luminous jet at high pressures (10–20 Torr). The density of N-atoms is determined in the jet and in the homogenous afterglows inside a post-discharge chamber of 5 litres for sterilization purpose.

2-The experimental set-up

The experimental set up is reproduced in Fig.1. In the first part of the reactor, a discharge in a quartz tube of 5 mm internal dia. is produced by a 2.45 GHz microwave surfatron at a power of 50-100 Watt. The second part is a treatment chamber in Pyrex of 15 cm dia. and 20 cm height. The gas flow can vary up to 3 Slm and the gas pressure in the reactor can be adjusted between 1 and 50 Torr by means of a throttle valve above the primary pump.
Samples are placed in the center of the post-discharge chamber for sterilization studies.
The optical emission from the plasma and the afterglow is collected by an optical fiber which is connected to a Jobin-Yvon 270M spectrometer with a CCD detector. The optical fiber can be positioned in 1) for the plasma analysis at the surfaguide gap, in 2) for the afterglow detection at the end of the 5 mm post-discharge tube and in 3) for the late afterglow detection inside the 5 liters reactor chamber.
Titration by NO of N -atom densities is performed in the post-discharge chamber.

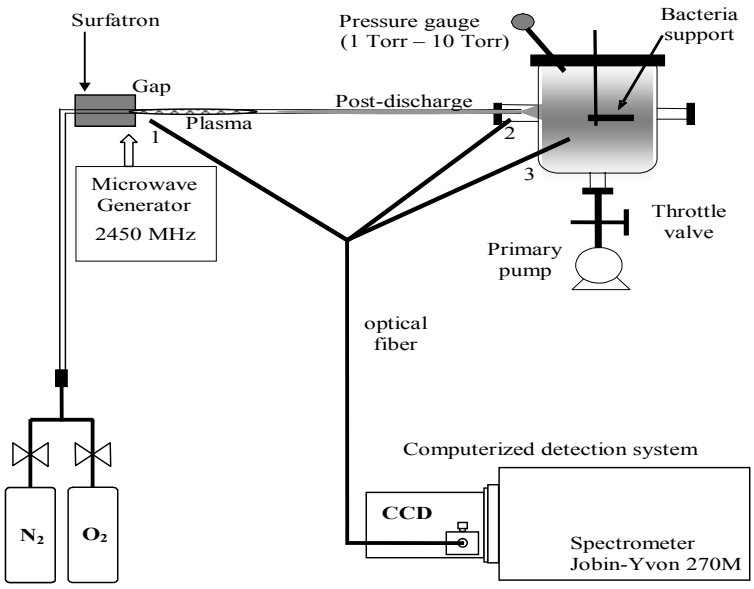

Figure 1 : experimental set up

3-Characterization of N_2 afterglows

With a flow rate higher than 1 Slm, a gas pressure higher than 4 Torr and a microwave power of about 100 Watt, it is observed a post-discharge jet after the end of the 5 mm quartz tube, at the entrance of the reactor chamber. This afterglow jet is surrounded in the reactor chamber by a late diffuse afterglow.

3-1.Characterisation of discharges and post-discharges by emission spectroscopy

The N_2, 1st.pos.emission at 4 Torr, 65 Watt in the plasma, recorded at position 2, at the end of the 5 mm quartz tube (see Fig.1), is reproduced in Fig.2a between 550 and 610nm.
In Fig.2b, it is reproduced the N_2, 1st.pos. at position 3 in the late afterglow. It is clearly observed a peak at 580 nm which characterizes the N+N recombination [6].
The same part of N_2, 1st pos. in the plasma gap (position 1) is reproduced in Fig 2c.

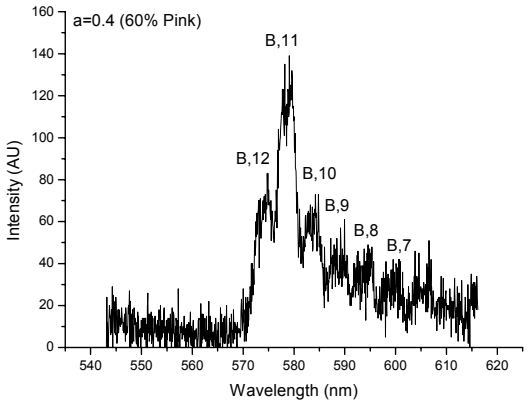

Figure 2a : N_2 1st pos.in the early afterglow

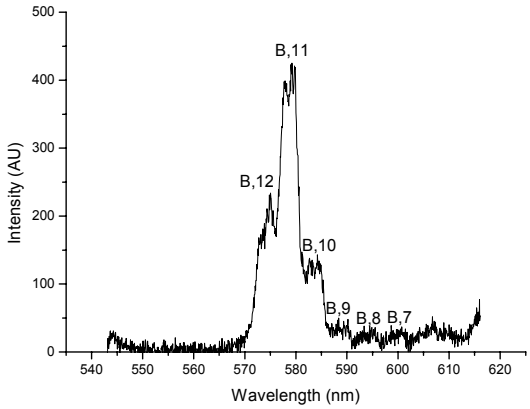

Figure 2b : N_2 1st pos.in the late afterglow

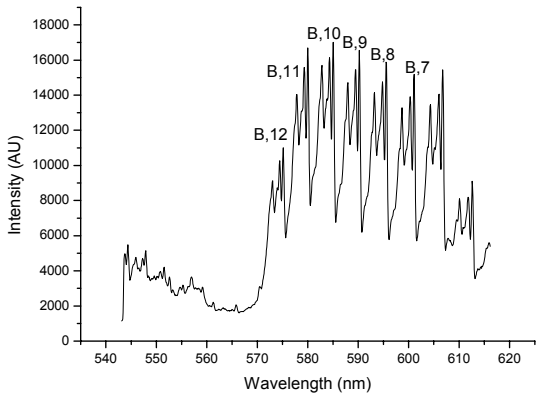

Figure 2c : N_2 1st pos. in the plasma gap

It is observed a broad vibrational distribution of the 1st pos.bands in the plasma gap (position 1), which appeared more and more contracted when going from the discharge tube end (position 2) to the chamber (position 3).

The vibrational distribution of the N_2, 1st pos syst. intensity in the post-discharge can be analysed to characterize the afterglows.

The variations of the normalised vibrational distribution of $N_2(B,v')$ density $r_{B,v'}$

(With $r_{B,v'} = [N_2B,v']/\Sigma_7^{12} [N_2B,v']$) versus v' is reproduced in Fig.3 for several values of a parameter a, with a= 1 for a pure N+N (Lewis-Rayleigh L.R) afterglow and a=0 for an early (pink) afterglow [6,7].

It is written :

$$r_{B,v'} = a\, R_{v'}(N+N) + b\, R_{v'}(Pink) \qquad (1)$$

where $R_{v'}(N+N)$ is the $N_2(B,v')$ vibrational distribution for the pure L.R afterglow (a=1 and b=0 in eq.1) and $R_{v'}(Pink)$ is the corresponding vibrational distribution in pure pink afterglow (a=0 and b=1).

It is presently found the following a–values : a=0.4 at 4 Torr and a=1 at 10–20 Torr, at the end of the 5 mm post-discharge tube which is the beginning of the post-discharge jet in the reactor (see Fig.1). At 4 Torr, it is a 60% pink afterglow. At higher pressures, the N+N recombination appears to be the dominant process at 10 -20 Torr.

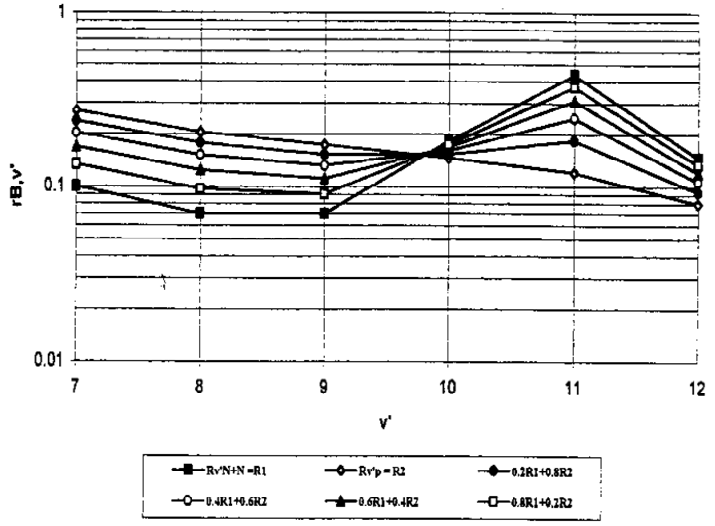

Figure 3 : diagram of $r_{B,v'}$ versus v'

The N_2, 580nm head intensity (I_{N2}) is given by the following equation :

$$I_{N2} = C_1 [N]^2[N_2] k_1 / \nu_1+k_2 [N_2] \quad (2)$$

where C_1 is a coefficient which is related to the photon emission volume, to the spectral response of the spectrometer, to the photon energy and to the band radiative frequencies, the brackets are for the atom and molecule densities, k_1 is the rate coefficients for the N+N recombination, ν_1 is the radiative frequency loss and k_2 is the quenching rate coefficient of the N_2 radiative state by N_2.

The N atom density (in relative unit) is then given by the following equation :

$$[N]^2 = k\, a\, I_{N2} \quad (3)$$

where $k=\nu_1+k_2 [N_2] / C_1k_1[N_2]$ and *a* is the parameter in Fig 3.

At pressure higher than 1 Torr, $\nu_1<k_2 [N_2]$.

3-2.Density of N -atoms after calibration by NO titration

The NO titration has been used to determine the N-atom densities as described in ref 8. An Ar-2% NO gas mixture is introduced through the reactor chamber. It has been checked a satisfactory mixing of the post-discharge and titration flows in the late afterglow for the following conditions : 0.5 slm, 4 Torr, 100 Watt with a measured N-atom density [N]=4(14) cm-3, corresponding to I_{N2}=270cc (spectrometer of Fig.1 with slit of 0.5 mm and integration time of 1s).

The C_1 coefficient in eq.2 has been calibrated to the homogenous late afterglow without afterglow jet at 4 Torr in pos.3 by taking into account the photon emission thickness of 15 cm : C_1=1 with 15 cm in pos.3 and C_1= 0.12 with 1.8 cm in pos.2.

In position 3 (Fig 2b), I_{N2}=350cc, a=1, C_1=1, it is obtained: [N]=4.6(14)cm^{-3} .

In position 2 (Fig 2a), I_{N2}=100cc, a=0.4, C_1=0.12, it is deduced: [N]=4(14)cm^{-3} .

The jet intensity is obtained by subtracting the homogenous emission at 4 cm above the jet from the total intensity in pos.3. Then the intensity of the afterglow jet of dia.1cm at pressure of 10–20 Torr is considered with C_1=6.7 (-2).

Variations of N-atom densities versus the gas pressure are in Fig.4 for the late afterglows (pos.3), inside and outside the plasma jet and for the early afterglow at the end of the 5mm dia.tube (pos.2).

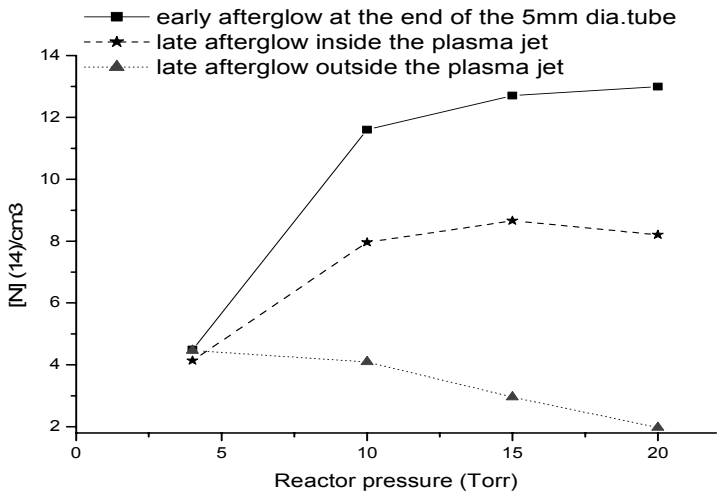

Figure 4: N-atom density versus the gas pressure

There is no difference of density in the late post-discharge at 4 Torr, inside or outside the discharge tube axis, indicating a homogenous late afterglow. Also about the same value of N-atom density is found at the discharge tube exit.

When the pressure is increasing, there is a more and more marked difference in the N-atom densities which are increasing at the discharge tube exit and in the afterglow jet, but which are decreasing in the diffuse afterglow, outside the jet.

3-3.Hydrodynamics and Kinetics modelling of N-atom density

A Fluent modelling of the flowing post-discharge was performed. The N-atom concentration along the reactor diameter (pos.3 in Fig.1) is reproduced in Fig.5, for gas pressures 4, 10, 15 and 20 Torr, at 1 Slm and 65 Watt in the plasma .The hydrodynamics and the loss of N-atoms on the reactor wall are calculated by the Fluent model as described in ref.10. The N-atom densities at the entrance of the reactor are the experimental values as given in Fig.4 (pos.2, black squares). The mean calculated values of N-atom densities along the reactor diameter at pos.3, and the experimental values are presented in table 1.

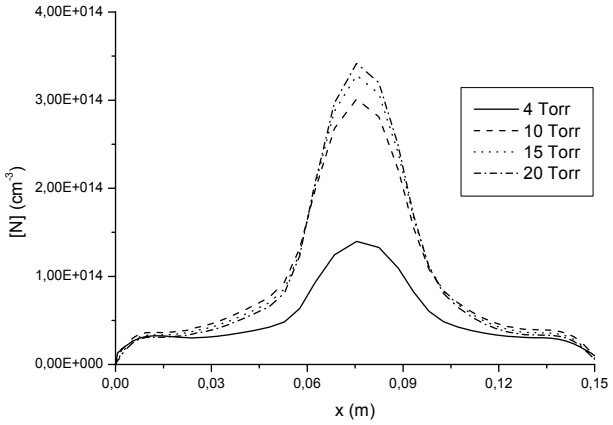

Fig.5 : Spatial distribution of N-atom density along the reactor diameter (position 3 in Fig.1)

	Calculated Values	Experimental Values
4 Torr	4.2 10^{13} cm^{-3}	4.6 10^{14} cm^{-3}
10 Torr	7.1 10^{13} cm^{-3}	4.6 10^{14} cm^{-3}
15 Torr	7.0 10^{13} cm^{-3}	3.7 10^{14} cm^{-3}
20 Torr	6.9 10^{13} cm^{-3}	2.9 10^{14} cm^{-3}

Table 1 : Calculated and Experimental Values, at different pressures, in the reactor chamber

The higher experimental values can be interpreted by a source of N-atoms in the post-discharge, resulting from collisions between excited N_2 molecules, such as $N_2(X, V)$, $N_2(A, a')$ metastables [11].

As shown in Fig.5, the jet of N-atoms in the reactor is enhanced between 10 and 20 Torr.

4 – Concluding remarks

The emission spectroscopy of the afterglows inside a reactor chamber for sterilisation has conduced to the following results :

-At low pressure, typically 4 Torr, with a plasma at 100 Watt in a tube of 5 mm.dia and a flow rate of 1 Slm, it is observed a homogenous post discharge with emission of N_2, 1^{st}.pos.bands which characterizes the N+N atom recombination.

-At higher pressures, up to 20 Torr, it appeared a post-discharge jet, surrounded by a diffuse homogenous afterglow.

The determination of N–atom densities by NO titration was only possible in the late afterglow. These atom densities have also been obtained in the jet post-discharge by calibrating the N_2, 580 nm band intensity, which is the signature of the N+N recombination. The calibration was taken in the best conditions for NO titration that is the late afterglow at 4 Torr, 0.5slm, 100Watt.

The N atom densities have been obtained in the early and late post-discharges. In the homogenous late afterglow at 4 Torr (1Slm, 65W), it has been measured a N-atom density of 4.5(14) cm^{-3}. At 10–20 Torr, the N-atom density in the post-discharge jet was higher than in the diffuse afterglow, outside the jet. The N-atom density increased in the jet but decreased outside as the pressure increased from 10 to 20 Torr.

Abstract
A flowing afterglow of pure molecular nitrogen at atmospheric pressure containing some tens to some thousands ppm of molecular oxygen is studied. For flows of 40 Slm, spectroscopic measurements down the discharge allows us to estimate concentrations in N-atoms , O^1S-metastable atoms and in C-atoms in imurity. With UV emission due to nitrogen oxide, the N-atoms and O^1S-metastable atoms are used to sporicidal effects and their relative role is estimated.
Keywords
Plasma spectroscopy, plasma kinetics, plasma sterilization.

1.Introduction

A large interest in flowing N_2-O_2 post-discharge appeared for sterilization processes of microorganisms at low gas pressures (1-10 Torr) [1-4] and at atmospheric pressure [5, 6].
The gas active species have been analysed in low pressure afterglows : N , O-atoms and UV emissions coming from NO(A) radiative states. Their densities have been determined by NO titration [7].The synergetic effects of N and O-atoms with UV and with the substrate temperatures have been reported in [1, 2] and in [3, 4], respectively. The nature and density of active species are less known in flowing post-discharges at atmospheric pressures , except for N-atoms in Ar-N_2 microwave discharges [8] and in pure N_2 post discharge [9,10]. The O, OH and NO_2 active species have recently been detected in atmospheric air DBD plasmas [11].
It is the purpose of the present communication to report the results of diagnostics by emission spectroscopy of radiative species in N_2 flowing post-discharges with a few quantity of O_2 (10^{-5} -10^{-3}) in high N_2 flow (40 Slm) at atmospheric pressure. The density of active species has been determined by using the situated kinetics reactions and after calibration of N atom density by NO titration. Density of O^1S-metastable atoms and of C-atoms in impurity into N_2 is evaluated.
Results of spore sterilization by specific active species are reported.

2.Experimental setup

The experimental set-up is reproduced in Figure1.
It uses the same device described in [9] which has the unique capability of propagating N atoms at atmospheric pressures over long distances in small diameter tube when feeded by pure nitrogen.
A fast pulsed corona discharge is produced between needles at a voltage of some 10 kV, a repetition rate of some 10 kHz and at low average current intensity such as the mean power is near 15 W [9]. Such a power is maintained constant all over the experiment stuffy. The N_2 flow rate (99.995% gas purity) was 40 Slm. A few O_2 quantity at flow rate between 0 and 50 sccm was introduced along the main N_2 flow up the discharge by means of a lateral tube (see Figure1).The post-discharge is in a quartz tube of internal diameter 6 mm where the emission spectroscopy is performed with a Stellarnet EPP 2000 spectrometer (resolution 1.5 nm) in the 200-800nm spectral range. At the same point, the tube is replaced by a 250 cm^3 box containing Bacillus Stearothermophillus spores when post-discharge sterilization effect is experimented.

3. Active species in the N_2 and N_2-O_2 afterglows

3-1 Observed emission spectra

The emission spectra in the afterglow, at a distance x=10 cm from the plasma, is reproduced in Figure 2 for a N_2 discharge (Figure 2a) and for a N_2–(2.5 10^{-5}) O_2 gas mixture (Figure 2b). In Figure 2a, it is observed the N_2, 1^{st}.pos.(580 nm).emission, resulting from the N-atom recombination. Not any other N_2 band appears, neither N_2, 2^{nd} pos nor N_2+, 1^{st}.neg as it is observed in the early (pink) N_2 afterglow [12]. It is concluded that such emission spectrum in Fig. 2a is a characteristic of a late N2 flowing afterglow with emissions of impurity bands such as NH (336 nm) and CN (359nm, 388 nm, 424 nm) bands resulting from reactions of atomic nitrogen with hydrocarbon gas impurities [13]. Such hydrocarbon impurities could come from the N2 gas tank or from a small etching of the polyamide tube by the N-atoms.

These latters disappear as early as O_2 is mixed in N_2, as shown in Figure 2b. Then, besides the always emitting N_2, 580 nm, it can be seen the NOγ (247.9 nm) and NOβ(320.7 nm) bands and a green band at 577 nm. This green band. is produced by the $N_2O(^1S) – N_2O(^1D)$ excimer transitions as reported in [14-16].

3-2. Production of radiative states

The $N_2(B,v'=11)$ state, at the origin of the 580 nm band in Fig.2a,b, is produced by the following N-atoms recombination :

$$N+N+N_2 \rightarrow N_2(B,v'=11) + N_2 \quad (a)$$

The CN–bands as observed in Fig.2a are produced in the afterglow by recombination of N and C-atoms [17] :

$$N+C+N_2 \rightarrow CN(B,v'=7) + N_2 \quad (b)$$

$CN(B,v'=7) \rightarrow CN(A,v'')$, with in particular, the 384.7 nm band for v''=7.

The NO bands in Fig.2b are coming from states NO(B, A). The NO(B) state, emitting the NOβ bands, is produced by the N + O recombination as follows :

$$N+O+N_2 \rightarrow NO(B) + N_2 \quad (c)$$

As for the NO(A), emitting the NOγ bands, the following excitation transfer is efficient :

$$N_2(A) + NO \rightarrow NO(A) + N_2 \quad (d)$$

where $N_2(A)$ are metastable states.

Finally, the $N_2O(^1S)$ excimer, at the origin of the green band, is produced from the $O(^1S)$ metastable as it follows :

$$O(^1S) + N_2 + N_2 \rightarrow N_2O(^1S) + N_2 \quad (e)$$

3-3.Density of radiative states

To determine the density of radiative states, it is necessary to know the loss terms which are by radiative emission and by N_2 quenchings. They are analysed in [7, 8, 10, 17].

It is reproduced here how to determine the $N_2(B,11)$, CN(B,7) and $N_2O(^1S)$ radiative state densities in the post-discharge.

For the $N_2(B,11)$ state, the dominant loss term for pressures higher than a few Torr is by the following quenching [7] :

$$N_2(B,11) + N_2 \rightarrow \text{products} \quad (f)$$

Then the pseudo-stationary state density of $N_2(B,11)$ is given by the following equation :

$$[N_2(B,11)] = k_a [N]^2 / k_f \quad (1)$$

where the brackets are for the specie density and $k_{a,f}$ are the rate coefficient of reactions (a) and (f), respectively.

For the CN(B,7) state, the ν_r^7 - radiative frequency cannot be neglected before the quenching frequency:

$$CN(B,7) + N_2 \rightarrow \text{products} \quad (g)$$

So that the pseudo-stationary state density of CN(B,7) is as follows:

$$[CN(B,7)] = k_b [C][N] k_b / \nu_r^7 + [N_2] k_g \quad (2)$$

As it concerns the $N_2O(^1S)$ excimer, the main loss term is the inverse of reaction (e), with a rate coefficient k_{-e}. The pseudo-stationary density of $N_2O(^1S)$ is then given by the following equation :

$$[N_2O(^1S)] = [O(^1S)][N_2]k_e/k_{-e} \quad (3)$$

3-4. Density of N, C and O(^{1}S) atoms

The N-atom density has been determined in the afterglow by the NO titration method as detailed in [7, 10]. It is obtained a nearly constant value in pure N_2 and in N_2-(0.125-12.5)10^{-4} O_2 gas mixtures of [N] = 4 10^{14}cm^{-3} with an uncertainty of about 30%.

The C-atom density is estimated by comparing the CN(B,7-X,7) , 384.7 nm and the N_2, 580 nm intensities,using the following relations:

$$I_{N2*} = c(\lambda = 580 \text{ nm}) [N_2(B,11)] A(N_2*) \quad (4)$$

$$I_{CN*} = c(\lambda = 384.7\text{nm}) [CN(B,7)] A (CN*) \quad (5)$$

where c(λ) is a coefficient depending of the spectral response of spectrometer and on the energy of emitted photon, A(N_2*) = A(B,11-A,7) and A(CN*) = A(CNB,7-X,7) are the radiative frequencies.

By replacing [CN(B,7)] and [N_2(B,11)] as given by equations 2 and 1, the intensity ratio of the two bands is as follows:

$$I_{CN*}/ I_{N2*} = \alpha_{CN} [C]/[N] \quad (6)$$

with $\alpha_{CN} = [N_2] k_g / \{k_a/k_f (\nu_r^7 + [N_2] k_g)\}$

In conditions of Fig.2a, a C-atom density of about 10^{12} cm^{-3} is estimated from a N-atom density of 4 10^{14} cm^{-3} as obtained by NO titration.

The O(^{1}S) metastable atom densities is now determined by comparing the emission intensity of N_2, 580 nm (I_{N2*}) and $N_2O(^1S)$-$N_2O(^1D)$, 577 nm (I_{N2O*}), with :

$$I_{N2O*} = c(\lambda = 577 \text{ nm}) [N_2O(^1S)] A\{N_2O*) \quad (7)$$

with A(N_2O*) = A(N_2O^1S-N_2O^1D). It is noted that c(λ) has the same value for the two considered bands.

By replacing [N_2O^1S] and [N_2(B,11)] as given by equations 3 and 1, the intensity ratio of the two bands is as follows :

$$I_{N2O*}/ I_{N2*} = [O(^1S)]/ [N]^2 \{[N_2] k_e k_f A(N_2O*) / k_{-e} k_a A(N_2*) \} \quad (8)$$

Variations of N_2, 580 nm, $O^1S.N_2$, 557 nm and NOβ, 321 nm, NOγ, 248 nm band intensities versus the O_2 percentage into N_2 are reproduced in Figure 3.

It is observed a nearly constant intensity of N_2, 580 nm, indicating a constant N-atom density (see eq.1). It is however observed a small flat maximum of the N_2,580 nm intensity which seems to appear at 10^{-4} O2 into N_2. Such a maximum has been previously observed[7] for about 10^{-2} O2 into N2 into a microwave flowing post-discharge at low gas pressure.

The I_{N2O*} at 577 nm shows a peak at 2.5-5.10^{-5} O_2 into N_2 and then sharply decreases.

The NOβ and NOγ band intensities reached maximum values at 20-50 10^{-5} O_2, with a slow decrease up to 130 10^{-5} O_2.

At the peak position of N2O*, the I_{N2O*}/I_{N2*} ratio is about 10. It is taken the following rate coefficients and radiative frequencies :

- $K_eA(N_2O*) / k_{-e}$= 4 10^{-18} cm3s-1 [14], in ref.16 : k_a=1.10^{-33} cm^{6}s^{-1} and k_f = 2.8 10^{-11} cm^{3}s^{-1} [18] and : A(N_2*)= 7.76 10^4 s^{-1} [19].

As [N_2] = 2.4 10^{19} cm^{-3} at the atmospheric gas pressure at room temperature, it is deduced from eq.8 that [O(^{1}S)] = 6 10^{10} cm^{-3} as [N] = 4 10^{14} cm-3.

The O(^{1}S) metastable and N atom dissociation rates are thus [O(^{1}S)]/[O_2] = 10^{-4} for 2.5 10^{-5} O_2 into N_2 and [N]/[N_2] = 2 10^{-5}.

4. Sterlilization results in the N_2 and N_2-O_2 afterglows

Calibrated drops of B-Stear. Spores, diluted in distilled water and dried at 40°C during 30 min., have been deposited on glass plates and then introduced in a 250cc box which is connected to the flowing afterglow.

The numbers of survivors after several times of the post-discharge treatment are reproduced in **Figure 4**. The initial number of B-Stear.spores was 2 10^5.

After a treatment time of 30 minutes, it remained 6 10^2, 2 10^2 and 1 10^2 spores in pure N_2, N_2-(2.5 10^{-4}) O_2 and N_2-(2.5 10^{-5})O_2, respectively.

As shown in **Figure 3**, the N–atoms are alone in pure N_2 post-discharge (with C-atoms in impurity). In the N_2–(2.5 10^{-4}) O_2 gas mixture, the NOγ(248nm) band intensity was at its maximum value. It is the O(^{1}S) metastable atoms which reached their maximum value in the N_2-(2.5 10^{-5})O_2 mixture.

A constant value of N-atom density was obtained in the three studied gas mixtures.
In the results of sterilization as shown in **Figure 4**, it appears that the $O(^1S)$ metastable atoms, coupled to the N-atoms, are the most efficient species to inactivate the B-Stear. spores, in spite of the small quantity of $O(^1S)$ in respect to N-atoms : $O^1S/N=10^{-4}$ as presently found.

5. Concluding remarks

Besides the biocidal effect previously observed in pure nitrogen and attributed to N atoms, working with small admixtures of oxygen in pure N_2 has allowed to evidence separately increasing efficiency of UV radiation and $O(^1S)$ metastable. Density of this latter has been measured.
This exhibits similarities and differences as compared to other studied afterglows. In [1], UV photons and oxygen atoms are shown as being the main inactivating species in N_2-O_2 low pressure mixtures. Owing to steps occurrence in the inactivation glow, their role is assumed to be killing and etching, respectively. In the case of atmospheric air studied in [11], there is no active UV emission but O and OH and NO_2 are present and are evidenced as being highly reactive species, playing the main role in microorganisms destruction. Nitrogen dioxide concentration has been measured around 500ppm.
The present study brings thus new results in the case of a specific atmospheric pressure afterglow with specific kinetic schemes for active species production. It remains however that the reduction effect is still low and has to be increased significantly in view of the chosen application. This could be achieved by increasing oxygen metastable atoms concentration.

Abstract

Hot wire plasma sputtering of graphite in a mixture of Ar and nitrogen was used to deposit N-doped DLC films on PTFE and Si supports. The surface and bulk composition of DLC films were analysed by XPS, FTIR, EELS and Auger depth profiling spectroscopy. The relationship between chemical composition, electronic structure and biological performances of deposited films has been investigated.

Keywords: plasma deposition, DLC films, cell adhesion, haemocompatibility

1. Introduction

Plasma assisted deposition of amorphous carbon and diamond-like carbon (DLC) thin films is an attractive technique to improve the surface mechanical properties and biocompatibility of medical polymers. The DLC coating influences in particular the interaction and adsorption of different proteins which in turn, controls the cell adhesion and behaviour. The DLC coatings have been demonstrated to be biocompatible in vitro and vivo in cardiovascular and orthopedic applications [1]. The past few years saw A growing interest in studying the structure and properties of N-doped DLC layers [1,2] has been seen in a past few years. It appears to be a promising coating to improve film properties such as elasticity, electrical conductivity, surface energy and to control biological performance [3].

Earlier [2,3] we reported the possibility of using hot wire plasma sputtering of graphite for deposition of DLC films with high adhesion to the hydrophobic PTFE support. The improved haemocompatibility of PTFE film after DLC coating was obtained on the stage of platelet adhesion. In this article we investigated the influence of nitrogen doping on the chemical and electronic structure of DLC coatings and correlation of a blood compatibility parameters such us platelet adhesion and degree of activation with the surface chemical composition and fraction of sp^3/sp^2 bonded. The other biological parameters of the surface of N-doped DLC films like vascular endothelial and smooth muscle cells attachment and growth, as well as fibrin formation and neutrophils adsorption was also estimated.

2. Experimental details

2.1. Plasma deposition techniques

The film deposition was carried out in hot wire plasma reactor. [2,3]. The square graphite target (25 mm × 25 mm) was located at 10 mm over the round sample holder (diameter 50 mm). The samples of PTFE and Si were exposed to deposition in glow discharge plasma by sputtering the target in the flow of Ar with various percentage of nitrogen (partial pressure 3 – 40 %). The temperature of sample holder during deposition was in the range 180-210^{o}C depending on plasma conditions and hot wire temperature. The last one was controlled by Micro Optical Pyrometer (Pyrometer Instr. Co., USA) and varied in the range 1950 – 2100 K depending on the filament current. The total gas flow and pressure in the plasma chamber was maintained at 25 sccm and 5×10^{-2} torr respectively. The temperature of sample holder during deposition was measured by chromel/alumel thermocouple

and ranged in 180-210 ^{0}C depending on plasma conditions. After deposition the samples were cooled in the reaction chamber under ventilation by Ar flow to the room temperature.

2.3. Surface characterization

The rate of deposition and thickness of carbon films deposited on Si wafer was measured by weighing of the sample before and after deposition on analytical microbalances, Auger depth profiling and AFM measurement of the profile after scratching.

The surface chemical composition before and after deposition on PTFE films was analyzed by XPS spectroscopy (Kratos Axis Ultra spectrometer, USA). The XPS spectra were obtained with 90-degree take-off angle by using monochromatised Al K_α source. The charge neutralizer was on for all the analysis.

The scattering spectra in micro-Raman mode were measured using 633 nm excitation wavelength of helium neon laser. The scattering light was collected in backscattering with CCD camera, using Renishaw Model 2000 Raman spectrometer. The incident laser power on the sample was in the range 0.3 – 1.2 mW.

IR spectra of carbon films deposited on Si substrate in the same run with polymer film were recorded using FTIR spectrometer Perkin-Elmer 1720X (Perkin-Elmer, USA). The IR spectrum of Si support was subtracted from the sample spectrum to obtain the transmittance spectrum of carbon layer.

Electronic structure of carbon coatings was investigated by electron energy loss spectroscopy (EELS). The energy loss spectra were measured in reflection mode using Kratos Axis Ultra spectrometer equipped with Kratos WX-410 electron gun system. The hemispherical electrostatic analyzer is used in retarding mode at the pass-energy 40eV. The primary electron beam energy was 1000eV. The analyzing electron beam is scanned on the area about 2mm x 2mm.

Concentration profiles of C, N and O atoms in the carbon film deposited on the Si wafer were performed with a scanning Auger spectrometer PHI-560. The low energy (1 keV) Ar^+ ions and a grazing sputter angle profiling (80° with respect to the normal) was used to improve the depth resolution and minimize the destruction of surface layer

The surface morphology of the samples was examined by AFM (model PicoSPM, Molecular Imaging, USA) and scanning electron microscopy (SEM) using secondary and backscattered electrons, 5 kV accelerating voltage, and magnification up to 5000 (JSM T330, JEOL, Japan).

2.3. Biological testing

Biological properties of carbon-coated PTFE were investigated using platelet adhesion testing, vascular endothelial and smooth muscle cells attachment and growth, whole blood contact and thrombelastography technique.

Platelet-rich plasma (PRP) was obtained by centrifugation of the whole blood at 100 g for 20 min at room temperature. The small PRP drops (50 µl) were placed onto sample surfaces and incubated in humid atmosphere for different periods (from 5 to 30 min). The samples incubated with PRP for 15 min were chosen for further analysis since the number of platelets adhered to the surface during this time interval was appropriate for quantification. Platelet adhesion patterns were investigated by SEM. The study of platelet adhesion was performed with informed consent of the donors. Five volunteers were included in the series of repeated experiments. The bottom leukocyte rich suspension obtained after centrifugation of blood was used to extract neutrophils. A suspension of $3x10^8$ neutrophils was labelled with 300µCi of In^{111} for 30 minutes at room temperature. Then the suspension was rinsed twice with PBS to remove the unbounded In^{111}. 100µl of the labelled suspension were incubated for 2h at 37°C. After the incubation, samples were rinsed twice with PBS and the amount of neutrophils uptake was evaluated by a gamma scintillation counter

Endothelial cells and smooth muscle cells were isolated from porcine aorta. Smooth muscle cells were subsequently extracted and seeded in tissue-culture flasks coated with porcine gelatine 0.2%. Cells were maintained at 37ºC in 5% CO_2-humified atmosphere and harvested by trypsinization when a monolayer was reached. Cells used as controls were seeded on Petri dishes or cover slides previously treated with porcine gelatine 0.2% (Sigma Aldrich, Milwaukee, USA). Adhesion of blood cells as well as the formation of fibrin on the sample surface was investigated by SEM. Immediately after collection, blood was incubated on the surfaces 30 minutes at 37°C. Than, the samples were washed twice with PBS to remove the non-adherent cells from the

surface and subsequently treated for SEM analysis. The thrombogenicity index was measured using a standard equipment Thrombelastograph D (Hellige GMBH, Germany). The measurement procedure is based on viscoelastic test that characterises formation and strength of the blood clot over the time.

3. Results and discussion

Identification of nitrogen containing groups in the N-doped DLC films was done by FTIR spectroscopy.

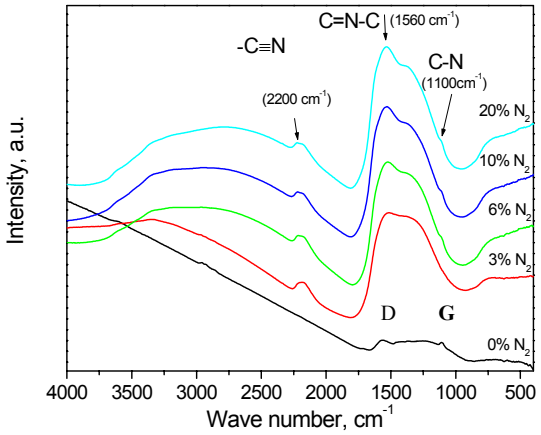

Figure 1 FTIR spectra of DLC films, deposited by sputtering of graphite in (Ar +N_2) plasma at different concentration of N_2 in gas phase (deposition time 2 h)..

Figure 1 shows FTIR spectra of DLC films, deposited by sputtering of graphite in (Ar +N_2) plasma at different concentration of N_2 in gas phase. The broad main band in the region 1000 – 1700 cm^{-1} is appeared with the doping of nitrogen and is attributed to the stretching vibration of CC bonds. Usually CC bonds in pure carbon films are not active in the IR absorption but only detected by Raman spectroscopy due to the high symmetry. However, carbon films doped with different amount of nitrogen reveal Raman-active G (1575 cm^{-1}) and D (1360cm^{-1}) bands in the IR spectra. Symmetric CC bonds become IR-active due to the nitrogen replacement of carbon which breaks the symmetry in six-fold carbon ring structure. The nitrogen replacement gives rise to a net dipole moment and makes active IR absorption. The IR absorption appeared at 2200, 1560 and 1100 cm^{-1} is indicated the formation of -C≡N, -C=N- and –C-N groups respectively in nitrogen doped carbon films.

Raman spectra (see Figure 2a) also show two basic C–C bands around 1575 cm-1 (*G* line) and 1360 cm-1 (*D* line) usually detected in amorphous and diamond-like carbon films. The band at 1575 cm^{-1}, in case of Raman scattering for amorphous carbon and polycrystalline diamond films, is usually assigned to graphite like sp^2 bonded carbon (G peak) while the scattering in the low frequency region around 1300 cm^{-1} has to be interpreted as scattering of sp^3 –bonded carbon plus a possible contribution of a disordered sp^2 phase (D peak). The optical probing depth for Raman spectroscopy, d , is determined by the absorption coefficient α for carbon layer at our excitation wavelength of 633nm, $d=1/(2x\alpha)$. Taking the optical constants for different carbons we could estimate the Raman probing depth to be 100 – 500 nm, which is comparable with the layer thickness. That is why the intensity of Raman bands for the N-doped carbon layers increased with the increase of nitrogen concentration in plasma. According to our measurements the increase of nitrogen concentration in plasma leads to the increase of deposition rate.

Figure 2b shows EELS spectra for N-doped carbon films in comparison with graphite. All curves contain elastic peak and two other peaks whose origin may be attributed to the plasmon excitation of all valence electrons (high energy $\delta+\pi$ plasmon peak) and π-electrons (low energy π-plasmon peak). The intensities and

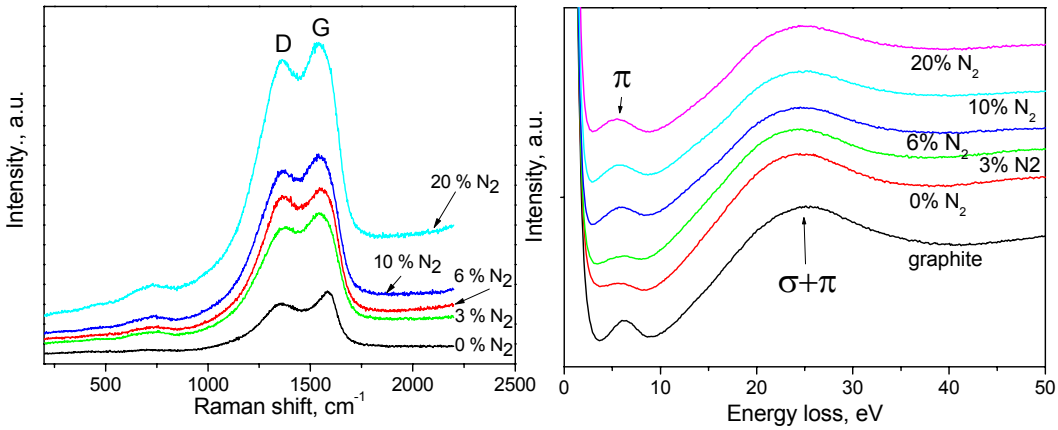

Figure 2 Raman spectra (a) and. energy loss functions (b), obtained for N-doped DLC films, deposited by sputtering of graphite in (Ar +N_2) plasma at different concentration of N_2 in gas phase (deposition time 2 h).

positions of the individual plasmon peaks for graphite and carbon film were calculated after background correction and subtracting the elastic peak, fitted by Gaussian function. The relative intensity ratio for these bands is proportional to the relative number of π-electrons, which is equal to 0.25 for graphite: I(π)/I(δ+π) = k*0.25. By calculating the constant parameter, k, from the graphite energy loss spectrum we can obtain the relative number of π-electrons in our carbon film from the measured intensities of two bands. The percentage of sp^3 value determined from EELS spectra of carbon films deposited at different nitrogen concentrations in plasma are given in Table 1. The substantial fraction of sp^3 bonded carbon around 60% was detected in DLC films deposited at low (3-6%) concentration of nitrogen in plasma. The increase of nitrogen in plasma and on the surface of our carbon film gives rise to the decrease of sp^3 fraction down to 20%. The energy of the main plasmon (δ+π) in carbon materials $\hbar\omega_p$ estimated from the energy loss spectrum along with the known chemical composition allows estimating the specific density of our carbon layers relative to graphite [2]. This value (also shown in the Table 1) is around 1,9 g/cm^3 for all our N-doped DLC films. Such a specific density is rather high in comparison with the density of polymer films but less then that observed for graphite.

The chemical compositions for DLC layers, deposited at different concentrations of nitrogen in plasma determined by XPS are also presented in the Table 1. One can see that the concentration of nitrogen on the surface reaches an upper limit 30,7 at.% with the increase of N_2 concentration in plasma. The presence of a relatively high concentration of oxygen (10 –14 at%) on the carbon layer may be explained by surface contamination and bonding of oxygen in post reactions with free radicals and other chemically active species formed by plasma treatment.

% N_2 in plasma	*depos. rate nm/min*	*C at%*		*N at%*		*O at%*		*sp3/ (sp^3+sp^2) %*	ρ *g/cm^3*

Table 1. Chemical and electronic structure of N-doped DLC films (from XPS, Auger depth profiling and EELS data).

Depth profiling measurements has shown the concentrations of carbon, nitrogen and oxygen atoms in the bulk. Only the traces of oxygen (2 -3 at. %) was observed in the bulk of N-doped DLC films, thus confirmed the post deposition origin of oxygen containing groups on the surface (see Table 1). The interesting finding is that the maximum concentration of nitrogen in the bulk (12,6%) is much less than that detected on the surface (30,7%). Possible explanation to that may be the segregation of nitrogen from the bulk to the surface in the

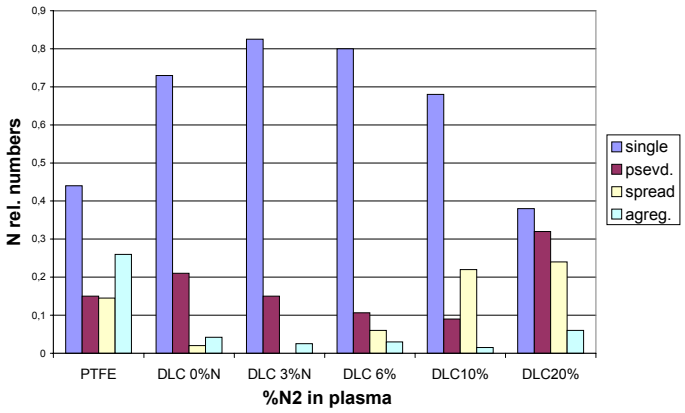

Figure 3. Diagram representing relative platelet quantities for different morphological classes observed by SEM for untreated and N-doped coated PTFE films deposited in different plasma conditions.

process of annealing the sample from 180-200^{0}C to the room temperature after deposition. The higher concentration of nitrogen in the bulk could be thermodynamically non-favourable for the structure of our DLC film at room temperature. Very close maximum concentration of nitrogen (9,7 at%) was reached by the authors [4] in the C:N films deposited in quite different plasma conditions by sputtering of graphite in RF discharge in the mixture of Ar with nitrogen.

To study the haemocompatibility of N-doped DLC film on the stage of cell adhesion the total number and aggregation of adhered platelets was measured. It is generally known, that increased platelet adhesion, activation and aggregation on implant surfaces exposed to blood initiates the formation of thrombus. In vitro analysis shown substantial decrease of total platelet adhesion and suppressed activation for all N-doped DLC coated samples in comparison with untreated PTFE The activation of platelets can be estimated by their morphology analysis. The better blood compatibility of the material is associated with the lower amounts of adhered, activated, spread or aggregated cells. In comparison with the surface of original PTFE which exhibits intensive platelet spreading and aggregation, N-doped DLC coating shows mainly single non-activated platelets and substantially less amount of activated, spread and aggregated platelets (Figure 3). The effect depends on the surface structure and concentration of nitrogen. The minimum activation of platelets was observed for the carbon films deposited with 3% nitrogen in plasma. These films contain 23,8% of nitrogen on the surface and are characterised by the relatively high content (62%) of sp^3 fraction. (see Table 1).

Analysing clotting time changes and trombogenicity factors we have found that N-doped DLC coating do not improve clotting time parameters and blood viscoelastic properties. However, investigation of cell

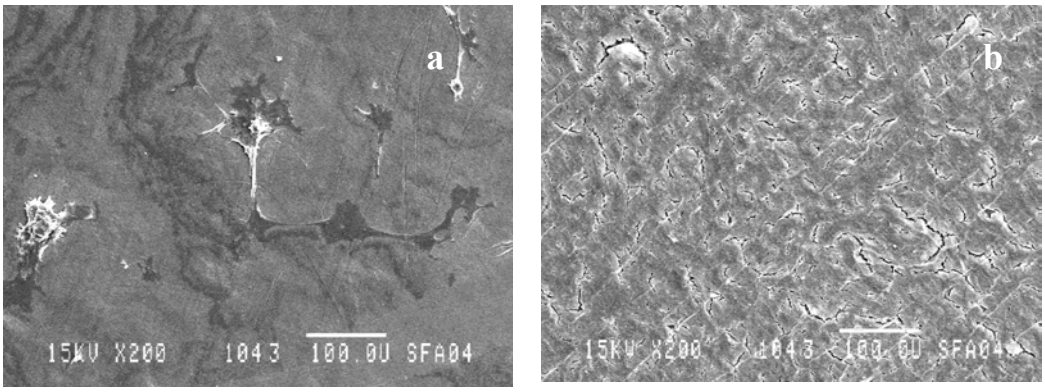

Figure 4. Endothelial cells attachment on virgin PTFE (a) and PTFE coated by N-doped DLC layer (7,8 at.%N) (b) after 72 hours of seeding.

culturing show very promising results. Endothelial and smooth muscle cells were analysed by SEM after 72 hours seeding. Only a low number of cells are able to adhere but not to proliferate on the virgin surface. In fact, even morphology displayed on untreated PTFE shows a bad spreading and numerous cases of apoptotic cells. DLC coated PTFE offers a better environment for cells, showing a good morphology and reaching a confluent monolayer 72 hours after seeding (see Figure 4). Based on these results, we can conclude that DLC coating strongly improves biological performances, allowing the formation of a cellular anti-thrombogenic layer on the surface, miming the natural vascular environment.

Study of the whole blood interaction with the surface allow us to analyse the processes of fibrin formation and red blood cells attachment. DLC-coated PTFE shows a little amount of fibrin and a virtually absent red cells attachment, while a fibrin net with numerous red cells entrapped was found on the untreated surface. Correlating these data with the time required for fibrin formation, we can suppose that fibrin do not strongly attach on DLC-coated PTFE. Thus, also from this point of view, the surfaces after the coating with DLC films are less thrombogenic then the untreated ones.

3. Conclusions.

By doping DLC films with nitrogen, different biological reactions of cells can be continuously adapted to the desired value. The results obtained are promising for further applications of N-doped DLC coating in cardiovascular field.

Abstract

The Naval Research Laboratory has developed a materials processing system based on plasmas produced by high-energy (≈ 2 keV) electron beams. These plasmas have numerous properties that allow operating regimes not accessible in systems using conventional plasma sources. The system is being used to examine the etching behavior of 193 nm and 248 nm photoresist material in argon plasmas. The initial results of this work are presented.

Keywords: Plasma Source, Electron Beam, Etching, Photoresist

1. Introduction

The Naval Research Laboratory has developed a materials processing system based on electron beam-generated plasmas for use in a variety of processing applications [1]. The systems utilizes a magnetically collimated, sheet of high-energy (≈ 2 keV) electrons to produce a planar plasma. The resultant plasma has unique characteristics when compared to conventional low-pressure plasma sources. When multi-kilovolt electrons pass through a gas, ionization is the dominant mechanism with the cross-sections being similar for most gases. Thus, little energy is consumed by non-ionizing, inelastic collisions and species generation can be regulated by adjusting the background gas concentrations. This in contrast to conventional discharges where the dominant inelastic collisions consume most of the delivered energy and ion production favors the species with the lowest ionization potential.

Also, in conventional discharges, the boundaries of the ionization region are not well defined and can vary greatly with gas pressure and composition or chamber geometry. In electron beam-produced plasmas, the ionization region is limited to the beam volume, which is well defined and uniform when the beam is magnetically confined. Outside the beam channel, the plasma density and ion composition are altered by ion-electron, ion-neutral, and ion-ion reactions and so electrodes (or substrates) can be independently positioned to take advantage of changes in the outwardly diffusing flux of ions and radicals.

Perhaps the most notable difference of electron beam-generated plasmas, is a low electron temperature. Conventional plasma discharges rely on externally applied electric fields to raise the plasma electron temperature so that a fraction of those electrons are energetic enough to ionize the gas and sustain the plasma. Because the electron beam ionizes the gas, no heating of the plasma electrons is required and they are quickly cooled by elastic and inelastic collisions. The resulting plasma electron temperatures are found to be 1.0 eV or lower [2], depending on the background gas. The temperature in molecular gas backgrounds tends to be lower than in noble gases due to the availability of excitation states that extend down to near zero energies. Since the electron temperature determines the plasma potential, ions incident to unbiased surfaces will also exhibit low energies [3], typically below 5 eV.

It is with these attributes in mind that electron beam generated plasmas are being used to investigate the etching behavior of 193 nm and 248 nm photoresist materials. The 193 nm photoresist material is, by necessity, thinner and based on a different polymeric structure than 248 nm photoresist material but has been found to be less robust than 248 nm photoresist material when subject to conventional argon and C_4F_8 based discharges [4]. In this work, we present and discuss experimental characterizations of electron beam-generated plasmas produced in argon, which are used to etch 193 nm and 248 nm photoresist material. The etch behavior of the photoresist materials will also be discussed.

2. Experimental

A number of systems are currently in use for plasma diagnostics and materials processing. While the chamber geometries vary, all systems operate in a similar fashion and consist of a few common components, which are shown in Fig. 1. A sheet-like beam of energetic electrons is produced by pulsing a linear hollow cathode to -2 kilovolts for a fixed pulse width and duty factor. The emergent beam passes through a slot in a grounded anode and is then terminated at a second grounded anode located further downstream. The electron beam volume between the two anodes defines the ionization source volume, with the dimensions set by the slot size (beam thickness and width) and the anode-to-anode distance (beam length). For these applications, the range of a 2 keV electron beam is much larger than the anode-to-anode length. A set of external magnetic field coils produce a coaxial magnetic field of 150 Gauss or higher. Magnetic fields of this magnitude keep the expansion of a 2 keV electron beam in 50 mTorr to less than 0.5 cm at a distance of about 50 cm [5].

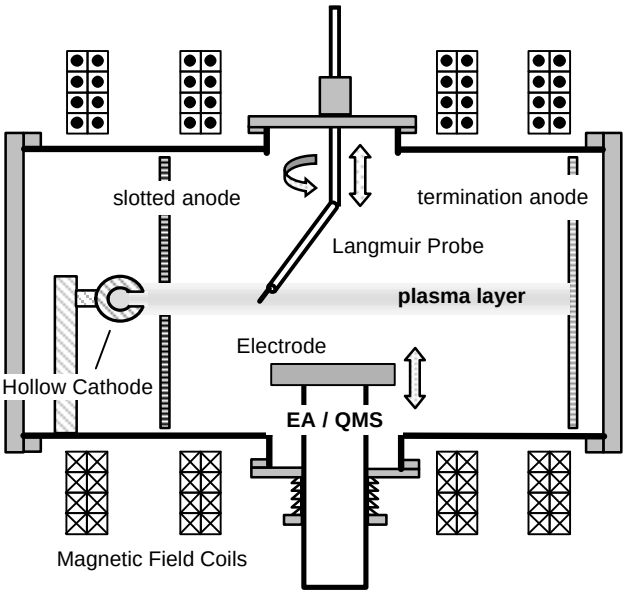

Fig. 1 The experimental apparatus used for plasma characterization.

Plasma Diagnostics

The experimental apparatus has been discussed previously [6] and is shown in the schematic of Fig. 1. The source volume in this system measures approximately 1 cm thick by 25 cm wide by 43 cm long. A dual energy analyzer/mass spectrometer (Hiden EQP 300 Plasma Probe) was used to measure mass-resolved ion energy distributions and ion fluxes sampled through a 20 μm diameter aperture located in the center of a grounded 5.7 cm diameter stainless steel electrode. Because the system was pulsed, all data acquisition was time resolved and the gating techniques have been described elsewhere [6].

The plasma electron temperature and plasma density, were determined using a Langmuir probe that was mounted on a multi-motion feedthrough and constantly heated with an internal resistive element to reduce surface contaminants. The electron temperature and plasma density were derived from a best fit of the I-V trace to a Maxwellian electron energy distribution using time-resolved probe techniques that have also been described elsewhere [7].

Etching Experiments

Details of the electron beam source and reactor used for the etching experiments can be found in [8] and the approach to system operation for etching applications have been previously described [9]. The system was similar to the experimental configuration of Fig. 1 except all diagnostics are absent and the ground electrode was replaced by a biasable stage upon which the photoresist material is mounted. Rf power was applied to the stage through a matchbox by an rf amplifier driven at 13.56 MHz. The rf signal was synchronized to the electron beam pulse so that the rf power was well coupled to the electron beam–produced plasma, thereby minimizing any undesirable rf discharge effects. Stage bias and currents were measured by an oscilloscope probe and current transformer on the atmosphere side of the electrical feedthrough. Forward and reflected powers were determined using an inline directional coupler.

1-2 cm^2 samples of blanket 248 nm (1000 nm thick) and 193 nm (400 nm thick) photoresist films on silicon substrates were adhered to the stage with silver print epoxy, placed in vacuo, and the chamber was evacuated to a pressure of at least ~10^{-5} Torr. The samples were then subjected to plasmas produced in 50-60 mTorr of high-purity argon (50 sccm) with the cathode operating at –2 kV for a range of pulse widths and duty factors in a 150

Gauss magnetic field. The samples were positioned 2.5 cm from the electron beam axis. Post-treatment, the systems was again evacuated to 10^{-5} Torr and then brought to atmosphere with nitrogen. *Ex situ* sample analysis included ellipsometry to determine etch depths and changes in refractive index, contact angle measurements of water drops on the surface, and x-ray photoelectron spectroscopy (XPS) to assess the surface chemical structure.

3. Results and Discussion

Plasma Diagnostics

Plasma diagnostics have been carried out on plasmas produced in 50 mTorr of argon using an electron beam produced by pulsing the hollow cathode to –2 kV for 6 ms at a 10% duty factor. Shown in Fig. 2 are Ar^+ ion energy distributions measured at a grounded electrode positioned 2.5 cm from the electron beam axis. One distribution (open circles) was acquired during a gate extending over nearly the entire pulse period. The other distribution (solid circles) was limited to the last millisecond of the electron beam pulse. The distributions indicate a low incident ion energy but clearly differ in breadth and shape. Complimentary probe data, measured on the beam axis and directly above the electrode, is shown in Fig. 3a. During the course of one period, the electron temperature was characterized by larger values just after the plasma was initiated, followed by a period of near steady-state values, and then a collapse in the afterglow. The electron temperature determines the plasma potential, which then sets the energy range of ions incident to the electrode from the plasmas. It's not surprising then, that the ion energy distribution acquired over the entire period (open circles in Fig. 1) was characterized by a broader energy distribution than the distribution measured when the electron temperature was nearly constant (solid circles in Fig. 1).

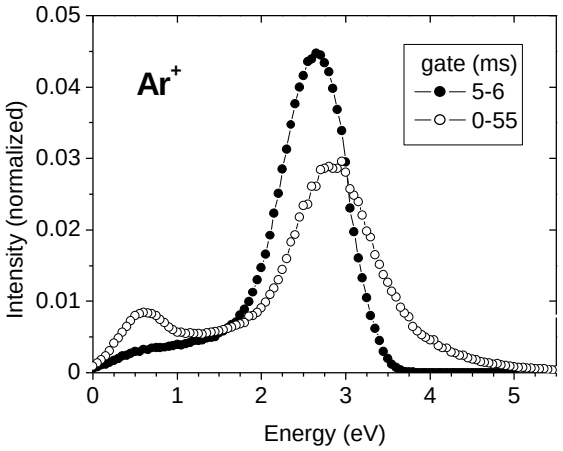

Fig. 2 Ar^+ ion energy distributions measured at a grounded electrode.

Also shown in Fig. 3 are the on axis plasma density and the total Ar^+ ion flux at the electrode. From these plots, it can be seen that the density and flux are reasonably well correlated. The slight temporal difference in relative intensities is expected since the density was measured on-axis and the flux was measured 2.5 cm from the electron beam axis.

A time-dependent ion flux adds a degree of freedom when considering possible surface effects in materials processing applications. A more detailed discussion of the temporal dependencies in argon plasmas can be found in [6]. Important to the etching applications is that the ion flux to the grounded electrode was characterized by low ion energies (< 5 eV). This provides the possibility of exploring the etch response at or near sputtering threshold energies in a high flux, low pressure environment. To explore higher ion energies, an applied bias is required. Previous studies [10] showed this can

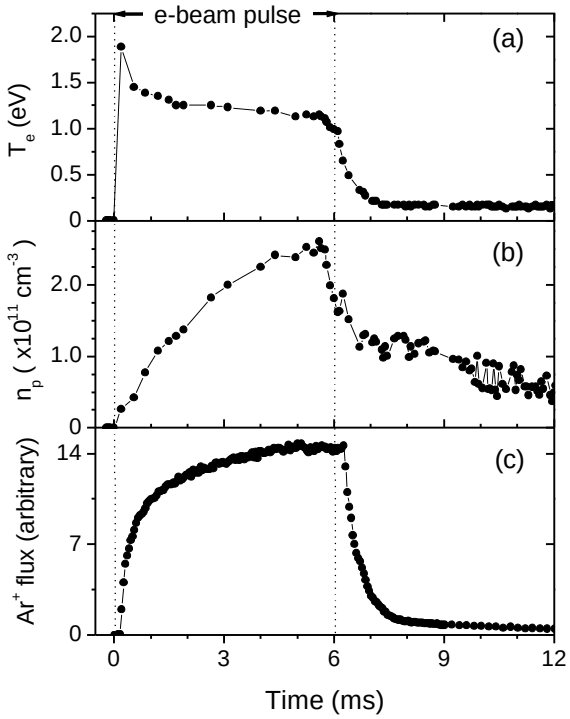

Fig. 3 (a) Electron temperature and (b) plasma density measured on the electron beam axis and (c) the Ar^+ ion flux measured at a grounded electrode located 2.5 cm from the beam axis.

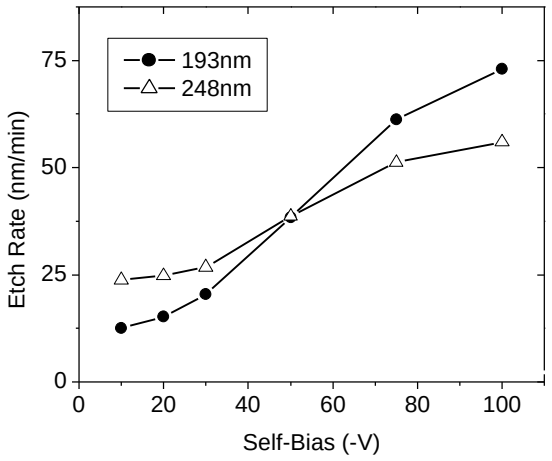

Fig. 4 Photoresist etch rate in electron beam-generated plasmas produced in argon.

be accomplished without altering the electron temperature, thereby providing a narrow energy distribution about a selected energy.

Photoresist Etching

Our work to date has focused on etch rate and limited surface characterization. The etch rate as a function of substrate bias and plasma duty factor for both 248 nm and 193 nm photoresist material are shown in Figs. 4 and 5. The substrate bias is the self-bias induced by the applied rf power, measured by the voltage probe. The experiments of Fig. 4 were carried out using a 4 ms pulse width and a 20% duty factor for a fixed exposure time of 2.5 min. These results are interesting in that the etch rate for the 248 nm photoresist is greater than the rate for the less stable 198 nm photoresist at low self-biases. For self-biases above –50 V the opposite was true, which is consistent with the results found using a transformer coupled plasma source operating at a self-bias of –100 V [4]. The finding of a larger etch rate for the 248 nm photoresist, which is based on a more stable aromatic backbone, compared to the 193 nm material at the low self-bias voltages is surprising. The reason for this behavior is currently being investigated.

The results of Fig. 5 indicate no strong dependence on the duty factor for a fixed pulse width (10 ms) and total exposure time (26 s), using a –10 V self-bias. Note that the relative etch depths shown were normalized by the forward rf power, to eliminate any difference in plasma production caused by operating at widely varying duty factors. Note however, that the slight increase in the etch depth of the 193 nm material with increasing off time suggests the initiation of reactions producing volatile products by the plasma exposure. These reactions, once initiated, will continue without additional particle bombardment and are consistent with a reduced chemical stability of the 193 nm material.

We also have performed ellipsometry, contact angle, and x-ray photoemission studies of plasma-treated photoresist materials. These show increasing surface roughness of both photoresist materials and changes in chemical structure of the 193 nm photoresist material after processing. Results of these studies will be reported in a future publication.

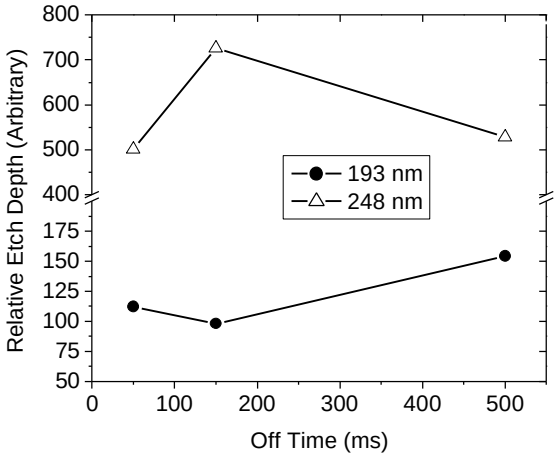

Fig. 5 Photoresist etch rate as function of plasma duty cycle. Off time indicates time between pulses.

4. Summary

Pulsed, electron beam-generated plasmas produced in argon were used to study the etch behavior of 193 nm and 248 nm photoresist material. Plasma diagnostics show the electron temperature, plasma density, and incident Ar^+ have clear time dependencies but in general, the plasmas are characterized by low electron temperatures (1 eV), high densities ($>10^{11}$ cm^3), and low ion energies (< 5 eV) at adjacent grounded electrodes. The etch rates for the photoresist materials were determined for a range of processing conditions. Interestingly, the etch rate of 193 nm photoresist was found to be lower than the etch rate of 248 nm photoresist for low substrate biases (incident ion energies below 50 eV) but was consistent with previous findings at higher bias conditions. Additional work is planned to further explore these behaviors.

Plasma polymer-coated pigments for use as corrosion inhibitors in organic coatings

Lin Yang, Hrishikesh Manian and W.J.van Ooij

Department of Chemical and Materials Engineering, University of Cincinnati, Cincinnati, OH-45221, USA

Abstract

Various metal corrosion inhibitors can be added to organic coatings to give them a self-healing property, namely, the corrosion inhibitors can protect the metal, when organic coatings on the metals are damaged, by diffusing to the exposed area. Chromate is one of the most effective and widely used corrosion inhibitors. Unfortunately it has to be replaced, due to its toxicity and carcinogenicity. Many candidates, which can chemically interact with metals and protect them, have been proposed as chromate replacements. However, one of the disadvantages of these pigments is that they are generally too soluble in water. Owing to this, the corrosion inhibition effect cannot be sustained over a longer period of time and the corrosion protection offered by the coating is compromised.

Hydrophobicity and reduced solubility of pigments can be achieved by using a plasma polymerization technique to encapsulate pigments with a hydrophobic film polymerized from fluorine-containing monomers. By tailoring the surface property of pigments in the plasma process, various pigments can be converted into suitable anti-corrosion pigments, which can enhance corrosion prevention for longer periods of time and improve the barring effect of the organic coating system on metal.

In this work, water soluble cerium acetate and sodium vanadate pigments were coated with plasma-polymerized perfluorohexane and octafluorotoluene films. Perfluorohexane does not have a high deposition rate. Therefore, faster-depositing films of octafluorotoluene were used in the latter part of the work. The coated pigments were used as corrosion inhibitors in a water-based organic coating in which the slow release effect of the pigments increases the corrosion resistance of the coating. The coated pigments were tested in an organic primer coating on aluminum alloys for their corrosion inhibiting ability.

Keywords: plasma polymer, corrosion, pigment, hydrophobicity, surface property.

1. Introduction

Corrosion of metals and alloys is a major problem confronting many industries such as automotive, aerospace, and building materials the world over. Organic primer coatings applied on surfaces of metals have been one of the most effective methods to protect metals from corrosion. However, metals may be corroded when any damage happens to organic primer coatings. In this case, inhibitors can be extremely critical in providing corrosion resistance for many metals. Many families of pigments, such as cerium compounds, vanadate, molybdate have been studied and proven to be promising corrosion inhibitors [1-3]. However, one of the disadvantages of these inhibitors is that they are generally soluble in water. Owing to this, those corrosion inhibitors cannot be used in organic coatings on metals and corrosion inhibition effects cannot be sustained over

a long period of time. A slow release property can be achieved by embedding these pigments in a polymer matrix [4]. Plasma polymerization has been explored for obtaining slow release property of organic pigments by coating with a hydrophobic layer of perfluorohexane [5]. Perfluorohexane does not have a high deposition rate and due to this the pigments have to be coated for a long time. In this work we used octafluorotoluene of faster depositing rate. The coated inorganic pigments were tested in organic primer coatings for their slow release property.

2. Experimental

2.1 Plasma polymer coating of the pigments

Perfluorohexane (C_6F_{14}, 95%) and octafluorotoluene (OFT, 98%) provided by Alfa Aesar Inc. were used as monomers to coat cerium acetate (CeAc) pigment and sodium vanadate which were obtained from Alfa Aesar and Fluka, respectively. The process of plasma polymer coating was carried out in a desktop plasma reactor set up with a Pyrex flask set as shown in Figure 1. The top portion was a vertical tube of 130 mm length and 60 mm diameter. The diameter of the flask at the bottom was 75 mm diameter. Two inlets were provided for monomer and pressure gauge. The inductively coupled plasma was excited using an RF generator operating at 13.56 MHz.

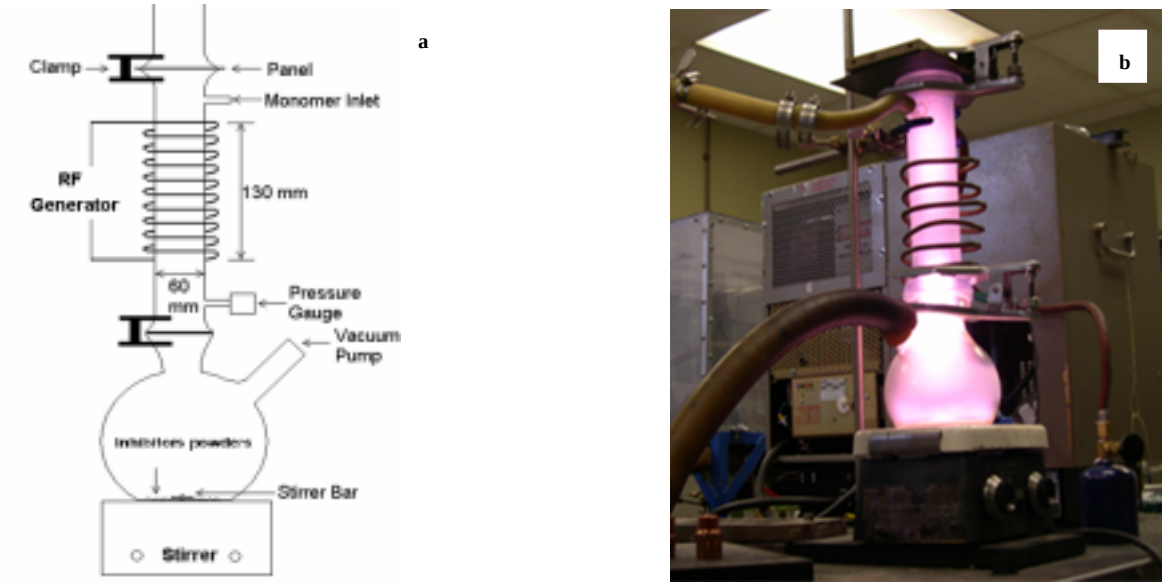

Fig. 1. Schematic view (a) and photograph(b) of the vertical plasma reactor used in this work

Pigment was coated with each monomer respectively. 10 g of the pigment was put in the bottom flask of the reactor. The reactor was pumped down to 7 Pa after which the monomer was introduced till the pressure reading was 45 Pa. The plasma was then generated at a power of 80 W. The pigments were coated for 30 to 60 minutes with continuous stirring by means of a magnetic stirrer.

2.2 Deposition rate study of monomers and characterization of polymer polymerization coating

The deposition rate of the monomers in process of plasma polymer coating was measured by Thermo Gravimetric Analysis (TGA). Ball clay obtained from Kentucky-Tennessee Clay was chosen to be coated in conditions similar to the pigments because it would not decompose before all the plasma polymer coatings were

removed in TGA. The deposition rates were calculated using a similar formula as in [6]. The dynamic wicking properties of pigment particles were measured by using a Lesca dynamic wicking meter. A certain amount of pigment powder was filled in the cylindrical glass tube with an end sealed with nylon mesh. The glass tube was tapped 200 times to ensure the pigment powder was tightly packed. The nylon mesh-sealed end of the vertically placed glass tube was contacted with water in a beaker. By the capillary attraction, water penetrated the pigment powder column through the contact of the nylon mesh with water. The penetration rate of water into the tapped column of pigment was measured using a four digits balance. The contact angle of the powder was calculated using the formula in [7] to determine the increase of hydrophobicity between the surfaces of plasma polymer-coated and uncoated pigment particles.

2.3 Study of slow-release property and durable corrosion inhibition of coated pigments

Fresh AA-2024 T3 substrates were ultrasonically cleaned in ethanol and DC polarizations were carried out on those cleaned AA-2024 substrates in 3.5 w.% sodium chloride solution in the presence of 2000 ppm of the OFT-coated cerium acetate. DC polarization curves were plotted at 10, 100 and 300 hrs. 2000 ppm uncoated cerium acetate and the OFT-coated cerium acetate were added respectively to deionized water to make solutions for conductivity measurement. Conductivities of the freshly prepared solutions were measured using YSI 3200 conductivity meter to verify the slow release properties of plasma polymer-coated pigments.

An organic primer coating was formulated from water based resins and silane. Acrylic resin ECO-CRYL and epoxy resin WD-510 were obtained from Resolution Corporation. Bis-[triethoxysilyl]ethane (BTSE) was provided by Gelest Inc. 1 w.% of pigment was mixed into the organic primer coating by a high shear blender for 5 minutes. The organic primer coating with the pigments uniformly dispersed in it was then applied on the AA-2024 T3 aluminum alloy substrates. Electrochemical Impedance Spectroscopy (EIS) studies were done on these coatings pigmented with plasma-polymer coated pigments by using the ECM8 Electrochemical Multiplexer from Camry Instruments and to test corrosion inhibition of the slowly released pigments over a long period of time.

3. Results and Discussion

3.1 Deposition rate of the monomers

The results of the deposition rate study are shown in Table 1. The OFT shows a deposition rate of 0.335 x 10^{-3} g/cm^2-min, almost three times of the value obtained by perfluorohexane. The deposition rates were calculated by the following formula and listed in Table 1.

Deposition Rate $= \frac{W}{T \times A}$, where, w is weight of deposited film obtained from TGA; T is deposition time; A is total area of pigments used for each run in TGA.

Table 1. The deposition rate results of C_6F_{14} and OFT obtained from TGA

Monomer	Film Weight (mg)	Total Area of Pigments (cm^2)	Treatment time (min)	Deposition rate 10^{-3} (g/cm^2-min)
C_6F_{14}	1.49	185.63	60	0.134
OFT	1.24	123.6	30	0.335

3.2 Wicking Property Studies

The pigments before plasma polymer coating were hydrophilic and of a small contact angle as can be seen from Table 2. The hydrophilic nature of the pigments can impair the corrosion resistance of organic primer coatings. With octafluorotoluene or perfluorohexane, surface modification could be carried out to increase the hydrophobicity of the pigments. As shown in Table 2, the plasma polymer coating from octafluorotoluene increases the water contact angle of the cerium acetate pigment by 60° and for sodium vanadate pigment by 18°. The perfluorohexane increases the contact angle by 42° in the cerium acetate pigment and by 15° for the sodium vanadate pigment. The increased hydrophobicity can be attributed to the presence of fluorine and the highly cross-linked structure in the deposited plasma polymer films.

Table 2. The wicking properties of the untreated and treated CeAC and BTA pigments

Pigment	Penetrating Water Weight (g)	Contact Angle (º)
CeAc	0.62	22
pp-OFT- CeAc	0.31	82
pp-C_6F_{14}- CeAc	0.38	64
$NaVO_3$	0.55	70
pp-OFT- $NaVO_3$	0.14	88
pp-C_6F_{14}- $NaVO_3$	0.22	85

3.3 Slow Release Studies of the Coated Samples

The results of DC polarization studies for 300 hours are plotted in Figure 2. The DC polarization curves for the OFT-coated cerium acetate pigment were shifted to a lower negative corrosion potential as the testing time increases from 10 hours to 300 hours. The cathodic portion of the curve also shifted to the left side, which indicates the pigment was slowly released through the plasma polymer coating and inhibited the cathodic corrosion reactions on the fresh prepared AA-2024 T3.

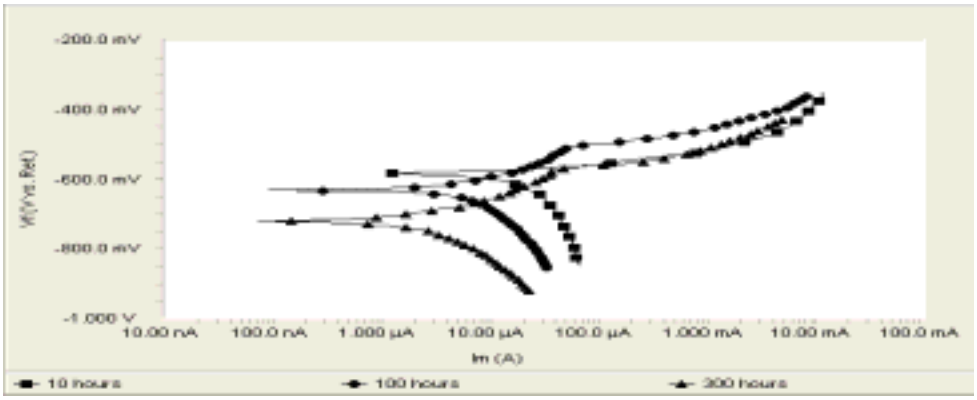

Fig. 2. DC Polarization curves of AA-2024 T3 in the solutions of 3.5% NaCl with 2000 ppm of the OF- coated CeAc for 300 hours

The conductivity measurement curves of cerium acetate and the OFT-coated cerium acetate are shown in Figure 3. The conductivity of uncoated cerium acetate ramped up to 800 μS within 60 seconds and kept constant till measurement was completed. It showed uncoated cerium acetate was very soluble and dissolved quickly on adding to the deionized water. The conductivity of the OFT-coated cerium acetate increased at a much slow rate than uncoated cerium acetate. After 250 seconds, the increasing rate of conductivity remained a constant value which demonstrated the OFT-coated cerium acetate can be slowly released at a certain low rate over a long time.

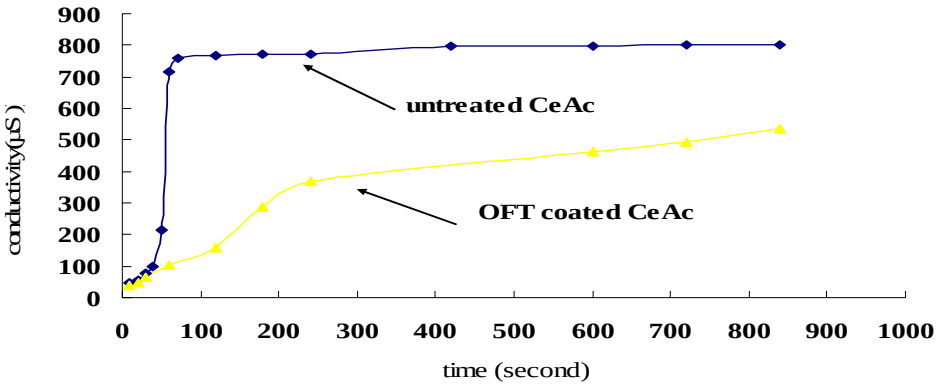

Fig. 3. Conductivity of OFTcoated CeAc and uncoated CeAc

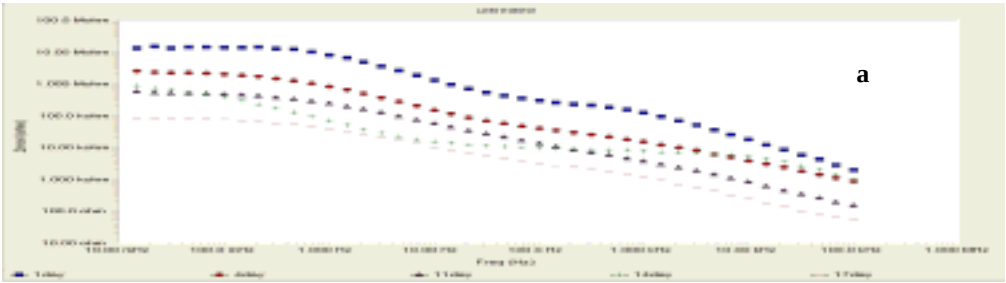
3.4 Corrosion Study

The corrosion performance of pigments in the organic primer coating was characterized by EIS. Figure 4 (a) shows the EIS curves of primer coating pigmented with 1 w.% cerium acetate without plasma treatment. The modulus in low frequency around 10 mHz decreased continuously in the period of test, which indicated the corrosion resistance kept reducing. Also, as test time increased, the curve showed more time constants where the slopes of curve changes. It may probably be caused by considerable amount of water uptake by the hydrophobic cerium acetate pigment. However, the primer coating pigmented with 1 w.% OFT-coated cerium acetate displayed a much better anti-corrosion performance. In Figure 4 (b), the low frequency modulus barely decreased for seventeen days and the slope of curve remained constant indicating little water penetrated the pigmented primer coating and no corrosion products were formed underneath the primer coating. This may be ascribed to hydrophobicity of the OFT-coated pigment which improves the water resistance of whole system and corrosion inhibition of the slowly released pigments. In Figure 4 (c), The OFT-coated sodium vanadate exhibited a slow release property and improved the corrosion resistance of the coating too.



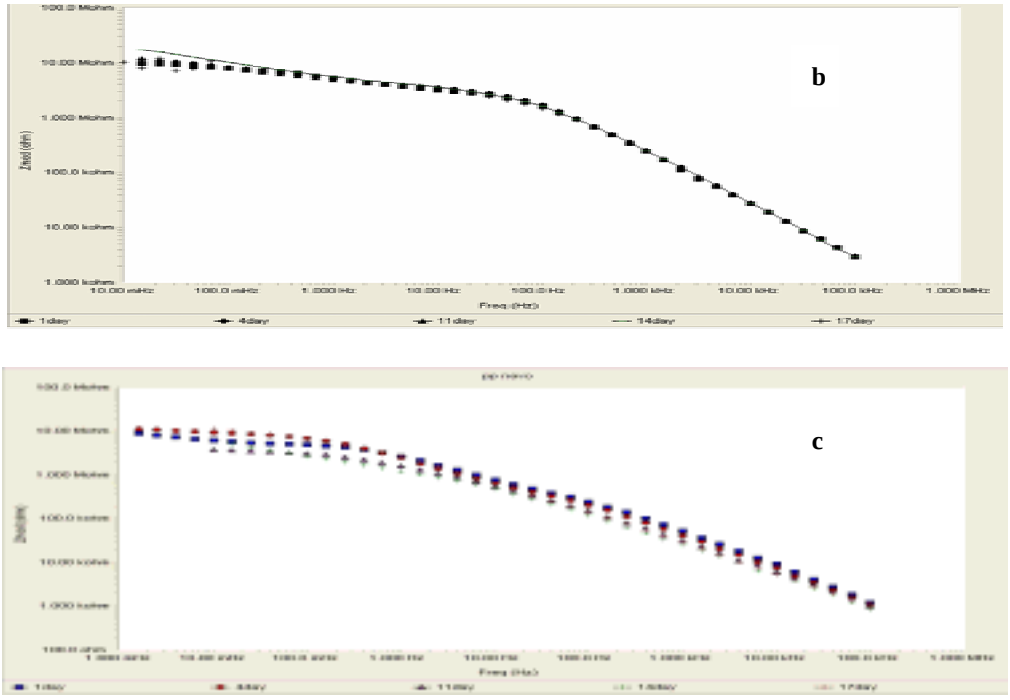


Fig. 4. EIS Bode plots of (a) uncoated CeAc, (b) OFT-coated CeAc, (c) OFT-coated $NaVO_3$ in 3.5% NaCl for 17 days.

4. Conclusions

Plasma polymerization can be used to modify the surfaces of pigments and thus convert hydrophilic pigments to hydrophobic inhibitors for organic primer coatings on metals. The plasma polymer-coated pigments are suitable to be incorporated in primer coating properly and enhance the corrosion protection by slowly be released to the exposed area of the scratched primer coating. By choosing the monomer for plasma polymerization, the deposition rate may be optimized. As demonstrated in our study plasma polymerization of octafluorotoluene has a faster deposition rate as compared to the perfluorohexane.

Abstract
In present paper we give some new results on our previously reported hard DLC/SiO_x films deposited from the mixtures of CH_4 and HMDSO and compare them with similar films deposited from CH_4/HMDSO/H_2 mixtures using a different generator. We show that significant drawbacks of the DLC films, high intrinsic stress, bad thermal stability and absorption in the visible range, can be limited by an incorporation of the SiO_x component and we notice that this conclusion is achieved for many DLC/SiO_x films in spite of the different method of preparation and, more surprisingly, of their different structure. However, particular film properties can be further improved by an optimization of the deposition conditions as concluded from the higher hardness of the films deposited from the CH_4/HMDSO/H_2 compared to the CH_4/HMDSO feed.

1. Introduction

The ability of carbon to form three different bonding states, sp^3, sp^2 and sp hybridizations, leads to the variety of synthesized materials containing just this one element. In case of chemical vapor deposition (CVD) where carbon is gained from various hydrocarbon gases we find a broad class of hydrogenated carbon materials, usually amorphous (a-C:H), in which the percentage of hydrogen is additional free parameter varying the material property. Although, there is a little confusion about the term "diamond like carbon" (DLC) we can concluded, according to Robertson [1], that DLC is an amorphous carbon (a-C) or a-C:H material containing high fraction of sp^3 bonding. According to their name the DLC films exhibit properties similar to diamond such as high hardness, good wear resistance, very low friction coefficient, transparency in infrared, good chemical inertness as well as high thermal and low electrical conductivity. Consequently, these films find a variety of applications for example as antireflective coatings, as insulators or semiconductors in microelectronics, biomedical coatings, protective coatings for magnetic recording discs and low friction, wear resistant coatings for micro-electromechanical devices (MEMs). In spite of their valuable properties, however, DLCs have also some drawbacks, namely bad thermal stability, high intrinsic compressive stress and absorption in the visible range. Therefore, the incorporation of other elements like silicon, oxygen, nitrogen or various metals into the amorphous network of DLC has been studied in last decade [2,3].

Based on actual search for nanocomposite materials and their unique properties, the DLCs containing silicon oxides (SiO_x), often referred as DLC/SiO_x nanocomposites, were prepared by various methods and their usefulness was evidenced by low intrinsic stress while keeping the other good mechanical properties of DLCs [4-7] and by improved thermal stability [8]. Moreover, Senkevich *et al.* [9] pointed out that these films exhibit significantly decreased absorption in the visible range that might be necessary for certain applications. The methods for preparation of DLC/SiO_x films can be divided into three categories, (i) hot filament PECVD using for example polyphenylmethylsiloxane [10] or polyvinylsiloxane [11] precursors with r.f. or d.c. biased substrate, (ii) r.f. capacitively [5,8,9] or inductively [7] coupled PECVD using tetraethoxysilane (TEOS) [5,8,9] or hexamethyldisiloxane (HMDSO) [7] and (iii) ion beam assisted deposition with sputtering of Si/SiO_2 target in hydrocarbon gas atmosphere [12]. It should be noted that in the r.f. PECVD approach a hydrocarbon gas (methane, styrene) is added to the organosilicon, besides argon or hydrogen [5,7,8]. Several authors assume that their films, although sometimes prepared by different method, have the same structure of two interpenetrating chemically weakly bonded amorphous networks, a-C:H and a-Si:O, as suggested by Dorfman [4,11]. In some cases, however, the arguments are not quite clear especially when, unlike Dorfman, they found the presence of Si-C bonds in the

films [6,12]. In this sense an exceptional structure of DLC/SiO_x nanocomposites, SiO_x nanoparticles embedded in a-C:H matrix, was reported by Chen and Hong [7].

2. Experimental

The films were prepared in r.f. glow discharges from the mixture of methane (CH_4) and HMDSO. The reactor was a vertically mounted Pyrex® cylinder closed by two stainless steel flanges with two inner parallel plate electrodes made of graphite. A detailed description of the reactor is given in Ref. [13]. The upper electrode was grounded. The bottom electrode was coupled to an r.f. generator (13.56 MHz) via a blocking capacitor. The diameter of the r.f. electrode was 150 mm and the distance between the electrodes was 55 mm. The r.f. voltage of the electrode was superimposed by a negative d.c. self-bias. The self-bias was a result of different electron and ion mobilities and a high asymmetric coupling, i. e. different areas of r.f. driven and grounded and/or floated surfaces in touch with plasma. The substrates for deposition (silicon wafers and glass) were placed on the r.f. electrode in order to achieve the film growth under bombardment of energetic ions. The flow rate of CH_4 was fixed at 1.4 sccm. The flow rate of HMDSO changed in the range 0–0.82 sccm in order to vary the flow rate ratio $q = Q_{\mathrm{HMDSO}}/Q_{\mathrm{CH4}}$.

The first series of the films (denoted as DSi) was prepared from various CH_4/HMDSO feeds using the r.f. generator PG 501 at the fixed power of 250 W as showed on the generator wattmeter. The total pressure before the deposition changed, due to the variation of the total gas flow, in the range 8–11 Pa. The negative self-bias U_{bias} varied from -320 V to -550 V as a function of the gas feed composition and the pressure. The second series of the films (denoted as HDS) was deposited with addition of hydrogen in the amount of 0.35 sccm to the CH_4 and HMDSO mixture using the r.f. generator Dressler. In this series the power was fixed at 50 W as given by the generator wattmeter in order to reach a similar range of the self-biases. The similar self-bias values were taken for the deposition instead of the same r.f. power because it was assumed the self-bias played more important role for the deposition than the power. Moreover, the question about a correct power measurement, especially in case of the generator PG 501, arose in relation to the power and self-bias discrepancy. The decision to keep the self-bias constant rather than power was confirmed by comparing the film properties such as hardness and intrinsic stress.

Films deposited on the silicon substrates were characterized by a UVISEL Jobin-Yvon phase modulated ellipsometer in the spectral range 240–830 nm at the incidence angles 55°–75°. The structure of the films was studied with transmittance measurements in the infrared (FTIR) and X-ray photoelectron spectroscopy (XPS). The complete atomic composition was determined by a combination of Rutherford backscattering (RBS) and elastic recoil detection (ERD) methods. The atomic fractions of C, O and Si were measured by RBS using 2.4 MeV protons perpendicularly bombarding the surface. ERD and RBS with an incident beam of 2.75 MeV α-particles at 75° to the surface normal were simultaneously used to determine the percentage of H.

The depth sensing indentation (DSI) was carried out on the films deposited on the glass substrates using a Fischerscope H100 tester (Vickers). Load-penetration curves were analyzed for several values of maximum applied loads from the whole possible load range of 1–1000 mN to asses the mechanical properties of the films such as hardness H, elastic modulus $Y = E/(1-\nu^2)$, where E is the Young's modulus and ν is the Poisson's ratio of the films and the like. The measured characteristics were corrected for the influence of the low elastic modulus and hardness of the glass substrate as discussed in the next section. The Vickers indentation may introduce substantial cracks and adhesive failures into the thin films. Analyzing the morphology of the indentation prints and measuring the critical load for cracking and/or delamination, it was possible to determine other material characteristics such as the fracture toughness and adhesive properties of the films [14].

3. Results and Discussion

In present paper we give some new results on our previously reported hard DLC/SiO_x films deposited from the mixtures of CH_4/HMDSO, i. e. the first series of the films as described in Experimental (DSi series), and compare them with similar films of the second series (HDS series) deposited from CH_4/HMDSO/H_2 mixtures using a different generator.

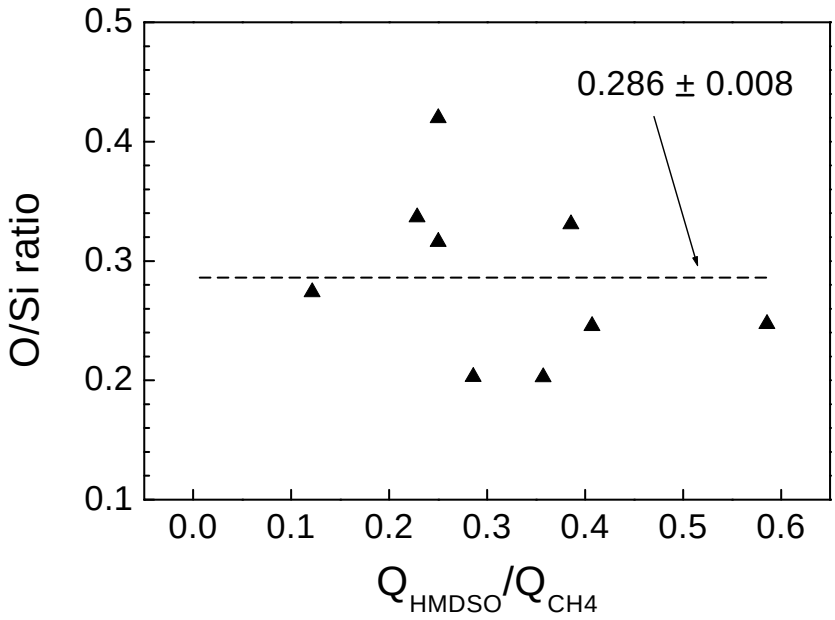

Figure 1: Oxygen-to-silicon ratio in the DLC/SiO_x films (DSi series) as a function of the HMDSO-to-methane flow rate ratio in the deposition mixture.

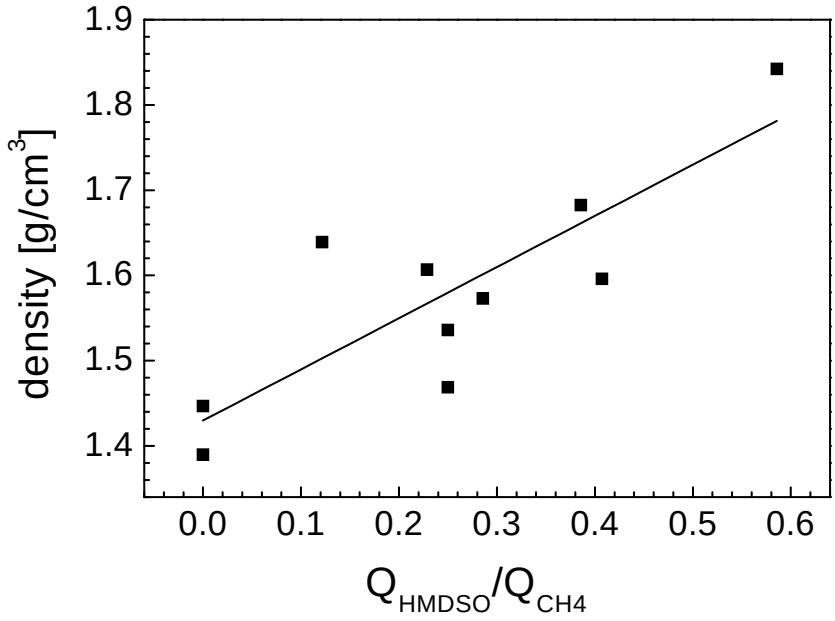

Figure 2: Density of the DLC/SiO_x films (DSi series) as a function of the HMDSO-to-methane flow rate ratio in the deposition mixture.

Table 1: Comparison of DLC and DLC/SiO_x films deposited with or without addition of hydrogen in the gas feed. The flow rate of CH_4 was 1.4 sccm. The atomic concentration of elements denoted by asterisk were obtained by an interpolation between two values for the closest HMDSO flow rates.

film	Q_{HMDSO} [sccm]	Q_{H2} [sccm]	U_{bias} [V]	C at. %	H at. %	Si at. %	O at. %	H [GPa]	Y [GPa]
DSi52	0	0	-320	63.5	35.8	0.3	0.5	23.0	159
HDS33	0	0.35	-544	54.6	42.0	0.6	2.8	25.4	167
DSi50	0.25	0	-460	50.3*	41.6*	5.9*	2.0*	18.8	123
HDS7	0.25	0.35	-460	45.8	44.0	7.2	3.0	23.3	127

As concern the DSi films a correlation between the HMDSO-to-methane flow rate ratio q and their deposition rate, atomic concentrations of C, H, Si and O elements in these films, their optical constants, plastic hardness and elastic modulus as well as the critical indentation depth for initiation of interfacial cracks was presented in Ref. [15]. It was shown that with increasing flow rate ratio q the concentration of Si, O and H increases on the expenses of C. However, the oxygen-to-silicon ratio in the films is scattered around a constant value of 0.286 ± 0.008 as depicted in Fig. 1. One can notice that this value is relatively low when compared with some other authors reporting to have this film component close to silicon dioxide [7,9]. As q varies from 0 to 0.6 the percentage of the $SiO_{0.29}$ component in the film increases up to 14 %. The density of the films is proportional to the q (see Fig. 2). However, all the films containing SiO_x have very similar values of the molar density which is in turn comparatively higher than in the pure DLC films from this series. Since the molar density evidences a degree of film packing the observed instantaneous increase of the film density is caused by replacement of lighter elements (C, H) by heavier Si and O.

The comparison of atomic compositions on the film surface as determined by XPS and in the film bulk by RBS shows that the film surface is more oxidized having the oxygen-to-silicon ratio (O/Si) as high as 2.5 for the lowest addition of HMDSO to CH_4 ($q = 0.17$). Contrary to the constant value in the film bulk the O/Si ratio on the film surface decreases with increasing percentage of HMDSO in the gas feed. This dependence levels out at about $q = 0.3$ reaching the stable, although quite scattered, value in the range 0.8–1.6. The relatively high amount of oxygen, 11.5 at. % (hydrogen excluded from considerations because it cannot be detected by the XPS), is found on the surface of pure DLC films. Moreover, some DLC films contain certain amount of oxygen, 1.6 at. % (excluding hydrogen), even in the bulk. Therefore we believe that the incorporation of the SiO_x component into the structure of DLC prevents a film oxidation since the silicon oxide layer at the surface serves as a barrier for oxygen.

Further information about the chemical structure of the DSi films was obtained from deconvolution of XPS atomic signals and FTIR. Both the methods confirm the presence of Si-C bonds, either on the surface or in the bulk, which is not observed for some DLC/SiO_x nanocomposites [4,7]. The percentage of Si-C bonds on the surface increases from 7 % for $q = 0.17$ up to 28 % for $q = 0.62$ on the expenses of C-C, C-H and C-O bonds. All the silicon related infrared absorption peaks are increasing in intensities with increasing HMDSO in the gas feed. However, the complex absorption band extending from 650 to 900 cm ^{1}, which contains the contribution from Si-C, Si-$(CH_3)_n$, Si-O-Si and Si-CH_2 bond vibrations, does not change its shape suggesting that the relative amount of Si-C bonds with respect to Si-O is stable.

Although the film hardness decreases with increasing q this tendency is very slow for q below 0.25 and the films deposited at q around 0.25 exhibit significantly improved fracture toughness [15]. This means a certain optimum amount of HMDSO in the gas feed can be found where the high hardness of the DLCs is pertained but simultaneously the high compressive intrinsic stress is significantly lowered. This effect can be further improved by an optimization of the deposition conditions as concluded from the higher hardness of the film HDS7 deposited from CH_4/HMDSO/H_2 compared to the film DSi50 deposited from CH_4/HMDSO feed (see Table 1). An example

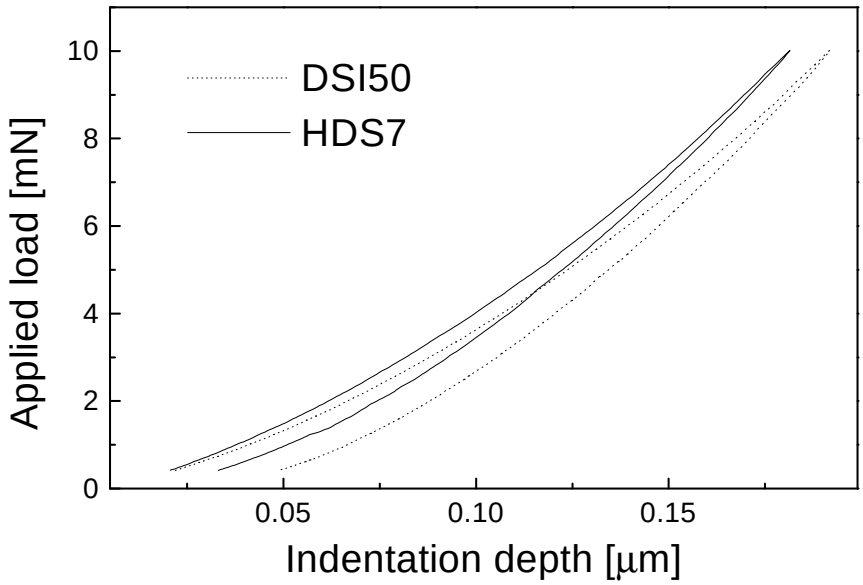

Figure 3: Loading and unloading curves for DLC/SiO_x films deposited at the HMDSO flow rate of 0.25 sccm without (DSi50) or with hydrogen (HDS7) in the gas feed. For the film atomic composition, hardness and elastic modulus of these films see Table 1.

of the loading and unloading curves for these two films is given in Fig. 3. From Table 1 we can see that the higher hardness of the DLC and DLC/SiO_x films deposited from the CH_4/HMDSO/H_2 mixture is related to a lower carbon-to-hydrogen ratio in the films. This effect will be studied in forthcoming paper.

Besides an improved fracture toughness of the DLC/SiO_x films an addition of the SiO_x component improves their thermal stability. This fact was discussed in details for the films from CH_4/HMDSO and CH_4/HMDSO/Ar gas feed in Ref. [16].

A detail study of the optical constants for the films of DSi series by combination of the spectroscopic ellipsometry and reflectometry using the dispersion model based on a parameterization of density of electronics states belonging to the valence and conduction bands showed that the absorption in the visible decreased in the DLC/SiO_x films with respect to the pure DLCs [17]. Similar conclusions were found in Ref. [18] for the films of the HDS series.

4. Conclusion

We have shown above that significant drawbacks of the DLC films, high intrinsic stress, bad thermal stability and absorption in the visible, can be limited by an incorporation of the SiO_x component. It is interesting to notice that this conclusion was achieved for many DLC/SiO_x films in spite of the different method of preparation and, more surprisingly, of their different structure. Here, we have compared two different series of the DLC/SiO_x films, particularly the films deposited from CH_4/HMDSO and CH_4/HMDSO/H_2 mixtures.

Abstract

An experimental investigation of detonation initiation by high-voltage nanosecond gas discharge was performed. The experiments were carried out in mixtures $C_3H_8+5O_2$ and $C_3H_8/C_4H_{10}+5O_2+xN_2$ ($0 \leq x \leq 10$) at initial pressure 0.15–0.6 atm. The discharge was allowed by an electric pulse with a duration of ∼60 ns and an amplitude of 4–70 kV. The energy deposition in the discharge ranged from 70 mJ to 12 J. Ignition delay time, speed of the flame front, electrical characteristics of the discharge were measured in the experiments. At conditions of the experiment we observed three modes of propagation of flame front: deflagration, transient detonation and Chapman-Jouguet detonation. Observations of discharge development and formation of the flame front were performed with the aid of an ICCD camera. In mixture $C_3H_8+5O_2$ a length of the deflagration-to-detonation transition amounts up to 130 mm at initial pressure of 0.3 atm and initiation energy of 70 mJ.

Experimental

The nanosecond discharge as a source of ignition has a set of advantages [1, 2]: high spatial uniformity, high efficiency of formation of reactive species, high power and coherence.

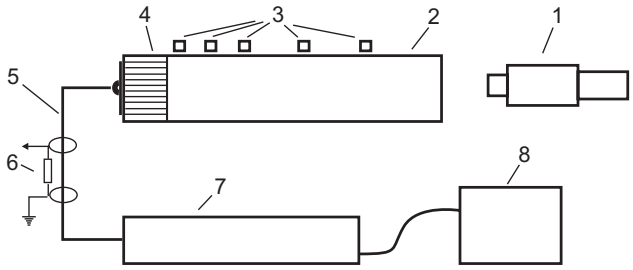

Figure 1: Scheme of experimental setup. 1 – ICCD camera, 2 – detonation tube, 3 – IR detectors, 4 – discharge chamber, 5 – high-voltage coaxial line, 6 – back-current shunt, 7 – high-voltage pulse generator (Marks type), 8 – power supply.

The experimental setup used is shown on fig. 1. The experiments were performed in a detonation tube with a diameter of 140 mm. The discharge device was attached to the end-plate of the detonation tube. The discharge chamber consists from 131 separated sections, which have common high-voltage and grounded electrodes. The discharge device provides uniform excitation at the length of 80 mm. The discharge chamber and the detonation tube are separated by an orifice plate. The orifices are arranged opposite to the each electrode. In the experiments the high voltage electrodes were supplied with a positive pulse with amplitude of 4–70 kV and duration at the half-width of 50 ns. Calculated reduced electric field ranges from 300 Td to 7000 Td near the high-voltage electrode. Given values of the reduced field lies in a range, which is optimal for ignition by discharge [1].

The high-voltage electric pulse was produced by a high-voltage pulse generator. The generator was assembled by Marks scheme. The Marks generator consists of 15 stages with capacity of 6 nF. The amplitude of the output pulse was adjusted by a voltage of a charge power supply. The Marks generator was driven by an auxiliary spark generator. The amplitude and duration of the output pulse were measured by a back-current shunt and capacitive gauge, which were mounted on a high-voltage feed line. The high-voltage line has coaxial geometry with water filling. The electric impedance of line Z was equal to 16 Ohm. The pulse reflected from the high-voltage electrode was not observed. The energy of discharge was calculated from the signal of back-current shunt.

Five IR detectors are placed along the axis of detonation tube. The detectors have a sensitivity range of 0.9–3.5 μm. They record an IR-emission of H_2O and CO_2. The flame speed was calculated from profiles of a voltage on the IR detectors. The speed of the detonation wave was measured with an accuracy of 80 m/s (3%) and the speed of the deflagration wave was measured with an accuracy of 20 m/s (7%).

Initial gas parameters: composition, pressure and temperature were measured in the experiments. The experiments were performed at initial pressures of 0.15–0.6 atm and ambient temperature in fuel mixtures: C_3H_8+5O_2 and C_3H_8/C_4H_{10} + 5O_2 + xN_2 (0≤x≤10), where C_3H_8/C_4H_{10} is a designation of liquified petroleum gas (LPG).

Ignition by Nanosecond Discharge

Firstly, we studied the influence of nitrogen on the ignition under the action of the nanosecond discharge. We measured induction time (fig. 2) and minimal ignition energy in mixtures C_3H_8/C_4H_{10} + 5O_2 + xN_2.

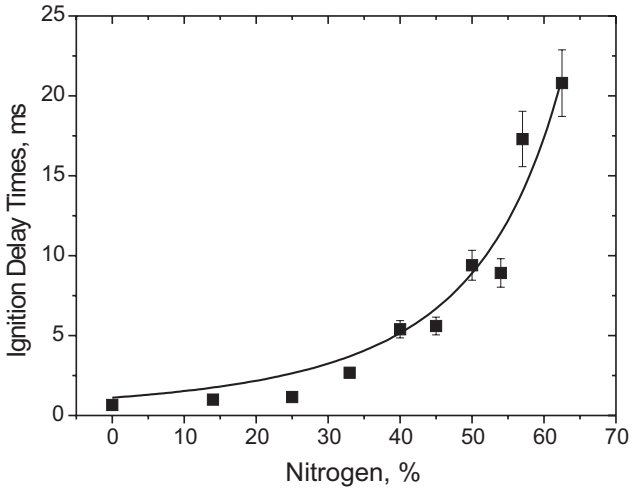

Figure 2: Ignition delay time in mixtures C_3H_8/C_4H_{10}+5O_2+xN_2 at initial pressure 0.3 atm. Line corresponds to eq. (**??**).

The nitrogen dilution: 1) decreases a ratio of the heat of combustion to the heat capacity; 2) decreases the concentrations of the fuel and oxygen; 3) increases a rate of recombination reactions; 4) decreases a formation of active particles. At high temperatures (1200–1800 K) the delay time of auto-ignition depends on the nitrogen dilution at fixed pressure as $\sim (1 - [N_2])^{-x}$, where x=0.45–0.65 [3]. In the case of auto-ignition the second consideration is the main. In our case the nitrogen dilution not only acts on chemical processes, but it reduces the generation of active species in the discharge. Probably, the forth consideration is stronger than others under the discharge ignition.

The induction time and the minimal ignition energy have the same dependence on the percentage of nitrogen in the mixture at a fixed initial pressure (fig. 3). The minimal ignition energy increases from 70 mJ at nitrogen fraction of 25% to 12 J at nitrogen fraction of 62.5%. The values of the energy of 0.07 and 12 J relate to the minimal and maximal operating energy of our discharge device. The energy deposition of 0.07 J corresponds to a heating of fuel mixture on 1 K. Hence the mechanism of the ignition is not a thermal. There is a critical value of active species produced by the discharge. The ignition progresses without an assistance, after the concentration of active particles exceeds the critical value.

The minimal ignition energy extrapolated to an nitrogen dilution of 77% amounts to 25 J. In our case the high value of the minimal ignition energy is explained by a high specific surface of the discharge device. The energy of the discharge is distributed among the 131 discharge section, which is a long tube with a ratio of the diameter to the length of 1/16. The high-voltage nanosecond discharge is characterized by a low energy deposition per an excited volume of a gas in contrast to other types of discharge. In the experiments this value was equal to approximately 0.3 J/l.

Modes of Flame Propagation

The fig. 4 is the summary plot of the experiments in the mixtures C_3H_8/C_4H_{10}+5O_2+xN_2 (0≤x≤10). The fig. 4 depicts the speed of the flame front measured at 412 mm apart from the discharge chamber. At relatively low pressures we observed a deflagration wave with a weak acceleration. At relatively high pressures we observed a C–J detonation wave. At intermediate conditions we observed a transient detonation wave.

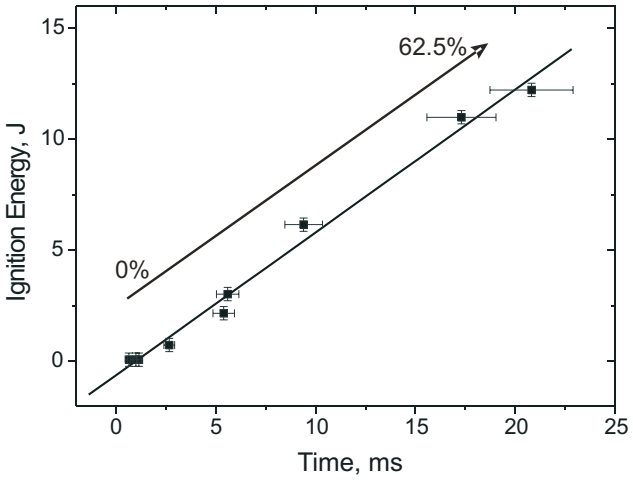

Figure 3: Minimum ignition energy and ignition delay time at difference nitrogen dilutions.

In this mode the flame front accelerates strongly on the motion in the tube. At these conditions the speed of the flame front increases from 500 m/s at position of 150 mm to 2000 m/s at position of 650 mm. It was ascertained that the mode of propagation of flame front is governed by the initial pressure and the mixture composition and the mode is independent of the discharge energy.

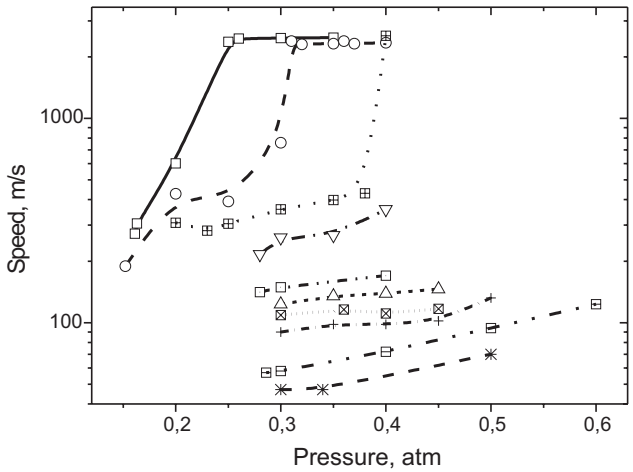

Figure 4: Speed of the flame front at 412 mm apart from discharge chamber in mixtures $C_3H_8/C_4H_{10}+5O_2+xN_2$. $\square$ – x=0 (0%), $\circ$ – x=1 (14%), $\boxplus$ – x=2 (25%), $\triangledown$ – x=3 (33%), $\boxdot$ – x=4 (40%), $\triangle$ – x=5 (45%), $\boxtimes$ – x=6 (50%), $+$ – x=7 (54%), $\boxminus$ – x=8 (57%), $*$ – x=10 (63%).

Formation of Flame Front

We carried out the observation of the discharge development and the formation of flame front through the end-plate of the detonation tube. The observation were performed using ICCD camera "La Vision Picostar 12 HR". The camera registers an emission in the range of wavelength of 300–800 nm. In the discharge the bandwidth $C^3\Pi_u,\ v' = 0 \rightarrow B^3\Pi_g,\ v'' = 0$ of nitrogen at 337 nm makes main contribution to the intensity.

The discharge has three time stages. On the first stage the emission intensity rises sharply. On the second stage the emission intensity falls sharply. The third stage is the after-glow stage. The duration of 1-st, 2-nd and 3-rd stages amounts ∼10, ∼50 and ∼500 ns, consequently. The durations of the stages increase with a rise of an initial pressure. The initial stage of the discharge (up to 10 ns) is spatially quasi-homogeneous, while in the subsequent stages the discharge localized over the few sections of the high-voltage electrode. After 0.5–10 ms (in relation to the initial conditions) from the moment of the discharge the mixture ignites in the discharge chamber. The flame is stronger in some sections of the discharge chamber than in others. Nevertheless the mixture inflames simultaneously and the flame front covers the whole cross-section of the

tube on the end-plate. A position of the flame front was determined by simultaneous measurements through the side-wall with the help of the IR sensors. When the flame front passes from the end-plate the length of the one diameter, the front is spatially homogeneous over the cross-section of the tube.

Initiation of Detonation

It were carried out special experiments to determine the conditions of the detonation initiation. The experiments were performed in $C_3H_8+5O_2$ mixture at initial pressure of 0.3 atm. An optimal conditions for the detonation initiation are reached at initiation energy of the discharge of 70 mJ. In this case the speed of the flame front is constant and is close to the C–J speed. A response (a width of the front) of the first IR detector corresponds to a flame wave that propagates with the supersonic speed. Hence the detonation wave is formed by the time of reaching the first IR detector, which it is confirmed also by the observation with the help of the ICCD camera through the end-plate. The length and time of DDT amount to L_{DDT}=130 mm and t_{DDT}=0.6 ms at initiation energy of the discharge of 70 mJ. In this case the length and time of DDT involve a length of the discharge chamber and the ignition delay time. The initiation energy per the cross-section amounts to 4 J/m^2.

In our case the initiation of detonation proceeds through two stages. On the first stage the nanosecond discharge excites the gas in the discharge chamber. On the second stage a chemical energy of about 1 kJ releases after an ignition delay of 0.5–20 ms. The released energy is enough to initiate the detonation in an appropriate conditions. The discharge produces more the active species near the high-voltage electrode. The gradient of active species [4] and actually the simultaneous energy release [5] assist the initiation of the detonation.

Conclusions

The experimental demonstration of the application of the high-voltage nanosecond gas discharge for the initiation of the detonation was performed. The developed discharge device initiates the detonation at the length of DDT up to 130 mm in a tube with a diameter of 140 mm.

The detonation was initiated by energy of 70 mJ (4 J/m^2) in mixture $C_3H_8+5O_2$ at initial pressure of 0.3 atm.

The measurements of minimal ignition energy and ignition delay time were performed in $C_3H_8/C_4H_{10} + 5O_2 + xN_2$ ($0 \le x \le 10$) mixtures at pressure range of 0.15–0.6 atm. The minimal ignition energy and ignition delay time depend strongly on the nitrogen dilution under the ignition by the high-voltage nanosecond discharge. The extrapolated value of minimal ignition energy amounts 25 J at the dilution level of 77%.

The voluminosity of the discharge is a demerit for ignition and it is a great advantage for detonation.

The discharge device initiate the deflagration wave, the transient detonation wave and the C–J detonation wave in $C_3H_8+5O_2$ and $C_3H_8/C_4H_{10} + 5O_2 + xN_2$ ($0 \le x \le 10$) mixtures. The mode of propagation of flame front is governed by the initial pressure and the mixture composition and the mode is independent of the discharge energy.

The discharge has the different intensity in the sections of the discharge chamber. After the ignition the flame front occupies the whole cross-section of the detonation tube. The non-uniformity of the flame front diminishes completely after passing the length of about the one diameter.
