Abstract
Amorphous carbon layer are frequently deposited by PECVD because of its high control of film quality, high efficiency and reproducibility. Here, a study of carbon layers deposited at weak heat balance process is shown. The effect of the precursor type in a MMP-DECR reactor on the film properties is reproted. From FT-IR, spectroscopic ellipsometry and optical emission spectroscopy, links between plasma parameters and film structure and properties have been shown.
Keywords : amorphous carbon, PECVD, plasma, spectroscopic ellipsometry, FTIR

Introduction

Hydrogenated amorphous carbon (a-C :H) films received a great interest since their advent [1], owing to their wide range of properties, such optical transparency, mechanical hardness. It is well known that a-C:H have a complex structure essentially due to the different types of hybridisation of carbon atoms: tetrahedral sp^3, trigonal sp^2 or linear sp^1. More, hydrogen atoms come to complicate more the structure of these films. The properties of a-C:H films are mainly controlled the relative sp^2 to sp^3 bonding ratio, as the amount of sp^1 sites is usually negligible. It is commonly accepted that the graphitic sp^2 clusters is embedded in the sp^3 matrix [2]. The sp^2 sites are responsible for electrical and optical properties whereas the sp^3 sites govern mechanical properties.
Due to their easily optical tune properties [4], a-C:H films are very interesting. So, they have been extensively studied with a variety of optical characterization methods such as Fourier Transform Infra-Red spectroscopy (FTIR), and spectroscopic ellipsometry (SE).
The object of this article is to show the effect of precursor hybridizations on the plasma deposited films when the plasma power increases.

Experimental details

a-C:H films have been deposited on Si substrates from ethane (C_2H_6), ethylene (C_2H_4) and acetylene (C_2H_2) in a dual DECR plasma reactor. The substrate holder was at room temperature. This temperature was not maintained constant during the deposition. The plasma was produced using a working pressure of 1mT. The plasma power varies from 70 W to 800 W.
The gaz phase is observed with an optical emission spectrometer (OES) in the UV-visible range (200-900 nm).
The chemical structure of the C_xH_y films was characterized by Fourier Transform Infrared spectroscopy (FTIR) in the absorbance mode using a Bio-Rad (FTS60A) spectrometer. The thickness was estimated by profilometer (KLA-TENCOR Alpha-Step IQ). Optical characterisations are measured by spectroscopic ellipsometer (SOPRA GES-5). Refractive indexes, extinction coefficient, and gap of films are calculated using a Cauchy or Forouhi model.
Then, as it is described in the literature [5], it is able to calculate the sp^2 hybridized carbon proportion (Csp^2) from the SE measurements. This method use the comparison of the film n_{eff} or effective number of valence electrons per atom taking part in optical transitions at low energies (<9eV) with the one of a pure graphite layer at the same energy:

$$Csp^2{}_{a-CH} = \frac{n_{eff,a-CH}(E \le 9eV)}{n_{eff,graphite}(E \le 9eV)} \qquad (1)$$

with $n_{eff} = K \frac{A}{\rho} \int_0^{E_M} 2Enk.dE$ (2)

where A=12, ρ is the density and K a constant.

Finally, the hydrogen concentration can be evaluated from FTIR measurements [6] by using the equation:

$$\%\,H = B \cdot \int_{\nu_1}^{\nu_2} \frac{\alpha(\nu)}{\nu} \cdot d\nu \qquad (3)$$

where B is a constant which depends on the film thickness and a constant determined from a standard material containing C-H bonds. α represents the absorbance and ν_1 and ν_2 the wave numbers at the edges of the CH absorption peaks

Results and Discussion

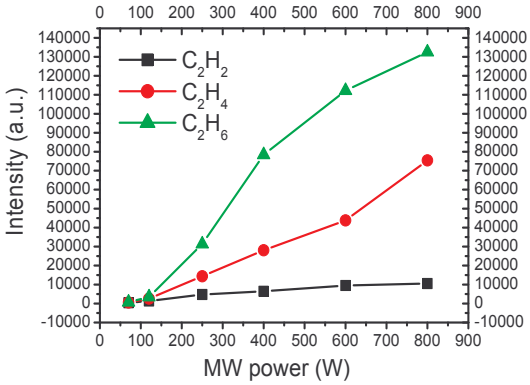

Figure 1 : H_α Optical emission vs. Micro wave power for C_2H_2, C_2H_4 and C_2H_6

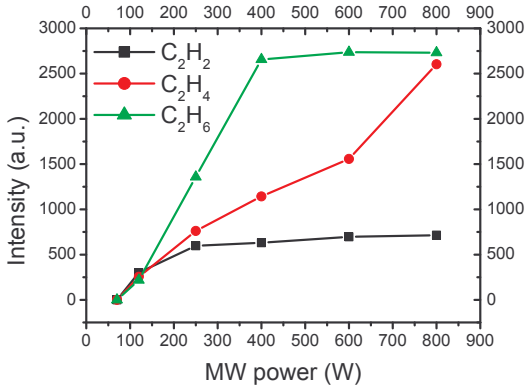

Figure 2: C_2 Optical emission vs. Micro wave power for C_2H_2, C_2H_4 and C_2H_6

The optical emission of these three type of discharge point to: first that C_2H_2 plasma are the less luminescent, different mechanism decomposition could explained this. Then, the C_2 emission at 516.5 nm intensity arises to a tableau at 400 W for C_2H_6 whereas the H_α intensity continues to growth. C_2H_2 gas has the same comportment but the tableau is obtained earlier, at 250 W. However, C_2H_4 plasma growths linearly when the power increases.

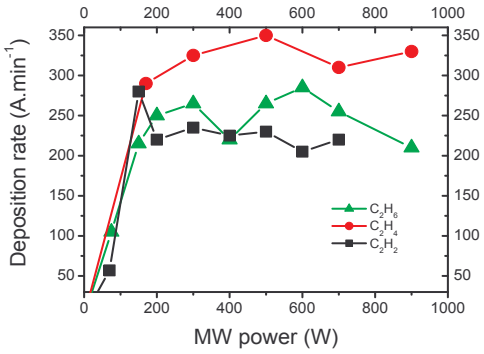

Figure 3 : Deposition rate vs. Micro wave power for C_2H_2, C_2H_4 and C_2H_6

Figure 3 shows the different deposition rate for each precursor. When the precursor should be completely dissociated, at high power, it appears that this deposition rate is equivalent for the three precursors, is equivalent. This phenomenon confirms the hypothesis we made that the number of carbon atoms is the parameter which control the deposition rate [7]. This rate is about 150 Å.min^{-1} with CH_4 precursor, 450 Å.min^{-1} with C_3H_8 precursor and here about 300 Å.min^{-1} with C_2H_4 precursor. Furthermore, it has been observed that C_2H_2 plasma, although they are generated at low pressure, produce powders. This behaviour can explain the weak difference of the deposition rate which is also observed with C_2H_6 precursor. For this last one, the plasma contains the large amount of H, an etching effect can be observed and limited the deposition rate.

The spectroscopic ellipsometry, in the range 0.25-1.6 µm, is a way to characterize film properties. Using a Cauchy model, the refractive index n and the extinction coefficient k can be calculated from ellipsometric measurements.
The variation of k (at 1.55 µm) and the amount of C-H bonds (% C-H) have the same shape for the three precursors (Figure 4). If we compare the three precursors, C_2H_6 films have the higher amount of CH bonds and C_2H_2 films the lowest ones. More films contain CH bonds, more k is high (Figure 6). Then, C-H bonds seem to play an important role on optical absorption. And, films which have the higher C_{sp2} rate present the higher value of k. Moreover, C_2H_2 films have the higher C_{sp2} rate and the C_2H_6 films the lowest (Figure 7). These last one are less absorbent than these first ones. So, it's obvious that CH bonds and the sp^2 hybridization of C atoms play a role in absorption property of the a-CH films, but C_{sp2} have a higher influence on this absorption.

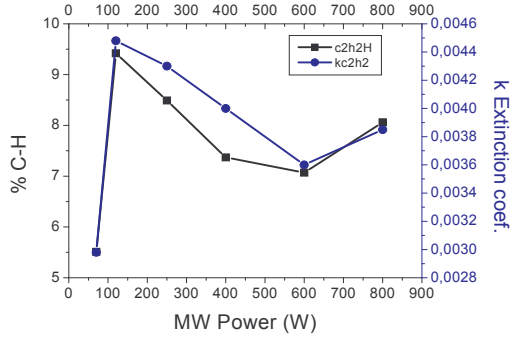

Figure 4: % CH bonds & k extinction coef. vs. Micro wave power for C_2H_2, C_2H_4 and C_2H_6

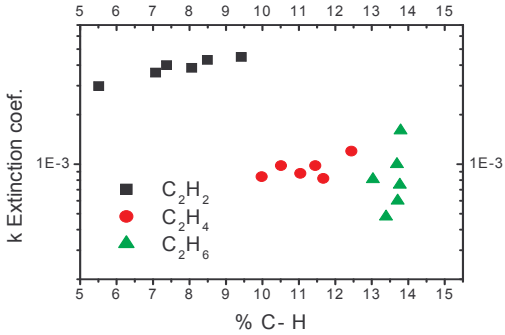

Figure 6 :k extinction coef. vs % CH bonds for C_2H_2, C_2H_4 and C_2H_6

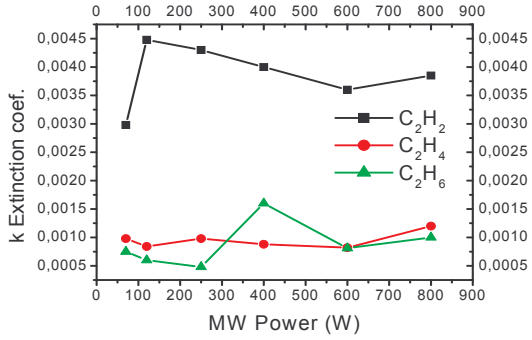

Figure 5 :k extinction coef. vs. Micro wave power for C_2H_2, C_2H_4 and C_2H_6

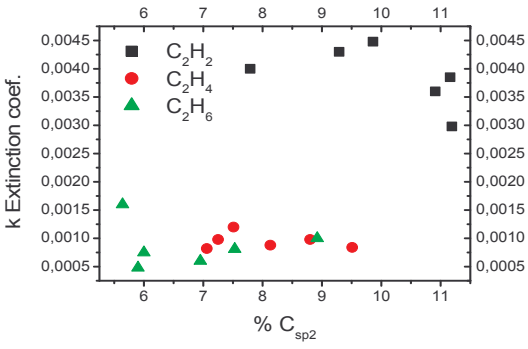

Figure 7 : k extinction coef. vs % C_{sp2} C_2H_2, C_2H_4 and C_2H_6

However, the evolution of the refractive index n is more complicate to understand (Figure 8) and to correlate. For C_2h_4 and C_2H_6 precursors, n evolutions are similar. Their evolutions comport three parts: first n growths, then reaches a plateau before falling. n values obtained with C_2H_4 is bigger than each

one obtained with C_2H_6 ; C_2H_4 films contain a higher rate of C_{sp2} (Figure 9). It is well know that in RF plasma, one way to improve n value is to increase the ionic bombardment during the deposition [8]. This bombardment result is to increase the C_{sp2} rate and decrease the amount of H in the film. So, the superior value of n for C_2H_4 films can be explained by a higher C_{sp2} rate. But, the C_{sp2} rate not control in totality the n value because some films obtain with C_2H_4 and C_2H_6 present a same concentration of C_{sp2} but have a different n as for example the sample at 600 W.

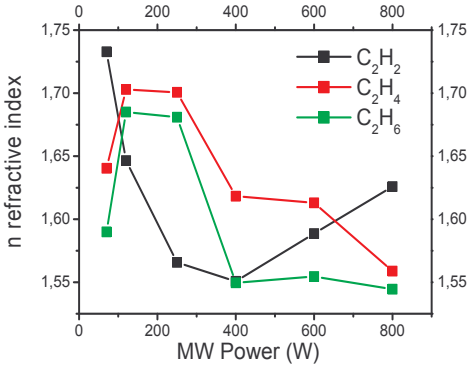

Figure 8: n refractive index. Vs MW power C_2H_2, C_2H_4 and C_2H_6

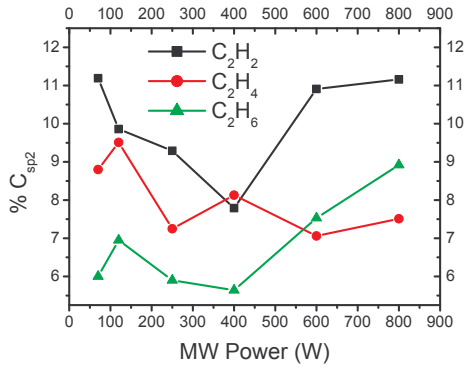

Figure 9 : % C_{sp2} vs. Micro wave power for C_2H_2, C_2H_4 and C_2H_6

Nevertheless, it is interesting to notice that for C_2H_6 precursor, from 400 W, all the curves show a particular comportment: n value stays constant, C_{sp2} rate increases linearly, and the intensity of C_2 optical emission arises a plateau too.
On the other hand, n evolution with plasma power for films realized with C_2H_2 precursor is less harebrained. The evolution of C_{sp2} and n according to the microwave power variation seem to have the same shape. The weak rate of hydrogen in this type of process could explain this behaviour. Due to this low amount of H, the ratio sp^2/sp^3 governs predominantly the properties of these films.

The FT-IR spectra set out the chemical structure of the different films realized. For each precursor, a particular signature is obtained (Figure 10). The absorption band of C_{sp2} carbon from, 1580 to 1680 cm^{-1}, present in the different film, is less and less intense when you consider C_2H_2, C_2H_4 and then C_2H_6.C_2H_6 has no double bond in its structure, this double bond forms during the process in or on the film. The deconvolution in 8 peaks at frequencies mentioned below in table 1 of the CH peaks around 2900 cm^{-1} of the Ft-IR spectra shows that sp^3 CH vibration at 2920 cm^{-1} is 4 to 5 times superior to the others contain in this remarkable peak. This behaviour is observed for the three precursors. So, as a general rule, these three types of films are essentially composed with C-C sp^3 bonds. This hypothesis is confirmed by the fact that the amount of C-H bonds and Csp2 bonds don't exceed about 10 %.

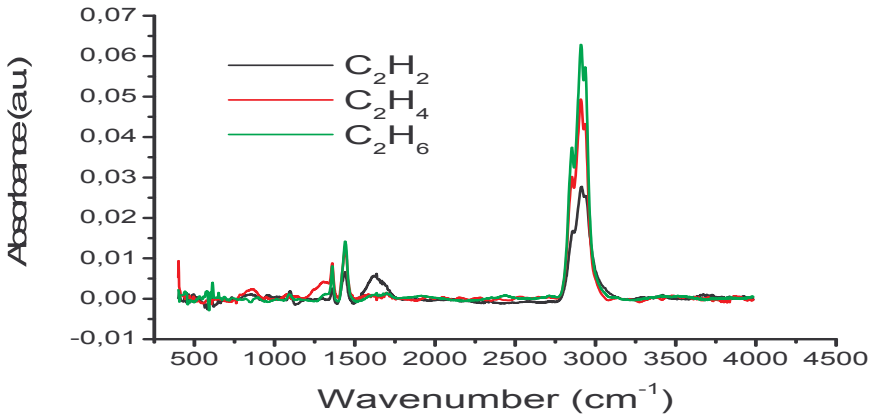

Figure 10 : FT-IR spectrum of a-CH films at 400 W

Bonding type	Stretching vibration (wavenumber (cm^{-1}))
sp^3 CH_2 symmetric	2850
sp^3 CH_3 symmetric	2865
sp^3 CH	2920
sp^2 CH_2 olifinic, symmetric	2950
sp^3 CH_3 asymmetric	2970
sp^2 CH olifinic	3000
sp^2 CH_2 olifinic asymmetric	3020
sp^2 CH aromatic	3045

Table 1 : Vvibrational frequencies [9]of CH_x peak

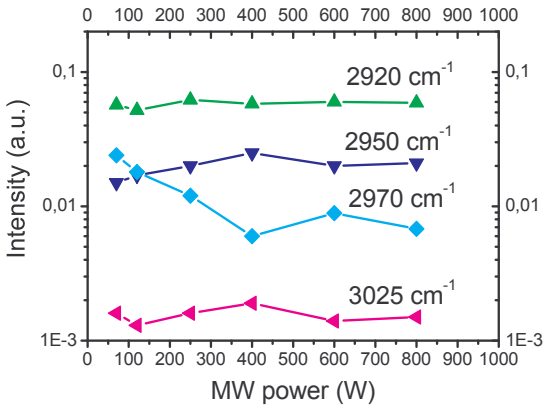

Figure 11: Peak intensity variation vs MW power for C2H4

For C_2H_6, the peaks intensities are near constant when the power increases, the totally decomposition of this gas from the lowest power could explain this. The constant value of H rate in the films reinforces this hypothesis. The evolution of the C_{sp2} rate is so explained by a bad estimation of the film density and then to an error on C_{sp2} estimation.
In the case of C_2H_4, the deconvoluated peaks intensities are also constant (Figure 11), except the peak at 2970 cm^{-1}, sp^3 CH_3, which decreases. This vibration represents the end of chains, so this decreasing can significated the chains' extension. And, the increasing of the peak at 2950 cm^{-1}, sp^2 CH_2 olifinic, shows a chain which became more sp^2 when the plasma power increases.
The same behaviour is observed with C_2H_2. Furthermore, the absorption peak at 2180 cm^{-1} (C_{sp1}) does not appear, even at lowest power: this triple bond is directly opened or broken and then, do not take part in the film's growth.
So, the hybridization or the H rate in the precursor leads to films with different chemical structure.

Conclusion

This study presents some results on three types of precursor. C_2H_2, C_2H_4 and C_2H_6 precursor have been studied and reveal that the structure and properties of the different films can be controlled with plasma parameters and precursor chemical structure. Material structures obtained are different with the precursor.
It is interesting to notice that C_2H_2 has different properties compared to the others ones. C_2h_4 and C_2H_6 are relatively close in terms of properties and chemical structure although the decomposition mechanisms seem to be different.
Furthermore, this kind of films, as they can be easily etched by oxygen plasma, could be used in microelectronic devices. Their tune properties offer a large range of applications.

Abstract
Plasma polymerization of allylamine is performed both in continuous wave (CW) and pulsed mode. The concentration of primary and secondary amines is evaluated by chemical derivatization technique. Secondary amines are found to be more abundant than primary amines. The maximum primary amine concentration of 7 NH_2 per 100 C atoms is obtained at low discharge power. Pulsed experiments with off-times in a range of 5-30 ms are remarkable for significantly higher deposition rate than that of continuous mode at the identical conditions.
Keywords: amines, pulsed plasma polymerization, chemical derivatization.

1. Introduction

Plasma polymerization is used to deposit polymer-like thin films by glow discharge of organic monomer vapors. Extensive research has examined the retention of amines by plasma polymerization of various amine-containing monomers [1-3]. However, allylamine is the most commonly utilized organic precursor. Amine containing plasma polymers can be utilized for modification of waste-water purification membranes [4, 5], as biocompatible surfaces in biomedical applications [6, 7] and in designing various sensors (for monitoring antigen-antibody interactions [8] or enzyme detection [9]).
In addition to CW mode, pulsing the plasma has been frequently applied to control surface chemical functionality by keeping the peak power constant while off-time (and average power) is varied [10-11]. The other way is to keep an average power constant with different peak powers [12-13]. These two approaches are compared here.

2. Experimental

Plasma polymerization of allylamine is performed in a reactor of a tubular type with capacitevely coupled 13.56 MHz excitation. The depositions are performed with a pressure of 25 Pa and a flow rate of 2.5 sccm. The average power ranges from 2 to 20 W and the duty cycle ranges from 1 (continuous wave or CW) to 0.1, with t_{on} of 2 ms (t_{off} 18 ms) utilized for pulsing experiments. A number of studies are also performed with t_{off} varying in 0.1-100 ms time domain with duty cycle and power being held constant.
Infrared measurements were performed using a Nicolet Impact 400 Fourier transform infrared (FTIR) spectrophotometer. The FTIR spectra of allylamine plasma polymer (pp-allylamine) deposited on intrinsic silicon wafers were acquired in transmittance mode with an uncoated silicon wafer used to record the reference spectrum.
XPS using a high-resolution monochromatic Al Kα x-ray source (15 keV, 25 mA emission current, VSW MX10 with 700 mm Rowland circle monochromator) and a 150 mm concentric hemispherical electron energy analyzer (VSW Class 150) is applied to determine the element composition of the films.
Chemical derivatization reactions with trifluoromethylbenzaldehyde (TFBA) and trifluoroacetic anhydride (TFAA) are performed to detect primary and secondary amines. The calculation procedure gives the amine concentration in number of groups per 100 carbon atoms and has been described in detail elsewhere [14]. The samples deposited on aluminum were cut into two pieces after plasma polymerization and stored in air. One piece was treated with TFBA for 8-10 and 60 days after deposition and the other with TFAA at the same intervals. Thus, all derivatization measurements of a given coating are performed on exactly the same film. XPS were acquired immediately before and after the derivatization reactions.
AFM (Quesant, Q-Scope™ 850) is applied in an intermittent contact mode (BBWavemode) to observe the surface and to measure the thickness of plasma polymers deposited on polished silicon. For the thickness measurements, a cellulose acetate mask was fixed on silicon substrate prior to deposition. After the deposition, the underlying cellulose acetate film was removed to produce a very sharp edge of plasma polymer, which was then scanned by AFM.

3. Results and discussion

The FTIR and the C 1s XP spectra of pp-allylamine are similar to those reported in literature [12] and not shown here. The presence of NH_x at 3200-3400 cm^{-1}, CH_x at 2850-2930 cm^{-1}, carbon double and triple bond structures at 2100-2200 cm^{-1} was confirmed. With increasing discharge power the intensity of carbon unsaturated bonds increases with respect to the other peaks, which is consistent with the results of the other authors [15] showing an increase in unsaturation of allylamine plasma polymer with power, mainly due to formation of nitrile groups.

The XPS analysis demonstrates that the chemical composition of pp-allylamine is very close to that of allylamine monomer. The film deposited at 2 W power in CW contains 64.5 at. % of C, 22.7 at. % of N and 12.8 at. % of O, whereas allylamine molecule has 75 at. % of C and 25 at. % of N. It should be also noted that there appears to be a slight decrease in nitrogen content with increasing average power both for CW and pulsed samples. Table 1 shows the elemental composition of plasma polymers deposited in the same experimental setup from diaminocyclohexane (DACH), ethylenediamine (EDA) and allylamine. The data for the precursors are also provided. The presence of several percent of oxygen in plasma polymers is due to ageing effects discussed in detail in [2]. Allylamine proves to be the best in terms of similarity of elemental composition to the parent monomer. The plasma polymer composition changes considerably in dependence of the monomer used. The nitrogen content increases in a pp-DACH/pp-Allylamine/pp-EDA sequence, being two times higher for pp-EDA than for pp-DACH. Similarly, the carbon component decreases in the same manner. The changes in film composition can be attributed mainly, but not exclusively, to the different composition of the precursor molecules. The least carbonaceous EDA produces the plasma polymer with the lowest carbon content. Nevertheless, DACH and allylamine monomers give different results. The molecular formula for DACH is $C_6N_2H_{14}$, and that of allylamine is C_3NH_7. Thus, the ratio between the elements in these two precursors is the same. However, allylamine deposits the films, which are very close to the precursor in elemental composition. The C/N ratio is 2.8 for pp-allylamine versus 3.0 for the monomer. In the case of DACH, the plasma polymer lacks nitrogen and C/N grows to 4.6. Among three monomers EDA molecule has the highest concentration of nitrogen, but it is the most vulnerable to the discharge. The nitrogen content drops from 50% in precursor to 33% in plasma polymer, and C/N increases almost two times from 1.0 to 1.9.

Table 1 The elemental composition of the plasma polymers and corresponding monomers

DACH				Experimental parameters
C, at. %	N, at. %	O, at. %	C/N	
75.9	16.4	7.7	4.6	2 W, 5 Pa, 0.85 sccm, 48 days aged plasma polymer
75	25	-	3.0	DACH monomer
EDA				
61.5	32.7	5.8	1.9	2 W, 5 Pa, 0.85 sccm, 49 days aged plasma polymer
50	50	-	1.0	EDA monomer
Allylamine				
64.5	22.7	12.8	2.8	2 W, 25 Pa, 2.5 sccm, 60 days aged plasma polymer
75	25	-	3.0	Allylamine monomer

XPS cannot by itself provide information about the amine concentration in plasma polymers and FTIR allows only qualitative estimation. Chemical functionalization prior to XPS analysis permits the unique identification of primary and secondary amine groups. Table 2 shows the amine concentration in pp-allylamine deposited in CW and the pulsed mode. Primary amines are efficiently formed, but secondary amines are more abundant. Stored in air, pp-allylamine films take up oxygen. Its concentration increases from ~8% after 8-10 days to ~13% after 60 days storage. However, both primary and secondary amines are found to be rather stable against oxidation in the air with NH_2 concentration slightly decreasing with time (Table 2). The same trend is observed for pulsed pp-allylamine.

When the peak power is held constant, pulsing does not have an effect on the concentration of primary amines. Primary amine content is the same for films deposited at 20 W in CW mode and at 2 W average power, D = 0.1 (with 20 W peak power) in a pulsed mode. However, the retention of the secondary amines is more effective in the case of pulsed pp-allylamine. In accordance with [3], the total amine concentration is higher for the pulsed polymerized samples. Thus, the observed increase in amine retention with longer off-times in our experiments is due to the secondary amines.

Table 2 Primary and secondary amine concentration in allylamine plasma polymers

Chemical group	Groups per 100 C atoms							
	CW				Pulsed			
	2 W		*20 W*		*2 W*		*20 W*	
	9 days	*60 days*	*9 days*	*60 days*	*9 days*	*60 days*	*9 days*	*60 days*
NH_2	7.2	5.5	4.4	3.7	4.1	4.3	1.8	1.6
NH	13.7	16.2	5.7	5.5	14.9	15.5	11.5	6.1
NH_2 + NH	20.9	21.7	10.1	9.2	19	19.8	13.3	7.7

Under constant average power conditions, the pulsing vs CW chemical changes are highly monomer dependent. Recent FTIR study of pulsed plasma polymerization of allylamine show noticeable increase of amine content with decreasing duty cycle [11, 12]. However, previous experiments with other monomers performed on a constant average power basis (i.e., with different peak powers) revealed no significant difference between samples prepared in CW and pulsed mode [13 and references therein]. However, the film composition was found to be strongly affected only by variation of average power. Our comparison of films deposited in CW vs. pulsed mode at constant average power (Table 2) confirms this finding, indicating that the total amine concentration does not depend strongly on the mode of operation (although the concentration of primary amines is slightly higher for the CW samples).

Overall, we have found that the power delivered into the discharge is the main parameter controlling the film composition. The films deposited at 2 W power in CW mode have twice as much total amine than those deposited at 20 W power. The difference between the pulsed polymerized samples is not large, but the trend is the same.

The chemical nature of this kind of plasma polymers is interesting not only in terms of elemental composition, but rather in terms of amine retention. The Fig. 1 provides the data on primary and secondary amine concentration for pp-DACH, pp-EDA and pp-allylamine obtained from the results of chemical derivatization. The most important point that should be addressed here is that the retention of primary amines is rather poor for all kinds of the monomers. The worst case is pp-EDA, which looses almost all of NH_2. Of all the monomers, EDA molecule is the richest with primary amines. However, pp-EDA contains only ~1 NH_2 per 100 C atoms. The best result is obtained using allylamine plasma polymerization. In this case, the concentration of primary amines is 5.5 per 100 C atoms, though it is still much lower than 33/100 C atoms of allylamine precursor.

The secondary amines are more abundant in all of the mentioned plasma polymers. The most remarkable is pp-EDA, in which the concentration of NH, in contrast to the lowest NH_2 content, is high, so that nearly all of the amines are of NH type. The pp-allylamine reveals approximately the same secondary amine concentration, but the fraction of primary amines is bigger. pp-Allylamine preserve more than half (~60%) of precursor's amines, though the most of them are transformed to secondary amine form. Compared to 18-20 NH_2 and NH groups per 100 C atoms for pp-EDA and pp-allylamine, the pp-DACH is much worse in terms of amine retention (only 10 groups per 100 C atoms).

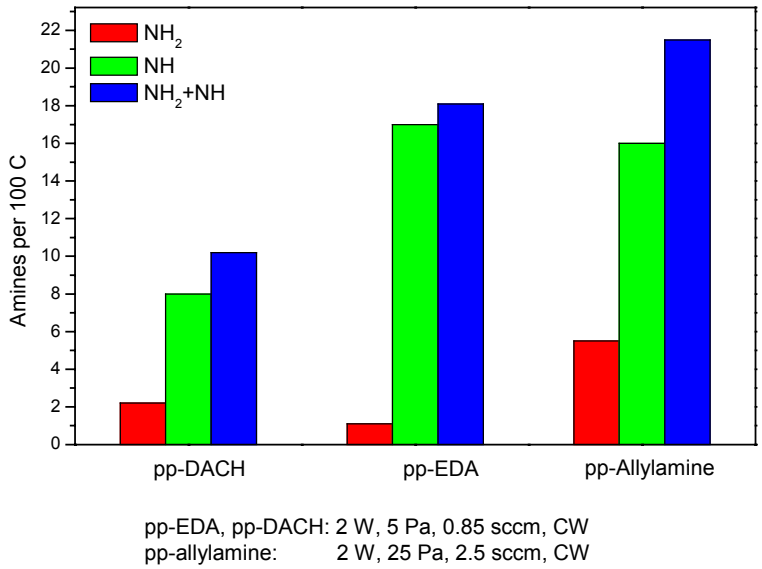

Fig. 1 The concentration of amines in plasma polymers. (Derivatization and XPS are performed in 48 days for pp-EDA, pp-DACH and in 60 days for pp-allylamine after deposition).

The chemical nature of the monomers is also seen in considerable difference in deposition rates (Table 3). The DACH molecule has the highest molecular mass (M=114 g/mol) and at given pressure this monomer supplies the biggest mass into the reactor volume, which makes the deposition rate of pp-DACH very high. EDA and allylamine have lower and almost equal molecular weights (60 and 57 g/mol, respectively), but the deposition rate of the latter is much higher. At given pressure the mass of allylamine and EDA precursor molecules contained in the reactor volume is almost the same given their similar molecular weights, so their difference in deposition rate can not be accounted for by different mass transfer on the surface. We believe that in the case of allylamine, plasma-induced reaction of carbon-carbon double bond of intact allylamine molecules with surface radicals plays a significant role in film formation.

Table 3 The deposition rates of amine containing plasma polymers, nm/min

Plasma polymer	flow 0.85 sccm	flow 2.5 sccm	Experimental parameters
pp-DACH	16		5 W, 5 Pa, CW, as-deposited
pp-EDA	4	2.5	
pp-allylamine		9	

The contribution of plasma-induced allylamine polymerization to the film growth is further supported by the pulsed experiments with varying off-time, other parameters (duty cycle 0.1, average power 2 W, pressure 25 Pa, flow rate 2.5 sccm) being held constant. Each deposition lasted for 10 minutes. The preliminary experiments found that the deposition rate is linear within at least half an hour of deposition. The thickness of plasma polymers was determined from the AFM images as shown in Fig. 2. It is worth noting that even ultra-thin pp-allylamine films (down to 5 nm) reveal the continuous character as deposited on silicon. For the films thinner than 5 nm, the roughness is of the same scale as the thickness. The term ‘film thickness’ is defined here as the distance between mean lines laid along the profiles of the film and the substrate. For comparison, pp-allylamine was deposited in CW mode (power 2 W, pressure 25 Pa, flow rate 2.5 sccm) with different deposition intervals.

The deposition rate of 0.4±0.1 nm/min was determined in CW mode. For the pulsed experiments, there is an interval of off-times between ~5 and ~30 ms where the deposition rate is much higher than that of CW at the identical conditions, reaching 1.80 nm/min. Out of the above range, the film growth is slower approaching the value of CW. Here we assume that the ion bombardment during on-time plays more or less destructive role in film formation. Taking into account that the characteristic time of bias decay during t_{off} is < 1 ms [16], there is still a certain ion flux on the surface at shorter off-times and the deposition resembles that in CW mode. At the t_{off} > 5 ms, the influence of charged particles on the polymerization processes when the plasma is off is minor. The film grows via the reaction of molecular fragments or intact monomer molecules with surface radicals. The deposition rate reaches maximum here. The decrease in deposition rate at the longer off-times is readily explained by completing recombination of the surface radicals with volume species. Apparently, at the t_{off} > 30 ms the majority of reactive species are already depleted.

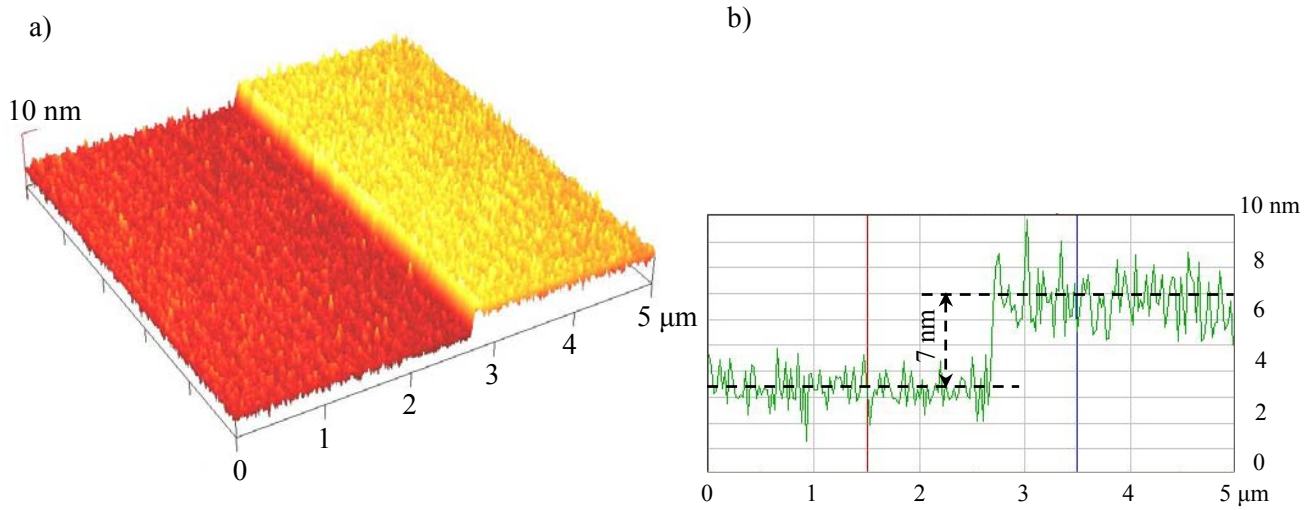

Fig. 2 pp-Allylamine deposited on Si (25 Pa, 2 W, CW): a) the AFM image; b) the film profile.

4. Conclusions

Allylamine is effective for deposition of amine rich coatings. The amine concentrations calculated here are close to those reported by others [3] and are significantly higher than amine concentration of plasma polymers deposited from other amine bearing precursors such as ethylenediamine and diaminocyclohexane. The highest values of amine content (7 NH_2 and 14 NH per 100 carbon atoms) were obtained for allylamine plasma polymers deposited at low (2 W) power. Both primary and secondary amines are found to be stable to oxidation on air with NH_2 concentration slightly decreasing with time.

CW and pulsed mode under equivalent average power input condition produce no noticeably different film compositions. However, pulsing at equivalent peak power results in increase of amine contents, which is due to secondary amines.

In the pulsing experiments with constant duty cycle and average power, a region of off-times between ~5 and ~30 ms exists where sharply increased values of film thickness are observed. This indicates a significant film formation during plasma off-time.

Thin film deposition on powder surfaces using atmospheric pressure discharge

V. Brüser, M. Hähnel, H. Kersten
Institute for Low Temperature Plasma Physics,Greifswald,Germany

Abstract
The deposition of SiO_x containing films on NaCl and KBr powder in dielectric barrier discharge under atmospheric pressure was investigated. As precursor hexamethyldisiloxane (HMDSO) and tetraethoxysilane (TEOS) in argon-oxygen gas mixtures were used. The deposited layers were studied by means of light microscopy, SEM, FTIR and XPS investigations. The particles were completely covered by SiO_x, with increasing oxygen concentration in the plasma the carbon content of the layer was decreased.
Keywords: Dielectric barrier discharge; Hexamethyldisiloxane; Tetraethoxysilane; Thin film deposition

1. Introduction

The dielectric barrier discharge (DBD) at atmospheric pressure has been used for many technical applications, for example ozone generation, gas cleaning, surface treatment of foils and fabrics [1]. Atmospheric pressure plasmas for surface treatment of materials become more and more important because in contrast to low pressure plasmas no vacuum devices are necessary. Therefore, batch processing can be avoided and treatment processes can be easily integrated into production lines.
For more than ten years the deposition of organosilicon layers on flat substrates has been studied by the use of various monomers [2, 3]. In this paper, the deposition of silicon containing thin films on powder particles is desribed. These coatings can be used as protection for luminescent particles or pigments against corrosion and humidity. Some pharmaceuticals need barriers for a slow release of the agent, too. The present contribution focuses on the deposition of SiO_x containing layers on powders. Hexamethyldisiloxane (HMDSO) and tetraethoxysilane (TEOS), respectively, were used as precursor.
For the modification of powder surfaces special techniques have to be applied to realize a homogeneous treatment. Therefore, the planar dielectric barrier discharge arrangement was combined with a vibrating conveyor device.

2. Experimental

In Fig. 1 the schematic diagram of the experimental apparatus is shown. The powder treatment system consists of three major parts: a mechanically agitating chamber for plasma treatment, a gas feeding system and a power source. On the bottom of the treatment chamber a planar surface dielectric barrier discharge arrangement is fixed. The discharge arrangement is made from a printed circuit board. One side of this circuit board is completely covered by a copper layer and represents the ground electrode. On the opposite side is the high voltage electrode consisting of an etched copper layer (Fig. 2). Between the stripes of the high voltage electrode a filamentary surface discharge is generated (Fig. 3). The bulk material of the circuit board consists of nonconducting material and represents the dielectric barrier. On the top of the treatment chamber a gas distributor for homogenous gas injection is arranged. The chamber is mechanically agitated by an electromagnet to move the powder through the plasma zone (Fig 1).
The atmospheric surface discharge is driven by a medium frequency pulse generator (Fourier Synthesis Pulse Generator, Ingenieurbüro Dr. Jürgen Klein) that has a frequency range between 1 Hz and 20 kHz and a maximum voltage of 20 KV. The pulse generator is controlled by a frequency generator (AFG 310 Sony/Tektronics).
Oxygen and argon are used as plasma gas. The liquid precursors hexamethyldisiloxane (HMDSO) and tetra-ethoxysilane (TEOS) are introduced by feeding argon through a bubbler. The gas composition in the plasma was investigated by mass spectrometry. Plasma treatments were carried out under following conditions:

Table 1 Treatment conditions

TEOS concentration [vol-ppm]	HMDSO concentration [vol-ppm]	Ar concentration [vol-%]	O_2 concentration [vol-%]	Gas flow [sccm]	Treatment time [min]
2000	/	95	4.8	210	30
/	1600	0..90	0..10	300	10

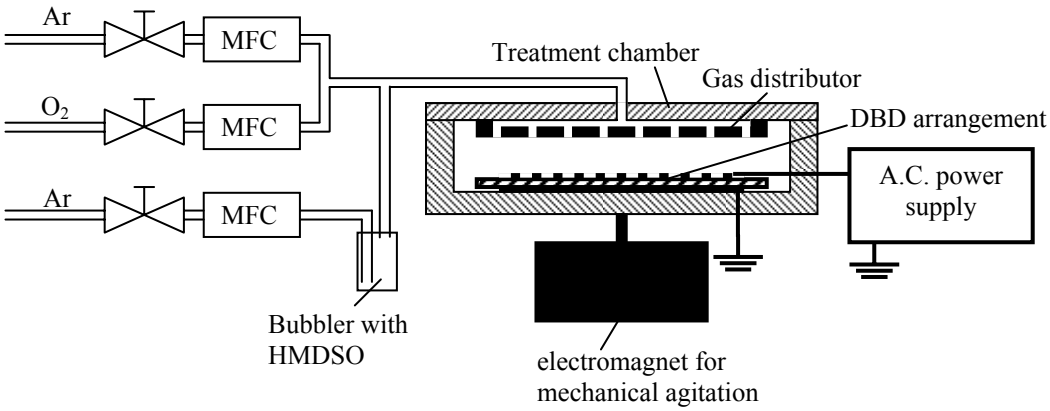

Fig. 1 Scheme of the experimental set-up

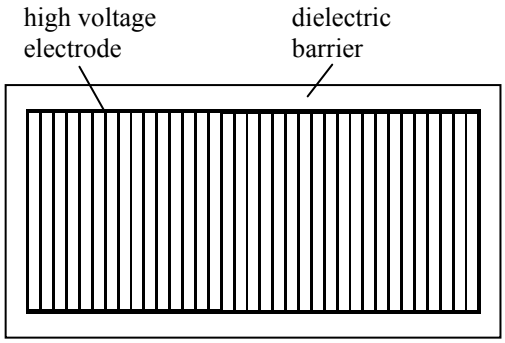

Fig. 2 Surface discharge arrangement (top view)

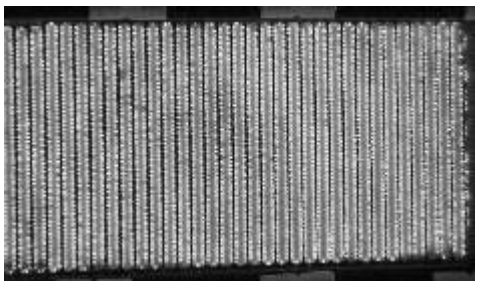

Fig. 3 Surface discharge

Silicon oxide containing layers have been deposited on NaCl and KBr powders used as model substances. The treated particles were characterized by light microscopy, scanning electron microscopy (SEM), infrared spectroscopy (FTIR), and photo electron spectroscopy (XPS).

3. Results and Discussion

Deposition in TEOS-Ar-O_2

NaCl powder was covered using TEOS precursor. The coated salt particles were examined with a light optical microscope and scanning electron microscope.

In Fig. 4 SiO_x coated crystals are shown. The NaCl crystals are completely covered by the layer. Later, the NaCl was removed by solving in water. Only a box consisting of the SiO_x containing material remains (Fig 5). Apparently, there are some holes in the layer which make a penetration of water into the box possible. A fraction of a solution residue of a coated NaCl was observed with SEM (Fig. 6). Also in this picture it is visible that the deposited coating consists of a compact layer. Hence, tiny (micro) glass boxes have been prepared.

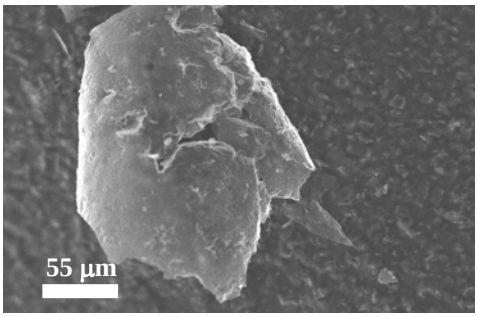

Fig. 6 Fraction of a SiO_x coating after dissolution of NaCl crystal in water. The coating was deposited in TEOS-Ar-O_2.

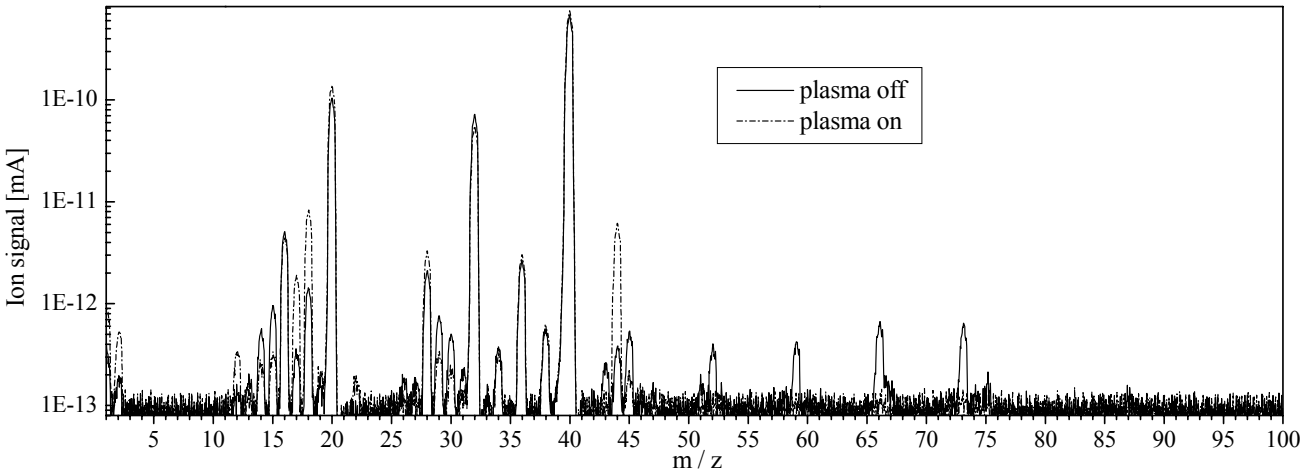

Fig. 7 Mass spectrum of HMDSO-Ar-O_2 mixture with and without discharge

Deposition in HMDSO-Ar-O_2

The gas phase of the treatment chamber containing Ar, O_2 and HMDSO was investigated by MS measurements (Fig. 7). With the used mass spectrometer only particle mass m/z ≤100 could be observed. In this range following signals can be related to HMDSO: CH_2^+ (m/z 14), CH_3^+ (m/z 15), $SiCH_3^+$ (m/z 43), $SiOH^+$ (m/z 45), $Si_2OC_2H_8^{++}$ (m/z 52), $SiC_2H_7^+$ (m/z 59), $Si_2OC_4H_{12}$ (m/z 66), $SiC_3H_9^+$ (m/z 73) and Si_2OH^+ (m/z 73) [4]. The signals disappear after ignition. However the content of CO_2 (CO_2^+, m/z = 44) and H_2O (H_2O^+ m/z = 18 and OH^+ m/z = 17) increases. This means, that HMDSO is mainly converted into the SiO_x layer, CO_2 and H_2O.

Fin ally, the composition of the deposited layer was investigated by XPS measurements. The plasma treatments were performed at four different oxygen concentrations in the range of 10-100 vol.-%. The content of oxygen in the layers of four treated samples remains almost constant (Fig. 8). The content of silicon and carbon slightly decrease with increasing oxygen concentration in the gas phase. At higher oxygen gas concentrations the content of Na and Cl of the coating increases. It is known, that at increasing oxygen concentration of Ar-O_2-HMDSO gas the thickness of deposited layers becomes smaller and the bulk of the particles can be detected [5].

In addition, the contents of SiC, SiO, SiO_2, SiO_3 and SiO_4 bonds in the coating were investigated [Fig. 9]. With increasing oxygen concentration in the plasma signals of SiO_3 and SiO_4 groups decrease and signals of SiC, SiO and SiO_2 groups increase. Apparently, in the films deposited at low oxygen concentrations not all carbon is bond on silicon. A part of carbon must be bond on oxygen or the content of C-C groups is higher. The plasma properties change with oxygen concentration due to the different ionization energies of oxygen and argon ($E_{ion,Ar}$ = 15,8 eV, $E_{ion,O2}$ = 12,5 eV). Hence, the decomposition of HMDSO depends essentially on the plasma properties.

The FTIR measurements of KBr coated in HMDSO-Ar-O_2 (10 vol-% O_2) show an absorption band of SiOSi at a wave number of 950 - 1250 cm^{-1} as shown in Fig. 10. However absorption bands between 1240 and 1300 cm^{-1} indicates $OSi(CH_3)_x$. These results are in accordance with the described XPS results.

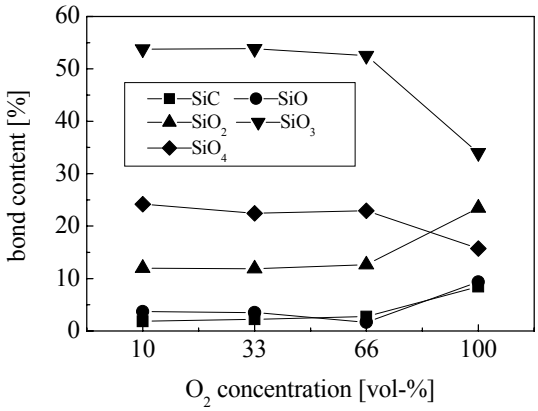

Fig. 9 Content of SiC, SiO, SiO_2, SiO_3 and SiO_4 bonds of coatings on NaCl deposited in HMDSO-Ar-O_2 with different oxygen concentrations

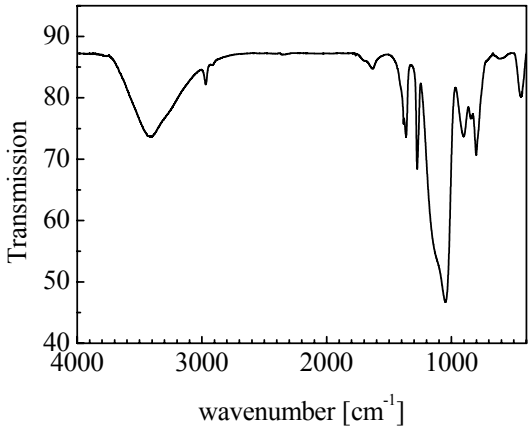

Fig. 10 FTIR spectrum of coated KBr particles

4. Summary

SiO_x containing layers have been deposited on powder particles by means of a mechanically agitated surface discharge arrangement. NaCl and KBr powders as model substances were treated using TEOS and HMDSO precursor. The coatings completely covered the crystals. In the plasma HMDSO is mainly converted to the film, CO_2 and H_2O. The deposited material contains Si, O and C. Contents of SiC and SiO_x bonds change with the oxygen concentration.

Abstract
A possibility of plasma-chemical synthesis of nanoparticles in heterophase gas-liquid plasma with use of the thermally nonequilibrium secondary discharge with a liquid electrode is investigated. Processing a toluene, a fine-dispersed soot powder containing micro- and nanosized carbon particles up to 10 nm is produced.
Keywords: plasma chemistry, synthesis, plasma-liquid system, secondary discharge, carbon nanoparticles.

1. Introduction

During the last years many research groups have investigated different methods of obtaining of carbon nano-particles by the use of the electric arc vaporization [1], catalytic pyrolysis and incomplete burning of hydrocarbons [2], laser ablation [3], microwave radiation [4], solar energy [5], and others. These methods are based mainly on the sublimation of a solid phase [6]. We propose an alternative approach – the plasma-chemical synthesis from a liquid phase using thermally nonequilibrium heterophase plasma [7]. This method is still poorly investigated but according to our experiments it can be a good method if it will be organized in due course. Among possible discharges of gas-liquid type, one type presents a special interest for us – it is the secondary discharge with a liquid electrode [8]. In this discharge, one electrode is connected with liquid while another electrode is maintained by the plasma flow from the auxiliary gas discharge [9]. Under the nonequilibrium plasma exposure including active electrons and temperature influence, the liquid hydrocarbon molecules can be decomposed through the partial oxidation/pyrolysis into the carbon source radical and atomic components, which then can form the carbon particles and structures.

In this work we present first results of our studies on the possibilities of the synthesis of carbon nanoparticles in plasma-liquid system using the toluene decomposition by the secondary discharge with a liquid electrode. Do not going into details of kinetics of plasma-chemical processes in this system we focus efforts on the experimental results first of all.

2. Experimental Methodology

The image and principal scheme of the experimental set-up used for studies of the process of plasma-chemical synthesis of carbon nanoparticles is shown in Fig. 1. It consists of a quartz glass & stainless steel reactor chamber and the electrical discharge system of gas-liquid type. We used a liquid toluene as a hydrocarbon-containing raw material and argon as a plasma-forming gas and transport gas flow. Argon was moved into the reactor top-down through the nozzle into the gap between two opposite rod copper electrodes, where the auxiliary arc discharge was burning and served as a source of plasma. Toluene was put into the reactor bottom-up through the hollow electrode and atomized through the nozzle as a spray of fine-dispersed droplets. The electric field of the secondary discharge was applied between the liquid electrode that served as cathode and the plasma flow of auxiliary arc discharge that served as anode for the secondary discharge at the same time. So the current of the secondary discharge passed through the blowing arc discharge plasma and through the dispersed gas-liquid medium. The discharge was powered by the HV DC source. In experiments we varied the current-voltage parameters, gas/liquid flow rates, and distance between the electrodes in order to optimize the process. The products of the plasma-chemical decomposition/pyrolysis and chemical vapor deposition/synthesis were collected and analyzed by available techniques of atom force microscopy (AFM), scanning electron microscopy (SEM) and optical microscopy (OEM).

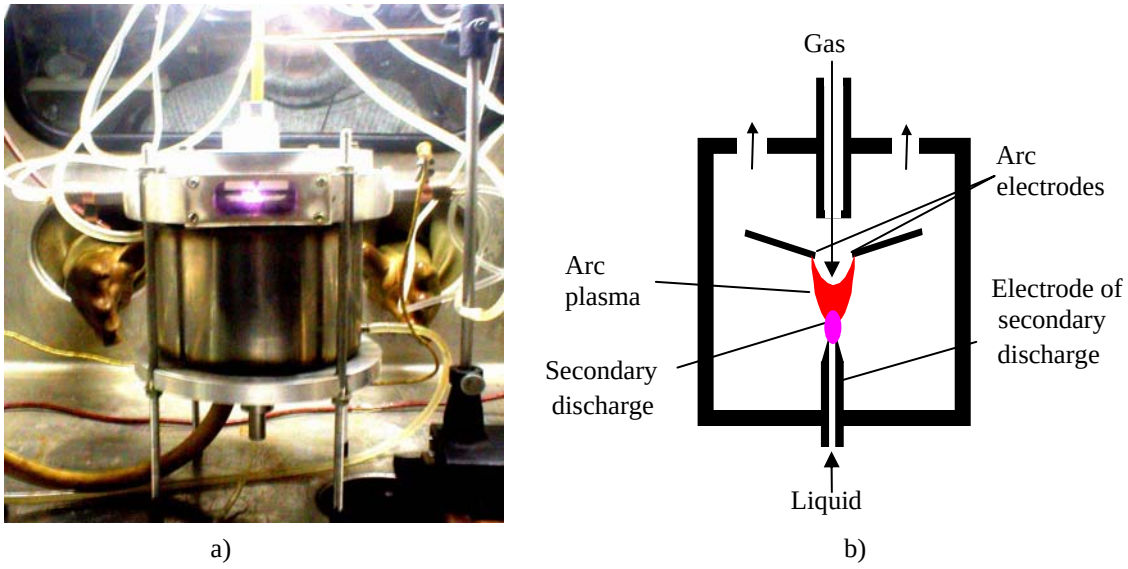

Fig. 1 Experimental set-up

3. Results and Discussions

In the result of the toluene treatment in the electro-discharge gas-liquid plasma-chemical reactor the output products were formed in three phases: (i) in a solid phase as a fine-disperse soot powder of black color; (ii) in a liquid phase as a fine-dispersed emulsion, and (iii) in a gas phase. The gaseous output products were taken out from the studied system and moved into another reactor, where they were burned in the auxiliary arc discharge. We were interested mainly by the liquid-phase and solid state output products collected in the primary reactor.

The obtained liquid-phase products after evaporating and cooling were deposited at the glass object plate in the form of a thin film with the incorporated carbon particles and were investigated with use of the optical electronic microscope. OEM analysis has shown the presence of microparticles with the sizes of 10 μm and less. Fig. 2 shows the typical OEM image of the carbonaceous deposits produced without any post-discharge purification. The obtained fine-dispersed carbon black powder was applied on the micaceous substrate and investigated with use of the atom force microscope. AFM analysis has shown the distribution of the large and small carbon particles with the sizes from 300 nm till 50 nm (Fig. 3). Since the heating of asphaltogenic mass led to polymerization of carbon-containing structures, in order to exclude the effects of the particles adhesion, the carbon black powder was crushed by the ultrasound method. For that purpose the powder was mixed with the distilled water, and the water solution was treated during several minutes by the ultrasound. After that water solution was evaporated, and the evaporation residue was investigated again by the AFM. In the result, the presence of carbon nanoparticles with the sizes of 5-10 nm were determined (Fig. 4).

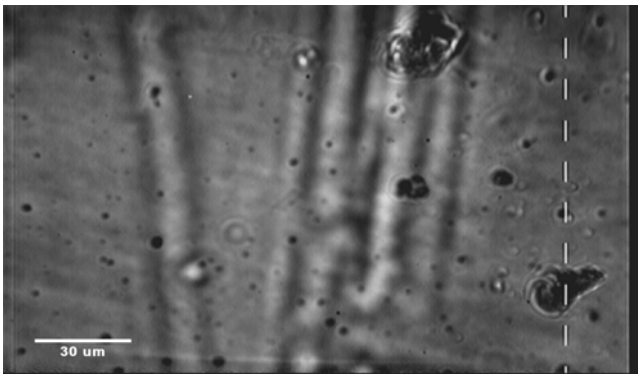

Fig. 2. Microphotograph image of the liquid film with carbon structures.

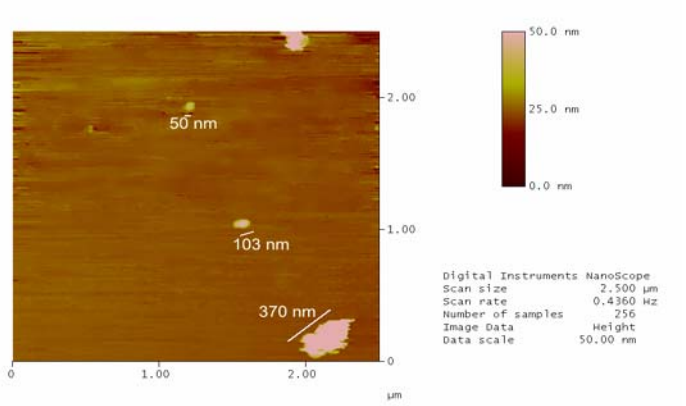

Fig.3. AFM image of dispersed carbon powder applied on the mica substrate.

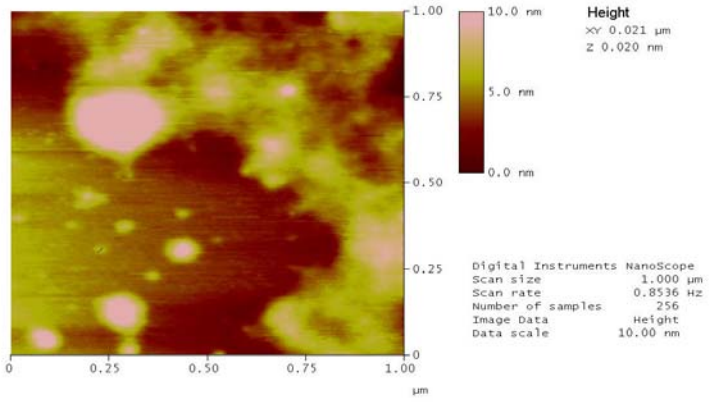

Fig.4. AFM image of dispersed carbon powder after the u.s. treatment.

Conclusions

We conclude that treatment of toluene in plasma-liquid system by means of the thermally nonequilibrium secondary discharge with a liquid electrode can be an effective method for producing of wide spectrum of carbon micro- and nanoparticles. The further research step will be a quantitative analysis of the yield/content and morphological characterization of the target nanostructures in the synthesized carbonaceous materials as well as the determination of efficiency and optimization of the process.

The work was partially supported by the Ministry of Education and Science of Ukraine.

Abstract

Thermal evaporation of polyethylene and polypropylene is performed with or without an activation of volatile fragments in a glow discharge. Without plasma assistance evaporated films are a mixture of aliphatic hydrocarbons. These films are not stable in contact with water. The activation in a glow discharge enhances cross-linking and the films become hydrocarbon plasma polymers. However, these plasma polymers resemble much more the original polymers.

Keywords

Evaporation of polymers, magnetron sputtering

1. Introduction

Evaporation of polymers has been attempted already in the 1960s [1,2]. The films were found composed of low molecular weight fragments and for better mechanical properties a post deposition UV light irradiation was recommended [2,3]. The evaporation of a large number of polymers has been treated by Hogarth and Iqbal [4]. We have decided to reinvestigate the above mentioned findings and compare a simple evaporation and "plasma assisted" evaporation [5] that may be seen as a specific plasma polymerization process.

2. Experimental

Evaporation of PP and PE was performed in cylindrical reactor pumped with rotary and diffusion pumps. The evaporation was performed in argon atmosphere at the presure 0.4 Pa and flow rate 2.5 sccm with or without simultaneous rf magnetron discharge (10 – 160 W). The magnetron equipped with a graphite target was aimed to initiate and sustain the glow discharge in Ar/hydrocarbon vapour mixture. Graphite known for its low sputtering yield was chosen to minimize the contribution of sputtering. The evaporation source was placed 5 cm above magnetron, and substrates were 10 cm and 15 cm above evaporation source for PP and PE, respectively. In the case of PP, a typical molybdenum evaporation boat was used. During the evaporation of PE, vigorous boiling led to bulk drops of polymer splashing out and reaching the substrates. A more sophisticated evaporation source was constructed, which consisted of a copper crucible with external heating delivered through the two molybdenum strips. The crucible was filled with a mixture of PE and copper granules to improve thermal transfer to the polymer. Evaporation temperature was controlled by a thermocouple and set to 350 °C for both polymers. The low-density polyethylene in granular form was purchased from Aldrich, and the polypropylene in sheet form was obtained from Goodfellow.

Silver coated glass for FTIR and water contact angle measurements and polished silicon for AFM analysis were used as substrates. Rf balanced planar magnetron 80 mm in diameter was driven by rf power supply ENI 600 W. Quartz crystal mirobalance was used for in-situ thickness monitoring. Quadrupole mass spectrometer (Hiden HAL 301 RC) was used for monitoring volatile fragments during the deposition proces. FTIR analyses were performed ex-situ on a Bruker Equinox 55 FTIR spectrometer, and XPS was performed on an angular-resolved x-ray induced photoelectron spectrometer ADES-400 (VG Scientific) equipped with Mg K^{α} radiation (1253.6 eV) and a rotable hemispherical energy analyser. AFM Quesant Q-scope 850 and Burleigh Metris 2000 were used for topography and thickness measurements.

3. Results and discussion

Films prepared by evaporation without magnetron discharge revealed similar roughness for both PP and PE (RMS 13.1 and 14.9 nm, respectively; measured at 20 micron scan size). When brought in contact with water they tend to swell and delaminate from the substrate surface. This might be an indication that evaporation of these polymers proceeds with significant thermal degradation of polymeric chains. As a result, the volatile fragments of lower molecular weight deposit a wax-like film, which is essentially a mixture of various hydrocarbon oligomers. To improve film stability a glow discharge was applied during evaporation. It was found that with increasing discharge power film roughness decreases down to 1.6 nm for PP at 80 W and 1.7 nm for PE at 120 W. AFM images show that in both cases at a certain power range the formation of branched sferulite-like structures occurs (10 W for PP and 40 – 120 W for PE at the evaporation temperature of 350 °C – Fig. 1). Deposition rate is very important for film formation and structure. It can be increased by higher evaporation temperature. However, in the case of PE, as the temperature of the source is raised above 400 °C vigorous boiling of the polyethylene happens. This causes an ejection of macroscopic particles of bulk polymer. These particles have sufficient energy to reach the substrate surface, and the surface is in this case very rough (Fig. 2).

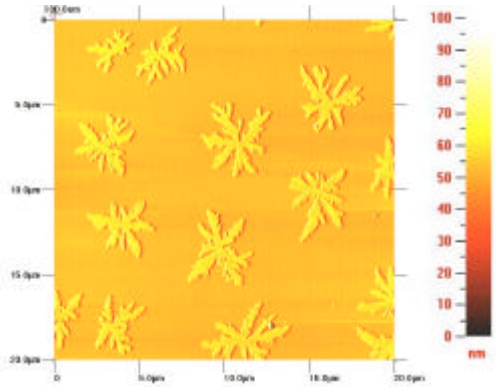

Fig. 1 . Sferulite-like structures on the PE film evaporated on Si at 350 °C with simultaneous 40 W discharge.

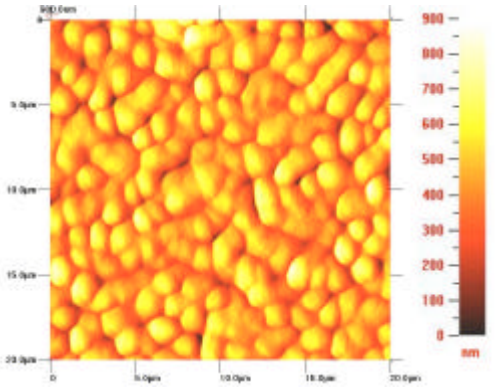

Fig. 2. PE film evaporated at 400 °C on Si with simultaneous 160 W discharge.

The application of a glow discharge during evaporation induced changes in a chemical composition as well. The FTIR spectra of the films deposited by evaporation of PP and PE with and without a glow discharge are presented in Fig. 3 and Fig. 4, respectively. The films evaporated without a glow discharge produce the spectra typical for aliphatic hydrocarbons with stretching and deformation vibrations of CH_x groups appearing slightly below 3000 and 1500 cm^{-1}, respectively. For both polymers, new peaks at 1650 and 1715 cm^{-1} develop with increasing discharge power. These can be assigned to C=C and C=O bonds, respectively. Furthermore, the spectra of the films prepared at low discharge powers are well resolved, whereas with increasing power the individual peaks widen and tend to merge. In the case of PP (Fig. 3), with increasing power the peaks related to absorption of CH_3 groups (2960 cm^{-1}) enhance with respect to CH_2 (2925 cm^{-1}). Comparison of the FTIR spectra of conventional polymers and of polymeric films prepared by magnetron sputtering [8, 9] to out present results shows that the films deposited without discharge are very similar to the classical bulk polymers. With increasing discharge power their chemical structure changes to that of plasma polymer films. The above findings indicate that glow discharge induces plasma polymerization processes, which in the case of hydrocarbon plasmas are generally recognized as based on radical addition, propagation and termination mechanism. This leads to the enhancement of cross-linking, oxidation and the enrichment of bonding environments of hydrocarbon groups. In the case of PE, the oxidation of the polymeric film is also indicated by an increase of a broad OH peak at 3500 cm^{-1}.

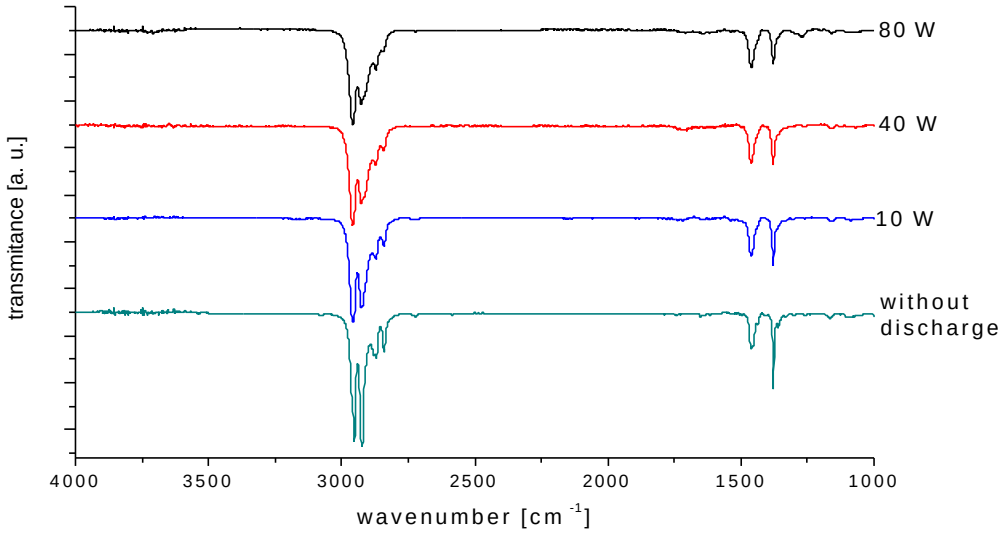

Fig. 3 The FTIR spectra of evaporated PP with or without glow discharge.

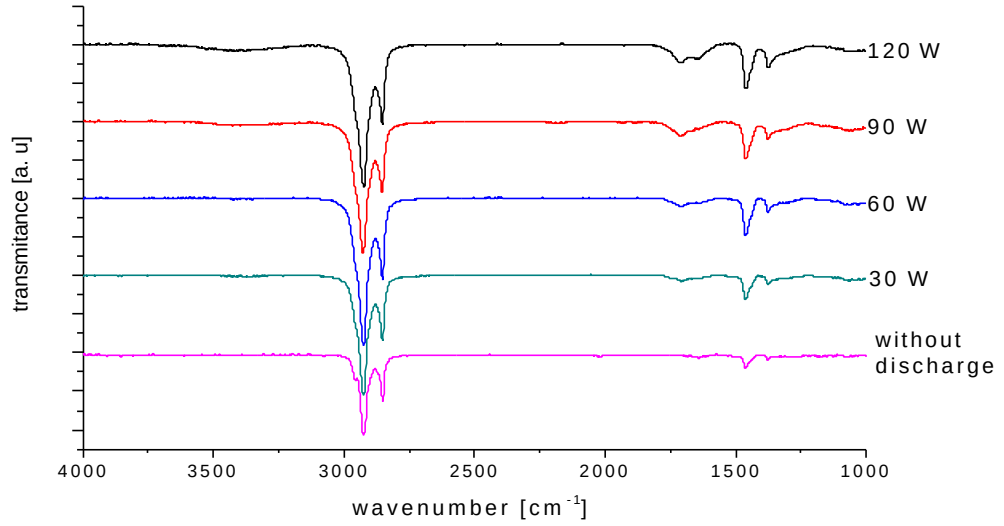

Fig. 4 The FTIR spectra of evaporated PE with or without glow discharge.

The high-resolution C 1s XPS spectra were measured on the PP evaporated films (not shown here). The spectra are featureless regardless the discharge power. However, the Full Width at Half Maximum increases from 1.5 eV for the sample deposited without glow discharge to 2.2 eV for the film prepared at 80 W. A slight asymmetry to the higher binding energy is also observed. We attribute the increase of the peak width and asymmetry to the contribution of carbon bound to oxygen functionalities. The elemental composition calculated from the XPS data is given in the Table 1. The atomic concentration of oxygen gradually increases from 2 % for the sample deposited without glow discharge to 16 % for the film prepared at 80 W. This supports the FTIR findings showing an enhancement of the film oxidation at higher discharge powers. The presence of a small amount of oxygen in the film deposited without discharge may be explained by the water absorbed in source materials. The mass spectral analysis of residual gases performed before and during the evaporation revealed

a considerable increase of intensity from the water species (17-19 amu) after the heating has been turned on. This is with good agreement with our previous work [8].

discharge power	C [at %]	O [at %]	O / C
no discharge	98	2	0.02
10 W	98	2	0.02
40 W	91	9	0.10
80 W	84	16	0.19

Table 1 Elemental composition of polymeric films prepared by evaporation of PP with simultaneous discharge obtained from XPS analysis.

Different chemical structure and surface morphology result in changes of water contact angle. With increasing power water contact angle decreases from 103° to 84° for PP and from 101° to 92° for PE (Fig. 5). The decrease of contact angle with increasing discharge power is in agreement with the chemical changes (increase of oxygen content). It may also be contributed by decrease of roughness, which is known to reduce contact angle on hydrophobic surfaces.

Mass spectrometry of neutral species was done during evaporation of PE, and the examples of the spectra are given in Fig. 6. In the case of evaporation without discharge, only Ar (ions Ar^+ 40 amu, Ar^{2+} 20 amu), water (ions H_2O^+ 18 amu, OH^+ 17 amu, H_3O^+ 19 amu), carbon (C^+ 12 amu) and low molecular weight hydrocarbon fragments (ions CH_x^+ 14 – 16 amu, $C_2H_x^+$ 27 – 29 amu and $C_3H_x^+$ 41, 43, 44 amu) are observed. Absence of higher hydrocarbon fragments has two possible explanations. First, the evaporated fragments may have mass beyond the ultimate limit of our mass spectrometer (300 amu). On the other hand, their partial pressure may be under the detection limit of the spectrometer. When the discharge is switched on (160 W discharge, evaporation temperature 400 °C), the higher hydrocarbon fragments up to $C_9H_x^+$ appear in the mass spectra. We attribute it to fragmentation of long hydrocarbon chain, which results in an increase of the partial pressure of the hydrocarbon components falling within the detection range of our spectrometer.

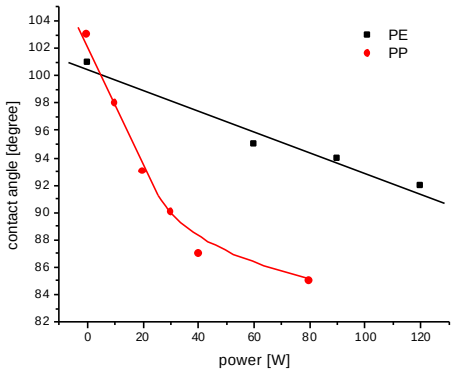

Fig. 5 Water contact angle on the films deposited by evaporation with or without glow discharge in dependence on discharge power.

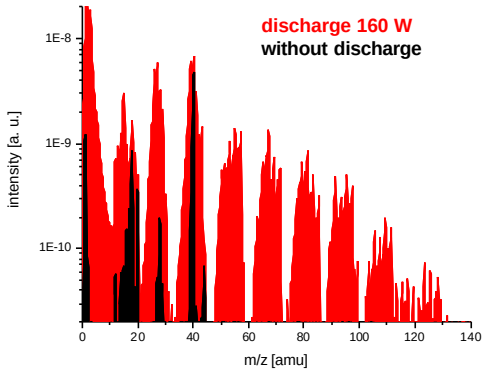

Fig. 6 The neutral species mass spectra during the evaporation of PE at 350 °C (black). Red peaks belong to the evaporation temperature 400 °C with 160 W discharge power.

3. Conclusions

It has been shown that films prepared by evaporation of PP and PE have similar chemical structure to that of conventional polymers. Dissolution in water implies that such films are composed of a mixture of the lower molecular weight hydrocarbon oligomers. The mechanical stability of these coatings can be improved if thermal evaporation is combined

with a glow discharge. Increasing the discharge power leads to the higher extent of cross-linking, and the films become hydrocarbon plasma polymers. However, at moderate discharge powers these hydrocarbon plasma polymers resemble the original polymers used for evaporation.

Abstract

The time dependent behavior of molecular nitrogen ions, following pulsed photoionization of near atmospheric pressure N_2, has been investigated using multi-photon laser techniques and kinetic modeling. Measured time dependent fluorescence spectra, during and after pulsed laser resonance-enhanced multi-photon ionization of N_2, together with a coupled rate equation model, allowed for the determination of the absolute densities of N_2^+ and N_4^+ as these species evolved.

1. Introduction

As the primary component of our atmosphere, molecular nitrogen has been the subject of extensive spectroscopic analysis. Over the past century, the numerous electronic states of N_2 and N_2^+ have been well defined in terms of energy and transition probability[1]. Time resolved nitrogen spectra, generated under controlled excitation, can thus produce information on the kinetic behavior of selected nitrogen states, both neutral and ionized. In this study, ionization and recombination kinetics are investigated under conditions applicable to near atmospheric pressure nitrogen discharges. This kinetic information is of value in studies of combustion processes, atmospheric phenomena, and gas discharges for industrial or laboratory use. This work introduces a new technique for determining N_2^+ and N_4^+ kinetic behavior using pulsed laser spectroscopy together with kinetic modeling. The ion species of interest, N_2^+ and N_4^+, are produced by applying pulsed laser resonance-enhanced multi-photon ionization (REMPI) to a near-atmospheric pressure N_2 system and allowing ion-molecule reactions to proceed. Results of particular interest include the modeled N_4^+ formation and reaction phenomena in nitrogen and air.

2. Theory

It is well known that $N_2^+(X\ ^2\Sigma_g)$ ions can be produced by near-ultraviolet laser excitation of ground state $N_2(X\ ^1\Sigma_g)$ via several resonant absorption bands[2]. The strongest of these absorption bands can be attributed to transitions involving (2+2) or (3+1) REMPI combinations as shown in figure 1, with intermediate states $N_2(a\ ^1\Pi_g)$ and $N_2(b\ ^1\Pi_u)$ being resonant with the second or third photons, respectively. This REMPI technique has been used in previous studies at relatively low N_2 pressures, to preclude collisional processes, where information was sought on intermediate state energy levels or N_2^+ product energies[3]. The higher N_2 pressures in the work presented here allowed the study of a number of reactions of the time-dependent photoionization product $N_2^+(X)$. In particular, the formation of the molecular-ion cluster $(N_2)_2^+$, commonly known as N_4^+, proceeds rapidly for pressures near atmospheric by the three-body reaction[3]

$$N_2^+(X) + N_2 + N_2 \rightarrow N_4^+ + N_2 \qquad (1)$$

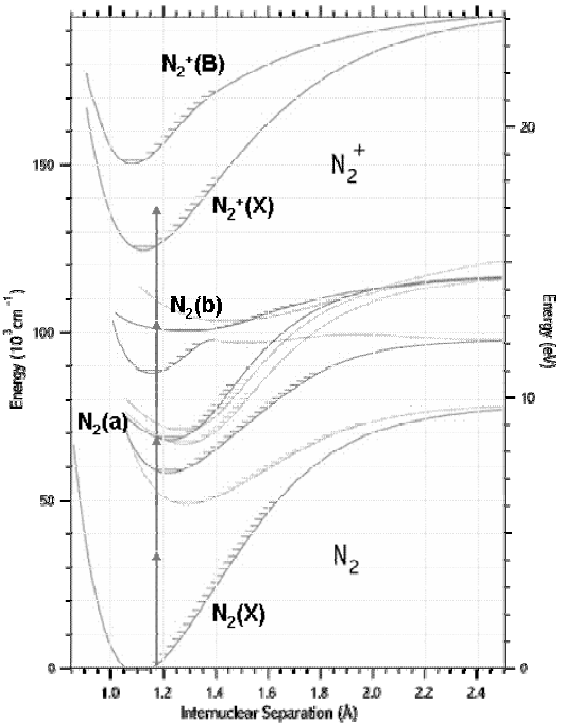

Figure 1. Energy level diagram of N_2 showing (2+2) and (3+1) multi-photon absorption processes through intermediate states $N_2(a)$ and $N_2(b)$

In the partially ionized environment following the REMPI pulse, the electron-ion recombination reaction becomes the primary loss mechanism for N_4^+ as[4]

$$N_4^+(X) + e^- \rightarrow N_2^* + N_2 \qquad (2)$$

Where N_2^* indicates an excited state of N_2. Specifically, this recombination channel leads to N_2 2nd positive system ($C\ ^3\Pi_u - B\ ^3\Pi_g$) fluorescence, which is observed and reported here for the first time using pulsed laser REMPI in N_2. The time dependence of this observed fluorescence, for times during and shortly after the laser pulse, provided information on the evolution of the electron-ion recombination, which was combined with known reaction rate constants to derive information on the time dependence of the N_4^+ density. Similar N_2(C-B) fluorescence has been previously observed in excitation of air by a short-pulse electron beam and attributed to N_4^+ recombination[5].

Also observed in this experiment is a relatively intense fluorescence corresponding to the 1st negative system, $N_2^+(B\ ^2\Sigma_u^+ - X\ ^2\Sigma_g)$, that occurs only during the laser pulse. To differentiate the two observed emission bands, the N_2^+(B-X) emission is henceforward referred to as "prompt fluorescence" while the N_2(C-B) emission discussed above is referred to as "delayed fluorescence". This prompt fluorescence has been mentioned in the literature[6], but its origin has not been thoroughly investigated. We have studied the possibility that the source of the prompt fluorescence is N_2^+(B) production resulting from a single photon photodissociation of N_4^+. With a sufficiently rapid build-up of N_4^+ by reaction (1), during the laser pulse, it is then energetically possible that N_4^+ laser photodissociation can occur and yield N_2^+(B) as a product from the reaction

$$N_4^+(X) + h\nu \rightarrow N_2^+(B) + N_2\ . \qquad (3)$$

Such excited state N_2^+(B) fragments have been experimentally observed from the photodissociation of N_4^+ with a laser in the range of 270-290 nm [7].

We have developed a coupled rate equation model, which describes the pressure and time dependence of both the delayed and prompt fluorescence signals originating from reactions (2) and (3). By using the appropriate known reactions rates along with the relative delayed fluorescence intensity data and the time dependent laser pulse intensity, the model determined the respective N_2^+ and N_4^+ densities that provide the best fit to the data. In general, the rate of temporal rise of the fluorescence signal was strongly dependent on the density of N_2^+ in reaction (1) while the post laser decay rate of the fluorescence was almost entirely dependent on the N_4^+ density (with $[N_4^+] \approx [e^-]$) in the recombination reaction (2). Fitting the delayed fluorescence rise and decay simultaneously allowed for this unique measurement technique of the absolute N_2^+ and N_4^+ densities.

3. Experiment

A pulsed ultraviolet laser, tunable within the 275-290 nm range, was used to photoionize N_2 gas via a resonance-enhanced multi-photon absorption process. The output of a 10 Hz Nd: YAG pumped dye laser operating with Rhodamine 6G dye over the wavelength range 550-580 nm was subsequently passed through a BBO frequency doubling crystal. This generated the working ultraviolet laser pulse with a linewidth of 0.02 cm^{-1} and a nominal energy of 4 mJ per pulse. The beam also passed through a variable uv attenuator to allow the power dependence of the laser absorption processes to be measured. The laser pulse energy was monitored with a beam back-reflection by a joulemeter which was then calibrated to calculate the working laser pulse energy. The uv pulse was then focused down with a 10 cm focal length lens to increase the optical power density and greatly enhance the multi-photon absorption process as the beam entered a quartz chamber with flowing N_2.

For this experiment, a fluorescence signal was collected from the laser focal region, in contrast to the normal REMPI procedures in which only an ion signal is collected. Observations of the fluorescence were restricted to the laser focal region of the chamber due to the relatively slow gas flow and the fact that most measurements

were taken within 100 ns of the laser pulse. The fluorescence induced by the laser absorption included two major bands at 337 nm, N_2(C-B), and 391 nm, N_2^+(B-X), respectively. The fluorescence was then collimated by a 5 cm diameter, 10 cm focal length lens and focused onto a fiber optic receiver with a second 10cm focal length lens. The optical signal was then coupled to a half-meter spectrometer equipped with a 1200 grooves/mm grating, blazed at 300 nm. The spectrally resolved fluorescence was recorded by an intensified charge-coupled device (ICCD) camera with a 512 x 512 pixel array. The camera was configured with a 2 ns optical gate that allowed for the reconstruction of a temporal profile of the fluorescence signal. Experimental control and data acquisition was accomplished with a PC using LabView software.

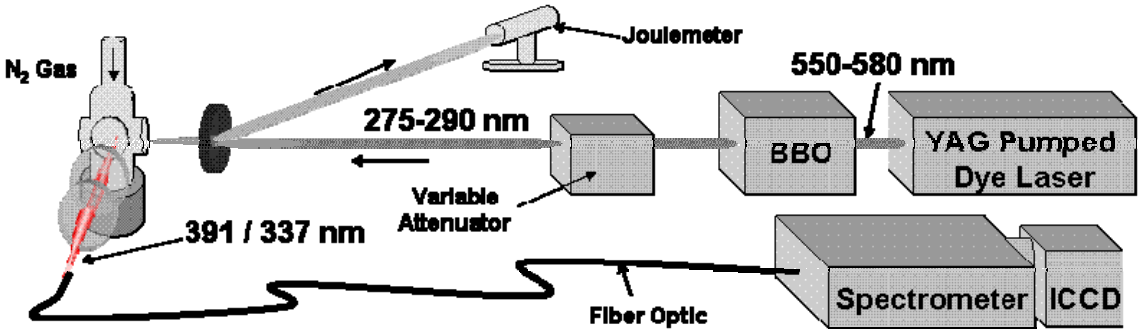

Figure 2: Sketch of experimental set up including laser source, quartz chamber, and optical detection apparatus.

4. Results and Discussion

• Laser Absorption Spectra

Measurements of the fluorescence intensity as a function of ultraviolet laser wavelength resulted in laser absorption spectra that were virtually identical when monitoring either the delayed fluorescence signal at 337 nm or the prompt fluorescence at 391 nm. Figure 3 shows an example of the fluorescence signal recorded at 391 nm as a function of laser wavelength. Several bandheads can be seen corresponding to resonant absorption from the $N_2(X\ ^1\Sigma_g)$ ground state to an intermediate state in the eventual formation of N_2^+. The bandheads of the intermediate N_2 states have been identified and are labeled on the plot with the vibrational sequence from $N_2(X,v''=0)$ in parenthesis. The bandheads corresponding to the $N_2(a\ ^1\Pi_g)$ and $N_2(b\ ^1\Pi_u)$ intermediate states are labeled in figure 3 by *a* and *b*, with less prominent features from $N_2(c_4'\ ^1\Sigma_u)$ and $N_2(b'\ ^1\Sigma_u)$ intermediate states being labeled by c_4' and b' respectively. The resonant absorption from ground state to $N_2(a\ ^1\Pi_g)$ is a 2 photon process where the absorption to the $N_2(b\ ^1\Pi_u)$, $N_2(c_4'\ ^1\Sigma_u)$ and $N_2(b'\ ^1\Sigma_u)$ states are all 3 photon processes.

Although the intensity distribution of absorption spectral features was independent of which fluorescence line was observed, it was dependent on other factors, such as laser power, as expected, but was also found to be dependent on pressure. For example, the rotational line intensity distribution within the N_2(a-X) bands was seen to change significantly as pressure varied from 100 Torr to 750 Torr. This pressure dependence was attributed to the rapid rotational quenching of the $N_2(a\ ^1\Pi_g)$ intermediate state during the laser pulse at higher pressure. The quenching altered the coupling scheme of the 2 photon ionization step since the probability of photoionization depends on a virtual intermediate state that is influenced by Rydberg states such as $N_2(o\ ^1\Pi_u)$ lying about 35,000 cm^{-1} above $N_2(a\ ^1\Pi_g)$[8]. The large fluctuations in the observed band intensities for the $N_2(b\ ^1\Pi_u)$ intermediate states was attributed to the rates of predissociation in the $N_2(b\ ^1\Pi_u)$ state which vary significantly with vibrational level. For the photoionization measurements discussed in the remainder of this paper, the laser wavelength was fixed at 283 nm, which corresponds with the bandhead of the a $^1\Pi_g$ – X $^1\Sigma_g$ (1, 0) resonant transition.

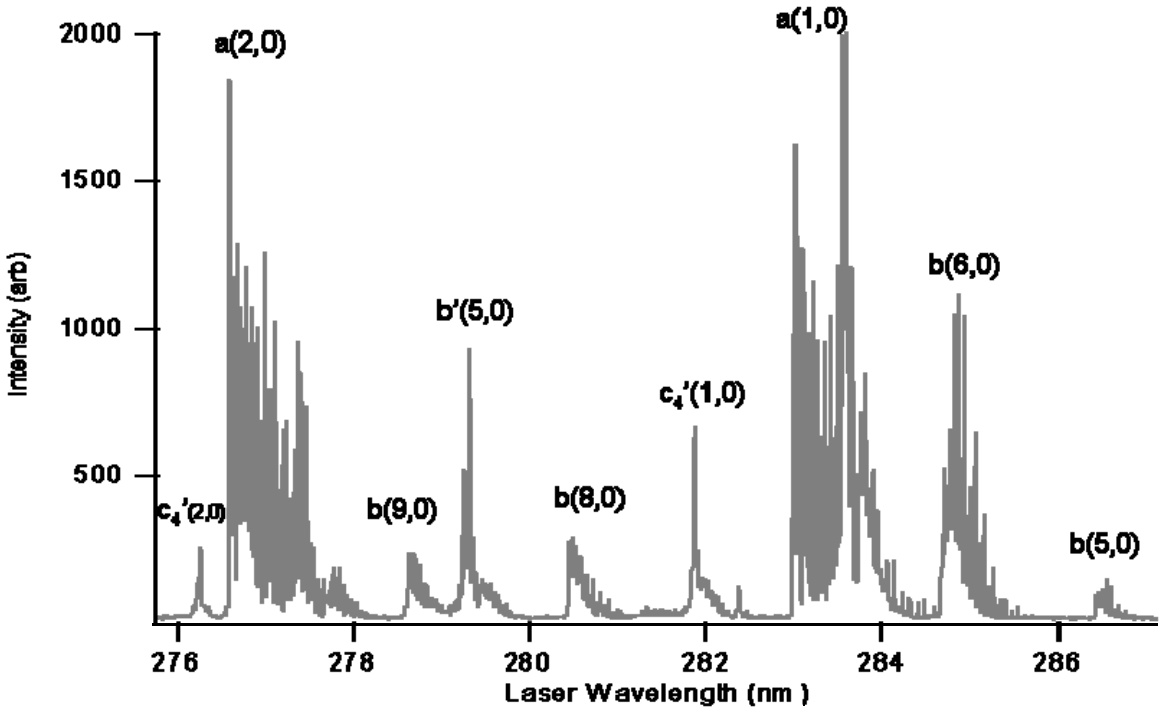

Figure 3: Example ultraviolet laser absorption spectrum taken in 750 Torr N_2 with bandheads labeled as a, b, c_4', and b' representing N_2^+ formation via resonant absorption through intermediate states $N_2(a^1\Pi_g)$, $N_2(b^1\Pi_u)$, $N_2(c_4'^1\Sigma_u)$ and $N_2(b'^1\Sigma_u)$ respectively.

• Fluorescence Data and Kinetic Model

Temporal profiles of the pulsed laser excitation, the prompt fluorescence and the delayed fluorescence are shown in figure 4 for an N_2 pressure of 250 Torr. Using known major reactions of the photolysis products and varying the laser absorption rates in the model, best fits were determined for both the prompt and delayed fluorescence (solid lines).

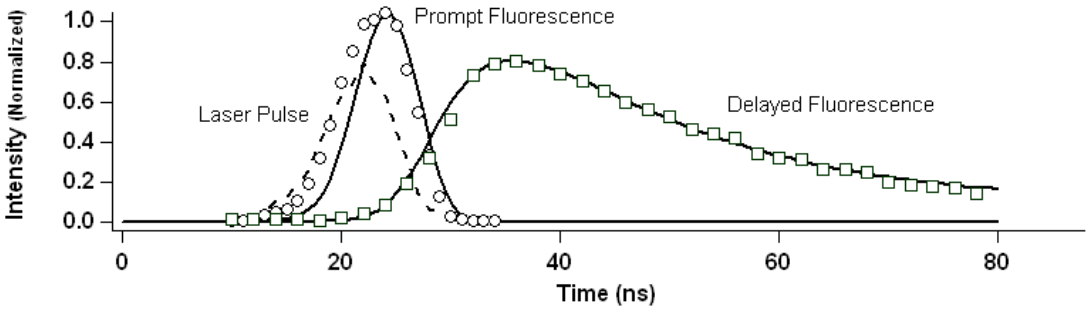

Figure 4: Experimental temporal profiles of laser pulse (dotted line), prompt fluorescence (circles) and delayed fluorescence (squares) with kinetic model fit of each fluorescence (solid lines)

The temporal rise of the prompt fluorescence was observed to slightly lag behind the exciting laser pulse rise and then sharply decay as the laser pulse diminished. This observation is consistent with our theory that the $N_2^+(B)$ upper state prompt fluorescence was produced only upon laser photodissociation of N_4^+. Since the N_4^+ formation was collisionally induced, the initial $[N_4^+]$ rise, and consequently the rise in $[N_2^+(B)]$ would be slightly slower than the laser rise time. The fluorescence, being a product of photodissociation, required the presence of the laser energy as well and thus decreased in intensity quickly as the laser decayed. At pressures below 100 Torr, formation of N_4^+ was calculated to be so slow that there would be minimal accumulation of N_4^+ before the laser

decayed. Our corresponding experiments found the prompt fluorescence signal did vary with pressure and was indeed very weak below 100 Torr.

As discussed earlier, the fitting procedure resulted as well in the determination of absolute densities of both N_2^+ and N_4^+ which are shown plotted as a function of time in figure 5. The plot clearly shows the importance of the N_4^+ ion species at our operating pressures, especially after the excitation source has been removed. The N_4^+ density continued to build until the laser pulse had terminated and the N_2^+ density became insignificant. The maximum ion density occurred shortly after the laser pulse at $[N_4^+] = 2x10^{13}$ cm^{-3}, which in 250 Torr of N_2 corresponds to a N_4^+/N_2 fraction of 2.5 ppm.

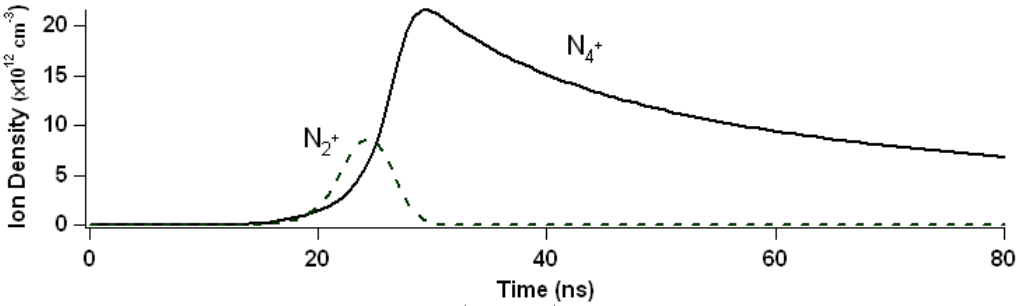

Figure 5: Temporal profile of absolute ion density of N_2^+ and N_4^+ in 250 Torr N_2 generated from kinetic model

5. Summary

Pulsed laser resonance-enhanced multi-photon ionization has been used in conjunction with temporally resolved fluorescence monitoring to study the kinetic behavior of N_4^+ and N_2^+ ions in near atmospheric pressure N_2. Mechanisms are proposed and modeled for the production of $N_2(C)$ and $N_2^+(B)$ during the photoionization and compared to fluorescence data. A least-squares fit of the measured, time resolved, fluorescence data to a coupled rate equation model allowed for the determinations of the absolute densities of both N_2^+ and N_4^+ during and after the laser pulse. This technique is adaptable to various system configurations or could be used in conjunction with other analytical techniques to more accurately determine N_4^+ or N_2^+ reaction rates at near-atmospheric pressure.

Abstract
The formation of carbon nanotubes (CNT) in a dc plasma-enhanced chemical vapor deposition (PECVD) was investigated. It was found that an increase of the CH_4 gas pressure produces an increase of the relative density of the C_2, C_3 molecules and the clusters and a decrease of the excited carbon atom number density in plasma. It was observed that in 10 Torr pressure of CH_4 gas, the ratio between the intensity of the graphite peak (G peak) and the disorder peak (D peak) in the Raman spectrum and the length of the obtained CNT were maxims.

1. Introduction

CNTs are increasingly becoming one of the most important materials for various applications in electronics, optics and biophysics. Up to now, several synthesis methods for CNTs growth, such as arc-discharge [1], laser ablation [2], chemical vapor deposition (CVD) [3] and plasma-enhanced CVD (PECVD) [4] have been investigated. All of these techniques require high temperature for the growing process, which is obtained in an electric furnace or with a hot filament. In our experiment we used dc plasma, which provides the advantage that the metal catalyst was deposited by argon sputtering inside the same vacuum chamber where CNTs were produced on a silicon substrate heated by Joule effect. This PECVD set-up offered the possibility to study plasma composition in the vicinity of the silicon substrate by spectroscopic methods.

In the present work, the number density of the excited carbon atom was measured by laser absorption spectroscopy (LAS) method. Plasma composition and the relative number density of CH radical, C_2, C_3 molecules, H atom, and clusters were measured by optical emission spectroscopy (OES) method. The morphology of the synthesized CNTs in PECVD was probed with a scanning electron microscope (SEM). Raman spectroscopy and Fourier Transform Infrared Spectroscopy (FTIR) characterized the composition of CNTs.

It was found that an increase of the CH_4 gas pressure produces an increase of the relative density of the C_2, C_3 molecules and the clusters and a decrease of the excited carbon atom number density in plasma. It was observed that at 10 Torr pressure of CH_4 gas, the ratio between the intensity of the graphite peak (G peak) and the disorder peak (D peak) in the Raman spectrum and the length of the obtained CNT were maxims. The formation of CNT was explained by the neutral-neutral gas-phase chemical reactions in the high-pressure range of the CH_4 gas plasma.

2. Experimental results

2.1. Production of CNT

The experimental setup for CNT synthesis and plasma diagnostics is schematically shown in Fig. 1. CNT was produced in dc plasma in CH_4 gas.

The cathode was a cylindrical rod of Ni (99.99 %) with a diameter of 15 mm. The anode plate was made from stainless steel, with a diameter of 60 mm. The distance between the electrodes was 7 mm. The silicon substrate (Nilaco, 100, 10x10x0.625 mm, resistivity $\leq 0.02\ \Omega$ m) was set in the space between the cathode and the anode, at a distance of ~ 3 mm far from the cathode.

A nickel thin film was deposited on a silicon substrate by sputtering of the nickel atoms from the cathode, in dc argon plasma. The film thickness was controlled by the sputtering time. The nickel film thickness was evaluated knowing the sputtering yield (the mass of the sputtered metal from the cathode in one hour, at a

discharge current of one Ampere) for the energy of Ar^+ of 600 eV. The sputtering yield of nickel atoms for Ar^+ at 600 eV is 1.34 [5]. In the present experiment nickel film was deposited by Ar^+ at ~ 50 eV, at 20 mA discharge current, in 8 Torr argon pressure and during 10 minutes. From these experimental conditions we evaluate the nickel film thickness to be ~ 50 nm.

After depositing the nickel film, the silicon substrate was heated at 750ºC, using a Joule heater. The substrate temperature was measured with an optical pyrometer. Typical resistance of the substrate including the contact resistance, 500 Ω before heating, was decreased at ~ 3 Ω after heating, due to the increased temperature of the silicon substrate [6].

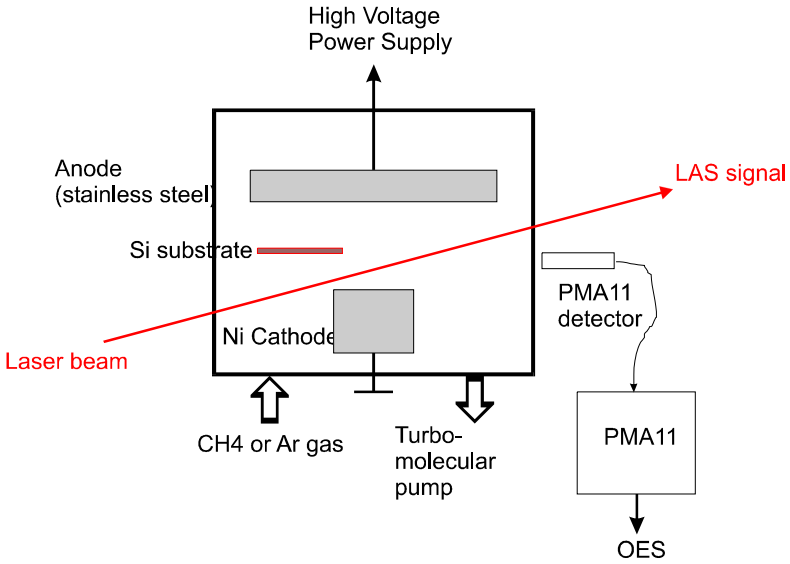

Fig. 1. Experimental setup.

A stable CH_4 discharge was obtained for gas pressures (p) from 2 Torr up to 20 Torr and for discharge currents (i) from 5 mA to 30 mA. The deposition time was one hour.

2.2. Plasma diagnostics

Plasma diagnostics consisted in: *(a)* measurements of the number density of the excited carbon atom by LAS, *(b)* measurements of the relative emission intensities of the excited CH radical, the excited C_2, C_3 molecules and clusters by OES and *(c)* calculation of the electron temperature from relative emission intensities of spectral lines of the hydrogen atom.

The number density of the excited carbon atom on $3^1P_1^0$ level (N_C) was measured with a commercial diode laser (DL: Hitachi 8325G, 40 mW maximum output with the central wavelength of 830 nm at 25°C). The DL wavelength ($\lambda = c/\nu$) was tuned to the resonance absorption of $C(3^1P_1^0 \rightarrow 3^1S_0)$ at λ_0^C = 833.744 nm. A photodiode (PD) and a lock-in amplifier (NF Electronic Instruments 5610B) were used to acquire the absorption signal [7]. The signal to noise ratio (S/N) of the $C(3^1P_1^o)$ atom absorption signal was ~ 10. The value of N_C was calculated by the following formula: $N_C = \left(8\pi g_i / g_j \lambda_0^2 A_{ji} L\right) \int_{\substack{absorption \\ line}} \left[1 - I(\nu)/I_0\right] d\nu$, where g_i (= 3) and g_j (= 1) are the statistical weights of the lower and the upper levels, respectively. A_{ji} (= 0.351×10^8 sec^{-1}) is Einstein coefficient for carbon transition at λ_0 = 833.744 nm. L is the absorption length, which is assumed equal to the diameter of the cathode (~ 15 mm). I_0 is the laser intensity before entering the plasma and $I(\nu)$ is the laser intensity after passing through the plasma. The dependence of N_C on p and i is shown in Fig. 2.

The emission spectrum of dc plasma CVD was analyzed in a range between 300 and 800 nm using a Hamamatsu PMA-11 (Photodiode Multichannel Analyzer) with 2 nm spectral resolution. The most intense OES

lines of the species produced by the decomposition of the CH_4 molecule were: CH radical at 431.4 nm ($A^2\Delta \rightarrow X^2\Pi$), 388.9 nm ($B^2\Sigma \rightarrow X^2\Pi$) and 314.3 nm ($C^2\Sigma \rightarrow X^2\Pi$), the C_2($A^3\Pi_g$) molecule (Swan System: $A^3\Pi_g \rightarrow X'^3\Pi_u$) and the C_3($^1\Pi_u$) molecule (Comet Head System: $^1\Pi_u \rightarrow {}^1\Sigma_g^+$), H atom at 656.3 nm (H_α), 486.1 nm (H_β) and 397.0 nm (H_ε). Many nickel lines were detected in OES from nickel atoms, which are sputtered from the cathode and excited in plasma (Fig. 3).

Table I lists some chemical reactions in gas-phase and the corresponding threshold energy, which can explain the appearance of C_2 molecule, C, H atoms and CH radical in plasma [8]. The gas-phase chemical reactions and the surface chemical reactions can explain the CNT formation in PECVD. In gas-phase the main chemical reactions are electron impact reactions (which conduct to dissociation, excitation, and ionization processes), neutral-neutral reactions and ion-neutral reactions. On the surface, the chemical interaction of neutrals and ions with the catalyst and the substrate are the most significant reactions.

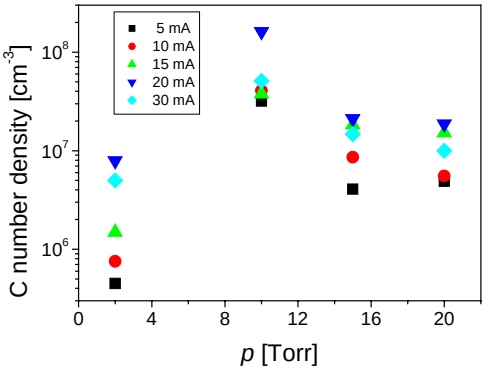

Fig. 2. Dependence of carbon number density on *p*.

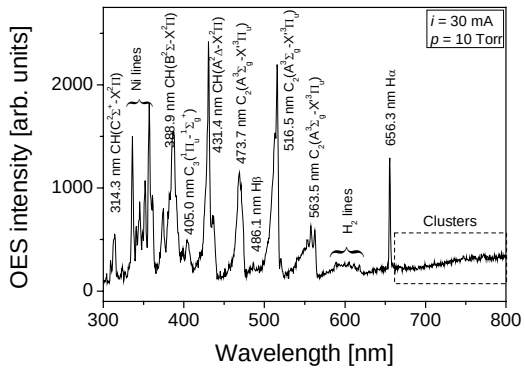

Fig. 3. OES spectra of dc CH_4 plasma (i = 30 mA and p = 10 Torr).

Assuming a quasi-thermal equilibrium in plasma, the electron temperature (T_e) was calculated using the ratio of the relative emission intensities of spectral lines of the hydrogen atom, using the relation: $kT_e = (E_\beta - E_\alpha)/(\ln(I_\alpha / I_\beta) + \ln(A_\beta g_\beta \lambda_\alpha / A_\alpha g_\alpha \lambda_\beta))$, where $E_{\alpha,\beta}$, $I_{\alpha,\beta}$, $A_{\alpha,\beta}$, $g_{\alpha,\beta}$, and $\lambda_{\alpha,\beta}$ are the upper level energy, the OES emission intensity, the Einstein emission coefficient and the wavelength of $H_{\alpha,\beta}$ lines, respectively [10]. Fig. 4 is shows the dependence of T_e on p, at i = 30 mA.

In OES, in the spectral region from 670 nm to 800 nm, a blackbody radiation was observed at different *p* and *i*. This continuum spectrum was attributed to the incandescence of hot carbon clusters or nanoparticles. The blackbody radiation is usually fit with the Planck function to determine particle temperature and to obtain a crude estimation of the particle size [11]. Similar results with the present OES results have been reported in Ref. [12], in a laser vaporization of a graphite/(Ni, Co) system for single-wall CNT synthesis.

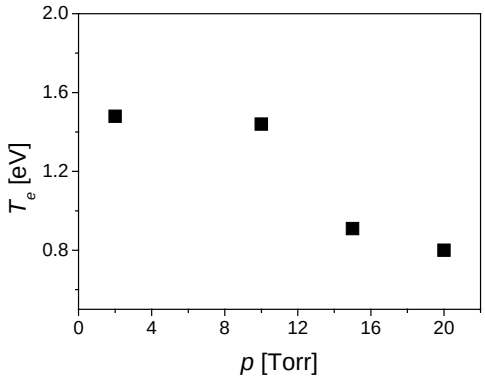

Fig. 4. Dependence of the electron temperature on *p* at *i* = 30 mA.

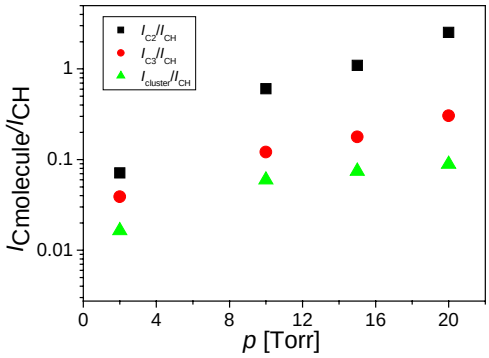

Fig. 5. Dependence of the relative densities of C_2, C_3 molecules and clusters on *p*, at *i* = 30 mA.

The relative intensity of the clusters in plasma is described by the OES intensity around 800 nm. The relative density of C_2, C_3 molecules and clusters are expressed as the ratios between the OES intensity of C_2, C_3 (I_{C2}, I_{C3}) and clusters ($I_{clusters}$), respectively and the OES intensity of the CH radical (I_{CH}), because the excitation energies of CH radical on $A^2\Delta$ level, C_2 molecule on $A^3\Pi_g$ level and C_3 molecule on $^1\Pi_u$ level are almost the same, ~ 3 eV. The dependences of the relative densities of C_2, C_3 molecules and clusters on *i* and *p* are shown in Fig. 5.

2.2 CNT analysis

CNTs were analyzed by Raman spectroscopy (JASCO NRS-1000HS), Fourier Transform Infrared Spectroscopy (FTIR, JASCO FT/IR 660 Plus) and scanning electron microscope (SEM, S4800, Hitachi).

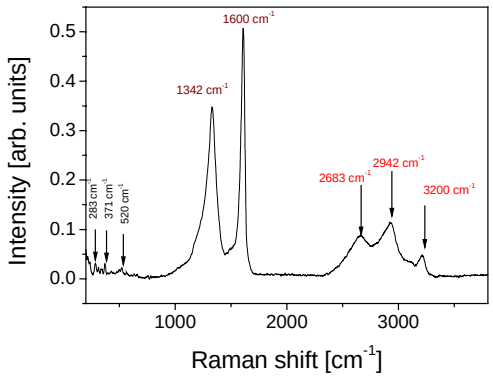

Fig. 6. Typical Raman spectrum of CNT produced in dc plasma, *p* = 10 Torr, *i* = 15 mA.

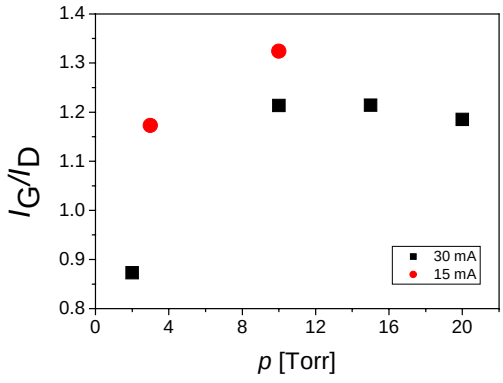

Fig. 7. Dependence of I_G/I_D on *p* and *i*.

Fig. 6 shows a typical Raman spectrum of CNT obtained in dc PECVD, in CH_4 gas. The Raman spectra of CNT have several peaks located between 200 and 3800 cm^{-1} [13, 14]. The most intense peaks occur at 1342 cm^{-1} (D peak), which indicates the presence of defects in graphite structure, and 1600 cm^{-1} (G peak), which represents E_{2g} Raman scattering mode of sp^2-hybridized carbon. Besides the D and G peaks, there are several smaller peaks at 283, 310, 337, 371 and 520 cm^{-1}. The peak at 520 cm^{-1} is due to the silicon substrate. The other four peaks are characteristic features arising from A_{1g} breathing mode of single-wall CNT [14]. These small peaks in Raman spectrum could suggest that a small quantity of single-wall CNT may be present in the deposition. The second-order Raman peaks of CNT occurs between 2000 and 3800 cm^{-1}. The peak observed at 2683 cm^{-1} and 3200 cm^{-1} is the second harmonics of D peak (2×1342 cm^{-1}) and G peak (2×1600 cm^{-1}), respectively. The peak at 2942 cm^{-1} is the sum of the D peak and G peak frequencies ($1342+1600$ cm^{-1}).

The degree of graphite in CNT can be characterized by the ratio between the intensities of G peak and D peak. Fig. 7 shows the dependence of I_G/I_D on p at two discharge currents.

From the transmission spectrum measured by a Fourier Transform Infrared (FTIR) spectrometer (JASCO FT/IR 660 Plus) (Fig. 8), IR absorption coefficient, $\alpha(\omega)$, was calculated. The thickness of the deposition was evaluated from SEM to be ~ 15 μm. The number of C-H bonds per unit volume was calculated as: $N_{CH} = A \int_{\substack{absorption \\ band}} \frac{\alpha(\omega)}{\omega} d\omega$, where A (= 1.35×10^{21} cm^{-2}) is a constant of the C-H_x stretching mode absorption around 3000 cm^{-1} and ω is the wavenumber [15]. N_{CH} was found to be ~ 2×10^{23} cm^{-3} for a deposition at i = 30 mA and p = 10 Torr.

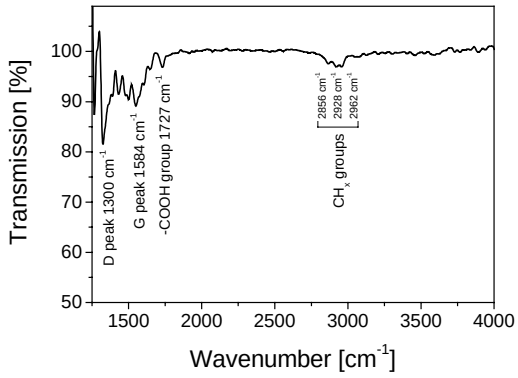

Fig. 8. A baseline corrected FTIR spectrum of CNT deposition in p = 10 Torr and i = 30 mA.

3. Discussion of the experimental results

The highest N_C was ~ 10^8 cm^{-3} in p ~ 10 Torr. N_C slightly depended on i. As p increased, N_C decreased and the relative densities of C_2, C_3 molecules and clusters increased (Fig. 2 and Fig. 5). As p increased T_e decreased (Fig. 4), and the number of dissociated molecules and clusters became smaller.

For the CNTs obtained in CH_4 plasma at p = 10 Torr and i ~ 15 – 30 mA, I_G/I_D was maxim, which corresponded to the same value of p where N_C was maxim. In this case, we can explain that in the formation process of CNT, the carbon atoms play a more important role than the bigger molecules of carbon. Hydrocarbon clusters and radicals contribute to amorphous carbon – hydrogen formation in the same time with CNT production. From SEM analysis presented (Fig. 9), we can observed that the obtained CNT are mixed with amorphous carbon. FTIR analyses proved that a large amount of amorphous carbon was also deposited (Fig. 8). The calculated value of N_{CH} was typical for a-C:H film, as reported in Ref. [15]. From SEM observation, CNT length was evaluated to be ~ 15 μm.

The presence of a high amount of sp^2 graphite in the composition of CNTs was also confirmed by the IR-active peak corresponding to G peak at 1584 cm^{-1} (Fig. 8). The peak at 1727 cm^{-1} corresponds to

nonconjugated carboxylic carbonyl group [16] and can be explained by oxidation of silicon substrate before deposition.

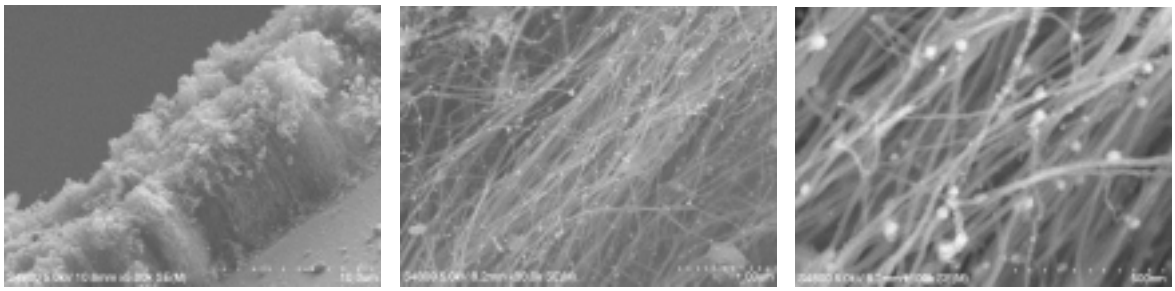

Fig. 9. SEM image of CNTs obtained in PECVD at i = 30 mA and p = 10 Torr.

These small peaks in Raman spectrum corresponding to the A_{1g} breathing mode of single-wall CNT (Fig. 6), could suggest that a small quantity of single-wall CNT may be present in the deposition [14].

4. Conclusions

The experimental results show that the maximum ratio of I_G/I_D was obtained when the number density of C atoms was maxim. The relative number density of the C_2, C_3 molecules and the clusters to the number density of CH radical increased with gas pressure. The increased number density of the C_2, C_3 and the clusters in plasma was determined by a low electron temperature and recombination processes. If the electron temperature was high, in low range pressure of CH_4 gas, the dissociation processes dominate in plasma. In this case, in low range pressure of CH_4 gas, the number density of C atoms was higher than in high range pressure.

The maximum length of CNT synthesized in PECVD in CH_4 gas, and the maximum ratio between G peak and D peak were obtained when the deposition was realized in 10 Torr pressure of CH_4 gas and 30 mA discharge current.

These experimental results cannot explain completely the mechanism of CNT formation.

Abstract
Composite coating for intrabone implants as a combination of capillary-porous titanium coating with deposited bioactive ceramic top layer is proposed. Porous coating is formed on an implant surface by atmospheric plasma spraying and bioactive ceramic layer is deposited over it by microplasma process in electrolytic solutions. High values of porosity and bioactive nature of these composite coatings are favorable for bone tissue growing in and fastening its connection with an implant.
Keywords: biomaterials; porous coatings; implants; plasma spray

1. Introduction

Connection of a bone skeleton with the help of implants remains an important problem of clinical medicine and material science. Bone tissue should easily grow into the surface layer of an implant ensuring strong and reliable connection.

One of the impressive examples of porous coatings applications is their use in medicine as components of orthopedic or dental implants significantly enhancing their performance. Porous metal and ceramic coatings deposited on implants facilitate bone ingrowth and implant fixation. This application area for coatings is one of the fastest-growing areas in the field of biomaterials [1-3].

The most common surface coatings used for metal implants include sintered beads, diffusion bonded wire mesh, and metallic plasma sprayed porous coatings. In conventional plasma spraying process, the operating parameters are adjusted such that the metal powder particles (most often commercially pure titanium, typically ~200 μm in diameter) being injected into the plasma are only partially melted as they are being accelerated toward the substrate. Plasma sprayed coatings are commonly 500 to 1000 μm thick, but they do not form a regular three-dimensional interconnected array of pores. The porosity of these coatings reaches ~30%, and the maximum pore size is about 50–150 μm. Relatively low mechanical strength of the plasma sprayed coatings may be associated with low contact area between the deposited particles. The plasma sprayed coatings essentially form irregular surfaces with very little interconnected porosity throughout the thickness of the coating.

For bone to grow into the porous coating, certain minimum pore sizes must be achieved. If these minimums are not met, either soft tissue will form or ingrowth will not occur at all. Studies [1-3] have shown that the minimum pore size for load bearing implants, such as artificial hips and knees, should be approximately 100 to 150 μm. Most porous coatings intended for intrabone implants have pore sizes that range from 100 to 500 μm. Observations suggest that the performance of porous-coated implants depends on the pore structure as a function of both the degree of pore interconnectivity and the volume of porosity. In particular, performance of an implant is greatly enhanced by the use of osteoconductive materials (osteoconduction is defined as the ability of a material to encourage bone to grow toward and along its surface).

Surface engineering plays a particularly significant role in implants design since the bone grows onto the surface, thus affecting the quality of the bond between bone and implant. Bone ingrowth is dependent on the material and biological properties of the surface of the implant but at a great extent also on its surface parameters. The key factors in a porous structure design are the surface roughness, pore size and the amount of pore interconnectivity.

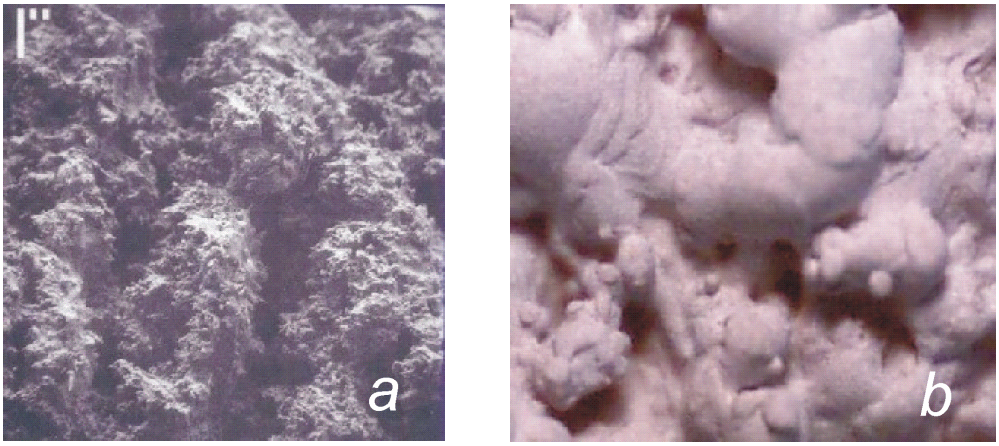

Fig. 1. SEM images of the surface of 3DCP Ti (a) and Ti+HA (b) coatings. Mark – 100 μm.

Bone fixation could be further maximized by means of deposition of hydroxyapatite (HA) layer over the porous coating on an implant. The osteoconductivity of HA facilitates bone contact by directing bone growth towards the implant and both to the coating. Osteoconductivity of HA coatings can guide bone growth into the pore space to enhance the mechanical bonding. With this aim microplasma electrolytic method could be used which allows receiving uniform bioceramic porous coatings on a complex geometrical relief.

A coating of HA, a major inorganic component of bone, on the metal surface has been suggested as the most effective way to give biocompatibility and osseoconductivity. Until today several coating techniques of HA on titanium alloys such as plasma spray coating, sputtering, chemical vapor deposition, electrophoresis, electrochemical deposition, and dip coating, have been explored and among these techniques plasma spray coating has mostly been highlighted for the applications. However, using plasma spray coating it is very difficult to obtain uniform HA coating and high bond strength between HA and Ti/Ti-alloy substrates.

A new concept of bone-implant volumetric boundary in the form of three-dimensional capillary-porous (3DCP) metallic (Ti) coating with deposited bioactive ceramic (BC) top layer (Fig. 1) is proposed in the present research. Porous titanic coating is formed on an implant surface by atmospheric plasma spraying (APS) and bioactive ceramic hydroxyapatite layer is deposited over it by microplasma process in electrolytic solutions.

2. Plasma spraying of porous coatings

The requirements to implants listed above, have stimulated a design of plasma sprayed porous coatings with regulable structure ensuring high osteoconductive properties and at the same time high strength characteristics of deposited surface layer. These conflicting objectives could be fulfilled by means of spatial separation of porous and condensed volumes of the coating. Such a new concept of bone-implant volumetric boundary in the form of three-dimensional capillary-porous titanium coatings was proposed in [4]. These coatings consist of cavities (open voids or valleys) and ridges (deposited material or peaks) growing from a surface of the substrate (Fig. 1a). The ridges may have micro-rough surface and include capillaries. The process of fabrication of 3DCP coatings is performed by atmospheric plasma spraying at off-normal spray angle of completely-molten particles to the substrate using Ti wire as a feedstock. The method of 3DCP coating buildup is based on the effect of shadow zones arising behind the particles already deposited to the substrate (e.g., [5]). The height of the ridges is of the same order as the mean height of the 3DCP coating. The surface area of the coating increases directly proportionally with the increase of the coating thickness, thus this type of coating is named three-dimensional.

Titanium used in 3DCP coatings is known as highly stable material which easily osseointegrates with bone [1-3]. Firstly, titanium is passive in aqueous solutions and the passive film that forms on titanium is stable even in a biological system. Secondly, oxide on titanium reacts with mineral ions, water and other constituents of biofluids that cause remodeling of the surface. It has been shown that calcium phosphate forms on the passive oxide film. The calcium phosphate formed on titanium is similar to apatite. Titanium therefore forms its own bioactive surface leading to osseointegration in a similar fashion to HA coated implants.

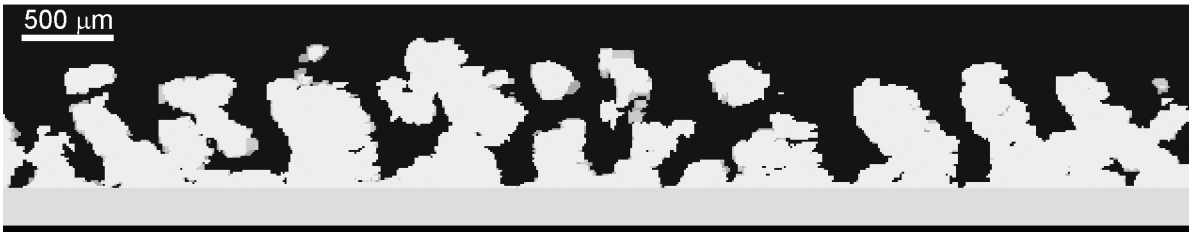

Fig. 2. Cross section of 3DCP coating. Spray angle θ = 30°. Computer simulations.

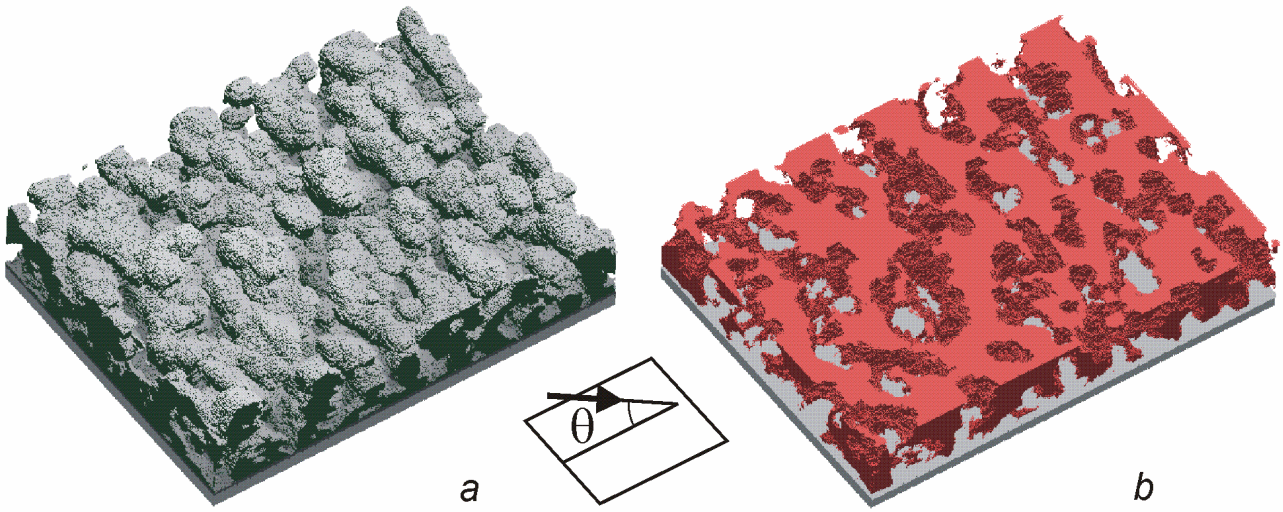

Fig. 3. 3D-images of 3DCP coating (*a*) and corresponding pore network (*b*). Spray angle θ = 30°. Substrate area 4×3 mm^2. Computer simulations.

The cavities represent the main porous fraction of the 3DCP coating; bone ingrowths into this volume. The structure of porous coating of this type itself promotes biological activity, since the size and shape of the cavities are favorable for bone ingrowth and healing.

Typical characteristics of plasma sprayed implant surface coatings are given in the Table 1. It is important to point out that experimental value of the volume available for bone ingrowth for 3DCP coatings is 6 times higher than the corresponding value determined for conventional plasma sprayed coatings [6].

Structural coating parameters were also predicted by numerical simulation of plasma spray coating build-up process using a three-dimensional discrete ballistic model. Depending on a sample geometry and angle of spray, typical numerical experiment describes layering of 20000−80000 individual particles. The model predicts coating porosity, thickness and roughness as functions of the spraying conditions. Depending on the deposited particles size and shapes of the resulting splats, different types of microstructures and porosities, and consequently different coating properties could be obtained. The simulation results for the spray angle θ=30° illustrating the coating structure and corresponding pore network which characterizes osteoconductivity are shown in Fig. 2 and 3.

Table 1. Characteristics of porous coatings deposited on intrabone implants

Parameter	Type of coating	
	Traditional plasma spray	3DCP coatings
Volume available for bone ingrowth, μm^3/ μm^2	71.0	413.9
Ra, μm	28.9	359
Rz, μm	144.9	824
Ra/Rz	0.155	0.436

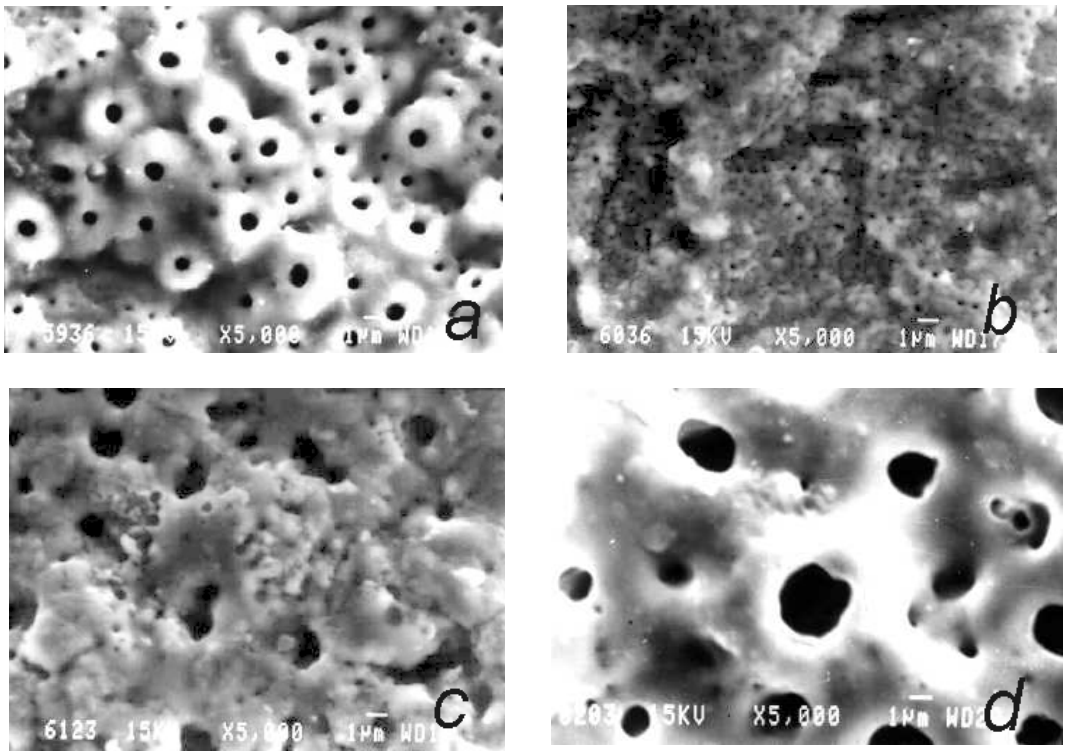

Fig. 4. Morphology of BC coatings deposited over 3DCP Ti coating in electrolytic solutions (Table 2). ×5000.

3. Microplasma deposition of bioactive ceramic coatings

Microplasma process is a room-temperature electrochemical method suitable for HA coating, and this technique may replace plasma spray coating. Microplasma electrolytic technique has the certain advantages on deposition of bioactive ceramic layers in comparison with conventional ways of deposition. Pulsed plasma deposition methods in solutions of electrolytes allow obtaining coatings with high adhesion due to high values of energy of local microplasma discharges on a surface of the processable sample, promoting creation of nanocrystal ceramic coatings. Microplasma process enables depositing BC films of uniform thickness on the coarce and rough surface of 3DCP Ti coatings over implants of complex shape [7,8]. This method can be applied for the formation of gradient coatings [9] with the internal layer consisting of thermodynamically stable TiO_2 formed by microplasma discharges generated at the surface and the outer nanostructured BC layer composed of Ca and P atoms.

During pulsed electrolytic microplasma process, BC coating is formed over titanium substrate consisting at least of two layers. The internal layer is composed of titanium oxides, and the external bioactive layer is sintered of calcium and phosphorus compounds and HA presenting in electrolyte as dispersed powder. The composition and structure of bioactive coating can be constructed: it depends on the composition of an alloy on which it is deposited, but in the greater degree on the composition of electrolyte. Also it is possible to design such properties of a coating as thickness, porosity, a roughness, and the pore sizes.

Table 2. Electrolyte composition and characteristics of BC coatings: element composition, thickness h, roughness R_a, pore surface concentration N, porosity P, pore diameter D

	Electrolyte composition	Ti	P	Ca	h, μm	R_a, μm	N, cm^{-2}	P, %	D, μm
(*a*)	Na_2HPO_4, HA	72.5	22.08	5.42	47	1.49	1×10^6	8	4.0
(*b*)	Na_2CO_3, HA	97.8	0.16	2.06	44	0.89	1×10^7	22	1.2
(*c*)	KOH, $Ca_3(PO4)_2$	96.6	3.19	0.23	33	0.86	9×10^6	14	2.5
(*d*)	Na_2HPO_4, $Na_2B_4O_7$, H_3BO_3	78.6	21.54	–	49	2.32	1×10^6	20	6.3

BC coatings on implants were obtained in electrolytic solutions containing calcium phosphates and HA at the applied voltage of 440 V and pulse duration 200 μs. BC coatings fabricated by microplasma process include crater shaped pores. BC coating composition, pore diameters and concentration depend strongly on electrolyte composition (Table 2, Fig. 4). All investigated coatings on titanium and its alloys have high chemical stability, they are not dissolved in acids and alkalis.

4. *In vivo* research

Research of fabricated implants *in vivo* was carried out with dogs (24 knee joints). The technique of experiment included formation of channels in distal epiphyses of femurs in which appropriate cylindrical implants (titanium rods 7 mm in length and 3.3 mm in diameter) were placed. Two types of surfaces were analyzed: implants without (control group) and with 3DCP Ti and BC coatings (experimental group). Results of biopsy have shown that implants with plasma sprayed porous Ti + HA coatings were strongly fixed in tissue of femoral condyle. A process of enchondral ossification was observed on the border between these implants and the bone tissue. Within the period of 16−24 weeks the bone beams have been formed directly integrating with coatings and repeating their surface relief (Fig. 5).

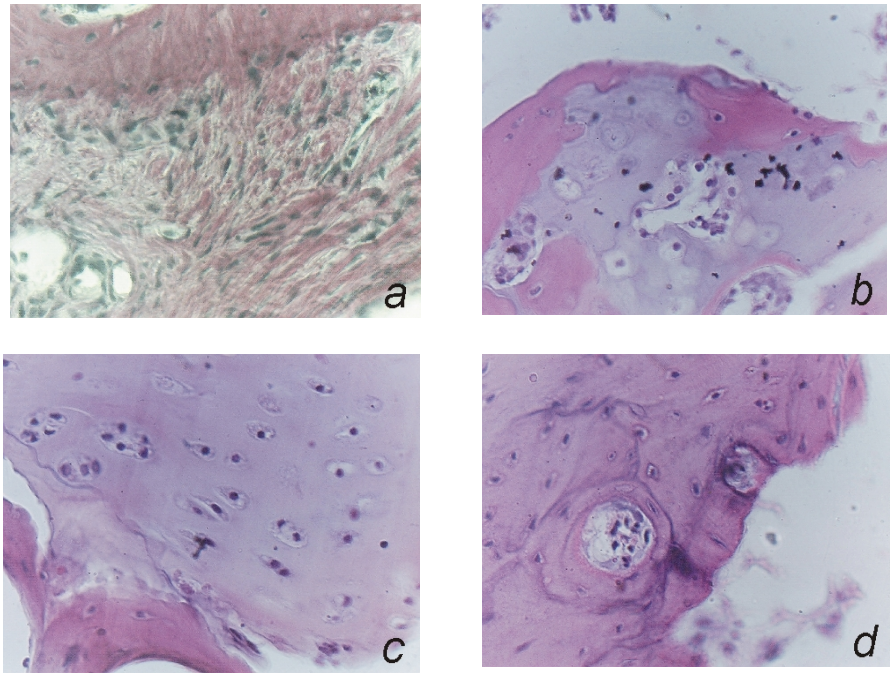

Fig. 5. Regenerative processes at the bone-implant boundary: (*a*) Ti implant without coating – increase in growth of the friable connective tissue around implant; (*b*) implant with 3DCP Ti coating – formation of clusters of chondrical tissue; (*c*) implant with 3DCP Ti + BC coating – processes of enchondrical ossification; (*d*) completing of the bone tissue formation. Dye: (*a*) Van Ghison; (*b*)–(*d*) heamatoxyline and eosin. ×400.

5. Intrabone implants with composite 3DCP Ti+BC coatings

The research of coating build-up process and porous structures obtained at off-normal spray angles have led to the development of the technology of fabrication of a new generation of effective composite porous coatings intended for intrabone implants.

The porosity of 3DCP coatings reaches 50%, and the widths of ridges and cavities may be regulated over a wide range from 5 up to 2700 μm. The small porosity (2–10 %) of the internal volume of the ridges allows achieving the values of adhesion and cohesion close to the values of feedstock (dense) sprayed materials. Special

conditions of plasma spraying process have allowed achieving the shear strength of 250 MPa at the coating porosity level of 45%. Favorable coating characteristics ensure reliable fastening a bone tissue in 3DCP coatings. One of the modifications of cementless hip prostheses with porous composite bioactive coating is shown in Fig. 6. About 80% of the surface of the prosthesis (Ti6Al4V) is covered by 3DCP Ti+HA coating with the thickness of 0.5–0.8 mm. This construction ensures reliable primary press-fit fixation and also secondary fixation due to osteointegration into the porous coating with bioactive top layer.

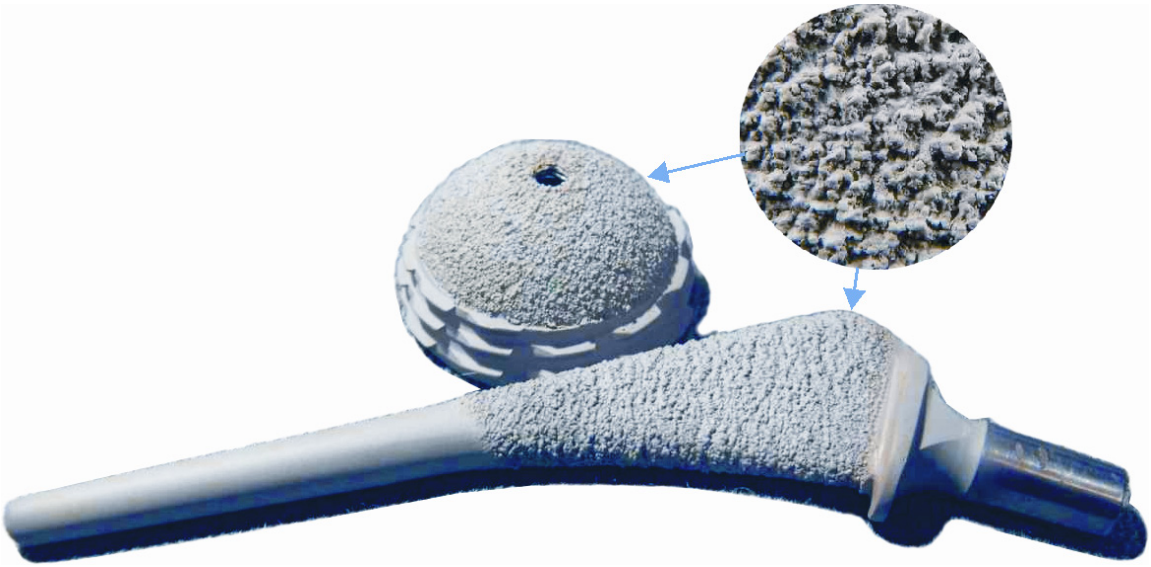

Fig. 6. Intrabone implants with 3DCP Ti+BC coatings.

6. Conclusion

Combined process of plasma spray-microplasma deposition of highly porous bioactive composite coatings with principally new structure and enhanced mechanical and operating characteristics has been developed. High values of porosity, surface area and excellent mechanical properties of 3DCP Ti + BC coatings proved to be favorable for bone tissue growing in and fastening of its connection with an implant. BC and 3DCP coatings successfully supplement each other by their surface structure: presence of micro and macroporosty is favorable for fastening of bone tissue on the implant surface. Bioactive properties of these coatings ensure high stability and strength of bone-implant bond.

Abstract
Novel technology of plasma spraying of three-dimensional capillary-porous coatings with principally new structure consisting of ridges and cavities has been developed. The process of fabrication of these coatings is performed under a sharp incidence angle of the plasma spray to the substrate. The method of spraying is based on the effect of shadow zones arising behind the particles already deposited to the substrate. Influence of the spray angle on coatings porosity, roughness and structure is investigated.
Keywords: porous coatings; computer modeling; plasma spray

1. Introduction

As a rule, porosity is considered to be a defect of plasma sprayed coatings. Nevertheless, highly porous coatings in some situations are desirable and they are widely used in various branches of technology, science, and medicine, serving like heat exchangers, catalytic surfaces, bioactive surface layers of intrabone implants, drug delivery elements, etc. The key factors in a porous structure design are the surface roughness, pore size and the amount of pore interconnectivity.

Structural, mechanical, and other properties of plasma sprayed coatings are controlled by the impingement, spreading and solidification of discrete molten particles which finally form splats on a substrate or previously deposited layers during plasma spraying process. The splat layering depends on the particle temperature and velocity at impact, the shape and topology of already deposited layers, the substrate temperature, the ability of the flattening particle to accommodate their pores, asperities, etc.

The advances in understanding of the process of plasma spraying have allowed controlling the coating properties, reliability and reproducibility. Recently, the important results of the intensive research in the field of plasma spraying both in experiments and modeling during the last five decades have been summarized in extended review publications [1,2].

The requirements of current technology have stimulated a design of plasma sprayed porous coatings with regulable structure ensuring high values of porosity, pore interconnectivity and at the same time high strength characteristics of deposited surface layer. These conflicting objectives could be fulfilled by means of spatial separation of porous and condensed volumes of the coating. Such a new concept of three-dimensional capillary-porous (3DCP) coatings was proposed in [3]. These coatings consist of cavities (open voids) and ridges (deposited material) growing from a surface of the substrate. The ridges may have micro-rough surface and include capillaries. The process of fabrication of 3DCP coatings is performed by atmospheric plasma spraying (APS) under a sharp incidence angle of completely-molten particles to the substrate. The method of 3DCP coating buildup is based on the effect of shadow zones arising behind the particles already deposited to the substrate (e.g., [4]). The height of the ridges is of the same order as the mean height of the 3DCP coating. The surface area of the coating increases directly proportionally with the increase of the coating thickness, thus this type of coating is named three-dimensional.

Various aspects of coating deposition at off-normal spray angles have been studied previously by different authors (e.g., [1,2] and literature cited therein) including peculiarities of coating buildup, splat formation, etc. However, as it was mentioned, in the majority of papers coating deposition at off-normal spray angles was considered as a process leading to the defective coating structure. At the same time, off-normal plasma spraying enables to create unique three-dimensional structures which could not be fabricated in any other technological process.

This paper describes the experimental and theoretical investigations of the coating growth at off-normal plasma spraying and the resulting structural and mechanical properties of 3DCP coatings.

2. Spraying conditions and coatings characterization techniques

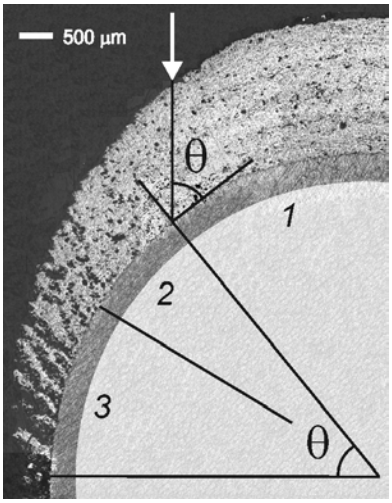
In the experiments presented in this paper, the feedstock was commercially pure titanium powder with a particle size distribution ranging from 36 to 63 μm and mean particle size of 49.5 μm. The coatings with a thickness up to 1 mm were deposited onto flat and cylindrical (diameter 10 mm) titanium substrates at different spray angles (here and hereinafter, as is customary, the spray angle θ is defined as the angle between the substrate surface and the impacting particles trajectories).

For the coatings deposition, plasma torch (20 kW, atmospheric pressure $Ar+N_2$) with special nozzle ensuring plasma flow extraction from the coating deposition zone, local protection from atmospheric oxygen and eliminating the heat influence of the plasma flow on the coating and substrate was used. The design of the extracting nozzle led to an increase in the neutrality of a gas medium in a spraying spot, a decrease in the thermal effect of a plasma jet on a sprayed coating, and an increase in the efficiency of heating a powder in the plasma jet. Decreasing the temperature gradient across a plasma jet is another important factor. Moreover, the nozzle increases the maximum velocity of sprayed particles up to 200 $m \cdot s^{-1}$.

The structural coatings characteristics were measured using optical microscopy, SEM and image analysis. For the investigations of the surface of Ti 3DCP coatings, soft hardware complex based on high resolution SEM Hitachi-800 was used. Planimetric and stereometric morphological surface analyses were performed by means image processing program [3]. Porous structures of the plasma-sprayed coatings were also analyzed by mercury intrusion porosimetry (MIP). Mechanical tests of the deposited porous coatings were performed using Instron equipment and original methods including shear tests with a help of a matrix with orifices for sample streching.

3. Effect of spray angle on coating structure

In order to illustrate influence of the spray angle on the coating structure in a single experiment under the same operating conditions, the plasma torch was oriented perpendicularly to the axis of the titanium cylindrical rod substrate with a diameter of 10 mm. In this case, as it is clear from Figure 1, the spray angle θ varies continuously from 0 to 90° along the cylinder surface.



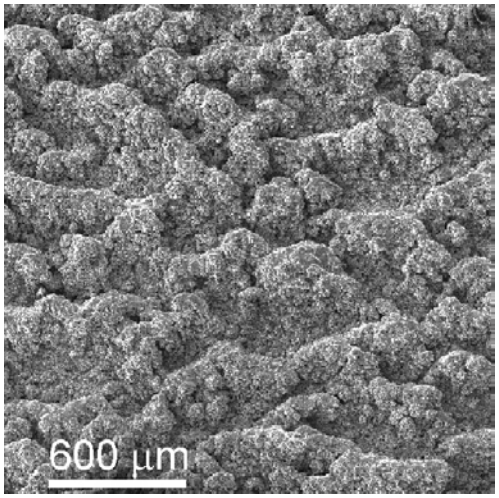


Figure 1. Cross section of cylindrical sample with plasma sprayed titanium coating (fragment). *1* – zone of low porosity, contains small-sized pores; *2* – transition zone, includes closed voids and large pores; *3* – zone of high porosity, consists of ridges. Arrow indicates the direction of spraying.

Figure 2. SEM image of the surface of titanium 3DCP coating deposited at the spray angle θ = 20°.

By its structure, the titanium coating sprayed onto the cylindrical substrate in some approximation could be divided into three zones (these zones are allocated on each side of the plane of symmetry which is normal to the cross section presented in Figure 1). In the central zone (*1*) the porosity is relatively low and the coating contains

pores which sizes do not exceed 20 μm. In the peripheral zone (*3*) the coating obtains a columnar structure and consists of ridges growing up from the substrate surface. The remaining zone (*2*) is transitional and includes closed voids and large pores with diameters of the order of ~60 μm. Depending on the spraying conditions (particles temperature, velocity, diameter, etc.), the dimensions of the transition zone are defined by the spray angles θ ranging from 40 to 50°.

The experiment with plasma spraying onto a cylinder is a visual demonstration of important morphological peculiarities of the coatings deposited at off-normal spray angles. While the mechanisms of pore formation in the central zone (*1*) are typical for traditional plasma spraying (incomplete filling of intersplat spaces by molten particles, splat curling, cracks, etc.), one more mechanism associated with the shadow effect described above appears in transitional (*2*) and especially in the peripheral (*3*) zones. Due to the relief shadowing, the absolute values of the local coating profile peaks heights and peak to peak distances increase with the decrease of the spray angle. Starting from some critical angle ($\theta < 40°$), isolated ridges appear on the substrate. It should be pointed out that the angle between a single ridge and the substrate surface does not coincide with the local spray angle; typical values of the slope angles of ridges are about 48–52° even at nearly zero spray angles. In the transition zone, during the process of growing up the neighboring ridges finally overlap each other, and as a result the closed pore network is formed within the coating. In the plane of the cross section (Figure 1) these large-sized pores are not connected with each other.

4. Coatings characterization

A series of titanium coating deposition experiments have been performed at a number of fixed values of the spray angle (Figure 2). Except traditional coatings characteristics such as roughness and porosity, various morphological parameters of porous coatings were considered: the equivalent pore diameter, defined as the diameter of a circle with the same area as the selected pore; the pore specific surface area, defined as the ratio of the surface of all the pores to the total volume; pore shape factor, defined as the ratio of lager to minor semiaxis of the ellipsoid inscribed into the real pore. These results are summarized in Table 1 and Figures 3 and 4.

Table 1. Morphological characteristics of Ti 3DCP coatings (SEM analysis).

Parameter	Spray angle	
	20°	30°
Total number of pores	$2.1 \cdot 10^5$	$2.9 \cdot 10^5$
Porosity, %	45.75	39.66
Minimum equivalent pore diameter, μm	0.54	0.61
Maximum equivalent pore diameter, μm	402.4	267.7
Mean pore diameter/dispersion, μm	1.86/13.5	1.77/10.3
Pores specific surface area, $\mu m^2/\mu m^3$	0.38	0.47
Pore shape factor	0.16–0.96	0.10–0.99

The experiments demonstrated that the amount of porosity and surface roughness increases slowly with decreasing the spray angle from 90° down to ~50°. After that a fast increase in these parameters occurs. These observations are in quite good qualitative agreement with the experimental results reported in [5] for alumina and titania composed particles deposited at off-normal spray angles.

Figure 4 compares the pore size distributions for the spray angles 90° and 30°. The allocation of pores in the coatings is of polymodal character. In the Ti 3DCP coating sprayed at 30° at least three groups of pores could be detected. The major part of porosity of the 3DCP coatings corresponds to large open voids – cavities between the ridges. The contribution of this type of pores with equivalent diameter of 100 μm and higher to the total coating porosity reaches 40–50%. The microstructure of the ridges is represented by the deformed solidified particles (splats) with the shapes typical to traditional thermal spraying process. In order to achieve the highest strength characteristics of porous coating, the ridges must be built-up of splats with maximum contact area between them. The sizes of the pores allocated in the ridges depend on the thickness of the formed splats which values according to experimental measurements may vary within 5–15 μm interval. Inclusion of semi-molten particles into the coating results in the appearance of pores with sizes close to the sprayed particle diameters.

Special conditions of plasma spraying process have allowed achieving the value of 250 MPa for the shear strength of 3DCP titanium coatings at the coating porosity level of 45% and surface roughness characteristics R_a = 359 μm, R_z = 824 μm, R_a/R_z = 0.436. The width of cavities of 3DCP coatings may be regulated over a wide range from 5 up to 2000 μm, and the width of ridges − from 200 to 2700 μm. Low porosity (2–10%) of internal volume of ridges allows to reach the values of adhesion and cohesion close to the values for initial (dense) spraying materials.

5. Model description and simulation results

Structural coating parameters can be predicted by numerical simulation of plasma spray coating build-up process. In principle, a strict plasma spray coating growth model could be developed based on the detailed description of numerous (typically, about 10^4–10^5) individual collisions of deposited particles with a substrate, their deformation and solidification as a splats. However, this requires solving complex coupled problems of hydrodynamics and heat transfer for every particle-surface collision. Although tremendous progress has been made in this area [6,7], modern computers can simulate splat formation and interactions only of a few splats. Therefore, some simplified approach to obtain information concerning coating structure should be used, such as continuous [8], stochastic [9] or discrete ballistic [10] models.

A modified three-dimensional discrete ballistic model of coating build-up has been developed, which is based on simplified semi-analytical splat formation models proposed in [4,11]. The algorithm used in simulations can be described shortly as follows: (1) individual particle trajectory tracking; (2) calculation of the coordinates of the particle collision with the coating or substrate surface; (3) determination of the local angle of impact β which differs from the spray angle θ due to the complex coating surface topology; (4) deposition of the particle mass at a point of collision into a curved disk-shaped splat depending on the particle temperature, mass, velocity and local impact angle according to the rules similar to that of used in [4,11]; (5) coating update (Figure 5).

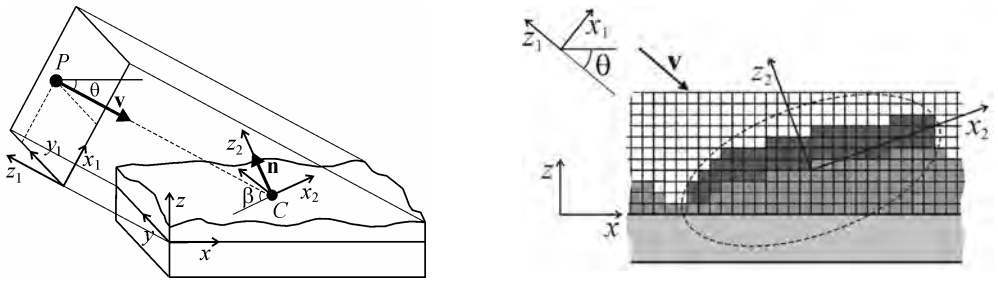

Figure 5. Coordinate system and schematic presentation of splat layering.

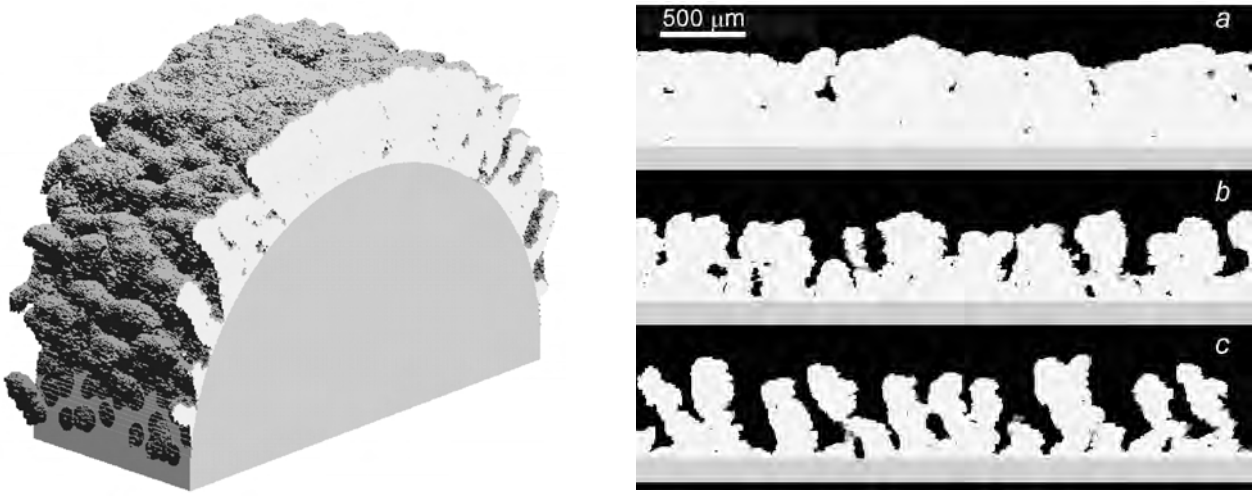

Figure 6. 3D image of cylindrical sample with plasma sprayed coating. Numerical simulation.
Figure 7. Coating cross sections for different spray angles θ: (*a*) 90°; (*b*) 45°; (*c*) 30°.

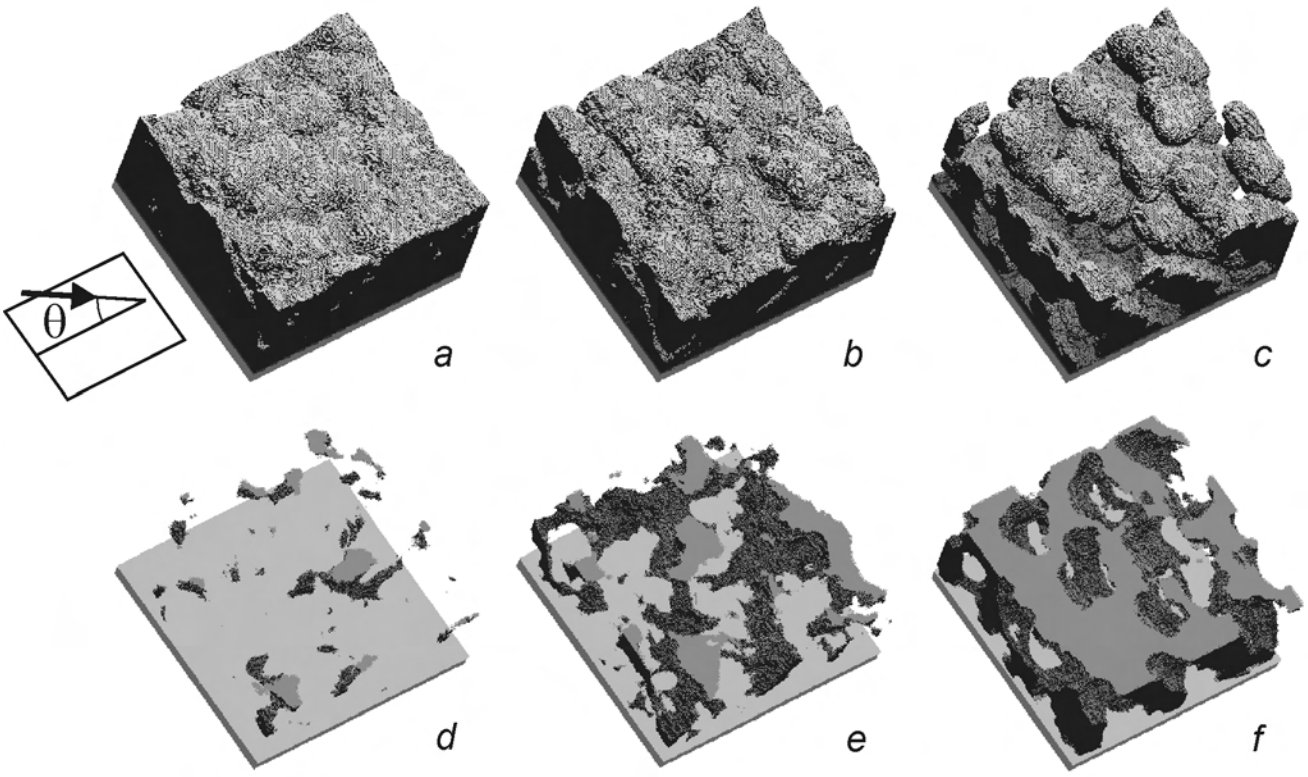

Figure 8. 3D images of coatings (*a*, *b*, *c*) and corresponding pore networks (*d*, *e*, *f*). Spray angles θ: (*a*, *d*) 90°; (*b*, *e*) 45°; (*c*, *f*) 30°. Substrate area 1000×1000 μm^2. Numerical simulation.

Depending on a sample geometry and angle of spray, typical numerical experiment describes layering of 20000−80000 individual particles. The simulation results illustrating influence of the spray angle on the coating structure for deposited Ti particles with diameter of 60 μm are shown in Figures 6−8. The model predicts coating porosity, thickness and roughness as functions of the spraying conditions. Depending on the deposited particles size and shapes of the resulting splats, different types of microstructures and porosities, and consequently different coating properties could be obtained.

Although several simplifying assumptions have been adopted in the model, in particular, semiempirical relations predicting the resulting shapes of the splats depending on the impinging molten particle impact parameters, the results of numerical simulations are in good qualitative agreement with experimental observations.

Conclusion

As a result of the studies of the process of coating formation at off-normal spray angles a novel technology of plasma spraying of highly porous coatings with principally new structure and enhanced mechanical characteristics was developed. These coatings consist of ridges growing from the surface of the substrate and separated one from another by cavities. The ridges may include micropores and capillaries. The total surface area increases directly proportionally with the increase of the thickness of the deposited coating. That is why this type of coatings was named as three-dimensional capillary-porous (3DCP). The process of fabrication of 3DCP coatings is performed under a sharp incidence angle of the plasma spray to the substrate and is based on the shadow effect.

Influence of the spray angle on morphological and mechanical characteristics of titanium coatings was investigated in experiments. It was found that in order to achieve the highest strength characteristics of porous coating, the ridges must be built-up of splats with maximum contact area between them. Low porosity of the internal volume of the ridges allows reaching the values of adhesion and cohesion close to the values of dense sprayed materials.

A three-dimensional discrete ballistic model based on the description of the consequence of individual molten spray particles impacts with the substrate was proposed for the interpretation of the experimental results and prediction of structural characteristics of deposited coatings depending on the spraying conditions.

The technology of plasma deposition of highly porous coatings is of great significance for biomedical applications, in particular, for enhancing bone ingrowth into the surface of implants [12]. High values of porosity, pore interconnectivity, large specific surface area and excellent mechanical properties of Ti 3DCP coatings proved to be favorable for bone tissue growing in and fastening of its connection with an intrabone implant.

Abstract
Experiments on pulsed laser deposition of Fe films on Si substrates were performed with the aim to analyze an energy spectrum and a dose of ions bombarding the film in strong pulsed electric fields. The goal of the study was to clarify the physical nature of the processes determining characteristics of the ion beam produced from the expanding plasma plume under different regimes of application of accelerating high-voltage pulses in order to establish the conditions in which it is possible to implant ions with a narrow energy spectrum.
Keywords: laser ablation; laser plasma; ion source; thin film deposition; ion implantation

1. Introduction

After irradiation of a target surface with nanosecond laser pulse, due to rapid material heating, evaporation and ionization, a plasma cloud is formed in front of the target and consequently expands away from the surface. Even at relatively low intensities near the threshold for ablation (0.2–1.0 $GWcm^{-2}$), measurements taken with nanosecond laser pulses, e.g. [1-3], show that the ablated material is significantly ionized, and the ions in the plasma plume obtain energies ranging up to several hundred of electron-volts. It was observed that both the mass flux and the average energy of the ions are strongly peaked about the target normal. The expansion of the plume is primarily driven by the plasma pressure gradients, but at the later stages there is an additional contribution from Coulomb interactions between the ions and the more mobile electrons and self-repulsion of the ions. The understanding of the temporal evolution of the ion energy distribution in the expanding cloud and the accompanying acceleration processes are of interest for many applications of laser-induced plasmas.

Vapor-plasma plumes initiated by high-intensity nanosecond laser pulses during irradiation of various materials may be employed in deposition of thin-film structures [4], as well as in generation of ion beams for the implantation processing of materials [5]. Depending on a processing parameters and applications, these laser-based technologies are known as pulsed laser deposition (PLD), pulsed laser ablation (PLA), ablation plasma ion implantation (APII), laser ion source (LIS), etc. In the past several years laser ablation techniques have received much attention, for example, in deposition of thin films and solid lubricants available for improving tribological functionality [6,7], semiconductor processing [3], etc.

The main advantage of the laser-based techniques is to generate ions of many elements by direct action on solid materials, instead of the conventional plasma immersed ion implantation (PIII), electron beam ion source (EBIS) and electron cyclotron resonance (ECR) sources which operate mainly on evaporated materials or gas mixtures. Ion source plasmas can be generated by laser beam from any solid material, even refractories and compounds, and requires no toxic precursor gases.

With pulsed laser deposition or implantation processes, the laser plume properties are known to depend critically on the laser fluence. But even at extremely high fluences of nanosecond laser pulse the ion energy does not exceed several keV. This energy is not high enough to initiate deep ion penetration, and hence the implanted layer is rather thin. The possibility exists of changing the conditions of film deposition by bombarding the surface with ions accelerated to sufficiently high energy by means of application of external electric field.

Since the first experiments on plasma immersion ion implantation [8], pulsed electric fields have been widely used in ion-implantation processing [9], as well as in adjusting the ion energy for plasma-enhanced deposition of thin films [10]. The possibility to increase the ion energy up to several tens of kilo-electron-volts using external electric fields in pulsed laser deposition of thin-film coatings was demonstrated in [3,6,7,11,12]. The method for accelerating ions from a laser ablation plume using pulsed fields is easy to implement; however, it is essential

that the ion dose and energy are precisely controlled to obtain the best properties of thin-film coatings. The ion beam may be controlled by varying the parameters of the high-voltage pulse, , the conditions of laser irradiation of the target, and the target-substrate geometry in the vacuum chamber.

The construction of a mathematical model that takes account of the mentioned above factors facilitates essentially the optimization of the conditions of thin-film formation. After the pioneering work [13] describing free plasma expansion into vacuum, tremendous progress has been achieved in the field of simulation of laser ablation plasmas (e.g., [14] and literature cited therein) but only a few theoretical investigations concern specific features of pulsed laser deposition or laser ion implantation in external electric fields.

In a number of studies [3,11], the dynamic sheath model of conventional PIII process [15] was adapted to the conditions of PLD (APII). A theory based on the Child–Langmuir law was applied to explain the long-time scale of the implanted ion current profile observed in laser ablation experiments with parallel target–substrate orientation [11]. This approach treats the case where the plasma plume is already in contact with the substrate and when the bias voltage is turned on.

This paper describes the results of the experimental and theoretical investigations of the factors that govern the dose and energy characteristics of ion bombardment during pulsed laser-induced deposition of thin films in strong pulsed electric fields. The goal of the study is to clarify the physical nature of the processes determining generation of the ion beam from the plasma plume under different regimes of application of accelerating electric pulse in order to establish the conditions in which it is possible to implant high-energy (>10 keV) ions with a relatively narrow energy spectrum. The investigations have been carried out with the Fe–Si system.

2. Experimental setup and diagnostic technique

A schematic diagram of the experimental setup is shown in Fig. 1. Q-switched Nd:yttrium-aluminum-garnet (YAG) laser with a wavelength of 1.06 μm and a laser pulse duration of 10 ns was used for the thin-film deposition. The laser beam guided by the scanning and focusing device was incident onto the target at an angle of 45°. The repetition rate of laser pulses was 10 Hz. The beam scanned the target area of 5×5 mm^2. The chamber was exhausted to a pressure of 10^{-4} Pa. A substrate was a Si(100) wafer located 8 cm away from the target, and the surfaces of the substrate and the target were oriented parallel to one another. The amplitude of the negative high-voltage pulse applied to the target reached 40 kV. The pulse generator activated from the laser-control unit triggered the high-voltage source with a given delay time relative to the laser pulse.

The processes proceeding in the laser-produced plasma upon applying high-voltage pulses were monitored by measuring the electric signals from the laser target. As it will be shown later, the signals measured at the target enable to receive important characteristics of the ion implantation process at the substrate. The energy and angular characteristics of the ion flow in the laser-generated plume were determined by measuring the time-of-flight (TOF) spectra with a detector.

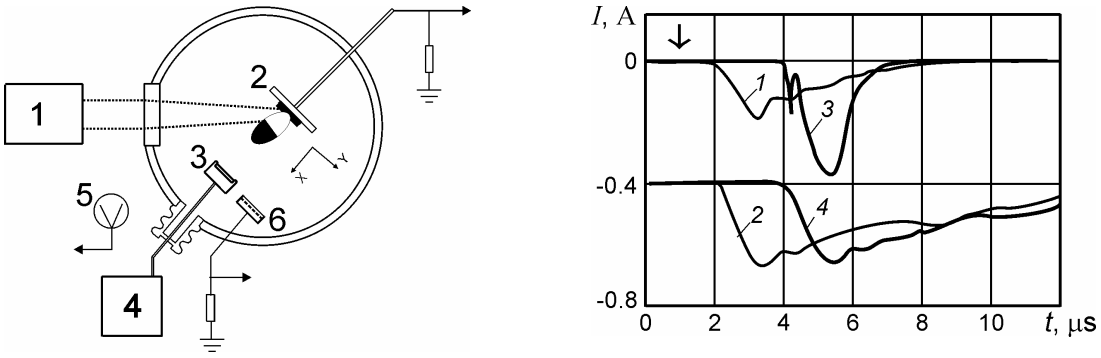

Figure 1. Schematic diagram of the main components of the experimental setup used for the pulsed laser deposition in pulsed electric fields and the detection of electric signals in the laser target: (*1*) Nd:YAG pulsed laser; (*2*) Fe target; (*3*) Si substrate; (*4*) pulsed high-voltage generator; (*5*) antenna; (*6*) ion detector.

Figure 2. Electric signals generated in the target (*1, 3*) and in the antenna (*2*, *4*) for different high-voltage pulse delay times of 1 and 3 μs. The moment of the laser pulse action is indicated by the arrow.

3. Characterization of laser ablation plasma ion sorce

In the experiments, the amplitude of the triangular high-voltage pulse (–40 kV) applied to the Si substrate and the laser fluence (7.5 J/cm^2) at the Fe target were fixed during the deposition. Owing to the high laser fluence at a relatively low power (20 mJ), the ionization of the laser plume was high, but the Fe vapor pressure near the substrate was low enough to avoid arcing.

The experiments on the detection of ion signals during free expansion (without external electric field) of the laser ablation plume in vacuum showed that the plume approached the substrate within ~2.5 μs after the beginning of the laser action. The ion density near the substrate increased for ~2 μs and, then, slowly decreased for ~10 μs. Measuring with a detector of the angular diagram of the laser-plume expansion in vacuum, it was found that the ion flux was peaked about the target normal in the angular range of ±30°. The ion energy did not exceed 400 eV, and the ion energy distribution obtained maximum within the interval of 150–200 eV.

The ion spectrum determined from the time-of-flight measurements was used to reconstruct the dynamics of the ion fraction of laser plume during its free expansion in vacuum. In particular, within 1 μs after the laser pulse the ion front propagates to a distance of ~2 cm from the target and the maximum plasma density decreases to ~6×10^{10} cm^{-3}. These data were used as the initial conditions for numerical simulations.

Parameters of the electric signals measured at the laser irradiated target depend significantly on the high-voltage delay time (Fig. 2). In the case when the accelerating voltage was turned on with the delay of 1 μs after the laser pulse, the electric signal at the target increased for ~1 μs and then decayed in a time interval of 6–7 μs.

Increase of the delay time resulted in the decrease of the signal length. If the high-voltage pulse was applied at the instant the ion front approached the substrate (delay time of 3 μs), the signal length reduced to ~2.5 μs, while the signal magnitude raised nearly twice. This signal initiated during the high-voltage rise time was formed at the peak of the accelerating voltage. In this case one may expect formation of the most narrow energy spectrum of the implanted ions. Further increase in the delay time leads to a smooth reduction of the signal amplitude.

4. Model description and simulation results

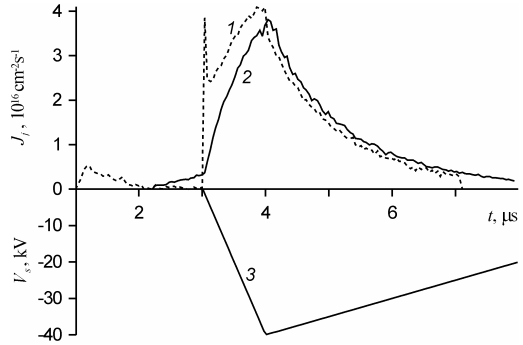
The particle-in-cell (PIC) algorithm was employed to solve the problem of ion source generation from the laser ablation plasma under conditions of varying density of the moving plasma plume in external electric field. The PIC code is a well-known tool for simulating plasma physics problems and it has been applied to a vast variety of problems, in particular, to description of both laser plasma expansion [16] and also conventional PIII processes [15].

Simulations were performed under several simplifying assumptions. A one-dimensional geometry was considered, since in vacuum the ablated plasma is sharply peaked and moves preferably in the forward direction along the normal to the target surface, especially after the high-voltage pulse is turned on. A representative time of laser plume formation is close to the laser pulse length (τ ~ 10 ns) and it is much less than duration of plasma expansion (several μs). By this reason, starting from an arbitrary time $t_0 >> \tau$, the plume propagation from the target to the substrate can be treated independently of the process of laser plasma ignition. To specify the initial plasma density and mass flow velocity, the experimental data were used. It was assumed that within 1 μs after the laser pulse, the plasma propagates to a distance x of 2 cm from the target and within this interval it obtains a bell-shaped density distribution $N_j(x)$ with the maximum value of 6×10^{10} cm^{-3}. The corresponding mass flow velocity is $u = 10^6$ cm s^{-1}. In the calculations typical values of the laser plasma temperature were employed: kT_j = 1 eV (here subscripts $j = i$ and e denote the plasma ions and electrons, respectively). The initial ion and electron velocity distribution functions $f_j(x,v,t=t_0)$ were presented by shifted Maxwellian distributions with the specified above parameters N_j, T_j and u corresponding to the plasma particles density, temperature and mass flow velocity, respectively.

As the boundary conditions for the Poisson equation, the known values of the potential at the grounded target $\varphi(x=0,t)=0$ and at the substrate $\varphi(x=x_s,t)=V_s(t)$ were used. The high-voltage pulse $V_s(t)$ applied to the substrate with the turn on delay τ_V was approximated by a triangular shape. The target – substrate distance was set equal to 8 cm. The total number of ions and also of electrons used in the simulations was up to 10^5.

Simulation of the laser plasma free expansion into vacuum shows that the first ions from the plume reach the substrate in ~2.3 μs and the maximum of the ion density arrives at the substrate within ~5 μs. Typical electric signals at the target and at the substrate are given in Fig. 3.

After accelerating voltage is turned on the electron flux to the target practically coincides with the ion flux to the substrate. This arises from the fundamental property of plasma to keep quasineutrality in the entire volume occupied by it. After application of the negative high voltage pulse, the ions from the plasma front are extracted by the accelerating field to the substrate. The electrons, on the contrary, are decelerated and they are not able to reach the substrate any more. Thus, in order to balance the ions outcome from the plasma, the surplus electrons are ejected from the plasma rear part and return back to the target. As a result, the electric signals at the substrate and at the target are close in shape within the whole period of the plasma expansion in the external electric field. In the experiments these signals are registered with unlike signs. Hence, the modeling results approve the validity of the monitoring of laser plasma ion implantation with a help of the signals from the target.



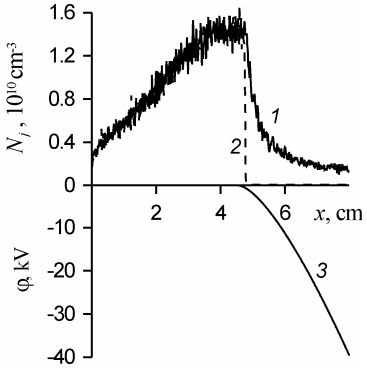


Figure 3. Variations with time t of the electron flux J_e at the target (*1*) and ion flux J_i at the substrate (*2*). Triangular high-voltage pulse V_s (*3*) is applied with the delay of $\tau_V = 3$ μs.

Figure 4. Spatial distributions of the number densities of ions N_i (*1*) and electrons N_e (*2*) and the plasma potential φ (*3*) during the plasma expansion from the target ($x = 0$) to the substrate ($x = 8$ cm) at the moment of time $t = 4$ μs. High-voltage pulse delay time $\tau_V = 3$ μs.

The representative structure of the expanding laser plasma at the stage of the action of the external electric field is shown in Fig. 4. During the whole process, in the major part of the expanding plume the quasineutrality condition is fulfilled, and the external electric field is almost completely screened by the plasma. At the plasma front, the charge separation takes place, and the ion sheath is formed between the plasma plume and the substrate. The ions are ejected to the substrate from the moving boundary of the plume where the electric field is very strong.

Computed dynamics of the ion density during the laser plume expansion in vacuum for the high-voltage pulse delay $\tau_V = 3$ μs is shown in Fig. 5. The ion current grows at the stage of the plume front movement toward the substrate (see also Fig. 3). Within this period of time the accelerating voltage after passing the absolute value maximum of 40 kV begins to decrease. Then the reverse motion of the plume front from the substrate to the target starts and thus the sheath extent increases. At the same time the expanding plasma as a whole continues its movement from the target to the substrate.

The simulations show that the ion energy spectrum and the ion bombardment time interval change to a great extent depending on the high-voltage pulse turn on delay time. Calculated ion fluxes to the substrate for different τ_V are presented in Fig. 6. Independently on the moment of the high-voltage switching on, the process of ion implantation is completed within the time of ~7–8 μs. An increase in the delay time τ_V leads to significant reducing of the high energy ion pulse at the substrate. For the delays $\tau_V \sim 3$–4 μs the calculated duration of the ion signal decreases to ~3 μs, and its amplitude grows nearly two times as compared to the case of $\tau_V \sim 1$ μs; this is in good agreement with the experimental data presented above. For larger turn on delays, a powerful signal of the accelerated ions is formed after relatively weak signal of the ions reaching the substrate before the high-voltage pulse is applied.

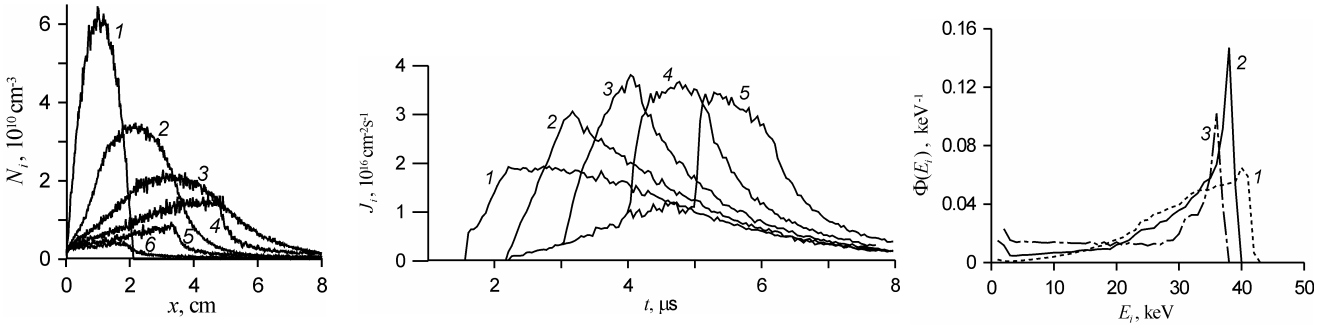

Figure 5. Dynamics of the ion density during the laser plume expansion for the regime with high-voltage delay τ_V = 3 μs. Digits near the curves (*1 – 6*) denote different moments of time t in μs.

Figure 6. Temporal variations of the ion flux density J_i at the substrate depending on the high-voltage pulse turn on delay time. Digits near the curves (*1 – 5*) denote delay times τ_V in μs.

Figure 7. Energy spectra of the ions bombarding the substrate for different high-voltage delays τ_V = 1 (*1*); 3 (*2*) and 5 μs (*3*).

The energy distributions of the ions bombarding the substrate for the regimes with different high-voltage pulse turn on delay times τ_V are given in Fig. 7. Simulation demonstrate that variations in time of a delay τ_V lead to noticeable changes in the resulting upper bound and width of the ion kinetic energy distribution. Calculations show that the upper bound of the ion energy distribution decreases from 43 to 40 keV as the delay time increases from 1 to 3 μs. At the same time, a fraction of high-energy ions increases.

5. Effect of high-voltage pulse parameters on laser ablation plasma ion source characteristics

For the conditions of the ion implantation to be optimized, it is necessary to select both proper conditions for the laser irradiation of the target and the time for the application of the high-voltage pulse. Both the results of numerical modeling and experiments with a triangular high-voltage pulse (with amplitude of up to 40 kV) demonstrated that the conditions proved to be optimal when laser pulses had medium power (20 mJ) and the delay of the high-voltage pulse was 3 μs.

Under these conditions, most of ions in the laser plume are concentrated in the space between the target and the substrate. Upon applying a high-voltage pulse, the plasma sheath quickly (in ~2–3 μs) spreads over the laser plasma; therefore, a major portion of the implanted-ion dose is acquired at the peak of the accelerating pulse. As large as 80% of implanted ions have a kinetic energy of approximately 30–40 keV.

Another implantation mode is implemented when the high-voltage pulse is applied with a short (~1μs) delay with respect to the laser pulse. In this case, the ions are accelerated from the front of the dense laser plasma; therefore, the ion-current pulse is governed by the dynamics of the laser plume, and its width is close to the target – substrate propagation time (~10 μs). Within this period of time, the accelerating voltage changed from −40 to 0 kV, which causes the energy spectrum of bombarding ions to broaden.

For long turn on delays (>5 μs), a broadening of the ion energy spectrum is due to the contribution of large amount of low-energy ions arriving to the substrate before the high-voltage pulse is applied. Only relatively small fraction of the ions can be accelerated to the required energies when the accelerating electric field is turned on. In addition, the ion energy broadening may occur because the implantation process involves all ions that are scattered throughout the vacuum chamber, in which the potential of the accelerating field varies from −40 kV (substrate) to 0 (chamber walls).

6. Conclusion

The potential of the laser ablation plasma as an effective ion source in the applied pulsed electric field was investigated. The experiments have demonstrated that pulsed laser deposition of thin films under applied high-voltage pulses provides means for the implantation of high-energy (several tens of keV) ions with a narrow

energy spectrum. In the experiments, it was established that the current characteristics of the plasma expanding from the target to the substrate depend significantly on the moment of application of the accelerating high-voltage pulses.

A physical model of laser-produced plasma expansion in vacuum in pulsed electric field based on the PIC algorithm was proposed for the interpretation of the experimental results and for the process optimization. Simulations demonstrated that variations in time of a delay τ_V lead to noticeable changes in the resulting upper bound and width of the kinetic energy distribution of implanted ions.

Both experiments with triangular high-voltage pulse and numerical simulations predicted that the ion energy spectrum occurred to be the optimal if the high-voltage pulse is applied at a moment of time (~3μs) when the ion component of the plume approached the substrate. In this case, the implanted ions have the highest energy close to the nominal value determined by the amplitude of the electric pulse. This regime is characteristic for the traditional plasma immersion ion implantation, when the ion current is governed by the dynamics of the plasma sheath in the substrate-to-target gap. An advance or delay in applying a high-voltage pulse causes the ion energy spectrum of bombarding ions to broaden.

By means of numerical simulation it was verified that the electron flux to the target practically coincides with the ion flux to the substrate after accelerating voltage is turned on, i.e. electric signals measured at the substrate and at the target are close in shape within the whole period of the plasma expansion in the external electric field. Thus, the modeling results approve the validity of the monitoring of laser plasma ion implantation with a help of the signals from the target.

In general, the investigations have demonstrated that the simple and cost-effective modified version of the traditional PLD technique provides the possibility of high-energy ion flux generation from laser ablation plasma for ion implantation and thin film deposition technologies.

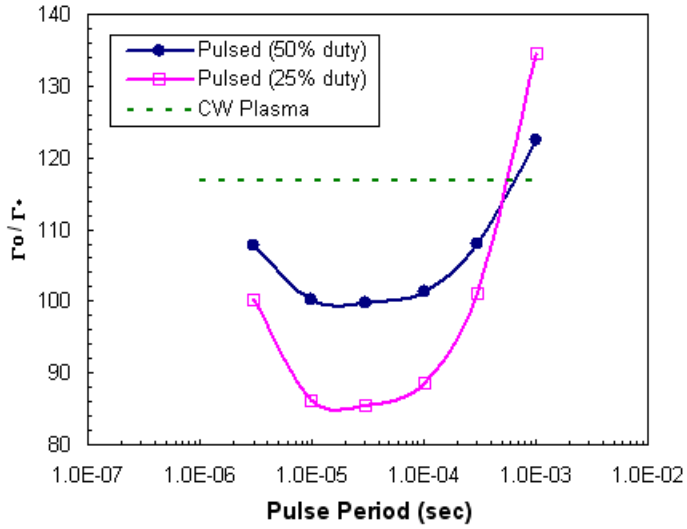
Abstract
Electronegative plasmas driven by steady power and by time-modulated power, with oxygen as the feedstock gas, have been investigated utilizing volume-averaged (global) models of a cylindrical plasma discharge. The variations of the ratio of neutral radical to ion flux (Γ_O/Γ_+), depending on the chamber geometry and power modulation conditions, were examined using a simple model with uniform spatial profiles and a new model with non-uniform spatial profiles, and the results from the models were compared.
Keywords electronegative plasma, global model, neutral radical

1. Introduction

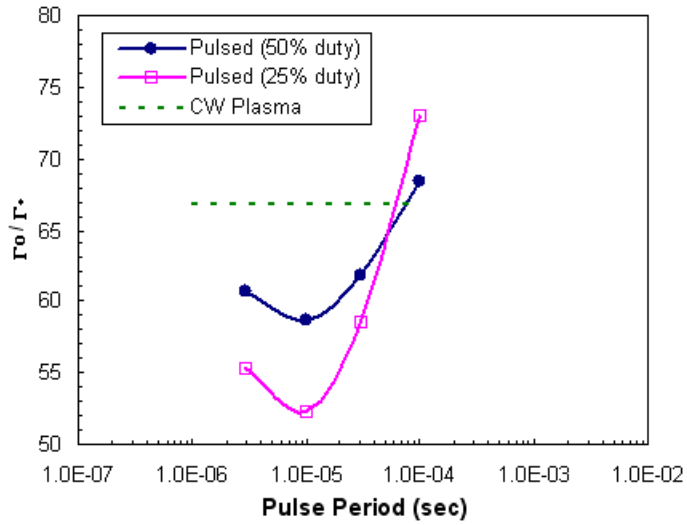
For the next generation plasma etching processes in the microelectronics industry, control and reduction of the ratio of neutral radical flux to ion flux (Γ_O/Γ_+) at the wafer surface is required to accomplish the patterning of the vertical etch profile in high aspect ratio features. To explore these processes, we investigated plasmas driven by steady power and by time-modulated power using various discharge models with oxygen as the feedstock.
The calculations of the plasma parameters have been made utilizing a volume-averaged (global) model of a cylindrical plasma discharge [1] [2] [3]. First, we used a simple model with uniform spatial profiles. In this model, all quantities are assumed to be uniform over a cylindrical discharge. This model can be applied to weakly electronegative discharges such as low pressure, high power, O_2 plasma [1]. However, there are significant errors in ignoring the effects of plasma profiles. Therefore, we have developed a new global model of cylindrical electronegative discharges with non-uniform spatial profiles and new expressions for the wall loss factors. This model is considered to be valid over a wider range of plasma parameters and pressures than the previous model.

2. Simple global model

This model assumes uniform spatial distribution of plasma parameters over the volume of bulk plasma, but includes a diffusive loss factor. However, the fluxes of both oxygen radicals and ions are approximated by assuming their densities are constant, $\Gamma_O = 1/4\, n_O v_O$ and $\Gamma_+ = n_+ u_B$, with v_O the oxygen thermal velocity and u_B the Bohm velocity. The global model consists of particle balance and power balance equations. In the particle balance equations, the reaction rates of O_2^+, O^- ions, electrons and the metastable oxygen molecules O_2 ($a\ ^1\Delta_g$) have been included. We consider pressures of 10 - 50 mTorr and plasma densities of 1×10^{10} - 1×10^{11} cm^{-3}. In this regime, the discharge is found to be weakly electronegative. A nearly sinusoidal waveform of the power pulse was used (rise and fall time = 50% of the pulse period). The power modulation period was varied to determine the optimum conditions for reduction of Γ_O/Γ_+. The effect of duty-ratio (on-time/period) on the reduction of Γ_O/Γ_+ was examined by comparing two different duty ratios (50% and 25%) together with a CW plasma case. Two chamber geometries with different aspect ratios (chamber height/diameter = 1/6 and unity) were examined to determine the influence of the surface-area/volume ratio. The diameter of the chamber was 30cm and the heights were 5cm and 30cm, respectively.
Figure 1 shows the plots of time-average flux ratio of oxygen neutrals to O_2^+ ions (Γ_O/Γ_+) with various pulse periods at 10 mTorr. The average power of smaller aspect ratio (b) is adjusted to yield similar values of steady state positive ion flux (Γ_+) on the wall as the aspect ratio of 1 in (a). At a fixed duty-ratio, the ratio Γ_O/Γ_+ is found to have a minimum value as the pulse period is varied, with the minimum value decreasing as the duty-ratio decreases. The pulse period that yields minimum Γ_O/Γ_+ decreases as the aspect ratio decreases. For steady-state discharges, reducing the aspect ratio by 6 leads to 43% reduction of Γ_O/Γ_+. For pulsed discharges, a 25% duty-ratio pulse with 50% rise and fall time can reduce the Γ_O/Γ_+ by an additional 27%.



(a)



(b)

Figure 1. Time-average flux ratio of oxygen neutrals to O_2^+ ions (Γ_O/Γ_+) with various pulse periods based on simple global model. (a) height/diameter = 1, average power = 200 Watt, (b) height/diameter = 1/6, average power = 66 Watt. (The average power of (b) was adjusted to yield similar values of steady state positive ion flux (Γ_+) on the wall for (a) and (b).)

3. Improved model with non-uniform spatial profiles

To improve the accuracy of the simulation, we developed a new model which incorporates non-uniform spatial profiles of ions and neutrals rather than uniform profiles. In this new model, we combined three models of plane-parallel electronegative discharges which are accurate over different negative ion densities: (a) a low-pressure two-region parabolic model which has parabolic electronegative core with low-pressure electropositive edges [4] [5]; (b) a one region parabolic electronegative model applicable at low pressure and high electronegativity; and (c) a one-region flat-topped electronegative model applicable at higher pressure and higher electronegativity. Calculating the edge-to-center density ratio using these profiles, the new model has improved the overall

accuracy over a wider range of plasma parameters and pressures than the previous model. Denoting the edge-to-center positive ion density ratios for the three regimes as h_a, h_b and h_c, respectively, then the approximate results for the h_l factors are:

$$h_a \approx \frac{0.86}{\left(3+\eta\frac{l_p}{\lambda_+}\right)^{1/2}}\frac{1}{1+\alpha_0} \equiv h_{l0}\frac{1}{1+\alpha_0} \tag{1}$$

which approaches the constant electropositive result h_{l0} as electronegetivity α_0 becomes negligible,

$$h_b \approx \frac{1}{\gamma_-^{1/2}+\gamma_+^{1/2}\frac{\eta}{(2\pi)^{1/2}}\frac{l_p}{\lambda_+}}\frac{\alpha_0}{1+\alpha_0} \equiv h_{l\infty}\frac{\alpha_0}{1+\alpha_0} \tag{2}$$

which gives a result $h_{l\infty}$ that is independent of both α_0 and n_{e0} as α_0 becomes large, and

$$h_c \approx \frac{1}{\gamma_-^{1/2}+\gamma_+^{1/2}\frac{n_*^{1/2}}{n_{-0}^{1/2}}} \tag{3}$$

which depends on n_{-0} but is independent of α_0 and n_{e0}. In the above three expressions,

$$\eta=\frac{2\mathrm{T}_+}{\mathrm{T}_+ + \mathrm{T}_-};\qquad \gamma_-=\frac{\mathrm{T}_e}{\mathrm{T}_-};\qquad \gamma_+=\frac{\mathrm{T}_e}{\mathrm{T}_+};\qquad l_p=\mathrm{L}/2;\qquad n_*=\frac{15}{86}\left(\frac{8e\mathrm{T}_+}{\pi\mathrm{M}_+}\right)^{1/2}\frac{\eta^2}{K_{\mathrm{rec}}\lambda_+} \tag{4}$$

where l_p is the half-length of the system, the subscript + and – denote positive and negative ions, the subscript 0 denotes the center value, and K_{rec} is the positive-negative ion recombination coefficient. To obtain a single description of the fluxes covering the full parameter range, we use a linear ansatz that sums the h_l for three regimes to determine an overall h_l factor:

$$h_l = h_a + h_b + h_c\,;\qquad \Gamma = h_l\, n_{+0}\, u_{\mathrm{B}} \tag{5}$$

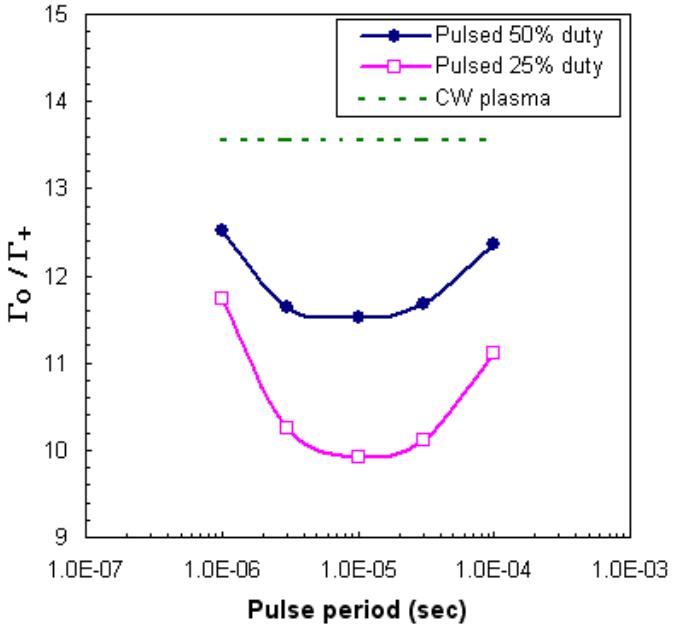
where the positive ion flux Γ is calculated as the product of the h_l, central positive ion density n_{+0} and the EP Bohm velocity, $u_B = (e\mathrm{T}_e/\mathrm{M})^{1/2}$.

We have also added particle balance equations for O_2 feedstock and O^+ ions, which were not implemented in the simple model. We introduced density-weighted averages for multiple positive and negative ion species, together with pressure-dependent effective volume and surface loss factors for the neutral species. To make the simulations more complete, we have also revised the chemical reaction coefficients used in the calculations based on recently reported results of cross section sets and measurements [6] [7].

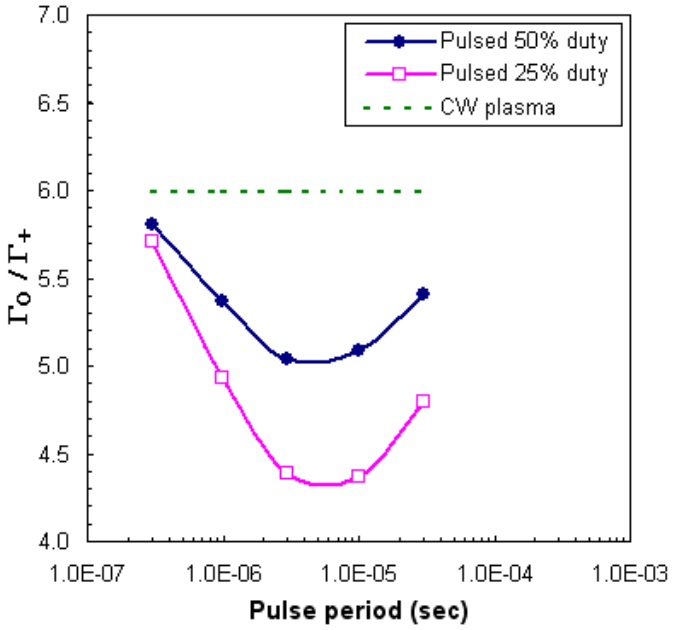
After testing the new model with a steady-power discharge, we applied it to the time-modulation case. The same nearly sinusoidal waveform of the power pulse was used (rise and fall time = 50% of the pulse period) as in the simple model case. The power modulation period was varied and the effect of duty-ratio (on-time/period) was examined by comparing two different duty ratios (50% and 25%) together with the CW plasma case. Two aspect ratios that were same as the simple model case (height/diameter = 1/6 and unity) were examined to determine the influence of the surface-area/volume ratio.

Figure 2 shows the plots of time-average flux ratio of oxygen neutrals to O_2^+ ions (Γ_O/Γ_+) with various pulse periods at 10 mTorr, based on the new model. The average power of smaller aspect ratio (b) is adjusted to yield

similar values of steady state positive ion flux (Γ_+) on the wall as the aspect ratio of 1 in (a). At a fixed duty-ratio, the ratio Γ_O/Γ_+ is found to have a minimum value as the pulse period is varied, with the minimum value decreasing as the duty-ratio decreases. The pulse period that yields minimum Γ_O/Γ_+ also decreases as the aspect ratio decreases. For steady-state discharges, reducing the aspect ratio by 6 leads to 56% reduction of Γ_O/Γ_+. For pulsed discharges, a 25% duty-ratio pulse with 50% rise and fall time can reduce the Γ_O/Γ_+ by an additional 27%.



(a)



(b)

Figure 2. Time-average flux ratio of oxygen neutrals to O_2^+ ions (Γ_O/Γ_+) with various pulse periods based on the new model. (a) height/diameter = 1, average power = 400 Watt, (b) height/diameter = 1/6, average power = 102 Watt. (The average power of (b) was adjusted to yield similar values of steady state positive ion flux (Γ_+) on the wall for (a) and (b).)

In this new result, the range of the values of flux ratios (Γ_O/Γ_+) is almost 10 times lower than result of the simple model. This difference is the result of the various changes implemented in the new model, such as the introduction of wall loss factor for the neutrals, using a higher value of wall recombination coefficients for the neutral oxygen, different reaction coefficient sets together with the introduction of O^+ ions, and the difference in the calculation of positive ion loss factors. Nevertheless, the resulting trend of Γ_O/Γ_+ reductions at the smaller aspect ratio with the optimal pulse period and lower duty ratio is found to be similar to the simple model.

4. Conclusions

The electronegative plasmas driven by steady power and by time-modulated power, with oxygen as the feedstock gas, have been investigated utilizing volume-averaged (global) models of a cylindrical plasma discharge. The variations of the time-average flux ratio of oxygen neutrals to O_2^+ ions (Γ_O/Γ_+) depending on the chamber geometry and power modulation conditions were examined using a simple model with uniform spatial profiles and a new model with non-uniform spatial profiles, and the results from the models were compared. In both models, at a fixed duty-ratio, the ratio Γ_O/Γ_+ is found to have a minimum value as the pulse period is varied, with the minimum value decreasing as the duty-ratio decreases. The ratio Γ_O/Γ_+ is reduced in the chamber geometry with lower aspect ratio, and the pulse period that yields minimum Γ_O/Γ_+ also decreases.
In future work, we will compare the simulation results with measured experimental results.

Abstract
Thermal plasmas open a new area for the bulk production of carbon nanostructures ranging from carbon black over fullerenes to carbon nanotubes with a high product selectivity.

Keywords : carbon black, fullerenes, nanotubes, 3-phase AC plasma system.

1. Introduction

Since the discovery of new forms of carbon such as Fullerenes and carbon nanotubes (CNT), in 1985, [1] and 1991, [2] respectively, carbon nanostructures remain at the forefront of the nanotechnology wave. However, carbon nanostructures have a long history : carbon black is indeed one of the oldest nanomaterials used by man since ancient civilizations in China and Egypt mixed soot into resins, vegetable oils or tar to create colors and inks. In addition, the first large scale industrial production of dispersed nanomaterials occurred with the production of carbon black early in the 20th century.

Continuous carbon black production techniques are usually based on combustion processes. These processes are characterized by a high level of CO_2 emissions since an important part of the carbon feedstock is burnt while the remaining part is converted into carbon black. In 2004, the carbon black industry was directly responsible for more than 25 million tons of CO_2 emissions (0.1 % of the total world CO_2 emissions). In addition, these processes hardly allow the independent control of some key processing parameters such as temperature profile, residence time or reactant concentration. On the other hand, present production techniques for fullerenes and carbon nanotubes production can only provide limited quantities and the availability of these new nanostructures in reasonable quantities, typically the order of several kilograms or tons, is a compelling necessity for the development of future applications.

In this context, new approaches using thermal plasma opens the way towards the mass production of carbon nanomaterials ranging from carbon black over fullerenes to nanotubes.

2. Apparatus

The overall process is presented in Figure 1. A 3-phase, 600 Hz, 260 kVA power supply is connected to a plasma torch, composed of three graphite electrodes, located at the top of the reactor. The plasma reactor is composed of a high temperature insulated chamber which upper part is equipped with a graphite nozzle where the hydrocarbon (HC) can be introduced. The external kiln of the reactor is water cooled. The system is equiped with a PTFE bag filter where carbon and gas are separated and collected. Gas network allows to provide different plasma gases or mixtures (N_2, Ar, He, CO, H_2) into the plasma system.

This technology, initially designed for the cracking of hydrocarbons [3-5], was adapted in order to treat solid carbon powders [6]. The overall process is illustrated in Figure 2. In this case, solid powder is transported together with the plasma gas to the arc zone. By opposition with the classical “arc process” generally used in fullerene and nanotube synthesis, the carbon rate is no more limited to the electrodes erosion but can be totally controlled. In addition, a system composed by a water cooled suction pipe combined with a recirculation loop was specially developed for the sampling of the species inside the reactor, their quenching and their transport up to a filter. This system has been designed to adjust the residence time and the quenching rate by changing the gas extraction point from the reactor and the gas flow rate in the recirculation loop. The reactant concentration being controlled by adjusting the plasma gas-precursor ratio.

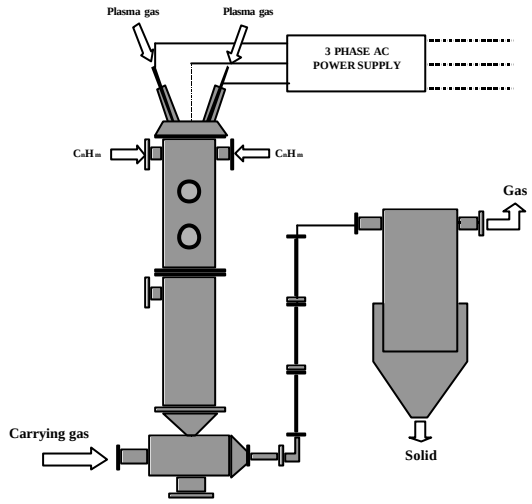

Figure 1 : Scheme of the plasma reactor for the production of carbon black (configuration 1)

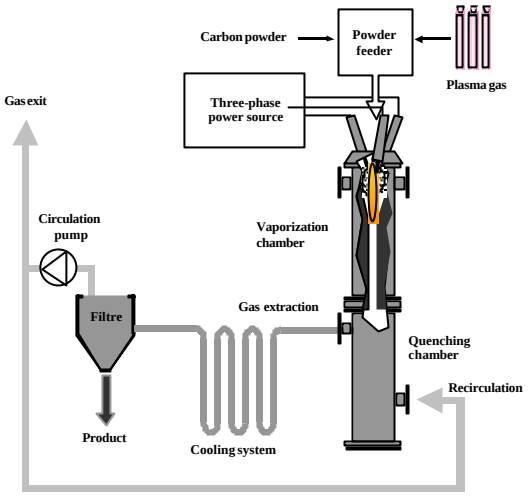

Figure 2 : Scheme of the plasma reactor for the synthesis of fullerenes and nanotubes (configuration 2)

Flow and wall temperatures were measured along the reactor. In the high temperature zones, the measurements were carried out by optical emission spectroscopy (OMS) and optical pyrometry, whereas R-type and K-type thermocouples were placed in the low temperature regions. The experimental set-up was in configuration 1 for carbon black production while configuration 2 was used for fullerenes and nanotubes synthesis.

3. Results

Carbon black

A large variety of carbon precursors (hydrocarbons), plasma gases, and operating conditions (flow rates, electrical power, injection points,…) have been investigated for the synthesis of carbon black. Depending on the operating conditions, different carbon black grades varying from typical low furnace blacks up to high temperature graphitised blacks could be obtained [7]. Figure 3 illustrates an example of typical structures obtained using colza oil as carbon feedstock. These structures are composed of branched-type aggregates, where central small spherical particles seem enrobed by a wrapping paper-like structure carbon layer. HRTEM shows that the elementary particles, which average diameter is around 30 nm, present a radial growth while the wrapping carbon layer shows a lateral growth, characteristic of high temperature carbon blacks, sometimes well crystallised.

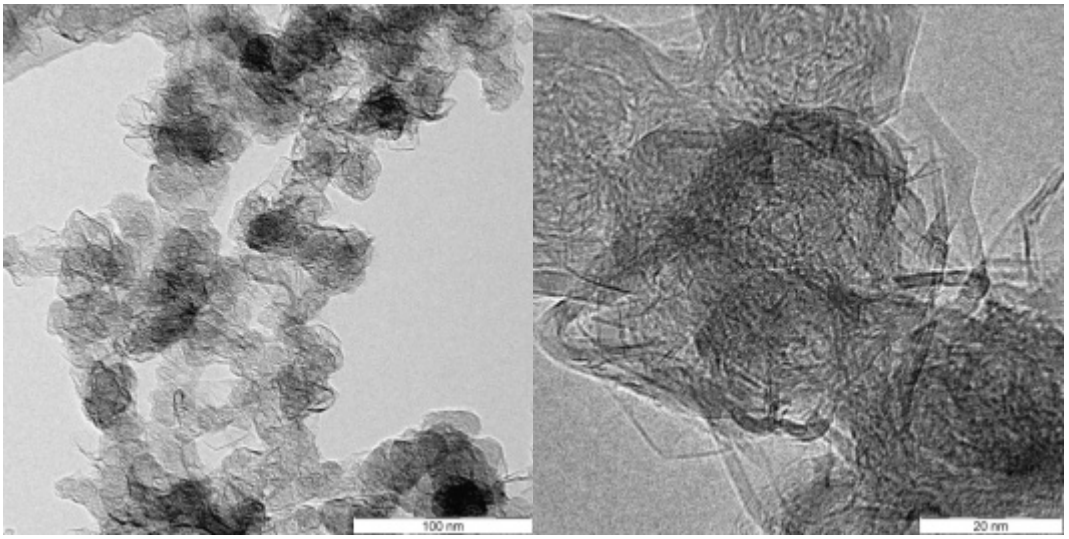

Figure 3 : TEM (left) and HRTEM (right) of a Plasma black aggregate obtained with colza oil

Fullerenes

For the production of fullerenes, pure dispersed carbon is introduced in the plasma reactor in the presence of an inert gas. Different parameters have been investigated: nature of the carbon precursor (acetylene black, graphite powder, carbon black,…) and plasma gases (He, Ar), arc current, gas and carbon flow rates, residence time and reactor geometries [8] . Contrary to the case of hydrocarbon cracking, where growth mechanisms are mainly governed by the hydrogen-carbon chemistry, the growth mechanisms are here based on the vaporisation-condensation of pure carbon into an inert atmosphere since neither hydrogen nor other carbon-combining gas is present in the system.

Figure 4 (left) represents the evolution of fullerene content in the soot (% C_{60} + C_{70}) versus carbon and gas flow rates (arbitrary unit) while Figure 4 (right) represents the fullerene yield evolution versus the two same parameters. These figures show the importance of the carbon dilution in the gas phase on these two parameters. So far the process for continuous fullerene synthesis is not fully optimised, however current yields typically of the order of 5 % (toluene extractable) have been obtained, the yield being however strongly dependent on throughput and noticeably higher yields have been achieved.

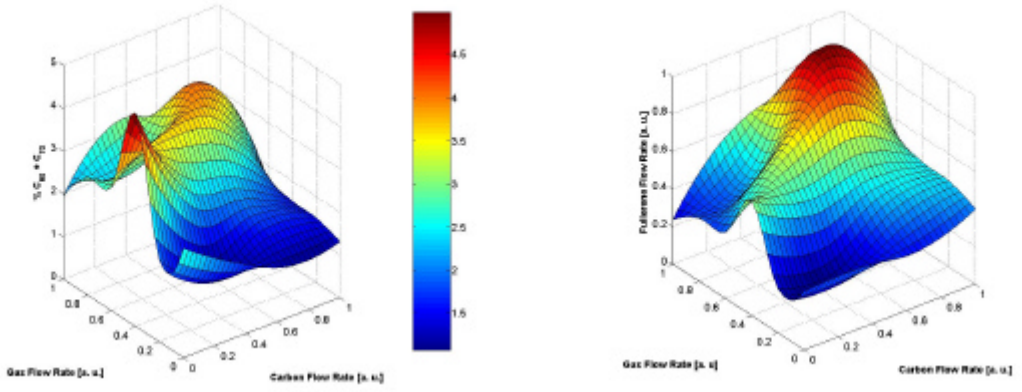

Figure 4 : Fullerene content and fullerene yield versus carbon and gas flow rates (arbitrary unit)

TEM analyses were performed on most fullerene soot. The obtained structures are radically different than the original precursors (acetylene black). Most structures show a typical “rounded” shape (left), very similar to those obtained by the arc or laser processes and described in literature, [9] while some other structures (right) present a very peculiar filamentous carbon organisation at the surface of the particle probably composed of nanocones.

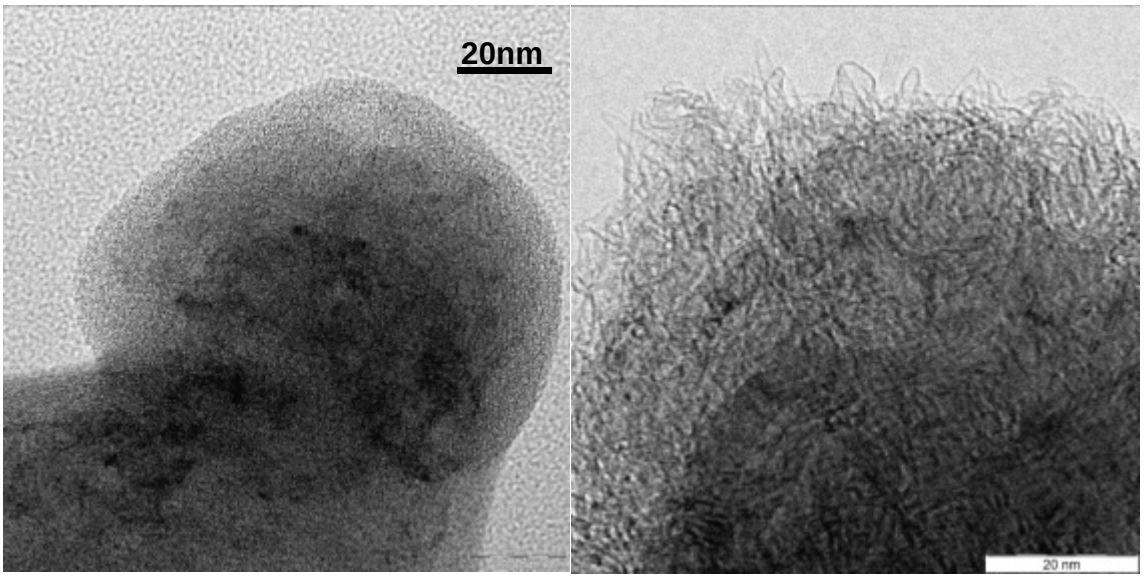

Figure 5 : TEM image of a typical “rounded shape” Fullerene soot (left). HRTEM detail of a filamentous surface of a fullerene soot (right).

Carbon Necklaces

Such structures represented in Figure 6 have been produced by injecting dispersed carbon together with a metal catalyst under a Nitrogen atmosphere (plasma gas), [10]. These nano-necklaces are up to several µm long with outer diameters in the range 50-100 nm. Carbon spheres are found to be regularly spaced along the filament. The necklace can include more than 50 units linked from the end of the bell to its head. In order to analyse their nano-structure, these carbon necklaces are also characterized by TEM, illustrating the repetition of an elementary unit looking like a nano-bell, sometimes filled. The joined segments in the carbon nano-necklaces are actually short variable-diameter compartments. Most unit are hollow however, some compartment are completely filled with the Ni-Co catalyst used during the synthesis. TEM and HRTEM pictures presented in Figure 7 show a high degree of graphitic organization of the carbon layers together with a detail showing intersection between two elementary successive cells.

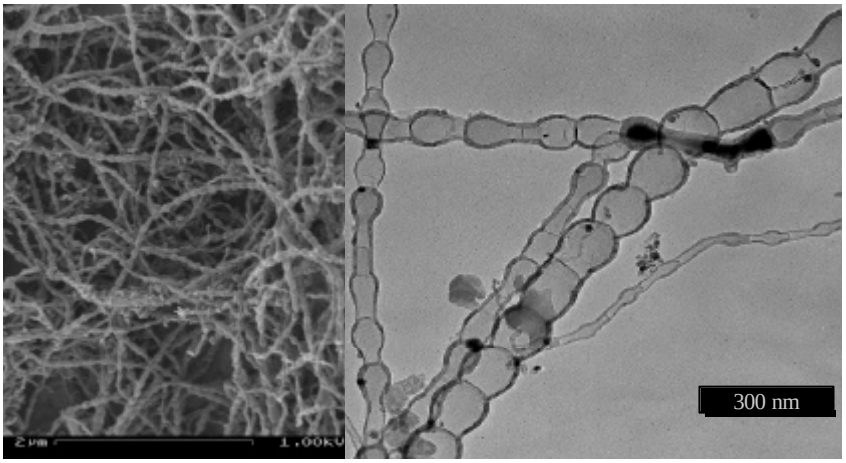

Figure 6 : SEM image (left) and TEM analysis (right) of the carbon "Necklaces" nanostructures

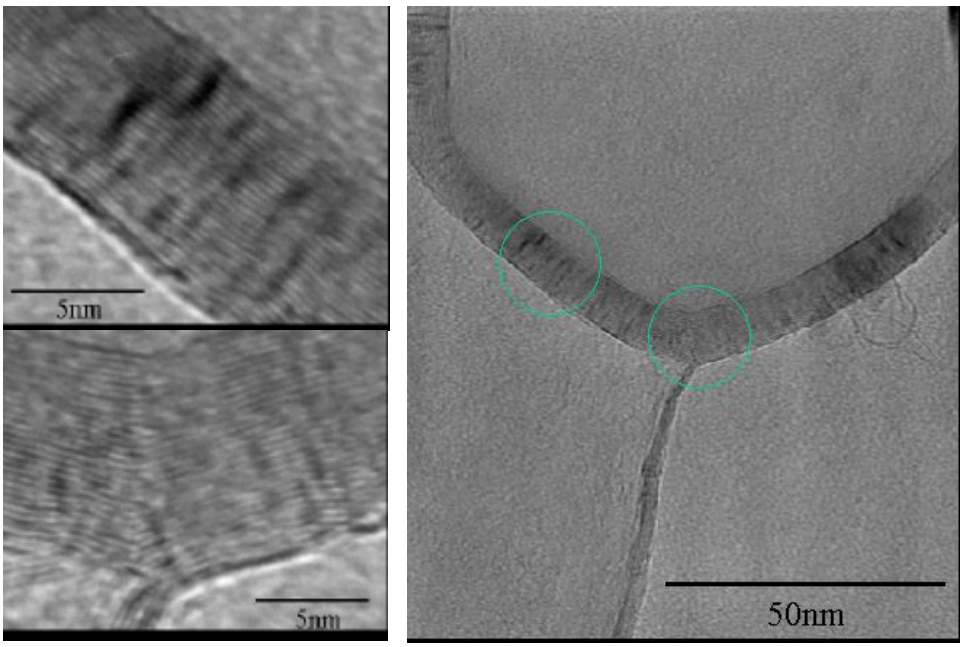

Figure 7 : HRTEM detail of the "Necklaces"carbon layers

These structures have some similarities with the "bamboo-like" ones but they differ from their typical rounded shape. This rounded shape suggests a similar growth mechanisms based on the absorption-segregation process of carbon into the metal catalyst, but differing by the temperature level: the metal catalyst being solid or liquid for "bamboo-like" and "necklaces" structures respectively.

Carbon Nanotubes

Single Wall Nanotubes (SWNT) have been obtained by injecting dispersed carbon together with a metal catalyst (generally cobalt or nickel) under an helium atmosphere and particular operating conditions, characterized by a high quenching velocity. SWNT, generally observed together with small metallic particles, often agglomerate to form bundles. Both bundles and particles can be covered by an amorphous carbon layer similar to fullerene soot. HRTEM images (right) indicate the presence of fullerenes molecules at the vicinity of a SWNT. At least one of the nanotube tips seems connected to metallic particles, what tend to be in agreement with the metal-carbon liquid droplet growth mechanism [11].

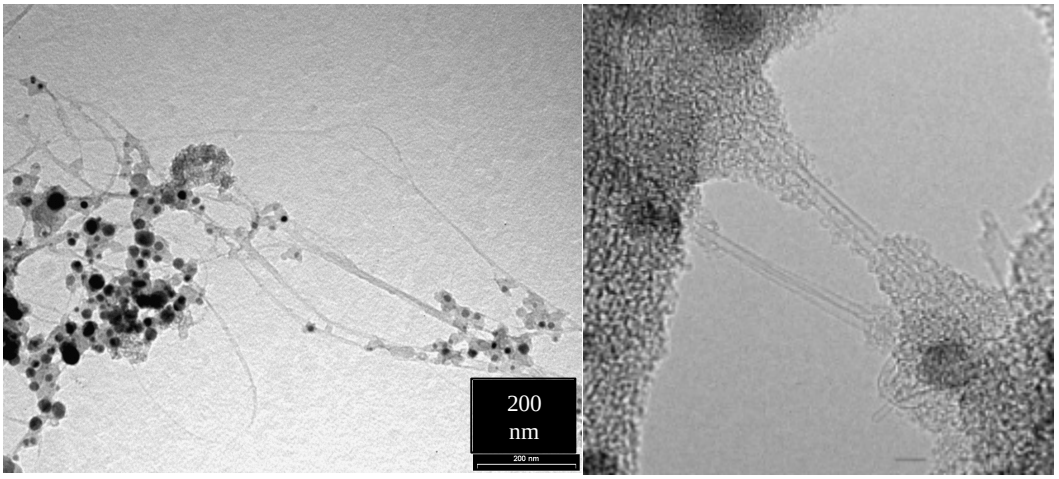

Figure 8 : TEM bundles of SWNT with metal particles (left) and detail by HRTEM (right)

Carbon Fibres

Another nanostructure family composed of long carbon chains has also been observed. Such structures represented on Figure 9 have been observed by injecting ethylene as carbon precursor together with a metal catalyst. The fibers diameter varies in the range of 20 – 50 nm with a length of few µm. Their structure seem composed of an axial stacking of carbon layers with a low graphitic organization. Similar structures have already been reported with the catalytic decomposition of hydrocarbons carried out at low temperature (< 1500 K), [12].

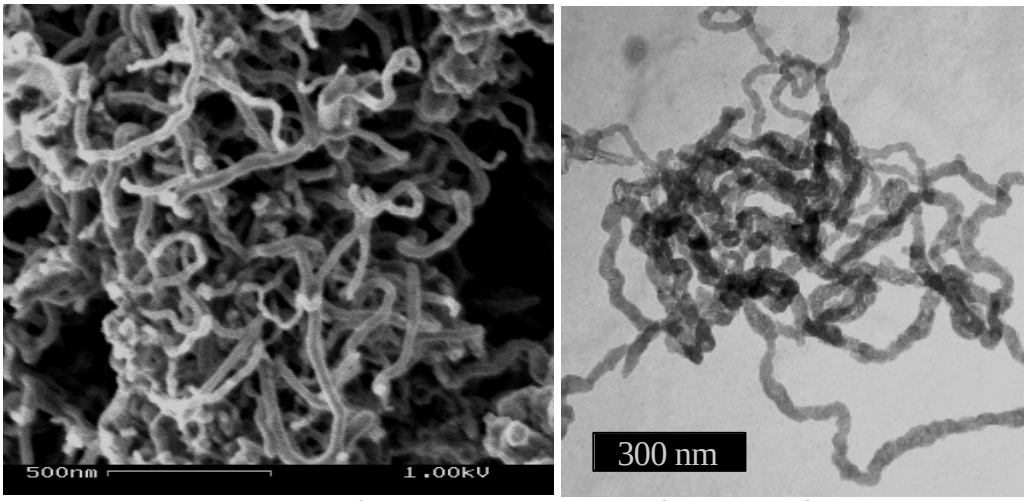

Figure 9 : SEM (left) and TEM (right) images of carbon nanofibres.

Conclusion

Plasma systems open a new area for the production of carbon nanostructures. These technologies are characterized by a very high versatility and flexibility. It has been demonstrated that the very same technology could be used for the production of a wide range of carbon nanostructures ranging from carbon black over fullerenes to carbon nanotubes with a high product selectivity. In the field of carbon black, the main difference with combustion methods is that the enthalpy applied to the system can be controlled totally

independently by means of an external electric power supply. As a consequence, any raw materials : liquid, solid or gaseous can be used, including waste oils, vegetable oils, plastics,…The process allows a more rational use of the raw material (100 % carbon yield), zero CO_2 emission on the site and the production of hydrogen as by-product. Finally, it is possible to control and de-correlate reaction temperature and aerosol concentration, two important parameters for the tailoring of final nanostructures. In addition, when using pure carbon under inert atmosphere, very high temperatures can be obtained (higher than 3,000 K up to 10,000 K) thus allowing in particular the vaporisation of carbon and the formation of chemical species such as C_1, C_2,.. whose species have been identified to play an important role as precursors for new carbon nanostructures such as fullerenes and nanotubes.

Electrical Characterisation of a low current-high voltage compact arc plasma torch

Jean-Damien Rollier, Laurent Fulcheri, José Gonzalez-Aguilar

Ecole des Mines de Paris, Centre for Energy and Processes, Sophia Antipolis, France

Abstract
A new compact plasma torch associated with a resonance power supply allows the generation of low power discharges (typically 100 W – 1 kW) under different regimes ranging from streamer over gliding arc to continuous discharges. The objective of this paper is a better understanding of the different observed behaviours through the determination of the main torch and power supply parameters, these two sub systems being highly coupled.

Keywords : high voltage, low current, compact arc plasma torch, electrical characterization, continuous, glidarc, streamer.

1. Introduction

Thermal plasmas have been widely used in industrial applications and more particularly in material related application requesting very high temperature. For lower temperature applications as those generally encountered in chemical gas processing, the use of non thermal plasmas (glidarc, glow discharge, DBD, corona, microwave…) is generally preferred for their lower energy consumption. In particular, non thermal plasmas have been emerging as an attractive alternative of standard (heterogeneous) catalytic systems. For example, the catalytic effect of non-thermal plasma for Synthesis gas production has already been demonstrated in several works [1-3]. This paper presents some advances obtained on a new low current high voltage compact arc plasma torch which is under development at CEP in the frame of gas phase chemical applications.

2. Experimental set up

The compact non thermal arc plasma torch is presented in Figure 2. The geometry is very similar to those encountered in classical high current DC plasma torches. An electric arc is established between a central (1) and an annular electrode (2). These two concentric electrodes being separated by a high voltage insulating ceramic material (3). A low current-high voltage arc discharge generated between the electrodes is blown down by a high velocity plasma gas injected radialy at the vicinity of the central electrode (4).
The generation of a low current high voltage arc discharge has been obtained using a power supply specially developed for this application. The power supply operates as a current source and it is based on a resonant converter technology. Here, a LC resonant circuit works as a selective filter: the current flowing to the load is controlled by the resonant tank impedance, which is controlled by the switching frequency in comparison with the tank resonant frequency (Figure 1). A 15,000 V maximum voltage can be obtained while maximum current is 660 mA. Contrary to high voltage transformers currently used for such applications, this power supply allows the continuous control of the arc current with a high accuracy in the range 200-600 mA. Tests have been performed using air as plasma gas with flow rates varying in the range 0.5 to 4 Nm^3/h using a mass flowmeter. Electrical signals have been analysed thanks to a 2 channels digital oscilloscope (HP 54615 B). Voltage measurements were performed using a 1:1000 probe (Elditest, GE3830) while discharge current was carried out using two methods (10 Ω shunt and a hall effect current probe : PR 30: LEM)

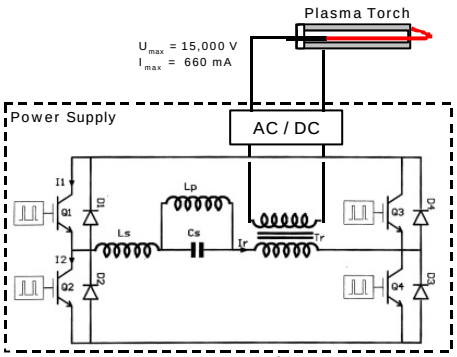

Figure 1: Electric scheme of the power supply

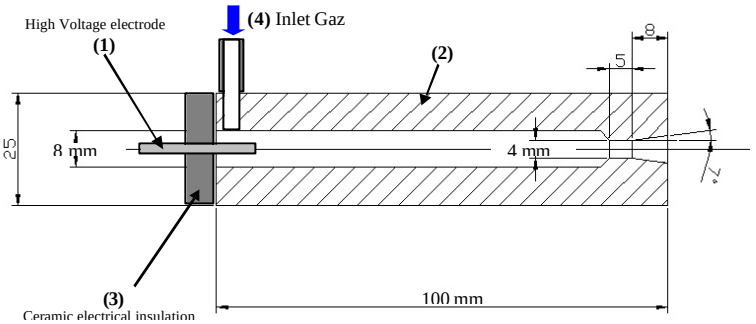

Figure 2: scheme of the compact plasma torch

3. Results

As shown in Figure 3, three different discharge regimes could be obtained by varying the arc current: a streamer regime at low current, a continuous regime at high current and a gliding arc regime at intermediate current. The boundaries between these different regimes is found to increase towards higher currents when increasing the air flow rate : at low flow rate (0.5 Nm^3/h), the limits between the streamer and gliding arc regimes and between the gliding arc and continuous regimes appear at 150 mA and 300 mA respectively. At high flow rate (4 Nm^3/h), the transitions take place at 300 mA and 430 mA respectively.

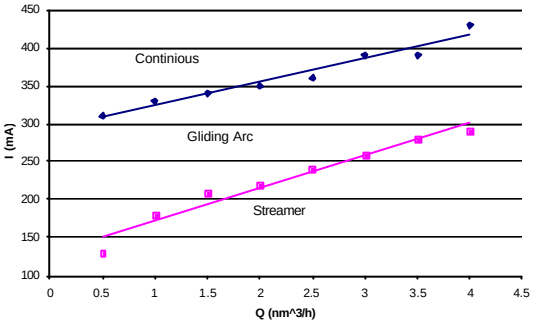

Figure 3: different discharge regimes versus current and flow rate

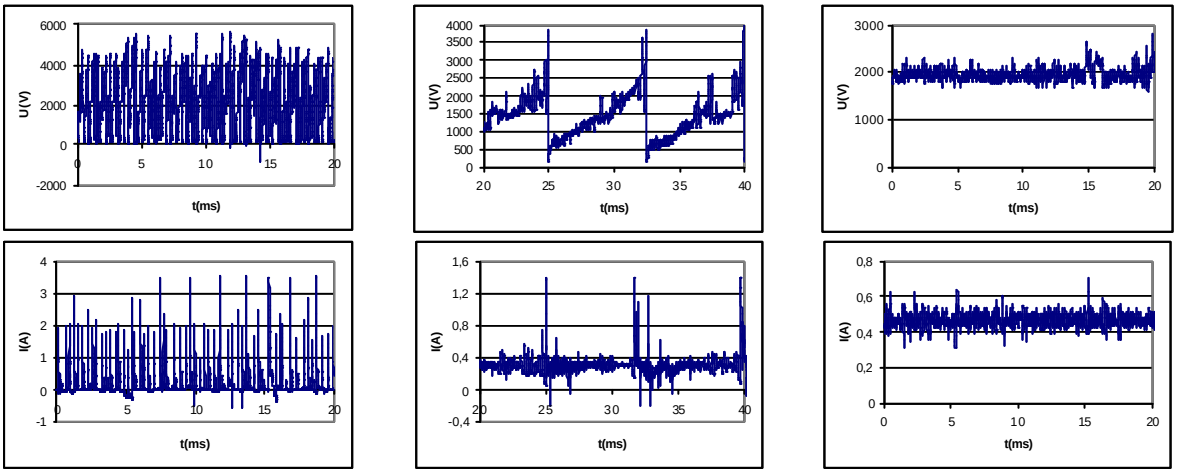
Figure 4 shows typical voltage and current time evolution for the three discharge regimes for streamer (a), gliding (b) and continuous (c) discharges obtained with a 2 Nm^3/h air flow rate and mean current 210 mA, 320 mA and 460 mA respectively.



(a) streamer regime (b) gliding arc regime (c) continuous regime

Figure 4: Time evolution of voltage and current

Streamer regime

This regime, characterized by high frequency discharges (typically higher than 2 kHz), appears at low current and it is characterized by a typical noise resulting of the high discharge frequency. As shown in

Figure 7, the time evolution analysis of the current and voltage streamer discharge reveals two different zones : a first zone characterized by a current peak which corresponds to a breakdown at the inter electrode gap ; a second zone where the voltage increases linearly while the current decreases down to zero until a new breakdown occurs. Under these conditions, the discharge is very thin and remains short and located at the vicinity of the central electrode as shown in Figure 5 and Figure 6. Actually, this regime corresponds to the power supply limits which does not allow to maintain a dynamic control of the discharge under such low current high voltage conditions. This is in particular due to the power supply response time which is not adapted to the breakdown frequency.

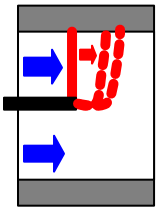


Figure 5 : Scheme of the streamer regime

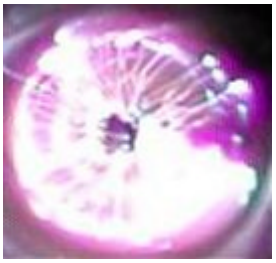

Figure 6 : Axial view of the streamer regime

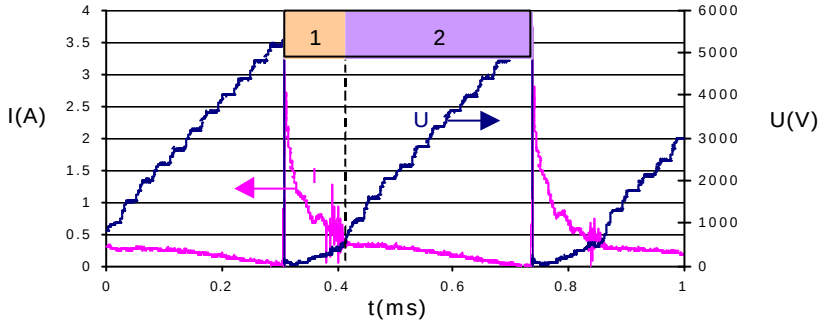

Figure 7 : Time evolution of of the current and voltage streamer discharge

Glidarc regime

This regime, characterized by a lower frequency (typically lower than 500 Hz) appears at higher current. As previously, the time evolution presented in Figure 8 shows a short current peak accompanying each breakdown. However, contrary to the previous case, the power supply allows an efficient control of the current which can be kept almost constant between two successive breakdowns since the response time of the power supply is lower than the breakdown periodicity.

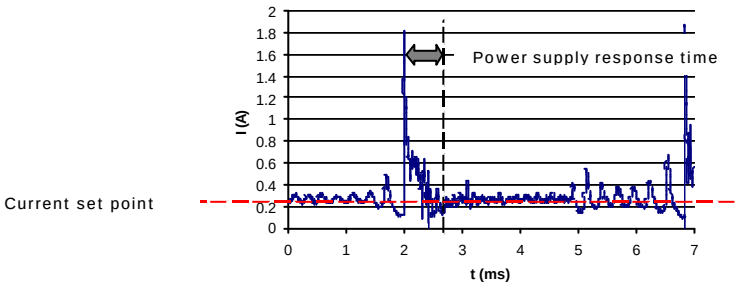

Figure 8 : Time evolution of current for the glidarc regime

The glidarc mechanism can be decomposed as follow [4-5]. After a breakdown occurring at the vicinity of the smallest inter-electrode gap, the arc is blown by the gas flow and its length increases. When increasing, the arc resistance increases together with the arc voltage up to reaching the breakdown voltage. Then, the arc stops, leaving the place to a new one. As a general rule, for given conditions (geometry, nature of the gas, gas flow rate), the higher the current the lower the glidarc frequency. This is the result of two opposite phenomena, the first one being the dominant one. One the one hand, the higher the current, the higher the arc temperature and the lower the arc resistance per unit of length so that the limit arc length can be increased

and the glidarc frequency decreased (the arc remaining "alive" more longer). On the other hand, the higher the current, the higher the arc cross section and the higher the drag force so that the relative arc shift (difference between gas and arc velocity) gets lower; the arc velocity increases and approaches the gas velocity (sweeping effect shrinks).
In addition, the arc current will also influence the dynamic behaviour of the arc through the "memory effect". Indeed the higher the current the higher the collision density and the concentration of ionised species.

This regime is strongly dependant on the hydrodynamic flow. The compact plasma torch developed at CEP has shown the existence of three different glidarc behaviours.

Regime "Glidarc 1"

This case is illustrated in Figure 9. The arc voltage varies between the breakdown voltage (approximately 3500 V) and the minimum voltage occurring once the arc is ignited at the smallest inter-electrode gap (A) (approximately 500 V). Depending on the gas flow rate, the arc length increases until the voltage reaches the breakdown voltage. The hydrodynamic conditions remaining almost constant between (A) and (B) as shown in Figure 10, the arc length and the arc voltage vary almost linearly versus time.

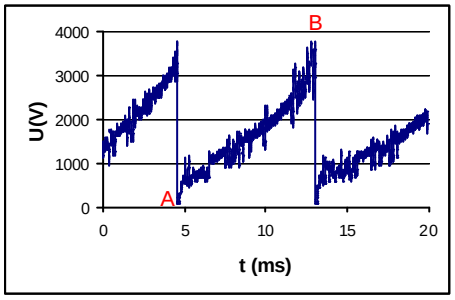

Figure 9 : Arc voltage time evolution "glidarc 1"

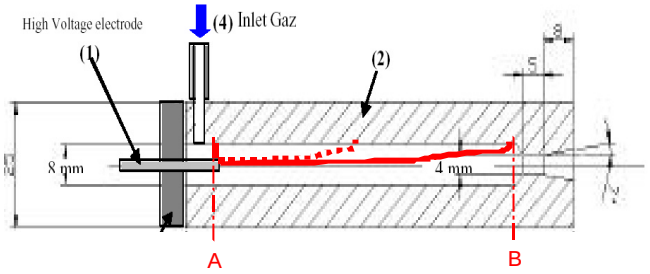

Figure 10 : Scheme "glidarc 1"

Regime "Glidarc 2"

When, for a given gas flow rate, the arc current is high enough, the arc is able to reach the output nozzle (B) before reaching the breakdown voltage as shown in Figure 11. In (B), the torch cross section decreases and the gas velocity is strongly increased. The arc is simultaneously accelerated and cooled down giving a stiff increase of the voltage slope (section [BC] in Figure 11). Both the breakdown and minimum voltages remain unchanged.

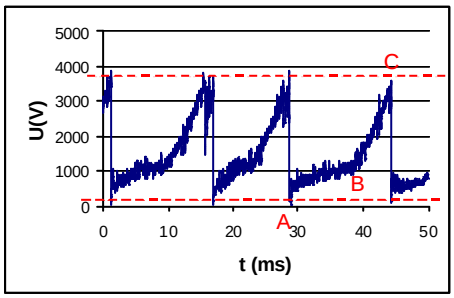

Figure 11 : Arc voltage time evolution "glidarc 2"

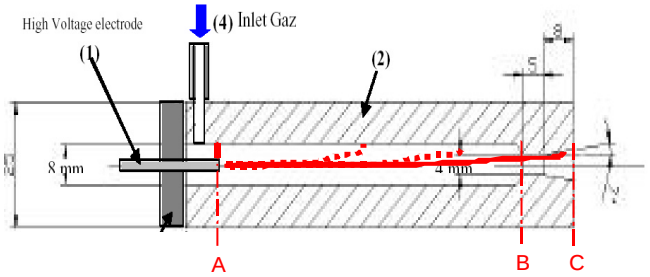

Figure 12 : Scheme "glidarc 2"

Under certain particular conditions, a third regime: "glidarc 3", intermediate between "regimes 2" and "continuous" may happen .

Regime "Glidarc 3"

Thanks to the "memory effect", it could happen that, after an arc extinction, a new breakdown will start directly from (B) as a result of a remaining ionised gas channel between A and B.

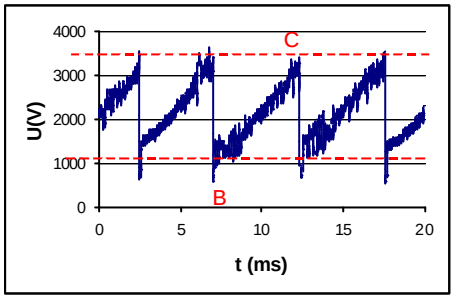

Figure 13 : Arc voltage time evolution "glidarc 3"

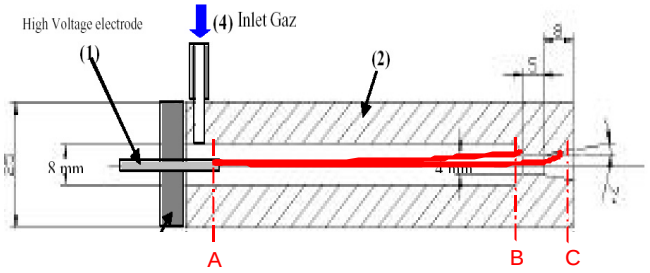

Figure 14 : Scheme "glidarc 3"

In this case, as shown in Figure 13, the minimum voltage, formally around 500 V for case 1 and 2, jumps very quickly to a higher level, typically 1000 V. This value corresponds approximately to the transition voltage observed in "regime 2" (point B in Figure 11).
In addition, the different "glidarc" regimes differ in term of frequency as shown in Figure 15. While frequencies vary continuously from "glidarc 1" to "glidarc 2", "glidarc 3" is characterised by higher frequencies what can easily be explained by different evolution zones of the arc, [A-B], [A-C] and [B-C] for regimes 1, 2 and 3 respectively .

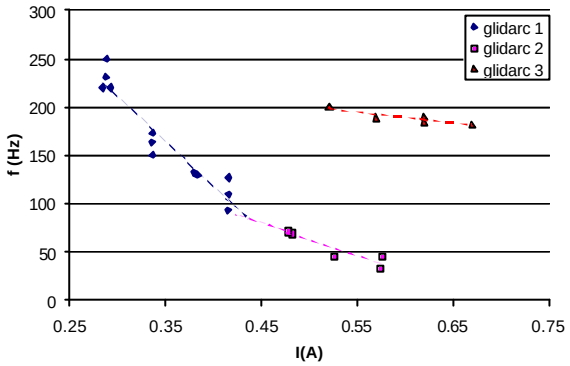

Figure 15 : Glidarc frequency versus arc current for the different arc regimes

To summarise this part, it has been demonstrated that the different glidarc regimes (1, 2 and 3) are mainly governed by the torch geometry, hydrodynamic conditions and arc current. The power supply allows a good control of the arc current for the different gliding arc regimes.

Continuous regime

Under certain conditions, it is possible to get a continuous stable discharge as shown in Figure 16. This is possible when the arc reaches the point C while the voltage remains lower than the breakdown value.

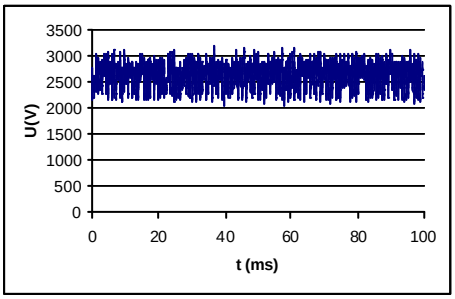

Figure 16 : Time evolution of the arc voltage for the continuous regime

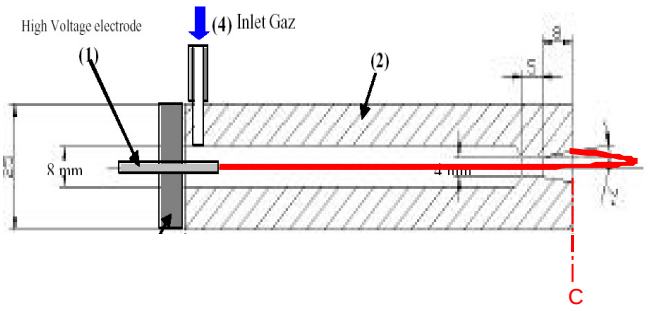

Figure 17 : Scheme of the arc for the continuous regime

As shown in Figure 18, for given conditions (gas flow rate and arc current), the arc voltage directly depends on the torch length. Consequently, it is possible to increase the torch length up to L_{max} by increasing the arc current. For $L = L_{max}$, the arc voltage equal the breakdown voltage corresponding to the smallest inter electrode gap. For higher lengths the continuous regime cannot be achieved.

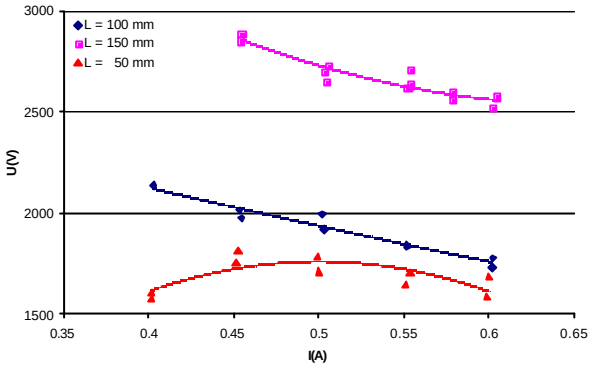

Figure 18 : Continuous regime mean characteristics versus torch length

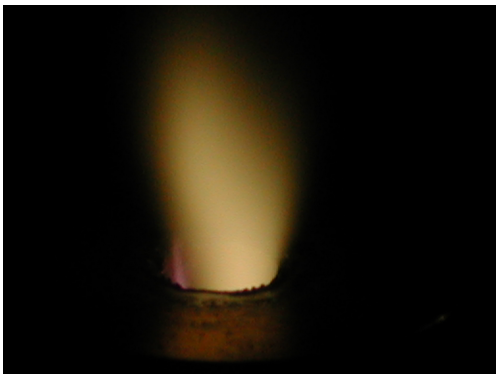

Figure 19: view of the plasma jet (continuous regime)

Conclusion

The new compact plasma torch associated to the resonance power supply allows obtaining low power discharges (typically 100 W – 1 kW) and different regimes ranging from streamer over gliding arc to continuous discharges under unusual current voltage characteristics (typically 100-500 mA, 2-10 kV). Contrary to conventional power supplies based on high voltage transformers currently used in gliding arc discharges systems, this power supply allows a continuous control of the mean discharge current with a high accuracy. This system is currently being tested in the frame of researches on plasma assisted hydrocarbon conversion.

Abstract

The aim of this study is to show that a Dielectric Barrier Discharge (DBD) at atmospheric pressure can be used to produce the water gas shift reaction. The inlet mixture composition and discharge electric parameters effects on the reactive species conversion rates and on the products concentration are studied. This preliminary investigation permitted to obtain a CO conversion rate close to 35%. A thermal modelling is compared to the DBD experimental data.

Keywords: Non thermal plasma, pulsed DBD, CO conversion

1. Introduction

The carbon monoxide is a pollutant stemming from the incomplete combustion of hydrocarbons but can be also produced during the steam reforming. CO is well known as dangerous for the health, the environment and for the fuel cell electrodes (CO level must be lower than 10 ppm to avoid electrodes poisoning). Recent works showed the possibility to produce hydrogen by a non thermal plasma technique from ethanol/water mixtures with results close to those obtained from catalytic reactors [1-4]. Nevertheless, the main disadvantage of the steam reforming is the high level of CO produced (up to 20% in catalytic and plasma processes). One possible way to reduce carbon monoxide is the water gas shift reaction (WGSR) which leads to H_2 and CO_2 following the reaction 1.

$$CO + H_2O \rightarrow CO_2 + H_2 \qquad \Delta H^0_{298} = -41 \text{ kJ.mol}^{-1} \qquad (1)$$

The steam reforming of bio-ethanol from the agriculture or agricultural residues associated with the WGSR can reduce the outlet CO leading to a nil global CO_2 balance. The amount of CO_2 produced is the same that consumed by the plants during their growth. The WGSR is widely studied in catalytic reactors [5-7].

In the present paper, an experimental investigation was conducted in order to demonstrate the feasibility of the WGS reaction by a pulsed Dielectric Barrier Discharges (DBD) reactor at atmospheric pressure. Until now, this reaction was described not possible by this technique. The influence of voltage and initial H_2O concentration on the CO and H_2O conversion rates and on the products mole fractions are presented.

2. Experimental

The inlet mixtures (CO/H_2O) were prepared in a gas handling system and their composition was controlled by calibrated mass flow controllers. Water vapour with controlled concentrations was added to the CO gas using controlled evaporator mixer CEM®. After mixing in the manifold, the gas reaches the reactor through a temperature-controlled line to avoid condensation. The reactor was placed inside a tubular furnace where the temperature is fixed at 120°C. The electrical discharge reactor used is a DBD reactor described previously [8]. The geometry was one of a wire to cylinder type with a tungsten wire (0.9 mm diameter) in a quartz tube with inner and outer diameter of 11 mm and 13 mm, respectively. An aluminium foil covered the dielectric tube and forms the outer electrode. The active volume of the DBD reactor can be adjusted by adjusting the length of the outer electrode. In this study, the reactor volume was fixed at 16 cm^3.

The DBD reactor is driven by a transformer powered by high-voltage ceramic capacitors (4 nF) disposed in Blumlein-like configuration. In this work, high voltages up to 40 kV output into pulses of 80 ns duration (FWHM) and short rise time (40 ns) are delivered. The pulse repetition rate could be varied from single shot to 220 Hz.

The time behaviour of voltage was measured using a Tektronix P6015A high voltage probe (1000x) and recorded on a Tektronix TDS 400A digital oscilloscope. Figure 1 shows an example of a typical recording of voltage across the electrodes as a function of time.

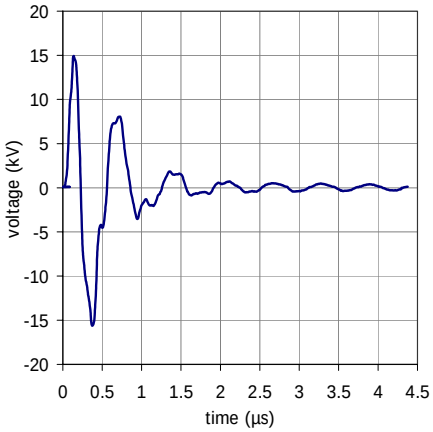

Figure 1. Typical recording of voltage pulse *vs.* time.

The outlet gas composition was analysed using micro gas chromatography (µGC, Varian CP2003-P) and Fourier Transform Infra Red spectroscopy (FTIR, Nicolet Magna-IR 550 series II). The µGC analyser was equipped with Molsieve 5Å and PoraPlot Q columns. The detection was assured by thermal conductivity detector (TCD) calibrated with standards of known composition.. The detected and analyzed species in that study are: H_2, CO, CO_2, and H_2O. The outlet H_2O concentration was estimated from C, H and O balances, since no other species were detected.

3. Results and discussion

Figures 2a and 2b show the influence of the inlet H_2O mole fraction and the applied voltage on the products mole fractions. Figure 2c presents H_2O and CO conversion rates as function of the inlet mixture composition and the applied voltage.

For the lowest applied voltage (20 kV), the H_2 and CO_2 mole fractions are constant in the range of inlet mixture composition studied (figure 2a). For higher applied voltage (30 kV), the H_2 and CO_2 concentrations depend strongly on the inlet mixture composition (figure 2b). When the inlet H_2O concentration rises from 0.40 to 0.80, H_2 and CO_2 mole fractions decrease from 0.11 and 0.105 to 0.08 and 0.067, respectively. H_2 and CO_2 mole fractions are in the same order of magnitude showing that CO and H_2O reacted mole by mole. Indeed, for a given mixture, the amounts of CO and H_2O consumed correspond to the CO_2 and H_2 produced.

We can observe (figure 2c) that the inlet H_2O mole fraction plays a major role on the conversion rate of the reactive species and on H_2 and CO_2 concentrations. An increase of the inlet H_2O leads to an increase of the consumption of the CO while H_2O conversion decreases. The CO conversion rate increases when the inlet CO concentration decreases.

The outlet concentrations and the conversion rates as a function of the voltage are shown in figure 3. One can note that, when the voltage increase, the H_2 and CO_2 mole fractions in the outlet gas increase from about 0.05 to 0.102. In the same time, H_2O and CO mole fractions decrease from 0.45 to 0.40 and, CO and H_2O conversion rate is multiplied by a factor 2 (figure 3b).

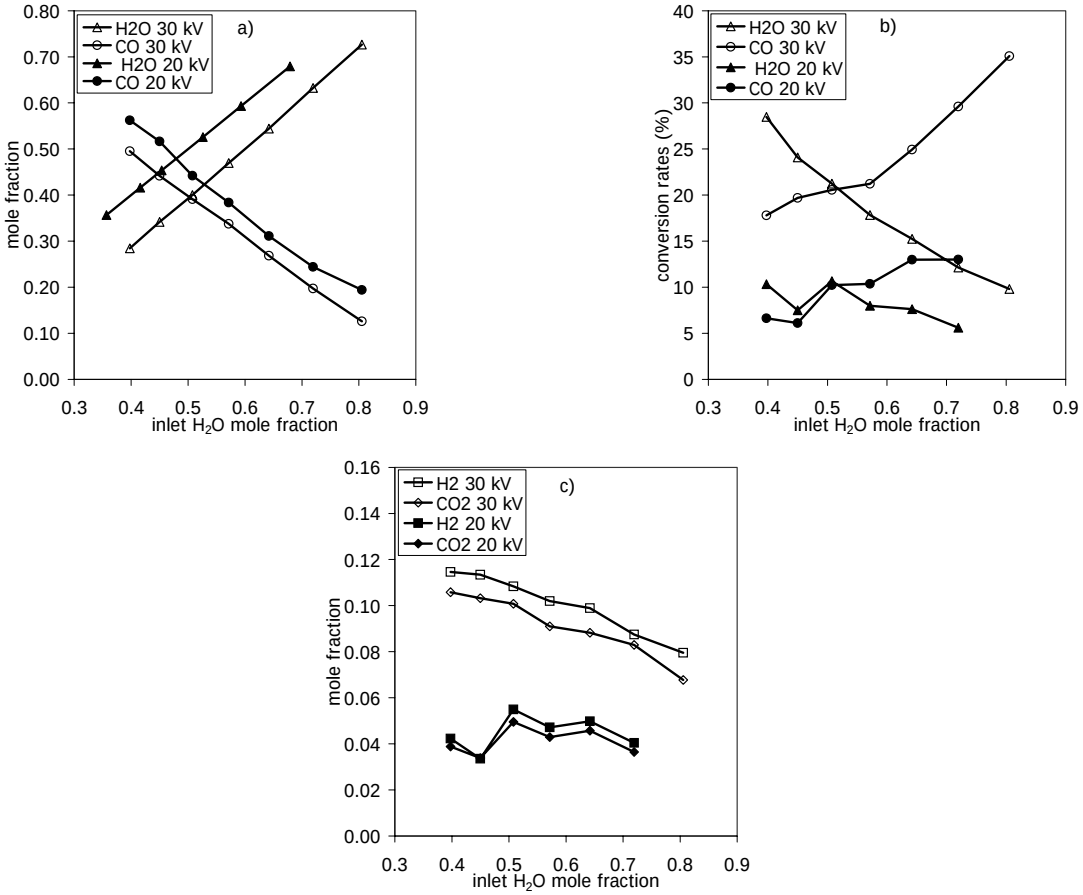

Figure 2. Influences of the inlet H_2O mole fraction and the peak voltage pulse on:
a) H_2O and CO mole fractions, b) CO and H_2O mole fractions and c) conversion rates of H_2O and CO.
Total flow gas = 147.5 sccm at 120°C.

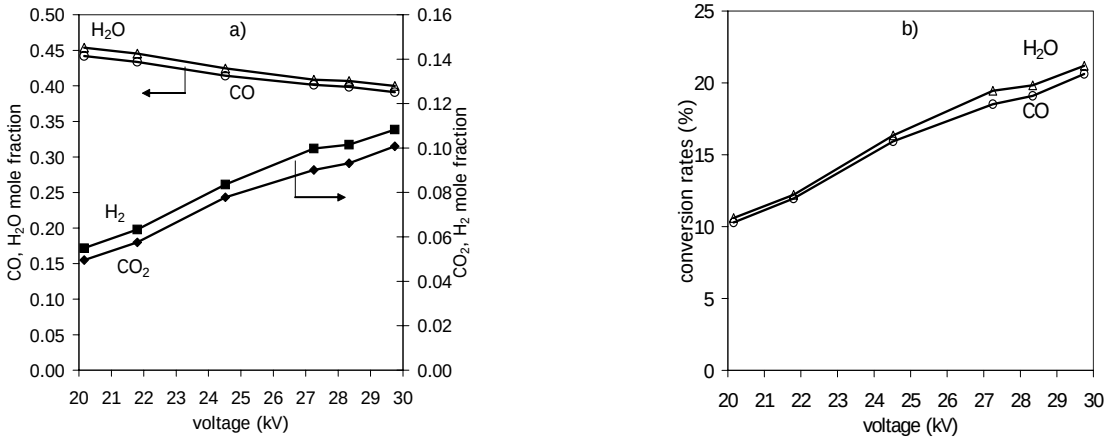

Figure 3. Effect of the applied voltage on: a) H_2O, CO, CO_2 and H_2 mole fractions
and b) CO and H_2O conversion rates.
Inlet mixture mole fractions: H_2O 0.508 - CO 0.492; total gas flow = 147.5 sccm; T = 120°C; f = 180 Hz.

Although the implied processes are typically non thermal one, it is interesting to compare the experimental results with classic kinetic models. Calculations obtained from Chemical Workbench 3.2 software [9] for a plug flow reactor are presented in figure 4. Two C-H-O mechanisms were used: GRImech 3.0 [10] (53 species and 325 reactions) and CH_4+O_2 combustion model from Chemical Workbench package (36 species and 134 reactions). We used these two models which led to similar results. The temperature of the plug flow reactor was adjusted to fit the experimental data.

Figures 4 show the mole fractions as a function of the inlet mixture composition. A fairly good agreement between the experimental and computational results is observed for the reactive species H_2O and CO (figure 4a). The profiles of the mole fraction and the trends *vs.* the inlet H_2O mole fraction are close to the experimental data. Gas temperatures used to simulate the non-thermal DBD reactor in GRImech and CH_4+O_2 combustion mechanisms are 1325 K and 1350 K, respectively.

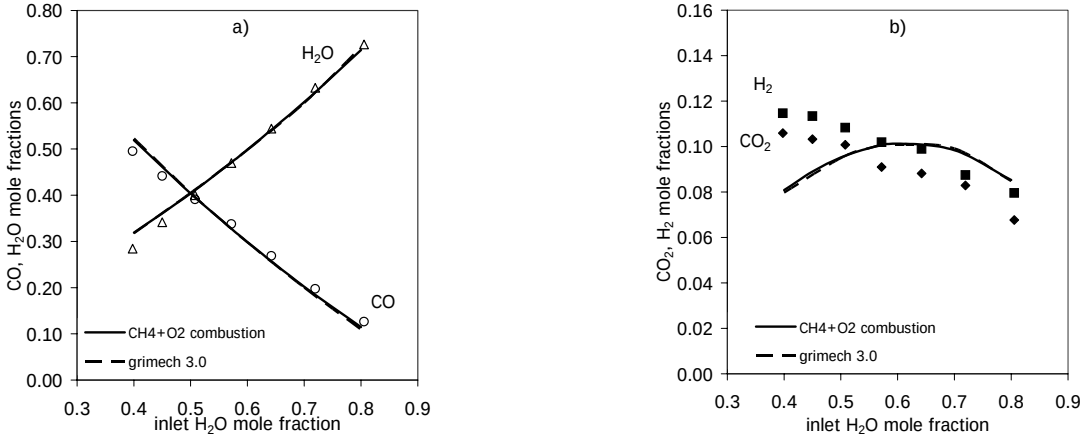

Figure 4. Effect of the inlet H_2O mole fraction on CO, H_2O, CO and H_2 mole fractions. Comparison between experimental data (symbols) and modelling (lines and dotted lines). Total gas flow = 147.5 sccm; T = 120°C; f = 180 Hz.

For a given gas mixture, the calculation using these two mechanisms gives close results concerning H_2 and CO_2 mole fractions. However, computed and experimental results are different in the range of low H_2O concentration. In that case, the mechanisms slightly underestimate the H_2 and CO_2 mole fractions values (about 0.11 for the experimental data and 0.065 for the modelling results). When H_2O concentration increases, modelling results shows an increasing of the products concentrations while the experimental data show a linear decrease.

From these comparisons between experimental and modelling results, we have simulated the effect of the voltage on the species concentration. The increase of the voltage is simulated by the increase of the gas temperature in the GRImech 3.0 plug flow reactor model. The increase of the applied voltage from 20 to 30 kV corresponds to an increasing of the gas temperature from 1288 to 1325 K, respectively (figure 5). A good agreement is obtained in the entire voltage domain studied for the species concentration.

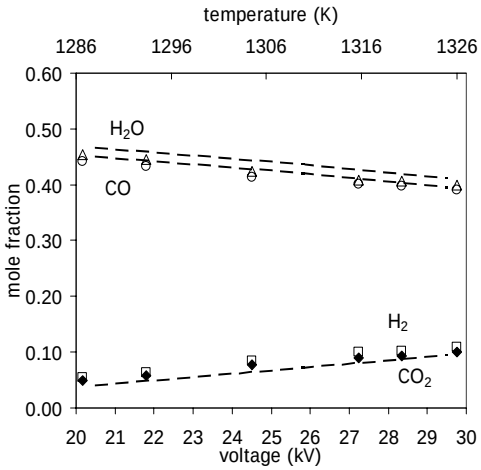

Figure 5. The effect of the inlet peak pulse on CO, H_2O, CO and H_2 mole fractions. Comparison between experimental data (symbols) and GRImech 3.0 modelling (dotted lines).
inlet H_2O mole fraction= 0.508; total gas flow = 147.5 sccm; T = 120°C; f = 180 Hz.

Conclusion

This work showed the potential of DBD reactor to realize the water gas shift reaction at atmospheric pressure. The conversion rates and the concentrations of the products were studied as functions of the inlet reactant mixture and the applied voltage. This preliminary investigation permitted to obtain conversion rates of CO close to 35% for the highest inlet H_2O mixtures studied. The applied voltage plays an important role in the CO conversion.

Results obtained from kinetic modelling show that the mechanisms used in the combustion chemistry are determining. The reactions implying electrons and ions, which are not taken into account in these models, can be then considered as initiators; they are followed by classic mechanisms which allow describing production of various species. We suggest representing a DBD reactor by an association of reactors models. The first reactor would represent a non thermal equivalent processing and the last one thermal reactor. To achieve real temperatures of the discharge reactor, vibrationnal and rotational temperatures measured by optical spectroscopy must be made and used in equivalent thermal models.

ABSTRACT

Because of its excellent combination of mechanical properties, corrosion resistance and chemical stability, the Ti-6Al-4V alloy is one of the most useful titanium alloys for aeronautical and biomedical applications. In case of wear absence, this material presents excellent corrosion resistance, including in the saline solutions media, similar to corporeal fluids, base of its bioengineering application. However, problems appear when localized wear starts causing intense corrosion. To improve corrosion wearing resistance, and fatigue strength as well, surface treatments by cold plasma plating and ionic implantation have been carried out. Present experimental work reports the surface characteristics improvements of Ti-6Al-4V alloy induced by a hybrid process performed by: Plasma Nitriding (PN) and Plasma Immersion Ion Implantation (PIII).

Key-words: Ti6Al4V, plasma, mechanical properties, biocompatibility

1. INTRODUCTION

The Ti-6Al-4V alloy is one of the most common titanium alloys intensively applied in aeronautical industries and also in biomedical areas [1]. This fact is attributed to its excellent combination of high mechanical and high chemical corrosion resistance [2,3], being the last characteristics originating from the passive oxide films formation on its surface [4,5] as a consequence of the surface oxidation process provided by contact with air [6]. This phenomenum almost avoid the penetration of oxidation process toward inner volume of this material which in turn minimize the metallic ion release into the biologic media [6]. The spontaneously formed oxide passivate the surface of this material leading to its biocompatible characteristics enhancement [4,7].

The major application for this material is in the area of aeronautic and space industries, allowing its use for some structural parts like for pressure vessels, aircraft turbines and compressor blades. Moreover, it has also been reported an important application of this material: for surgical implantations [1,7,8,9], due to its good characteristic of biocompatibility [1].

The Ti-6Al-4V alloy is classified as $\alpha+\beta$ alloy, presenting density of 4,43 g/cm^3, therefore 56% of the corresponding value of the steel and approximately double of the aluminum [10,11].

Despite of, above mentioned, very interesting characteristics of Ti-6Al-4V, this alloy presents a relatively poor tribological characteristics. Its friction coefficient is about 0,8 [12], and when a localized wear is started. This effect can cause through contacting surface an intense corrosion [11,13] producing ultimate damage of specimen produced by this material. To improve corrosion and wearing resistance, as well as fatigue strength, surface treatments such as cold plasma plating and ionic implantation have been investigated [11].

The present work aims to improve the tribological properties of the Ti6Al4V alloy treating it by a combination of two plasma assisted processes: Plasma Nitriding and Plasma Immersion Ion Implantation, in the sense to increase the nitride layer thickness as observed in another preliminary work [11].

2. EXPERIMENTAL PROCEDURE

The experiments were carried out on Ti-6Al-4V samples with 10 mm dia. x 1 mm thick disks. They were polished up to mirror like surface is achieved, mounted in a sample holder, and then they were adequately positioned in the reactor chamber, whose schematic diagram is presented in the figure 1. The plasma chamber was initially vacuum pumped up to residual pressure of 2,0 x 10^{-3} Pa and then argon gas is introduced for approximately 10 min. After this purging stage, the argon gas is replaced by nitrogen gas. Experimental conditions are resumed in Table I. Some samples were only treated by PIII process, while others were treated by combinations of PIII and PN processes. The ionic bombardment produced a heating condition of the samples to the temperatures up to 400 ºC.

All treated samples as well as the original Ti-6Al-4V sample (TAV), which has been taken as reference, were characterized by means of surface hardness using nanoindentation technique, chemical composition profile using Auger Electron Spectroscopy and surface topography uisng Atomic Force Microscopy. Two samples (TAV and #7) were analysed by means of its friction coefficient using the ball on disk method.

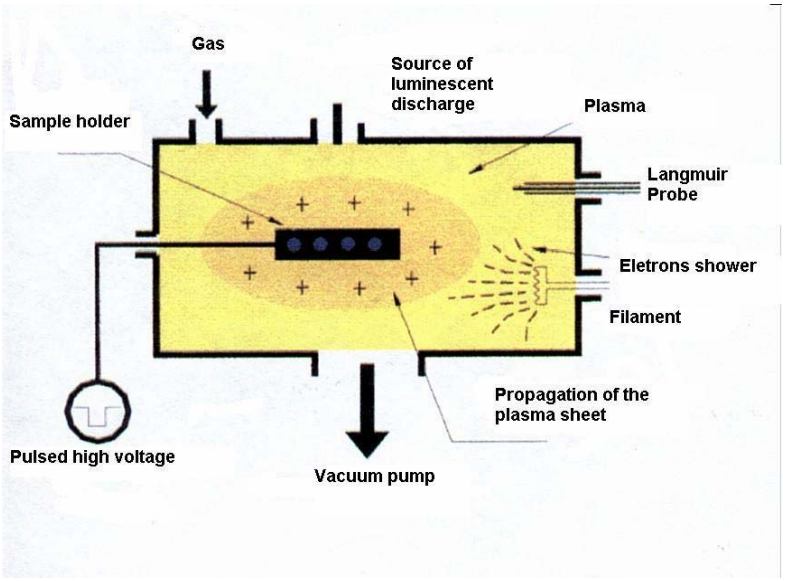

Figure 1 - Schematic diagram of experimental set up (plasma immersion ion implantation reactor)

Table I. Experimental conditions used.

Sample	1		2 and 4	3		5 and 6		7
Process	PIII	PN	PIII	PIII	PN	PIII	PN	PIII

Pressure (Pa)	$8x10^{-2}$	$8x10^{-2}$	$7.2x10^{-2}$	$8x10^{-2}$	$8x10^{-2}$	$8x10^{-2}$	$8x10^{-2}$	$7,6x10^{-2}$
Time (min)	75	75	150	75	75	75	240	45
Frequency (Hz)	400		400	400		400		300
Pulse (μs)	20		20	20		20		50

3. RESULTS AND DISCUSSIONS

The results obtained from hardness measurement as a function of indentation penetration depth for representative samples are presented in Figure 2. A relatively small variation of hardness was observed for untreated sample (reference sample). This characteristic is a consequence of bulk homogeneity of the samples. All plasma treated samples showed larger variation of this parameter with penetration depth, which can easily inferred as due to the formation of a harder layer at surface of the sample. The comparative analysis of results originating from all treated samples showed that PIII + PN both for 75 min, presented most effective hardening of the material,

leading to the interpretation that this compound process can be a interesting alternative process if main objective of treatment is to improve the hardness of this material.

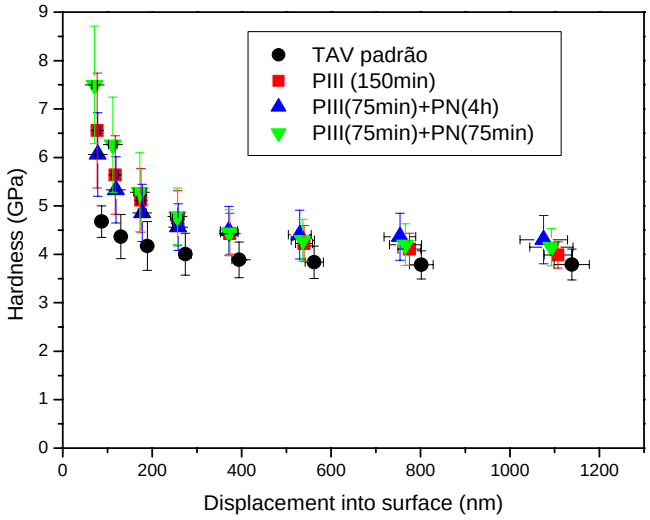

Figure 2 - Hardness of samples measured by nanoindentation technique (TAV is reference sample without any surface treatment)

The AES technique (Auger Electron Spectroscopy) can show the chemical composition at the surface of sample, and by its association of etching technique a depth dependent concentration profile for each element can be obtained. The figure 3-a shows the results obtained from reference sample (TAV) while figure 3-b corresponds to the results obtained from sample # 2. These results show that the carbon and oxygen are present in the original sample surface, probably forming TiC and TiO_2. The single PIII process can produce 65 nm thick nitride layer, while PIII + PN hybrid one performed for sample # 6 (not shown in figure 3) produced only 15 nm thick. This result can tentatively understand that is due to the concurrent sputtering process introduced by PN, which simultaneously with implantation of N by PIII removes the freshly forming nitride layer. This result is also confirmed by AFM analysis of surface. It was also verified that all treated samples presented a thin oxygen layer at its surface. It can be observed that the formation of complex compounds like oxide, carbide and nitride at the surface of the sample almost vanish the presence of vanadium and aluminum at the surface of samples. This effect is, for instance, suitable for many applications, specially for implantation [14].

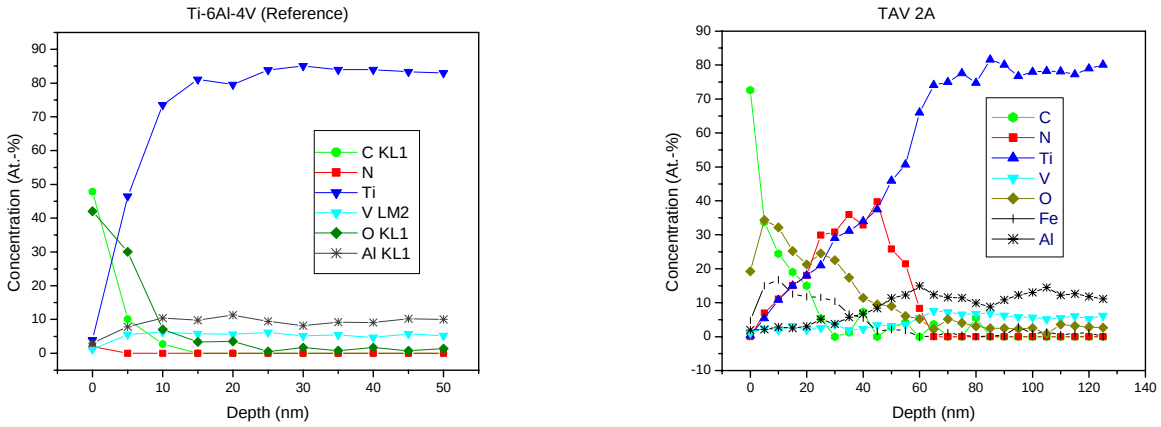

Figure 3 - Concentration of chemical elements as a function of surface depth obtained by AES technique.

Two representative 3-D micrographs obtained by AFM are presented in figure 4. The comparative analysis of these two micrographs leads to the confirmation of the AES results in the sense that the sample #4, treated only by PIII process presents larger RMS (Root Mean Square) roughness of 6,9nm, compared to the 1,8nm of sample #5. This means that PN process associated with PIII smoothen the sample surface probably sputtering process. All analyses shown evidence that both plasma based surface treatment processes can modify the mechanical properties of the Ti-6Al-4V alloy, probably, improving its tribological property.

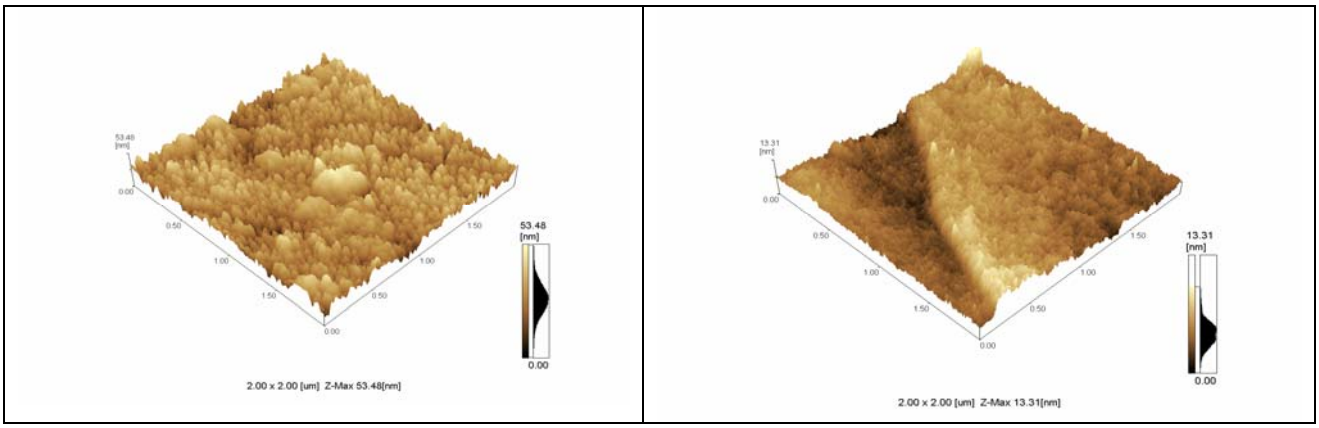

Figure 4 - AFM topography of: (a) sample 4 treated by PIII and (b) sample 5 treated by PIII + PN.

The figure 5 shows the ball on disk wear resistance tests results, for reference sample and for sample #7, treated by single PIII for 45 min. These tests allow us to confirm that the friction coefficient of original Ti-6Al-4V is about 0.8, which can be minimized to 0.3, as consequence of new material layer formed at its surface.

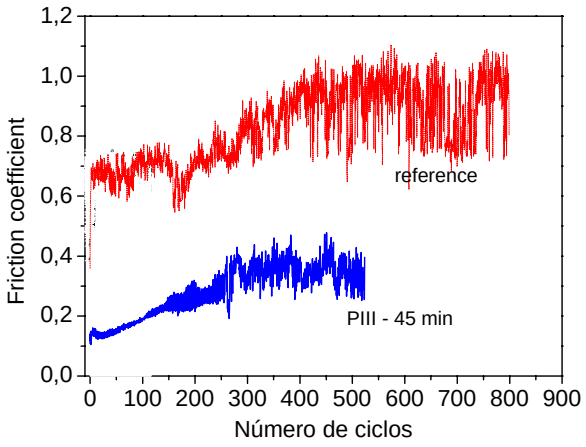

Figure 5 - Friction coefficient measurement results by ball on disk method

4. CONCLUSIONS

The set of results can lead us to the conclusions that the surface Ti-6Al-4V alloy properties can be modified by treatment processes performed in this work, being the single PIII the best process when deeply distributed nitrogen layer is requested for some specific application, but the combined PIII + PN process is more suitable to produce hardest and smooth surface.

The surface hardness increase induced in Ti-6Al-4V by processes studied can be attributed to nitrogen implantation effect, as confirmed by the nitrogen profile measurente by AES technique.

The deepest implantation of nitrogen was performed by PIII process for 150 min, producing 65 nm thick nitride layer. The thinnest nitride layer, with about 15nm, was observed in the material treated for PIII (75 min) + PN (240 min). These results are attributed to sputtering involved in the hybrid process.

New combinations of processing parameters are being carried out aiming thicker layer of implanted nitrogen with more hard and smooth surface sample production.

Abstract

Hydrogen-rich gas can be efficiently produced in compact plasma boosted reformers by the conversion of variety of hydrocarbon fuels including natural gas and diesel. Previous studies of methane steam reforming using a gliding arc reactor at atmospheric pressure, shows a promising results (H_2 concentration higher than 55%). In order to improve reactor efficiency, decreasing input electrical power and increasing methane conversion, small amount of oxygen was added to the CH_4-H_2O mixture.

Keywords: Steam reforming, methane, hydrogen, sliding discharge, non-thermal plasma

1. Introduction

Natural gas attracts considerable attention as an alternative energy source to petroleum. One of the reasons why it is possible for natural gas to become the first resource is its high H to C ratio compared to those of coal, and oil [1]. Accordingly, natural gas has a best future as a resource to product hydrogen. However, methane is one of the most stable molecules, and thus, it is difficult to induce a selective reaction using methane to produce special molecules.

There are several methods to produce synthesis gas (syngas) but most of them (40%) are obtained by steam reforming (SR) [2]. The conventional catalytic technology presents several shortcomings such as large size of the equipment, high investments and exploitation costs, limitations on rapid response, catalyst sensitivity to poisons, and extreme operating conditions that limit the lifetime of reactors [3]. Therefore, a process, which converts methane directly into syngas and other valuable products under sweet conditions, is expected to be a challenge from the viewpoint of industry as well as science. Plasma reformer seems to be one of the solutions. Plasma is known to be a very high energy density media and gives an attractive alternative for hydrogen and syngas production. In this approach, the plasma could replace catalysts and accelerates chemical reactions due to both temperature and active species effect. Plasma reactors represent an incisive approach by their simplicity, compactness and low price.

Produce hydrogen and syngas via methane steam reforming was experimentally investigated in various plasma reactor configurations [4]. Obtained results were promising (H_2 concentration higher than 55%).

Due to its high reactivity, oxygen was used in several processes working on hydrocarbons conversion into syngas in partial oxidation (POX) process.

$$CH_4 + \tfrac{1}{2} O_2 \Leftrightarrow 2H_2 + CO \qquad \Delta H = -36 \text{ kJ/mole} \qquad (1)$$

The reaction is exothermic and nor indirect heat exchanger neither catalyst are needed because of its high temperature. It was used in auto-thermal reformer to provide heat and to raise steam for the steam reforming endothermic reaction:

$$CH_4 + H_2O \Leftrightarrow 3H_2 + CO \qquad \Delta H = 206 \text{ kJ/mole} \qquad (2)$$

The present work is a continuation of our previous studies regarding the syngas production by steam reforming of methane [4]. We will present an experimental study of oxygen effect on the methane conversion and hydrogen production using glidarc discharge reactor at atmospheric pressure.

2. Experimental

The plasma reactor shown in Figure 1 consists of three anodes arranged around of a single cathode. Three channels electrical power supply is used to power up the three cascading discharges. Each channel consists of two transformers with rectifiers allowing two running phases: the ignition at high voltage and low current intensity, and a complementary energy supply with higher current.

Discharges are ignited between electrodes and then pushed by the gas flow. A magnet was used in order to produce a rotating effect in the discharge region. The discharge column is a plasma string with a visible diameter less than one millimeter that slides in the gas flow and the magnetic field region (figure 1). The plasma string performs a helix movement and looks like a wrapped wire around the cathode.

Using this type of reactors, plasma can sweep a large part of the inlet gas and maintains its non-equilibrium behavior. In the usual gliding discharges, the plasma thermalization was avoided by using external current limitation (resistors, reactors, etc).

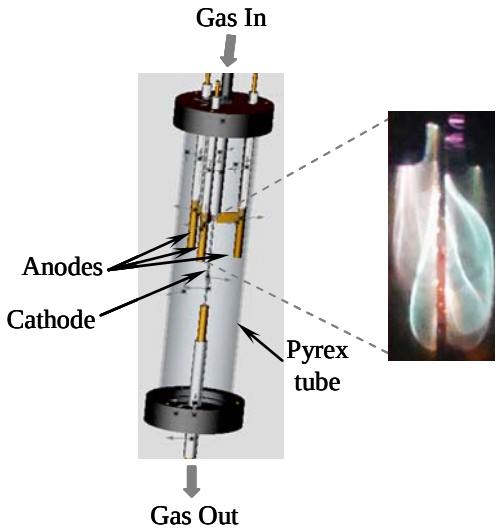

Figure 1: Schematic of the sliding discharge reactor

The discharge behaviour in a magnetic field is quite different than the usual gliding discharges. The first effect is the increase of the mixing properties of the reactor [4]. In the case of magnetic blow out, the force acting on the lengthening discharge column is proportional to the product between the current and the magnetic-field strength. This force produces a very rapid lengthening of the discharge column. The de-ionisation occurs much faster, leading to the mixing of the discharge gases with the cold gas through which the core is forced to pass in its rapid motion. Due to the magnetic field, a self-limitation of the current intensity is produced.

Figure 2 shows the typical voltage and current waveforms for one of the three discharges. For clarity of the diagram, the high voltage is plotted as a negative signal. As can be seen on this figure, the discharge behaviour is not definitely periodic due to the instabilities in the growing discharge. The electrical power is obtained by averaging results over a large number of periods.

All experiments were conducted at atmospheric pressure. The water and methane are mixed before injection in a heating line. The gas temperature was fixed at about 500 K for all the experiments. The exhaust gas from the reactor was passed through a condenser. The major gaseous components were analysed online and quantified using tow techniques: micro gas chromatography (µGC, Varian CP2003-P) and Fourier Transform Infra Red spectroscopy (FTIR, Nicolet Magna-IR 550 series II). The µGC analyser was equipped with Molsieve 5Å and PoraPlot Q columns and the detection was assured by thermal conductivity detector (TCD) calibrated with standards of known composition. The major gas components identified were H_2, CH_4, and CO. Also, a small amount of CO_2 and C_2 hydrocarbons have been detected (concentration lower than 1% in all cases studied).

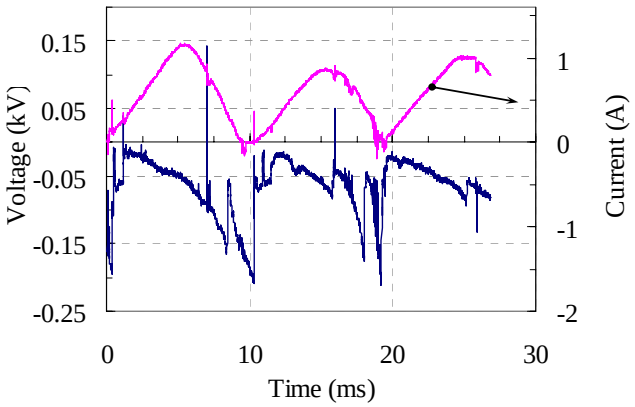

Figure 2: Typical voltage and current waveforms

3. Results and Discussion

Figure 3 shows an example of H_2, CO, CH_4 and CO_2 concentrations as a function of the inlet O_2 amount added in the CH_4-H_2O mixture. These results were compared with those obtained in the case of water-methane mixtures and showed in figure 4.

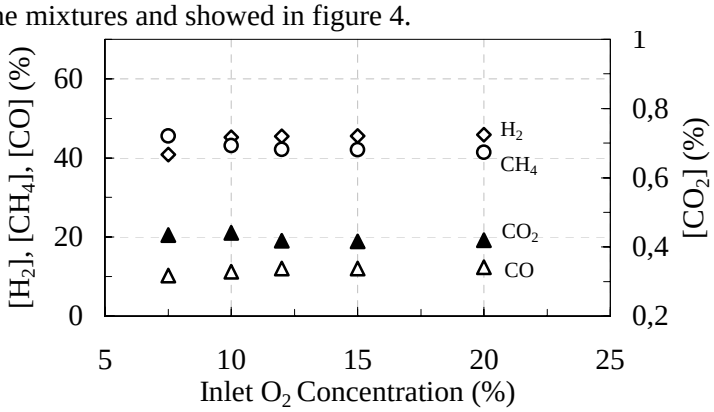

Figure 3: H_2, CH_4, CO and CO_2 concentrations as a function of O_2 concentration in H_2O-CH_4–O_2 mixtures. (Inlet gas temperature: 500 K, Electrical power: 830 W, flow rate: 15 L/min, Initial CH_4 molar fraction: 30 %)

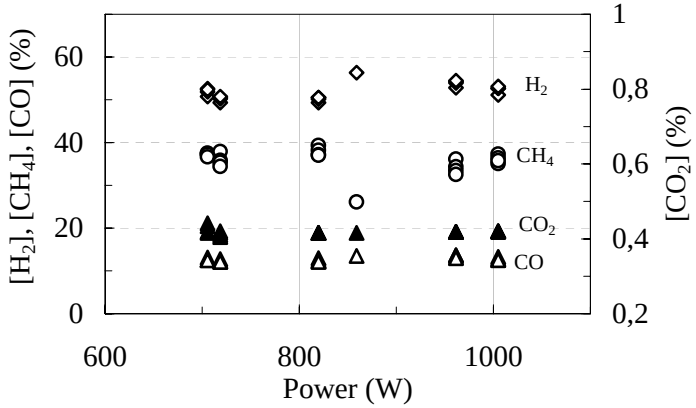

Figure 4: H_2, CH_4, CO and CO_2 concentrations as a function of electrical power in H_2O-CH_4 mixtures. (Inlet gas temperature: 500 K, Gas flow rate: 15 L/min, Initial CH_4 molar fraction: 30 %)

From figures 3 and 4, we note that, adding up to 20% of O_2 in methane-water mixtures do not affect significantly the CO, CH_4 and CO_2 concentrations obtained after plasma treatment. Nevertheless, the H_2 molar fraction slightly decreases in the case of presence of O_2. The addition of O_2 does not seem to be the solution to improve CH_4 conversion. It seems that oxygen reacts preferentially with H_2 to form H_2O.

Taking into account the main products identified at the reactor outlet and the decrease of the outlet H_2 molar fraction, we calculate the characteristic parameters (conversion, selectivity) of our process following the main possible reactions given below:

	CH_4 + H_2O ⇔ $3H_2$ + CO				**ΔH = 206 kJ/mole**	(1)
Initial (moles)	1	b				
Consumed (moles)	x					
Final (moles)	1-x	b-x	3x	x		

	CH_4 ⇔ $2H_2$+ C				**ΔH = 74.6 kJ/mole**	(2)
Initial (moles)	1-x					
Consumed (moles)	y					
Final MF	1-x-y	2y				

	$2H_2$ + O_2 ⇔ $2H_2O$				**H = -285.83 kJ/mole**	(3)
Initial (moles)	3x+2y	c	b-x			
Consumed (moles)	2y					
Final (moles)	3x+2y-z	c-z	b-x+2y			

The x, y, c, and z parameters represent the amount of methane consumed via the steam reforming reaction (equation 1), the amount of methane consumed via the cracking reaction (equation 2), the amount of inlet oxygen, and the amount of hydrogen converted in water, respectively. Accordingly, the total amount of methane converted will be equal to (x+y). The steam reforming and cracking reactions selectivity are calculated from the ratios (x/(x+y)) and (y/(x+y)), respectively. Figure 6 gives the results of these calculations as a function of the O_2 concentration added to the CH_4 - H_2O mixture. These results show that the addition of O_2 (up to 20%) promotes the cracking reaction (equation 2). In these experiments, one can note that a large quantity of soot was deposited on the plasma reactor wall in the case of high O_2 concentration and could be explained by the decrease of the H_2O/CH_4 molar ratio (<2) [5].

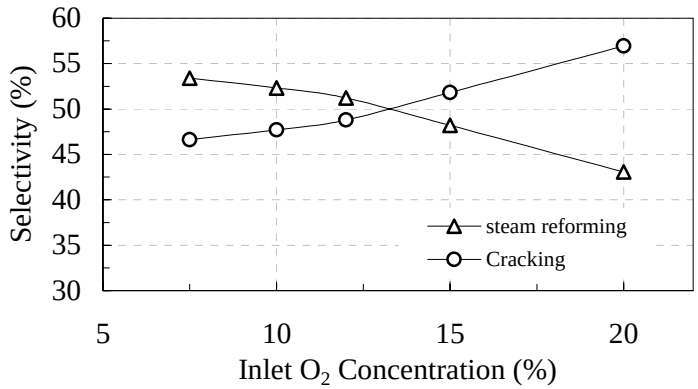

Figure 5: Selectivity variation us a function of the feeding parameters of the reactor

4. Conclusion

Compared with other processes, gliding arc reactor showed encouraging results and seems have a great future in the production of hydrogen from hydrocarbons. The addition of O_2 is not a solution to improve CH_4 conversion and to decrease input electrical power. Therefore, further investigations must be performed in order to increase both conversion and selectivity.

Abstract

A gas phase oxidation process using a sub-µs pulsed DBD has been studied to simultaneously remove SO_2 and NOx from gas stream that simulated glass manufacturing industry exhausts. SO_2 and NOx ($NO+NO_2$) removal efficiencies are evaluated as a function of gas temperature, specific energy and inlet SO_2 concentrations. About 100% of the SO_2 are removed from the gas stream containing 163 ppm of SO_2 at an energy cost of about 45 eV/removed molecule. The SO_2 removal efficiency was not significantly affected by the temperature in the range 100-500°C. The fraction of NOx removed was limited to a value of 30% in all cases studied. These results indicate that DBD plasmas have the potential to remove SO_2 from gas streams without additives.

Keywords: Pulsed dielectric barrier discharge; SO_2 removal; NOx removal

1. Introduction

The reduction of harmful greenhouse gases, such as sulfur and nitrogen oxides - SO_2 and NOx (including NO and NO_2), from industrial processes and vehicle exhausts is one of the critical and urgent topics in environmental and pollution control researches. These molecules have adverse effects on human health and have a great contribution to acid rain which has had detrimental effects on ecosystems.

Removal of these pollutants from flue gases can be achieved by conventional methods combining wet scrubbers and catalytic converters. However, these methods require additives (ammonia, urea, or lime), catalyst, and additional waste water treatment processes.

Many recent investigations [1-2] have paid attention to new technologies and suggested that the non-thermal plasma (NTP) could be one of the most effective methods for simultaneously removal of SO_2 and NOx ($NO+NO_2$) from flue gas at relatively low energetic costs. NTP that has a low gas temperature and a high electron temperature can be produced by a variety of electrical discharge methods (pulsed corona discharge, barrier discharge, and dc discharge) [3-6] or electron beam irradiation [1,7]. Regarding their intrinsic properties well adapted to treat large gas quantities, pulsed corona and dielectric barrier discharge (DBD) techniques are two of the more commonly methods used for producing electrical discharge plasmas. In these plasmas, gas phase radicals such as hydroxyl (OH), hydroperoxyl (HO_2) and oxygen atoms (O) were generated that simultaneously oxidize SO_2 and NO to SO_3 and NO_2, respectively. These oxides react with water to form acids molecules consisting of H_2SO_4 and HNO_3, respectively. In an industrial application of this process, the acid molecules could be chemically neutralized with the added ammonia (NH_3) to form salts ($(NH_4)_2SO_4$ and NH_4NO_3) which can be recovered as a dry powder using conventional particle collector and can be sold as a useful product (agricultural fertilizer) [7].

In the present work, an experimental investigation was conducted to remove simultaneously SO_2 and NOx from simulated glass industry exhausts based on SO_2-NO-NO_2-O_2-H_2O-CO_2-N_2 mixtures using a sub-microsecond DBD at atmospheric pressure.

2. Experimental facility

The experimental system consists of a continuous flow gas generation system, laboratory-scale DBD reactor, and a gas detection system (Figure 1). The system was described in detail previously [8] but is briefly described for clarity.

Synthetic gas containing mixtures of O_2, N_2, NO, NO_2, CO_2, SO_2, and H_2O were prepared in a gas handling system. The gas composition was controlled with calibrated high-precision mass flow controllers. Water vapor with controlled concentrations was added to the gas mixture using controlled evaporator mixer CEM®. It consists of a liquid flow control, a carrier gas control and a mixing chamber for liquid and carrier gas with heat exchanger for total evaporation. This device can provide a high reproducibility and a very stable water vapor flow. After mixing in the manifold, the gas then passes through a temperature-controlled line which preheats the gas and prevents condensation. The compositions of the gas mixtures studied are shown in table 1. Experiments were conducted at two flow rates (3 and 10 L/min) corresponding to residence times of the flue gas in the DBD reactor of about 320 ms and 1.07 s, respectively.

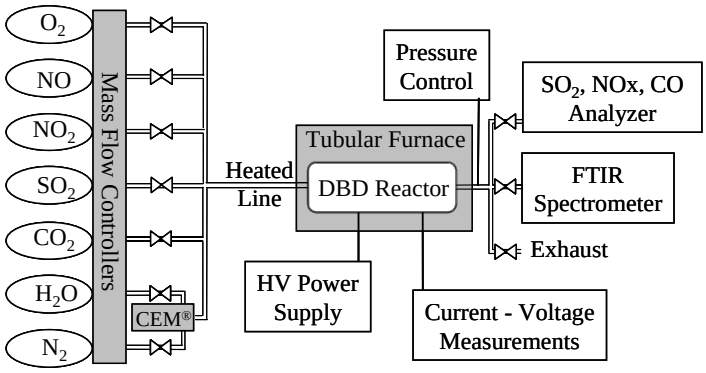

Figure 1: experimental arrangement

Table 1: Gas mixtures studied

	O_2	H_2O	CO_2	NO	NO_2	SO_2	N_2
Gas mixture #1	8%	16%	14%	523 ppm	49 ppm	163 ppm	62%
Gas mixture #2	8%	11.5%	16.5%	373 ppm	39 ppm	630 ppm	64%

The DBD reactor geometry was one of a wire to cylinder type. It consists of a 0.9 mm-diameter tungsten wire in a 16 mm-long quartz tube with inner and outer diameters of 11 mm and 13 mm, respectively. A brass mesh covers the dielectric tube and form the other electrode. The length of the outer electrode can be adjusted and then determine the active volume of the DBD reactor. Results presented in this paper were obtained with a plasma volume of about 16 cm^3. The DBD reactor was placed inside a tubular furnace and the gas mixture temperature can be adjusted from room temperature to 500°C.

The DBD reactor was powered by a home made high voltage pulses with amplitude up to 30 kV into 80 ns (FWHM) pulses and short rise times (40 ns) at variable pulse repetition rate (up to 200 Hz). The discharge pulse energy into the plasma was about 32 mJ. The fast voltage rise time allows achieving significant overshoot of breakdown voltages (kilovolts per nanosecond) and allowing working at larger reduced field values (E/n) than in AC-conventional DBD. The time-behavior of the voltage and the current, shown in figure 2, were measured with a Tektronix P6015A high voltage probe (1000x) and current transformer Europulse 9001. The signals from the probes were recorded on a Tektronix TDS 3034B digital oscilloscope.

The specific input energy which is the discharge energy to unit volume of the treated gas is given by:

$$E_s = \frac{E_p \cdot f}{Q} \qquad (1)$$

where E_p is the discharge pulse energy, f the pulse repetition frequency, and Q the gas flow rate at standard conditions (25°C and 1 atm). At a constant flow rate, changing the specific energy means changing either frequency and/or discharge pulse energy. In general, the experiments were performed with pulse energy of 32 mJ in the frequency range from 15 Hz to 160 Hz.

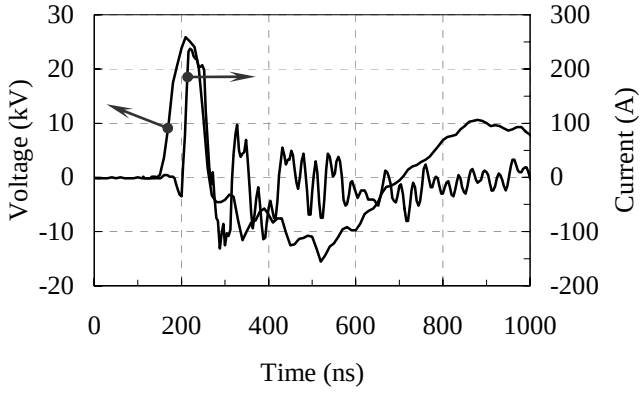

Figure 2: Typical voltage (a) and current (b) pulses

The product gases were analyzed online and quantified using Fourier transform infrared absorption spectrometer (FTIR, Nicolet Magna 550) equipped with a heated 10 m-multiple pass absorption cell. FTIR analysis collected 12 scans for each spectrum at a spectral resolution of about 0.5 cm^{-1}. Absorbencies were converted to concentrations using calibration plots. An electrochemical analyzer (QUINTOX KM 9006) was also used for monitoring continuously SO_2, NO, NO_2, NOx as well as CO levels in the gas stream.

3. Results

In the gas phase under oxygen and water rich conditions, DBD is a very effective means for oxidizing NO to NO_2 and SO_2 to SO_3 [9-12]. Analysis of gas composition at the outlet of the plasma reactor revealed the existence of compounds already reported in the literature. Beside the main products of the plasma such as NO_2, CO, and CO_2, we should highlight the presence of by-products such aldehydes (CH_2O, CH_3CHO), formic acid (CH_2O_2), ethyl and methyl nitrate ($C_2H_5ONO_2$, CH_3ONO_2). Figure 3 shows some species observed in the case of "dry mixture". Small amount of nitrous acid was measured indicating the presence of moisture in the system, possibly arising from the air supply or from moisture adsorbed onto the walls of the gas handling system.

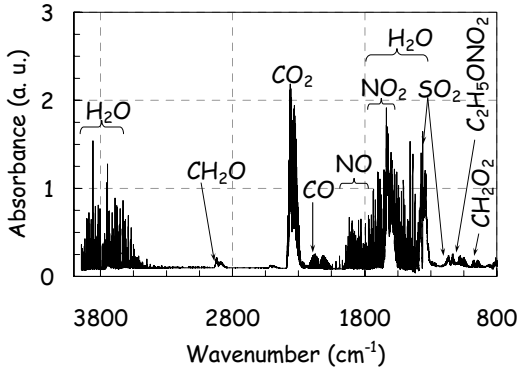

Figure 3: Typical FTIR spectrum: NTP processing of O_2 (8%)-CO_2 (14%)-NO (523 ppm)-NO_2 (49 ppm)-SO_2 (158 ppm)-N_2

The removal efficiency parameter is sometimes used instead of concentrations for the description of decomposition processes. For the molecule X (X could be SO_2, NO, or NOx) this parameter is defined by the following equation where the subscripts denote if the discharge was turned on or turned off.

$$\eta_X\ (\%) = \left(\frac{[X]_{Off} - [X]_{On}}{[X]_{Off}} \right) .100\% \qquad (2)$$

SO_2 removal efficiency η_{SO2} as a function of gas temperature is shown on figure 4 for selected SO_2 inlet concentrations $[SO_2]_{off}$ (158 ppm and 630 ppm) and specific energies E_s (10 J/L and 30 J/L). These measurements show that the highest SO_2 removal efficiency is obtained at temperature above the condensation of water and remain constant in the range 100-500°C. Even at relatively low specific energy (10 J/L), SO_2 removal efficiency higher than 80% was obtained at 163 ppm SO_2 inlet concentration. When SO_2 inlet concentration increase, the SO_2 removal efficiency decrease to a value of about 60% at $[SO_2]_{off}$=680 ppm. Although η_{SO2} is higher at a lower inlet SO_2 concentration, the amount of SO_2 molecules removed from the gas stream is larger for increasing inlet SO_2 concentration (figure 5). Note that the absolute SO_2 removal is a function of specific energy deposited to the gas. In our case, higher total removal can be achieved by operating at higher frequencies (see equation 1). These results could be compared with those using additives such as NH_3 and H_2O_2 in combination with corona discharge. The SO_2 removal efficiency is strongly correlated to energy cost per SO_2 removed molecule (W-value). As example, for the case of gas mixture#1, W-value for SO_2 is dramatically reduced to values scaling from ≈ 45 eV at 30 J/L down to ≈ 15 eV at 10 J/L.

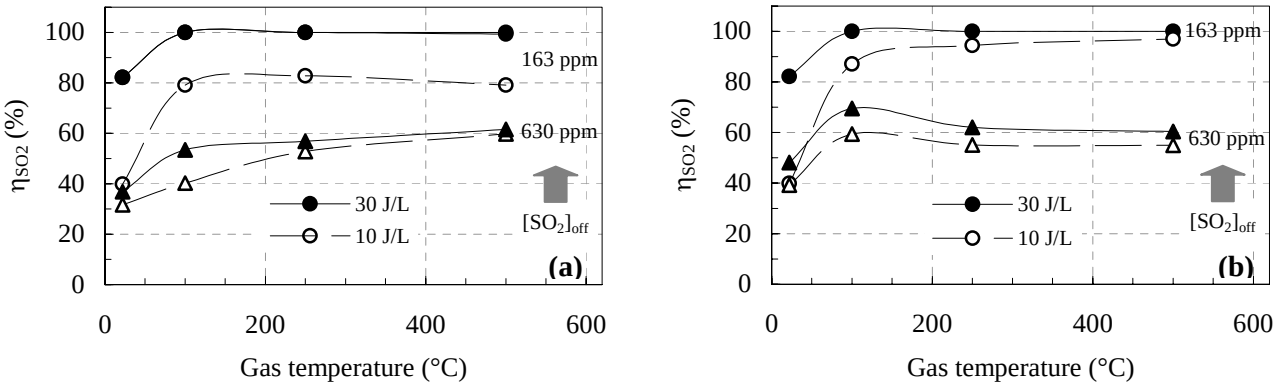

Figure 4: SO_2 removal efficiency as a function of gas temperature and specific energies for two different SO_2 initial concentrations (gas flue rate: a) 3 L.min^{-1}; b) 10 L.min^{-1}).

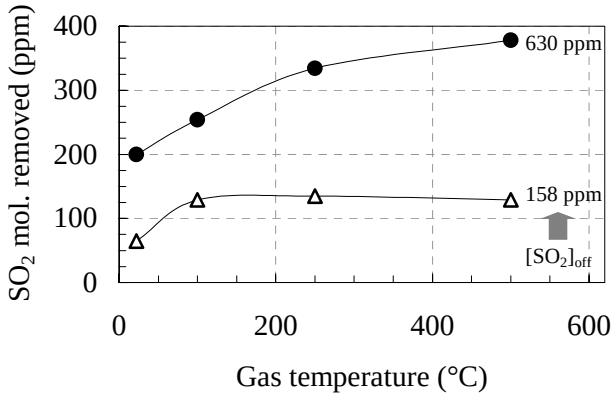

Figure 5: Amount of SO_2 molecules removed as a function of gas temperature for the two gas mixtures at flow rate of 3 L.min^{-1} and specific energy deposition of 10 J/L.

Output NO and NO_2 concentrations as a function of gas temperature for the gas mixture#2 is shown in figure 6. At a given temperature, the NO concentration decreases while that of NO_2 increases with increasing the specific energy deposition. The fraction of NOx (sum of NO and NO_2 concentrations) removed was limited to a

value of 30% in all cases studied in that work. These results could be explained by the NO_2 to NO reduction reactions that counterbalance the NO to NO_2 oxidation processes. One possible way to enhance NOx conversion is the introduction of a small amount of reducing agent (hydrocarbons or ammonia for example) as additives to increase the reactivity of the plasma [2,8,10,12].

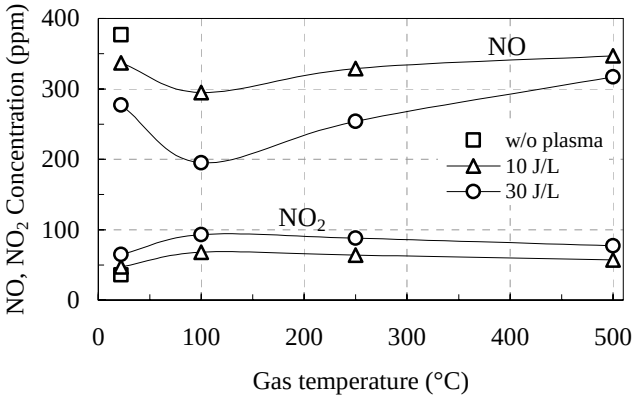

Figure 6: NO and NO_2 concentration as a function of gas temperature for two specific energies (10 and 30 J/L). Gas mixture#2, flow rate=10 $L.min^{-1}$.

4. Conclusion

The dielectric barrier discharge has been proved to be an effective tool to remove SO_2 and NOx pollution from simulated glass manufacturing industry exhaust at atmospheric pressure. Removal efficiencies of SO_2 and NOx are dependant on specific energy and inlet concentration of SO_2. For a specific energy of 30 J/L, simultaneous removal efficiencies for SO_2 and NOx at inlet concentrations of 163 and 570 ppm are as high as 100% and 30%, respectively.

Scaling these results to industrial flow rates (1000 $m^3.h^{-1}$) indicates that energy consumption three times lower than that of conventional technologies (SCR, SNCR, Reburning) can be obtained. In addition to environmental advantage, NTP process using pulsed DBD appears technically simple and economic compared with the other technologies.

Abstract

A new promising technology based on plasma treatment of air-fuel mixtures in the thermal engines could provide new opportunities for obtaining substantial emissions reductions and improving the ignition of combustion. In this work, a first series of experiments using a plasma prototype reactor powered by a 10 kHz high voltage step-up transformer is presented. Results show an H_2 enrichment (4-10%) of inlet gas mixture after plasma treatment.

Keywords: Methane, hydrogen, non-thermal plasma

Introduction

Among the existing pollution sources, motor vehicles are seen as a major contributor to air pollution by nitrogen oxides (NOx), carbon monoxide and dioxide (CO and CO_2), unburned hydrocarbons (UHC), and fine particles matter (PM). Reducing the fuel consumption as well as the harmful exhaust emissions require an improvement of the engine combustion techniques and a better understanding of the physical-chemistry phenomena occurring during of the ignition and combustion phases in the engines.

Plasma reactor can generate electrical discharges in gas flow containing mixtures of air and hydrocarbons with controlled proportions. The plasma energy deposition is associated with the production of reactive species through electron-impact dissociation of gas molecules present in the gas flow. These radicals are the active species of the plasma that eventually lead to the acceleration of the hydrocarbon reformation reactions and, in the final step, a hydrogen rich gas mixture is obtained.

The plasma treatment could also improve the catalytic steam reforming process by decreasing the sensitivity to the type of hydrocarbon, lowering the poisoning risk of catalysts and extending their operating temperature window. The onboard hydrogen production could also improve the combustion starting in lean burn engines. The presence of hydrogen in the combustion chamber is supposed to greatly enhance the propagation velocity of the flame and avoids the ignition failures in lean burn engine. This effect is also beneficial on the NOx emission because dilution reduces the maximum temperature and leads to a low nitrogen oxides production. This approach is particularly attractive for the lean burn gasoline engines and engines running on natural gas because a small level of hydrogen can allow a correct operation.

In this work, first series of experiments using a "sliding discharge" with a prototype specially designed for motor bench tests were presented.

Experimental

The plasma reactor consists of two electrodes between which thread-like plasma develops. The operation mode of this type of reactor is very similar to the sliding discharge device described in previous publications [1-6]. Experimental reactor is shown in figure 1.

Air- CH_4 experiments were carried out with methane concentrations higher than the explosive limit (15%) [7-8] i.e. ranging between 16% and 35%. Mixtures with higher CH_4 concentration had been not studied because of carbon deposition phenomena.

The power supply operating conditions must be flexible in order to allow us a good synchronization between the discharge and the admission of gases in the engine combustion chamber. According to the

engine regime, the plasma treatment duration must be regulated. At a speed of 2000 round per minute, this duration is approximately 15 ms.

The energy deposition into the plasma could be varied by varying either the repetition frequency or the input voltage. In this work, adjustment of the input continuous voltage was selected in order to obtain a progressive variation of the injected energy into the plasma.

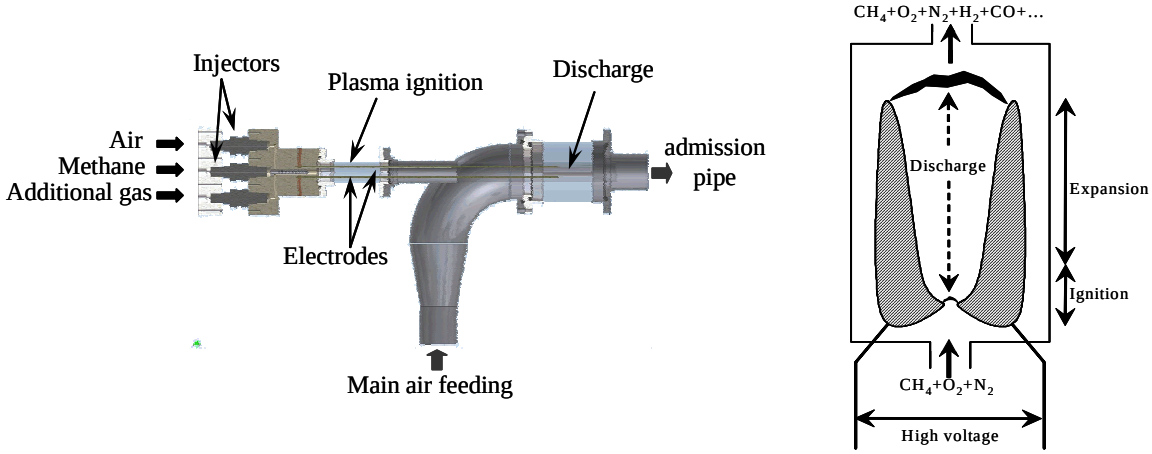

Figure 1: Experimental reactor
a) Motor bench reactor b) Schematic of sliding discharge

The current and voltage waveforms were measured using a Tektronix Hall effect probe TCP202 and a Tektronix high voltage differential probe ST500 connected to a voltage divider with a ratio of 0.01, respectively. The signals from the probes were recorded on a Tektronix digital oscilloscope TDS 460A and processed in a PC.

After plasma processing the exhaust gases were analyzed online and quantified using a Fourier Transform InfraRed absorption spectroscopy – FTIR - (Nicolet Magna 550) equipped with a heated 10 m-multiple pass absorption cell, and a micro Gas Chromatography - µGC - (VARIAN CP 2003P). In that exploring phase, the hydrogen, carbon monoxide, carbon dioxide and water production were mainly presented and discussed.

Results

a) Power variation

Total flow rate corresponding to these experimental conditions is constant (41 L/min, 19% of CH_4, 81% of air). Analysis gas results at the outlet reactor are given on figure 2.

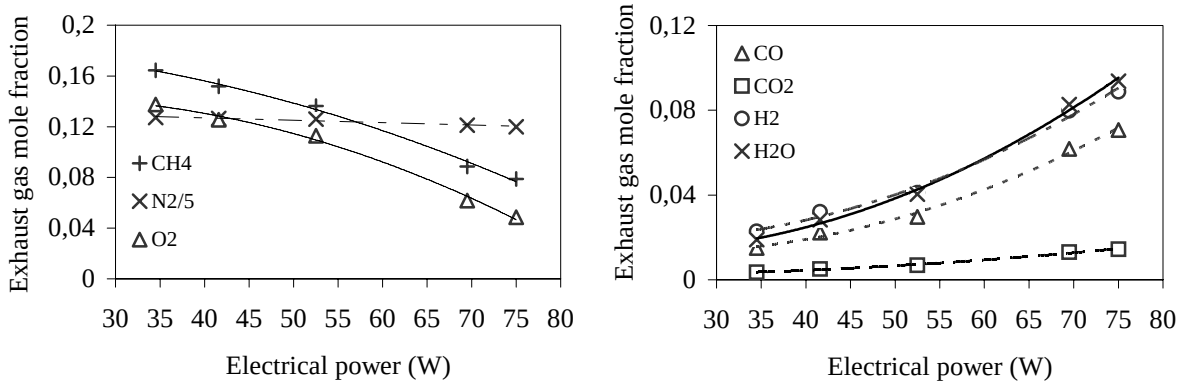

Figure 2: Exhaust gas composition as a function of electrical power (total flow rate=41 L/min)

As it can be seen in figure 2, non linear variation of CH_4 conversion and H_2 production are observed. As the power is increasing the CH_4 conversion and H_2 production are increasing. For the maximum power (75 W), the CH_4 conversion is about 58% and the H_2 production rate is about 9%.

b) Composition variation at constant air flow rate and constant electrical power

Air flow rate corresponding to these experimental conditions is constant (33 L/min). Average power determined from oscilloscope recording is 50 W. As shown on figure 3, the CH_4 consumption is corresponding to the H_2, H_2O, CO and CO_2 production. The CH_4 and O_2 concentrations decrease with the CH_4 inlet. The figure 3 shows that the enrichment of fuel in hydrogen is possible with the use of low electrical power.

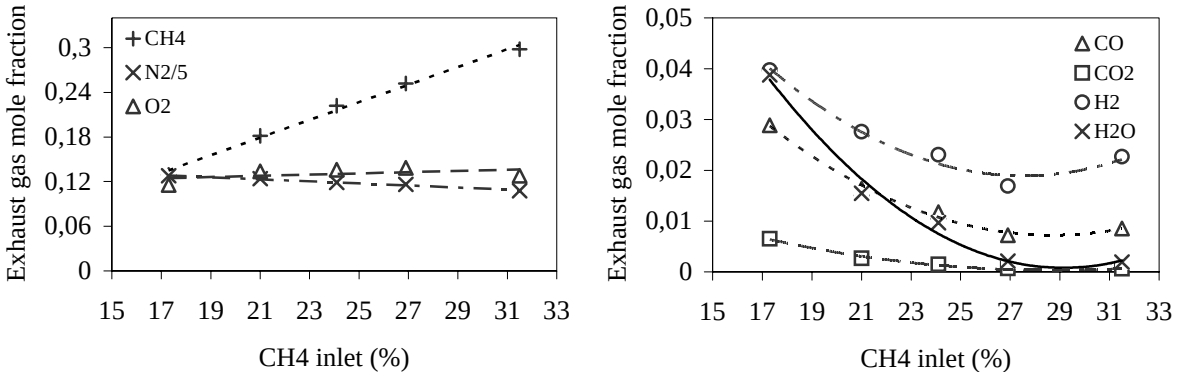

Figure 3: Exhaust gas composition as a function of CH_4 inlet(air flow rate=33 L/min, electrical power=50 W)

c) Outlet reactor temperature

Thermocouples were laid out at the outlet reactor in order to measure the gas temperature after the plasma treatment. The presence of the discharge produces a heating of the system. The energetic supply corresponds to two contributions: the first is the electrical power provided to plasma by Joule effect, the second is the energy provided by the exothermic reactions ignited by the plasma. Figure 4 shows the outlet gas temperature as function of CH_4 initial molar fraction. The outlet gas temperature decreases when the CH_4 initial molar fraction increases. The maximum gas temperature was observed for a CH_4 concentration of 17%, which corresponds to a strong reactivity of the system. This rise in temperature, which increases when one approaches the high explosive limit, is probably related to the starting of the combustion process.

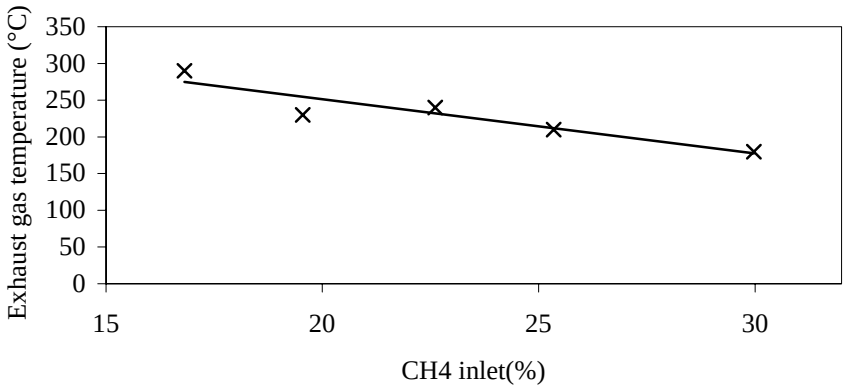

Figure 4: Outlet reactor gas temperature as a function of CH_4 inlet (air flow rate=33 L/min, electrical power=50 W)

d) Calorific value of the outlet mixture (CH_4-H_2)

The net calorific value of a mixture (C_m) is calculated from the relation $C_m = \Sigma(x_i.C)$, where x_i and C are the molar fraction and the net calorific value of each component, respectively.

The net calorific values of H_2 and CH_4 are 2.98 and 9.95 kWh/m^3, respectively. We calculated the net calorific value of the outlet CH_4 - H_2 mixture. Figure 5 shows that this calorific value is a decreasing function of the electrical power provided to plasma. Indeed, as previously announced, the effectiveness of

the conversion of methane into hydrogen is as high as the electrical power provided to plasma is high. For the maximum power (75 W), there is the weakest C_m (6.25 kWh/m^3). This result shows that the H_2 enrichment generates fuel mixtures releasing less energy (C_m value) than methane (C value). Then, it is obvious that the interest of such a treatment improve combustion processes as well as reduction of emitted pollutants.

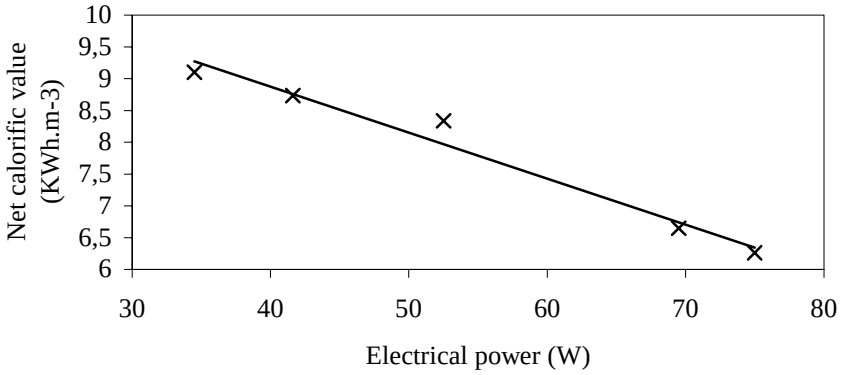

Figure 5: Net calorific value of CH_4-H_2 mixture as a function of electrical power (total flow rate=41 L/min)

The above results confirm the interest of the study for the corresponding application. Improvement of diagnostics for both plasma and chemical mechanisms is underway.

Conclusion

The treatment of methane - air mixture by plasma as well as the chemical analysis of the gas products was carried out. In the present work, only H_2, CO, CO_2 and H_2O were quantified. The molar fraction of hydrogen at exhaust gas is about 9% for an input electrical power of 75 W. We should now check that this quantity is suitable for inducing positive effects on the engine operation. Reduction of the net calorific value shows that the only interest would be to support the ignition of combustion and the emission reduction. Tests on the motor bench are envisaged soon.

Plasma characterizations in a Hollow Cathode System for Thin Film Growth

H. S. Maciel, G. Petraconi, K. G. Grigorov, R. S. Pessoa and G. Murakami

Technological Institute of Aeronautics, Department of Physics – Plasma and Processes Laboratory (LPP), 12228-900, ITA – CTA, São José dos Campos, SP, Brazil.

Abstract

The application of the hollow cathode discharge (HCD) in plasma PVD processing is mainly based on two phenomena: the production of high-density plasma and the generation of hot electrons. In this work the plasma properties generated by a HCD system were studied by means of a Langmuir probe and mass spectrometry. Additionally AlN thin films were grown on silicon substrates at temperature in the range of (25 – 150) ºC and characterized with respect to the crystalline structure and morphology using XRD and AFM analyses respectively. The influences of the deposition parameters on the plasma properties were studied and the film properties were discussed.

1. Introduction

High-density plasma typical for the hollow cathodes discharges is based on efficient avalanche multiplication of electrons known as hollow cathode effect (HCE) [1]. The hollow cathode effect is a special situation for the glow discharge between two closely separated cathode surfaces. This effect occurs when the length of the cathode fall region becomes as large as the separation distance between the two cathodes. The loss of electrons is low because the negative walls of the cathode repel them and they oscillate between the cathodes. Thus, at the same power the hollow cathode exhibits a plasma density of one to two orders of magnitude higher than that of conventional planar electrodes. Hollow cathode discharges also have an important characteristic that combines two important processes, i.e. sputtering and excitation/ionization of the sputtered atoms [2, 3].

The optimization of the HCD system for application in plasma processing device extends the studies of ref. [3] and constitutes the main objective of this work. I order to implement the plasma-assisted deposition processes a thorough and detailed characterization of the plasma parameters was required. Besides the conventional Langmuir probe technique, plasma spectrometry is reliable and widely used technique.

2. Experimental set up

The deposition HCD system was allocated (shown in Fig. 1) in a cylindrical vacuum glass chamber of 130 mm internal diameter and 300 mm length. The chamber was preliminary evacuated using a combination of rotary and diffusion pumps to achieve a residual pressure of 10^{-2} Pa. The hollow cathode cavity consists of two parallel aluminum plates having as wording gas a mixture of argon and nitrogen within the pressure range of (10 – 50) Pa. The discharge was generated by a dc power supply of (0 – 1000) V and its electrical characteristics showed a dependence on the inter-cathode distance which was varied in range (3.5 – 1.5) cm. A Helmholtz coil was used to produce a low intensity and uniform B-field within the range of (0 – 30) × 10^{-3} T. The magnetic confinement increases the power density along the axis of the discharge.

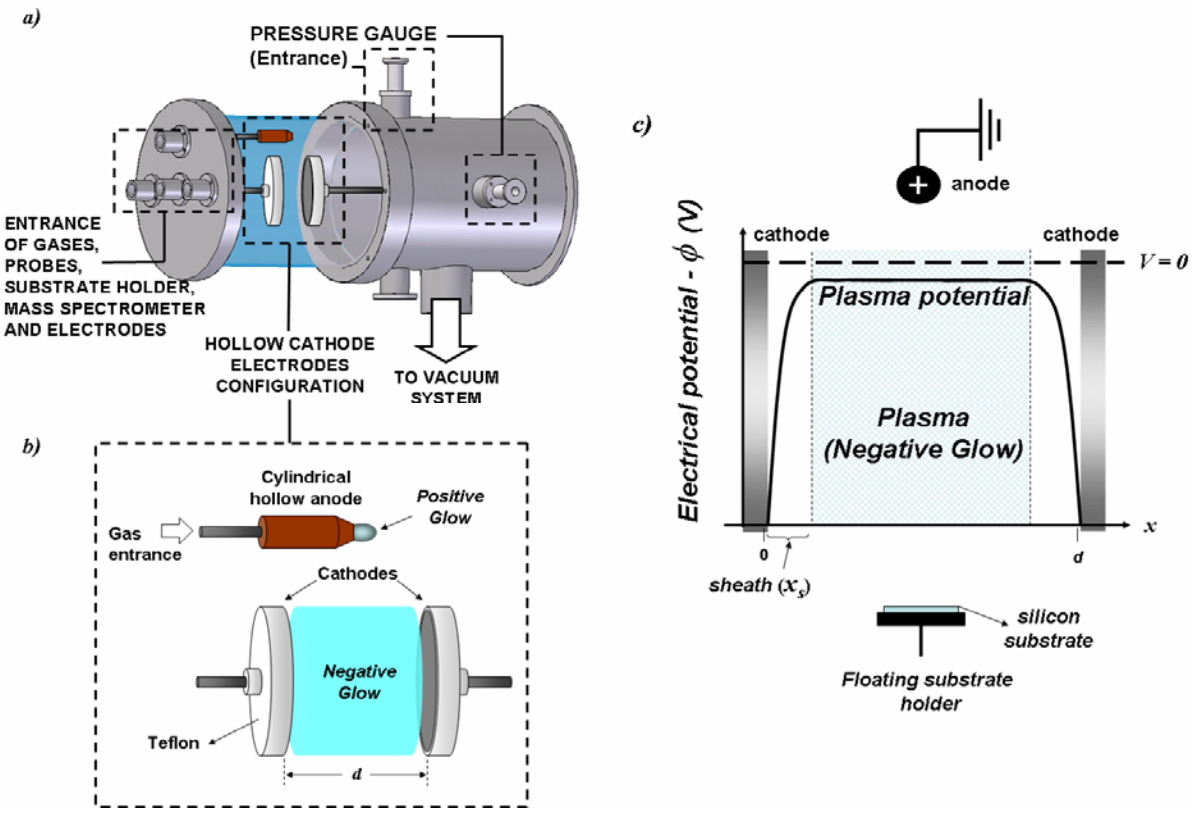

Figure 1. Schema of the HCD reactor - (a), HC source - (b) and deposition configuration - (c).

The Plasma diagnostic was carried out by Langmuir probes and mass spectrometry techniques. The Langmuir probe consists of a tungsten cylindrical electrode with area of 2-mm^2. The probe can be inserted into the vacuum chamber via accesses at frontal of the chamber. The hollow cathode electrodes can be moved axially along a traveling length of 150 mm. This layout enabled to place the probes at any distance from the HC source, so as to study different plasma regions. The measurements were performed at the same probe position and in different external discharge conditions.

A mass spectrometer AccuQuad^{TM} with a resolution of 1 amu was adapted to the vacuum chamber trough a drifting tube for monitoring the mass spectra for different discharge process parameters. The species were sampled through a micro orifice located at the mass spectrometer's entrance. The typical operation pressure within the mass spectrometer was 10^{-5} Pa. The collected spectra were recorded in the mass range from 1 to 100 amu.

The type of crystalline structure, orientation and grain size was investigated by Philips 1830 diffractometer in θ - 2θ scan mode. Moreover, the morphology of the surface and its roughness were studied using an Atom Force Microscope (AFM) SPM-9500 J3.

3. Results and discussion

3.1. Analysis of plasma parameters of the HC discharge

a) Langmuir Probe

Typical results of the HC plasma probe I-V measurements are given in Fig. 3-a showing a family of I-V plots designed for different products $P.d$, P and d being the pressure and inter-cathode distance respectively. As

one can see, the plots differ mostly in the electron saturation currents (I_{e0}), plasma potential (V_p) and floating potential (V_f).

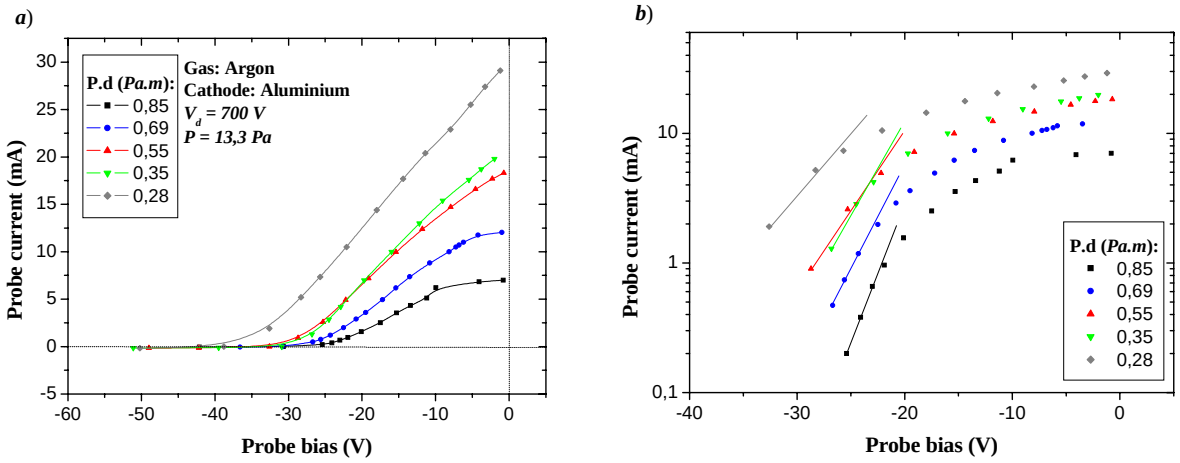

Figure 2. Probe current versus the probe bias for argon buffer gas (a); Probe Current (Ln) versus probe bias (b).

The plasma parameters (n_i, T_e, V_p, V_f, λ_D) are derived from the measured *I-V* characteristic assuming a Maxwellian distribution of electrons [7]. Special interest draws the region with probe voltages between the floating potential (the potential when $I_e = I_i$) and the plasma potential, $V_f < V < V_p$. The slope of the straight lines in this region (Figure 2-b) is related to the value of the electron temperature Te [3]. The values of the electron density n_e and the Debye length λ_D (1) has been calculated by using the conventional probe theory previously described in [4].

$$\lambda_D = 7400\left(\frac{T_e}{n_e}\right)^{1/2} mm \tag{1}$$

The plasma in this system is a type of "cold plasma" ($T_i << T_e$) and, therefore the differences between the plasma and the floating potentials are proportional to the electron temperature [4]. For a typical argon (M = 40) and nitrogen (M = 28) plasma, the proportionality factor is 5.40 and 5.19 respectively.

$$V_P - V_f = \frac{kT_e}{2e}\ln\left(\frac{2m_i}{\pi m_e}\right) = 5.4\frac{kT_e}{e} \text{ (Argon)} \tag{2}$$

These parameters are quite good in order to estimate the electric field E_s in the region of the plasma sheath around of an inserted sample in the volume of the plasma. Thus, through the values obtained by Eq. 1 and Eq. 2, we can evaluate the electric field in the plasma region assuming that no collisions occur within the probe sheath,

$$E_s = \frac{V_p - V_f}{n\lambda_D} \tag{4}$$

Hutchinson [4] got a relation between the thickness of the probe sheath (x_s) and the Debye length. For argon x_s = 4.97 λ_D and nitrogen x_s = 4.84 λ_D. All these parameters are calculated and listed in Table 1 for Ar and N_2 gases used in this work.

Table 1. The measured Ar and N_2 plasma parameters for operating conditions - V_d = 700V, P = 13.3 Pa, d = 2.5 cm.

Gas	n_p (10^{17} m^{-3})	T_e (eV)	V_p - V_f (V)	λ_D (μm)	x_s (mm)	E_s (kV/m)
Argon	1.4	4.5	25.9	34.0	0.17	152.3
Nitrogen	3.5	4.8	24.9	27.0	0.13	191.2

Figure 3 illustrates the electron density and the electron temperature as a function of the *P.d* parameter when different gases are used. To maintain plasma in reactive gas discharge higher currents are required than in cases of inert gases, as the argon. As observed, higher current densities (of the order of 10^{17} m^{-3}) and temperatures of electrons (between 1 and 4.5 eV) can be reached when reactive gases are used, i.e. the hollow cathode effect becomes more pronounced.

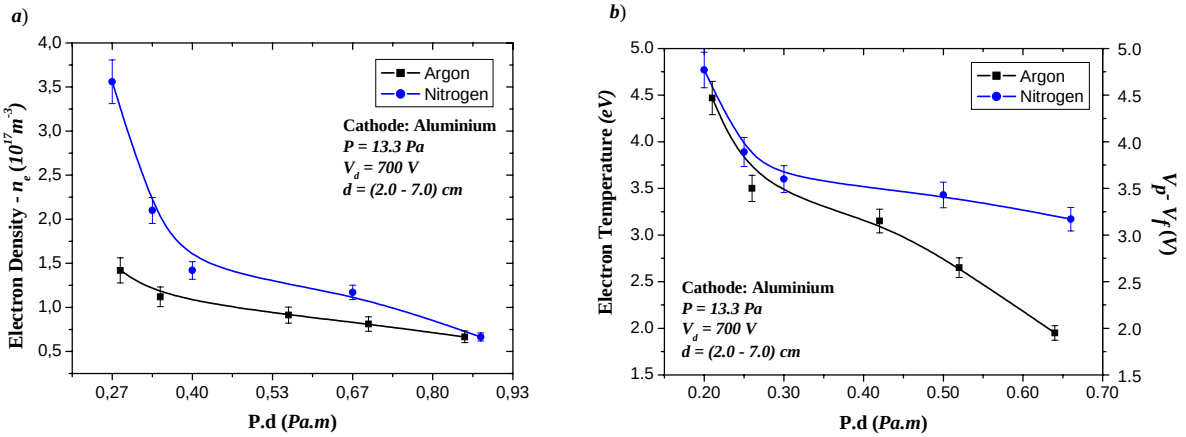

Figure 3. Electron density n_e versus the *P.d* product for Ar and N_2 gases (a); Electron temperature T_e and the probe potential sheath fall V_p - V_f versus the *P.d* product in the same experimental conditions (b). The discharge voltage is 700 V.

The application of perpendicular magnetic field to the cathode surface facilitates the ignition of the discharge and improves the HCE – increase the time of residence of electrons in the inter-cathode cavity and reduce the lateral diffusion. As a consequence the discharge current and the electron density are increased [3].

Interesting effect concerning the electron temperature when a magnetic field is applied was observed and displaced in Figure 4. In this figure, we also evaluate the variation of the potential fall in the sheath of the probe as function of *P.d*. It is known that the application of a magnetic field onto a glow discharge has equivalent effect to an increase of the pressure of the gas, leading to a reduction of the effective electron temperature. This effect is stronger at lower range of *P.d* as observed in Fig 4.

b) Mass Spectrometry

Due to the ion bombardment and the enhanced cathode temperature, the hollow cathode target can be sputtered and/or evaporated and it contributes to film growth when the source is used for film deposition. Through mass spectrometry technique some species in the plasma gas phase could be monitored for various operational conditions of the discharge. In Figure 5 the relative partial pressure (%) for AlN^+ and Al^+ peaks was plotted as function of the inter-cathode distance, for two pressure values. For discharges processes when the operation pressure is lower (left part of the curve) the curve indicates that the generation of molecules of aluminum nitrite reaches a maximum for *P.d* = 0,7 Pa.m. This tendency vanishes at higher-pressure values (right part of the curve).

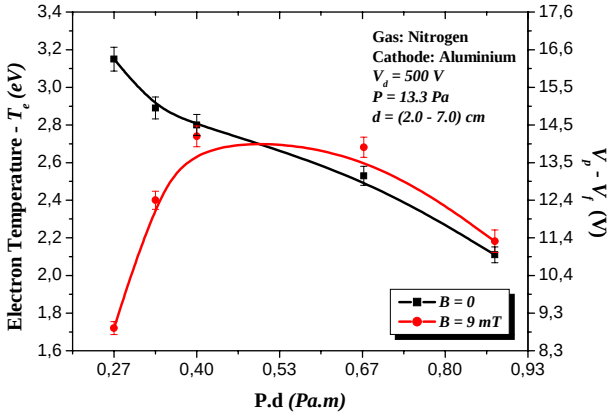

Figure 4. Electron temperature T_e and probe potential sheath fall V_p - V_f versus product $P.d$ for HCD in N_2 gas for two values of magnetic field.

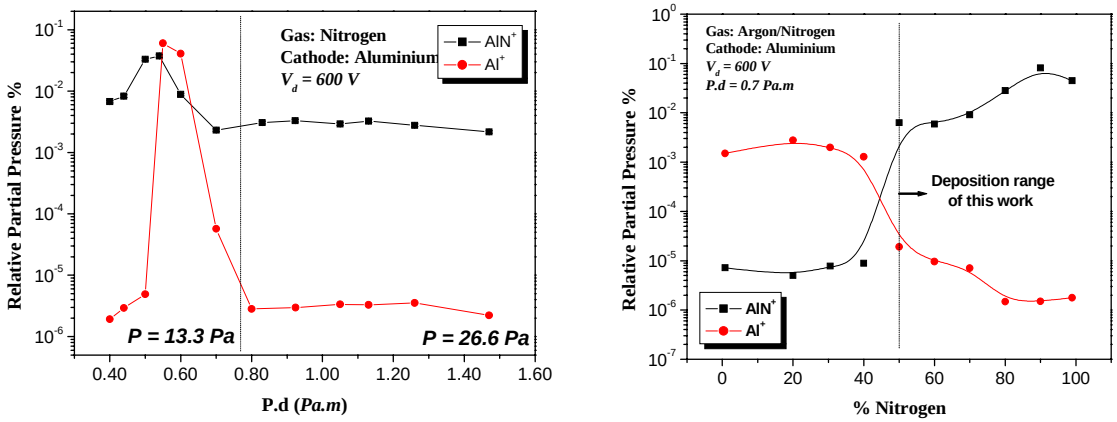

Figure 5. Variation of the aluminum (27 amu) and AlN^+ (41 amu) peaks for HCD in nitrogen gas for two pressure values - 13,3 and 26,6 Pa (a); Variation of the AlN and Al atom signals as a function of the percentage of nitrogen in the Ar gas mixture (b).

Fig 5-b shows one to one dependence describing the dynamic of the AlN formation as a function of the nitrogen gas content in the discharge. The growing rate depends on the nitrogen percentage. If nitrogen gas exceeds 40 % in the Ar-N_2 mixture the reactive film growth can reach and exceed the growth rate of pure metal (Al) film.

3.2. AlN-film analysis

Figure 6-a shows a typical AlN spectrum with very strong reflections at 32.88^o corresponding to AlN (100) crystalline orientations referring to the hexagonal type wurtzit. This sharp and intense peak is common for the highly textured phases similar to a single crystal. Besides the crystallographic orientation, another important parameter calculated is the coherent domain of reflection (CDR), which, in general, describes the dimensions of one crystal or grain containing micro crystals with identical spatial orientation of the axis a, b and c. The CDR was calculated using the Debye-Scherrer formula revealing a 100 nm sized domains grown in columnar way consisting of crystals oriented with his axe “c” parallel to the silicon surface. The topography of the crystals is

shown on Fig 6-b, which reveals smooth and densely packed surface. The mean grain radius is 20 nm with rms roughness of 2.5 nm.

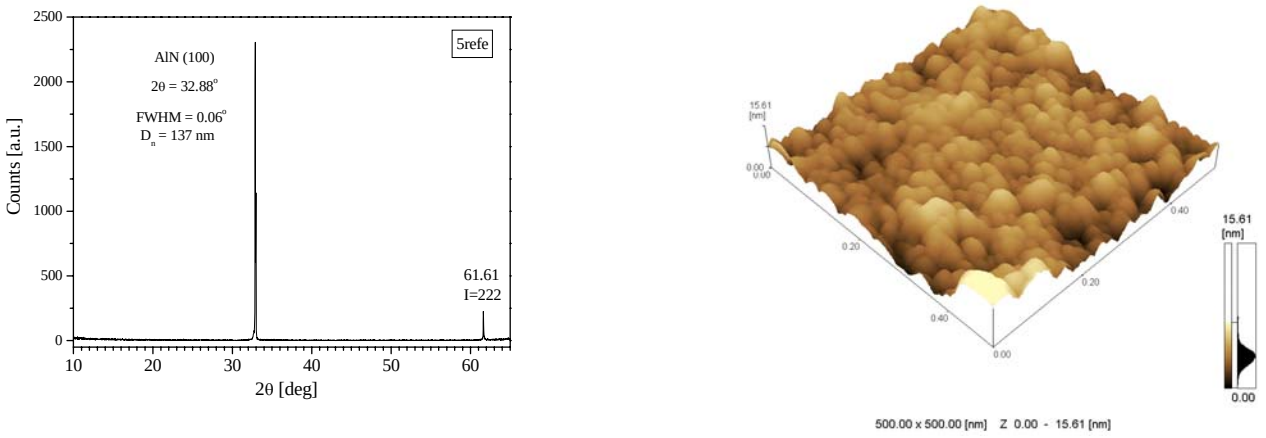

Fig. 6. X-ray diffraction pattern of sample deposited in 50% N_2 atmosphere at P = 13.3 Pa and V_d = 600 V (a); AFM scan in dynamic mode of AlN sample deposited for 15 minutes (b).

4. Conclusions

The plasma density and the electron temperature were measured in a HCD system by using a single Langmuir probe placed inside the plasma bulk and reaches the order of (10^{16} – 10^{17}) m^{-3} and (1 – 4) eV respectively at dc discharge voltage of 600 V. Detailed analysis of the plasma properties using probe techniques and mass spectrometry, at different nitrogen gas flows, could guide the establishment of favorable geometric and gas-pressure conditions for enhanced plasma parameters aimed at plasma material processing. The obtained optimal conditions allow growing of high quality AlN thin films with sufficient deposition rate assuring thus an alternative method for synthesis of this material.

Study of plasma-solid interaction in electronegative gases by the combination of particle simulation technique and evolutionary modelling

J. Šimek, R. Hrach, D. Sedlák, P. Jelínek

Charles University, Faculty of Mathematics and Physics, Department of Electronics and Vacuum Physics
Prague, Czech Republic

Abstract
Self-consistent particle models of plasma are precise, but the performance of standard algorithms is rather low. Another particle simulation technique of plasma-solid interaction is a non self-consistent one, where the distribution of electric potential near the substrate is given analytically. But the accuracy of these simulations is in general low as it depends on simplified assumptions about electric field used. The evolutionary modelling was used to combine good features of these two techniques.

1. Introduction

The understanding of processes in the boundary layer between plasma and immersed metal substrates is important both in probe diagnostics and in plasma-chemical technologies. However, the interpretation of experimental data is often difficult as the substrates or probes perturb their local surroundings. The application of Langmuir probe diagnostics of such plasma is limited, because the original theory was developed for the collisionless plasma only. The situation is more urgent in the case of electronegative plasma, as the presence of negative ions complicates not only the theoretical interpretation of experimental data but also the physical and chemical processes in plasma (see Fig. 1)

.

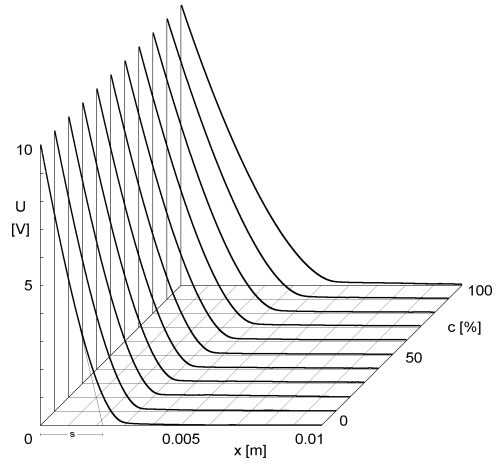

Fig. 1: Distribution of electric potential near the substrate for various concentrations of negative ions in plasma [1].

For the analysis of plasma-solid interaction besides standard experimental and theoretical methods of study, the technique of computer simulation proved to be very successful approach. The computer simulation technique seems to be very promising tool to analyse the cases where the theoretical description cannot be used – substrates of complicated forms, higher pressures, plasma consisting of more types of particles including negative ions, chemically active plasmas, plasma in magnetic field, etc. There are two basic techniques of the plasma sheath simulation – fluid modelling and particle simulation techniques. Fluid models are much more efficient, however their accuracy is very limited. The self-consistent particle models of collisional plasma can bring precise results but the performance of standard algorithms is rather low – in Fig. 2 there are shown time requirements of main parts of the self-consistent models of various spatial dimensions. Time demands of the

molecular dynamic part strongly increase with number of particles in the model. Also the solution of Poisson equation is very time consuming, being the crucial part for 3D model, where more sophisticated algorithms must be used. Sometimes an older particle simulation technique is used, when the distribution of electric potential near the substrate is given analytically by solving the diffusion equation for some simplified situations. In this case the number of charged particles in the model can be reduced and the performance of resulting code increased, however the accuracy of derived results is again low as it depends on the simplified assumptions about the local electric field used. In our contribution, we tried to combine good features of two particle simulation techniques, self-consistent and non self-consistent, in order to increase both the accuracy of simulation and the performance of resulting codes. For this purpose the evolutionary modelling technique was used, which is able among others to generalize various experimentally derived dependencies.

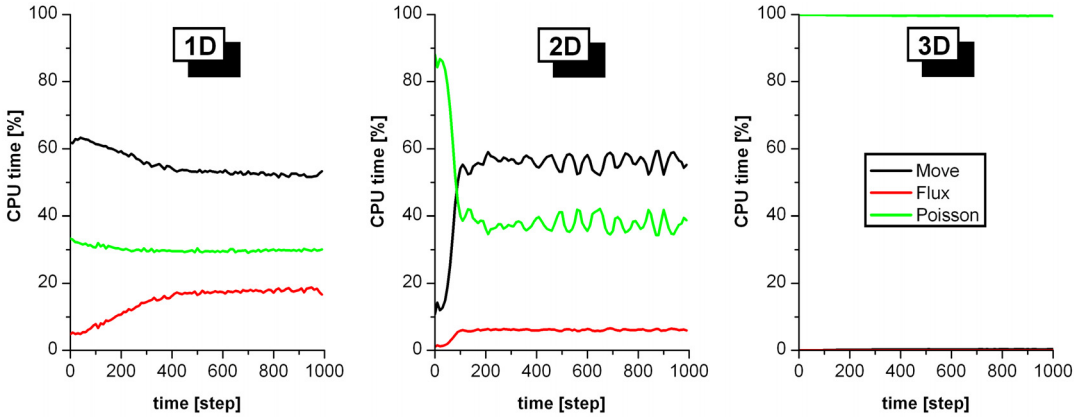

Fig. 2: Evolutions of time requirements for self-consistent models of different spatial dimensions. Main parts of the models are: source of particles (*Flux*), executing molecular dynamic part together with treatment of collisions (*Move*) and force calculations (*Poisson*). Real duration of 1 time step: 1D .. 0.2s, 2D .. 0.4s, 3D .. 250s (P4 3.2GHz).

2. Self-consistent models

The main task of our study is to analyse processes taking place during the interaction of plasma containing negative ions with immersed metal substrates. For this purpose the computer experiment analysing the multicomponent plasma containing electrons, positive ions, negative ions and neutral particles was prepared and the most precise technique of simulation was used – the self-consistent particle simulation approach.

The primary task is the study of sheath evolution and the determination of trajectories of charged particles both in the sheath and presheath. The typical particle model of plasma-solid interaction consists of following parts [2]:

- Source of particles – undisturbed plasma consisting of argon atoms, oxygen molecules, electrons, positive argon ions and negative molecular oxygen ions.
- Interactions – neutral particles are treated as neutral background with which the charged particles interact. For electrons elastic collisions, excitations and ionisations of neutral particles, possibly dissociative attachments with oxygen molecules are considered [3]. For ions elastic collisions, charge transfers and possibly detachments for negative oxygen ions are taken into account.
- Trajectories of charged particles – between scattering events the trajectories in both external and local electric fields are simulated using molecular dynamics method (leap-frog scheme).
- The scattering events are simulated using Monte Carlo method. Due to energy dependence of cross sections of interactions under consideration, the null-collision technique must be used.

- Force calculations – standard PIC technique is used in CIC modification, i.e. the forces are obtained from electric potential calculated from Poisson equation.

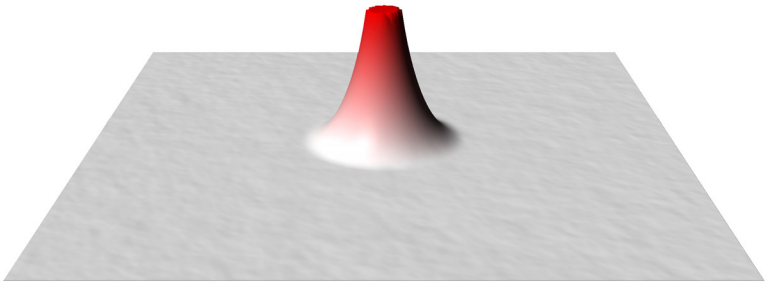

Fig. 3: Distribution of electric potential near the cylindrical probe

The cylindrical substrate was chosen, as it corresponds to the most common form of Langmuir probes. The dimensionality of prepared models was either 1D or 2D, i.e. one or two spatial coordinates and three velocity coordinates were used.

The results of self-consistent modelling of the sheath and presheath (see Figs. 1 and 3) can be used for the determination of the distribution of electric field U in the vicinity of substrates. For the determination of the distribution U various techniques can be used:

- Simple tabulating of results of self-consistent simulation.
- Approximation of derived data by simplified formulae by numerical methods.
- Preparation of analytical formulae by the evolutionary modelling technique,

the last method being the most sophisticated and increasing the performance of resulting codes. The self-consistent approach, especially in higher dimensions, is extremely time-consuming; therefore the reduction of demands on computer time is very desirable.

3. Evolutionary modelling

Evolutionary modelling is a computational method inspired by evolution. It is an optimisation technique that is able to generate functions on the basis of the principles of evolution genetic operators – selection, fitness evaluation, mutation and crossover. These functions are encoded in tables, which represent the compressed neighbourhood-matrix of the canonical acyclic graphs. An implementation of evolutionary modelling begins with a population of tables (typically randomly generated). Fitness value expressing quality of approximation is assigned to each table in the main loop of evolutionary modelling. Then selection operator is applied on evaluated population – tables that represent a better approximation (better fitness) have more chances to be "reproduced" than tables that have poorer quality. Crossover and mutation operators are applied on the new population. This is repeatedly performed until some stop-condition is fulfilled. The main problem in evolutionary modelling is finding efficient encoding and choosing sufficient crossover probability and mutation probability.

4. New generation of non self-consistent models

Standard non self-consistent models use very simplified formulae for the electric field distribution near the substrate so their results are not in most cases trustworthy enough. Our new approach consists of several steps. First, we developed self-consistent model corresponding to studied problem. Then we prepared large set of self-consistent results obtained for various combinations of discharge parameters and plasma compositions. This is the most time-consuming part, however, firstly, the calculation was performed for a limited number of

configurations only, secondly, the older results can be used and, thirdly, for some problems the self-consistent simulation can be performed in lower-dimensions. These data were then processed by program based on evolutionary modelling technique. With the help of genetic algorithms we are able to derive a set of formulae for the electric field distribution in the sheath region of plasma, i.e. generalization of potential distribution for various parameters.

After exact analytical formulae are derived, the much more effective non self-consistent approach can be used for similar conditions of simulation. As a result we can work with efficient computer technique, while the preciseness of results corresponds to original self-consistent calculations, i.e. is radically increased compared to old non self-consistent calculations. The numerical comparison of derived results shows that the increase in the computational speed is about 3 orders of magnitude for one- and two-dimensional simulations and at least 6 orders of magnitude for three-dimensional modelling, the exact values depend on the plasma parameters in the model.

5. Results

As an application of suggested approach one problem from the plasma physics is studied – the probe diagnostics in medium pressures. It is well known that the biased probe is surrounded by a local electric field attracting the charged plasma particles of one sign and repulsing the oppositely charged particles – see Fig. 4 for cylindrical configuration. However, the ability of probe to collect electric current depends not only on its geometry and bias, but also on the scattering of electrons and ions in the sheath and presheath. The theoretical interpretation of experimental results is based on the collisionless Langmuir theory and the collisions are included additionally by various approximations, the main question being if the scattering of charged particles in the sheath increases or decreases the probe current. With the help of these corrections the theory can be extended to slightly collisional plasma (Fig. 5), however it cannot be used in modern applications of high-pressure plasmas.

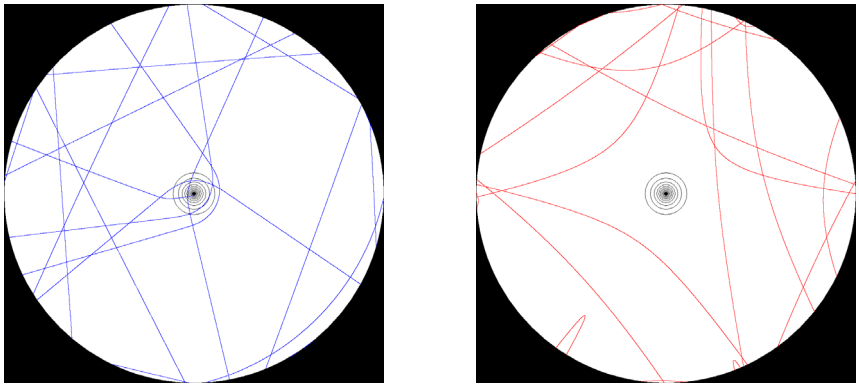

Fig. 4: Collisionless argon plasma, voltage bias +10 volts. Left – electrons, right – positive Ar ions.

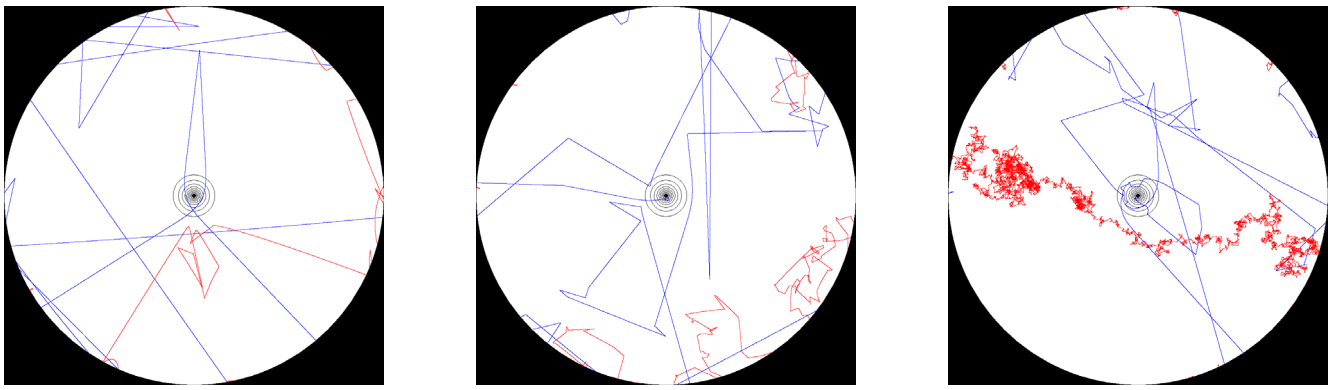

Fig. 5: Collisional argon plasma, voltage bias +10 volts, different pressures: left – 1.33 Pa, centre – 13.3 Pa, right – 133 Pa.

Examples of trajectories of individual charged particles in the vicinity of cylindrical biased probe are shown in Figs. 4 and 5. The changing character of the transport at higher pressures can be seen, especially for ions. Also the time demands are growing as the mean free paths decrease with increasing pressure and scattering events become more important.

6. Conclusions

If we summarise advantages and disadvantages of suggested approach, we can state that the standard non self-consistent models use very simplified formulae for the electric potential distribution, so their results are not precise enough. With the help of evolutionary modelling it is possible to obtain results with accuracy of self-consistent models but also with much less demands on computational time.

Morphological study of metal/dielectric composite films prepared by plasma chemical technologies

J. Šimek, R. Hrach

Charles University, Faculty of Mathematics and Physics, Department of Electronics and Vacuum Physics, Prague, Czech Republic

Abstract
Composite films of the structure metal/dielectric prepared by plasma chemical technologies far bellow the percolation threshold typically consist of metal objects with excellent uniformity. When characterising the structural properties of composite films the information about the forms of individual metal objects and about their distribution in dielectric matrix must be derived. The present contribution is devoted to the second task, both the well-known and new methods of mathematical morphology being used.

1. Introduction

The composite films represent class of promising materials [1]. Especially composite metal/dielectric films consisting of metal particles embedded into an oxide or polymer matrix have received more and more attention in last few years due to their interesting optical, mechanical and electrical properties.

Composite material can be obtained by embedding metal particles (Ag, Au, etc.) into a matrix of dielectric film (Al_2O_3, SiO_2, carbon, etc.). There exist several techniques for the preparation of composite films. One possibility is the thermal evaporation of the complete structure metal/oxide – the metal is evaporated from one source and the oxide film is deposited simultaneously from another one (e.g. [2]). Similar to that, in [3] composite films were obtained by the ion-beam sputter deposition technique. However, the most important technology is the plasma deposition technique. There are different ways to prepare metal containing plasma polymer films, such as simultaneous plasma etching and plasma polymerisation, plasma polymerisation of organometallic compounds, or simultaneous plasma polymerisation and metal evaporation. A great variety of these composite films can be achieved by using different polymers and metals [4]. The most popular are various fluoropolymers and films prepared by polymerisation of hydrocarbons. Even semiconductors have been embedded into a polymer matrix.

Depending on the concentration of metal atoms in the composite film there are three possible types of the metal containing dielectric structures: for small metal volume fraction the films consist of metal particles completely insulated from each other embedded in a polymer matrix, with increasing concentration of metal atoms the metal-dielectric transition is observed and metal objects form a percolation structure, and for high concentration of metal the composite films are created by metal layers with polymer inclusions. The main interest in the literature is given either to composite films with small amount of metal or to the films near the percolation transition, when the charge transport is studied. As there exists close connection between morphology of composite films and their physical properties (optical, electrical, etc.), the morphological analysis of composite thin films is very important.

2. Morphological analysis of composite structures

The goal of the morphological analysis of composite films is to characterise:

- the forms of individual metal objects in the film,
- the three-dimensional spatial distribution of objects.

TEM investigations reveal that bellow the percolation threshold the composite films prepared by plasma chemical methods consist of small nanometer-sized metal particles with excellent uniformity embedded in an amorphous dielectric matrix. In this case the analysis of size distribution of objects is based on the integral transform method [5] and the unfolding problem results in the determination of the distribution function of

objects' radii. With increasing metal concentration the forms of metal clusters become more complicated and the methods for their analysis are complicated too.

The second, more important task is to derive the spatial (three-dimensional) distribution of metal objects in the composite films on the basis of two-dimensional information. If the film is thin enough, it is possible to derive information about bulk composition and structure of composite films either from their planar sections or from their projections (see Fig. 1), while for the thicker layers the micrographs of the sections can be used only. There exist numerous methods designed for the study of metal films in two dimensions – i.e. for the morphological analysis of discontinuous or semicontinuous metal films created on dielectric substrates (e.g. [6] - [8]), however the methods well suited for the analysis of three-dimensional composite films must be yet created. Theoretical approach to the unfolding problem of composite films often leads to the nearly invincible difficulties; therefore a computer experiment would be more suited for that purpose.

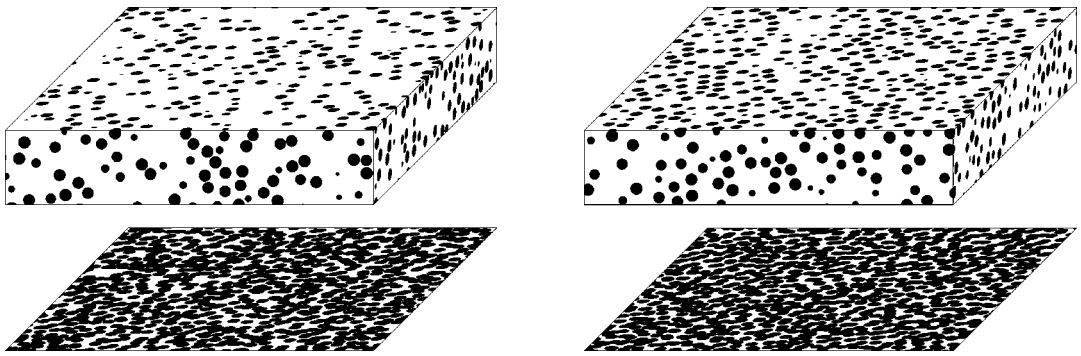

Fig. 1: Schematic view of two composite films with small volume metal fraction and various films parameters together with main sources of morphological information – planar sections and projections of the films.

In two dimensions the well-known methods based on the mathematical morphology [6] are commonly used. While direct application of these methods in three-dimensions is possible and leads often to interesting results (see e.g. [9] - [12]), the exact interpretation of derived results is not clear enough and detailed analysis is required. The main problem is that the available two-dimensional information is not sufficient for the complete reconstruction of three-dimensional distribution of objects and the results have probabilistic character only.

In our recent publication [13] we analysed several morphological algorithms intended for the spatial analysis of two-dimensional discontinuous metal films, tested their sensitivity for the determination of various physical parameters of island structures and suggested new one-number features. In the present contribution we extended this analysis upon morphological methods applicable to composite metal/dielectric films at low and medium volume metal fraction, when the composite layers consist of individual objects.

3. Model

For testing methods convenient for partial reconstruction of three-dimensional information from two-dimensional images a simple computer experiment was prepared. Our model of composite film with a small metal volume fraction, i.e. with so-called filling factor *ff*, is based on a hard-sphere technique. In a three-dimensional working region (typical dimensions are from 1000×1000×100 pixels to 5000×5000×500 pixels, pixel being the length unit in our model and the *z*-axis is oriented perpendicular to working region) metal objects are generated. The spherical form of objects is assumed in accordance with experiments. The object's diameters are either constant or have the Gaussian distribution of magnitudes.

The objects are generated randomly not touching each other. The minimum distance between edges of objects is a model parameter called diffusion zone ΔZ. For given number of objects and for given objects' radii there exists

a limit ΔZ_{max}. With the help of the model parameter $\Delta Z \in \langle 0, \Delta Z_{max} \rangle$ it is possible to influence the randomness of spatial distribution of objects in composite structure.

Simulated images used for the image analysis of composite films can be prepared either as a random sections parallel to the (x,y) plane or as projections of the whole working region. Examples of such images can be seen in Fig. 1 – left for $\Delta Z = 0$ and right for $\Delta Z = \Delta Z_{max}$.

There exist more sophisticated models based on various modifications of both hard-sphere and soft-sphere techniques, e.g. [12], however for our purpose of the algorithms testing the basic hard-sphere model is sufficient.

4. Results

For the purpose of analysis of various morphological methods a large set of simulated composite structures was prepared with different combinations of model parameters. Examples of parts of images derived from the simulated structures are demonstrated in detail in Figs. 2 and 3 (maximally random structures) and 4 (fully arranged structures).

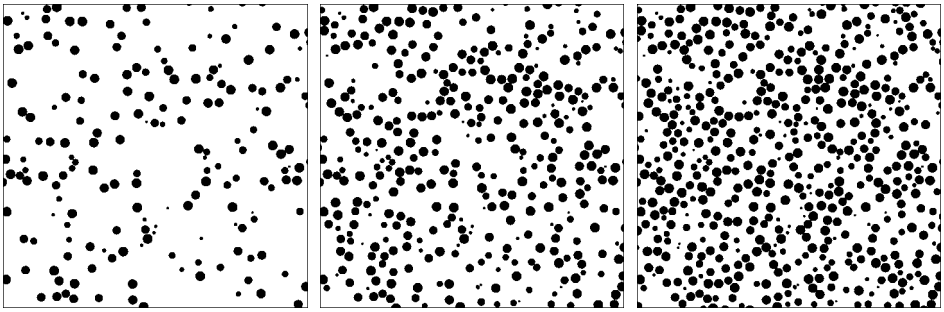

Fig. 2: Sections of composite structures generated with diffusion zone $\Delta Z = 0$ and filling factors *ff* equal to 0.1 (left), 0.2 (middle) and 0.3 (right).

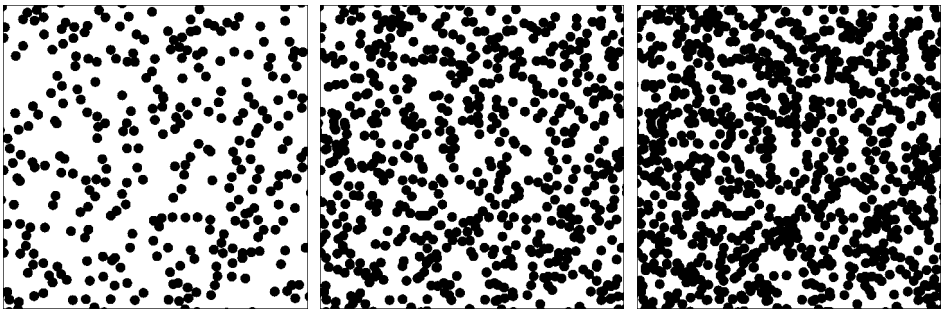

Fig. 3: Projections of composite structures generated with $\Delta Z = 0$ and *ff* = 0.1 for different film thicknesses – 100 (left), 200 (middle) and 300 (right).

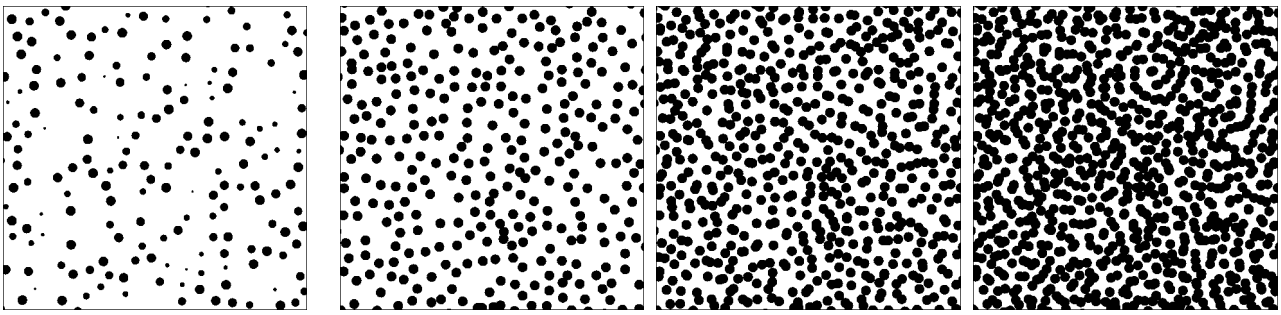

Fig. 4: Images of a composite structure generated with $\Delta Z = \Delta Z_{max}$ and $ff = 0.1$. Left: section, other images: projections for different film thicknesses – 100, 200 and 300 (right).

Morphological analysis of derived images was performed by a complete set of morphological algorithms: radial distribution function, distribution of nearest neighbours, contact distribution function, covariance, chord-length distribution, quadrat counts method and Voronoi tessellation. Some examples of obtained morphological characteristics can be seen in Figs. 5 and 6. These characteristics were obtained again for maximally random and maximally arranged structures.

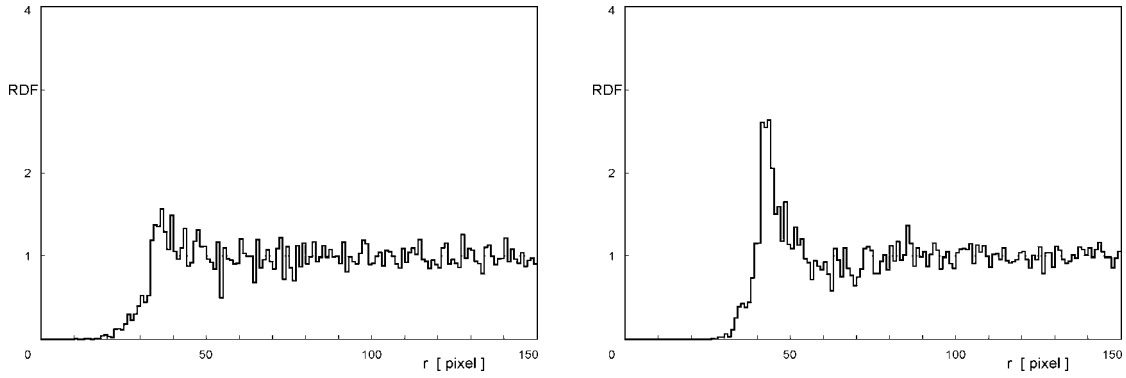

Fig. 5: Radial distribution function of images of sections of composite structures generated with diffusion zone $\Delta Z = 0$ (left) and ΔZ_{max} (right).

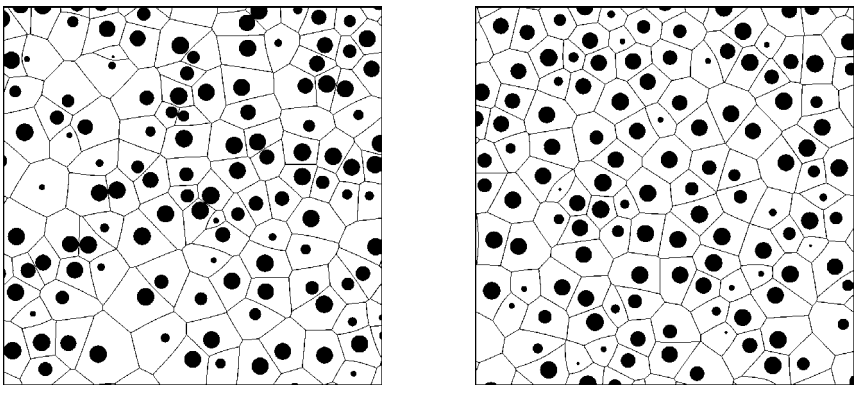

Fig. 6: Voronoi tessellation of images of sections of composite structures generated with diffusion zone $\Delta Z = 0$ (left) and ΔZ_{max} (right).

From these figures it can be seen, that some morphological methods are sensitive enough to the arrangement of objects in the composite structure, however that merely on the basis of morphological characteristics it is

difficult to describe the degree of arrangement quantitatively. For this purpose individual features of morphological methods [13] are much more convenient, because they can be created in accordance with the demands of individual studied systems.

5. Discussion

From the morphological analysis of images of both sections and projections of simulated composite structures it follows (e.g. [10]-[11]) that the Voronoi tessellation is one of the most sensitive morphological methods for the description of object arrangement in composite films. For this purpose we tried to suggest a set of features based on this method and to compare their efficiency for the quantitative characterisation of object arrangement in composites.

According to this method (sometimes known as Wigner-Seitz cells method) the whole image is divided into ´tiles´ or cells surrounding individual objects creating the image. The tiles consist of image pixels for which the distance to given object is minimal. The forms of these tiles depend on the degree of objects arrangement – see Fig. 6. However, as was shown in [13], the distribution of tiles depends not only on the distribution of objects in the image, but also on various technical parameters as the number of objects in image, on image resolution, etc. In order to remove the dependence of derived information on unimportant image parameters, it is necessary to introduce appropriate numerical feature, which will characterise the most important image properties.

In [13] for the description of two-dimensional discontinuous metal films three features based on the distribution of areas of Wigner-Seitz cells were suggested:

- the ratio of second and first moments of the distribution of areas of Wigner-Seitz cells,
- the mean value of the distribution of form factors of Wigner-Seitz cells, and
- the dispersion of the distribution of form factors of Wigner-Seitz cells.

It was found there that the first suggested feature for Wigner-Seitz cells is the best, however the more sensitive features can be derived from the radial distribution function criterion. For the analysis of images derived from three-dimensional composite films the situation differs from the case of discontinuous metal films. First, there exist two sources of information – sections and projections. It was found that the projections could be used for very thin composite layers only; therefore the analysis of images-sections of composite film is more universal. Second, as for composites the Voronoi tessellation (together with covariance function) is the most sensitive morphological method, we tested the features based on this method. Besides three numerical features suggested in [13] for two-dimensional discontinuous metal films, we applied and analysed several further features:

- angularity of individual cells (number of edges),
- length distribution of edges,
- distribution of angles between edges in the cell,
- distribution of perimeters of individual cells, etc.

This group of features we can denominate as differential and the first group as integral. Comparison of results obtained by both groups of numerical features indicates that while the second group brings more detailed information, the analysis of its results is much more difficult than analysis of the results obtained by integral features. Therefore the applicability of individual features depends on the purpose of morphological analysis of composite structures – if we need the global information about studied structure, the integral features are more convenient, if the details are important, some of differential features are used. The differences between individual differential features were found to be unimportant.

It was found that all features, both integral and differential, lose their accuracy for large filling factors because the objects become arranged. However, for large filling factors the composite films are changing their character as the dielectric-metal transition occurs and all physical mechanisms in films vary, therefore this decrease of sensitivity of suggested morphological features is unimportant.

Abstract
CB granules and flat graphite slabs have been treated in O_2/NH_3-plasma in order to improve the adsorption of acid/basic chemical species from liquid and gas phase. Surface plasma modifications have been detected on flat graphite by means of XPS and WCA with water solutions at different pH [1-2]. Boehm titrations and tests with an home-made Pyrex glass system have been performed on CB to evaluate the adsorption properties for HCl and NH_3 in vapour/gas phase, respectively.
Keywords: CB, acid/base surface adsorption properties.

Introduction

Carbon Black (CB) is the commonly accepted generic name for a wide variety of finely divided carbonaceous powders or granules produced by the partial combustion or thermal decomposition of liquid or gaseous hydrocarbons under controlled conditions. The carbon content of CB materials usually ranges from 83 to 99 % [3], with oxygen and hydrogen being the other most common elements. The surface area, structure and composition of CB change widely, depending upon several factors in the manufacturing process and operating conditions.
Today, Carbon Black and related materials are widely utilized as reinforcing fillers in polymeric matrix, as adsorbents and filters for gases and liquids, as support for catalysts and for many other uses. For many years, for instance, CB has been the main inexpensive reinforcing filler in rubber goods [4]. It is used, also, as adsorbing material in cigarette filters with the aim of detaining toxic molecules (acids, bases, organics, etc.) produced during the combustion of tobacco.
Both surface chemistry and morphology of carbonaceous materials play a crucial role in adsorption, adhesion and other relevant properties. Surface chemical features of CB granules or powders are reported, in literature, to be successfully modified by low temperature plasma treatments in several kinds of electrical and geometrical systems. Most of them deal with O_2-based feeds, with the aim of increase the surface density of the O-functionalities and, consequently, the adsorption properties [5-6]. In fact, although handling fine particles materials in a low pressure environment and allowing an homogeneous plasma treatment is some what complicated and requires special reactor designs, many examples exist in literature about low pressure plasma processing of organic and inorganic powders substances [7-8]. Few studies are reported, however, on the knowledge of the authors on the possibility of tuning the surface acid/base character of carbon-based materials, while this approach is extensively utilized for flat polymers [9-10].
In this work granules of CB (0.1-2 mm; DC W60 16*25; *Filtrona*) and flat graphite slabs (1 mm thick, 3x3 cm, *Goodfellow*) have been plasma treated in a particular home-made rotating plasma reactor (**Figure 1**), able to keep stirred and homogeneously plasma-treated up 500 g of granular materials. RF (13,56 MHz) low pressure glow discharges fed with O_2, NH_3 and O_2/NH_3 mixtures have been utilized, at 20 and 100 W of input power in the conditions reported in **Table 1**.

Tab.1: Experimental conditions for plasma treatments of CB and flat graphite samples.

The chemical surface modifications, induced on plasma-treated CB, expressed in terms of C, O and N atomic percent, have been estimated by means of X-Ray Photoelectron Spectroscopy (XPS). Plasma parameters have been optimized (time, rpm), on CB and graphite, by means of XPS in order to have similar effects on the surface composition of the two different substrates. WCA measurements have been carried out, with water solutions at different pH, on flat graphite with the aim of studying the acid/base character imparted to the functionalized surface. Boehm's titrations [11] have been performed, with NaOH and HCl water solutions, on CB before and after plasma treatment, in order to tune the acid/base surface adsorption properties for basic and acid molecules in liquid phase, respectively. Finally, the surface adsorption properties modifications, for basic and acid compounds, have been tested in vapour/gas phase with an home-made Pyrex glass test system (**Figure 2**), with HCl vapours and NH_3 as probes. Particularly, the tunability of this kind of response has been taken into account by varying feed gas composition and input power of the discharge.

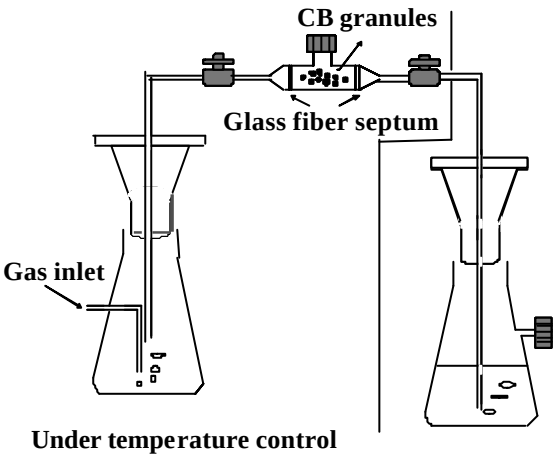

Fig. 2: Scheme of the home-made Pyrex glass system to test CB adsorption properties for acid or basic vapor/gas compounds.

Results and discussion

XPS and WCA measurements

From wide scan XPS of untreated flat graphite, only carbon and a small contamination of oxygen have been detected, whose relative approximate amounts are C1s 96.6 % and O1s 3.4 %, respectively. Small spot XPS survey spectra of CB untreated granules reveals traces of elements such as N, Na, Ca, K and Cl (< 1 %) besides C (89.9 %) and O (7.5 %) as the main surface elements. Graphite has been used as reference substrate for XPS analysis. The effect of O_2/NH_3-plasma treatments have been investigated, in terms of XPS atomic surface composition, on flat graphite plasma treated. Results on CB samples have been found similar.

Data are represented in **Figure 3**, where C, O, N atomic percent is reported as a function of the O_2 percent in O_2/NH_3 feed. C % and O % data for untreated samples are included.

As it can be easily observed, O and N surface content increases with the related gas source in the feed, O_2 and NH_3, respectively. This effect is stronger for oxygen, which also reaches a plateau (higher at higher power). At 100 W a larger introduction of N- and O-functionalities is observed. It is important to note that XPS data show that the treatment in a 100 % NH_3-plasma leads not only to the grafting of N-groups, but also to increase the surface oxygen density, probably due to the uptake of oxygen from air after the plasma treatment.

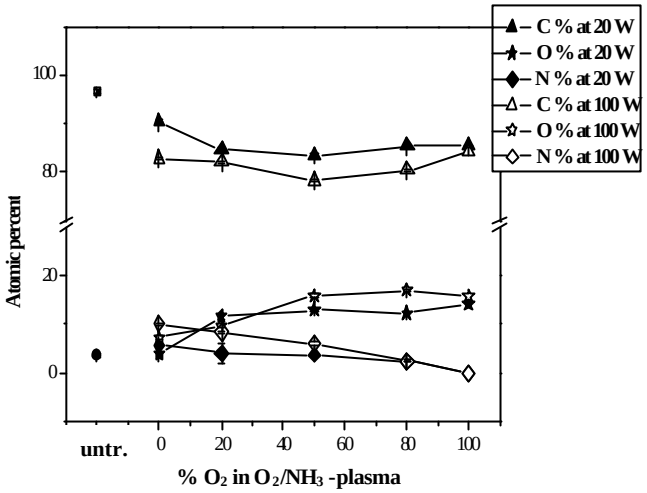

Fig. 3: XPS atomic percent for flat graphite treated in O_2/NH_3 RF plasma at 20 W and 100 W. All measurements were performed within 12 h from treatment.

WCA vs pH measurements have been performed on plasma treated graphite slabs. **Figure 4** reports only the results obtained at 100 W.

In all cases the contact angle is clearly lower than untreated graphite, due to the grafted polar groups. In pure O_2-plasma the treated surface becomes acid for the grafted O-groups, since WCA decreases with increasing pH. When NH_3 is added to the feed, a surface amphoteric behaviour develops, certainly due to the presence, at the same time, of both acid (O-containing) and basic (N-containing) groups. All WCA trends, in fact, besides 100 % O_2, show a drop at both ends, even though with different slope.

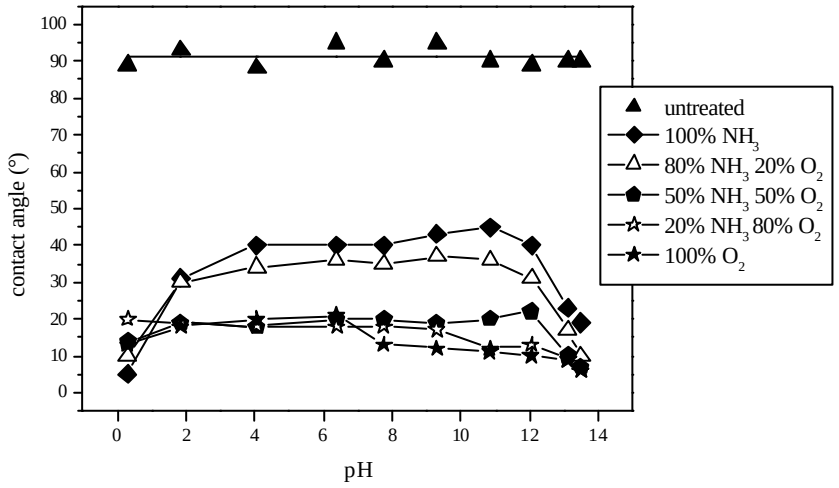

Figure 4: WCA vs pH data for flat graphite treated in O_2/NH_3 RF plasma at 100W.

Similar trends have been obtained at 20 W, with a less marked overall WCA decrease respect to untreated graphite, probably due to the *etching* effect of the plasma treatment, which is a function of the input power.

Boehm titrations

Surface adsorption properties of plasma treated CB granules in water have been tested with the titration method proposed by Boehm [11] for acid and basic compounds. A 20 ml volume of 0.02 N HCl or NaOH water solution was added to vials containing 1 g of untreated or treated CB granules. Samples have been shaken for 24 h at 180 rpm; after that, CB has been decanted from the solution. The unreacted excess of acid or base have been determined (five replicated per CB sample) by titration with NaOH or HCl 0.1 N.

The data, expressed as adsorbed equivalents of H^+ and OH^- per gram of CB, are shown in **Figure 5** as a function of the O_2/NH_3 composition of the plasma feed, at 20 and 100 W of RF power.

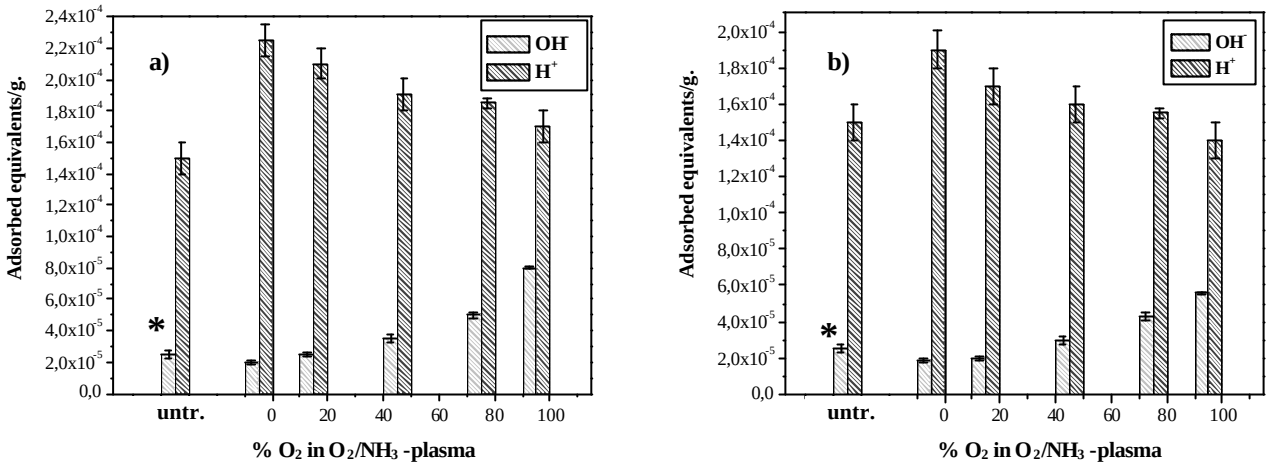

Fig. 5: Boehm's titration results for CB granules before and after plasma treatment at 20 W (a) and 100 W (b). All measurements have been repeated five time.
* OH^- is released from untreated CB.

It is possible to note that the untreated sample adsorbs a small amount of H^+ ions. From these data, moreover, we can conclude that the untreated CB samples give basic reaction with water. This is confirmed by the increase of pH (from 6.01 to 9.83) of 20 ml of bi-distilled water where 1g of untreated CB was kept under constant mechanical shake for 24 h. After any treatment in O_2/NH_3-plasma the CB surface increases the acid character and this effect becomes more clear increasing the O_2 content in the feed. On the contrary, CB becomes more and more basic increasing the NH_3 percent in the plasma. The treatment performed in a 100 % NH_3-plasma fed, imparts also a partial acid character to the surface. This amphoteric character can be probably justified taking in account the oxygen uptake from air after plasma treatment, as the XPS results, shown in Figure 3, have highlighted. Bohem results shown for CB agree with WCA vs pH data shown previously in Figure 4 for flat graphite. All data confirm that a NH_3-based plasma is more effective in imparting a basic character, than O_2-plasma in imparting an acid one. This is also evident by comparing the amount of H^+ equivalents adsorbed by the NH_3-treated surfaces respect to the corresponding OH^- amount retained by O_2-plasma modified CB surfaces.
This behaviour is more evident for samples treated at 20 W (Figure 5a); this is more clearly shown in **Figure 6**, where a comparison of the adsorbed equivalents percent of H^+ and OH^- are reported, respect to the initial ion concentration in HCl or NaOH solutions, for all CB samples.

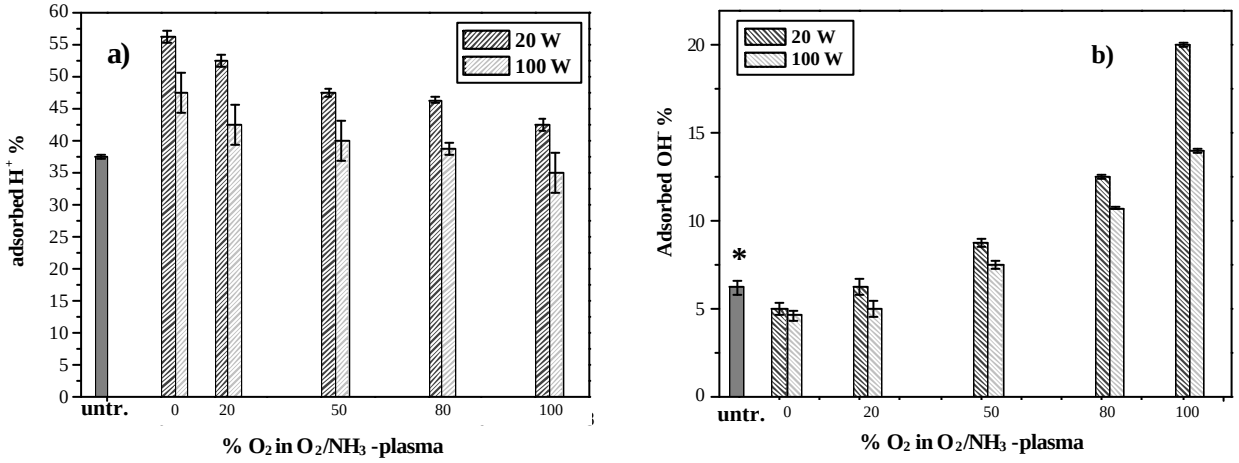

Fig. 6: H^+ (a) and OH^- (b) adsorbed equivalents percent (Boehm's titrations) for CB granules before and after plasma treatment at 20 W and 100 W. All measurements have been repeated five time.
* OH^- is released from untreated CB.

Acid/base vapour/gas adsorption tests

Acid/base surface adsorption properties for modified CB for vapour/gas compounds have been tested with an home-made test system schematized in Figure 2. Vacuum sealing is ensured by steel clamps. At the centre of the system there is a flask with 100 ml of HCl 12 N to test the basic adsorption properties of 0.1 g of CB granules, before and after plasma treatment. CB is positioned in a glass chamber in the system, between two glass fiber filters. All the system is under thermal control, maintained at 50 °C.

60 sccm of N_2 were used to strip HCl vapours from the flask. Vapours were collected in 100 ml of bi-distilled water contained in an external flask, at room temperature, after 20 min in contact with the CB granules. HCl collected was titrated with NaOH 0.2 N. From the difference between H^+ equivalents collected when the test chamber is empty and those titrated when 0.1 g of CB is in the chamber, we can estimate the amount of basic groups present at the surface of 1g of CB. To test the acid surface adsorption properties of treated and untreated CB, 15 sccm of NH_3 has been used. In this case, ammonia was collected in 100 ml of 0.15 N HCl, at room temperature, after 15 minutes in contact with 0.1 g of treated or untreated CB granules. NH_3 collected was determined by back-titration of the HCl solution utilizing NaOH 0.2 N. The amount of acid surface sites was estimated as seen above for basic sites. **Figure 7** displays the adsorbed equivalents percent of HCl and NH_3 as a function of the O_2 content in the O_2/NH_3 feed. Untreated samples adsorb only a small amount of acid or base, about 6 %, while plasma treatments induce a clear increment of the surface basic and acid adsorption properties. In particular, it is evident that the acid character rises with the O_2 percent in the gas feed while, on the contrary, the CB basic character increases with NH_3 amount. Also in this case, as for Boehm's titrations (Figures 5 and 6), NH_3 fed discharges result more effective than O_2 in modifying CB surfaces. In fact, the amount of HCl equivalents adsorbed by NH_3-treated surfaces is larger than the NH_3 retained by O_2-plasma modified ones.

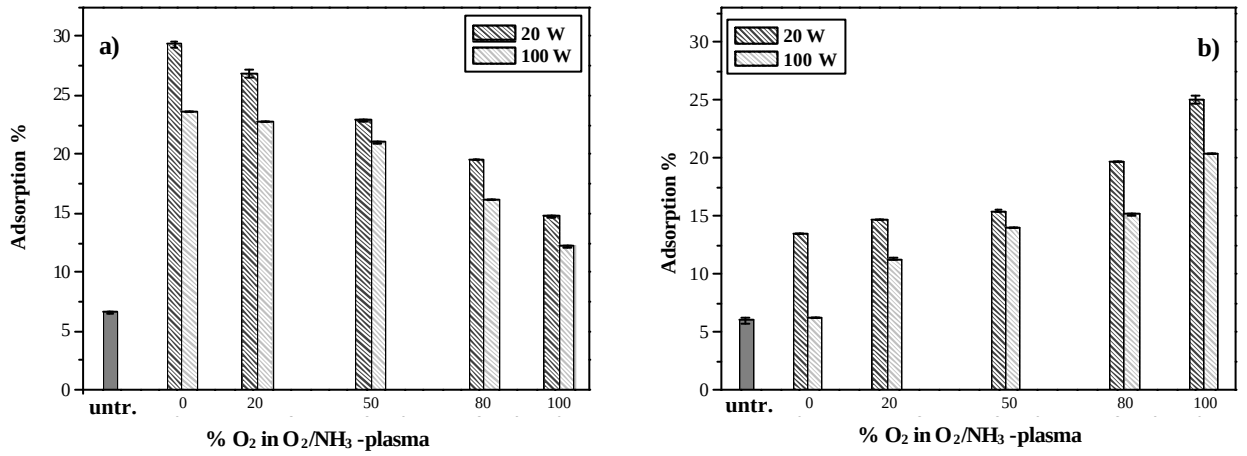

Fig. 7**:** Adsorption % data for CB granules before and after plasma treatment at 20 W and 100 W, for HCl (a) and NH_3 (b). All measurements have been repeated five time.

Also from this figure, the amphoteric behaviour of NH_3-plasma treated CB surfaces is evident, in agreement with Bohem's titrations results and WCA data. It is evident that plasma treatment at 20 W is more effective in modifying the acid/base surface character of carbonaceous substrates than the corresponding treatment at 100 W. Also this result agrees with Boehm's titrations conclusions.

Conclusions

In this work it has been shown that glow discharges, fed with O_2 and/or NH_3, can modify the surface chemical composition and improve the acid/base surface adsorption properties of CB granules, as a function of the input power and of the feed composition. O_2 RF-discharges, in detail, develop acid groups (O-containing), while NH_3 discharges develop basic ones (N-containing) and impart, after air exposure, an amphoteric behaviour to the carbonaceous substrates. Mixed O_2/NH_3-plasma treatments impart an intermediate acid/base surface character, which is a function of the O_2/NH_3 feed ratio. RF plasma modified

CB samples, furthermore, show an evident rise of their adsorption properties for acid and basic compounds in liquid and in vapour/gas phase.

Experimental study of pattern formation in unipolar-pulsed dielectric barrier discharges

S.N. Abolmasov[1], T. Shirafuji[2] and K. Tachibana[3]

[1]Venture Business Laboratory, [2]International Innovation Center, [3]Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan

Abstract

Formation of complex patterns lateral to the current flow in a short planar dielectric barrier discharge system, excited by positive voltage pulses, is investigated experimentally. The current-voltage measurements and optical diagnostics provide evidence that patterned dielectric barrier discharges in helium, argon and krypton are driven by conditions of V_{gap}, j = const; similar to low pressure DC normal glow discharges. New mechanisms for pattern formation in gas discharge systems are proposed.

Keywords

Dielectric barrier discharge, unipolar-pulsed excitation, pattern formation, normal cathode spot

1. Introduction

Spatiotemporal pattern formation in systems driven away from equilibrium is a long-standing problem in many fields of science. Much work (mainly theoretical) has been done over the years to get a better understanding of the phenomenon [1]. It seems that pattern formation in DC discharges is related to the existence of a negative slope region in the voltage versus current characteristic curve of the discharge [2, 3]. The picture, however, becomes more complex in the case of dielectric barrier discharges (DBDs) due to their transient nature and, therefore, some authors believe that surface charge accumulated on the electrode dielectric may also come into play [4, 5]. Nevertheless, it is also believed that DBDs in short gaps are formed due to Townsend breakdown mechanism, similar to low-*pd* DC discharges (*pd*: pressure times discharge gap width) [4, 5]. It is reasonable, therefore, to assume that spatiotemporal patterns observed in DC discharges and those in DBDs are probably similar in nature. The aim of this study is to answer the question of whether it is true or not.

Since the problem is multiparametric it is important to simplify it as much as possible. Due to this reason, we have used: 1) pulsed excitation of DBDs (to control the voltage rise time independently of the frequency), 2) noble gases (to minimize elementary plasma processes) and 3) no gas flow (to simplify the gas dynamics).

2. Experimental

Fig. 1 illustrates a schematic of the electrode system used in the experiments. Two identical quartz plates with conducting, optically transparent [indium tin oxide (ITO)] coatings on their counter side were used as the electrodes, to permit the optical characterization of discharge uniformity using a digital camera. The transparency of the ITO coatings was about 80%. Four squares forming a cruciform structure on the periphery of the circular electrodes provided favorable wire-plane geometry for corona discharges. One of the electrodes was grounded while the other was powered by a unipolar-pulsed, high-voltage power supply

(positive pulses of amplitude up to 10 kV, 5 kHz repetition frequency, 50% duty factor). The electrode system with a 0.3 mm discharge gap was mounted inside a hermetic Pyrex cylinder pumped to a base pressure of about 1 mTorr. Discharges were generated in noble gases such as helium, argon and krypton. The voltage applied to the top electrode was measured with a 1:1000 high-voltage probe. The total current passing through the discharge was monitored by measuring the voltage drop across a 1 kΩ (low inductive) resistor that was placed in series with the grounded electrode. The displacement current (I) was determined by measuring the current (I_M) through a known capacitance (C_M = 22 pF) placed in parallel with the discharge cell [$I = C_g(dV/dt) = (C_g/C_M)I_M$, where C_g is the capacitance of the discharge gap]. The difference between the currents yielded the discharge current.

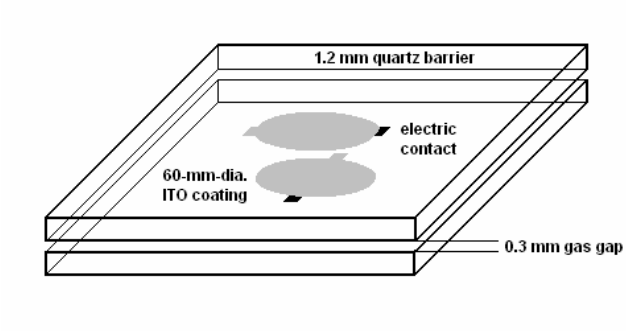

Fig. 1. Electrode geometry used in the experiments.

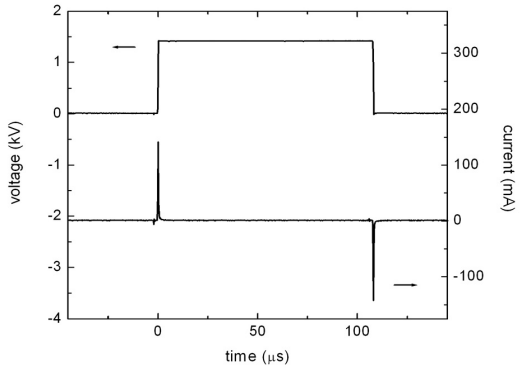

Fig. 2. Typical voltage/current oscillograms in the case of helium DBD at p = 260 Torr.

3. Results and discussion

Fig. 2 shows typical voltage and current oscillograms of a 5 kHz, unipolar-pulsed DBD. It can be seen that two current pulses corresponding to two consecutive discharges are generated per voltage pulse, similar to bipolar pulse excitation. The second discharge, which occurs at the falling edge of the voltage pulse, is induced by electric charges stored on the electrode dielectric during the initial discharge. The discharge duration is about 1 μs, as can be seen in Figs. 3 and 4. Here the images of helium and argon DBDs and their discharge current oscillograms show that the barrier discharges exhibit behavior similar to that found in DC glow discharges. Namely, as the discharge current is varied its density at the cathode remains unchanged, and the discharge area changes. Only when the discharge covers the entire electrode area, an increase in the applied voltage leads to a rise in the current density, and the discharge enters the abnormal glow regime (see two left images in Figs. 3 and 4). Note that the displacement (first) and discharge (second) current peaks in helium DBD usually appear separated from each other, which is not the case in argon and krypton DBDs. Fig. 4 shows the discharge current of argon DBD (after displacement current subtraction), indicating that the value of normal current density in argon is about two times higher than that in helium (Fig. 3). It should be emphasized that the breakdown voltage and normal current density values of krypton DBD were close to those of argon DBD within the pd-range under consideration [(3–23) Torr cm].

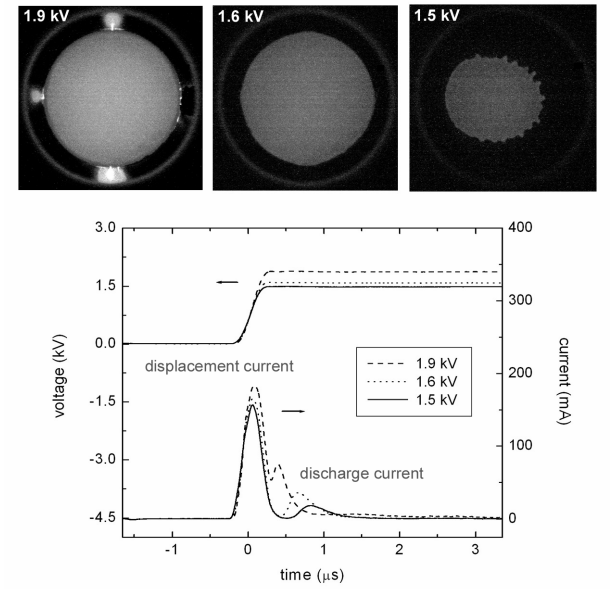

Fig. 3. Abnormal/normal discharge modes in helium at p = 600 Torr and their current/voltage oscillograms. (1 s exposure time)

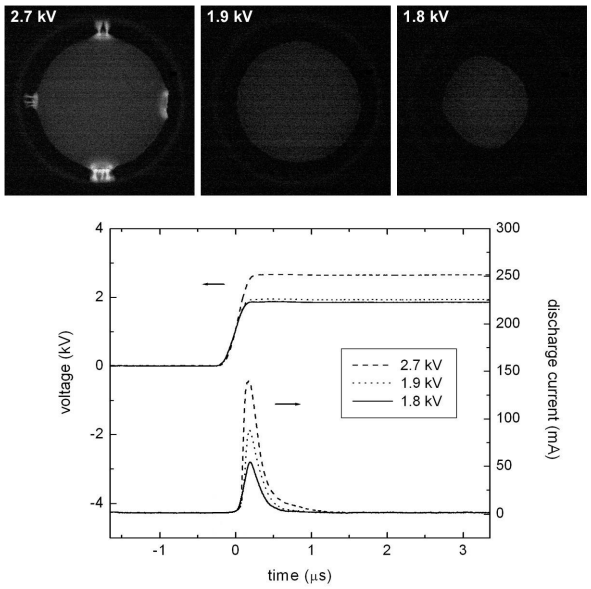

Fig. 4. Abnormal/normal discharge modes in argon at p = 200 Torr and their current/voltage oscillograms. (1/30 s exposure time)

Quasi-stationary discharge patterns were observed in helium with decreasing gas pressure (p < 600 Torr), while it was opposite in the case of argon and krypton (p > 200 Torr). The discharge current measurements combined with optical observations also confirmed that the patterned DBDs in the three noble gases operate in the normal glow regime.

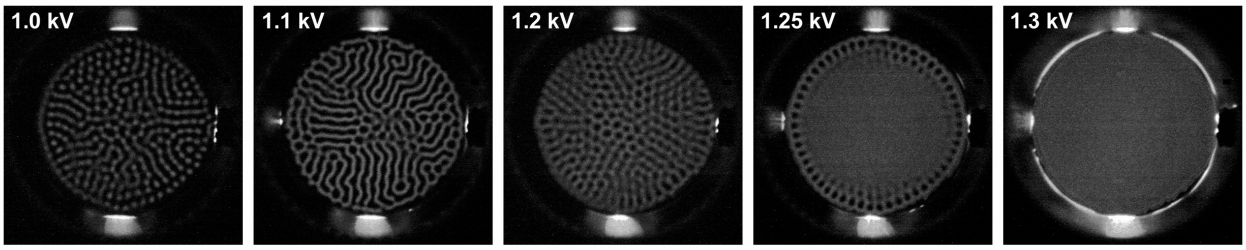

Fig. 5. Pattern formation in helium at p = 150 Torr: voltage amplitude dependence (voltage amplitude is shown in the upper left corner). (1 s exposure time)

Fig. 5 shows a typical pattern obtained in helium at p = 150 Torr which exhibits the well known transitions *dot pattern => stripes => hexagons => homogeneous state* and vice versa with increasing/decreasing voltage pulse amplitude. It can be seen that during the normal glow mode the luminosity of the pattern keeps constant (suggesting V_{gap}, j = const) and increases only when the discharge enters the abnormal glow mode at V = 1.3 kV. The pattern looks very similar to that reported in [6], where 40-125 kHz, 0.4 μs rise time, square wave excitation has been used to create DBDs in 0.05-0.06-mm-gaps between two plane-parallel, 0.076-mm-thick dielectric barriers (Corning 0211 Microsheet) in flowing helium at p = 760 Torr. It should be noted that despite a marked difference in the experimental devices, the voltage impulse rise time and

pd-factor (~ 4.5 Torr cm) are identical in both experiments. This fact speaks against dependence of the pattern upon impurities [7] and supports the importance of discharge current density value in the pattern formation. Note that at the moment of breakdown (or discharge termination by voltage decrease) the discharge appeared (disappeared) in the form of a large number of identical dots accompanied by diffuse corona discharge around the electric contact squares (1.0 kV case in Fig. 5).

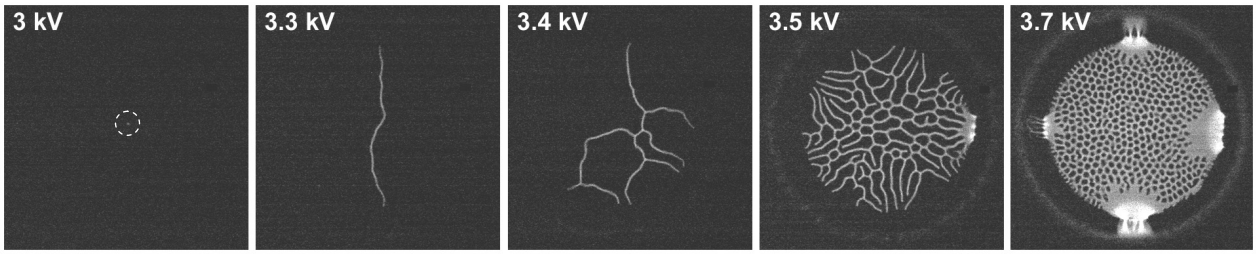

Fig. 6. Voltage amplitude effect on discharge pattern in argon at p = 600 Torr (voltage amplitude is shown in the upper left corner). (1/30 s exposure time)

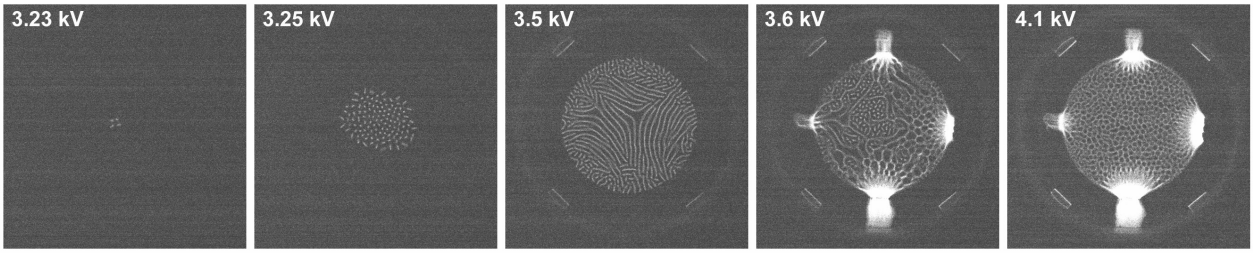

Fig. 7. Pattern formation in krypton at p = 600 Torr: voltage amplitude dependence (voltage amplitude is shown in the upper left corner). (1/8 s exposure time)

Unlike the patterned DBD in helium, the breakdown stage of patterned DBDs in argon and krypton is characterized by the presence of intense streamer-like corona and the appearance of stripe pattern, as can be seen in Figs. 6 and 7. Noteworthy, the low-voltage states here (with V < 3.6 kV) can only be obtained by lowering the discharge current and in both gases the discharge disappears in the form of one discharge dot (or normal cathode spot). One can also see that the hexagonal symmetry inherent to helium DBD is broken in argon and krypton DBDs and the discharge stripes here tend to split rather than merge. The later is probably a result of repulsive Coulomb force among the discharge stripes (or dots); the value of normal current density in argon (krypton) is somewhat higher than that in helium, as shown above. On the other hand, thermal effects also become more pronounced in argon and krypton. This is especially the case of krypton (because of its high atomic mass), in which such phenomena as quantization of discharge stripes (Fig.7: 3.5/3.6 kV) and replication of discharge dots (Fig. 7: 3.23/3.25 kV) were observed as the gas temperature (as well as the electrode temperature) reached a certain value. Thus, a pattern state in krypton DBD can depend on the discharge history– the phenomenon known in the DBD literature as a “memory effect” [5, 8]. According to the classification given in [7], the patterns shown in Figs. 5 and 6 can be classified as type I patterns, while that in Fig. 7 as type II pattern. It also seems that the radius of a discharge spot in these patterned DBDs is

inversely proportional to the atomic mass of the working gas (He > Ar > Kr). The same radius dependence upon gas type was also reported by Radu *et al.* [5] for AC driven DBDs in noble gases. Note that type II patterns behave qualitatively in the same way as (arc) cathode/anode spots (spots replicate from/into each other). Therefore, we assume that the physics involved in their formation is different from that of type I patterns.

Turning now to description of the pattern formation (type I patterns), it is interesting to raise the questions of why a Townsend discharge being homogeneous starts to constrict laterally as the discharge current is increased and what determines the radius of a constricted discharge channel (or normal cathode spot). Moreover, why in one case the discharge constriction leads to the formation of one normal cathode spot, while in the other it results in the appearance of a discharge pattern. To our knowledge, none of theoretical models existing today answer these questions; see, e.g., [2-4, 9].

Looking back over 35 years, by the early seventies Vlasov *et al*. [10] reported that the presence of negative glow plasma, whose thickness is several times larger than the length of cathode fall region l_c, is necessary for the existence of normal glow discharge mode. In other words, a subnormal discharge constricts laterally with an increase in discharge current only in the case of $pd > (pd)_{min}$ (on the right branch of the Paschen curve). For $pd < (pd)_{min}$ there is a direct transition from a subnormal to an abnormal discharge, which occurs without radial constriction; the subnormal and abnormal discharges cover the entire area of the cathode. For example, the normal cathode fall is established in neon when the distance between the electrodes equals to at least $4l_c$ [10].

A distinguishing feature of negative glow region is the existence of a reversal of the axial electric field which is related to the fact that the negative glow is analogous to externally sustained plasma [11]. Electrons emitted from the cathode and accelerated in the high, sheath electric field release their energy in the low-field region which defines the negative glow. Most textbooks on gas discharge physics [12-15] also indicate that the net space charge in this region is negative, composed of slow electrons. These electrons being located close to the cathode surface will feel the electrode surface charge concentrated on the electrode edge. The electrostatic repulsive force they exert because of their negative charges will constrict the discharge channel. During the constriction process the second repulsive force between slow electrons will grow and compensate finally the external repulsive force. Thus, the radius of normal cathode spot should be determined by the force balance. We believe that this is the scenario for how a normal cathode spot is established, in contrast to "multiplication maximum mechanism" described in [15].

On the other hand, our recent experiments [7, 16] as well as few observations reported by other authors [17 (see Fig. 7b), 18] show that the electrode boundary is likely to be responsible for the formation of type I patterns in short planar discharge systems (rather than "mysterious" negative differential conductivity [2, 3]). In this case, the electrostatic repulsive force among charged particles trapped on the electrode edge as well as edge corona discharge [7] might be possible triggering mechanisms for the pattern formation. Interestingly, the presence of corona discharge is most likely at the breakdown stage in patterned DBDs (Figs. 5, 6 and 7), while it is absent during the formation of one normal cathode spot and appears here only when the discharge becomes abnormal (Figs. 3 and 4).

4. Conclusion

The experimental results presented in this study show that DBDs in short gaps behave similar to low pressure (low-*pd*) DC glow discharges. The results also suggest (in addition to the results reported in [7]) that there are (at least) two mechanisms for pattern formation in gas discharge systems corresponding two types of discharge patterns. These mechanisms involve different physical processes and should, therefore, be treated in different manners. The first mechanism which is believed to be responsible for pattern formation in subnormal discharges involves processes at the electrode periphery. Consequently, the formation of type I patterns is an inherently three dimensional (3-D) problem which, in addition, requires a kinetic treatment of the electron dynamics due to the appearance of cathode layer [19]. Moreover, the pattern evolution can also take place in the normal glow regime, i.e., under conditions of V_{gap}, j = const, as experimentally shown above. On the other hand, thermal processes can cause the appearance of type II patterns, whose description would require taking into account thermodynamics. Thus it is clear that the negative differential conductivity alone (as a universal criterion) cannot explain a variety of experimentally observed patterns. In our view, Monte Carlo methods which are found to be useful in solving 3-D problems, albeit computer-time-intensive, might be helpful for the analysis of the phenomenon.

Abstract
Radiative heat transfer must include particles contribution in studies on thermal plasma gas-phase synthesis due to close relation between temperature and particle tailoring. This work explores an improved method for taking into account the particle presence. Expressions for the extinction and the scattering coefficients providing a dependence of the local temperature are given.

Key words : CFD modelling, radiation, absorption coefficient, scattering coefficient, soot.

1. Introduction

Particles contribute quite significantly to radiative heat transfer in plasmas processes. This contribution plays a crucial role when high requirements on temperature control are needed. This is usually the case in gas phase synthesis since the produced material tailoring depends on the particles thermal history [1, 2, 3].
In thermal plasma gas-phase synthesis of carbon nanostructures such as carbon blacks [4], fullerenes [5] or carbon nanotubes [6], plasma is used as a heat source for achieving the thermal decomposition or the vaporisation of a carbon feedstock. The requirements on the temperature control appear during all process stages from nucleation-aggregation to quenching, including annealing. In all of them, radiative heat exchanges are modified by the simultaneous actions of the synthesised nanoparticles and by the residual feedstock. Consequently, a good description of the particles effects on radiative transfer must be performed.
In a previous work [7], particles were considered to be non-diffusive Rayleigh emitters given that size parameter $x = \pi D/\lambda << 1$, with D, the particle diameter and λ, the wavelength. The complex refractive index was maintained constant at a certain value, which was related to the characteristic wall temperature inside the plasma reactor. However, internal temperature gradients could be high enough to invalidate the characteristic temperature concept that was used to define the soot refractive index. Therefore, this approach should be examined carefully in order to verify if a more sophisticated radiation model for improving the particulate effects on radiative heat transfer is required.
In this work, an improved version of the radiation model will be proposed and compared with the simple model. This new model, which includes the temperature dependence of the soot refractive index, is applied to the study of a geometry for soot formation from a hydrocarbon cracking by plasma using the commercial code Fluent.

2. General model

The radiation model was implemented in the framework of a general model devoted to study the thermal decomposition of methane by a nitrogen plasma jet. The general model assumes that the flow is highly turbulent and the gas is optically transparent and in local thermodynamic equilibrium.
A renormalization group (RNG) based k-epsilon model is employed for taking into account the turbulence. Within this model, the turbulent viscosity μ_t is calculated by $\rho C_\mu k^2/\varepsilon$, with ρ, the fluid density; k , the turbulent kinetic energy; ε , the dissipation of the turbulent kinetic energy and C_μ, a model constant equals to 0.0845.
The chemical composition is described by a non-premixed model. Two convection-diffusion equations are solved, which correspond to the mixture fraction $\bar{f}$ (or mass fraction originated from the hydrocarbon stream)

$$\frac{\partial}{\partial t}\left(\rho \bar{f}\right)+\nabla\cdot\left(\rho u \bar{f}\right)=\nabla\cdot\left(\frac{\mu_t}{\sigma_t}\nabla\bar{f}\right) \qquad (1)$$

and the mean mixture fraction variance $\overline{f''^2}$

$$\frac{\partial}{\partial t}\left(\rho\overline{f'^2}\right)+\nabla\cdot\left(\rho u\overline{f'^2}\right)=\nabla\cdot\left(\frac{\mu_t}{\sigma_t}\nabla\overline{f'^2}\right)+C_g\mu_t\Delta\bar{f}-C_d\rho\frac{\varepsilon}{k}\overline{f'^2} \tag{2}$$

where σ_t, C_g and C_d are model constants, whose values are 0.85, 2.86 and 2.0, respectively. The mixture fraction variance is used in the closure model describing turbulence-chemistry interactions. All instantaneous values of thermochemical scalars, such as density, temperature, and species mass fractions, are uniquely related to the mixture fraction and the enthalpy: $\varphi=\varphi(f,H)$. The time-averaged values are calculated as

$$\overline{\varphi}\approx\int_0^1\varphi\left(f,\overline{H}\right)p(f)df \tag{3}$$

where $p(f)$ is the probability density function (PDF), which describes the temporal fluctuations of f in the turbulent flow.

In this work, a β-function PDF has been chosen,

$$p(f)=\frac{f^{\alpha-1}(1-f)^{\beta-1}}{\int f^{\alpha-1}(1-f)^{\beta-1}df} \tag{4}$$

with

$$\alpha=\bar{f}\left[\frac{\bar{f}(1-\bar{f})}{\overline{f'^2}}-1\right]\ \text{and}\ \beta=(1-\bar{f})\left[\frac{\bar{f}(1-\bar{f})}{\overline{f'^2}}-1\right].$$

Reactive chemical species were limited to the following ensemble: C, C_2, C_2H, C_2H_2, C_2H_4, C_2N, C(s), CH_2, CH_3, CH_4, CN, H, H_2, HCN, N, N_2, NCN, NH, NH_2, NH_3.

Soot formation was incorporated by a two-step Tesner model [6], which involve two transport equations. They correspond to the soot mass fraction and the normalised radical nuclei concentration. It was assumed that CH_4 is the particle precursor.

3. Radiation model

The radiation model is based on the resolution of the radiative heat transfer equation:

$$\frac{dI(\mathbf{r},\mathbf{s})}{ds}+(a+\sigma_S)I(\mathbf{r},\mathbf{s})=a\,m^2\frac{\sigma T^4}{\pi}+\frac{\sigma_S}{4\pi}\int_0^{4\pi}I(\mathbf{r},\mathbf{s})\Phi(\mathbf{s}\cdot\mathbf{s}')d\Omega' \tag{5}$$

where $I(\mathbf{r},\mathbf{s})$ is the radiation intensity at position $\mathbf{r}$ and in the direction $\mathbf{s}$, a and σ_s are the absorption and the scattering coefficients, respectively, m is the complex refractive index, σ is the Stefan-Boltzmann constant, T is the local temperature and Φ is the phase function. For media with mono-dispersed particles, the absorption and the scattering coefficients are expressed as

$$a=\frac{3}{2}\frac{Q_{ext}f_v}{D},\ \sigma_S=\frac{3}{2}\frac{Q_{sca}f_v}{D} \tag{6}$$

with Q_{ext} and Q_{sca} the extinction and scattering efficiencies and, f_v, the volume fraction, which is defined as $\pi/6\cdot D^3\cdot n$, where n is the particles concentration. The extinction and scattering efficiencies are (to terms of order x^4) [8]

$$Q_{ext}=4x\,\mathrm{Im}\left\{\frac{m^2-1}{m^2+2}\left[1+\frac{x^2}{15}\left(\frac{m^2-1}{m^2+2}\right)\frac{m^4+27m^2+38}{2m^2+3}\right]\right\}+\frac{8}{3}x^4\,\mathrm{Re}\left\{\left(\frac{m^2-1}{m^2+2}\right)^2\right\}, \tag{7}$$

$$Q_{sca}=\frac{8}{3}x^4\left|\frac{m^2-1}{m^2+2}\right|^2. \tag{8}$$

The refractive index is calculated as a function of the temperature and the wavelength by using the theory proposed by Lee and Tien [9]. In order to estimate the local refractive index as a function of temperature, the characteristic wavelength is by applying the Wien's Law.

Discrete Ordinate Model is employed for solving eq. 5, as implemented in the CFD code FLUENT.

4. Test geometry and boundary conditions

A simple geometry was used to test the model described above. A cylinder of radius R and length L in which a plasma jet is injected axially and a hydrocarbon is introduced in the radial direction at a distance l from the top. Following table contains the boundary conditions.

	Momentum	Energy	Turbulence	Mixture Fraction	Soot	Radiation
Plasma Inlet	$\mathbf{u}(r)$	$T(r)$	$k(r)$, $\varepsilon(r)$	0	0	emissivity(T)
CH_4 Inlet	$\mathbf{u}(r)$	$T(r)$	$k(r)$, $\varepsilon(r)$	1	0	emissivity (T)
Outlet	Mass conservation	Extrapolated	Extrapolated	Extrapolated	Extrapolated	emissivity ($300K$)
Inner Wall	Non-slip Condition		Standard Wall Function [9]	$\partial f / \partial n = 0$	$\partial / \partial n = 0$	emissivity = 0.9
External Wall		300 K				

5. Results

Figure 1 shows the evolution of the complex refractive index as a function of temperature by using the radiation model described previously. Real and imaginary parts of the refractive index decrease monotonically with temperature. At temperatures higher than 1800 K, the real part of the refractive index is almost constant around 1.86, whereas the imaginary part changes smoothly between 0.68 and 0.52. Consequently, the previous approach, which assumed that the refractive index was constant, is roughly valid at high temperatures.

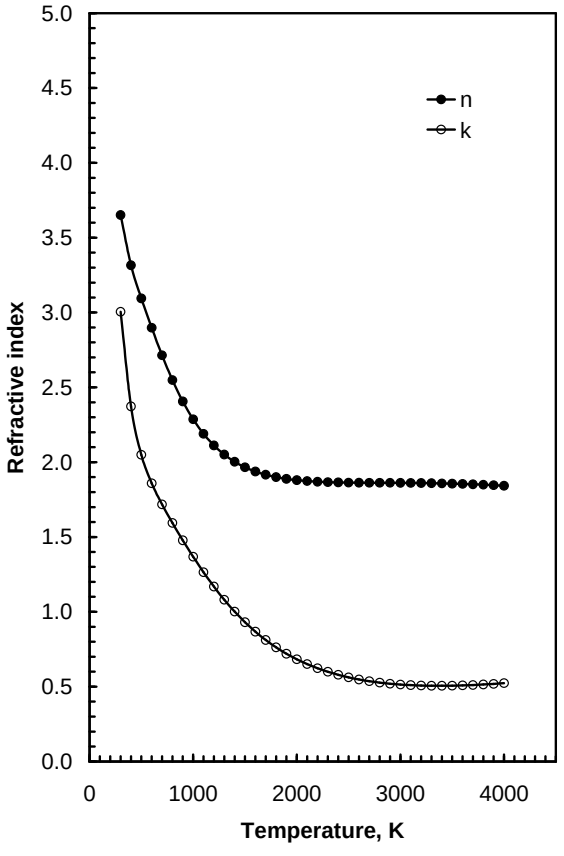

Figure 1. Refractive index versus temperature.

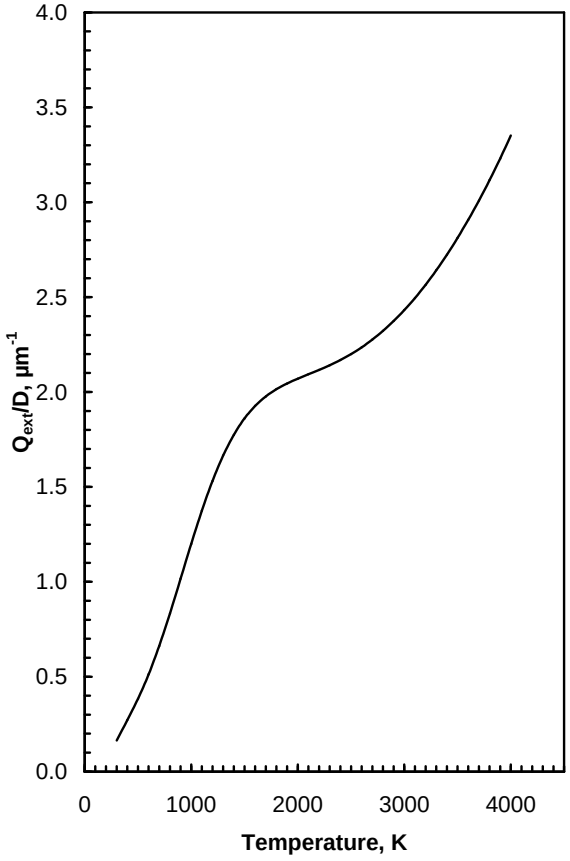

Figure 2. Absorption coefficient at Rayleigh limit.

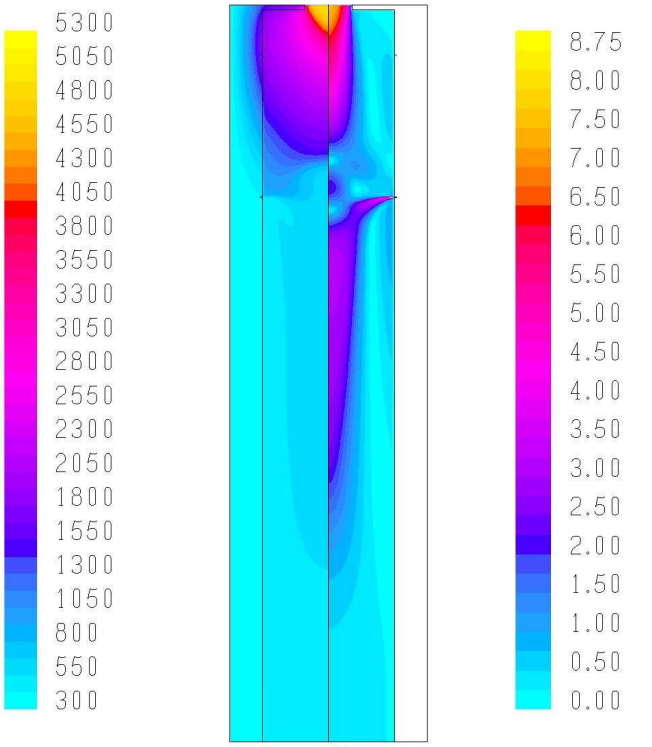

Figure3. (a) Temperature (K), (b) Velocity (m/s).

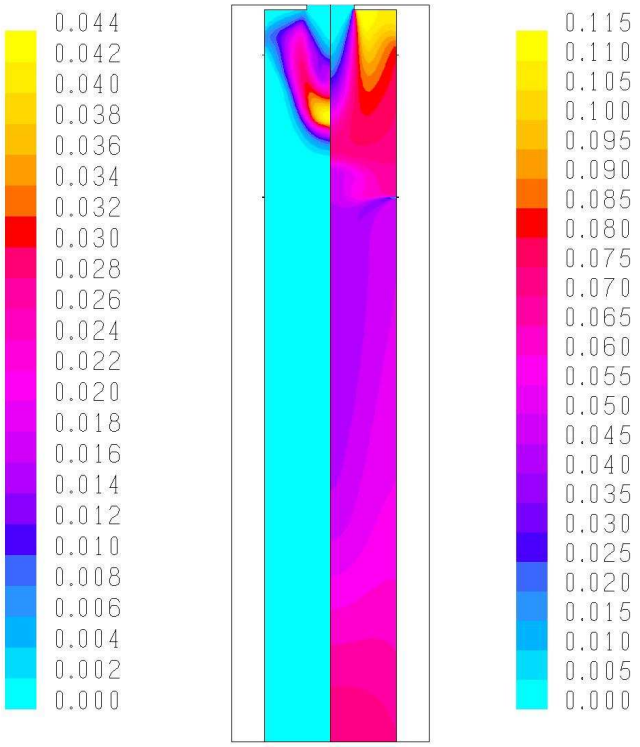

Figure 4. (a) Nuclei mass fraction (10^{15} particles/kg), (b) Soot mass fraction.

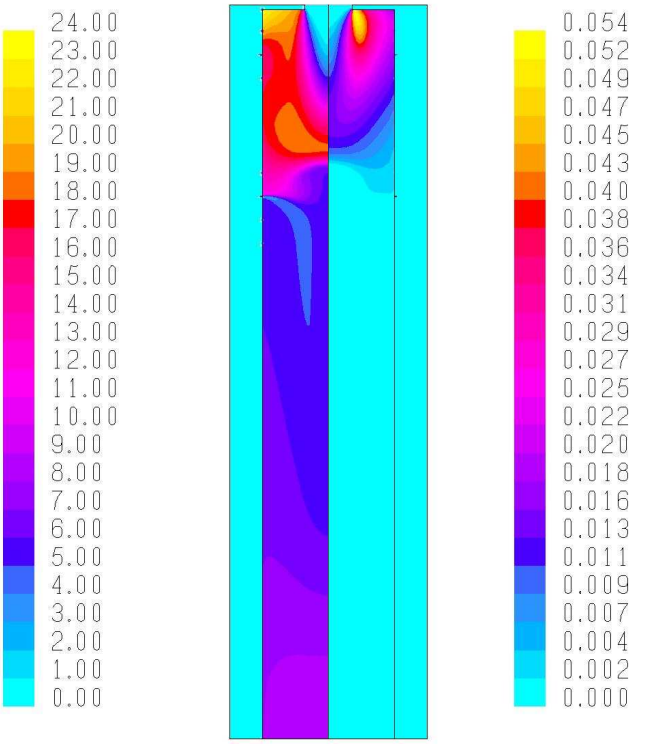

Figure 5. (a) Absorption and (b) scattering coefficients.

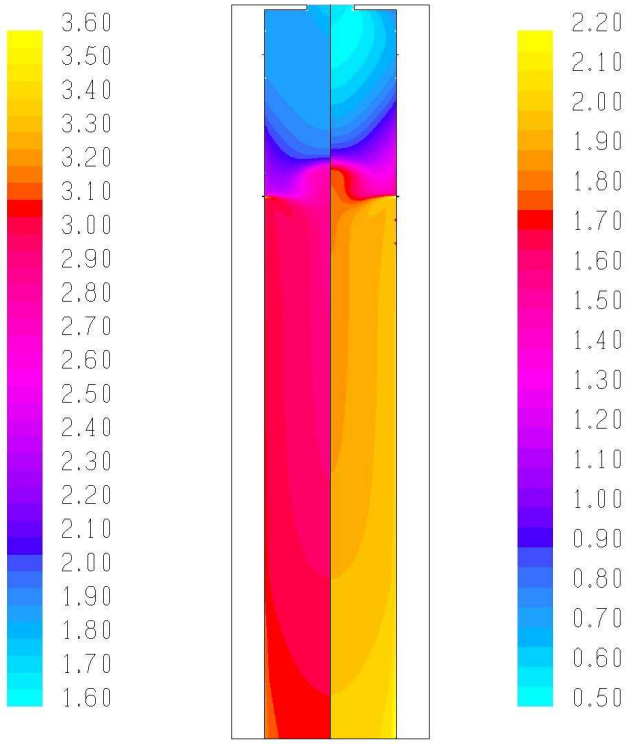

Figure 6. Complex Refractive index, $m = n - j\,k$. (Left) Real part, n and (Right) Complex part, k.

Figure 2 illustrates the absorption coefficient dependence on the temperature. In this picture, the absorption coefficient has been calculated in the Rayleigh limit (that neglects terms of order higher than one). Contrary to the refractive index, the absorption coefficient increases with the temperature, showing a small plateau around 2000 K. In the region comprised between 1000 K and 4000 K, the magnitude grows up by a factor three.
Series of figures from 3 to 6 shows typical field distributions obtained with the test geometry when methane is injected at $l = 0.25\ L$ and at 4.8 g/s flow rate. Two temperature zones become visible in figure 3.a. The first zone is characterised by temperatures higher than 1800 K, whereas the second has temperatures lower that 700 K. The limit between both regions, in which temperature quenches considerably, is located at methane injection level. Simulation shows that the gas cooling down is mainly caused by the mixing of the plasma and the methane jets, leading up to the thermal decomposition of methane. Thus, particle nucleation is placed in the contact region between the two jets, as seen in figure 4.a. Nevertheless, the soot is concentrated in the upper part of the reaction chamber just in the corner (fig. 4.b). This is due to the vortex generated by the plasma jet.
As result of the particle presence and the temperature, the absorption and scattering coefficients are higher in the upper temperature zone than in the lower. Both coefficients contribute to make more uniform the temperature field.
The refraction index is approximately constant within each temperature zone. In the hot zone, the refraction index change smoothly even if temperature varies between 4000 to 1800 K, as it is expected from its temperature dependence (fig.1). In the cold zone, the refraction index behaviour is caused by the uniformity of the temperature field.

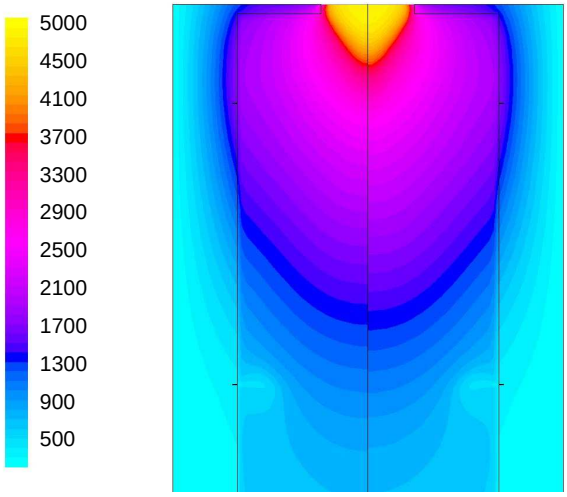

Figure 7. Temperature comparison $m = 1.86 - j\ 0.68$ (left) and $m(T)$ (right).

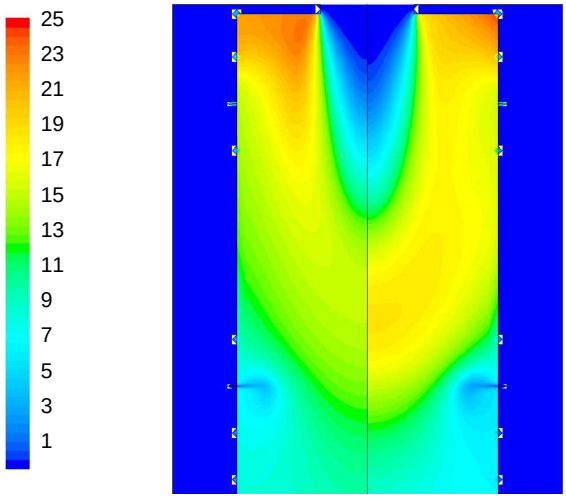

Figure8. Absorption coefficients comparison with $m = 1.86 - j\ 0.68$ (left) and $m(T)$ (right).

Therefore, absorption and scattering coefficients are mainly dependent on the volume fraction and the role of refractive index is secondary. Figure 7 and 8 shows the comparison of temperature and absorption coefficient distributions when the temperature dependence of the refractive index is taking into account or not. In this case, the refractive index is $1.86 - j\ 0.68$. Both approaches predict a mean free path of photons in the hot region between 4 cm and 10 cm. However, there is a deviation in the absorption coefficients as high as 20%.
Notice that if the chamber dimensions (radius or length) are larger than the photons mean free path, the medium will be optically thick, and the differences between the two approaches will decrease.

4. Conclusions

Radiative heat transfer must consider particles contribution in studies on thermal plasma gas-phase synthesis due to close relation between temperature and particle tailoring. This work explored an improved method for taking

into account the particle presence. Expressions for the extinction and the scattering coefficients are given providing a dependence of the local temperature.
The comparison of two models (constant and temperature-dependent refractive index) show that the assumption of constant refractive index is not valid at low volume fractions and gas temperatures lower than 1500 K. Then, it remains a good approach in the hot plasma zone.

The role of negative ions in the sheath formation

P. Jelínek, R. Hrach, J. Šimek, V. Hrachová, P. Bartoš

Charles University, Faculty of Mathematics and Physics, Department of Electronics and Vacuum Physics
Prague, Czech Republic

Abstract
The transport of electrons and ions to metal substrates immersed into plasma is studied by computer experiment in the plasma of electronegative gases. As input data for modelling the results of both measurement and simulation of the dc glow discharge in oxygen/argon plasma were used. The formation of the sheath region and the spatial and temporal evolutions of distributions of individual charged species in the presence of negative ions are investigated.

1. Introduction

The interaction of both inert gas plasmas and chemically active plasmas with immersed substrates takes part in many technological applications as plasma processing of materials, plasma oxidation or plasma-assisted deposition processes. Special attention must be given to technologies using electronegative gases because of their importance in practice and in the same time the difficulties in theoretical description. The presence of three-component plasma containing besides electrons and positive ions also negative ions significantly alters the formation of the sheath and in such way modifies the fluxes of charged species to the substrate. As a consequence the detailed analysis of physical and chemical processes taking part during plasma-solid interaction in such plasmas is much more complicated and the theoretical description of both technological results and probe diagnostics is difficult, especially in dynamic regime. Therefore, in such plasmas the computational approach is a convenient alternative to the theory and computer experiments can help to analyse experimental data obtained in electronegative gases.

The theoretical/computational description of the complete process of electronegative plasma-solid interaction consists of several stages – characterisation of bulk properties of plasma, formation of sheath region and calculation of the transport of charged species from undisturbed plasma to metal substrate immersed into plasma, followed in some plasma chemical technologies by the description of physical or chemical processes on the surfaces of substrates.

In our contribution the sheath formation as a part of plasma-solid interaction in gas mixtures containing oxygen is studied by the combination of direct measurement and computer modelling. This study is a continuation of our contribution presented during the last 16th ISPC conference in Taormina [1]. Moreover, in the present 17th ISPC conference another contribution [2] is presented, devoted to the complementary problem, i.e. to the analysis of complete process of plasma oxidation of metals, where the plasma-solid interaction is one of the most important parts.

2. Volume processes

In the first part of our study the volume of the electronegative plasma is characterised. For this purpose two different techniques were used:

- experimental approach
- computational approach.

The measurements were performed in a positive column of dc glow discharge either in pure oxygen or in mixtures of oxygen with rare gases – argon, neon or helium. Our studies were made in a pressure range 67 to 800 Pa, the composition of mixtures and the discharge current being experimental parameters. For the study of plasma properties optical, microwave and probe diagnostics were used. Some experimental results can be found in [3], [4] as well as in [2]. Examples of obtained experimental results can be seen in Fig. 1. During the

measurements the axial electric field was determined together with the electron density, effective collision frequency and temperature of electrons for various combination of experimental parameters. Some of these experimental results were used as input data for following computer simulations.

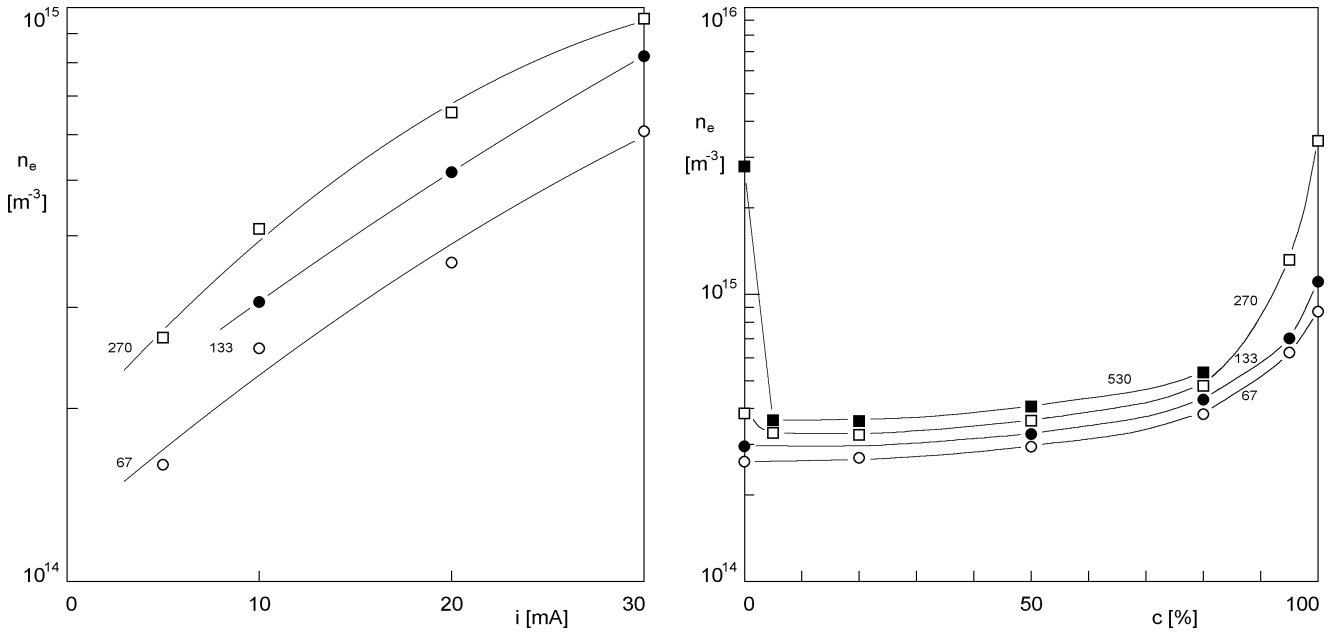

Fig. 1: Measured electron density n_e [1]. The parameter is a pressure of gas mixture in Pa.
Left – O_2 plasma, measurement in the dependence on discharge current i.
Right – O_2/Ne plasma, dependence on concentration of inert gas c.

Plasma composition in the undisturbed region was studied with the help of computer experiment, too. The model of bulk of oxygen plasma was based on a macroscopic kinetic approach, when the steady-state concentrations of various species can be found as a solution of a set of linear differential equations corresponding to conservation laws for individual species in the discharge – e.g. [5].

The model of O_2/Ar plasma consists in the present moment of 196 reactions between 21 types of neutral, charged and excited species. The reaction set includes the basic physical processes and consists of three parts – reactions between oxygen particles, reactions in argon and mixed reactions oxygen-argon. As a result the concentrations of the most important neutral and charged species in the plasma were derived for various discharge parameters – see Tab. 1.

neutral and excited species					
O_2: 1.0	O: 7.5×10^{-1}	$O_2(^1\Delta_g)$: 1.5×10^{-1}	$O_2(^1\Sigma_g^+)$: 4.3×10^{-3}	O_3: 7.7×10^{-5}	…
1.0	2.5×10^{0}	4.3×10^{-6}	2.0×10^{-3}	7.5×10^{-5}	…

positive charged species			
O_2^+: 1.6×10^{-6}	O^+: 5.2×10^{-10}	O_4^+: 3.0×10^{-10}	...
1.1×10^{-6}	2.0×10^{-9}	1.1×10^{-9}	...

negative charged species				
e: 1.3×10^{-6}	O^-: 2.6×10^{-7}	O_2^-: 8.6×10^{-9}	O_3^-: 4.6×10^{-10}	...
1.0×10^{-6}	8.8×10^{-8}	5.9×10^{-10}	1.1×10^{-10}	...

Tab. 1: Calculated concentrations of most important species in pure oxygen plasma. First line: 60 Td, second line: 100 Td.

The three most important negative species were found to be electrons and negative oxygen ions both atomic and molecular; the most important positive particle is the molecular oxygen ion. Results shown in Tab. 1 were obtained for the zero concentration of argon in the mixture. With increasing concentration of argon the number of positive argon ions increases and Ar^+ ions become the most important positive particle. In the same manner increases the influence of electrons among negatively charged particles.

3. Plasma-solid interaction

The steady-state results, both experimental and computational, mentioned in previous section were used as input data for the basic part of our study, which was devoted to the description of the transport of charged species through the region of disturbed plasma near the substrate.

It is known that the role of negative ions in the formation of sheath region in the vicinity of metal substrate immersed into plasma is very important. The reason of this behaviour is, that the creation of sheath and presheath is influenced not only by charges of interacting particles but also by their masses. While the masses of the main positive particles (Ar^+, O_2^+ and O^+) are comparable, the masses of the basic negative species – electrons and O^- ions – differ profoundly.

Therefore, our basic model was devoted to the analysis of the role of negative ions in the sheath formation. The technique of simulation used was a hybrid particle simulation approach, i.e. the combination of molecular dynamics and Monte Carlo methods (so-called method PIC-MC). In reality, we prepared several models, which differ in the dimensionality and geometry – models were either one-, two- or three-dimensional in space and described interactions of electronegative plasma with planar, cylindrical or spherical substrates. All models are self-consistent, i.e. charged particles generate during their transport to the substrates local electric fields that influence their further movement. This approach is rather precise, however extremely time-consuming. Therefore some sophisticated techniques of computer simulation must be applied, as the introduction of variable statistical weights of particles depending on their positions, switching between several time scales or changing the numbers of particles during the simulation.

All models are based on similar assumptions. Charged particles originate in undisturbed O_2/Ar plasma consisting of most important positive and negative species shown in Tab. 1. The number of species differs according to the purpose of modelling – for the study of sheath formation only the most important species, where the most of the charge is concentrated, are introduced (negative: electrons and O^- ions, positive: Ar^+ and O_2^+ ions). For the detailed analysis even the species with lower concentrations can be taken into account. Trajectories of charged particles were calculated by the combination of deterministic molecular dynamics method, when the equations of motion were solved by the Verlet algorithms. The scattering of charged particles by neutrals was treated by stochastic Monte Carlo method. The mean free paths for individual interactions were obtained from experiments [6] and their energy dependences were compensated by the null-collision technique. The types of interactions introduced into models were elastic scattering, charge transfer, excitation and ionisation. The input physical data for simulation were taken from the oxygen/argon dc glow discharge - pressure 133 Pa, ion and gas temperature 300 K, electron temperature between 20,000 and 30,000 K, time step for the Verlet algorithm given by the movement of electrons 10^{-11} to 10^{-12} s.

4. Results

Most of simulations were made for planar configuration, as this geometry corresponds to typical technological arrangement. In this case a simplified one-dimensional model can be used. The second analysed configuration was cylindrical, which can be studied either one- or two-dimensionally. As a result the distribution of electric potential in the sheath and presheath region was derived. The simulation enabled us to observe the changes in energy distribution functions of both electrons and ions during their transport through the sheath, to calculate the fluxes of charged particles and to derive energies of impinging particle on the surface of substrate. These results can be used in the study of plasma chemical technologies as plasma oxidation of metals.

The modelling was performed both in static and dynamic regimes. In static regime, when only steady state results are important, the simulation can be accelerated by introducing various time steps for electrons and ions. In order to study the influence of negative ions on the plasma properties near the substrates of immersed solids, the relative concentrations of these ions were changed as a parameter of modelling. While in real situation the concentrations of negative ions represent maximally several tenths of the total negative charge, our model parameter varied in the whole range from 0 to 100 %.

In Figs. 2 to 4 some results of simulations are presented – the distribution of electric potential in the sheath region (Fig. 2), concentrations of individual charges species in the distance *x* from the substrate (Fig. 3) and velocity and angular distributions of both electrons and ions near the substrate (Fig. 4, the solid lines denote theoretical Maxwell distributions).

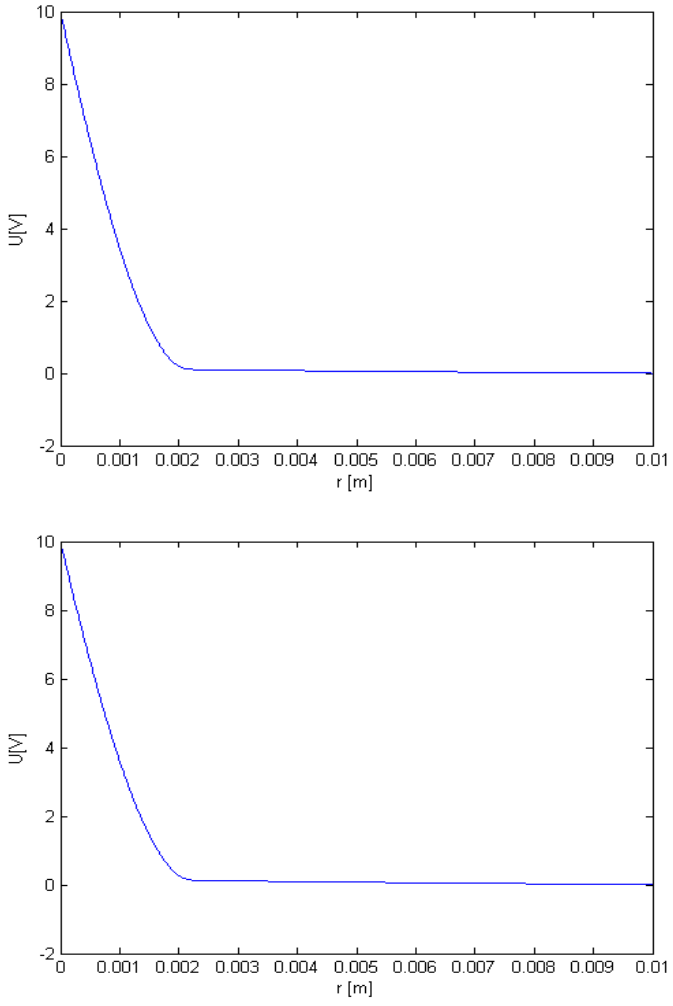

Fig. 2: Distribution of electric potential *U(x)* near the positively biased electrode for various relative concentrations of negative ions *c*. Relative concentration of negative ions 10 % - upper part, 20% - bottom part.

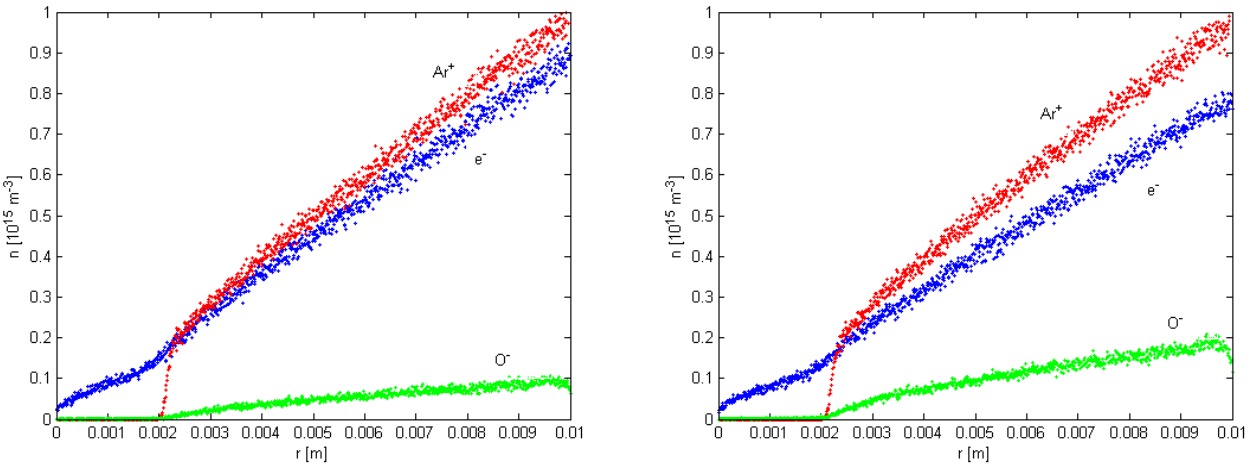

Fig. 3: Spatial distribution of concentrations of most important charged species *n(x)*.
Relative concentration of negative ions 10 % - left part, 20% - right part.

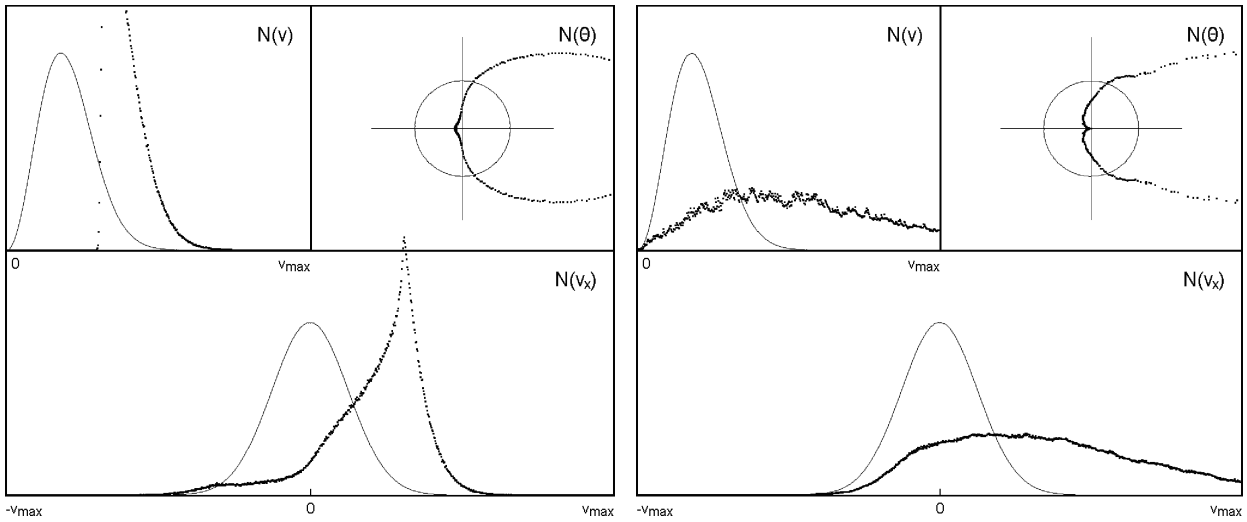

Fig. 4: Distributions of negatively charged particles impinging substrate – electrons (left) and ions (right).
Parameters: voltage bias +5 volts, relative concentration of negative ions 10 %.

5. Discussion

The presence of negative ions influences profoundly the properties of the sheath region, the transport of charged species from the plasma to immersed substrates and as a consequence all technological processes based on the application of electronegative plasmas. However, the different behaviour of electrons and negative ions can be demonstrated in the best way in dynamic regime, e.g. during application of step voltage bias or at higher frequencies. The most remarkable results can be obtained when the electric field in the vicinity of metal substrates reverses its sign and the space charge trapped in the sheath is suddenly released [7].

During the simulation there were observed some discrepancies in the role of negative ions during sheath formation derived by computer simulation compared to theoretical considerations. In order to clarify these differences another simulation of fundamental processes in plasma is now being performed and the first results will be published soon.

Deposition of hydrocarbon films by means of helium-ethylene fed dielectric barrier discharges

F. Fanelli, R. d'Agostino, F. Fracassi

Department of Chemistry, University of Bari, Istituto di Metodologie Inorganiche e Plasmi - CNR, Bari, Italy

Abstract
The present work provides a detailed study of helium-ethylene glow dielectric barrier discharges. Particular attention has been given to different process parameters in order to clarify both discharge operational mode and coating properties. The effect of ethylene concentration, total gas flow rate, excitation frequency and applied voltage have been investigated. It has been observed that a polyethylene-like coating can be obtained with deposition rates ranging between 20 and 80 nm min^{-1}.
Keywords: glow dielectric barrier discharge, ethylene, deposition

Introduction

In recent years glow dielectric barrier discharges (GDBDs) have received an increased attention since they appear to be a promising alternative to low pressure plasmas for surface processing of materials even though, due to the quite restrictive conditions under which stable and homogeneous discharges can be obtained, an adequate process control is not available so far. Efforts are in progress to evaluate the utilization of this non-equilibrium plasma technique for surface modification of materials and for this purpose the generation of homogeneous dielectric barrier discharges in several gases is under study [1-5]. Particular attention should be given to the influence of process parameters on the operational mode of the discharge and to the fact that the addition of a reactive monomer to the feed gas, as it is required in deposition processes, can drastically affect discharge stability and behaviour.
Our study aims to contribute to this thematic by providing a detailed exploration of helium-ethylene fed glow DBDs in order to clarify both discharge behaviour and coating properties.
Plasma enhanced chemical vapour deposition (PECVD) of hydrogenated amorphous carbon (a-C:H) thin films at low pressure have been widely studied utilizing several monomers. A good process control, which allows to obtain deposits with defined characteristics, such as hydrogen concentration and Csp^3/Csp^2 ratio, has been achieved [6-9]. Interesting results have been reported since 70's; for instance in 1974 Kobayashi *et al.* [10] studied the plasma polymerization of ethylene and they obtained a polymer-like coating (high hydrogen content). The results were exploited to raise the hypothesis of a free-radical polymerisation mechanism that mainly occurs in the gas phase.
One of the first investigations of atmospheric pressure deposition in hydrocarbons containing discharges has been published in 1979 by Donohoe and Wydeven [11]. The polymerisation of ethylene diluted in He in an uniform atmospheric pressure pulsed discharge was described. In this pioneristic work a soft polymer with a low cross-linking degree was obtained. The polymerization of ethylene in He containing atmospheric pressure glow discharges (APGDs) has also been studied by Yokoyama *at al.* [12]. A polyethylene-like film similar to those deposited with low pressure PECVD was obtained. Many other studies concerning the hydrocarbon deposition in DBD have been reported in the scientific literature, and frequently also in a filamentary discharge regime [13-19].
In the present work the results of a-C:H thin film deposition in GDBD fed with helium-ethylene are reported. The effect of ethylene concentration, residence time inside the discharge and input power have been investigated. The discharge has been characterized by means of electrical measurements and optical emission spectroscopy. In order to obtain indications on the reactive fragments generated inside the discharge, the stable species contained in the gas effluent have been sampled and analysed using gas chromatography with mass spectrometry detection. The coatings has been characterized by means of XPS and FT-IR.

Experimental

The experimental apparatus consists of a parallel plate electrode system (5 mm of interelectrodic gap) contained in a Plexiglas box, each electrode (3 x 3 cm^2 area) is covered by a 0.6 mm thick Al_2O_3 plate (CoorsTek, 96% purity). The plasma is generated by means of an AC high voltage (HV) power supply, composed by a variable frequency generator (TTi TG215), a linear amplifier (Outline PA4006) and a high

voltage transformer (Montoux). The excitation frequency (f) can be changed in the range 0.5 kHz – 30 kHz and the applied voltage can be raised up to 10 kV_{rms}.
The discharge was fed with He-C_2H_4 mixtures (Airliquide, Helium C, Ethylene N35), the gas flow rates were controlled by MKS mass flow controllers. Feed gas was introduced in the interelectrodic zone through a slit and is pumped through a second slit positioned on the opposite side.
The electrical characterization of the discharge was performed with a digital oscilloscope (Tektronix TDS2014). The voltage applied to the electrodes was measured by means of a high voltage probe (Tektronix P6015). The discharge current (I_m) was evaluated by measuring the voltage drop across a 50 Ω resistor connected in series with the grounded electrode.
Optical emission spectroscopy was performed in the UV-Vis region using an Optical Multichannel Analyser (OMA) equipped with a monochromator (0.300 m focal length imaging monochromator SP-300i ACTON, 1200 g/mm grating) and a CCD intensified detector (SpectruMM^{TM} 100B, Princeton Instruments).
A stainless steel liquid nitrogen trap, located between the reactor and the rotary pump, allows to sample the stable species contained in the exhaust gas. The sampling was performed for three hours, then the trap was isolated and the condensate dissolved in nonane (Aldritch, 99+% purity) and analysed using gas chromatography with mass spectrometric detection. The GC apparatus (GC 8000^{Top} Thermoquest Corporation) is equipped with an J&B DB-1 capillary column (polydimethylsiloxane 0.25 μm thick stationary phase, length of 30 m, i.d. of 0.25 mm) and with a quadrupole mass spectrometer (Voyager, Finngan, Thermoquest Corporation). Mass spectra were recorded in the m/z range 15 – 500 u.m.a. at the standard ionizing electron energy of 70 eV. The products were identified by means of available libraries [20].
The chemical characterization of the coating was carried out by means of XPS analyses, performed with a PHI ESCA 5300 with non-monochromatic Mg K_α radiation (1253.6 eV), and by FTIR (Bruker Equinox 55 spectrometer) analyses of film deposited onto CaF_2 substrates. Film thickness was measured on substrate partially masked during deposition using an Alpha-Step® 500 KLA Tencor Surface profilometer at different positions inside the interelectrode gap (in the region 10 – 20 mm from the gas entrance inside the discharge area), i.e. as a function of gas residence time. In order to compare the results obtained under different experimental conditions, the average value of the deposition rate ($r_{d\ av}$) has been considered; at each experimental point an error bar corresponding to the minimum and maximum values of the measured deposition rate has been associated.
The experimental conditions utilized for the study are listed in table 1.

f (kHz)	V_a (kV_{pk-pk})	φ_{He} (slm)	$\varphi_{C_2H_4}$ (sccm)	[C_2H_4] (%)
20	2.8	2	2 –10	0.1 – 0.5
20	2.8	2 – 5	10 – 25	0.5
10 - 30	2.8	2	10	0.5
20	2.8 – 4.0	2	10	0.5

Table 1. Process parameters for GDBD in helium-ethylene mixtures

Results
The electrical characterization of the discharge has shown that microdischarges appears for excitation frequency lower than 9 kHz, whatever the concentration of ethylene in helium is. However, if the frequency is higher than 10 kHz a periodical discharge current signal can be observed up to 0.5 % of ethylene in the gas feed. Figure 1 shows that the current is periodical with the same period of the applied voltage and it is formed by only one peak per half cycle, as for a typical current signal of a GDBD in helium [4]. The higher the ethylene concentration, the higher the breakdown voltage and the discharge peak amplitude.
Moreover, the discharge current is formed by only one peak per half-cycle only if the applied voltage is lower than 3.4 kV_{pp}, while for higher values of the applied voltage, secondary current peaks appear in addition to the principal intense one (figure 2). The periodicity of the current signal and the individual current pulse duration suggest that the discharge is still homogeneous, even though it operates with successive breakdowns during a single half cycle. These multiple current pulses usually are produced when the applied voltage exceeds the breakdown voltage [21, 22].

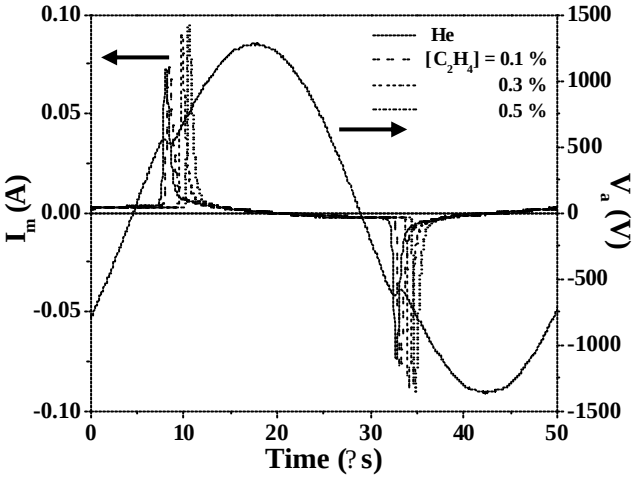

Figure 1. Applied voltage and measured current waveforms for pure helium and for three different ethylene concentrations (f = 20 kHz, V_a = 2.8 kV_{pp}, $[C_2H_4]$ = 0.1, 0.3, 0.5 %)

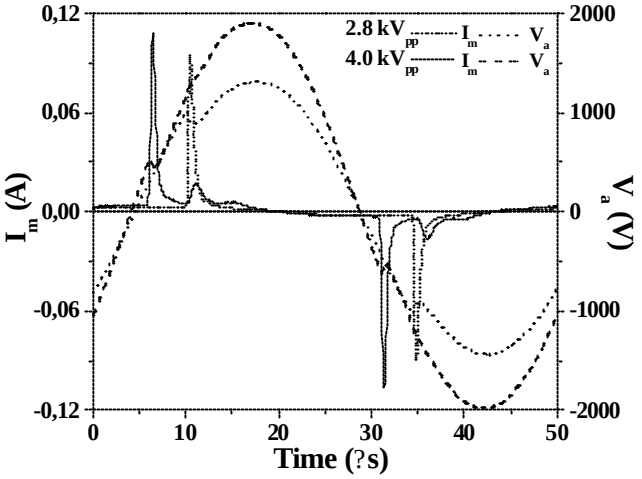

Figure 2. Applied voltage and measured current waveforms for two different values of the applied voltage (f = 20 kHz, V_a = 2.8 kV_{pp} and 4.0 kV_{pp}, $[C_2H_4]$ = 0.5 %).

As expected, as a consequence of the gas injection system the thickness of the deposit increases as a function of the distance from the gas admission (i.e. of residence time of the gas) inside the discharge area (figure 3). By increasing the frequency, i.e. the number of current pulses per unit of time, a linear growth of the discharge power can be observed together with a linear increase of the deposition rate from 20 nm min^{-1} up to 80 nm min^{-1} (figure 4). On the other hand by increasing the voltage at fixed excitation frequency, i.e. the energy per each half cycle, an approximately linear growth of the power density and a less pronounced increase of deposition rate is observed (figure 5).

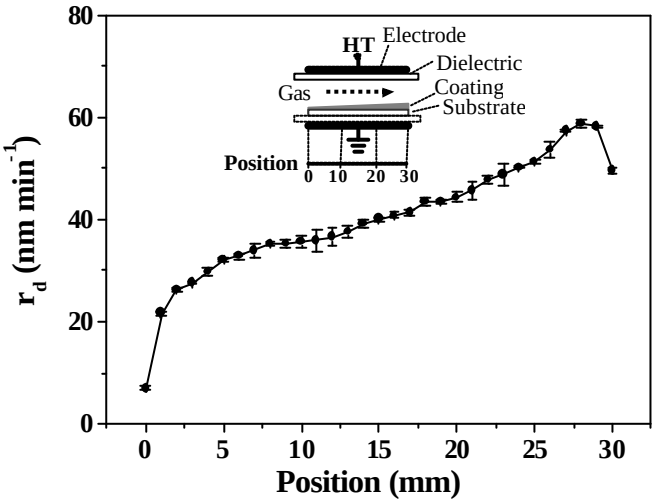

Figure 3. Schematic of the electrode system and typical deposition rate profile as a function of the position in the discharge area (f = 20 kHz, V_a = 2.8 kV_{pp}, φ_{He} = 2slpm, $\varphi_{C_2H_4}$ = 10 sccm, $[C_2H_4]$ = 0.5 %,)

Figure 6 shows the normalised FTIR absorption spectra of the deposits as a function of excitation frequency. The main spectral feature is the broad band between 3000 and 2800 cm^{-1}, due to CH stretching vibration modes and the two signals between 1480 and 1370 cm^{-1} due to CH_2 and CH_3 bending. Any olefinic CH signal can be observed. The intensity and the structure of the CH stretching band are consistent with an amorphous, weakly cross-linked and polymer-like structure with mainly hydrogen bonded to sp^3 carbon [6,

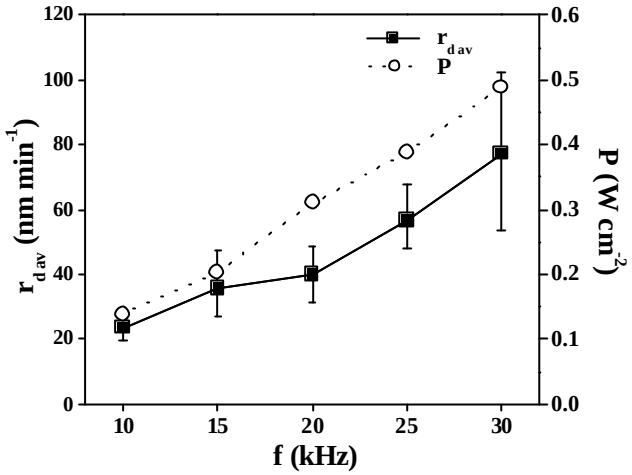

Figure 4. Deposition rate and discharge power as a function of frequency at a fixed applied voltage of 2.8 kV_{pp} ([C_2H_4] = 0.5 %).

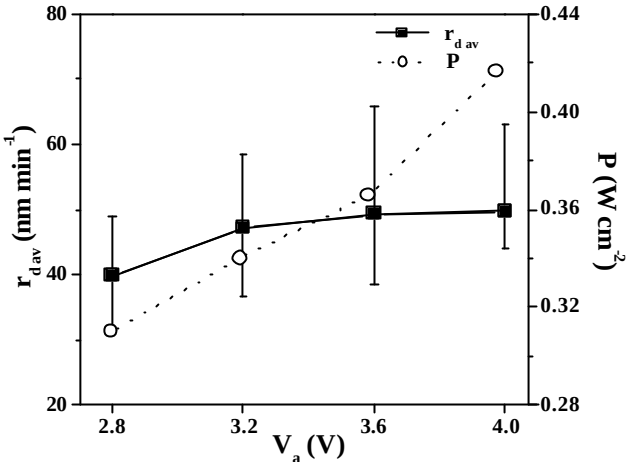

Figure 5. Deposition rate and discharge power as a function of applied voltage at a fixed frequency of 20 kHz ([C_2H_4] = 0.5 %).

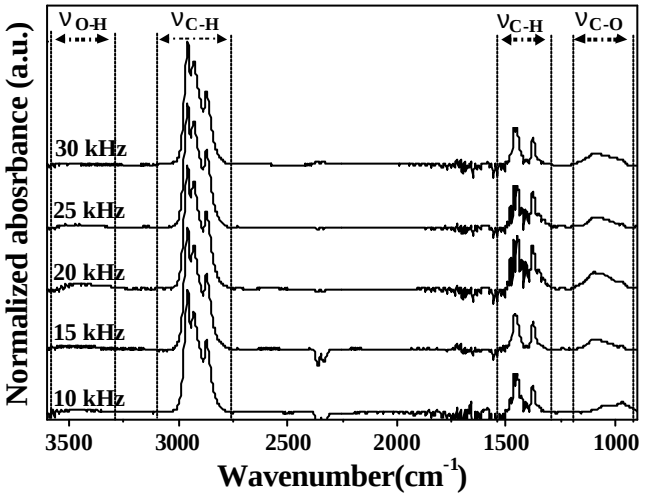

Figure 6. Normalized absorbance FTIR spectra of films deposited as a function of frequency (V_a = 2.8 kV_{pp}, [C_2H_4] = 0.5%).

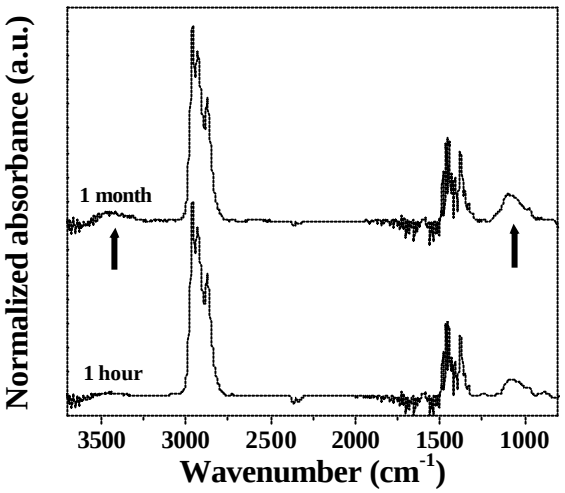

Figure 7. Normalized absorbance FTIR spectra of films deposited as a function of storage time (f = 20 kHz, V_a = 2.8 kV_{pp}, [C_2H_4] = 0.5%)

23-26]. Some oxygen is also contained in the coating in form of OH (3450 cm^{-1}) and C-O (1090 cm^{-1}) groups [24, 26]. These functionalities are due to O_2 and H_2O contaminations in the Plexiglas box, which generate oxygen containing groups during the deposition process, and/or to coating oxidation after atmosphere exposure. The FTIR spectra of figure 6 show that the chemical characteristics of the coatings is not appreciably affected by frequency variation; XPS analyses, on the other hand, show that oxygen concentration is lower than 3 % for all the experimental conditions explored.

In order to investigate the stability of the coating the FTIR analysis of a coating obtained at 0.5% C_2H_4, 20kHz and 2.8 kV_{pp} has been repeated after one month of storage in ambient air. Only a slight increase of the OH and C-O bands have been detected with respect of the as deposited film (figure 7). The oxygen uptake due to ageing is confirmed by comparing the XPS spectra performed after 1 hour and 1 month from deposition: the concentration of atomic oxygen increases from 0.8 % up to 2.5 %.

Optical emission spectroscopy investigation have been carried out in order to identify the main emitting species. For this purpose the emission of helium plasma has been compared with that of helium-ethylene plasma. He GDBD is characterized by intense emissions originated from helium and impurities i.e. nitrogen, oxygen and water; among contaminants, N_2^+ emission at 391 nm resulted the most intense. After ethylene addition to the feed gas, the total emission intensity of the spectrum decreases, the emissions of impurities

are drastically reduced (e.g. the emissions of oxygen containing species completely disappear for all ethylene concentrations) and the CH (4300Å system) and C_2 (Swan system) emissions appear.
Figure 8 shows a typical chromatogram of by-products sampled with the cold trap. The concentration of by-products is always very low and it is not affected by the experimental conditions. Several saturated and unsaturated hydrocarbons have been sampled, however butane is the most abundant specie.

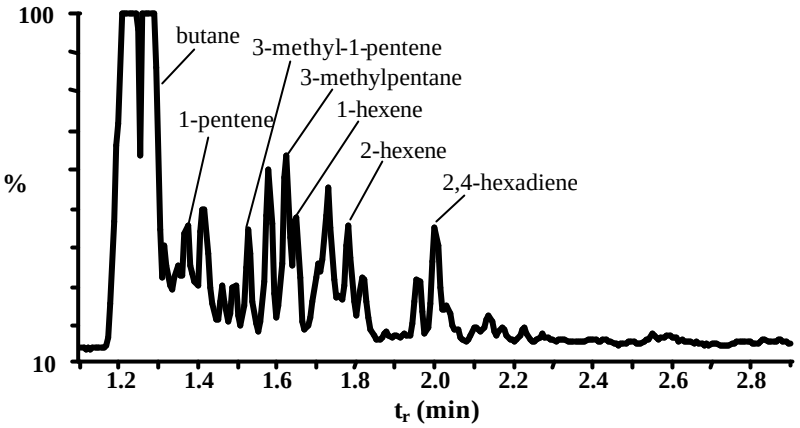

Figure 8. Typical gas-chromatogram of exhaust (f = 20 kHz, V_a = 2.8 kV_{pp}, $[C_2H_4]$ = 0.5 %, φ_{He} = 2slpm, $\varphi_{C_2H_4}$ = 10 sccm, sampling time = 3h).

Conclusion

The results shown in previous section allow to state that it is possible to deposit thin hydrocarbon films in a glow dielectric barrier discharge regime with good control of process parameters. In helium-ethylene GDBD the deposition of a soft polymer-like coating occurs and the high content of sp^3 carbon indicates the strong reactivity of the double bond present in the ethylene structure.
The oxygen uptake observed can be ascribed to contaminations in the discharge and/or to post-deposition reactions with atmospheric oxygen or water. It has been observed that by increasing the total gas flow rate, i.e. by reducing the gas residence time, the oxygen content of the coating can be reduced. The moderate ageing of the coating, evaluated with the oxygen uptake during storage indicate that the coatings are quite stables and do not contain high quantities of reactive species.
Since any evidence of powders formation has been obtained it is possible to suppose that the contribution of gas phase reaction to the polymerization process is quite low and that gas-surface reaction plays the major role. The results of GC-MS investigation and in particular the low concentration of by-products support this hypothesis, in fact only butane, derived from ethylene dimerisation, is formed in appreciable quantity.
Further investigations will be carried out for a better comprehension of the deposition mechanism.

Effects of the spraying parameters on the evaporation of the sprays in radio frequency inductively coupled plasmas

Yanguang Shan, Javad Mostaghimi

Centre for Advanced Coating Technologies
Department of Mechanical & Industrial Engineering, University of Toronto, Canada

Abstract
A spray model was developed to study the effects of the spraying parameters on the evaporation and transportation of liquid spays in a 20.0 kW plasma torch. The heights that the spray can reach in the torch were predicted for a variety of spray parameters and hydrocarbon liquids. It was found the increase of the spray cone angle increases heat transfer between the spray and the plasma. The height of complete evaporation for liquid sprays increases with the increase of the liquid mass flow rate and droplet size.
Keywords: Spray model; liquid sprays; evaporation and transportation; inductively coupled plasma

1. Introduction

The trend in plasma synthesis and deposition processing has been that of the increasing use of the radio frequency inductively coupled plasma (RF-ICP) and the liquid or solution precursors. The radio frequency inductively coupled plasma has relatively large volume, lower plasma velocity, and more uniform temperature distribution. It allows better process control and axial material injection. In solution plasma spraying and thermal plasma chemical vapor deposition, liquid precursors are injected into the radio frequency inductively coupled plasma along the axial direction via a spray, where exposure to high temperatures makes them evaporate, decompose and react, and then form a hard coating/film onto a solid substrate. Wilden *et al.* [1] and Bouyer *et al.* [2] deposited silicon carbide (SiC) film by feeding different liquid precursors into a radio frequency inductively coupled plasma reactor. The properties of the sprayed or deposited coatings or films are extremely sensitive to process parameters. These include the torch operating conditions, droplet size distribution of the spray, the spray trajectory and evaporation within the discharge, species diffusion and reaction, substrate position and temperature. To get better quality coatings or films, it is necessary to understand the effect of these spraying parameters on the spraying process.

2. Models

A typical RF-ICP torch geometry is schematically shown in Fig.1.The model used here is an extension of the model developed by Mostaghimi [3]. The plasma was assumed to be in local thermodynamic equilibrium state, laminar and incompressible flow, 2-D axi-symmetric and optically thin. Both displacement currents and viscous dissipation effects were neglected. The time-dependent equations governing the conservation of mass, momentum, and energy along with the vector potential form of Maxwell's equations were solved simultaneously to get the temperature and flow fields of the plasma.

$$\frac{D\rho}{Dt} + \rho\nabla\cdot\vec{u} = S_c^s, \tag{1}$$

$$\rho\frac{D\vec{u}}{Dt} = -\nabla P + \nabla\cdot\mu\nabla\vec{u} + \vec{j}\times\vec{B} + \vec{S}_m^{\,s}, \tag{2}$$

$$\rho\frac{Dh}{Dt} = \nabla\cdot k\nabla T + \vec{j}\cdot\vec{E} - Q_R + S_E^{\,s}, \tag{3}$$

$$\rho\frac{DY}{Dt} = \nabla\cdot D_{AB}\nabla Y + S_c^{\,s}. \tag{4}$$

$$\mu_0\sigma\frac{\partial A_R}{\partial t} = \nabla^2 A_R - \frac{A_R}{r^2} + \mu_0\sigma\omega A_I, \quad (5)$$

$$\mu_0\sigma\frac{\partial A_I}{\partial t} = \nabla^2 A_I - \frac{A_I}{r^2} - \mu_0\sigma\omega A_R, \quad (6)$$

where ρ is the plasma density, t is time, P is pressure, μ is the viscosity, k is the thermal conductivity, D_{AB} is the diffusion coefficient , h is the enthalpy, T is the temperature, $\vec{u}$ is the velocity vector, Y is the vapor mass fraction, $\vec{j}$ is the current density vector and $\vec{j} = \sigma\vec{E}$, σ is the electrical conductivity, $\vec{B}$ is the magnetic induction, $\vec{E}$ is the electric field intensity, Q_R is the volumetric radiative loss, S_c^s, S_m^s, and S_E^s represent source terms due to plasma-spray interaction effects [4]. μ_0 is the permeability of free space. A_R and A_I are the real and imaginary parts of the vector potential, respectively. Details of the source terms and the initial and boundary conditions of this model can be found in Ref. [4].

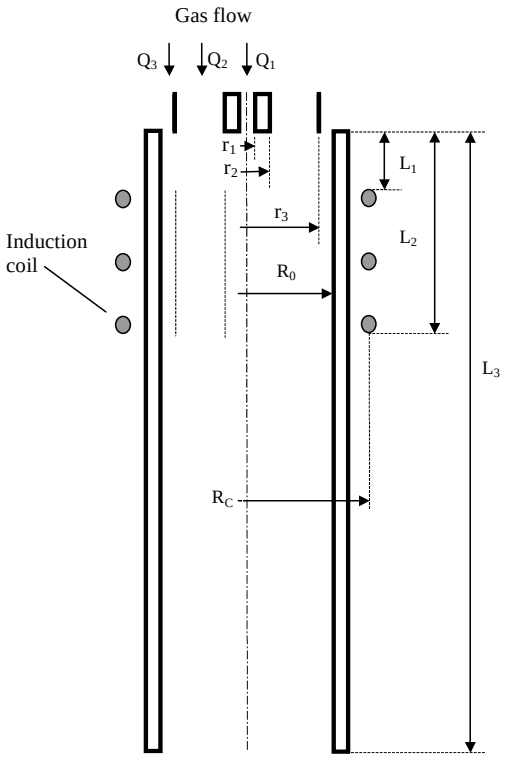

Figure 1 Torch geometry

The evolution of the spray was obtained by solving the spray equation [5]

$$\frac{\partial f}{\partial t} + \nabla_{x_i}\cdot(f\phi_i) = \dot{f}_{coll}, \quad (7)$$

where f is droplet probability distribution function, $\dot{f}_{coll}$ is the source term due to droplet collisions, x_i represents $\vec{x}, \vec{v}, r_d, T_d$, ϕ_i represents $\vec{v}$ $\vec{F}$, R, and $\dot{T}_d$, which are time change rates of velocity, radius and temperature for an individual droplet. $\vec{x}$ is the droplet position, $\vec{v}$ is the droplet velocity, r_d is the equilibrium radius of droplet, T_d is the droplet temperature which is assumed to be uniform within the droplet. The trajectory and evaporation model for an individual droplet is given in the Ref [4]

The droplet collisions calculation was performed for a pair of droplets if, and only if, they are in the same computational cell. Two types of collisions are accounted for. If the collision impact parameter b is less than a critical value b_{cr} the droplets coalesce, if b exceeds b_{cr} , the droplets maintain their sizes and temperatures but undergo velocity changes. The details for the calculation of droplet collisions were given in Ref. [5].

The spray model was implemented into the plasma model. The plasma phase was solved using SIMPLER method [6]. A stochastic Monte Carlo technique combined with the discrete particle method was used to determine the characteristics of the spray and the interactions between the spray and the plasma gas, as well as the droplet collisions within the spray [4, 5].

3. Results and discussion

The torch geometry and typical operating parameters of the ICP are listed in Table 1. All symbols in Table 1 correspond to those of Figure 1. First, the water spray was used in the calculations. A spray parametric study was followed. These parameters include: the liquid mass flow rate, the droplet size distribution, the spray cone angle,

and the injection velocity. The evaporation and the collisions of hydrocarbon spray droplets in plasma are also predicted. For the poly-disperse spray, the x-squared droplet size distribution with a 15.0 μm SMD (Sauter Mean Diameter) was used (Fig. 2). Droplets are introduced into the plasma from random positions behind the exit of the center tube of the torch. Droplet collisions model was turned off unless indicated.

Table 1 Torch geometry and typical operating parameters.

r_1: 0.5 mm	R_0: 25.0 mm	L_2: 74.0 mm	Inlet swirl:20.0 m/s	Q_1 (Ar): 3.0 L/min

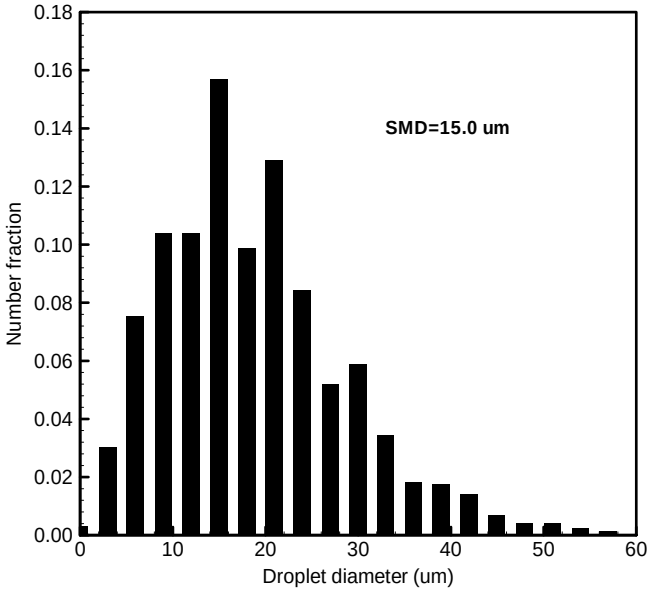

Figure 2 Droplet size distribution with SMD=15.0 μm.

3.1 Plasma fields and the spray evolution

Figure 3 shows the predicted quasi-steady state temperature, flow, and concentration fields of the plasma with the spray pattern. Very large gradients are evident. It can be seen that the plasma is cooled locally along the spray region. The droplets of the spray are delivered to downstream by the plasma gas. As the spray travels through the plasma, it evaporates and the vapor diffuses into the plasma gas.

3.2 The effect of the liquid mass flow rate on the spray evaporation

In this case, the liquid was injected into the plasma at mass flow rates of 1.0g/min, 3.0g/min, and 5.0g/min, respectively. The spray was poly-disperse with SMD=15.0 μm. The initial velocity of the injected droplets was 15.0 m/s. The spray cone angle was 15.0°. The maximum height where the spray completely evaporates in the plasma torch was recorded. The model predicts that a poly-disperse spray with a 7.5 μm SMD survives 108.5 mm, 117.1 mm, and 127.9 mm at liquid mass flow rates of 1.0 g/min, 3.0 g/min, and 5.0 g/min, respectively. As expected, since the increase of the mass flow rate leads to an increased cooling of the plasma, the height of complete evaporation of the spray in the plasma increases with the increase of the spray mass flow rate.

3.3 The effect of the spray cone angle on the spray evaporation

The liquid was injected into the plasma with different spray cone angles (0°, 15°, and 30°) at a 3.0 g/min mass flow rate. The other parameters were the same as those in section 3.2. The model predicts that a poly-disperse

spray with a 15 μm SMD survives 124.0 mm, 117.1 mm, and 114.9 mm at spray cone angles of 0°, 15°, and 30°, respectively. The height of complete evaporation decreases with the increase of the spray cone angle. It also shows that the effect decreases with the increase of the spray cone angle. This is because the increase of the spray cone angle leads to increased heat transfer between the spray and the plasma, but the droplets of the spray cannot penetrate into the high temperature region anymore when the spray cone angle reaches a certain value.

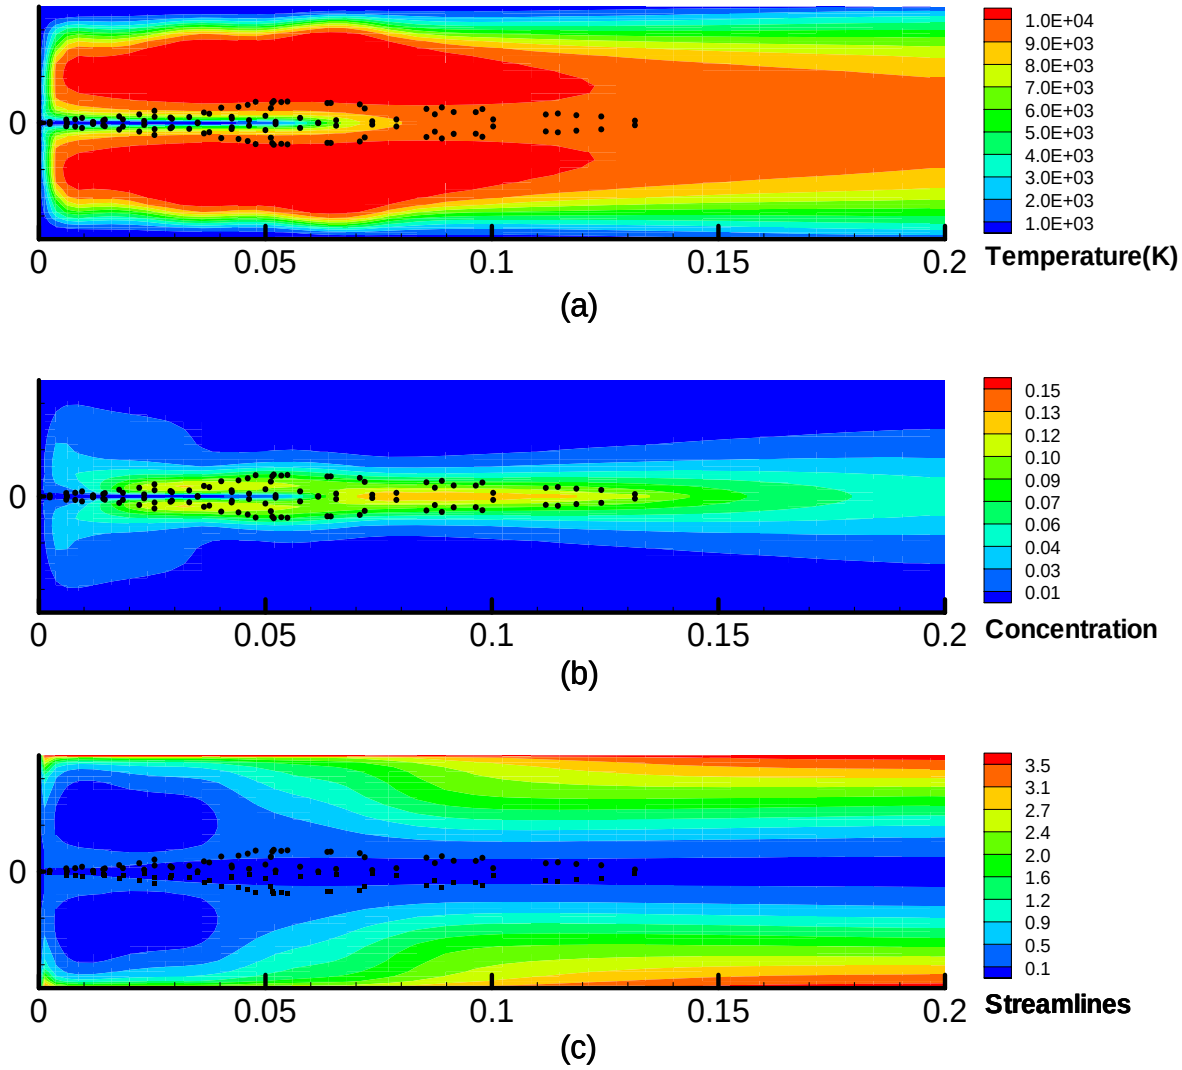

Figure 2: Plasma temperature, flow, and concentration fields with the spray pattern. (a) Temperature, (b) Vapor mass concentration, and (c) Normalized streamlines.

3.4 The effect of the injection velocity on the spray evaporation

The liquid was injected into the plasma with different initial velocities (5.0 m/s, 10.0 m/s, and 15.0 m/s) at a 3.0 g/min mass flow rate. The other parameters were the same as those in section 3.2. The model predicts that a poly-disperse spray with a 15 μm SMD survives 122.1 mm, 119.6 mm, and 117.1 mm at injection velocities of 5.0 m/s, 10.0 m/s, and15.0 m/s, respectively. Since the spray with a lower injection velocity leads to increased local cooling of the plasma than the spray with a higher injection velocity, the height of complete evaporation of the spray decreases with the increase of the injection velocity. However, if the injection velocity reaches such a value that the spray cannot obtain enough heat to evaporate, the height of complete evaporation of the spray will increase with the increase of the injection velocity.

3.5 The effect of the droplet size on the spray evaporation

The liquid was injected into the plasma with different Sauter mean diameters (10.0 μm, 15.0 μm, and 20.0 μm) at a 3.0 g/min mass flow rate. The other parameters were the same as those in section 3.2. The model predicts that the spray with a 10.0 μm SMD survives 103.4 mm, the spray with a 15.0 μm SMD survives 117.1 mm, and the spray with a 20.0 μm SMD survives 138.8 mm in the plasma, respectively. As expected, the height of complete evaporation of the spray increases with the increase of the Sauter mean diameter.

3.6 Modeling the evaporation of hydrocarbon sprays

The studies in previous sections were focused on the injection of water sprays into the radio frequency inductively coupled plasma. In thermal plasma chemical vapor deposition and hazardous liquid waste destruction technologies, hydrocarbon sprays are of great theoretical and practical importance. The injection and evaporation of several hydrocarbon sprays in the inductively coupled argon plasma was simulated in this section. Those hydrocarbon sprays are heptane (C_7H_{16}), dodecane ($C_{12}H_{26}$), and hexadecane ($C_{16}H_{34}$).

The hydrocarbon sprays were injected into the plasma at a mass flow rate of 3.0g/min. The spray was poly-disperse with SMD=15.0 μm. The initial velocity of injected droplets was 15.0 m/s. The spray cone angle was 15.0°. The droplet collision model was used to investigate the effect of droplet collisions on the evaporation of the spray. The results are shown in Table 2. The results in Table 2 show that droplet collisions in all cases lead to an increase in the height of complete evaporation for the liquid spray.

Table 2: The height of complete evaporation for hydrocarbon sprays in the plasma

Substances	The height of complete evaporation in the plasma	
	Without collisions	With collisions
Heptane (C_7H_{16})	57.5 mm	63.4 mm
Dodecane ($C_{12}H_{26}$)	64.3 mm	78.3 mm
Hexadecane ($C_{16}H_{34}$)	67.4 mm	77.2 mm
Water (H_2O)	117.1 mm	155.2 mm

4. Conclusions

A stochastic spray model was used to simulate the injection of liquid sprays into a 20 kW radio frequency inductively coupled plasma. The effects of spray parameters on the evaporation of liquid sprays were investigated. It was found that the liquid mass flow rate and the droplet size are the most important factors that influence the evaporation of the spray. The height of complete evaporation for liquid sprays increases with the increase of the liquid mass flow rate and droplet size. The increase of the spray cone angle leads to an increased heat transfer between the spray and the plasma. Droplet collisions may lead to an increase in the height of complete evaporation for the liquid spray. This model was also able to predict the evaporation and transportation of hydrocarbon sprays in the plasma under different operating conditions.

Abstract
A specific case of the nonequilibrium atmospheric pressure air jet (APAJ) plasma in the blowing arc discharge is studied by optical emission spectroscopy (OES). From relative intensities of atomic lines and molecular bands, the temperatures of excitation of electronic states of free atoms, T_E, and vibrational and rotational states of molecules, T_V and T_R, were determined in different conditions. It is found there is no local LTE in APAJ plasma during its space/time evolution, and effects of the strong non-isothermally, $T_E > T_V > T_R$, have a place.
Keywords: plasma chemistry, blowing arc discharge, air jet plasma, non-equilibrium, non-isothermality

1. Introduction

Spectroscopic characterization of the air plasma in electric discharges is of permanent interest in many labs because of various important applications in plasma chemistry [1]. From the optical spectra emitted by plasma one can deduced all basic plasma parameters and its state: composition of chemical elements (according to emitted lines), populations of excited atoms and molecules upon energetic levels (from the intensity of spectral lines), densities of charged and neutral particles (from the broadening of spectral lines), temperatures of excitation of atomic and molecular states (from the relative or absolute spectral intensities). The main condition is a correct use of spectroscopic diagnostics in every specific case, e.g. application of the approximation of the optically thin plasma in conditions of high pressure, approximation of plasma quasi-neutrality and approximation of the local thermodynamic equilibrium (LTE) in conditions of high non-isothermality when characteristic temperatures of different plasma components may be differenced within the relation: electron temperature $T_e >$ vibrational temperature $T_V >$ rotational temperature $T_R \geq$ translation gas temperature T_g [2].

The factor of non-izothermality has a fundamental importance for efficiency of plasma-chemical processes in reactive plasma. While most of the discharge energy goes into the mean energy of electrons and not just to the gas heating, it gives the desirable reactivity and selectivity of plasma-chemical transformations [3]. Among possible types of nonequilibrium discharges: spark, corona, barrier, etc [4] which can produce non-thermal plasmas at high atmospheric pressures, one specific case is very interesting for us. This is a transverse arc in a blowing flow with a stationary current column or with a rotating one in a vortex flow. It is an intermediate case of the high-voltage low-current self-sustained discharge with a self-adjustable arc supported by the plasma flow [5]. It differs from the non-stationary gliding arc of Czernichowski type [6] by the fixed arc length. It also has a convective cooling of the plasma column by airflow but without conductive heat losses at the walls since this is a free arc jet. An intensive transverse ventilation of the arc plasma increases its ionization non-equilibrium and non-isothermality [7]. The blowing arc was tested successfully in different variants with the primary and secondary discharges in our current investigations in Kiev University for the plasma processing of various homo- and hetero-phase gaseous and liquid substances [8-9]. However, despite of achievements in practical applications, there are still enough issues for research. One of the main points is a mechanism of the transition from the quasi-equilibrium to non-equilibrium, i.e. from the thermal to non-thermal ionization.

In this work, we present results of our spectroscopic characterization of the air plasma in the transverse blowing arc discharge at atmospheric pressure conditions in order to determine the level of plasma non-isothermality and get more deep understanding in physics of non-equilibrium processes in such discharge.

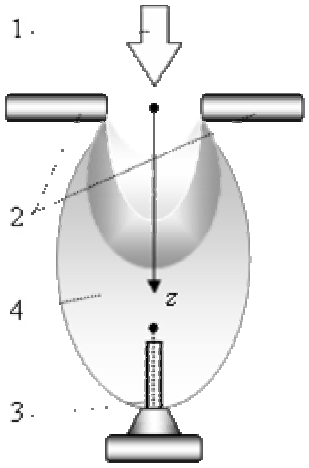

Fig.1. Scheme of the transverse blowing arc discharge: 1 is an air nozzle, 2 are the electrodes, 3 is the probe, 4 is the air plasma jet.

2. Experimental Methodology

Experiments were done for a scheme of the transverse blowing arc as shown in Fig.1. A free air jet ran from the nozzle top-down across two opposite electrodes where the discharge was burned and formed a bright crescent-shaped electric arc as well as a highly reactive plasma afterglow. We used the rod electrodes with diameter d = 6 mm. A nominal gap between electrodes from which we started was δ = 1 mm. Since electrodes were not cooled, the electric discharge energy was transferred totally to the air plasma. We applied electrodes made from the copper and graphite in order to see a spectroscopic difference. The air nozzle was axisymmetric, with the inner diameter $\varnothing$ = 1 mm, made from the stainless steel. It was installed vertically perpendicular to the electrode axis at the nominal length L= 20 mm and centered between electrodes. We used a standard technical air system supply with the flow controller. It was a high enough gasdynamic pressure in the airflow to blow out the electric arc downstream. In fact, we can regulate the arc discharge geometry as by the gap δ between electrodes and by the length L between the nozzle exit and electrodes. The last allows to control both the air blowing of the arc and the air cooling of electrodes. Then, we can regulate the airflow rate, G, and discharge current, I_d, in order to vary a process. The discharge was powered by the HV DC source with a dropping output characteristics at the ballast resistance in the circuit. Current-voltage parameters were measured by the standard digital electronics. For optical diagnostics, a classic method of optical emission spectroscopy was applied. The plasma radiation was detected by two means: 1) portable rapid PC-operated CCD-based multi-channel optical spectrometer MOSA (F/5, 1200 l/mm grating, 3648-pixel array TCD1304AP) that provides a wide wavelength survey within 200-1100 nm with a spectral resolution 0.3 nm; and 2) spectral machine KSVU23, including the scanning monochromator MDR23, photomultiplier FEU100, ADC controller and PC recorder, which provided a high spectral resolution up to 0.01 nm within 200-800 nm but slow scan speed. Measurements were conducted in different cross-sections along the arc jet. Images were normally focused by the quartz lens at the bench 5-focus distance from the arc directly on the spectral device entrance slit (0.025x0.2 mm). In case of MOSA, a fine long UV optical fiber with the microlens focusing was used. The spatial pointing accuracy was about 0.1 mm. For calibration, the etalon spectral sources: mercury, deuterium, and tungsten lamps were applied. Within the available spectrum of UV-VIS-NIR wavelengths, we monitored all remarkable emissions and identified all basic atomic lines of N, O, H as well as molecular bands of NO, N_2, O_2, OH and other excited species, which we were able to recognize [10]. For temperature diagnostics, we utilized relative intensities of the analytical CuI lines (a product of the electrode emission) and OI lines in order to determine the temperature of electronic states of free atoms, T_E, and we used the N_2 $2^{(+)}$ bands (a dominating component of the plasma-forming gas) in order to determine the temperature of vibrational states of excited molecules, T_V, by the Ornstein method as a commonly accepted approach in the thermal plasma [11]. This method does not require a calibration but for accuracy it needs well-resolved spectral lines covering the maximum difference in energies. It is assumed that plasma is optically thin and spectral lines are not self-absorbed. The gas kinetic temperature T_g was derived from the temperature of rotational molecular states, T_R, that is, because of a non-resolved rotational spectral structure, determined by the comparison of the measured spectral profile of individual N_2 $2^{(+)}$ bands and the theoretical spectra calculated on the known molecular constants for the N_2 *E-V-R* transitions, assuming the Boltzmann population distribution and using the Gauss-like instrumental line shape function $\Delta\lambda$. The necessary spectroscopic data were taken from the databases [12-13]. Errors in measurements of the emissivity did not exceed ±30%, temperatures were determined with the uncertainty ±15%. In order to increase the accuracy of measurements in conditions of spatial/temporal instabilities of the burning arc, the procedure of statistical averaging was performed. The min. exposure time was 7 ms, time between scans was 1 μs, max. signal accumulation time was 4 s. On this base, we draw the curves of changes of the specific emission intensities and characteristic temperatures along the plasma flow depending on the discharge current I_d and the airflow rate G. The overall studies were conducted within the range of variations I_d = 100-1000 mA and G = 20-220 cm^3/s at atmospheric pressure conditions.

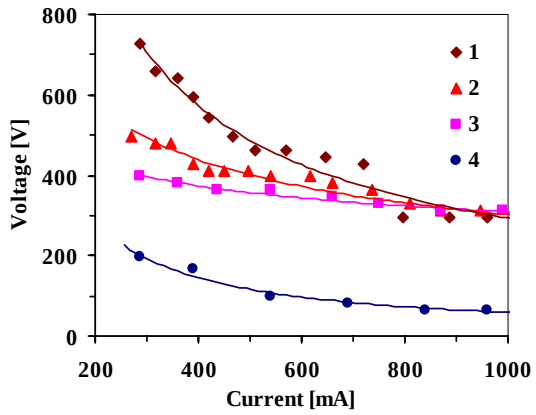

Fig.2. *I-V* curves of the blowing arc discharge in the air flow: G = 75 cm^3/s (curve 1), 40 cm^3/s (2), 20 cm^3/s (3), and 0 cm^3/s (4). P = 1 atm. Cu rod electrodes: d = 6 mm, δ = 1.5 mm, L = 20 mm.

3. Results and Discussions

A transverse arc discharge in the airflow was ignited with a high voltage at the shortest distance between the electrodes that corresponds to breakdown when the electric field reached ~3 kV/mm [4]. Under the action of the gasdynamic pressure of the incident air flow, the electric arc was forced to bow down and elongated along the stream, so that the current increased and the voltage dropped down a little bit. The air flow led not only to bending and to blowing of the arc current channel but also to stabilization of the plasma column due to the convective withdrawal of energy (radiative losses are neglected). Due to a high-speed flow, the air plasma jet had to be turbulized, and this additionally contributed to the suppression of the ionization-overheating instability in plasma. Thus, gas dynamics and convective heat mass transfer favored the steady arc burning.

Fig.2. shows the typical current-voltage characteristics of the transverse blowing arc discharge in comparison with the usual arc in air. As is seen, in the range of low currents the *I-V* curves have a dropping character as for the high-voltage discharges. It points out that the blowing arc has a self-adjusting length, and the current channel in the airflow is auto-stable despite of all visible non-uniformity and fluctuations in time and space. With the increasing airflow rate, the electric field strength increases. But in the range of high currents, the voltage becomes independent on the airflow rate. It is explained by the saturation of the carrying capacity of the electric arc in the discharge at the given geometry of electrodes.

Fig.3 shows a typical spectrum of the emission of the air plasma in the studied discharge as registered by MOSA (exposure time 20 ms). We see it is rich of spectroscopic information. We recognized here the nitride oxide NO γ-system ($A^2\Sigma^+$-$X^2\Pi$: (0-0) 226.3, (0-1) 236.3, (0-2) 247.1 nm, etc); nitrogen N_2^+ $1^{(-)}$ system ($B^2\Sigma^+_u$-$X^2\Sigma^+_g$: (0-0) 391.4, (1-0) 358.2, (1-1) 388.4, (0-1) 427.8 nm), N_2 $2^{(+)}$ system ($C^3\Pi_u$-$B^3\Pi_g$: (0-0) 337.1, (0-1) 357.7, (0-2) 380.5, (1-0) 315.9 nm, etc), and even weak N_2 $1^{(+)}$ system ($B^3\Pi_g$-$A^3\Sigma^-_u$: 570-750 nm). Among atomic lines, we identified hydrogen HI lines (Ballmer Hα 656.3, Hβ 486.1 nm), oxygen OI lines (777.3, 844.6, 926.0 nm), and nitrogen NI lines (746.8, 818.8, 868.3 nm). There are a lot of copper CuI lines due to the evaporation of electrodes (in case of graphite electrodes we saw nothing) but the strongest lines 324.7 and 327.4 nm are over-saturated, others are overlap with some N_2^+ $1^{(-)}$ and N_2 $2^{(+)}$ bands, so for diagnostics only CuI 510.5, 515.3, 521.8 and 578.2 nm were used. The choice of molecular bands for diagnostics was also optional because they were not always observed well. Thus, the interference of CuI lines and N_2 $2^{(+)}$ bands precluded the diagnostics of the OH $A^2\Sigma$-$X^2\Pi$ (0-0) bands at 306.4-308.9 nm. The appearance of the CN $B^2\Sigma^+$-$X^2\Sigma^+$ Violet bands at 388 nm and NH $A^3\Pi_i$-$X^3\Sigma^-$ UV band at 336 nm in the regime of high currents disturbed the diagnostics of nearby N_2^+ $1^{(-)}$ and N_2 $2^{(+)}$ bands. The NO γ-bands sometime were 3-5 times weaker. Therefore, the most results were obtained with the N_2 $2^{(+)}$ bands (0-0) 337.1, (2-4) 371.0, (1-3) 375.5, (0-2) 380.5, and (1-4) 399.8 nm. The band (1-4) was less intensive than the band (0-0) but it had a distortion-less spectral profile provided better *V-R* diagnostics.

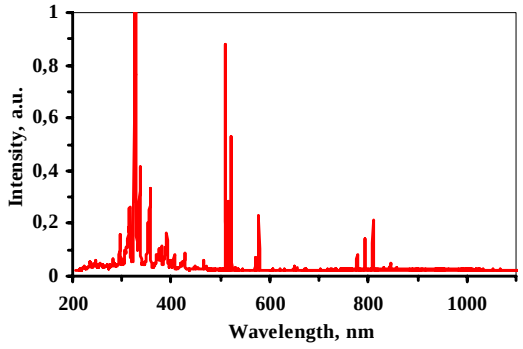

Fig.3. Emission spectrum of air plasma in the blowing arc discharge. P = 1 atm, G = 75 cm^3/s, U_d=0.6 kV, I_d = 400 mA, Cu electrode. z = 3 mm. $T_e \approx$ 0.7 eV; $T_V \approx$ 0.3 eV, $T_R \approx$ 0.1 eV.

A distinguishing feature of the plasma column in the transverse blowing arc discharge is their curvature along the flow, and so all dependencies of the emission intensities and spectral distributions in the plasma along the z-axe downstream are of non-linear character. Fig.4 shows typical dependencies of the emissivity I_λ(z) for the CuI line 510.5 nm in the discharge along the flow. Here, normalized curves 1-5 correspond to the airflow rates G = 40, 75, 110, 150, 190 cm^3/s and discharge current I_d = 200 mA. The absolute emissivity $I_{\lambda Cu}$ changes very much with

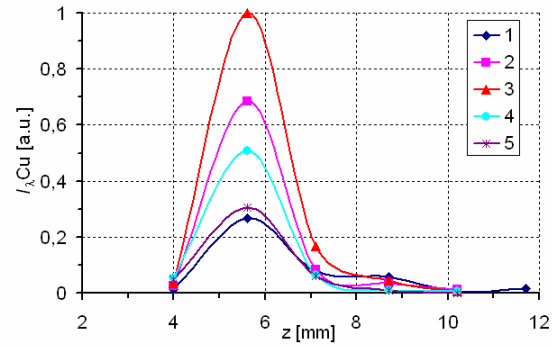

Fig.4. Emissivity of the CuI line 510.5 nm along the air plasma flow: G = 40 cm^3/s (curve 1), 75 cm^3/s (2), 110 cm^3/s (3), 150 cm^3/s (4), and 190 cm^3/s (5). I_d = 200 mA.

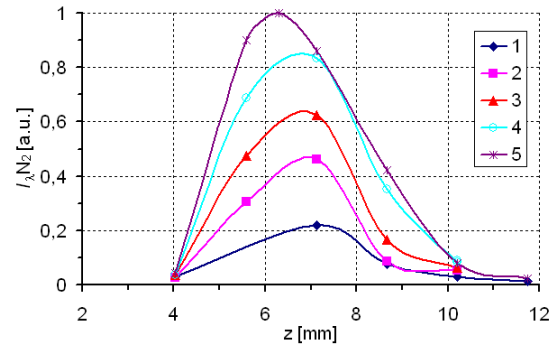

Fig.5. Emissivity of the N_2 $2^{(+)}$(0-0) band 337.1 nm along the air plasma flow: G = 40 cm^3/s (curve 1), 75 cm^3/s (2), 110 cm^3/s (3), 150 cm^3/s (4), and 190 cm^3/s (5). I_d = 200 mA.

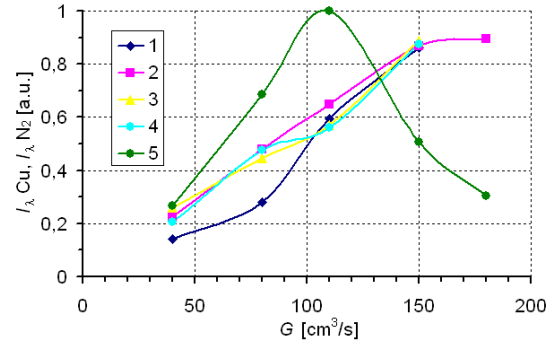

Fig.6. Emissivity of the N_2 $2^{(+)}$(0-0) band 337.1 nm (curves 1-4) and CuI line 510.5 nm (curve 5) vs. the airflow rate G. I_d = 100 mA (curve 1), 200 mA (2,5), 300 mA (3), and 400 mA (4). z = 5.5 mm.

the airflow rates G but the spatial position of its maximum I_λ^{max} at the distance z = 5.5 mm from the electrode axis and its longitudinal length $\Delta z \approx 2$ mm for all curves are almost constant. It tells about the quasi-stability of the arc current channel in the range of the used flow rates at the given arc discharge geometry. The observed effect of the "ignition" of the luminescence of electronically excited Cu atoms in the discharge plume tells about the overheating of electrons resulted from the kinetic non-equilibrium conditions in the gasdynamically moving and convectively cooling air plasma.

The distribution of the emission intensity of the N_2 $2^{(+)}$ head bands along the z-axe of the discharge also is non-monotonic character. Fig.5 shows typical dependencies of the emissivity $I_\lambda(z)$ for the N_2 $2^{(+)}$ (0-0) band 337.1 nm in the plasma along the flow. Here, normalized curves 1-5 also correspond to the airflow rates G = 40, 75, 110, 150, 190 cm^3/s and discharge current I_d= 200 mA. The comparison of longitudinal distributions $I_{\lambda Cu}$ and $I_{\lambda N2}$ in Fig.4 and Fig.5 tells that the $I_{\lambda N2}$ distributions are sufficiently larger and someway shifting downstream relatively to the $I_{\lambda Cu}$ curves. At the distance z = 10 mm the N_2 $2^{(+)}$ (0-0) emission is still visible, and taking into account the flow rate, we can estimate that the residence time of the excited species in the plasma flow is 0.5-2 ms. With above notes about the arc current channel and plasma dynamics, it evidences that the afterglow in this discharge is conditioned by the emission of electronically excited N_2 molecules.

With the discharge current I_d the absolute emissivity $I_{\lambda N2}$ 337.1 nm increased (by few tens percent) but it reacted more strongly (in direct proportion) to the increase in the airflow rate G. It is illustrated in Fig.6 by curves 1-4, taken at the distance z ≈ 5.5 mm for different values I_d = 100, 200, 300, 400 mA (see also Fig.5). In comparison with the almost linear dependence $I_{\lambda N2}(G)$, the dependence $I_{\lambda Cu}(G)$ is non-linear. This is clear shown in Fig.6 by the curve 5, given for the $I_{\lambda Cu}$ 510.5 nm at z ≈ 5.5 mm and I_d = 200 mA (see also Fig.4). The functional extreme of $I_{\lambda Cu}$ is obtained at G = 110 cm^3/s. Such behavior of the CuI emission can be explained by the fact that, on the one side, the increasing G at the fixed I_d should lead to the increase of the level of nonequilibrium of the air plasma due to the acceleration of the energy carry-over from the arc current channel, and therefore to the increase of the emissivity of Cu atoms. On the other side, with the increasing of the air flow and air-cooling, the erosion of electrodes and therefore the emission of Cu atoms decreased.

On the base of the measured relative intensities $I_{\lambda Cu}$ and $I_{\lambda N2}$, assuming the partial Boltzmann distribution and using the Boltzmann plot, the temperatures of electronic excitation of Cu atoms, T_E, and vibrational excitation of N_2 molecules, T_V, were determined. In this technique, the plot $\ln(I_{\lambda Cu}\lambda^3/gf) = \ln C - E_E/kT_E$ vs. E_E gives T_E (here E_E is the excitation energy, g is the statistical weight, f is the probability of atomic transition, C is a constant for all CuI lines); and the plot $\ln(I_{\lambda N2}\lambda^4/q) = \ln B - E_V/kT_V$ vs. E_V gives T_V (here E_V is the vibrational energy, q is the FCF probability of vibrational transition, B is the constant for

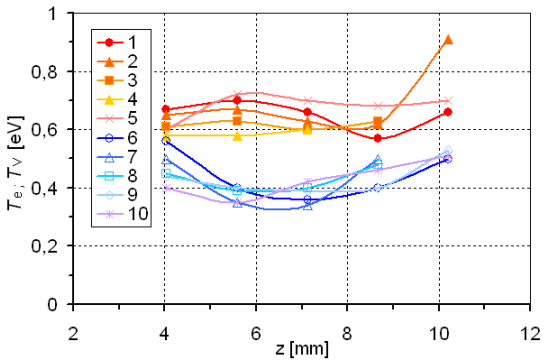

Fig.7. Electronic temperature of Cu atoms T_e (curves 1-5) and vibrational temperature of N_2 molecules T_V (curves 6-10) along the plasma flow: G = 40 cm^3/s (1,6), 75 cm^3/s (2,7), 110 cm^3/s (3,8), 150 cm^3/s (4,9), and 190 cm^3/s (5,10). I_d = 200 mA.

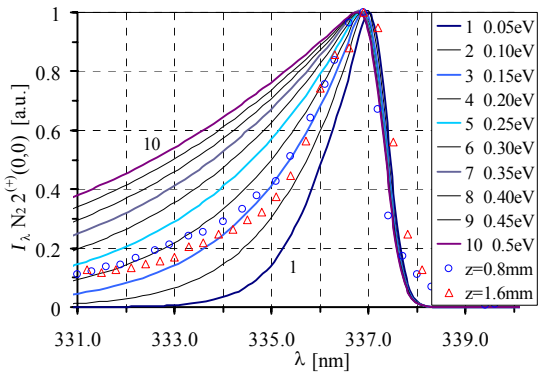

Fig.8. Emission spectra of the N_2 $2^{(+)}$(0-0) band 337.1 nm in the air plasma flow: experimental data (signs) vs. theoretical (curves) at different rotation temperatures T_R. G = 40 cm^3/s, I_d = 480 mA.

all considered N_2 bands). Due to a relatively high density of electrons that should be in the arc in air at atmospheric pressure, i.e. when inelastic electron collisions are high, we suggest $T_e \approx T_E$ as usual for such plasma [14].

As is expected, the electron temperature T_e and vibrational temperature T_V differenced very much, so that $T_e/T_V >> 1$ everywhere. At that, a level of non-isothermality is not permanent along the plasma flow. It depends not only on the discharge current I_d but also on the airflow rate G that is blowing the arc plasma column, providing convective heat mass transfer. Especially large temperature differences occur during the plasma relaxation in the afterglow zone. Fig.7 shows experimental dependencies T_e(z) and T_V(z) along the discharge at I_d = 200 mA for the different G: curves 1-5 are T_e, and curves 6-10 are T_V; curves 1, 6 are G = 40 cm^3/s; curves 2, 7 are G = 75 cm^3/s; curves 3, 8 are G = 110 cm^3/s; curves 4, 9 are G = 150 cm^3/s; and curves 5, 10 are G = 190 cm^3/s. As is seen, along the plasma flow the T_e is 0.7-0.6 eV while the T_V is 0.4-0.3 eV. The results obtained from the temporally and spatially integrated records are located in the core of the plasma column, and we suppose that the longitudinal distributions T(z) obtained from the spectra I_λ(z) are maximal due to averaging of the radial profile. The highest value $T_e \approx$ 1.4 eV was measured in the center of the arc at G = 0. In the blowing discharge, T_e decreases while T_V keeps longer. Then increasing the arc current I_d, the value T_e becomes larger. At the lager airflow rate G, the gradient T_e becomes smaller.

The non-equilibrium of the air plasma in the blowing arc discharge follows also from the estimation of the rotational temperature of electronically excited N_2 molecules, T_R. It was determined from the emission spectra of selected N_2 $2^{(+)}$ bands, assuming a Boltzmann population distribution and collisional termalization of rotational states. Here we suggested $T_g \approx T_R$ as usual in such plasma [14]. Fig.8 shows the results of numerical fitting of the V-R spectrum for the N_2 $2^{(+)}$ (0-0) band 337.1 nm, calculated at different T_R from 0.05 to 0.5 eV with the step 0.05 eV, from the curve 1 that is T_R = 0.05 eV to the curve 10 that is T_R = 0.5 eV, in comparison with the measured data (apparatus function Δλ=0.6 nm) at the distances z = 0.8 and 1.6 mm for G = 40 cm^3/s and I_d = 200 mA. The best contour fit of T_R is to be 0.15 eV. In fact, it differences from the T_V and T_e more than twice. Along the plasma flow, T_R keeps at the level 0.1-0.2 eV within experimental uncertainty, increasing slightly downstream due to the bulk gas heating. This evidences about kinetic non-equilibrium state in the discharge even without going into details of the kinetics of elementary plasma-chemical processes.

Thus, we found that during the evolution of the air plasma in the blowing arc discharge the characteristic temperatures varied very much depending on the power injected into the plasma. However, with the exception of the afterglow, within the arc zone the gas and electron temperatures are coupled at the level of T_g ~ 2000-3000 K and T_e ~ 8000-12000 K, respectively. This indicates, in the blowing arc we have the same transitional regime as in the gliding arc [15] when it is supported both by the thermal ionization (function of gas temperature) and by the direct electron impact (function of electric field). It is particularly remarkable that despite of atmospheric pressure, the air plasma in the blowing arc discharge remains ionizational non-equilibrium with the overheated electron component due to the effective convective heat carry-over. According to our estimation in comparison with the hypothetic case of LTE Saha's law, the degree of ionization nonequilibrium is as high as 10^2-10^3.

It is worth to note that besides the pure air, we tried out the blowing arc discharge for non-thermal ignition of air/spirit and petrol mixtures. This work is currently done at Kiev University, and results of pilot experiments are quit satisfied resulting in the fast ignition and expansion of the burning both across the flow and downstream. However, details are out of the scope of this paper and will be reported later.

Conclusion

1. We are convinced that a high-voltage transverse blowing arc discharge working in air of atmospheric pressure can be a source of non-thermal plasma with a relatively high level of ionization. We found that there is no local LTE in this arc discharge air plasma during its space/time evolution, and measured/estimated characteristic temperatures are within a relation: $T_e \sim T_E > T_V > T_R \sim T_g$, where the temperature of electronic excitation of free atoms differences from the temperatures of vibrational and rotational states of electronically excited molecules more then twice. Therefore, a conventional two-temperature approach with T_e for electrons and T_g for heavy particles is not valid in this case. Another character effect is an "ignition" of the plasma luminescence in the discharge plume resulted from the kinetic nonequilibrium conditions. The factors that effecting on the plasma non-equilibrium state, are not only electric parameters and discharge power injected into the plasma but also the gas dynamics and convective heat mass transfer in the plasma flow.
2. Taking into account the high plasma density, high electronic excitation temperature, easy control of the discharge potential and possibility of stimulation of selective chemical reactions at relatively low gas temperatures and high atmospheric pressures, we believe that this type of the nonequilibrium arc discharge in the atmospheric air flow can be very suitable for many technological applications including non-thermal plasma-assisted ignition/combustion of hydrocarbon fuels and plasma-enhanced modification of combustion products.
3. On the results of our investigations we conclude that even small variations in the air plasma conditions due to their spatial and temporal instability, decomposition, contamination, etc can produce large visual changes in the spectral emission which is functionally related with the temperatures and concentrations of plasma components, so the optical emission spectroscopy of electronically excited molecules and atoms in the air plasma could serve as a simple and reliable tool for the characterization and control of the non-equilibrium plasma state in the blowing arc discharge in different experimental conditions.

Surface Modification of Textiles by Pulsed Ammonia Plasma

X.J. Dai, L. Kviz, and R.J. Denning

CSIRO Textile & Fibre Technology, PO Box 21, Belmont, Geelong, Vic. 3216, AUSTRALIA

Abstract

The application of a pulsed ammonia plasma to produce high concentrations of $\cdot NH_2$ radicals for the introduction of amino functional groups on textile surfaces, particularly on wool, was investigated. It was found the pulsed ammonia plasma provides an effective plasma activation process and can be used to control chemical reactions on the substrate surface to effectively and selectively produce surface functionalities.

Keywords
Pulsed ammonia plasma, amino groups, polyethylene (PE), wool

1. Introduction

The attachment of amino groups to polymer surfaces is particularly attractive because amines are relatively reactive nucleophiles. Amino groups on the surface provide reactive sites for either covalent or interfacial adhesive bonding of chemical compounds that can be used to control interactions of the surface with its environment. Such functional groups on substrate surfaces have been widely applied to biomolecules and protein immobilization as well as in cell growth [1-4].

Amino groups are usually incorporated on the surface using either ammonia or amines in a plasma discharge. Ammonia is a non-polymer-forming gas, while amines deposit a plasma polymer layer. Continuous ammonia plasma has been used for the treatment of various materials and has been the subject of many papers [1, 5-8]. It has been reported that the primary amino radical ($\cdot NH_2$) is the species most likely to react with surface radicals produced by an ammonia plasma [6]. For a surface treatment it is essential that sufficient $\cdot NH_2$ radicals are produced that can effectively react with the substrate surface. Usually, in continuous ammonia plasmas, H_2 is added to the NH_3 feed to increase the production of $\cdot NH_2$ radicals [7]. In this work an alternate method of producing $\cdot NH_2$ radicals for the modification of textile surfaces, particularly wool fabrics, has been investigated using a pulsed ammonia plasma.

2. Experiment

A. Pulsed Ammonia Plasma

The experiments were performed in a 1.7 litre electrodeless plasma reaction chamber schematically shown in Figure 1. The chamber pressure was controlled using a rotary pump at a base pressure of less than 1×10^{-1} Pa. Electronic mass flow meters were used to monitor the inlet gas flow. Fabric samples were held on a horizontal support located at the chamber center.

Ammonia, provided by BOC Gases, with a purity of >99.99% was used without further purification. The pulsed plasma was produced by an RF generator, supplying RF power to the external antenna around the chamber through a matching network. RF power was pulsed at a range of frequencies and duty cycles (D), calculated as $D = \frac{T_{on}}{T_{on} + T_{off}}$, where T_{on} and T_{off}

are the time when the plasma is "On" and "Off" respectively. The average power, calculated as $P_{av} = P_{peak}$ x D, ranged from 10 to 20 W with duty cycles varying from 0.1 to 1 (Continuous Wave), where P_{peak} is the power applied during the "On" phase.

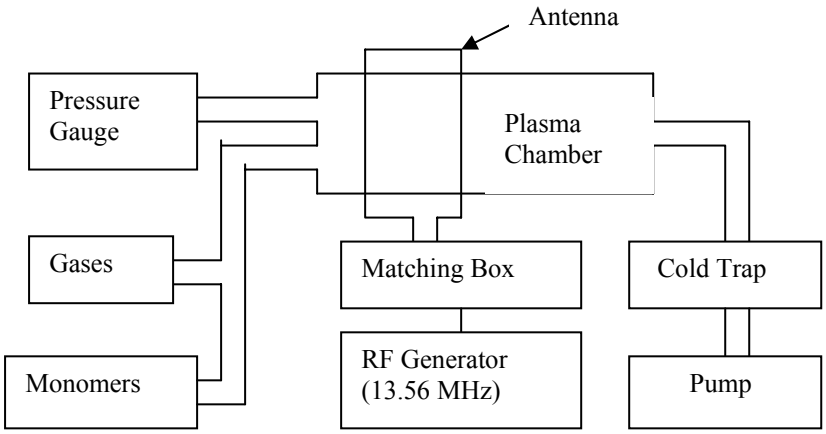

Figure1. Schematic diagram of the experimental apparatus

The RF pulse in gaseous ammonia produces $\cdot NH_2$ radicals as described in equations (1) and (2). The "Off" portion of the pulse provides sufficient time for grafting the $\cdot NH_2$ radicals to the textile surface with minimum interference by charged particles and UV photons. By selecting the plasma parameters, it is possible to optimize the surface reactions and minimize recombination reactions that form additional ammonia and ·NH radicals (3) or hydrazine (4) [9,10].

$$NH_3 + energy \rightarrow \cdot NH_2 + \cdot H \quad (1)$$

$$NH_3 + \cdot H \rightarrow \cdot NH_2 + H_2 \quad (2)$$

$$\cdot NH_2 + \cdot NH_2 \rightarrow NH_3 + \cdot \dot{N}H \quad (3)$$

$$\cdot NH_2 + \cdot NH_2 \rightarrow N_2H_4 \quad (4)$$

B. Materials and Surface Analysis

A lightweight plain woven wool fabric (155g/m^2), made from 20µm Australian merino wool, was used as the substrate in the experiments. Samples (15cm x 30cm) were cleaned using Soxhlet extraction in dichloromethane for 4 hours to remove residual processing lubricants and other possible contaminants. Polyethylene (PE) was used as a reference substrate because of the similarity of its surface energy to that of normal wool. The PE samples were ultrasonically cleaned in a hexane/isopropyl alcohol (1:1) mixture for 30s and then air dried.

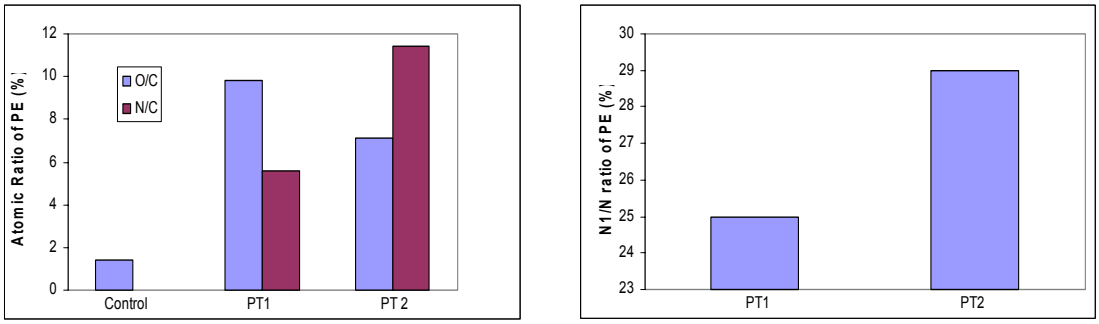
Changes to the surface chemistry of the samples were observed using X-ray photoelectron spectroscopy (XPS) in a Kratos analytical AXIS-HSi equipped with a monochromatised Al Kα X-ray source at a power of 200 W (10kV and 20mA). The samples were mounted on a multi-sample holder using double-sided adhesive tape. A jet of dry nitrogen was used to remove any loose contamination (dust) from the sample surface. Typical pressures during analysis were between 2 and 5 x 10^{-6} Pa. Survey spectra for identification of all elements and their atomic concentrations were obtained over the range 0 - 1200 eV. High resolution spectra (40eV pass energy) were then recorded for selected elements (e.g. O, C, N, S) in order to obtain more specific data regarding chemical structure.

A Digital Instruments Dimension 3000 scanning probe microscope was used to examine the adhesion force and topographical nature of the sample surfaces before and after the plasma treatment. The instrument was operated in contact mode using a silicon nitride probe, consisting of a V-shaped cantilever (nominal spring constant κ = 0.12 N/m) with a square pyramidal tip, to acquire images and force curves in air. Scanning Electron Microscope was conducted using a Hitachi S4100 Field-Emission Scanning Electron Microscope (FeSEM), operating at 1KV with a 5mm working distance using carbon-coated film and fabric samples.

Surface energy changes of wool were measured using the Wilhelmy balance principle as described previously [11]. This method was further developed [12] for measuring the changes in the surface energy of plastic films and synthetic fabrics through a calibration curve established from the net water absorption values measured using the Wilhelmy method and the absolute values from Softal test inks [13] (range 34 mJ/m^2 - 72 mJ/m^2 non-continuous).

3. Results and Discussion

As many plasma parameters may affect the properties of the modified surface, we focused on a number of key plasma parameters in our experiments to determine the most suitable experimental conditions for grafting amino groups to the surface. The variables investigated included pulse frequency, duty cycle, RF power, pressure, and treatment time. From simple water drop tests, we found that the most hydrophilic surfaces were produced at a duty cycle, D of 0.2 and a pulse frequency, f of 200Hz. These two parameters were maintained constant for the remainder of the work.

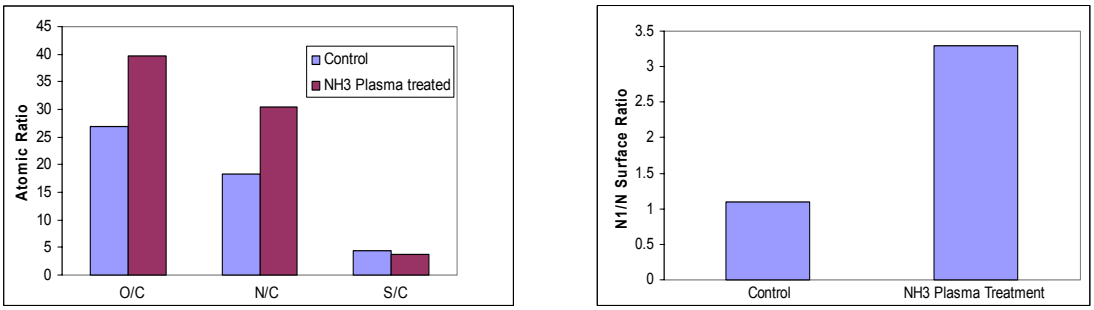


(a) (b)

Figure 2 XPS elemental ratio of PE before and after the pulsed NH_3 plasma treatments
(PT1: P_{av}=15W, p=7 Pa, t=20sec; PT2: P_{av}=15W, p=30 Pa, t=40sec)
(a) Atomic ratio N/C and O/C; (b) Atomic ratio of N1/N

Figure 2 shows the XPS results for PE before and after treatment with the pulsed ammonia plasma. The atomic ratios of nitrogen to carbon (N/C) and oxygen to carbon (O/C) (Figure 2(a)) are significantly different for the different plasma treatment conditions (PT1 and PT2). The higher O/C ratio at a pressure 7 Pa (PT1) is consistent with previous work that found that the highest concentration of atomic oxygen (n[O] peak) was produced at an oxygen pressure of 5 Pa [14] using a similar plasma source to that used here. The N/C ratio increased in going from PT1 to PT2, as well as the ratio of primary amine groups (N1) to total nitrogen (N) (N1/N) shown in Figure 2(b). It is believed that the increase of N/C and N1/N ratios at the plasma condition PT2 was due to the pressure change (30Pa) as the surface energy reached the saturation level at a treatment time of approximately 20 seconds (see Figure 6). Therefore, the adjustment of some plasma parameters allows the selective production of reactive species and modification of the surface.

Although PE has a similar surface energy to the bound lipid layer on the wool fiber surface, wool has a much more complex surface [15]. It is characterized by a highly cross-linked protein matrix acylated with fatty acids, predominantly 18-methyleicosanoic acid [16]. The fatty acids are believed to be attached to the surface protein via a thioester linkage to cysteine residues with the hydrocarbon tail oriented directly away from the surface [17]. Figures 3 (a) and (b) shows the XPS elemental ratios, O/C, N/C, S/C (sulfur to carbon) and N1/N for untreated and treated wool fabrics. Compared to untreated wool, the total nitrogen content of the plasma treated wool surface increased by 66% and the primary amine content increased by 200%.



(a) (b)

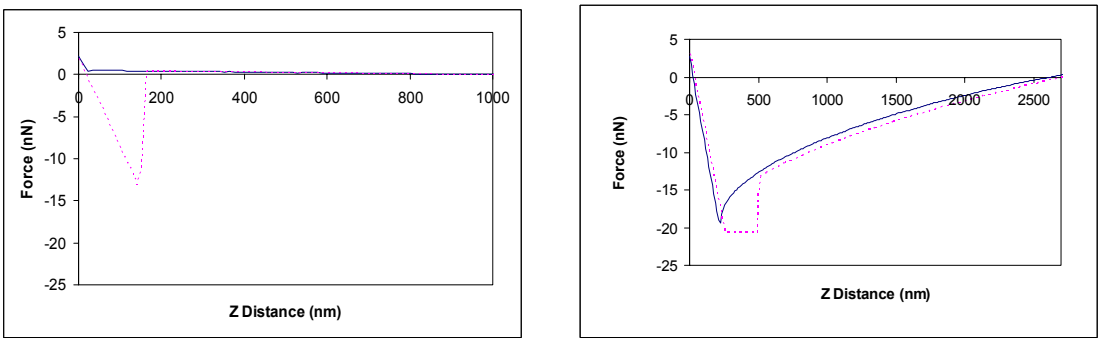
(a) Atomic ratios O/C, N/C, S/C; (b) Atomic ratio of N1/N

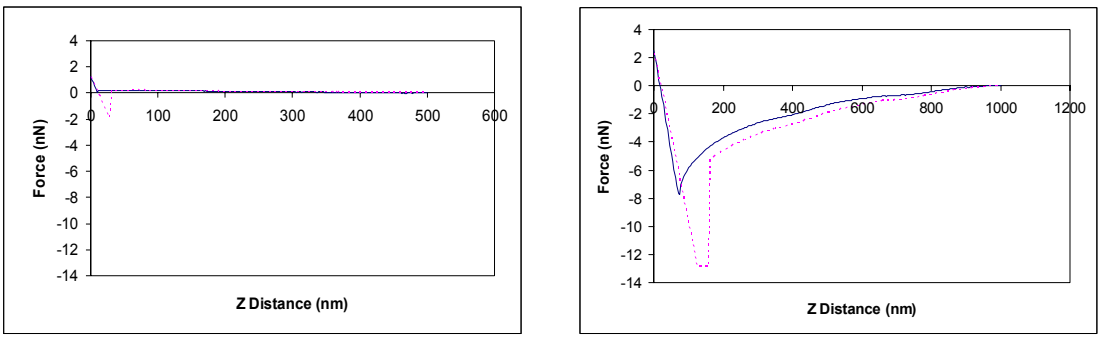
An important indicator for ammonia plasma surface modification is an improvement in the adhesion of polymers to the surface. The improvement can be achieved by increasing the surface energy following introduction of reactive groups. The ammonia plasma modifies the surface by grafting nitrogen and oxygen polar groups, which are detected by XPS analysis. The modified surface was further characterized using an AFM to measure force distance curves and by wettability measurements to assess surface energy changes.

Figures 4 and 5 show the force distance curves measured by AFM for untreated and the pulsed ammonia plasma treated PE and wool respectively.



(a) (b)

Figure 4 The force-distance curves of PE measured by AFM
(a) untreated; (b) the pulsed NH_3 plasma treated, P_{av}= 20W, p=30Pa, t=60sec

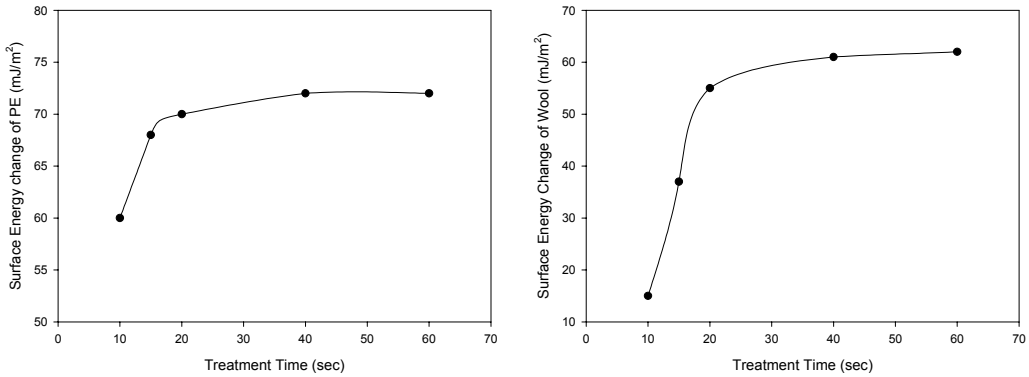


(a) (b)

Figure 5 The force-distance curves of wool measured by AFM
(a) untreated; (b) the pulsed NH_3 plasma treated, P_{av}= 20W, p=20Pa, t=40sec

The X-axis is the distance (in Z direction) from the base of the AFM cantilever to the sample surface. The solid lines are approach curves and dotted lines are retract curves. In Figure 4(a), in the region of Z distance from 20nm to 1000nm the tip is above the sample surface and no force is experienced by the tip. At 20 nm it touched the surface and further movement in the Z distance resulted in a positive force (deflection) on the cantilever. At about 2 nN the tip is retracted but adheres to the surface until about –14 nN before pulling loose. This value (14nN) represents the adhesion between the tip and the sample surface. For the treated PE (Figure 4(b)), there is a strong attraction between the tip and the sample surface in air out to about 2500 nm, as well as adhesion during retraction. (Note: the adhesion spike has been truncated due to the signal going off the detector). Similar results can be seen for the wool, shown in Figures 5(a) and (b). The results show that there are much greater adhesion forces and attraction forces between the surface and the AFM tip for the pulsed NH_3 plasma treated PE and wool than the controls.

These results are in agreement with the wettability measurements, shown in Figure 6. As the plasma treatment time increased, the surface energy change increased, before reaching saturation (72 mJ/m^2 for PE and 62 mJ/m^2 for wool) at a treatment time of approximately 20 seconds.



(a) (b)

Figure 6 Surface energy changes of PE (a) and wool (b) via the pulsed NH_3 plasma treatment time
P_{av}=15W, p=30Pa

SEM images of the treated and untreated wool fibres show no significant change on surface physical structure, indicating the pulsed ammonia plasma is a mild form of surface modification.

4. Conclusion

It has been demonstrated that a pulsed ammonia plasma is an effective method for grafting amino functional groups onto the surfaces of PE and wool. It has also been shown that surface functionality can be selectively modified and the relative concentration of primary amine groups grafted onto the surface varies with the plasma treatment conditions. Wettability measurements show that the surface energy is significantly increased after the pulsed ammonia plasma treatment while AFM measurements show that surface adhesion can also be greatly improved.

Acknowledgments

The authors would like to thank Dr. T. R. Gengenbach for the XPS measurements and his valuable discussions, Dr. J. Maxwell for the AFM measurements and Dr. M. Huson for the data analysis and his valuable discussions, Mrs. C. Coombs for the SEM images, and Drs. D.J. Evans and R. Cranston for their valuable discussions.

Effects of Microstructure on Reflectance of Thermal Barrier Coatings

T. Ma, M. Kambara, K. Eguchi, T. Yoshida

Department of Materials Engineering, the University of Tokyo, Tokyo 113-8656, Japan

Abstract

Reflectance of YSZ and Al_2O_3-YSZ coatings with different microstructures was compared at room temperature. It is clearly observed that the specially engineered microstructure, produced by the twin hybrid thermal plasma spraying system, affect substantially the coating's reflecting capability. Plasma spray PVD coating with cross-bracing structure has higher reflectance compared to the plasma powder sprayed coatings with splats construction, and the typical EB-PVD coatings. This indicates the coating prepared by thermal plasma PVD possesses added advantage as TBC in suppressing the radiative heating particularly at high temperature use.

Keywords TBCs, microstructure, reflectance

1. Introduction

Thermal radiation in infrared region plays an important role in the heat transfer process especially at the temperature higher than 1700K, due to its intensity proportional to the fourth power of temperature. Thermal barrier coatings (TBCs), used in aircraft and gas turbines for thermal insulation, are expected to have higher light reflectance, together with lower thermal conductivity, which are important issues for the next generation TBC system. In general, at a given material, the reflectance varies significantly with its microstructure and the surface conditions. This in turn suggests that effective thermal insulation of TBC can be achieved by controlling its microstructure. A special ZrO_2-8%Y_2O_3 coating with multiple sharp interfaces within its columnar microstructure produced by EB-PVD was reported in Ref.[1], in which the continuous flux of the vapor cloud was periodically input by using a shutter mechanism. It revealed that the picturesque multiple layer structure is beneficial to increase the reflectance. Y. Kagawa[2,3] reported another ZrO_2/Al_2O_3 multilayer coating produced by spin coating process and its light reflectance showed a repeated increase/decrease behavior. The constant value of the difference between neighboring peak-to-peak wavelength suggested that the origin of the increase/decrease was interference of reflected light at the ZrO_2/Al_2O_3 interfaces. These reports indicate that microstructure is one of the factors affecting reflectance. In this paper, the effect of novel microstructure on reflectance is presented for YSZ and Al_2O_3-YSZ composite TBCs prepared by plasma spraying technology.

2. Experimental

YSZ and Al_2O_3-YSZ coatings with different microstructures were prepared by the twin hybrid thermal plasma spraying system, in which two hybrid plasma torches are equipped. This system allows production of a variety of TBCs with PVD and/or splats structure, by tuning input power, powder size, powder feeding rate, distance from torch to substrate, and so on.[4,5] In order to maintain low substrate temperature during deposition, water-cooled substrate holder was used. The

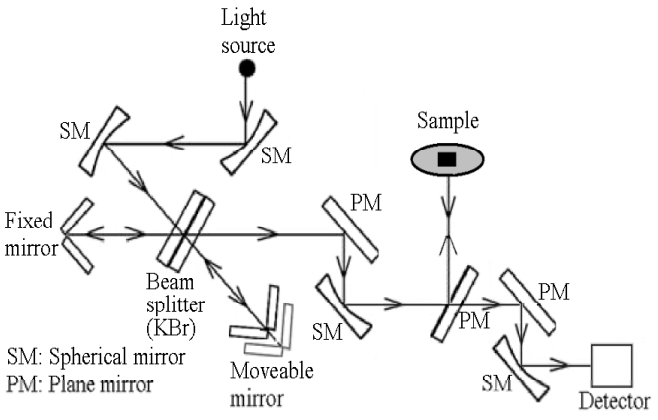

Fig.1 Schematic of an optical system for the measurement of IR reflectance

substrate temperature was measured by a thermal couple. In the interest of evaluating the reflective characteristics only from the freestanding coatings, the TBCs were deposited on graphite plates so that they can be removed easily from the substrates. All specimens were carefully polished under the same condition (1200 surface finish and slurry polished) and the cross sections were observed by FE-SEM (JEOL-6340, Japan). The reflectance perpendicular to the specimen surface was measured by Fourier-transform infrared spectrometer (FT/IR-670 Plus, JASCO Corp, Japan). The optical system for the measurement of IR reflectance is shown in Fig.1. Although the reflective property at high temperatures should be measured, the measurement was carried out at room temperature due to less significant dependence of reflectance of zirconia on temperature.[3,6]

3. Results and discussion

Figure 2 shows the cross sections of the typical specimens produced by twin hybrid thermal plasma spraying system. Specimens (a) and (b) represent the columnar YSZ PVD structure, which were prepared by spraying smaller powder less than 15μm in diameter on the stationary water-cooled substrate. The distance from torch to substrate was different in the processing. There are some additional layers formed within the PVD columnar grains (hereafter called cross-bracing structure) in the specimen (a), whereas no such special structure is present in the specimen (b). On the other hand, (c) and (d) are the typical powder sprayed structure consisted of YSZ and Al_2O_3-YSZ composite splats. These were prepared with one torch (c) and twin torches (d) by injecting 63~88μm powders on a rotating substrate during deposition.

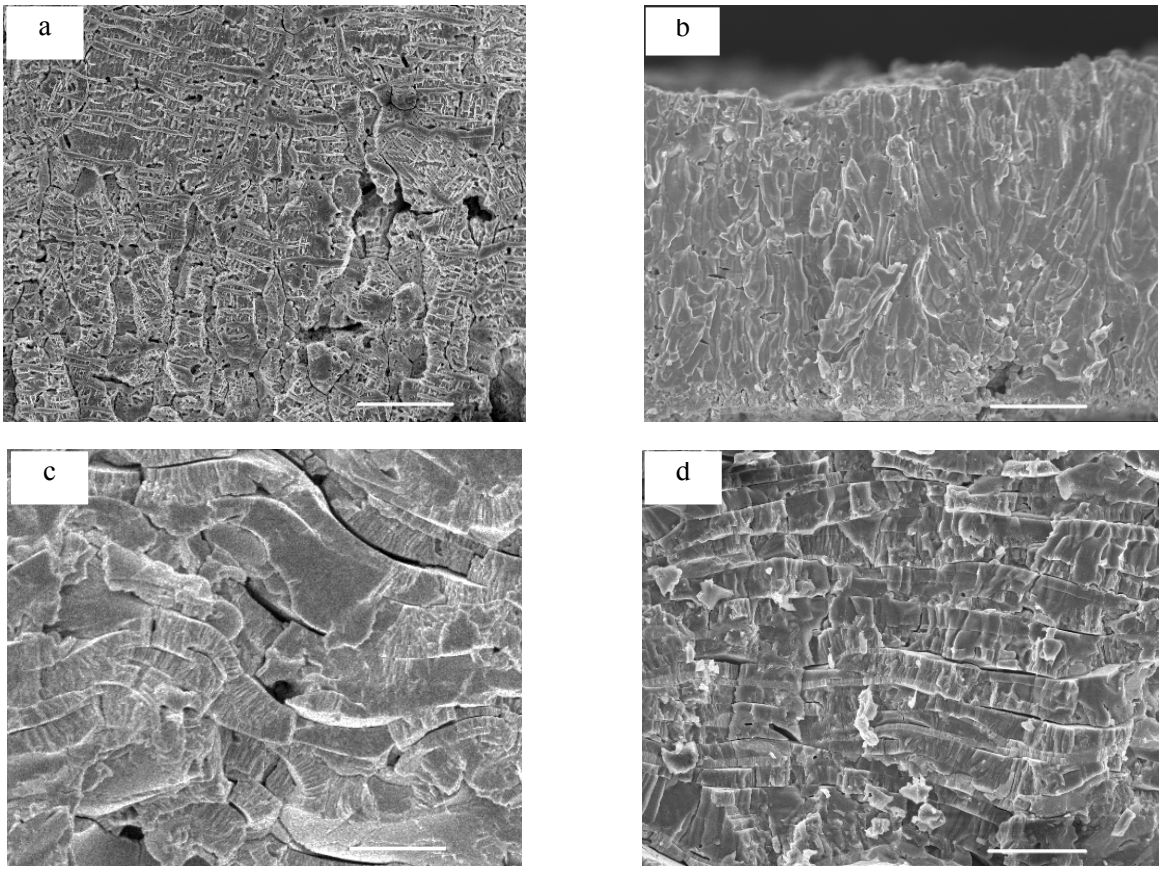

Fig.2 Cross sectional micrographs of TBCs with different microstructures; the white bar represents 20μm. (a) 8YSZ PVD structure with aligned layers within columnar grains, torch-substrate distance: 50 mm; (b) 8YSZ PVD structure, prepared under similar conditions as the case (a) except the torch-substrate distance: 30 mm; (c) 8YSZ powder sprayed structure; (d) Al_2O_3-8YSZ powder sprayed composite structure.

The reflectance of these specimens was measured as a function of wavelength of IR light as shown in Fig.3. The theoretical reflectance R for ZrO_2 and Al_2O_3 by an estimation with Fresnel's Law[7] ($R=\left[(\bar{n}-1)/(\bar{n}+1)\right]^2$, where $\bar{n}$ is refractive index) is also included in Fig.3. The refractive index of ZrO_2 is 2.0-2.1 at wavelength range 1.0-5.0μm[8], the index for Al_2O_3 is 1.68, 1.65, 1.62, 1.60 at wavelength of 2μm, 3μm, 4μm, 5μm, respectively[3]. It shows that the specimens with splats structure have lower reflectance than the theoretical values. No big difference is found between (c) and (d) despite their different compositions. The wavy surfaces and micro pores inside the splats of (c) and (d) as observed in Fig.2 may scatter the incident light randomly and therefore reduce the reflectance measured at right angle. This implies that microstructure is an additional factor to affect the reflecting capability besides material property and surface condition. On the other hand, the reflectance of the PVD specimens is found to be higher than the theoretical values. This may be caused by the fact that the vertically aligned dense PVD columnar grains effectively reflect the incident light to the right angle. In addition, the cross-bracing grains within PVD columnar crystals as shown in Fig.4, which are t′ phase formed due to rapid cooling rate during deposition, make possibly additional contribution to enhance the reflectance. In fact, the light with a wavelength, λ, reflected at an object with a certain thickness, can be enhanced when the quarter wavelength criteria ($-1/4\,\lambda < \delta < 1/4\,\lambda$, where δ is optical path length) is applied[10]. In the case of the Infra-red (λ =1-10μm) incident perpendicular to a platelet grain, the light reflection will be enhanced when the thickness is smaller than 1.25μm. From Fig.4, in comparison, the average thickness of the grains aligned transversely is roughly estimated to be around 0.5-1.2μm, which is in good agreement with the size of the object calculated from the criteria above.

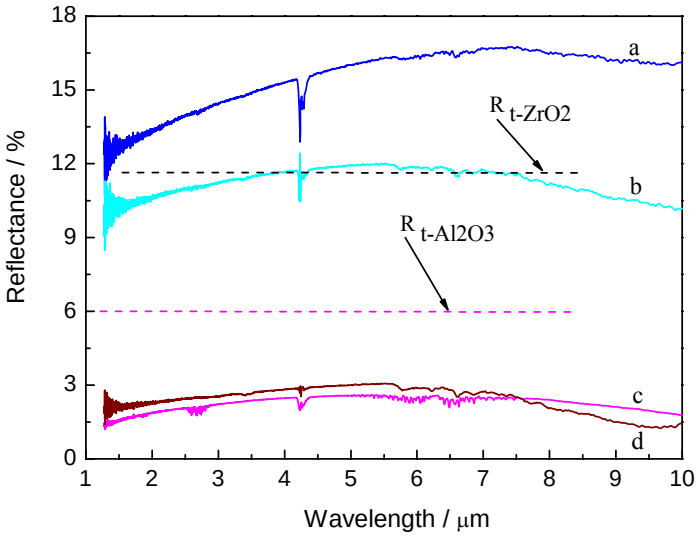

Fig.3 Reflective curves of TBCs with different microstructures of (a)~(d) shown in Fig.2. $R_{t\text{-}ZrO2}$ and $R_{t\text{-}Al2O3}$ are theoretical reflectance for ZrO_2 and Al_2O_3, respectively. The depressions at wavelength of 4.2μm are thanks to absorbance of carbon dioxide in the air.[9]

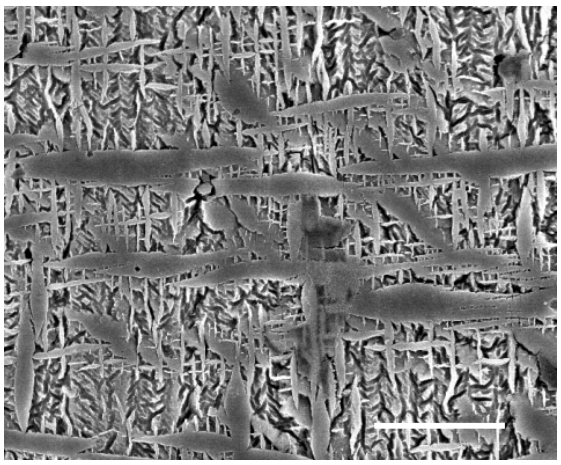

Fig.4 Cross sectional micrograph of the coating with cross-bracing grains, the white bar represents 5μm.

Electron beam physical vapor deposition (EB-PVD) and atmospheric plasma spraying (APS) are the other two kind of typical processes for TBC preparation. In order to compare the coatings' reflective property produced by different processing, several specimens prepared by Plasma Spraying PVD, EB-PVD and APS were carefully polished at the same

conditions to obtain the uniform surface roughness. Fig.2 (a) and Fig.5 show cross section micrographs of this three kind of coatings, of which reflectance was measured as a function of wavelength of light as shown in Fig.6. It can be seen that APS coating has the lowest reflectance in this comparison. This is because the cracks, pores and wavy surfaces within the specimen greatly decreased the measuring reflectance at right angle. As for EB-PVD, though it seems no significant porosities in the coating, the vertical gaps between the columnar crystals decrease the density and may enhance the absorption of incident radiation at normal direction. The coating produced by plasma spraying PVD has the highest reflectance because of its high density, low porosity and special cross-bracing structure, which has been analyzed in the above paragraph.

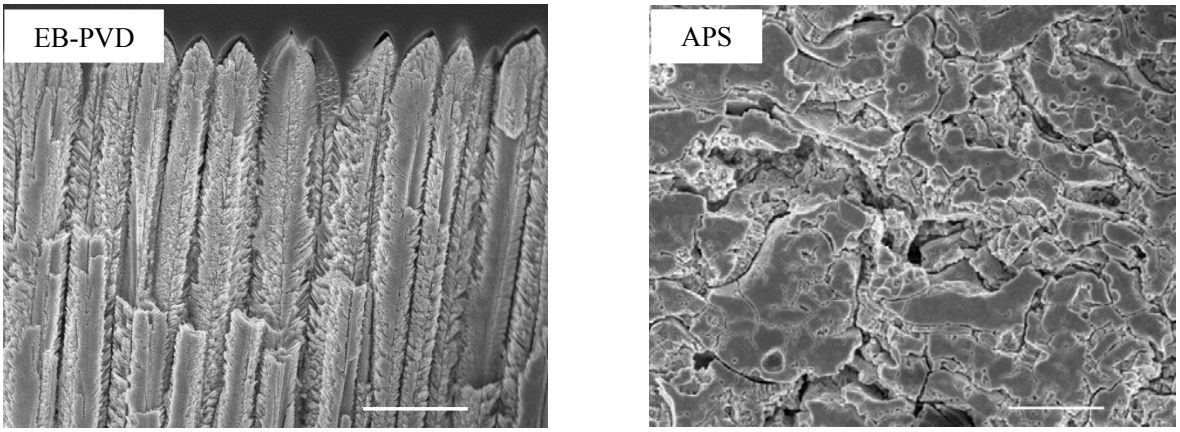

Fig.5 Cross section micrograph of TBCs prepared by EB-PVD and APS processing, the white bar represents 20μm.

Additional experiments are needed to confirm the detailed effects of microstructure on reflectance of TBCs. Nevertheless, the present results clearly indicate that the coatings with cross-bracing PVD structure, produced by twin hybrid thermal plasma spraying system, have high potential as TBC used at higher temperatures.

Experimental investigation of the magneticlly enhanced RF discharge in methane.

S.V. Avtaeva, T. M. Lapochkina and D.K. Otorbaev*

Kyrgyz-Russian Slavic University, *Kyrgyz National Academy of Sciences, Bishkek, Kyrgyz Republic.

1. Abstract

Under conditions of the coronal equilibrium in the magnetically enhanced capacitive RF discharge in methane inverse populations of the excited hydrogen states were observed. These populations of excited states of hydrogen atoms can form in the dissociative recombination of H_2^+ ions: $H_2^+ + e \to H + H^*$. Also the molecular hydrogen parameters and ratio of atomic hydrogen to molecular hydrogen were investigated using spectroscopy methods.

2. Introduction

At present time low-temperature plasma in mixtures of hydrocarbon containing gases with noble gases and hydrogen is an object of greeting interest. This is cased with applications of the plasma for plasma deposition of amorphous hydrogenated carbon films. In the plasma deposition methods, the structure and properties of deposited carbon films can be varied widely by changing the deposition parameters.

In this paper the populations of hydrogen atom excited states, hydrogen molecule distributions on vibrational and rotational energy levels, and ratio of atomic hydrogen to molecular hydrogen in the magnetically enhanced RF discharge in methane were investigated using emission spectroscopy methods.

3. Experimental details

A magnetically enhanced asymmetric capacitive coupling RF reactor was used in the experiments. The reactor chamber consisted of the stainless steel cylindrical vessel of diameter 30 cm and height 25 cm with ports to allow optical diagnostics. The chamber walls were grounded. RF power (frequency 13.56 MHz) from a RF generator was applied to the stainless steel plane square electrode ($10\times10\times1.6$ cm^3) arranged in the middle of the chamber. The power supply was connected to the electrode through a special matching device. Two magnetic coils induced a homogeneous magnetic field with respect to the vertical symmetry axis in the chamber. The discharge operating parameters were adjusted in the range: power 90÷110W, methane pressure 1 ÷ 5 Pa, magnetic field 50÷200 G. An optical system based on a high-resolution monochromator and photomultiplier was used to measure the spectral line intensities.

4. Hydrogen atom distributions on energy levels

The emission spectrum of the magnetically enhanced RF discharge in methane was studied in the wavelength range of 420-660 nm. In the spectrum hydrogen spectral lines of Bulmer's series and molecular bands of CH-radicals and molecular hydrogen were observed. The effect of the magnetic field on intensities of hydrogen spectral lines and the molecular bands was studied. Relative intensities of Bulmer lines H_α, H_β, and H_γ were used for investigation of the hydrogen atom distributions on the excited states with quantum numbers n=3, 4 and 5. In a case of the coronal equilibrium populations N_k of excited atomic states can be presented as

$$N_k = N_0 N_e \cdot \sigma_{\max} \langle \sigma(\varepsilon) v_e \rangle \cdot \tau_k . \qquad (1)$$

Here $\sigma(\varepsilon)$ is a form –function identical for all excited states, as the excitation cross sections of Bulmer lines H_α, H_β, H_γ have close dependencies on electron energy [1], $\sigma_{\max}$ is the excitation cross section in maximum and τ_k is lifetime of the excited state. Under invariable conditions in the discharge the equation (1) can be written as

$$N_k \propto const \cdot \sigma_{\max} \tau_k , \qquad (2)$$

where *const* has the same value for all three excited states . As one can see, relative populations of the hydrogen excited states weakly depend on discharge parameters in the case of coronal equilibrium. On the other hand, population of the excited state N_k is related with spectral line intensity I_{ki} : $N_k = const \cdot \frac{I_{ki} \cdot \lambda_{ki}}{A_{ki}}$ (3).

Relations (1) and (3) were used for reconstruction of the hydrogen atom distributions on excited states theoretically and experimentally, accordingly. Dependencies of $\ln(N_k) \sim \ln\left(\frac{I_{ki}\lambda_{ki}}{A_{ki}}\right)$ and $ln(N_k) \sim \ln(\sigma_{\max} \cdot \tau_k)$ on the excited level energy of hydrogen atoms are shown in figure 1. Discharge operating parameters for each of five experimental derived distributions are presented in table 1. When doing the theoretical calculations we neglected the differences in the excitation energy of the excited states (n=3, 4 and 5). Taking this difference into account would result in increase in population of low energy levels relative to upper levels.

Table 1. Operating parameters of the RF discharge in methane, which correspond to atomic hydrogen distributions on excited states presented at figure 1.

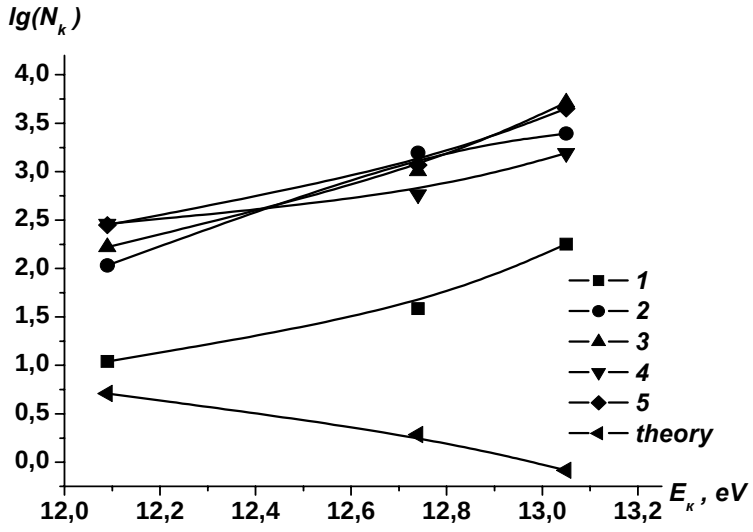

Figure 1. Dependencies of $\ln(N_k) \sim \ln\left(\frac{I_{ki}\lambda_{ki}}{A_{ki}}\right)$ (1÷5) and $ln(N_k) \sim \ln(\sigma_{\max} \cdot \tau_k)$ (theory) on energy of the excited states for Balmer H_α, H_β, H_γ lines.

As one can see (figure 1), in the RF discharge in methane the inverse populations of the excited hydrogen states are realized. These hydrogen atom distributions on excited states cannot be explained in terms of processes of the direct excitation of hydrogen atoms by electron impact or directly in the dissociative excitation by interactions of electrons with methane molecules.

As it was shown in simulations [2], in the capacitive RF discharge in methane rather high concentration of hydrogen molecular ions is realized. H_2^+ ions can be effectively destroyed in the dissociative recombination $H_2^+ + e \to H + H^*$. The ionization energy of H_2 molecule equal to *15.42 eV*, the dissociation energy of H_2^+ ion equal to *2.65 eV* [3]. So the energy defect equal to *12.77 eV*, this energy is close to excitation energy of the excited state of hydrogen atom H^* (n=4) E_β*=12.74 eV* (H_β) and, hence, process of $H_2^+ + e \to H + H(k=4)$ will be resonant, practically. The dissociative recombination of H_2^+ ions can also lead to creation hydrogen excited states H^* with n=3 or 5, however, the creation rates for H^*(n=3) will be the lowest. Most effectively dissociative recombination run by collisions of molecular ions with slow electrons, for H_2^+ the process cross section increases from ~10^{-16} cm^2 to ~ 10^{-14} cm^2 under decrease in electron energy from 1 eV to 0.01 eV [4]. Thus, the dissociative recombination cross section exceeds the cross sections of the direct excitation of H^*(n = 3, 4, 5) by electron

impact from the ground state of hydrogen atom [1] in $\sim 10^2 \div 10^4$ times. It is necessary to notice, that under average electron energy of 2÷3 eV typical for capacitive RF discharges the electron energy distribution function (EEDF) at energies of 12÷13 eV is essentially lower than in energy range of 0.01÷1 eV, (at T_e=2 eV ratio F (13 eV)/*F* (1eV) $\sim 10^{-2}$). In that way, rate constant of the H_2^+ dissociative recombination with creation of the excited hydrogen atoms H^* ~ in 10^5 times will exceed rate constant of direct excitation of H^*(n = 3, 4, 5) by electron impact from the ground state of H. Hence, the dissociative recombination of H_2^+ can form inverse population of the excited states of hydrogen atoms in the RF discharge in methane.

5. Molecular hydrogen

In the emission spectrum of the magnetically enhanced capacitive RF discharge in methane a plenty of molecular hydrogen lines in the wave length ranges of 4400 – 4800 Å and 4900 – 6400 Å, including Fulcher system of H_2 ($d^3\Pi_u\nu' - a^3\Sigma_g\nu''$; $\nu'= \nu''= 0,1,2,3$) are observed. The typical view of vibrational bands of Fulcher system H_2 ($d^3\Pi_u\nu' - a^3\Sigma_g\nu''$; $\nu'= \nu''= 0,1,2,3$) liying in the wave length range from 6000 Å to 6400 Å is shown in figure 2. At equilibrium hydrogen molecule distribution on the vibrational levels the vibrational temperature of the molecular hydrogen can be appreciated on best coincidence of an experimentally measured distribution of intensities in vibrational bands of the Fulcher system with theoretically calculated distributions [5]. In this case vibrational distribution function is defined by expression:

$$f_v = \frac{1}{Q_v} e^{-G(v)hc/kT_{vib}}, \qquad (4)$$

here v is the vibrational quantum number, $G(v)$ is the vibrational energy term, T_{vib} is the vibrational temperature in the ground state , Q_v is the vibrational partition function, and c, h, k are known constants.

The vibrational distribution of hydrogen molecules in an exited state is connected with the vibrational distribution in the ground state by expression [5]:

$$f_v'(v') \propto \sum_{v^0} q_{v^0 v'} f_v(v^0) e^{-\Delta E_{vib}/kT_e}, \qquad (5)$$

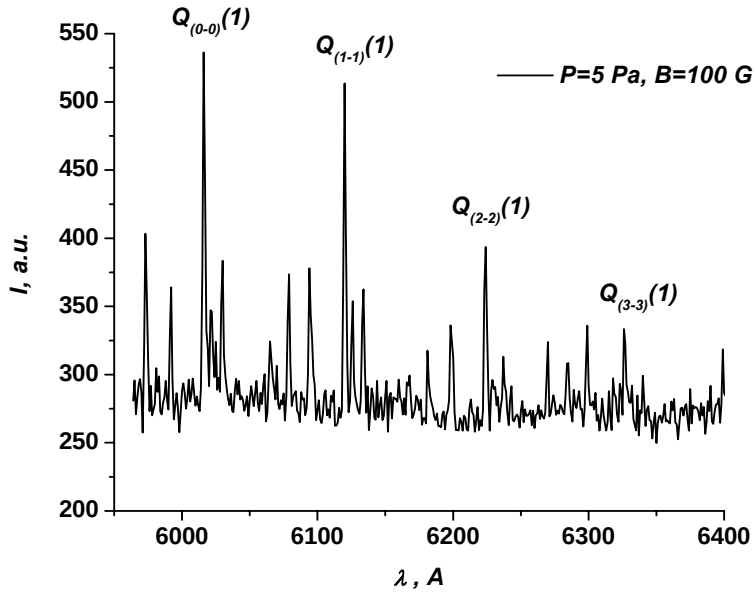

Figure.2. The typical view of a part of the Fulcher system spectrum in emission of the RF discharge in methane.

where ΔE_{vib} is difference in energies of vibrational levels with quantum numbers v' and v^0 in exited and ground electronic states, T_e is the electron temperature, and $q_{v^0 v'}$ - the Franck-Condon factors.

The vibrational band intensity distributions is determined by Franck-Condon factors $q_{v'v''}$ for the radiative decay: $I_{v'v''} \propto f'(v') q_{v'v''}$. (6)

The typical intensity distribution in the vibrational bands of the Fulcher system $H_2(d^3\Pi_u\nu' - a^3\Sigma_g\nu''; \nu'= \nu''= 0,1,2,3)$ observed in the emission spectrum of the RF discharge is presented in figure 3. The theoretically distributions calculated for equilibrium distribution of hydrogen molecules on vibrational levels is also presented in figure 2. Intensity values are normalized to intensity value of the (1-1) vibrational band.

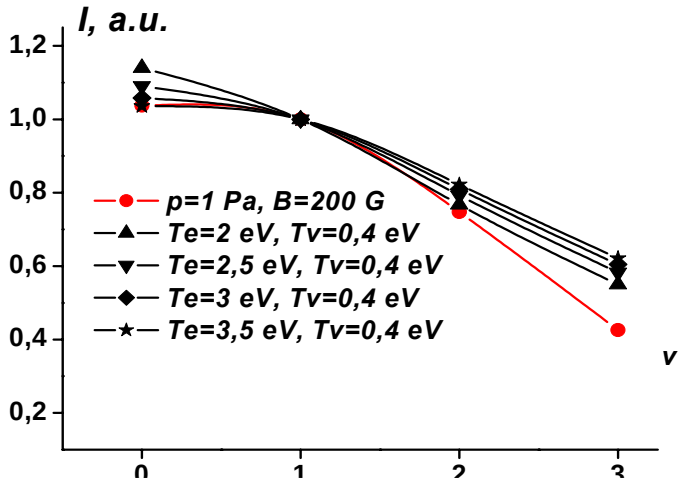

Figure. 3. Intensity distributions of vibrational bands of the Fulcher system in emission spectrum of the RF discharge (P=1Pa, B=200G) and theoretically calculated distributions at the given values of Te and Tv.

vibrational quantum number. It results in reduction

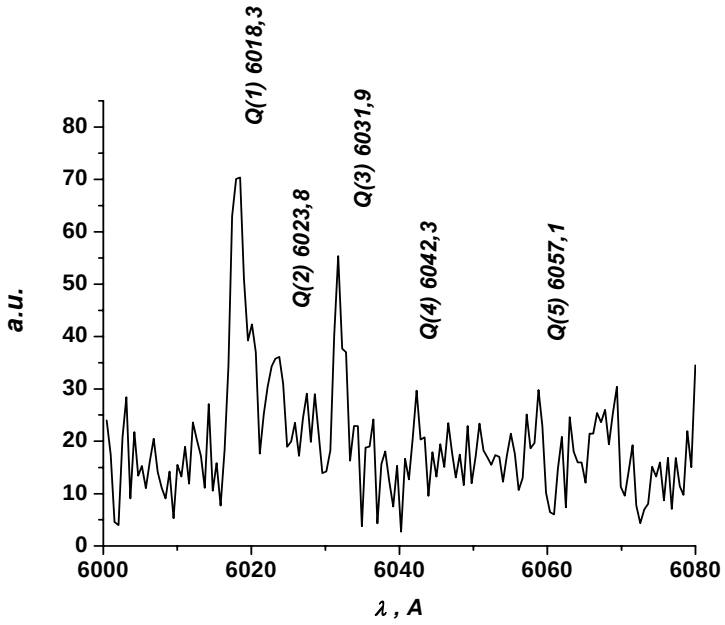

Figure 4. The typical view of spectrum of (0-0) vibrational band of the α-Fulcher system.

As at pressure 1 Pa, so at 5 Pa the experimentally observed intensity distributions in the vibrational bands of the Fulcher system essentially differ from equilibrium distributions, the vibrational levels with quantum numbers v'=2 and v'=3 are noticeably impoverished in comparison with equilibrium distributions. The return situation is observed at magnetic field 50 Гс and methane pressure 1 Pa.

Taking into account that the most part of molecules are on two lower vibrational levels it is possible to define vibrational temperature for two-level system. Vibrational temperature of molecular hydrogen determined by this way lays in limits of 0,2-0,5 eV.

Apparently, observed distributions of hydrogen molecules on vibrational levels testify about increase in rate constants of elementary processes with participation of vibrationally - exited hydrogen molecules with growth of populations of the vibrational levels with higher quantum numbers in comparison with equilibrium populations.

Intensity distributions of rotational lines in the (0-0) vibrational band of the Fulcher system were used for measuring the rotational temperature of hydrogen molecules. Also ratio of atomic hydrogen to molecular hydrogen were determined using optical actinometry method on ratio of relative intensities of the H_α*(6563 Å, n'=3→n=2)* and the Q1 rotational line of the (0-0) vibrational band of the Fulcher system.

The typical view of the (0-0) vibrational band of the α-Fulcher system is shown in figure 4. Rotational temperature of hydrogen molecules in the RF discharge in methane was determined on distribution of relative intensities of Q rotational lines in the (0-0) vibrational band of the Fulcher system. The rotational temperature T'_{rot} of hydrogen molecules in the exited state $d^3\Pi_u$ was determined on inclination of rectilinear dependence of $\ln\left[\frac{I_{K'K''}}{g_I(2K'+1)}\right]$ on

F(K'). Here $I_{K'K''}$ is rotational line intensity, K is rotational quantum number, g_I is degeneracy due to the nuclear spin, g_I =1 for even rotational levels and g_I =3 for odd rotational levels, $F(K')$ is the rotational energy term. Molecule rotational energy distribution function in excited state is connected with the distribution function in the ground state by expression:

$$f'_{rot}(K') = \sum_{K^0} R_{K^0K'} f^0_{rot}(K^0), \qquad (7)$$

where K^0 and K' are quantum numbers, $R_{K^0K'}$ are the Hönl-London factors. This relationship was used to get dependence of T^*_{rot} on (T_{rot}). The received values of the rotational temperature of hydrogen molecules in the ground state were in the temperature range of 480-570 K. The rotational temperature grows with increase in magnetic field and methane pressure.

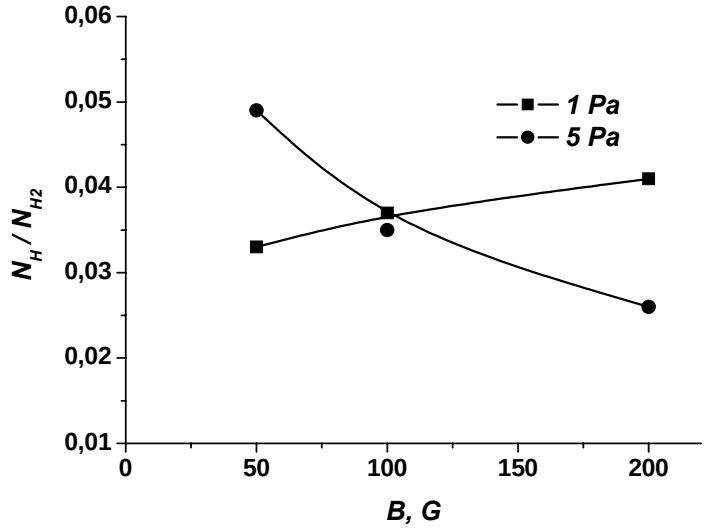

Figure 5. Ratios of atomic and molecular densities as a function of magnetic field and methane pressure in the RF discharge in methane.

In conditions of coronary equilibrium the intensity ratio of atomic and molecular lines of hydrogen can be used for determining density ratio of atomic and molecular hydrogen. Density ratio of atomic to molecular hydrogen is connected with ratio of relative intensities of the atomic line H_α*(6563 Å, n'=3→n=2)* and the rotational Q (*k=1*)-line of the*(0-0)* vibrational band of H_2 α-Fulcher system by relationship:

$$\frac{N_H}{N_{H_2}} = \frac{I_{H_\alpha}}{I_{H_{F(0-0,1)}}} \cdot \frac{\lambda_{H_\alpha}}{\lambda_{H_F}} \frac{\frac{f'_{rot}(k=1)}{Q_r}\sigma^{(0-0)}_{em}}{A_{H_\alpha}\tau^H_{n=3}\sigma^{H(n=3)}_{\max}} \cdot \frac{1}{(1+C_{thr}(\varepsilon))}, \qquad (8)$$

here N_H, N_{H2} are atomic and molecular hydrogen densities; $I_{H\alpha}$, $I_{HF(0-0,1)}$, $\lambda_{H\alpha}$ λ_{HF} are relative intensities and wave lengths of the atomic line H_α*(6563 Å, n'=3→n=2)* and the rotational Q (*k=1*)-line of the*(0-0)* vibrational band of H_2 α-Fulcher system, $f'_{rot}(k=1)$ is the population probability of the rotational level with *k=1*, Q_r is the rotational partition function, $A_{H\alpha}$ is the transition probability for H_α, $\tau^H_{n=3}$ is radiative lifetime for H_α, $\sigma^{H(n=3)}_{\max}$, $\sigma^{(0-0)}_{em}$ are excitation cross sections, $C_{thr}(\varepsilon)$ is the correction factor, which is taking into account a difference in dependencies of the cross sections on electron energy [5].

At figure 5 ratios of N_H / N_{H_2} as dependencies on methane pressure and magnetic field are shown. One can see, the opposite dependencies of N_H / N_{H_2} on magnetic field were observed at pressure 1 and 5 Pa. Growth of N_H / N_{H_2} ratio with increase in magnetic field at pressure 1 Pa is caused by increase in electron density and, as a result, by growth of dissociation rates both methane and its radicals, and hydrogen molecules by collisions with electrons. Change in dependence of N_H / N_{H_2} on magnetic field with increase in pressure is apparently caused by reduction of free path length of atoms and radicals with increase in pressure and corresponding growth of return processes rates, resulting in formation together with other products and molecular hydrogen. As it was shown in [6], atomic hydrogen density in the magnetically enhanced capacitive RF discharge in methane under similar conditions changes in a range $7*10^{10} \div 6*10^{11}$ см$^{-3}$. Taking into account the

calculated values of N_H / N_{H_2}, values in a ranges of (1.9÷2.5)*10^{12}см$^{-3}$ at pressure 1 Pa and 8.1*10^{12} см$^{-3}$ ÷2.3*10^{13}см$^{-3}$ at pressure 5 Pa have been received for molecular hydrogen densities.

Abstract
A new type of arc plasma reactor with twelve-phase alternating current (AC) discharge for synthesis of carbon nanotubes (CNTs) is proposed. A couple of six discharge electrodes by which have mutually electrical connection between them to enlarge the high temperature regions in the reactor are arranged to three dimensional locations. A new method of CNTs fabrication by this reactor which accomplishes to enlarge the suitable growth region in high-purity and at high yield was developed.

Keywords Arc plasma, Twelve-phase AC discharge, Carbon nanotubes

1. Introduction

A large number of applications for arc plasma have been used for the welding and cutting of metals up to this time. Arc plasma as the energy source with effective heat efficiency has been also tried to open new technological field for better global environment with related new industrial markets, including plasma chemical reaction.

In general, the power source for generating arc plasma is accomplished by using a direct current (DC) power supply. This is the larger the capacity the higher the cost of apparatus for inverting from AC to DC. On the other hand, the single-phase and the three-phase AC power supply have already been proposed for the same application fields. Since these systems have a characteristic of intermittent discharge, the high power arc plasma systems generated by AC power supply have not been fully developed. In order to improve this defect, a multiple-phase AC power supply has been developed. To obtain a more effective arc plasma generator by expanding this concept, we have developed a twelve-phase AC power supply [1]. The most important advantage of this system is that there are large number of discharging paths among electrodes in comparison with the case of the single-phase and the three-phase systems. Therefore, some of the plasmas always exist for continuing smoothly the discharging action. It seems as if this system was driven by the DC power supply instead of actual commercial AC power supply (60 Hz) [2].

Since CNTs discovered in 1991 at first time [3], many researchers have been provided its unique physical and chemical properties, and applications to nano-scale devices. Several methods for synthesis of CNTs such as DC arc-discharge [3, 4], laser ablation and thermal chemical vapor deposition (CVD) have been presented. The DC arc-discharge method can synthesize CNTs in highest quality than the other methods mentioned above. However its yields are much lower. Up to date, CVD method is the mainstream of mass fabrication of CNTs. In order to avoid the disadvantage of the DC arc-discharge method, the twelve-phase AC arc-discharge method is proposed here. The purpose of this paper is to describe the techniques for obtaining its method and to show the experimental results for synthesizing CNTs by using this new type of arc plasma reactor.

2. Twelve-phase AC power supply for arc plasma reactor

2.1 Three-phase to twelve-phase conversion

Figure 1 shows the electrical circuit diagram of the transformers for converting from the three-phase AC to the twelve-phase AC and the schematic connection diagram of the plasma reactor. The input of the three-phase power supply is connected to 200V commercial power lines. The primary coils of transformers are divided into two parts: one is the Δ connection and the other is the Y connection. The twelve-phase power supply can be realized by the combination of these circuits. From the Y connection, the voltage components V_x, V_y, V_z, V_x', V_y', and V_z' of the six-phase AC are defined by the following equations:

$$V_i = V_m \sin(\omega t - \frac{n}{3}\pi), (i = x, y, z), (n = 0,2,4) \quad (1)$$

$$V_i' = V_m \sin(\omega t - \frac{n}{3}\pi), (i = x, y, z), (n = 1,3,5) \tag{2}$$

where V_m and f are the maximum value of the sinusoidal wave and the frequency of the AC (60 Hz), respectively.

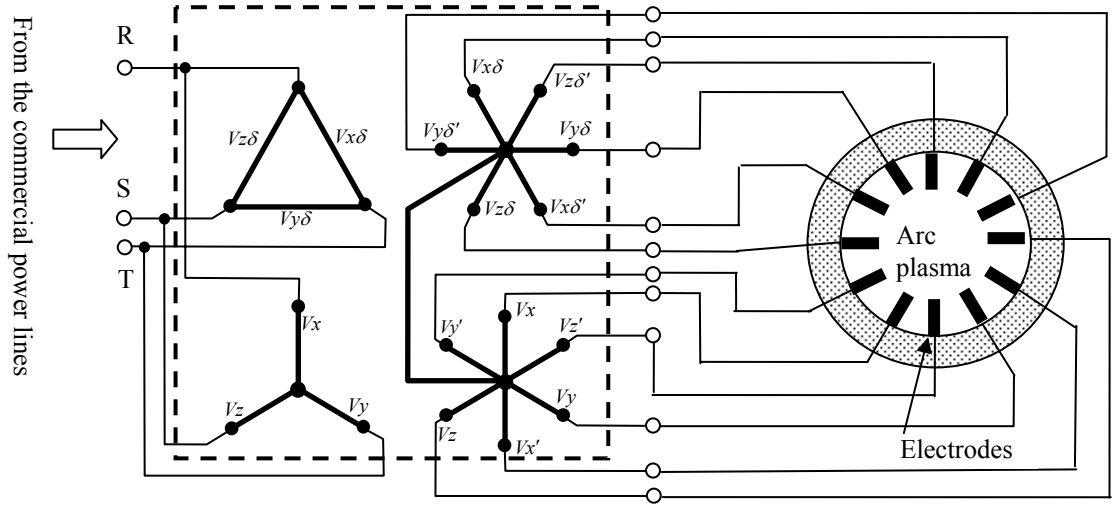

Fig. 1 Electrical circuit diagram and schematic temporary connection diagram of the plasma reactor

From the Δ connection, the voltage component $V_x\delta$, $V_y\delta$, $V_z\delta$, $V_x\delta'$, $V_y\delta'$, and $V_z\delta'$ are defined by the following equations:

$$V_i\delta = V_m \sin(\omega t - \frac{n}{6}\pi), (i = x, y, z), (n = 1,5,9) \tag{3}$$

$$V_i\delta' = V_m \sin(\omega t - \frac{n}{6}\pi), (i = x, y, z), (n = 7,11,15) \tag{4}$$

2.2 Advantages of the twelve-phase AC discharger

The configuration of twelve electrodes are symmetrically arranged to bring out the advantages of the twelve-phase discharge. The geometrical arrangement of the tips of electrodes is indicated in Fig. 2. In the case of the distance between electrodes No.5 and No.7 is unity, the ratio of the distance among other electrodes have the values as shown in the same figure.

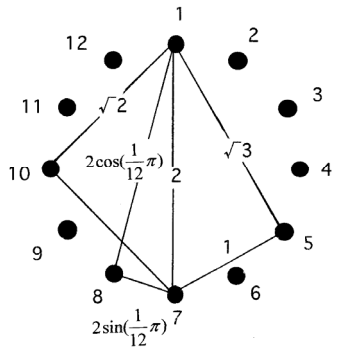

Fig. 2 The geometrical arrangement of the tip of electrodes

In general, the voltage applied between each electrodes and neutral point of the secondary coil of the transformer for the twelve-phase AC power supply can be described by following equation.

$$V_i = V_m \sin(\omega t - \frac{(i-1)}{6}\pi), (i = 1.....12) \tag{5}$$

From this equation, we can obtain the difference of the voltage between the electrode No.1 and the others. These are explained as follows:

$$V_2 - V_1 = 2\sin(\frac{1}{12}\pi)V_m \cos(\omega t + \frac{1}{12}\pi) \tag{6}$$

$$V_3 - V_1 = V_m \cos(\omega t + \frac{1}{6}\pi) \tag{7}$$

$$V_4 - V_1 = \sqrt{2}V_m \cos(\omega t + \frac{1}{4}\pi) \tag{8}$$

$$V_5 - V_1 = \sqrt{3}V_m \cos(\omega t + \frac{1}{3}\pi) \tag{9}$$

$$V_6 - V_1 = 2\cos(\frac{1}{12}\pi)V_m \cos(\omega t + \frac{5}{12}\pi) \tag{10}$$

$$V_7 - V_1 = 2V_m \cos(\omega t + \frac{1}{2}\pi) \tag{11}$$

Here we should notice that the ratio of the voltage amplitudes in equations (6)-(11) is equal to the ratio of the geometrical distances shown in Fig. 2. As the phase shift is kept constant every moment by the combination of transformers, the values of voltage/distance among each electrode are also constant every moment.

2.3 Power supply for the twelve-phase AC discharge

To realize the power supply for the generation of twelve-phase AC discharge, twelve pieces of single-phase AC arc welding transformer (DAIHEN B-250) were used. These welders are the conventional ones and have a dropping characteristic. The input voltage, the maximum non-loading output voltage, the typical loading voltage, the wattage and the range of output currents are 200 V, 80 V, 32.5 V, 12.4 kW and from 75 A to 250 A, respectively. Two pairs of six transformers are connected to the commercial AC line (three-phase 200 V, 60 Hz) with the figures of Δ and Y connections. Twelve output lines from the transformers are directly connected to the corresponding electrodes of the reactor.

Fig. 3 Setup of the twelve-phase AC power supply

Fig. 4 Photograph of the twelve-phase AC arc discharge

Fig. 3 shows the setup of the twelve-phase AC power supply. The picture of the twelve-phase AC arc discharge is shown in Fig. 4. Typical voltage and current waveforms of the single-phase AC arc discharge and the twelve-phase ones are shown in Fig. 5 and Fig. 6, respectively.

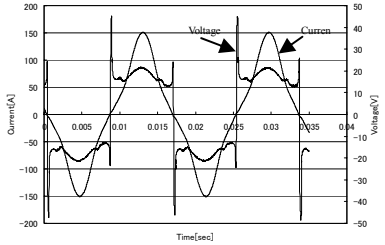

Fig. 5 Voltage and current waveforms in case of single -phase AC

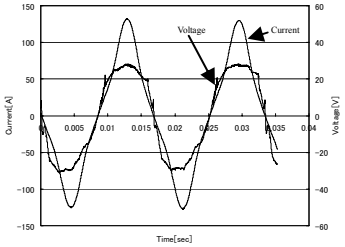

Fig. 6 Voltage and current waveforms in case of twelve-phase AC

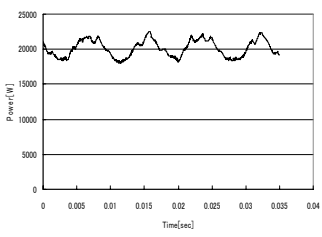

Fig. 7 Total power waveform in case of twelve-phase AC

Fig. 6 indicates the twelve-phase AC arc discharges which do not have an intermittent discharge. The waveform of the total power in the case of twelve-phase is also shown in Fig. 7. The ripple of the total power was 6.3%.

3. Synthesis of carbon nanotubes

3.1 A new type of arc plasma reactor

A new type of arc plasma reactor with twelve-phase AC discharge for mass fabrication of CNTs is shown in Fig. 8. The CNTs were produced by a twelve-phase AC arc discharge among carbon electrodes in helium gas. The electrodes of graphite rod 12mm in diameter, 500mm in length having the purity of 99.995% are configured horizontally in the reactor as shown in Fig.4. Since the electrodes are consumed by evaporation, the arc gaps among electrodes are kept constant by the motor-drive systems of which are adjusted by the voltage among them.

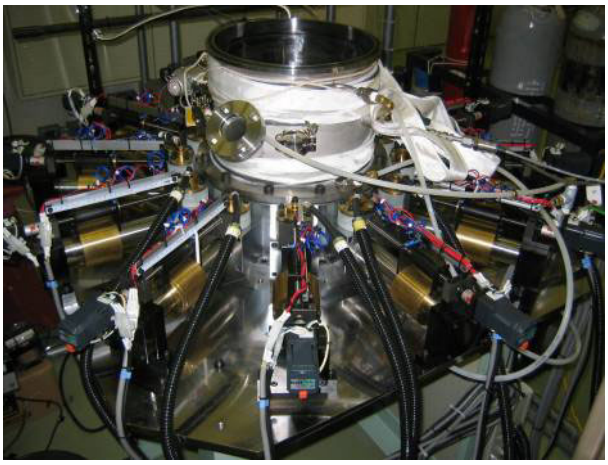

Fig. 8 A new type of arc plasma reactor for mass fabrication of CNTs

3.2 Experimental setup

Figure 9 shows the schematic diagram of the experimental setup inside of the reactor. The substrate made of the stainless steel plate (sus304, 50 mm in width, 320 mm in length and 1 mm in thickness) suspended from the ceiling of the reactor. The tip of the substrate was apart 10 mm above from the center of twelve electrodes configuration. The diameter of the plasma surrounded by the tips of twelve electrodes is approximately 60 mm.

After purging in the chamber, helium gas (purity 99.99%) is introduced and sets at 600 torr. The discharging voltage and its current are 20-45 V and 70-100 A, respectively. The carbon electrodes contain nickels as the catalyst for CNTs synthesis at 10wt. %.

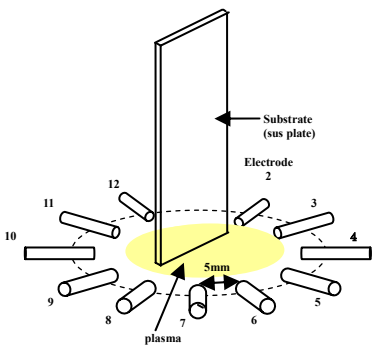

Fig. 9 Schematic diagram of the experimental setup inside the reactor

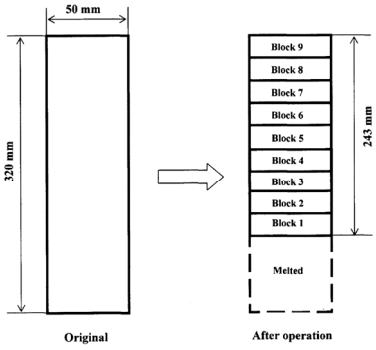

Fig. 10 Substrate for CNT deposition (original and after operation)

3.3 Experimental results and discussion

The CNTs synthesis is strongly related to the temperature of condensation and growth of carbon

molecules in plasma [5, 6], therefore the deposition was carefully analyzed to investigate the effect of deposition temperature. During the discharge for one hour, CNTs were prepared from the evaporation of the electrodes. A lot of soot-like deposit was obtained on the surface of the substrate as well as on the inner surface of the reactor. Figure 10 shows the original substrate and after operation one. The surface of remained substrate was divided equally into nine blocks. The deposit on the substrate is carefully gathered from nine sampling blocks. The products were examined using scanning electron microscopy (SEM), transmission electron microscopy (TEM) and Raman spectroscopy with a 514.5nm Ar^+ laser and were also characterized by using an energy dispersive X-ray analysis (EDX)

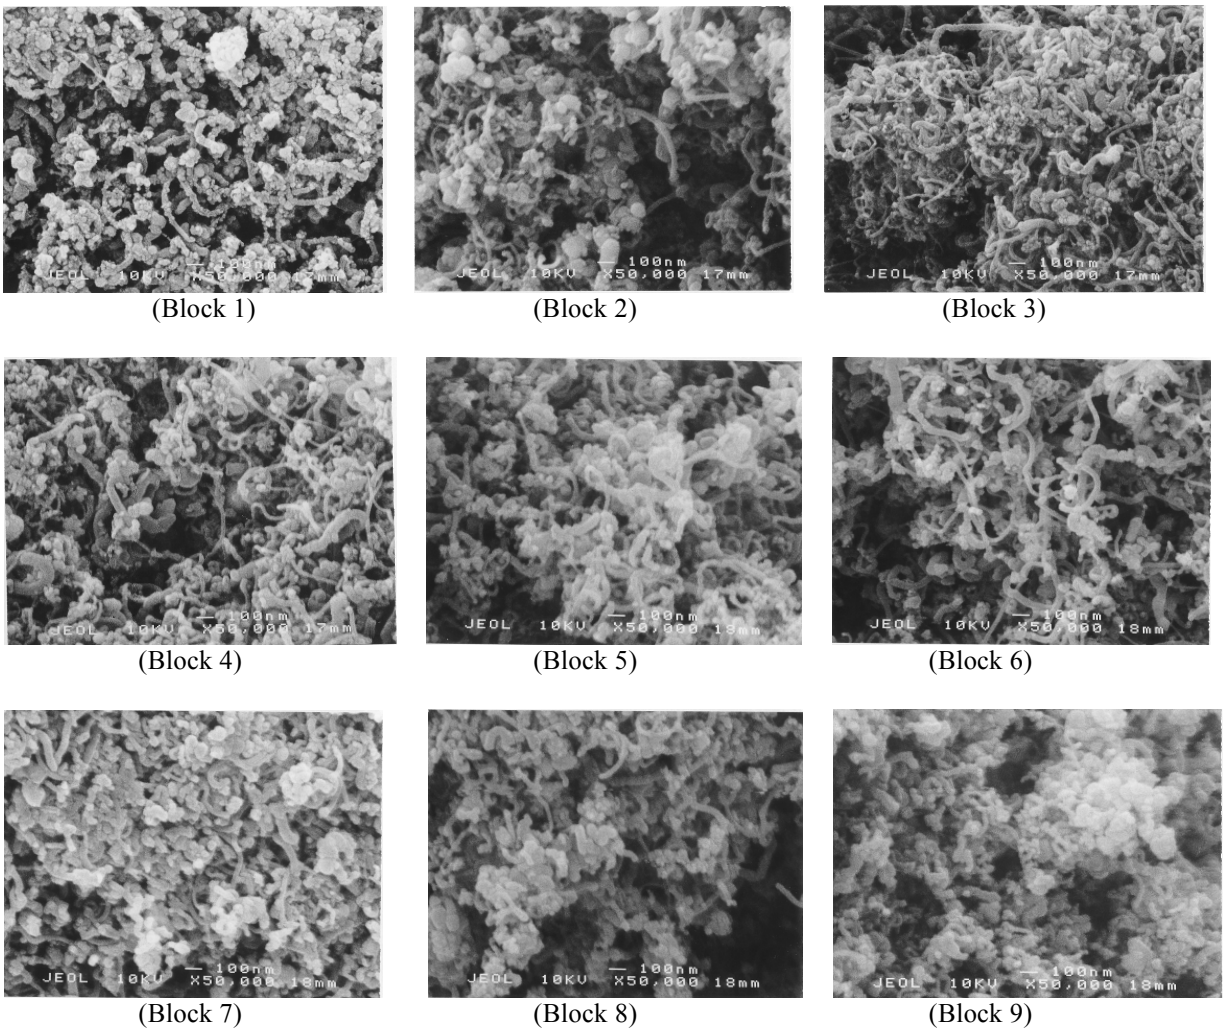

Fig. 11 SEM images of the CNTs from gathering nine blocks on the substrate

The SEM images of crude samples at each block of the substrate are shown in Fig.11. The clusters of carbon particles which are considered to be amorphous carbons are much more observed at the images of blocks 1, 2, 7, 8, and 9 in comparison with the images of blocks 3-6. On the contrary, CNTs with much less amorphous carbons are observed at the images of blocks 3-6. The surface temperature at the tip of block 1 of the substrate is estimated at 1400 degree Celsius of its melting point. The surface temperature of the bottom of block 9 was measured at 800 degree Celsius by using the thermocouples. From these evaluations, the temperature distribution on the substrate can be roughly estimated with the linear assumption of the temperature distribution. The optimum temperature for CNTs synthesis is approximately in the range from 1000 to 1250 degree Celsius. This result was congruous well with previous report [7]. From the morphological observation of blocks 2 and 8, even though their locations are not suitable for fabrication of CNTs, the length of it in block 8 is shorter than that of block 2. The multi-walled CNTs of 20 nm-40 nm in diameter shown in Fig. 12 were produced not only on the substrate but also on the wall of reactor. Nickel particle filled with the CNTs shown in Fig. 13 was identified by the energy dispersive X-ray spectrometry.

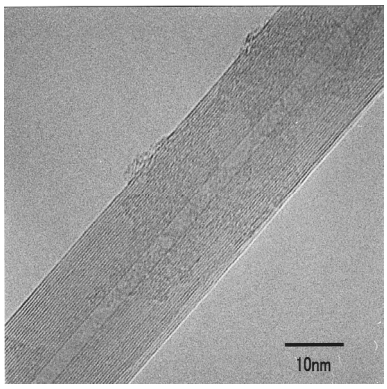

Fig. 12 TEM image of the multi wall CNTs

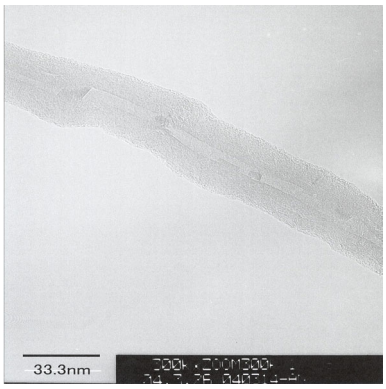

Fig. 13 CNTs filled with nickel particles

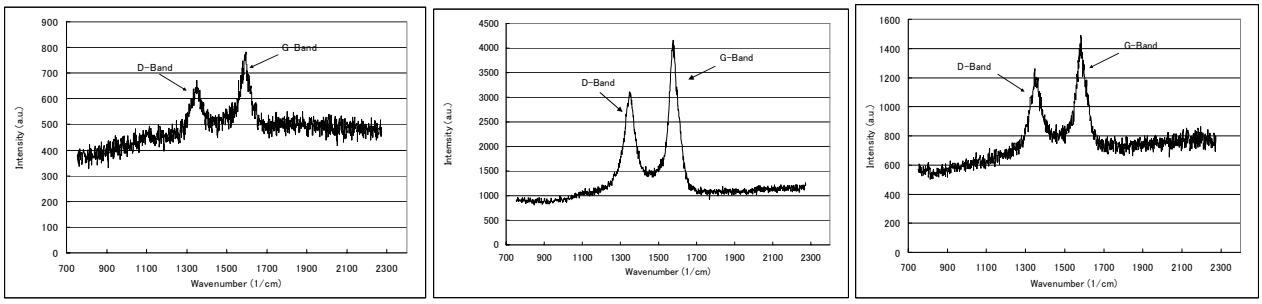
Raman spectrum shown in Fig. 14 contains the G-band (1580 cm^{-1}) and the D-band (1360 cm^{-1}). In general, the G-band shows the CNT oriented peak and the D-band shows the amorphous carbon or the structure defects of CNTs oriented peak. The synthesis of CNTs is not clearly found out on the block 1 shown in Fig.14 (a). Fig.14 (c) shows CNTs and the amorphous carbon are both synthesized on the block 8. On the contrary, the strong peak of G-band caused by synthesis of CNTs was appeared on the block 6 shown in Fig.14 (b). These results were congruous very much with the morphological observation of SEM images mentioned above.



(a) block 1 (b) block 6 (c) block 8

Fig. 14 Raman spectrum of the CNTs on the substrate

4. Conclusions

We have described the techniques for obtaining the new type of arc plasma reactor with twelve-phase AC discharger. This configuration can provide the attractive advantages of the arc plasma in superior stability and long continuity. A new method of CNTs fabrication by using this reactor which accomplishes to enlarge the suitable growth region in high-purity and at high yield was developed. The optimum temperature for CNTs synthesis is approximately in the range from 1000 to 1250 degree Celsius. The multi-walled CNTs of 20 nm-40 nm in diameter were produced

Abstract
We report on experimental and theoretical study of dc magnetized discharge in cylindrical magnetron device. The experimental study encompasses Langmuir probe and emissive probe diagnostics the theoretical one 2D Particle-In-Cell (PIC) model of the dc discharge in the mentioned system.
Cylindrical magnetron, Langmuir probe, emissive probe, Particle-In-Cell

1. Introduction

Magnetically confined plasma is used in a wide range of plasma applications. DC magnetized discharges are commonly used in plasma processing e.g. for thin film layer coating and etching. In our work we concern on dc magnetized discharge in cylindrical magnetron device. The theoretical description of plasma as well as understanding of processes and mechanism of discharge formation is easier due to symmetrical configuration of magnetron device.

2. Experimental device

Our cylindrical magnetron device has been in detail described e.g. in [1] so that only a brief description will be given here. Cylindrical magnetron consists of two coaxial electrodes – grounded stainless steel tube (anode) and water cooled cathode at its axis. Discharge area is constrained by two metallic limiters connected to cathode potential. Plasma in cylindrical magnetron is confined by homogenous magnetic field parallel to the anode axis. This is created by couple of magnetic coils and can vary up to 40 mT. The cylindrical magnetron is schematically depicted in figure 1. Magnetron usually operates in noble gases at pressures 1 – 10 Pa. Cylindrical magnetron device is evacuated by turbomolecular pump backed by dry compressing piston pump. The ultimate pressure is below 10^{-2} Pa. Plasma parameters in magnetron can be determined by means of electrical probes located in radially movable feedthrough in the central plane of magnetron. Some experimental data presented here were obtained in another cylindrical magnetron that differs from above-mentioned only in length of discharge area (30 cm instead of 12 cm) and electrodes diameter. Let us to denote these two magnetrons like "longer"

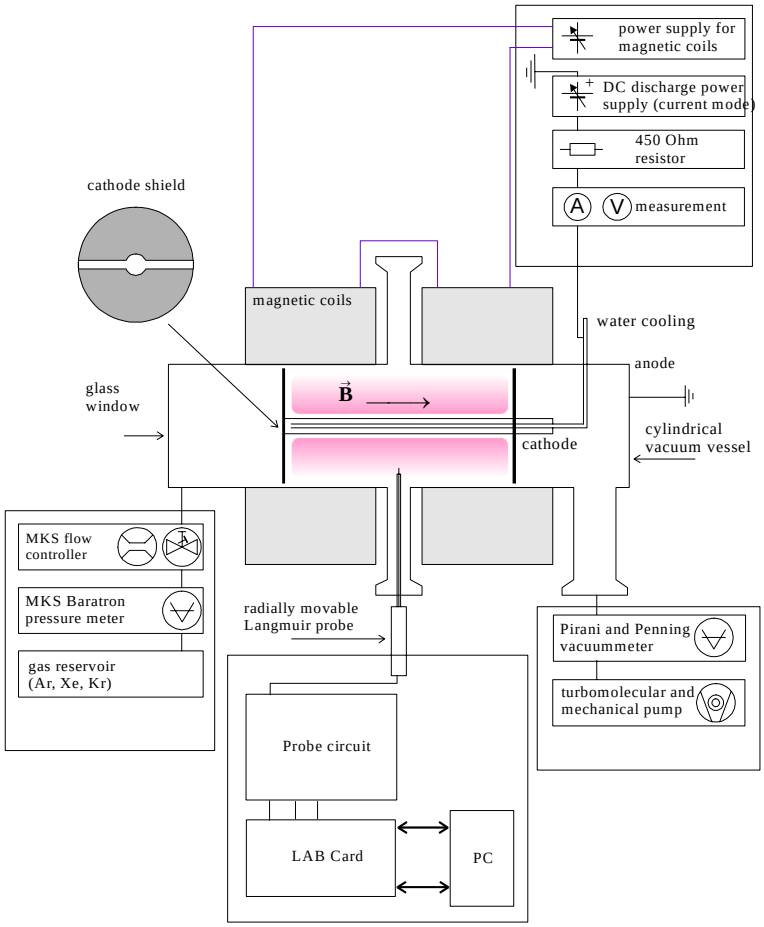

Figure 1: Cylindrical magnetron scheme. Faculty of Mathematics and Physics, Charles University in Prague.

and “shorter” for easier handling in this text. Cathode radius of the “longer” magnetron is 9 mm, anode radius is 28 mm. Dimensions of the “shorter” magnetron are given in figure 2.

3. Particle-In-Cell model of the magnetron

For theoretical description of the discharge in magnetron we used two dimensional Particle-In-Cell code OOPIC [2] developed at the University of California, Berkeley. 2D model of discharge is needed because discharge is not homogenously distributed along the whole discharge region [3]. The scheme of the region for the 2D PIC simulation of a discharge in the cylindrical magnetron is depicted in figure 2. In order to reduce computational effort we placed reflecting boundary to the middle of the magnetron and we simulated only half of the discharge area length (from the center of the discharge region to the left limiter). Though only one half of the discharge area in magnetron was modeled, simulations still needed relatively huge computational power because Debye length in magnetron is typically tens of micrometers and needs to be resolved by grid.

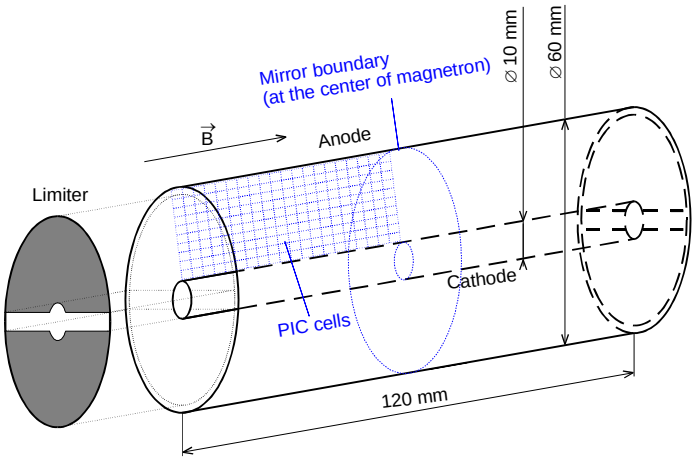

Figure 2: Scheme of region for 2D PIC simulation of discharge in the “shorter” magnetron.

4. Comparison of PIC results with experiment

An example of computational results of OOPIC model is presented in figure 3. Comparison of computational density profile with Langmiur probe data is given in figure 4 for two different experimental conditions. Considering that maximum of the electron density is proportional to the applied power we can see satisfactory agreement of model results with experimental data. Electron density maximum is approx. at the

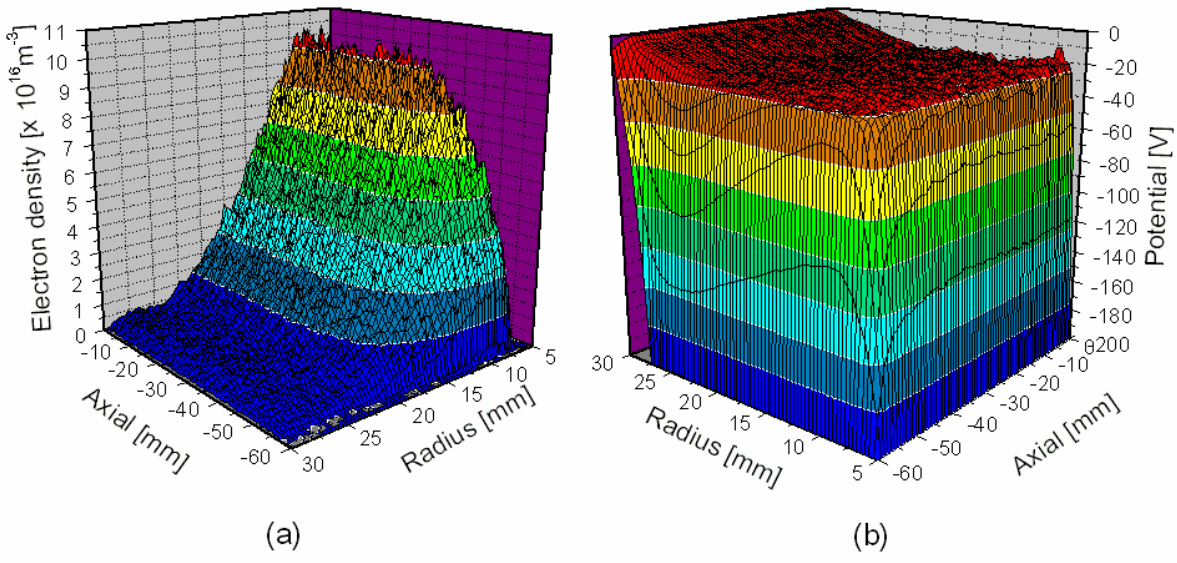

Figure 3: OOPIC simulation results of Argon discharge in magnetron at p = 4 Pa, B = 20 mT, $U_{Cathode}$ = -200 V. Data are from snapshot taken at discharge time t = 6,4.10^{-7}s. Density profile used for initial condition was obtained from former simulation with rougher computational grid. Zero of axial coordinate denotes center of magnetron; r_{Anode} = 30 mm; $r_{Cathode}$= 5 mm. Cell dimension is comparable with Debye length (i.e. 500×1250 cells).
(a) electron density profile, (b) potential profile (for better view 90° clockwise rotated).

same position in experiment as well as in PIC simulation. Electron density fall profile corresponds better with data obtained at higher magnetic field (25 mT, 5 Pa – note ratio of the magnetic induction and pressure B/p= 5 mT/Pa is the same in both experimental cases) in region of positive column. Potential profile obtained in the simulation is depicted in figure 3b. We can see relatively broad region, where the plasma potential remains practically constant – positive column. It is good result in comparison with our former 1D PIC simulations [4] and also former 2D simulations using grid with larger cells [5] (and also presented in printed abstract of this symposium), where we observed relatively big potential fall in this region. Recent results depicted in figure 3 were obtained in simulation with more precise grid. Length of cells was already comparable with Debye length. Although the broad region of the almost constant potential was observed in this simulation (i.e. well developed region of the positive column), anode fall is relatively big (approx. 20 V) and reach relatively far into the discharge volume. In contrast to that, experimental data obtained via Langmuir probe diagnostics showed that the potential fall in the anode region as well as in the positive column is only a few volts at these experimental conditions. More detailed view of the potential obtained in the simulation (figure 3b) is depicted for three different axial positions in figure 5.

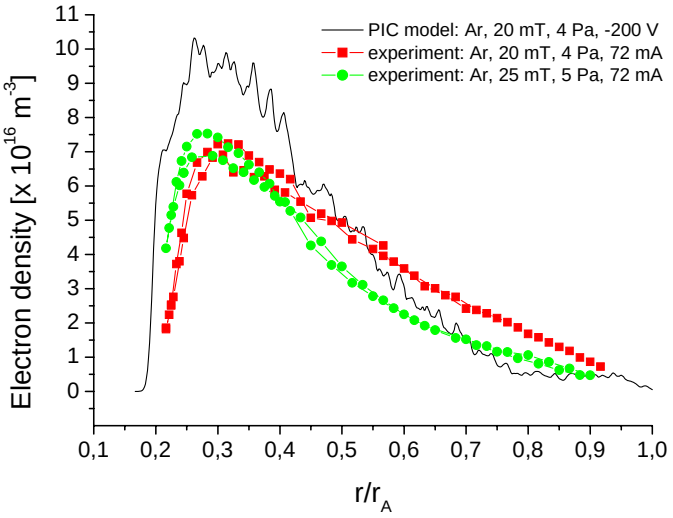

Figure 4: Comparison of computational density profile with data obtained in magnetron via Langmuir probe. r_A is anode diameter

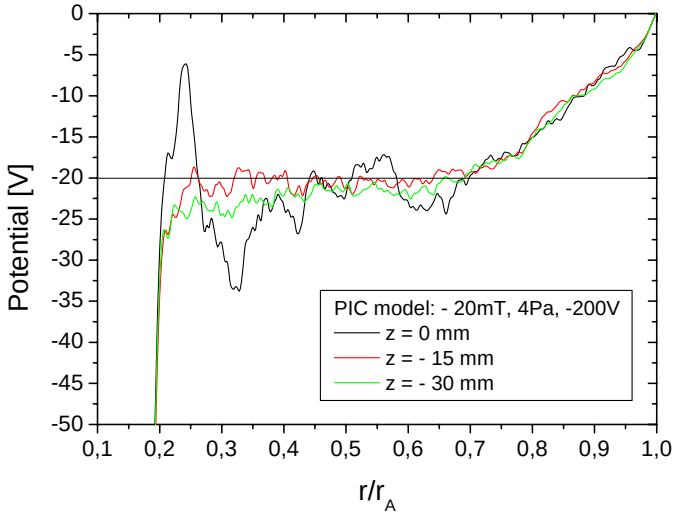

Figure 5: Detail of computational potential profile at three different axial positions. r_A is anode diameter, z = 0 denotes the center of the magnetron.

In order to validate experimental plasma potential profile by another independent method we measured plasma potential profile in cylindrical magnetron by emissive probe too (in fact with kT_e/e difference [6]). These measurements have been realized in the "longer" magnetron. Emissive probe data are depicted in figures 6 and 7. According to dependence of the floating potential on the probe heating that is depicted in figure 6 we set operating point for our next measurements. We chose heating current I_{HEAT} = 1.3 A that was already good approximation of plasma potential at given experimental conditions. Emissive probe data (see figure 7) confirmed results obtained by Langmuir probe: potential fall in the region of the positive column was only a few volts as well as the potential fall in the anode region.

Large potential fall in anode region can be caused by some of these factors: a) grid is not still precise enough, b) discrepancy is observed because of the noise in potential caused by small number of superparticles per one cell, c) model doesn't involve all processes participating in burning discharge (especially proper description

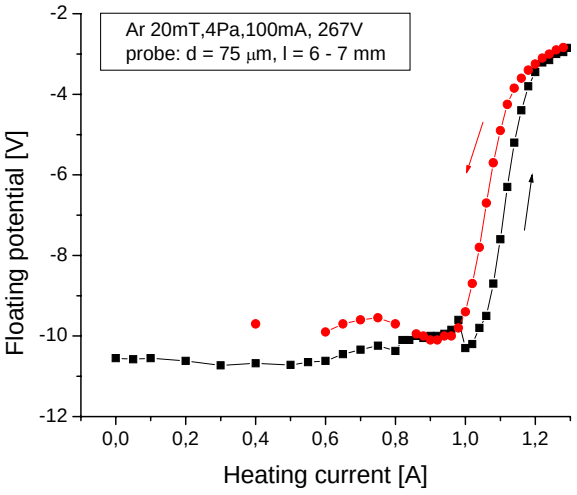

Figure 6: Heating characteristics of emissive probe. Operating point determined at 1.3 A.

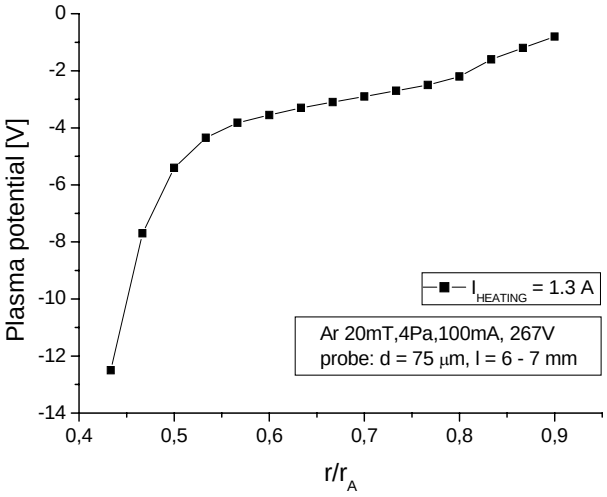

Figure 7: Radial profile of plasma potential obtained by strongly emitting probe in "longer" magnetron.

of plasma interaction with anode surface). Solution of this discrepancy of the model with experiment will be object of our future work.

Conclusion

Experimental and theoretical study of dc magnetized discharge in cylindrical magnetron device was presented at this place. Results of 2D PIC simulation were compared with data obtained by means of Langmuir probe and emissive probe diagnostics. Despite that qualitative agreement of simulation with experiment was found in electron density profiles, further improvement of model is needed because of discrepancy in potential profile. Simulation resulted to potential profile with well developed region of positive column but with relatively big anode fall, that protrudes relatively far into the discharge volume. This phenomenon doesn't correspond with experiment.

Abstract
It is known that nanotubes can be synthesized from carbon monoxide in a plasma reactor with Atmospheric Pressure High-Voltage Discharge (APHVD) at electric field about 1 kV/cm. This field is sufficient for formation of excited molecules of CO in plasma, owing to collisions with the high-energy electrons. Excited CO molecules are capable of activating the synthesis of nanomaterial. At the same time, the gas translational temperature can be remained on optimal level, appropriate for synthesis (about 700-800 K). However, APHVD is operated at low power only, not more than 0.2-0.3 kW. In this work we propose that similar conditions can be attained with much higher power in a plasma reactor with magnetic annular arc. The results of the study of electrical characteristics of such reactor are represented.

1. Introduction

Carbon nanotubes (CNT), considered as a new form of pure carbon, attract attention due to its unique mechanical and electrical properties. The growing number of applications for CNT has resulted in their increasing demand. Major obstacle in wide application of CNT consists in exclusively high cost and absence of large-scale manufacturing techniques. Nowadays, several methods of CNT production are being actively studied in laboratories. Most of them involve the variation of three principal techniques such as arc discharge, laser vaporization of graphite targets and chemical vapor deposition. All above-mentioned methods are exclusively labor-intensive and inefficient, which restrains scaling up their production for application in various industries. Thus, the development of new technique and technology for continuous production of CNT is very important now.

As it was shown in [1,2], a relatively high yield of carbon nanomaterial can be obtained in plasma reactor with Atmospheric Pressure High-Voltage Discharge (APHVD). This discharge is characterized by substantial non-equilibrium effects and is attractive for many potential applications. The authors [1,2] attained nanomaterial productivity at a rate of 1.5 g/hr with plasma reactor of 0.25 kW electric power. A methane-air mixture was used as plasma-forming gas. X-ray analysis showed that produced carbon material includes single wall carbon nanotubes (25-30%), fullerenes (12-20%) and diamond fraction (nearly 2-5%). By hypothesis of the authors [1,2], the proposed technique of CNT manufacturing consists in performing the Boudouard CO disproportionation reaction with participation of vibrationally excited molecules of carbon oxide [3]

$$\begin{gathered} \mathrm{CO}(v)+\mathrm{CO}(w) \rightleftarrows \mathrm{CO_2}+\mathrm{C} \\ E_v + E_w \geq 5.5\ \mathrm{eV} \end{gathered} \qquad (1)$$

where carbon monoxide molecules CO(v) and CO(w) are in vibrational quantum states v and w. Exceeding the reaction activation barrier of 5.5 eV can be achieved by the excitation of upper vibrational levels of CO molecules by electrons accelerated in high electric field. Since the activation energy for this reaction is provided by vibrational energy mode, the gas kinetic temperature can be kept at a value in the range 700-800 K, suitable for carbon nanomaterials formation.

By its electric characteristics, APHVD occupies intermediate position between glow and arc discharges and is realized in a relatively wide range of discharge voltage (~1–10 kV) and direct current (~0.02–0.2 A). In the experiments [1,2] the discharge electric field was near to 1 kV/cm at currents of 100-120 mA. As it is well known, the more effective formation of carbon nanomaterials occurs over the catalysts containing atoms of Fe,

Ni, Zr, Mo, Co. In APHVD the cathodes, made from these metals, serves as the source of catalytic particles regulated by erosion.
The serious drawback of APHVD is the transition into low-voltage electric arc discharge at current exceeding 0.2-0.3 A, which limits the net power of the installation. In order to avoid this limitation we investigated plasma chemical reactor, based on Magnetic Annular Arc (MAA), as possible apparatus for effective realization of Boudouard CO disproportionation reaction at continuous regime for large scale CNT production. Basically, MAA constitute an electric arc rotating between two coaxial electrodes in the presence of high intensity axial magnetic field at atmospheric pressure. At this kind of installation it is possible to attain a high electric field at substantially higher discharge current.

2. Experimental setup

The schematic drawing of the experimental setup is shown in Figure 1. The installation was equipped with copper ring electrodes. The outer electrode was the cathode, inner diameter of 50 mm, and anode (inner electrode) with outer diameters of 36, 48 or 48.8 mm for different experiments. Thus, a radial inter-electrode arc gap was 7, 1 or 0.6 mm, respectively. The electrodes in the form of narrow rings were isolated from the adjacent part of the setup by thermal- and electro-insulating spacers. The insulation permits to limit axial displacement of the arc and hold the arc length nearly the inter-electrode gap.
The whole system was equipped with a coaxial magnetic-arc-deflection system composed of a pair of solenoids. The solenoids create magnetic field up to 3.7 Tesla. Under the action of Lorentz force the electric arc rotates at high frequency, which was measured by photo-sensor mounted opposite the inter-electrode gap. For more stable axial location of the arc, we applied local decrease in the magnetic field obtained by location of solenoids at proper distance one from another.
The experiments were carried out at atmospheric pressure in air.

3. Results and Discussion

In Figure 2 we present one of the most important characteristics of MAA, i.e. the arc voltage *U* versus magnetic field *B* for three different inter-electrode gaps. We see that the arc voltage increases linearly with magnetic field, while it was practically independent on the arc current (in the range up to 600 A) for our experiments. This phenomenon was observed elsewhere [4,5].

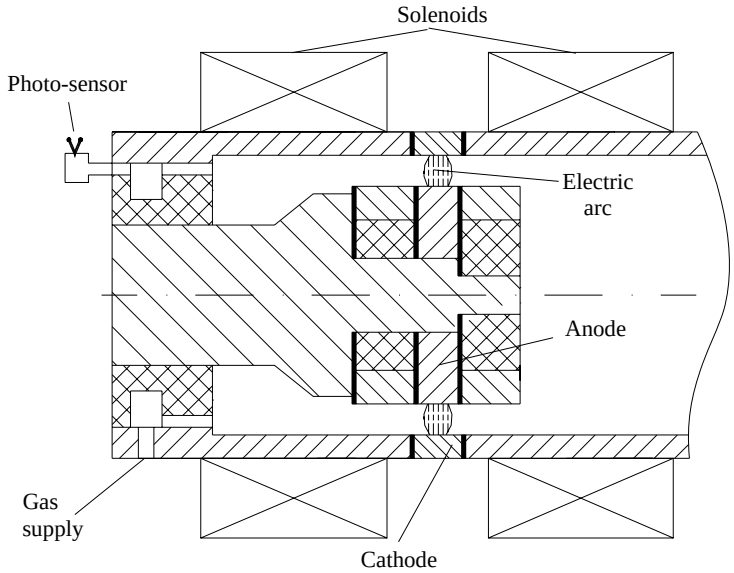

Figure 1. Experimental setup.

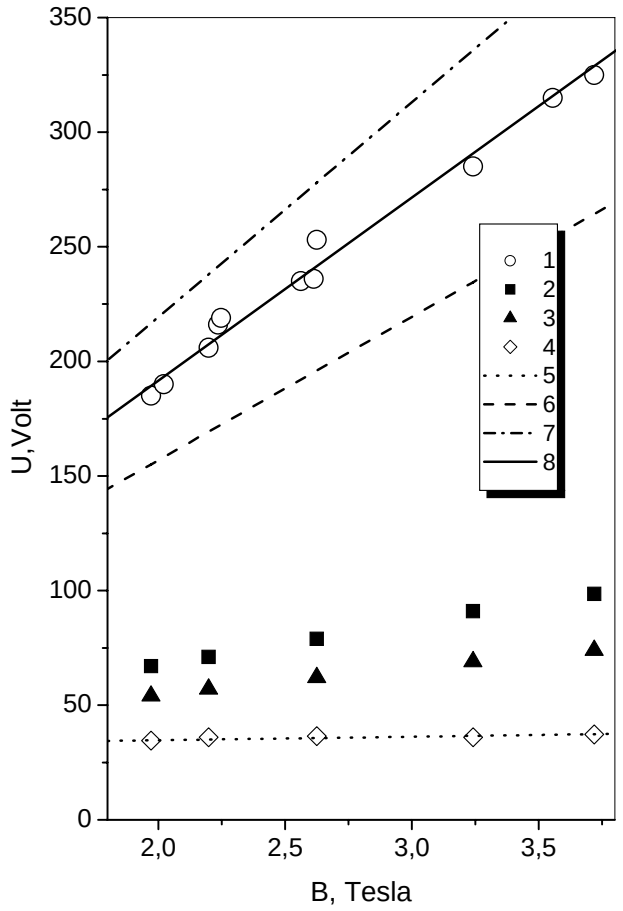

Figure 2. The arc voltage versus magnetic field for arc current of 350 A in air. Experimental data: 1 - points with inter-electrode gap of 7 mm; 2 – 1mm; 3 – 0.6 mm. 4 – U_0 from linear extrapolation of points 2 and 3 to *L=0* mm; 5 – linear fitting of U_0; 6 - radial gap between electrodes 7 mm. Calculations in accordance with eq. (4): 6 – $V_{ion}=V_{Ar}$, $m=m_{Ar}$; 7 – $V_{ion}=V_{N2}$, $m=m_{N2}$; 6 – $V_{ion}=V_{N2}$, $m=m_{Ar}$.

Besides of large inter-electrode gap, L=7 mm, we have measured discharge voltage drop U at ultra short gaps: L = 1 and 0.6 mm. Then, assuming linear dependence $U(L)$, the sum of near- electrode (cathode and anode) voltage drops $U_0=U(L=0)$ was obtained as a result of linear extrapolation of arc voltages obtained on short gaps. Points 4 in Figure 2 (closed symbols) represent the result of linear extrapolation U to inter-electrode gap of L=0. This points can be approximated by a linear function of magnetic field $U_0(B)$. Thus we can conclude that for high magnetic fields arc column voltage (without U_0) and, respectively, effective electric field $E=U/L$ in arc column are linear functions of magnetic field.

Theoretical explanation of the linear nature of *U-B* dependence for the first time has been proposed for the diffuse vacuum electrical discharges in the homopolar devices, and based on the hypothesis of critical ionization velocity v_c of plasma [6,7]. According to this hypothesis, starting with a certain small degree of ionization, the plasma velocity increases with magnetic field but no increase in ionization takes place, until the critical velocity v_c is reached. A further increase in the magnetic field leads to no increase in velocity but an increase in the degree of ionization. In other words, the drift velocity of plasma component in the magnetic field has a constant value for given gas, until total ionization was achieved. In the works [6,7] it was considered a situation where a plasma and a neutral gas are in relative motion across magnetic field. Rapid ionization occurs when a free relative kinetic energy source corresponding to motion perpendicular to the magnetic field in the system exceeds the ionization potential of the neutrals. A critical velocity for anomalous ionization was therefore hypothesized by Alfvén [6] to exist at

$$\frac{1}{2}mv_c^2 = eV_{ion}. \qquad (2)$$

Here e is the magnitude of the electronic charge, V_{ion} is the ionization potential, and m is the mass of a neutral particle. Above v_c the energy in the relative motion should be rapidly used to ionize the neutral gas.

This process, called the critical ionization velocity (CIV), is essentially an instability-driven ionization mechanism where neutral gas is ionized in a more abrupt and efficient manner than can be accounted for by classical means (binary collisions, thermal electron impact, photoionization, charge stripping, charge exchange, etc...).

Subsequently a similar explanation of *U-B* linear dependence was extended to the magnetic annular arcs. There were attempts to explain the phenomenon by a sort of collective interactions, microturbulence, etc., but a rigorous theory of ionization mechanism was not elaborated, until now [6-10]. In the absence of the azimuthal

uniformity of the discharge, i.e., in the spoke-similar arc discharges *U-B* dependence keeps linear nature and could be calculated, using the same formulas as diffuse discharge [11-14].

Theoretical studies and observations of staged CIV interactions in the laboratory have characterized the phenomenon as one in which the free energy source associated with the directed kinetic energy of the relative motion between two plasma components excites plasma micro-instabilities. These instabilities would then channel a substantial part of the relative kinetic energy to heat electrons preferentially creating a substantial population of electrons with energies above V_{ion}, which would then contribute to a substantially enhanced ionization process. The energy going into ionization ultimately comes from the relative motion (i.e. the arc column kinetic energy) and consequently the CIV interaction results in slowing down the relative velocity to near v_c during the interaction.

The instability, typically of the lower hybrid mode, is originally ignited by the cross-streaming of "seed" charged particles (arc column) in the neutral gas with respect to plasma particles and maintained through the cross-streaming between newly created and old charged particle populations. The lower hybrid wave can easily be destabilized by an ion beam perpendicular to magnetic field when the beam velocity is above the ion thermal speed. It must be emphasized that in all CIV scenarios a "seed" of charged particle must initially exist in the neutral gas.

In strong magnetic fields the ion drift $\vec{v}_E$ perpendicular both electric $\vec{\mathbf{E}}$ and magnetic $\vec{\mathbf{B}}$ fields

$$\vec{v}_E = \frac{\vec{\mathbf{E}} \times \vec{\mathbf{B}}}{B_0^2}. \qquad (3)$$

Integrating (3) in the inter-electrode gap and assuming $v_E=v_c$ we obtain the arc voltage in the form

$$U = U_0 + v_c BL, \qquad (4)$$

where U_0 – the sum of near-electrode voltage drops.

The calculated value of arc voltage *U* is shown in the Figure 2 (see lines (6)-(8)). The calculation on the base of nitrogen data (as the main component of plasma) showed the values of arc voltage below obtained experimental points (line 6). For this case the sum of energy of dissociation (9.756 eV) and ionization (15.5 eV, see [15]) of nitrogen was used as $V_{ion}=V_{N2}=25.256$ eV and $m=m_{N2}=4.65\times10^{-26}$ kg.

Following Alfven's hypothesis, one expects a burning voltage must be corresponding to the critical velocity of the specimen with lowest relation V_{ion}/m. The argon is well-known as easiest-to-ionization and heaviest component of air and posses the lowest value of V_{ion}/m. The arc voltage corresponding to critical velocity on the base of argon data (V_{ion} = 15.76 eV, $m=m_{Ar}=6.62\times10^{-26}$ kg) is shown as line 7 in the Figure 2 and exceeds the experimentally obtained one.

Assuming that, first of all, the argon atoms are ionized and owing to posses the greatest mass they can easy dissociate and ionize other specimen of air. Thus for this process we calculated the arc voltage using ionization potential of nitrogen $V_{ion}=V_{N2}$ and argon mass $m=m_{Ar}$. In this case, calculated values of arc voltage *U* agrees well with the experimental points 1 (see line 8 in Figure 2).

In accordance with (4) the electric field in MAA can be estimated as $E=Bv_c$. Thus for the CO-H_2-N_2 mixture, utilized in APHVD experiments, even for a pair C-H_2 with lowest ionization potential we obtain an electric field that exceeds 1 kV/cm at 5 Tesla. This value is approximately the same as for the APHVD. In practical situations the electric field in multi-component plasma depends on main phenomenon of interaction (exchange channel) between plasma components. Hence, it is possible to find experimentally appropriate regimes and local of reaction zone within reactor with relatively low mean temperature and substantial contribution in vibration energy of carbon monoxide in order to perform the mentioned Boudouard CO disproportionation reaction. Moreover, MAA permits to scale-up the power and utilize catalyst of different kind and phase: solid, liquid, gas.

4. Conclusion

Electric characteristic of plasma chemical reactor based on Magnetic Annular Arc were studied. It was shown that there is a possibility to obtain the conditions when discharge plasma exists in non-equilibrium state at atmospheric pressure. Specific characteristic of installation is high electric field, which linearly depends on applied magnetic field. An instability-driven ionization mechanism, where neutral gas is ionized in a more

abrupt and efficient manner, is assumed to explain observed phenomenon. By hypothesis, a substantial part of the relative kinetic energy is channeled to heat electrons, preferentially creating a substantial population of electrons with energies above ionization energy. This permit attains the highest values of electric field, similar to APHVD. The plasma chemical reactor is dedicated to perform Boudouard CO disproportionation reaction in order to obtain the carbon nanoparticles in large scale.

Characterization via image analysis of the arc spray using two different wires

M.P. Planche, H. Liao, C. Coddet

LERMPS, UTBM, Site de Sévenans, 90010 Belfort Cedex – France

Abstract
The aim of this study was to investigate the droplets formation in the wire arc spraying process using simultaneously two different materials, namely copper and steel, in order to better understand the role of each electrode on in-flight particle properties when changes are performed in the process. Particles were collected at the spray distance in different points in the spray jet and average content and particle sizes were determined from image analysis. The evolution of particle characteristics showed important modifications in function of the radial position or the electrode nature. Finally, the role of each electrode was related to the droplets formation and coating characteristics in view of optimizing the arc spray process.

1. Introduction

Wire arc spraying is a technique that uses two conductive, consumable wires. A continuous d.c. arc sustained by an electrical source melts the crawling wire tips. A wire arc spray gun consists of a nozzle that directs a high velocity air jet to the wire tips and a wire feed mechanism that moves the wires forward. A gas flow atomizes the tips of the melting wires and accelerates the resulting small droplets toward the substrate being coated. The gas stream is responsible for forming the initial droplets after the removal of the molten material from the wire tips (primary break up), for atomizing the larger droplets (secondary break up) and for accelerating them towards the substrate. Then, higher gas velocities will result in the generation of finer particles which are accelerated to higher velocities [1, 2]. Dynamic forces of the atomizing gas stream are acting on the arc as well as on the droplets lead to different particle sizes, which, in turn, determine the coating properties [3]. In the d.c. two wires arc spray process, one of the wires is connected to the positive electrode, the other to the negative one. According to the results presented in the literature [4, 5], an important difference between those two electrodes exists leading to an asymmetric melting behaviour of two wires. Indeed, the anode melts slowly, resulting in elongated relatively large droplets while the cathode melting is rather localized which gives rise to relatively small droplets. As a consequence, this uneven melting affects the spray pattern and the coating structure [6]. Moreover, depending on the working parameters, deposit microstructures and properties can be strongly affected by the noticeable differences in the thermal and the kinetic backgrounds of the formed particles [7]. Therefore, in this study, the role of the electrodes, either anode or cathode, was considered with the objective of pointing out the differences between them in terms of particle characteristics and coating properties. A set of measurements was performed to quantify the characteristics of particles at several locations in the jet. For each location, particles were also collected in water and image analysis allowed to determine the percentage and size of each material. Some coatings were also sprayed and their thickness and microstructures analysed. Some correlations were then searched in order to demonstrate the role of each electrode in the particles formation.

2 Experimental procedures

2.1 Wire arc spray process and parameters

A TAFA 9000 arc spray gun (Tafa Inc. Concord, NH) was used for this work. A current of 150A, a voltage of 30V and 100 m^3/h atomizing air flow rate were set up for all the experiments. 1.6 mm diameters steel and copper wires were produced by Tafa®, respectively referenced 38T and 05T. The composition of these wires is given respectively in table 1 and table 2.

Table 1. Composition of TAFA 38T wire.

Element	Fe	C	P	S	Mn	Si
% in weight	97.7	0.8	0.4	0.3	0.7	0.1

Table 2. Composition of TAFA 05T wire.

Element	Cu	Zn	Pb	Sn	Si	Mn
% in weight	97.7	0.04	0.01	0.8	0.3	0.8

The main properties of these materials are summarized in table 3.

Table 3. Properties of Fe and Cu.

	Copper	Steel
Melting temperature (K)	1358	1808
Vaporisation temperature (K)	2840	3023
Density (kg/m^3)	8920	7874
Thermal conductivity (W/m.K)	401	80.2

2.2 Particles collection

Particles were first collected by directing the spray jet onto water at the location corresponding to the coating built up. The scheme of this procedure was already described in [2]. A receptacle of water was used to collect the particles passing through a 2.5 mm diameter capillator. The time of spray for this static position was about 60 seconds in order to collect enough particles. Then, depending on the nature of the electrodes, experiments were systematically performed with the two arrangements; i.e. copper anode / steel cathode and steel anode / copper cathode. Particles collection was performed at the constant axial distance of 150 mm from the nozzle exit and for three different radial locations: -2 cm, 0 and 2 cm relatively to the spray jet centre. After proper drying, photographs of the particles were taken. A photograph of these particles collected in the jet axis is given in Fig. 1 as an example.

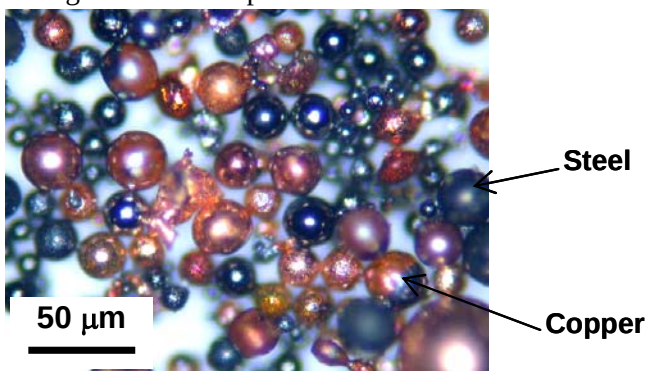

Figure 1. Photograph of collected particles.

It can be first observed that all the particles are spherical and solidified during impact on water and second, that steel particles can be easily distinguished from that of copper. It can be noted too that droplets from the two wires are not in contact during their flight because only individual droplet composed either of steel or of copper is observed. Thus, a clear identification of steel and copper particles was possible, leading to the determination of their respective number fraction and average diameter and allowing a statistical treatment of the data.

2.3 Coating built up

The substrates were prepared with grit blasting and placed 150 mm from the gun on a stationary mound. Polished cross sections of the sprayed coatings were digitalized using a Nikon EPIPHOT optical microscope coupled with a Nikon COOLPIX E955 digital camera. Pictures were taken at different radial locations in the coating corresponding to those of the particle collection, as shown in Fig. 2.

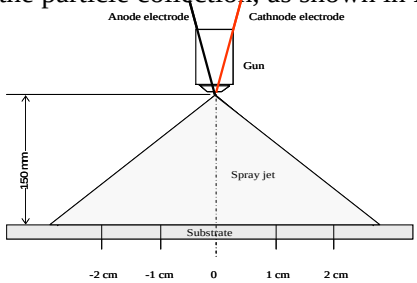

Figure 2. Locations of coating cross sections.

About 20 pictures were taken in order to cover an area important enough around the defined locations. The analyzed area of one picture is 50x40 µm² and the total area corresponds to 80000 m² for one location.

Magnification, field of vision and illumination conditions were kept unchanged to ensure consistency of these pictures and then to obtain a significant comparison between them. Because some colour differences are well marked between each specimen, an image analysis program using the RGB value as a colour criterion was used to clearly recognize the different features in the coating. This way, the area fraction of each element could be estimated with accuracy.

3 Experimental results

3.1 Analysis of the collected particles

The obtained pictures were digitalized using the «Graftek» software®. An example of images is given in Fig. 3 corresponding to particles collected in the central location in the spray jet with a steel anode and a copper cathode (Fig. 3.a) and a copper anode and a steel cathode (Fig. 3.b). Comparing these images, it can be clearly observed that important modifications in particle characteristics in terms of size and number exist when electrodes material are changed. Steel particles are bigger when steel is used as anode and only a few copper particles are present in this case; an anode copper leads to a better homogeneity of the type of particles not only in size but also in number. Statistical measurements were made on about 600 to 800 particles for each experiment in order to estimate the average diameter of each type of particles as well as their respective number fraction.

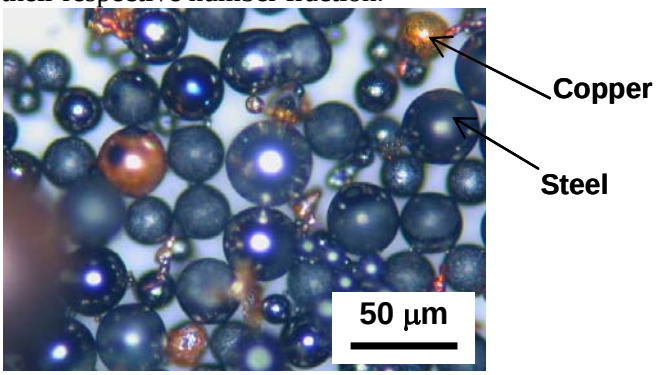

Figure 3.a. Particles in the centre of the jet sprayed with a steel anode and a copper cathode.

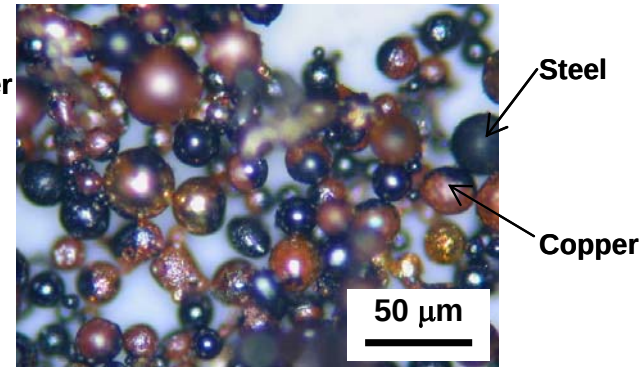

Fig. 3.b. Particles in the centre of the jet sprayed with a copper anode and a steel cathode.

3.1.1 Evolution of the average number fraction of individual wires

Fig. 4 (a) and 4 (b) present the results obtained at three different locations in the spray jet at 150 mm from the gun exit.

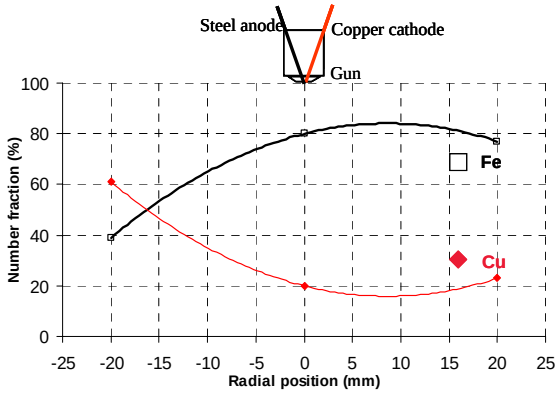

Figure 4.a. Evolution of the number fraction of particles sprayed with a steel anode and a copper cathode.

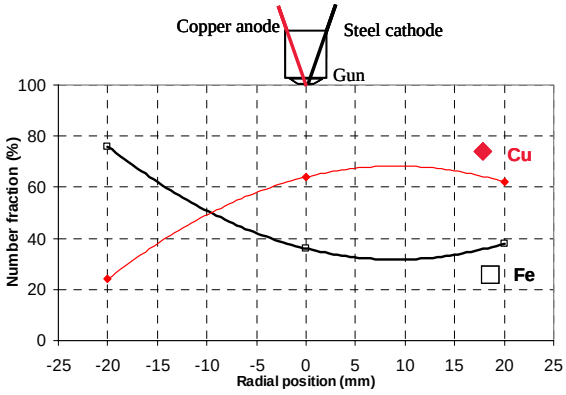

Figure 4.b. Evolution of the number fraction of particles sprayed with a copper anode and a steel cathode.

It can be observed that these particles ratii are largely dependant on the electrodes nature and on the location in the spray jet. Indeed, when the analysis location changes radially from – 2 to + 2 cm, inversed evolutions are observed demonstrating the cross – over behaviour of the particles during their flight. That leads to a percentage for one type of material the highest in location the furthest from the original position of the wire. Moreover, using steel anode conduces to obtain a number fraction almost majoritary (33% to 78%) in

comparison to that obtained with copper anode that does not exceed 64%. The same observation can be made for cathode electrodes with a number of steel particles always bigger than that of copper particles. One parameter allowing to explain this phenomenon is the difference of the melting temperature of these two materials. With a melting temperature the lowest for copper, it can be supposed that some copper droplets can instantaneously disappear due to vaporization restricting finally drastically the number of copper droplets in the image analysis.

3.1.2. Evolution of the average particle diameter of individual wires

The respective evolutions of steel and copper diameters are given in figure 5 corresponding to a process working either with steel anode / copper cathode (Fig 5 a) or with copper anode / steel cathode (Fig 5 b). These evolutions are function of the radial positions at 150 mm from the gun exit.

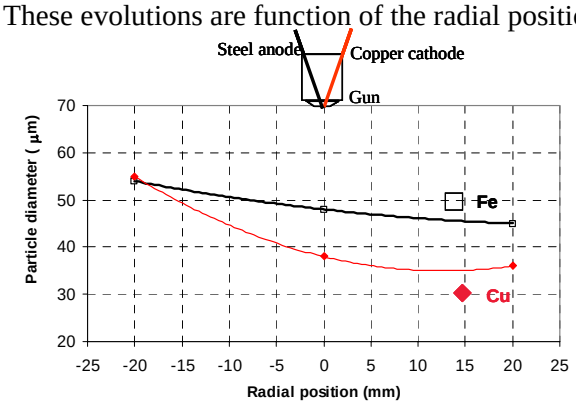

Fig. 5.a. Evolution of the diameter of particles sprayed with a steel anode and a copper cathode.

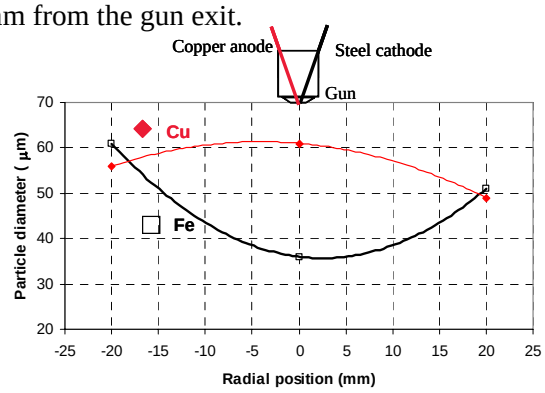

Figure 5.b. Evolution of the diameter of particles sprayed with a copper anode and a steel cathode.

Looking at the evolutions of particle diameter obtained for the same locations (Fig. 5), anode electrode allows to obtain the bigger diameters in comparison to those produced by the cathode. As already observed through high speed camera imaging [4], this is due to the diffuse attachment of the arc at the anode tip which heats a large part of the wire surface creating consequently droplets with big diameter. Respectively, the smaller diameters corresponding to the cathode electrode are attributed to the constricted attachment of the arc which is responsible of the very small detachments of molten metal. Moreover, for the location in the jet centre, the particles generated by copper anode have a bigger diameter (60 µm) than that given by steel anode (48 µm). That can be explained by their melting temperature difference which makes the melting of copper wires easier and leads to the formation of bigger particles.

3.1.3 Evolution of the average volumetric percentage

From the results obtained by both evolutions (numerical fraction and droplet diameter), the average volumetric percentage of each material can be deduced using the following relations:

$$V(steel) = N(steel)\frac{\pi}{6}d^3(steel) \quad (1)$$

$$V(copper) = N(copper)\frac{\pi}{6}d^3(copper) \quad (2)$$

where N is the number and d the mean diameter of each material.

$$\%\ of\ copper = \frac{V(copper)}{V(Total)} \quad (3)$$

where $$V(Total) = V(copper) + V(steel) \quad (4)$$

Fig. 6 presents the evolution of these percentages for the two different process combinations. The role of the anode is clearly demonstrated because the volumetric percentages obtained either for steel anode or for copper anode are superior to 85% in the jet axis which are the result of the higher diameters found in this location. It appears also that a minor percentage of copper exists in the eccentric positions (-2 and +2 cm) relatively to steel percentages. Consequently, these results suggest that the contribution of the anode electrode in the coating built up will be largely preponderant. Moreover, with the low melting temperature of

copper, it can be assumed that the smallest copper particles can instantaneously disappear due to vaporization phenomena decreasing finally their contribution in the volumetric percentages.
This conclusion if confirmed by the determination of the mean volumetric fractions for the three locations. Indeed, it is interesting to note that a globally minor volumetric fraction (50 %) of copper exists in comparison to steel one (65 %). To conclude, that proves the copper disappearance because the velocity imposed on the wires advance is the same. This remark will be confirmed in the future by the coating microstructure analysis.

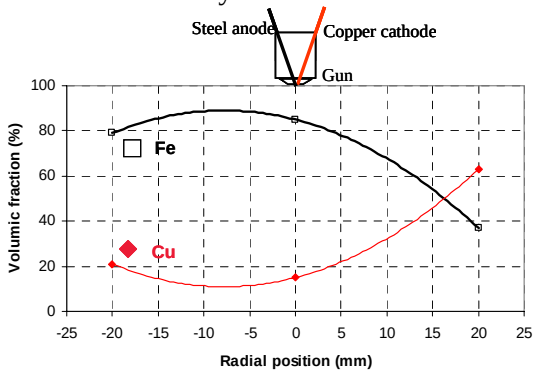

Figure 6.a. Evolution of the volumic fraction of particles sprayed with a steel anode and a copper cathode.

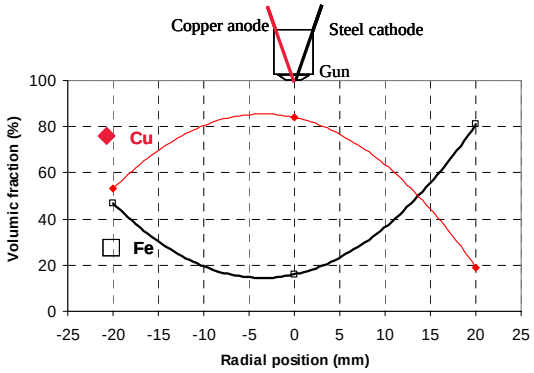

Figure 6.b. Evolution of volumic fraction of particles sprayed with a copper anode and a steel cathode.

4 Coating microstructure

From image analysis of a cross section of sprayed deposit, typical microstructure of these deposits is given in figure 7. This figure corresponds to the microstructure obtained at 150 mm from the gun exit for respectively steel anode / copper. This image reveals predominant regions including dark and light colours which correspond respectively to copper and steel materials. Using the image analysis program to distinguish the different colours present in the coating, the area fraction of steel and copper can be quantitatively defined and compared to previous results.

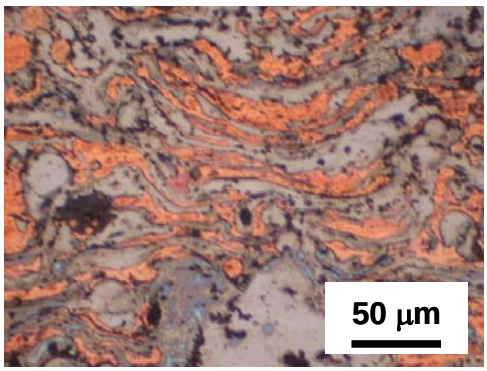

Figure 7. Typical microstructure of coating sprayed with steel anode and copper cathode in the jet centre at 150 mm from the gun exit.

Figures 8 gives the microstructures of deposits obtained at the two eccentric positions (+ 2 and – 2 cm relatively from the jet axis) and for the two different electrodes arrangements corresponding respectively to steel anode / copper cathode (Fig 8 a) and to copper anode / steel cathode (Fig 8 b).
The variations of steel and copper contents along the cross section of the deposit follow the same tendency than that presented by particle analysis i.e. the cross behaviour of the particles during their flight is clearly observed. It can be observed that the highest quantity of one or the other material regardless to the fact of where the measurements are performed. In order to give a quantitative description of material distribution in the different coatings, its cross section are digitalized by using an optical microscope and the images analyzed via the computer image analysis. Due to random phenomenon which takes place in the spray process, it can be assumed that the area fraction determined from the images analysis is directly proportional to the volumetric fraction previously examined. In conclusion, after comparing these results, a good correlation can be found between the two giving no more than 5% difference between them.

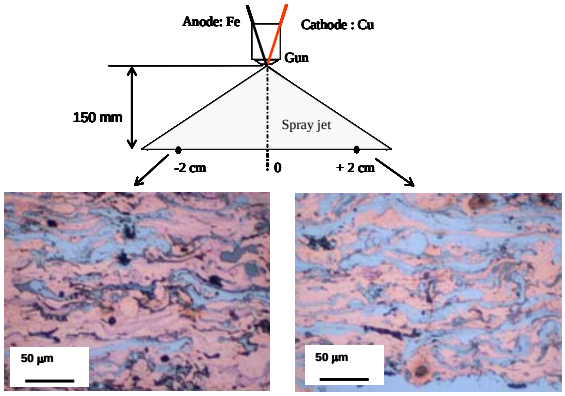

Figure 8.a. Microstructures of coating sprayed with a steel anode and a copper cathode at +2 and -2 cm from the jet axis.

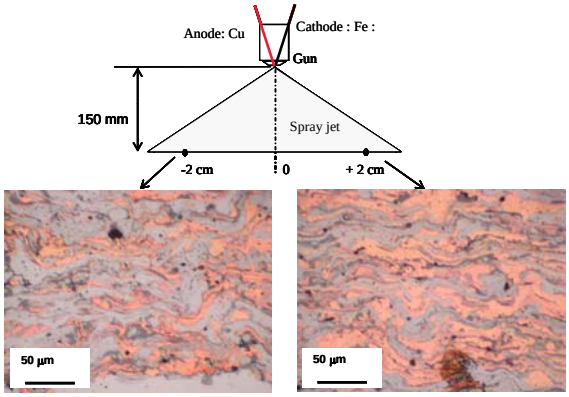

Figure 8.b. Microstructures of coating sprayed with a copper anode and a steel cathode at +2 and -2 cm from the jet axis.

5 Conclusion

Commercially available 1.6 mm in diameter TAFA steel (30T) and copper (05T) wires are sprayed together with the TAFA 9000 spray process at a voltage of 30V with a current intensity of 150 A with a total 100 m^3/h air as atomizing gas. With the help of a specific set up dedicated to collect the particles at different radial locations, + / -2 cm relatively from the jet axis and at 150 mm from the gun exit, the analysis of these collected particles allows to quantitatively define the electrode function in terms of particles production.It is interesting to observe that while steel particles increase from the left to the right, copper particles decrease in the similar way accordingly, regardless to the fact that copper and steel wires are positioned on the right and left hand side of the axes of symmetry respectively. That demonstres the cross over behaviour of the particle trajectories. Finally, it is proved that the asymmetric melting, droplet forming and detaching behaviour of the two wire tips affect the spray pattern, especially the coating microstructure. Appreciable differences are pointed out in coatings containing a majority of steel or copper relatively to the material anode used for spraying. Then, it is clearly shown that the use of steel anode leads to greater percentage of this material than that corresponding to copper anode. In conclusion, the microstructure analysis presents the same material content distribution as that already estimated by image analysis, with a maximum deviation between them not higher than 5 %. It has been proved that the smallest copper particles produced by the hottest electrode (the anode) vaporize immediately leading to losses of this material in the coating.

Abrasion Resistant Coatings for Glazing Applications Technology Scale up

T. Miebach, C. D. Iacovangelo, M. Mercedes, T. W. Kim, W. A. Morrison

GE Global Research Center, General Electric Company, Niskayuna, NY, USA

Abstract
We have investigated the different aspects of arc design with regard to industrialization criteria in an effort to optimize the arc design. Examples will be given of how arc design can be modified to improve arc efficiency and performance. Principles to compare and characterize different arc designs in the coating process were developed. Finally, during this work an understanding of the deposition process was sought and some insights were gained on the relationship between arc and/or plasma parameters and the performance of the deposited coating.

Keywords
Expanding thermal plasma, abrasion resistant coating, plasma arc design

Introduction

GE Global Research has been actively pursuing the coating of polymer surfaces with a variety of coatings that allow plastics, such as polycarbonate, to be used to replace glass in transportation and architectural window applications [1]. Plasma based deposition processes have been used in the past to generate various relevant functional coatings, e.g. abrasion resistant or UV absorbing coatings, at substrate temperatures low enough to be compatible with most plastics. However, most plasma deposition processes are not able to coat polymer surfaces at high rates and uniformly over large areas and thus have not been proven to be cost effective.

Schram and Kroesen, at the Eindhoven University of Technology (EUT), developed a deposition process using an individual expanding thermal plasma source (ETP) [2]. It was shown previously that the ETP technology could be used to apply a large variety of coatings at a high rate (typically in the order of 2-30 micron/min) over areas with a diameter in the range of 10-15 cm. Schaepkens et al. reported on the scalability of this process and the development of a unique, high-rate, large area plasma deposition process at General Electric to generate various functional coatings on polymeric substrates [3,4]. The process relies on the integration of a multiple individual ETP sources into an array to form a multi-source plasma deposition setup. Large areas can be coated by translating large area substrates past the array. It has been shown that the versatile control of parameters in the ETP setup (i.e. arc current, gas flow rates and working pressures) enables specific tuning of the film properties (i.e. chemical composition, optical and mechanical properties) [5].

EXATEC LLC was founded as a joint venture of Bayer Material Science and GE Advanced Materials specifically with the automotive market in mind. EXATEC is developing technologies to enable the use of polycarbonate in automotive glazing systems and its R&D covers all processes and manufacturing steps. As part of this portfolio of technologies, plasma enhanced chemical vapor deposition (PECVD) using an ETP arc as the plasma source is used for the vacuum deposition of an abrasion resistant layer on polycarbonate substrates. This technology was successfully scaled to a production scale unit at EXATEC's facility in Wixom, MI, USA. In the process of scale up a variety of issues were addressed, the reactor design, the accommodation of larger substrates, the industrialization of the arc design, process development and coating performance, to name a few.

This work will focus on the subject of plasma arc design, its implications on arc performance and the industrialization process. Maecker first introduced the ETP arc in 1956 [6]. Modifications to the original design were made to study non-ideal plasma effects [7] and the physics of strongly flowing cascaded arcs plasma [8]. Changes were made by Kroesen for the development of the plasma deposition process [2,9], but since then little or no changes were reported.

For the use of an ETP arc in an industrialized application a variety of aspects need to be considered. Functional aspects related to process development have been described in numerous references cited above.

With the process scale up the question of variability (arc to arc for multiple arc systems) and stability (in extended operation) becomes of interest. Also to be considered are aspects of cost. Both, initial cost and operations cost, the latter related to reliability and serviceability, come to the forefront. We have investigated the different aspects of arc design with regard to the criteria above in an effort to optimize the arc design. Reducing the number and complexity of the components involved is one strategy to address the requirements above. Examples will be given of how arc design can be modified to improve arc efficiency and performance. Criteria to compare and characterize different arc designs in the coating process were developed. Finally, during this work an understanding of the deposition process was sought and some insights were gained on the relationship between arc and/or plasma parameters and the performance of the deposited coating.

Experimental

The experimental approach was to investigate the effect of arc design changes on the plasma properties and ultimately coating performance. The different arc designs were characterized by total ion flux measured in amps (A). The amount of argon that is ionized was measured by a Langmuir probe [10]. A commercial probe, SmartProbe™ from Scientific Systems, Ltd., was used. This is an automated Langmuir probe system including an auto linear drive, which provided spatially or time resolved measurements of a wide range of plasma parameters. The probe was positioned perpendicular to the arc on a linear drive capable of scanning across the plasma jet. The ion flux was measured at about 25cm from the plasma source, i.e. at the same position as a typical working distance (WD). From the measured current-voltage (I-V) curve different plasma parameters can be derived. The key measurement parameter gained from the I-V curve that is used for the subsequent calculations in this work is the uncorrected ion flux P_i measured in mA/cm^2. To characterize an arc, the uncorrected ion flux is measured as a function of radial distance across the expanding plasma at the given WD. The data obtained is fitted to a Gaussian distribution and from the area under the curve (A_r) and width (w_r, Gaussian width) obtained from this fit the total ion flux was calculated as

$$Total\ Ion\ Flux = A_r w_r \sqrt{\pi/2} \qquad (1)$$

This total ion flux together with the width of this Gaussian distribution will be used to describe and compare the expanding thermal plasma process conditions.

Coating depositions were done at 45 mTorr process pressure. In the examples given below, the substrate were 4”x 4” pieces of commercially available silicon hard coated polycarbonate sheets from GE Structured Products. The substrate was coated with 2 layers of abrasion resistant coatings. Each layer was deposited by passing the sample by the arc using 0.19 standard liters per minute (slm) of D4 under the arc conditions described below. A first coating was applied at an oxygen flow rate of 0.3 slm and the second layer at an oxygen flow rate of 0.8 slm. The coating performance was evaluated with regard to coating thickness, adhesion and abrasion resistance. The coating thickness was measured by incorporating pieces of silicon chips on top of the substrate to be coated and the thickness measured *ex situ* using spectroscopic ellipsometry. The coating adhesion was determined according to the ASTM D3359 cross hatch test before and after a 3-day immersion in 65 ºC water and is expressed as a ranking from 0B to 5B. Taber abrasion resistance was determined in accordance with ASTM D1044, i.e. the increase in haze measured after 1000 cycles of Taber abrasion using CF-10 wheels with a 500 g load was measured.

Results and discussion

The expanding thermal plasma arc is an example of a wall stabilized plasma source. The original EUT arc, as described by Kroesen [2] and shown in Figure 1, consists of three cathodes and an anode separated by a stack of four or more electrically isolated copper plates. The copper plates define the plasma channel in which the arc column is stabilized. In addition, this plasma channel provides the flow restriction, which leads to an increased pressure in the arc housing where the arc originates at the cathode.

One approach to meet the requirements for an industrialized arc outlined above is to simplify and reduce the number of components. A single, adjustable cathode has been described in the patent literature [11]. Using Langmuir probe measurements, no difference was observed utilizing three vs. one cathode for an EUT style arc. The advantage of an adjustable arc is in the potential to adjust for arc-to-arc variability and long term arc drift during operation.

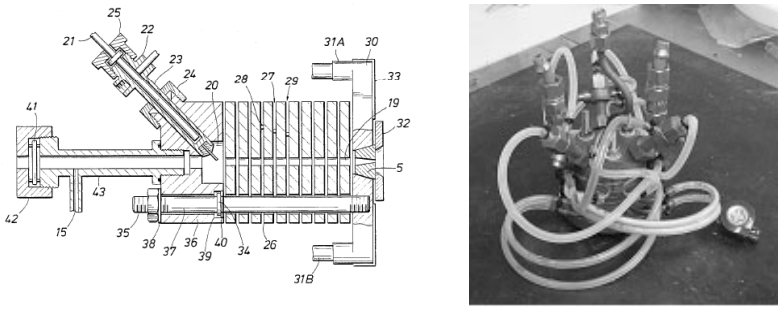

Figure 1: Schematic design and picture of the original EUT design

To investigate the possibility of changing the cascade plate (CP) design, various styles and numbers of cascade plates were investigated. Selected data is summarized in Table 1. Different comparisons can be made from this data table. Comparing data sets A, B and C one can see the effect on total ion flux with changing number of cascade plates at constant diameter. An initial drop in ion flux is observed going from 4 to 2 cascade plates. This is accompanied by a loss in power corresponding to the reduced plasma resistance because of the shorter channel length. Reducing the number of CP from 2 to 1, however, the total ion flux remains the same, while the arc power drops further. Examples C through F illustrate that the ion flux can be recovered and indeed exceeded by reducing the channel diameter of the single CP. With decreasing channel diameter the power requirements to run at constant currents increases. In addition, the amount of total ion flux generated with the input power indicates varying efficiencies of the different designs.

Data set	***CP Design***	***Orifice Diameter*** [mm]	***Number of CP***	***Total Ion Flux*** [A]	***Gaussian Width*** [mm]	***Power*** [kW]	***Efficiency (flux/power)*** [A/kW]
A	Straight	4	4	47.8	219	2.87	16.7
B	Straight	4	2	39.7	201	2.00	19.9
C	Straight	4	1	39.8	206	1.55	25.7
D	Straight	2.54	1	52.8	220	2.09	25.3
E	Straight	2	1	72.2	241	2.85	25.3
F	Straight	1.8	1	77.9	248	3.62	21.5
G	Cone	1.3 / 3.4	1	47.5	227	2.36	20.1
H	Invt. cone	3.4 / 1.3	1	58.0	242	2.70	21.5

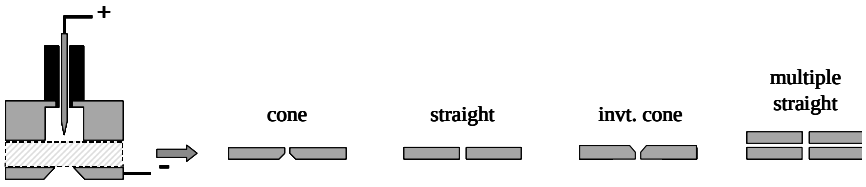

Table 1: Summary of cascade plate design changes investigated. All arcs were measured under identical current controlled conditions (2.0 slm Ar flow, 70 A arc current and 45 mTorr chamber pressure)

Examples G and H illustrate that this interaction between the plasma and the cascade plate is even more complex. A cascade plate with a cone shaped orifice was investigated in two different configurations. While, from a flow dynamics perspective, both configurations represent similar conductance, the interaction with the plasma leads to different ion flux and arc power.
The data presented in Table 1 illustrates the effect changes in cascade plate geometry can have on the flux and Gaussian width. This geometry dependence adds to the typical arc control parameters, argon flow and arc current. Combining results from all straight channel arc designs, Figure 2 shows the dependence of total ion flux, Gaussian width and arc power on CP diameter, argon flow and current.

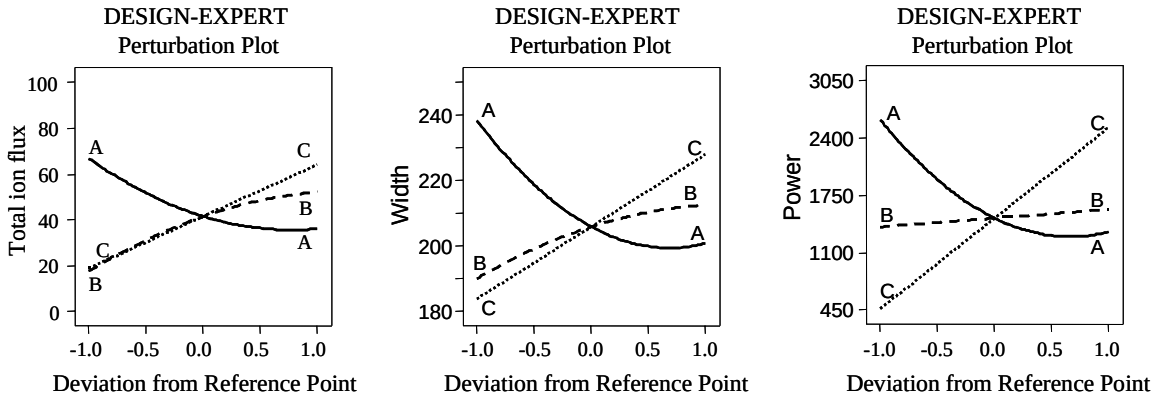

Figure 2: Pertubation plot showing observed trends for total ion flux, Gaussian width and power as a function of CP orifice diameter (A, solid line), argon flow (B, dashed line) and arc current (C, dotted line).

Trends for the three arc parameters are very similar. With decreasing CP orifice diameter, the ion flux, Gaussian width and power increase exponentially. The same parameters increase linearly with current. The argon flow reaches a limiting plateau. The interaction between argon flow and current can shift this plateau indicating a current and an argon limited operating region. Little effect of argon flow on power is observed. While the trends shown here are for a single straight CP, they hold true for any of the investigated CP designs or numbers. What does change is the magnitude of the trends with respective geometries.

The data so far shows that a multitude of parameters can be applied to change the output of the arc. One of the very practical questions is how to compare the different arc designs and operating parameters with respect to coating performance. For this purpose, coating depositions were made with two different arc designs. The first arc designs that were used are the original EUT arc design as shown in Figure 1 using four CP and a triple cathode. The comparison was made to a single cathode, single CP design with a 1.8 mm orifice diameter shown in Figure 3.

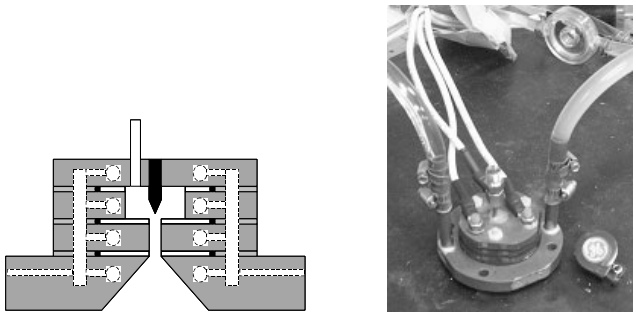

Figure 3: Schematic design and picture of a single CP arc design (patent pending)

Depositions were made at a range of ion flux. This range was achieved by employing various combinations of argon flows and currents. Figure 1 shows the obtained coating thickness for a two pass coating as a function of total ion flux. The data includes depositions by both arcs and a good correlation was observed.

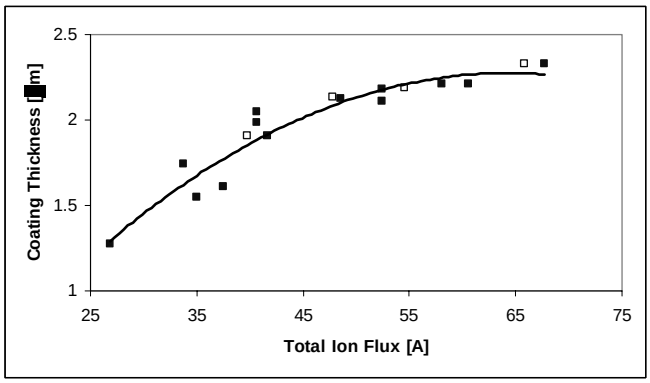

Figure 4: Coating thickness as a function of ion flux for both arc designs investigated.

In addition to this correlation on coating thickness a comparison of the coating Taber abrasion performance is made in Table 2. The Taber abrasion performance at identical arc conditions (i.e. argon flow and current, data set I + J) shows a significant difference between the two arcs (1.7 % and 6.6 % Δhaze for the two arcs, respectively). Data sets K + L shows the same two arcs adjusted to bracket a much narrower ion flux range, which gave virtually identical performance.

Data set	***Orifice Diameter*** [mm]	***Number of CP***	***Argon flow*** [slm]	***Current*** [A]	***Total Ion Flux*** [A]	***Thickness*** [µm]	***Taber abrasion Δhaze*** [%]
I	4	4	2	60	39.8	1.91	1.7
J	1.8	1	2	60	65.8	2.33	6.6
K	4	4	2	70	47.8	2.13 (0.04)	1.3 (0.3)
L	1.8	1	1.65	55	54.6	2.19 (0.08)	1.4 (0.2)

Table 2: Comparison of two arc designs

Summary

We have investigated the different aspects of arc process and design with regard to industrialization criteria in an effort to optimize the arc design. It was shown that the combination of argon flow, arc current and CP geometry can change the output of the arc over a wide range with respect to total ion flux, Gaussian width and arc power. Depositions of abrasion resistant layers using different arc designs showed that total ion flux was the central parameter to achieve parity between different arc designs.

Abstract

This paper presents an improved physical model for a high intensity discharge, derived from the balance of energy equation. The effects of energy dissipation caused by conduction and radiation are also considered. The resultant model is presented in Matlab as a two terminal device. The model's validity has been confirmed with experimental measurements. Analytical results reveal that the efficiency and the modulation depth of the plasma temperature at low frequency, can be improved using a square current power supply.

Keywords- HID lamp modeling, Electronic ballast design, plasma temperature modulation depth, square current power supply.

1. Introduction

Discharge lamp modeling is essential in the investigation and design of high frequency converters for high intensity discharge (HID) lamps and plasma torches.

A very extensive research, concerning arc lamp models can be found in the literature [1-2]. One of the most successful models is the balance of energy model [3], which considers the conservation of energy equation in the discharge column. The electric field applied in the discharge column, gives the power transmitted to the electrons and then transferred to the gas atoms via elastic and inelastic collisions among electrons, atoms and other species participating in the discharge. Consequently the gas is heated up and then removed by thermal conduction, radiation, convection and diffusion. The two latter forms can be ignored because the lamps are normally operated in vertical position and the conduction effect predominates over the diffusion effect [4].

The increment of temperature inside the lamp can be deduced from the Elenbaas-Heller equation, [5], including the radiation losses and using the concept of "effective temperature" (T_{eff}) (Channel Model). The HID is supposed to have a constant temperature T_{eff} for the cylinder radius $r \langle R_{el}$, (where R_{el} is the radius of the electrode), for $r \rangle R_{el}$ the current density and radiation intensity are negligible, since the temperature is very low in this zone. The model incorporates significant aspects of physical mechanisms occurring in the HID. A mathematical description of this instantaneous conductance $\left(g = {}^{i_a}\!/\!_{V_a} \right)$ was first proposed by O. Mayr [3], who assumes that the conductance increases exponentially with the thermal energy stored in the arc.

Among existing models, two approaches are of particular importance in terms of their ability to simulate the electrical characteristic of a lamp over a wide frequency range an easy implementation on electrical simulation software [6], [7]. In [6] a Matlab HID lamp model was proposed; however does not take into account the lamp physical process, which is critical and essential to the lamp performance. In [7] a Pspice HID lamp model that can be used for high and low frequency operation has been proposed, but its interface is complicated for the user.

The model described in this paper, was implemented in MATLAB as a two terminals device. The aim of this model is its user-friendly interface and is able to predict the HID behavior at different frequencies and power requirements. Using the results obtained with the proposed model we can investigate and establish the compromise between supply current frequency and waveform shape to improve the luminous efficacy. Also we can obtain some measures related with the efficiency discharge for example the modulation depth of the plasma temperature.

2. HID Modeling

The fundamental idea of the developed MATLAB model (Figure 1) consists in the representation of the HID lamp as a voltage dependent source. It is well know that:

$$I_{lamp} = \frac{V_{lamp}}{R_{lamp}} \tag{1}$$

where I_{lamp} is the instantaneous current trough the lamp, V_{lamp} is the instant voltage, R_{lamp} is the instantaneous lamp's electrical resistance, which can be obtained by solving $R_{Lamp} = \int_V L/(\sigma_\Sigma S) dV$. In this last equation σ_Σ is the global conductance of the plasma being equal to the sum of the specific conductance of gases that compose the plasma, V is the volume, L and S are the discharge length and cross-section respectively.

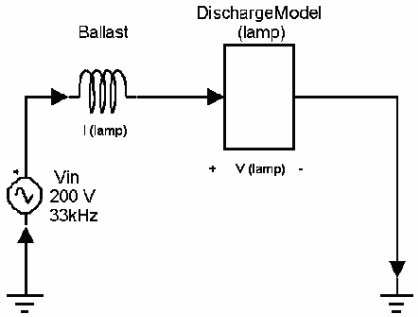

Figure 1. Model proposed for a HID discharge.

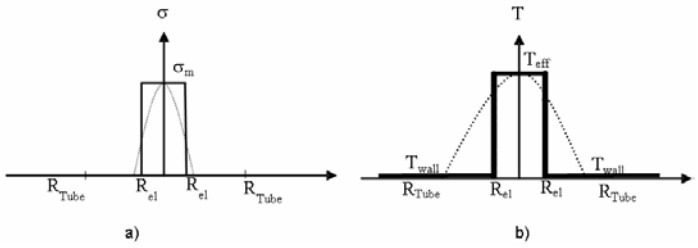

Figure 2. Channel model assumptions a) distribution of conductivity σ along the arc column radius b) distribution of temperature along the arc column radius.

For weakly ionized plasma the conductance is it giving by: [8]

$$\sigma_i = \sigma_{oi} \frac{T^{0.75}}{\sqrt{p}} e^{\frac{-E_i}{2kT}} \tag{2}$$

where σ_{oi} is a constant of each gas component i, T is the arc's core temperature, p is the pressure of the gas, E_i is the ionization energy for each element and k is the Boltzmann's constant. As can we see the conductance depends strongly on the temperature; therefore to describe the electrical process of the HID lamp, the thermodynamic state should be explained. Based on the equation of the power balance we can determine the heat increment in the arc using the following equation.

$$dQ = (P_{in} - P_{out})dt = mC_p dT \tag{3}$$

where the input power to the lamp is P_{in}, P_{out} is the power losses (radiation P_{rad} plus conduction P_{cond}), dt is the increment of time. m is the discharge cylinder mass, C_p is the heat capacity, and dT is the temperature increment. In addition, if we consider that $m = \varphi V$ where: φ is the density and V is the volume, then by using Eq. (3) we can find the discharge temperature, which is necessary to know the electrical characteristics of the lamp.

$$\frac{dT}{dt} = \frac{(P_{in} - P_{rad} - P_{cond})}{\varphi V C_p} \tag{4}$$

The present study was conducted under some simplified considerations of the channel model shown in Figure 2.

1. The arc in the high pressure lamp is confined to a plasma cylinder.
2. The plasma is in a Local Thermal Equilibrium (LTE) state.
3. The arc is composed of a two-layer cylinder:
    - The radius of the internal layer is equal to the electrode radius, R_{el}
    - The external radius of the external layer is equal to the arc tube internal radius.

- The arc´s length is equal to the gap between electrodes.

4. All physical properties in each layer are constant.
5. Electrical current only appears in the internal layer core.
6. The energy (P_{out}) losses are due to radiation and heat conduction.
7. The influence of the arc´s tube, electrodes and bulb is neglected.

Under these assumptions, the increase in heat per a unit length can be expressed by:

$$dQ = \left[c_{arc}\varphi_{arc}\pi R_{el}^2 + K_{Tred}c_{per}\varphi_{per}\pi\left(R_{tube}^2 - R_{el}^2\right)\right] \tag{5}$$

where c_{arc}, c_{per} are the heat capacity of the internal and external layers respectively; $\varphi_{arc}, \varphi_{per}$ represent the density of the internal and external layer's medium, consequently; R_{tube}, R_{el} - arc cavity and electrodes radius, respectively, K_{Tred} -factor keeping the temperature reduction in the arc's periphery

The input power to the lamp per unit length P_{in} is:

$$P_{in} = \frac{V_{lamp}I_{lamp}}{L_g} \tag{6}$$

where: L_g is the distance between electrodes.

The formula for the radiated energy P_{rad} :

$$P_{rad} = 2\pi R_{el}\varepsilon(T) \tag{7}$$

where: $\varepsilon(T)$ arc's surface emissivity. The heat conduction losses P_{con} are described by the law:

$$P_{con} = k(T - T_{amb}) * 2\pi R_{el} \tag{8}$$

where $k = k(T)$ coefficient of heat transfer.

By taking into account the lamp geometry and all the energy losses (P_{out}), a differential equation that describes the state of the arc, can be deduced:

$$\frac{dT}{dt} = \frac{\frac{v_{lamp}\ i_{lamp}}{L_g} - 2\pi R_{el}\left[\varepsilon(T) + \kappa(T - T_{amb})\right]}{\pi\left[c_{arc}\ \varphi_{arc}\ R_{el}^{\ 2} + k_{Tred}\ c_{per}\ \varphi_{per}\ (R_{tube}^{\ 2} - R_{el}^{\ 2})\right]} \tag{9}$$

To solve this equation, we use the numerical values of the parameters: $c_{arc}, c_{per}, \varphi_{per}, \varphi_{arc}$ in [7]. The procedure of solution adopted in this study is summarized in Figure 3. We use this algorithm to know the discharge's temperature, and from this we can obtain the arc's surface emissivity $(\varepsilon(T))$, the coefficient of heat transfer $(k(T))$ and the discharge electrical characteristics.

Figure 4 shows the block diagram of the developed Matlab HID model, which considers two input variables (discharge's current and voltage) needed to solve the energy balance equation.

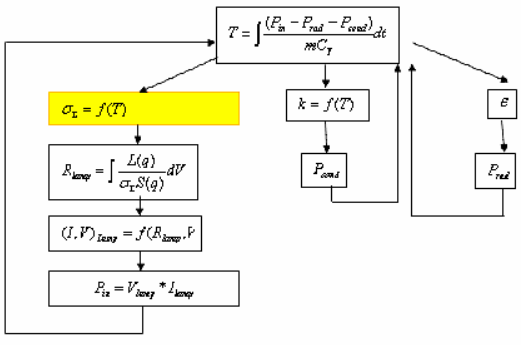

Figure 3. Structured solution for the described equation.

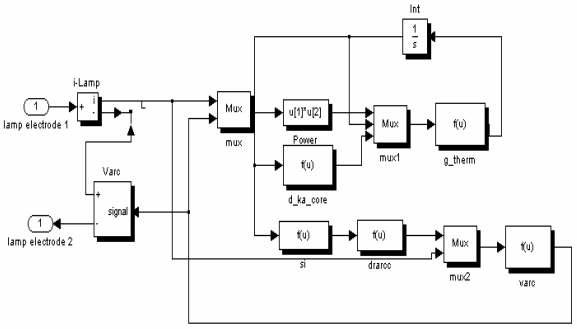

Figure 4. Block diagram of HID lamp model.

3. Simulation and experiments

The HID model implemented in MATLAB was verified using some experimental measurements. In order to compare the model response and lamp's experimental characteristics, it was necessary to power the lamp and then acquire the values of current and voltage. As we can see (Figure 5) the model response shows a good correspondence with the experimental results at low frequency (60 Hz).

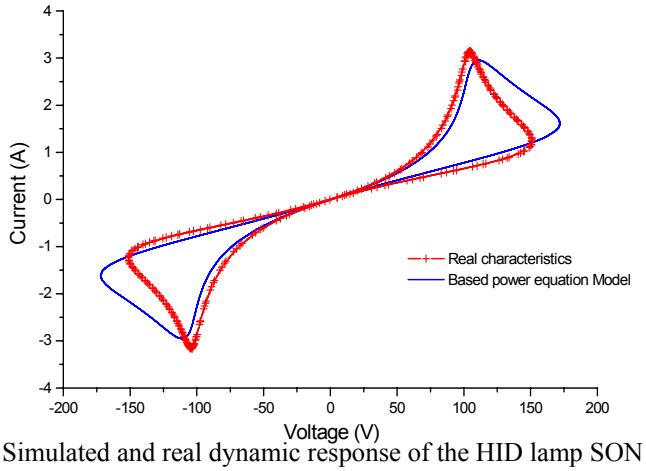

Figure 5. Simulated and real dynamic response of the HID lamp SON T- 400, 60 Hz.

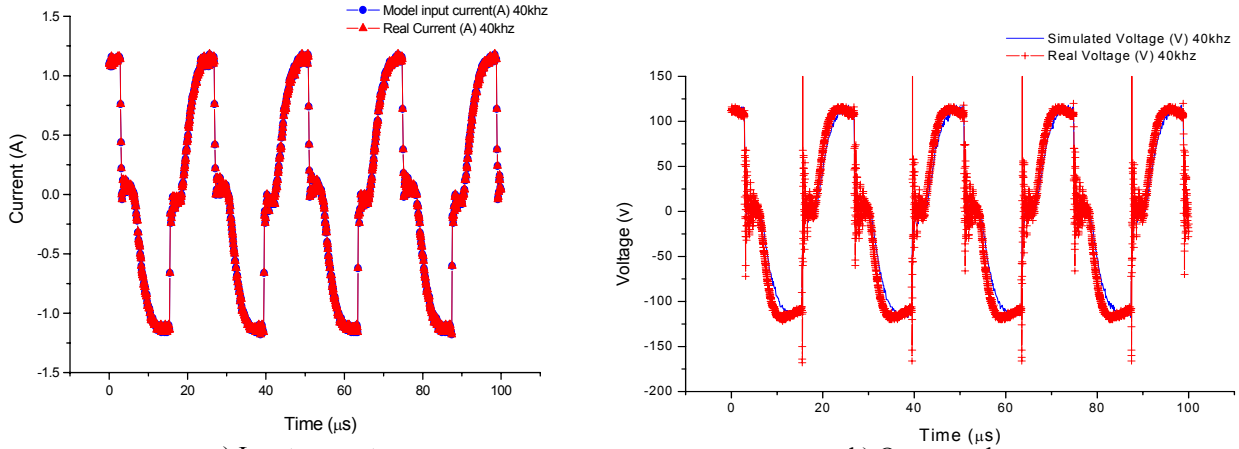
Figure 6 shows the model's high frequency performance. We can observe that the simulated dynamic response for the HID at high frequency shows also a good correspondence with the experimental results; so the model emulates the lamp operation at high and low frequency, according the experimental behavior of the lamp.



a) Input current b) Output voltage

Figure 6. Simulating and real dynamic response of the HID current and voltage 40 kHz.

4. Influence of current waveform on HID lamp operation.

New electronic components and converters structures, make possible operate HID lamps at different frequencies and waveforms. A problem presented in high frequency operation is the occurrence of discharge distortions caused by acoustics waves.

Efficient light production in ac-supplied HID lamp is strongly dependent on plasma conditions during the complete half-cycle. A significant luminous efficacy gain is obtained by using sinusoidal current waveform with frequencies of tens of kilohertz or with rectangular current waveforms at lower frequencies (1-4 kHz.).

Simulations of the lamp conductance at several operating conditions can be useful to select a supply frequency and current waveform for electronic ballast design.
When the HID works with a sinusoidal current supply at low frequency, the electrons and ionized atoms have enough time to recombine, but when this discharge is operated at higher frequencies electrons and ions do not recombine, and the charge carrier density is high enough at each current reversal, and not extra power is needed to reignite the discharge [9]. The change of discharge conductance occurring by these effects can be observed in Figure 7; a strong variation in the conductance can be obtained working with sinusoidal waveforms at low frequencies while working with rectangular waveforms these variations are hardly minimized.

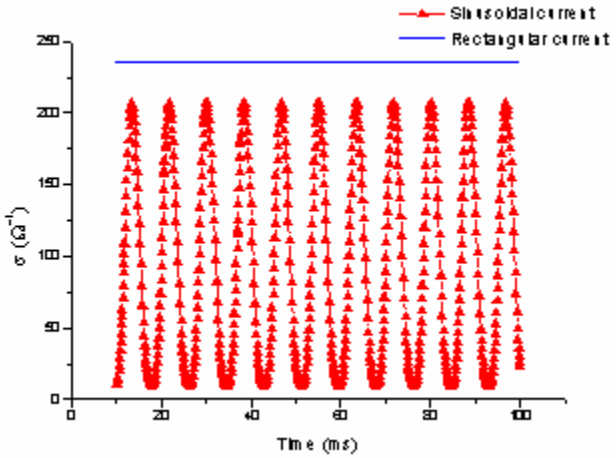


Figure 7. Conductance variations of HID lamp supplied with sinusoidal current and with rectangular waveform at 60 Hz.

The variation in the conductance is associated with efficiency. In this case the luminous efficacy of HID lamp supplied with sinusoidal current depends on frequency waveform and on the phenomenon of saturation related with the time constant of electron temperature [10]. At least two sustancial advantages can be obtained using rectangular current:

- The absence of the cataphoresis effects (normally they occur under dc operation).
- The absence of discharge distortion by acoustic resonance, because it is possible to work at low frequencies, where acoustic resonance does not longer exist.

5. Modulation Depth of the Plasma Temperature

A very useful parameter for lamps designers is the Modulation Depth of the Plasma Temperature MDPT $\left(\Delta T/T\right)_f$, which relates the temperature variations with respect the average temperature occurring in the HID as a function of the operation frequency f .

The model described here Figure 4 was supplied with both waveforms: rectangular and sinusoidal, at different frequencies.The average temperature and the temperature variations can be deduced in function of the operation frequencies, the data obteined are depicted in Figure 8. We can see that the MDPT of the plasma discharge is reduced from 25% at 60Hz to 1% at 12 KHz, if a sinusoidal current is used. When a square wave pulse is applied, the MDPT is notably reduced (lower than 2%) even at low frequencies.
Therefore, by using a converter square wave pulses the thermal strengths in the electrode material is considerably reduced and the lamp life time is generally extended.
Operating at low MDPT results in remarkable improvement of the power factor. Thus, the operation characteristics of the HID lamp under square wave pulses would appear to approach those found under DC operation, but avoiding the cataphoresis effect in the electrodes.

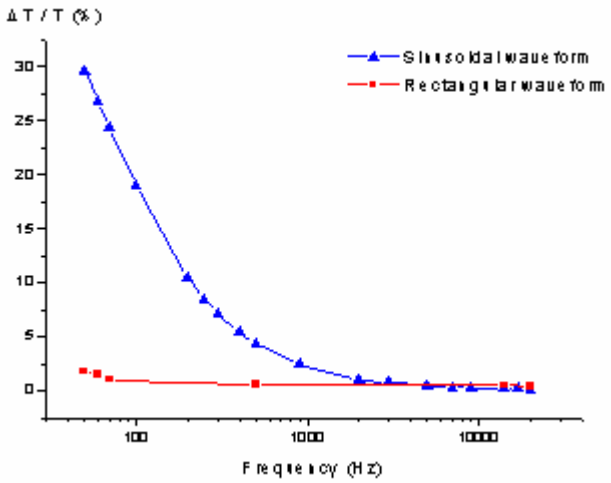

Figure 8. Modulation depth of the plasma temperature in a 400W HID lamp as a function of supply current's waveform and frequency

6. Conclusion

By using the balance of energy equation occurring in an electrical discharge, a simple and effective model has been developed. This model, emulates the behavior of HID working at low and high frequencies. The solution was implemented in MATLAB and presented as a two terminal element compatible with electronic circuit simulators.

Using this model we showed that the current waveform has a strong influence on the luminous efficiency in HID lamps. Rectangular current waveform operation at 60 Hz offers higher efficiency than that obtained when sinusoidal waveforms are used. This efficiency increase is caused by the faster current polarity reversal at each half cycle and, therefore, the plasma retains a higher degree of ionization. The gain obtained with rectangular current supply remains constant in a wide range of frequencies. However the rise time must be small (some μs), otherwise the gain in efficiency will be smaller and frequency dependent.

Abstract
The Buck Converter here proposed successfully sustains a plasma discharge with high power transfer efficiency. To avoid the excessive semiconductor power dissipation during commutations, a resonant snubber cell is introduced to achieve zero-current transitions. The operation principle under steady-state is presented.
Keywords: Buck Converter, state-variables analysis, Zero Current Switching, Plasma Torch

1. Introduction

In order to obtain a good performance of the plasma torch operation, it is necessary to use a current supply instead of a voltage supply. In this work a Buck Converter (BC) is proposed as a current source for the excitation of a plasma torch. The BC is one of the most studied systems [1, 2] with a wide variety of applications. The structure of this type of converter is very simple (just a few elements are needed to control high current intensities); it is of low cost and easy to control. Nevertheless, the available commercial semiconductors still do not have neglectable internal resistance R_{DS}, when the semiconductor is in its ON state. Normally, the R_{DS} value is around 16mΩ. Although it seems to be a quite low resistance, when high intensity currents of about 100A flow, the power dissipation becomes an important drawback. To avoid this effect, several transistors (Q_1, Q_2, Q_3) are connected in parallel, as shown in figure 1, representing a good option to decrease the equivalent serial resistance R_{DS}. In consequence, the power dissipation is reduced in the converter. All these transistors are controlled with just one single pulse width modulation (PWM) signal.

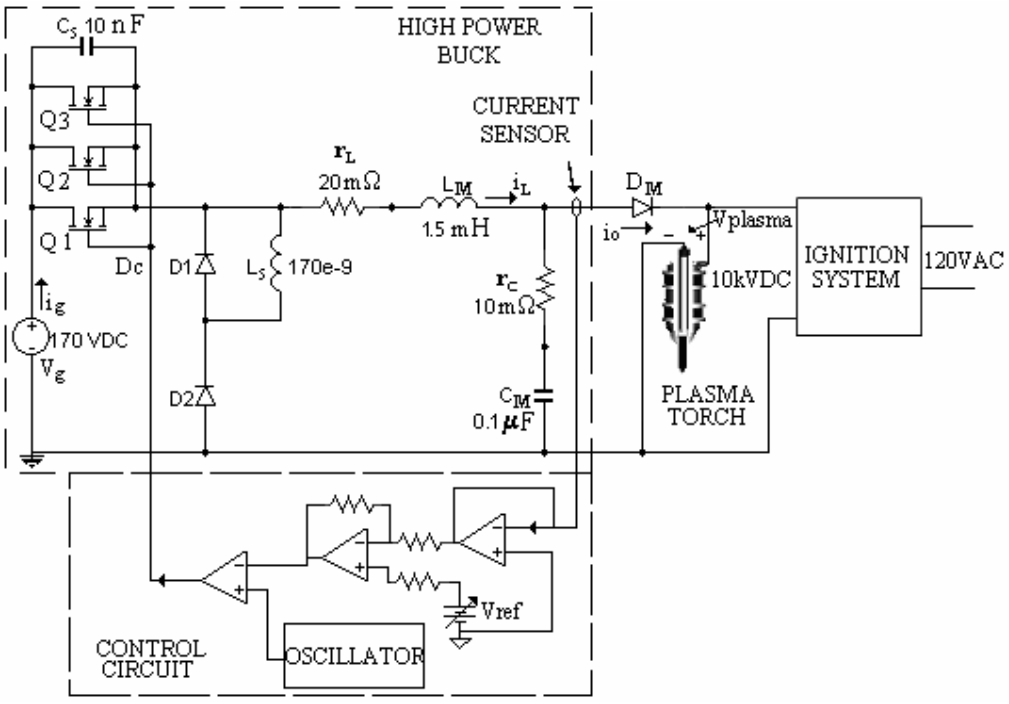

Figure 1. Complete power supply system with Buck Converter.

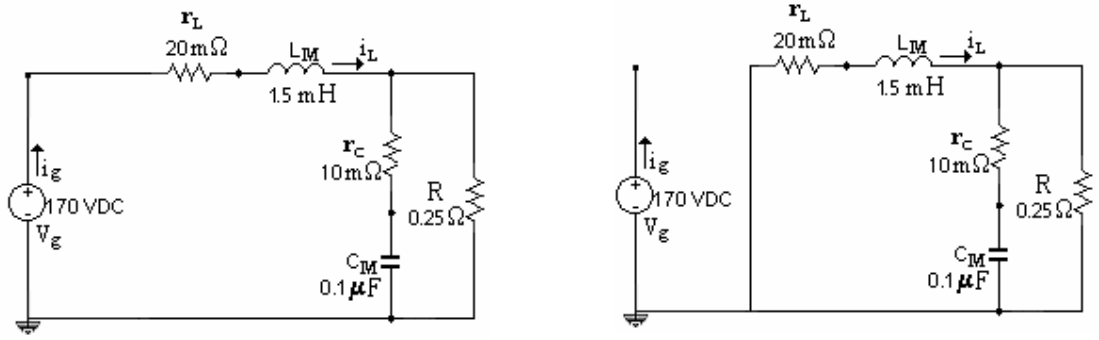
The system proposed is depicted in figure 1, the BC is connected to the plasma torch. The ignition system is also included in this figure, but it is only used during the plasma ignition. The BC is used to sustain the normal operation of the plasma torch. The diode D_M is used to protect the BC against high voltage impulsions, during the ignition phase. A very simple active snubber cell provides Zero Current Switching

(ZCS) [3]. This snubber cell is implemented by using a quasi resonant circuit with no significant cost and neither complexity. The elements composing this snubber cell are D_1, D_2, L_s and C_s. L_S is of 170nH approximately which this is obtained from di/dt of D1, C_S is of 10nF. The incorporation of a snubber circuit improves the efficiency during the commutation of this converter because it can operate with soft switching successfully at very wide load ranges at considerably high frequencies [3-5]. The main transistors (Q_1, Q_2, Q_3) do not have any additional voltage and current stress.

2. State-variable analysis.

A powerful analysis habitually used to deduce the behavior of power electronic systems is based on state variable analysis [6-8]. It allows the formulation of a transfer function relating the plasma voltage (P_{lasma}) respect to the duty cycle (δT), which is necessary, to propose a closed loop control for the plasma current flowing trough the plasma torch. The state variable analysis includes the parasitic elements such as the equivalent resistance r_C of the filter capacitor C_M and those of the inductance r_L. The elements conformed the snubber cell are only considered in the simulation, appearing in the numerical results section.

The BC behavior can be linearized by using state-variable analysis. The Bode plots obtained in the next section, can be used to determine the appropriate compensation in the feedback loop for the desired steady state and transient responses.



a) b)

Figure 2. Circuits state of BC, a) ON state and b) OFF state.

The canonical form of the state-variables is:

$$\overset{*}{\mathbf{x}} = \overline{\mathbf{A}}\,\mathbf{x} + \overline{\mathbf{B}}\,\mathbf{u} \qquad , \qquad \mathbf{y} = \overline{\mathbf{C}}\mathbf{x}$$

During each circuit state a linear approaching is obtained by means of the state-variable vector **x** consisting of the inductor current $\dot{x}_1$ and the capacitor voltage $\dot{x}_2$. In this power converter operation, two circuit states exists (figure 2): one state corresponds to when the switch (Q1...Q3) is ON and the other, when this switch is OFF as is shown in figure 2 a) and b) respectively. Therefore, during each circuit state we can write the following state equations:

$$\left[\dot{\mathbf{x}}\right] = \mathbf{A_1}\left[\mathbf{x}\right] + \mathbf{B_1}\,V_g \qquad 0 \le t \le \delta T$$
$$\left[\mathbf{V}_C\right] = \mathbf{C_1}\left[\mathbf{x}\right]$$

$$\left[\dot{\mathbf{x}}\right] = \mathbf{A_2}\left[\mathbf{x}\right] + \mathbf{B_2}\,V_g \qquad \delta T \le t \le T$$
$$\left[\mathbf{V}_C\right] = \mathbf{C_2}\left[\mathbf{x}\right]$$

Where $\mathbf{A}_1$, $\mathbf{A}_2$, $\mathbf{B}_1$, $\mathbf{B}_2$, $\mathbf{C}_1$ and $\mathbf{C}_2$ are matrices; ***x*** and $\boldsymbol{V}_C$ are state variables. Using Laplace transformation and some others algebraic operations, a generalized expression, considering all matrices element is obtained [8]:

$$G(s)\frac{\tilde{v}_o(s)}{\tilde{d}(s)} = C\left[sI - A\right]^{-1} \bullet \left[(A_1 - A_2)X_{dc} + (B_1 - B_2)V_d\right] + \left[(C_1 - C_2)X_{dc}\right] \qquad (1)$$

When transistors are in ON state, the equations obtained are (2) and (4), while for the OFF state, the equations are (3) and (4).

$$\dot{x}_{1ON} = -\frac{(Rr_c + Rr_L + r_c r_L)}{L_M (r_c + R)} x_1 - \frac{R}{L_M (r_c + R)} x_2 + \frac{V_g}{L_M} \tag{2}$$

$$\dot{x}_{1OFF} = -\frac{(Rr_c + Rr_L + r_c r_L)}{L_M (r_c + R)} x_1 - \frac{R}{L_M (r_c + R)} x_2 \tag{3}$$

$$\dot{x}_{2ON-OFF} = \frac{Rx_1 - x_2}{C_M (r_c + R)} \tag{4}$$

The state variables of interest are equations (5).

$$\text{With} \quad \dot{x}_2 = \frac{dv_C(t)}{d(t)}, \dot{x}_1 = \frac{di(t)}{d(t)} \tag{5}$$

Matrices $\mathbf{A}_1$ and $\mathbf{A}_2$ have the same values; therefore buck matrices are evaluated as:

$$A_1 = A_2 = \begin{bmatrix} -\frac{(r_c + r_L)}{L_M} & -\frac{1}{L_M} \\ \frac{1}{C_M} & -\frac{1}{RC_M} \end{bmatrix} \quad B_1 = \begin{bmatrix} \frac{1}{L_M} \\ 0 \end{bmatrix} \quad B_2 = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{6}$$

Finally, the transfer function describing the Buck circuit is obtained:

$$G(s)\frac{\tilde{v}_o(s)}{\tilde{d}(s)} = v_g \left(\frac{r_C C_M}{L_M C_M}\right) \left(\frac{s + \frac{1}{r_C C_M}}{s^2 + \left[\frac{1}{RC_M} + \frac{r_C + r_L}{L_M}\right] s + \frac{1}{L_M C_M}} \right) \tag{7}$$

By including the variables representing the radial resonant frequency (ω_o) and the switching radial frequency (ω_c) in (4), a new equation is deduced:

$$G(s) = \frac{\tilde{v}_o(s)}{\tilde{d}(s)} = v \left(\frac{\omega_o^2}{\omega_c} \right) \left(\frac{s + \omega_c}{s^2 + 2\zeta\omega_o s + \omega_o^2} \right) \tag{8}$$

Where it can be found by comparison of (7) and (8):

$$\omega_o = \frac{1}{\sqrt{L_M C_M}}, \omega_c = \frac{1}{r_C C_M}, \zeta = \frac{1}{2R}\sqrt{\frac{L_M}{C_M}} + \frac{(r_C + r_L)}{2}\sqrt{\frac{C_M}{L_M}} \tag{9}$$

3. Numerical results

According with the real components used in the BC prototype the parameters given in equations (5), (6), can be established: r_C=10mΩ; r_L=20 mΩ; C_M=0.1μF; L_M=1.5mH; V_g=170VDC. During plasma torch stable operation, at equilibrium point, the plasma discharge can be represented by a 0.25Ω resistance. By substitution of all these parameters and by using some Matlab commands, a Bode diagram can be obtained describing the BC behavior for a frequency range (10 to 10^{10} rad/seg) as it is appreciated in figure 3. By

analyzing the Bode diagram a compensator circuit can be proposed in the feedback loop to improve the converter stability [9, 10, 11].

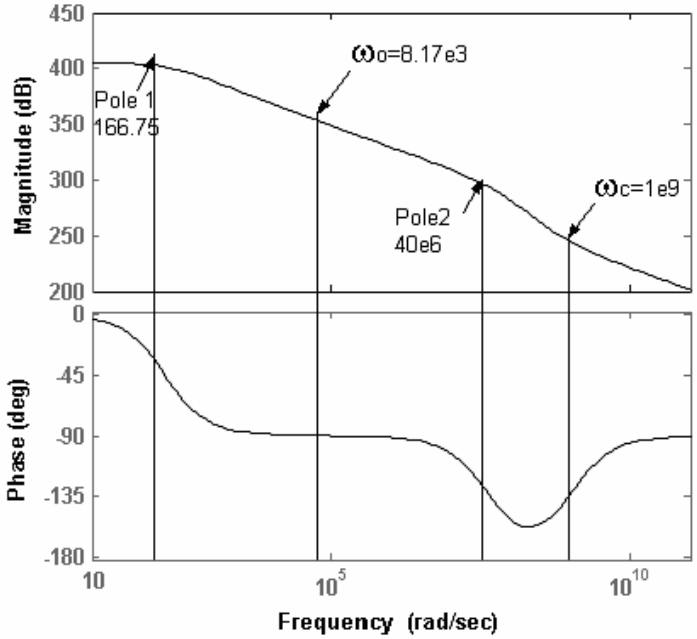


Figure 3. Bode Diagram of Buck Converter

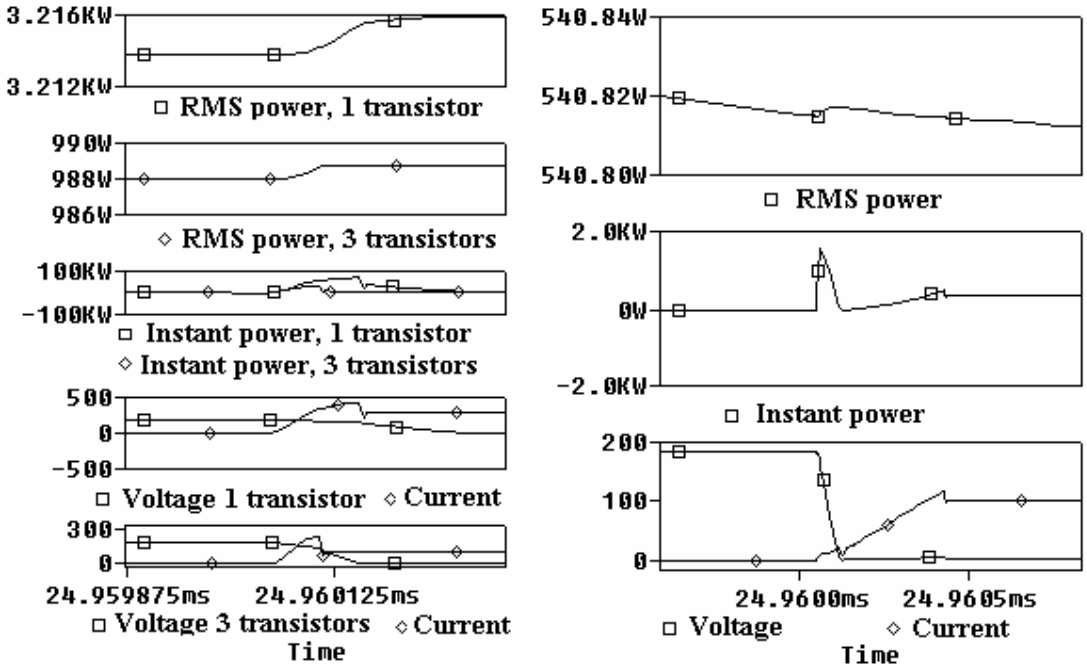
To show a comparison between hard and soft switching, 3 circuits were simulated by using ORCAD software:

- the first circuit was conform without snubber and with one transistor or single hard switch (SHS),
- the second without snubber and with three transistors or three MOS in hard switch (TMHS),
- the third is analyzed with three MOS and with snubber cell or three MOS in soft switch (TMSS).



a) b)

Figure 4. Simulation with a) hard commutations and b) soft commutations.

Results are presented in figure 4. A comparison between SHS and TMHS is illustrated in figure 4a. In the power graph, it can be appreciated that the power in the TMHS is 989W, while in the SHS is about 3.21kW. The instantaneous power peak in the TMHS is at about 20kW and in the SHS is at about 80kW. The low power occurring in the TMHS is certainly due to its low resistance obtained in the parallel arrangement of the three transistors, instead of just one transistor.
In figure 4b, results of the TMSS simulation are shown; as we can see, the RMS power is 540W and the instant power peak is 1.8kW. A significant dissipation reduction is obtained because the MOS are switched under zero current conditions thanks to the snubber cell operation.

4. Conclusions

All semiconductor devices operate under soft switching. The MOS transistors are subjected to no additional voltage and current stresses. This converter operates successfully under variable load conditions appearing during plasma torch operation. Consequently, the dissipation losses are minimized and the energy transfer to the plasma torch is achieved with very high efficiency of nearly 92% at full power capacity.
By using the transfer function, a simple closed loop control can be proposed to improve the stability of the current source.
A generalized state-plane analysis method for soft-switching Buck Converter was presented in this paper. By applying this, a simple computer-aided analysis and mathematical modeling could be realized.

The operational behavior and stability of the Buck Converter is analyzed during duty cycle variations. However, some other specific effects appearing during finite switching times during experimental tests are not treated in this work.

ABSTRACT: Dielectric barrier discharge NH_3/He microplasma (NH_3/He-DBDMP) under a high-pressure environment close to atmospheric pressure (720-730 Torr) has been employed for the local surface functionalization of amino groups on the surface of bulk polyethylene. Optical emission spectra were taken by varying the applying voltage and gas flow rate to study the characteristics of the microplasma and to find a suitable condition for functionalization. The incorporation of amino groups on the local surface (500 μm in diameter) by the microplasma treatment has been identified by X-ray photoelectron spectroscopy (XPS).

KEYWORDS : dielectric barrier discharge (DBD), ammonia, polyethylene, localized treatment, optical emission spectroscopy (OES), Lissajou method, x-ray photoemission spectroscopy (XPS)

Ⅰ. INTRODUCTION

Functionalizing polymer substrates by plasmas has wide range of applications [1]. By adding functions to the surface of the polymer, surface properties can be altered. However, achieving functionalization by conventional low-pressure plasmas requires expensive high-vacuum systems and overall long time from preparing to the treatment. In order to solve these problems, dielectric barrier discharge microplasma (DBDMP) under a high-pressure environment close to atmospheric pressure (720-730 Torr) is a suitable tool. DBDMP can be generated in high-pressure environment with low power, which leads to both high-density ($\sim 10^{12}$ cm^{-3}) and low-temperature plasma (several hundred K for gas temperature) [2]; hence saving both power and time for functionalization without employing expensive high-vacuum systems. Additionally, DBDMP can easily control the functionalization point in limited space both two dimensionally and three dimensionally. This localization can be applied to micro electro mechanical system (MEMS) and polymerization technique used for developing immunosensor [3]. Not only limited space but also large area can be functionalized by arrayed DBDMPs.

In this study, NH_3/He -DBDMP has been employed for the local surface functionalization of amino groups on the surface of bulk polyethylene. We focus on both characterization of NH_3/He-DBDMP and also the incorporation of local surface by the microplasma treatment.

Ⅱ. EXPERIMENTAL SETUP

Figure 1 shows a schematic of our system to generate the DBDMP. The system consists of a function generator, an amplifier, a main chamber, a microplasma torch, and a rotary pump. To keep the gas isolated from the air outside, the pressure of the main chamber is maintained at 720-730 Torr. The holder is set in

front of the torch so that the gap between the torch and the substrate will be 500 μm when treating the center of the polymer substrates. NH_3/He-DBDMP is generated at the end of the microplasma torch, in a quartz tube with an inner diameter of 500 μm. The stainless steel wire (300 μm in diameter), which penetrates through the hole of the quartz tube, is the driving electrode, and the conductive paste around the quartz tube is the grounding electrode. Together, it serves as a capacitively coupled electrode with dielectric barrier in between. Gases (NH_3 and He) are introduced through the flow meter and the pressure was monitored with a vacuum gauge. Irrespective of the NH_3 gas flow rate, the He gas flow rate is always kept constant at 200 sccm during the experiment. The NH_3/He-DBDMP (500 μm in diameter) actually generated in this system is shown in Figure 2.

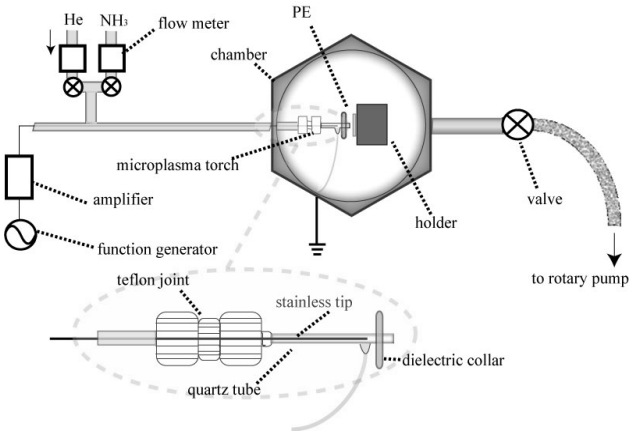

Fig. 1 Schematic diagram of the experimental setup.

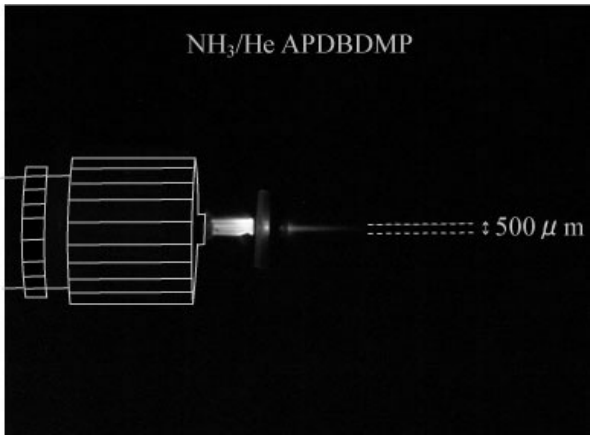

Fig. 2 NH_3/He-DBDMP (V = 1.9 kV, f = 7 kHz, Q_{NH3} = 5 sccm, Q_{He} = 200 sccm).

The polymer substrate used in this study is a low-density polyethylene (SANPLATEC). Samples were prepared in the form of 0.5 mm thick square-shaped coupons (10×10 mm). They are purified by extraction with hexane/isopropyl alcohol mixture for 1 hour and stored in a desiccator prior to each plasma treatment.

To study the characteristics of the NH_3/He-DBDMP, optical emission spectroscopy was performed with Acton Research Corporation SpectraPro-300i monochromator with a focal length of 300 mm equipped with 1200 grooves/mm grating, and photons were detected with Acton Research Corporation CCD detection system for analysis of the 310-360 nm domain.

The power consumption of the NH_3/He-DBDMP is measured with Lissajou method, which is illustrated in Figure 3. The voltages across the discharge electrodes from the oscilloscope (TDS 5104 digital phosphor oscilloscope) are plotted as a function of the voltage across the test capacitor C_{test}. The power consumption is obtained by measuring the area of the Lissajou curve and multiplying it to capacitance C_{test} and the frequency of the applying voltage V (Figure 6) [4].

The local incorporation of the NH_3/He-DBDMP treated polyethylene surface is identified by XPS measurements. The XPS apparatus we employed in this experiment is a PHI

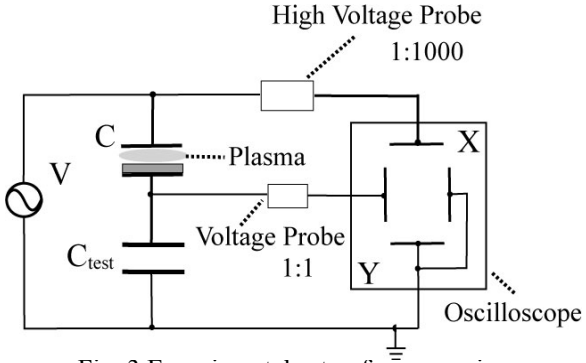

Fig. 3 Experimental setup for measuring NH_3/He-APDBDMP power consumption.

Quantum2000, using monochromated AlK_{α}(1486.7eV) radiation, the analysis area being 200 μm in diameter. The electron take-off angle used is 45°. To avoid differential charging effects of nonconducting polyethylene samples, an electron flood gun is used for neutralizing. The binding energy analysis was referenced to the C1s signal of the aliphatic hydrocarbon at 285 eV. The peak fitting was done by using Multipak V6.1A software and for the peak shape, a mixture of Gaussian and Lorentzian was chosen. Furthermore, by measuring the atomic concentrations of N1s on 361 points over NH_3/He-DBDMP treated area, we have succeeded to map and visualize the locality of NH_3/He-DBDMP treatment. The distance between the nearest measurement points is 300 μm.

Ⅲ. RESULTS AND DISCUSSION

A. Characterization of the microplasma by optical emission spectroscopy (OES)

In this study, we focused on NH radicals, which play an important role in functionalization of amino groups to find a suitable condition for functionalizing amino groups on polyethylene surface with our system. Figure 4 is the optical emission spectra of NH radicals as a function of applying voltage. It shows that as the applying voltage increases, the intensity of the radicals increases. However, 1.9 kV is the maximum limit of applying voltage in our system because the discharge mode transit to arc and ends up destructing the electrode part.

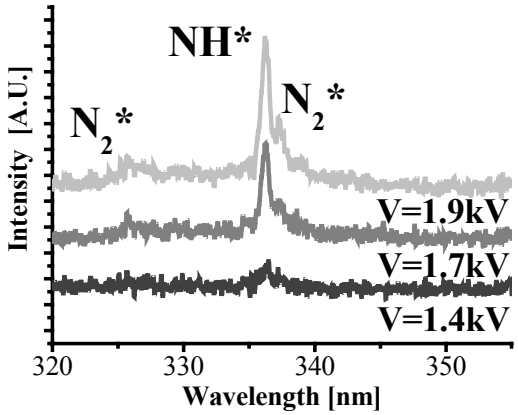

Fig. 4 OES spectra of NH radical as a function of applying voltage V (f = 7 kHz, Q_{NH3} = 5 sccm, Q_{He} = 200 sccm).

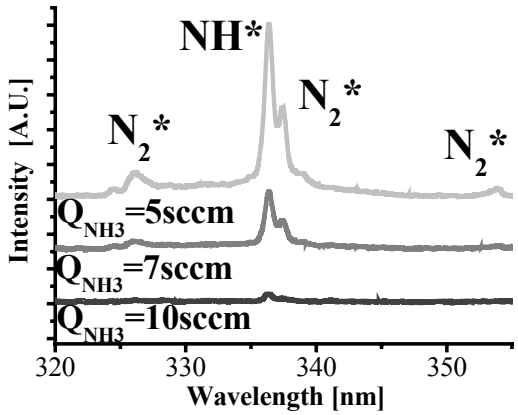

Fig. 5 OES spectra of NH radical as a function of NH_3 gas flow rate Q_{NH3} (V =1.9 kV, f = 7 kHz, Q_{He}= 200 sccm).

On the other hand, Figure 5 is the optical emission spectra of NH radicals as a function of NH_3 gas flow rate. Note that the He gas flow rate is constant at 200 sccm. It shows that as the NH_3 gas flow rate increases, the intensity of the radicals decreases. This is explained by the Penning effects of helium metastables. He metastable particles consume their energy by dissociating and ionizing ammonia. When NH_3 gas flow rate increases, NH_3 particles receiving energy from He metastables increase although the He gas flow rate does not change. Hence the mean energy that NH_3 particles get from He metastables decreases, and dissociated and ionized NH_3 particles before flowing outside of the electrodes decrease. Taking into account that formation of NH radicals involves dissociation and ionization, the explanation agrees well with the result. We must also note that in our system, 5sccm was the minimum limit of the stable NH_3 gas flow.

B. Power measurement of the microplasma by Lissajou method

The power consumption of the NH_3/He-DBDMP is obtained by multiplying the capacitance C_{test} and the frequency of the applying voltage to the area of the Lissajou curve (Figure 6), and under the suitable condition for amino groups functionalization in this study (V = 1.9 kV, f = 7 kHz, Q_{NH3} = 5 sccm, Q_{He} = 200 sccm), it was 6.2 mW. Comparing the result to the power consumed by the other conventional plasmas employed in surface treatment system, it is about 1/10,000~1/1,000.

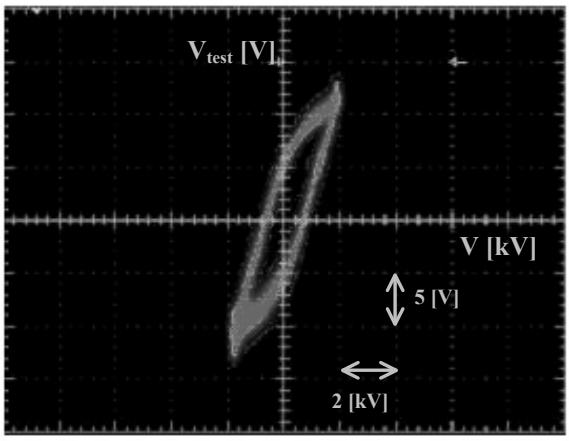

Fig. 6 Lissajou curve (V = 1.9 kV, f = 7 kHz, Q_{NH3} = 5 sccm, Q_{He} = 200 sccm).

C. Characterization of microplasma treated polyethylene surface by X-ray photoelectron spectroscopy

Three kinds of surface treated polyethylene samples by NH_3/He-DBDMP under the suitable condition for amino groups functionalization in this study (V = 1.9 kV, f = 7 kHz, Q_{NH3} = 5 sccm, Q_{He} = 200 sccm) were measured by XPS. They differ in the treatment time (1, 10 and 100 s). The results show that the longer microplasma treatment time, the more N and O components get incorporated on the surface of the polyethylene (Figure 7).

The C1s peak of the nontreated polyethylene is composed of a single peak centered at 285 eV corresponding to the methylene groups. The NH_3/He-DBDMP treatment broadens this C1s peak, which indicates the incorporation of new functional groups on the surface of a polyethylene. However, it is difficult to determine and quantify the C-NH_2 from the C1s spectra since there are too many kinds of combining possibilities of functional groups. Figure 8 is the deconvoluted high-resolution spectra of N1s. It shows that two different peaks can fit the N1s peak, and quantities of the nitrogen-containing groups incorporated on the surface were evaluated from them. The lower binding energy peak at 399 eV corresponds to the amino

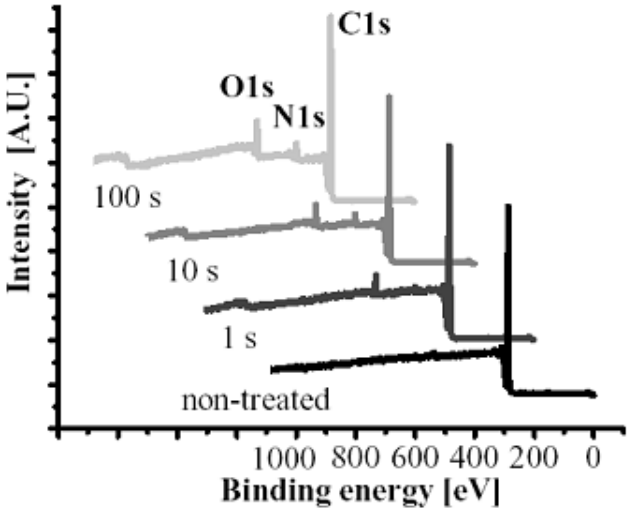

Fig. 7 XPS spectra of nontreated (a) and NH3/He 1s (b), 10s (c), 100s (d) microplasma-treated polyethylene.

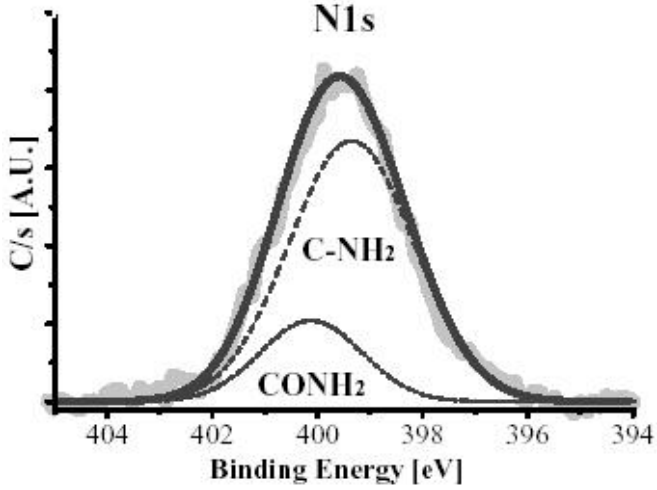

Fig. 8 Deconvoluted high-resolution XPS spectra of N1s.

groups (C-NH_2) and the higher binding energy peak at 400 eV corresponds to amide groups ($CONH_2$). Table Ⅰ shows that although the power dissipated into the plasma is small(1/10,000~1/1,000), almost the same or more quantity of amino groups are functionalized on the surface of polyethylene compared to other plasma surface treatment. Moreover, selectivity of amino groups functionalization (NH_2/N) in this work is relatively high compared to other works. The O1s peak can be also deconvoluted into two different peaks. The lower binding energy peak corresponds to carbonyl groups and the higher binding energy peak corresponds to ether or alcohol.

Figure 9(a) and (b) are the results of localization mapping of N1s XPS signal counts for 1 s and 100 s treatment respectively. We have achieved localized N1s area which is about 500 μm in diameter at 1s treatment. The size corresponds to the inner diameter of quartz tube. Although, it apparently shows that as the treatment time increases, the N1s incorporated area spreads. This fact indicates the possibility of the even smaller N1s functionalized area below 1 s treatment time.

Table Ⅰ. Comparison of Polymer Functionalization Results Reported in Other Literatures and Our Result.

Ⅳ. CONCLUSIONS

The amino groups were functionalized on a local surface of the low-density polyethylene by NH_3/He-DBDMP. Optical emission spectroscopy (OES) has been used for the characterization of the NH_3/He-DBDMP. Intensity of the NH radicals which play an important role on functionalizing amino groups, increases as applying higher voltage and as lowering the NH_3 flowing rate. The latter result can be explained by the mean energy that NH_3 particles recieve from He metastables. Lissajou method has been used to obtain the total power consumption of the NH_3/He-DBDMP in our system and it was 6.2 mW under the condition of V = 1.9 kV, f = 7 kHz, Q_{NH3} = 5 sccm, and Q_{He} = 200 sccm. The value is about 1/10,000~1/1,000 of those of other conventional plasma surface treatment system. X-ray photoelectron spectroscopy has been used for the characterization of NH_3/He-DBDMP treated polyethylene surface. The data from XPS shows that the increase of treatment time results in the increase of N and O components incorporation on the surface of the polyethylene. Although the power dissipated into the plasma is small, almost the same or more quantity of amino groups are functionalized on the surface of polyethylene compared to other plasma surface treatment. This is the advantage of the high-density plasma generated at atmospheric pressure in a small space. The results of localization mapping to visualize the locality of NH_3/He-DBDMP treatment show that as the treatment time increases, the N1s incorporated area spreads. This fact indicates the possibility of the even smaller amino groups functionalized area for shorter treatment time.

Abstract

Etching characteristics of high-*k* dielectric materials (HfO_2) and metal electrode materials (Pt, TaN) have been studied in high-density chlorine-containing plasmas. The etching of HfO_2 was performed in BCl_3 without rf biasing, giving a high etch selectivity of >10 over Si and SiO_2. The etching of Pt and TaN was performed with high and low rf biasing, respectively, giving a high etch selectivity of >8 over HfO_2 and SiO_2 in Ar/O_2 for Pt and in Ar/Cl_2 for TaN.

Keywords: high-*k*, plasma etching, ECR, gate oxides, gate electrodes, HfO_2, Pt, TaN

1. Introduction

As integrated circuit device dimensions continue to be scaled down, increasingly strict requirements are being imposed on plasma etching technology. The requirements include the etch anisotropy, profile control, feature size or critical dimension control relative to the mask layer, selectivity to the mask and underlying layers, and also microscopic uniformity of these etch parameters. For gate etch processes, a precise control of the profile and critical dimension of gate electrodes and a high selectivity to gate oxides have historically been the two most important issues to be addressed. In practice, the gate width of advanced microelectronic devices is projected to be scaled down to much less than 100 nm, and the thickness of gate oxides is also reduced down to 2 nm or less for conventional SiO_2.

Regarding gate dielectrics, the technological challenge continues for growing ultrathin SiO_2 films of high quality, to maintain the gate capacitance without increasing the gate leakage current and reducing the oxide reliability; however, the ultimate solution would rely on high dielectric constant (*k*) materials. Recent efforts have been made to replace SiO_2 with silicon-oxynitrides of slightly higher dielectric constant, and nowadays, new high-*k* (>20) dielectrics or metal oxides such as Al_2O_3, HfO_2, ZrO_2, and their silicates and aluminates are being developed to replace SiO_2 [1,2]. In practice, the metal oxides give the required specific gate capacitance at a considerably larger thickness as compared to SiO_2. In integrating these materials into device fabrication, an understanding of the etching characteristics of high-*k* materials is strongly required for their removal prior to forming the source and drain contacts. It should be noted that high-k dielectrics are generally difficult materials for etching, owing to their non-volatile etch products or halogen compounds.

Moreover, for gate stacks with high-*k* dielectrics, gate electrodes of conventional poly-crystalline silicon (poly-Si) tends to cause some problem of the depletion layer present in doped poly-Si gate materials. Thus, for lower equivalent oxide thicknesses, recent efforts have also been made to replace poly-Si gate electrodes with metal gates of WN, TiN, TaN, Ru/RuO_2, Pt, and/or Ir [1,2]. It should be noted that some of these metals (Pt, Ir) are also difficult materials for etching, owing to their non-volatile halogen compounds.

Plasma etching of high-*k* oxides and metal electrodes has been studied in the application of ferroelectric materials, buffer layers, and capacitor dielectrics to memory devices. However, only a few studies have recently been concerned with the plasma etching of high-*k* dielectrics [3-13] and metal electrodes [11,13] for the application of high-*k* gate stacks. Pelhos *et al*. studied the etching of high-*k* gate dielectric $Zr_{1-x}Al_xO_y$ thin films in helical resonator plasmas with Cl_2/BCl_3 [3]. Sha *et al*. investigated the etching of ZrO_2 in electron cyclotron resonance (ECR) plasmas with Cl_2/Ar [4] and BCl_3/Cl_2 [6], and also the etching of HfO_2 in ECR BCl_3/Cl_2 plasmas [7,8]. Norasetthekul *et al*. reported on the etching of HfO_2 in inductively coupled plasmas (ICP) with Cl_2/Ar, SF_6/Ar, and $CH_4/H_2/Ar$ [5]. Moreover, Maeda *et al*. reported on the HfO_2 etching in ICP CF_4 and $Cl_2/HBr/O_2$ plasmas [9]. Chen *et al*. investigated the etching of HfO based high-*k* films in ICP plasmas with Cl_2/HBr and CF_4/CHF_3 [10]. Emphasis of most of these studies has been placed on etch chemistries giving an etch selectivity of >1 over the underlying Si [3-8] and SiO_2 [9], and further on a better understanding of the physics and chemistry underlying the processing. More recently, Kota *et al*. have reported on the etching of metal/high-*k* stacks ($TiN/TaN/HfO_2$) in ICP plasmas with BCl_3- based chemistries [11]. It is further noted that the etching of high-*k* dielectrics is also indispensable with low ion energies and/or less ions, for chamber cleaning of the chemical vapor deposition (CVD) and atomic layer deposition (ALD) apparatuses to prepare high-*k* thin films.

We have investigated the high-density plasma etching of HfO_2 with attention being focused on etch chemistries and plasma conditions to achieve a much higher selectivity of >>1 over Si and SiO_2. We found the highly selective

etching of HfO_2 over Si in ICP fluorocarbon plasmas [12]; in some detail, the selectivity was >5 in C_4F_8/Ar plasmas, where carbon and/or carbonaceous species would work as surface inhibitors on Si, contributing to the high selectivity. Moreover, we demonstrated that the HfO_2/Si selectivity is further increased to >>10 in C_4F_8/Ar/H_2 plasmas, where the fluorocarbon polymer deposition on Si would be enhanced significantly by adding H_2, as in the situation of high selective etching of SiO_2 over Si with fluorocarbon plasmas.

This paper presents a highly selective etching of HfO_2 over the underlying Si and SiO_2 in ECR chlorine-containing plasmas without rf biasing [13]. The idea is that the lowered energy of incident ions would reduce the etch rates of Si and SiO_2 significantly as compared to HfO_2, thus contributing to the high selectivity. The paper also presents the etching of Pt and TaN in ECR chlorine-containing plasmas [13], with emphasis on the etch anisotropy and selectivity of metal electrodes over HfO_2 and SiO_2 (over the underlying high-*k* and the mask materials).

2. Experimental

The experimental setup is shown in Fig. 1 for ECR plasma etching. The plasma reactor consisted of a plasma and a specimen chamber grounded. A set of solenoid coils were placed around the former, providing divergent magnetic fields to produce and transport ECR plasmas to a sample for etching in the specimen chamber. The discharge was established by 2.45-GHz right-hand circularly polarized microwaves of TE_{11} mode injected trough an entrance quartz window at the top of the plasma chamber, and the 875-G ECR resonance was located near the end of the plasma chamber. The specimen chamber, 36 cm in diameter and 40 cm long, had an end port for pumping and several side ports for diagnostics, containing a 16-cm-diam floating electrode or substrate holder ~20 cm downstream (B≈200 G) from the ECR resonance region. The electrode was water cooled, and capacitively coupled to a 13.56-MHz rf power supply through an impedance matching network for additional rf biasing. Feedstock gases employed were Cl_2 BCl_3. O_2, and their mixtures with Ar, being introduced into the reactor, evacuated to a base pressure $<10^{-6}$ Torr, through a set of small holes at side walls of the reactor. The experiments were performed at incident microwave powers of nominally P_{MW}= 400-600 W, rf bias powers of nominally P_{rf}=0-150 W, and a gas flow rate of 40 sccm in total; the reactor gas pressure was varied from P_0=5 to 20 mTorr (0.665 to 2.66 Pa).

The etched depth was measured by stylus profilometry; in some cases, the film thickness of dielectrics was measured by optical interferometry, and the film thickness of metals was obtained from the sheet resistance measured by the four probe method. The etch rates were calculated by dividing the etched depth or thickness by the etching time. Moreover, the chemical composition on wafer surfaces was examined with x-ray photoelectron spectroscopy (XPS), and the etched profile was with scanning electron microscopy (SEM). In addition, several diagnostics were employed to characterize the plasma around the wafer position during processing: optical emission spectroscopy (OES), microwave interferometry, and Langmuir probe measurement.

Samples for etching were 50-nm-thick HfO_2 films prepared by CVD on Si substrates, and 200-nm-thick Pt and TaN films prepared by reactive sputtering on thermally oxidized Si substrates. Separate Si and thermal SiO_2 substrates were employed for reference of etching. To examine the etched profiles, patterned samples were also employed with a 200-nm-thick hard mask (SiO_2 mask) pattern feature of lines and spaces, where the nominal pattern width was in the range 0.4–10 μm. It is noted here that the Pt samples had 10-nm-thick Ti films deposited as an adhesion layer between Pt and SiO_2. The samples were cleaved into 2 cm^2 pieces, and attached on a 6-in.-diam Si wafers, which were then mechanically clamped into place on the wafer stage; backside helium was injected for increased wafer thermal contact.

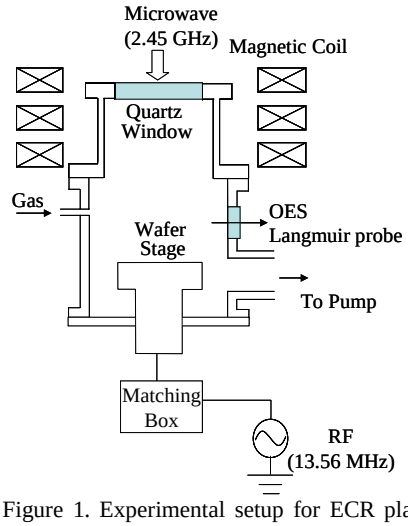

Figure 1. Experimental setup for ECR plasma etching.

3. Results and Discussion

3.1 Etching of high-k dielectrics

Figures 2(a) and 2(b) shows the etch rates of HfO_2, Si and SiO_2 in BCl_3 without rf biasing, as a function of pressure P_0 at P_{MW}=600 W and as a function of microwave power P_{MW} at P_0=10 mTorr, respectively. The gas flow rate was 40 sccm in total. The etching of HfO_2 films occurred at pressures between P_0=8 and 12 mTorr. The etch rate of HfO_2 was about 5 nm/min in maximum at P_0=10 mTorr, where the etch selectivity was >10 over Si and SiO_2. It should be noted that at lower P_0≤6 mTorr, the deposition occurred on all surfaces of HfO_2, Si, and SiO_2, and that at

higher $P_0 \geq 15$ mTorr, the etching of HfO_2 did not occur; moreover, the etching of Si and SiO_2 was found to occur only at around P_0=8 mTorr. The Langmuir probe measurements indicated that at P_0=10 mTorr with P_{MW}=600 W, the difference between the plasma and floating potentials was V_p-$V_f \approx 15$ V, increasing and decreasing with increasing and decreasing the P_0, respectively. In addition, as the microwave power was increased from P_{MW}=400 to 600 W at P_0= 10 mTorr, the etch rates of all the films increased, where the HfO_2 etch rate was in the range 3-5 nm/min and the selectivity of HfO_2 over Si and SiO_2 exceeded 10.

Figure 2(c) shows the etch rates of HfO_2, Si and SiO_2 in BCl_3 without rf biasing, as a function of pressure P_0 at P_{MW} =600 W, derived from the data of Figure 2(b) after removal of the deposited films on surfaces by using the solvent of alcohol. It should be noted that at low pressures $P_0 \leq 6$ mTorr, the etching was found to occur on HfO_2 surfaces, while the etching was insignificant on Si and SiO_2 surfaces. Figure 2(d) shows the etched depth or thickness of HfO_2, Si and SiO_2, measured as a function of time in BCl_3 without rf biasing, at P_0=5 mTorr and P_{MW}=600W. It should be noted that the etching of HfO_2 was found to occur during approximately <0.5 min, and then the deposition occurred on HfO_2; in contrast, on Si and SiO_2 surfaces, only the deposition occurred after the induction period.

Figure 3 shows SEM micrographs of the HfO_2, Si and SiO_2 surfaces exposed to ECR BCl_3 plasmas without rf biasing during 5 min at P_{MW}=600 W and P_0=5 and 10 mTorr. At P_0=5 mTorr, all surfaces of HfO_2, Si, and SiO_2 were found to be rough, or the surface morphologies were poor, probably owing to the films or materials deposited. In contrast, all the surfaces were smooth at P_0=10 mTorr, on which the etching occurred.

Figure 4(a) shows the XPS spectrum of Hf $4f_{7/2}$ and Hf $4f_{5/2}$, obtained from HfO_2 sample surfaces for three different conditions: (i) HfO_2 surfaces before plasma exposure; and HfO_2 sample surfaces exposed to BCl_3 plasmas without rf biasing during 5 min at P_{MW}=600 W and P_0= (ii) 5 mTorr (deposit- ed) and (iii) 10 mTorr (etched). Note that the conditions (ii) and (iii) correspond to those of Figure 3.

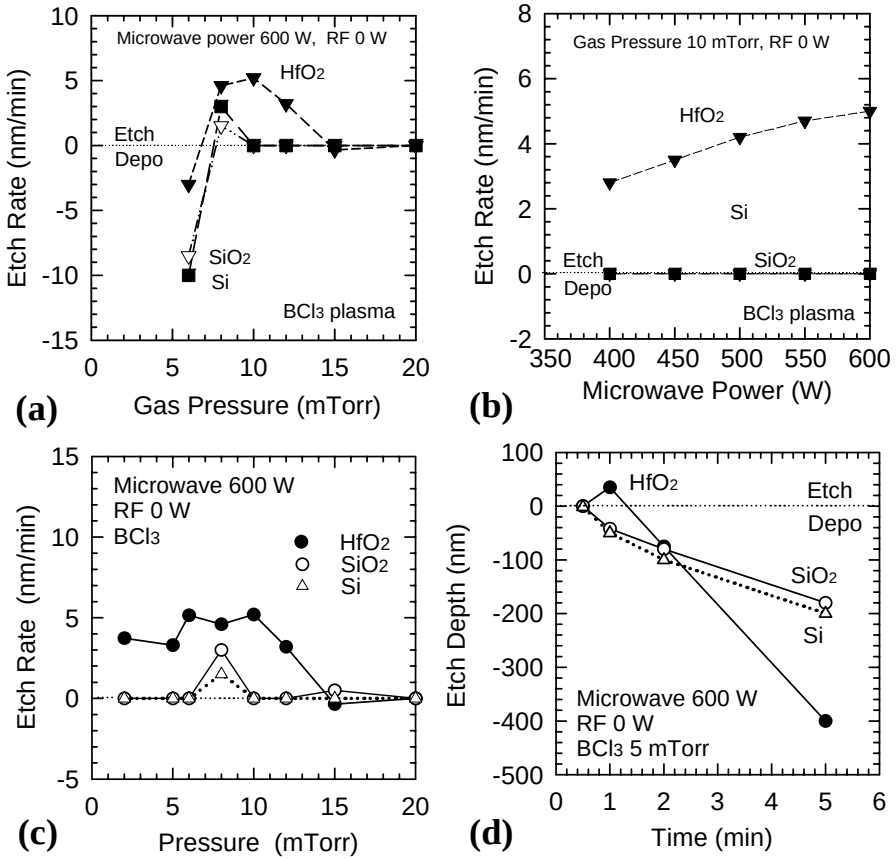

Figure 2. Etch rates of HfO_2, Si and SiO_2 in ECR BCl_3 plasmas without rf biasing, (a) as a function of pressure P_0 at P_{MW}=600 W and (b) as a function of microwave power P_{MW} at P_0=10 mTorr. The gas flow rate was 40 sccm. Also shown were (c) the etch rates derived from the data of (a) after removal of the deposited films on surfaces, and (d) the etched depth or thickness measured as a function of time at P_0=5 mTorr and P_{MW}=600 W.

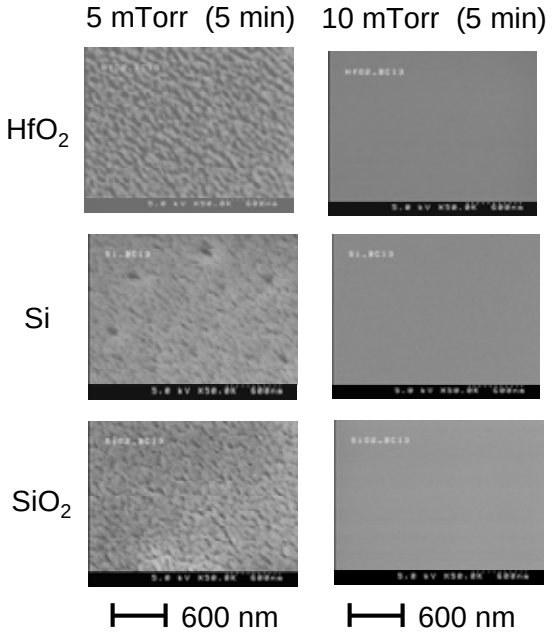

Figure 3. SEM micrographs of the HfO_2, Si and SiO_2 surfaces etched in (or exposed to) ECR BCl_3 plasmas without rf biasing during 5 min at P_{MW}=600 W and P_0=5 and 10 mTorr.

Also shown is the spectrum obtained from (iv) Si surfaces exposed to BCl_3 plasmas under the same operating conditions of (ii). The similar spectrum of Hf 4*f* was observed from (i) virgin and (iii) etched HfO_2 surfaces, while the spectrum intensity was relatively small from (ii) HfO_2 sample surfaces obtained under deposition conditions, implying that the deposited surfaces were covered with thin films or material layers containing no Hf species.

Figure 4(b) shows the XPS spectrum of Cl 2*p* and B 1*s*, obtained from HfO_2 and Si surfaces for the same conditions of Figure 4(a). No significant spectrum was observed from (i) virgin and (iii) etched HfO_2 surfaces. Note that no peaks on the etched surfaces may be attributed to the exposure of samples to atmosphere after the experiment. In contrast, the similar spectrum of Cl 2*p* and B 1*s* was observed from (ii) HfO_2 and (iv) Si sample surfaces obtained under deposition conditions, implying that some BCl_x species or films were deposited on all the surfaces of interest. Moreover, Figure 4(c) shows the XPS spectrum of O 1*s* from HfO_2 and Si surfaces for the same conditions of Figures 4(a) and 4(c). The similar O 1*s* spectrum was observed from (i) virgin and (iii) etched HfO_2 surfaces, being attributable probably to Hf-O bonding of HfO_2. In contrast, the O 1*s* spectrum on (ii) HfO_2 and (iv) Si sample surfaces under deposition conditions exhibited a chemical shift attributable possibly to B-O bonding, which may be caused by the exposure of samples to atmosphere containing O_2 after the experiment.

It should be concluded that HfO_2 thin films can be etched with a high selectivity over Si and SiO_2 in high-density BCl_3 plasmas without rf biasing. At lower pressures, the deposition of BCl_x occurs on all the surfaces of interest; however, on HfO_2 surfaces, the deposition follows the etching that occurs during a few tens of seconds after some induction period. If the deposition can be suppressed under some

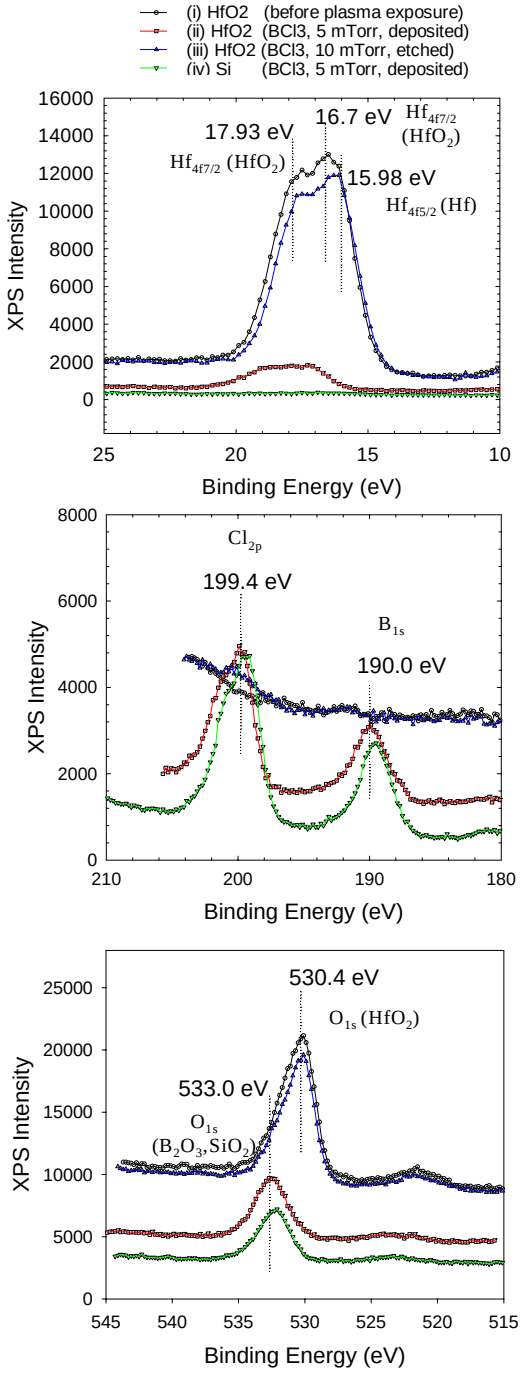

Figure 4. (a) XPS spectrum of Hf $4f_{7/2}$ and Hf $4f_{5/2}$, obtained from HfO_2 surfaces (i) before plasma exposure and (ii)(iii) exposed to BCl_3 plasmas without rf biasing during 5 min at P_{MW}=600 W and P_0=5 and 10 mTorr. Also shown is (iv) the spectrum obtained from Si surfaces exposed to BCl_3 plasmas under the same conditions of (ii). Moreover, XPS spectrum of (b) Cl 2*p* and B 1*s* and (c) O 1*s* were obtained from HfO_2 and Si surfaces for the same conditions of (a).

operating conditions, the HfO_2 etch rate would be significantly enhanced.

3.2 Etching of metals

Figures 5(a) and 5(b) show the etch rates of Pt, TaN, HfO_2, SiO_2 and Si as a function of Cl_2 concentration ratio in Ar/Cl_2 and as a function of O_2 concentration ratio in Ar/O_2, respectively, under the condition at a microwave power of P_{MW}=600W, an rf bias power of P_{rf}=150 W, and a pressure of P_0=10 mTorr. The gas flow rate was 40 sccm in total. Under these conditions, the peak-to-peak amplitude of the rf bias voltage was measured to be in the range V_{pp}=440-530 V. The etch rate of Pt in Ar/Cl_2 was about several tens of nm/min, being almost independent of Cl_2 concentration. The selectivity of Pt was in the range 0.4-1.5 over HfO_2, and in the range 0.9-1.6 over SiO_2, indicating that highly selective Pt etching over HfO_2 and SiO_2 is difficult in Ar/Cl_2. Note that under these conditions, the TaN etch rate exceeded > 300 nm/min when adding a small amount of Cl_2, probably owing to the formation of highly volatile products $TaCl_x$.

In contrast, by adding a small amount of O_2 to Ar, the etch rates of TaN, HfO_2, SiO_2, and Si significantly decreased, while the etch rate of Pt decreased slightly, resulting in a high etch selectivity of > 8 over HfO_2 and SiO_2 with >20% O_2 added. These results of the etching behavior of Pt is similar to previous studies for the application of high-*k* metal oxides to capacitor dielectrics in memory devices [14-16]; in practice, the etching of Pt relies primarily on physical sputtering through energetic ion bombardment on surfaces.

Figures 6(a) shows the etch rates of Pt, TaN, HfO_2, SiO_2 and Si as a function of Cl_2 concentration ratio in Ar/Cl_2, under the condition at a microwave power of P_{MW}=600W, an rf bias power of P_{rf}=30 W, and a pressure of P_0=10 mTorr. Under these conditions, the peak-to-peak amplitude of the rf bias voltage was measured to be in the range V_{pp}=100-160 V. Note that under these low rf bias power conditions, the etching of Pt did not occur, owing to lowered energy of ion bombardment; moreover, without rf biasing, the etching did not occur for all the metal films of interest. The etch rate of TaN increased significantly with increasing Cl_2 concentration, being about 200 nm/min in pure Cl_2, where a high etch selectivity of > 8 was achieved over HfO_2 and SiO_2. Figure 6(b) shows the etch rates of TaN and Pt as a function of rf bias power P_{rf} at 50% Cl_2 added in Ar/Cl_2, otherwise under the same condition of Figure 6(a). The threshold of P_{rf} or incident ion energy was found to be significantly lower for TaN than for Pt;

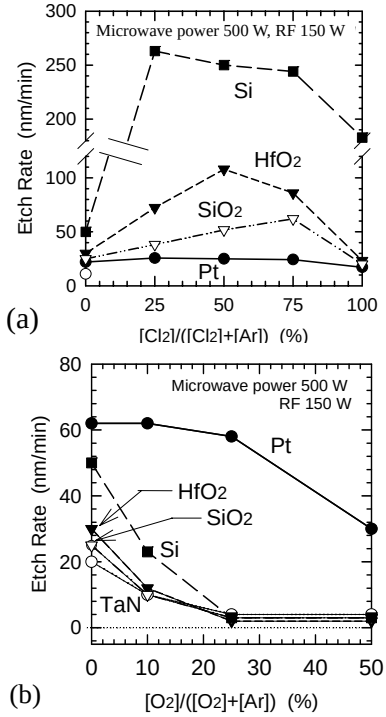

Figure 5. Etch rates of Pt, TaN, HfO_2, SiO_2, and Si (a) as a function of Cl_2 concentration ratio in Ar/Cl_2 and (b) as a function of O_2 concentration ratio in Ar/O_2, under the condition at a microwave power P_{MW}=500W, an rf bias power P_{rf}=150 W, and a pressure P_0=10 mTorr. The gas flow rate was of 40 sccm in total.

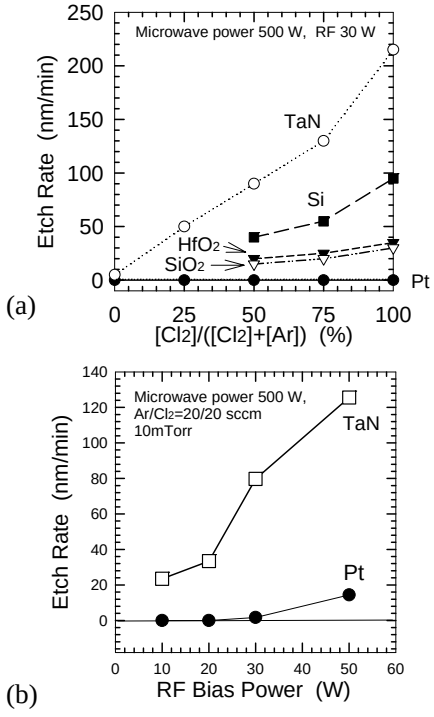

Figure 6. (a) Etch rates of Pt, TaN, HfO_2, SiO_2 and Si as a function of Cl_2 concentration ratio in Ar/Cl_2, under the condition at P_{MW}=500W, P_{rf}=30 W, and P_0=10 mTorr. Also shown are (b) the etch rates of TaN and Pt as a function of P_{rf} at 50% Cl_2 added in Ar/Cl_2, otherwise under the same condition of Figure 6(a).

in practice, the etching of TaN may occur at P_{rf}=0 or without rf biasing after some breakthrough at the beginning of etching. These results imply that the etching of TaN relies primarily on ion-assisted etching, with the chemical nature being high as compared to Si.

Figure 7 shows SEM micrographs of a nominally 0.4 μm line feature of Pt and 0.6 μm line feature of TaN, approximately just etched at 20% O_2 in Ar/Cl_2 with P_{rf}=150 W for Pt and at 75% Cl_2 in Ar/Cl_2 with P_{rf}=30 W for TaN; otherwise, the operating conditions were the same for Pt and TaN with P_{MW}=500 W and P_0=10 mTorr. A hard (SiO_2) mask was employed for the patterned samples. The etched profile of Pt was outwardly tapered, owing to the redeposition of etch or sputter products on feature sidewalls [14-16]. In contrast, the etched profile of TaN was found to be almost anisotropic, probably owing to the ion-enhanced etching that occurred.

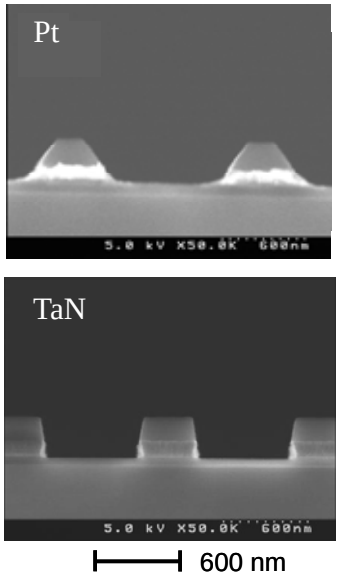

Figure 7. SEM micrographs of a 0.4 μm line feature of Pt and TaN, etched at 20% O_2 in Ar/Cl_2 with P_{rf}=150 W for Pt and at 75% Cl_2 in Ar/Cl_2 with P_{rf}=30 W for TaN. Other -wise, the operating conditions were the same for both with P_{MW}=500 W and P_0=10 mTorr,

4. Conclusion

Etching characteristics of high-*k* dielectric materials (HfO_2) and metal electrode materials (Pt, TaN) have been studied using high-density ECR chlorine-containing plasmas. Attention was focused on etch chemistries and plasma conditions to achieve a high etch selectivity of >>1 for HfO_2 over the underlying Si and SiO_2; regarding Pt and TaN, the emphasis was placed on the etch anisotropy and selectivity of metal electrodes over HfO_2 and SiO_2 (over the underlying high-*k* and the mask materials). The etching of HfO_2 was performed in BCl_3 without rf biasing, giving a high etch selectivity of >10 over Si and SiO_2. The etching of Pt and TaN was performed with high and low rf biasing, respectively, giving a high etch selectivity of >8 over HfO_2 and SiO_2 in Ar/O_2 for Pt and in Ar/Cl_2 for TaN. Further investigations are now in progress for the etched profiles and for the etching of stacks of metals/high-*k*, along with the numerical simulation of the feature profile evolution concerned and with a better understanding of the physics and chemistry underlying the phenomena observed.

X-ray scattering for in situ observation of nano sized silicon clusters during Meso Plasma fast rate epitaxy

M. Kambara, Y. Hamai and T. Yoshida

Department of Materials Engineering, The University of Tokyo, Tokyo 113-8656, JAPAN

Abstract

X-ray scattering measurement was attempted to observe in situ the possible formation of nano size clusters during medium pressure plasma CVD, in which high rate epitaxial growth has been achieved. X-ray beam was focused in the plasma/substrate boundary and the scattered signals were collected at an angle of 30˚. A distinguishable difference in intensities was observed before and during deposition, and was also varied with the silane gas flow rate, RF power input and the working pressure. These variations are potentially explained by altered size and number density of scatters, plausibly silicon clusters formed in the plasma / substrate boundary, which might be responsible for the morphological change of the film observed.

I. Introduction

In the course of film growth from vapor, atom and/or molecular precursors in an environment ahead of the solid growth interface determine critically the development of microstructure and the resultant properties of the solid. This is due mainly to its degree of spatial freedom in controlling the chemical and physical characteristics of the precursors. As a result, high pressure processing in general achieves enhanced deposition rates owing to its increased number density but tends to form agglomerated structures due to excessive particle coagulation. However, it would be still possible to attain effective precursor arrival, migration and accommodation on film surface if the precursors are to be controlled appropriately. Physical modeling on particle formation from high temperature plasma environment has predicted the nucleation of up to 1nm size clusters in the plasma/substrate boundary region and its significant contribution to an enhanced deposition rate [1]. Indeed, homoepitaxial silicon films have been produced at a rate as fast as 100nm/sec, as well as polycrystalline silicon thick films at 1μm/sec by medium pressure plasma (Meso Plasma) [2,3]. In addition, the possible presence of nano sized precursors in these experiments was supported by the ex-situ techniques such as microtrench and TEM observation [4]. These in turn imply that the processing is tuned or controlled to realize high rate deposition of a variety of films if the characteristic information of such nano clusters through direct observation is made possible.

Characterization of these in-flight (nucleating and growing) nano sized particles is typically carried out by Time-Of-Flight [5], Differential Mobility Analyze [6] and Laser scattering. Although the first two techniques allow analysis of particles as small as several nano meter sizes, these require collection of the particles from the reaction environment. This implies that, as an in-situ technique, these techniques are not applicable to the cases where nano particles are in reaction, nucleating and growing, during collection. Light scattering, on the other hand, can be a choice to observe particles in reaction based on Rayleigh or Mie scattering criteria [7]. However, the size of the particle to be observed is critically limited by the wavelength of the light used, which is several hundreds of nano meters at the smallest if laser is used as a light source. Therefore, to observe several nano sized particle, light with much smaller wavelength, such as X-ray, have to be employed. So far, only one group has attempted Soft X-ray scattering to observe soot inception in combustion flame at atmospheric pressure condition [8]. However, no attempt of this measurement has been reported for thin film processing where the nano sized clusters play critically essential roles upon controlling the structure.

In this work, we have thus adopted x-ray scattering to Meso Plasma CVD for observation of nano clusters in rather high dense and in-reaction environment, and evaluated its feasibility of being an in-situ technique to control nano particle formation during processing.

II. EXPERIMENTAL

Meso plasma CVD and X-ray scattering experiment has been carried out in the inductively coupled plasma with argon carrier gas (12slm) as shown in a schematic experimental set up of Fig.1.

The reaction chamber was initially evacuated up to 10^{-4}Pa. Silicon thin films were deposited under various pressures (6~50Torr), silane gas flow rates (5~20sccm) and RF power inputs (10~20kW) conditions. The temperature of the substrate was monitored at the bottom by the thermocouple inserted from the water-cooled copper substrate holder.

The X-ray beam generated with a copper target at 40kV and 2mA was focused with a focal diameter of 700μm at the plasma/substrate boundary, and the scattered light was collected by a solid-state detector (SSD) placed at scattering angles of 5˚ and 30˚. The slits were positioned in the X-ray path appropriately to eliminate the possible noise (multiple-scattered X-ray at chamber wall) and to collect the signal from only the plasma flame. In addition, to avoid the emission of Ar and Si, Ni filters were also placed in front of SSD counter to collect the X-ray at Cu Kα energy, which is the sum of the scattered X-ray from plasma / natural gases and from possible clusters within the plasma / substrate boundary region.

Measurement at a certain deposition condition was carried out under high vacuum before deposition (V_0), in the Ar plasma (P), during deposition with silane gas injection (D) and after deposition under high vacuum (V). This set of measurements allows an evaluation of the effects of residual gases, plasma and substrate (or the thin film deposited) on the intensities measured. The net intensity from the particles was then obtained by subtracting intensities during deposition from that in Ar plasma, and was compared with the morphology of the film so produced.

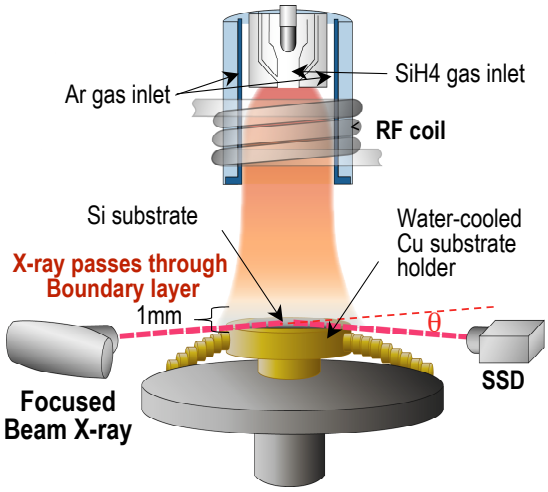

Fig.1 Schematic illustration of the experimental set up. Plasma carrier gas and silane gas were injected from top of the coil. The X-ray tube and SSD counters are positioned in the same horizontal plane which is tuned to the substrate position with sub-mm precision.

III. Results and discussions

Prior to the measurement during deposition, the effect of the environment gas species on X-ray intensity was measured. Figure 2 show the pressure dependences of scattered (transmitted) intensity by He, N_2 and Ar gases, measured at 0˚ and 30˚, respectively, and compares with those calculated with absorption coefficients and atomic scattering factors. In the case of 0˚, for all the gases, a monotonic decrease in intensity was observed with increasing the total pressure, although the intensity through Ar gas decreases rather rapidly in contrast to less significant influence of pressure of He and N_2. On the other hand, for the case of the scattering at 30˚, the scattering intensity increases monotonically with pressure for He and N_2, while that by Ar gas decreases, having the maximum at around 50Torr. These variations show a good agreement with the calculated pressure dependence. This is explained qualitatively by the combined contribution of the increased number densities of both the absorbing medium and of scattering objects with an increase in the pressure. In addition, it should be noted that no remarkable difference in intensity was observed between in the Ar plasma compared to that for natural Ar due probably to less ionization in the meso

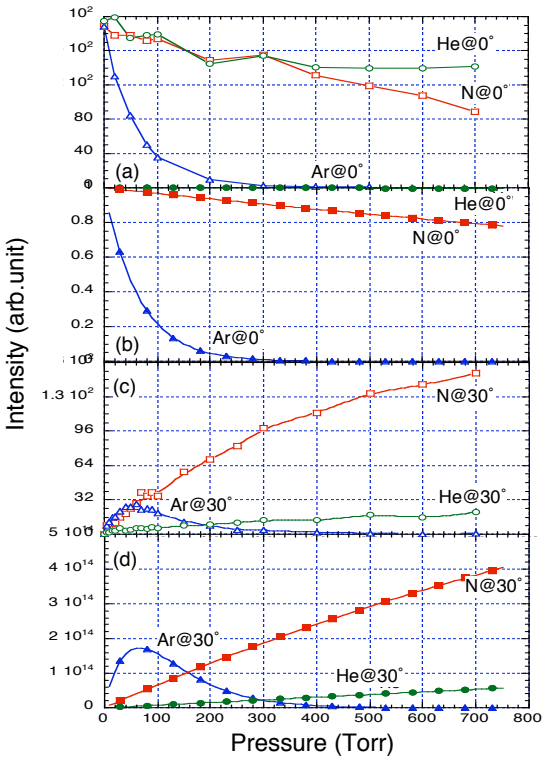

Fig.2 Pressure dependences of X-ray intensity through various gas atmospheres:
(a) experiment measured at 0˚, (b) calculation at 0˚, (c) experimental at a scattering angle of 30˚ and (d) calculation at a scattering angle of 30˚.

plasma condition.

The effect of the X-ray beam position on the x-ray intensities was then measured. Figure 3 shows the time evolution of the scattered intensity, measured at 30˚ before and after plasma deposition, at different X-ray - substrate positions. By fixing the X-ray beam position constant, the substrate height was changed so that the beam passes (a) within the plasma core flame, (b) through the possible plasma/substrate boundary layer and (c) at the bottom of the boundary and possibly interacts with substrate. In the case of (a), no detectable signal was collected under vacuum (10^{-4} Pa) after deposition (V), indicating no effect of interaction of X-ray with substrate, while the intensity during deposition (D) is nearly the same with or slightly smaller than that at plasma (P). On the other hand, the arrangement of (b) attains higher and distinguishable intensity of (D) than that of (P) although the intensity (V) is also increased after deposition. This tendency is found further enhanced in the case of (c).

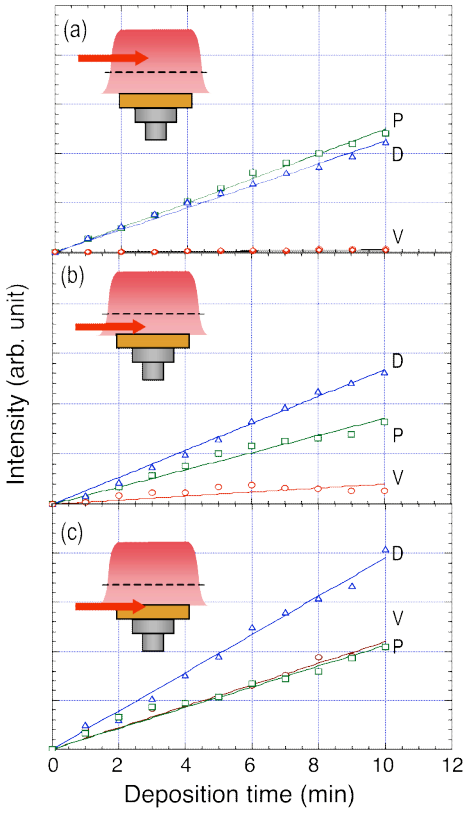

Fig.3 Time evolution of X-ray intensities, measured in Ar plasma before deposition (P), during deposition (D) and under vacuum after deposition (V), for the different substrate to X-ray beam positions; (a) X-ray in the plasma flame, (b) in the boundary and (c) at substrate. The height of substrate for (a) and (c) is lower and higher by1mm than that for (b), respectively. (all the intensities are already subtracted by the intensity measured at the initial high vacuum (V_0)).

As a general tendency, an addition of hydrogen gas to Ar plasma leads to an increase in transmitted X-ray and to a decrease in the scattering intensity. Similar tendency could be expected for silicon vapor, as the scattering cross section (atom scattering factor) and absorption coefficient for Si and H are smaller than those for Ar. As a result, when the silane gas was injected in the Ar plasma and dissociated into silicon and hydrogen atoms, the scattering intensity could be reduced from that only of Ar gas. This effect is substantially dependent on the amount of silane gas injected, but reasonably accounts for the slight decrease in the intensity (D) than (P) as observed in the case of (a).

On the other hand, the possible sources for an increase of (D) than (P) would be either the substrate (films grown) interaction or some other scattering objects or both. The effect of the former is clearly identified by the intensity (V) measured after deposition in vacuum, as is observed in the cases of (b) and (c). Recalling that the intensity (D) is the sum of the X-ray scattered by all the possible scattering objects in the boundary region, the subtraction of (V) from (D)-(P) gives a contribution only from the additional scatters within the boundary excluding the effect from the film or substrate. In the case of (c), this amount was estimated to be nearly negligible, which clearly indicates that the intensity (D) is fully due to the interaction with the film. In contrast, the amount of (D)-(P)-(V) for the case of (b) remains finite and suggests the presence of the additional scattering objects upon injection of silane gas despite the small number density of the silicon atoms in this experiment of the order of $10^{14}/cm^3$. Considering less significant scattering by silicon atoms evident from the case of (a), therefore the possible scattering object would be the silicon clusters formed by the gas phase condensation in the boundary between plasma / substrate.

Another important result involved in this set of measurements is that the appropriate height of the x-ray from the substrate is identified for observation of the clusters. Also, it should be noted that the intensity for each measurement varies with time rather linearly, suggesting the deposition process environment was carried out at steady state.

At a fixed X-ray beam and substrate arrangement, measurement was carried out at various plasma deposition conditions. Figure 4 summarizes the changes in the scattering intensity from scatters with (a) total pressure at a constant silane gas flow rate of 20 sccm and power of 15 kW, (b) silane gas flow rate at a constant total pressure of 6 Torr at 15kW and (c) RF power input at silane gas flow rate of 20

sccm and 6 Torr (all other deposition conditions are maintained constant). Note that these intensities are the net scattering intensities from scatters (possibly clusters) after subtracting that at plasma from that at deposition. It is clear that the intensity increases with increasing the total pressure and silane gas flow rate. These results would be largely affected by an increased number density of the scatters. On the other hand, the similar increase in the intensity was observed when the RF power input was increased, although the pressure and the silane gas flow rate were both maintained constant. This is partly because the scattering intensity increases with decreasing the size of scatterers as is calculated from the Mie scattering theory (forward scattering becomes pronounced if the size of scatters increases in contrast to the wavelength of light, leading to a decrease in the intensity at larger scattering angles). This tendency is further enhanced by the increased number density of smaller scatterers at a fixed number of atoms (at a constant reaction gas concentration). Simultaneous and multiple measurements at several scattering angles should be needed for quantitative characterization of the scatterers. Nevertheless, as shown in Fig.5, the structure of the films deposited at different RF powers was found to vary from aggregation of nano grains to epitaxially planar growth interface, as has been observed in Meso Plasma CVD [3]. It is therefore plausible that there is an obvious correlation between the intensity and the film morphology, and also that the possible clustering of silicon atoms is responsible for the structural variations of the films.

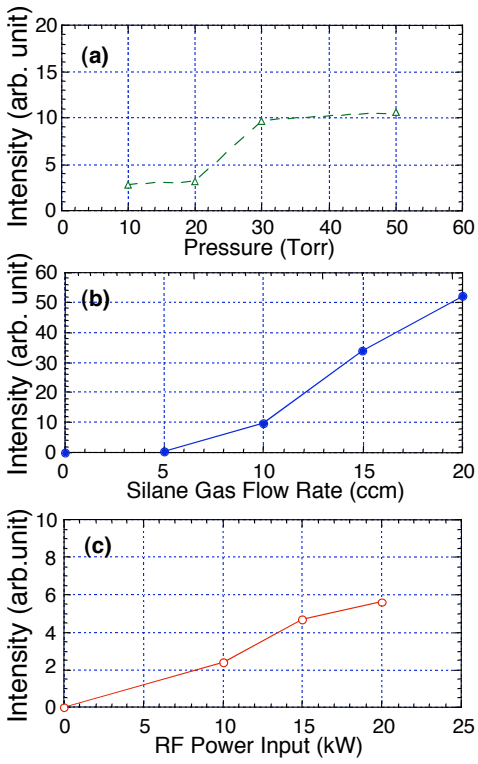

Fig.4 Variation of the scattered X-ray intensities with (a) pressure, (b) Silane gas flow rate and (c) RF power input.

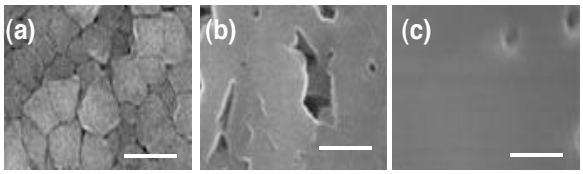

Fig.5 SEM surface images of the films deposited at different plasma RF power input; (a) 10kW, (b) 15kW and (c) 20kW.

IV. Conclusions

In situ X-ray scattering measurement was attempted to observe the possible cluster formation during meso plasma CVD. When the X-ray passes through the plasma /substrate boundary, the scattering intensity during deposition was distinguishably increased compared to that at only Ar plasma. Furthermore, this difference in the intensity was altered with the plasma conditions, while various microstructures were also observed in the films so deposited. These results potentially suggest that the additional scatters, plausibly Si clusters, were formed in the plasma / substrate boundary and could influence substantially on the evolution of the film structures. Although detailed analysis and establishment of this technique are necessary, as such the x-ray scattering was found effective to observe the condensation process in situ.

Abstract

We investigate the film-deposition process by CH_4/Ar plasma, using infrared spectroscopy in multiple internal reflection geometry (MIR-IRAS). The IRAS data show that sp^2- and/or sp- C_XH_Y species predominantly stick on Si substrates, when ratio of partial pressure of CH_4 to total pressure is low, and that sp^3-CH_X species predominantly stick on it when the ratio is high. We think that chemical states of the deposited films can be controlled by changing the fraction of CH_4.

1. Introduction

Methane (CH_4) plasma has been widely employed to deposit many kinds of carbon related materials, such as diamond, diamond like carbon (DLC), carbon nanotube and so on. In order to synthesize these materials precisely we must control chemical states of films from the initial stage of film deposition. Of course, many efforts have contributed to the fundamental understanding of their growth process. However, the growth process has not been fully understood yet. This is because there are many parameters to synthesize the carbon related materials. One of them is dilution gas. Argon (Ar) and hydrogen (H_2) are usually used as dilution gas in the CH_4 plasma process. It is well known that hydrogen content is high in the films deposited using the H_2/CH_4 plasma, compared with that deposited using Ar/CH_4 plasma.

We investigate the film-deposition processes by Ar/CH_4 plasma, using in-situ and real time infrared absorption spectroscopy in multiple internal reflection geometry (MIR-IRAS).

2. Experiments

An MIR-IRAS monitoring system was installed in a plasma enhanced chemical vapor deposition (PECVD) reaction chamber equipped with a plasma source and a gas delivery system in this study,

as shown in Fig. 1. The base pressure of the chamber was maintained below 1×10^{-6} Torr. Plasma excitation was accomplished by a 13.56 MHz rf power of 10 W through a π-type matching network to a coil wrapped around a 30 mm diameter Pyrex tube. The total pressure is set at 0.1 Torr. The Ar and CH_4 gas mixture was introduced into the Pyrex tube. The ratio of the partial pressure of CH_4 to the total pressure (CH_4+Ar) was changed. Radicals and other species generated in the rf field region were transported to the downstream region and reacted on a Si sample mounted 20 cm apart from one end of the helical antenna.

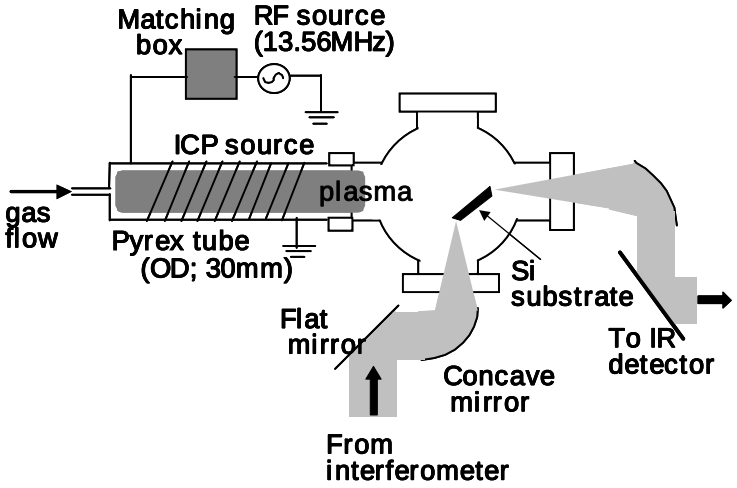

Fig.1 Experimental setup

The Si(100) sample surfaces used here were treated with the traditional RCA cleaning before the sample was set in the chamber. The chemical state of the surface was monitored using the MIR-IRAS technique. The samples were 0.5 × 10 × 40 mm^3 with 45^o bevels on each of the short edges. Infrared radiation that exited an interferometer (BOMEM MB-100) was focused at normal incidence onto one of the two bevels of the sample, and traveled through the wafer with internally reflecting about 80 times. The radiation that exited the sample at the other bevel was focused onto a liquid-N_2-cooled HgCdTe (MCT) detector.

3. Results and discussion

Fig.2 shows IRAS spectra of Si(100) surface that was exposed to CH_4/Ar plasma when the ratio of partial pressure of CH_4 to the total pressure was 50 %. The broad peaks are observed at frequencies more than 3000 cm^{-1} from the initial stage. The peak increases its intensity as plasma

exposure time passes. These peaks are attributed to sp^2- and/or sp- CH_X species [1]. Another peak is also observed around 2165 cm^{-1}. It is due to the C≡C species. The sp^2- and/or sp-CH_X species play an important role in film deposition from the initial stage in this condition.

Fig. 3 shows the IRAS spectra of Si(100) surface that was exposed to CH_4/Ar plasma when the ratio of partial pressure of CH_4 to the total pressure was 80 %. Three peaks are observed at frequencies less than 3000 cm^{-1}. The shapes of the spectra are essentially the same as that obtained from the exposure of Si surface to H_2/CH_4 plasma generated at 0.1 Torr [2]. These peaks are attributed to sp^3-CH_X species. No clear peaks are observed at frequencies more than 3000 cm^{-1} and at around 2165 cm^{-1} in Fig.3. It indicates that there are little sp^2- and/or sp-CH_X species in the film. Then, we consider they little contribute to the film deposition in this condition.

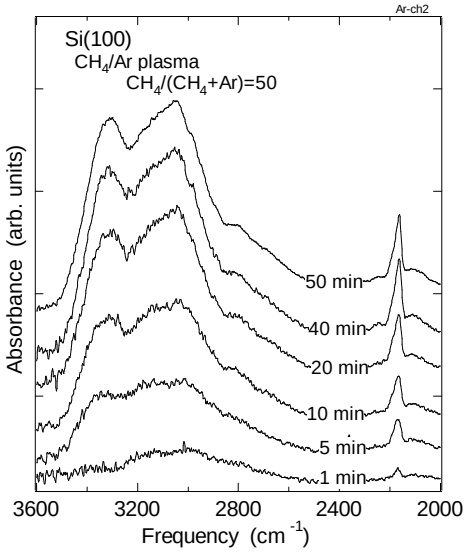

Fig. 2 IRAS spectra of Si surface that was exposed to CH_4/Ar plasma generated by a 13.56 MHz rf power of 10 W at 0.1 Torr. The partial pressure of CH_4 is 50% of the total pressure.

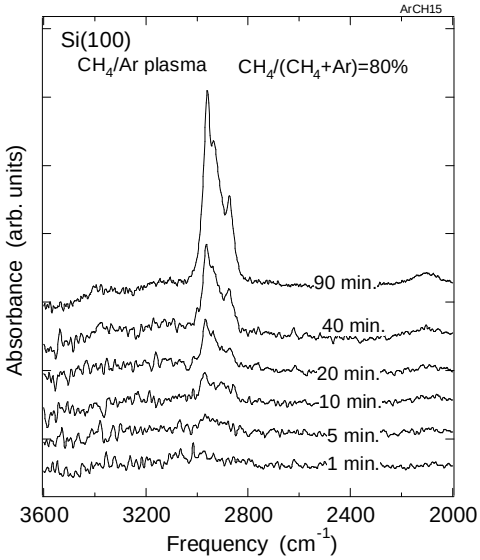

Fig. 3 IRAS spectra of Si surface that was exposed to CH_4/Ar plasma generated by a 13.56 MHz rf power of 10 W at 0.1 Torr. The partial pressure of CH_4 is 80% of the total pressure.

The CH_4/Ar plasma predominantly generated sp^2- and/or sp- C_XH_Y species, which stick on Si substrates, when the ratio of partial pressure of CH_4 to the total pressure is low. On the other hand, the plasma predominantly generates sp^3-CH_X species such as -CH_3 radicals when the ratio is high. These results indicate that the chemical states of the deposited film can be controlled by changing the ratio of partial pressure of CH_4 to the total pressure. We also suggest that the difference can be attributed to plasma-generated species. We think that the plasma-generated CH_X species is

dehydrogenated by the generation of ArH species in the CH_4/Ar plasma, and that as a result, the sp^2- and/or sp- CH_X species are easily formed when the ratio of partial pressure of CH_4 is low. Further studies are needed in order to clarify this consideration.

4. Conclusion

We have investigated the film-deposition process by CH_4/Ar plasma, using infrared spectroscopy in multiple internal reflection geometry (MIR-IRAS). The IRAS data showed that sp^2- and/or sp- C_XH_Y species stick on Si substrates, when ratio of partial pressure of CH_4 to total pressure is low, and that sp^3-CH_X species stick on it when the ratio is high. We think that the chemical states of the deposited films can be controlled by changing the ratio of the partial pressure of CH_4 to the total pressure.

Synthesis of AlN spherical nano-structured composite particles using transferred type DC arc plasma

Mikimasa Iwata*, Shizue Furukawa, Tadashi Amakawa and Kazuo Adachi

Central Research Institute of Electric Power Industry (CRIEPI), Yokosuka, JAPAN
(*m-iwata@criepi.denken.or.jp)

Abstract
Aluminum nitride (AlN) composite particles consisting of nano-particles dispersed on the surface of spherical micro-particles are one of the materials necessary for developing solid insulating materials with high thermal conductivity. This paper describes the synthesis of AlN composite particles using transferred type DC arc plasma. The diameters of micro-particle and nano-particle were controlled by varying the travelling time of the raw particles in the arc plasma and the flow rate of reacting/quenching gas.

1. Introduction

Downsizing of electrical equipment has meant that such equipment now requires a high thermal conductivity. To develop polymer insulating materials with high thermal conductivity, it is necessary to add large quantities of ceramic particles with high thermal conductivity, e.g. aluminum nitride (AlN), to organic insulating materials. Using composite particles consisting of nano-particles dispersed on the surface of spherical micro-particles is considered a good way of achieving a high ceramic particle content [1]. However, the conventional method for synthesizing composite particles requires the plural processes of synthesizing the spherical micro-particle, and the nano-particle, and mixing the two kinds of particles [2]. Another method using a spray fluidized bed granulator requires only one process for synthesizing the composite particles. However the method requires long process-time because the composite particles are synthesized by gradual agglomeration of small particles [3]. Therefore, another simple method for synthesizing the composite particles needs to be developed. On the other hand, in order to synthesize the insulating materials, it is necessary to clarify the optimal composite particle conditions, that is, the shape of synthesized particles, the volume fraction of micro-particles in the synthesized particles [4] and diameters of micro-particle and nano-particle. Therefore it is important to develop a simple method of controlling the particle conditions of synthesized composite particles.

The method utilizing transferred type arc plasma is considered a good choice for synthesizing nano-particles with a high production rate and lower costs, because the transferred type arc plasma has a long high temperature zone and the advantage of making it easy to upgrade plasma power [5]. We may expect to synthesize composite particles simply by controlling the evaporation conditions of the raw material in the transferred type arc plasma and the reacting/quenching conditions of the raw material vapour. This paper describes the synthesis of AlN composite particles using transferred type DC arc plasma. The influences of operating parameters on the shape of the synthesized particle, the volume fraction of micro-particles in the synthesized particles and the diameters of micro-particle and nano-particle were clarified.

2. Experimental conditions and analyzing method

2.1 Experimental setup and conditions

Figure 1 shows the experimental setup. A transferred type arc plasma was generated between a tungsten cathode of a plasma torch and a graphite anode in a chamber. The distance between the two electrodes (plasma length) was 25-75 mm. The cathode consisted of a tube-shaped electrode, and the anode a rod-shaped electrode, and the two electrodes were water-cooled. The raw material (crushed AlN particle) was injected into the arc plasma through the cathode using a plasma gas (nitrogen [N_2]). The flow rate of the plasma gas was 5-20 litres/min. By varying the flow rate of the plasma gas and the plasma length, the travelling time of raw particles in the arc plasma was changed. Diameter of the raw AlN particle was below 25 μm with a feed rate of 2.1 g/min and a feed time of 1-2 minutes. DC arc current was 140 A and arc voltage 100-150 V. A suction pipe was positioned downstream from the anode. The distance between the anode and the tip of the suction pipe was 100 mm. A reacting/quenching gas was blown into the suction pipe. Ammonia (NH_3) was used as the reacting/quenching gas. The flow rate of the reacting/quenching gas was 5-20 litres/min. The surface of the raw AlN particle would evaporate in the arc plasma and the aluminum

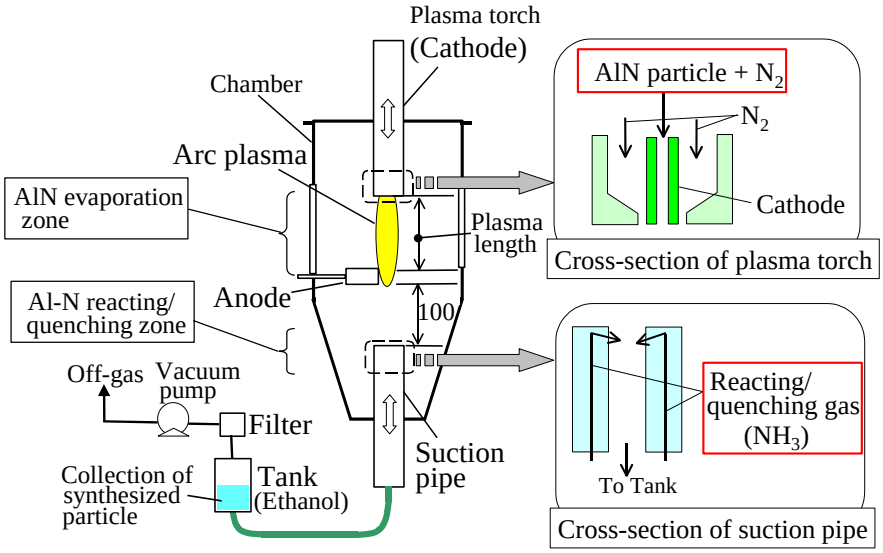

Figure 1. Experimental setup.

(Al) gas would surround the AlN particle, then the Al gas would react with and be quenched by the reacting/quenching gas. Therefore, composite particles consisting of nano-particles dispersed on the surface of spherical micro-particles would be synthesized. The synthesized particles were collected in a tank. The off-gas was exhausted through the suction pipe, the tank and a filter using a vacuum pump. The tank contained ethanol in order to prevent the oxidation of the synthesized particles. The pressure in the chamber was 20-50 kPa.

2.2 Method of measuring velocity of particles in arc plasma and temperature of arc plasma

The flight velocity of the AlN particles in arc plasma was estimated by video observation. Some bright lines were observed in the arc plasma owing to high emission from AlN particles in the arc plasma. The exposure time of the video observation was 1 ms. The flight velocity of the particle was estimated using the length of the observed bright lines and the exposure time. The spectroscopic observation of the arc plasma was carried out. The temperature of the arc plasma was determined by comparing the observed intensities of two spectral lines, i.e. 694.5 nm and 742.3 nm of nitrogen atom, assuming that the arc plasma was in local thermodynamic equilibrium (LTE). The upper energy levels of these spectral lines are 13.6 eV and 12.0 eV respectively.

2.3 Method of analyzing the synthesized particles

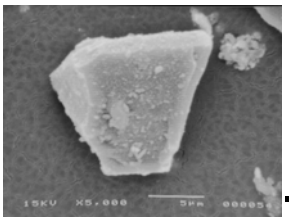
The AlN content in the synthesized particle was analyzed by x-ray diffraction (XRD) using the same method as in reference [5]. The shape and diameter of the synthesized particle were analyzed by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). By image processing of the SEM photograph, the degree of circularity and projected area equivalent diameter of the synthesized particle were measured using the same method as in reference [6].

The average diameter of the synthesized particles was measured by the Brunauer-Emmett-Teller (BET) method. Using the projected area equivalent diameter and the average diameter of the synthesized particles containing micro-particle and nano-particle, the diameters of micro-particle and nano-particle were estimated.

3. Experiment results and discussions

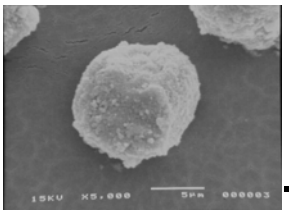
3.1 Velocity of particles in arc plasma and temperature of arc plasma

The velocity of particles injected into the arc plasma was determined approximately 10 m/s, 20 m/s and 40 m/s, when the flow rate of plasma gas was 5 litres/min, 10 litres/min and 20 litres/min, respectively. The travelling time of raw particles in the arc plasma was estimated using the measured velocity and the plasma length.



(Degree of circularity : 0.70)

(a) Raw particle



(Degree of circularity : 0.82)

(b) Synthesized particle

Figure 2. SEM photographs of particles.

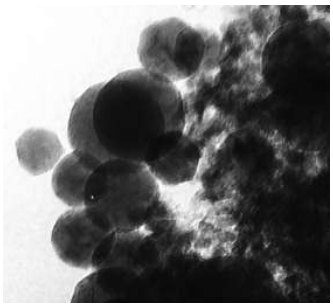


Figure 3. TEM photograph of synthesized particle surface

The temperature of the arc plasma in the central-axis was determined approximately 7,000 K. The radial temperature distribution was estimated by fitting in with the numerical result [7] of the radial temperature distribution of nitrogen arc plasma. The radially average temperature of the arc plasma was determined approximately 3,500 K, assuming that the diameter of arc plasma was 20 mm by video observation and the temperature of the plasma edge was 3,000 K because the radiation intensities of nitrogen arc plasma increases abruptly when the temperature was more than 3,000 K [8].

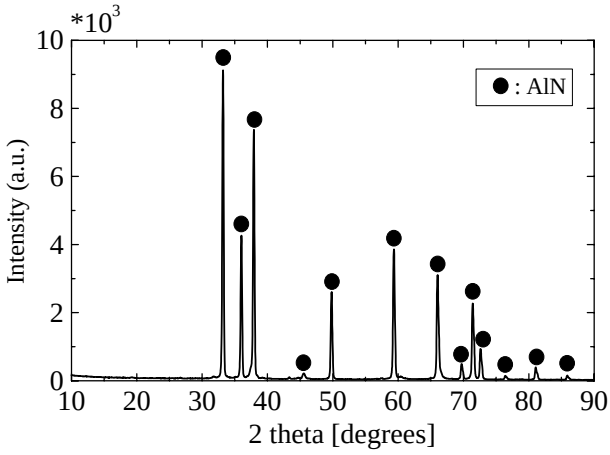

Figure 4. XRD profile of synthesized particles.

3.2 Shape and surface state of synthesized particles

Figures 2(a) and (b) show SEM photographs of the raw and synthesized particles, respectively. The shape of the raw particle was angular and that of the synthesized particle became relatively spherical. As described in the previous paper [6], the average degree of circularity of raw particles was 0.75 and that of synthesized particles increased to approximately 0.9 when the travelling time of raw particles in the arc plasma increased more than 2 ms. Figure 3 shows a TEM photograph of the synthesized particle surface. The TEM observation clarified that many small particles less than 100 nm adhered uniformly to the surface of the synthesized particle.

3.3 AlN content in synthesized particles

Figure 4 shows an example of an XRD profile of the synthesized particles. Only AlN peaks were observed in the XRD profile. The AlN content in the synthesized particles was estimated at more than 99 %. However, a weak Al peak was observed in an XRD profile when the travelling time of raw particles in the arc plasma was relatively long (5 ms) and the flow of the reacting/quenching gas was relatively little (5 litres/min). It was considered that the result was due to the condensation of non-reacted Al gas that was generated from the evaporation of the raw AlN particle in the arc plasma. Figure 5 shows the calculation result of the condensation temperature of non-reacted Al gas for the NH_3/AlN system. The calculation method was described in reference [5]. Calculation conditions (molar rate, pressure) were similar to the experimental conditions described in section 2.1. As the non-reacted rate of Al gas increased and the ratio of NH_3/AlN decreased, the condensation temperature of the Al gas increased. When the travelling time of raw

particles in the arc plasma was relatively long (5 ms) and the flow of the reacting/quenching gas was relatively little (5 litres/min), the quantity of the Al gas was so much that non-reacted rate of Al gas would be high and the ratio of NH_3/AlN would be low, therefore, the condensation temperature of the Al gas would be 1,600-1,800 K. On the other hand, the temperature of the space where the reacting/quenching gas was blown in the suction pipe was measured in reference [5]. The measured temperature of the space was 1,600-1,700 K. Hence, the non-reacted Al gas would condense and the some Al nano-particles would be synthesized, when the travelling time of raw particles in the arc plasma was 5 ms and the flow of the reacting/quenching gas was 5 litres/min.

Both these results and the result mentioned in section 3.2 suggest that the surface of the raw AlN particle evaporated in the arc plasma and the consequential generated Al gas reacted with and was quenched by the NH_3 gas, and finally AlN nano-particles were synthesized and adhered to the surface of the spherical micro-particles.

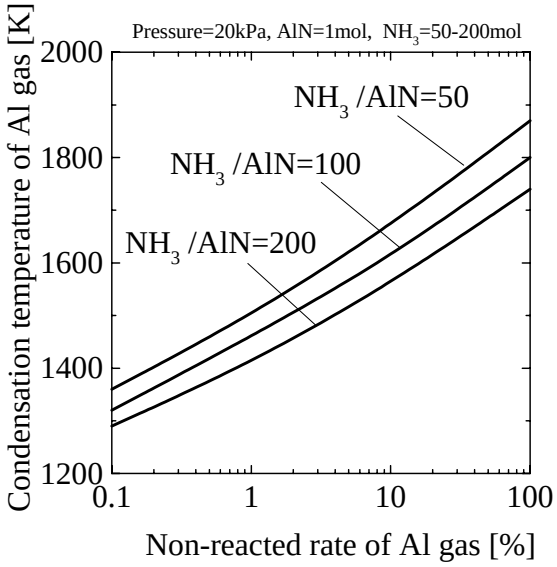

Figure 5. Condensation temperature of non-reacted Al gas for NH_3/AlN system.

3.4 Diameter of micro-particles

The circular plots in figure 6 show the diameter of micro-particles obtained from experiments. The diameter of the micro-particles in the synthesized particles decreased as the travelling time of raw particles in the arc plasma increased.

The broken curves in figure 6 show the calculated results of change in diameter of particles. The calculations took into account the decrease in particle diameter with the particle progress in the arc plasma using the same method as in reference [6]. The temperature of the arc plasma was set around the 3,500 K measured as an average temperature of the arc plasma in section 3.1. Calculations for figure 6 showed good agreement with the experimental results except the case that t_P was 5 ms. The video observation clarified that the arc plasma had a tendency to bend when t_P was 5 ms because the flow rate of plasma gas was relatively little (5 litres/min) and the plasma length was relatively long (50 mm). Therefore, it is considered that the raw particles passed through the relatively low temperature zone (e.g. 3,200 K) of the arc plasma and the calculation for figure 6 did not show good agreement with the experimental results when t_P was 5 ms.

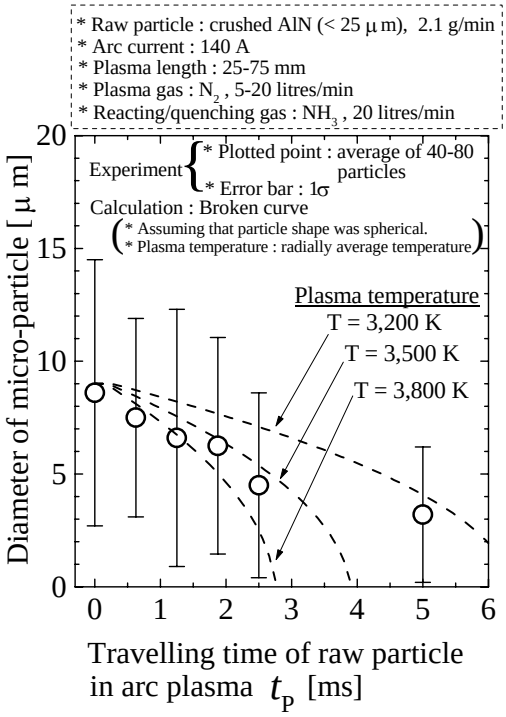

Figure 6. Dependence of diameter of micro-particles on its travelling time in arc plasma.

3.5 Volume fraction of micro-particles in the synthesized particles

The volume of vapour that was origin of the nano-particles was calculated using the diameter difference between the raw particles and the micro-particles. It was considered that the all nano-particles synthesized from the vapour were not collected in the suction pipe of the chamber because the vapour has a tendency to

spread in all directions. The collection rate of the nano-particles in the suction pipe was approximately 10 % in the previous report [9]. Therefore, the adherence rate of nano-particles on the micro-particle to all synthesized nano-particles was set at 10 %. The volume fraction of micro-particle in the synthesized particles was determined using these values mentioned above.

The circular plots in figure 7 show the volume fraction of micro-particles in the synthesized particles obtained from experiments. The volume fraction of micro-particles decreased as the travelling time of raw particles in the arc plasma increased. The volume fraction of micro-particles changed from 80 % to 50 % by varying the travelling time of raw particles in the arc plasma from 2 ms to 5 ms. The broken curves in figure 7 show the calculated results of change in the volume fraction of micro-particles. The calculation result was obtained using the calculated results of figure 6. The temperature of arc plasma was set around the 3,500 K measured as an average temperature of the arc plasma in section 3.1. Calculations for figure 7 showed good agreement with the experimental results except the case that t_P was 5 ms. The result was due to the same reason as mentioned in section 3.4.

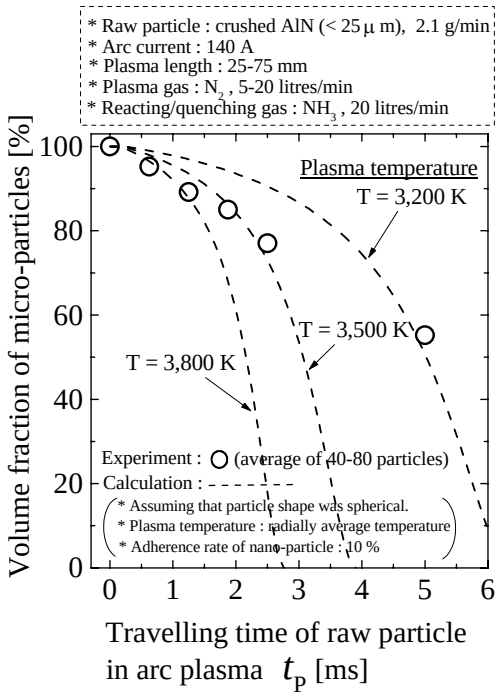

Figure 7. Volume fraction of micro-particles in synthesized particles.

3.6 Diameter of nano-particles

As shown in figure 8, the diameter of the nano-particles in the synthesized particles (circular plots) increased from 20 nm to 40 nm, when the travelling time of raw particles in the arc plasma increased from 1 ms to 5 ms. The diameter d of the nano-particles was investigated numerically using a Brownian collision-coalescence model as follows [10],

$$d = k * T^{0.2} * V^{0.4} \text{ ------ } (1)$$

where T is the temperature of the nano-particle synthesized space, V is the vapour density in the nano-particle synthesized space and k is constant.

The broken curve in figure 8 show the calculated results of change in diameter of nano-particles using the equation (1) when the diameter in case of t_P = 0.6 ms was basis. The temperature T was measured in the previous paper [5]. The vapour density V was calculated using the diameter difference between the raw particle and the micro-particle of the synthesized particle as shown in figure 6. The calculation result showed a similar tendency to the circular plots.

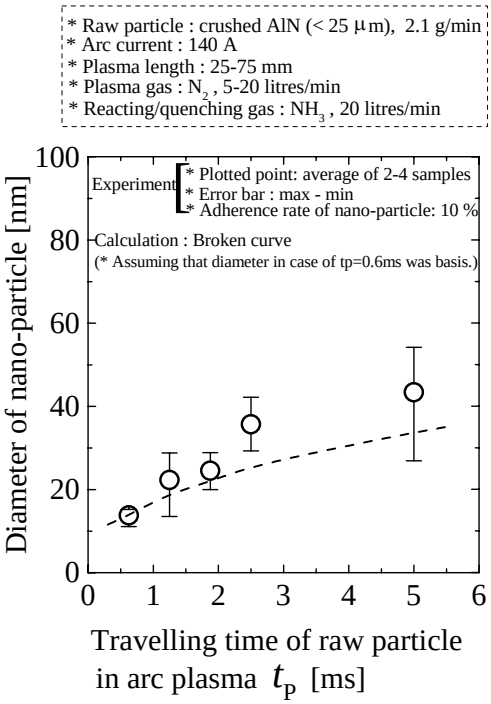

Figure 8. Dependence of diameter of nano-particles on its travelling time in arc plasma.

As shown in figure 9, the diameter of the nano-particles (circular plots) decreased from 80 nm to 40 nm when the flow rate of reacting /quenching gas increased from 5 litres/min to 20 litres/min. The broken curve in figure 9 show the calculated results of change in diameter of nano-particles using the equation (1) when the diameter in case of F_{RQ} = 5 litres/min was basis. The vapour density V was calculated assuming that V decreased inverse proportionally as F_{RQ} increased. The calculation result showed a similar tendency to the circular plots.

4. Conclusions

AlN composite particles consisting of nano-particles dispersed on the surface of spherical micro-particles were synthesized by simple method of using transferred type DC arc plasma. When the travelling time of the raw AlN particle (< 25 μm) in the nitrogen arc plasma was more than 2 ms, the degree of circularity of raw particles increased from 0.75 (raw particle) to approximately 0.9 and the shape of the synthesized particle was nearly spherical. The TEM observation clarified that many small particles less than 100nm adhered uniformly to the surface of the synthesized particle.

The volume fraction of micro-particles in the synthesized particles and the diameters of micro-particle and nano-particle were controlled by varying the travelling time of the raw particles in the arc plasma from 2 ms to 5 ms and the flow rate of reacting/quenching NH_3 gas from 5 litres/min to 20 litres/min. The experimental results of the diameters showed a similar tendency to the calculation results. From these results, the way to control the AlN composite particle conditions was clarified.

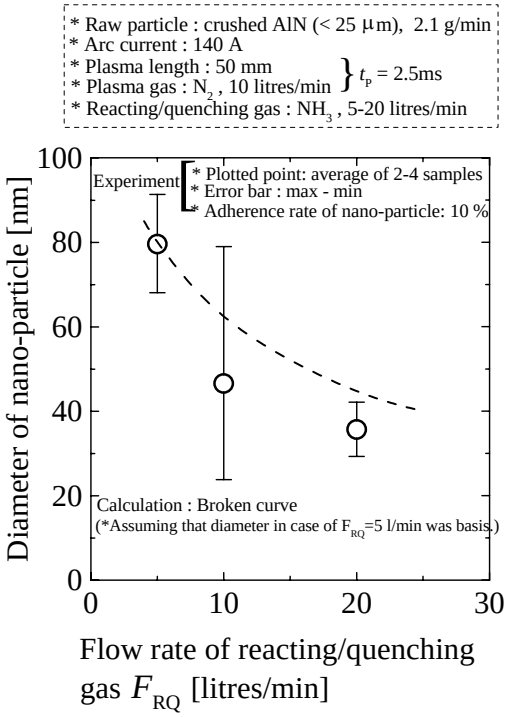

Figure 9. Dependence of diameter of nano-particles on flow rate of reacting/quenching gas.

Reduction of Oxygen Content in Atmospheric Plasma Jet: Shrouding by Reactive and Nonreactive Gas

T. Kavka, M. Hrabovsky, O. Chumak, A. Maslani

Institute of Plasma Physics, ASCR, Za Slovankou 3, Prague, Czech Republic

Abstract
The ambient air is entrained intensively into atmospheric pressure thermal plasma jets. A system for shielding plasma jet has been used to improve jet characteristics and reduce oxygen content. Two gases have been applied as a shroud gas – argon and acetylene. Argon shrouding resulted in slight changes of the plasma jet properties. The plasma jet became wider with small reduction of the oxygen content. Acetylene caused strong decrease of the oxygen content due to chemical reactions. Temperature of the plasma jet as well as velocity increased.

Keywords: entrainment shroud

1. Introduction

Plasma spraying of metals is usually accompanied by oxidation of sprayed material, which affects resulting coating. The plasma spraying is a two stage process. In the first stage particles are introduced into the plasma jet, where they are heated, melted and accelerated toward the substrate, where the second stage, i.e. deposition, cooling down and solidification takes place. Processes occurring in both stages have an influence on resulting coating properties and one of the serious problems is oxidation mentioned above. Although the second stage, during which the deposited solidified material interact with ambient atmosphere consisted mostly of the air, is much longer than the first stage, the in-flight oxidation in the high temperature environment plays critical role in the resulting oxide content in the sprayed coatings. In-flight oxidation begins due to gas-solid interaction during heating of particles in the plasma jet containing oxygen from air entrained into the jet. Hence, reduction of the oxygen content in the plasma jet is a question of great importance.

There are several methods how to avoid or at least reduce oxygen content in plasma jets. The simplest and the most economical method is shroud nozzle attached to the exit of the plasma torch. The shroud nozzle can provide both a solid shield and a gas shroud. The solid shield acts as a barrier preventing the air entrainment into the jet. In a gas shroud the solid shield is replaced by gas formed around the jet preventing mixing of the plasma with air [1]. Usually gases contained in plasma forming medium (e.g. Ar, N_2) are used as a shroud gas and they are supplied close to the exit nozzle parallel to the main flow. In the present paper the effect of the reactive gases as acetylene, methane and a mixture of oxygen with hydrogen is studied together with the effect of nonreactive argon shroud gas. Reactive gases combust intensively when react with oxygen in the plasma jet and are significantly more effective for decreasing the oxide content in plasma sprayed powders. Previous study of metallic coatings sprayed with different shrouding gases has shown that inert shrouding is ineffective in decreasing the oxide content and the oxide layers are thicker in comparison with the shrouding by reactive gases [4].

The aim of the present paper is a study of the shroud effect on the properties and composition of the plasma jet. Both the shroud gas and the solid shield were used in experiments. The effect of shroud gas nature and flow rate on properties of the plasma jet is discussed.

2. Experimental setup

Plasma jet was generated by hybrid argon-water plasma torch [5]. The schematic diagram of the torch with the shielding system is shown in Figure 1. The plasma jet generated by this torch is formed a mixture of argon, supplied along the cathode in the upstream part of the torch, with water vapor, which entrances and mixes up with argon plasma in the downstream water stabilized part. A long arc column results in high arc voltage and thus, high power given rise to high temperatures of the plasma. The important feature of the torch is the external rotating anode, which provides reduction of the strong erosion of the anode surface in the atmosphere containing

oxygen. The anode makes it difficult to provide good protection of the arc column close to the exit nozzle in the air atmosphere. That is why in the present experiments the shielding system was positioned at the distance 25 mm from the exit nozzle downstream the anode.

The system for shielding consisted of a ring for shroud gas distribution and supply, and a solid wall. The ring was 78 mm in diameter and 10 mm in width of the front part (Fig. 2). It was made of stainless steel and was not cooled. Several holes with diameter of 1 mm were made in the ring to distribute shroud gas around the plasma jet. The shroud gas flow was directed parallel to the jet axis. The solid wall was made from a ceramic tube 100 mm in length, which was placed downstream the ring. The tube was removable and was not water cooled. The ceramic wall protected surrounding of the plasma jet from air entrance altering surrounding atmosphere. The shielding system was centered with the respect to the exit nozzle. First, the feeding of the shroud gas was made through one tube entering to the distributing ring at its top (Fig. 2 a)). But this arrangement turned out to be unsatisfactory as it could not provide proper distribution of the shroud gas around the jet. As a result the flow rate of the shroud gas at the bottom part of the ring was higher than at the top part. To avoid improper distribution the ring was divided inside into three sections by partitions and shroud gas was supplied from three different sides (Fig. 2 b)).

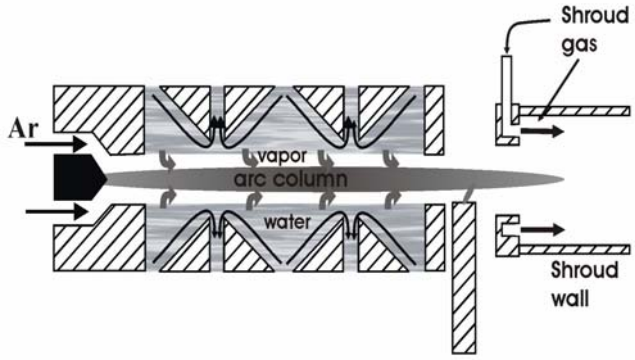

Figure 1 Hybrid argon-water torch with the system for shielding

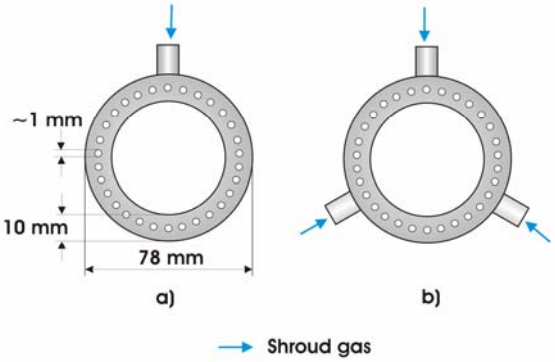

Figure 2 The ring for gas shroud distribution: a) one gas entrance; b) three gas entrances

The choice of the shroud gases was dictated not only by necessity to reduce oxygen content entrained from the surrounding, but also by plasma gas contained oxygen from the products of dissociation and ionization of water. Several gases were applied. First, effect of nonreactive argon was studied. Further, argon was replaced with reactive acetylene, methane, and safety mixture of hydrogen with nitrogen (5% of H_2). The problem with gas distribution appeared when pure acetylene was used as shroud gas. At the temperatures about 400 °C the pyrolysis of acetylene starts. As the ring was not cooled its temperature rose fast during acetylene combustion. The carbon precipitated inside the ring blocking the holes. To avoid this effect acetylene was mixed with nitrogen.

Measurements of the plasma jet characteristics were done with the help of the enthalpy probe system connected to the mass spectrometer. Enthalpy probe allowed to measure plasma jet temperature and velocity while mass spectrometer was used to determine plasma composition. The plasma torch was moved in horizontal and vertical direction allowing a scanning of free jet in axial and radial directions with the step of 5 mm.

All present measurements were done under atmospheric pressure conditions. In all experiments argon flow rate was 17.5 slm and arc current was 300 A. Arc voltage under these conditions was about 250 V, which corresponded to arc power of 75 kW. Such a high arc power resulted in high heat fluxes in the plasma jet in spite of strong air entrainment and it was impossible to make measurements in the regions close to the nozzle because of the permissible level of heat flux, which could be sustained by enthalpy probe tip. The enthalpy probe scanned

the jet at the distance of 200 mm from the exit nozzle, which corresponded to the 65 mm from the end of the ceramic wall.

The freezer was inserted into the gas sample line of the enthalpy probe system to avoid entrance of water vapor into the system, which could damage it. As enthalpy probe evaluate gas characteristics based on the measured gas composition, the recalculation of all measured characteristics should be done due to the fault determination of the gas composition. But present measurements were done at the distance of 200 mm from the exit nozzle. At such a distance plasma jet represents mostly heated ambient gas rather than plasma forming gas because of the strong entrainment. The amount of plasma forming medium drops here to about 5%. Under these condition the error caused by water vapor, which was not taken into account, was negligible and measured values supposed to be equal to real values of the jet characteristics.

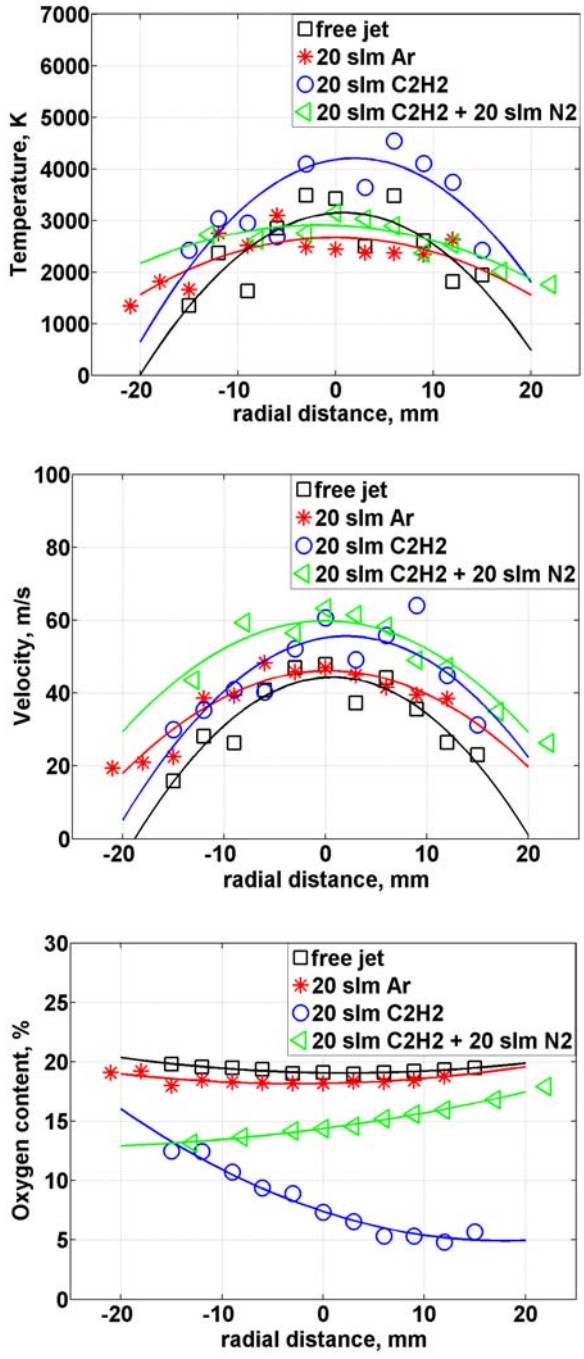

Figure 3 Properties of the plasma jet at the distance 200 mm without shroud gas and with argon and acetylene shrouding (shrouding with the ceramic tube)

3. Results and discussion

The plasma jet generated by hybrid argon-water torch is characterized by an intensive interaction with surrounding atmosphere and air entrainment [6]. The effect of the shroud gas was studied for two cases – with and without ceramic wall. Figure 3 represents properties of the plasma jet then solid wall was applied, while in the Figures 4 and 5 there are results then ceramic tube was removed.

Temperature, velocity and oxygen content in the jet are shown for free jet, when no shroud gas was applied, and for the cases of shrouding by argon and acetylene and its mixture with nitrogen. The oxygen percentage in the free jet shows that the jet consisted mostly of the heated air. The zero point on the x axis corresponds to centerline of the jet, which is usually shifted with respect to plasma torch axis because of interaction of the main plasma flow with an anode jet [7].

The results showed just small effect of the argon shrouding on the properties of the plasma jet. The profiles of the plasma jet characteristics shows that the shroud gas improved free stream region as plasma jet became wider without strong gradients at the jet fringes. Temperature of the jet went down slightly because of the influence of cold argon consuming a part of energy from the jet for its heating. The velocity of the jet remained unchanged. Concentration of oxygen decreased just a little. Further increasing of the argon flow rate up to 120 slm resulted just in minor changes of oxygen content in the jet center accompanied by minor

temperature reduction. These results indicate that air entrainment is most intensive in the part of the jet close to the nozzle exit, which was not protected by the gas shielding while in the region, where shroud gas acted, entrainment rates already slowed down.

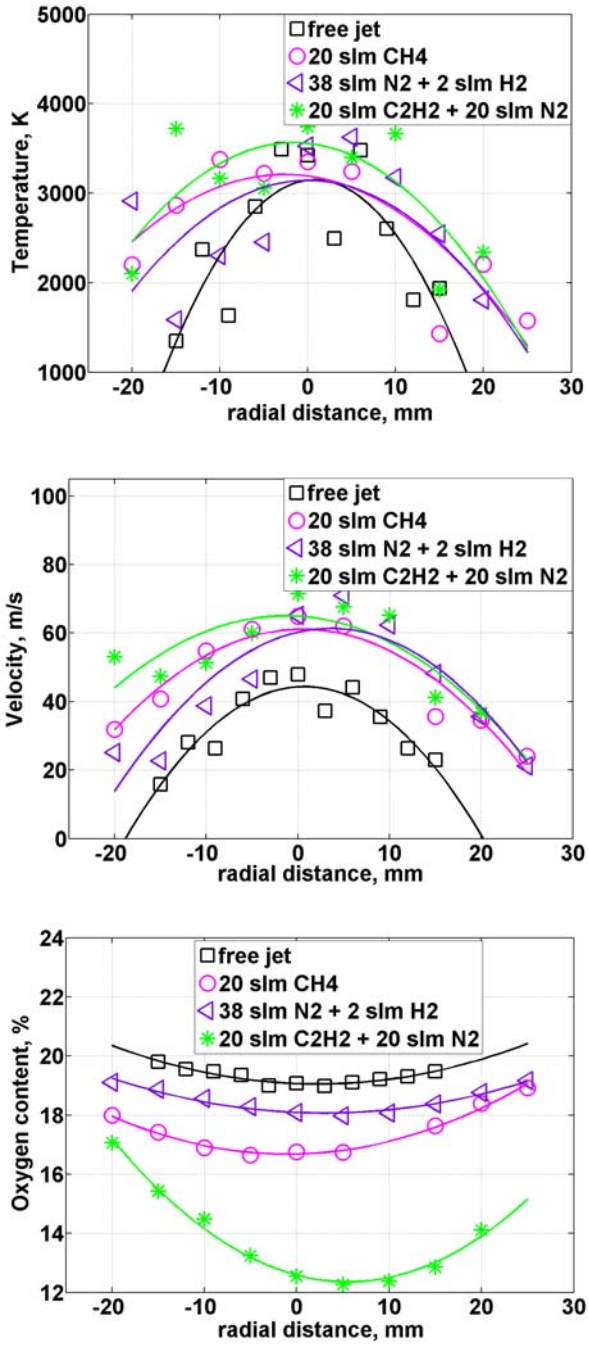

Figure 4 Properties of the plasma jet at the distance z = 200 mm without shroud gas and with CH_4, N_2/H_2 and C_2H_2/N_2 shrouding (shrouding without the ceramic tube)

Argon shroud gas was replaced by reactive acetylene. The acetylene reacts very intensively with the oxygen already at the temperatures near 300 °C. A reaction of acetylene with oxygen results in the formation of carbon oxides. Moreover, the injection of acetylene introduces a further energy source as the combustion heat of 58.6 MJ/m3 will be released. The results showed strong changes of the plasma jet characteristics when acetylene was applied. Oxygen content was reduced when acetylene flow rate was increased and already 20 slm of acetylene allowed reducing oxygen content to values about 5 % at the jet centerline. Temperature and velocity of the jet increased. This effect was caused by a reaction of oxygen with acetylene accompanied by heat evolution. Consequently, the high-temperature high-velocity region was extended significantly. This is expected to provide better particle heating and acceleration with less particles oxidation, and thus improving spraying process efficiency and deposition quality. The shifted profile of the oxygen content was caused by nonuniform distribution of the shroud gas due to the holes, which became cluttered because of acetylene pyrolysis.

Mixing of acetylene with the same amount of nitrogen resulted in better distribution of the shroud gas around the jet. As nitrogen is diatomic gas it consumed energy from the plasma flow for the dissociation. Thus, adding of nitrogen caused reduction of temperature. Moreover, higher total shroud gas flow rate resulted in a higher discharge velocity of the shroud gas through the holes. This could affect process of acetylene combustion. On the other hand, higher shroud gas flow rate led to smaller velocity gradients at the jet fringes, which in turn reduced process of the plasma jet deceleration caused by entrainment. Thus, plasma jet velocity was increased.

In the Figure 4 there are results of the experiments when ceramic tube was removed and only the effect of the shroud gas was studied. In addition to mixture of acetylene with nitrogen, methane and the mixture of nitrogen with hydrogen were examined. Methane is also combustible, but is more stable and its pyrolysis starts at much higher temperatures, which allowed us to use it without addition of other gases. Like acetylene, methane is also a source of heat as its combustion is accompanied by release of 37 MJ/m^3

of heat. In the reaction of combustion one molecule of methane binds 2 molecules of O2, whereas molecule of acetylene 2.5. In spite of this, methane is preferable as a shroud gas since it is better to store and to handle. Beside these, a safety mixture of hydrogen with nitrogen was examined in the experiments – 5 % of H_2.

Similarly as in case of the ceramic tube, shroud gas apply resulted in the flattening of the plasma jet characteristics for all shroud gases. Using of the H_2/N_2 mixture led to increasing of the temperature at the plasma jet fringes, while centerline temperature was unchanged. Temperature of the jet was a little higher when acetylene and methane were used because of the released heat of combustion. Velocity increased for all shroud gases, the centerline velocity increased by almost 30 % from 45 m/s to near 60 m/s. The results show that H_2/N_2 shrouding only replaces air from the ambient atmosphere and thus reduces available oxygen to be entrained from the surrounding. Hydrogen binds oxygen atoms but its amount is too small to provide proper oxygen elimination. Acetylene and methane not only replace air but also consume significant amount of oxygen in

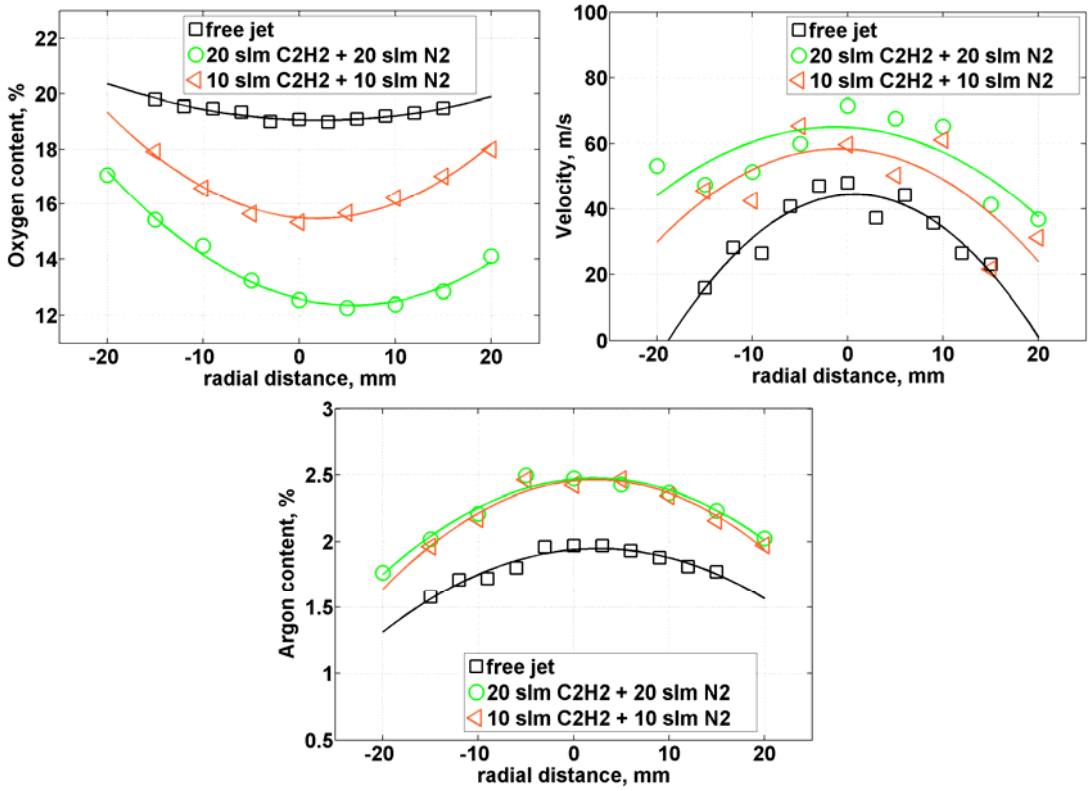

Figure 5 Effect of the shroud gas flow rate on the properties of the plasma jet at the distance z = 200 mm without the ceramic tube

process of combustion. Acetylene shrouding provided the best results of oxygen reduction together with improvement of the plasma jet characteristics.

The effect of acetylene flow rate is illustrated in Figure 5. Acetylene flow rate was set to the values of 10 and 20 slm. Acetylene was mixed with the same amount of nitrogen to get 50 % mixture. Oxygen content decreased for higher flow rates of the shroud gas, while velocity increased. The argon content reflects amount of plasma in the plasma jet. The plasma content increased when C_2H_2/N_2 shrouding was used, but it was almost independent on shroud gas flow rate. Increasing of the shroud gas flow rate had no effect on the center of the jet and had only negligible effect on the plasma jet fringes. The results confirmed that the entrainment process was slowed down when C_2H_2/N_2 mixture was supplied what would be the consequence of two factors. As the shroud gas discharges from the holes its starts to react intensively with air. Reaction of the acetylene with oxygen is

accompanied by heat release, which results in heating of the plasma jet surrounding. Thus, air bubbles getting into the plasma jet in the process of the entrainment [8] and cooling and slowing down the jet have lower density and could travel quicker in the plasma jet in comparison with cold air bubbles. The process of the plasma jet velocity reduction slows down. Moreover, in contrast to stagnant air surrounding, shroud gas moves concurrently with the plasma jet reducing velocity gradients at the jet fringes and slowing down the process of the bubble formation.

4. Conclusions

The effect of the shroud gas was studied on the plasma jets generated by hybrid DC torch with water-argon stabilization of arc. The shroud gas was distributed around the jet with the help of the ring with holes. Different reactive and nonreactive gases were used for shrouding – pure argon, acetylene, and methane and mixtures of nitrogen with acetylene and hydrogen. The ceramic tube was also tested to improve shielding of the jet as it protected plasma jet surrounded from the air entrance.

The study showed that entrainment of the surrounding air into the jet is significant even with shrouding. The highest entertainment rates are at the regions close to the exit nozzle, where high velocity plasma flow enters to the stagnant ambient air. That is why protection of this part of the jet is a question of great.

All shroud gases used in experiments affected plasma jet making the profiles of the jet characteristics flattened with higher temperatures and velocities and reduced amount of oxygen. Ar and H_2/N_2 shrouding only replace air from the jet surrounding, while CH_4 and C_2H_2 shrouding remove oxygen in the process of combustion as well. Moreover, both acetylene and methane are a source of extra heating as a large amount of heat release during combustion, which would provide better particle heating. Acetylene improved plasma jet characteristics most of all used shroud gases but difficulties connected with handle this unstable gas force to replace it with more stable methane which would be the best shielding gas from the tested in present experiments.

Experimental investigation of industrial ashing equipment

C. Hayden

Plasma Research Laboratory, School of Physics, Dublin City University, Ireland
Email: Chanel.Hayden@dcu.ie

Abstract
An experimental investigation was carried out on industrial ashing equipment by means of mass spectrometry and optical emission spectrometry (OES) diagnostic techniques. The tool under analysis comprises of an upstream Microwave-RF downstream configuration at an operating pressure of 850mT. The neutral species present in the discharge (N, O, NO, N_2O, NO_2) were analysed for a variety of physical conditions and compared with a simple kinetic model.
Keywords Radio-frequency (rf), ashing, photoresist, UV-VIS (ultraviolet-visible)

1. Introduction

O_2-N_2 plasmas are widely used in a number of industrial processes such as surface treatment [1], cleaning and polymer etching [2]. Microelectronic devices are manufactured by a sequence of processes in which layers of materials are grown or deposited then etched in a particular pattern, plasma ashing is one such process. Etching involves a chemical solution, which can sometimes leave a residue on the substrate affecting the performance of a device. Ashing is the process of removing photoresist residue from an etched wafer. This is accomplished by using a plasma source to create single atom reactive species that combine with photoresist to form 'ash', which is removed by the vacuum system. This procedure may also change the chemical character of the polymer in desirable ways such as improved adhesion properties. The reactor configuration can greatly affect the etch rate, for instance plasmas generated by microwave achieve faster polymer etching than rf sources [3]. A number of gas mixtures can be employed in this process, for example O_2 and N_2 or SF_6 and O_2, in this case O_2 and N_2 are used. The ashing tool consists of a downstream plasma configuration (see figure 1) in which plasma is formed remotely by a microwave plasma source and channelled to the wafer through a diffuser plate or showerhead. The wafer is placed on a heated radio-frequency (rf) chuck in the downstream region, which enhances ion bombardment on the surface. This type of arrangement allows electrically charged particles time to recombine before they reach the wafer surface and prevents damage to the substrate. The process gases are used in a specific proportion from which the microwave plasma source generates the monatomic reactive species. The reactive species recombine at different rates, leaving some active species available for processing the wafer. In this paper we will present a spectrometric analysis of an ashing discharge. We will also discuss a global model representation of this equipment.

2. Experimental

Figure 1 shows the experimental arrangement with one of the diagnostic connections in place. It consists of two plasma regions separated by a diffuser plate or showerhead. In the upper region, the working gas enters a plasma cavity where it is excited by a 1 kW microwave source operating at 2.45 GHz. This reaction area is separated from the main discharge by gas transport piping and a diffuser plate. The plasma is sustained by a continuous flow of 810 sccm O_2, 90 sccm N_2 at 850mT. The efflux from the microwave discharge flows though a showerhead into the downstream chamber containing the work-piece, which rests on a rf powered electrode. This rf chuck is heated to about 65˚C and operates at 13.56 MHz with a power of approximately 200 W. The work-piece is therefore exposed to energetic ions produced by the downstream capacitive discharge and a flux of radicals produced predominantly in the upstream source. The diagnostics are applied on the downstream chamber as access to the microwave region is very limited. In this experiment, a Pfeiffer QMS200 quadrupole mass-spectrometer was used to analyse relative concentrations of chemical species. As the mass-spectrometer is pressure sensitive with a maximum limit of 1e-4 mBar while the operating pressure of the tool under investigation is of the order of 1e-3 mBar, the set-up required the inclusion of a diaphragm. A number of apertures of varying diameters were tested to obtain an optimum signal. In this case, a 0.25 mm aperture yielded the strongest signal. It was placed between the outer chamber wall and a gate-valve

connecting the mass-spectrometer with the appropriate adaptors. The neutral species present in the discharge (N, O, NO, N_2O, NO_2) were analysed for a variety of physical conditions.

Optical Emission Spectrometry measurements were performed using a custom built optical fiber probe and feed-through with Ocean Optics HR2000 and USB2000 spectrometers. These spectrometers have ranges of 200-650 nm and 200-875 nm respectively, see Table 1. The optical fiber was a 400 μm solarisation-resistant material designed for measurements in the UV-VIS range of the spectrum. The probe was first enclosed in ceramic tubing so that only the tip was exposed before inserting into the plasma. A number of measurements were taken for a range of microwave and rf power settings as well as varying gas fractions.

3. Results

Experiments were performed to investigate the effects of gas pressure, microwave power, rf power, gas flow rate and gas composition on the plasma. Signals for a number of neutral species resulting from the O_2-N_2 discharge were analysed from mass-spectrometric data taken. Firstly, the gas fraction of O_2-N_2 was fixed at 810sccm O_2 and 90sccm N_2 for varying microwave power values from 750 to 2000W with rf power on (at 195W) and off. Figure 2 (a) and (b) show the variation in signal for O_2 and N_2 respectively at 850mT.

In figure 2(a), there is an almost linear decrease in ion current with increasing power for both rf on and off. When the rf power is extinguished the signal is greater, indicating a higher neutral density. Figure 2(b) shows very little change in signal with rf power off except at higher microwave powers.

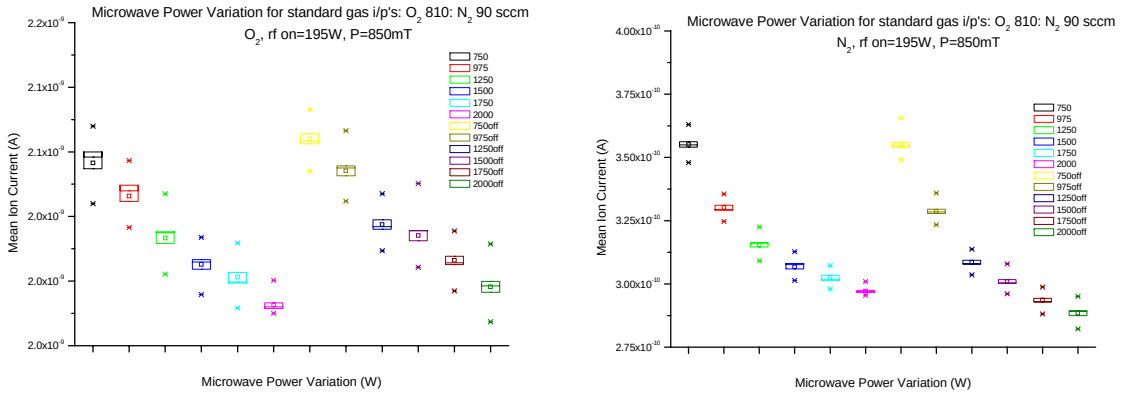

Figure 2. Mean variation in signal current with microwave power from 750-2000W, with rf on=195W, rf off=0W, pressure=850mT for (a) O_2 (b) N_2

Decreasing the pressure from 850mT to 700mT gave rise to reduced errors as shown figure 3(a) and an overall increase in signal current. Figure 3(b) displays the signal obtained for NO increasing with microwave power. The signal is greater when rf power is extinguished.

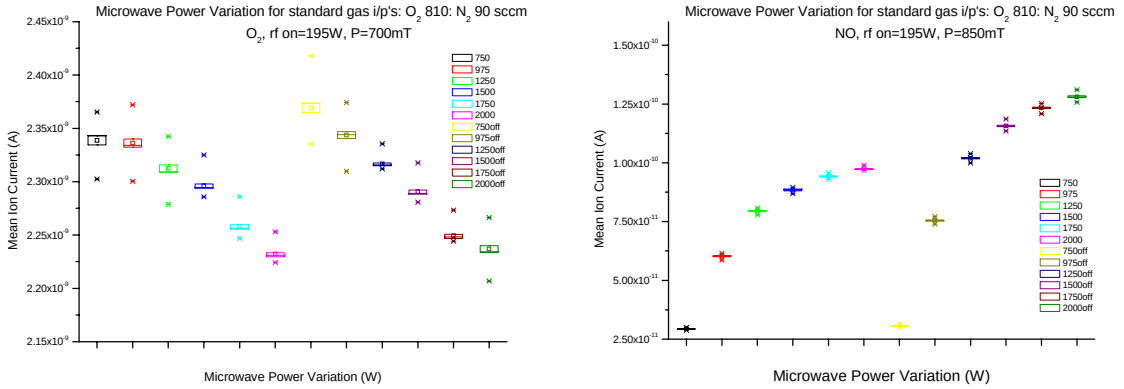

Figure 3(a) O_2 signal variation with microwave power for rf on and off at 750mT (b) NO at 850mT

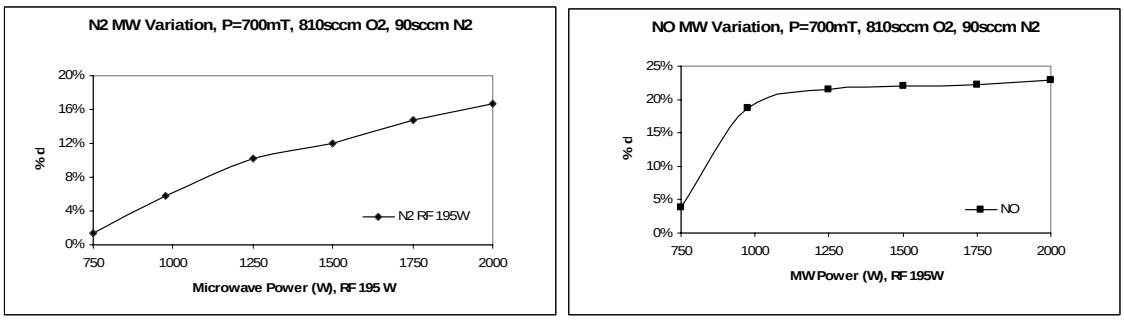

Figure 4. These graphs show the normalized percentage dissociation (%d) of (a) N2 and (b) NO for microwave power variation at 700mT with rf power fixed at 195W.

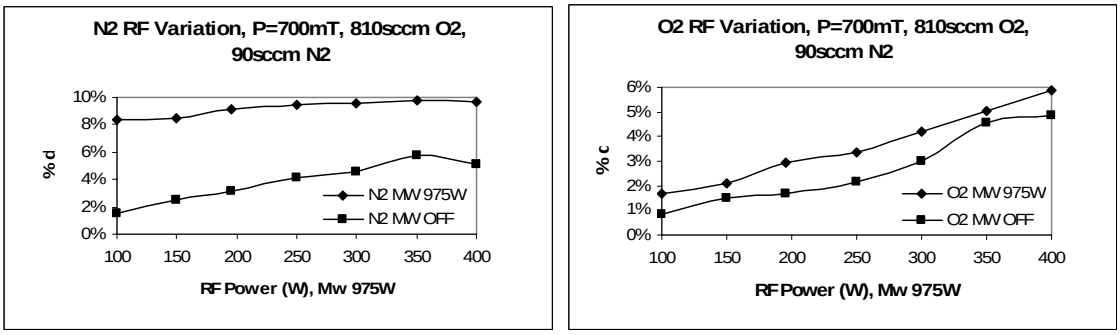

Figure 5. The plots above show the dissociation (%d) of (a) N2 and (b) O2 for changes in rf power values with microwave power off and at 975W.

With a fixed gas fraction of O_2-N_2 for varying microwave and rf power values, the corresponding dissociation degree was calculated. Low ion current signals for N_2O and NO_2 were observed for microwave power changes with a decrease in signal for both species when the rf source is extinguished.

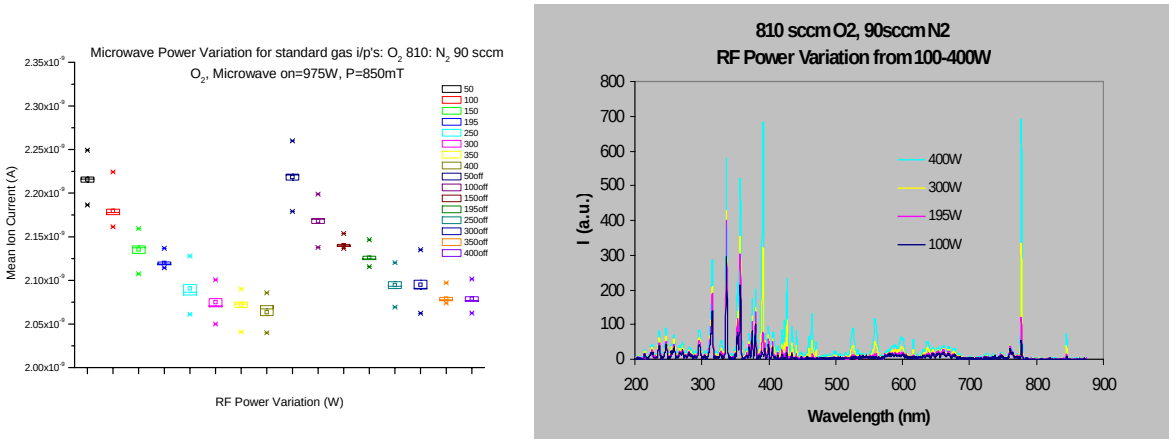

Figure 6. (a) RF power variation of O_2 current signal at 850mT from 50-400W and (b) Optical emission spectra of O_2 for variations in rf power from 100-400W.

Varying external parameters such as power, pressure and gas ratio, result in different excited states thus shifts in intensity and wavelength can be observed. Monatomic radicals increase in intensity as can be seen @777nm and 845nm, Molecular radical @761nm doesn't show changes in intensity for increasing power

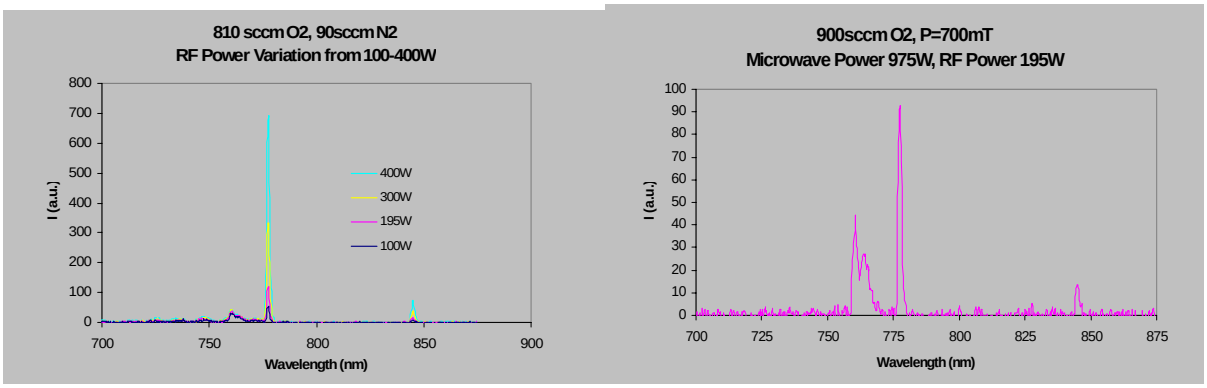

Figure 7. Optical emission spectra of (a) rf power variation from 100-400W for 810sccm O_2, 90sccm N_2 and (b) 900sccm O_2 at microwave 975W, rf 195W.

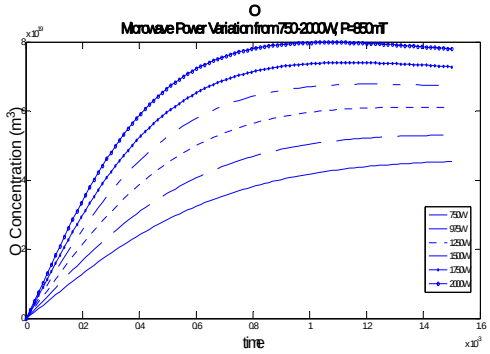
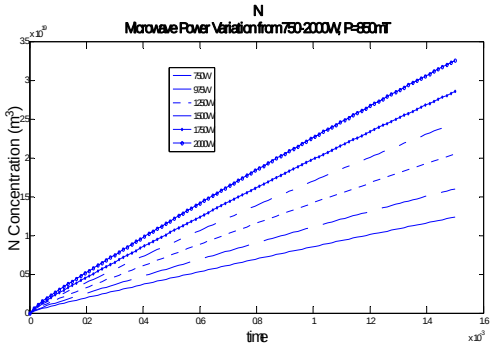
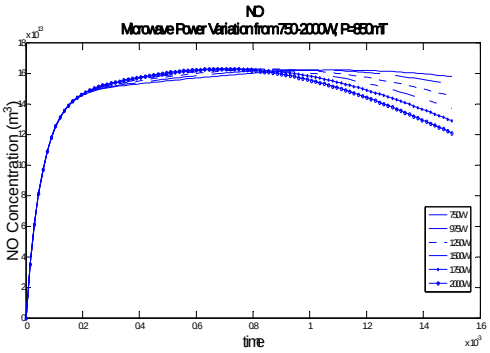
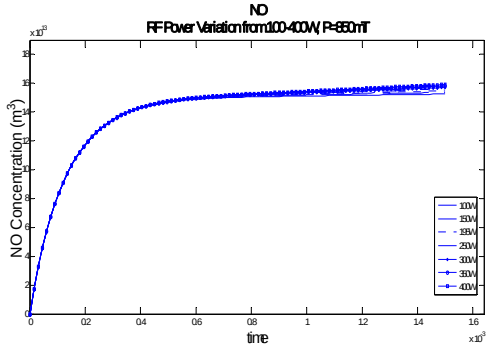
Global Model Solver - Predict spatially averaged quantities. Good: low computational cost, can have complex chemistry. Bad: limited accuracy, no spatial information. Electron power, gas flow-rates, chamber geometry, gas temperature and numerous chemistry sets are used to simulate the experiment.

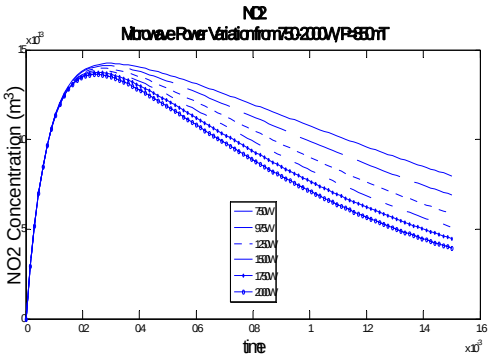








Changes in rf power have less affect on concentration of NO



NO2 reacts with O to form NO and O2

4. Conclusion

There is very limited space for applying diagnostics to a tool and so customisation is often required.
Ensure stability of mass-spec. The percentage dissociation for O_2 and N_2 increased with rising rf power however this percentage dropped when the microwave power was extinguished as shown in Figure 2 above. Ion current signals were higher for microwave off due to a greater volume of the neutral gas reaching the downstream region before being excited and dissociated into radicals. The concentration of NO and NO_2 was found to grow with increasing microwave power with N_2O decreasing. The results were compared with a simple kinetic model and some agreement was found.

Abstract

Paper presents results of experiments investigating possibility of synthetic fibres´ hydrophobicity improvement with the atmospheric dielectric barrier discharge. For experiments polyester (PES) fibres (fabric) were used. Experiments were performed in air under atmospheric pressure. There were studied relation between modification time, discharge power and hydrophobicity expressed by area of feathering and also modification effect aging .

Keywords: atmospheric dielectric barrier discharge, plasma modification, PES fabric, hydrofobicity

1. Introduction

At present synthetics and among them polyester are widely used in industry, but applied finishing methods are often confronted with strict environmental protection laws. These problems and pursuit of low cost production result in permanent search for alternative finishing and treatment methods. This single-minded effort is also continually paid to the polyester fibres characteristics improvement (because of the polyester low wettability, high hydrophobicity, low adhesion, high oil impurities cohesion and undesirable electric discharge generation) since begin of the polyester production.

The most reliable way to improve them seems to be the change of surface characteristics, adhesion and corresponding surface energy being those often used.

At present there is a large number of methods for fibers´ surface formation during manufacturing. Surface formation resulting in fibres higher wettability, higher adhesion and dyeability etc. can be performed e.g. by enzymatic hydrolysis, chemical grafting, laser application or low pressure and atmospheric pressure plasma application.

Plasma consists of many excited particles modifying the fibre surface. The effect of the surface plasma modification depends on properties of used gas, because of methane, ethylene, ethanol participation in the graftage, oxide, tetrafloromethane (CF4) and ammonia can be used for sloughing, or noble gases as helium, neon, argon etc. effectivity as admixtures for better chemical processes initialisation. Modification characteristics also depend on properties of the used working gas and the way of plasma generation. Atmospheric plasma seems to be the most suitable both from the economical perspective (low running cost in contrary with the low plasma processes) and from ecological point of view (it is a solvent free and dry process and it is characterized with extreme low chemicals consumption in contrary with chemical processes). One of ways to get the atmospheric plasma is the dielectric barrier discharge.

Manufacturing the composite of tyre cord PES fibres and styrene-butadiene rubber (SBR) matrix in car industry [1] was accompanied with problems connected with adhesion. Beside them fibres were also polluted with lubricants from preceding technological operations. Desired modification could be performed e.g. with classical chemicals application, but this method was unsuitable from ecological point of view. Further possibility was the plasma treatment. Combination of the clean up with acetone and atmospheric nitrogen plasma treatment led to improvement of adhesion of about 100%. The modification effect was sufficiently permanent in time.

Another example of nitrogen dielectric barrier discharge application was creation of hydrophilous surface for palladium catalyzer absorption simplification [2] in case of electroless nickel deposition, necessary treatment time in nitrogen plasma had been very short (1s).

To improve the deep coloring effect of polyethylene terephtalate fabric, anti reflective coating layers had been deposited on the surface of the fabric with two different organo-silicon compounds as HMDS, TTMSVS using atmospheric pressure plasma [3]. The best results of the deep coloring effect on PET fabric had been obtained from the HMDS polymerized film treated for 15 minutes and TTMSVS polymerized film

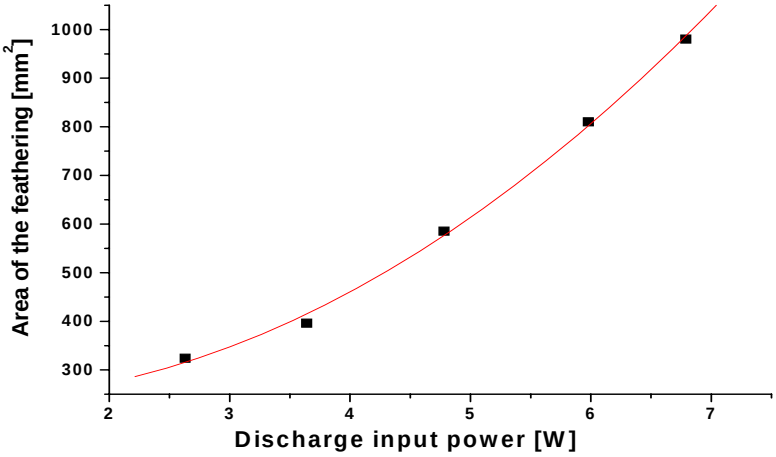

Fig. 1. Feathering area dependence on dielectric barrier discharge input power.

treated for 5 minutes. Sputter-etched PET fabric had also shown good coloring effect at atmospheric pressure of He/O_2 mixed gas.

Dielectric barrier discharge was also used on industrial scale for textile modification. New equipment for a two-meter-wide textile plasma activation is mentioned in [4]. Its efficient inlet system gave the opportunity to reduce the oxygen concentration in the plasma treatment chamber in continuous operation mode significantly, so that treatment could be performed in a defined process gas composition independent on the environment. Hydrophilic as well as hydrophobic and oleophobic modification on textiles could be performed on the same equipment by change of its parameters.

Technical textiles can be also effectively protected against water and oil penetration in a cost-effective dry dielectric barrier discharge-based continuous plasma process using Ar/FC_4 mixtures [5].

Plasma Ireland produces industrial equipments substantially improving bonding of PET textiles with polyurethane resin as measured by peel strength via grafting of polar groups [6].

In industrial praxis it is sufficient if modification effect time duration is limited to a shorter time period, when special procedures, e.g. dying, would be performed. Therefore there is no need for search of methods leading to permanent modification effect so that we consider the modification effect reduction after some days as unimportant in praxis.

This contribution supplements preceding works reporting results of polyester fabric modification by atmospheric corona discharge [7] and by low-pressure radio-frequency and microwave discharges [8]. Our research focused on a systematic study of possibilities of the polyester fabric hydrophobicity control and modification efficiency in atmospheric dielectric barrier discharge. Experiments were performed in air, because of its attractive low cost, and there was studied connection between dielectric barrier discharge input power and polyester fabric's hydrophobicity and modification effectivity.

2. Experimental

For all experiments there were used specimens made from the polyester cloth with the trade name Tesil 12. Their cleaning consisted of following steps: specimen double washing in water solution of a proper washing agent, rinsing in running water, double washing in distilled water, chemical cleaning and drying before discharge application.

Dielectric barrier discharge was generated between two large plane iron electrodes, both with diameter 45 mm and 10 mm thick. One of them was grounded. The glass barrier was created with a (83×83) mm, 2 mm thick glass table stuck to the other electrode. The interelectrode distance was fixed at 10 mm. The electrodes were put into open cylindrical vessel (diameter 153 mm, height 146 mm). Textile specimens were placed right on the grounded large plane electrode during modification. All experiments were performed in stationary air under atmospheric pressure $(743 \div 754)$ torr and room temperature $(20 \div 22)°C$. A.C. voltage $(6{,}8 \div 10{,}4)$ kV was applied to the electrodes, typical discharge current values were hundreds of μA. Modification time was $(30 \div 600)$ seconds.

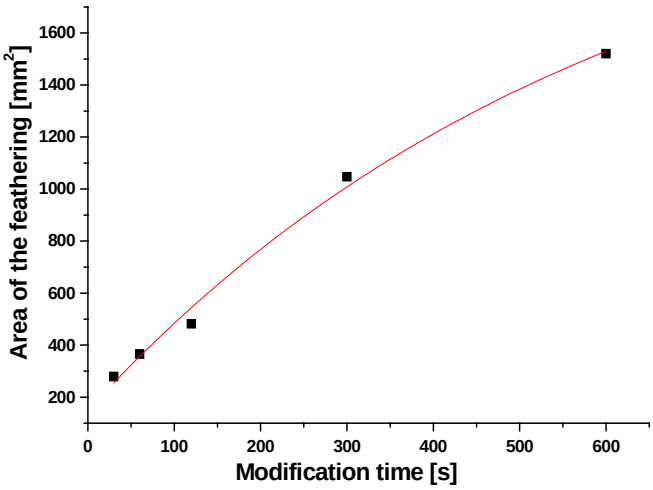

Fig. 2. Feathering area dependence on modification time.

Modification efficiency was compared by means of hydrophobicity, which was evaluated by the drop test [9], 20 µl of distilled water being the test liquid. Relevant feathering spot size was recorded with a ccd camera, the area of the spot in the 60th second after start of the test was used as the standard for the evaluation. The experiment was stopped if the drop did not soak into the fabric after 10 minutes from the start.

Results and discussion

Feathering area grew in proportion both to the atmospheric dielectric barrier discharge input power and modification time. More effective modification expressed by the treated fabric area changes could be achieved by the discharge input power rise (Fig. 1). For in experiment used input power values the feathering area-time dependence seemed to be sharply rising, hence small change of input power resulted in greater change of the hydrophobicity. Reached modification efficiency maximum corresponded to the input power of 6,8 W. Unfortunately, we did not probably reach potential modification efficiency maximum, when treated fabric surface would be fully saturated with active particles. This reality caused by disposable power supply properties seemed to be confirmed with feathering area–modification time characteristic (Fig. 2), too.

Experiments showed that the fabric modified with dielectric barrier discharge had an increased sorption. The modification effectivity (i.e. effect permanency) had changed in time, during first 24 hours the feathering spot size and hence also modification effectivity had sharply diminished (Figs. 3, 4). The curve shape changes might be connected with the modification degree of the fabric, i.e. the efficiency drop might be connected with the transformation of created hydrophilous function groups on the surface of fabric. Transformation might be caused by chemical reactions of created hydrophilous function surface groups with air components. Dipoles orientation might also changed backwards in time coming into the primary orientation. Five days after modification there was measured no important difference in hydrophobicity of modified and unmodified specimens. Modified fibres were stocked in air at atmospheric pressure.

Comparison with results of similar experiments performed with an atmospheric corona discharge [7] indicate that modification by atmospheric dielectric barrier discharge might be more appropriate tool for the polyester fabric modification than the atmospheric corona discharge.

Conclusions

1) Atmospheric dielectric barrier discharge modification effect grew with both the discharge input power and modification time duration rise. It seems, that its potential modification efficiency maximum, when treated fabric surface would be fully saturated with active particles, was not reached during our experiments.
2) The modification effect had sharply diminished in time. Study of the polyester fabric RF

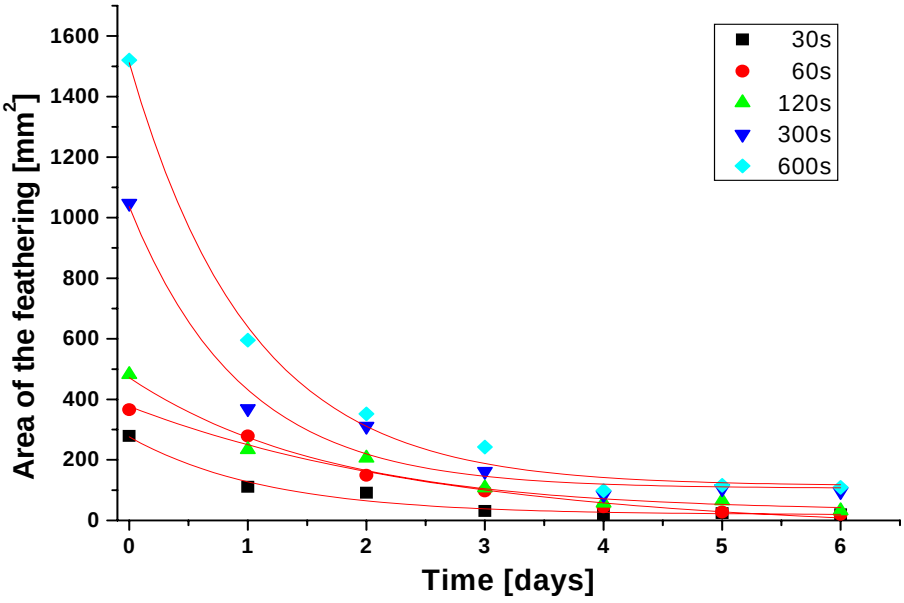

Fig. 3. Air barrier discharge plasma polyester fabric modification effect aging expressed in the feathering spot size time changes for different modification times.

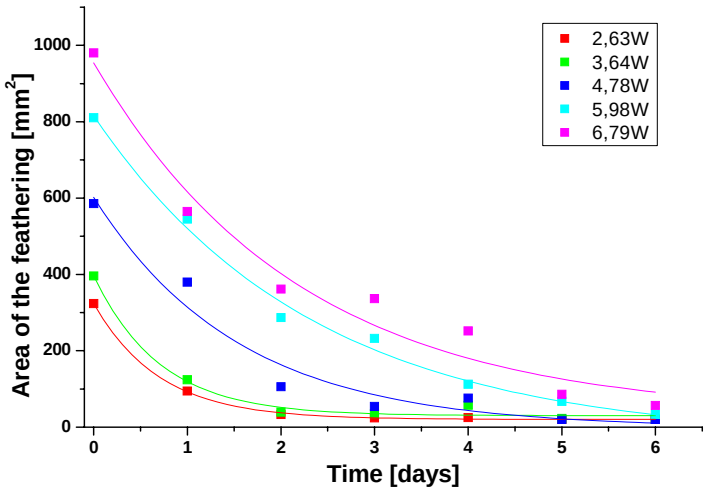

Fig. 4. Air barrier discharge plasma polyester fabric modification effect aging expressed in the feathering spot size time changes for different discharge input power

3) atmospheric dielectric barrier discharge modification effect aging expressed in the feathering spot size time changes indicated that the modification effect evidently lasted for about 48 hours, and then became extinct. 5 days after modification there was measured no important difference in hydrophobicity of modified and unmodified specimens.
4) Modification with atmospheric dielectric barrier discharge might be more appropriate tool for the PES fabric modification than the atmospheric corona discharge [7].

Theoretical Analysis of In-Flight and After-Impact Particle Chemistry in Plasma Spraying

D. Kolman[1], K. Volenik[2]

[1] *Dept. Mechanical Engineering, Czech Technical University, Prague, Czech Republic*

[2] *Institute of Plasma Physics, Czech Academy of Sciences, Prague, Czech Republic*

This paper describes a comprehensive model for the simulation of the interaction of a multi-species particle with its surrounding gas phase. The interactions modeled include heat and mass transport from/to the particle and the corresponding transports inside the particle. Furthermore, chemically limited processes at the particle surface, and phase changes and stoichiometric constrains inside the particle are considered. The model is applied to iron and steel in-flight and after-impact oxidation, and the results are compared to experiments.

Keywords: Modeling, Plasma Spraying, Oxidation, Iron, Chromium

1. Introduction

Chemical changes accompanying inevitably heating, melting, impingement and solidification of particles during plasma spraying are a serious although frequently unsolicited phenomenon. In case of metals, oxidation and reduction changes are of greatest importance. In any case, an understanding and a subsequent control of these changes are of vital interest to both academia and industry.

The rate of any reaction between the particle and the gas phase species is determined by an interplay of several processes - reactant and/or product diffusion through the particle gas phase boundary layer; surface reactions; reactant and/or product diffusion through the altered subsurface layer; and reaction at the interface between the already altered layer and the bulk. Each of these processes may be rate limiting and all have to be considered simultaneously. Individual process rates are quite temperature sensitive, thus the extent of the transformation has to be traced from particle introduction into the plasma up to its impact at the substrate. Furthermore, spatial and temporal oscillation of the plasma background pose a question whether we study of "typical" particle or particle ensemble. This contribution studies changes of a *typical* particle, both *in-flight* and *after-impact* at a substrate. Some of the mathematical details of the model may be found in [1].

2. Components of the analysis

The system that is being modeled consists of a spherically symmetric particle together with its adjacent gas-phase boundary layer. For the description of the species transport across the boundary layer species continuity equation in terms of mole fractions is utilized. It has be shown numerically that the pressure equilibration time is much smaller that other time scales, thus convection trough the boundary layer has not to be considered. The energy transport is described by an analogous equation of conservation of energy written in terms of temperature. All equations include a temporal change of the respective quantities, a diffusion term and a source term due to homogeneous chemical reactions in the gas phase.

The passage from the gas-phase to the condensed phase and vice versa is described by surface chemical reactions and their kinetic rates. In general, additivity of the reactions with respect to both gas-phase and condensed species is assumed. Apart from the purely chemical processes, vaporization of the condensed species is also considered.

There exists always a layer under the surface of the particle that has already undergone some chemical modification – an altered zone. In the situation under consideration it is usually strictly distinguishable from the bulk material and thus these two zones are conveniently treated separately. Transport of chemical species in any of these two zones is given by a diffusion equation, energy transport by a heat conduction equation. Due to the fact that the relationship between temperature and enthalpy in the region of phase changes is not unique, the heat

transfer equation can not be expressed directly in terms of temperature and temperature is therefore computed from enthalpy separately using a more complicated relation.

At the interface between the altered zone and the bulk zone, infinite reaction rates are assumed and the composition of the altered zone is limited by stoichiometric considerations only.

Finally, the growth of the altered zone and particle size change are given by the sum of the appropriate surface reaction rates and vaporization rates, respectively.

3. Implementation details

1D unsteady species and energy conservation equations in all media are discretized both in space and time and a set of finite difference equations is formed. On a single time level, composition and gas-phase energy equations are solved implicitly with a tri-diagonal Gauss elimination, condensed phase energy equation is solved explicitly with a time sub-stepping. The extend of the altered zone is being traced, and, when appropriate, a new computation point is added. Thermodynamic and transport properties as well as chemical reaction rates are evaluated locally in each computational point and in each time step. A Unified Approximation for Mixture Transport Properties for Multicomponent Boundary Layer Applications is applied in the gas-phase [2].

It has been shown previously [1] that in case of metal oxidation there is no strong melt circulation on the surface of the particle that would keep removing the oxide from from the surface into the interior of the particle. On the other hand, impermeable oxide layer has lead to insufficient metal vaporization. Thus, the particle is assumed to be covered with the oxide, most of the time molten, but the metal vapor forming under the oxide layer is allowed to escape from the particle.

Finally, during the after-impact analysis, particle spreading is modeled by a particle macroscopic mechanical energy balance following [3].

4. In-flight and after-impact oxidation and vaporization of alloy particles

The model introduced above is applied to oxidation, vaporization, impact and spreading of metallic alloy particles, in particular to Fe-Cr particles in a water-stabilized plasma torch of the Institute of Plasma Physics in Prague [4]. In this case, both Fe and Cr form a range of oxides: FeO to Fe_3O_4 and Cr_2O_3 to Cr_3O_4. Data on surface reaction rates and diffusion rates for the temperature range under consideration are almost nonexistent and are mostly extrapolated and/or estimated from analogous problems. Metal vaporization rates are given by Langmuir equation, oxide vaporization is negligible. In general, Cr oxidation is at least an order of magnitude faster than Fe but diffusion in chromium oxide is more than an order of magnitude slower than in iron oxide. It should be noted that oxidation reactions are considered irreversible but metal vaporization is limited by the corresponding equilibrium vapor pressure.

After some minor optimization with respect to the in-flight experimental data, the following oxidation and vaporization rates were obtained:

Fe oxidation rates (mol/m²s)

2Fe(c)+O2=>2FeO(c)	$R = 3\cdot 10^4 \exp(-16000/T) C_i S_i$	[extracted from 5,6]
Fe(c)+O=>FeO(c)	$R = 4\cdot 10^3 \exp(-10170/T) C_i S_i$	[est. by analogy with other metals 7,8]
Fe(c)+OH=>FeO(c)+H	$R = 4\cdot 10^3 \exp(-10170/T) C_i S_i$	[same activity as O]

where C_i is the concentration of the participating gas phase species, S_i is the fraction of the corresponding unbounded metal atoms at the oxide surface.

Cr oxidation rates (mol/m²s): order of magnitude faster that Fe

4/3Cr(c)+O2=>4/3$CrO_{3/2}$(c)	$R = 6\cdot 10^5 \exp(-16000/T) C_i S_i$
2/3Cr(c)+O=>2/3$CrO_{3/2}$(c)	$R = 8\cdot 10^4 \exp(-10170/T) C_i S_i$
2/3Cr(c)+OH=>2/3$CrO_{3/2}$(c)+H	$R = 8\cdot 10^4 \exp(-10170/T) C_i S_i$

Metal vaporization (mol/m²s): $V = \frac{p_i^{eq} X_i - p_i}{\sqrt{2\pi W_i RT}} = \frac{A_i \exp\left(-B_i/T\right) X_i - p_i}{\sqrt{2\pi W_i RT}}$

Fe(c) <=> Fe(g) $A_i = 1.30 \cdot 10^{11}$, $B_i = 43980$ [after 9]

Cr(c) <=> Cr(g) $A_i = 1.16 \cdot 10^{11}$, $B_i = 41190$ [after 9]

where p_i is the actual vapor pressure of the corresponding gas-phase species, X_i is the fraction of the corresponding metal atoms at the metal-oxide interface.

The second decisive factor in the oxidation process are the diffusion rates of the ions inside the condensed material:

First, the allowed ranges of oxides formed have been determined to be:

FeO to Fe_3O_4 i.e. $Fe_{1+a}O_{4/3}$, $a \leq 1/3$

Cr_2O_3 to Cr_3O_4 i.e. $Cr_{1+b}O_{3/2}$, $b \leq 1/8$

Next, the diffusion coefficients have been determined (m²/s):

Fe↔O in solid FeO $D = 1.18 \cdot 10^{-6} \exp(-14954/T)$ [10]

Fe↔O in molten FeO $D = 1.50 \cdot 10^{-3} \exp(-14954/T)$ [11]

Cr↔O in solid Cr_2O_3 $D = 1.37 \cdot 10^{-5} \exp(-30500/T)$ [10]

Cr↔O in molten Cr_2O_3 $D = 5.30 \cdot 10^{-6} \exp(-15400/T)$ [est.]

Finally, adjustable multipliers have been introduce to make diffusion in “foreign” oxide more difficult,

Fe in $CrO_{3/2}$ d = 0.05

Cr in FeO d = 1.00

The particles under consideration are either pure iron or steel AISI 410 with 13 wt% chromium. The particle SMD is 120 μm. Typical in-flight residency time is about 10 ms, and the gas composition is assumed for simplicity to be composed of 50% air + 50% water vapor. The particle experiences gas-phase temperatures between 500 K and 3500 K depending on its particular trajectory (determined within the computation).

After impact, in the time range considered, the particle cools slightly bellow its solidification temperature. Typical time for which the splat surface is exposed to the ambient atmosphere before it is covered by another impacting particle is estimated from the mass load, the target size and the spraying deposition efficiency, and is found to be about 20 ms.

5. Results and discussion

This section presents results concerning the influence of alloy composition, and both time development and integrated results are shown. First, simulation results for in-flight oxidation are given.

Figure 1. depicts the temporal development of the boundary layer temperature that the particle feels, particle surface (oxide) temperature, volume of iron oxide and volume of chromium oxide as they are recorded during the flight in case of steel particles. Similarly, Figure 2. shows the same quantities for pure iron particles.

When we compare the two above cases it is seen that the temperature situation does not differ much: The increasing temperature of the surrounding leads to a corresponding increase in the oxide temperature - the little kink around 3 ms is the release of the latent heat of melting. At after about 2/3 of the flight time, the particle accumulates enough heat and starts to be cooled by the relatively cold gas in the tail of the jet.

The oxidation situation, on the other hand, is quite different: The take-off of the oxidation is slightly delayed to about ½ of the flight time in case of the chromium steel, then a strong chromium oxidation takes place with iron oxidation volume lagging significantly behind, and, eventually, chromium oxidation and iron oxidation rates become smaller and almost identical. In case of pure iron, oxidation starts little earlier and more gradually already in the solid phase but after the zenith in the temperature, the oxidation rate decreases too.

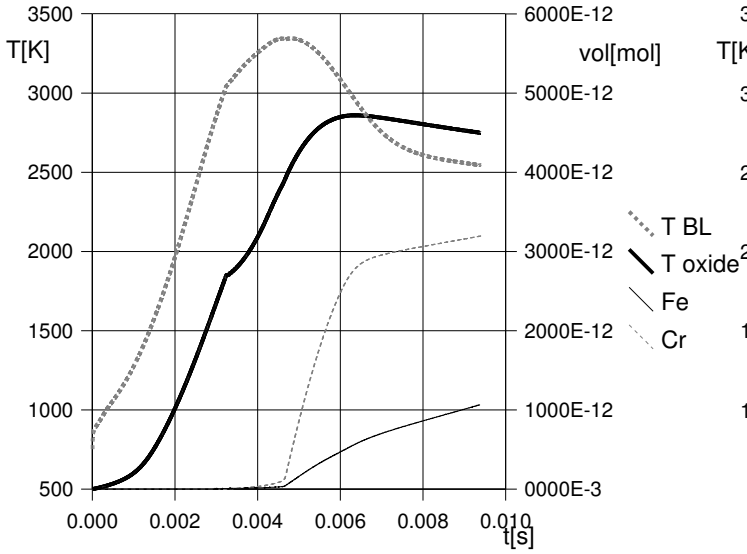

Figure 1. In-flight development of boundary layer temperature, oxide temperature, and FeO and $CrO_{3/2,}$ molar volumes, steel 13 wt% Cr.

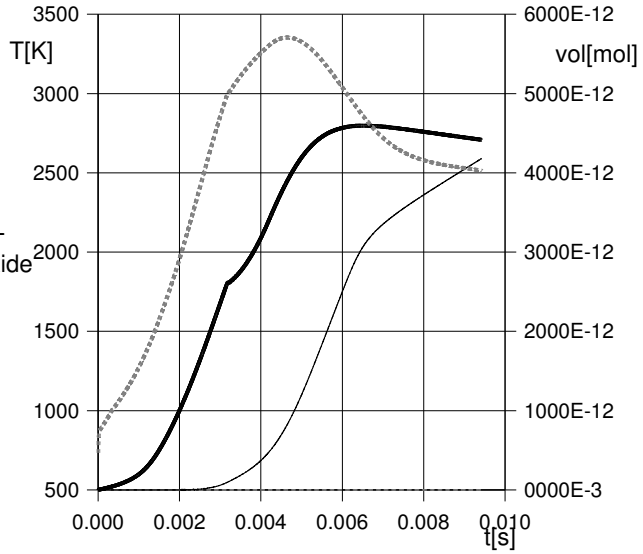

Figure 2. In-flight development of boundary layer temperature, oxide temperature and FeO molar volume, pure iron.

The corresponding results for the situation after impact are shown in Figure 3. Here, only oxide volumes are shown, one curve corresponds to the temporal development of the iron oxide in case of oxidation of pure iron, and the other two curves represent the iron and chromium oxide volumes in case of 13 wt% steel. Here, the oxidation in case of pure iron is much higher than in case of the chromium steel, and in both cases is almost linear in time as the particle surface and its temperature do not change (after first few milliseconds) in time. In both cases, this is oxidation bellow the particle melting temperatures for most of the exposure time.

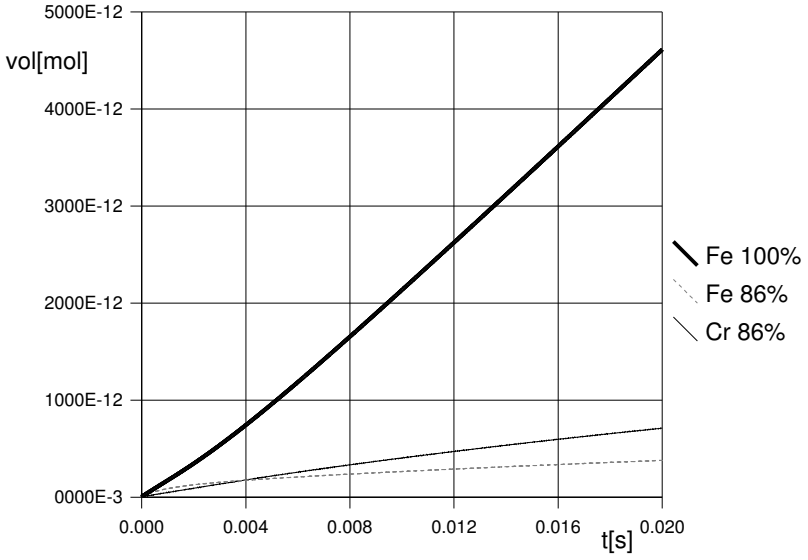

Figure 3. After-impact development of FeO and $CrO_{3/2}$ molar volumes, pure iron and steel 13 wt% Cr (14 vol%).

6. Comparison with experimental data

After some tuning of the kinetic parameters, the trends agree well with experimental data, namely the chromium content, trends in the overall oxidation extent and the dependence on whether it is in-flight or after-impact oxidation. The results are summarized and compared with experimental data in Figures 4 and 5. (The minor difference in the initial chromium content is accidental).

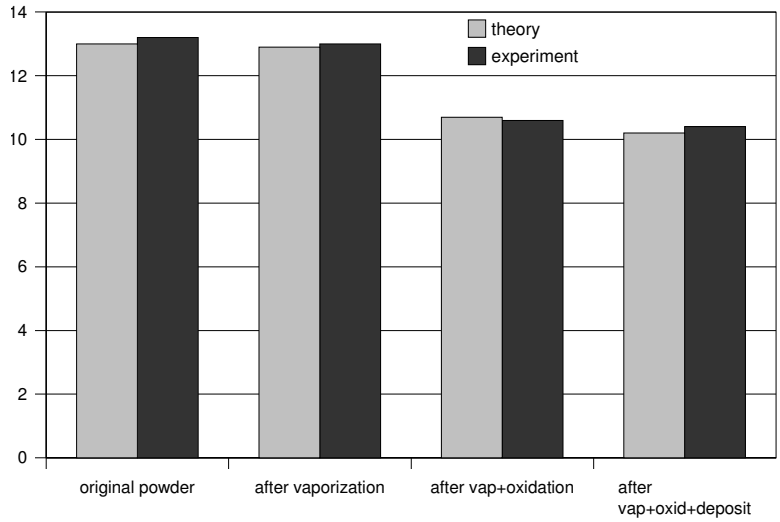

Figure 4. Chromium content [wt %] in steel 13 wt% Cr at various stages of processing - comparison of theory with experiments. Note that „after vaporization“ represents the in-flight content of the whole particle, „after vap+oxidation“ represents the in-flight content of the metal alloy only.

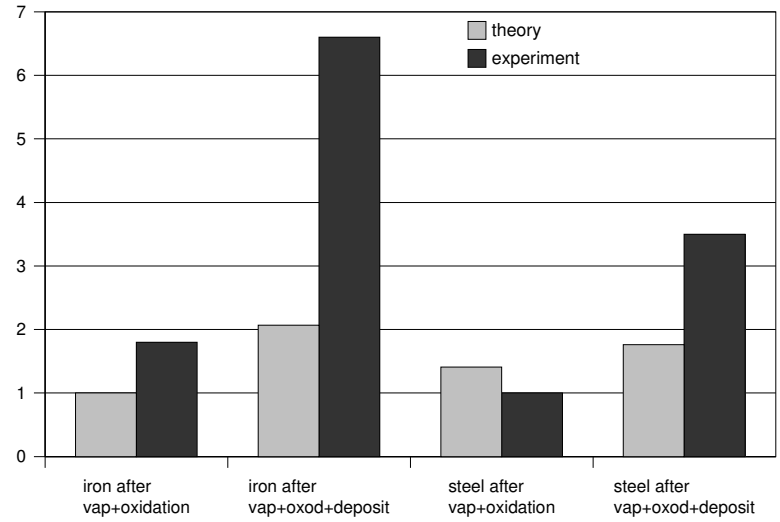

Figure 5. Oxygen content [wt %] in iron and steel 13 wt% Cr at various stages of processing - comparison of theory with experiments.

Figure 4 gives the experimental and simulated values of chromium weight content in the material at various stages of its processing. Thus, this figure tells us whether the composition results obtained are correct. Figure 5, on the other hand, provides similar data for oxygen content found in the material and serves thus as an indicator of the correctness of the overall oxidation extent.

In case of after-impact oxidation, the oxidation extent is visibly underestimated. The only plausible explanation to it is an underestimate of the splat surface area (experiments show mostly splashing whereas simulation considered an orderly splat). The lower oxidation rate after impact in case of steel reflects well with the

overall character of chromium steels, i.e. the chromium is added into it exactly for the purpose of reducing oxidation under standard conditions.

7. Summary and conclusions

In this work, the latest development on a comprehensive model for theoretical analysis of in-flight and after-impact chemistry is reported. The model includes a finite difference simulation of the heat and mass transport through different phases involved in the process, and is particularly suitable for the studies of oxidation/reduction of alloy particles. This is demonstrated on an analysis of the oxidation of pure iron and of the commercial steel AISI 410 under the water-stabilized plasma spraying conditions.

As the model is rather complex, its use requires an estimate of a range of kinetic parameters. A set of such parameters for the system Fe-Cr-O and the appropriate plasma gas environment (oxidation, vaporization and diffusion rates) has been developed and to a certain degree optimized, and has been presented above.

It may be said that the model and its kinetic parameters succeeded in reproducing the experimental observations, namely it gives the right proportion between iron and chromium oxidation. Also, as judged from the indirect evidence of the chromium content, the vaporization assumptions and rates seem to be correct (it is experimentally impossible to obtain direct vaporization data). The predicted values differ in the total oxidation extent after impact when being lower than the data obtained with the water-stabilized plasma system of the Institute of Plasma Physics in Prague. This discrepancy may be rectified by a better representation of the splat surface area considering splashing of the deposited material.

Abstract

In order to improve the fire retardancy properties of the polyamide-6 (PA6), vinylphosphonic acid monomer (VPA) was graft-polymerized onto the PA6 using a low-pressure microwave plasma process. The property was achieved by creating covalent bonding between PA6 and the phosphorus polymer. The grafting and the polymerization processes were characterized by IR (ATR), the thermal stability by TGA and the fire retardancy performances by LOI and UL94 tests.

Keywords: Cold plasma; Vinylphosphonic acid; Fire retardancy; Polyamide.

1. Introduction

In the course of our studies aimed at making polyamide-6 fire retardant, several studies have been performed using cold remote plasma enhanced vapor deposition [1-4], or using cold plasma polymerization of a fluorinated acrylate [5,6].

This work is a part of an ongoing project to study the effectiveness of the plasma-induced graft polymerization (PIGP) procedure as a novel method to confer new and durable properties to synthetic polymers, without altering their bulk properties. With the PIGP procedure, an argon microwave (MW) plasma is used to induce, in one step, the grafting and the polymerization of acrylic, or vinylic monomers containing the functional groups needed to impart the desired properties. One advantage of PIGP procedure is that the polymerization occurs with structure retention of the monomer. Furthermore, the desired properties are obtained by creating covalent bonds between the substrate and the growing polymer on the surface leading to a durable effect.

In this study, the PIGP procedure is used to impart durable flame retardant properties to polyamide-6 (PA6) using functional monomers containing phosphorus, such as vinylphosphonic acid (VPA) (Fig.1). The argon microwave (MW) plasma is used to induce the polymerization of VPA according to the reaction presented in figure 2. The treated (PA6) were characterized by IR (ATR) spectroscopy and thermal analysis. The fire retardancy performances of the coated PA6 were evaluated using Underwriters Laboratories (UL 94) and limiting oxygen index (LOI) tests.

Monomer (VPA)

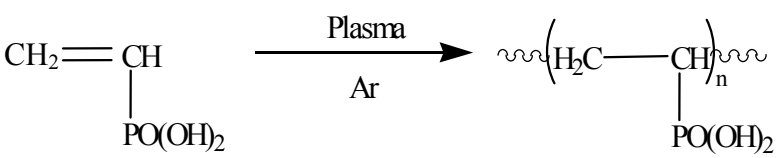

Fig. 2 : Reaction of plasma induced polymerization of VPA

2. Experimental

2.1. Materials

Polyamide 6 plates ($10\times10\times0.3$ cm^3) were prepared from pellets supplied by Radilon company using a darragon press at 260 °C under a pressure of 10^6 Pa. The monomer (VPA), the photo-initiator 2-hydroxy-2-methylpropiophenone (Darocur1173) and the solvents butanol-1 and ethanol were purchased from Aldrich Company and were used as received. Argon and Oxygen gases were obtained from Air Liquide Company.

2.2. Cold plasma process

The experimental set-up is described elsewhere [7,8]. An argon glow discharge was generated in an aluminum reactor chamber (27 l) at 2.45 GHz with a continuous out power ranging from 0 to 600 W. The chamber was pumped down to 10.7 Pa using a pump (E2M28 PEPE, Edwards), and the argon gas was introduced into the chamber at a certain flow rate. When the pressure becomes constant, the generator was switched on and adjusted to a certain power value, which gives rise to a continuous glow discharge.

2.3. Graft polymerization process

In the first step the polyamide plates were rinsed using ethanol and dried for 5h at 70 °C. Then after, they were pre-treated by an oxygen plasma (flow rate: 0.5 l/min; P = 100 W, t = 10 min) and subsequently a 6 µm film of VPA in Ethanol solution (200 g/l) in the presence of 3.5% by weight of the Darocur 1173 was applied onto the PA6 surface. In the next step, the samples were treated by Ar plasma (flow rate: 0.5 l/min; P = 250 W; t = 30 min). Finally, the treated plates were washed at room temperature with Ethanol for 24 h, in order to remove the residual monomer and dried at 70 °C.

2.4. Poly(vinylphosphonic acid) deposit characterization

The kinetic of the reaction of polymerization was followed by using ^{31}P NMR. The spectra were recorded using Brucker WP 300. The chemical shifts were expressed in ppm using H_3PO_4 (85%) as external reference. The deposits were characterized using FT-IR technique. The Infrared spectra were recorded using a Perkin-Elmer Spectrometer one, continuously variable-angle ATR accessory equipped with a diamond crystal.

Thermogravimetric (TG) analyses were performed using a Setaram apparatus from 20 to 800 °C at a heating rate of 10 °C/min under air flow (Air Liquide grade, 5×10^{-7} m^3/s measured in standard conditions). Samples in the powder form were placed in an open vitreous silica pans. Precision of temperature measurements was ±1.5 °C.

2.5 Fire retardancy performances of coated PA-6

The limiting oxygen index (LOI) test was measured according to the standard oxygen index test (ASTM D2863/77) [9] with a Stanton Redcroft instrument. This test provides a comparative numerical value for research and quality control. It is based on the determination of the limiting percentage of oxygen in a nitrogen oxygen mixture which will just sustain the candle-like burning of a sample. The UL 94 vertical burning test was measured according to ASTM D635-77 [10]. A burner flame is applied to the free end of the specimen for two 10 second intervals separated by the time it takes for flaming combustion to cease after the first application. Two sets of 5 specimens are tested. Different criteria are recorded for each specimen as indicated in table 1. The best flame retardancy rating of V-0 is achieved when the after-ignition burn time is less than 10s in each ignition and no drips are allowed.

3. Results and discussion

3.1. Kinetic study

The kinetic of the polymerization of VPA induced by an Ar plasma have been investigated by studying the influence of the power of the plasma as a function of time. The experiments were monitored by ^{31}P NMR spectroscopy.

For various treatment times, the ratio p = I_p (polymer) /(I_p(monomer)+I_p(polymer))

Where: I_p(polymer) is the intensity of NMR signal from phosphorus in polymer structure and I_p(monomer) is the intensity of NMR signal from phosphorus in the monomer form.

This ratio allows the conversion rate monomer to polymer p and the amount $1-p$ of remaining VPA monomer to be evaluated. Figure 3 shows the evolution of the remaining amount of VPA monomer versus time of treatment for different microwave powers. Four phases can be observed. In the first one (0 – 4 min) the rate of conversion of the monomer increases with MW power. This increase can be correlated to the increase of the concentration of radicals emanating from the Darocur decomposition. In the second phase, the monomer concentration remains quite stable. It is characterized by an increase of the deposit viscosity and by the formation of a superficial film. The third phase corresponds to a decrease in the kinetic of polymerization due to the fact that the diffusion of the active species through the film becomes the limiting factor. The last phase corresponds to the termination reactions.

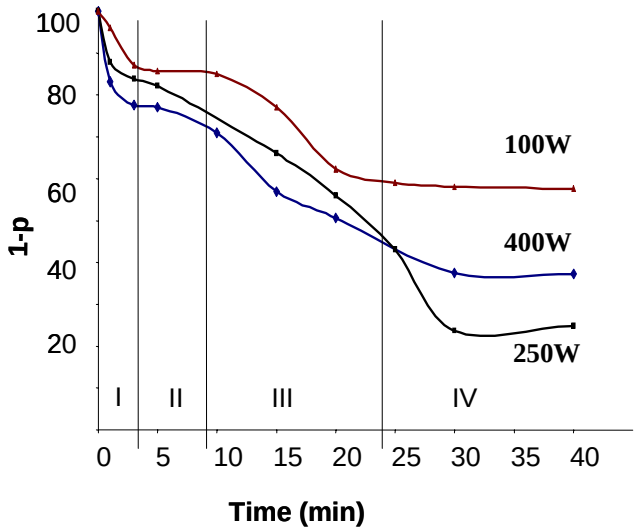

Figure 3: Kinetics of polymerization in an Ar MW plasma of VPA with 3.5% (w/w) Darocure (Ar flow rate=500 sccm; thickness film=6 µm).

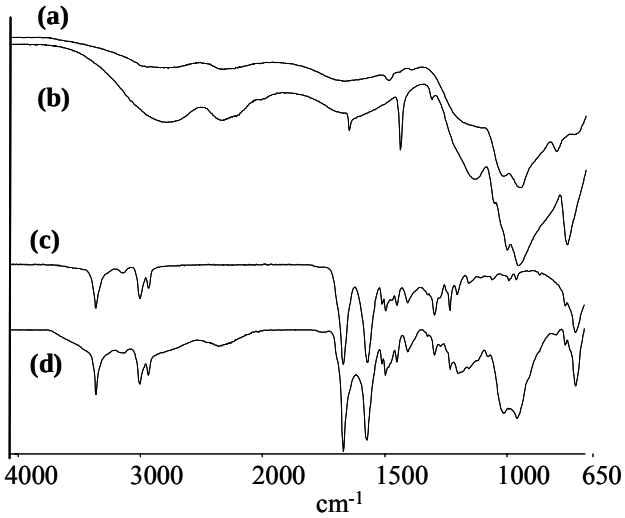

Figure 4: IR (ATR) spectra of VPA monomer (a), polyVPA (b); virgin PA(6) (c) and PA6-g-polyVPA (d).

3.2. Surface characterization

3.2.a. ATR-IR spectroscopy

Figure 4 shows the ATR-IR spectra of VPA monomer (a), polyVPA (b); virgin PA(6) (c) and the PA6-g-poly(VPA) (d), after washing with Ethanol for 24 hours. AVP spectrum shows the main characteristic bands at 727, 924 and 1103 cm^{-1} corresponding respectively to ν(P-C), ν(P-OH) and

ν(P=O). The two bands at 1405 and 1614 cm^{-1} are characteristic of the vinyl group (δCH_2= and νC=C). The polymerization induces logically the disappearance of these last bands as evidenced from the polyVPA spectrum. The PA6-g-polyVPA spectrum (d) compared to the virgin PA6 (c) shows the characteristic absorption bands at ν = 2286 cm^{-1}, ν = 1165 cm^{-1} and ν = 979 cm^{-1} corresponding to the νOH, ν(P=O) and ν_{as} P-O(H) respectively. However, the absorption bands characteristic for ν N-H (3296 cm^{-1}), ν_s and ν_{as}(C-H) (2864 and 2934 cm^{-1}), Amide (I) (νC=O) and Amide (II) (νC-N + δN-H) (1635 and 1540 cm^{-1}) of PA-6 are still visible which indicates that the depth of the deposited layer is lower than the analyzed depth (≈1µm).

3.2.b. Thermogravimetric analysis

Figure 5 shows TGA curves for virgin PA6 (a), PolyVPA (b) (polymerized under Ar Plasma, VPA in 1-Butanol solution (200 g/l) in the presence of 3.5% by weight of the Darocur 1173 (flow rate: 0.5 l/min; P = 250 W; t = 30 min)) and PA6-g-PolyVPA (c). Evidently, the orgnophosphorus layer reduces the thermal stability as indicated by a decrease in the onset temperature of degradation. The temperature for 10% mass loss $T_{10\%}$ decreased from 315 °C for virgin PA6 to 240 °C for PA6-g-PolyVPA. It can also be seen from Fig.5 that the orgonophosphorus coating has a strong effect on the char forming tendency. Whereas the virgin PA6 degrades completely upon heating to 600 °C, a thermally stable residue is formed at 600 °C of 20wt% for the PA6-g-PolyVPA. This residual weight increases up to 40 wt%, when the PA6-g-PolyVPA is treated with 0.5M aqueous solution of sodium hydroxide (NaOH), as presented in Fig.6. It is possible that this increase in the char yield arise as a result of surface cross-linking, assisting in retaining material in the condensed phase during combustion and encouraging the formation of char as previously reported by Wilkie and al [11-12]. Moreover, an increase of temperature of the major step of degradation is observed. Indeed, it passes from 240°C to 317°C when the PA-g-PolyVPA is treated with 0.5M NaOH. This increase could be explained by the loss of the acidic character of the polyVPA layer leading to the formation of a more thermally stable residue at a higher temperature.

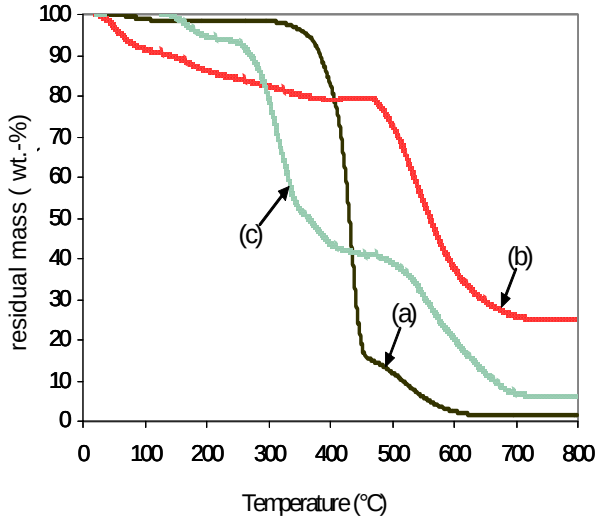

Figure 5: TG curves for virgin PA6(a), polyVPA(b) and PA6-g-polyVPA (c)

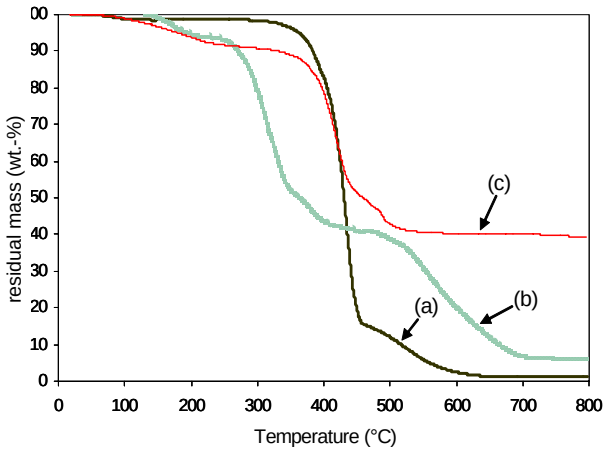

Figure 6: TG curves for virgin PA6(a), PA6-g-polyVPA (b) and PA6-g-polyVPA treated by 0.5M NaOH (c)

3. 3. Fire retardancy performances of PA6-g-PolyVPA

The LOI values for virgin and treated PA6 are given in table 2. It shows that the fire performances of PA6-g-PolyVPA are increased. Indeed, the LOI of the grafted PA6 is higher than that of unmodified PA6. The performance depends on the concentration of VPA solution. The highest LOI, obtained by treating the PA6 with a pure VPA, reaches a value of 45% and the UL 94 rating correspond to V0.

Criteria Conditions	**V-0**	**V-1**	**V-2**
Total flaming combustion for each specimen	≤10 sec	≤30 sec	≤30 sec
Total flaming combustion for all 5 specimens of any set	≤50 sec	≤250 sec	≤250 sec
Flaming and glowing combustion for each specimen after second burner flame application	≤30 sec	≤60 sec	≤60 sec
Cotton ignited by flaming drips from any specimen	NO	NO	YES
Glowing or flaming combustion of any specimen to holding clamp	NO	NO	NO

Table 1. Material Classification

Samples	**LOI (vol. %)**	**UL 94 rating**
Virgin PA6	25	NC
PA6-g-polyVPA (600g/l)	29	V1
PA6-g-polyVPA (800g/l)	35	V0
PA6-g-polyVPA (pure VPA)	45	V0

Table 2: UL rating and LOI values for virgin PA6 and the PA6-g-VPA

4. Conclusion

In the present work we have investigated a new approach to the flame retardancy of polyamide 6 using a cold plasma process by grafting and polymerizing the vinylphosphonic acid VPA onto the PA6 surface. This modification leads to significant reductions in flammability as evidenced by increased LOI values and increased yields of char formation during oxidative degradation. These performances are explained by the fact that the phosphorus acid -containing groups are active in the condensed phase by assisting intermolecular cross-linking promoting the formation of a protective char layer.

Exploring Radical-Surface Interactions During Plasma Etching and Deposition

Ellen R. Fisher, Department of Chemistry Colorado State University, Fort Collins, CO 80523-1872

Abstract:

Plasma-enhanced chemical vapor deposition (PECVD) and plasma etching are an integral to the microelectronics industry as well as to development of biomaterials, hard coatings and other widespread applications. Many mechanistic details for plasma processing of materials remain unknown. Understanding surface interactions of plasma species provides critical molecular level information about plasma processing. In addition, power dissipation and energetics are also important for elucidation of mechanistic details in plasmas. The imaging of radicals interacting with surfaces (IRIS) technique examines interactions of radicals during plasma processing of a variety of materials. This technique combines molecular beam and plasma technologies with laser-induced fluorescence (LIF) to provide spatially-resolved 2D images of radical species involved in film formation or etching. IRIS allows for direct determination of radical-surface interactions *during* plasma processing. Furthermore, IRIS provides direct information on the energetics of plasma-generated radicals as well as for species scattering off of surfaces. Specifically, IRIS provides data on the kinetic translational temperature and the rotational temperature of radicals in plasma systems. IRIS data for species in PECVD and etching environments will be presented. This work concentrates on the energetics of radicals such as SiH, CH, OH, and SO_2 during deposition or etching of silicon-based or carbon-based materials. Comparisons will be made between the surface interactions of individual species (i.e. comparison of the main group hydrides indicates not all open shell molecules are highly reactive) to elucidate the chemistry of both the molecules and the plasma processes.

Plasma Chemical Behavior of Inductively Coupled Fluorocarbon Plasmas

H. Fukumoto, K. Ono and K. Takahashi

Department of Aeronautics and Astronautics, Graduate School of Engineering, Kyoto University, Kyoto, Japan

Abstract

Chemical behavior has been simulated of inductively coupled plasmas. The fluorocarbon gases, CF_4 and C_4F_8, were employed in the simulation, and the results were compared with each other. There was little difference in the spatial distribution of electron density and temperature between CF_4 and C_4F_8 plasmas; on the other hand, there was large difference in some chemical species between in the two.

1. Introduction

Radio-frequency discharges in low-pressure fluorocarbon gases have been widely used for the etching of thin SiO_2 layers on Si in the microelectronics fabrication [1]. During plasma etching, several different kinds of reactive ions and neutrals occur in the plasma, being incident on substrate surfaces being etched: feedstock gas species and their fragments (or reactants), reaction products (or etch products) from the substrate, impurities from chamber walls, and mask materials. An etching process is much complicated because it contains many chemical reactions and many chemical products. The composition of neutrals and ions depends on many kinds of conditions: ICP input power, pressure, mass flow rate, material and temperature of electrodes and chamber walls, material of wafer, and so on.

In the near future, the process of ultra large scale integrated circuit (ULSI) devices will need a precisely controlled process technology for processing micro structures with sub 0.1-μm patterns and aspect ratios of over 10 on 30-cm-diameter wafers. To achieve the technology, it is necessary to produce uniform ion fluxes by using low-pressure and high-density plasmas. Many kinds of plasmas sources are being researched and developed. However, there are many problems to be solved, arising from the existence of magnetic fields, complicated dissociation of reactive gases, interaction with chamber walls, and so on [2]. Thus, a better understanding of the chemical behavior of reactive plasmas for etching is strongly required, to develop an advanced plasma etching technology for microelectronics and MEMS devices. In this work, the chemical behavior is simulated of inductively coupled fluorocarbon plasmas, to understand the spatial structure of plasmas.

2. Modeling

A schematic of the ICP source studied is shown in Fig. 1. The reactor has a radius R=15 cm and a length H=9 cm, with a dielectric window at the top of the chamber. The plasma is generated by a five-turn RF coil driven at radio frequencies of 13.56 MHz. The coil current induces time-varying magnetic fields which in turn induce the electric fields that couple the rf power to the plasma electrons within a skin depth layer near the plasma-dielectric interfaces. A wafer stage 10 cm in radius is located at the bottom of the chamber. Feedstock gas is supplied through a gas inlet ring located just under the dielectric window, being pumped away through an annular ring vacuum pump port.

Maxwell's equations are solved to obtain the power deposition into the plasma. The power deposition profiles are then used in the electron energy equation to calculate electron temperatures. The rate coefficients for chemical reactions, which are a function of electron temperature, are transferred as

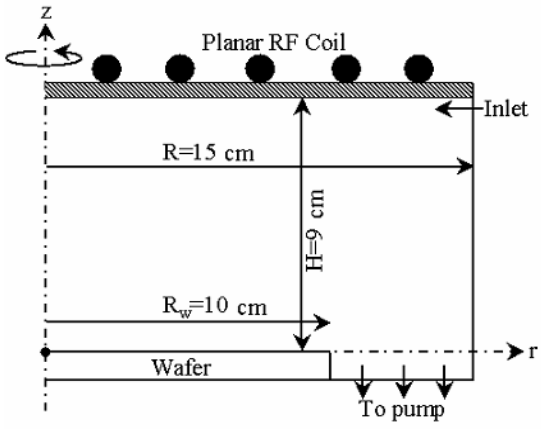

Fig. 1. A schematic of the ICP reactor studied in the present simulation.

source and sink terms to the charged and neutral species rate equations. At plasma-surface boundaries, the surface site balance model acquires fluxes of reactants from the plasma fluid model, implements surface reaction mechanisms, assigns surface coverages, and then places back fluxes of products to the plasma fluid model as boundary conditions. Electron density gives the plasma conductivity used in Maxwell's equations. By iterating these procedures until the solution converges, a self-consistent steady-state solution can be obtained.

The electromagnetic fields are obtained by solving Maxwell's equations. In this study, the rf spiral coil is approximated by concentric coils. With the axisymmetric assumption, we only consider the azimuthal component of the inductive electric field E_θ.

$$\nabla^2 E_\theta = j\omega\mu_0\sigma E_\theta, \tag{1}$$

where σ is the plasma conductivity, ω is the driven frequency, and μ_0 is the permeability of vacuum.

The diffusion and chemical reactions are taken into account for neutral species. We employed Fick's law instead of solving full momentum equations. This reduces computational time tremendously as compared to solving Navier-Stokes equations. The flux of the kth neutral species is given by

$$\boldsymbol{\Gamma}_k = -D\nabla n_k, \tag{2}$$

where D is the diffusion coefficient, and n_k is the kth neutral density. Then, the continuity equation of the kth neutral species is expressed as

$$\frac{\partial n_k}{\partial t} = -\nabla\cdot\boldsymbol{\Gamma}_k + \sum_j R_{kj}, \tag{3}$$

where R_{kj} is the production/destruction rate of the kth neutral species due to the reaction event j. Neutral species also flow into and out of the discharge as a result of pumping. For the feedstock gas, only the particles entering the chamber have to be considered. The gas temperature is assumed to be uniform at room temperatures (T_n = 300 K = 0.026 eV).

The fluid approach is adopted to model the behavior of charged species as well. A Maxwellian electron energy distribution function (EEDF) is assumed. Kimura *et al*. measured the EEDF in an inductively coupled CF_4 plasma source with Langmuir probes, and they showed that the EEDF is Maxwellian even at pressure of 2 mTorr [3]. Then, the electron energy balance is expressed as

$$\frac{\partial}{\partial t}\left(\frac{3}{2}n_\mathrm{e}k_\mathrm{B}T_\mathrm{e}\right) = W - \nabla\cdot\boldsymbol{q}_\mathrm{e} - \upsilon_\mathrm{m}\frac{3m_\mathrm{e}}{M}n_\mathrm{e}k_\mathrm{B}\left(T_\mathrm{e}-T_\mathrm{n}\right) - \sum_j R_{\mathrm{e}j}\Delta H_{\mathrm{e}j}, \tag{4}$$

where T_e is the electron temperature, ν_m is the electron momentum transfer collision frequency, M_n is the mass of neutral species, $R_{\mathrm{e}j}$ is the rate of the inelastic electron impact collision j, $\Delta H_{\mathrm{e}j}$ is the inelastic electron-impact collision energy loss/gain in the jth collision, and k_B is the Boltzmann constant. The electron energy flux $\boldsymbol{q}_\mathrm{e}$ is composed of heat conduction and convection as

$$\boldsymbol{q}_\mathrm{e} = -\kappa_\mathrm{e}\nabla T_\mathrm{e} + \frac{5}{2}k_\mathrm{B}T_\mathrm{e}\boldsymbol{\Gamma}_\mathrm{e}, \tag{5}$$

where $\boldsymbol{\Gamma}_\mathrm{e}$ is the electron flux, and κ_e is the electron thermal conductivity given by

$$\kappa_\mathrm{e} = \frac{3}{2}k_\mathrm{B}D_\mathrm{e}n_\mathrm{e}. \tag{6}$$

The drift diffusion approximation is employed to model the electron and ion fluxed in the chamber. To avoid solving the plasma sheath structure, we assume the continuity equation covers all of the chamber area except for the sheath region. Based on the assumption of the quasi-neutrality

$$\sum\nolimits_+ n_+ = \sum\nolimits_- n_-, \tag{7}$$

and congruence of flux

$$\sum\nolimits_+ \boldsymbol{\Gamma}_+ = \sum\nolimits_- \boldsymbol{\Gamma}_-, \tag{8}$$

which means that the total positive ion flux out of any region is equal to the total negative ion and electron flux, and that the plasma is treated with the ambipolar diffusion model. Here, subscripts '+' and '-' indicate positive ions and negative ions/electrons, respectively. The continuity equation for the ith charged species is then

described as

$$\frac{\partial n_i}{\partial t} = -\nabla \cdot \left(\mu_i n_i \boldsymbol{E} - D_i \nabla n_i\right) + \sum_j R_j, \tag{9}$$

where the sum of R_j is over the collisions that produce or destroy the ith ion. With the drift-diffusion approximation, the ith ion flux is given by

$$\boldsymbol{\Gamma}_i = \mu_i n_i \boldsymbol{E} - D_i \nabla n_i. \tag{10}$$

Here, the diffusion coefficient D_i and the mobility μ_i of the ith ion are given by

$$D_i = \frac{k_B T_i}{M_i \nu_{\text{in}}}, \quad \mu_i = \frac{q}{M_i \nu_{\text{in}}}, \tag{11}$$

where q, M_i, T_i are the charge, mass and temperature of the ith ion, and ν_{in} is the ion-neutral collision frequency. $\boldsymbol{E}$ is the plasma electrostatic field derived from the flux balance of charged species. Substituting eq. (10) into eq. (8), we have

$$\boldsymbol{E} = \frac{\sum_+ D_+ \nabla n_+ - \sum_- D_- \nabla n_-}{\sum_+ \mu_+ n_+ + \sum_- \mu_- n_-}. \tag{12}$$

Chemical species in C_4F_8 plasma are assumed to be more than in CF_4 plasma. In CF_4 plasma, we assume CF_4, CF_3, CF_2, CF, F, CF_3^+, CF_2^+, CF^+, F^- and electron. In C_4F_8 plasma, we assume C_4F_8, C_2F_3, C_2F_4, C_3F_5, C_3F_7, $C_2F_3^+$, $C_2F_4^+$, $C_3F_5^+$ and $C_3F_7^+$ in addition to species already assumed in CF_4 plasmas. The reactions assumed in the gas phase are 21 in CF_4 plasma and 51 in C_4F_8 plasma [4-9]. They contain ionizations, dissociations and recombinations of the species.

3. Results and Discussion

The nonlinear partial differential equations were discretized in space with finite-volume approximations. Then, we integrated the set of ordinary equations with the fully implicit scheme, assuming an initial two-dimensional profile for all of the species densities and electron temperature. When the time variations in these quantities disappear, the calculated values correspond to the solutions for the steady state. The ICP power at 13.56 MHz is applied, and CF_4 or C_4F_8 pure gas is supplied into the chamber. The nominal operating conditions are: a gas pressure of 20 mTorr, an ICP power of 250 W, and a mass flow rate of 200 sccm.

The volume-averaged densities of ions and electrons are compared in Fig. 2. The density of CF_3^+ is the largest among the positive ions in CF_4 and C_4F_8 plasmas. That is as large as the electron density. The density of CF_2^+ in CF_4 plasma is much larger than that in C_4F_8 plasma. The spatial distribution of CF_2^+ is shown in Fig. 4. In the following figures, the CF_4 plasma is indicated by (a) and the C_4F_8 plasma is indicated by (b). The density peak in Fig. 4 (a) is around z-axis; on the other hand, the density peak in Fig. 4 (b) is under the forth coil from the most inner coil. The peaks positions are different from each other in Figs. 4 (a) and (b). In addition, the densities of $C_2F_4^+$ and $C_3F_5^+$ in Fig. 2 are major among the positive ions in C_4F_8 plasma. It is supposed that the reactions (13) and (14) play an important role.

$$C_4F_8 + CF_2^+ \rightarrow C_3F_5^+ + C_2F_4 + F, \tag{13}$$

$$C_2F_4 + CF_2^+ \rightarrow C_2F_4^+ + CF_2. \tag{14}$$

The volume-averaged compositions of neutral radicals are compared in Fig. 3. The densities of F are the largest in CF_4 and C_4F_8 plasmas. It is supposed that the F is derived from many kinds of the dissociations. The densities of CF_2 are not large different between CF_4 and C_4F_8 plasmas, nor those of CF_3. However, the density of C_2F_5 in CF_4 plasma is much larger than in C_4F_8 plasma though the C_2F_5 is generated from CF_2 and CF_3. To help to comprehend the large difference in the density of C_2F_5, the spatial distributions of CF_2 and CF_3 give a good direction. The spatial distribution of CF_2 is shown in Fig. 5 and that of CF_3 is shown in Fig. 6. In Fig. 5 and Fig. 6, the distributions of CF_2 and CF_3 in C_4F_8 plasma are mostly flat over the whole computed area; on the other hand, those in CF_4 plasma are steeper than those in C_4F_8 plasma, and so the density peaks in CF_4 plasma are clear. The peaks positions in CF_4 plasma are under the coils and correspond to each other. Thus, the C_2F_5 in CF_4 plasma may be generated much more efficiently than in C_4F_8 plasma.

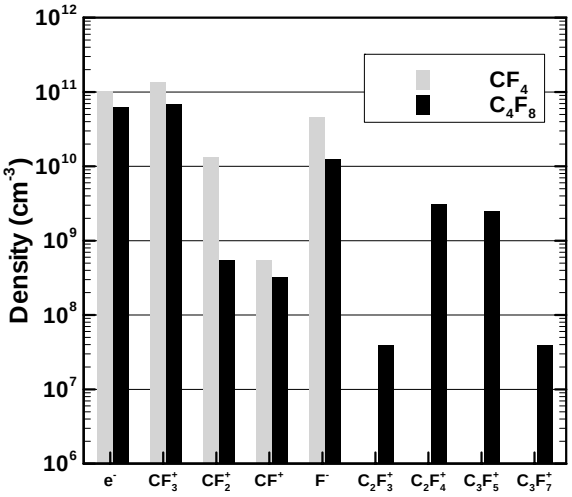

Fig. 2. Volume-averaged concentration of ions in CF_4 plasma and C_4F_8 plasma.

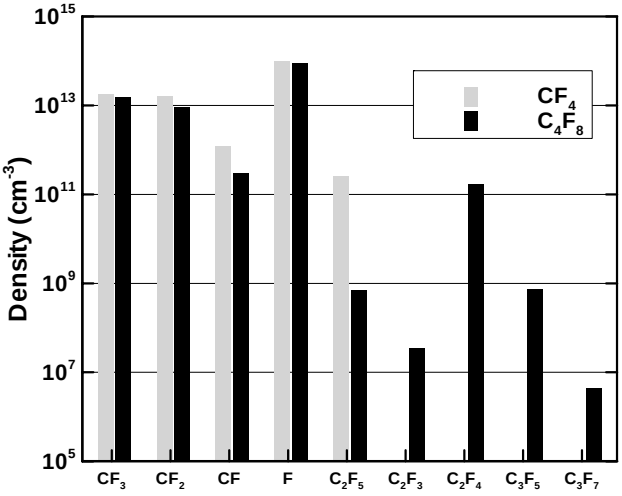

Fig. 3. Volume-averaged concentration of neutral radicals in CF_4 plasma and C_4F_8 plasma.

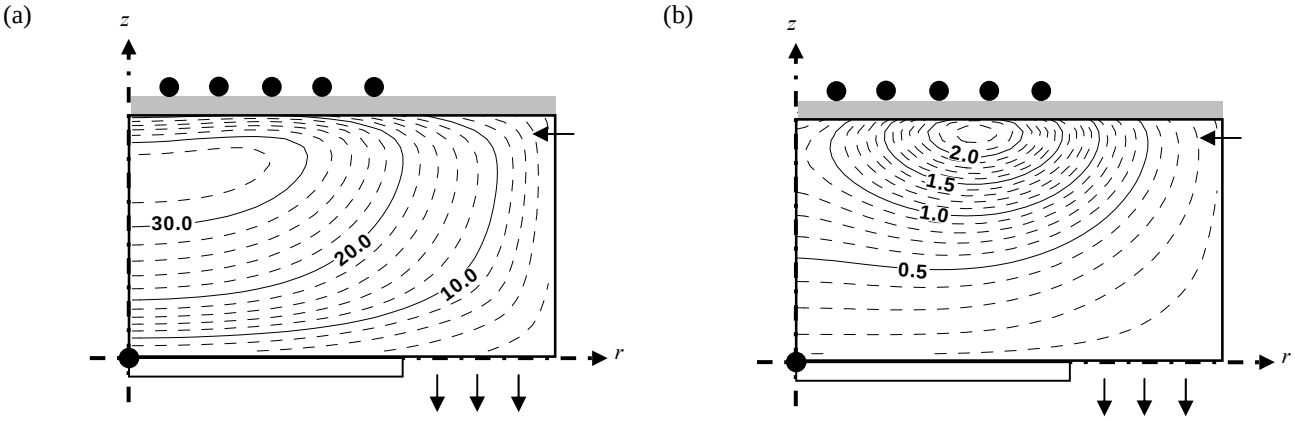

Fig. 4. Spatial distribution of the CF_2^+ density ($\times 10^9$ cm^{-3}) (a) in CF_4 plasma and (b) in C_4F_8 plasma.

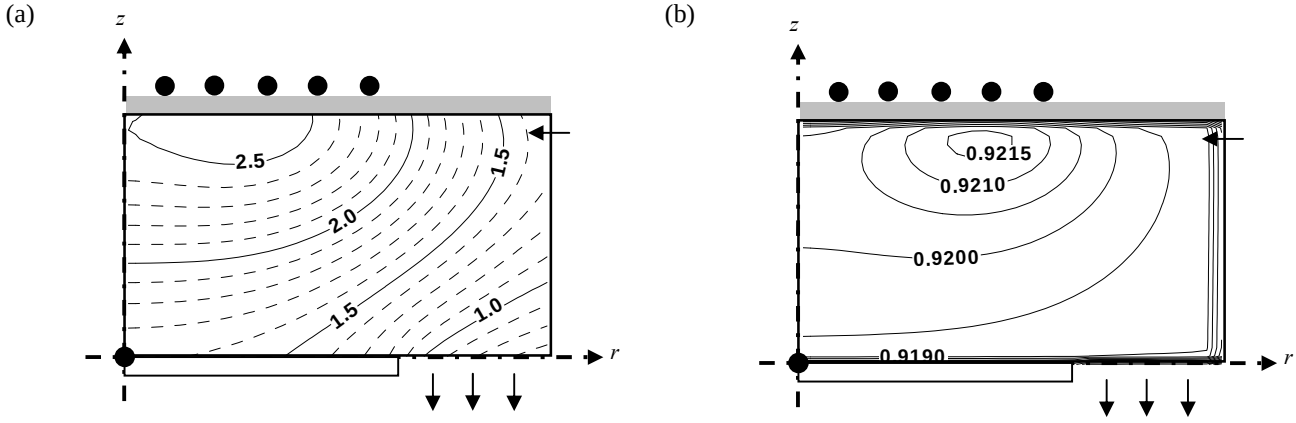

Fig. 5. Spatial distribution of the CF_2 density ($\times 10^{13}$ cm^{-3}) (a) in CF_4 plasma and (b) in C_4F_8 plasma.

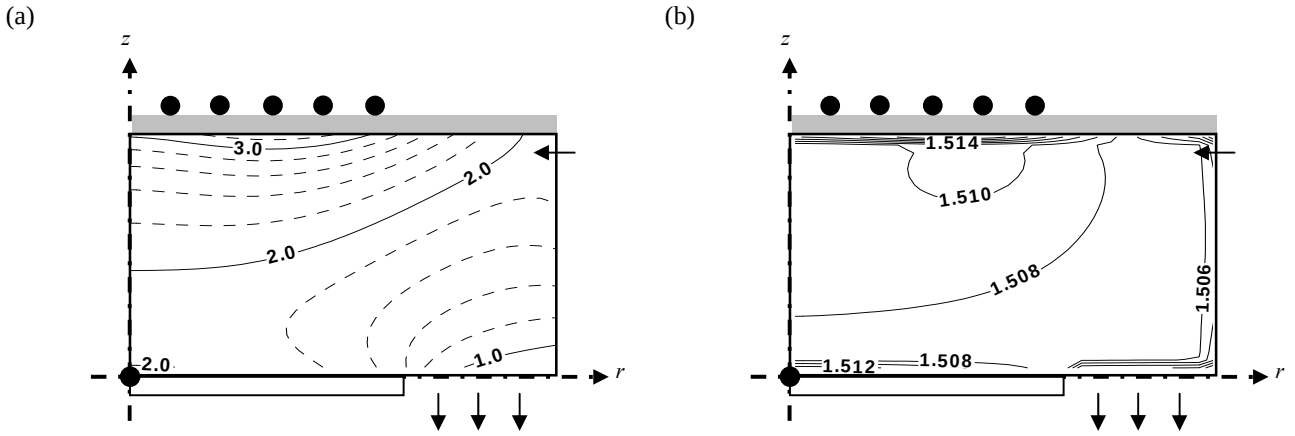

Fig. 6. Spatial distribution of the CF_3 density ($\times 10^{13}$ cm^{-3}) (a) in CF_4 plasma and (b) in C_4F_8 plasma.

The spatial distribution of electron density is shown in Fig. 7 and that of electron temperature is shown in Fig. 8. In Figs. 7 (a) and (b), the electron density peaks are observed in under the coils. The temperature peaks are just under the forth coil from the most inner coil in Figs. 8 (a) and (b). The temperature in Fig. 8 (b) is lower than in Fig. 8 (a) over the whole computed area. The electron energy may be absorbed more in C_4F_8 plasma than in CF_4 plasma because there are more reactions of ionization and dissociation in C_4F_8 plasma. The distributions shapes are quite similar over the whole computed area between (a) and (b) in Fig. 7 and Fig. 8.

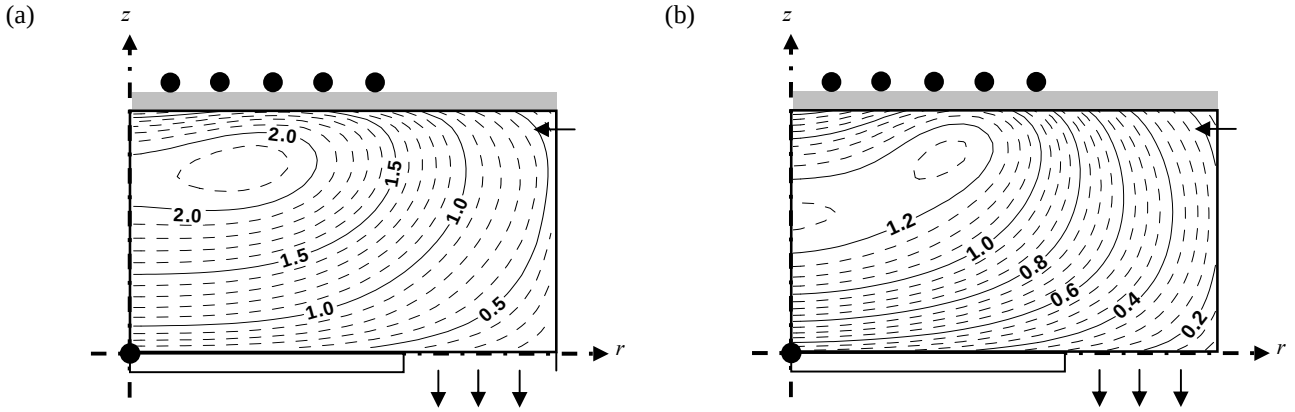

Fig. 7. Spatial distribution of the electron density ($\times 10^{11}$ cm^{-3}) (a) in CF_4 plasma and (b) in C_4F_8 plasma.

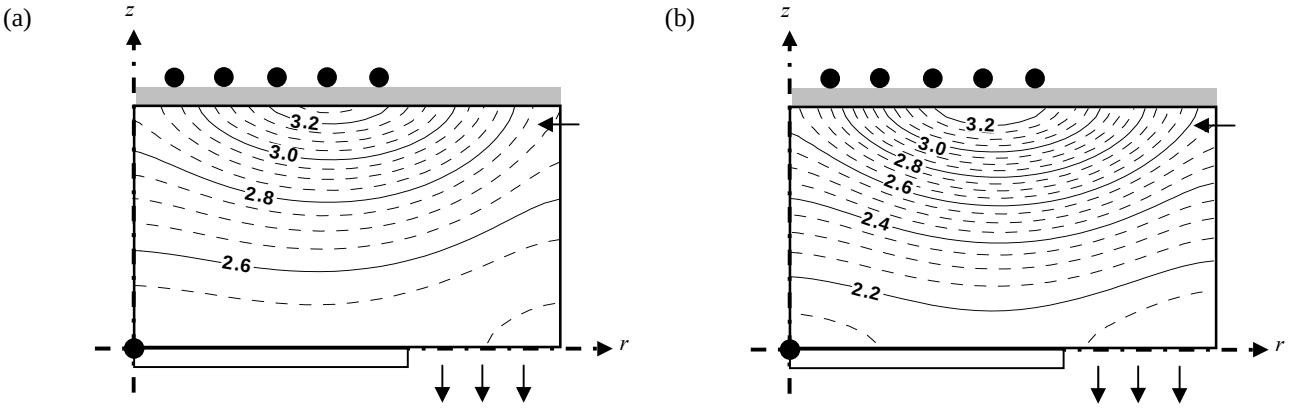

Fig. 8. Spatial distribution of the electron temperature (eV) (a) in CF_4 plasma and (b) in C_4F_8 plasma.

For further discussion, we investigated the inductively coupled CF_4 and C_4F_8 plasmas with a quadrupole mass spectrometer. Figure 9 shows the mass spectra without electron beams for ionization. The both of plasmas was at a gas pressure of 20 mTorr, an input power of 280 W, and a gas flow rate of 2.5 sccm. The ion energy, which corresponded to the plasma potential concerned, was measure to be 16 V in Fig. 9 (a) and 14 V in Fig. 9 (b). Many chemical species are observed which could not be assumed in the simulation. Some common properties are found in the simulation and the measurement. In Fig. 2 and Fig. 9 (a), regarding the CF_x^+ ions (x=1-3) in CF_4 plasma, the concentration is lager for species with lager x. In Fig. 2 and Fig. 9 (b), the $C_2F_4^+$ and $C_3F_5^+$ in C_4F_8 plasma are major species in positive fluorocarbon ions.

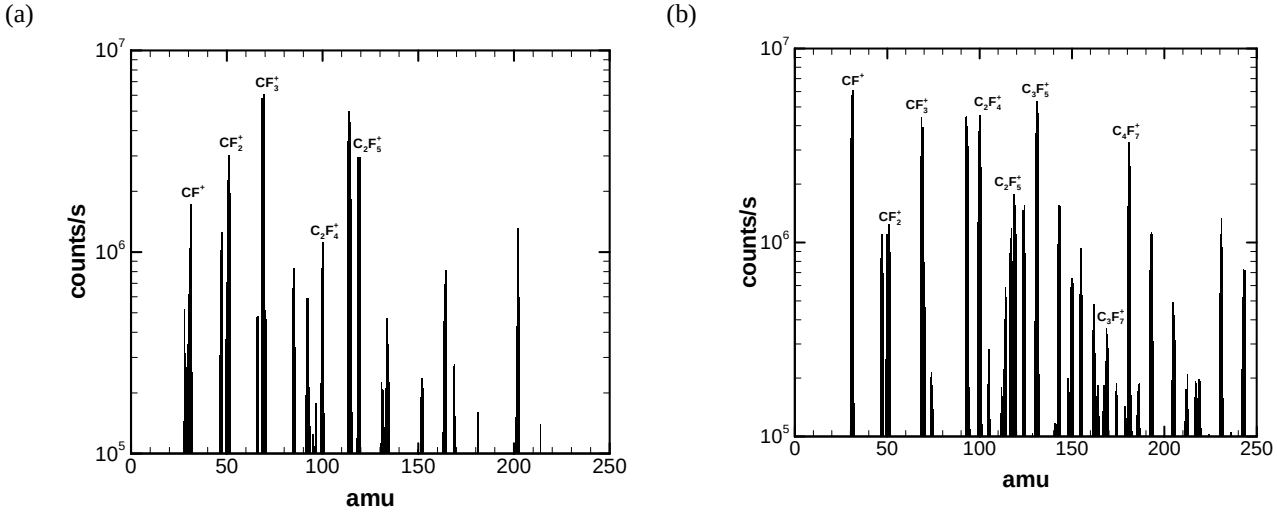

Fig. 9. Mass spectrum for inductively coupled (a) CF_4 plasma and (b) C_4F_8 plasma, without electron beams for ionization.

4. Conclusions

A two-dimensional fluid simulation of inductively coupled CF_4 and C_4F_8 plasmas source has been performed. The fluid model consisted of Maxwell's equations, rate equations for neutrals and ions, and energy balance equation for electrons. The surface reaction model employed a concept of surface coverage. By coupling these models, steady state solutions were obtained in a self-consistent fashion. The numerical results clarified the internal structure of inductively fluorocarbon plasmas. There was little difference in the spatial distributions of electron densities and temperatures between CF_4 and C_4F_8 plasmas; on the other hand, there was large difference in the spatial distributions of some chemical species between in the two. Some results from the simulation and the measurement corresponded to each other.

Abstract

A thermal RF induction plasma of standard design have been used to modify graphite particles. The materials were treated in an argon/oxygen-plasma to modify the morphology and the surface of the particles. During plasma treatment the former platelet graphite particles were converted into spheroidized, rounded or potato-shaped particles. Additionally the particle surfaces were modified by introducing oxygen functionalities and the specific surface area of the graphite was reduced.

1. Introduction

Graphitic or graphitized carbonaceous materials are widely used as anode materials for Lithium-ion rechargeable batteries. To increase the performance, cycle life, stability and safety of this type of energy storage device, the development of high performance carbon materials is urgently required. In this connection, the surface characteristics, the pore structure and the morphology of the carbon material have a quite special relevance.
A thermal RF induction plasma of standard design, normally used for the synthesis of nanopowders, for spheroidization of meltable substances or for the deposition of coatings, have been used to modify graphite particles.

The graphite particles were treated in an argon-oxygen-plasma to modify the morphology and the surface of the particles with respect to the using as anode materials in Lithium-ion rechargeable batteries.

The plasma treated graphite particles were analyzed by scanning electron microscopy (SEM), X-ray photoelectron spectroscopy (XPS), and specific surface area (BET).

2. Experimental

In this study, two different artificial graphite powders, which consist mainly of nonspheric, irregular, and flat particles, have been treated under various reactive thermal plasma conditions. The graphite powders were modified in a thermal RF induction plasma at atmospheric pressure. The RF induction plasma has proven to be a very attractive tool both for the thermal treatment of powders and for materials synthesis. The use of inert atmospheres and the absence of electrodes produces the very clean plasmas, which are essential for some processing applications. Additionally, RF induction plasma can be made much larger and more uniform than other thermal plasma systems. Moreover, thermal plasma techniques offers the advantage of a continuous one-step process with the potential for a versatile, cost-effective technology for the industrial-scale production of many advanced materials for demanding applications in high tech industries.

The laboratory-manufactured moderate-scale RF induction plasma synthesis facility mainly consisted of four components: the plasma torch with radio frequency generator, the graphite powder and gas supply systems, the water-cooled reactor together with the heat exchanger, and the filter system for powder collection. The principle of the reactor has been described previously in detail [1]. The plasma torch consists of an air-cooled quartz confinement tube of 50 mm diameter surrounded by a three-turned induction coil of 30 mm length and 60 mm diameter. The plasma torch was powered by a radio frequency power supply (Steremat, Berlin, model GI5/5D-047, maximum plate power 5 kW, nominal frequency 2.5 – 5 MHz) operating at a frequency of 4 MHz and a plate power of 3 kW. The discharge parameters were kept constant in the experiments. The upstream part of the

set-up was the distribution head made of stainless steel. This distribution head combines the probe for powder injection and the inlet of the plasma gases into the discharge chamber, the sheath gas to protect the walls and the central plasma-forming gas. The sifted graphite powders (smaller than 50 µm and 50-80 µm diameter), carried by an argon gas, is injected into the hot plasma core through a graphite probe. The graphite probe was installed in the axis of the distribution head, and it was adjusted so that the tip position was located at the first turn of the induction coil.

The torch is discharged into the downstream part that consists of a water-cooled steel reactor. The reaction zone is followed by a quench zone, in which the gases and the particles are rapidly cooled. The high temperature reacting system was quenched by adding cold argon gases at the reaction zone exit. In addition a water-cooled quenching chamber was located after the reactor allowing cooling by gas expansion.

The plasma treated graphite powders were collected by solid-gas separation on a cloth filter.

The plasma was operated with argon and various argon-oxygen-mixtures as central and sheath gas, respectively. The powder feed rate was 35 - 100 g/h.

3. Results

For the plasmachemical modification of graphite two different graphite powders of the sieve fractions 50 – 80 µm (graphite powders A) and < 50 µm (graphite powders B) have been used. Both starting materials consist mainly of relatively flat irregular polyhedral surfaces and are characterized by a relatively high content of very small particles. This two types of particles were plasma treated using an Ar/O_2 plasma of different oxygen content. Fig. 1 shows the SEM images of the starting and the plasma treated graphite powders A of the 50-80 µm sieve fraction. It is clearly shown in the SEM images, that during the plasma treatment the structure of the particles was modified by oxidation forming rounded particles. The shape of the former irregular platelet particles were converted into spheroid and potato-like particles. At the same times the content of the small particles was drastic diminished. This effect is attributed to the evaporation of carbon as well as to the formation of carbon oxides during passing the plasma zone.

Fig. 2 shows the SEM images of the graphite powders B (sieve fraction < 50 µm) before and after plasma treatment. The plasma treated material at low oxygen

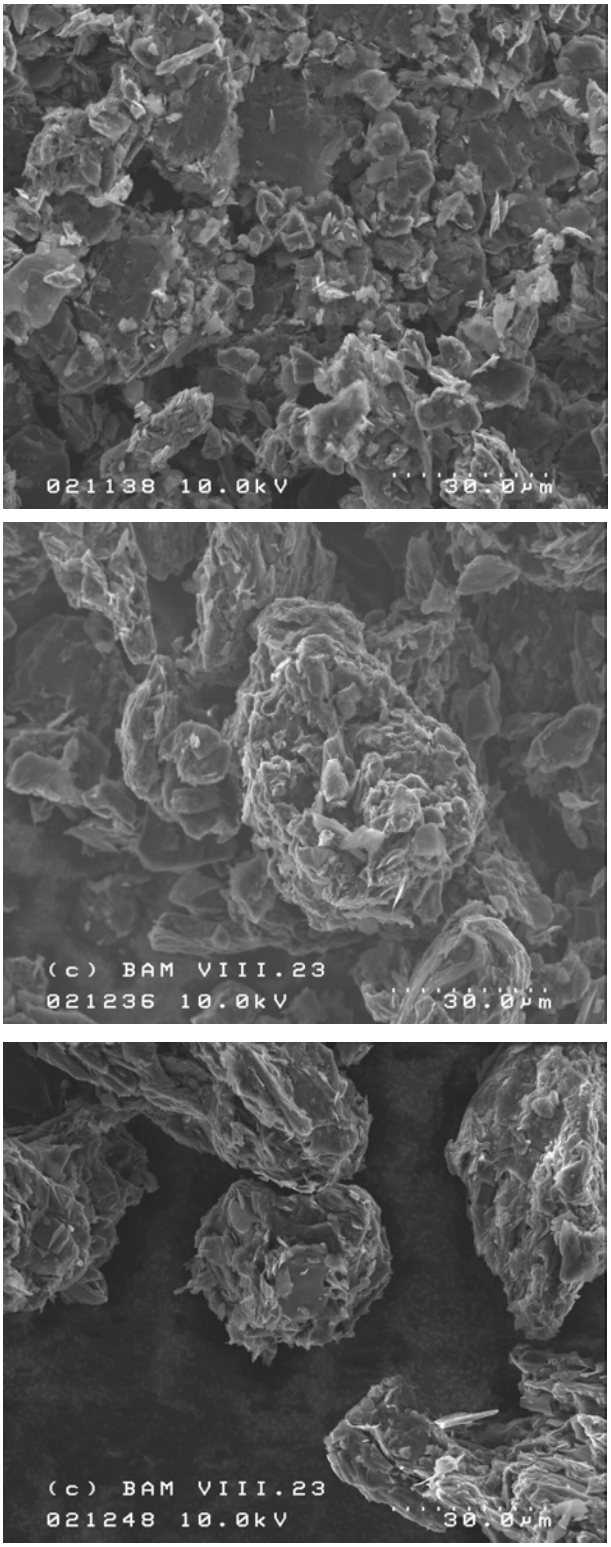

Fig. 1: Evolution of morphology of the graphite powders A (50-80 µm) by plasma treatment. SEM images of the starting powder (top) and the plasma treated graphite powders at lower (middle) and higher (bottom) oxygen concentration in the plasma gas.

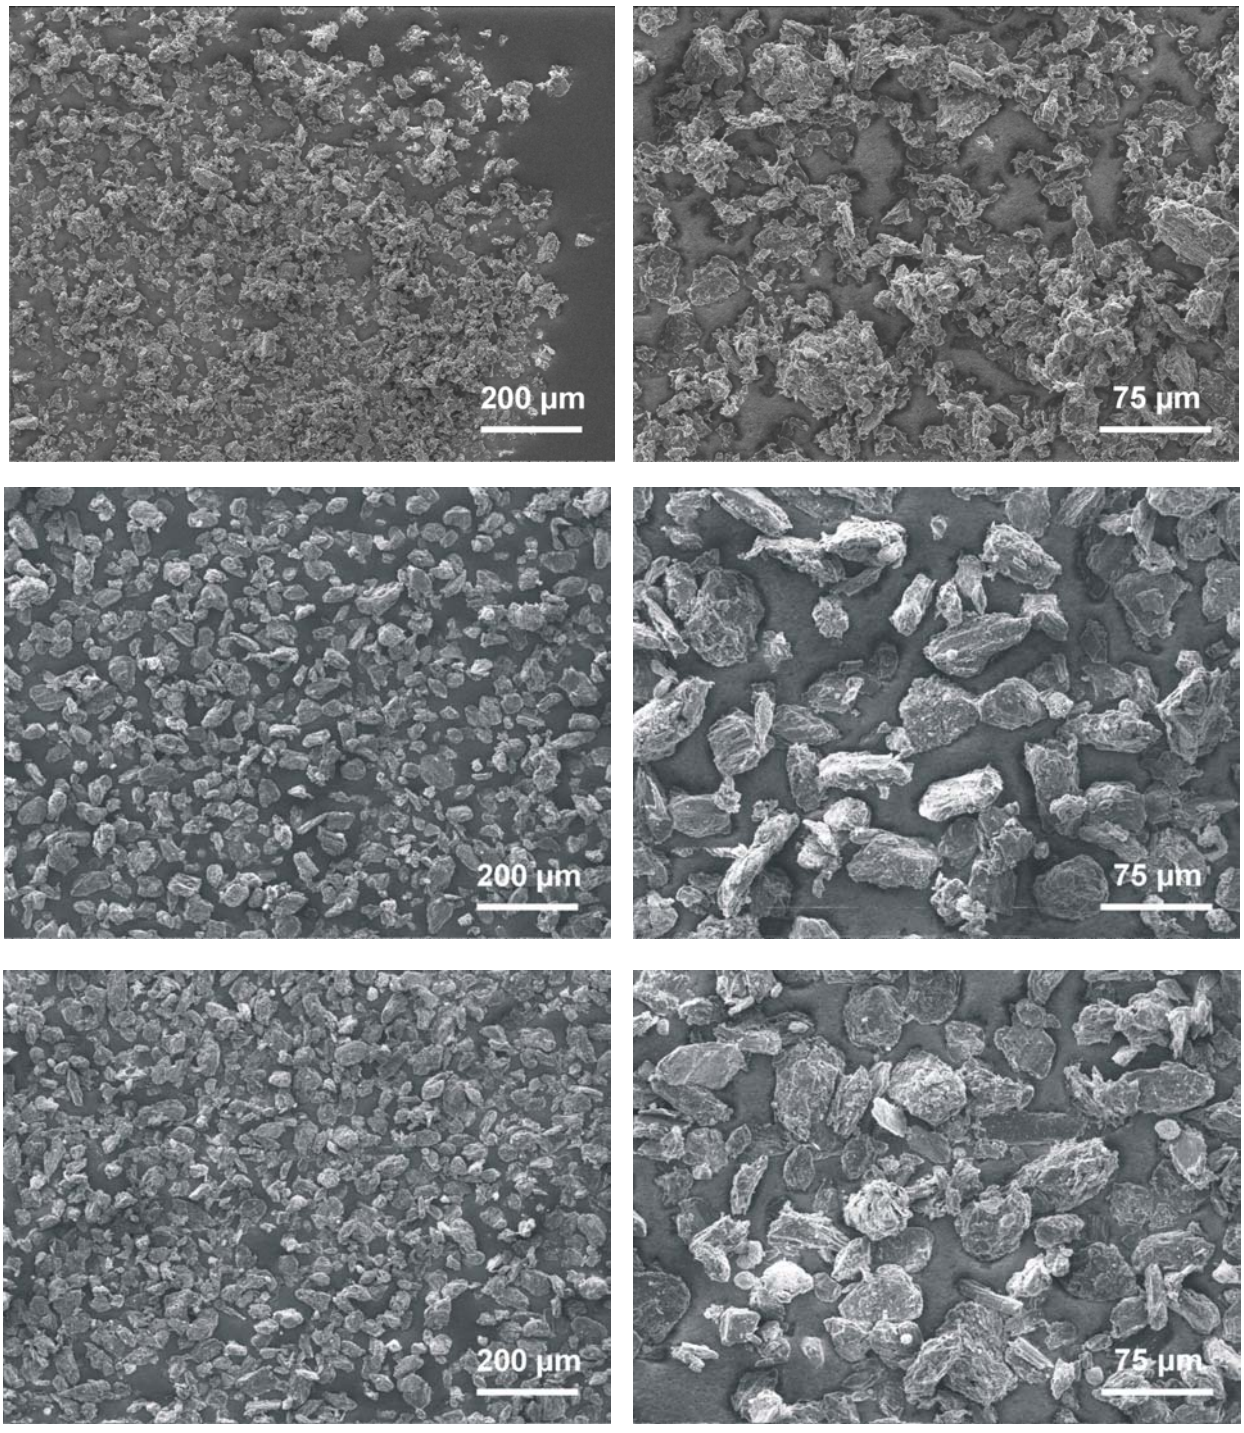

Fig. 2: Evolution of morphology of the graphite powders B (<50 µm) by plasma treatment. SEM images of the starting powder (top) and the plasma treated graphite powders at lower (middle) and higher (bottom) oxygen concentration in the plasma gas.

and high oxygen partial pressure shows clearly the spheroidized, rounded and potato-like graphite particles. The effect of the spheroidization is observed independently of the particle size used in the experiments (Figs. 1 and 2). Both the formation of the spheroidized particles and the diminishing content of the small particles are favored by increasing content of oxygen in the plasma gas.

XPS investigations shows that the surface of the graphite particles were modified by introducing oxygen functionalities in the range of up to 4.5 at % depending of the oxygen content of the plasma gas (Fig. 3 and 4). The O1s XPS spectra of the starting powder A and the plasma-treated powders at low and higher oxygen content in the plasma gas shows 1.8, 2.9, and 4.5 at % oxygen, respectively. This oxygen on the surface belongs to different functional oxygen groups. Peak fitting shows that the surface groups consists mainly of -C-OH, >C=O and -COOH groups.

The starting graphite powders A shows a BET surface area of 3.7 m^2/g. After the plasma treatment with lower and higher oxygen content in the plasma gas the BET surface area was reduced to 2.8 and 2.4 m^2/g, respectively (Fig. 5). This demonstrates clearly that the specific surface area of graphite particles can be drastic reduced by treatment in an Ar/O_2 plasma.

The spheroidization of the particles together with the formation of oxygen functionalities at the particle surface and the reduction of the BET surface area are good assumptions to improof the electrochemical properties of graphite powders for use as anode material in Lithium-ion rechargeable batteries. Therefore the plasma modified graphite powders were used to prepare anodes for Li-ion rechargeable batteries and the electrochemical properties were tested. The discharge capacity of cells with anodes made of the plasma-treated graphite powders was clearly improved in comparison to the cells with anodes made of the original graphite powders [2].

Summary

The thermal RF induction plasma has been used to modify the morphology and the surface of graphite particles. It has been found, that during argon-oxygen plasma treatment the former platelet graphite particles were converted into spheroidized, rounded or potato-like particles. At the same times the content of the small particles was drastic reduced.

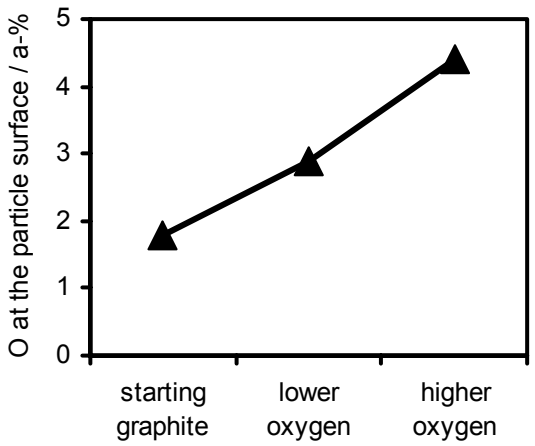

Fig. 3: Oxygen content by XPS of the starting graphite powders A (50-80 µm) and the plasma-treated powders at different oxygen concentration in the plasma gas.

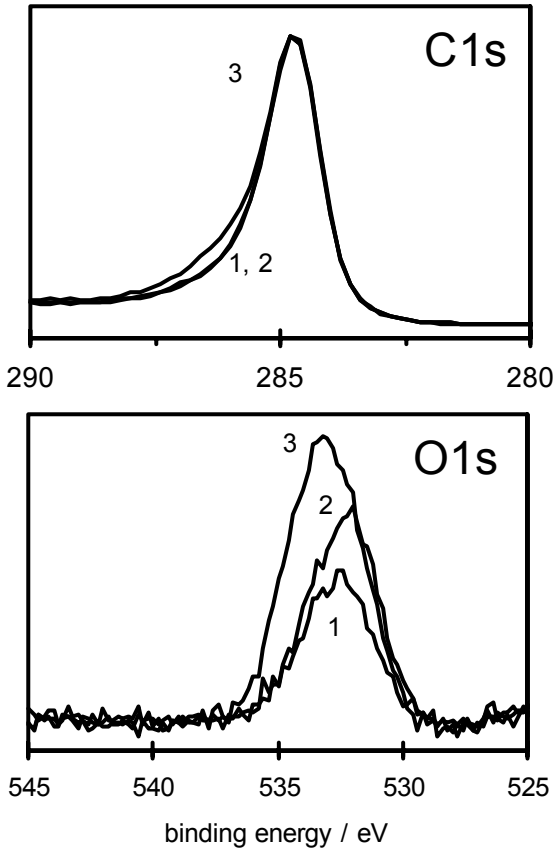

Fig. 4: XPS spectra of graphite powders A (50-80 µm)
(starting powder (1) and the plasma treated powders at lower (2) and higher (3) oxygen content in the plasma gas).

The graphite particles found to be modified in the surface by introducing oxygen functionalities mainly consisting of -C-OH, >C=O and -COOH groups. Additionally, during plasma treatment the specific surface area of the graphite was reduced.

The plasma treated graphite powders were used to prepare anodes for Li-ion-batteries which shows excellent charge/discharge efficiency during cycling.

Abstract

Crumpled carbon nanosheets (CNSs) of a quasi-two-dimensional graphite structure are synthesized by thermal decomposition of methane using a DC plasma torch of hollow electrodes type operated in a reversed polarity mode. FE-SEM images show that the synthesized products solely consist of a large number of individual CNSs, which are stacked with random orientation and interlaced each other. The material analyses of BET and XRD indicate that the CNSs synthesized by this new method have excellent physico-chemical properties such as large surface area and highly graphitized structure with good crystallization.

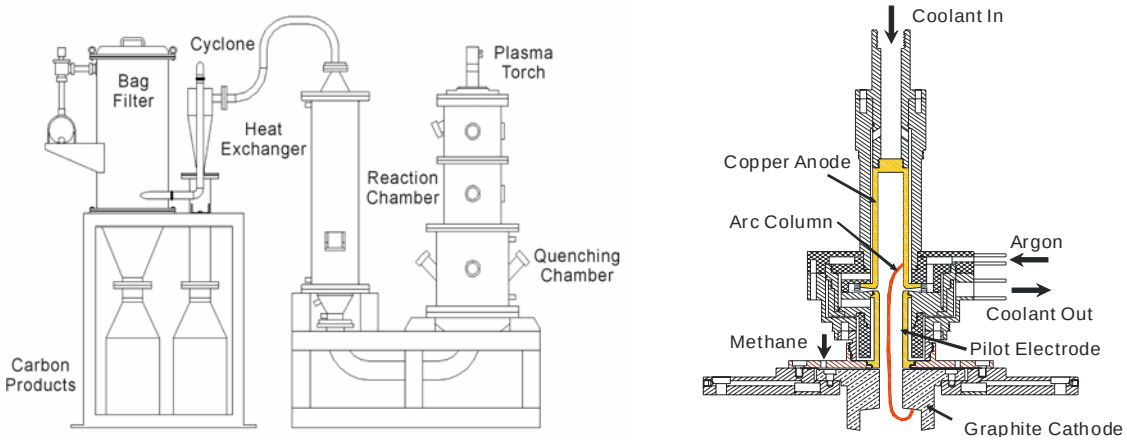
1. Introduction

A sheet-like carbon structure named as carbon nanosheet or nanowall, has been reported as a common by-product during fullerenes and carbon nanotubes (CNTs) preparations by using arc discharge or laser ablation method [1]. This material has a high aspect ratio with good chemical stability due to its sheet-like graphitic structure, and such unique properties are very attractive for storage of hydrogen gases and fuel cell applications [2]. Moreover, the CNSs with sharp and ultra thin edges of less than 20 nm can be utilized as effective electron emission sites in the fabrications of high-performance vacuum electronic devices [2-3]. Compared to other self-assembled carbon nanostructures such as CNT and fullerene, only limited knowledge has been so far established on the property and production of CNSs, and more intensive studies on CNSs are now needed to explore their further potential applications.

Recently, physical properties of CNSs have been investigated by examining field emission characteristics of them [3], and the samples used in these lab-scale experiments have been grown mostly by plasma enhanced chemical vapor deposition (PECVD) techniques, in which well-aligned and ultra thin CNSs were successfully synthesized from decomposition of methane. For an expansion of their commercial usage, mass and continuous productions of high purity CNSs are essential. However, conventional arc discharge methods are inevitably accompanied by other carbon allotropes like CNT and fullerene [1], and CVD methods are usually subject to low product yields [2]. Above all, both the existing processes are basically operated in a batch mode and are not easy to be scaled up.

For the above reasons, a new method for the preparation of high quality CNSs in a continuous mode is proposed in this experimental work utilizing a DC thermal plasma torch. Thermal plasmas have been broadly used in material industries for synthesis of new materials by taking advantages of their high enthalpy contents and temperatures around 2,000 ~ 20,000 K [4]. Therefore, a high growth rate of CNSs is achievable with thermal plasmas due to a bountiful supply of carbon atoms generated from a thorough decomposition of feedstock, i.e., methane (CH_4). The physico-chemical properties of the synthesized CNSs are also investigated by some microscope images, X-ray diffraction and static gas adsorption techniques. Finally, in order to find effects of torch input conditions on the formation of CNSs, a series of processing experiments are conducted with three different levels of input power.

2. Experimental setup



(a) (b)

Fig. 1. Schematic layout of a DC thermal plasma processing system (a) and cross-sectional view of a DC plasma torch of hollow electrodes type (b) used for synthesis of carbon nanosheets (CNSs).

For a continuous synthesis of high quality CNSs, a prototype reactor system mounted with a DC plasma torch are built as shown in Fig. 1. The reactor system consists of four major parts: a reaction chamber, a quenching chamber, a heat exchanger and a particle collection system (i.e., bag filter and cyclone). The stainless steel reaction chamber (0.32 m in outer diameter, 0.65 m in length) contains a graphite liner (0.1 m in inner diameter) surrounded by thermal insulator in order to extend high temperature reaction regions by minimizing thermal losses to the reactor wall.

Among a variety of DC thermal plasma torches, a plasma torch of hollow electrodes type has been chosen as a heat source because it is appropriate for high power operations up to several hundreds kW and can use any kind of gas as a plasma forming gas [4]. Instead of adopting a conventional electrode polarity of inner-cathode and outer-anode configuration, a reverse polarity operation mode with a graphite cathode extruded is employed to reduce erosion rates of both the electrodes and to avoid formation of unwanted impurities from electrode wear. Moreover, a feedstock gas of CH_4 is directly injected into the graphite cathode region for its complete decomposition. The overall processing system for thermal plasma aided material synthesis has the following additional advantages:

1) in a reverse polarity, plasma flows become more turbulent because of the chaotic motion of cathodic arc root at the torch exit, and mixing of reactants with hot plasma gases are significantly enhanced.
2) the hot graphite cathode wall provides a high-temperature environment in the injection region of feedstock in contrast with a water-cooled cold copper cathode.
3) the direct injection of feedstock inside the graphite electrode region usually results in an increment of arc resistance and the corresponding arc power subsequently rises by about 20 ~ 40 %.
4) a strong electric field (~ 10^5 V/cm) near the cathode region is formed and it is considered as an important factor influencing the growth mechanism of self-assembled carbon nanostructures.

The material properties of the produced carbonaceous materials are analyzed by field emission scanning electron microscope (FE-SEM, JEOL, JSM-6330F), transmission electron microscope (TEM, JEOL, JEM-1010), X-ray diffraction (XRD, Bruker, D-5005) and static gas adsorption techniques of Brunauer-Emmett-Teller (BET).

3. Experimental results and discussion

3.1. Methane decomposition experiments

The synthesis experiments for CNSs are performed with a DC power of about 48 kW and argon is used as a plasma forming gas. For the stable generation of plasma jets, the Ar flow rate of 140 slpm is kept constant and the CH_4 gas of 20 slpm is introduced into the plasma in the cathode region without addition of any catalyst. All experiments are conducted under an atmospheric pressure environment with the reactor pre-heated for 8 minutes.

Figure 2 shows the temporal evolutions of reactor temperature and arc voltage measured during the methane decomposition experiments. Just after injection of methane at 8 min, the reactor temperature drops a little, but recovers its original value in several minutes. Since the temperature is measured at the entrance of the quenching chamber (z = 500 mm from the torch exit), the maximum temperature measured here is somewhat low (800 K) compared with that at the torch exit. As expected in the torch design, the arc voltage increases rapidly from 140 V to 220 V after methane injection, and eventually has a saturated value of 180 V. Therefore, the relevant arc power rises by about 40 % without increasing arc current. For a 12-minute operation, a few tens of grams of carbonaceous materials are collected from the cyclone and the bag filter.

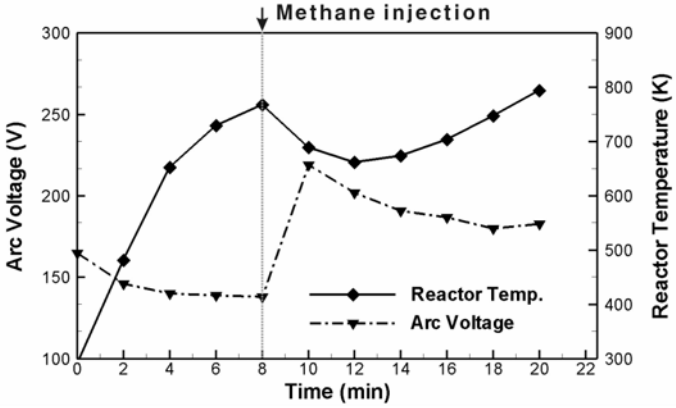


Fig. 2. Changes of reactor temperature and arc voltage measured with time during the methane decomposition experiments when methane injection of 20 slpm starts at 8 min after the torch ignition (arc current = 250 A).

3.2. Material property analyses on the produced carbonaceous materials

The morphological properties of the produced carbonaceous materials are investigated by FE-SEM images. As clearly seen in Fig. 3, the main products solely consist of a large number of individual CNSs, which are randomly oriented and interlaced each other. The width and height of the produced CNSs ranges from 100 nm to 150 nm. The thin edges of the CNSs are also clearly identified from their FE-SEM images and the average thickness of the CNSs is estimated to be less than about 10 nm from Fig. 3(b). Since most of the CNSs prepared from CVD methods are usually grown on the substrates for a long processing time, they resemble vertically standing walls [2]. But in the present thermal plasma process, the CNSs grow primarily in the free space and then they are stacked in the collection chamber. Therefore, the overall features of the final products look like a coral as appeared in Fig 3(a).

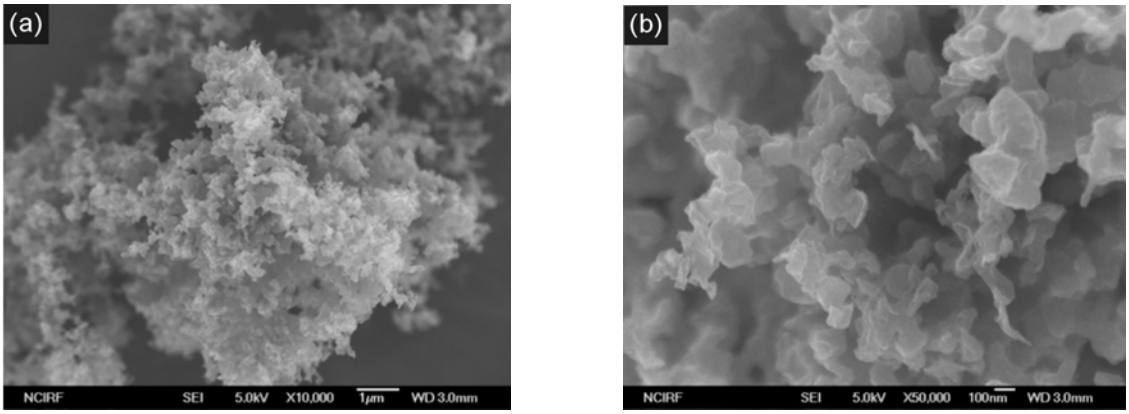

Fig. 3. FE-SEM images of the carbon nanosheets (CNSs) produced by the DC thermal plasma process.

Figure 4 is the TEM images showing micro-structures of the individual CNSs synthesized in this work. The dark fringes observed in the TEM images indicate the graphene layers of the CNSs and represent the cross sections of the planar surfaces of the CNSs. The observed graphene layers are parallel to the adjacent ones and stacked orderly along the c-axis (crystallographic axis) with a uniform interval. Thus it is certain that the CNSs possess well-aligned graphitic structures. The thickness of the stacked graphene layers ranges from 5 nm to 15 nm and its average value is estimated as about 10 nm from a partially enlarged image in Fig. 4(b). The other surfaces perpendicular to the c-axis are transparent in the TEM images, which reveal indirectly that the thickness of the produced CNSs are very thin.

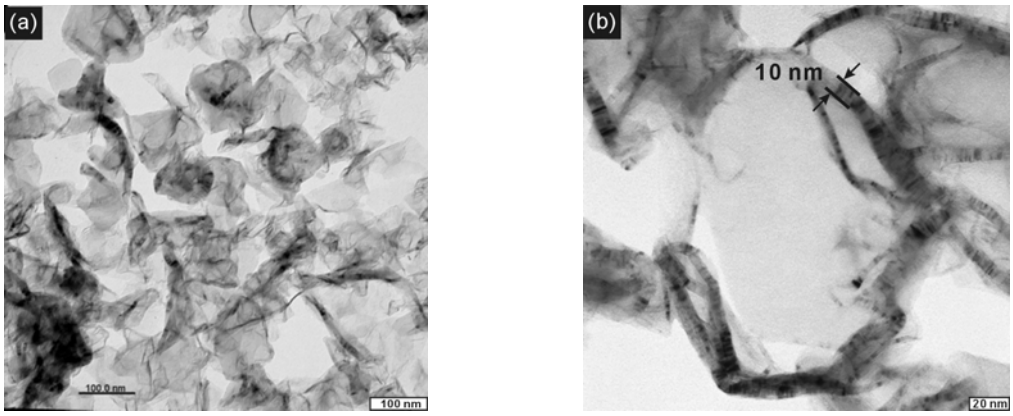

Fig. 4. TEM images of the carbon nanosheets (CNSs) produced by the DC thermal plasma process.

The micro-structural properties of the CNSs are further investigated using an XRD method and Fig. 5 shows the typical X-ray diffraction patterns of the produced CNSs. From the reflection peak of a (002) plane, the interplanar distance (d_{002}) of the (002) plane is calculated as 3.44 Å, which is very close to that of bulk graphite (3.35 Å). As a first-order approximation, the crystallite size (L_c) of the individual CNSs is also calculated as 10.6 nm by the Debye-Scherrer formula. These results are well consistent with the previous SEM and TEM observations, in which the average thickness of the CNSs is found as 10 nm. It is concluded from the XRD analysis that the produced CNSs are strongly graphitized with a high degree of crystallization. Since a good crystallinity usually provides higher electrical conductivity, the synthesized CNSs are expected to have a great potential for conductive applications such as electrical cell. Moreover, the internal structures of the CNSs consist of the well-ordered graphene layers, which are known as one of the toughest two-dimensional structure. Thus the products would be more robust and versatile in practical applications compared with other one-dimensional structures like CNTs and nanofibers.

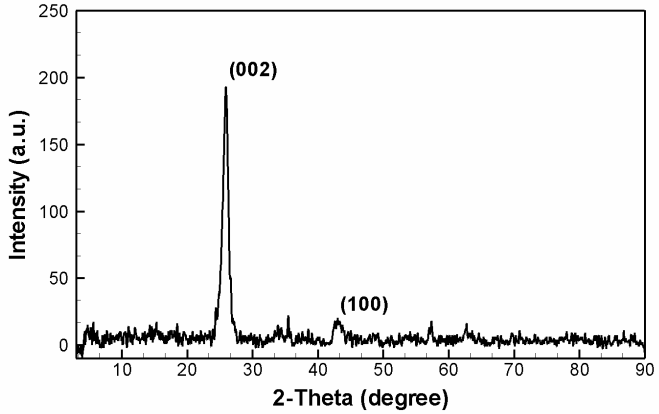

Fig. 5. X-ray diffraction (XRD) patterns of the produced carbon nanosheets (CNSs).

From the morphological structures of the CNSs observed in the previous FE-SEM images, it is expected that the produced CNSs have a larger specific surface area because of their corrugated sheet-like features. A standard BET with nitrogen adsorption test is carried out for determining the specific surface area of produced CNSs, which turns out to range from 41.5 to 48.4 m^2/g much higher than those of natural graphite (1.7 ~ 6.0 m^2/g) and exfoliated graphite sheets (24.1 m^2/g). Therefore, this synthesized material can also serve as a good conductive catalyst in various practical applications for improving performance of other functional materials.

In order to find effects of torch input power conditions on the formation of CNSs, a series of experiments have been conducted with three different levels of input power as listed in the Table 1.

Table. 1. Various torch operation conditions for methane decomposition experiments.

Input Power (kW)	Current (A)	Avg. voltage(V)	Argon (slpm)	Methane (slpm)
16 kW	100	161	120	20
32 kW	180	179	130	20
48 kW	250	193	140	20

Figure 6 compares the morphologies of the various carbonaceous materials synthesized under the different power conditions. As clearly seen in the images, the sizes of the products are reduced as the input power decreases. In the low power condition, the plasma temperature is considerably cooled down by injection of cold methane gas. Under such a low temperature condition, the growth or graphitization process of the carbon materials is not significant and most of the products remain as tiny carbon particles having a turbostratic structure. As the input power increases, however, the sizes of the products become larger due to a long residence time of the reactant in the high temperature region, and the morphologies of the products also change from a spherical shape to a two-dimensional sheet-like one. The differences among the reaction products are apparently appeared in the following TEM image in Fig. 7.

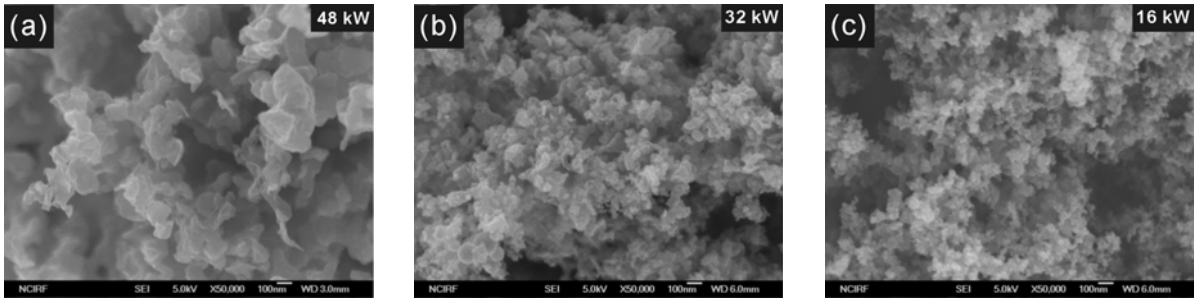

Fig. 6. FE-SEM images of the carbonaceous materials synthesized under three input power conditions.

Two kinds of carbonaceous materials, A and B, are found in the TEM image of Fig. 7, and they seem to be synthesized under different torch conditions of low and high powers, respectively. The fine spheroidally shaped particles (marked as ‘A’, 20 ~ 30 nm in size), which used to be typically observed in the TEM images of the conventional carbon blacks (CBs) [5], are fused together to form a chain of particles. The foregoing images of the CNSs, shown in Fig. 4, are also observed in Fig. 7 marked as ‘B’. It is believed from the above results that carbon atoms are likely to be synthesized into spherical CBs (i.e., isotropic and quasi-amorphous structure) under a low temperature condition. On the other hand, in a high temperature condition, carbon atoms grow into highly crystallized CNSs, which exhibit strong anisotropies in their structural dimension and physical property.

The anisotropic growth mechanism of CNSs under thermal plasma environments is a very interesting and curious aspect to be closely examined. In the present thermal plasma processing system, there is no asymmetric source affecting the direction of carbon atoms growth, while in the conventional CVD method, biased electric fields and catalysts are usually provided in order to guide an anisotropic growth of carbonaceous materials [2]. Wire-shaped CNTs are also observed in the carbon deposits collected from the inner surface of the graphite cathode as shown in Fig. 8.

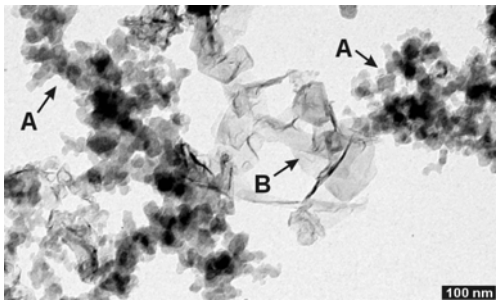

Fig. 7. TEM image of coexisting carbon blacks (A) and carbon nanosheets (B), which seem to be synthesized under different power conditions of the plasma torch.

The CNTs are well-aligned in one direction and considerable carbon flakes (i.e., sheet-like carbon) are observed nearby the roots of the CNTs as well. During the thermal plasma process, the cathodic arc root is attached to the cathode inner surface, which is then exposed to high temperature and high velocity of thermal plasma flows. Thus it can be conjectured that the high temperature and directional plasma flows inside the graphite cathode may contribute to the anisotropic growth of the carbonaceous materials. From such a physical reasoning, an external injection of hydrocarbons near the torch exit into the turbulent and relatively low-temperature plasma jets normally results in a synthesis of CB-like carbonaceous materials [5].

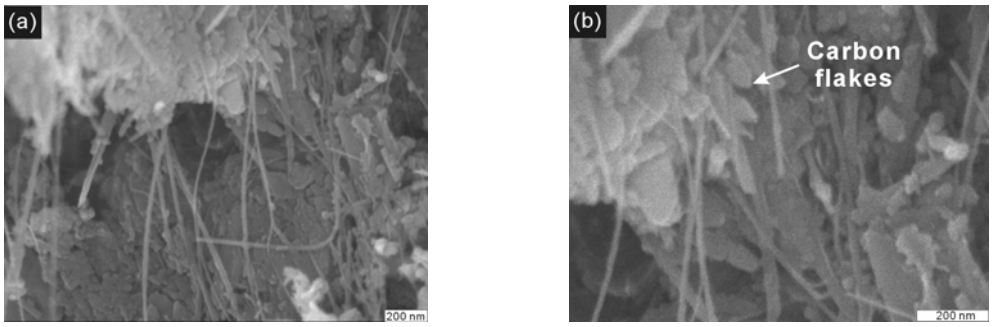

Fig. 8. FE-SEM images of the carbon nanotubes (CNTs) and carbon flakes synthesized inside the cathode.

4. Conclusion

A new DC thermal plasma processing system has been developed to make an attempt to produce high quality CNSs in a continuous manner. In the experiments, randomly distributed CNSs with thin edges are successfully synthesized from methane decomposition using the new processing system. The synthesized CNSs exhibit high degree of crystallization and possess high specific surface areas as well because of their corrugated sheet-like features. Thus the CNSs are expected to have better electric conductivity and adsorption capacity, which are very attractive features for various industrial applications such as energy storages and fuel cells. Though the detailed growth mechanism of CNSs in the thermal plasma environment is not ascertained, high temperature atmosphere and strong directional flows inside the electrodes may play an important role in the formation of CNSs. Finally, the results of various material analyses indicate that the DC thermal plasma process developed in this work will be very effective for the mass production of CNSs with the advanced properties.

Characterization of microhollow cathode discharges

B. N. Sismanoglu and J. Amorim

Departamento de Física, Instituto Tecnológico de Aeronáutica, Centro Técnico Aeroespacial, 12228-900, São José dos Campos, SP, Brazil.

Abstract

This work is devoted to the study of the electrical characteristics of microhollow cathode discharges (MHCD) at moderate to high-pressure in argon for different geometries. Experiments have been performed to determine the so-called Paschen's curves, that is, the dependence of the breakdown voltage on the product between the electrodes gap and gas pressure (p*d*). Using MHCD, stable discharges could be ignited for pressures ranging from 12 to 800 Torr, in a very wide range of current densities and electrodes materials.

Keywords: microhollow cathode discharges, breakdown, moderate pressure non-thermal plasma

1. Introduction

A microhollow cathode discharge device (MHCD) consists of a metallic cathode with a hole in the center and an arbitrarily shaped metallic anode, separated by an insulator (mica in our case). When a discharge is ignited in such a configuration, the negative glow is spatially confined in the cathode cavity. The electric field in this region creates a trough, which is responsible for the strong acceleration of the electrons. It may cause an oscillatory motion of the electrons in the cavity (pendulum electrons), between the two opposite cathode fall regions. These pendulum electrons can undergo many ionizing collisions with the background gas thus creating a high-density plasma which emits intense radiation [1,2]. Secondary electrons emitted from the cathode area come to enhance this phenomenon. The range of discharge operating pressure varies inversely with the hole diameter *D* of an MHCD. For atmospheric-pressure operation the hole diameter must be in order of $100\mu m$ [3].

Such micro discharges are in the category of non-thermal plasma, $T_e >> T_i$, and its low operation cost, allied to small size and low power consumption, is an attractive to the plasma applications possibilities in industry, like surface treatment, generation of UV and VUV radiation, reduction of pollutants, gas lasers, biological decontamination, thin film deposition, mainly in a high pressure operation. Microplasmas can be generated in a high-pressure operation, in accordance with the White-Allis similarity-law, in rare and molecular gases or in air. In argon gas operation, for example, an MHCD with hole size of about $200\mu m$ lead the operation of discharges at pressures of about *1000 Torr* [3].

2. Experimental set-up

The electrodes of our open MHCD are made of 100μm thick molybdenum or cuprum foils separated by a $250\mu m$ spacer of mica with holes from *200* to $700\mu m$ (diameter) through cathode, dielectric, and anode. A closed MHCD in a cathode plane geometry (for anode hole diameters smaller than 700μm) were also used in these experiments. Supply voltages were typically between *250 V to 700 V* and sustaining glow (discharge) voltages were in the range of *200 V - 400 V* for Ar. Discharge currents I_{DIS} varied between *0.1mA* and *8.0 mA*. The experiments were performed for an (*pD*) interval between 0.24 and 56 Torr cm. The operating gas was moderate to high-pressure Ar, between *12* to *800 Torr*. The electrode system is placed in a cylindrical quartz chamber with *10 cm* diameter and *16cm* length. Before each experiment the chamber was cleaned, dried and evacuated to about *1mTorr*. After that, was filled with pure argon gas (*99.995%*) and placed at the desired pressure. A series of $47K\Omega$ resistors were used to limit the discharge current. Experiments with

atmospheric air were also developed. A digital camera was used to record the appearance of the glow discharge.

3. Experimental results

In Fig. 1 is shown the evolution of the current with voltage applied to an open MHCD in Ar, DC operated when current and pressure were varied. In these curves the normal and subnormal mode of glow discharge is observed.

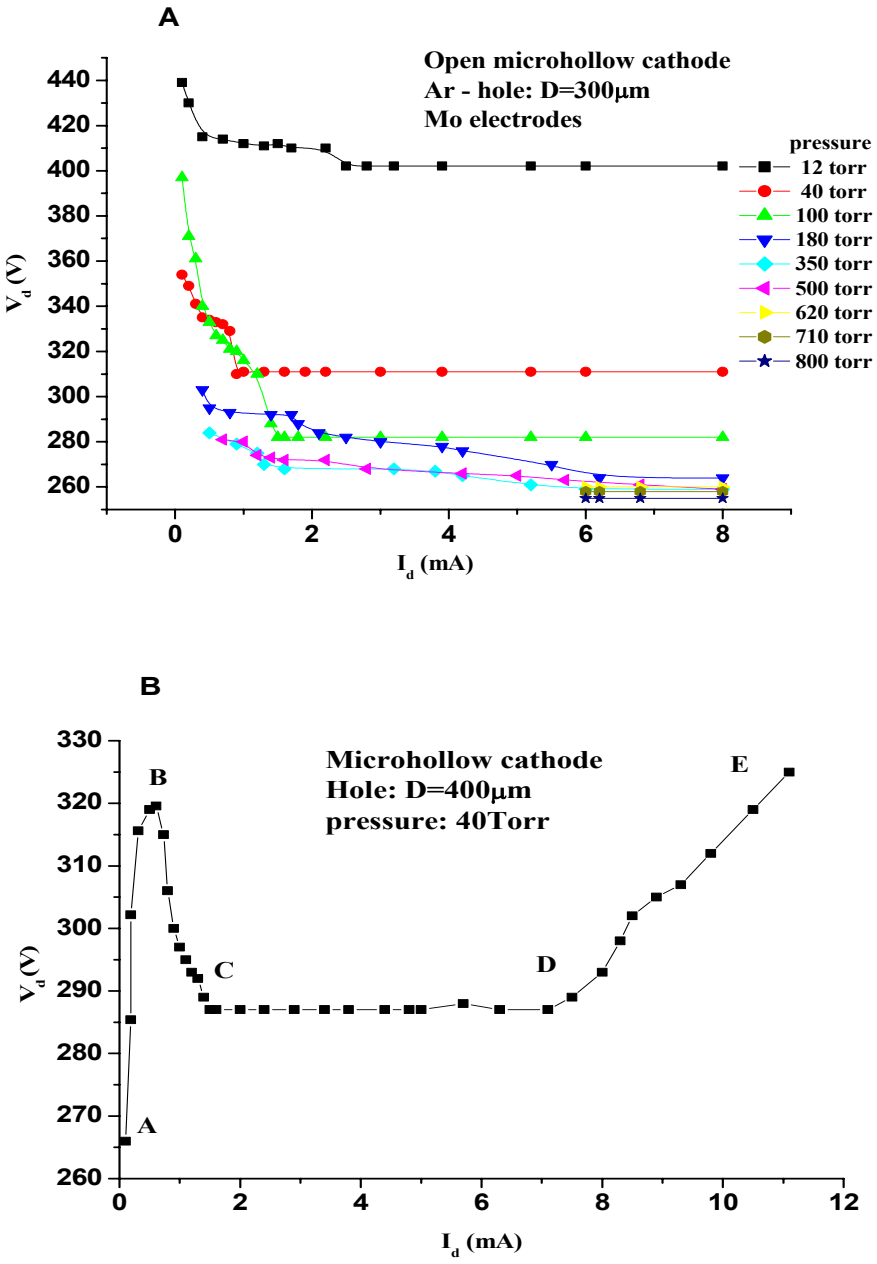

Fig. 1. (A) V-I characteristics for open MHCD operated in Ar with hole diameter of *300μm* at various operating pressures. (B) V-I curve for a hole diameter of *400μm* at *40Torr*.

Fig. 1A shows V-I characteristics of an open MHCD in Ar in the pressure range of *12 – 800 Torr*. As pressure increases, the sustaining voltage decreases due to more favorable conditions for ionization.
Fig. 1B graphs, the Townsend discharge mode (AB region) in low current and a positive differential resistance followed by a hollow cathode mode (BC region), were a drop of the voltage follows from the amplification of DC discharge current. In this region is established the hollow cathode effect in the cathode cavity. The confinement of the discharge inside the hole can be seem by the optical appearance of the glow. With the increasing of the discharge current, one can observe the gradually expansion beyond the cavity covering the cathode surface. The normal glow discharge mode, with constant voltage and increasing current (CD region) precede the anomalous glow discharge (DE region), where a positive slope in the current-voltage characteristics is observed. We, generally, avoid the abnormal mode of operation, beyond *10mA* due to overheating of the sample. On the other hand, limiting the cathode surface, the positive slope in I-V curve is always present. A closed microhollow cathode consists of a metal-insulator-metal device with a blind hole in the cathode surface.

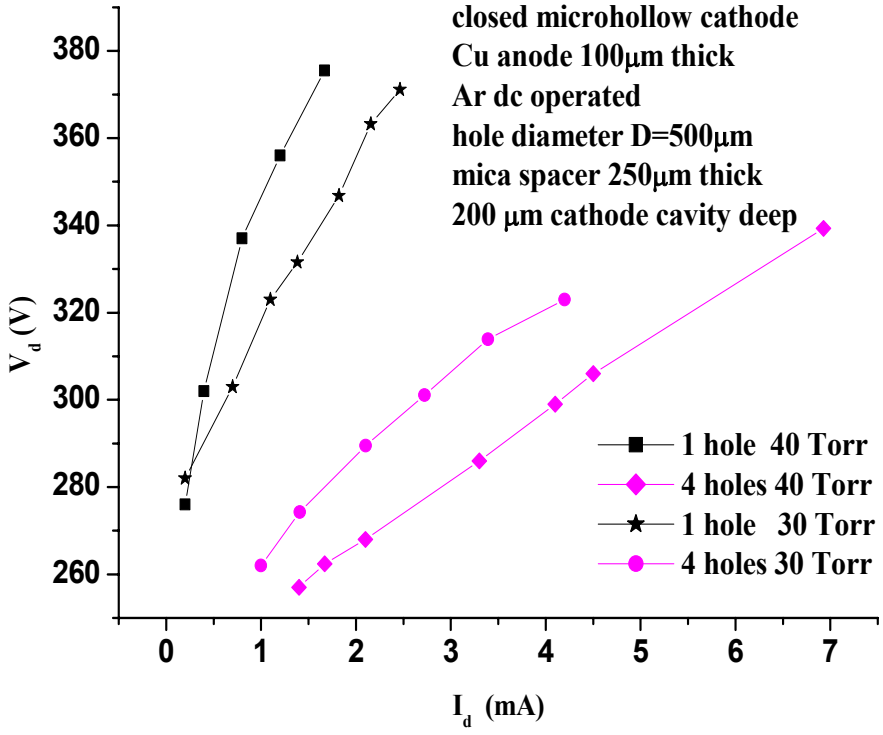

Fig.2. V-I characteristics for closed microhollow cathode DC operated in Ar, with hole diameter of *500μm* at a pressure of *30* and *40Torr*, for *1* and *4* holes (parallel operated).

In this configuration a positive slope is observed in V-I characteristics and a parallel operation is possible (Fig.2). Here, the plasma serves like a resistor of approximately *15KΩ* at a pressure of *30 Torr*. In this case the plasma was ignited in a four holes plate in Ar dc operation. With an increasing of the pressure, keeping V_d constant, a higher current is needed to maintain the glow lightening in all holes. We can limit the cathode area covering it with an insulator [4]. This way, in open microhollow cathode configuration, a jumping to abnormal mode is observed after gas ignition occurs. Here again, a parallel stable operation is possible without ballasting the individual discharges. Fig. 2 shows the I-V curve for MHCD operated with one and

four holes. As can be seen, the positive slope of I-V curve is present in both cases. In four holes operation the sustaining voltage is reduced for a given discharge current.

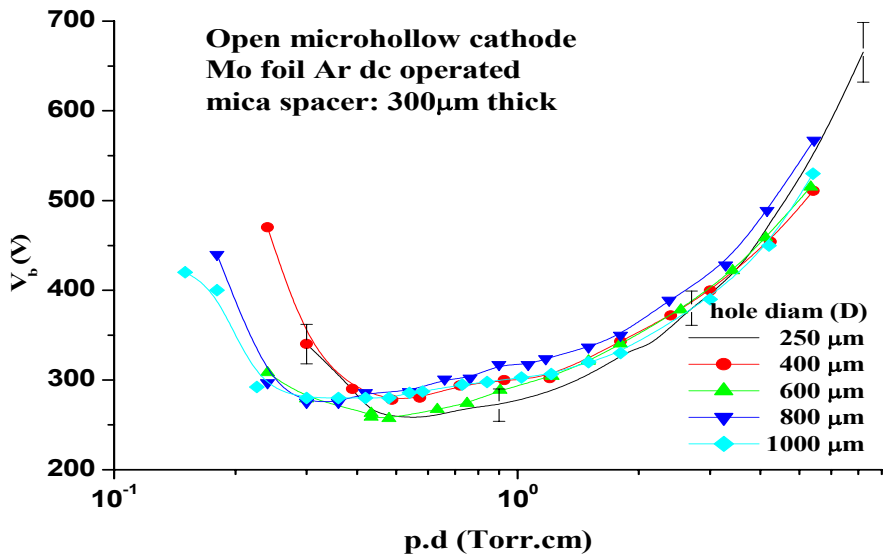

Fig. 3. Paschen curve for microhollow cathode discharge for various hole diameter.

To obtain the Paschen curve of the MHCD, large load resistors were used to limit the discharge current, and hence assuming a Townsend mechanism of breakdown. In Fig.3 shows Pashen's curves for various hole diameters, for MHCD with mica spacer d = *500μm*, in Ar DC operation. According to the Allis-White similarity law, the *pD* product is in the rage of 1 to 10 Torr cm, for hollow cathode operations. The different size holes MHCD does not change very much the breakdown voltage for pd greater than 0.3 Torr cm.
Figure 4 presents Paschen´s curves for MHCD´s constructed with different materials. Aluminum is the material that favors the operation at lower voltages while nickel and molybdenum needs high voltages for breakdown.

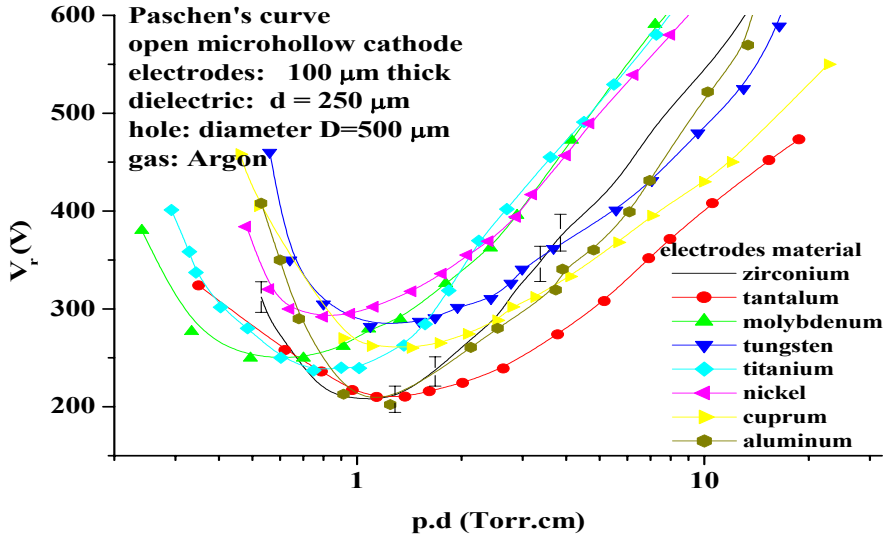

Fig. 4. Paschen´s curve for microhollow cathode discharges for different cathode materials.

Mechanically drilled holes has non-uniform opening surface, with incorporated micro-protrusions in it. This, allied with the cathode surface roughness, and for a small gap spacing (of several microns) between electrodes (mica thickness), induces phenomena of electron field emission and tunneling. For this gap, the macroscopic electric field becomes very large and the field emission may be responsible for the breakdown in low pressure operations, instead of Townsend electron avalanche mechanisms.

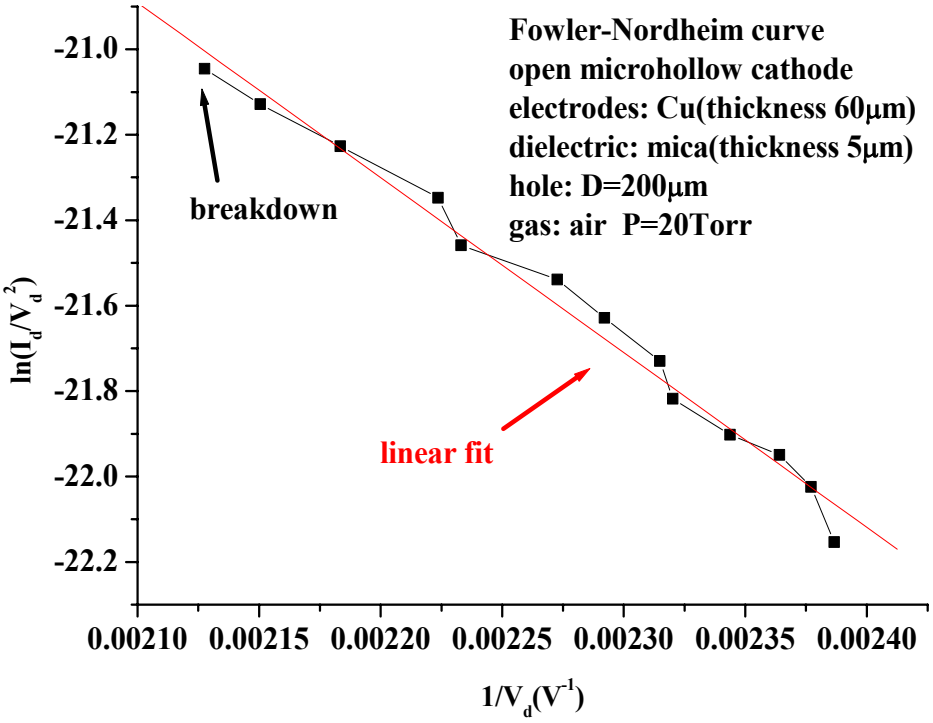

Fig. 5. Fowler-Nordheim plot for $5\mu m$ gap device, near breakdown.

One can use the Fowler-Nordheim equation and obtain a microscopic electric field just above the cathode surface to observe this quantum phenomenon. The total current I_d is given by $I_d = (\lambda a S F^2/\Phi) \exp(-\mu b \Phi^{3/2}/F)$, were a and b are universal constants given by $a = 1.5414.10^{-6} A\ eV\ V^{-2}$ and $b = 6.8309\ eV^{-3/2}\ V\ nm^{-1}$[5], λ and μ are generalized correction factors, Φ is the work function for the relevant point of the emitting surface, $F = \beta E$ is the microscopic electron field, for a field amplification factor β. The I-V curve was plotted for microhollow cathode, in air discharge operated at *20 Torr*, Cu cathode with a single $200\mu m$ diameter hole and a very thin mica spacing (about $5\mu m$) the electrodes. In figure 5 a straight line, with negative slope, was obtained when $ln(I_d/V_d^2)$ is plotted versus V_d^{-1}, a so-called FN plot, for this device configuration. It was employed $\Phi = 4.6\ eV$ for Cu electrodes, which lead us to obtain $\beta = 80$ and $F = 10V/nm$, which is a good value for a local microscopic field needed to start the field emission.

4. Conclusions

The V-I characteristic of the open MHCD (Fig. 1) was measured and found to be similar to the well-known characteristic of a low-pressure glow discharge, showing different modes of operation. At low current it

presents a Townsend mode followed by a transition to a normal glow discharge. The Townsend discharge is characterized by small current (typically less than *0.5 mA*). The charge density in the hole is low and does not disturb the electric field between the electrodes, which is in this case mainly axial oriented. Increasing the current, the axial electric field begins to be distorted by the space charge accumulated inside the cathode and a strong radial electric field develops. The potential distribution in the gap becomes strongly non-uniform and the cathode fall is generated. The enhanced electric field at the cathode facilitates ionization processes and correspondingly a fall in the sustaining voltage and a rise in the current is observed [3]. The discharge concentrates inside the hole.

The breakdown voltage depends on the nature of the gas at the same pd product. A Paschen's curves are given in Fig. 4 for open MHCD´s. All of that have the well-known Paschen curve "U" shape. It can be seen that in the region of the minimum, for Cu and Mo electrodes in Ar gas operation, the breakdown voltage and the $(pd)_{min}$ product are in reasonable agreement to the ones found in literature [1]. However, in microhollow cathode operations, as in low pressure hollow cathode operations, the left-hand Paschen's curve is shifted to a lower breakdown voltage, compared to a plane-plate glow discharge. This is in accordance with the hollow cathode effect, due mainly to the "pendulum electrons", which ionizes more efficiently, in low pressures, compared to a glow discharge. Due to micro protrusions existing around the opening hole there is an enhancement of the local electric field, lowering the breakdown voltage. This high local electric field can emit electrons by tunneling or field emission process, and for small gaps, be the responsible for the breakdown process.

Sol-gel Coatings on Ambient Plasma on Polymers

Srikantha Sahu[1], Shirshak Dhali[1], Bakul Dave[2]

Abstract

Here we discuss the properties of sol-gel coatings on addition polymers treated with ambient plasma. The plasma is generated by a coaxial dielectric barrier discharge operating at atmospheric pressure in Argon or Helium carrier gas. The afterglow interacts with the surface and the ambient air. Contact angle measurements and peel strength measurements were done to study the effectiveness of plasma treatment.

1. Introduction

Radio frequency (RF) plasma treatments at low pressures have been employed to improve the surface properties of commodity polymers, increasing the range of potential applications for these materials. In applications were adhesion is important, the required treatment need not be specific. However, in applications involving biomaterials, the treatment would be very specific. The reactive species in plasma, resulting from ionization, dissociation, and excitation processes, include positive and negative ions, neutral species, atoms, metastables, and free radicals. Inductively coupled inert gas plasmas, that are commonly used in these applications have species with a broad range of energies: Plasma components include ions (10-30 eV), electrons (0-10 eV), and UV and vacuum UV radiation. In reactive gas plasmas such as oxygen, ablation or etching occur, resulting in the formation of small volatile degradation products. In inert gas plasmas, the dominant process is hydrogen abstraction [1].

Plastics constitute the majority of engineering materials due to their versatility and applications. While the plastics offer major advantages in terms of cost-effectiveness, ease of forming different shapes and architecture and their compatibility with traditional materials, the plastics suffer a serious drawback in comparison to ceramics when it comes to optical and mechanical properties as well as long term degradation due to thermal and UV radiation. Especially vulnerable in this context are the addition polymers, which mostly comprise of stand-alone architectures without any protective coatings. Design of suitable coatings that can seamlessly integrate with the polymer structures during post-processing steps can not only confer stability against environmental factors but also provide value-added benefits to vast applications field of plastics in general.

At low pressures, the ions will play an important role in the interaction causing polymer degradation and crosslinking [2]. In atmospheric pressure discharges, the role of ions is not important, whereas metastables and radical chemistry becomes important. Choi et al have shown that the metastable He^* in a helium discharge is capable of scission of polymers in a polypropylene surface [3].

From a manufacturing point, ambient plasmas operating at atmospheric pressure is desirable compared to low pressure confined processing. We have used ambient atmospheric pressure plasma to treat polymer surfaces prior to sol-gel coatings. The contact angle measurements and peel test indicate improved adhesion. However, these plasmas are very different from

low pressure plasma commonly used for polymer treatment. The energetic ions are absent and most plasma chemical reactions are based on neutral chemistry.

At atmospheric pressures, essentially there are two methods for producing non-thermal plasmas; (1) a corona discharge and (2) a barrier-type ac discharge. The dielectric-barrier discharge, also known as a silent discharge or a partial discharge, is widely used in industry for ozone synthesis. This discharge is intermittent and the current exhibits a large number of spikes when the discharge is burning. Experimental investigations in atmospheric air have

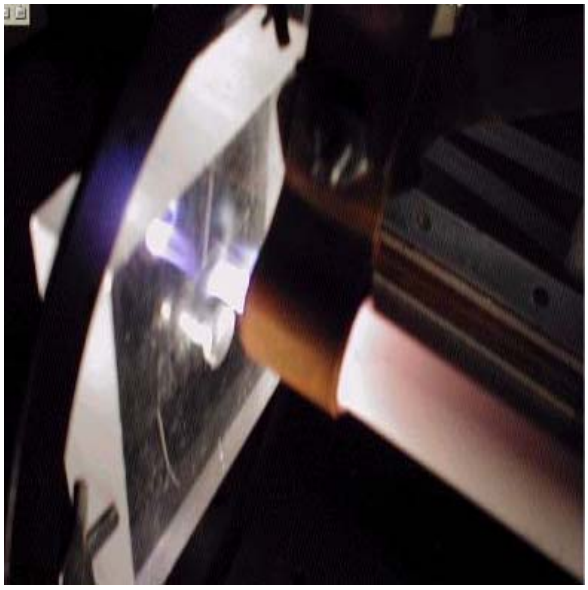

Figure 1: Picture of an RF ambient plasma treating a sample of plastic

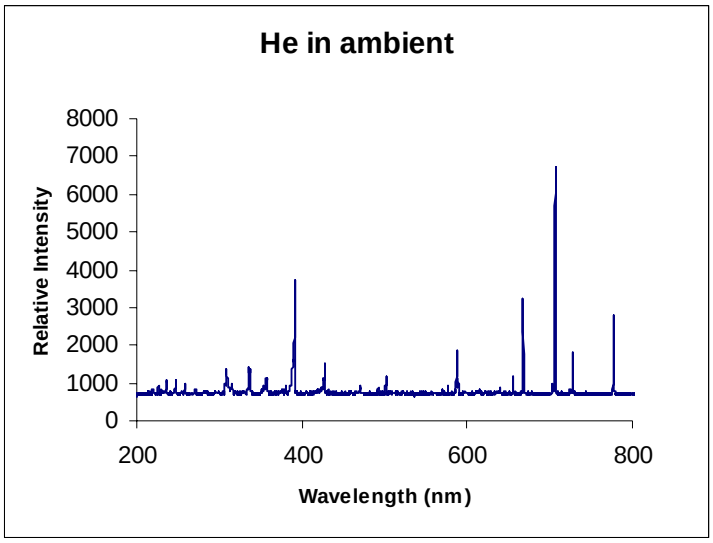

Figure 2: Optical emission spectra of He afterglow in ambient air.

demonstrated that current flows on a large number of partial discharges. These partial discharges are best characterized by streamers, which are a result of space charge dominated transport at high electric fields [4].

2. Results and Discussions

Shown in Fig. 1 is the picture of atmospheric pressure plasma treatment of a sample of plastic. In the configuration shown, the discharge is "struck" in a noble gas (Argon) and the reactive gas is added in the afterglow. The centered electrode is bored to allow the reactive gases to flow into afterglow. This is critical for the stability of the discharge: Gases like H_2 and O_2 are attaching and change the physical characteristics of the discharge. Due to increase in breakdown voltage, even for concentration of reactive gases in few percentages, it is difficult to strike a discharge using radio frequency (RF). From our experience, RF is the most suitable power source because it can be tuned to the load easily compared to low frequencies. The plasma is an afterglow and is not confined between electrodes like conventional plasma. This has the advantage of treating blind holes and difficult to reach areas of molded parts. This type of a source can also be mounted on a robotic arm with proximity sensors. The plasma has both convective and diffusive flow. The force of the gas flow produces a directional flow and density gradient produces diffusive flow. In plasma chemical devices, the aim is to produce desired radicals to carry out a particular reaction. The main thrust for atmospheric pressure plasma for our application is the production of high-energy metastables, H and O radicals. The ambient afterglow discharge is a cold discharge with most of its energy being utilized for the production of excited species. The afterglow interacts with the ambient gas and a typical optical emission

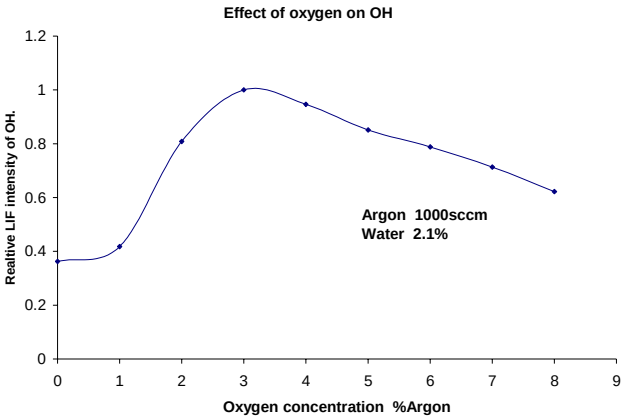

Figure 3: The relative concentration of OH for different gas composition.

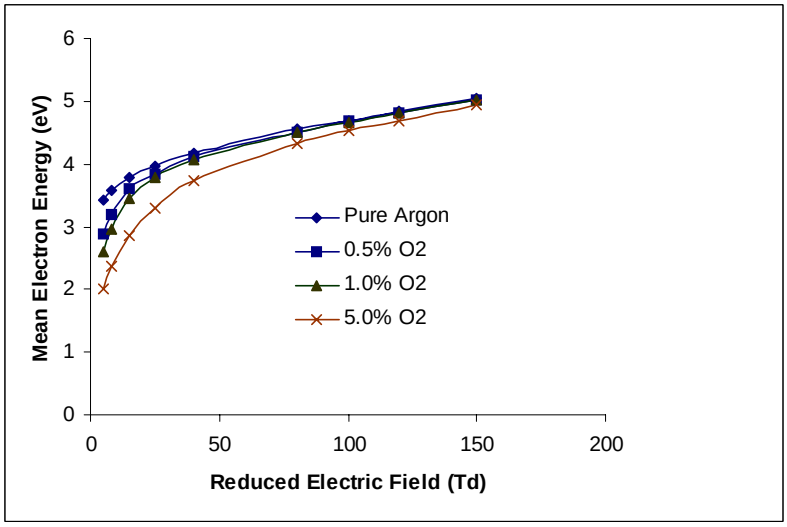

Figure 4: Calculated mean energy of different composition of Oxygen in

spectrum of the helium afterglow is shown in Figure 2. The highest peak in the spectrum is $O^*(3p \rightarrow 3s)$ at 777.2. Clearly the He metastables excite the oxygen molecules to produce excited oxygen atoms. Experimental investigation of OH radicals can be done with Laser Induced Fluorescence. Figure 3 shows the Laser Induced Fluorescence (LIF) intensity in an Argon/H_2O/O_2 discharge. The OH increases with O_2 concentration up to a certain point and then decreases due to the adverse effect of increasing O_2 concentration on the discharge.

In order to understand the influence of discharge parameters such as gas composition and discharge power on the radical concentration, a model has to be developed for the afterglow plasma. The model starts with Monte-Carlo calculations of the electron energy distribution function. The cross section data required for these calculations was obtained from the Joint Institute for Laboratory Astrophysics website (http://jilawww.colorado.edu/research/colldata.html). The electron energy distribution function is then used to calculate all electron related rates and mean electron energy, a plot of which is shown in Fig. 4. From the power and voltage applied to the discharge, the electron density and the rates can be estimated.

The use of silica-based coatings has been used to alter the properties of polymers and metals. For polymeric substrates, the silica-based coatings have been largely through the use of chemical and/or physical vapor deposition processes. The films of silica and other oxides modify the properties of plastics such as optical properties including anti-glare, anti-reflection, permeability of gases, and to protect food products from oxygen. The coatings in these applications have focused on nonporous silica or oxides layers deposited using high energy curing process. On the other hand, liquid phase deposition of silica layers on plastics has also been accomplished using hexafluorosilicic acid as means to enhance their optical properties. The use of sol-gel methods using alkoxysilane precursors requires polymeric substrate that can exhibit covalent or hydrogen bonding with silicate species. With hydrophilic polymers such polyester sol-gel coatings can be deposited directly due to interactions of silicate species with the polymer. However, with addition polymers such as polyethylene, polypropylene, and polystyrene, which only contain hydrocarbon chains, the deposition of sol-gel coatings usually requires pretreatment of the polymer surface for

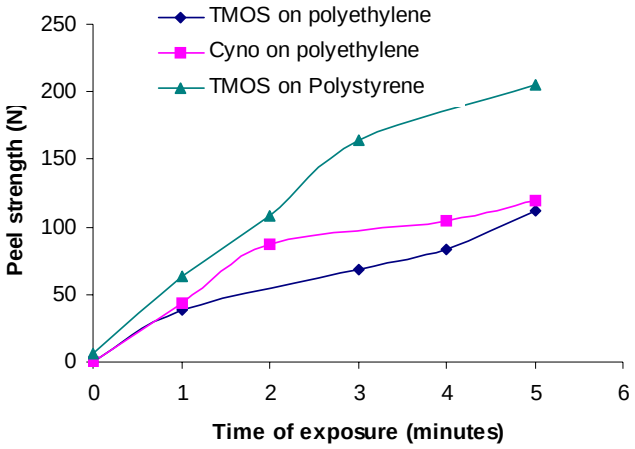

Figure 6: Peel strength of sol-gel coatings on polyethylene and polystyrene.

adhesion. The use of plasma to activate the surfaces of such polymers has been shown to facilitate the deposition of sol-gel overlayers [5].

The sol-gel process is a low temperature solution-based method for making ceramic oxide glasses such as SiO_2, SnO_2, TiO_2, V_2O_5 etc. In the sol-gel process, a suitable precursor (usually an alkoxo or chloro complex) is hydrolyzed to generate a solid-state polymeric oxide network. Initial hydrolysis of the precursor generates a liquid sol, which ultimately turns to a solid porous gel. The procedure involves formation of glass from a solution phase, and considerable flexibility in inorganic, organic, or biological modification of the resulting material is possible [6].

The afterglow interacts with the surface and the ambient air. In such plasmas, optical emission spectroscopy shows the presence of excited oxygen molecules and oxygen atoms [7]. The surface modification can occur by oxidation of plastic surface with the oxygen radicals available in plasma of atmospheric pressure. Hydroxyl-(-OH-) AND KETO-(=O) groups formed in the surface act as anchor points for chemical reactions with the ink and adhesive. The oxidation of the surface leads to an elevated surface energy level and in most cases increased adhesion. The increased surface energy due to plasma treatment is indicated by the lowering of contact angle with treatment time as shown in Figure 5.

The treated samples were coated with various types of sol-gels. Figure 6 shows the 180 degree peel strength of coatings with exposure time. The peel strength increases with increasing treatment time. However different sol-gel coatings show different behavior depending on the substrate. The cyno- precursors did not form coating on polystyrene even with plasma treatment.

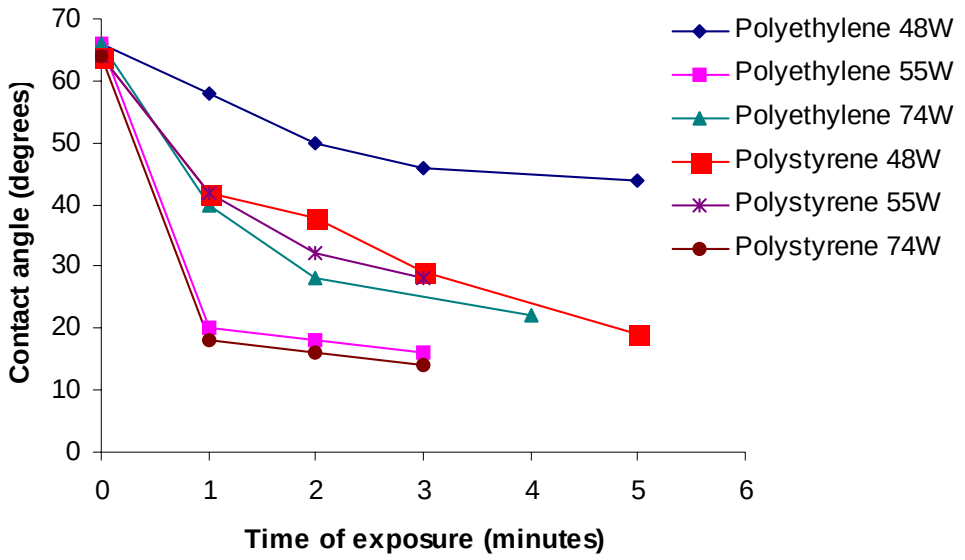

Figure 5: Contact angle of Polyethylene and polystyrene for different exposure time as a function of input power.

3. Conclusions

The experimental results indicate that surface treatment of addition polymers improve the hydrophilic properties of polymer surfaces and produce improved adhesion of sol-gel coatings.

This work was partially supported by a grand from the National Science Foundation.

Destruction of dichloromethane by thermal plasma

B. Bournonville, D. Guenadou and E. Meillot

CEA Le Ripault, BP 16, 37 260 Monts, France

Abstract
A new-patented process employing thermal plasma for the destruction of organic halogen liquid wastes is proposed. Using plasma torch as high temperature source, this safe system can destroy a great variability of wastes, even mixed together. At the exit of the process, only no-toxic compounds are produced as atmospheric gases, liquid water and halogen sodium salt. As test molecule, dichloromethane has been treated: the results show a complete destruction with reject of clean gases in the atmosphere.
Keyword: inductive thermal plasma, waste destruction, organic halogen liquid, dichloromethane.

1. Introduction

The manufacturing of numerous products from human activity generates a lot of wastes. The quantity and the variety of wastes increase with the global industry development. At the same time, environmental laws evolve and create severe stresses leading to more and more important stocks of wastes without elimination way. Then, most of gas, liquid or solid wastes must be treated, recycled or destroyed.
Destroying wastes, which cannot be easily and safety recycled, can be really feasible by combustion if these wastes do not present high temperature stability and do not imply toxic off-products after burning. Destroying toxic high-stability wastes requires high-energy processes. For this reason, thermal plasma processes, which present a high energy power and a great adaptability, have been first applied for vitrifying fly ashes from domestic waste incinerators, for example, with the EUROPLASMA process. Another application concerns also asbestos vitrifying by the same process. State of the art shows many thermal plasma processes destroying gases or vitrifying solid wastes. After solids, the second application has been to destroy gases such as ozone depleting gases. For example, the PLASCON process has been developed to remove CFC but also liquids such as dichlorophenoxyacedic (2-4 D) or oils contaminated by PCB [2]. Other plant is the one built by NIPPON STEEL CORP. in Japan to remove chlorofluorocarbons [5]. Other research papers have been proposed using different kinds of plasma [3-6].
In nuclear industry, the problem is more significant due to the adding of radioactivity. The 1991's French law, called BATAILLE law, stipulated that different ways of elimination must be explored to stock or to diminish and to store the wastes emanated from nuclear activities. That is why, the French atomic energy agency, CEA, has high interests for all new industrial treatments of diversified wastes.
To response to the directives, CEA has decided to study, in first step, chemical destruction of no-radioactive halogen organic mixed wastes in a new process based on thermal inductive plasma torch. In a first step, this process has destroyed pure organic molecules without halogen. All introduced products show a rapid and total destruction and induce the formation of no-toxic gases. These experiments validate the feasibility of the process with no halogen molecules. Then, the process has been validated with dichloromethane as an example of halogen organic molecules. This process, in progress to be patented, has been studied as an answer to elimination or reduction of nuclear waste stocks; so, its economical evaluation has not yet been performed.
The aim of this process is to destroy completely a wide range of halogen liquid wastes, pure or mixed, and to exhaust only no-toxic gases with trapping the halogen molecules as mineral salts. Its final aim is to develop a clean process for treatment of radioactive organic halogen compounds.

2. Description of the process

Thermodynamic and kinetic simulations permit the operating condition definition before experiment. To avoid formation of toxic $COCl_2$ and solid carbon (soot), hydrogen and oxygen are required in the recombination zone. They are introduced as liquid water form. Simulation predictions have shown a very fast destruction of dichloromethane and formation of simple molecules with 2 or 3 atoms (CO, CO_2, HCl, H_2, Cl) by atom recombination. To achieve oxidation of explosive H_2 and toxic CO, oxygen, as air injection, is added. This leads to no CO and H_2 left, without NOx formation.
Short description of the pilot is presented here without details due to the in-progress-patent study. Inductive plasma torch, PL 50 gun from TEKNA Inc., working with argon/hydrogen mixing, transforms the electric

energy into mainly thermal energy at the head of the reactor (figure 1). It is a double-flux gun, one in the central network of the torch (only argon), the second along the wall as sheath gas (mixture of argon and hydrogen). Air as plasma gas is not an appropriate opportunity because of NOx formation. This kind of technology presents the interest of using a wide range of gases and the introduction of compounds-to-destroy directly inside the torch, in the highest temperature zone and that, without any gun material degradation. The gases are ionized at high temperature (more than 12 000 K) as thermal plasma and flow inside the reacting chamber. This one presents a studied design to avoid cold areas, with a refractory wall. Wastes and water adding are introduced in the plasma plume at the head of the reaction chamber.
The high temperatures, allied with a long time life (less than 1 s) of the products in the hot zone, lead to vaporize and to break up completely the molecules, even the most stabilized one, in elementary atoms. The molecular flow rates of the two fluids (wastes and water) are in correlation such as the carbon and halogen atom numbers from wastes and the oxygen and hydrogen atom numbers can react following the reactions:

$$C + 2O \leftrightarrow CO_2 \qquad (1)$$

$$Cl + H \leftrightarrow HCl \qquad (2)$$

An excess of water can saturate the previous reactions. At the end of the first destruction zone, an air introduction accelerates and achieves the oxidation of carbon and hydrogen. After complete reactions, the off-gases are cleaned in a wet treatment unit with soda to trap halogen atoms, and then are cooled by a heat exchanger. Pump unit has two goals: firstly evacuating the off gases and secondly regulating the inside pressure in the process.

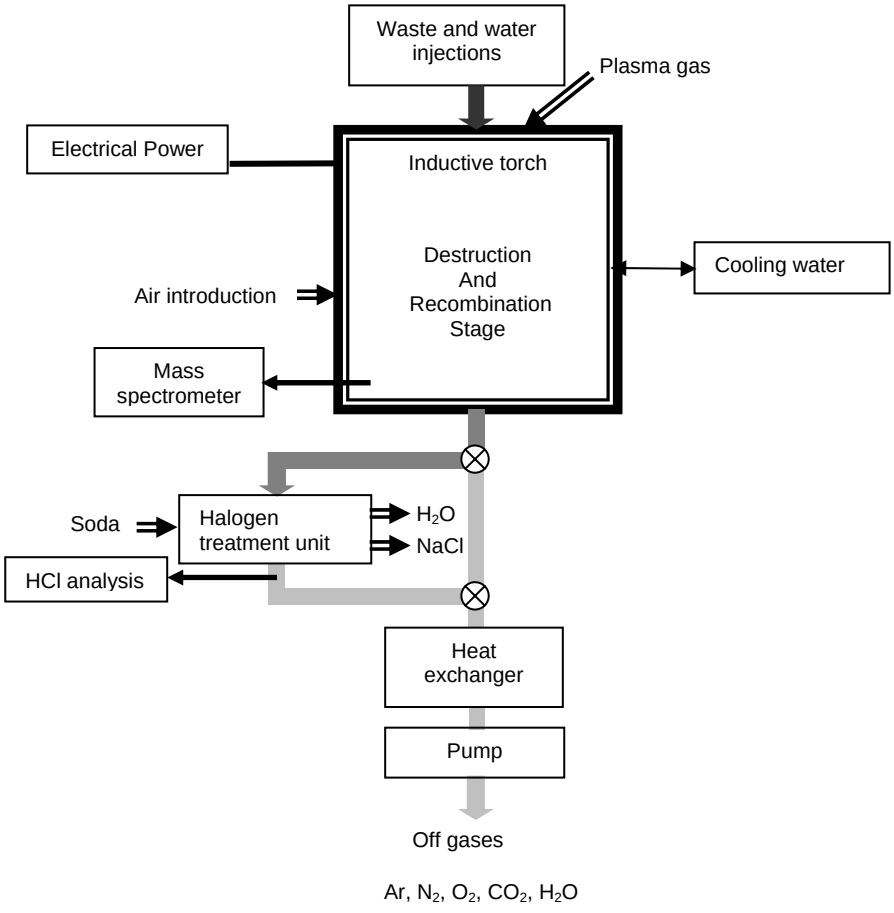

Figure 1: Simplified set-up of the process.

3. Operating conditions and analysis setup

3.1 Operating parameters

The main operating parameters are collected in Table 1. Argon and hydrogen are introduced in the torch to generate the thermal plasma. Hydrogen increases the enthalpy of the gases. The plate power is around 41 kW. Due to the rather bad thermal efficiency of inductive gun, less than 50% of the electric power is

transferred to the gases at the torch exit. The products to destroy, here dichloromethane, are injected in the plume. For dichloromethane destruction, the water flow rate ratio is depending on the equation (3). An excess of water is introduced to saturate the basic reaction in the first step.

$$CH_2Cl_2 + 5H_2O \leftrightarrow CO_2 + 2HCl + 3H_2O + 2H_2 \qquad (3)$$

Table 1: operating parameters of the process.

Parameters	Values and units
Argon central flow rate	30 slpm
Argon sheath flow rate	105 slpm
Hydrogen sheath flow rate	7 slpm
Plate power	41 kW
Additional air flow rate	200 slpm
Dichloromethane flow rate	15.8 g/mn
Additional water flow rate	17.0 g/mn
Soda initial concentration in treatment unit	7% mass
Pressure	$0.9\ 10^5$ Pa

3.2 Analysis materials

Gases are analysed at the end of reaction zone, after air introduction, by mass spectrometer (PFEIFFER VACCUM type MONISTAR GSD 300 C2). Several thermocouples measure the gas temperature, before and after air injection for example, to control the well-done oxidation reactions. Before exhaust into the atmosphere, HCl concentration measurements are realized with an OLDHAM analyser (LASERGAS 2000).

4. Results

The results are presented versus experimental time. All experimental parameters have been recorded each two minutes. Several injections have been carried out in the same test and so experiments can show the rather good stability of the process because of test duration. Dichloromethane and water feedings are represented by darkest grey zone while, before and after the injection, only water introduction is coloured in brightest grey to clean the injection system and reactor.

4.1 Gas temperature

In the destruction and recombination stage, just before air adding and without liquid injection, the gas temperature has risen up to around 1200 °C (first curve of Figure 2) when the thermal equilibrium was steady. This temperature, measured quite far from the plasma torch, is in good agreement with simulation results [1]. These results imply that the high upstream temperatures are efficient to destroy completely the wastes.

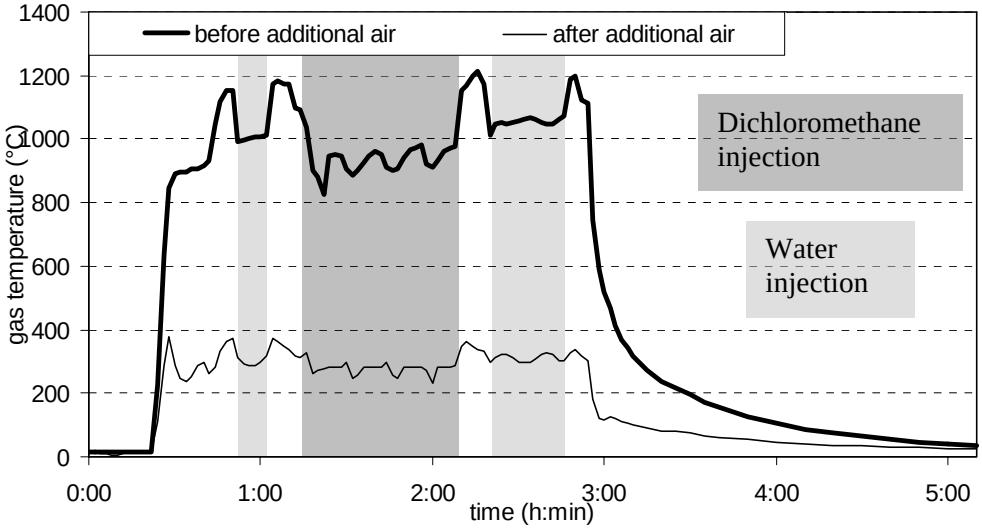

Figure 2: Gas temperature during dichloromethane injection experiment.

The only water introduction (at the flow rate of 28 g/mn) into the plasma induces a temperature drop of about 150°C (Figure 2), due to molecular decomposition, at the first step of the temperature measurement. Introducing the dichloromethane/water mixture in the process has leaded to the severe temperature drop: the temperature was less than 1000 °C during around fifty minutes after one hour and a quarter time. Although the volume flow rate of dichloromethane and water was similar than single water injection, the temperature drop during the dichloromethane injection is more important due to the endothermic reaction of the hydrochloric acid formation. After three hours experiment, the process has been stopped. The gas temperature has decreased rapidly first and more slowly in a second time: this effect is due to the energy stored in the refractory wall.
After air adding and still without liquid injection, the gas temperature has risen up to nearly 375°C (second curve on Figure 2). The curve has the same trend than the previous one with less amplitude.

4.2 Gas composition

After molecular combinations, the mass spectrometer analyses show the presence of only simple molecules: Ar, N_2, O_2, CO_2, H_2O, and HCl. No dichloromethane has been detected. Then, the destruction and removal efficiency must be very high (close to 100%).
With these analyses, following the evolution of the gas composition versus time is possible (Figures 3, 4 and 5). Some analyses have been rejected because there were incoherent, certainly due to electromagnetic interference.

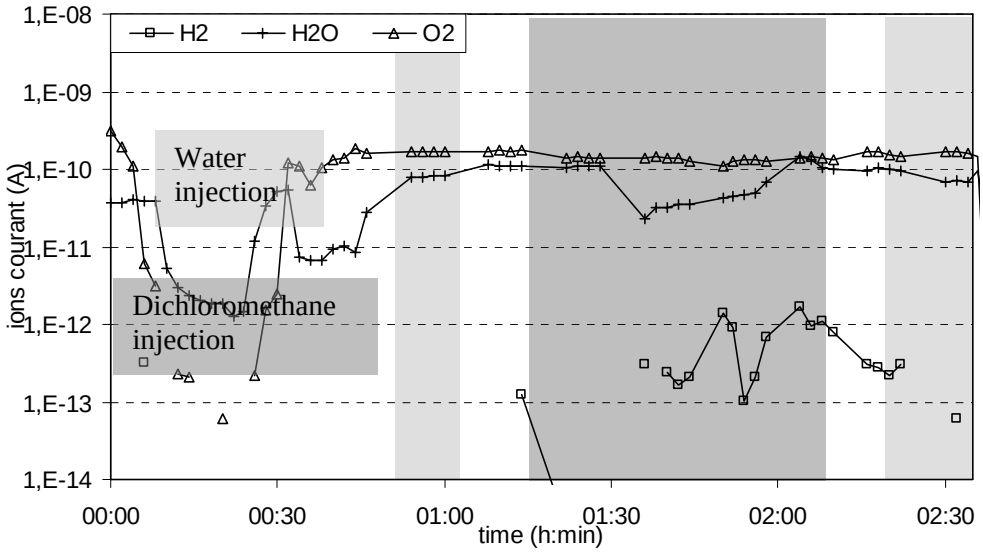

Figure 3: H_2, H_2O and O_2 composition signal during dichloromethane injection experiment.

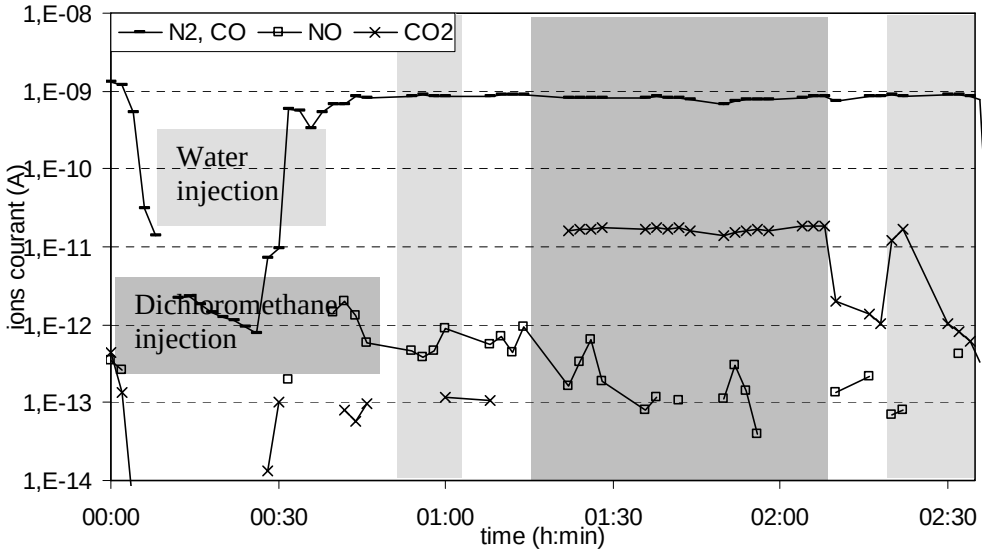

Figure 4: N_2, NO, CO and CO_2 composition signal during dichloromethane injection experiment.

In Figure 3, only H_2, H_2O and O_2 compositions are first plotted, process working. O_2 appears in excess while H_2 seems completely transformed in vapour. The water evolution is particular. The quantity of steam has increased with the beginning of the Ar/H_2 plasma. Then, in the first half of the dichloromethane injection, a notable decrease has appeared. After that, the water quantity has increased regularly until the end of the dichloromethane injection. Assumptions about water deposition by condensation on cold walls and deposit saturation could be proposed.
In Figure 4, results concerning carbon and nitrogen oxidation are presented. Firstly, if CO and N_2 are plotted together, due to similar molecular mass, this curve remains stable during plasma presence although the CO_2 line shows important increases when dichloromethane is injected. So, if the carbon oxidation has not been completely achieved, that has stayed at low level. At the beginning of the second water injection, there is a short peak of CO_2 due to the injection tube cleaning. Secondly, nitrogen oxides have left under low concentrations, process working, and so no nitrogen oxide treatment unit is needful.

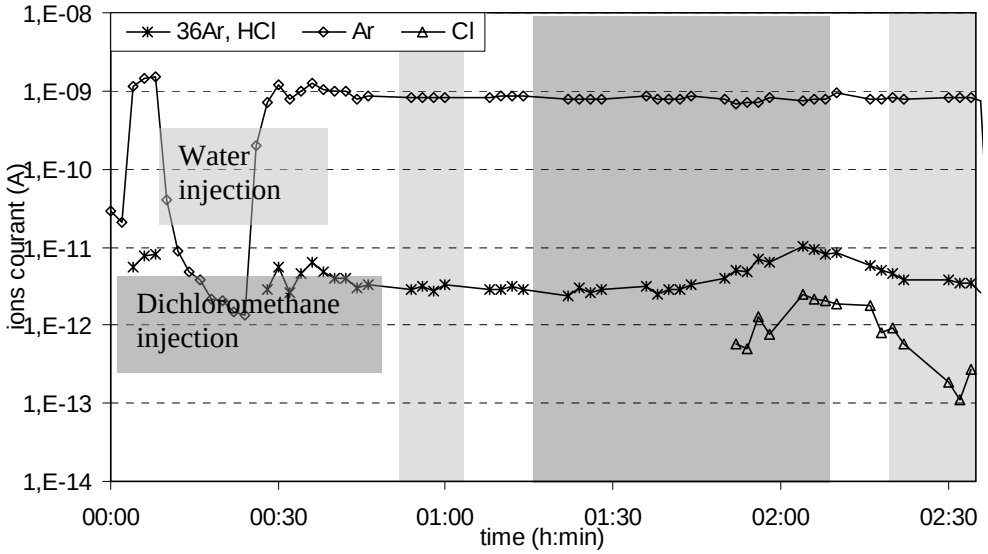

Figure 5: Ar, HCl and Cl composition signal during dichloromethane injection experiment.

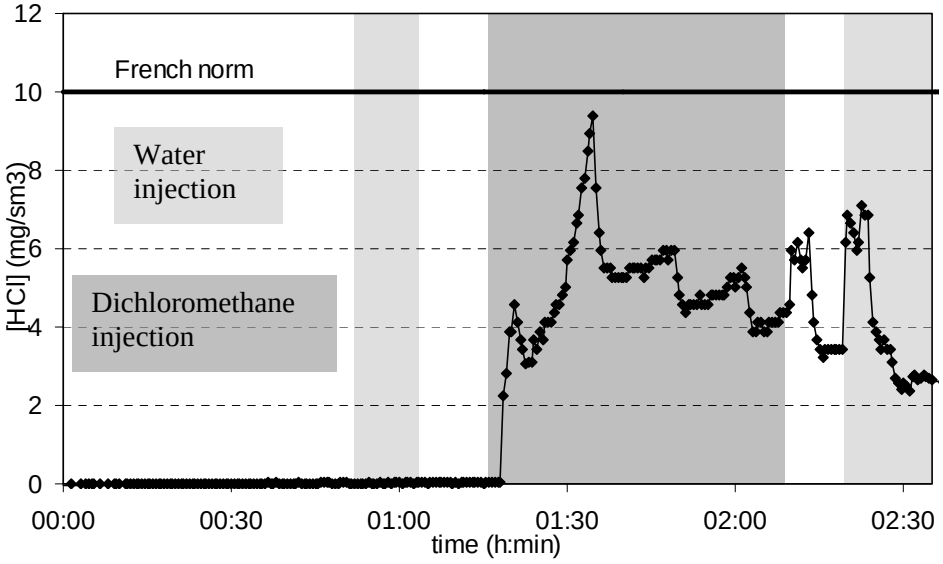

Figure 6: Hydrochloric acid ejection into atmosphere during dichloromethane injection experiment.

Figure 5 shows signals of chloride species and also argon for the main line. This one does not evolve while dichloromethane injection or no. So, the evolution of the second line, which indicates the presence of both argon (^{36}Ar) and hydrochloric acid, proves only appearing of hydrochloric acid when injection working. Unlike the CO_2 evolution, which has increased and decreased drastically when the dichloromethane injection

started and stopped, the hydrochloric acid evolution has been smoother. The delay before seeing the hydrochloric acid is higher than for CO_2 and the increase of HCl concentration, as its decrease, has been progressive. The increases in H_2O and HCl seem to follow the same slope. Their evolution could be linked by a saturation phenomenon.
After air addition, the gas cools down on cold wall. Consequently, there is an important condensation of steam on the reactor wall. When dichloromethane is introduced into the plasma, a great HCl formation appears and the hydrochloric acid has a great affinity with liquid water. Then, a part of HCl dissolves into the condensed water. So, when the liquid is saturated by hydrochloric acid, equilibrium is obtained and the HCl concentration in the gas increases enough to be detected by the mass spectrometer. A great quantity of liquid highly concentrated in HCl (40% of the introduced chlorine) has been founded at the bottom of the reactor, before halogen trap unit. That's confirmed this hypothesis.
After that, the gas treatment unit has trapped efficiently hydrochloric acid gas and has limited its concentration in off gases (Figure 6). The HCl concentration is always lower than 10 mg/sm^3 (the French HCl off-gas concentration norm used for dangerous waste incineration [7]): when the treatment unit parameters have been correctly fixed, equilibrium has started and the concentration was less than 6 mg/sm^3. This light concentration of gaseous hydrochloric acid during the dichloromethane injection indicates also the well-operating treatment of the process, which trap 60% of introduced chlorine.

5. Conclusion

Due to necessity of destroying high stability liquid halogen wastes, a new process has been proposed and is in progress to patent. Based on thermal inductive plasma torch and working with water adding in the hot destruction area, it is safe and robust.
The measured temperatures, before additional air injection, far from the plasma zone, are high and in correlation with previous simulation results. They represent the first evidence of the good destruction rate.
After additional air, the gas composition, caught by mass spectrometer analyses, is exempt of initial products to destroy, here dichloromethane. The process presents a very high destruction rate: only no toxic but simple gas molecules have been rejected into the atmosphere after a gas treatment for hydrochloric acid. In this case, chloride has been trapped as minerals salts.
New developments are carried on: after simple products such as dichloromethane or chloroform [8], destructions of several halogen liquid waste mixtures are in progress. Optimisation study of operating parameters will also be proceeded.

Abstract:

Temperatures in a plasma arc cutting system were measured using optical emission spectroscopy. Several methods were used to calculate the temperature and absolute ion emission intensity was found to be the best technique for temperature determination. Using this temperature measurement method the effects of arc current, plasma flow rate and torch geometry were determined. The arc current had a large effect on the plasma temperature, while the flow rate and geometry affect the expansion of the plasma jet leaving the torch nozzle.

Introduction:

Plasma arc cutting is a widely used industrial process in the metal fabrication industry. It uses a transferred arc to melt a conductive work-piece while a high speed gas jet removes the molten material. The plasma properties, as well as the cutting performance, are strongly influenced by several cutting process parameters. Some of these process design parameters include: geometry of the torch nozzle, shield gas flow configuration, plasma and shield gas flow rates and plasma cutting current. The goal of this investigation is to understand the effect of many of these parameters on the characteristics of the cutting plasma. This research will improve understanding of the plasma cutting arc, which can lead to improvements in plasma cutting torch design, as well as develop tools that can be useful in the torch design process.

Experimental setup:

The plasma source for this investigation is a Hypertherm HT2000 plasma cutting system. Major components of this system include a power supply, high frequency starter, gas supply and controls and a cutting torch. During cutting, a conductive work-piece is connected as the anode in the cutting system. In this experiment the work-piece has been replaced by a water-cooled rotating copper ring, which allows operation of the torch without the cost or by-products associated with cutting material. Measurements of the plasma arc are obtained using a CCD camera and spectrometer. Figure 1 shows a schematic of the experimental setup including components of the cutting system, optics and measurement equipment. The experimental torch setup is the same used for previous cutting torch studies [1].

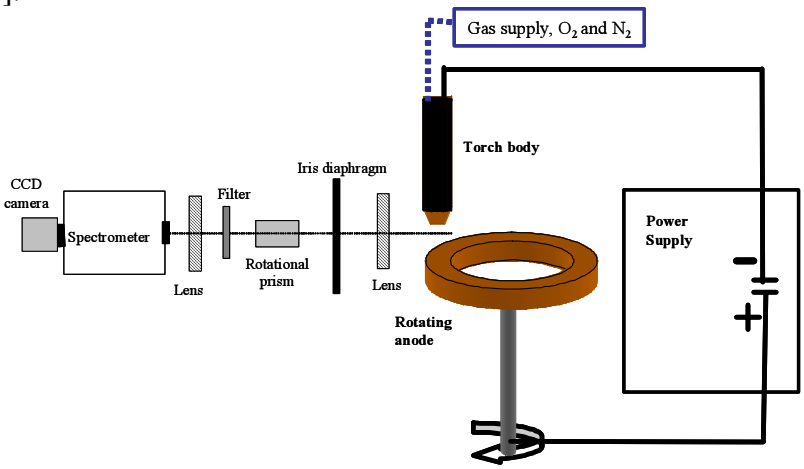

Figure 1. Schematic of experimental setup.

The optical components shown in fig. 1 magnify and rotate the arc image before it enters the spectrometer. The CCD detector used has a spectral resolution of 0.01 nm and a spatial resolution of 0.018 mm. Rotation of the image allows application of the high spatial resolution to the arc radius. Axial measurements are obtained by traversing the optical system up and down along the arc axis. Spatial resolution in the axial direction is 0.5 mm. In order to provide sufficient access to the plasma for measurement, the torch is mounted 15 mm above the surface of the anode. This standoff distance is much larger than the common cutting standoff of 3 to 4 mm.

The internal torch components greatly influence cutting performance and are therefore an important topic in this study. Figure 2a shows the components of the cutting torch, often referred to as torch consumables because they need to be replaced periodically. Each consumable set has a hafnium cathode set in water-cooled copper. The plasma gas flows through a copper nozzle with a shroud or shield gas flowing on the outside of the nozzle. Two consumable geometry designs are commercially available for the HT2000. The standard consumable set is shown in fig. 2a while fig. 2b shows a consumable set geometry with the trade name of HySpeed consumables. The major difference between the two consumable sets is in the length and shape of the nozzle bore and the introduction of the shield gas to the plasma jet.

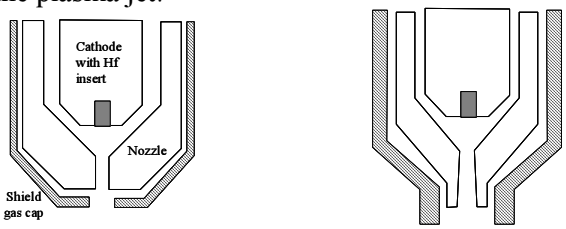

Figure 2. Torch consumables for standard geometry (a) and HySpeed geometry (b)

Typical operating conditions are a current of 200 A with a plasma gas flow of 39 slm of oxygen and a shield gas flow of air at 130 slm. In the case of the experimental investigation the shield gas flow is changed to pure oxygen to aid in the interpretation of the spectroscopic data. The nozzle exit diameter of standard consumables is 2.08 mm and 2.48 mm for HySpeed consumables.

The plasma temperature can be determined from the spectroscopic data. With certain assumptions about the plasma, i.e. it is in LTE and at 1 atm pressure, the plasma emission of a specific line of a given species can be related to the temperature. This relationship is shown in fig. 3 for an oxygen atom line and an oxygen ion line.

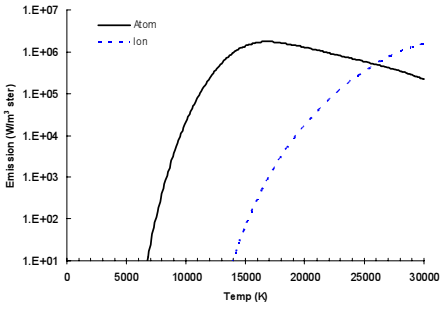

Figure 3. Plasma emission vs. temperature for oxygen atom and oxygen ion emission lines

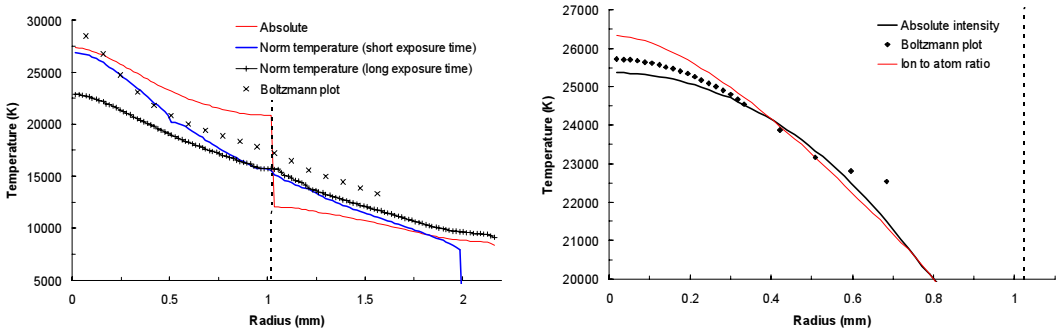
Several possibilities for temperature calculation are available in this arc because both atomic and ionic oxygen exist. From the atomic emission lines the temperature may be derived from an absolute intensity measurement of the plasma together with a tungsten calibration source. The temperature is then obtained from data similar to that in fig 3. The ratio of different lines of the same species can be used to construct a Boltzmann plot to determine the temperature. If the temperature in the center of the arc is higher than the temperature of

maximum emission for atomic lines, the norm temperature or off-axis peaking method can be used. Oxygen ions can be used with the absolute intensity method and the Boltzmann plot method. Also, if both atomic and ionic emission lines are visible at the same location in the arc, their ratio can be used for the temperature calculation. A total of 6 distinct possible methods for determining the temperature from spectroscopic measurements exist for this plasma source.

Results:

Radial temperature profiles were obtained using all of the available calculation methods. Figure 4 shows the temperature values obtained from methods based on atomic lines (fig. 4a) and ion emission lines (fig. 4b) All measurements were taken at a distance of 7 mm from the exit of the shield cap using the standard consumable geometry. The dashed line at 1 mm indicates the location of the edge of the nozzle.



(a) **(b)**

Figure 4. Radial temperature profiles for different temperature calculation methods based on atoms (a) and ions (b)

Emission from the atom lines shows an off-axis maximum that allows for the use of the norm temperature method. Figure 4a contains 2 profiles derived using the norm temperature method. The difference between the two profiles is the exposure time. A short exposure time (~10μs) and a long exposure time (~10ms) were used. The long exposure integrates the emission over the exposure time. Temperatures from long exposure time measurements show very little variation between measurement repetitions. The short exposure time results in a large difference between repetitions, but also in consistently higher temperatures at the arc center. The same off-axis peak that is used for calibration in the norm temperature method leads to the discontinuity in the temperature profile when using the absolute method. The calibrated emission profile does not reach a maximum value that is as large as the maximum possible emission value. Because the use of the norm temperature method uses this peak for calibration, there is no discontinuity in the results from this method, only a lower temperature value in the center and a higher value below the norm temperature. The Boltzmann plot data support the existence of a higher temperature in the arc center. Three lines were available for the Boltzmann plot.

Temperature measurement methods that rely on the emission from oxygen ions are shown in fig 4b. These measurements show a temperature near 26000 K in the center and the agreement between these methods is much better. Because 7 lines were used for constructing the Boltzmann plot, the results from this method should be fairly accurate. Good agreement between the Boltzmann method and the absolute line intensity method is also a sign that the assumption of atmospheric pressure, needed for the absolute intensity method, is valid at the measurement location. The ion to atom line ratio is also very similar to the other ion based measurements at the arc center. The effects of exposure time are much smaller for the ion lines.

Radial temperature profiles at several locations along the axis of the arc are obtained from the absolute intensity method using ion emission lines. Measurements without the shield cap were made to characterize the plasma in the region immediately after the nozzle exit, while measurements with the shield gas flow were made to simulate actual operating conditions.

Figure 5 shows radial temperature profiles at several axial distances from the nozzle exit plane using the standard consumable geometry. This figure clearly shows the under-expanded nature of the plasma jet leaving the torch nozzle. The arc quickly expands outward and the temperature decreases significantly in the first 1.5 mm after the nozzle exit. This is followed by a rapid increase in the temperature 2.5 mm from the exit plane then a much slower axial temperature drop. At all axial locations, the intensity of the ion emission is not large enough to provide a measurement beyond the edge of the nozzle radius of 1 mm.

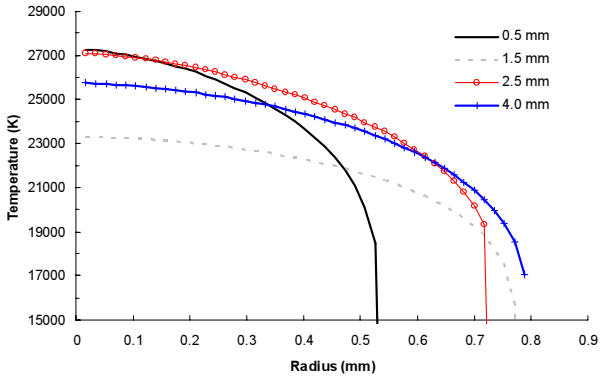


Figure 5. Radial temperature profiles at several axial locations from the nozzle exit plane. Temperature was calculated using absolute ion emission and standard consumables

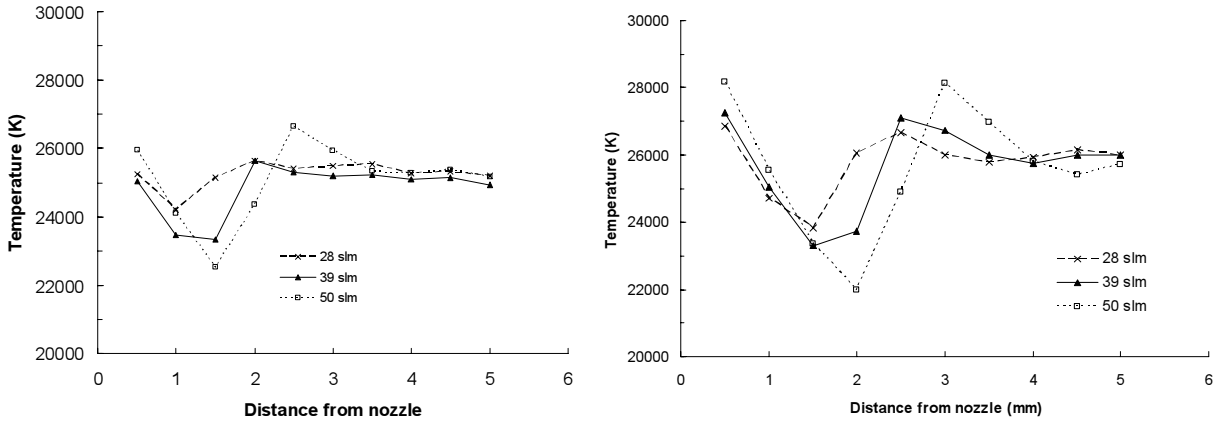
Figure 6 shows the centerline arc temperature calculated using the absolute ion line intensity method along the axis of the arc for 3 different plasma gas flow rates at currents of 200 A and 160 A using standard consumables without shield flow. Increasing the flow rate increases changes in temperature in the expansion region of the jet. The locations of the maximum and minimum temperatures are also shifted downstream with increasing flow rate. There is no measurable change in the arc temperature due to changes in the plasma gas flow rate beyond the expansion region.



(a) **(b)**

Figure 6. Centerline temperatures for different plasma gas flow rates at 160 A (a) and 200 A (b)

Reducing the current from 200 A to 160 A reduces the fully developed temperature after the expansion region by 900 K. For the same flow rate the expansion region is shifted downstream and the temperature extremes are increased for increasing current. The radius of the high temperature region measured with the ion lines was also smaller for 160 A.

The plasma temperatures produced by the two consumable geometry designs were also compared. This comparison was performed with and without the shield cap in place. The shield cap covers most of the large temperature fluctuations in the expansion region. The shield gas flow itself has the small effect of lowering the arc temperature for the first 1.5 mm downstream of the shield cap for the standard consumables and has no measurable effect on temperature for the HySpeed consumables. In fig. 7 the centerline temperatures for both consumable types are shown. Solid lines indicate measurements made when operating with a shield gas flow of 130 slm of oxygen and dashed lines indicated that the shield cap was removed for measurement near the nozzle exit.

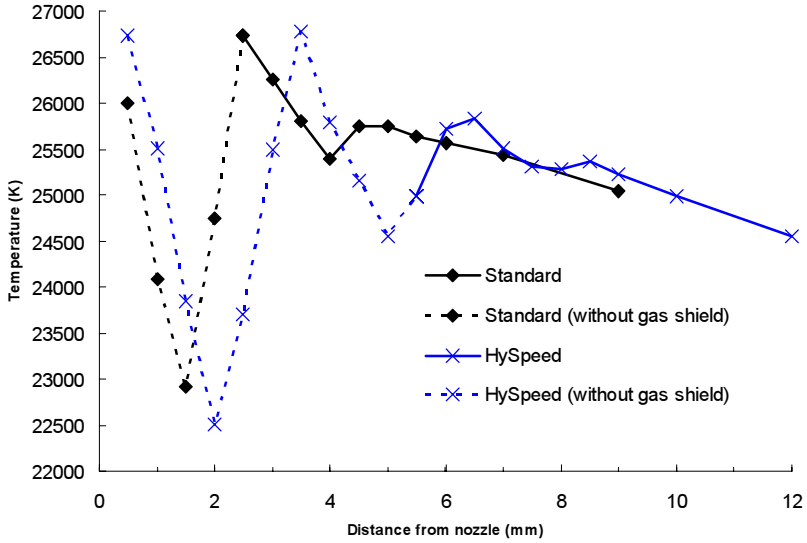


Figure 7. Centerline temperature for standard and HySpeed consumables with shield gas flow (solid lines) and with the shield cap removed (dashed lines)

The major difference between the consumable geometries is seen in the jet structure in the arc expansion region. HySpeed consumables show 3 well defined temperature peaks at 3.5 mm, 6.5 mm and 8.5 mm from the nozzle exit while the standard consumable peaks are seen at 2.5 mm and 4.5 mm from the nozzle exit. Once the jet expansion is complete the temperatures of the two consumable geometries are very similar.

Discussion:

For temperature measurement in this 200 A cutting arc, ion emission gives the most accurate values. Good agreement between the ion line methods is an indicator that there are no errors in system calibration, application of the measurement method or major violations of the underlying assumptions in the central region of the arc. Atom emission lines also give temperature values that are within 15% of the values calculated using the ion lines, another indicator of the accuracy of the temperature values obtained. The ion lines are most useful because they are most sensitive to temperature changes in the temperature range near the center of the arc. This high sensitivity allows the detection of small changes that result from design changes in the cutting system. This advantage of sensitivity can be seen from fig. 3, above 15000 K the change in emission with temperature is very small for the available atomic lines but is quite large for ion lines up to a temperature of 30000 K.

The steepest temperature gradient in the arc is near the edge of the nozzle radius. In this region the ion emission drops off quickly limiting the application of this method to the central region of the arc. Unfortunately, the atom line emission is not very sensitive in this region and these lines still have a large uncertainty in temperature measurement. Besides errors introduced due to a lower sensitivity of the emission coefficient with respect to temperature, short term intensity fluctuations (~100 μs) have been observed in the arc fringes indicating fluid dynamic instabilities. Time resolved measurements in the arc fringes will yield different temperature values

than time averaged measurements. In addition, the temperature values may not be valid in this arc fringe region due to deviation from LTE, which is assumed for all the calculation methods.

Because the jet exiting the nozzle is under-expanded, there are axial fluctuations in temperature as the jet adjusts to match atmospheric pressure. The pressure is also changing in this region [2]. When using the absolute line intensity method to calculate plasma temperature, a pressure of 1 atm is assumed. A violation of this assumption will lead to errors in the temperature calculation. The Boltzmann plot method is independent of the pressure because it is the relative emission from several lines. However, the Boltzmann plot is not as sensitive as the absolute line intensity method and is more affected by sources of uncertainty in the measurement. Large changes in temperature are visible using this method but smaller differences are not detectable. The absolute intensity method was still used in the expansion region because the error due to the pressure assumption in the absolute method is acceptably small [3]. It has been estimated that a pressure deviation 20% at 20000K leads to a temperature error of 200 K. The emission is also much more sensitive to changes in temperature. A 20% change in pressure will produce the same change in emission as a 2% change in temperature.

Arc current had the strongest influence on the temperature of the arc. Changes in the nozzle geometry or plasma gas flow rate only changed the expansion region of the arc. The observed changes are consistent with a change in the pressure inside the nozzle. For a given flow rate, decreasing the current leads to a smaller arc which gives more area for cold gas flow through the nozzle. This reduces the pressure drop in the nozzle and makes the jet expansion region shorter with smaller temperature changes.

Conclusions:

A spectroscopic method for measuring the temperature has been used to characterize a plasma cutting arc. The accuracy of this system has been established by using several different methods of temperature measurement which all give similar results. With this system ion line emission is the best method for temperature measurement, and this method is capable of detecting the effects of several cutting torch design parameters on the plasma temperature. The arc current has the most influence on arc temperature, while the nozzle geometry and gas flow rate influence the jet expansion at the torch exit.

Abstract
The probe and spectroscopy studies of a two-phase gas-liquid plasma system with a secondary electric discharge with a liquid electrode are presented. The existence of the jump of the electric field potential at the plasma-liquid interface and its dependence on the current and polarity of the discharge is demonstrated. Its shape, amplitude and pulsations depend on the distance from the liquid surface. It is found that during the cw burning of the secondary discharge in water vapors of low pressure, plasma is effectively enriched by free hydrogen.
Keywords plasma chemistry, gas-liquid plasma, secondary discharge, potential jump, hydrogen

1. Introduction

Plasma chemistry long time has been developing commonly considering plasma as a chemical active medium, which activity is instituted by high temperatures and high concentrations of reactive components: ions, electrons, radicals, excited particles, and photons [1]. Today it became clear the charge for such high activity of plasma is a low selectivity of plasma-chemical transformations, i.e. chain multi-channeling and weak control of processes. It is generally supposed the main way of increasing a plasma-chemical selectivity lies in moving from the thermal to non-thermal plasma. However, existing gas-discharge sources of non-equilibrium plasma can provide at best only the non-isothermality. It means the situation when the temperature of electrons differs from characteristic temperatures of heavy particles at the average energy of electrons lower than energies where the cross-sections of excitation for inelastic processes, such as dissociation of molecules, are maximal [2]. It is hard to advance the cause in the bulk plasma even in the transitional mode of non-thermal plasma, but it is possible to extend opportunities by organizing the heterophase plasma, providing branched contact between gas-discharge plasma and solid- or/and liquid substances. In this direction, two-phase gas-liquid plasma systems are of great interest [3]. They are based on self-maintained discharges having one or two immersed electrodes. Among them, electrolytic glow, corona, spark, barrier, gliding arc, and others are well-known [4]. But, despite of wide usage of these discharges, their physics and chemistry in gas-liquid systems are not studied well. Many discharges still have no theoretical description for explanation of electric-physical phenomena occurring in the positive column, near-electrode zones, and especially at the plasma-liquid interface. The main peculiarity of such plasma systems is the presence of the free liquid surface which represents an intense emitter of liquid molecules brought into the discharge volume at the atomization of liquid solution and formation of gaseous plasma-chemical products. The second peculiarity is conditions of gas-liquid plasma generation, corresponding to the saturated vapor pressures at given temperatures. For aqueous solutions, the lower pressure limit can be reached only under the continuous exhaust pumping. Under such conditions, the electric discharge burning represents the ascending branch of the Paschen curve, which determines the development of thermal plasma instabilities. Other factor contributing to the development of ionization instabilities in gas-liquid plasma is related with a presence of negative ions. Despite all problems, it is clear that gas-liquid plasma systems can be very effective because of (i) transition to non-thermal plasma with a high level of ionization nonequilibrium; (ii) realization of uniform parameters at the plasma-liquid interface, and (iii) efficient control during discharge operation. On the ground of the above consideration, a special interest for us presents the secondary gas-liquid discharge with a liquid electrode, supported by means of the auxiliary plasma flow [5]. In this discharge, one electrode is immersed in liquid while another belongs to the auxiliary self-maintained discharge in gas-vapor medium. In the present work, we study physical properties of such plasma-liquid system at low-pressure (~ 1 Torr) conditions.

2. Experimental Methodology

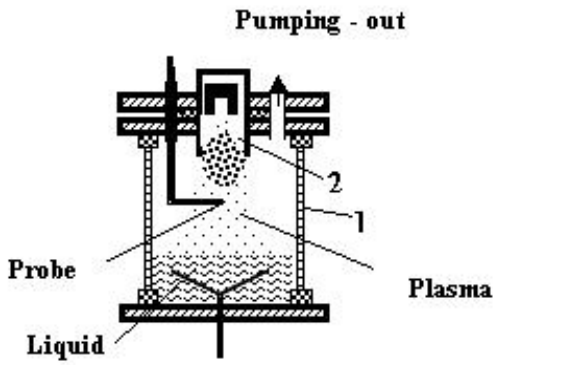

Fig. 1. Plasma chemical reactors for investigation of plasma-liquid systems of low pressure.

The scheme of the experimental setup used for studies of the low-pressure plasma-liquid system is depicted in Fig. 1. It consisted of the quartz vacuum chamber 1 and the electrical discharge system of gas-liquid type including the coaxial-end discharger 2. The electric field of the secondary discharge was applied between the metallic electrode immersed into liquid volume and the auxiliary discharge plasma source that anode served as an electrode for the secondary discharge at the same time. The distance between the source of the plasma flow and the liquid surface did not exceed 7 cm, while the height of the liquid column above the immersed electrode was 2-3 cm. This electrode had a conic form with diameter 6 cm, providing a stable state of the liquid surface under the discharge operation. The working liquid solution was distilled water. The discharge is powered by the DC source at the ballast resistance $R = 4$ kΩ in the circuit. Current-voltage parameters were measured by standard digital electronics. In order to measure the spatial distributions of the potential of the electric field in plasma-liquid system, we used a plasma probe technique. The probe of diameter 300 μm and 1 mm long was connected via the divider with a division factor 2,000 directly to the inverting entrance of the oscilloscope. The ionometric technique was also available for plasma diagnostics. For optical diagnostics, besides imaging photography, a method of optical emission spectroscopy was applied. The plasma radiation was monitored by the portable rapid PC-operated CCD-based multi-channel UV-VIS-NIR optical spectra analyzer in the range of wavelengths 200-1100 nm (spectral resolution 0.3 nm). For spatial point-to-point monitoring, a fine long optical fiber with a micro-lens focusing was used (pointing accuracy ~0.1 mm). For calibrations, the etalon spectral lamps were applied. From the measured spectra the population and temperatures of electronically excited atoms of hydrogen and oxygen were determined by the method of relative intensities [6] (diagnostic uncertainty ±10%). Measurements were conducted in different cross-sections along the secondary discharge at different polarities the electrodes.

3. Results and Discussions

Fig. 2 presents photo images of the low-pressure secondary discharge system operation in the absence of water: (a) is the burning of the auxiliary coaxial-end discharge; (b) is the secondary discharge at a positive polarity of the conic electrode, and (c) is the secondary discharge at a negative polarity of the conic electrode.

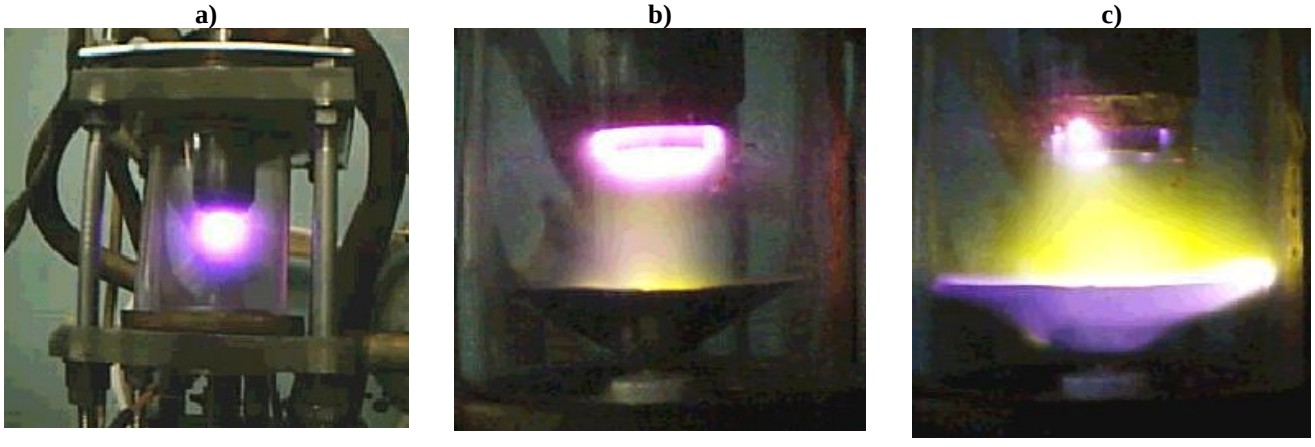

Fig.2. Photos of the low-pressure secondary discharge system without liquid electrode.

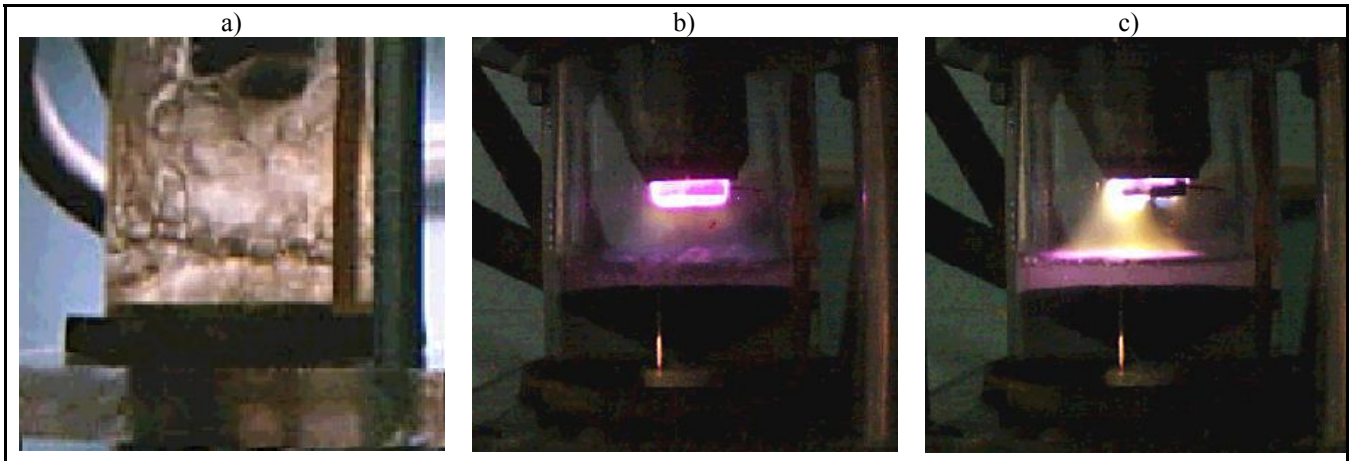

Fig. 3. Photos of the low-pressure plasma-liquid system with liquid electrode.

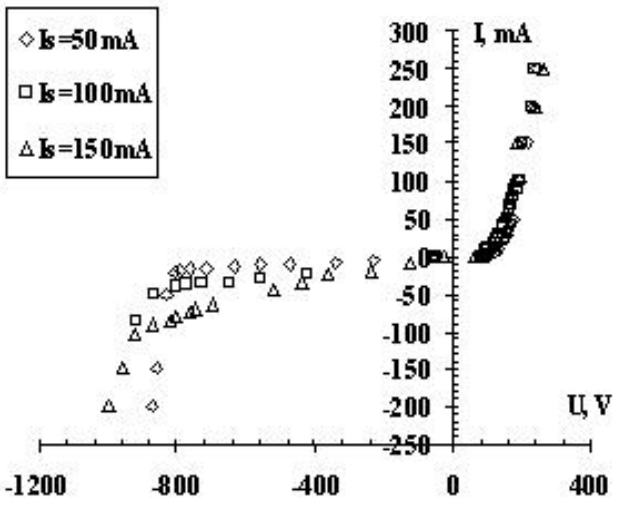

Fig. 4. Volt-ampere charecteristics of the secondary discharge.

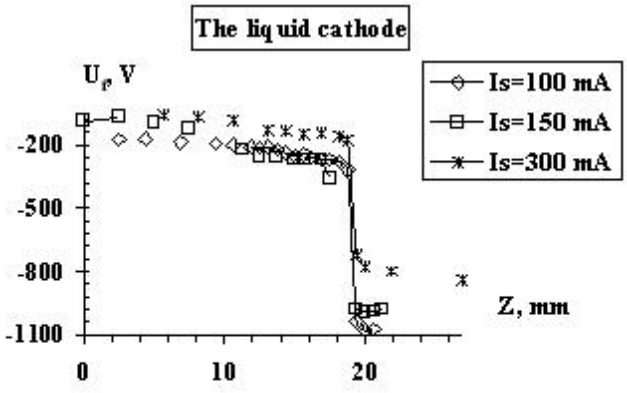

Fig. 5. Axial distribution of the floating potential of the electric field in plasma-liquid system with liquid cathode.

The feature of the secondary discharge operation in the presence of water was its vigorous boil on reaching the pressures below the saturated vapor pressure at given temperature (see photo in Fig. 3a). After complete evaporation of dissolved gases (vacuum outgassing took several minutes) the water boiling was ended and the secondary discharge was switched on. Fig.3b and Fig.3c present images of the plasma-liquid system operation with a live discharge for two different modes: (b) is the secondary discharge with a positive polarity of the immersed electrode ("liquid cathode"), and (c) is the secondary discharge with a negative polarity of the immersed electrode ("liquid anode"). In both modes the plasma column has a truncated cone-shape with extension at the liquid surface. Its size varies as the discharge current. The state of the liquid surface also depends on the discharge conditions. In case of the negative polarity of the liquid electrode its surface was quite normal (without visual bifurcations).

The measurements of current-voltage characteristics of the secondary discharge in plasma-liquid system have shown that in the range of low currents its behavior is similar to usual *I-V* curves of the probe, while in the range of high currents it has a sharp growth character as for the secondary gas discharge in strong electric fields [2]. Typical dependences of the secondary discharge current I_d at different potentials of the liquid electrode U_d and various values of the auxiliary discharge source current I_s are given in Fig. 4. The measurements of the axial distribution of the floating potential of the electric field in plasma-liquid system with a liquid cathode at the typical value of the secondary discharge current I_d = 150 mA and different currents of the auxiliary discharge I_s = 50-300 mA are presented in Fig. 5. Here, a distance from the auxiliary discharge downstream is 2 cm. These

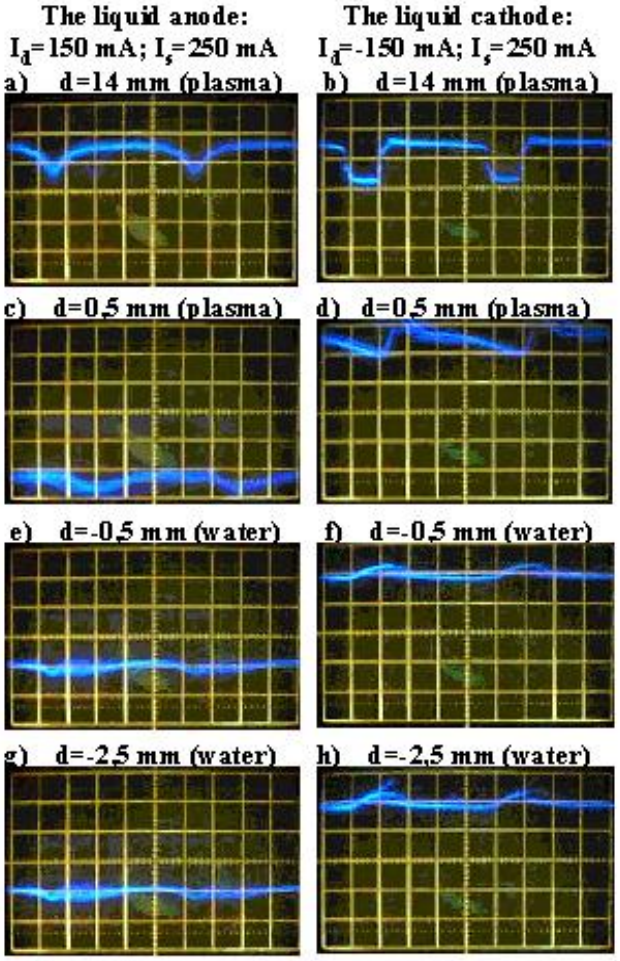

Fig. 6. The probe signals on an inverted unclosed entry oa oscillograph at different distances of a probe from plasma - liquid border.

measurements indicate the existence of a region near the liquid surface where the axial gradient of the plasma potential rises sharply. Such an increase of the voltage where plasma contacts liquid, can be interpreted as a decrease of the electroconductivity due to the process of dissociative attachment of electrons to H_2O molecules: $e+H_2O=OH^-+H$. It is assumed that mobility of negative ions OH^- near the liquid surface is lower than mobility of positive ions H^+ [5]. At the same time, a potential jump at the plasma-liquid interface can be associated with the basic peculiarity of the secondary discharge maintained due to the plasma flow from the auxiliary discharge. There is always a jump of the potential between the electrode and surrounding plasma due to a shielding effect of space charges. It gives possibility to control the secondary discharge voltage jump near its electrode by variation of the auxiliary discharge voltage, if the jump width is less than the free electron path length. The probe measurements revealed also a fact of pulsations of the potential caused by the ripple voltage of the power supply. Their amplitude and shape vary along the discharge and depend on the distance from the liquid surface and polarity of electrodes (Fig. 6). The peak amplitude is situated near the output electrode of the auxiliary discharge.

The results of optical emission spectroscopy of plasma-liquid system in the secondary discharge with a liquid electrode after the vacuum outgassing have shown the presence of wide spectrum of excited species in output products including components of dissolved gases but most intensive emissions belong to hydrogen-containing species: H (atomic lines of Ballmer series Hα 656.3 nm, Hβ 486.1 nm, Hγ 434.0 nm), OH ($A^2\Sigma$-$X^2\Pi$ 0,0-band at 306-309 nm) and oxygen (atomic lines OI 777.3, 844.6, and 926.0 nm). Fast response of the CCD spectrograph (min exposure time ~7 ms) allowed to explore the temporary changes in intensities of the emission of separate atomic lines H and molecular bands OH during the secondary discharge burning within the time t = 1-30 min. This monitoring has shown that in the modes with a liquid anode the intensity of H lightly increases with the magnification of time of treatment. The monitoring of the modes with a liquid cathode has revealed a strong decrease of intensity of H and a gradual decrease of intensity of OH. The representative dependence of intensity I_λ for the Hα line 656.3 nm is given in Fig. 7. The corresponding dependences for the temperature of electronic excitation of H atoms T^* determined from the relative intensities I_λ are presented in Fig. 8. The values T^* vary in the range from 0.4 to 0.5 eV depending on the discharge conditions. They have somewhat different character of dependency: in the modes with a liquid cathode the T^* decreases, while in the modes with a liquid anode the T^* grows. The obtained dependences $I_\lambda(t)$ and $T^*(t)$ allowed to make the estimation of concentration of released hydrogen. It turned out that the number of H atoms has tendency to increasing, and its greater accumulation is in plasma-liquid system with a liquid cathode. Apparently, basic mechanism of formation of hydrogen in the low-pressure plasma-liquid system is connected with electrochemical processes near the metallic electrode immersed in water. This deduction correlates with the above note about the stability of the liquid surface in plasma-liquid system with a liquid cathode.

Conclusions

On the results of our investigation of the secondary discharge with a liquid electrode, supported by the auxiliary plasma flow based on the discharge in water vapors of low pressure, we can conclude the following:

- In the two-phase plasma-liquid system under conditions of the low-pressure secondary discharge with a liquid electrode, a jump of the electric field potential on the gas-liquid interface exists. It depends on the current and polarity of the discharge. The pulsations of the potential are caused by the ripple voltage of the power supply. Their amplitude and shape vary along the discharge and depend on the distance from the liquid surface and polarity of electrodes. The peak amplitude lies near the anode of the auxiliary discharge.
- The current-voltage characteristics of the secondary discharge with a liquid electrode are similar to those for typical secondary gas discharges. In case when the potential of the liquid against plasma is positive, the current is by two orders higher than that in case of the negative potential.
- The emission spectroscopy of the plasma-liquid system in the low-pressure secondary discharge has shown the presence of wide spectrum of excited species in output products including components of dissolved gases but most intensive emissions belong to hydrogen-containing species H and OH. The population temperature of H atoms determined from the relative intensities varies in the range 0.4-0.5 eV depending on the discharge conditions. At that time the concentration of H atoms has tendency to increasing. It means that during the cw burning of the secondary discharge in water vapors at low pressure, plasma is effectively enriched by free hydrogen.

Abstract
A two-dimensional magnet-gas-dynamic model is considered for the ceramic material microwave heating in a channel of the rectangular waveguide. The alumina and surrounding air characteristics are calculated at atmospheric pressure in microwave radiation field at frequency of 2.45 HHz.

Introduction

In our days modern technologies are intensively applied to manufacture ceramic products, using microwave radiation, which allows realization of porous materials and gas phase [1-2] volumetric heating. The Institute of Applied Physics RASc has created special equipment of 20 kWt for ceramic materials treatment in continuous (electromagnetic fields frequencies 30-85 HHz) and pulse (several hundreds kilowatts; electromagnetic fields frequencies 110-170 HHz) modes. The materials obtained at microwave heating have better mechanical characteristics and resistance to fissuring, because in multi-mode cameras fed by the microwave radiation a high uniformity of the power volumetric distribution is realized.

In this work a self-consistent two-dimensional model of the ceramic cylinder stationary microwave heating in the rectangular waveguide is developed due to electromagnetic wave H_{10} power dissipation in Earth's gravitational field.

Model

We consider a microwave heating of the ceramic pattern of cylindrical shape, oriented perpendicular to wide walls of the rectangular waveguide of section $a \times b$ (fig.1) at the expense of electromagnetic power dissipation supplied by the TE-wave with components $\vec{E}(0;\, E_y = E;\, 0)\exp(i\omega t - ikz)$, $\vec{B}(B_x;\, 0;\, B_z)\exp(i\omega t - ikz)$. Stationary heating is ensured by heat removing from the cylinder surface due to heat conductivity and laminar convective cooling in gas environment (air at atmospheric pressure). In two-dimensional approximation we neglect the characteristics changes along the electric-field intensity vector (along the cylinder axis in parallel with narrow walls of the waveguide).

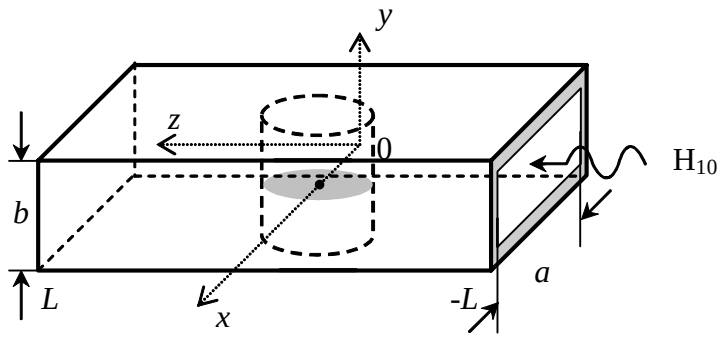

Figure 1. Scheme of the ceramic cylinder microwave heating in the rectangular waveguide.

Equations. We describe a process of microwave heating in Cartesian rectangular coordinates (fig.1) on the basis of stationary continuity equations, Navier-Stokes equations, power balance and wave equations:

$$\frac{\partial}{\partial x}(\rho u) + \frac{\partial}{\partial z}(\rho w) = 0$$

$$\rho u\frac{\partial u}{\partial x} + \rho w\frac{\partial u}{\partial z} = -\frac{\partial p}{\partial x} + 2\frac{\partial}{\partial x}\left(\eta\frac{\partial u}{\partial x}\right) + \frac{\partial}{\partial z}\left[\eta\left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}\right)\right] - \frac{2}{3}\frac{\partial}{\partial x}\left[\eta\left(\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z}\right)\right] - (\rho_\infty - \rho)g_x$$

$$\rho u\frac{\partial w}{\partial x}+\rho w\frac{\partial w}{\partial z}=-\frac{\partial p}{\partial z}+\frac{\partial}{\partial x}\left[\eta\left(\frac{\partial u}{\partial z}+\frac{\partial w}{\partial x}\right)\right]+2\frac{\partial}{\partial z}\left(\eta\frac{\partial w}{\partial z}\right)-\frac{2}{3}\frac{\partial}{\partial z}\left[\eta\left(\frac{\partial u}{\partial x}+\frac{\partial w}{\partial z}\right)\right]-(\rho_\infty-\rho)g_z$$

$$\rho uC_p\frac{\partial T}{\partial x}+\rho wC_p\frac{\partial T}{\partial z}=\frac{\partial}{\partial x}\left(\lambda\frac{\partial T}{\partial x}\right)+\frac{\partial}{\partial z}\left(\lambda\frac{\partial T}{\partial z}\right)+\frac{1}{2}\omega\varepsilon_0\varepsilon_I E^2;\frac{\partial^2 E}{\partial x^2}+\frac{\partial^2 E}{\partial z^2}+\frac{\omega^2}{c^2}(\varepsilon_R-i\varepsilon_T)E=0.$$

Here: $\vec{V}=(V_x=u,\ V_z=w)$- is velocity; p - pressure; T - temperature; $\vec{g}=(g_x,g_z)$ - gravitational acceleration vector; ρ, C_p, η, λ - density, thermal capacity, viscosity, thermal conductivity; ε_R, ε_I - real and imaginary parts of complex dielectric permeability; $\omega=2\pi f$ - cyclic frequency; $k=\sqrt{(\omega/c)^2-(\pi/a)^2}$ - longitudinal propagation number; c – velocity of light; ε_0 - electric constant; i - imaginary unit.

Boundary conditions are set on a rectangular contour of the accounted region $0\le x\le a, -L\le z\le L$ (fig.1):

on inflow boundary – the conditions of normal gas inflow at given pressure and superposition of incident and reflected electromagnetic waves in the rectangular one-mode waveguide are:

$$z=-L\ :\ p=p_0,\ u=0,\ \partial(\rho w)/\partial z=0,\ T=T_\infty,\ E=\left[E_I\exp(-ikz)+E_R\exp(ikz)\right]\sin(\pi x/a);$$

on outflow boundary – the conditions of normal outflow or inflow of gas and passed electromagnetic wave are:

$$z=L\ :\ p=p_0,\ u=0,\ \partial(\rho w)/\partial z=0,\ \partial T/\partial z=0,\ E=E_T\exp(-ikz)\sin(\pi x/a);$$

on side boundaries – the conditions of "adhesion" on cold ideally conducting waveguide walls are:

$$x=0;a\ :\ u=0,\ w=0,\ T=T_\infty,\ E=0,$$

where E_I, E_R, E_T are amplitudes of incident, reflected and passed H_{10} waves.

Solution technique is based on the end-to-end account at which a self-adjointness of tasks in solids and gases on boundaries of their separation is reached by introduction of transport factors, determined as average harmonic ones [3]. We make the discretation of the equation by the method of control volume. The pressure field is calculated with help of the SIMPLER-procedure [3]. Temperature in the center of pattern's profile $(a/2, 0)$ is T_0, input microwave power P_I is determined interactively. Boundary conditions for E will be reduced to radiation conditions:

$$z=-L\ :\ \frac{\partial E}{\partial z}-ikE=-2ikE_I\exp(-ikz)\sin(\pi x/a),\quad z=L\ :\ \frac{\partial E}{\partial z}+ikE=0.$$

As the wave equation determines the amplitude of the electric field intensity to a free constant multiplier, the first condition is substituted by the correlation $z=-L:\tilde{E}=\sin(\pi x/a)$. An interactive character of the condition on the right boundary is saved. The obtained numerical solution $\tilde{E}(x,z)$ is scaled $E(x,z)=K_E\tilde{E}(x,z)$ with coefficient $K_E=|E_0|/|\tilde{E}|$ at $x=a/2,\ z=0$. The module $|E_0(a/2,0)|$ ensures the power balance for current (on given iteration) values of required variables in control volume with temperature T_0. By the obtained field $E(x,z)$ we calculate amplitudes E_I, E_R, E_T and respective microwave powers $P_{I,R,T}=kE_{I,R,T}^2 ab/4\mu_0\omega$.

Results

For an example one made calculation of pattern of the ceramic (baked alumina, density 97%) microwave heating in air at atmospheric pressure in the rectangular waveguide 72×32 mm with the electric field intensity f = 2.45 HHz. Thermo-physical characteristics of Al_2O_3 and air are given by temperature functions. Spatial orientation of the waveguide in Earth's gravitational field is g = 9.8 m/s^2, $\vec{g}(0, g_z=-g)$, $\vec{g}(g_x=-g, 0)$.

As a result of accounts it was found (fig.2) that the ceramic cylinder profile is drain for vector of Umov-Pointing. The electric field propagation around axis is "saddle" (in the cylinder center minimum field is realized toward the wave propagation and maximum – in transverse location). "Focusing" field's effect is observed on backside of the cylinder profile directed toward waveguide H_{10}-wave propagation, where maximum temperature value is realized.

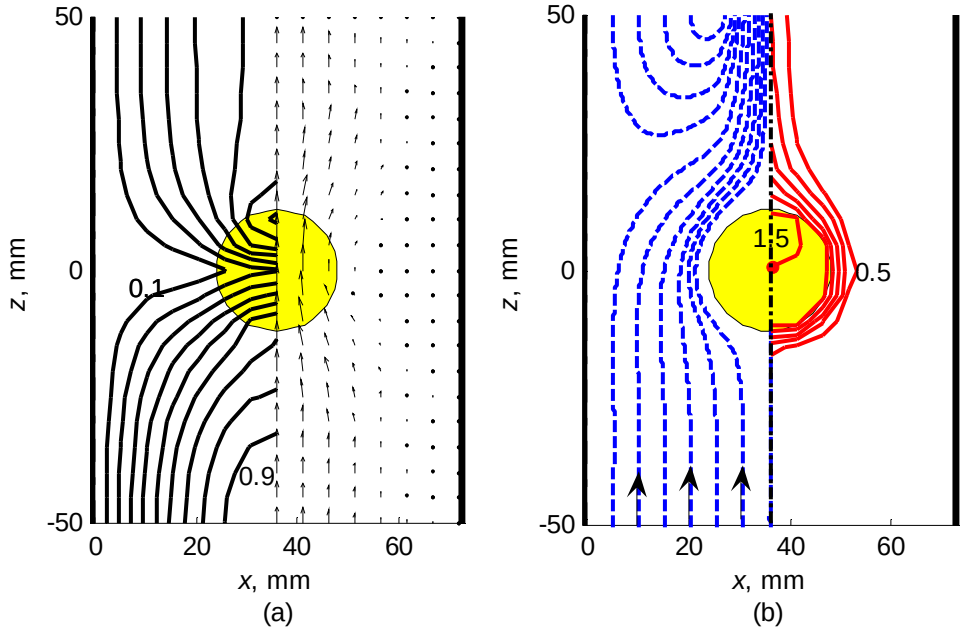

Figure 2. (a) Isolines of the electric field intensity module E/E_*, from 0.1, pitch 0.1 (E_*=0.59 kV/cm); a field of Umov-Pointing vector; (b) isotherms from 0.1, pitch 0.2 kK and 1.5 kK (firm lines) and gas flow lines (dotted line) at natural convection: $g_z = -g$; $V_{ext} = 0$ (P_I = 1.18 kW; P_R = 0.35 kW;P_d = 0.05 kW; P_T = 0.78 kW).

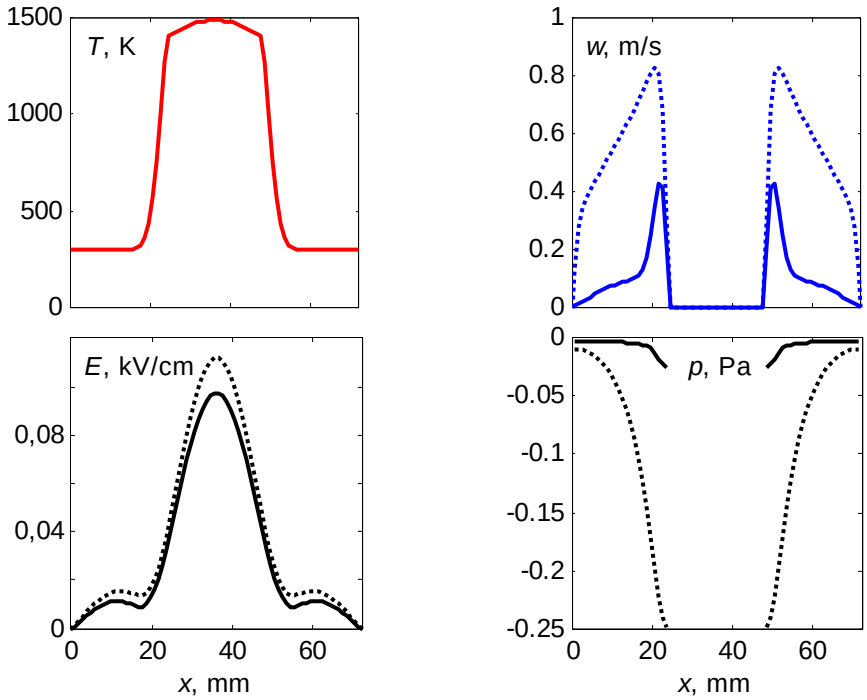

Figure 3. Temperature distribution T, velocity components w, module of the electric field intensity $|E|$ and pressure p at $z = 0$; $g_z = -g$; $V_{ext} = 0$ (firm lines); 0.5 m/s (dotted line).

At natural convection ($V_{ext} = 0$) a picture of gas flow lines and heat flows on the waveguide walls rather depend on the ceramic cylinder spatial orientation in Earth's gravitational field (fig.2, 5a). But this influences little the product heating.

A degree of temperature field heterogeneity in the cylinder profile, a temperature and gas-dynamic structure of the exterior cooling gas flow essentially depend on a type of convective cooling. At gas pumping in the waveguide (forced convection) a cold gas flow intensively cools the cylinder front, increasing a temperature gradient in the product (fig.3-4) and, accordingly, expands the isotherm on the cylinder back (fig.5b). When the velocities of a cold gas, blowing around a ceramic cylinder are $V_{ext} > 1$ m/s, a role of natural convection similar the waveguide orientation in gravitational Earth's field is inessential.

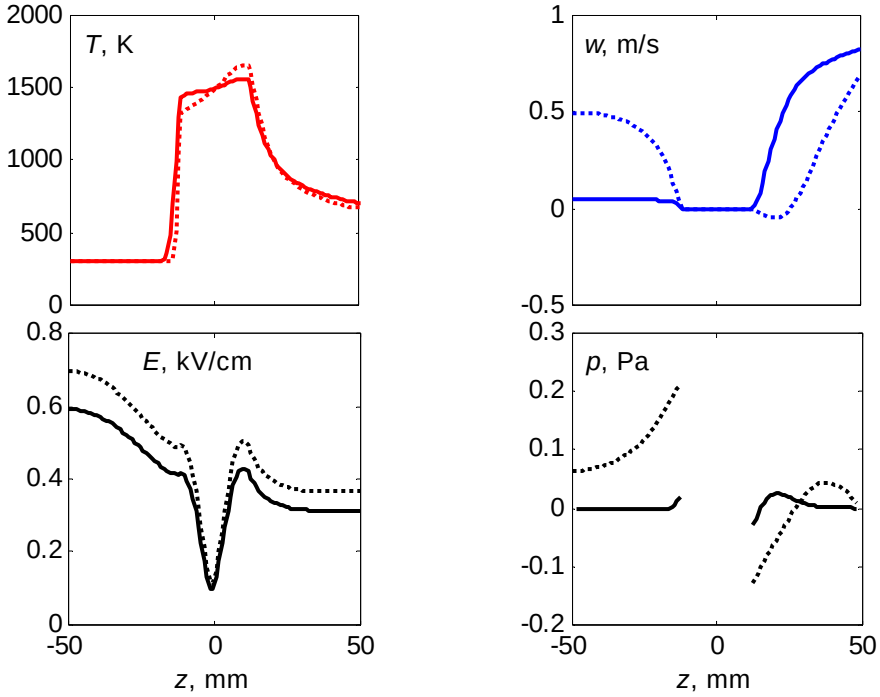

Figure 4. Distributions of temperature T, velocity w, the electric field intensity module $|E|$ and pressure p at x = 36 mm; $g_z = -g$; $V_{ext} = 0$ (firm lines); 0.5 m/s (dotted lines).

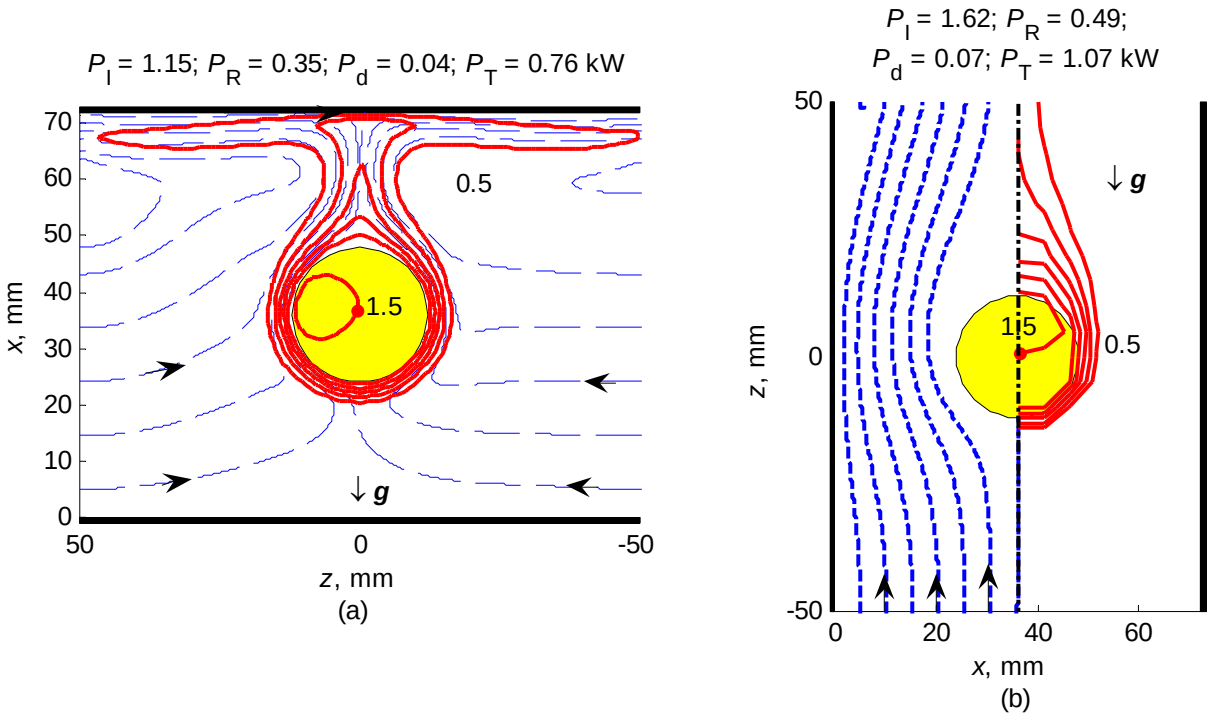

Figure 5. Isotherms in kK (firm lines) and gas flow lines (dotted lines) at natural convection (a) $g_x = -g$; $V_e = 0$; (b) $g_z = -g$; $V_{ext} = 0.5$ m/s.

Abstract

This paper presents a numerical analysis and experimental investigation of air and steam plasma gasification of petrocoke. Numerical analysis was carried out using the software package TERRA. From the data produced from the analysis, the optimal medium and operating parameters for the gasification process were discovered. Using these results, preliminary experiments on plasma steam gasification of petrocoke were carried out, producing high quality Syngas. The numerical calculations and experimental results corresponded with one another.

Introduction

The world's petroleum reserves are limited. Based on current global consumption, it has been estimated that this reserve will be depleted in approximately 40 to 60 years. Due to the dwindling petroleum supplies, the development and usage of secondary oil sources such as: lake oil, oil sands, and soils near oil fields and pipelines, is crucial. During the production of hydrocarbons, the thermal processing of oil sands also produces petrocoke. Petrocoke is solid fuel consisting of fixed carbon, tar and ash. Direct utilization of petrocoke is difficult because of its hardness and high tar content. A potential use of petrocoke is plasma gasification in air or steam medium that converts the organic mass of coke into high-calorific synthesis gas ($CO + H_2$) prevents nitrogen and sulphur oxides production in the plasma reactor.

Numerical analysis showed that from both energy and ecological standpoint steam gasification using an internal heat source is the process of choice. Using a plasma gasifier source in the steam gasification process allows for the production of high quality syngas without the dilution with incineration gases. Steam gasification using a plasma gasifier was chosen for experimental investigation. High quality syngas was produced from the petrocoke. Its yield reached 93.6% which correlated with predicted syngas concentration ($CO + H_2 = 97\%$).

1. Numerical analysis

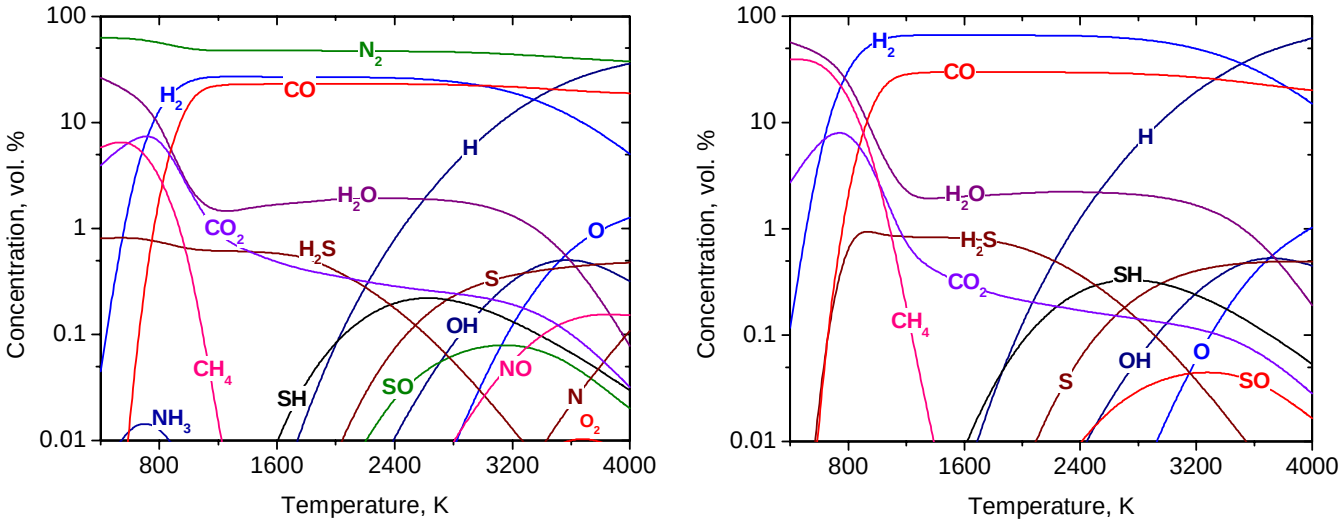
Petrocoke produced from Canadian oil sands was used in the study. The petrocoke is composed of (mass %): C = 69.65; $C_{3.28}H_{60.67}$ = 25.428; H_2O = 0.99; S = 5.64; SiO_2 = 1.305; Al_2O_3 = 0.778; Fe_2O_3 = 0.6; CaO = 0.099; K_2O = 0.068; MgO = 0.052; Na_2O = 0.037; Hg = 0.003. The organic mass was approximately 97% and the mineral mass was only 3%. Note in nature there is no such substance as $C_{3.28}H_{60.67}$. It is conventional molecular formula characterizing the hydrocarbon component of the coke.

To select a more rational way of gasification, thermodynamic analysis of the processes of air and steam petrocoke gasification was performed. Software package TERRA [1] was used for thermodynamic modelling of the pertocoke plasma gasification. This software was created for high-temperature process computations and is based on the principle of maximizing entropy for isolated thermodynamic systems in equilibrium. TERRA has its own database of thermochemical properties for more than 3,500 chemical agents over a temperature range of 300 to 6,000K. Calculations were performed using the following initial data: temperature was varied from 400 to 4,000 K at pressure 0.1 МПа. The first set of calculations the feed was assumed to consist of 100 kg of coke plus 460 kg of air. In the second set of calculations the feed was assumed to consist of 100 kg of coke plus 120 kg of water steam. The gas phase species (Fig. 1), degree of coke gasification (Fig. 2) and specific power consumptions for the processes (Fig. 3) were calculated for the both variants.

Using air gasification (Fig. 1) in a temperature interval of 1,000 to 2,600 K the gas phase mainly consists of molecular nitrogen (N_2) and synthesis gas (CO + H_2). When the concentration of hydrogen is about 26.9% (T=1,400K), the concentration of carbon monoxide is about 22.9% and the concentration of nitrogen is about 47.4%. Under these conditions the sulfur is presented as hydrogen sulfide (H_2S) with a concentration of less than 0.7%. Oxidant concentration (H_2O and CO_2) in this temperature interval does not exceed 2.1%. At the temperature over 2,000 K in gas phase atomic hydrogen (H) is present. Its concentration reaches 35.9% by the temperature 4,000 K. At the temperature exceeding 2,200 K hydrogen sulfide dissociates onto atomic sulfur (S) and sulfur hydride (SH). Total maximal concentration of them is about 0.5%. At temperature above 3,000 K in gas phase hydroxyl (OH) and atomic oxygen (O) appears. Their total concentration is about 1.5%. At temperature exceeding 3,200 K in gas phase nitrogen oxide (NO) is noticed. Its concentration reached 1,500 ppm.

Using steam gasification in a temperature interval of 1,200 to 2,800 K, the gas phase (Fig. 1 on the right) mainly consists of synthesis gas. When the concentration of hydrogen was about 67% (T=1,400K), the concentration of carbon monoxide was about 29.8% and sulfur was present as sulfur hydrogen (about 0.8%). The oxidants concentration (H_2O and CO_2) is not exceed 2.5% in that temperature range. At temperatures greater than 2,000 K atomic hydrogen is appeared in gas phase. Its concentration reaches 62.2% at the temperature 4,000 K. At temperatures greater than 2,200 K hydrogen sulfide dissociates into atomic sulfur and sulfur hydride with total maximal concentration of them reaching 0.5%. At temperatures greater 3,000 K in gas phase hydroxyl and atomic oxygen is appeared. Their total concentration was less than 1.5%. In contrast to the air gasification, in the process of steam gasification nitrogen oxides are not formed.

Note that concentration of syngas obtained in the process of steam gasification is significantly greater one got in the process of air gasification.



the petrocoke air gasification

the petrocoke steam gasification

Figure 1. Concentrations of gas phase species (organic mass) variation with temperature

One of the main features of the petrocoke gasification process is the dependence of degree of carbon gasification on temperature (Fig. 2). It was calculated in accordance with the following formula.

$X_c = \frac{C_{init} - C_{fin}}{C_{init}} \cdot 100\%$, where C_{init} and C_{fin} is initial carbon concentration in the petrocoke and final carbon concentration in the solid residue at current temperature of the process correspondingly.

Gasification degree increases with the temperature in the both variants and reaches 100 % at close and relatively low values of temperature, which are 1,000 K for air gasification and 1,050 K for steam gasification of the petrocoke. Thus for the both variants carbon from the petrocoke completely transforms into the gas phase mainly in the form of CO (Fig. 1).

Specific power consumptions for the gasification processes were calculated by the difference of working medium (petrocoke and oxidant) enthalpy in initial (T=298 K) and final (current temperature of the process) conditions. The calculations results for the both processes are presented in Fig. 3. At that specific power consumptions were related to one kilogram of initial petrocoke (curves 1 and 3) and to one kilogram of the target product syngas (curves 2 and 4). At the temperatures above 1,000 K specific power consumptions increase smoothly with the gasification processes temperature. Note that in the temperature interval from 1,400 to 2,600 K, where syngas concentration is maximal (Fig. 1) and practically permanent, specific power consumptions for the both processes smoothly increase. It is significant that absolute values of specific power consumptions related to one kilogram of petrocoke (curves 1 and 3) both for steam and for air gasification are almost equal, at that specific power consumption for the process of air gasification in temperatures above 1,900 K is even slightly greater one for steam gasification. But values of specific power consumptions related to one kilogram of syngas are different noticeably for the both variants (curves 2 and 4). For example at temperature 1,400 K, when syngas concentration has its maximal value, specific power consumption for the process of steam gasification of petrocoke is quite less than one for the process of air gasification and amount to 3.24 and 4.46 kW·h/ kg of syngas correspondingly.

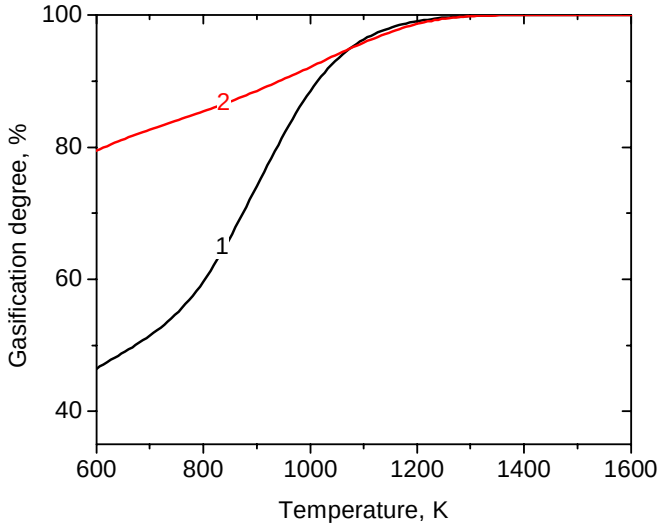


Figure 2. Petrocoke gasification degree variation with temperature

1 – air gasification; 2 – steam gasification

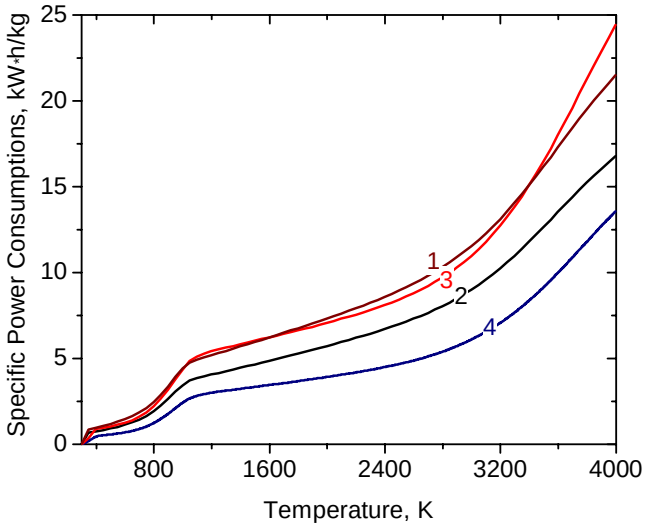

Figure 3. Specific power consumptions for the process of petrocoke gasification variation with temperature

1, 2 – air gasification; 3, 4 – steam gasification; 1, 3 – values related to 1 kg of coke; 2, 4 – values related to 1 kg of syngas

Thus numerical investigation showed that both from energy and ecology point of view for petrocoke gasification more perspective process is its steam gasification with use of internal heat sourse. And for example this sourse could be plasma one. It will allow getting the temperature required for the process of gasification without additional fuel incineration and the target product syngas dilution with inert products of combustion.

Plasma-steam gasification of petrocoke allows converting the organic mass of the coke into high-calorific synthesis gas ($CO + H_2$) that is free from nitrogen and sulphur oxides in a plasma reactor. This conversion can be written as following gross-reaction: $C + H_2O = CO + H_2 - Q = 131500$ kJ/mol. The plasma sourse energy compensates the heat absorbing or endothermic effect Q of this reaction. This process is widely known for power coal gasification [3-9].

2. Experiment

Petrocoke plasma steam gasification experiments were conducted on the laboratory gasifier with 100 kW of nominal electric power (Fig. 4) [2]. The gasification process was carried out according to the following procedure: an arc was fired between the rod and ring electrodes in the combined plasma reactor 1. Then, coke-dust from coke feeder 7 was fed through two ejectors mounted on the reactor cover. Fed through the ejectors steam pulverized the coke-dust over the cross-section of the gasifier. The steam-pulverised coke mixture entering to the arc zone, heated to high temperatures by the arc rotating in magnetic field, thus producing a two-phase plasma flow where the coke gasification occurred. The solid residue produced in the process was withdrawn through the orifice plate 2 into the slag catcher 3. The gaseous products were withdrawn into a ventilation system through gas and slag separation chamber 2 than through chambers for synthesis gas removal 4 and hydration 6. As a result of experiments on the basis of material and heat balances making up, the major indexes of coke plasma gasification were found.

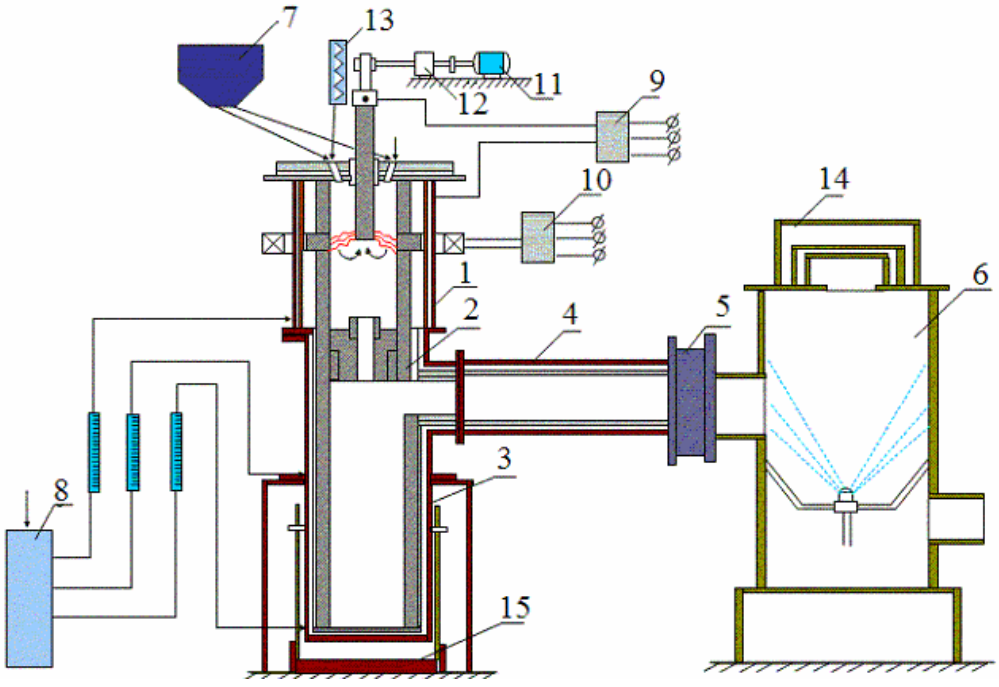

Figure 4. Scheme of Plasma Unit for Coke Steam Gasification.

1 – plasma gasifier; 2 – gas and slag separation chamber and orifice; 3 – slag catcher; 4 – chamber of synthesis gas removal; 5 –the system of gas flow measure; 6 – chamber of hydration; 7 – pulverized coke feeder; 8 – the cooling system; 9, 10 – electric power supply system; 11, 12 – gear for rod electrode supply; 13 – water steam generator; 14 – safety valve; 15 – stand for slag catcher.

To control the installation efficiency and to define the process integral indexes like mass averaged temperature, specific power consumption, syngas concentration, coke gasification degree components of the mass and heat balance of the experimental plant were measured.

The equations of material and heat balance of the experimental set-up take the following form:

$$G_2 + G_3 + G_4 + G_5 = G_6 + G_1 + G_7 \text{ , kg/h} \quad \text{and} \quad W_0 + W_1 = W_2 + W_3 + W_4 + W_5 + W_6 \text{ , kW,}$$

where G_2, G_3, G_4, and G_5 are the flow rates of coke, steam, carrier gas for coke pulverisation, and electrode graphite, respectively; G_6, G_1, G_7 are the mass rates of slag (solid residue), effluent gases, and pulverised coke (fume and fine particles) being removed, respectively; W_0 is the heat output of the arc, W_1 is the heat supplied with steam at T = 405 K; the heat losses to the cooling water in the unit assemblies are: W_2 from the reactor; W_3 from the gas and slag separation chamber; W_4 from the synthesis-gas cooling chamber; W_5 from the slag catcher; W_6 from the heat carry-over in the effluent gas stream.

The arc electric power is determined from wattmeter. The heat input in steam is calculated as: $W_1 = G_3 \cdot H_1$, kW, where $H_1 = H°_{405K} + \Delta H°_{steam} = 0.05 + 0.63 = 0.68$ kW·h/kg of steam. $\Delta H°_{steam}$ is the heat of vaporization.

The heat loss in the effluent gases is determined from the effluent gas temperature (T_g), flow rate (G_1), and composition obtained through the gas analysis. The measured temperature, pressure, and composition of gases are fed into the TERRA code [1] and the specific enthalpy of the effluent gases is computed for specified values of the parameters mentioned above. The gas mixture heat output is calculated as follows:

$$W_6 = H_6 \cdot G_1 \text{ , kW, where } H_6 = \int_{300}^{T_g} C_p \cdot dT \text{ is the specific enthalpy of the gas mixture.}$$

Thus, except for W_6, all the components of the heat balance equation are measured during the experiment. At that metering error of water flow for heat losses of the experimental plant determination is less that 1% of meter scale. Metering error of the cooling water temperature is ±0.1 K. Chromel-alumel and platinum-platinum-rhodium thermocouples provide measuring of outgoing gas temperature. The gas temperature metering error is ±0.01 K. For high temperature measurements infrared thermometers allowing to measure temperature to 4000 K were used. Metering errors depends on temperature interval of measurements and can reach ±2% from measured temperature. Measurement system Prowirl 77F used for measuring steam flow through reactor allows measuring flow range of 10^{-3} to 10 m^3/s. It provides measurements of the flow values within 0.1% accuracy. For the outgoing gases flow measurement differential manometer is used. The accuracy for its values is also within 0.1%. One of the major components of the experimental plant is the system of coke-dust supply to the gasifier. Metering error of the dust consumption is not less than ±0.5 g/s.

The gas is subject to chromatographic analysis. Carrier gas is helium or argon, detectors are thermal conductivity sensors. Analysis of the light gas like H_2, CO, O_2, N_2 and CH_4 is provided in the columns filled with molecular sieve CaX and analysis of CO_2 in the columns filled with silica gel. Absolute calibration method was used for the chromatograph data handling. A sampling is implemented in several point of the installation including plasma reactor. The composition of the solid residue is examined by chemical and X-ray phase analyses. To determine carbon gasification degree absorption-weight method is used. According to absorption-weight method carbon is determined through the carbon dioxide that is formed as a result of the solid residue sample combustion and following absorption of it by ascarit (KOH or NaOH covering asbestos).

Conditions of the experiments and their results are shown in Table 1. The plasma reactor power was 60kW in the both experiments. At that measured thermal efficiency of the plasma gasifier was about 80%.

It is seen from the table that the ratio of steam flow to the petrocoke consumption was varied in interval 1.2-1.4. The steam flow initial temperature was 140^{O}C. The petrocoke gasification degree (Xc) varied from 76.3 to 78.6%. The increased concentration N_2 and O_2 in comparison with calculated ones can be explained by uncontrolled air inflow through sealing disks of the unit as it works under discharge 10-15 mm of water lift. The

synthesis gas maximal yield was 93.6%. That is in good agreement with the predicted syngas concentration ($CO + H_2 = 97\%$).

Table 1. Experimental results

G_{COKE}, kg/h	G_{STEAM}, kg/h	Concentration, vol.%				T, K	Xc, %
		H_2	CO	N_2	O_2		
2.5	3.5	53.5	33.9	11.8	0.8	2,500	76.3
2.5	3.0	57.4	36.2	6.0	0.4	2,960	78.6

The received from the petrocoke syngas is a high-quality power gas, and it can be used for synthetic liquid fuel (methanol) synthesis: $CO + 2H_2 = CH_3OH$ [4]. Syngas [3] of this quality is high-potential reducing agent instead of metallurgical coke for iron ore direct reducing. Also plasma steam gasification is perspective method for hydrogen production through water steam decomposition by petrocoke carbon.

Plasma-deposited thin films, useful for medical and biotechnological applications

This contribution will focus on several applications of polymers in contact with a biological environment. Thus, the requirements for appropriate interaction (often summarized as biocompatibility) of the respective materials surfaces with living cells (mammalian as well as prokaryotic cells) and bio-molecules will be discussed in the frame of usually mentioned surface properties like wettability etc.
Following some short remarks on polymers in general and on those used for biomedical application will be given.

In a following step several plasma-chemical approaches for the generation of well defined surfaces with uniform functionalities are described. A short discourse on the historical development and the state of the art of these approaches will be presented. The needed densities and availability of the functionalities, so far possible, will be given in functions per surface area or per film volume. The surface analytical methods useful for the qualitative and quantitative estimation of the chemical functions on surfaces and in thin films will also be shortly presented. The different plasma-chemical strategies for the deposition of a chemically uniform film on surfaces are evaluated with respect to their technical and economical appropriateness. From this viewpoint stability aspects will be discussed. Therefore a short overview on stability aspects of plasma modified surfaces will be given

Beside surface properties like surface energy, surface charges and roughness the aspects of structuring (2D) and penetration into trenches, fissures and pores (3D) will be discussed. Examples of plasma-carboxylated two- and three-dimensional structures will be shown and discussed with respect to the penetration depth.

Some special applications as for example the production of regio-selective finished surfaces of separation membranes, a field where an unique potential of plasma-technology is obvious, will be presented in more detail.

For surface preparation of polymers by glow discharges and related techniques, some implications on reactors have to be taken into account and will be discussed as well as some analytical tools, which are appropriate for the development of surfaces useful for biotechnological application.

Finally an outlook on future needs (from a biotechnological viewpoint) and trends in plasma technology (with respect to polymer modification) will be given.

TOWARDS A NEW ERA OF PLASMA SPRAY PROCESSING

T. Yoshida
Department of Materials Engineering, The University of Tokyo, Tokyo 113-8656, Japan
e-mail : yoshida@plasma.t.u-tokyo.ac.jp

For the last 30 years, I have been engaged in studying plasma processing based on materials science, namely, plasma materials engineering. I started with the study of thermal plasma processing, especially plasma-particle interaction and co-condensation process of high temperature vapors, and then expanded to the ultrafine particle synthesis and to thermal plasma PVD, CVD and powder spraying for coating applications. 10 years ago, I also started to utilize medium pressure plasma with an aim at super-high rate deposition of pure silicon, and found that the peculiar characteristic of this plasma is suitably called “Meso-plasma” as a new category of plasmas. Looking back my research carrier, the research field would be characterized mainly by the words: plasma and vapor condensation, and is fortunately fit to the recent global trend of materials R&D which is shifting from “monolithic” to “materials system” and from “bulk” to “thin film & coating”, although this was not the case 30 years ago.

It is, on the other hand, a clear consensus that the primary factor in materials development is “affordability” and it must be considered at every step in processing; unless otherwise, all the efforts are only for the sake of research. It is thus a natural consequence that the plasma processing, as an affordable and effective thin film & coating technology, is attracting global attentions in materials engineering. Unfortunately, however, the current plasma spray thin film & coating technology seems not yet to reach the sufficient level to meet the requirements from the fields where this technique was not applicable in the past. In fact, considering the present status of all the thin film & coating related markets on the basis of this technology developed over the last thirty years and its future possible evolution, the rapidly growing desires, such as the next-generation thin film devices and nano-coatings, would not be fully gratified if the currently available technologies are only used. I suppose that I am not the only one who believes that new standpoints and principles with the fundamental research concept should be introduced from both plasma processing science and materials science & engineering perspectives.

In this context, this lecture will point out the disregarded but important issues involved in the conventional plasma spray processing and infer the future potential of novel plasma spray processing with an use of extended feedstock like gases, liquids and various sized powders. In particular, special attention will be given to our recent challenges aiming at a development of novel deposition processes for silicon films by maso-plasma CVD, and of thermal barrier coatings by novel comprehensive plasma spraying.

Nanoparticles and Plasmas

Steven L. Girshick
University of Minnesota, Minneapolis, USA

Long before the term “nanoparticle” was coined it was known that plasmas are one of the most effective ways to synthesize ultrafine particles, with nanoscale dimensions, of many different substances. Since the 1960s both DC and RF thermal plasmas have been used to generate ultrafine powders for various applications, particularly for production of advanced ceramics. On the other hand, starting around 1990 interest began to grow in the problem of unwanted nucleation of contaminant particles in low-pressure semiconductor processing plasmas. Over the last several years there has been an enormous increase in the level of research activity, in contexts ranging from the deliberate synthesis of nanoparticles in low-pressure plasmas, for applications such as advanced solar cells, optical displays and electronic devices, to use of thermal plasmas for high-rate production of nanoparticle films as superhard coatings. At the same time, the continued shrinking of microelectronics feature sizes is making the nanoparticle contamination problem ever more challenging.

This lecture will give an overview of nanoparticles in both thermal and nonthermal plasmas, and will review the current state of understanding of nanoparticle nucleation, growth, coagulation, charging and transport in plasmas. Current research in our laboratory at the University of Minnesota is focused on three broad themes. The first involves the use of thermal plasmas to synthesize nanoparticles at high rates, but then seeks to develop approaches either to deposit these nanoparticles in controlled fashion (*e.g.* by hypersonic impaction or aerodynamic focusing) so as to form useful nanostructured materials, or to process the particles in flight (*e.g.* by growing films on particle surfaces), or both. The second theme involves studies of particle nucleation in chemically reacting low-pressure plasmas, including both deposition and etching systems. Particle nucleation in nonequilibrium plasmas exhibits a rich range of phenomena, many of which are not found in thermally-driven systems. The final theme concerns the development of computational models that simulate nanoparticle formation and dynamics in plasmas. This work ranges from the development of more efficient numerical methods for solving the aerosol general dynamics equation, two-way coupled to detailed plasma/chemical kinetic models, to Monte Carlo simulations of particle transport.

PLASMA AIDED COMBUSTION

S.M.Starikovskaia, I.N.Kosarev, E.I.Mintoussov, A.Yu.Starikovskii
Moscow Institute of Physics and Technology, Dolgoprudny, 141700, Russia

Abstract

The efficiency of nanosecond discharges as active particles generator for plasma assisted combustion and ignition has been investigated. The study of nanosecond barrier discharge influence on a flame propagation and flame blow-off velocity was carried out. With energy input negligible in comparison with burner's chemical power, a double flame blow-off velocity increase was obtained. The present paper shows that, besides proper form of energy input, proper organization of discharge is of great importance. It was found that active particles (O and OH primarily), which are produced in the streamer head under its action, play the most significant role in the effect of combustion acceleration. The model of flame acceleration, suggested in the previous work, was confirmed by the new experimental data. Ignition of homological series of hydrocarbons from CH_4 to C_4H_{10} under the action of nanosecond discharge was investigated. Significant shift of ignition delay time in comparison with autoignition was obtained for all mixtures. Experiments with ignition by excimer laser flash-photolysis were carried out to study the role of excited atomic species in the ignition of combustible mixtures.

Introduction

The problem of the uniform ignition and efficient combustion of a gas mixture is of crucial importance from both scientific and technological standpoints. The oxidization of a fuel proceeds via a chain mechanism, which is very fast. The delay time of ignition is limited by the rate at which active centers are produced, usually by thermal dissociation. For this reason, the total rate of reaction is, in fact, higher with artificial initiation of a chain. The easiest way to produce free radicals is to decompose the weakest bond of a molecule.[1] The two mechanisms by which a discharge can affect a gas should be taken into account when using a discharge to initiate combustion. For discharges resulting in the formation of an equilibrium (or nearly equilibrium) plasma (e.g., sparks and arcs), the main factor that reduces the delay time of ignition is local heating of gas and, accordingly, the increase in rate of thermal dissociation.[2–4] In the case of a nonequilibrium plasma, the main mechanism initiating chain reactions is dissociation and excitation of molecules by electron-impact. The question of the efficiency of using nonequilibrium plasmas still remains open despite of the fact that theoretically even relatively small amount of atoms and radicals ($\sim 10^{-5}$–10^{-3} of the total number of the gas particles) can shift equilibria in the system and initiate a chain reaction.

In the present paper we analyze three radical – influenced chemically reacting systems: plasma assisted combustion of premixed fuel – air mixtures at atmospheric conditions; plasma assisted ignition of homological series of hydrocarbons in preliminary heated mixtures and ignition of mixture containing N_2O and hydrogen by laser flash-photolysis and the discharge.

Combustion Experiment

The main part of the experimental setup is a quartz nozzle with rectangular section. Three different nozzles, with 2.2, 2.5 and 4.3 mm in width and the same length of 30 mm were investigated. Stainless steel 0,8 mm thick high-voltage electrode was placed inside the nozzle, and the grounded electrodes were situated near the nozzle edges, parallel to them. In order to prevent a transition of the discharge into a spark form, they were set tightly into quartz tubes. On applying a voltage to the gap, a barrier discharge occurred, so the maximum possible current was limited by the dielectric. You can find more detailed description of the setup in.[5]

To fix the point of streamer start and the number of streamers as well, the high-voltage electrode has a number of pins on its upper edge. Two electrodes were used - with 8 and 15 pins, so the number of streamers could be 16 or 30 respectively. The nozzle and images of discharge and flame are presented in fig.1.

Earlier it was shown by the authors in[5] by picosecond ICCD camera images that the energy inputs in the mixture only during the first 10-20 ns of pulse duration, and then the region of energy release moves beyond the zone of mixture flow and is situated near the grounded electrodes. To increase the effectiveness

of energy input, the principal scheme of high-voltage generator has been changed entirely. Instead of rotation interruptor scheme with pulses of 77 ns FWHM, we used the idea of magnetic compression to reduce the pulse length. In the present work we used three different types of pulses: with FWHM 7, 19 and 24 ns. The voltage on the discharge gap could be 14 kV or 22 kV, the nanosecond pulse polarity was positive. Pulse repetition rate could be varied within the range of 400-1000Hz.

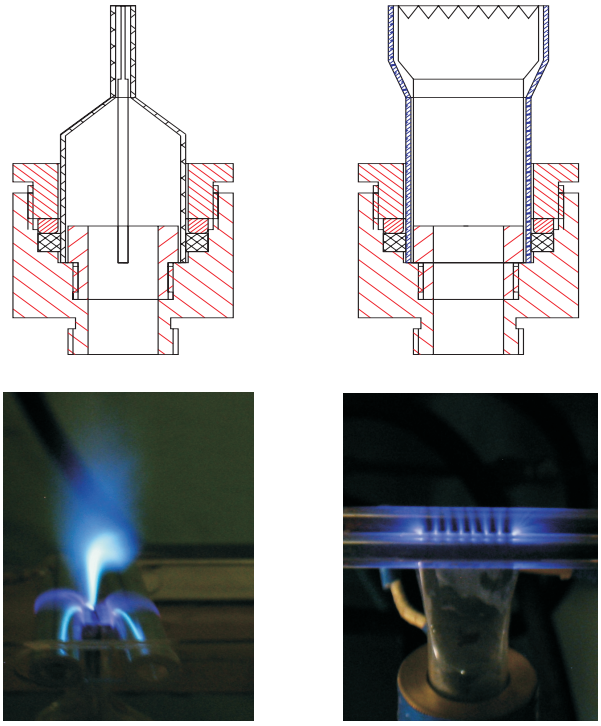

Figure 1: Quartz nozzle and discharge view

The investigations of active particles production were performed by emission spectroscopy methods. The recording facility consisted of CCD-line (spectral range of $\lambda = 200$–800 nm) and MDR-41 monochromator (with an operating range of $\lambda = 190$–600 nm and a linear dispersion of 0,96 nm/mm). The optical system was calibrated using a standard emission source (a calibrated DDS-30 deuterium arc lamp emitting in the range 190–500 nm).

Combustion. Results and Discussion

It was shown in,[1] that in processes of combustion acceleration and flame velocity increase the main role is played by active particles (such as O, H, OH and so on), which are responsible for chain branching. The production of additional centers results in acceleration of chemical kinetic processes. Another important feature is the proper organization of energy input. The energy should be put inside the gap and lead to radical production (instead of gas ionization or thermal heating). Streamer type of discharge totally corresponds to these condition. The main area, where active particles are produced, is the streamer head, which is quite small (~ 0.05 cm for typical voltages of 10–20 kV[6]), but has high values of reduced electric fields (up to 800 Td).

We used two different high-voltage electrodes - with 8 and 15 pins. In fig 2 and fig 3 the comparison of the discharge influence on propane-air flame blow-off velocity is shown. It's seen quite well that both types of electrodes lead to flame acceleration for the cases of 14 kV and 22 kV. But the effectiveness of such influence is different - the effect is greater for 15-pin electrode (Fig.4), because of the larger quantity of streamer. So, the flame stabilization occurs due to the plasma action and hardly depends on the local overheating near the steel plate pins, because estimations shows that overheating is greater in case of 8-pin electrode.

The energy input in both cases was the same and was equal approximately to 2-5 mJ per pulse (2-5 W of total power). This value corresponds to 0,5% of the chemical power of the burner. The equivalent value of gas heating by this energy is 10-20 K. This fact confirms the thesis about the importance of the way we put energy in the mixture.

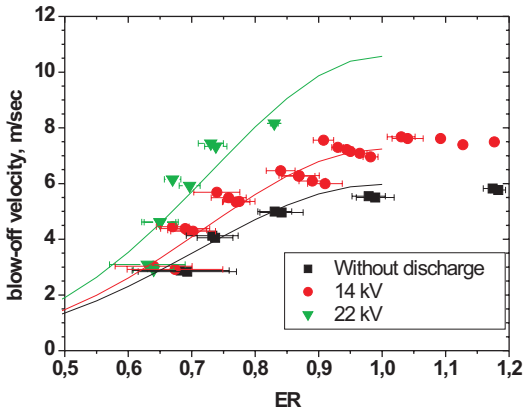

Figure 2: Flame blow-off velocity increase with 8-pin HV electrode

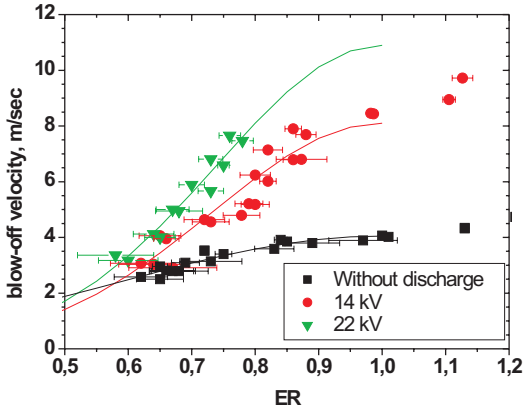

Figure 3: Flame blow-off velocity increase with 15-pin HV electrode

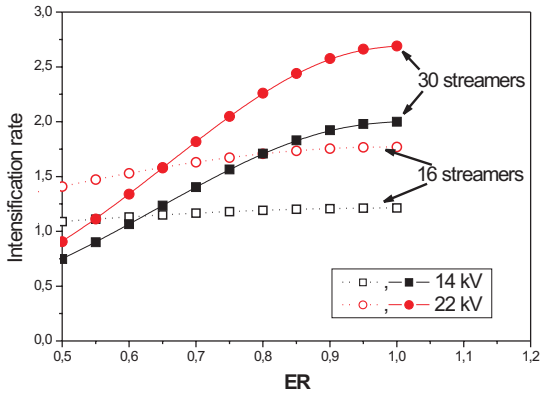

Figure 4: The comparison of the effectiveness of influence. 8-pin versus 15-pin HV electrode

We just have showed that if we are making pulse shorter (24 ns vs 77 ns in the previous work[5]), we can increase the efficiency of energy input (we've reduced energy input more than 2 times, and still have the same increase in flame blow-off velocity). But the duration of pulse should be greater than the time

of streamer propagation through the gap where mixture flows, to provide full overlapping of the nozzle by the streamer. The streamer velocity was calculated in,[6] and is equal to 0.6 mm/ns under the voltage of 22 kV, so in the case of 14 kV, as in our experiment, the velocity value is even lower. On the images (Fig.5) it is shown that in the regimes near blow-off point streamer prefers go through the weakly ionized zone just below the flame instead of the shorter way. Calculations were made for the time of the gap overlapping, and the result is approx. 8 ns in the case of 2 mm nozzle (track length is 5 mm), and even greater in the case of 4.3 mm nozzle.

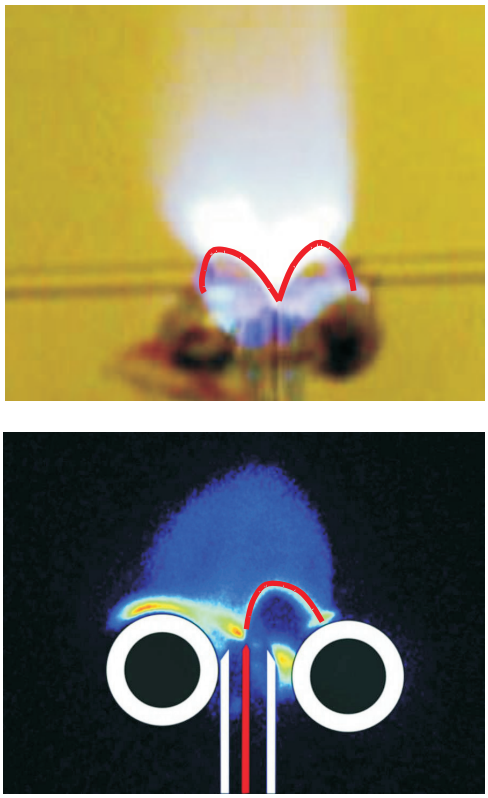

Figure 5: The streamer track in the gap. Top image was obtained by common camera, bottom one - by ICCD picosecond camera, the gate is 1 ns

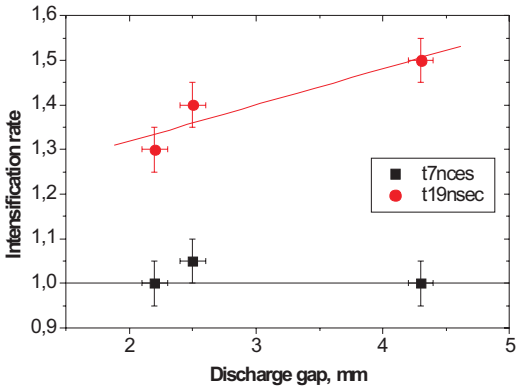

Figure 6: The discharge influence on flame blow-off velocity for different pulse durations

To confirm these arguments, a number of experiments has been performed. Two types of additional line pieces were used to provide different pulse duration (FWHM 7 ns and 19 ns). It was found that at frequency 500 Hz and ER=0.8 19 ns pulse is much more efficient than 7 ns one for all three nozzles, and

the advantage of using 19 ns grows with nozzle widening (Fig.6), as it was predicted earlier.

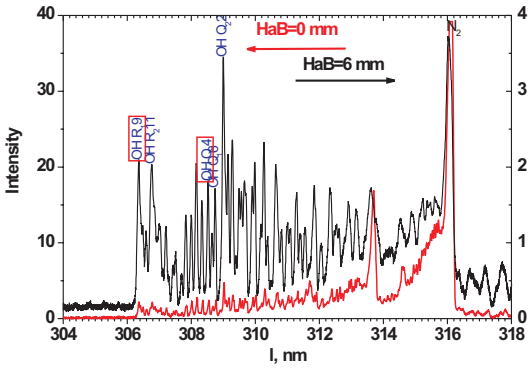

Figure 7: OH* spectra in methane-air flame under discharge action at HaB=0 mm and HaB=6 mm

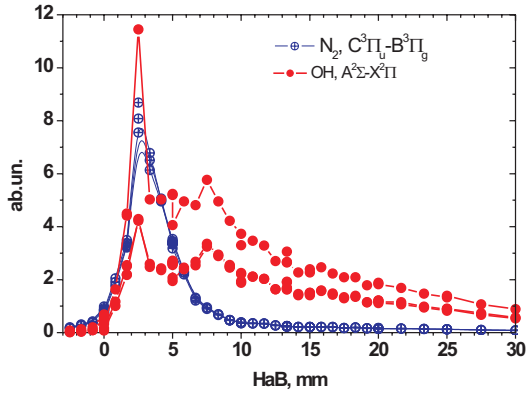

Figure 8: OH* profile along the HaB in methane-air flame

A series of experiments were made to prove the correctness of the model of flame acceleration and kinetic scheme, suggested in the previous work.[5] It's worth to remind that, according to,[5] the main role is played by radicals, which appears under the non-equilibrium nanosecond discharge action. That's why it's very important to make spectroscopic investigation of the flame itself and the flame under discharge action. In,[5] the profile of OH radical along the height above burner in propane-air flame was presented. That result was based on the non-resolved spectrum ($OH(A^2\Sigma, v' = 0 \rightarrow X^2\Pi, v'' = 0)$) at 306.4 nm with quite a large apparatus function of monochromator (2.4 nm). This caused a question, is the first peak of the typical "two-humped" spectrum connected with N_2 production in the discharge (second positive system of nitrogen $C^3\Pi_u \rightarrow B^3\Pi_g$ has intense lines on the wavelengths of 315.9 nm (1→0), 313.6 nm (2→1) and 311.6 (3→2))? In the present work, using CCD-line with signal accumulation mode, it became possible to obtain rotationally resolved spectrum of OH radical in methane-air flame. The spectra of OH* for two different heights (0 mm and 6 mm) above the burner are presented in fig.7. It's distinctly seen that in the region below 310-312 nm we can use any rotational line of OH* spectrum to build the dependence between OH* emission and height above burner (HaB). The result is presented in fig.8, and this figure confirms the previously obtained one for propane-air mixture as well as the importance of OH radical in flame and the similarity of kinetic processes, which lead to flame blow-off velocity increase, for the vast majority of premixed hydrocarbon-air flames. The results for methane-air flame blow-off velocity increase (fig.9) are in agreement with this theory.

Using OH rotationally resolved spectra, the rotational temperature was calculated. The technique of temperature determination is described in.[7] We used the ratio of $R_1(9)$ (λ=306.3565 nm) line and $Q_1(4)$ (λ=308.3278 nm) line. In the case of equilibrium flame, the rotational temperature, obtained in a such

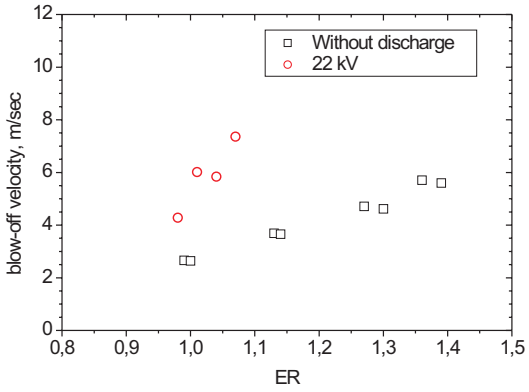

Figure 9: Methane-air flame blow-off velocity increase

way, is close to the translational temperature (the radiative time of living of $A^2\Sigma$ level is 690 ns,[8] and the typical time between particles collisions is about 30 ns, so the Boltzmann distribution of particles at rotational levels occurs before radiation). Experimental OH rotational temperature profiles along the height above burner in methane-air flame are presented in fig.10

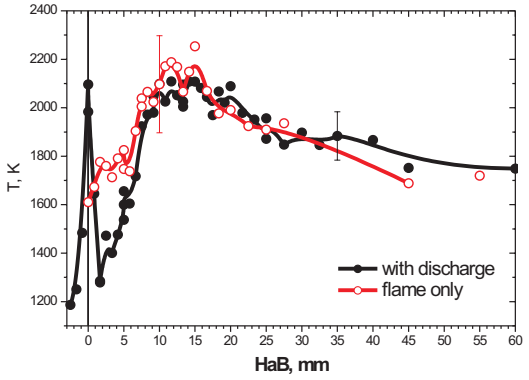

Figure 10: Experimental OH rotational temperature profile along the HaB in methane-air flame

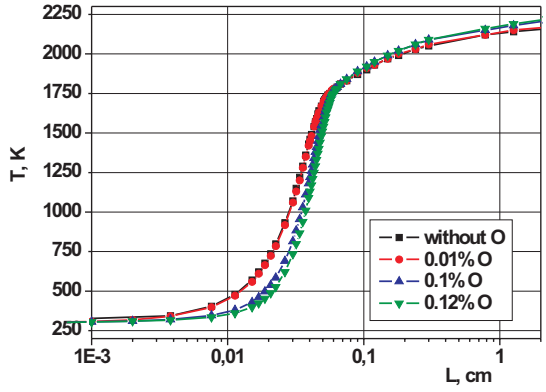

Figure 11: Calculated temperature profile along the HaB in methane-air flame

The comparison of experimental profile with calculated one shows a good data agreement. The theoretical model is based on changing in initial mixture composition under the discharge action.

An additional proof to the suggested theory and the model of radical influence lies in the results of experiments with $Ar/O_2/C_3H_8$ mixture. We have changed the nitrogen in the mixture to argon in order to prevent active particles formation. According to the model, the main channel of O and OH production is the quenching of electronically-exited triplet states of N_2 on the oxygen molecules in processes:

$$N_2(A^3\Sigma_u^+) + O_2 \rightarrow N_2(X^1\Sigma_g^+) + O + O; \quad (1)$$
$$N_2(B^3\Pi_g) + O_2 \rightarrow N_2(X^1\Sigma_g^+) + O + O; \quad (2)$$
$$N_2(C^3\Pi_u) + O_2 \rightarrow N_2(X^1\Sigma_u^+) + O + O; \quad (3)$$
$$N_2(a'^1\Pi_g) + O_2 \rightarrow N_2(X^1\Sigma_u^+) + O + O. \quad (4)$$

or dissociation of oxygen molecule, which can proceed via its electronically excited states:

$$O_2(\text{el.exc.}) \rightarrow O(^3P) + O(^3P); \quad (5)$$
$$O_2(\text{el.exc.}) \rightarrow O(^3P) + O(^1D). \quad (6)$$

So, the substitute of nitrogen to argon should reduce the amount of atomic oxygen and decelerate flame in comparison with $N_2/O_2/C_3H_8$ mixture. Indeed, the results (fig.12) showed that the phenomenon in argon mixture is much more weaker. This is an evidence for our flame acceleration model.

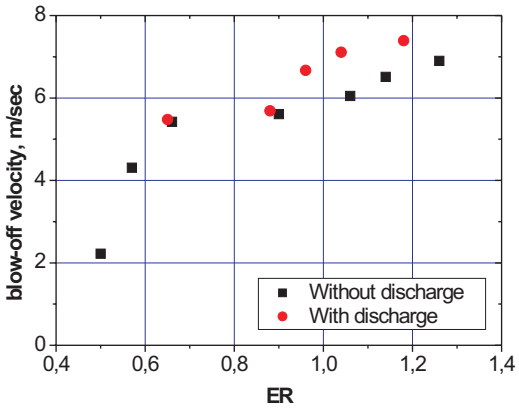

Figure 12: Flame blow-off velocity increase for $Ar/O_2/C_3H_8$ mixture

Ignition Experiment

The influence of nonequilibrium plasma pulsed discharge as an ignitor of combustible mixtures at various pressures and temperatures were investigated via shock tube technique. Experiments were carried out behind a reflected shock wave, as in classic experiments on the autoignition of combustible mixtures.[9,10] The experimental setup (see Fig. 13) consisted of a shock tube (ShT) with a discharge cell (DC), a gas evacuation and supply system, a system for ignition with discharge, and a diagnostic system. The shock tube (25×25-mm square cross section) had a 1.6 m long working channel. The length of the high-pressure cell (HPC) was 60 cm. There were two pairs of windows for optical diagnostics along the stainless-steel working channel. The last section of the shock tube with a 25×25-mm square cross section was made from 40 mm thick plexiglas and had eight optical windows (quartz and MgF_2). The metal end plate (EP) of the tube served as a high-voltage electrode. Another electrode was the grounded steel section of the shock tube.

The nanosecond discharge was initiated at the instant at which the reflected shock wave arrived to the observation point (point A in Fig. 13). High-voltage pulses were produced with a Marx type high-voltage generator (HVG). At the output of the forming line, the voltage growth rate was about 8 kV/ns, which

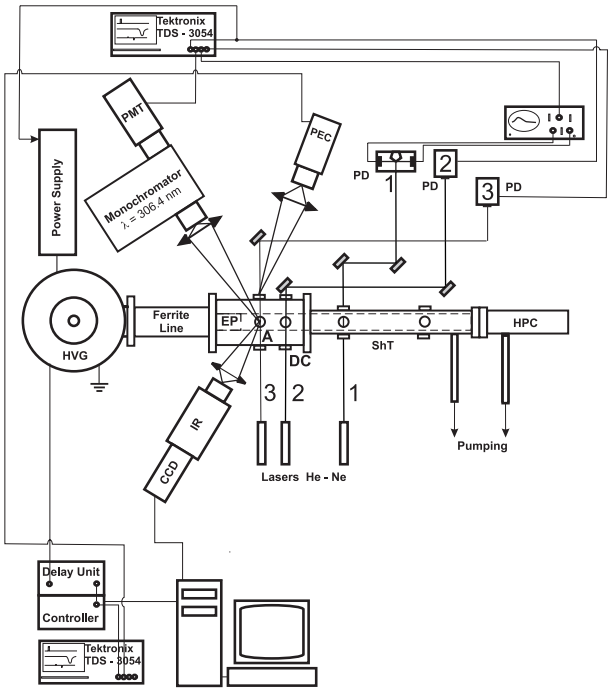

Figure 13: Scheme of the experimental setup. CCD — A — cross-section of measurement, CCD-camera, DC — discharge cell, EP — end plate, HPC — high pressure cell, HVG — high voltage generator, ShT — shock tube, PD — photodiode, PEC — photoelectric cell, PMT — photomultiplier.

enabled the operation of the gas discharge in the form of a fast ionization wave (FIW) in the dielectric section of the shock tube. The velocity of the ionization wave front was 10^9–10^{10} cm/s, depending on the experimental parameters.

The diagnostic system consisted of a system for monitoring the shock wave parameters, a system for detecting ignition, a system for studying the spatial structure of the discharge and combustion, and a system for monitoring the electric parameters of the nanosecond discharge. Velocity of a shock wave was measured by Schlieren system consisted of three HeNe lasers and a set of photodiodes (PD). The gas density (ρ_5), pressure (P_5), and temperature (T_5) behind the reflected shock wave were determined from the known initial gas mixture composition, the initial pressure, and the velocity of the incident shock wave. Ignition delay time was controlled using OH emission ($\lambda = 306.4$ nm, $A^2\Sigma(v' = 0) \rightarrow X^2\Pi(v'' = 0)$ transition) in microsecond time scale. Simultaneously we controlled emission from the discharge with nanosecond time resolution, current through the discharge cell and voltage drop between high-voltage electrode and cross-section of measurement.

Ignition. Results and Discussion

As a reference result, we considered data obtained for the methane – synthetic air stoichiometric mixture, diluted by argon.[11] What is important that we came back to this mixture during 1.5 years with a gap of a half of a year, and a summary of all these data, published, for example, in,[12] confirms an excellent reproducibility of the results.

The question about efficiency of ignition of different hydrocarbons in homological series by the nanosecond discharge is still remains open. This part of the paper is devoted to results of experimental investigation of ignition delay under the action of a nanosecond discharge. The experiments were carried out with a set of stoichiometric mixtures $C_xH_{2x+2} : O_2$ (20%) diluted by Ar (80%) for hydrocarbons from CH_4 to C_4H_{10}. The temperature behind the reflected shock wave (T_5) varied from 980 to 1630 K, and the pressure (P_5) was 0.17 to 1.0 atm. Composition of investigated mixtures is represented in Table 1.

The strongest change in OH emission intensity had been observed for methane – oxygen mixture, diluted by argon. This is shown in Fig. 14. For the conditions of this pair of experiments, Schlieren signals are practically the same, but discharge (it is indicated by a vertical line in the Figure) shifts the ignition delay by hundreds of microseconds. The same effect, but less pronounced, is observed for all series of hydrocarbons. As an example, difference in emission with and without discharge is represented

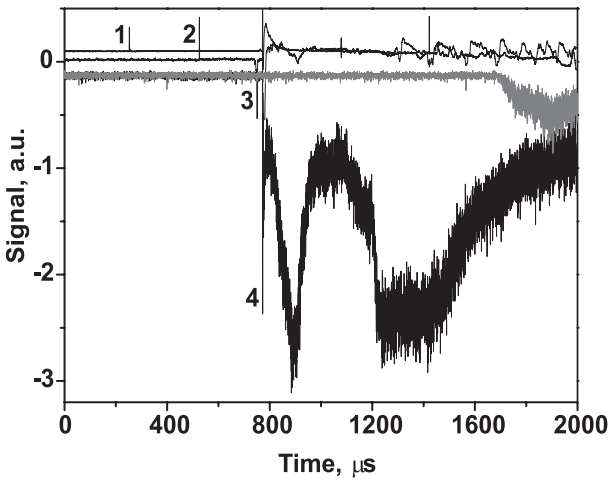

Figure 14: Typical oscillograms from Schlieren detectors (upper curves) and from photomultiplier (two lower curves). Methane–containing mixture. 1, 2 – direct shock wave, 3 – reflected shock wave, 4 - discharge. Gray curve from photomultiplier corresponds to autoignition, black one – to ignition by FIW.

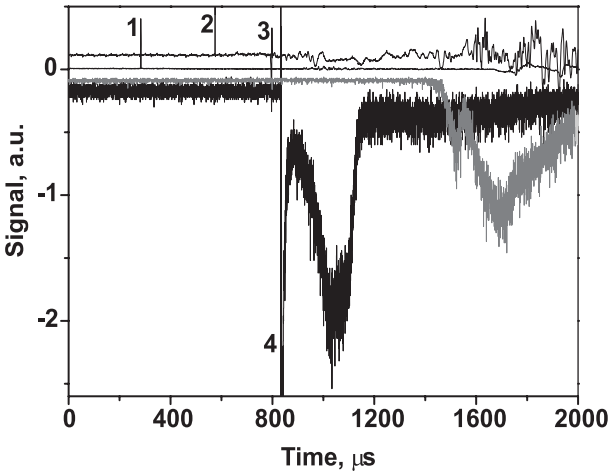

Figure 15: Typical oscillograms from Schlieren detectors (upper curves) and from photomultiplier (two lower curves). Butane–containing mixture. 1, 2 – direct shock wave, 3 – reflected shock wave, 4 - discharge. Gray curve from photomultiplier corresponds to autoignition, black one – to ignition by FIW.

Table 1: Investigated mixtures

Alkane	CH_4	C_2H_6	C_3H_8	C_4H_{10}
	6.7%	4.4%	3.3%	2.7%
O_2	13.3%	15.6%	16.7%	17.3%
Ar	80%	80%	80%	80%

for butane – oxygen mixture, too (see Fig. 15).

Figures 16–19 demonstrate dependence of ignition delay time for autoignition and ignition by nanosecond discharge for all investigated mixtures. It is clearly seen that ignition delay is well-pronounced in all the cases. Difference for C_4H_{10} is the strongest in a region of 1100–1200 K, while for C_3H_8 the difference is practically constant within a range of 1400–1600 K and comprises about 200 K.

Energy measurement have been performed for different mixtures. The results are demonstrated in the Fig. 20. It is obvious that the energy values are of the same order of magnitude as in methane-containing mixture. This is quite clear, because for mixture with 80% of Ar dilution and $13 - 17\%$ of O_2, energy input into discharge will be determined preferably by Ar–O_2 mixture. It is seen from the Figure, that

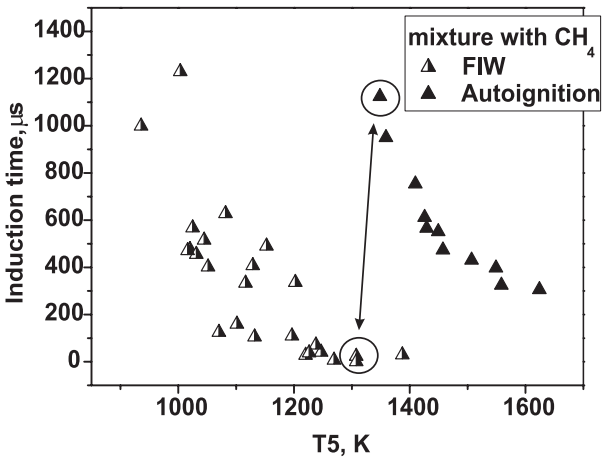

Figure 16: Ignition delay time *vs* temperature for methane – containing mixture.

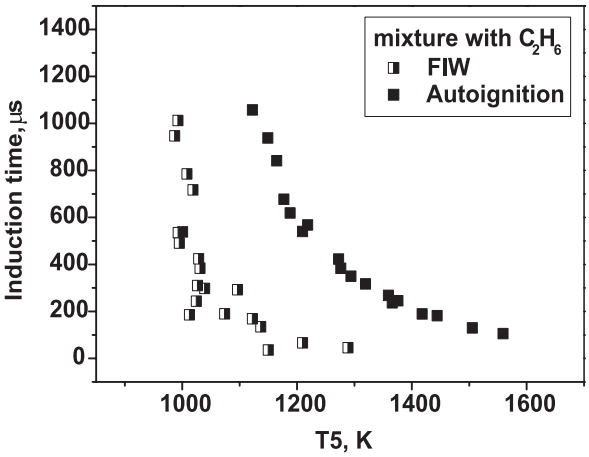

Figure 17: Ignition delay time *vs* temperature for ethane – containing mixture.

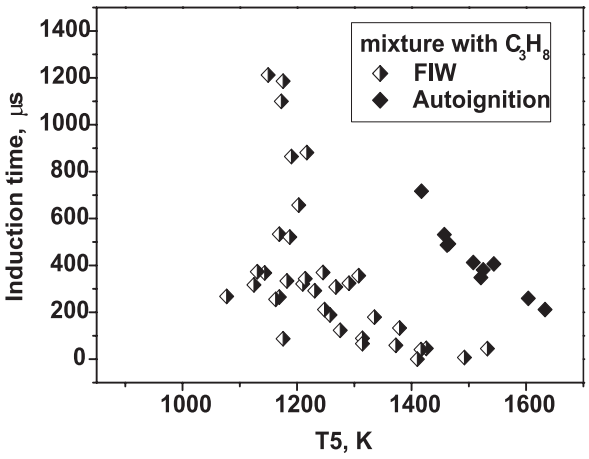

Figure 18: Ignition delay time *vs* temperature for propane – containing mixture.

the main part of experimental point is within interval 7-13 mJ/cm^3 (this region is separated with two horizontal lines).

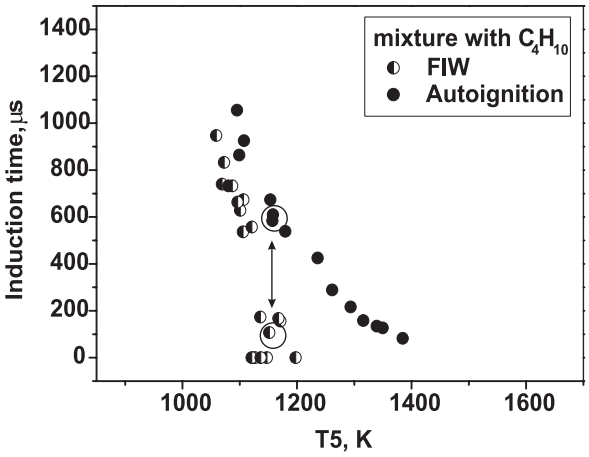

Figure 19: Ignition delay time *vs* temperature for butane – containing mixture.

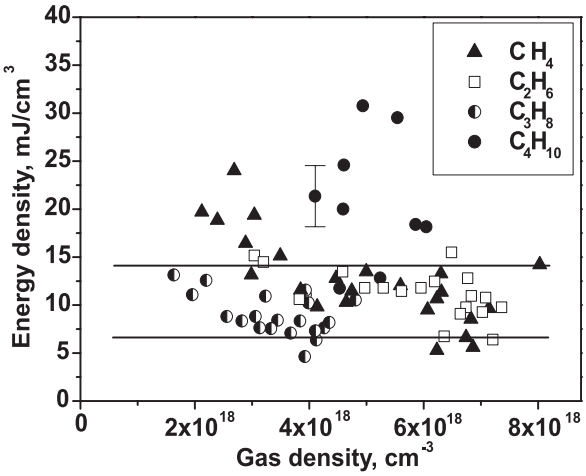

Figure 20: Energy input into a gas for different gases.

Laser Ignition. Experiment

The diagnostic system used for ignition by the discharge was modified to control ignition by laser flash-photolysis. A flash of UV-radiation of ArF excimer laser ("Center of Physical Devices" production, Troitsk, $\lambda = 193$ nm) was organized behind the reflected shock wave instead of the nanosecond discharge. Laser output reached 0.2 J. The laser radiation was supplied to the dielectric section of the shock tube through the optical window perpendicularly to the shock tube axis in the same cross-section were we performed measurements in a case of the ignition by nanosecond discharge. Laser spot had approximately rectangular shape with 5×21 mm dimensions and was controlled by special sensible paper.

A piroelectric detector (PEM21) with 21 mm diameter of receiving site was used to determine energy input from laser radiation into the gas. Signal from PEM21 was controlled every time before the experiment, when the system was pumped up to 10^{-2} Torr and then during the experiment. Knowing spectral transmission of MgF_2 windows in this spectral range (were controlled by Varian Cary50 Spectrophotometer) we calculated energy input into a gas. We organized experiment so, that energy input in the discharge and energy input from a laser were within one order of magnitude. We controlled initial gas pressure and shock wave velocity, and parameters behind the reflected shock wave were calculated as in the previous case. Ignition delay time was calculated from the OH emission at 306 nm.

The experiments were repeated with the same mixture for autoignition, discharge initiation of ignition and ArF flash-photolysis. Ignition delay times were compared for all cases. To make these experiments, we chosen N_2O as a main absorbing component. Really, N_2O is known to be very efficient as an oxidant. On the other hand, it absorbs radiation at 193 nm better than molecular oxygen. To demonstrate this, cross-sections of molecular oxygen and N_2O molecule are represented in the Fig. 21. So, experiments

were performed in gas mixture N_2O:H_2:Ar = 1:1:8. In our earlier experiments 1% of CO_2 was added to a gas mixture for control of a gas temperature using emission in IR range of spectrum.

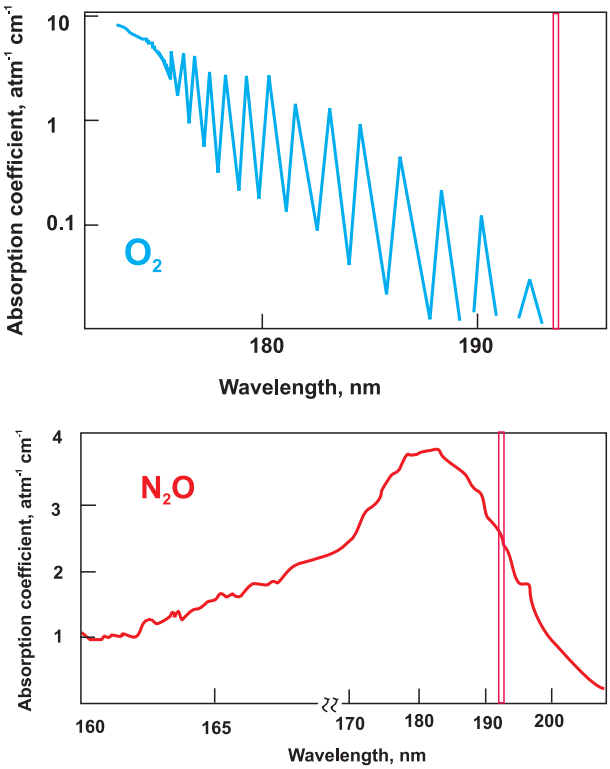

Figure 21: Cross-section of absorption: **a** — for molecular oxygen, **b** — for nitrous oxide. Region of ArF laser generation is marked with vertical lines.

Laser Ignition. Results and Discussion

Typical energy input in a gas in experiments with flash-photolysis is demonstrated by Fig. 22. The shape of a laser beam is quite uniform It is represented in a right hand side of the figure. Energy value obtained by piroelectric gauge was divided by volume 5x20x25 mm, where 25 mm is a transverse size of a shock tube channel.

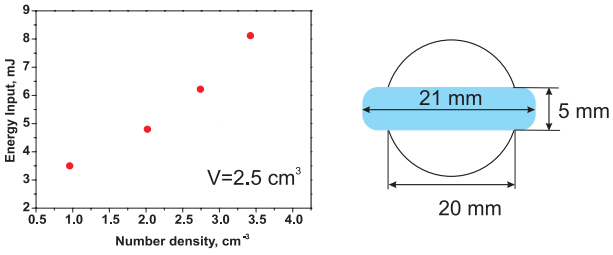

Figure 22: Typical energy input in experiments with laser flash–photolysis. A shape of a laser beam is on the right part of a figure.

It is known that N_2O photolysis takes place via the reactions:

$$N_2O + h\nu = N_2 + O(^1D), \tag{7}$$

$$N_2O + h\nu = N_2 + O(^4S), \tag{8}$$

at this weight of reaction (7) is 99%. $O(^1D)$ is a metastable atom, its life time is 150 s, and usually it looses excitation in collisions with other species. It may destruct N_2O via the reactions

$$N_2O + O(^1D) = N_2 + O_2, \tag{9}$$

$$N_2O + O(^1D) = NO + NO. \tag{10}$$

On the other hand, $O(^1D)$ has to be active in ignition. The results of our preliminary experiments (with 1% CO_2 in gas mixture) demonstrated no effect on ignition delay, in spite of a fact that nanosecond discharge shifts the threshold by hundreds of K, which is typical for this discharge in different gas mixtures. Behavior of mixture with 1% CO_2 additive is illustrated by Fig. 23.

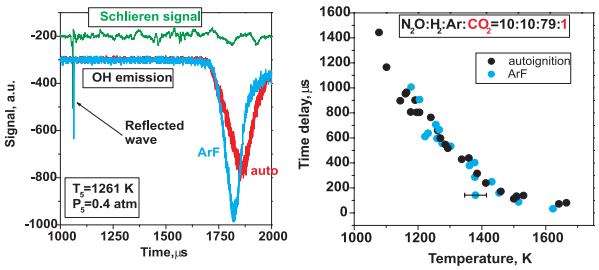

Figure 23: Typical oscillograms and time delay dependence upon gas temperature for gas mixture with additive of carbon dioxide.

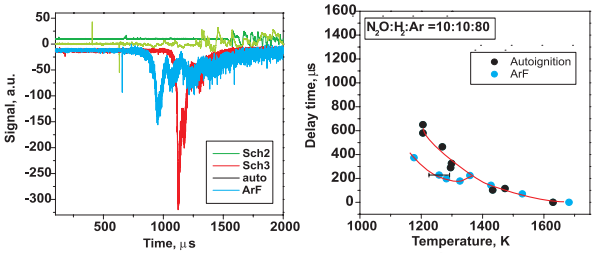

Figure 24: Typical oscillograms and time delay dependence upon gas temperature for gas mixture without additive of carbon dioxide.

We tried to use mixture N_2O:H_2:Ar = 1:4:5 (also with 1% CO_2) and to focus laser radiation, but we were not able to shift the ignition delay. At the same time, in gas mixture N_2O:H_2:Ar = 1:1:8 without CO_2 additives we have obtained some systematic result, which is represented in the Fig. 24. We obtained at least four points, where ignition by laser differed significantly from autoignition.

Previous analysis demonstrate the following: on one hand, CO_2 is rather strong quencher[13] of $O(^1D)$ radicals:

$$O(^1D) + CO_2 = O(^3P) + CO_2^*. \tag{11}$$

Constant rate for the reaction (11) is $2 \cdot 10^{-11}$ cm^3/s, and typical estimated time of $O(^1D)$ destruction in our system due to the presence of CO_2 may be as short as 2 μs. On the other hand, there is a lot of species, even in our system, which are much more active as excited oxygen atoms quenchers. They are, first of all, water and molecular hydrogen. In principle, water is a final product of combustion process and its amount may not be enough on the initial stage to prevent CO_2 to quench atomic oxygen. As for hydrogen, it do quenches $O(^1D)$, but this is one of main helpful reaction in our system. We believe, that this point need to be investigated more carefully. It is necessary to obtain results for the shift of ignition delay by flash–photolysis again, just to be sure that they are reproducible and to analyze them.

Conclusion

The study of efficiency of nanosecond discharge plasma on combustion and ignition process has been carried out. The following conclusions could be made:

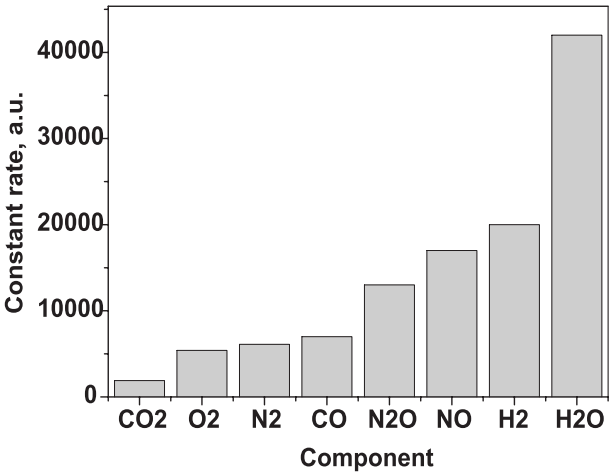

Figure 25: Comparison of constant rates for quenching of excited oxygen atom.

For nanosecond plasma assisted combustion, with energy input negligible in comparison with burner's chemical power, a double propane-air flame blow-off velocity increase was obtained. It was shown experimentally that the results for methane-air flame are similar with propane-air one. Besides proper form of energy input, proper organization of discharge is of great importance. It was found that the effectiveness of plasma-assisted combustion depends on type of discharge, pulse duration, pulse repetition rate and other parameters, which are responsible for active particles production. It was found that active particles (O and OH primarily), which are produced in the streamer head under its action, play the most significant role in the effect of combustion acceleration. The model of flame acceleration, based on nitrogen quenching on oxygen molecules, with production of O and OH radicals, was confirmed by the new spectroscopic investigations and experiments with $Ar/O_2/C_3H_8$ mixture, where discharge influence is small because of the absence of mechanism of active particles production.

The investigation of efficiency of the nanosecond discharge to ignite homological family of hydrocarbons has been started. Gas mixtures of methane, propane and butane has been investigated under the same experimental conditions. It is demonstrated that high-voltage nanosecond discharge is an efficient tool of ignition of different hydrocarbons. Results for the ignition delay and shift of a temperature threshold under the action of nanosecond discharge have been obtained experimentally.

Experiments to investigate ignition delay shift under the action of excimer laser flash-photolysis have been organized. It was found that small additives of CO_2 may influence significantly on the results. Preliminary analysis of possible mechanisms of $O(^1D)$ de-excitation has been performed. Ignition delay shift under the action of flash-photolysis has been obtained systematically in four points. Additional experiments are planned to prove or refute these preliminary results. In a case we will obtain the ignition delay shift it will be possible to estimate efficiency of excited atoms in the process of ignition. In a case the experiments will not demonstrate the difference between autoignition and ignition by flash-photolysis, we will have a ponderable reason to organize investigation of influence of charged particles (ions) on the ignition delay.

Abstract

Boron-doped multi-walled carbon nanotubes (MWCNTs) were generated by arc discharge in water by using B-doped graphite electrodes. The product morphology was studied by SEM and HRTEM microscopy. The structure features were determinated by Raman and EELS spectroscopy. Optical emission spectroscopy (OES) was performed to evalute the temperature and C_2 content distributions in arc plasma.

1. Introduction

Since the discovery of multi-walled carbon nanotubes (MWCNTs) in 1991 [1], they have been extensively studied for various applications. Their small dimension, high strenght and the remarkable physical properties make them very promising emmiters for field emission devices. Due to the size-effect and structure diversivity of nanotubes, the physical properties strongly depend on their stucture, size and chemical composition. Different diameter, length and chirality of MWCNTs give a rise to diverse physical and mechanical properties. It is believed that the atom inclusions into hexagonal network such as nitrogen, phosphorus or boron can enhance e.g., MWCNTs' eletronic properties by creating electrons or holes.
Boron-doped MWCNTs were synthesized by using many various techniques including dc arc discharge [2], microwave plasma chemical vapor deposition [3], laser vaporization method [4], and substitution reaction [5]. Recently [6], we reported that arc discharge in water generates various carbon nanostructures (nanotubes, onions, and encapsulates). In this study we report boron-doped MWCNTs synthesis by arc discharge in water by using B-doped homogeneous graphite electrodes.

2. Experimental

The equipment, based on a gas phase arc-discharge system previously used for fullerenes and CNTs formation [6], was modified to facilitate a continous d.c. arc discharge in water. The anode and cathode (6 mm diameter) were immersed to a depth of ca. 3 cm in deionized water (1 dm^3) contained in a transparent glass trough. The electrodes were aligned horizontally. The brass electrode holders were free to mowe, forward and backward, which enabled proper electrode gap adjustment to be made during arc discharge (Fig. 1).

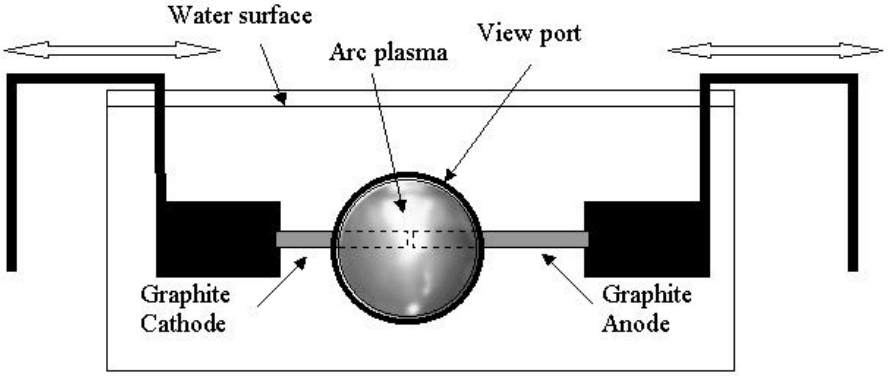

Fig. 1. Electrodes arrangment for arc discharge in water.

Upon ignition the electrode gap was maitained at ca. <0.7 mm, to avoid arc disruption We used a digitally controllable power suplly with constant voltage output up to 90 V. Four tests were performed, where boron content in the anode was varied between 0 and 11 at. % (Table 1).

Table 1. Experimental detail.

Test No.	Current [A]	Voltage [V]	Anode erosion rate [mg s^{-1}]	Boron concentration in anode [at. %]
1	40	28	2.5	0
2			2.4	1
3			3.1	3
4			3.2	11

During discharge, the spectroscopic features of the plasma emission were monitored optically by using a ST8 CCD camera coupled with a high resolution spectrograph, in order to identify the atomic lines and molecular bands. Considering quantitative diagnostics, such a task in the case of the arc discharge in water is a very difficult one because of high arc fluctuation, small arc gap, and progressing decrease of water transparency caused by carbon particles dispersed in water. Therefore, the information characterizing the plasma was inferred only from C_2 radical radiation which is mainly associated with the Swan band system d ^3Đ_g a $3Đ_u$. The emission band 0-0 (516.5 nm) was used for temperature assesment and contribution of carbon in the plasma phase evaluation. The C_2 content was determined applying the method based on the phenomenom of self-absorption which highly influences the intensity of the band with respect to the intensity of the non-overlapped rotational component [7].

The collected products from the bottom of the reactor were analyzed by using scanning electron microscopy (ultra high-resolution field emission SEM, Leo 1530). The samples were also subjected to ultrasound treatment in ethanol for 15 min, and then transferred to a Cu grid coated with a holey carbon film for high-resolution transmission electron microscopic investigations (HRTEM, Jeol 3010). Raman spectroscopy (Jobin YvonSpex T64000) was applied to evaluate the structure features of the products.

3. Results and discussion

Fig. 2 shows the SEM pictures obtained in test 1-4. The product consisted of mainly carbon nanotubes, but other carbon nanoparticles are also present. The amount of CNTs increase with increasing the boron content in the anode. These nanotubes are ca. several nm in diameter, and a few micrometers in length. In the case of 11% B-doped anode thicker bundles of MWCNTs were found (Fig. 2D). The abudance of CNTs increased also with increasing the B concentration in anode. The highest yield of CNTs was obtained in test 4 (Fig 2D). These result could suggest, that boron favours the formation of CNTs.

The morphological details were investigated by HRTEM (Fig. 3). Based on the images, the diameter of MWCNTs was found to be between 10 and 25 nm. There were no correlation beetwen boron content in the anode and the diameter of obtained carbon nanotubes. The graphitization degree of MWCNTs decrease with boron concentration, what is clearly seen in Figs. 2C and D. The graphene sheets are not planar, due to the substitution carbon by boron atoms. This phenomena was also shown earlier [8]. The thin amorphous coating (ca. 1-2 nm) was observed in samples from tests 3 and 4.

The produced MWCNTs were also studied by Raman spectroscopy. First-order Raman measurements were performed using a 647.1 nm laser. There were two peaks located at ca. 1330 and 1590 cm^{-1}, corresponding to D and G lines of graphite, respectively. The D band is normally explained by relaxation of the wave vector selection rule due to the effect of the finite size of the crystal in the material [9]. The D/G ratio increases also with the decreasing of the graphite crystal size and its crystallization degree. The latter is also related with the presence of boron in the hexagonal lattice of graphite. Fig. 4 indicates that the I_D/I_G ratio increses with increasing the boron concentration. This implies that boron decreases the graphitiziation. Thus, the boron-doping effect strongly influences the crystallinity of CNTs. This results was also discussed with HRTEM ivestigation. In the case of the sample obtained in test 3 we measured the B content in the individual CNTs by EELS technique. It was found to be 1.0 +/- 0.4 at. %. It means, that ca. 30% of the starting amount of boron was incorporated in CNTs fomation. The measurements of B content in other samples are under way.

The carbon arc discharge in water is similar to that of a standard carbon arc discharge in helium [6]. The strongest bands and lines are still asosciated with C_2 radicals (d ^3Đ_g a ^3Đ_u, e.g., 516.5 nm), carbon atoms and ions. The average plasma temperature in water was found to be ca. 4000-6000 K. The obtained

temperatures for all electrodes were within the same range. The C_2 column density was between $1*10^{15}$ and $6*10^{15}$ cm^{-2}. It follows from thermodynamics that at such temperatures and C_2 content the total carbon vapor pressure is between 3 and 54 kPa. These results are similar to those obtained in helium, during arcing B-doped anodes [10].

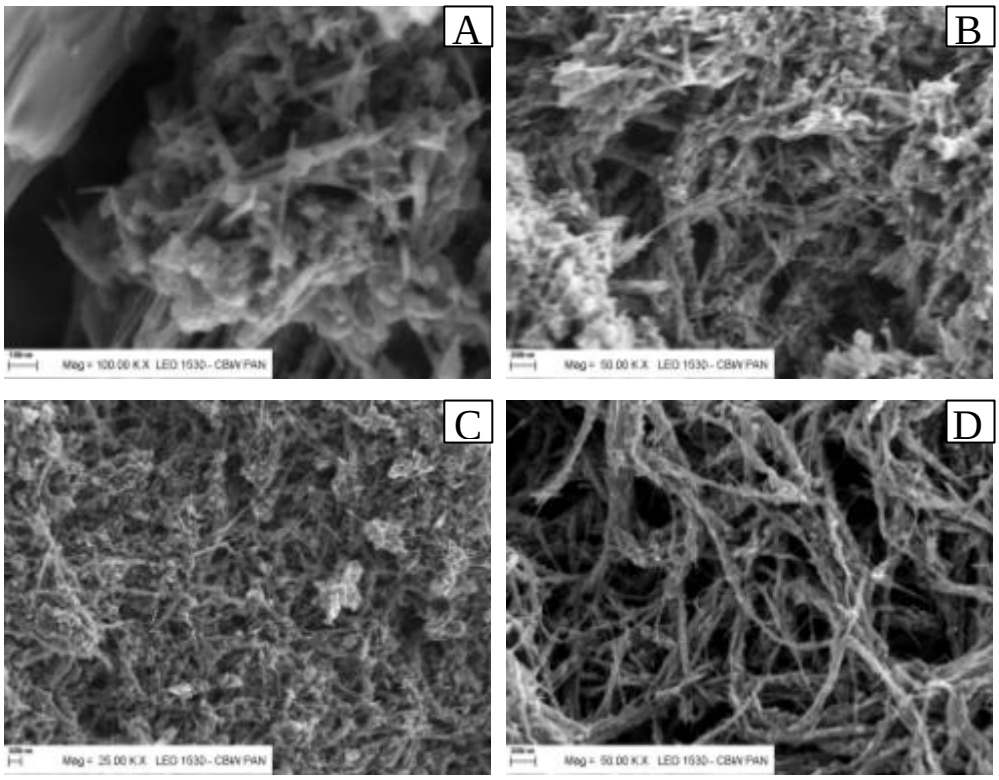

Fig. 2. SEM images of product obtained in test 1 (A), 2 (B), 3 (C), and 4 (D).

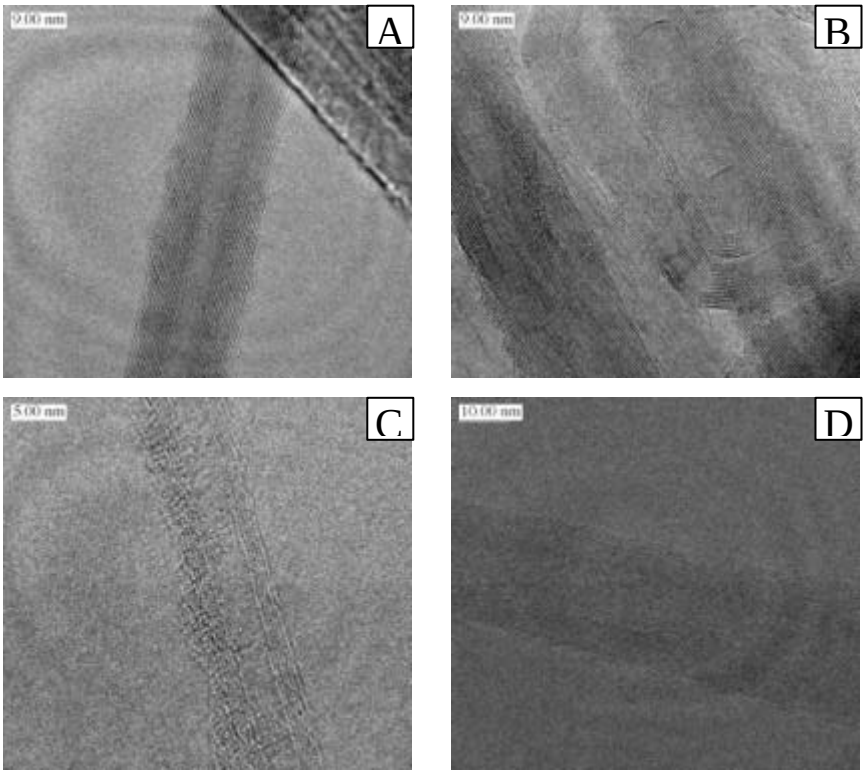

Fig. 3. HRTEM images of product obtained in test 1 (A), 2 (B), 3 (C), and 4 (D).

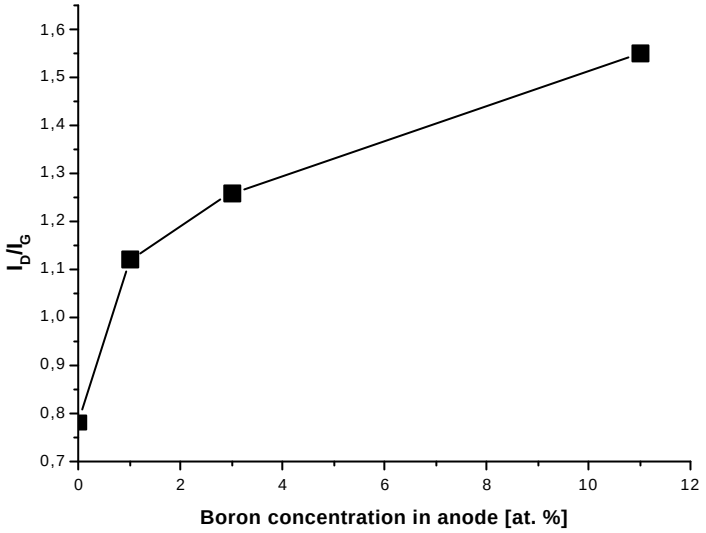

Fig. 4. I_D/I_G ratio of undoped and various concentrations of boron-doped CNTs.

4. Conclusion

We have demonstrated the production of B-doped MWCNTs in the arc discharge in water. The boron concentration in anode strogly influenced the yield and the structure of obtained MWCNTs. The temperatures and C_2 contents were similar to those observed in carbon arc in helium gas. This study has also shown that water arc-discharge technology simplifies the traditional He discharge for nanostructured carbons production: no special equipment, vacuum or gas are needed.

Effect of substrate geometry on deposition of thermally sprayed coating particles

V. R. Srivatsan, Q. Zhu, A. Dolatabadi
Department of Mechanical and Industrial Engineering, Concordia University, Montreal, Canada.

Abstract
Simulations of solid particles in a highly compressible gas flow in a high velocity thermal spray process are presented. The Lagrangian method is used for tracking the particles in the gas phase. Effects of geometric configuration of the substrate and particle landing position for different particle sizes are analyzed. It is found that the geometry of the substrate and size of particles have a significant effect on the normal velocity of the particle upon impact on a substrate. Deviation of particle trajectory for various particle sizes is presented.

Key words: Deposition efficiency; Substrate geometry; Lagrangian particle tracking.

1. Introduction:

Thermal spray coatings are formed by the impingement of a stream of particles in high temperature on a substrate. Extensive use of thermal spray process is found in the aerospace, power generation and more recently in automotive industries to provide protective coatings on components that are exposed to heat, corrosion, and wear. For example, in HVOF process, a mixture of fuel and oxygen fed in to a specially designed nozzle; ignites at a high pressure and this combustion accelerates the particle fed along with the carrier gas inside a converging–diverging nozzle. By the interaction with the gas phase, the injected particles attain high velocity (above 400 m/s) at relatively low temperature (less than 2400ºC), thereby gaining high kinetic and thermal energy. High particle kinetic energy coupled with high thermal energy, upon impact leads to the formation of a dense, well adhered coating.

The goal of any thermal spray process is to attain high deposition efficiency. In practice, from 20% up to 55 % of the particles fed to a spray gun escape from the field and are not deposited on the substrate, which leads to low deposition efficiency [1]. This is the result of having many particles with low normal velocity upon impact on the substrate [2]. For industrial applications, improving the deposition efficiency is a critical task to be taken in to consideration. A close inspection of the gas-particle flow near the substrate shows that the curvature of the substrate is an important factor which determines the gas flow field in the region near the substrate [3].

In this work we have attempted to study the effect of geometry of the substrate and size of the particles on deposition efficiency by analyzing the gas flow and the particle trajectory and impact velocity near the substrate. We have compared the flow pattern near the substrate of three different shapes i.e., Flat, Concave, and Convex. Consequently, the trajectory of the particles of different sizes and their deposition characteristic on the above mentioned substrates were examined.

2. Methodology:

A thermal spray process usually involves supersonic viscous turbulent flow with solid particles. In order to capture the characteristics of the gas-solid particles flow, a compressible two-phase flow analysis is required. The governing equations are solved for the gas phase in an Eulerian frame, and equation of motion for a solid particle in the Lagrangian framework. Inert solid spherical particles are modeled, and a uniform temperature distribution inside each particle is considered (lumped capacitance system). A four-step chemical reaction [3] is used to model the combustion.

2.1 Governing Equations:

2.1.1. Gas phase

The governing equations for the gas phase are the continuity, momentum, energy, and ideal gas state equations for viscous, compressible, and turbulent flow. The equations are expressed in Cartesian tensor form with the Einstein summation convention:

Continuity Equation:

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho u_j)}{\partial x_j} = 0 \tag{1}$$

Momentum Equation:

$$\frac{\partial}{\partial t}(\rho u_i) + \frac{\partial}{\partial x_j}(\rho u_j u_i) = -\frac{\partial p}{\partial x_i} + S_{u_i} + \frac{\partial}{\partial x_j}\left\{\mu_{eff}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - \frac{2}{3}\mu_{eff}\frac{\partial u_l}{\partial x_l}\delta_{ij}\right\} \tag{2}$$

Energy Equation:

$$\frac{\partial}{\partial t}(\rho H) + \frac{\partial}{\partial x_j}(\rho u_j H) - \frac{\partial p}{\partial t} = \frac{\partial}{\partial x_j}\left(\lambda \frac{\partial T}{\partial x_j} + \frac{\mu_t}{\mathrm{Pr}_t}\frac{\partial h}{\partial x_j}\right) + S_E + \frac{\partial}{\partial x_j}\left\{u_j\left[\mu_{eff}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - \frac{2}{3}\mu_{eff}\frac{\partial u_l}{\partial x_l}\delta_{ij}\right] + \mu\frac{\partial k}{\partial x_j}\right\} \tag{3}$$

where $\mu_{eff} = \mu + \mu_t$, $H = h + \frac{1}{2}(u_i u_i) + k$, λ, k, and S are effective viscosity, total enthalpy, thermal conductivity, turbulent kinetic energy, and source terms, respectively. The standard k-ε turbulence model of Launder and Spalding [4] is considered, where k is the turbulent kinetic energy and ε is the rate of its dissipation.

2.1.2 Particle Phase

The motion of each particle in the gas-particle flow is modeled by the Lagrangian particle tracking method. Two-way coupling between the gas and particulate phases is provided by source terms in the momentum and energy equations which include the effect of particulate phase on the gas phase. The equation of motion for a particle in the gas flow is as follows [5]

$$m_p \frac{d\vec{U}_p}{dt} = \frac{1}{2}\rho_g A_p C_D \left(\vec{U}_g - \vec{U}_p\right)\left|\vec{U}_g - \vec{U}_p\right| + \vec{F} \tag{4}$$

where m_p is the mass of particle, U_p and U_g are instantaneous particle and gas velocities, respectively. ρ_g is the gas density, A_p is the particle cross-sectional area and F denotes external forces such as gravitational force. Integrating the above equation of motion for a particle, results in the particle velocity. Second integration over the time step will result in the particle position.

2.2 Numerical Technique

This work uses Fluent™ version 6.1.22 computer code, which is commercially available from Fluent.Inc technology. A finite volume method for predicting flows at supersonic speeds is employed for an axi-symmetric geometry. The primary variables are the velocity components, pressure and temperature in Cartesian coordinates. Density is linked to pressure via an equation of state. The computational domain is subdivided into a number of quadrilateral control volumes.

All the dependent variables and fluid properties are stored in the control volume center i.e., cell-centered. Integrating the conservation laws over each control volume, results in systems of non-linear algebraic equations which are solved simultaneously.

3. Results and Discussion:

We have presented the results obtained for the three substrate configurations with two different particle sizes. The behavior of the gas phase is first analyzed and then the trajectory of particle in the gas phase is observed and the results are discussed below.

3.1 Gas Phase

General characteristics of the flow for three different substrates (Flat, Convex and Concave) are shown in Figure 1-a, b, and c, respectively. At the throat section of the nozzle, the Mach number is around 1 and as the sonic flow expands in the diverging section of the nozzle, a supersonic flow develops in this region. Finally, the high speed gas leaves the nozzle with an average Mach number of 2.3. Four or possibly five shock diamonds can be identified before the flow stabilizes to atmospheric pressure due to the fact that shocks are attenuated by turbulent shear layers. Furthermore, the gas flow is decelerated and diverted near the substrate. A bow shock can be observed near the substrate as a result of the jet impingement on the wall. It is evident from these results that the flow regime is changed significantly near the substrate due to the gas flow impingement on the wall. More importantly, variation of the flow regime is strongly dependent on the shape of the substrate. Resolving the supersonic flow and its interaction with the coating particles in this critical region (i.e. near the substrate) is eminent to predict particle conditions such as particle trajectory, velocity, and temperature upon impact.

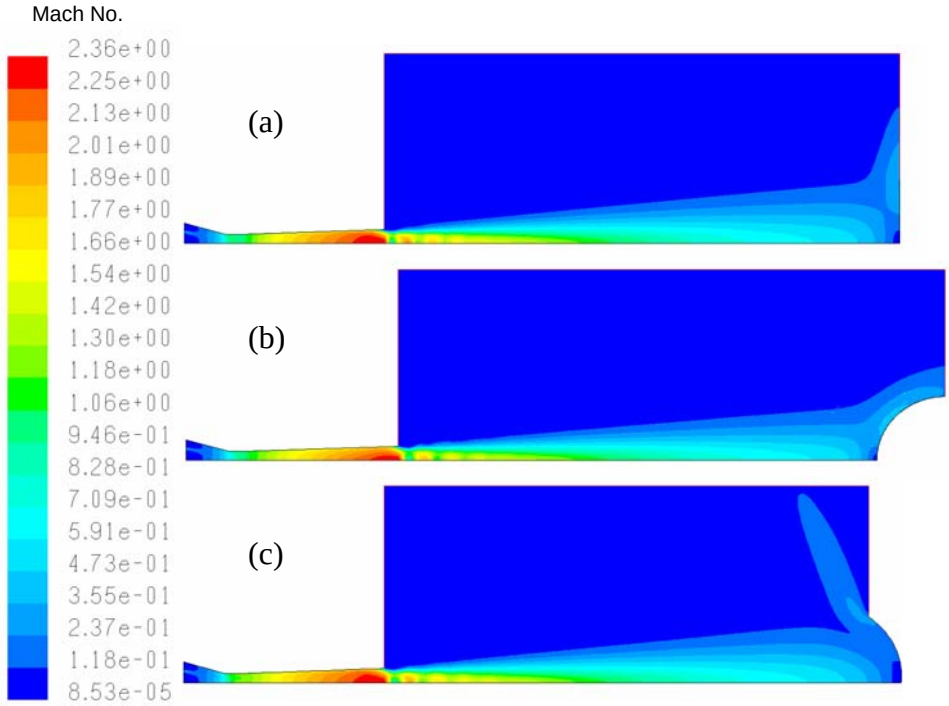

Figure 1: Mach number Contour of gas impinging on (a) Flat (b) Convex and (c) Concave Substrates

3.2 Particle Phase:

Figure 2 illustrates velocity of Nickel particles with a diameter of 10 μm impacting on substrates with three different shapes. The trajectory of particles near the substrate is significantly altered for the three different geometries. This is mainly due to the variation of the strength and shape of bow shocks formed over the three different geometries (Figure 1). A close inspection of the results of particle trajectories near the substrates shows that the particle landing position on the substrate also differs from each other for the three different shapes. Here, as the particle size is too small (in the order of 10 micron), some of the particles are flushed away by the gas before impinging on the substrate. Moreover, as it is shown in Figure 2-b due to the convex nature of the substrate, the particle streams which are injected slightly away from the centerline are deviated and their deposition on the substrate is questionable. However, for the concave substrate case (Figure 2-c) the inward curvature traps even those particle streams which are away from the centerline.

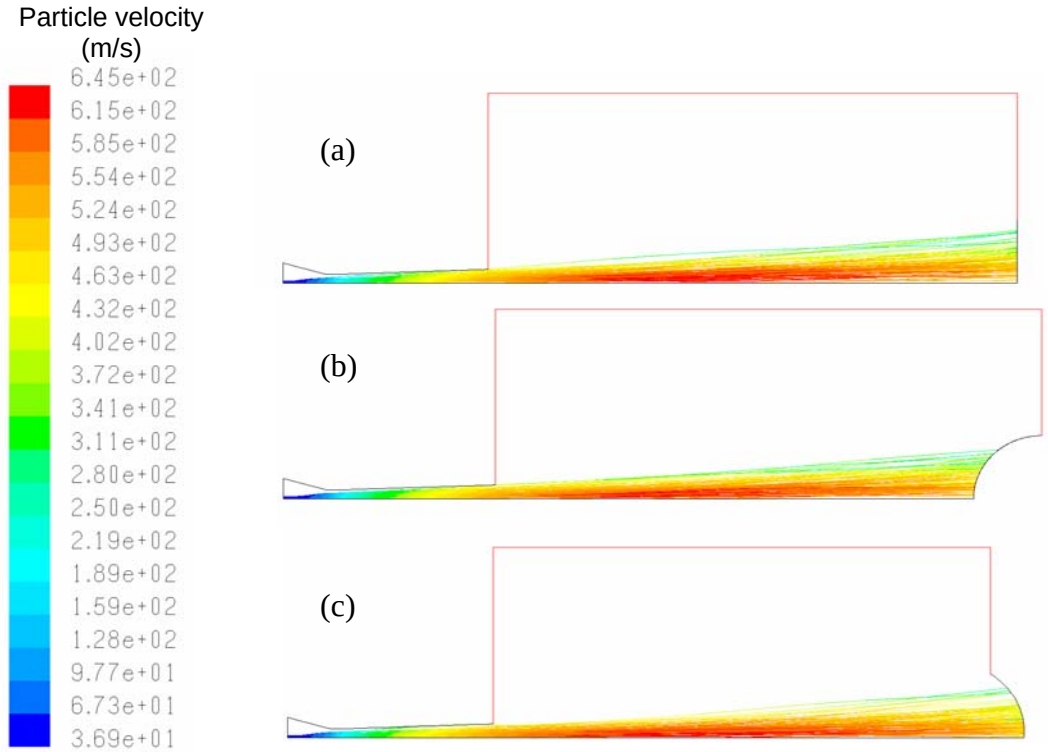

Figure 2 Particle trajectory and velocity with a size of 10 μm for (a) Flat, (b) Convex, and (c) Concave Substrates

Study of heavier particles with a size of 30 μm is shown in Figure 3. In this case, the deviation of particle trajectory from the centerline is smaller compared to that of 10 micron particles. This can be described by evaluating the particle Stokes number, which is the ratio of particle response time to a time characteristic of the fluid motion. Stokes number would be in the order of 10^2-10^3. With such high Stokes numbers, particles do not respond quickly to the variation of the gas velocity field. Because of this, the heavier particles are less sensitive to the bow shocks consequently to the shape or curvature of the substrate. This effect can be observed by comparing the results shown in Figure 3 for flat, convex, and concave substrate configurations.

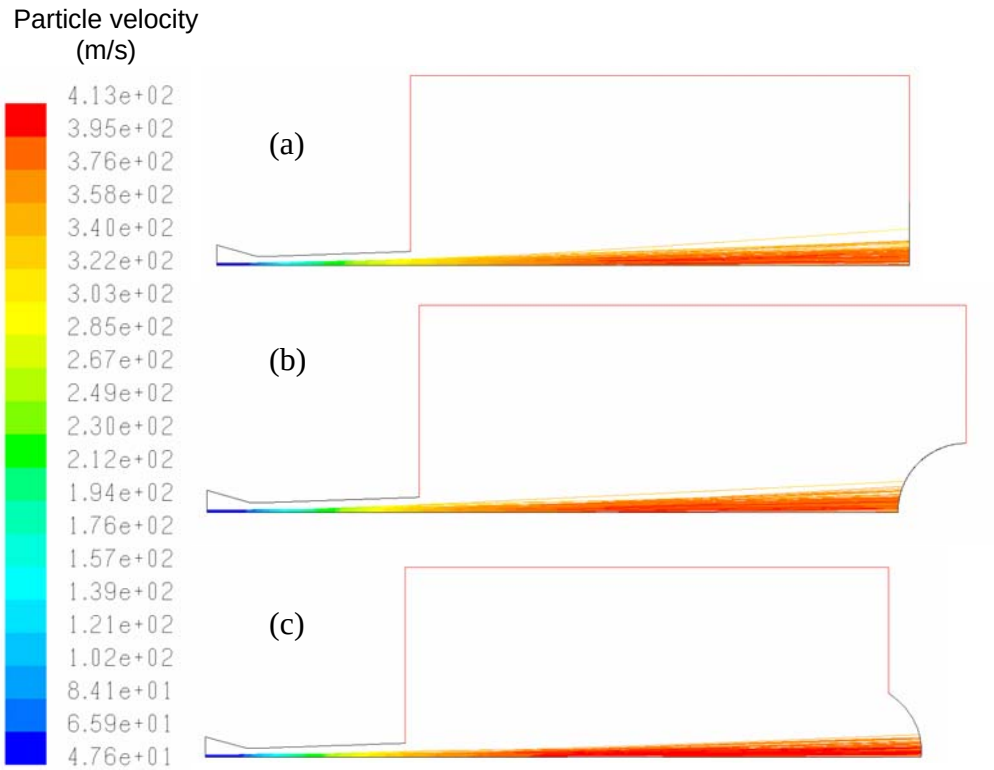

Figure 3: Particle trajectory and velocity with a size of 30 µm for (a) Flat, (b) Convex, and (c) Concave Substrates

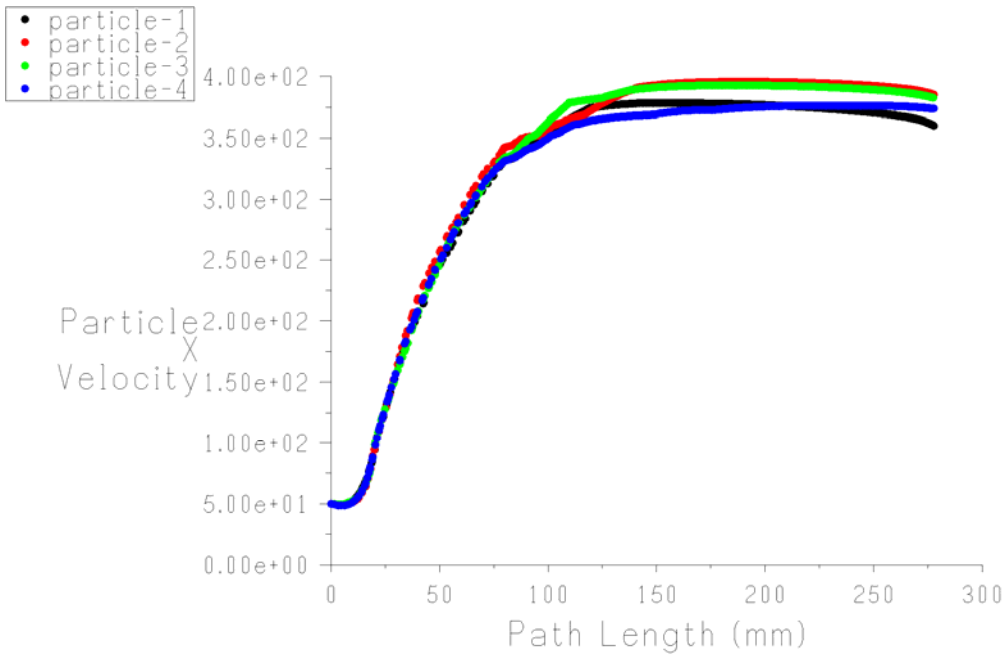

Figure 4: Plot of Axial Velocity Vs Path Length

These observations lead to a conclusion that heavy particles have better chances of sticking to the substrate. However, the particle landing velocity is an important factor for deposition of particles on the substrate. Figure 4 shows the plot between particle velocity and path length of 4 particle streams with a size of 30 μm. It is clear that the velocity of 30 micron particles is least affected by the presence of shocks near the nozzle exit and near the wall. It is also observed that the average particle velocity near the wall is 400 m/s. This gives particle sufficient kinetic energy, which when added to the thermal energy, makes the particle stick well on the substrate.

4. Conclusion and Future Work:

The effects of substrate geometry and particle size on deposition of coating particles are studied in this work and results were presented for different substrate geometries with various particle sizes. It is found that, smaller particles deposit easier on a concave substrate than on the other two. Interestingly, it is observed that particles with higher sizes have better chance to stick on the substrate, irrespective of the shape of the substrate on which they impact.

The future work will be dedicated in finding out an optimum size of the particle which attains maximum normal velocity upon impact on a substrate. Focus will also be made to extend the supersonic zone of the gas phase and smooth transition of flow from supersonic to subsonic velocities, which would minimize the loss of impact velocity of particles, providing sufficient kinetic energy, which in turn, increases the deposition efficiency.

Abstract :
Exposure of TiO_2 aqueous suspension of Orange G to activated species of humid air non thermal plasma of gliding arc leads to oxidative degradation. We demonstrate that there is an optimum TiO_2 concentration (2g/L) at the which the rates of decolorization and degradation are maximum.
The decolorization efficiency and COD reduction were 100% and 91.7% respectively, while they were only 98.4% and 63.5%without catalyst.This results were obtained after 180 min of treatment.

Keywords:
Non thermal plasma; gliding arc; Orange G; plasmacatalysis; UV-VIS spectra; TiO_2

1. Introduction

Various textiles industries use different types of organics dyes. Fifteen percent of the world production of dyes is lost during the dyeing process and it released in textile effluent. The release of those colored wastewaters has serious consequences for the environment. It is well know that some azo-dyes are highly carcinogenic [1]. Classical waste removal processes such as biodegradation, flocculation, ozonation, adsorption are currently used, but they become inadequate [2,3] nowadays with respect to the more drastic imposed environmental regulations.
Advanced oxidation processes have been used to treat various organic pollutants [4-7]. Among these processes, heterogeneous photocatalysis was found as an emerging destructive technology leading to the total mineralization of organics dyes [8-18].
In this study, we propose the use of an advanced oxidation process: the gliding arc technique which generates reactive species OH°. We considered the gliding arc as a new degradation technique which is able to degrade pollutant molecules [19, 20]. We report in this work on the results relevant to the treatment of TiO_2 aqueous suspension of azo dye (Orange G) of this particular non-thermal plasma.

2. Experimental section

Orange G was purchased from Accros Organic (Fig. 1) and used as received without further purification. Titanium dioxide Merck (surface area 11 m^2/g) was used as catalyst. Other chemicals used in the study were of analytical reagent grade quality. The colored suspensions were magnetically stirred in the dark for 60 min to reach the adsorption equilibrium. Aliquots were taken at regulars intervals, centrifuged and filtered through 0.45 μm filter.
The gliding arc system was described previously [21]. An electric is created between two metallic electrodes raised a convenient voltage difference (10 kV). The arc is blown away by a gas flow air the axis of the system and glides towards the end of the electrode before it breaks and a new arc forms. A plasma is generated by the arc in a volume located at the tips of the electrodes.
A UV-VIS spectrophotometer "Biomat 3 (Thermospectronic)"was used to the determination of the decolorization at the maximum of absorbance $\lambda = 478$ nm.
The mineralization of the dye was monitored by measuring the chemical oxygen demand (COD) using the French AFNOR norm. The organic matter was oxidized by potassium dichromate $K_2Cr_2O_7$. The excess of potassium dichromate was measured out by Mohr salt titration.
COD was calculated from the expression

$$COD\ (mg\ O_2/L) = 8000\ X\ (V_{MB} - V_{MS})\ X\ N_M\ /V_0$$

Where V_{MB} and V_{MS} are the volumes of standard Mohr salt solution used for the blank and the sample respectively. N_M is the normality of Mohr salt solution, and V_0 is the volume of the sample.

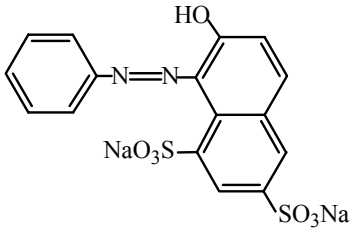

Fig.1. Structure of Orange G

3. Results

3.1 Treatment in absence of TiO_2

-The spectrum of Orange g in the visible region exhibits a main band with a maximum at 478 nm and a shoulder at 440 nm. The band at 478 nm reveals the presence of the azo form, whereas the shoulder at 440 nm indicates the presence of the azo form.

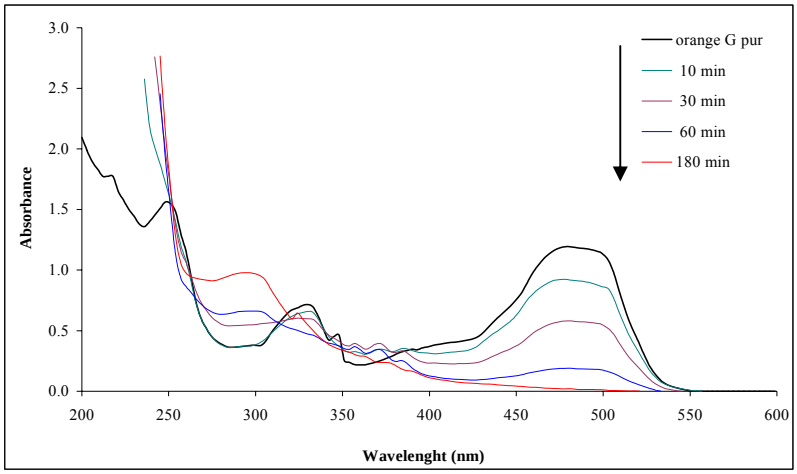

Fig. 2. UV-VIS spectra of the aqueous solution of Orange G at t=0 and after 10, 30, 60, 180 minutes of plasma treatment. C_{OG} = 80 µM, pH = 5.4

It is well known that azo group (–N=N–) of the Orange G is the basic reason for its visible color. We observed (fig.2) the visible absorbance of the dye solution becomes lower. These is explained by considering the breaking down of the azo bond and the formation of smaller products [22, 23]. The absorbance peaks in the visible region disappeared during plasma treatment (Fig. 3). In the meantime, new peaks between 200 and 260 nm appeared, which indicates new structure units formed. The 260 nm absorbance peak is attributed to the multi-substituted benzene (e.g., benzendicarboxylic acid [24] produced from degradation of the naphtalene ring (330 nm) [25].

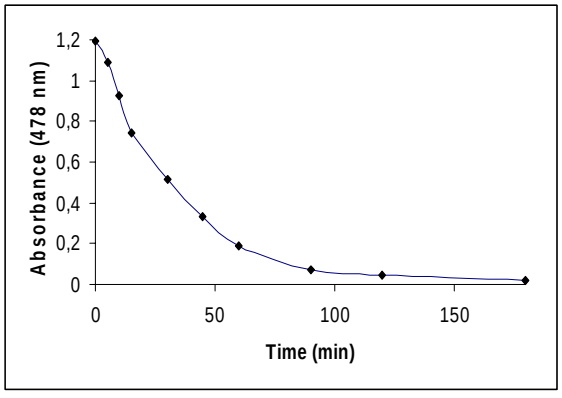

Fig. 3. Plasma decolorization of Orange G (80 µM)

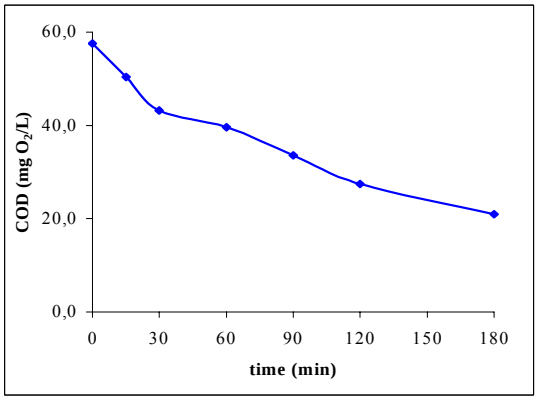

Fig. 4. Plasma degradation of Orange G (80 µM)

The degradation of Orange G has been followed using the COD. The disappearance of the COD expresses the mineralization of the dye by oxidation reaction by hydroxyl radicals, which follows the equation (1):

$$C_{16}H_{10}N_2O_7S_2^{2-} + 21O_2 \longrightarrow 16CO_2 + 2NO_3^- + 4H^+ + 2SO_4^{2-} + 3H_2O \quad (1)$$

The COD values decreased as the treatment time increased as we can see on figure (4). The COD removal of Orange G was 63% after 3 hours of treatment, while the color removal was 98.41%. We noticed that the decolorization is easier than COD removal (Table. 1).

Table.1. Effect of plasma treatment on decolorization and degradation of Orange G

time (min)	% Decolorization	% Degradation
0	0	0
5	8.81	
10	22.57	
15	37.42	12.5
30	56.62	25
45	72.32	
60	84.23	31.25
90	94.04	41.67
120	96.39	52.26
7180	98.41	63.54

3.2 Treatment in presence of TiO_2

a. Effect of catalytic dose

The dye solution (80 µM) was exposed to system plasma/TiO_2 during 180 minutes with different catalytic doses (0.5 g/L, 1 g/L, 1.5 g/L, 2 g/L, 2.5 g/L, 3 g/L). Table. 2 shows percent decolorization and degradation of dye as function of catalytic dose. The decolorization and increases with increase in catalytic dose

At 2 g/L the dye was found to be almost completely decolourized (100%) after 180 minutes of treatment, while the degradation rate reaches the maximum (91.67%). Hence, an optimum catalytic dose 2 g/L was selected.

Table. 2. Effect of Catalytic dose on decolorization and degradation of Orange G treated by plasma/TiO_2

Catalytic dose (g/L)	% Decolorization	% Degradation
0	98.41	63
0.5	99.16	70.83
1	99.33	72.50
1.5	99.75	83.33
2	100	91.67
2.5	99.92	83.33
3	99.83	78.33

The decrease in the percentage of degradation at higher catalyst loading may be due to deactivation of activated molecules by collision with ground state molecules. Agglomeration and sedimentation of TiO2 particles were observed elsewhere when 2.5 g/l of catalyst was added to the dye solution [26].

b. Effect of pH

At the start of the treatment the pH was 5.4, but during the process of degradation the pH decreased and at the end it was measured to be < 2.

The non-thermal plasma generates OH° radicals which are responsible for strong oxidising properties; while the NO° radicals are know as parent molecules for acid derivatives HNO_2, HNO_3 which induce a steep pH lowering of the solution.

For the Orange G, the decrease of pH favors it degradation. During the treatment, there is a combination effects of OH° radicals created from plasma and OH° radicals produced on the surface of TiO_2 (eq. 2). If the dye is adsorbed on the TiO_2 surface, it can be both oxidized by OH° and/or by photogenerated holes (eq. 3).

$$TiO_2 + h\upsilon \longrightarrow e^-_{Cb} + h^+_{vb} \quad (2)$$

$$H_2O + h^+_{Vb} \longrightarrow OH^\circ + H^+ \quad (3)$$

Also the adsorbed dye molecules may be directly oxidized by the valence band holes to form dye radical cations which ultimately cause dye degradation [25-29].

c. Effect of the optimum catalytic dose

The decolorization was studied in the presence and absence of 2 g/l of TiO_2, which is the optimum catalytic dose. Figure 5 shows a plot of percent decolorization of Orange G versus treatment time. The reaction was found to be less in the absence of catalyst. Figure 6 shows the degradation in the presence and absence of catalyst, the rate of mineralization is higher with TiO_2, the dye was found to have mineralized to the extent of 91.67%, while it was 63% without catalyst, after 180 minutes of treatment. The results are indicating that TiO_2 is a prerequisite for the plasma degradation process.

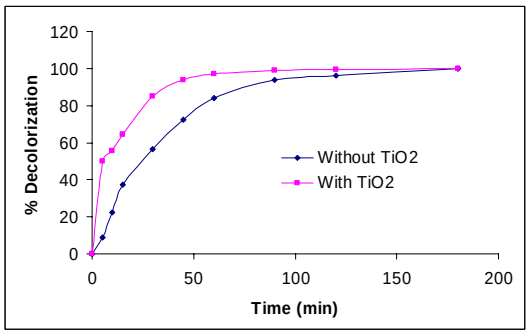

Fig. 5. Decolorization with and without TiO2

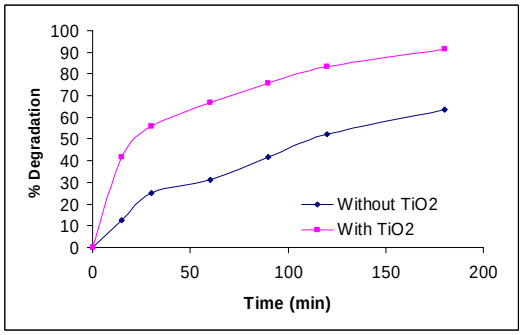

Fig.. 6. Degradation with and without TiO_2

d. Kinetic analysis

Ours results show that the plasma/TiO_2 process is efficient to degrade azo dyes in aqueous solution and to remove solution color. The kinetic study show a first order kinetic for the decolorization and the degradation as confirmed by the linear transform $\ln(C_0/C) = - kt$. The rate constants were as follows:

- Decolorization in absence of TiO_2: $k = 0.0316\ min^{-1}$, $R^2 = 0.995$
- Decolorization with 2 g/l of TiO_2: $k = 0.0509\ min^{-1}$, $R^2 = 0.983$
- Degradation in absence of TiO_2: $k = 0.0054\ min^{-1}$, $R^2 = 0.987$
- Degradation with 2 g/l of TiO_2: $k = 0.0127\ min^{-1}$, $R^2 = 0.971$

Conclusion

The degradation of the azo dye Orange G by non-thermal plasma has been studied in aqueous medium. We have shown that the gliding arc technique is efficient for azo dye degradation. It is explicitly exhibited by the absorbance decrease, color disappearance and COD decrease in azo dye solution under study.

Exposure of Orange G solution to the non-thermal plasma in the presence of TiO_2 gives the best efficiency for lower treatment time. The influence of the concentration of TiO_2 has been evaluated: the plasmacatalytic reaction was favoured by an optimum catalytic dose.

The results indicate that the decolorization is faster with TiO_2 and the mineralization could be achieved up to 90%

Abstract- Methane conversion to higher hydrocarbons and valuable products using a plasma activated and the hybrid dielectric-barrier discharge (DBD)-catalyst reactor was investigated under ac high voltage conditions. Perovskite type and ZSM-5 employed as the catalyst in this study. The experiments were carried out in a quartz tube with external diameter of 9 mm and the reaction zone with length of 15cm, at atmospheric pressure. Methane and oxygen as reactants and helium as a dilution gas were used in the experiments. The effect of system variables including CH_4/O_2 ratio in the feed, applied voltage and feed flow rates and also catalyst have been studied. The results show the selective production of syngas and C_2 hydrocarbons. In the blank DBD reactor without catalyst the feed composition ratio CH_4/O_2 =4 and feed flow rate 40ml/min gives the maximum methane conversion about 8% at 8kV for applied voltage. The main product in the DBD reactor filled with zeolite was syngas at optimum temperature 200^{o}C. The experiments show that at the studied temperature range in this work, both blank and filled DBD reactors with zeolite produce syngas as the main product. The optimum voltage for C_2 and C_2H_4 production in the hybrid catalyst-plasma reactor in this study was between 8- 10 kV. The maximum 40% yield for syngas production at temperature 200^{o}C in the presence of zeolite catalyst in the DBD reactor was achieved. At the catalyst free DBD reactor the production of syngas at the studied temperature reveals the temperature independency and is about 30%. The hybrid perovskite type catalyst-DBD reactor shows no enhancement in the results at studied temperature range.

Keywords: dielectric barrier discharge, zeolite, methane conversion, plasma, syngas

Introduction- Methane contributes to the building up green house effect. Any success in the research of a utilization of methane will help to slowing down a green house gases production. On the other hand the relatively abundant resource of natural gas and its low cast makes it as a good choice for carbon-based fuel, and other chemicals. Presently natural gas uses mostly as an fuel in industry and household heating devices, with no economic value and negative environmental impacts.

Methane can be indirectly converted to liquid chemicals, traditionally known as GTL(Gas to Liquid). Methane is converted to syngas (i. e. H_2 and CO) through steam reforming, partial oxidation and/or steam-CO2 reforming processes. Syngas under high pressure and relatively high temperature conditions in the presence of catalyst (e.g. Cobalt or Fe catalysts) produces wide rang of hydrocarbons, from C_1 to wax. In the other process methane under high temperature condition and the presence of catalyst, is directly converted to higher hydrocarbons mainly ethylene, that is known as OCM (Oxidative Coupling of Methane) [1, 2]. The tough thermodynamic conditions, product selectivity problem, catalyst deactivation, make researchers to investigate the other applicable ways mainly plasma technology[3-9]. In this study the conversion of methane to higher hydrocarbons and syngas via gas discharge is investigated.

Experimental Setup –The details of experimental system used in this study has been given in ref. [8]. Nevertheless we give the brief description here. The set up consist of home made power supply, reactant feeding system, quartz reactor and gas

chromatograph for product analyzing, Figure (1). Methane and oxygen are introduced as the feeds and helium employed as diluent gas.

Results and Discussion- In this study the effects of feed ratio, applied voltage, feed flow rate and the presence of catalyst on the methane conversion and product selectivity are investigated.

Figure (2) shows the methane conversion as a function of applied voltage. The methane conversion increases with enhancement of the applied voltage. Increasing of methane conversion with applied voltage is the same trend for catalyst-DBD and blank DBD reactors. In the same way methane conversion is raised with reactant residence time in the reactor. Figures (3)-(5) show that the methane conversion and ethane and ethylene yield how impact by CH4/O2 ratio in the feed. Figure (6) shows the product selectivity in the DBD reactor with the presence of perovskite type catalyst as a function of applied voltage. As it can be seen the maximum methane conversion in the presence of perovskite catalyst and room temperature is less than 6%. The perovskite catalyst is in favor of the reaction selectivity to C2 production. The low conversion of methane affects the C2 yield in the presence of perovskite catalyst and generally the product yields in DBD reactor. Figure (7) shows the variation of product selectivity in the blank DBD reactor with applied voltage. As it can be seen the maximum yield of C2 production is about 4%, which is comparable with results of perovskite -DBD reactor at room temperature. Of course it should be mentioned that the activation temperature for this type of catalyst is high (more than 550^{o}C) in the traditional methods (i. e. without plasma) for methane conversion such as OCM. Anyway this study conducted for investigation of the likely synergic effects of catalyst and plasma in the DBD reactor at room temperature. Since plasma can provides enough electron for catalyst surface for electron transfer reactions between catalyst surface and gas phase reactants, even at room temperature. Figure (8) shows the product yield as a function of system temperature in the case of zeolite-DBD reactor hybrid. As it can be seen the main products is syngas with about 40% yield.

Conclusion – In this work the catalyst-DBD hybrid reactor and blank DBD reactor were studied for their ability in methane conversion to higher hydrocarbons and valuable products. Results of this study show the low methane conversion and also good product selectivity in catalyst-DBD hybrid reactor. The ZSM-5-DBD hybrid reactor shows good selectivity for syngas production.

Time-dependent two-dimensional two-temperature chemical non-equilibrium model of Ar-N_2 pulse modulated induction thermal plasmas: Influence of coil-current modulation on thermal non-equilibrium

Yasunori Tanaka

Division of Electrical and Computer Engineering, Kanazawa University, Kakuma, Kanazawa 920-1192, JAPAN

Abstract

The author developed a time-dependent two-dimensional two-temperature chemically non-equilibrium (TD-2D-2T-NCE) model for an unique high-power Ar-N_2 pulse-modulated induction thermal plasma (PMITP) to obtain variations in electron and heavy particle temperatures, particle composition as well as the gas flow field considering the diffusion, convection and reaction rate effects. Influence of modulation conditions of the coil current were numerically studied on the temperature and gas flow fields in such an Ar-N_2 PMITP.

1. Introduction

The pulse-modulated induction thermal plasma (PMITP) or the high-power pulse-modulated inductively coupled plasma (high-power PMICP) is one of the advanced breakthrough techniques in thermal plasma fields. This PMITP technique has been developed by Ishigaki *et al.*, and Sakuta [1, 2] to encounter difficulty of the control of thermal plasma temperature and also to introduce a new function of thermal plasma system. Modulation of the coil current sustaining induction thermal plasmas enables one to control the time-averaged temperature of thermal plasmas, and also gas flow velocity periodically. In addition, introduction of thermal and chemical non-equilibria even in thermal plasmas by a sudden application of the electromagnetic field in pulse-modulated operation is expected to enhance controllability of reactions and temperature in thermal plasmas.

In order to investigate such unique PMITP behaviors, experimental and numerical approaches have been made. For example, Ohashi *et al.*have applied the PMITP to the improvement of luminescence of ZnO emission[4]. The author and co-workers have been experimentally studying the stable operation region, transient response, and temperature control of the PMITP [3]. We also developed a thermofluid PMITP model on the assumption of local thermal equilibrium (LTE) [5]. This LTE model supported to understand the transport of mass, momentum, energy, gas flow and temperature fields in the PMITP. However, further understanding of reactions and particle density distributions in the PMITP has greatly been required for the advanced material processings in non-LTE states. For this purpose, we have so far developed a one-temperature chemically non-equilibrium model of Ar-N_2 PMITP in transient state [6], and also a two-temperature chemical non-equilibrium model of Ar-N_2 induction thermal plasmas but in steady state [7]. The Ar-N_2 induction thermal plasmas can be used for high-speed nitriding processes of materials. This two-temperature chemical non-equilibrium model considers diffusion and convection, reaction rate effects on particle composition, transport and thermodynamic properties. In this paper, the author newly develops and reports a time-dependent two-dimensional two-temperature and chemically non-equilibrium (TD-2D-2T-NCE) model for Ar-N_2 PMITP considering reaction rates and difference between electron and heavy particle temperatures. The use of this model makes it possible to investigate pulse-modulation conditions on electron and heavy particle temperature fields, as well as the evolution in particle density distributions considering reaction rates, convection and diffusion effects. From this model, it was found that lower SCL and longer off-time enhances deviation between electron and heavy particle temperatures just after a sudden increase in coil-current amplitude.

2. Modelling of Ar-N_2 PMITP

2.1. Hypothesis

The following are assumed in Ar-N_2 PMITPs in the present calculation: (a) In Ar-N_2 PMITPs, there are only the electron and seven heavy particles: Ar, Ar^+, N_2, N_2^+, N and N^+. (b) All heavy particles have the same temperature with a Maxwellian energy distribution function. On the other hand, the electron energy distribution function also follows the Maxwellian law although its mean energy is not always equal to that of heavy particles. This means that electron temperature T_e can be different from heavy particle temperature T_h. (c) Electrons lose their kinetic energies through elastic collisions with heavy particles and also through inelastic collisions involving related ionization and dissociation reactions. However, the present calculation ignores inelastic collision involving electronic, rotational and vibrational excitations for simplicity. (d) The energy required for a reaction is supplied from the electron kinetic energy if one of the reactants is the electron. The released energy from a reaction is transferred to the electron kinetic energy if one of the products is the electron. Otherwise, the energy is exchanged from or to the kinetic energy of heavy particles. (e) The plasma has an axissymetric structure. (f) The gas flow is laminar. (g) The optically thin assumption is made. (h) Pressure in the PMITP

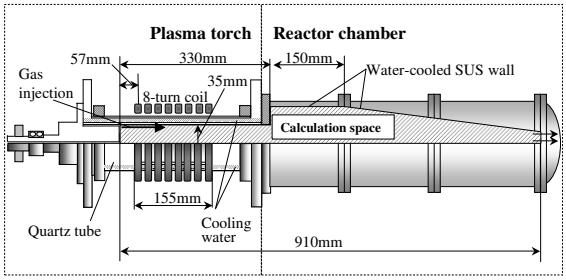

Fig. 1. Plasma torch configuration and calculation space.

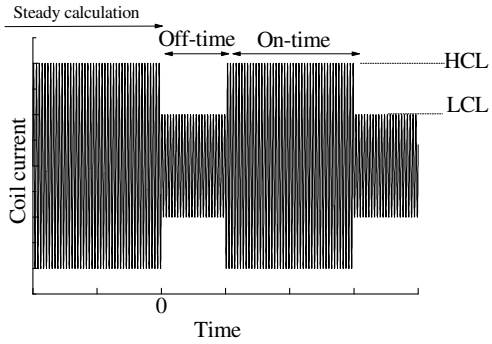

Fig. 2. Coil current for sustaining the pulse-modulated induction thermal plasmas

is approximately the atmospheric pressure. (i) Quasi-neutrality of electrical charges is established. (j) The displacement current by alternative electric field is neglected.

2.2. Governing equations, reactions, thermodynamic and transport properties

On the basis of the hypothesis mentioned in the previous section, Ar-N_2 PMITP behavior can be expressed in Table.1 In this table, Eq.(1) is the mass conservation equation, Eqs.(2) and (3) are the momentum conservation equations for axial or radial direction, respectively, Eq.(4) the energy conservation equation of heavy particles, Eq.(5) the energy conservation equation of the electron, Eq.(6) the mass conservation equation of species j, Eq.(7) is the Maxwell equation for vector potential. In addition, Eqs.(8) and (9) indicate the phasors of electromagnetic fields using the derived phasor of the vector potential, Eq.(10) is the reaction heat per unit volume and time, Eq.(11) the enthalpy concerning the translational motion of heavy particles, Eq.(12) the energy transfer from elastic collisions between electrons and heavy particles, Eq.(13) the relative thermal velocity between the electron and heavy particles, Eq.(14) the relation between number density n_j and molar fraction Y_j of species j, Eq.(15) the equation of state, Eq.(16) the quasi charge neutrality. It should be noted that a time-dependent two-temperature model was adopted for considering thermal non-equilibrium effect in this work. At the same time, chemical non-equilibrium effects were also taken into account here. These governing equations were simultaneously solved by the SIMPLE method.

Table 2 indicates the reactions taken into account in this calculation. Thirty reactions including 15 forward and their backward reactions were considered. These are the same reactions taken into account in the previous paper [7]. The reaction rates of these forward reactions α_ℓ^{f} were assumed to follow the Arrhenius' law.

Thermodynamic and transport properties such as the electrical conductivity σ, the viscosity η, the translational thermal conductivity of heavy particles $\lambda_{\mathrm{h}}^{\mathrm{tr}}$, the thermal conductivity of electrons $\lambda_{\mathrm{e}}^{\mathrm{tr}}$, and the effective diffusion coefficients for species j, D'_j, were calculated using the first order approximation of Chapman-Enskog method. These formula are described in Eqs.(21)–(28) [7].

2.3. Plasma torch, calculation space and conditions

Figure 1 shows a schematic diagram of the plasma torch used in the experiment and treated in the present calculation. The plasma torch is composed of two coaxial quartz tubes cooled by water. This torch has an eight-turn induction coil, which is connected with a MOSFET inverter power source through an L-C series matching circuit. A reaction chamber is installed at the downstream of the plasma torch. The wall of this chamber is cooled by flowing water.

In this calculation, the cross section of the plasma torch and the reaction chamber as hatched in Fig.1 was set for the calculation space. The gas flow rates of Ar and N_2 were set to 100 and 2.5 slpm, respectively. Pressure at center of the torch head was fixed at 101 325 Pa. The boundary conditions were the same to those in the previous literature [7] except the coil-current modulation. Figure 2 illustrates the coil-current waveform involving the definition of modulation parameters. The pulse modulation produces four controllable parameters: the higher current level (HCL), the lower current level (LCL), the on-time and off-time as described in this figure. The shimmer current level (SCL), which is a ratio of lower to higher current levels (LCL/HCL), is also defined. The on-time is fixed at 10 ms.

First, calculation was made for steady state of Ar-N_2 induction thermal plasma without coil-current modulation at a fixed input power of 27 kW. Using this steady state calculation result as an initial value, transient state calculations were performed for gas flow, temperature and particle density fields for eight modulation cycles of the coil current.

Tab. 1. Governing equations.

Mass conservation:

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho u)}{\partial z} + \frac{1}{r}\frac{\partial (r\rho v)}{\partial r} = 0 \tag{1}$$

Momentum conservation:

$$\begin{aligned}\frac{\partial (\rho u)}{\partial t} &+ \frac{\partial (u\rho u)}{\partial z} + \frac{1}{r}\frac{\partial (rv\rho u)}{\partial r} \\ &= -\frac{\partial p}{\partial z} + 2\frac{\partial}{\partial z}\left(\eta \frac{\partial u}{\partial z}\right) \\ &+ \frac{1}{r}\frac{\partial}{\partial r}\left[\eta r\left(\frac{\partial u}{\partial r} + \frac{\partial v}{\partial z}\right)\right] + \mu_0 \sigma \Re[\dot{E}_\theta \dot{H}_r^*]\end{aligned} \tag{2}$$

$$\begin{aligned}\frac{\partial (\rho v)}{\partial t} &+ \frac{\partial (u\rho v)}{\partial z} + \frac{1}{r}\frac{\partial (rv\rho v)}{\partial r} \\ &= -\frac{\partial p}{\partial r} + \frac{\partial}{\partial z}\left[\eta\left(\frac{\partial v}{\partial z} + \frac{\partial u}{\partial r}\right)\right] \\ &+ \frac{2}{r}\frac{\partial}{\partial r}\left(\eta r \frac{\partial v}{\partial r}\right) - 2\eta\frac{v}{r^2} + \mu_0 \sigma \Re[\dot{E}_\theta \dot{H}_z^*]\end{aligned} \tag{3}$$

Translational energy conservation of heavy particle:

$$\begin{aligned}\frac{\partial (\rho h')}{\partial t} &+ \frac{\partial (u\rho h')}{\partial z} + \frac{1}{r}\frac{\partial (rv\rho h')}{\partial r} \\ &= \frac{\partial}{\partial z}\left(\lambda_{\mathrm{h}}^{\mathrm{tr}} \frac{\partial T_{\mathrm{h}}}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\lambda_{\mathrm{h}}^{\mathrm{tr}} \frac{\partial T_{\mathrm{h}}}{\partial r}\right) \\ &+ \sum_{j\ (j\neq \mathrm{e})}^{N}\left[\frac{\partial}{\partial z}\left(\rho D_j' h_j' \frac{\partial Y_j}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\rho D_j' h_j' \frac{\partial Y_j}{\partial r}\right)\right] \\ &- \sum_{\ell\ (\beta_{\mathrm{e}\ell}^{\mathrm{f}} \cdot \beta_{\mathrm{e}\ell}^{\mathrm{r}} = 0)}^{L} \Delta Q_\ell + E_{\mathrm{eh}}\end{aligned} \tag{4}$$

Energy conservation of electron:

$$\begin{aligned}\frac{\partial}{\partial t}\left(n_{\mathrm{e}}\frac{5}{2}\kappa T_{\mathrm{e}}\right) &+ \frac{\partial}{\partial z}\left(u n_{\mathrm{e}}\frac{5}{2}\kappa T_{\mathrm{e}}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(rv n_{\mathrm{e}}\frac{5}{2}\kappa T_{\mathrm{e}}\right) \\ &= \frac{\partial}{\partial z}\left(\lambda_{\mathrm{e}}^{\mathrm{tr}}\frac{\partial T_{\mathrm{e}}}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\lambda_{\mathrm{e}}^{\mathrm{tr}}\frac{\partial T_{\mathrm{e}}}{\partial r}\right) \\ &- \frac{\partial}{\partial z}\left(\frac{1}{m_{\mathrm{e}}}\frac{5}{2}\kappa T_{\mathrm{e}}\Gamma_{\mathrm{e}z}\right) - \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{1}{m_{\mathrm{e}}}\frac{5}{2}\kappa T_{\mathrm{e}}\Gamma_{\mathrm{e}r}\right) \\ &- \sum_{\ell\ (\beta_{\mathrm{e}\ell}^{\mathrm{f}} \cdot \beta_{\mathrm{e}\ell}^{\mathrm{r}} \neq 0)}^{L} \Delta Q_\ell + \sigma \dot{E}_\theta \dot{E}_\theta^* - P_{\mathrm{rad}} - E_{\mathrm{eh}}\end{aligned} \tag{5}$$

Mass conservation of species j (for N, N^+, N_2^+, Ar^+):

$$\begin{aligned}\frac{\partial (\rho Y_j)}{\partial t} &+ \frac{\partial (u\rho Y_j)}{\partial z} + \frac{1}{r}\frac{\partial (rv\rho Y_j)}{\partial r} \\ &= \frac{\partial}{\partial z}\left(\rho D_j' \frac{\partial Y_j}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\rho D_j' \frac{\partial Y_j}{\partial r}\right) \\ &+ m_j \sum_{\ell=1}^{L}(\beta_{j\ell}^{\mathrm{r}} - \beta_{j\ell}^{\mathrm{f}})\left(\alpha_\ell^{\mathrm{f}} \prod_{i=1}^{N} n_i^{\beta_{i\ell}^{\mathrm{f}}} - \alpha_\ell^{\mathrm{r}} \prod_{i=1}^{N} n_i^{\beta_{i\ell}^{\mathrm{r}}}\right)\end{aligned} \tag{6}$$

Maxwell equation by vector potential:

$$\frac{\partial^2 \dot{A}_\theta}{\partial z^2} + \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial \dot{A}_\theta}{\partial r}\right) - \frac{\dot{A}_\theta}{r^2} = \bar{i}\mu_0 \sigma \omega \dot{A}_\theta \tag{7}$$

$$\dot{H}_z = \frac{1}{\mu_0}\frac{1}{r}\frac{\partial}{\partial r}(r\dot{A}_\theta), \quad \dot{H}_r = -\frac{1}{\mu_0}\frac{\partial \dot{A}_\theta}{\partial z} \tag{8}$$

$$\dot{E}_\theta = -\bar{i}\omega \dot{A}_\theta \tag{9}$$

Reaction heat per unit volume and time:

$$\Delta Q_\ell = \psi_{\mathrm{reac}\ell}\left(\alpha_\ell^{\mathrm{f}} \prod_{i=1}^{N} n_i^{\beta_{i\ell}^{\mathrm{f}}} - \alpha_\ell^{\mathrm{r}} \prod_{i=1}^{N} n_i^{\beta_{i\ell}^{\mathrm{r}}}\right) \tag{10}$$

Translational enthalpy of heavy particles:

$$h' = \sum_{j\neq \mathrm{e}} Y_j h_j', \qquad h_j' = \frac{1}{m_j}\left(\frac{5}{2}kT_{\mathrm{h}}\right) \tag{11}$$

Energy transfer from electron to heavy particles:

$$E_{\mathrm{eh}} = \sum_{j\neq \mathrm{e}} \frac{3}{2}\kappa(T_{\mathrm{e}} - T_{\mathrm{h}})\frac{2m_j m_{\mathrm{e}}}{(m_j + m_{\mathrm{e}})^2} n_j n_{\mathrm{e}} \pi \bar{\Omega}_{\mathrm{e}j} \bar{v}_{\mathrm{e}j} \tag{12}$$

$$\bar{v}_{\mathrm{e}j} = \sqrt{\frac{8\kappa T_{\mathrm{e}}(m_{\mathrm{e}} + m_j)}{\pi m_{\mathrm{e}} m_j}} \tag{13}$$

Relation between mass density and mass fraction:

$$n_j = \frac{\rho Y_j}{m_j} \tag{14}$$

Equation of state:

$$\rho = \frac{p}{\dfrac{Y_{\mathrm{e}}}{m_{\mathrm{e}}}\kappa T_{\mathrm{e}} + \displaystyle\sum_{j\neq \mathrm{e}} \frac{Y_j}{m_j}\kappa T_{\mathrm{h}}} \tag{15}$$

Quasi-neutrality:

$$\frac{Y_{\mathrm{e}}}{m_{\mathrm{e}}} = \frac{Y_{\mathrm{Ar}^+}}{m_{\mathrm{Ar}^+}} + \frac{Y_{\mathrm{N}_2^+}}{m_{\mathrm{N}_2^+}} + \frac{Y_{\mathrm{N}^+}}{m_{\mathrm{N}^+}} \tag{16}$$

Balance of mass fraction:

$$Y_{\mathrm{Ar}} = Y_{\mathrm{Ar}}^{\mathrm{TOT}} - Y_{\mathrm{Ar}^+} \tag{17}$$

$$Y_{\mathrm{N}_2} = Y_{\mathrm{N}_2}^{\mathrm{TOT}} - Y_{\mathrm{N}} - Y_{\mathrm{N}^+} - Y_{\mathrm{N}_2^+} \tag{18}$$

Admixture ratio N_2 to Ar:

$$Y_{\mathrm{N}_2}^{\mathrm{TOT}} = \frac{m_{\mathrm{N}_2} Q_{\mathrm{N}_2}}{m_{\mathrm{Ar}} Q_{\mathrm{Ar}} + m_{\mathrm{N}_2} Q_{\mathrm{N}_2}} \tag{19}$$

$$Y_{\mathrm{Ar}}^{\mathrm{TOT}} = 1.0 - Y_{\mathrm{N}_2}^{\mathrm{TOT}} \tag{20}$$

Effective diffusion coefficient of heavy particle:

$$D_j' = \frac{1 - Y_j}{\displaystyle\sum_{k\neq j} \frac{x_i p \Delta_{ij}^{(1)}}{\kappa T_{\mathrm{h}}}} \tag{21}$$

Electrical conductivity:

$$\sigma = \frac{e^2}{\kappa T_{\mathrm{e}}} \frac{n_{\mathrm{e}}}{\displaystyle\sum_{j\neq \mathrm{e}} n_j \Delta_{\mathrm{e}j}^{(1)}} \tag{22}$$

Viscosity:

$$\eta = \sum_{j=1}^{N} \frac{m_j n_j}{\displaystyle\sum_{i=1}^{N} n_i \Delta_{ij}^{(2)}} \tag{23}$$

Translational thermal conductivity of heavy particle:

$$\lambda_{\mathrm{h}}^{\mathrm{tr}} = \frac{15}{4}\kappa \sum_{i\neq \mathrm{e}} \frac{n_i}{\displaystyle\sum_j \xi_{ij} n_j \Delta_{ij}^{(2)}} \tag{24}$$

Translational thermal conductivity of electron:

$$\lambda_{\mathrm{e}}^{\mathrm{tr}} = \frac{15}{4}\kappa \frac{n_{\mathrm{e}}}{\displaystyle\sum_j \xi_{\mathrm{e}j} n_j \Delta_{\mathrm{e}j}^{(2)}} \tag{25}$$

$$\frac{1}{\Delta_{ij}^{(1)}} = \frac{3}{8}\sqrt{\frac{\pi\kappa T_{\mathrm{h,e}}(m_i + m_j)}{2m_i m_j}} \frac{1}{\pi \bar{\Omega}_{ij}^{(1,1)}} \tag{26}$$

$$\frac{1}{\Delta_{ij}^{(2)}} = \frac{5}{16}\sqrt{\frac{\pi\kappa T_{\mathrm{h,e}}(m_i + m_j)}{2m_i m_j}} \frac{1}{\pi \bar{\Omega}_{ij}^{(2,2)}} \tag{27}$$

$$\xi_{ij} = 1 + \frac{(1 - m_i/m_j)(0.45 - 2.54 m_i/m_j)}{(1 + m_i/m_j)^2} \tag{28}$$

where t: time (s), r: radial position (m), z: axial position (m), u: axial flow velocity (m/s), v: radial flow velocity (m/s), ρ: mass density (kg/m^3), p: pressure (Pa), T_{h}: heavy particle temperature (K), T_{e}: electron temperature (K), P_{rad}: radiation loss (W/m^3), n_j: number density of species j (m^{-3}), Y_j: mass fraction of species j, x_j: mole fraction of species j, m_j: mass of species j (kg), $\Gamma_{\mathrm{e}r}$, $\Gamma_{\mathrm{e}z}$: radial and axial electron flux due to ambipoler diffusion (1/m^2/s), α_ℓ^{f}, α_ℓ^{r}: rate coefficients of forward and backward reaction ℓ, respectively, $\beta_{j\ell}^{\mathrm{f}}$, $\beta_{j\ell}^{\mathrm{r}}$: stoichiometric number of species j in forward and backward reaction ℓ, μ_0: permeability of vacuum (H/m), κ: Boltzmann constant (J/K), $\dot{A}_\theta$: vector potential (V·s/m), ω: angular frequency of coil current (rad/s), $\dot{E}_\theta$: electric field strength (V/m), $\dot{H}_z$: axial magnetic field strength (A/m), $\dot{H}_r$: radial magnetic field strength (A/m), $\bar{i}$: complex index ($\bar{i}^2$=−1), $\psi_{\mathrm{reac}\ell}$: reaction heat for reaction ℓ (J), $\pi\bar{\Omega}_{ij}^{(1,1)}$: momentum transfer collision integrals (m^2), $\pi\bar{\Omega}_{ij}^{(2,2)}$: viscosity collision integrals (m^2), Q_{Ar}: Ar gas flow rate (m^3/s), Q_{N_2}: N_2 gas flow rate (m^3/s), N: total number of species, L: total number of reactions.

3. Results and discussions

3.1. Temperature variation

Figure 3 shows the time evolution in T_e and T_h at (z, r)=(165 mm, 16 mm) for SCL=60 % at an on-time/off-time of 10/5 ms, respectively. This position corresponds to the one at which T_h is the highest in steady state. Both the temperatures T_h and T_e have periodical changes according to the coil-current modulation. After five cycles from pulse-modulated operation, a periodical steady state can be seen in the temperature evolutions. Another important fact in this figure is that T_e rapidly increases just after a sudden increase in coil-current amplitude. This rapid increase in T_e leads to 500 K higher T_e than T_h, which means an introduction of thermal non-equilibrium condition even in high-power atmospheric-pressure plasmas.

Figures 4 and 5 show two-dimensional time variations in electron temperature (T_e) and heavy particle temperature (T_h) fields in an Ar-N_2 PMITP during off-time and on-time durations, respectively. Unique and large changes in T_e and T_h can be found especially around the plasma torch region. An decrease in coil-current amplitude from t=104 to 110 ms decays both T_e and T_h, and then the high-temperature area with T_e and T_h >9000 K is shrunk as represented in Fig.4. This decrease in coil-current amplitude, however, extends an area around 8000 K to the downstream portion of the plasma torch. This is due to an fluid inertia effect in the atmospheric-pressure plasmas in this case. On the other hand, an increase in the coil-current amplitude increases both T_e and T_h in the plasma torch region, and then these reaches beyond 9000 K as indicated in Fig.5. It can be also seen that T_e and T_h below 6000 K do not change so much around the downstream of the reaction chamber.

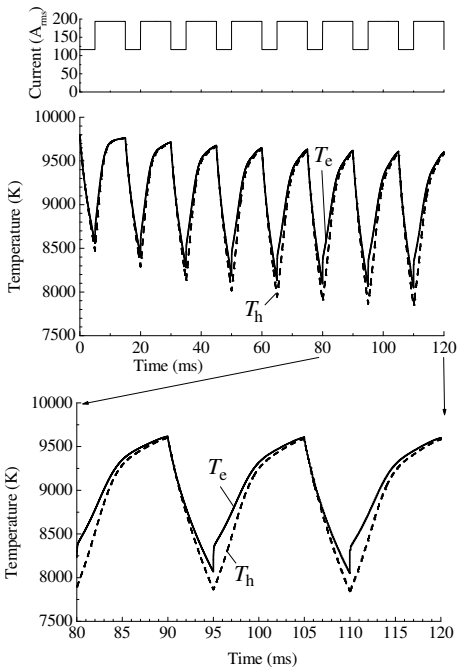

Fig. 3. Time evolution in T_e and T_h at high-temperature point in an Ar-N_2 PMITP for SCL=60 %.

3.2. Enhancement of deviation from thermal equilibrium by coil-current modulation

In order to verify deviation from thermal equilibrium in the PMITP, the dynamic behaviors of the radial distributions of T_e and T_h are depicted for an on-time duration from t=110 to 114 ms in Fig.6. The sudden increase in coil-current amplitude at t =110 ms rapidly increases T_e with time at radial position r > 15 mm, i.e. around the tube wall. After that, T_h around r < 25 mm gradually increases with time. Thus, thermal non-equilibrium condition that means $T_\mathrm{e} > T_\mathrm{h}$ can be found near the tube wall. In this way, pulse-modulation of the coil-current amplitude yields a thermal non-equilibrium condition in transient state even in high-power high-pressure plasmas. Around the plasma center axis, we can confirm T_e close to T_h, which indicates that thermal equilibrium condition is almost established there.

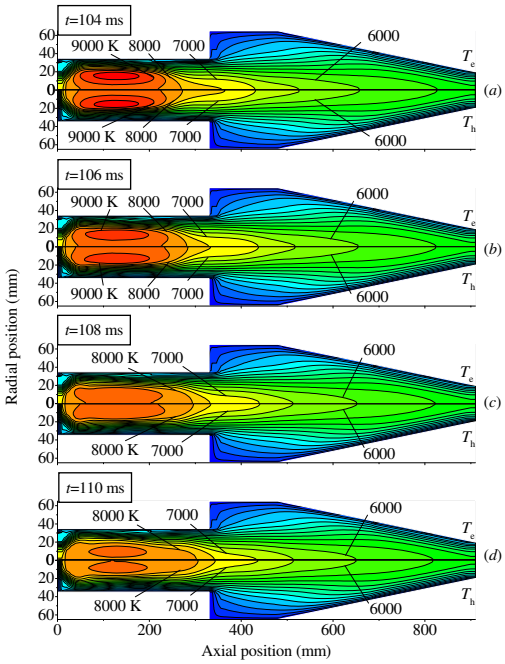

Fig. 4. Transient distributions of T_e and T_h during 'off-operation' in an Ar-N_2 PMITP.

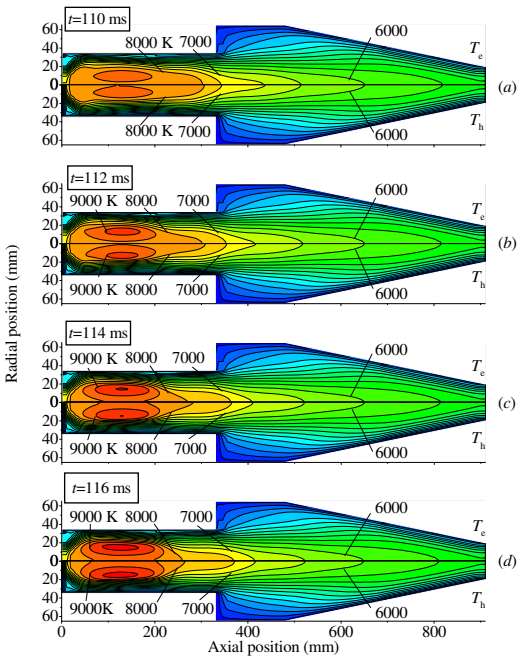

Fig. 5. Transient distributions of T_e and T_h during 'on-operation' in an Ar-N_2 PMITP.

3.3. Dynamic behavior of N atom density distribution

It is very important to investigate transient distributions of nitrogen atomic density in the plasma torch and the reaction chamber for nitriding processings [8]. Figures 7 and 8 depicts dynamic behavior of N atomic density in Ar-N_2 PMITP for SCL=60 % at on-time/off-time=10/5 ms. Remember that the effects of reaction rates, convection and diffusion were considered in this calculation. Nitrogen atoms have higher density around axial positions $320 < z < 370$ mm, i.e. around the inlet of the reaction chamber. This means that the above axial positions may be preferable for nitriding processings of materials. The N atoms are also found to be modulated and controlled with coil-current amplitude modulation. Such N atoms are produced mainly by dissociation of N_2 around $20 < r < 25$ mm in high-temperature region in the plasma torch, and then they are transported to the downstream portion around radial center of the plasma torch by gas flow convection. On the other hand, N atom density at further downstream portion $z > 500$ mm in the reaction chamber hardly changes with the coil-current modulation.

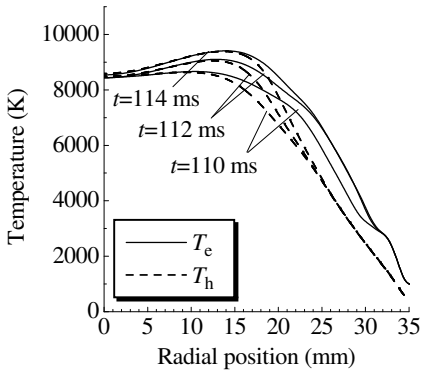

Fig. 6. Transient radial distributions of T_e and T_h during 'on-operation' at an axial position of 155 mm in an Ar-N_2 PMITP for SCL=60 %.

3.4. Effect of modulation condition on temperature variation

Next, effect of the coil-current amplitude modulation conditions such as SCL and off-time were also studied on temperature variation and deviation from thermal equilibrium. Figure 9 presents time evolutions in T_e and T_h at (z, r)=(165 mm, 16 mm) for various SCL at a fixed on-time/off-time of 10/5 ms. It can be noticed that lower SCL causes lower T_e and T_h just before on-operation, which indicates that setting SCL can control minimum values of T_e and T_h in modulation cycle. Just after on-operation, for example at t =50 or 65 ms, only T_e increases much more rapidly than T_h. This is because the higher electric field strength is applied suddenly to the plasmas with on-operation, and accelerates the electrons there. This rapid increase in T_e means that large deviation from thermal equilibrium can be realized by decreasing SCL even in this atmospheric pressure high-power plasmas.
Figure 10 shows the effect of off-time on T_e and T_h variations and deviation from thermal equilibrium. It is seen that longer off-time can causes larger modulation in T_e and T_h and larger deviation from thermal equilibrium.

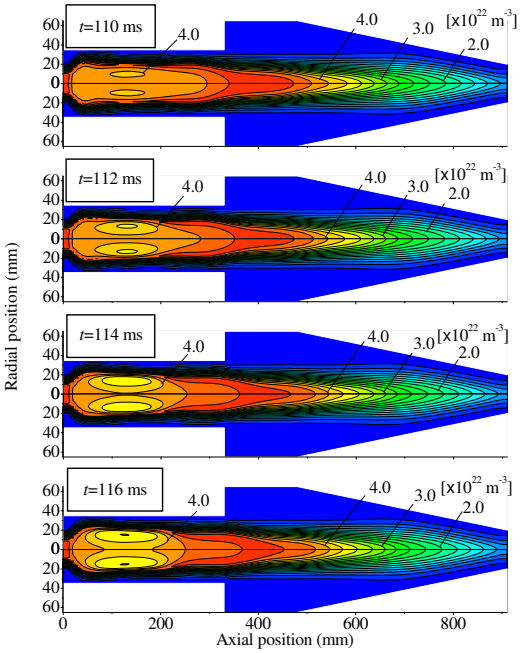

Fig. 8. Transient distributions of N atomic density during 'on-operation' in an Ar-N_2 PMITP.

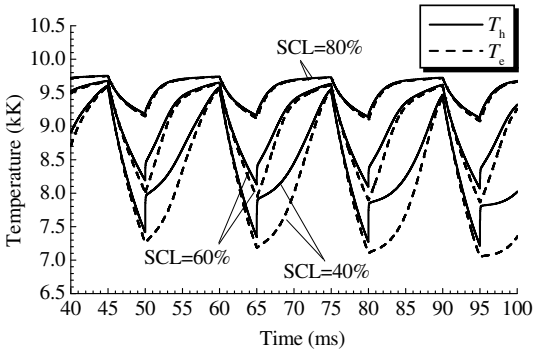

Fig. 9. Time evolutions in T_e and T_h at high-temperature point in an Ar-N_2 PMITP for various shimmer current levels.

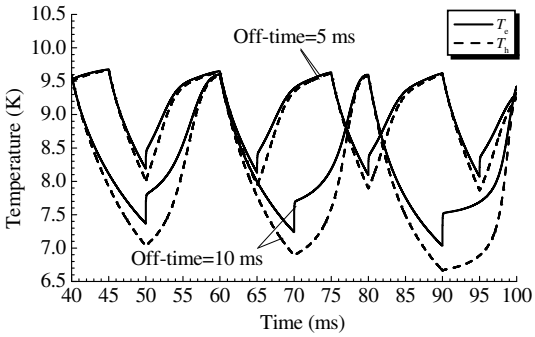

Fig. 10. Time evolutions in T_e and T_h at high-temperature point in an Ar-N_2 PMITP for off-times.

4. Conclusions

The author developed a time-dependent two-dimensional two-temperature chemically non-equilibrium model for high-power Ar-N_2 PMITP. Using this model, the controllability of electron and heavy particle temperatures, thermal non-equilibrium and N atomic density in the PMITP were investigated. The results revealed that lower shimmer current level and longer off-time was found to cause larger temperature variation and larger deviation from thermal equilibrium.

Abstract

This paper addresses high-speed surface nitridation of a titanium metal using novel high-pressure high-power pulse-modulated induction thermal plasmas (PMITP or high-power PMICP). The PMITP method is one of unique techniques for controlling electron and heavy particle temperatures and radical densities in time domain in high-power thermal plasmas. Pulse-modulation of the coil current sustaining Ar-N_2 PMITPs was found to enhance N atom flux flowing into the downstream chamber. The irradiation of Ar-N_2 PMITPs made nitridation of the titanium metal surface within five minutes with little thermal damages.

1. Introduction

High-power induction thermal plasmas around atmospheric pressure have great advantages such as remarkably high enthalpy and high radical density compared with cold plasmas, and little contamination because of no electrodes. From these advantages, induction thermal plasmas have been widely used for many material processing fields such as syntheses of nanopowders, superconducting and diamond films. However, their too high enthalpy is difficult to be controlled only by the conventional setting of gas flow and electrical input powers to thermal plasmas under steady states. This uncontrollable high enthalpy may cause thermal damages on the substrates and grown films. In order to control this high enthalpy and temperature, we have developed a pulse-modulated induction thermal plasma (PMITP) system. This system can modulate the amplitude of coil current sustaining thermal plasmas [1]–[3]. Such the coil-current modulation leads to thermal plasmas under transient states, and enables us to control thermal plasma temperature and radical density in time domain. Furthermore, it can promote chemical and thermal non-equilibrium states even in high-power atmospheric pressure plasmas. We have investigated unique dynamic behaviors of such a PMITP by experimental and numerical approaches [4]–[6]. Recently, Ohashi *et al.* have applied the PMITP to the hydrogen doping on ZnO [7]. They successfully found that irradiation of the Ar-H_2 PMITP can dope hydrogen atoms into ZnO and then improve its photoluminescence. However, there have been still a few reports on application of the PMITP to the material processings.

In the present work, we report experimental results about the first trial application of Ar-N_2 PMITPs to the high-speed surface nitridation of titanium metal. It is known that nitridation generally requires a long processing time about several hours using conventional methods such the gas nitriding method and the ion nitriding method. In the present experiment, spectroscopic observation was carried out to find the radiation intensity of nitrogen atomic spectral line around the installed position of titanium metal targets. Titanium target surface was found to be modified to TiN by irradiation of Ar-N_2 PMITP within five minutes with little thermal damages.

2. Pulse modulation of coil current for PMITP

Figure 1 shows essential elements of pulse amplitude-modulation of the coil current for sustaining a PMITP. The PMITP is established by the amplitude-modulated coil current with a fundamental frequency of 450 kHz in our case. The pulse modulation of the coil current induces four controllable parameters. They are 'HCL' which is the higher current level, 'LCL' the lower current level, 'on-time' the time period with the higher current level and 'off-time' the time period with the lower current level. Setting these four parameters can change dynamic behaviors of the PMITP. However, it is noted that these parameters have a relationship for stable operation of the PMITP [3]. We also define 'SCL; shimmer current level' as a ratio LCL/HCL. The control of these parameters can bring the following expected features and effects: (i) control of time-averaged power and temperature/enthalpy of the thermal plasmas in time domain, (ii) extremely high or low electromagnetic field operation can be made during on/off-operation of the coil-current, (iii) thermally and/or chemically non-equilibrium effects in thermal plasma could be introduced by sudden application of the electric field.

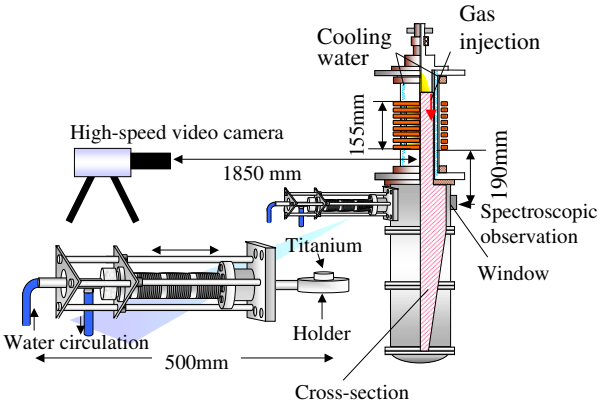

Fig. 3. Plasma torch and target holder.

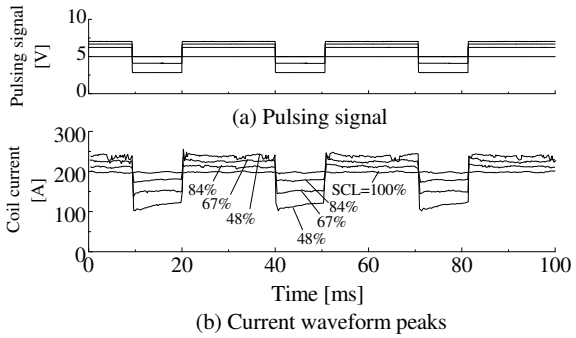

Fig. 4. Coil current controlled for a fixed time-averaged power of 15 kW.

3. Experimental setup and experimental conditions

For sustaining a PMITP with a high-power conversion efficiency, we adopted a MOSFET inverter power supply for a power source. Figure 2 shows the electric circuit system for PMITP used in the experiment [3]. The system includes four parts: a rectifier circuit, an inverter circuit, an impedance-matching circuit and an induction plasma torch. The rectifier circuit has six diodes with a smoothing capacitor to produce dc power. The dc power is converted into ac one with the inverter circuit including two MOSFET (Metal Oxide Semiconductor Field Effect Transistor, rated 150V/460A) units. These units are operated at a fundamental frequency of 450 kHz. The MOSFET inverter part has a much higher power-conversion efficiency over 85 % than a conventional vacuum tube during dc/ac inverter performance. A MOSFET inverter power supply was connected to the induction coil through a series LC matching circuit. This system can modulate the 450 kHz current with a hundred several amperes by controlling fire angle of the MOSFETs.

Figure 3 illustrates a schematic diagram of the plasma torch for PMITPs. The plasma torch is composed of two coaxial quartz tubes with a 330 mm length. The inner tube has an inside diameter of 70 mm. Between these two tubes, cooling water flows to keep the temperature of the tube wall to be 300 K. This plasma torch has an eight-turn induction coil around the quartz tube. At downstream portion of the plasma torch, a water-cooled reaction chamber is installed. This chamber has a tapered shape to make rapid cooling of the hot gas in this chamber. Argon and nitrogen gas mixture was supplied as a sheath gas along the inside wall of the inside quartz tube. Total gas flow rate was fixed at 100.0 slpm. Nitrogen gas flow rate Q_{N_2} was set to a value from 0.0 to 9.0 slpm. Pressure inside the chamber was fixed at 31 kPa (=230 torr) with an automatic feed-back pressure controller. The “on-time” and “off-time” was set to 10 and 5 ms, respectively.

A two-piled titanium metal target with a diameter of 15 mm and a thickness of 5.0 mm was located on a water-cooled target holder in irradiation experiments. The target holder was fixed at 190 mm below the coil-end to make nitridation of the target surface by Ar-N_2 PMITP irradiation. The irradiation time was set to 3–10 minutes.

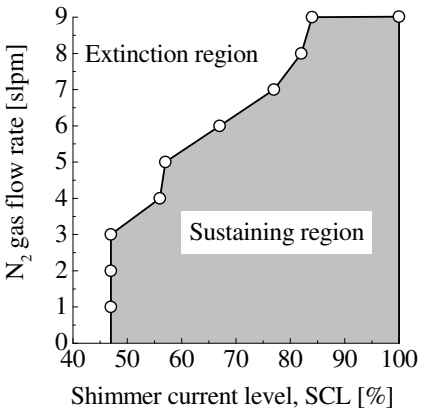

Fig. 5. Stable operation region of Ar-N_2 PMITP at a time-averaged input power of 15 kW at a pressure of 31 kPa. The total gas flow rate is 100 slpm.

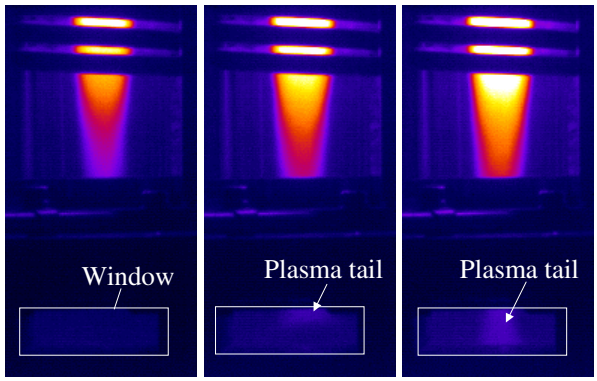

(a) SCL=100% (b) SCL=70% (c) SCL=40%

Fig. 6. High-speed video pictures of visible light emission from 98%Ar-2%N_2 PMITP at a time of its maximum volume in a modulation cycle. Pressure is 31 kPa. The time-averaged input power is fixed at 15 kW.

Optical emission spectroscopic (OES) observation was also carried out at 190 mm below the coil through the observation window installed at downstream portion of the plasma torch. In this OES method, we measured time evolution in radiation intensities of a nitrogen atomic line at a wavelength of 746 nm. A high-speed video with a complementary metal-oxide semiconductor (C-MOS) optical array sensor was also set up at 1850 mm far from the plasma torch. This C-MOS sensor has a sensitivity for visible light between 400–800 nm. The exposure time of this high-speed video camera was set to 10 μs, whereas a frame rate was independently set to 3200 frame/s.

4. Control of fixed time-averaged input power into thermal plasma

In the present experiments, a time-averaged electric input power to the inverter power supply in a modulation cycle was fixed for any modulation condition. This is to find modulation effects of the coil current on the internal state of thermal plasmas under the almost same electric power cost condition. Figure 4 depicts the pulsing signal and the controlled coil-current amplitude in this fixed time-averaged power condition. For SCL=100%, the coil-current amplitude was fixed at constant value. For the modulation cases, on the other hand, the HCL was controlled to be higher while the LCL was lower than those in SCL=100% case.

5. Experimental results

5.1. Stably sustaining region of the Ar-N_2 PMITP

Stable sustain of the Ar-N_2 PMITP is necessary for any applications. This stable sustain of the PMITP is limited by modulation and gas flow conditions. Figure 5 presents the experimentally obtained stably-sustaining region of Ar-N_2 PMITP at a fixed power of 15 kW. At SCL=100 %, i.e. in continuous operation mode, Ar-N_2 induction thermal plasma can be established in Q_{N_2} range of 0–9 slpm. However, in the coil-current amplitude modulation mode, Ar-N_2 PMITPs cannot be sustained for a higher Q_{N_2}, which leads to extinction of the plasmas. Figure 5 shows that increasing ratio of Q_{N_2} to the total gas flow makes it difficult to sustain Ar-N_2 PMITP. This difficulty arises mainly from energy consumption necessary for dissociation, vibrational and rotational excitations of N_2 molecules. Furthermore, decreasing SCL reduces the sustaining region of Ar-N_2 PMITP as indicated in this figure. This is ascribed to larger disturbances of the coil current by the lower SCL modulation. The Ar-N_2 PMITP should be operated in this stably sustaining region.

5.2. Dynamic behavior of Ar-N_2 PMITP observed with a high-speed video camera

First of all, we investigated the unique dynamic behavior of Ar-N_2 PMITPs. A high-speed video capture is useful for understanding the dynamic behavior of two-dimensional visible light emission region from Ar-N_2 PMITP. The region with high visible-light emission generally corresponds to the high-temperature region for thermal plasmas. Figure 6 represents high-speed video pictures around the downstream portion of the plasma

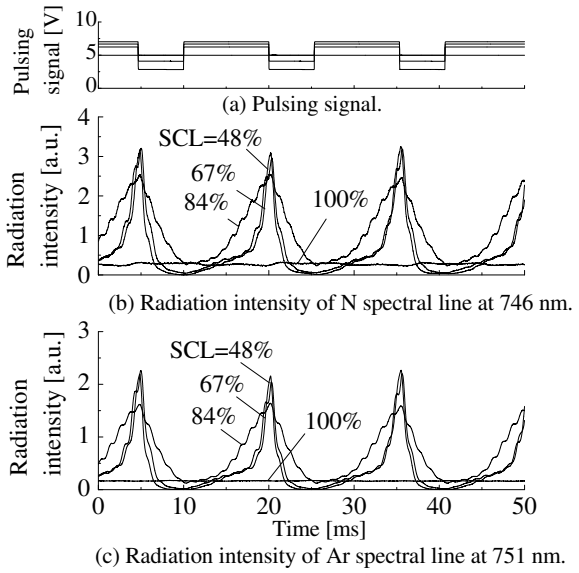

Fig. 7. Time evolutions in radiation intensities of N atomic line at 746 nm and Ar atomic line at 751 nm in 98%Ar-2%N_2 PMITP. The pressure is fixed at 31 kPa, the time-averaged input power is 15 kW.

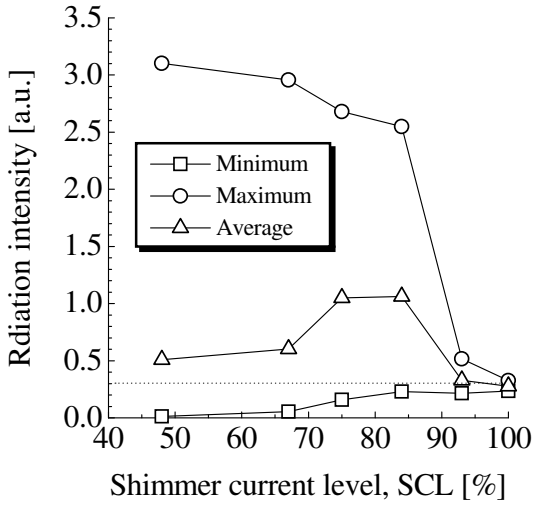

Fig. 8. Dependence of radiation intensity of N atomic line at 746 nm on shimmer current level in 98%Ar-2%N_2 PMITP.

torch and the observation window in the reaction chamber. The observation window position corresponds to the target position in irradiation experiments described later. These pictures were taken at just before off-operation at SCL=70 and 40 %. At just before off-operation, the volume of plasmas becomes its maximum in the coil-current modulation cycle in the modulation modes. As seen in these figures, at SCL=100 %, i.e. in continuous operation mode, the high light emission area from plasmas is smaller than those in the modulation case, and the light from the "plasma tail" around the observation window cannot be seen. However, the plasma tail can be found from the observation window in the modulation mode. This indicates that decreasing SCL causes a large variation in PMITP and then the plasma tail reaches much more to the downstream portion.

5.3. Enhancement of N excited atom flux by current-modulation

We made spectroscopic observation of the plasma tail from the observation window at 190 mm below the coil end to find dynamic behaviors of Ar-N_2 PMITP in detail. Figure 7 (a) indicates the pulsing signal, and Figs.(b) and (c) indicate time evolutions in radiation intensities of a N atom spectral line at a wavelength of 746 nm and that of an Ar atomic line at 751 nm, respectively. The radiation intensities of the N atomic line and the Ar atomic line can be found to change periodically with the modulation of the coil current.

For modification of metal surfaces, radicals and excited particles flux of N atom onto the metal surface is of importance. The radiation intensity I_{N746} of the N atomic line measured here is expressed by

$$I_{\mathrm{N746}} = \int_{\Omega} N_m A_{mn} h\nu_{mn} dV = A_{mn} h\nu_{mn} \int_{\Omega} N_m dV = A_{mn} h\nu_{mn} \bar{N}_m \tag{1}$$

where N_m is the number of the excited N atoms with an upper level m, A_{mn} the transition probability from levels m to n, h the Planck constant, ν_{mn} the frequency of photon, Ω the observation region, $\bar{N}_m$ the number of excited N atoms with an upper level m in Ω region. This equation means that variation in the measured radiation intensity I_{N746} is proportion to variation in the number of excited N atoms $\bar{N}_m$ in the observation region. It is thus considered that the number of excited N atoms $\bar{N}_m$ itself is modulated and changed as indicated in Fig.7(b). We can also see that changing SCL cause differences in waveform of I_{N746}, and thus difference in dynamic behavior of $\bar{N}_m$. Smaller SCL produces a sharp or spike-like change in waveform of I_{N746} around coil-current transition from HCL to LCL. It also enhances peak values of I_{N746} just before off-operation. This means that decreasing SCL enhances the number of N atoms flowing into the reaction chamber just before off-operation.

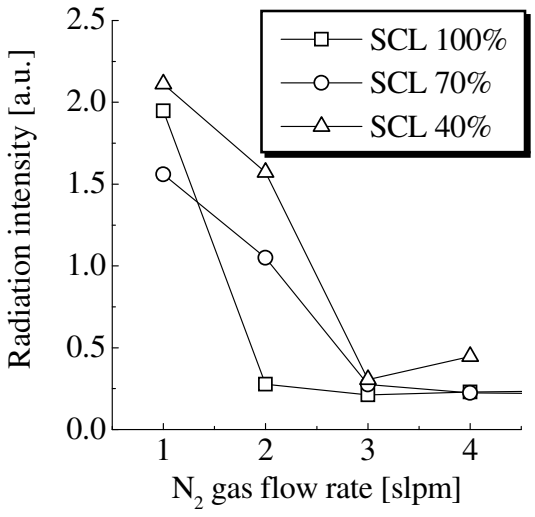

Fig. 9. Dependence of radiation intensity of N atomic line at 746 nm on N_2 gas flow rate.

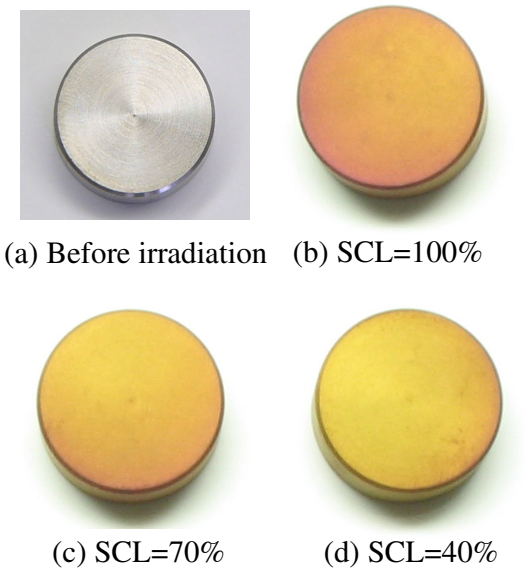

Fig. 10. Photograph of Ti surface irradiated by 98%Ar-2%N_2 PMITP at a time-averaged power of 15 kW at a pressure of 31 kPa. Irradiation time is 5 min.

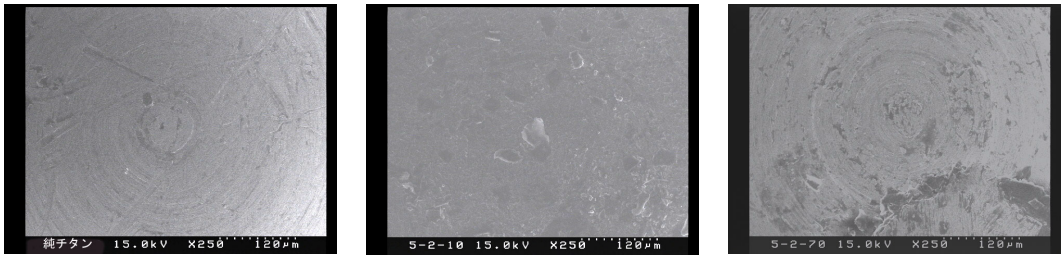
Fig.8 plots these peak and minimum values of I_{N746} versus SCL. The time-averaged I_{N746} were also evaluated from the measured I_{N746} as follows:

$$I_{N746}^{Tave} = \frac{1}{2T_{cyc}} \int_{t}^{t+2T_{cyc}} I_{N746} dt \tag{2}$$

where T_{cyc} is the modulation cycle time which was set to 15 ms in this case. This quantity I_{N746}^{Tave} is proportion to the time-averaged $\overline{N}_m$ flowing into the reaction chamber. As seen in this figure, the maximum radiation intensity markedly increases with reducing SCL, while the minimum decreases with reducing SCL. This represents that controlling SCL can enhance peak value of $\overline{N}_m$ flowing into the chamber just after off-operation. Another important fact is that the time-averaged I_{N746}, i.e. I_{N746}^{Tave} increases with reducing SCL. This result means that the modulation of the coil current enhances the total excited N atomic flux produced in the plasma torch into the reaction chamber. This may also enhance nitridation reactions in the chamber in irradiation experiments.
Figure 9 shows dependence of the time-averaged radiation intensity of the N atomic line I_{N746}^{Tave} on N_2 gas flow rate Q_{N_2}. Increasing Q_{N_2} decreases I_{N746}^{Tave} for any SCL in spite of an increase in N atom as an injected gas. This is due to temperature decay by increasing Q_{N_2}. The molecule N_2 have a large vibrational and rotational cross sections around 2.0–3.0 eV, and requires dissociations by impact of electrons. These consumes the electron energy and then the temperature. The essential point in this figure is that decaying rate of I_{N746}^{Tave} on Q_{N_2} is smaller in the modulation mode than in the continuous mode at SCL=100 %. As a result, I_{N746}^{Tave} at SCL=70 % is higher than that at SCL=100 %, especially at Q_{N_2}=2.0 slpm. This means that total N atomic flux can flow more effectively into the reaction chamber in modulation mode than in continuous mode.

5.4. Irradiation experiments of Ar-N_2 PMITP to the Ti target

To investigate enhancement effect of N atom flux by Ar-N_2 PMITPs around the reaction chamber, a titanium metal target was installed at downstream portion of the plasma torch as indicated in Fig.3 for its nitridation. The titanium can be an indicator for N atomic flux in the reaction chamber. Figure 10 indicates photographs of Ti surface irradiated by 98%Ar+2%N_2 PMITP at 15 kW at a pressure of 31 kPa. Irradiation time is 5 minutes. Gold-like color, which is TiN color, can be seen from these surface in any SCL case. However, some violet color is also seen around the target for SCL=100 %. Figure 11 represents SEM observation results of the target surface irradiated by Ar-N_2 PMITP. The surface originally has a circle Little thermal damage can be found for the surfaces of the targets.



(a) Before irradiation. (b) SCL=100%. (c) SCL=70%

Fig. 11. SEM Photograph of Ti surface irradiated by 98%Ar+2%N_2 PMITP at 15 kW at a pressure of 31 kPa. Irradiation time is 5 min.

5.5. XRD analysis of surface by Ar-N_2 PMITP irradiation

In order to find the surface crystal composition, XRD analysis were made for the targets irradiated by the Ar-N_2 PMITP. Figure 12 shows the XRD spectra of Ti surface before and after irradiation by Ar-N_2 PMITP. For a Ti target before irradiation, only Ti spectra can be found. After irradiation of Ar-N_2 PMITP, TiN spectra can be seen for any SCL cases. These spectra is seen to be influenced by SCL. At SCL=70 %, Ti_2N spectra at 34 and 52^o are seen. This might be due to insufficiency of N atom flux and temperature. These results indicate that controlling SCL can change surface crystal state of the target.

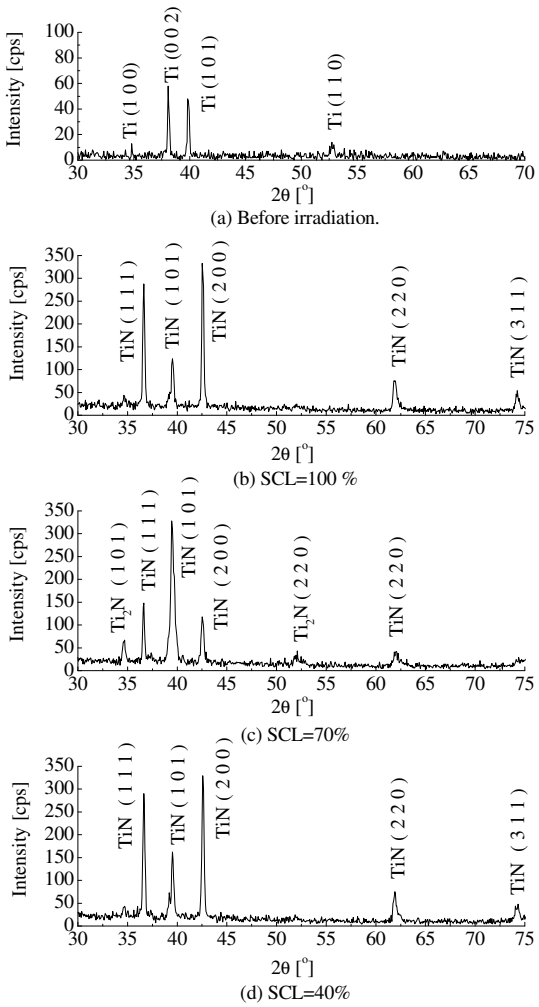


Fig. 12. XRD spectra of Ti surface irradiated by 98%Ar-2%N_2 PMITP at 31 kPa. The irradiation time is 5 min.

6. Conclusions

The Ar-N_2 pulse-modulated induction thermal plasma was applied to the surface nitridation of titanium. The modulation of the coil current causes a much more transport of excited nitrogen atoms to the downstream portion of the plasma torch, which may promote surface nitridation of the target. The target surface irradiated by Ar-N_2 PMITP was analyzed by a XRD analyzer. The result indicates TiN spectra was influenced by shimmer current level of the coil current modulation.

Abstract

Visible-light responsive Fe- and N-doped TiO_2 nanocrystalline powders have been synthesized via Ar/O_2 RF thermal plasma oxidizing mists of liquid precursors containing Ti^{4+} and the dopant elements. Structure and optical properties of the powders are characterized by XRD, TEM, SEM, Raman spectroscopy, and UV-Vis spectroscopy. Both Fe- and N-doping narrow the bandgap of TiO_2, allowing visible light responses of the powders and hence their potential applications as photocatalysts under visible light illumination.

Keywords RF thermal plasma, TiO_2 nanocrystals, N-doping, Fe-doping, phase structure, bandgap, photocatalysis

1. Introduction

TiO_2 remains the most promising photocatalyst up to date but is only activated by irradiating with ultraviolet (UV) light due to its relatively wide bandgap (~3.2 eV). As UV light accounts for only ~5% of the solar energy compared to visible light (~45%), any shift in its optical response from UV to the visible spectral range will have a remarkable positive effect on the practical application of the material. There seem two general approaches to achieve visible light responses of TiO_2: substituting the Ti sites of TiO_2 lattice with metal cations, mainly transition metals like Fe^{3+} [1], and doping TiO_2 with nonmetallic elements, typically nitrogen [2]. The synthesis of Fe-doped TiO_2 has been achieved by wet chemical routes, but either post annealing that exclusively results in phase segregation is necessary or the Fe/Ti ratio in the resultant powders significantly deviates from that of the starting solution. N-doping is generally made by annealing pure TiO_2 powders under N-containing atmospheres (usually NH_3), but has drawbacks of non-uniform dopant distribution, as the nitriding reaction starts at particle surfaces. RF thermal plasma is characterized by its extremely high temperature (up to ~10^4 K) and rapid heating and cooling rates (~10^{5-6} K/s), which are particularly suitable for the synthesis of both lightly and heavily doped oxides with homogeneous dopant distribution and good crystallinity in a very short time. We report here the synthesis of Fe- and N-doped TiO_2 nanocrystals via Ar/O_2 thermal plasma oxidation of liquid precursor mists. The use of mists ensures atomic level mixing of the elements and high supersaturation of the evaporated species upon plasma oxidation, which favors nanocrystal formation upon condensation. The effects of dopant on phase structure and photo-response of the resultant TiO_2 powders are investigated in detail.

2. Experimental

The experimental conditions for the synthesis of Fe-doped TiO_2 nanopowders are as follows: plate power, 25kW;

central gas, 30L/min of Ar; sheath gas, 70L/min of Ar plus 20L/min of O_2; atomization gas, 5L/min of Ar; chamber pressure, 66.7kPa; precursor feeding rate, 3.5-4.0g/min. Fe-doped TiO_2 nanoparticles are synthesized by injecting organic solutions containing titanium tetra-*n*-butoxide (TTBO) and ferrocene (Fe/Ti=0-20at%, stabilized with diethanolamine (DEA, DEA/TTBO=1:1 in molar ratio) into the center of the thermal plasma plum through an atomization probe.

The fundamental conditions for synthesizing N-doped TiO_2 powders are the same as described above, except that the O_2 flow rate in the plasma sheath ($Ar+O_2$=90 L/min) was varied in the range 10-90L/min to investigate its effects on the phase constituent and nitrogen content of the resultant powders. DEA is employed here not only as a stabilizer for TTBO but also as the nitrogen source. To achieve effective doping, a higher DEA/TTBO molar ratio of 4 was used.

Characterizations of the nanopowders were achieved by elemental analysis, XRD, TEM, SEM, Raman spectroscopy, and UV-Vis spectroscopy. Photocatalytic activities of the powders were evaluated via bleaching methyl orange solutions under visible light (>400 nm) irradiations.

3. Results and discussion

Chemical analysis confirmed that the prescribed Fe/Ti molar ratios (*R*) in the precursor solutions have been kept to the final powders. XRD analysis (Fig. 1) revealed that the resultant nanopowders exclusively contain anatase and rutile. At dopant concentrations up to *R*=5at%, the XRD patterns show normal peaks with symmetric shapes (Fig. 1). Fe-doping dramatically promotes rutile formation, due to the oxygen vacancies created for charge compensation upon substituting Fe^{3+} for Ti^{4+} sites. Metastable anatase instead of thermodynamically stable rutile is formed as the major phase in the undoped sample, which is consistent with our predictions obtained through theoretical calculations based upon classical nucleation theory, that is, anatase preferentially nucleates from deeply undercooled TiO_2 melts while rutile from less deeply undercooled ones [3].

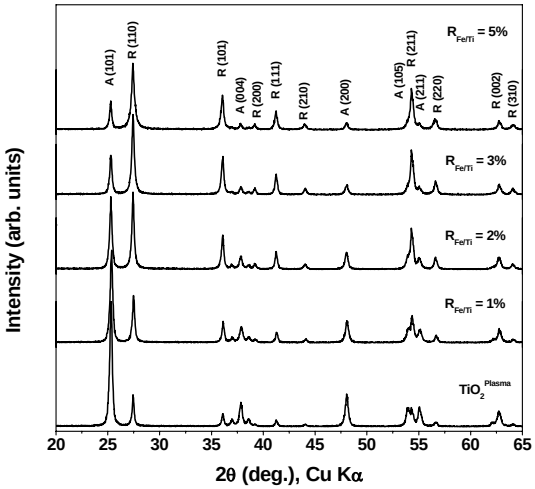

Fig. 1. XRD patterns of the powders with *R* up to 5at%.

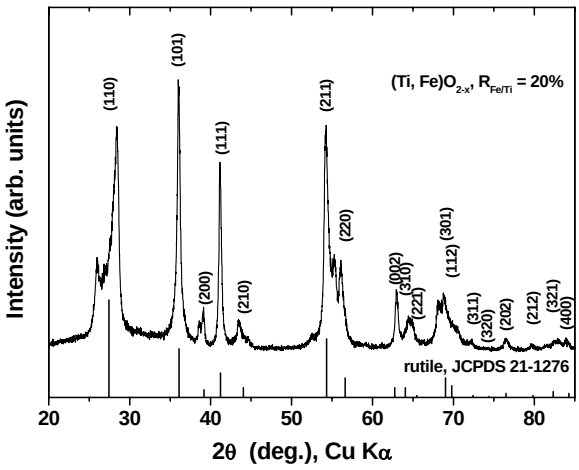

Fig. 2. XRD pattern of the powder with *R*=20at%.

In the heavily doped samples (R=10 and 20at%), The diffraction peaks expect for (101), (111), and (002) exhibit asymmetry, which was enhanced with increasing R (Fig. 2). The asymmetric peaks, with (110) in particular, are significantly broadened and weakened, which reflects misalignment of the slabs in such a way that the d-spacing was not well defined in the [110] direction. Figure 3 shows Raman spectra of the powders with R up to 20at%. Special attentions were paid to the anatase E_g mode at 146.2 cm^{-1} and the rutile E_g mode at 448.1 cm^{-1}, as increasing the oxygen vacancies in the crystal structure of TiO_2 causes right-hand shift of the former while left-hand shift of the latter [4], which was clearly observed at R up to 2at%. At higher R values, the E_g mode of rutile keeps constant at ~402.5 cm^{-1}, suggesting that the oxygen vacancy level in the rutile structure has reached its maximum. Besides, significantly decreased intensities were observed for the Raman bands with increasing Fe^{3+}addition, mainly owing to the increased absorption of the excitation light by the sample. TEM observations indicate that the surplus oxygen vacancies in the samples with R above 2at% cluster to form extended defect structure like crystallographic shear plane (Fig. 4). Iron doping lowers the energies for both indirect and direct transitions TiO_2 (Fig. 5), suggesting their potential use as photocatalysts under visible light illuminations.

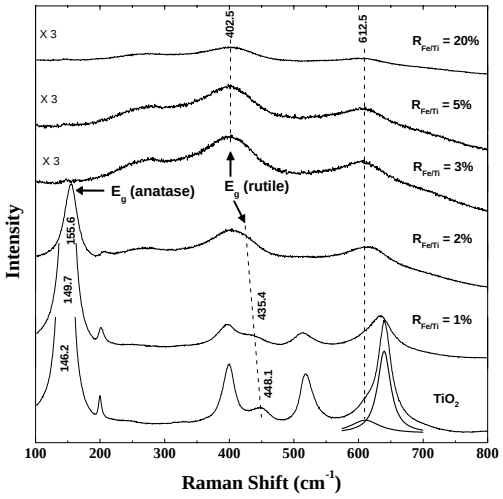

Fig. 3. Raman spectra of the Fe-doped TiO_2 samples

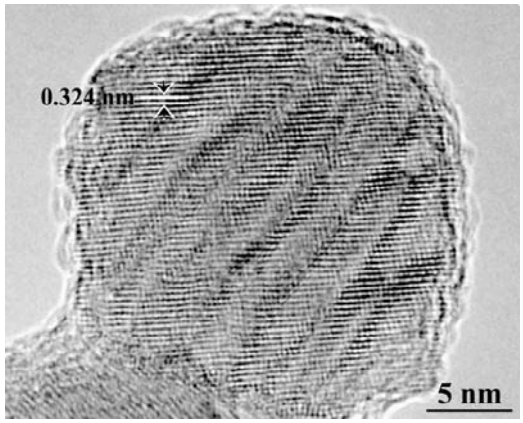

Fig. 4. TEM image showing the clustering of oxygen vacancies

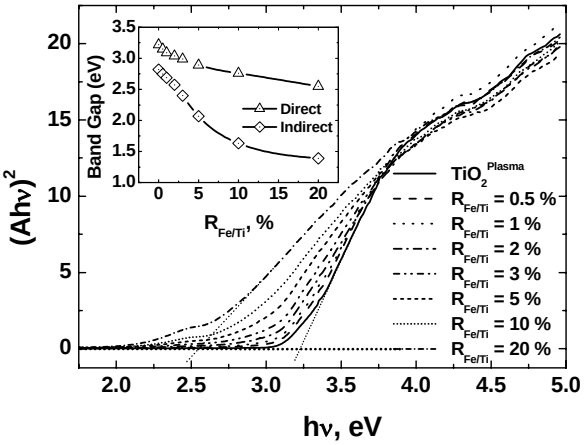

Fig. 5. Bandgap narrowing of TiO_2 by Fe^{3+} doping

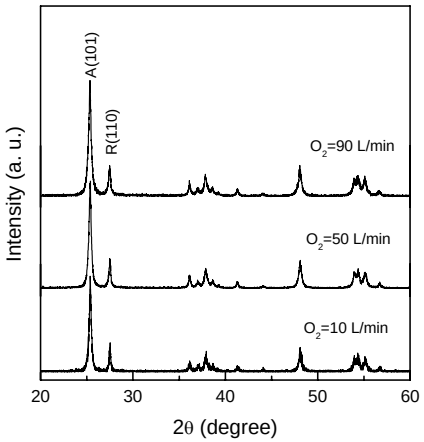

Fig. 6. XRD patterns of the N-containing TiO_2 powders

For N-doped TiO_2 samples, XRD analysis (Fig. 6) shows that they contain only anatase and rutile, and again, metastable anatase was formed as the major phase (>70 wt%), irrespective of the oxygen input rates in the plasma sheath. The anatase content tends to increase at a higher O_2 flow rate (Fig. 7), which might be understood from the facts that (1) the increased addition of diatomic oxygen gas improves thermal conductivity of the thermal plasma, which causes deeper undercooling of the TiO_2 melt at the plasma tail and therefore favors anatase nucleation [3], and (2) a higher O_2 input reduces oxygen deficiencies in the TiO_2 gas clusters, beneficial to anatase formation upon gas phase condensation. A similar phenomenon was observed during our previous work on TiO_2 synthesis via RF thermal plasma oxidation of TiC and TiN particles [5,6]. The nitrogen concentration tends to increase along with the anatase content (Fig. 7), implying that nitrogen is readily doped into the anatase lattice. The powders show weak dependence on the O_2 input in the plasma sheath, and have average crystallite sizes of ~40 nm and specific surface areas of ~30-50 m^2/g. Figure 8 shows typical morphologies (SEM) of the plasma generated N-doped TiO_2 powders. Though particles having diameters bigger than 100 nm are present, most of the crystallites have sizes around 35 nm and are largely dispersed. These two distinctly different types of particle morphologies were considered to be due to the different trajectories of the precursor mists in the hot zone of the thermal plasma.

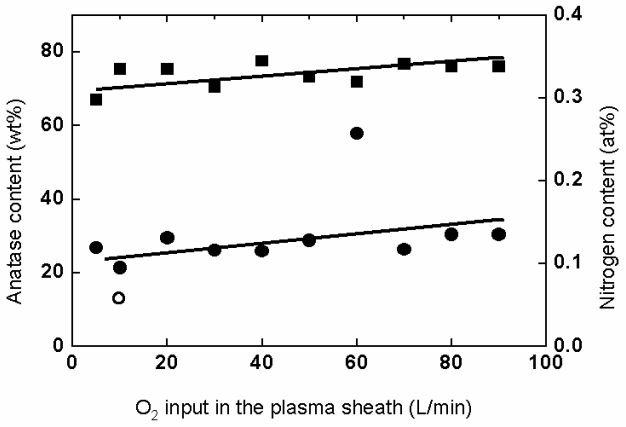

Fig.7. Anatase and N contents of the powders, as a function of the O_2 input in the plasma sheath.

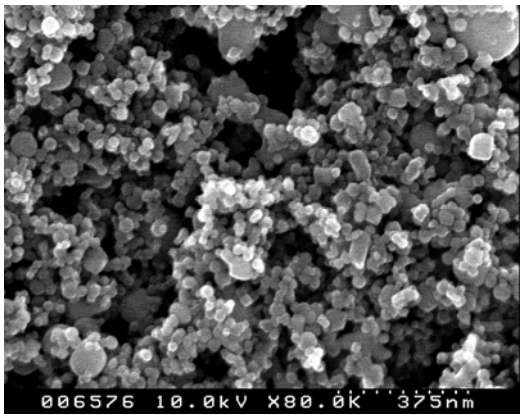

Fig. 8. SEM micrograph showing morphology of the N-doped TiO_2 powder synthesized with 10L/min of O_2 input

Figure 9 shows UV-Vis spectra of the TiO_2 powder synthesized with 10 L/min of O_2 input in the plasma sheath, compared with that of the Degussa P25 powder. The P25 powder has a bandgap of ~3.04 eV, while the N-doped powder exhibits a narrowed one of ~3.00 eV, showing bandgap narrowing of the N-doped TiO_2. the N-doped TiO_2 powders exhibit higher efficiencies than Degussa P25, a model photocatalyst, in the bleaching of methyl orange solution (100 μ mol/L) under visible light (>400 nm) irradiation (Fig. 10).

Abstract
Spherical artificial graphite powders, so-called as mesocarbon microbead powders, were treated in Ar-H_2-SF_6 radio-frequency inductively coupled thermal plasma. Sulfur and fluorine incorporated into particles. An anode of lithium-ion rechargeable battery made from plasma-treated powder had a discharge capacity as much as 13% greater than that made from untreated powder, while its irreversible capacity loss (ICL) was as much as 9% less. More interestingly, the specific ICL calculated by dividing the ICL by surface area decreased as the surface area increased.
Keywords: Lithium ion rechargeable battery; Anode material; Graphite powder; Surface modification; Electrochemical property.

1. Introduction

Carbonaceous materials have been proven to be an inexhaustible source for scientific research and technological development, such as electrode of lithium ion rechargeable battery [1,2]. Surface and chemical modifications are usually the first step for the application of carbon materials [3,4]. The modifications can change surface composition and structure, active surface area (ASA) and total surface area (TSA), which all play important roles in carbon chemical reactions and applications. The concept of ASA was firstly introduced by Laine and his co-workers in 1963 [5]. The way used to characterize the ASA was to remove surface defects by heat treatment and then measuring the amount of oxygen subsequently chemisorbed. The extent of ASA was thought to be a function of such properties of the carbon as crystallite size, crystallite orientation, vacancy concentration in the basal plane, and impurity concentration, type, and location.

For battery applications, the electrochemical lithium intercalation and de-intercalation capacities are important characteristic of carbon materials, which strongly influence the energy density. While, during the first charge and discharge cycle, an irreversible capacity loss (ICL) always exists, and the ICL has been attributed to the solid electrolyte interphase (SEI) formation and other side reactions. Carbon surface structure has a great influence on the ICL of electrodes [6].

Radio frequency inductively coupled thermal plasma (RF-ICP) treatment has been proved to be a successful way to modify carbon surface for its high temperature, high energy density, high chemical reactivity properties and high heating and cooling rate (~10^6K/min) [7]. The aim of this work is to study the effect of Ar-H_2-SF_6 plasma treatment induced active surface of MCMB powder on the electrochemical properties of the anodes made from these materials [8].

2. Experimental set-up

The carbon used in this investigation was mesocarbon microbeads (MCMB), which is a kind of artificial graphite. The RF induction plasma generating and powder feeding apparatus have been shown elsewhere [9]. The plasma conditions were set as follows: Power, 40kW; plasma gas, Ar 15 L/min; sheath gas, Ar (60 L/min) and H_2 (3 L/min). The powder carrier gas was a mixture of Ar and SF_6, and its total flow rate was set as 10 L/min, in which the SF_6 flow rate was changed from 0.4 to 1.0 L/min. The plasma was generated at the reactor pressure of 27 and 53 kPa. Surface morphology of MCMB powders was observed using scanning electron

microscopy (SEM, HITACHI S-5000). Surface area was measured by N_2 adsorption using the Brunauer-Emmett-Teller (BET) method (BEL JAPAN, BELSORP18). Oxygen content measurement was performed on an oxygen/nitrogen analyzer (HORIBA, EMGA-650). Sulfur content measurement was carried out on a carbon/sulfur analyzer (LECO CS-444). Fluorine content was measured by ion chromatography. Fourier transform infrared (FTIR) experiments were carried out on a BIO-RAD FTS-65 FTIR spectrometer. Electrochemical properties were measured in non-aqueous solvents containing 1 M $LiClO_4$. Sample electrodes were prepared by following way: Poly vinylidene fluoride was used as the binder and slurry was spread on copper foil and dried at 150℃ under vacuum for one hour; a 1mol/cm^2 solution of $LiClO_4$ in a 50:50 mixture of ethylene carbonate (EC) and diethyl carbonate (DEC) was used as the electrolyte; the electrochemical cell was set up in a dry box under argon atmosphere and the charge/discharge behavior of the cell was measured galvanostatically at the current density of 0.25 mA/cm^2 between 0 and 3 V vs. Li/Li$^+$ at 25℃.

3. Results and discussion

Figure 1 shows typical surface morphologies of the original MCMB and the plasma treated MCMB powders. The original MCMB in Fig.1(a) has polyhedral shape, while Fig. 1 (b) reveals that some particles have a lot of holes after plasma treatment. Figure 2 gives the FTIR results on the original and the plasma treated powders. The peak at 1716cm^{-1} in plasma treated sample represents the C=O double bond stretching vibration in the form of C–C=O, and peaks at 1222cm^{-1}, 1364cm^{-1} and 984cm^{-1} represent the C=S bonds, which are attributed to the chemical reactions of carbon and sulfur. Figures 1 and 2 prove that the surface structure and chemical composition of MCMB have changed greatly after plasma treatment, which should be responsible for the change of the electrochemical properties

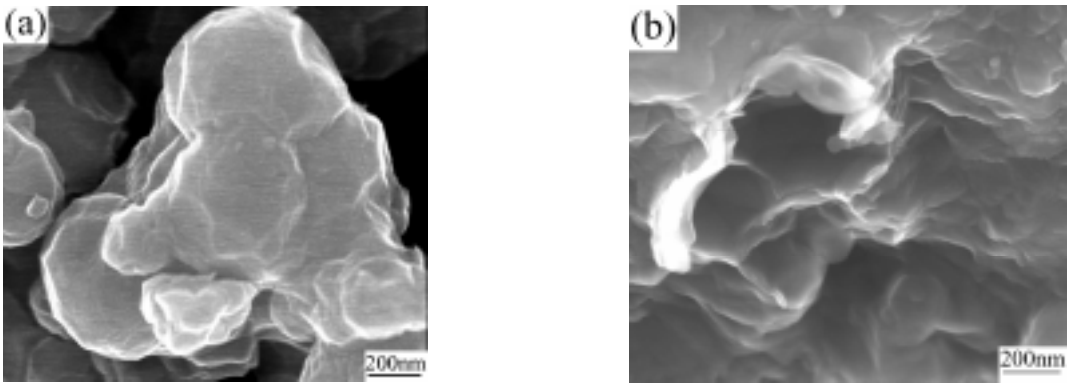

Fig. 1 Surface morphologies of original and plasma treated MCMB; (a) original MCMB. (b) plasma treated MCMB.

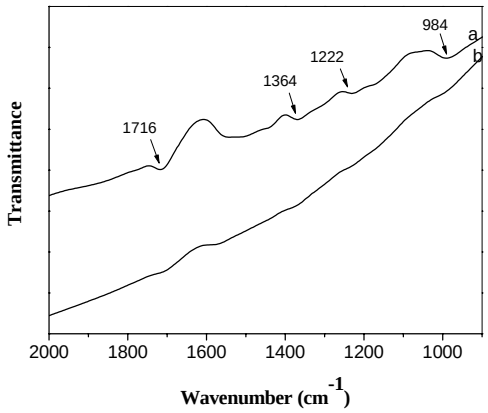

Fig. 2 FTIR results of original and plasma treated MCMB; (a) original MCMB. (b) plasma treated MCMB.

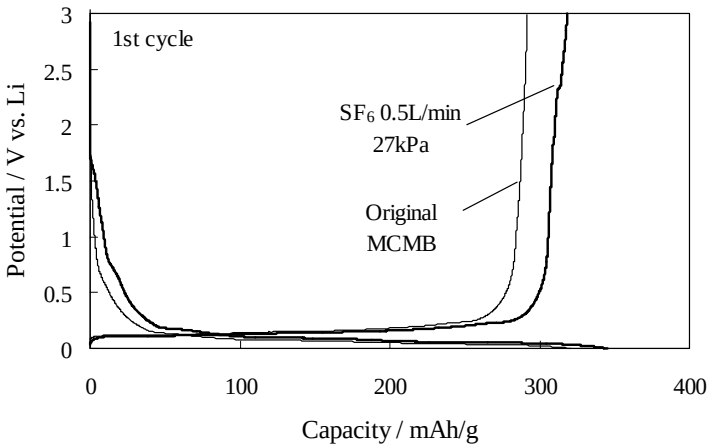

Fig. 3 First charge/discharge curve of original MCMB and plasma treated MCMB (SF_6 flow rate: 0.5L/min; reactor pressure: 27kPa).

Figure 3 shows the first charge/discharge curves of the original and the plasma treated MCMB powders (SF_6 flow rate: 0.5L/min; reactor pressure: 27kPa). It can be seen that the plasma treatment gave the great increase of discharge capacity at the first charge/discharge cycle. Figure 4 shows the relationship between the specific ICL and the BET surface area. This figure demonstrates that the specific ICL (the calculation method is dividing ICL by TSA) decreases with the increase in BET surface area, and the relationship is approximately exponential. The curve also suggests that the carbon surface is not uniformly active for irreversible capacity loss. Figure 5 shows the relationship between the specific ICL (the calculation method is dividing ICL by the content of O+S+F) and the content of O+S+F. Since the content of active site of O+S+F can be an indicator of the ASA, this figure demonstrates that that the ASA is not the only reason to be responsible for the ICL. Figure 5 also shows that within certain extent of ASA, the specific ICL decreases with the increase in ASA.

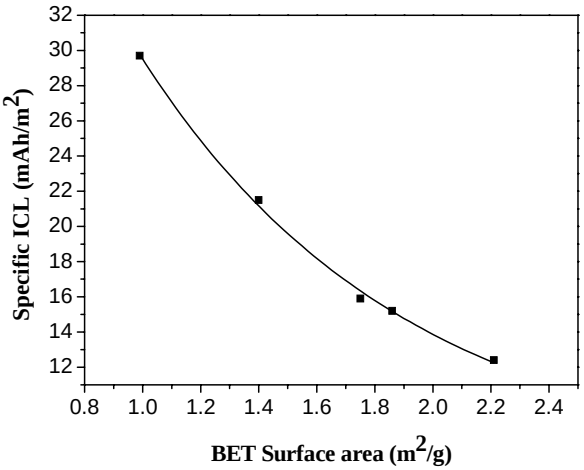

Fig. 4 Relationship between the specific irreversible capacity loss (in respect to the BET surface area) and BET surface.area

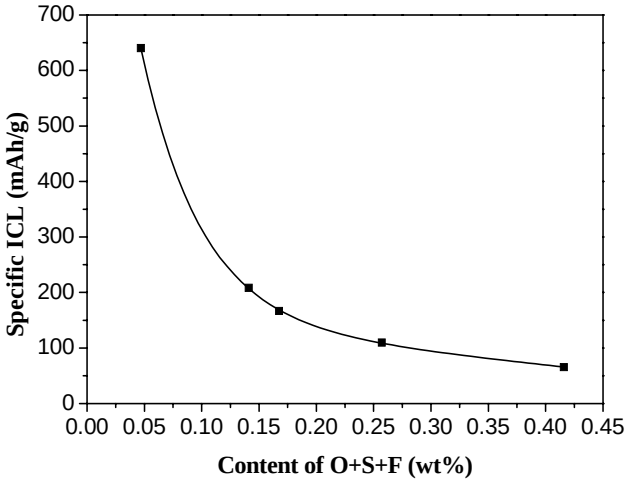

Fig. 5 Relationship between the specific irreversible capacity loss (in respect to the content of O+S+F) and the content of O+S+F.

5. Conclusion

In summary, we have demonstrated that the electrochemical properties of MCMB as an anode of lithium-ion rechargeable battery have a great relationship with the surface area and active surface area. Within certain extent, the specific irreversible capacity loss decays nonlinearly with the increase of surface area and active surface area.

Abstract :

The design of solid fuel engine nozzle requires a good knowledge of the recession behaviour of the ablative thermal barrier (heat transfer and ablation processes). The use of aluminium-enriched propergol results in the formation of alumina droplets that impinge and form a liquid film at the nozzle surface modifying the ablation processes. To validate an aerothermochemical model developed by Snecma Solid Propulsion, an experimental simulation has been developed to characterize and measure the surface recession of a carbon/phenolic composite under the impact of alumina droplets.
This paper presents the experimental setup which combines two direct current (d.c.) plasma torches in a controlled atmosphere chamber that are used both to fuse and accelerate alumina particles. The behavior of the alumina droplets before impact (velocity and temperature) and the plasma fields close to the target are examined.
The recession measurements are obtained through a feedback control of the position of the sample top. Recession rate evolution has been studied according to experimental parameters

Introduction :

The development of spatial engines is based on the regularity, reliability of the engine and the improvement of the ratio carried weight to that of the engine. That is why for many years, engines with solid propergols have been developed [1, 2]. Using composite materials appeared very rapidly to be the solution to palliate the weight of the refractory materials used at the beginning while keeping their mechanical resistance [3, 4]. However these materials are submitted to very severe stresses: temperatures over 3000K, high and low pressure (0.1 to 4 MPa), very aggressive chemical environnement (OH, CO, Cl…). Besides to increase the thrust during the take off, the solid propergol is enriched with aluminium particles. During combustion they react with oxygen increasing the combustion temperature and thus the thrust by 6 to 8%. However this combustion produces alumina particles resulting in a multi phase flow, adding to the stresses of the composite wall impact and chemical erosion. For example Fabignon [5] shows that these alumina particles result in the formation of an alumina liquid film on the nozzle wall. However, models of the nozzle wall surface recession such as that developed by SNECMA Solid Propulsion, do not predict very well the phenomena, even after backing the model to experiments. The wall recession is underestimated. Thus it is mandatory to understand the history of the alumina film from its right beginning (interaction drop-solid) to its elimination (reaction film-wall, liquid feeding and ejection) through its evolution (study of the interfaces liquid-wall and drop-liquid). This work presents the experiment developed to simulate the hot multi-phase flow with two spray d.c. plasma torches in a controlled atmosphere chamber and the results of the carbon/phenolic composite ablation for different conditions.

Experiment:

- **Description of the experimental set up developed at SPCTS Laboratory (Limoges, France):**

The aim of this set-up is to reproduce the impacts of liquid alumina particles onto a composite flat substrate as well as the formation of a liquid alumina film keeping the substrate temperature over 2300K. Unfortunately, the real conditions (chemical composition and pressure) cannot be reproduced. To achieve a rather flat particle flux, two d.c plasma torches have been chosen to limit the gas velocity. These torches have an anode-nozzles with internal diameter of 8 mm, and an angle between both, which can be varied between 40 and 120 (see fig 1). For each torch the power dissipated in the gas can reach 20kW and the mean gas temperature close to the chamber wall can be over 900K. Thus the chamber walls are water cooled

under a pressure of 1.2 MPa. The chamber comprises two parts: a cylinder where the two torches are positioned with windows allowing optical diagnostics and a cone to evacuate the hot gases and particles. The pressure in the chamber is controlled by a primary vacuum pump and a monitored vane. The argon atmosphere (to avoid a too fast substrate oxidation) is kept at 50 kPa.

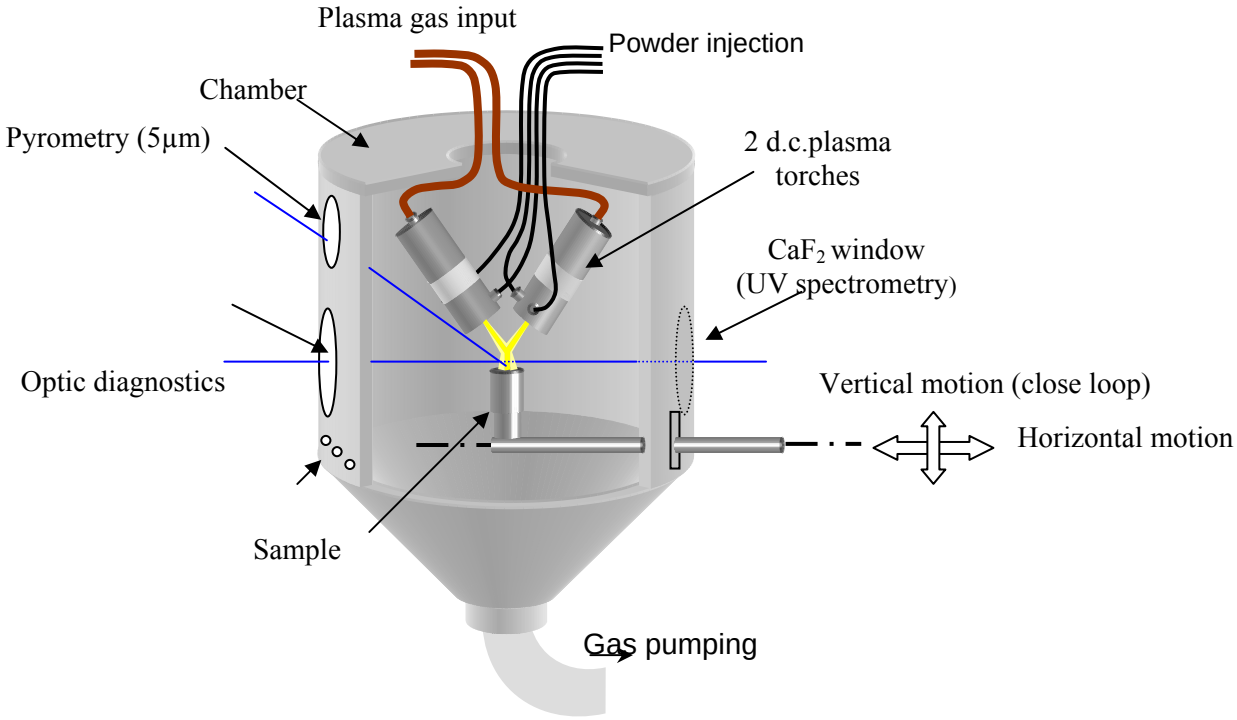

Fig1: Scheme of the experimental set-up

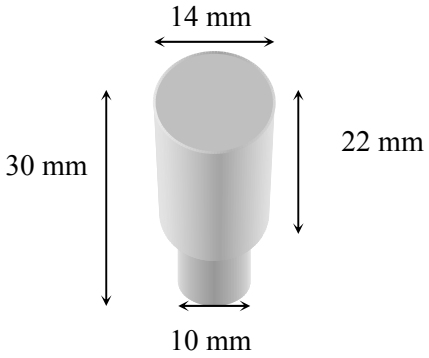

Fig 2: Geometrical aspect and dimensions of the carbon/phenolic

The substrate made of carbon/phenolic has the size shown in fig2. The useful height (upper part) is 22mm. In order to achieve a regular heating and wear of the substrate it rotates at 200 r.p.m. The substrate holder is water cooled but the rotating axis which can reach temperatures as high as 3000K is made of tungsten. The substrate holder can be moved up and down at a variable velocity controlled by the position of the substrate top measured with the help of a laser (λ=632.8nm) and a photodiode. This system allows keeping the substrate position constant and thus following its erosion by the relative displacement of the substrate holder.

Particles are injected orthogonally to both torches axis, the injector 1.8 mm in internal diameter being disposed internally in the plane of the two torch axis. Thus with the rotation of the substrate, the powder distribution is almost flat onto a disk 12mm in diameter centred on the substrate axis. Powder feed rates can be varied between 1 and 3 kg for each torch for alumina particles in the size range 10 – 40 µm.

- **Diagnostic techniques**

The species present in the plasma jets have been determined by emission spectroscopy. The plasma jet temperature is measured by using the OH band at 306 nm according to a method developed by De Izzara [6]. Of course the spectrum intensity is much lower in argon atmosphere because of the low oxygen pressure. An imaging technique with a CCD camera has also been used allowing comparing very rapidly different torch working conditions. Of course the camera was calibrated with spectroscopic measurements. As the temperature below 2500K is difficult to measure with OH bands in the jet fringes the position where the

extremity of a rod of alumina (1mm in diameter) melts, allows determining the position were temperatures reach 2326K.

The heat flux received by the composite substrate has been measured with the help of a water cooled calorimeter: typical values are between 1 and 10 MW/m2.

The velocity of the in-flight alumina particles was measured with the Spray Watch.

The surface temperatures of the substrate and alumina film were measured with an IR pyrometer (4.87 – 5.3 µm), wavelength range where the plasma emission is very low [7]. Using a grey filter and calibrating the pyrometer has allowed extending the temperature range up to 3500K. The windows are made of CaF_2, and corrections are made to account of its absorption. The alumina emissivity is that proposed by Rosenbaun et al [8]. Thermocouples (W-W.Rh) disposed at different distances along the substrate axis allow measuring the temperature gradient within it.

Results and discussion

All results will be presented for the working conditions summarized in fig 3 caption.

- **Characterization of the plasma jet**

Fig 3 shows a typical temperature distribution of the two plasma jets. The informations given by the different techniques are complementary.

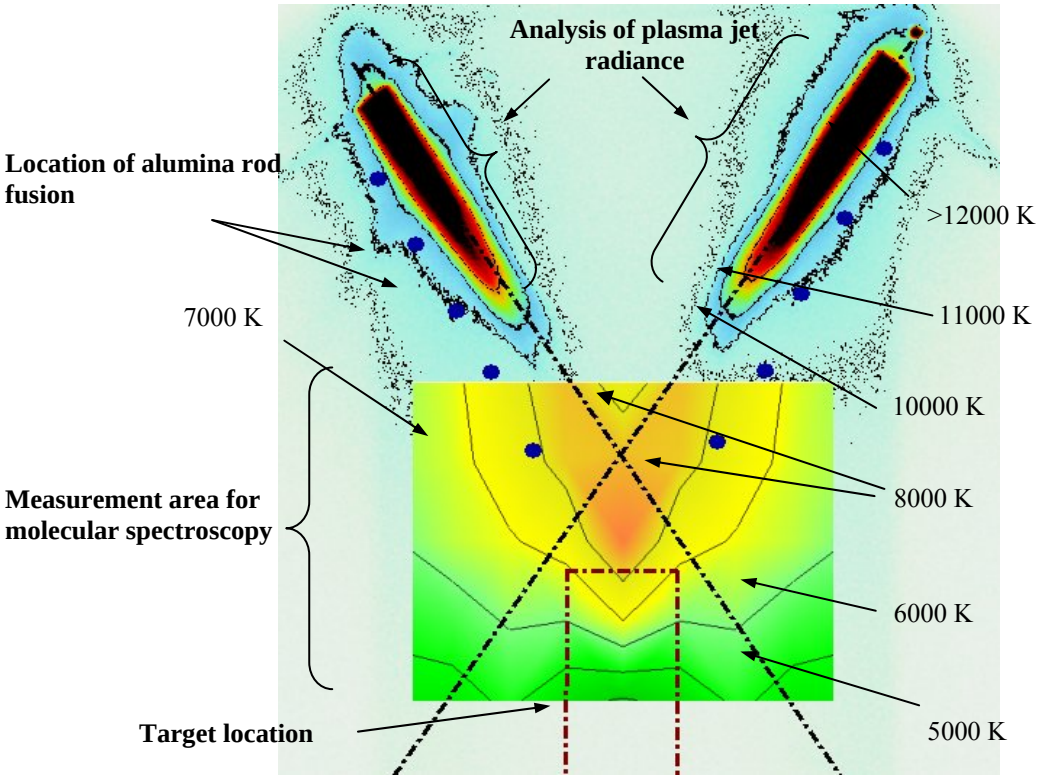

Fig 3: Temperatures distributions obtained with different diagnostics working conditions: anode-nozzle i.d. 8mm, I=600A, Ar-H2 plasma (45-15 slm) flowing in air at $p=10^5$ Pa, angle of both torches=60°

The importance of the hydrogen percentage on the heat flux imposed to the substrate for the 60° torch angle is shown in fig 4.

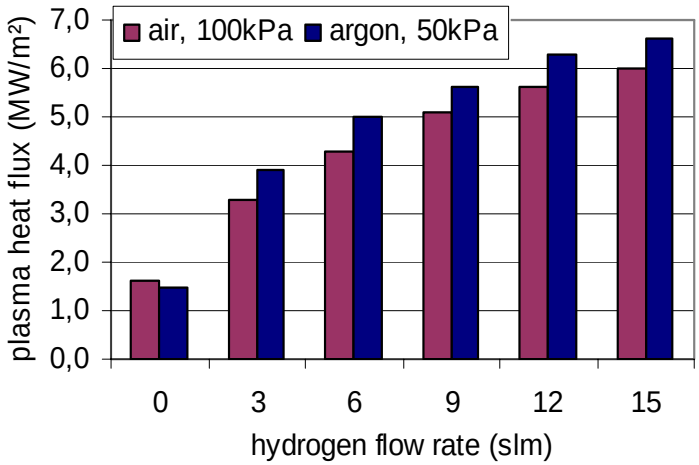

Fig4: Heat flux received by the calorimeter (working conditions of fig 3)

- **Study of the sample erosion**

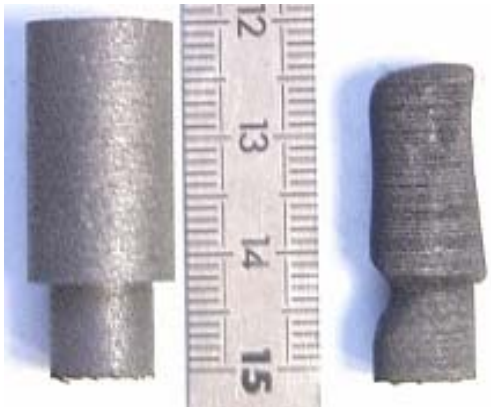

Fig 5 : Initial sample (left) submitted to the plasma as shown in fig 6.

Fig 5 shows the evolution of the aspect of the initial sample (left) submitted to the plasma without powder in argon atmosphere during 90 sec.

Almost no surface recession can be observed (less than 1mm). It seems that the sample has been a little expanded in spite of a mass loss of 25%. In air atmosphere, the mass loss is over 42% with a surface recession of 4mm in height and 3 mm in diameter. As soon as the powder is injected the wear of the sample is drastically increased. First when increasing the powder flow rate, the relative velocity of recession increases linearly with the powder mass flow rate, and then reaches a plateau for a powder flow rate of about 3kg/h

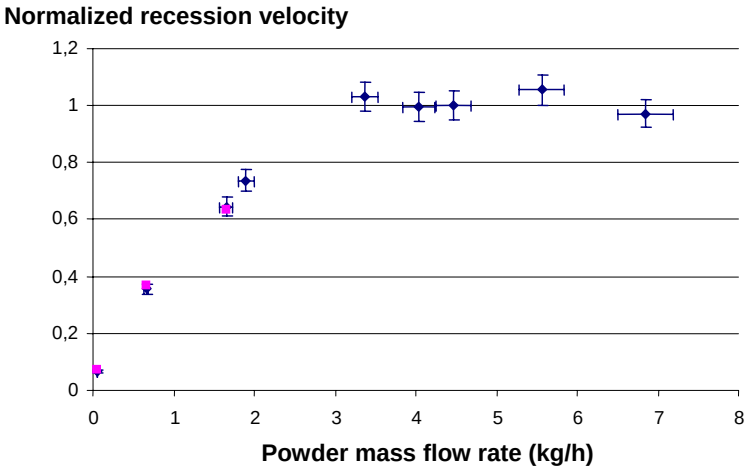

Fig 6: Normalized recession velocity evolution with alumina mass flow rate (in each torch).

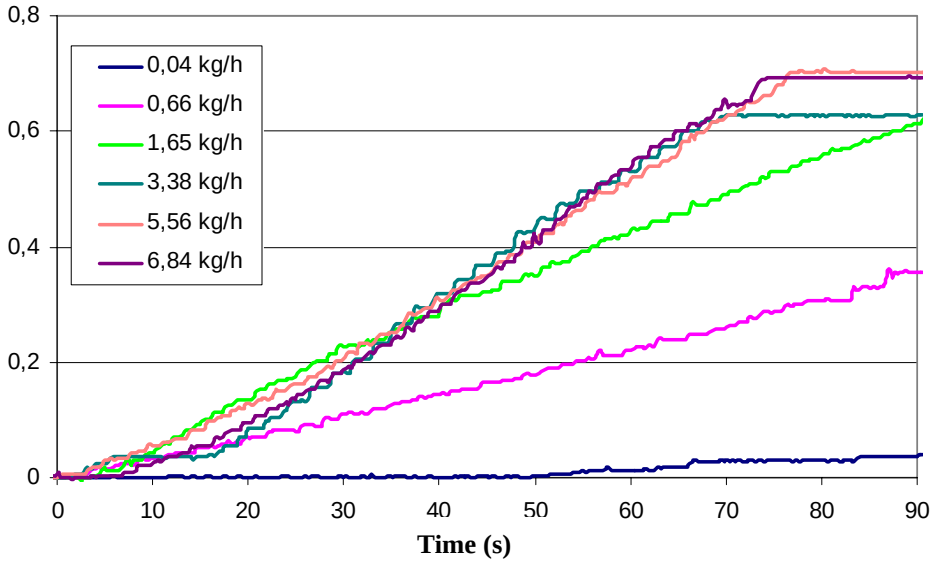
This result is confirmed by the results presented in fig 7, representing the time-evolution of the normalized displacement of the sample for different powder flow rates.

Normalized recession velocity



Discussion: Without the powder the wear of the sample is mainly due to the reaction of the hot carbon with oxygen to form CO. Of course in air atmosphere this wear is drastic. However it is relatively limited in argon controlled atmosphere due to the relatively low pressures of oxygen. When looking at the surfaces with SEM it can be observed that the fibres are no more imbedded in the phenolic resin and they exhibit a sharp-pointed tip. This phenomenon is probably due to the evaporation of the fibres by the very important heat flux (see fig 4). With alumina particle a typical observation is shown in fig 8.

	Without powder	Powder flow rate : 0,04 kg/h
	Powder flow rate : 0,66 kg/h	Powder flow rate : 1,65 kg/h
	Powder flow rate : 3,38 kg/h	Powder flow rate : 5,56 kg/h

Fig 8: Surface of the composite material after the alumina particle impacts. Magnification 800

The aspect is similar to that observed in air for samples submitted to oxyacetylenic flame or a laser. Fibres exhibit well marked brushes already observed under the impact of solid particles [9]. It is also possible observing holes in certain areas which means that chemical reactions between alumina and fibres

could have occurred. Moreover, in the chamber spherical particles of alumina in which pieces of fibres are imbedded can be collected. Alumina buttons in a graphite crucible were submitted to the plasma jet. When plasma heating a closed graphite crucible containing the composite and an alumina button, the composite fibres look the same as those observed after alumina impact and fibres seem to have reacted with liquid alumina. Works are in progress to reproduce these experiments in a furnace where temperatures of 2500K can be achieved.

Conclusion

An experimental set-up with two d.c. spray torches in a controlled atmosphere chamber has been realized to follow the wear of carbon/phenolic composites. The sample movement is continuously controlled to keep the distance plasma-sample constant during the sample wear. First the sample has been submitted to the plasma jet alone and then to molten alumina particles which flow rate was varied between 0.2 and 6 kg/h. The erosion rate increases linearly with the powder mass flow rate, but over a critical value of the later, the erosion rate reaches a plateau. The erosion phenomena are first a pyrolysis of the phenolic resin, followed by the weakening of the fibre resistance by chemical reaction liquid alumina – carbon fibre.

1 Abstract

Organic materials consisting of mixed amorphous and crystalline phases were obtained by using a sublimable di-para-xylylene crystalline monomer .The process combines recondensation with plasma polymerization techniques in the same reactor. The materials were submitted to oxygen plasma etching experiments. It is shown that the etching process of the amorphous plasma polymerized film is significantly more effective than the etching of the crystalline phases embedded in the material.

2 Introduction

The aim of the present work is to investigate the oxygen plasma interaction mechanisms with organic materials surfaces in amorphous or crystalline phases. There are many situations where organic materials, polymers are in contact with oxygen containing plasmas. Such as, in plasma sterilization, the microbes and bacteria have to be removed. Infection free surfaces are created. Organic contaminants have to be removed from metallic or polymeric surfaces before further process like painting, soldering or gluing. To avoid wet cleaning which lead up products detrimental for the environment, considerable efforts have been made to promote plasma cleaning [1-3]. In other applications, like polymer surface treatment, a surface roughening, surface structuring (or nanostructuring) can be necessary, accompanied by modification of surface topography and change of its physical and chemical properties.

In many of the above mentioned situations, the surface cleaning or modification are apparently due to the plasma selective attack of the crystalline and amorphous phases of the material. Consequently, it would be of interest to examine the phenomena associated to the plasma etching of amorphous and crystalline phases of materials. Aiming to that, materials consisting of organic microcrystals embedded in amorphous matrix have been specially prepared, starting from the crystalline dimer di-para-xylylene (DPX) and using condensation and plasma polymerization, and where submitted to oxygen plasma. The materials were characterised by using XRD, AFM, SEM and profilometer measurements.

3 Experimental

The experimental set-up used for film deposition presented in figure 1 was also described previously in detail [4]. A tubular glass reactor of 8 cm external diameter, 50 cm long was used, provided with flanges at both ends, appropriate for substrate and precursor cell holding and with ports for vacuum measurement and gas admission. The plasma was generated in argon atmosphere by applying a radiofrequency (13.56 MHz) voltage between two external annular electrodes placed on the glass tub. The DPX vapors were produced by heating a sublimation cell (glass ampoule). The vapours are transported toward a water cooled substrate

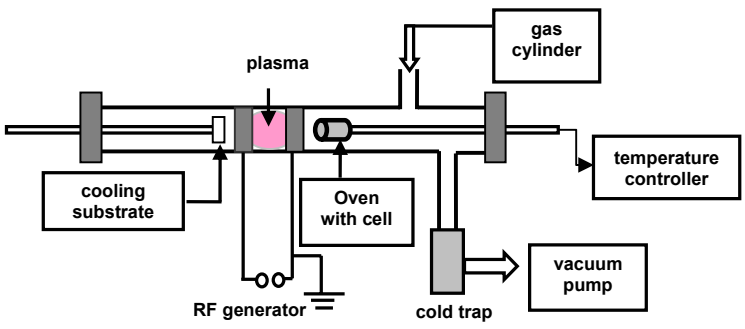

Figure 1. Experimental set-up – schematic view

by a gas flow (argon) at low pressure (10^{-1} mbar). Along their way from the cell to substrate the vapours pass across the RF discharge zone where plasma is present when the RF voltage is applied to the electrodes.

The heating of the sublimation cell was performed by a home made low caloric capacity electrical oven. The sublimation temperature was measured with a thermocouple placed in the wall of the sublimation cell and maintained at values appropriate for the process via a temperature controller, with errors in the range of 1-2 Celsius degrees.

Plasma etching was performed in a bell jar reactor represented in figure 2. This reactor was made up with a Pyrex glass cylinder closed by two stainless steel plates. The cylinder was 32 cm in diameter and 31 cm high. A Trivac D 25B was used as a primary pump. Gas was introduced by the upside of the reactor, controlled by a MKS mass flow controller. A MKS Baratron capacitance manometer was used to check the pressure.

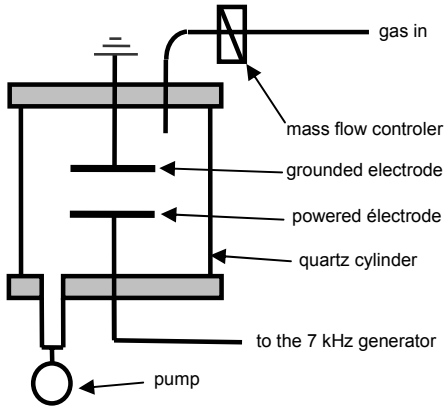

Figure 2. Low frequency plasma reactor used for etching

The two stainless steel parallel plates electrodes, 10 cm in diameter, were powered by a low frequency amplifier at 7 KHz. The sample was placed on the powered electrode. Plasma power was calculated from the measurements of the discharge current and voltage across the electrodes. The reactor was first pumped down to 0.1 Pa , and then pure molecular oxygen was introduced. The flow rate has been controlled to achieve a pressure of 53 Pa (400 mTorr). The injected power was about 0.35W during two run of 2 minutes each.

The process was controlled by OES. Atomic oxygen emission at 844 nm was recorded. The argon (5%) was introduced to attempt actinometric measurements. Unfortunately due to a very low electronic density of the etching oxygen plasma, the density of atomic oxygen was very low and the main path to produce excited atomic oxygen was found to be a dissociation /excitation process of molecular oxygen. These phenomena make unreliable the actinometric measurements, and further studies are necessary in order to describe the processes.

The monomer decomposition was monitored by OES measurements, the carbon containing radicals (CO, CH) appearing in the spectra during the plasma process. As substrate silicon, quartz, glass may be used. The deposited films were studied by X-Ray Diffraction (XRD), Atomic Force Microscopy (AFM), Scanning Electron Microscopy (SEM), revealing the amorphous/crystalline nature of the material. The modification of the amorphous/crystalline mixed material due to oxygen plasma etching was done by SEM measurements.

4 Results and discussion

4.1 Deposition of the mixed phase organic material

The method for precursor injection used in this work was the DPX sublimation. In the usual plasma polymerization methods, the sustaining species necessary for film growth are obtained by feeding plasma with vapors of organic or metalo-organic volatile substances, in liquid state at process temperature. This work differs strongly in comparison to the usual methods, the vapors being obtained by sublimation of a solid state precursor. As it is known [5], the properties of the material are dependent on the W/F (W power, F mass flow) composite parameter known as Yasuda parameter. It was previously shown for parylene-like thin film deposition by DPX plasma polymerization that the quality of material is strongly dependent of this parameter as well. Consequently, the control of power and mass flow has a great importance for the process.

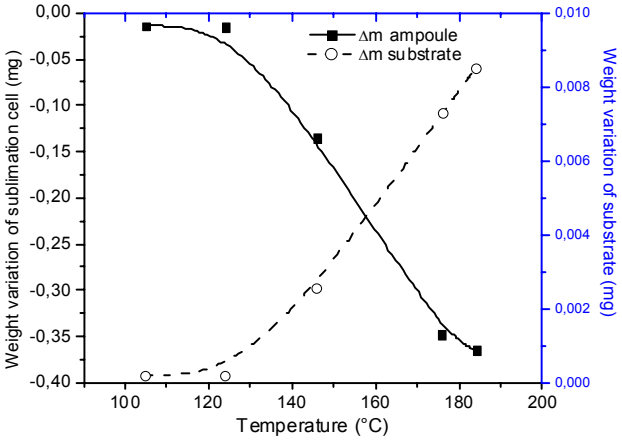

Figure 3. Temperature dependence of DPX amount sublimated from the cell, and recondensed on the substrate.

Whereas the power control is quite easy with normal radiofrequency generators provided with auto matching, the control of mass flow can be very difficult due to the particularities of sublimation process. Indeed, around the sublimation temperature the sublimation rate is strongly dependent on the temperature.

An experiment was performed in which the mass loss of the sublimation cell was measured for different sublimation temperature. The dependence of the mass loss on temperature is shown in figure 3. It is seen that the mass loss changes rapidly with the temperature, in such a manner that a small variation in temperature produces a large variation of the mass flow. One concludes that a precise and rapid temperature control is necessary in order to insure a good reproducibility. This was realized with a small resistive tubular oven having a small caloric capacity and inserted directly into the plasma reactor. The sublimation cell, consisting of a glass ampoule was placed inside this oven.

A condensation experiment was performed simultaneously with the sublimation experiment. The mass of a cooled silicon substrate was measured before and after the sublimation step, for various sublimation temperatures. The results are presented in the Figure 3 as well.

In figure 4, the XRD pattern of a sample obtained from a condensation experiment is shown. It proves that the mass increase is due to the deposition of material having a crystalline structure which was identified as being that of DPX.

The crystallites growth during the condensation process was studied by AFM. The images presented in figure 5 are recorded at 10x10 μm^2. For short recondensation times, 30 seconds and 1 minute respectively, we can see small particles on the substrate (figure 5 a, b). When increasing the recondensation time, the dimension of the particles starts to increase (figure 5 c, d). The crystallites size varies from about 300 nm up to a few microns, depending on the recondensation time.

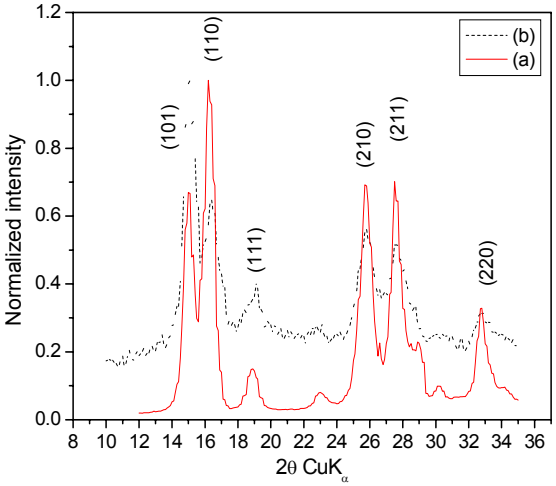

Figure 4. The XRD pattern of the material collected at substrate a) without RF discharge b) with RF discharge (20 W)

In the presence of the RF discharge the vapours created by sublimation are fragmented by collisions with plasma particles and transported to the substrate. A material containing both crystalline and amorphous phases can be realized at low power values, when only partial decomposition of DPX is realized. An example of XRD pattern of a sample obtained for such a mixed phase material is presented in figure 5b. For power values that are high enough to produce the complete decomposition of DPX vapours amorphous films are formed [1].

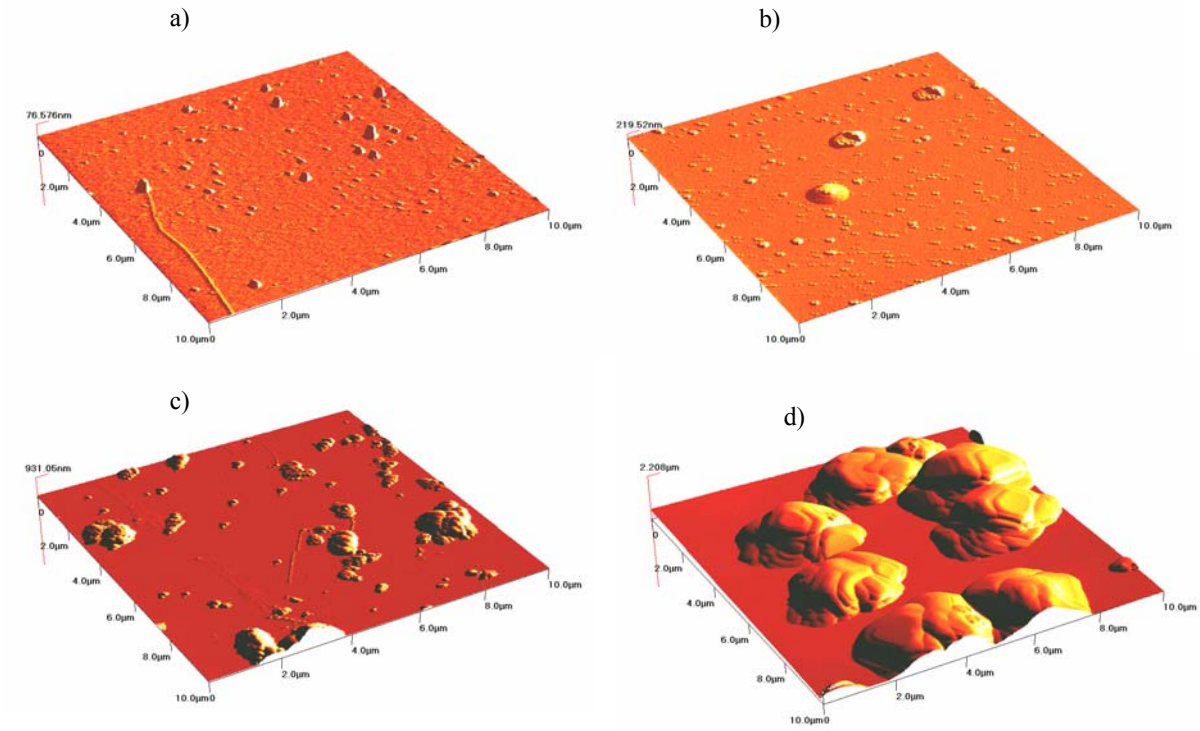

Figure 5. AFM images of the material deposited at different recondensation times:
a) 30 seconds; b) 1 minute; c) 5 minutes; d) 15 minutes

4.2 Etching experiments

The film was deposited at 40 W, for 10 min, at 3.8 mbar argon pressure. Figure 6(a) and 6(b) are pictures of the deposit before etching. We can see two strips on the left side and on the bottom of the picture 6(a),. They have been made with a blade on the samples by removing out the deposited material in order to increase the visibility of the film on the substrate and to create a position reference for the SEM observation after etching. The fine lines along the strips can be associated to the micro-trenches made on the sample due to the softness of the removed material.

White spots are images of the microcrystals of di-para-xylylene, deposited together with the parylene-like amorphous phase (in grey) during the course of the fabrication of the layer. These spots are more visible on the picture 6(b), done with a higher magnification (x8000).

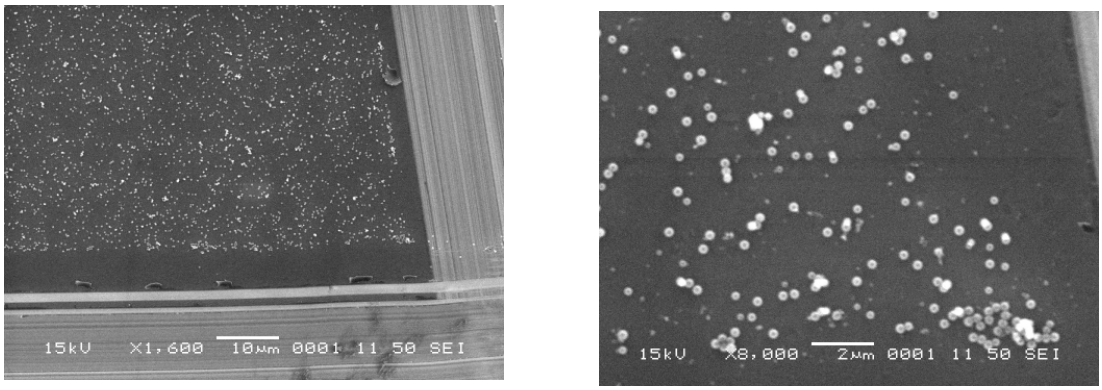

Figure 6. SEM images of a composite thin film before etching at a x1600(a) and a x8000(b) magnification

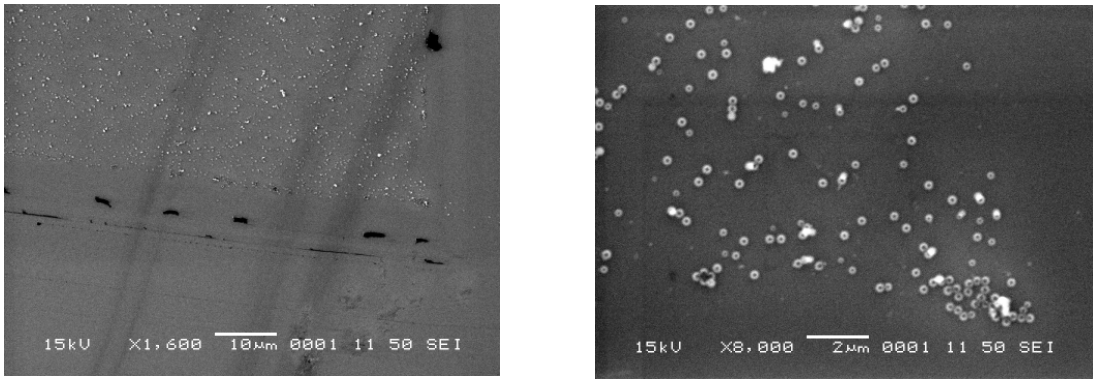

Figure 7. SEM images after 2 min of O_2 plasma etching at a x1600(a) and a x8000(b) magnification

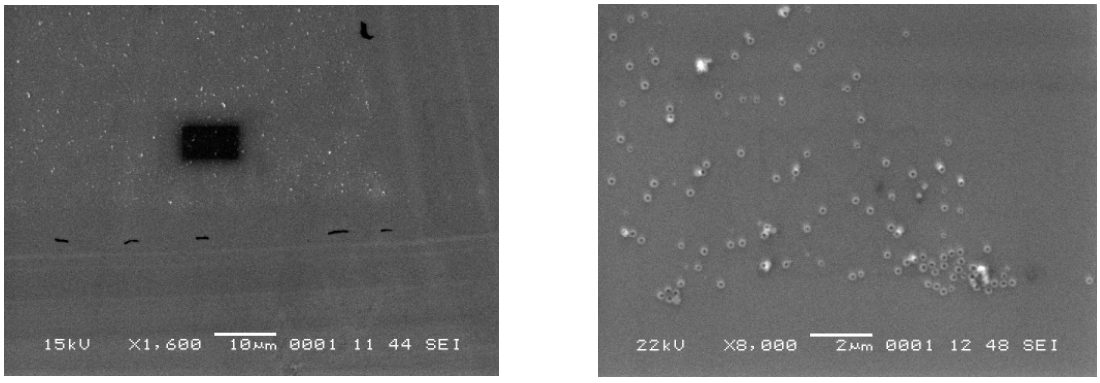

Figure 8. SEM images after 4 min of O_2 plasma etching at a x1600(a) and a x8000(b) magnification

Figure 7 (a) and (b) represent the same area than figure 6(a) and (b). Those pictures have been taken after a two minutes O_2 plasma treatment in the reactor represented in figure 2. The amorphous smooth phase is no longer visible whereas the white crystallites are still visible.

Pictures on figure 8(a) and (b) show the same area after a second treatment of two minutes of O_2 plasma. The smaller crystals have disappeared but the majority of them are still here.

We can consider spherical the shape of the microcrystals. Low frequency O_2 plasma etching is mainly anisotropic. If less than half of the volume of each microcrystal has been etched, it cannot be revealed with a top view of the surface. That's why we can't rigourously conclude that microcrystal etching is more efficient than amorphous phase etching. The amorphous phase thickness knowledge and the microcrystals diameter knowledge would permit us to conclude about O_2 plasma etching selectivity between amorphous and crystalline phase. Due to the amorphous phase softness, it was nearly impossible to measure the layer thickness with a profilometer. However, it appears clearly from figures 7 and 8 that only the crystalline part of the sample remains visible after 2 to 4 minutes under O_2 plasma. If we consider that microcrystals and amorphous layer thicknesses are close,, we can conclude that the amorphous phase etching process is significantly more effective than the crystalline phases etching.

Conclusion

A technique of mixed phase (amorphous and crystalline) organic materials growth was described. The materials consist of microcystals embedded in an amorphous matrix. The technique is based on the use of sublimable crystalline monomers. The vapours obtained by sublimation are used as precursors in the growth process. The material is obtained by combining in the same experimental set-up the condensation and plasma polymerization.

Materials deposited by this technique from di-para-xylylene monomer were submitted to oxygen plasma etching experiments. It is shown that amorphous parylene-like layer disappear from the surface faster than the crystalline phases embedded in the material. On the assumption that amorphous phase thickness and microcrystals diameter are close, we can conclude that the etching process of amorphous parylene-like film is significantly more effective than the etching of the crystalline phases embedded in the material.

Introduction

It is well known that plasma polymer films are not perfectly stable after deposition. This change is due to chemical reactions of radicals with themselves and with the surrounding molecules.
In most cases these undesirable evolutions is considered as a drawback to use these films in microelectronics devices. However it was proposed to gain benefits from gas absorption on plasma films by developping gas sensors. (1–3). On the other hand during the deposition process adsorption of species at the surface is one of the key phenomena controlling the growing process. It is then important to analyse the adsorption of gases especially the monomer molecule introduced in the plasma reactor. In this paper adsorption of various gases : organosilicon monomer, H_2O, alcool, ketones at the surface of plasma films was observed and analysed as a function of the nature of the gas and the plasma parameters used for the deposition . Hexamethyldisiloxane (HMDSO) was used as a monomer and a quartz crystal microbalance (QCM) measures the thickness and the deposition rates and the mass adsorbed on the film after the introduction of different gases in the reactor.

Experiments:

A bell jar reactor with two parallel plate electrodes was used for deposition of plasma films from HMDSO. A silicon substrate is located on the lower electrode to measure the thickness of the film. The plasma is powered by a low frequency power supply (7 kHz) and the power was actually calculated from the measurements of the discharge current voltage across the electrodes and phase between current and voltage signals.. The reactor is first pumped down to 10^{-3} mbars then the monomer is introduced and the working pressure adjusted with a needle valve.
The quartz crystal was mounted at the edge of the plasma. Of course the deposition rate on the quartz was much smaller than on the substrate.
The resonance frequency of the quartz before any deposition was 6 MHz. The sensitivity of the oscillation frequency shift was 1 Hz and is directly related to the mass deposited on the quartz crystal. The well known Sauerbrey equation (4)

$$T_f = (N_q d_q / d_f f_q^2)\,(f_q - f_c) \qquad (1)$$

where T_f is the film thickness (deduced from the mass, density and deposition area)

d_q and d_f are the quartz and film densities

N_q a constant depending on the quartz

f_q and f_c are the resonant frequencies for the uncoated and coated quartz

gives a relationship between the frequency shift and the deposited mass. Note that in our case, the frequency shift was always negligible compared to the oscillation frequency (Hundred Hz against MHz), the deposited mass is then proportional to the frequency shift.
In our experiment we first start by depositing a film. The deposited thickness was recorded by the measurement of the frequency shift assuming density of 2 g/cm^3. Then the reactor was pumped down and various gas introduced. Then the frequency shift due to the absorption of molecules from the gas phase was recorded as a function of time.

Results and discussion:

Figure 1 shows the frequency shift during several successive depositions. It can be pointed out that the deposition rate is different during the two first runs then reaches a stable value. We believe this result show the role of the nature of the substrate. The surface was initially made of a gold layer deposited on the quartz; this surface was step by step covered by the plasma film As soon as the initial quartz surface was completely coated, the growth rate remains constant.

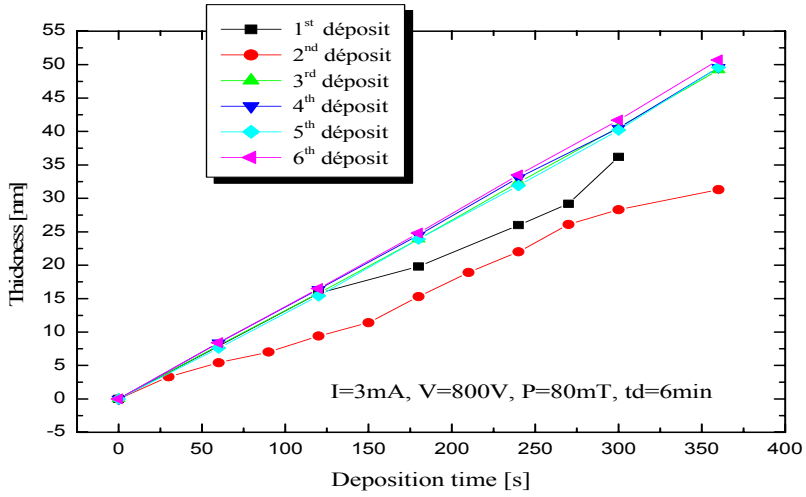

Figure 1 : Deposition kinetics for successive layers on the same quartz substrate

Monomer and water adsorption on the deposited film:

During the deposition process monomer molecules as well as its fragments adsorb on the surface of the growing film and contribute to its formation . It is then interesting to get a quantitative evaluation of this effect at least for monomer molecules.

Figure 2 shows the frequency shift due to the adsorption of HMDSO molecules on plasma deposited film from HMDSO. In this experiment, the pumping units were stopped after deposition. The valve introducing HMDSO was wide open ; then we assumed that adsorption occurs at the vapour pressure of HMDSO at 20°C which is about 40mBars. For comparison, adsorption on uncoated quartz was shown on the same figure. Obviously the plasma deposited layer enhanced the mass adsorbed on the surface. Also, the adsorption kinetic is slow since a steady state wasn't reached after 60mn.

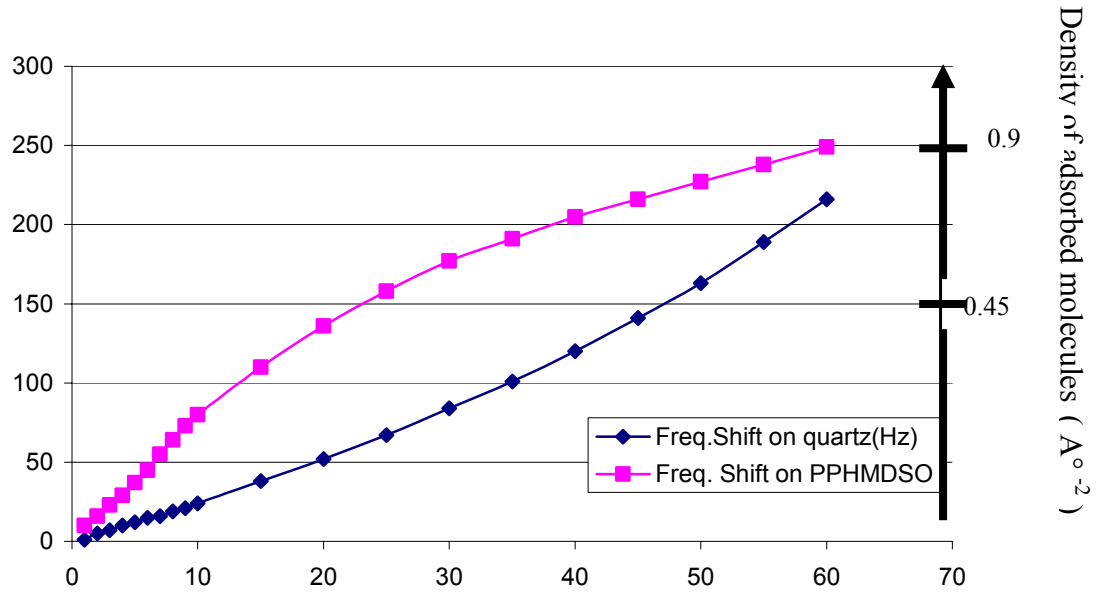

Figure 2: Adsorption of HMDSO molecules on Plasma polymerized HMDSO films and on the uncoated quartz.

Firstly, we checked that the frequency shift was not induced by some change in the working pressure in the reactor; in fact no change was recorded if argon is used to fill the reactor from the base pressure to 100 mBars. Hence the frequency shifts observed later are due to the absorption of molecules on the plasma film.
A larger adsorption might be due to an increase of the roughness (under certain conditions, plasma films deposited from HMDSO exhibited a "cauliflower" shape which increases the real surface interacting with the gas phase) [5]. Roughness measurements gave the same values for coated and uncoated quartz. Then only the nature of the surface can explain the differences in the amount of HMDSO adsorbed.
It is well known that QCM is only sensitive to the mass. It is useful to calculate the number of adsorbed molecules per unit area. This calculation is made using Eq (1), the mass of HMDSO (162 uma)and the Avogadro number. The practical equation becomes :

$$n\ (cm^{-2}) = 4.56 \cdot 10^{13}\ \Delta f\ (Hz)$$

where n is the number of adsorbed molecules per square centimetre.
The result of this calculation is given on the vertical axis on the right side of the figure.
The experimental values show that some of the adsorbed molecules diffuse into the film or we might have several adsorbed layers. For example, a frequency shift of 300 Hz would mean 1.4 molecules per $A°^2$ which is obviously impossible if a single monolayer without diffusion into the film is considered.
Another interesting molecule is water. Same procedure than before was followed: after deposition, pumping system was stopped then water vapour was introduced and it is assumed that the adsorption process took place under the water vapour pressure at 20°C which is
Figure 3 shows the adsorption kinetic of water molecules on coated and uncoated quartz. Also the mass was translated in terms of molecules per unit area (vertical axis on the right side).
A larger adsorption was also observed on the plasma film compared to the uncoated quartz.

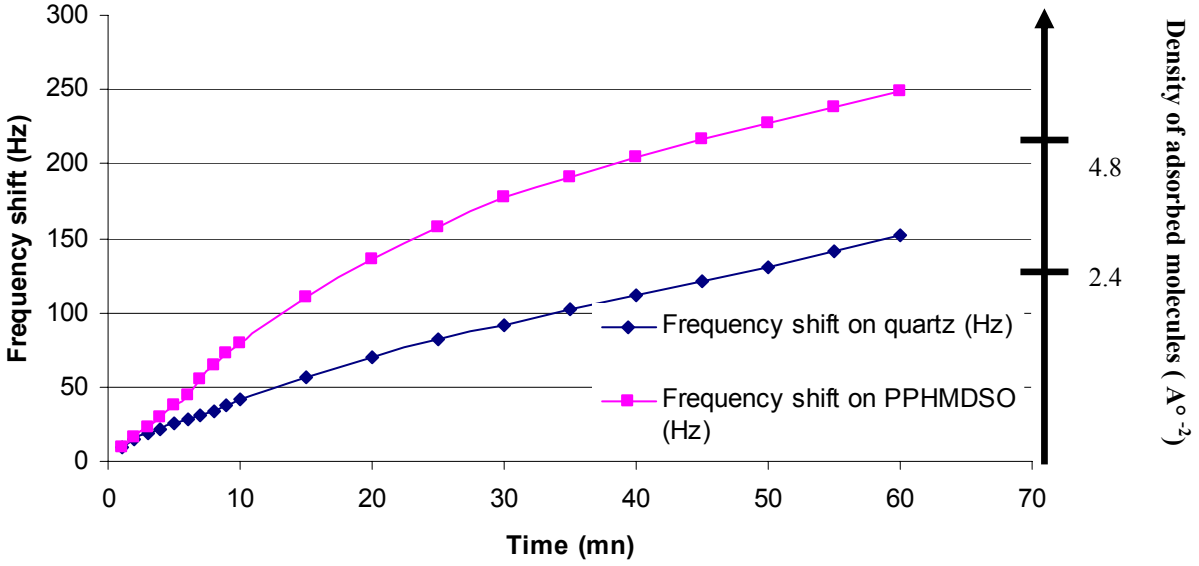

Figure 3 : Frequency shift (left axis) and density of water molecules adsorbed (right axis) on a quartz surface and on a plasma deposited film from HMDSO

Calculations of the number of water molecules adsorbed per unit area on the surface gave the practical equation:

$$n\ (cm^{-2}) = 24.18\ \ 10^{13}\ \Delta f\ (Hz)$$

A frequency shift of 200 Hz gives 48.36 10^{15} molecules /cm^2 which corresponds to 4.8 molecules / $A°^2$.
The size of o water molecule is about 9 $A°^2$. Then water molecules are probably diffusing inside the film or form clusters at the surface or both.

Same experiments using different thicknesses have been made. The idea is that if there is no diffusion inside, adsorption would be independent of the thickness since the surface will be supposed the same for each sample.
Results are shown on figure 4. Obviously there is an effect of the thickness. Surprisingly, it seems that the adsorption is reduced whereas the thickness of the film increases. We expected an opposite variation. The reason could be due to our experimental procedure. In fact a plasma film is deposited then, absorption measurements are carried out. In a second step a second layer was deposited on the first one and new absorption measurements are made and the thickness in supposed to be the addition of the two layers. So, some errors could be introduced due to the fact that several successive absorption measurements are made on the same quartz and there is no evidence that all the adsorbed molecules during the first step desorbed before the second step. Nevertheless, if the surface was the only parameter controlling absorption no differences would be expected because the plasma parameters for deposition were kept constant. Then, surface and subsurface properties are involved in the adsorption process.

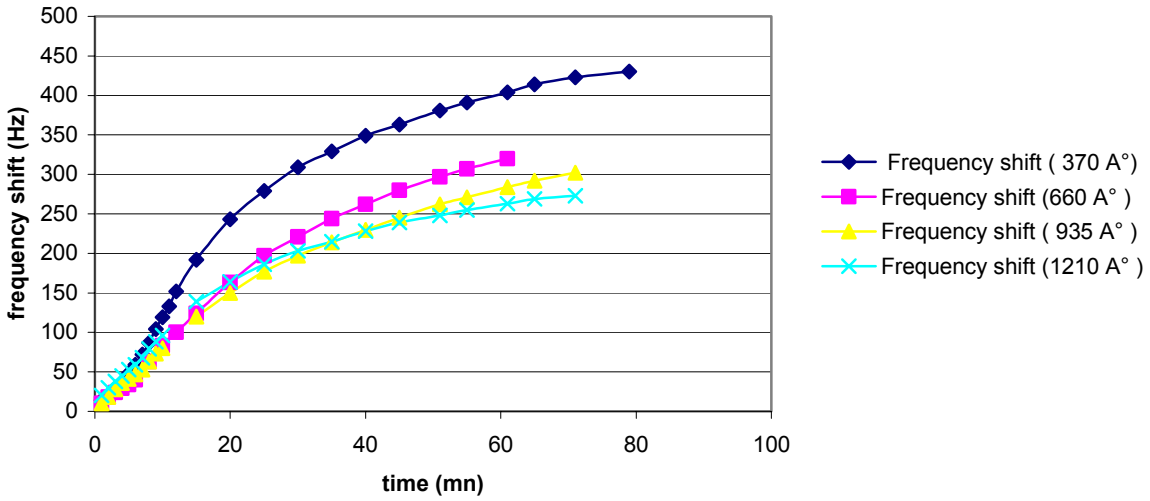

Figure 4: Frequency shift due to adsorbed water on plasma deposited HMDSO films of different thicknesses.

Adsorption of HMDSO, water , ethanol and propanol:
A comparison of HMDSO, water and two alcohols was made to control the role of the polarity and size of the adsorbed molecules. A plasma film 100nm thick was deposited from HMDSO. Then the tested molecules were introduced. For each experiment the pressure of the gas phase is the vapour pressure at 20°C.
Figure 5 shows the results in terms of frequency shift . These results could lead to a wrong estimation of the adsorption process. In fact they have to be translated in terms of number of adsorbed molecules per unit area, as shown on figure 6. A° square has been choosen for a better representation of the phenomena at a molecular scale.

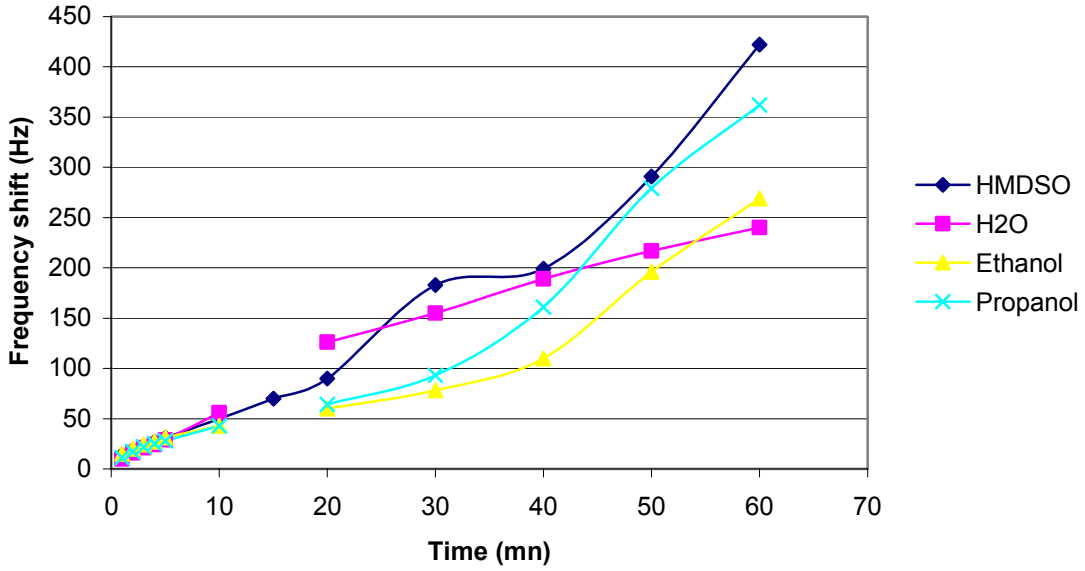

Figure 5 : Frequency shift due to the mass adsorbed on the plasma film for four different molecules.

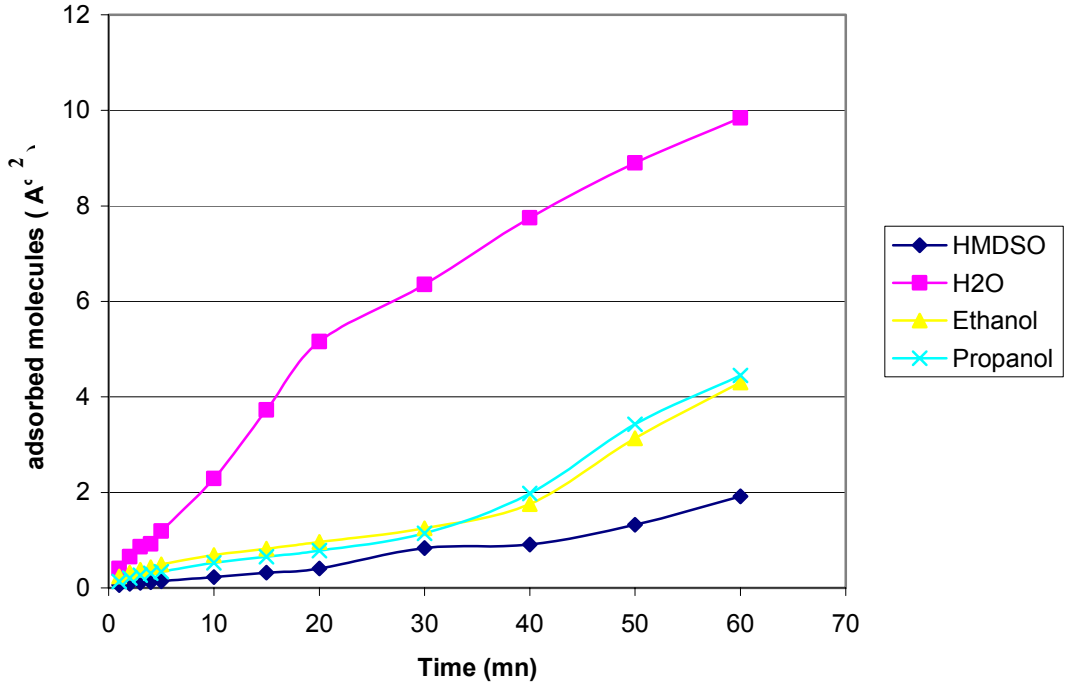

Figure 6 : Results of figure5 re- plotted in terms of number of adsorbed molecules per $A°^{2}$

Now it can clearly be seen that the large and weakly polar HMDSO molecules are much less adsorbed than the smaller and polar water and alcohol molecules. Size effect between ethanol and propanol doesn't play an important role. Water is the most easily adsorbed molecule and their densities clearly involve either a diffusion process inside the film or clusters of molecules at the surface.

Effect of the structure of the surface on the absorption:

Up to now, all the experiments where made on plasma deposited films from pure HMDSO. Previous papers report and discuss the structure and composition of these films [6 – 8]. As expected from the structure of the monomer, - Si – O – Si – is the backbone of the plasma polymer film. The presence of C – H and Si – $(CH_3)_x$ IR absorption bands (with x = 1, 2 or 3) give evidence of the organic part of the deposit.

Before adsorption experiments, these films are submitted to an oxygen plasma. The result of this post treatment is to crosslink the first monolayers due to the etching of the organic part of the plasma film.
A typical example of the effect of the post treatment on HMDSO and water adsorption is given on figure 7.

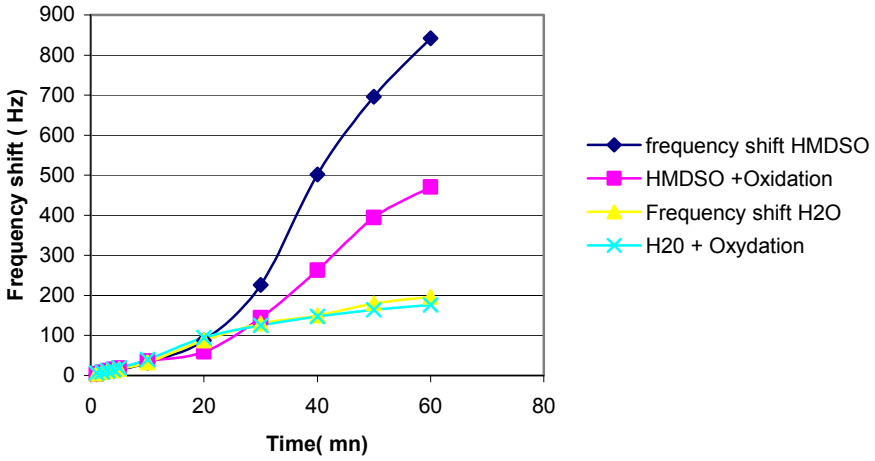

Figure 7: Adsorption of HMDSO and H2O molecules before and after a post treatment of plasma films by an oxygen plasma.

The post treatment reduces by a factor of 2 the mass of HMDSO adsorbed . This is probably due to the crosslinking of the first monolayers of the plasma film making much more difficult the diffusion into the bulk. Moreover a closer examination of our results shows that the treatment has almost no effect during the first 15 mn . Up to this time the surface is mainly involved ; diffusion process become important at longer times whereas all the adsorption sites on the surface are occupied.
Water molecules due to their much smaller size are not very sensitive to the crosslink as shown on figure 7.

Conclusions:

Adsorption of non polar, polar, large and small molecules on plasma deposited HMDSO films have been carried out. A quantitative evaluation of the mass and number of molecules adsorbed was made using a QCM which gives a very good sensitivity. Adsorption is in all cases much larger on plasma films than on a uncoated quartz crystal. We demonstrate that this difference is not due to a change in the roughness. Among all the molecules tested so far, largest adsorption occurs for water molecules probably due to their ability to diffuse inside the film. The lowest adsorption was observed for the molecules use to produce the plasma film. They are weakly polar and their size is very large. Crosslinking the surface of the film using an oxygen plasma reduces drastically the adsorption of large molecules and doesn't change the adsorption of water.

Abstract

This study investigated the sterilization effects of a new atmospheric plasma source, which is a brush-shaped direct current (DC) glow discharge of argon created under one atmospheric pressure. With nutrient broth and standard methods agar as supporting media, a cell reduction in a level of 6 orders of magnitude was observed for both *Escherichia coli* and *Micrococcus luteus* with a few minutes of plasma treatment. The plasma treatment effects on the bacteria cell structures were examined using scanning electron microscopy (SEM).

Keywords: DC glow discharge; atmospheric plasma; sterilization; *Escherichia coli*; *Micrococcus luteus*

Introduction

Rapid, safe, and effective sterilization process is of utmost importance in protecting not only the hospital patients, but the public in general by supplying safe foods, clean water and air. Although the traditional heat based sterilization methods are being extensively used, there is urgency in developing new and improved technologies for sterilization, pasteurization, disinfection. Such urgency is because of the more and more extensive use of heat-sensitive tools nowadays as well as the appearance of heat-resistance microorganisms, such as prion, the protein which causes Creutzfeldt-Jacob disease, more commonly known as "mad cow disease" [1]. In these cases, the traditional heat-based sterilization techniques such as autoclaving (moist heat) and ovens (dry heat) are not suitable.

Sterilization by low-temperature plasmas, which are partially ionized gases, is an alternative to conventional and/or traditional sterilization methods. Low-temperature plasmas, which can be easily created at low-pressure (e.g., less than 10 torr) by applying an electrical field, contains a huge amount of reactive species including various atoms, ions, energetic electrons, UV irradiation. Because of the existence of these reactive plasma species, low-temperature plasma technique has proven to be an effective alternative to many existing sterilization methods. Since early 1990s, several types of plasma sterilizers are now commercially available in the market and are being used in biomedical areas [2]. In spite of their excellent sterilization efficiency, the currently available plasma sterilization processes with regard to medical uses have several major limitations, such as the restricted volume of the plasma reactor and one or more vacuum and chemical cycles required during the process.

Low-temperature atmospheric plasma is a new emerging plasma technology. Because it is operated in open-air, the use of such an atmospheric plasma torch can easily overcome the limitations imposed by the currently available vacuum-based plasma sterilizers. Since it is operated at one atmospheric pressure, atmospheric plasma eliminates the use of vacuum equipment and thus significantly reduces the cost as well as the operation complexity. Such atmospheric plasma techniques can be used not only for surface sterilization and/or decontamination in biomedical, food areas, but also with potential applications in biological warfare defense such as in killing anthrax or other biological warfare agents [3-5].

Results and discussions

In this study, a novel atmospheric cold plasma technology, an atmospheric cold plasma brush (ACPB) [6] with a proprietary design, was investigated for a rapid and effective destruction of various bacteria. The pictorially views of this plasma source operated with argon gas is shown in Fig. 1.

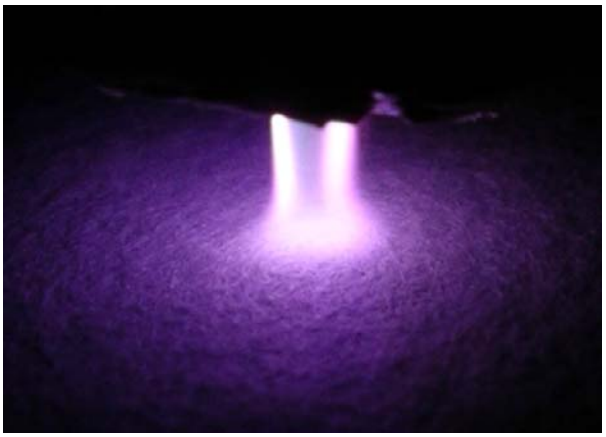

FIGURE 1. Pictorial view of APB plasma source.

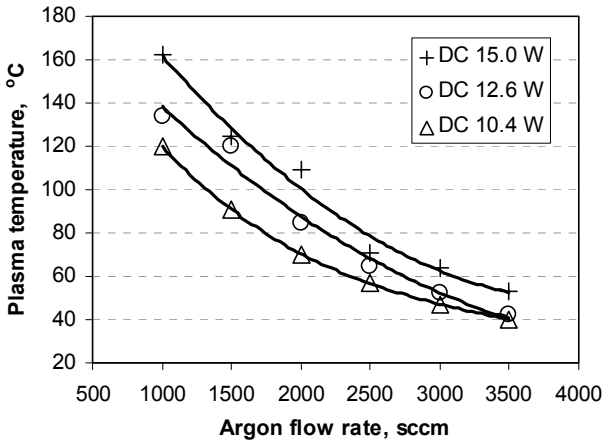

FIGURE 2. Gas phase temperature of APB with argon flow rate.

Such an atmospheric argon plasma source can be operated under very low electric power level (several watts), and as a result very low plasma temperature can be achieved [6]. Fig. 2 shows the gas temperature of this argon atmospheric plasma measured using thermocouple method at various plasma conditions. It can be seen the gaseous temperature of the plasma could reach 40 ^{o}C under the plasma conditions shown in Fig. 2.

1. *Plasma sterilization effects on Escherichia coli and Micrococcus luteus*

With filter papers as supporting media, bacteria of *Escherichia coli* and *Micrococcus luteus* were subjected to the low-temperature atmospheric plasmas of argon. The plasma conditions was controlled at 1500 sccm of argon flow and 15 W of DC power input, which give the gas phase temperature of 125 ^{o}C. Fig 3 shows the survival curves of the two bacteria as a function of plasma exposure time. As can be seen in Fig. 3, 90% of *Escherichia coli* were killed within 2 minutes of plasma exposure; and only 1% *Escherichia coli* colony was detected after 5 minute plasma exposure. In the case of *Micrococcus luteus*, 90% of the cells were killed after a 15 second exposure, while no colonies grew on the agar plate after a 3 minute plasma exposure.

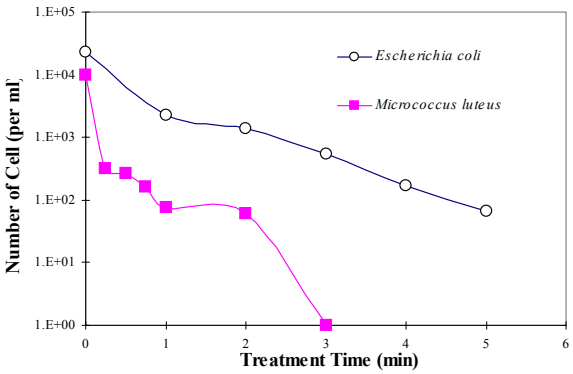

FIGURE 3. Survival curves of *Escherichia coli* and *Micrococcus luteus* on filter paper medium after argon atmospheric plasma treatment with argon flow rate of 1500 sccm and DC power input of 15 W.

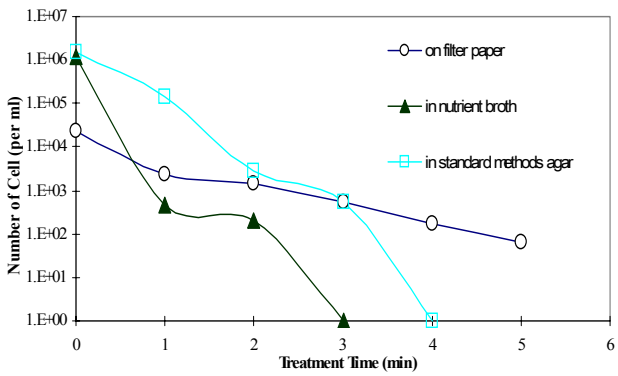
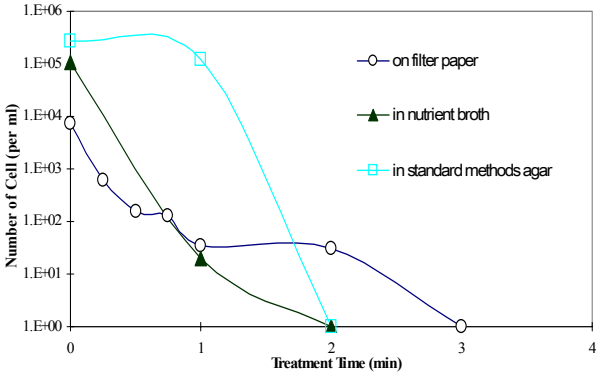
2. *Effects of supporting medium*

The plasma sterilization effects on *Escherichia coli* and *Micrococcus luteus* were investigated with different supporting media, including nutrient broth, standard methods agar, and the filter paper. Fig. 4 shows the survival curves of two bacteria on these supporting media upon argon plasma exposure. As shown in Fig. 4, among the three media, plasma treatment enables the fastest cell reduction of 6 orders of magnitude on nutrient broth. When seeded in nutrient broth, a 6 orders of magnitude *Escherichia coli* cell reduction requires 3 minute plasma treatment; and *Micrococcus luteus* needs 2 minute plasma exposure. With standard methods agar, one

more minute plasma treatment is required for *Escherichia coli* when compared with nutrient broth media. While seeded in filter paper, both two bacteria needs the longer exposure times in order to achieve the similar level of cell reduction.



(a) *Escherichia coli*

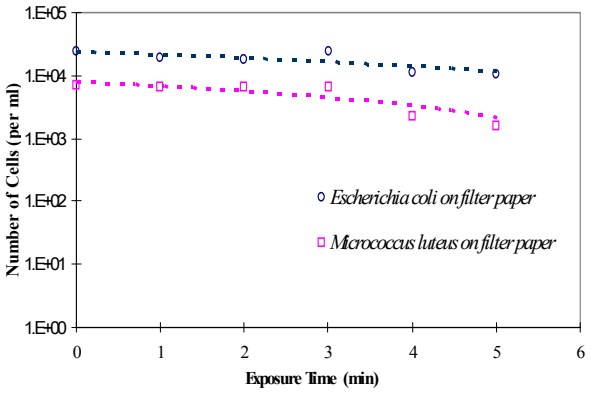


(b) *Micrococcus luteus*

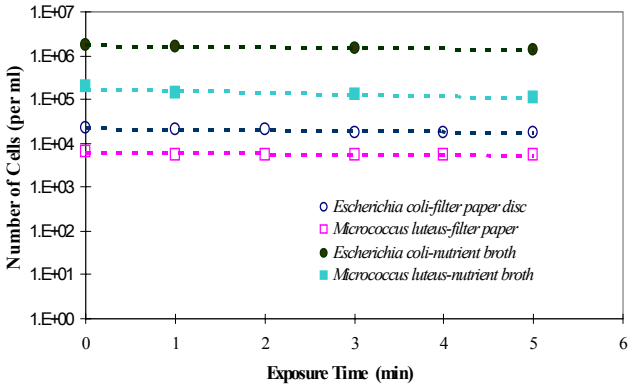
FIGURE 4. Survival curves of (a) *Escherichia coli* and (b) *Micrococcus luteus* in various supporting media after argon atmospheric plasma treatment with argon flow rate of 1500 sccm and DC power input of 15 W.

The fast plasma killing of the two bacteria on nutrient broth is mainly because of the direct attack of plasma species on the bacteria cells. It was observed that the droplets of the nutrient broth dried out within one minute plasma exposure. This enables direct contact of the plasmas to the bacteria cells. With nutrient broth as supporting medium, no stain of *Escherichia coli* and *Micrococcus luteus* was observed after 4 minute plasma treatment. A possible reason for the very different plasma sterilization time is the plasma penetrating efficiency with different culture mediums. The filter paper used in this study is a porous solid and requires plasma penetration to kill the bacteria cells resided inside the pores. The colloid state of agar could slow down the plasma penetration but was eventually destroyed through evaporation of water with longer plasma treatment time.

3. *Effects of heat and gas blowing on cell reduction*



(a) dry heat effect



(b) gas blowing effect

FIGURE 5. Sterilization effects of at 125°C and at a 1500 sccm on Escherichia coli and Micrococcus luteus seeded on filter paper and nutrient broth.

In order to distinguish the plasma sterilization effects from the possible heat effect of the plasmas, a sterilization test to elucidate the dry heat effect was performed using a temperature controllable oven (Fisher Scientific Isotemp Vacuum Oven Model 282 A). Under the operating condition studied, the gas phase temperature of the

argon plasmas was 125 ^{o}C. Therefore, *Escherichia coli* and *Micrococcus luteus* on filter papers was kept inside the oven with temperature set at 125 ^{o}C. The cell survival curves of the two bacteria subjected to the dry heat was shown in Fig 5(a). It was confirmed that the 125 ^{o}C dry-heat treatment did not show any killing effect on both bacteria within 5 minute exposure. These data indicated the heat carried by the argon atmospheric plasmas did not contribute to the sterilization effects shown in Figs. 3 and 4.

A high follow rate of argon higher than 500 sccm is necessary in order to blow the argon glow discharge out of the discharge chamber and form a free brush-shaped plama jet. To determine if the high flowing plasma gas could blow the bacteria cell off the supporting media, the blowing effect of argon gas on the two bacteria was examined by flowing the argon gas at the same flow rate (1500sccm) without igniting electrical discharge. Fig. 5 (b) shows the cell survival curves of *Escherichia coli* and *Micrococcus luteus* on different supporting media with argon gas blowing on the surface. From Fig. 5 (b), it can be seen that the high flow argon gas did not reduce the cell number of both bacteria on all three supporting media. The results shown in Fig. 5 indicate that the sterilization effects of argon plasmas are due to the presence of reactive plasma species, but not the heat or the high flowing gas it carries.

4. *Effects of plasma conditions*

In creation of atmospheric plasmas, the power input and gas flow not only affect the plasma density, but also the plasma temperature s shown in Fig. 2. Consequently, it is expected that these plasma operating parameters should have a certain degree of influence on the plasma sterilization results. Therefore, the effects of power input and argon flow rate of the plasma on the sterilization of the two bacteria were also examined.

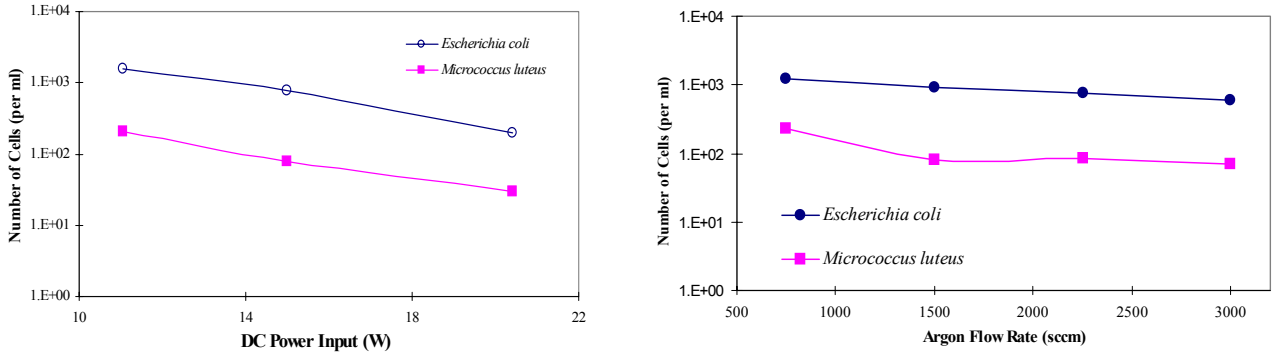


FIGURE 6. The surviving cell numbers of *Escherichia coli* and *Micrococcus luteus* on filter papers as a function of plasma parameters: (a) plasma power and (b) argon flow rate after 1 minute plasma treatment under condition, if not specified in the plots, of 1500 sccm argon and 15 W DC power input.

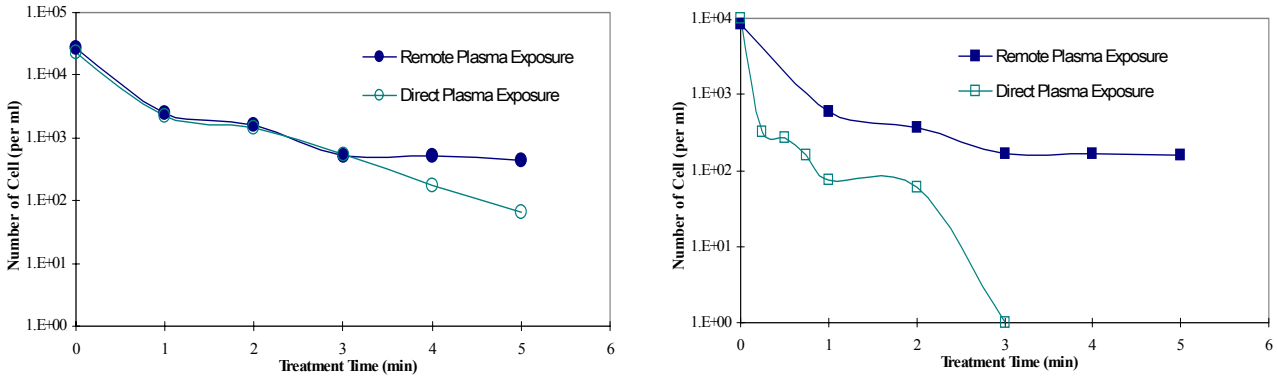
Fig. 6(a) shows the cell survival number changes of both *Escherichia coli* and *Micrococcus luteus* on filter paper medium with DC power input of the plasma under a fixed argon flow at 1500 sccm and plasma treatment time of 1minute. It can be seen that higher DC power input did result in fast killing of both bacteria. Fig. 6(b) shows cell survival number changes of the two bacteria with argon flow rate of the plasmas under a fixed DC power of 15 W and plasma treatment time of 1 minute. Since it doesn't affect plasma density, the change of argon flow rate in the plasmas did not affect the bacteria killing rate.

5. *Effects of remote plasma* exposure

In atmospheric plasmas, the plasma species could lose its energy or reactivity in a very short time due to the much higher collision frequency among the plasma particles. The life time of the reactive plasma species is much shorter when compared to that in low-pressure plasmas. As a result, the plasmas could lose their reactivity dramatically in a remote position (away from the glow). To examine the sterilization effects of a remote plasma, the bacteria seeded in filter papers were subjected to plasma exposure in the down stream at a position 2 mm away from the glow. The long-life plasma species from the plasmas were allowed to diffuse and get in contact with the bacteria cells resided on the supporting media. Fig. 7 shows a comparison of the cell survival curves of

the two bacteria upon a remote plasma exposure and direct plasma exposure. It was observed that the remote plasma exposure causes much slower cell reduction on *Micrococcus luteus* than the direct plasma exposure.



(a) *Escherichia coli* (b) *Micrococcus luteus*

FIGURE 7. Comparison of the survival curves of *Escherichia coli* and *Micrococcus luteus* on filter papers under direct plasma exposure and remote plasma exposure (2 mm away from the plasma glow). Argon atmospheric plasma conditions are 1500 sccm argon and 15 W DC power input.

6. *SEM images of plasma treated Escherichia coli and Micrococcus luteus*

SEM measurements were used to examine the cell structure changes of the two bacteria upon plasma treatments. Figs. 8 and 9 show the SEM images of untreated and plasma treated *Escherichia coli* and *Micrococcus luteus* respectively. From Fig. 8, it was observed that the *Escherichia coli* cells were severely damaged and only some cell debris was detected by SEM with the argon plasma sterilized samples. The SEM measurements on *Micrococcus luteus* shown in Fig. 9 provided the similar information, i.e. the bacteria cells were damaged by argon plasma treatment. After the plasma treatment, the size of *Micrococcus luteus* cells was significantly reduced and the shape of the dead cells was distorted. The distorted cell shape shown in Fig. 9 indicated that the lipid moieties have been lost after the plasma treatment.

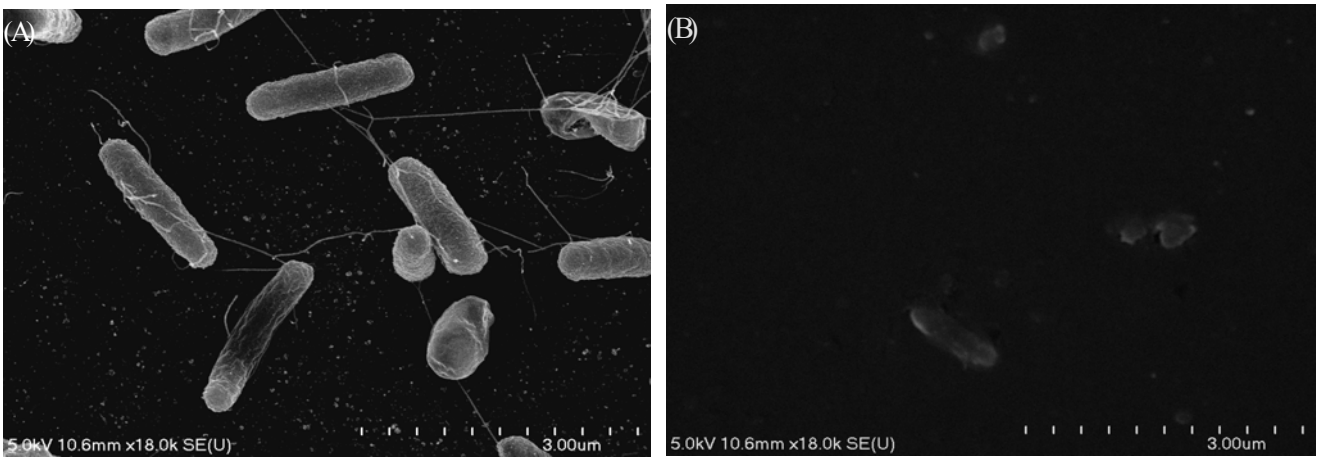


FIGURE 8. Scanning electron micrographs of (A) untreated *Escherichia coli* control and (B) 5 min plasma treated *Escherichia coli* seeded on filter paper under plasma condition of 1500 sccm and 15 W DC power input.

A possible sterilization mechanism of argon atmospheric plasma is the continuous impact on the bacterial cells by energetic plasma species such as argon ions, electronically excited neutrals. The characteristic energies of the argon ions and neutrals is in the level of ~ 15 eV and >11 eV, which are much higher than the bonding energy of the organic molecules constituting microorganisms. Thus, even simple argon plasmas should have sterilization ability to destroy various microorganisms. D.A. Mendis et al. suggested charged particles might cause the

rupture of the outer membrane of the bacterial cell [7,8]]. Therefore, the plasma exposure could eventually damage the cell structure or the cell membrane, and consequently destroys the viability of the cells.

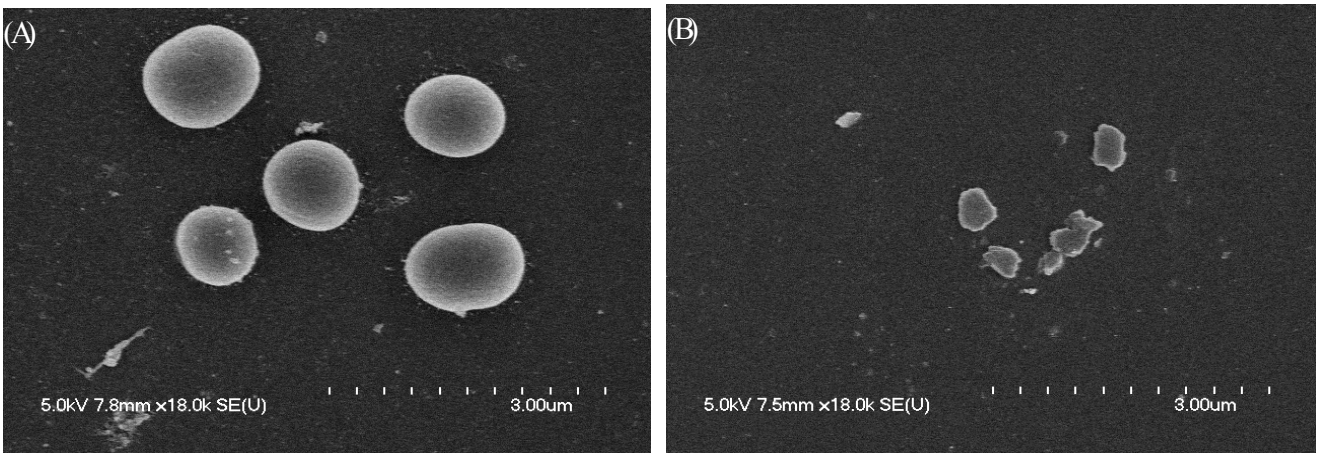

FIGURE 9. Scanning electron micrographs of (A) untreated *Micrococcus luteus* control and (B) 5 min plasma treated *Micrococcus luteus* seeded on filter paper under plasma condition of 1500 sccm and 15 W DC power input.

Conclusions

The plasma sterilization capability demonstrated through this study indicated the tremendous potential of this low-power driven atmospheric plasmas as a promising alternative sterilization technique. Such a low-power atmospheric plasma source is cost effective in both fabrication and operation, simple and safe to use, requires much less treatment time as compared with traditional sterilization methods. The low-power feature of such an atmospheric plasma source makes it not only applicable to various heat-sensitive materials or device, but is also practical to assemble an array of individual plasma brushes for sterilizing large surface or object. This study is our first step to demonstrate the applicability of low-power atmospheric plasma source in sterilization application. Further investigation focusing on elucidation of plasma chemistry effects on sterilization efficiency are being performed in our laboratories and the results will be reported and published in due course.

Abstract

The method of intersecting beams of C_{60} fullerene clusters and of electrons was used to investigate the formation of C_{60}^+ and C_{60}^- ions and the radiation. The ionization σ^+ and electron-attachment σ^- cross sections were measured for electron energy E_e = 0.1 ÷ 100 eV. For E_e < 0.5 eV, the formation of C_{60}^- was found to be defined by the polarization capture of an *s*-electron. The "delayed" ionization under collision of C_{60}^* with the surface was observed. The rate of radiative cooling of C_{60}^{+*} ion was found to be $5.5 \cdot 10^5$ eV/s at $T(C_{60}^{+*})$ = 3150 K.

1. Introduction

Fullerenes are distinguished by their exceptional stability towards fragmentation. The dominant dissociation channel – the evaporation of C_2 unit – begins within typical mass spectrometric time scale only after pumping into C_{60} cluster several tens of eV (see review [1] and references therein). This fact gives rise to different decay modes of these metastable highly energized nanoparticles, i.e. actively studied "delayed" autoionization of energy-rich C_{60} cluster [2]. Radiative cooling of C_{60} [3, 4] is competitive to decay channels.

Large number of inner degrees of freedom results in quasicontinuous function of C_{60}^- formation in reaction $C_{60} + e^-$ [5]. In this process the largest attachment cross section is achieved at $E_e \to 0$, and at E_e > 7.5 eV the C_{60}^- states which are unstable against electron auto-detachment are formed.

2. Experimental

Figure 1 shows the scheme of experimental setup. An electron beam 2.5 mm in diameter was formed with an oxide-coated cathode 1 and electron-optical diaphragms 2 and 3. Collector assemblies 5-7 ensured a complete accumulation and recording of the ions, $I^{+,-}$, and electron, i_e, currents. The electron energy E_e was set by the voltage between electrodes 1 and 4. The scale of energy E_e was calibrated by the retarding potential method. The retarding potential between electrodes 6 and 4 at which the current i_e was reduced by a factor of two was taken to be equal to E_e. The magnetic field between magnets 8 prevented the electron beam from broadening.

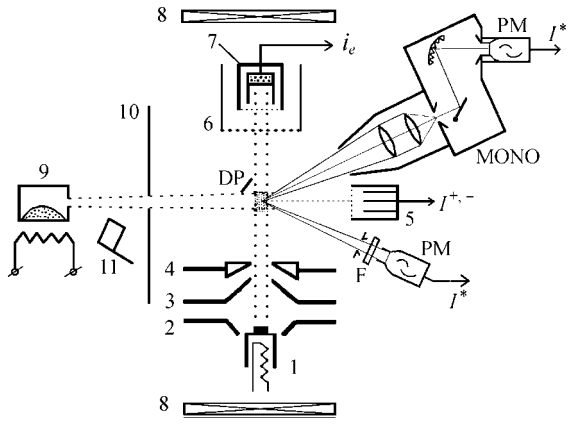

Fig. 1. Experimental setup.

The beam of fullerene clusters was formed by using C_{60} vapor flowing from an effusion source 9 through an opening 2.4 mm in diameter and was collimated by a diaphragm 10 with a 3-mm aperture. In order to take into account the contribution made to the ion current and to radiation by the background gas of the vacuum chamber (the pressure of this gas was about $4 \cdot 10^{-5}$ Pa), the C_{60} beam was cut off by an electromagnetic gate 11, whereby the ion current and the photon flux from the background gas could be measured.

In the energy region E_e greater than the width of the energy distribution function f_e(E) of electrons (0.3 eV

in this study), the absolute values of the cross section $\sigma^+(E_e)$ and $\sigma^-(E_e)$ are determined by the formula [6] $\sigma^{+,-} = I^{+,-} / (i_e \cdot n \cdot l)$, where n is the density of C_{60} clusters in the region of beam intersection, and l is the length of this region. The density n was determined on the basis of the weight of the C_{60} clusters condensed over a fixed time in a trap mounted on the beam path. For $E_e < 0.3$ eV, the cross section $\sigma^-(E_e)$ was determined by comparing the E_e dependences of the currents $I^-(C_{60}^-)$ and $I^-(SF_6^-)$. It is well known that the formation of SF_6^- ions is caused by *s*-electron capture and is characterized by a narrow resonance at $E_e \to 0$ [7].

Radiation from the region of beams intersection was recorded by a system of short-focus lenses, a monochromator (MONO) with the spectral range of 200-800 nm, inverse dispersion of 3.2 nm/mm, 0.3-mm slits, and a photomultiplier (PM). The spectral sensitivity of the optical system was determined with the aid of a reference tungsten lamp. In order to increase the signal, a wideband filter F with the transmission band at half-height of $\Delta\lambda$ = 150 nm and a center at λ = 500 nm could be placed instead of the monochromator. The spatial sensitivity of the optical system was determined by scanning with a point source.

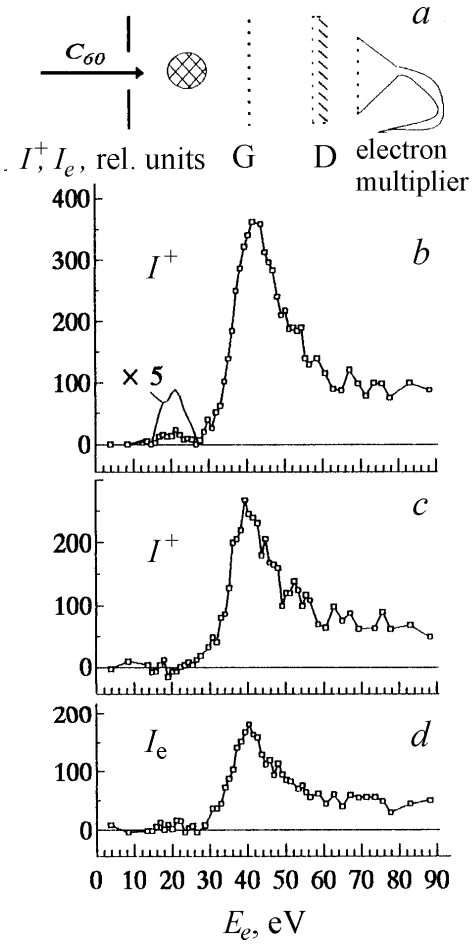

Fig. 2. Scheme of the surface-induced delayed ionization experiment (a); the behavior of ion (b, c) current and electron (d) current resulted from surface impact as a function of the energy E_e. The values of electrode voltages for grid G, dynode D and multiplier, respectively, are: (b) –30, +3200, –2100; (c) +30, –600, –2100; and (d) +30, –3200, –2100 V.

In order to identify the contribution of C_{60}^{+*} ions to the total radiation, an electric field between deflecting plates (DP) was applied to the beam intersection region. The fact that the field of the plates did not distort the geometry and the parameters of the electron beam was checked by measuring the intensity of radiation from the short-lived states of N_2^{+*} ($B^2\Sigma_u^+$) ion. The modulation of the electron beam (with a frequency of 80 Hz) and synchronous detection of signals improved the signal-to-noise ratio.

The effect of surface-induced ionization of C_{60}^{**} formed by electron impact was observed in an experiment with the scheme shown in Fig. 2a. The following elements were placed on the fullerene-beam axis downstream the region of intersection with the electron beam: at a distance of 26 mm – a grid G, then 3 mm from the grid – a louvered dynode D with the second grid in front of it, and 7 mm from dynode – a channel electron multiplier. The aluminum plates of the dynode D arranged at an angle of 45° with respect to the C_{60} beam were used as the target. The second grid in front of dynode ensures a uniform electric field between G and D. The total transparency of the grids was as large as 90%, therefore we disregard the collisions with their surface and take into consideration only collisional ionization of C_{60}^{**} with the louvered dynode. The primary C_{60}^+ and C_{60}^- ions that were formed upstream of the grid G were retarded by the field of the grid G and of the electrode D. This was tested at E_e = 0.2 and 52 eV, which correspond to the maximal cross sections for the formation of negative and positive C_{60} ions (see below). The time of C_{60} travel in the beam from the region of interaction with electrons to the grid G (estimated from the average velocity of C_{60} clusters in effusive beam at 744 K, 174 m/s) was about 150 μs.

3. Results and Discussions

Surface-induced C_{60} ionization. The formation of C_{60}^+ over a time scale of the order of the time it takes a molecule to traverse the

electron beam may be referred to as fast ionization. The term delayed ionization (DI) is used to denote the formation of C_{60}^{+} ions after the escape of an excited C_{60}^{*} cluster from the beam intersection region. An electron may be emitted from the cluster either because of the statistical distribution of energy over the internal degrees of freedom (thermionic emission) or upon decay of primary quantum excitation.

We know of only one study where DI was observed after the excitation of C_{60} by electron impact [8]. The electron-energy dependence of the DI current, $I^{+}(E_e)$, in [8] peaked at E_e = 43 eV and was attributed to the excitation of C_{60} to long-lived Rydberg states (longer than 130 μs) which decayed in an electric field.

In this study we have found the electron-induced formation of C_{60}^{**} metastable states, which decayed at surface collision with C_{60}^{+} formation. The Fig. 2b, c, d gives the E_e dependences of currents $I^{+}(C_{60}^{+})$ of ions and I_e of electrons formed at C_{60}^{**} impact to aluminum target in 150 μs after C_{60}^{**} formation. In contrast to the results of [8], we did not find any effect of electric fields up to 3.5 kV/cm. For this reason, we believe that the DI current was associated, first of all, with the existence of long-lived (metastable) electron-excited states C_{60}^{**}, which decayed into a C_{60} ion and an electron upon hitting the metal surface. The dependence $I^{+}(E_e)$ characterizes the cross section of C_{60}^{**} metastable states formation σ^{**}. The maximum of σ^{**} is shown to be at E_e = 41.5 eV. It is remarkable that this value is essentially equal to the threshold energy of fragmentation $C_{60} \rightarrow C_{58} + C_2$ by electron impact [9]. Possibly, the fragmentation limits the life-time of C_{60}^{**}. Note that, in Fig. 2, a small maximum is observed of the DI current at an energy E_e = 21 eV, which coincides with the plasmon excitation energy in C_{60} [12, 13]. This remarkable fact indicates directly that quantum excitations contribute to DI.

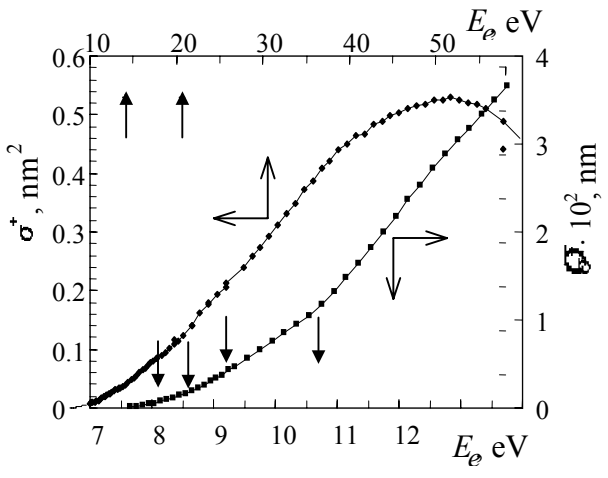

Fig. 3. Cross section of C_{60}^{+} formation.

Electron-induced ionization of C_{60}. The fast ionization of C_{60} by electron impact was investigated, for example, in [10, 11], with the cross sections $\sigma^{+}(E_e)$ measured there being markedly different. In this study, we measure the cross section $\sigma^{+}(E_e)$ up to E_e = 60 eV. The measured values of $\sigma^{+}(E_e)$ are given in Fig. 3, where the initial segment is shown on an enlarged scale. One can see that a maximum of $\sigma^{+}(E_e)$ = 0.53 nm^2 is attained at E_e = 52 eV. At the initial segment of the $\sigma^{+}(E_e)$ plot, we can clearly see breaks at E_e = 8.1, 8.6, 9.2, 10.7, 14.1, and 20.5 eV (indicated by arrows). These breaks correspond to autoionization states of C_{60}. The first two values coincide with the positions of breaks on the curves of $\sigma^{+}(E)$ for the photoionization of C_{60} [12]. The values of energy E_e = 10.7 and 20.5 eV are close to the plasmon excitation energy [13], and C_{60}^{2+} ions show up at $E_e \approx$ 20 eV [14].

Because the dependence $\sigma^{+}(E_e)$ proved to be linear between the breaks, we determined the ionization potential of C_{60}, U_i = 7.6 eV, by extrapolating the linear segment to the region E_e < 8.1 eV. For the ionization of C_{60} by synchrotron radiation, the value of U_i = 7.58 eV was obtained [12].

Electron attachment to C_{60}. The electron attachment to C_{60} cluster was investigated, for example, in [15, 16, 17], but the absolute values of $\sigma^{-}(E_e)$ did not measured.

Figure 4 gives the E_e dependences of the cross section σ^{-}: points 1 – experiment, curve 2 – calculation. The nonmonotonicity of the dependence 1 for E_e < 0.2 eV is due to the increase in error of I^{-}/i_e ratio with decreasing E_e. It was found that the measured at E_e < 0.3 eV $I^{-}(SF_6^{-})$ and $I^{-}(C_{60}^{-})$ currents are fitted well with the

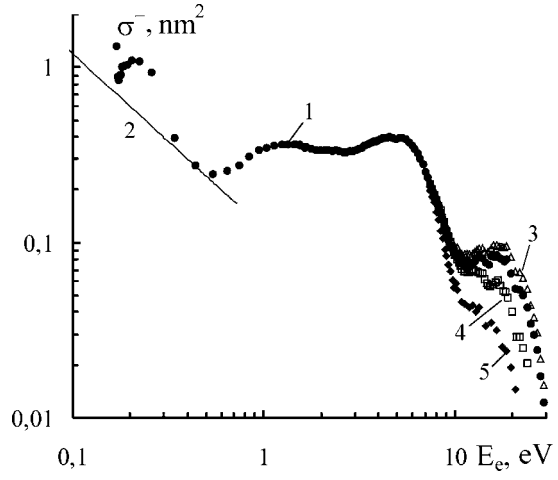

Fig. 4. Cross section of C_{60}^- formation.

dependences $I^- = \int_0^\infty \sigma^-(E_e) f_e(E_e) dE_e$, where $\sigma^-(C_{60}^-)$ are given by expression for polarizative caption [18]: $\sigma^- = (\pi a_0^2/2E_e)\cdot\{1 - \exp[-4(2\alpha E_e)^{1/2}]\}$. Here a_0 – Bohr radius, other values are taken in atomic units, α is the polarizability of C_{60}. We used the mean of the values obtained in [19]: $\alpha(C_{60})$=756. At E_e > 7.5 eV, C_{60}^- ions are unstable against electron autodetachment, and the observed cross section $\sigma^-(E_e)$ depends on the time t it takes an ion to travel the distance from the formation point to the ion collector. Figure 4 shows the effective cross sections $\sigma^-(E_e)$ for five values of time t : (3) 40, (1) 60, (4) 80, and (5) 100 μs.

Thermoemission of electrons and photons. Earlier we observed, that the spectrum of radiation in the wavelength range λ = 300 up to 800 nm from the region where the beam of C_{60} clusters and the electron beam intersect is similar to the Planck radiation spectrum [4, 20]. An analogous spectrum was observed in [3] in the case of evaporation of C_{60} by laser irradiation. Here we have found that the main contribution to radiation comes from C_{60}^{+*} ions which are produced as a result of thermionic emission and determined the main radiative characteristics of these ions.

Figure 5 gives the radiation intensity as a function of the electric-field strength, ξ, between the deflecting plates DP (see Fig. 1) at E_e = 40 (curve 1) and 65 eV (curve 2). The radiation was detected with an optical filter. The same figure also shows the calculated electric-field-strength dependence of the residence time of a C_{60}^+ ion in the observation region, t(ξ) (curve 3). One can see that the main contribution to radiation comes from C_{60}^+ ions. For high values of ξ, the time t and, hence, the intensity of ion radiation are proportional to $\xi^{-1/2}$. By expressing the dependences $I^*(\xi)$ in terms of coordinates $I^*(\xi)$ and $\xi^{-1/2}$ and extrapolating them to the

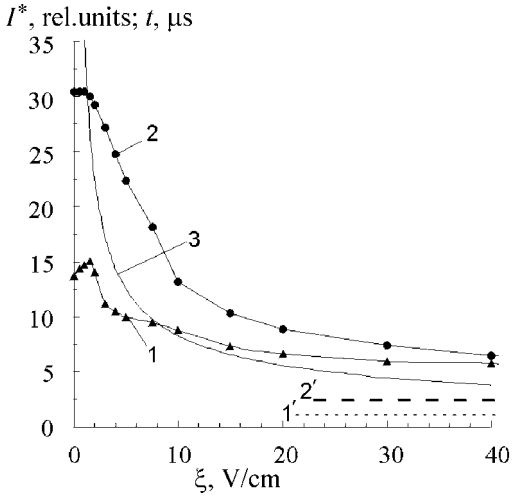

Fig. 5. The intensity of radiation from C_{60}^* and C_{60}^{+*} (1, 2) and the residence time of C_{60}^{+*} ion in the observation region as functions of the electric-field strength. Contributions from C_{60}^* neutrals (1', 2') (see text).

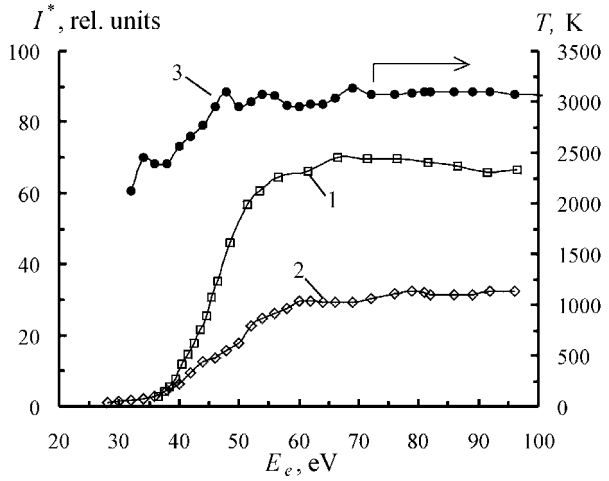

Fig. 6. The intensity of radiation (1, 2) and the temperature of radiating particles (3) as functions of the electron energy E_e.

origin, we have found that the contribution of neutral particles to radiation does not exceed 16 and 4% at E_e = 40 and 65 eV, respectively. In Fig. 5 these values are indicated by lines 1' and 2'.

Figure 6 gives the E_e dependences of I^* during measurements of radiation in the scheme with a filter (points 1) and with a monochromator (λ = 540 nm, $\Delta\lambda$ = 3 nm) (points 2). Also given in Fig. 6 is the brightness temperature as a function of $T(E_e)$ (points 3) obtained by approximation of radiation spectra at different values of E_e by the modified Planck formula from [4, 21]. In the wavelength range of $[\lambda, \lambda + \Delta\lambda]$, such a particle emits a photon flux

$$j(\lambda, T) = 2\pi c S \Delta\lambda \varepsilon_0 \left\{ \lambda^4 \left[\exp\left(\frac{hc}{\lambda k_B T} \right) - 1 \right] \right\}^{-1}, \qquad (1)$$

where $S = 4\pi d^2$ is the area of the radiating sphere of diameter d, and $\varepsilon_0(\lambda, T)$ is the emissivity (blackness factor) of particle.

The behavior of $I^*(E_e)$ suggests that the contribution of C_{60}^+ to radiation becomes dominant for E_e > 33 eV. The temperature $T(E_e)$ = 3150 K is established at $E_e \geq$ 47 eV. This is possibly due to the E_e dependence of the energy ΔE_v transferred from the electron to the cluster. According to the calculation results of [22], the internal energy of C_{60} at T = 3150 K is approximately equal to 37 eV. Adding U_i = 7.6 eV and substracting the energy of C_{60} in the effusive beam we obtain ΔE = 40 eV.

The cross section σ^* of the production of a radiating C_{60}^{+*} ion by electron impact is determined by comparing the intensities of radiation from C_{60}^{+*} and $N_2^{+*}(B^2\Sigma_u^+)$ at a wavelength λ = 391 nm as measured on the basis of the same experimental scheme. We have $I(N_2^{+*})/I(C_{60}^{+*}) = n_N \sigma_N^* / (n \sigma^* t j)$, where n_N and n denote the density of N_2 and C_{60} in the region of beams intersection, $\sigma_N^* \approx 1.7 \cdot 10^{-3}$ nm^2 is the cross section of excitation of observable radiation from N_2^{+*} [23], and $t = 3.5 \cdot 10^{-5}$ s is the time during which the C_{60}^{+*} ion traverse the optical-observation region. The lifetime of $N_2^{+*}(B^2\Sigma_u^+)$ is $\tau^* = 6 \cdot 10^{-8}$ s >> t, that is, the current of N_2^{+*} ions is equal to the photon flux. From the ratio $I(N_2^{+*})/I(C_{60}^{+*})$ at E_e = 60 eV, we obtained $\sigma^* \approx 2 \cdot 10^{-2}$ nm^2. This value appeared to be approximately 20 times smaller than the maximum cross section for C_{60} ionization by electron impact, but it is much larger than σ_N^* for $N_2^{+*}(B^2\Sigma_u^+)$ radiation.

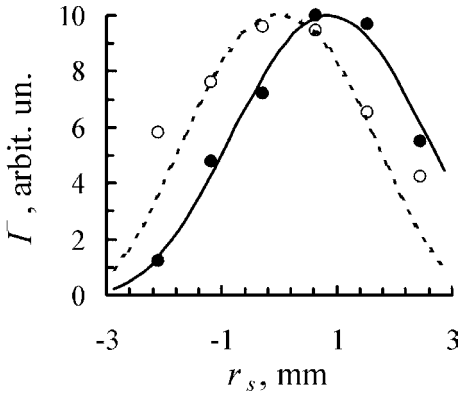

Fig. 7. The transverse profiles of electron-induced radiation (E_e = 70 eV) of the C_{60}^{+*} (•) and $N_2^{+*}(B^2\Sigma_u^+)$ (o) ions.

The kinetics of thermionic emission and of radiation was determined from a comparison of the experimental and calculated dependences (per C_{60}^{+*} ion) of the radiation intensity I^* on the electric field strength of the DP plates, assuming the first-order approximation for the kinetics of formation of C_{60}^{+*} ions by thermionic emission. The radiative cooling constant was taken from integration of Eq.(1) over the wave length. The calculation parameters were d = 1 nm, and T = 3150 K 6 ms, l = 540 nm,.The best agreement between calculations ond experimental data was obtained at ε_0 = 6 and thermionic emission time τ_e = 6 μs. This results in the rate of radiative loss of energy by a C_{60}^{+*} ion of $5.5 \cdot 10^5$ eV/s.

The delay of radiation due to the finite time of thermionic emission is clear manifested in measurements of transverse

profile of the C_{60}^{+*} emission region. This profile together with the profile of $N_2^{+*}(B^2\Sigma_u^+)$ radiation at a wavelength λ = 391 nm are shown in Fig. 7 with black circles and open circles correspondingly. Both profile were measured without electric field. Due to small lifetime the profile of $N_2^{+*}(B^2\Sigma_u^+)$ emission coincides with the profile of the exciting electron beam (corrected for the spatial sensitivity of our optical system) and corresponds well to calculations on the assumption that electron beam is cylindrical (see dash line in Fig 7). The maximum of the C_{60}^{+*} ion profile appears to be shifted downwards the beam moving to 0.9 mm, which at average cluster velocity 174 m/s corresponds to delay time 6.1 μs. The scatter of the data on the rate constant for C_{60}^{*} delayed autoionization is rather large. For example, with data taken from [24], we obtained the rate constant $1.2\cdot10^5$ s^{-1} at the C_{60}^{*} cluster temperature 3100 K, i.e. the ionization characteristic time 8.6 μs, cluster temperature 3200 K results in values $2.9\cdot10^5$ s^{-1} и 3.4 μs, correspondingly. Thus in our experiments it is the delayed ionization that is responsible for radiating ions formation.

Dose Dependence of Surface Hardness

by Low Energy Ion Irradiation on PMMA

(JAPAN)

M. Arai, E. Hatsugai, N. Hamamura, T. Iwao, and M. Yumoto

(*Musashi Institute of Technology in Japan*)

Abstract

It will know that a low energy ion irradiation is a powerful method for nm order modification of polymer surface properties of polymers. If sp^3 coupling are formed at the surface of PMMA(polymethylmethacrylate) by ion irradiation, an improvement of wear resistance and hardness will be expected. In the report, change of the hardness and the chemistry bonding by the low energy N_2 ion irradiation on to PMMA is reported. It is also reported that the result of HOPG(Highly Oriented Pyrolytic Graphite) for the clarification of the structure of PMMA.

1. Introduction

In light guide, optical fiber, optical disk, and liquid crystal display (LCD), etc. that support the information technology the importance of the transparent polymer material has risen. Especially PMMA is called the alias organic glass, and excels in the transparency, possesses a low birefringent rate, and is used widely. However, when this is used as an optical material such as displays and lenses, it is necessary to improve wear resistance. Generally, the coating method is used for the improvement of wear resistance. But, because the thickness of the coating layer by the method is a micrometer order, the coating material influences an optical characteristic of the material. Then, it is necessary to form the structure of the nanometer order like a hard film such as DLC(Diamond Like Carbon) and CN_x(Carbon Nitride) on the surface.

The ion irradiation method of the energy of several 100 eV is one of the surface modification method. This method can control the properties in the thin modified layer depending on the kind of the irradiated molecules and atoms, and a kinetic energy of the irradiated ions. Especially, it is reported that the ion irradiation with its penetration kinetic energy of 100eV is effective to the formation of the covalent binding (sp^3 bond). Moreover, the depth the ion in to the material is a nanometer order. Therefore, it can be expected that it is an effective technique for forming the modified layer along the demand of the mentioned above.

By the way, the development of the surface layer with some functions polar component surface energy and a by the nitride processing is paid to attention because nitrogen compounds is a material with high stability. For instance, it is reported that the surface of the sample an improvement of abrasion resistance[(1)] and a large magnitude of smooth surface was obtained[(2)].

In this report, the aim with PMMA by the acceleration energy 100 eV, is to clarify the structure of the modified layer on PMMA which the hardness is improved by the nitrogen ion irradiation with its energy of 100 eV. But, it is very difficult to identify the structure of the polymer. Then, the change of the structure by the nitrogen ion irradiation is investigated by using HOPG as the analysis of the structure is easier. The relation between the change of the hardness of PMMA after low energy ion irradiation processing and the change of elation between chemical structures obtained of HOPG is shown and is discussed.

2. Experimental

<2•1> Surface Treatment

Figure 1 shows the schematic diagram of treatment apparatus. Before the irradiation, the chamber was evacuated to less than 1.3×10^{-4} Pa. The gas used was commercial grade nitrogen (purity 99.999%). Under the pressure at 1.3×10^{-2} Pa, ions were accelerated by 100 V constant, and the amount of the irradiation has been changed as a parameter within the range from 1.5×10^{15} to 6.0×10^{16} ions/cm^2. Sample were a commercial PMMA plate(8 mm × 8 mm × 0.5 mm) and the HOPG plate(ZYB grade, 6 mm × 12 mm × 1.7 mm). The PMMA sample was washed by using an ultrasonic washing with ethanol for ten minutes, and was dried in a desiccator to remove impurities on the surface. After the surface treatment, the sample was taken out in the atmosphere, for the surface analysis.

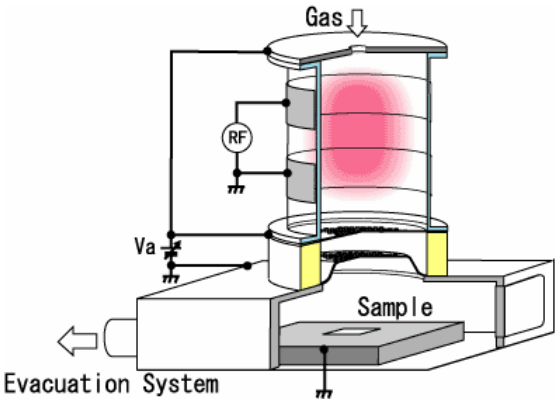

Fig.1 Processing system

<2•2> Analysis Method of Sample Surface

The sample were analyzed by using AR-XPS(X-ray Photoelectron Spectroscopy) (Surface Science Instruments SSX-100, X-ray source (Al Kα) : 1487 eV) and Raman spectroscopy(HORIBA Jobin Yvon T-64000, excitation light source : 514.5 nm). Because the sample during the measurement was exactly electrified, the electron of 10eV was irradiated on the sample by the neutralizing gun.

Figure 2 shows the principle of the depth profile analysis. In fact, the analyzer is anchored in position, and the sample stand is rotated. X rays are incidence from the direction of the rotation axis of the sample stand.

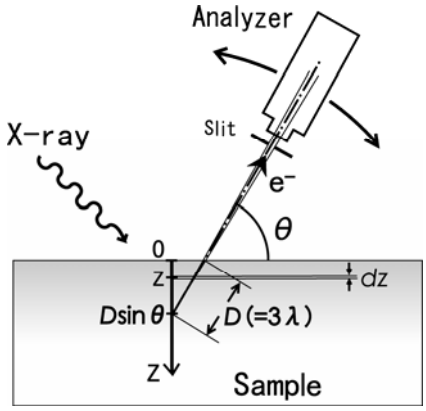

Fig.2 Angle-resolved XPS[2]

The depth profile of each atom was calculated by using equation (1).

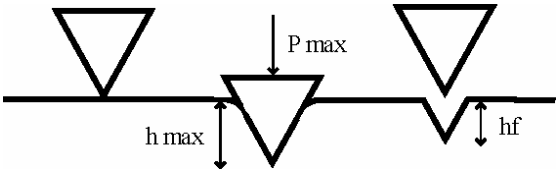
$$I = \int dI = \int_0^{D\sin\theta} \frac{1}{\sin\theta} k(z) S \sigma E n(z) \exp\left(-\frac{z}{\lambda \sin\theta}\right) dz \quad \cdots (1)$$

Where, I is the spectrum intensity, $n(z)$ is the depth profile of the composition which corresponds to the number of photoelectrons generated at the depth z, θ is the photoelectron take off angle, λ is the electron inelastic mean free path, S is the X-ray irradiation area, and k(z) is a compensation function in the measurement device.

<2•3> Surface Harness Measurement

The Nanoindentation test machine(Hysitron, Triboscope) was used for the measurement of hardness. The diagrammatic illustration of the metrology is shown in Figure 3 [(3)]. The needle made of the diamond is operated in the vertical direction, and the pushing load is continuously changed. The method is a method of dynamically measuring the sinking crowding to it, and can evaluate a very thin reforming layer. The hardness of the sample is requested by the except load curve of load-displacement curve. When the pushing depth at permissible capacity at rated load center distance P_{max} assumes that the project area in the area where h_{max} and the pushed needle have come in contact with the sample is A, hardness H of the sample is defined by the equation (2). To adjust the needle invasion depth to several nm, the load added to the needle was assumed to be 4μN for PMMA and 10μN for HOPG.

$$H = \frac{P\max}{A} \quad \cdot \cdot \cdot (2)$$



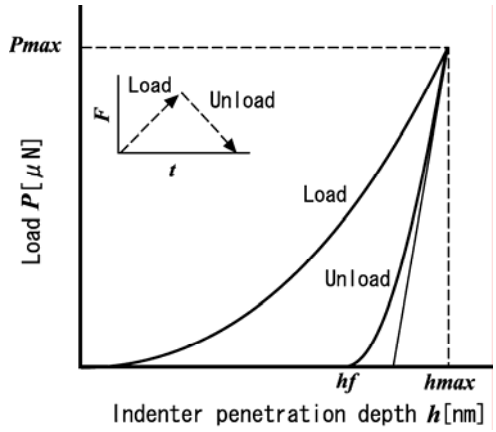


Fig.3 Hardness measurement of nanoindentation test[(3)]

3. Experimental Results and Discussion

<3•1> Hardness Measurement

Figure 4 shows the results of the hardness measurement by the nanoindentation test. The test was repealed ten times, and the bar in the figure shows the maximum and the minimum values.

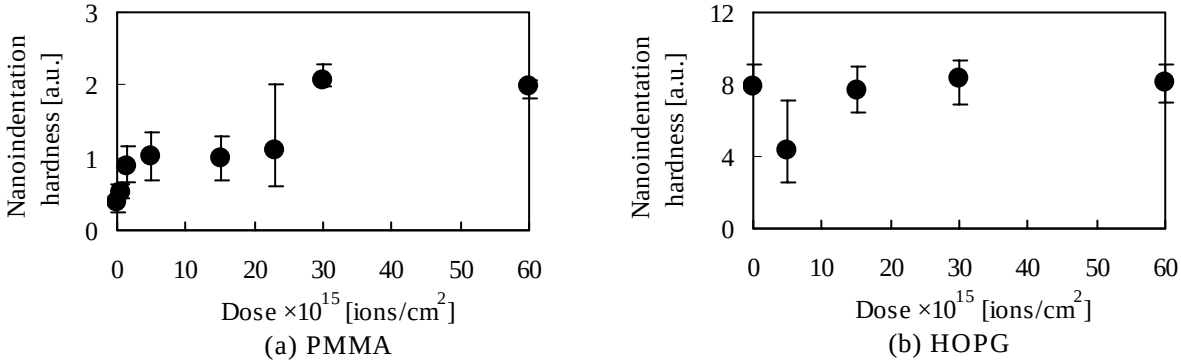

Fig. 4 N_2 dose dependent of surface hardness

Hardness of PMMA which ion was irradiated increased depending on the amount of ion irradiation. Hardness increases suddenly around the most at amount 3.0×10^{16} ions/cm^2. Its magnitude increased about three times compared with the untreatment PMMA, and showed saturation with the value. Hardness decreased in HOPG in case of a small amount of the irradiation, often that hardness increased, too, depending of the amount of the irradiations. Hardness increased up to the amount 3.0×10^{16} ions/cm^2 of the

irradiation as well as PMMA, and hardness was saturated. The untreated HOPG is a high density material. Therefore, it hardness is high. However, the hardness decreased under the small amount of irradiation. It is said that HOPG to which the ion is irradiated will become an amorphous structure. Afterwards, the change of the structure was introduced and change of the might hardness increase by the ion irradiation. That is, it is expected that the structure of PMMA and HOPG in amount of 3.0×10^{16} ions/cm^2 irradiation may be similar.

<3•2> Change of composition

Figure 5 shows the N_2 dose dependence of composition.

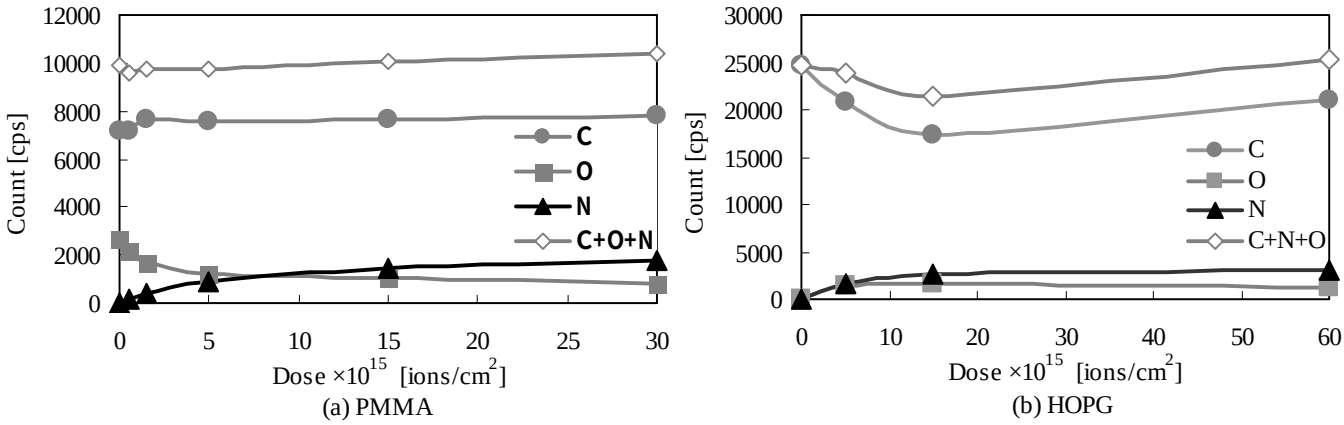

Fig.5 N_2 dose dependence of composition

In PMMA, oxygen decreaseds as the amount of the irradiation increase, and nitrogen increased. The binding energy of hydrogen is lower than that of the carbon and oxygen though hydrogen cannot be measured by XPS. It is thought that combination of hydrogen and oxygen such as C-H and C=O is resolved by the ion irradiation, and the nitrogen is introduced. Because sum of the each composition increased a little by increasing the amount of the irradiation, it is thought that the density on the surface of the sample increases by the ion irradiation. It is thought that binding of nitrogen and the carbon is chiefly effective in the improvement of hardness because an increase of nitrogen irradiation into the sample and of the hardness.

In HOPG, the carbon decreased by the ion irradiation with a little amount of the irradiation. And nitrogen and oxygen were introduced. Afterwards, the composition of the carbon and nitrogen increased, and oxygen didn't increase. The composition of oxygen didn't depend on the change in the amount of the irradiation. It is thought that the oxygen that adhered to the surface was introduced by the ion irradiation as. Sum of each composition increased depending on the amount of the irradiation.

It is thought that the reason why the hardness shown in Figure 4 decreases under a small amount of iradiation is that itsthe density falls, and it changes into an amorphous structure. Based on the above results, it is thought that bindings of nitrogen and the carbon is chiefly effective in the improvement of hardness.

<3•3> Density Distribution

Figure 6 shows the calculated results of the density profile against distribution to the amount of the irradiation.

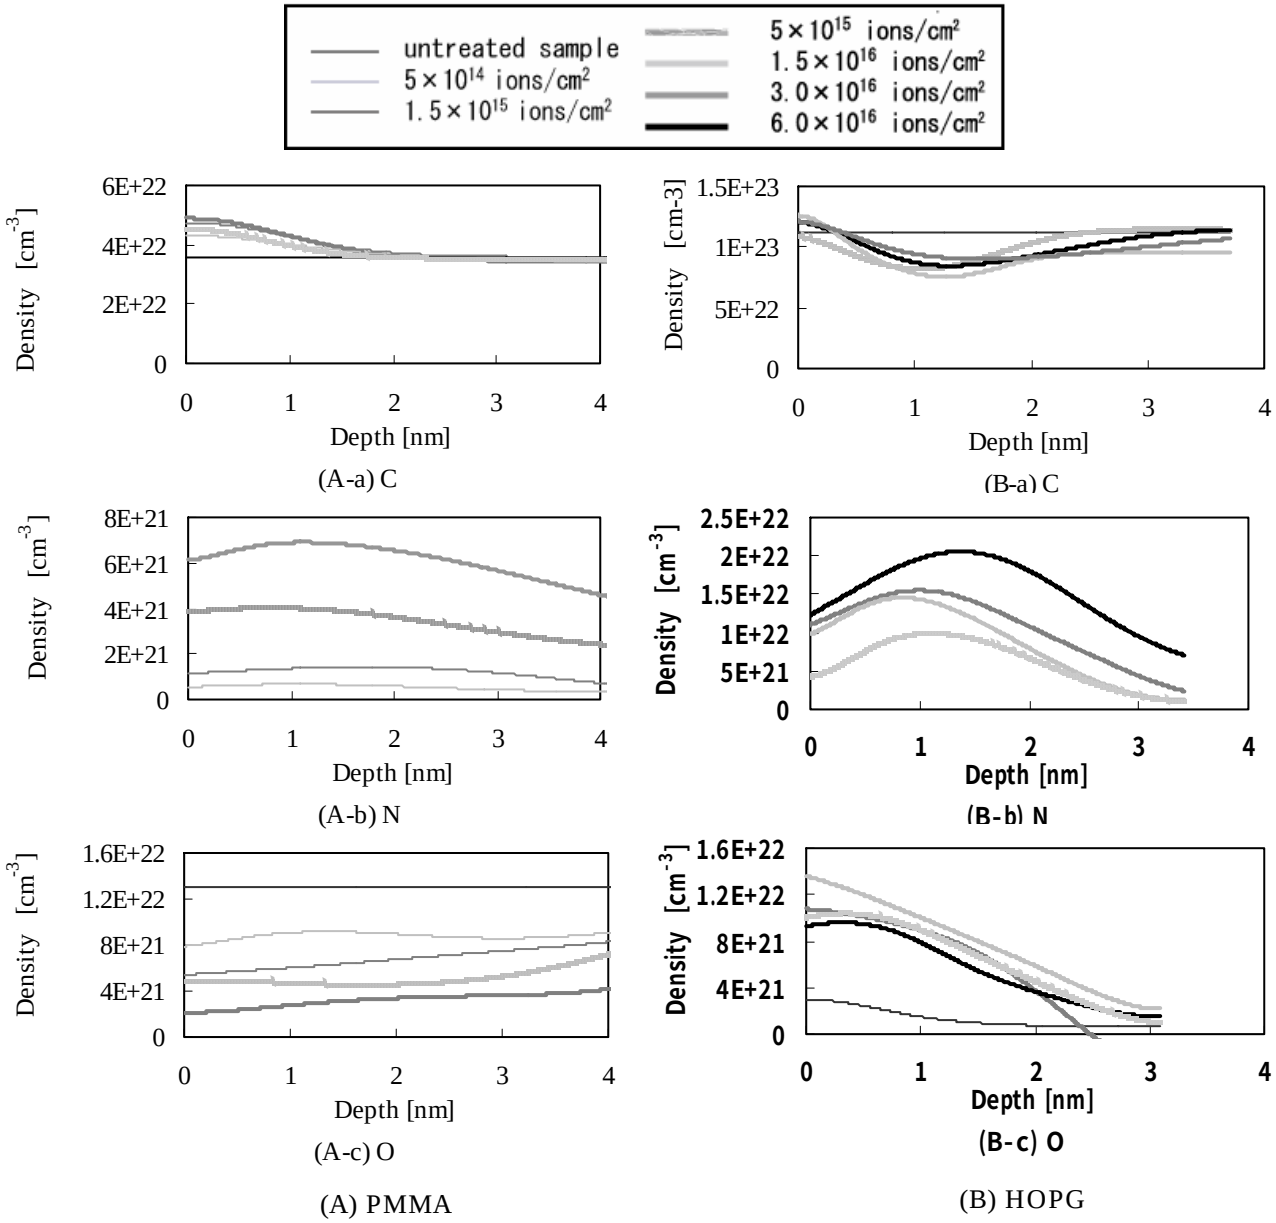

Fig.6 Depth profile of Carbon, Oxygen and Nitrogen

In PMMA, nitrogen was introduced into the sample amount of 1-2nm the depth of. Oxygen was resolved on the surface, and the density of the carbon increased on the surface of the sample. The amount of the introduction of nitrogen increased, and oxygen decreased for an increase in the amount of the irradiation. The improvement in the hardness was anticipated with basing on the increase of the combination of charcoal element and nitrogen, because there are small changes of the density of the charcoal element for the increase in the amount of radiation. In HOPG, nitrogen, around depth was introduced into the sample of 1-2nm. Oxigen was introduced at the surface, and the carbon decreased up to 1 to 2 nm depth, and the density was increases mean the surface. The change according to an increase in the amount of the irradiation appears only to nitrogen. It is expected that the improvement of hardness is brought about by uniting nitrogen and the carbon having increased as well as PMMA from the above-mentioned result.

<3･4> chemical structure

From the hardness improvement are brought about the introduction of the combination including charcoal element and nitrogen. However, it is very difficult to analyze the PMMA surface of the nm order. Bond state of PMMA can be forecast from the connection state of HOPG because it is expected that connection state of PMMA and HOPG after the ion irradiation is similar. Then, the result of analyzing combined state of HOPG by the Raman spectrum analysis method is shown in Figure 7.

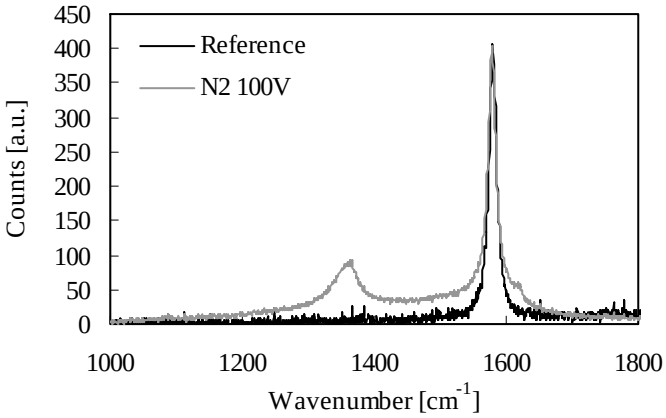

Fig.7 Raman Spectra (HOPG)

D band in the vicinity of 1360cm^{-1} and G band in the vicinity of 1580cm^{-} show the sp2 bonding and the sp^3 bonding the carbons respectively. The resalts showed that the sp^3 bonding of C-N was detected.

It is clear that the sp3 bonding of C-C and C-N is generated to HOPG by the nitrogen ion irradiation. Based on the above result, It is expected that there is a possibility that the sp3 bonding of C-C and C-N is generated also in PMMA, and hardness increases from this.

4. Conclusions

The hardness of, PMMA by nitrogen ion irradiation increased about three times hardness compared with untreated PMMA. Chemical bonding of C and N is chiefly related to the improvement of hardness. It is expected that the improvement of the hardness of PMMA by which nitrogen ion irradiation is due to the formation of the sp^3 structure of C-C and C-N, because the sp^3 structure of C-C and C-N was formed on the HOPG surface by nitrogen ion irradiation.

Effect of crosslinking structure on Modified PMMA by using Low Energy Ion Irradiation

E. Hatsugai, M. Arai, T. Iwao, N. Hamamura, M. Yumoto
(Musashi Institute of Technology, Japan)

Abstract

The surface modification of PMMA was done by using low energy ion irradiation. It is known that an irradiation of low energy ions for surface modification forms a thin modified layer of several nm with a crosslink formation. In this paper, the effect of the crosslinking structure on diffusion prevention of the dyeing molecule in modified layer is analyzed. The dyeing agent of PMMA was used to evaluate an amount of the penetration in by the diffusion in the modified layer. If the crosslinking structure is formed by the surface modification, the diffusion of a dyeing agent should be prevented. Ion dose or ion accelerating voltage is changed, and correlation of crosslinking layer and experimental condition is analyzed quantitatively by measuring transmittance or absorbance as a difference of amount of diffusion of dyeing agent. In this paper, the relation between crosslinking structure and diffusion control of molecule is clarified from these results.

1. Introduction

Polymer materials have many excellent properties in the field of the optoelectronics such as a high mass production, a lightweight, a low price and a high transparency. Especially, PMMA (poly-methyl-methacrylate) which has a high transmittance is used in various fields such as an optical fiber and an optical lens. However, it has a low wear-resistance, and its surface gets small cracks easily and the transparency decreases. Therefore, an improvement of a low wear-resistant is required.

It is well-known that formation of the crosslinking structure at the surface is effective for an improvement of a wear-resistance [1]. On the other hand, to give a wide range refractive-index distribution in an optical waveguide, some dopants are dispersed in the waveguide. In this case formation of crosslinking structure is useful for preventing the diffusion of dopant. Thus, the various functions can be obtained by formation of crosslinking structure at the surface.

An irradiation of low energy ions for surface modification is expected to obtain a thin modified layer of several nm with a crosslink formation [2][3]. If the crosslinking structure is formed in the sample surface by carrying out ion the irradiation, the surface becomes stable chemically and it is possible to be hard to melt to a solvent. Actually, when the solvent was dropped, it was shown that there were few amounts of the dissolution [4].

In this paper, the effect of the crosslinking structure on diffusion prevention of the molecule in modified layer is analyzed. The dyeing agent of PMMA was used in order to evaluate the quantitatively. If the crosslinking structure is formed by the surface modification, invasion of a dyeing agent should be prevented. Then, the correlation of a crosslinking layer and processing conditions was quantitatively analyzed by measuring the difference in the transmissivity of light when changing the ion energy. In this paper, the relation between crosslinking structure and diffusion control of molecule is clarified from these results.

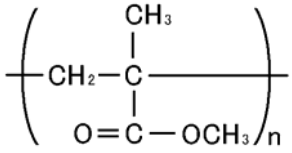

Fig. 1: Molecular structure of PMMA

2. Experiment

2.1 Experimental setup

Processing system is shown in figure 2. Before the irradiation, the chamber was evacuated to less than 1.3×10^{-4}Pa.The gas was commercial nitrogen. Under the pressure at 1.3×10^{-2}Pa, the irradiation was carried out. The ion dose was 1.0×10^{-16}ions/cm^{-2} in which nitrogen concentration of the sample shows saturation. Ion accelerating voltage was 100 and 1000V. The sample was a commercial PMMA film of 0.2mm in thickness.

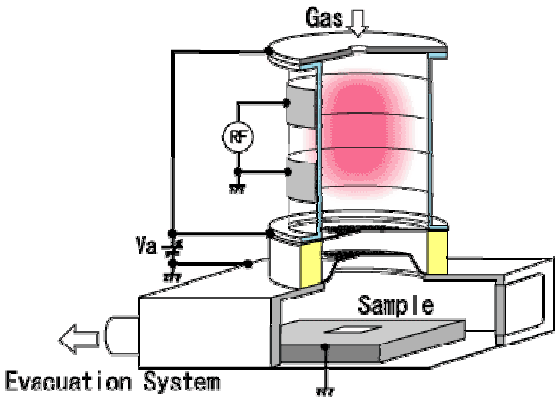

Fig. 2: Processing system

2.2 Transmittance measurement procedure of untreated sample when dyeing time is changed

Dye was diluted to 5% with the aqua pura, and was warmed up to 70 degrees C. Untreated sample was dipped 15min, 30min, and 60min in the dyeing agent. After dyes, the sample was cleaned by an ultrasonic way in an aqua pure bath for ten minutes and was dried up. After that, transmittance and the absorbance were measured.

2.3 Transmittance measurement procedure of treated sample when ion accelerating voltage is changed

The surface processed both sides respectively by ion acceleration voltage 100V and 1kV. Dye is diluted to 5% with the aqua pura, and it warms it to 70 degrees C. Treated sample dyed green leaving 60min in the dyeing agent. After dyes, the sample was cleaned by an ultrasonic way in an aqua pure bath for ten minutes and was dried up. After that, transmittance was measured.

3. Result and discussion

3.1 Transmittance measurement result of untreated sample when dyeing time is changed

Measurement result of transmittance is shown in figure 3, measurement result of absorbance is shown in figure 4, and absorbance area at each processing time is shown in figure 5. The relation between absorbance:A and transmittance:T is $A=\log_{10}1/T$. Transmittance is large in green wavelength area for 460nm to 570nm as shown Fig.3. There is absorption in the wavelength areas other than green (Fig.4). The absorbance area grows depending on the dye time (Fig.5). The results show that the dyeing agent diffuses in to the sample as time passes.

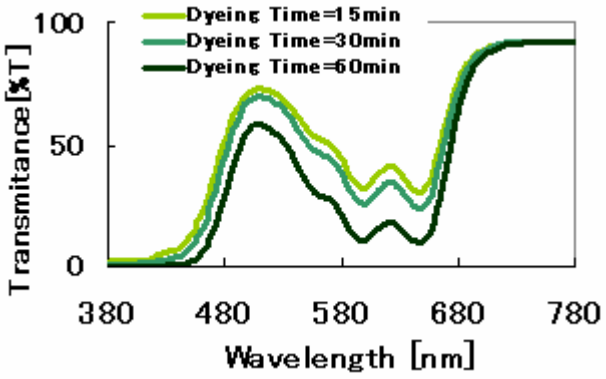

Fig. 3: Transmittance (Sample: Uuntreated, Dyeing time [min] = 15, 30, 60)

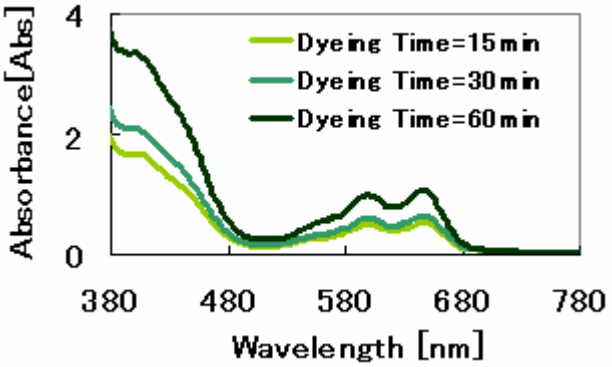

Fig. 4: Absorbance (Sample: Uuntreated, Dyeing time [min] = 15, 30, 60)

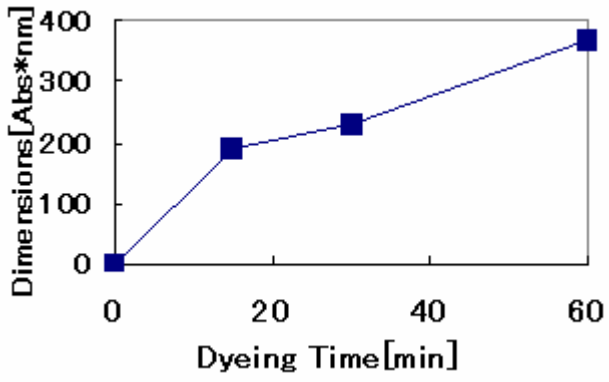

Fig. 5: Integral of Absorbance

Here, the result is dominated by a diffusion phenomenon assuming one-dimensional. Thus the diffusion of the dyeing agent follows diffusion equation shown by equation (1).

$$\frac{\partial u}{\partial t} = D\frac{\partial^2 u}{\partial x^2} \qquad (1)$$

u: Concentration of dyeing agent, *D*: diffusion coefficient, *t*: time, *x*: distance

The one-dimensional solution of the diffusion equation is an equation (2).

$$u(x,t) = \frac{1}{\sqrt{4\pi Dt}}\exp\left(\frac{-x^2}{4Dt}\right) \qquad (2)$$

Then, equation (1) was assumed D=1, t=15, 30, and 60, and calculated. Figure 6 shows the result. Moreover, the calculation result of equation (3) is shown in figure 7.

$$U = \int_0^{\infty} \frac{1}{\sqrt{4\pi Dt}}\exp\left(\frac{-x^2}{4Dt}\right)dx \quad (3)$$

It is understood that the concentration area increases depending on the dye time (Fig. 7).

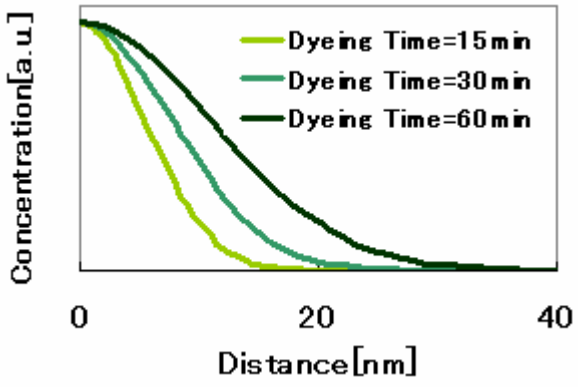

Fig. 6: Solution of Diffusion Equation (T = 15, 30, and 60, D = 1)

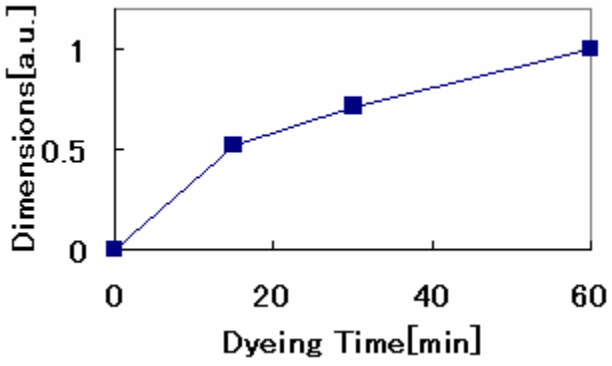

Fig. 7: Concentration area

3.3 Transmittance measurement result of treated sample when ion accelerating voltage is changed

If the crosslinking structure is formed by the surface modification, diffusion of a dyeing agent should be prevented. Then, the difference of the transmittance when the ion accelerating voltage was changed was measured. Figure 8 shows the ratio of the transmittance of dyed sample and sample not dyed by processing it under the same condition. Moreover, the absorbance is shown in Figure 9. Figure 10 shows the result of the change in the absorbance area when the accelerating voltage is changed. Transmittance increased when the ion acceleration energy raised (Fig.8). In a word, when the ion accelerating voltage rises, it is shown that the amount of the invasion of the dyeing agent is a little (Fig.9). Absorbance of treated sample with the ion accelerating voltage 1000V as compared with 100V is about 1/10 decreased (Fig.10).

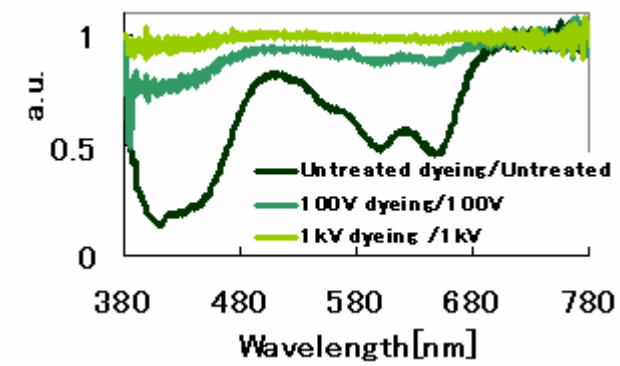

Fig. 8: Transmittance (Sample: Treated Ion energy [V] = 0, 100, 1000)

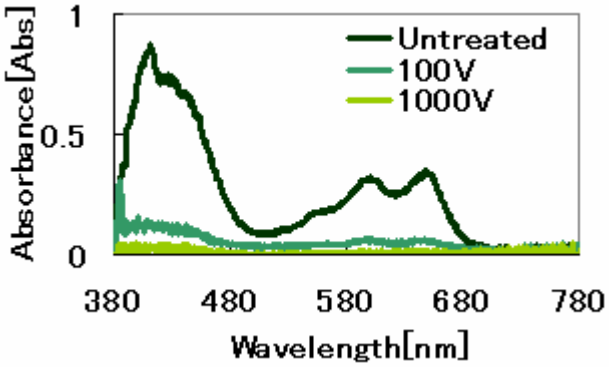

Fig. 9: Absorbance (Sample: Treated, Ion energy [V] = 0, 100, 1000)

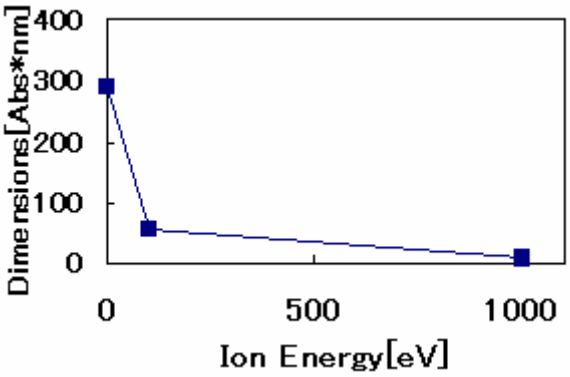

Fig. 10: Dimensions of Absorbance

This phenomenon follows the diffusion equation as mentioned above. Here, it is thought that modified layer and bulk have changed because of formation of crosslinking layer on the surface. From the result of projected range, the invasion depth of nitrogen is 1.2nm in 100V, 5.6nm in 1000kV respectively. It is assumed that the diffusion coefficient of surface 1.2nm and 5.6nm is approximately 1/10, 1/30, and 1/100 of the bulk, and calculated the diffusion equation (1). Figure 11 shows the result. Figure 12 shows each concentration area. When the diffusion coefficient of surface 1.2nm is 1/10, 1/30, and 1/100 of the bulk, the concentration area decreases about 17%, 47%, 87% respectively (Fig. 12). When the diffusion coefficient of surface 5.6nm is 1/10, 1/30, and 1/100 of the bulk, the concentration area decreases about 68%, 81%, 89% respectively (Fig. 12). Difference of amount of invasion was able to be detected as a difference, when there was one digit difference of the diffusion coefficient, if the thickness of the modified layer is only 0-6nm (Fig. 11).

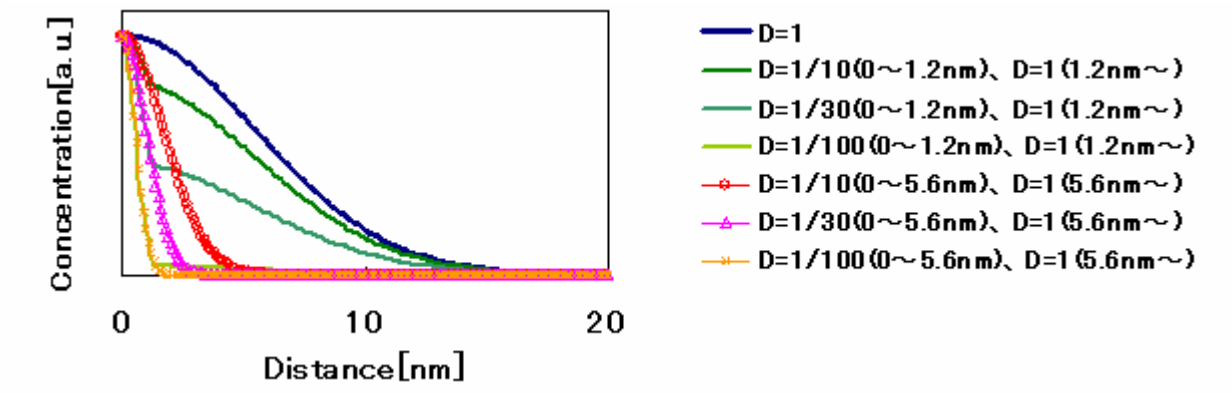

Fig.11: Solution of Diffusion Equation (T = 1, D= 1, 1/10, 1/30, 1/100)

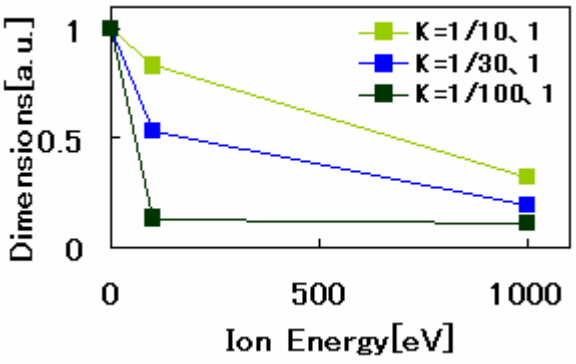

Fig.12: Concentration area

Here, the cross section of surface by ion irradiation was modeled as shown in figure 13. The crosslinking structure was formed thickly since the ion with high energy penetrated deep in to the sample. According, it is thought that the dyeing agent was prevented from diffusing. The crosslinking structure was formed thinly since the ion with low energy penetrated shallow, it is thought that the dyeing agent come through the crosslonking structure and diffuses to the bulk.

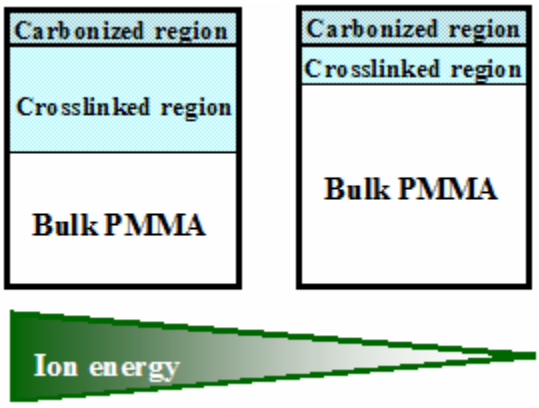

Fig. 13: Cross-sectional model

Conclusion

The surface modification of PMMA was done by using low energy ion irradiation. An irradiation of low energy ions for surface modification is expected to obtain a thin modified layer of several nm with a crosslink formation. In this paper, the effect of the crosslinking structure on diffusion prevention of the molecule in modified layer was analyzed. The dyeing agent of PMMA was used to evaluate an amount of diffusion in the modified layer. As a result, the absorbance decreases by 80%, 97% with irradiating the nitrogen ion of 100eV, 1000eV compared with the untreated. Difference of amount of invasion was able to be detected as a difference, when there was one digit difference of the diffusion coefficient, if the thickness of the modified layer is only 0-6nm.

Refractive index control of polymer thin film by using plasma enhanced polymerization

Tetsuji Sato, Kazunori Moriki, Motoshige Yumoto

Musashi Institute of Technology, Tokyo, Japan

Abstract

The polymer waveguide was fabricated by using plasma enhanced polymerization for refractive index control. Because the single-mode optical waveguide of specific refractive index difference becomes pretty large such as about 4.6 percent currently, there is a problem with bad optical coupling efficiency when light is coupled from the optical fiber to the waveguide. It is necessary to reduce the specific refractive index difference to improve the optical coupling efficiency. It aimed to examine whether the refractive index control of one small digit was possible in this research to improve the optical coupling efficiency with the optical fiber now. From the result, it has been understood to be able to reduce the specific refractive index difference by one digit.

1. Introduction

A silica (SiO_2-GeO_2) thin film that deposited on the silicone substrate by using the flame hydrolyzing method is used for an optical coupler and an optical splitter, etc. that are the optical devices for wavelength division multiplexing communications, currently. It is necessary to heat-treat it by a thousand and several hundreds K in order to make this deposited thin film transparent. This fabrication of the optical functionality device mixed with other materials difficultly. On the other hand, the low-cost polymer waveguide can be fabricated by the solvent evaporating easily after spreading the dissolved polymer by using the spin court method. Moreover, because it is also possible to disperse a nonlinear optical low molecule etc., it is used to make an optical switch and wavelength conversion of the optical functionality device etc. However, the form of the film thickness control with high accuracy and a steep boundary with the different kind material thin film is difficult in the spin court method. Therefore, the development of the polymer thin film form technology by a dry process is hoped.

The benzene of monomer for the core layer and the cyclohexene for the clad layer are confirmed to be able to fabricate the single-mode waveguide of 0.6 micrometers in core diameter by previous researches. Because the core diameter of waveguide becomes very small at 0.6 micrometers, in the case of coupling the light between the optical fiber and the optical functionality element, it is necessary to improve the coupling efficiency. As for the fiber-optic communication, the single-mode fiber of about 9 micrometers in core diameter is used generally. It is necessary to fabricate the waveguide with the core of the film thickness at the same level in order to improve the coupling efficiency. Therefore, it is necessary to adjust the specific refractive index difference between the core and clad to about 0.35 percent. The single-mode optical waveguide of specific refractive index difference becomes pretty large such as about 4.6 percent currently.

In this paper, the refractive index is controlled such as one small digit in order to improve the optical coupling efficiency with the optical fiber. Then, the ratio of double bond in the formed film was changed by controlling the ratio of benzene and cyclohexene of the monomer material, and it was tried to control the

refractive index. Moreover, the ratio of fluorine in the film formed was changed by controlling the ratio of Ar and CF_4 of atmospheric gas, and it was tried to control the refractive index.

2. Experiment

Figure 1 shows pattern diagrams of plasma CVD experiment. The pyrex glass of 200 mm in the diameter was used for a reactive room. After the oxide film on the surface of the silicon substrate of 10 mm × 10 mm had been removed, it is put on the earth electrode of a parallel plate electrode of the electrode distance 100 mm in the diameter 35 mm. It was made to evaporate at the room temperature by using benzene and cyclohexene of the material, and they were introduced into the reactive jurisdiction throughtheflow meter. Moreover, Ar and CF_4 of the atmosphericgas were introduced in a reactive tube different from the material monomer.

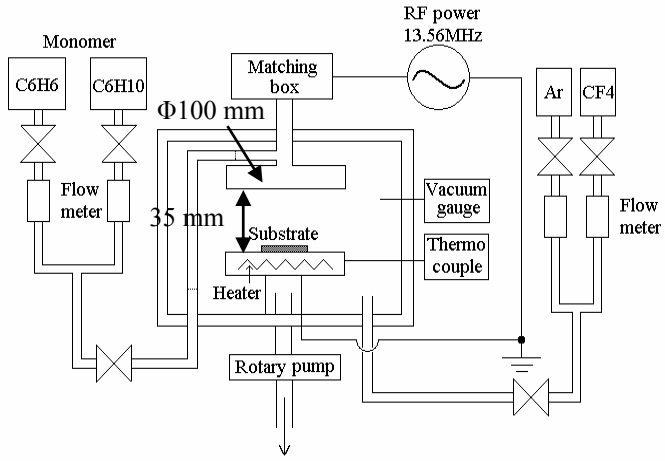

Fig.1 Schematic view of plasma enhanced polymerization equipment

The substrate was heated and to temperature was set at 373 K, because it is prevented from remain unreacted monomer in the polymer film. However, when the a-C:H thin film is heated to 573 K or more, it is reported to do CH_4 and H desorption [1]. Moreover, it is reported that it is necessary to reduce impressed electric powers up to about 0.01 W/cm^2, in order to suppress the generation of dangling-bond caused by desorption of hydrogen, and to obtain the polymer state thin film [2]. Therefore, an applied electric power was to be 1W. In addition, the pressure in the chamber was to be 0.3 and 0.4 in the case of Ar and CF_4, respectively, because it is reported that in there is no change the ratio of $C_4H_2^+/C_4H_3^+$ and $C_6H_6^+/C_6H_5CH{=}CH_2^+$ within the range of pressure from 0.3 to 0.65 Torr in the case of making the styrene into a monomer material, changing pressure, the RF electric power and analyzing mass spectrometry in the chamber [3].

As valuation method, the refractive index of formed thin film is measured by using spectrum ellipsometer and the structure of the thin film was evaluated by using FT-IR and XPS.

3. Results and discussion

3. 1 Refractive index control by changing the benzene and cyclohexene of material mixture gas

The refractive index of deposited thin film was measured from 600-1600 nm by using the spectroscopic ellipsometer. The refractive index in the case of 800 and 1300 nm is shown in Figure 2. The refractive

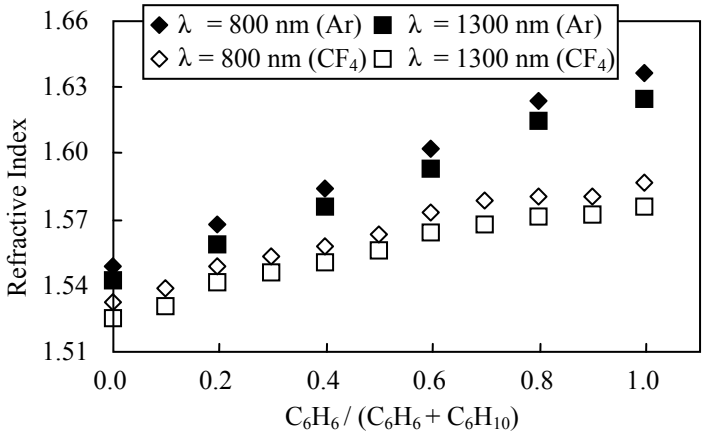

Fig.2 Refractive index change in each wavelength

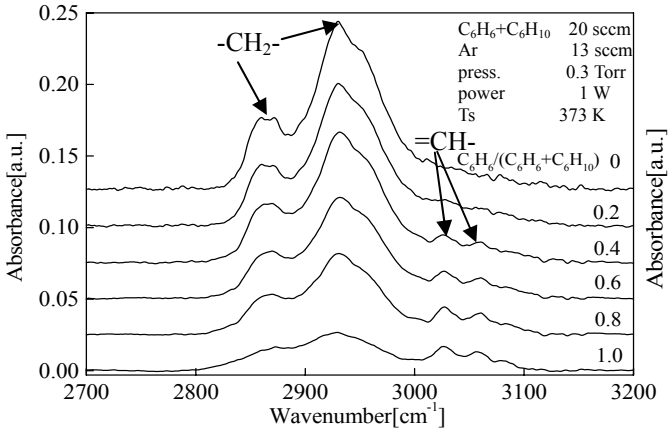

Fig.3 FT-IR spectrum of polymerization film on Si at Ar

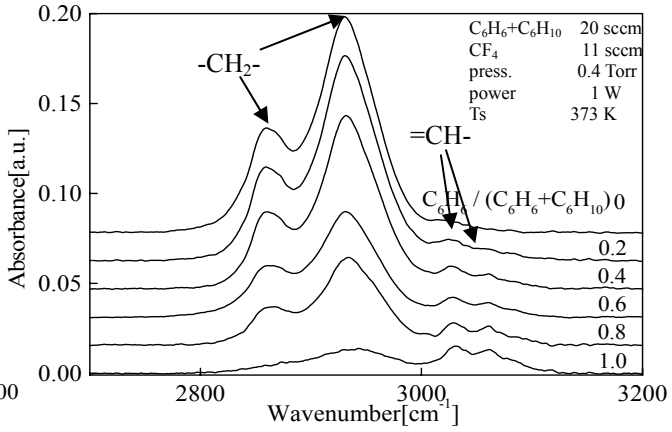

Fig.4 FT-IR spectrum of polymerization film on Si at CF_4

index increases in proportion to the mixture ratio of benzene. This slope of Ar and CF_4 becomes 0.09 and 0.05, respectively. Therefore, it is possible to make the specific refractive index difference between the core and clad below 0.5 percent, because the difference of mixture ratio between them becomes 0.07 (Ar) or 0.14 (CF_4).

Figure 3 shows the FT-IR spectrum of the thin film formed in the Ar atmospheric gas. Figure 4 shows the FT-IR spectrum of the thin film formed in the CF_4 atmospheric gas. The 2860 and 2924 cm^{-1} of wavenumbers indicate an infrared absorption spectrum of the CH stretching vibration that originates in the sp^3 (CH_2) bond. The 3030 and 3060 cm^{-1} of it indicate an infrared absorption spectrum of the CH stretching vibration that originates in the sp^2 (CH) bond [4]. The infrared absorption with CH stretching vibration of the sp^3 (CH_2) bond was compared with it of the sp^2 (CH) bond. When the mixture ratio of benzene increases, the sp^2 bond increases. The refractive index depends on the ratio of sp^2 and sp^3 in a thin film. In fact, the amount of the double bond can be controlled.

3. 2 Refractive index control by changing Ar and CF_4 of atmospheric mixture gas

Figure 5 shows the refractive index change in the formed thin film. The refractive index decreases by increasing the mixture ratio of CF_4. A decrease in the refractive index examined whether it was the one by what influence by using the XPS measurement.

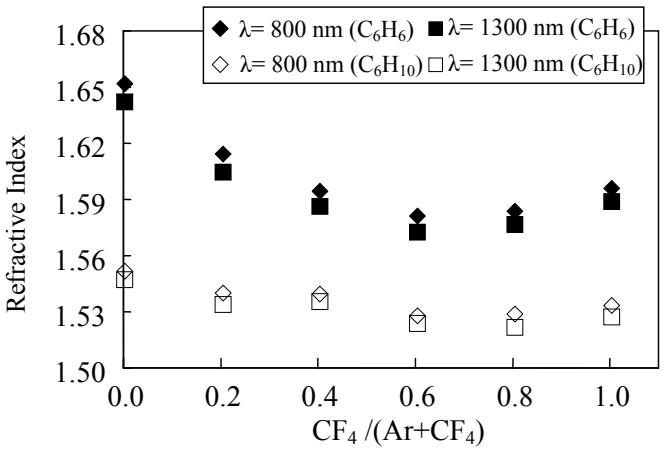

Fig.5 Refractive index change in each wavelength

The amount of the introduction of the fluorine when benzene and cyclohexene of the material gas are used is shown in Figure 6 and the C1s spectrum is shown in Figure 7. The amount of the introduction of fluorine increases rapidly between from 0 to 0.2 of mixtures ratio of CF_4. The amount of the introduction of fluorine becomes constancy at 0.2 or more. The mixture ratio of CF4 becomes 0.2, a small amount of fluorine entering from Figure 7 for benzene and it is thought that the

structure has CF (aromatic), CF, and CF_2 [5][6]. Moreover, the film from which the shake up peak was seen was made. These structures might be not change with fluorine at 0.2 or more. The mixture ratio of CF_4 is 0.2 for cyclohexene and it is thought that the structure has CHF, CF, and CF_2. Moreover, the shake up peak was not seen. These structures might be not change with fluorine at 0.2 or more. It is thought that the mixture ratio of Ar and CF_4 is changed as a result, and the structure doesn't change with fluorine. It is thought that the refractive index decreased by the difference of the amount of the introduction of fluorine.

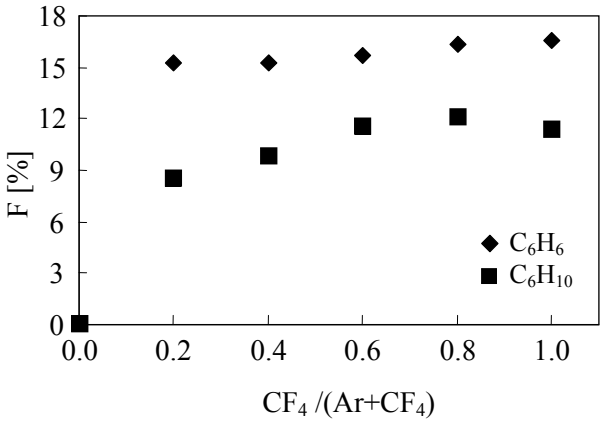

Fig.6 Introduction amount change in fluorine

Therefore, it is possible to make the specific refractive index difference between the core and clad below 0.35 percent, because the difference of mixture ratio between them becomes 0.05 (benzene) or 0.15 (cyclohexene).

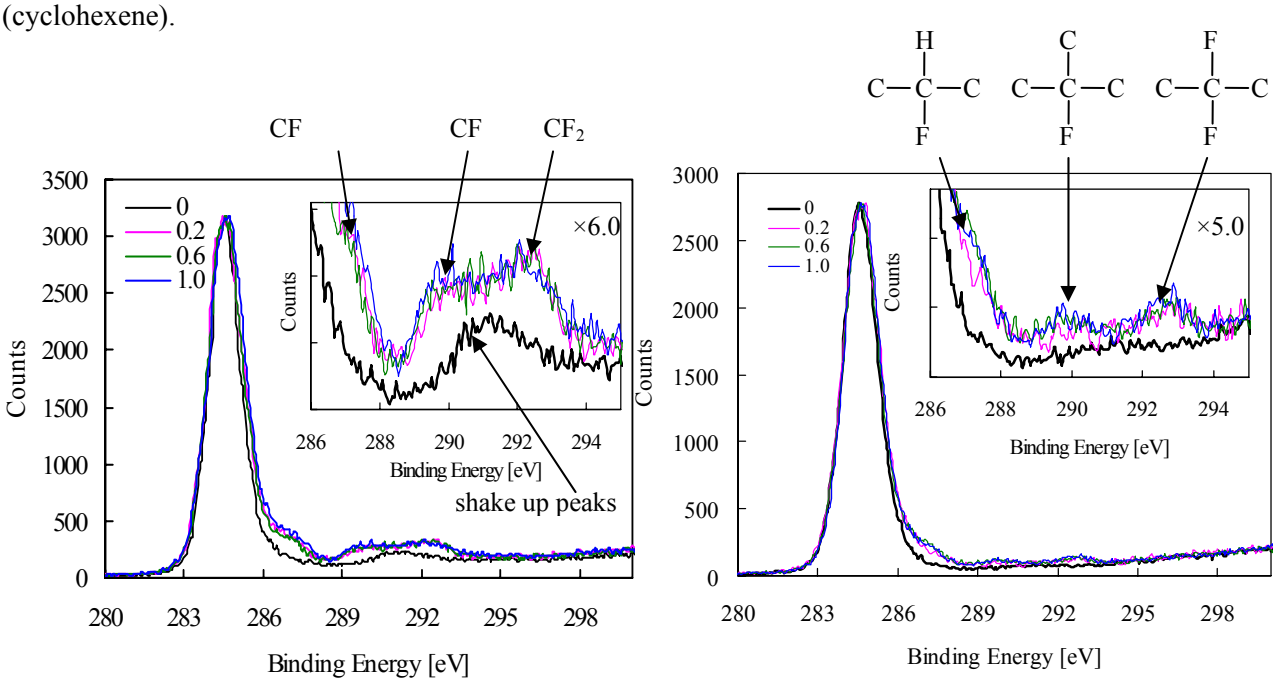

Fig.7 C1s spectrum

4. Conclusion

The refractive index clarified the straight change into the mixture ratio by changing the ratio of the sp^2 bond and the sp^3 bond by changing the mixture ratio of material benzene and cyclohexene. It is possible to make the specific refractive index difference between the core and clad below 0.5 percent, because the difference of mixture ratio between them becomes 0.07 (Ar) or 0.14 (CF_4). The single-mode waveguide of the core diameter 5 micrometer core can be formed with the specific refractive index difference below 0.5 percent.

Abstract
We present the pulsed dc magnetron sputtering method in which a nickel target is sputtered in a mixture of argon and reactive gas oxygen. The flow rate of oxygen is modulated periodically in time and during deposition when oxygen flows is cut off to remove the oxide formed on the target. Modulated deposition process was monitored directly by optical emission spectroscopy, the deposition rate and partial pressure measurement. The variations of atomic ratio in NiO films were revealed by SIMS method.
Keywords: reactive magnetron sputtering, gas flow modulation, nickel oxide, SIMS

1. Introduction

Magnetron discharges in reactive gases are currently used for deposition of compound films. Reactive magnetron deposition can be used for oxides deposition, but it is a complex process, the kinetics of which occur in several stages: transport of gas into the reaction zone [1], conversion of molecules into active states (ionization, dissociation, excitation, etc. [2]), transport of active particles towards the surfaces (target, substrate and chamber walls), their interaction with surfaces [3] and the removal by pumping from the chamber of the resultant products. Behavior of process and thin film properties will be affected then by extension of each stage. Moreover, the overall process is reactive (reactive gas is nitrogen, inert gas is argon), and thus to a great extent non-linear and show hysteresis in the process parameters. Thus the gas flow conditions and final composition of the gas mixture can play a significant role in these processes. Reactive magnetron discharge regime can be unstable due to the relation between the sputtering and the consumption of oxygen either by the target or by the deposited film. Generally reactive sputtering with metal target is often faced with the following difficulties. One is reduction of deposition rate due to the presence of reactive gases. The other is formation of a compound at the target surface caused by a reaction with induced gas. The second phenomena are called poisoning of the target and sometimes cause poor reproducibility of film formation. In reactive sputtering it may be possible to obtain the desired compound composition with several different combination of processing parameters [4]. It is therefore very important to be able to individually control these parameters [5]. Modulation of the flow modulation of oxygen was investigated as a possible method of enhancing the deposition process when preparation oxide and nitride films [6-8]. The flow rate of oxygen is modulated periodically in time and during deposition when oxygen flows is cut off to remove the oxide formed on the target [9-11].

Here we present the pulsed dc magnetron sputtering method in which a nickel target is sputtered in a mixture of argon and reactive oxygen gas. The mass flow rate of oxygen is modulated in the fashion of a rectangular wave function. The influence of the oxygen flow rate on the deposition rate, the target potential and the Ni/O ratios in NiO thin films are investigated.

2. Experimental

The experiments were carried out in the experimental apparatus which contained of a dc custom-built magnetron sputtering source with a Ni target. Measurements of flow conditions were realized at constant total pressure of the working mixture and its value was 0.5 Pa. The flow rate of oxygen was modulated periodically in time (Fig.

2). During the first period, the oxygen flow was on for 45 s and in the second period, O_2 flow was cut off (5 s). A constant pulse period of T=50 s was used. The oxygen mass flow rates were 10, 30 and 50 sccm, respectively, during t_{on}=45 s, whereas the injection of oxygen was completely stopped during t_{off}=5 s. In this study, the rectangular wave function has been used because it appears as the simplest of the possible flow modulations. The discharge power was maintained at 600 W.

The light emitted from discharge was collected from a certain point near the target by two UV lenses and 1 mm aperture (mounted in between) onto the entrance slit 0.3 m monochromator Bentham M300E. A photomultiplier Hamatsu R955 was mounted just behind the exit slit of the monochromator. The photomultiplier signal was sent to current supply, then to analogue-digital converter and the spectra stored on a microcomputer. This optical system was mounted upon a vertically moving table, which enables us to observe the emitted light from plasma along the target. The spectral range between 300 and 900 nm was investigated. In order to study the influence of oxygen flow 10, 30 and 50 sccm, respectively, on the OES spectra we selected Ni (352.4 nm), Ar (751.4 nm) and O (777.0 mm) lines on which to focus. Partial pressure measurements were realized at the constant values of pumping speed and of chamber volume by a capacitance manometer (MKS Baratron). The changes of deposition rates ware monitored by a thin film thickness and deposition rate monitor (Inficon) with a quartz crystal sensor head. A quadrupole SIMS instrument Physical Electronics PHI ADEPT 1010 with primary ion beam Cs^+ was used to depth compositional analysis of NiO films prepared by this process.

3. Results and discussion

In our previous study we defined the sputtering modes for the continuous addition of oxygen at NiO deposition [11]. The oxygen flow rates we used here were based on these results. The conditions of the oxygen flow rates and period were respectively 10 sccm and 50 s, 30 sccm and 50 s, 50 sccm and 50 s. The first condition corresponds to the experimentally observed condition for the metal-sputtering mode while the two other conditions are valid for the oxide-sputtering mode for the continuous addition of oxygen.

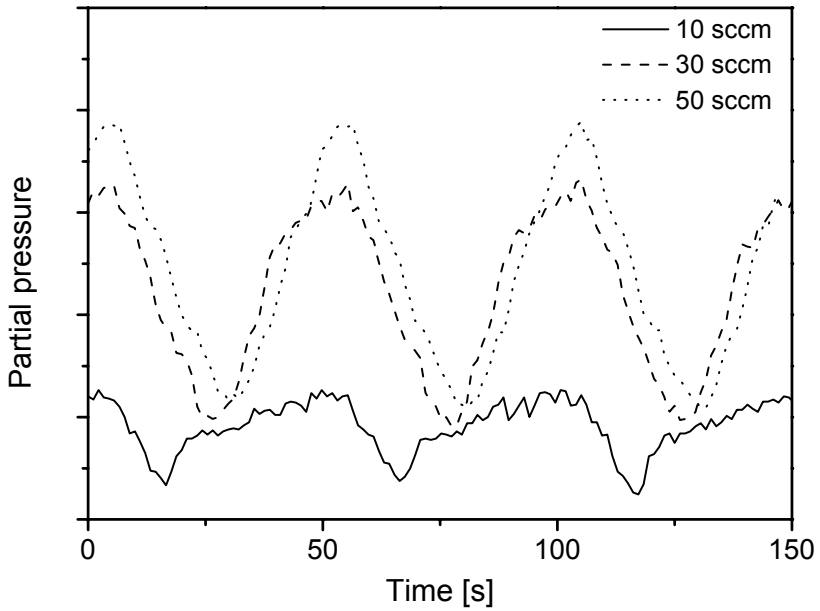

Fig. 1: Oxygen partial pressure in the deposition chamber during an oxygen-on and oxygen-off period.

The partial pressure measurements were realized at constant values of pumping speed and of chamber volume without the plasma. Fig. 1 shows the change of the partial pressure of oxygen during an oxygen-on and oxygen-off period for various oxygen flows. The time for the increase and decrease of the partial pressure is determined

by pumping speed, chamber volume and oxygen flow. Using the modulation unit we controlled the oxygen flow and this lead to an oscillating oxygen concentration during the sputtering process. When the oxygen flow is cut off, the partial pressure will be decreased and the decrease in the partial pressure will enhance the deposition rate. This can be explained by an increased pumping speed resulting from gettering of oxygen by continuously deposited nickel.

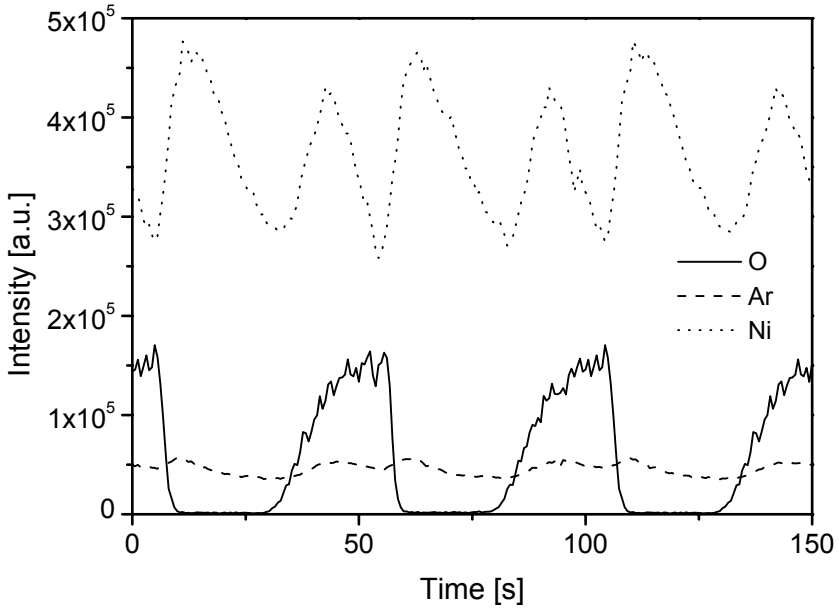

Fig. 2: Time dependencies of OES signals of nickel, oxygen and argon for periodic oxygen addition 50 sccm.

OES yields interesting information on excited species, atoms, molecules and radicals present in the plasma as well as qualitative variations of these species with respect to the discharge conditions. The corresponding variations of the intensities of Ni (352.4 nm), O (777.0 nm) and Ar (751.4 nm) lines against the oxygen flow rate are given in Fig. 2. We note that the changes are due to the oxygen modulation and they reflect the coverage of the target. During the oxygen-off period the peak intensity from Ni line rapidly increases while the oxygen OES signal indicating the concentration of excited oxygen molecules in the plasma decreases.

The variations of the deposition rate and real time measurements of the nickel target potential for the periodic oxygen addition were recorded (Fig. 3). The maximum NiO deposition rate was observed for 10 sccm oxygen flow and its value is almost constant. We suppose that this deposition process remains predominantly in the metal-sputtering mode, because the Ni target potential exhibits weak changes from 430 to 445 V. The poisoning compound layer on the surface of the target is thin enough and partially formed to rapidly restore the process in metal-sputtering mode. For 30 and 50 sccm oxygen flow rate, respectively, the poisoning compound layer is thicker and the oxidized surface expands. Sputtering yield is reduced as well as the deposition rate. The metal-sputtering mode cannot achieve and is vanished under the oxide-sputtering mode. In the oxide-sputtering mode the poisoning of the target becomes serious because of the higher secondary electron emission coefficient of the oxide compared to that of pure metal, the total number of electrons near the target increases and hence a higher target current can be achieved at lower voltage. Therefore, it can be seen that the target potential changes in the range from 318 to 385 V but the characteristic values for the metal-sputtering mode were not reached. This conclusion is in agreement with the partial pressure measurements when we observe the higher values that are characteristic for metal-sputtering mode.

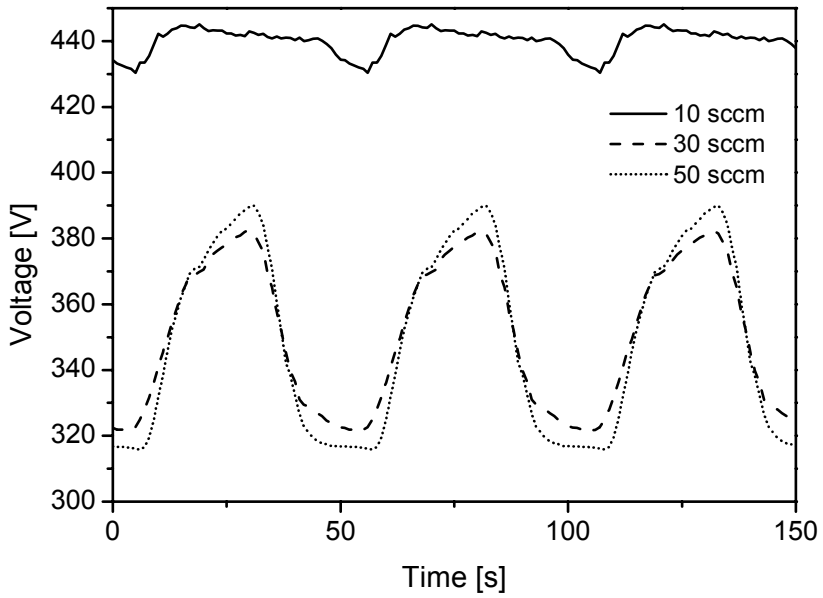

Fig. 3: Real time measurements of nickel target potential for periodic oxygen addition.

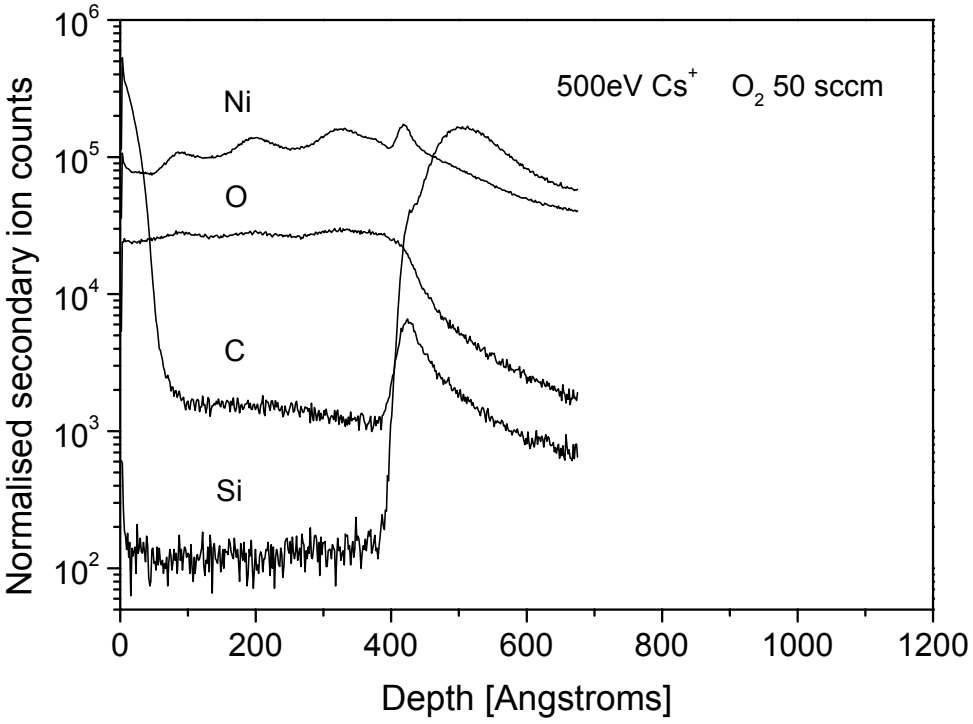

Fig. 4: SIMS depth profile taken from NiO film prepared at 50 sccm oxygen flow.

Some samples on silicon substrates have been deposited by repeated oxygen-on and oxygen-off cycles during three periods. In the case of the sample prepared at 10 sccm oxygen flow rate the SIMS depth profiling shows that the composition of the layer is essentially invariant with depth and the level of Ni and O are not practically affected by periodic oxygen addition. On the other hand, SIMS measurements from samples prepared at 30 and 50 sccm oxygen flow rate clearly record the oscillation of Ni and O in the depth profile (Fig. 4). Then, the

behavior of the Ni target potential changes not only the deposition rate but also the composition and variations of Ni/O atomic ratios in NiO films. We conclude that in order to get a higher NiO deposition rate in the oxide-sputtering mode, pulsing of the oxygen flow rate is a suitable method. The enhancement of the deposition rate is caused by processes on the target during removal of oxide compounds from its surface. It was found that the oxygen concentration strongly increases immediately when the O_2 flow is cut off. Then, pulsing of oxygen affects the NiO growth process and chemical composition of the films.

4. Conclusion

A controlled pulsing of the oxygen flow rate has been investigated for reactive magnetron deposition of nickel oxide thin films. A sputtering process to enhance and change the deposition rate and the target potential of NiO in the reactive magnetron system was proposed using flow modulation of oxygen. This pulsing method can modify and control the properties of the films and suppress the instabilities in the reactive sputtering. By this process thin NiO films with the different Ni/O ratios can be deposited alternatively and the multilayered film results.

Deposition of SnO_2 nanostructured thin films by PECVD : role of the excited O_2 species on the film properties

J. Pulpytel, M. Jubault, W. Morscheidt, J. Amouroux, F.Arefi-Khonsari

Laboratoire de Génie des procédés Plasmas, ENSCP-Université Pierre et Marie Curie Paris VI, Paris, France

Abstract

Nanostructured tin oxide thin films were fabricated by a PECVD process. The threshold ionization technique (TIMS) was used to measure O_2 ($^1\Delta_g$) and O_2 ($^1\Sigma_g^+$) densities during the deposition of tin oxide. The densities of these species have been correlated with the effective electron temperature and electron density determined by integration of the electron-energy-distribution-function (EEDF). Furthermore, these results have been shown to be correlated to the trend of the electronic conductivity of SnO_2 thin films.

1. Introduction

SnO_2-based materials are widely used in many fields. Among all tranparent conductive oxides (TCO), SnO_2:F is the most often used to make energy-conserving windows, due to its low emissivity ("low-e") [1]. In addition, due to the excellent properties for sensors, SnO_2 has become the most investigated material for metal oxide sensors since the first Tagushi sensors in 1970 [2]. The optical and electrical performance of a TCO depends not only on its chemical composition, but also on the method used for its preparation.

Argon/oxygen/tetramethyltin ($Sn(CH_3)_4$ or TMT) were used to deposit tin oxide films using a capacitively coupled RF 13.56 MHz reactor. The latter was composed of nanosized particles (6-10 nm) in particularly interesting for gas sensing applications [3] but also for transparent conductive coating on polymers [4].

The present paper describes mass spectrometric measurements of O_2 ($^1\Delta_g$) and O_2 ($^1\Sigma_g^+$) densities using the threshold ionization technique (TIMS) and EEDF measurements via a Langmuir probe technique. The correlation between these two diagnostic methods is investigated. The electronic conductivities of tin oxide thin films determined from four-point probe measurements was monitored as a function of certains deposition parameters and related to the relevant plasma characteristics. Morphological and structural analyses from transmission electron microscopy (TEM) are also reported.

2. Experimental

The geometry of the experimental setup for TIMS and EEDF measurements is shown in Fig. 1. A capacitively coupled discharge (CCD) was produced in a 16 cm diameter cylindrical stainless steel vessel, between two parallel plates separated by a distance of 3 cm. The shower-head powered aluminum electrode was 10 cm in diameter and the grounded stainless steel one was 3 cm in diameter. The voltage of the RF signal at the powered electrode is recorded using a Tektronix P6015 high-voltage probe and a Lecroy waverunner LT 342 oscilloscope. The system can be evacuated to a base pressure of $8x10^{-4}$ Pa ($6x10^{-6}$ Torr). Mixtures of argon/oxygen, controlled by MKS mass flow controllers (1259 B), were studied first, before introducing small quantities of TMT (0.5-2%) with a MKS vapor source mass flow controller (1150C). The total flow and the operating pressure were kept constant at 10 sccm and 15 Pa (110 mTorr) respectively.

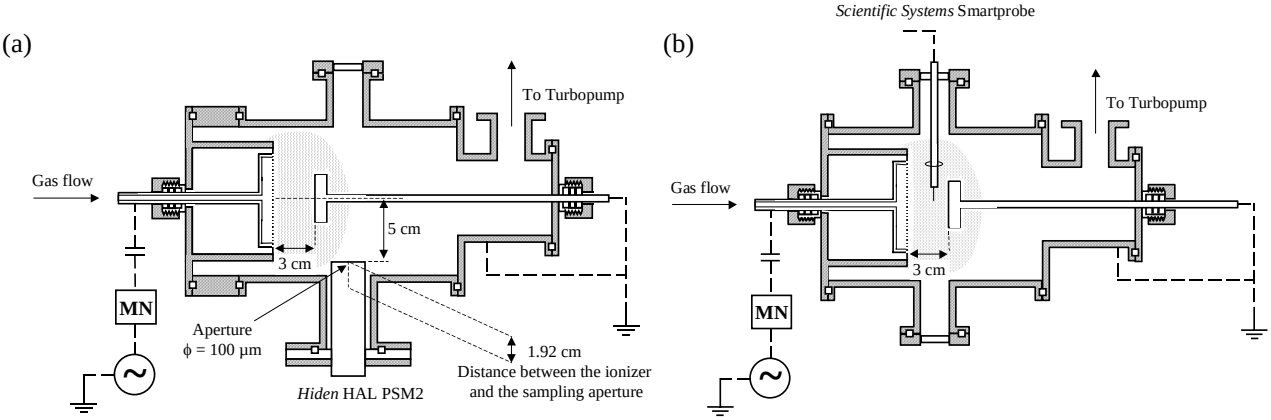

Fig. 1. (a) Schematic of the capacitively coupled plasma reactor with the singly differentially pumped mass spectrometer. (b) Schematic of the capacitively coupled plasma reactor and the Langmuir probe.

A Hiden PSM2 quadrupole mass spectrometer was mounted to detect neutral species from the plasma. The 100 µm diameter aperture was located 8 cm from the center of the plasma. The distance between the ionizer and the sampling aperture was 1.92 cm. A base pressure of 1.3×10^{-6} Pa (10^{-8} Torr) was achieved in the mass spectrometer chamber, and the operating pressure in the mass spectrometer increased up to 1.1×10^{-4} Pa (8×10^{-7} Torr) for 15 Pa (110 mTorr) in the plasma chamber. The electron energy scale was standardized by argon, the ionization energy of which is $I(Ar\ ^1S_0 \rightarrow Ar^+\ ^2P_{3/2}) = 15.8$ eV. The width in the energy distribution of the electron beam is about 0.5 eV at half-maximum.

The Langmuir probe system was a RF compensated Smartprobe from Scientific Systems. The tungsten wire (10 mm, 190 µm ϕ) was introduced in the center of the discharge, where the electron density was measured to be above 5.10^9 cm^{-3} enabling an effective auto-cleaning of the tip. Probe cleanliness was verified by the similiraty of the EEDF recorded sequentially at the same conditions.

For electrical measurements, the room temperature sheet resistance of the films was determined using the four-point probe method (Keithley 224 and 195A). A JEOL 100 CXII (100 KeV) microscope was used for TEM observations on ultrathin tin oxide thin films prepared under the conventional preparation method ; the films were mechanically polished and thinned with ionic bombardment. The TEM images were analysed with the software Visilog 5.4.

3. Measurements of O_2 ($^1\Delta_g$) and O_2 ($^1\Sigma_g^+$) densities by TIMS

Considering the mass spectrum of the figure 2, the signal on mass 32 attributed to O_2^+ is shown as a function of the energy of the electrons emitted by the filament. The ionization potential of O_2 molecules is at $E_I = 12.2$ eV. However, when the discharges were initiated, O_2^+ ions have been detected before the ground-state ionization threshold indicating a population of electronically and vibrationally excited species. The 10 % decrease in the O_2^+ intensity at high energies with "Discharge On" is probably due to the dissociation of molecular oxygen to atomic one. According to the equation (1), the density of singlet O_2 (O_2 ($^1\Delta_g$) and O_2 ($^1\Sigma_g^+$) denoted as O_2*) is obtained by [5] :

$$\frac{n_{O_2^*}^{On}}{n_{Ar}^{Off}} = \left(\frac{A^{O_2^* \rightarrow O_2^{*+}}}{A^{Ar \rightarrow Ar^+}} \right) \left(\frac{\lambda^{Ar \rightarrow Ar^+}}{\lambda^{O_2 \rightarrow O_2^{*+}}} \right) \left[\frac{\alpha(Ar^+)}{\alpha(O_2^+)} \right] \qquad (1)$$

where n_{Ar}^{Off} is the number density of Ar in the ionization chamber (plasma off), $A^{O2 \rightarrow O2^{*+}}$ and $A^{Ar \rightarrow Ar^+}$ are the slopes of the linear fits to O_2^{+*} signal and Ar^+ signal respectively. $\lambda^{O2^* \rightarrow O2^{*+}}$ and $\lambda^{Ar \rightarrow Ar^+}$ are the slopes of the linear fits of the cross sections of ionization of O_2* and Ar ionization respectively, assuming that the ionization cross sections for the molecules at corresponding excess energies were almost equal, i.e. $\lambda^{O2^* \rightarrow O2^+} \cong \lambda^{O2 \rightarrow O2^+}$. The parameter $\alpha(Y)$ is estimated to be $(m/e)^{-0.85}$ and is the Y specie m/e dependent transmission efficiency of the quadrupole mass filter and the m/e dependent detection coefficient of the detector.

This yields a density of singlet oxygen molecules between 3×10^{13} - 4×10^{14} cm^{-3} and a density ratio up to 18% of the total O_2 molecules as shown in Fig. 3.

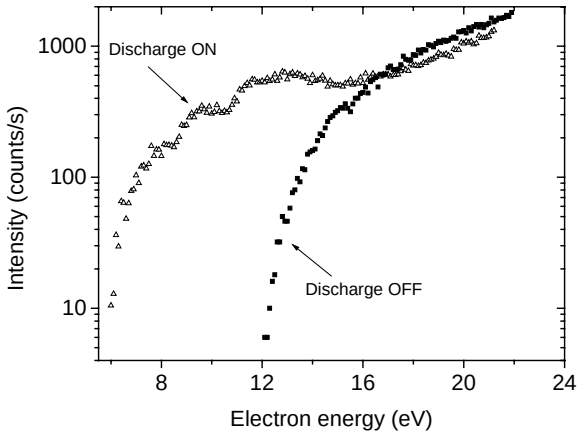

Fig. 2. TIMS with m/e = 32 for 34% Ar – 66% O_2 mixture, P = 15 Pa(110 mTorr), RF voltage = 550 V.

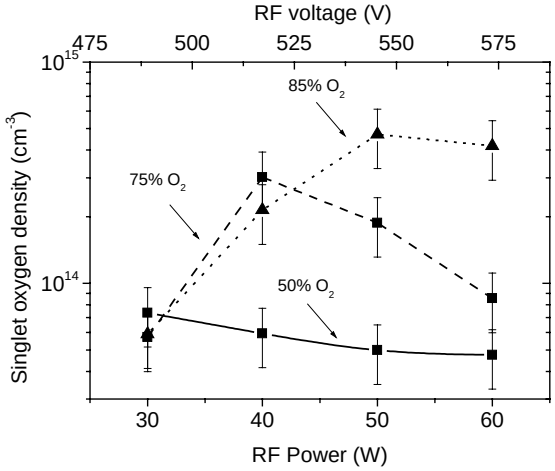

Fig. 3. Density of singlet oxygen molecules as a function of O_2 mole percentage in the feed gas.

4. Langmuir probe EEDF measurements

In our previous work [6], the EEDF or F(ε) was not reported. The electron-energy-probability-function (EEPF) or f(ε) can be determined with the Druyvesteyn formula (2) [7] :

$$f(\varepsilon) = \frac{2 \cdot I_e^{''}}{e^3 \cdot A} \cdot (2 \cdot m)^{1/2} = \frac{F(\varepsilon)}{\sqrt{\varepsilon}} \qquad (2)$$

where I_e" is the second derivative of the current, m and e are the electron mass and charge respectively, A is the probe area and ε is the probe potential with respect to the plasma potential. In our discharges, the EEPF at 15 Pa (110 mTorr) can be represented as a bi-Maxwellian with a cold-electron group having temperature T_{ec} and density n_{ec}, and a hot-electron group characterized by T_{eh} and n_{eh}. These parameters can be obtained by integration of the EEDF (3), (4) :

$$n = \int F(\varepsilon) \cdot d\varepsilon \qquad (3) \qquad T_e = \frac{2}{3} \cdot \int \varepsilon \cdot F(\varepsilon) \cdot d\varepsilon = \frac{2}{3} \cdot \langle \varepsilon \rangle \qquad (4)$$

An EEPF obtained by the probe is shown in Fig. 4. The evolution of the electron temperatures are also shown in Fig. 5.

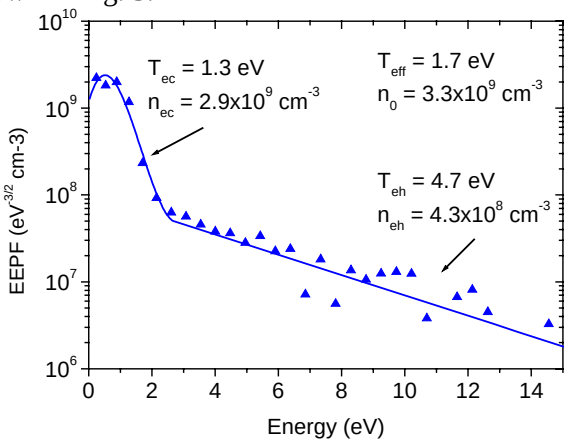

Fig. 4. The EEPF measured in an Ar(25%)/O_2(75%) discharge at 390 V and 15 Pa.

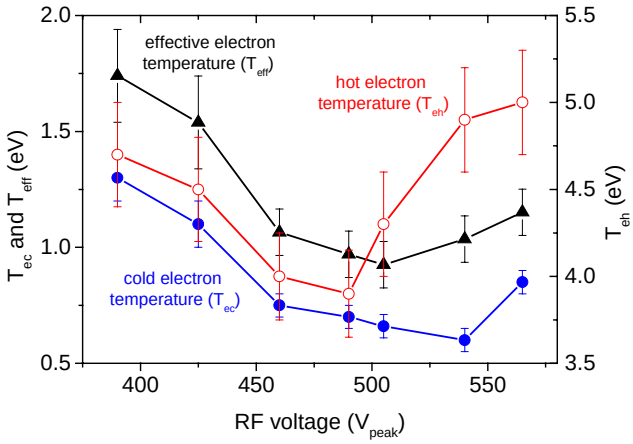

Fig. 5. Electron temperatures and effective electron temperature in an Ar(25%)/O_2(75%) discharge at 15 Pa.

5. Electrical properties of SnO_2 thin films

The sheet resistance R_s of our tin oxide films have been determined by 4-point probe measurements.
The figure 6 shows the evolution of the sheet resistance for undoped tin oxide thin films.

6. Nanostructure of SnO_2 thin films

Figure 7 shows the TEM image of a SnO_2 sample with a 100,000 magnification. The micrograph exhibits a uniform and continuous distribution of spherical nano-sized grains (6-10 nm) agglomerated . A statistical analysis of the size distribution obtained by image analysis is shown in Fig. 8.

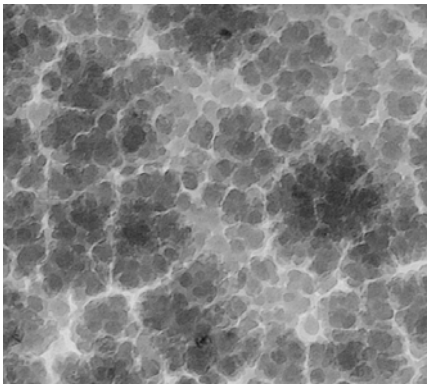

Fig. 7. Transmission electron microscopy of tin oxide nanoparticles thin films (x 100,000).

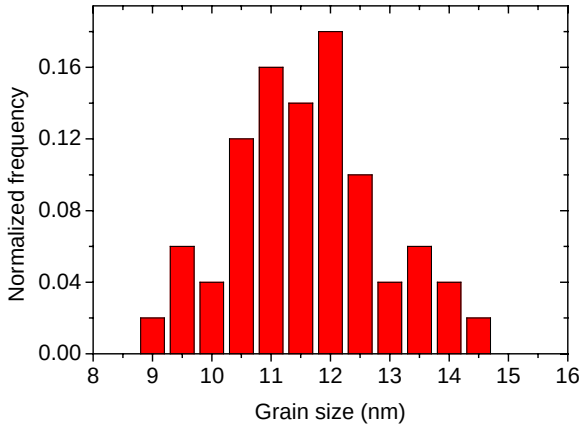

Fig. 8. Histogram of particle diameters obtained from image analysis.

7. Correlations between TIMS and Langmuir probe measurements

In what follows the results are presented in Fig. 9. On one hand, the effective electron temperature measured at low voltage is a few electron-volts (1.5-1.7 eV) with an electron density of the order of 10^9 cm^{-3}. By increasing the RF voltage, the electron temperature drops dramatically to about 0.9 eV, while the electron density rises to $2x10^{10}$ cm^{-3}. Then, the electron temperature rises again after a critical voltage denoted by V_{probe}* at 505 V. This phenomenon has been also observed in other discharges too [8]. On the other hand, the densities of singlet oxygen molecules increases up to $3x10^{14}$ cm^{-3} for a critical voltage denoted by V_{TIMS}* at 515 V, then decreases. By coupling Langmuir probe measurements with TIMS ones, one can conclude that the trend of the singlet molecular oxygen formed in the discharge is what could be expected, i.e. at 0.9 eV, where the effective electron temperature is minimum, the concentration of singlet oxygen is maximum. This may be explained by the effective electron temperature which is close to the energy levels of O_2 ($^1\Delta_g$) and O_2 ($^1\Sigma_g^+$), respectively at 0.97 eV and 1.63 eV, so a large population of electrons can populate these energy levels and this is why a maximum of the concentration of these species has been observed.

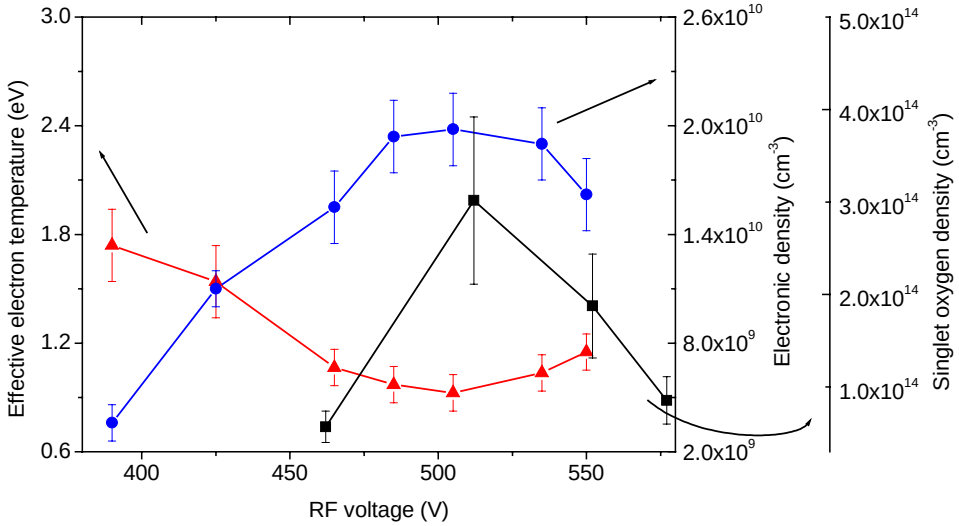

Fig. 10. The correlation between TIMS and Langmuir probe measurements for 25% Ar – 75% O_2 at 15 Pa

8. Influence of the singlet oxygen density on tin oxide thin films resistance

Figure 10 shows the decrease of the SnO_2 sheet resistance as a function of the increase of density of singlet molecular oxygen. These results show that excited molecular oxygen is one of the species which plays an important role in the carbon stripping of the deposited films leading to conductive ones.

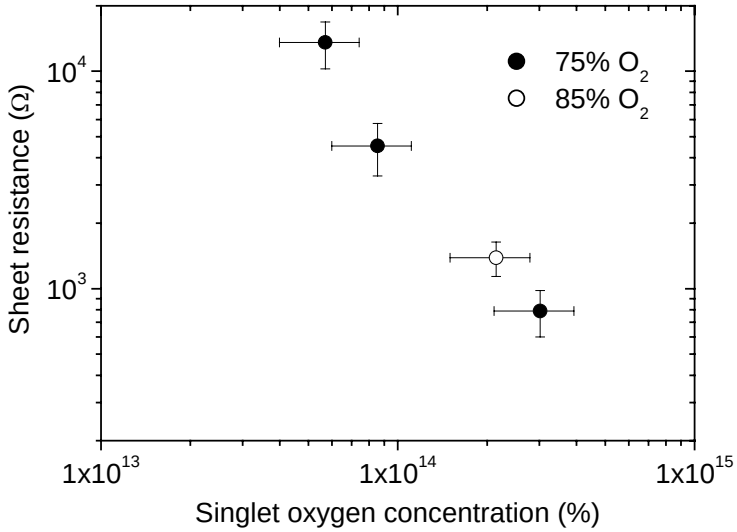

Fig. 10. SnO_2 sheet resistance as a function of the singlet oxygen density for 75% O_2 and 85% O_2 mixtures at 15 Pa

9. Conclusion

By combining mass spectrometric study and Langmuir probe measurements, it has been possible to explain the evolution of the singlet oxygen molecules, and the change in the sheet resistance of the thin films deposited. The trend of the variation of the O_2 ($^1\Delta_g$) and O_2 ($^1\Sigma_g^+$) is ruled by the energetic characteristics of the discharge. Indeed, the maximum density of such species has been observed at the highest electron density and the lowest temperature. The deposition of carbon free tin oxide films may be explained by the high chemical reactivity of singlet molecular oxygen amongst other species with organic compounds.

Abstract

The paper is devoted to the study of the RF discharge utilized for carbon film deposition. The emission spectroscopy method is applied for plasma diagnostics. The formation of CH molecule non-equilibrium rotational distribution is found. The chemical mechanism of production of the hot rotational distribution of CH molecules is considered.

Keywords

Emission spectroscopy, RF discharge, Chemical Vapour Deposition, Rotational temperature, Honl-London factors.

1. Introduction

Nowadays the Chemical Vapour Deposition (CVD) of thin films having different composition and morphology is widely used in scientific research and technology. An RF discharge is very often used for that purpose due to the possibility of decreasing the rate of electrode erosion in such a discharge and, therefore, eliminating the electrode material impact on the quality of the obtained films. In the present work an RF discharge in pure methane is used to deposit carbon films of various morphology. The emission spectroscopy method was used for plasma diagnostics. The CH $A^2\Delta \rightarrow X^2\Pi_r$ (431.4 nm) emission band was investigated in detail. It is shown that rotational temperature $A^2\Delta$ does not correspond to the gas translational temperature. The analysis of the formation of CH molecule non-equilibrium rotational distribution was carried out.

2. Experimental setup

The experiments were carried out on the setup whose scheme is in fig.1. The volume of the working chamber is about 40 dm^3. The plasma-forming gas was methane, it was activated by the RF discharge with frequency f = 5.28 MHz. The deposition was carried out on silicon substrates situated on the bottom powered electrode. Both one-electrode and two-electrode schemes were used for the deposition. In the latter case the gas gets into the discharge gap of 2.5 cm in length through 170 holes in the top ground electrode. The electrode diameter is 10.0 cm. Typical conditions of the deposition film experiment are as follows: the RF voltage amplitude is 400 V, the gas flow is 1 sccm, and the gas pressure is varied within 4÷40 Pa. Significant self-bias in the potential of the powered electrode was observed in the both installation schemes (up to 95% of the amplitude).

For pressures higher than 10 Pa there usually occurs the growth of fine dispersed hydrogen-carbon structures rather than diamond-like films. This can be explained by the change in the mechanism of electron growth in the discharge at the increase in the pressure (transformation from the low current α-regime of the RF discharge to the high-current γ- regime [1]). It should be noted that α- and γ- regimes differ, in particular, in the temperature of electrons in the middle area of the discharge gap [2].

Optical spectra of the discharge glow were investigated in the two-electrode scheme. There are two glow regions of the discharge in methane in the visible range: one is above the electrode layer of the power electrode, the other is close to the electrode surface (fig.2).

As the pressure grows, the top glow region goes down and its volume decreases. Hydrogen lines H_β (486.1 nm) and H_γ (434.0 nm), and CH $A^2\Delta \rightarrow X^2\Pi_r$ (431.4 nm) emission band system are most intensive. The glow near the top electrode was not observed within the investigated pressure range in the experiments. The radiation from different glow regions was in turns focused upon the monochromator input slit, the spectral resolution being higher than 0.4 nm. A CCD-array with a linear characteristic was used as a emission-measuring device. The discharge glow spectra were obtained for various methane pressures: 40, 21, and also for 6.6 and 4.4 Pa, all these pressures are typical for a CVD-process.

3. Discussion

One of the most important parameters of the weakly ionized plasma is the temperature of the neutral gas that directly or indirectly influences practically all the processes occurring in plasma. The temperature determines the rate of physical and chemical processes, the direction and the intensity of thermal flows, the reduced electric field strength and the average energy of electrons, the width of spectral lines etc. To determine the gas temperature the method of relative intensities for electronic-vibrational-rotational (EVR) lines of two-atom molecules is used [3].

In this paper the CH $A^2\Delta \rightarrow X^2\Pi_r$ band system was investigated. The spectroscopic data of these states were taken from [4-7]. For the Boltzmann distribution of rotation levels with the temperature T'_{rot} the intensities of the spontaneous radiation of the individual EVR line are determined by the following expression [7-9]:

$$I_{n'v'J' \rightarrow n''v''J''} \propto \cdot \left(\nu_{n'v'J' \rightarrow n''v''J''}\right)^4 S_e q_{v'v''} S_{J'J''} g_{s,a} \exp\left(-\frac{hcF'(J')}{kT'_{rot}}\right) \quad (1)$$

where $\nu_{n'v'J' \rightarrow n''v''J''}$ is the wave number of the $n'v'J' \rightarrow n''v''J''$ transition, n indicates the electron state, v is the number of the vibrational level, J is the total momentum of the rotational level, the values with one prime refer

to the top state, those with two primes to the low one; S_e is the electron momentum of the transition, $q_{v'v''}$ is the Frank-Condon factor, $S_{J'J''}$ is the Honl – London factor, $F'(J')$ – is the rotational term of the top level, $g_{s,a}$ is the value that takes into consideration the difference between statistic weighs of symmetric and anti-symmetric states of homo-nuclear molecules, h is the Plank constant, c is the light velocity, k is the Boltzmann's constant.
The rotational terms of doublet states were determined from relationships [8]:

$$F_1(J) = \nu_0 + B_v\left[\left(J+\tfrac{1}{2}\right)^2 - \Lambda^2 - \tfrac{1}{2}\sqrt{\Lambda^2 Y(Y-4) + 4\left(J+\tfrac{1}{2}\right)^2}\right] - D_v\left[\left(J-\tfrac{1}{2}\right)\left(J+\tfrac{1}{2}\right) - \Lambda^2\right]; \quad (2)$$

$$F_2(J) = \nu_0 + B_v\left[\left(J+\tfrac{1}{2}\right)^2 - \Lambda^2 + \tfrac{1}{2}\sqrt{\Lambda^2 Y(Y-4) + 4\left(J+\tfrac{1}{2}\right)^2}\right] - D_v\left[\left(J+\tfrac{1}{2}\right)\left(J+\tfrac{3}{2}\right) - \Lambda^2\right]; \quad (3)$$

where $\nu_0 = T_e' - T_e'' + G_{v'}' - G_{v''}''$, $G_v = \omega_e\left(v+\tfrac{1}{2}\right) - \omega_e x_e\left(v+\tfrac{1}{2}\right)^2 + \omega_e y_e\left(v+\tfrac{1}{2}\right)^3 + \omega_e z_e\left(v+\tfrac{1}{2}\right)^4 + \ldots$,
$B_v = B_e - \alpha_e\left(v+\tfrac{1}{2}\right) + \gamma_e\left(v+\tfrac{1}{2}\right)^2 + \ldots$, $D_v = D_e + \beta_e\left(v+\tfrac{1}{2}\right) + \ldots$, v is the number of the vibrational level, $Y = A/B$.

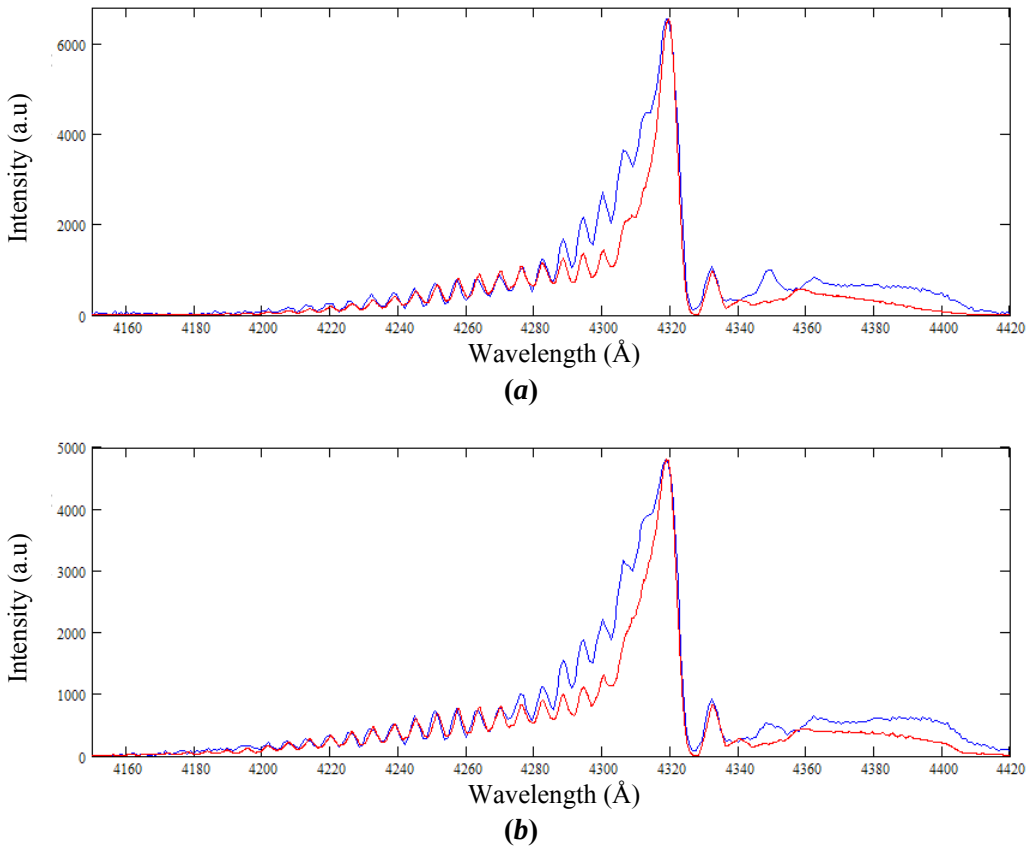

Fig. 3. Experimental and calculation spectra of CH molecules in $A^2\Delta \rightarrow X^2\Pi_r$ system bands at the pressure of 40 Pa, U_{RF} = 400 V, the self-biase of U_{bias} = 340 V, f = 7 MHz.
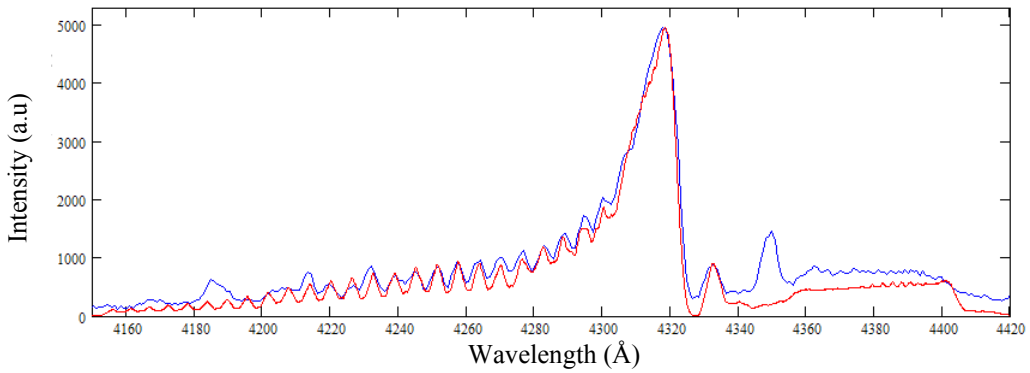
(*a*) the top glow area, the rotation temperature of T_{rot}=1900 K, the vibration temperature of T_{vib}=2900 K, the maximal glow intensity of I_{max}= 6557 a.u.
(*b*) the low glow area, T_{rot}=2900 K, T_{vib}=2900 K, I_{max}= 4814 a.u.

The Honl - London factors were calculated according to [8]. It should be noted that the levels with the vibration number $N' > 27$ for the zero vibrational level pre-dissociate, therefore, they were not taken into consideration in the calculation. In figures 3-4 there is a comparison of experimental and calculation spectra of CH molecule glow in the Δv=0 sequence in the RF discharge under different pressures of methane. In calculations, separate

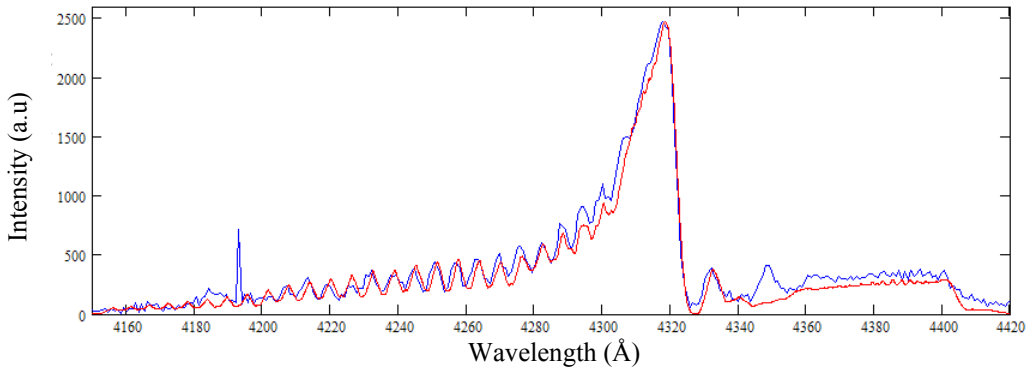
peaks were summed with the apparatus function having a triangle shape with the half width at half height of 0.19 nm. Rotational and vibrational temperatures were adjusted to the best coincidence for the line intensities. The temperatures calculated in such a way are shown in Table 1.

Table 1. Rotational and vibrational temperatures of CH molecule glow in two regions at various pressures.

Pressure, Pa		40	21.8	6.6	4.6
Top glow	T_{rot}, K	1900	2300	4300	4500
	T_{vib}, K	2900	2700	2700	2800
Low glow	T_{rot}, K	2900	3500	4400	4400
	T_{vib}, K	2900	2900	2700	2600



(a)



(b)

Fig. 4. Experimental and calculation spectra at the pressure of 4.6 Pa, U_{RF}= 400 V, U_{bias} = 397 V, f = 7 MHz.
(*a*) the top glow area, T_{rot}=4500 K, T_{vib}=2800 K, I_{max}= 4964 a.u.
(*b*) the low glow area, T_{rot}=4400 K, T_{vib}=2600 K, I_{max}= 2476 a.u.

According to figures 3 and 4, the rotational distribution of CH molecules in the excited $A^2\Delta$ states has a high rotational temperature, up to 4400 K, that very much exceeds the gas temperature estimated by other methods and not exceeding 1200 K. That makes it possible to conclude that the emission in the given band system for the studied regions of RF discharge parameters cannot be used for determining the gas temperature. Comparison of the calculation spectrum with the experimental one results in two features in the behavior of spectra at the gas pressure variation. The first feature is as follows: the growth of the pressure is accompanied by the decrease in the rotational temperature, down to the gas one, that indicates a rising role of the rotational relaxation with the growth of the pressure. The other feature is as follows: there is increase in the divergence between the calculation and experimental results within low rotation levels $J = 1.5 \div 6.5$ of the main branches R_1 and R_2. It

should be noted that according to the calculation of spectra the closely spaced $A^1\Pi \rightarrow X^1\Sigma^+$ Duglas-Hersberg band system of CH^+ ions, $B^2\Sigma^- \rightarrow X^2\Pi_r$ band system of CH molecules for the sequence $\Delta v=-1$, $d^3\Pi_g \rightarrow a^3\Pi_u$ Swan band system of C_2 molecules for the sequence $\Delta v=2$ as well as emission of C_3 molecules (which are within 4050 Å) do not make any contribution into this spectrum region. The calculation with two rotational temperatures did not bring to the better agreement either. Therefore, it is necessary to find the reason for the divergence between the calculation and experimental spectra within 4280 – 4320 Å wavelengths.

It is known that at electron excitation of molecules the rotational distribution function for the ground state is repeated in the exciting state due to the rotation number selection rules. Therefore the high rotational temperature of CH molecules in the $A^2\Delta$ state indicates that either the main exciting mechanism is the indirect electron impact and it is required to search for other mechanisms of exciting CH molecules to the $A^2\Delta$ state, or the thermodynamic equilibrium between rotational and translational degrees of freedom fail to be established. The analysis of chemical processes of CH formation showed that there was no real chemical mechanism of creating CH molecules in the exited state due to the small binding energy between C and H. And the processes of dissociative excitation of methane molecules by an electron impact with the formation of $CH(A^2\Delta)$, which should actively take place within the near cathode region at the input of the gas into the discharge area, are not important under our conditions. That is indicated by the above mentioned absence of the methane glow in the top area of the discharge gap (fig.2).

The calculation of the gas composition for our conditions was carried out according to the model including 98 chemical processes. Table 2 contains the gas composition, which was established in 4 ms from the initial mixture of 20%H + 20%H_2 + 60%CH_4. The starting pressure was set to be equal to 40 Pa, the gaseous temperature was 800 K. Table 3 shows the basic processes of the chemical model in which CH molecules and singlet $CH_2(S)$ molecules with excitation energy of 0.357 eV participate and these processes play an important role in forming a strong non-equilibrium excitation of rotational degrees of freedom of CH molecules. In our opinion the mechanism of the non-equilibrium formation is as follows.

In exothermal reactions (5) and (28) which are the primary channels of CH molecule formation, the energy defect is used for making the rotational non-equilibrium of CH molecules in the ground state. According to Table 2, the main components of gaseous mixture in the working chamber are hydrogen and methane molecules, whose rotational constants (60.8 cm^{-1} for H_2, 5.24 cm^{-1} for CH_4) considerably differ from the rotational constant of CH molecules (14.9 cm^{-1} in the ground state). Therefore the rotational relaxation of CH molecules is highly complicated in such a system.

Table 2. Established composition of gaseous mixture (T_g=1019 K, $N = 2.845\times10^{15}$ cm^{-3}) in the discharge from the original mixture 20%H + 20%H_2 + 60%CH_4, under the pressure of 40 Pa and the temperature of 800 K.

Radical	N, cm^{-3}	Radical	N, cm^{-3}	Radical	N, cm^{-3}	Radical	N, cm^{-3}
H	1.55×10^{14}	C	4.35×10^{10}	**CH_3**	2.46×10^{14}	C_2H_3	5.98×10^{10}
H_2	9.86×10^{14}	CH	1.98×10^{10}	**CH_4**	1.41×10^{15}	C_2H_4	8.49×10^{12}
C_2	7.14×10^{6}	CH_2	1.03×10^{11}	C_2H	8.36×10^{7}	C_2H_5	2.96×10^{11}
$C_2(X)$	1.02×10^{5}	$CH_2(S)$	5.16×10^{10}	C_2H_2	4.17×10^{12}	C_2H_6	3.47×10^{13}

Let's estimate the acceptable for the considered mechanism rate coefficient of the rotational relaxation rate from the condition of the typical rotational relaxation time being greater than the lifetime of CH molecules. With taking into account the fact that the basic loss channels are processes (3), (27), (31) and (33), the lifetime of CH molecules is determined according to the following relationship:

$$\tau_{CH} \approx \left(k_3[H]+k_{27}[H_2]+k_{31}[CH_3]+k_{33}[CH]\right)^{-1} \approx 4.3\ \mu s.$$

This time interval is an order of the magnitude longer than the radiation lifetime of the $A^2\Delta$ state, equal to 500 ns [6], therefore, the basic loss channel for the excited state is the radiation decay. Finally we have the following estimation for the rotation relaxation coefficient:

$$k_{rot} < \left(N\tau_{CH}\right)^{-1} \approx 1.6\times10^{-10}\ cm^3/s.$$

where N is the methane density. The obtained constant is quite reasonable, therefore we can conclude that the presented mechanism for forming the hot rotational distribution of CH molecules is physically consistent and quite possible. To establish final details of the mechanism for the non-equilibrium formation it is necessary to carry out the calculation of the rotation kinetics of CH molecules for each level, that is rather a complicated problem at present due to no valid coefficients.

Table 3. The basic processes with participation of CH and $CH_2(S)$ radicals

No. of the process in the model	Process	Process rate ($cm^{-3}s^{-1}$)	Rate constant k (cm^3/s)	Energy defect ΔE (eV)
3	$H + CH \rightarrow C + H_2$	8.42×10^{14}	2.74×10^{-10}	1.01
5	$H + CH_2(S) \rightarrow CH + H_2$	4.00×10^{14}	4.98×10^{-11}	0.473

Abstract. A novel atmospheric-pressure plasma-polymerised, nitrogen (N)-rich ("PPE:N") thin film material has been deposited using a pilot-scale dielectric barrier discharge (DBD) reactor. Characteristics of PPE:N deposits are described in detail. Adhesion, proliferation and micropatterning of different cell types, for example, the usually non-adherent U-937 human macrophages, is demonstrated. The critical role of N concentration, [N], is discussed.
Keywords: dielectric barrier discharges (DBD), deposition, biomaterials, cell adhesion, cell patterning.

1. Introduction

Biotechnological applications show an ever-increasing need for surfaces permitting control over cell functions. These so-called "smart" surfaces are specifically engineered to provide solutions to particular challenges. For example, chondrocytes which are rounded *in vivo* become flattened and fibroblastic when cultured on conventional culture plates. One possible solution involves the use of nano-/micro-patterned surfaces that permit greater control of the cell environment. By creating an array of cell-adhesive islands in a non-adherent matrix, the spreading of cells may be limited [1], and ultimately control over phenotype conservation and gene expression may be achieved. It is known that most cell types do not adhere to hydrophobic polymer surfaces like polyethylene, polypropylene, polystyrene or PTFE. However, hydrophilic surfaces, for example those functionalized by plasma or VUV treatments [2], are known to promote cell adhesion. A good example is the commercial product "Primaria"^{TM}, plasma nitrided polystyrene [3]. We report a promising novel material, nitrogen-rich plasma-polymerised ethylene (PPE:N), which is deposited on various substrates of interest, using an atmospheric pressure dielectric barrier discharge (DBD) apparatus in this laboratory. Its characteristics, high nitrogen content and high surface energy, render it a promising candidate for providing tailored solutions to the challenges described above. In this study we present the characteristics of this novel thin film material and of its cell-adhesive properties. We demonstrate reproducible, selective adhesion of U-937 human macrophages, epiphyseal and growth plate chondrocytes, mesenchymal stem cells, aortic vascular smooth muscle cells (VSMC) and dermal fibroblasts on PPE:N surfaces. Finally, we show the critical importance of nitrogen concentration, [N], by correlating the adhesion of different cell types on surfaces with varying [N], as we also reported elsewhere [4].

2. Experimental Methodology

2.1 Deposition of PPE:N and Micropatterning

The topics of plasma chemistry and plasma polymerisation are well covered in some excellent monographs [5, 6], and will not be addressed in detail here. While much of that literature relates to low-pressure, non thermal ("cold") plasmas, "cold" plasmas generated at atmospheric pressure via the use of so-called dielectric barrier discharges (DBD) have gained increasing importance in recent years [7]. The plasma-polymerised PPE:N films discussed here are exclusively of this latter variety, although they may in principle also be produced via traditional low-pressure plasma techniques [6]. PPE:N films were deposited on several types of polymer substrates identified below; these were placed on a 2 mm thick float glass plate (see below). Biaxially oriented polypropylene (BOPP) was the main substrate material for cell-culture experiments; this 50 μm thick isotactic polymer film, graciously provided by 3M Company, has been described elsewhere [2]. However, to suit the

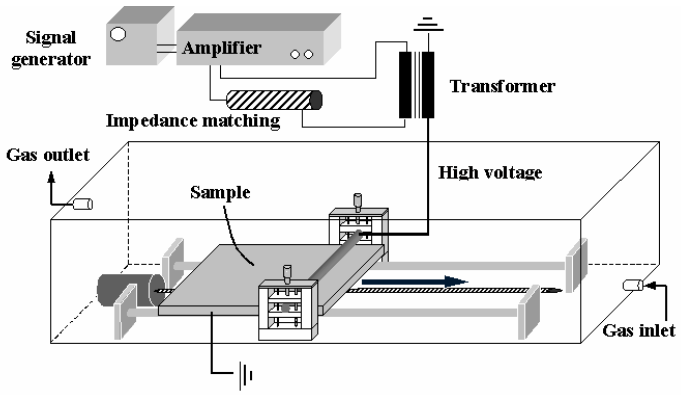

Figure 1: Schematic diagram of the DBD plasma deposition apparatus.

needs of other applications, PPE:N was also deposited on a variety of other substrates, for example, 125 μm thick PTFE used in endovascular implants, 25 μm thick PET, and 50 μm thick Teflon® FEP film.

Figure 1 depicts the atmospheric pressure DBD apparatus used for depositing the PPE:N films [8]; it comprises a grounded, planar Al electrode and a cylindrical, dielectric-coated stainless steel high voltage (HV) electrode. The 2 mm thick glass plate mentioned earlier is placed on the planar Al electrode and it serves as a second dielectric layer, as described in detail elsewhere [8]. The precursor gas mixture is introduced into the discharge zone, an adjustable 1 mm wide gap between the HV electrode and the glass plate, using a gas diffuser (not shown on Fig. 1) to ensure the requisite high gas purity. Gas flow rates (N_2 – 10 standard liters/minute, slm; C_2H_4 – 5 to 60 standard cm^3/minute, sccm) are controlled by electronic mass flow controllers. The roughly 1 cm wide plasma zone is generated with a commercial power source and transformer (Enercon Industries, model LM2727-03, 450 kVA maximum output) at a typical frequency of 10 kHz and peak voltage of 18 kV. After the carefully precleaned substrate was introduced into the DBD system, the latter was purged with the precursor gas flow for approximately 10 min. The discharge was then initiated and monitored with a digital oscilloscope, the voltage and current being measured with the help of a resistive probe (Tektronix, model P6015A) and a 50 Ohm resistor, respectively. The substrate was made to move back and forth under the HV electrode at precisely controlled speed, 10 mm/s, for up to two dozen cycles, depending on the desired PPE:N film thickness. For the micropatterning experiments, special 25 μm thick Kapton® polyimide masks were placed over the substrate. These masks were fabricated with an excimer laser coupled to a precise positioning system, to create the following square arrays of circular holes (hole diameter -pitch): 30 μm – 60 μm; 30 μm – 200 μm; 100 μm – 200 μm, with array areas ranging from 1 to 4 cm^2. Care was taken to assure intimate contact between the mask and substrate surface during deposition runs.

2.2 Materials Characterisation and Cell Culture

A detailed description of characterisation and cell culture methodologies is available elsewere [4], so that only a rapid overview is presented here. PPE:N films were characterised by X-ray photoelectron spectroscopy (XPS) and by attenuated total internal reflectance FTIR (ATR-FTIR) to gather information about surface composition and functional groups, including quantification of the functionality of greatest interest, primary amines, which was obtained by chemical derivatisation with trifluoromethylbenzaldehyde [9]. Contact angle goniometry (CAG) measurements were carried out according to the method of Owens and Kaelble [10], from which the surface free energy, γ_s, can readily be determined. Individual PPE:N dots were imaged with an atomic force microscope (AFM) in contact mode. Film thickness, d, and refractive index, n, of PPE:N films were measured using a variable-angle spectroscopic ellipsometry (VASE), and values of d were also confirmed by profilometry (Dektak) measurements of steps created with the Kapton® masks.

Prior to each of the cell culture experiments, individual cell lines were suspended and counted in medium that generally consisted of Dulbecco's modified eagle medium (DMEM) with 5 to 10 % fetal bovine serum (FBS). For each experiment a 100 μl volume of cell suspension, containing typically $2X10^5$ cells, was carefully pipetted onto a 1 cm^2 PPE:N surface that was previously placed face-up on the flat bottom of a 24-well plate for cell

culture. All cell types were left to adhere to the substrate surfaces in a humidified incubator at 37°C, 5% CO_2 in air, for 1h before careful removal of the remaining medium with a pipette. Fresh cell-free medium was then pipetted into the wells (1 ml in each well) and photomicrographs of the surfaces were taken.

3. Results and Discussion

3.1 Material Characteristics

As mentioned in section 2.2, elemental compositions of the PPE:N films obtained by XPS, combined with ATR-FTIR data, permitted us to semi-quantitatively determine the concentrations of functional groups at the sample surfaces. Typical elemental concentrations ranged from 17 to 36 at.% nitrogen, [N], about 4 at.% oxygen, [O], the balance being carbon. Hydrogen is, of course, also present in the films but cannot be detected by XPS; high [N] values, as determined from eq. (1),

$$[N] = \frac{N}{N+O+C} \times 100\% \qquad (1)$$

are the main attribute of these PPE:N films, in comparison to other work in the literature; to the best of our knowledge, no earlier work has reported [N] as high as the value of 36.3% we observe here. Regarding [O], even though oxygen is excluded from the precursor gas, long-lived free radicals and other active species at the sample surface can react with oxygen and/or water vapour when the sample is exposed to the ambient atmosphere [6, 8]. The [O] value was minimised by lengthy storage of samples in feed gas mixture after the discharge had been terminated. Also, since the material described is a highly cross-linked plasma-polymer, it does not undergo the well-known "hydrophobic recovery", or aging effect observed in plasma surface modification techniques [8], so that surface elemental concentrations are stable over time. In fact, such stability was demonstrated by comparing 6 month-old PPE:N coatings on BOPP with samples freshly deposited under the same conditions: none of the characterisation methods detected any significant differences between the two sample groups. The value of [N] in PPE:N can be readily and reproducibly controlled by varying C_2H_4 concentration, $[C_2H_4]$, in the feed gas, higher $[C_2H_4]$ resulting in lower [N] in the deposited films. This control over PPE:N composition is an important attribute of our methodology, in that it enables controlled adhesion of different cell types simply by changing [N], as will be shown below.

ATR-FTIR spectra show the main functional groups in the PPE:N to be amines (their order cannot be determined by this method), nitriles and some amides. High resolution XPS of the N 1s peak can indicate relative concentrations of different N-species, but cannot provide quantitative information. Given the random structure of plasma polymers [6], any particular functional group can possess a broad distribution of binding energies. This assertion has been confirmed by high resolution XPS spectra taken also with a narrow monochromatic X-ray source (0.3 eV width, compared with 0.7 eV for the ESCALAB instrument); all spectra were similar in shape and width, which confirms that the broad convoluted peaks result from a distribution of energies rather than from polychromatic X radiation. Primary amine concentrations, $[NH_2]$, were found to vary from 5 to 10 % NH_2/N, the most abundant being at 3.5% NH_2/C, similar to literature data for plasma-modified polymer surfaces [11]. Interestingly, $[NH_2]$ does not appear to depend strongly on $[C_2H_4]$ in the precursor gas.

The films' surface energy, γ_s, indicative of their wettability by aqueous media, was found to increase with rising [N] from 27.0 mN/m (or dynes/cm) for virgin BOPP to about 58 mN/m for [N]=30%, similar to Guimond's findings for BOPP surfaces modified by DBD treatments with pure N_2 gas [8]. Here, too, the ~ 30 mN/m increase is entirely due to that in the polar component, γ_s^p, in turn related to the content of highly polar groups (amines, amides, etc.). In view of the above, it is not surprising that cell adhesion should manifest strong correlation with γ_s and wettability, as evidenced in section 3.2 below. The deposition rate, R, (from profilometry and ellipsometry measurements) of PPE:N films was found to vary with $[C_2H_4]$ in the precursor gas. Values of R ranged from about 2 nm/s (for $[C_2H_4]$ = 5 sccm) to 9 nm/s (for $[C_2H_4] \approx 30$ sccm), comparable to values found in the plasma-polymerisation literature [6]. In all conditions, R is sufficiently high and not a limiting factor in this study; all cell culture experiments were carried out using 150-200 nm thick films.

Figure 2 A shows a photomicrograph of a "30-200" Kapton® mask; well-defined dots of deposit are visible on the substrate at the same magnification (not shown here). For the case of a 200 nm deposit on an unmasked

glass surface, each dot had a height of about 150 nm, measured by Dektak and by AFM, on account of some masking by the 25 μm thick Kapton® film. An AFM image of a single dot (Fig. 2 B) shows the well-defined 30 μm diameter "mound"; note that for visual purposes the Z scale has been amplified 100-fold compared with the X and Y scales. The deposition was well confined by the mask, which was in good contact with the surface, since no film was deposited outside the 30 μm boundary.

3.2 Cell Culture

In order to demonstrate the great potential of PPE:N for cell culture and tissue engineering, a wide variety of experiments have been conducted, many using nominally 200 nm of PPE:N with 29.5 % [N], deposited on the substrate of particular interest. This choice constituted a compromise between adequate surface energy and deposition rate values. All of the cell types under study were first cultured on large-area coated surfaces that were partially masked during deposition, in order to compare adhesion on the bare substrate and on PPE:N. Figures 3 A to D are representative examples of these experiments. Substrates for each cell type were deliberately chosen to induce adhesion contrasts, so that the cells adhered to the coating but not to the substrate (U-937 human macrophages, epiphyseal and growth plate chondrocytes on BOPP, and mesenchymal stem cells on Teflon^{TM} FEP), or to simulate a specific application (VSMC and fibroblasts on PTFE). In all cases, cells were seen to selectively adhere to PPE:N after one hour of contact with cell suspensions. The adhesion contrast is particularly strong and noteworthy in the case of the U-937 macrophages, since these cells are non-adherent to almost all previously known cell culture surfaces [12]. Of equal interest was the finding that the cells maintained a rounded morphology after adhesion. To investigate the viability of cells on PPE:N for extended periods of time, the following proliferation studies were undertaken: U-937 macrophage cell suspension was left in contact with the surface for 1h before removing medium and excess cells, in the presence only of culture medium; cell counts were then performed and cells were found to survive and proliferate on the PPE:N surface, an important finding for future applications [12]. Following these experiments, a macrophage suspension was left in contact with a micropatterned (30 μm holes, 200 μm pitch) BOPP surface for 1h (see Fig. 3 E). Evidently, small groups of up to ten cells adhered readily and selectively only to the PPE:N islands, as anticipated from the results presented above. A suspension of growth plate chondrocytes was also left in contact for 1h with a different (100 μm holes, 200 μm pitch) micropatterned surface, since 30 μm holes were found to be inadequate. To test the longevity of these chondrocytes on the patterned surface, they were kept in culture for 9 days before a micrograph was taken (Fig. 3 F). This experiment, too, clearly shows that chondrocytes adhered selectively to micropatterns, even after many days in culture [2].

In the preceding paragraph and in Fig. 3 A to D we have noted that an [N]-rich PPE:N deposit, with [N] = 29.5%, evidently constitutes a surface on which all cell types examined readily adhered and proliferated. In view of this fact and of our ability to vary [N] at will, the following additional sets of experiments were conducted in order to examine cell adhesion behaviour at lower [N] values: U-937 macrophages and growth plate chondrocytes were cultured on PPE:N-coated BOPP substrates, but now the [N] values were systematically decreased by enriching the N_2/C_2H_4 gas mixture with ethylene during plasma deposition of the PPE:N coatings. Coated substrates with [N] values ranging from 36.3% downward to 17.5% were then exposed to concentrated cell suspensions for 1 hr durations, following which photomicrographs of the cell cultures were taken. Figure 3 G and H show such micrographs of macrophages for the cases [N] = 25% and 23%, respectively. Clearly, a

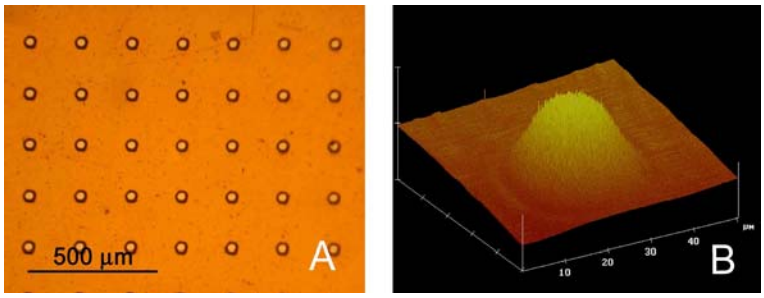

Figure 2: PPE:N film micropatterning : Kapton ® mask – (A) 30 μm holes every 200 μm; (B) AFM image of a single 30 μm PPE:N dot, shaped like a "mound".

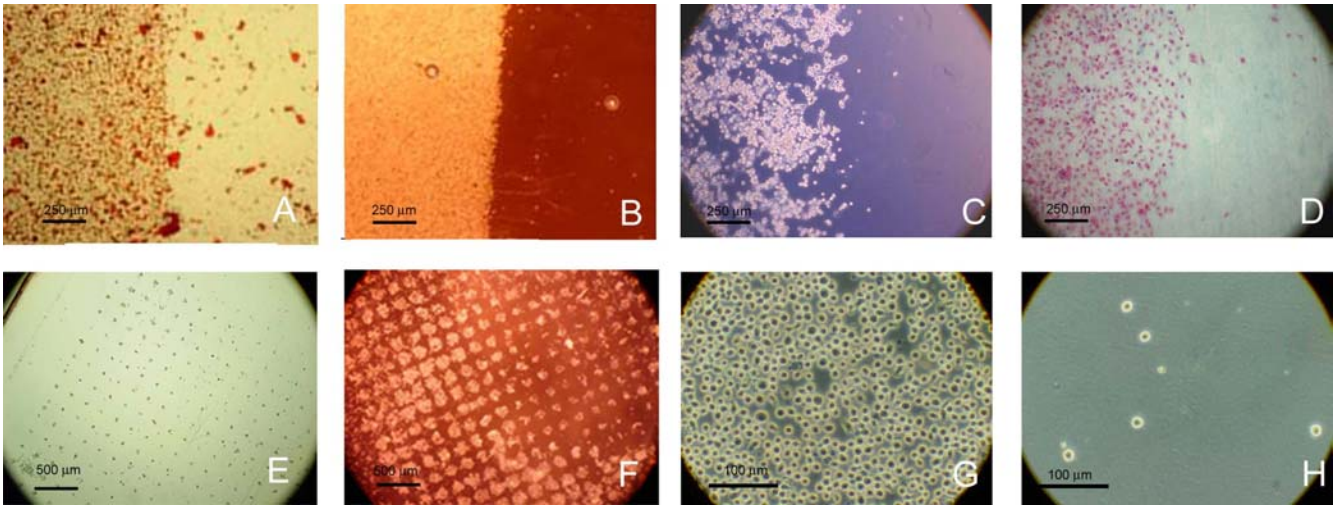

Figure 3: Cell culture and micropatterning on various substrates: Cell adherence to PPE:N coatings with [N] = 29.5% on partially-masked surfaces, with coatings and cells on the left sides of the images: (A) growth plate chondrocytes on BOPP, (B) human U-937 macrophages on BOPP, (C) fibroblasts on Teflon FEP, and (D) VSMC on PTFE. Cell adhesion on PPE:N-micropatterned BOPP substrates: (E) U-937 macrophages, and (F) growth plate chondrocytes. Adhesion of U-937 macrophages to PPE:N films (on BOPP) of varying [N], after 1hr of culture: (G) 25%, (H) 23%.

"critical" value of nitrogen concentration, $[N]_{crit}$, exists between 25% and 23%, a value below which this cell-type does not adhere to PPE:N. The micrographs shown here are typical and fully representative for many repeated experiments: for [N] ≥ 25%, adhering cells formed a single continuous monolayer after 1 hr, even if the cell suspension was highly concentrated. On the contrary, for [N] < 25%, the observed number of cells adhering to the PPE:N surfaces was no different from the case of uncoated, pristine BOPP (or polystyrene, PS, or other commercial polymers), namely virtually nil. A similar series of experiments was also conducted with growth plate chondrocytes, where the value of $[N]_{crit}$ was found to lie between 19% and 17.5%.

As proposed by Ohl, Schröder and their collaborators [1, 11, 14], these observations are probably related to the concentration of surface-near primary amine ($-NH_2$) groups: the higher the [N] value, the greater is the likelihood that the concentration of such groups, $[NH_2]$, is also high. The protonated amine group possesses a localised positive charge which may, in aqueous solution at physiological pH values, attract negatively charged biomolecules. In view of their known high reactivity, amine groups are therefore believed to covalently couple proteins, thereby giving rise to immobilisation of biomolecules and cell adhesion.

4. Conclusions

Novel, nitrogen-rich PPE:N thin films have been deposited using an atmospheric pressure plasma polymerisation technique that is both economical and efficient. An important attribute are their high, stable and adjustable nitrogen content, relatively high primary amine concentration, and their high surface energy (wettability). Also, since we are dealing with deposition (as opposed to surface modification), PPE:N films can be applied on many different substrates, including inorganic ones. Based on these characteristics, PPE:N is an excellent candidate for cell culture and tissue engineering experiments, including those on micropatterned surfaces created with the help of Kapton® masks used here. The present cell culture experiments have shown that PPE:N promoted selective adhesion of many cell types, including the usually non-adherent human U-937 macrophages. Micropatterned adhesion of cells on PPE:N islands was rapid and effective; in the case of growth plate chondrocytes the pattern was conserved, even after 9 days in culture. Finally, we have demonstrated the existence of a "critical" nitrogen concentration, $[N]_{crit}$, of these PPE:N coatings below which specific cell lines did not adhere to the surfaces.

Effect of electrical excitation type on the removal of isopropyl alcohol from dry air using a dielectric barrier discharge

J. Jarrige, N. Blin-Simiand, F. Jorand, L. Magne, S. Pasquiers, C. Postel

Laboratoire de Physique des Gaz et des Plasmas, Bât. 210, Université Paris XI , 91405 Orsay cedex, France

Abstract
The conversion of isopropyl alcohol (IPA) in a transient filamentary plasma (DBD discharge) has been studied in dry air. It has been shown that the removal efficiency of IPA is greatly improved when the electrical excitation of the DBD is changed from an AC to a pulsed one. Carbonated oxidation by-products are mainly acetone, CO and CO_2. Preliminary experiments have been also performed using a photo-triggered discharge which allows to obtain an homogeneous plasma. Same products have been detected.
Keywords - Dielectric barrier discharge - Phototriggered discharge - VOC abatement - Isopropanol

1. Introduction

The removal of molecular atmospheric pollutants by non-thermal plasmas is under investigation since the beginning of the eighties, and it has been shown that transient electrical discharges, such as dielectric barrier (DBD) or corona discharges, are powerful means to eliminate Volatile Organic Compounds (VOCs) at low concentration (less than 1 %) in the ambient air [1-4]. Isopropyl alcohol (IPA), $CH_3CH(OH)CH_3$, is one of the VOC molecule for which few studies have been performed up to now [5-7]. This molecule is widely used in chemical industries for extraction or purification of products such as oils, gum, perfume, ... It is also used as a solvent in paints and varnishes. In this paper, we examine the effect of the electrical excitation type of a DBD working at 1 bar and ambient temperature on the removal of IPA from dry air. However, because of the strong non-homogeneity of such a plasma, a detailed understanding of the chemistry involved in the pollutant removal and formation of by-products is quite hard to achieve. Therefore, in order to get a more precise knowledge of this chemistry, we have also undertaken experiments using a photo-triggered discharge [8]. Owing to the medium homogeneity, this type of pulsed high pressure pre-ionised discharge allows useful comparison between experimental results and predictions of self-consistent 0D-discharge and kinetic models. Formerly designed for the development of high-power lasers [9, 10], the photo-triggering technique has been more recently applied to gas mixtures ($N_2/O_2/H_2O$) relevant for atmospheric pollutant removal, such as NO [11] or light olefins [12]. In the present work, type of by-products which followed oxidation of IPA in the non-homogeneous reactive medium of DBD discharges are compared to those detected at the exit of a photo-triggered discharge reactor.

2. Experimental set-up

The first experimental set-up was composed of three parts : (i) a continuous gas flow generating system, (ii) a DBD reactor, and (iii), a gas sampling analysis and detection system. The dry air-like (20 % O_2) flow was kept constant at 0.7 sl/mn. The liquid IPA was continuously injected with a syringe through a vaporizer producing gaseous IPA. The alcohol streamed along a glass rod located at the center of a heated tube through which air flowed. The DBD reactor was made of a pyrex tube (inner diameter 11 mm, wall thickness 1.6 mm) [13]. The high voltage central electrode was made of stainless steel screw (diameter 3 mm). The grounded outer electrode (10.7 cm long) was made of stainless steel wire mesh and covered up the outside of the dielectric. Two types of power supply have been used to energize the DBD, firstly, an AC type working at a frequency of 50 Hz with an adjustable peak-to-peak voltage between 1 and 60 kV, and, secondly, a pulsed type with a positive polarity at a fixed peak voltage of 40 kV and with a repetition frequency which can be chosen between 1 Hz and 1 kHz. The electrical energy deposited in the discharge has been determined either using the Lissajous figure method (for AC excitation), or following measurements of the voltage and current time evolutions (for pulsed excitation) using adapted probes. The treated gas mixture was flowing from the DBD reactor to the gas analysis apparatus (Micro Gas Chromatography CP-4900) equipped with a thermal conductivity detector.
On the other hand, the photo-triggered discharge cell has been described in detail in reference [12]. An homogeneous plasma is obtained between two flat electrodes, 24 cm in length and 2 cm in width, separated

by a gap d=1.2 cm. These electrodes are inserted in an acrylic cell which acts as insulator, and are connected to the output of a symmetrical one-stage Fitch generator. The lower electrode is electrically grounded while the upper one, the cathode, is perforated with many 1 mm in diameter holes over a surface 24x2 cm^2. An auxiliary corona discharge device is located under the cathode in order to uniformly pre-ionise the discharge volume (57.6 cm^3) through the holes, by UV-photons. In the present experiment, the electrical energy deposited in the discharge is 300 mJ per pulse. The current pulse duration of the main discharge is 30 ns with a peak value of about 1.5 kA. The total pressure of the N_2/O_2/IPA mixture has been fixed to 400 mbar in order to achieve a well reproducible homogeneous discharge from shot to shot at a repetition frequency up to a few Hz, with a gas flux fixed to 1 sl/mn. Infrared Fourier transform spectroscopy has been used to detect molecules at the exit of the photo-triggered reactor. The spectrometer is a MIR8000 from Oriel, with a maximum spectral resolution of 0.5 cm^{-1}, equipped with a long path absorption cell (Infrared Analysis model V-16).

3. Removal of IPA by dielectric barrier discharges

In figure 1 and 2 are shown the IPA concentration measured at the exit of the DBD, $[IPA]_{exit}$, as function of the specific deposited energy, E_{dep} (in Joule/litre), in the case of the AC (fig.1) and pulsed (fig.2) electrical excitation, and for five values of the initial pollutant concentration, $[IPA]_0$, ranging from 50 ppm up to 640 ppm.

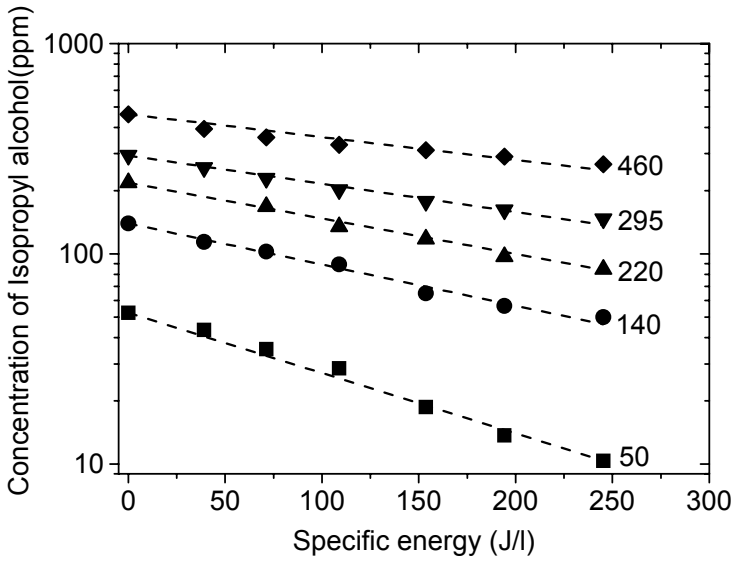

Figure 1 - Concentration of isopropyl alcohol at the exit of the DBD reactor as function of the specific deposited electrical energy, for AC excitation. Values of the initial concentration are given on the figure, in ppm.

$[IPA]_{exit}$ exhibits an exponential decrease when E_{dep} increases up to 250 J/l, i.e.

$$[IPA]_{exit} = [IPA]_0 \exp(-E_{dep}/\beta) \quad (1)$$

where the β parameter increases linearly when $[IPA]_0$ increases,

$$\beta_{AC} = 130 + 0.604\ [IPA]_0 \quad (2)$$

This law is identical to the one already observed in many studies on VOC removal by filamentary discharges [3, 4]. It has been also obtained when the DBD is energized using the pulsed electrical excitation, for an initial IPA concentration between 140 ppm and 640 ppm. In this case we have determined the following β parameter function,

$$\beta_P = 77 + 0.157\ [IPA]_0 \quad (3)$$

for $[IPA]_0$ higher than 200ppm; at low concentration, 140 ppm, β_P is lower than the value given by (3).

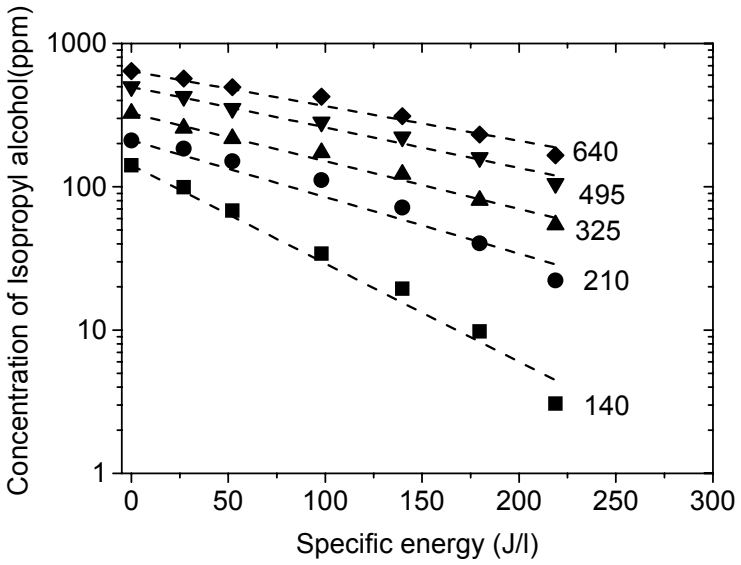

Figure 2 - Concentration of isopropyl alcohol at the exit of the DBD reactor as function of the specific deposited electrical energy, for pulsed excitation. Values of the initial concentration are given on the figure, in ppm.

In figure 3 are plotted evolutions of β_{AC} and β_P versus $[IPA]_0$. It can be seen that β_P is much lower than β_{AC}, which means that the removal of isopropyl alcohol is much easier to achieve in the case of a pulsed electrical excitation of the DBD than in the case of the AC excitation. Such an effect has been previously observed for the removal of NO from diesel engine exhaust gases [14], and we have also obtained very recently similar results on acetaldehyde in dry air [13].

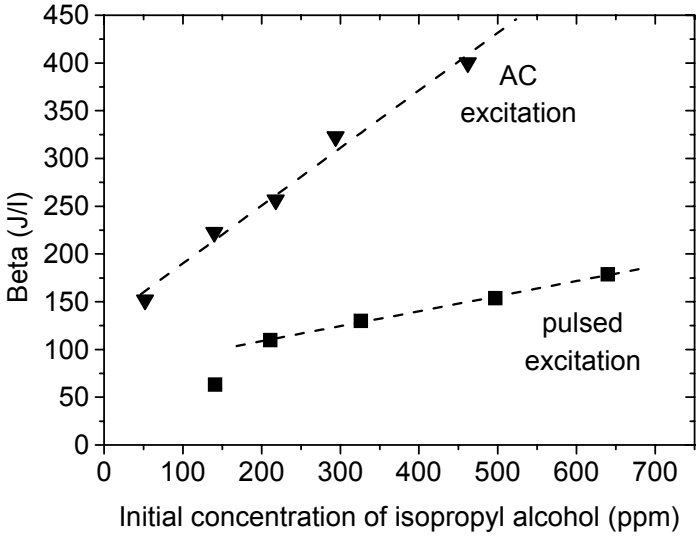

Figure 3 - The β parameter for AC and pulsed electrical excitation of the DBD.

4. By-products

The detected molecules at the exit of the DBD reactor have been the following (beside H_2O, which concentration has not been quantified) : $CH_3C(O)CH_3$ (acetone), CO, CO_2, H_2 and C_2H_4. No other compounds have been detected using Micro Gas Chromatography, and no solid or liquid deposit has been seen on the discharge tube walls. Acetone and carbon oxides are the most important products. In figure 4 are plotted concentration values of all molecules, as a function of the specific energy, in the case of the pulsed electrical excitation and for an initial IPA concentration value equal to 640 ppm. The total carbon

concentration is given in figure 5, taking into account the carbon contained in the remaining IPA for each value of the deposited energy.

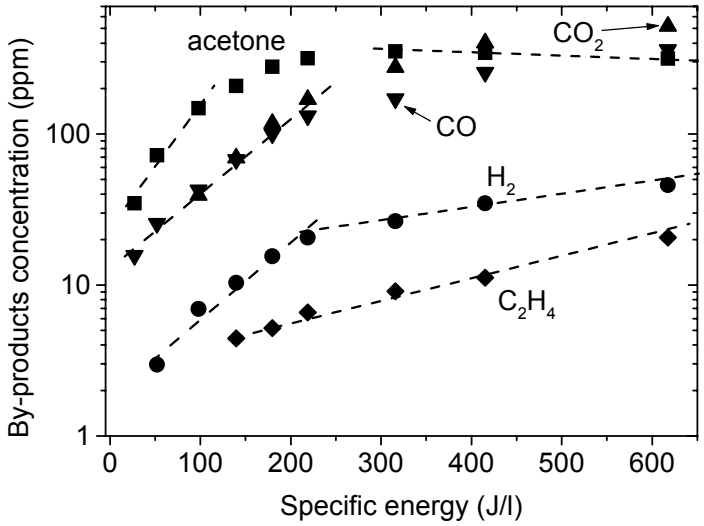

Figure 5 - Concentration of by-products at the exit of the DBD reactor as function of the specific deposited electrical energy, for the pulsed excitation and an initial concentration of IPA equal to 640 ppm.

It can be seen in figure 5 that the acetone concentration rapidly increases when the deposited energy increases up to 300 J/l. However it decreases slowly for higher energy values. In this experiment, the energy is increased through the increase of the discharge repetition frequency (the applied voltage is constant). As the gas flow is kept constant, the increase of the frequency induces the increase of the number of discharges performed in the mixture. As a result acetone molecules are also removed. On the other hand, CO and CO_2 concentrations exponentially increase when the energy increases up to 250 J/l. The ratio between this two concentration values is close to unity, except for the highest energy values for which the CO_2 concentration is slightly above the CO one. In this range of energy, the increase of the carbon oxides concentrations is less pronounced than in the low energy range.

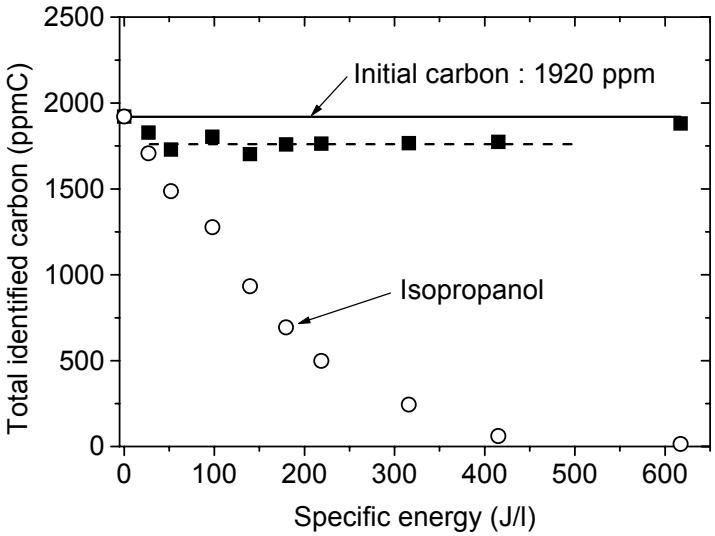

Figure 6 - Total identified carbon concentration at the exit of the DBD reactor as function of the specific deposited electrical energy, for the pulsed excitation and an initial concentration of IPA equal to 640 ppm.

The carbon balance shown in figure 6 emphasizes that the concentration of unidentified products is only 160 ppmC for the chosen experimental conditions, in the whole energy range studied. IPA molecules are in great part converted to acetone and carbon oxides.

The same by-products have been detected at the exit of the photo-triggered reactor, except C_2H_4. Moreover the FTIR spectra show the presence of formaldehyde (CH_2O) and formic acid (HCOOH) molecules, as it can be seen in figures 7a and 7b on which are displayed the absorbance measured in the long path cell after subtraction of the acetone and isopropanol contribution. Some products remain unidentified. Works are in progress to quantify IPA removal and concentration of by-products, for the photo-triggered discharge, using both FTIR spectroscopy and gas chromatography coupled with mass spectrometry.

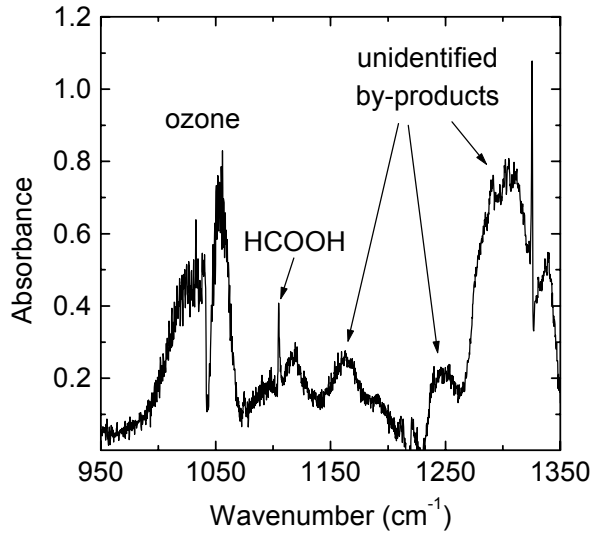

Figure 7a - Example of FTIR spectrum measured at the exit of the photo-triggered reactor. Identification of ozone and formic acid.

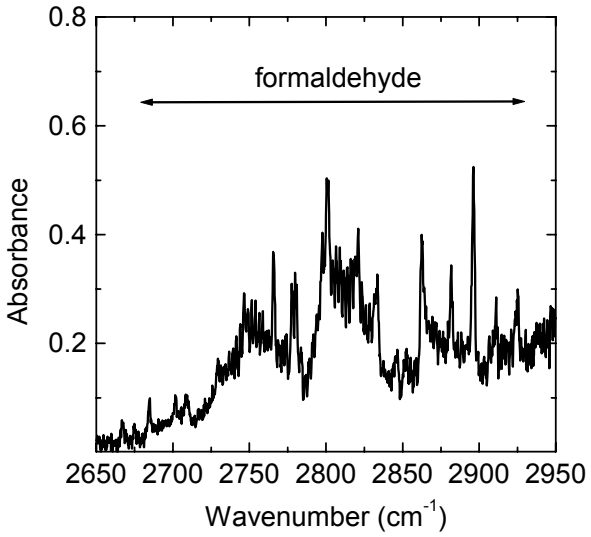

Figure 7b - Example of FTIR spectrum measured at the exit of the photo-triggered reactor. Identification of formaldehyde.

5. Simplified kinetic analysis

One can suggest well-known kinetic mechanisms to explain the removal of IPA and the production of acetone. Indeed the IPA molecule can be oxidized to give the 2-hydroxypropyl radical, $CH_3C(OH)CH_3$, according to the two following reactions [15],

$$O + CH_3CH(OH)CH_3 \rightarrow CH_3C(OH)CH_3 + OH \quad (R1)$$

$$OH + CH_3CH(OH)CH_3 \rightarrow CH_3C(OH)CH_3 + H_2O \quad (R2)$$

Thus acetone is produced by reaction of 2-hydroxypropyl with oxygen atoms,

$$O + CH_3C(OH)CH_3 \rightarrow CH_3C(O)CH_3 + OH \quad (R3)$$

or by reaction with oxygen molecules,

$$O_2 + CH_3C(OH)CH_3 \rightarrow CH_3C(O)CH_3 + HO_2 \quad (R4)$$

Acetone can be also oxidized as follows,

$$O + CH_3C(O)CH_3 \rightarrow CH_3C(O)CH_2 + OH \quad (R5)$$

$$O + CH_3C(O)CH_3 \rightarrow CH_3C(O)CH_2 + H_2O \quad (R6)$$

but rate constants for reactions (R5) and (R6) are respectively two order and one order of magnitude lower than those of reactions (R1) and (R2). This can explain, almost qualitatively, experimental results plotted in figure 5. However such a simple scheme has not yet been clearly demonstrated, as far as IPA removal and acetone production are concerned in absolute values. Moreover, analysis of the gas mixture reactivity reveals that by-products such as CH_2O, HCOOH, CO and CO_2 should not be formed directly after the first steps described above. A complete kinetic modeling of the N_2/O_2/IPA mixture is under development in order to achieve a comprehensive understanding of experimental results obtained with the photo-triggered discharge, and to see how this kinetic can help in the interpretation of the effect of electrical excitation type on IPA removal and by-products formation in filamentary discharges.

6. Conclusions

Type of the electrical excitation of the dielectric barrier discharge has a great influence on the removal of isopropyl alcohol in dry air. A pulsed excitation is much more efficient than an AC excitation. Explanations

are probably to be found in a higher production rate of oxygen atoms. Other molecules have to be studied also, for example hydrocarbons or aldehydes. Future works will be devoted to a detailed kinetic analysis of the N_2/O_2/IPA mixture homogeneously energized by the photo-triggered discharge.

Abstract

The densities of NH and NH_2 radicals in an expanding Ar-NH_3 and Ar-NH_3-SiH_4 plasma were determined as a function of the NH_3 and SiH_4 flow. The NH and NH_2 radicals were measured using cavity ringdown absorption spectroscopy and the typical densities are in the order of 2×10^{12} cm^{-3} for NH and 6×10^{12} cm^{-3} for NH_2. A simple reaction scheme that explains the observed trends is presented. Finally, the detection of N radicals in the plasma by threshold ionization mass spectrometry is demonstrated.

Silicon nitride, expanding thermal plasma, cavity ringdown spectroscopy, NH and NH_2 radicals

1. Introduction

Ammonia plasmas have numerous applications in industry. They are, for example, used for surface treatment of polymers to improve the wettability and biocompatibility, for surface passivation of electronic devices and for nitridation of dielectric and metallic materials. However, one of the most important applications of NH_3-based plasmas is the deposition of silicon nitride films, that are used for encapsulation purposes of organic LEDs, as dielectric materials in the microelectronics industry and as antireflection coating on (multi-)crystalline silicon solar cells. These films are generally deposited from N_2-SiH_4 reactant mixtures [1,2] or from NH_3-SiH_4 reactant mixtures [3]. Despite the widespread use of amorphous silicon nitride (a-SiN_x:H) in industry, the exact growth mechanism of these films from NH_3-SiH_4 plasmas is not known. For example, the role of silane radicals, ammonia radicals, and possibly aminosilane radicals [4] in the growth process is still not resolved. To obtain insight into the role of the various radicals in the plasma we have carried out absolute density measurements of NH and NH_2 radicals in a remote Ar-NH_3 and Ar-NH_3-SiH_4 plasma by means of cavity ringdown spectroscopy (CRDS). Furthermore, we have used threshold ionization mass spectrometry (TIMS) to detect nitrogen radicals in the Ar-NH_3 plasma.

2. Experimental setup

Figure 1 gives an overview of the experimental setup that consists of the expanding thermal plasma setup, the laser system and optics used for cavity ringdown spectroscopy and the Hiden threshold ionization mass spectrometer. The expanding thermal plasma has been described extensively in the literature [5,6]. Briefly, a cascaded arc plasma source creates a plasma at high pressure (~ 400 kPa) that subsequently expands from a conical shaped nozzle into a low pressure reactor (~ 20 Pa). The plasma is created in a channel filled with Ar gas between three cathode tips and one common anode, that are separated by 4 cascaded plates at floating potential. For a pure Ar plasma, the ionization degree of the plasma depends on the source current and can be as high as 15 %. In downstream region, the electron temperature and heavy particle temperature are low (~ 0.3 eV) and the ion and electron density are in the order of 10^{13} cm^{-3}. Due to the low electron temperature, the highly reactive ions initiate the dissociation reactions with the precursor gases that are injected in the downstream region. This is different from radiofrequency plasma sources, that rely on electron induced chemistry. Processing steps, such as etching or deposition, take place in the downstream region where other precursor gases, such as NH_3 and SiH_4 are injected. In this particular experiment, NH_3 is injected in the nozzle and SiH_4 is injected in a ring situated 10 cm downstream from the nozzle.

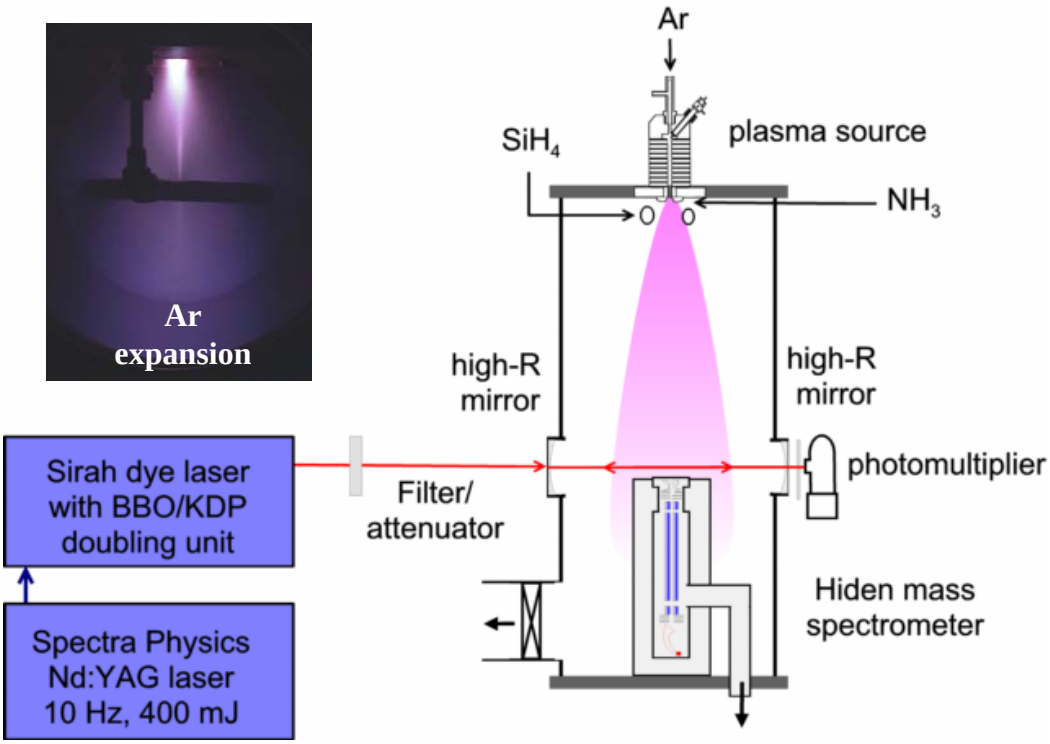

Figure 1: A schematic overview of the experimental setup with the cascaded arc plasma source, the laser system used for cavity ringdown spectroscopy and the Hiden mass spectrometer. The inset shows a typical Ar plasma expansion.

The NH and NH_2 densities were measured by cavity ringdown spectroscopy. This sensitive absorption measurement technique is very suitable for gas phase measurements of radicals in a plasma. It is based on the detection of the lifetime of an optical pulse inside a high finesse cavity that consists of two plano-concave, high reflectivity mirrors. The decay rate of the light intensity in the cavity is measured through one of the mirrors. If an absorbing medium is present in the cavity, the lifetime of the light pulse in the cavity will be shortened. The difference in lifetime (ringdown times) between an empty cavity and a cavity with absorbing species can be related to the density of the absorbing species in the cavity, when information on the cross section and absorption path length is known. In our experiment, the density of the NH radical was determined using the "isolated" $P_{3,3}(9)$ absorption line of (0,0) band of the $A^3\Pi \leftarrow X^3\Sigma^-$ transition at 339.52 nm (29543.25 cm^{-1}), while the NH_2 radical was detected at the "isolated" $\Sigma^P Q_{1,7}$ absorption line of the (0,9,0) – (0,0,0) band of the $\tilde{A}^2A_1 \leftarrow \tilde{X}^2B_1$ transition at 597.21 nm (16744.53 cm^{-1}). The peak absorption cross sections of both lines are similar (3.4 10^{20} m^2 for NH and 5.5 10^{20} m^2 for NH_2 at a gas temperature of 1750K), but the partition functions (state sums) used for the calculation of the total densities are different due to more rotational and vibrational freedom of the triatomic NH_2 [7].

In all experiments described in this paper, the plasma source was operated on a argon flow of 55 standard cubic centimeter per second (sccs) and the current through the channel was 45 A. NH_3 is injected in the nozzle with flows varying between 0 and 17 sccs, while the pressure in the reactor was kept constant at 20 Pa by changing the position of the gate valve to the pumps. Silane (SiH_4) was injected in a ring at approximately 10 cm from the nozzle. Usually, at a position of 39 cm from the source a substrate holder is placed that can be used for the deposition of silicon nitride films. All cavity ringdown measurements have been done at 36 cm from the plasma source (3 cm in front of the substrate holder). However, the substrate holder can be replaced by a threshold ionization mass spectrometer to measure radicals and stable species in the plasma beam. The sampling orifice of the mass spectrometer is situated 56 cm from the plasma source.

3. NH and NH_2 densities in an Ar-NH_3 expanding plasma jet

Figure 2 shows the absolute densities of NH and NH_2 radicals measured at 36 cm from the plasma source as a function of the injected NH_3 flow. The arc current used is 45 A and the downstream pressure was kept constant at 20 Pa. The NH density increases rapidly and saturates at a value of 2.0×10^{12} cm^{-3} for NH_3 flows greater than ~3 sccs. The NH_2 density shows a different behavior than the NH density. It increases more gradually and reaches a level of 6.0×10^{12} cm^{-3} at an injected flow of 17 sccs, but does not saturate. Langmuir probe measurements in the Ar-NH_3 plasma have shown that the ion density decreases by 3 orders of magnitude when 3 sccs NH_3 is injected in the plasma. Therefore, the saturation of the NH density at 3 sccs suggests a production mechanism for NH that is ion dominated. We propose the following basic reactions to explain the observed trends for the NH and NH_2 radical densities. First, the argon ion reacts with the ammonia molecule, creating molecular ions:

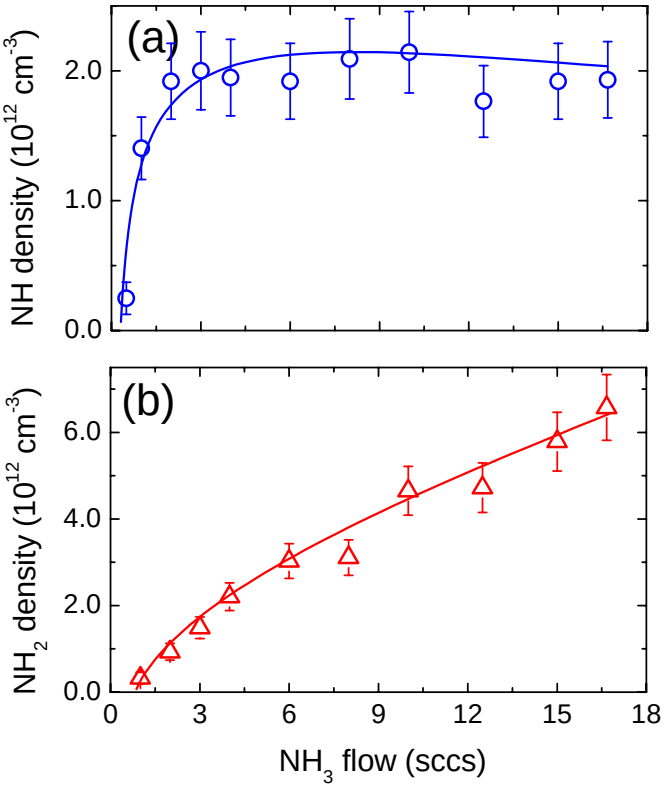

Figure 2: The NH (a), NH_2 (b) and NH_3 (c) density in an expanding Ar-NH_3 plasma. The lines are a guide to the eye.

$$Ar + NH_3^+ \rightarrow \begin{matrix} Ar + NH_3^+ \\ Ar + NH_2^+ + H \\ ArH^+ + NH_2 \end{matrix} \qquad (1)$$

This reaction has a rate constant of $1.85\text{x}10^{-9}$ cm^3s^{-1} and the channel that results in NH_3^+ is dominant [8]. Subsequently, the NH_3^+ recombines dissociatively at a very fast rate (rate constant ~$1\text{x}10^{-7}$ cm^3s^{-1}):

$$NH_3^+ + e \rightarrow \begin{matrix} NH + 2\,H \\ NH + H_2 \\ NH_2 + H \end{matrix} \qquad (2)$$

The dissociative recombination reaction results in NH and explains the saturation of the NH density when the ion density has diminished drastically (for NH_3 flows greater than 4 sccs). Reaction (2) also produces NH_2, but the NH_2 density does not saturate for higher NH_3 flows. Therefore, additional NH_2 is most likely produced by another reaction that is especially important for high NH_3 flows. One of the possibilities for this reaction is the following ion-molecule reaction:

$$NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2 \qquad (3)$$

This reaction produces NH_2 radicals, particularly at high NH_3 flows and has a rate of $1.7\text{x}10^{-9}$ cm^3s^{-1} [9], which is comparable to the rate of reaction (1). Also the dissociative recombination of NH_4^+ that is produced by reaction (3) leads to NH_2. Another reaction that can possibly explain the observed NH_2 trend is the atomic H induced dissociation of NH_3 molecules.

To check the proposed reaction scheme, we measured the NH density and the NH_3 consumption as a function of the argon ion flow from the plasma source. For both cases, we found a linear dependence on the Ar^+ flow, which is consistent with the expectations based on the proposed reaction scheme [7]. The NH_2

density, however, does not show a pronounced increase as function of the Ar^+ flow, which also indicates a different production mechanism for NH and NH_2 radicals [7].

4. NH and NH_2 densities in an Ar-NH_3-SiH_4 expanding plasma jet

Figure 3 shows the NH and NH_2 density in an Ar-NH_3-SiH_4 plasma as a function of the silane flow for a NH_3 flow of 17 sccs. The plasma source current is 45 A and the downstream pressure is 20 Pa. After a small initial increase, the NH density decreases gradually reaching a value of ~ 1.5×10^{12} cm^{-3} for an injected SiH_4 flow of 5 sccs. The NH_2 density decreases faster when SiH_4 is injected. For 5 sccs SiH_4 in the plasma, the NH_2 density is comparable to the NH density and approximately 1.5×10^{12} cm^{-3}. The decrease of the NH density might be explained by a competition between the charge transfer reaction of Ar^+ with SiH_4 and of Ar^+ with NH_3 [reaction (1)]. For NH_2, the decrease is much more pronounced and therefore, another loss mechanism is probably dominant. One possibility for this mechanism is a reaction of NH_2 radicals with silane radicals creating aminosilanes radicals. The initial increase in NH density for low SiH_4 flows might be caused by a change in the surface reaction probability for a depositing and non-depositing environment.

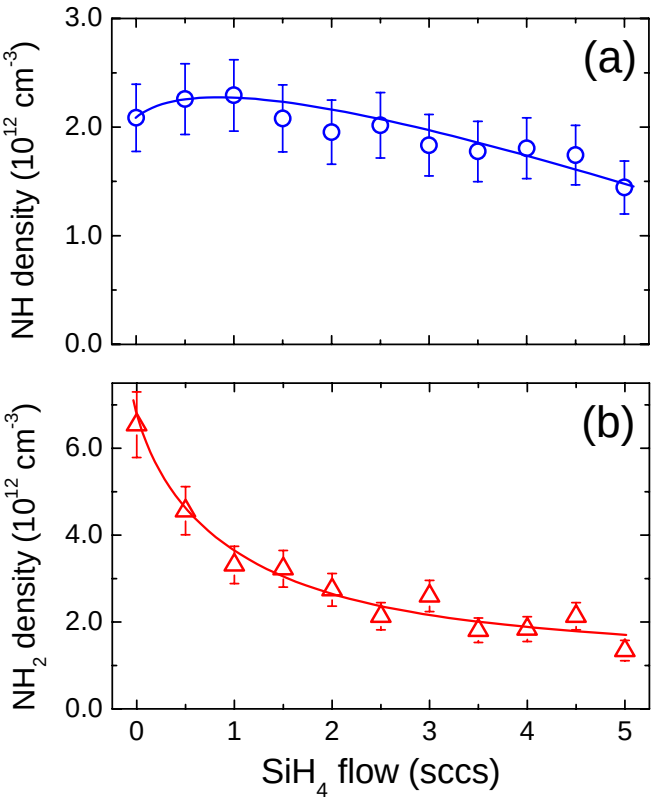

Figure 3: The NH (a) and NH_2 (b) density versus the injected SiH_4 flow. The lines are a guide to the eye.

5. Detection of N radicals

N radicals are much easier detected my mass spectrometry than by cavity ringdown spectroscopy, because the optical transitions of the N radical are in the vacuum ultra violet. Therefore, we used threshold ionization mass spectrometry (TIMS) [1] to detect N radicals in an Ar-NH_3-SiH_4 plasma. TIMS is based on the fact that direct ionization of a radical by an electron ($N + e \rightarrow N^+ + 2e$) requires less energy than dissociative ionization of a parent molecule ($NH_3 + e \rightarrow N^+ + H_2 + H + 2e$). For example, direct ionization of a N radical requires ~ 15 eV, while dissociative ionization of NH_3 resulting in N^+ requires ~ 23 eV. Here we present the first measurements of N radicals in an Ar-NH_3 plasma. Figure 4 shows the number of counts at mass 14 versus the electron energy for an Ar-NH_3 plasma ("plasma on") and for an Ar-NH_3 gas mixture

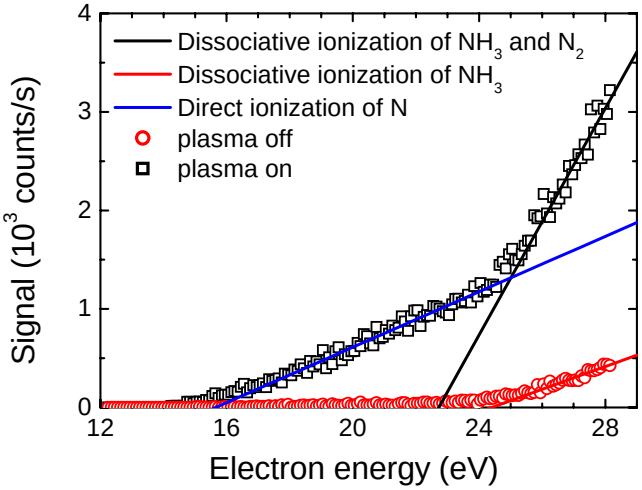

Figure 4: The signal of the mass spectrometer at mass 14 as a function of the electron impact ionization energy for plasma on and plasma off situation (Ar-NH_3 plasma).

("plasma off"). Clearly the signal for plasma on shows two distinct regions that are related to direct ionization of N radicals and to the dissociative ionization of NH_3 molecules. However, for the plasma on case, the slope of the dissociative ionization is steeper than for the plasma off case, which is not expected as NH_3 is consumed by the plasma. This indicates that also the dissociative ionization of N_2 molecules (~24 eV) that are created in the plasma contributes to the plasma on signal. This contribution can not be distinguished from the contribution of dissociative ionization of NH_3 (~23 eV) due to the small energy difference between both cases. By looking at the slope of the signal at low electron energy, the contribution of N radicals can be distinguished from the contribution of dissociative ionization of NH_3 molecules and N_2 molecules. For the plasma off signal, only the contribution of dissociative ionization of NH_3 molecules is present.

6. Conclusions

In this contribution, we have presented the NH and NH_2 density in an expanding Ar-NH_3 plasma jet measured by means of cavity ringdown spectroscopy. The maximum NH density is in the order of 2×10^{12} cm^{-3}, while the maximum NH_2 density is approximately 6×10^{12} cm^{-3}. The trends as a function of NH_3 flow, however, are different, suggesting a different production mechanism for both radicals. When SiH_4 is injected in the Ar-NH_3 plasma, the densities of both NH and NH_2 radicals decrease to approximately 1.5×10^{12} cm^{-3}. The different trends of both radicals as a function of the SiH_4 flow suggest again different loss mechanisms. In the future, threshold ionization mass spectrometry will be extended by N radical measurements as a function of NH_3 and SiH_4 flow and by measurements of SiH_x (x=0-3) radicals in the Ar-NH_3-SiH_4 plasma. The densities of these radicals as a function of several plasma parameters (flow ratio, current, pressure) will be valuable information to identify the main growth precursor for silicon nitride films.

Abstract
A novel plasma reactor has been developed in scope of the joint Czech-Japan project. The plasma system is aimed at preparation of functionally nanostructured thin films of high reproducibility. Controlled deposition of the nanostructured films is a new technological step for creative design and application of complex film systems in smart materials. Functionally gradient and/or multilayered nanostructured thin films of continuously or quasi-continuously varying physicochemical properties are worthwhile as compatible interlayers among distinct materials.

Keywords: PE CVD; thin film; multilayer; gradient film

1. Introduction

Technological applications of new materials often require them to be in the form of thin films. Many thin-film processing techniques have been developed for the fabrication of monolayers and single layers. Some of the techniques are able to prepare high quality thin films with high reproducibility. This level of technology has enabled us to deal with more complicated film systems. Over the last ten years, scientists from varying backgrounds have rallied around a versatile new method for the synthesis of multilayer thin films [1]. Because the layer-by-layer assembly method provides opportunities for creative design and application of function-specific films, the field has experienced an initial period of exponential growth. In complex systems, new properties appear that are not observed for each individual component. Plasma-enhanced chemical vapor deposition (PE CVD) is one of the perspective techniques [2] suitable for deposition of complex film structures.

In PE CVD, chemical activation is achieved by supplying electrical power to a gas at reduced pressure (10^{-1}–10^{3} Pa). At that pressure, the application of a sufficiently high voltage creates a visible glow, called glow discharge plasma. The low temperature plasma consists of about equal concentration of ions and electrons. Charge recombination processes and relaxation of electronically excited atoms and molecules cause the visible glow. The electrical power is coupled into the gas through the mediation of plasma electrons. The energetic electrons in the plasma ionize the gas, if only to a minor extent – about one part per million. The electrons chemically activate a much larger fraction of the gas, about 1 percent. The increased chemical activity of the gas (monomer vapor) results primarily from dissociation of the molecules into smaller species, called radicals. Radicals are chemically unsaturated and therefore capable of chemical reactions at high rates; they are the species that react at a surface (substrate) and contribute to film formation. Plasma polymerization is a film-forming process, in which growth of low-molecular-weight molecules (monomers) into high-molecular-weight molecules (polymers) occurs with the assistance of the plasma energy [3]. It should be emphasized, that the adjective "plasma" does not mean a kind of activated species propagating polymeric chains in plasma polymerization in contrast to radical or ionic polymerizations. The term "plasma" means an energy source to initiate polymerization reactions. In many cases, polymers formed by plasma polymerization show distinguished chemical composition, and chemical and physical properties from those formed by conventional polymerizations, if the same monomer is used for the two polymerizations. This uniqueness of plasma polymers results from the reaction mechanism of the polymer-forming process.

2. Nanostructured films

Plasma-polymerized organosilicones constitute a class of materials with a rich and varied scientific background. This class of materials possesses a special characteristic, which distinguishes it from other

plasma polymers. It is the ability to vary and control the degree of organic/inorganic character (that is, the carbon content) by appropriate choice of fabrication variables. This allows one to control many physico-chemical properties over wide ranges resulting in an extraordinary potential for useful applications, which are now only beginning to be tapped. The organosilicon plasma polymers are widely observed with respect to the potential for optical, mechanical and electronics applications. These materials were reviewed in Ref. 4,5.

The mechanical properties (hardness, Young's modulus, adhesion, internal stress) of thin films are of great importance with respect to applications such as protective coatings to improve wear resistance or possibly as lubrication. Therefore thin films of quite different mechanical properties are required. Multicomponent materials such as composites require functional films (interlayers) that are embedded among components (reinforcing fiber, polymer matrix) to improve their compatibility and it is expected that ductile and flexible films of the elastic modulus value about 10^0 GPa are expected to fulfill the demands [6]. The Young's modulus and thickness of the interlayer are among the main parameters influencing composite performance [7]. Model calculations even suggest controlling the composite strength and toughness by varying the interlayer modulus [8]. Experimental data drawn from the literature indicate that thin films of variable moduli can be deposited even by the same monomer using plasma techniques. However, most of the materials, such as a-Si:H [9], a-SiN:H [10], a-SiO_2:H [10], a-C:H [9,11] or a-SiCO:H [12], are too stiff materials of the modulus higher than 40 GPa (Fig. 1).

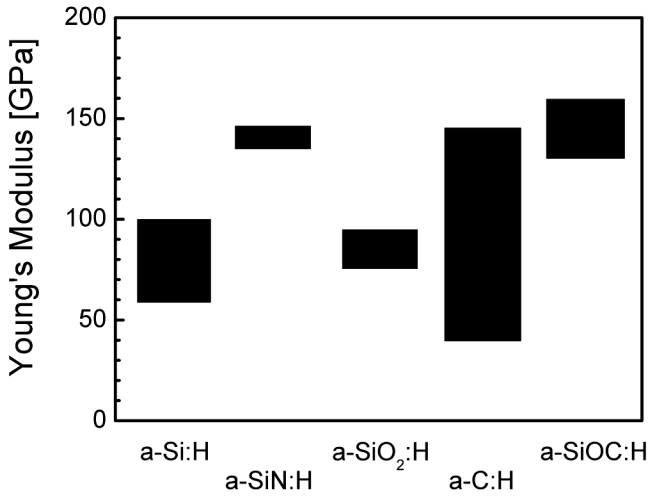

Fig. 1. Range of elastic modulus corresponding to thin films prepared by plasma techniques.

Our team in cooperation with research workers in UK was successful in deposition of hydrogenated amorphous silicon oxycarbide (a-SiCO:H) single layers of RF-power controlled Young's modulus (4 – 40 GPa) [13,14]. The soft and highly elastic films of a thickness ranging from 15 nm to 4 μm were deposited on planar glass and silicon substrates using an inductive coupling plasma system [15]. Our films were prepared at a relatively low power density, and the lower plasma energy therefore seems to be the reason for the reduced elastic modulus. Monomer molecules are more activated and fragmented forming a higher density of free radicals, if the plasma energy increases, and the reactive species results in a highly cross-linked polymer.

In general, a utilization of interlayer with the modulus about that of the polymer matrix (3-4 GPa) or even lower results in problems with a very sharp fiber/interlayer interface (Fig. 2(b)). A simple gradient interlayer could suit better; see Fig. 2(c). In that case, both the interfaces are not so sharp and the interlayer material is not so stiff. More sophisticated modulus profile can be suggested to ensure a strong but tough composite using a functionally gradient nanostructured interlayer; see Fig. 3 (solid line) [16]. Preparation of an interlayer with chemical and physical properties continuously varying from those of the fiber to those of the matrix without any interface could be an ambitious aim.

Multilayer thin films (sandwiches) can be prepared using the fabrication "bottom-up". Thus, a nanostructured interlayer can be prepared as layer-by-layer (Fig. 3, dashed line), where the film thickness of a single layer could be only several tens of nanometers and single layers have to be bonded each other using strong chemical bonds. We could construct a functionally gradient nanostructured interlayer "without" interfaces if any coating technology would be able to prepare film of continuously varying properties in one deposition. Such a nanotechnology could be worth for formation of the controlled interphase in

multicomponent materials. With respect to our experience we expect that the plasma-enhanced chemical vapor deposition has the potential to be successful in preparation of functionally nanostructured thin films.

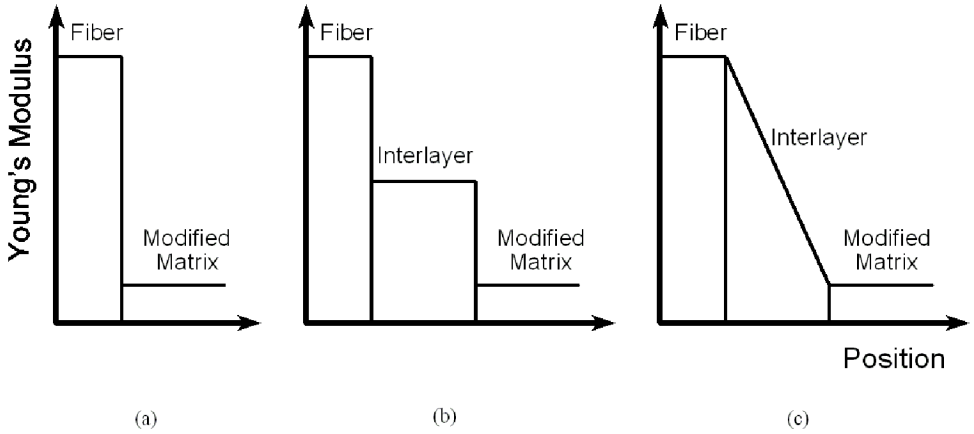

Fig. 2. Schematic illustration of the elastic modulus profile across the fiber/interlayer/matrix composite system (multicomponent material): (a) without interlayer, (b) homogeneous interlayer, (c) gradient interlayer.

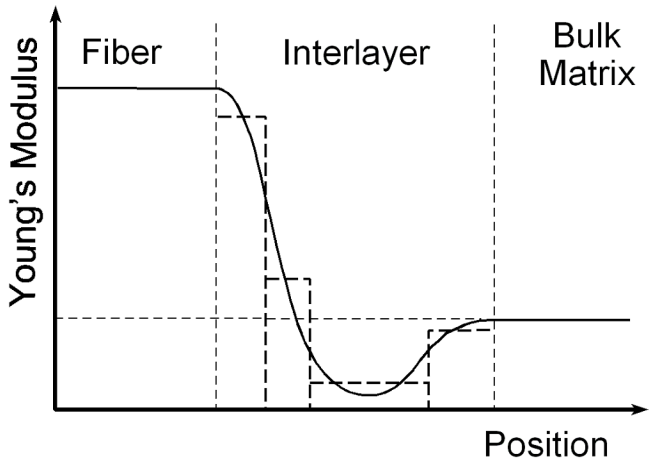

Fig. 3. Schematic illustration of elastic modulus profile across the fiber/interlayer/matrix composite system (multicomponent material) with a functionally gradient nanostructured interlayer prepared as layer-by-layer (dashed line) or in one deposition (solid line).

3. Technological apparatus

A novel plasma reactor has been developed in scope of the joint Czech-Japan project (2002-2004) supported by the Czech and Japan Ministry of Education. The plasma system (Fig. 4) is aimed at preparation of functionally nanostructured thin films of high reproducibility. The internal setup of our deposition chamber, using plan-parallel electrodes, was derived from a typical capacitive coupling system, but our apparatus of new creative design was equipped with many non-standard components. A special construction of bottom rotary electrode (ø 114 mm) (Fig.5) enabled us to stick in/out samples (Fig.6) into/from the chamber under vacuum, and so without reactor contamination, using a magnetic drive (linear and rotary, BOC Edwards) and a special load lock mounted inside of differentially pumped side chamber. Next, the rotary electrode can be heated/cooled ranging from –100 to 300 °C and biased ranging from –500 V to +500 V. An upper electrode (ø 135 mm) of shower-type can be positioned in a distance of 20 – 60 mm from the bottom one. A movable substrate shutter can be used to deposit film at steady-state plasma conditions. An RF-generator (Cesar 1310, 13.56 MHz, 1000 W, Dressler) was connected to the system using an automatic matching network (VM 1000A, Dressler). It was possible to achieve a range of effective power density from 1×10^{-4} to 4×10^{0} W cm^{-3} (1×10^{-3} to 4×10^{0} W cm^{-3}) using pulsed (continuous) plasma regime with respect to the movable top electrode.

A turbomolecular pump (TMU 261 P, Pfeiffer Vacuum) with a dry scroll pump (TriScroll 300, Varian) as the first stage and an LN2-cooled trap were selected to evacuate the system in order to eliminate oil vapor, minimize a rest of water in all vacuum chambers and thus acquire the basic pressure ~ 10^{-6} Pa. Cleaning of the system, substrate pretreatment, and deposition process were automatized via control unit.

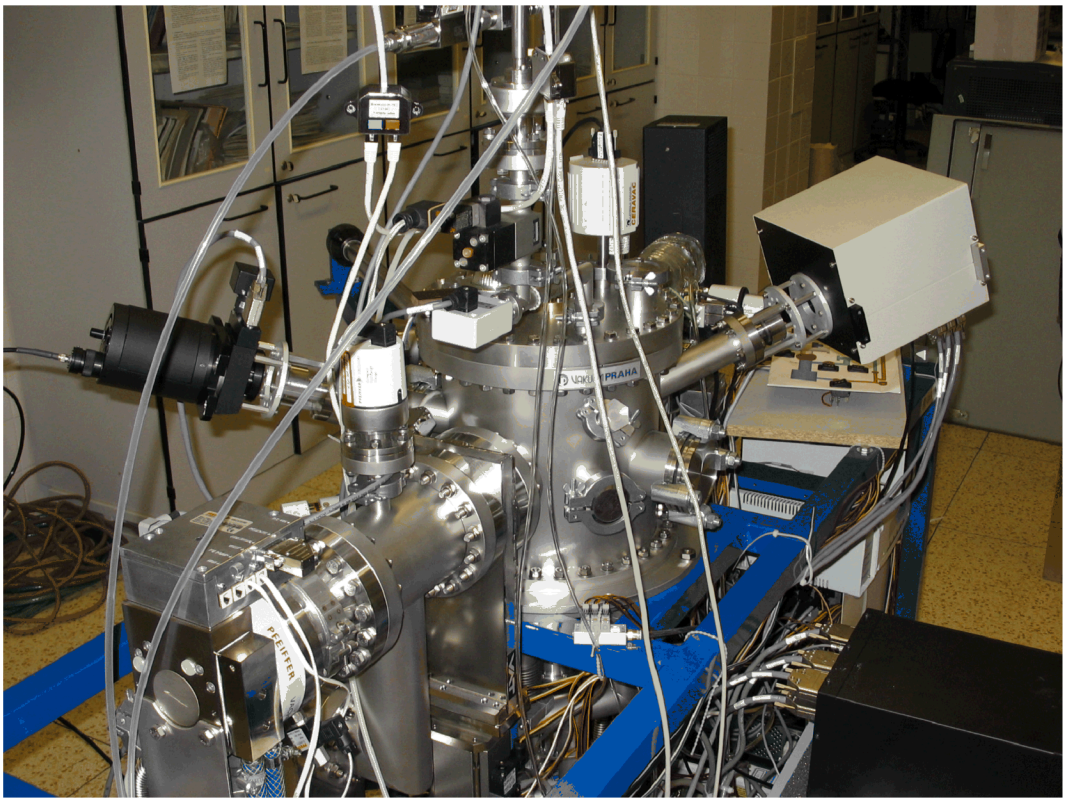

Fig. 4. A real view of new technological apparatus.

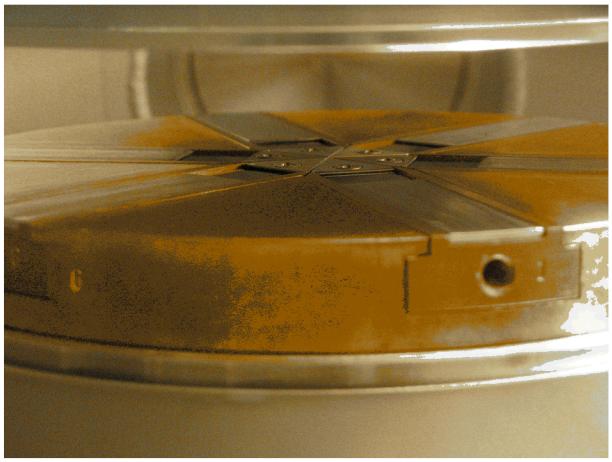

Fig. 5. Bottom rotary electrode with substrate holders inside.

Fig. 6 Substrate holders.

The reactor was equipped by mass spectrometer (Process Gas Analyser HPR-30, Hiden Analytical), in-situ spectroscopic ellipsometer (UVISEL, Jobin Yvon), and optical emission spectrometer (Triax 550, Jobin Yvon) to monitor the plasma process and film growth (Fig. 7). The in-situ ellipsometry enables analyses not only single layers but also multilayers [17-19] with respect to their thicknesses and optical constants. New numerical simulations enabled fast analyses of measured ellipsometric data corresponding to complex

multilayer and gradient nanostructures. The optical constants of a newly grown ultrathin layer should be used as a feedback for the control of deposition conditions during a nanostructure growth. This is a new conception of a controlled plasma process (PE CVD).

Controlled deposition of the functionally nanostructured thin films is a new technological step for creative design and application of complex film systems in smart materials. Functionally gradient and/or multilayered nanostructured thin films of continuously or quasi-continuously varying physicochemical properties are worthwhile as compatible interlayers among distinct materials.

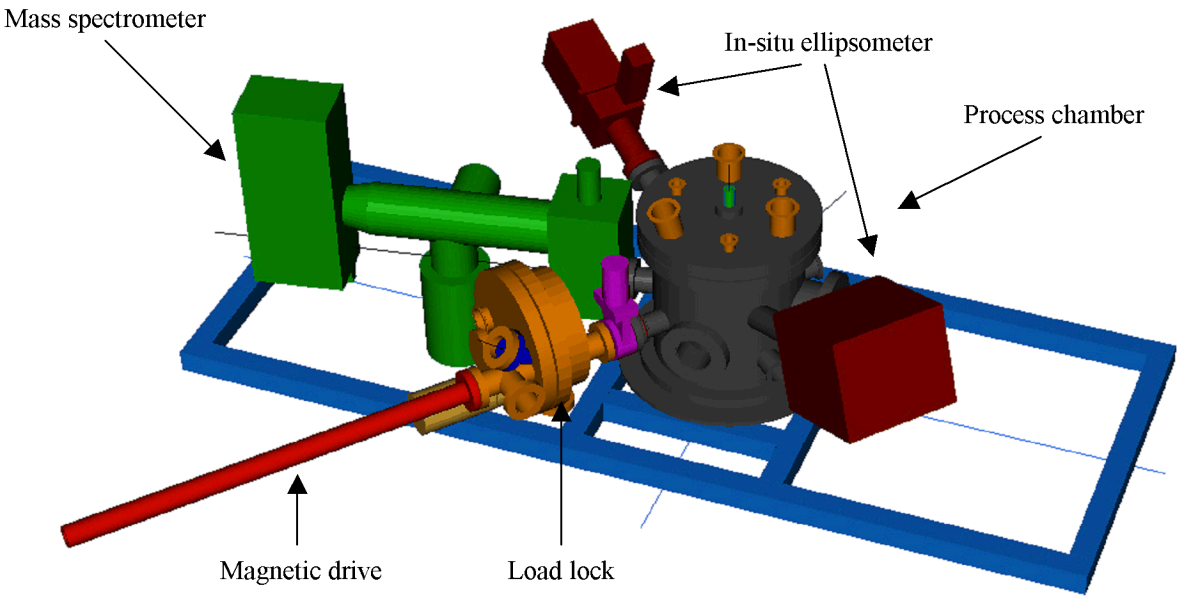

Fig. 7. Schema of process chamber with load lock, magnetic linear drive, mass spectrometer, and in situ ellipsometer.

4. Conclusion

We are going to promote our experience with a deposition of single layers of controlled properties. The controlled construction of nanostructured multilayers and gradient thin films of a given elastic modulus (hardness) and/or refractive index profiles, using the plasma-enhanced chemical vapor deposition (PE CVD), is the main objective of new activities. Thin and ultrathin single layers and functionally nanostructured thin films will be deposited using a high-tech RF capacitive coupling system equipped by in-situ spectroscopic ellipsometer, optical spectrometer and process gas analyzer. The deposition system will be automatized to enable precise and fast varying of deposition conditions via control unit (PC) and all the deposition process (pretreatment of substrate, deposition steps, post-treatment of layered structure) will be programmed. Analyses of measured ellipsometric data provide optical parameters during the growth of complex multilayer or gradient nanostructures. The optical constants of a newly grown ultrathin layer will be used as a feedback for the tuning of deposition conditions during a nanostructure growth. This is quite a new conception of the controlled plasma process (PE CVD). Selected organosilane monomers and their mixtures with a gas together with other suitable silane and non-silane monomers have to be utilized for the preparation of functionally nanostructured thin films with controlled organic/inorganic character. The deposited films and their layered nanostructures will be extensively characterized by microscopic and spectroscopic techniques in order to determine surface morphology, microstructure, and chemical structure. Selected mechanical and optical parameters across the nanostructured thin film will be determined as a function of deposition conditions and the structure-property relations will be discussed as well. We expect that new properties and phenomena could appear in such complex systems that are not observed for each individual component.

Abstract
Plasma-polymerized thin films of vinyltriethoxysilane were deposited on IR-transparent silicon wafers using plasma-enhanced chemical vapor deposition. Deposited films were characterized by spectroscopic techniques (RBS, ERDA, XPS, FTIR) in order to compare their elemental composition and chemical structure. We were able to influence/control the elemental composition and chemical structure of the plasma polymer films in relatively wide ranges by increasing the effective power.

Keywords: PE CVD; thin film; organosilicon; FTIR; RBS; ERDA; XPS

1. Introduction

The vinyltriethoxysilane (VTES) monomer is one of silane coupling agents [1] recommended for surface modification of glass fibers employed as reinforcements for polyester-matrix composites. The VTES molecule is a multifunctional one, which reacts at one end with the glass surface and at the other end with the polymer matrix. In principle, a polysiloxane interlayer prepared by wet chemical process from VTES should provide a strong but tough bond [2] between the reinforcement and the polymer matrix. However, the real polycondensed film is heterogeneous [3] with respect to the uniformity and film thickness. The molecules of silane coupling agent have a tendency towards self-condensation, forming siloxane oligomers rather than complete bonding with the glass surface [4,5], which results in deterioration of composite performance. We would like to introduce a plasma-polymerized vinyltriethoxysilane (pp-VTES) as homogeneous film (interlayer) and demonstrate a variety of the films with respect to their chemical properties that could be controlled by deposition conditions.

2. Experimental

Pp-VTES films were deposited on IR-transparent silicon wafers using a helical coupling pulsed-plasma system (13.56 MHz); details on the apparatus have been described in Ref. 6. The vacuum system was evacuated to a pressure of 5×10^{-3} Pa and then flushed with argon gas (10 sccm) for 10 min. A basic pressure of 2×10^{-3} Pa was established in the deposition chamber after flushing. Monomer vapor at a mass flow rate of 0.45 sccm (process pressure was 0.02 mbar) was introduced into the deposition chamber using a dose valve. The plasma was ignited at a selected effective power ranging from 0.05 to 25 W, using pulsed plasma with t_{on} = 1 ms and a total power of 50 W. When the deposition process was ended, all the apparatus was flushed by argon gas and after 30 min the chamber was flooded by air to atmospheric pressure and the prepared specimen conveyed from the chamber into a desiccator to avoid contamination before measurements.

Films of the thickness ranging from 0.2 to 1.4 μm were subjected to chemical analysis. The elemental composition, atomic surface density, and density of thin films were studied by conventional and resonant Rutherford Backscattering Spectrometry (RBS) and Elastic Recoil Detection Analysis (ERDA) methods using Van de Graaf generator with a linear electrostatic accelerator. The depth profiles of heavy elements were measured by RBS using 2.73 MeV alpha particles impinging perpendicularly on sample surface and detected scattered under the laboratory scattering angle of 170 deg. The Si and C, O content were measured by using 2.4 MeV protons as projectiles. The reason for this is the enhanced selectivity for some lights elements as admixtures. The ERDA and RBS with incident beam of 2.75 MeV alpha particles at 75 deg to sample surface normal was simultaneously measured. The hydrogen atoms recoiled under the angle of 30 deg were detected with a surface barrier detector covered with 12 μm thick Mylar stopping foil. Similar uncovered surface barrier detector was used for simultaneous detection of alpha particles scattered under the laboratory scattering angle of 170 deg. Small aluminium propeller covered by thin gold layer and checked by simultaneously measured RBS monitored the amount of impinging alpha particles needed for ERDA

normalization. The RBS was evaluated by computer code GISA 3 [7] and the ERDA by SIMNRA code [8] both using cross-section values from SigmaBase. The charge of impinging alpha particle was not measured directly and thus the evaluation of RBS with alpha particle was used to estimate amount of impinging alpha particles needed for ERDA normalization. The estimated accuracy of composition measurements was about 5 at%.

The Si, C and O bulk contents were correlated with the surface one determined from analyses of the photoelectron spectra using X-ray Photoelectron Spectroscopy (XPS). The composition of elements in the surface region (top 6–8 nm) of the deposited layers was studied by XPS on an ADES 400 VG Scientific photoelectron spectrometer using Mg K_α (1253.6 eV) photon beam at the normal emission angle. Atomic concentrations were determined semi quantitatively assuming the model concerns a solid that is homogeneous in composition [9]. Peak areas were corrected for inelastic background [10], photoelectron cross-sections, asymmetry parameters [11], inelastic mean free paths [12], and the measured transmission function of the electron energy analyzer [13]. The estimated accuracy of composition data was about 2 at%.

Infrared measurements in the wavenumber range from 400 to 4000 cm^{-1} were carried out using a Nicolet Impact 400 Fourier transform infrared (FTIR) spectrophotometer in an H_2O-purged environment. Transmission spectra were obtained on films deposited on one-side polished crystalline silicon wafers. An absorption subtraction technique was applied to remove the spectral features of Si wafers. The spectral resolution was 2 cm^{-1}. Approximately 128 scans were recorded to achieve the signal-to-noise ratio.

3. Results and discussion

It was possible to prepare continuous and homogeneous coatings on planar substrates with a film thickness ranging from 15 nm to 2 μm. The film thickness and optical constants were determined from ellipsometric data (UVISEL Jobin Yvon). Optical data were processed using a model of single homogeneous film on the semi-infinite silicon substrate. The deposition rate varies as a function of the effective power in a range of 1–120 nm min^{-1} and the film thickness could be controlled by deposition time. The surface roughness (RMS) of pp-VTES films measured only several nanometers as obtained using AFM (Accurex IIL, Topometrix).

The bulk elemental compositions corresponding to the pp-VTES film deposited at different power and were evaluated from RBS/ERDA measurements are given in Fig. 1. There was no evidence about a depth profile in measured spectra of films with the film thickness up to 2 μm and thus we could state that the films were homogeneous. We can notice form the Fig. 1 that the hydrogen concentration was almost the same (40 – 45 at%) for all the films. However, the carbon concentration increased and oxygen and silicon concentrations decreased significantly when the effective power was enhanced.

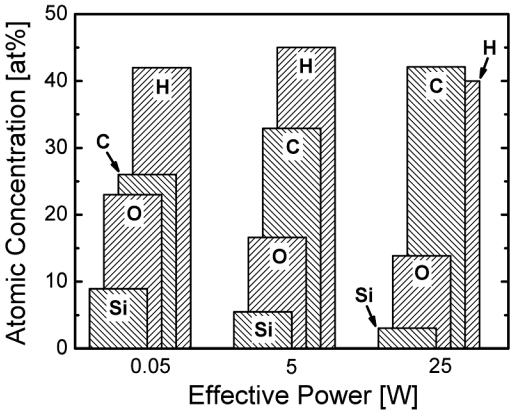

Fig. 1. Elemental composition of pp-VTES films deposited at different power determined form RBS/ERDA.

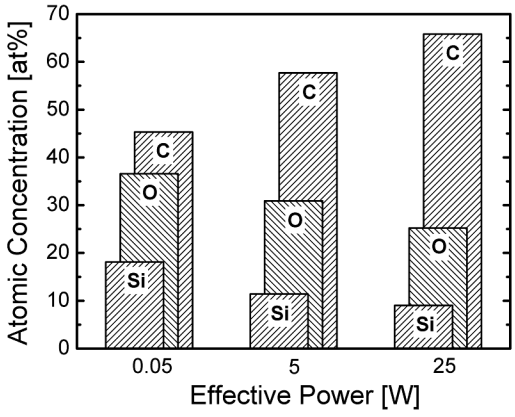

Fig. 2. Elemental composition of pp-VTES films deposited at different power determined form XPS.

Using the same samples, the elemental compositions at the surface layer (6-8 nm) of pp-VTES films were determined from the integral intensities of the C 1s, O 1s, and Si 2p signal of the XPS spectra recorded. The determined atomic concentrations (Fig. 2) exhibited the same trends with respect to the power as the

previous data (Fig. 1). Carbon, oxygen and silicon concentrations evaluated from RBS/ERDA measurements were recalculated eliminating the hydrogen concentration in order to enable comparison between the bulk and surface data (XPS), see Fig. 3. We could find a perfect agreement among the concentration values corresponding to bulk and surface data. The difference is only up to 5 at%, which is within an accuracy of the RBS method.

Element ratios in the monomer molecule compared with those for pp-VTES films prepared at different power gave a picture about great changes in plasma polymer (Fig. 4). The ratios were calculated using the bulk concentrations (RBS/ERDA). One can see that the organic/inorganic character of the film, represented by the element ratio of C/Si, varied in a wide extent from 2.9 to 13.9, when the power was enhanced. In a similar way, the O/Si ratio increased from 2.6 to 4.6 and, the C/O ratio increased from 1.1 to 3.0, when the effective power was enhanced form 0.05 to 25 W. The determined results revealed that the plasma polymer deposited at low power (0.05 W) was deficient of carbon atoms and that one deposited at higher power (25 W) was deficient of silicon atoms. The molecular formula of the monomer, $SiO_3C_8H_{18}$, and the plasma polymer one, $SiO_3C_6H_{8.2}$, corresponding to the pp-VTES film deposited at a power of 5 W, seemed to be similar but the chemical structure of plasma polymer was quite different.

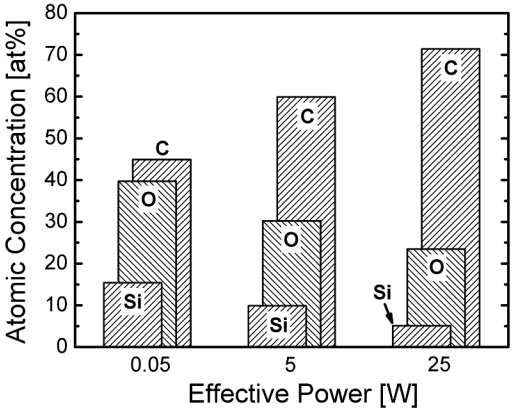

Fig. 3. Carbon, oxygen and silicon concentrations evaluated from RBS/ERDA measurements and recalculated eliminating the hydrogen concentration.

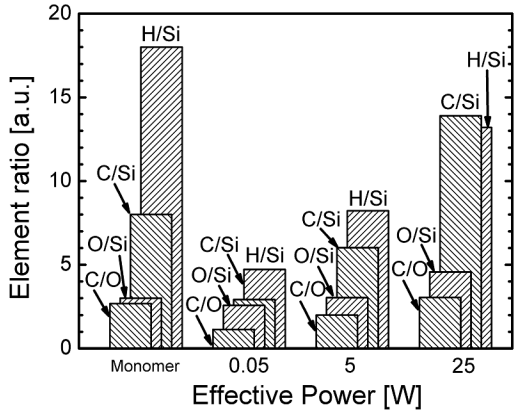

Fig. 4. Comparison among element ratios corresponding to monomer molecule and pp-VTES films deposited at different power.

Figure 5 shows typical FTIR spectra of the pp-VTES films prepared at different effective power (0.05, 5, 25 W). The absorption bands at 2970–3000 cm^{-1} were assigned to CH_3, CH_2 stretching vibrations [14] and a decreased intensity corresponding to the methyl groups evidenced a decrement of this species in plasma polymer films deposited at high power (25 W). Two bands (965 cm^{-1} and 1163 cm^{-1} [14]) assigned to the Si–O–C stretching vibration in ethoxy groups were not evident in spectra of high-power deposited pp-VTES film and this phenomenon corresponded well to a descent of methyl groups. The CH_2 asymmetric stretching vibrations at 3058 cm^{-1} [15], C=C stretching vibrations at 1600 cm^{-1} [15], CH_2 deformation vibrations at 1410 cm^{-1} [15], and =CH waging vibrations at 1010 cm^{-1} [15] corresponding to the vinyl groups were not apparent in all IR spectra of pp-VTES films. The pp-VTES films seemed to be free of vinyl groups or plasma polymer could content a low density of the groups as the absorption bands were of low intensity even at the monomer spectrum. Increasing the power, a new absorption band could be found at 3200–3700 cm^{-1} assigned to the OH stretching vibrations [14,15] and one at 1710 cm^{-1} corresponding to the carbonyl stretching vibrations [16]. The dominant absorption band in all the spectra could be found at a range of 1000–1200 cm^{-1}. The absorption band at 1072 cm^{-1} [16] corresponds to the Si–O–Si/Si–O–C stretching vibrations in continuous random network, which forms the basic chemical structure of the material prepared at lower power (0.05 and 5 W). The band decreased when the effective power was enhanced (25 W).

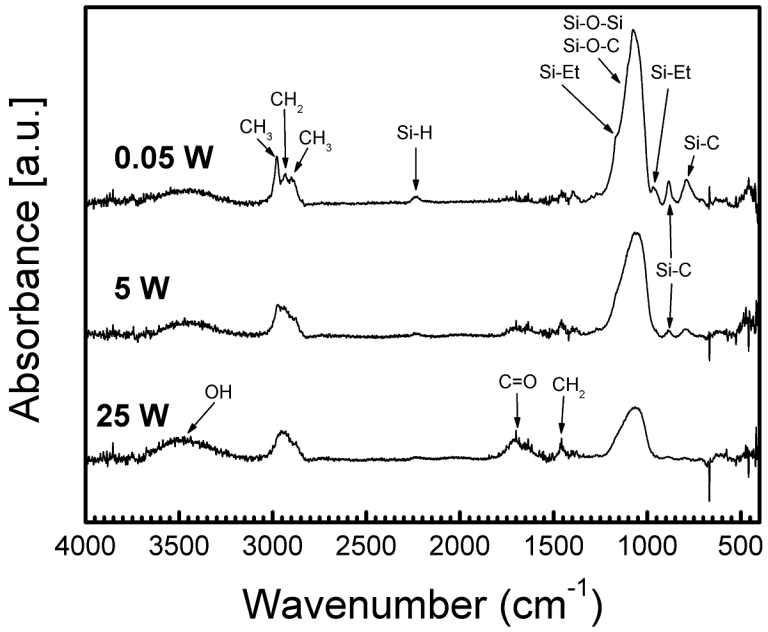

Fig. 5. Infrared spectra of pp-VTES films deposited at different power.

4. Conclusion

Plasma-polymerized vinyltriethoxysilane (pp-VTES) films were deposited on planar silicon substrates using pulsed plasma (PE CVD). The deposition rate could be controlled by power and the thickness of plasma polymer film could be easily varied in a range of 15 nm – 2 μm with the film surface relatively flat. Ellipsometric and RBS/ERDA data gave evidence about the single homogeneous film. The bulk (RBS/ERDA) and surface (XPS) elemental composition of films agreed within an error up to 5 at%. The hydrogen concentration was almost the same (40 – 45 at%) for all the pp-VTES films. The organic/inorganic character of the pp-VTES film was varied extensively and can be expressed by bulk element ratio of C/Si, which increased from 2.9 to 13.9, when the effective power enhanced from 0.05 W to 25 W. Molecular formulas of the monomer and plasma polymers deposited at different power varied as follows:

Monomer	$SiO_3C_8H_{18}$
0.05 W	$SiO_{2.6}C_{2.9}H_{4.7}$
5 W	$SiO_{3.0}C_{6.0}H_{8.2}$
25 W	$SiO_{4.6}C_{13.9}H_{13.2}$

The pp-films were constituted by Si–O–Si/Si–O–C network with side ethoxy groups that decreased when increasing the power. The absorption bands corresponding to the C=O and OH stretching vibrations were apparent for plasma polymer films deposited at higher power. However, the vinyl groups in the pp-VTES were not confirmed by FTIR spectroscopy even if a very low power was used.

Abstract:
The composition of HMDSO microwave plasma phase at 4.10^{-3} mbar and of the corresponding films were studied by FTIR spectroscopy, under different power conditions. We have shown that the thin film composition is related to the plasma phase composition The interpretation of these observations led to a proposal involving a chemical mechanism: the increasing decomposition of HMDSO into by-products, which themselves decompose all the more as power increases, plays a determining role.
Keywords: hexamethyldisiloxane, plasma, gas phase infrared spectroscopy, SiOxCHy

1. Introduction

Under plasma conditions, thin film deposition often results from the surface reactions of neutral active species. Therefore, the properties and the quality of deposited film depend on the relative contribution of these species to the film growth. Understanding how the dissociation conditions affect these contributions provides important guidance in finding the mechanism leading from the initial precursors to the film formation. This paper focuses on the hexamethyldisiloxane (HMDSO) dissociation mechanism and the resulting species as well as the relationship between these species and the nature of the deposit. Although ions can also be important for deposition and film properties, in our case the deposition is mainly due to neutral active species. No direct analyses of HMDSO dissociation products can be found in the literature. It has only been indirectly studied. The works carried out by Magni [1] and Alexander [2] in radiofrequency discharges using mass spectrometry suggest a breaking of both Si-O and C-Si bonds after electron impact. Besides, studies in microwave discharge using Direct Electron Cyclotronic Resonance (DECR) [3-5] have shown that a large production of hydrocarbon molecules is an evidence of C-Si bond breaking in HMDSO plasma. Besides the HMDSO thermal dissociation may also lead to other organosilicon species [6].A determination of HMDSO by-products under different radiofrequency plasma conditions (100 mTorr) was undertaken by F.Fracassi et al [7]. They essentially detect many linear and cyclic oligomers containing -$(CH_3)_2$SiO-chemical group.The aim of this work is to contribute to the understanding of HMDSO plasma deposition mechanism at very low pressures (few mbar) through the Fourier transform infrared analysis of the gas phase and the the chemical analysis of the deposits.

2. Experimental

The experimental reactor coupled to the gas infrared measurement setup, schematically represented in figure 1, has been described elsewhere [3,4]. The optical length of the infrared beam can be adjusted by multi-reflection to a maximum of 44 m. The spectra were recorded by means of Biorad FTS 60A FTIR spectrometer. The data reported were obtained with a resolution of 0.5 cm^{-1}. The detection threshold of our IR setup was around 5 10^{10} molecules.cm^{-3}. The plasma was a MMP-DECR at 2.45 GHz. The analyses were carried out at a total pressure of 4.10^{-3} mbar with power ranging from 60 to 600 watts. As during a run the mirrors and KBr windows could be covered with a deposit, a particular attention was paid to estimate the mirror coverage by a deposit. Before each experiment, a base line was recorded as the background for the new experiment. Moreover, spectra of the empty reactor were recorded after each run. After a run, no significant signal was obtained on the mirrors with respect to infrared measurement in the plasma gas phase. Fourier Transform Infrared spectroscopy (FTIR) gives information on the neutral species present in the plasma.

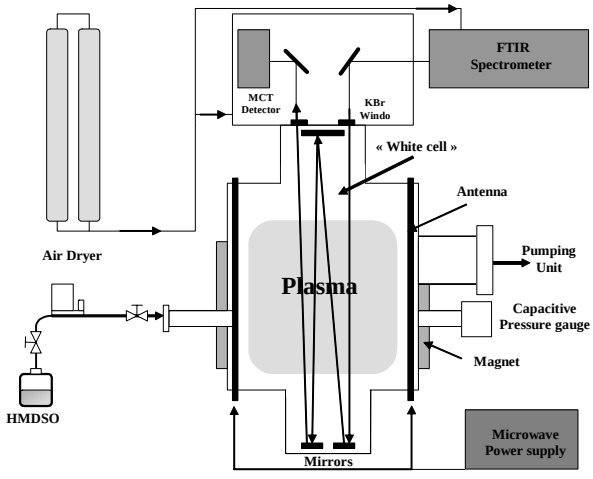

Figure 1: Microwave reactor coupled to the gas infrared measurement setup

3. Results and discussion

A. Pure hexamethyldisiloxane FTIR spectra.

The Beer Lambert law was checked at different pressures with a 40 m path length within the pressure range used in our experiments. Figure 2 shows a typical HMDSO spectrum. An identification of HMDSO bands has been already done in previous works [1,3][4][8]. Table 1 lists the bands observed in the present study. In the νCH regions, the asymmetric stretching CH_3 mode, the symmetric bending CH_3 mode (ν_s δ CH_3 in Si $(CH_3)_x$ $1 \leq x \leq 3$) and two rocking modes (ρCH_3 in $Si(CH_3)_x$) respectively appear at 2964 cm^{-1}, 1260 cm^{-1} and 850, 834 cm^{-1}(weak shoulder). Besides, in the νSiO regions, the stretching mode of Si-O-Si bridge band appears at 1072 cm^{-1}.

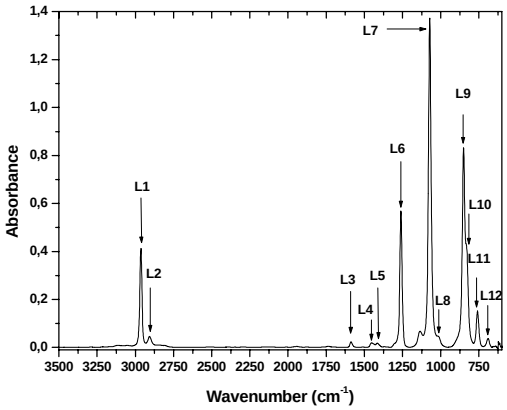

Figure 2: Pure HMDSO FTIR spectrum at 4.10^{-3}

B. Analysis of the plasma phase

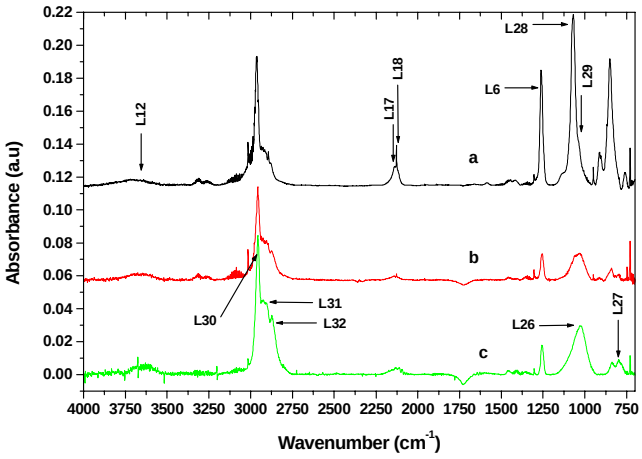

Figure 3: Plasma FTIR spectra at different microwave powers: a (60 W), b (170 W), c (600 W),

In order to accurately examine the HMDSO by-products in the plasma phase we have to get rid of the residual HMDSO spectrum bands (Figure 3). At low microwave powers, figure 3a clearly shows IR bands at 3660 cm^{-1}, 2138 cm^{-1}, 2128.5 cm^{-1}, 1260 cm^{-1}, 850 and 834 cm^{-1}. The presence of hydrocarbons is also observed. The bands at 2128.5 cm^{-1}, 2138 cm^{-1}, 914 cm^{-1}, 903 $cm^{-1}$are in the range of SiH bands. The main difference with respect to the initial plasma spectrum is the appearance of an important band at 1068 cm^{-1} which could be the signature of Si-O-Si bridge which normally appears at 1072 cm^{-1} for the monomer HMDSO. This slight wavenumber shift is probably due to a small Si-neighbourhood modification. A very small shoulder also appearsg at 1025 cm^{-1}. A study of HMDSO radiofrequency discharges [7] at about 100 mbar showed the production of tetramethylsilane (TMS) , trimethylsilanol, ethyltrimethylsilane, pentamethyldisiloxane(PMDSO), ethylpentamethyldisiloxane. At low plasma power in DECR (60W), our spectra do not show any TMS bands such as the 868.7 cm^{-1}(vs) and 1254 cm^{-1} absorbtion bands [4]. A theoretical work from McKean [9] for $(CH_3)_3SiH$ (TriMS) predicted a very strong absorption at 2128.5 cm^{-1}. Except the very strong band appearing around 2128.5 cm^{-1}, the TriMS bands are more difficult to identify in the plasma because of their low amplitudes with respect to the other bands. Nevertheless, one of the bands either at 903 or at 914 cm^{-1} can be assigned to the SiH bending mode of TriMS. According to McKean[9] this mode is at 908 cm^{-1}. The presence of this species at low power can partly explain the m/z peaks at 73 $(Si(CH_3)_3^+$, M^+_{TriMS} -1) and 59 $(SiH(CH_3)_2^+$, M^+_{TriMS} -15) observed in mass spectrometry [2]. Besides, the band at 1068 cm^{-1} together with the remaining bands at 1262 cm^{-1} and 850 cm^{-1} indicate the presence of some products with the same structure as HMDSO. PMDSO should be the molecule involved considering the SiH stretching band at 2139 cm^{-1} and one of the SiH bending bands at around 910 cm^{-1}. The m/z peak at 133 $(H(CH_3)_2SiOSi(CH_3)_2^+$, M^+_{PMDSO}- 15) in mass spectrometry also detected by Alexander [2] argues for the presence of PMDSO. Finally the very weak band at 3660 cm^{-1} could indicate the presence of trimethylsilanol traces. Thus, PMDSO, TriMS and hydrocarbons seem to be the main HMDSO by-products present in the gas phase under low power conditions. The situation seems more complex under high power conditions (600 W) with the presence of bands at 2956 cm^{-1}, 2924 cm^{-1} 2878 cm^{-1} and 1025 cm^{-1}(Fig.3c). However, with respect to the gas phase spectrum under low-power conditions (60 W), the strong increase of the CH stretching bands in the 2900 cm^{-1} range, the disappearance of the bands at 2128.5 cm^{-1}, 850 $cm^{-1}$and 759 cm^{-1}, and the

band shift from 1068 to 1022 cm^{-1} are worth mentioning and can draw comments. The first interesting observation concerns the TriMS absence which is unambiguously characterized by the 2128.5 cm^{-1} band disappearance. The band disappearance at 1068 cm^{-1} clearly indicates no significant PMDSO presence. As a confirmation of the HMDSO, PMDSO and TriMS disappearance, the band at 850 cm^{-1}, which is a signature of $-Si(CH_3)_3$ in these monomers, shifted to 837 cm^{-1}. This behaviour implies a modification of chemical environment of the $-Si(CH_3)_3$ group. Moreover, the $-Si(CH_3)_3$ amount is low at this power as revealed by the weakness of the 837 cm^{-1} band and the disappearance of the weak band at 760 cm^{-1} corresponding to Si-C in $-Si(CH_3)_3$.

The modification of the main band at 1072 cm^{-1} attributed to Si-O-Si bridges in pure HMDSO also draws comments on the evolution of the gas phase species. Under low power conditions, the appearance of species such as PMDSO leads to a band at 1068 cm^{-1}. This 4 cm^{-1} shift is consistent with the slight chemical modification between HMDSO and PMDSO. Under high power conditions, only a broad band at 1022 cm^{-1} comes as a signature of Si-O-Si. This 50 cm^{-1} shift from the reference position in pure HMDSO and the broadening of the band result from a larger structural change in the Si-O-Si bridge-containing molecules. Based on Li et al. [10], this wavenumber shift to lower energy can be attributed to the molecules containing small siloxane chains with a gradually increasing molecular weight. The appearance of a band at 796 cm^{-1} indicates either the presence of Si-O-Si bending mode or that of Si-C with an environment different from $Si(CH_3)_3$. Under high power conditions, the slight increase of the OH band at around 3660 cm^{-1} is also noteworthy and reveals the reaction between ≡Si-O° and the hydrogen at the deposit surface to form SiOH-containing products in the gas phase Notice that in the gas phase of HMDSO/oxygen plasma, Creatore et.al [11] detected a large amount of such products.

C. Relationship between the gas phase composition and the deposit composition

The band between 1040 and 1020 cm^{-1} pertaining to the infrared spectrum of HMDSO plasma deposits (Fig.4a - 60 W) has been ascribed to Si-O-Si stretching mode in a disturbed environment $-((CH_3)_2SiO)_n-$. Recall that the Si-O-Si stretching mode in the HMDSO gas phase peaked at 1072 cm^{-1} and that the difference between monomer and deposit is mainly due to carbon substitutions by oxygen atoms to form the (Si-O)n backbone with some CH_3 or CH_2 branching on silicon site [10]. Actually, the spectra recorded at low and high power were different to each other (Fig. 4 spectra normalized to the same thickness, Table 2). At low power

(60 W), the spectrum exhibits a main band at 1032 cm^{-1} (Table 2, Fig.4a) whereas the deposit spectrum under a high power shows a broad band at around 1022 cm^{-1} (Table 2, Fig.4c). Another feature in the deposit spectrum under a low power condition (60 W) is a very small Si-H content whereas for deposits obtained at higher powers (>150 Watt, Fig 4b and c, Table 2), this content is large.Taking into account the preceeding gas phase analysis, the following global comment can be drawn. Under low powers, the gas phase mainly contains hydrocarbon molecules, trimethylsilane, pentamethyldisiloxane and a large amount of HMDSO whereas the deposit is characterized by Si-O-Si bridges (1034 cm^{-1}), a low SiC (or Si-O) content (796 cm^{-1}), a large $Si(CH_3)_3$ content (840 and 760cm^{-1}) and a very low content of SiH bonds (2129 cm^{-1}). On the other hand at a high power (600 W), molecules possibly containing $(Si-O)_x$ coupled with a large amount of hydrocarbon branching seems to be dominant in the gas phase. Then the deposit contained with Si-O-Si bridges (1023 cm^{-1}) as well as a significant ≡Si-H amont (2139 cm^{-1}), a large Si-C (or Si-O) amount (796 cm^{-1}) and very few $Si(CH_3)_3$ groups(834 cm^{-1}). Note that no significant Si-OH bonds were detected in the deposit although infrared spectra show the presence of few silanol groups in the gas phase. The low concentration in the gas phase can explain the absence of Si-OH in the deposit. The following interpretation can be given to the preceding observations. Although the presence of a $-(Si-O)_n-$ backbone is on the whole unquestionable, the occurrence of a few $Si-CH_2-Si$ bridges or $Si-CH_2-CH_x$ – is possible. Indeed, recent papers on thin film deposition from hexamethyldisilane [12] have shown that the infrared spectrum of deposits exhibits a broad band at 1020 cm^{-1} which has been ascribed to the $Si-(CH_2)n-Si$ bridge (wagging mode $1 \leq n \leq 2$). Obviously, this deposit does not contain Si-O bonds. The presence of the CH_2 groups at 2873 cm^{-1} in the gas phase and 2876 cm^{-1}(Fig. 4c, Table 2) in the deposit could indicate the presence of some $Si-CH_2-Si$ or $Si-CH_2-CH_x$ bridges -.Taking into account the presence of molecular species in the gas phase such as CH_4, TriMS and PMDSO as assumed by mass spectrometry [2][5][7] and confirmed by our work, it is clear that the radicals associated with these species, i.e., °CH_3, °$Si(CH_3)_3$ and $(Me)_3SiOSi$ °$(Me)_2$ radicals could be involved in the deposition process. These radicals also partly react with the surface to form volatile stable molecules in addition to the deposit. We underline the fact that the dissociation products after gas-phase recombination or/and species desorption by surface recombination lead to the stable molecules detected in the gas phase. It can be seen from our results that surface effects cannot be ignored to correctly understand the origin of some neutral species in the gas phase. This remark is even more important under our plasma conditions since the pressure in the reactor was lower than 5 10^{-3} mbar keeping the probability of chemical reactions in the gas phase very low. Besides, let also remark that under high power, the large HMDSO consumption can favour the electron interaction with HMDSO by-products leading to a partial modification

Table 2: Comparison between the infrared bands (in cm^{-1}) of HMDSO plasma deposits obtained under different power conditions.

of the deposition process chemistry. In this respect, the large production of hydrocarbon in the gas phase explains the carbon deficit in the deposit as measured by XPS. Indeed, the C/Si ratio decreases below 2 in the deposit instead of 3 in HMDSO. Moreover, taking into account, the global oxygen deficit concerning the HMDSO by-products, it is consistent to find an increase of [O]/[Si] ratio in the deposit with respect to HMDSO ([O]/[Si] =0.5). That was found in reference [2] at a low power ([O]/[Si] =0.7) and in reference [13] at a high power ([O]/[Si])= 1) . These last observations lead to the conclusion that both carbon and silicon atoms are missing in the deposit as compared to the HMDSO atomic composition. This is consistent with the large amount of stable species such as hydrocarbons, $H\text{-}Si(CH_3)_3$ or $(CH_3)_3\text{-}(CH_3)_2Si\text{-}O)x\text{-}Si\ H(CH_3)_2$ and so on, which are present in the gas phase and pumped out. This view is confirmed by the work of Fracassi et al. [7] who detected these kinds of products in HMDSO radiofrequency discharges. Alexander et al. [2] have shown, by means of TOF SIMS analysis of deposits that a lot of heavy ionized fragments involved few $-(Si{=}CH_2)$ units which were attributed to $Si\text{-}CH_2\text{-}Si$ breaking. Nevertheless as already shown, the deficit of both carbon and silicon compared to oxygen in the deposit is compensated by their excess in the gas phase.

D. Mechanism proposal

At a low power, the mechanism assumed by Magni [1] appears to be quite consistent with our results. They proposed the following dissociation reactions :

$$(CH_3)_3SiOSi(CH_3)_3 + e^- \rightarrow (CH_3)_3SiO°Si(CH_3)_2 + CH_3° + e^-$$
$$(CH_3)_3SiOSi(CH_3)_3 + e^- \rightarrow °Si(CH_3)_3 + (CH_3)_3SiO° + e^-$$
$$\text{or } (CH_3)_3SiOSi(CH_3)_3 + e^- \rightarrow °Si(CH_3)_3 + (CH_3)_2SiO + °CH_3 + e^-$$

Three out of the obtained radicals, $(CH_3)_3SiO°Si(CH_3)_2$, $CH_3°$ and $°Si(CH_3)_3$ can explain the presence of TriMS, PMDSO and methane in the gas phase as described above. Of course, these radicals may also contribute to the deposit and to polymer chain ends. The large content of $Si(CH_3)_3$ (840 cm^{-1}) in the deposit could also be related to the $Si(CH_3)_3$ radicals.

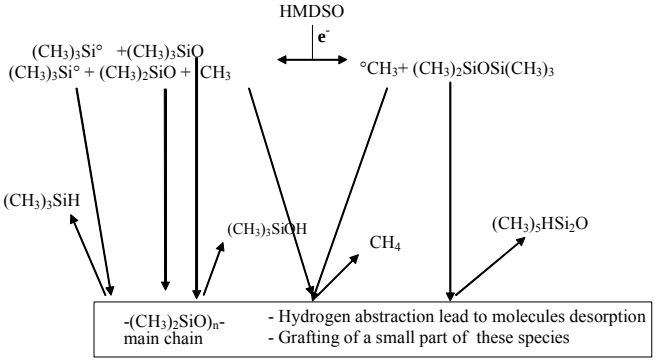

Figure 5: Simplified reaction pathway for deposition at low powers.

The main structure of the deposit based on a -(SiO)- backbone probably arises from the other two radicals whose generic formula is $(CH_3)_xSiO$. Two arguments are in favour of this proposal. Firstly, the atomic composition of these radicals is quite close to the O/Si ratio observed in the film. Secondly, the very weak band at 3660 cm^{-1} (O-H bonds) could confirm the presence of $(CH_3)_3SiO°$ radical which can induce the silanol production by hydrogen abstraction from the deposit surface. Moreover, the FTIR spectrum of the gas phase at intermediate power (170 Watt, Fig.3b) shows a broad band with a maximum between 1055 cm^{-1} and 1030 cm^{-1}. This indicates the presence of molecules containing $-((CH_3)_2SiO)_x-$ ($2 \leq x \leq 3$) as shown by Fracassi in radiofrequency discharge [7] and confirmed by mass spectrometry [2]. Based on the proposed mechanism, the only means to obtain these small oligomers is the reaction of $(CH_3)_xSiO$ species with each other in order to increase the $-(SiO)_y-$ chain length (Fig. 5). In any situation, the deposit composition (O/Si ≈1) leads to the conclusion that the most reactive and probably the main mechanism for deposition is:

$$\text{either } n\,(CH_3)_3\,SiO° \rightarrow (CH_3)_3Si\text{-}(OSi(CH_3)_2)_{n-2}\text{-}Si(CH_3)_3 + (n\text{-}2)\,CH_3$$
$$\text{or dangling bond} + n(CH_3)_2SiO \rightarrow \text{site-}[(CH_3)_2SiO]_{n-1}\text{-}(CH_3)_2Si\text{-}O°$$

At higher powers (≥ 400 Watt) in the gas phase, the large CH bands at around 2957, 2924 and 2873 cm^{-1} with respect to $Si\text{-}(CH_3)_x$ and Si-O-Si bands let us think that the heavy stable hydrocarbon molecules or/and hydrocarbon groups are grafted onto siloxane-like species containing chains such as : $((CH_3)_2Si\text{-}O)_x\text{-}Si\text{-}(CH_2)_y\text{-}Si$ or $((C_xH_y)_2Si\text{-}O)_z$. If we consider the corresponding deposits, the hydrocarbon group content (between 2959 cm^{-1} and 2876 cm^{-1}) is very low with respect to that of the SiH, $SiCH_3$ and Si-O-Si groups. In the layer, the importance of the bands at 796 cm^{-1} (SiC or Si-O) with respect to the very weak band at 834 cm^{-1} ($Si(CH_3)_3$) indicates the disappearance of the $Si(CH_3)_3$ group in the deposit. These last observations on the deposition process could be explained based on a modification of the discharge composition. At a high power, HMDSO is almost totally consumed and the gas phase is dominated by its by-products. Then,

electrons can also interact with these by-products to form new radical species which can contribute to the deposition process (Fig.6). For instance, reactions such as the following might be possible :

$$CH_4 + e^- \rightarrow CH_3^{\bullet} \text{ and } CH_2^{\bullet\bullet} \text{ and } CH^{\bullet\bullet\bullet} + x\, H^{\bullet} + e^-$$

$$HSi(CH_3)_3 + e^- \rightarrow H^{\bullet}Si(CH_3)_2 + CH_3 + e^-$$

$$PMDSO + e^- \rightarrow H(CH_3)_4{}^{\bullet}Si_2O + CH_3 \text{ and } H(CH_3)_2{}^{\bullet}SiO \text{ (or } H(CH_3)SiO + {}^{\bullet}CH_3) + {}^{\bullet}Si(CH_3) + e^-$$

It can be noticed that the obtained radicals contain Si-H bonds which can explain the presence of such bonds in the deposit.

As observed in the infrared spectra of both the gas phase and the deposit, the gradual change in composition from low power to high power is due to a combination of HMDSO depletion and HMDSO by-product formation. This obviously leads to variable chemical composition of the deposits even though the main chain is controlled by SiO oligomerization.

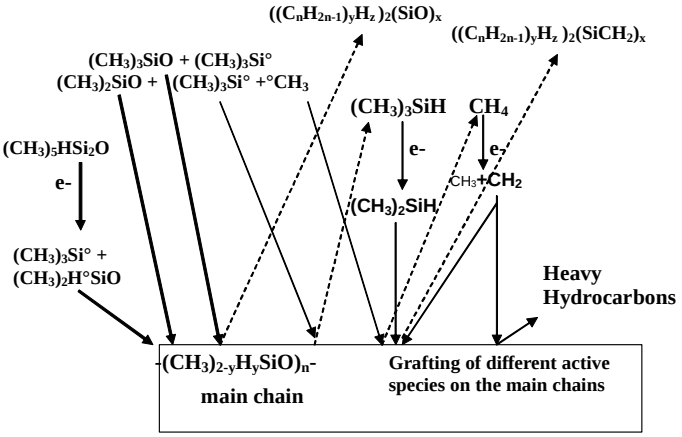

Figure 6: Simplified reaction pathway for deposition at high powers (>100 Watt)

5. Conclusion

Plasma deposition processes from siloxane monomers have only been described so far in the literature as the formation of a $(Si\text{-}O)_n$- backbone resulting from the siloxane break-up of organic groups in the gas phase or at the surface.It is commonly assumed that the dominant reactive gas phase species are the main deposit precursors. The present work reveals a more complex situation. It is especially interesting to note that the deposit structure is more or less a kind of reverse of what is in the gas phase. Broadly speaking, given the chemical structure of the initial monomer and its fragmentation, just a few basic chemical species are involved in the deposition process whereas the other active radicals partly react with the surface to form volatile molecules. At low powers, the species issued from the primary HMDSO dissociation stages dominate the process. The radical surface reaction produces stable species such as TriMS, PMDSO and CH_4 obtained after a radical recombination. On the other hand, $(CH_3)_xSiO$ seems to be the main deposit precursors. At a higher power the HMDSO byproducts in the gas phase are also dissociated by electronic impact producing new radicals which contribute to the deposit. This leads to an increase of the grafting rate of the (Si-O) chains in the films. Meanwhile the length of the siloxane chains in the gas phase increases. This is also the case in the deposit as shown by the shift of the Si-O-Si stretching towards energy as low as 1020 cm^{-1} and a large decrease in the $Si(CH_3)_3$ group amount. This shift could also be favoured by the formation of -Si-CH_2-Si - bridges.

Complete Oxidation of Volatile Organic Compounds Using Plasma-Driven Catalysis and Oxygen Plasma

H.H. Kim, A. Ogata, S. Futamura

Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

Abstract

In this paper we will present a complete oxidation technology of volatile organic compounds (VOCs) using a cycled operation of adsorption and decomposition of adsorbed VOCs using oxygen plasma. This cycled operation system was developed based on the extraordinary oxygen-dependent characteristics of the plasma-driven catalyst system. Complete decomposition of VOC to CO_2 was achieved with this cycled system using oxygen plasma without forming CO and any nitrogen oxides. The influence of VOC concentration and the temperature condition of oxygen plasma will be discussed.

Keywords; Nonthermal Plasma, Corona discharge, Plasma-Driven Catalysis, Oxygen plasma, Volatile organic compound (VOC), Catalyst

1. Introduction

Volatile organic compounds (VOCs) released into the atmosphere as a consequence of man-maid emission undergo a complex physical-chemical transformations before they are decomposed or deposited to the earth's surface. Many of these VOCs are considered to be carcinogenic, teratogenic and mutagenic. There is, therefore, an urgent need to develop more effective and inexpensive techniques for the treatment of VOCs. Application of nonthermal plasma (NTP) technology has been investigated for the removal of SO_2, NOx, odors, and VOCs from many industrial fields [1-3]. Substantial progress has been achieved during the last two decades [4]. In the practical application of NTPs for the abatement of VOCs, suppression of harmful byproducts is required as well as the high energy efficiency.

One of the remarkable recent trends in the NTP application for air pollution control is the combination of NTP with catalyst in either of single-stage or two-stage [5-7]. The single-stage and the two-stage process are referred to as plasma-driven catalysis (PDC) and plasma-enhanced catalysis (PEC), respectively. It has been reported by the authors that the PDC system is much more efficient than that of the ordinary gas-phase homogeneous plasma reactors (dielectric-barrier discharge, pulsed corona, surface discharge) in terms of energy efficiency, carbon balance, byproduct etc [8]. Decomposition of various aromatic compounds showed CO_2 selectivity of around 75%, which was 30-40% higher than those with the conventional plasma reactors [9]. Continuous operation of the PDC system showed stable performance without any catalyst deactivation over 150h. Table 1 summarizes the differences between the conventional NTP alone processes and the PDC system. Both the plasma alone and the PDC system are not influenced by gas hourly space velocity

Table 1. Comparison of NTP alone and plasma-driven catalysis

Parameter	Plasma alone	PDC
Kinetics	First-order $\eta(\%) = \{1 - \exp(-k_E \cdot \mathrm{SIE})\} \times 100$	Zero-order $\eta(\%) = \frac{k_E \cdot \mathrm{SIE}}{C_0} \times 100$
GHSV (residence time)	No influence	No influence
Oxygen content	No influence	Large influence
Carbon balance	Poor	Good
Aerosol formation	Yes	No
IP *vs* decomposition efficiency	Highly related	Unrelated

* The rate constant k_E is referred to as energy constant. The unit for first-order and zero-order are LJ^{-1} and $ppm \cdot J^{-1}L$, respectively.

(i.e. residence time) because the characteristic time of plasma chemical reactions is usually short enough relative to the gas residence time. Kinetics of VOC decomposition in the PDC system shows a zero-order, which indicates the important role of surface reaction in the decomposition of VOCs. Maximum applicable energy to the PDC reactor should be less than about 120 J/L because formation of nitrogen oxides sharply increases at SIE above this value. In this sense, the flow-type PDC reactor only can be applied for the decomposition of VOCs with concentrations below about 100 ppm. One important characteristics of the PDC system that we focused on in this work is the influence of oxygen content on the decomposition efficiency. In contrast to the plasma alone processes, which show constant performance at given specific input energy regardless of oxygen content, the decomposition efficiency of VOC in the PDC system shows almost linear increase with oxygen content. In addition to the decomposition efficiency, the selectivity of CO_2 also remarkably increased with oxygen content. Based on the highly oxygen content-dependent property of the PDC system a cycled system of adsorption and the decomposition of adsorbed VOCs using oxygen plasma has been proposed by the authors. The expected advantages of this cycled process include high energy efficiency, high CO_2 selectivity and no formation of nitrogen oxides.

2. Experimental

Figure 1 shows the concept of the cycled process for the complete destruction of VOCs. This system is operated in two separated modes of adsorption and the decomposition of adsorbed VOCs using oxygen plasma. This cycled process is based on the highly oxygen content-dependent behavior of the PDC system. The experiment system consisted of two PDC reactors, valves, AC power supply, gas cylinders, mass flow controllers, and Fourier transform infra red (FITR) spectrometer (Perkin Elmer, Spectrum One). The catalysts used in the PDC reactor were 2.0 wt% Ag/TiO_2 catalysts. Two PDC reactors were connected in

parallel. In the adsorption mode VOC is removed by adsorption on the catalyst surface without plasma application. When the catalyst bed reached a saturated adsorption, then the gas flow was switched to the other line for continuous adsorption. The catalyst bed reached saturated adsorption was then purged with oxygen and the decomposition of adsorbed VOC was started with oxygen plasma. Benzene was used as model compound of VOC in this work. The additional cost for the use of oxygen can be minimized by operating the decomposition cycle at closed system after purging the catalyst bed with oxygen.

Adsorption mode was operated at room temperature to maximize the benzene adsorption on the catalyst. Regeneration mode using oxygen plasma was operated at room temperature and 100 ^{o}C to know the effect of temperature on the decomposition of adsorbed benzene.

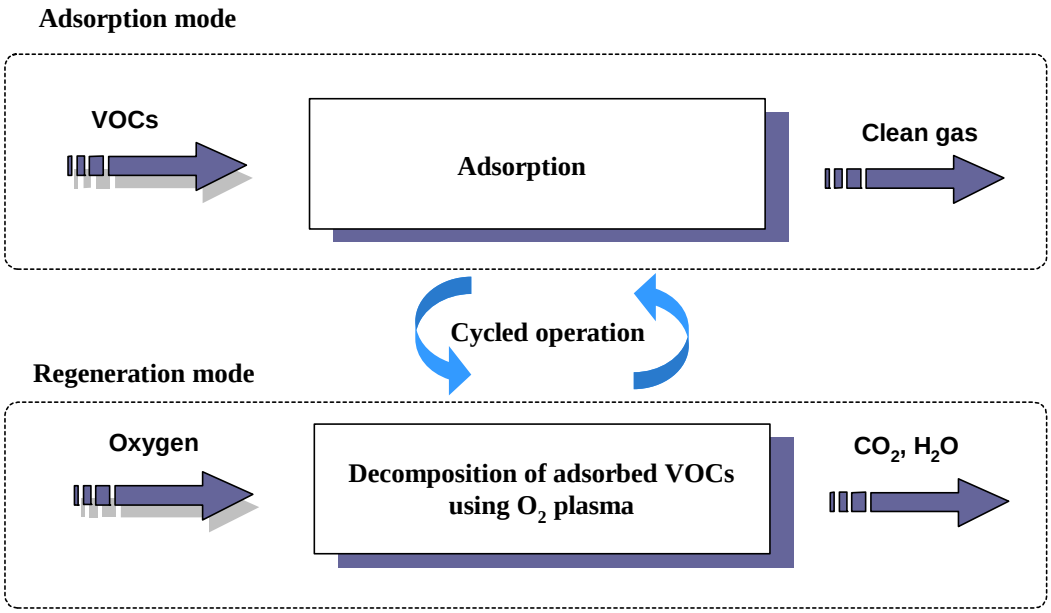

Figure 1. Schematic diagram of the cycled process for the complete destruction of VOCs.

Discharge power of the oxygen plasma was measured using V-Q Lissajous figure method. A condenser of 100nF capacitance connected in series to the ground line of the plasma reactor. The charge Q (i.e. time-integrated current) was measured with a 10:1 probe. Specific input energy (P/Q_f) is the ratio of discharge power (P_{dis} in watt) in the plasma reactor to gas flow rate (L/min).

$$\text{SIE (J/L)} = \frac{P_{dis}}{Q_f} \times 60 \qquad (1)$$

In the case of the cycled operation equivalent specific input energy (SIE_{eq}) was introduced to evaluation the energy consumption.

$$\text{SIE}_{eq}\text{ (J/L)} = \frac{(P_{dis})_{Ave}}{(Q_{Ads})_f} \times \frac{T_{Oxy}}{T_{Ads}} \times 60 \qquad (2)$$

Here, $(P_{dis})_{Ave}$ and $(Q_{Ads})_f$ indicate the average discharge power of oxygen plasma for the decomposition of adsorbed VOC and gas flow rate during the adsorption, respectively. T_{Oxy} and T_{Ads} indicate the period of oxygen plasma and the time of adsorption, respectively.

3. Results and Discussion

Figure 2 shows the required energy for the complete decomposition of benzene using the cycled process using oxygen plasma. Time to reach breakthrough in the adsorption was varied from 30 to 95min depending on the inlet benzene concentrations. Oxygen plasma completely oxidized the adsorbed benzene to CO_2., which is impossible with the conventional plasma alone processes or the flow-type PDC system. The SIE_{eq} for the decomposition of adsorbed benzene largely depended on the benzene concentration. The higher the benzene concentration, the larger the SIE_{eq} for the complete decomposition of adsorbed benzene. These results can be explained by the zero-order kinetics of the PDC system. In the zero-order kinetics the amount of VOC decomposition is only determined by SIE but not by the concentration of benzene. Our preliminary data indicated that the specific input energies to achieve complete decomposition of 60 ppm and 205 ppm benzene were about 150 J/L and 310 J/L, respectively. It should be noted that the values shown in the Figure 2 indicate the required energy to decompose the adsorbed benzene with more than 99% CO_2 selectivity. Temperature actually had no influence on the SIE_{eq} within the tested conditions. The data obtained at room temperature and 100 ^oC fell on single line. Further enhancement can be possible by optimizing the plasma parameters for the regeneration mode and the use of proper adsorbent/catalyst.

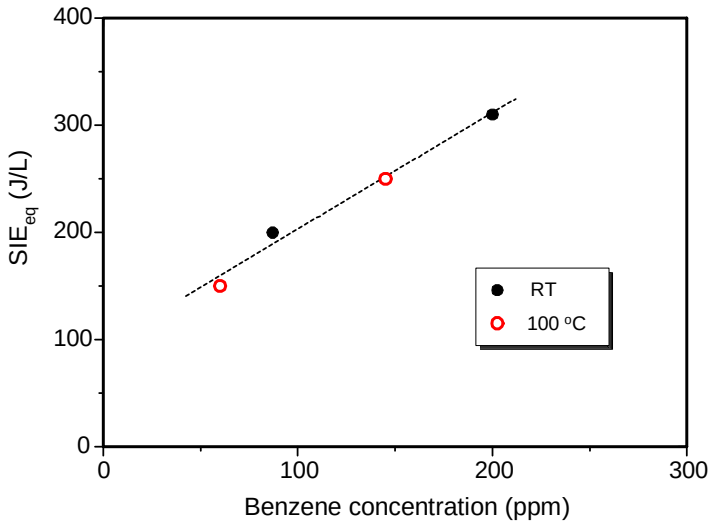

Figure 2. Required energy for the complete decomposition of benzene using the cycled operation system. PDC reactor packed with 2.0wt% Ag/TiO_2 catalysts was used. Adsorption was operated at room temperature in both cases.

When nitrogen is present in gas mixture plasma can produce nitrogen oxides. Figure 3 shows the formation of nitrogen oxides (NO_2 and N_2O) in the flow-type PDC system as a function of the oxygen content in the gas stream. In the gas-phase plasma processes nitrogen oxides exist in different oxidation level; NO, N_2O, NO_2, N_2O_5, HNO_2, HNO_3. On the other hand, nitrogen oxides exist mostly as NO_2 and N_2O in the outlet of the PDC reactor. Therefore only NO_2 and N_2O were measured in this study. The formation of NO_2 changed drastically with the oxygen content. The maximum formation was found at 10% oxygen and then decreased with further increase of oxygen. On the other hand, formation of N_2O was quite sensitive to the oxygen content below 10%, and was slow down at higher oxygen content. From the data shown in Figure 3, it can be

concluded that the increase of oxygen partial pressure can reduce the formation of nitrogen oxide. However, it is difficult to suppress the formation of nitrogen oxides completely. In order to complete the decomposition of adsorbed VOC in a short time, it will be necessary to maintain the specific input energy much higher than those of the flow-type PDC reactor. These results indicated that the operation of the regeneration mode must be done at 100% oxygen to minimize the formation undesirable byproducts.

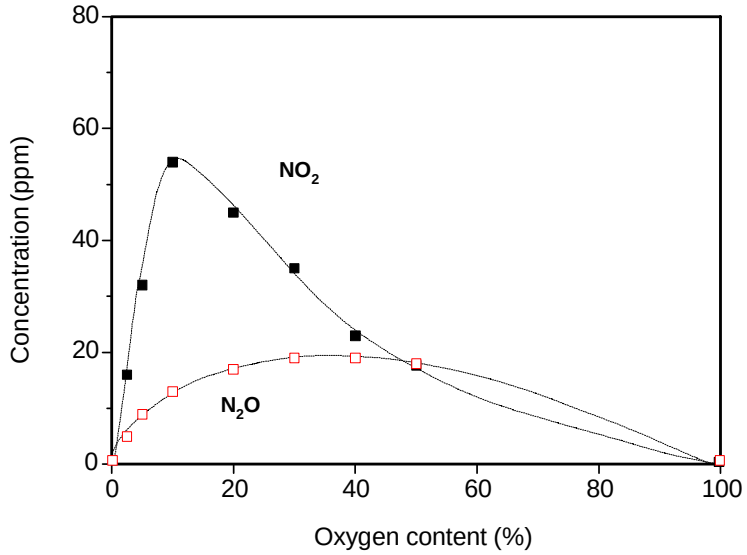

Figure 3. The effect of oxygen content on the formation of NO_2 and N_2O in the flow-type PDC system. Specific input energy was 130 J/L.

Abstract
In the framework of European project "ytriD" two reactors for water treatment with corona pulsed discharges have been studied. In one reactor there is a water film on the bottom, in the other there is aerosol spray. The ozone generation and phenol removal have been investigated for the two available reactors. Both reactors proved their high efficiency in ozone production (~80 g/kWh in ambient air) and phenol removal (up to 48 g/kWh). The phenol conversion yield increased up to ~90 g/kWh with addition of $FeSO_4$ or NaOH.

Keywords: pulsed corona discharge, ozone creation, phenol removal, water cleaning

1. Introduction

Low-temperature plasma applications for environmental purposes are intensively studied and implemented. Many recent studies have been focused on the industrial gas cleaning only. Pulsed corona discharge, one of the Advanced Oxidation Techniques (AOT's), is widely used in that field [1,2]. Recently, attempts to use pulsed corona technique for wastewater treatment have been successfully undertaken [3,4,5]. In those tests corona was created in the liquid phase. Relatively new approach [6] is the creation of the electrical discharges in the air phase. In such configuration, pulsed corona becomes a powerful source for the ozone and other radicals, with high oxidation potentials. Active species created in the air phase are diffused easily into the thin layer of liquid, where they can react with impurities.

Within the framework of European project "ytriD" [7] two reactors to study the effects of corona on wastewater are available. Those reactors utilize two different approaches to the problem of transport of the reactive species in to the liquid phase. In the first one -aerosol reactor- the liquid is sprayed in form of aerosol between electrodes. The reaction takes place in the droplets and at their surface. In the second one, called Corona Above Water (CAW) reactor, discharge takes place in air phase, above thin layer of liquid. As a model molecule to study the reactors' cleaning efficiency, the phenol was chosen because of its well-known chemistry and use by other authors [6,8].

Both reactors proved their very good efficiency in the ozone production and phenol removal [10], there is still need for optimizing process and reactors for obtaining even better efficiency. The improvements can be done: i) to the electrical setup (changing the electrical properties of the system), ii) to the chemical process (additives), iii) to the physical conditions (gap distance, wire length). Previous studies show that the conversion efficiency of corona discharges can likely be improved by the application of additives. Addition of NaOH [8] (leading to increase of pH level) and Fe(II,III) salts [9] can significantly improve the decomposition of phenol in pulsed corona discharges reactors.

2. Experimental set-ups

Reactors and electrical systems.

The reactors and electrical circuits have been described in [10]. The CAW reactor is a hermetic construction, to prevent the corona products from escape. The reactor envelope is made of Perspex; its inside dimensions are 8x5.5x38cm. The sidewall thickness is 10mm and bottom wall 4mm. The 4 electrodes, 0.2 mm in diameter, are placed in cover of the reactor. The horizontal distance between the electrodes is 2cm. The cathode is placed outside the reactor, at the bottom side. The gap between cathode and anodes is 4,5cm. The bottom section of the CAW reactor is made from one piece of Perspex, to prevent sparking and

leakages. Compared to [10], the system operates at lowered voltage and current for better stability.. The setup can operate with frequencies from 5-25 Hz with the pulse duration of ~100ns, with the ~40kV voltage peak and 80A of current. The energy value for performed experiments is in the range of 50-60mJ per pulse, i.e. the average power is only 0.25-0.5W. The reactor can operate in a batch type configuration or the water flow system can be incorporated.

The aerosol reactor build in Soreq [11] is a metal cylinder with 120 L of volume. Inside a system of cathodes and anodes is placed. The distance between the electrodes is 3cm. The liquid and the air supply system are connected at the bottom of the reactor. A compressor is installed in the system. Its function is to recycle the air, containing large amount of ozone, back to the reactor. The residence time of the liquid in the reactor is ~1min. The liquid flow is 15L/h. The reactor is driven by a compact all solid-state power supply. Energy per pulse is up to 0.5J with a repetition rate up to 1kHz, i.e. power up to 500W.More detail on the power supply can be found in [11].

Measurements setup

The ozone concentration is measured by the absorption technique using an Ocean Optics HR2000 spectrometer. As a light source the deuterium lamp is used. The ozone concentration values are taken at 266nm wavelength. In CAW reactor optical fibers with lenses are placed in the discharge area. In the aerosol reactor probes are positioned at the duct connecting output of the reactor with compressor.

For concentration measurements of the phenol solution a LIF setup is constructed using a Quantel Brilliant Ultra YAG laser with 4 mJ/pulse output at 266 nm and an Ocean Optics HR2000 spectrometer. The system is calibrated for the range between 1 and 0,1 mMol/L of phenol solution. The calibration curve gives a very good fit (R^2=0,98). Comparative tests with HPLC technique show very small differences (<2%) between those two measuring techniques.

3. Results and discussion

Effect of atmosphere medium on ozone production process

In the first test the ozone concentration was measured in CAW reactor. The electrical system operated with 45kV voltage measured at the reactor with 80A of current. Calculated energy per pulse was 50mJ.

Fig.1 indicates the effect of gas composition on ozone concentration. The reactor was filled with ambient air or with oxygen. For those two cases the ozone concentration above the liquid was observed as well as the removal of phenol from a 150ml of 1mMol/L solution was determined.

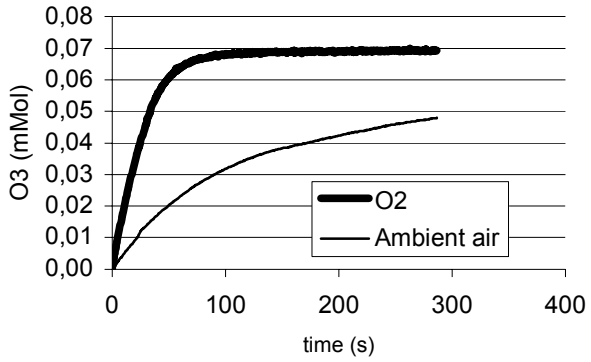

Fig.1. Ozone creation in ambient air and oxygen atmosphere

As is shown in the graph in Fig.1 the oxygen atmosphere significantly influences the ozone production rate. The yield of ozone calculated from the initial slopes rise from 80g/kWh in case of ambient air, up to 190g/kWh for oxygen atmosphere.

Effect of reactor fillings on ozone creation process

Fig.2 presents the effect of different reactor fillings on ozone concentration. The reactor was filled with ambient air (total air volume of 780ml), with 150mL deionized water and 150 ml of 1mMol/L phenol solution (total air volume 650ml both). The ozone yield has been calculated from the starting slope, it leads to 85 g/kWh.

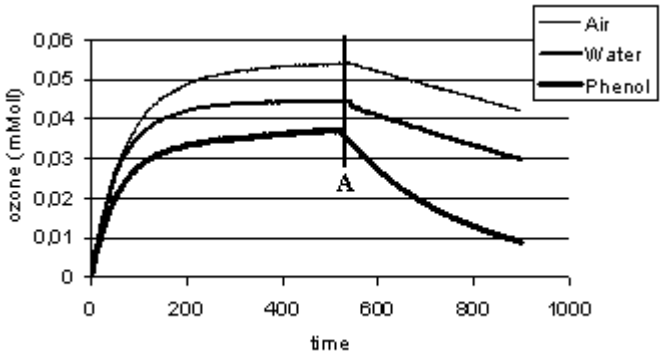

Fig.2. Ozone creation and dissipation for different fillings of the reactor.

As can be seen in the graph, the shapes of the initial lines of ozone concentration are also similar. After around 60s the linear growth changes due to saturation. It is clearly seen that type of filling highly influences the ozone concentration in the reactor. This is expected because in presence of water and phenol solution the mass transfer process starts. Ozone molecules diffuse in to the liquid where they are scavenged by the water molecules as well as transited in to OH* radical [12]. In case of phenol solution additional reaction with phenol molecules takes place [13].

The total ozone concentration after 500s has been calculated. In the reactor filled with air 27mMol of ozone were produced. The presence of deionized water 4mMol of total ozone created had been diffused in to the water. The presence of phenol solution decreased it again with same amount, leading to 19mMol of ozone in the air after 500s.

In the next part of the experiment the corona was turned off after 500s (line A on the graph) and the decay of ozone has been observed. As is shown in Fig.2 the curves for ozone concentrations in reactor filled with air and water have similar slopes. From simulations it was obtained that, for the reactor filled with air the main mechanism for ozone degradation is its degradation in the volume. Layer of liquid has no significant influence on the ozone decomposition. When the maximum level of ozone saturation in water is reached no more ozone molecules are transferred into the liquid phase, thus the decomposition in volume become predominant. This is consistent with the result of fig.2.

In presence of phenol solution the ozone molecules in boundary phase reacts with phenol and its by-products allowing more ozone to transfer from the air phase. The faster decay of ozone concentration in air confirms this idea. This result is also useful to improve the simulation model. The initial part of the decomposition curve has an exponential shape. After 300s 45% of phenol was removed leading to the yield of 48g/kWh.

Effect of pH value on phenol removal

Fig.3 shows the dependence of the pH solution on phenol removal. The different amounts of NaOH and HCl have been added to 150 ml of 1mMol/L phenol solution to obtain desired levels of pH. In the next step the solutions had been treated with the corona for 5 min. With the pH level of 2 29% of the phenol had been removed. With increasing the pH value the removal rate increase.

At pH=5, which corresponds 1mMol phenol solution without addition, 45% of phenol had been removed. Increasing pH value above 6 causes the removal rate to increase with even higher rate. At pH=10 the phenol removal reached 90%. The yields of phenol removal are shown in Tab.1. The experimental results are in

agreement with reaction mechanism reported by other authors. With acidic condition the direct reaction between ozone and phenol molecules becomes predominant. At high pH values OH* radicals decompose less likely allowing the phenol molecules to react with them. Thus the phenol decomposition increases.
During treatment of phenol solution the drop of pH has been observed (Hoeben 1999). It is explained by the creation of organic acids, like acetic acetic and muconic acid from the phenol decomposition. Thus that effect negatively influences the efficiency of the process with time. On the other hand slight increase of pH above 6 can significantly improve the phenol removal. Results of performed experiments will help to create more effective system.

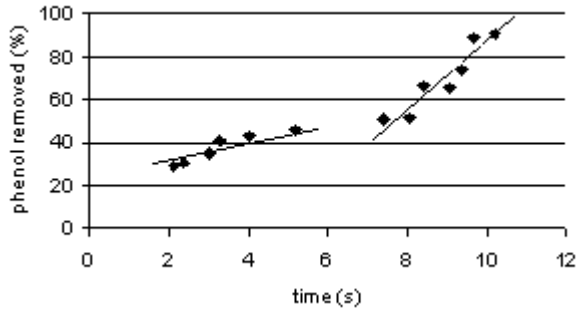

Fig.3 Phenol removal as a function of pH value

Effect of additives on phenol removal

Addition of several metals, which have special oxygen transfer properties, can affect the efficiency of the treatment process. The Fenton's reactions involving iron-catalyzed hydrogen peroxide are well known [9]. In this catalytic reaction hydrogen peroxide can react with iron(II) and iron (III) ions creating, among other species, the hydroxyl radical. OH* radical is used later in the cleaning process.

The phenol removal rate was significantly improved when the addition of 100mMol/L FeSO4 was added to 1 mMol/L of phenol solution. As can be seen in Tab.1 The addition the 3ml addition of Fe2+ solution increased the phenol removal rate up to 94%, with phenol yields up to 98 g/kWh. The obtained result indicates that Fenton's catalytic reaction took place. It also reveals that the amount of H_2O_2 created by the decomposition of ozone in water [12] is sufficient for Fenton's reaction to start.

Table.1 Phenol removal and yield with different additions

	Phenol removed (%)	Phenol yield (g/kWh)
1 mM/L phenol	45	48
pH=2	29	30
pH=10	91	95
Fe2SO4 1ml	69	72
Fe2SO4 2ml	86	90
Fe2SO4 3ml	94	98

Ozone creation and phenol removal in aerosol reactor

The ozone concentration profiles were measured in the aerosol reactor operating with different electrical settings. Lines 1 and 4 in fig.4 indicate the corona power dependence on the ozone creation process. The increase in input power from 20W with ozone yield of 55 g/kWh (line 1) to 50W with yield of 104 g/kWh (line 3) significantly influences the ozone concentration. However, for given input power the use of higher energy pulses with lower frequencies leading to faster ozone build-up and higher yield up to 140 g/kWh (line 2).

To check the cleaning efficiency of the aerosol reactor initial tests with treatment of 1 mMol/L phenol solution were performed. The samples of solution for different electrical settings of the power source were collected. Results showed the 60% removal for repetition rate of 200Hz and 200mJ per pulse. The yield of phenol reaches the value of 21 g/kWh. For 500Hz repetition rate and 280 mJ per pulse 92% of phenol

been removed, while phenol yield drops to 9 g/kWh. Results indicate that the residence time of the liquid in the reactor may be not sufficient to fully penetrate the liquid droplets by the ozone molecules. These results show that there is a trade-off between high removal yield and high cleaning efficiency.

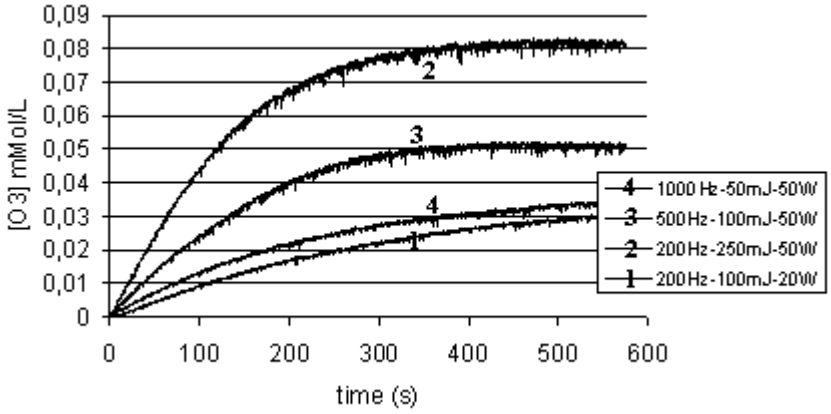

Fig.4. Ozone concentration profiles depend on the pulse energy and frequencies

4. Conclusions

The effect of several chemical and electrical properties on ozone creation and phenol removal was investigated. The CAW technique has proven its high efficiency in ozone production and phenol removal. The ozone concentration in the reactor reaches level of 0.08mMol/L (4g/m^3), and yields of up to 90 g/kWh in ambient air and 190 g/kWh in oxygen atmosphere. The reactor is capable of removing up to 45% of phenol with yield of 48 g/kWh in 5 min. The increase of pH due to NaOH addition can increase the removal up to 91% and phenol yield up to 95 g/kWh in 5 min. The additional creation of the hydroxyl radicals in presence of iron salts (Fenton's reactions) increased the phenol conversion up to 94% and yields to 98 g/kWh. The air phase discharge is capable of creating the sufficient amount of H_2O_2 molecules for Fenton's catalytic reaction to start. Ozone concentration profiles obtained with aerosol reactor indicates the need of use less frequent, high energy pulses. The aerosol reactor is very efficient source of ozone. The aerosol reactor is capable of removing up to 92% of phenol with very short residence time (<1 min).

Obtained results will help to create a chemical model of the conversion process and implement it to industrial application, which is the final stage of the ytriD project.

Abstract

A meter-scale high-density *surface wave plasma* (SWP) for manufacturing giant microelectronics devices such as liquid crystal display and solar cell is diagnosed with several techniques. Standing modes of surface waves at 2.45 GHz are detected by a movable antenna, and the measured wave distributions are in good agreement with FDTD simulation of surface waves. Three dimensional measurements of electron density and temperature are made by a Langmuir probe array movable in meter-scale. In order to obtain information of radical distribution in large-area plasma, *wide-view* OES (optical emission spectroscopy) technique is developed. Applications of SWP to silicon thin films deposition and silicon oxidation processes are presented along with electron density monitoring by a *surface wave probe*.

1. Introduction

There has been a great need for meter-scale plasma sources for giant materials processing. The typical examples of giant plasma processing are thin film transistor manufacturing for meter-size LCD (liquid crystal display) panel, deposition of silicon thin films for photovoltaic power generation, surface coating of housing glass plate for UV and IR light cut, hardening plastic materials, surface modification of paper and plastic films to give either hydrophobic or hydrophilic properties, and abatement of toxic gases.

To date, linearly-long magnetron plasma sources have been used for sputter deposition of electrically conductive thin films on the materials which are conventionally moved normal to the plasma axis. On the other hand, large-area capacitively coupled plasmas (CCPs) have widely been used for large-scale CVD and etching processes. However, the 13.56 MHz CCPs have drawbacks of low plasma densities ($<10^{10}$ cm^{-3}). Recent studies of CCPs produced at the discharge frequency in a range of VHF (30 – 100 MHz) revealed considerable increase in plasma density, however standing wave effect and edge effect significantly degrade the plasma uniformity. Thus, the VHF CCPs are classified to be medium-density and medium-size plasmas.

Recently, we have developed a new technology for production of large-area uniform high-density plasmas based on surface wave excitation at 2.45 GHz [1]. The key technologies employed here are a dielectric-filled waveguide and a careful design of slot antenna array. In the preliminary experiments, using a large discharge vessel of 1 m in length and 0.3 m in width, we obtained a plasma density of ~$5x10^{11}$ cm^{-3} with ~10 % uniformity in 2.5 kW argon discharge at 50 mTorr.

Here, we describe the giant microwave discharge technology and present the plasma characterization by several diagnostic tools, together with some examples of applications of the large plasmas to materials processing.

2. Production of Meter-scale Microwave Plasma

The critical challenges for production of meter-scale microwave plasmas are (1) how to avoid huge atmospheric pressure (eight tons/m^2) acting on a dielectric window for microwave injection, and (2) how to design an antenna-plasma coupling so as to attain the plasma uniformity over meter-size. The first issue was dodged by employment of a dielectric-filled waveguide and antenna system, which is contained in a low-pressure plasma chamber. Figure 1(a) shows a conventional method of microwave plasma excitation where a thick dielectric

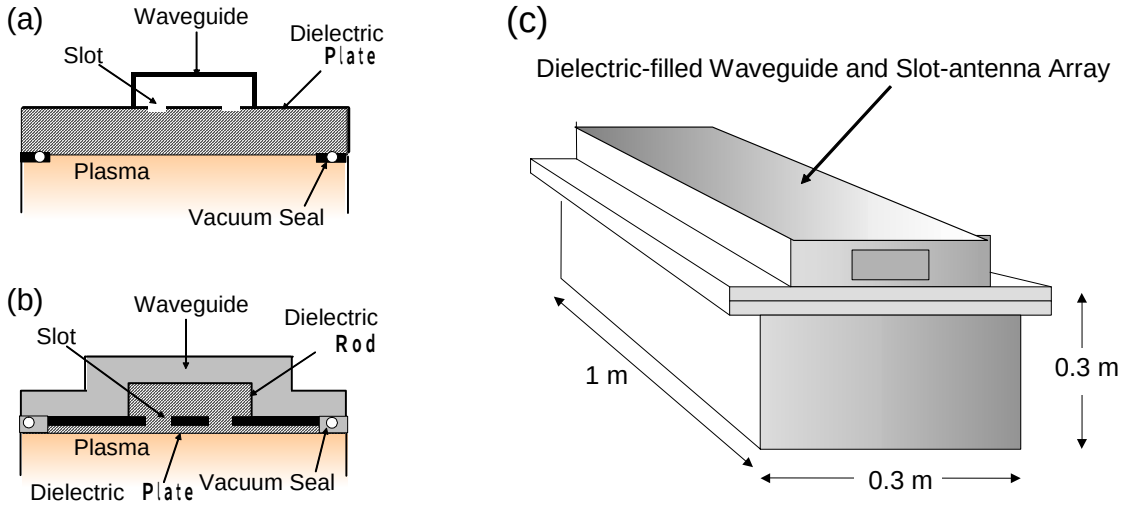

Fig. 1. (a) Conventional microwave injection through thick dielectric plate, (b) a new type of microwave injection through thin dielectric plate under dielectric-filled waveguide, and (c) schematic view of a meter-size microwave plasma apparatus.

plate (> 7 cm thick for a 1 m^2 quartz plate) is required to make vacuum seal between a plasma chamber and a waveguide with slot-antenna array. Such thick dielectric plate is extremely expensive and inconvenient for maintenance, and it also leads to a difficulty in control of surface wave excitation.

Thus, we developed a new scheme of microwave injection illustrated in Fig. 1(b). Here the waveguide is inserted into a plasma chamber with a vacuum seal using a dielectric partition inside the waveguide. As shown in Fig. 1(b), the slot antenna array and the large-area dielectric window are installed underneath the waveguide at the same ambient pressure as the plasma region. Since there exists no pressure difference in both sides of the large dielectric plate, no mechanical stress acts on the plate, and hence the plate thickness can be made as small as possible, say 1 cm or less, in spite of meter size.

In this scheme, the waveguide pressure is same as the plasma chamber pressure, so that unfavorable anomalous discharges might occur inside the waveguide and near the slot antennas due to the much stronger

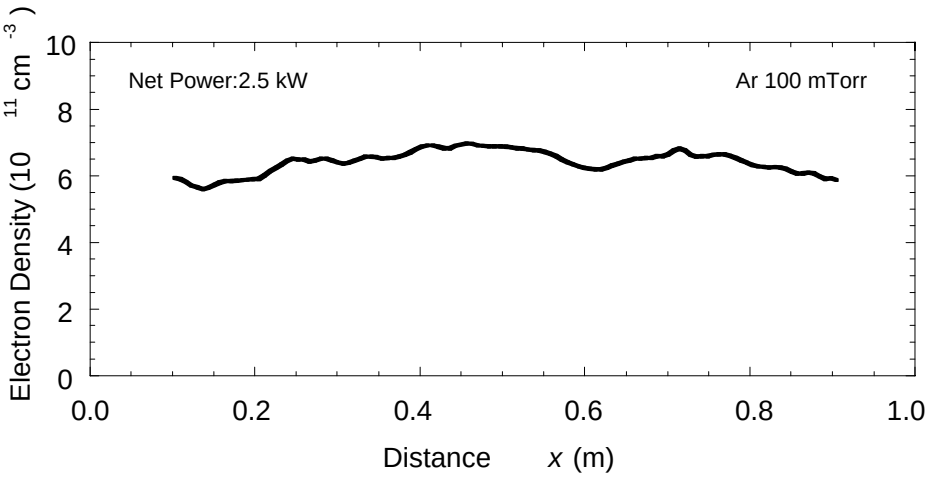

Fig. 2. The axial distribution of electron density produced by 2.45 GHz 2.5 kW microwave at 100 mTorr in argon.

microwave field intensity than in the plasma chamber. In order to prevent a stable plasma from such accidental discharges, the spaces inside the waveguide and the slots were fully plugged with dielectric material (quartz).

The second issue mentioned above was solved by a careful design of slot antenna array. Firstly, the design should meet a requirement of impedance matching at the waveguide entrance port between the microwave source and the load including the quartz-filled waveguide, slots, and open space. Secondly, in order to generate a meter-size uniform plasma, the slot antenna array is required to radiate the same microwave power from each slot which is distributed at the same interval along the waveguide axis in parallel to the *x*-axis.

These requirements were fulfilled in the present antenna array according to analytical approach and numerical simulations of electromagnetic fields; 25 slots aligned in two parallel lines along the x-axis, the slot size and spacing properly adjusted for obtaining a good impedance matching.

As a result, the new microwave injection scheme carefully designed in this way turned out to successfully work in producing a high-density large flat plasma in a chamber (1 m x 0.3 m x 0.3 m) shown in Fig. 1(c). For example, Fig. 2 shows the axial profile of electron density measured by a motor-driven Langmuir probe system in the discharge conditions of 2.5 kW, 100 mTorr argon. The electron density as high as $6x10^{11}$ cm^{-3} was obtained with a sufficient uniformity over one meter in length. A plasma of one-meter-square in area will easily be produced by installing three identical waveguide systems similar to the present waveguide system.

3. Microwave Field Measurement

In the SWP produced by microwave discharge at 2.45 GHz, surface waves propagating underneath a quartz plate parallel to the x-y plane were detected by a movable antenna. The standing modes of surface waves were successfully identified to be *m*=26 in the *x*-direction and *n*=11in the *y*-direction. Figure 3 compares the wave intensity profile in the *y*-direction measured in the experiment (solid line) and simulated in the relevant FDTD (*finite difference time domain*) method (dashed line). Here the wave electric field in the *z*-direction was measured at the distance *z*=1.5 cm from the quartz plate at the electron density of $6.4x10^{11}$ cm^{-3} produced by the microwave power of 2.5 kW in argon at 100 mTorr. As seen in Fig. 3, a very good agreement was obtained between the experiment and the simulation, suggesting the excitation of mode *n*=11 in the in the y-direction.

The similar comparison of the x-direction revealed the excitation of longitudinal mode *m*=26.

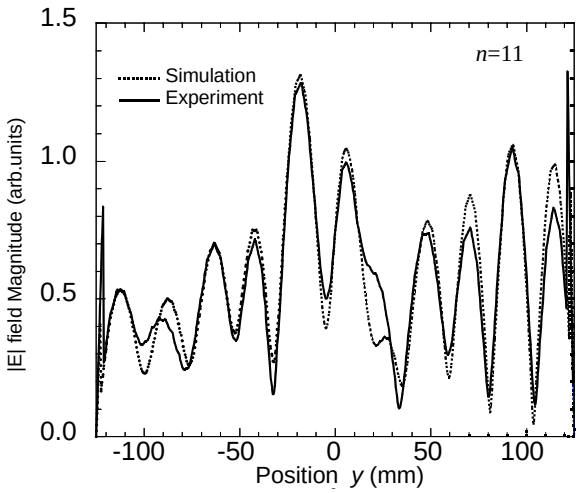

Fig. 3. Comparison of microwave field distributions along the y-direction between the experiment and the simulation.

4. Three-D Langmuir Probe Measurement

Three dimensional measurements of electron density and temperature were made by a Langmuir probe array movable in meter-scale. The linear probe array along the *y*-axis, which can be shifted along the *z*-axis, is driven along the *x*-axis by a stepping motor system. Computer-controlled data acquisition of probe *V-I* curves enables the three-dimensional measurement of electron density, temperature, and potential in the meter-scale plasma. Figure 4 shows the electron density as a function of the position *y* for the different discharge powers at 100 mTorr in argon. At low powers, the plasma is localized at the slot region ($y < 4$ cm). However, at the power higher than 2 kW, a fairly uniform high-density ($6x10^{11}$ cm^{-3}) plasma of 30 cm in width and 100 cm in length

was generated.

The observed plasma expansion with microwave power is well explained taking account of a wave propagation characteristics and the power balance. Namely, the surface wave launched from each slot propagates along the quartz plate in the *y*-direction, depositing the wave energy to electrons. The waves are reflected at the position giving the surface wave (SW) resonance at the density 3.6×10^{11} cm^{-3}, below which the waves are evanescent. As the discharge power is increased, the electron density increases and the SW resonance points shift outward, which in turn gives rise to successive expansion of the plasma width.

Such behavior is quantitatively examined based on the equation of power balance in a global model: the absorbed power is consumed for creation of electron-ion pairs in gas phase and the Bohm loss to walls. Comparison between the estimated plasma width and the measured width showed a good agreement not only for a pure argon discharge, but also an oxygen-mixure discharge.

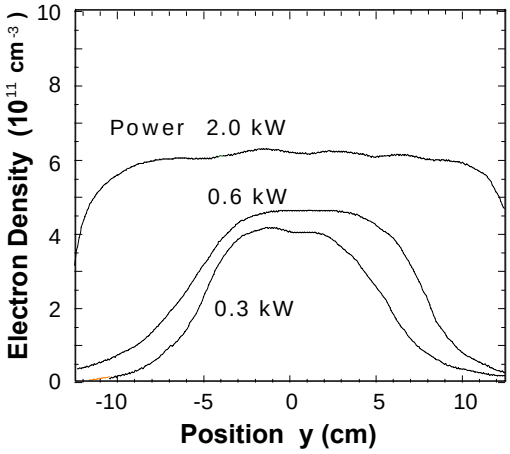

Fig. 4. Electron density profile along y-direction.

5. Wide-view OES Measurement

Optical emission spectroscopy (OES) is a simple and convenient tool to obtain information of radical species, plasma density, and electron energy distribution function. The OES measurement is conventionally done picking up the optical emission from plasma through a line-of-sight along a narrow beam. In order to obtain the information over a large area at a glance, a *wide-view OES* is developed where the optical emission is taken in a wide angle from a narrow viewing port. Combining optical filterswith this system enables *actinometry* measurement of radical species distribution in a large volume plasma.

6. Applications of SWP and Surface Wave Probe

Applications of SWP to meter-scale thin films formation are promising in manufacturing giant electronic devices. With liquid crystal display process in mind, plasma oxidation of silicon surface at low wafer temperatures is reported with oxygen radical detection. Furthermore, in order to apply the SWP to solar cell processing, we present high-speed deposition (>10 nm/s) of micro-crystalline silicon films at 500 K obtained in 20 % SiH_4/H_2 discharge, while poly-crystalline silicon films of large grain size (>200 nm) at 700 K are formed in 2 % SiH_4/H_2 discharge [2].

In such reactive plasmas, a conventional Langmuir probe is useless due to contamination of the probe surface. A novel tool, *surface wave probe* [3, 4] enables us to measure the local absolute electron density even when the probe surface is soiled with processing plasmas. The tool relies on absorption of surface waves resonantly excited around the probe head at critical frequencies, which mainly depend on the electron density. Recent improvement of this technique expands an applicable range of electron density from 10^8 to 10^{12} cm^{-3}, and of discharge pressure from 10^{-4} to 10 Torr.

NUMERICAL INVESTIGATION OF NO EFFECT ON THE IGNITION OF HYDROGEN AND HYDROCARBONS IN NON-PREMIXED LAYERS OF COLD FUEL AND HOT AIR

V.A. Bityurin, A.N. Bocharov and E.A. Filimonova
Institute for High Temperatures of RAS, Izhorskaya , 13/19, 125412, Moscow, Russia

Abstract
To determine a range of temperatures and corresponding to them NO concentrations for purposes of plasma-assisted combustion the axi-symmetric problem of the radial development of electrical arc channel was carried out. The one-dimensional combustion simulation of cold H_2 (T_0=300 K) and air (T_0=790-200 K) and chemical kinetics combustion modeling in H_2-air and CH_4-air mixtures holding the different NO percentage (10^{-3}-3%) was performed. The comparison with experiment in the counter-flow jets was done.
Keywords: ignition, induction time, chemical kinetics mechanism, electrical discharge, simulation.

1. Introduction

On study of plasma-assisted combustion it is widely used several kind of electrical discharges. One of them is arc discharge. The arc discharge was employed under investigation of the ignition and combustion in the counter-flow jets of oxidant (air) and cold fuel (gaseous propane) in the work [1]. The products of reactions initiated by arc discharge differently influence ignition of non-premixed layers of fuel and oxidant. One-dimensional simulation of mixing and combustion showed that the ignition time in each point of combustion zone is determined by the multi-component diffusion [2]. Radicals (O atoms) in hot air zone resulting from discharge play a part of source of high-enthalpy component and bring to the growth of temperature due to recombination and other chemical reactions, and O atom weakly affects the induction time [2]. This is the principle distinction from the preliminary premixed fuel and oxidant where the presence of radicals reduces the induction time appreciably. Other important component produced in discharge zone is nitrogen oxide. Its concentration may amount to some percents. Experiments carried out in H_2-air mixture [3] and in the counter-flow jets [4] showed nitrogen oxide may promote hydrogen and hydrocarbons combustion under rather low temperatures of 770-1300 K in some range of pressure, temperatures and NO concentrations.

In given paper to determine the nitrogen oxide influence area on ignition time and temperature the axi-symmetric problem of the radial development of electrical arc channel in air was carried out. The radial dependences of temperature and NO concentration in several time instants were obtained. The goal of modeling was to find the main processes, which affect the ignition rate and temperature ignition limit. The one-dimensional simulation of NO effect on induction time in the system of cold hydrogen (T_0=300 K) and sufficiently hot air (T_0=790-1100 K) holding the different NO percentage (10^{-3}-3%) was performed. The comparison with results in preliminary mixed fuel and air, and with experiment in the counter-flow jets was done. The chemical kinetics mechanism of hydrocarbons (CH_4, C_2H_2, C_3H_8) oxidation and combustion was assembled to describe the influence of NO on theses processes. The dominated reactions for every stage, induction time in dependence on temperature, CH_4 and NO content in CH_4-air mixture are presented.

2. Simulation of electrical arc discharge

The computational model used in simulating the evolution of electric discharge is basically described in [5]. In the current paper options related to the non-equilibrium plasma are omitted and it is assumed that both heavy particles and electrons have the same temperature at any location of the plasma bulk. The discharge is supposed to occur in the gap between two flat electrodes. The length of the gap is taken to be 1 cm. External electric circuit is assumed to provide 1 Ampere DC current in the gap. It is also guessed that electric field strength has only one component aligned with the electrode-to-electrode direction. Neglecting near-electrode phenomena one can consider all plasma properties unchangeable in the electric current flow direction. Finally, axi-symmetric discharge is considered. All these assumptions allow formulating the one-dimensional axi-symmetric problem to calculation of plasma properties in the gap.

The numerical model is based on a solution to Navier-Stokes equations coupled with the mass conservation equations for every species. The source terms in the species conservation equations are evaluated from 7 species chemical kinetics model. Transport properties of multi-component fluid are estimated on the base of temperature approximations to collision integrals of viscous and diffusion type. Details are referred to [6, 7]. Thermodynamic properties of species are determined by specifying the formation enthalpies and polynomial dependencies of constant-pressure heat capacities on temperature. Ideal gas equation-of-state is assumed to hold for every species, and Dalton's law is used to determine the gas pressure. Relationship between electric field strength and total current is resulted from Ohm's law. To complete total plasma resistance is to be calculated.

Initial and boundary conditions are specified as follows. As initial state the plasma column is specified, in which Gaussian distribution of temperature and electrons along radius is given. Typically, 0.5 mm was used as the half-width of Gaussian; at-axis temperature was taken between 5500-7000K; at-axis electron mole fraction was tried between $10^{-6} – 10^{-5}$. The electrons were balanced with NO^+. Initial radial distribution of density is calculated at pressure $P_0 = 10^5$ Pa, and temperature distribution described above. Symmetry conditions are set at the symmetry axis, i.e. zero radial derivatives for all variables except radial velocity are specified at the axis, and zero radial velocity is set at R = 0. At the outer boundary distant from the symmetry axis on 4 cm, zero derivatives are specified along with fixed static pressure value, $P_0 = 10^5$ Pa.

In Fig.1 the temperature and NO radial distributions in the vicinity of arc channel is presented. The thin horizontal and vertical lines mark the range of low temperature T=770-1100 K where nitrogen oxide may accelerate the oxidation process of hydrogen. According to Fig.1 these temperatures are corresponded [NO]=0.05-1%. The NO concentration is "frozen" when airflow drifts NO from discharge zone and may achieve the amount more then 1 percent. In general the formation near discharge of some NO distribution is determined by velocity of airflow, pressure and fuel flow rate. Non-uniform NO distribution in airflow may bring to cellular structure of ignition and non-uniform character of initial stage of combustion.

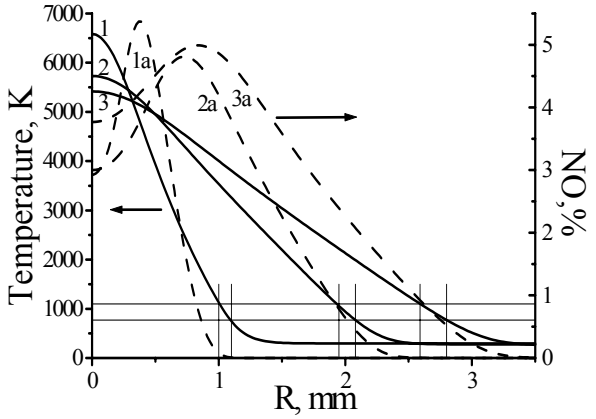

Fig.1. Radial evolution of arc channel in air. Dependences are given for different instants of time: 1,1a - 40 μs, 2,2a - 500 μs, 3,3a – 800 μs . Thin lines mark the ranges where sensitization of ignition is possible: T=770-1200 K, [NO]=0.05-1%.

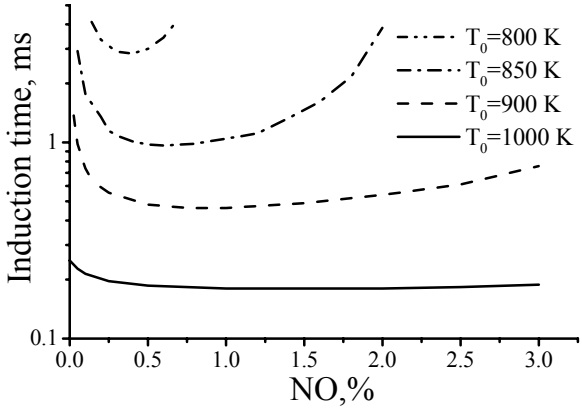

Fig.2. Induction time in dependence on initial NO content in hot air at the boundary of fuel and oxidant layers for several temperatures of hot zone. (H_2 layer is at T_0=300K).

3. Discussion of results

3.1. Ignition of hydrogen in non-premixed mixture

The calculations showed non-monotone ignition character at the boundary of two layers in dependence on NO concentration as well as in stochiometric H_2-air mixture. The NO influence already begins with a small concentration, for example, 10 ppm for mixture. The induction time was defined in the maximum of H atom concentration; this moment corresponds to the temperature of 1600 K at the boundary of layers. Fig.2 illustrates

the dependence of induction time on NO percentage for H_2 and air layers at initial air temperature of 800-1000 K. The minimum induction time τ_{in} at $P=10^5$ Pa and $T_0=900$ K of air is observed at 0.5-1% NO and equal to ≈460μs, whereas in the stochiometric mixture $\tau_{in}=225$ μs. Nitrogen oxide virtually does not influence ignition of hydrogen at $T_0 \geq 1100$ K for non-premixed gases and stochiometric mixture. These results are in agreement with experimental dependences [3,4]. In the absence of NO at $T_0<930$ K and in the presence of 2.1% NO at $T_0=850$ K the ignition at the boundary of two layers did not occur at the time less 4.2 ms (residence time of ignition kernel in the reaction volume). It is noted τ_{in} rapidly increases near $T_0=900$ K without NO, and for stochiometric mixture τ_{in}~6 ms at $T_0=910$ K as in experiment [8] as in our calculations.

In Fig.3 the dependence of temperature ignition limit as a function of NO concentration in air is shown. Corresponding to these temperature values the ignition time at the boundary is found in the range of 3-4.2 mc. The results of experiments in counter-flow jets [14] at strain rate $k_{exp}=300$ $s^{-1}$are indicated by symbols. The distance between two nozzles was equal to 2 cm. These values are limited the residence time of ignition kernel in the reaction zone. In given work the calculation domain was limited by 2 cm and the boundary between cold and hot layers was located in the middle of domain. The direct comparison is possible only taking into consideration a tangential component of flow velocity, for example, in two-dimensional simulation, because of counterflow improves the mixing, and as a consequence, accelerates the ignition. However, in experiment [9] the ignition temperature at $P_0=10^5$ Pa virtually was insensitive to strain rate in the fairly wide range. In Fig.3 one can see if a conterflow is available the temperature ignition limit decreases from 910 K without NO to 770 K with 0.14% NO, but in calculations it decreases from 930 K to 790 K at 0.3% NO.

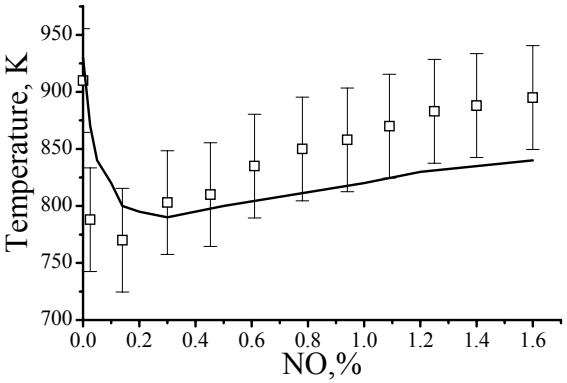

Fig.3. Ignition temperature in dependence on NO concentration in air at the boundary of two layers (H_2 layer is at $T_0=300$ K). The lines are modeling, symbols are experiment [4].

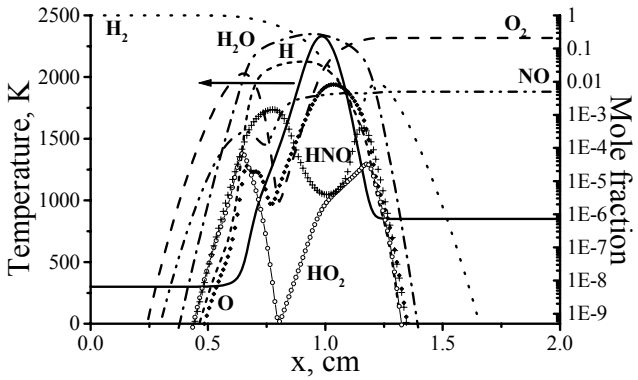

Fig.4. Temperature and concentrations of components within 1.2 ms in ignition kernel. H_2 layer is at $T_0=300$ K, air layer is at $T_0=850$ K, $[NO]_0=0.5\%$.

During induction time a mixing zone of fuel and oxidant amounts to some millimeters, its width is determined by diffusion and thermal conductivity. The distribution of most components at ignition instant and combustion has a non-monotone behavior with some extremums (see Fig.4). The size of combustion zone may define with respect to H_2O profile line; it is about 1 cm. The behavior of NO_2 is close to HO_2 profile line.

In the combustion process with NO the chemical kinetics scheme and role of individual components are changed, for example, HO_2. This radical facilitates branching instead of termination of chain (reactions (5), (6)). The main reactions, which result in sensitization of ignition or prohibit the branching of chain under certain conditions of temperature and concentrations, are following:

$$H_2+O_2 \leftrightarrow OH+OH \quad (1)$$
$$H+O_2+H_2 \leftrightarrow HO_2+H_2 \quad (2)$$
$$H+O_2+O_2 \leftrightarrow HO_2+O_2 \quad (3)$$
$$H+O_2+N_2 \leftrightarrow HO_2+N_2 \quad (4)$$
$$HO_2+NO \leftrightarrow OH+NO_2 \quad (5)$$

$H+NO_2 \leftrightarrow OH+NO$ (6)
$O+NO_2 \rightarrow NO+O_2$ (7)
$NO_2+M \leftrightarrow O+NO+M$ (8)
$H+NO+M \leftrightarrow HNO+M$ (9)
$OH+NO+M \leftrightarrow HNO_2+M$ (10)

Reactions (1)-(5) essentially influence the initial combustion process and induction time. At high initial NO concentration the disappearance of O and H atoms in interacting with nitrogen oxide becomes appreciable and the combustion process does not develop (reactions (8)-(10)). The kinetic scheme included 15 components and 77 elementary reactions. The constants rates have been taken mainly from [10]. This kinetic scheme has been tested (without NO) on experiments [3,8,11] and results of comparison was very good.

The modeling showed the maximum temperature shift was observed at $[NO]_0$=0.3% and equal to 140 K (without NO T_0=930 K) for non-premixed layers of H_2 and air, and 175 K (without NO T_0=915 K) for stoichiometric H_2-air mixture. The ignition occurred at time ~4 ms.

3.2. Ignition of hydrocarbons in preliminary mixed gases

Chemical kinetics mechanism included about 1000 elementary reactions for 160 components, which may be reduced according to conditions of modeling. Rate constants of reactions were taken from many sources. Some of them are pointed out in the work [12] devoted to $DeNO_x$ in the presence of hydrocarbons from exhaust gas on the base of non-thermal plasma processes. The kinetic scheme has been applied a test to experiments of CH_4 conversion in the presence of NO at T=800-1000 K with low concentrations of these species of 100-200 ppm [13], and ignition delay measurements in the shock tube in methane-ethane mixture [14]. The simulated results agree well with the experimental data.

Fig.5a shows the typical concentration profiles at temperatures of lower 1600 K for mixture of 9.5%.CH_4+19%O_2+71.5% N_2. The first stage (t < 1 ms) is characterized by CH_3, OH, H and O radical production mainly in the reactions

$CH_4 \rightarrow H + CH_3$ (11)
$CH_4 + O_2 \rightarrow HO_2 + CH_3$ (12)
$HO_2 + NO \rightarrow OH + NO_2$ (5)
$O_2 + CH_3 \rightarrow O + CH_3O$ (13)
$O_2 + CH_3 + M \leftrightarrow CH_3O_2 + M$ (14)
$O_2 + CH_3 \rightarrow O + O + CH_3$ (15)
$O_2 + CH_3 \rightarrow OH + CH_2O$ (16)
$NO + CH_3O_2 \rightarrow CH_3O + NO_2$ (17)
$CH_3O + M \rightarrow H + CH_2O + M$ (18)
$H + O_2 \rightarrow O + OH$ (19)
$O + CH_4 \rightarrow OH + CH_3$ (20)
$H + CH_4 \rightarrow H_2 + CH_3$ (21)
$OH + CH_4 \rightarrow H_2O + CH_3$ (22)

Profiles of O and H radicals are close to the OH concentration behavior. The duration of this stage depends only initial temperature and matrix gas.

The second stage named of conversion stage is beginning when OH and H concentrations achieve the first maximum (t ~ 1 ms in Fig.5a). The hydrocarbon (CH_4, C_2H_6, C_3H_8 and other) and oxygen concentrations are slowly decreasing at almost constant temperature in contrast of rapid production of main conversion products (H_2 and CO) due to reactions (3)-(5), (10), (14)-(22) and

$H + O_2 + CH_4 \rightarrow HO_2 + CH_4$ (23)
$CH_3 + NO_2 \rightarrow CH_3O + NO$ (24)
$H + NO_2 \rightarrow OH + NO$ (6)
$O_2 + HNO \rightarrow OH + NO_2$ (25)
$CH_3O + NO \rightarrow CH_2O + HNO$ (26)
$OH + CH_2O \rightarrow H_2O + CHO$ (27)
$O_2 + CH_2O \rightarrow HO_2 + CHO$ (28)

$$H + CH_2O \rightarrow H_2 + CHO \quad (29)$$
$$CHO + M \rightarrow H + CO + M \quad (30)$$
$$O_2 + CHO \rightarrow HO_2 + CO \quad (31)$$
$$CH_2O + M \rightarrow H_2 + CO + M \quad (32)$$

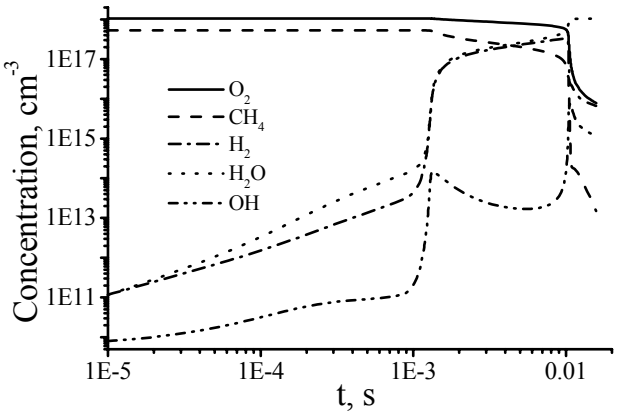

Fig. 5a. Concentrations of some components as a function of time in combustion of 9.5%.CH_4+19%O_2+71.5% N_2 mixture. T_0=1300 K, $P_0 = 10^5$ Pa.

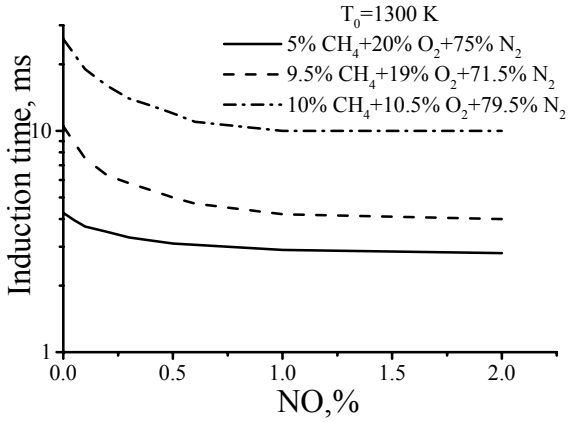

Fig. 6. Induction time in dependence on initial NO content for several methane mixtures. $P_0 = 10^5$ Pa.

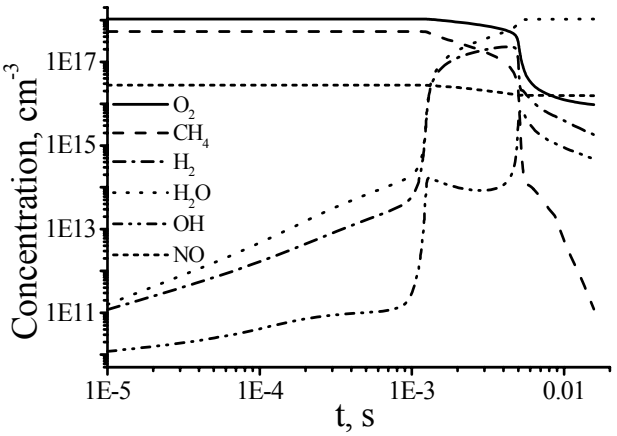

Fig. 5b. Concentrations of some components as a function of time in combustion of 9.5%.CH_4+19%O_2+71.5% N_2 mixture with 0.5% NO. T_0=1300 K.

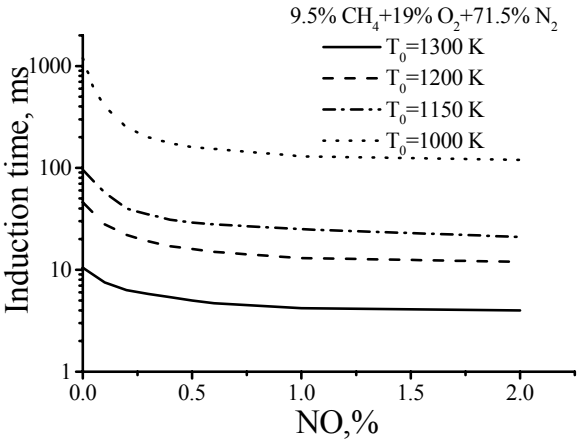

Fig. 7. Induction time in dependence on initial NO content for several temperatures for stochiometric methane mixture.

At the ignition moment (t=10.5 ms in Fig.5a) in the case of poor and stochiometric mixtures the H_2, CO, CH_4 concentrations are sharply decreasing and OH concentration achieves the second maximum. Third stage is combustion stage with CO_2 and H_2O formation and temperature growth. Following leading reactions of final step together with reactions (6), (18), (22), (27), (29)-(31) are dominating:

$$H_2 + OH \rightarrow H + H_2O \quad (33)$$
$$OH + CH_3OH \rightarrow H_2O + CH_3O \quad (34)$$
$$OH + CH_3OH \rightarrow H_2O + CH_2OH \quad (35)$$
$$OH + OH \rightarrow O + H_2O \quad (36)$$

$OH + HO_2 \rightarrow O_2 + H_2O$ (37)
$OH + CO \rightarrow H + CO_2$ (38)
$CO + HNO \rightarrow CO_2 + NH$ (39)
$CHO + NO_2 \rightarrow H + CO_2 + NO$ (40)
$HO_2 + CHO \rightarrow OH + H + CO_2$ (41)

NO addition doesn't influence the duration of first stage but shortens the conversion stage. Fig. 5b demonstrates this effect in the presence of 0.5% NO for the same mixture as noted above in Fig.5a. Duration of conversion stage is reduced by a factor of two basically owing to reactions (5), (6), (17), (24), (25) and depends on NO content in mixture. HO_2 radical also facilitates branching of chain as in combustion of hydrogen however influence of terminating reactions (8)-(10) is less evaluated then in H_2 combustion. For this reason 2% NO and 1% NO result in similar diminution of conversion stage (See Fig.2 and Fig.7).

In Fig.6 one can see the summary result of NO effect on induction time for poor, stoichiometric and rich methane mixtures at T_0=1300 K. Induction time is decreased from 4.25 ms to 3.2 ms and from 26 ms to 12 ms for poor and rich mixtures correspondingly. At NO content more than 0.5% induction time almost doesn't change.

The most pronounced NO effect on reduction of induction time exhibits at low initial temperature. It is obvious from Fig. 7. Results are presented for stoichiometric methane mixture at four initial temperatures. At T_0=1000 K the induction time is reduced by the order of magnitude from 1.2 s to 120 ms..

4. Conclusions

Thus, NO effect on ignition and combustion takes place in comparatively narrow range of temperatures and sufficiently wide range of NO concentrations. Induction time at the boundary of fuel and oxidant with different temperatures (H_2 and air) is greater than induction time for stochiometric H_2-air mixture by a factor of two and more under considered conditions. The ignition temperature is shifted to lower values, at more than 100 K. In hydrocarbon–air mixtures NO affects only the conversion stage of combustion process shortening it up to the order of magnitude.

Full Paper

Aerosol Assisted Plasma Deposition of Barrier Coatings using Organic-Inorganic Sol-gel Precursor Systems**

By Dirk *Vangeneugden,* Sabine Paulussen, Olivier Goossens, Robby Rego* and *Klaus Rose*

Hybrid organic-inorganic monomers and sol-gel systems thereof, obtained via wet-chemical hydrolysis, were atomised and introduced in an atmospheric pressure dielectric barrier discharge (DBD). The obtained coatings were analysed by means of Fourier transform infrared spectroscopy (FTIR), Raman spectroscopy and field emission scanning electron microscopy (FESEM). Films deposited on PET foil were tested for their oxygen barrier properties. Plasma assisted coating deposition of the sol-gel systems proved to be superior to wet-chemical application and conventional thermal or UV curing. However, the best barrier performance was obtained with a coating from a new high molecular weight non-hydrolysed siloxane precursor.

1. Introduction

The use of polymer films has increased drastically over the last decades. The range of applications is very divers and still expanding: from food packaging over medical components to substrates for electronic displays.[1] However, the demanded specifications for polymer films are also increasing systematically as well as the pressure on their environmental impact and production costs. Today, one of the key challenges is to develop alternative environmental save and improved barrier coating technologies against water and gas permeation.
Barrier coating technologies for polymer films can be subdivided roughly in two categories: atmospheric and vacuum based technologies. The atmospheric techniques consist of applying a lacquer followed by a post-curing treatment (thermal, UV or e-beam irradiation). Vacuum coatings mainly concern aluminium metallization or, when transparency is a requisite, metal oxide (MeOx) deposition. The limitations of these state-of-the-art technologies are related to barrier performance and/or cost and functionality. The values for oxygen transmission rates (OTR) and water vapour transmission rates (WVTR) realized industrially today are 1-3 orders of magnitude higher than targeted for future demanding applications (OTR ≈ WVTR ≈ 10^{-2}).[2] Today, only some very specific multilayer combinations of lacquers and MeOx coatings have

demonstrated acceptable overall performance.[2-4] The complexity of the processes to obtain such a multilayer significantly increases the process costs. Moreover, some films are incompatible with vacuum deposition technology due to out-gassing. The presented work aims at the development of a novel atmospheric plasma deposition technology which offers better performance and increased functionality at reduced cost.

Low temperature atmospheric pressure plasma treatment by means of dielectric barrier discharges (DBD) constitutes an emerging technology for foil treatment.[5] The technology is closely related to current industrial corona treatment which is widely used in foil production and finishing processes.[6,7] DBD systems have been developed and optimised for the sterilization and activation of surfaces before printing, gluing or top-coating.[5,8-12] However, in recent years laboratory and semi industrial scale experiments have demonstrated the interesting capabilities of this technology for in-situ coating deposition.[13-18] This can be done by injection of gaseous or vaporized chemical precursors in the plasma discharge. Unlike low pressure plasma deposition which generally targets metal oxide or nitride coatings, atmospheric pressure DBD is most suited for deposition of organic and hybrid organic-inorganic coatings. Moreover, atmospheric plasma technology allows to circumvent one of the major drawbacks of current low pressure plasma technologies: the need for expensive and limited volume vacuum equipment.

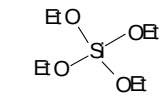
Until recently, the variety of coating precursors used in DBD deposition was limited to gaseous chemicals and liquid precursors with a high vapour pressure and/or high thermal stability which considerably limited the coating capabilities. Furthermore, deposition rates are in most cases to low (e.g. 1 µ/h for siloxanes) to meet the requirements for in-line production.[2] The use of nano-sized aerosols enables to overcome the latter limitations. It allows to make use of the full variety of chemical compounds available today and to increase the deposition rates drastically. The presented work describes the deposition of hybrid organic-inorganic nano-composite coatings by injection of hybrid precursors and sol-gel systems thereof (ORMOCER®) to the plasma as aerosol particles formed by atomisation.[19,20]

2. Results and Discussion

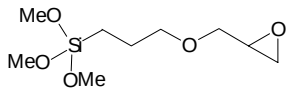
Sol-gel coatings of silicon oxide are known to give good barrier properties.[19,20] Common sol-gel precursor systems for these coatings are made by controlled hydrolysis of e.g. tetraethoxysilane (TEOS). (Figure 1) These transparent coatings have a dense and highly cross-linked silicate structure but are also quite brittle.

In order to reduce the brittleness of sol-gel coatings organic building blocks can be incorporated. This can be done by preparing sol-gel systems using organically modified precursor compounds like glycidoxypropyltrimethoxysilane (GLYMO), methacryloxypropyltrimethoxysilane (MEMO) or propyltrimethoxysilane (PTMO). (Figure 1) The resulting hybrid organic-inorganic coatings are more flexible due to a lower oxidic cross-link density.[19] Aerosols of these (partially) hydrolyzed sol-gel precursors have been introduced into a nitrogen DBD plasma.

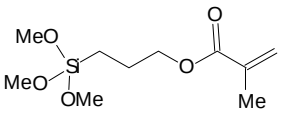
The criterion for the selection of these monomers is the expected difference in behavior under plasma conditions due to the presence of different functional groups. During sol-gel processing, hydrolysis and condensation of organically functionalized alkoxysilanes result in the formation of an inorganic pre-polymer bearing some functional groups. The latter can act as an anchor point for the formation of an additional organic network which may be formed under plasma conditions.



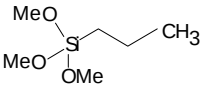
Tetraethoxysilane
TEOS



Glycidoxypropyltrimethoxysilane
GLYMO



Methacryloxypropyltrimethoxysilane
MEMO



Propyltrimethoxysilane
PTMO

Figure 1: Silane sol-gel precursors

TEOS will form an inorganic network on hydrolysis bearing no organic groups. An inorganic network is also formed by hydrolysis of GLYMO and MEMO. However, the functional groups present in these compounds allow additional organic cross-linking via epoxide and acrylate polymerization, respectively. PTMO forms an inorganic backbone bearing non-reactive saturated hydrocarbon (propyl) group. As a consequence, pre-polymers of the latter have not much possibilities to react further via conventional chemical polymerization routes.

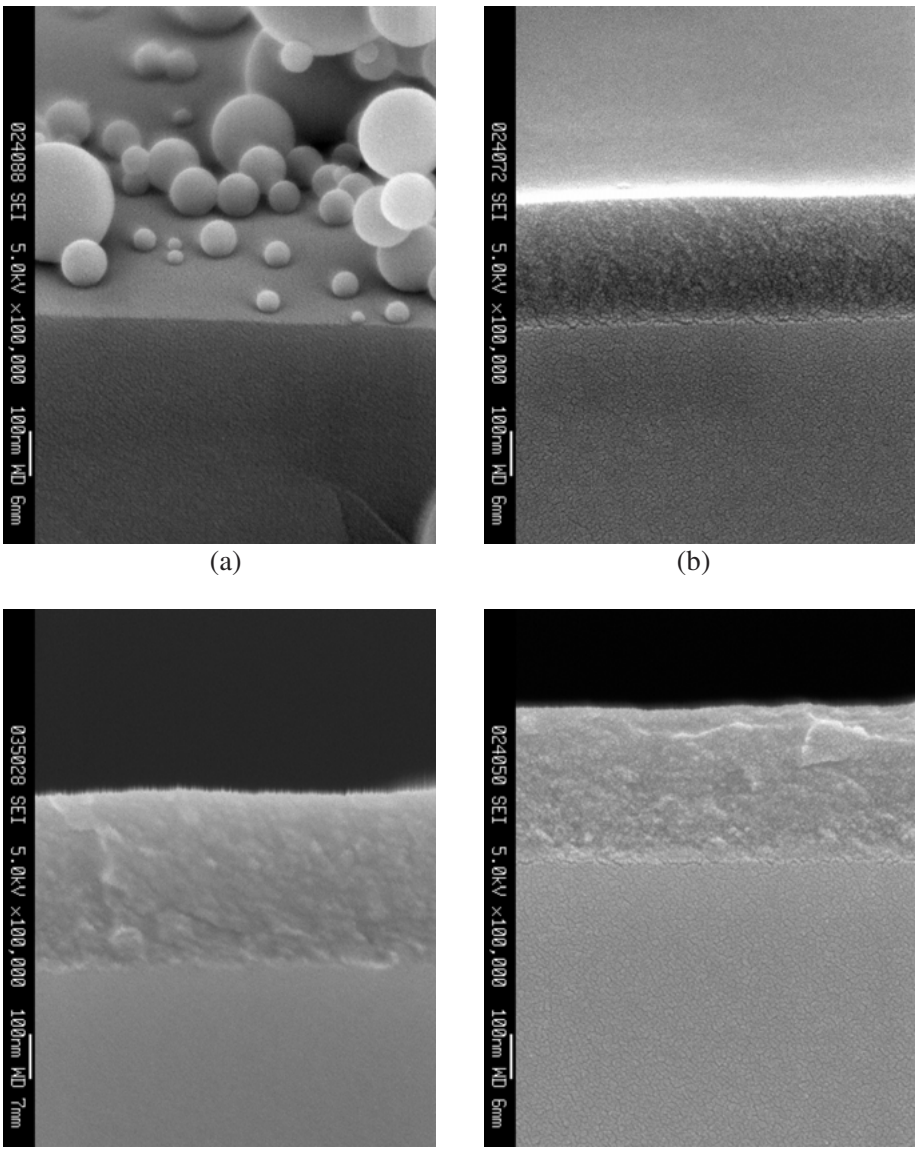
From all previously mentioned hydrolyzed solutions a plasma coating could be obtained, except from the TEOS-solution. The latter gave rise to a powder like deposition, which can be explained by the absence of organic groups on the inorganic prepolymer. Depending on the type of precursor, the plasma conditions and the set-up used, deposition rates varied between 40 and 175 nm/min. (Table 1)

Table 1: Plasma deposition rates of pure and hydrolized sol-gel precursor

Precursor	Coating thickness (nm)	Deposition time (min)	Deposition rate (nm/min)	Physical appearance
TEOS	500	10	50	smooth coating
GLYMO	300	10	30	smooth coating
MEMO	400	10	40	smooth coating
PTMO	1000	10	100	smooth coating
TEOS sol-gel	---	2	---	powder
GLYMO sol-gel	250	2	125	smooth coating
MEMO sol-gel	400	10	40	smooth coating
PTMO sol-gel	350	2	175	smooth coating

Coating thickness was measured close to the gas inlet. In stationary plasma deposition experiments coating thickness generally decreases substantially in relation to the distance from the gas inlet. Results of plasma deposition experiments with non-hydrolized silane precursors are also included in Table 1. Although the hydrolized precursor systems are diluted in alcohol, deposition rates of the sol-gel systems seem to be higher than those obtained via direct plasma deposition of the precursors.

Under equal conditions, the growing rates obtained with the PTMO and GLYMO sol-gel systems were significantly higher than the one obtained with the MEMO sol-gel system. The reason for this is still unclear. The fact that the PTMO sol-gel system polymerizes easily and gives rise to a smooth coating proves that polymerization does not occur exclusively in the classical chemical way. Figure 2 shows FESEM pictures of cross sections of plasma coatings obtained from the hydrolyzed precursor solutions.



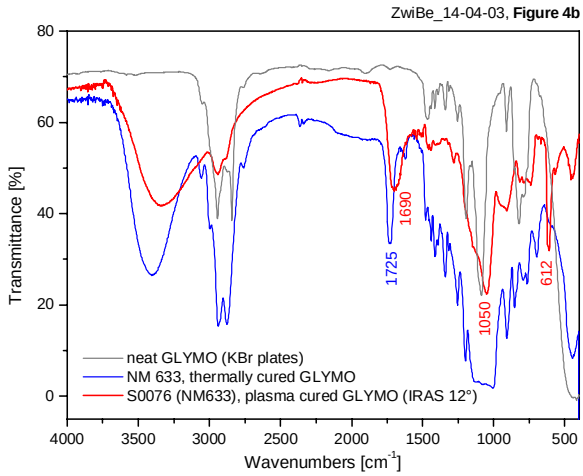
(a) (b)

(c) (d)

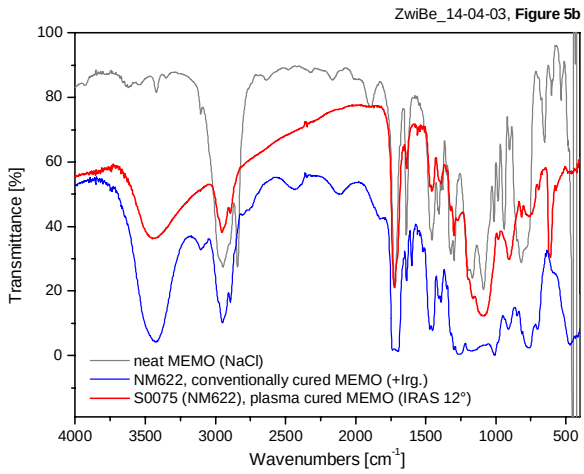
Figure 2: FESEM pictures of cross sections of plasma depositions obtained from hydrolyzed solutions of TEOS (a), MEMO (b), PTMO (c) and GLYMO (d). Pictures (a) and (b) were taken under a tilting angle of 25°. Deposition times were 2 minutes except for the MEMO-solution (10 minutes).

Transparent and homogeneous coatings from GLYMO and MEMO sols were obtained both after conventional curing (GLYMO: 1 h/130 °C; MEMO: 20 sec UV curing at 5,93 J/cm^2) and by plasma deposition/curing. In both cases organic cross-linking (GLYMO: ring opening polymerization; MEMO: radical initiated –C=C-polymerization) and inorganic Si-O-Si cross-linking/condensation occurred.
The organic cross-linking/polymerization was observed via IR-spectroscopy (Figure 3a + 3b). The GLYMO spectra exhibit the formation of a carbonyl signal (plasma: 1690 cm^{-1}, thermal: 1725 cm^{-1}) indicating the ring opening reaction. The MEMO spectra show a significant decrease of the –C=C-double bond (1640 cm^{-1}) indicating organic polymerization.

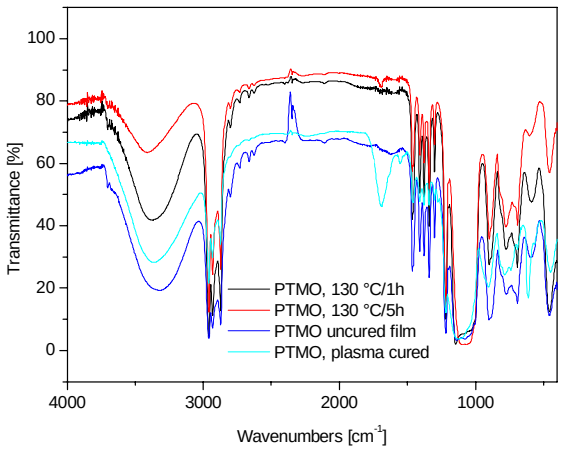
A completely different behavior was found for plasma and thermally cured PTMO. In PTMO no reactive organic polymerizable group is present. Hence, only SiOH condensation reactions are possible under classical conditions. Films obtained by plasma deposition were non-sticking, whereas films obtained after thermal curing (1-5 h/130°C) were still sticky. During thermal treatment only SiOH condensation can take place, which is not as effective as in TEOS. During plasma deposition/curing additional organic cross-linking is expected to takes place. The IR spectrum of thermally cured PTMO is identical to the non-cured film, whereas the spectrum of plasma cured PTMO exhibits a carbonyl signal at 1695 cm^{-1} indicating also oxidation reaction in the organic chain (Figure 3c).



a)



b)



c)

Figure 3: FTIR spectra of a) GLYMO, b) MEMO and c) PTMO precursors and sol-gel based coatings thereof after both conventional (thermal or UV) and plasma curing/deposition

Raman spectra of conventional (thermal) and plasma cured PTMO sol-gel coating shows that the aliphatic groups are not strongly affected or decomposed by the plasma treatment. (Figure 4) The fingerprint regions in the Raman spectra of plasma cured and thermally cured PTMO layers show identical signals. However, the fact that the thermally cured PTMO layer is still sticky while the plasma cured layer is not, indicates that an additional cross-linking process is taking place under plasma conditions. Since there are no significant differences in the Raman signals of $-CH_2-$ and $-CH_3$ groups, it could be assumed that plasma improves the cross-linking and curing of the inorganic siloxane network for PTMO sol-gel systems. More thorough analysis with FTIR and Si-NMR should be able to clarify the differences in chemical structure of both types of coating.

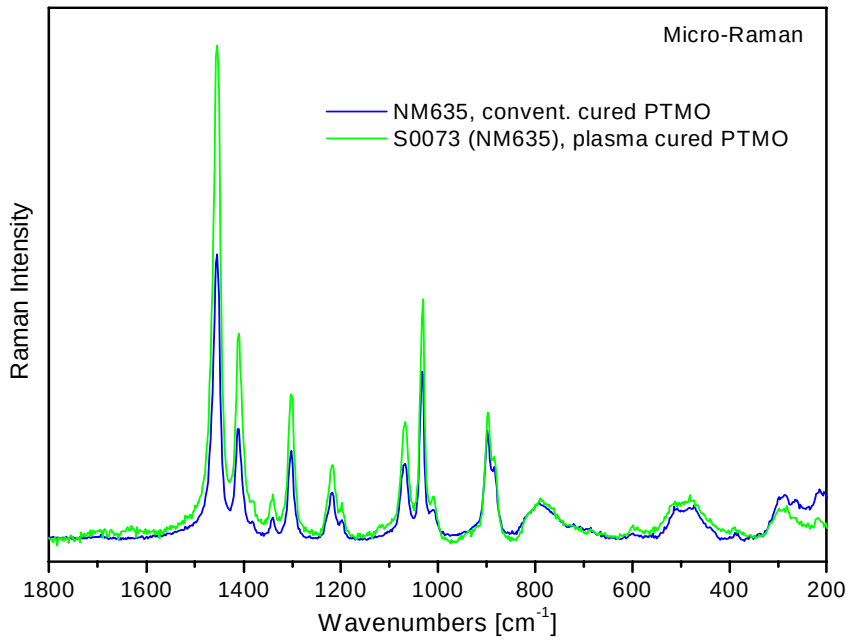


Figure 4: Raman spectra of the plasma cured and thermally cured coatings obtained from a hydrolyzed PTMO solution.

In order to evaluate the influence of plasma induced cross-linking on the physical coating properties, the oxygen permeability of coated PET films was determined. Both thermally and plasma cured coatings were three micron thick. As can be seen in Figure 5, the oxygen permeability decreases significantly from thermally cured PTMO to plasma cured PTMO coatings on PET films. The reason is the more densely cross-linked structure obtained after plasma curing.

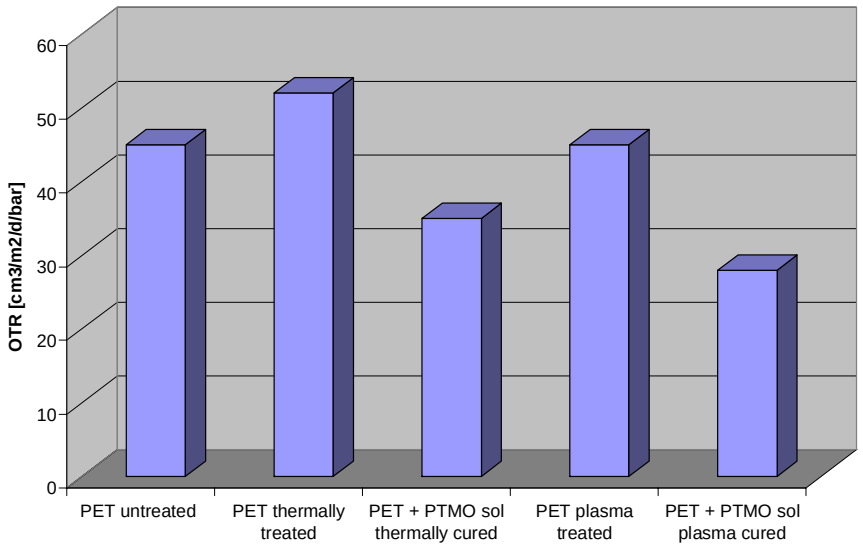

Figure 5: Oxygen permeability of PTMO sol-gel coated PET after conventional curing and plasma deposition/curing

In order to obtain even better barrier coating properties and higher deposition rates for DBD plasma coatings the addition of a high molecular weight inorganic cross-linker (Bayresit) to the sol-gel systems was investigated. (Figure 6)

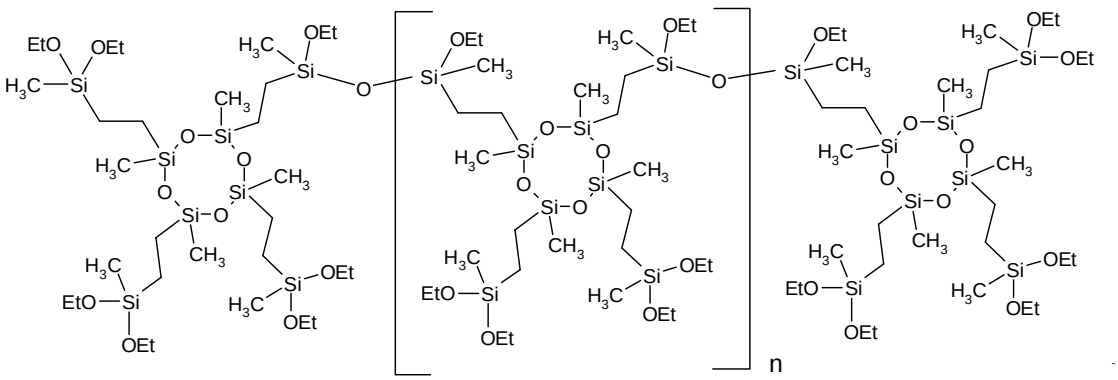

Figure 6: Chemical structure of Bayresit

Under standard curing conditions (MEMO: UV-curing; PTMO, GLYMO: thermal curing) coatings were still sticky and very soft indicating non-sufficient curing. This effect cannot be explained up to now. However, a first preliminary plasma deposition of a Bayresit/PTMO sol-gel system (50:50 molar ratio) resulted in a well cured film. Furthermore and rather surprisingly, plasma coatings obtained from the latter

compound in its pure form gave rise to very low oxygen transmission rates (< 10 cm³/m²/d/bar on PET). (Figure 7)

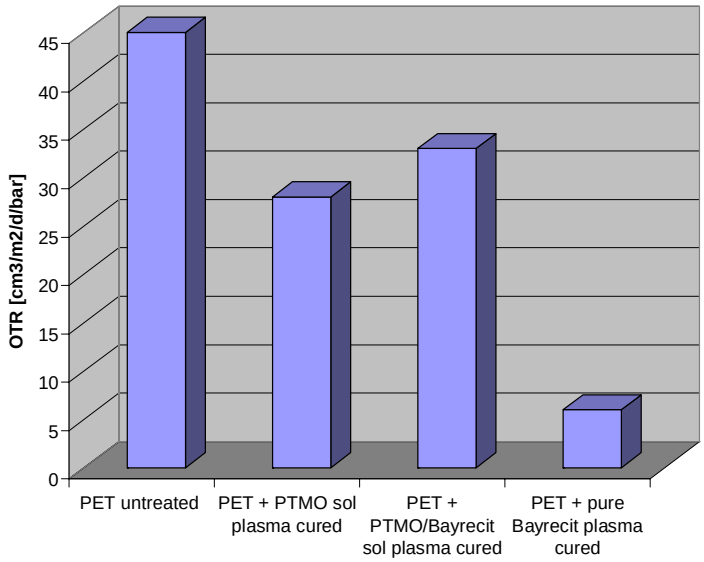

Figure 7: O_2-permeation of plasma coated PET films

3. Conclusions

Sol-gel technology opens-up a wide range of chemical possibilities in coating deposition, especially with respect to nanoscopic variations of inorganic and organic groups or structural elements. Coatings prepared from these materials can be tailored towards many different applications including barriers, scratch resistance and many others. However, the classical curing processes (thermal and UV) do not always exploit the full potential of these materials.

The presented work shows that plasma curing of aerosol droplets of hybrid sol-gel precursor solutions prior and during deposition on a substrate surface is advantageous to conventional wet-chemical coating and subsequent thermal or UV curing. Due to the high surface area of the atomized sol and the extremely reactive plasma environment, increased cross-linking takes place. This results in faster curing and better barrier properties of the obtained coatings.

However, the best barrier performance was obtained with a coating from a new high molecular weight non-hydrolysed siloxane precursor. Further experiments should allow to improve the barrier performance even more and to gain more insight in the exact physico-chemical structure of these coatings.

4. Experimental

The experimental configuration of the DBD system consists of two parallel electrodes (160 x 180 mm), both covered with an insulating borosilicate glass plate of 3 mm thickness. (Figure 8) In order to perform tests in a controlled atmosphere, the electrode configuration is mounted in a closed vessel which is evacuated and subsequently filled with the carrier gases before deposition is started. To ensure stable plasma operation, the gap between the electrodes is limited to 2 millimetres. Plasma discharges were generated by a 20 kV/200 mA AC power supply (Melec) with variable frequency connected to a high voltage transformer. The maximum output power is 3 kW and the frequency can be varied in the range of

50 Hz- 100 kHz. The discharge voltage is measured by means of a high voltage probe (Tektronix P6015A) while the discharge current is measured by means of a current probe (Tekronix A6312). The discharge current and discharge voltage are monitored on a digital oscilloscope (Tektronix TDS 3052). The carrier gas is introduced between the parallel plates by a gas distribution unit. The gas flow rate is controlled by mass flow controllers (MKS Instruments, Multi Gas Controller 647B).
The reported deposition experiments were performed in nitrogen (15 l/min) at a frequency of 9 kHz and power densities between 0.5 to 1.5 W/cm^{2}. Polydisperse submicron aerosols of the liquid precursors and sol-gel systems were added to the gas flow by means of an atomizer (TSI, model 3076 or model 9306A). Deposition times were set at 2 to 10 minutes.

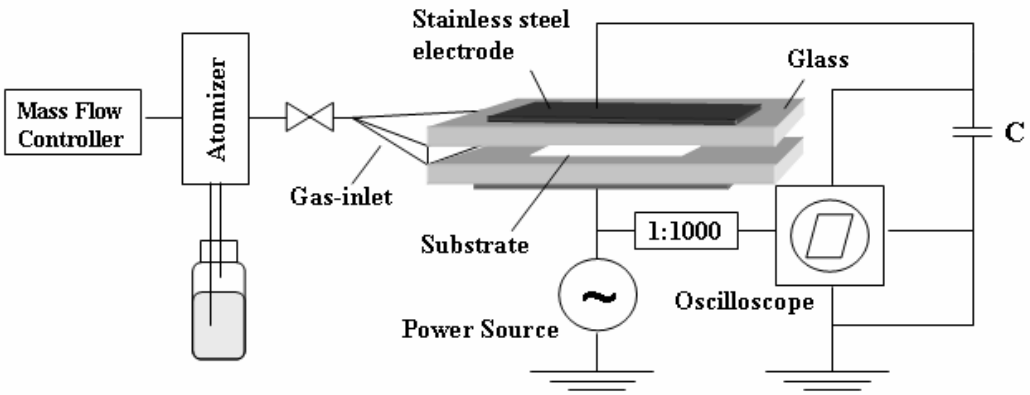

Figure 8: Experimental setup of DBD equipment

The hydrolysis conditions of the monomers and the stability of the sols were investigated. The use of ethanol in a ratio of silane precursor:ethanol = 2:1 and the use of hydrochloric acid as a catalyst have been found advantageous for the synthesis of stable sols. In the case of GLYMO and MEMO very stable sols were obtained exhibiting only a slight increase of viscosity and a low increase of molecular weight after 3-4 weeks of storage at 25 °C. The PTMO and the TEOS sols gelled after 12 days and 17 days respectively. Storage under freezing conditions increases the stability significantly. (Figure 9)

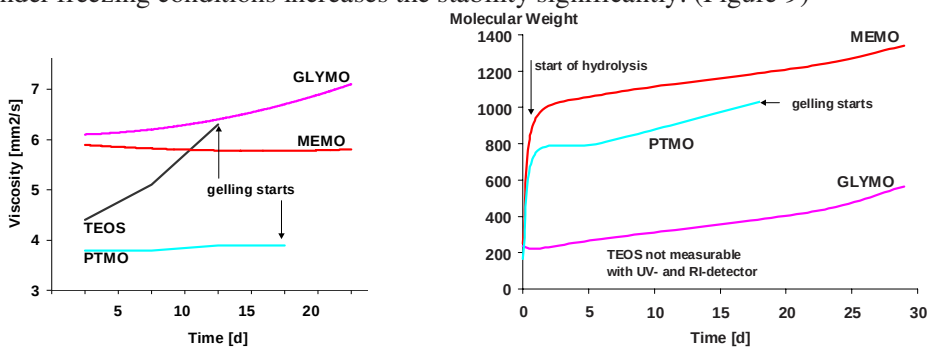

Figure 9: Stability of precursor sols at 25 °C (left); Molecular weights given relative to polystyrene standards (right)

Combinations of Bayresit as inorganic cross-linker with the coating forming and plasma active silanes MEMO, GLYMO and PTMO resulted in stable sols after hydrolysis (sol-gel processing). In general a lower amount of water had to be used for the hydrolysis reaction in order to obtain stable sols. In case of

stoichiometric amount of water gelling occurred very rapidly. This effect indicates clearly the high degree of cross-linking which is achieved after sol-gel processing.

To obtain suitable samples for the different analytical techniques, various substrates are placed between the electrodes such as glass slides, pieces of single and double polished silicon wafers, pieces of plastic foil (PET) and polished stainless steel platelets.
The deposits were characterized by various surface analysis techniques. The coating thickness was determined by a UBM-Microfocus profilometer. Cross-sections of the plasma polymer coatings were studied by field emission scanning electron microscopy (FESEM, JSM-6340F, Jeol). Oxygen transmission rates (OTR) were measured according to DIN 53380 at 23 °C and 50 % relative humidity. A Nicolet Nexus FT-IR spectrometer equipped with a Spectra Tech ATR module (Thermo, USA) was used for the deduction of functional groups present in the coating.

Effect of synthesis conditions on the morphology of ZnO powder produced in RF thermal plasma

Z. Károly, L. Gál, J. Szépvölgyi

Institute of Materials and Environmental Chemistry, Chemical Research Center, HAS
H-1525 Budapest, POB 17, Hungary

Abstract
We have investigated the synthesis of nanophase ZnO particles in inductively coupled RF thermal plasma reactor. Precursor materials were the solutions of zinc-nitrate-hexahydrate that was sprayed into the plasma flame. Particles nucleated from aqueous solutions were usually bigger than those nucleated from ethanol solutions if other conditions were unchanged. We found good correlation between the mean particle size of the product particles and the total gas flow rate in the plasma reactor.

Keywords
Zinc-oxide, nanophase particles, RF plasma

1. Introduction

The electronic and optical properties of ceramic materials are greatly influenced by the size, morphology, purity and chemical composition of the particles they comprised. Nanophase ZnO with different morphologies has potential applications in varistors, gas sensors, catalysts, pigments, ceramics, electrical and optical devices [1]. Besides, ZnO is one of the few oxides that show quantum confinement effects in an experimentally accessible size range [1]. Consequently, synthesis and morphology control of ZnO nanoparticles has received great attention recently. Several routes have been developed for the synthesis of ZnO powder such as hydrothermal synthesis [2], precipitation [3], sol-gel technique [4], spray pyrolysis [5], thermal decomposition etc. This work is aimed at preparing nano-sized ZnO particles in inductively coupled, RF thermal plasma reactor.
Intrinsic features of RF thermal plasmas provide favorable conditions for the synthesis of nanophase particles. The extremely high temperature prevailing in the center of the plasma is capable of evaporating most of the precursor materials. Rapid cooling of vapors taking place in the tail flame results in very fine particles as a result of high supersaturation. By-products, if there is any, are usually removed as gas. One of the main advantages of thermal plasmas that chemically less complicated, low cost materials could do as precursors.
Precursor materials injected into the hot region of the plasma are vaporized, the vapors are quenched rapidly outside the plasma flame, and nano-sized particles are formed due to high supersaturation. In contrast to model calculations, our experiences revealed that solid powders fed into the plasma do not evaporate totally. This results from the fact that even feeding is difficult to realize, and precursor particles are either oversized (having mean particle size of several ten microns) or heavily agglomerated with high porosity. For the aforementioned reasons, in this work precursors of ZnO synthesis have been sprayed into the plasma as solutions. We have investigated the mechanism of particle formation and the effect of the synthesis conditions on the morphology of formed particles.

2. Experimental

The experimental apparatus consisted of an RF generator attached to a four-turn RF inductively coupled plasma torch (TEKNA PL35), a reactor chamber, a cyclone and a filter. Scheme of the experimental setup was presented in other papers [6]. Air and argon were used as sheath and plasma gas, respectively. Gas flow rates and plate power were varied in the different tests. Precursors were aqueous and ethanol solution of $Zn(NO_3)_2 \cdot 6H_2O$ of various concentration.. A peristaltic pump was used to deliver the liquid feedstock at a constant a rate of 8 $ml \cdot min^{-1}$ to the atomizer nozzle, where it was dispersed by 3 $l \cdot min^{-1}$ of argon gas into fine droplets. The obtained powder was collected from the reactor wall and from the cyclone, respectively. Crystal phases of the product

were determined by XRD. Mean crystallite size was calculated from the peak broadening of particular XDR peaks. SEM and TEM apparatus was used to reveal the particle morphology of the as-prepared powders.

3. Results and discussion

Operating conditions and main characteristics of product powders are summarized in Table 1. Product particles show great differences in terms of morphology, size and crystalline nature, as well. Comparison of typical XRD patterns of the products made from aqueous and ethanol solutions, respectively, are shown in Fig.1.

Table 1 Operating conditions and results of nanosized ZnO production

Test	Precursor		Flow rates	Plate power	Size	Fraction of
	solution	Molarity	$l \cdot min^{-1}$	kW	nm	ZnO, %
1	aqueous	2,0	60	19	165	95
2	aqueous	1,5	71	21	-	68
3	aqueous	2,0	70	20	141	26
4	aqueous	1,0	73	23	123	100
5	ethanol	1,0	90	15	123	100
6	ethanol	1,1	91	15	123	100
7	ethanol	1,1	120	15	52	100
8	ethanol	1,3	73	23	247	100
9	ethanol	1,0	76	23	197	100
10	ethanol	1,6	65	16	329	100
11	ethanol	1,0	65	16	329	100

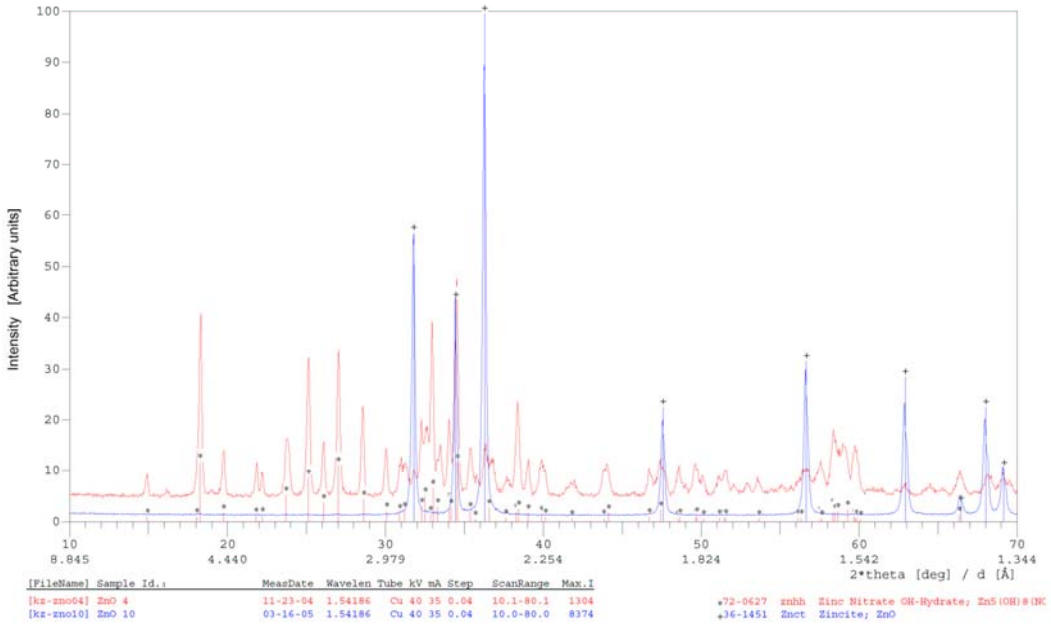

Fig. 1 XRD patterns of products

When starting from ethanol solution feedstock, product material invariably consisted of well-crystallized ZnO phases (blue line in Fig. 1). Peaks refer to a hexagonal wurtzite structure with lattice constants of a=0.325 nm and c= 0.521 nm. In contrast, using aqueous solution precursors, the abundance of peaks besides the characteristic peaks of ZnO crystals (red line in Fig. 1) indicates the presence of other nitrate hydroxide hydrate phases. Although, complete decomposition of zinc nitrate hexahydrate finishes up to 350°C, several factors such as low residence time, dense loading that retard the thermodynamic equilibrium to be attained, result in a partial decomposition only. It is confirmed by the correlation established between the proportion of the hydroxide phases remained after treatment in the product and the applied specific power (Fig. 2). It appears from the correlation that higher specific power is required in order to obtain pure ZnO powders. In this point of view particular route entails much higher power consumption due to the rather high proportion of water to be evaporated.

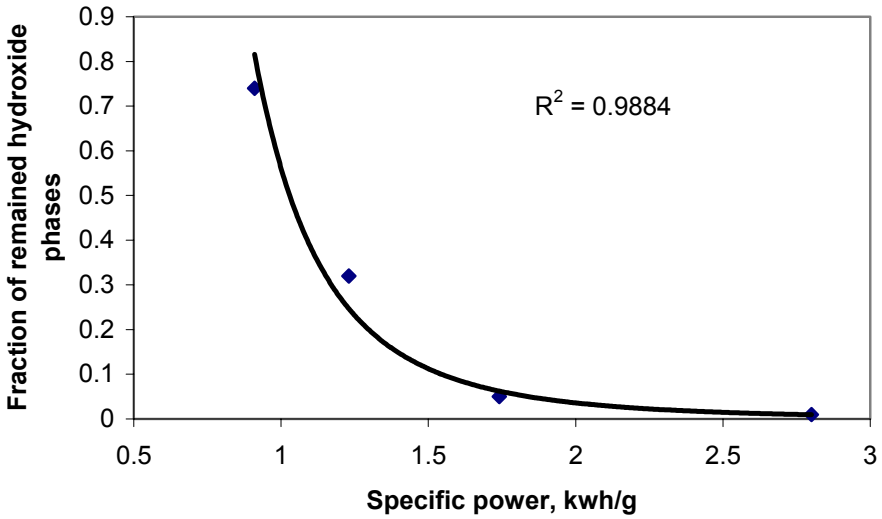

Fig. 2 Effect of the specific power on transformation of precursors

In terms of mean particle size, particles produced from ethanol solution were generally smaller in comparison with aqueous solution counterparts. The mean size was affected in the greatest extent by the total gas flow rates of plasma gases. Quite a good correlation could be established between them despite the fact that size determination from XRD peak broadening inherently entails about 10% uncertainty above calculated values of 100 nm. According to the correlation (Fig. 3), mean particle size can be decreased by increasing gas flow rates. Increased flow rate has twofold effects: it reduces the residence time of the nucleated particles in the hot region and also reduces the volume concentration of Zn-containing species in the vapor. Gas flow rate is, however, limited by the suction capacity of the vacuum pump. Effects of other process parameters on the mean size were negligible.

Morphology of product particles exhibit great diversity; dots, rods, tetrapods and spheres could also be observed among them. Even the particular test resulted in particles of various morphologies simultaneously, however, their ratio varied in each test. Different morphologies suggest different crystallization mechanisms.

According to the general procedure for synthesis of nanophase materials by plasma treatment, the nanophase particles nucleate from the vapor phase by homogeneous condensation as a result of high super-saturation due to rapid cooling. Depending on the residence time a nucleated particle spend in the hot zone, particles may grow further by condensation or coagulation. The simultaneous presence of dots, nanorods (Fig. 4a) or particles of other shapes is presumably the consequence of the different thermal history of the species. In some tests, most of the powders are made up tetrapod-shaped ZnO crystals of different size (Fig. 4b). The arms of these tetrapods are single crystal hexagonal ZnO with a [0001] growth direction. It is under debate whether the nuclei of

tetrapod ZnO structure are metallic zinc [7] or zinc-suboxides (ZnO_x) [8] The lack of atomic zinc lines in the range of 200-600 nm on the optical spectrographs confirms the latter mechanism. Nevertheless, it seems to be evident that tetrapods can be developed in an atmosphere being locally deficient in oxygen.

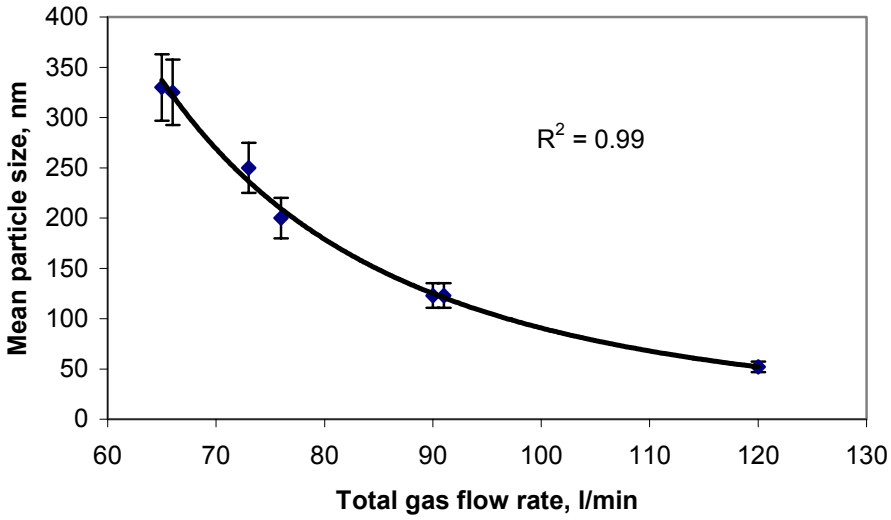

Fig. 3 Effect of gas flow rate on the mean particle size

Nucleation in aqueous solution tests did not follow the above mechanism, but rather resembles flame spray processes. The solvent, water molecules evaporate from the fine droplets, while nucleation takes place within the supersaturated droplets. As a result, relatively large, submicron or micron sized, tabular or spherical grains are formed that consisted of primary particles of 100-200 nm size (Fig. 5). Using sufficiently high power, this particle-to-particle conversion mechanism could be altered and nano-sized or tetrapod particles can also be prepared.

Fig. 4 TEM images of nanophase ZnO particles

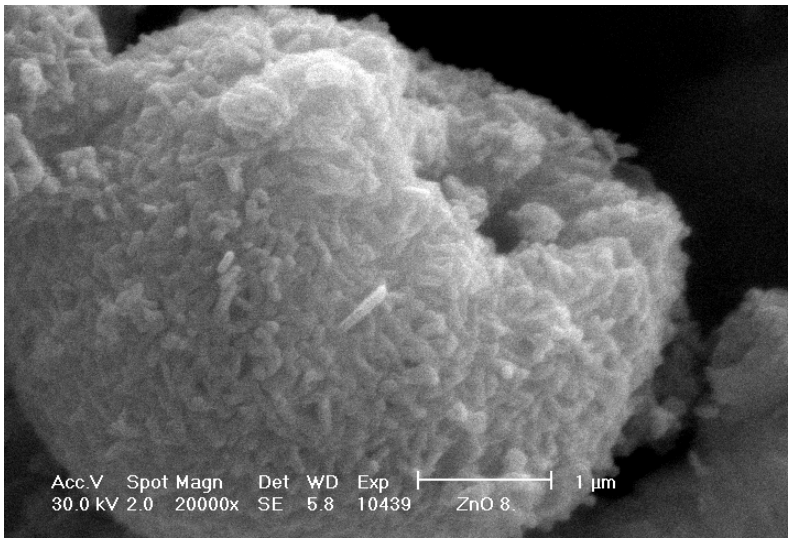

Fig. 5 SEM image of a ZnO grain synthesized from aqueous solution

4. Conclusions

We have investigated the preparation of nanophase ZnO particles in RF thermal plasma reactor from different precursors. We found that the flow rate of the working gases has the greatest effect on mean particle size that was generally higher starting from aqueous solution. Particles differed in size and morphology even in the same test. It can ultimately be attributed to the strongly different trajectories and thermal histories of nucleated particles.

How Can the Carbon Black Yield From Freons Be Raised in Thermal Plasma Decomposition?

K.A. Főglein, J. Szépvölgyi

Institute of Materials and Environmental Chemistry, Chemical Research Center, Hungarian Academy of Sciences
H-1525 Budapest, POB 117, Hungary

Abstract
Freon decomposition in RF thermal plasma conditions was investigated in this work. The main reaction product was solid soot. Correlations were established among conditions of processing and soot yield.

Introduction
Carbon nanomaterials exhibit a rich polymorphism including nanosized particles, single- and multi-wall carbon nanotubes (CNTs), fullerenes [1], necklaces, graphitic onions, toroids, boxes etc. Each discovery of a new morphology in carbon materials opens to new field of application. It is expected that these structures have potential impact in applicative domains such as molecular electronics or high strength composite materials.
Carbon materials are mainly produced by conventional techniques such as arc discharge, laser ablation, chemical vapor deposition (CVD), AC-plasma, MW-plasma or RF plasma technologies. Structure and amount of synthesized carbon nanostructures strongly depend on the applied technique.
In this work decomposition of freons was studied in RF thermal plasma, in a systematic way. Our goal was to establish the effect of reaction conditions leading to maximum yield of carbon black as main product of decomposition.

Experimental
The RF induction plasma torch used in this work had a standard design with a quartz glass confinement tube of 27 mm I.D. The plasma reactor was connected to air-cooled quenching and powder collection sections. The plasma power was provided by a 3-turn induction coil from an RF generator operating at an oscillator frequency of 27.17 MHz.
High-purity argon was used as plasma (8 $l \cdot min^{-1}$ (STP)) and sheath (21 $l \cdot min^{-1}$ (STP)) gases, and also as the carrier gas of reactants. Oxygen or hydrogen gases, if any, were added to the carrier gas with a flow rate of 0.6 $l \cdot min^{-1}$ (STP).
Analytical grade model compounds, such as CCl_4, $CHCl_3$, CH_2Cl_2 and $CFCl_3$ were injected in a swirl direction through a transverse slot into the plasma tail flame region. The solid main product was mainly condensed on the wall of the reactor, and also in the collector and the filter. The soot was extracted by toluene using the Soxhlet method to separate its carbon black content.

Experimental design
The experiments were designed by computer code STATISTICA. Four factors at three levels each were considered in the experimental planning (Table 1).

Table 1. The factors and their levels

Factors		***Levels***		
		1	***2***	***3***
Power [kW]		1.6	2.1	2.6
Plasma gases		Ar	Ar + O_2	Ar + H_2
Model compounds	*F-Cl-H*	C-F-Cl_3	C-Cl-Cl_3	C-H-Cl_3
	0, 1, 2 H	C- Cl_2-Cl_2	C-HCl-Cl_2	C-H_2-Cl_2
Sampling place		Reactor	Collector	Filter

Results and Discussions

To find relationship between parameters of processing and carbon black yield, the plasma conditions should be characterized in a complex way. For this reason we defined the specific energy of processing (E_{SP}, $kWh \cdot g^{-1}$) as follows:

$$E_{SP} = \frac{P}{G} \tag{1}$$

where P is the plate power (kW) and G is the feed rate of precursor ($g \cdot h^{-1}$).

The soot contained adsorbed organic compounds on its surface, which were removed by toluene extraction. The carbon black yield from decomposition ($Y_{C(s)}$, %) was calculated by the following equation:

$$Y_{C(s)} = \frac{M \cdot G_{C(s)}}{144 \cdot G} \tag{2}$$

where $G_{C(s)}$ is the formation rate of extracted carbon black ($g \cdot h^{-1}$), G is the feed rate of precursor ($g \cdot h^{-1}$) and M is the molas mass of precursor (g/mol).

Dependence of $Y_{C(s)}$ on the composition of precursor

Previous investigations [2] revealed that in neutral conditions the carbon black yield ($Y_{C(s)}$) changes as a function of specific energy along a Gaussian curves. The carbon black yield is plotted against the specific energy in Fig 1. In experiments presented in this work not the total energy range that could be considered in particular system was studied only some characteristic sections have been investigated in order to determine the E_{SP}, where the E_{SP}-$Y_{C(s)}$ function reaches its maximum..

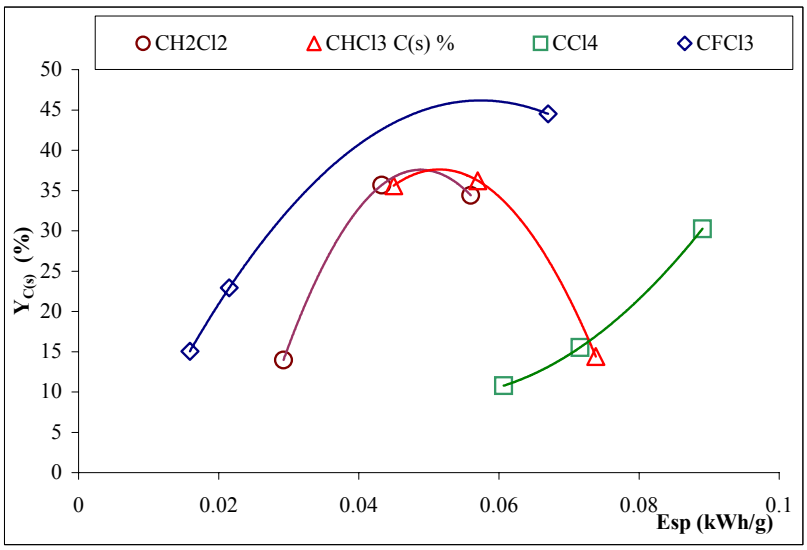

Figure 1. Carbon black yield as a function of specific energy of processing

Run of the E_{SP}-$Y_{C(s)}$ curves in Fig. 1 is explained as follows:

- At low E_{SP} values the plate power is not enough for the complete decomposition to atoms and remains radicals in the system. Carbon black yield rises with increasing E_{SP}, caused by the higher effectiveness of precursor decomposition.
- At high E_{SP} values complete decomposition is possible, caused by the higher temperature of plasma flame. The products make a stay in the hot zone for a longer period. This fact facilitates the formation of

high order hydrocarbons on the soot surface, accompanying by the drop of C(s) concentration in the system.

- The maximum E_{SP} values occur where the first mechanism turns into the second one.

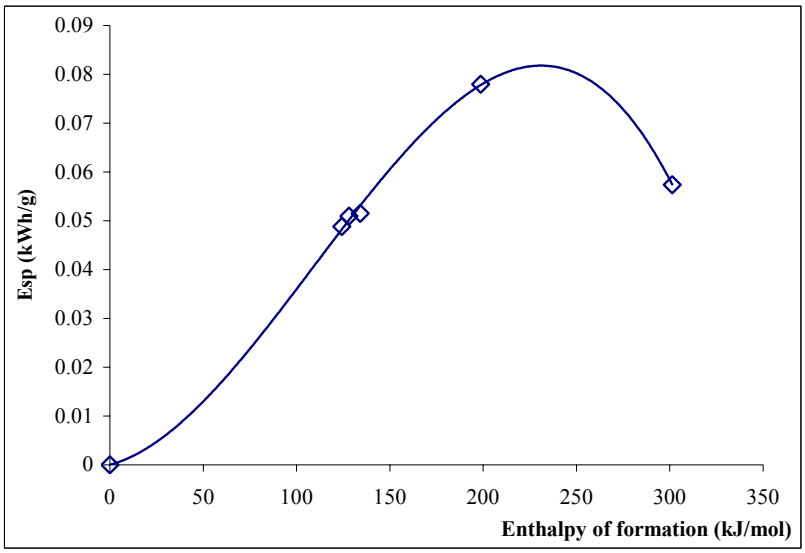

Figure 2. Specific energies belonging to maximum carbon black yield as plotted against formation enthalpy of precursors

Specific energy values belonging to maximum carbon black yield depends on the formation enthalpy of precursors (Fig. 2). After having determined this curve for a given plasma system, it can be used to predict for other precursors the probable E_{SP} where $Y_{C(s)}$ reaches its maximum.

Dependence of $Y_{C(s)}$ on sampling spot in the $CFCl_3$ case

Carbon black yield of $CFCl_3$ was the highest among precursors studied in this work. Thus, it was investigated in more detailed later on. We observed that for $CFCl_3$ the maximum yield of carbon black depended on the spot of sampling, as well (Fig. 3).

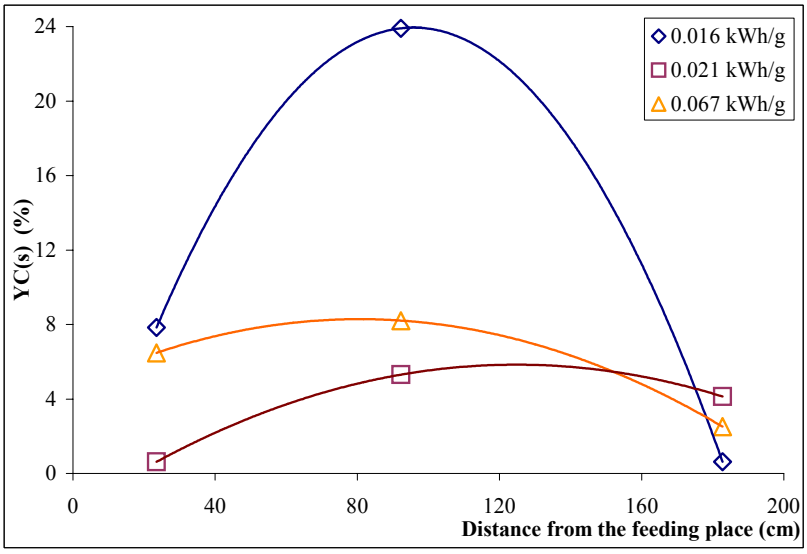

Figure 3. Dependence of $Y_{C(s)}$ on the spot of sampling at different specific energies for $CFCl_3$

Close to the spot of feeding the C(s) concentration was low due to formation of small organic compounds which condensed on the reactor wall. At greater distances from the feeding spot the solid product, in addition to carbon black, contained different organic molecules crystallized on the surface of the carbon black as it had been proved by GC-MS investigations [3].

Dependence of $Y_{C(s)}$ on the quality of carrier gas in the $CFCl_3$ case

The carbon black yield depended on the composition of the gas phase, too. The gas composition was changed by adding hydrogen or oxygen to the carrier gas. Changes of $Y_{C(s)}$ as a function of distance from feeding spot for different gas compositions (pure Ar, 0.5% O_2 + 99.5% Ar, 0.5% H_2 + 99.5% Ar) are plotted in Fig. 4. Run of curves in pure argon and hydrogen-argon mixture is rather similar which refers to similar reaction mechanisms in both cases. In the presence of oxygen, the carbon black yield is very low, and it is actually independent of the spot of sampling.

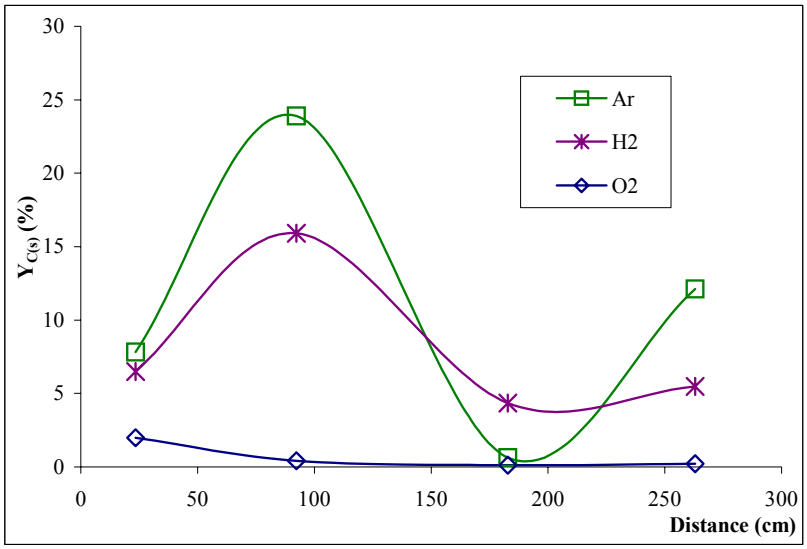

Figure 4. $Y_{C(s)}$ as a function of distance from the feeding spot for $CFCl_3$ in different atmospheres

Evaluation of experimental data by computer code STATISTICA

Experimental results were evaluated by computer code STATISTICA in order to establish the effect of process parameters on $Y_{C(s)}$. Several Greco Latin Squares (GLSs) were drawn and analyzed. Results of calculations are plotted in 3 by 3 GLSs where we distinguished three of four factors only (Fig. 5) or in the 4 by 4 ones, where we applied all factors (Fig. 6). We established that:

- At a given sampling spot, the lowest carbon yield was achieved for CCl_4, while the highest for CH_2Cl_2.
- The carbon yield depended directly on the plate power.
- Both in oxidative and reducing conditions, the carbon black content of the soot decreased as compared to decomposition in argon atmosphere.
- Soot of highest carbon black content was collected from the reactor and from the gas filter, respectively.

Another goal of our work was to test the significance of different factors as above. For this reason the Square Sum (SS) was calculated for all GLSs. Their average is plotted in Fig. 7. The higher the Square Sum, the greater is its effect on carbon black production. The results can be summarized as follows:

- Composition of carrier gas has the greater effect on $Y_{C(s)}$.
- Plate power and composition of precursors actually have similar effect on $Y_{C(s)}$.
- Spot of sampling actually does not influence the carbon black yield.

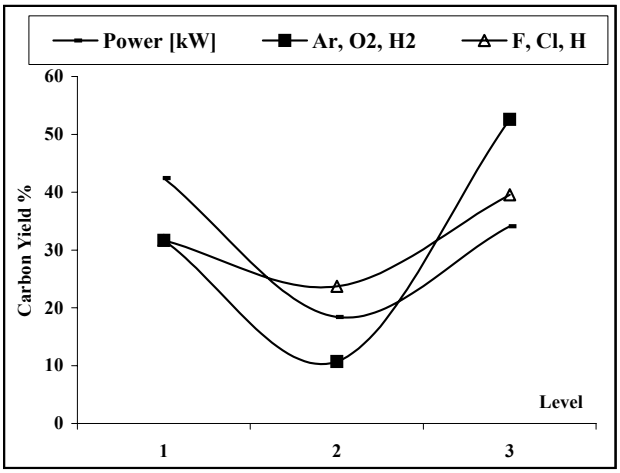

Figure 5. F-Cl-H systems - Sampling from the same place

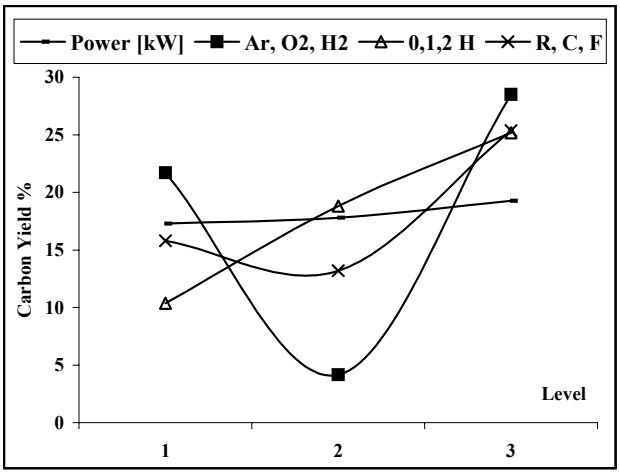

Figure 6. All four factors for the 0, 1, 2 H systems

Conclusions

The carbon black yield from decomposition of different freons can be increased by changing the conditions of thermal plasma processing as follows:

- **Plasma gas**: using pure Ar plasma instead of Ar-H_2 or Ar-O_2 ones;
  - H_2 decreases the carbon black content of the soot, because hydrogen facilitates formation of hydrocarbons.
  - O_2 depresses the soot yield, but it increases the carbon black content of the soot.
- **Specific energy:** the task is to determine the maximum of E_{SP}-$Y_{C(s)}$ function for each model compound.
- **Flow rate of carrier gas:** the lower, the better, because the degree of decomposition depends on the feed rate of precursors.
- **Distance of sampling spot from the feeding point**: for each model the maximum of E_{SP}-sampling distance correlation should be determined by experiments

PRODUCTS OF CCl_2XY DECOMPOSITION IN THERMAL PLASMA

K.A. Főglein, P.T. Szabó, J. Szépvölgyi

Institute of Materials and Environmental Chemistry, Chemical Research Center, Hungarian Academy of Sciences
H-1525 Budapest, POB 17, Hungary

Abstract
Decomposition of different CFCs (of CCl_2XY stoichiometry) has been studied in RF thermal plasma reactor in order to find correlations among conditions of processing, degree of decomposition and composition of products. Mechanism of decomposition depended on the composition of model compounds. In addition to gaseous products, solid soot and different halogenated hydrocarbons were identified as main products of decomposition.

Keywords: Freons, RF thermal plasma, decomposition

Introduction

Conversion of freons into more useful species is a great challenge even nowadays. Solid, liquid and gaseous products can form during their decomposition. In addition to decomposition of freons and thus, to decrease their harmful environmental impacts, much attention is being paid to transform particular materials to useful products such as carbon spheres and carbon nanostructures. These products have great potential of application p as emitters for field emission arrays, nano-composite fillers, manifold energy storage devices and secondary battery electrodes [1,2]. Equally great theoretical and practical importance was given to the production of C_2 hydrocarbons, synthesis gas and methanol as useful chemicals [3]. Formation of harmful gaseous products could be avoided by setting the plasma conditions properly. To initiate conversion of freons, the strong C-F and C-Cl bonds should be broken and halogens should be taken off the system. It can be realized by different methods, including pyrolysis, direct oxidation, catalytic reactions and decomposition in electrical discharges or thermal plasmas. This work is aimed at revealing the differences in product distribution during the decomposition of model compounds of various compositions in thermal plasma conditions.

Experimental

The RF induction plasma torch has a standard design with a quartz glass plasma confinement tube of 27 mm I.D. The plasma reactor was connected to air-cooled quenching and powder collection sections. The plasma power was provided by a 3-turn induction coil from an RF generator operating at an oscillator frequency of 27.17 MHz. High-purity argon was used as plasma (8 $l \cdot min^{-1}$ (STP)), sheath (21 $l \cdot min^{-1}$ (STP)) gases and also as the carrier gas of the reactants. Oxygen, if any, was added to the carrier gas with a flow rate of 0.6 $l \cdot min^{-1}$ (STP).
Analytical grade model compounds, such as CCl_4, $CHCl_3$ and $CFCl_3$, were injected in a swirl direction through a transverse slot into the plasma tail flame region. After having reached the steady-state operation samples were taken from the exhaust gas. These samples were immediately analyzed by GC-MS. The solid soot was mainly condensed on the reactor wall. The soot was extracted by toluene using the Soxhlet method and the extracts were subjected to GC-MS analysis.
The GC-MS measurements were carried out on a VG-ZAB2-SEQ mass spectrometer connected to a HP 5890 gas chromatograph. A 50m long HP-5MS fused silica capillary column was used for separation. Helium was applied as carrier gas with a flow rate of 2 ml min^{-1}. The temperature was programmed as follows: 80°C for 4 min then increased by 5°C min^{-1} up to 250°C and kept there for 10 min. The mass range of mass spectrometer was 30-800 m/z.
In order to identify the gaseous decomposition products, a 100 µl sample was collected from the exhaust gas by a gas-tight Hamilton syringe. The sample was subjected to GC-MS analysis. Another 100 ml sample was collected by an IR gas-cell for FT-IR monitoring. FT-IR measurements were carried out on a PE FT-IR spectrometer equipped by a DTGS detector.
The processing conditions where characterized by the specific energy defined as follows:

$$E_{sp} = P/G \quad (1)$$

where E_{SP} is the specific energy of processing ($kWh \cdot g^{-1}$), P is the plate power (kW) and G is the feed rate of precursors ($g \cdot h^{-1}$). The unreacted fraction of model compounds during plasma treatment was calculated from the results of FT-IR analysis by the following equation:

$$UF = 100 \cdot (1-F_{in}/F_{out}) \quad (2)$$

where UF % is the unreacted fraction, F_{in} is the amount of model compound in the feed material (mol) and F_{out} in the exhaust gas.

Results and Discussions

Decomposition of model compounds in Ar plasma

It was found that decomposition of different models started and completed at different specific energies. $CFCl_3$ decomposed more easily as compared to CCl_4 and $CHCl_3$ (Fig. 1). Its decomposition is taking place through formation of different intermediates, such as CCl_4, CF_3Cl, CF_4, and CF_2Cl_2 [4]. The plasma temperature and the mean residence time of intermediates in the hot zone determined the composition and the amount of intermediates. The higher the specific energy, the longer the residence time of models in the plasma flame region. Thus, beyond a minimum value of UF, concentration of $CFCl_3$ slightly increased with increased E_{SP} in the exhaust. It can be explained by the cross-reactions of intermediates leading to the re-formation of CF_3Cl.

$$2\ CF_2Cl_2 \rightarrow CF_3Cl + \mathit{CFCl_3} \quad (3)$$
$$CCl_4 + CF_3Cl \rightarrow CF_2Cl_2 + \mathit{CFCl_3} \quad (4)$$

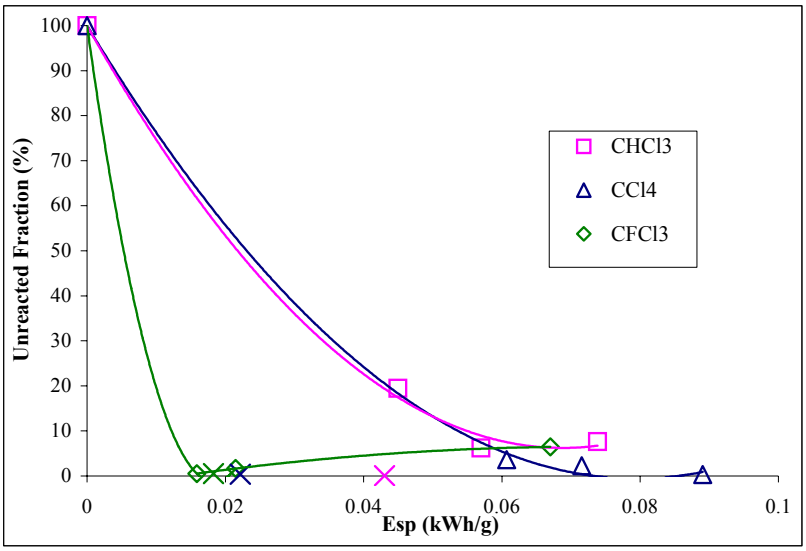

Figure 1. The unreacted fraction of $CHCl_3$ as a function of specific energy

No complex intermediates are formed during decomposition of CCl_4 and $CHCl_3$, respectively [5]. CCl_4 and $CHCl_3$ can be re-formed directly from the primary products of their decomposition. Thus, CCl_4 and $CHCl_3$ could re-form more easily at lower E_{SP} values than $CFCl_3$. However, at higher specific energies this difference disappears.

Formation of soot in CCl_4 decomposition in Ar plasma

In all cases, oot was formed as main solid product of decomposition. It consisted of carbon black, and on its surface it contained halogenated organic compounds which were extracted by toluene. The solid residue of the extraction was carbon black. The soot and carbon black yields in the CCl_4 case are plotted in Fig. 2. The soot yield was defined as the rate of soot mass related to the mass of precursor. The carbon black yield was calculated as the ratio of the carbon black mass related to the mass of carbon in CCl_4 to be treated. Fig. 2 reveals that both soot and carbon black increase with specific energy It is explained by the higher gas temperature and the longer residence time of intermediates in the hot zone leading to more soot formation and also to the formation of more complex organic molecules adsorbed on the surface of soot particles.

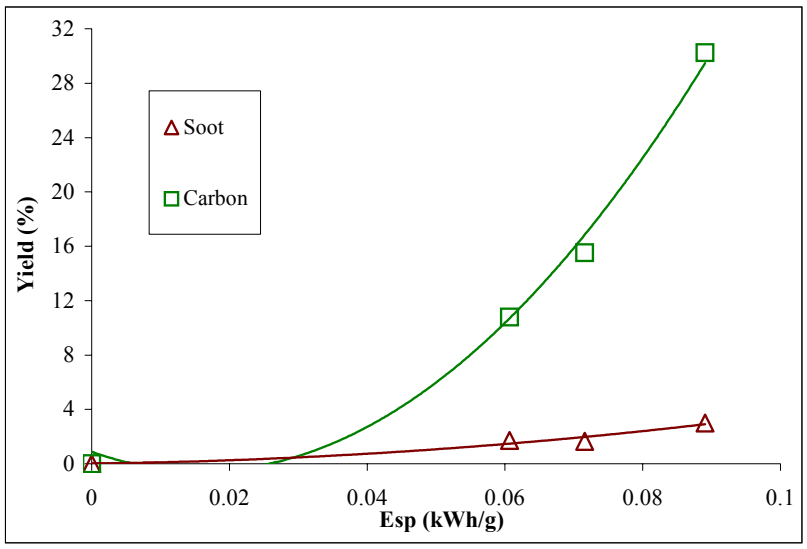

Figure 2. Soot yield and carbon yield as a function of plasma energy

The effect of the carrier gas flow rate in $CHCl_3$ decomposition

It was found that decomposition of $CHCl_3$ depended on the flow rate of carrier gas and hence, on the feed rate of $CHCl_3$ (Fig. 3). At lower flow rates, concentration of precursor was lower, while its mean residence time was longer in the hot plasma zone. It resulted in a more complete decomposition i.e. less unreacted $CHCl_3$. Increase of the flow rate led to higher precursor concentration and shorter residence time in the hot zone. Thus, the unreacted part of $CHCl_3$ increased with the flow rate of carrier gas.

Effect of the plasma gas composition on the $CFCl_3$ decomposition

In addition the pure argon plasma, decomposition of model compounds was investigated in argon-oxygen plasma, as well. In order to compare efficiency of decomposition in the presence and in absence of oxygen, respectively, the experimental data were extrapolated to unreacted fraction of 10%. Specific energies relating to particular decomposition were plotted against specific energy in Fig. 4. Decomposition of CCl_4 and $CHCl_3$ was more effective in oxygen. However, decomposition of $CFCl_3$ was actually not affected by changing the composition of plasma gas in given limits.

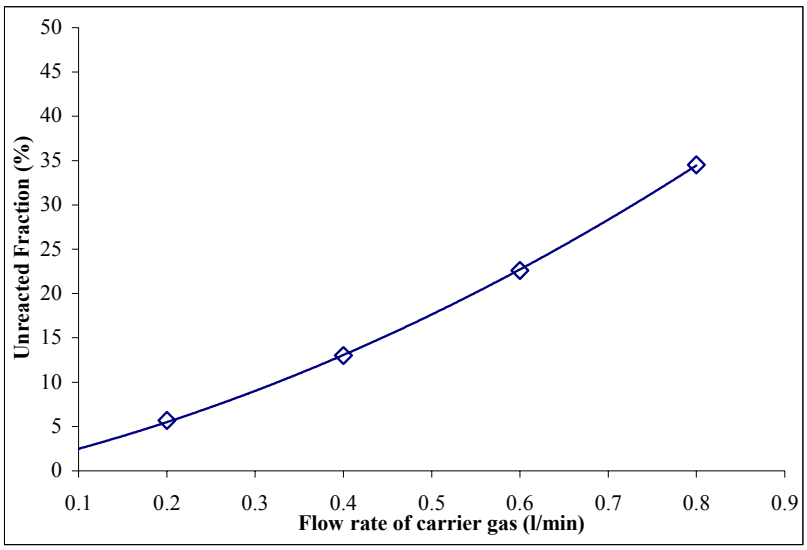

Figure 3. Decomposition rate as a function of carrier gas flow rate

Analysis of the extract from the soot and the exhaust of processing

Results of the GC-MS analyses of extracted fractions and that of FT-IR analyses of exhaust of processing are summarized in Table 1. It can be established that:

- Per-chlorinated products are very stable and they formed even in the presence of hydrogen.
- Chlorine is removed from the system in the presence of oxygen only.
- Replacement of one chlorine atom with one hydrogen atom led to formation of chloro-hydrogenated benzene derivatives, in addition to per-chlorinated benzene.
- Replacement of two chlorine atoms with hydrogen atoms resulted in formation of per-chlorinated and per-hydrogenated products, as well as HCl.
- Increase of hydrogen atoms in the model compounds decreased the number of products.
- Dimethyl-benzene was a very stable product that could form even from the hydrogen contamination of plasma gas.
- Replacement of one chlorine atom with fluorine atom led to formation of fluoro-chloro-benzene derivatives.
- Presence of oxygen in the plasma gases depressed soot formation; however, it increased the carbon black content of the soot.
- Addition of hydrogen to the plasma gas resulted in more soot formation.

Conclusions

On the basis of experiments as above, the following conclusions can be drawn:

- The model compounds decomposed with different rates according to different reaction mechanisms.
- The main product of decomposition was; its carbon black content increased with specific energy of processing.
- Poly-halogenated hydrocarbons were formed in different compositions and different amounts from different freons.

Abstract

Five synthetic graphite powders (4827-Asbury Mills, KS4 and KS6-Timcal, graphite-Aldrich and flake - Alfa) having different mean particle size in the range of 3 to 12 μm were processed in the thermal plasma reactor at atmospheric pressure. In the experiments, effects of feed rate of graphite powder and the helium content of plasma flame on the fullerene yield were studied.

Keywords: RF plasma, fullerenes, graphite

1. Introduction

Since fullerenes may become important building blocks of future technologies such as optoelectronics and photovoltaics, and products such as batteries and fuel cells, development of a technology for large scale production of fullerene at low cost seems to be a topic of outstanding importance [1-3].

Thermal plasma methods for fullerene synthesis have not been investigated in details up to now, in spite of the intensive research on fullerenes, which dates back several years. Many questions are still not answered, especially those regarding the synthesis of higher fullerenes. No feasible technology was developed and implemented for the industrial production fullerenes [2].

A previously developed theoretical model of fullerene formation established that the fullerene yield depended on the following parameters: *(i)* concentration of evaporated carbon in the reactor, *(ii)* mean velocity of the plasma gases in the plasma region and *(iii)* the maximum plasma temperature [4,5]. Inductively coupled, radiofrequency (RF) thermal plasmas offer good possibilities to meet these requirements: more voluminous plasma flames are formed with lower gas velocities compared to arc plasmas. Thus, the mean residence time of reactive species in the hot plasma region is longer in RF thermal plasmas. Powder-like fullerene precursors can be easily introduced into RF plasmas and the feed rate of powders can be changed independently of the RF plasma parameters.

In the present work, five graphite powders from different producers were tested as potential precursors of fullerene synthesis in RF plasma reactor. Our first goal was to establish the optimum particle size for the effective evaporation of graphite particles. It is obvious that the lower is the particle size the evaporation is more effective. However, fine carbon particles are susceptible to agglomeration and agglomerated particles evaporate with lower efficiency than separate ones. The highly efficient evaporation is a key factor in terms of C_2 concentration in the plasma reactor because high value of C_2 concentration facilitates fullerene formation.

2. Experimental procedure

Different graphite powders (4827 from Asbury Mills, KS4 and KS6 from Timcal, flake from Alfa Aesar and graphite from Aldrich) were treated in a thermal plasma reactor at atmospheric pressure. The mean particle size of particular powders varied in the range of 3 to 12 μm. The RF power was produced by a generator operating at 3-5 MHz. A plate power of 30 kW was coupled inductively to a TEKNA PL-35 torch connected to the water-cooled plasma reactor, cyclone and dust filter [5]. Typical gas compositions

of RF plasma are presented in Table 1. The graphite powder was injected axially to the top of the plasma flame with feed rates from 30 to 180 $g \cdot h^{-1}$.

Table 1. Typical gas compositions in the RF plasma reactor.

No.	Sheath		Central	Carrier	Helium
	(Ar, slpm)	(He, slpm)	(He, slpm)	(He, slpm)	(%v/v)
1	50	0	18	3	30%
2	34	22	18	12	60%

Morphology of precursors was characterized by scanning electron microscopy (SEM, Philips XL30 ESEM). The mean crystallite size (L_{002}) was determined from the Fourier (Voight method) analysis of single XRD-line profile. The mean particle size of precursors was measured by laser diffraction technique using Malvern Master Particle Sizer M6.10. The specific surface area of precursors was determined by BET method.

In our experiments, the main product was solid soot collected mainly from the reactor wall. To separate fullerenes, the soot was extracted by toluene at a 100 mg solid/10ml liquid ratio for one minute at 20°C. Amount of fullerenes in the filtered extract (defined as fullerene yield) was measured by UV-VIS spectrophotometer against reference solutions.

3. Results and discussion

Morphological properties of graphite powders used as precursors are presented in Table 2. The highest fullerene yield was obtained with KS4 graphite as precursor (Fig. 1). The other precursors exhibited significantly lower fullerene yields. No direct correlation was found between the mean particle size of precursors (D_{50}) and the fullerene yield. In spite of their similar D_{50} and D_{90} values, processing of Timcal KS4 and Asbury 4827 powders led to quite different fullerene yields. Thermal conductivity of the powders may have a strong effect on the evaporation rate as well.

Table 2. Morphological properties of graphite powders used as precursors.

Precursor	D_{50} (µm)	D_{90} (µm)	S* ($m^2 \cdot g^{-1}$)	$L_{002}{}^{b}$ (Å)	D_{50}/L_{002}
Asbury 4827	3.2	6.3	118	87	370
Timcal KS4	3.7	6.4	26	118	310
Timcal KS6	4.4	7.3	20	109	400
Alfa flake	7.6	14.1	10	144	530
Aldrich powder	11.8	27.5	13	140	840

* Specific surface area

The thermal conductivity of graphite particles cannot be measured in a direct way. For this reason, we defined the ratio of mean particle size and crystallite size (D_{50}/L_{002}), as a parameter characterizing thermal conductivity of precursor. It is reasoned by the fact that particular ratio is proportional to the number of crystallite boundaries, and thus, to the thermal conductivity of graphite powder. The lower this ratio, the higher the thermal conductivity is (Table 2).

Plotting of fullerene yield against D_{50}/L_{002} ratio (Fig. 2) revealed that the highest fullerene yield was obtained in processing of KS4 graphite, which had the lowest D_{50}/L_{002} ratio. The Asbury 4827 graphite is also characterized by a low D_{50}/L_{002} ratio. However, much lower fullerene yield was obtained from this precursor than it could be expected from the D_{50}/L_{002} ratio. It is explained by the extremely high specific surface area of Asbury 4827 graphite (Table 2). The high specific surface area refers to porous microstructure that reduces thermal conductivity.

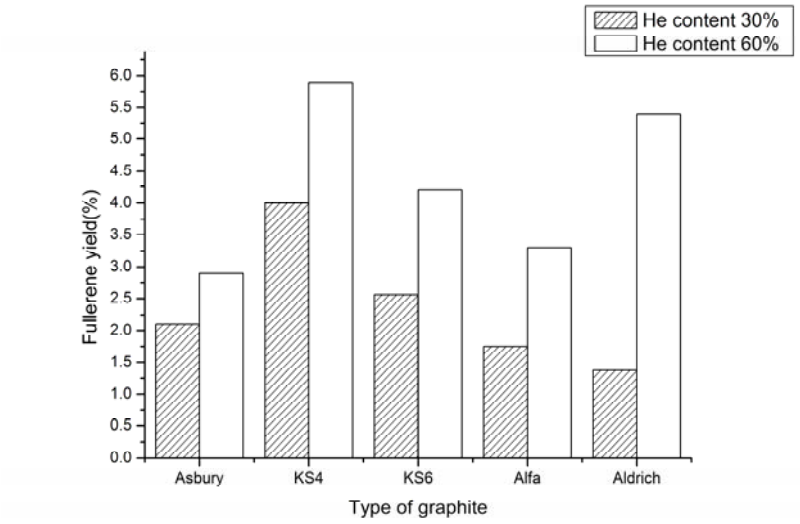

Fig. 1**.** Fullerene yield from different precursors at plate power of 30 kW and different helium content of plasma gas

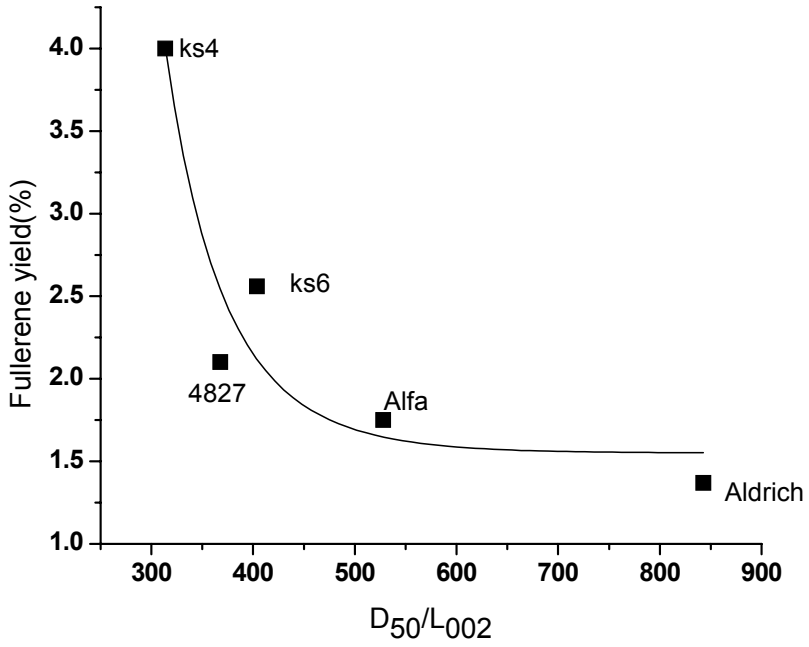

Fig. 2**.** Fullerene yield as plotted against precursor parameter of D_{50}/L_{002} at 30% helium content in the plasma gas

The fullerene yield (i.e. the fullerene content of soot) and the production rate (i.e. mass of fullerene produced in unit time) are plotted against feed rate of KS4 powder in Fig. 3. The fullerene yield decreased, while production rate increased with feed rate. Similar tendencies were observed during processing of other precursors, as well. For KS4 graphite, the highest fullerene yield was 5.9%. Lower fullerene yields and production rates were obtained from other precursors as compared to KS4 graphite.

The fullerene yield was plotted against feed rate of precursors at different gas compositions in Fig. 3. It was observed that increase of the helium concentration from 30% to 60% resulted in 50% increase in fullerene yield. It refers to the importance of heat transfer phenomena in fullerene formation in particular conditions.

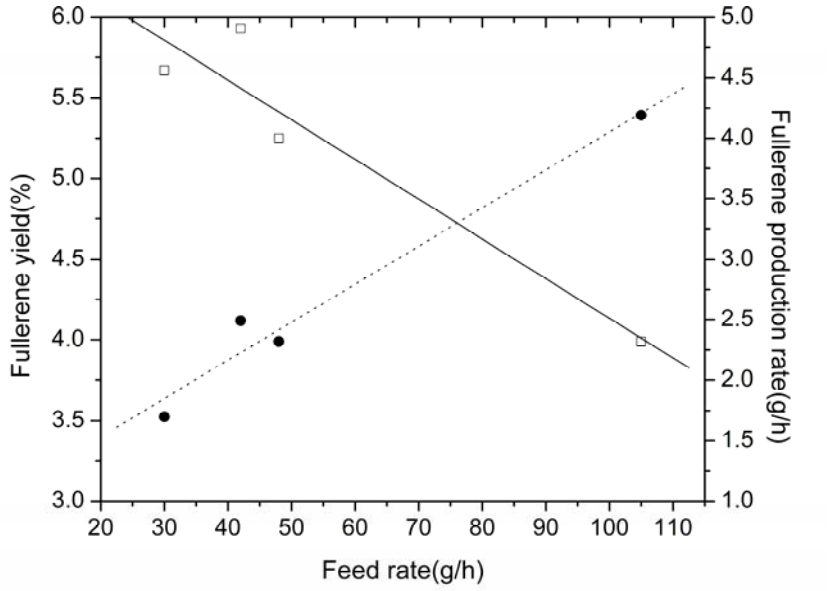

Fig. 2**.** Fullerene yield (full line) and production rate (dashed line) as plotted against feed rate of precursor KS4.

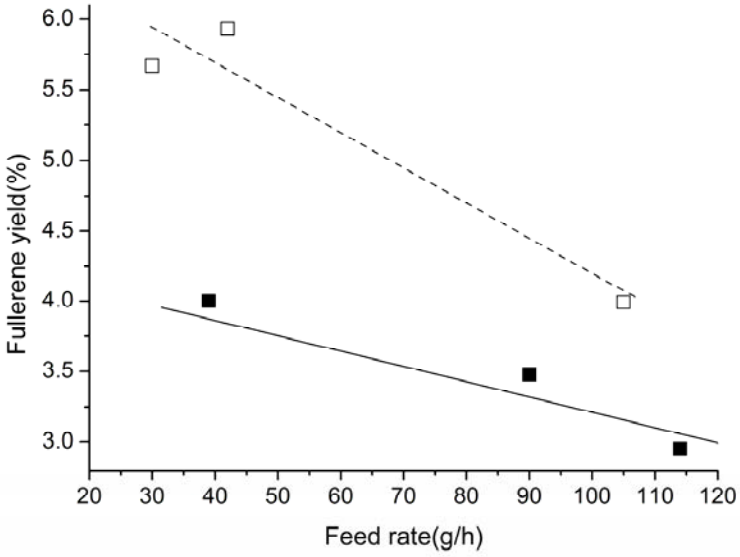

Fig. 3. Fullerene yield as plotted against feed rate of precursor KS4 at different gas compositions (helium concentration of 30% and 60% are represented by full and dashed lines, respectively).

The main factors having effect on the synthesis of fullerenes from graphite powders in RF thermal plasma reactor are as follows: *(i)* the properties of precursors and *(ii)* the plasma parameters. Both factors have significant effect on the concentration of C_2 radicals in the high temperature zone. It is well known that C_2 radicals are the basic blocks of fullerenes.

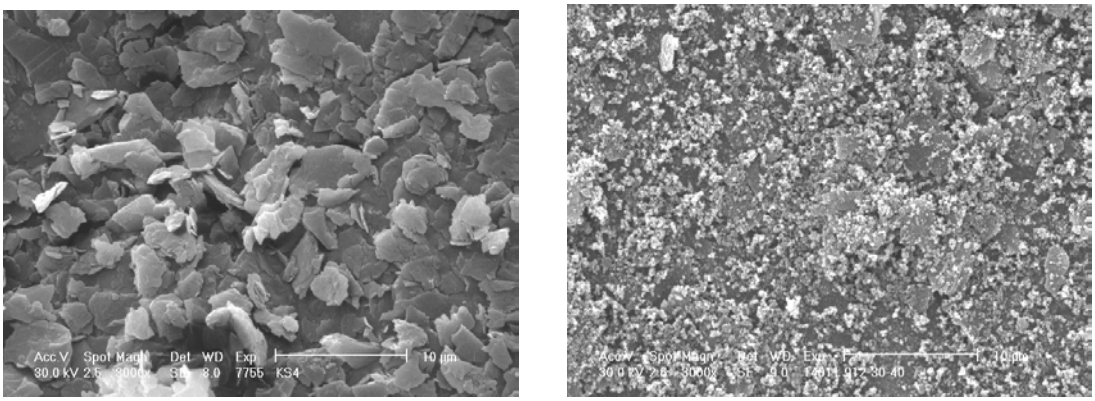
On the basis of information from the relevant literature and results presented in this work, fullerene formation in RF thermal plasma conditions takes place in the following steps:

- Heating of particles injected into the plasma flame to their sublimation temperature (~4000K). Particles of different size reach this temperature at different sites of the plasma flame, and hence, in different times. The heating time for the smallest (1-5 μm) particles is in the microsecond range. The largest particles (15-20 μm) are heated to 4000K in about 100 μs [6].
- Evaporation of graphite particles at about 4000K. Particles are evaporated roughly in the same period of time as required for their heating.
- Formation of chains, rings, polycyclic structures and defective cages [7].
- Transformation of defective cages to perfect structure upon annealing. A cluster of C_{60} is formed in 2 ns at 3000 K. Transformation into a perfect fullerene structure needs annealing for about 52 ns [8, 9].

The main physical properties of precursor that determine heating and evaporation rate are the mean particle size and the heat conductivity. Our calculations and experiments demonstrated that particle size is an important factor of processing. Particles of characteristic size above 20 μm cannot evaporate in given plasma conditions. On the other hand, a decrease in the particle size did not result in a monotonous increase of fullerene yield. It is well known that the heat conductivity of disordered carbon structures, such as carbon black, can be lower of 2-3 orders of magnitude than that of ordered carbon structures, like graphite. Differences in structural orderliness of precursors may lead to differences in their heat conductivity, as well. Although Asbury graphite has the lowest particle size, its particles can be heated to the sublimation temperature for a relatively long period of time, due to its rather disordered structure and porous nature. The Aldrich graphite and Alfa flake have the most ordered structure and hence, the highest thermal conductivity. However, they contain bigger particles, as well, that hardly evaporate.

In Figs. 4. and 5. SEM micrographs of KS4 and Aldrich graphite powders before and after RF plasma processing are presented. Cumulative volume distribution vs. particle diameter was calculated for all graphite powders by the Diameter Distribution Analyzer software [10]. Extent of evaporation, defined as the volume of particles having diameters lower than 1μm related to the total volume of particles, were found as 13% for KS4 and 3% for Aldrich graphite. These graphite powders resulted in the highest (KS4) and lowest (Aldrich) fullerene yield, respectively, at 30kW plate power and 30 % helium content of the plasma gas (Fig.1).

On the SEM micrographs of products (Figs. 4b. and 5b.), both non-evaporated and evaporated particles can be observed. Condensed carbon formed spherical, nano-sized particles, while the non-evaporated graphite preserved its disk-like shape. Presence of non-evaporated particles in the condensation zone of the plasma reactor results in fast deposition of gaseous carbon species onto surface of particles. To verify the catalytic effect of the solid surface or the impurities of graphite on fullerene formation needs further investigations. Even the detrimental effect of the fast deposition cannot be excluded.



a b

Fig. 5. SEM micrographs of the Aldrich graphite precursor (a) and the soot produced there from at 30 kW and 30% of He in the plasma gas (b).

4. Conclusion

Five graphite powders (4827 from Asbury Mills, KS4 and KS6 from Timcal, flake from Alfa Aesar and graphite from Aldrich) having different mean particle size were processed in an RF thermal plasma reactor at atmospheric pressure. It was found that the mean particle size of precursors has an important, but not exclusive effect on the evaporation efficiency. Micro-structural orderliness of precursors, which determines their thermal conductivity, is another significant property that should be considered in the interpretation of observed phenomena. In this work, KS4 graphite from Timcal proved to be the best precursor of fullerene synthesis.

From plasma parameters affecting fullerene yield, effects of the feed rate of precursors and composition of plasma gas were studied in details. The fullerene yield decreased, while the production rate increased with the feed rate. High helium content of the plasma gas favoured evaporation of graphite particles, and thereby, promoted fullerene formation. It was reasoned by the good thermal conductivity and high ionisation potential of helium.

Abstract
The aim of this work is to investigate in a realistic manner the behaviour of inductively coupled plasma torches operating at atmospheric pressure, by means of an improved turbulent version of the 3-D model based on customized CFD commercial code FLUENT© previously used to describe configurations with simplified gas inlet section [1-4].

1. Introduction

Standard numerical models of Inductively Coupled Plasma Torches (ICPTs) in literature usually make the assumption of laminar and uniform velocity field for the inlet boundary conditions [5]. Moreover the modelled inlet section is positioned near the bottom of the induction coil in order to reduce the computational domain. The details of the inlet gas section of the ICPTs are thus neglected, overcoming also the necessity of a turbulence model which should be necessary in this high velocity and low viscosity region.
In this work the gas injection section of an industrial Tekna Plasma Systems Inc PL-35 plasma torch is included in the model without geometry simplifications, refining the mesh at the injection points, in order to perform a more realistic simulation of the inlet region of the discharge and to investigate the effects of the inlet turbulent region on the simulation results. In particular, special attention is devoted to the modelling of the actual inlet gas section, which is characterized by two different sets of 8 and 18 circumferentially distributed injection points with a diameter of 0.8 mm for the tangential plasma gas and the axial sheath gas, respectively. A carrier gas introduced axially by means of an injection probe is also considered.
The standard Reynolds Stress Model is used to describe turbulence phenomena in the discharge. Unlike in the previously studied configurations with simplified gas inlet section, the use of a turbulent model is here necessary due to the high Reynolds numbers occurring near the gas injection regions as a consequence of the low argon viscosity value at ambient temperature and of the high gas injection velocity related to the small dimensions of the inlet points.

2. Modeling assumption

The mathematical model is based on the hypothesis of optically thin *Ar* plasma under local thermodynamic equilibrium (LTE) condition and includes the coupled set of continuity, momentum, energy and turbulence transport equations for the plasma flow along with the vector potential equations for the electromagnetic field, taking into account the actual shape of the helicoidal induction coil. The operating conditions are: discharge power of 15 kW, RF induction frequency of 3 MHz and inlet mass flow rates of 60, 15 and 2.5 slpm for the sheath, plasma and carrier argon gases, respectively. Details on the model and the geometry can be found in [1-5].
Simulations are performed over a network cluster of double processor calculators in order to use the full capabilities of the 3-D modelling in a time-dependent framework.

3. Results

In Fig. 1(a) the temperature field is shown in a 3-D view in order to underline the effects on the discharge of the actual coil shape. The views for two planes passing through the axis of the torch are presented in Fig. 1(b) for a more detailed rapresentation of the temperature field. The direct comparison of the temperature fields resulting from the two different models done in Fig. 2, shows that in terms of shape and 3-D displacement the main behavior of the discharge is the same for the two models. The differences are located mainly in the upstream region near the probe side and near the exit section. Another comparison between tangential velocity fields done

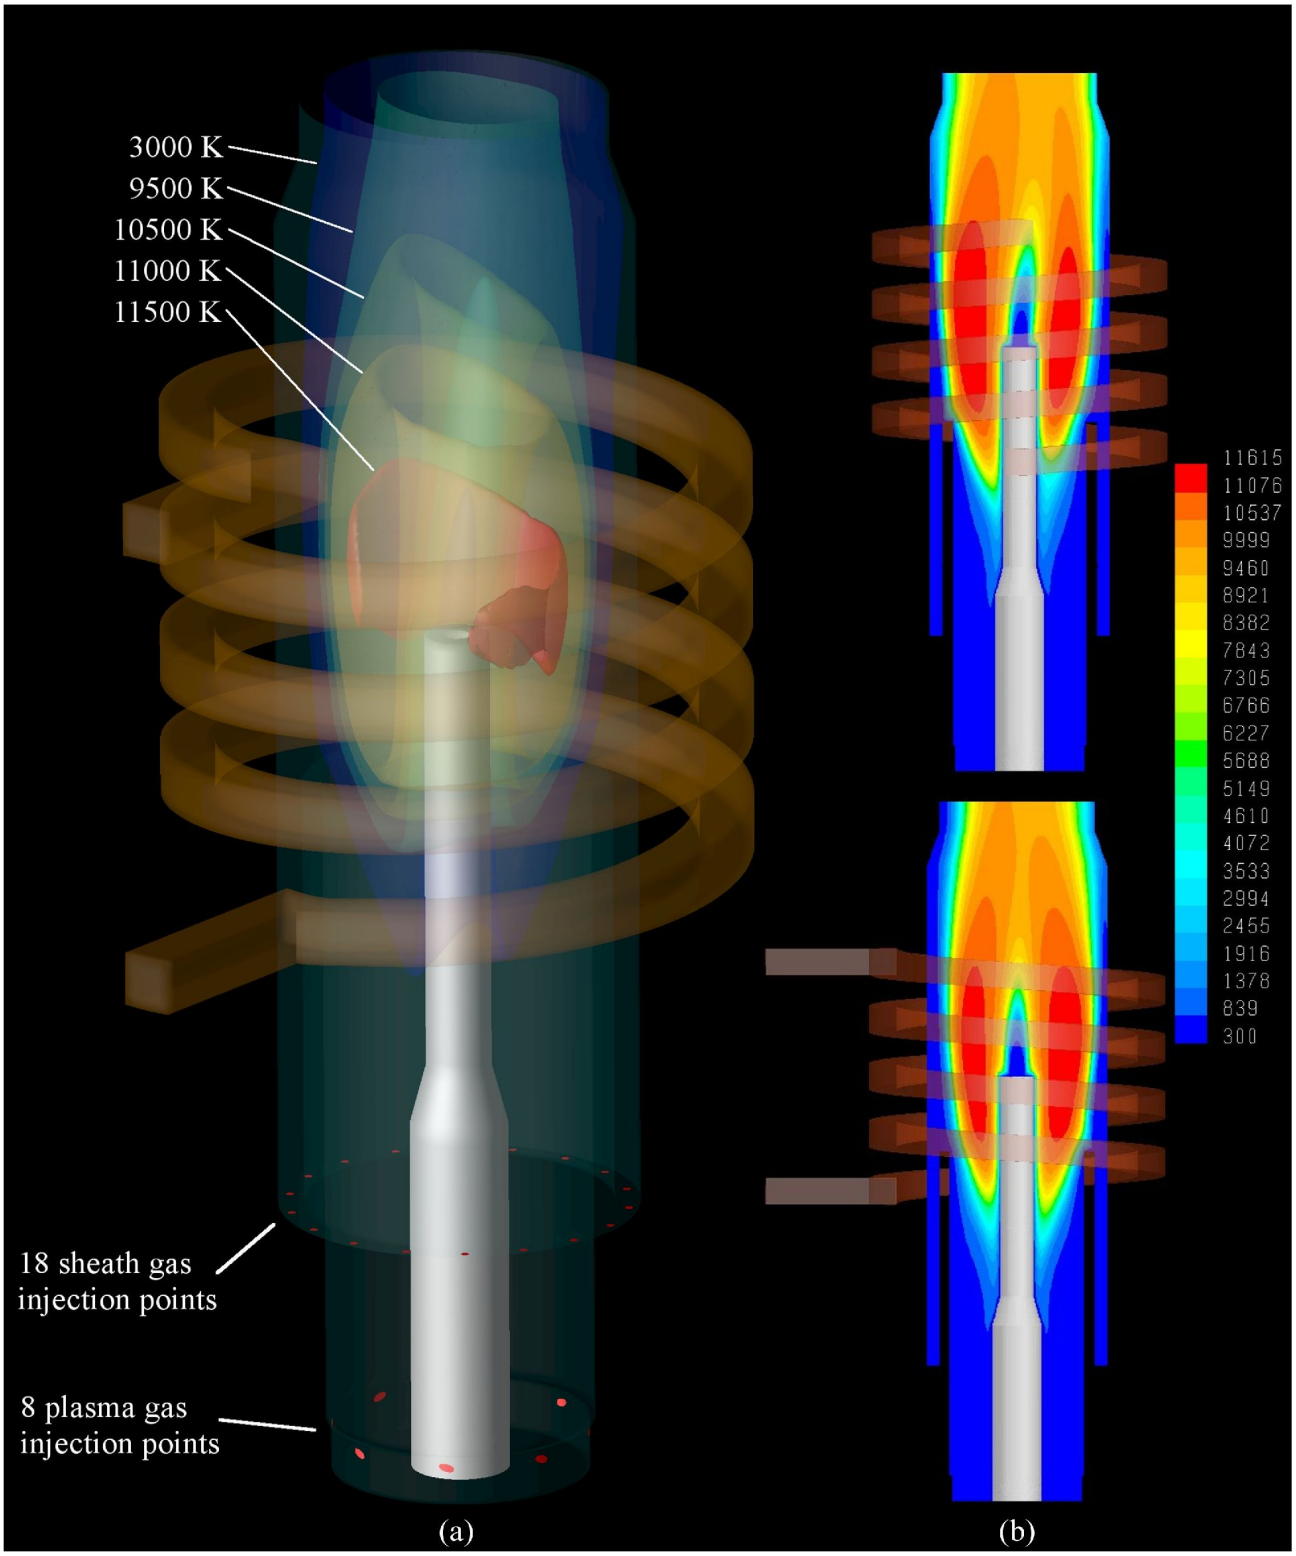

Fig. 1 Temperature fields [K] in a fully 3-D view and on two orthogonal planes passing through the axis of the torch. Operating conditions for the ICPT Tekna PL-35 are: discharge power of 15 kW, RF induction frequency of 3 MHz and inlet mass flow rates of 60, 15 and 2.5 slpm for the sheath, plasma and carrier Argon gases, respectively

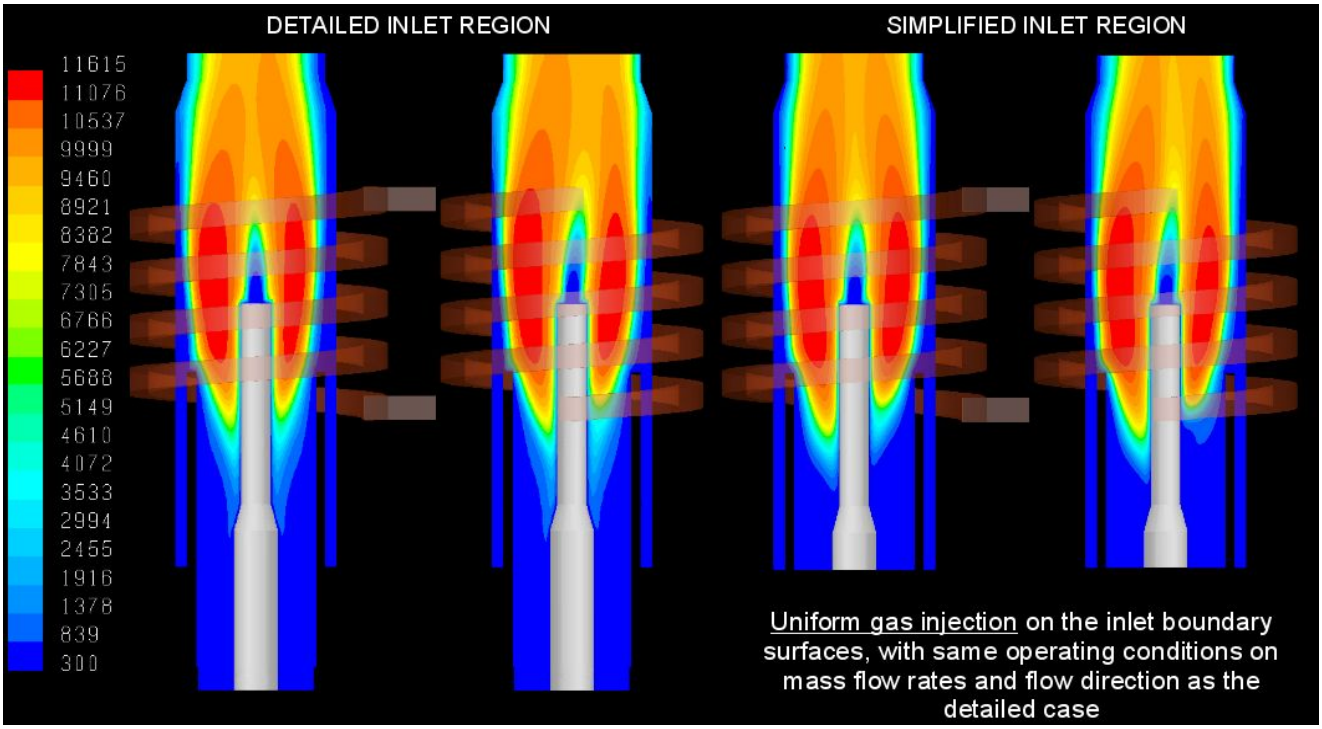

Fig. 2 Comparison between temperature fields [K] for the detailed and the simplified inlet region model.

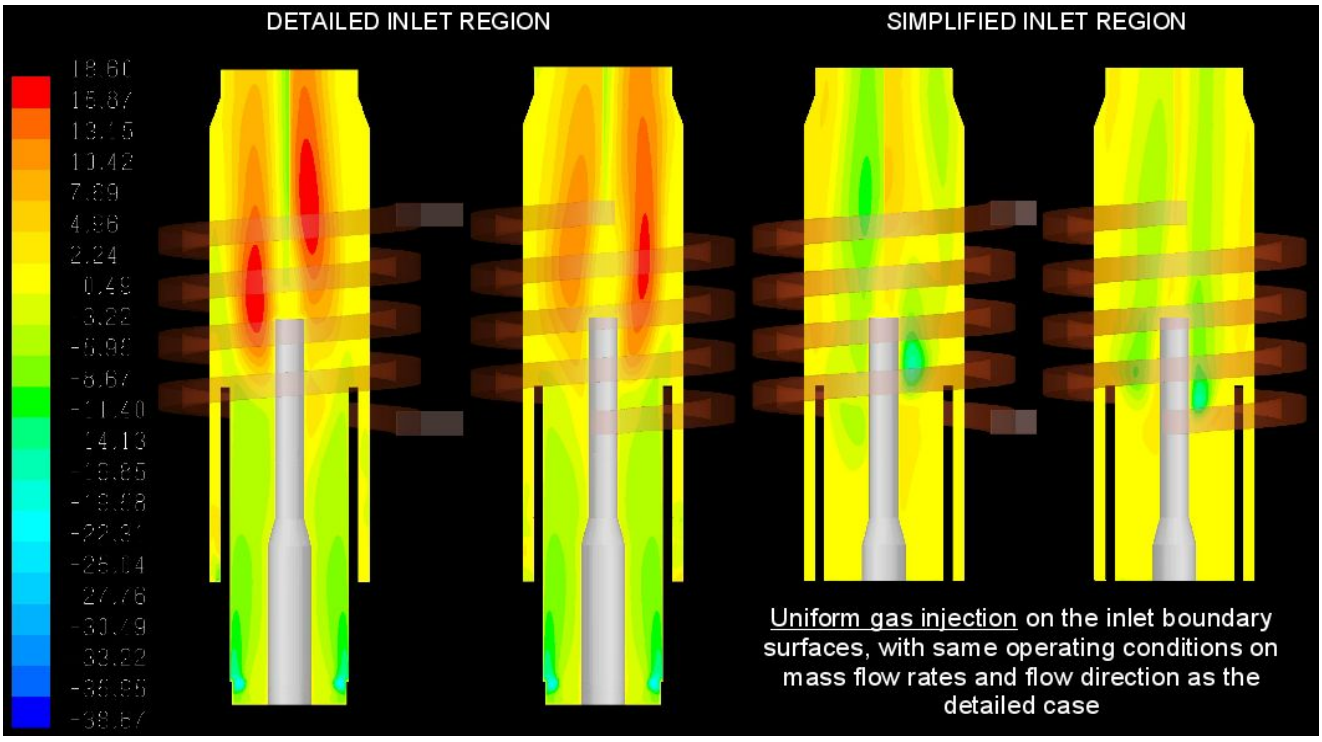

Fig. 3 Comparison between tangential velocity fields [m/s] for the detailed and the simplified inlet region model.

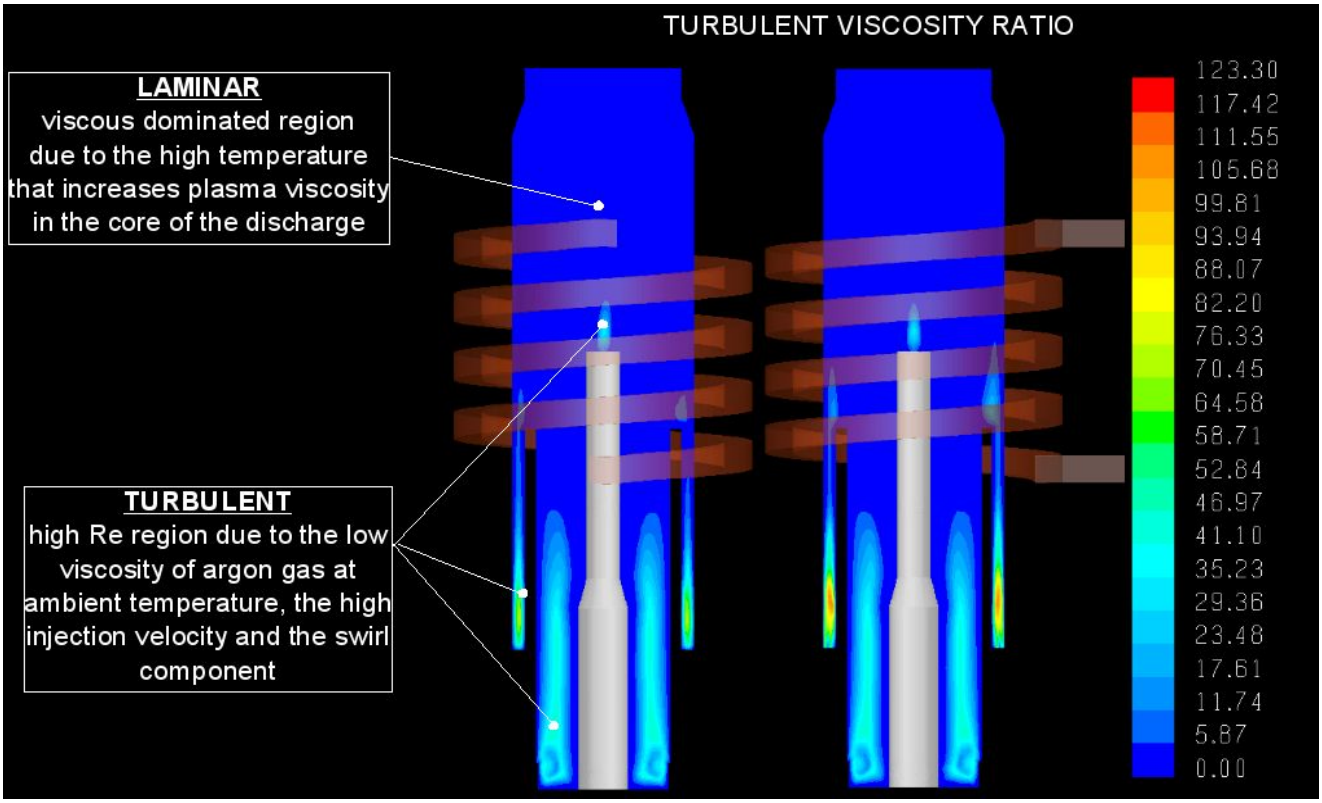

Fig. 4 Turbulent viscosity ratio for the detailed inlet region model.

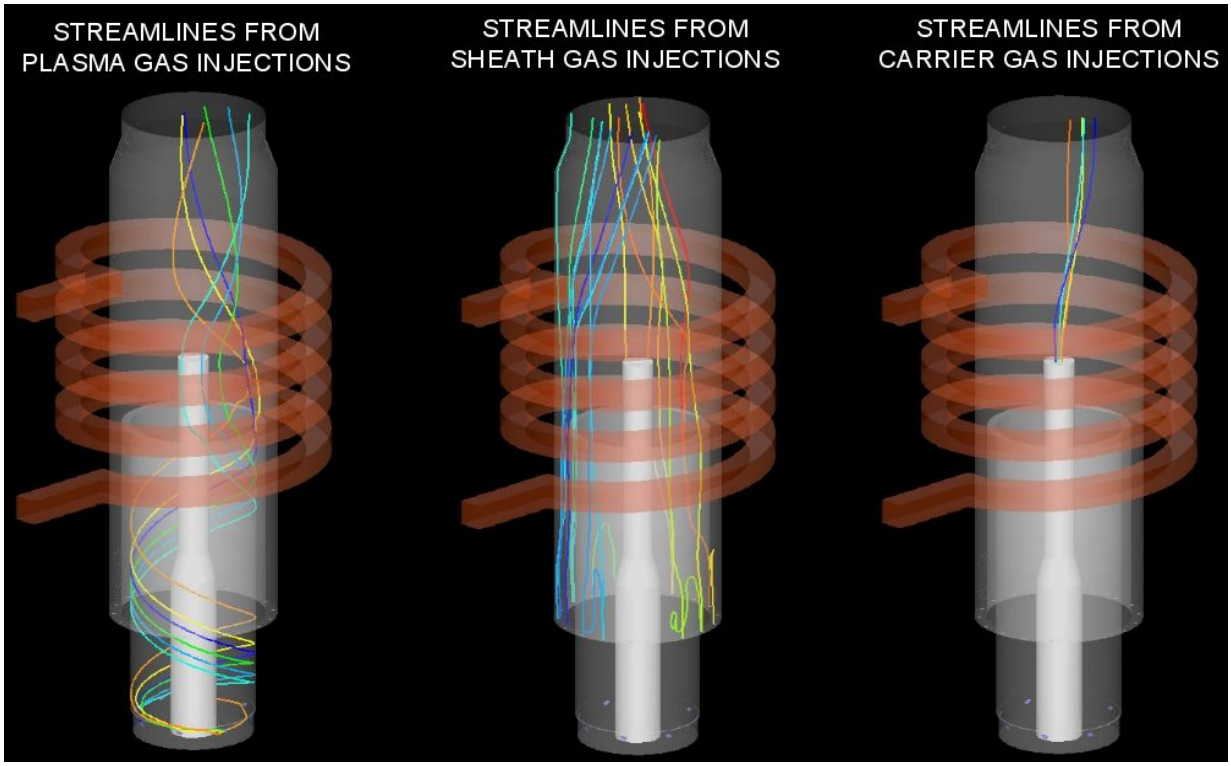

Fig. 5 Streamlines starting from carrier, sheath and plasma gas injection points.

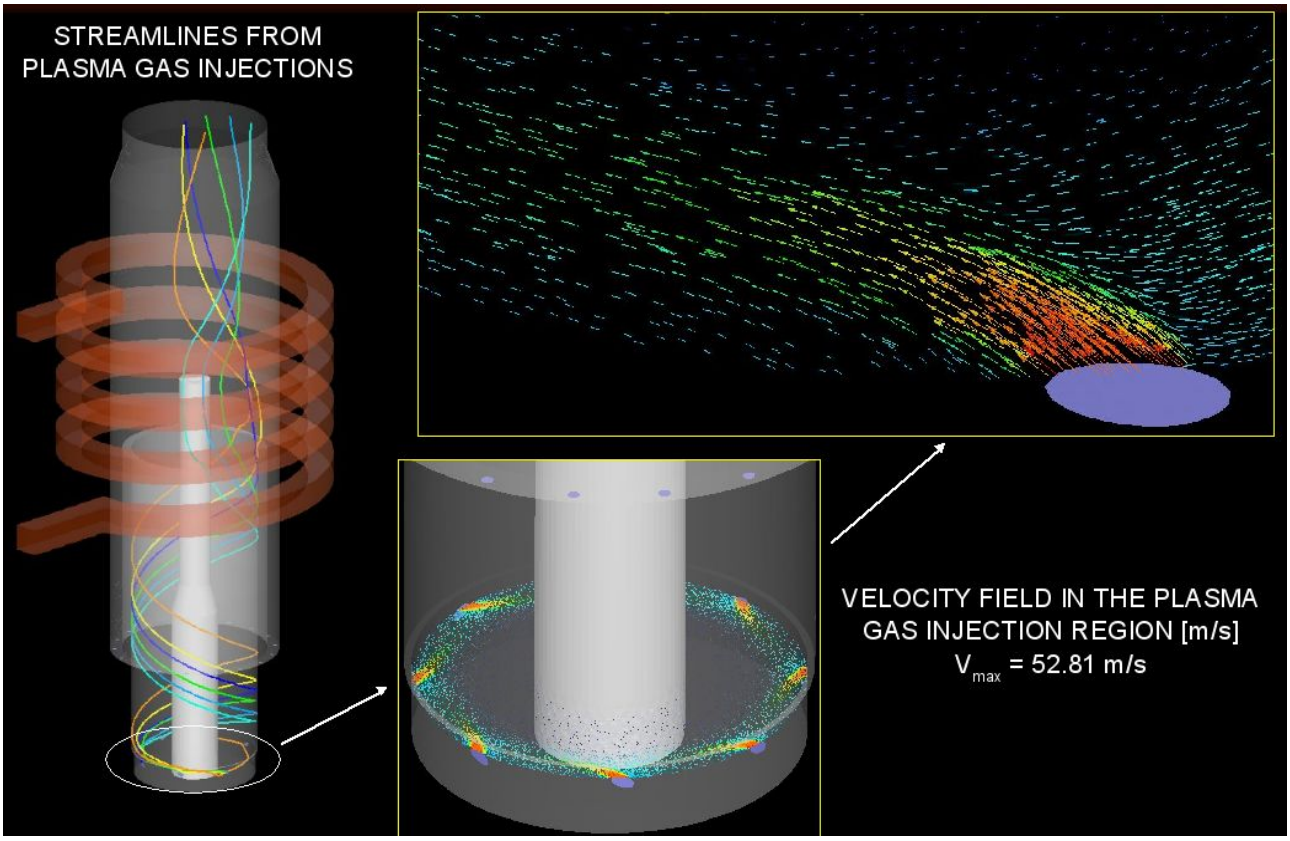

Fig. 6 Details of the velocity field in the plasma gas inlet section.

in Fig. 3, shows a very different characterization in terms of direction and magnitude for the two different models. The turbulence affected region is shown in Fig. 4 where the turbulence viscosity ratio shows that the inlet region of the plasma and the sheath gas inlet section is characterized by non negligible turbulence effects, while the discharge is quite laminar due to the high viscosity of the plasma [6]. In Fig. 5 the streamlines generated from the different inlet gas region are presented. The plasma gas shows a strong swirl direction in the upstream region and the streamlines cross the core of the discharge in the coil region while the sheath gas streamlines tents to remain near the wall in order to avoid the excessive heating of the confinment tube. Fig. 6 shows the details of the velocity vector in the plasma gas inlet region.

4.Conclusions

Comparisons between simplified and detailed modelling of the inlet regions of an industrial ICPT show that differences on the simulation results are mainly on the velocity field and in a less order of magnitude on the temperature field. The computational cost of this more complex fluid dynamic modelling (domain size and model complexity due to the RSM) is thus justified for the fields of application in which the knowledge of the velocity of the plasma plays an important rule, like the simulation of particle thermal history and trajectory inside an ICPT discharge.

Abstract

In this paper, numerical simulations of the trajectory and heating history of powders injected through a carrier gas in inductively coupled plasma torches working at atmospheric pressure have been performed within a fully 3-D FLUENT©-based model [1-3], taking into account the effects of plasma-particle interaction and the turbulent dispersion of the particles, in the frame of a stochastic approach.

1. Introduction

Inductively coupled plasma torches (ICPTs) are successfully used as high-temperature sources in a wide range of applications, such as spheroidization and purification of both metallic and ceramic powders. However, the effectiveness of these processes strongly depends on a large number of parameters, including the torch operating conditions and the type and characteristics of the injected powders. This causes the try and fail approach to be expensive and difficult to carry out. In this frame, numerical modeling represents a useful tool that may help in the design and optimization of these processes. Several numerical models have been developed in a recent past: 2-D axisymmetric models [4,5] for the analysis of the motion and heating history of the particle inside the torch region, as well as 3-D models to simulate thermal plasma jets with particle and carrier gas injected downstream of the torch exit [6]. Recently, a new 3-D FLUENT-based model for the evaluation of the trajectory and thermal history of particles injected, by means of an injection probe, together with a carrier-gas, into ICPTs working at atmospheric pressure has been presented by the authors [7]. In this paper we present a selection of new results obtained for different types and characteristics of the injected particles.

2. Modeling assumptions

The fully 3-D FLUENT-based model previously developed by the authors [1,2], suitably modified to keep into account the appropriate source-sink terms in the continuity, momentum and energy equations, is employed to calculate plasma temperature and velocity fields in the torch region. Continuity, momentum and energy equations are solved for optically thin plasmas under the assumptions of LTE, while an extended grid model is adopted for the treatment of the electromagnetic field. Simulations are performed over a network cluster of double processor calculators in order to use the full capabilities of the 3-D modelling. A Reynolds Stress Turbulence Model is used in order to predict turbulence inside the discharge and in the reaction chamber. Particles are fed both axially, with injection velocity equal to that of the carrier gas, at the exit section of the torch; they are assumed to be spherical with no internal temperature gradients. Particles trajectory and thermal history are obtained by solving the motion and energy balance equations, respectively, also accounting for particle evaporation effects and turbulence dispersion, as done in [6,7] with the final aim of putting into evidence the importance of a 3-D treatment of the problem for particular working conditions of the torch within various injection procedures. Computational domain for the particle tracking is here extended also downstream the torch region in order to simulate powders behaviour at the exit of the system, so allowing one to suitably design the reaction chamber typically used in this kind of induction plasma processing of materials. Numerical results are presented for different particle diameters. The effects of the particle injection on the plasma is suitably taken into account by adding proper exchange terms in the fluid dynamics equations, as explained in [3]. The particles trajectory is obtained by solving the following equation of motion:

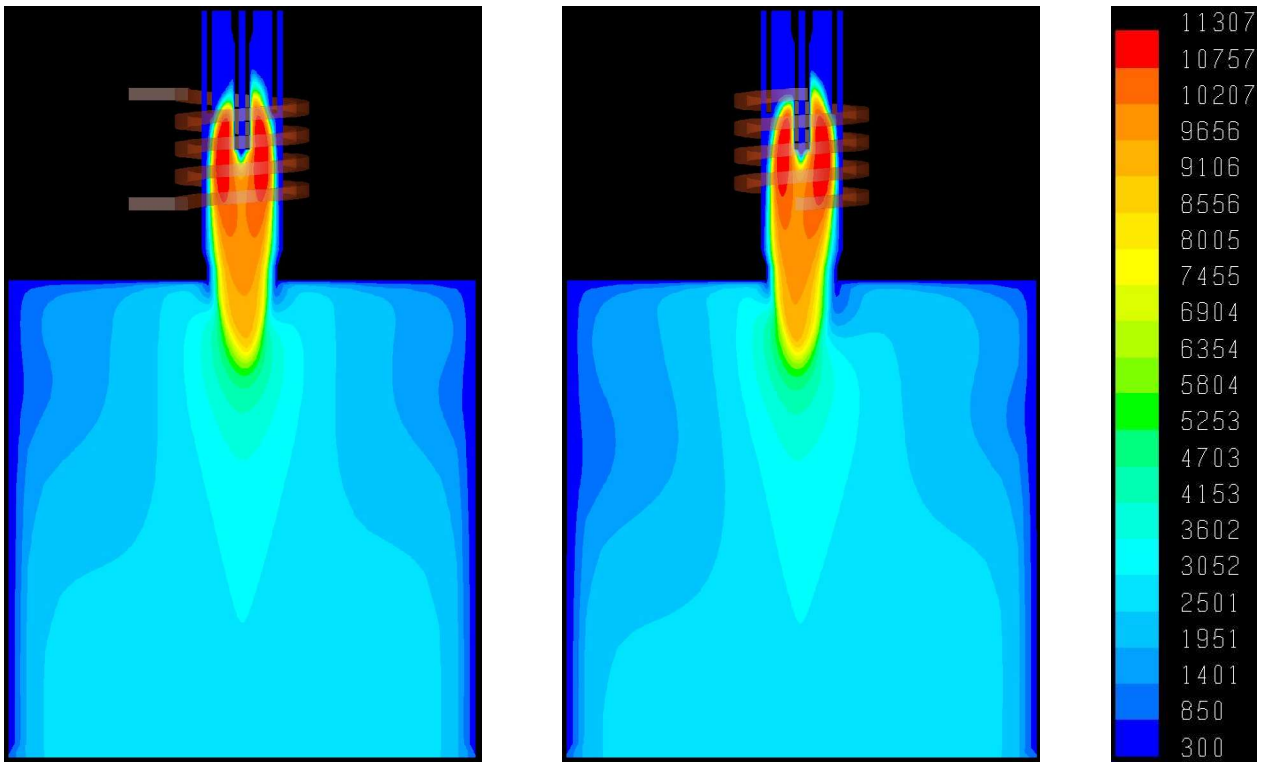

Fig. 1 Plasma temperature [K] in two perpendicular planes passing through the axis of the torch; operating conditions for the Tekna PL-35 torch are: Q_1 (Ar carrier gas)=0.5 slpm; Q_2 (Ar plasma gas)= 15 slpm; Q_3 (Ar sheath gas)= 60 slpm; f = 3 MHz; P= 10kW, <u>without</u> partcles injection.

$$\rho_p \frac{d\mathbf{v_p}}{dt} = \left(\frac{3\rho_\infty C_D}{4d_p}\right) |\mathbf{v}_\infty - \mathbf{v_p}| (\mathbf{v}_\infty - \mathbf{v_p}) + \mathbf{g}(\rho_p - \rho_\infty)$$

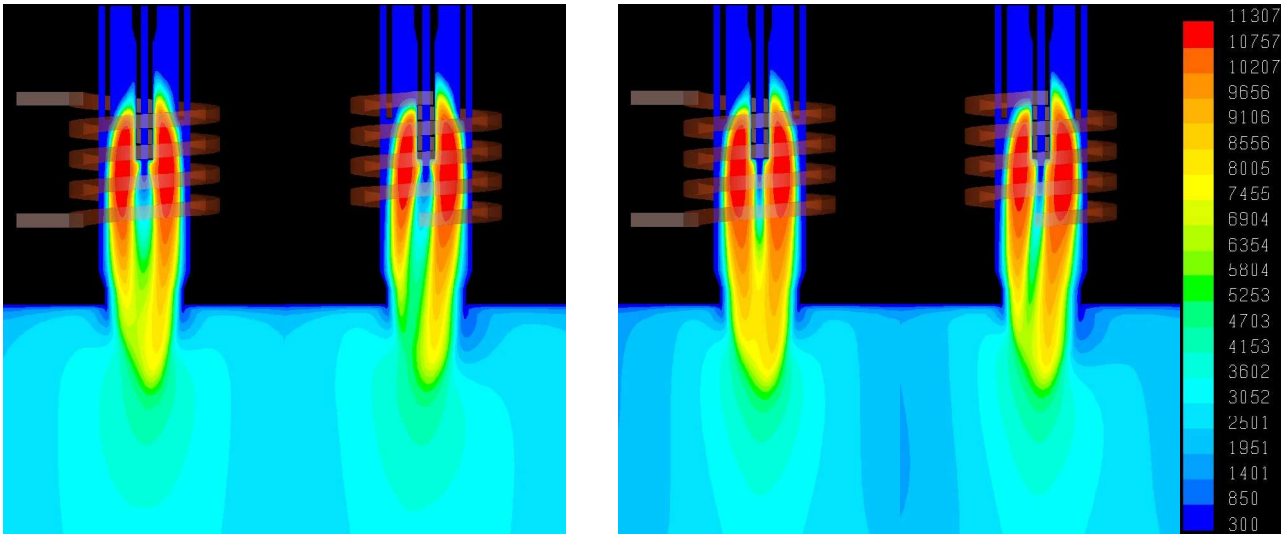
where $\mathbf{v}_\infty$ and ρ_∞ are the velocity and density of the plasma. In order to take into account turbulence dispersion $\mathbf{v}_\infty$ is the sum of the mean velocity (obtained by the RANS approach) and a stochastic contribution due to the turbulence intensity in every point of the domain. $\mathbf{v}_p$, d_p, ρ_p are the velocity, diameter and density of the particle, respectively; $\boldsymbol{g}$ is the gravitational acceleration; C_D is the drag coefficient which is calculated as in [6] but neglecting the Knudsen (rarefaction) effect. The heating history of the particle in the solid-phase is obtained by solving the energy balance equation:

$$m_p c_p \frac{dT_p}{dt} = A_p h_c (T_\infty - T_p) - A_p \epsilon\sigma \left(T_p^4 - T_a^4\right)$$

where mp and A_p are the mass and the surface area of the particle; c_p and ρ are the specific heat and the emissivity of the particle material; σ is the Stefan--Boltzmann constant; T_a is the room temperature and h_c is the convective coefficient. As soon as the particle temperature reaches the melting point, it is assumed to remain constant and the liquid-phase fraction x, is calculated by integrating the equation:

$$\frac{dx}{dt} = \frac{6q}{\rho_p d_p \lambda_m}$$

where q is the net specific heat flux transferred to the particle, and λ_m is the melting latent heat of the particle material. As soon as the evaporation



(a) (b)

(c)

Fig. 2 Plasma temperature [K] in two perpendicular planes passing through the axis of the torch; operating conditions for the Tekna PL-35 torch are: Q_1 (Ar carrier gas)=0.5 slpm; Q_2 (Ar plasma gas)= 15 slpm; Q_3 (Ar sheath gas)= 60 slpm; f = 3 MHz; P= 10kW, with 20 g/min of Al_2O_3 particles with diameter (a) d = 25 μm, (b) d = 50 μm and (c) d = 100 μm.

point is achieved, the temperature of the particle is kept constant while its diameter reduces itself according to the following law:

$$\frac{dd_p}{dt} = -\frac{2q}{\rho_p \lambda_v}$$

Details on the model used in this work can be found in [3]. It is worth noting that, in the present model, no mass transfer between particles and plasma is accounted for; i.e. the eventual evaporated fraction of the particles does not alter the composition of the surrounding plasma gas, which is considered to be always pure argon.

3. Simulation results

In Fig.1 the plasma temperature fields on two planes perpendicular one to each other for the case with no particle injection are shown for a Tekna PL-35 plasma torch working under operating conditions characterized by Q_1 =0.5 slpm; Q_2 = 15 slpm; Q_3 = 60 slpm, with respect to to the schematic of the torch given in [7]. The

frequency *f* of the current flowing in the torch coil is equal to 3 Mhz and the discharge power, P, is set to 10kW.

In Fig. 2, Fig.3 and Fig.4, we present simulation results concerning the injection of Al_2O_3 particles with diameters in the range 25 - 100 μm in a Tekna PL-35 plasma torch working under the same operating conditions as the case reported in Fig. 1, but for the presence of particle injection. In Fig. 2(a) the plasma temperature on two perpendicular planes passing through the axis of the torch is shown for the case with injection of particles with diameter equal to 25 μm; In Fig. 2(b) and in Fig. 2(c) the same visualization as reported in Fig. 2(a) are given for the case with injection of particles with diameter equal to 50 μm and 100 μm, respectively. In Fig. 3(a), Fig. 3(b) and Fig. 3(c), the plasma axial velocity magnitude for the same operating conditions and particle injection corresponding to the cases shown in Fig. 2(a), Fig. 2(b) and Fig. 2(c), respectively, are shown. In Fig. 4(a), Fig. 4(b) and Fig. 4(c), we present the particle concentration fields corresponding to the cases shown in Fig. 3(a), Fig. 3(b) and Fig. 3(c), respectively.

Abstract

A 3-D time-dependent numerical model useful for the analysis of a dc transferred argon arc has been developed. The model allows to investigate the influence on the behaviour of the arc and on the evolution of the temperature distribution inside the anode of an external magnetic field induced by a current flowing in a moving leading wire parallel to the axis of the cathode. If the current of the arc and the current of the external conductor have opposite directions, the magnetic fields mutually repel and the arc is deflected losing its natural axisymmetric configuration. This practice to obtain a deflected arc may find applications in the industrial processing of materials as, for example, in surface treatment of metallic substrates.

Keywords: transferred arc plasma torches, magnetic deflection, numerical simulations, thermal treatment.

1. Introduction

The aim of this work is to investigate by means of a 3-D time-dependent numerical model the behavior of a transferred arc plasma operating at atmospheric pressure, for the treatment of a metallic substrate material [1], using a customized version of the CFD commercial code FLUENT® [2,3]. Unsteady flow and heat transfer equations are solved together with the two equations of the RNG k-ε turbulence model and with the equations of the scalar potential and of the vector potential, for an argon plasma in local thermodynamic equilibrium, over a computational domain that includes the region between the two electrodes, where the discharge takes place, as well as the anodic region. The developed model allows also the evaluation of the effects of the presence of an external magnetic field generated by a electric direct current flowing in a moving leading wire whose axis is parallel to the axis of symmetry of the cathode on the shape and characteristics of the arc and on the evolution of the temperature distribution inside the metallic substrate on which the arc is attached.
It is well known that, if the current of the arc and the current flowing in the leading wire have opposite directions, the magnetic fields repel reciprocally. As a consequence, the electric arc is deflected and its natural axisymmetric configuration is lost. Such a practice to obtain a deflection of the electric arc has found in recent years useful application in the industrial processing of materials as, for example, in surface treatment of metallic substrates.
With this regard, even though several excellent papers have been published in the recent past on the 2-D and 3-D modelling of transferred arc in both undeflected and deflected arc configurations (for example, [4-8] just to name but a few), a time-dependent 3-D numerical study of the transferred arc plasma torch including the anodic region in the computational domain has not been developed so far, to the authors' knowledge. So, we propose to evaluate the transient effects of an imposed external magnetic field on the three-dimensional shape of the arc and on the evolution of the temperature distribution inside the anode on which the arc is attached, with the final aim of optimizing the treatment process of the metallic substrate. The effects on the substrate temperature evolution of different patterning for the arc treatment and of different current intensities and positions of the leading wire with respect to the torch have been investigated.

2. Modelling approach

The 3-D time-dependent model developed at the University of Bologna [3] for the simulation of atmospheric pressure transferred arc plasma torches both in undeflected and magnetically deflected configurations relies on the following main assumptions:

- the plasma is supposed to be optically thin;
- the plasma is supposed to be in local thermodynamic equilibrium (LTE);
- the viscous dissipation is neglected;
- the plasma flow is assumed to be turbulent and it is modelled by the FLUENT®-implemented RNG k-ε model;
- electrode sheaths are not taken into account;

Under these assumptions, the governing equations of mass, momentum and energy may be written as follows:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0$$

$$\frac{\partial (\rho \mathbf{u})}{\partial t} + \nabla \cdot (\rho \mathbf{u}\mathbf{u}) = -\nabla p + \nabla \cdot \left[\mu \left(\nabla \mathbf{u} + \nabla \mathbf{u}^T\right)\right] + \mathbf{J} \times \mathbf{B} + \mathbf{F}$$

$$\frac{\partial (\rho h)}{\partial t} + \nabla \cdot (\rho \mathbf{u} h) = \nabla \cdot \left(\frac{k}{c_p} \nabla h\right) + \mathbf{J} \times \mathbf{E} - Q_R$$

and the scalar and vector potential equations are the following:

$$\nabla \cdot (\sigma \nabla V) = 0$$

$$\nabla^2 \mathbf{A} = -\mu_0 \mathbf{J}$$

In the previous equations **u** is the plasma velocity, h is its enthalpy, T is the temperature, p is the pressure, ρ is the plasma density, k is the plasma thermal conductivity, c_p is the plasma specific heat, μ is the plasma viscosity, **E** is the electric field, **B** is the magnetic induction, **J** is the arc current density, Q_R is the volumetric radiative losses, σ is the plasma electrical conductivity, μ_o is the magnetic permeability of the free space, V is the scalar potential, **A** is the vector potential. The magnetic induction, **B**, is obtained from the vector potential, **A**, by means of the relation: $\mathbf{B} = \nabla \times \mathbf{A}$. Finally, the term **F** appearing in the Navier Stokes equation is the deflecting force acting on the arc due to the current in the leading wire. This force may be readily obtained by means of the relation $\mathbf{F} = \mathbf{J} \times \mathbf{B_C}$ once the external magnetic induction $\mathbf{B_C}$ has been calculated with the following formulae:

$$B_{C,x} = \mu_o I_C \frac{\cos(\arctan(y/x))}{2\pi\sqrt{x^2+y^2}}$$

$$B_{C,y} = \mu_o I_C \frac{\sin(\arctan(y/x))}{2\pi\sqrt{x^2+y^2}}$$

$$B_{C,z} = 0$$

where B_{Cx}, B_{Cy} and B_{Cz} are the Cartesian components of the external magnetic induction generated by the current (whose intensity is I_C) flowing in the leading wire, parallel to the z-axis (the axis of symmetry of the cathode) [6].

The selected turbulence model is the FLUENT®-implemented RNG-based k-ε one, which is a two-equations model with a form similar to the standard k-ε model derived from the instantaneous Navier-Stokes equations using a mathematical technique called "renormalization group" (RNG) methods. The two equation of the model are the following:
Ù

$$\frac{\partial}{\partial t}(\rho k) + \frac{\partial}{\partial x_i}(\rho k u_i) = \frac{\partial}{\partial x_j}\left(\alpha_k \mu_{\text{eff}} \frac{\partial k}{\partial x_j}\right) + G_k + G_b - \rho\epsilon - Y_M$$

$$\frac{\partial}{\partial t}(\rho\epsilon) + \frac{\partial}{\partial x_i}(\rho\epsilon u_i) = \frac{\partial}{\partial x_j}\left(\alpha_\epsilon \mu_{\text{eff}} \frac{\partial \epsilon}{\partial x_j}\right) + C_{1\epsilon}\frac{\epsilon}{k}(G_k + C_{3\epsilon}G_b) - C_{2\epsilon}\rho\frac{\epsilon^2}{k} - R_\epsilon$$

where G_k is the generation of turbulence kinetic energy due to the mean velocity gradients; G_b is the generation of turbulence kinetic energy due to buoyancy and Y_M represents the contribution of the fluctuating dilatation in compressible turbulence to the overall dissipation rate. Finally, α_k and α_ε are the inverse effective Prandtl numbers for k and ε, respectively [9].

The governing equations described so far are solved by the FLUENT® solver on a structured computational grid made up of hexahedrons and prisms. The *User-Defined Scalar* (UDS) approach, described in [10] has been adopted for the treatment of the electromagnetic field, while the extra source terms appearing in the transport equations have been implemented by means of *User-Defined Functions* [9] suitably implemented.
The number of cells making up the grid varies between 1.0×10^6 and 1.8×10^6, while the time-step adopted throughout the calculations is kept constant throughout the simulations ($\Delta t = 10\times10^{-5}$ s).
The thermodynamic and transport coefficients of the argon plasma used for the numerical simulations are those given in [11].
The calculations have been performed by PlasMac, a cluster of workstations available at CIRAM & DIEM of the University of Bologna. Such a resource allows for a large reduction in computational time as well as for the treatment of complex computational domain otherwise not manageable with traditional personal computers.

The arc configuration and the implemented boundary conditions are the same as those presented in [6]. In all the simulation presented in this paper the argon flow rate is equal to 0.0003 Kg/s.

3. Selected results

In Fig. 1(a) and in Fig. 1(b), the plasma temperature fields on two planes perpendicular one to each other and passing through the axis of the cathode are shown for the case of undeflected arc configuration (the current flowing in the external conductor is $I_C = 0$). In Fig. 1(c) and in Fig. 1(d) the temperature fields inside the metallic substrate are shown, for the same two planes of Fig. 1(a) and Fig. 1(b), respectively, and under the same operating conditions, while in Fig. 1(e), the temperature field on the upper surface of the anode (interface plasma-anode) is shown. It may be noticed that the temperature field is both the discharge region and the anodic region is axisymmetric because of full axisymmetric configuration of the torch.

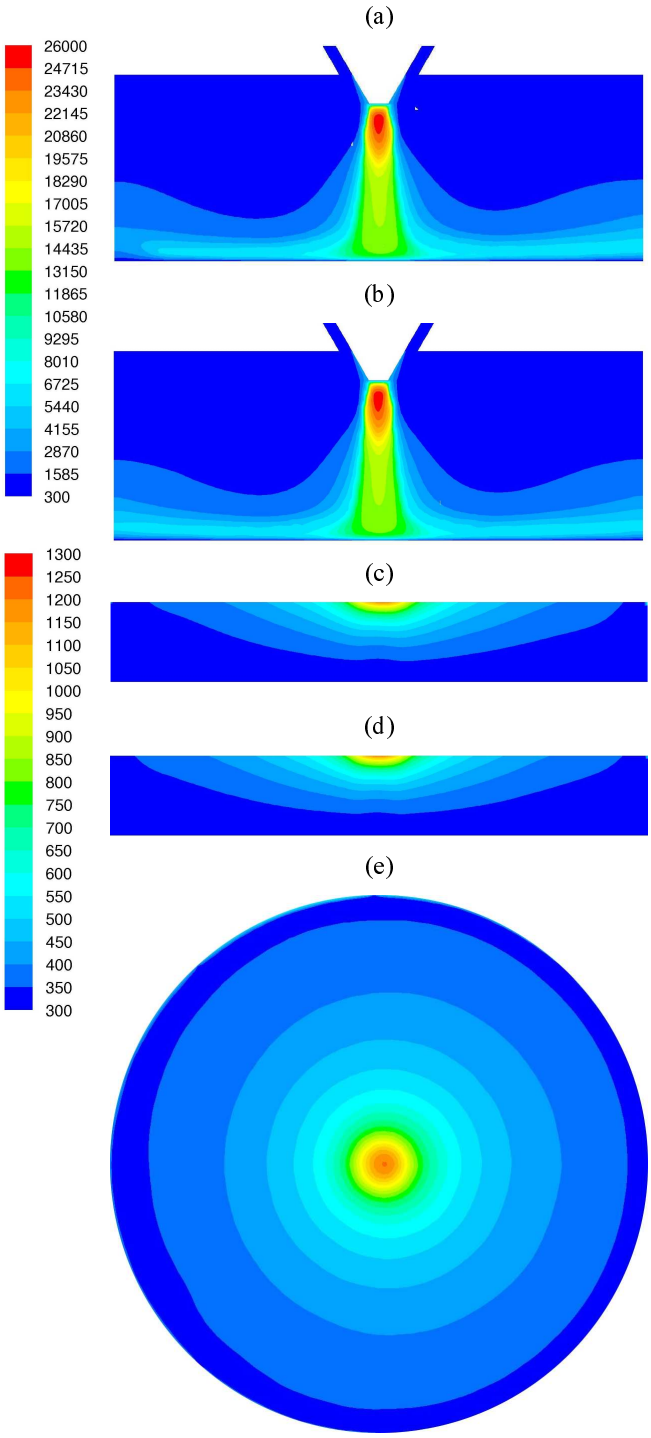

Fig. 1. Temperature distribution [K] in the discharge region (a,b) and inside the anode (c,d) on two planes perpendicular to each other and passing through the axis of the cathode, and on the upper surface of the anode (e) in absence of deflecting current.

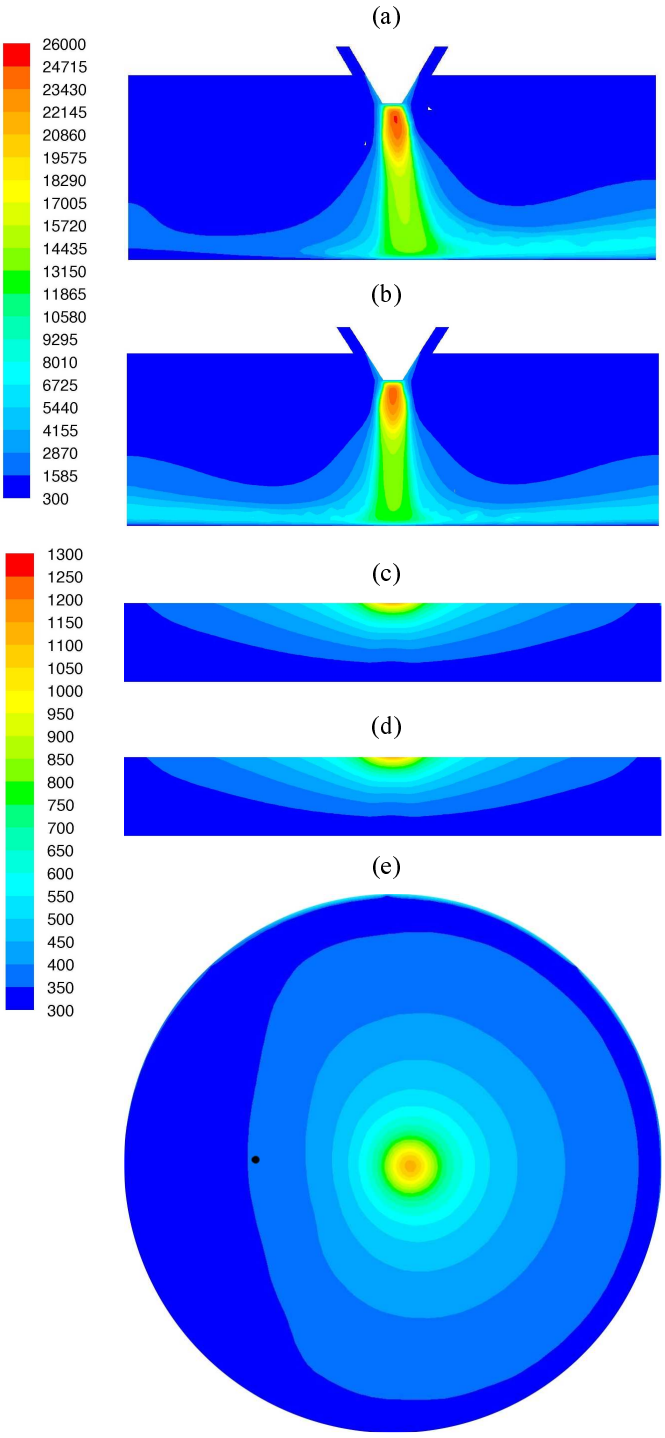

Fig. 2. Temperature distribution [K] in the discharge region (a,b) and inside the anode (c,d) on two planes perpendicular to each other and passing through the axis of the cathode, and on the upper surface of the anode (e). The position of the wire is evidenced by the black dot if Fig. 2(e).

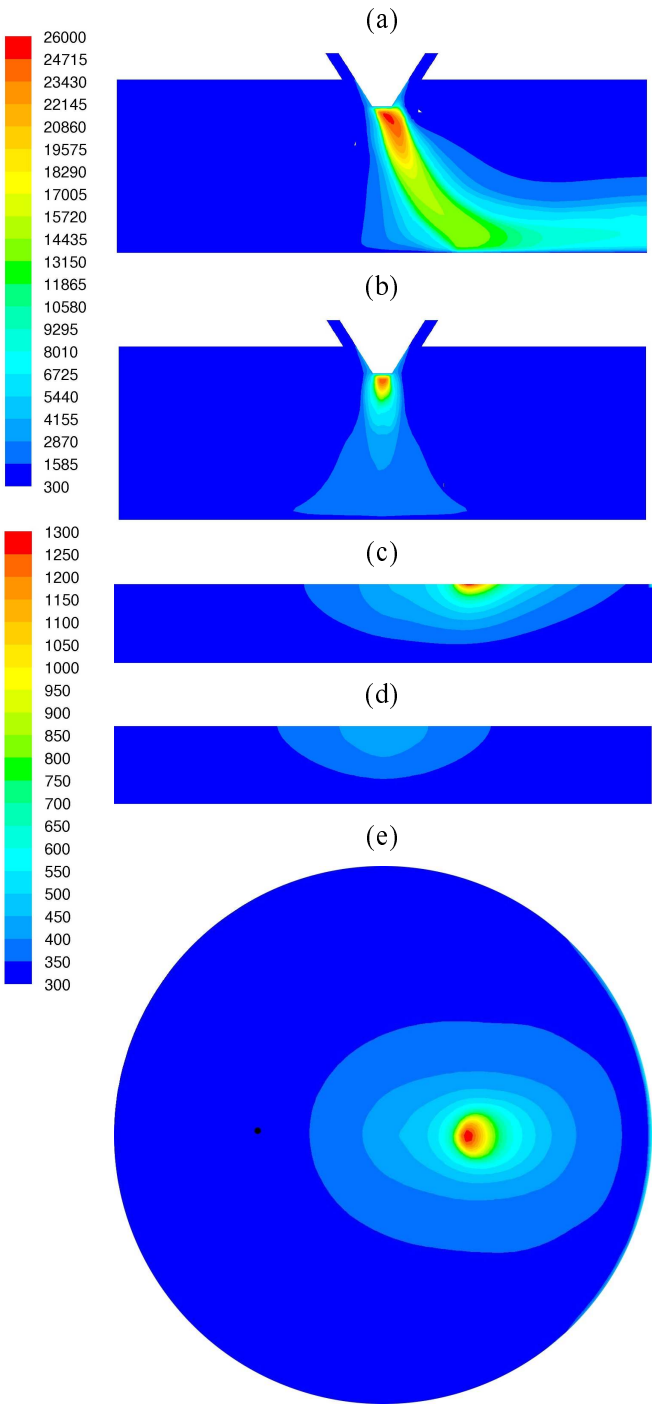

Fig. 3. Temperature distribution [K] in the discharge region (a,b) and inside the anode (c,d) on two planes perpendicular to each other and passing through the axis of the cathode, and on the upper surface of the anode (e) at *t=0* with a deflecting current flowing in a moving wire whose instantaneous position is evidenced by the black dot in Fig. 3(e).

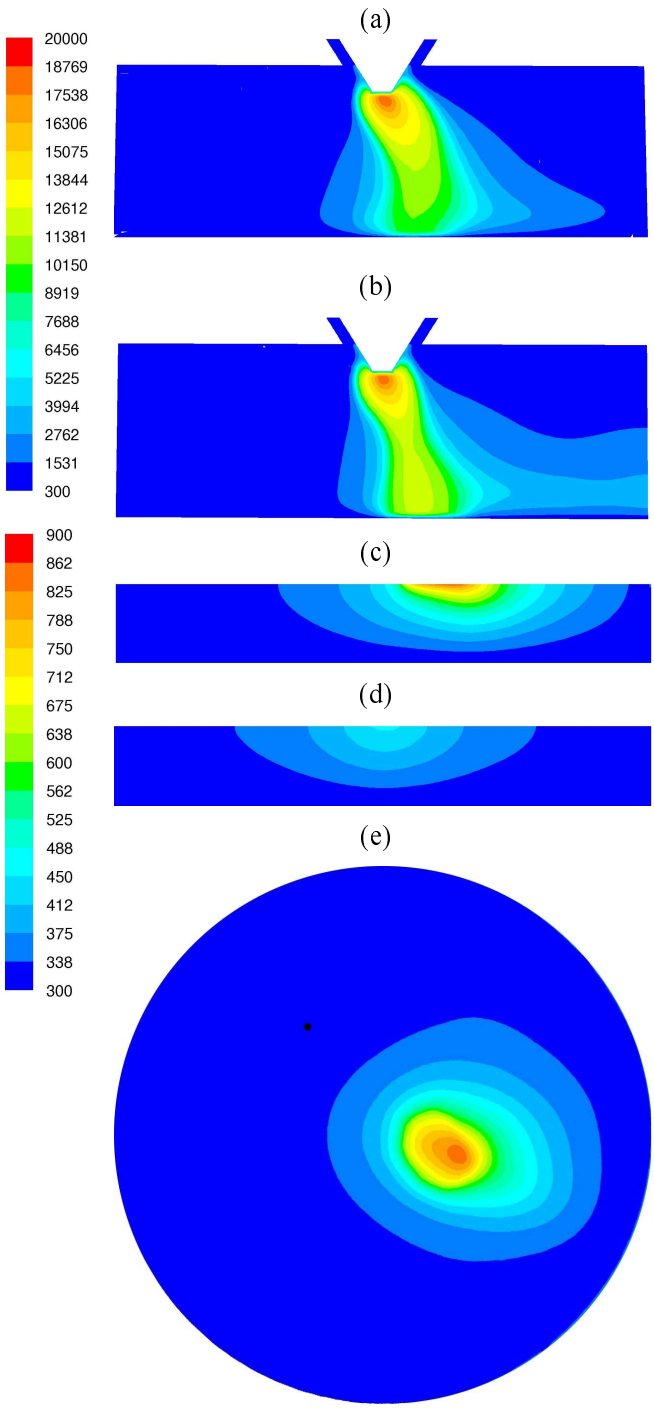

Fig. 4. Temperature distribution [K] in the discharge region (a,b) and inside the anode (c,d) on two planes perpendicular to each other and passing through the axis of the cathode, and on the upper surface of the anode (e) at *t = 0.16 s* with a deflecting current flowing in a moving wire whose instantaneous position is evidenced by the black dot in Fig. 4(e).

If Fig. 2(a) and in Fig. 2(b) the plasma temperature fields on the same planes as those of Fig. 1(a) and Fig. 1(b) are given for the case in which the electric arc is deflected by the presence of a magnetic field induced by a current flowing in a wire parallel to the axis of the cathode and with intensity I_C = 50 A. In Fig. 2(c) and Fig. 2(d) the corresponding temperature fields inside the substrate are shown, for the same two planes of Fig. 2(a) and Fig. 2(b) and under the same operating conditions. Finally, in Fig. 1(e), the temperature field on the upper surface of the anode is given. In this case, the symmetry of the discharge and of the temperature distribution in the substrate is lost because of the presence of the deflecting external magnetic field. In Fig. 2(e) the position of the leading wire in which the current flows is evidenced by the black dot.
In Fig. 3 and in Fig. 4, the results of a time-dependent simulation are presented. In this case, the leading wire in which the deflecting current flows is fixed for $t < 0$ and it starts moving around the axis of the cathode with an angular velocity $\omega = 2\pi$ at $t = 0$, keeping its axis parallel to the axis of the cathode. In Fig. 3(a-d) and Fig. 4(a-d) the temperature fields in the discharge and in metallic substrate are shown for the times $t = 0$ and $t = 0.166$ s. Fig. 3(a,b) and Fig. 4(a,b) give, for these two different instant times, the plasma temperature fields on two planes orthogonal one to the other and both passing through the axis of the cathode, one of these two planes containing the wire. In Fig. 3(c,d) and in Fig. 4(c,d) the temperature distribution inside the metallic anode and on the same planes of the corresponding Fig. 3(a,b) and 4(a,b) are shown.
The position of the wire at $t=0$ is evidenced in Fig. 3(e), while its position after $t=0.166$ s is evidenced in Fig. 4(e).

Abstract

The aim of this work is to investigate by means of a 3-D numerical model the fluid flow and temperature distribution of a plasma transferred electric arc discharge generated between two suspended metallic electrodes. This *twin torch* device is used inside a plasma furnace for hazardous waste incineration and asbestos inertization. Flow and energy equations are solved for an optically thin plasma under conditions of LTE, while the electromagnetic field equations are solved in their scalar and vector potential form.

Keywords: transferred arc plasma torches, numerical simulation, hazardous waste incineration.

1. Introduction

In the past, research on the subject of DC transferred arc *twin torch* systems has been done [1] concerning 3D simulation of flows inside a plasma furnace devoted to combustion/vitrification of radioactive wastes, based on a molten glass bath under an electric arc transferred between two metallic parallel electrodes (cathode and anode) under the hypothesis that the arc shape closes itself through the molten bath. The arc domain was modelled on a 3D structured mesh representative of the SHIVA melter geometry integrating two parallel torches, providing results on the plasma side for electrical potential, arc shape, and temperature of the plasma and comparing them with some experimental results such as emission spectroscopy or arc observation with an high speed camera. Also results for glass domain are given for an example through velocity, temperature and volumetric power distributions and shape of the obtained glass ingot.
Centro Sviluppo Materiali (CSM) S.p.A. is one of the most important European industrial research centres in the field of materials (steel, special alloys and ceramics), related manufacturing processes, coating technologies dedicated to wear and tear, corrosion and thermal insulation problems and innovative forming technologies (rapid prototyping, hydroforming, superplastic forming, laser welding). CSM started to use plasma torches in 1987 carrying out, with commercial torches, a 1 MW plant installed in an Italian steel-works for liquid steel temperature control (about 1550 °C) in a continuous casting plant [2]. For application over waste, characterized by problems of corrosion and high turbulence, CSM developed its own dedicated plasma torches that assure high reliability and high efficiency. Particular attention was also paid to enhance the most important torch components (electrodes and nozzles) using specific CSM competence: special materials, coating technologies, advanced mechanical design, thermal fluid-dynamic simulation. In this direction the development of a 3-D plasma arc model used on FLUENT® code has been carried out recently in cooperation with the University of Bologna.

2. Modelling approach

2.1 Governing equations

A three-dimensional computational model useful for the simulation of a transferred arc plasma torch involves the

simultaneous solution of the coupled set of non-linear fluid-dynamic, electromagnetic and energy transfer equations.

The main simplifying assumptions on which the developed model relies are the following:
- the discharge is stationary;
- the plasma is described as a simple mono-component fluid;
- the plasma is optically thin and in local thermodynamic equilibrium (LTE);
- the turbulent plasma flow is described by the renormalization group (RNG) turbulence model;

Taking into account the previous assumptions, the equations of the conservation of mass and momentum take the following form:

$$\nabla \cdot (\rho \mathbf{v}) = 0$$

$$\nabla \cdot \rho \mathbf{v}\mathbf{v} = -\nabla p + \nabla \cdot \tau + F_L$$

being ρ the density of the fluid, $\mathbf{v}$ the velocity of the fluid, p the pressure, τ the stress tensor and F_L the Lorentz force due to the interaction of the conductive fluid and the electromagnetic field. The energy equation is solved without taking into account the viscous dissipation:

$$\nabla \cdot \rho \mathbf{v} h - \nabla \cdot k \nabla T - \frac{5}{2}\frac{k_B}{e}\left(\mathbf{j} \cdot \frac{1}{C_p}\nabla h\right) = Q_J - Q_R$$

where h is the enthalpy of the fluid, k is the thermal conductivity of the fluid, k_B is the Boltzmann constant, e is the electron charge, $\mathbf{j}$ is the current density and C_P is the specific heat at constant pressure of the fluid.
The last term on the left hand side of the equation represents the enthalpy transport due to stream of the conductive electrons. Finally, Q_J is the energy dissipated in the discharge by Joule effect and Q_R represents the radiative losses.
The equations for the calculation of the electrostatic potential V, and of the vector potential $\mathbf{A}$, are the following:

$$\nabla \cdot \sigma \nabla V = 0$$

$$\nabla^2 \mathbf{A} + \mu_0 \mathbf{j} = 0$$

where σ is the electrical conducibility of the plasma, $\mathbf{j} = \sigma\mathbf{E} = -\sigma \nabla V$ represents the current density and μ_o is the magnetic permeability of the vacuum. The electromagnetic equations are solved, by the FLUENT® solver, by means of a *user-defined scalar* (UDS) approach, in a way similar to that described in [3].
In all the performed calculations, the required database of thermodynamic and transport properties has been worked out starting from the raw data calculated at CSIRO (Sydney, Australia) [4,5].
The calculations have been performed by PlasMac, a cluster of workstations available at CIRAM & DIEM of the University of Bologna. Such a resource allows for a large reduction in computational time as well as for the treatment of complex computational domain otherwise not manageable with traditional personal computers.

2.2 The twin torch configuration

The *twin torch* configuration is schematically represented in Fig. 1.

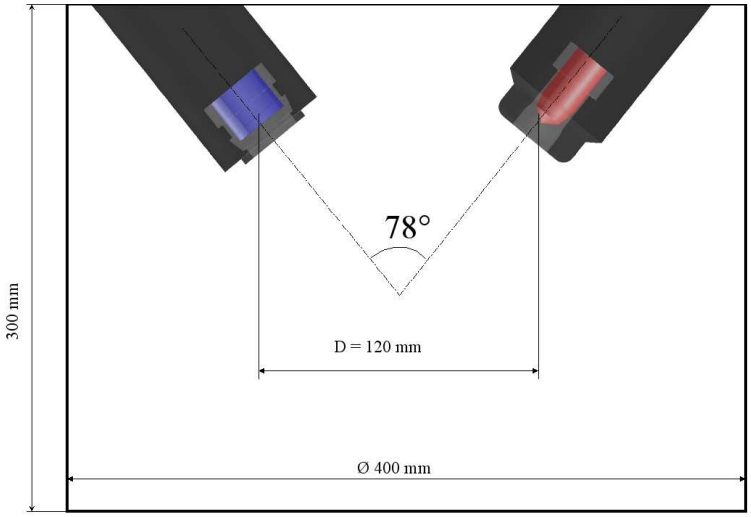

Fig.1 The twin torch configuration.

The computational domain does not extend to the whole reactor, since the simulation of the complete three-dimensional configuration would be too computationally expensive. The domain is thus limited to the region between the cathode and anode where the discharge takes place, as shown in Fig. 1.
The profile of the current density on the cathodic surface is given as a boundary condition. In the simulations performed, this profile is parabolic:

$$\mathbf{j}(r) = -\sigma \nabla V = -j_{max}\left[1 - \left(\frac{r}{R_0}\right)^2\right]$$

where $j_{max} = 0.8\times10^7$ A/m^2 is the maximum value of the current density on the cathode, r is the distance from the axis of the cathode, R_0 is a reference value calculated imposing a given value of the total current, I, on the cathodic surface. On the anodic surface the electrical potential is assumed to be zero, while on all the other surfaces of the model the current flux is assumed to be zero. The temperature value given as a boundary condition on the anodic and cathodic surfaces comes from previous calculations developed by CSM S.p.A.; on all the other surfaces the temperature is fixed at 500 K. The FLUENT®-implemented pressure-outlet condition is selected as a boundary condition for the momentum equation on the external boundaries of the computational domain, while the traditional *no-slip* condition is imposed on all the solid walls. In the performed *twin torch* simulations the working gas is either pure Ar or a mixture of Ar-H_2 with an H_2 content equal to 5% by volume, treating the plasma as a one-component fluid and so neglecting the demixing effects [6] .

3. Simulation results

The results presented in this section come from numerical simulations of the *twin torch* under operating conditions typical of the industrial applications developed at CSM S.p.A. The electrical current of the arc I imposed on the surface of the cathode as a boundary condition, is equal to 1500 A and to 1000 A, while the anodic and cathodic gas flow rates are, respectively, 5.34 m^3/h and 4.74 m^3/h.
A three-dimensional visualization of the isotemperature surfaces in the pure Ar discharge for both the cases of 1500 A and 1000 A are reported, respectively, in Fig. 2(a) and in Fig. 3(a), in which the deflection of the anodic and cathodic plasma jets due to the repulsive effects induced by the Lorentz force are appreciable. A more detailed visualization of the plasma temperature fields in the regions close to the two electrodes is reported in Fig. 2(b) and in Fig. 3(b) for the cases with I = 1500 A and with I = 1000 A, respectively.
An analysis of Fig.2(a) and Fig.3(a) highlights that, as the total electric current I of the arc decreases, the extension of the high temperature region of the discharge decreases too, although the shape of the discharge remains qualitatively almost unchanged. The decrease in the volume of the high temperature region of the

discharge is strictly related to the decrease in the total amount of the energy dissipated in the discharge by Joule heating.

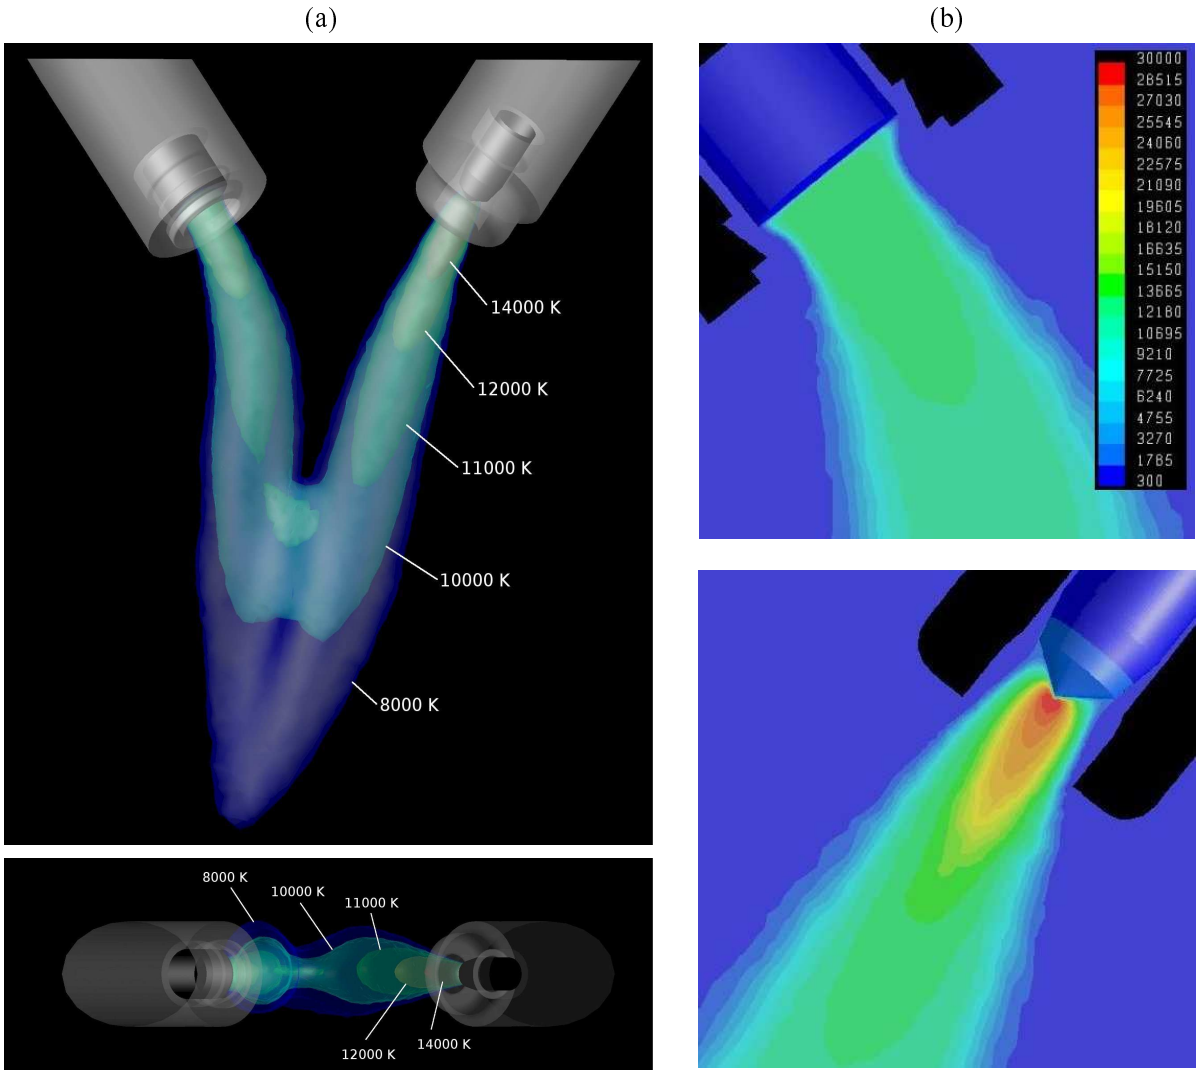

Fig. 2. Isotemperature surfaces in the discharge (a) and details of the plasma temperature [K] in the region close to the anodic (top) and cathodic (bottom) surfaces (b). Operating conditions: I=1500 A; pure Ar as working gas.

The maximum plasma temperature, located close to the cathodic surface, is close to 30000 K for both the cases presented in Fig. 2(a) and in Fig. 3(a), while in the proximity of the anodic surface the plasma temperature reaches a value close to 12000 K. It is interesting to note that these values of the plasma temperature close to the electrodes are mainly influenced by the maximum value of the current density on the surfaces of the electrodes, and are not noticeably influenced by the total electric current of the arc.

The *twin torch* configuration has also been simulated under operating conditions in which an homogeneous mixture of Ar and H_2 is injected as working gas. In this case, the diffusion of the two species has been neglected due to the low content of H_2 considered in the present case (equal to 5% by volume).
In Fig. 4(a) a three-dimensional visualization of the plasma temperature isosurfaces for the *twin torch* operating with the considered Ar-H_2 mixture under the operating conditions characterized by total electric current I = 1500 A is shown. The main difference between the plasma temperature presented in Fig. 4(a) and the one

presented in Fig. 2(a) (referring to a *twin torch* operating under the same conditions but for the composition of the gas, which is pure Ar), consists in higher values of the plasma temperature close to the anodic region. In fact, in the simulation with Ar-H_2 mixture a value close 14000 K is found, while for pure Ar case, in the same region a temperature close to 12000 K was found. From the comparison of these two figures, it may also be noticed that the macroscopic behavior of the discharge is not considerably affected by the injection of such a quantity of H_2. A detailed visualization of the plasma temperature fields in the anodic and cathodic regions is shown in Fig. 4(b).

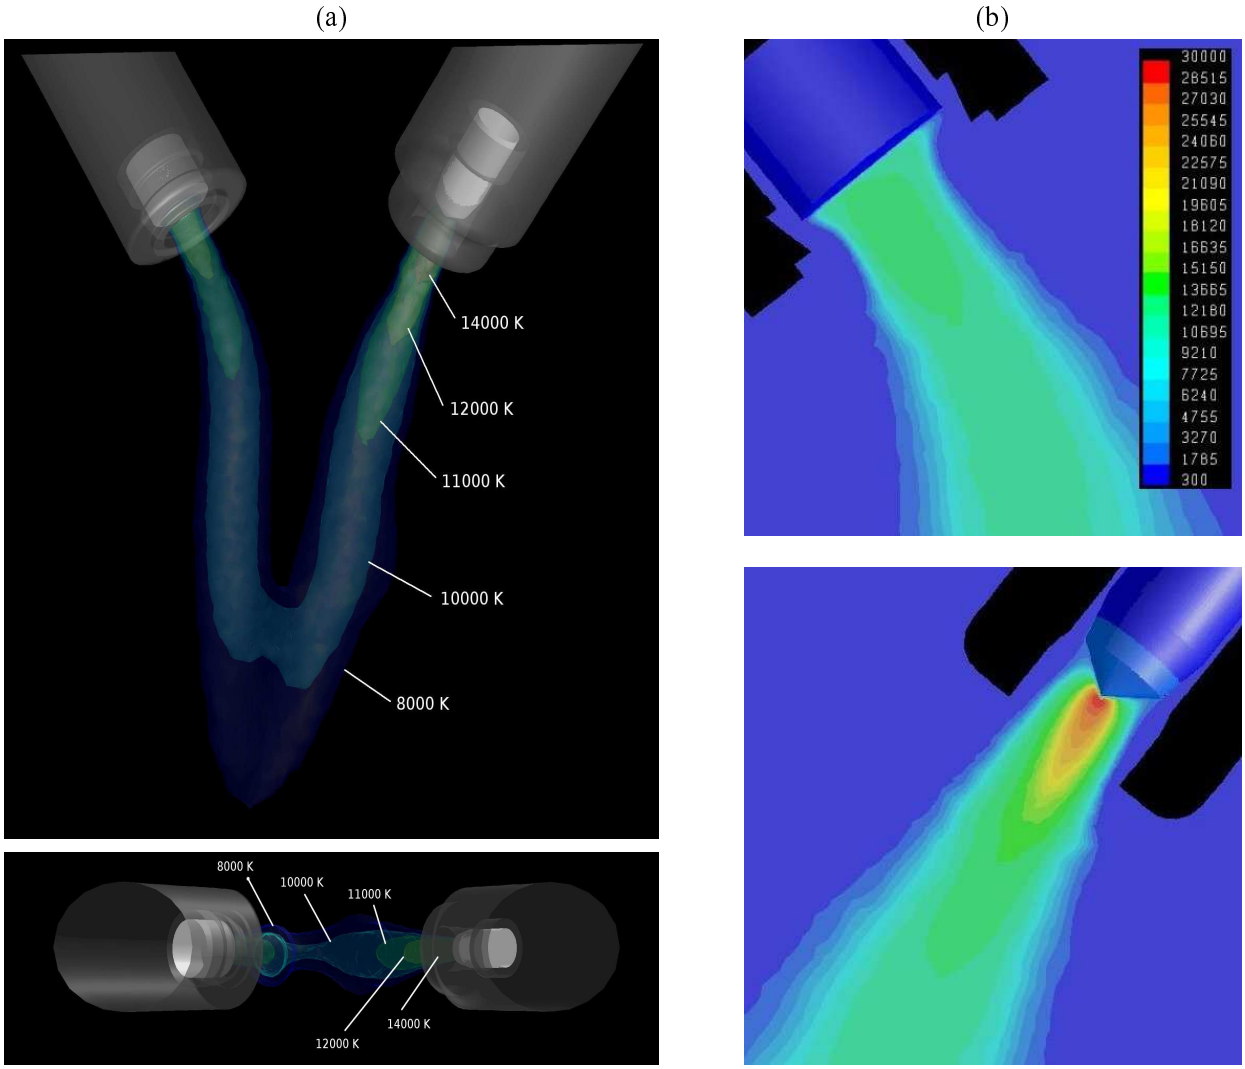

Fig. 3. Isotemperature surfaces in the discharge (a) and details of the plasma temperature [K] in the region close to the anodic (top) and cathodic (bottom) surfaces (b). Operating conditions: I=1000 A; pure Ar as working gas.

Abstract
The aim of this work is to investigate by means of a 3-D time-dependent numerical model the plasma flow and heat transfer inside a DC non-transferred arc plasma torch operating at atmospheric pressure [1-6], using a customized version of the CFD commercial code FLUENT©.

1. Introduction

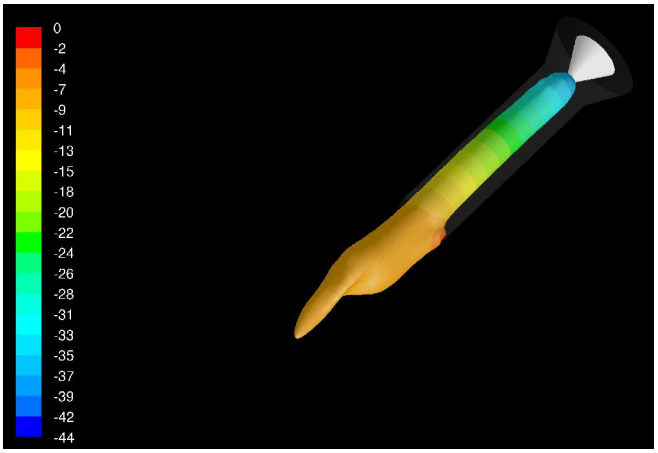
Modeling of a DC non transferred arc is a very difficult task since the discharge is often characterized by instabilities due to the anode-arc attachment motion that leads to strong fluctuations of the temperature and velocity fields in times of the order of the 10^{-5} s [1,2]. In the recent literature the modeling of this kind of devices [3-5] is performed by means of 3-D codes but restricted to steady state configurations. Recently a 3-D time dependent model has been presented [6] enforcing the restriking of the anode in the region of the torch where the electric is sufficiently high, by means of a modification of the anode boundary conditions, following some experimental observations.
In this work a 3-D time dependent model is developed to simulate the behavior of a DC non-transferred plasma torch without any external assumption on the anode restriking and attachment in order to achieve a self consistent model. Moreover the downstream expasion of the plasma jet after the torch nozze is included in the domain, using a LES turbulence model.

2. Modeling assumption

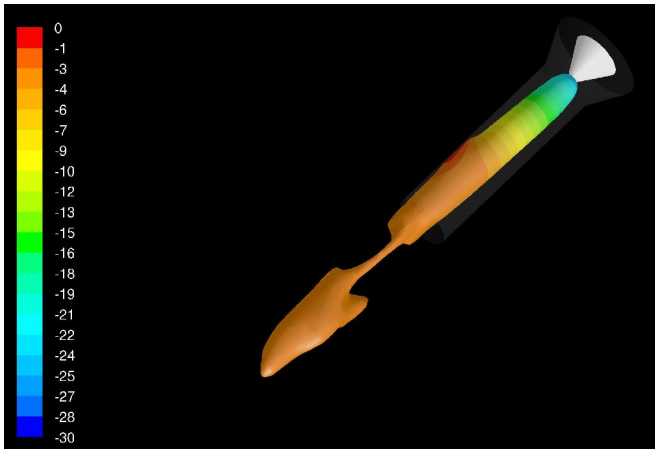
Unsteady flow and heat transfer equations are solved together with the scalar and vector electromagnetic potential equations, for an Ar optically thin plasma under conditions of LTE. We refer to [3,6] for the details on the equations and on the boundary conditions since they are basically the same. Geometry is taken as in [3] in order to have a literature basis for comparison. Cathode and anode regions are taken into account in a simplified way, neglecting the non equilibrium effects of the sheath region. The current is I = 150A and is imposed on the cathode tip, while the gas mass flow rate inlet is of $4x10^{-4}$ Kg/s with a swirl angle of 30°. The motion and the restrikes of the discharge on the anode wall, resulting from the drag of the flow particles acting on the anode spot, are obtained without any external enforcement on the placement of the new attachment (as done in [6]). Instead, an uniform zero electric potential condition on the anode wall is imposed as boundary condition. Due to the low time step size (10^{-6} s) needed for the description of the transient phenomena inside the torch, an advanced LES turbulence model with a Smagorinsky-Lilly subgrid-scale model [7] is used in order to describe the turbulence effects on the flow field, solving the dynamic behavior of the larger scale turbulence eddies.
Simulations are performed over a network cluster of double processor calculators due to the large computational requirements of the unsteady model and the grid refinement needed for the turbulence model in a full 3-D environment.

3. Results

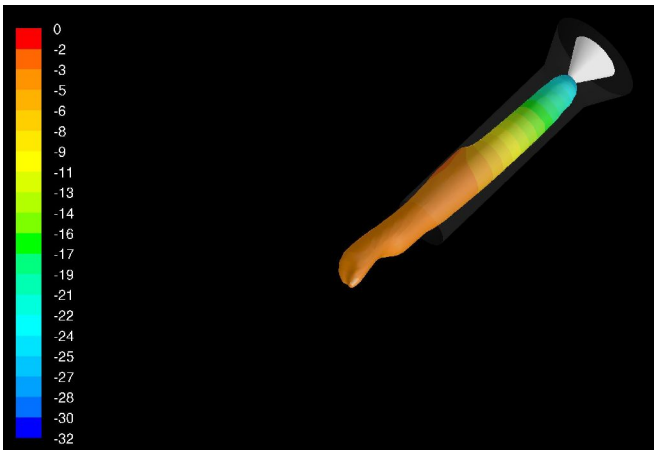
In order to capture the unsteady movements of the anode attachment and the details of the turbulence eddies the time step used in this simulation is $2.5x10^{-6}$s. In Fig. 1 the electric potential contours are shown on the isosurface at 8000 K at different times. A first restrike is shown from t = 0ms to 0.15ms, while for t = 0.3ms to 0.6ms the arc anode attachment is moving downstream under the effects of the fluid dynamic drag force, with a slowly increasing of the maximum voltage. It is possible to see also that the point of attachment slightly rotates due to the presence of the swirl component on the velocity. The other restrikes occour for t = 0.75ms and t =



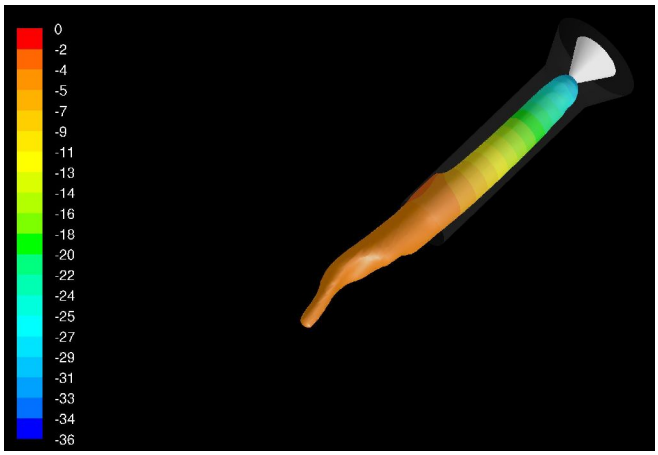
0 ms



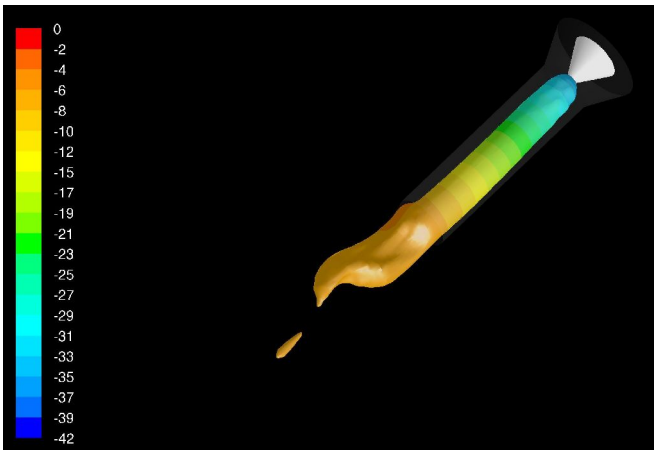
0.15 ms



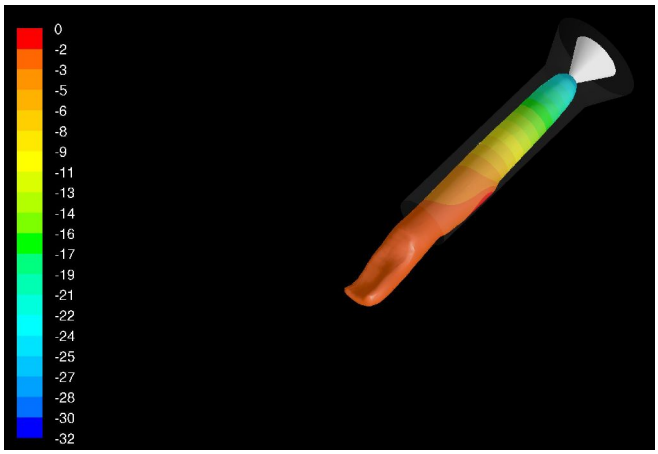
0.3 ms



0.45 ms



0.60 ms



0.75 ms

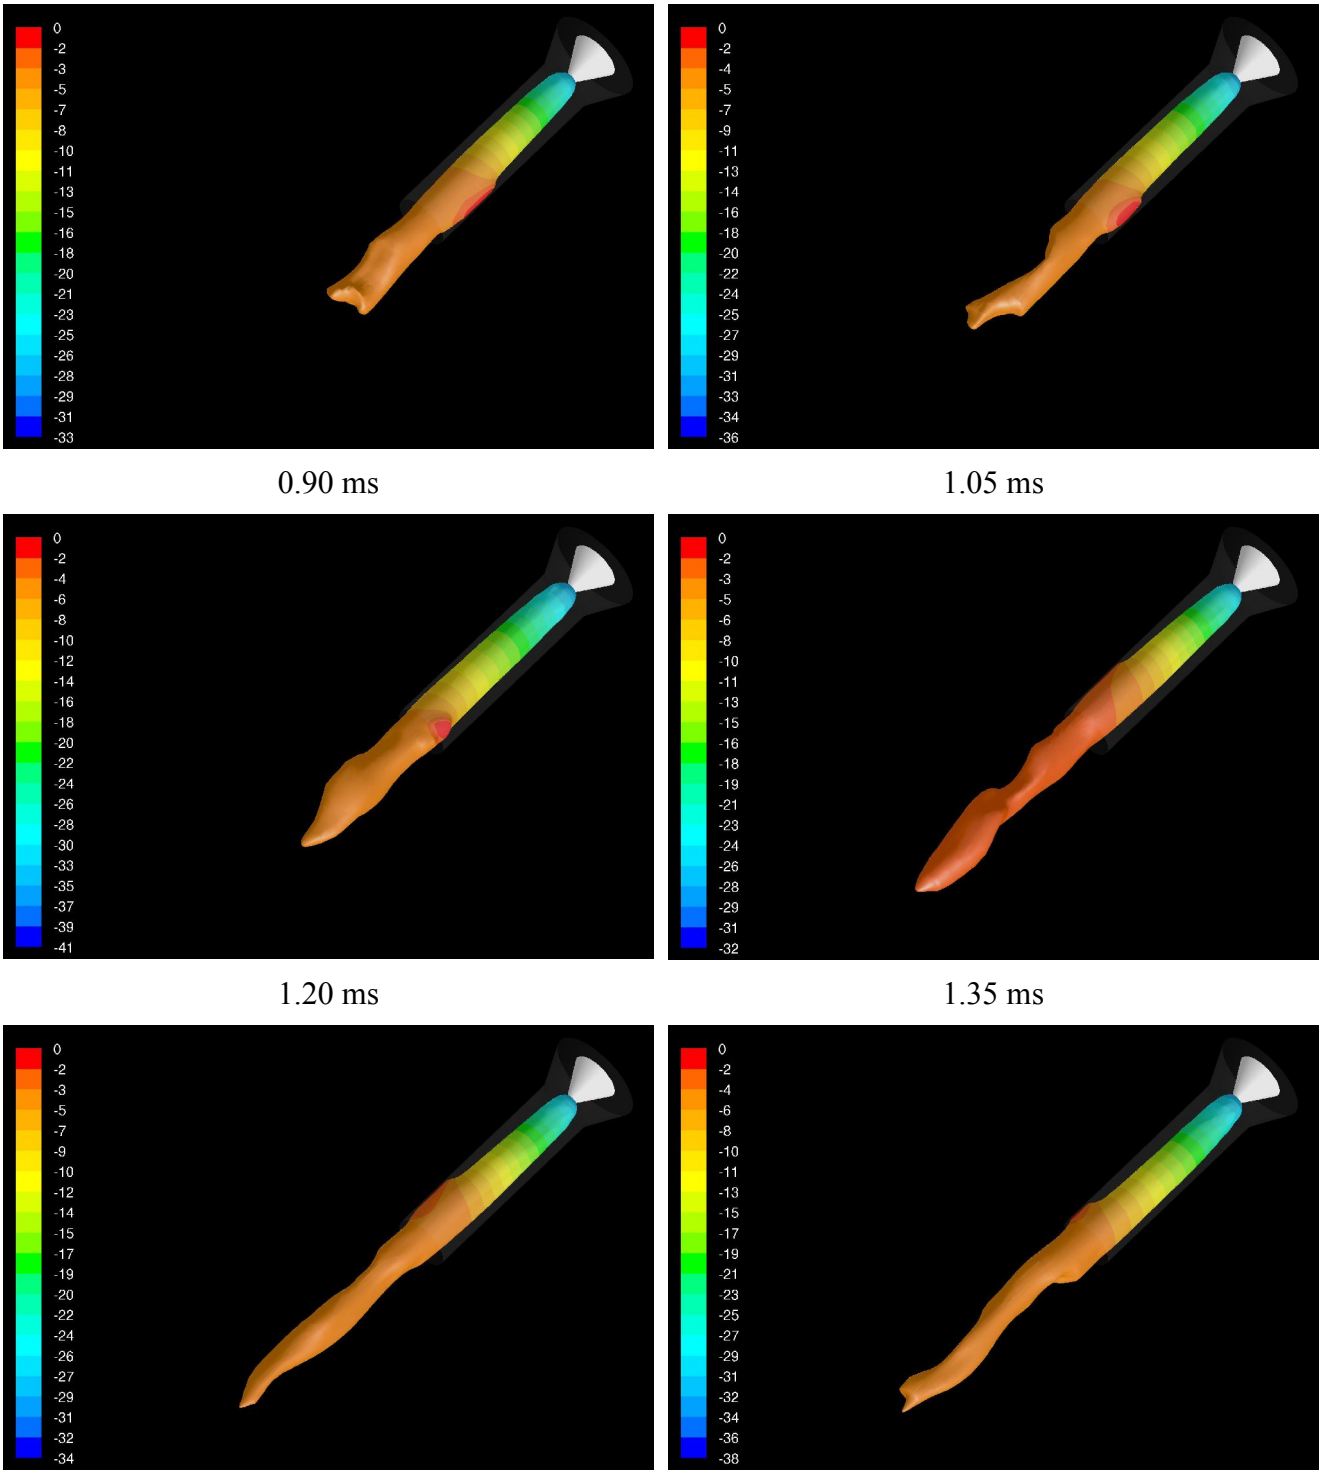


Fig. 1 Instantaneous electric potential [V] on the isosurface at 8000 K in different times.

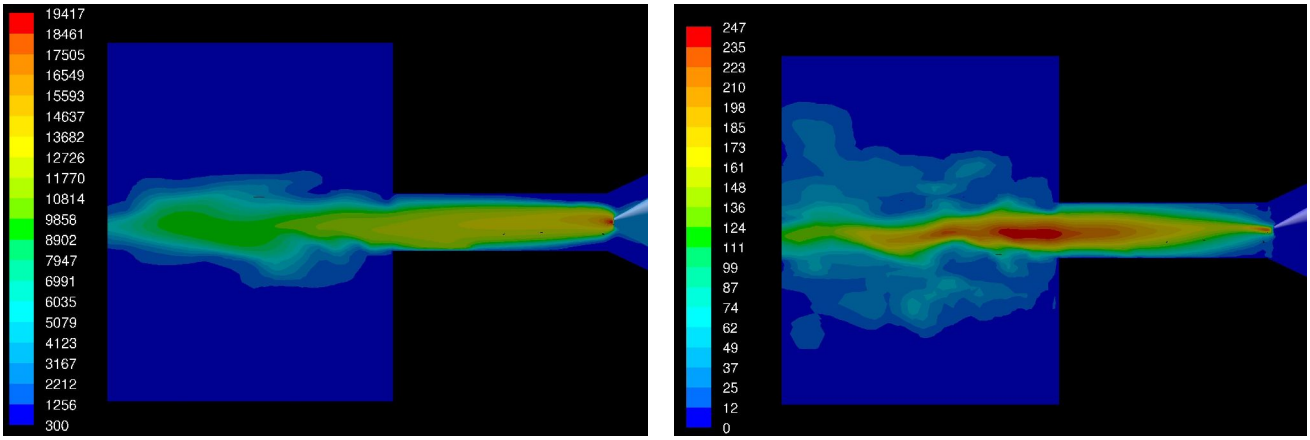

(a) (b)

Fig. 3 Instantaneous (a) temperature field [K] and (b) velocity field [m/s] on a plane for t = 1.50ms.

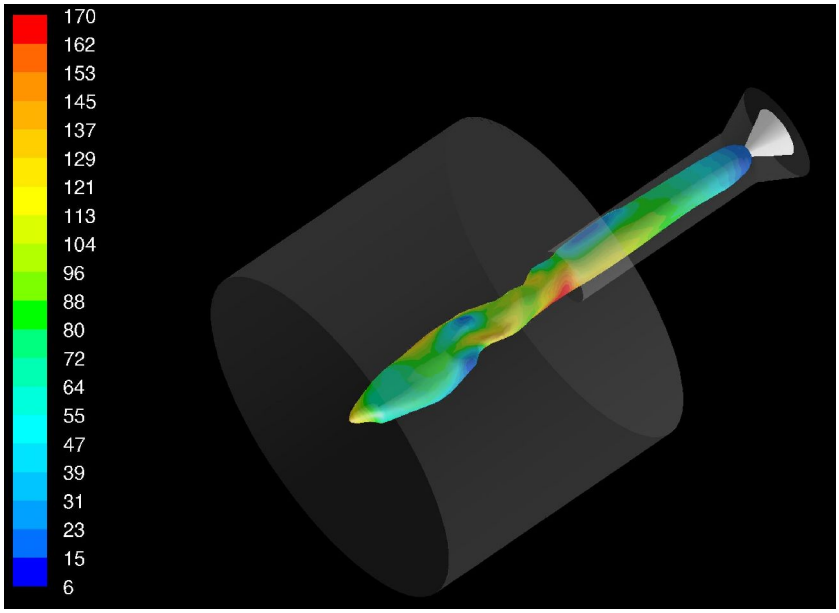

Fig. 4 Instantaneous velocity magnitude [m/s] on the isosurface of 7000K for t = 1.50ms.

1.35ms. The shape of the 8000 K isosurface after the exit nozzle of the torch is quite irregular due to the LES turbulence model, that describes the instantaneous flow field at every time step without any time filtering as done in the RANS models (for example k-ε or RSM). These figures can be interpreted as images taken from an high speed camera with a low shutter speed. In Fig. 2 the instantaneous temperature and velocity fields are shown on a plane passing through the axis of the torch. Again is possible to see the strong irregular shape of these fields in the region downstream the nozzle, expecially for the velocity. Inside the torch cylinder the flow field is quite laminar, due to the high viscosity of the plasma and the smaller length scale. In Fig. 4 the velocity magnitude is plotted on the 7000K isosurface in order to put in evidence the low speed of the plasma gas in the point of the anode attachment. This point is seen by the fluid particles as an obstacle on their motion, due to the high viscosity of the plasma forming the arc spot. The low temperature gas flows around it and the maximum on the velocity magnitude is located on the opposite wall side. In Fig. 5 the instantaneous electric potential on the isosurface of $3x10^6$ A/m^2 for t = 1.50ms is shown, underlining the point of attachment and the path of the current inside the discharge.

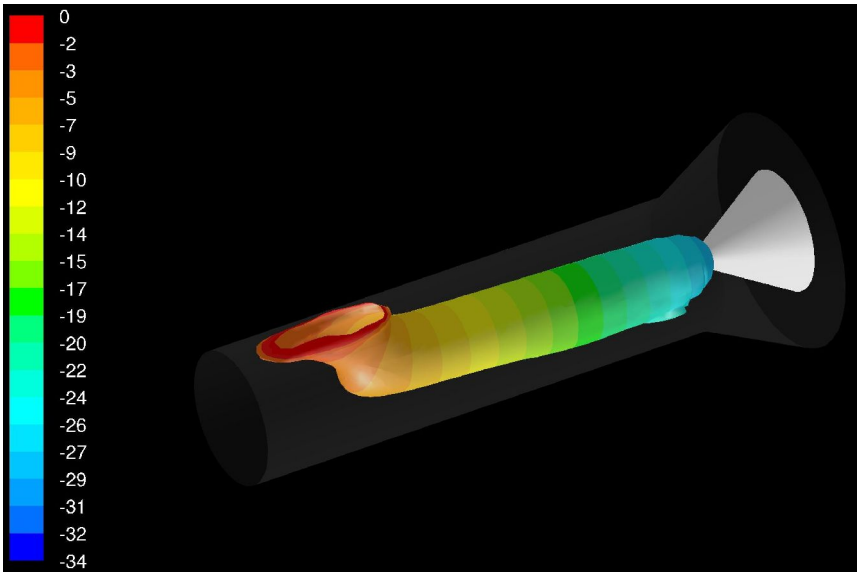

Fig. 5 Instantaneous electric potential [V] on the isosurface of $3x10^6$ A/m^2 for t = 1.50ms.

Conclusions

Simulation results of a 3-D time dependent LES model of DC non-transferred arc have been presented. The anode attachment motion and restrike is described without any external assumption. Results seems to be quite in agreement with experimental observations done in [1,2]. This model is far from being perfect, especially in the anode boundary layer treatment where the non equilibrium effects have been neglected and seems to be very important in the evaluation of the location of the restrikes. Another important step will be the comparison of the results with experimental measurements in order to tune the model, since the LES approach is still in a stage of verification in the different fields of application in which it could be used. The next step will be a two temperature model in order to take into account the anode attachment in a more accurate way.

Abstract
The aim of this work is to investigate by means of a 3-D numerical model the behaviour of a transferred arc plasma torch operating at atmospheric pressure, for the cutting of a metallic substrate material, using a customized version of the CFD commercial code FLUENT©. The metallic substrate and the keyhole are included in the computational domain in order to take into account their effects on the flow field of the discharge at the nozzle exit. The detailed gas injection section and the cathode chamber are included in the computational domain as well.

keywords: plasma cutting torches, transferred arc plasma torches, metal cutting.

1. Introduction

Transferred arc plasma torches are widely used in industrial cutting process of metallic materials because of their ability to cut a wide range of metals and because of the very high productivity that can be achieved with this technology [1]. The plasma arc cutting process is characterized by a transferred electric arc that is established between an electrode that is part of the cutting torch (the cathode) and another electrode that is the metallic workpiece to be cut (the anode). In order to obtain a high quality cut and a high productivity (low cutting time) the plasma jet must be, among the other things, as collimated as possible and must have the higher achievable power density. With this regard, modelling and numerical simulation may be very useful tools for the investigation of the characteristics of the plasma discharge generated in these kind of devices, as well as for optimization of industrial cutting torches. In recent years, numerical simulation has gained popularity as a tool for torch design and a lot of excellent papers have been published on this topic (se, for example, [1-4], just to name but a few).
In this paper we present a three-dimensional numerical model recently developed by some of the authors within a customized version of the CFD commercial code FLUENT© in the framework of a research contract between the University of Bologna and Cebora S.p.A.
Fluid flow and heat transfer equations are solved together with the coupled electromagnetic ones for an air optically thin plasma assumed to be in local thermodynamic equilibrium. The details of the gas injection section and of the cathode chamber are included in the computational domain in order to determine the effects of the geometry on the flow field characteristics of the discharge and to optimize it in the design phase.
The metallic substrate with the keyhole is included in the computational domain only for electrical and fluid-dynamics purposes, in order to take into account its effect on the flow field of the discharge at the nozzle exit. Experimental measurements are performed in order to evaluate the keyhole shape and diameter for different cutting conditions. In order to investigate the behavior of the device during pre-cutting phase 2-D simulation of the non-transferred nozzle-attached arc are also considered.

2. Modelling approach

Two-dimensional and three-dimensional computational models for the simulation of a transferred arc plasma torch require the simultaneous solution of the coupled set of non-linear fluid-dynamic, electromagnetic and

energy transfer equations. Such computational models have been developed starting from previously developed numerical models implemented by some of the authors for the simulation of atmospheric pressure inductively coupled plasma torches [5] and of transferred arc plasma torches both in free-burning arc configuration and in configuration with gas injection [6].
In the model developed for plasma cutting torch presented here, turbulence phenomena are taken into account by means of a k-ε RNG model in order to better describe the flow field inside the device.

The main simplifying assumptions on which the developed models rely are the following:
- the discharge is stationary;
- the plasma is described as a simple mono-component fluid (air);
- the plasma is optically thin and in local thermodynamic equilibrium (LTE);
- the turbulent plasma flow is described by the renormalization group (RNG) turbulence model;

Taking into account the previous assumptions, the equations of the conservation of mass and momentum take the following form for the three dimensional case:

$$\nabla \cdot (\rho \mathbf{v}) = 0$$

$$\nabla \cdot \rho \mathbf{v}\mathbf{v} = -\nabla p + \nabla \cdot \tau + F_L$$

being ρ the density of the fluid, **v** the velocity of the fluid, p the pressure, τ the stress tensor and F_L the Lorentz force due to the interaction of the conductive fluid and the electromagnetic field. The energy equation is solved without taking into account the viscous dissipation:

$$\nabla \cdot \rho \mathbf{v} h - \nabla \cdot k \nabla T - \frac{5}{2}\frac{k_B}{e}\left(\mathbf{j} \cdot \frac{1}{C_p}\nabla h\right) = Q_J - Q_R$$

where h is the enthalpy of the fluid, k is the thermal conductivity of the fluid, k_B is the Boltzmann constant, e is the electron charge, **j** is the current density and C_P is the specific heat at constant pressure of the fluid.
The last term on the left hand side of the equation represents the enthalpy transport due to stream of the conductive electrons. Finally, Q_J is the energy dissipated in the discharge by Joule effect and Q_R represents the radiative losses.
The equations for the calculation of the electrostatic potential V, and of the vector potential **A**, are the following:

$$\nabla \cdot \sigma \nabla V = 0$$

$$\nabla^2 \mathbf{A} + \mu_0 \mathbf{j} = 0$$

where σ is the electrical conducibility of the plasma, $\mathbf{j} = \sigma\mathbf{E} = -\sigma \nabla V$ represents the current density and μ_o is the magnetic permeability of the vacuum.
The electromagnetic equations are solved, by the FLUENT® solver, by means of a *user-defined scalar* (UDS) approach, in a way similar to that described in [7].
The equation for the two-dimensional case are a subset of the presented equations and will not be presented here.
The thermodynamic and transport coefficients of the air plasma used for the numerical simulations are those given in [8].

All calculations have been performed by PlasMac, a cluster of workstations available at CIRAM & DIEM of the University of Bologna. Such a resource allows for a large reduction in computational time as well as for the treatment of complex computational domain otherwise not manageable with traditional personal computers.

3. Results

As a first step in the analysis of this kind of device, a two-dimensional axi-symmetric non-transferred configuration of a CP-160 CEBORA plasma cutting torch has been simulated. This configuration is typical of the first ignition phase of the cutting torch, where the pilot arc is approached to the workpiece in order to establish the transferred configuration in which the cutting phase will be initiated. In the first non-transferred phase the anode is the nozzle of the torch, while in the second transferred phase the anode is the workpiece to cut. The effect of the inlet pressure on the non-transferred discharge shape is shown in Fig. 1. A first effect is the increase on the inlet pressure that leads to an increase on the plasma maximum temperature reached inside the nozzle. A second effect is on the attachment point of the discharge to the anode which is dragged downstream by the increased velocity of the fluid that tents to create a low temperature gas shield on the internal cylindrical surface of the nozzle, preventing the attachment of the arc point in this position. For a sufficiently high pressure the arc is closed on the nozzle exit surface. The two-dimensional code predicts a cylindrical uniform attach due to its intrinsic limitations, while the actual attachment will be a single spot due to the magnetic constriction forces.

The three-dimensional model has been applied to a CP-200 CEBORA plasma cutting torch, including the details of the inlet gas section as shown in Fig. 2. A detail of the temperature field resulting from simulation is shown in Fig. 3 while the electric potential on the 13000 K isosurface is shown in Fig .4. The inclusion of the inlet region allows a better understand the characteristics of the flow in the upstream region of the plasma chamber and to perform a better design of the torch component. An example is in Fig. 5, where the turbulence viscosity ratio in the inlet region is shown.

Abstract
The results of studies of operational regimes of the two hollow needles-to-mesh electrical discharge enhanced by the mixture of air or mixture of air with n-heptane are given. The n-heptane decomposition efficiencies for the discharge with stainless steel mesh, with the mesh coated by the layer of TiO_2 or with the mesh covered by TiO_2 globules are presented.

1. Introduction

The non-thermal plasma based technologies are becoming more and more important for a wide range of applications such as destruction of volatile organic compounds (VOC) in air streams, because of their energy selectivity and their capability for the simultaneous removal of various pollutants [1-4]. Corona discharge (DC, AC or pulsed), dielectric barrier discharge in a confined space and others have been tested for these purposes [4]. Recently, it has been shown that a combination of non-thermal plasma with catalysis leads to very promising results for the destruction of atmospheric pollutants at relatively low energy cost [5-8].
The corona discharge reactors involve different electrode configurations, a wire-to-cylinder most frequently, a corona torch, a point-to-plate and a multi-point-to-plate.
The corona discharge is a relatively low power electrical discharge. Both discharge stabilization and discharge power enhancement can be achieved by applying a gas flow with respect to the active electrode. Contrary to the electrode system and gas flow regime proposed in [1, 6, 9], in this paper we proposed a hollow-needle-to-mesh electrode configuration in which an atmospheric pressure discharge is enhanced by a mixed VOC/air flow through the needle electrode [2]. The advantage of this arrangement of the airflow with respect to the active electrode is that all the mixture passes through the discharge and therefore is affected by the plasma chemical processes.
Titanium dioxide (TiO_2) is an n-type semi-conductor, biologically and chemically inert, and existing in rutile and anatase phase. A series of its energy levels is associated with covalent bonding between atoms composing the crystallite (valence band) and a second series of spatially diffuse higher energy levels is associated with conduction in the macromolecular crystallite (conduction band) [10]. Both series are strictly separated by a fixed energy gap of 3.2 eV [12]. Incidence of UV light of a higher energy than this band gap, e.g. originating from de-excitation processes in the plasma-reactor, can promote electrons from the valance band to the largely vacant conductance band. Simultaneously, a positive hole with strong oxidizing capability is formed [10, 11]. In order for photo-catalysis to be productive chemically, electron-hole pair recombination followed by energy dissipation as heat, must be suppressed by fast trapping either of the electrons, or the holes or both, not exceeding the time constant of recombination which is a fraction of nanoseconds [10, 12]. The anatase TiO_2 is predominantly used, because it has a higher O_2 adsorbing capacity than rutile TiO_2 [10]. The contaminating organic substrates themselves can react as adsorbed traps for the photo-generated holes.
In this paper the operational regimes of the reactor and the results of an n-heptane decomposition study are presented. This study was performed using a stainless steel mesh electrode, either uncoated or coated by a TiO_2 layer or as base structure for a layer of Aerolyst TiO_2 catalyst globules, produced by the Degussa AG. We used two needles to increase the energy density and to test possible scaling for future application.
For our experiments we chose n-heptane $CH_3(CH_2)_5CH_3$ because it is a common part of organic solvents and automotive fuels (petrol) and because it represents a wide group of saturated hydrocarbons.

2. Experimental arrangement

The experimental set up is shown in Figure 1. In a cylindrical plasma-chemical reactor, an electrical discharge is created between two hollow stainless steel needles and a mesh electrode. The needles with inner and outer diameter of 0.7 mm and 1.2 mm respectively and a 15° sharp tip, are placed in a diametrical plane of the reactor, one at each side of the reactor axis, in fact the mirror axis for the needle positions. The tip's inner faces are pointing towards each other and the inter-needle distance w is set to 9 mm. A metallic mesh R 0.60, made by M-Metall Italy, situated perpendicularly to those needles, is used as a second electrode. The rhombus mesh cells have dimensions 0.60×0.50 mm^2 and thickness 0.15 mm. In this study, two types of mesh are used, namely a mesh with a TiO_2 coating and an uncoated mesh used as underlying base structure for a 3 mm thick catalyst bed of TiO_2 globules. The inter-electrode distance d is varied from 4 mm to 10 mm by a 2 mm step.

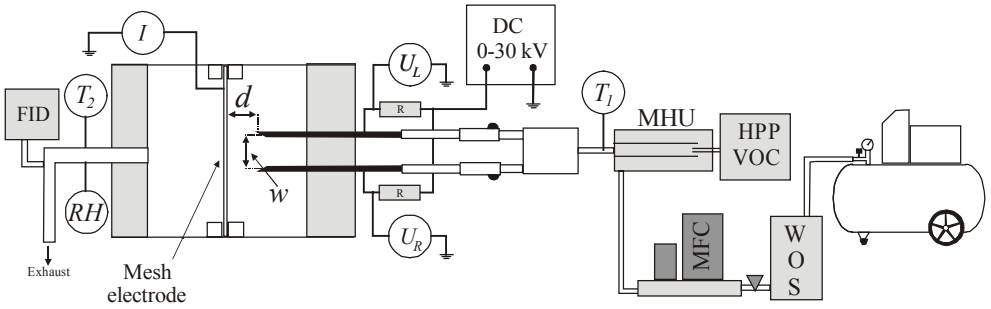

Figure 1. Experimental arrangement

A gas flow, either clean environmental air or a mixture of air and n-heptane, passes through the needles. A compressor supplies the required pressure. Before entering the needles, the air is dried and cleaned by the water and oil separator WOS. A Bronkhorst mass flow controller sets the flow rate. The air enters the mixing and heating unit MHU that is preheated to the temperature of 90°C. In this unit, a precise dosage of n-heptane is added to the preheated air using a high-pressure pump HPP followed by the evaporation of the n-heptane at temperature 150ºC. The mixture temperature is measured by a thermocouple T_1.

A DC power supply provides voltage up to 30 kV. The polarity of the needles can be changed. Both needles have a ballast resistor R = 5.30 MΩ. At the output of the reactor, two sensors are placed to detect both the outlet temperature T_2 and the relative humidity RH. For the purposes of an n-heptane decomposition study, there is also a FID total hydrocarbon analyser HC 51 (measuring range 0 -1300 ppm) present at the outlet.

3. Experimental results

3.1. Electrical discharge in air

The first set of experiment was devoted to the study of stable operational regimes of the discharge in air. The V-A characteristics were obtained for different inter-electrode distances and for different polarities of the needles. For d = 10 mm, the inter-electrode distance exceeded the inter-needle distance and the existence of a potential difference between both needles, originating from a possible asymmetry in the mutual needle positioning and a slightly different tip curvature, caused an unstable discharge. In order to obtain the highest possible energy density, with regard to future decomposition studies, we chose d = 8 mm. Therefore only for this distance the V-A characteristic is shown in figure 2. Negatively and positively biased needles reveal a V-A characteristic different in shape and voltage levels, which is obviously due to different discharge mechanisms for both polarities. To be self-sustaining a positive corona requires a lower voltage, i.e. lower fields (13.8 kV/cm versus 15.6 kV/cm), because of lower losses.

3.2. Electrical discharge in the mixture of air with n-heptane

For discharges in the mixture of air with n-heptane, again differently biased needles result in different V-A characteristics. Figure 3 shows that for needles biased negatively, the voltage increases for low currents and then

reaches a plateau, rather than it reaches a maximum, as was the case for discharges in air. For positive biased needles, again a maximum is obtained. However, the voltages are significantly higher than for discharges in air. This is not seen for negatively biased needles. This could be explained by photon absorption in n-heptane, limiting the creation of secondary electrons in a discharge with needles biased positively. Still the voltage level for positively biased needles remains for all current levels significantly lower than for negatively biased needles. Therefore, the latter configuration is chosen for further decomposition studies.

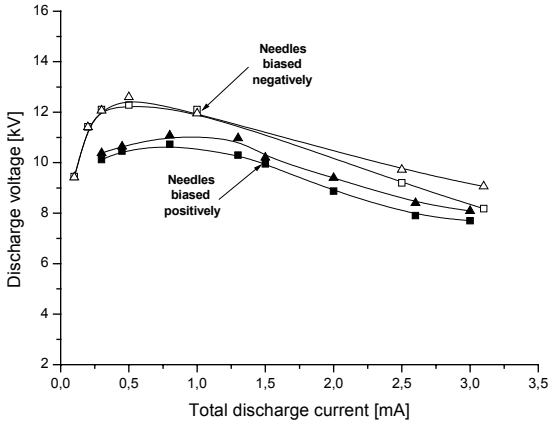

Figure 2. V-A characteristics for two-needles-to-mesh discharge in a air; Q_{AIR} = 20.3 slm; d = 8 mm. (left needle: squares, right needle: triangles)

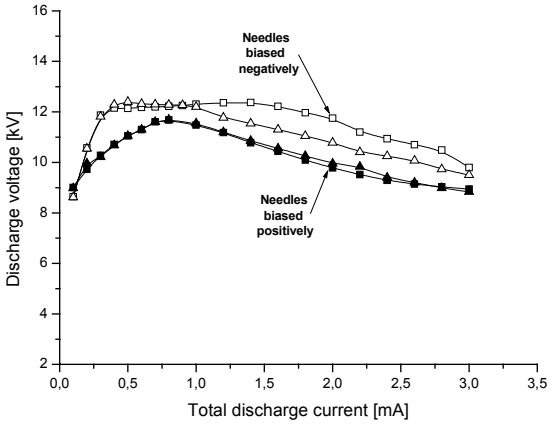

Figure 3. V-A characteristics for two-needles-to-mesh discharge in a mixture of air with n-hepatane; n-heptane concentration = 33 ppm; Q = 20.3 slm; d=8 mm. (left needle: squares, right needle: triangles)

3.3. Decomposition studies

All results described in this section were performed with the discharge with the needles biased negatively, as explained in previous section. The experiments were performed for three different secondary electrode configurations, namely with an uncoated stainless steel mesh, a stainless steel mesh coated with a layer of TiO_2 and a stainless steel mesh as a base structure for a layer of TiO_2 catalyst globules.

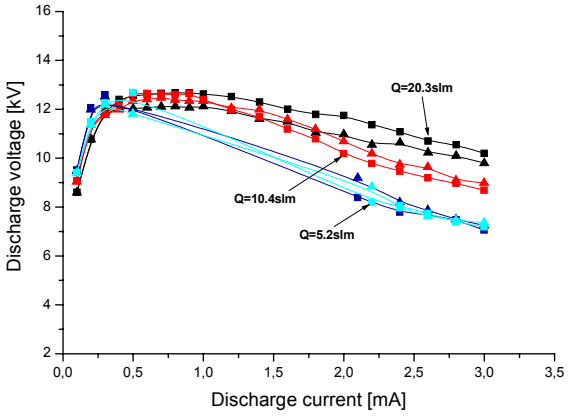

Figure 4. V-A characteristics for two needles to uncoated mesh discharge in a mixture of air and n-heptane. Needles biased negatively; d=8 mm; n-heptane concentration = 33 ppm. (left needle: squares, right needle: triangles)

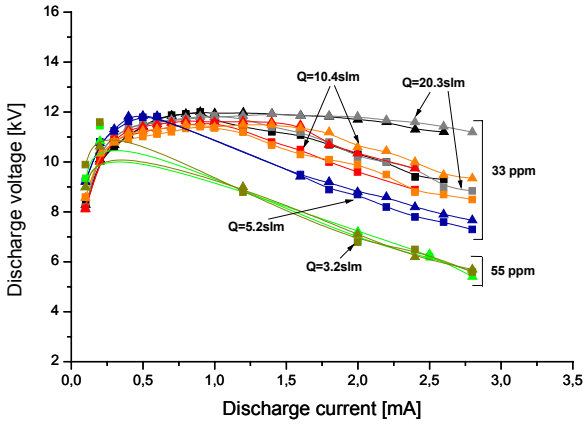

Figure 5. V-A characteristics for two needles to coated mesh discharge in a mixture of air and n-heptane. Needles biased negatively; n-heptane concentration = 33 ppm, d = 8 mm. (left needle: squares, right needle: triangles)

The V-A characteristics for these experiments are shown in figures 4, 5 and 6 respectively. The values of decomposition efficiencies for the first two sets of experiments were obtained for the discharge current of 2.8 mA at different flow rates. They are presented in Table 1. The experimental results for the TiO_2 globules are not included in this table because the removal efficiencies for different power densities were obtained at constant flow rate through a variation of the input electrical power.
Figure 6 also includes the V-A characteristic of the discharge in air. The airflow rate in both cases was 5.2 slm.

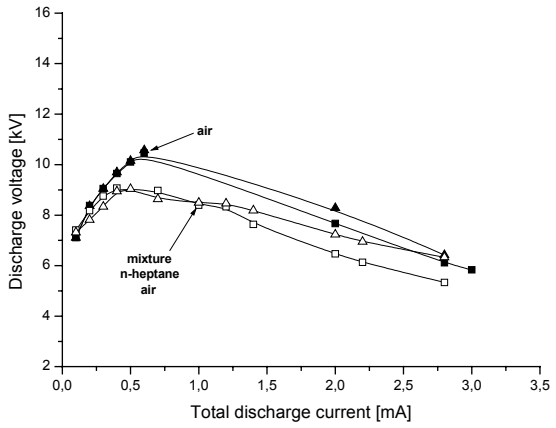

Figure 6. V-A characteristics for two needles to mesh with a layer of TiO_2 granules discharge in air and in the mixture of air with n-heptane; Q=5.2 slm; needles biased negatively; d = 8 mm; n-heptane concentration = 33 ppm. (left needle: squares, right needle: triangles)

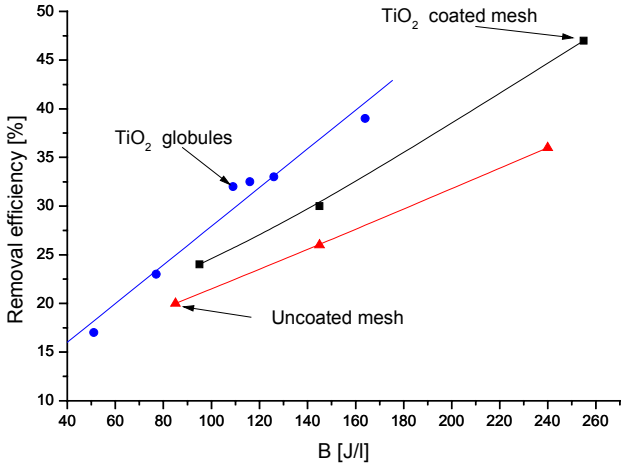

Figure 7. Decomposition efficiency versus energy density for discharge in a mixture of air and n-heptane. Needles biased negatively, d = 8 mm; n-heptane concentration = 33 ppm.

Table 1. Removal efficiency vs. flow rate and mesh type;
Needles biased negatively; d = 8 mm; n-heptane concentration = 33 (55*) ppm.

Flow Rate [slm]	20.3	10.4	5.2	3.2
Uncoated mesh	20	26	36	--
Coated mesh	24	30	47	37.5*

3.4. Decomposition studies – Summary

The decomposition efficiencies versus energy density for the discharge in the mixture of air with n-heptane for the discharge with an uncoated mesh, mesh coated with TiO_2 layer and finally for the discharge with the layer of TiO_2 globules on the mesh are shown in Fig. 7. In order to obtain high energy density the inter-electrode distance d was chosen to be 8 mm.

4. Conclusions

The layer effect of the TiO_2-coated mesh on V-A characteristics of the discharge in the mixture of air with n-heptane can be seen from the comparison of Fig. 4 and Fig. 5. As far as the decomposition experiments were performed with the inter-electrode distance d = 8 mm, the comparison was made for this distance only. From these two figures it is seen, that for all three flow rates coating of the mesh in the region of low currents

decreases discharge voltage. For higher currents the difference between V-A characteristics for coated and uncoated mesh is smaller.

Significant difference however exits among V-A characteristics for the discharge with the layer of TiO_2 globules on the mesh and the discharge with an uncoated mesh and the mesh coated with the layer of TiO_2. The results obtained from the comparison of Figs. 4, 5 and Fig.6 for the flow rate 5.2 slm reveal that for particular current the discharge with TiO_2 globules requires smaller voltage.

From Fig. 7 it is seen that n-heptane decomposition efficiency increases with increased energy density. It is also seen that for particular energy density the decomposition efficiency is the highest for the discharge with the layer of the TiO_2 globules, smaller for the mesh coated with the layer of TiO_2 and the smallest for the discharge with an uncoated mesh. These results can be explained by the effect of photo catalyst TiO_2 on decomposition efficiency. In case of TiO_2 globules the photo catalysts area exposed to the UV emitted from the discharge is higher than for the case of TiO_2 coated mesh, therefore the decomposition efficiency must be higher.

Formation of Modified Layer on HOPG by Low-energy Ion Bombardment

N.Hamamura and A.Yoshida
Musashi Institute of Technology
1-28-1 Tamazutsumi Setagaya-kuTokyo 158-8557, Japan

Abstract

An ion irradiation at low-energy of < 1 keV is expected to introduce a thin modified-layer about several nm onto polymers or carbon materials. Using the irradiation with nitrogen ion, a formation of a nitrogen containing diamond like carbon is expected to introduce on the surface. In the report, to clarify the structure of modified-layer, nitrogen ion irradiation to HOPG (highly oriented pyrolytic graphite) was carried out. As the result, it was suggested that the irradiated nitrogen is introduced preferentially at the edge or at the defect of basal plane.

Keywords: HOPG, Nitrogen ion irradiation, Modified-layer, Depth profile, Chemical bonding state

1. Introduction

Surface modification of polymers using gaseous plasmas is one of a method for improvement its properties such as a wettability and an adhesivity. The authors have studied on surface modification of polymers by using nitrogen plasma under high $\boldsymbol{E}/\boldsymbol{n}$ ($\boldsymbol{E}$: electric field, $\boldsymbol{n}$: gas density) condition [1] and low-energy nitrogen ion irradiation. From the result, a wettability and an adhesivity were improved with nitrogen introduction. And, the properties such as an increase of a chemical stability and of hardness were improved. It is considered that not chemical functional groups but also a bridged structure exist in the modified-layer. And, it was deduced that the improvement was accelerated by the irradiation of nitrogen ions about 100 eV. By the way, during the processing, many kind of active species such as electron, radical, and UV or VUV are also irradiated. Many researchers have studied on the contribution of active species to improvement of the property [2][3]. And, a structure of the modified-layer was suggested which consists of polar groups on the surface and bridged structure below the surface to several mm [3]. However, it is not fully characterized for thin surface layer about several nm.

To characterize the structure of the modified-layer, the authors have used AR-XPS (angle resolved X-ray photoelectron spectroscopy) to obtain the depth profile, which is able to analyze the sample surface with nondestruction. As the result, irradiated with the ion energy of 100eV on the sample, nitrogen introduction was occurred preferentially about 3nm below the surface. It was deduced a formation of thin modified-layer of several nm and an existence of a bridged structure including carbon-nitrogen bond [4]. And, the existence of the structure brought about the increase of surface hardness was suggested. However, the characterization requires thin analysis depth about several nm on the surface, a reaction process during the irradiation and characterization of the modified-layer was not clarified. In case of carbon materials as the sample, it is expected that a kind of nitrogen containing amorphous DLC (diamond like carbon) may form on the surface. And, the structure is able to characterize by using Raman spectroscopy which depth is several 10 nm. Using a commercial graphitic plate as the sample [5], the structural change by the irradiation was detected a little because of poor reproducibility. Therefore, the sample is required to use materials which composition and the structure have been clarified.

In the report, using HOPG as the samples, the analyses on the chemical bonding state were carried out to clarify the ion energy and dose dependence on the formation.

2. Experiments

2.1 Ion irradiation

Samples were commercial ZYB grade HOPG which size was 6 x 12 x 1.7 mm^3. Nitrogen ion was irradiated onto the samples which surface was peeled off using adhesive tape. Figure 1 shows a schema of

experimental setup. Before the irradiation, the chamber was evacuated to less than 1.0×10^{-4} Pa. The gas was commercial nitrogen. Under the pressure at 1.3×10^{-2} Pa, the irradiation was carried out using an iongun of VARIAN #981-2043. The distance between the substrate and the iongun was 100 mm. Irradiation area on the sample was 10 mm in diameter. The ion dose was 1.0×10^{17} cm^{-2} in which nitrogen concentration of the sample shows saturation [5].

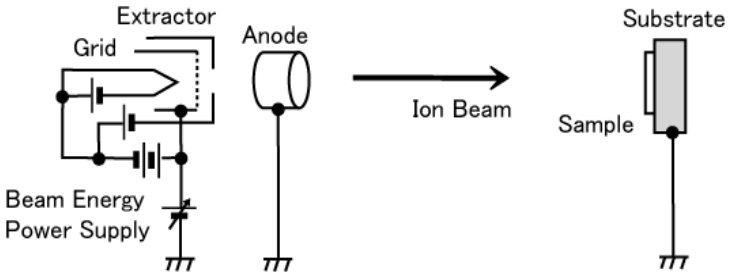

Fig.1 Experimental setup

2.2 Characterization

The samples were analyzed by using AR-XPS, Raman spectroscopy, and FT-IR.

AR-XPS was carried out using Surface Science Instruments SSX-100 which X-ray source was Al Kα 1486 eV. Figure 2 shows a schema of AR-XPS and the profiles were calculated using equation 1.

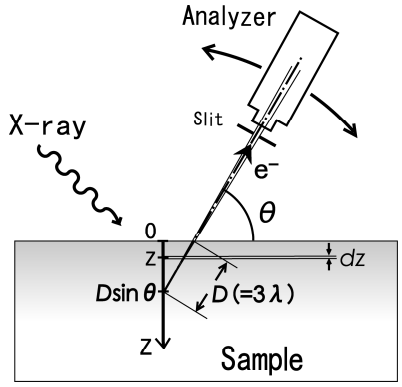

Fig.2 Angle-resolved XPS

$$I = \int dI = \int_0^{D\sin\theta} k(z) S \sigma E n(z) \exp\left(-\frac{z}{\lambda \sin\theta}\right) dz \qquad (1)$$

Where, I is the spectrum intensity in depth at z, $n(z)$ is the depth profile of the composition which corresponds to the number of photoelectrons generated in the depth at z., θ is the photoelectron take off angle, λ is the electron inelastic mean free path, S is the X-ray irradiation area, and $k(z)$ is a compensation function in the measurement device.

Varying θ and detecting I, $n(z)$ is obtained.

Chemical bonding state of carbon was analyzed by using micro Raman spectroscopy of HORIBA Jobin Yvon T-64000 of which spot size was 1 mm and the wavelength for the excitation is 514 nm.

3. Results and discussion

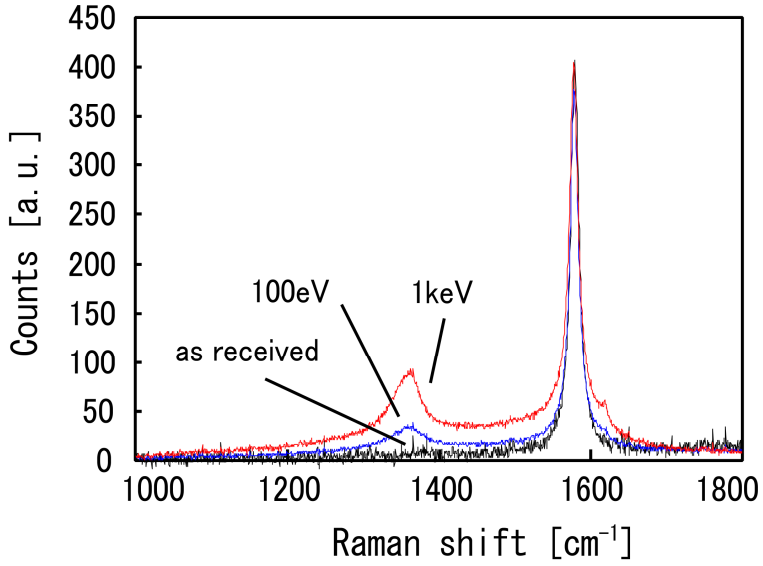
3.1. Structure of modified-layer

Table 1 shows composition of the sample analyzed by XPS. Nitrogen was detected on the irradiated surface. Increasing the energy, nitrogen concentration on the surface was increased. The oxygen contamination was detected several % and was depended little on the ion energy. It is deduced that the oxygen contamination is occurred preferentially after the irradiation.

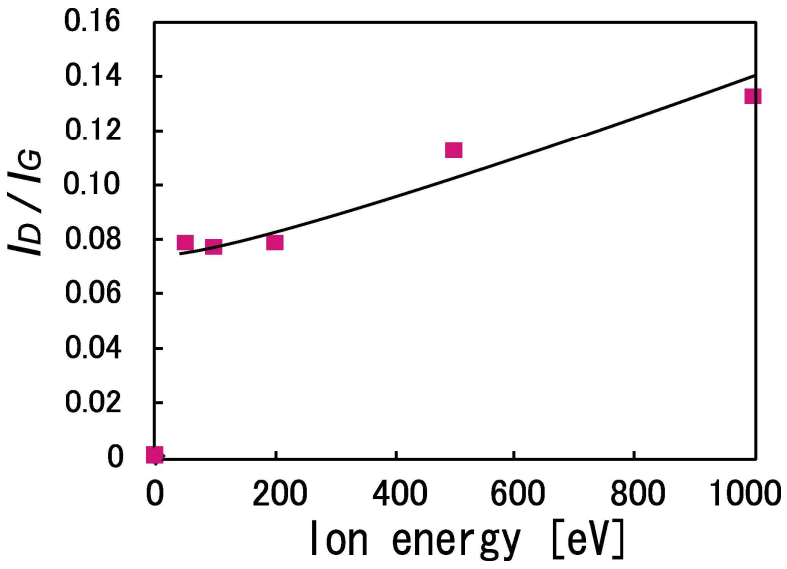
Figure 3(a) shows Raman spectra. Irradiated the samples, G-band at 1560 cm^{-1} decreased and D-band about 1360 cm^{-1} appeared and increased. The result suggests a degradation of C-(sp^2)C and a generation other bonding on the surface by the irradiation. A broad peak around 1450 cm^{-1} appeared. The peak corresponds C-N bonds. Increased with the introduction of nitrogen, an introduction of C-N bonds is expected. On the other hand, the peak is also corresponds to a fluorescence of C-(sp^3)C bonds which often detected using longer excitation wavelength of Raman spectroscopy. Using the excitation light with short wavelength is required to distinguish these bonding states.

Table 1 composition of irradiated sample

Energy [eV]	C [%] ([cps])	N [%] ([cps])	O [%] ([cps])
Reference	95.6 (4739)	0 (0)	4.4 (217)
50	77.8 (3461)	14.2 (634)	8.0 (357)
100	76.5 (3198)	15.5 (648)	8.0 (336)
200	76.9 (3188)	15.3 (633)	7.8 (325)
500	78.9 (3244)	14.5 (595)	6.6 (271)
1000	79.1 (3260)	13.1 (540)	7.8 (321)



(a) Raman spectra



(b) I_D/I_G

Fig.3 Raman spectra and I_D/I_G

I_D/I_G peak ratio of D-band to G-band is shown in figure 3(b). Increased the ion energy, the ratio increased. The increase corresponds a destruction of C-(sp^2)C and a generation of other bonding state. Thus, it is considered that the destruction depends on the increase of the ion energy. On the other hand, increasing the ion energy, an increase of the implantation depth is considered. The analysis depth of Raman spectroscopy is about several 10 nm. Thus, increasing the modified-layer, it is considered that D-band is easily detected. It is also suggested that the increase of D-band is due to an increase of the thickness of the modified-layer.

Figure 4 shows depth profiles of nitrogen in the sample. Nitrogen concentration increased about 2 nm at 100 eV and about 3 nm at 1 keV from the surface. Increasing the ion energy, nitrogen was introduced inner region. Using SRIM2003 calculation in case, the ion range was estimated 0.8 nm at 100eV and 3.5 nm at 1 keV respectively. The implantation depth obtained by the depth profile showed agreement with that of SRIM calculation. The result suggests that the thickness of the modified-layer depended on the ion energy without the structural change. Increasing the energy, the thickness is due to increase.

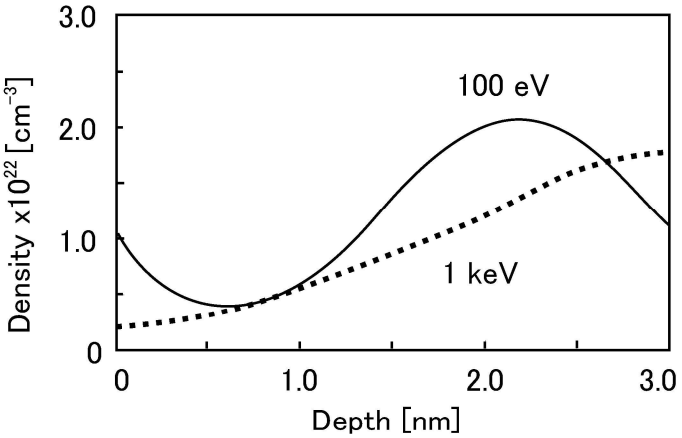


Fig.4. Depth profiles of nitrogen

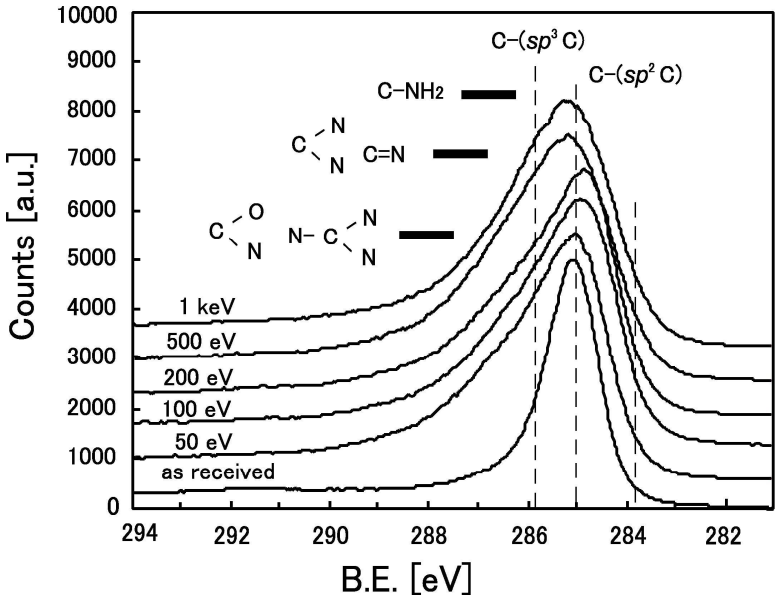
Figure 5 shows C1*s* and normalized N1*s* XP core level spectra. Irradiated the samples, C1*s* spectra were broadened to higher binding energy which contain C-(sp^3)C or C-N bonds. A decrease of the peak about 285eV corresponded to C-(sp2)C suggests a degradation of C-(sp^2)C of HOPG and a formation of the modified-layer on the surface, which shows agreement the spectral change of Raman spectra shown in Fig. 3. N1*s* spectra after the irradiation showed same shape and were depended little on the ion energy. Thus, the chemical bonding state of nitrogen in the modified-layer is depended little on the ion energy. Increasing the ion energy with the same ion dose, increase of the thickness without change of chemical bonding is considered.

The spectrum is able to separate into three peaks A, B, and C which corresponded to C-NH_2 or pyridine like (A), pyrrole like or quarternary nitrogen (B), and N-O (C). However, it is also agreed generally that the peak A and the peak B attributed to CN(sp^3) and CN(sp^2) [6]. Thus, other analysis is required to clarify the chemical bonding state.

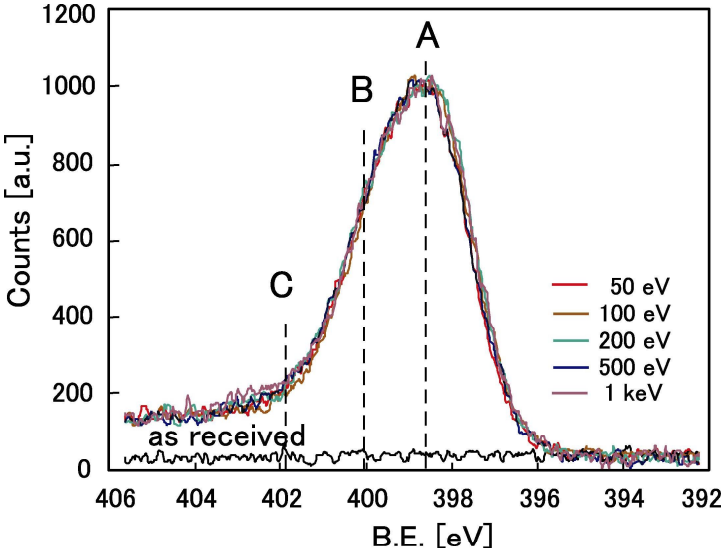
3.2. Introduction process of modified-layer

From the above discuss, it is considered that the structure of the modified-layer does not depend on the ion energy and the introduction is depended on the ion dose. Increasing the ion energy, the thickness of the modified-layer is increased and it is expected that chemical bonding states will be detected using FT-IR.

Figure 6 shows infrared spectra of the samples irradiated with the energy of 1 keV, which obtained by subtraction the spectrum before the irradiation. A peak at 1750 cm^{-1} was detected, which corresponds to oxygen containing groups such as –COOH or >C=O. The peak changed a little by the ion dose.



(a) C1*s*



(b) N1*s*

Fig.5 XP core level spectra

Two peaks at 870 cm^{-1} and at 660 cm^{-1} were detected on the irradiated sample, which correspond to a defect of basal plane. A broad peak around 3200 cm^{-1} corresponds to primary or secondary amines. And, a peak at 1350 cm^{-1} corresponds to anilines. A pyridine like nitrogen was detected as a weak peak around 800 cm^{-1}. A quarternary nitrogen was detected little. Thus, it is considered that irradiated nitrogen is introduced preferentially at the defect or at the edge of basal plane. Increased the ion dose, these peak decreased. It is considered that the defect of the basal plane was increased and the modified-layer was decomposed by increase of the ion dose.

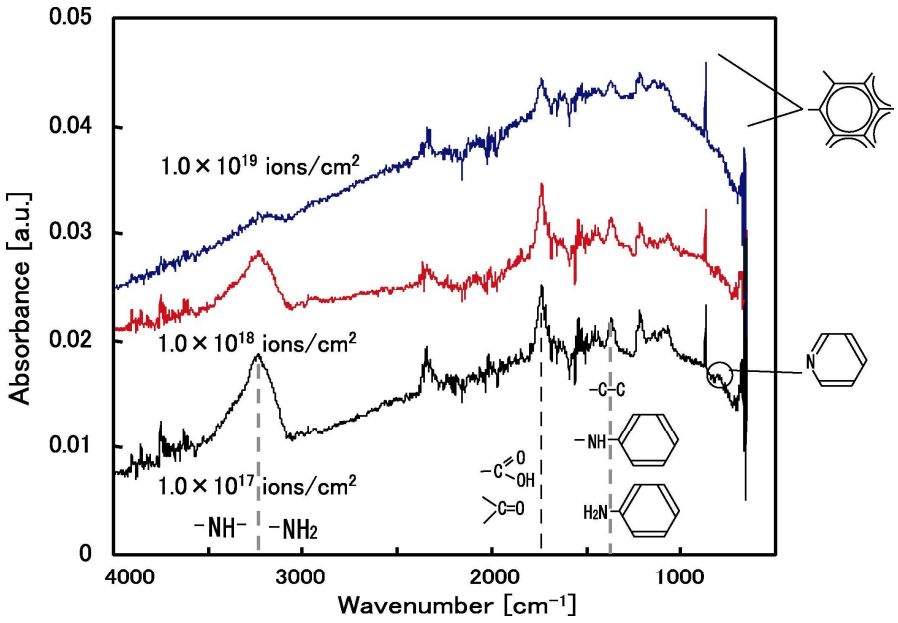


Fig.6 Infrared absorption spectra

4. Summary

The reaction mechanism during low energy nitrogen ion irradiation of HOPG was studied. And, the structure of the modified-layer was characterized. From the result, it was summarized as follows.

(1) Increasing the ion energy, the thickness of the modified-layer increased without structural change.

(2) Increasing the ion dose, the defect of basal plane was increased.

(3) Nitrogen introduction occurred preferentially at edge plane or at the defect of basal plane. And, the formation of pyridine or amine group is suggested.

Abstract
A process involving a subsonic thermal plasma expansion is reported for the synthesis of aluminum nanoparticles. Parametric studies of particle formation were performed. Particles were characterized by scanning mobility particle sizing, scanning and transmission electron microscopy, and electron dispersive X-ray spectroscopy. The produced aluminum particles had number-mean diameters below 20 nm. Particles were found to consist of a crystalline aluminum core encapsulated in a thin oxide surface layer.

Keywords: aluminum nanoparticles, thermal plasma synthesis

Introduction

Energetic materials are chemical compounds or mixtures that store significant quantities of energy. They typically include propellants, explosives, and materials for pyrotechnics. Metals that have been used or considered for these purposes include aluminum, titanium, magnesium, boron, zirconium and beryllium. Among these metals, aluminum has been used extensively [1]. For conventional size solid propellants, the reaction kinetics are largely controlled by mass transport rates between reactants, which establishes the limit of the energy release rate. However, when the particle size is reduced, especially into the nanometer range, the rate of diffusion-controlled processes becomes comparable to that of chemical reactions, resulting in a sharp increase in the rate of energy release [2]. Consequently there has been an increased research effort regarding the use of nano-aluminum in high-energy explosives, and aluminum nanoparticles are claimed to produce more rapid and efficient burning of solid propellants than other existing powders, thus gaining interest for applications such as rocket fuels [3-4].

Compared to other available methods of producing nanoparticles, such as thermal evaporation [5], electrochemical methods [6], and laser methods [7], thermal plasma methods can achieve high-rate synthesis of nanoparticles. Because of the high temperatures in the reaction zone, thermal plasmas can be used for complete dissociation of reactants into their elements. This leads to considerable chemical flexibility with regards to reactants.

Experimental procedures and results

A schematic of the particle synthesis apparatus and associated diagnostics is shown in Figure 1. An argon-hydrogen plasma is generated by a DC arc at near-atmospheric pressure, and is expanded in subsonic flow through a ceramic nozzle to ~53 kPa pressure. The main plasma gases, argon at a flow rate of 30 slm and hydrogen at 0.5 slm, are controlled by mass flow controllers. $AlCl_3$ was used as the aluminum precursor. $AlCl_3$ is a powder at room temperature, with a normal sublimation temperature of 183°C. $AlCl_3$ vapor was generated by subliming $AlCl_3$ powder (anhydrous, reagent grade, Alfa Aesar) in a packed bed similar to the one used by Powell et al [8]. The packed bed is composed of a stainless steel tube filled with 5-mm-diameter glass beads (Chemglass Inc.). Heating wire follows a serpentine path inside the bed to facilitate uniform heating in the range of 165-180°C. Preheated argon, with flow rate ranging from 100-200 sccm, was used to mix and carry the $AlCl_3$ vapor from the packed bed to the reactor. The amount of $AlCl_3$ vapor introduced into the reactor was determined from calibration runs in which the packed bed was weighed before and after a period of reactant injection. The $AlCl_3$ feed rate is affected by the flow rate of argon carrier gas. The mixture of heated argon and $AlCl_3$ vapor is delivered to the reac-

tion chamber through well insulated lines, and through an injection ring and nozzle ports into the plasma. The injection ring and nozzle ports are water cooled, which potentially causes the problem of $AlCl_3$ condensation and clogging of the feed path. To avoid this both the injection ring and the nozzle ports are internally wrapped with mica insulation.

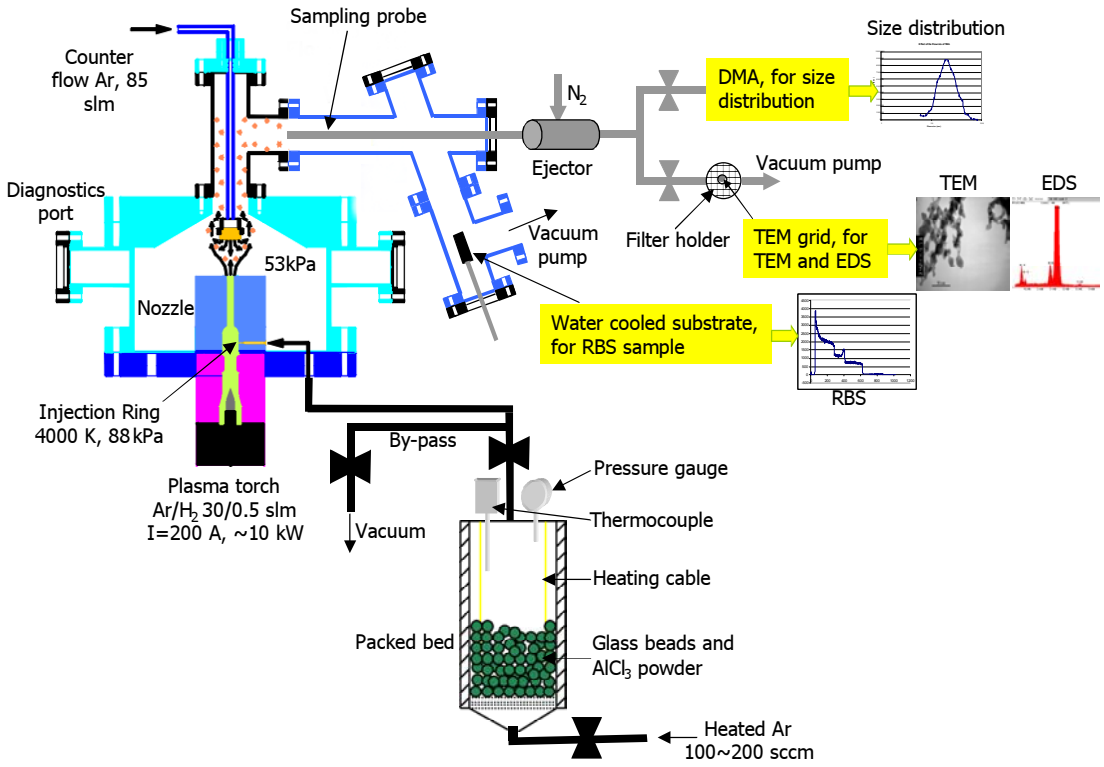

Figure 1. Schematic of system for synthesizing and characterizing aluminum nanoparticles.

Based on modeling of temperature profiles, aluminum particles are expected to nucleate near or shortly downstream of the nozzle exit. A cold argon counterflow opposes the plasma jet exiting the nozzle. The purpose of the counterflow is to provide dilution and cooling, so as to reduce both particle coagulation and particle-particle coalescence, thereby maintaining small primary particle size. Balancing of the momenta of the plasma jet and the counterflow produces a stagnation layer, as seen in Figure 2.

For on-line size distribution measurements a capillary sampling probe is inserted into the reactor downstream of the counterflow tube. The sample passes to a two-stage nitrogen ejector, which dilutes it typically by a factor of approximately 6000, thereby suppressing further coagulation and particle growth. The diluted sample then passes to a scanning mobility particle sizer (SMPS), which consists of a differential mobility analyzer (DMA, TSI model 3085) in series with a condensation particle counter (CPC, TSI model 3007). Measurements of particle size distributions were obtained for various sets of operating conditions. Conditions that varied included the hydrogen flow rate, the flow rate of the argon carrier gas containing the $AlCl_3$ vapor, and whether the argon counterflow was on or off. The hydrogen flow rate was found to have little effect on particle size distributions for the range of flow rates tested (0.5-2.5 slm), and thus only the 0.5-slm case is reported here.

Figure 3 shows measured size distributions for various reactant carrier gas flow rates. By weighing the packed bed before and after the experiment, it was determined that the 200-sccm carrier gas case corre-

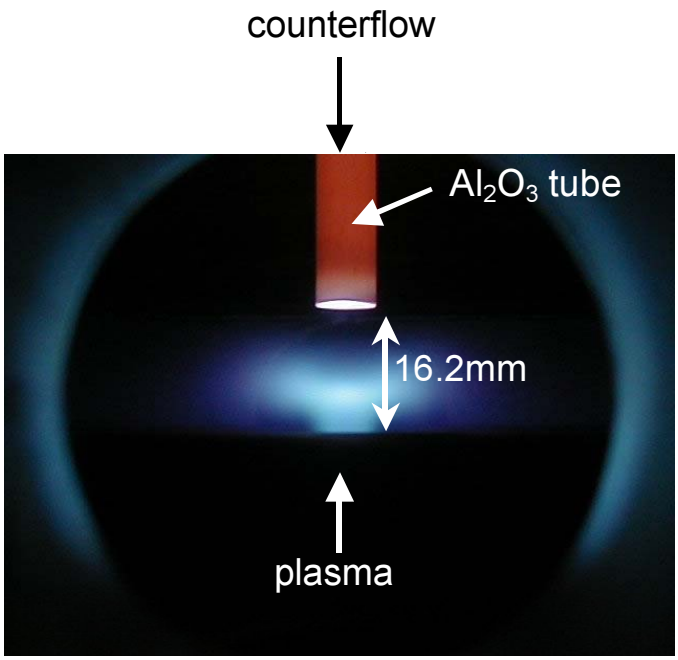

Figure 2: Photograph of stagnation layer obtained with a counterflow of 85 slm argon. A small amount of methane has been added to the counterflow to enhance the stagnation layer luminosity.

sponded to a $AlCl_3$ vapor flow rate of ~20 sccm. For given packed bed temperature the $AlCl_3$ vapor flow rate scales on the carrier gas flow rate. Higher precursor flow rates are seen to produce higher particle concentrations, which in turn favors particle coagulation, resulting in larger values of number-mean particle diameter. For the above running conditions (200 sccm carrier gas, counterflow on), SMPS measurements show a peak in the particle number distribution around 17 nm.

A counterflow configuration has previously been used to control particle size and size distribution [9]. Figure 4 shows measured particle size distributions with and without use of counterflow. The decrease in particle concentration with counterflow corresponds with the dilution due to the counterflow. This decreased particle concentration causes coagulation to be reduced, and therefore the mean particle size is smaller in the case with counterflow on.

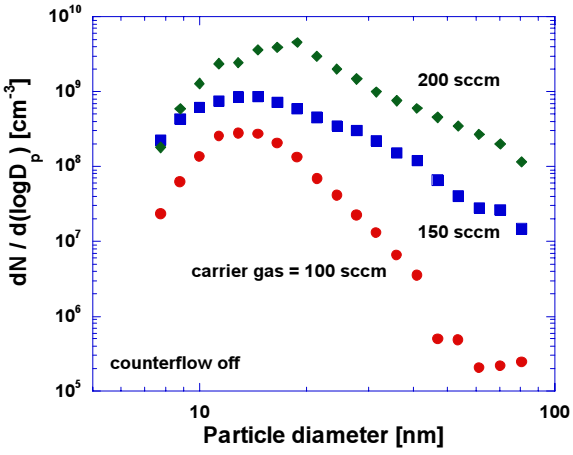

Figure 3. Measured particle size distributions for various flow rates of the reactant carrier gas.

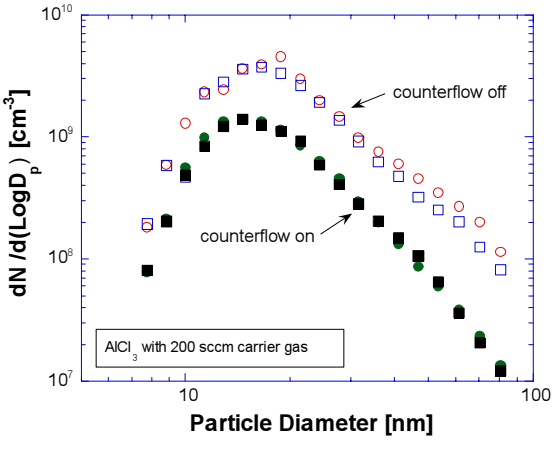

Figure 4. Measured particle size distributions, with and without use of counterflow.

Samples for scanning electron microscopy (SEM) were obtained from the orifice plate inside the dilution ejector. SEM analysis was obtained with a JEOL-6500 FEG SEM at 15kV operating voltage and a working distance of 9.5 mm. Transmission electron microscope (TEM) grids were placed on a filter holder downstream of the ejector. TEM images were obtained with a JEOL 1200 (accelerating voltage ~120kV) and, for high-resolution TEM (HRTEM), a FEI Tecnai G2 30 FEG (accelerating voltage ~300kV).

An SEM image of particles produced in the base case experiment is shown in Figure 5. Particles appear to be spherical and unagglomerated. An example of a TEM micrograph of aluminum particles produced in the base case and deposited onto a filter holder located downstream of the ejector is shown in Figure 6. The TEM image indicates that these particles are mostly smaller than 20 nm, consistent with the SMPS measurements. Energy dispersive X-ray spectroscopy (EDS) analysis of these particles is shown in Figure 7. The EDS spectrum shows a clear aluminum peak, and also indicates the presence of oxygen.

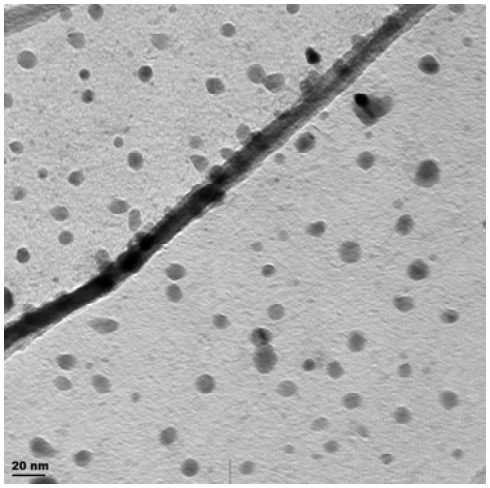

Figure 6. TEM image of particles deposited onto filter holder located downstream of ejector. Long wire in image is from TEM grid.

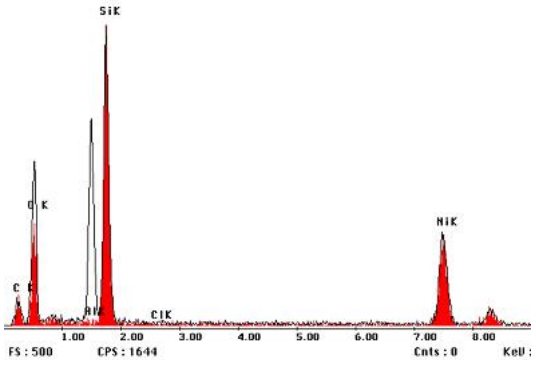

Figure 7. EDS analysis of particle elemental composition. Shaded peaks are from the background signal due to the C-coated Si_3N_4 TEM grid.

Aluminum nanoparticles readily oxidize when they are removed from the reactor, as a result of which it is difficult to obtain TEM analysis of bare Al particles. A previous surface characterization study [10] showed that when Al nanoparticles are exposed to air for a short time they became covered with a < 5-nm-thick amorphous and compact surface oxide layer. Figure 8 shows HRTEM images of a relatively large (~125-nm diameter) particle. The image shows that this particle has an amorphous layer with a thickness of 2-5 nm. The (111) lattice fringe shown in the circled area of the image on the right has a measured lattice spacing of 2.344 ±0.013 Å, in good agreement with the lattice spacing for (111) aluminum of 2.338 Å [11]. Combining these observations with the EDS measurements, one can conclude that the particles have a crystalline aluminum core with an amorphous oxide coating, consistent with results from the literature [10]. Due to the highly pyrophoric property of aluminum particles, especially when the particles are in the nanoscale size range, the particles need to be isolated from contact with air. Partially oxidizing the particles to form a thin alumina layer at the surface is one easy and common way to accomplish this, as the oxide layer can inhibit further diffusion of oxygen, thereby maintaining the aluminum core. However, from the viewpoint of potential applications for the aluminum nanoparticles, for example as solid propellants, a drawback of this approach is that the oxide layer is a barrier to reaction, as the oxide layer must crack open before combustion can occur. An alternative approach is to coat the particles with a non-oxide passivating layer of some other substance, possibly a polymer, that can serve as a diffusion barrier to oxygen until the shell is burned off. A study of such an approach is currently in progress.

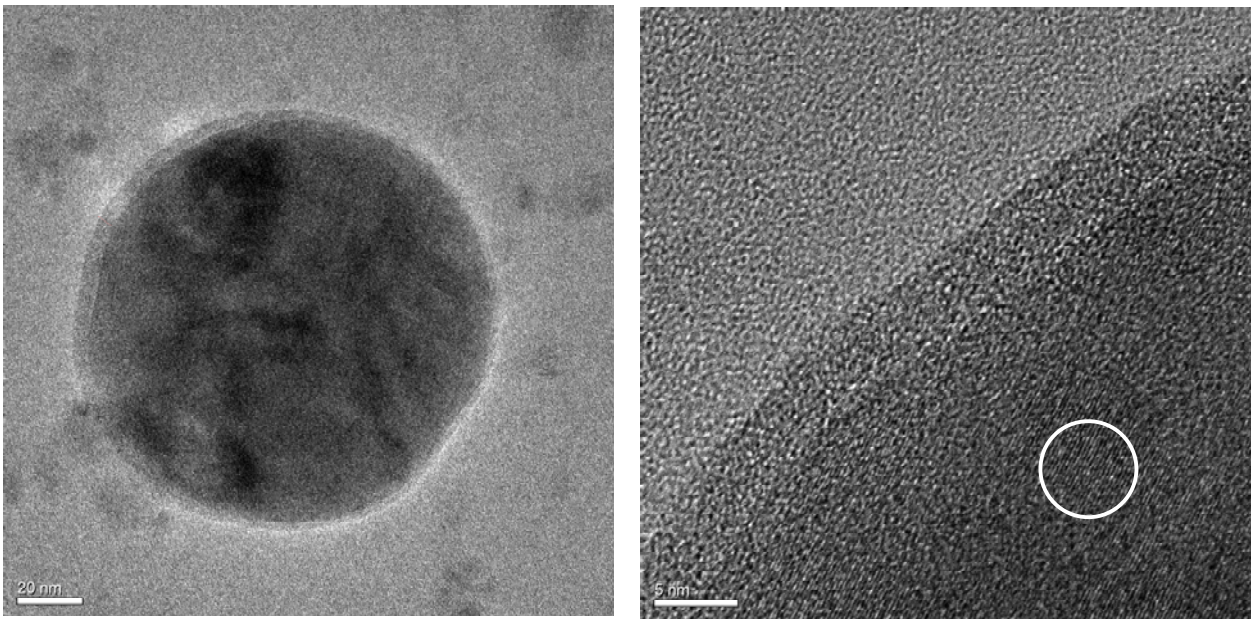

Figure 8. High-resolution TEM images of an aluminum particle with an amorphous surface layer. Circle on image on right highlights lattice fringes associated with (111) aluminum.

Conclusions

A DC thermal plasma process has been used to produce aluminum nanoparticles with the use of $AlCl_3$ vapor as precursor. Number-mean particle sizes were below 20 nm. Spherical, nonagglomerated aluminum particles were obtained, coated with a thin oxide layer. Particle concentrations and size are affected by the $AlCl_3$ vapor flow rate and by the use of a cold counterflow. Studies are in progress to further control the particle size and to passivate these pyrophoric particles by forming suitable coatings.

Abstract
Nitrogen solubility in Fe-Cr alloys treated in H_2+N_2 abnormal glow discharge (AGD) is investigated at different temperatures for a better understanding of the thermodynamic process. The glow was sustained by a DC pulsed source with 700 V of amplitude and variable pulse width to adjust the AGD power and thus, the sample temperature. Sample temperatures were between 860 and 1100°C a discharge pressure of 10 Torr. For times between 15 and 60 minutes mass yielding of the samples was measured after treatment and its structure analyzed by X-ray diffraction. With a increase in chromium content a mass increase is observed after AGD treatment. Samples with chromium content higher than 13%, partially transform its initial ferritic structure to austenitic and CrN structures at 950°C. At a temperature of 1100°C only samples with 28% chromium content showed any structural transformation after 60 minutes. In iron samples the role of the sputtering processes evidently predominates over the thermodynamic ones due to the loss of mass and its unchangeable structure, after abnormal glow discharge treatment.
Keywords: Nitrogen absorption, Low pressure Abnormal Glow Discharge, Thermodynamic process.

1. Introduction

The equilibrium content of nitrogen [N] in steel depends on three variables of state: temperature T, nitrogen partial pressure P_N and the alloy concentration of the steel. Equation (1) allows quantifying the different possibilities of enhancing the poor solubility of pure iron [1]

$$\ln[N]_{Fe-X} = \ln[P_N] - e_N^X[X] - \frac{\Delta H_o}{RT} - \frac{\Delta S_o}{R} \qquad (1)$$

An increase in the partial pressure of the nitrogen and the addition of an alloying element *X* with negative interaction parameter e_N^X (see Table 1[2,3]) will support the nitrogen solubility. Because ΔH_o is proportional to e_N^X a ternary high chromium alloy (e_N^X <0) will show a decrease of nitrogen solubility in all three phases upon heating as shown in Figure 1 [4,5].

Nitrogen solubility in steel can be achieved in the cathode of an abnormal glow discharge (AGD) with nitrogen atmosphere [6]. The N_2+H_2 gaseous mixture is a good atmosphere for the AGD nitrogen absorption process because it provides a better energetic distribution of nitrogen ionic species [7] and improves the interaction of nitrogen species with the cathode surface [8]. Recent works also shows that N_2+H_2 atmosphere with very low partial pressure of H_2 decreases the AGD power and enhance the nitrogen transference of plasma to alloy sited on the discharge cathode [9].
In this work nitrogen solubility in Fe and Fe-Cr alloys, treated in N_2+H_2 AGD, is investigated at different temperatures to better understand the thermodynamic process.

2. Experiment

The samples used were cylinders with 8,70 mm in diameter and height of between 3,50 and 4,50 mm prepared by powder metallurgy standard procedures [10,11], utilizing iron carbonyl powder and master alloy powder of 74% chromium content. Pure iron samples were also submitted to this process. Table 1 shows chromium content of Fe-Cr alloys submitted to nitrogen absorption on the cathode of 80% $N_2$and 20% H_2 AGD. Pressure was 10 Torr and flux 4 cm^3/s. The glow was sustained by a DC pulsed source of a rectangular

Table 1-Chromium contents of Fe-Cr alloys measured by EDX.

Alloy	1	2	3	4
Cr (% in mass)	13,9	18,7	23,6	28,4

signal with a 700 V amplitude and pulse variable width (8-180μs) to adjust the AGD power and thus, the sample temperature. Before nitrogen treatment the samples were cleaned during 15 minutes in 80%Ar+20%H_2 AGD [9,10] at a pressure of 10 torr a flux of 4 cm^3/s and temperature 900°C. Treatment temperatures were between 860 and 1100°C during 15 minutes. Nitrogen absorption times up to 60 minutes at 1100°C were also used.

After treatment, sample mass variation was measured with a four figure electronic balance. Structural analysis of the treated samples was carried out by X ray diffraction (XRD) with Cu K_α radiation.

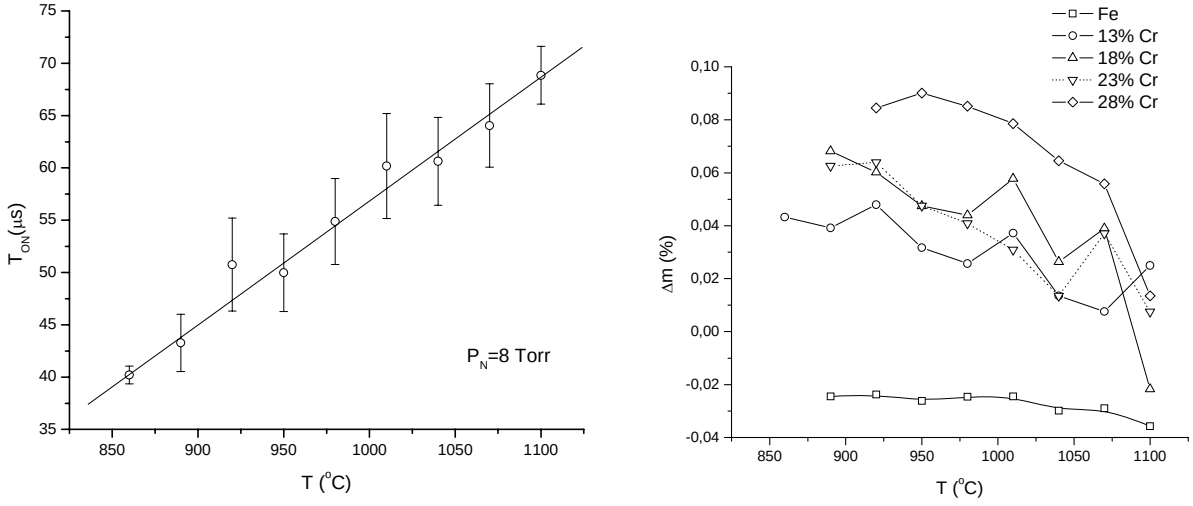
3. Results and discussion

3.1. Power versus Temperature

Figure 2(a) shows the relationship between temperature and power (Pulse width: T_{ON}) in 80% N_2+20% H_2 AGD used in the nitrogen absorption process. Temperature increases from 40 to over 78 μs as a result of greater number of ions and neutrals impinging on the cathode surface and then transferring their kinetic energy [12,13] when pulse width is increased at the same pressure, gaseous mixture and flux conditions.

3.2. Nitrogen absorption

Figure 2b presents mass yielding (Δm) obtained by the samples after nitrogen absorption in AGD. The decrease in Δm with the temperature observed in Figure 2b could be related to the thermodynamic behavior of Fe-Cr alloys (Equation 1) which predicts a nitrogen loss when the temperature is increased [4,5]. Besides thermodynamic considerations, the sputtering process, inherent to AGD, could also influence the mass yielding by causing it decrease when the temperature is increased. This is because temperature increase is associated to an increase of T_{ON}, as shown in Figure 2b, and also the quantity of ions and neutrals that impact the sample surface per pulse. Thus, when temperature is increased, the sputtering process decreases Δm. It is



(a) **(b)**

Figure 2-a) Cathode temperature of AGD versus discharge power (T_{ON}) and b) sample mass variation versus temperature during 15 minutes of treatment.

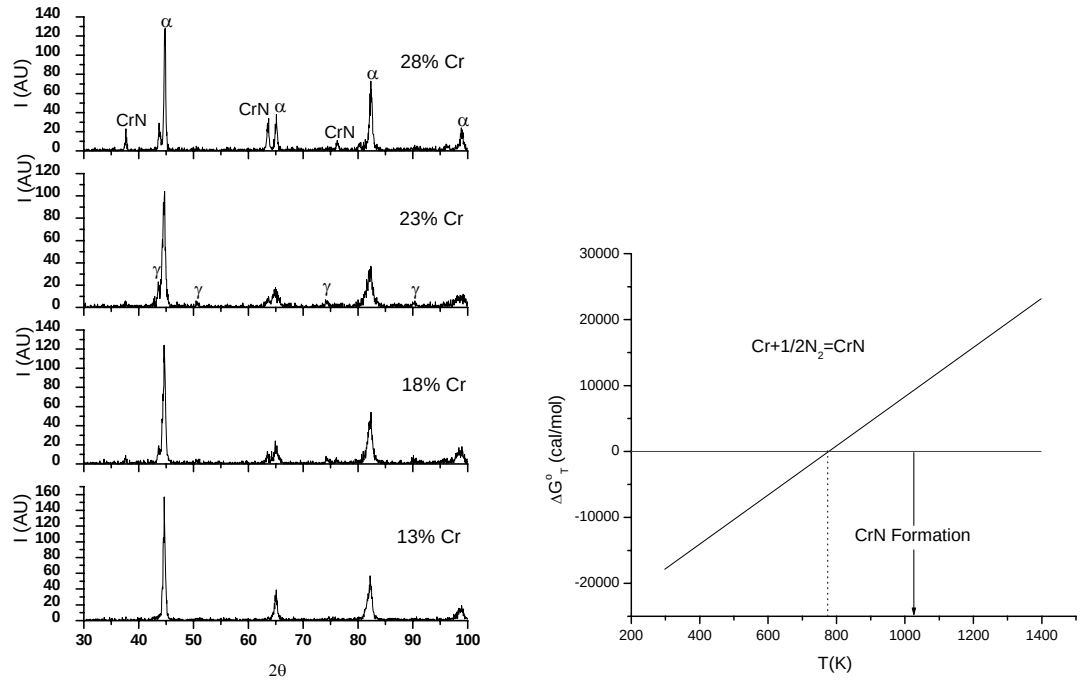
difficult to determine the contribution of each competitive process (thermodynamic of Fe-Cr system and sputtering) on Δm increase and in some cases, it is only possible to observe the dominant process. That is, when Δm is positive, it is the thermodynamics of the nitrogen absorption in Fe-Cr system, which predominate. On the other hand, when Δm is negative, the sputtering is the predominant process.
The increases in Δm with a chromium content, shown in Figure 2b, also agrees with equation 1 when Δm is considered as a function of the chromium content, in Fe-Cr alloy, and the interaction parameter (e_N^X see Table 1) of it alloy is included.
Iron samples showed a Δm negative at all temperatures in N_2+H_2 AGD which reveals that sputtering prevails over the thermodynamic process of nitrogen absorption by the iron network in these experimental conditions. Nitrogen absorption in iron at the temperatures used would need much higher nitrogen partial pressure similar to gaseous metallurgical process [1]. Indeed, energetic nitrogen species yielded in AGD can be sufficient to satisfy the nitrogen absorption requirements in Fe-Cr stainless steel alloys, at these temperatures, but this in not sufficient for pure iron where nitrogen solubility is very poor [14,15].

3.3-XRD

XRD spectres of Fe-Cr alloys submitted to AGD at 950°C during 15 minutes are shown in Figure 3a for all chromium content utilized. Besides the characteristic peaks of Fe-Cr alloy ferritic structure (α), diffractograms of Figure 3a also shows an austenitic phase (γ) and chromium cubic nitride (CrN) peaks in samples with chromium content higher than 13%. Thus, nitrogen absorption partially transform the existing ferritic phase, in these alloys, and promotes the appearance of austenite and chromium nitride with chromium content of 21% which was studied by Quiu [16].
Because of the absence of any additional structure in samples with 13% of chromium, the nitrogen must be in solid solution in its original crystalline network.
Chromium nitride observed by XRD presents a formation free energy $\Delta G_T°$ as a function of the temperature as shown in Figure 3b for 1 atm of nitrogen pressure [17]. As shown in Figure 3b, at a nitrogen partial pressure of 10 Torr and a temperature of 950°C, CrN formation is not possible from a thermodynamic point of view. However, in the presence of plasma, as studied by Vepřek [18], the equilibrium temperature of thermodynamic systems can be changed and reaction rates can also be increased. Here, favorable conditions are generated by the presence of energetic species rich in nitrogen, coming from the cathodic region, so, thermodynamic equilibrium is dislocated to regions of higher temperatures and CrN kinetic formation is favoured. These chromium nitride precipitates were produced at yet higher temperatures (950°C) than those predicted in Figure 3b (~800K).
Nitrogen absorption at 1100°C only reports structural changes for samples with 28% of chromium content, after 60 minutes (as shown in diffractogram of Figure 4). Under these conditions the nitrogen quantity absorbed is sufficient to promote α→γ structural transformation in Fe-Cr alloy but is not sufficient for CrN formation. Nitrogen absorbed in samples with lower chromium content must be insufficient to saturate the ferritic network and thus transform their structures.
Iron samples didn't show any structural transformation after AGD treatment under the conditions used in this work. This confirms the previous results shown in Figure 2b where the sample presents loss of its mass. In pure iron, sputtering is the process that prevails over a possible thermodynamic process in the Fe-N system. In fact, at higher temperatures than 950°C and lower pressures utilized in AGD, all iron nitrides are not stables [19]. This also explains why iron nitrides do not appear in the structures of Fe-Cr stainless steel studies.

4. Conclusions

After Fe-Cr alloys were treated in AGD under the above mentioned conditions the following conclusions may be drawn:
Temperature decreases mass yielding of Fe-Cr alloys in AGD, as does the gaseous metallurgical process.



(a) **(b)**

Figure 3-a) XRD of Fe-Cr alloys after 15 minutes in N_2+H_2 AGD at 950°C and b) Formation free energy against temperature for CrN at 1 atm nitrogen pressure.

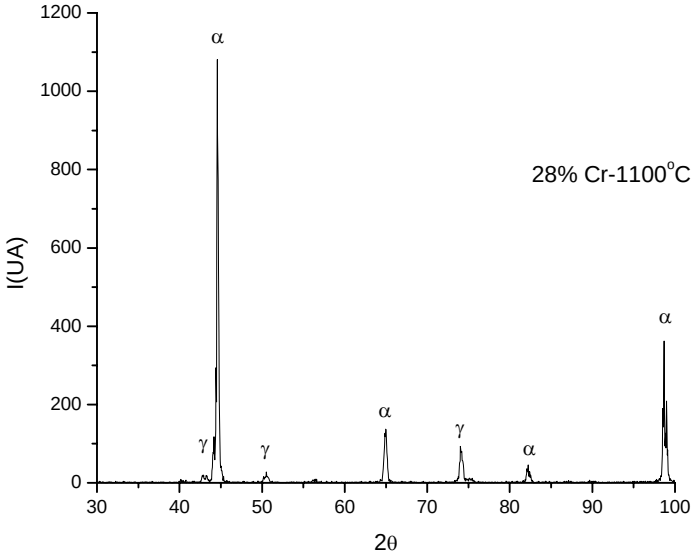


Figure 4-XRD for 28% Cr sample after 60 minutes in AGD at 1100°C.

Mass increase in Fe-Cr stainless steel alloys made evident the role of chromium in attracting nitrogen to wards the inside of the iron alloys, which agree with the thermodynamic behavior of the gaseous metallurgical process.

Nitrogen absorbed by samples with chromium content higher than 13% changed its ferritic structure to nitrogen austenite and NCr precipitates.
Nitrogen absorbed by 13% chromium alloy may be in solid solution in its crystalline network.
At 1100°C the nitrogen supply by the AGD is not sufficient to satisfy the thermodynamic requirements of nitrogen absorption in Fe-Cr alloys. To increase the quantity of nitrogen absorbed it may be necessary to increase the treatment time or the chromium content of the alloy.
In iron samples the sputtering is the predominant process and the thermodynamic processes inherent in the Fe-N system are absent.

Experimental Studies on a Sub-microsecond Pulsed Dielectric Barrier Discharge at Atmospheric Pressure

XinPei Lu and Mounir Laroussi
Electrical and Computer Engineering Department &Center for Bioelectrics
Old Dominion University, Norfolk, VA 23529

ABSTRACT:

In this paper, non-thermal atmospheric pressure plasma is generated by a pulsed dielectric barrier discharge with different mixtures of helium and nitrogen. The gas temperature is found to be about 350K. The UV emission power density, P_{UV}, reaches its highest level when 5 to 10 percent N_2 is mixed to a balance of helium. Further, the emission spectra show that the UV is emitted by NO. In addition to NO, excited N_2, N_2^+, OH and He are also present in the plasma. The concentrations of NO and NO_2 are also measured.

Keywords: Pulsed Discharge, UV, Radicals, Atmospheric Pressure, Cold Plasma.

I. INTRODUCTION:

Because of their enhanced chemistry at low operating temperatures, atmospheric pressure non-thermal plasmas have recently become the enabling technology in several emerging novel applications such as surface modification of polymers, biological and chemical decontamination of media, and aerodynamic drag reduction and shock wave mitigation [1-3].

To enhance the ionization and excitation processes, fast rising voltage pulses (pulse widths from tens to hundreds nanoseconds range) were suggested by several researchers. Liu and Neiger [4,5] and Laroussi et al. [6] applied sub-microsecond unipolar pulses to dielectric barrier discharges (DBD) at low pressure and high pressure, respectively. Liu and Neiger [4] found that the energy efficiency for ozone synthesis is 30% higher with pulsed DBD than that driven with sine wave voltages. Mildren and Carman [7,8] found that the UV power output from a xenon excimer lamp driven by ~150ns short pulses had an energy efficiency three times higher than the same lamp excited by sine wave voltages.

An attractive feature of pulsed discharges is that two consecutive plasma ignitions occur per each applied voltage pulse. The first ignition occurs at the voltage pulse rising edge, and the second at the falling edge of the voltage pulse [4-6]. The second discharge ignites without energy input from the external circuit, the required voltage being provided by the accumulated surface charges left from the first discharge. This process ultimately leads to a much improved power transfer to the plasma.

In this paper, a study of the UV emission and active species generation efficiency from an atmospheric pressure pulsed DBD for various gas mixtures containing different percentages of He and N_2 is presented. First, a brief discussion on the current-voltage characteristics of the discharge is presented. Then, the gas temperature is measured by comparing the experimental N_2(C-B) 0-0 transition spectrum with simulation results. This is followed by a detailed study of the UV emission power density from the discharge for different percentages of He and N_2 and different pulse frequencies. To identify the excited species responsible for the UV emission and other chemically important species, emission spectroscopy was used. Because of the presence of oxygen (from residual traces of air), molecules such as NO and NO_2 were formed. Therefore, a calibrated multi-gas detector was used to measure the absolute concentrations of NO and NO_2 for different pulse frequencies.

II. EXPERIMENTAL SETUP

The discharge device comprises two parallel electrodes separated by a gap. One of the electrodes is made of a 2" x 2" aluminum plate covered by an alumina (Al_2O_3) sheet (See Figure 1). The dimensions of the Alumina sheet are: 75mm × 75mm × 1mm. The second electrode is made of a copper disc (diameter of 5.7 cm) with several holes through which the operating gas is injected. The diameter of the holes is about 1mm. The distance between nearby holes is 5mm. This copper electrode is not covered by a dielectric. The distance of the gap between the electrodes is adjustable from 1mm to few centimeters. The gas flows out of the holes and into the discharge gap. A multi-gas manifold with flow meters was used to adjust the percentage of He and N_2. The

plasma was driven by a pulse generator capable of producing narrow high voltage pulses (pulse width few hundreds ns) at adjustable repetition rates. Detailed description of the pulsed power supply can be found in [6].

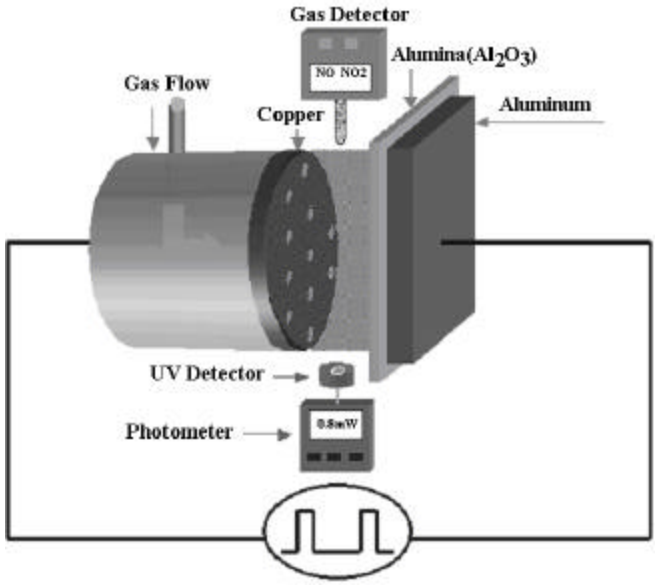

Fig. 1 Experimental setup of the discharge system with diagnostics.

For the identification of excited species and the determination of gas temperature, optical emission spectroscopy (OES) was conducted with a half-meter spectrometer (Acton Research SpectraPro 500i). To carry out absolute measurements of the emitted UV power, a radiometer/photometer (International Light. Inc. Model: IL1400A)(165-310nm) was used. The distance from the UV detector to the axis of the copper disk was 6cm. To identify the excited species responsible for the UV emission, and the other chemically important species present in the plasma, emission spectra in the 200-800nm range were recorded. The absolute concentrations of NO and NO_2 were measured by a multi-gas detector (RAE System: Model PGM-7840). The gas detector was located 1cm from the plasma surface.

III. EXPERIMENTAL RESULTS

Except when indicated otherwise, the following experimental results were obtained when the applied voltage, pulse width, and the gap distance were set to V_a=9kV, t_{PW}=500ns, and d_{gap}=2mm, respectively.

3.1 Current-Voltage Characteristics

Figure 2 shows the applied voltage pulse, V_a, the voltage across the dielectric, V_d, the voltage across the gas gap, V_g, and the corresponding discharge current, I_{dis}. Helium with traces of air was the operating gas. The voltage pulse repetition rate is 1 kHz. Two distinct current pulses indicating two consecutive discharges are clearly visible. The first pulse occurs at the rising front of the voltage pulse and the second current pulse occurs at the falling front of the voltage. These two current pulses are about 100 ns wide. The current curve shown in Figure 2 represents the actual discharge current, which was obtained by subtracting the displacement current (due to cable capacitance, the dielectric equivalent capacitance, and the gas gap equivalent capacitance) from the total measured current [6].

The voltage across the dielectric is calculated by the ratio of the time integral of the current through the DBD and the dielectric capacitance, C_d (C_d = 145 pF) [6]. The voltage across the gas gap is simply given by: $V_g = V_a - V_d$. Note that V_g exhibits a negative pulse when the applied voltage, V_a, decays. This negative pulse is induced by the charges previously collected on the surface of the dielectric plate. It is this voltage pulse that is responsible for the re-ignition of the discharge and the occurrence of a second current pulse at the falling edge of the applied voltage pulse.

Figure 3 shows the total power supplied or received by the power supply, P_{supp}, and the power dissipated in the plasma, P_{gas}. P_{supp} is the product of the total current supplied by the power source and the applied voltage

V_a. P_{gas} is the product of I_{dis} and V_g. During the first rising front of the applied voltage P_{supp} includes both the power dissipated in the plasma and the reactive power stored in the various capacitors (cable, dielectric, and gas). At the falling front of the applied voltage the sign of P_{supp} is negative which represents a power returned to the power source. The curve representing P_{gas} shows the power dissipated in the plasma during the first and the second discharge.

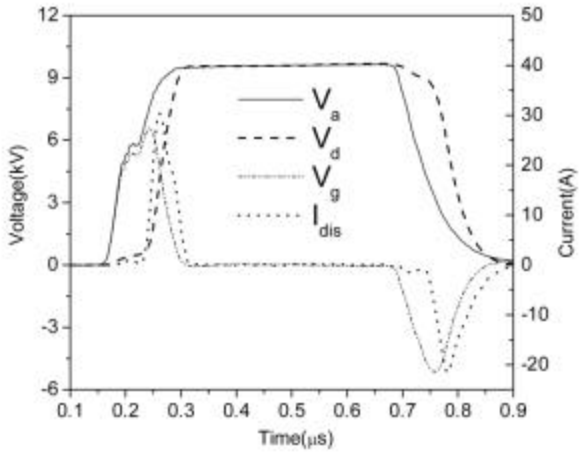

Fig. 2 Applied voltage, V_a, voltage across the dielectric, V_d, voltage across the gas gap, V_g, and the discharge current, I_{dis}, versus time. Operating gas: Helium with traces of air . Gap distance is 2.5 mm and pulse rep-rate is 1 kHz. [6]

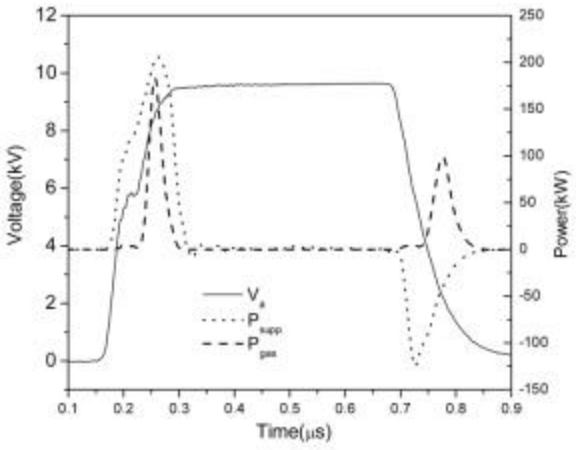

Fig. 3 Applied voltage, supply power, P_{supp}, and gas dissipated power, P_g, versus time. When P_{supp} is positive the power is supplied from source to load, and when P_{supp} is negative the power is restored from load to source [6]

3.2 Gas Temperature Measurement

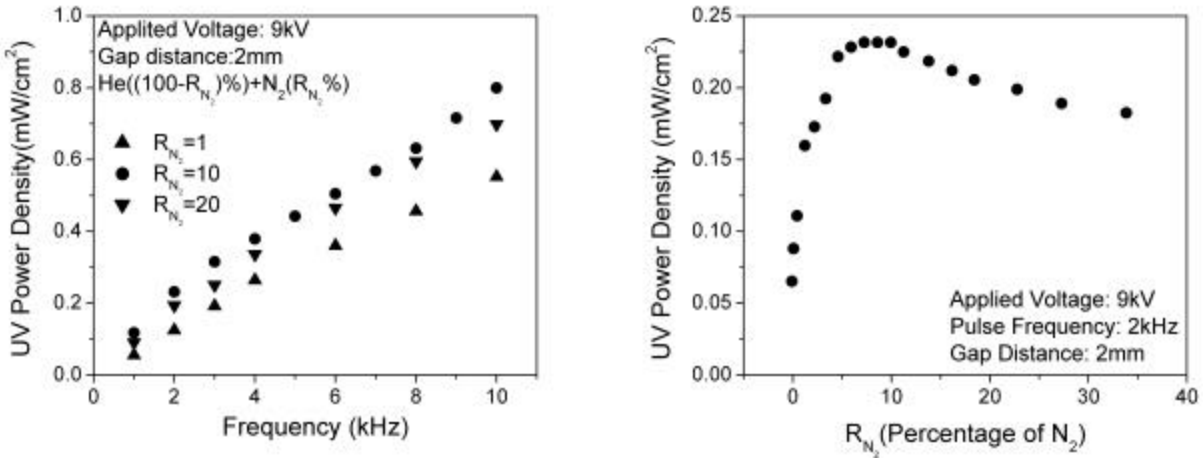
One of the attractive features of non-equilibrium plasmas is that the gas temperature remains close to room temperature. Here, the gas temperature was determined by analyzing the rotational structure of the N_2 second positive system emission. This rotational structure contains information on the rotational temperature. Because of the low energies needed for rotational excitation and the short transition times, molecules in the rotational states and the neutral gas molecules are in equilibrium. Therefore, the gas temperature can be directly inferred from the rotational temperature [9]. To determine the gas temperature, we compared the experimentally measured spectra with simulated spectra of the 0-0 band of the second positive system of nitrogen at different temperatures. It was estimated that the gas temperature was about 350K for helium plasma. When different percentages of N_2 were added to helium, it was found that the gas temperature did not change appreciably. In addition, when the pulse frequency was increased from 1kHz to 10kHz, the gas temperature only increased slightly (less than 50K).

3.3 UV Power Measurement

The integrated UV power emitted by the discharge was measured for various mixtures containing different percentages of He and N_2. When only helium is used as operating gas, the emitted UV power density, P_{UV}, increased linearly with the pulse frequency, reaching about 0.18mW/cm^2 at 10kHz. When only nitrogen is used P_{UV} initially increased with the pulse frequency, but around 6 kHz, it reached a saturation value of about 90 μW/cm^2.

To optimize the UV emission power density, helium mixed with different percentages of N_2 was used. Figure 4(a) shows that, for three different percentages of N_2 in a He balance, P_{UV} increases linearly with pulse frequency, and is much higher than that when only He or N_2 is used. According to Figure 4(a), P_{UV} is highest when 10 % of nitrogen (He(90%) + N_2(10%)) was used. In this case, P_{UV} is more than 4 times higher than that of the helium only case. To further investigate how the percentage of N_2, R_{N2}, affects P_{UV}, we measured P_{UV} with

He((100- R_{N_2})%)+ N_2(R_{N_2} %) as operating gas mixtures at a fixed pulse frequency of 2kHz. Figure 4(b) shows that, when the percentage of N_2 was increased from 0 to 5 percent, P_{UV} increased from about 0.07mW/cm^2 to 0.23mW/cm^2. Increasing the percentage of N_2 up to about 10 percent did not greatly affect the value of P_{UV}. However, further increase of N_2 beyond 10% led to a decline in P_{UV}.



(a) (b)

(R_{N2}: percentage of N_2)

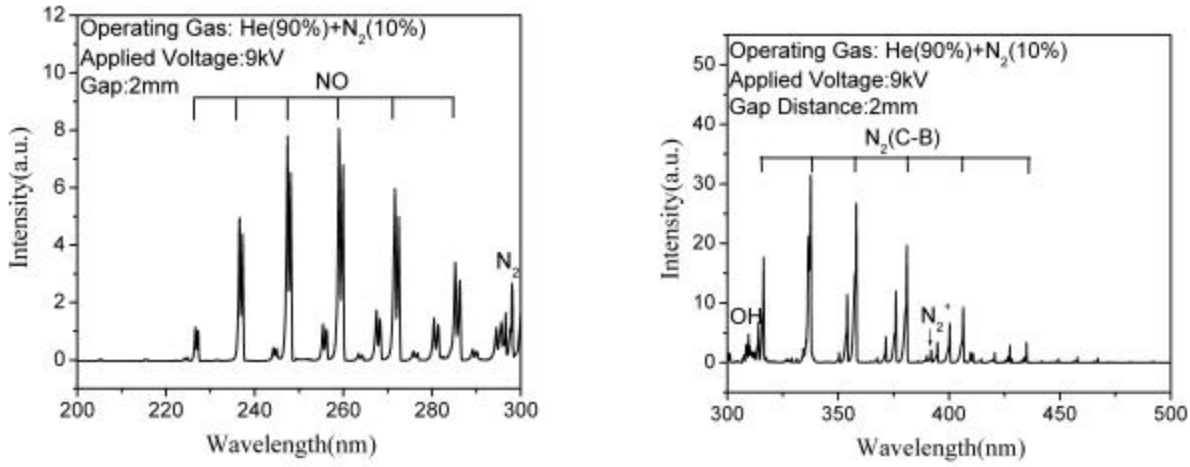
3.4 Emission Spectra

To better understand the UV emission characteristics, and to identify the presence of chemically reactive excited species in the plasma, emission spectroscopy was used to measure the emission spectra in the 200-800 nm wavelength range, under different gas operating conditions. For all of the recorded emission spectra, the pulse repetition rate f was 1kHz, and the operational parameters of the spectrometer were unchanged (grating: 1200g/mm, slit width: 100μm).



(a) (b)

Fig. 5 Emission Spectra from (a) 200nm to 300nm and (b) 300nm to 500nm for the He(90%) +N_2(10%) plasma. Trace amounts of oxygen are present from residual air.

Figure 5(a), which shows the emission spectra from 200 to 300 nm for a He(90%) + N_2(10%) mixture, clearly indicates that excited NO are the main source of the UV emission with contribution from the N_2(C-B) emission. Varying the percentages of He and N_2 we observed similar emission spectra but with weaker

intensities. Spectra in the wavelength range 300-500nm (Figs. 5(b)) reveal the presence of excited OH, N_2 and N_2^+ in the plasma. Helium emission was observed in the 500nm – 800nm wavelength range.

3.5 Measurement of NO and NO_2 Concentrations

Since most of the emission in the UV range was found to originate from NO and since NO is easily oxidized to NO_2 by reaction with O_2, O_3, etc [10,11], we measured the absolute concentrations of NO and NO_2. A multi-gas detector was used for this task. The maximum measured NO and NO_2 concentrations for a He(90%) + N_2(10%) mixture were about 8ppm and 4ppm, respectively.

IV. DISCUSSION

The results presented above clearly show that the optimal UV emission comes from the He(90%) + N_2(10%) plasma, where nitrogen oxide, NO, dominated this emission (the residual traces of air provided the oxygen to form NO). This optimized UV emission can be explained as follows. In order to enhance UV emission, NO had to be excited to the NO($A^2\Sigma^+$) state (Excitation energy E_{NO*}=5.5 eV). This can occur via collisions with helium metastables, He*, or with $N_2(C^3\Pi_u)$ (Excitation energy E_{N2*C}=11.1 ev). According to the spectra that we measured, the N_2(C-B) emission intensity from the plasma with a He(90%) + N_2(10%) mixture was several times higher than that of a helium only or nitrogen only plasmas. Because the mass of N_2 is 7 times higher than that of He, the NO excitation cross section by $N_2(C^3\Pi_u)$ is likely to be higher than that by He^*. Therefore, the plasma with the higher $N_2(C^3\Pi_u)$ concentration will excite more NO, and as a result emits more UV. To confirm this assumption, we also measured the N_2(C-B)(0-0) transition bandhead intensity (337nm) for different percentages of N_2 and He mixtures. The experimental results show that the emission intensity of this bandhead has a very similar behavior as that of the emitted UV power density shown in Fig. 4(c).

Since most of the UV emission came for the excited NO molecule, the presence of trace amounts of oxygen is therefore required. However, if too much oxygen is added to the gas mixture, the UV emission drops drastically. When just 1% of oxygen was added to a He (89%) + N_2 (10%) mixture, the intensity of the NO emission lines between 200 nm and 300 nm became very weak. Two reasons contribute to this result: 1. In the presence of oxygen NO is quickly oxidized to NO_2. Measurements of the absolute concentration of NO_2 showed a two order of magnitude increase (up to 500 ppm of NO_2) when 1% of oxygen was added; 2. Since oxygen has a large electron attachment cross-section, it affects the electron energy distribution function in a way that results in less excited species and consequently less UV emission.

Another important observation was that the UV emission power density from a nitrogen plasma was weaker than that from a helium plasma (both in the presence of trace amounts of air). This is because without the presence of He metastables, the only pathway to excite the ground state of N_2 to N_2(C) state is via electron impact. This process cross-section is smaller than that via He*. So the concentration of N_2(C) state is lower and as a result less NO is excited and less UV is emitted from the nitrogen plasma.

V. CONCLUSION

The electrical and emission characteristics of a diffuse pulsed dielectric barrier discharge were investigated in this paper. The gas temperature of the plasma was measured to be close to 350K. The UV emission power density, P_{UV}, measurements show that proper mixture of He and N_2 improves the UV emission dramatically. With 5 to 10 percent of N_2 mixed with He, P_{UV} reached about 0.8mW/cm^2 (for f = 10kHz), and was more than 4 to 9 times higher than that for He or N_2 plasmas, respectively. The emission spectra show that most of the UV was emitted by excited NO and N_2. The emission spectra from a He(90%) + N_2(10%) plasma show relatively high concentrations of excited NO and N_2. In addition to NO, NO_2 and excited OH, N_2^+, O were detected.

SPECTROSCOPIC DETERMINATION OF THE TEMPERATURE IN AN EXPANDING H_2O-AR DC ARCJET

V. Sember. A. Mašláni
Institute of Plasma Physics, ASCR, Za Slovankou 3, 182 21 Prague, Czech Republic

Abstract
Optical emission spectroscopy is used to determine the temperature in a supersonic plasma jet expanding from a H_2O-Ar dc arc torch into a chamber maintained at a pressure of 4 kPa. The excitation and ionization temperatures are derived from argon, oxygen and hydrogen atomic lines, and argon ionic lines. The rotational and vibrational temperatures are obtained from UV OH $A^2\Sigma \rightarrow X^2\Pi$ bands. Various stages of departure from thermodynamic equilibrium are found for populations of both atomic and molecular excited states.

Keywords
Optical emission spectroscopy; Supersonic plasma jet; Argon; OH radical, Nonequilibrium

1. Introduction

The contribution addresses the problem of temperature measurement in a supersonic plasma jet of thermal plasma source by means of optical emission spectroscopy (OES). Jets of this kind are generated by expanding plasma from a remote source into a low-pressure chamber, the pressure being typically in the range of 10^0-10^1 kPa, and can be utilized, among others, for fast deposition of dense coatings [1]. Depending on the nozzle design and ratio of the inlet to chamber pressure, a variety of plasma flow structures is obtained: from subsonic to under- or overexpanded supersonic with a normal shock wave and/or oblique shock wave boundary [2].

Because of its simplicity and non-intrusive nature, the latter being the main advantage in supersonic conditions, OES is widely used powerful diagnostic technique, which can readily provide a wealth of information about excited species. Although the low-pressure supersonic jet is usually far from thermodynamic equilibrium, the kinetic temperature of free particles can be still well established. The question what is the relation between the temperatures obtained by OES, which in fact characterize a partial equilibrium among a particular manifold of excited states, and the electron or heavy particle temperatures is still open. Usually it is believed that the electronic excitation or vibrational temperatures are close to the electron temperature and the rotational temperature is close to the heavy particle temperature. Expanding plasma jets, however, are characterized by strong recombination resulting in an overpopulation of higher excited states with respect to the ground state and even if an apparent Boltzmann equilibrium is established among these states, the temperature derived from a Boltzmann diagram could be different from the electron temperature, e.g. [3],[4]. Molecular spectra, on the other hand, can be dominated by the radiation from nascent molecules, the ro-vibrational distribution of which is controlled by a particular chemical reaction in question rather than by elastic collisions of particles, e.g. [5][6].

2. Experimental arrangement

The measurements were performed on the plasma jet generated by the hybrid water-argon dc arc torch in a low-pressure chamber. In the hybrid torch the arc chamber is divided into short cathode part, where the arc is stabilized by tangential argon flow, and the rest is stabilized by a water vortex [7]. The operating parameters were: current 200 A, voltage 140 V, argon flow rate 13 slm, and chamber pressure 4 kPa. The spectra were recorded with a Jobin-Yvon imaging spectrograph Triax 550 fitted with a CCD detector. The spectral resolution with a grating 1200 grooves/mm was about 0.08 nm in the spectral region of 300 nm. The jet was strongly under-expanded with a well-pronounced expansion region without a noticeable oblique shock structure followed by a relatively faint normal shock front, after which the expansion continued subsonically. The electron number density decreased from $4\text{x}10^{22}$ m^{-3} at the exit nozzle down to $1.5\text{x}10^{21}$ m^{-3} in the expansion region before the shock front.

3. Spectroscopic methods

The electronic excitation temperature T_{ex} was derived from Boltzmann diagrams of all sufficiently resolved argon, oxygen and hydrogen (Balmer H_β-H7) atomic lines detected in VIS and near IR region. We also calculated the ionization temperature T_S from the ratio of emission coefficients of argon ionic and atomic lines using Saha equation and the electron number density obtained from Stark broadening of H_β line. Note that by the term 'temperature' we understand the parameter characterizing a particular distribution of the excited states population assumed to be in thermodynamic equilibrium.

Figure 1 shows typical Boltzmann diagrams obtained from argon atomic lines at three different positions in the plasma jet. The first one is taken at the nozzle exit on the jet centerline and reveals almost perfect Bolzmann distribution of the excited level populations with a well defined excitation temperature. The next two ones are taken respectively at the boundary and at the core of the jet in the expansion region near the shock front. These two diagrams demonstrate that the lowest measured 4p states with the upper level energy around 1.07×10^5 cm^{-1} (~13 eV) are underpopulated with respect to the higher states and that this underpopulation increases towards the core of the expansion region. The Boltzmann temperature obtained from higher excited states T_{ex}^{H} (Ar I) is then taken as the excitation temperature T_{ex} (Ar I). In the case of Boltzmann diagrams obtained from oxygen and hydrogen atomic lines shown in Figure 2 this effect is negligible.

The rotational T_{rot} and vibrational temperatures T_{vib} were obtained by fitting UV OH $A^2\Sigma \rightarrow X^2\Pi$ bands measured in the region of 280-319 nm to the simulated spectra using LIFBASE software [8]. The ro-vibrational

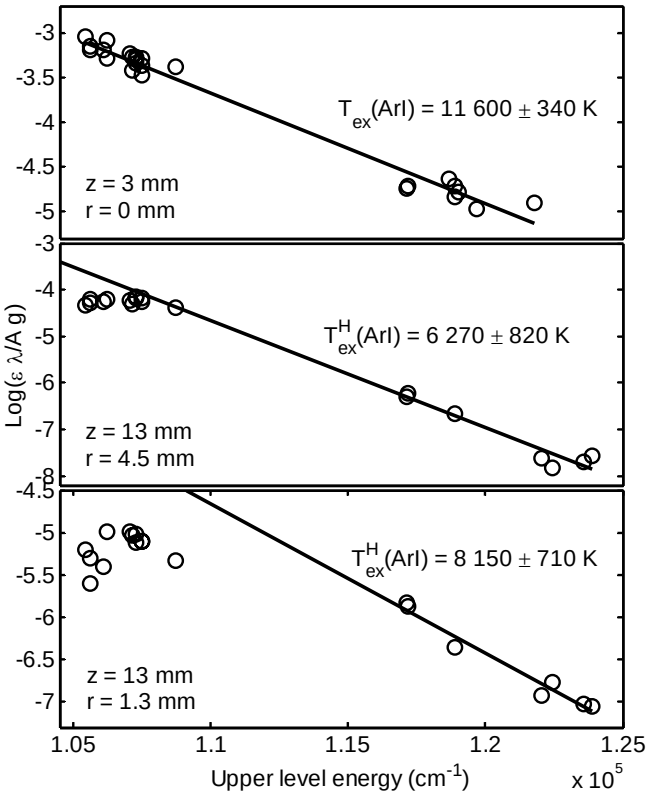

Figure 1. Boltzmann diagrams of Ar I lines at three positions in the plasma jet; *z* and *r* are respectively the distance from the nozzle exit and radial distance from the jet centerline.

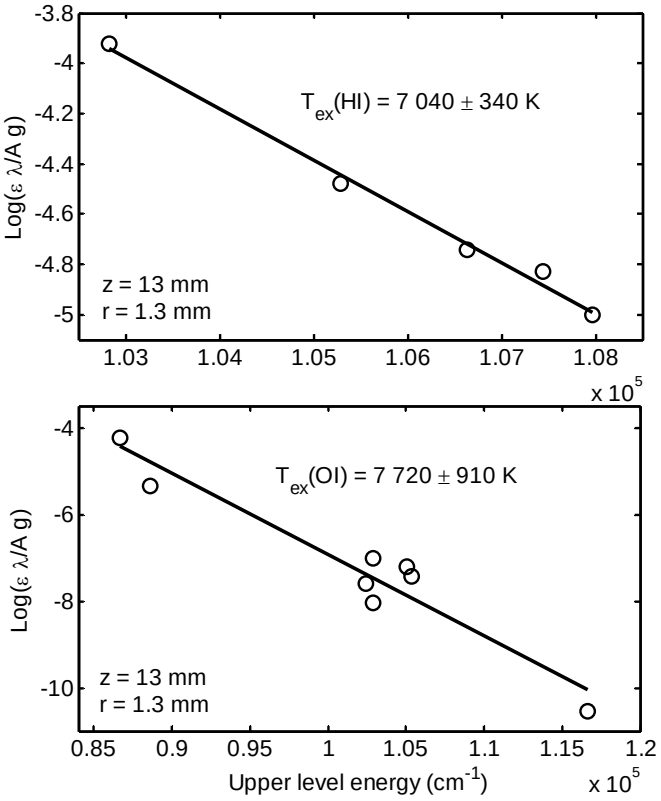

Figure 2. Boltzmann diagrams of H I and O I lines in the expansion region close to the jet centerline.

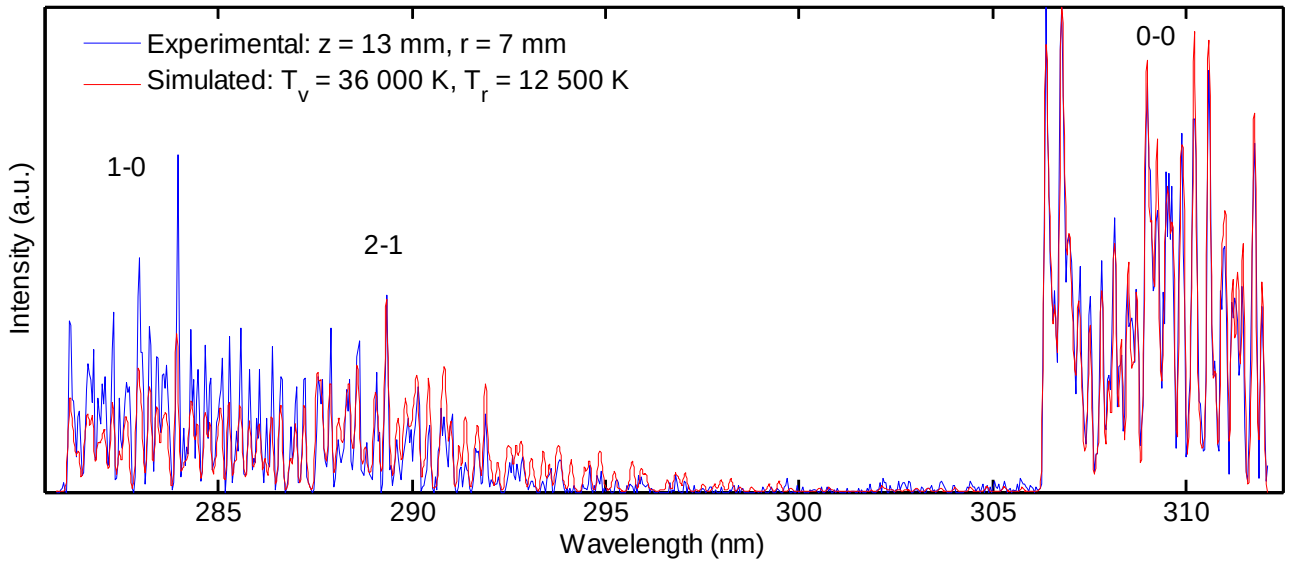

Figure 3. Experimental and fitted simulated OH spectrum at the periphery of the jet in the expansion region.

structure in our spectra was not sufficiently resolved to examine Boltzmann diagrams of rotational and vibrational level populations. To characterize the ro-vibrational distribution at least qualitatively, we fitted the different parts of the measured spectra separately. Thus, the rotational temperature T_{rot}(0-0) was derived by fitting the part of the vibrational transition 0-0 that is unaffected by other significant transitions, the vibrational temperature T_{vib} (1-0, 2-1) by fitting the part of the spectrum dominated by vibrational bands 1-0 and 2-1, and the same approach was used to obtain T_{rot} (1-0) and T_{vib} (0-0, 1-0).

Figure 3 demonstrates one of the most extreme result of the fitting procedure corresponding to the experimental spectrum taken at the far periphery of the jet in the expansion region. The spectrum comprises a vibrational sequence $\Delta v = 1$ and the vibrational band (0-0). The best fit gives a very high vibrational temperature resulting mainly from a relatively high intensity of the sequence $\Delta v = 1$ with respect to that of the sequence $\Delta v = 0$. On the other hand, the intensity ratio of the bands (2-1) and (1-0) corresponds apparently to a quite lower temperature. Note that OH spectra, in contrast to the atomic spectra, are evaluated only at the jet periphery and without applying Abel inversion, and they are just as they were measured and calibrated for spectral response.

4. Results

We performed two series of measurements. The first one was focused on the measurement of OH spectra and H_β line within the whole supersonic domain. The second series included atomic spectra of argon, hydrogen and oxygen, and since it was much more time consuming, it was restricted only to two distinctive positions in the plasma jet, i.e. at the nozzle exit and in the expansion region near the shock front. Since our experiment was not quite reproducible, the results for both series are slightly different.

Results of the first series are summarized in Figure 4. The figure represents radial profiles of all the calculated temperatures together with the profiles of electron number density. The latter can serve as an indication of the shape of the jet core. There are noticeable differences between each calculated temperature that increase towards and even beyond the jet boundary. On the other hand, both rotational and vibrational pairs of the temperature seem to converge to the same value near the jet core. This value is, however, different for both rotational and vibrational temperature, especially in the expansion region as the rotational temperature increases with increasing distance from the nozzle. Notice that we can distinguish between ‘hot’ and ‘cold’ both rotational and vibrational distributions. There is also sharp increase of the temperature T_{vib} (0-0, 1-0) close to the jet boundary.

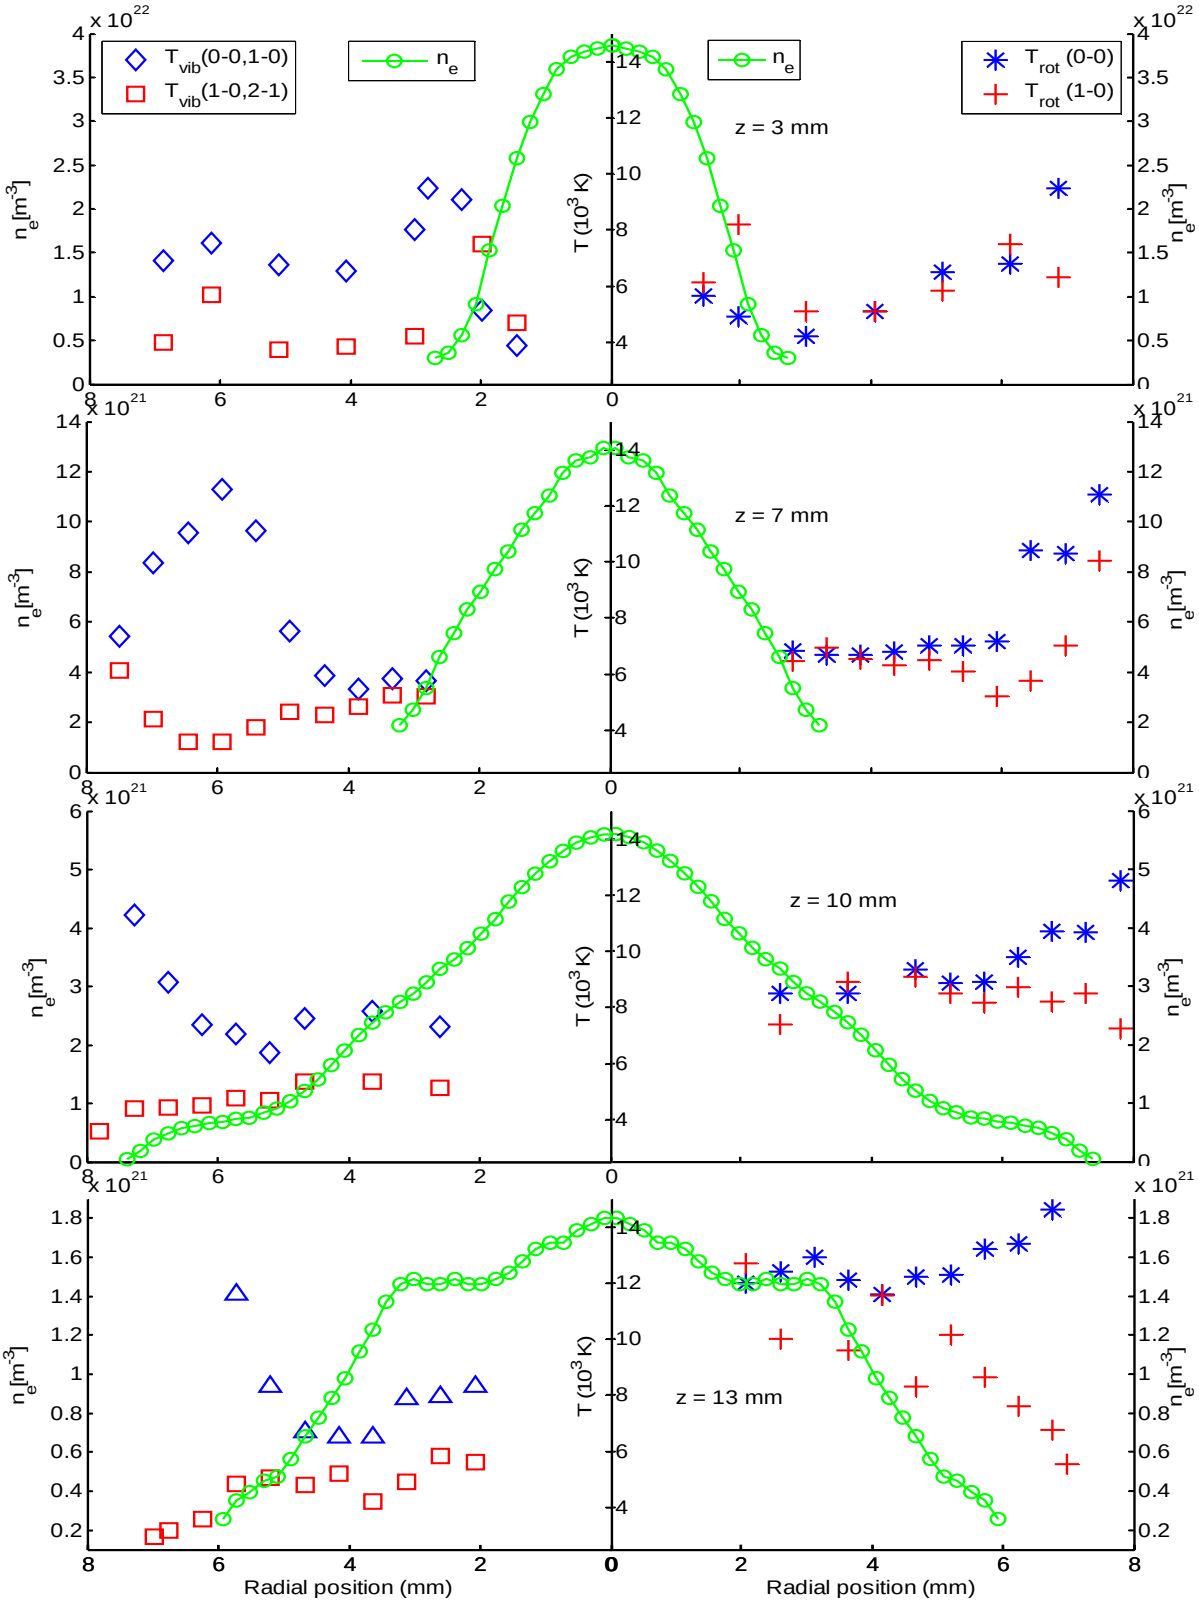

Figure 4. Radial profiles of rotational and vibrational temperatures, and electron number density at four distances z from the exit nozzle.

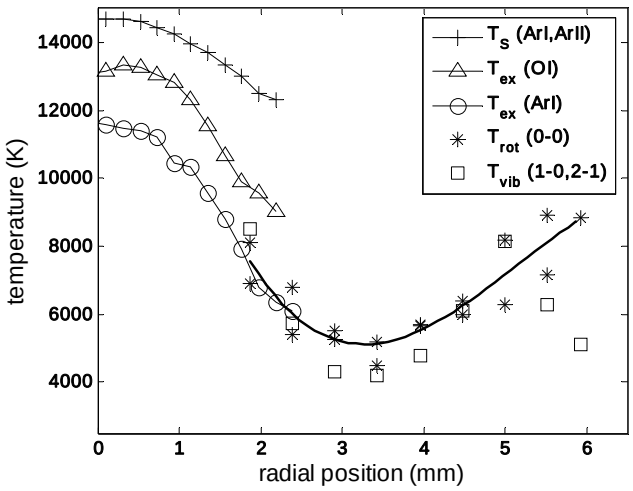

Figure 5. Radial profiles of the temperature at the nozzle exit.

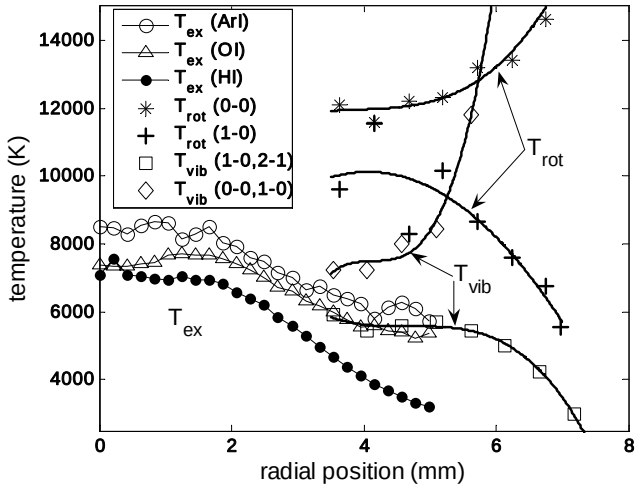

Figure 6. Radial profiles of the temperature in the expansion region.

Figures 5 and 6 show results of the second series of measurements at the nozzle exit and in the expansion region respectively. At the nozzle exit, the atomic excitation temperature T_{ex} (Ar I) is obtained from the complete Boltzmann diagram as no sign of overpopulation of higher excited states was noticed. Boltzmann diagram of O I lines gives a little bit higher excitation temperature than that of Ar I lines but still within the estimated error. T_{ex} (H I) was not determined as the hydrogen lines were too broad. The 'Saha' temperature T_S is of about 3000 K higher than T_{ex} (Ar I) on the jet axis and this difference increases to 5000 K close to the jet periphery. Both rotational and vibrational temperatures agree well with T_{ex} (Ar I) at the jet periphery and increase outside the jet boundary ($r > 3$ mm). The results suggest that the jet at the nozzle exit is relatively close to LTE and the elevated T_S at the jet periphery can be explained by diffusion of free electrons.

In the expansion region, the excitation temperatures derived from atomic spectra are similar with the maximum in the jet core around 8 000 K. The figure reveals once again the 'hot' and 'cold' character of both rotational and vibrational distributions and this effect increases with increasing radius. The idea of superposition of two independent distributions is supported by the fact that for some 0-0 bands the fitting procedure gives not only the temperature much higher than that of 1-0 band but also the temperature that is close to the latter one. There is, however, a noticeable difference between rotational and vibrational temperatures. While the vibrational temperature approaches the atomic excitation temperature at the jet periphery, the rotational temperature significantly exceeds the excitation temperature and is much higher than at the nozzle exit.

4. Conclusions

The results can be summarized as follows:

- Populations of higher atomic states remain close to the Boltzmann distribution for the whole supersonic region. The lower excited states, as indicated in the case of argon 4p states, are underpopulated, which is typical for recombining plasmas. It is, however, not quite evident to what extent the atomic excitation temperature represents the electron temperature. Nevertheless, the comparison of temperatures obtained from both atomic and molecular spectra suggests that at the nozzle exit the plasma can be close to the local thermal equilibrium.
- The rotational temperature is much higher in the expansion region than the vibrational temperature, which seems to be in contrast to the assumption that the former should represent the heavy particle temperature and the latter the electron temperature.
- The intensity distribution in the OH spectra can be interpreted as a result of both the departure from the thermal equilibrium and superposition of 'hot' and 'cold' OH radicals, which can be interpreted as a result of

competition between various chemical reactions leading to the creation of OH radical and collisional relaxation.

- We assume that reactions with argon metastable states may be responsible for the high vibrational excitation at the jet boundary [9], and an extremely 'hot' rotational distribution outside the jet can be explained by photodissociation of H_2O that is supposed to be abundant in the chamber atmosphere [10].

Deformation and Solidification Process of Single Sprayed Zirconia Droplets Impinging on Substrate – In-situ Measurement and Numerical Simulation –

K. Shinoda, A. Yamada, T. Koseki, T. Yoshida

Department of Materials Engineering, Graduate School of Engineering, The University of Tokyo, Tokyo, Japan

Abstract

We developed an in-situ measurement system that enables us to correlate the splat morphology of each droplet with its thermal history during its impinging on substrate. In this study, we have measured the impacting process of yttria-stabilized zirconia droplets by the developed in-situ measurement system. The viscosity of zirconia was estimated via in-situ measurement and was compared with that of alumina. The kinematic viscosity of zirconia at melting point is approximately three times smaller than that of alumina. The most interesting finding is that the plateau-like area was observed in the thermal history. It indicated that the solidification process can occur near the end of the flattening process.

Keywords In-situ measurement, yttria-stabilized zirconia, rapid deformation and solidification, splat morphology, SOLA-VOF, supercooling

1. Introduction

With the increase of the operation temperature of gas turbines, which is now reaching the application limit of Ni-base superalloys, the microstructure of yttria-stabilized zirconia (YSZ) coatings as the main component of thermal barrier is demanded to be controlled at nano level[1]. Therefore, the number of basic researches is increasing to elucidate elementary processes in plasma spraying such as deformation and solidification of droplets impinging on the substrate. However, those processes have not been yet fully understood because the sprayed droplets are too small (10 – 100 μm) and their deformation and solidification are too fast (1 – 10 μs) to measure precisely. Moreover, the lack of high temperature physical properties of YSZ prevents us from numerically simulating these processes precisely.

Moreau *et al*. firstly measured the temperature of TiC particles impacting on a stainless steel substrate under dc plasma spraying via a double-wavelength fiber optic and showed the feasibility of infrared monitoring of the temperature of a plasma sprayed particle at the moment of and immediately after the impact[2]. Moreau *et al.* also monitored cooling rates of molybdenum particles impinging on substrates, and investigated the influence of coating thickness on the cooling rates of plasma-sprayed particles impinging on those substrates[3, 4]. Vardelle *et al*. developed a measurement system consisting of two high-speed two-color pyrometers and measured the temperature, the velocity, and the size of a zirconia particle prior to its impact on a steel substrate and its flattening and cooling during impinging under dc plasma spraying[5, 6]. Gougeon and Moreau developed simultaneous independent measurement of splat diameter and cooling time during impact on a substrate of plasma-sprayed molybdenum particles, in which they measured the shading area of laser beam during spreading[7]. However, the correlations between the splat morphology and the measurement results are not always sufficient in their system. More recently, direct observation of droplet impact by a high-speed CCD camera coupled to a microscope was reported and the impact behaviors such as rebound, deposition, splashing, spattering, were systematically studied[8]. The system was effective in evaluating splashing mode; however, the thermal history during impact could not be measured.

In this context, we have developed an in-situ measurement system that enables us to correlate splat morphology of each droplet with its thermal history[9-11]. We have measured and investigated the deformation and solidification process of sprayed YSZ droplets by the developed in-situ measurement system with the help of numerical simulation.

2. Experimental

The in-situ measurement system used is shown schematically in Fig. 1. The system consists mainly of a hybrid plasma spraying system, a single particle collection apparatus, two sets of emission detectors, and a data storage apparatus. The hybrid plasma spraying system consists of an rf power supply of 4 MHz-60 kW, a dc power supply of 10 kW, a dc-rf hybrid plasma torch, and an airtight chamber. This system made it

possible to measure the deformation and solidification process under a wide variety of conditions such as: 1) wide range of powder size up to 100 μm, 2) particle velocities ranging from 20 to 70 m/s, and 3) various atmospheres as well as a wide pressure range.

The way how to collect single sprayed particles is described in detail in the Ref[9]. Two optical systems were used to detect the thermal emission from a particle. One was used to measure the surface temperature and velocity of an in-flight particle immediately before the particle impinged, and was connected to the collimator, which is utilizing the method developed by Sakuta and Boulos[12]. We selected 500/ 800 nm and 700/ 1000 nm wavelengths for the measurement of particle temperature before and during impact, respectively. The detected signal of in-flight particle itself works as a trigger for the record of sequential measurement for the event of particle flattening. The other system was connected to the emission condenser that consisted of two optical lenses with the focal lengths of 40 mm and 70 mm. This condenser focused at an angle of 20 degrees on the substrate and its viewing field on the substrate was an ellipse of 1.7 mm – 5 mm. The sets of photomultipliers used were Hamamatsu-made R1104/R1104 and R943-02/R3310-02 for 500/800 nm of the in-flight particle measurement and for 700/1000 nm of the impact, respectively. The data were collected by a digital oscilloscope and sent to a PC via GP-IB. The droplet diameter was calculated from the volume of the deposited splat. The volume was measured precisely with a three-dimensional laser microscope, KEYENCE VK-8500, that could measure the three-dimensional morphology, which was also used to examine the backside of splats. In addition, the substrate holder was designed to be movable horizontally with a speed up to 1 mm/s in order to avoid overlapping of the substrate. The substrate temperature was controlled by an electric heater made of molybdenum spiral wire and measured by thermocouple set below the substrate.

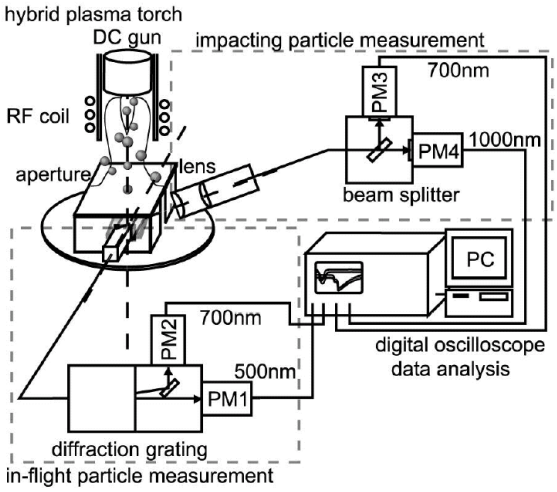

Fig. 1. Schematic diagram of the in-situ measurement system.

Table 1 shows the spraying conditions. Powders are injected into the dc plasma jet at an angle of 30 degree from the torch axis through a tube of 2 mm in internal diameter passed through inside the anode. Fused and crushed 8YSZ powder with size distribution ranging from 63 to 88 μm was used. 8%H_2-Ar atmospheric hybrid plasma was adopted to spray powders onto a quartz substrate. The substrate measured 25 mm long by 10 mm wide by 0.6 mm thick, and its surface roughness was 0.04 μm. The stand-off distance was set to 80 mm. The powder feeding rate was adjusted below 0.6 g/min to limit the number of particles impinging on the substrate. The substrate temperature was set at approximately 700 K to obtain disk-shaped splat[13]. The sampling rate was set to a 0.1 μs interval and the sampling point was 5000 pts for each channel, for each splat. When emission signals are detected, a shutter set above the BN plate was closed; the signals are recorded; the substrate is moved about 1 mm; then the shutter is opened again and next trial run is started. In this manner, 15 to 20 splats were collected in each experiment.

Table 1. Typical Experimental conditions

Parameters	Settings
Internal diameter of dc torch (mm)	6
Dc Ar gas flow rate (slm)	10
Dc current (A)	300
Internal diameter of rf torch (mm)	40
Rf tangential Ar gas flow rate (slm)	10
Rf radial Ar gas flow rate (slm)	30
Rf radial H_2 gas flow rate (slm)	5
Rf input power (kW)	50
Powder carrier gas flow rate (slm)	2
Powder feeding rate (g/min)	0.6
Stand-off distance (mm)	80
Substrate temperature (K)	700

3. Results & Discussion

Figure 1 shows laser microscope images of a single sprayed splat from both top and bottom side and the 1:1 corresponding waveforms to the splat. This particle impinged the substrate at 48 μm in diameter, 65 m/s in velocity, and 3550 K in temperature. The diameter of splat was 163 μm; hence, the degree of flattening was 3.4. Cooling rate was estimated from the initial gradient of temperature during impact to 8.1 $\times 10^7$ K/s and the thermal contact resistance was, therefore, estimated to be 5.3×10^{-6} m^2K/W.

On the other hand, the lack of knowledge of the high-temperature properties of zirconia has clearly prevented the development of realistic simulation. In reality, there are only few papers referring the

viscosity. For example, Fantassi *et al.* assumed constant value of 0.04 Pa·s[14] and Vardelle *et al.* used the equation: μ[Pa·s] = 0.1exp(-2.95+5993/T)[6] based on an analogy with the temperature dependence of alumina viscosity. Hence, we have estimated the viscosity of zirconia, μ, by substituting the results into the model: $D/d = 0.83Re^{0.2}$[15]. Each value could be fitted by the Arrhenius-type equation: μ[Pa·s] = 0.0037 exp (6100/T) revealing 0.028 Pa·s at 3000 K as shown in Fig. 3. The viscosities of alumina reported in literatures[16-21] are also shown for the purpose of comparison. The viscosity of zirconia does not increase rapidly with the increase of supercooling, which was different from what was expected. This low viscosity in the supercooled region will be the main reason why supercooled droplets can show similar flattening degree with superheated droplets[11]. The kinematic viscosities at melting points of zirconia (3000 K) and alumina (2328 K) are 4.9×10^{-6} m^2/s and 1.5×10^{-5} m^2/s[21], respectively. The value of zirconia is approximately three times smaller than that of alumina, which suggests that zirconia particles may flatten better than alumina particles once they are fully melted. Note that the activation energy for zirconia viscosity was derived as 51 kJ/mol, which is much lower than the value of 247 kJ/mol proposed by Sudreau *et al.* and rather close to the values 87 kJ/mol and 68 kJ/mol estimated by Grosse and Hirai relationships for metallic alloys, respectively[22]. The derived value of μ is only a rough estimation; nevertheless, the fact that we can deduce even the unknown viscosity of zirconia clearly reveals the powerfulness of our approach.

A Numerical simulation of the droplet impact processes about the splat shown in Fig. 2 has been conducted by basically solving the full Navier-Stokes and energy equations coupled with the Volume of Fluid (VOF) approach to track the surface of a deforming droplet. We adopted the 2-dimensional impact model utilizing SOLA-VOF algorithm, which was firstly developed by Pasandideh-Fard *et al.*[23, 24] and extended to include supercooling effects by Chae *et al.*[25]. The thermo physico-chemical properties of zirconia and quartz glass substrate used here were shown in Table 2. The simulation result shows flattening degree is 4.5, which is 20 % higher value than the experimental value.

Figure 3 shows the 700 and 1000 nm emission waveforms from the particle during the impact. Surface temperature calculated from the waveforms and the dimensionless diameter derived from numerical simulation are also shown in the figure. Calibration of the temperature during impact was performed by equalizing impact temperature with in-flight temperature of the particle. Noise reduction or smoothing was conducted by using Savitzky-Golay method[26]. The spreading time estimated from the measurement is 2.1 μs, and is in a good agreement with the 90 % spreading time, 2.2 μs, derived from the numerical calculation. The difference in flattening degree between the experiment

zirconia (l)	5700	713	2.32	0.43
zirconia (s)	5700	604	2.32	
quartz	2000	900	1.17	

Properties were quoted from Vardelle (1995) and Chase (1998).

and the simulation may be explained by the effect of shrinkage, because we observe the rim of collected splat is much larger than that of calculated splat. This is consistent with the previous suggestion[7] that actual splat should show large shrinkage. The most interesting finding is that the plateau-like area is observed around 4.6 μs after the impact. This plateau indicates that in this droplet the solidification started near the end of the deformation process. Further investigation is needed to confirm this, but the obtained results suggest that the solidification can start near the end of the flattening and may affect the flattening process.

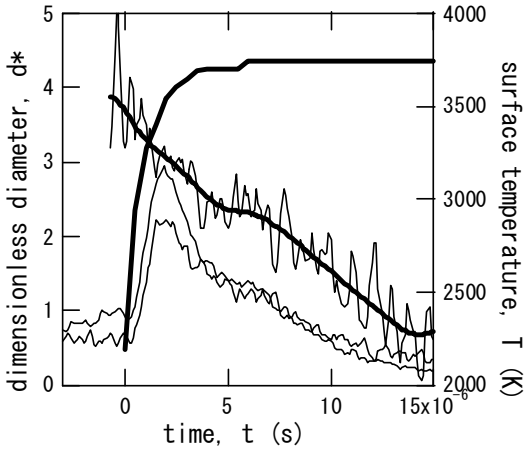

Fig. 4. Measured thermal history and calculated dimension less diameter during particle impact.

4. Conclusion

In-situ measurement of deformation and solidification process was conducted via highly developed in-situ measurement system. It enabled us to collaborate with numerical simulation in addressing solidification problems. The most interesting findings is that solidification may occur around the end of flattening process.

Abstract
Pyrolysis of biomass in thermal plasma was experimentally studied in reactor with dc arc plasma torch stabilized by combination of gas flow with water vortex. Crushed wood was used as a model substance for treatment of organic waste materials. Temperature distribution within the reactor, power balances of the process and composition of produced gas were measured. Synthetic gas with high content of hydrogen and CO was produced.

Key words: plasma pyrolysis, biomass, dc arc gas/water plasma

1. Introduction

The gasification of biomass to produce synthesis gas (syngas) offers an alternative to fossil fuels. Since syngas contains hydrogen and carbon monoxide, it has the potential to be used as a re-burning fuel to reduce NO_x emissions. Common biomass gasification technologies are based on the reaction between a heated carbon source with limited amounts of oxygen and steam. Thermal plasma offers possibility of decomposition of biomass by pure pyrolysis in the absence of oxygen. In the process all energy needed for gasification comes from plasma, no energy for decomposition is produced by combustion. The process acts also as energy storage – electrical energy is transferred to plasma energy and then stored in produced syngas. The main advantage is better control of composition of produced gas, higher heat capacity of the gas and reduction of unwanted contaminants like tar, CO_2 and higher hydrocarbons.

Most of the experiments with plasma pyrolysis have been performed with arc plasma torches with relatively high flow rates of plasma gas. Production of syngas from wood in plasma generated in ac air plasma torches is discussed in [1]. Coal gasification in hydrogen, air and steam plasma was studied in [2, 3]. In [4] wood was gasified in steam plasma. The mean enthalpy of plasma, given by ratio of net arc power to gas flow rate, was usually not higher then 10 MJ/kg [1 - 4]. The high flow rate of plasma ensures good mixing of plasma with treated material. However, produced synthetic gas contains components of plasma gas, usually nitrogen and oxygen if air or nitrogen are used as plasma gases [1, 3]. The usage of mixtures of inert gas with hydrogen [5, 6] eliminates this disadvantage but it increases cost of the technology. Therefore steam was used as plasma gas in [2, 4].

In this paper a dc plasma torch with gas/water stabilized arc, usually applied for plasma spraying, is used [7]. Plasma gas is mixture of steam with small amount of argon. Due to principle of arc stabilization by water vortex the flow rate of plasma gas is very low and plasma enthalpy is more than 200 MJ/kg and mean plasma temperature more than 15 000 K [7, 8]. This is the main difference from gas plasma torches with steam used as plasma gas [2, 4] where temperatures are lower then 4 000 K. The utilization of high enthalpy, high temperature plasma offers advantages in possibility of adjusting high reaction temperature. As low amount of plasma carries high energy, the power needed for heating of plasma to reaction temperature is very low and the efficiency of utilization of plasma power for waste destruction is extremely high. The paper describes first series of experiments in the plasma reactor with high enthalpy gas/water plasma torch designed for destruction of solid waste materials and gasification of biomass.

2. Experimental system

The experimental plasma-chemical reactor (Fig. 1) with water-cooling system has been designed to operate at a wall temperature up to 1700 C. The inner lining of the reactor was made from special

refractory ceramics. Ceramic insulation wall with the thickness of 400 mm reduces power loss to the walls. All parts of reactor chamber were water-cooled and calorimetric measurements on cooling circuits were made. The material container was equipped with a continuous material supply system with controlled flow rate. The pressure in the supply conveyer was automatically kept higher then the

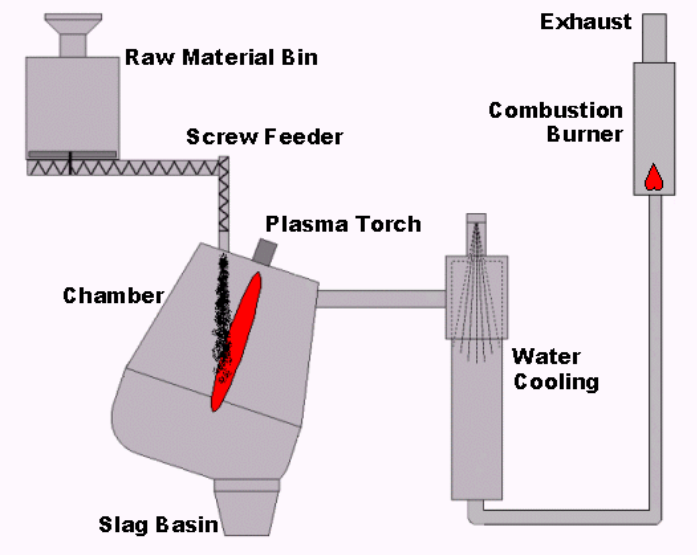

Fig. 1. Schematics of experimental reactor for plasma pyrolysis

pressure inside the reactor by controlled nitrogen flow to prevent reactor gases flow into the material supply system. Crushed wood was supplied to the reactor and was injected into plasma jet in the position about 30 cm downstream of the input plasma entrance nozzle at the reactor top. It was partially gasified during its flight within the jet, the non-gasified part of the wood falls onto the bottom of the reactor where it was gasified in the hot gas flow. The exit tube for exhaust gas was in the upper part of the reactor, so as the produced gases passed through the zone of high temperature within plasma jet or close to it. Inputs for additional gases for control of reactor atmosphere are at three positions in the upper part of the reactor.

Table 1. Experimental parameters

	Run 1	Run 2
Arc current [A]	350	450
Arc power [kW]	95	138
Steam plasma flow rate [g/s]	0.2	0.25
Argon plasma flow rate [slm]	12	12
Torch efficiency [%]	58	59
Argon flow rate in anode chamber [slm]	20	33
Nitrogen flow rate [slm]	4	4
CO_2 flow rate [slm]	23	0
Power loss to the reactor [kW]	16	18
Power available for material treatment [kW]	39	63
Material (wood) mass flow rate [kg/hour]	20	20
Humidity of treated wood [%]	7	7

The gas produced in the reactor flowed through the connecting tube to the quenching chamber, which was created by a cylinder with the length of 2 m. At the upper entrance of the cylinder the gas was quenched by a spray of water from the nozzle, positioned at the top of the cylinder. The water flow

rate was automatically controlled to keep the temperature of gas at the end of quenching chamber at 300 ^{o}C. The gas then flows into the combustion chamber where it is combusted in the flow of the air. Plasma was produced in the torch with dc arc stabilized by combination of gas flow and water vortex [7]. The torch generates an oxygen-hydrogen-argon plasma jet with extremely high plasma enthalpy and temperature. The torch is attached to the reactor at the reactor top. The anode of the torch is created by a rotating water-cooled disc, which is positioned outside the arc chamber downstream of the torch exit nozzle [7]. The anode of the torch was thus inside the reactor and it was separated from the reactor volume by a water-cooled wall. Additional argon was supplied into the anode chamber to protect anode from flow of reaction gases. Plasma enters the reactor volume through the nozzle with diameter of 40 mm in this wall.

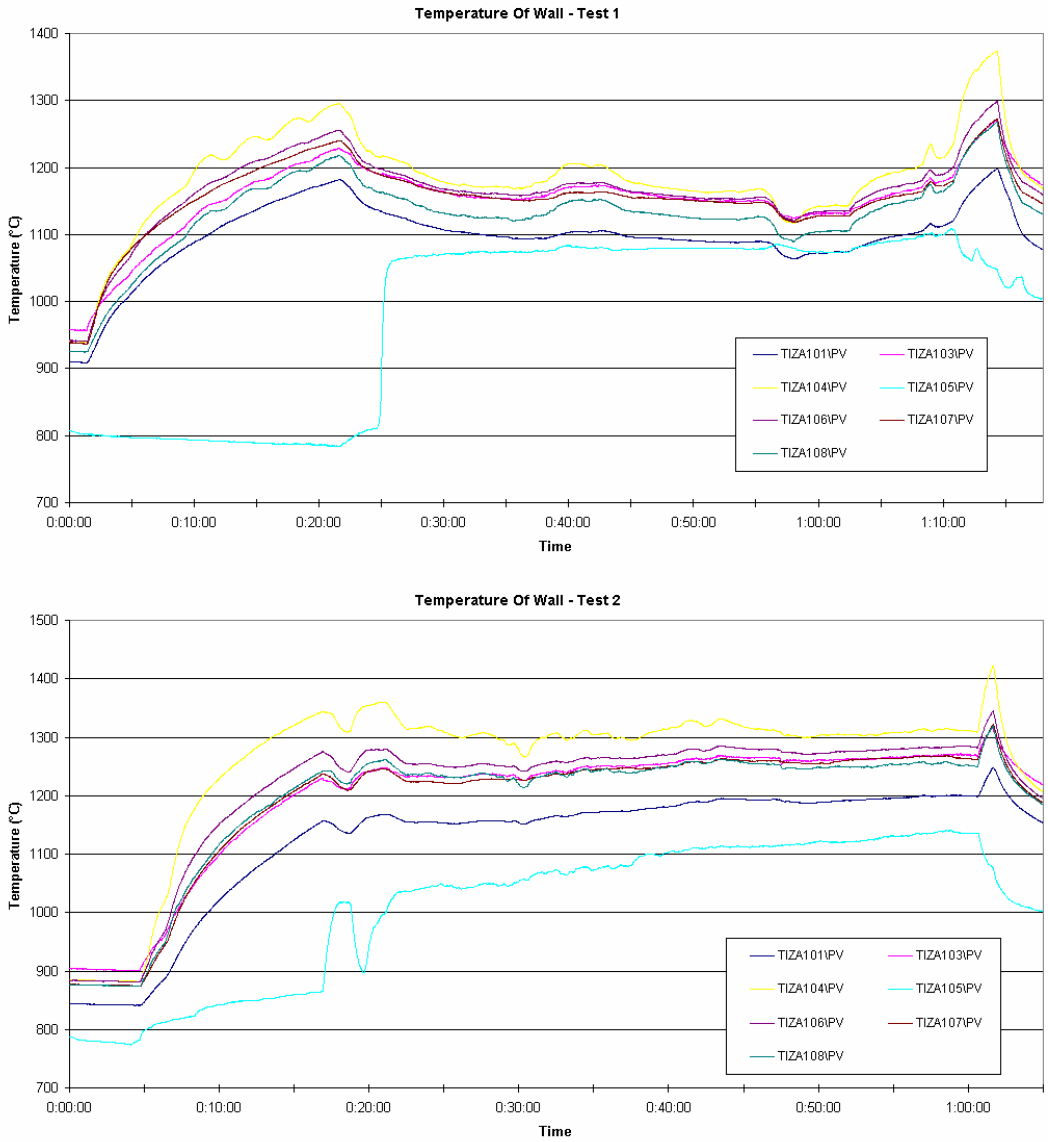

Fig. 2. Temperatures of reactor wall in several positions (TIZA 101, 103, 104, 106, 107, 108) and temperature of produced syngas at position of gas sample collection (TIZA 105).

Measuring system included monitoring of plasma torch operation parameters, temperatures in several positions inside the reactor and calorimetric measurements on cooling water loops. The temperature of inner wall of the reactor was measured in six positions by thermocouples. The flow rate of reaction gas was measured using a Pitot-static tube flow meter, gas temperature was measured at the input and output of quenching chamber. The composition of produced gas was measured at the output of reactor

before the gas enters the quenching chamber. The tube for collection of samples was cooled by the water spray at the input of the quenching chamber. The gas analysisys was made by a quadruple mass spectrometer Balzers QMS 200. As the gas can contain some amount of steam which could after condensation block or damage the inputs of the spectrometer, the freezing unit was connected into the gas sample circuit.

3. Results.

Before the experiments the reactor was pre-heated by the gas burner to temperature about 900°C. The results of two runs are presented in this paper. At each run the torch was operated for about one hour. The basic experimental parameters are in Table 1. The flow rate of crushed wood was the same in the both runs, the water content in the wood was 7% of weight. CO_2 was added into the reactor in the first run to increase the oxygen content and to reduce production of solid carbon deposits within the system.

The temperatures of inner wall of the reactor in several positions during the both runs are shown in Fig. 2. The time of arc ignition corresponds to the sudden steep increase of temperatures at the time t = 1.5 min in the first run and the time t = 5 min in the second run. The time of start of supply of the wood was t = 20 min in the first run and t = 16 min in the second run. The temperature of gas measured at the output of the reactor, where samples for gas analysis were taken, is shown in Fig. 2 as well. The sudden changes of the temperature at the beginning of wood supply were caused by adjusting the thermometers into their measuring position in the center of the exhaust tube. The temperature of gas is somewhat lower then the reactor temperature as the gas was cooled down in the exhaust tube.

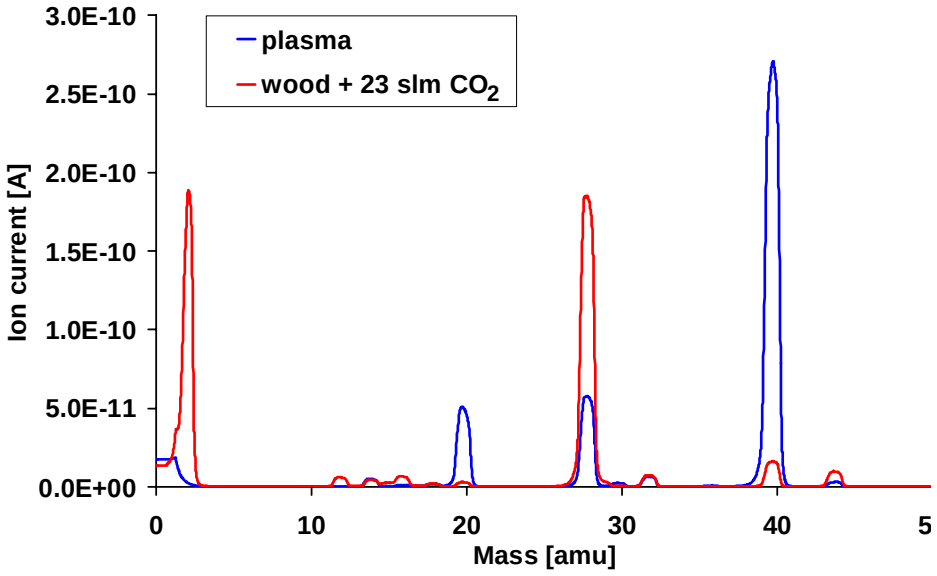

Figure 3. Mass spectra of exhaust pyrolysis gas (red) compared with the gas spectrum without material feeding (blue).

It can be seen that the differences of temperatures at different positions does not exceed 150°C despite of the fact that the reactor is heated by concentrated plasma jet with high velocity and temperature and low mass flow rate. Natural turbulence of generated plasma jet as well as disturbances of plasma flow caused by the interaction with solid evaporating material ensure strongly turbulent conditions within the reactor and thus sufficiently homogeneous heating of all parts of the reactor volume. After material is injected the temperatures fell down but were stable for the whole time of material feeding. Small differences in temperatures measured in different positions prove good mixing process in the reactor. The temperature increase at the end of the records correspond to reduction of flow rate of material.

Table 2. Composition of gases at the output from the reactor (in volume %)

	H_2	CO	CO_2	O_2	Ar	N_2
No material fed	0.5	-	0.5	1.3	89.1	8.6
Run 1 – sample 1	46.3	45.2	1.9	1.6	5.1	-
Run 2 – sample 1	40.6	43.4	5.3	2.4	8.4	-
Run 2 – sample 2	42.0	44.3	3.4	2.5	7.8	-
Run 1 – theory	44.0	47.8	0	2.0	5.5	0.7
Run 2 – theory	45.9	45.1	0	0.4	7.9	0.7

The example of mass spectrum of exhaust gas compared with the mass spectrum of gas flowing from the reactor without material feeding is shown in Fig. 3. Results of analysis of gas samples are shown in Table 2. The first line gives the composition of exhaust gases in case when only plasma torch was operated. Equilibrium concentrations of reaction products, calculated for experimental flow rates of input substances under the assumption of complete decomposition of cellulose, water and CO_2 into hydrogen and carbon monoxide, are shown for the both runs in the last two lines of Table 1. It can be seen that in the both cases almost complete decomposition of wood into mixture of hydrogen and carbon monoxide occurred, the concentration of CO_2 was only several percent. Argon concentrations correspond to the flow rate of argon into the torch and the anode chamber, flow rate of nitrogen corresponds to amount of nitrogen in pressure control input of the material feed conveyer. The results show that all material was decomposed in the reactor and thus sufficient heat transfer takes place in the reactor between flowing plasma, solid injected material and produced gases.

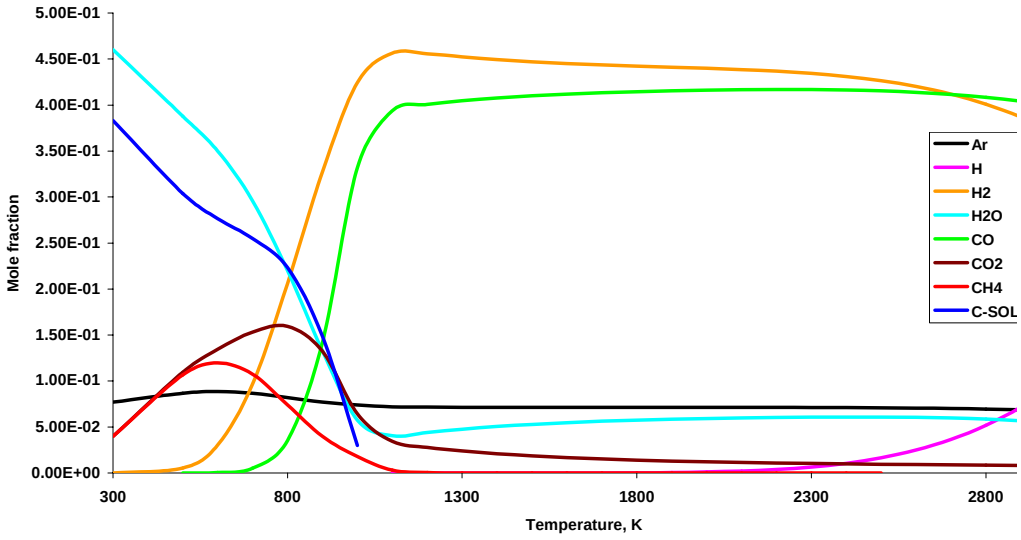

Fig. 4. Equilibrium composition of mixture of cellulose (1 mol) and water (1 mol) in dependence on temperature calculated using code ASTRA.

For comparison, the temperature dependence of composition of mixture of 1 mol of cellulose with 1 mol of water, which approximately corresponds to the test conditions, calculated under the assumption of existence of thermodynamic equilibrium using the computer code ASTRA, is shown in Fig. 4. It can be seen that for temperatures above approximately 1000°C the reaction gas is composed mostly from mixture of hydrogen with CO with small percentage of CO_2, steam and argon.

4. Conclusions.

The plasma reactor for pyrolysis of waste was operated with wood used as a model substance. High enthalpy, low plasma flow rate plasma jet generated in hybrid gas/water torch was used as a source of plasma. The experiments prove that homogeneous heating of volume of plasma reactor and proper mixing of plasma with treated material were ensured despite of very low plasma mass flow rate. The conditions within the reactor ensure complete destruction of tested substance. Synthetic gas with high content of hydrogen and carbon monoxide and low concentration of carbon dioxide with high caloric value was produced. The concentration of hydrogen is higher than the maximum values reported for classical treatment of biomass. The main advantage of use of plasma torch with water-stabilized arc is in composition and low flow rate of plasma. The content of other gases commonly present in gas stabilized systems is very low. In further experiments the effect of experimental conditions on mass and energy balances of the process will be studied.

Influence of the applied frequencies on plasma characteristics in dual frequency reactors: a numerical study

V. Georgieva and A. Bogaerts
Department of Chemistry, University of Antwerp (CDE), B-2610 Antwerp, Belgium

Abstract
A one-dimensional particle-in-cell/Monte Carlo (PIC/MC) model is used to investigate the influence of the applied frequencies on the plasma characteristics in $Ar/CF_4/N_2$ discharges sustained in dual frequency reactors. The simulations were carried out for a high frequency (HF) of 27, 60 or 100 MHz and a low frequency (LF) of 1 or 2 MHz. It is observed that the decoupling of the two sources is possible with increasing the applied HF to very high values (above 60 MHz) and it is not defined by the frequency ratio.
Keywords PIC/MC method, dual frequency reactor, CF_4 plasma.

1. Introduction

Dual frequency reactors were introduced in the early 90s but recently there has been an increasing interest and study of these systems [1-6]. The two-frequency scheme allows independent control of the ion flux and ion bombardment energy, which is important for surface etching applications, and this cannot be achieved by the conventional single frequency capacitively coupled (cc) reactor.
The purpose of the present work is to study the influence of the applied frequencies on the plasma characteristics in $Ar/CF_4/N_2$ discharges by means of a PIC/MC method. In Sec. 2 the input parameters and the outline of the model are given. In Sec. 3 the results of the simulation, such as the plasma density, ion current, electron and ion average energies and energy distributions, average sheath potential and width, and ionization rates, are presented and discussed. Finally, in Sec. 4 a summary is given.

2. Description of the model

A schematic diagram of the cc rf reactor considered in this study is shown in Fig.1. The plasma is sustained between two parallel plates, each 20 cm in diameter and separated from each other by 2 cm. One of the electrodes is driven by a dual frequency voltage source, i.e. the applied voltage is

$$V = V_{HF}\sin(\omega_{HF}t) + V_{LF}\sin(\omega_{LF}t), \quad (1)$$

where V_{HF} and V_{LF} are the HF and LF voltage amplitudes, and ω_{HF} and ω_{HF} are the applied HF and LF. The other electrode is grounded. The computation is based on a one-dimensional coordinate space and three-dimensional velocity space PIC/MC algorithm. The motion of the charged particles is simulated by the PIC method using the standard explicit 'leap frog' finite difference scheme [7].
The collisions between the charged particles are added by combining the PIC model with a MC procedure [8, 9]. The charged species, which are followed in the model, are: electrons, Ar^+, CF_3^+, N_2^+, F^-, and CF_3^- ions.

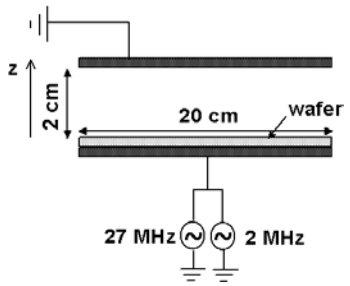

FIG. 1. Schematic diagram of the reactor

The interactions between the particles are treated by a MC method. To calculate collision probabilities, it is necessary to have the corresponding collision cross-section data, which are not always available. Hence, the present model uses several techniques to define the collision probabilities even when the collision cross-sections are unknown. The outlines of all techniques and the data for electron-neutral and ion-neutral collisions, electron-ion and ion-ion recombination considered in the model are given elsewhere [3,4]. We recall here only the expression for the energy width ΔE of the ion energy distribution function (IEDF) in dual frequency reactors, which was obtained in Ref. 4 and will be used to discuss the results

$$\Delta E = \frac{8\lambda_2 e\overline{V_s}}{3\bar{s}\omega_{LF}}\left(\frac{2e\overline{V_s}}{M}\right)^{1/2}, \quad (2)$$

where $\overline{V_s}$ and $\bar{s}$ are the average sheath potential and width, respectively, λ_2 is a parameter determined from the sheath potential plot as a function of the phase in the LF cycle and $\lambda_2 \le 1$, ω_{LF} is the applied LF, M is the mass of the ion, and e is the electron charge.

3. Results and discussion

The calculations are performed for an $Ar/CF_4/N_2$ mixture at a ratio of 0.8/0.1/0.1 at a pressure of 30 mTorr. The gas temperature is set to 300 K. The choice of the grid spacing and the time steps is defined by the accuracy criteria for PIC/MC codes with explicit mover [10].

Figure 2 presents the simulation results, averaged over one or two LF cycles, for the plasma density in the discharge center (a), the ion current density at the powered electrode (b), and the electron energy in the discharge center (c) as a function of the LF voltage amplitude. The calculated characteristics for the (27+2) MHz case are averaged over 2 LF cycles since one LF cycle does not contain an integer number of HF cycles. The HF voltage amplitude is kept at 200V, while the HF is 27, 60, or 100 MHz. The LF voltage amplitude is 0, 100, 200, 300 or 400 V and the LF is 1 or 2 MHz. The simulations for (27+1) MHz, when the LF voltage is higher than 200 V, could not be performed because the two sheaths expand and become comparable with the electrode gap, so that the plasma cannot be sustained.

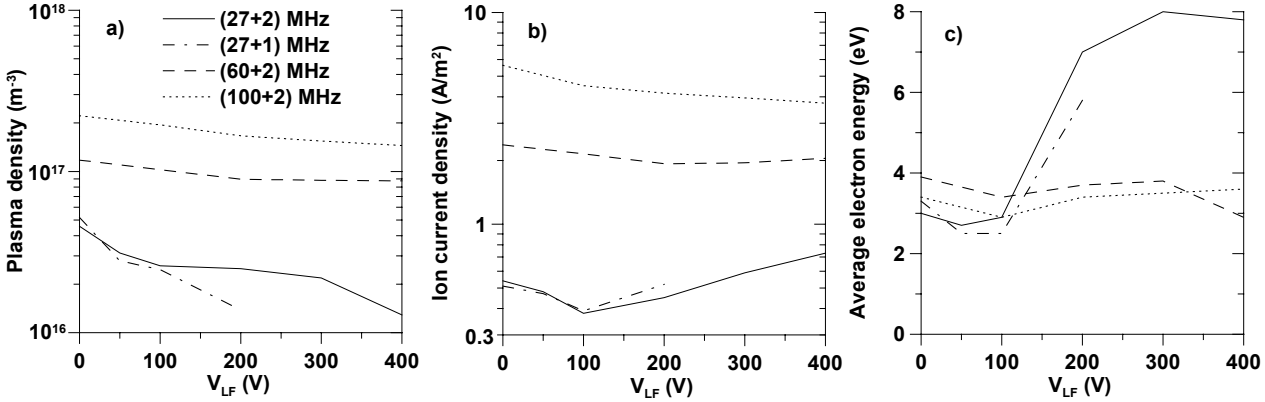

FIG. 2. Calculated plasma density (a), ion current density (b), and electron energy (c), averaged over the LF cycle as a function of the applied LF voltage amplitude at different frequency regimes; V_{HF} = 200 V.

It can be seen that for all investigated frequency schemes the introduction of the second LF voltage source decreases the plasma density in the discharge center [Fig. 2(a)]. Further, the drop is not very pronounced for the (60+2) and (100+2) MHz cases, while it decreases more clearly with increasing LF voltage for the other two frequency schemes. The ion current density exhibits a similar behavior as the plasma density for the (60+2) and (100+2) MHz regimes [Fig. 2(b)]. For the (27+2) and (27+1) MHz cases the ion current density shows a minimum at a LF voltage of 100 V and because of that, we made an additional simulation at 50 V. It is observed that the ion current decreases with varying the LF voltage from 0 till 100 V and it increases with further increase of the LF voltage, i.e. the ion loss increases. On the other hand, the electron energy also increases abruptly after 100 V [Fig. 2(c)] and consequently, the ionization rate, i.e. the ion production increases. The net effect of these processes is, however, a drop in the plasma density. The average electron energy shows little dependence on the LF voltage for the (60+2) and (100+2) MHz cases. Although the (27+1) and (60+2) regimes have a similar HF/LF ratio, it is observed that the LF voltage source has substantial influence on plasma density and ion current density at a HF of 27 MHz and the decoupling is possible only at higher primary frequencies. Therefore, independent control of plasma density and ion current is determined by the primary frequency and not by the frequency ratio, which was also experimentally observed [2].

Figure 3 shows the simulation results, averaged over one or two LF cycles, for the sheath potential (a) and width (b), and ion bombardment energy of Ar^+ and CF_3^+ ions (c). The calculated N_2^+ energy has values close to that of the Ar^+ and therefore we do not present it. A rise in the LF voltage leads to an increase of the sheath potential

and to an expansion of the sheath [Fig. 3(a) and (b)]. A similar behavior of the sheath width was observed experimentally [2] and numerically [6].

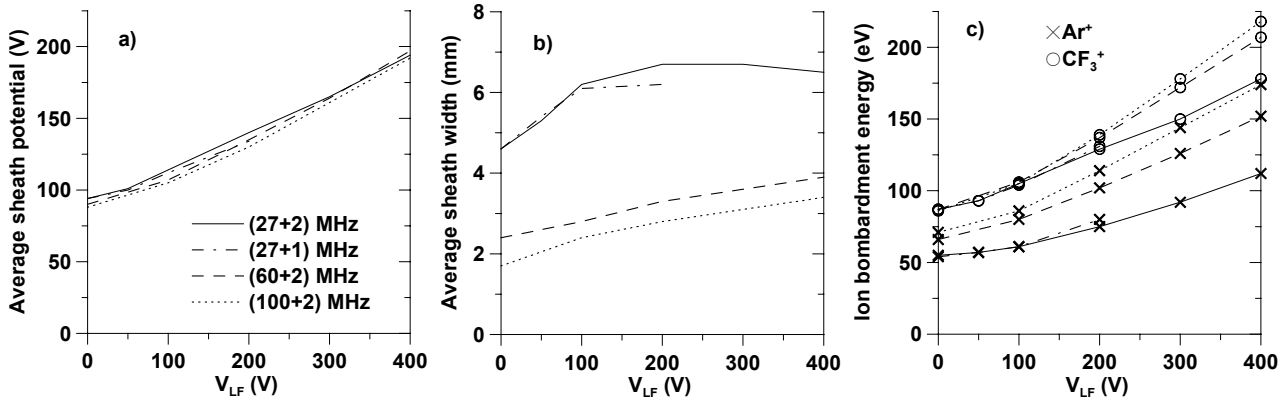

FIG. 3. Calculated sheath potential (a) and width (b), and Ar^+ and CF_3^+ bombardment energy (c), averaged over the LF cycle as a function of the applied LF voltage amplitude at different frequency regimes; V_{HF} = 200 V.

The ion energy [Fig. 3(c)] increases with the LF voltage because the sheath potential increases. Since the CF_3^+ ion does not experience charge exchange (see Ref. 4 for details about ion-neutral collisions), and therefore retains its energy, its average energy at the electrodes is higher, in comparison with the other two ions for the same operating conditions.

It is impossible to present the IEDF for all simulated operating conditions due to limited space, so that we have chosen to present them at a LF voltage of 200 V for the four frequency schemes (Fig. 4). The bimodal structure of the IEDF in the dual frequency reactors was discussed in detail elsewhere [4]. Figure 4 shows that the energy width, ΔE, increases with the HF when the LF is the same (cf. solid, dashed and dotted lines). According to Eq. (2) the energy width does not depend on the HF explicitly. However, it is inversely proportional to the average sheath width, which decreases with increase of the primary frequency [Fig. 3(b)]. The average sheath potential and the parameter λ_2 are calculated to be almost the same for the (27+2), (60+2) and (100+2) MHz cases. Furthermore, it is observed that the IEDF is broader when the LF is lower (cf. the solid and dash-dotted lines). Indeed, the energy width is inversely proportional to the LF in Eq. 2. The average sheath potential and width [Fig 3(a) and (b)], as well as the parameter λ_2 are calculated to have close values for the (27+2) and (27+1) MHz schemes. Consequently, the energy width increases with increasing the HF or decreasing the LF. The same behavior was observed for the other applied LF voltage amplitudes.

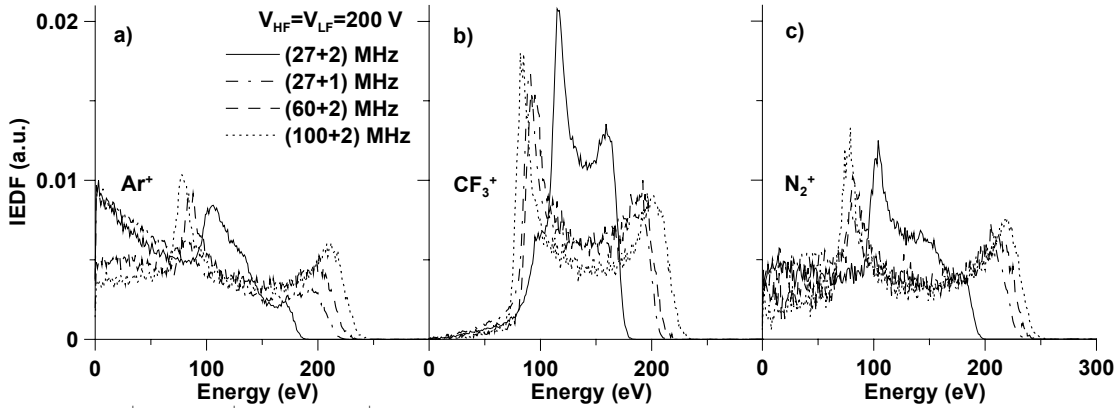

FIG. 4. Calculated Ar^+ (a), CF_3^+ (b), and N_2^+ (c) IEDF, averaged over the LF cycle, at HF and LF voltage amplitudes of 200 V at different frequency regimes.

Concerning the influence of the HF, it appears from Fig. 2 and 3 that the plasma density and ion current increase, and the sheath width decreases with HF, for the same LF voltage. The electron energy is between 3 and 4 eV for

the (60+2) and (100+2) MHz cases, and it increases with the LF voltage for the other two frequency schemes. The average ion energy [Fig. 3(c)] increases with HF because the sheath width decreases, and consequently the ions experience fewer charge exchange and elastic collisions with neutrals on their way to the electrodes, and therefore they retain their energy. A similar dependence of the plasma characteristics on the driving frequency was found in single frequency reactors [11].

A more detailed investigation of the simulations for a HF of 60 MHz and a LF of 1 or 2 MHz, keeping the LF voltage constant at 200 V or 0 V, i.e. single frequency scheme, and varying the HF voltage, shows that the plasma density and ion current density are only weakly affected by the second LF voltage source. Figure 5 presents the simulation results, averaged over the LF cycle, for the plasma density in the discharge center (a), the ion current density at the powered electrode (b), and the electron energy in the discharge center (c). The solid lines denote the results as a function of the LF voltage when the HF voltage is kept constant at 200 V for the (60+2) and (60+1) MHz cases. The dashed lines represent the calculations as a function of the HF voltage keeping the LF voltage constant at 200 V for the (60+2) and (60+1) MHz cases. Finally the dash-dotted lines illustrate the results for a single frequency reactor of 60 MHz, as a function of the driving voltage.

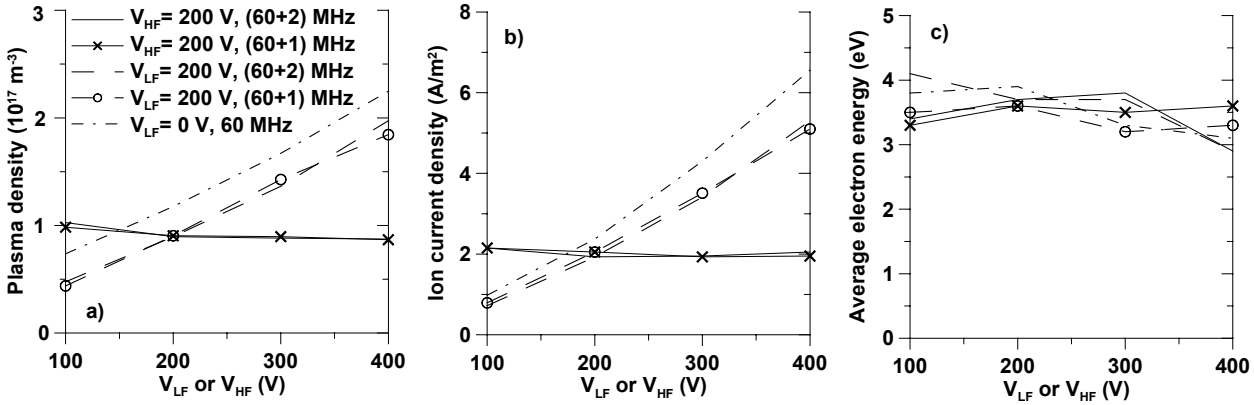

FIG. 5. Calculated plasma density (a), ion current density (b), and electron energy (c), averaged over the LF cycle as a function of the applied LF or HF voltage amplitude at different frequency regimes.

The plasma density slightly decreases from 10^{17} to $9\text{x}10^{16}$ m^{-3} when the LF voltage increases from 100 to 400 V and the HF voltage is kept at 200 V (solid lines) for both the (60+2) and (60+1) MHz cases. The ion current density is also nearly independent from the LF voltage and its value is about 2 A/m^2. The average electron energy in the bulk varies between 3 and 4 eV. It can be seen that for the (60+1) MHz case the LF voltage does not affect the EEPF and ionization rate [Fig. 6 (a) and (b), respectively]. The same is observed for the (60+2) MHz case and therefore, we do not present these results.

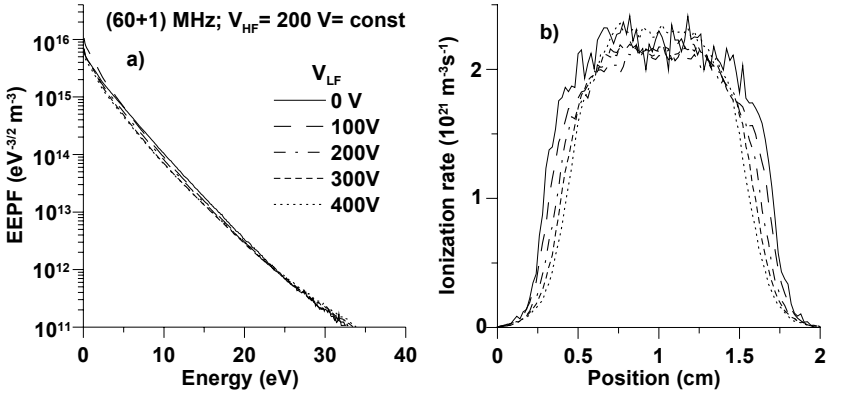

FIG. 6. Calculated EEPF (a) and ionisation rate (b) at a HF voltage of 200 V and LF voltages of 0, 100, 200, 300 and 400 V for the (60+1) MHz regime.

For the opposite operating condition, i.e. when the HF voltage is varying and the LF voltage is kept constant at 200 V, it is found that the plasma density scales linearly with the HF voltage [Fig. 5(a), dashed lines]. It increases from $5\text{x}10^{16}$ to $2\text{x}10^{17}$ m^{-3}. The same scaling law was observed in single frequency reactors [12]. Consequently, the plasma density shows the same dependence on the driving frequency, as if the second voltage source was not connected. However, the values of the plasma density are somewhat lower in comparison with the single frequency regime at the same driving voltage amplitudes [compare the dashed and dash-dotted

line in Fig. 5(a)]. It was already observed that introducing the second voltage source decreases the plasma density for any of the investigated frequency schemes [Fig. 2 (a)].

The ion current density increases with HF voltage from 0.7 to 5.3 A/m^2 [Fig. 5(b), dashed line] for both (60+2) and (60+1) MHz cases. It is found to scale as $j \sim V_{HF}^{3/2}$, which is similar to the scaling law in single frequency regime [Fig. 5(b), dash-dotted line]. Therefore, like the plasma density, the ion current density shows the same dependence on the driving frequency as if the second voltage source was not connected, but its values are somewhat lower than that in the single frequency reactor for the same HF voltage amplitude.

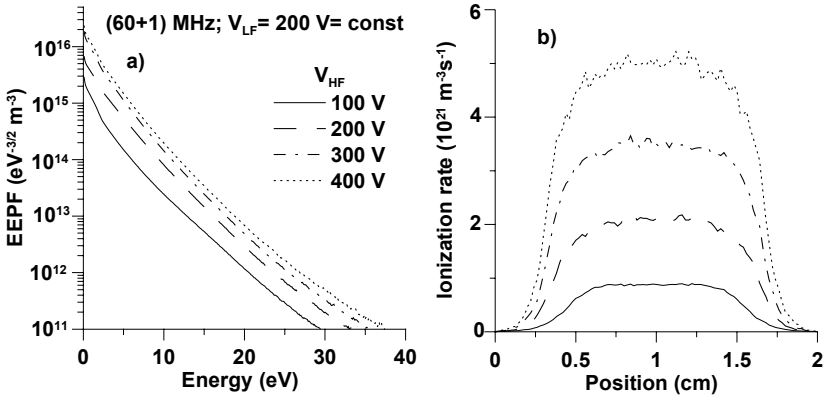

FIG. 7. Calculated EEPF (a) and ionisation rate (b) at a LF voltage of 200 V and HF voltages of 100, 200, 300 and 400 V for the (60+1) MHz regime.

The electron energy in the bulk varies between 3 and 4 eV [Fig. 5 (c)]. It can be seen that the slope of the EEPF is almost the same for all investigated HF voltage amplitudes [Fig. 7(a)] for (60+1) MHz, and the distribution is more or less Maxwellian so that the average electron energy does not change considerably. The number of high energy electrons increases with HF voltage and consequently the ionization rate also increases [Fig. 7(b)]. Similar behavior of the averaged energy, EEPF, and ionization rate is observed for the (60+2) MHz and single frequency reactor.

The sheath potential increases linearly with the applied voltage and consequently with the LF or HF voltage amplitude [Fig. 8(a) and see Eq. (1)]. The sheath expands with increasing the LF voltage [Fig. 8(b), solid lines], and it contracts with increasing the HF voltage [Fig. 8(b), dashed line] in the dual frequency regime, but it is wider in comparison with the single frequency case for the same HF voltage (compare with dash-dotted line). The sheath width is only weakly dependant on the applied voltage in the single frequency case [Fig. 8(b), dash-dotted line]. Other authors also observed that the applied voltage did not influence the sheath width in a single frequency reactor [12]. The average ion bombardment energy [Fig. 8(c)] increases with the LF or HF voltage amplitude, because the sheath potential increases with the applied voltage. The average ion energy increases with decrease of the LF because the IEDF is broader [see Fig. 9(a) and Eq. 2].

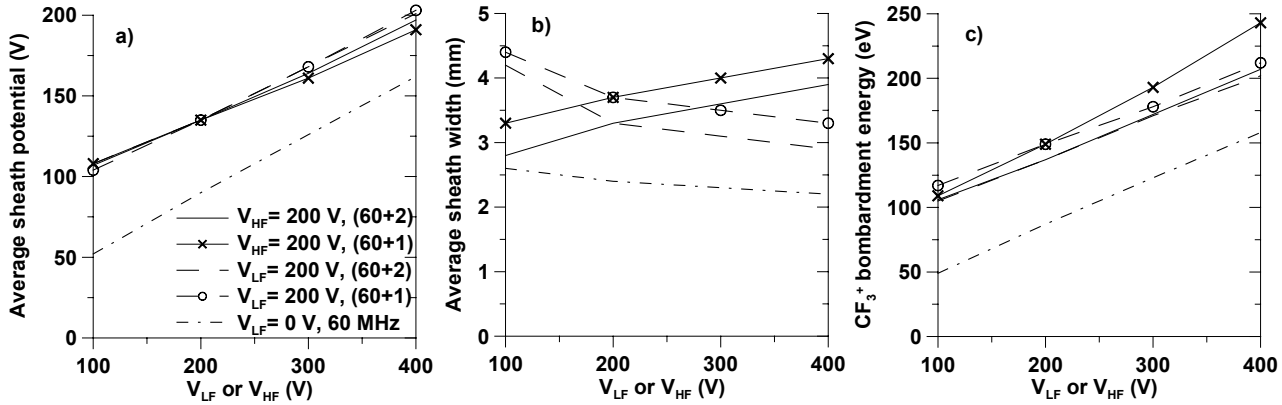

FIG. 8. Calculated sheath potential (a) and width (b), and CF_3^+ bombardment energy (c), averaged over the LF cycle as a function of the applied LF or HF voltage amplitude at different frequency regimes.

Figure 9 presents the CF_3^+ IEDF for the (60+1) and (60+2) MHz cases at HF and LF voltages of 200 and 100 V,respectively, (a), and dependence of the IEDF on the LF voltage (b) or HF voltage (c) for the (60+1) MHz

regime. The CF_3^+ ions reach higher energy with decrease of the LF or increase of the applied voltages. This behavior is observed for the other considered positive ions and for all the investigated frequency schemes. It was shown above that the IEDF is broader with increase of the HF (see Fig. 4). Consequently, the ion energy depends on both voltage sources and cannot be controlled only by the LF source.

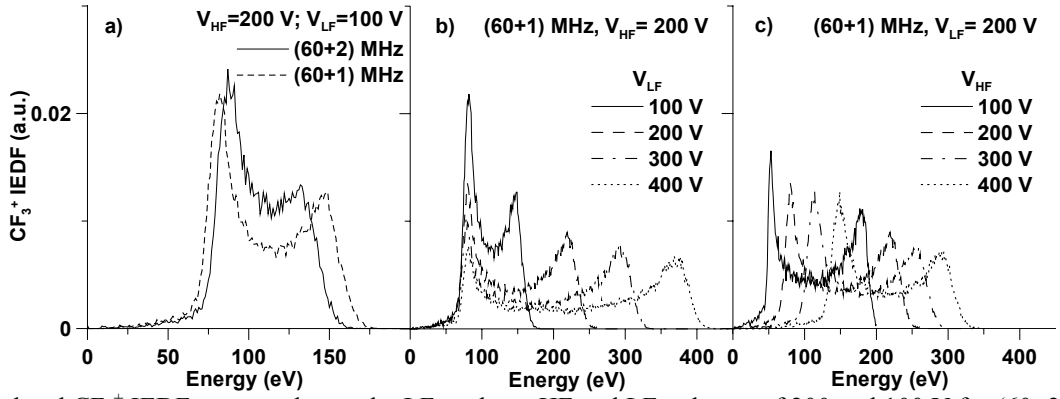

FIG. 9. Calculated CF_3^+ IEDF, averaged over the LF cycle, at HF and LF voltages of 200 and 100 V for (60+2) and (60+1) MHz cases (a), at different HF voltage amplitudes (b) and LF voltage amplitudes (c) for the (60+1) MHz case.

4. Summary

A detailed numerical investigation by means of the PIC/MC method was made to study the influence of the applied frequency sources on the plasma characteristics in $Ar/CF_4/N_2$ plasmas in a dual frequency reactor.

It is observed that the decoupling of the two sources is possible with increase of the applied HF to values of 60 MHz and higher, and it is not defined by the frequency ratio. The plasma density and ion current density show the same dependence on the driving voltage as if the second voltage source was not connected, but their values are somewhat lower than that in the single frequency reactor for the same HF voltage amplitude. The electron energy, EEPF and ionization rates are almost unaffected by the LF source. The plasma density and ion current increase, and the sheath width decreases with HF when the other operating conditions are the same. The average ion bombardment energy increases with HF or LF voltage amplitude when the other voltage amplitude is kept constant, because the sheath potential increases with the sum of the applied HF and LF voltages. Finally, the IEDF is broader with increasing the HF or decreasing the LF.

Removal of Methanol and Dimethyl Sulfide by Pulsed Corona Discharge: Energy Efficiency and Byproducts Formation

E.H. Lock, A.V. Saveliev, L.A. Kennedy

Department of Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, USA

Abstract
The removal of methanol and dimethyl sulfide in a pulsed corona discharge is studied experimentally varying process parameters such as applied voltage, pulse repetition rate, initial concentration of pollutant, temperature and humidity of the process stream. Specific consideration is given to the formation of unwanted byproducts. Total removal costs are evaluated using emission credit method and required electric energy inputs.
Keywords: pulsed corona, pollution control, methanol, dimethyl sulfide

1. Introduction

Non-thermal plasma techniques have shown very promising results to address the current increasing pollution problems caused by a variety of sources such as hydrocarbon burning electric power generating plants, diesel engines exhausts, paper mills, steel and chemical production plants. Among other pollutants successfully treated with plasmas are volatile organic compounds such as toluene, trichloro-ethylene, acetone, methanol, dimethyl sulfide, carbon tetrachloride, etc. [1, 2].

For complete characterization of pollutant removal process, not only the removal efficiency but also the generation of byproducts and cost of their secondary treatment must be considered. However, there are a limited number of studies analyzing formation of byproducts during plasma assisted removal of VOCs [3]. In the present work, the influence of the process parameters such as temperature, humidity, and pulse repetition rate on the destruction efficiency of methanol and dimethyl sulfide is studied experimentally using a pulsed corona discharge reactor. Another objective of this work is to evaluate the costs of the removal process and find the optimal condition for application of the industrial scale plasma removal systems. Considerable attention is directed towards the effect of humidity since there are conflicting reports describing humidity effect on the efficiency of the removal process and byproduct formation. The byproducts generated during the destruction of methanol and dimethyl sulfide are identified and the influence of process parameters on their concentrations is studied.

2. Experimental Approach

A schematic diagram of pulsed corona reactor is shown in Fig. 1. The corona discharge is generated in a wire-in-cylinder coaxial electrode system by a thyratron-based variable-voltage, variable-frequency power supply. The delivered power was varied from 0.2 to 12 W by controlling the high voltage pulse amplitude and the pulse repetition rate that ranged from 15 to 1000 Hz. Pulses of approximately 100 ns duration and 10 ns rise time were transmitted to the corona electrode by means of a 50 Ω coaxial cable. The inner high voltage electrode was 0.5 mm diameter Inconel wire. The outer electrode was 1 m long cylindrical stainless steel tube with a 22.2 mm internal diameter. An external aluminum jacket surrounded the outer electrode in order to achieve uniform heating of the reactor. The reactor was placed in tubular furnace (model 3200, Lindberg, Inc) that was operated over the temperature range 50 to 180 °C. A series of J-type thermocouples were used to ensure the uniformity of temperature at various reactor points.

To evaporate the liquid compounds and to properly mix the different chemicals, a stainless steel mixing chamber, heated to 160 °C and filled with glass beads, was placed before the reactor. Because of the different chemical nature of dimethyl sulfide (DMS) and methanol, two different approaches were used to generate industrial-like streams. Methanol was dissolved in water and pumped with a syringe pump (Model 200, KD Scientific) and sprayed into the gas stream. DMS was supplied as a gas mixture using nitrogen as a balance gas. A mass flow controller measured the inlet gas flow rate that was maintained at 2 slm during all experiments.

This resulted in residence times of 7 seconds. The air was provided by a dry zero air supply that insures no influence of residual humidity or organic compounds from the room air.

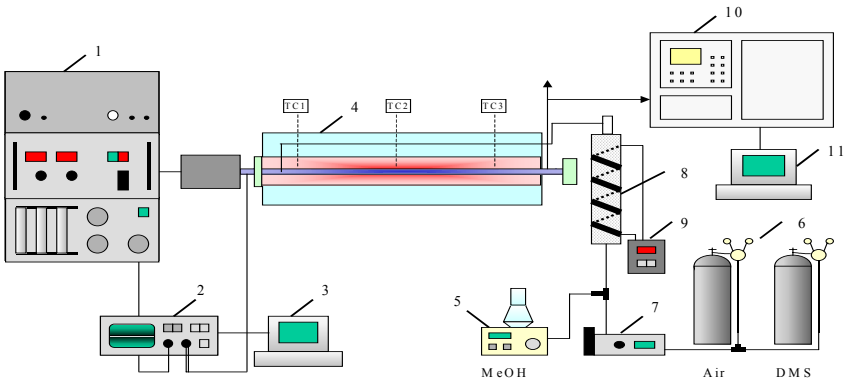

Fig. 1. Schematic of the experimental setup: 1 - pulsed power supply, 2 - oscilloscope, 3,11 -computers, 4 - pulsed corona reactor, 5 - syringe pump, 6 - air and DMS supply cylinders, 7 - mass flow controller, 8 - mixing chamber, 9 - temperature controller, 10 - gas chromatograph.

Voltage was measured using a high voltage probe (Model D 6015 A, Tektronix Inc.), current measurements were performed using a current monitor (Model 411, Pearson Inc.). Electrical characteristics were acquired with a digital oscilloscope (HP 546126 B) and the digitized wave forms were transmitted to a computer and analyzed with HP 34801A Bench Scope software. Concentrations of VOCs were determined using a gas chromatograph (Varian Inc, Model 3800), analyzing input and output samples. CO, NO_x and SO_2 were measured with a CO Analyzer (Thermo Environmental Instruments), a NO_x Analyzer (Thermo Environmental Instruments) and a SO_2 Analyzer (Horiba), respectively.

The figures of merit used in this work are the destruction and removal efficiency (DRE), and the specific energy input (SEI). The destruction and removal efficiency is defined as a ratio of the difference between the initial concentration C_0 and final concentration C to the initial concentration C_0. DRE is dimensionless and it is usually presented as a percentage. In the economic evaluation of the removal process the price of electricity and fines associated with pollutant emissions are taken into account.

3. Results and Discussion

The initial pollutant concentration for these experiments was 1000 ppm. The pulse repetition rate of 1000 Hz for methanol and 250 Hz for dimethyl sulfide and voltage of 12 kV were held constant. Figure 2 presents the influence of temperature and humidity variation on the removal efficiency of methanol and dimethyl sulfide. An increase of temperature results in increase of the electron mean energy leading to higher removal efficiencies. The effect of humidity on the experimental results is more intriguing. For both pollutants the best results were observed at absolute humidity of 0.5 %. This suggests the important role of water and, in particular, OH radicals in oxidation and removal of organic species. Small amounts of added water vapor effectively contribute to the removal process, while high water contents reduce removal efficiencies. Studies by Ono and Oda [4] on OH concentration at different humidity levels show that the maximum concentrations of OH radicals are produced at humidity of 0.5 %, which is in agreement with our findings. However, increase in

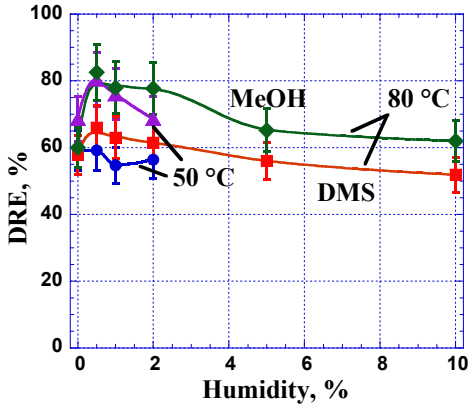

Fig. 2. DRE dependence on humidity. The initial concentrations of methanol and DMS are 1000 ppm.

humidity beyond 0.5% reduces the efficiency of the process affecting the electron distribution function and mean electron energies attainable at given peak voltages. As a result the pollutant removal for 5% and 10 % humidity are much lower compared to the 0-2% humidity levels.

Due to the small pulse duration (~100 ns) and large interpulse intervals, the pulses at repetition rates below o.1 MHz are practically independent from each other. For a constant flow rate, SEI is proportional to the pulse repetition rate and power input to the single corona pulse. The energy of the pulse, in turn, can depend on chemical composition of the gas, e.g. humidity level and pollutant concentration. As shown in Fig. 3, the removal of dimethyl sulfide with initial concentration of 1000 ppm requires much less energy compared to removal of the same methanol concentration. The power of the pulse for DMS was varied only slightly for 50 and 80 °C resulting in almost constant SEIs. In the case of methanol the increase of temperature produced slightly higher SEI values. At a constant temperature, increasing the humidity levels decreases SEI due to the lower electron temperatures, lower ionization rates and, hence, lower discharge currents.

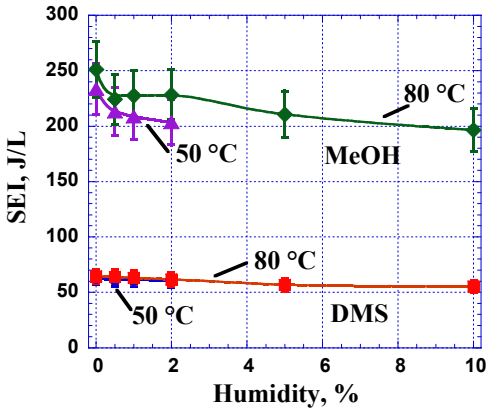

Fig. 3. SEI dependence on humidity for 1000 ppm methanol and dimethyl sulfide streams.

In summary, temperature increases the mean electron energy that has twofold effect: it increases the removal efficiency and the specific energy input. Humidity increases the efficiency until the threshold of 0.5%. Further increase of humidity causes decrease in efficiency and in power levels due to the reduction of electron temperatures.

The above observation raises the question how the energy of the generated electrons affects the removal efficiency and byproducts generation. Two ways to control discharge power were implemented in our experimental studies. The power input can be control independently by a variation of peak pulse voltage and by a variation of pulse repetition rate. The experimental results obtained using these approaches are shown in Fig. 4. In one set of experiments (case 1) the voltage was increased from 8 kV to 14 kV keeping the pulse repetition rate constant at 250 Hz. In another set (case 2) the peak pulse voltage of 8 kV was kept constant and the repetition rate was increased from 250 Hz to 1316 Hz. Other experimental conditions included temperature of 80 °C, initial pollutant concentrations of methanol and DMS equal to 1000 ppm and 800 ppm respectively and 0% humidity. As shown in Fig. 4, increasing the energy of the pulse causes much stronger increase in both efficiency and byproducts levels. For example, for DMS at power of 3W the differences in the efficiencies and NO_2 levels between cases 1 and 2 are respectively 15 % and 15 ppm. There are also different trends for two cases: raising the energy of the pulse causes exponential increase, while raising the frequency causes linear increase of NO_2 concentration and the removal efficiency. High energy electrons (e.g., from electron beam sources) are usually considered to be favorable for achieving the high removal efficiencies at low SEIs. However, as suggested by our results, these energetic electrons could be more effective in generation of unwanted byproducts as well. To find the most favorable conditions for pollution control always means to find the best compromise between the attainable removal efficiency and byproducts levels. In particular, the acceptable byproduct levels can be defined using the permissible exposure limits (PEL) set by the Occupational

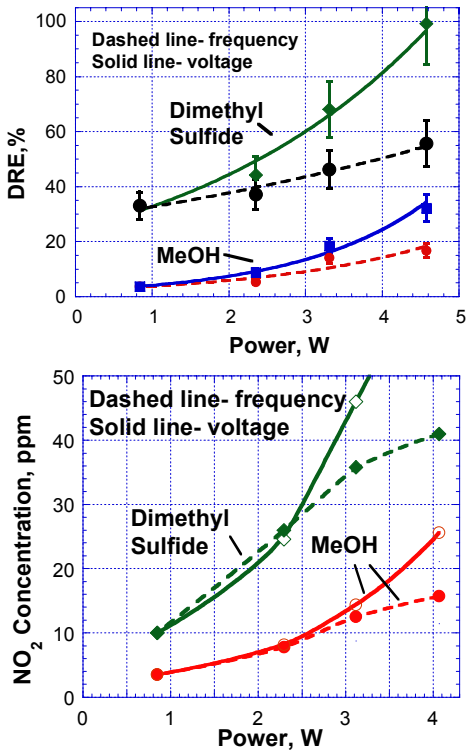

Fig. 4. DRE and NO_2 dependence on power.

Safety and Health Administration [5] and by the permissible amounts of pollutants that can be discarded in the atmosphere. For example, in the case of methanol PEL value is 200 ppm. This suggests that for a stream initially containing 1000 ppm of methanol a removal efficiency of 80 % and above will be required.

Byproducts formed during methanol destruction include CO and NO_x. CO is very dangerous and unwanted byproduct in any waste treatment process. It is generated by oxidation of HCO, HC_2O, CH_2, CH_2OH, CH_2CO and other intermediate products in the removal process of methanol and dimethyl sulfide. CO is also produced from reactions of CO_2 with N and O radicals. DMS oxidation processes have been studied extensively in atmospheric chemistry. These studies suggest that the major oxidation products are SO_2, NO_x and CO. Unfortunately studies on the plasma destruction of DMS are scarce. In our experiments we detected small amounts of methanol formed at intermediate powers. These trace amounts can completely destroyed applying higher SEIs. Simultaneous formation of NO_2 and SO_2 as byproducts occurs in the case of dimethyl sulfide removal. This suggests a possible interaction between their formation pathways. Indeed, as shown in Fig. 4, the generated concentrations of NO_2 for DMS are larger by almost a factor of two compared to methanol. Possible explanation for this can be attributed to reactions of sulfur containing radicals such as CH_3S, CH_3SOO, CH_3SO and CH_3SO_2 with NO and NO_2. SO_2 is very dangerous byproduct because of its oxidation in the troposphere to H_2SO_4 and is considered as a potential cause for the acid rain. No intermediate species like HNO_2, HNO_3, HSO_3, H_2SO_4 were detected in the output.

Figure 5 shows the processing of the stream with initial methanol concentration of 1000 ppm. Almost complete destruction of methanol is achieved at energy input of 300 J/l. However, the corresponding values of formed CO and NO_2 at this point are 1200 ppm and 80 ppm, respectively. At further power increase, the level of CO ppm starts to drop decreasing to about one third of the maximum value at 800 J/l. At the same time NO_2 level increases linearly with power reaching 250 ppm; this is 3 times higher than the previous value of 80 ppm. These results show that another important issue related to the selection of the optimal operating conditions is to know the price of discarding into the atmosphere a certain type of pollutants. Although the penalties for higher byproduct amounts in the exhaust streams are determined on case-by-case basis, the new policy of emission trading allowed us to conduct approximate cost analysis.

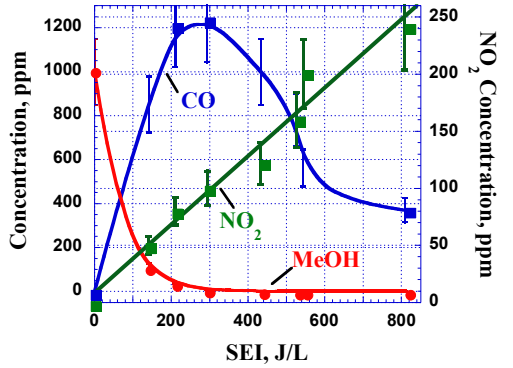

Fig. 5. Byproduct generation by removal of methanol.

The prices (per ton) for NO_x, SO_x and VOC emissions [6] are evaluate as \$1000, \$175, and \$3500, respectively. The price for CO is assumed to be \$150 based on reports from other sources. The cost of electricity is taken as 5.8 cents per kWh [7]. The cost analysis was performed for a gas flow rate of 100,000 m^3/h. For initial concentration of 1000 ppm, the estimated cost of untreated methanol emissions is 385 \$/h. The post treatment cost includes the cost of emitted CO, NO_2, and residual methanol. It initially drops with applied power and then slightly increases (Fig. 6). The total cost is the sum of the post treatment emission cost and the cost electricity. As shown in Fig. 6, the total cost has a minimum of approximately \$350 and then increases due to increase of electrical cost. However, by working at the conditions corresponding to this minimum savings can been realized by using pulsed corona discharge reactor.

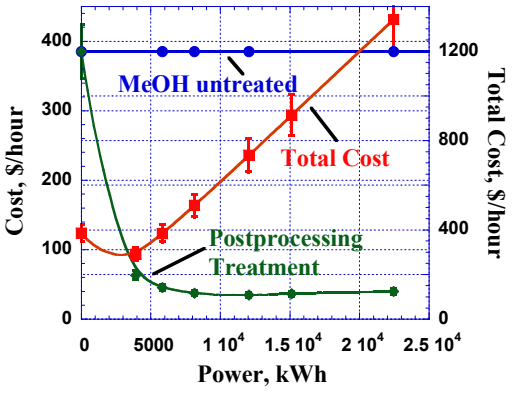

Fig. 6. Cost analysis of treatment of 1000 ppm methanol stream with flow rate of 100,000 m^3/h.

In addition to NO_2 and CO, SO_2 and methanol are formed as byproducts during the removal of dimethyl sulfide. The experiments were performed at the same operating conditions as described for Fig. 4. As shown in Fig.7, with increase of the power the SO_2 concentration raises to almost 700 ppm for the initial concentration of dimethyl sulfide of 800 ppm. This means that almost all of the latter is converted to SO_2. The increase of the power first leads to increase of methanol concentration to 50 ppm and than to its decrease. This implies that methanol would be completely destroyed by higher powers. The generated NO_2 and CO levels are less than 100 ppm and 600 ppm, respectively. The cost analysis for this system at the higher flow rate is presented in Fig. 8. As was shown above dimethyl sulfide was easier to remove than methanol. The lower electrical power is needed for this pollutant removal, which mean that savings as high as 600 $/h are realized. So based on our cost analysis for methanol and dimethyl sulfide it can be concluded that depending on the pollutant type and initial pollutant concentration pulsed corona discharge can be a successful pollution control technique.

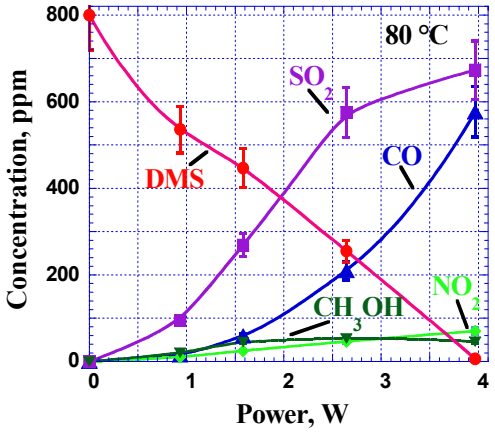

Fig. 7. Byproduct generation by removal of dimethyl sulfide.

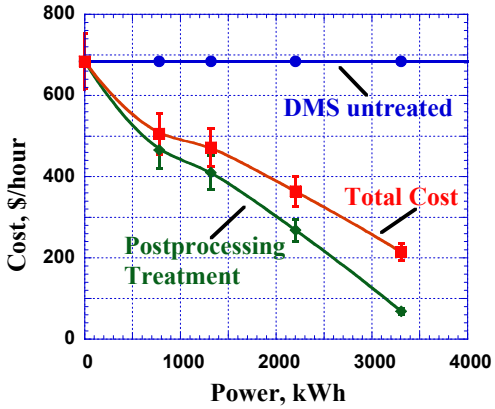

Fig. 8. Cost analysis of treatment of 800 ppm dimethyl sulfide.

4. Conclusions

In this paper the removal of the volatile organic compounds (methanol and dimethyl sulfide) and the influence of the process parameters such as temperature, humidity, pulse energy and pulse repetition rate are studied experimentally. Byproducts that are generated for these two pollutants are measured and the total cost of their treatment for industrial scale system is evaluated. It is shown that the mean electron energy is increased with temperature resulting in higher removal efficiencies and specific energy inputs. Small amounts of water vapor increase the effectiveness of the pollutant oxidation process until the threshold observed at absolute humidity of 0.5 %. Further increase of water content in the air stream causes decrease in the efficiency at given peak discharge voltages. At higher the mean electron energies the amounts of generated byproducts are large. This raises the question of finding the optimal process conditions as a compromise between required removal efficiency and acceptable byproduct levels.

A STUDY OF NANOCRYSTALLINITY IN nc-Si, nc-Si, C and nc-Si, Ge FILMS DEPOSITED BY PECVD

M. M. Giangregorio, M. Losurdo, P. Capezzuto, G. Bruno
Institute of Inorganic Methodologies and of Plasmas IMIP-CNR via Orabona, 4 – 70126 Bari, Italy

Abstract

Si-based thin films, including nc-Si, $Si_{1-x}Ge_x$ and $Si_{1-x}C_x$ alloys, have been deposited by plasma enhanced chemical vapor deposition (PECVD) using SiF_4:H_2, SiF_4:GeH_4:H_2 and SiF_4:CH_4:H_2 plasmas, respectively. The SiF_4-based plasmas are characterized by the fact that low flux of CH_4 and GeH_4 are used for incorporation of C and Ge in the alloys. The correlation between alloys nanostructure and optical properties is investigated using Raman and ellipsometry spectroscopies. The role of fluorine atoms in the growth chemistry and material nanostructure is discussed.

1. Introduction

Basic capabilities of silicon technologies, including photovoltaics, electronics and optoelectronics [1-3], can be improved by "bandgap engineering" using Si-based alloys, such as silicon germanium ($Si_{1-x}Ge_x$) and silicon carbon ($Si_{1-x}C_x$), which provide a tunable band gap from values lower than 1eV using $Si_{1-x}Ge_x$ to values higher than 2.5eV using $Si_{1-x}C_x$ [4]. Apart from alloy composition of amorphous thin films, nanostructure is an additional factor for tuning properties and functionality. For instance, nanocrystalline silicon (nc-Si) is widely investigated for optoelectronics, due to its photoluminescence, which can be tuned by the crystallite size. Nano/microcrystalline silicon is attractive for thin film transistors (TFTs) and $Si_{1-x}Ge_x$ and $Si_{1-x}C_x$ alloys are used for solar cells.

In this paper, we present a study of the nanotructure and optical properties of hydrogenated $Si_{1-x}Ge_x$:H and $Si_{1-x}C_x$:H alloys deposited by plasma enhanced chemical vapor deposition (PECVD) using SiF_4:GeH_4:H_2 and SiF_4:CH_4:H_2 plasmas, respectively. These non-conventional plasmas proposed as alternative to generally used hydrogenated systems such as SiH_4-CH_4-H_2 [5] and SiH_4-GeH_4-H_2 [6] presents the advantage of small addition of CH_4 or GeH_4 to the SiF_4 plasma for incorporation in the film of C% and Ge% higher than 40%.The role of fluorine atoms, compared to hydrogen atoms, on the material structure and composition is discussed. The impact of alloys films heterogeneity on the optical gap is focused. Spectroscopic ellipsometry (SE) is used to establish a correlation between the film structure and optical response.

2. Experimental

Deposition of (a) silicon, (b) $Si_{1-x}C_x$ and (c) $Si_{1-x}Ge_x$ films with different structure going from amorphous to nanocrystalline were deposited by parallel-plate r.f. 13.56 MHz PECVD on Corning glass, at a pressure of 0.3 Torr, a r.f. power in the range 10-30W and at a temperature of 250°C, using fluorinated (a) SiF_4-H_2 plasmas with a SiF_4/H_2 ratio in the range 0.1-10 to have film with different structure, (b) SiF_4-CH_4-H_2 plasmas, with a SiF_4 flux of 20 sccm, while the CH_4 flux was varied in the range 0.1-0.3 sccm to have films with different carbon content while the H_2 flux was changed in the range 0.1-30 sccm to have film with different structure and (c) SiF_4-GeH_4-H_2 plasmas, with SiF_4 and H_2 fluxes of 10 and 1 sccm, respectively, while the $GeH_4/(SiF_4+GeH_4)$ ratio was varied in the range 0-5 to have films with different germanium content and different structure.
The film anatomy has been analyzed by spectroscopic ellipsometry (SE).

Spectroscopic ellipsometry measures the change in the polarization state of light when it interacts with an optical system. SE spectra of the real, $\langle\varepsilon_1\rangle$, and imaginary, $\langle\varepsilon_2\rangle$, parts of the pseudodielectric function, $\langle\varepsilon\rangle = \langle\varepsilon_1\rangle + i\langle\varepsilon_2\rangle$, were acquired with a phase modulated spectroscopic ellipsometer (UVISEL-Jobin Yvon) in the range 0.75-6.5eV. SE spectra were analyzed using the Bruggeman effective medium approximation (BEMA) [7]. The dielectric functions of nc-Si with grain size of ≈3nm [8] and of a-Si from ref. [9] were used.

Optical functions of $Si_{1-x}C_x$:H films were analyzed using the tetrahedron model [10] for representation of the Si-C bond configuration. Using this approach, we discerned films with the same overall carbon content but with different nanostructure and Si-C bond configurations

The approach used to analyze optically the $Si_{1-x}Ge_x$:H thin films consists in parameterization of the dielectric function $\varepsilon(E) = \varepsilon_1(E)+i\varepsilon_2(E)$ as a function of the photon energy, E, using the Tauc-Lorentz equation [11-12] that fits amorphous semiconductor dielectric functions over a wide energy region. The energy gap, obtained by the parameterization procedure, gives information on the incorporated Ge content and on the film structure.

SE results are corroborated by Raman measurements. The composition of alloys was determined from energy dispersive spectroscopy (EDS) and X-ray photoelectron spectroscopy (XPS).

3. Results

Figure 1a shows the dependence of the film crystalline and amorphous volume fraction and of microporosity as a function of the SiF_4/H_2 ratio. With the decrease of the SiF_4/H_2, the crystalline fraction, fc, increases while the amorphous fraction, fa, decreses. Indeed the nanostructure changes also depending on other experimental parameters such as the He dilution. Figure 1b shows the imaginary, $<\varepsilon_2>$, part of the pseudodielectric function of silicon films deposited at a SiF_4/H_2 ratio of 2 (low ratio) and 6 (high ratio). The presence of the E_1 and E_2 peaks at 3.4eV and 4.2eV gives evidence of the crystallinity of the silicon films which is enhanced in films deposited at low SiF_4/H_2 ratio (sharper E_1 and E_2). The crystallinity of the silicon films, determined by the SE analysis, has also been confirmed by Raman measurements (see inset in figure 2b) which shows the predominant peak at ~510cm^{-1} due to the TO vibration of Si crystallites.

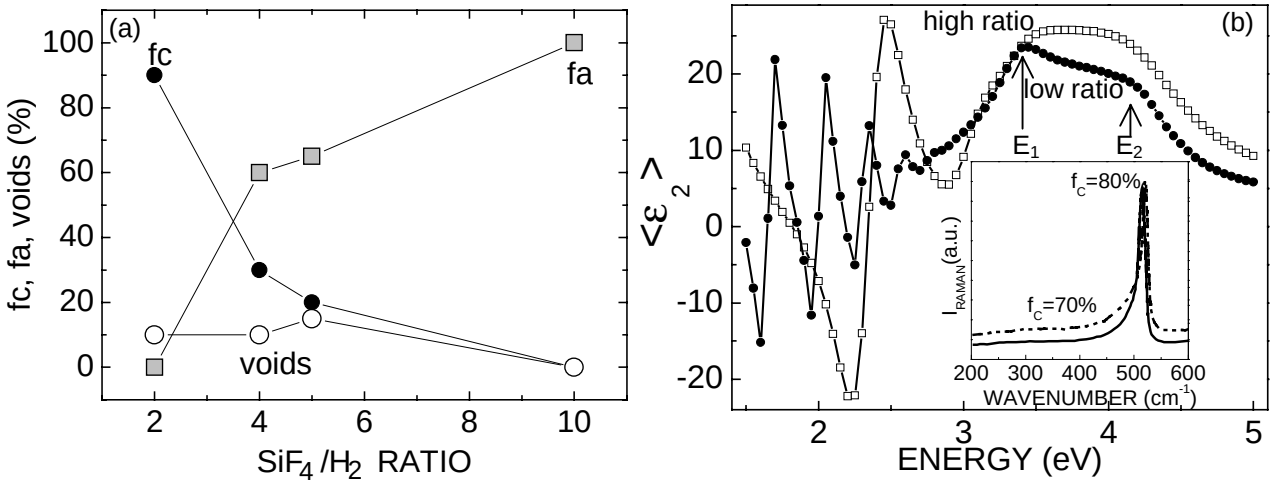

Fig. 1: (a) Dependence of μc-Si the film crystallinity and microporosity on the SiF_4/H2 ratio; (b) Imaginary, $<\varepsilon_2>$, part of the pseudodielectric function of silicon films deposited at a SiF_4/H_2 ratio of 2 (low ratio) and 6 (high ratio). Raman spectra of silicon films with different crystalline fraction, fc, is also reported in the inset.

The SiF_4/H_2 ratio acts on the relative concentration of the fluorine atoms and of the film building-blocks, which have been identified in the SiFx radicals and atomic hydrogen [13-14]. These results indicate an important role of the fluorine atoms in the improvement of film nanocrystallinity and in controlling the film nanotructure. In particular, fully nanocrystalline films with large grains are obtained at the border-line between the Si deposition and etching processes, the latter being operated by fluorine atoms, as discussed in the below.

The SiF_4/H_2 ratio is an important parameter also for deposition of $Si_{1-x}C_x$ alloys. Figure 2a shows the SE spectra of the imaginary part, $<\varepsilon_2>$, of the pseudodielectric function of films deposited at different

SiF_4/H_2 ratio and the same CH_4 flux of 0.2sccm. The films resulted to have the same carbon content, C%=14, but different structure. In particular, the broad peak at approximately 3.6 eV is indicative of the amorphous character of the sample deposited at SiF_4/H_2=4 and a r.f. power of 20W. Conversely, the presence of the E_1 and E_2 CPs at about 3.4 eV and 4.2 eV, characteristic of crystalline silicon, gives evidence of the nanocrystallinity of the sample, which has been deposited at SiF_4/H_2=40 and a r.f. power lower than 15W. These spectra provide evidence that the optical properties of $Si_{1-x}C_x$ alloys depend, not only on C content, but also on nanocrystallinity. In particular, the blue-shift of the interference system for the nanocrystalline sample indicates a higher optical gap for materials with a crystalline phase present. The presence of Si-crystallites with a grain size of ≈10nm can be also seen in the Raman spectrum shown in the inset of figure 2a.

The effect of the alloy composition and silicon nanocrystalline volume fraction on the optical band gap is summarized in Fig. 2b. Here, the E_{04} gap, which is defined as the energy at which the absorption coefficient, α, is 10^4 cm^{-1}, is shown. The E_{04} gap increases with the carbon content, in agreement with theoretical and experimental analyses [15] but for the same C% the segregation of silicon nanocrystallites in a SiC matrix further increases the E_{04} gap value. Therefore, the advantage of nc-$Si_{1-x}C_x$:H alloys is that a lower C% (7%) results in E_{04} gap values as high as that of amorphous a-$Si_{1-x}C_x$:H film with very high (>27%) C-content.

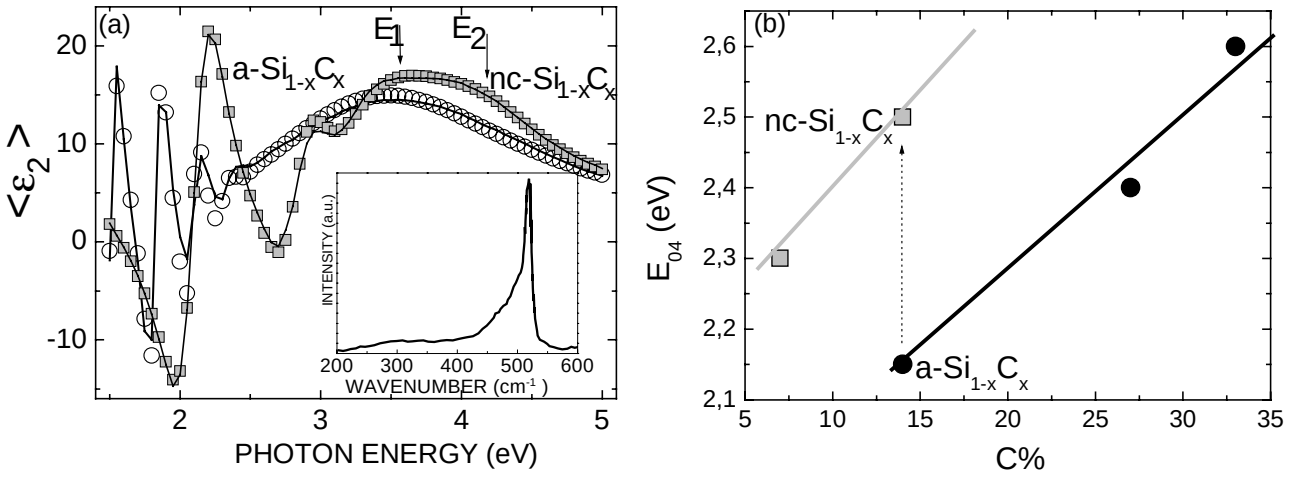

Fig.2: (a) Experimental (symbols) and calculated (line) SE spectrum of the imaginary part, $<\varepsilon_i>$, of the dielectric function of a-$Si_{1-x}C_x$ and nc-$Si_{1-x}C_x$ films with different structure. Raman spectrum of nanocrystalline nc-$Si_{86}C_{14}$ film is shown as inset; (b) Plot of the E_{04} optical gap of a-$Si_{1-x}C_x$ (full symbols) and nc-$Si_{1-x}C_x$ (empty symbols) as a function of carbon content and nanostructure.

Figure 3a shows the SE spectra of the real, $<\varepsilon_1>$, and the imaginary, $<\varepsilon_2>$, parts of the pseudodielectric function of hydrogenated silicon-germanium ($Si_{1-x}Ge_x$:H) films deposited on silicon substrate at a different $GeH_4/(SiF_4+GeH_4)$ % ratio, resulting in a Ge content ranging from 25% to 60%.

The optical properties of the $Si_{1-x}Ge_x$:H films were parameterized by a "five-parameters" Tauc-Lorentz dispersion equation [11-12]. The Tauc-Lorentz parameterization gives the values of the band-gap as a function of Ge-content, which are summarized in Fig. 3b. Here, various values reported in literature are indicated as gray region. A bandgap value of 1.42 eV is found for the $Si_{0.4}Ge_{0.6}$ alloy, which cannot be explained by the Ge content, but is related to quantum effect due to the presence of Ge nanocrystals. The presence of Ge nanocrystals has also been found by Raman measurements. Raman spectra for the films with the extreme compositions of $Si_{0.75}Ge_{0.25}$ and of $Si_{0.4}Ge_{0.6}$ are shown in Fig. 4. The spectrum of the $Si_{0.75}Ge_{0.25}$ film is typical of an amorphous alloy with broad lines centered at ~290, 400 and 470cm^{-1} corresponding, respectively, to Ge-Ge, Ge-Si and Si-Si vibrations. No evidence of segregation of micro- or nanocrystalline

silicon and or of the alloys phase is found. Conversely, the narrower mode of Ge-Ge bonds at ~270 cm^{-1} indicates that Ge nanocrystals segregate in the Ge-rich $Si_{40}Ge_{60}$ alloy, impacting on the optical gap.

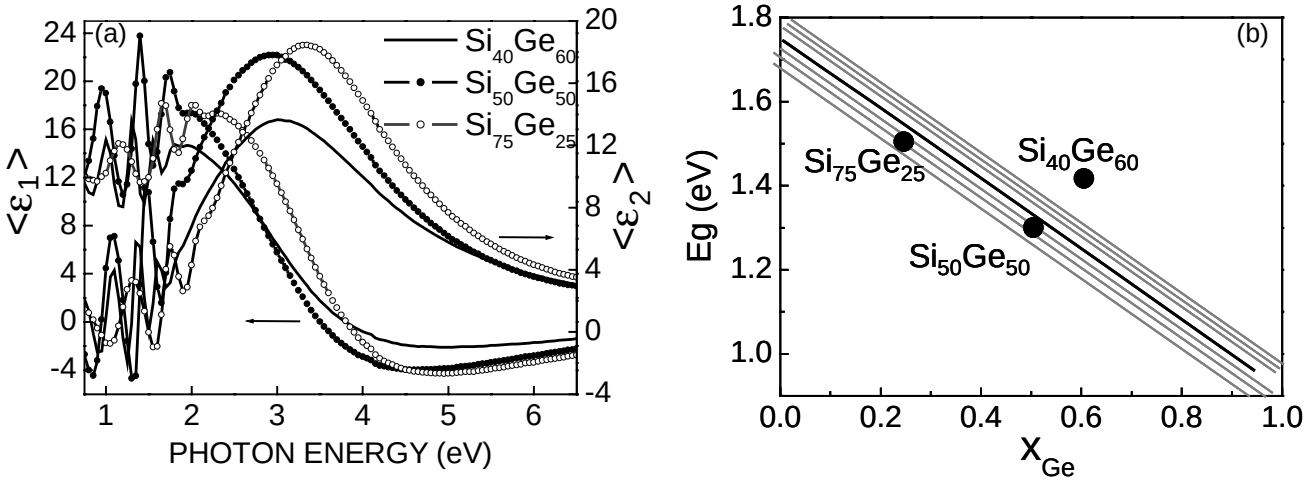

Fig.3: (a) Experimental (symbols) and calculated (line) SE spectrum of the real, $<\varepsilon_r>$, and the imaginary part, $<\varepsilon_i>$, of the dielectric function of $Si_{1-x}Ge_x$:H films with different Ge content; (b) Dependence of the optical gap of $Si_{1-x}Ge_x$:H on Ge composition. Circles are for experimental value for our samples. Shadow area is for data from various samples in literature.

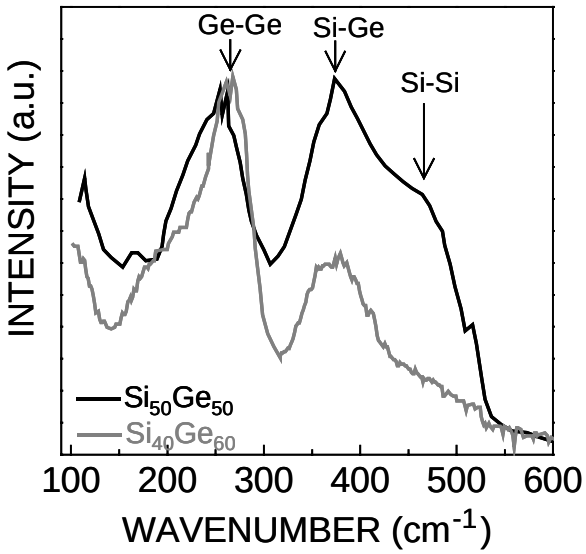

Fig. 4: Raman spectra of $Si_{1-x}Ge_x$ alloys with different composition

4. Discussion

Hydrogenated SiH_4-based and fluorinated SiF_4-based plasma systems are characterized by different chemical behaviors. This difference is enhanced in deposition of nano-crystalline materials, where the deposition/etching competition determines the overall growth. In particular, it is known that in SiH_4-H_2 plasmas, the silicon nanostructure depends on H_2 dilution and, hence, on the concentration of atomic hydrogen, which is the etchant enhancing the degree of crystallinity [16]. In the hydrogenated system the

etching rate follows the order C>Si>Ge. This means that in the Si:Ge binary system, atomic hydrogen will preferentially etch Si than Ge, whereas C is preferentially etched than Si in Si:C
In the fluorinated SiF_4 system, the etchant specie is atomic fluorine. In this case, the etching rate follows the order Ge>Si>C. Therefore in the binary Si:Ge, Si is preferentially etched than Ge, while Si is preferentially etched with respect to C in Si:C.
The growth of nc-Si films from SiF_4-H_2 plasmas, according to the deposition/etching chemical model, [17-18], is determined by a balance between deposition promoted by H atoms ($r_G=k_G[SiF_x]$ [H]) and etching processes operated by fluorine atoms ($r_E=k_E[F]$), giving reason of the crucial importance of the SiF_4/H_2 ratio in deposition of microcrystalline thin films.
In SiF_4-CH_4-H_2, the SiF_4/H_2 ratio is important since it controls the relative concentration of the atomic fluorine and hydrogen, the former etching the amorphous Si-phase (while they do not etch the carbon because of the low desorption rate of CFx radicals that are well known to be precursors for the deposition of fluoro-polymers[19]), the latter etching preferentially the amorphous C-phase. Being the fluorine atoms stronger etchant, the amorphous-to-microcrystalline Si transition occurs, resulting in segregation of Si crystallites in the a-$Si_{1-x}C_x$ matrix.
In the case of SiF_4-GeH_4-H_2 plasma mixtures for deposition of $Si_{1-x}Ge_x$ alloys, atomic fluorine preferentially etches the amorphous Ge-phase, promoting segregation of Ge nanocrystallites in the Ge-rich alloys.

5. Conclusions

Silicon, $Si_{1-x}C_x$ and $Si_{1-x}Ge_x$ thin films with different microstructure have been deposited by PECVD using SiF_4:H_2, SiF_4:GeH_4:H_2 and SiF_4:CH_4:H_2 plasmas. It is found that the flux ratio of the fluorinated- to-hydrogenated precursors is an important parameters for the control of the film nanostructure. The description of the complex anatomy of the films has evidenced the key role of the F-atoms density, and, hence, of the etching-to-deposition competition in determining the nanocrystallinity of the film. It is found that Si nanocrystallites preferentially segregate in a-$Si_{1-x}C_x$ matrices, whereas Ge nanocrystallites preferentially segregate in a-$Si_{1-x}Ge_x$ matrices. The impact of the film nanostructure on optical gap is also discussed, and it is found that segregation of a nanocrystalline phase yields an increase of the optical gap.

Abstract

The real-time computational simulation of arc melting performance with considering complex interactions and solid-liquid mushy zone in molten anode has been successfully conducted for providing the fundamental data for highly economical performance arc melting process. The configuration of molten anode predicted by realistic numerical model shows the quantitative agreement with the experimental data. The effect of sulfur content concentration in molten metal on the welding structure is discussed in detail. Finally, the heat exchange efficiency and molten cross-sectional area are evaluated under different cathode vertex angles for optimum welding process with high efficiency.

Keywords: Arc melting system, complex interactions, mushy zone, real-time computational simulation

1. Introduction

Arc flow can be regarded as one of the multi-functional fluids, since it has high-energy flux, various gases selectivity and electromagnetic controllability[1]. Since the stable and controlled heating can be performed easily by an arc, it has been extensively utilized as arc melting systems[2] such as arc welding for material processing and arc ash melting for environmental processing. However, the arc processing needs relatively higher cost compared with the conventional treatment by combustion, since the arc can be produced only by large electric power and also the expensive electrodes and reactor are easily consumed for short running time[3]. For this reason, the optimization of operating conditions for the improvement of melting performance and high process efficiency has been expected eagerly in the industrial world. Nevertheless, it is experimentally difficult to clarify the physical phenomenon in detail and to optimize the operating conditions of an arc-electrodes system, since the thermofluid field of an arc and the interaction between an arc flow and molten anode are very complex in the extreme conditions. Therefore, the numerical modeling is expected to be one of the effective approaches to solve this problem. In the most of the previous numerical modelings, an arc flow and electrodes are treated separately and boundary conditions are partly given by using experimental data. Furthermore, the influence of solid-liquid mushy zone[4] in molten anode on the molten pool structure has not made clear yet so far.

In the present study, computational simulation of arc melting system with complex interactions are carried out with the purpose of providing the fundamental data for high performance arc melting process. In the electromagnetic thermofluid analysis, the integrated system modeling is proposed considering the complex interactions between arc flow and molten anode interface with temperature dependent surface tension and also considering solid-liquid mushy zone in molten anode[4]. The computational domain covers the entire region

including arc flow, electrodes, molten anode pool, mushy zone. Based on this integrated system modeling, the effects of sulfur content concentration in molten anode and cathode vertex angle on the molten pool structure and heat exchange efficiency are clarified numerically.

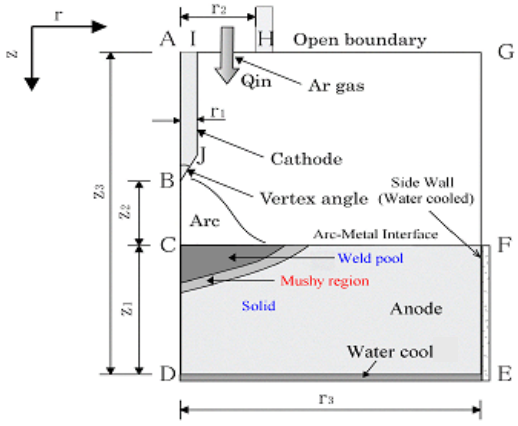

Fig.1 Computational domain for arc melting system.

2. Arc Flow Analysis

2.1. Governing Equations

Figure 1 shows a schematic illustration of a free burning arc-electrodes system and the coordinate system. In order to derive the governing equations, the following assumptions are introduced here[5].

1) The argon arc is regarded as an ideal gas and a continuous fluid. It is optically thin in Local Thermodynamics Equilibrium (LTE) state.
2) The thermofluid field is laminar, steady and axisymmetrical two-dimensional (2D).
3) The induction magnetic field has an axisymmetrical and azimuthal component.
4) There are temperature dependent thermodynamic and transport properties.
5) The surface tension on molten pool interface is given as a function of temperature.
6) The viscosity in the solid-liquid mushy zone is given as a function of liquid fraction.
7) The viscous dissipation and compressed work are neglected.
8) Only radiation loss from argon is considered.
9) Radiation, evaporation and deformation on the both cathode and anode surfaces are neglected for simplicity.

Under these assumptions, the governing equations for arc and electrodes region are presented as follows.

Conservation of Mass

$$\frac{\partial \rho_{Ar,a}}{\partial t} + \frac{\partial}{\partial z}\left(\rho_{Ar,a} u\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\rho_{Ar,a} v\right) = 0 \tag{1}$$

Conservation of Momentum

$$\begin{aligned}\frac{\partial}{\partial t}\left(\rho_{Ar,a} u\right) + \frac{\partial}{\partial z}\left(\rho_{Ar,a} u^2\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\rho_{Ar,a} uv\right) &= -\frac{\partial p}{\partial z} + 2\frac{\partial}{\partial z}\left(\eta_{Ar,a}\frac{\partial u}{\partial z}\right) \\ + \frac{1}{r}\frac{\partial}{\partial r}\left(r\eta_{Ar,a}\left(\frac{\partial u}{\partial r} + \frac{\partial v}{\partial z}\right)\right) - \frac{2}{3}\frac{\partial}{\partial z}\left(\eta_{Ar,a}\left(\frac{\partial u}{\partial z} + \frac{1}{r}\frac{\partial (rv)}{\partial r}\right)\right) &+ j_r B_\theta + \rho_{Ar,a} g\end{aligned} \tag{2}$$

$$\begin{aligned}\frac{\partial}{\partial t}\left(\rho_{Ar,a} v\right) + \frac{\partial}{\partial z}\left(\rho_{Ar,a} uv\right) + \frac{1}{r}\frac{\partial}{\partial r}\left(r\rho_{Ar,a} v^2\right) &= -\frac{\partial p}{\partial r} + \frac{\partial}{\partial z}\left(\eta_{Ar,a}\left(\frac{\partial v}{\partial z} + \frac{\partial u}{\partial r}\right)\right) \\ + \frac{2}{r}\frac{\partial}{\partial r}\left(r\eta_{Ar,a}\frac{\partial v}{\partial r}\right) - \frac{2}{3}\frac{\partial}{\partial r}\left(\eta_{Ar,a}\left(\frac{\partial u}{\partial z} + \frac{1}{r}\frac{\partial (rv)}{\partial r}\right)\right) &- \eta_{Ar,a}\frac{2v}{r^2} - j_z B_\theta\end{aligned} \tag{3}$$

Conservation of Energy

in the arc region:

$$\frac{\partial}{\partial t}(\rho_{Ar} h)+\frac{\partial}{\partial z}(\rho_{Ar} hu)+\frac{1}{r}\frac{\partial}{\partial r}(r\rho_{Ar} hv)=\frac{\partial}{\partial z}\left(\frac{\lambda_{Ar}}{C_{p_{Ar}}}\frac{\partial h}{\partial z}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(\frac{r\lambda_{Ar}}{C_{p_{Ar}}}\frac{\partial h}{\partial r}\right)$$
$$+\frac{j_z^2+j_r^2}{\sigma_{Ar}}+\frac{5}{2}\frac{k_b}{e}\left(\frac{j_z}{C_{p_{Ar}}}\frac{\partial h}{\partial z}+\frac{j_r}{C_{p_{Ar}}}\frac{\partial h}{\partial r}\right)-Ra-\frac{(\dot{q}_{c\leftrightarrow Ar}+\dot{q}_{a\leftrightarrow Ar})dS}{dV} \quad (4)$$

inside the electrode for solid phase:

$$\frac{\partial}{\partial t}(\rho_{c,a}h)=\frac{\partial}{\partial z}\left(\frac{\lambda_{c,a}}{C_{p_{c,a}}}\frac{\partial h}{\partial z}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(\frac{r\lambda_{c,a}}{C_{p_{c,a}}}\frac{\partial h}{\partial r}\right)+\frac{j_z^2+j_r^2}{\sigma_{c,a}}+\frac{(\dot{q}_{c\leftrightarrow Ar}+\dot{q}_{a\leftrightarrow Ar})dS}{dV} \quad (5)$$

inside the anode molten pool and the solid-liquid mushy zone :

$$\frac{\partial}{\partial t}(\rho_a h)+\frac{\partial}{\partial z}(\rho_a hu)+\frac{1}{r}\frac{\partial}{\partial r}(r\rho_a hv)=\frac{\partial}{\partial z}\left(\frac{\lambda_a}{C_{p_a}}\frac{\partial h}{\partial z}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(\frac{r\lambda_a}{C_{p_a}}\frac{\partial h}{\partial r}\right)+\frac{j_z^2+j_r^2}{\sigma_a}+\frac{\dot{q}_{a\leftrightarrow Ar}dS}{dV} \quad (6)$$

Heat flux between the cathode and the arc :

$$\dot{q}_{c\leftrightarrow Ar}=-\lambda_{c\leftrightarrow Ar}\left(\frac{\partial T}{\partial z}+\frac{\partial T}{\partial r}\right)-\frac{|\mathbf{j}_e|}{e}\left(\frac{5}{2}k_b T_{Ar}+e\phi_c\right)+\frac{|\mathbf{j}_i|}{e}\cdot eV_{Ar}-\varepsilon_c\alpha T_c^4 \quad (7)$$

Heat flux between the anode and the arc :

$$\dot{q}_{a\leftrightarrow Ar}=-\lambda_{a\leftrightarrow Ar}\frac{\partial T}{\partial z}+\frac{j_z}{e}\left(\frac{5}{2}k_b T_{Ar}+e\phi_a\right)-\varepsilon_a\alpha T_a^4 \quad (8)$$

Enthalpy :

$$h=\int_0^T C_{p_{Ar,a,c}}dT+f_L L \quad (9)$$

Conservation of electric current

$$\frac{\partial}{\partial z}\left(\sigma_{Ar,a,c}\frac{\partial}{\partial z}\phi\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(r\sigma_{Ar,a,c}\frac{\partial}{\partial r}\phi\right)=0 \quad (10)$$

Ohm's law

$$j_z=-\sigma_{Ar,a,c}\frac{\partial\phi}{\partial z},\quad j_r=-\sigma_{Ar,a,c}\frac{\partial\phi}{\partial r} \quad (11)$$

Ampere's rule

$$\frac{1}{r}\frac{\partial}{\partial r}(rB_\theta)=\mu_0 j_z \quad (12)$$

2.2. Boundary Conditions

Figure 1 shows computational domain. Arc melting system consists of a cylindrical thoriated tungsten cathode (W+2wt%Th) and a stainless anode (SUS304). The roots of both electrodes are cooled at 300K. The boundary conditions for thermofield and electrical potential are summarized below.

in the arc region and cathode region

symmetric axis AB : $\frac{\partial T}{\partial r}=0,\quad \frac{\partial\phi}{\partial r}=0$

symmetric axis BC : $\frac{\partial T}{\partial r}=0,\quad \frac{\partial\phi}{\partial r}=0,\quad \frac{\partial(\rho u)}{\partial r}=v=0$

outflow boundary FG : $\frac{\partial^2 T}{\partial r^2}=0,\quad \frac{\partial\phi}{\partial r}=0,\quad \frac{\partial(\rho u)}{\partial r}=\frac{\partial(r\rho v)}{\partial r}=0$

outflow boundary GH : $\frac{\partial^2 T}{\partial r^2}=0,\quad \frac{\partial \phi}{\partial z}=0,\quad \frac{\partial(\rho u)}{\partial z}=\frac{\partial(\rho v)}{\partial z}=0$

inflow boundary HI : $T=300\mathrm{K},\quad \frac{\partial \phi}{\partial z}=0,\quad u=u_{in},\quad v=0$

cooled cathode surface IA : $T=300\mathrm{K},\quad -\sigma_{\mathrm{W}}\frac{\partial \phi}{\partial z}=j_{in}$

cathode surface IJB : $u=v=0$

in anode and molten pool region

symmetric axis CD : $\frac{\partial T}{\partial r}=0,\quad \frac{\partial \phi}{\partial r}=0,\quad \frac{\partial(\rho u)}{\partial r}=v=0$

cooled anode surface DE : $T=300\mathrm{K},\quad \phi=0,\quad u=\mathrm{v}=0$

anode side EF : $T=300\mathrm{K},\quad \phi=0,\quad u=\mathrm{v}=0$

arc-anode interface CF :

On the anode surface (CF), solid, liquid phase and solid-liquid mushy zone appear depending on liquid fraction f_L defined as a function of temperature. Phase is decided by the solidus line (1740K) and liquidus line (1750K) of stainless steel.

$$\begin{cases} \text{solid phase } (T_a < T_{solidus}): & f_L=0,\quad u=\mathrm{v}=0 \\ \text{solid-liquid mushy zone } (T_{solidus} < T_a < T_{liquidus}): & f_L=\dfrac{T_a-T_{solidus}}{T_{liquidus}-T_{solidus}},\ u=0,\ -\eta_{\mathrm{a}}\dfrac{\partial v_a}{\partial z}=-\eta_{\mathrm{Ar}}\dfrac{\partial v_{Ar}}{\partial z}+\dfrac{\partial \gamma}{\partial T}\dfrac{\partial T}{\partial r} \\ \text{liquid phase } (T_{liquidus} < T_a): & f_L=1,\ u=0,\ -\eta_{\mathrm{a}}\dfrac{\partial v_a}{\partial z}=-\eta_{\mathrm{Ar}}\dfrac{\partial v_{Ar}}{\partial z}+\dfrac{\partial \gamma}{\partial T}\dfrac{\partial T}{\partial r} \end{cases}$$

2.3. Numerical Conditions and Procedures

Table 1 shows the system configuration and operating conditions. The thermofluid field is solved by Semi-Implicit-Method for Pressure Linked Equation (SIMPLE) method[6] using Tri Diagonal-Matrix Algorithm (TDMA). The electromagnetic field is solved by SOR method. In this study, 90 of grid points are applied in both axial and radial directions. The thermo-dynamic and transport properties of argon, tungsten and stainless steel are given as a function of temperature.

Table 1. System configuration and operating conditions.

Operating pressure	$p_0=1.013\times10^5$ Pa
Arc current	$I=150$ A
Gas flow rate	$Q_{in}=15$ l/min
Cathode radius	$r_1=1.6$ mm
Nozzle radius	$r_2=10.8$ mm
Anode radius	$r_3=25$ mm
Cathode vertex angle	$\theta=30^\circ, 60^\circ, 90^\circ, 120^\circ$
Anode thickness (SUS304)	$z_1=10$ mm
Sulfur content	$n_s=40,\ 220$ ppm
Electrode gap	$z_2=5$ mm
Computational axial length	$z_3=25$ mm

3. Numerical Results and Discussion

Figure 2 shows the shape of molten pool approximately 20 seconds after arc generation under the condition of cathode vertex angle of 60° and high sulfur content. The available experimental result[7] is also shown for comparison. Although comparing with experiment, melting width in radial direction on the surface of anode is a little narrower due to thermal nonequilibrium effect near anode surface, relatively a good agreement with the experimental data is observed. This confirms that the proposed numerical model with solid-liquid mushy zone is valid when dealing with the arc melting process.

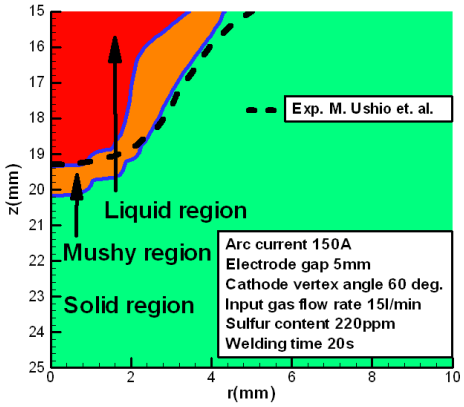

Fig.2 Comparison of numerical molten pool and experimental one.

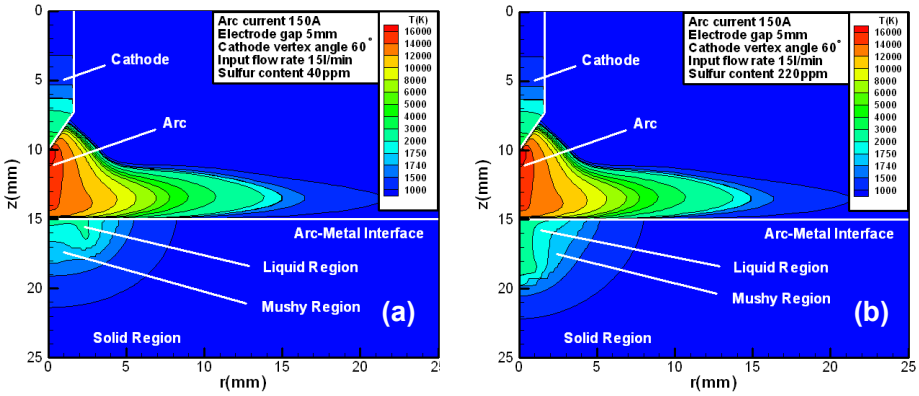

Fig.3 Effect of sulfur content on the arc melting process and molten pool penetration ((a) in case of sulfur content 40ppm, (b) 220ppm).

Figures 3(a) and 3(b) show the effect of sulfur content on the molten pool penetration. It is found that sulfur content does not affect the arc flow so much, however, the welding structure changes drastically by sulfur content. In the case of low sulfur containing in SUS304 as shown in Fig.3(a), the molten metal spreads outward due to the dominant shear force from cathode jet and outward surface driven flow at the arc-molten anode interface. On the other hand, in the case of high sulfur containing in SUS304, the molten pool penetrates downward in the core region due to the inward surface driven flow resulting from surface tension and heat concentration in the core region.

Figure 4(a) shows the input electrical power, heat input to anode material and heat exchange efficiency as a function of cathode vertex angle. Figure 4(b) shows the effect of cathode vertex angle on the cross-sectional area of weld penetration. Here, heat exchange efficiency η is defined as the ratio between heat input to the anode and input electrical power to the arc melting system. It is found from Fig.4(a) that almost the constant heat exchange efficiency of ~80% is maintained regardless of cathode vertex angle, although the input electrical power decreases with the increase of cathode vertex angle due to less electrical current concentration near the cathode tip. As shown in Fig.4(b), the largest cross-sectional area of weld penetration can be obtained for the cathode vertex angle

of 60° due to effective heat transfer.

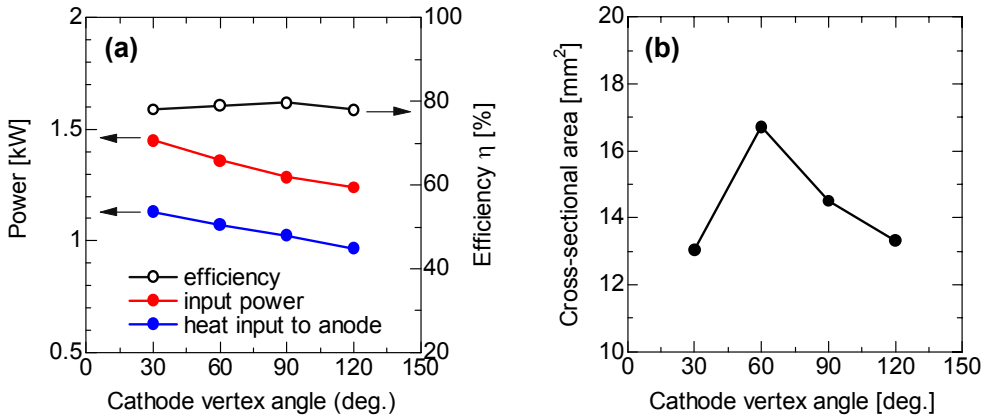

Fig.4 Effect of cathode vertex angle on (a) input power, heat input to anode and heat exchange efficiency, (b) cross-sectional area of weld penetration for sulfur content of 220ppm.

4. Concluding Remarks

For the optimization of arc melting system, the present study proposed the new numerical model considering the complex interactions between arc flow and molten anode interface with temperature dependent surface tension and also considering solid-liquid mushy zone in molten pool. Based on this numerical model, real-time computational simulation of arc melting system is conducted with the purpose of providing the fundamental data for high quality arc melting process. The results obtained from this study can be summarized as follows:

(1) The shape of molten pool predicted from this numerical model considering solid-liquid mushy zone shows a good agreement with the experimental data. Therefore, the numerical model proposed in this study is valid when dealing with the arc melting process.

(2) The welding structure changes drastically by sulfur content. In the case of low sulfur content, the molten metal spreads outward due to the shear force from cathode jet and outward surface driven flow at the arc-molten anode interface. On the other hand, in the case of high sulfur content, the molten pool penetrates downward in the core region due to the inward surface driven flow and heat concentration in the core region.

(3) Almost the constant heat exchange efficiency of ~80% is maintained regardless of cathode vertex angle. The largest cross-sectional area of weld penetration can be obtained for the cathode vertex angle of 60°.

Abstract
Amorphous silicon carbide (a-SiC_x:H) films have been deposited by plasma enhanced chemical vapour deposition from $CH_4/SiH_4/NH_3$ plasma on n-type (0.015 Ωcm) crystalline silicon (c-Si) in a small volume parallel plate plasma reactor. The elemental composition of the films has been studied using RBS and ERD analysis. Chemical bonding in the films has been studied using the IR technique. The surface morphology and topography of the deposited films have also been characterized by atomic force microscopy.
Keywords: silicon carbide, plasma deposition, RBS, AFM, IR.

1. Introduction

In recent years, nanotechnology has become widely applied in the life sciences, electronics and optoelectronics where it has come to play an increasingly important role. Silicon carbide is a material with remarkable potential for applications in nanotechnology. It shows superior characteristics as a semiconductor and excellent resistance to high temperature, abrasion and radiation [1]. In addition to high-temperature applications, SiC has potential for use in high-power and high-frequency [2]. However, SiC has several advantages over other wide-band gap semiconductors at the present time including commercial availability of substrates [3], known device processing techniques, and the ability to grow a thermal oxide for use as masks in processing, device passivation layers, and gate dielectrics. Furthermore, SiC can also be used as a thin buffer layer for the growth of diamond films on silicon substrates [4]. For example, a-$Si_{1-x}C_x$:H was used as a wide window material to enhance the conversion efficiency of amorphous solar cell. The significance of this material follows from the fact that its electrical and optical properties can be controlled by varying the carbon, silicon and hydrogen composition of the film.

N-doped SiC films have been prepared by various techniques, which include: pyrolysis of polymer precursors [5], chemical vapour deposition (CVD) at elevated temperatures [6], bias-assisted hot filament (CVD) [7], radio frequency plasma-enhanced CVD (PECVD) [8], microwave PECVD [9], electron cyclotron resonance PECVD [10], pulsed laser deposition [11], ion beam sputtering [12] and reactive magnetron sputtering [13]. PECVD technique offers an attractive opportunity to fabricate amorphous hydrogenated N-doped amorphous hydrogenated SiC films at intermediate substrate temperatures and it provides high quality films with good adhesion, good coverage of complicated substrate shapes and high deposition rate.

In this contribution the attention has been focused on the structural properties of a-$Si_{1-x}C_x$:H films prepared by the plasma enhanced chemical vapour deposition (PECVD) of silan SiH_4 and methane CH_4 as a function of the flow rate. Samples with different amounts of N were achieved by a small addition of ammonia NH_3 into the gas mixture of silane SiH_4 and methane CH_4. The properties were investigated by RBS, ERD, IR and AFM measurement techniques.

2. Experimental

PECVD silicon carbide films were deposited in a high frequency parallel-plate plasma reactor, in which the frequency, the RF power and the substrate temperature were maintained at 13.56 MHz, 0.06 Wcm^{-2}, and 350°C respectively. The diameter of electrodes was 12 cm, and they were 6 cm apart. The RF power was fed to the

upper electrode, while the lower electrode, which held the substrates, was grounded. A n-type silicon wafer with resistivity 0.015 Ω cm and (111) orientation was used as the substrate for the a SiC:H films. Prior to deposition, standard cleaning was used to remove impurities from the silicon surface, and the 5% hydrofluoric acid was used to remove the native oxide on the wafer surface. The wafer was then rinsed in deionized water and dried in nitrogen ambient. A gas mixture of SiH_4, CH_4 and NH_3 was directly introduced into the reaction chamber, and the flow rates of these gases were 10 sccm, 20-40 sccm and 2-5sccm respectively. The concentration of silicon carbon and nitrogen was determined by RBS method. The hydrogen concentration was determined by the ERD method. For this purpose the $^4He^+$ ion beam from a Van de Graff accelerator at JINR Dubna was applied. The energy 2.4 MeV was chosen. The target was tilted at an angle of 15^o with respect to the beam direction and the recoiled protons were measured in forward at an angle of 30^o. Chemical compositions were analyzed by infrared spectroscopy. The IR spectra were measured from 2000 to 400 cm^{-1}. Film morphology was assessed by Atomic Force Microscopy.

3. Results and discussion

The thickness and refractive index of the SiC films were measured by a Gaertner Ellipsometer. For technological conditions which represented by samples T1 and T2 with the flow SiH_4 10 sccm, the CH_4 40 sccm and the NH_3 5 and 2 sccm, respectively, the deposition rate was 5 nm per minute and refractive index was in the range 2.2-2.3. For samples T3 and T4, SiH_4 flow 10 sccm, CH_4 flow 25 sccm and NH_3 flow 2 and 5 sccm, respectively, the deposition rate was 4 nm/min and the refractive index was in the range 2.3-2.4. Our results show that the deposition rate increases if the flow of CH_4 is increased, however the value of refractive index is decreases. Figure 1 show RBS spectra of four samples T1, T2, T3 and T4 with different deposition conditions of the deposited amorphous silicon carbide films.

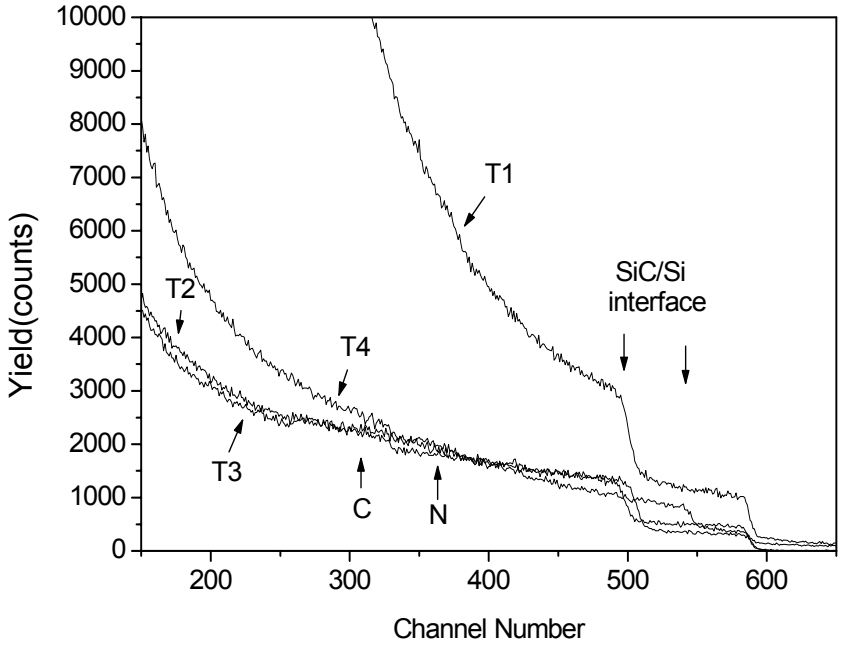

Fig. 1: RBS spectra of SiC films deposited onto a silicon substrate for 2 MeV alfa particles detected at scattering angle of 170^o. The spectra are for samples T1 (thickness of film 220 nm), T2 (190 nm), T3 (210 nm) and T4 (170 nm).

After modelling, we can show from calculated results the presence of small amounts of oxygen but the concentrations of hydrogen in the SiC films are approximately 20 at. %. In the case of samples T1and T2 the concentration of silicon, carbon and nitrogen are 25, 40 and 10-12 at.% respectively. The concentration of Si and C in samples T3 and T4 are 30, 35 and 10-12 at % respectively. There was no evidence of the substrate mixing into the films. Hydrogen was detected by means of elastic recoil detection. The ERD analyses show that the amount of incorporated H for samples T1, T2, T3 and T4 were 22 at %, 20 at % 19 at % and 18 at % respectively. The concentration of H increases with increasing CH_4 flow. The IR spectra in Figure 2 revealed the main absorption region between 500 and 1500 cm^{-1} due to the presence of Si-C, Si-H, Si-N and N-H bonds.

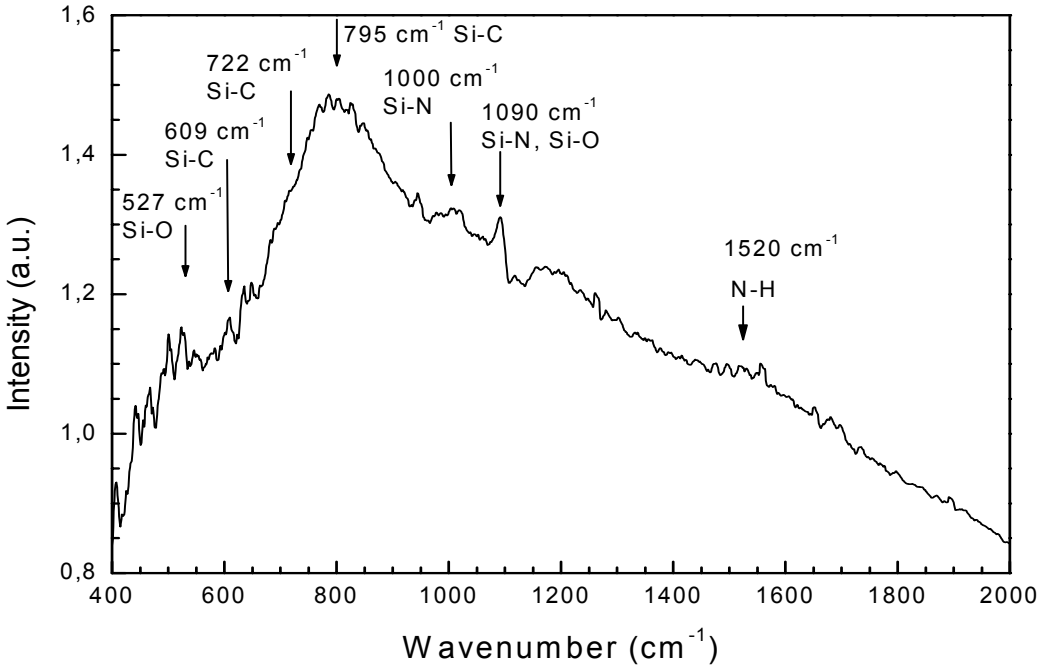

Fig. 2: Typical infrared spectra for all samples T1, T2, T3 and T4. Differences of IR spectra between samples are very small.

The AFM micrographs (Figure 3.) of the SiC films prepared by PECVD reveal that the film surface is rather smooth and compact. The mean roughness R and the root mean square RMS of the samples, as deduced from the AFM analysis, are similar.

4. Conclusion

We have investigated the structural properties of amorphous silicon carbide films prepared by plasma enhanced chemical vapour deposition The experimental results obtained from this work can be summarized as follows. The RBS results showed that the concentrations of Si, C and N in the films are practically the same. The concentration of hydrogen was determined by the ERD method and the value is approximately 20 at %. The films contain a small amount of oxygen. IR results showed the presence of Si-C, Si-N, N-H, and Si-O bonds.

Controllable Thermofluid Field of Reactive Plasma Jet Impinging onto the Substrate

H. Nishiyama[1], T. Sato[1], G. Chiba[1] and H. Takana[1]

[1] *Institute of Fluid Science, Tohoku University, Sendai, Japan*

Abstract

When the nonequilibrium Ar/N_2 plasma jet is impinging onto the substrate, the effects of operating pressure, applied magnetic field on radiation intensity from nitrogen radicals, plasma jet configuration near substrate and heat flux into the substrate are experimentally clarified. Finally, constant value control of radiation intensity, substrate heat flux, jet axis deviation and jet width fluctuation are achieved by using PI control method with suppressed fluctuation to stabilize an unstable plasma jet.

Keywords: Control, Plasma jet, Unstable behavior, Substrate, Nitriding

1. Introduction

Plasma jet has been extensively utilized for material processes and waste treatments so far [1-3]. Since there are rotating arc root behaviors in the torch, pulsating particle carrier gas flow, turbulent behavior in the downstream and strong interaction with the substrate, plasma jet is easily apt to experience the unstable behaviors [4, 5]. Especially it is very important to suppress the unstable plasma-substrate interaction and make the impinging jet more stable for high quality processes of surface modification and coating on the substrate. However, there are few papers concerning control of plasma jet for material processing [6-10].

The main objective of the present paper is to clarify experimentally the correlations between operating conditions and plasma jet characteristics in order to determine the important controlled and manipulated variables, when the nonequilibrium Ar/N_2 plasma jet is impinging onto the substrate for nitriding. The effects of operating pressure, applied magnetic field on radiation intensity from nitrogen atomic radicals, heat flux into the substrate, fluctuating jet axis and jet width are clarified. Finally, feedback control system is successfully constructed to achieve constant value control of nitrogen atom radiation from plasma near substrate and heat flux into the substrate by operating back pressure. The jet axis deviation and jet width fluctuation are effectively suppressed for stabilization by applied magnetic field using PI control method.

2. Experimental setup and procedures

The details of the experimental facilities are omitted here [8]. Table 1 shows the experimental conditions in the present study. The SUS303 substrate (W 34 mm × H 160 mm × T 22 mm) is set vertically in the middle of the test section held by two solenoidal coils. *Z* axis shows the flow direction and *r* axis shows perpendicular to *z* axis, respectively. The origin is the center of the substrate. Heat

Table 1 Experimental conditions

1st gas	Ar
1st gas flow rate	30 (Sl/min)
1st discharge current	30 (A)
1st discharge power	0.9 (kW)
2nd gas	N_2
2nd gas flow rate	30 (Sl/min)
2nd discharge current	80 (A)
2nd discharge power	5.6 (kW)
Background pressure	650~1100 (Pa)
Axial magnetic flux density	0~0.44 (T)

and r axis shows perpendicular to z axis, respectively. The origin is the center of the substrate. Heat flux into the substrate is measured by water cooled heat flux sensor (CAPTEC) embedded in the substrate. The substrate can be moved transversely to obtain the continuous data. The radiation intensity emitted from Ar/N_2 plasma is measured by optical analyzer (330-1100 nm) and by Si photodiodes (400-1000 nm) especially for control. The radiative plasma jet behavior is visualized by CCD camera at the sampling rate of 1/60 s to evaluate the jet axis and width of oscillating plasma jet. The jet width is defined as the radial distance between two radial locations showing half maximum radiation intensity. The fluctuating intensity is the ratio of standard deviation to averaged jet width. Furthermore, jet axis location is defined as the centerline between defined jet widths.

Figure 1 shows a schematic illustration of feedback control systems for an unstable plasma jet impinging onto a substrate. The control systems consist of a detecting element for the controlled values such as heat flux, radiation intensity, monitored jet axis and jet width, a control element for outputting the PI control signal and a final control element for a manipulated variables such as applied magnetic flux density and background pressure. The transfer function for PI control method is given by Eq.(1) as follows [11]:

$$G(s) = K_p\left(1 + \frac{1}{T_I s}\right) \tag{1}$$

where K_p, T_I are gain constant and integral time, respectively.

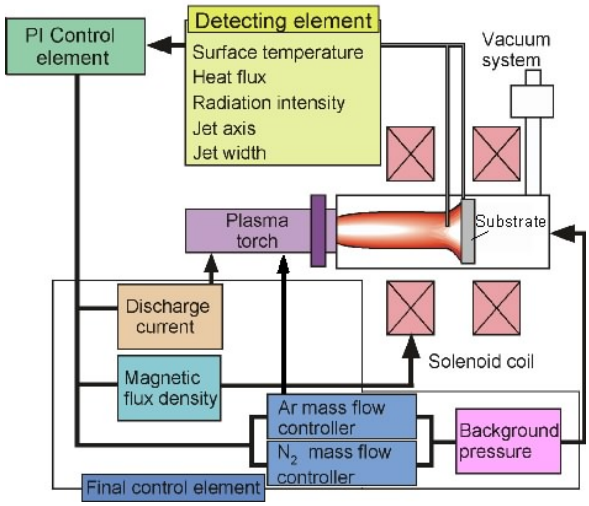

Figure 1 Schematic illustration of feedback control systems

3. Experimental results and discussion

3.1 Thermolfluid characteristics

Figure 2 shows the iso-contour of substrate heat flux as functions of background pressure and applied magnetic field intensity. The substrate heat flux at stagnant point r = 0 mm can be increased nearly two times by operating background pressure, although there is a little effect of applied magnetic flux density. This means that the background pressure is dominant operating valuable for controlling substrate heat flux.

Figure 3 shows the iso-contour of relative radiation intensity of 821.6 nm near substrate as functions of background pressure and applied magnetic field intensity. This radiation intensity is the strongest and comes from nitrogen atom. The radiation intensity increases considerably for lower background pressure and higher magnetic flux due to the plasma jet elongation toward downstream.

3.2 Control characteristics

Figure 4 shows the PI control characteristics substrate heat flux by operating background pressure based on their correlations as shown in Fig.2. When the discharge current I_p changes like step from 80 A to 90 A as a disturbance, the substrate heat flux can be kept nearly constant value of 55 kW/m^2 at stagnation point for K_p = 25 and T_I = 2.4 seconds.

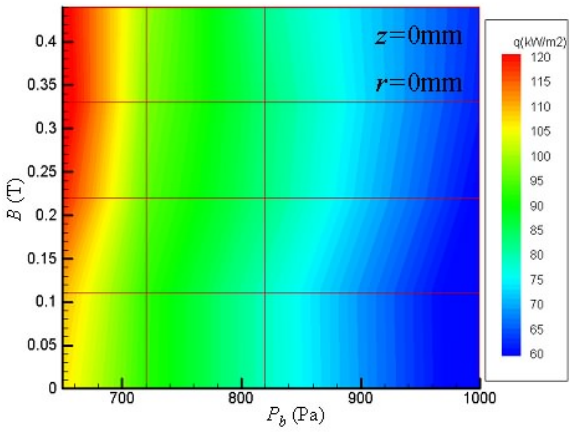

Figure 2 Iso-contour of substrate heat flux

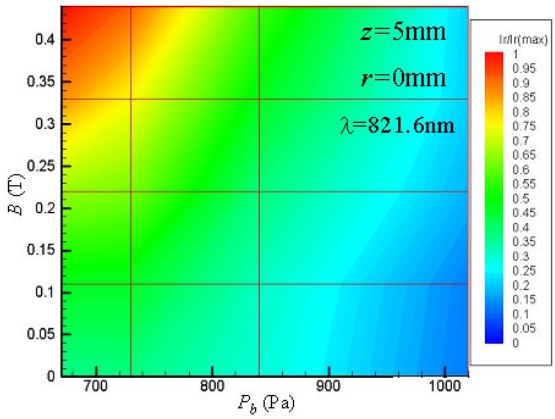

Figure 3 Iso-contour of radiation intensity from nitrogen atom

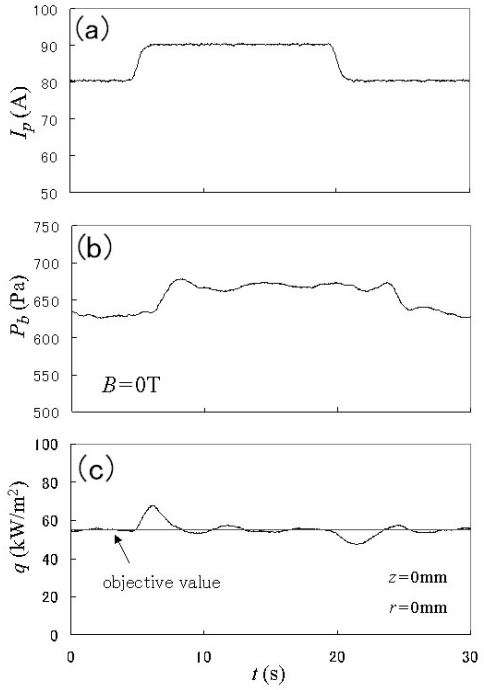

Figure 4 PI control characteristics of substrate heat flux

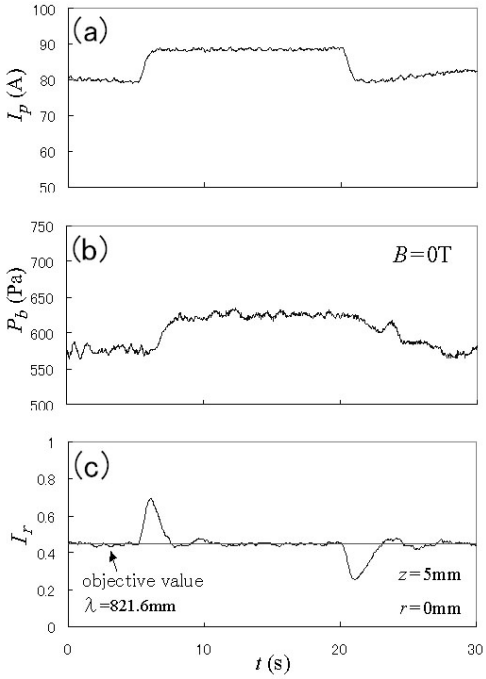

Figure 5 PI control characteristics of radiation intensity from nitrogen atom

Figure 5 shows the PI control characteristics of radiation intensity of nitrogen atom at 821.6 nm by operating background pressure based on their correlations as shown in Fig.3. When the discharge current I_p changes as the same behavior as in Fig.4, the radiation intensity can be kept constant value of 0.45 adjacent to substrate for K_p = 1300 and T_I = 2.4 seconds. This means that number density of nitrogen atom can be kept constant against a disturbed discharge current prior to impinging for high quality substrate nitriding.

Figure 6 shows the step response of jet axis position to the applied magnetic flux density. a' means the standard deviation of jet axis position in the radial direction. When the magnetic field is applied like step from 0.05 T to 0.44 T, the standard deviation and fluctuation intensity of jet axis position are decreased effectively.

Figure 7 shows the PI control characteristics of jet axis position for constant value of 1.5 adjacent to substrate by applying magnetic field for K_p = 0.04 and T_I = 0.6 seconds. It takes about 6 seconds to approach to the desired constant value. This shows that the plasma jet behavior can be stabilized and become axisymmetry by applying magnetic field.

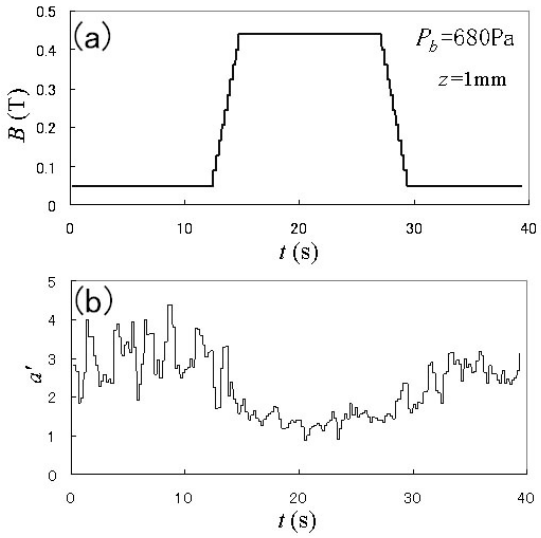

Figure 6 Step response of jet axis position to applied magnetic field

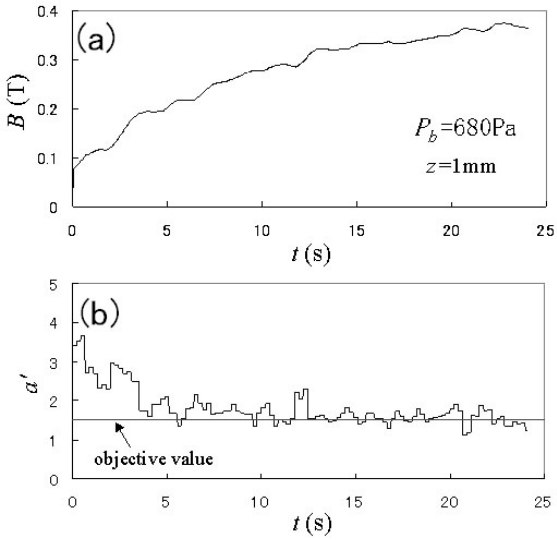

Figure 7 PI control characteristics of jet axis position

4. Conclusion

The correlation between operating conditions and controlled variables for argon/nitrogen plasma jet impinging onto the substrate is clarified experimentally. The control characteristics of impinging reactive plasma jet are obtained for high quality nitriding. The results obtained in the present study are as follows.

(1) The substrate heat flux and radiation intensity from nitrogen radical atom adjacent to substrate can be kept constant by operating background pressure using PI control method against a disturbed discharge current.
(2) The unstable behavior of impinging plasma jet onto the substrate can be stabilized by applying magnetic field effectively.

Abstract

A DC-RF hybrid plasma flow is used for in-flight particle processing, where particle size of rutile TiO_2 particles is converted from 2 micrometer to submicron. Four typical particle size distributions of obtained products are confirmed after the treatment. The size of ultra fine particles (UFPs) is nearly 100 nm. The mean particle diameter of UFPs becomes small with decreasing operating pressure. The conversion ratio from the initial precursors to UFPs increases with decreasing operating pressure, decreasing swirl gas flow ratio and injecting a large amount of quench gas flow rate. Operating conditions are optimized to decrease mean particle diameter of UFPs, increase its conversion ratio and stabilize a plasma flow simultaneously by multi-input and multi-objective optimization method. Finally, conversion ratio from initial precursors to UFPs, whose mean particle diameter is 140 nm, is nearly 90 % by stable plasma flow by the optimized operating conditions.

1. Introduction

A thermal radio frequency inductively coupled plasma (RF-ICP) flow has been investigated intensively for material processing so far, because it has prominent advantages for in-flight treatment because of plasma purity, large volume, steep temperature gradient, long residence time and easy controllability by flow condition. Injected precursors are evaporated momentary and complex metallurgical reactions are taken place in an RF-ICP flow. On the other hand, it has also some disadvantages due to the large effect of flow condition on the plasma characteristics, such as plasma instability and strong back flow by a recirculation due to Lorentz force at an RF coil region. Then, a DC-RF hybrid plasma flow is expected to overcome such disadvantages of an RF-ICP flow for material processing [1]. A DC-RF hybrid plasma flow is produced by combining a supplemental direct current (DC) plasma jet with an RF-ICP flow, and it has been investigated by some researchers [2-6]. Compared with a conventional RF-ICP flow, there is prominent advantages in a DC-RF hybrid plasma flow because it is possible to inject reactants axially to the centerline region from the torch head and then, the reactants can obtain high enthalpy during passing though the plasma core region with much acceleration by a DC plasma jet. This unique feature could be utilized for in-flight particle treatment because evaporation of solid particles needs much more enthalpy than some other reactants such as gas or gel. The application of a DC-RF hybrid plasma flow system has been investigated by Yoshida intensively.

In the present study, the in-flight treatment of rutile TiO_2 particle is investigated. Rutile TiO2 is very attractive material in these days because its reactivity such as absorption and dissociation can be enhanced by producing a stable oxygen vacancy on its surface by annealing or sputtering [7]. In addition, a DC-RF hybrid plasma flow has good advantages in dealing with such stable materials at high temperature, which cannot be dealt by chemical process. The fundamental correlation between operating conditions and

properties of produced TiO_2 fine particles is clarified comprehensively for in-flight particle treatment using a DC-RF hybrid plasma flow system. Finally, the operating conditions are optimized by multi-input and multi-objective optimization [8] to achieve the most efficient processing by a DC-RF hybrid plasma flow system in viewpoints of particle size, conversion rate and plasma stability.

2. Experimental Setup

A DC-RF hybrid plasma system consists of RF plasma torch, DC plasma torch, reaction chamber, powder feeder, gas supply control systems for an RF plasma torch and a DC plasma torch, monitoring system and vacuum system.

Figure 1 (a) shows the schematic illustration of a DC-RF hybrid plasma flow system with gas injections. This system consists of a 3-turn RF induction coil, DC electrodes, which are installed at the top of an RF torch. There are mainly four kinds of gas injection modes to control a plasma flow. The sheath gas, which is the main gas to produce an RF plasma flow, is injected from the narrow space between the inner wall of the quartz tube whose diameter is 44 mm and the DC torch outside, respectively. The central gas is injected from the central gas nozzle at the center of the DC torch. The central gas is discharged to produce a DC plasma jet. The swirl gas is mixed in the sheath gas before injection into the RF torch, and circumferential velocity of the sheath gas swirl is controlled by the swirl gas ratio in the sheath gas. The carrier gas is injected diagonally from the two carrier gas nozzles on both sides of the central gas nozzle. Operating pressure is controlled by the flow valve in front of the rotary pump.

Figure 1 (b) shows the schematic illustration of the inside of a DC-RF hybrid plasma torch and the particle collector. The quench gas is injected from the copper tube ring with the 12 inside inlets of 2 mm diameter into the centerline region radially at 130 mm downstream.

In this study, RF power, DC power, carrier gas flow rate are fixed at 7 kW (4MHz, 7 kV, 1A), 1 kW (40 V, 25A) and 4 l/min, respectively, to clarify the fundamental effects of inlet flow condition on the characteristics of the obtained products such as particle size and structure. Commercial rutile TiO_2 particles with diameter of 2 micrometer (Wako Chemical, Japan) are employed as initial precursors. Its are provided at 250 mg/min for one minute by the carrier gas. Experiments are conducted for one minute. The products attached on the inside surface of the quartz tube and that accumulated on the collector bottom, both which are shown in Fig. 1 (b), are independently collected for comparison. The particle size distribution is measured by particle size analyzer (MT3000, Microtrac Inc. , USA) after 9 minutes ultra sonic treatment. On the other hand, the obtained samples are characterized by X-ray diffractometry (XRD) analysis (RINT2000, Rigaku, Japan) using CuKα radiation. Particle size and morphologies are characterized by scanning electron microscope (SEM) (S4100, Hitachi, Japan).

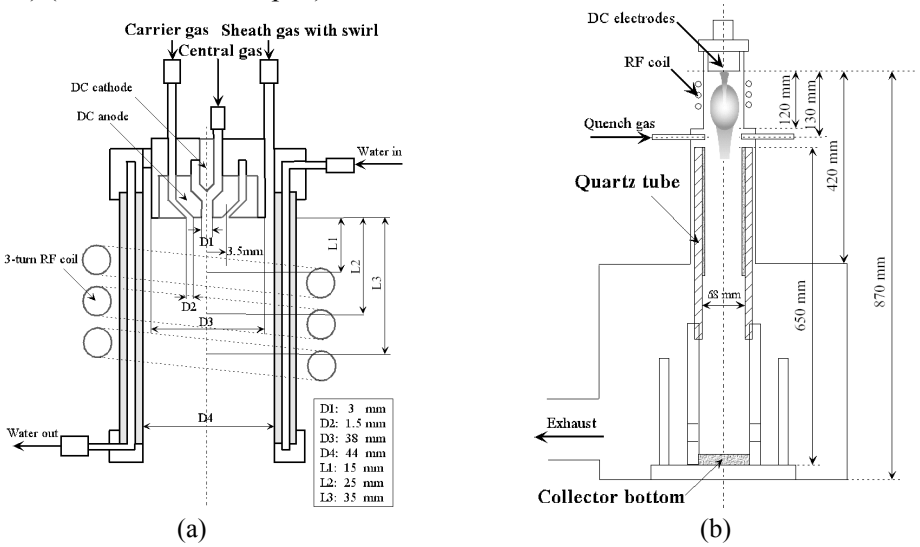

Figure 1. Schematic illustrations of (a) a DC-RF hybrid plasma system and (b) the detailed design of torch region

3. Experimental Results

Figure 2 shows particle size distributions of obtained products at various operating pressures; where sheath gas flow rate Q_{Sh}, swirl gas ratio R_{Sw}, central gas flow rate Q_C, carrier gas flow rate $Q_{Carrier}$ and quench gas flow rate Q_Q are 20 l/min, 1, 3 l/min, 4 l/min and 0 l/min, respectively. Typical four peaks are confirmed in the figure. The smallest particles, which have polygonal shape as shown in Fig. 3, are produced by homogeneous nucleation [9-10] and called as ultra fine particles (UFPs) in this study. These UFPs are accumulated on the collector bottom as agglomerates because these have large specific surface and easily agglomerates each other. The second smallest peak is from fine particles (FPs), which is produced by heterogeneous nucleation on the submicrom size particles of the initial precursors. These submicron size particles can pass through the plasma core region without evaporation because of small heat transfer due to large Knudsen effect. Then such particles act as seeds in a nucleation region at the plasma tail. The third smallest peak is from no treated particles (NTPs), which pass through the plasma core region without evaporation. The largest peak is from large agglomerated particles (LAPs), which are produced from the agglomerates by sintering due to long residence time and large heating in the plasma tail region.

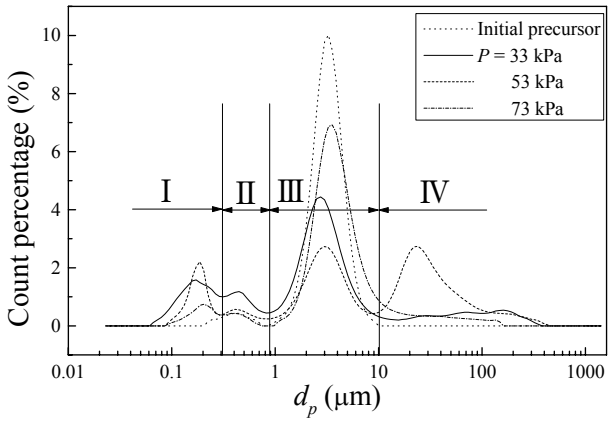

Figure 2 Particle size distribution at various operating pressures

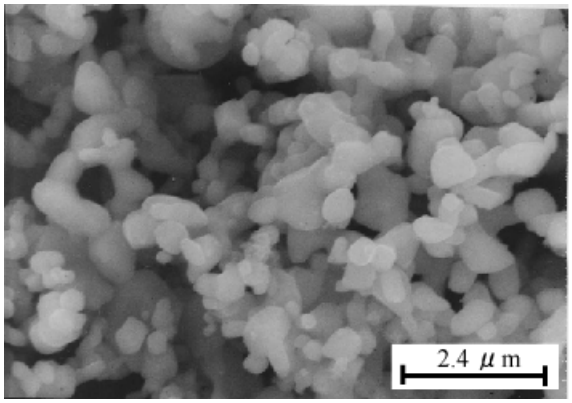

Figure 3 SEM image of UFPs

Figure 4 shows mean particle diameter and cumulative percentage of UFPs in Fig. 2. Mean particle diameter of UFPs increases with increasing operating pressure. Several conditions are required to suppress particle growth, such as rapid removal of nuclei from the nucleation region, decrease in density of nuclei and supersaturation [11-12]. Particle residence time in the nucleation region at the plasma tail increases with increasing operating pressure because particle velocity at the plasma core region is decelerated by a recirculation due to Lorentz force [13]. In addition, particle heating also becomes prominent with increasing operating pressure because of long particle residence time and decrease in Knudsen effect [14-16] and then, evaporation increases with increasing operating pressure. Therefore, particles grow large during the long residence time and large nuber density of nuclei in the nucleation region at large operating pressure. On contrary to it, the cumulative percentage of UFPs decreases with increasing operating pressure.

Figure 5 shows particle size distribution with the various quench gas flow rates. When the quench gas flow rate is 20 l/min, the effect of the quench gas is small because the quench gas is entrained by a strong recirculation at the coil downstream region and diffused into the plasma flow without reaching the nucleation region [17]. However, the effect of the quench gas flow becomes prominent with a large amount of the quench gas flow rate of 50 l/min. Supersaturation [18] is produced at the plasma tail region, where nucleation takes place, by a large amount of quench gas because the quench gas penetrates the coil downstream recirculation without being entrained.

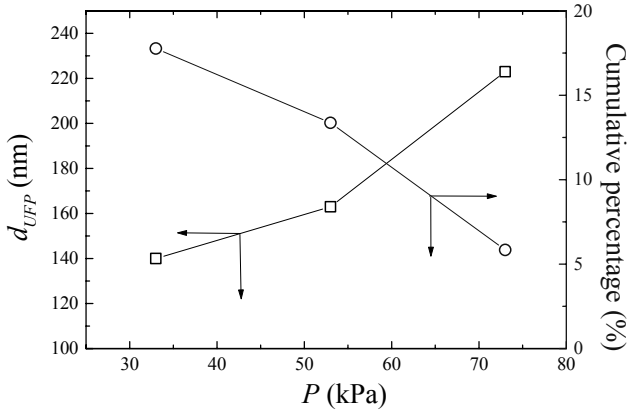

Figure 4 Mean particle diameter and cumulative percentage of UFPs

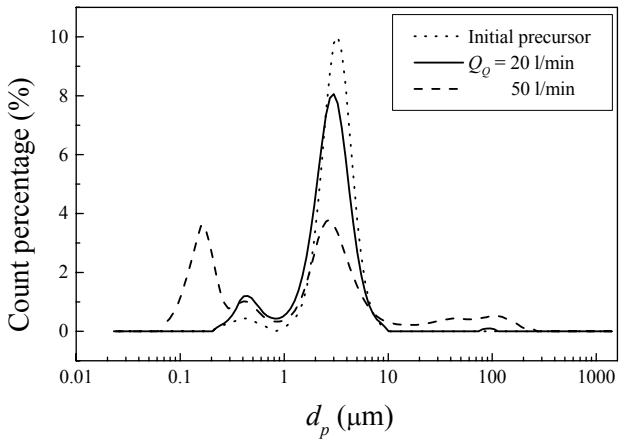

Figure 5 Particle size distribution at quench gas flow rates at 33 kPa

4. Optimization

Multi-input and multi-objective optimization, in which factorial design approach and genetic algorism are combined [8], is conducted. Fixed operating conditions are carrier gas flow rate of 4 l/min and RF power frequency of 4 MHz in this study. Working gas is argon. Initial precursor is rutile TiO_2 of 2 μm and supplied at 76.2 mg/min The following seven parameters, such as operating pressure (P kPa), sheath gas flow rate (Q_{Sh} l/min), central gas flow rate (Q_C l/min), swirl gas ratio (R_{Sw}), quench gas flow rate (Q_Q l/min), RF power (P_{RF} kW) and DC power (P_{DC} kW) are employed as input parameters in the present study. These input parameters are assigned to Taguchi type full factorial design of OA (L_8) in Table 1 as linear model; where RF powers of 9 kW and 10 kW are obtained from RF plate voltages of 6 kV and 6.5 kV, and anode currents of 1.5 A and 1.6 A, respectively. DC powers of 1 kW and 2 kW are obtained from DC voltages of 40 V and 80 V, and constant DC current of 25 A, respectively. The following output parameters are evaluated for the products obtained from the collector bottom. Mean particle diameter (d_{UFP} nm) of UFPs and conversion ratio ($R_{Conversion}$ %) from the initial precursors of 2 μm to UFPs distributions are chosen as output parameters. Additionally, disappearance RF power (P_d kW), which is measured when RF-ICP flow is distinguished with decreasing RF power, is also employed as important output parameter. This parameter shows the plasma stability. Injection rate of the initial precursors strongly depends on the plasma stability. The obtained results for the operating conditions in Table 1 are shown in Table 2. Conversion ratios from the starting material to UFPs are more than 70 % for these operating conditions because of large powers of an RF-ICP and a DC plasma jet.

and the contribution ratio of RF power on the disappearance RF power does not exist.

The following three equations showing the correlation between the input parameters and the each output parameter are obtained from the Tables 2 and 3 in a DC-RF hybrid plasma flow system.

$$d_{UFP} = 131.5 + 7(Q_C - 3.5) - 0.15(Q_Q - 30) \quad \text{.....(1)}$$

$$R_{Conversion} = 81.14 - 0.294(P - 40) + 0.086(Q_{Sh} - 30) + 2.473(R_{Sw} - 0.5) + 0.127(Q_Q - 30) - 3.013(P_{RF} - 9.5) \quad \text{.....(2)}$$

$$P_d = 6.21 + 0.037(P - 40) - 0.042(Q_{Sh} - 30) + 0.784(Q_C - 3.5) - 1.211(R_{Sw} - 0.5) + 0.052(Q_Q - 30) \quad \text{.....(3)}$$

Figure 6 shows the Pareto-optimal resolutions to minimize mean particle diameter of UFPs, maximize conversion ratio to UFPs and minimizing disappearance power simultaneously. UFPs less than 130 nm are obtained at large conversion ratio of nearly 90 % under a stabilized plasma flow by multi-input and multi-objective optimization.

Table 3 Contribution ratios of the input parameters on the output parameters

	d_{UFP} (nm)	$R_{Conversion}$ (%)	P_d (kW)
P (kPa)	3.52	57.42	10.88
Q_{Sh} (l/min)	0.39	4.96	14.14
Q_C (l/min)	76.56	1.70	12.50
R_{Sw}	3.52	10.16	29.85
Q_Q (l/min)	14.06	10.66	22.06
P_{RF} (kW)	1.56	15.09	
P_{DC} (kW)	0.39	0.00	1.02
e	9.38	6.67	10.60
T	100.00	100.00	100.00

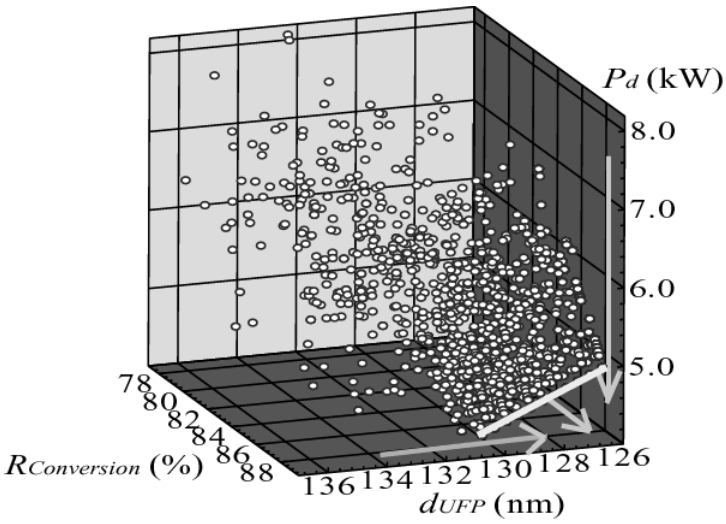

Figure 6 Pareto-optimal resolutions obtained by multi-input and multi-objective optimization

5. Conclusions

1. Several typical distributions of obtained products are confirmed in this study. The mean size of ultra fine particles due to homogeneous nucleation is nearly 100 nm and it increases with increasing operating pressure because particle residence time in the condensation region becomes small.
2. Quench gas effect of producing ultra fine particles becomes prominent at a large amount because a small amount of quench gas is diffused into the plasma core region by a strong recirculation due to Rorentz force.
3. The operating condition is optimized by multi-input and multi-objective optimization to decrease the mean size of ultra fine particles, increase the conversion ratio to ultra fine particles and stabilize the plasma flow during the processing. Under the optimized operating condition, the mean size of ultra fine particles is less than 130 nm, the conversion ratio is nearly 90 % and the plasma flow is very stable during the processing.

Glow Characterization in Plasma Deposition Systems

Qingsong Yu, Chun Huang, YenFong Chan, Mary Gilliam, H.K. Yasuda

Department of Chemical Engineering, Center for Surface Science and Plasma Technology, University of Missouri-Columbia, Columbia, MO 65211, USA

Abstract

The nature of the glow formed in plasma polymerization systems is significant different from simple gas plasmas, in which the well-known *negative glow* is the dominant glow. Investigation to direct current (dc) glow discharges of a series of typical organosilicon and hydrocarbon monomers indicated that *cathode glow* constitutes the characteristic glow in plasma polymerization systems. Plasma diagnostic results obtained from these plasma deposition systems indicated that polymerizable species are mainly created in *cathode glow* region.

Keywords: plasma polymerization, DC glow discharge, trimethylsilane, hydrocarbons, cathode glow, dissociation glow, negative glow, optical emission spectroscopy

Introduction

Plasma deposition of organic gases or vapors in an electrically ignited glow discharge has found wide applications in both high-tech and traditional industries. However, the reaction mechanism in plasma deposition, e.g., how chemically reactive species are created and how these species influence the deposition characteristics and properties, has not been well-understood to date. Due to the difficulty in characterizing deposition plasmas, the ionization concept gained by the analysis of an inert gas discharge is generally applied to plasma polymerization processes. Our recent studies on plasma deposition in direct current (dc) glow discharges indicates that, however, the glow formation and glow characteristics in a glow discharge of organic gas, which deposits materials, are significantly different from that in an inert gas discharge [1-3]. In a dc discharge of an inert gas, the dominant glow, i.e., the well-known negative glow where ionization mainly occurs developed at a distinctive distance away from the cathode, whereas the cathode remained in the dark space [4-5]. In a strong contrast to this situation, in dc plasma deposition systems, the dominant or primary glow was the cathode glow, which formed on the cathode surface. In a dc glow discharge, the location of the plasma glow represents the electron energy level therein. Therefore, the discovery of the dominant cathode glow in dc deposition processes has extremely important implications in the understanding of electric breakdown and creation mechanisms of chemically reactive species in depositing plasmas, i.e. through electron-impact dissociation and/or ionization of organic molecules. In this study, the glow formation in DC glow discharges of a series of organic monomers was investigated using optical photography and optical emission spectroscopy (OES) and the results thus obtained are presented and discussed.

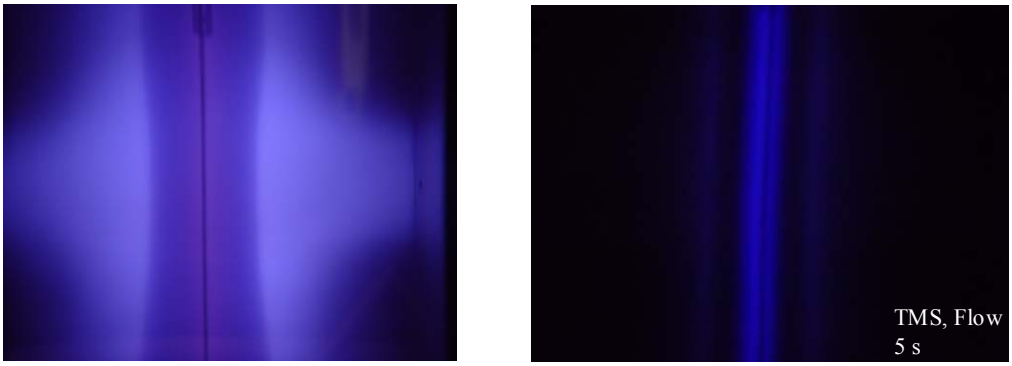
Experimental

A bell-jar type reactor was used in capturing the luminous gas phases. The bell-jar has the dimension of 46 cm in height and 44.5 cm in diameter. A cold rolled steel plate (10.2 cm by 15.2 cm by 0.08 cm) was used as the center electrode, which is the cathode in DC discharge. The two counter-electrodes consisting of a pair of cooled titanium electrodes (18.1 cm by 18.1 cm by 0.16 cm) equipped with magnetic field assembly (magnetron) were placed 10 cm apart. Eight pieces of permanent magnet bars were attached equidistantly on the backside of each anode with the south-pole pointing to the center of the iron plate. The magnetic field strength of each magnet ranged from 700 gauss to 800 gauss. The use of magnetron counter electrodes is not essential to this study. However, it is much easy to identify the negative glow by the use of magnetron anode, because the anode magnetron creates a funnel shaped negative glow and makes the boundary of the negative glow easier to be identified.

Results and discussions

1. Glow discharge of an organosilicon

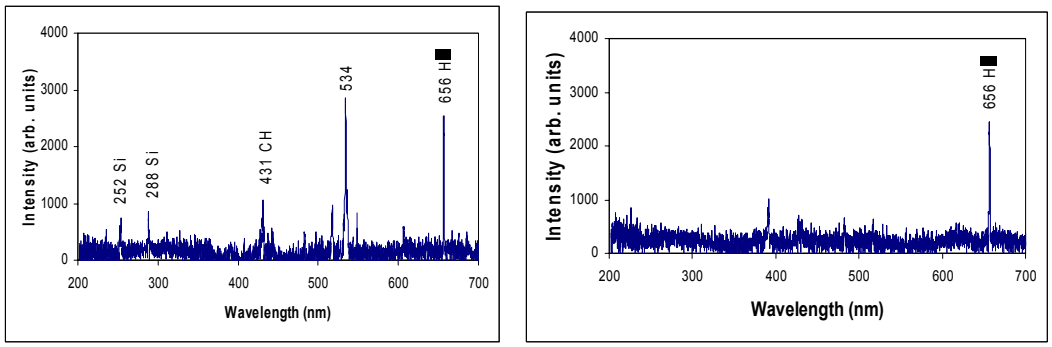
Fig. 1 depicts the luminous gas phase in DC glow discharge of Ar and trimethysilane (TMS) with one cathode positioned in the middle of two magnet-enhanced anodes (i.e., anode magnetrons). It was noted that, in Ar discharge (Fig.1a), the center cathode was always surrounded by a dark space. At the same time, a well recognizable funnel-shaped negative glow exists in some distance away from the cathode on both sides, because two magnet-enhanced anodes are used against one center cathode plate. The funnel-shaped negative glow appears with anode magnetrons.



(a) Ar discharge (b) TMS discharge

Figure 1. Pictorial view of dc glow discharges of (a) argon and (b) trimethysilane (TMS): 1 sccm gas flow, 50 mtorr, 5 W dc power input.

In a strong contrast to Ar glow discharge, as shown in Fig. 1b, a *cathode glow* appeared on the cathode surface constitutes the primary glow in TMS glow discharge system. Under similar discharge conditions, the primary cathode glow in TMS discharge is weaker than the negative glow observed in Ar discharge. In TMS discharge, the cathode glow which literally adhered to the cathode surface evidently indicated that cathode glow is a low-energy glow because of its intimate position from the cathode. In other words, it is reasonable to consider that the primary cathode glow in TMS glow discharge is due to the dissociation of TMS molecules caused by slow or low-energy electron-impacts. It is also important to recognize that, in TMS DC glow discharge, a very feeble or secondary glow exists away from the cathode (approximately the same location where the negative glow was observed with Ar discharge).



(a) OES of cathode glow (b) OES of negative glow

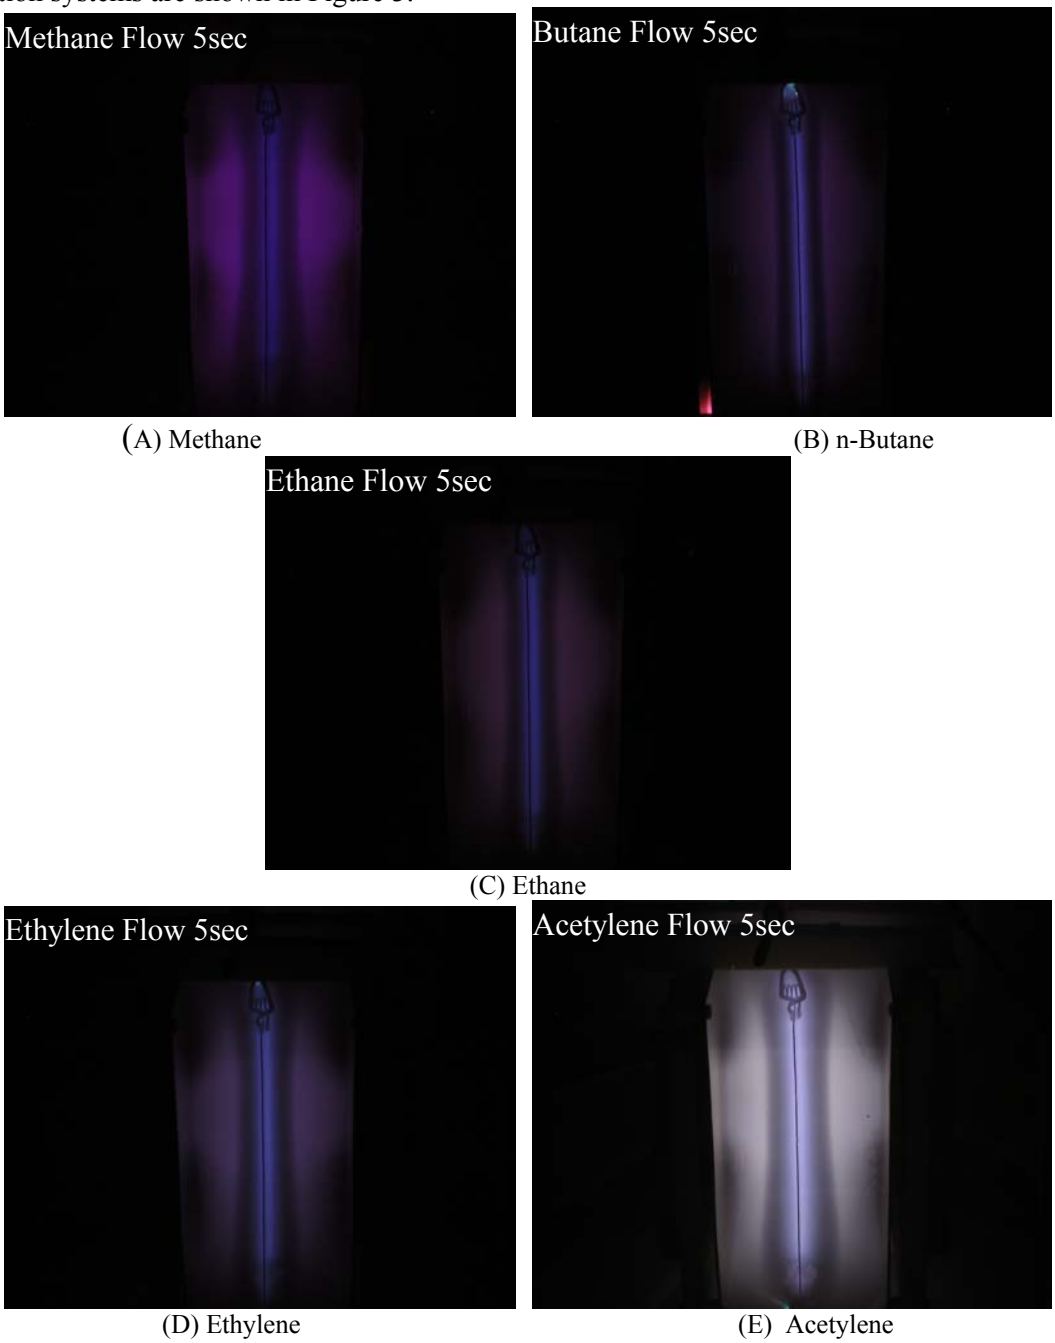
Figure 2. Optical emission spectra (OES) measured from (a) *cathode glow* and (b) *negative glow* in a DC glow discharge of trimethylsilane (TMS): flowing system, 1 sccm TMS, 50 mtorr, DC power 5W

The OES spectra measured from *cathode glow* and *negative glow* in TMS dc plasmas were shown in Fig. 2. From Fig. 2, it can be seen that the feature of optical emission in *cathode glow* is significantly different from that in negative glow. In the *cathode glow*, the reactive species such as CH free radicals and Si atoms that can contribute to plasma polymerization govern the photo-emission spectrum as shown in Fig. 2a. Although not identified at this time, the strong emission at ~ 534 nm appeared in OES spectrum of *cathode glow* has been

verified to be from a polymerizable species by monitoring its emission intensity change with discharge time in a closed TMS DC discharge system. In contrast, as seen from Fig. 2b, the Hα emission line from hydrogen atoms dominates the optical emission from negative glow in a TMS DC glow discharge.

2. Glow discharges of hydrocarbons

Consistent results were also obtained from plasma systems of a series of hydrocarbon monomers, including methane, ethane, n-butane, ethylene, and acetylene. The pictorial views of these hydrocarbon plasma polymerization systems are shown in Figure 3.



(A) Methane (B) n-Butane

(C) Ethane

(D) Ethylene (E) Acetylene

Figure 3. Pictorial view of DC glow discharges of (A) methane, (B) n-Butane, (C) Ethane, (D) Ethylene, and (E) Acetylene in a flow reactor system. Conditions are 1sccm hydrocarbon, 50 mtorr system pressure, 5 watt direct current power input.

It can be seen in Fig. 3, as a characteristic glow in plasma polymerization systems, the strong *cathode glow* was observed in DC glow discharges of the all the hydrocarbon monomers examined. The relative intensity of the both cathode glow and negative glow varies with the hydrocarbon monomer structures. While the *cathode glows* showed similar glow intensity, the secondary negative glow intensified with the increase in the H/C ratio of the monomers, CH_4 (A: H/C = 4) > C_2H_6 (C: H/C = 3) > C_4H_{10} (B: H/C = 2.5). In contrast, the glow intensity of both *cathode glow* and *negative glow* intensified while the chemical structure changes from saturated Ethane (C) to unsaturated Ethylene (D: double bond) and Acetylene (E: triple bond). Fig. 4 shows the OES spectra from both the *cathode glow* and *negative glow* regions of methane, ethane, and acetylene DC polymerization systems.

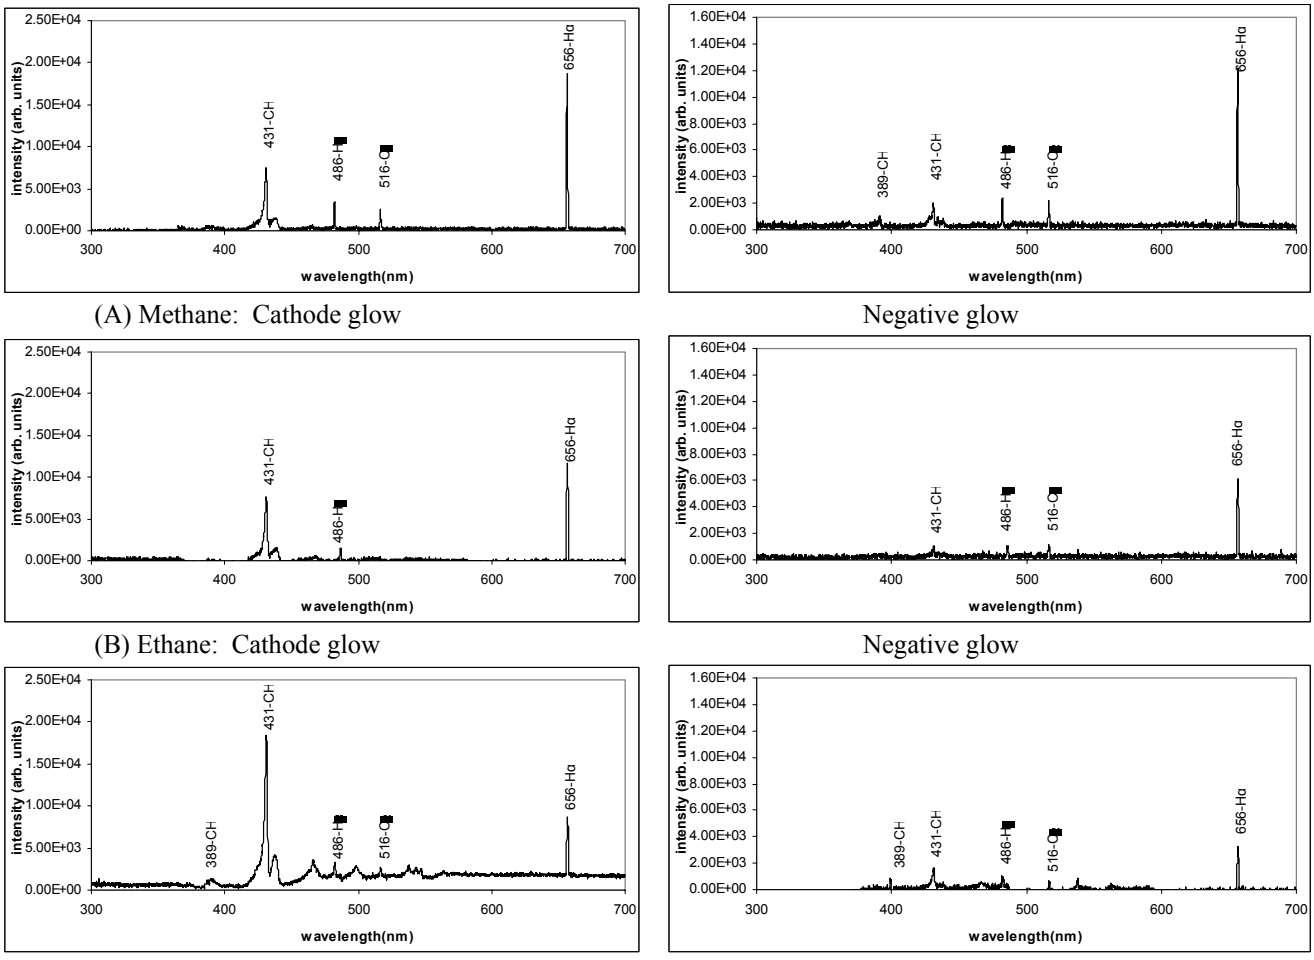


Figure 4. Optical emission spectra (OES) measured from *cathode glow* and *negative glow* regions in a DC glow discharge of (A) methane, (B) ethane, and (C) acetylene in a flowing reactor system with 1 sccm monomer, 50 mtorr, DC power 5W.

From the OES spectra shown in Fig. 4, the photo-emission of CH free radicals that can contribute to plasma polymerization as intermediate precursors mainly appeared in the *cathode glow* region of the plasma systems. In contrast, the main photo-emission from the *negative glow* region of the plasma systems is Hα species, which are non-polymerizable. It was also noticed that the bright *cathode glow* observed in acetylene glow discharge as shown in Fig. 3 gave rise to the strongest photo-emission of CH free radicals. These OES data is well consistent with the rapid deposition of acetylene monomer in a glow discharge under similar plasma conditions. Since the cathode glow is attached to cathode surface, the electron energy level in cathode *glow region* is much less that in the *negative glow* region. The low-energy electrons in the *cathode glow* are considered are mainly responsible for the dissociation of the monomer molecules and especially these unsaturated hydrocarbons such as ethylene

and acetylene. Therefore, a brighter *cathode glow* was observed in Fig. 3 and stronger photo-emission from CH species, an intermediate product of the dissociation reaction of the hydrocarbon molecules upon electron-impact, was detected by OES measurements from acetylene glow discharge shown in Fig. 4.

3. Glow discharges in a closed reactor system

Plasma polymerization was performed in a closed reactor system with an aim to investigate the glow dependence with chemical species in the system. Fig. 5 shows the glow characteristic change of Ethane DC glow discharge with discharge time. It was found that, in the initial plasma polymerization stage, the *cathode glow* constituted the dominant glow of the system. However, the cathode glow became weaker with the increase of the discharge time, i.e. plasma polymerization time. Eventually, the secondary *negative glow* became the primary glow of the system.

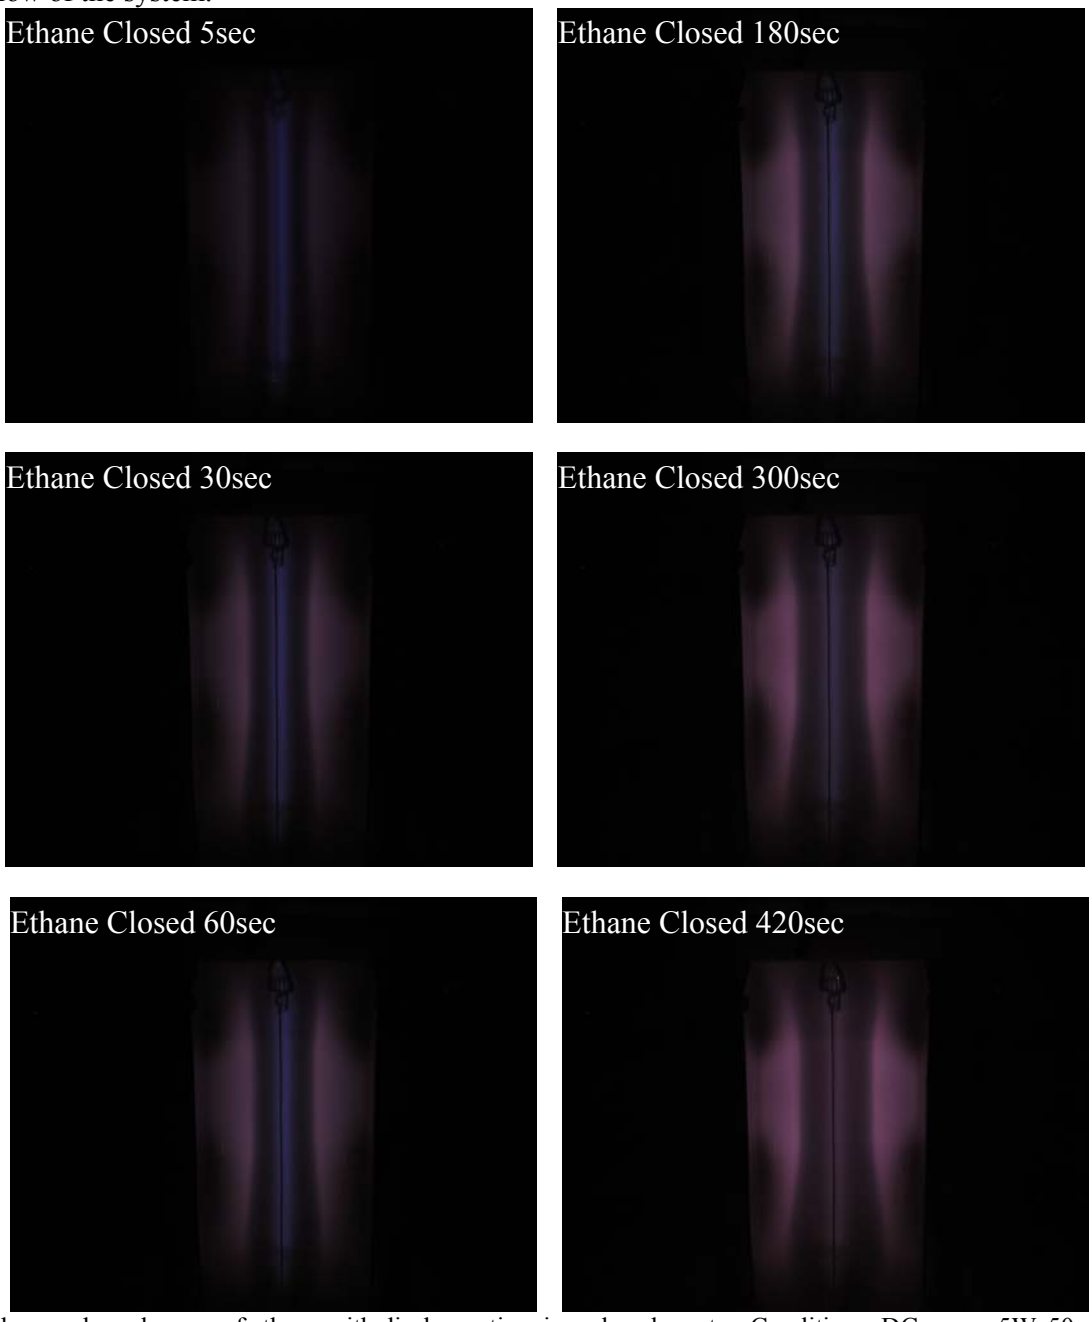

Figure 5. Plasma glow changes of ethane with discharge time in a closed reactor. Conditions: DC power 5W, 50 mtorr.

OES was used to monitor the emission intensity change of the major photo-emitting species in both glow regions of Ethane glow discharges in a closed reactor. Fig.6 shows the time dependence of emission intensity of CH and H species from both *cathode glow* and *negative glow*. It can be seen the CH species disappeared after a certain period of plasma polymerization due to material deposition to solid phase. In contrast, after the disappearance of CH species, the Hα emission reached a saturated level that is corresponding to the stronger *negative glow* as observed in Fig. 5. These results obtained in a closed plasma polymerization system further confirmed that the cathode glow is mainly responsible for the creation of polymerizable species, while the *negative glow* is related to non-polymerizable species.

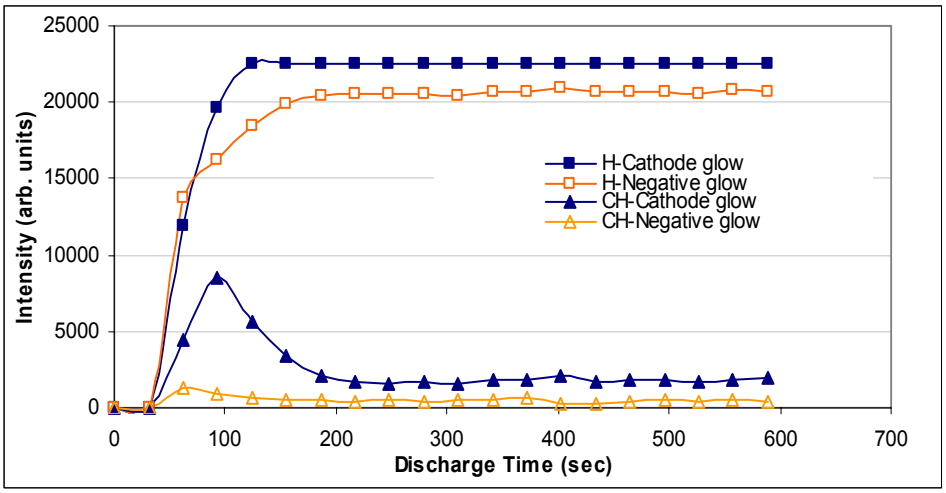

Figure 6. Time dependence of emission intensity of CH (431nm) & H_α species from *cathode glow* and *negative glow* regions in DC glow discharges of ethane in a closed reactor with 50mtorr system pressure and 5 watt DC power input.

Conclusions

The results obtained in this study clearly indicated that the glow formation in a plasma polymerization system is very different from that in a simple gas plasma system such as argon. The *cathode glow* in which low-energy electron impact dissociation occurs is the characteristic glow of a plasma polymerization or deposition system. In contrast, the negative glow formed in a position away from the cathode that contains high-energy electrons dominates in simple gas glow discharge systems. OES investigation on plasma polymerization systems of both organosilicon and hydrocarbon monomers indicated that the *cathode glow* is the plasma region where the main polymerizable species are formed. On the other hand, the negative glow is where the non-polymerizable species such as H atoms were observed. It can be concluded that, in a DC plasma polymerization system, the low-energy electron impact dissociation in the cathode glow mainly contributes to the creation of plasma polymerizable species and therefore control the plasma polymerization process.

Abstract

In this study, we investigated the internal sterilization technique using microwave-excited volume-wave plasma. To produce the volume-wave plasma, we employed the planar cylindrical microwave launcher installed inside the vacuum chamber. The spores of population of 10^6 were irradiated with volume-wave plasma discharges in He and O_2 mixture gas. It is noted that when the spores were set inside of the plasma discharges, they were completely killed within 1 min discharge. It is also found from the SEM analysis that spores after oxygen plasma irradiation had changed significantly in length and width, due to the chemical etching process by the oxygen radicals. The present results demonstrated a successful internal sterilization with volume-wave plasma at a relatively low temperature less than 70 °C.

1. Introduction

Sterilization of medical instruments has been conventionally performed using a dry-heat or hot-steam technique for heat-resistant materials, or the ethylene-oxide gas for heat-sensitive materials. However, there are various issues in the present sterilization methods; for example, the former method is limited to use the sterilized materials, such as the metal or glass implements. As for the ethylene-oxide gas sterilization, the environmental problems due to its toxicity are recently concerned. Therefore, it is desired to develop a new type of sterilization technique, which makes it possible to sterilize the medical instruments safely and rapidly at low temperature.

Up to now, various low-temperature plasma sterilization techniques have been developed using low-pressure glow discharges[1], glow discharges at atmospheric pressure[2-4], downstream plasma produced by microwave excitation[5], moving atmospheric microwave plasma[6] and surface- wave plasma.[7-9]

The problem of the plasma sterilization is essentially on the treatment of the surface only. In order to sterilize inside the medical instruments wrapped with perforated plastic packing, it is required to produce the plasma inside

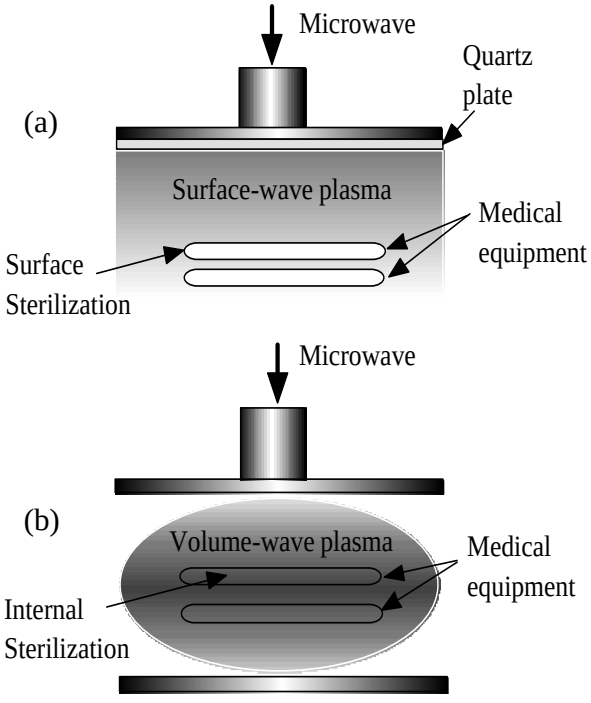

Fig. 1 Schematic drawings of (a)surface-wave plasma and (b)volume-wave plasma sterilization techniques.

the packing material. To overcome this problem, we propose here to use the volume wave plasma for plasma sterilization, as shown in Fig. 1.

2. Experimental setup

Schematic drawing of the experimental setup to produce the volume-wave plasma is shown in Fig. 2[10]. The inner diameter and the height of cylindrical vacuum chamber are 250 mm and 500 mm, respectively. The chamber is pumped down to order of mTorr by a rotary pump. Microwave launcher consisted of a coaxial waveguide and a cylindrical planar cavity, inside of which a thin dielectric plate was used. In this launcher system, the vacuum was sealed by an O-ring in a small area, so that the thickness of quartz plate was reduced significantly. A circular quartz plate having a diameter of 220 mm and a thickness of 8 mm was used inside the planar microwave launcher. A stainless steel punched plate with a hole-diameter from 8 mm was attached on the quartz plate as shown in Fig. 2. The narrow gap between the cylindrical side of quartz plate and the metal wall of microwave launcher was set to be 4 mm. The 2.45 GHz microwave guided by a rectangular waveguide was transferred to the microwave launcher via a coaxial waveguide.

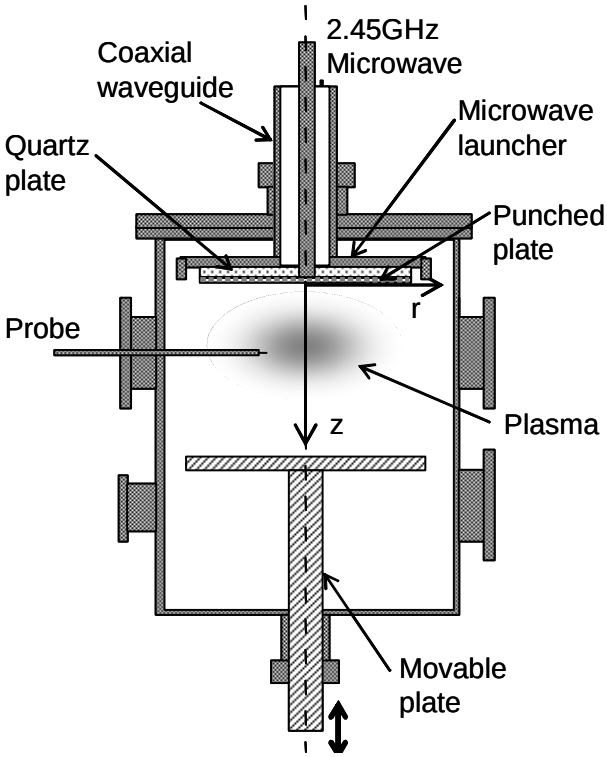

Fig. 2 Schematic drawing of the experimental setup of volume-wave plasma with a planar microwave launcher.

Output power of 2.45 GHz magnetron was variable from zero to 1.5 kW. Microwave through a number of apertures of punched plate penetrate into the chamber as evanescent wave. By adjusting the position of facing metal plate, VWP discharge can be produced between the launcher and metal plate, as shown in Fig. 3. As the biological indicators (B.I), we used *Bacillus subtilis* of a population of 10^4 to 10^8 and *Bacillus stearothermophilus* of a population of 1.5×10^6.[11]

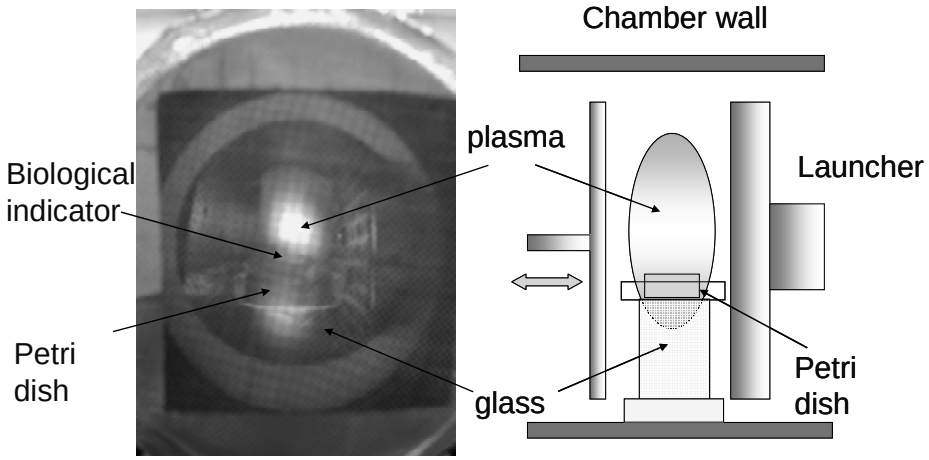

Fig. 3 Photograph of the He/O_2 plasma discharge taken from the side port window(left) and a schematic drawing of its cross-sectional view(right).

The spores were put on the Petri dish located just below the plasma ball, as shown in Fig. 3.

3. Results and discussion

First, we measured the electron density and temperature profiles of volume-wave plasma (VWP) using a double probe technique. Figure 4 shows the photograph of VWP and the geometrical relation between the plasma and the probe. Scanning the probe radially, we measured the density and temperature distributions, as shown in Fig. 5. Peak electron density was roughly 5~7x10^{10} cm^{-3} which is comparable to the cutoff density of 7.4x10^{10} cm^{-3} for 2.45 GHz microwave. The electron temperature in the center region was of 5~6 eV.

In the VWP sterilization measurements, we used two types of biological indicators. One type of B.I. is *B. Subtilis*, where the spores are painted inside the glassine strip having a size of 5 mm x 37 mm. A set of steri-chart having spore populations from 10^4 to 10^8 [11] was used in the volume wave plasma sterilization without taking them off wrapped glassine envelopes.

We varied the plasma irradiation period up to 10 min and simultaneously measured the stage temperature using thermo label sheets attached on the surface of Petri dish. After the plasma irradiation, the spores are incubated in culture tubes during several days at the incubation temperature of 35-40 °C for *B. subtilis*. It was found that B.I. having spores of 10^5 and 10^6 were sterilized for 10 min He/O_2 plasma discharge. The temperature of the Petri dish was roughly 70 °C or less from the measurement using a thermal label. Thermal damage of wrapping paper or strip was not seen at all.

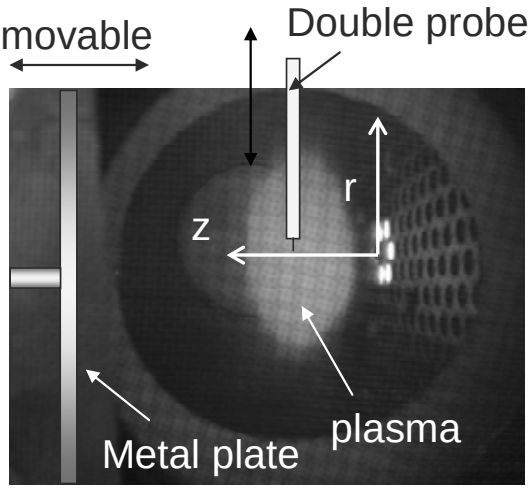

Fig. 4 Photograph of volume-wave plasma and schematic drawing of the double probe measurement.

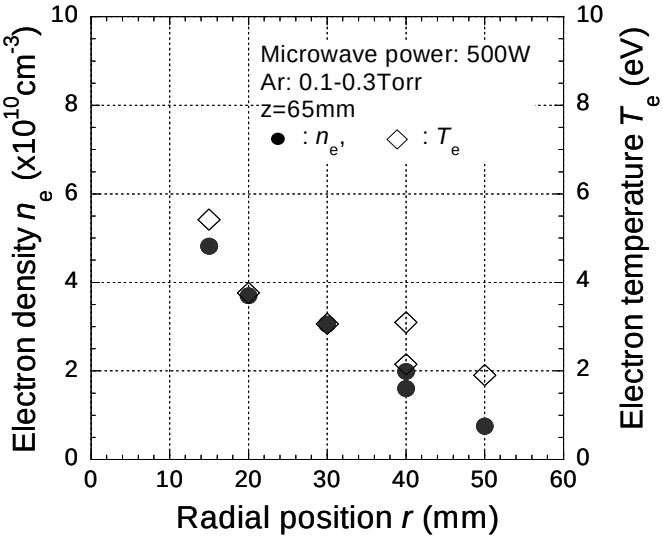

Fig. 5 Radial profiles of electron density and temperature in the volume-wave plasma.

To study the survival curves of the VWP sterilization, we used another B.Is, where the spores of population of 1.5~3x10^6 were painted on the small stainless steel disc. [11] Spores were directly irradiated by the plasma ball for different plasma discharge durations at different positions with respect to the plasma ball. Figure 6 shows the results of colony-counting measurements for different spore positions; that is, inside of the plasma, edge of the plasma and outside of the plasma, respectively. It is noted that the spores were killed within one minute in case of inside the plasma ball. The D value was evaluated from the slope of survival curve to be 20 sec or less. The temperature of the glass dish was heated to roughly 90°C or less, possibly due to the strong interaction with the CW plasma discharge. But it is believed that the spores are not killed by the heat effect under the present experimental conditions. At the edge region of the plasma ball, spores were reduced rapidly

in early plasma irradiation period, but the surviving spores decreased with a slightly slow rate. To confirm the sterilization, it will need about 20 min assuming a linear decay. Here temperature was roughly 70 °C or less. Away from the plasma ball, the sterilizing effect was weakened significantly. In the case of outside the plasma region, it will take longer plasma treatment. The D-value was estimated as roughly 4 min.

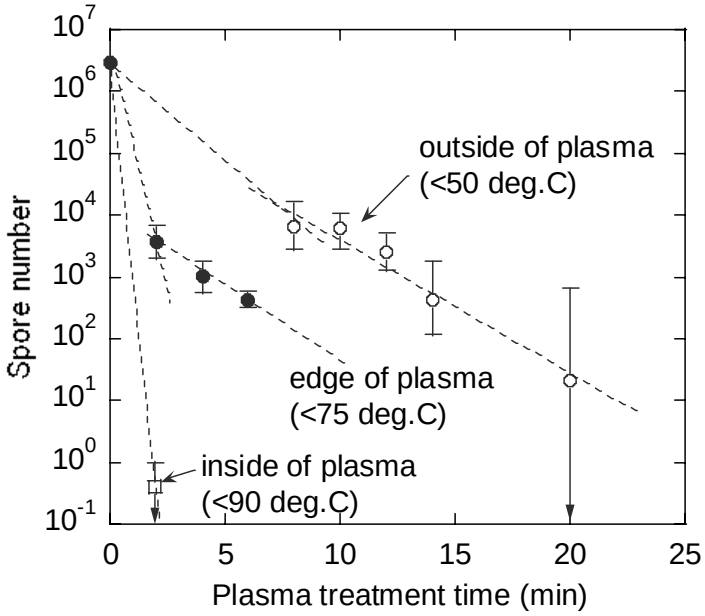

Fig. 6 Survival curves of spores irradiated with the VWP at different position; inside, edge and outside of the plasma ball.

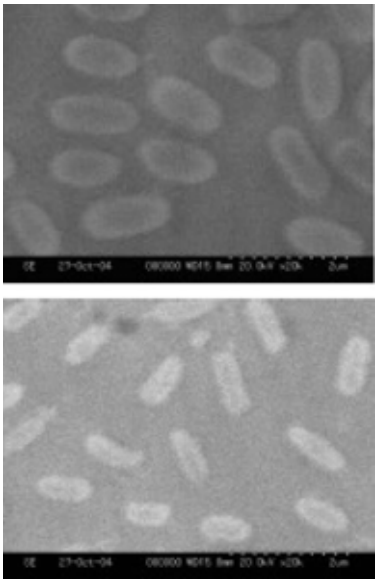

Fig. 7 SEM images of the spores irradiated by the oxygen plasmas for 2 min (top, not sterilized) and ones for 8min.(bottom, sterilized).

The spores irradiated by the volume wave plasma were studied using the Scanning electron microscope(SEM). Figure 7 shows the SEM images of spores treated for 2 min and 8 min plasma discharges. In the former case, the spores were not killed, so that the spores had almost the same shapes as those of original ones. In the latter case, however, the spores were sterilized and their sizes were significantly reduced. These results were very similar to the previous experimental results of surface wave plasma sterilization with pure oxygen plasma discharge.[8, 9]

4. Conclusion

In this study, we investigated the internal sterilization technique using microwave-excited volume wave plasma for application to the sterilization of the wrapped medical instruments. The volume-wave plasma was produced using the internally installed microwave launcher. The density of the plasma ball was measured with the double probe and we found that the electron density was comparable or lower than cutoff density. The spores of population of 10^4 to 10^8 were irradiated for different durations by the volume-wave plasma discharges in He and O_2 mixture gas. We confirmed that the spores of a population of 10^6 were sterilized with 10 min VWP treatment even though the BI strip was packed with the glassine envelope. Especially, it is noted that when the spores were irradiated directly with plasma discharge, they were killed within 1 min of plasma discharge. It is also found from the SEM analysis that spores after oxygen plasma irradiation had changed significantly in length and width, due to the chemical etching process by the oxygen radicals. The present results showed the successful sterilization with volume-wave plasma at a relatively low temperature less than 70 °C.

Abstract

We developed a novel type of planar cylindrical microwave launcher installed inside the vacuum chamber for the production of large-area processing plasma. Microwave launcher consisted of a coaxial waveguide and a cylindrical planar cavity, inside of which a large-area thin quartz plate was inserted. We tested two types of microwave launchers, one was a closed cylindrical cavity structure and the other was a leaky open cavity structure. With a 1.5 kW microwave source, we have demonstrated the production of large-area, surface-wave plasma (SWP) using Ar gas. With the microwave launcher of a leaky open cavity structure, SWP with a spatial uniformity of ±3.5 % over 160 mm in radius was achieved at pressure of 20~30 Pa. Numerical analyses using the electromagnetic wave simulator, MAFIA, have been also carried out to study the electric field distribution radiated from the microwave launcher and to explain the experimental results.

1. Introduction

For large-size ULSI manufacturing or meter-size liquid crystal display panel, it has been required to develop the large-area uniform plasma sources. In plasma CVD, such as deposition of amorphous silicon, carbon nanotube or crystalline diamond films, the large-area plasma source has been also needed. However, it is not easy to achieve the plasma uniformity over the large cross section. Among the various plasma devices, surface wave plasma (SWP) is one of promising plasma sources satisfying the requirements for a compact, large-area plasma processing tool[1-6]. So far, we have been developing the large-area SWP excited by 2.45 GHz microwaves[7-9] or 915 MHz UHF waves[10] using a slot antenna excitation. In the SWP, a density jump has been observed when the incident power or operating gas pressure changed. This originated from the surface-wave mode, determined from the boundary conditions between the dielectric window and plasma, in addition to the chamber geometry and incident wave frequency [11]. Thus, by increasing the incident power or gas pressure, the plasma density satisfying a certain surface-wave mode was selectively allowed. From the practical aspects, such a discontinuous behavior of the plasma density is undesirable for the actual material processing. Another problem in enlarging the plasma device is the dielectric window for vacuum sealing. For enlargement of the chamber cross section, it is needed to use a thick, large dielectric plate to withstand a huge pressure force. Therefore, reduction of thickness of dielectric window is also another remaining issue.

In order to overcome these problems, we have developed a new type of microwave launcher installed inside the vacuum chamber [12]. Microwave launcher consisted of a coaxial waveguide and a cylindrical planar cavity, inside of which a thin dielectric plate with 500 mm diameter and 10 mm thickness was inserted. Huge pressure force can be held by a thin quartz plate in the proposed internally mounted launcher. In the proposed launcher, furthermore, resonant cavity mode was determined by the cavity geometry independently of plasma density. Therefore, it is expected that mode jump was avoidable in the present system. Preliminary experiments have been carried out to demonstrate the plasma production using a large-area

plasma chamber with a diameter of 600mm and a height of 350mm. To understand the experimental results, we also performed numerical analysis of electromagnetic wave fields using the MAFIA field simulator.

2. Experimental Set-up

Schematic drawing of the experimental setup with a microwave launcher is shown in Fig. 1[12]. The 2.45 GHz microwave guided by a rectangular waveguide was transferred to the microwave launcher via a coaxial waveguide. Microwave power of 2.45 GHz magnetron is variable from zero to 1.5 kW. The vacuum chamber was pumped down to order of mTorr by a rotary pump. For the measurements of plasma parameters, we used a Langmuir probe with a 0.7 mm-diameter platinum wire tip. In Fig. 2, we show a schematic drawing of the assembled microwave launchers. A circular quartz disc having a diameter of 500 mm and a thickness of 10 mm was used inside the planar microwave launcher. Two types of cavity structures were used. In TYPE I launcher, stainless steel punched plate with a hole-diameter from 4 mm to 10 mm was attached over the quartz plate. Microwave can penetrate through small holes as evanescent waves to produce the plasma. In TYPE II launcher, a half-size metal plate was attached in the center of the quartz surface to form a leaky open cavity.

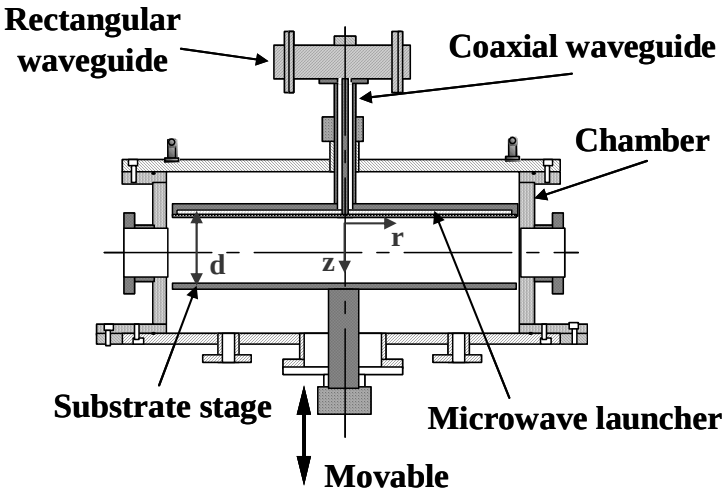

Fig.1 Schematic drawing of the experimental setup with a planar microwave launcher.

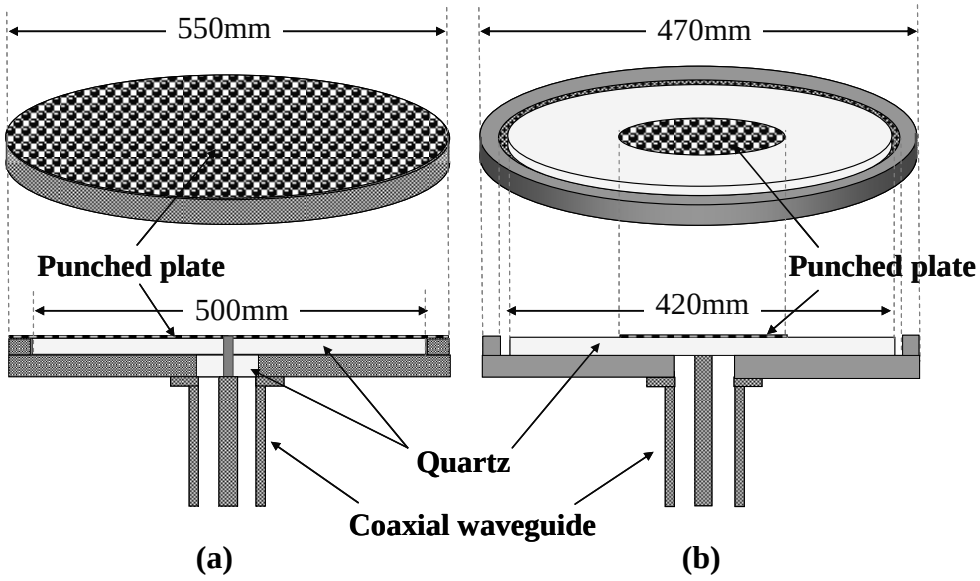

Fig. 2 Structures of microwave launchers of (a) TYPE I and (b) TYPEII, where in TYPE I, a punched plate having a hole size of 4-10mm was attached to the front surface and inTYPE II, a metal plate was partly attached in the center of the quartz surface.

3. Experimental results and discussion

We tested the plasma production using two types of internally mounted microwave launchers, shown in Fig. 2. Figure 3 shows pictures of Ar plasma discharges in case of TYPE I launcher, where microwave power was 500 W and 1.5 kW at pressure of 74 mTorr. These pictures were taken from the small side-port, so that they showed only a part of plasma discharge. As shown in Fig. 3, plasma discharge spreads radially as the incident power increases. When the input power was increased to 1.5kW, plasma discharge was gradually spread over the whole area of the launcher without any density jump. Spatial distributions of ion saturation currents were measured by scanning the

Langmuir probe horizontally at the axial position of z=4 cm far from the launcher surface. Here, microwave power was 1 kW at pressure of 74 mTorr. It is shown that density profile is peaked at the central region. Electron density at the center corresponds to roughly $1\sim2\times10^{11}\,cm^{-3}$. Plasma density rapidly decreased with the radial position. As it will be described later, density profile is closely related with the spatial distribution of electric field penetrating through the small holes of punched metal plate. Hence, we also tested another structure of microwave launcher, TYPE II launcher, in which the circular stainless steel plate with a diameter of 200 mm was used to hold the quartz plate in place of punched plate, as shown in Fig. 2(b). Picture taken from the side-port was shown in Fig. 5. With this type of launcher, we observed more uniform density profile over a diameter of 400 mm, as shown in Fig. 6, which was measured at z=11cm from the launcher. Electron density corresponds to roughly $5\times10^{9}\sim10^{10}\,cm^{-3}$, which is fairly low compared with the results in TYPE I launcher, because a strongly hollow type of profile near the launcher was diffused out and smeared out in the down stream region. When

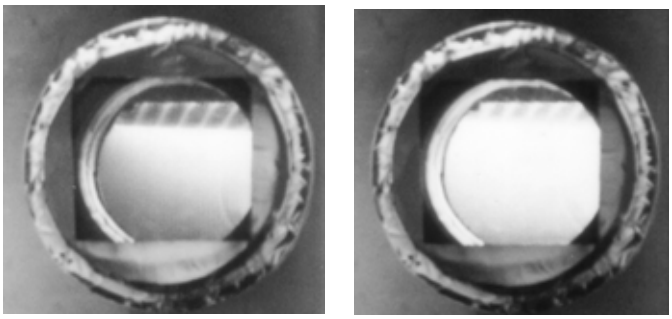

Fig. 3 Pictures of Ar plasma discharges in case of TYPE I launcher where microwave power was (a)500 W and (b)1.5 kW at pressure of 74 mTorr.

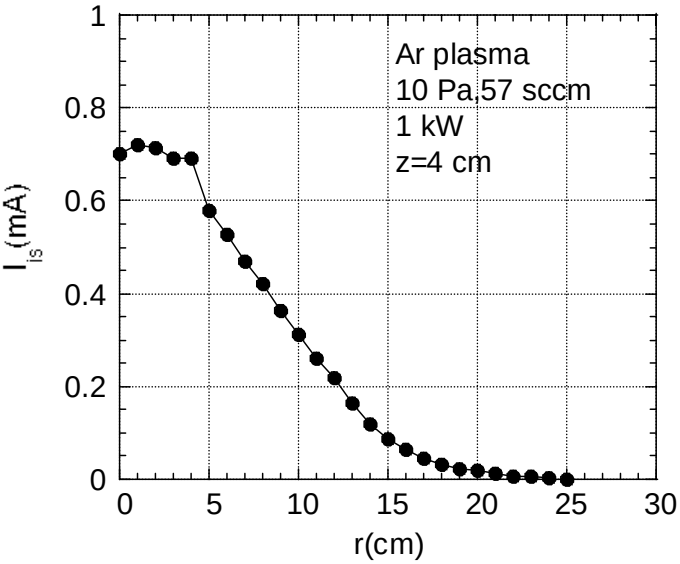

Fig. 4 Spatial distribution of Ion saturation currents in case of TYPE I launcher where microwave power was 1 kW at Ar gas pressure of 74 mTorr.

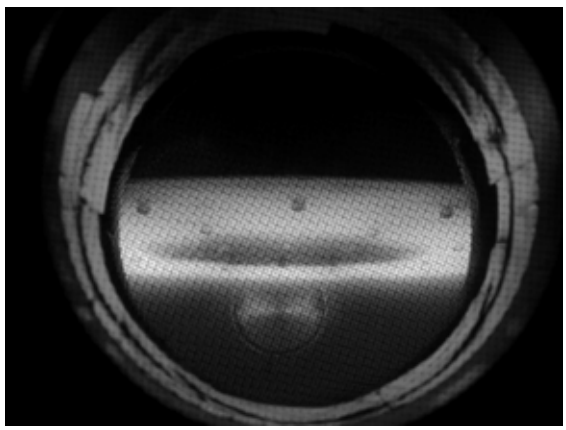

Fig. 5 Pictures of Ar plasma discharges in case of TYPE-II launcher where microwave power was 1kW at pressure of 190 mTorr.

increasing the input power up to 1.5 kW, density smoothly changed without any density jump.

Figure 6 shows the spatial distributions of ion saturation currents measured by the Langmuir probe at axial position of z=11 cm far from the launcher surface. Here, microwave power was varied from 100 W to 1.3 kW at Ar gas pressure of 140 mTorr. As shown in Fig. 6(a), uniform density profiles over a diameter of 300 mm were obtained for the input power rage from 500W to 1 kW. Here, the electron density was estimated to be roughly ~10^{10} cm^{-3}. When the incident power was less than 500 W, the ring shape plasma was produced surrounding the metal punched plate. With increasing the power, the plasma was broadened over the microwave launcher. Figure 6(b) show the ion saturation current versus the incident power at different radial positions. It is seen that the density linearly increased without any density jump as the incident power.

To investigate the field distribution launched from the microwave launcher, we performed the numerical simulation using the MAFIA. Figure 7 shows results of field analysis of the spatial distribution of electric filed intensity in the cases of TYPE I and TYPE II launchers. In case of TYPE I, the microwave field is fully spread toward the edge of the launcher and forms a concentric resonant field pattern of TM_{08} mode. Microwave can penetrate into the vacuum chamber through a number of small holes of the punched plate, as evanescent waves. Figure 7(a) shows one example of spatial distribution of field intensity radiated from the TYPE I launcher. It is seen that the field strength is strong in the central region of the launcher. This is consistent with the plasma density distribution shown in Fig. 4, where the plasma density will be peaked at the center. On the contrary, Fig. 7(b) shows that the electric field propagates through the quartz plate in the central part and uniformly radiate toward the vacuum chamber. It suggests that plasma will be produced just below bare quartz

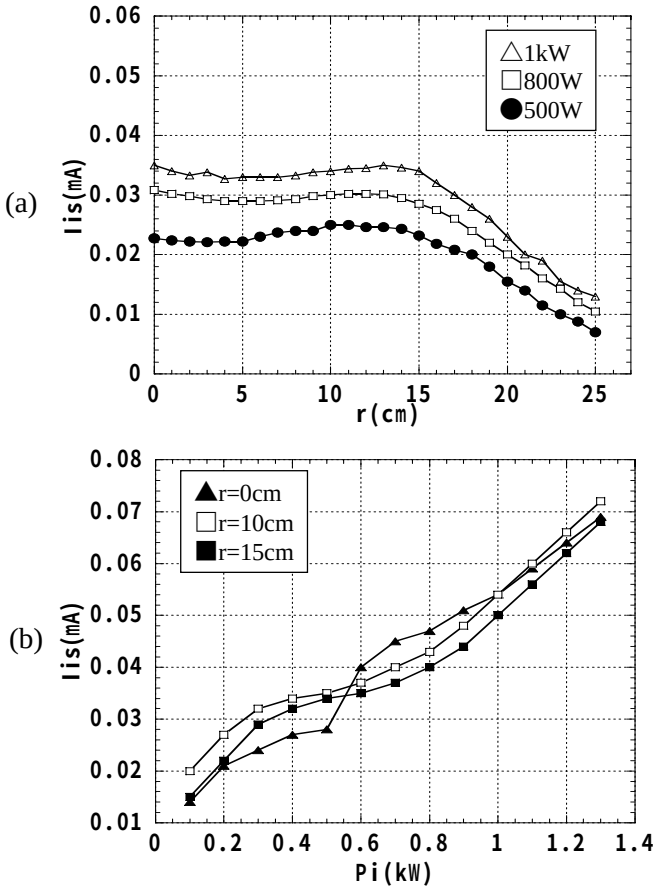

Fig. 6 (a) Radial profiles of ion saturation currents and (b) relation between the ion saturation currents and incident power in Ar plasmas.

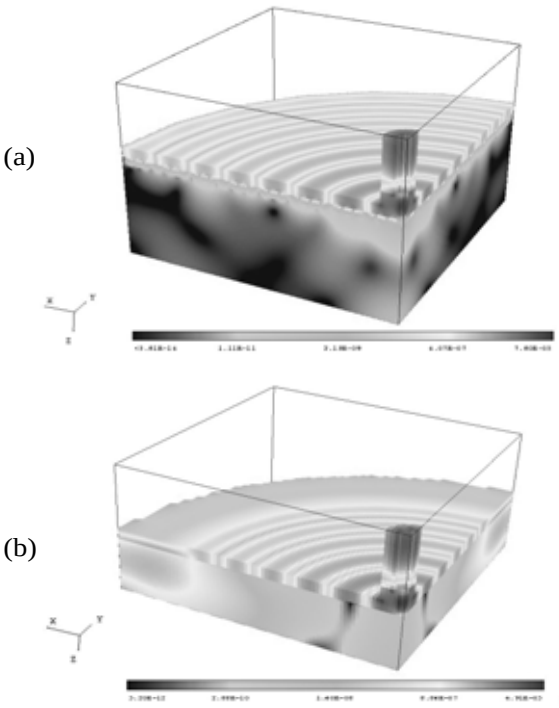

Fig. 7 Field intensity distributions of electric filed intensity in cases of (a) TYPE-I and (b) TYPE-II launchers.

surface. Actually, the ring shape plasma can be produced along the quartz surface, as shown in Fig. 5. Near the launcher surface, plasma had a strongly hollow type distribution. However, due to the particle diffusion, plasma became more uniform in the downward region, as shown in Fig. 6.

Lastly, it is noted that wave field penetrating through a number of small holes is of evanescent wave. From the MAFIA simulation, we found that the decay length of evanescent wave is typically 8-10mm in the free space. Plasma will be produced by the evanescent waves penetrating through the small holes, depending on the wave field strength. Thus, to obtain more uniform density profile, it will be necessary to design the punched plate with spatially controlled hole distributions.

4. Conclusion

In this study, we demonstrated novel type of planar cylindrical microwave launchers installed inside the vacuum chamber for production of large-area processing plasma. Two types microwave launchers with a diameter of 550 mm, closed and open cavity structures were tested to compare plasma production. A large-area thin quartz plate having a thickness of 10~15 mm was used for vacuum sealing in the planar cylindrical launcher. Field analysis using the electromagnetic field simulator has been carried out to study the electric field distribution radiated from the launcher and to explain the experimental results. We demonstrated that the microwave plasma having a diameter of roughly 300 mm was successfully produced using TYPE II launcher at Ar gas pressure of 0.5~1 Torr and an input power of 500-1500W.

Abstract

Low-temperature plasma sterilization has been experimentally demonstrated using surface-wave plasma excited by a 2.45 GHz microwave. We used *Geobacillus stearothermophilus* spores with a population of 10^6 as biological indicators(BIs), and irradiated them with oxygen plasma discharges generated with CW microwave power of 750 W or pulse-modulated microwave instantaneous power of 1.5 kW. All the BI samples were sterilized by irradiating them for 150 sec total microwave on time or longer.

Keywords: surface-wave plasma, oxygen plasma, plasma sterilization, pulse-modulated SWP

1. Introduction

Conventional methods used in the sterilization of medical instruments have been mainly performed using dry heat or hot steam autoclave for heat resistant instruments, and ethylene oxide (EtO) gas for heat sensitive instruments. The disadvantage of the dry heat or hot steam sterilization is that they can only be applied to instruments that can withstand the high temperatures. The disadvantages of EtO gas sterilization are that EtO is toxic, carcinogenic, inflammable and the threat to the environment of chlorofluorocarbons (CFCs). As well, it takes one or more weeks for the EtO levels to return to safe levels, which is much longer than the time required to sterilize the equipment. Another type of sterilization method, which combines hydrogen peroxide gas with an RF discharge plasma, is commercially available.[1] Currently, this equipment is assumed to effectively sterilize due to the high concentration of hydrogen peroxide rather than to the plasma component.

At present, various low-temperature plasma sterilization techniques have been developed, such as low-pressure glow discharge [2], glow discharges at atmospheric pressure [3,4], downstream plasma produced by microwave excitation [5,6], moving atmospheric microwave plasmas [7], and surface-wave plasmas [8-10]. The plasma sterilization method has certain advantages over conventional methods, including a low sterilization temperature (often less than 70°C) and a short sterilization period of several minutes to 1 hour.

Previously, we reported that a 6-order reduction in spores could be achieved after only a 3-minute irradiation with low-pressure oxygen surface-wave plasma.[9] In this paper, we investigated the effect of low-temperature sterilization using continuous microwave (CW) and pulse-modulated surface-wave plasmas (SWPs). The effect of nitrogen gas addition on the sterilization was studied in the oxygen plasma.

2. Experimental Setup

A schematic drawing of the SWP device is shown in Fig. 1. The 2.45 GHz microwave guided by a rectangular waveguide was fed into the stainless steel chamber (diameter of 40 cm and height of 40 cm) filled with discharge gas, through slot antennas cut in the broad face of each waveguide.[11] The launched

microwave power can be variable from zero up to 3 kW. We can operate pulse-modulated plasma discharges using the pulsed microwave system with a modulation frequency from DC to 80 kHz. The vacuum chamber was pumped down to the order of 10^{-5} Torr with a turbo-molecular pump. For the experiments on plasma sterilization, we utilized the O_2 discharges at pressure of about 30~70 mTorr and 120~130 mTorr with O_2 gas flow rate of 200 sccm; we also utilized N_2 and N_2-O_2 discharges at pressure of about 60~90 mTorr with total gas flow rate of 100 sccm. As for the biological indicators (BIs), we used a population of $1.5x10^6$ and $3.0x10^6$ *Geobacillus stearothermophilus* spores (ATCC No.12980) painted on a small stainless steel disc.[12] These BI samples were placed in Petri dishes set onto substrate stage with a diameter of 20 cm about 15~23 cm below the quartz vacuum window. During plasma irradiation, the stage temperature was measured using thermo-label sheets attached to the Petri dish under a piece of thin glass. The piece of thin glass was used to avoid any direct interaction between plasma and thermo-label sheet.

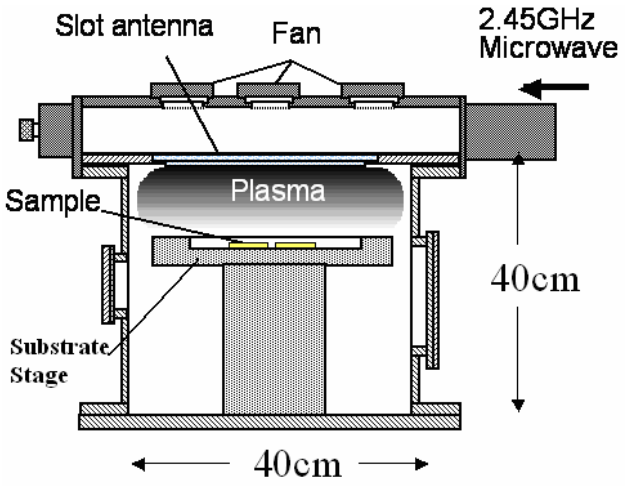

Fig. 1 Cross-sectional view of the surface-wave plasma device with a diameter of 40 cm.

After plasma irradiation, the spores were incubated in culture tubes with culture solution for 7 days at an incubation temperature of 55~60 °C as is standard for *Geobacillus stearothermophilus*. After the incubation process in the culture tubes, we determined whether the spores were perfectly sterilized or not. The color of the culture solution changed from purple to yellow, if the spores were still viable. Since we use the *Geobacillus stearothermophilus* with a population of $1.5x10^6$ and $3.0x10^6$, we assume that successful sterilization is at least a 6-order reduction in viable spore population from its original value.[12]

3. Experimental Results and discussion

First, we showed the experimental results of the oxygen plasma sterilization of $1.5x10^6$ *Geobacillus stearothermophilus* spores while substrate stage was about 15 cm below the quartz window, discharge pressure was at about 30~70 mTorr, O_2 gas flow rate was 200 sccm.

We utilized oxygen plasma excited by 500 W, 750 W, 1000 W, 1500 W and 2000 W CW power. Two BI samples for each plasma irradiation period were simultaneously put on the Petri dish on the stage. One sample was used for the incubation test and the other was used for the colony counting method. The plasma irradiation period was varied from 30 sec by 10-second steps, while CW power was kept at 1000 W and 1500 W. The Petri dish temperature increased from 20°C at room temperature to 60°C after 130 s plasma discharge excited by 1 kW CW power or 50 s plasma discharge excited by 1.5 kW CW power.

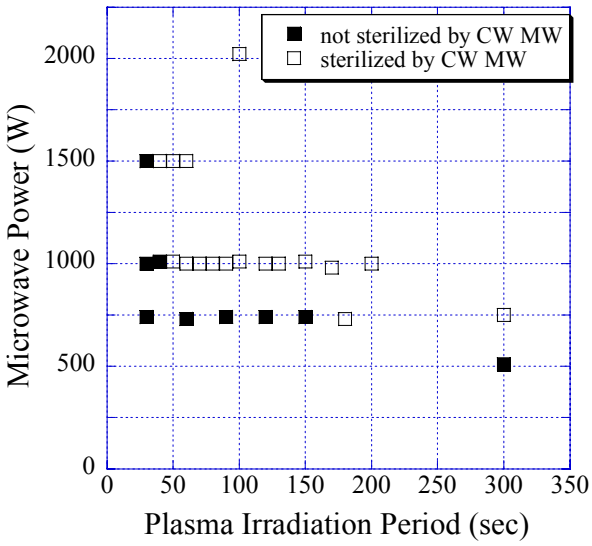

Fig. 2 Experimental results of sterilization between CW microwave power and plasma irradiation period.

The sterilization effect could be confirmed for

samples irradiated for 50 s or longer while CW power was 1 kW and samples irradiated for 40 s or longer while CW power was 1.5 kW. We also tested other parameter conditions using CW plasma as shown in Fig. 2. We draw the conclusions that BI can be sterilized by CW oxygen plasma under conditions: a) CW power should not be less than 700 W; b) plasma irradiation period should not be less than 40 sec; and c) at least total microwave energy of 50 kJ is needed.

In our previous paper, we reported BI could not be sterilized by argon plasma excited by 700 W CW power.[10] We also tested the sterilization effects of the oxygen radicals and UV radiation emitted from the oxygen plasma. We deduced from the experiment that the spores were mainly killed by some chemical reactions with oxygen radicals, rather than the UV radiation in the oxygen plasma experiment.[8] To study the detail of oxygen radicals, we have been investigating pulse-modulated microwave plasma sterilization.

In order to investigate temperature increase caused by irradiation of oxygen plasma excited by pulse-modulated microwave power, we used 1 kHz pulse-modulated microwave power with on-duration of 500 μs and instantaneous power of 1.3 kW. The plasma irradiation period was varied from zero to 5 min by 30-second steps. The stage temperature increased from 23°C at room temperature to 35°C after 5 min plasma irradiation. We tested several different parameter conditions by using the pulsed microwave system. We varied the pulsed modulation frequency of the pulsed operation, the microwave on-duration, the instantaneous microwave power and the total microwave on time. After the incubation process, the sterilization effects could be confirmed as shown in Fig. 3. From these results, we draw the conclusion that the least instantaneous microwave power and the total microwave on time needed for pulse-modulated microwave plasma sterilization are roughly determined from the total microwave energy of 200 kJ.

Figure 4 shows the results of colony count measurements for CW and pulsed microwave sterilization. We noted here that microwave pulses having instantaneous power of 2.0-2.2 kW with on-duration of 10 μs could sterilize the spores with almost the same sterilization characteristic as in the CW

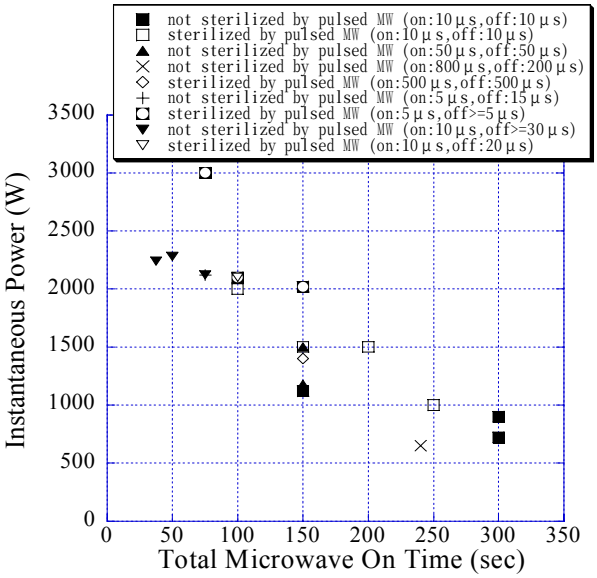

Fig. 3 Experimental results of sterilization between instantaneous microwave power and total microwave on-time.

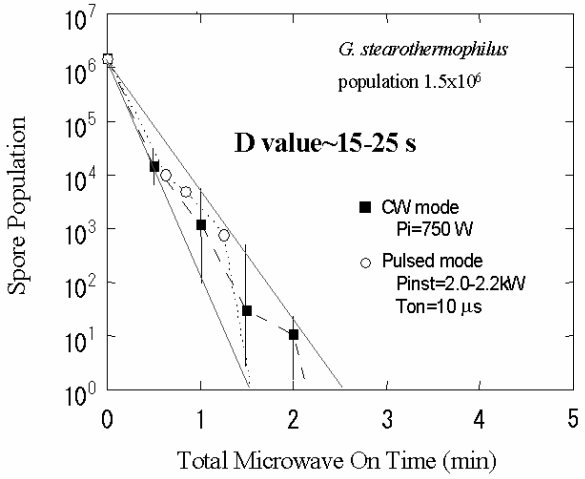

Fig. 4 Comparison of survival curves of CW and pulsed microwave plasma sterilization.

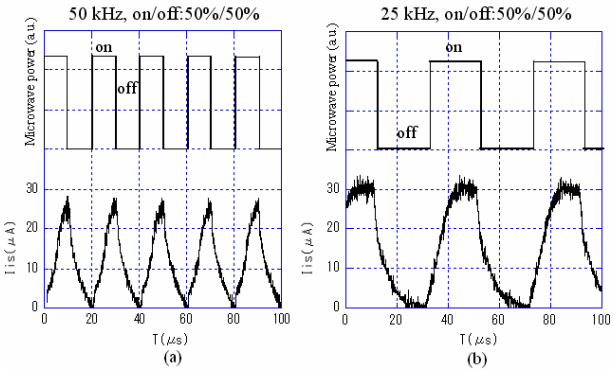

Fig. 5 Probe signals of pulse-modulated oxygen plasmas: (a)modulation frequency =50 kHz, (b)modulation frequency =25 kHz

operation, with the D-values of 15~25 s.

To study lifetime of oxygen plasmas, we applied diagnostic method by a Langmuir single-probe. The probe was inserted into chamber 55 mm below the quartz window. Negative bias voltage was 30 V, and the resistance in the probe circuit was 1 kΩ.

Under the conditions that gas pressure was 60 mTorr and duty ratio was 50%, we obtained two waveforms of ion saturation current produced when pulsed modulation frequency was 50 kHz and 25 kHz, respectively as shown in Fig. 5. From the waveforms of ion saturation currents, we found that plasma density saturated about 10 μs after the microwave onset. After the turn-off of the microwave pulses, ion saturation currents decayed with different time constants, that is, they initially decayed with a time constant of about 10 μs and then decayed with a longer time constant of about 30 μs. Thus, there existed plasma particles during 30 μs at least. It is expected that the oxygen with metastable states, such as $O^*(^1D)$ or $O_2^*(^1\Delta_g)$, can play an important role in the sterilization process.

Next, we showed the experimental results of the oxygen plasma sterilization of 3.0×10^6 *Geobacillus stearothermophilus* spores while substrate stage was about 23 cm below the quartz window, discharge pressure was at about 120~130 mTorr, O_2 gas flow rate was 200 sccm.

In Fig. 3, we noted a special case of two different on-duration periods with instantaneous microwave power of 1.5 kW and total microwave on time of 150 s had different sterilization results. These results might be explained by considering the effect of oxygen radicals. To study the characteristics of oxygen plasma sterilization using pulse-modulated microwave, we fixed instantaneous power at 1.5 kW and on/off duty ratio as 50%, then changed on-duration per modulation signal when total microwave on time kept same. Figure 6 showed the latest sterilization results by using pulse-modulated microwave oxygen plasma. From the figure, we found all the BI samples were sterilized by pulse-modulated oxygen plasma when the total microwave on time was longer than 150 s. Based on the thermo-label measurements, it was shown that the surface temperature of Petri dish during the 300 s processing period (150-s total microwave on time plus 150-s total microwave off time) was always less than 70°C. While the total microwave on time was shorter than 150 s, we found the longer on-duration per pulse was required,for the shorter total microwave on-time. Related with Fig. 5, the reason might be when total microwave on time is fixed, total saturation period of ion saturation current increases with on-duration per pulse. During longer saturation period of ion saturation current, more efficient oxygen radicals, which are considered as key factor in oxygen plasma sterilization, can be generated.

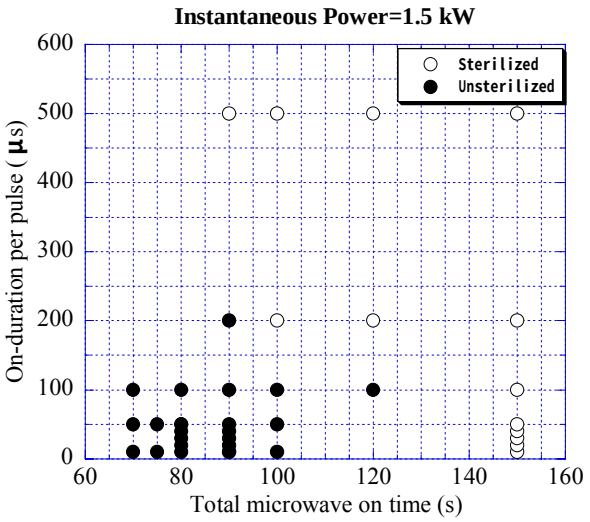

Fig. 6 Experimental results of sterilization between on-duration per pulse and total microwave on time.

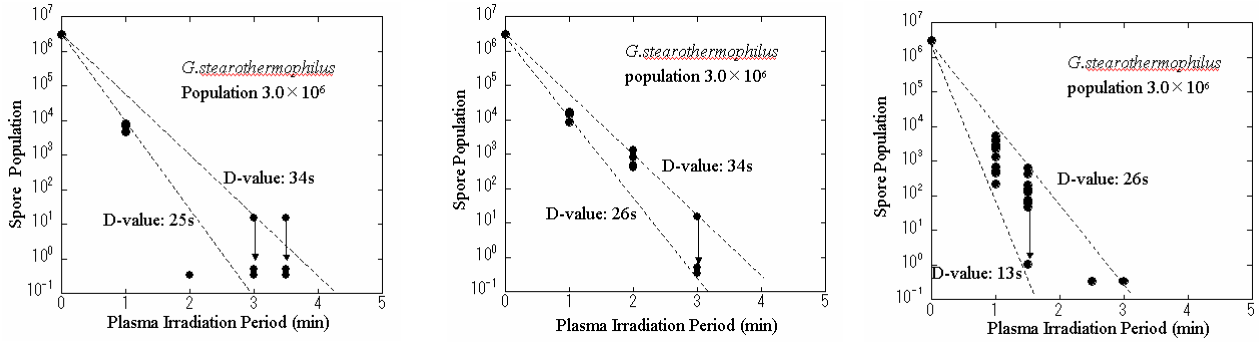
Since discharge pressure and position of placed BI samples were changed, we tested O_2 discharge CW SWPs using *Geobacillus stearothermophilus* spores again. The sterilization effect could be confirmed for samples irradiated by oxygen plasma for 150 s or longer while CW power was 750 W.

At last, we showed effects of nitrogen gas addition in sterilization experiments using CW SWP. We utilized 3.0×10^6 *Geobacillus stearothermophilus* spores while substrate stage was about 23 cm below the quartz window, discharge pressure was at about 60~90 mTorr, total gas flow rate was 100 sccm. We fixed microwave power at 750 W.



(a) pure O_2 plasma (b) pure N_2 plasma (c) N_2-O_2 plasma

Fig. 7 Survival curves for *G.. stearothermophilus* spores irradiated by 2.45 GHz surface-wave plasma.

The survival curves measured with the colony count method were shown in Fig. 7. Here, we defined the D-value as the time taken to decrease the number of spores by one order. From Fig. 7(a), we found that D-value was roughly 25~34 s and the shortest sterilization period were 3.5 min (210 s) for 100 sccm O_2 plasma. From Fig. 7(b), D-value was roughly 26~34 s and the shortest sterilization period was 3 min (180 s) for 100 sccm N_2 plasma. From Fig. 7(c), D-value was roughly 13~26 s and the shortest sterilization period was 3 min (180 s) for 20 sccm O_2 and 80 sccm N_2 gas mixture discharge plasma. The gas mixture consisting of 20% O_2 and 80% N_2 was similar to the compositions of air. Therefore, sterilization using air discharge SWPs is expected.

To study the shape and size of the spores before and after irradiation by different gas species discharge plasmas, we carried out measurements using a scanning electron microscope (SEM). It was shown that the length and width of the spores dramatically decreased after only a 4 min oxygen plasma irradiation. The ellipsoidal spores shrank to jellybean-like slender shapes.[9] This could be attributed to chemical etching by the oxygen radicals generated in the oxygen plasma. However, in the case of the nitrogen plasma, the spore shapes were almost identical to the original ones, which differed from the findings with oxygen plasma or oxygen radical irradiation. This result could possibly be caused by UV photons emitted by the nitrogen plasma. In the case of 20 sccm O_2 and 80 sccm N_2 gas mixture discharge plasma, the width of the spores seemed a little broader than the one in the case of pure oxygen plasma. We deduced the higher percent of O_2 in discharge gas was set, the slimmer shape of spores could be obtained.

4. Conclusion

In the present paper, we reported the effects of low-temperature plasma sterilization using CW and pulse-modulated surface-wave excited oxygen plasmas. When discharge pressure was at about 30~70 mTorr, O_2 gas flow rate was 200 sccm, BI samples with $1.5\text{x}10^6$ *Geobacillus stearothermophilus* spores were completely killed by being irradiated for 50 s or longer while CW power was 1 kW and being irradiated for 40 s while CW power was 1.5 kW. When discharge pressure was at about 120~130 mTorr, O_2 gas flow rate was 200 sccm, all the BI samples with $3.0\text{x}10^6$ *Geobacillus stearothermophilus* spores were sterilized by pulse-modulated oxygen plasma when the total microwave on time was longer than 150 s and instantaneous power was kept at 1.5 kW.

We also reported the effects of low-temperature plasma sterilization using CW nitrogen plasma. When discharge pressure was at about 60~90 mTorr, total gas flow rate was 100 sccm, microwave power was kept at 750 W, BI samples with $3.0\text{x}10^6$ *Geobacillus stearothermophilus* spores were sterilized after 3 min N_2 or N_2-O_2 plasma irradiation.

Abstract

Synthesis of carbon nanotubes(CNTs) using microwave plasma CVD with catalytic nanoclusters has been studied. Nickel-carbon composite nanoclusters were fabricated using the dc arc discharge using a pair of graphite-Ni composite electrodes in a vacuum chamber filled with He and methane mixture gas at 50~100 Torr. Large-area surface-wave plasma (SWP) device with a diameter of 400 mm was used for growth of CNTs on the Ni-C clusters evaporated-Si substrate. Surface morphology has been studied using the field emission type scanning electron microscope (FE-SEM) and transmission electron microscope (TEM). It was found that the diameters of multi-walled CNTs were reduced from 50~100 nm in the case of Ni-evaporated Si to roughly 20 nm or less by using the present technique.

1. Introduction

Recently, field emission performances of carbon nanotubes(CNTs) have been extensively studied aiming at developing the cold electron emitter materials for the next generation flat panel display. Compared with other materials, such as the diamond film or diamond-like carbon films, CNTs have great advantages of lower emission electric fields and larger emission currents[1]. In general, the closely grown CNTs have a poor emission performance because of the field screening effect [2,3]. In order to achieve good emission performance, it is necessary to grow CNTs having a high aspect ratio, i.e., a ratio of CNT length to its diameter. Moreover, CNTs should be grown at a spatially regulated position.

So far, CNTs have been fabricated using various types of production techniques. For instance, DC arc discharge has been originally studied for production of single-walled CNTs[4,5]. In this technique, the CNTs have grown on the top of cathode electrode directly. For the practical use of CNTs, they have been purified as separated CNT wires and used by painting and holding on the substrate. Thus it might be awkward to use them as spatially regulated field emitters, as described above. On the other hand, the thermal CVD or plasma CVD techniques have been widely studied to grow CNTs on the catalyst deposited on the substrate beforehand. In the thermal CVD, it is often reported that single-walled CNTs could be produced. However, when the deposition area is too small, CNTs lay down due to Van der Waar's force. Thus, it is important develop the technique to grow single-walled CNTs vertically on the small catalyst surface in thermal CVD method. In the plasma CVD technique, it is reported that multi-walled CNTs were often produced. Nevertheless, advantages of plasma CVD are to be capable of growing vertically aligned CNTs by applying bias voltage between the substrate and plasma and of growing them uniformly over the large-area substrate.

In this study, we propose to grow CNTs with narrower diameter using the catalytic Ni-C nanoclusters prepared with the DC arc discharge in He and methane mixture gas.

2. Experimental Set-up

A schematic drawing of the experimental setup is shown in Fig. 1.[6] Surface-wave plasma (SWP) was produced in a 400 mm-diameter, cylindrical vacuum chamber by introducing a 2.45 GHz microwave through a quartz window via slot antennas[7,8]. A heater stage was installed about 15 cm below the quartz window of the microwave launcher inside the vacuum chamber. Growth of CNTs was carried out on the <100> n-type silicon wafer substrates placed on the substrate stage installed inside the chamber. Effective area of the substrate stage was 200 mm in diameter, where the substrate temperature could be controlled up to 850 °C by external heater and water-cooling system. Silicon substrates were cleaned beforehand by acetone in an ultrasonic bath and then Ni-C clusters were deposited on them using vacuum evaporation technique.

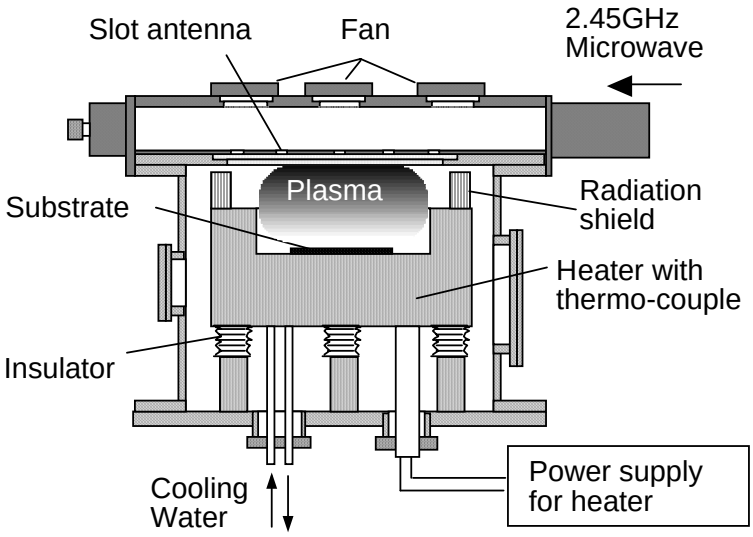

Fig. 1 Schematic drawing of the experimental setup for surface-wave plasma CVD.[6]

The SWP was sustained by the microwave power of 700W at gas pressure of 10 Torr for discharge duration of 10 min. The Ni-C nanoclusters were prepared using dc arc discharge method, as shown in Fig. 2. Stainless-steel vacuum chamber with 200 mm in diameter[9] was evacuated down to mTorr by rotary pump and then filled with He gas only or He and methane mixture gas at about 50~200 Torr. One of two graphite electrodes was made by molding Ni powders with graphite cements. By flowing a high current of 100 ~200 A between two electrodes, various Ni-C clusters were produced. Soot produced in arc discharge was collected with a cover and they were mixed with ethyl alcohol in the ultrasonic bath to select small size of clusters out from the clear supernatant liquid. Filtered soot including small size Ni-C clusters was painted and annealed on silicon substrate before CNT growth procedure. The CNT growth was carried out with two different plasma discharges; that is, a mixture gas of H_2, Ar and CH_4 at the gas flow rates of 100sccm, 50sccm and 20sccm, and a mixture gas of N_2 and CH_4 gas at 150sccm and 20sccm. During plasma discharge, substrate stage was kept at temperature of 700~750°C. For comparison, we also carried out the CNT growth on Ni evaporated silicon substrate under the same plasma discharge conditions.

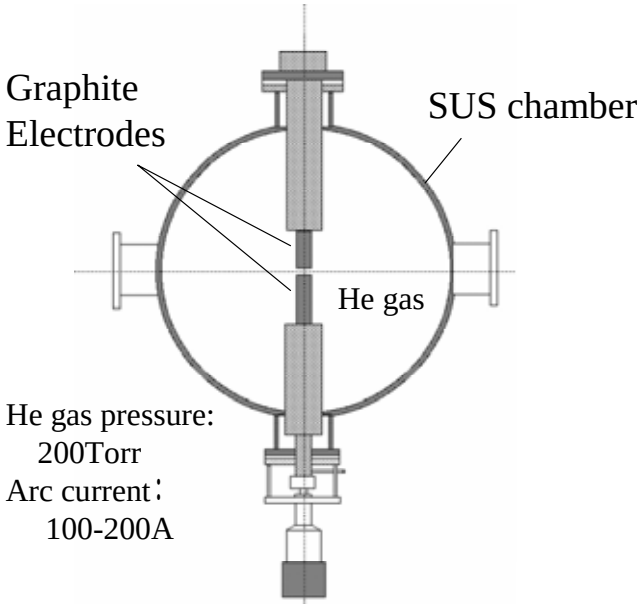

Fig. 2 Schematic drawing of experimental setup for production of Ni-C nanoclusters.

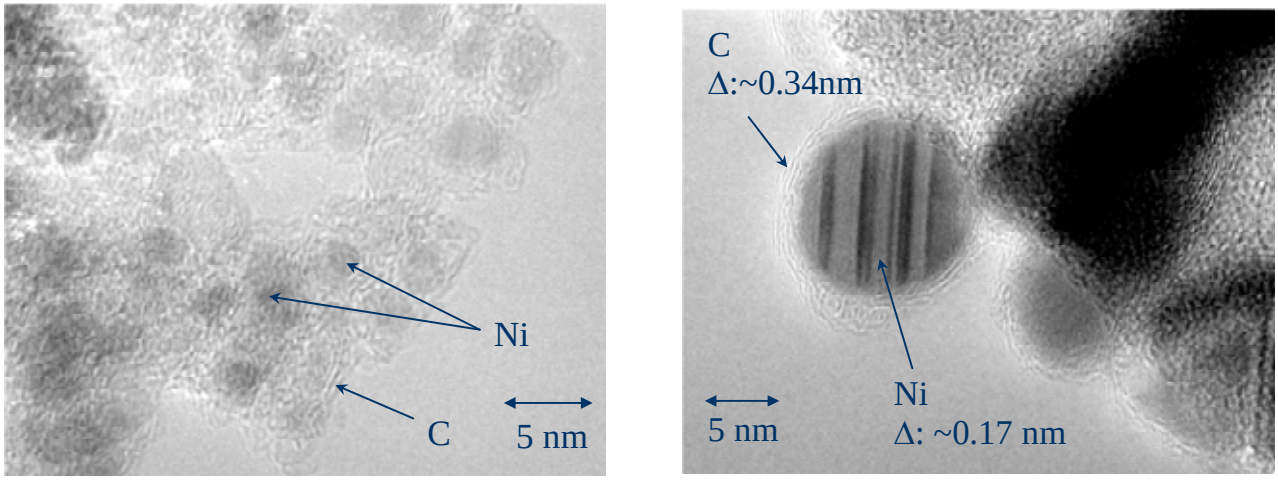
3. Results and discussion

The structures of Ni-C clusters were analyzed with transmission electron microscope (TEM). Figure 3 shows typical TEM images of Ni-C composite clusters. It is seen that the clusters consisted of nano-sized Ni spherical grains and carbon layers surrounding each Ni grain, as shown in Fig. 3(a) and 3(b). Figure 3(a) shows TEM image of grape-like structures of Ni-C clusters, where sizes of Ni grains are typically 5 nm or less. Figure 3(b) shows the image of an isolated cluster with a slightly larger diameter of 10 nm. It shows the lamellar crystal structure of Ni atoms with an interlayer distance Δ of 0.17 nm are surrounded by several carbon layers with an interlayer distance Δ of 0.34 nm.



(a) (b)

Fig. 3 TEM images of Ni-C composite clusters; (a) grape-like structure of clusters and (b) isolated structure of N-C cluster.

To discuss the difference between the CNTs in the cases of conventional Ni evaporated method and the present technique, we analyzed them using the field-emission type of scanning electron microscope(FE-SEM) Figure 4 shows multi-walled CNTs with diameter of typically 50~100 nm randomly grown on Ni evaporated Si substrate. We tested two discharge conditions, that is, one is the case of H_2, Ar and CH_4 mixture gas, and the other is that of N_2 and CH_4 mixture gas. In the former case, Ar was added to obtain the more stable discharge in surface-wave plasma. Here, total gas flow rates were kept to be 170 sccm for both the cases.

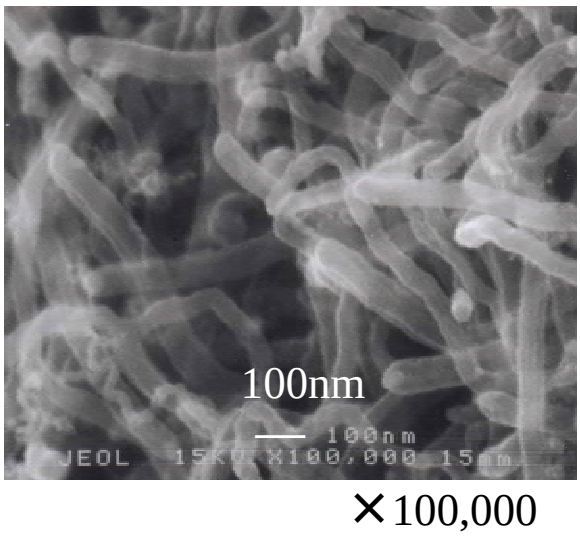


Fig. 4 FE-SEM image of CNTs grown on the Si substrate, where Ni film was used as catalyst and deposited beforehand.[6]

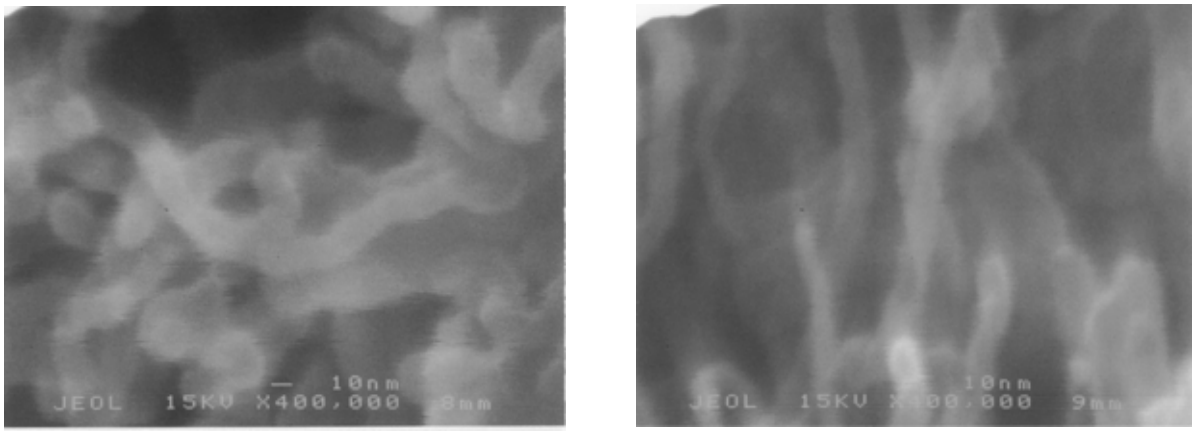
Figure 5(a) shows the FE-SEM of the CNT samples deposited on the Ni-C clusters deposited Si substrate with a mixture gas of H_2, Ar and CH_4 at the gas flow rates of 100sccm, 50sccm and 20sccm.



(a) x 400,000 (b) x 400,000

Fig. 5 FE-SEM images of CNTs deposited by SWP with (a)H_2, Ar and CH_4 mixture gas and (b) N_2 and CH_4 mixture gas, when Ni-C clusters were used as catalyst.

Although a various sizes of CNTs were observed, narrower ones had diameter of 10~20 nm. Figure 5(b) shows the FE-SEM of the CNT samples when a mixture gas of N_2 and CH_4 were used at the gas flow rates of 150sccm, and 20sccm. Typical sizes of CNTs were almost the same as those in Fig. 5(a).

To investigate fine structure of CNTs, we have carried out the TEM analysis of CNTs. Figure 6 shows one of typical images of TEM analysis of multi-walled CNTs in the case of N_2 and CH_4 mixture gas. It clearly shows the multi-walled CNT structure having 26 carbon layers surrounding a catalytic Ni cluster.

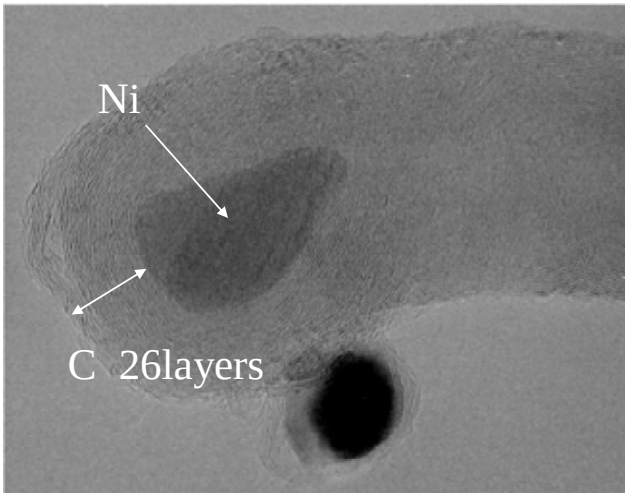


Fig. 6 TEM image of CNT deposited by SWP with N_2 and CH_4 mixture gas.

4. Conclusion

Synthesis of CNTs using microwave plasma CVD with catalytic nanoclusters has been studied. Catalytic nanoclusters were fabricated using the dc arc discharge using a pair of graphite-Ni composite electrodes in a vacuum chamber filled with He gas at 50~100 Torr. Nanoclusters with a number of Ni-C composites deposited on the cover in the vacuum chamber were used as the catalyst for the carbon nanotube growth. Large-area surface-wave plasma (SWP) device with a diameter of 400 mm was used for growth of CNTs on Ni-C cluster evaporated Si substrate. The surface morphology has been studied using the field emission type scanning electron microscopy (FE-SEM) and transmission electron microscope (TEM). It was found that the diameters of CNTs was reduced from 50~100 nm to roughly 20 nm or less by using the present technique.

Abstract

We have developed plasma CVD method using low pressure dielectric barrier discharge in a micro channel, such as a narrow capillary or a channel graved in a Pyrex chip. And we have investigated the possibility of uniform deposition on the inner surface by using our plasma technique and obtained successful results. In this work, we would like to describe the generation of a packed bed plasma as another type of microplasma, which is discharged in a narrow capillary filled with small particles, and to report the qualitative characteristics of the plasma CVD on the inner surface of the packed bed capillary.

Keywords

microplasma, dielectric barrier discharge, chemical vapor deposition, particle, packed bed

1. Introduction

Various microplasmas have been developed and many basic and application studies have been done since the concept of microplasma was proposed. In particular, application studies of microplasmas in the fields of micro total analysis system (μ-TAS) and microelectromechanical system (MEMS) have been developed extensively. Although various studies relate to the inner wall modification of a micro channel utilizing a microplasma [1,2], there have been relatively few studies that tried to investigate plasma chemical vapor deposition (P-CVD) on the inner surface of a sealed micro channel without using a lithography technique.

We have developed P-CVD method using low pressure dielectric barrier discharges in a micro channel, such as a narrow capillary or a channel graved in a Pyrex chip with electrodes attached to the outer surface. And we have investigated the possibility of uniform deposition of platinum thin film on the inner surface by using our plasma technique and obtained successful results [3]. Our electrode arrangement has the important advantages that the length of the gap is not limited to the order of a micron, and that it can be adjusted. Since the electrode arrangement makes it capable to adjust the gap to a few centimeters, it is possible to attain a low spark voltage even at low pressure of the order of a few torrs, according to Paschen's law. Low pressure CVD processes have the advantages of making the adhesion of films to a wall surface possible, and of enabling precursors to be introduced effectively into a CVD reactor even if, such as is the case of organometallic compounds, which they have a low vapor pressure. In addition, it is expected that the microplasma with the electrode arrangement can be applied to P-CVD on the inner surface of channels that have complex shapes, because the plasma can be generated without inserting an electrode.

In this paper, after summary of our previous study we would like to describe the generation of a packed bed plasma as another type of microplasma, which is generated in a narrow capillary filled with small particles, and to report the qualitative characteristics of the P-CVD on the inner surface of the packed bed capillary.

2. Experimental

In our previous work, the micro capillary plasma was generated by dielectric barrier discharge between

cylindrical graphite electrodes (ϕ4mm) pierced by a capillary as shown in Fig. 1. A fused silica capillary of 450μm o.d., 320μm i.d., and 150mm length was used. The precursor, platinum bisacetylacetonate $Pt(C_5H_7O_2)_2$ (Aldrich, 97%), was used. The capillary temperature and precursor temperature were fixed to 200 °C and 170 °C, respectively. For details of the previous work the reader should refer to [3].

Fig 2 shows the schematic diagram of the P-CVD apparatus in this work. The packed bed plasma was generated with a similar electrodes arrangement pierced by a capillary to the previous work. The glass capillary of 1.5mm o.d., 1.0mm i.d., and 140mm length was packed with glass beads (300μm ~ 500μm) or silica gel particles (200 μm ~ 500 μm). The flow rate of carrier gas was controlled with a mass flow controller (Model 3200SR, KOFLOC). Helium and oxygen mixture was used as the carrier gas. The pressure in a capillary was measured at the upstream and downstream point of the capillary by pressure gauges and the average value was defined as the system pressure. The precursor of palladium hexafluoroacetylacetonate ($Pd(C_5HF_6O_2)_2$) was set in the heated tube located at the upstream of the capillary, vaporized, and introduced into the capillary. Carrier gas and the precursor vapor flowed through the capillary in the direction of the grounded upstream electrode towards the downstream electrode where high voltage was applied. The temperature of the heated tube filled with the precursor was fixed to room temperature (22~27 °C), and the atmosphere temperature around the capillary was measured by a thermocouple. A high voltage power amplifier (Model 20/20C, Trek) was used as the power supply. Plasma current and input power were measured by a Lissajous figure on a digital oscilloscope.

3. Results and Discussion

3.1 Plasma CVD in a micro capillary

This section discribes the outline of our previous study.

Fig. 4(a) shows the profiles of the platinum amount deposited on inner surface of a fused silica capillary by the P-CVD method. These results were obtained by varying the frequency. An increase in frequency

corresponds to an increase in input power. The times required for film deposition completion are 30sec (2kHz), 150 sec (5kHz), and 375 sec (10kHz), respectively. The upstream and downstream electrode positions are located between –12~–8 mm and 8~12 mm, respectively. Note that the scale of the longitudinal axis is logarithmic. The results indicate that as input power is increased, the time required for film deposition completion is longer, and the deposited amount is larger.

Fig. 4(b) shows the profiles, which indicate the progression in time for similar experimental conditions. The figure shows that little platinum is deposited around the point of the downstream electrode at 50 sec and 120sec. In these conditions, the decomposition of the precursor and film deposition mostly takes place at the upstream range in the plasma and the precursor is no longer transported to the range around the downstream electrode. In addition, judging from little deposition in the range of –20~–4 mm after 50 sec, it is clear that the plasma discharge region is shortened as film deposition proceeds. Therefore, it seems reasonable to conclude that film deposition starts locally at the inner surface attached with an upstream electrode, and is completed at a downstream electrode.

Hence, we can suggest the model as shown in Fig. 5. When the plasma discharge in a capillary is maintained between a downstream electrode and the end of a deposited film, it is reduced in length automatically as film deposition proceeds, as shown in Fig. 5(a). This phenomenon works effectively to create uniform films in the P-CVD process even if the concentration gradient of the precursor in the microchannel is steep. After completion of film deposition, surface discharge at the outer surface around electrodes is generated as shown in Fig. 5(b).

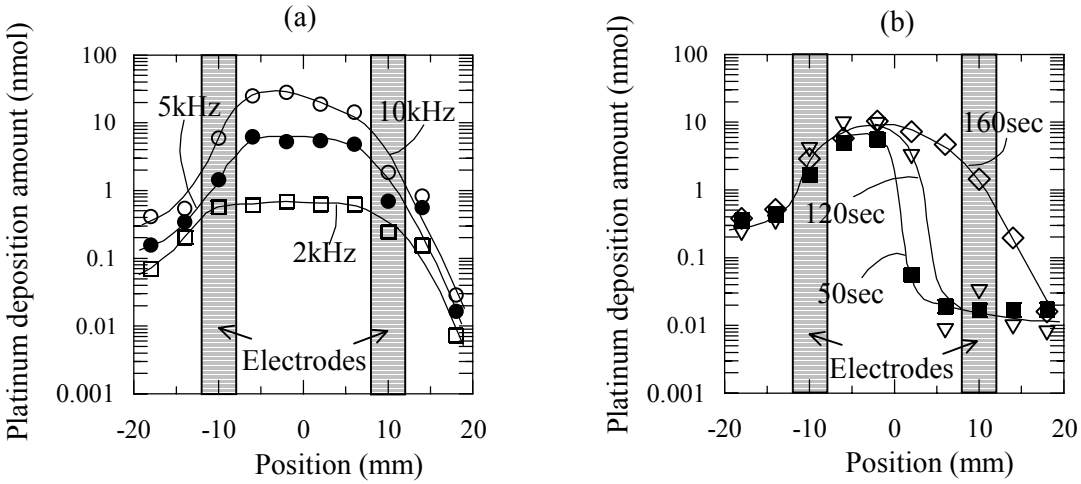

Fig. 4 Profiles of the platinum amount deposited on inner surface of a fused silica capillary varying plasma frequency (a) and deposition time (b).

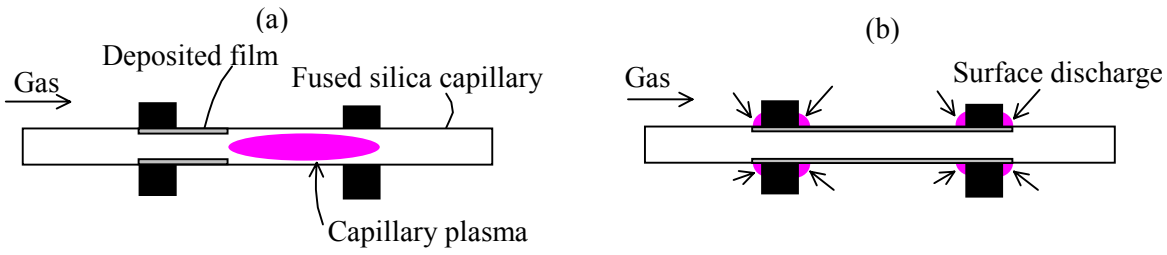

Fig. 5 Schematic illustrations of the discharges during deposition (a) and after deposition (b).

3.2 Plasma generation in a packed bed capillary

Microplasma in a capillary packed with glass beads or silica gel particles can be generated successfully between electrodes as shown in Fig. 3. The discharge space size is limitted to the order of a micron by the particles and the capillary wall. Igniting the plasma in a capillary packed with particles requires higher spark voltage than in a capillary without them. Also the pressure, which provides the Paschen's minimum spark voltage, is higher. For example, the helium plasma in a capillary packed with silica gel particles can be generated above $4kV_p$ and $7kV_p$ with the electrode gap of 8mm and 12mm, respectively under the optimum pressure of about 40 torr, while in a capillary without them about $2kV_p$ with the approximate gap under a few torrs. Considering that the product of pressure (torr) and gap (cm) which provides the minimum spark voltage is 2.5 torr·cm in helium atmosphere according to Paschen's law, the gap length would be about 600 μm. We can recognize from these facts that in a packed bed plasma reactor, the practical gap length for Paschen's law should be the space size surounded by particles, while the electrodes gap decides the electric field strength. So, for a longer capillary P-CVD, plural electrodes are effective since it is possible to adjust the electrode gap to a shorter one, igniting plasma at a lower voltage.

3.3 Plasma CVD in a packed bed capillary

Fig.6 shows photographs of the plural electrodes arrangement and of the capillary with the deposited thin film including palladium without packing paticles. This film was deposited by P-CVD for 150 minutes under the condition of 3 torr and low freaquency (800 Hz) after 90 minutes P-CVD under the condition of 6 torr and high frequency (5kHz). Gas composition, applied peak voltage and capillary temperature were fixed to $He/O_2=1/1$, $V_p=1.5kV_p$, and room temperature, respectively. It is observed that the positions attached electrodes have deep brown color because of precuesor decomposition promoted in the cathod sheath region near the electrodes. Also it is found that the film color under the high freaquency condition is deeper than under the low frequency one and the color shades into transparent brown gradually downstream as shown in Fig. 6. Therefore, it is clear that the film deposited under the low freaquency condition is thinner than under the high freaquency one and that the film thickness has gradient downstream. We can conclude that plasma frequency under fixed voltage condition is an important parameter, which decides the film thickeness and gradient.

The plasma is not extinguished even when the film is deposited all over between the electrodes. Why this result is different from our previous work, which shows that the end of the deposited film can work as an

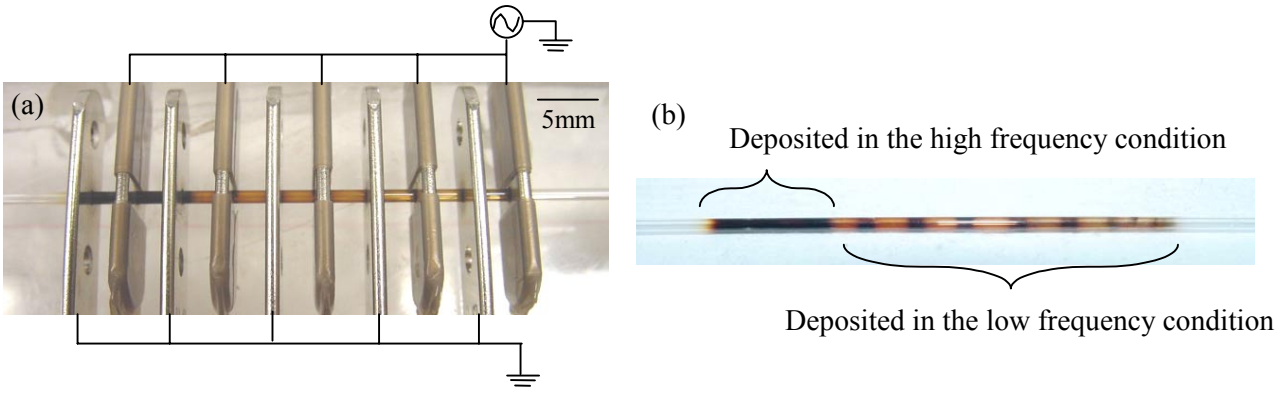

Fig. 6 Photographs of the plural electrodes arrangement (a) and of the capillary with a deposited thin film including palladium without packing paticles (b).

electrode to shorten the plasma region automatically, is that the electrical conductivity of deposited film in this work is different from previous one since low substrate temperature decreases film conductivity in P-CVD [4].

Fig. 7 shows the photograph of the capillary packed with glass beads and the deposited thin film including palladium at the substrate temperature of 130 °C. The film is black metallic and must have high electric conductivity because of the high substrate temperature. In fact the plasma is shortened as deposition proceeds. However, the deposited film is not uniform contrary to our previous results. The cause of the difference has not yet been found. The film is deposited also on the surfaces of glass beads in the capillary.

In the case of the capillary packed with silica gel particles, the precursor is not transported to the plasma region, being adsorbed to the silica gel particle surface in the range of the capillary entrance as shown in Fig. 8. In the case that the precursor is adsorbed on silica gel particles before packing in the capillary subsequence plasma treatment decomposes the adsorbed precursor to change the silica gel color from yellow to black. However, generating the plasma in a capillary packed with silica gel adsorbed by the precursor requires higher applied voltage than with not adsorbed.

Fig. 7 The photograph of the capillary packed with glass beads and the deposited thin film including palladium at the substrate temperature of 130 °C.

Fig. 8 Silica gel particles adsorbed by $Pd(hfac)_2$.

Conclusion

In this work, we described the generation of a packed bed plasma as another type of microplasma, which was generated in a narrow capillary filled with small particles and reported the qualitative characteristics of the P-CVD in the packed bed capillary. We conclude the following:

(1) Microplasma in a capillary packed with glass beads or silica gel particles can be generated successfully. And the generating condition is much different from the one without packing particles.
(2) For a longer capillary P-CVD, plural electrodes are effective.
(3) In the case of packed glass beads, P-CVD is done successfully although the film uniformity has a problem. The P-CVD process behavior is dependence on some parameters such as plasma frequency and substrate temperature. Quantitative research of the dependency is a further issue.
(4) In silica gel particles, the precursor transport is blocked by adsorption to the surface of them.

Surface analysis of plasma induced reactions on organic model substrates

M. Giza, J. Raacke, G. Grundmeier

Max-Planck-Institute for Iron Research, Duesseldorf, Germany
E-mail: grundmeier@mpie.de

Abstract

The influence of reactive species from an oxygen plasma on an organic model surface has been investigated by the use of a plasma cell which was developed for in-situ FTIR spectroscopy as well as in-situ Kelvin probe measurements of plasma modified surfaces. The presented application of this new in-situ analytical device shows that the monolayer sensitive infrared absorption spectroscopy in combination with the measurement of work function is suitable to provide new insights in plasma induced surface modifications.

Keywords: Fourier transform infrared spectroscopy, Kelvin probe, oxygen plasma, self-assembly monolayer, in-situ diagnostic.

1. Introduction

Self-assembly films of organic molecules have been employed as model systems for the investigation of surface functionalization of polymers by cold plasmas. In this case the chemical composition, degradation and disorientation of molecular chains, orientation of polar groups which are introduced in non-polar monolayer are of interest [1].
Ex-situ investigations of plasma modified organic surfaces are not able to eliminate the undefined influence of the environment, which contains species such as organic molecules, carbon dioxide, water and oxygen. These species lead to a change in the surface chemistry and ex-situ analytical methods are not really showing the surface properties directly after the plasma modification. This has led to some in-situ investigations of plasma processes [2, 3]
The content of the here presented work is the application of a plasma cell which is combined with in-situ infrared reflection absorption spectroscopy (IRRAS) and in-situ Kelvin probe (KP). The sample under investigation is a self-assembled monolayer (SAM) of octadecylmercaptane which was functionalized in an oxygen plasma. The influence of the oxidation to the surface chemistry and work function is reported.

2. Experimental details

The experimental setup as already described in [3] is shown in Fig. 1. The sample holder can be moved by a stepper motor with defined velocities through the plasma zone to the diagnostic position. A set of electrodes allows the generation of low pressure remote plasmas by applying an alternating, pulsable, and adjustable voltage (typically 30.7 kHz). The plasma treated surface can be analyzed by Fourier transform infrared spectroscopy (Biorad Excalibur 3000) and a Kelvin probe.
Flame annealed gold surfaces were used for the here presented fundamental studies, which consist of monoatomically flat terraces with Au(111) orientation. These surfaces can then be covered with self-assembled organo thiol monolayers (octadecylmercaptane) which were adsorbed from a $2x10^{-3}$ M ethanol solution.

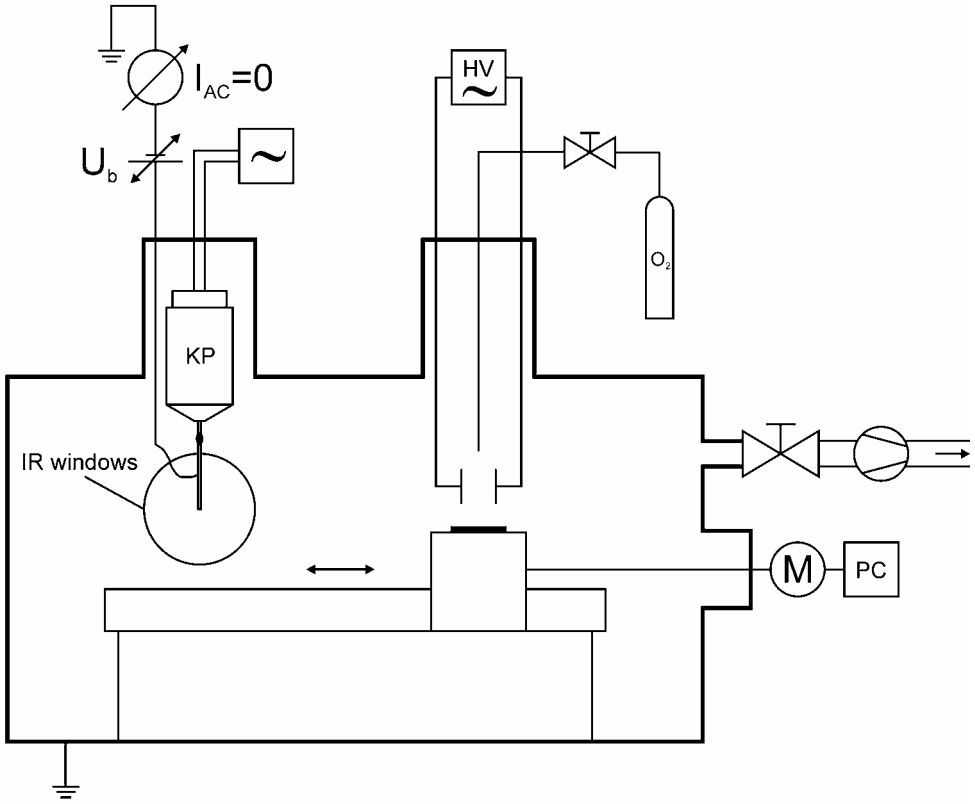

Fig. 1: Experimental set-up of the combination of in-situ FT-IRRAS and KP with a plasma cell [3]

3. Results and discussion

A self-assembled monolayer of octadecylmercaptane was treated in an oxygen plasma and the changes of the surface chemistry and potential were measured in-situ by FT-IRRAS and the Kelvin Probe.
Fig. 2 shows infrared absorption spectra after the modification in each case relative to the untreated state. Subsequently, the surface was exposed to an oxygen plasma (at a pressure of 0.3 mbar) four times for 1 s and for 4 s in a final step. The oxygen plasma treatment leads to an etching of the hydrocarbon chains (2850-2980 cm^{-1}) and to a build up of carbonyl functions (1720 cm^{-1}). The CH_2/CH_3 peak ratio increases after each plasma treatment. This behavior suggests that the etching process starts from the outer surface of the monolayer with the oxidative removal of the CH_3 functions. This assumption could be confirmed by ToF-SIMS measurements of the monolayer before and after exposure to the oxygen plasma. These ex-situ measurements show a significant increase of oxygen amount in the layer after the plasma treatment with nearly constant concentration of sulfur-oxygen compounds.

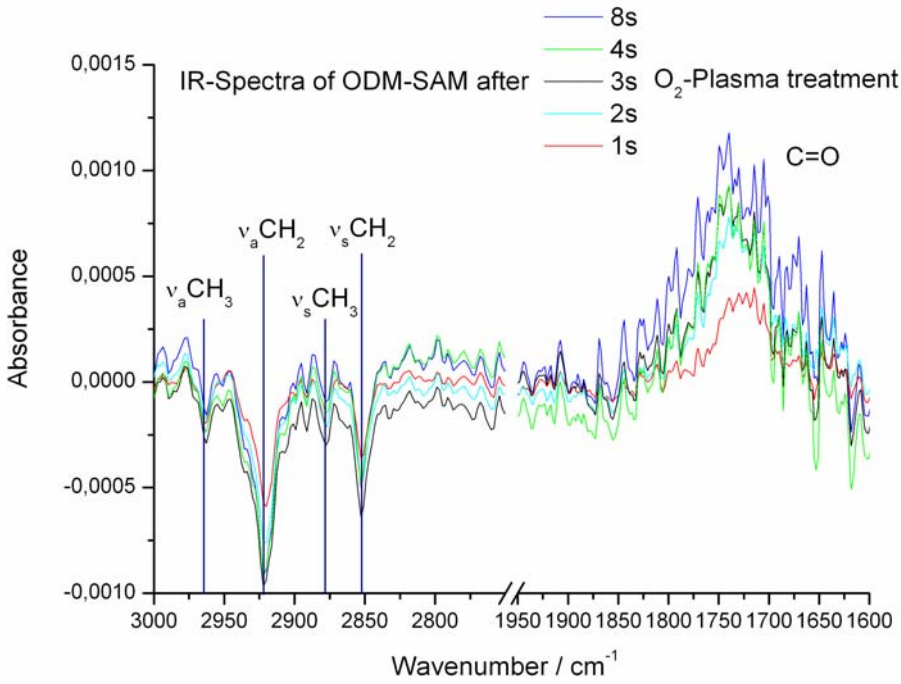

Fig. 2: FT-IRRAS measurements of an oxygen plasma treated octadecylmercaptane self-assembly monolayer

This indicates that no significant oxygen diffusion through the monolayer occurs. The proper description of the mechanism of such plasma-surface interaction requires further in-situ investigations.
Parallel to the etching of the hydrocarbon chains carbonyl functions are generated on top of the surface. The intensity of this carbonyl peak increases with etching time up to a maximum level.

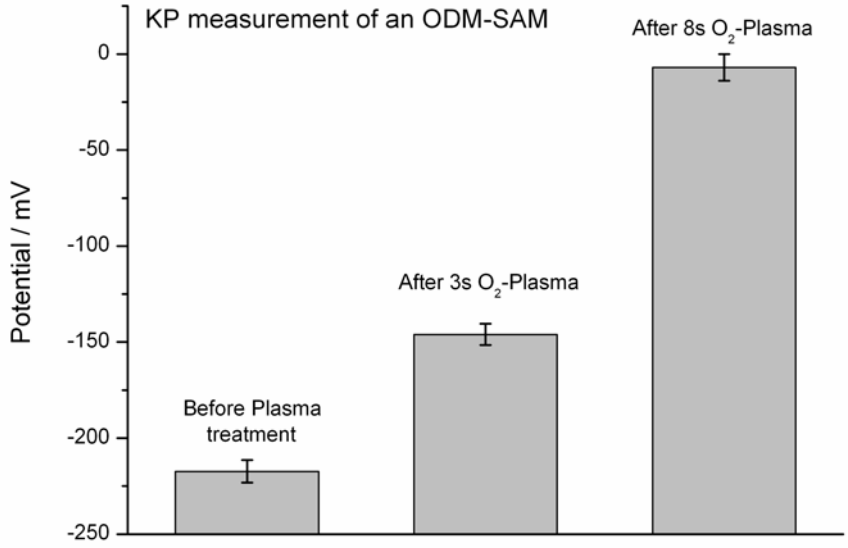

Fig. 3: Influence of oxygen plasma treatment on the surface potential of an octadecylmercaptane self-assembly monolayer

Parallel to the record of infrared spectra, in-situ surface potential measurements have been done. The signals of the Kelvin probe before and after selected plasma treatments are shown in Fig.3. The surface potential increases by about 85 mV after 3 s oxygen plasma and by further 125 mV after additional 5 s of plasma treatment. The reason for the increasing surface potential is a floating dipole layer composed of the carbonyl groups at the ends of the hydrocarbon chains. This can be modeled theoretically by the Helmholtz equation [4]:

$$\Delta V = \frac{\mu \cos\theta}{A\varepsilon\varepsilon_0} \qquad (1)$$

which represents the change of potential in a parallel plate capacitor due to the introduction of a dipole layer. The numerator describes the dipole moment component perpendicular to the surface and the denominator the effective area of each dipole and the dielectric constant of the layer.

4. Conclusions

The experiment described above shows that with in-situ measurements on well defined model surfaces an extremely high sensitivity for changes in the surface chemistry on the subnanometer scale can be achieved. This approach eliminates any undefined influence of the environment. With the described experimental setup a very powerful tool was realized for future in-situ investigations of plasma-surface interactions and for tailoring of well defined surface layers.

Two dimensional time-dependent self-consistent modeling of non-transferred plasma torches

N. Sakthivel and S. Chaturvedi
Institute for Plasma Research, Bhat, Gandhinagar-382 428, INDIA

Abstract
We have performed axisymmetric, 2-D, time-dependent, self-consistent fluid modeling of non-transferred plasma torches. The current density distribution is calculated accounting for the complex geometry and the spatio-temporal variation of resistivity of the partially-ionized plasma. The code can handle a variety of plasmagen gases, including mixtures. Radiation loss is calculated ignoring reabsorption. The plasma parameters obtained at the torch exit have been compared with published experimental and theoretical results.
Keywords: torch, non-transferred, radiation, current density, MHD, plasma

1. Introduction

Plasma torches have been employed as sources of thermal plasmas for a number of applications. Early modeling of plasma torches covered only the plume region, assuming a temperature and velocity profile at the torch exit. During the past decade, a variety of work has been reported including the arc as well as plume regions [1-4]. These studies, by and large, are subject to two major limitations. Firstly, all these studies have assumed some spatial variation of the current density through the plasma, based on experimental studies of free-burning arcs [5]. The current density distribution in the arc region and the anode-cathode potential difference have been calculated numerically based upon the assumed current density profile. This needs prior knowledge of the current density profile for specifying the boundary conditions. In reality, the current density should be determined self-consistently by the spatial distribution of electrical resistivity, the system geometry and the applied voltage. Secondly, most of these studies solve only the steady-state equations. This means that they cannot provide information related to temporal variation in torch parameters, such as fluctuations in electrode voltage, which occur even during normal operation. Furthermore, several applications, such as plasma pyrolysis, require determination of transients due to injection of extra material into a pre-existing torch.

There is, therefore, a pressing need for a time-dependent analysis which determines the current density distribution self-consistently with fluid parameters. We are attempting to satisfy this need, and the present work is the first step in that direction.

In this paper, we report on a two-dimensional (2-D), axisymmetric, time-dependent, self-consistent model of non-transferred plasma torches. The current density distribution has been calculated self-consistently with fluid flow for a given potential at the electrodes. The model can be applied to fairly complex geometries, limited only by the need for axisymmetry. In this paper, we describe the mathematical models used and compare our results with published data.

2. Mathematical model and Assumptions

Fluid flow in this model is determined by a solution of the Navier-Stokes equations for conservation of mass, momentum and energy. This is accomplished using a locally-modified version of the Conchas-Spray code [6]. Conchas-Spray is a time-marching finite-difference code that uses a partially -implicit numerical scheme, which can handle Lagrangian, Eulerian or mixed meshes. The detailed equations can be found in [6].

The spatial variation of the current density inside the torch is calculated by solving the current continuity equation for the given torch geometry and the applied potential, using a modified form of a Finite Element code listed in Ref.[7]. This equation is given by

$$\nabla.(\sigma \nabla\phi) = 0$$

where σ is the space- and time-dependent electrical conductivity, ϕ is the electric potential and the current density $\underline{\mathbf{J}} = -\sigma \nabla\phi$.

The density- and temperature–dependent plasma electrical conductivity has been calculated using the SIGDCS code [8], which takes into account both electron-neutral and Coulomb collisions. Inclusion of both contributions is necessary when dealing with plasmas having a degree of ionization less than unity, when neither type of collisional process may be neglected [8]. The applied potential difference V(t) between the electrodes has been allowed to vary in time according to a proportional feedback algorithm for an assumed current waveform I(t). This is an approximation to the constant-current power supply commonly used in such systems.

The temperature- and density-dependent average charge state and enthalpy of the plasma have been calculated using the IONMIX code [9]. IONMIX calculates the steady state distribution of different charge states for a mixture of elemental species. This calculation is done by assuming detailed balancing, taking into account processes like collisional ionization and recombination, radiative recombination, dielectronic recombination, collisional excitations and deexcitation,and radiative dacay. The rate coefficients are based upon the hydrogenic approximation. The required ionization potentials for different charge states are experimental values taken from the literature [10]. For this work, we have used IONMIX to generate charge state and enthalpy tables for an argon plasma, over the required range of densities and temperatures.

As a first step, the plasma is assumed to be optically thin; hence radiation loss is accounted for by using a volumetric loss rate that neglects re-absorption. The temperature-dependent volumetric radiation loss data for argon have been taken from [1].

Electromagnetic forces have not been taken into account in the present version of the model, but will be added soon. The code can handle a variety of plasmagen gases, including mixtures. To our knowledge, this is the first time-dependent, fully self-consistent MHD model of plasma torches. This will allow us to self-consistently predict the spatio-temporal evolution of plasma and arc parameters for different torch configurations (geometry, dimensions, flow rates, applied potential).

The following major assumptions have been made in the present version of the study:

1. The arc and the fluid flow are assumed to be axisymmetric.
2. The arc is assumed to be in local thermodynamic equilibrium (LTE), so a single temperature prevails for all plasma components.
3. The plasma is assumed to be optically thin – however, we plan to add a radiation transport model.
4. The cathode tip is assumed to be flat.
5. There is no swirl at the inlet and the flow is laminar – the fluid solver is, however, capable of handling swirl as well as turbulent flow.
6. Electromagnetic forces have been ignored – however, this feature is now being added.

3. Computational Domain and Boundary Conditions

The computational domain used in this study is given in Fig.1, which is very similar to the one used in [1] except for slight deviations in the cathode dimensions and the inflow area. The gas is injected at the inlet (line BC). The inflow density is arbitrarily taken to be 1.784×10^{-3} g/cm^3, while the inflow temperature is taken as 1,000 K [2]. The axial velocity (v_r) at the inlet is assumed to have a parabolic profile, given by

$$v_r = v_{max} \ [1.0 - (r/R_{max})^2] \qquad 0 \le r \le R_{max}$$

where r=0 at the rightmost edge of the cathode, v_{max} is the maximum velocity at the inlet and R_{max} is the radial distance between the cathode and anode. The peak inflow velocity has been adjusted to get the required mass inflow rate. The radial velocity (u) is set to zero at the inlet. A no-slip boundary condition has been assumed at

the electrode boundaries. Along EF, we have assumed a free-slip boundary condition. A continuative outflow boundary condition (zero gradients in all quantities) has been assumed along GF. AG is the axis of symmetry.

For the solution of $\phi(r,z)$ and the current density profile J(r,z), appropriate potentials are applied to the cathode and anode surfaces, the difference between these being the inter-electrode voltage V(t).

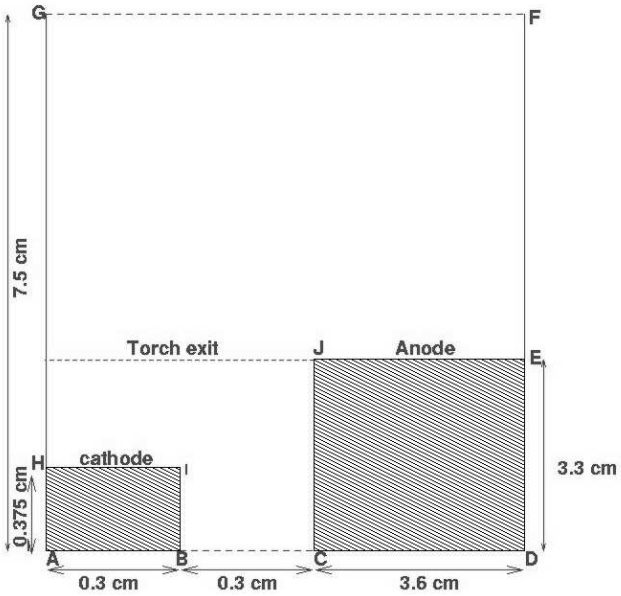

Figure 1. Schematic of computational domain of the plasma torch used in this study (not to scale).

4. Validation and Comparison

a) Preliminary Validation

The validation of the 2-D code has been carried out at each stage of its implementation and development. In the first stage, the code implementation has been checked with a sample problem as given in [6]. This involves an internal combustion engine with a chamfered bowl geometry, with octane spray injection into a cylinder containing air. The mixture is ignited and the progress of the flame front is followed. The results were compared with the results of [6] and a good match obtained. In the second stage, for fluid flow problems, we considered fluid flow in a cylindrical pipe with a constant cross section. Nitrogen gas enters at one end of the cylinder and exits at the other end. The study was carried out for both subsonic and supersonic flow. The inflow velocity profile was taken as parabolic, similar to that obtained in laminar flow through a pipe. This yields maximum velocity near the axis of symmetry and zero velocity at the outer walls, corresponding to a no-slip boundary condition. The maximum velocities chosen for supersonic and subsonic flow were 600 m/sec and 15 m/sec, respectively. In both cases, the inflow gas mass density was taken as 1.09×10^{-3} g/cc and the temperature as 300 K. At the exit, axial gradients of all fluid quantities were assumed to be zero and the radial velocity was also set to zero. In both cases, we obtained good conservation of energy and mass and "reasonable" spatial profiles of fluid quantities.

In the third stage, a typical non-transferred arc torch geometry was examined. This consists of a small flat cathode near the axis of symmetry and a ring anode near the outer wall, very similar to Figure 1. The gas enters in the annular space between the electrodes. In this case too, the inlet velocity profile has been taken as

parabolic, with a maximum velocity of 15 m/sec. In this stage, calculations were performed for two different problems. The first was gas flow without any joule heating. In the second case, we assumed a constant joule heating rate in some cells lying in the arc region. In both cases, mass and energy conservation were found to be acceptable.

The finite element code [7] that has been used for calculating the current density distribution has been validated in both rectangular and cylindrical geometry with electrodes by assuming a constant resistivity and voltage throughout the domain. Conservation of the total current across different axial locations has been checked and found to be correct.

b) Comparison with published results

Since the present work yields the temporal variation of spatial profiles, it is necessary to run the simulation long enough for fluid parameters to reach a quasi-steady-state. It is only at that point that a meaningful comparison can be made with published steady-state results.

In this section, we present our predictions of time-dependent operating conditions in the torch and compare plasma parameters with Westhoff's experimental data and predictions for the B23 case [1]. This involves a system where a hot argon plasma, created within the arc region, flows out of the torch exit into an argon environment. The operating current is 250 A, the mass inflow rate is 0.29 g/sec, and there is no swirl at the inlet. The computational domain used in this study is given in Figure 1. The specified density and temperature at the torch inlet for argon are 1.784×10^{-3} g/cc and 1000 K respectively.

Figure 2 shows the temporal variation of mass outflow rate. The mass outflow rate oscillates between 0.1 – 0.5 g/sec, more-or-less symmetrically around the constant inflow rate. The calculated voltage for this case in [1] is 20.1 volts for an experimentally-measured current of 250 Amps. In our study, we have allowed the voltage to vary according to a feedback control algorithm using only proportional control. The control parameter has been adjusted so as to produce a mean current of 250 Amps. The current and voltage variation are shown in Figures 3 and 4 respectively. The mean current stays around 250 Amps and the mean voltage stays around 14.5 V. However, this voltage does not include the electrode fall. Allowing for a cathode drop of around 4.5 volts, this shows reasonable agreement with the reported value of 20.1 volts [1].

Figure 5 compares our estimates of the radial temperature profile near the torch exit with numerical and experimental data from Westhoff [2]. Westhoff's data were reported at a distance of 1 mm from the torch exit, while we are reporting our results at 0.75 mm from the exit. Over the radial extent of the cathode, and of the anode, our temperatures are consistently lower than those from Westhoff. However, in the intervening gap, our temperatures are higher. Figure 6 shows a comparison of the radial profiles of axial velocity near the torch exit. Since experimental measurements are not available, only simulations results are compared. We find that our predictions are higher by a factor of up to 4.7. We are presently unable to account for this discrepancy.

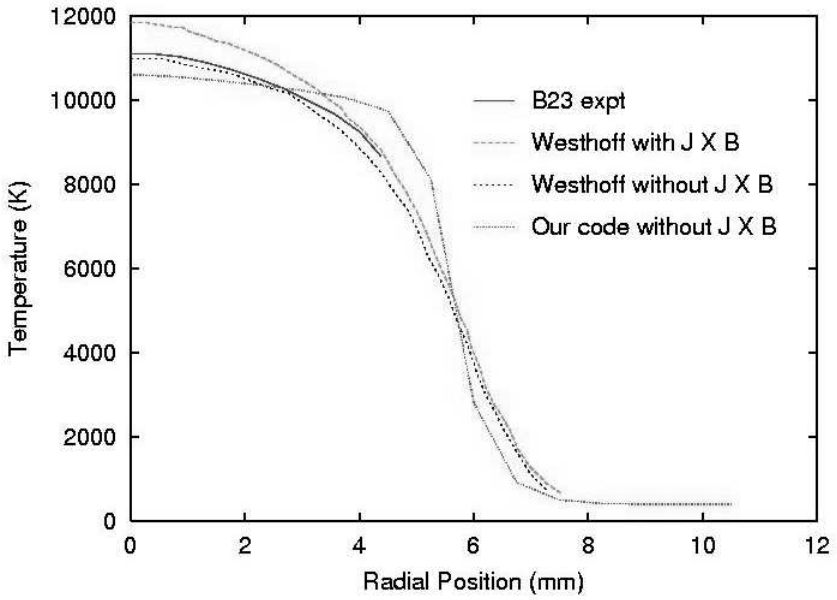

Figure 5: Comparison of temperature profiles in the radial direction near torch exit

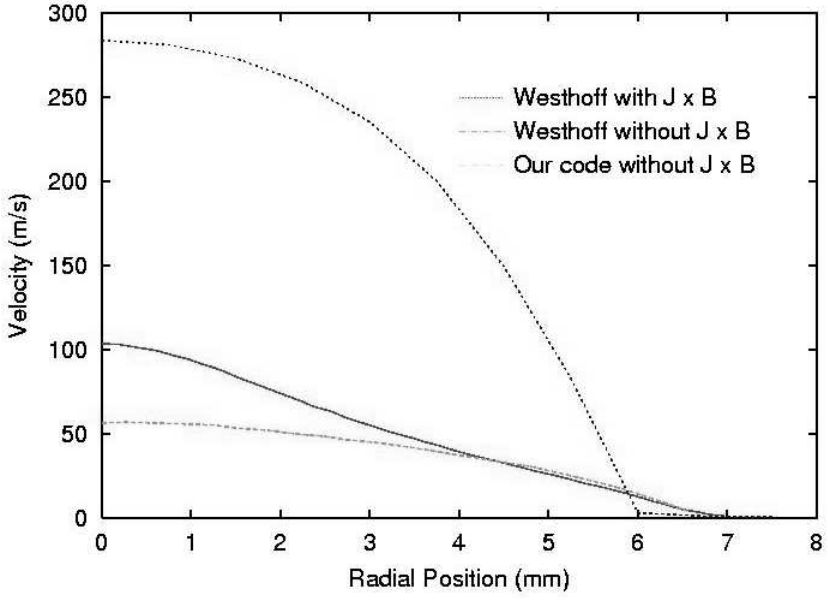

Figure 6: Comparison of axial velocity profile along radial direction near torch exit

5. Conclusions and future work

We have performed axisymmetric, 2-D, time-dependent, self-consistent fluid modeling of non-transferred plasma torches. The model includes a self-consistent calculation of the current density profile throughout the plasma. To our knowledge, this is the first time-dependent, fully self-consistent MHD model of plasma torches. This will allow us to self-consistently predict the spatio-temporal evolution of plasma and arc parameters for different torch configurations.

A comparison of our code results with published work shows that the predicted voltage variation, as well as the radial temperature profile at the torch exit, are in fairly good agreement. However, substantial differences exist in the axial velocity level, which needs further analysis.

In the future, apart from attempting to understand this discrepancy, we also plan to include electromagnetic forces as well as a more sophisticated model for radiation transport.

Abstract

Amorphous fluorinated carbon films have been prepared by plasma enhanced chemical vapor deposition method using C_6F_6 at substrate temperature of 400°C. Thermal stability up to 400°C is automatically achieved. Dielectric constant of the films is 2. Infrared absorption spectra of the films have indicated that the films contain benzene rings, and F/C ratio is unity as seen in monomer molecules. No film deposition has been observed if C_4F_8 or C_5F_8 is used as a source monomer at this substrate temperature.

Keywords plasma polymerization, C_6F_6, low-k, thermal stability, in situ FT-IR

1. Introduction

In ultra-large-scale integrated circuits (ULSI), it is necessary that the dielectric constant k of inter-metal dielectric (IMD) should be low for decreasing resistance-capacitance time delay. A few years ago, it had been said that k<2 would be required in 2005. However, due to difficulties in the low-k integration, practical application of new low-k materials has been always achieved a few years later of scheduled ITRS roadmap. Recently, we have reported possibility of k<2 with a-C:F (porous) films using two monomers of C_5F_8 and C_6F_6 as shown in **Fig.1** [1]. However, its thermal stability was poor. Therefore, we have changed our target to k=2 with high thermal stability (>400°C). In this work, we have performed film deposition at 400°C.

In the case of a-C:H and/or SiOC, high temperature deposition is relatively easy, because its deposition rate is reasonably high. However, in the case of a-C:F, its deposition rate fairly decreases with increasing substrate temperature, which has been demonstrated by using C_4F_8 [2]. In order to achieve high deposition rate, we have used C_5F_8 instead of C_4F_8. However, its deposition rate was not enough, and crack has been observed after cooling the samples [3].

Therefore, we examined C_6F_6, because it has benzene structure with pi-bonded carbons, which enhanced polymerization and high deposition rate will be expected. If this is possible, needless to say, thermal stability up to deposition temperature is certified automatically. In addition to this, benzene structure is thermally stable. Therefore, its structure and F/C ratio will be kept even after landing on the high temperature substrate. This may work to increase k-value because relatively low F/C ratio of unity of C_6F_6 is not favorable in comparison to conventional Teflon (F/C=2). However, its structural symmetry may work to reduce polarization and k-value.

In this paper, we report that low-k (k=2) a-C:F with carbon ring structure is available by plasma polymerization of C_6F_6 at 400°C, and its reaction mechanisms are discussed on the basis of *in situ* FTIR diagnostics of gas phase of the C_6F_6 plasma.

2. Experimental

Films were deposited with PE-CVD (or plasma polymerization as described later) method using C_6F_6 as a monomer and ICP as a plasma source. Substrate temperature T_{sub} was varied from room temperature (RT) to 400°C. Flow rate and pressure the monomer was 5 sccm and 50 mTorr, respectively. Typical deposition time was 30 min. RF power was 100 W. Chemical composition of the films was characterized by FTIR and XPS. Thermal stability of the films was characterized by measuring residual thickness after thermal treatment at 400°C for 30 min in N_2 ambient. Dielectric constant of the films was determined by capacitance measurements of MIS structure of Al/Film/p^+-Si.

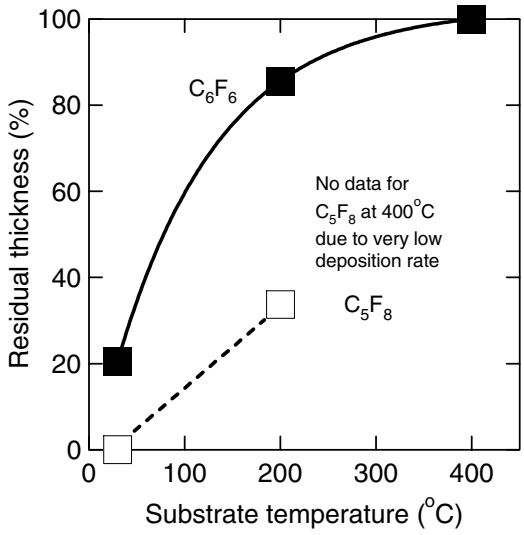

Fig.2 Residual thickness of the films, deposited with C_5F_8 and C_6F_6, after thermal treatment at 400oC for 30 min in N2 ambient.

3. Results and discussion

3.1 Deposition rate (at 400°C)

Figure 1 shows film deposition rate as a function of T_{sub}. For comparison, data for C_5F_8 and C_6F_6 are shown in the figure. Deposition rate of C_6F_6 at room temperature is as high as 80 nm /min, while that of C_5F_8 is 10 nm/min under the same condition. Deposition rate for both monomers decreases with increasing T_{sub} as known generally even in the case of C_6F_6. However, the most important fact is that C_6F_6 plasma can deposit films even at high T_{sub} at which C_5F_8 plasma cannot deposit films as can be understood from the data for T_{sub}=400°C. This is due to highly polymerizing nature of π bonds in benzene ring in C_6F_6.

3.2 Thermal stability (residual thickness)

Figure 2 shows residual thickness of the films after thermal treatment at 400°C for 30 min in N_2 ambient. As can be seen in the figure, the films deposited with C_6F_6 have higher thermal stability in comparison to C_5F_8. Especially for the films deposited at room temperature, the film from C_5F_8 is not left on the substrate after the thermal treatment, while the film from C_6F_6 remains 20% of initial thickness. Regarding the films deposited at 400°C, the films from C_5F_8 may have thermal stability up to 400°C. However, due to impossibility of film deposition from C_5F_8 at 400°C, no data for T_{sub}=400°C can be presented for C_5F_8 in the figure. On the other hand, needless to say, the film deposited with C_6F_6 at 400°C shows thermal stability up to 400°C automatically, because it has been deposited at 400°C.

3.3 Dielectric constant

Figure 3 shows relative dielectric constant of the films deposited with C_6F_6 at RT, 200 and 400°C. Regarding the films deposited at room temperature, their dielectric constant is as high as 2.8 for as deposited films and

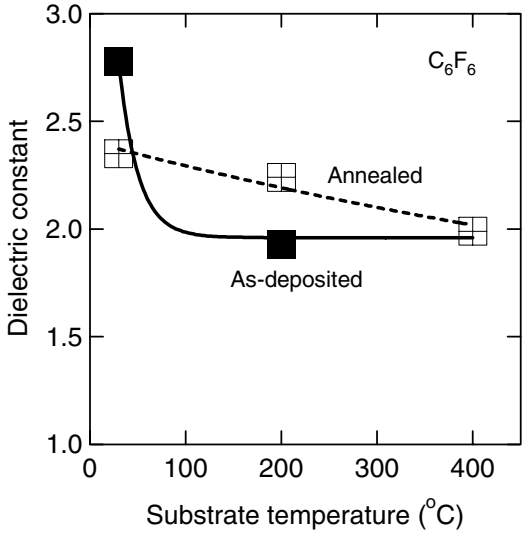

Fig.3 Dielectric constant of the films deposited with C_6F_6 at RT, 200 and 400°C. Dielectric constant after the thermal treatment is also shown for comparison.

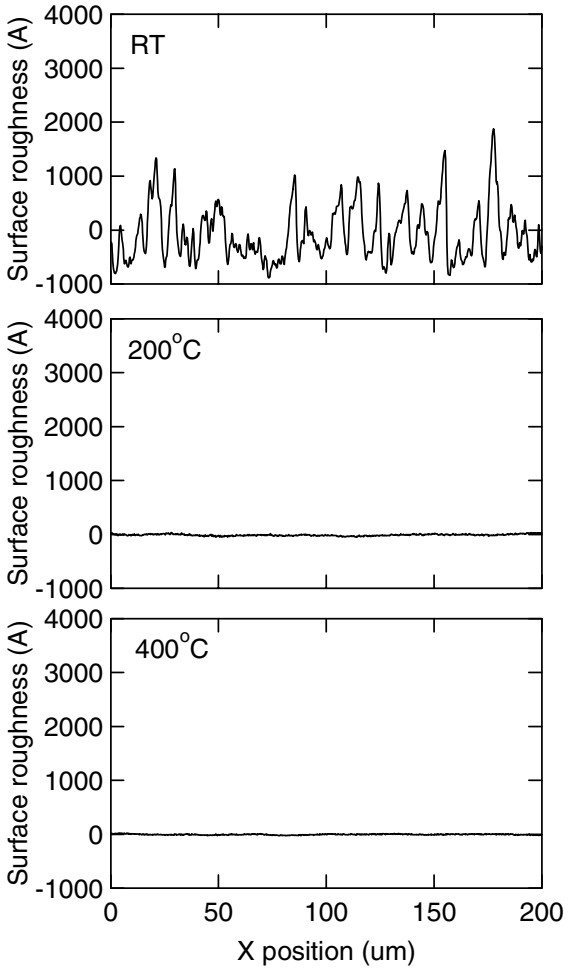

Fig. 4 Surface roughness observed on the films deposited at room temperature, and smooth surface on the films deposited at 200 and 400°C.

decreases to 2.4 after thermal treatment. Causes of this are not clear at present, surface roughness may cause this phenomenon, because only the samples deposited at room temperature have quite rough surface as shown in **Fig.4**. This roughness can be explained by high sticking probability of precursors. Because of highly polymerizing nature of C_6F_6, its product through electron impacts must have the similar nature, and surface migration to smoothen surface should be suppressed, which leads to rough surface. The films deposited under such condition, must be less cross-linked and poor thermal stability as indicated in **Fig.2** and **3**.

For the films with smooth surface, k-value increases or is stable after thermal treatment. Slight increase of k-value for the films deposited

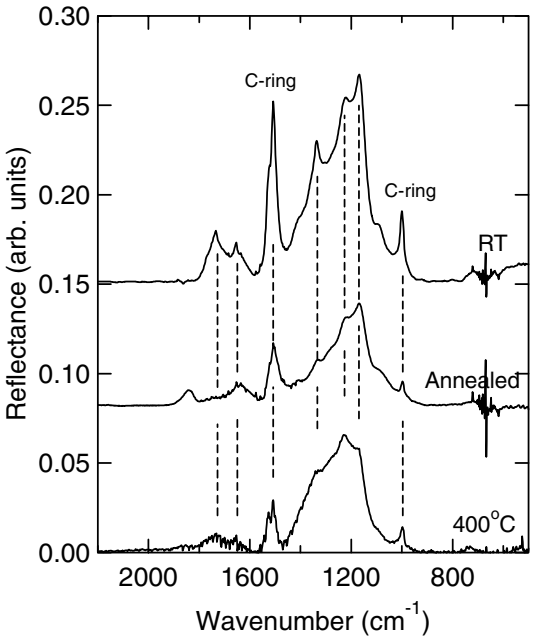

Fig.5 FTIR spectra of the films deposited with C_6F_6 at room temperature and 400°C. Spectrum after thermal treatment of RT deposited films are shown for comparison,

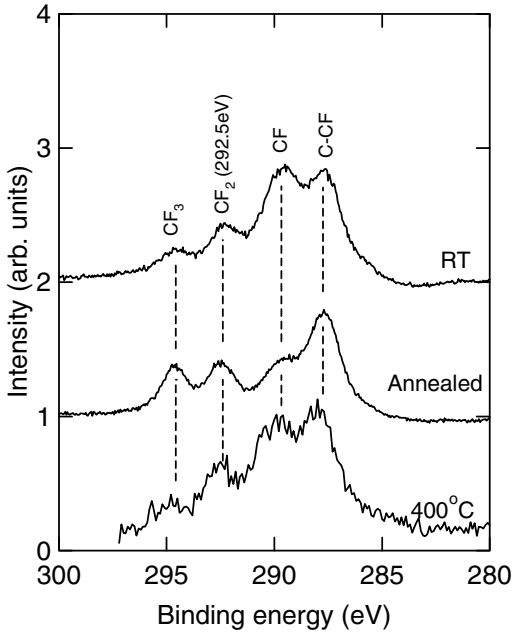

Fig.6 C(1S) region of XPS spectra of the films deposited with C_6F_6 at room temperature and 400°C. Spectrum after thermal treatment of RT deposited films are shown for comparison,

at 200°C can be explained by shrinking of the films because its thickness reduction is only 20%, while that of C_5F_8 film is as high as 60% or more which cannot be explained by only shrinking but also vaporization of the film.

The films deposited at 400°C, as expected, do not show marked variation in k-value after thermal treatment at 400°C, namely, they are stable at 400°C.

3.4 Structure of the films

As long as characterizing k-value and thermal stability, they are perfect as a low-k material with k=2. In order to see how they are realized, structural properties of the films were investigated by FTIR and XPS.

Figure 5 shows FTIR spectra of the films deposited with C_6F_6 at room temperature and 400°C (Spectrum after thermal treatment of RT deposited films are shown for comparison). These spectra are not resemble to conventional broad IR absorption peak corresponding to random amorphous a-C:F structure. As indicated in the figure, clear carbon ring IR peaks are observed, which means that benzene ring structures are incorporated in the films, and suggesting electron impact in the plasma does not lead full fragmentation of the monomers (with keeping monomer's original molecular shape). This scheme should not be termed as CVD but polymerization which incorporates functional structure of the monomers in the deposited films.

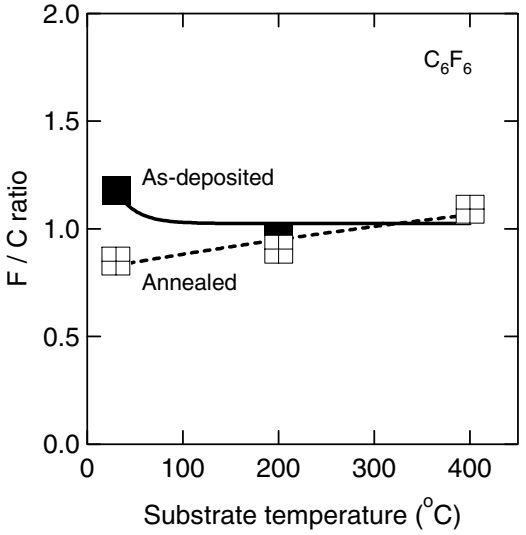

Fig. 7 F/C ratio of the films as a function of substrate temperature.

XPS spectra of the films also support above model. **Figure 6** shows XPS spectra of the film deposited at 400°C together with that at RT and after thermal treatment. The films deposited at room temperature and 400°C show similar XPS spectra. However, the spectra after thermal treatment of the RT deposited films show reduction of C-F bond peak intensity. As the thickness reduction of RT deposited films is as large as 80% after the thermal treatment (this is considered to be due to vaporization), weakly bonded C-F containing structure exists in the films. This structure is also suggested by quite large surface roughness of the films deposited at room temperature as described above subsection. On the other hand, the film deposited at 400°C did not show marked difference in XPS spectra after the thermal treatment.

By using relative sensitivity and instrument function, F/C ratio can be calculated from area intensity of C(1S) and F(1S) region of XPS spectra. **Figure 7** shows F/C ratio of the films, in which F/C ratio is close to unity as in the case of C_6F_6 monomer. Although this data also support incorporation of ring structure with C-F bonds, F/C=1 is smaller than F/C=2 for Teflon, which has k=2. Therefore, k=2 for F/C=1 cannot be explained by conventional model of F/C ratio vs. k-value for amorphous a-C:F films which contains only random network of C-C and C-F_x. At this moment, we do not have quantitative theory to explain k=2 for F/C=1.

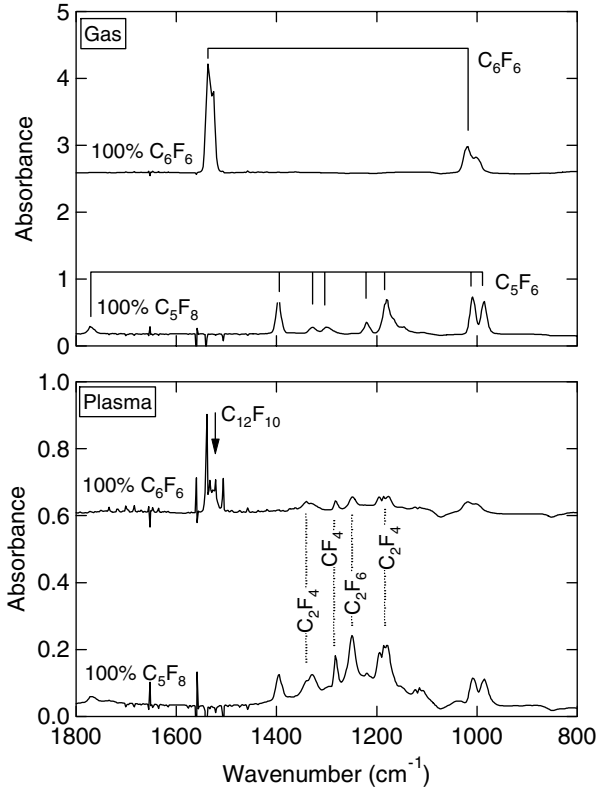

Fig.8 *In situ* FTIR spectra of the gas phase of C_6F_6 and C_5F_8 gas / plasma.

However, this must have relationship to symmetric structure of C-F ring structure brought by nature of C_6F_6 monomers.

3.5 *In situ* FTIR

As described above, C_6F_6 plasma can prepare unique a-C:F (or a-C:F:C_6F_x amorphous/polymer blend). In order to investigate deposition mechanisms, *in situ* FTIR of the gas phase has been performed. **Figure 8** shows spectra of the gas and plasma of C_6F_6 (together with those of C_5F_8 for comparison). As can be seen in the figure, the plasma of C_6F_6 does not show small molecules such as CF_4, C_2F_4 and C_2F_6 which are pronounced in the case of C_5F_8. This means that C_6F_6 molecule is not fully fragmented in the gas phase (while C_5F_8 is mostly fragmented to less carbon containing species). In the plasma of C_6F_6, the interesting peak appears in the spectrum, which is not observed in C_5F_8 plasma, namely, $C_{12}F_{10}$. Production of $C_{12}F_{10}$ suggests that $C_6F_6+e \rightarrow C_6F_5+F+e$ and $2C_6F5 \rightarrow C_{12}F_{10}$ are occurring in the gas phase. As the large pressure reduction has been observed just after ignition of plasma, this must be occurring in the gas phase. However, quite high deposition rate on the room temperature substrate, this reaction must be occurring also on the surface (surface polymerization). As this model can explain C-rin g incorporation in the films deduced from IR spectra of the films, F/C=1 and majority of C-F and C-CF deduced from XPS investigation, this model is considered to be the most probable one for our C_6F_6 plasma polymerization process.
